$[Sc(Me_3AsO)_6]Br_3$ gave some npd thermal parameters for O and C and all were subsequently refined with an isotropic model.

5. Supplementary data

Crystallographic data for the structures have been deposited with the Cambridge Crystallographic Data Centre (CCDC) and given numbers 173058 $[ScBr_2(Ph_3PO)_4]Br\cdot 1/2Et_2O$, 173059 $[Sc(Me_3AsO)_6]Br_3$, 173060 $[ScCl_2(Ph_3AsO)_4]Cl$. Copies of the data can be obtained on request from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.ac.uk or www: http://www.ccdc.cam.ac.uk) quoting the deposition numbers.

Acknowledgements

We thank the EPSRC for support and Professor M.B. Hursthouse for access to the Nonius Kappa CCD diffractometer.

described [10] some years ago, showing a new mode of bidentate coordination for this ligand, involving an N–C–O bridging unit.

We report here the preparation of new dinuclear orthometallated palladium(II) derivatives with bridging succinimide, maleimide or phthalimide ligands acting in the coordination mode mentioned above. We also present a novel synthesis route of mononuclear N-bonded succinimidato derivatives, by reaction of the corresponding dinuclear precursor with neutral ligands. Spectroscopic characterization of the new compounds and the structure elucidation by X-ray diffraction analyses of both mononuclear and binuclear derivatives is also given.

2. Experimental

2.1. Materials and physical measurements

C, H and N analysis were carried out with a Perkin–Elmer 240C microanalyser. IR spectra were recorded on a Perkin–Elmer spectrophotometer 16F PC FT-IR, using nujol mulls between polyethylene sheets. NMR data (^{1}H, ^{13}C, ^{31}P) were recorded on a Bruker AC 200E or a Varian Unity 300 spectrometer. Mass spectrometric analyses were performed on a Fisons VG Autospec double-focusing spectrometer, operated in the positive mode. Ions were produced by fast atom bombardment (FAB) with a beam of 25-KeV Cs atoms. The mass spectrometer was operated with an accelerating voltage of 8 kV and a resolution of at least 1000.

The cyclometallated precursors [{Pd(μ-OOCMe)-(C^N)}$_2$] [C^N = azobenzene or 2-phenylpyridine] were prepared as described in the literature [12]. The commercially available chemicals were purchased from Aldrich Chemical Co. and were used without further purification, and all the solvents were dried by standard methods before use.

2.2. Preparation of the complexes [{Pd(μ-NCO)-(C^N)}$_2$] [C^N = azobenzene (azb); –NCO– = succinimide (suc) (**1a**), phthalimide (**2a**) (phtal) or maleimide (mal) (**3a**); C^N = 2-phenylpyridine (phpy); –NCO– = succinimide (**1b**), phthalimide (**2b**) or maleimide (**3b**)]

The azobenzene or 2-phenylpyridine complexes were obtained by treating the appropriated precursor ([{Pd(μ-OOCMe)(azb)}$_2$] or [{Pd(μ-OOCMe)(phpy)}$_2$], respectively) with the corresponding imide (molar ratio 1:2) in acetone, according to the following general method. To an acetone (20 ml) solution of [{Pd(μ-OOCMe)(C^N)}$_2$] (0.07 g, 0.101 mmol if C^N = azb; 0.07 g, 0.109 mmol if C^N = phpy) the stoichiometric amount of ligand was added. The solution was refluxed for 2 h and then concentrated to one-fifth of the initial volume. Slow addition of diethyl ether caused the precipitation of the title complexes, which were filtered off, air-dried and recrystallized from acetone–ether.

2.2.1. [{Pd(μ-suc)(azb)}$_2$] (**1a**)

Yield: 57% (*Anal.* Calc. for $C_{32}H_{26}N_6O_4Pd_2$: C, 49.8; H, 3.4; N, 10.9. Found: C, 49.7; H, 3.5; N, 10.7%). IR (cm^{-1}): 1722s, 1566s (C=O str.). 2.4. Crystal structure determination of [{Pd(phpy)(μ-suc)}$_2$] (**1b**) and [Pd(azb)(suc)(PPh_3)] (**4a**)

Data for **1b** were collected using a single crystal of approximate dimensions $0.5 \times 0.5 \times 0.3$ mm. Accurate cell parameters were determined by least-squares fitting of 25 high-angle reflections. The scan method was ω with the range of *hkl* ($-22 \le h \le 22$, $-14 \le k \le 0$, $0 \le l \le 23$) corresponding to $2\Theta_{max} = 60.84°$. The structure was solved by direct methods and refined anisotropically on F^2 [33]. Hydrogen atoms were introduced in calculated positions. The final R factor was 0.0481 [$R_w = 0.1139$, where $w = 1/\sigma^2(F_o^2) + (0.0678P)^2$ and $P = (F_o^2 + 2F_c^2)/3$] over 5115 observed reflections [$I > 2\sigma(I)$].

Data for **4a** were collected using a single crystal of approximate dimensions $0.2 \times 0.4 \times 0.3$ mm on a Siemens SMART diffractometer under a stream of N_2 at 173 K. Crystallographic data are summarized in Table 1. An empirical absorption (SADABS) was applied [34]. The structure was solved by direct methods and refined on all F^2 data using the SHELX suite of programs on a Silicon Graphics computer [35]. All non-hydrogen atoms were anisotropic refined, hydrogen atoms were introduced in calculated positions. The final R factor was 0.0264 [$R_w = 0.0712$, where $w = 1/[\sigma^2(F_o^2) + (0.0652P)^2 + 6.4628P]$ and $P = (F_o^2 + 2F_c^2)/3$] over 5439 observed reflections [$I > 2\sigma(I)$].

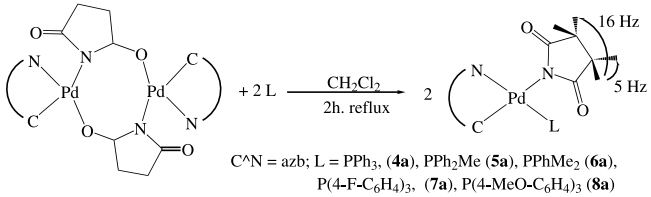
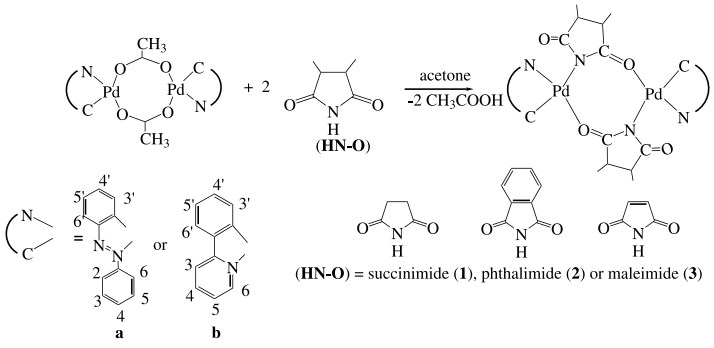
3. Results and discussion



In acetone, the acetato-bridged cyclometallated dimers $[\{Pd(\mu\text{-}OOCMe)(C\hat{}N)\}_2]$ (C^N = azb or phpy) react under the conditions described in the experimental section with succinimide, phthalimide or maleimide to give dinuclear complexes (**1a**–**3a**, **1b**–**3b**) in which the imidato ligands replace the bridging acetate group as presented in Scheme 1.

The new azobenzene derivatives are air-stable brown solids, while the 2-phenylpyridine complexes present a yellow colour. Infrared spectra of all compounds show the characteristic absorptions of the corresponding cyclometallated ligand, partially overlapped with those attributed to imidato–carbonyl stretching. Thus, two medium intensity bands at 1595 and 1552 cm^{-1} were occasionally observed in the IR spectra of the azobenzene compounds, whilst relevant bands for 2-phenylpyridine derivatives appeared at 1604 and 1576 cm^{-1}. Two strong bands in the range 1731–1720 and 1600–1566 cm^{-1} suggested coordination of one carbonyl group to the metal as a part of an –NCO– bridging unit, according to previously reported data [10]. It has been claimed that this bridging structure would remove the twofold symmetry of the free or N-bonded imidato ligand increasing the intensity of the symmetric absorption. This higher frequency mode $\nu_{sym}(CO)$ is normally weak in cyclic imides, as shown later for compounds (**4a**–**8a**, **4b**–**8b**) in whose spectra the band has negligible intensity compared with the antisymmetric $\nu(CO)$ absorption.



Further evidence for the dinuclearity of complexes (**1a**–**3a**, **1b**–**3b**) comes from the FAB mass spectrometry, as can be implied by the *m*/*z* values for the observed fragments (see Section 2). Spectra of the new bridged compounds show a similar fragmentation pattern which includes the peaks corresponding to $[\{Pd(NCO)(C\hat{}N)\}_2]^+$ and $[\{Pd_2(NCO)(C\hat{}N)_2\}]^+$. The abundances of the signals around the pattern ion are consistent with the natural isotopic abundances.

The ^1H and ^{13}C NMR data are collected in the experimental section and Scheme 1 shows the labelled cyclometallated ligands. The ^1H spectra exhibit the expected resonances for these ligands, together with the corresponding signals of the bridging imidato units that are partly overlapped with the former in the case of phthalimide and maleimide derivatives. Moreover, the succinimidato protons in the 2-phenylpyridine derivative (**1b**) appear as a broad singlet at 2.76 ppm, whereas the spectrum of the azobenzene analogue (**1a**) shows a complex multiplet centered at 2.69 ppm. By analogy with previously reported results in related systems [10], this behaviour may be explained in view of the fact that the azophenyl and methylene groups were close in complex **1a**. On the other hand, the distinction of two different carbonyl signals, shifted downfield from the one observed for the corresponding free ligand, is the only remarkable feature in the ^{13}C NMR spectra of the new compounds. On the basis of previously reported data [27,28], the singlet that appears at lowest field has been assigned to the carbonyl atom coordinated to palladium.

We have also investigated the reaction of the succinimidato-bridged compounds (**1a**,**1b**) with tertiary phosphines, in an attempt to obtain a parallel behaviour to that shown by the well known halide-bridged dimers: bridge splitting to yield the mononuclear derivatives [Pd(C^N)(X)(L)]. The halogen-like character of the succinimido ligand suggested by McCleverty and coworkers [10] should play an important role in the formation of the mononuclear N-bonded imidato derivatives presented in Scheme 2.

Reactions take place in dichloromethane under continued reflux, yielding brown (**a** compounds) or yellow (**b** compounds) air stable solids with negligible molar conductivity values. Acetone was avoided as a solvent since we found that it tends to stay occluded (lost at 118 °C) in the new complexes. The subsequent strong IR band around 1720 cm^{-1} interfered the monitoring of the reactions by this technique, as it appears in the typical range of absorption for imidato bridging units discussed before. Thus, the spectra show the expected bands for the corresponding cyclometallated backbone, together with those attributed to the incoming neutral ligand and one strong carbonyl band in the range 1566–1586 or 1600–1634 cm^{-1} for azobenzene and 2-phenylpyridine derivatives, respectively.

The ^{1}H and ^{31}P NMR data of the mononuclear complexes are collected in Section 2, the latter consisting of singlets with chemical shifts in the usual range for Pd(II) complexes. With regard to the ^{1}H NMR spectra, they show the expected resonances of the cyclometallated and succinimidato ligands, together with those attributed to the corresponding coordinated phosphine. The assignment of the cyclometallated protons was made by comparison with our previously published data [11]. An interesting aspect, also found before in cyclometallated complexes with iminophosphines [11], is the appreciable coupling to the phosphorus atom exhibited by the $H^{3'}$ in azobenzene derivatives, and $H^{3'}$, H^{6} in compounds with 2-phenylpyridine. On the other hand, basically two different behaviours were observed for aliphatic protons of succinimidato, depending on the steric hindrance introduced by the phosphine ligand in the *cis*-position. Thus, rotation about the Pd–N axis might be hindered when bulky phosphines (**4**, **5**, **7**, **8a**,**b**) coordinate the metal, and two resonances that integrate two protons each (*syn*-/*anti*-, see Scheme 2) are observed, while just one multiplet signal appears in the spectra of compounds **6a** and **6b** with less voluminous substituents. VT ^{1}H NMR experiments were carried out in an attempt to get coalescence of signals and to calculate the energy barrier associated with the Pd–N rotation, but it could not be achieved in the range of temperatures allowed by usual deuterated solvents. Nevertheless, similarly hindered rotations about M–N bonds have been attributed previously to steric factors [27,36,37].

3.1. X-ray structures of [{Pd(μ-suc)(phpy)}$_2$] (**1b**) and [Pd(azb)(suc)(PPh_3)] (**4a**)

Selected bond distances and angles are presented in Table 2. The coordination around the Pd atoms is

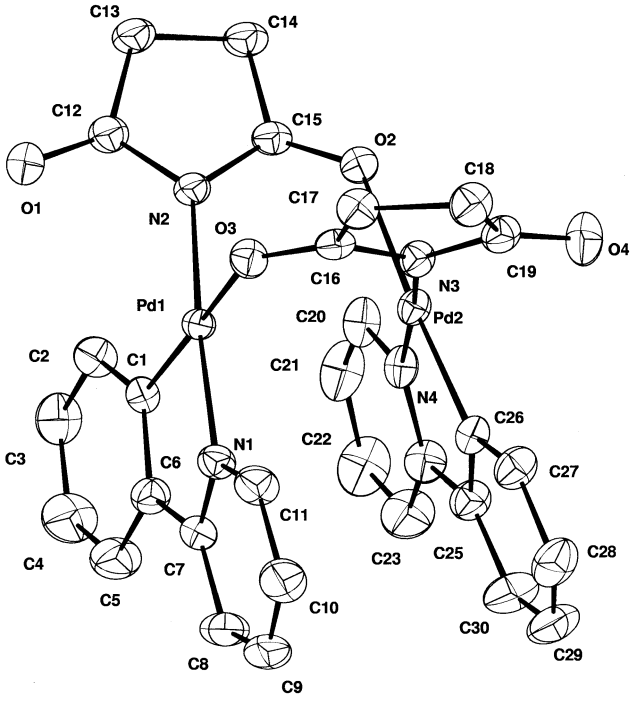

Fig. 1. Molecular structure of complex **1b**.

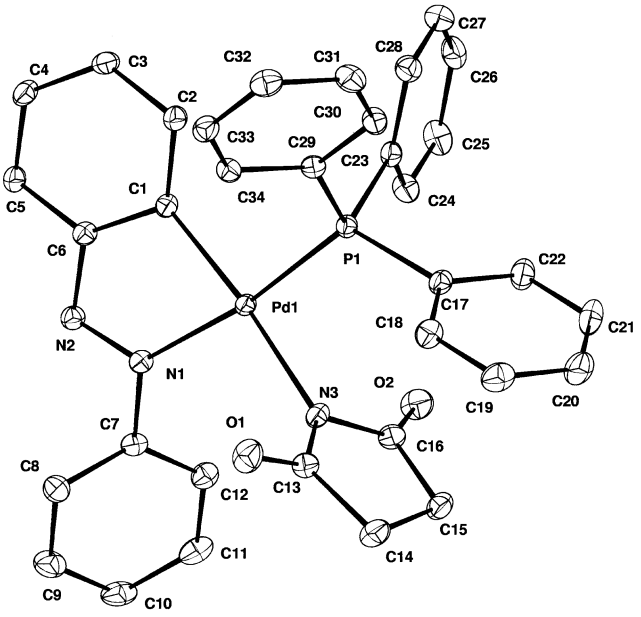

Fig. 2. Molecular structure of complex **4a**.

approximately planar. The narrow NPdC angle, (80.8° and 78.4° in the dinuclear and mononuclear complexes, respectively), in the *ortho*-metallated moiety is similar to that found in complexes containing the same ligand [11]. The structural analysis of complex **4a** confirms the relative *cis*-position of the phosphine ligand and the metallated carbon atom suggested by the NMR data. This is the typical arrangement of the phosphine group in cyclopalladated complexes of the type [Pd(C^N)(phosphine)(X)] (X = anionic monodentate ligand) due to the so-called *transphobia* effect [38,39].

In the succinimide ligand the C=O distance, 1.239(5) Å, is elongated in the bridged group with respect to the non-coordinated C=O, 1.211(5) Å, and to the mononuclear one, 1.221(3) Å. The Pd–N distance is larger in the mononuclear complex and the Pd(1)–Pd(2) distance in dinuclear compound **1b** is rather short (2.9544(7) Å). The angle between the best plane through the succinimide and the coordination plane is 72.40° in dinuclear **1b** (Fig. 1) and 79.22° in mononuclear **4a** (Fig. 2). In the bridged complex the 2-phenylpyridine ligands are nearly parallel, (dihedral angle = 12.89°), while the planes through the succinimide ligands form an angle of 85.96°.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 173327 for compound **1b** and 173328 for compound **4a**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

UV–Vis spectra (CH_2Cl_2 solution), IR spectra (KBr disk), and ^1H NMR spectra ($CDCl_3$) were recorded on a Shimadzu UVPC 1601 spectrophotometer, a Perkin–Elmer 783 spectrometer, and a Bruker FT 300 MHz spectrometer, respectively. The numbering scheme used for ^1H NMR assignment is the same as in crystallography. Spin-spin structures are abbreviated as follows: s, singlet; d, doublet; t, triplet; m, multiplet. Cyclic voltammetry (in MeCN, 0.1M TEAP) was done at a platinum working electrode under nitrogen atmosphere on a PAR model 370-4 electrochemistry system [23]. Microanalyses (C, H, N) were performed using a Perkin–Elmer 2400 Series II elemental analyzer.

2.2. Synthesis of chlorbis(2-amidothiophenolato)triphenylphosphinerhenium(V), [Re(atp)$_2$(Cl)(PPh$_3$)] (**2a**)

To a suspension of $ReOCl_3(PPh_3)_2$ (100 mg, 0.120 mmol) in 10 ml of toluene was added 30 mg (0.240 mmol) of 2-aminothiophenol, (H_2atp). The resulting mixture was heated to reflux for 15 min affording a reddish brown solution. The solvent was then removed under reduced pressure, and the solid thus obtained was dissolved in 5 ml of dichloromethane, and the solution was subjected to chromatography on a silica gel column (20 × 1 cm; 60–120 mesh, BDH). A deep reddish brown band was eluted out with a benzene-acetonitrile (25:1) mixture. Removal of solvent under reduced pressure afforded the pure complex which was dried in vacuo over fused calcium-chloride Yield: (57 mg, 65%). *Anal* Calc. for $C_{30}H_{25}ClN_2S_2PRe$: C, 49.34; H, 3.45; N, 3.84. Found: C, 49.28; H, 3.49; N, 3.87%. UV–Vis (λ_{max}, nm (ε, $M^{-1}cm^{-1}$)): 447(11450); 326(5730). IR(cm^{-1}, KBr pellet): 3250(NH), 320(Re–Cl). ^1H NMR ($CDCl_3$) δ: H5, H11 7.80 (d, *J* 8.1 Hz); H2, H8 7.56 (d, *J* 8.4 Hz); H4, H10 7.08 (t, *J* 7.2 Hz); H3, H9 6.92 (t, *J* 7.3 Hz). N–H, 12.46(s); aromatic multiplets, 7.28–7.48.

2.3. Synthesis of bromobis(2-amidothiophenolato)triphenylphosphinerhenium(V), [Re(atp)$_2$(Br)(PPh$_3$)] (**2b**)

To suspension of $[ReO(OEt)Br_2(PPh_3)_2]$ (100 mg, 0.102 mmol) in 10 ml of toluene was added 25.6 mg (0.204 mmol) of 2-aminothiophenol, H_2atp. The same procedure as in the previous preparation was then followed affording the reddish brown complex. Yield: (53.9 mg, 68%). *Anal.* Calc. for $C_{30}H_{25}BrN_2S_2PRe$: C, 46.51; H, 3.25; N, 3.62. Found: C, 46.46; H, 3.29: N, 3.65%. UV–Vis (λ_{max}, nm (ε, $M^{-1}cm^{-1}$): 453(6740); 335(4284). IR (cm^{-1}, KBr pellet): 3252(NH). ^1H NMR ($CDCl_3$) δ: H5, H11 7.89 (d, *J* 8.0 Hz); H2, H8 7.65 (d, *J* 8.3 Hz); H4, H10 7.15 (t, *J* 7.5 Hz). H3, H9 7.03 (t, *J* 7.4 Hz); N–H 12.77(s); aromatic multiplets, 7.28–7.35.

2.4. Synthesis of iodobis(2-amidothiophenolato)triphenylphosphinerhenium(V), [Re(atp)$_2$(I)(PPh$_3$)] (**2c**)

This was synthesized in the same manner as (**2b**) using $[ReO(OEt)I_2(PPh_3)_2]$ (100 mg, 0.098 mmol) and H_2atp (24.4 mg, 0.196 mmol) Yield: (52 mg, 65%). *Anal* Calc. for $C_{30}H_{25}IN_2S_2PRe$: C, 43.84; H, 3.06; N, 3.41. Found: C, 43.78; H, 3.11; N, 3.45%. UV–Vis (λ_{max}, nm (ε, $M^{-1}cm^{-1}$)): 463(8090); 347(8760). IR (cm^{-1}, KBr pellet): 3250 (NH). ^1H NMR ($CDCl_3$) δ: H5, H11 7.93 (d, *J* 7.7 Hz); H2, H8 7.67 (d, *J* 8.4 Hz). H4, H10 7.12(m); H3, H9 7.12(m); N–H 13.08(s); aromatic multiplets, 7.33–7.52.

2.5. Conversion of [Re(atp)$_2$(Cl)(PPh$_3$)] to [Re(atp)$_3$]

To a solution of [Re(atp)$_2$(Cl)(PPh$_3$)] (100 mg, 0.137 mmol) in 10 ml of toluene was added 17.12 mg (0.137 mmol) of H_2atp. The resulting mixture was heated to reflux for 60 min affording a deep green solution. The solvent was then removed under reduced pressure and the solid thus obtained was dissolved in 10 ml of acetone and kept for slow evaporation for a few days to get the pure complex which was dried in vacuo over fused calcium chloride, Yield: (62.3 mg, 83%). The [Re(atp)$_2$(Br)(PPh$_3$)] and [Re(atp)$_2$(I)(PPh$_3$)] complexes could be similarly converted to [Re(atp)$_3$].

2.6. X-ray crystallography

Single crystal of $[Re(atp)_2(Cl)(PPh_3)].2CH_2Cl_2$ were grown by slow diffusion of hexane into dichloromethane solution the crystals rapidly lost the solvent of crystallization and crystallinity in air. A crystal was sealed over the mother liquor for crystallography. Cell parameters were determined by a least-squares fit of 30 machine-centered reflections ($14^\circ \le 2\theta \le 28^\circ$). Data were collected by the ω scan technique in the range $3^\circ \le 2\theta \le 50^\circ$ for [Re(atp)$_2$(Cl)(PPh$_3$)] on a Siemens R3 *m*/*V* four-circle diffractometer with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation at 25 °C. Two check reflections after each 198 reflections showed no significant intensity reduction. All data were corrected for Lp effects and absorption [24].

The metal atom was located from Patterson maps, and the rest of the nonhydrogen atoms emerged from successive Fourier synthesis. The structure were refined by full-matrix least-squares procedures on F^2. All nonhydrogen atoms were refined anisotropically. Hydrogen atoms were included at calculated positions. Calculations were performed using the SHELXTL V5.03 [25] program package. The two dichloromethane molecules in the lattice are disordered. Significant crystal data are listed in Table 1.

Table 1
Crystallographic data for $[Re^{V}(atp)_2(Cl)(PPh_3)]\cdot 2\ CH_2Cl_2$ (**2a**)

Empirical formula	$C_{32}H_{28}Cl_5N_2PReS_2$
Formula weight	899.10

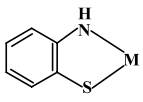
b (Å)	13.529 (5)
c (Å)	14.944 (4)
α (°)	115.61 (2)
β (°)	97.78 (2)
γ (°)	92.27 (3)
V (Å^3)	1740.2 (10)
Z	2
$D_{calc.}$ (Mg m^{-3})	1.716
μ (mm^{-1})	4.067
θ Range (°)	1.70–25.00
R [a], wR_2 [b] $[I > 2\sigma(I)]$	0.0744, 0.1796
Goodness-of-fit on F^2	1.046

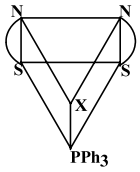


[a] $R = ||F_o| - |F_c||/\Sigma|F_o|$.
[b] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

The twist angle (ϕ) is defined and calculated according to a published procedure [26]. In the case of $[Re(atp)_2(Cl)(PPh_3)]$, let cen a and cen b be the centroids of the faces N1, N2, Cl1 and S1, S2, P1, respectively. The dihedral angles between planes of cen a, cen b, N1 and cen a, cen b S1; cen a, cen b, N2 and cen a, cen b, S2 and cen a, cenb, Cl1 and cen a, cen b P1 are respectively 5.5°, 8.8° and 9.7°. The average value, 8.0°, is taken as ϕ. The angular parameters for $[Re(atp)_3]$ were either taken directly from the published work or were computed using the available atomic coordinates [15]. Here the twist angle is 7.9° is the average of the three dihedral angles 7.4°, 7.8° and 8.5° between planes defined in the same manner as in the case of $[Re(atp)_2(Cl)(PPh_3)]$.

3. Results and discussion

3.1. Synthesis and characterization



The bidentate ligand used in the present work is 2-aminothiophenol (H_2atp) which is prone to chelate metal ions in diionised form as in (**1**). The basis of this choice is the

1

proven ability of this ligand to stabilize the trigonal prismatic geometry upon tris chelation as in $[Re^{VI}(atp)_3]$ [15,16], $[Tc^{VI}(atp)_3]$ [27] and $[Mo^{VI}(atp)_3]$ [28].

The reaction of $[Re^{V}OCl_3(PPh_3)_2]$ with H_2atp in boiling toluene afforded a reddish brown solution from which $[Re^{V}(atp)_2(Cl)(PPh_3)]$ of coordination type (**2a**) could indeed be isolated in satisfactory yield. For the success of the synthesis it is crucial to control both the reaction time (15 min) and metal: ligand (1:2) mole ratio. Use of $[Re^{V}O(OEt)Br_2(PPh_3)_2]$ and $[Re^{V}O(OEt)I_2(PPh_3)_2]$ in place of $[Re^{V}OCl_3(PPh_3)_2]$ in the above synthesis afforded the bromo (**2b**) and iodo (**2c**) complexes, respectively.

(**2a**), X = Cl

(**2b**), X = Br

(**2c**), X = I

Our interest in oxorhenium chemistry [29–31] prompted us to examine the above $Re^{V}O$ reagents incorporating X(Cl, Br, I) and PPh_3 coligands as starting materials for the reaction with H_2atp. It was hoped that ionised H_2atp would displace the oxo atom forming chelate rings of type (**1**) but with retention of some X/PPh_3 coordination. This happened in practice.

Selected characterization data for (**2a**–**2c**) are given in the Section 2. The complexes are uniformly diamagnetic corresponding to the spin paired d^2 configuration (idealized $a_1'^2$) [1]. In solution the complexes display two characteristic allowed bands in the UV–Vis region. Their energy decreases slightly as in the order (**2a**) (447, 326 nm) > (**2b**)(453, 335 nm) > (**2c**) (463 nm, 347 nm). In IR the N–H stretch is seen as a sharp feature near 3250 cm^{-1}.

The two coordinated atp^{2-} ligands are equivalent in solution giving rise to two ^{1}H NMR doublets and two triplets in the aromatic region, 6.5–8.0 ppm (J, 7.0–8.5 Hz). The N–H proton resonance occurs as a characteristic singlet at 12.46°, 12.77° and 13.08 ppm for (**2a**), (**2b**) and (**2c**), respectively. The signal 'disappears' upon addition of D_2O to the solution.

3.2. Crystal and molecular structure

Only complex (**2a**) afforded single crystals in the form of loosely held solvate $(\mathbf{2a})\cdot 2CH_2Cl_2$ which was stable only in presence of the mother liquor. A molecular view of the complex is shown in Fig. 1 and selected bond parameters are listed in Table 2. The CH_2Cl_2 molecules are highly disordered and occupy cavities in the lattice.

The ReS_2N_2ClP coordination sphere has distorted trigonal prismatic geometry as in (**2a**). The synthetic procedure used always afforded the same complex and no evidence of the existence of the possible geometrical isomers could be found. The areas of the triangular faces defined by S1, S2, P1 and N1, N2, Cl1 are 4.38 and 3.97 Å^2, respectively. The prism is thus tapered.

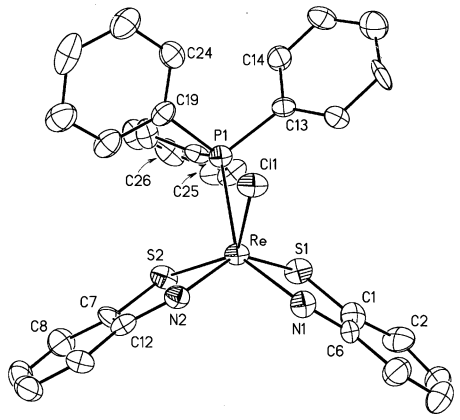


Fig. 1. Molecular view and atom-labeling scheme for $[Re(atp)_2(Cl)(PPh_3)]$. All nonhydrogen atoms are represented by 30% thermal probability ellipsoids.

Certain angular parameters diagnostic of the geometry are: twist angle (ϕ), dihedral angle (ω_1) between one coordination plane and another, dihedral angle (ω_2) between a coordination plane and a triangular face and angle (θ) at the metal site between two donors in *trans* positions. In the present complex the ϕ value is 8.0°. The other angles (Table 2) span the ranges: ω_1, 113.7°–124.7°; ω_2, 80.2°–98.7° and θ, 123.3°–142.7°. It is instructive to compare these parameters with those of the structurally characterized tris chelate $[Re(atp)_3]$ [15] as well as with those of idealised D_{3h} and O_h geometries (Table 3).

Whereas the span of the angular parameters of $[Re(atp)_2(Cl)(PPh_3)]$ is generally higher, the averages invariably lie close to those in $[Re(atp)_3]$.

Even though the metal oxidation state in $[Re(atp)_2(Cl)(PPh_3)]$ is lower than that in $[Re(atp)_3]$ the average Re–N (1.97 Å) and Re–S (2.30 Å) lengths in the former are slightly shorter than those (2.00 and 2.35 Å, respectively) in $[Re(atp)_3]$ [15]. In absence of the third chelate ring the two atp^{2-} ligands are pulled closer to the metal in $[Re(atp)_2(Cl)(PPh_3)]$. We are unable to compare the Re–Cl(2.438(3)) and Re–P (2.450(4)) lengths with those in other trigonal prismatic systems, since no such system exist. In pseudooctahedral species Re^{V}–Cl [29–31] and Re^{V}–P [20,32,33] lengths usually lie in the ranges 2.31–2.39 and 2.46–2.52 Å, respectively.

Table 3
Angular parameters [a] of $[Re(atp)_2(Cl)(PPh_3)]\cdot 2CH_2Cl_2$ and $[Re(atp)_3]$

Parameters [b]	$[Re(atp)_2(Cl)(PPh_3)]$	$[Re(atp)_3]$	D_{3h}	O_h
ϕ (°)	8.0	7.9	0	60
ω_1 (°)	113.7–124.7(119.3)	119.0–119.8(119.3)	120	90
ω_2 (°)	80.2–98.7(90.5)	84.4–95.1(91.4)	90	54.7
θ (°)	123.3–142.7(134.4)	128.2–140.3(134.3)	135.6	180

[a] Average values are given in parenthesis.
[b] For definition see text.

The similarity of the properties of (**2b**) and (**2c**) with those of (**2a**) strongly suggest that the former species also have gross trigonal prismatic geometry, although the extent of distortion could be different in the three species. We thus have here the first examples of the trigonal prismatic complexes of type $M(bidentate)_2(monodentate)_2$. Further unusual feature of (**2**) include the presence of the bulky PPh_3 as a ligand and the presence of the d^2 metal ion (Re^{V}). Structurally characterized trigonal prismatic metal complexes of good standing (using $\phi < 10°$ as a criterion) generally contain only d^0 or d^1 metal ions [9–11,14,15,18,27,28]. We are excluding

the cases where the geometry is forced by ligand structure (clathro-chelates) [34].

3.3. Metal redox and reaction with H_2atp

In acetonitrile solution the $[Re(atp)_2(Cl)(PPh_3)]$ species display a quasireversible cyclic voltrametric response near 0.7 V versus SCE (Table 4). The response is assigned to the Re^{VI}–Re^{V} couple, the reduction potential of which decreases slightly in the order **(2a)** > **(2b)** > **(2c)**.

Upon treating the type **(2)** species with one mole of H_2atp in boiling toluene in air for 1 h, the PPh_3 and X^- ligands are replaced by atp^{2-} affording the tris chelate $[Re(atp)_3]$ in excellent yield. In this reaction the metal undergoes spontaneous aerial oxidation ($Re^{V} \rightarrow Re^{VI}$). This happens because of the large decrease in the Re^{VI}–Re^{V} reduction potential ($E_{1/2}$ of $[Re(atp)_3]$, −0.12 V [16]) upon tris chelation. The stabilization of the d^2 configuration (Re^{V}) in the present complex is promoted by the PPh_3, X pair of ligands.

4. Conclusion

The synthesis and characterization of the first family of trigonal prismatic complexes, $[Re^{V}(atp)_2(X)(PPh_3)]$, belonging to type M(bidentate)$_2$ (monodentate)$_2$ has been achieved by reacting $Re^{V}O$ reagents with H_2atp. The species are further unusual in having a bulky ligand (PPh_3) and d^2 configuration.

Pentavalent rhenium is redox stabilized in the family by the PPh_3, X ligand pair. The complexes react with H_2atp in air affording the tris chelate $[Re^{VI}(atp)_3]$ where the hexavalent metal is stabilized. Further work on the design and isolation of different molecular trigonal prismatic chelate type are in progress.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 174267 for compound **(2a)**. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Table 4
Cyclic voltametric data in acetonitrile solution (0.1 M TEAP) [a]

Compound	$\frac{E_{1/2}/V(\Delta E_p/mV)}{Re^{VI}/Re^{V}}$
(2a)	0.72(80)
(2b)	0.70(120)
(2c)	0.68(120)

[a] Conditions: working electrode, platinum; reference electrode, SCE; scan rate 50 mV s^{-1}. $E_{1/2} = 1/2\ (E_{pa} + E_{pc})$, where E_{pa} and E_{pc} are anodic and cathodic peak potentials, respectively, $\Delta E_p = E_{pa} - E_{pc}$.

The coordination chemistry of copper is important for a variety of reasons such as modelling its sites present in biological systems, display of stereochemical diversity on interaction with organic substrates, formation of oligomers and polymers, interesting magnetic properties etc. [1–23]. In view of our interest in the study of metal–sulfur bonds, structural and spectroscopic properties of interaction of heterocyclic thiones, thiosemicarbazones and phosphine sulfuides/selenides with several transition and non-transition metals have been reported [9–42].

In the literature, neutral heterocyclic thiones form sulfur-bridged dinuclear copper(I) complexes, namely $[Cu_2(C_5H_5NS)_4I_2]$ (**5**) [24], $[Cu_2(imdtH_2)_4Cl_2]$ (**6**) {imdtH$_2$ = 1,3-imidazolidine-2-thione, II} [25], $[Cu_2(meimtH)_4Cl_2]$ (**7**) [26], $[Cu_2(meimtH)_4(SCN)_2]$ (**8**) [27], $[Cu_2(C_5H_5NS)_6]X_2$ {X = Cl, **9**, Br, **10**} [28,29], $[Cu_2(meimtH)_6](BF_4)_2$ (**11**) {meimtH = 1-methylimidazoline-2-thione, III} [30], $[Cu_2(imdtH_2)_6](ClO_4)_2$ (**12**) [31], $[Cu_2(pymtH)_2Cl_2(p\text{-}Tol_3P)_2]$ (**13**) {pymtH = pyrimidine-2-thione, IV} [32],$[Cu_2(C_5H_5NS)_2Br_2(m\text{-}Tol_3P)_2]$ (**14**) [33], $[Cu_2(C_5H_5NS)_2Br_2(PPh_3)_2]$ (**15**) [34], $[Cu_2(C_5H_5NS)_2I_2(p\text{-}Tol_3P)_2]$ (**16**) [6], $[Cu_2(tzdtH)_2Cl_2(p\text{-}Tol_3P)_2]$ (**17**) (tzdtH = 1,3-thiazolidine-2-thione, V} [35] and $[Cu_2(meimtH)_5](SO_4)\cdot 3H_2O$ (**18**) [36].

In this paper, copper(I) complexes with C_5H_5NS containing tertiary phosphines as co-ligands are reported with the objectives of: (i) understanding the effect of substituents on Ph groups attached to P atoms and anion on the Lewis acidity of the Cu(I) centre; (ii) studying the Cu(I)···Cu(I) interaction; and (iii) analysing factors controlling the formation of sulfur-bridged dinuclear copper(I) complexes with various heterocyclic thioamides. It may be mentioned that preparations and other details of the complexes have appeared elsewhere [12,32,34].

2. Experimental

2.1. Preparation of complexes

2.1.1. $[CuBr(\eta^2\text{-}S\text{–}\mu\text{-}C_5H_5NS)(p\text{-}Tol_3P)]_2$ (*1*)

NMR spectroscopy and also preparation details of compound **1** are described earlier [6]. To $CuBr_2(C_5H_5NS)_2$ {0.100 g, 0.22 mmol} suspended in $CHCl_3$ (15 cm^3) was added a solution of excess p-Tol$_3$P (0.136 g, 0.44 mmol) in $CHCl_3$ (15 cm^3) and the mixture was refluxed for 2 h. The clear solution formed was filtered and concentrated. A yellow solid started forming on cooling to room temperature (r.t.), which was filtered, washed with EtOH and dried in vacuo. Yield: 70%, m.p. 208–210 °C. *Anal*. Found: C, 55.3; H, 4.22; N, 2.50. Calc. for $C_{52}H_{52}Br_2Cu_2N_2P_2S_2$: C, 55.9; H, 4.65; N, 2.50%. UV data (λ_{max}, nm): 367mb (CS), 288s (py), 251s (Ph). IR data (cm^{-1}): 3162w (νN–H), 1127s (νC=S), 1098s (νP–C), 809s (ρC–CH$_3$), 219sb (νCu–Br) [7,8]. The crystals were grown from CH_2Cl_2–$CHCl_3$–MeOH mixture.

2.1.2. $[CuCl(C_5H_5NS)(Ph_3P)]_2$ (*2*)

To $CuCl(C_5H_5NS)$ {0.100 g, 0.48 mmol} suspended in $CHCl_3$ (15 cm^3) was added a solution of Ph_3P (0.125 g, 0.48 mmol) in $CHCl_3$ (15 cm^3) and the mixture was refluxed for 2 h. The clear solution formed was filtered and concentrated. A yellow solid started forming on cooling to r.t., which was filtered, washed with EtOH and dried in vacuo. Yield: 65%, m.p. 190–192 °C. *Anal*. Found: C, 57.6; H, 4.40; N, 2.94. Calc. for $C_{46}H_{40}Cl_2Cu_2N_2P_2S_2$: C, 58.5; H, 4.23; N, 2.97%. UV data (λ_{max}, nm): 367mb (CS), 285s (py), 250s (Ph). IR data (cm^{-1}): 1126s (νC=S), 1097s (νP–C), 327sb (νCu–Cl).

2.1.3. $[CuI(C_5H_5NS)(Ph_3P)]_2$ (*3*)

To CuI {0.100 g, 0.52 mmol} suspended in $CHCl_3$ (20 cm^3) was added solid C_5H_5NS (0.058 g, 0.52 mmol) and a solution of Ph_3P (0.138 g, 0.52 mmol) in $CHCl_3$ (15 cm^3) and the mixture was refluxed for 2 h. The clear solution formed was filtered, concentrated to 1/3 of its initial volume and addition of 10 cm^3 of petroleum–ether (60–80 °C) formed a bright yellow solid which was filtered, washed with Et_2O and dried in vacuo. Yield: 70%, m.p. 218–220 °C. *Anal*. Found: C, 49.2; H, 3.69; N, 2.56. Calc. for $C_{46}H_{40}Cu_2I_2N_2P_2S_2$: C, 49.0; H, 3.55; N, 2.49%. UV data (λ_{max}, nm): 355wb (CS), 285s (py), 247 (Ph). IR data (cm^{-1}): 3105w (νN–H), 1124s (νC=S), 1096s (νP–C), 136sb (νCu–I).

2.1.4. $[CuCl(\eta^1\text{-}S\text{–}\mu\text{-}C_5H_5NS)(Ph_3P)_2]$ (*4*)

The crystallisation of **2** from CH_2Cl_2–EtOH mixture resulted in the formation of the monomer **4** as revealed by its X-ray crystal determination.

2.2. Elemental analyses and spectroscopic techniques.

The C, H and N elemental analyses were obtained with a Carlo-Erba 1108 microanalyser. The m.p. was determined with a Gallenkamp electrically heated apparatus. The electronic absorption spectra were recorded on a Shimadzu Graphicord 240 UV–Vis spectrophotometer. The IR spectra were recorded in KBr pellets (4000–400 cm^{-1}) or Nujol mull in polythene sheets (500–100 cm^{-1}) on a Bruker IFS 66V spectrometer. The NMR spectra were recorded in $CDCl_3$ using a Bruker AMX 300 spectrometer at 300.14, and 75.48 MHz probe frequencies (^{1}H and ^{13}C, respectively) with TMS as the internal reference.

2.3. Crystal structure determinations

A yellow crystal of **1** (or yellow plate crystals of **4**) was mounted on a glass fibre and used for data collection. Cell constants and orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range of $14.077^\circ < \theta < 42.253^\circ$ for **1** and $16.036^\circ < \theta < 19.597^\circ$ for **4** on an Enraf–Nonius CAD 4 automatic diffractometer [43]. Data were collected at 293 K using Cu Kα radiation ($\lambda = 1.54184$ Å) and the ω-scan technique and corrected for Lp effects [44]. A semi-empirical absorption correction (ψ-scan) was made [45].

The structure was solved by direct method [46] and subsequent difference Fourier maps, and refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [47]. For **1** all hydrogen atoms were located from difference Fourier maps while for **4** all hydrogens were located in their calculated positions (C–H 0.93 Å) except the one bonded to N1, which was located from the Fourier map. The located hydrogens were refined isotropically whereas calculated ones were refined using a riding model. Atomic scattering factors were taken from International Tables for X-ray crystallography [48] and molecular graphics from ZORTEP [49]. A summary of the crystal data, experimental details and refinement results are listed in Table 1. Tables 2 and 3 contain bond lengths and angles while NMR data are given in Tables 4 and 5.

3. Results and discussion

3.1. Synthesis, IR and NMR spectral studies

Reaction of $CuBr_2(C_5H_5NS)_2$ with p-Tol_3P in $CHCl_3$ in a 1:2 mole ratio formed dinuclear compound **1** which yielded crystals in the CH_2Cl_2–$CHCl_3$–CH_3OH solvent mixture. Similarly $CuCl(C_5H_5NS)$ reacted with Ph_3P in $CHCl_3$ (1:1 mole ratio) to form **2**; while compound **3** was formed by reacting CuI with C_5H_5NS and Ph_3P in a 1:1:1 mole ratio. The melting points of complexes **2** and **3** are different, though close, to the reported values {lit. value [34], **2**, 196–199 °C; **3**, 210–212 °C} and the difference may be attributed to the different packing densities. The crystallisation of **2** from a CH_2Cl_2–C_2H_5OH mixture resulted in the formation of **4** as revealed by X-ray crystallography. It is significant to note that reaction of $CuCl(C_5H_5NS)$ with Ph_3P in a 1:2 mole ratio formed the monomer **4** [12]. Compound **3** did not yield good quality crystals.

The IR spectra of the complexes showed characteristic peaks due to C_5H_5NS and tertiary phosphines at altered positions and some important ones are listed in Section 2. The presence of a ν(N–H) peak in the region 3105–3164 cm^{-1} as a weak peak in the complexes shows that C_5H_5NS is not deprotonated in the complexes and a strong ν(C=S) peak at 1139 cm^{-1} in the free ligand shifts to the low energy region, 1124–1127 cm^{-1}, again as a strong peak in the complexes. This shows that C_5H_5NS coordinates to the Cu(I) centre via its thione sulfur and the magnitude of the coordination shift is similar to that reported in the literature [6]. Tentative assignments to ν(Cu–X) X = halogen bands are also made (cf. Section 2) [6–8].

The presence of a broad signal due to NH protons in the range δ 13.93–14.92 ppm at a lowfield shows that pyridine-2-thione is coordinating to the Cu(I) centre as a neutral ligand (free ligand, $\delta_{NH} = 13.40$ ppm) (Table 4). There is a lowfield shift in H(6), H(5) and H(4) protons of C_5H_5NS, while H(3) protons remain nearly unaffected. The ^3J coupling constants show variable trends for different ring protons; for example, the J_5 value for H(6) proton decreases, for H(4) proton J_3 and J_5 become equal, for H(3) J_4 and for H(5) J_4 and J_6

Symmetry transformations used to generate equivalent atoms: $-x+2$, $-y+1$, $-z+1$.

decrease marginally. As regards phosphines, *o*-, *m*- and *p*-protons show lowfield shifts but are unresolved for Ph_3P (Table 4).

The C(2) signal of coordinated C_5H_5NS shows a significant upfield shift relative to the free ligand; C(6) and C(3) signals show small lowfield shifts; C(4) signals are nearly unaffected and finally C(5) signals also show upfield shift (Table 5). The upfield shift of C(2) signals shows that coordination of Cu(I) to the S atom of C_5H_5NS increases the aromatic character of the pyridyl ring. The anionic $C_5H_4NS^-$ shows upfield shifts if it binds to a metal centre via S only and it is attributed to increased aromatic character of the pyridyl ring [6]. As regards ^{13}C NMR signals for the phosphines, the behaviour is summarised as follows: (i) *ipso*-carbons for both ligands show upfield shifts; (ii) *ortho*-carbons for Ph_3P also show the same behaviour, but for *p*-Tol_3P they are nearly unaffected; (iii) the *para*-carbon for Ph_3P also shows an upfield shift and for *p*-Tol_3P it is reversed; and finally (iv) for *meta*-carbons the trend is irregular and nearly unaffected.

3.1.1. Crystal and molecular structures

The atomic numbering schemes of $[CuBr(\eta^2\text{-}S\text{–}\mu\text{-}C_5H_5NS)(p\text{-}Tol_3P)]_2$ (**1**) and $[CuCl(\eta^1\text{-}S\text{–}\mu\text{-}C_5H_5NS)(Ph_3P)_2]$ (**4**) are shown in Figs. 1 and 2, respectively. The selected bond lengths and angles are given in Table 2. The basic structural unit of **1** is a centrosymmetric dimer with no interaction between the dimers and the S atoms of C_5H_5NS molecules bridge two Cu atoms forming a strictly planar Cu_2S_2 core. Each Cu atom is further bonded to a P atom of *p*-Tol_3P and one bromine atom and thus Cu acquires a distorted tetrahedral geometry. Two tetrahedra share a S–S edge and the *trans*-bromine atoms stabilise the dimer with strong intramolecular hydrogen bonds [N–H···Br, 3.319(5); H···Br, 2.41(5) Å and N–H–Br bond angle = 163(5)°] similar to those observed in literature [6,25]. The pyridyl ring of the thione ligand is planar and makes an angle of 63.66° with the plane of the Cu_2S_2 core.

The Cu–Br bond distance, 2.446 Å, is shorter than that (2.493 Å) in $[Cu_2(C_5H_5NS)_2Br_2(m\text{-}Tol_3P)_2]$ (**14**) [33] (the sum of ionic radii, 2.73 Å) [50]. The two short and two longer Cu–S bonds, 2.389 and 2.415 Å form a parallelogram of the Cu_2S_2 core, similar to other dimeric Cu(I) complexes listed in Table 3 and bond lengths are similar in value. The Cu–P bond distance of 2.238 Å is

Table 3
Bond lengths (Å) and angles (°) for Cu_2S_2 core of dinuclear copper(I)-heterocyclic thione complexes

Compound	Cu···Cu	S···S	Cu–Sb_{br}	Cu–S–Cu	S–Cu–S	Reference

[d] Unresolved signals δ_{NH} for **1**–**3** and ligand are 14.43, 14.92, 13.93, 13.40 ppm, respectively.

comparable to that (2.243 Å) in analogous $[Cu_2(C_5H_5NS)_2I_2(p\text{-}Tol_3P)_2]$ (**16**) [6], but shorter than in monomeric tetrahedral complexes [12,33]. The C–S bond distance of 1.717 Å is longer than (1.690 Å) in analogous **16**, but close to those in **13** [32], **14** [33] and **15** [34]. The Cu–S–C angles (108.41°, 113.12°) are similar to those (107.0(4)°, 116.5(5)°) in analogous **16**.

The bond angles around Cu in compound **4** reveal a distorted tetrahedral geometry with different Cu–P and Cu–S bond distances unlike those observed in the dimer **1** (Table 2). The structural parameters are similar to the ones reported earlier in literature [12]. In **1**, the non-bonded H(1)···Br bond distance of 2.41(5) Å is longer than that (2.348(2) Å) in $[Cu_2(C_5H_5NS)_2Br_2(m\text{-}Tol_3P)_2]$ (**14**) [33], but shorter than that (2.49 Å) in $[Cu_2(C_5H_5NS)_2Br_2(PPh_3)_2]$ (**15**) [34]; all these are longer than that (2.39 Å) in the monomer $[Cu(C_5H_5NS)Br(PPh_3)_2]$ (**22**) [34]. The H···Br separation is about 0.6 Å shorter than the sum of the van der Walls radii (3.00–3.45 Å) [50] and therefore fulfils Hamilton's criterion for hydrogen bond formation [51]. The H···Cl bond separation of 1.94(12) Å in **4** is much shorter than that (2.23 Å) in analogous monomer $[Cu(bztzdtH)Cl(PPh_3)_2]$ (**23**) {bztzdtH = benz-1, 3-thiazolidine-2-thione} [52] as well as that (2.30 Å) in the related dimer $[Cu_2(pymtH)_2Cl_2(p\text{-}Tol_3P)_2]$ (**13**) {pymtH = pyrimidine-2-thione} [32].

From the reactions of copper(I) halides with tertiary phosphines reported to date, it is noted that there is no monomeric tetrahedral complex with a substituted tertiary phosphine; however monomeric trigonal planar copper(I) complexes, viz. $[CuBr(o\text{-}tol_3P)$(thiazolidine-2-thione)] [37], $[CuCl(o\text{-}tol_3P)$(pyrimidine-2-thione)] and $[CuI(o\text{-}tol_3P)$(pyridine-2-thione)] [38] have been reported. The large cone angles of substituted tertiary phosphines appear responsible for the different behaviour [39]. Our efforts to get tetrahedral or trigonal planar complexes using pyridine-2-thione and *m*- or *p*-tol_3P resulted in the formation of dinuclear copper(I) complexes [6]. However, copper(I) bromide with unsubstituted tertiary phosphines, e.g. triphenyl phosphine, formed both monomeric $[Cu(C_5H_5NS)Br(PPh_3)_2]$ (**22**)

and dimeric $[Cu_2(C_5H_5NS)_2Br_2(PPh_3)_2]$ (**15**) [34] complexes. Similarly, with copper(I) iodide there are monomeric $[CuI(PPh_3)_2$(pyrimidine-2-thione)] (**24**) with a NH···I separation of 2.65 Å [40] and probably dinuclear $[Cu_2(C_5H_5NS)_2I_2(PPh_3)_2]$ (structurally uncharacterised) [34]. Whereas pyridine-2-thione with copper(I) chloride formed only the monomeric $[Cu(C_5H_5NS)Cl(PPh_3)_2]$ complex [12], benzothiazole-2-thione however stabilised the dinuclear complex [CuCl(benzothiazole-2-thione)$(PPh_3)]_2$ (**25**) [41]. Relatively strong NH···Cl hydrogen bonding in **4** favours the monomeric complex while dinuclear **25** has a NH···Cl separation of 2.169 Å indicating a weak interaction [41].The analytical data of the stoichiometric reaction of copper(I) chloride with Ph_3P presumably showed the formation of a dinuclear complex (cf complex **2**, Section 2); however, the crystallisation of **2** led to the formation of the monomer **4** and it creates doubt about the existence of the dinuclear copper(I) chloride complex **2** [34]. It may be concluded from the above discussion that the intramolecular NH···X(halogen) bonding and nature of the heterocyclic thioamide both determine the formation of monomeric or dimeric copper(I) complexes.

3.2. Cu···Cu bond distances in homologous dinuclear copper(I) complexes

Table 3 contains a list of dinuclear copper(I) complexes with a series of heterocyclic-2-thiones namely pyridine-2-thione (C_5H_5NS), 1,3-imidazolidine-2-thione ($imdtH_2$), 1-methylimidazoline-2-thione (meimtH), pyrimidine-2-thione (pymtH) and 1,3-thiazolidine-2-thione (tzdtH) with tertiary phosphines as co-ligands in some cases. These compounds can be categorised into four types: (i) $[Cu_2(\mu\text{-S–NH})_2X_2]$ (**5**, **7**, **8**); (ii) $[Cu_2(\mu\text{-S–NH})_6]X_2$ (**9**, **10**, **11**, **12**); (iii) $[Cu_2(\mu\text{-S–NH})_2X_2L_2]$ (**1**, **13**, **14**, **15**, **16**, **17**); and (iv) $[Cu_2(\mu\text{-S–NH})(S\text{–NH})_3Cl_2]$ (**6**), $[Cu_2(\mu\text{-S–NH})(S\text{–NH})_4](SO_4)\cdot 3H_2O$ (**18**) {μ-S–NH indicates bridging S-bonding and S–NH indicates terminal S-bonding; X = halogen, and L = a tertiary phosphine}. Except in *type* (*iv*), all other complexes contain a Cu_2S_2 core with two heterocyclic-2-thione ligands bridging the Cu centres via S-donor atoms and in these compounds it can be noted that Cu···Cu and S···S distances (based on reported values) vary in a complementary manner. Generally a decrease in Cu···Cu bond distance is accompanied by an increase in S···S distance.

In the parallelogram Cu_2S_2, the Cu···Cu bond distances vary with the change in ligand and the anion and in *type* (*i*) compounds (**5**, **7**, **8**), the shortest distance is observed in **8** with each copper bonded to four S atoms unlike three S and one halogen atom to each Cu in **5** and **7** (distances 2.861–3.139 Å). Thus the more polarisable SCN^- group has a strong influence in bringing two Cu atoms closer for interaction. In *type* (*ii*) compounds, with each Cu bonded to four S atoms, the Cu···Cu distances (2.686–3.007 Å) vary in the sequence: **12** < **10** < **9** < **11** and it is certainly the

effect of the ligands and the non-bonded anions. It may be noted that the shortest Cu···Cu distance is observed in **12** among all the dinuclear compounds listed in Table 3. Similarly, in *type* (*iii*) compounds with each Cu bonded to two S, one P atom and one halogen atom, Cu···Cu distances fall in the range 3.250–3.508 Å except compound **14** which has a distance of 2.691 Å close to that in **12**. Finally in *type* (*iv*) compounds with one S atom bridging the two Cu atoms, the Cu···Cu distances (3.308–4.506 Å) are among the longest.

Some general trends in Cu···Cu bond distances are revealed as follows: (i) when each copper is bonded to four sulfur atoms, the Cu···Cu bond distances decrease (2.686–3.007 Å; compounds **8**, **9**–**12**) because the electron rich Cu atoms enhance metal–metal interaction; (ii) when each copper is bonded to two S, one P and one halogen atom, the Cu···Cu distances increase (3.250–3.508 Å; compounds **1**, **13**–**17**, except **14**) and this behaviour can be explained in terms of reduction in electron density at the Cu centres in view of pi-bonding from the metal to d-orbitals on phosphorus and this increases the Cu···Cu distance. Whereas complex **14**, having a *m*-tol_3P ligand, showed the short Cu···Cu distance of 2.691 Å, the same was not true for $[Cu_2Br_2$(thiazolidine-2-thione$)_2$(*m*-$tol_3P)_2]$ (**26**) [42] in which the Cu···Cu distance increased to 3.347 Å. It shows that Cu···Cu distance varies with the nature of the thione ligand and is independent of the substituent on the Ph group.

For compounds having three S atoms (2.914–3.139 Å; compounds **5**, **7**) and one halogen bonded to each Cu atom, though many examples are not available, the distances in between the two extremes are observed. Finally in *type* (*iv*) compounds (**6**, **18**), the Cu···Cu distance is longest (4.506 Å) in **6** because one Cu is bonded to three S and one halogen atom and the second Cu is bonded to two S and one halogen atom and this decreases electron density at the Cu centres thus weakening the Cu···Cu interaction. Interestingly in **18**, with each Cu bonded to three S atoms, the distance (3.308 Å) is quite short and comparable to that observed

in the compounds **1**, **13**–**17**. In short, an electron withdrawing halogen or a metal to ligand pi-bonding group decreases Cu···Cu interaction and an increase in number of sulfur groups bonded to Cu enhances Cu···Cu interaction.

The Cu–S–Cu and S–Cu–S bond angles in compounds with a Cu_2S_2 core vary with Cu···Cu distance. A shorter distance is accompanied by smaller Cu–S–Cu and larger S–Cu–S bond angles and vice versa and for *type* (*iv*) compounds the Cu–S–Cu bond angles are the largest. It is interesting to note that the angular flexibility at S is very large (67.2°–137.3°) and is of great consequence for controlling metal–metal interactions.

4. Supplementary material

Supplementary data are available from the Cambridge Crystallographic Data Centre, CCDC Nos. 164391–164390 for compounds **1** and **4**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

One of us (T.S.L.) is thankful to Professor J.S. Casas of University of Santiago, Spain, for instrumental facilities. Financial help from CSIR for a computer grant is also gratefully acknowledged. Authors thank the referees for useful comments on the manuscript.

reductive elimination of hydrogen. The reaction of complex **1** with pyrazine (pyz) in CH_2Cl_2 afforded the triangular Rh_3 complex $[Rh_3(PPh_3)_6(pyz)_3](ClO_4)_3\cdot CH_2Cl_2$, in contrast to the formation of the dinuclear Rh hydrido complex $[Rh_2(H)_4(PPh_3)_4(Me_2CO)_2(pyz)](ClO_4)_2\cdot EtOH$ in Me_2CO. The reaction of complex **1** with 4,4'-trimethylenedipyridine (tmdp), having a long spacer, in CH_2Cl_2 provided the dinuclear Rh non-hydrido complex $[Rh_2(PPh_3)_4(tmdp)_2](ClO_4)_2$. In this study, as further investigations, the reactions of complex **1** with nitrogen ligands such as 2-(4-thiazolyl)benzimidazole (tbz), pyridazine (pdz), imidazole (im) and pyrimidine (pmd) in CH_2Cl_2 were examined according to Scheme 1. Several mononuclear Rh complexes were isolated and their structures were crystallographically characterized.

2. Experimental

2.1. General procedures

All operations were carried out using standard Schlenk techniques under N_2 atmosphere. All the organic solvents were distilled by general methods before use. $RhCl_3\cdot 3H_2O$, 2-(4-thiazolyl)benzimidazole, pyridazine, imidazole and pyrimidine were commercially purchased from Steam and Aldrich and used without further purifications. $[Rh(H)_2(PPh_3)_2(EtOH)_2]ClO_4$ (**1**) was synthesized according to the literature [8]. IR spectra were recorded on a Perkin–Elmer System 2000 FT IR spectrometer as a KBr pellet. UV–Vis spectra were recorded on a HITACHI U-3500/U-4000 spectrometer. ^1H NMR spectra were measured at room temperature (r.t.) on a JEOL JNM-A 500 FT NMR spectrometer. Trimethylsilane was used as an internal reference.

Scheme 1.

2.2. Preparation of Rh complexes with nitrogen ligands

2.2.1. $[Rh(H)_2(PPh_3)_2(tbz)]ClO_4$ (**2**)

A 5 ml CH_2Cl_2 solution of $[Rh(H)_2(PPh_3)_2(EtOH)_2]ClO_4$ (**1**) (41.1 mg, 0.05 mmol) was added to the tbz ligand (10.1 mg, 0.05 mmol) in CH_2Cl_2 (5 ml). After stirring for 30 min, the reaction solution was filtered. The yellow filtrates were introduced into 5 mm diameter glass tubes and were layered with hexane as the diffusion solvent. The glass tubes were sealed and allowed to stand at r.t. for 2 days. Light yellow crystals of complex **2** were collected. Yield: 43.7 mg (94%). IR (KBr pellet, cm^{-1}): 2081 (Rh–H), 1435, 1095, 696 and 519. ^1H NMR (CD_2Cl_2, 23 °C, ppm): δ 11.98 (N–H of benzimidazole), 8.19 (2-H of thiazolyl), 8.08 (4-H of benzimidazole), 7.00–7.59 (Ph of PPh_3), 6.03 (5-H of benzimidazole), −15.60 (Rh–H) and −16.30 (Rh–H). *Anal.* Calc. for $C_{46}H_{39}P_2N_3SRhO_4Cl$: C, 59.40; H, 4.23; N, 4.52. Found: C, 59.26; H, 3.97; N, 4.33%.

2.2.2. $[Rh(H)_2(PPh_3)_2(pdz)_2]ClO_4\cdot 2CH_2Cl_2$ (**3**) and $[Rh(H)Cl(PPh_3)_2(pdz)_2]ClO_4\cdot CH_2Cl_2$ (**4**)

Complex **3** was prepared in the same manner as for complex **2**, using the pdz ligand (8.0 mg, 0.10 mmol). Light yellow crystals of complex **3** were obtained 2 days later at the middle part of the glass tubes. Yield: 43.4 mg (82%). IR (KBr pellet, cm^{-1}): 2046 (Rh–H), 1435, 1093, 697 and 521. ^1H NMR (CD_2Cl_2, 23 °C, ppm): δ 9.16 (3,6-H of prd), 8.57 (5-H of prd), 8.21 (4-H of prd), 7.20–7.48 (Ph of PPh_3), and −16.89 (Rh–H). *Anal.* Calc. for $C_{46}H_{44}P_2N_4RhO_4Cl_5$: C, 52.17; H, 4.19; N, 5.29. Found: C, 51.68; H, 4.11; N, 5.33%.

The reaction solution was allowed to stand for a further 2 weeks and colorless crystals of complex **4** were collected at the upper part of the glass tubes. Yield: 4.0 mg (8%). IR (KBr pellet, cm^{-1}): 2174 (Rh–H), 1435, 1093, 696 and 523. *Anal.* Calc. for $C_{45}H_{41}P_2N_4RhO_4Cl_4$: C, 53.59; H, 4.10; N, 5.56. Found: C, 53.32; H, 4.03; N, 5.86%.

2.2.3. $[Rh(H)_2(PPh_3)_2(im)_2]ClO_4\cdot 2CH_2Cl_2$ (**5**) and $[Rh(H)Cl(PPh_3)_2(im)_2]ClO_4\cdot CH_2Cl_2$ (**6**)

Complex **5** was prepared in the same manner as for complex **3**, using the im ligand (6.7 mg, 0.10 mmol). The reaction solution was allowed to stand at r.t. for 2 days and light yellow crystals of complex **5** were obtained at the middle part of the glass tubes. Yield: 38.1 mg (74%). IR (KBr pellet, cm^{-1}): 2051 (Rh–H), 1435, 1095, 695 and 520. ^1H NMR (CD_2Cl_2, 23 °C, ppm): δ 10.09 (N–H of im), 7.21–7.61 (Ph of PPh_3), 6.71 (2-H of im), 6.57 (4-H of im), 6.31 (5-H of im) and −16.85 (Rh–H). *Anal.* Calc. for $C_{44}H_{44}P_2N_4RhO_4Cl_5$: C, 51.06; H, 4.28; N, 5.41. Found: C, 51.44; H, 4.42; N, 5.57%.

The reaction solution was allowed to stand at r.t. for another 2 weeks and colorless crystals of complex **6** were collected at the upper part of the glass tubes. Yield: 1.0 mg (2%). IR (KBr pellet, cm^{-1}): 2133 (Rh–H), 1434, 1094, 696 and 523. *Anal.* Calc. for $C_{43}H_{41}P_2N_4RhO_4Cl_4$: C, 52.46; H, 4.20; N, 5.69. Found: C, 52.51; H, 4.11; N, 5.53%.

2.2.4. $[Rh(H)_2(PPh_3)_2(pmd)_4]ClO_4\cdot CH_2Cl_2$ (7) and $[RhCl_2(pmd)_4]ClO_4$ (8)

Complex **7** was prepared in the same manner as for complex **3**, using the pmd ligand (8.0 mg, 0.10 mmol). Complex **7** was obtained as white precipitates. Yield: 36.0 mg (74%). IR (KBr pellet, cm^{-1}): 2060 (Rh–H), 1584, 1435, 1094, 696 and 520. ^1H NMR (CD_2Cl_2, 23 °C, ppm): δ 9.17 (2-H of pmd), 8.73 (6-H of pmd), 8.28 (4-H of pmd), 7.26–7.38 (Ph of PPh_3), 7.01 (5-H of pmd) and −17.30 (Rh–H). *Anal.* Calc. for $C_{45}H_{42}P_2N_4RhO_4Cl_3$: C, 55.49; H, 4.35; N, 5.75. Found: C, 55.92; H, 4.20; N, 5.58%.

Yellow crystals of complex **8** were collected 4 days later at the lower part of the glass tubes. Yield: 3.5 mg (12%). IR (KBr pellet, cm^{-1}): 1595, 1411, 1122, 706 and 625. *Anal.* Calc. for $C_{16}H_{16}N_8RhO_4Cl_3$: C, 32.37; H, 2.72; N, 18.88. Found: C, 32.68; H, 2.61; N, 18.69%.

2.3. X-ray crystallography

For each complex, a suitable crystal was sealed into the glass capillary (0.7 mm, GLAS) and mounted on the crystal goniometer. The intensity data of all the single crystals were collected on the Rigaku/Mercury CCD system using graphite monochromated Mo Kα radiation ($\lambda = 0.710691$ Å). The structures of complexes **2**, **5** and **6** were solved by the direct method (SIR-92 for **2** and **5**; SIR-97 for **6**) [9], and expanded using Fourier techniques [10]. The structure of complex **3** was solved by the heavy-atom Patterson method [11] and expanded using Fourier techniques [10]. The hydride hydrogen atoms were located and refined isotropically. All other hydrogen atoms were included but not refined. The non-hydrogen atoms were refined anisotropically. The final cycle of full-matrix least-squares refinement was based on 5251, 4348, 4418 and 6594 observed reflections ($I > 3\sigma(I)$) for complexes **2**, **3**, **5** and **6**, respectively. The unweighted and weighted agreement factors of $R = \Sigma||F_o|-|F_c||/\Sigma|F_o|$ and $R_w = [\Sigma\, w(F_o^2-F_c^2)^2/\Sigma\, w(F_o^2)^2]^{1/2}$ were used. The atomic scattering factors and anomalous dispersion terms were taken from ref. [12]. All calculations were performed using the TEXSAN crystallographic software package [13]. The detailed crystal data of all complexes are summarized in Table 1.

3. Results and discussion

3.1. Crystal structures

3.1.1. $[Rh(H)_2(PPh_3)_2(tbz)]ClO_4$ (2)

In the reaction of complex **1** with the nitrogen ligand, the tbz ligand acted as a bidentate chelate ligand and led to the typical mononuclear Rh hydrido complex **2**. Since no crystallographic structures of Rh complexes containing the tbz ligand have been reported, complex **2** is the first example of a Rh hydrido complex with the tbz ligand. Fig. 1 shows the cation moiety of complex **2** together with the atomic labelling scheme. The Rh atom is coordinated by two P atoms, two N atoms and two hydride atoms in a distorted octahedral environment. The two PPh_3 ligands are nearly in *trans*-positions with a P(1)–Rh–P(2) angle of 167.06(8)°. The Rh coordination plane defined by two N atoms of the tbz ligand and two hydride atoms are coplanar with the mean deviation of 0.0365 Å. Two heterocyclic rings of the tbz ligand are nearly coplanar with a mean deviation of 0.0707 Å. The average Rh–P, Rh–N and Rh–H distances of 2.299, 2.197 and 1.58 Å are similar to those of other analogous hydrido complexes [14]. The H···H distance of 2.08 Å is characteristic of hydrido complexes [15]. The N(1)–Rh–N(2) angle of 76.1(2)° is within the range of values of other Rh complexes with bidentate nitrogen ligands [16]. Selected bond distances and bond angles are listed in Table 2.

3.1.2. $[Rh(H)_2(PPh_3)_2(pdz)_2]ClO_4\cdot 2CH_2Cl_2$ (3)

The structure of the cation moiety of complex **3** is presented in Fig. 2. The Rh atom is coordinated by two PPh_3 ligands, two pdz ligands and two hydride atoms to afford a mononuclear Rh complex in a slightly distorted octahedral geometry. In each pdz ligands, one of the two N atoms is bonded to the Rh atom. The two pdz ligands, in *cis*-positions, are inclined against the N_2RhH_2 coordination plane at an angle of 31.2(2)°. On the other hand, two PPh_3 ligands in *trans*-positions are bent toward the two hydrides with a P(1)–Rh–P(1′) angle of 163.89(5)°. The Rh–P, Rh–N and Rh–H distances of 2.3033(9), 2.181(3) and 1.44(4) Å are similar to those of other Rh hydrido complexes [14]. The H···H distance of 2.03 Å is within the range of values found in other hydrido complexes [15]. Selected bond distances and angles are listed in Table 3.

Metal complexes with the pdz ligand as a heterocyclic ligand have been relatively limited, in comparison with those with the pyrazine ligand [17]. Although recently there have been several crystallographic reports on complexes with pdz ligands [18], Rh complexes with the pyz ligand are few. The crystal structure of complex **3** is remarkable as a Rh hydrido complex with the pdz ligand.

3.1.3. $[Rh(H)_2(PPh_3)_2(im)_2]ClO_4{\cdot}2CH_2Cl_2$ (5)

The structure of the cation moiety of complex **5** is shown in Fig. 3. The structure of complex **5** essentially resembles that of complex **3**. The Rh atom is coordinated by two PPh_3 ligands, two im ligands and two hydride atoms in a distorted octahedral geometry. The two im ligands in *cis*-positions are slightly inclined against the N_2RhH_2 coordination plane at an angle of 27.7(2)°, which is smaller than that (31.2(2)°) of complex **3**. The two PPh_3 ligands are in *trans*-positions and the P(1)–Rh–P(1′) angle of 163.13(5)° is similar to that (163.89(5)°) of complex **3**. The Rh–P, Rh–N and Rh–H distances of 2.2955(9), 2.189(3) and 1.50(4) Å are close to those of other Rh hydrido complexes [14]. The H···H distance of 2.07 Å is in the range of those found in other hydrido complexes [15]. Selected bond distances and angles are listed in Table 4.

Our survey of Rh complexes with the im ligand and its derivatives described the tetranuclear complex [Rh(2-Meim)$(CO)_2]_4$ (2-Meim = 2-methylimidazole) [19a], the dinuclear complex $[NBu_4][Rh_2(cod)_2(dcbi)]{\cdot}2^i$PrOH (dcbi = 4,5-dicarboxyimida-zole) [19b], the mononuclear complexes $[RhCl_2(N\text{-Meim})_4]Cl{\cdot}2H_2O$ (Meim = *N*-methyl-imidazole) [19c] and [imH][*trans*-$RhCl_4(im)_2$] [19d]. However, there are no reports of X-ray structures of Rh hydrido complexes with the im ligand. To the best of our knowledge, this is the first crystal structure of a Rh hydrido complex with the im ligand.

[a] Symmetry codes: $-X+2, -Y, Z$.

3.1.4. $[Rh(H)Cl(PPh_3)_2(im)_2]ClO_4{\cdot}CH_2Cl_2$ (6)

After light-yellow single crystals of complex **5** were obtained according to Scheme 1, colorless single crystals of complex **6** were collected from the same reaction solution 2 weeks later. The structure of the cation moiety of complex **6** is revealed in Fig. 4. The coordination sphere around the Rh atom consists of two PPh_3 ligands, two im ligands, one Cl atom and one hydride atom, providing a distorted octahedral geometry. It is interesting that the two im ligands are located in the *trans*-positions and are separated by the Cl atom and the hydride atom. This structural feature is greatly different from that in complex **5**. The P(1)–Rh–P(2) angle of 177.26(4)° is much larger than those of 163.89(5)° and 163.13(5)° in complexes **3** and **5**, respectively. Therefore the PPh_3 ligands in the *trans*-positions are almost linearly located. The average Rh–P distance of 2.362 Å is longer than those of normal Rh and Ir hydrido complexes [4,7]. The average Rh–N distances of 2.056 Å are shorter than those of 2.181(3) and 2.189(3) Å in complexes **3** and **5**, respectively. The Rh–Cl distance of 2.498(1) Å is longer than those found in other hydrido complexes [4] owing to the *trans* influence of the nitrogen ligands. Selected bond distances and angles are listed in Table 5.

3.2. Reactions of $[Rh(H)_2(PPh_3)_2(EtOH)_2]ClO_4$ with nitrogen ligands in CH_2Cl_2

According to Scheme 1, the reactions of the Rh hydrido complex **1** with nitrogen ligands were attempted and their reaction processes were monitored by ^{1}H NMR and UV–Vis spectra. The addition of the tbz

ligand to complex **1** in CD_2Cl_2 initially showed two new quintet ^{1}H NMR signals of hydride species at −15.60 and −16.30 ppm at r.t., together with the quintet ^{1}H NMR signal of an hydride species at −22.16 ppm, which should be attributed to hydrides of complex **1**. After about 1 h, the ^{1}H NMR signal of complex **1** completely disappeared and the two new ^{1}H NMR signals only remained. These facts indicate that Rh hydrido complex **2** with the tbz ligand was formed in CH_2Cl_2 solution. Similarly, on the reaction of complex **1** with pdz, im and pmd ligands, the ^{1}H NMR signals of the hydride species could be observed at −16.89, −16.85 and −17.30 ppm for complexes **3**, **5** and **7**, respectively. On the other hand, as shown in the time-course UV–Vis spectra (Fig. 5), complex **1** dissolved in CH_2Cl_2 at 23 °C displayed the color change from yellow to the dark brown solution of $[Rh_2(PPh_3)_2\{(\eta^6\text{-}C_6H_5)Ph_2P\}]_2]^{2+}$ ($\lambda_{max} = 410$ nm ($\varepsilon = 3056\ cm^{-1}\ M^{-1}$)) [7]. The further addition of tbz ligand to the CH_2Cl_2 solution exhibited the color change from dark-brown to a yellow solution ($\lambda_{max} = 420$ nm ($\varepsilon = 2235\ cm^{-1}\ M^{-1}$)) and the formation of complex **2** was completed after about 50 min. On the basis of these structural studies in solution and the above-mentioned crystallographic

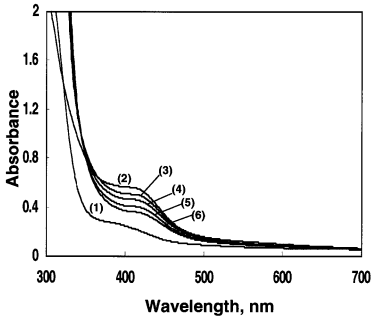

Fig. 5. The time-course UV–Vis spectra in CH_2Cl_2 at 23 °C. After the dissolving of complex **1**: 10 (1) and ≥ 50 (2) min. After the addition of the tbz ligand to complex **1**: 20 (3), 30 (4), 40 (5) and ≥ 50 (6) min. $[c] = 1.7 \times 10^{-4}$ M.

studies, it was concluded that the reaction of complex **1** with nitrogen ligands such as tbz, pdz, im and pmd ligands provided mononuclear Rh hydrido complexes without the reductive elimination of hydrogen. We previously demonstrated that the reactions of complex **1** with nitrogen bridging ligands such as pyrazine and 4,4′-bipyridine derivatives in CH_2Cl_2 could afford di- and trinuclear Rh non-hydrido complexes[7] with the reductive elimination of hydrogen. The results in this study are greatly different from those previously found. Although the detailed reason is not obvious at the present, it is probably considered that nitrogen ligands such as tbz, pdz and im ligands are structurally difficult to bridge Rh centers owing to the steric repulsion against the phenyl group of the PPh_3 ligand and should lead to mononuclear Rh hydrido complexes with nitrogen ligands, without the reductive elimination of hydrogen.

As mentioned in the Section 2, when the reaction solution of the Rh hydrido complex **1** with pdz, im and pmd ligands was allowed to stand for more than 2 weeks, Rh complexes **4**, **6** and **8** [20] with a coordinated Cl atom were collected in the same glass tubes, respectively. The reaction solution of complex **1** with the tbz ligand did not provide the corresponding Rh complex with a coordinated Cl atom since the tbz ligand played a role as a bidentate chelate ligand. In this study, the monitoring of their formation process by ^{1}H NMR and UV–Vis spectra over 2 weeks has not been carried out and the structure of **6** could only be crystallographically characterized. At the present, although their formation mechanisms are not obvious in detail, it is considered that the Cl atom is probably derived from the CH_2Cl_2 solvent since it has been known that $[RhCl(PPh_3)_2]_2$ was produced by the reaction of $[Rh_2(H)_2(PPh_3)_4(Me_4Si_2O)_2]$ with CH_2Cl_2 as the solvent [21].

3.3. Consideration on crystallographic study

The four crystallographic studies revealed the significant structural differences among their bond distances and bond angles of complexes **2**, **3**, **5** and **6**. In complex **6** with the Cl atom, the average Rh–N distance of 2.056 Å is shorter than those (**2** (2.197(7) Å), **3** (2.181(3) Å) and **5** (2.189(3) Å)) of the other Rh complexes without the Cl atom. In contrast, the average Rh–P distance of complex **6** (2.362 Å) is slightly longer than those of **2** (2.299 Å), **3** (2.3033 Å) and **5** (2.2955 Å). The P–Rh–P angle of **6** (177.26(4)°) is rather larger than those of **2** (167.06(8)°), **3** (163.89(5)°), **5** (163.13(5)°) and other Rh hydrido complexes [4,7]. These changes should probably be caused by the repulsion between the bulky Cl atom and the *trans*-nitrogen ligands. The Rh–Cl distance of 2.499(1) Å in complex **6** is also longer than those of

other Rh hydrido complexes [4] owing to the *trans* influence of the nitrogen ligands.

It is suggested that complex **2** possesses a meaningful inter-planar interaction between the nitrogen ligand and the corresponding phenyl group of PPh_3. The mean inter-planar distance between the benzimidazole portion of the tbz ligand and the phenyl group including the C(11) atom is 3.409 Å with a dihedral angle of 10.2°, and that between the thiazolyl group of the tbz ligand and the phenyl group including C(29) atom is 3.422 Å with an angle of 27.1°. A similar intra-molecular interaction has been known in previous reports [22]. This consideration is also supported by other structural parameters in complex **2**: the Rh(1)–P(1)–C(11) bond angle of 112.2(3)° is smaller than Rh(1)–P(1)–C(17) of 117.4(3)° and Rh(1)–P(1)–C(23) of 113.6(3)°. The Rh(1)–P(2)–C(29) bond angle of 111.9(2)° is smaller than Rh(1)–P(2)–C(41) of 118.0(3)° and Rh(1)–P(2)–C(35) of 114.3(3)°.

In complex **6**, it should be noted that the intra-molecular C–H···Cl hydrogen bonds exist between the Cl atom and hydrogen atom at the 2-position in im ligands. The C(1)···Cl(1) and C(4)···Cl(1) distances are 3.339(5) and 3.306(6) Å, respectively. Thus interactions are probably caused by the steric repulsion within the bulky PPh_3 ligands. The possibility of Rh···H agostic interaction and attractive Cl···H–C hydrogen bonds in Rh complexes with the PPh_3 ligand has recently been reported [23]. This suggestion is consistent with the results of the density functional analysis [23]: the intra-molecular steric repulsion can force one of the phenyl rings of the PPh_3 ligands toward the metal center.

4. Supplementary materials

Crystallographic data for the X-ray crystal structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC, Nos. 169897 (**2**), 169896 (**3**), 169895 (**5**) and 169898 (**6**). Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1233-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

dimensional complexes such as discrete complex ions, complex molecules and catena polymeric chains. Mixed ligand complexes with 2D networks are very rare. Additionally, most work was restricted to the low members of the saturated α,ω-dicarboxylate anions and only a few studies have been carried out using sebacate anions ($OOC–(CH_2)_8–COO$) as ligands [39]. Recently, McCann et al. have found that Cu(II) and Mn(II) α,ω-dicarboxylato complexes possess antimicrobial and anti-Candida activity [40,41]. In this paper, we report two sebacato-bridged Cu(II) complexes $^2_\infty[Cu_2(phen)_2L_{4/2}](H_2O)_6$ (**1**) and $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2](HL)_2(H_2L)(H_2O)_4$ (**2**). Within complex **1**, the $[Cu_2(phen)_2]$ subunits are interlinked by sebacato ligands into 2D grid-like open networks. The principal building blocks in complex **2** are the dinuclear $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2]^{2+}$ complex cations resulting from two $[Cu(phen)_2]$ moieties bischelated by sebacato ligands. In both complexes, significant π–π stacking interactions play important roles in supramolecular assembly.

2. Results and discussion

2.1. Syntheses

Our earlier investigation indicated that reactions of equimolar $CuCl_2$, 1,10-phenanthroline, sebacic acid ($H_2L = HOOC–(CH_2)_8–COOH$) with Na_2CO_3 in CH_3OH/H_2O produced $[Cu(phen)L]\cdot 3H_2O$ [42] and $[Cu_2(phen)_2(H_2O)_2(OH)_2](HCO_3)_2\cdot 6H_2O$ [43] at pH = 6.4 and 10.2, respectively. However, reactions of phenanthroline, sebacic acid and $Cu(OH)_2$, which was freshly precipitated by addition of NaOH to an aqueous solution of $CuCl_2\cdot 2H_2O$, yielded $^2_\infty[Cu_2(phen)_2L_{4/2}](H_2O)_6$ (**1**) and $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2](HL)_2(H_2L)(H_2O)_4$ (**2**) at pH = 6.4 in EtOH/H_2O (1:1 v/v) and CH_3OH/H_2O (1:1 v/v), respectively. This finding implies that a neutral solution is obviously favorable for the sebacate anions to coordinate to Cu atoms. Additionally, self-assembly of Cu(II) ions with phen and sebacic acid is solvent dependent and the products rely on the Cu(II) sources used even though the same solvent mixture was employed.

2.2. Structure of $^2_\infty[Cu_2(phen)_2L_{4/2}](H_2O)_6$ (1)

The basic building subunits in **1** are the centrosymmetric $[Cu_2N_4O_4]$ dimers resulting from edge-sharing of two $[CuN_2O_3]$ square pyramids via two μ_2 carboxylato O atoms at the canted edges (Fig. 1). As usual, the basal Cu–O bond distances of 1.944 and 1.963 Å are slightly shorter than the Cu–N bond distances of 2.020 and 2.035 Å, and the axial Cu–O bond distance is 2.407 Å (Table 2). The Cu atom is displaced by 0.049(1) Å from the best plane defined by O(1), N(1), N(2) and O(3)^a towards the apical O(3)^b atom. The Cu···Cu distance within the dimer is 3.419(1) Å. The $[Cu_2N_4O_4]$ dimers are interlinked by the bridging sebacato ligands into 2D $^2_\infty[Cu_2(phen)_2L_{4/2}]$ open layers with rhombus-like 52-membered rings and the chelating phen ligands disposed on both sides (Fig. 1). Such grid-like networks extend infinitely parallel to (101) and are arranged so that adjacent phen planes from different layers face antiparallel to each other with the interplanar phen-to-phen distance of 3.51 Å, suggesting substantial π–π stacking interactions [44–49]. The chelating phen ligands of the 2D layers exhibit nearly perfect coplanarity.

Each carboxylate group of the bridging sebacato ligand offers one O atom, respectively, to coordinate one Cu atom and to bridge two Cu atoms. As expected, the C–O bond length to the bidentate carboxylate O atom is 1.282 Å, slightly longer than that (1.273 Å) to the monodentate carboxylate O atom, and the C–O bond lengths to the non-coordinating carboxylate O atoms are averaged at 1.239 Å.

Out of the three crystallographically distinct H_2O molecules intercalated between 2D $^2_\infty[Cu_2(phen)_2L_{4/2}]$ layers, one donates two hydrogen atoms to two non-coordinating carboxyl O atoms of different sebacato ligands belonging to the same layer, while the remaining two participate in hydrogen bonds both to the non-coordinating carboxyl O atom and to the third water O atom ($d(O\cdots O) = 2.785–2.852$ Å, $\angle(O–H\cdots O) = 144^\circ–177^\circ$).

2.3. Structure of $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2](HL)_2(H_2L)(H_2O)_4$ (2)

The crystal structure is composed of the centrosymmetric dinuclear $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2]^{2+}$ complex cations, twisted hydrogensebacate anions, linear sebacic acid molecules and lattice H_2O molecules.

The dinuclear complex cations are generated from two $[Cu(phen)_2]$ moieties bischelated by one 'Z' shaped sebacato ligand (Fig. 2). The Cu atoms are each octahedrally surrounded by four N atoms from two phen ligands and two O atoms from one carboxyl group of the bridging sebacato ligand to complete '4+1+1' coordination geometry with one pyridyl N atom and one carboxyl O atom at the apical positions. The basal Cu–O(3) bond length is 1.976 Å and the basal Cu–N bond distances fall in the range 2.014–2.044 Å. The axial Cu–N(4) and Cu–O(4) bond lengths are 2.241 and 2.692 Å, respectively. Two phen planes and the carboxyl plane around the Cu atom stand nearly perpendicularly to one another.

Within the crystal structure, the divalent complex cations are arranged so that the symmetry related phen ligands of the adjacent complex cations face antiparallel

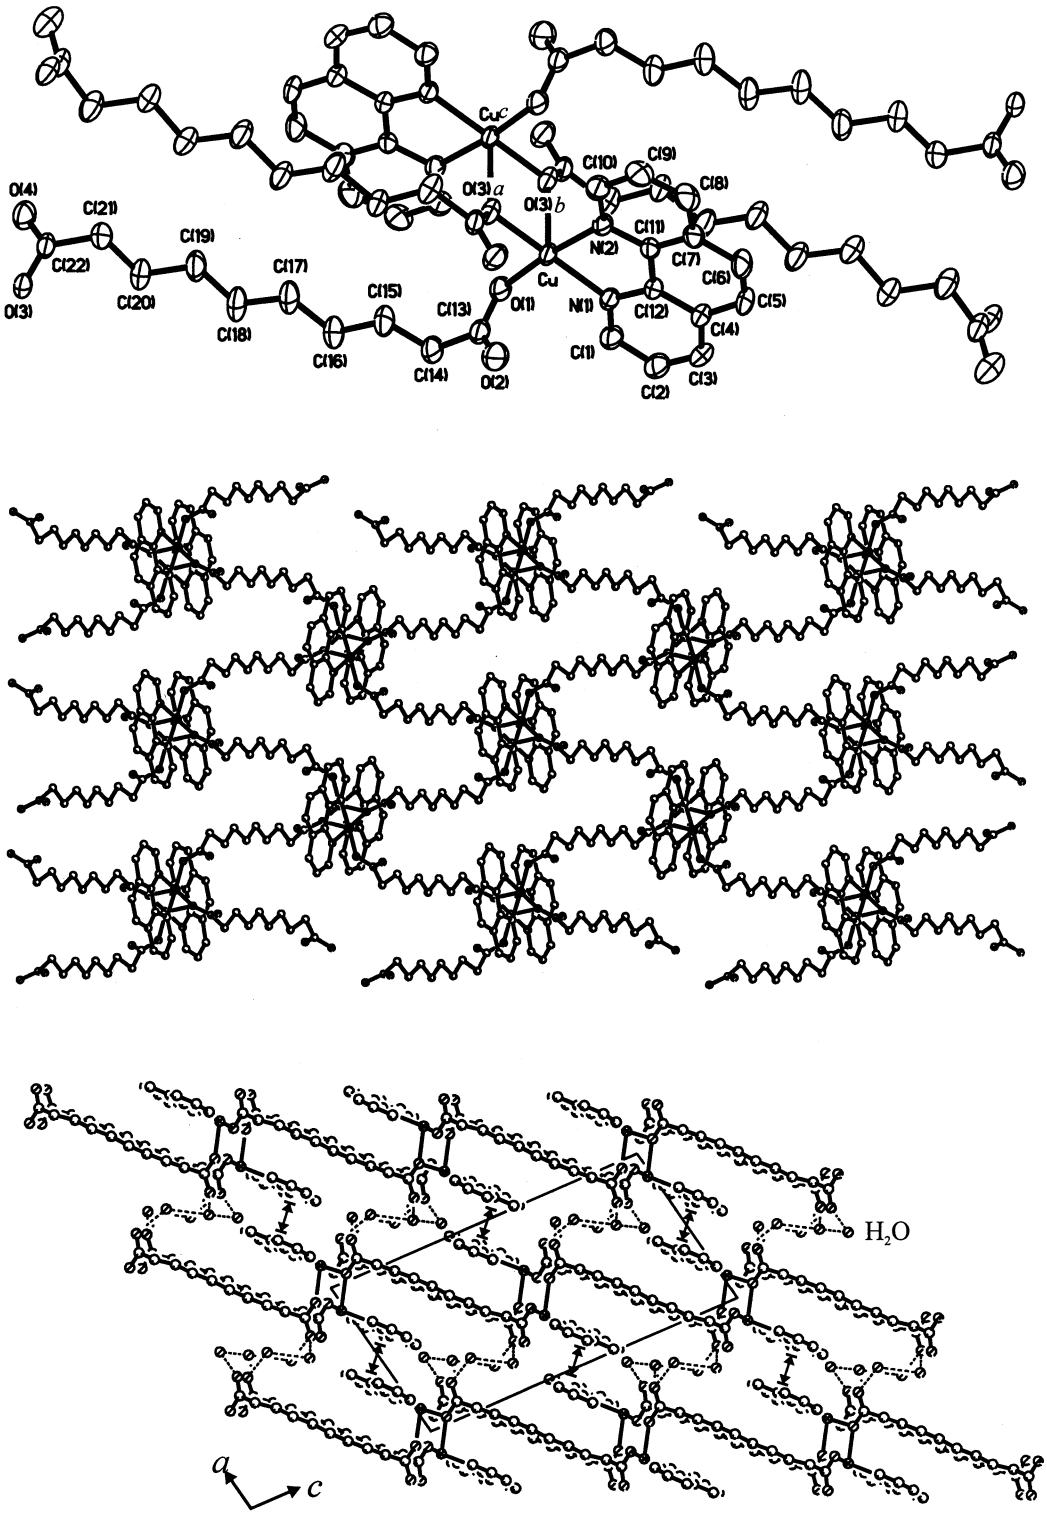

Fig. 1. (Top) ORTEP view of a selected subunit of the 2D $^{2}_{\infty}[Cu_2(phen)_2L_{4/2}]$ layer with displacement ellipsoids (45% probability) and atomic labeling, (middle) a section of the 2D $^{2}_{\infty}[Cu_2(phen)_2L_{4/2}]$ layer, and (bottom) supramolecular assembly of 2D $^{2}_{\infty}[Cu_2(phen)_2L_{4/2}]$ layers with H_2O molecules in tunnels parallel to [010] in **1**; the π–π stacking interactions and hydrogen bondings are indicated by double arrows and dashed lines, respectively.

to each other and the mean phen-to-phen distance of 3.43 Å indicates strong intercationic π–π stacking interactions [44–49]. Through such interactions, the complex cations are assembled into positively charged open networks extending infinitely parallel to (100) (Fig. 3).

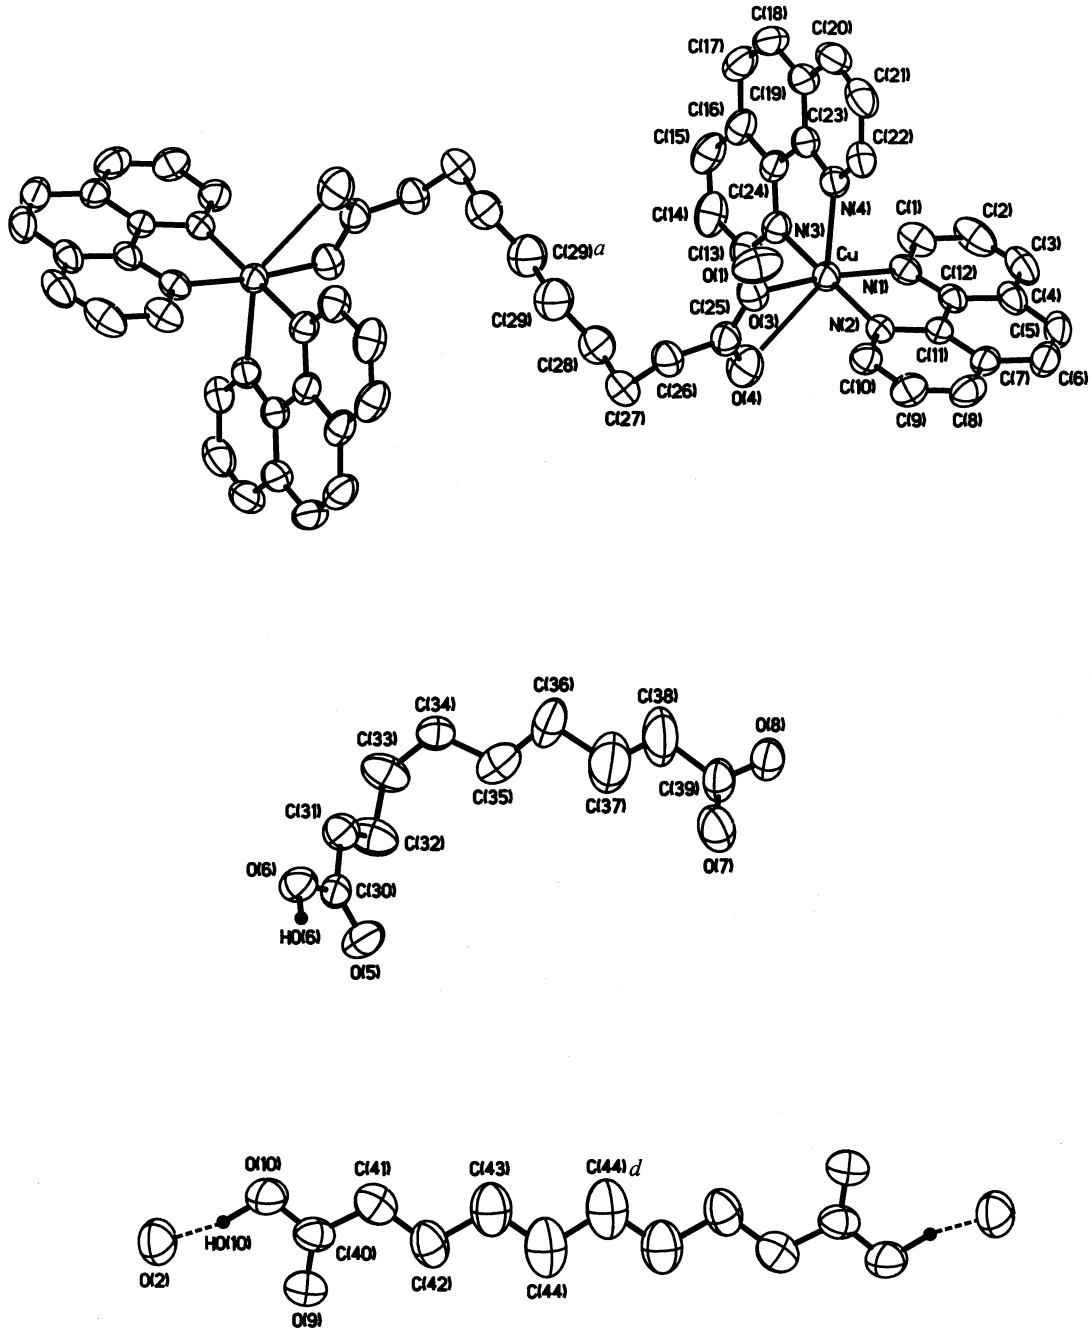

Fig. 2. ORTEP view of (top) divalent $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2]^{2+}$ complex cation, (middle) hydrogensebacate anion and (bottom) sebacic acid molecule in **2** with displacement ellipsoids (45% probability) and atomic labeling.

Along the [100] direction, the twisted hydrogensebacate anions are linked into 1D zigzag chains via strong head-to-tail hydrogen bonds ($d(O(6)\cdots O(8)^b) = 2.562$ Å, $\angle(O(6)\text{–}H\cdots O(8)^b) = 166^\circ$, b: $x+1$, y, z). Additionally, the carboxylate group of the hydrogensebacate anion, via two carboxylate O atoms, is hydrogen bonded to two crystallographically distinct H_2O molecules (Table 2), of which one accepts hydroxyl hydrogen atom from the linear sebacic molecule to form a strong hydrogen bond with $d(O(10)\cdots O(2)) = 2.531$ Å and $\angle(O(10)\text{–}H\cdots O(2)) = 167^\circ$. Moreover, the H_2O molecules are hydrogen bonded to each other. Such extensive hydrogen bonds assemble the twisted hydrogensebacate anions, linear sebacic molecules and water molecules to form negatively charged open bilayers parallel to (001). The resulting bilayers are held together by the interweaving of the positively-charged open networks (Fig. 4). Furthermore, the carboxylate O(3) strongly coordinated to Cu atom forms hydrogen bond to one water molecule, which is found important for the interdigita-

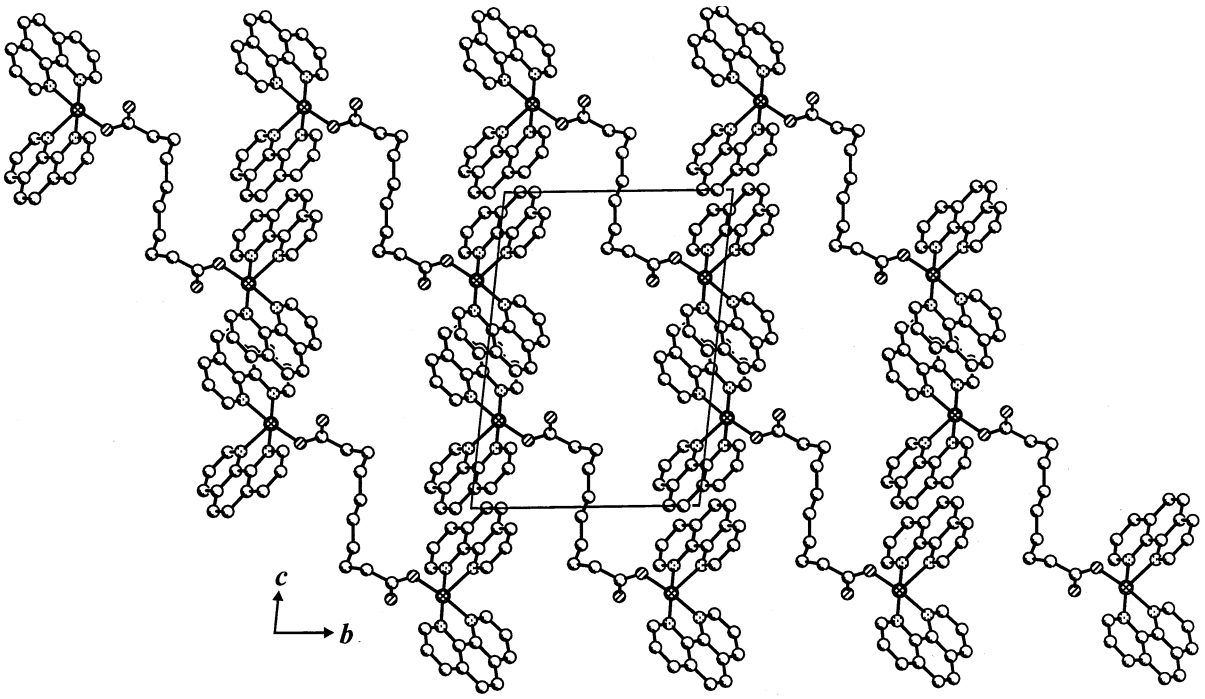

Fig. 3. Supramolecular assembly of the divalent $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2]^{2+}$ complex cations via π–π stacking interactions into 2D positively charged network in **2**.

tion of the negatively charged bilayers and the positively charged networks.

For the present 'Z' shaped twisted sebacato ligands, the C–O bond length to the coordinating O(3) atom is 1.272 Å, significantly longer than that to the O(4) atom (1.224 Å), and the bite O(3)–C(25)–O(4) bond angle is 122.7(4)°. As far as the hydrogensebacate anions and sebacic acid molecules are concerned, all the C–C and C–O bond lengths are of normal values.

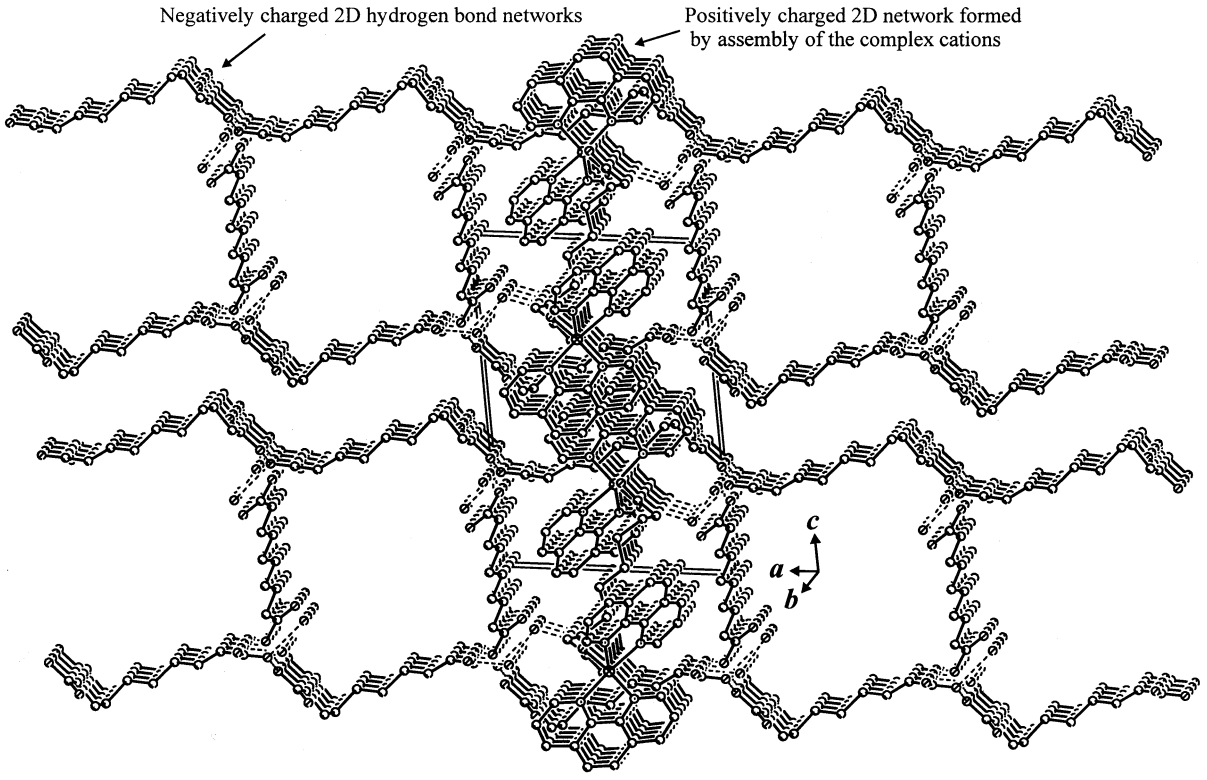

Fig. 4. Negatively charged 2D hydrogen bonded networks with the complex cations in **2**.

Comparison of the title complexes **1** and **2** with the previously-reported [Cu(phen)L]·3H_2O indicates that the sebacate anion is an interesting flexible ligand bridging Cu atoms in three modes, that is, (i) the 'L' shaped twisted sebacato ligands in [Cu(phen)L]·3H_2O bis-monodentately link Cu atoms into 1D chains which are assembled via π–π stacking interactions into supramolecular bi-chains [42], (ii) the nearly linear sebacato ligands in **1** tridentately interlink Cu atoms into 2D open networks and (iii) the 'Z' shaped twisted sebacato ligand bis-chelate two Cu atoms to form dinuclear complex cations in **2**.

3. Experimental

All chemicals of p.a. grade were commercially available and used without further purification. The C, H and N microanalyses were performed with a Heraeus Rapid—CHNO elemental analyzer. The FT-IR spectra were recorded from KBr pellets in the range 4000–400 cm^{-1} on a Protege 460 spectrometer.

3.1. Preparation of $^{2}_{\infty}[Cu_2(phen)_2L_{4/2}](H_2O)_6$ (1)

Addition of 6.0 ml (1 M) NaOH to a stirred aqueous solution of $CuCl_2·2H_2O$ (0.43 g, 2.50 mmol) in 5.0 ml H_2O yielded a blue precipitate, which was separated, washed with distilled water several times until free from detectable Cl^- ions and finally added to a stirred solution of sebacic acid (0.51 g, 2.50 mmol) in 50 ml EtOH/H_2O (1:1 v/v). To the resulting suspension was added phenanthroline monohydrate (0.50 g, 2.50 mmol). The mixture was further stirred for approximately 30 min and the insoluble solid was filtered off. The filtrate (pH = 6.4) was allowed to stand at room temperature. Slow evaporation for several days afforded a small amount of dark blue crystals. *Anal.* Calc. for $C_{44}H_{60}Cu_2N_4O_{14}$: C, 53.06; H, 6.07; N, 5.62. Found: C, 53.39; H, 5.98; N, 5.36%.

3.2. Preparation of $[(phen)_2Cu(\mu\text{-}L)Cu(phen)_2](HL)_2(H_2L)(H_2O)_4$ (2)

An analogous procedure was employed except that 50 ml CH_3OH/H_2O (1:1 v/v) was used instead of EtOH/H_2O. Blue crystals were formed in a blue filtrate (pH 6.4) by slow evaporation for several days. Yield: approximately 65%. *Anal.* Calc. for $C_{44}H_{60}Cu_2N_4O_{14}$: C, 61.26; H, 6.31; N, 6.50. Found: C, 60.83; H, 6.12; N, 6.89%. IR (cm^{-1}): 3410vs (br), 2929s, 2853s, 1570vs, 1515vs, 1426vs, 1302m, 1226m, 1146m, 1105m, 953vs, 724vs, 647m.

3.3. Crystal structure determination

The reflection intensities for complexes **1** and **2** were collected at 293 K on a Bruker P4 diffractometer with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) using the ϑ–2ϑ scan technique. SHELXS-97 [50] and SHELXL-97 [51] programs were used for structure determination and refinements. The structures were solved by direct methods and refined with full-matrix least-squares techniques. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms associated with carbon atoms were generated geometrically, while the aqua and hydroxyl hydrogen atoms were located from the difference Fourier syntheses. Details of crystal data, collection and refinement of the two

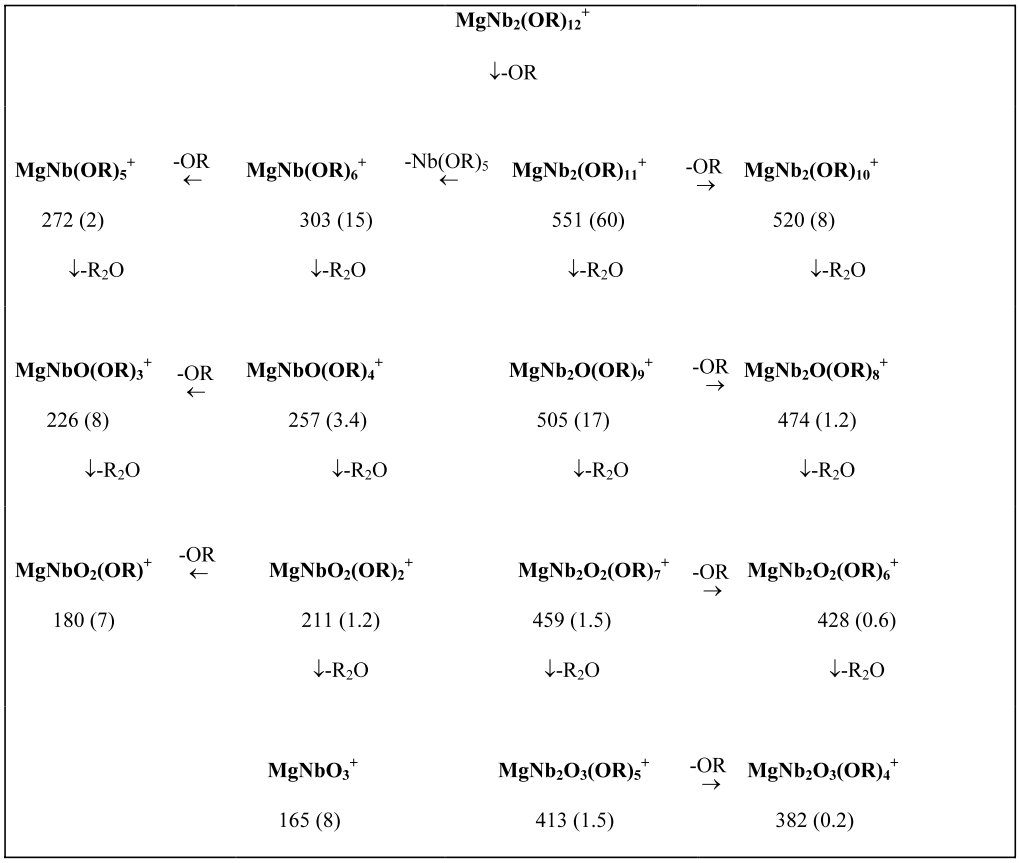
The only magnesium-containing oxo-derivative known so far was $[Mg(^nBuOH)TaO(OBu^n)_5]_4$, in the center of the molecule of which was found a cube with Mg atoms and μ_4-oxogroups in its vertices [6]. The present work reports the results of investigation on the interaction of magnesium and niobium methoxides and also the structure of crystalline magnesium oxomethoxoniobate.

2. Experimental

All operations were carried out in dry nitrogen atmosphere using a dry box. MeOH was dehydrated by refluxing over magnesium methoxide with subsequent distillation. The starting alkoxides were prepared by conventional techniques—$Mg(OMe)_2 \cdot 3.5MeOH$ was crystallized from solutions obtained by dissolution of magnesium metal in methanol [7], and $Nb(OMe)_5$ was obtained by anodic oxidation of the metal in alcohol, using LiCl as the electrolyte [8]. IR spectra of **2** and the Nujol mulls of **1** were registered using a Perkin–Elmer FTIR 1600 spectrometer, mass-spectra—with a MI 1201 spectrometer (direct probe insertion, 70 eV, 220 °C). X-ray powder patterns were registered with a STOE STADY-P diffractometer (Cu Kα radiation). ^{1}H NMR spectra were obtained for $CDCl_3$ solutions of **2** and **1** using a Bruker 400 MHz spectrometer.

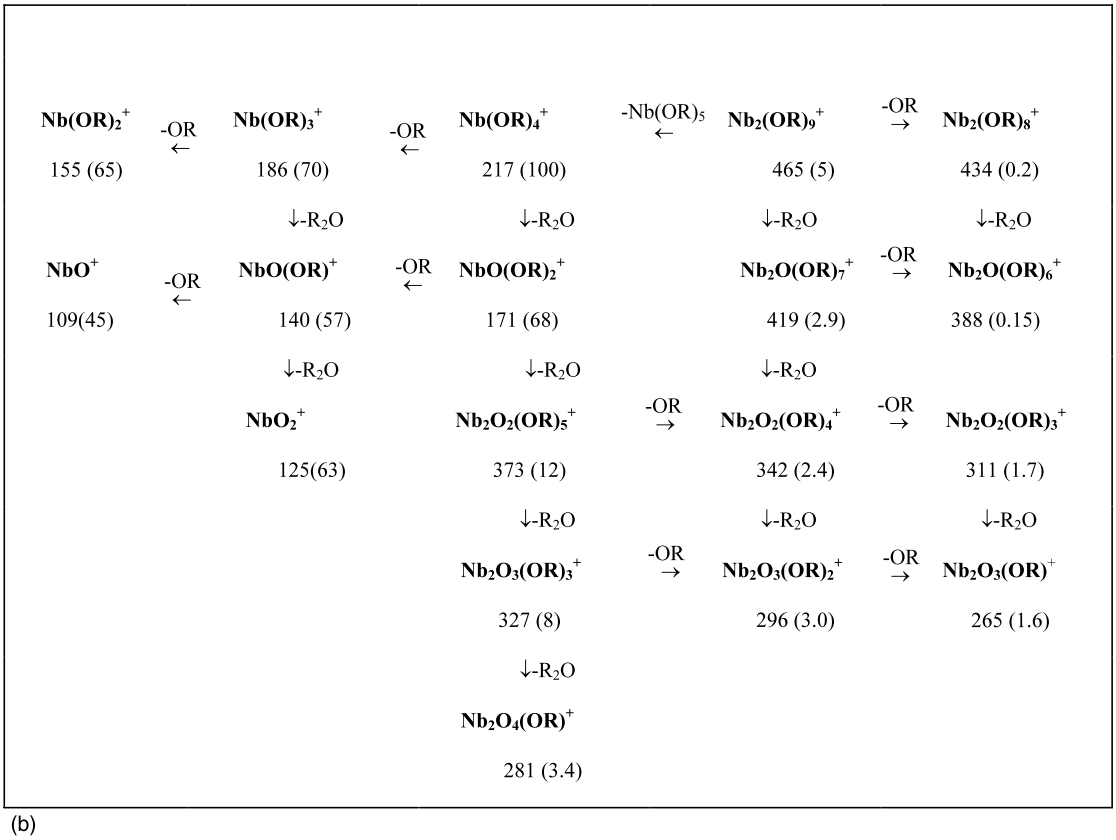
2.1. Synthesis and isolation of *1* and *2*

On partial evacuation of a solution containing 3.17 g (0.0368 mol) of $Mg(OMe)_2$ and 18.29 g (0.0736 mol) $Nb(OMe)_5$ in 100 ml MeOH up to the total concentration of alkoxides of approximately 40% and subsequent cooling to ~0 °C was achieved the crystallization of complex **1**. The yield after washing with a minimal amount of alcohol was 5.36 g (25%). *Anal.* Found: C 24.1; H 6.23; **M** Mg+Nb 33.6. Calc. for $C_7H_{23}O_8MgNb$: C 23.8; H 6.5; M Mg+Nb 33.2%. IR, cm^{-1}: 3420 s (*ν*-OH), 1456 m, 1376 w, 1148 sh. w, 1108 s, 1072 vs, 1056 sh. vs, 1034 s, 878 vs (*ν*-Nb=O), 528 sh. m, 482 vs, 440 sh.w.



Compound **1** is insoluble in hydrocarbons and poorly soluble in the parent alcohol at room temperature (r.t.). It is not transferred into the gas phase under the conditions of mass-spectrometric experiment. Its X-ray powder pattern can be indexed using the parameters obtained in the single crystal X-ray experiment. *I* (%); *d* (Å); (*hkl*): 33, 8.82 (011); 100, 7.85 (−101); 12, 7.41 (110); 22, 7.07 (−111); 12, 5.78 (120); 9, 5.44 (111); 12, 4.99 (012); 6, 4.37 (−122); 7, 4.20 (200); 8, 3.72 (032); 7, 3.57 (−113); 7, 3.46 (211); 5, 3.21 (023); 5, 3.16 (042); 5, 2.98 (−223); 5, 2.96 (231); 8, 2.95 (301); 7, 2.92 (202); 7, 2.83 (21-2).

The ^{1}H NMR spectrum of the solution obtained by extraction of crystals of **1** with boiling deuterochloroform contains in addition to a comparably rather strong methanol signal (3.48 ppm, singlet) originating apparently from elimination of the solvating methanol molecules from **1**, three well-defined singlets at 4.27, 4.16 and 3.20 ppm with approximately 2:2:1 integration ratio (their positions being temperature-independent in the 0–50 °C temperature interval). The latter can be assigned to the protons of the methyl groups of the terminal, doubly bridging and triply bridging methoxide groups, respectively, in the molecule of **1**.



Further concentration of the mother liquor, separated from the crystals of **1**, led to formation of a viscous liquid containing $MgNb_2(OMe)_{12} \cdot 2MeOH$ (**2**) and excess of $Nb(OMe)_5$ (formed on crystallization of **1**), that turned into a glass-like solid at −20 °C. The IR spectrum of the latter was very close to that of **1** except for the absence of the Nb=O band. The mass-spectrum of **2** is shown in Fig. 1. The ^{1}H NMR spectrum of **2** is rather simple in analogy with the spectra of other alkaline earth alkoxoniobates [9]: there is only one signal present for protons of the alkoxide groups (4.00 ppm, singlet) and one signal for the solvating alcohol molecules (3.46 ppm, singlet). It should be noted that the spectra of **2** do usually contain rather weak but distinguishable signals corresponding to **1** (their intensity varies with respect to that of the signal at 4.00 ppm). This fact confirms the supposition that **1** is formed on spontaneous decomposition of **2**.

2.2. Crystallography

X-ray quality crystals of **1** were grown from MeOH at −5 to 8 °C. The crystals were placed in glass capillaries, and sealed under nitrogen atmosphere. Complex **1**, $C_{14}H_{46}O_{16}Mg_2Nb_2$, $M = 704.95$, Monoclinic, Space group $P2(1)/n$, $a = 8.863(2)$ Å, $b = 15.902(4)$ Å, $c = 11.111(4)$ Å, $\beta = 107.63(3)^\circ$, $V = 1492.3(7)$ Å^3, $D_{calc} = 1.569$ g cm^{-3} for $Z = 2$, λ(Mo Kα) = 0.71073 Å, 2615 [$R_{int} = 0.0400$] independent reflections which were collected at 22 °C up to $2\theta_{max} = 50.00^\circ$ with a Bruker SMART CCD 1k diffractometer. The empirical absorption correction was made using Bruker SADABS program ($\mu = 0.871$ mm^{-1}). The structure was solved by standard direct methods; the coordinates of all non-hydrogen atoms were obtained from the initial solution and refined together with the temperature factors first in isotropic and then in anisotropic approximation. The hydrogen atom coordinates, except for those of the active hydrogen atoms H(1) and H(2) located in the difference Fourier syntheses, were calculated geometrically and included into the final solution in isotropic approximation. Final discrepancy factors are $R_1 = 0.0341$, $wR_2 = 0.0753$. The largest difference peak and hole 0.329 and −0.428 e Å^{-3} were located in the direct proximity of niobium atoms. All calculations were

performed on an IBM PC using the SHELXTL-NT program package [10].

3. Results and discussion

Interaction of magnesium and niobium methoxides in MeOH was found to lead to a liquid complex with $MgNb_2(OMe)_{12}\cdot 2MeOH$ (**2**) composition. The formation of **2** was in our experiments accompanied by precipitation of minor amounts of the crystalline poorly soluble oxocomplex, $[MgNbO(OMe)_5(MeOH)_2]$ (**1**). The yields of the latter increased on subsequent storage of solutions even rigorously protected from moisture, indicating that a slow non-hydrolytic decomposition process leading to the formation of the oxospecies took place in this case. This result provides one more confirmation to the observation that bimetallic oxocomplexes are often formed in the systems containing liquid $M^{II}M^{V}_2(OR)_{12}\cdot 2ROH$ (M^V = Nb, Ta) complexes due to decomposition of the latter. Examples can be taken from $[SrTaO(OMe)_5(MeOH)_{2.5}]_4$, $[MgTaO(OBu^n)_5(^n\text{-}BuOH)_4]_4$ and $[BaM^VO(OEt)_5(EtOH)_{1.5}]_4$ [2,6], $[Pb_6Nb_4O_4(OEt)_{24}]$ etc. [11].

The $MgNb_2(OMe)_{12}\cdot 2MeOH$ (**2**) compound is in all its properties, such as composition, physical state and behavior in the gas phase, analogous to its tantalum analog [3], but possesses a lower stability. Its mass spectrum (Fig. 1) contains along with the ions corresponding to the fragmentation pattern of **2**, all the major peaks of $Nb(OMe)_5$, having much higher intensity, which is caused by the thermal dissociation of **2**, and possibly also the presence of niobium methoxide admixture in the samples. The fragmentation of **2** is very close to that described for $MgTa_2(OMe)_{12}\cdot 2MeOH$ [3], which also undergoes even partial thermal dissociation. Fig. 1 contains also the mass spectrum of free $Nb(OMe)_5$ (displaying better completeness compared with that reported earlier in [12]). Its fragmentation pattern differs substantially from that of $Ta(OMe)_5$, where the major transformations are connected with elimination of OH and HCHO groups [13].

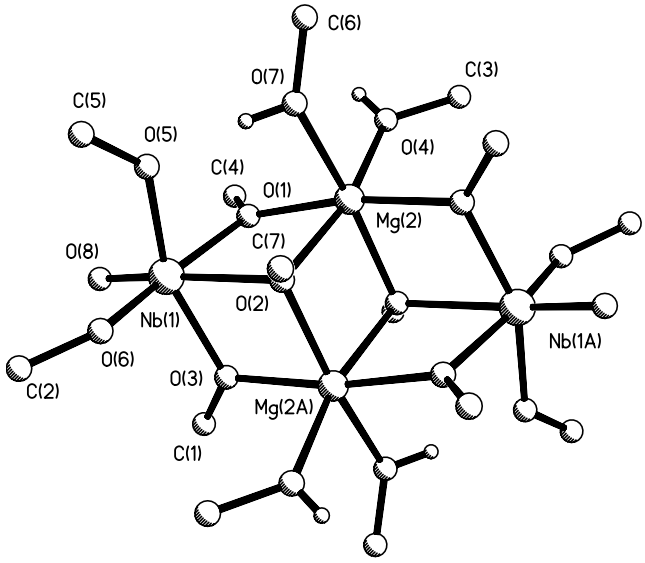

Fig. 2. The molecular structure of $Mg_2Nb_2O_2(OMe)_{10}(MeOH)_4$ (**1**).

$Mg_2Nb_2O_2(OMe)_{10}(MeOH)_4$ (**1**), is, as many other oxoalkoxides, rather scarcely soluble in alcohol at room temperature but dissolves on heating with partial destruction of the molecules.

The dimeric molecule of **1** (Table 1, Fig. 2) belongs to the well-known $Ti_4(OMe)_{16}$ type [14] characterized by a planar arrangement of four metal atoms. Such molecules contain two different kinds of metal positions, one (M^1) with two terminal groups and two bonds with tridentate ligands and the other (M^2) with three terminal groups and one bond to a tridentate ligand. In the molecule of **1** the M^1 positions are occupied by magnesium atoms (2MeOH molecules being the terminal ligands) and the M^2 ones by niobium atoms (two OMe- and one oxogroup as the terminal ligands). This arrangement with a less electronegative metal atom in the M^1 position and more electronegative transition metal atom in the M^2 one is characteristic of the majority of the structures of this type such as $Li_2Ti_2(OR)_{10}$, $R = Pr^i$, $C_5H_{11}^{neo}$ [15,16], $[Li_2Nb_2(OCH_2SiMe_3)_{12}]$ [17], $[Mg_2(MoO_2)_2(OMe)_{10}(MeOH)_4]$ [18] and $[Na(EtOH)_2]_2(WO)_2(OEt)_{10}$ [19]. A less common alternative arrangement is exemplified in particular by the structure of $[LiNbO(OEt)_4(EtOH)]_2$, where the octahedrally coordinated Nb atom occupies the M^1

position and the tetrahedrally coordinated Li, the M^2 position [2].

In the octahedral coordination sphere of niobium atoms in the molecule of **1** the Nb–O bond lengths increase regularly with the increase in number of bonds formed by the oxygen atom from the shortest Nb(1) = O(8) 1.741(2) Å, the doubly bonded 'ylous' oxygen via terminal OMe, 1.914(3) and 2.008(3) Å; the bidentate bridging, 2.065(2) and 2.071(3) Å, to the tridentate methoxide ones, 2.246(2) Å. At the same time all the bond lengths in the octahedron around the magnesium atom lie in the interval of 2.055(3)–2.141(3) Å independent of the function of the ligands, indicating thus a predominantly ionic character of bonding. This permits us to consider the complex **1** as an ion pair, $[Mg(ROH)_2]_2^{2+}$ $[NbO(OR)_5]_2^{2-}$ (in analogy with $[Na(EtOH)_2]_2^{+}$ $[WO(OEt)_5]_2^{-}$ [19]), all the Nb–O bond lengths in the molecule of **1** are 0.1–0.15 Å longer in comparison with its structural analog $[LiNbO(OEt)_4(EtOH)]_2$ [2], the Mg–O bond lengths being quite close to those observed in the known structures such as $Mg(OMe)_2 \cdot 3.5$ MeOH [7] or $[Mg(^nBuOH)TaO(OBu^n)_5]_4$ [6]).

However, the C–O bond lengths in the coordination arrangement of both metals correlate with the bonding character of the ligands (average distances being 1.397 Å for terminal, 1.411 Å for bidentate and 1.424 Å for the tridentate ones). The same can be noticed for the M–O–C angles, which are 130.1°–139.6° for the terminal groups, 123.2°–129.1° for the bidentate and 116.9°–119.6° for the tridentate bridges. The same regularities in the changes of molecular parameters have been observed in the molecules of $[LiNbO(OEt)_4(EtOH)]_2$ or $Ti_4(OMe)_{16}$ [2,14].

The alcohol molecule containing the O(7) atom forms an intramolecular hydrogen bond with a length of 2.606(6) Å with the O(5) atom of an alkoxide group, while that containing the O(4) atom form an intermolecular hydrogen bond with a length of 2.676(6) Å, with the O(8) atom of the neighboring molecule.

Compound **1** provides one more example of rather scarce niobium alkoxides containing terminal 'ylic' oxygen atoms. To this group belong $NbO(OR)_3$ [20], $[NbO(OC_6H_3Ph_2\text{-}2,6)_3]$ [21], and also the bimetallic complexes such as $[LiNbO(OEt)_4(EtOH)]_2$ [2] and $[Li_2(NbO)_2O(OCMe_2CH_2OMe)_6]$ [22]. More stable supposedly and definitely more represented are the structures containing oxo-bridges, such as $[NbO(OC_6H_3Pr^i_2\text{-}2,6)_3]_2$ [23], $[Nb_3O_2[O(CMe_2)_2O]_4[O(CMe_2)_2OH]$, $[Nb_4O_4[O(CMe_2)_2O]_2[OPr^i)_8]$ [24], $Pb_6Nb_4O_4(OEt)_{24}$ [11], $(ReO_4)_2Nb_4O_{12}(OMe)_{14}$, [25], and also $Nb_8O_{10}(OEt)_{20}$ originating from the decomposition of $NbO(OR)_3$ [20].

The decrease in the M=O bond multiplicity in the series V, Nb, Ta (due to the increase in the energy of d_π-orbitals of the metal atom) causes inability to form the terminal 'ylic' bonds for tantalum. This results, in particular, in the absence for tantalum of the monomeric $MO(OR)_3$ oxoalkoxides (known for niobium [20]), with stable dinuclear $Ta_2O(OR)_8$ molecules with 2 μ-O- and one μ-OR bridges being formed instead [13]. It turns then natural that the oxoalkoxides of niobium and tantalum turn to be isomorphous only when the 'ylic' groups are absent at Nb atoms such as, for example, in $M^V_8O_{10}(OEt)_{20}$ [26], and $[BaM^VO(OEt)_5(EtOH)_{1.5}]_4$ [2,6]. It is interesting in this sense to compare the decomposition products of $LiM^V(OEt)_6$, where M^V = Nb, Ta. In the first case it leads to $[LiNbO(OEt)_4(EtOH)]_2$, containing a terminal doubly bonded oxygen atom, while in the case of tantalum the polyoxotantalates—$[LiTa_9O_{13}(OEt)_{20}(EtOH)]$ and $[Li_8Ta_8O_{14}(OEt)_{20}(EtOH)_8]$—containing numerous oxobridges have been isolated [26][1]. Taking into consideration these circumstances it is possible to suppose that magnesium alkoxotantalates should on decomposition give only molecules containing oxobridges like $[Mg(^nBuOH)TaO(OBu^n)_5]_4$ [6].

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC no. 177452 for compound **1**. Copies of this information may be obtained free of charge from the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

The authors would like to express their gratitude to Mr. E.V. Alexeev for the assistance in carrying out the synthetic experiments, to Rolf Andersson for the aid with the NMR studies and the Swedish Council for Scientific Research for financial support of this work.

complexes than can prepared in the presence of water should be potentially more useful catalysts, and the synthetic routes based on aqueous solutions of alkali molybdates in hydrobromic acid attain special relevance.

The existence of the species $MoO_2Br_2(H_2O)_2$ in solutions of alkali molybdates in concentrated hydrobromic acid, and in the ether extracts, is well established [18]. Recently we reported that $MoO_2Br_2(H_2O)_2$ can be readily extracted from aqueous solutions with diethyl ether in an almost quantitative manner, and the resulting ether solution stored for weeks at room temperature [16]. Here we report on the utility of the ether solution in the synthesis of anhydrous addition compounds of MoO_2Br_2 with representative amides, sulfoxides and phosphine oxides, some of them previously prepared by other procedures.

2. Experimental

2.1. General procedures and measurements

Unless otherwise specified all operations were carried out in air. Diethyl ether was distilled over Na-benzophenone ketyl prior to use. DMSO was dried over calcium hydride and distilled in vacuo. DMF, DMA, NMP and HMPA were distilled under reduced pressure. Phosphine oxides were prepared by oxidation of the parent phosphines with hydrogen peroxide and characterized by elemental analysis (C, H) and NMR spectroscopy. $(CH_3)_3CSH$ was purified by distillation under nitrogen prior to use. All other reagents were commercial products and were used without further purification. Conductivity measurements were made with a Crison 522 conductivimeter. Elemental analyses (C, H, N) were performed on a LECO CHNS-932 analyzer (Module VTF-900 for O). Bromine was eventually determined by gravimetry as AgBr and molybdenum by titration with lead(II) nitrate [19]. IR spectra were recorded on a Nicolet Impact 410 (Software OMNIC for Windows) spectrometer. NMR spectra were recorded on a Varian Unity Inova-400 spectrometer (400 MHz for ^1H and 161.92 MHz for ^{31}P). Chemical shifts are relative to TMS (^1H), or external 85% H_3PO_4 (^{31}P), with downfield values reported as positive. Coupling constants J are given in Hz.

2.2. Preparation of the complexes

2.2.1. Preparation of the diethyl ether solution of $MoO_2Br_2(H_2O)_2$

One gram (4.14 mmol) of powdered $Na_2MoO_4\cdot 2H_2O$ was added with stirring on 8 g (ca. 46.5 mmol) of concentrated hydrobromic acid at room temperature (r.t.) to obtain a clear yellow solution. Then 10 ml of dry diethyl ether was added slowly with stirring. The reaction is exothermic and a significant part of diethyl ether dissolves in the HBr solution. The upper ether phase was collected and the extraction process repeated twice more. The combined extract was stirred for 5 min with 1 g of anhydrous magnesium sulfate. The solution was collected by filtration and the magnesium sulfate washed with three 3-ml portions of diethyl ether. About 30 ml of a light yellow solution containing more than 95% of the original molybdenum, was obtained. This solution was used for the synthesis of addition compounds, for which the yield is given with respect to $Na_2MoO_4\cdot 2H_2O$.

2.2.2. Preparation of $MoO_2Br_2L_2$ ($L = DMF$, HMPA, Ph_2SO)

A solution prepared as above was treated with 8.3 mmol of L in 10 ml of diethyl ether. The light yellow precipitate was filtered, washed with three 3-ml portions of diethyl ether and dried under vacuum.

$MoO_2Br_2(DMF)_2$: Yield 1.73 g (96%). IR(cm^{-1}): ν(Mo=O) 904, 941; ν(C=O) 1646. ^1H NMR ($CDCl_3$): 8.37 ppm (s, 1H, H–CO), 3.15 ppm (s, 3H, N–CH_3), 3.08 ppm (s, 3H, N–CH_3). *Anal*. Found: C, 16,82; H, 3.32; Mo, 21.80; N, 6.38. Calc. for $C_6H_4Br_2MoN_2O_4$: C, 16.61; H, 3.25; Mo, 22.11; N, 6.46%.

$MoO_2Br_2(HMPA)_2$: Yield 2.51 g (94%). IR(cm^{-1}): ν(Mo=O) 902, 939; ν(P=O) 1193, 989. ^1H NMR ($CDCl_3$): 2.72 ppm (d, $^3J_{H-P} = 9.7$ Hz, 18H, N–CH_3). ^{31}P NMR ($CDCl_3$): 29.0 ppm. *Anal*. Found: C, 22.1; H, 5,48; Mo, 14.51; N, 12.80. Calc. for $C_{12}H_{36}Br_2MoN_6O_4P_2$: C, 22.31; H, 5.62; Mo, 14.85; N, 13.01%.

$MoO_2Br_2(Ph_2SO)_2$: Yield 2.72 g (95%). IR(cm^{-1}): ν(Mo=O) 902, 929; ν(S=O) 987, 1001. ^1H NMR ($CDCl_3$): 7.3–7.8 ppm (m, 10H, Ph). *Anal*. Found: C, 41.40; H, 2.99; Mo, 13.66. Calc. for $C_{24}H_{20}Br_2MoO_4S_2$: C, 41.64; H, 2.91; Mo, 13.86%.

2.2.3. Preparation of $MoO_2Br_2L_2$ ($L = DMSO$, MePhSO)

The $MoO_2Br_2(H_2O)_2$ solution was treated with 8.0 mmol of L in 5 ml of acetone. The light yellow solid was filtered, washed with three 3-ml portions of diethyl ether and dried under vacuum.

$MoO_2Br_2(DMSO)_2$: Yield 1.71 g (93%). IR(cm^{-1}): ν(Mo=O) 889, 924; ν(S=O) 989, 1034. ^1H NMR ($CDCl_3$): 2.64 ppm (s, 6H, CH_3). *Anal*. Found: C, 10.80; H, 2.68; Mo, 21.50. Calc. for $C_4H_{12}Br_2MoO_4S_2$: C, 10.82; H, 2.72; Mo, 21.61%.

$MoO_2Br_2(MePhSO)_2$: Yield 2.05 g (87%). IR(cm^{-1}): ν(Mo=O) 900, 929; ν(S=O) 987, 1001. ^1H NMR ($CDCl_3$): 7.4-7.7 ppm (m, 5H, Ph), 2.95 ppm (s, 3H, CH_3). *Anal*. Found: C, 29.82; H, 2.93; Mo, 16.63. Calc. for $C_{14}H_{16}Br_2MoO_4S_2$: C, 29.60; H, 2.84; Mo, 16.89%.

2.2.4. Preparation of $MoO_2Br_2(OPPh_3)_2$

The $MoO_2Br_2(H_2O)_2$ solution was treated with 8.0 mmol of $OPPh_3$ in 30 ml of acetone. The mixture is stirred for 10 min and the light yellow microcrystalline precipitate was filtered, washed with three 3-ml portions of diethyl ether and dried under vacuum. Yield 3.36 g (96%). IR(cm^{-1}): ν(Mo=O) 904, 946; ν(P=O) 1174. ^1H NMR ($CDCl_3$): 7.2–7.9 ppm (m, 30H, Ph). ^{31}P NMR ($CDCl_3$): 41.9 ppm. *Anal*. Found: C, 50.66; H, 3.41; Mo, 11.49. Calc. for $C_{36}H_{30}Br_2MoO_4P_2$: C, 51.21; H, 3.58; Mo, 11.36%.

2.2.5. Preparation of $MoO_2Br_2(dppmO_2)$

The $MoO_2Br_2(H_2O)_2$ solution was treated with 4.0 mmol of $dppmO_2$ in 10 ml of dichloromethane. The light yellow microcrystalline precipitate was filtered, washed with three 3-ml portions of diethyl ether and dried under vacuum. Yield 2.71 g (93%). IR(cm^{-1}): ν(Mo=O) 900, 941; ν(P=O) 1153. ^1H NMR ($CDCl_3$): 7.3–7.6 ppm (m, 12H, Ph), 7.7–7.9 ppm (m, 8H, Ph), 3.87 ppm (t, $^2J_{H-P} = 12.3$ Hz, 2H, CH_3). ^{31}P NMR ($CDCl_3$): 39.6 ppm. *Anal*. Found: C, 42.55; H, 3.08; Mo, 13.84. Calc. for $C_{25}H_{22}Br_2MoO_4P_2$: C, 42.64; H, 3.15; Mo, 13.62%.

2.2.6. Preparation of $MoO_2Br_2(OPMePh_2)_2$

The $MoO_2Br_2(H_2O)_2$ solution was treated with 8.0 mmol of $OPMePh_2$ powder. The mixture was stirred for 30 min and then the solvent was removed in vacuo. The resulting solid was dissolved in acetone (5 ml) and diethyl ether (25 ml) was added with stirring. The white precipitate was filtered, washed with three 3-ml portions of diethyl ether and dried under vacuum. Yield 2.59 g (87%). IR(cm^{-1}): ν(Mo=O) 901, 941; ν(P=O) 1163. ^1H NMR ($CDCl_3$): 7.3–7.9 ppm (m, 10H, Ph), 2.25 ppm (d, $^2J_{H-P} = 13.2$ Hz, 3H, CH_3). ^{31}P NMR ($CDCl_3$): 46.2 ppm. *Anal*. Found: C, 43.10; H, 3.48; Mo, 13.51. Calc. for $C_{26}H_{26}Br_2MoO_4P_2$: C, 43.36; H, 3.64; Mo, 13.32%.

2.2.7. Preparation of $MoO_2Br_2L_2$ ($L = OPBu_3$, $OPOct_3$)

An ether solution of $MoO_2Br_2(H_2O)_2$ prepared as above, and containing 4.0 mmol of molybdenum, was treated with 8.0 mmol of L in 5 ml of diethyl ether. The solution was evaporated in vacuo at r.t. and the resulting light yellow waxy material pumped at 10^{-3} mbar for 10 h.

$MoO_2Br_2(OPBu_3)_2$: Yield 2.94 g (98%). IR(cm^{-1}): ν(Mo=O) 900, 939; ν(P=O) 1186. ^1H NMR ($CDCl_3$): 1.98 ppm (c, $^3J_{H-H} = 8.2$ Hz, $^2J_{H-P} = 18.2$ Hz, 2H, $-C_\alpha H_2-$), 1.63 ppm (m, $^3J_{H-H} = 8.2$ and 7.5 Hz, 2H, $-C_\beta H_2-$), 1.44 ppm (m, $^3J_{H-H} = 7.3$ and 7.5 Hz, 2H, $-C_\gamma H_2-$), 0.93 ppm (t, $^3J_{H-H} = 7.3$ Hz, 3H, CH_3). ^{31}P NMR ($CDCl_3$): 67.9 ppm. *Anal*. Found: Br, 21.72; Mo, 13.51. Calc. for $C_{24}H_{54}Br_2MoO_4P_2$: Br, 22.06; Mo, 13.24%.

$MoO_2Br_2(OPOct_3)_2$: Yield 4.35 g (99%). IR(cm^{-1}): ν(Mo=O) 900, 939; ν(P=O) 1199. ^1H NMR ($CDCl_3$): 1.96 ppm (c, $^3J_{H-H} = 7.5$ Hz, $^2J_{H-P} = 18.2$ Hz, 2H, $-C_\alpha H_2-$), 1.60 ppm (c, 2H, $-C_\beta H_2-$), 1.30 ppm (m, 2H, $-C_\gamma H_2-$), 1.26 ppm (m, 8H, $-CH_2-$), 0.87 ppm (t, $^3J_{H-H} = 7.3$ Hz, 3H, CH_3). ^{31}P NMR ($CDCl_3$): 67.2 ppm. *Anal*. Found: Br, 14.77; Mo, 9.23. Calc. for $C_{48}H_{102}Br_2MoO_4P_2$: Br, 15.06; Mo, 9.04%.

2.2.8. Preparation of $MoO_2Br_2(NMP)_2$

The $MoO_2Br_2(H_2O)_2$ solution was treated with 8.3 mmol of NMP in diethyl ether (5 ml). A green oil immediately was formed. The oil was dissolved in acetone (5 ml) and filtered. To the resulting clear solution diethyl ether (25 ml) was added with stirring. The light yellow precipitate was filtered, washed with three 3-ml portions of diethyl ether and dried under vacuum. Yield 1.67 g (83%). IR(cm^{-1}): ν(Mo=O) 906, 947; ν(C=O) 1634. ^1H NMR ($CDCl_3$): 3.55 ppm (t, $^3J_{H-H} = 7.5$ Hz, 2H, $N-CH_2-$), 3.03 ppm (s, 3H, $N-CH_3$), 2.99 ppm (t, $^3J_{H-H} = 7.5$ Hz, 2H, CH_2-CO), 2.15 ppm (s, $^3J_{H-H} = 7.5$ Hz, 2H, $-CH_2-$). *Anal*. Found: C, 24.30; H, 3.61; Mo, 19.59; N, 5.59. Calc. for $C_{10}H_{18}Br_2MoN_2O_4$: C, 24.71; H, 3.73; Mo, 19.74; N, 5.76%.

2.3. Oxidant ability of the complexes

The oxidant ability of the complexes to transform $(CH_3)_3CSH$ into $(CH_3)_3CS-SC(CH_3)_3$ has been determined by measuring the ratio thiol/disulphide by ^1H NMR spectroscopy. In a NMR tube, 0.01 mol of the bromocomplex finely powdered was placed. Then 0.3 ml of $(CD_3)_2CO$ was added and finally 0.3 ml of 0.04 mol dm^{-3} solution of $(CH_3)_3CSH$ in the same solvent. The tube was flame sealed in a nitrogen atmosphere, shaken and immersed in a water bath at 55 °C. For adducts with $OPBu_3$ and $OPOct_3$, 0.3 ml of 0.01 mol dm^{-3} solution of each compound and 0.3 ml of 0.04 mol dm^{-3} solution of $(CH_3)_3CSH$ were used. The conversion of thiol to disulphide was followed by measuring the intensity of the methyl signals ($\delta = 1.39$ ppm for $(CH_3)_3CSH$, and 1.29 ppm for $(CH_3)_3CS-SC(CH_3)_3$) at 3, 6, 9, 21 and 24 h. Solutions of $(CH_3)_3CSH$ (0.02 mol dm^{-3}) and L (0.01 mol dm^{-3}) in $(CD_3)_2CO$ were used as blanks. Table 1 shows the percent oxidation of the thiol to disulphide for each bromocomplex at 3 and 24 h.

2.4. Crystal-structure determinations

Suitable single crystals were grown at r.t. by diffusion of diethyl ether on acetone solutions of the complexes in a dry atmosphere. Crystal data for $MoO_2Br_2(HMPA)_2$: tetragonal, *I4(1)cd*, yellow, $a = 14.61730(10)$, $b = 14.61730(10)$, $c = 24.4423(3)$ Å, $\alpha = \beta = \gamma = 90°$, $V =$

Table 1
Percent oxidation of $(CH_3)_3CSH$ to $(CH_3)_3CS-SC(CH_3)_3$ by $MoO_2Br_2L_2$ in $(CD_3)_2CO$ at 55 °C, after 3 and 24 h

$MoO_2Br_2L_2$	3 h	24 h
$MoO_2Br_2(OPPh_3)_2$	6	19
$MoO_2Br_2(OPBu_3)_2$	8	22
$MoO_2Br_2(OPOct_3)_2$	17	30
$MoO_2Br_2(OPMePh_2)_2$	8	20
$MoO_2Br_2(dppmO_2)$	6	27
$MoO_2Br_2(DMF)_2$	17	24
$MoO_2Br_2(NMP)_2$	19	28
$MoO_2Br_2(HMPA)_2$	7	20
$MoO_2Br_2(DMSO)_2$	100	
$MoO_2Br_2(MePhSO)_2$	81	98
$MoO_2Br_2(Ph_2SO)_2$	31	84

5222.48(8) Å^3, $Z = 8$, $R = 0.0277$, $R_w = 0.0574$. Crystal data for $MoO_2Br_2(dppmO_2)$: tetragonal, *I4(1)*, yellow, $a = 19.2795(4)$, $b = 19.2795(4)$, $c = 28.7288(8)$ Å, $\alpha = \beta = \gamma = 90°$, $V = 10678.5(4)$ Å^3, $Z = 16$, $R = 0.0390$, $R_w = 0.0549$.

Crystals of $MoO_2Br_2(HMPA)_2$ (block, yellow, dimensions $0.25 \times 0.15 \times 0.05$ mm) and $MoO_2Br_2(dppmO_2)$ (block, yellow, dimensions $0.25 \times 0.25 \times 0.20$ mm) were used for the structure determination. X-ray data were collected using a Brucker SMART CCD area detector single-crystal diffractometer with graphite monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å) by the phi-omega scan method. A total of 1271 frames of intensity data were collected for each compound. The first 50 frames were recollected at the end of data collection to monitor for decay. The integration processes yield a total 16760 for $MoO_2Br_2(HMPA)_2$ and 32541 for $MoO_2Br_2(dppmO_2)$, of which 2992 and 10537, respectively, were independent. Absorption corrections were applied using SADABS program (maximum and minimum transmission coefficients 0.836 and 0.457 for $MoO_2Br_2(HMPA)_2$; and 1.000 and 0.831 for $MoO_2Br_2(dppmO_2)$). The structures were solved using the Brucker SHELXTL-PC software by direct methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were included in calculated positions and refined in the riding mode. For $MoO_2Br_2(HMPA)_2$ convergence was reached at a final $R_1 = 0.0277$ [for $I > 2\sigma(I)$], $wR_2 = 0.0635$ (for all data), 129 parameters, with allowance for the thermal anisotropy for all non-hydrogen atoms. Residual electron densities extremes were 0.19 and -0.62 eÅ^{-3} and the goodness-of-fit on F^2 was 0.996 for all observed reflections. For $MoO_2Br_2(dppmO_2)$ convergence was reached at a final $R_1 = 0.0390$ [for $I > 2\sigma(I)$], $wR_2 = 0.0812$ (for all data), 613 parameters, with allowance for the thermal anisotropy for all non-hydrogen atoms. Residual electron densities extremes were 0.45 and -0.48 eÅ^{-3} and the goodness-of-fit on F^2 was 0.884 for all observed reflections. Crystal data and details on the data collection and refinement are given as supplementary material.

3. Results and discussion

3.1. Synthesis and characterization of the complexes

Representative classes of simple ligands that are able to displace water from the coordination sphere of hard metallic centers without significant hydrolysis are amides, sulfoxides and phosphine oxides. Only a very reduced number of addition compounds of MoO_2Br_2 with these ligands has been obtained from aqueous solutions of molybdates in hydrobromic acid [9,12,15]. In our experience it is difficult to obtain pure products by addition of the ligands to aqueous solutions. A large excess of ligand is required to compete successfully with the water present in the system. According to this the use of non aqueous solutions of $MoO_2Br_2(H_2O)_2$ is expected to be superior to the aqueous ones for preparative purposes.

We have found that a number of addition compounds of MoO_2Br_2 with amides, sulfoxides and phosphine oxides can be readily obtained by addition of the stoichiometric, or slightly higher, amount of the ligand to a diethyl ether solution of $MoO_2Br_2(H_2O)_2$. The use of solutions of $MoO_2Br_2(H_2O)_2$ in methyl isobuthyl ketone, a more efficient extractant than diethyl ether for this species, led to less pure products. Other O-donor ligands such as amine oxides and arsine oxides, represented by pyridine oxide and triphenyl arsine oxide, seem to be too basic for the proton to prevent the formation of the corresponding adducts. We also failed in preparing compounds with trimethyl, tributhyl and triphenyl phosphates.

The choice of the solvents and conditions to prepare each compound was essentially based on the solubility of the reactants and the insolubility of the products. We found it is important to dry the starting ether solution with a desiccant inert toward the hydrated dioxomolybdenum(VI) bromide such as magnesium sulfate, as well as to use anhydrous freshly distilled solvents for dissolving the ligands and for the washings, to obtain dry products in high yield. This is surely due to the need of removing the water displaced from the coordination sphere of molybdenum. Indeed, the crude ether extract is water-saturated and usually contains finely dispersed droplets of the aqueous solution so that the precipitates retain the excess water initially present or released in the reaction. The capability of pure diethyl ether to dissolve water helps to obtain dry products.

We failed to find a solvent in which the addition compounds of $OPBu_3$ and $OPOct_3$ were insoluble or could be crystallized. Attempts to purify these bromo-complexes by chromatography on silica or alumina led

to partial decomposition as evidenced by the appearance of blue by-products. So special care is required in the preparation of these compounds by using stoichiometric amounts of reactants. The existence of these waxy compounds should be regarded with caution because of the difficulty for full characterization. However, we propose the usual stoichiometry specially based on ^{31}P NMR evidence.

It is also worth noting that the NMP complex has tendency to form green oils, even when a very pure amide is used. Related to this is the fact that all our attempts to obtain the derivative with *N*,*N*-dimethyl acetamide (DMA) failed, whereas we could prepare $MoO_2Cl_2(DMA)_2$ by a parallel procedure. It is probable that the size of the halogen, plays a decisive role in the low stability of $MoO_2Br_2(NMP)_2$ and in precluding the formation of a stable adduct of MoO_2Br_2 with DMA.

As expected, all compounds have a low thermal stability. However, with the exception of the NMP derivative, they can be stored for weeks at room temperature, and heated to 60 °C in an inert atmosphere for hours, without significant decomposition.

The compounds -excluding those of $OPBu_3$ and $OPOct_3$- are slightly soluble in dichloromethane and chloroform and noticeably more soluble in acetone, solvent in which they are non electrolytes. $MoO_2Br_2(DMSO)_2$ is very soluble in DMSO and behaves as a 1:2 electrolyte. However, the complex can not be readily recovered from the solution. Waxy materials are obtained in all attempts to recover the original product by precipitation with organic solvents, presumably because the displacement of coordinated DMSO in the cationic species $[MoO_2(DMSO)_n]^{2+}$ ($n > 2$) by the bromide ion is difficult.

The IR spectra of the compounds are characterized by two strong bands in the region 880–950 cm^{-1} which indicates that, as usual for dioxomolybdenum(VI) species, all of them contain the *cis*-MoO_2 moiety [3]. A relationship between the position of these bands and the nature of the neutral ligands is expected since the electronic pi-donation from the oxo ligands to molybdenum should be influenced by the electronic density on the metal, in turn affected by the remaining ligands. In this regard it is worth noting that the mean value for ν(Mo=O), $\bar{\nu}(\bar{\nu} = (\nu_s + \nu_{as})/2)$, is lower for sulfoxide than for phosphine oxide complexes. A closer look to these values shows that for each series of compounds $\bar{\nu}$ decreases as the number of aliphatic chains in the ligand increases. According to this, sulfoxides should be stronger donor than phosphine oxides, and alkyl stronger donor than arylderivatives. In the same context, the high $\bar{\nu}$ values displayed by amide complexes suggest that amides are less basic than sulfoxides and phosphine oxides. Consistent with this we have observed that the readily available $MoO_2Br_2(DMF)_2$ is an excellent starting material for the synthesis of sulfoxide and phosphine oxide complexes.

The stretching bands for O–C, O–S and O–P in the coordinated ligands are shifted to lower wavenumbers with respect to those of the free ligands. This is indicative of coordination to molybdenum via the oxygen atom [20].

No special features are observed in the ^1H and ^{31}P NMR spectra of the complexes. The signals characteristic for the free ligands are shifted, as usual, to lower fields upon coordination. However, we have found evidence that the exchange between coordinated and free phosphine oxides does not proceed rapidly at room temperature. Indeed, upon addition of phosphine oxide to samples of the corresponding phosphine oxide complex in $CDCl_3$, two well separated signals are apparent in the ^{31}P NMR spectra. For example, the system $MoO_2Br_2(OPBu_3)_2$–$OPBu_3$ shows two signals at 50.0 ppm for free, and at 68.1 ppm for coordinated ligand. This behavior can be exploited to test the purity of the tributhyl and triocthyl phosphine oxide complexes, difficult to prepare and characterize, and eventually to transform a non stoichiometric product into the stoichiometric one.

3.2. Molecular structures

Based on the stoichiometry and structure for similar adducts it is probable that all compounds be closely related. The molecular structure for $MoO_2Br_2(HMPA)_2$ and $MoO_2Br_2(dppmO_2)$ was determined from single-crystal X-ray diffraction analysis. A view of $MoO_2Br_2(HMPA)_2$ is shown in Fig. 1. Fig. 2 shows the two distortional isomers, (a) and (b), of $MoO_2Br_2(dppmO_2)$ present in the unit cell. Selected bond lengths and angles are listed in Table 2.

As expected, the molybdenum is coordinated in a pseudo-octahedral fashion by two *cis* oxo, two *trans* bromide, and two *cis* O-donor ligands. Distortions from

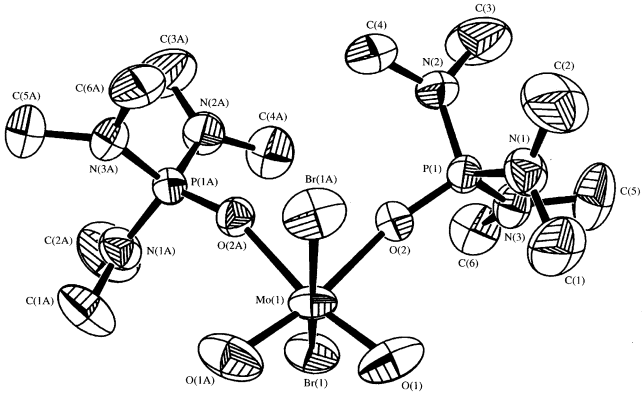

Fig. 1. Molecular structure and atom-labeling scheme for $MoO_2Br_2(HMPA)_2$, (50% probability ellipsoids); hydrogen atoms are omitted.

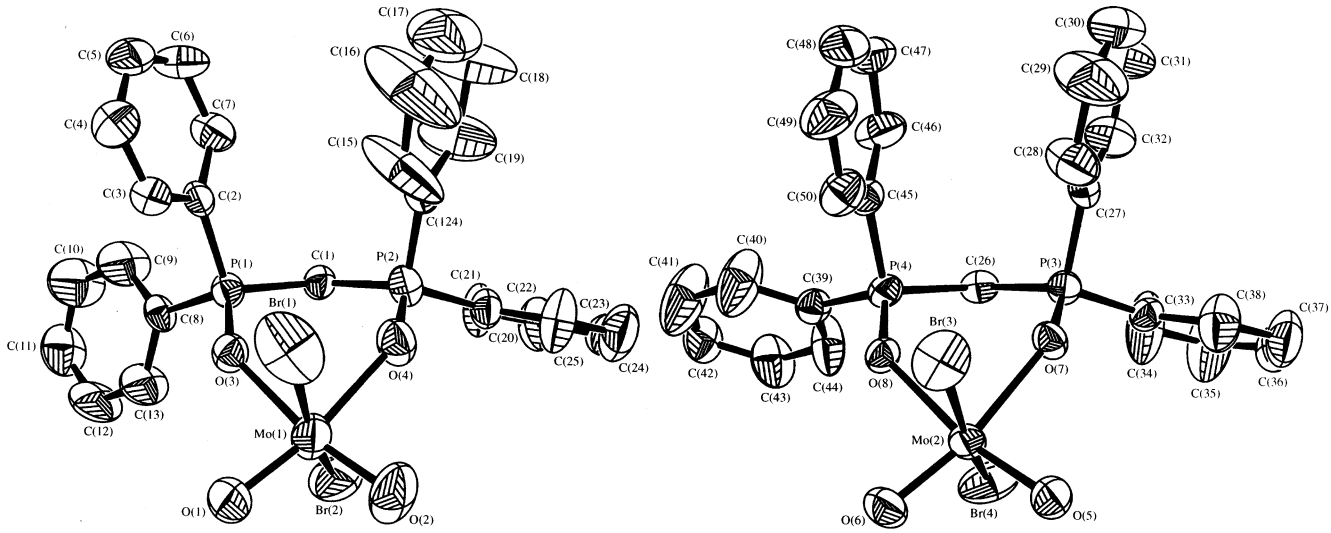

Fig. 2. Molecular structure and atom-labeling scheme for $MoO_2Br_2(dppmO_2)$, (50% probability ellipsoids); hydrogen atoms are omitted.

the theoretical octahedral geometry (see Table 2) are explained in terms of interligand repulsions.

The Mo–O(oxo) bond lengths, and the *cis*-$MoO(oxo)_2$ angles, are within the narrow range usually found in dioxomolybdenum(VI) compounds (1.65–1.75 Å and 95–110°, respectively). The Mo–Br distances, and the Br–Mo–Br angles, are comparable to those reported for other $MoO_2Br_2L_2$ complexes [5,11–16].

$MoO_2Br_2(HMPA)_2$ shows three couples of identical Mo-ligand distances. However, in $MoO_2Br_2(dppmO_2)$ the Mo-ligand distances in each pair of bonds with the same ligand are slightly different, which is probably due

to different interligand repulsions derived from the non planar conformation of the chelate ring. The Mo–O(neutral ligand) in the HMPA complex is significantly shorter than those in that of $dppmO_2$, as expected according to the superior basicity of HMPA with respect to phosphine oxides.

In $MoO_2Br_2(dppmO_2)$ the diphosphine dioxide behaves in the usual manner, bidentate chelate [21], although the ligand is also known to function in other complexes as bridging [22] and monodentate [23]. It should be noted that in the unit cell there are two distinct molecules, that can be regarded as distortion isomers. This fairly peculiar behavior is presumably due to packing forces.

3.3. Oxidant ability of the complexes

In a previous paper we reported that $MoO_2Br_2(DMSO)_2$ catalyzes the oxotranfer from DMSO to PPh_3 [17]. Here, we have found that these compounds react with excess of common organophosphines and phosphites at room temperature leading to brown or green solutions. This is indicative of oxotransfer processes from the dioxomolybdenum center to the P-oxoaceptor. The evolution of the foul-smelling dimethyl sulphide was detected with the DMSO complex, suggesting the potential of the sulfoxide complexes to work as oxotransfer catalysts from sulfoxides to phosphorus(III) compounds.

As these compounds are relatively resistant to hydrolysis, it is worth testing their oxidant capability in reactions in which water is produced. That some dioxomolybdenum complexes are able to oxidize thiols to disulphides was proved years ago [24]. To compare the oxidizing potential of the bromocomplexes for this transformation we have measured the rate of oxidation of *tert*-buthylmercaptan, a thiol somewhat resistant to oxidation, to the corresponding disulphide. For this study, we used a molar ratio thiol/bromocomplex = 4, on the assumption that Mo(VI) could be reduced to Mo(IV) in the oxidation process and that replacement of bromide by thiolate in the coordination sphere of molybdenum might eventually occur.

Table 1 shows the percent conversion of thiol to disulphide at 3 and at 24 h, when the reaction is virtually stopped in all cases except that of the Ph_2SO complex which requires about 3 days for completion. The results from these observations can be summarized as follows.

No evidence of replacement of bromide by thiolate was found during the process, according to the persistence in the position of the signals corresponding to the thiol.

For amide and phosphine oxide complexes the reaction stops in the vicinity of 25% thiol oxidation. As the reaction progresses a green or brown color develops in the solution and a blue solid forms. This suggests that, in case oxomolybdenum(IV) species were initially formed, they comproportionate with the parent dioxomolybdenum(VI) complex to afford oxomolybdenum(V) products resistant to reduction. Examination by IR spectroscopy of the solids formed at the end of the process showed the absence of dioxomolybdenum(VI) species, but the information was insufficient to demonstrate that only a dinuclear oxomolybdenum(V) product was formed. It is probable that deviations from 25% conversion (the ideal value for reduction of Mo(VI) to Mo(V)) are due to decomposition processes.

The sulfoxide bromocomplexes oxidize complete and selectively the thiol to disulphide. The rate of oxidation decreases from DMSO to MePhSO to Ph_2SO. Under these conditions the free sulfoxides do not react with the thiol. Since the thiol is unable to reduce dioxomolybdenum(VI) beyond oxomolybdenum(IV) we conclude that these complexes behave as oxotransfer catalysts for the oxidation of *tert*-buthylmercaptan to *tert*-buthyldisulphide.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 156946 and 175434 for $[MoO_2Br_2(OP[N(CH_3)_2]_3)_2]$ and $[MoO_2Br_2(CH_2[P(O)(C_6H_5)_2]_2)]$, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

water molecule to the copper(II) ion in the complexes with *N*,*N*-dimethyl isoleucine, or *N*,*N*-dimethyl-valine.

The interactions of amino acid side-chains in the metal ion complexes were studied by potentiometric pH-titrations [4,5]. Sigel and coworkers pointed out that in organic solvents interactions between aliphatic amino acid side-chains can be formed only if 2N–2O atoms in the ligand field of the copper(II) ion in the complex were arranged in the *trans*-fashion. In such an arrangement, the amino acid side-chains are located on the same side of the metal-ion coordination sphere allowing aliphatic van der Waals contacts. Upon addition of organic solvents the shift in equilibrium between *cis*- and *trans*-isomers was detected in a number of copper(II) complexes by EPR spectroscopy [6].

The crystal structures of the two modifications of bis[*N*,*N*-dimethyl-isoleucinato]copper(II), with [7] and without [8] apical water, showed different conformations of the amino acid side-chains. In the complex with bound water amino acid side-chains were located in the equatorial plane, while in the absence of apical water, in the axial position. The crystal structure of bis[*N*,*N*-dimethyl-alaninato]copper(II), resolved recently, showed the copper(II) coordination polyhedron strongly distorted [9].

In this work, the role of the water molecule coordinated to the copper(II) on the motional properties of bis[*N*,*N*-dimethyl-isoleucinato]copper(II) complex dissolved in deuterated methanol is investigated. Our hypothesis is that in the methanol solution exchange of the apical water molecule between the copper(II) ion and the solvent in bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II) may be related to the conformation change of the amino acid side-chains.

2. Experimental

2.1. Methods

The EPR spectra of the two complexes were studied as a function of temperature (from 276 to 334 K) at two microwave frequencies (S-band, $\nu = 3.860$ GHz, and X-band, $\nu = 9.346$ GHz). The X-band EPR spectra were taken on a Varian E-109 spectrometer, equipped with a Bruker variable temperature control unit. The aqueous solution cell was previously dried with nitrogen stream.

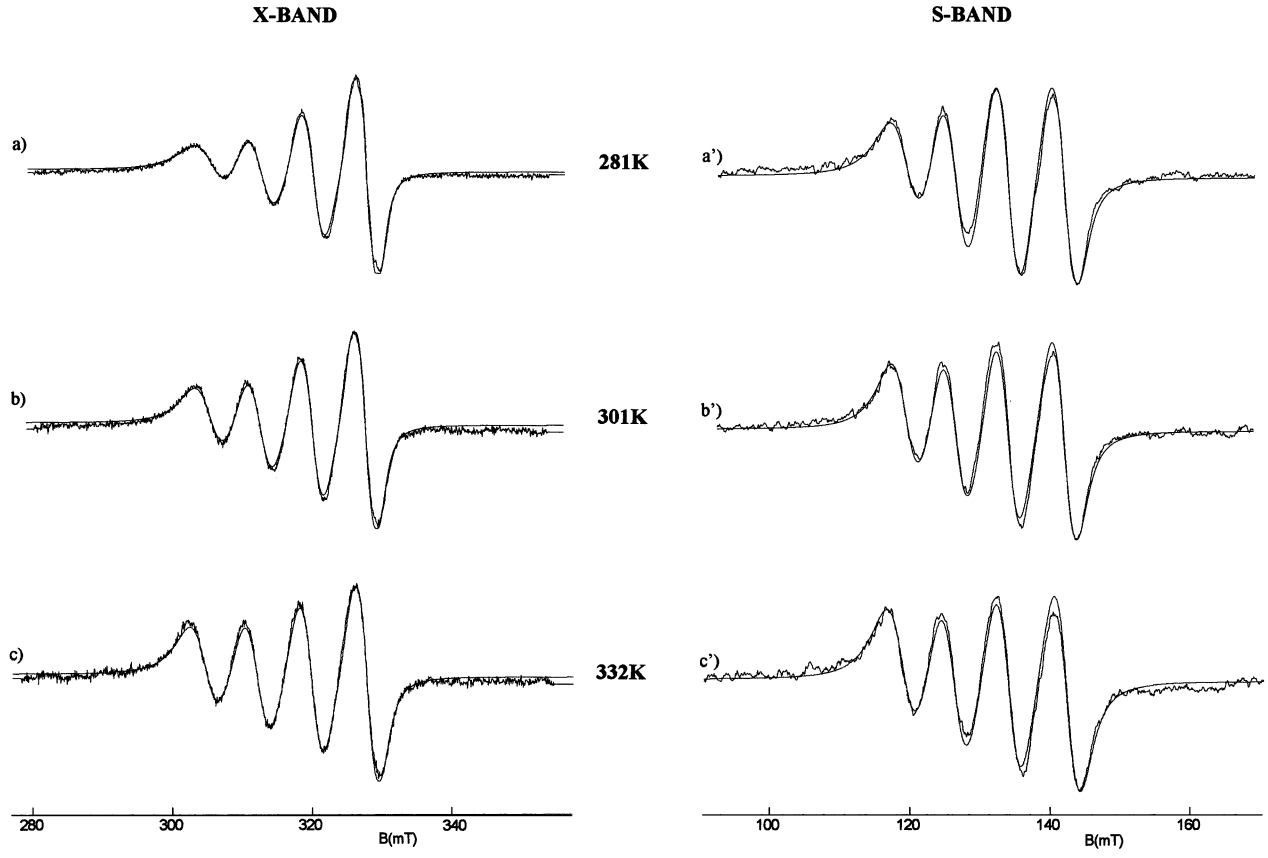

Fig. 1. EPR spectra of bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II) dissolved in dried deuterated methanol and taken at X-band ($\nu = 9.346$ GHz) at; a, 281 K; b, 301 K; c, 332 K and at S-band ($\nu = 3.870$ GHz) at a′, 281 K; b′, 301 K; c′, 332 K. The spectra are fitted with the COSMOS program and the EPR spectral parameters characteristic for the blue complex with bound water are reported in Table 1.

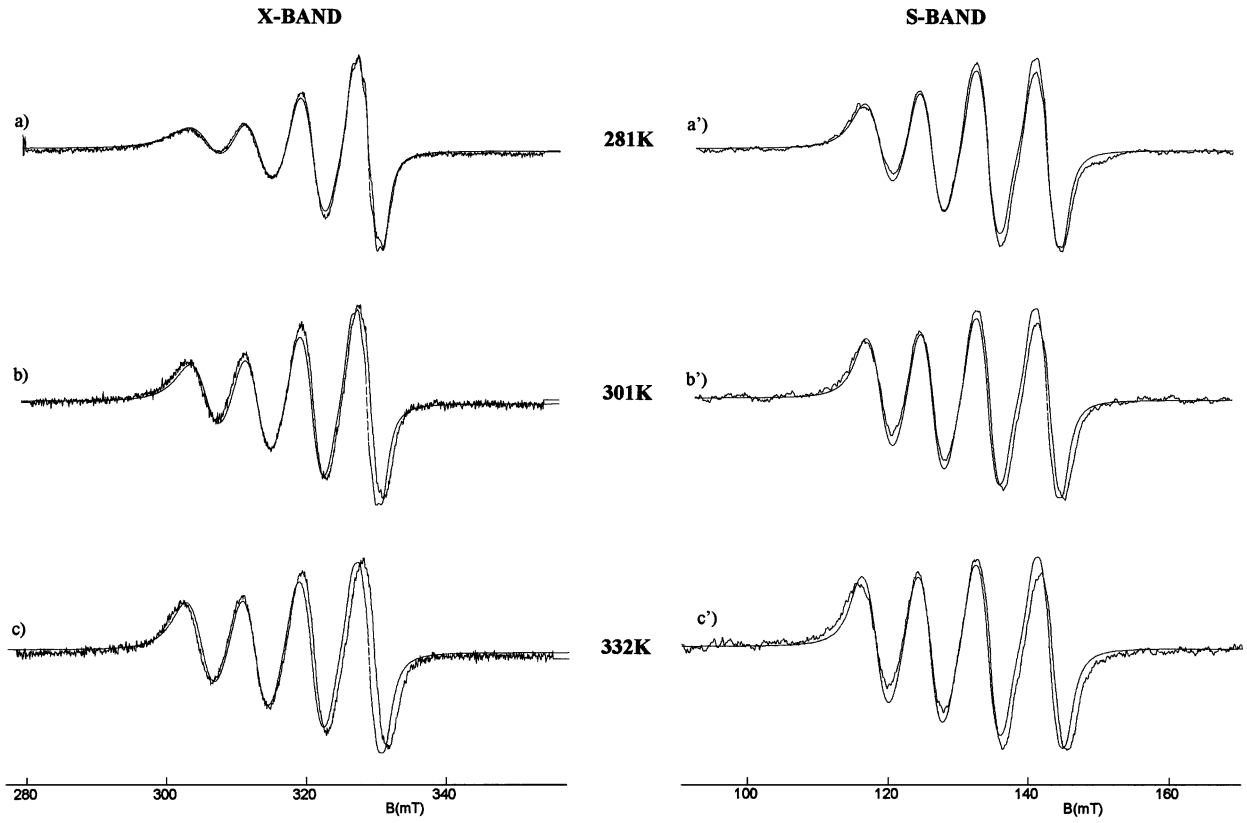

Fig. 2. EPR spectra of bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II) dissolved in dried deuterated methanol and taken as a function of the temperature at X-band ($\nu = 9.346$ GHz) at: a, 281 K; b, 301 K; c, 332 K; and at S-band ($\nu = 3.870$ GHz) at a′, 281 K; b′, 301 K; c′, 332 K. The spectra are fitted with the COSMOS program and the EPR spectral parameters characteristic for the blue water complex are reported in Table 1(a).

The S-band EPR spectra were recorded with a microwave bridge, equipped with the loop-gap resonator, from Jagmar (Krakow, Poland) and with a Bruker variable temperature control unit. Microwave frequencies were measured with an XL Microwave Model 3120 counter (Jagmar).

The *g*-factor was measured relative to diphenyl-picryl-hydrazil (DPPH), as an external marker ($g_{DPPH} = 2.0036 \pm 0.0003$). The extra dry (dried over molecular sieves) deuterated methanol was purchased from Cambridge isotope Laboratory USA. The EPR flat cell was closed with the stopper and protected from air humidity with parafilm. Concentrations of about 0.1 mmol dm^{-3} of the complexes were used. Temperature dependence of the methanol viscosity was measured in the viscosimeter with a falling ball.

2.2. Complexes preparation

Amino acids (Merck) were methylated by the method of Bowman and Stroud [10]. Ligands were characterized by elemental analysis, NMR and mass spectroscopy.

2.2.1. Elemental analysis

N,*N*-dimethyl-L-α-alanine (M.W. = 117.0), white crystals (melting point, m.p. = 182–183 °C), elemental analysis: C (Calc. 51.26%) 51.2%; N (Calc. 11.96%) 11.99%; H (Calc. 9.46%) 9.34%. *N*,*N*-dimethyl-L-α-isoleucine (M.W. = 159 150), white hygroscopic crystals (m.p. = 162–163 °C), elemental analysis: C (Calc. 60.34%) 60.21%; N (Calc. 8.79%) 9.02%; H (Calc. 10.76%) 10.66%. The copper(II) complexes were prepared by the method by Nash and Shaefer [11].

3. Theory

EPR spectra of bis[aminoacidato]copper(II) complexes are determined by four resonance transitions arising from the hyperfine coupling between the electron spin of the copper(II) (configuration $3d^9$) and the nuclear spin ($I_{Cu} = 3/2$). The position of the lines are determined by the hyperfine tensor A_{Cu} and a *g*-tensor related to the spin-orbit coupling. The average of the diagonal values of *g* and A_{Cu} tensors is observed in solutions, and the rotational correlation time of the complex (τ_2), the time modulating the energies related to *g* and *A* anisotropy, describes the dynamics of the system in solutions [12–17].

The EPR spectra were calculated by COSMOS program developed by G. della Lunga, R. Pogni and R. Basosi [18,19]. The EPR simulation program COSMOS can cover

virtually all of the dynamic conditions of copper(II) complexes, from 'fast tumbling' to 'incipient slow motion' in the computer program. The program allows the simultaneous occurrence of the two copper(II) isotopes to be considered. A procedure for the best fit of the experimental spectrum, based on the minimization program [19] is to allow variations of the input magnetic parameters, as well as the rotational correlation time τ_2. The program calculates line-positions, lineshapes and linewidths. In the program, the spin-rotational contribution [13] was included. In the fast motion region the approximation for the rotational correlation time holds:

$$\tau_2 = \frac{1}{6\sqrt{D_{xy}D_{zz}}}$$

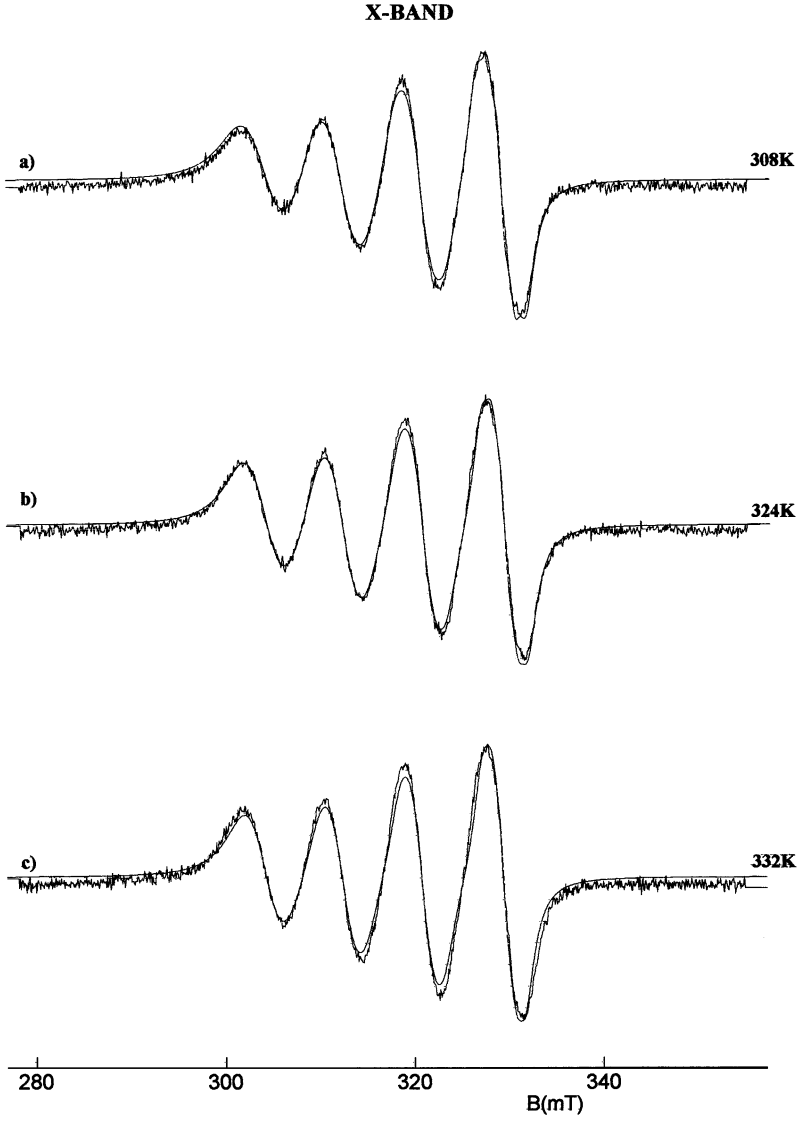

Fig. 3. X-band ($\nu = 9.346$ GHz) EPR spectra of bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II) dissolved in dried deuterated methanol and taken at, a, 308 K; b, 324 K; c, 332 K. The spectra are fitted with the COSMOS program with EPR parameters characteristic for the complex without apical water, Table 1(b).

where D_{xy} and D_{zz} are the diffusion tensor components. For the isotropic motion the diffusion tensor components can be considered equal. The best fit of the experimental spectra was found using the Simplex and Levenberg–Marquardt optimization procedures.

4. Results and discussion

Multifrequency EPR analysis [15,16] combined with computer simulations of the EPR spectra in solutions, is a useful tool for determination of the chemical structures and dynamic properties of copper(II) complexes in systems of biological interest. The requirements for a good fit of the copper(II) spectra recorded at different microwave frequencies put constraints on the chosen EPR parameters. Then, computer simulations of the EPR spectra minimize problems arising from the lack of details of the room temperature (r.t.) experimental spectra, and permit determination of dynamic properties of the copper(II) complexes (i.e. the rotational correlation time, τ_2).

The reorientation correlation time τ_2, describes Brownian motion of the Cu(II) complex in solution and is expressed as: $\tau_2 = (1/k)V_{\text{eff.}}(\eta/T)\kappa$, where $V_{\text{eff.}}$ is the effective volume of the complex, η is the viscosity of the solvent, k is the Boltzman constant, T is the temperature (in K) and κ is the anisotropic interaction parameter, the second rank tensor related to EPR spectral parameters [20]. If the copper(II) complex retains one conformation in the examined temperature interval, τ_2 will be a linear function of η/T, with the coefficient of linearity proportional to the effective volume of the solvatized complex.

In Fig. 1, the EPR spectra of bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II) in dried deuterated methanol solution taken at 281 K (a) 301 K (b) 332 K (c) at X-band, and (a′), (b′), (c′), at S-band, are reported. In Fig. 2, the EPR spectra of bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II) dissolved in dried deuterated methanol taken at, 281 K (a), 308 K (b), 332 K (c) at X-band, and (a′), (b′), (c′) at S-band are displayed. For each temperature, the line shapes of the spectra were fitted with COSMOS program. The starting magnetic parameters for the fast motion simulations were obtained from the corresponding low temperature EPR spectra ($T = 77$ K).

The simulated spectra of the bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II) complex (Fig. 1), show a good fit with the experimental ones. The simulations have been obtained using the same g and a parameters (Table 1) for all the temperatures at both frequencies. Only the diffusion tensor components were free to vary in order to fit properly the line shapes of the EPR spectra with the temperature variation. On the other hand, in the case of bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II) (Fig. 2) the fit (Table 1(a)) is not so good for all the examined temperatures. Above 300 K, a shift of g_o to lower values, concomitant with an increase of a_o is observed for all the recorded spectra.

In Fig. 3, the X-band EPR spectra of the bis[*N*,*N*-dimethyl-isoleucinato]copper(II) taken at 308 K (spectrum a), 324 K (spectrum b) and 332 K (spectrum c), are

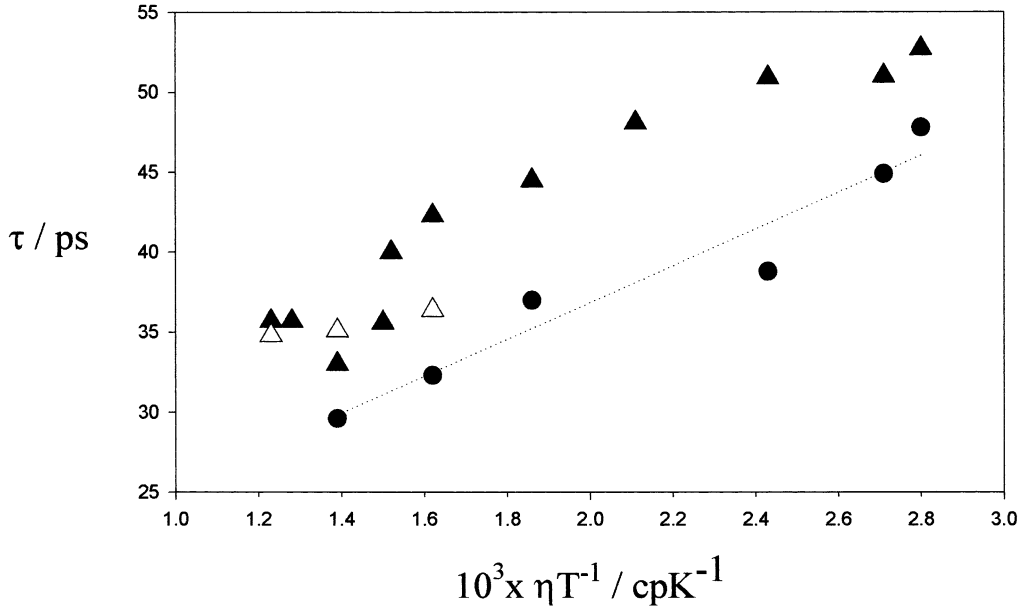

Fig. 4. Reorientation correlation times, τ_2 (ps), of the two complexes dissolved in CD_3OD, as a function of the viscosity of the solvent, η (poise $\times 10^{-3}$), over the temperature, T (K) are reported. Each point on the curve is obtained by fitting the experimental EPR spectra with the COSMOS program: circles, bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II); black triangles, bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II); white triangles, τ_2 (ps) values for the bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II) complex without apical water.

displayed. The spectra are paired with the simulations that gave the best fit with the parameters reported in Table 1(a). As the simulated spectra reported in Fig. 2 do not fit well the experimental ones, a new fit with different g and a values for the EPR spectra above 300 K is attempted (see Fig. 3 and Table 1(b)). The difference in the parameters (Table 1(a and b)) in the two cases, may be ascribed to the release of the apical water from the copper coordination sphere above 300 K with the concomitant formation of the complex without apical water [3].

The values of the rotational correlation time, τ_2, determined from the calculated EPR spectra are plotted as a function of η/T and are compared in Fig. 4 for the two copper(II) complexes studied. A linear dependence of the rotational correlation time, τ_2, on η/T for bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II) (circles) is observed. The slope of the straight line determined for the alaninato complex is related to the effective volume of the complex and suggests one conformation of the complex in the whole temperature range measured. A reversible temperature dependence was obtained.

More complex and irreversible dependence of τ_2 on η/T is obtained for bis[*N*,*N*-dimethyl-isoleucinato]copper(II) (Fig. 4, triangles). Smaller values of the rotational correlation time τ_2 than predicted for the linear dependence of τ_2 on η/T are obtained at the temperatures above 300 K, suggesting a smaller effective volume of the solvated complex. The change may be related to the release of the apical water molecule from the complex, because EPR spectra taken above 300 K were fitted better (Fig. 3) with the parameters (Table 1(b)) similar to the complex dissolved in the dried CH_2Cl_2. The complex dissolved in CH_2Cl_2 was fitted well with parameters: $g_o = 2.109$; $g_{||} = 2.248$; $g_{\perp} = 2.040$; $a_o = 9.1$ mT; $a_{||} = 18.5$ mT; $a_{\perp} = 4.4$ mT (Simfonia, Bruker). The straight line of τ_2 on η/T in the whole temperature interval 245–300 K was obtained [21].

The τ_2 values displayed in Fig. 4 are obtained using the equation reported in the experimental part, under the reasonable assumption of the isotropic motion of the

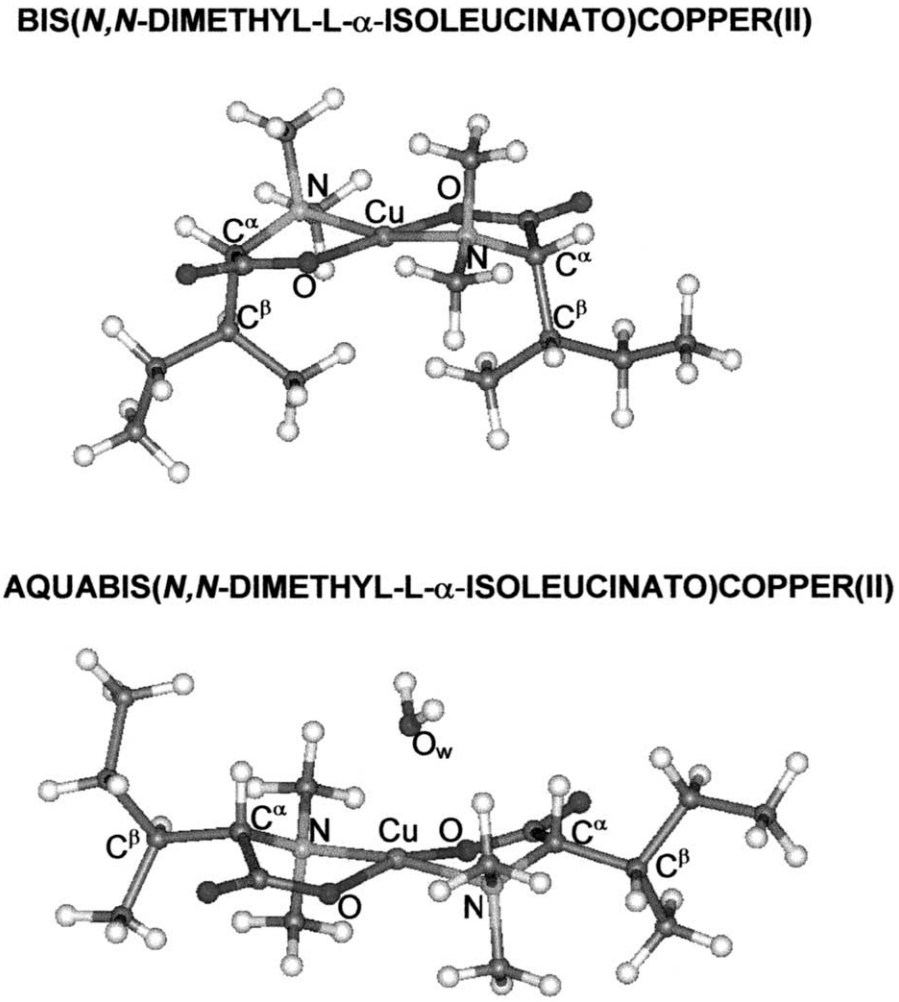

Fig. 5. Proposed conformation change for binding of water molecule to bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II).

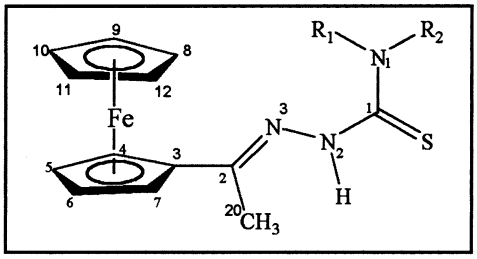
two complexes. Nevertheless, a more careful analysis of the diffusion tensor components for the two complexes had to be attempted. In the case of the bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II) complex, the best fit of the spectra was obtained if D_{zz} was kept unchanged in the whole range of temperatures. For the bis[*N*,*N*-dimethyl-isoleucinato]copper(II) complex a more anisotropic motion might be inferred, because the best fit could only be obtained with decreasing values of D_{zz} with increase of temperature. This is evident in the whole range of temperature examined, probably due to the longer aliphatic side-chains (2-methyl-buthyl-) compared with that of the bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II) complex (–methyl). Above 300 K, the anisotropic motion of the isoleucinato complex is always present, but the differences in the diffusion tensor components are accompanied by changes in the magnetic parameters suggesting formation of another complex, probably one without the apical water.



5. Conclusions

Temperature dependence of the Brownian motion of the examined copper(II) complexes in dried deuterated methanol solutions is studied by EPR spectroscopy. Linear temperature dependence of the rotational correlation time, τ_2 on η/T is obtained for bis[*N*,*N*-dimethyl-L-α-alaninato]copper(II), of short amino acid side-chains (–methyl). In the whole temperature range examined (276–332 K), EPR spectra of this complex are fitted well with the parameters that we ascribe to the complex with bound water, suggesting one type of the complex solute–solvent interaction.

More complex temperature dependence of τ_2 on η/T is obtained for the bis[*N*,*N*-dimethyl-L-α-isoleucinato]copper(II), of the longer aminoacid side-chains (2-methyl–butyl–). The EPR parameters characteristic for the complex with bound water could not fit the EPR spectra above 300 K. The parameters that fit well the EPR spectra of this complex above 300 K, are very close to those of the copper(II) complex without the apical water [21]. Smaller values of τ_2 than predicted above 300 K, indicate conformation change of the complex above that temperature, concomitant with the release of the apical water from the copper(II) coordination sphere (Fig. 5).

Scheme 1.

HL^1–HL^5 (see Scheme 1), and of their complexes with the cation $TlMe_2^+$. X-ray studies showed marked variability in coordination mode, including the relatively uncommon formation of four-membered chelate rings. The preparation and structure of HL^1 have previously been reported by Fang et al. [16].

2. Results and discussion

2.1. Structures of the ligands

Table 1 lists selected bond lengths and angles of HL^{3-5}, and Fig. 1 shows the structures and numbering schemes of HL^3, HL^4 and one of the two crystallographically independent molecules of HL^5. Like HL^1 [16] and most thiosemicarbazones [4b,15], both HL^3 and HL^4 adopt E configuration with respect to the C(1)–N(2) bond. The main cause of this is probably that it allows N(1) and N(3) to form an intramolecular hydrogen bond [17]; both of the HL^5 molecules, in which this bond is impossible because of the disubstitution of N(1), adopt Z configuration. In all three compounds the bond lengths in the thiosemicarbazone chain C(2)N(3)N(2)C(1)S(1)N(1) are within the usual ranges [4b,15,18].

In crystals of HL^5 there are two similar but crystallographically independent molecules, **a** and **b**. Their bond lengths and angles are generally similar, but in some cases are clearly not identical in view of the corresponding standard deviations (Table 1).

2.2. Structures of the complexes

The structures and numbering schemes of the $TlMe_2^+$ complexes of HL^2–HL^4 are shown in Figs. 2 and 3, and selected bond lengths and angles are listed in Table 2.

In $[TlMe_2(L^2)]$ and $[TlMe_2(L^4)]$ the ligands chelate the metal through their N(2) and S atoms, forming four-membered chelate rings (Fig. 2(a/b)). This coordination

mode, which is unusual among thiosemicarbazones, was first observed in this class of compounds in another dimethylthallium(III) complex [19], and later in complexes with organometallic derivatives of Group 13 elements (Al, Ga and In) [20–22] and with Pd [23]. It allows the deprotonated ligand to retain its stabilizing N(1)–H···N(3) hydrogen bond, which in $[TlMe_2(L^4)]$ is actually stronger than in the free ligand, with an N(1)···N(3) distance of 2.580(6) Å as against 2.629(2) Å. In the $(L^4)^-$ complex, thione-to-thiol evolution is reflected by the lengthening of C(1)–S and the shortening of C(1)–N(2) with respect to their lengths in free HL^4.

The Tl–C distances and C–Tl–C angles in the $(L^2)^-$ and $(L^4)^-$ complexes are similar to those found in other complexes of dimethylthallium(III) with thiosemicarbazone ligands [4b,15], but the Tl–N distances (both about 2.50 Å) are somewhat shorter than those previously observed (2.55–2.59 Å), although this difference does not seem to be sufficient to give rise to qualitative differences in coordination geometry. The Tl–S distances (2.78 and 2.75 Å) are also shorter than those found in most other $TlMe_2^+$ complexes of thiosemicarbazones (2.80–2.99 Å) [4b], the only exception being the complex with cyclopentanonethiosemicarbazone, in which Tl–S has a length of 2.627(5) Å [4b].

In $[TlMe_2(L^2)]$ the Tl–S and Tl–N(2) bonds are supplemented by a weak Tl···S interaction with a neighboring molecule that serves to link the molecules in chains. If this interaction is taken into account, the coordination polyhedron is a square pyramid according to Addison's [24] criterion ($\tau = 0.12$). As in the free ligand [25], the C(2)N(3)N(2)C(1)S(1)N(1)C(13) chain is practically flat (the rms deviation from the least squares plane is 0.041), and it makes angles of 32.1° with the cyclopentadiene ring and 71.5° with the least-squares plane through S(1), Tl, C(191) and C(192) (from which the rms deviation is 0.029).

In $[TlMe_2(L^4)]$, there are no intermolecular interactions and the coordination polyhedron is a highly distorted tetrahedron [C(191–Tl(1)–C(192) = 159.2(3)° and N(2)–Tl(1)–S(1) = 59.62(11)°]. A coordination

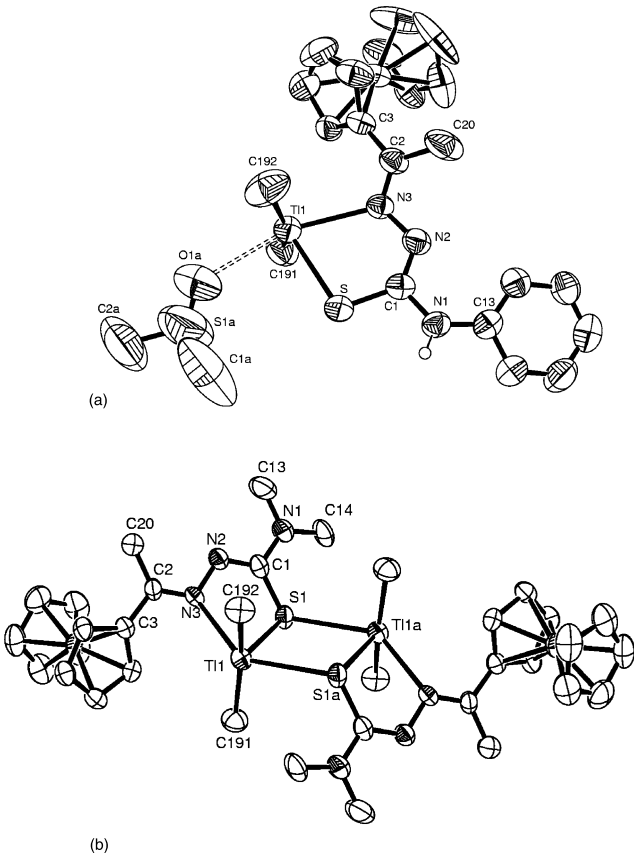

Fig. 3. ORTEP drawing of (a) $[TlMe_2(L^3)(dmso)]\cdot dmso$ and (b) $[TlMe_2(L^5)]$, showing their molecular structures and the labeling schemes used.

number of four is unusually low for $TlMe_2^+$ compounds, and this is the first time it has been found in a thiosemicarbazone complex of this cation; hitherto, all such complexes have had coordination numbers of five, six or seven. In $[TlMe_2(L^4)]$, the thiosemicarbazide/acetyl chain (rms = 0.083) makes angles of 25.3° with the cyclopentadiene ring and 70.2° with the S(1)TlC(191)C(192) plane (rms = 0.027).

The most significant difference between $[TlMe_2(L^2)]$ and $[TlMe_2(L^4)]$ is thus the presence in the former of an intermolecular Tl···S interaction that determines a different coordination environment for the metal and creates a supramolecular structure consisting of chains running parallel to the *y*-axis. It may also be noted that this intermolecular interaction appears to weaken the intramolecular Tl–S bond, which has a length of 2.779(7) Å in $[TlMe_2(L^2)]$ as against 2.7545(18) Å in $[TlMe_2(L^4)]$.

In $[TlMe_2(L^3)(dmso)]\cdot dmso$ the deprotonated ligand chelates the organometallic cation via its N(3) and S atoms, as is usual in this kind of thiosemicarbazone complex [4b,15], so forming a five-membered chelate ring. The coordination number of the thallium atom is made up to five by a bond with a dmso oxygen atom, the resulting coordination polyhedron being a square pyramid with the sulfur atom apical (τ [24] = 0.0017). The lengths of the Tl–S, Tl–N and Tl–C bonds are within the ranges observed in similar compounds [4b], but the Tl–O bond is rather long [2.803(8) Å], though considerably shorter than the sum of the van der Waals radii (3.50 Å [26]). This coordination mode appears to shorten Tl–S and lengthen Tl–N with respect to the N(2),S-coordination of the L^2 and L^4 complexes.

The phenyl ring in $[TlMe_2(L^3)(dmso)]\cdot dmso$ is practically coplanar with the rest of the thiosemicarbazide moiety [rms deviation for C(2)N(3)N(2)C(1)S(1)N(1)-C(13)C(14)C(15)C(16)C(17)C(18), 0.1193]. This structure makes angles of 63.7° with the planes of the ferrocene rings, and 89.9° with the S(1)TlC(191)C(192) plane. The second dmso molecule is occluded in the lattice.

In $[TlMe_2(L^5)]$ a thiolic thiosemicarbazonato anion chelates the metal via its N(3) and S atoms. In addition, the S atoms of pairs of neighboring molecules bridge between the metal atoms, forming weakly bound centrosymmetric dimers (the Tl–$S^{\#2}$ distance, 3.07(16) Å, is longer than usual, though shorter than the sum of the van der Waals radii, 3.76 Å [26]). The coordination polyhedron is a highly distorted square pyramid (τ [24] = 0.31) in which the tightly bound sulfur is apical. The Tl–S, Tl–N(3) and Tl–C distances are similar to those found in other complexes of dimethylthallium(III) with monoanionic organic ligands [14], although the replacement of the weak Tl···O bond of the $(L^3)^-$ complex by a Tl···S bond lengthens both Tl–S and Tl–N. The C(3)C(2)C(20)N(3)N(2)C(1)S(1)N(1)C(13)C(14) chain is almost flat (rms = 0.0981) and makes angles of 25.6° with the cyclopentadienyl ring and 55.4° with the S(1)Tl(1)C(191)C(192) plane (rms = 0.0293).

In the solid state, all the complexes retain the E configuration of the ligands about the C(2)–N(3) bond (see [16,25] for HL^1 and HL^2 and Fig. 1 for HL^3–HL^5).

2.3. IR spectra

The chief IR bands of the ligands were identified on the basis of data for similar compounds [7].

In the 3400–3100 cm^{-1} region, where the ν(N–H) bands lie, deprotonation makes the spectra of the complexes simpler than those of the free ligands, leaving only the ν(N(1)–H) bands. The shifts of these bands in $[TlMe_2(L^1)]$–$[TlMe_2(L^4)]$ with respect to their positions in the spectra of the free ligands must be attributed to changes in hydrogen bonding, since in $[TlMe_2(L^1)]$–$[TlMe_2(L^4)]$ N(1) is not coordinated to the metal.

The coordination via the sulfur atom shifts ν(C=S) to lower wavenumbers than in the free ligands, where it appears near 800 cm^{-1}. The C=N stretching vibration also shifts to lower wavenumbers; this occurs regardless of whether the ligand coordinates via N(2) (as in $(L^2)^-$ and $(L^4)^-$) or N(3) (as in $(L^3)^-$ and $(L^5)^-$), and the

Symmetry operations: #1: $-x+0.5$, $y-0.5$, $-z+0.5$; #2: $-x+1$, $-y$, $-z+1$.

magnitude of the shift is likewise uncorrelated with the coordination mode, probably because it is also influenced by the involvement of N(3) in hydrogen bonds when it does not coordinate to the metal.

The 1650–1450 cm^{-1} region of the IR spectrum of $[TlMe_2(L^1)]$, from the X-ray data for which it was not possible to calculate a structure, shows two strong bands similar to those found in the spectra of N(2)-coordinated N(1)-unsubstituted thiosemicarbazones [19,27]. It is, therefore, reasonable to infer that the ligand is also N(2)-coordinated in $[TlMe_2(L^1)]$.

Coordination does not significantly affect the ferrocene bands [28].

2.4. NMR spectra

The NMR spectra of the ligands and complexes in dmso-d_6 (see Section 4) are in some cases complicated by the presence of several different species (*vide infra*) and were interpreted with the aid of ^1H–^{13}C HMQC and HMBC experiments.

The ^1H NMR spectra of all the ligands except HL^5 show a single series of strong signals, suggesting that in these cases there is a single predominant species present. That of HL^1 shows the two protons on N(1) to be non-equivalent, which is attributable to one of them being involved in an N(1)–H···N(3) hydrogen bond.

The ^1H NMR spectrum of HL^5 shows two series of signals, which differ most as regards the N(2)H signal and which we attribute to distinct species HL^5**a** and HL^5**b** with different conformations with respect to the C(1)–N(2) bond, one being Z and the other E.

Coordination induces a number of changes in the ^1H NMR spectra of the ligands. In all cases, the signal located near 10 ppm disappears as the result of deprotonation. In the spectrum of the $(L^1)^-$ complex the two N(1) protons are now equivalent, probably due to there now being no N(1)–H···N(3) hydrogen bond and to a coordination-induced change in the multiplicity of C(1)–N(1) (this bond is longer in the complexes than in the free ligands). The spectra of the $(L^2)^-$, $(L^4)^-$ and $(L^5)^-$ complexes indicate the presence of more than one species (two for $(L^4)^-$ and $(L^5)^-$, three for $(L^2)^-$), determination of the relative abundances of which was unfortunately prevented by the complexity of the spectra. The presence of three species of $[TlMe_2(L^2)]$

(**a**, **b** and **c**) suggests that these species may differ with respect to C(2)–N(3) as well as C(1)–N(2), i.e. as regards the relative positions of the ferrocene group and the thiosemicarbazide chain.

The ^{1}H NMR signals of the ferrocene group lie between 4.1 and 4.9 ppm in the spectra of the free ligands. Of the slight shifts observed upon coordination, the most important are, as expected, those affecting the signals of C(4) and C(7) (see the scheme in the Section 1), which though less than 0.2 ppm in the cases of $(L^1)^-$, $(L^2)^-$ and $(L^4)^-$ reach 0.3 ppm for $(L^5)^-$ and 0.4 ppm for $(L^3)^-$. These shifts doubtless reflect extension of the delocalized π-system of the thiosemicarbazide chain into the cyclopentadiene ring.

The $TlMe_2^+$ moiety shows up as a single signal in the ^{1}H NMR spectra of all the complexes, including those that are present in more than one form. This means that either the organometallic cation is rapidly exchanged between ligands with different configurations, or that the breadth of these signals is too great to allow observation of the difference between the signals of N(2),S- and N(3),S-coordinated species, which is probably small. The existence of coordination in solution, which is expected in view of the generally poor ionogenicity of dimethylthallium(III) complexes of thiosemicarbazones in dmso [20], is supported by the values of $^{2}J(^{1}H–^{205}Tl)$, 394–408 Hz, being considerably smaller than the 438 ± 2.1 Hz found for dimethylthallium(III) perchlorate [29].

The ^{13}C NMR spectra of all the compounds are in keeping with their ^{1}H NMR spectra. C(1) can be seen to be much more shielded in the complexes than in the free ligands, which indicates a shift from the thione form N(2)–C(1)=S towards the thiol form N(2)=C(1)–S consequent upon coordination of the sulfur atom to the metal. The $^{1}J(^{205}Tl–^{13}C)$ values of the $(L^1)^-$, $(L^2)^-$ and $(L^5)^-$ complexes, 2935–2967 Hz, are larger than that of dimethylthallium(III) perchlorate (2918.2 Hz), but that of $[TlMe_2(L^4)]$ is smaller, 2911 Hz; in the case of $[TlMe_2(L^3)]$, poor solubility prevented identification of $TlMe_2^+$ signals.

3. Conclusions

In conclusion, we have prepared five previously unsynthesized acetylferrocene thiosemicarbazonates of dimethylthallium(III), in yields of about 50% or better, by reacting a solution of the corresponding thiosemicarbazone in methanol or ethanol with a freshly prepared aqueous solution of dimethylthallium hydroxide. The structures of three of the thiosemicarbazones and four dimethylthallium(III) complexes were determined by X-ray crystallography. The complexes differ as regards the coordination number of the metal (four or five), the size of the chelate rings (four- or five-member) and the presence or absence of intermolecular Tl···S interactions, showing that this type of ligand has considerable coordinational versatility. One of the complexes also acquired a dmso ligand molecule upon recrystallization from this solvent. The ^{1}H and ^{13}C NMR spectra of the complexes in dmso-d_6 solution suggest that the thiosemicarbazone ligand remains coordinated in this solvent, and also indicate the presence of more than one species, which probably differ as regards the relative positions of the ferrocene group and the thiosemicarbazone chain.

4. Experimental

4.1. Materials and methods

Thiosemicarbazide (from Fluka), acetylferrocene and 4-methyl-3-thio-, 4-phenyl-3-thio-, 4-ethyl-3-thio- and 4,4-dimethylthiosemicarbazides (all from Aldrich) were used as received. Me_2TlI was prepared as per Gilman and Jones [30], and dimethylthallium hydroxide by stirring Me_2TlI with excess freshly precipitated silver oxide in deionized water and removing AgI by filtration.

Elemental analyses were performed on a Fisons Instruments EA1108CHNS-O microanalyser. Melting points (m.p.) were determined with a Büchi apparatus. Mass spectra were recorded on a Kratos MS50TC spectrometer and the mass for the metallated peaks (*vide infra*) is refereed to the isotopes ^{205}Tl and ^{56}Fe. IR spectra were recorded using KBr discs on a Bruker IFS66V FT-IR spectrometer and are reported in cm^{-1}. The ^{1}H and ^{13}C NMR spectra of dmso solutions were recorded on Bruker WM-250, AMX-300 or AMX-500 apparatuses; chemical shifts are expressed on the δ scale (downfield shifts positive) relative to tetramethylsilane. All physical measurements (including the X-ray diffraction studies) were carried out in the RIAIDT services of the University of Santiago de Compostela.

4.2. Preparation of the ligands HL^n

A solution (HL^1, HL^4, HL^5) or suspension (HL^2, HL^3) of the appropriate thiosemicarbazide (6.60 mmol) in water (45 ml) was added dropwise to a stirred hot solution of acetylferrocene (6.60 mmol) in ethanol (40 ml). Acetic acid (1 ml) was added, and the mixture was refluxed for 15 min and then stirred for a further 12 h. The resulting orange (HL^1–HL^4) or red (HL^5) solid was filtered out and dried under vacuum (yield 75–85%). Single crystals suitable for X-ray study were obtained from the mother liquor (HL^5) or by recrystallization from dichloromethane–hexane (HL^3) or chloroform–cyclohexane (HL^4).

4.2.1. HL^1

M.p. 169 °C. Found: C, 52.3; H, 5.6; N, 13.4. $C_{13}H_{15}N_3SFe$ requires: C, 51.8; H, 5.0; N, 13.9%. 4.3. Synthesis of the complexes

4.3.1. $[TlMe_2(L^1)]$

A freshly prepared aqueous solution of $Me_2Tl(OH)$ (0.60 mmol) was added dropwise, with stirring, to a solution of HL^1 (0.2 g, 0.60 mmol) in methanol (10 ml) cooled in an ice-bath. The orange solid so obtained was filtered out and dried under vacuum. Yield 50%. M.p. 119 °C. Found: C, 34.5; H, 3.8; N, 7.9. $C_{15}H_{20}N_3SFeTl$ requires: C, 33.7; H, 3.7; N, 7.9%. MS (FAB, nitrobenzyl alcohol), *m/z*(%): 535 (58) [M], 301 (28) [HL^1], 235 (100) [Me_2Tl], 205 (63) [Tl], 185 (16) [HL^1–C(Me)NNHC(S)NH_2]. IR: 3447s, 3326s,br, ν(N–H); 1568vs,br, ν(C=N); 807m, ν(C=S); 528m, ν_{asim}(C–Tl–C). ^{1}H NMR: δ[N(1)H_2] 6.63s(2); δ[C(20)*H*] 2.02s(3); δ[Tl(CH_3)$_2$] 0.87d(6); [J(^{1}H–^{205}Tl)] 396.3 Hz. ^{13}C NMR: δ[C(1)] 171.7; δ[C(2)] 150.2; δ[C(3)] 85.1; δ[C(20)] 15.6; δ[Tl(*C*H_3)$_2$] 21.1; [J(^{13}C–^{205}Tl)] 2935.0 Hz.

4.3.2. $[TlMe_2(L^2)]$

A freshly prepared aqueous solution of $Me_2Tl(OH)$ (0.64 mmol) was added dropwise, with stirring and mild heating, to a solution of HL^2 (0.2 g, 0.64 mmol) in ethanol (40 ml). Upon concentration under vacuum the mixture afforded an orange solid that was filtered out and dried under vacuum. Yield 53%. Single crystals suitable for X-ray study were obtained by recrystallization from ethanol–water. M.p. 179 °C dec. Found: C, 35.5; H, 4.0; N, 7.7. $C_{16}H_{22}N_3SFeTl$ requires: C, 35.0; H, 4.0; N, 7.7%. MS (FAB, nitrobenzyl alcohol), *m/z*(%): 549.0 (18) [M], 315.0 (33) [HL^2], 235.0 (49) [Me_2Tl], 205.0 (37) [Tl], 185.0 (10) [HL^2–C(Me)NNHC(S)NH(Me)]. IR: 3356s, ν(N–H); 1528vs, ν(C=N); 786m, ν(C=S); 530m, ν_{asim}(C–Tl–C). ^{1}H NMR: δ[N(1)*H*] (**a**: 7.05s, **b**: 6.17s, **c**: 6.31s)(1); δ[N(1)CH_3] (**a**: 2.85m, **b**: 2.72m, **c**: 2.79m)(3); δ[C(20)*H*] (**a**: 2.00s, **b**: 2.31s, **c**: 2.26s)(3); δ[Tl(CH_3)$_2$] 0.77d(6); [J(^{1}H–^{205}Tl)] 401.2 Hz. ^{13}C NMR: δ[C(1)] **a**: 176.3, **b**: 170.1; δ[C(2)] **a**: 148.9, **b**: 156.9, **c**: 152.6; δ[C(3)] **a**: 85.4, **b**: 87.4; δ[C(20)] **a**: 15.3, **b**: 19.2, **c**: 23.2; δ[N(1)*C*H_3] **a**,**c**: 30.3, **b**:30.4; δ[Tl(*C*H_3)$_2$] 20.3; [J(^{13}C–^{205}Tl)] 2954.3 Hz.

4.3.3. $[TlMe_2(L^3)(dmso)]\cdot dmso$

A freshly prepared aqueous solution of $Me_2Tl(OH)$ (0.66 mmol) was added dropwise, with stirring and mild heating, to a solution of HL^3 (0.25 g, 0.66 mmol) in ethanol (45 ml). One-third of the solvent was removed under vacuum, and the remaining solution was stored in a refrigerator for 12 h. The orange solid so obtained was filtered out and dried under vacuum. Yield 81%. Single crystals suitable for X-ray study were obtained by

4.4. X-ray crystallography

Crystal data were collected at room temperature (r.t.) on either a Bruker SMART CCD 1000 diffractometer [31] or an Enraf–Nonius MACH3 automatic diffractometer [32] using graphite-monochromated Mo Kα radiation (wavelength 0.71073 Å). The structures were solved using direct methods followed by normal difference Fourier techniques. The hydrogen atoms were included in the model at ideal geometrical positions. In [$TlMe_2(L^3)$(dmso)]·dmso the hydrogens of C(1B) and C(2B) are disordered and were not included in the model. Full-matrix least-squares refinement was performed treating the non-H atoms anisotropically. The atomic scattering factors used were those provided with SHELX-97 [33]. Other programs used were ORTEP-3 [34] and PLATON-98 [35]. Crystal and refinement data for the ligands and compounds are listed in Tables 3 and 4, respectively.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication number CCDC 168313 (HL^3), 168314 (HL^4), 168315 (HL^5), 168316 [$TlMe_2(L^2)$], 168317 [$TlMe_2(L^3)$(dmso)]·dmso, 168318 [$TlMe_2(L^4)$], 168319 [$TlMe_2(L^5)$]. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk.or www: http://www.ccdc.cam.ac.uk).

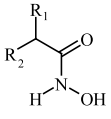
extracts [14,15]. This suggests that, under physiological conditions, the reductive release of iron from its hydroxamate siderophore complex is a viable process, particularly in the presence of an iron(II) trap such as porphyrin.

The electrochemical behavior of iron(III) complexes with aminohydroxamic acids has not been investigated to date. In the present paper, the cyclic voltammetric behavior of iron(III) complexes with alanine- (**1**), serine- (**2**), lysine- (**3**), histidine- (**4**) and glutamo-γ-hydroxamic acid (**5**) (Scheme 1) has been studied at hanging mercury drop electrodes. The objective was to determine the mechanism involved in the electron transfer processes and to gain some insight into the influence of ligand substituent effects on the redox potentials. The rate constants for the irreversible dissociation of iron(II) complexes were calculated. Comparison of the redox potentials with the redox potentials of some natural hydroxamates identified as siderophores is discussed.



2. Experimental

2.1. Materials

All aminohydroxamic acids were used as purchased from Sigma. Iron(III) perchlorate stock solution was prepared from recrystallized solid iron(III) perchlorate hydrate (Aldrich) and standardized for Fe^{3+} ion spectrophotometrically in strong acid [16]. All other chemicals were of analytical grade and were obtained from Merck, except for sodium dihydrogen phosphate, which was purchased from Kemika (Zagreb, Croatia).

2.2. Methods

Cyclic voltammetry experiments were performed with an EG&G Princeton Applied Research Model 273A potentiostat controlled by the Model 270/250 Research Electrochemistry Software v. 4.30. Cyclic voltammetric studies were carried out using a hanging mercury drop working electrode (EG&G Princeton Applied Research Model 303A), a platinum wire auxiliary electrode and an Ag/AgCl reference electrode. The potentials were scanned from −0.1 to −1 V, employing scan rates between 10 mV s^{-1} and 20 V s^{-1}. All measurements were performed with positive feedback iR compensation.

	R_1	R_2
1	NH_3^+	CH_3
2	NH_3^+	CH_2OH
3	NH_3^+	$CH_2CH_2CH_2CH_2\ NH_3^+$
4	NH_3^+

Scheme 1. Structures of the aminohydroxamate ligands.

The studied complexes were generated in situ by addition of an appropriate amount of acidic iron(III) perchlorate stock solution to a solution of ligand in 0.05 M phosphate buffer at constant ionic strength ($I = 1.0$ M $NaClO_4$) thermostatted at 25 °C. The pH measurements were made with a Radiometer PHM 85 pH-Meter using a combined glass electrode (Radiometer PHC 2406L). All solutions were purged for 15 min with water-saturated argon, whereafter a continuous stream of argon was passed over the solutions throughout the measurement.

3. Results and discussion

3.1. Solution behavior of iron(III) aminohydroxamates

Equilibria occurring in aqueous solutions of iron(III) with **1**, **2**, **3**, **4** and **5** have been studied by a spectrophotometric method [17–21]. The species distribution diagrams based on the determined stability constants for iron(III) aminohydroxamates were calculated using the same experimental conditions under which their cyclic voltammetric measurements were performed. These data illustrate that the electrochemical behavior of all complexes was investigated under the conditions where the hexacoordinated iron(III) complex (FeL_3 or FeL_2 for **4**) is the main complex species (98.3–100%) present in solution at pH 7 and an iron(III)/ligand ratio of 1:40. In the pH range studied all the aminohydroxamate complexes investigated have the amino group in its protonated form.

3.2. Electrochemical behavior of iron(III) aminohydroxamates

Electrochemical studies of a solution of iron(III) with $c_M = 1 \times 10^{-3}$ M and excess of ligand ($c_L/c_M = 20$–80) at pH 6–8 were carried out by cyclic voltammetry using a hanging mercury drop electrode. Although the cathodic peaks with their anodic counterparts were observed (Fig. 1), these systems do not display simple redox behavior and a detailed analysis is therefore required. In cyclic voltammograms, one well-defined reversible or quasi-reversible cathodic peak was observed for all of the aminohydroxamate complexes investigated. Free

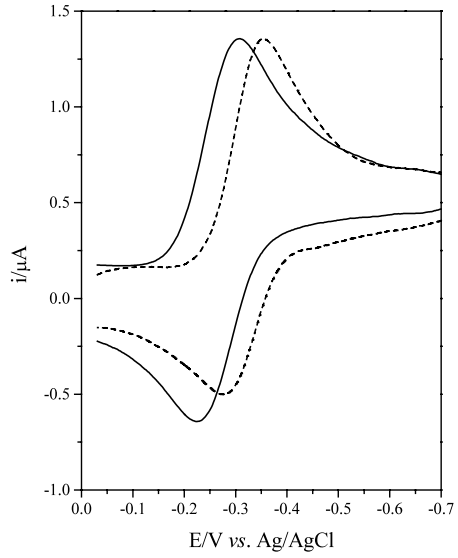

Fig. 1. Cyclic voltammograms of the iron(III) complex with alanine- (solid line) and glutamo-γ-hydroxamic acid (dashed line). Conditions: $c_{Fe} = 1 \times 10^{-3}$ M, $c_L/c_{Fe} = 40{:}1$, 0.05 M NaH_2PO_4, 0.05 M $Na_2B_4O_7$ at pH 7 and 1 M $NaClO_4$, $T = 25.0$ °C; hanging mercury drop electrode at 100 mV s^{-1} scan rate.

ligands are electrochemically inactive in the potential range investigated. The current peak height (i_p^c) is linear with the scan rate, v, and with $v^{1/2}$ for $v < 5$ V s^{-1}, suggesting a diffusion control, although at higher scan rates a weak adsorption of the complexes at the mercury surface was observed. Peak separations $\Delta E_p = E_p^c - E_p^a$ of about 60 mV were noticed in all cases, except for **4**, as expected for a reversible one-electron reduction process (Table 1).

A reduction wave with a typical quasi-reversible pattern was observed for the complex with histidinehydroxamic acid. The values of ΔE_p of about 90 mV were found at low scan rates, but increased up to 120 mV when the scan rate changed from 0.5 to 20 V s^{-1}. The quasi-reversible character of this system was also confirmed by the observation of a cathodic shift of E_p^c of about 30 mV for a tenfold increase in the scan rate. The current function ($i_p^c/v^{1/2}$) is independent of the scan rate and the ratio of anodic to cathodic peak current, i_p^a/i_p^c, is equal to unity, indicating that the iron(II) complex formed in the electro-reduction is stable within the time scale of the experiment.

The reversibility of the systems investigated was checked at a scan rate of 10 mV s^{-1} (Fig. 2). The irreversibility of cathodic current peaks obtained clearly

	5	−346	14.61	0.96	132

Conditions: $c_{Fe} = 1 \times 10^{-3}$ M, $c_L/c_{Fe} = 40{:}1$, 0.05 M NaH_2PO_4, 0.05 M $Na_2B_4O_7$ at pH 7 and 1 M $NaClO_4$, $T = 25.0$ °C; hanging mercury drop electrode.

shows that charge transfer is followed by a homogeneous chemical reaction, except in the case of **4**. Analysis of the effect of scan rates on the voltammograms shows that the values of $i_p^c/v^{1/2}$ are approximately constant with scan rate. On the other hand, a dependence of the reduction potentials on the scan rates was noticed (Table 1), namely E_p^c for all the complexes investigated changes cathodically by about 20–30 mV when the scan rate changes from 0.1 to 1 V s^{-1}. The ratios of i_p^a/i_p^c were changed from 0.52 to 0.98 for scan rates between 0.1 and 1 V s^{-1}. The increase of i_p^a with scan rates is due to the fact that at higher scan rates there is less time for an irreversible chemical reaction. For the iron(III) complexes with **5**, the highest value of i_p^a/i_p^c is about 0.79 when $v = 5$ V s^{-1}, which means that the chemical reaction is fast enough for its influence on anodic peak current to be observed at very high scan rates. All of these electrochemical results suggest a typical EC mechanism, which includes a reversible electrochemical process (E) followed by an irreversible chemical reaction (C) [22].

The reduction potentials in these systems were observed to become more cathodic with increasing pH. The pH dependence on the redox potential can be used to determine the proton stoichiometry of the electrode reaction. For pH values between 6 and 8, a cathodic shift of E_p^c was observed, at an approximate rate of 70 mV per pH unit (Fig. 3). This observation is consistent with protonation of the reduced species, the iron(II) complexes, indicating involvement of one proton and one electron in the redox processes according to Eqs. (1) and (2):

$$Fe(III)L_3 + e^- \Leftrightarrow Fe(II)L_3 \quad (1)$$

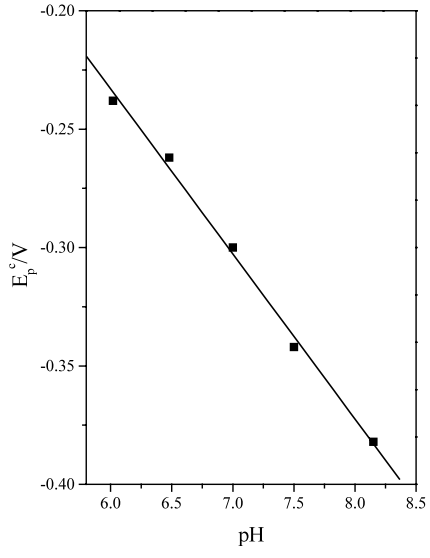

Fig. 3. Cathodic shift of the reduction peak (E_p^c) observed in the cyclic voltammograms of the iron(III) alaninehydoxamate as a function of pH at scan rate $v = 100$ mV s^{-1}. Conditions are as given in Fig. 2.

$$Fe(II)L_3 + H^+ \Rightarrow Fe(II)L_2 + HL \quad (2)$$

Thus, the global mechanisms include an electrochemical step (E), followed by an irreversible chemical dissociation of the reduced complexes.

It is possible to calculate the stability constant of the iron(II) complex from the difference between the peak potentials for the reduction of the $Fe(H_2O)_6^{3+}$ ion and of its complex in a situation where the iron(III) and iron(II) complexes are fully coordinated and no ligand exchange occurs in the reduced form of the complex during the time frame of the experiment [23]. The necessary conditions are an excess of the ligand and a sufficiently high pH. Since it was impossible to find any conditions with complete reversibility for the electrochemical reaction without disturbance by a coupled chemical reaction, no evaluation of the stability constant for the reduced complexes of aminohydoxamate was carried out. However, literature data [12] for the stability constants of the acetohydroxamate iron(II) complexes suggest that the $Fe(II)L_2$ species is highly favored (94.8%) under the same experimental conditions used for the cyclic voltammetric measurements. This may explain why the chemical reaction (eq. 2) is favored despite a high free ligand concentration present in solution.

The rate constants for the irreversible dissociation decomposition of the iron(II) complexes, following the reversible reduction of the iron(III) complexes (eqs 1 and 2) have been determined using the Nicolson and Shain theoretical approach [22]. The pseudo-first order kinetics is assumed because the solutions were buffered, which means that the H^+ concentration was essentially unchanged during the voltammetric measurement. The working curve of i_p^a/i_p^c, as a function of $\log k_d\tau$, was used, where τ is the time in s required to scan from $E_{1/2}$ to the switching potential $E_\chi = -900$ mV. Redox potentials $E_{1/2}$ were determined from cyclic voltammograms by taking an average of the cathodic and anodic peak potentials $[(E_p^c + E_p^a)/2]$. The calculated values k_d were obtained as an average of several single point

Table 2
Scan rate effect on the i_p^a/i_p^c ratio and calculated kinetics parameters for the iron(III) lizinehydroxamate at pH 7, $c_{Fe} = 1 \times 10^{-3}$ M, $c_L/c_{Fe} = 40{:}1$, $T = 25.0$ °C, $I = 1.0$ ($NaClO_4$)

calculations (Table 2), corresponding to the different scan rates in the range 100–900 mV s^{-1}, where adsorption effects were neglected.

3.3. Ligand substituent effects

Electrochemical studies of the iron siderophore and model siderophore complexes reveal a strong influence of the type and the number of metal binding groups on the redox potential, with relatively little influence of the ligand structure, although the latter statement is based on limited data. On the other hand, investigations of the ligand substituent effects on the redox potentials in the substituted benzohydroxamic acid complexes of iron indicate that the more electron donating groups shift the potential to more negative values [24]. In order to determine the effect of the electronic and steric properties of the R substituent in the ligand side chain on the redox potential, different aminohydroxamate ligands were chosen. The presence of other functional groups in the hydroxamic acid molecules, such as amino, hydroxyl or carboxyl ones, offers the possibility of formation of the complex in which they participate as electron pair donors. In spite of these possibilities, the spectrophotometric results show that complexation occurs by coordinating both the carbonyl and OH oxygen atoms of the hydroxamate group to the iron(III) center for all the complexes investigated, except for **4**. Involvement of the amino group and the imidazole ring nitrogen atom in the coordination of histidinehydroxamic acid to iron was detected [25]. The shift in the coordination mode from bi- to tridentate, from O to N atom and from five- to six-membered ring was reflected in a change of the mechanism involved in the electron transfer process. On the other hand, it is reasonable to expect that the participation of nitrogen atoms in the complexation should be reflected more in the difference of the redox potential. A comparison of the reduction peak potentials obtained for the various iron(III) aminohydroxamates is given in Table 3. The reduction potential of **5** is more negative than the potentials of other complexes. This behavior could be explained taking into account that the amino group in the γ-position relative to the carbonyl group has a less pronounced electron withdrawing effect compared with the effect of the NH_3^+ group in an α-position. Complex **1** ($R = CH_3$) has a more positive potential than **2** ($R = CH_2OH$), consistent with the electron donating effect of the hydroxyl group, although their stability constants for the tris complexes are very similar. If the observed difference in the redox potential between the investigated complexes could be explained on the basis of the electronic effect of the substituent on the carbonyl group, the most positive redox potential would be expected for **3**, due to a longer alkyl chain with a positively charged amine terminal group. The obtained results show that this complex has a more negative potential than **1**. However, this observation may be reasonably rationalized by a comparison of the stability constants of these complexes, which indicates that the redox potential was shifted to more negative values as the stability of the complex increased (Table 3). It is obvious that the differences in aminohydroxamate ligands influence the rate constants for irreversible dissociation of the iron(II) complexes, as the ligand increases the stability of the iron(III) complex relative to the corresponding Fe(II) complex. Why complex **3** has a lower k_d value than the complexes with more positive potentials is unclear.

Table 3
Reduction peak potentials, logarithmic equilibrium constants of the iron(III) aminohydroxamate complexes and the rate constants for the irreversible dissociation of the iron(II) complexes

Complex	$E_{1/2}$ (mV)	log K [a]	k_d (s^{-1}) [b]
1	−272	−3.638	0.15(1)
2	−290	−3.628	0.19(2)
3	−300	−2.886	0.05(1)
4	−258		
5	−324	0.653	0.51(3)

Standard deviations are shown in parentheses.
[a] $K = [Fe(III)L_3][H^+]^3/[Fe(III)][HL]^3$.
[b] Conditions: $c_{Fe} = 1 \times 10^{-3}$ M, $c_L/c_{Fe} = 40{:}1$, 0.05 M NaH_2PO_4, 0.05 M $Na_2B_4O_7$ at pH 7 and 1 M $NaClO_4$, $T = 25.0$ °C; hanging mercury drop electrode.

4. Conclusion

Analysis of the reduction potentials shows that the values obtained are much lower than those found for the naturally occurring siderophores, including ferrioxamine B ($E_{1/2} = -0.69$ V vs. the standard Ag/AgCl electrode), which has a positively charged amine side chain as well [10]. The potentials are in the range of potentials for physiological reductants such as NADH [26]. Such electrochemical behavior, namely the easy reduction accompanied by dissociation of the reduced species, gives some support for considering these compounds as potential siderophore models. Furthermore, in all the investigated complexes, except for **4**, the NH_3^+ groups may remain free for eventual hydrogen binding interaction with proteins in the required molecular recognition functions, as proposed by the outer-membrane receptor protein involved in ferrioxamine transport [27].

bonds prevented sensible conclusions being obtained, in particular regarding the Sn–X bonds. In addition to the X-ray data, solution ^{1}H, ^{13}C and ^{119}Sn NMR and far-IR spectral data are presented.

2. Experimental

NMR spectra were run on Bruker 300 and Varian 400 MHz instruments, IR spectra on Nicolet Magna 760 FTIR and Nicolet Fourier-transform spectrometers. Melting points were measured on a Melt-TempII instrument and are uncorrected.

2.1. Synthesis

Compound **1** (X = Neo) [9] was obtained by a published procedure and **1** (X = OSn(Neo)$_3$) was a gift from Dow Chemical Co.

Compound **1** (X = Neo). IR (CsI, cm^{-1}): *v*: 462, 391, 259, 158. [**1**: X = OSn(Neo)$_3$]. IR (CsI, cm^{-1}): *v*: 454, 419, 396, 374, 256, 157.

2.1.1. 1 (X = Cl)

To a solution of **1** (X = OSn(Neo)$_3$) (0.5 mmol) in Et_2O was added aqueous HCl (2 ml of 1.0 M solution). After sonification for 5 min, the organic phase was collected and evaporated. Crystals of **1** (X = Cl) were obtained by slow evaporation from an Et_2O solution; m.p. 117–119 °C; lit. [3] value 117.5–118.5 °C.

IR (CsI, cm^{-1}): *v*: 461, 394, 311(Sn–Cl), 266, 160.

2.1.2. 1 (X = Br)

To a solution of **1** (X = Neo) (2.0 mmol) in $CHCl_3$ was added, dropwise with stirring, a solution of Br_2 (2.0 ml) in $CHCl_3$ at −10 °C. After addition was complete, the temperature was allowed to rise to ambient. Complete reaction occurred after 2 h as shown by the decoloration of the reaction mixture. The solvent was removed under vacuum to leave a solid, which was washed with cold MeOH. Crystals of **1** (X = Br) were obtained by slow evaporation from an Et_2O solution; m.p. 112–113 °C; lit. [3] value 109.5–110 °C.

IR (CsI, cm^{-1}): *v*: 457, 398, 266, 212(Sn–Br), 164.

2.1.3. 1 (X = I)

To a solution of **1** (X = Br) (0.55 mmol) in Me_2CO was added a solution of KI (1.75 mmol) in warm Me_2CO. The reaction mixture was stirred at room temperature (r.t.) for 1 h, filtered and the filtrate evaporated. The residue was extracted with CH_2Cl_2 and the extractions were partially evaporated. Colorless crystals of **1** (X = I) were obtained by further slow evaporation; m.p. 117–118 °C; lit. [3] value 116.5–117.5 °C.

IR (CsI, cm^{-1}): *v*: 454, 396, 268, 172(Sn–I).

2.1.4. 1 (X = F)

Solutions of **1** (X = Br) (0.60 mmol) in Et_2O and NaF (3.66 mmol) in water were mixed. A little decyltrimethylammonium bromide was added and the mixture was sonicated for 10 min. Sodium sulfate was added and the organic phase collected. Slow evaporation of the organic solution gave crystals of **1** (X = F); m.p. 99–100 °C; lit. [3] value 98–100 °C.

IR (CsI, cm^{-1}): *v*: 497(Sn–F), 444, 263, 178.

2.1.5. 1 (X = N_3)

To a solution of **1** (X = Br) (0.25 mmol) in EtOH was added a solution of NaN_3 (2.5 mmol) in warm EtOH. The reaction mixture was stirred at r.t. for 30 min, filtered and the filtrate evaporated. The residue was extracted with Et_2O and the extracts gave colorless crystals of **1** (X = N_3) on slow evaporation; m.p. 98–99.5 °C; lit. [3] value 96–96.5 °C.

IR (CsI, cm^{-1}): *v*: 2069 (N_3), lit. [3] value 2072, 456, 386, 266, 153.

2.1.6. 1 (X = NCS)

To a solution of **1** (X = Br) (0.3 mmol) in Me_2CO was added a solution of KNCS (2.2 mmol) in warm acetone. The reaction mixture was stirred at r.t. for 1 h, filtered and the filtrate evaporated. The residue was extracted with CH_2Cl_2 and the extracts gave colorless crystals of **1** (X = NCS) on slow evaporation; m.p. 98–99.5 °C.

IR (CsI, cm^{-1}): *v*: 2021(NC), 459, 399, 303(Sn–N), 268, 167.

2.1.7. 1 (X = OAc)

Compound **1** (X = OSn(Neo)$_3$] (0.15 mmol) was dissolved in acetic acid (3 ml, 5.2 mmol). The solution was evaporated under vacuum and gently heated to leave a residue of **1** (X = OAc). This was recrystallized from acetic acid; m.p. 85–88 °C; lit. [3] value 86.5–87 °C.

IR (CsI, cm^{-1}): *v*: 1667 (CO) (lit. [3] value 1660), 456, 402, 292, 266, 160.

Selected ^{1}H, ^{13}C and ^{119}Sn NMR spectral data for **1** are displayed in Table 1.

2.2. Crystallography

2.2.1. Data collection

Intensity data for **1** (X = Br, I, N_3 and OAc) were obtained, at 150 K in all cases, by means of the Enraf Nonius KappaCCD area detector diffractometer of the EPSRC's crystallography service at Southampton. The entire process of data collection, cell refinement and data reduction was accomplished by means of the programs DENZO [16] and COLLECT [17]. Correction for absorption by a semi-empirical method based upon the variation in intensity of equivalent reflections was achieved with the program SORTAV [18]. Data for **1**

(X = NCS) were obtained at 297 K with a Bruker SMART 1000 CCD area detector diffractometer. SMART software [19] was used for data collection and the program SAINT [19] for cell refinement and data reduction. A semi-empirical correction for absorption similar to that noted above was applied by means of the program SADABS [19].

2.2.2. Structure solution and refinement

The same procedure was used for all **1**. Structure solutions providing positions for the majority of the non-H atoms were obtained by application of the direct methods procedure of SHELXS-97 [20]. Thereafter difference map calculations to find any missing non-H atoms and completion of the refinement process were carried out with SHELXL-97 [21]. In the final stages of refinement H atoms were placed in calculated positions and refined with a riding model. Further details of the processes of data collection and structure refinement are available in Table 2. The program, ORTEP-3 [22], was used to obtain the Figures.

3. Results and discussion

3.1. General

The syntheses of the various compounds **1** were achieved by bromo-dealkylation of **1** (X = Neo) or by anion exchange using as reagents either **1** (X = Br), with Y^- (Y = F, I, NCS or N_3), or **1** (X = OSn(Neo)$_3$), with HCl or HOAc. Complete anion exchanges were indicated from the physical properties, including NMR and far IR spectra.

3.2. Crystallography

The solid state structures were not merely studied to determine the coordination at tin, but to investigate the conformations and molecular arrangements in **1**, compounds in which there are three relative bulky hydrophobic groups (the neophyl ligands) and a relatively small polar region (the Sn–X fragment).

[a] In all cases, absorption correction was semi-empirical from equivalents and refinement by full-matrix least-squares on F^2.

The crystals used in the crystallography were grown by evaporation of $CHCl_3$ solutions. Unsolvated compounds were obtained for **1** (X = N_3, NCS and OAc), while solvates, [**1**·1/4$CHCl_3$] were isolated for **1** (X = Br and I).

As well as the structures of **1** (X = Br, I, N_3, NCS and OAc), the structure of the previously reported compound **1** (X = Cl) [6] at 150 K is also discussed here. All these molecules are themselves not inconsiderable in size requiring the placement, in the absence of coincident crystallographic and molecular symmetry, of at least 32 non-H atoms per molecule. The situation is further complicated by the fact that the asymmetric unit of **1** (X = N_3) and **1** (X = NCS) contains two complete molecules and that of **1** (X = Br), **1** (X = I) and **1** (X = OAc) no less than four. This has prompted the following labeling convention. The atoms of every neophyl group have been labeled numerically in the same manner (Fig. 1), e.g. in every case C1 is bonded to Sn1 and the methyl and phenyl groups are C3 and C4 and C5 to C10, respectively. There is not, however, complete consistency in the numbering of the atoms of the methyl and phenyl groups in relation to their orientation with respect to the molecule as a whole.

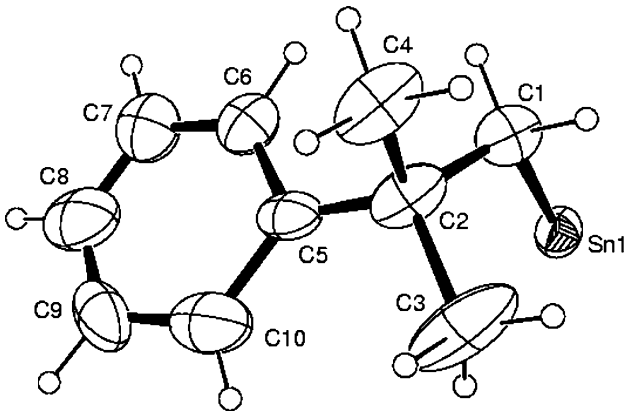

Fig. 1. The general atom numbering scheme used for the carbon atoms of the neophyl groups in **1**, see text. The example shown is the asymmetric unit of **1** (X = Cl) omitting the Cl atom. Non-H atoms are shown as 30% ellipsoids and H atoms as small circles.

For **1** (X = N_3) and **1** (X = NCS), the two independent molecules are termed I and II: in molecule I, the tin atom is Sn1a, the three neophyl ligands/their constituent atoms are identified by the suffices A/a, B/b and C/c, while in molecule II, the tin atom is Sn1b and the suffixes used for the three neophyl groups/atoms are D/d, E/e and F/f. In each of **1** (X = Br), **1** (X = I) and **1** (X = OAc), which have four independent molecules in the asymmetric unit, a similar system is utilized. The four independent molecules are termed I, II, III and IV, having tin atoms Sn1a, Sn1b, Sn1c and Sn1d, respectively. The neophyl group suffices are here A, B and C (in molecule I), D, E and F (in molecule II), G, H and I (in molecule III) and J, K and L (in molecule IV): the atoms within each neophyl ligand take the appropriate lower case suffix. A similar strategy as used for Sn has been applied to the labeling of the halide, X, in molecules of **1** (X = Br) and **1** (X = I). The general numbering of the other X group atoms are (Sn1)–N1–N2–N3 in **1** (X = N_3), and (Sn1)–N1–C11–S1 in **1** (X = NCS) and (Sn1)–O1–C11(O2)–C12 in **1** (X = OAc).

3.2.1. Geometry at tin

Selected bond lengths and angles for **1** (X = Cl, Br, I, N_3 and NCS) are listed in Tables 3 and 4, while selected geometric data for **1** (X = OAc) are provided in Table 5. Molecules of **1** (X = Cl, Br, I, N_3 and NCS) clearly contain four-coordinate tin centers, with distorted tetrahedral geometries. Each independent molecule of each compound **1** (X = Cl, Br, I, N_3 and NCS) has a very similar geometry, with relatively small differences in the C–Sn–X and C–Sn–C bond angles for each X. In each molecule, the three smallest angles subtended at tin are the C–Sn–X angles. The bulk of the neophyl groups results in the opening up of the C–Sn–C angles. The average C–Sn–X angles are 99.67°, 101.6°, 102.5°, 100.6° and 99.7° in **1** (X = Cl, Br, I, N_3 and NCS) and are influenced by both the size of the ligand X and the length of the Sn–X bond. The Sn–X bond lengths, averages for all but **1** (X = Cl), are 2.382(3), 2.545(2), 2.714(8) Å for X = Cl, Br and I, respectively, and are close to the appropriate sums of the covalent radii of 2.39, 2.54 and 2.73 Å [23].

The average Sn–N bond lengths in **1** (X = NCS) and **1** (X = N_3) are 2.119(2) and 2.247(12) Å, respectively, compared with the sum of the covalent radii for Sn and N of 2.15 Å [24]. There are no intermolecular Sn···N contacts in **1** (X = N_3) or Sn···S contacts in **1** (X = NCS) less than 4.0 Å. The closest intermolecular contacts in a particular molecule of **1** (X = NCS) are S···S at 3.6429(16) Å—that is close to the sum of the van der Waals radii. Smaller triorganotin *N*-thiocyanates, such as Me_3SnNCS {Sn–N and Sn–S = 2.15(6) and 3.13(2) Å} [24], Ph_3SnNCS {Sn–N and Sn–S = 2.199(11)–2.248(10), and 2.897(4)–2.952(4) Å} [25,26] and (p-$MeC_6H_4)_3SnNCS$ {Sn–N and Sn–S = 2.195(5) and 3.0255(2) Å} [26], exist in the solid state as zig-zag polymers due to NCS bridging with five-coordinate tin atoms. The more hindered compounds, $Me_2[(PhMe_2Si)_3C]SnNCS$ {Sn–N = 2.12(3) Å} [27] and (o-$MeC_6H_4)_3SnNCS$ {Sn–N = 2.067(6) and 2.066(6) Å} [26], on the other hand, are monomeric in the solid state with four-coordinate tin centers. Compound (o-$MeOC_6H_4)_3SnNCS$ {Sn–N = 2.090(5) Å} [26], is also molecular, but here there is a suggestion of a weak intramolecular Sn–O interaction [Sn–O 2.961(4) Å, ∠ N–Sn–O = 152.19(17)°] and hence an increase in the coordination number at Sn to 5, but this clearly has little effect on the Sn–N bond length.

The Sn–N bond length in monomeric t-Bu_3SnN_3 [28] is a little shorter, at 2.101(4) Å, than those found in **1** (X = N_3). Smaller triorganotin azides, e.g. Me_3SnN_3 [29], are N-bridged in the solid state. The Sn–N bond lengths in [(**1**: X = triazole)·0.5H_2O] [5] are 2.123(6) and 2.105(7) Å.

Compound **1** (X = OAc) was the only trineophyltin compound studied here that was other than four-coordinate, as a result of the acetate group tending to be a bidentate chelating ligand and the tin centers becoming five-coordinate (Fig. 2). As shown by the Sn–O distances, there is a strong asymmetry in the acetate chelate bonding, with one strong and one weak bond: the primary Sn–O1 bond lengths fall in the range 2.070(5)–2.117(4) Å with the Sn–O2 separations between 2.963 and 3.069 Å. These values can be compared with sums of covalent radii and van der Waals radii of 2.15 and 3.70 Å [23]. Noticeably too, the primary C–Sn–O1 angles fall into three distinct groupings, with ranges of 93.84° ± 0.82°, 103.13° ± 1.33° and 107.75° ± 0.55°, see Table 5. The C–Sn–C angles in **1** (X = OAc) also show a slightly greater variation than those in **1** (X = Cl, Br, I, N_3 and NCS). The geometry at tin is best described as being on the pathway from tetrahedral to

Table 3
Selected bond lengths (Å) for **1** (X = Cl, Br, I, N_3 and NCS) [a]

[a] The three Sn—C1(n) bond lengths in each molecule have been placed in order of increasing bond length. The particular C1(n) atom involved in each bond has been indicated by the lower case letter, a, b, c etc., which, as indicated in the text, are associated with neophyl ligands, A, B, C etc.

trigonal bipyramidal, with the carbonyl oxygens, O2, in quasi axial positions and O1 in the quasi equatorial sites. A similar situation of a *cis*-R_3SnO_2 arrangement pertains in **1** (X = O_2CCH_2OPh) [7] and in other hindered triorganotin carboxylates [30]. The most frequently found structural type, however, for unhindered triorganotin carboxylates is a carboxylate bridged polymeric chain with *trans*-R_3SnO_2 cores [31], for example, as found in Me_3SnOAc [32].

3.2.2. The existence of rotamers

In all of the structures discussed here the molecules are propeller shaped (Fig. 3) and as a consequence can, and do, exist in two rotameric forms. In one form (type R), when viewed along the Sn–X bond from X to Sn, the phenyl groups of the neophyl substituents are displaced in a clockwise direction. In the other (type L) the displacement is anticlockwise. In **1** (X = Cl), the example shown in Fig. 3, both forms are present due to the operation of the crystallographic bar4 (fourfold rotary inversion axis) and equivalently the *d*-glide of the cubic space group *I*-43*d* and the structure is racemic. It is, however, polar because the space group lacks a center of symmetry and the bar4 creates a molecular arrangement with the overall symmetry of a regular tetrahedron whose orientation relative to the unitcell edges can differ from one crystal to another. The structures of **1** (X = N_3) and **1** (X = NCS), being centrosymmetric, are of course racemic and non-polar. By accident of choice in both cases both molecules of the bimolecular asym-

[a] Distance and angle table for bidentate acetate anion comprising carboxyl O1, O2 and C11 and methyl group C12 which creates a trigonal bipyramidal coordination around Sn1 with equatorial O1, C1 and C2 (Sn1—C1 ⇐ Sn1—C2) and axial O2 and C3.

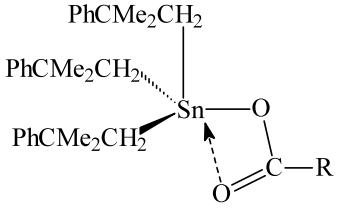

Fig. 2. Trineophyltin carboxylates (**1**: X = OAc or O_2CCH_2COPh).

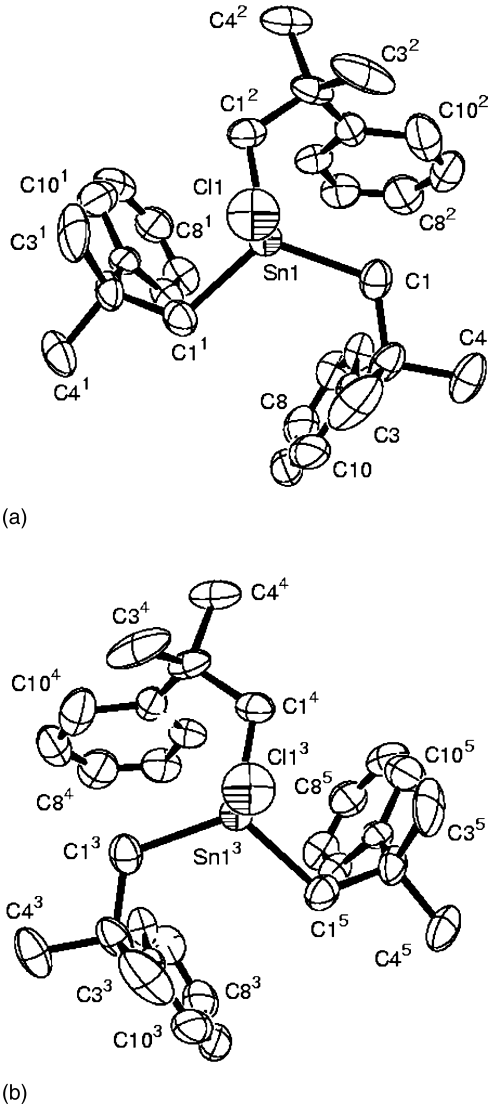

Fig. 3. Two molecules of **1** (X = Cl) displaying (a) the 'clockwise' type R rotamer and (b) the 'anticlockwise' type L rotamer. Non-H are shown as 30% ellipsoids and H have been omitted for clarity. Selected atoms are labeled with symmetry codes for (a) 1: z, x, y; 2: y, z, x and (b) 3: $1/4+x, 1/4+z, 1/4+y$; 4: $1/4+y, 1/4+x, 1/4+z$ and 5: $1/4+z, 1/4+y, 1/4+x$.

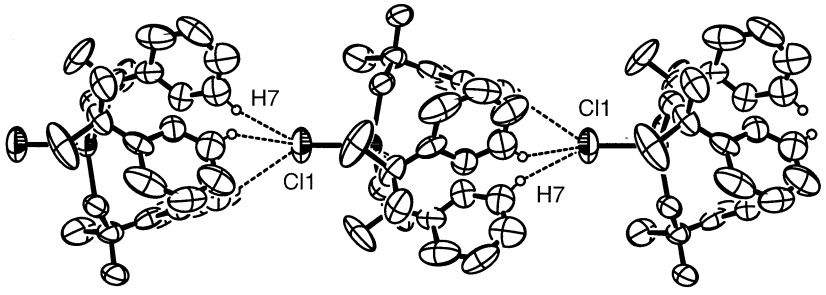

Fig. 4. A portion of a linear chain of head to tail molecules, as indicated by PLATON [39] of **1** (X = Cl) propagated in the direction of a diagonal of the cubic unitcell [111]. Non-H are shown as 30% ellipsoids and H7, involved in C—H···Cl intermolecular contacts (dashed lines), is the only H shown. The molecules in the portion of the chain shown alternate in terms of rotameric type as R at the extremes and L in the center. The parameters associated with the C7—H7···Cl contacts are C—H, H···Cl and C···Cl 0.95, 2.79 and 3.622(8) Å, respectively, and C—H···Cl 146.47°.

metric unit are of the same hand but of type L for **1** (X = N_3) and type R for **1** (X = NCS). In each of **1** (X = Br), **1** (X = I) and **1** (X = OAc) all of the molecules in the asymmetric unit are of the same hand, type R for **1** (X = Br) and isostructural **1** (X = I) and type L for **1** (X = OAc). Since all of these last three structures lack a center of symmetry or any other form of crystallographic symmetry element to bring about inversion of molecular symmetry, all of the molecules in a particular crystal must then be of the same hand. However, since there is no element of handedness in the synthesis of the compounds, and no evidence of disorder, a bulk sample of any one of them must contain crystals of one hand in admixture with crystals of the other in equal parts by volume which allows for variation in crystal size.

3.2.3. Molecular packing

With one slight exception, all of the compounds have entirely molecular structures with only van der Waals forces controlling the packing of the molecules and three situations arise. The first is the exception namely **1** (X = Cl). Here the molecules, with crystallographic threefold axial symmetry, are packed head to tail in rigorously linear rows (Fig. 4). This arrangement permits weak H-bond like intermolecular contacts of the form C7–H7···Cl′ with, for the 150 K structure [6] (CSD ref. code FOZRER) [33], symmetry code $5/4-y$, $3/4-x$, $z-1/4$ and C–H, H···Cl and C···Cl 0.95, 2.79 and 3.622(8) Å, respectively, and C–H···Cl 146.47°. The second case is that of **1** (X = OAc) in which the molecules can be perceived as forming layers parallel to (001) with molecules II and III forming one layer centered approximately on $z = 0.15$ and molecules I and IV forming the other centered on $z = 0.65$ (Fig. 5). The third and last case applies to all of the other structures. The molecules are now found in columns in which all of the molecules are the same (all molecule I or all molecule II etc. but never mixed) and all of the same rotameric type (R or L, see above) because each molecule is related to the next by the operation of a crystallographic twofold screw axis propagating the columns in the direction of *b* (Fig. 6).

In all of **1** (X = Br, I, N_3 and NCS), four such columns pass through the unit cell and in **1** (X = Br) and **1** (X = I) all of the molecules in all of the columns are of the same type and, as it happens, of type R. In centrosymmetric and therefore racemic **1** (X = N_3) and **1** (X = NCS), however, it is the all-molecule I or all-molecule II columns which are related in pairs by the crystallographic centers of symmetry and hence there is still no mixture of R and L type molecules within a single column. The chloroform solvate molecules of **1** (X = Br) and **1** (X = I), simply occupy cavities between the columns.

3.3. Spectroscopy

NMR spectral data obtained for **1** in this study were in agreement with those reported in the literature. In the humid atmosphere of Rio de Janeiro, **1** [X = OSn(Neo)$_3$] in solution was rapidly hydrolyzed to **1** (X = OH), as shown by the δ^{119}Sn value 77.1 ppm, obtained after several minutes in solution. Lockhart [12] reported values of 54.8 and 75.9 ppm for **1** (X = OSn(Neo)$_3$) and **1** (X = OH), respectively, in $CDCl_3$ solution. The

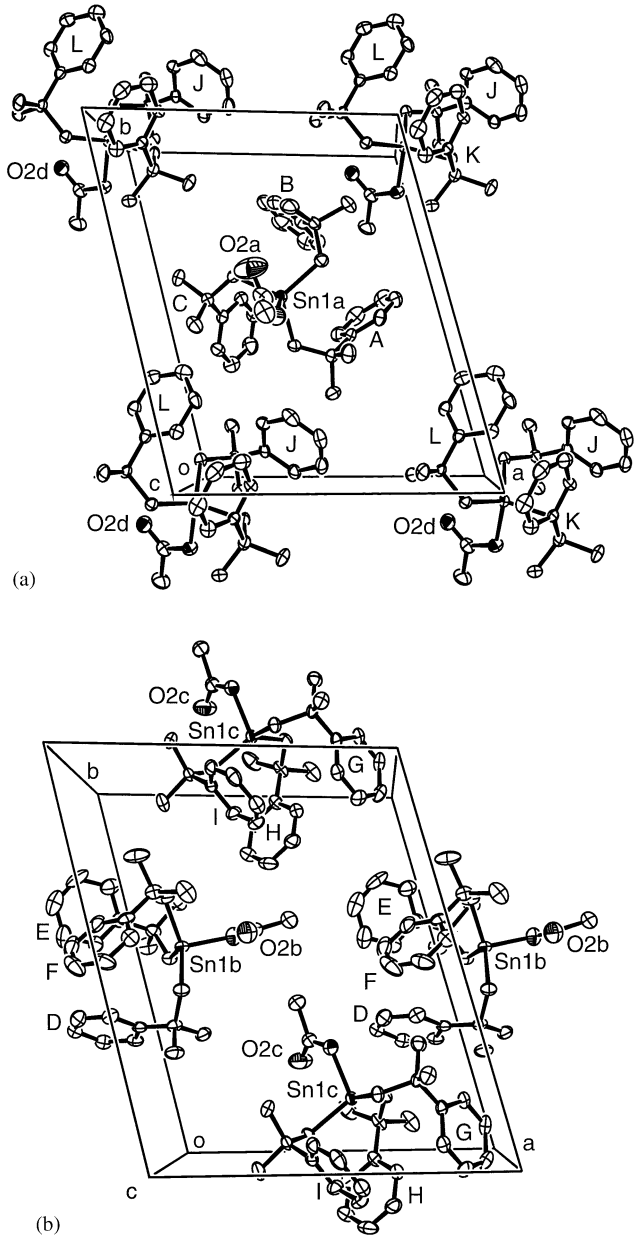

Fig. 5. Molecules of **1** (X = OAc) in layers parallel to (001) comprising (a) molecules I and IV in a layer centered on $z = 0.65$ and (b) molecules II and III in a layer centered on $z = 0.15$. Non-H are shown as 50% ellipsoids and H have been omitted for clarity. Labels on selected Sn and O and group suffices (see text) identify the molecules and neophyl groups.

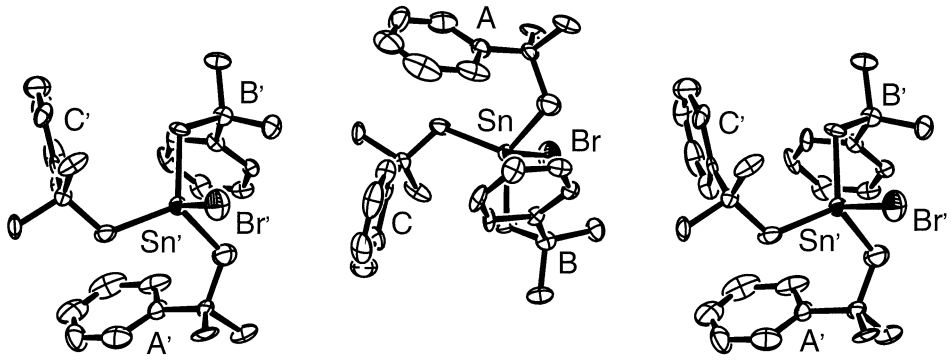

Fig. 6. A portion of a chain of molecules I in **1** (X = Br) propagated in the direction of b. Non-H atoms are shown as 50% ellipsoids and H have been omitted for clarity. In addition to labeled Sn and Br atoms, neophyl groups are identified by group suffices, A, B and C. Symmetry codes for primed atoms: $-x, y+1/2, 1-z$ (left) and $-x, y-1/2, 1-z$ (right).

product isolated from solutions, however, was always **1** [X = OSn(Neo)$_3$]. Lockhart also indicated similar effects [12].

Triorganotin chlorides, bromides and iodides, R_3SnX (R = unfunctionalised organyl group; X = Cl, Br or I), are generally monomeric four-coordinate species in non-coordinating solvents and in the solid state [34]. Hence there are much data available on spectral parameters for such species in solution. On the other hand, R_3SnF, except the most hindered compounds, such as (2.4,6-$Me_3C_6H_2)_3SnF$ [35], $Ph_2[(Me_3Si)_3C]SnF$ [36], $Me_2[(PhMe_2Si)_3C]SnF$ [36] and **1** (X = F), are aggregated species in the solid state and are poorly soluble in organic solvents. Reported NMR data for triorganotin fluorides in solution are thus limited. The $^1J(^{119}Sn-^{19}F)$ value for **1** (X = F) = 2301 ppm in $CDCl_3$ solution is similar to the reported values for other monomeric R_3SnF compounds, $Ph_2[(Me_3Si)_3C]SnF$, $Me_2[(PhMe_2Si)_3C]SnF$ and $Me_2[(Me_3Si)_3C]SnF$ [24] [$^1J(^{119}Sn-^{19}F) = 2376$, 2374 and 2463 ppm, respectively]. The $\delta^{119}Sn$ values for the monomeric trialkyltin fluorides are also similar: $\delta^{119}Sn$ values for **1** (X = F), $Me_2[(PhMe_2Si)_3C]SnF$ and $Me_2[(Me_3Si)_3C]SnF$ are 138.8, 124.5 and 146.9 ppm, respectively. The $^1J(^{119}Sn-^{14}N)$ values in **1** (X = NCS) and $Me_2[(PhMe_2Si)_3C]SnNCS$ [27] are very close, 125 and 123 Hz, respectively, and are appreciably greater than those [90 ± 4 Hz] quoted for (o-$MeC_6H_4)_3SnNCS$ and (o-$MeOC_6H_4)_3SnNCS$ [26]. The $\nu(NC) = 2021$ cm^{-1} value in **1** (X = NCS) is lower than quoted values for four-coordinate triorganotin *N*-thiocyanates, e.g. $Me_2[(PhMe_2Si)_3C]SnNCS$ {2066 cm^{-1}} [27] and (o-$MeC_6H_4)_3SnNCS$ {2045 cm^{-1}} [26].

Values of ν(Sn–X) in simple R_3SnX (e.g. R = Me, Et, Bu, Ph) are generally in the regions: 170–210 (X = I), 220–265 (X = Br), and 325–385 cm^{-1} (X = Cl), irrespective of phase [37], whereas values for R_3SnF depend on the phase, due to differences in aggregation. Gas phase values for R_3SnF (e.g. R = Me, Et, Bu, Ph) (i.e. for monomeric species) have been reported to be in the range 555–590 cm^{-1}, while values for the aggregated species as solids are quoted as 340–380 cm^{-1} [37]. The ν(Sn–X) values for **1** (X = Cl, Br or I) in CsI, viz. 311, 212 and 172 cm^{-1} respectively, fall in the expected regions. The ν(Sn–F) value [497 cm^{-1}] in molecular **1** (X = F) can be compared with the values, 535 and 537 cm^{-1}, found in (2.4,6-$Me_3C_6H_2)_3SnF$ [35] and (o-$MeOC_6H_4)_3SnF$ [38], respectively, both shown by X-ray crystallography to be monomeric. The latter compound, just like (o-$MeOC_6H_4)_3SnNCS$ [26], has indications of S–O intramolecular interaction and hence a higher coordination.

4. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Center, CCDC numbers 178628–178632 for compounds (**1**: X = Br, I, N_3, NCS and OAc), respectively. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk).

enthalpy of sublimation of 1 mol of adduct is equal to the enthalpy of sublimation of one mol of the ligand [1]. So it was assumed that the intermolecular forces in the adduct and ligand should be very similar since the crystalline structure of the ligand complex remains virtually unchanged in the gaseous phase. Such hypothesis was confirmed by experimental results, since the obtained enthalpy values exhibited a variation [4] within ± 10 kJ mol^{-1}.

The purpose of this paper is to report the non-isothermal kinetic thermogravimetric study for the adducts $ZnX_2 \cdot 2hmpa(c)$ (X = Cl, Br, I and hmpa = hexamethylphosphoramide), as well as showing that some thermochemical parameters normally measured or calculated by using reaction-solution calorimetry data, can also be estimated from thermogravimetric or spectroscopic (IR) data. So, a series of empirical correlations involving calorimetric, t.g. and IR data are established.

2. Experimental

The adducts of the general formula $ZnX_2 \cdot 2hmpa$ (X = Br and I; hmpa = hexamethylphosphoramide) were prepared as previously described [5]. A slight excess of the ligand in relation to the desired stoichiometry was added to the metal halide solution in light petroleum ether. The resulting solution was stirred and warmed to 60 °C to allow the complete dissolution of the salt. Upon cooling, the adduct started to settle and the solid was filtered off, washed with ether and dried in vacuum.

The adduct $ZnCl_2 \cdot 2hmpa$ was obtained by the direct dissolution of a stoichiometric amount of the metal halide in pure ligand. The product was washed with double distilled water and dried under vacuum at 30 °C for 10 h.

The elemental analysis was performed on a Perkin–Elmer CHN analyzer. The IR spectra were obtained on a Bomem spectrophotometer in KBr discs. The thermogravimetric curves were obtained on a DuPont apparatus, model 1090B, under argon atmosphere, with a heating rate of 5 °C min^{-1}. The scanning differential calorimetric (DSC) curves were obtained under the same conditions, by using DuPont 2000 equipment.

The kinetic parameters for the thermal degradation of the three adducts were calculated through the Coats–Redfern method [6], employing the data collected in the non-isothermal thermogravimetric curves.

3. Results and discussion

3.1. Solution calorimetry, t.g. and d.s.c data

The obtained IR results are in agreement with a coordination involving the P=O group of the hmpa molecule [5]. The thermogravimetric curves for the three synthesized adducts are shown in Fig. 1. All calculated kinetic parameters obtained through the Coats–Redfern method [6] are listed in Table 1.

The profile of the thermogravimetric curves of these adducts clearly showed that the thermal stability of the

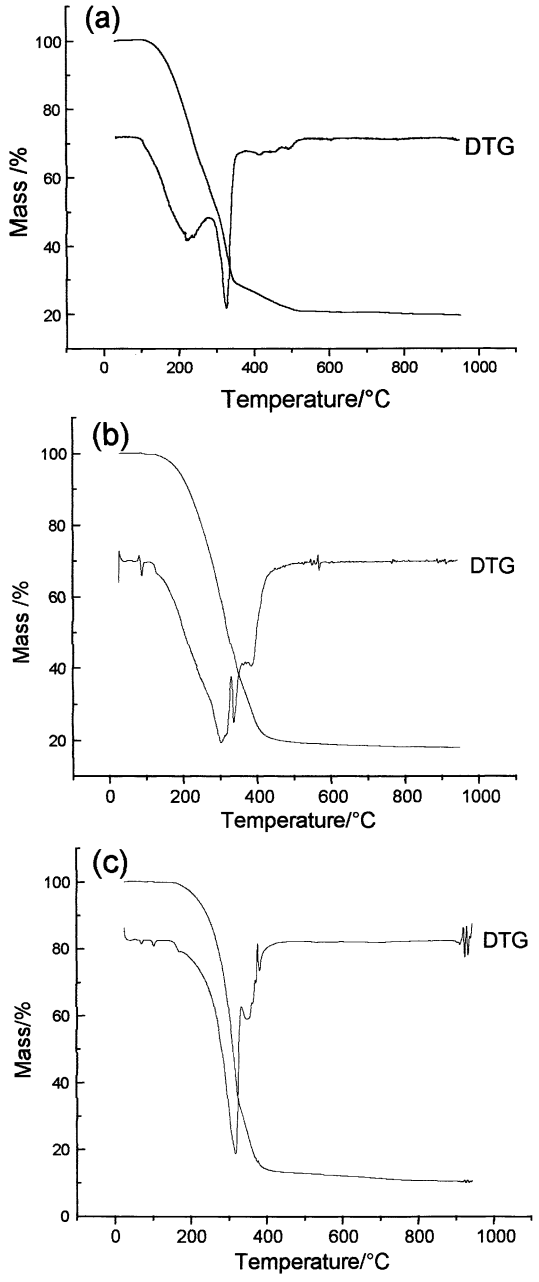

Fig. 1. Thermogravimetric curves for the adducts $ZnX_2 \cdot 2hmpa$: X = chloride (a), bromide (b) and iodide (c).

Table 1
Kinetic parameters calculated through Coats–Redfern method for the non-isothermal degradation of the adducts $ZnX_2 \cdot 2hmpa$

$ZnX_2 \cdot 2hmpa$	E_a (kJ mol^{-1})	A	n
Cl	44	3.1×10^3	1
Br	94	6.6×10^6	1
I	215	4.4×10^{23}	1

E_a is the activation energy, A is the frequency or pre-exponential factor and n is the order of reaction.

compounds decreased in the order: Cl < Br < I. This is the same sequence found for the activation energy (E_a) values for the corresponding thermal degradation processes: $ZnX_2 \cdot 2hmpa(c) \rightarrow ZnX_2(c) + 2hmpa(g)$.

Based on the collected data, the ratio between t_i, the Kelvin temperature of the beginning of the thermal degradation, and the corresponding E_a values listed in Table 1, gives: 387/44 = 2.63 395/94 = 4.20 and 440/215 = 8.80. These data can be summarized by the empirical equation: t_i (K)/E_a (kJ mol^{-1}) $\cong 2^b$, which exponential value ranges from 1 to 3. A plot of E_a values as function of t_i is shown in Fig. 2. As can be observed, a straight line is obtained with a coefficient of correlation of 0.99, providing the empirical equation:

$$E_a = 3.043 \times t_i - 1122.130 \quad (1)$$

The standard molar enthalpy of formation of the considered adducts in the condensed phase presented the following values: −1596, −1532 and −1408 kJ mol^{-1} for chloride, bromide and iodide [5], respectively. By plotting this sequence of values as function of the E_a values, again a straight line was obtained as shown in Fig. 3. Then, a new empirical equation was established as:

$$\Delta_f H^\circ_m = 1.086 \times E_a - 1639.738 \quad (2)$$

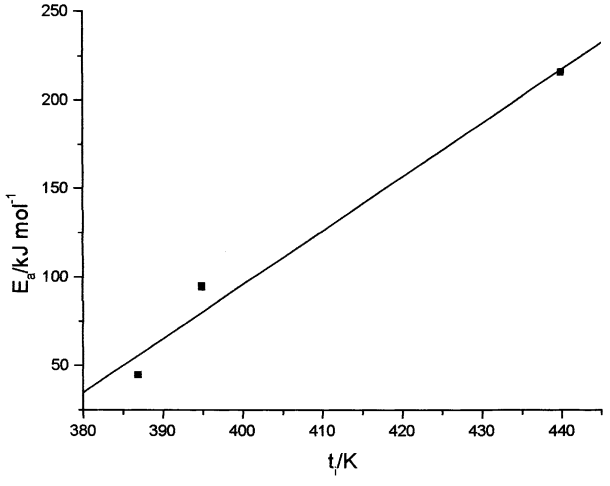

Fig. 2. Activation energy values (E_a kJ mol^{-1}) as a function of the Kelvin temperature for the beginning of the thermal degradation (t_i K), for the $ZnX_2 \cdot 2hmpa$ adducts.

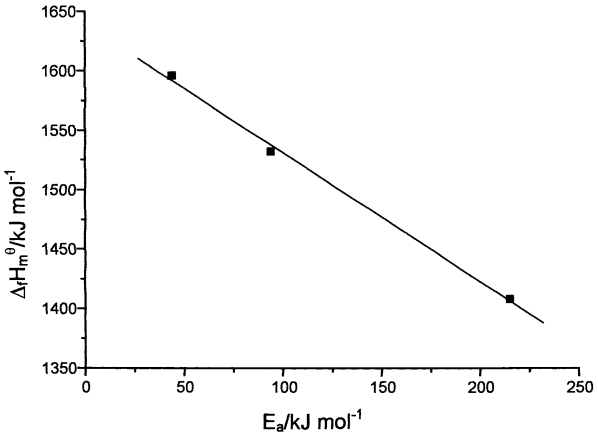

Fig. 3. Standard molar enthalpy of formation ($\Delta_f H^\circ_m$ kJ mol^{-1}) as function of the activation energy for the thermal degradation process (E_a kJ mol^{-1}), for $ZnX_2 \cdot 2hmpa$ adducts.

This obtained equation opens the possibility of estimates for an enthalpic value, which is normally obtained from calorimetric measurements, by using a simple kinetic parameter derived from thermogravimetric data.

The order of reaction 'n' obtained for the thermal degradation processes gives a unity value for these three adducts, as listed in Table 1. Such a fact suggests a similar behavior for the adducts on heating, which implies a certain degree of isomorphism [7]. The temperatures of fusion, t_{fus}, determinated by DSC analysis gave the values 108, 125 and 166 °C for the chloride, bromide and iodide adducts, respectively. The increase in melting temperature values suggests an enhancement of the intermolecular interactions of the adducts from chloride to iodide. This sequence is in agreement with t_i as well as E_a values. The relationship t_i/t_{fus} is almost constant and near to unity for the three adducts: 1.02, 0.99 and 1.00 for Cl, Br and I adducts, respectively.

The lattice enthalpy ($\Delta_M H^\circ_m$) for the adducts, associated with the process: $ZnX_2 \cdot 2hmpa(c) \rightarrow ZnX_2(g) + 2hmpa(g)$, was calculated to give [5] 375; 380 and 365 kJ mol^{-1}, for Cl, Br and I, respectively. These values enabled the acquisition of an interesting empirical equation related to melting temperature, t_{fus}. As observed for dimethylethyleneurea adducts [8], the lattice enthalpy values are adjusted to the empirical equation [9]:

$$\Delta_M H^\circ_m = 0.11 \times M \times \Delta^1_{cr} H^\circ_m (t_{fus}) \quad (3)$$

where M is the molar mass of the ligand and $\Delta^1_{cr} H^\circ_m (t_{fus})$ is the enthalpy of melting of these adducts, at the melting temperature, as determined by DSC data, whose values are 18.90, 19.52 and 16.46 kJ mol^{-1}, for chloride, bromide and iodide adducts, respectively.

3.2. Themochemistry and IR spectroscopy

From the point of view of coordination chemistry, the nature of the donor atom on the ligand molecule as well as the number of ligands involved in bond formation are associated to important features related with the mean metal–ligand bond enthalpy, ⟨D⟩(M–L) [4,10,11].

To establish an equation relating thermochemical and IR data, only adducts of zinc halides with two ligands, which are generally tetrahedral, were chosen. The selected adducts of zinc halides are those with urea (u) [12], methylurea (mu) [13], dimethylurea (dmu) [14], dimethylformamide (dmf) [15] tetramethylurea (tmu) [16], dimethylacetamide (dma) [17], dimethylethyleneurea (dmeu) [8], ε-caprolactam (cl) [18], γ-butyrolactam (bul) [19] and hexamethylphosphoramide (hmpa) [5]. In these adducts, all ligands coordinate through oxygen, and so C=O or P=O stretching frequencies of such ligands decrease upon coordination [1–5,7–19]. For this series of adducts, it is observed that the mean zinc–oxygen bond enthalpy ⟨D⟩(Zn–O) is correlated to the variation (decrease) in the stretching frequency $\Delta\nu$, of the C=O or P=O groups (free ligand-coordinated ligand). Based on this fact, the following empirical equation is proposed:

$$\langle D\rangle(Zn\text{–}O) = \alpha + \beta + \Delta\nu \quad (4)$$

where α and β represent the acidic and basic contributions associated with metal halide and ligand, respectively.

The decrease in α values from chloride to iodide, as shown in Table 2, is followed by the tendency in increasing the anionic radii, which also imply an enhancement of their polarizability. On the other hand, β values comprise the donor ability as well as the steric effect of the molecule of the ligand. For example, by considering a sequence of similar ligands, an increase in β values occurred from urea to methyurea, giving 73 and 92, respectively. However, these values decrease progressively from methyl- to tetramethylurea, which has a value of 27. This behavior can be explained taking into account the positive inductive effect of the methyl groups (increased basicity of the donor atom) as well as their effect from the point of view of steric hindrance (larger metal–ligand bond lengths). So, the β values reflects the basicity as well as volume of the ligand molecule.

The α and β values shown in Table 2 were established as follows: the $\Delta\nu$ experimental values for adducts with zinc halides and dmf [15] were chosen and a value of 25 was attributed for α, associated with $ZnCl_2$. From this value, α values for $ZnBr_2$ and ZnI_2 were also calculated as well as β for the same ligand. Afterwards, using the experimental data from adducts of $ZnCl_2$ and the other ligands, a complete series of β values were established.

The second step is dedicated to the application of the proposed equation by using the parameters shown in Table 2 for the adducts $ZnX_2{\cdot}2L$ (X = Br, I and L = u, mu, dmu, tmu, dma, dmeu, cl, bul, hmpa). The collected results obtained are listed in Table 3, where the thermochemical (calorimetric) and IR ⟨D⟩(Zn–O) values are compared.

The results derived from IR data shows a relatively good agreement with the thermochemical data. To evaluate how good the IR results are, one needs to bear in mind that: (a) thermochemical data for ⟨D⟩(M–O) are obtained from $\Delta_g H^\circ_m$ values. In that case, the adduct must be found in the gaseous phase, whereas $\Delta\nu$ values are calculated from infrared spectra obtained for solid adducts; (b) α and β values for metal halides and ligands were obtained from ⟨D⟩(M–O) thermochemical data, which were calculated considering that the enthalpy of sublimation for adducts is equal to the enthalpy of sublimation for the respective ligands. Such a hypothesis is based on a series of sublimable adducts, and could not be true for all adducts; (c) $\Delta\nu$

$ZnBr_2{\cdot}2dmeu$	137	137	0.0

[a] Δ% = (infrared − thermochemical) × 100.

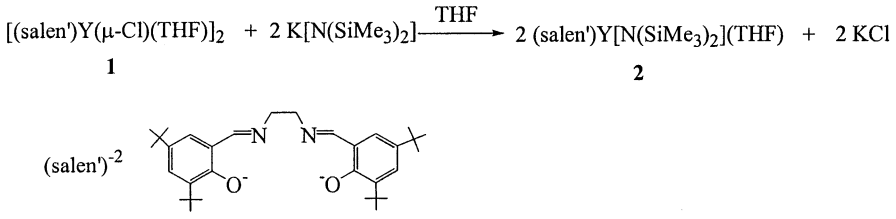
were assumed to contain only C=O or P=O stretching vibrational modes. In reality, there are other components included in such vibrational modes [20,21] that could not be completely considered and are, of course, different for each ligand molecule. Nevertheless, taking into account all these facts, the results obtained may be considered quite good.

For adducts of zinc halides with dmf [15] the metal–ligand stretching frequency values, ν(M–L) are available in the range from 412 to 420 cm^{-1}. From these values an empirical correlation was also established. Then, the relationship between ν(M–L) and $\langle D\rangle$(Zn–O) values was obtained and the results are presented in Table 4.

The ratio involving ν(M–L)/$\langle D\rangle$(M–L) increases from chloride to iodide, reflecting the increase of the anion radii. Another observation related to these values comes from the fact that the considered ratio is nearly equal to $n+1$, where n is the number of ligands.

These series of data open the possibility of estimating $\langle D\rangle$(M–O) values by using IR results, establishing an exciting connection between spectroscopy and calorimetry.

4. Conclusion



The obtained experimental results lead to the establishment of a series of empirical equations relating calorimetric, thermogravimetric and IR data. The very simple observed empirical relations could be explored to achieve a most profound knowledge of the physical and chemical behavior of adducts. These kinds of correlations were not restricted to zinc adducts, since they were also observed for copper and cobalt adducts with cyclic amides [22,23] or amino acids [24].

Table 4
ν(Zn–L)/$\langle D\rangle$(Zn–L) values for $ZnX_2\cdot$ndmf adducts

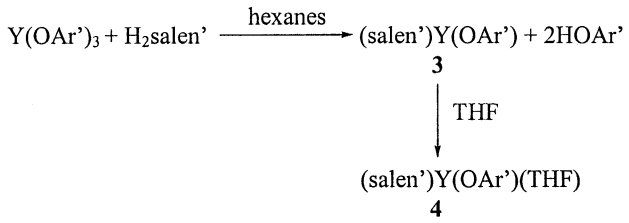
Scheme 1.

salen′. Complexometric analysis was consistent with the formula (salen′)Y[N(SiMe$_3$)$_2$](THF), **2**.



2.2. Synthesis of [(salen′)Y(OC$_6$H$_3^t$Bu$_2$-2,6)], 3, and [(salen′)Y(OC$_6$H$_3^t$Bu$_2$-2,6)] (THF), 4

The synthesis of an aryloxide complex from **1** was subsequently attempted since it had been reported previously that (salen′)Y(OC$_6$H$_3^t$Bu$_2$-2,6)](THF) could be made [7]. Ionic metathesis of **1** with LiOAr′ (OAr′ = OC$_6$H$_3^t$Bu$_2$-2,6) did not produce a pure aryloxide by ^{1}H NMR spectroscopy. Instead, the ^{1}H NMR spectrum of the product was complicated and suggested that multiple products had formed.

However, reaction of Y(OAr′)$_3$ [15] and H$_2$salen′ in hexanes precipitated a yellow solid that had a simple NMR spectrum consistent with (salen′)Y(OAr′), **3**. Complex **3** displayed high solubility in coordinating solvents, such as THF, and was moderately soluble in benzene and toluene, but had only limited solubility in alkanes. Attempts to crystallize **3** in a non-coordinating medium were unsuccessful. However, when **3** is concentrated in a 50/50 mixture of toluene–THF and cooled to −35 °C, yellow crystals are obtained which were analyzed by X-ray crystallography and determined to be the THF adduct (salen′)Y(OAr′)(THF), **4** (Scheme 2, Fig. 1). As expected [7], **2** could be transformed quantitatively to **4** by reaction with HOAr′ in THF, Scheme 3.

2.3. Synthesis of (salen′)Y(hfac)(THF)$_2$, 5

Although **3** was not easily synthesized by ionic metathesis, this synthetic approach did succeed with the chelating oxygen donor ligand hexafluoroacetylacetonate (hfac). **1** reacts with Na(hfac) to form a yellow solution and a white precipitate according to Scheme 4.

Scheme 2.

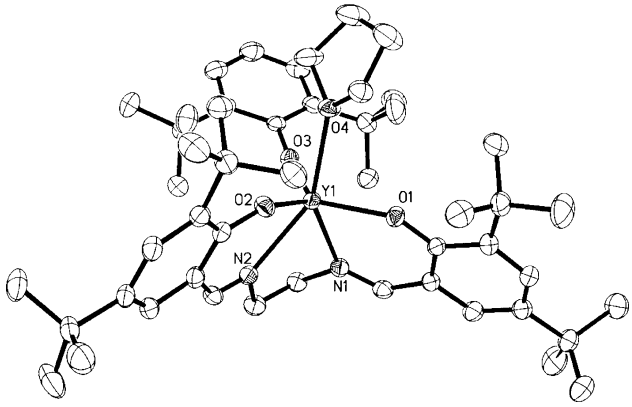


Fig. 1. Thermal ellipsoid plot of [(salen′)Y(OC$_6$H$_3$Bu$_2^t$-2,6)(THF)], **4**, drawn at the 50% probability level with hydrogen atoms omitted for clarity.

The yellow product had a ^{1}H NMR spectrum consistent with the formula (salen′)Y(hfac)(THF)$_2$, **5**, and the IR spectrum contained two strong absorbances at 1660 and 1613 cm^{-1} attributable to [C=O]$_{hfac}$ and [C=N]$'_{salen}$. X-ray diffraction confirmed the identity of this product as (salen′)Y(hfac)(THF)$_2$, **5**, Fig. 2.

2.4. Synthesis of organoyttrium salen′ complexes

In attempt to isolate an organometallic complex of the salen′ yitrium system, the reaction of **1** and KC$_5$Me$_5$ was examined. (salen′)Y(C$_5$Me$_5$), **6** could be isolated in good yields (Scheme 5) and was fully characterized by NMR, IR and X-ray diffraction (Fig. 3). In contrast, when **1** reacts with simple lithium alkyls, LiR (R = Me, CH$_2$SiMe$_3$, CH(SiMe$_3$)$_2$), in toluene at −78 °C, a mixture is indicated by the complicated ^{1}H NMR spectrum. These mixtures could result from attack of the alkyl on the imine portion of the salen′ ligand as has been reported to occur in Group IV systems [16,17]. The susceptibility of the imine bonds to nucleophilic attack could be further enhanced by coordination to the highly electropositive metal.

2.5. Structural comparison of yttrium–salen′ complexes

The Y–O(salen′) distances in **4**, **5**, and **6** range from 2.141(2) to 2.240(2) Å while the Y–N(salen′) interactions range from 2.392(3) to 2.559(3) Å (Table 1). These

$$\underset{\mathbf{2}}{\text{(salen')Y[N(SiMe}_3)_2\text{](THF)}} + \text{HOAr'} \xrightarrow{\text{THF}} \underset{\mathbf{4}}{\text{(salen')Y(OAr')(THF)}} + \text{HN(SiMe}_3)_2$$

Scheme 3.

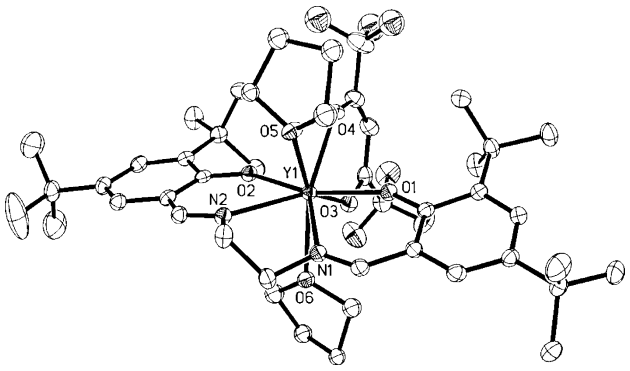

Fig. 2. Thermal ellipsoid plot of (salen′)Y(hfac)(THF)$_2$, **5**, drawn at the 50% probability level with hydrogen atoms omitted for clarity.

distances are consistent with Ln–O and Ln–N salen′ distances in other reported Schiff base complexes when metal sizes are taken in consideration [20] (Ln–O and Ln–N): [(salen′)Y(μ-Cl)(THF)]$_2$ [14], 2.143(2) and 2.492(3) Å; (salen′)Y[N(SiMe$_2$H)$_2$](THF) [7], 2.16 and 2.27 Å; [(*N*-(2,4,6-trimethylphenyl)salicylideneimine)$_2$La(μ-Cl)(THF)] [10], 2.295(11) and 2.659(16) Å; [(*trans*-(±)-*N*,*N*′-bis(salicylidene)-1,2-cyclohexanediamine)Sm(C$_5$H$_5$)]$_2$(μ-THF)(THF)$_2$ [9], 2.30(6) and 2.56(5) Å.

The salen′ moieties in complexes **4**–**6** adopt bent geometries about the yitrium metal center as measured by the dihedral angle between the two phenyl rings. The aryloxide, **4**, which has the largest deviation from planarity, 60.2°, is followed by the pentamethylcyclopentadienyl, complex **6**, with a 44° angle, and the hfac complex, **5**, with a 17° angle. These angles show that the salen′ ethylene backbone is flexible and is able to adopt a preferred orientation with respect to the steric bulk of the second ligand in the complex, i.e. the alkoxide, hfac, or cyclopentadienyl group.

The 2.128(2) Å Y–O(OAr′) distance in **4**, the 2.383(2) and 2.404(2) Å Y–O(hfac) distances in **5**, and the 2.372 Å Y-(C$_5$Me$_5$ ring centroid) length in **6** are similar to analogous bond lengths in other yttrium complexes containing these groups: e.g. 2.096(4) Å, Y–O(OAr′) in (C$_5$Me$_5$)Y(OC$_6$H$_3^t$Bu$_2$-2,6)$_2$ [18]; 2.283(7) and 2.322(6) Å, Y–O(hfac) in [(triglyme)Y(hfac)$_2$]$^+$ [19]; and 2.381 Å, Y-(C$_5$Me$_5$ ring centroid) in (C$_5$Me$_5$)$_2$YCl(THF) [20]. These comparisons suggest that salen′ can provide coordination equivalent to that of (C$_5$Me$_5$)(OC$_6$H$_3^t$Bu$_2$-2,6), (hfac)(triglyme), or (C$_5$Me$_5$)Cl(THF).

3. Conclusion

These studies have shown that the readily obtainable chloride, [(salen′)Y(μ-Cl)(THF)]$_2$ and ionic metathesis reactions are synthetically useful in making yttrium complexes ligated by salen′. Reactions of **1** with KN(SiMe$_3$)$_2$, Na(hfac), and KC$_5$Me$_5$ all form the corresponding products in high yields. Although the chemistry of salen′ as an ancillary ligand is promising, it contains a reactive imine functional group that is prone to nucleophilic attack. This can interfere with the isolation of complexes of reactive alkyl and hydride groups.

4. Experimental

The chemistry described below was performed under nitrogen with rigorous exclusion of air and water by Schlenk, vacuum line, and glovebox techniques. Solvents were purified by distillation over sodium or potassium benzophenone ketyl. KN(SiMe$_3$)$_2$ was purchased from Aldrich and used as received. [(salen′)Y(μ-Cl)(THF)]$_2$ [14] and Y[(OC$_6$H$_3$Bu$_2^t$-2,6)$_2$]$_3$ [15] were prepared by literature methods. NMR spectra were recorded using a Bruker DRX400 or a General Electric GE500 spectrometer. Infrared spectra were recorded on a ReactIR1000 system (Applied System Inc.) as thin films in toluene. X-ray crystallographic data were obtained on a Bruker CCD platform diffractometer. Complexometeric analyses were obtained as previously described [21].

4.1. (Salen′)Y[N(SiMe$_3$)$_2$](THF), 2

In a glovebox KN(SiMe$_3$)$_2$ (52 mg, 0.26 mmol) was added to a slurry of **1** (180 mg, 0.26 mmol) in 5 ml of toluene. After stirring for 12 h, the dark orange–red slurry was centrifuged to remove KCl. The solvent was removed by rotary evaporation and the dark orange–

	2.148(2)	2.418(3)	

red oil was stirred for 15 min in hexanes. Removal of solvent by rotary evaporation gave a dark orange powder (155 mg, 72%). *Anal*. Calc. for $C_{42}H_{72}N_3O_3Si_2Y$: Y, 10.9. Found: Y, 11.2%. ^{1}H NMR (C_6D_6): δ 7.73 (s, 2H), 7.69 (d, 2H, $J = 2.5$ Hz), 7.03 (d, 2H, $J = 2.5$ Hz), 4.39 (q, 2H, $J = 6.0$ Hz), 4.10 (b, 4H, $\Delta\nu_{1/2} = 125$ Hz), 2.82 (q, 2H, $J = 6.0$ Hz), 1.63 (s, 18H), 1.50 (b, 4H, $\Delta\nu_{1/2} = 120$ Hz), 1.36 (s, 18H), 0.26 (s, 18H). ^{13}C{^{1}H} NMR: δ (C_6D_6) 170.6, 164.4, 139.2, 136.8, 130.0, 129.7, 122.6, 70.2, 59.0, 35.7, 34.1, 31.7, 30.3, 25.4, 5.3. IR 2957vs, 2907s, 2868s, 1617vs, 1536s, 1463s, 1440s, 1413s, 1390s, 1274w, 1235w, 1200w, 1166s, 1054w, 1027w, 980w, 837m cm^{-1}.

4.2. (Salen′)Y($OC_6H_3Bu^t_2$-2,6)(THF)$_{0,1}$, **3**, **4**

Addition of H_2salen′ (111 mg, 0.22 mmol) to a white slurry of Y(OAr′)$_3$ (159 mg, 0.22 mmol) in 5 ml of hexanes immediately generated a yellow solution. Within a few minutes, a yellow precipitate appeared. The reaction was stirred overnight and the slurry was centrifuged to separate a yellow solid and light yellow solution. The yellow solid was isolated and dried by rotary evaporation (151 mg, 85%). X-ray quality crystals were grown from a 50/50 mixture of toluene–THF at −35 °C. *Anal*. Calc. for $C_{50}H_{75}N_2O_4Y$: Y, 10.4. Found: Y, 9.9%. ^{1}H NMR (C_6D_6): δ 7.73 (d, 2H, $J = 2.4$ Hz), 7.65 (s, 2H), 7.31 (d, 2H, $J = 7.7$ Hz), 7.06 (d, 2H, $J = 2.4$ Hz), 6.82 (t, 1H, $J = 7.7$ Hz), 3.73 (q, 2H, $J = 6.5$ Hz), 2.76 (q, 2H, $J = 6.5$ Hz), 1.69 (s, 18H), 1.46 (s, 18H), 1.36 (s, 18H). ^{13}C{^{1}H} NMR (C_6D_6): δ 170.9, 164.1, 139.8, 138.0, 137.8, 130.6, 129.6, 129.3, 124.9, 122.7, 116.7, 58.2, 35.7, 34.7, 34.1, 31.7, 30.6, 30.1. IR 2958vs, 2912s, 2873s, 1614vs, 1537s, 1437m, 1321m, 1259a, 1205w, 1166m, 1097w, 1027w, 841w, 803w cm^{-1}.

4.3. (Salen′)Y(hfac)(THF)$_2$, **5**

Na(hfac) (51 mg, 0.22 mmol) was added to a yellow slurry of **1** (152 mg, 0.22 mmol) in 5 ml of THF. After stirring for 12 h, the yellow slurry was centrifuged and the solvent was removed from the yellow solution under vacuum (169 mg, 82%). X-ray quality crystals were grown from a toluene solution at room temperature (r.t.). *Anal*. Calc. for $C_{45}H_{63}N_2O_6F_6Y$: Y, 9.6. Found: Y, 9.4%. ^{1}H NMR (C_6D_6): δ 7.91 (s, 2H), 7.70 (d, 2H, $J = 2.6$ Hz), 7.11 (d, 2H, $J = 2.6$ Hz), 6.48 (s, 1H), 3.40 (b, 8H, $\Delta\nu_{1/2} = 116$ Hz), 3.28 (s, 4H), 1.64 (s, 18H), 1.37 (s, 18H), 1.14 (b, 8H, $\Delta\nu_{1/2} = 124$ Hz). ^{13}C{^{1}H} NMR (C_6D_6): δ 168.6, 165.0, 140.5, 135.7, 129.7, 129.1, 120.8, 91.9, 69.4, 63.3, 35.5, 34.0, 31.8, 29.9, 25.2. 4.4. (Salen′)Y(C_5Me_5), **6**

KC_5Me_5 (33 mg, 0.19 mmol) was added to **1** (133 mg, 0.19 mmol) in 5 ml of THF. The reaction was stirred for 12 h, the yellow slurry was centrifuged, and the solvent was removed from the yellow solution by rotary evaporation to give a yellow oil. Hexanes were added, the mixture was stirred, and solvent was removed from the oil by rotary evaporation to give a yellow solid (103 mg, 75%). X-ray quality crystals were grown from a 50/50 toluene–hexanes mixture at r.t. *Anal*. Calc. for $C_{46}H_{80}N_3O_4Si_2Y$: Y, 12.4. Found: Y, 11.6%. ^{1}H NMR (C_6D_6): δ 7.71 (d, 2H, $J = 2.3$ Hz), 7.70 (s, 2H), 7.07 (d, 2H, $J = 2.3$ Hz), 3.60 (q, 2H, $J = 6.5$ Hz), 2.68 (q, 2H, $J = 6.5$ Hz), 2.00 (s, 15H), 1.75 (s, 18H), 1.36 (s, 18H).

$^{13}C\{^{1}H\}$ NMR (C_6D_6): δ 169.9, 164.9, 140.2, 136.8, 130.0, 129.5, 122.4, 116.7, 58.3, 35.8, 34.1, 31.7, 30.3, 11.1. IR 2957vs, 2907s, 2868s, 1610vs, 1532s, 1463w, 1440m, 1413m, 1390m, 1359w, 1316s, 1274s, 1254s, 1200m, 1166s, 1096w, 1058w, 1027w, 984w, 930w, 911w, 876w, 849m cm^{-1}.

4.5. X-ray data collection, structure determination, and refinement for [(salen′)Y($OC_6H_3Bu^t_2$-2,6)(THF)], 4

A colorless crystal of approximate dimensions 0.16 × 0.19 × 0.25 mm was mounted on a glass fiber and transferred to a Bruker CCD platform diffractometer. The SMART [22] program package was used to determine the unit-cell parameters and for data collection (30 s per frame scan time for a sphere of diffraction data). The raw frame data was processed using SAINT [23] and SADABS [24] to yield the reflection data file. Subsequent calculations were carried out using the SHELXTL [25] program. The diffraction symmetry was 2/*m* and the systematic absences were consistent with the centrosymmetric monoclinic space group $P2_1/n$ which was later determined to be correct. Details are in Table 2.

The structure was solved by direct methods and refined on F^2 by full-matrix least-squares techniques. The analytical scattering factors [26] for neutral atoms were used throughout the analysis. There were 2.5 molecules of toluene solvent present per formula unit. The half molecule of solvent was modeled as a disorder over an inversion center. Hydrogen atoms were included using a riding model. At convergence, $wR_2 = 0.1788$ and GOF = 0.0631 for 586 variables refined against 15 186 unique data. As a comparison for refinement on *F*, $R_1 = 0.0631$ for those 9780 data with $I > 2.0\sigma(I)$. Subsequent complexes were handled as described for **4**.

4.6. (Salen′)Y(hfac)(THF)$_2$, 5

A yellow crystal of approximate dimensions 0.17 × 0.20 × 0.33 mm was mounted on a glass fiber and transferred to a Bruker CCD platform diffractometer (30 s per frame scan time for a hemisphere of diffraction data). The diffraction symmetry was 2/*m* and the systematic absences were consistent with the centrosymmetric monoclinic space group $P2_1/c$ which was later determined to be correct.

Disorder was present in the CF_3 group and both THF molecules. Atoms F(4)–F(5), C(38)–C(40), C(43) and C(44) were disordered and included using multiple components with partial site-occupancy factors. Hydrogen atoms were included using a riding model. At convergence, $wR_2 = 0.1533$ and GOF = 1.032 for 518 variables refined against 10 952 data. As a comparison for refinement on *F*, $R_1 = 0.0576$ for those 8653 data with $I > 2.0\sigma(I)$.

4.7. (Salen′)Y(C_5Me_5), 6

A yellow crystal of approximate dimensions 0.10 × 0.15 × 0.25 mm was mounted on a glass fiber and transferred to a Bruker CCD platform diffractometer (30 s per frame scan time for a hemisphere of diffraction data). The diffraction symmetry was *mmm* and the systematic absences were consistent with the orthorhombic space group $P2_12_12_1$ which was later determined to be correct.

Hydrogen atoms were included using a riding model. At convergence, $wR_2 = 0.0592$ and GOF = 0.934 for 424 variables refined against 9633 data. As a comparison for refinement on *F*, $R_1 = 0.0452$ for those 6021 data with $I > 2.0\sigma(I)$. The absolute structure was assigned by refinement of the Flack parameter [26].

erally contain tertiary amino groups and are often labelled as sila-drugs, e.g. siladifendol, (3-piperidinopropyl)diphenylsilanol which contains intra-molecular O–H···N hydrogen bonds [6] or silapridinol, (2-piperidinoethyl)diphenylsilanol which contains inter-molecular O–H···N hydrogen bonds [7]. A related secondary amine derivative, 3-(*cyclo*hexylamino)propyldimethylsilanol, has been reported to form inter-molecular O–H···N hydrogen bonds [8].

2. Experimental

The adducts **1**–**3** were obtained as crystals from dichloromethane solutions of Ph_3SiOH and the amine at room temperature (r.t.). The 1:1 adducts were obtained from solutions of the reagents in 1:x ratio of silanol:amine for $x = 1$ or 2 for 4-phenylpyridine or acridine, $x = 1$, 2 or 4 for 4,4′-bipyridine. Infrared spectra were recorded on a Perkin–Elmer Paragon 1000 Fourier Transform Spectrometer. Samples were prepared as KBr discs. All ^{1}H NMR spectra were recorded on a Bruker Avance 300 MHz spectrometer. Tetramethylsilane was used as the standard and deuterated chloroform as the solvent. All NMR spectra were recorded at ambient temperature. Melting points (m.p.) were recorded on an Electrothermal IA 9000 Series digital m.p. apparatus. Elemental (C/H) analyses were carried out on an Exeter Analytical Inc., CE 440 Elemental Analyser at the Microanalytical Laboratory, University College, Cork.

Bulk samples of the 4-phenylpyridine adduct **1**, m.p. 53–55 °C, the 4,4′-bipyridine adduct **2**, m.p. 103–106 °C, and the acridine adduct **3**, m.p. 96–97 °C afforded satisfactory chemical (C, H and N) analysis.

Adduct **1**, Ph_3SiOH:4-phenylpyridine. Found: C, 80.7; H, 5.9; N, 3.2. $C_{29}H_{25}NOSi$ requires: C, 80.7; H, 5.8; N, 3.2%. IR (KBr disc) ν_{max} (cm^{-1}): (only very strong or strong vibrations are reported) 1428, 1118, 1115, 899, 739, 709, 698, 511. NMR (ppm): ^{1}H 3.69 (s, 1H), 7.31 to 7.43 (m, 15H), 7.55 to 7.58 (m, 7H), 8.51 (d, 2H).

Adduct **2**, Ph_3SiOH:4,4′-bipyridine. Found: C, 77.8; H, 5.8; N, 6.6. $C_{28}H_{24}N_2OSi$ requires: C, 77.7; H, 5.6; N, 6.5%. IR (KBr disc) ν_{max} (cm^{-1}): (only very strong or strong vibrations are reported) 1589, 1428, 1118, 1112, 895, 804, 708, 612, 510. NMR (ppm): ^{1}H 4.15 (s, 1H), 7.18 to 7.36 (m, 9H), 7.43 to 7.45 (m, 4H), 7.56 to 7.58 (m, 6H), 8.59 (d, 4H).

Adduct **3**, Ph_3SiOH:acridine. Found: C, 81.9; H, 5.6; N, 3.1. $C_{31}H_{25}NOSi$ requires: C, 81.75; H, 5.5; N, 3.1%. IR (KBr disc) ν_{max} (cm^{-1}): (only very strong or strong vibrations are reported) 1516, 1428, 1116, 1112, 888, 741, 708, 699, 510, 506. NMR (ppm): ^{1}H 3.28 (s, 1H), 7.25 to 7.39 (m, 9H), 7.46 to 7.50 (m, 2H); 7.55 to 7.58 (m, 6H), 7.69 to 7.73 (m, 2H), 7.92 (d, 2H), 8.13 (d, 2H), 8.60 (s, 1H).

2.1. Crystal structure analysis for compounds *1*, *2* and *3*

Crystal data are given in Table 1. Data for **1** and **2** were collected on a Nonius MACH 3 diffractometer using graphite monochromatised Mo Kα radiation, $\lambda =$

0.71073 Å. Data for **3** were collected on a Bruker SMART-1K CCD area detector diffractometer using graphite monochromatised Mo Kα radiation and an Oxford Cryosystems open-flow N_2 gas cryostat [9]. Unit cell parameters were determined using the SMART [10] program from the centroids of 828 reflections with 2θ values between 27.4° and 59.7°. Reflection intensities were integrated using the SAINT program [11]. For all three compounds no absorption correction was performed. The structures were solved by direct methods [12], refined by full-matrix least-squares on F^2 [13] and analysed for non-covalent interactions [14]. The weighting scheme employed was $w = 1/[\sigma^2(F_o^2)+(aP)^2+bP]$ where $P = (F_o^2+F_c^2)/3$.

For **1** and **2**, the hydroxyl hydrogen was located from a difference Fourier electron density map and all other hydrogen atoms were geometrically placed in calculated positions. All hydrogen atoms were allowed to ride on their parent atom with $U_{iso}(H) = 1.2\ U_{eq}(C)$ and $1.5\ U_{eq}(O)$. Idealised C–H distances were fixed at 0.93 Å. For **3**, all hydrogen atoms were found from difference Fourier maps and their coordinates and isotropic atomic displacement parameters were refined.

3. Results and discussion

All adducts reported here were formed with the triphenylsilanol: amine ratio 1:1. This occurred even when a 2:1 ratio of Ph_3SiOH: 4,4′-bipyridine was reacted together. Views of the structures of **1**, **2** and **3** are shown in Figs. 1–3. Important distance and angle data are given in the legends to the Figures. Compounds **1**, **2** and **3** are monomeric with single O–H···N hydrogen bonds. In all adducts the silicon is tetrahedrally coordinated and all the angles at silicon are close to 109.5°. The

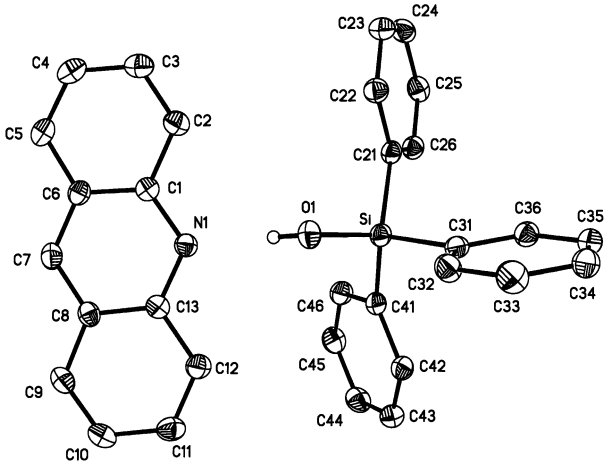

Fig. 3. A view of **3** showing the numbering scheme. Selected distances (Å) and angles (°): Si1–O1 1.6355(10), Si1–C31 1.8705(12), Si1–C41 1.8714(13), Si1–C21 1.8755(13), N1–C1 1.3512(15), N1–C13 1.3524(15), C1–C6 1.4334(16), C6–C7 1.3961(17), C7–C8 1.3943(18), C8–C13 1.4351(16), O1–Si1–C31 104.69(5), O1–Si1–C41 110.45(5), C31–Si1–C41 112.53(5), O1–Si1–C21 110.78(5), C31–Si1–C21 108.56(5), C41–Si1–C21 109.74(5), C1–N1–C13 118.65(10), N1–C1–C6 122.79(11), C7–C6–C1 117.69(11), C8–C7–C6 120.45(11), C7–C8–C9 123.12(11), C7–C8–C13 117.97(11), N1–C13–C8 122.40(11).

average Si–C distances in **1**, **2** and **3** are 1.869(3), 1.867(4) and 1.8725(13) Å. There are no unusual distances or angles within the aromatic rings in any of the sections of the adducts. The structures of **1**, **2** and **3** are remarkably simple compared with the reported structures of some amine adducts of disiloxanediols or trisiloxanediols which may be either discrete molecules or contain infinite chains formed through either O–H···N or O–H···O hydrogen bonds, [3,4,15] (see Table 2).

The O···N bond distances and O–H···N angles are 2.768(3), 2.789(4) and 2.7631(14) Å and 163°, 164° and 176(2)° in **1**, **2** and **3**, respectively, Table 2. The distances in **1** and **2** are the same within 3σ and likewise for **1** and **3**. However, the distances in **2** and **3** are not the same within 3σ vide infra. The O(H)···N distances are indicative of moderately strong inter-molecular hydrogen bonds [13] and are at the lower end of the reported range of such distances in silanol–amine adducts which extends from 2.681(6) Å in $\{Ph_2SiOSi(OH)_2O\}_2$(pyridine)$_2$ [16] to 3.054(4) Å in $\{(HO)SiPh_2OSiPh_2OSiPh_2(OH)\}_2$(pyridine)$_3$ [4]. The related dimensions in the $[\{(Me_3Si)_3C\}Ph_2SiOH]_2$·TMEDA adduct are 2.75 Å and 158° [5], and in the secondary amine derivative, 3-(*cyclo*hexylamino)propyldimethyl silanol, the mean values for the two independent molecules in the unit cell are 2.75 Å and 171° [8]. In general, inter-molecular O(H)···N hydrogen bond distances are greater than intra-molecular distances as in, for example the siladrugs (3-piperidinopropyl)diphenylsilanol which contains intra-molecular O–(H)···N hydrogen bonds of 2.685 Å [6] and (2-piperidinoethyl)diphenylsilanol which contains inter-molecular O–H···N hydrogen bonds of 2.758 Å [7]. In the latter two compounds the O(H)···N angles are essentially the same at 173.2° and 172.5(2)°, respectively.

Table 2
Hydrogen-bonding in adducts of silanols with aromatic amines

	Type of complex	Types of hydrogen bonding present	Manner of chain propagation
Ph_3SiOH adducts			
4-Phenylpyridine (1:1) [a]	Discrete molecule	O–H···N	None
4,4′-Bipyridine (1:1) [b]	Discrete molecule	O–H···N	None
Acridine (1:1) [c]	Discrete molecule	O–H···N	None
$(HO)SiPh_2OSiPh_2(OH)$ adducts			
Pyridine (1:1) [d]	Infinite chain	O–H···N and O–H···O	O–H···O
Pyrimidine (1:1) [e]	Infinite chain	O–H···N and O–H···O	O–H···O
Pyrazine (2:1) [f]	Infinite chain	O–H···N and O–H···O	O–H···N
2,2′-Bipyridine (1:1) [g]	Infinite chains	O–H···N	O–H···N
Pyridazine (3:2) [h]	Discrete molecule	O–H···N and O–H···O	None
$(HO)SiPh_2OSiPh_2OsiPh_2(OH)$ adducts			
Pyridine (2:3) [i]	Discrete molecule	O–H···N and O–H···O	None
Pyrazine (4:1) [j]	Discrete molecule	O–H···N and O–H···O	None
(D) $[\{Ph_2SiOSi(OH)_2O\}_2]$ adduct			
Pyridine (1:2)[k]	Infinite chain	O–H···N and O–H···O	O–H···O

[a] O···N 2.768(3) Å, O–H···N 163°, Si–O 1.625(2) Å (this work).
[b] O···N 2.789(4) Å, O–H···N 164°, Si–O 1.630(3) Å (this work).
[c] O···N 2.7631(14) Å, O–H···N 176(2)°, Si–O 1.6355(10) Å (this work).
[d] O···N 3.001(3) Å, Si–O 1.6201(14) Å [4].
[e] O···N 2.963(5) Å, O–H···N 163°, Si–O 1.624(2) Å [4].
[f] O···N 2.718(3) Å, O–H···N 168°, Si–O 1.6267(17) Å [4].
[g] O···N 2.869(2) and 2.846(2) Å, O–H···N 159 and 167°, Si–O 1.622(2) and 1.6201(12) Å [4].
[h] O···N 2.75(1) and 2.75(2) Å [3], Si–O 1.62 and 1.63 Å [17].
[i] O···N 2.722(3) and 3.054(4) Å, O–H···N 150 and 174°, Si–O 1.6096(14) and 1.6250(15) Å [4].
[j] O···N 2.706(2) Å, O–H···N 168°, Si–O 1.6282(14) Å [4].
[k] O···N 2.699(6) and 2.681(6) Å, O–H···N 175(3) and 177(3)° [16], Si–O 1.609 and 1.610 Å [17].

The Si–O distances, 1.625(2), 1.630(3) and 1.6355(10) Å for **1**, **2** and **3**, respectively, are almost indistinguishable at the 3σ. All the Si–O distances are typical of measured Si–O distances in amine adducts of silanols and siloxanediols [4,17]. The average Si–O distance in crystalline Ph_3SiOH, which exists as two independent tetrameric O–H···O hydrogen bonded species, is 1.645(7) Å [18].

Comparing compounds **1**–**3**, it is notable that **3** has the shortest O···N distance, the longest Si–O distance and a Si–O–N angle closest to linearity. These features suggest that **3** contains the strongest O–H···N hydrogen bond in these three adducts.

In both **1** and **2** there is an interplanar twist of the amine's aromatic rings. The twist angles for planes containing the C(3)–C(4)–C(7) and C(4)–C(7)–C(8) atoms, see Figs. 1 and 2 are 33.6(4)° and 27.6(6)° for **1** and **2**, respectively. In comparison, the interplanar twist angles in 4,4′-bipyridine [19], which possess two crystallographically independent molecules, are 18.50(12)° and 34.85(10)°. Theoretical studies indicate that a value of 48.6° can be expected and this may be compared with 37.2° determined from gas phase measurements [20]. There is no significantly enhanced inter-ring π overlap in the amine portions of the adducts.

For **1** and **2**, there is a layer structure present parallel to the *yz* plane. The layers containing the triphenylsilanol molecules are shown in Fig. 4. The silanol molecules are arranged in layers which contain an hydrophobic core formed by numerous interactions of both π–π stacking and C–H···π type between phenyl groups. The π–π stacking interactions are characteristic

of multi-phenyl systems [21] with, for example, the shortest centroid–centroid distance in **1** at 4.4 Å for the ring containing atoms C(41)–C(46) and its centrosymmetrically related neighbour with the rings aligned in a parallel fashion. In general, C–H···π interactions may be characterised by the angle at the hydrogen atom (the angle α in Fig. 5) and the perpendicular distance of the H atom from the plane of the ring. Typical values may be between 120° to 180° with distances of up to 3.2 Å [21]. The values found in **1** and **2** are normal for such systems; for example, in **1** the distance from H(24) to the ring containing atoms C(31)–C(36) is 2.9 Å and the angle α is 148°. The silanol groups are orientated away from the hydrophobic core and form a hydrophilic exterior which interacts with the layers of amines via hydrogen bonding. The amine layers are held together by π–π stacking between the phenyl and/or pyridyl rings, for example in **1** the centroid–centroid distance is 4.5 Å and the dihedral angle between the planes is 34°. There are C–H···π interactions present as well, for example in **1** the distance is 3.0 Å at 118°. The structure of **3** also contains π–π stacking which is notably stronger than in **1** and **2**, with the centroid–centroid distance in **3** being 3.6 Å and the dihedral angle between the planes is 2.3°. There are also seven C–H···π interactions present in **3** and these involve both the amine and the silanol.

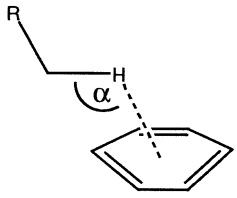

Fig. 5. Schematic diagram of the pertinent features for describing C–H···π interactions.

It is not clear why Ph_3SiOH does not form a 2:1 adduct with 4,4′-bipyridine when the reaction is carried out with a molar ratio $\geq$2:1 since both nitrogen donor sites in 4,4′-bipyridine appear to be identical. Indeed, the N–C bond distances and C–N–C angles in both the 4,4′-bipyridine and 4-phenylpyridine parts of the adducts **1** and **2** are the same at the 2σ level. It is possible that no 2:1 adduct is observed because there would be no contribution to the overall stability of the crystal from π–π stacking between the 4,4′-bipyridine molecules.

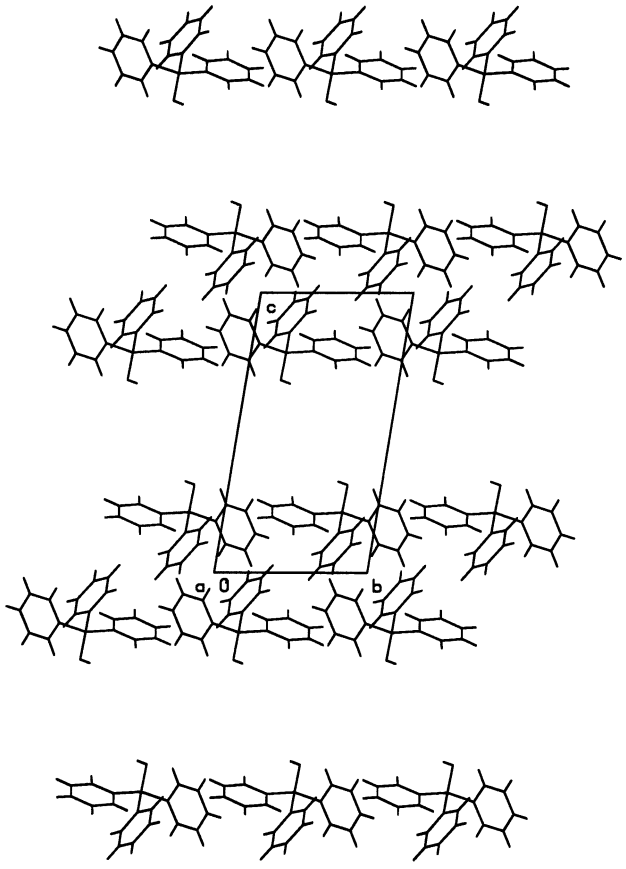

Fig. 4. Packing diagram for **1** showing the hydrophilic exterior and the hydrophobic core of the silanol double layer sheets. The amine molecules have been omitted for clarity.

4. Supplementary material

Supplementary crystallographic data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) on request, quoting the deposition numbers 169134 (for **1**), 169133 (for **2**), and 169135 (for **3**).

Scheme 1. Structure of nickel(II) complexes.

characterised in some of the solvents used, [1a,1c,1d,5] but they are included to provide a coherent framework for the overall study reported.

2. Results and discussion

2.1. Cyclic voltammetry of nickel(II) complexes

The complexes studied can be divided in two groups, based on their electrochemical response (Table 1). Complexes with non-aromatic imine bridges (**1**–**7**; group **A**) show, in the potential range used, one reduction process in all solvents used. With increasing scan rates (v), a linear dependence between i_p and $v^{1/2}$ is observed (similar slopes for the i_{pc} vs. $v^{1/2}$ and i_{pa} vs. $v^{1/2}$ plots), and the cathodic–anodic peak potential separations are similar to those observed for the couple Fc^+–Fc, and the ratios i_{pa}/i_{pc} are solvent independent, constant and equal to 1 for all the scan rates used. Electrochemical data for complexes of group **A** are thus consistent with one electron, diffusion-controlled, reversible reduction process [6].

Complexes with aromatic imine bridges (**8** and **9**; group **B**) present, in all solvents and for scan rates in the range 0.02–0.5 V s^{-1}, cyclic voltammograms with one cathodic wave at 1.210 V $< -E_{pc} <$ 1.378 V and one anodic wave at 0.282 V $< -E_{pa} <$ 0.630 V (Fig. 1(a)). Despite their large separation ($\approx$0.75 V), the two waves are related, as no anodic wave could be detected when the potential is cycled from 0 to −1.0 V.

With increasing scan rate a linear dependence between i_p and $v^{1/2}$ is also observed, but with quite different slopes for the i_{pc} versus $v^{1/2}$ and i_{pa} versus $v^{1/2}$ plots, which implies different diffusion coefficients for the reduced and oxidised species, and suggests significant structural changes upon reduction.

Peak potential dependence with complex concentration at a constant scan rate in dmf was also studied. For **8** and **9**, the values of E_{pa} are independent of complex concentration, whereas those of E_{pc} are shifted to more negative potentials when the complex concentration is reduced. For a scan rate of 200 mV s^{-1}, E_{pc} is shifted by 21 mV for [Ni(saloph)] (**8**) and 20 mV for [Ni(saloph-Cl_2)] (**9**), when the complex concentration is tenfold reduced.

Similar results have been described in literature for dmf solutions of complex **8** [5,7] and have been interpreted as a one-electron reversible reduction process followed by a fast chemical reaction leading to the formation of a stable new product, which is oxidised to the original complex.

Floriani et al. [8,9] have isolated the product of sodium reduction in the solution of [Ni(saloph)]. X-ray and magnetic data show that the product, formulated as $[Ni(saloph)]_2Na_2$, is a diamagnetic Ni(II) dimeric compound which is composed of two monomeric units linked by one of the carbon imine atoms that has been reduced to an amide carbon. Vianello et al. [5], based on the similarity between the cyclic voltamograms of $[Ni(saloph)]_2Na_2$ and [Ni(saloph)] in dmf, suggested that the electro-reduction of [Ni(saloph)] in this solvent produces in a first step a nickel(II) anion radical due to reduction of the imine bond to an amide bond, followed by a fast dimerisation reaction to yield the Ni(II) dimeric species, $[Ni(saloph)]_2^{2-}$. These species are then reversibly oxidised to the parent complex by cleavage of the bonding between the two monomer units. We presuppose the same mechanism for reduction of complexes **8** and **9** in all solvents used, and experimental evidence for the formation of the radical intermediate species have been obtained by EPR (see below).

Cyclic voltammograms recorded in dmf using very high scan rates, typically in the 1–60 V s^{-1} range exhibit in the reverse scan a new anodic wave at potentials similar to those of the cathodic wave, whereas the anodic wave at more positive potentials looses intensity as the scan rate is increased (Fig. 1(b)). When the scan rate reaches 60 V s^{-1}, the cyclic voltammograms, in all solvents, resemble those of a reversible type system with $E_{1/2} = 1/2(E_{pa} + E_{pc}) = -1.380$ for **8** and $E_{1/2} = -1.298$ V for **9**, and the ratio i_{pa}/i_{pc} reaches 1. The new anodic wave is attributed to the oxidation of the reduced monomeric species, in the absence of dimerisation; by using very fast scan rates the monomeric reduced species are oxidised before the dimerisation reaction takes place.

An estimate of the dimerisation rate constant, k_{dim}, can be obtained from the difference between E_{pc} (obtained for a scan rate of 50 mV s^{-1}, where the system is kinetically controlled by the dimerisation

[a] The values were obtained at 0.05 V s^{-1}.
[b] The $E_{1/2}$ values are calculated as $1/2(E_{pc}+E_{pa})$.
[c] Refers to electrolysis.
[d] Complexes have low solubility in this solvent.
[e] Obtained at 60 V s^{-1}, see text for details.

reaction) and $E_{1/2}$ for a scan rate of 60 V s^{-1}, where the system is approximately reversible and diffusion controlled. Under the experimental conditions in which the system is kinetically controlled by the dimerisation reaction, E_{pc} is expressed by the equation [5,7]:

$$E_{pc} = E_{1/2} - 0.058 + 0.0197 \log k_{dim} + 0.0197 \log(c/v)$$

For complex solutions with $c = 2.00 \times 10^{-3}$ mol dm^{-3} in dmf and using the $E_{1/2}$ calculated at 60 V s^{-1}, k_{dim} was found to be: $4.08 \pm 0.67 \times 10^5$ mol^{-1} dm^3 s^{-1} ($E_{pc} = -1.355$ V) for [Ni(saloph)] (**8**) and $3.23 \pm 0.53 \times 10^5$ mol^{-1} dm^3 s^{-1} ($E_{pc} = -1.275$ V) for [Ni(saloph-Cl_2)] (**9**). The presence of electron withdrawing Cl groups in the imine bridge reduces the electronic density in the imine bond which would hinder the dimerisation process.

2.2. Coulometry of nickel(II) complexes

Electrochemical reduction of complexes of group **A** produces a colour change from reddish to dark blue (**1**–**5**) or dark green (**6** and **7**), whereas reduction of **8** and **9** (group **B**) led to brown–green solutions, implying the formation of new species that depend on the precursor. Plots of the cathodic current, i_c, against the time of electrolysis exhibit exponential decay typical of first-order processes for all complexes. On the other hand, plots of i_c versus q (charge transferred during the electrolysis) are quasi-linear, which suggests the transference of a constant number of electrons during electrolysis [6]. The i_c–q plots were used to obtain the values of q (∞) by extrapolation to $i_c = 0$, which has enabled the estimation of the number of electrons, n, involved in the reduction process (Table 1) [6]. The observation that the resulting n values are ≈1 for complexes **1**–**7** (Table 1), provides additional confirmation that only one electron is involved in the reduction process of these complexes. For complexes **8** and **9**, the values of n are also ≈1, which indicates that only one imine bond is involved in the reduction and dimerisation reactions. The values of n were not corrected for blank solutions, but reduction of these solutions under the experimental conditions used produces only a small contribution for the cathodic current. Thus, the small deviations from unity can be attributed to residual charge from oxidation of traces of molecular oxygen or support electrolyte reductions.

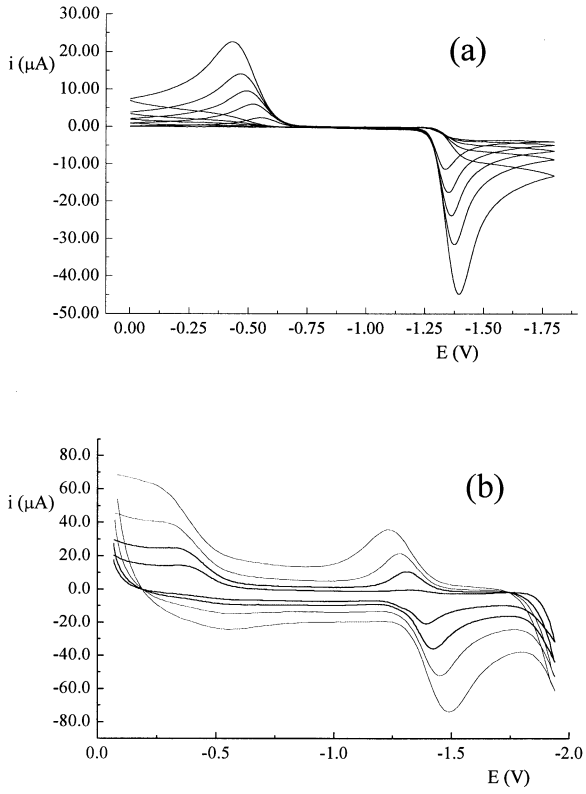

Fig. 1. Cyclic voltammograms of the complex [Ni(saloph)] (**8**) (group B) in dmf at scan rates in the range: (a) 0.02, 0.05, 0.10, 0.20 and 0.5 V s^{-1} and (b) 5, 10, 20, and 40 V s^{-1}.

2.3. EPR and electronic spectroscopy of reduced species

Analysis of electrochemical data has shown that all complexes of group **A** and **B** are reduced by an electron charge transfer process, but that different species are produced by complexes with aromatic and non-aromatic imine bridges, a consequence of different reduction processes. Coupling EPR and electronic spectroscopy provides further characterisation of the reduced species.

It must be pointed out that all complexes were also reduced with Na(Hg) and in the same solvents used for coulometric reductions. As the resulting solutions have the same colours and identical frozen solution EPR spectra it is possible to conclude that the same reduced species are formed by chemical and electrochemical reduction. The following description is thus applicable to chemically and electrochemically reduced nickel(II) complexes.

Frozen solution EPR spectra of reduced species from group **A** in any of the solvents are very similar, and show large g tensor anisotropy with $g_{av} \approx 2.12$–2.15, typical of metal centred reduced species, in this case nickel(I) complexes. The spectra of reduced solutions of **1**–**5** are rhombic and exhibit hyperfine splittings in the two high magnetic field regions ($a \approx 0.6$–1.0 mT) due to the interaction of the unpaired electron with two nitrogen atoms of the polydentate ligand (Fig. 2(a)). For reduced **6** and **7**, the EPR spectra are apparently axial, with no detectable hyperfine splittings in any g region (Fig. 2(b)).

In the absence of single crystal EPR measurements for these complexes, the observed similarity between the g features from both type of spectra with those of other Ni(I) complexes with similar ligands and with tetraaza macrocyclic ligands, [10–13] and of analogous isoelectronic d^9 Cu(II) complexes, [14–16] can be taken as support for the following orientation scheme for tensor axes in complexes **1**–**7**: $g_1 = g_z$, $g_2 = g_x$ and $g_3 = g_y$, where g_1 and g_3 refer to the lowest and highest magnetic field values, respectively (obviously, $a_1 = a_z$; $a_2 = a_x$ and $a_3 = a_y$). The observation that $g_z > g_x$; g_y implies a $B_{1g}(d_{xy})^1$ ground state for all the Ni(I) complexes [17–21]. All EPR spectra were manipulated and simulated as described in the Section 4; EPR parameters are summarised in Table 2. Spectra of each complex are practically independent of the solvent used, thus providing an indication that the reduced nickel complexes keep their four-coordinate geometry.

Analysis of the g and a(N) values show that complexes **1**–**5**, which possess an ethylenediimine based bridge, exhibit very similar values, but that their g values are smaller and their a(N) are larger than those of complexes with three and four atoms in the imine bridge (**6** and **7**). By taking into account data for Cu(II) complexes, [22] this observation provides an indication that the Ni(I) complexes with a long diimine bridge exhibit larger tetrahedral distortions than those with ethylenediimine based bridges (**1**–**5**). Additional indirect evidence for the larger tetrahedral distortion of Ni(I) complexes **6** and **7**, can be gathered from the existence of larger distortions in the corresponding Ni(II) complexes, as observed in the crystallographic structures of the latter complexes [23,24].

Frozen EPR spectra of electro-reduced complexes of group **B** (**8**–**9**) are quite different: they exhibit a low intensity pseudo isotropic signal at $g \approx 2.007$–2.010 (Fig. 2(c)), assigned to a radical, which provides an indication that reduction of these complexes involves ligand based processes. The low intensity isotropic signal must thus be due to monomeric Ni(II) radical species present in solution, probably a consequence of the existence in solution of an equilibrium between monomeric and dimeric species.

Electronic spectra of the Ni(I) species obtained by reduction of the corresponding Ni(II) complexes can also be divided into two sets. Spectra of reduced complexes **8**–**9** are similar to those of the parent Ni(II) complexes, thus suggesting a similar electronic structure in dimeric complex.

On the other hand, electronic spectra in dmf of all Ni(I) species obtained by reduction of **1**–**7**, are practically identical for all complexes and comparable to those

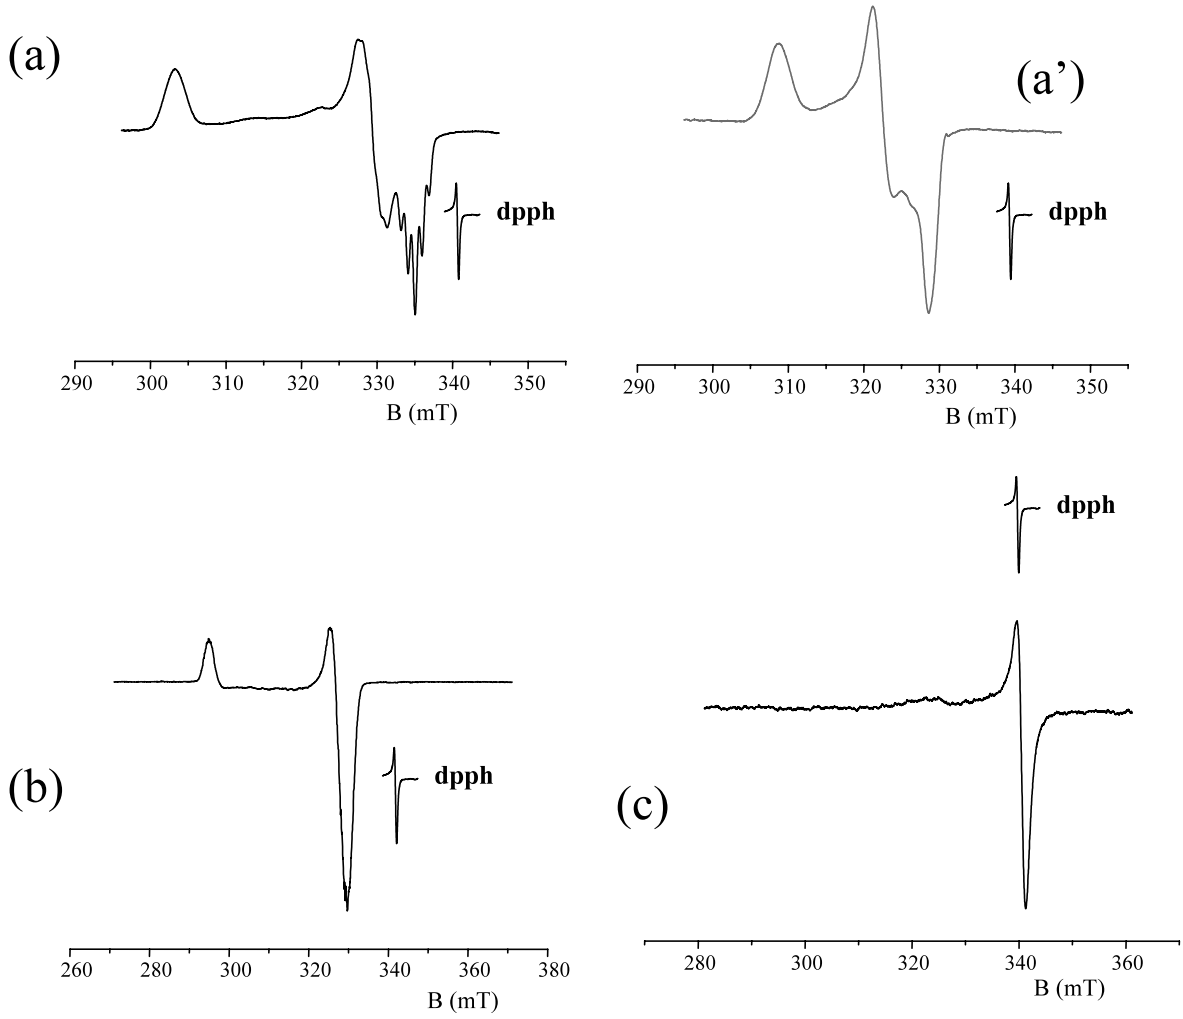

Fig. 2. Frozen solution EPR spectra of the reduced species in dmf (−120 °C): (a) $[Ni(\alpha,\alpha'\text{-}Me_2salen)]^-$; (b) $[Ni(salbd)]^-$ and (c) $[Ni(saloph)]_2^{2-}$ in N_2 atmosphere and (a′) $[Ni(\alpha,\alpha'\text{-}Me_2salen)]^-$ in CO atmosphere.

of similar Ni(I) compounds described in literature [13,25–29]; they show a medium intensity band at $\lambda = 800–830$ nm ($\varepsilon = 1100–1800$ dm^{-3} mol^{-1} cm^{-1}) with a shoulder at higher energies $\lambda = 637–760$ nm ($\varepsilon = 3200–5100$ dm^{-3} mol^{-1} cm^{-1}), and high-intensity bands in the UV region $\lambda < 400$ ($\varepsilon > 10\,000$ dm^{-3} mol^{-1} cm^{-1}) (Fig. 3(a) and Table 2). On the basis of their extinction coefficients the low energy band can be tentatively assigned to a d–d transition, albeit with a large contribution from ligand orbitals, and the shoulder at higher energy to charge transfer bands. The wavelength of the d–d band in spectra of reduced species is bathochromic shifted by about 30% relative to the d–d transitions of the precursor Ni(II) complexes, which occur in the range $\lambda = 550–500$ nm (Table 2) [13,25–29]. This indicates a weakening in the ligand field caused by the decrease in effective nuclear charge of the metal centre concomitant with its reduction. The extinction coefficients for Ni(I) complexes are usually much larger than those observed for similar Ni(II) complexes which is attributed to a large degree of covalency in the metal–ligand bonds (see below) [13,25–29].

Using the splitting scheme proposed by Nishida et al. [30,31] for the d-orbitals in isoelectronic square–planar copper(II) complexes with di-negatively charged tetradentate ligands, $d_{x^2-y^2} < d_{z^2} < d_{xz} \leq d_{yz} < d_{xy}$, and assuming the same d-splitting for the isoelectronic Ni(I) complexes used in this work, the low energy band in each spectrum can be assigned to the transition $d_{xz} \approx d_{yz} \leftarrow d_{x^2}$.

Confirmation for this assignment is provided by EPR data. Ni(I) complexes are at best of D_{2h} symmetry and using the g equations deduced for d^9 systems with B_{1g} ground state, the values of σ and π-out-of plane covalency parameters, α^2 and δ'^2, respectively, can be estimated from the g_x and g_y values [18–21]. This calculation was made using the methodology outlined in [13], with the further assumption that the low-energy electronic band corresponds to the transition $d_{xz} \approx d_{yz} \leftarrow d_{z^2}$. The values of these parameters, summarised

[a] g_{av} is calculated as $1/2(g_x+g_y+g_z)$.
[b] A_N(N) are expressed in mT and have been obtained as described in Section 4.2; only in dmf the spectra have the appropriate resolution.
[c] The electronic bands have been deconvoluted with the program ORIGIN.
[d] Refers to parent Ni(II) complexes.
[e] The complexes are not soluble in this solvent.
[f] The signal is pseudo isotropic and the value corresponds to g_{av}.
[g] No metal reduction occurs.

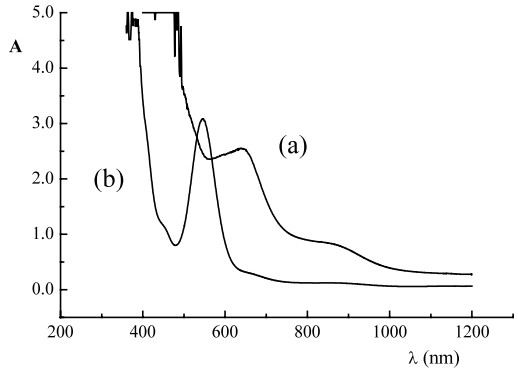

Fig. 3. UV–Vis spectra in dmf of $[Ni(salen)]^-$ (1 mmol dm^{-3}) in: (a) N_2 and (b) CO atmospheres.

in Table 2, compare with those observed for other Ni(I) complexes with similar ligands [11–13,32,33] which provides indirect support for the assignment. The values indicate that covalency is greater for the π-out-of plane bonding, suggesting large π delocalisation between the ligand and the metal centre. The lower planarity of the Ni(I) complexes with a long aliphatic diimine bridge (**6**, **7**) is also evidenced by the larger values calculated for δ'^2.

2.4. Reactivity of reduced species towards Lewis bases

No changes in the frozen EPR spectra or electronic spectra were observed upon addition of pyridine, imidazole or triphenylphosphine (in stoichiometric or excess molar ratio) to nickel reduced solutions, either freshly electrolysed or chemically reduced, an indication that neither these Ni(I) species interact with the strong Lewis bases, nor do the nickel(II) dimeric species. Probably the monodentate N and P donors ligands act as weaker π acceptors than the tetradentate ligand in stabilising the Ni(I) species.

2.5. Reactivity of reduced species towards carbon monoxide

The binding of CO, a stronger π acceptor ligand, with complexes **1**–**9** was assessed by studying the reduction process by cyclic voltammetry and coulometry under a CO atmosphere, and the reduced species were characterised by EPR and electronic spectroscopy.

2.6. Cyclic voltammetry and electrolysis

No changes were observed in the cyclic voltammograms of complexes of group **B** (**8**, **9**) obtained under a CO atmosphere when compared with those under a nitrogen atmosphere. This suggests no interaction between CO and the nickel species, and corroborates further that reduction of group **B** complexes does not involve the metal centre. Contrastingly, the voltammograms of group **A** complexes are slightly different from those in a nitrogen atmosphere: a reduction process is always observed, but (i) the ΔE values are larger; (ii) the values of ΔE increase significantly with increasing scan rates; and (iii) the i_{pa}/i_{pc} ratios are smaller than 1, which suggests a slow reaction between the nickel species and CO [6,7].

In order to get further information on the interaction of CO with reduced complexes of **1**–**7**, electrolysis of the Ni(II) complexes were made in a CO atmosphere. During the electrolysis a change in colour was observed from red to crimson, which differs from the dark blue–green colour of the reduced species in a nitrogen atmosphere, indicating the presence of different species in solution. Cyclic voltammograms obtained after electrolysis show one reduction process with $\Delta E = 60$–70 mV at $v = 50$ mV s^{-1}, and with $i_{pa}/i_{pc} = 1$, but with $E_{1/2}$ at slightly more positive potentials than those observed in a N_2 atmosphere. In Table 3 are summarised the electrochemical data for the complexes in CO atmosphere. The new electrochemical process corresponds to reduction of nickel species with axial coordinated CO; the more positive $E_{1/2}$ values imply that coordination of CO originates more stable Ni(I) species.

The difference between $E_{1/2}(N_2)$ and $E_{1/2}(CO)$ can be taken as a measure of the extent of CO coordination. From data in Tables 1 and 3 it is possible to infer that complexes with large tetrahedral distortions (**6** and **7**) show the weaker interactions with CO, and that complexes with ethylenic bridges, except those with axial substituents (**2**, **3** and **4**), exhibit the strongest interactions. These results suggest that the planarity of the coordination sphere $[(Ni^I)N_2O_2]^-$ plays an important role in the CO interaction with the nickel centre.

2.7. EPR and electronic spectroscopy of reduced species with bound CO

Frozen EPR spectra of nickel species with bound CO have g features similar to those obtained in a N_2 atmosphere, but with larger anisotropy and rhombicity ($g_{av} \approx 2.15$, $\Delta_{xy} \approx 0.06$–0.07). EPR data are summarised in Table 4, and an analysis of data in this table shows that the reduced species are still Ni(I) complexes with a $B_{1g}(d_{xy})^1$ ground state, as $g_z > g_x, g_y$. Furthermore, the observation that g_z and g_x have been shifted to lower magnetic field values and that no hyperfine splitting could be detected in any of the g regions (Fig. 2(a)) suggests that only one CO molecule is bound per nickel centre, leading to a square pyramidal geometry for the Ni(I) complexes, as a six-coordinate complex would have the g_z and g_x shifted to higher magnetic fields [14,22]. EPR spectra of the reduced species that interact less extensively with CO (**6**,**7**) show a sobreposition of the parent Ni(I) complex and the one with bound CO.

[Ni(saloph-Cl_2)]$_2^{2-}$	[b]						

[a] Data obtained in dmf at 0.050 V s^{-1}.
[b] No changes were observed in the voltammogram obtained under a CO atmosphere.

Electronic spectra of these CO bound Ni(I) complexes are quite different from those of their parent complexes and show one intense electronic band at $\lambda_{max} = 546$ nm ($\varepsilon = 5000$–6900 dm^{-3} mol^{-1} cm^{-1}) and several high intense bands in the UV region (Fig. 3). The new band in the visible region occurs at the same energy for all the complexes and taking in account their extinction coefficient they can be assigned to a M→CO charge transfer band and is indicative of the high π acceptor capacity of CO. The non-observation of any d–d band can be accounted for by a combination of two factors. First, the energy of the d–d bands is increased due to the high ligand field of CO; second, that of the CT bands is decreased due to the high π acceptor capacity of CO. As a consequence the CT bands that occur in the same region mask less intense d–d bands.

3. Concluding remarks

Species generated by one-electron electrochemical reduction of the nickel(II) Schiff base complexes reported in this work were characterised by combining EPR and UV–Vis–NIR spectroscopy and the results obtained allow for unambiguous identification of the electron transfer site. Reduction of nickel complexes was found to be solvent independent, but on the other hand the final reduction product depends largely on the ligand diimine bridge. Complexes with aromatic diimine bridges, (Group **B**), yielded ligand-centred reduced species, whereas those with aliphatic imine bridges, (group **A**), exhibit metal-centred reduction processes. Furthermore, the observation that the $E_{1/2}$ values for all complexes are practically solvent independent implies that the solvent does not participate in the charge transfer process, and indicates that the reduced nickel species must keep their tetracoordinate geometry. This result must be contrasted with the oxidation process of the same complexes, for which the solvent has a marked influence on oxidation site (metal vs. ligand), with good donor solvents favouring formation of Ni(III) complexes [34–39].

As referred above the extent of unsaturation not only is critical in controlling the ultimate reduction site, but influences also the $E_{1/2}$ values, as complexes with greater unsaturation exhibit the more positive values. Furthermore, the size of the imine bridge and the substituents in the ligand were also found to influence $E_{1/2}$ values. There is a pronounced positive shift in $E_{1/2}$ values when the number of carbon atoms in the aliphatic chain of the

EPR values and electronic bands in CO atmosphere in dmf

Complex	g_z	g_x	g_y	g_{av} [a]	λ_{max}/nm (ε/M^{-1} cm^{-1}) [b]
[Ni(salen)]$^-$	2.307	2.104	2.044	2.152	546 (6800)
[Ni(saltMe)]$^-$	2.302	2.106	2.039	2.149	546 (6000)
[Ni(Cl_2-saltMe)]$^-$	2.303	2.107	2.040	2.150	546 (6900)
[Ni(salhd)]$^-$	2.305	2.086	2.056	2.149	546 (6200)
[Ni(α,α′-Me_2salen)]$^-$	2.308	2.111	2.035	2.151	546 (6800)
[Ni(salpd)]$^-$	2.295	2.114	2.052	2.154	545 (5000)
[Ni(salbd)]$^-$	2.294	2.121	2.044	2.153	546 (4600)
[Ni(saloph)]$_2^{2-}$				2.006 [c]	
[Ni(saloph-Cl_2)]$_2^{2-}$				2.007 [c]	

[a] g_{av} is calculated as $1/2(g_x + g_y + g_z)$.
[b] The electronic bands have been deconvoluted with the program ORIGIN.
[c] There is no interaction of the reduced species with CO, the signal corresponds to that observed in the absence of CO.

imine bridge is increased. The larger hole sizes and larger tetrahedral distortions of [Ni(salpd)] (**6**) and [Ni(salbd)] (**7**), [23,24] make it easier to accommodate the size increase expected upon reduction of the metal and thus the more positive $E_{1/2}$ values.

The number, ring position and electronic characteristics of the substituents also influence the reductive properties of the complexes: introduction of chloride atoms increases the stability of the reduced state (comparison between **2** and **3**), whereas the introduction of methyl groups decreases the stability of reduced complexes (comparison of **1** and **2** with **7**). This behaviour is attributed to changes in the electronic density in the metal centre induced by the substituents. In the absence of steric effects, electron-withdrawing substituents decrease electron density on the metal making it easier to reduce, whereas electron donating groups will have the opposite effect. The position of the methyl groups in the ligand is also important, as introduction of two methyl groups in the imine carbon fragment, –C=N, shifts the $E_{1/2}$ to more negative values than four methyl groups in the aliphatic imine bridge.

Due to the large π delocalisation between the Ni(I) and thepolydentate ligands (as quantified by σ and π-out-of plane covalency parameters, α^2 and δ'^2), no interaction with monodentate N and P donor Lewis bases could be observed. However, with a stronger π acceptor like CO, a strong interaction was observed and more stable Ni(I) species were formed as proved by their more positive $E_{1/2}$ values and lower energy charge transfer bands.

4. Experimental

4.1. Reagents, solvents and nickel(II) complexes

The solvents for syntheses were of reagent grade (Merck), and those for spectroscopic and electrochemical measurements were of analytical grade (Merck, pro analysi); all were used as received. Tetra-*n*-butylammonium perchlorate (TBAP) was prepared by published procedures from tetrabutylammonium chloride (Aldrich) and perchloric acid (Merck, p.a.) and recrystallised twice from ethanol [40] (CAUTION: perchlorates are hazardous and may explode). Carbon monoxide gas was purchased from Praxair.

The nickel(II) complexes [Ni(salen)] (**1**), [Ni(saltMe)] (**2**), [Ni(salhd)] (**4**), [Ni(salpd)] (**5**) and [Ni(α,α′-Me_2salen)] (**7**), [Ni(saloph)] (**8**), [Ni(saloph-Cl_2)] (**9**) have been prepared and fully characterised in [35,36]. The complexes [Ni(Cl_4saltMe)] (**3**) and [Ni(salbd)] (**6**) have been prepared by standard methods [35,36] and characterised by elemental analysis: [Ni(Cl_4saltMe)], *bis*(3,5-tetrachlorosalicylaldehyde)tetramethylethylenediamine: $NiC_{16}H_{18}N_2O_2Cl_4$. *Anal*. Calc.: C, 40.8; H, 3.9; N, 5.9. Found: C, 40.2; H, 3.8; N, 5.5%.

[Ni(salbd)], *bis*(salicylaldehyde)butylenediamine: $NiC_{18}H_{18}N_2O_2$. *Anal*. Calc.: C, 61.2; H, 5.1; N, 7.9. Found: C, 61.1; H, 5.0; N, 8.1%.

4.2. Physical measurements

Electrochemical measurements were performed using an EG&G PAR 273 potentiostat–galvanostat using solutions 1 mmol dm^{-3} in nickel(II) complex and 0.1 mol dm^{-3} TBAP. Cyclic voltammograms were obtained in a standard one-compartment electrochemical cell using a platinum-disc electrode (area of 0.0314 cm^2) as working electrode, a platinum gauze as the counter electrode and an Ag–AgCl (1 mol dm^{-3} NaCl) reference electrode. All voltammograms were obtained without IR feedback compensation and measured potentials were not corrected for liquid junction potentials. All potentials are reported relative to that of the Ag–AgCl (1 mol dm^{-3} NaCl) reference electrode and to $E_{1/2}$ of the ferrocenium–ferrocene couple. Cyclic voltammetry was performed in Me_2SO, dmf and MeCN in the potential range -1.0– -2.0 V using scan rates 0.02–0.5 V s^{-1}; for complexes of group B scan rates in the range 5–60 V s^{-1} were also used. Under the experimental conditions used and for scan rate 0.05 V s^{-1}, $E_{1/2}$ (ΔE) for Fc^+–Fc couple are 0.50 V (0.09 V) in Me_2SO, 0.50 V (0.10 V) in dmf, and $E_{1/2} = 0.48$ V (0.085 V) in MeCN.

Controlled potential electrolysis was carried out under a N_2 or a CO atmosphere at a potential 0.1 V higher than the cathodic peak potentials. The electrochemical cell has two compartments: one for the platinum-gauze working electrode and the other for the platinum-gauze counter electrode, which are separated by a silica frit. A Ag–AgCl (1 mol dm^{-3} NaCl) reference electrode was used.

Room-temperature (r.t.) electronic spectra of nickel(II)–(I) complexes were recorded with a Schimadzu UV/3101PC spectrometer in the range 1500–200 nm. Solutions of nickel(II)–(I) complexes, under an atmosphere of N_2 or CO, were typically 1 mmol dm^{-3}.

The EPR spectra were obtained with an X-band Bruker ESP 300E spectrometer equipped with Bruker B-VT 2000 temperature accessory controller, in a dual cavity and using diphenylpicrylhydrazyl (dpph; $g = 2.0037$) as standard; the magnetic field was calibrated by use of Mn^{2+} in MgO. Typical experimental conditions used were: microwave power 10–15 mW, modulation amplitude 0.5 mT; modulation frequency 100 kHz. Spectra were recorded at -120 °C, using sealed quartz tubes and the reported EPR parameters were obtained by computer simulation, [41] using a rhombic g tensor. As the spectra in Me_2SO and CH_3CN have lower resolution than in dmf, the values of superhyperfine

splittings obtained for spectra in dmf were used to simulate spectra in the former solvents. Even for spectra in dmf the superhyperfine couplings with the ligand nitrogen atoms had to be obtained from second-derivative EPR spectra, after a Fourier transformation and the subsequent elimination of all high-frequency components with a cut off filter just above the typical frequency components of nitrogen hyperfine coupling. After back-transformation to the magnetic field space, the noise at high frequencies introduced by differentiation is eliminated.

4.3. Reduction of Ni(II) complexes

Nickel(I) species were generated in-situ by electrolysis or chemical reduction of 1 mmol dm^{-3} solutions of the corresponding nickel(II) complexes under strict anaerobic conditions. Electrochemical reduction was performed in all solvents used the procedure outlined above. Chemical reduction was performed in dimethylformamide using an excess of 5% sodium mercury amalgam. The solution–amalgam was stirred for 15 min, and a fast solution colour change was observed. The progress of the reduction was monitored by UV–Vis and EPR spectroscopy and was assumed to be complete (1 mmol dm^{-3} in Ni(I) species, at approximately 15 min), when no changes in intensity of the EPR signals and in the absorbance of electronic bands were detected.

Manipulations of nickel(I) species were carried out in a nitrogen atmosphere, by use of standard Schlenk techniques and/or of a glove box. Addition of pyridine, imidazole and triphenylphosphine to freshly electrolysed or chemically reduced solutions was performed under anaerobic conditions at r.t. The resulting solutions were immediately transferred to EPR tubes and frozen in liquid nitrogen. Adducts with CO were prepared by making the reduction (electrochemically and chemically) under a CO atmosphere.

(II)

In both syntheses, the yield of decaphenylmolybdenocene is very low (~ 5%). Decaphenylmolybdenocene is quite stable towards air and moisture, and is sparingly soluble in all common solvents. However, it can easily be oxidised by bromine in dichloromethane to a product formulated as decaphenylmolybdenocenium tribromide. This compound can be reduced to decaphenylmolybdenocene by magnesium in a mixture of dichloromethane and methanol. Both molybdenum compounds were characterised only by elemental analyses, magnetic susceptibility and melting point determination [29,30]. The reaction chemistries of decaphenylmolybdenocene and its cation have not been reported.

In contrast, then, to the unknown $[Mo(C_5H_5)_2]$ and to '$[Mo(C_5Me_5)_2]$', the compound formulated as $[Mo(C_5Ph_5)_2]$, decaphenylmolydenocene, although produced only in low yield, is remarkably stable, being indefinitely stable in air [29,30].

Because of their low solubilities, only one of the transition metal decaphenylmetallocenes, $[Fe(\eta^5\text{-}C_5Ph_5)_2]$, has been structurally characterised and even in that case, the structure failed to refine well, although the metallocene structure is clear [32]. However, even the seemingly simple $[Fe(\eta^5\text{-}C_5Ph_5)_2]$ can also exist as its linkage isomer, $[Fe(\eta^5\text{-}C_5Ph_5)_2]$ $[Fe\{(\eta^6\text{-}C_6H_5)C_5Ph_4\}]$ [33], and both $[Fe(C_5Ph_5)_2]$ isomers have been shown to undergo complicated series of isomerisations/protonations/deprotonations in the solid state and in solution [33–35]. We have remarked previously [36] that the $[M(\eta^5\text{-}C_5Ph_5)_2]$ conformation can be distinguished from the isomeric $[M\{(\eta^6\text{-}C_6H_5)C_5Ph_4)\}(\eta^5\text{-}C_5Ph_5)]$ [33] on the basis of a set of strong absorptions at approximately 1500, 741, 713 and 699 cm^{-1} in the infrared spectrum of the former. However, this diagnosis was unknown at the time of the synthesis of $[Mo(C_5Ph_5)_2]$ and in any case, no infrared data were reported. Thus, although there is no reason to suspect that $[Mo(C_5Ph_5)_2]$ has other than a metallocene structure, $[Mo(\eta^5\text{-}C_5Ph_5)_2]$, nor is it obvious that it has. However, clearly the strict analogue of $[Mo(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)H]$ is not possible in the pentaphenylcyclopentadienyl system.

In contrast to $[Mo(\eta^5\text{-}C_5Me_5)(\eta^6\text{-}C_5Me_4CH_2)H]$, $[Mo(C_5Ph_5)_2]$, has been oxidised by bromine to $[Mo(C_5Ph_5)_2]Br_3$, which can be reduced to $[Mo(C_5Ph_5)_2]$ by magnesium turnings [30]. $[Mo(C_5Ph_5)_2]Br_3$ is the first, and is still the only, 'decaphenylmetallocenium' salt of the second and third transition metals. The structures of decaphenylmetallocenium salts of Cr, Fe, Co and Ni have all been determined and the cations shown to adopt the $[M(\eta^5\text{-}C_5Ph_5)_2]^+$ configuration [36–38].

Accordingly, we report here the crystal structure and so preliminary cyclic voltammetric data for 'decaphenylmolybdenocenium' tribromide.

1. Results and discussion

Decaphenylmolybdenocene was prepared by the method of Holtzapple [30]. Although we explored several other possible routes, this synthesis, although low yielding, was still the most convenient preparation of decaphenylmolybdenocene, which was obtained as a red solid, insoluble in all common solvents.

Several unsuccessful attempts were made to find alternative, higher yielding, routes to decaphenylmolybdenocene. For example, reactions of $Mo(OAc)_2$ or $MoCl_5$ with $Li(C_5Ph_5)$, of $Mo(CO)_6$ or $[Mo(CO)_3(CH_3CN)_3]$ with C_5Ph_5Br did not produce the desired decaphenylmolybdenocene.

Decaphenylmolybdenocene was isolated as a bright-red air stable solid identified as $[Mo(C_5Ph_5)_2]$ by conversion to $[Mo(C_5Ph_5)_2]^+$ salts, and by comparison of its infrared and mass spectra with those of other decaphenylmetallocenes. It is sparingly soluble in most solvents. The infrared spectrum of decaphenylmolybdenocene we prepared by the method of Holtzapple [30] contains strong absorptions at 1500, 739 s, 711 vs, and 700 vs cm^{-1}. The presence of these absorptions in the infrared spectrum of $[Mo(C_5Ph_5)_2]$ suggests [36] that $[Mo(C_5Ph_5)_2]$ does indeed have the bis-pentahapto, decaphenylmetallocene, structure, $[Mo(\eta^5\text{-}C_5Ph_5)_2]$, rather than the mixed η^5, η^6 structure of the linkage isomer. In this respect, it represents the first molybdenum metallocene stable under ambient conditions.

The compound previously formulated as $[Mo(C_5Ph_5)_2]Br_3$ was prepared by oxidation of $[Mo(C_5Ph_5)_2]$ with Br_2 in dichloromethane [29]. We have confirmed this synthesis and prepared $[Mo(C_5Ph_5)_2]BF_4$ by a route similar those used for its Cr, Fe, Co and Ni analogues [32,36–38]. Both

$[Mo(C_5Ph_5)_2]Br_3$ and $[Mo(C_5Ph_5)_2]BF_4$ could be reduced reversibly to the neutral species by magnesium turnings or by $NaBH_4$ in a mixture of methanol and dichloromethane. Both decaphenylmolybdenocenium salts are air-stable as solids and stable in dichloromethane, or under ether, hexane or pentane for a week without noticeable degradation. However, they were rapidly reduced to the neutral decaphenylmolybdenocene in solvents such as tetrahydrofuran, acetonitrile and methanol. No analogous reaction was found among other decaphenylmetallocenium complexes. In this respect, $[Mo(C_5Ph_5)_2]^+$ is more reactive than the other decaphenylmetallocenium cations reported to date.

1.1. Cyclic voltammetry

In view of the long standing and general interest in the electron transfer chemistry of metallocenes [39,40], the chemical reversibility of the $[Mo(C_5Ph_5)_2]^{+/0}$ couple, the absence of any data directly obtained from $[Mo(C_5R_5)_2]$ compounds (the datum for $[Mo(C_5H_5)_2]$ was obtained from a cyclic voltammogram of the solution generated by the irreversible two electron coulometric reduction of $[Mo(C_5Ph_5)_2Cl_2]$ [39]), the existence of, albeit very reactive, $[Cr(C_5H_5)_2]^-$, [41] and the synthetic utility of a variety of $[M(C_5R_5)_2]^{n\pm}$ ions, [42,43] it was of interest to examine the electron transfer reactions of $[Mo(C_5Ph_5)_2]^+$. Cyclic voltammograms of $[Mo(C_5Ph_5)_2]BF_4$ were obtained under similar conditions to those used to study other decaphenylmetallocene analogues. Two reversible redox processes at -0.46 and -1.92 V, corresponding to the $[Mo(C_5Ph_5)_2]^{+/0}$ and $[Mo(C_5Ph_5)_2]^{0/1-}$ couples, respectively, were observed.

Strelets et al. reported a value of -1.65 V for the $[Mo(C_5H_5)_2]^{+/0}$ couple which was observed by means of rapid scanning cyclic voltammetry in DMSO and by low-temperature voltammetry techniques in tetrahydrofuran [44]. The '$[Mo(C_5H_5)_2]$' was produced by the irreversible two-electron reduction of $[Mo(C_5H_5)_2Cl_2]$. However, given the generally small difference between the $E_{1/2}$ values of $[M(C_5H_5)_2]^{+/0}$ and $[M(C_5Ph_5)_2]^{+/0}$ couples, confirmation of this value would be useful. Literature values of the $E_{1/2}$ values of selected metallocenes, decamethyl-, nonaphenyl- and decaphenyl-metallocenes (converted to a common scale) are collected in Table 1. The generally more positive oxidation potentials of the $[M(\eta^5\text{-}C_5Ph_5)_2]$ compounds relative to their $[M(\eta^5\text{-}C_5Me_5)_2]$ analogues offers some rationalization for the very high reactivity of $[Mo(\eta^5\text{-}C_5Me_5)_2]$ which might be expected to be very easily oxidised [26].

The decaphenylmolybdenocium cation, $[Mo(C_5Ph_5)_2]^+$ is a moderately good oxidant. The anion, $[Mo(C_5Ph_5)_2]^-$, may be a useful reductant. However, since any synthetic applications of these reagents are likely to require a higher-yielding synthesis, this chemistry was not pursued.

1.2. X-ray diffraction

Air-stable crystals of $[Mo(C_5Ph_5)_2]BF_4$ were obtained as a dichloromethane and water solvate complex, $[Mo(C_5Ph_5)_2]BF_4\cdot 0.5CH_2Cl_2\cdot 0.75H_2O$, similar to those of the chromium and cobalt analogues. The solvated salt crystallises in the space group $P\bar{1}$, isostructural with other decaphenylmetallocenium complexes (Table 2).

The structure and dimensions of $[Mo(C_5Ph_5)_2]^+$ are comparable to those of the known $[M(C_5Ph_5)_2]^+$ (M = Cr, Fe, Co and Ni) cations. The crystallographic data have been deposited.

Selected bond distances and angles for the $[Mo(C_5Ph_5)_2]^+$ cation (Fig. 1) are collected in Table 3.

The C_5 rings of each of the ligands are almost planar to within 0.0094 Å. The two ligand C_5 rings are parallel and adopt the staggered configuration observed for other decaphenylmetallocenium cations. The *ipso* carbon atoms of the phenyl rings are displaced on the opposite side of the C_5 plane (average 0.149 Å, range

0.132–0.173 Å) from the molybdenum atom. This value is the smallest among the known decaphenylmetallocenium cations due to the longer Mo–r_{cent} distance compared with those of known decaphenylmetallocenium cations (Table 4). The phenyl rings are canted at an average angle of 49.7° (range 44.6°–53.3°) with respect to the C_5 ring and adopt the 'paddle wheel' orientation. The average Mo–C (2.376 Å) and Mo–r_{cent} (2.040 Å) distances are the longest among the known decaphenylmetallocenium cations (Table 4) as expected for a second row metal with few valence electrons to occupy the bonding molecular orbitals. However, the Mo–r_{cent} and average Mo–C distances of the 15 electron $[Mo(C_5Ph_5)_2]^+$ cation are slightly shorter than those reported for the 18 electron half-sandwich complex $[Mo(C_5Ph_5)(CO)_3I]$ (2.042 and 2.378 Å, respectively) [46]. Further comparisons are not possible since no other molybdenocene derivatives or molybdenum complexes containing the (C_5Ph_5) ligand have been structurally characterised. The dimensions of the C_5 rings of the decaphenylmolybdenocenium cation are regular, similar to those observed in other decaphenylmetallocenium cations and the half-sandwich complex, $[Mo(C_5Ph_5)(CO)_3I]$.

Table 4
Comparison of selected average metric data for decaphenylmetallocenium cations of Mo, Cr, Fe, Co and Ni

$[M(\eta^5\text{-}C_5Ph_5)_2]^+$	M–(ring centroid) (Å)	Average M–C (Å)	C–C(C_5) (Å)	Reference
Mo	2.040	2.376	1.432	This work
Cr	1.935	2.282	1.429	[36]
Fe	1.810	2.164		[38]
Co	1.750	2.133	1.43	[36]
Ni	1.837	2.206	1.434	[38]

2. Conclusion

Decaphenylmolybdenocene exists in the solid state with two η^5-ligands, apparently isostructural with $[M(\eta^5\text{-}C_5Ph_5)_2]$ (M = Fe, Cr, Ni, Co) [37]. It undergoes a one electron oxidation and a one electron reduction, both of which are reversible on the cyclic voltammetric timescale and both of which occur at synthetically useful potentials. Oxidation to the decaphenylmolybdenocenium cation with Br_2 or NO^+ is near quantitative. The decaphenylmolybdenocenium cation exists as discrete $[Mo(\eta^5\text{-}C_5Ph_5)_2]^+$ units, with parallel C_5 rings of the two ($\eta^5\text{-}C_5Ph_5^-$) ligands and is thus isostructural with $[Mo(\eta^5\text{-}C_5Ph_5)_2]^+$ (M = Cr, Fe, Co, Ni) [36–38]. The $[Mo(\eta^5\text{-}C_5Ph_5)_2]^{n+}$ ($n = 0$, 1) compounds are unique amongst $[Mo(\eta^5\text{-}C_5R_5)_2]$ (R = H, Me, Ph) in having metallocene structures at r.t. The compounds may be useful as synthetic reagents if a higher yielding synthesis can be developed.

3. Experimental

All reactions were carried out at atmospheric pressure under an inert atmosphere of high purity argon (99.995%, CIG) or nitrogen (99.995%, CIG), unless otherwise stated, and manipulations were performed using conventional Schlenk techniques [47]. All solvents used were Analytical Reagent grade and were distilled under an atmosphere of nitrogen and used within 24 h. All solvents were degassed by bubbling with inert gas for at least 0.5 h before use. Tetrahydrofuran (Merck or Rhône–Poulenc) and diethylether (Merck) were predried over sodium wire, and distilled from sodium benzophenone ketyl. Toluene (BDH), was distilled from sodium wire. Dichloromethane (Rhône–Poulenc), was distilled from calcium hydride. Tetraphenylcyclopentadienone, tetramethylsilane, molybdenum hexacarbonyl, $NOBF_4$ (all Aldrich) were used as received. C_5Ph_5H and C_5Ph_5Br, were prepared as described previously [48]. Melting points were determined using a Gallenkamp Melting Point Apparatus in air and are uncorrected. Elemental analyses were carried out by one of the following departments: the Australian Microanalytical Service in Melbourne, the Microanalytical Service at the Australian National University or at the JEAF in The University of Sydney. Infrared spectra were recorded on a Digilab FTS-40 infrared spectrophotometer either as a solution or as a suspension in a potassium bromide matrix. The resolution used was 4 cm^{-1} and the number of scans was 16. ^1H NMR spectra (200.13 MHz) were recorded on a Bruker AC-200F spectrometer. Spectra were referenced internally to the residual solvent resonances [CD_2Cl_2 (δ 5.31 ppm)] or to tetramethylsilane (δ 0.00 ppm). Mass spectra were performed by Dr. X. Song of the School of Chemistry, University of Sydney. They were obtained via a direct insertion probe using an electron impact ion source at 200 °C (variations as required), 70 eV ionisation voltage and 8 kV acceleration voltage using a Kratos MS 902 double focussing mass spectrometer. Electrochemical experiments were performed using a BAS 100 W Electrochemical Analyser. The sample cell was fitted with a plastic top that could be sealed almost air-tight. A three-electrode configuration was used. The working electrode was a BAS glassy carbon disc (3 mm diameter) which was polished with an alumina (0.25 mm grade) suspension on a velvet polishing cloth, then rinsed with distilled water and acetone, and then dipped in the solvent of use for 1 min before each cyclic voltammogram was recorded. The auxiliary electrode was a platinum wire (0.5 mm diameter, 4 cm length) which did not need cleaning between voltammograms but was cleaned by rinsing with 5 M aqueous HNO_3, distilled water and the solvent used prior to each set of experiments. The reference electrode was a BAS Ag/AgCl/NaCl (3 M) electrode with a vycor frit. All samples were thoroughly degassed with high purity argon (CIG) which was passed through a scrubber and a drying tower to remove any traces of oxygen and water, respectively. All potentials are quoted relative to the ferrocenium/ferrocene redox couple, which was observed at approximately 500 mV against the reference electrode [Ag/AgCl/NaCl (3 M)]. Samples were prepared as approximately 1 mM solutions with tetra(*n*-butyl)-ammonium tetrafluoroborate (TBATFB approximately 0.1 M) as the supporting electrolyte. TBATFB was prepared either from aqueous HBF_4 (35% v/v, Merck) and (n-C_4H_9)NOH (40% w/w, Aldrich) or by recrystallisation of TBATFB (Aldrich) three times from ethyl

acetate/diethyl ether in air, then drying in vacuo. Full IR (100%) compensation was employed in each scan. All measurements were carried out in dichloromethane solution with 0.1 M TBATFB as the supporting electrolyte and a scan rate of 100 mV s^{-1}.

A black prismatic crystal of $[Mo(C_5Ph_5)_2]BF_4 \cdot 0.5CH_2Cl_2 \cdot 0.75H_2O$ having approximate dimensions of $0.38 \times 0.25 \times 0.17$ mm was attached to a thin glass fibre and mounted on an Enraf–Nonius CAD4 diffractometer employing graphite monochromated Mo Kα radiation generated from a sealed tube. Cell constants were obtained from a least-squares refinement using the setting angles of 25 reflections in the range $2\theta = 16.60°$ and 24.00°. Data were collected at a temperature of 21 ± 1 °C using ω–2θ scans to a maximum 2θ value of 49.96°. The intensities of three representative reflections measured every 60 min did not change significantly during the data collection. Lorentz and polarisation corrections were applied to the data. An empirical absorption correction based on azimuthal scans of three suitable reflections was also applied to the data. Processing and calculations were undertaken with the TEXSAN [49] crystallographic software package. Neutral atom scattering factors were taken from Cromer and Waber [50]. Anomalous dispersion effects were included in F_{calc} [51] and the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley [52]. The values for the mass attenuation coefficients were those of Creagh and Hubbell [53]. The structure was solved in the space group $P\bar{1}$ (#2) by direct methods with SIR92 [54] and expanded with difference Fourier maps generated by DIRDIF [55]. The asymmetric unit contains two crystallographically independent molecules each residing on inversion sites, a disordered BF_4^- counterion, a 0.5 occupancy dichloromethane solvate molecule and two water oxygens sites with occupancies of 0.5 and 0.25. The BF_4^- counterion is rotationally disordered about the B(1)–F(1) axis and five fluorine sites were used to model the disorder. In general, the non-hydrogen atoms were modeled anisotropically, the exceptions being C(71), B(1), F(4), F(5), O(1) and O(2), which were refined with isotropic thermal parameters. The hydrogen atoms included in the model were placed at calculated positions with group thermal parameters. Two sites in the asymmetric unit were treated as partially occupied water oxygen sites and no hydrogens were included for these isotropically refined sites. The BF_4^- ion is disordered and was modeled with five fluorine sites. The asymmetric unit population of a dichloromethane solvate molecule was refined and then fixed at 0.5 and no hydrogens were included for this molecule.

3.1. Synthesis of decaphenylmolybdenocene

Into a 250 ml two neck Schlenk flask fitted with a condenser were charged $Mo(CO)_6$ (1.87 g, 7.08 mmol) and toluene (100 ml). The initially colourless solution was refluxed for 18 h producing a colour change to deep yellow. The reaction was cooled to r.t. and the solvent was removed under reduced pressure to yield pale yellow crystalline $[Mo(toluene)(CO)_3]$ which was used without further purification. Into the same reaction flask was added a solution of diphenylacetylene (6.3 g, 35.4 mmol) in dry heptane (100 ml). The mixture was heated to reflux for 16 h. The deep red precipitate was collected by gravity filtration and washed with dichloromethane in air until the washings became colourless (0.59 g, 8.3%). IR ν_{max} (KBr, cm^{-1}) 3054w, 3036w, 1600m, 1500s, 1444m, 1177w, 1074w, 1026w, 799w, 781m, 739s, 711vs, 700vs, 618w, 555s. MS (EI, *m/e*, %) 988 (M^+, 100%), 543 ($M^+ - C_5Ph_5$, 14), 494 (M^{2+}, 6), 446 ($C_5Ph_5H^+$, 22)

3.2. Synthesis of decaphenylmolybdenocenium tetrafluoroborate

Solid $NOBF_4$ (0.10 g, 0.86 mmol) was added to a well-stirred suspension of $[Mo(C_5Ph_5)_2]$ (0.51 g, 0.52 mmol) in dichloromethane (30 ml). The mixture was stirred for 2 h and filtered to yield a green filtrate. This was mixed with ether (30 ml) to produce a green crystalline precipitate, which was recrystallised from dichloromethane/ether (0.40 g, 72%) m.p. 260 °C. Anal. Calc. for $C_{70}H_{50}MoBF_4$: C 78.29; H, 4.69. Found: C, 78.4; H, 4.7%. ^1H NMR (ppm 200 MHz) δ 13.8 (s, br, Ar–*H*), 7.25–6.79 (m, Ar–*H*), 1.27 (s, Ar–*H*), 0.88 (s, Ar–*H*), 0.13 (s, br, Ar–*H*). Scheme 1.

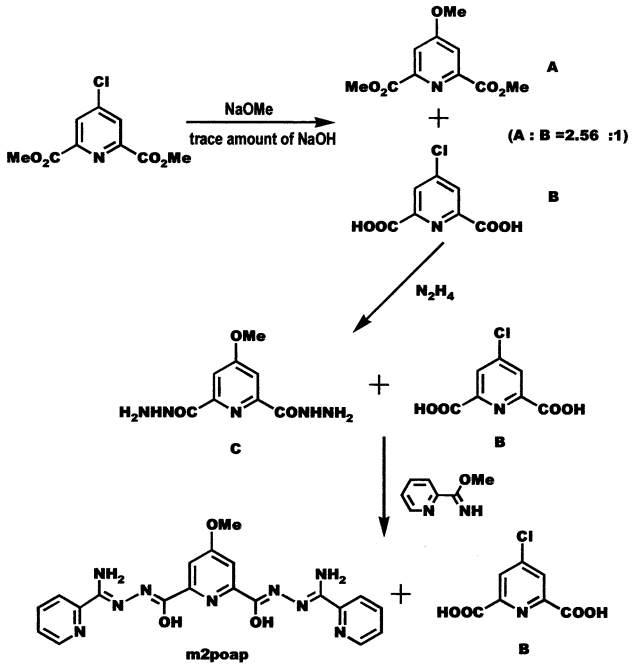
2. Experimental



2.1. Physical measurements

Infrared spectra were recorded as Nujol mulls using a Mattson Polaris FT-IR instrument. Mass spectra were obtained with VG Micromass 7070HS instrument. Micro-analyses were carried out by Canadian Microanalytical Service, Delta, Canada. Variable temperature magnetic data (2–300 K) were obtained using a Quantum Design MPMS5S SQUID magnetometer with field strengths in the range of 0.1–5.0 T. Samples were prepared in aluminum pans, and mounted inside straws for attachment to the sample transport rod. Background corrections for the sample holder assembly and diamagnetic components of the complexes were applied.

2.2. Synthesis of ligands and complexes

2.2.1. m2poap

The synthesis route of m2poap is shown in Scheme 2. A methanolic solution of sodium methoxide (2.60 g, 0.130 mol sodium in 100 mL methanol) was mixed with a methanolic solution of 4-chloro-dimethyl-2,6-pyridinedicarboxylate (11.5 g, 0.05 mol in 30 ml methanol). The resulting clean solution was refluxed for 2 h, followed by removing ~100 ml methanol. The white precipitate, which formed was filtered off and washed with methanol then ether. Yield 10.7 g. However, this product proved to be a mixture of 4-methoxy-dimethyl-2,6-pyridinedicarboxylate (**A** in Scheme 2) and 4-chloro-2,6-pyridinedicarboxylic acid (ClpicH$_2$) (**B** in Scheme 2), in a the ratio of **A**:**B** of ~ 2.6:1, which was deduced from the purification result of the final ligand, m2poap.

Scheme 2.

This probably occurred because the methanol used was not dry enough.

The mixture was suspended and stirred with hydrazine hydrate in 60 mL methanol at room temperature. **A** was converted into 4-methoxy-2,6-pyridinedicarboxylic acid dihydrazide (**C** in Scheme 2), but no change apparently occurred to **B**. This impure dihydrazide (**C** with a small amount of **B**) was further reacted under refluxing conditions with the methyl ester of iminopicolinic acid, which was prepared in situ by the reaction of 2-cyanopyridine (15.6 g, 0.150 mol) with sodium methoxide solution, produced by dissolving sodium metal (0.35 g, 0.015 mol) in dry methanol (150 ml). The final ligand m2poap (with a small amount of **B**) with filtered and washed with methanol then ether. Yield 16.7 g. M.p. 245–250 °C. The melting point of the purified sample (purified in hot water) is 258–260 °C. IR: ν_{max}/cm^{-1} (Nujol) 3415, 3315, 3217 (νNH_2, νOH), 1672, 1631($\nu C{=}O$ and $\nu C{=}N$) and 993 (py); *m/z* 411 ($M-H_2O$), 397 ($M-2H_2O$), 369,307,279,253, 223, 194, 162, 105. The complexation reactions were done with the crude sample of the ligand m2poap. Purification of the ligand was carried out subsequent to the structural determination of **1**.

2.2.2. Synthesis of $[Cu_9(m2poap-2H)_4(Clpic)_2(H_2O)_4](NO_3)_6\cdot 22H_2O$ (1)

The crude ligand m2poap (0.43 g, 1.0 mmol) was added to a warm (~60 °C) solution of $Cu(NO_3)_2\cdot 6H_2O$ (0.87g, 3.0 mmole) in 10 ml H_2O and 5 ml methanol. The resulting mixture was stirred for a few minutes at that temperature forming a clear solution,

which was filtered. Dark khaki-green crystals suitable for X-ray diffraction formed from the filtrate after standing for several days at room temperature (r.t.). Yield: 66%. IR (Nujol mull, cm^{-1}), 3550 (w) (νH_2O); 3300 (w), 3152 (w) (νNH_2); 1673 ($\nu C{=}N$); 1613 (νCOO); 1017 (m) (νpy). *Anal.* Found for **1**: C, 31.87; H, 2.92; N, 17.28. Calc. for $(C_{20}H_{17}N_9O_3)_4(C_7H_2NO_4Cl)_2Cu_9(NO_3)_6\cdot 26H_2O$: C, 31.92; H, 3.52; N, 17.42%.

2.2.3. Synthesis of $Cu_3(m2poap{-}2H)(NO_3)_4\cdot 4.5H_2O$ (**2**)

The ligand m2poap (0.43 g, 1.0 mmol) was added to a solution of $Cu(NO_3)_2\cdot 6H_2O$ (0.87 g, 3.0 mmol) in 10 ml acetonitrile and 10 ml methanol at room temperature. The resulting mixture was stirred for a few minutes at r.t. (no heat). A clear deep green solution formed, which was filtered. A green crystalline precipitate formed from the filtrate after standing overnight at room temperature. Yield: 72%. IR (Nujol mull, cm^{-1}), 3502 (w) (νH_2O); 3350 (w), 3187 (w) (νNH_2); 1693, 1676 ($\nu C{=}N$); 1039, 1004 (m) (νpy); 1797(w), 1751(w) (NO_3). *Anal.* Found for **2**: C, 24.99; H, 2.29; N, 19.32. Calc. for $(C_{20}H_{17}N_9O_3)Cu_3(NO_3)_4\cdot 4.5H_2O$: C, 25.26; H, 2.75; N, 19.14%.

2.3. X-ray crystallography

The diffraction intensities of a dark green, almost black prismatic crystal of **1** were collected with graphite monochromatized Mo Kα X-radiation (rotating anode generator) using a Bruker P4/CCD diffractometer at 193(1) K to a maximum 2θ value of 52.8°. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods [10,11]. All atoms except hydrogens were refined anisotropically. Hydrogen atoms were placed in calculated positions with isotropic thermal parameters set to 20% greater than their bonded partners, and were not refined. Neutral atom scattering factor [12] and anomalous-dispersion terms [13,14] were taken from the usual sources. All other calculations were performed with the TEXSAN [15] crystallographic software package using a PC computer. Crystal data collection and structure refinement details are given in Table 1. Two methanol molecules appear in the X-ray structure, which appear not to be present in the dried analytical sample (vide supra).

3. Results and discussion

3.1. Structure of $[Cu_9(m2poap{-}2H)_4(Clpic)_2](NO_3)_6\cdot(CH_3OH)_2\cdot 16H_2O$ (**1**)

The structure of the nona-nuclear cation in **1** is shown in Fig. 1, and selected bond distances and angles are listed in Table 2. Fig. 2 shows a simplified structure with non-donor atoms of the terminal ligand groups removed. The structure is unique within this class of compounds in that it contains two different ligands—deprotonated m2poap and $ClpicH_2$. The $Clpic^{2-}$ results from the batch of ligand being impure ($ClpicH_2$ is a hydrolysis product of the starting material methyl-4-chloro-2,6-pyridine dicarboxylate (Scheme 2), which is present at a level of ~30%). Nine copper(II) ions are arranged in the familiar [3 × 3] grid with oxygen bridges linking each adjacent pair of metals. Three deprotonated m2poap ligands are arranged in parallel on one face of the grid, while on the other two tridentate $Clpic^{2-}$ ligands flank a central m2poap ligand, with the pyridine rings of the three ligands being roughly parallel. Copper atoms Cu(2), Cu(4), Cu(8), Cu(6) and Cu(5) are six-coordinate, while the other coppers at the corners of the square grid are five-coordinate, with a water molecule

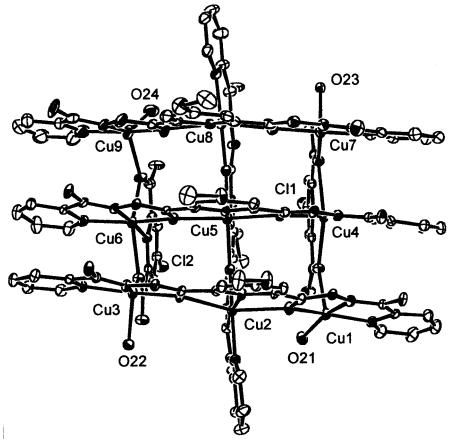

Fig. 1. Structural representation of the cation in **1** (40% thermal ellipsoids) with hydrogen atoms omitted.

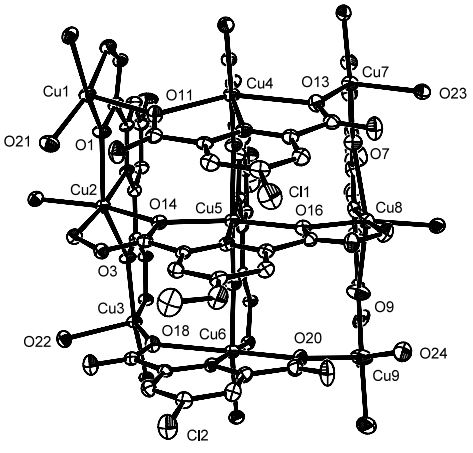

Fig. 2. Simplified structural representation of the core in **1**, highlighting the two pyridine dicarboxylate ligands.

completing the coordination spheres in each case. The corner copper atoms (Cu(1), Cu(3), Cu(7), Cu(9)) have distorted square-pyramidal geometries, while the side coppers have tetragonally elongated octahedral geometries, and the central copper Cu(5) has a tetragonally compressed octahedral geometry. The two $Clpic^{2-}$ ligands bridge three metals within the grid with the carboxylate oxgen donor atoms acting in an unusual bridging capacity. The m2poap ligands act in a heptadenetate fashion in the usual way, filling nine metal coordination sites. Cu–Cu separations fall in the range 3.54–4.10 Å, with three having very short distances (Cu(3)–Cu(6) 3.545(3) Å, Cu(6)–Cu(9) 3.831(4) Å, Cu(4)–Cu(7) 3.670(3) Å). It is no accident that the $Clpic^{2-}$ oxygen atoms bridge these metal atoms and that the angles subtended at the bridging oxygens are also very small (110.1(2)°, 121.1(2)°, 114.8(2)°, respectively). Cu(1)–O(11)–Cu(4) is also small (124.9(2)°), despite a quite long Cu–Cu separation (4.059(4) Å). This leads to a somewhat more distorted grid than those observed previously [5–7].

The inclusion of two 4-chloro-2,6-dipicolinate ligands in the structure may be serendipitous, but it shows that a nominally monotopic, chelating ligand, can have its coordination character completely changed if it is placed in an environment where other related tritopic ligands create a coordination framework into which it can be accommodated by virtue of its similar core dimensions. We are not aware of this coordination mode for a simple ligand of this sort. Within the grid all of the connections between copper centers around the peripheral ring of eight metals are either axial/axial (d_{z^2}/d_{z^2}) or axial/equatorial ($d_{z^2}/d_{x^2-y^2}$), based on the metal ion geometry. This leads to strict magnetic orbital orthogonality (vide infra). The central copper (Cu(5)) has an unusual d_{z^2} ground state, with four long equatorial Cu–O distances in the range 2.112–2.226 Å, and two short axial Cu–N distances (1.902(5) Å, 1.928(5) Å), and so nominally its connections to neighboring copper atoms Cu(2), Cu(4), Cu(6) and Cu(8) are also magnetically orthogonal.

3.2. Structure of $[(m2poap-2H)Cu_3(NO_3)_4]\cdot 4.5H_2O$ (**2**)

Although crystals of **2** have been obtained, a structural solution has not yet been possible. The green color of **2** differs markedly from **1** (almost black), and elemental analysis is consistent with a 1:3 (L:M) trinuclear derivative. Two other examples of linear trinuclear complexes $[Cu_3(2poap-2H)(CH_3CO_2)_4]\cdot 3H_2O$ and $[Cu_3(2poap-2H)\ (H_2O)(DMF)_3(CH_3OH)_2]\cdot(BF_4)_4$ with a closely related ligand [16], involve an almost *trans* (N–N)-bridged linear trinuclear arrangement, resulting in quite strong antiferromagnetic exchange. Such systems are rare with ligands in this class, but appear to form when strong donor solvents or coordinating anions are used and are synthesized without significant heating. Compound **2** is expected to have a similar structure. Preliminary results indicate that recrystallization of some trinuclear Cu(II) derivatives in water, with heat-

ing, converts them to the corresponding nona-nuclear grid complexes [17].

3.3. Magnetic properties

The room temperature magnetic moment for **1** ($5.6\mu_B$) (Fig. 3) is consistent with a nona-nuclear system ($5.2\mu_B$ for the spin only case), and it drops to a minimal value of $5.26\mu_B$ in the range 30–40 K, followed by a sharp rise to $7.18\mu_B$ at 2 K. This behaviour is consistent with the other reported [3 × 3] copper(II) grids [5–8], and indicates a combination of antiferromagnetic and ferromagnetic coupling. The exchange Hamiltonian expression for **1** is given in Eq. (1). The total spin state (S') values, and

$$H = -J1\{S_1\cdot S_2 + S_2\cdot S_3 + S_3\cdot S_6 + S_6\cdot S_9 + S_8\cdot S_9 + S_7\cdot S_8 + S_4\cdot S_7 + S_1\cdot S_4\} - J2\{S_2\cdot S_5 + S_5\cdot S_6 + S_5\cdot S_8 + S_4\cdot S_5\} \quad (1)$$

their energies for all spin vector combinations were evaluated in the normal way [18], and substituted into the Van Vleck equation within the internal structure of the software package MAGMUN-4.0 [19]. The magnetic data were fitted to Eq. (1) within MAGMUN-4.0 to give $g = 2.146(3)$, $J1 = 1.8(3)$ cm^{-1}, $J2 = -27.0(7)$ cm^{-1}, TIP $= 450 \times 10^{-6}$ emu mol^{-1}, $\rho = 0.003$, $\theta = -0.1$ K ($10^2R = 0.97$; $R = [\Sigma(\chi_{obs} - \chi_{calc})^2/\Sigma\ \chi^2_{obs}]^{1/2}$; ρ = fraction paramagnetic impurity, θ = Weiss-like temperature correction), as the best-fit result. The solid line in Fig. 3 was calculated with these parameters. The orthogonal bridging arrangement around the external ring of eight copper atoms leads to the positive ferromagnetic $J1$ (Cu_8 ring) value, while the negative, antiferromagnetic $J2$ is rationalized in terms of a fluxional magnetic ground state associated with the unusual, tetragonally compressed central copper (Fig. 2), typical of these structures [5,6,8]. On the basis of the nominal d_{z^2} ground state one would expect not to have antiferromagnetic exchange involving the central copper, but the clearly defined $J2$ indicates that on average this metal center interacts with one adjacent copper antiferromagnetically, and this can be rationalized in terms of the copper ion undergoing fluxional motion within a hole in which the metal 'd' orbitals have some orientational freedom. $J1$ is somewhat larger than $J1$ for the analogous grid complex $[Cu_9(2poap)_6](NO_3)_{12}\cdot 9H_2O$ (0.52 cm^{-1}) [8], which can reasonably be associated with the closer average Cu–Cu spacing in **1** (3.928 vs. 4.214 Å) [6]. $J2$ is comparable with the previous value (−24.3 cm^{-1}) [8], expected on the basis of the similarities in the coordination spheres of the central copper atoms.

Magnetization data for **1** as a function of field were determined at 2 K, and shown in Fig. 4. The magnetization increases sharply with increasing field and approaches saturation at 5.0 T. The data were fitted to the standard Brillouin function and the best-fit gave $g = 2.10$ for $S = 7/2$ (solid line in Fig. 4). The experimental data fall slightly short of the theoretical line as would perhaps be expected, given the combination of intramolecular ferromagnetic and antiferromagnetic exchange, but clearly indicate an $S = 7/2$ magnetic ground state, consistent with the variable temperature analysis.

The profile of magnetic moment as a function of temperature for **2** is illustrated in Fig. 5, and is completely different from **1**. The general shape of the profile is typical for a trinuclear derivative with strong intramolecular antiferromagnetic exchange. The data were fitted to a simple linear model based on the Hamiltonian expression shown in Eq. (2)

$$H = -J\{S_1\cdot S_2 + S_2\cdot S_3\} \quad (2)$$

which assumes that coupling between the extreme copper centers is insignificant. A reasonable fit was obtained using MAGMUN-4.0 [19] for $g = 2.260(4)$, $J = -159(2)$ cm^{-1}, TIP $= 160 \times 10^{-6}$ emu mol^{-1}, $\rho = 0.044$, $\theta = -0.2$ ($10^2R = 0.93$). The solid line in Fig. 5 was calculated with these parameters. The fairly large $-J$ value is consistent with N–N bridging in a situation where the metal ions are disposed with their magnetic orbitals arranged in a *trans* arrangement around the N–N single bond [6,20,21].

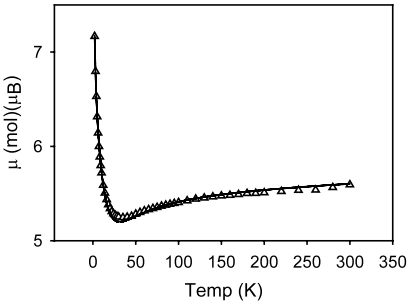

Fig. 3. Variable temperature magnetic data for **1**. The solid line corresponds to the best fit to Eq. (1) with $g = 2.146(3)$, $J1 = 1.8(3)$ cm^{-1}, $J2 = -27.0(7)$ cm^{-1}, TIP $= 450 \times 10^{-6}$ emu mol^{-1}, $\rho = 0.003$, $\theta = -0.1$ K ($10^2R = 0.97$).

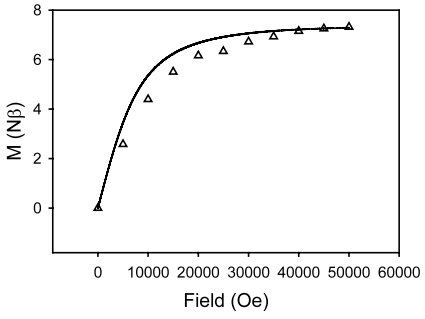

Fig. 4. Magnetization data as a function of field at 2 K for **1**. The solid line represents the best fit to the Brillouin function for $S = 7/2$, $g = 2.10$.

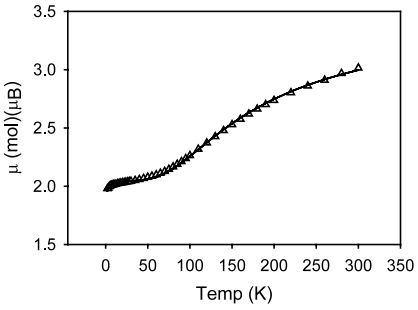

Fig. 5. Variable temperature magnetic data for **2**. The solid line represents the best data fit to Eq. (2), with $g = 2.260(4)$, $J = -159(2)$ cm^{-1}, $TIP = 160 \times 10^{-6}$ emu mol^{-1}, $\rho = 0.044$, $\theta = -0.2$ ($10^2R = 0.93$).

4. Conclusions

The serendipitous presence of a ligand impurity has lead to a most unusual mixed ligand [3 × 3] Cu_9 grid, with substantially different core geometry than in previous examples, and has provided an arrangement of ligands where the pyridine-2,6-dicarboxylate moiety can adopt a most unusual tritopic coordination mode bridging three metal ions. Also a trinuclear derivative is produced under different reaction conditions as the major product. Magnetic data are clearly rationalized, based on the geometrical features of the two structures.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 176299 for compound **1**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

procedures [12]. UV-VIS spectra were recorded in dichloromethane solutions on a Systronics 119 spectrometer. IR spectra were recorded with a Perkin–Elmer 597 spectrophotometer as KBr pellets. ^{1}H NMR were recorded in Varian AMX 400 instrument using tetramethylsilane as an internal standard. ^{31}P NMR spectra were recorded on a Varian AMX 400 instrument in $CDCl_3$ with ortho phosphoric acid as a reference. C, H, N and S analysis were carried out with Perkin–Elmer 2400 elemental analyser. Melting points were determined with a Boetius micro heating table and are uncorrected.

2.2. Synthesis of new binuclear ruthenium(II) complexes

All the new complexes were prepared by the following general procedure. To a solution of [RuHCl(CO)(PPh_3)$_3$], [RuHCl(CO)(PPh_3)$_2$(py)], [RuHCl(CO)(PPh_3)$_2$(pip)] or [RuHCl(CO)(PPh_3)$_2$(mor)] (0.1 g; 0.10–0.13 mmol) in benzene (25 cm^3), the appropriate thiobis(β-diketone) (0.012–0.031 g; 0.050–065 mmol) was added and the mixture was heated under reflux for 5 h. The resulting solution was concentrated to approximately 3 cm^3 and cooled. Light petroleum (60–80 °C) (5 cm^3) was then added whereupon the product complex separated. The solid was filtered off, washed and recrystallised from CH_2Cl_2/light petroleum mixture and dried in vacuo.

2.3. Catalytic oxidation of cinnamyl and benzyl alcohol

To a solution of alcohol (1 mmol) in chloroform (20 cm^3), *N*-methylmorpholine-*N*-oxide (3 mmol) and the ruthenium complex (0.01 mmol) were added. The solution was heated under reflux for 3 h. The mixture was filtered and the filtrate was dried over anhydrous sodium sulphate. Then it was evaporated to dryness and extracted with diethyl ether. The ether extract was filtered and evaporated to give the corresponding aldehyde which was then quantified as their 2,4-dinitrophenylhydrazones [12].

2.4. Procedure for antibacterial studies

The nutrient agar medium was prepared by taking 1 L of water in a conical flask followed by the addition of following ingredients one by one (i) beef extract = 3.0 g, (ii) yeast extract = 3.0 g, (iii) peptone = 5.0 g and (iv) sodium hydroxide = 5.0 g. The resulting solution was stirred well to get a clear solution. The pH of the solution was adjusted to 7.5 ± 0.2. After that, 15 mg of agar was added to the solution. The above said set up was sterilized at 120 °C for 15 min. A total of 20 cm^3 of the sterilised medium was poured into the sterilized Petri plates and allowed to solidify. The plates were inoculated with spore suspensions of *Bacillus* sp., *Escherichia coli* and *Pseudomonas* sp. The compounds to be tested were dissolved in DMSO to a final concentration of 0.25 and 0.5% and soaked in filter paper discs of 5-mm diameter and 1-mm thickness. These discs were placed on the already seeded plates and incubated at 35 ± 2 °C for 24 h. The diameter (mm) of inhibition zone around each disc was determined after 24 h and the results are recorded in Table 5. Streptomycin was used as a standard.

3. Results and discussion

The complexes of the general formula {[RuCl(CO)(PPh_3)(B)]$_2$(bis-β-dk)} [where B = PPh_3, pyridine (py), piperidine (pip) or morpholine (mor); bis-β-dk = thiobis(β-diketone)] were synthesised by the reactions of [RuHCl(CO)(PPh_3)$_3$], [RuHCl(CO)(PPh_3)$_2$(py)], [RuHCl(CO)(PPh_3)$_2$(pip)] or [RuHCl(CO)(PPh_3)$_2$(mor)] with the respective thiobis(β-diketones) in a 2:1 molar ratio in benzene as shown below.

$$[RuHCl(CO)(B)(PPh_3)_2] + H_2(\text{bis-}\beta\text{-dk}) \xrightarrow[\text{reflux, 5 h}]{\text{benzene}} \{[RuCl(CO)(B)(PPh_3)]_2(\text{bis-}\beta\text{-dk})\}$$

The analytical data (Table 1) and molecular weight determined (cryoscopic method) for these complexes are in good agreement with the above molecular formula. In all the reactions, it has been observed that the thiobis(β-diketone) behaves as a bifunctional tetradentate bridging ligand by substituting one of the triphenylphosphines and a chloride ion from each mole of the starting complex to form the binuclear complexes.

The new products obtained from the reactions of [RuHCl(CO)(PPh_3)$_3$] with the thiobis(β-diketones) contained two triphenylphosphine on each ruthenium ion, whereas the corresponding reactions of [RuHCl(CO)(PPh_3)$_2$(py)], [RuHCl(CO)(PPh_3)$_2$(pip)] or [RuHCl(CO)(PPh_3)$_2$(mor)] with the thiobis(β-diketone) ligands yielded new complexes with only one triphenylphosphine ligand on each ruthenium ion. These observations do indicate a more labile nature of Ru–P bond compared to the Ru–N bond of the heterocyclic nitrogen bases to the ruthenium ion in these complexes. The difference in the strength of Ru–P and Ru–N bonds may be explained as due to the better σ donating ability of the nitrogen bases [9] compared to that of triphenylphosphine.

3.1. IR spectra

The IR spectrum of (Hacac)$_2$S exhibits a strong band in the 1560 cm^{-1} region, attributable to a strongly conjugated chelated carbonyl group [11]. Absence of a band in the region 780–800 cm^{-1} implies the absence of a hydrogen attached to the carbon joining the two C=O

Table 1

groups. The IR spectra of (Hba)$_2$S and (Hdbm)$_2$S exhibit ν(C=O) at 1650 and 1670 cm^{-1}, respectively, indicating the presence of free carbonyl groups. The presence of a medium intensity band at 780 cm^{-1} in both the ligands is characteristic of CH out-of-plane bending mode [13].

In the IR spectra of all the thiobis(β-diketonato) complexes (Table 2), two bands appeared in the region 1550–1620 cm^{-1}. These bands are characteristic of the mixed modes of vibrations arising from the normal coordinates having contribution from ν(C=O) and ν(C=C) of coordinated β-diketonate groups [14]. From this it is inferred that the thiobis(β-diketones) coordinate to the metal in the conventional O,O bonding mode bridging two [RuCl(CO)(PPh$_3$)(B)] units. A strong band around 1950 cm^{-1} in all the complexes has been assigned to terminally coordinated carbonyl ligand [13]. In the IR spectra of complexes, a medium intensity band is observed in the 1000–1020 cm^{-1} region, characteristic of the coordinated pyridine, piperidine or morpholine [15].

3.2. Electronic spectra

All the ruthenium complexes are found to be diamagnetic which suggests that their geometry ought to be pseudo-octahedral. If the field around Ru^{2+} is assumed as octahedral, the ground state of ruthenium(II) (t_{2g}^6 configuration) should be $^1A_{1g}$. The excited states corresponding to $t_{2g}^5 e_g^1$ configuration are $^3T_{1g}$, $^3T_{2g}$, $^1T_{1g}$ and $^1T_{2g}$ in increasing order of energy. Thus, four bands corresponding to the transitions from $^1A_{1g}$ to $^3T_{1g}$, $^3T_{2g}$, $^1T_{1g}$ and $^1T_{2g}$ should appear in the electronic spectra of the complexes. Regarding charge transfer bands, no band due to L→M transitions is possible in the visible region in the low spin d^6 system [16]. Moreover, the presence of carbonyl and triphenylphosphine as ligands which are capable of producing strong ligand field e_g^* levels place these levels relatively high in energy. As a result, the bands due to charge transfer transitions L$\pi \rightarrow e_g^*$ or L$\sigma_u \rightarrow e_g^*$ should lie in the higher energy region. Therefore, the lowest charge transfer band due to excitation of an electron from metal t_{2g} level to unfilled molecular orbital derived from the π* level of the ligands ($t_{2g} \rightarrow t_{1u}$ or t_{2u}) should appear relatively in high energy region compared to those due to $t_{2g} \rightarrow e_g^*$ transitions [16].

The electronic spectra of all the complexes taken in dichloromethane showed two bands (Fig. 1) in the region 274–225 nm. Based on the values of extinction coefficient ($\varepsilon = 12{,}560$–$18{,}750$ dm^3 mol^{-1} cm^{-1}), both bands have been assigned to charge transfer transitions arising from an excitation of an electron from metal t_{2g} level to unfilled molecular orbitals derived from the π*

level of the ligands [17]. The nature of the observed electronic spectra and the position of absorption bands are consistent with those of other similar octahedral ruthenium(II) complexes [18,19].

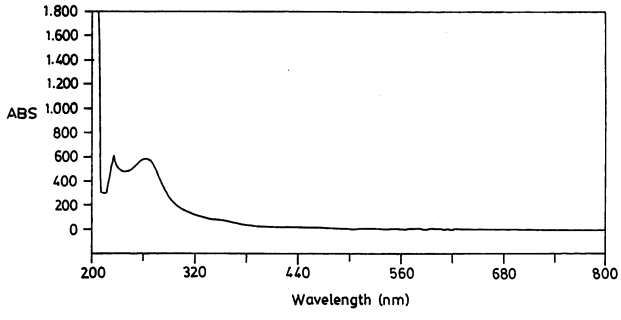
3.3. ^{1}H NMR spectra

All the ruthenium(II) complexes exhibit a multiplet at 6.32–8.11 ppm which has been assigned to the protons of phenyl groups present in the triphenylphosphine and thiobis(β-diketone). A singlet observed around 1.21–1.82 ppm in thiobis(acetylacetonato) and thiobis(benzoylacetonato) bridged complexes has been assigned to the methyl protons. The absence of a resonance at approximately 12 ppm in the complexes indicates deprotonation of the enolic group of thiobis(β-diketones) and coordination of the ligand to the metal through O,O donor atoms. The representative spectrum is displayed in Fig. 2.

3.4. ^{31}P NMR spectra

^{31}P NMR spectra were recorded for a few complexes in order to confirm the presence of triphenylphosphine groups and to determine the geometry of the complexes. The observation of six sharp singlets in the spectrum of $\{[RuCl(CO)(PPh_3)_2]_2(acac)_2S\}$ (Fig. 3) and $\{[RuCl(CO)(PPh_3)_2]_2(dbm)_2S\}$ suggests that the compound is a mixture of three possible geometrical isomers (I, II and III). The observation of two singlets around 28 and 45 ppm for the complexes $\{[RuCl(CO)(PPh_3)(pip)]_2(ba)_2S\}$ and $\{[RuCl(CO)(PPh_3)(mor)]_2(dbm)_2S\}$ can be explained as due to a mixture of two geometrical isomers (IV and V). Similar assignment has been made for linkage isomers of diphosphinepalladium nitrite complexes on the basis of ^{31}P NMR [20] Table 3.

In all the complexes, the IR spectrum showed a strong absorption around 1940–1970 cm^{-1}. If the position of CO is *trans* to PPh_3 in the structures II and III, the CO stretching should appear slightly at a higher frequency (ca. 2000 cm^{-1}) due to the presence of π-accepting PPh_3 group *trans* to CO group [21]. In the structures IV and V, the isomers with Cl and CO *trans* to each other are unlikely because of steric hindrance between pyridine and PPh_3 [22].



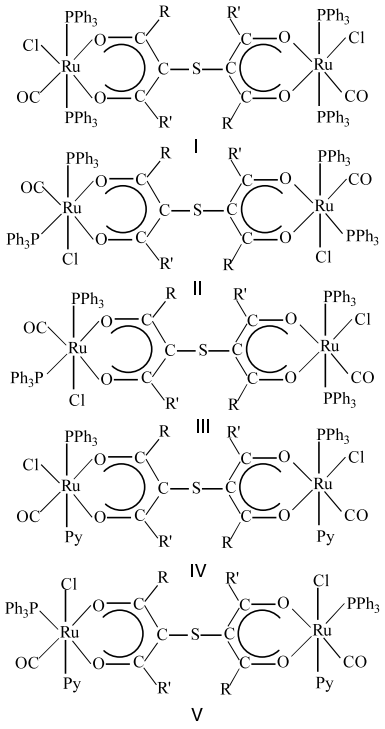


Fig. 1. Electronic spectrum of $\{[RuCl(CO)(PPh_3)(py)]_2(dbm)_2S\}$.

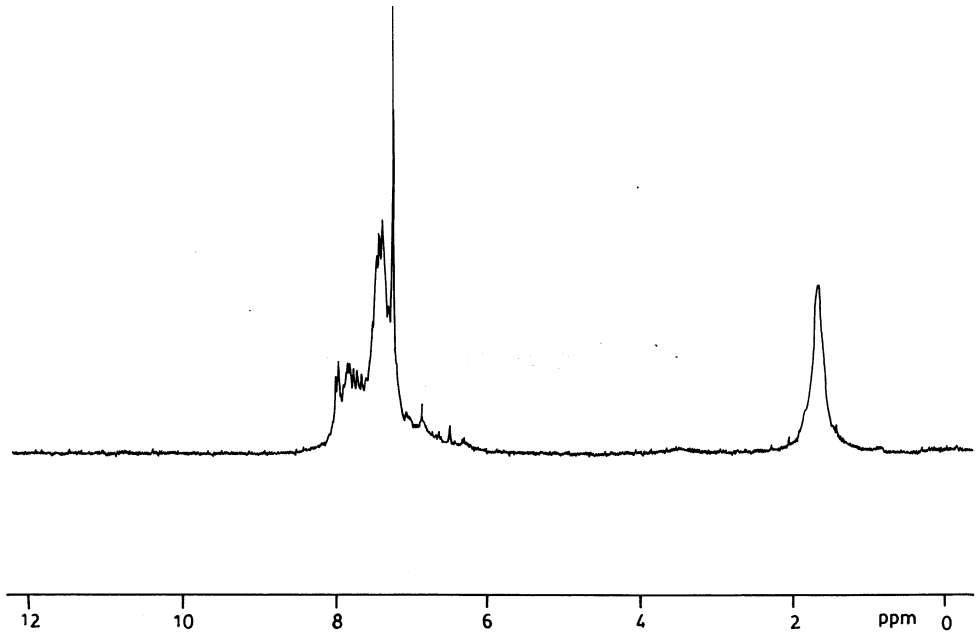
3.5. Catalytic activity

The results of the catalytic oxidation by ruthenium(II) complexes are summarised in Table 4. The oxidation of cinnamyl and benzyl alcohol using the different ruthenium complexes as catalysts in the presence of *N*-methylmorpholine-*N*-oxide (NMO) as co-oxidant were carried out in chloroform. The aldehydes formed after 3 h of reflux were quantified as their 2,4-dinitrophenylhydrazone derivatives. In no case was there any detectable oxidation of alcohols in the presence of *N*-methylmorpholone-*N*-oxide alone without the ruthenium complex. All the synthesised binuclear ruthenium complexes were found to catalyse the oxidation of alcohol to aldehyde but the yields and the turnovers were found to vary with different catalysts.

Complexes that do not contain heterocyclic nitrogen bases exhibit better catalytic activity than the complexes with heterocyclic nitrogen bases. This result is in accord with our observation, taking into account the stronger binding of heterocyclic bases to ruthenium ion, as compared to triphenylphosphine. The formation of the active species is therefore less favoured in the former case than in the latter, resulting in lower catalytic yield [23]. Further, the catalytic activity of binuclear complex, $\{[RuCl(CO)(PPh_3)_2]_2(acac)_2S\}$ has been compared with similar mononuclear complex, $[RuCl(CO)(PPh_3)_2(acac)]$ (VI) and it has been observed that binuclear complex is



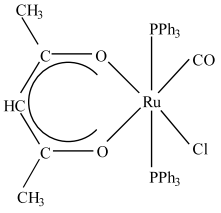


Fig. 2. ^{1}H NMR spectrum of {[RuCl(CO)(PPh$_3$)$_2$](ba)$_2$S}.

better catalyst than the mononuclear complex. This could be because, in binuclear complexes, the catalytically inert M^{n+1}–O–M^{n+1} species formation from possible active species M^{n+2}=O, is less likely than mononuclear complexes, because of its bigger size [24].

VI

3.6. Biocidal studies

The in vitro antibacterial screening of the ligands and some of their ruthenium(II) complexes have been carried out against *Bacillus* sp., *E. coli* and *Pseudomonas* sp. by disc diffusion method [25]. Triplicate plates were maintained in the antibacterial assays. The standard error for each assay is presented in the parenthesis. From the results (Table 5), it has been observed that ruthenium complexes showed better activity than the free ligands. This can be attributed to the Tweedy's chelation theory [26], according to which, chelation reduces the polarity of the central metal atom mainly because of partial

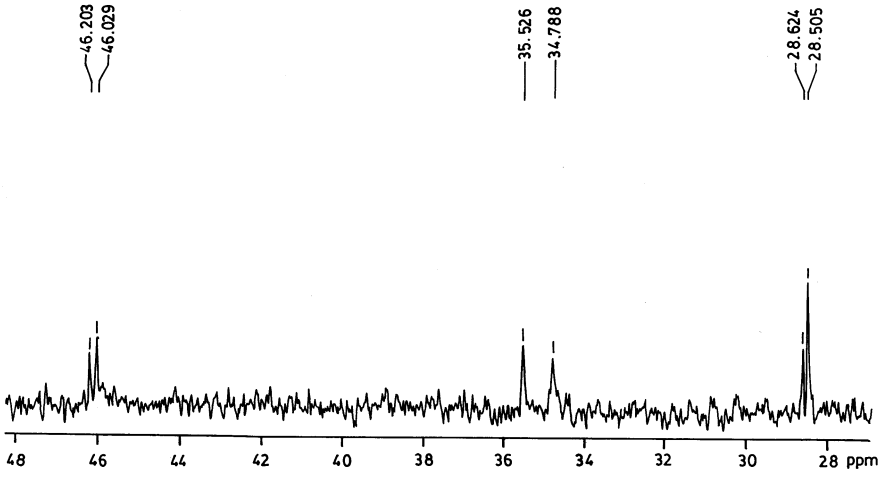

Fig. 3. ^{31}P NMR spectrum of {[RuCl(CO)(PPh$_3$)$_2$]$_2$(acac)$_2$S}.

sharing of its positive charge with a donor group and possible π-electron delocalisation taking place over the whole ring. This increases the lipophilic character of the metal chelate, which favours the permeation of the complexes through the lipid layer of cell membrane. Though the complexes possess activity, it could not reach the effectiveness of the standard drug, Streptomycin. The inhibition activity of the compounds increases with increase in the concentration of the solution.

Table 5
Antibacterial activity data for selected complexes

Compound	Diameter of inhibition zone (mm)					
	Bacillus sp.		*E. coli*		*Pseudomonas* sp.	
	0.25%	0.5%	0.25%	0.5%	0.25%	0.5%
$(Hacac)_2S$	7 (±0.8)	9 (±1.4)	6 (±0.8)	9 (±1.6)	8 (±1.4)	9 (±0.0)
$\{[RuCl(CO)(PPh_3)_2]_2(acac)_2S\}$	11 (±1.4)	14 (±1.4)	10 (±1.6)	12 (±1.4)	11 (±2.2)	13 (±0.8)
$\{[RuCl(CO)(PPh_3)(py)]_2(acac)_2S\}$	12 (±0.8)	14 (±2.8)	9 (±1.4)	12 (±1.6)	10 (±1.4)	12 (±1.4)
$(Hba)_2S$	8 (±0.8)	10 (±1.6)	7 (±0.8)	10 (±1.4)	7 (±0.8)	9 (±0.8)
$\{[RuCl(CO)(PPh_3)_2]_2(ba)_2S\}$	12 (±1.4)	16 (±2.8)	11 (±0.8)	14 (±0.8)	10 (±1.4)	13 (±1.4)
$\{[RuCl(CO)(PPh_3)(py)]_2(ba)_2S\}$	12 (±1.6)	15 (±2.8)	11 (±0.8)	15 (±1.4)	10 (±0.8)	14 (±1.4)
$(Hdbm)_2S$	6 (±0.0)	10 (±1.6)	7 (±0.8)	9 (±0.8)	6 (±0.0)	9 (±1.4)
$\{[RuCl(CO)(PPh_3)_2]_2(dbm)_2S\}$	11 (±1.4)	13 (±2.2)	11 (±0.8)	14 (±2.8)	10 (±1.4)	15 (±2.8)

during which time triethylammonium hydrochloride separated from the colourless solution. This precipitate was removed by suction filtration and the filtrate evaporated to dryness in vacuo to give a white solid product. Yield: 3.92 g, 75%.

2.2. $(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)$ (**2**)

A solution of 1,2-phenylenephosphoro-chloridite (4.65 g, 16.7 mmol) in thf (60.0 cm^3) was added dropwise over a period of 1 h to a stirred solution of piperazine (0.72 g, 8.3 mmol) and triethylamine (1.69 g, 2.3 cm^3, 16.7 mmol) in thf (70.0 cm^3). Stirring was continued for a further 2 h, during which time triethylammonium hydrochloride separated from the colourless solution. This precipitate was removed by suction filtration and the filtrate evaporated to dryness in vacuo to give a white solid product. Yield: 2.15 g, 71%.

2.3. $(C_2H_4O_2)PN(C_2H_4)_2NP(C_2H_4O_2)$ (**3**)

A solution of 2-chloro-1,3,2-dioxaphospholane (5.69 g, 4.0 cm^3, 45.0 mmol) in thf (70.0 cm^3) was added dropwise over a period of 1 h to a stirred solution of piperazine (1.93 g, 22.5 mmol) and triethylamine (4.54 g, 6.2 cm^3, 45.0 mmol) in thf (80.0 cm^3). Stirring was continued for a further 2 h, during which time triethylammonium hydrochloride separated from the colourless solution. This precipitate was removed by suction filtration and the filtrate evaporated to dryness in vacuo to give a white solid product. Yield: 4.31 g, 72%.

2.4. cis-$[PtCl_2\{Ph_2PN(C_2H_4)_2NPPh_2\}]$ (**4**)

To a solution of $[PtCl_2(cod)]$ (0.100 g, 0.26 mmol) in dichloromethane (5.0 cm^3) was added solid $Ph_2PN(C_2H_4)_2NPPh_2$ (0.120 g, 0.26 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (10.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.152 g, 79%.

2.5. cis-$[PtCl_2\{(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)\}]$ (**5**)

To a solution of $[PtCl_2(cod)]$ (0.100 g, 0.26 mmol) in dichloromethane (15.0 cm^3) was added solid $(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)$ (0.097 g, 0.26 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (15.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.150 g, 89%.

2.6. cis-$[PtMe_2\{(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)\}]$ (**6**)

To a solution of $[PtMe_2(cod)]$ (0.080 g, 0.24 mmol) in dichloromethane (10.0 cm^3) was added solid $(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)$ (0.087 g, 0.24 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (40.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.089 g, 63%.

2.7. cis-$[PdCl_2\{Ph_2PN(C_2H_4)_2NPPh_2\}]$ (**7**)

To a solution of $[PdCl_2(cod)]$ (0.100 g, 0.35 mmol) in dichloromethane (5.0 cm^3) was added solid $Ph_2PN(C_2H_4)_2NPPh_2$ (0.160 g, 0.35 mmol) and the yellow solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (10.0 cm^3) added. The yellow product was collected by suction filtration. Yield: 0.137 g, 62%.

2.8. cis-$[Mo(CO)_4\{Ph_2PN(C_2H_4)_2NPPh_2\}]$ (**8**)

To a partially dissolved solution of $[Mo(CO)_4(pip)_2]$ (0.500 g, 1.30 mmol) in dichloromethane (20.0 cm^3) was added solid $Ph_2PN(C_2H_4)_2NPPh_2$ (0.590 g, 1.30 mmol). The solution was heated to reflux for approximately 15 min and allowed to cool to r.t. The solution was concentrated under reduced pressure to approximately 2.0 cm^3 and methanol (15.0 cm^3) added. The yellow product was collected by suction filtration. Yield: 0.635 g, 72%.

2.9. $[Ph_2P(AuCl)N(C_2H_4)_2NP(AuCl)Ph_2]$ (**9**)

To a solution of [AuCl(tht)] (0.071 g, 0.22 mmol) in dichloromethane (5.0 cm^3) was added solid $Ph_2PN(C_2H_4)_2NPPh_2$ (0.050 g, 0.11 mmol) and the colourless solution stirred for approximately 1 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (5.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.054 g, 53%.

2.10. $[(C_6H_4O_2)P(AuCl)N(C_2H_4)_2NP(AuCl)(C_6H_4O_2)]$ (**10**)

To a solution of [AuCl(tht)] (0.184 g, 0.58 mmol) in dichloromethane (15.0 cm^3) was added solid $(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)$ (0.104 g, 0.29 mmol) and the colourless solution stirred for approximately 1 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (30.0

cm^3) added. The white product was collected by suction filtration. Yield: 0.205 g, 86%.

2.11. $[(C_2H_4O_2)P(AuCl)N(C_2H_4)_2$-$NP(AuCl)(C_2H_4O_2)]$ (**11**)

To a solution of [AuCl(tht)] (0.160 g, 0.50 mmol) in dichloromethane (15.0 cm^3) was added solid $(C_2H_4O_2)PN(C_2H_4)_2NP(C_2H_4O_2)$ (0.068 g, 0.25 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (30.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.140 g, 76%.

2.12. $[\{RuCl_2(\eta^6$-p-$MeC_6H_4^iPr)\}_2\{Ph_2PN(C_2H_4)_2NPPh_2\}]$ (**12**)

To a solution of $[\{RuCl(\mu\text{-}Cl)(\eta^6\text{-}p\text{-}MeC_6H_4^iPr)\}_2]$ (0.250 g, 0.40 mmol) in thf (20.0 cm^3) was added solid $Ph_2PN(C_2H_4)_2NPPh_2$ (0.185 g, 0.40 mmol) and the brown solution stirred for approximately 12 h. The solution was concentrated under reduced pressure to approximately 2.0 cm^3 and diethyl ether (10.0 cm^3) added. The red–brown product was collected by suction filtration and washed with diethyl ether (2×10.0 cm^3). Yield: 0.299 g, 69%.

2.13. $Ph_2PN(C_5H_{10})NPPh_2$ (**13**)

A solution of chlorodiphenylphosphine (6.87 g, 5.6 cm^3, 31.2 mmol) in thf (50.0 cm^3) was added dropwise over a period of 1 h to a stirred solution of homopiperazine (1.56 g, 15.6 mmol) and triethylamine (3.13 g, 4.3 cm^3, 31.3 mmol) in thf (75 cm^3) at r.t. Stirring was continued for 2 h, during which time triethylammonium hydrochloride separated from the colourless solution. This precipitate was removed by suction filtration and the filtrate evaporated to dryness in vacuo to give a white solid product. Yield: 4.92 g, 68%.

2.14. $[Ph_2P\{Se\}N(C_5H_{10})N\{Se\}PPh_2]$ (**14**)

To a toluene (20 ml) solution of selenium (0.075 g, 0.904 mmol) was added $Ph_2P\{Se\}N(C_5H_{10})N\{Se\}PPh_2$ (0.207 g, 0.281 mmol). The reaction was stirred and heated to reflux for 2–3 h. The product was collected by suction filtration under nitrogen atmosphere and an off-white product was isolated. Yield: 0.123 g, 70%.

2.15. cis-$[PtCl_2\{Ph_2PN(C_5H_{10})NPPh_2\}]$ (**15**)

To a solution of $[PtCl_2(cod)]$ (0.100 g, 0.26 mmol) in dichloromethane (10.0 cm^3) was added solid $Ph_2PN(C_5H_{10})NPPh_2$ (0.125 g, 0.26 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (40.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.180 g, 92%.

2.16. cis-$[PtMe_2\{Ph_2PN(C_5H_{10})NPPh_2\}]$ (**16**)

To a solution of $[PtMe_2(cod)]$ (0.100 g, 0.30 mmol) in dichloromethane (10.0 cm^3) was added solid $Ph_2PN(C_5H_{10})NPPh_2$ (0.140 g, 0.30 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (30.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.130 g, 64%.

2.17. cis-$[PdCl_2\{Ph_2PN(C_5H_{10})NPPh_2\}]$ (**17**)

To a solution of $[PdCl_2(cod)]$ (0.152 g, 0.53 mmol) in dichloromethane (20.0 cm^3) was added solid $Ph_2PN(C_5H_{10})NPPh_2$ (0.250 g, 0.53 mmol) and the yellow solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (40.0 cm^3) added. The yellow product was collected by suction filtration. Yield: 0.300 g, 87%.

2.18. $[Ph_2P(AuCl)N(C_5H_{10})NP(AuCl)Ph_2]$ (**18**)

To a solution of [AuCl(tht)] (0.192 g, 0.60 mmol) in dichloromethane (15.0 cm^3) was added solid $Ph_2PN(C_5H_{10})NPPh_2$ (0.140 g, 0.30 mmol) and the colourless solution stirred for approximately 1 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (35.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.214 g, 76%.

2.19. $(C_6H_4O_2)PN(C_5H_{10})NP(C_6H_4O_2)$ (**19**)

A solution of 1,2-phenylenephosphoro-chloridite (4.65 g, 16.7 mmol) in thf (55.0 cm^3) was added dropwise over a period of 1 h to a stirred solution of homopiperazine (0.84 g, 8.3 mmol) and triethylamine (1.69 g, 2.3 cm^3, 16.7 mmol) in thf (85.0 cm^3). Stirring was continued for a further 2 h, during which time triethylammonium hydrochloride separated from the colourless solution. This precipitate was removed by suction filtration and the filtrate evaporated to dryness in vacuo to give a white solid product. Yield: 2.58 g, 82%.

2.20. cis-$[PtCl_2\{(C_6H_4O_2)PN(C_5H_{10})NP(C_6H_4O_2)\}]$ (**20**)

To a solution of $[PtCl_2(cod)]$ (0.179 g, 0.48 mmol) in dichloromethane (15.0 cm^3) was added solid

$(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)$ (0.180 g, 0.48 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (30.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.104 g, 84%.

2.21. *cis-[PtMe$_2${(C$_6$H$_4$O$_2$)PN(C$_5$H$_{10}$)-NP(C$_6$H$_4$O$_2$)}] (**21**)*

To a solution of [$PtMe_2$(cod)] (0.100 g, 0.30 mmol) in dichloromethane (10.0 cm^3) was added solid $(C_6H_4O_2)$-$PN(C_2H_4)_2NP(C_6H_4O_2)$ (0.114 g, 0.30 mmol) and the colourless solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (35.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.120 g, 66%.

2.22. *cis-[PdCl$_2${(C$_6$H$_4$O$_2$)PN(C$_5$H$_{10}$)-NP(C$_6$H$_4$O$_2$)}] (**22**)*

To a solution of [$PdCl_2$(cod)] (0.285 g, 1.00 mmol) in dichloromethane (25.0 cm^3) was added solid $(C_6H_4O_2)$-$PN(C_5H_{10})NP(C_6H_4O_2)$ (0.378 g, 1.0 mmol) and the yellow solution stirred for approximately 2 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (30.0 cm^3) added. The yellow product was collected by suction filtration. Yield: 0.520 g, 94%.

2.23. *[(C$_6$H$_4$O$_2$)P(AuCl)N(C$_5$H$_{10}$)-NP(AuCl)(C$_6$H$_4$O$_2$)] (**23**)*

To a solution of [AuCl(tht)] (0.140 g, 0.44 mmol) in dichloromethane (15.0 cm^3) was added solid $(C_6H_4O_2)$-$PN(C_5H_{10})NP(C_6H_4O_2)$ (0.083 g, 0.22 mmol) and the colourless solution stirred for approximately 1 h. The solution was concentrated under reduced pressure to approximately 1.0 cm^3 and diethyl ether (30.0 cm^3) added. The white product was collected by suction filtration. Yield: 0.150 g, 81%.

2.24. *(C$_2$H$_4$O$_2$)PN(C$_5$H$_{10}$)NP(C$_2$H$_4$O$_2$) (**24**)*

A solution of 2-chloro-1,3,2-dioxaphospholane (5.69 g, 4.0 cm^3, 45.0 mmol) in thf (55.0 cm^3) was added dropwise over a period of 1 h to a stirred solution of homopiperazine (2.25 g, 22.5 mmol) and triethylamine (4.54 g, 6.2 cm^3, 45.0 mmol) in thf (100.0 cm^3). Stirring was continued for a further 2 h, during which time triethylammonium hydrochloride separated from the colourless solution. This precipitate was removed by suction filtration and the filtrate evaporated to dryness in vacuo to give a white solid product. Yield: 4.91 g, 78%.

2.25. *^{i}Pr$_2$PN(C$_5$H$_{10}$)NP^{i}Pr$_2$ (**25**)*

A solution of diisopropylphosphinechloride (1.61 ml, 0.01 g, 10.0 mmol) in thf (20 cm^3) was added dropwise to a stirred solution of homopiperazine (0.49 g, 4.89 mmol) and degassed Et_3N (1.40 ml, 0.01 g, 10.0 mmol) in thf (20 cm^3) at r.t. The reaction mixture was stirred for a further 2 h, during which time triethylammonium hydrochloride separated from the colourless solution. This precipitate was removed by suction filtration and the filtrate evaporated to dryness in vacuo to give an oily colourless product.

2.26. *[^{i}Pr$_2$P{Se}N(C$_5$H$_{10}$)N{Se}P^{i}Pr$_2$] (**26**)*

To a toluene (10 ml) solution of selenium (0.105 g, 1.330 mmol) was added solid ligand L^3 (0.212 g, 0.638 mmol). The reaction was stirred and heated to reflux for 2–3 h under reflux. The product was collected by suction filtration under nitrogen atmosphere and an off-white product was isolated. Yield: 0.146 g, 47%.

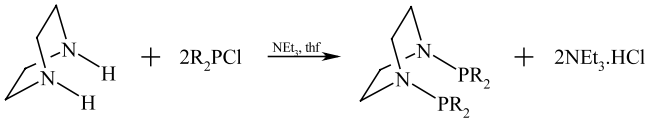
2.27. *cis-[PtCl$_2${^{i}Pr$_2$PN(C$_5$H$_{10}$)NP^{i}Pr$_2$}] (**27**)*

To a solution of [$PtCl_2$(cod)] (0.202 g, 0.541 mmol) in dichloromethane (10 ml) was added solid ligand L^3 (0.180 g, 0.541 mmol). The mixture reaction was stirred for 2 h then diethyl ether (5 ml) was added to solubilise the cod moiety whilst the complex is insoluble and was precipitated as a white solid. After 15 min in the ultrasonic bath, the sample was filtered, the white solid was washed with diethyl ether. Yield: 0.324 g, 50%.

2.28. *Crystallography*

Crystallography was performed using a Bruker SMART diffractometer; full hemisphere of data with 0.3° 'slices', r.t., Mo Kα radiation and empirical absorption corrections. All of the other non-H atoms were refined anisotropically with the hydrogen atoms being refined in idealised geometries. All calculations employed the SHELXTL program system [16].

Compound **7**: $C_{28}H_{28}Cl_2N_2P_2Pd$ $M = 631.8$, monoclinic, space group $P2_1/n$, $a = 11.223(1)$, $b = 27.882(3)$, $c = 17.936(2)$ Å. $\beta = 96.646(3)°$ $U = 5575$ Å^3, $Z = 8$ (two independent molecules), $D_{calc} = 1.51$ g cm^{-3}, $F(000) = 2560$, μ(Mo Kα) = 1.62 mm^{-1}. Of 24 012 measured data, 7949 were unique and observed [$I > 2.0\sigma(I)$] to give $R = 0.080$ and $wR_2 = 0.1421$.



Compound **15**: $C_{47}H_{58}Cl_{10}N_2P_2Pt3$ $M = 1652.7$, orthorhombic, space group $Pca2(1)$, $a = 16.556(1)$, $b = 9.814(1)$, $c = 33.1291(1)$. $U = 5383$ Å^3, $Z = 4$, $D_{calc} = 2.04$ g cm^{-3}, $F(000) = 3152$, μ(Mo Kα) = 8.37 mm^{-1}. Of 21 988 measured data 7523 were unique and observed [$I > 2.0\sigma(I)$] to give $R = 0.0291$ and $wR_2 = 0.0712$. The

H atoms on one of the solvent molecules was not included in the refinement.

$Ph_2(O)PNC_4H_8NP(O)Ph_2 \cdot H_2O$: $C_{28}H_{30}N_2O_3P_2$ $M = 504.5$, monoclinic, space group $P2_1/n$, $a = 9.736(1)$, $b = 12.868(3)$, $c = 10.940(2)$ Å. $\beta = 111.89(1)^\circ$ $U = 1272$ Å^3, $Z = 2$, $D_{calc} = 1.32$ g cm^{-3}, $F(000) = 532$, μ(Mo Kα) = 0.204 mm^{-1} (there was considerable decomposition during data collection and no absorption correction was applied). Of 2560 measured data 1414 were unique and observed [$I > 2.0\sigma(I)$] to give $R = 0.0376$ and $wR_2 = 0.0858$.

3. Results and discussion

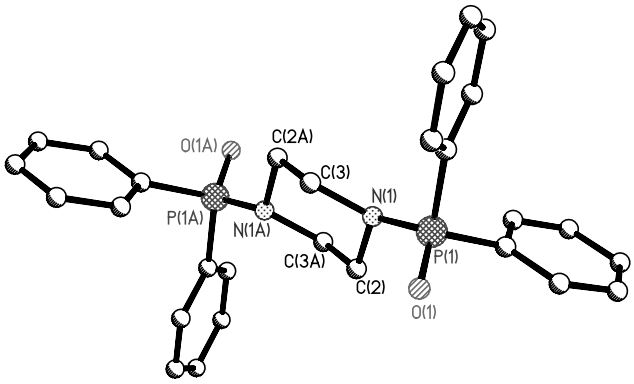
Reaction of piperazine with 2 equiv. of the chlorophosphines Ph_2PCl, $R_2 = Ph_2$ (**1**), $C_6H_4O_2$ (**2**) and OC_2H_4O (**3**)

$R_2 = Ph_2$ (**1**), $C_6H_4O_2$ (**2**) and OC_2H_4O (**3**)

(1)

$(C_6H_4O_2)PCl$ and $(C_2H_4O_2)PCl$, in the presence of NEt_3, proceeds in thf to give **1**, **2** and **3** respectively (Eq. (1)).

Addition of the chlorophosphine in thf to a solution of piperazine in thf, at r.t., results in the immediate precipitation of $[Et_3NH]Cl$ as the reaction proceeds. Removal of the ammonium salt by filtration, reduction of the volume of thf in vacuo and addition of diethyl ether gives the new species in 70–80% yield. The $^{31}P\{^1H\}$ NMR spectrum of **1** comprises a singlet at δ(P) 62.9. The possibility of this peak representing the mono-substituted amine was rejected after performing in situ ^{31}P NMR studies. Monitoring of the reaction mixture at regular intervals, immediately after completion of the chlorodiphenylphosphine addition, shows a phosphorus-containing species, with a chemical shift of δ(P) 35.1, to be the initial reaction product. This is assumed to be the mono-substituted amine and gradually decreases in intensity as the reaction proceeds, to leave **1** as the only phosphorus containing compound. The $^{31}P\{^1H\}$ NMR spectrum of **2** and **3** are singlets at δ(P) 144.2 and 137.9 ppm respectively; the large downfield shift when compared with **1** reflecting the close proximity of the phosphorus centre to the strongly electronegative oxygen atoms. Although stable for short periods in the solid state in solution **1**–**3** oxidise readily in solution in air. Crystals of **1O$_2$** were obtained from a CH_2Cl_2 solution of **1** and the structure is shown in Fig. 1



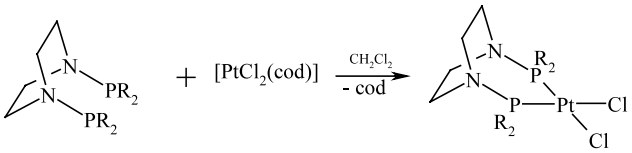


Fig. 1. Solid state structure of $Ph_2P(O)N(C_2H_4)NP(O)Ph_2$.

with selected bond lengths and angles in Table 2. The piperazine ring adopts a chair conformation with the P=O groups being on opposite sides of the molecule.

Reaction of **1** and **2** with equimolar quantities of $[PtCl_2(cod)]$ in dichloromethane (Eq. (2)) to yield the seven-membered, *P,P′* chelates **4** and **5**.

$R_2 = Ph_2$ (**4**), $C_6H_4O_2$ (**5**)

(2)

The $^{31}P\{^1H\}$ NMR spectra of both compounds are singlets with satellites from coupling to ^{195}Pt, the nature of the substituent groups on the phosphorus being reflected in the positions of the chemical shifts (δ(P) 53.5 and 99.6 ppm, respectively) and the magnitude of the $^1J(^{195}Pt-^{31}P)$ coupling constants (3972 and 5480 Hz, respectively) which are in accord with values previously reported for similarly substituted phosphines when *trans* to a chloride in a Pt(II) complex **2** [5,17,18] also reacts with $[PtMe_2(cod)]$, in dichloromethane, to produce the *P,P′* chelate *cis*-$[PtMe_2\{(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)\}]$ (**6**).

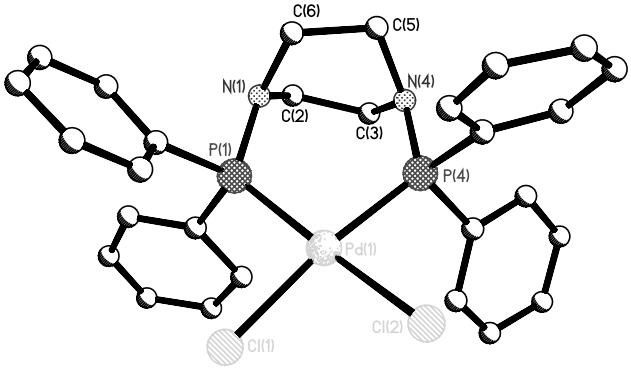

Fig. 2. Solid state structure of *cis*-$[PdCl_2\{Ph_2PN(C_2H_4)_2NPPh_2\}]$ (**7**).

Similarly, the reaction of **1** with an equimolar quantity of $[PdCl_2(cod)]$ in thf results in the bidentate, *P*,*P*′ chelate complex *cis*-$[PdCl_2\{Ph_2PN(C_2H_4)_2NPPh_2]$ (**7**). The X-ray structure of **7** contains two crystallographically independent molecules and shows the product to have the expected square-planar geometry about the Pd centre (Table 2, Fig. 2). The bidentate nature of the co-ordination to the metal results in the formation of two seven-membered Pd–P–N–C–C–N–P ring systems The $N(C_2H_4)_2N$ backbone of the ligand adopts a boat conformation and forms an 'umbrella-like' structure around the Pd centre. The structure also reveals that the square-planar palladium centre is some-

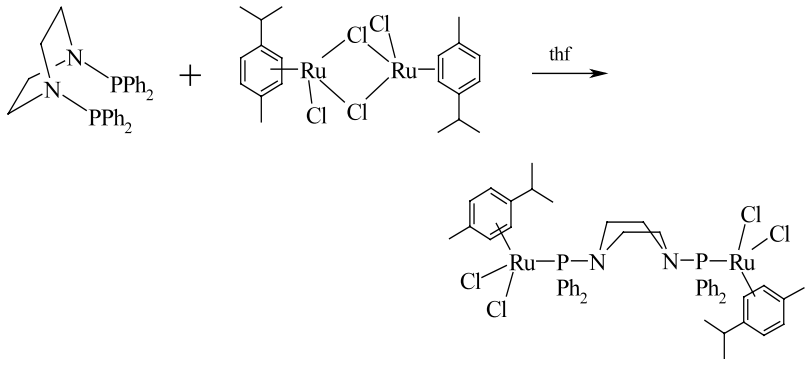
what distorted and in both of the two independent molecules the bite angle of the piperazine is larger than the ideal 90° [94.0 (2°) and 94.7 (2°)] and the Cl–Pd–Cl angles are also greater than 90° [92.1 (2°) and 92.0 (2°)]. The mean deviations of PdP_2Cl_2 from the plane are 0.14 Å for one of the molecules and 0.02 Å for the second. In both molecules the P–N, Pd–P and P–Cl bond lengths are all typical of single bonds.

(3)



form seven-membered metallacycles. Reactions with compounds containing Au(I) and Ru(II) show that **1**–**3** can also act as a bridging ligands between two metal centres (Eq. (4)).

R = Ph (**9**), $C_6H_4O_2$ (**10**) OC_2H_4O (**11**)

(4)

Analogous ligands to **1**–**3** can be synthesised by reacting the same chlorophosphines with homopiperazine which differs from piperazine by containing an extra CH_2 group, therefore, forming a seven-membered nitrogen–carbon ring system. Reaction of homopiperazine with 2 equiv. of Ph_2PCl, $(C_6H_4O_2)PCl$ and $(C_2H_4O_2)PCl$, in the presence of NEt_3, proceeds in thf to give **13, 19** and **24.** Reaction of $^{i}Pr_2PCl$ with homopiperazine yields the analogous ^{i}Pr derivative **25**. The δ_P values of all three aryl ligands are slightly downfield from the values observed for the analogous piperazine derivatives, **1**–**3**, suggesting that the addition

The reaction of **1** with $[Mo(CO)_4(pip)_2]$ in dichloromethane proceeds, with displacement of the piperidines, to give **8** (Eq. (3)). The $^{31}P\{^{1}H\}$ NMR spectrum of **8** displays a singlet at δ(P) 97.2, a downfield shift of around 35 ppm upon complexation whilst its IR spectrum contains four strong bands due to ν(CO) (2021, 1917, 1901 and 1888 cm^{-1}), confirming the *cis* structure. Compounds **4**–**8** demonstrate the ability of $Ph_2PN(C_2H_4)_2NPPh_2$ and $(C_6H_4O_2)PN(C_2H_4)_2NP(C_6H_4O_2)$ to act as bidentate chelating ligands and

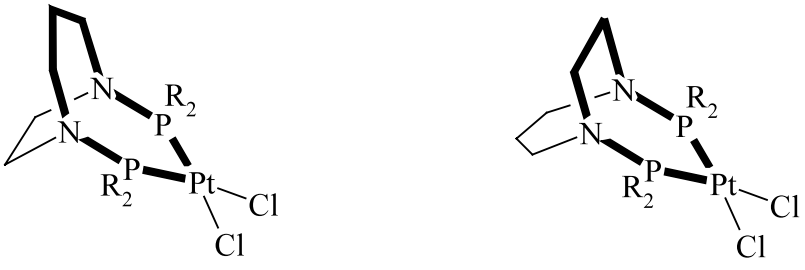


Fig. 3. Different ring sizes in complexes containing the homopiperazine based ligands.

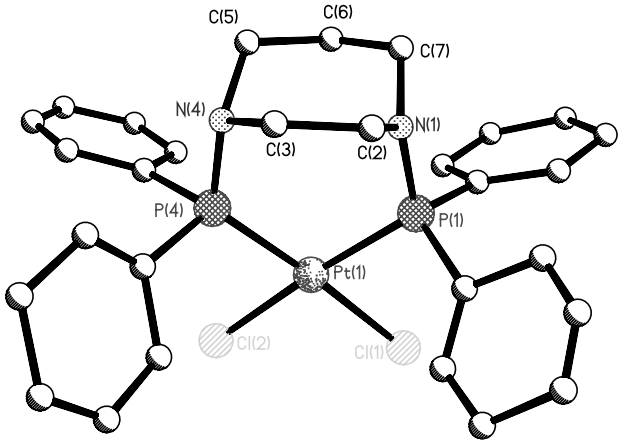

Fig. 4. The structure of $[PtCl_2\{Ph_2PN(C_5H_{10})NPPh_2\}]$ in the crystal structure of $[Pt(cod)Cl_2]_2 \cdot [PtCl_2\{Ph_2PN(C_5H_{10})NPPh_2\}]$.

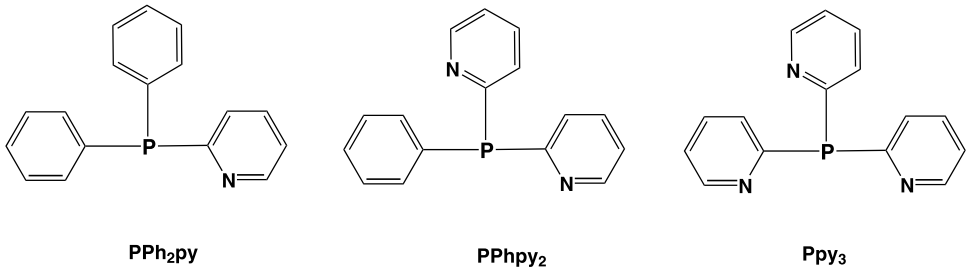
of an extra CH_2 group into the ligand backbone causes a slight deshielding of the phosphorus centres. The homopiperazine derivatives form complexes in an analogous fashion to their piperazine analogues. Spectroscopic data for the new compounds are summarised in Tables 1–3.

The Pt(II), Pd(II) and Mo(0) complexes of **13**, **19** and **24** contain seven- and eight-membered (Figs. 3 and 4) chelate rings. The spectroscopic data for derivatives of the two amines, which incorporate the same phosphorus substituents, are very similar suggesting that the extra CH_2 in the homopiperazine ligands has little effect on the electronic properties of the ligands and resulting complexes.

The X-ray structure of *cis*-$[PtCl_2\{Ph_2PN(C_5H_{10})NPPh_2\}][PtcodCl_2]_2$ was obtained. It reveals that the P–Pt–P bite angle is expanded to 97° as a consequence of the homopiperazine backbone.

This work clearly demonstrates the usefulness of simple organic nitrogen containing rings in the formation of large bite angle phosphines.

4. Supplementary material



Crystallographic data for the structural analyses has been deposited with the Cambridge Crystallographic data centre, CCDC Nos. 176413–176415. Copies of this information may be obtained free of charge from The Director CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK. (fax: +44-1223-336-033; email: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk.

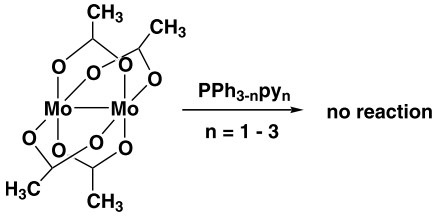
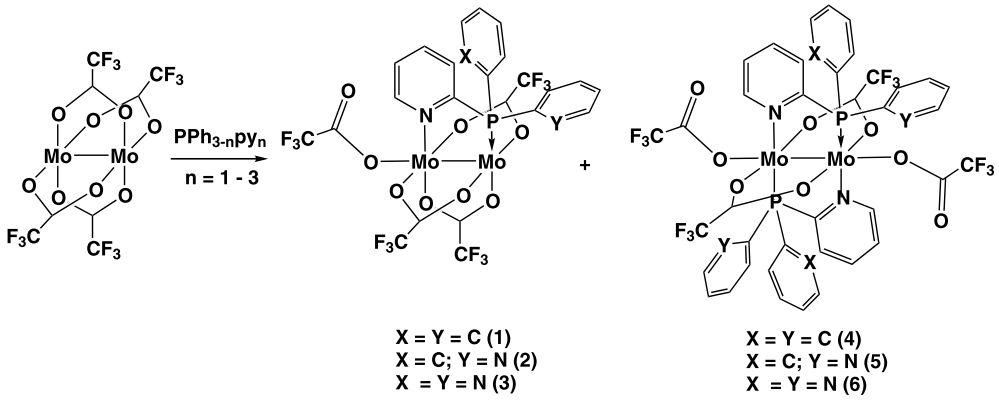


Scheme 1.

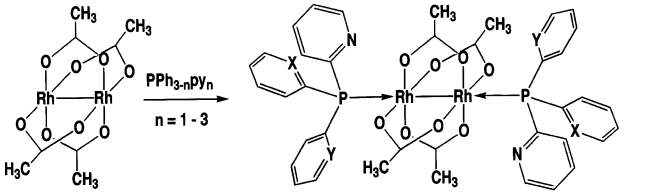
tion process while the pyridine ligand would otherwise protect the potential coordination site, thus enhancing the initiator stability. In this work, we report the syntheses and characterization of dimolybdenum and dirhodium compounds bridged and/or axially coordinated by PPh_2py, $PPhpy_2$ and Ppy_3 ligands. The X-ray crystal structures of selected complexes are described as well.



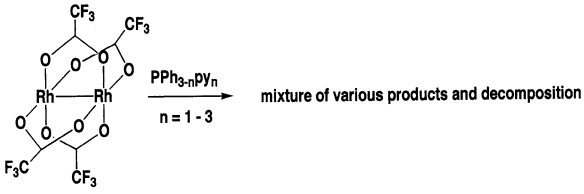
2. Results and discussion

2.1. Synthesis

The reaction of $Mo_2(\mu\text{-}O_2CCF_3)_4$ with 2 equiv. of the corresponding ligand at room temperature yields the complexes **1**–**3**, respectively, with only one $CF_3CO_2^-$ group in the axial position according to Eq. (1). When excess of ligand (fourfold in these cases) is used at room temperature, complexes **4**–**6** (complex **6** is always contaminated with derivative **3**), with two axial $CF_3CO_2^-$ groups are formed according to Eq. (2). Even under reflux conditions a mixture of **3** and **6** is isolated after 4 h, containing only approximately 73% of complex **6**. Reaction of a much higher excess of Ppy_3 with $Mo_2(\mu\text{-}O_2CCF_3)_4$ leads to a mixture of products as well. The reason for this behavior might be that a coordination of Ppy_3 disfavors the coordination of a second ligand of this type in *trans* position, due to the more pronounced *trans* effect of Ppy_3 in comparison to $PPhpy_2$. The *cis* position is probably not available for a second Ppy_3 ligand because of steric reasons. The compounds **1**–**6** are insoluble in CH_2Cl_2, CH_3CN, diethyl ether, and decompose in methanol, DMF and DMSO. This decomposition could be due to an opening of the pyridine–N bond to the metal center in the presence of donor solvents with subsequent cleavage of the metal–metal bond.



(1)



(2)

The orange–red complexes **7**–**9** can be prepared by reacting excess of ligand with $Rh_2(\mu\text{-}O_2CCH_3)_4$ at room temperature (Eq. (3)). The same products **7**–**9**, however, are also formed when $Rh_2(\mu\text{-}O_2CCH_3)_4$ and the ligands are reacted in a 1:1 stoichiometric relationship. Half of

the Rh_2 starting complex remains unchanged, but no product with only one axial ligand is formed. Heating or even refluxing the reaction mixture also does not influence the outcome to our experience (i.e. no equatorial substitution products are formed). The rhodium complexes **7**–**9** are soluble in CH_2Cl_2, but insoluble in THF, acetone and CH_3CN. It is noteworthy in this context that $Mo_2(\mu\text{-}O_2CCH_3)_4$ does not react with PPh_2py, $PPhpy_2$ and PPy_3 (see Eq. (1)). The interaction of $Rh_2(\mu\text{-}O_2CCF_3)_4$ with PPh_2Py, $PPhPy_2$ and PPy_3 leads to a mixture of different products and decomposition products (Eq. (4)). It was, unfortunately, not possible to separate the compounds and characterize them properly.

(3)

(4)

The explanation for the different reaction behavior of the Mo_2 and Rh_2 complexes seems to be that the stronger Mo–O interactions (in contrast to the weaker Rh–O interactions) in the tetra acetato derivatives cannot be easily cleaved by the pyridylphosphines under the reaction conditions applied. The weaker Mo–O bonds to the electron withdrawing tetrakis(trifluoroacetato) ligands are easier to break. In both cases, however, an attack on the axial positions is not observed, probably due to the generally weak interactions of $Mo(II)_2$ units with ligands in this position. In the case of the Rh_2 complex, the tetra acetato complex reacts with the pyridylphosphines, since the interactions with ligands in the axial positions of the Rh–Rh unit are stronger and lead to more stable products. Equatorial bonds, however, are also not cleaved in the Rh_2 complexes. In the case of the more reactive $Rh_2(O(O)C\text{–}CF_3)_4$ derivative, the axial and equatorial positions are available to an attack and the reaction leads to a product mixture. Some of the products are probably not stable and undergo further reactions, thus leading to an inseparable mixture of product compounds.

We found no indication for the formation of orthometallated triaryl phosphines bridging the M–M bonds in any of our reactions. Despite the fact that there are several related compounds forming orthometallated products, this was not observed in our case since our reaction conditions obviously do not favor the abstraction of aryl ring protons. With appropriately changed reaction conditions, however, it might be possible to generate orthometallated derivatives [4j] [11]. The geometry of the examined compounds (see X-ray part) would—at least in principle—allow such reactions.

2.2. Thermogravimmetry

The complexes **1**, **4** and **7** as well as the pyridylphosphine PPh_2py and the starting materials $Mo_2(O(O)CCF_3)_4$ and $Rh_2(O(O)CCH_3)_4$ have been examined by thermogravimmetry (TGA). PPh_2py starts subliming at approximately 179 °C and sublimes completely, not leaving any residue. $Rh_2(O(O)CCH_3)_4$ has a decomposition onset at 278 °C and $Mo_2(O(O)CCF_3)_4$ starts subliming at 226 °C. The compound **7** displays a decomposition onset at 296 °C, being about 20 °C higher than that of the Rh_2 starting material, while compound **4** starts decomposing at approximately 220 °C, slightly below the sublimation point of the Mo_2 starting material. The same is true for compound **1**, which starts decomposing at 211 °C. In the case of compound **1** only one pronounced decomposition step is observed. It starts decomposing slowly with an onset at approximately 211 °C, continues (beginning at 290 °C) with a sharper decline and then keeps loosing mass until the end of the measurement at 650 °C. The total mass loss until the end of the more pronounced step is about 40% of the original mass, which would be the sum of one trifluoro acetate ligand and the PPh_2py ligand. The total mass loss until the end of the measurement at 650 °C is about 68% of the original mass. In the case of compound **7**, one clear decomposition step is observed. It accounts for 30% of the original mass and leads to an unspecific further decomposition, which reaches a total mass loss of 45% at 650 °C.

The observed curve shapes and mass losses indicate that in all three cases (complexes **1**, **4** and **7**) the decomposition starts-as expected-with a loss of an axial ligand. Then the complexes start losing equatorial ligands. A sublimation of the complexes without decomposition is not observed.

2.3. X-ray crystallography

The molecular structures of compounds **5** and **6** have been determined by single crystal X-ray crystallography. PLATON representations of compounds **5** and **6** are

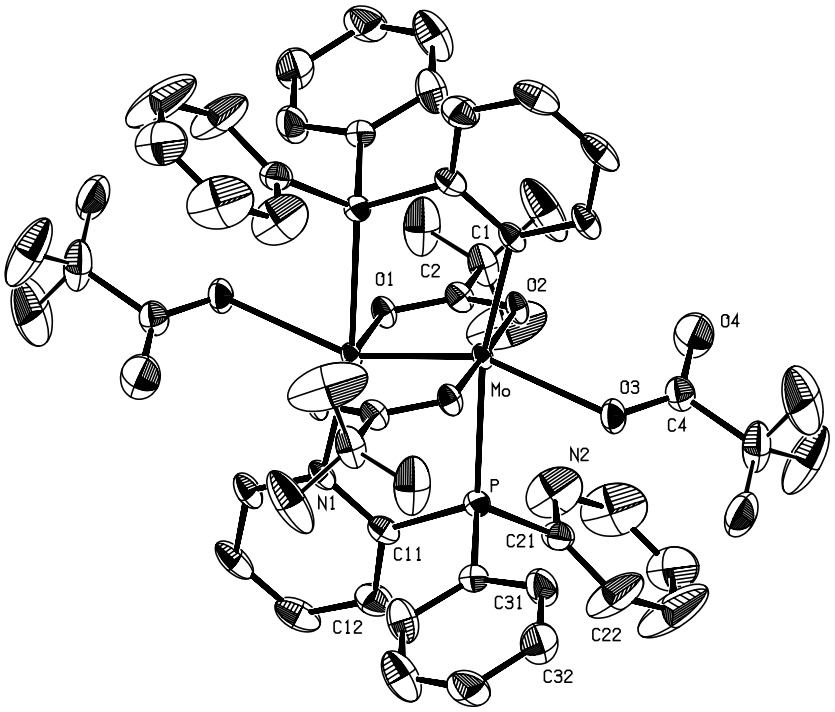


Fig. 1. ORTEP [15] drawing of the molecular structure of the major form of **5** in the solid state; thermal ellipsoids are at the 50% probability level and hydrogens omitted for clarity.

shown in Figs. 1 and 2, respectively. Selected bond distances and angles are listed in Table 1 for the compounds **5** and **6**.

The dimolybdenum centers are coordinated by two bridging CF_3COO^- ligands, which are *trans* positioned to each other. The complex resides on a crystallographic

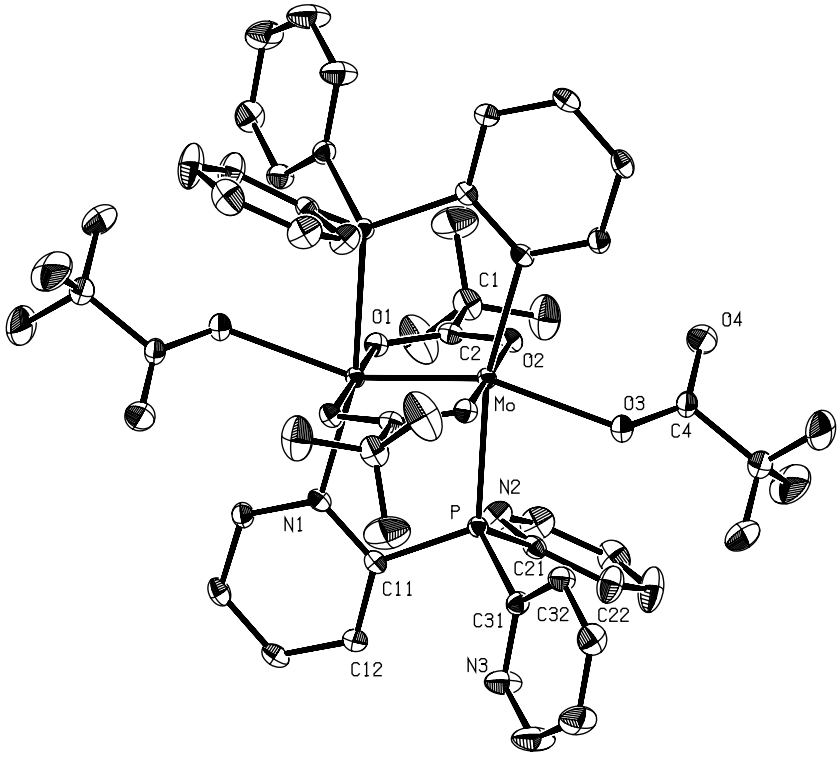

Fig. 2. ORTEP [15a] drawing of the molecular structure of **6** in the solid state; thermal ellipsoids are at the 50% probability level and hydrogens omitted for clarity.

Table 1
Comparison of selected structural data for complexes **5** and **6**. Mo and Mo′ are connected via the symmetry operation (−x, −y, 1−z) for **5** and (−x, −y, −z) for **6**, respectively

	5	**6**

O4–C4–C3	115.6(3)	115.09(18)

center of inversion. The other two CF_3COO^- groups coordinate to one of the metal centers in the axial position. The two 2-pyridylphosphine ligands are in a head-to-tail (HT) relationship and are *trans* to each other. A similar structure has been reported for $Mo_2(\mu\text{-}PPh_2Py)_2(\mu\text{-}CH_3COO)_2Cl_2$ by Cotton and Matusz [3h,3i]. In our case and in that of Cotton's compound the thermodynamically more favored HT relationship and not the generally more common head-to-head (HH) arrangement is observed. The reason for the formation of the HT product might in our case be the stepwise formation of **4**–**6** from the in-situ precursors **1**–**3**, which display only one bridging ligand. The first $P(Ar)_3$ ligand probably directs the second $P(Ar)_2$ ligand to the thermodynamically more favored HT arrangement, assisted by the long reaction time at high temperature and the steric bulk of the ligands. As can be seen in Fig. 1, the short Mo–N distance, close to the region of axial coordination, together with the long Mo–P distance and the other two uncoordinated pyridyl groups directed away from the axial region cause a displacement of the axial CF_3COO^- group away from the 'linear' axial site by 156.69(5)° (compound **5**) or 156.11(4)° (complex **6**), respectively.

Similar observations are reported for other dimolybdenum(II) compounds in the literature [3h]. Due to the strong interaction of axial CF_3COO^- group with the Mo_2^{4+} moiety, the Mo–Mo distances, 2.1901(3) Å for **5** and 2.1884(2) Å for **6**, respectively, are approximately 0.1 Å longer than in the precursor complex $Mo_2(\mu\text{-}O_2CCF_3)_4$ (Mo–Mo: 2.090(4) Å) [12]. The Mo–Mo bond lengths observed in the compounds **5** and **6** are among the longest Mo–Mo quadruple bond distances reported to date. [13,14] This lengthening in comparison to the starting material is due to the weakening of the Mo–Mo bond by the axial ligand coordination.

2.4. Vibrational spectroscopy

The solid-state IR spectra of complexes **1**–**6** show strong absorption bands in the range of 1650–1700 cm^{-1}, indicating the presence of monocoordinated carboxylate group(s) [3f]. The vibrations observed at 1687 (**4**), 1690 (**5**) and 1684 cm^{-1} (**6**) are assigned to terminal carboxylate groups. The vibrations at 1650 (**1**), 1654 (**2**) and 1647 cm^{-1}(**3**) are also assigned to the terminal carboxylate group. The vibrations located at approximately 1600 cm^{-1} represent the asymmetric stretching vibration of the bridging trifluoroacetates. The Raman active ν(Mo–Mo) band shows that in the case of **4**, **5** and **6** the Mo–Mo bond strength is significantly weakened by the change of the coordination mode (**4** (305 cm^{-1}), **5** (307 cm^{-1}), **6** (308 cm^{-1})) in comparison to the axially uncoordinated precursor $Mo_2(\mu\text{-}O_2CCF_3)_4$ (397 cm^{-1}) [8]. The Mo–Mo stretching modes of the complexes **1**, **2** and **3**, observed at 375 cm^{-1} for **1**, 376 cm^{-1} for **2** and at 378 cm^{-1} for **3** indicate a much less pronounced influence on the strength of the Mo–Mo quadruple bond, since only one axial ligand is present. The influence of exchanging a Ph group in the ligand by a py ligand, however, has seemingly very little influence on the Mo–Mo bond strength and is of the same order of magnitude as the error range of the measurement.

The vibrations of the bidentate acetato groups are located at 1600, 1423, 623, 507 cm^{-1} for **7**, 1596, 1434, 650, 542 cm^{-1} for **8** and at 1594, 1422, 695, 561, 525 cm^{-1} for **9**, respectively. These vibrations indicate that only one type of carboxylate exists; the strong Raman band at 335 cm^{-1} (**7**), 337 cm^{-1} (**8**) and 338 cm^{-1} (**9**) refers to the complete symmetric Rh–O vibrations of RhO_4 square-planar fragments. Its asymmetric vibrations can appear as IR active mode. In addition, the very intensive Raman band at 285 cm^{-1} (**7**), 287 cm^{-1} (**8**) and 289 cm^{-1} (**9**) can be assigned to the Rh–Rh stretching mode. The Rh–Rh vibration of $Rh_2(Ac)_4$ is

located at 351 cm^{-1}. Unlike equatorial coordination patterns of these pyridylphosphine ligands to the $Mo_2(\mu\text{-}O_2CCF_3)_4$ moiety, these pyridylphoshpines prefer axial interaction with $Rh_2(\mu\text{-}O_2CCH_3)_4$ under the conditions applied. The compounds $Rh_2(\mu\text{-}O_2CR)_4L_n$ ($n = 1$ or 2) are the largest class of dirhodium(II) compounds known to date [14].

2.5. NMR spectroscopy

The ^1H NMR signals of the pyridyl groups in complexes **7**, **8** and **9** display only a slight downfield shift in comparison to the free ligand. Complexes **7** and **8** display seven signals in the aromatic region and one singlet for the acetate $-CH_3$-group, while complex **9** shows four signals in the aromatic region and one singlet for the acetate CH_3-group. All observed ^1H NMR signals are very sharp and the signals in the aromatic region display the expected J-couplings. This is in accord with the postulated structures of the complexes **7**–**9**. Temperature-dependent ^1H NMR spectroscopy was performed to examine fluxionality of the acetates, i.e. exchange of axial and equatorial ligands in solution. However, no broadening or splitting in the temperature range of -90 to 30 °C was observed.

The $^{13}C\{^1H\}$ NMR spectra of the complexes **7** and **8** show nine signals in the aromatic region, the spectrum of compound **9** displays five signals in the aromatic region. These signals as well as the signals of the $-CH_3$ groups and the C(O)O moieties are in accord with the expectations for the suggested structures of the complexes **7**–**9**.

The $^{31}P\{^1H\}$ NMR signals, located at -15.26 (compound **7**) -8.99 (complex **8**) and -2.64 ppm (complex **9**), are broad triplets (half widths ca. 150–160 Hz) in all three cases at room temperature. At -75 °C the signals get significantly sharper. The signals appear to be a doublet of doublets with $^1J_{P-Rh} \approx 45$ Hz, $^2J_{P-Rh} \approx 35$ Hz. The ligand signals are shifted almost 11 ppm upfield for complex **7** and about 6 ppm upfield in the case of complex **8** in comparison to free ligand. The shift change in comparison to the free ligand in the case of complex **9** is smaller, only approximately 1.5 ppm. These observations indicate that the Ppy_3 ligands do not exchange so readily electron density with the metal centers as the PPh_2py and the $PPhpy_2$ ligands. The ability to act as electron acceptor is less pronounced in the electron rich Ppy_3 ligand.

Since the complexes **1**–**6** are insoluble in all common organic solvents, ^{31}P solid-state NMR spectra were measured of all complexes described in this work. Only complex **4** shows sufficient solubility in CH_2Cl_2 to receive a $^{31}P\{^1H\}$ solution NMR spectrum. In the case of the Mo_2 derivatives the solid-state ^{31}P NMR signals are slightly more low field shifted in the row $PPh_2py > PPhpy_2 > Ppy_3$. The opposite trend is observed for the free ligands in solution. The shift difference between coordinated and free ligands is $>$ 30 ppm. Shift differences of this order of magnitude are not uncommon for equatorially coordinated phoshine ligands. The shift differences between the complexes with one or two axial ligands observed here, however, are in quite small, only in the order of 1 ppm. In the case of the axially coordinated phoshine ligands in the compounds **7**–**9** the trend observed in solution (see above) also holds for the solid state. The shift difference between solid state and solution is in all three cases < 2 ppm. The splitting of the solid-state ^{31}P NMR signals due to a P–Rh coupling cannot be observed. The solid state signal are in general very broad.

2.6. Electronic absorption spectroscopy

The electronic absorption spectra of the soluble complexes **7**, **8** and **9** were measured in methylene chloride at room temperature. The lowest energy absorptions centered at 486 nm ($\varepsilon = 350$ M^{-1} cm^{-1}) for compound **7**, at 496 nm ($\varepsilon = 600$ M^{-1} cm^{-1}) for compound **8** and at 568 nm ($\varepsilon = 250$ M^{-1} cm^{-1}) for compound **9** are tentatively assigned to $\pi^*(Rh_2) \rightarrow \sigma^*(Rh_2)$ transitions [14].

3. Conclusions

Compounds of the formula $M_2(\mu\text{-}O_2CCR_3)_n(O_2CCR_3)_4\text{–}(PPh_mPy_{3-m})_x$ (M = Mo or Rh; R = H or F; $n = 2$ or 3; $m = 1$ or 0; $x = 1$, or 2) can be synthesized depending on the starting material and the reaction conditions. The *trans*-$Mo_2(\mu\text{-}O_2CCF_3)_2(O_2CCF_3)_2\text{–}(PPhPy_2)_2$ (**5**) and *trans*-$Mo_2(\mu\text{-}O_2CCF_3)_2(O_2CCF_3)_2(PPy_3)_2$ (**6**) are among the first complexes of this general type characterized by X-ray crystallography. While the Mo_2-complexes displaying two phosphine ligands in equatorial positions and one or two trifluoroacetato ligands in axial positions are insoluble or instable in all common organic solvents, the Rh_2-complexes with two 2-pyridylphosphine ligands in axial positions as bridging ligands are soluble. These latter complexes could, in principle, act as model initiators/catalysts for the polymerization/hydrogenation of cyclopentadiene, and are currently under investigation with regard to this aspect in our laboratory.

4. Experimental

All preparation and manipulation were carried out under an oxygen- and water-free argon atmosphere using standard Schlenk techniques. Methylene chloride was distilled over calcium hydride and diethyl ether over sodium–benzophenone, and kept over 4 Å molecular

sieves. Acetone was dried over 4 Å molecular sieves, too. Anhydrous THF, $Mo_2(\mu\text{-}O_2CCF_3)_4$, $Rh_2(\mu\text{-}O_2CCH_3)_4$, bisphenyl-(2-pyridyl)phosphine (PPh_2py), phenyl-bis-(2-pyridyl)phosphine ($PPhpy_2$) and tri-(2-pyridyl)phosphine (Ppy_3) were prepared according to literature procedures [14,2g].

Elemental analyses were performed in the Mikroanalytisches Labor of the TU München in Garching (M. Barth). Solution ^1H, ^{13}C and $^{31}P\{^1H\}$ NMR were measured with a Bruker Avance DPX-400 spectrometer. The solid-state ^{31}P NMR spectra were recorded at room temperature (298 K) on a Bruker MSL 300 NMR spectrometer using a 4 mm double bearing MAS probehead and ZrO_2 rotators. A spinning speed of 8000 Hz was applied. Chemical shifts are reported on the scale with respect to δ (H_3PO_4(concentration)) = 0 ppm and were referenced to the second, external standard [$NH_4(H_2PO_4)$]; δ ($NH_4H_2PO_4$) = 1.1 ppm. IR spectra were obtained on a Perkin–Elmer FT IR spectrometer using KBr pellets as IR matrix. Electronic absorption spectra were run using a Perkin–Elmer Lambda 2UV–Vis spectrometer. TGA data were obtained by a Perkin–Elmer TGA 7 thermobalance. Each 3–10 mg sample was heated in a dynamic He atmosphere (purity 5.0, flow 45 sccm) using a 50–650 temperature program at a rate of 10 K min^{-1}.

4.1. Preparation of $Mo_2(\mu\text{-}O_2CCF_3)_3(O_2CCF_3)(PPh_2Py)$ (1)

To a stirred solution of $Mo_2(\mu\text{-}O_2CCF_3)_4$ (0.322 g, 0.5 mmol) in 15 ml of CH_2Cl_2 was added an equimolar amount of $PPhPy_2$ (0.132 g, 0.5 mmol) in 10 ml of CH_2Cl_2. An immediate reaction took place with the formation of a bright red precipitate, which was collected after 2 h stirring, washed with portions of CH_2Cl_2 and dried under oil pump vacuum. Yield: 90%. *Anal*. Calc. for $C_{25}H_{14}F_{12}Mo_2NO_8P$ (907.23): C 33.10, H 1.56, N 1.54. Found: C 32.82, H 1.52, N 1.48%. Selected IR data (ν, cm^{-1}): 1650s, 1606vs, 1436m, 1192vs, 1166vs, 1094m, 987m, 856m, 730s, 600w, 547w, 518m. ^{31}P MAS NMR (δ, ppm): 32.28.

4.2. Preparation of $Mo_2(\mu\text{-}O_2CCF_3)_3(O_2CCF_3)(PPhPy_2)$ (2)

To a stirred solution of $Mo_2(\mu\text{-}O_2CCF_3)_4$ (0.322 g, 0.5 mmol) in 15 ml of CH_2Cl_2 was added an equimolar amount of $PPhPy_2$ (0.132 g, 0.5 mmol) in 10 ml of CH_2Cl_2. An immediate reaction took place with the formation of a bright red precipitate, which was collected after 2 h stirring, washed with portions of CH_2Cl_2 and dried under oil pump vacuum. Yield: 90%. *Anal*. Calc. for $C_{24}H_{13}F_{12}Mo_2N_2O_8P$ (908.21): C 31.74, H 1.44, N 3.08. Found: C 31.82, H 1.42, N 2.98%. Selected IR data (ν, cm^{-1}): 1654s, 1608vs, 1431m, 1192vs, 1161vs, 984m, 854m, 723s, 597w, 543w, 518m. ^{31}P MAS NMR (δ, ppm): 30.48.

4.3. Preparation of $Mo_2(\mu\text{-}O_2CCF_3)_3(O_2CCF_3)(PPy_3)$ (3)

The synthetic procedure applied was similar to that used for compound **1a**. PPy_3 was employed instead of $PPhPy_2$. Yield: 87%. *Anal*. Calc. for $C_{23}H_{12}F_{12}Mo_2N_3O_8P$ (909.20): C 30.38, H 1.33, N 4.62; Found: C 29.95, H 1.45, N 4.60%. Selected IR data (ν, cm^{-1}): 1647s, 1608s, 1452m, 1426s, 1193vs, 1164sh, 990w, 856m, 803m, 777w, 730s, 520m. ^{31}P MAS NMR (δ, ppm): 29.19.

4.4. Preparation of trans-$Mo_2(\mu\text{-}O_2CCF_3)_2(O_2CCF_3)_2(PPh_2Py)_2$ (4)

The same procedure was applied as described for compound **1**, only the molar ratio of the $Mo_2(\mu\text{-}O_2CCF_3)_4$: PPh_2Py being 1:2. The resulting compound was of purple color and partial soluble in CH_2Cl_2. The product was, therefore, extracted with portions of cold CH_2Cl_2. Yield: 60%. *Anal*. Calc. for $C_{42}H_{28}F_{12}Mo_2N_2O_8P_2$ (1170.50): C 43.10, H 2.41, N 2.39. Found: C 43.26, H 2.64, N 2.12%. Selected IR data (ν, cm^{-1}): 1687s, 1650vs, 1606vs, 1436m, 1192vs, 1166s, 1094m, 856m, 838m, 793m, 730s, 696m, 528m, 425w; Selected Raman data (ν, cm^{-1}): 1690s, 1199vs, 860w, 836m, 429w, 305s; UV–Vis (CH_2Cl_2 solution): λ_{max} = 276 nm (sh), λ_{max} = 339 nm, (ε = 50 900 $M^{-1}cm^{-1}$), 548 nm (ε = 500 M^{-1} cm^{-1}), ^{31}P MAS NMR (δ, ppm): 31.04.

4.5. Preparation of trans-$Mo_2(\mu\text{-}O_2CCF_3)_2(O_2CCF_3)_2(PPhPy_2)_2$ (5)

The same procedure was applied as described for compound **1a**, only the molar ratio of the $Mo_2(\mu\text{-}O_2CCF_3)_4$: $PPhPy_2$ being 1:4. The resulting compound was of purple color. Yield: 85%. Crystals suitable for X-ray crystallography were obtained by layering a solution of $Mo_2(\mu\text{-}O_2CCF_3)_4$ in CH_2Cl_2 with $PPhPy_2$, dissolved in diethyl ether. *Anal*. Calc. for $C_{40}H_{26}F_{12}Mo_2N_4O_8P_2$ (1172.47): C 40.98, H 2.24, N 4.78. Found: C 40.46, H 2.10, N 4.62%. Selected IR data (ν, cm^{-1}): 1690vs, 1650sh, 1607m, 1192vs, 1166s, 856m, 831m, 791m, 597w, 425w, 379w, 331w, 223w, 137vw. Selected Raman data (ν, cm^{-1}): 1693vw, 1670vw, 1589vs, 1203w, 1144m, 865w, 831w, 772w, 619w, 430w, 376w, 344s, 307vs. ^{31}P MAS NMR (δ, ppm): 30.99.

4.6. Preparation of trans-$Mo_2(\mu\text{-}O_2CCF_3)_2(O_2CCF_3)_2(PPy_3)_2$ (6)

The procedure was similar to that described for compound **1** with the following exceptions: the molar

ratio of starting materials used was $Mo_2(\mu\text{-}O_2CCF_3)_4$:$PPy_3 = 1{:}4$. And the reaction mixture was refluxed for 4 h. The resulting product was purple. The product yield is 63%, however, the obtained material is mixed with complex **1** (27% based on elementary analysis). Attempts to isolate clean complex **6** were not successful due to its insoluble in all common organic solvents. *Anal*. Calc. for $C_{38}H_{24}F_{12}Mo_2N_6O_8P_2$ (1174.45): C 38.86, H 2.06, N 7.16. Found: C 38.38, H 1.94, N 7.50%. Selected IR data (ν, cm^{-1}): 1684sh, 1647s, 1608vs, 1194vs, 1164s, 857m, 836w, 795w, 509m, 382w. selected Raman data (ν, cm^{-1}): 1685vw, 1648vs, 1608vs, 1592m, 1209vw, 867w, 839w, m, 798s, 523vvs, 510s, 388vs, 354s, 308vs. ^{31}P MAS NMR (δ, ppm): 29.45.

4.7. Preparation of trans-$Rh_2(\mu\text{-}O_2CCH_3)_4(PPh_2Py)_2$ (7)

$Rh_2(\mu\text{-}O_2CCH_3)_4$ (0.111 g, 0.25 mmol) and twofold stoichiometric amount of PPh_2Py (0.133 g, 0.50 mmol) was put into a Schlenk tube and 10 ml CH_2Cl_2 was added. A red-brownish solution was immediately formed and the solution was stirred for 2 h. Then the volume of the solution was reduced to 5 ml and layered by *n*-hexane. After 4 days red-brownish tiny crystals were collected. The yield is 65% based on $Rh_2(\mu\text{-}O_2CCH_3)_4$. *Anal*. Calc. for $C_{42}H_{40}N_2O_8P_2Rh_2$ (968.55): C 52.06, H 4.16 N 2.89. Found: C 52.23, H 4.12, N 2.61%. Selected IR data (ν, cm^{-1}): 1600vs, 1585s, 1423s, 1346m, 1192vs, 1154s, 1020w, 854m, 777w, 731s, 623w, 507m; Selected Raman data (ν, cm^{-1}): 1590m, 1425m, 1352w, 1120s, 285s; ^1H NMR(CD_2Cl_2, δ, ppm): 1.63(s, 12H, C**H**$_3$C), 7.21(d, 2H), 7.33(m, 12H), 7.55(dt, 8H), 7.69(d, 2H), 7.84(d, 2H), 8.66(d, 2H); ^{13}C NMR(CD_2Cl_2, δ ppm): 30.05 (**C**H_3C), 123.8, 128.8, 129.0, 129.1, 133.0, 135.3, 136.0, 150.3, 159.5 (aromatic *C*–H signals), 193.3(**C**O_2). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, δ, ppm): −15. 67(t). ^{31}P MAS NMR (δ, ppm): −17.44. UV–Vis (CH_2Cl_2 solution): $\lambda_{max} = 332$ nm (sh), $\lambda_{max} =$ 363 nm, ($\varepsilon = 14\,400$ M^{-1} cm^{-1}), 486 nm ($\varepsilon = 350$ M^{-1} cm^{-1}).

4.8. Preparation of trans-$Rh_2(\mu\text{-}O_2CCH_3)_4(PPhPy_2)_2$ (8)

$Rh_2(\mu\text{-}O_2CCH_3)_4$ (0.111 g, 0.25 mmol) was dissolved in 10 ml of THF to produce a bright green solution. The fourfold stoichiometric amount of $PPhPy_2$ (0.264 g, 1.00 mmol) in 10 ml of acetone was then added. The red-brownish precipitate was gradually formed and the suspension was stirred for 2 h. The crude product was washed several times with THF (3 × 5 ml), acetone (3 × 5 ml), and then dried in oil pump vacuum. The yield is 83% based on $Rh_2(\mu\text{-}O_2CCH_3)_4$. *Anal*. Calc. for $C_{40}H_{38}N_4O_8P_2Rh_2$ (970.53): C 49.50, H 3.95, N 5.77. Found C 49.42, H 4.03, N 5.58%. Selected IR data (ν, cm^{-1}): 1596vs, 1434vs, 1422vs, 1374s, 1320m, 1128w, 1015w, 650w, 542s, 380w, 289w. Selected Raman data (ν, cm^{-1}): 1587m, 1438w, 1386vw, 1327w, 1128s, 580vw, 337s, 287vvs, 240sh. ^1H NMR(CD_2Cl_2, δ, ppm): 1.63(s, 12H, C**H**$_3$C), 7.26(dd, 4H), 7.47(m, 6H), 7.62(dt, 4H), 7.88(d, 4H), 8.02(d, 4H), 8.70(d, 4H). ^{13}C NMR(CD_2Cl_2, δ ppm): 24.2(**C**H_3C), 123.6, 128.4, 130.4, 131.8, 133.3, 135.3, 136.5, 150.2, 159.5 (aromatic *C*–H signals), 193.0(**C**O_2). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, δ, ppm): −8.99(t). ^{31}P MAS NMR (δ, ppm): −9.45. UV–Vis (CH_2Cl_2 solution): $\lambda_{max} = 496$ nm ($\varepsilon = 600$ M^{-1} cm^{-1}), $\lambda_{max} = 318$ nm, ($\varepsilon = 36\,500$ M^{-1} cm^{-1}), $\lambda = 356$ nm (sh).

4.9. Preparation of trans-$Rh_2(\mu\text{-}O_2CCH_3)_4(PPy_3)_2$ (9)

The procedure applied was analogous as described for complex **3.** PPy_3 was used instead of $PPhPy_2$ as a ligand. The yield based on $Rh_2(\mu\text{-}O_2CCH_3)_4$ is 92%. *Anal*. Calc. for $C_{38}H_{36}N_6O_8P_2Rh_2$ (972.50): C 46.93, H 3.73, N 8.64. Found: C 46.96, H 3.70, N 8.53%. Selected IR data (ν,

4.10. X-ray crystal structure determination

Crystallographic data for **5** and **6** are summarized in Table 2. Data were collected at low temperature (123 K) on a Nonius KappaCCD device at the window of a rotating anode (**5:** *theta range*: 1.82–26.07°, *index ranges*: $-11 \le h \le 11$, $-12 \le k \le 12$, $-14 \le l \le 14$, *crystal dimensions*: $0.13 \times 0.15 \times 0.20$ mm; **6:** *theta range*: 2.26 to 27.50°, *index ranges*: $-11 \le h \le 11$, $-12 \le k \le 12$, $-16 \le l \le 16$, *crystal dimensions*: $0.24 \times 0.28 \times 0.33$ mm) [15b]. Absorption correction and decay correction were applied during the scaling procedure [15c]. Both structures were solved by direct methods [15d] and refined anisotropically by full-matrix least-squares on F^2 [15e]. Neutral atom scattering factors for all atoms and anomalous dispersion corrections for the non-hydrogen atoms were taken from the International Tables for Crystallography [15f]. All non-hydrogen atoms of the two complexes where refined anisotropically. All hydrogen atoms were placed in calculated positions riding on the parent carbon atom (**5**). All hydrogen atoms were found in the difference Fourier map and refined with individual isotropic thermal displacement parameters (**6**). Both molecules reside on a crystallographic center of inversion. In **5** both trifluormethyl groups are disordered over two positions in the bridging $(O_2C)CF_3$ ligand (91:9) and in the monodentate $(O_2C)CF_3$ ligand (71:29).

5. Supplementary material

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication numbers CCDC-175526 (**5**) and -175527 (**6**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk].

Acknowledgements

G.Z. thanks the *Katholischer Akademischer Ausländer-Dienst* (KAAD) for a Ph.D. stipend. J.Z. is grateful to the *Deutscher Akademischer Austauschdienst* (DAAD) for a Ph.D. grant. Professor Dr. W.A. Herrmann is acknowledged for continuous support of our work, the Fonds der Chemischen Industrie (FCI) for financial support and Dr. É. Bencze for helpful discussions and experimental assistance in vibrational spectroscopy.

unusual nature of the reactivity of the dibenzylamine ligand with Me_3Al and Me_3Ga, where orthometalation occurs at higher temperatures, and to observe the influence of the nature of R on the planarity of the central Al_2N_2 ring.

Herein we report the synthesis, ^1H and ^{13}C NMR, and mass spectral characterization of $[Pr^n_2AlN(CH_2Ph)_2]_2$ (**3**), $[Bu^n_2AlN(CH_2Ph)_2]_2$ (**4**), and $[Bu^i_2AlN(CH_2Ph)_2]_2$ (**5**). The ^{13}C and ^1H NMR data of $[R_2AlN(CH_2Ph)_2]_2$ where R = Me, Et, Pr^n, Bu^n and Bu^i are compared in terms of the R group and with data for the previously reported $[R_2AlNMe_2]_2$ series [33]. X-ray molecular structure data for $[Et_2AlN(CH_2Ph)_2]_2$ (**2**) and $[Bu^n_2AlN(CH_2Ph)_2]_2$ are reported and are contrasted with that of $[Me_2AlN(CH_2Ph)_2]_2$ [27]. The structural data for these three aminoalanes are also compared with data for $[MeAlN(H)CH_2Ph]_2$ [34] and $[RAlN(CH_2Ph)$-μ-$(CH_2C_6H_4)]_2$ [26,27] in terms of the Al_2N_2 ring geometry and with $Me_3Al{\cdot}HN(CH_2Ph)_2$ [35]. The ^1H and ^{13}C NMR and molecular structure data for the series $[Me_2AlN(CH_2Ph)_2]_2$ (**1**) [27], $[Me_2GaN(CH_2Ph)_2]_2$ [31], and $[Me_2InN(CH_2Ph)_2]_2$ [36] are discussed in terms of the nature of the Group 13 metal and related to trends in the NMR and molecular structure data for their respective adducts $Me_3M{\cdot}HN(CH_2Ph)_2$ [28,35,37,38].

2. Experimental

2.1. General procedures

Standard inert atmosphere techniques were used for the synthesis and handling of all compounds. Hexane and toluene were distilled over calcium hydride and under an atmosphere of nitrogen. Dibenzylamine, Aldrich, was stored over molecular sieves. The trialkylaluminum compounds, Texas Alkyls, Inc., were used as obtained. Benzene-d_6, Aldrich, was deoxygenated by bubbling with dry nitrogen and stored over molecular sieves. The synthesis and characterization of **1** [28] and **2** [29] have been previously reported. ^1H and ^{13}C NMR data for **1**–**5** were collected on 0.20 M benzene-d_6 solutions of the compounds using a Bruker DRX 400 NMR spectrometer. ^{13}C DEPT, 2-D ^1H–^1H COSY, and 2-D $^{13}C\{^1H\}$ HETCOR NMR spectra were obtained using standard Bruker software. Chemical shifts for all spectra were referenced to those of the solvent. The ^1H and ^{13}C NMR data for **1** and **2** were collected to complete the ^1H NMR assignments for **1** and to have a set of comparable NMR data collected under the same experimental conditions. IR data were collected using a Bruker Vector 22 FT IR spectrometer. Samples were prepared as split mulls in Kel-F and Nujol on KBr plates. EI MS data for **1**–**5** were obtained on a Finnigan MAT95Q spectrometer with an electron energy of 70 eV. The samples were introduced using a direct insertion probe under inert atmosphere conditions. Elemental analyses were performed by E&R Microanalytical Laboratory, Inc., Parsippany, NJ. Melting points were obtained in sealed capillaries and are uncorrected.

2.2. Synthesis of $[Pr^n_2AlN(CH_2Ph)_2]_2$ (3), $[Bu^n_2AlN(CH_2Ph)_2]_2$ (4), and $[Bu^i_2AlN(CH_2Ph)_2]_2$ (5)

Each aminoalane dimer was synthesized by mixing $HN(CH_2Ph)_2$ and the respective trialkylaluminum in a 1:1 mol ratio in pentane solution (For **3**, 5.12 mmol (0.800 g) Pr^n_3 Al with 5.22 mmol (1.03 g) $HN(CH_2Ph)_2$; for **4**, 5.14 mmol (1.02 g) Bu^n_3 Al with 5.07 mmol (1.00 g) $HN(CH_2Ph)_2$; for **5**, 5.09 mmol (1.01 g) Bu^i_3 Al with 5.07 mmol (1.00 g) $HN(CH_2Ph)_2$). The pentane was then removed under vacuum and the neat adduct heated at about 110 °C until gas evolution ceased. Compounds **3** and **4** were recrystallized from hexane solutions at −15 °C. Compound **5** is an oil and was purified by vacuum distillation.

2.3. Characterization of 1–5

2.3.1. $[Me_2AlN(CH_2Ph)_2]_2$ (1) [28]

^1H NMR: δ_H −0.081 (s, 12H, H1), 4.16 (s, 8H, H10), 6.98 (m, 4H, H12), 7.01 (m, 4H, H13), 6.995 (m, 2H, H14). ^{13}C NMR: δ_C −7.57 (C1), 52.65 (C10), 136.63 (C11), 129.31 (C12), 128.08 (C13), 127.25 (C14). MS (EI): *m*/*z* 491 (M^+ −Me), 310 (M^+ −$N(CH_2Ph)_2$), 295 (M^+ −$N(CH_2Ph)_2$−Me), 254 ($M^+/2+H$), 238 (100, $M^+/2$−Me), 160 ($M^+/2-C_7H_9$), 65 ($C_5H_5^+$), 57 (Me_2Al^+).

2.3.2. $[Et_2AlN(CH_2Ph)_2]_2$ (2) [29]

^1H NMR: δ_H 0.56 (q, 8H, H1), 1.49 (t, 12H, H2), 4.25 (s, 8H, H10), 7.01 (m, 8H, H12), 7.05 (m, 8H, H13), 7.00 (m, 4H, H14). ^{13}C NMR: δ_C 2.00 (C1), 10.60 (C2), 52.40 (C10), 136.63 (C11), 129.24 (C12), 128.1 (C13), 127.30 (C14). MS (EI): *m*/*z* 533 (M^+ −Et), 503 (M^+ −Et−EtH), 252 ($M^+/2$−Et), 222 ($M^+/2$−Et−EtH), 196 ($(C_6H_5CH_2)_2N^+$), 120 ($C_6H_5CH_2NHCH_2^+$), 106 ($C_6H_5CH_2NH^+$), 91 (100, $C_7H_7^+$), 65 ($C_5H_5^+$).

2.3.3. $[Pr^n_2AlN(CH_2Ph)_2]_2$ (3)

M.p. 145–146 °C. ^1H NMR: δ_H 0.61 (m, 8H, H1), 1.90 (m, 8H, H2), 1.21 (t, 12H, H3), 4.29 (s, 8H, H10), 7.01 (m, 8H, H12), 7.04 (m, 8H, H13), 7.00 (m, 4H, H14). ^{13}C NMR: δ_C 14.86 (C1), 20.66 (C2), 21.68 (C3), 52.54 (C10), 136.63 (C11), 129.23 (C12), 128.07 (C13), 127.30 (C14). IR (cm^{-1}): 3087 (w), 3061 (w), 2915 (m), 2859 (s), 1168 (m), 1045 (s), 976 (w), 874 (m), 734 (s), 696 (s), 615 (m). Calc. MW: 618.86 g mol^{-1}. Cryo. MW: 613 ± 15 g mol^{-1} (0.050–0.055 m in benzene). MS (EI): *m*/*z* 575 (M^+ −Pr^n), 531 (M^+ −Pr^n −Pr^nH), 378

($M^+ - N(CH_2Ph)_2 - Pr^n$), 266 ($M^+/2 - Pr^n$), 197 ($(C_6H_5CH_2)_2NH^+$), 196 ($(C_6H_5CH_2)_2N^+$), 120 ($C_6H_5CH_2NHCH_2^+$), 106 ($C_6H_5CH_2NH^+$), 91 (100, $C_7H_7^+$), 65 ($C_5H_5^+$). *Anal.* Calc. (Found) for $C_{40}H_{56}Al_2N_2$: C, 77.63 (77.57); H, 9.12 (9.04); N, 4.53 (4.74)%. Yield 62%.

2.3.4. $[Bu^n_2AlN(CH_2Ph)_2]_2$ (4)

M.p. 113–116 °C. ^{1}H NMR: δ_H 0.63 (m, 8H, H1), 1.885 (m, 8H, H2), 1.54 (h, 8H, H3), 1.035 (t, 12H, H4), 4.34 (s, 8H, H10), 7.047 (m, 8H, H12), 7.052 (m, 8H, H13), 7.00 (m, 4H, H14). ^{13}C NMR: δ_C 11.17 (C1), 29.33 (C2), 29.62 (C3), 14.01 (C4), 52.58 (C10), 136.68 (C11), 129.30 (C12), 128.09 (C13), 127.34 (C14). IR (cm^{-1}): 3085 (w), 3062 (w), 3028 (m), 2953 (s), 2919 (s), 2889 (m), 1163 (m), 1051 (s), 906 (m), 874 (s), 850 (m), 731 (s), 699 (s), 681 (m), 635 (s). MS (EI): *m/z* 617 ($M^+ - Bu^n$), 559 ($M^+ - Bu^n - Bu^nH$), 280 (100, $M^+/2 - Bu^n$), 222 ($M^+/2 - Bu^n - Bu^nH$), 132 ($AlNCH_2$-$C_6H_5^+$), 106 ($C_6H_5CH_2NH^+$), 105 ($C_6H_5CH_2N^+$), 91 ($C_7H_7^+$). *Anal.* Calc. (Found) for $C_{44}H_{64}Al_2N_2$: C, 77.98 (77.98); H, 9.35 (9.36); N, 4.33 (3.99)%. Yield 95%.

2.3.5. $[Bu^i_2AlN(CH_2Ph)_2]_2$ (5)

^{1}H NMR: δ_H 0.65 (d, 8H, H1), 2.35 (n, 4H, H2), 1.254 (d, 24H, H3), 4.33 (s, 8H, H10), 7.067 (m, 8H, H12), 7.064 (m, 8H, H13), 7.013 (m, 4H, H14). ^{13}C NMR: δ_C 23.37 (C1), 26.76 (C2), 28.96 (C3), 52.94 (C10), 136.66 (C11), 129.43 (C12), 128.03 (C13), 127.31 (C14). IR (cm^{-1}): 3088 (w), 3062 (w), 3031 (m), 2948 (s), 2862 (s), 1496 (m), 1187 (m), 1049 (s), 954 (m), 872 (s), 740 (s), 698 (s). Calc. MW: 674.96 g mol^{-1}. Cryo. MW: 647 ± 32 g mol^{-1} (0.050–0.055 m in benzene). MS (EI): *m/z* 659 ($M^+ - Me$), 560 ($M^+ - 2Bu^i$), 559 ($M^+ - Bu^i - Bu^iH$), 494 ($M^+ - 2C_7H_9$), 436 ($M^+ - 2C_7H_7 - Bu^iH$), 280 ($M^+/2 - Bu^i$), 224 ($M^+/2 + H - 2Bu^i$), 222 ($M^+/2 - Bu^i - Bu^iH$), 197 ($(C_6H_5CH_2)_2NH^+$), 196 ($(C_6H_5CH_2)_2N^+$), 141 ($Bu^i_2Al^+$), 119 ($C_6H_5CH_2NCH_2^+$), 106 ($C_6H_5CH_2NH^+$), 91 (100, $C_7H_7^+$), 65 ($C_5H_5^+$). *Anal.* Calc. (Found) for $C_{44}H_{64}Al_2N_2$: C, 78.30 (77.98); H, 9.56 (9.85); N, 4.15 (4.30)%. Yield 86%.

2.4. Structural studies for 2 and 4

In the structural studies, an X-ray quality crystal was sealed into a thin-walled glass capillary under anaerobic conditions. The crystal was then mounted and aligned upon an Enraf Nonius CAD4 single-crystal diffractometer. Intensity data (Mo Kα, $\lambda = 0.71073$ Å) were collected at room temperature using graphite-monochromatized radiation. All data were corrected for Lorentz and polarization effects as well as for absorption. Details of each data collection are given in Table 1. The crystallographic calculations were carried out on an IBM-PC with the use of the Siemens SHELXTL-PC program package [39]. The analytical scattering factors for neutral atoms were corrected for both $\Delta f'$ and $i\Delta f''$ components of anomalous dispersion [40]. Each structure was solved by the use of direct methods. Positional and anisotropic thermal parameters of all non-hydrogen atoms were refined. Hydrogen atoms were not located directly, but were input in calculated positions with $d(C–H) = 0.96$ Å and with the appropriate staggered-tetrahedral geometry [41]. The isotropic thermal parameter of each hydrogen atom was then verified by means of a final difference-Fourier synthesis in which no chemically meaningful residuals were found. Selected bond distances and angles for structures **2** and **4** are tabulated in Table 2.

centrosymmetric space group $P\bar{1}$ (No. 2). This was verified by successful solution and refinement of the crystal structure. The structure refined to convergence with $R = 3.95\%$ and $R_w = 4.32\%$ for those 1684 reflections with $|F_o| > 6.0\sigma|F_o|$ and $R = 7.94\%$ for all data.

3. Results and discussion

3.1. ^1H and ^{13}C NMR data and chemical shift analysis

The ^1H and ^{13}C NMR chemical shifts for compounds **1**–**5** were obtained using several 1-D and 2-D NMR techniques. The determination of the ^1H NMR chemical shifts for the hydrogens of the alkyl groups are straightforward. The ^1H NMR spectra of the methyl, ethyl, and the *iso*-butyl groups are first-order. The ^1H NMR spectra for *n*-propyl and *n*-butyl groups are more complicated due to restricted conformational averaging about the C(1)–C(2) bond. The initial assignments were verified by ^1H 2-D COSY NMR experiments. Due to the low electronegativity of the aluminum atom, the chemical shifts of the C(1) CH_2 groups are to higher field than the chemical shifts of the other alkyl group protons. For example, for the ethyl group in **2**, the CH_2 group chemical shift is $\delta_H = 0.56$ ppm, whereas that of the CH_3 group is $\delta_H = 1.49$ ppm. The ^{13}C NMR chemical shifts of the alkyl group carbons for **1**–**5** were obtained from simple decoupled 1-D ^{13}C NMR spectra, ^{13}C NMR spectral editing (DEPT-135) experiments, and from $^{13}C\{^1H\}$ 2-D HETCOR experiments. The ^{13}C NMR chemical shifts for the alkyl groups in **1**–**5** are typical of those for R bound to aluminum. The ^{13}C NMR methyl group resonance in **1** consists of a broad singlet at −7.57 ppm, as a result of the low electronegativity and quadrupole moment of the aluminum atom. The C(1) methylene group resonances in **2**–**5** are also broadened. The ^1H NMR resonances for the CH_2 portion of the benzyl group consist of a singlet in each case and are in the range of 4.15–4.34 ppm. The corresponding ^{13}C NMR resonances are in the range of 52.36–52.94 ppm for **1**–**5**.

The ^1H and ^{13}C NMR chemical shift assignments for the aromatic part of the benzyl group are more challenging. The ^1H NMR spectra are non-first order, with the resonances occurring in a narrow range about 7.00 ppm. The *ipso* ^{13}C and tentative *ortho*, *meta*, and *para* ^{13}C NMR assignments were made by comparison of the ^{13}C proton decoupled, ^{13}C proton coupled, and ^{13}C DEPT-45 NMR spectra. The *ortho*, *meta,* and *para* assignments were then verified on the basis of high-resolution 2-D $^{13}C\{^1H\}$ HETCOR experiments.

The benzyl CH_2 group and *ortho* ring protons become more deshielded as the steric bulk of the alkyl group bound to the aluminum atom increases. For example, the CH_2 δ_H data are: R = Me, 4.16 ppm; R = Et, 4.25 ppm; R = Pr^n, 4.29 ppm; R = Bu^n, 4.34 ppm; and R = Bu^i, 4.33 ppm. This trend is similar to that for the ^1H NMR chemical shift data for the three aminoalane series, $[R_2AlR']_2$, where R = Me [28], Et [29] and Bu^i [30] and R′H is a secondary amine. Here, as the steric bulk of R increases, the protons of the C(1) and C(2) carbons of the amine shift to more positive chemical shift values (ppm). This effect is well documented for the ^1H NMR chemical shifts of aluminum–nitrogen compounds in aromatic solvents [15] and is attributed to the more sterically demanding alkyl groups on the aluminum atom disrupting the formation of solvent collision complexes, preventing the influence of the ring current of the solvent on the chemical shifts. A similar trend is noted in a comparison of the ^{13}C NMR chemical shifts for the C(1) and C(2) amine carbons for the $[Me_2AlR']_2$ and $[Et_2AlR']_2$ series versus that of the analogous $[Bu^i_2\ AlR']_2$ series. The amine group also influences the ^1H and ^{13}C NMR chemical shifts of the alkyl groups on the aluminum atom. The δ_H values for the C(1) and C(2) protons of R for **1**–**5** are, on the average, 0.48 ppm and 0.30 ppm, more positive, respectively, for the $[R_2AlN(CH_2Ph)_2]_2$ series compared with the $[R_2AlNMe_2]_2$ series [33]. Similar trends are noted for the ^{13}C NMR chemical shifts for the two series.

The ^{13}C and ^1H NMR chemical shifts for the methyl group in the adducts, $Me_3M{\cdot}HN(CH_2Ph)_2$, where M = Al [28], Ga [37] and In [37] are dependent upon the metal present with $\delta_H = -0.38$, −0.10 and −0.11 ppm, and $\delta_C = -8.06$, −5.10 and −6.68 ppm, respectively. For the $[Me_2MN(CH_2Ph)_2]_2$ dimers, $\delta_H = -0.081$, 0.21, and 0.13 ppm for $[Me_2AlN(CH_2Ph)_2]_2$ (**1**) [28],

$[Me_2GaN(CH_2Ph)_2]_2$ (**6**) [31] and $[Me_2InN(CH_2Ph)_2]_2$ (**7**) [34,36], respectively. The methyl group δ_C values are also dependent on the metal present with $\delta_C = -7.57$, -5.91 and -6.80 ppm, for **1**, **6**, and **7**. The benzyl CH_2 and *ipso* carbon ^{13}C chemical shifts move downfield significantly upon substitution of In or Ga for Al where the ordering is (most downfield shift) In > Ga > Al. These chemical shift effects have been generally attributed to the different electronegativities of the metals (Al, 1.5; Ga, 1.6; In, 1.7) [42].

3.2. Mass spectral data for compounds 1–5

The EI MS for **1**–**5** do not show the existence of molecular ion peaks (M^+). Instead for **1**–**4**, $[M^+ - R]$ ion peaks are observed, indicative of the loss of one alkyl group bound to the aluminum atom. This observation is consistent with the results of mass spectral data on other aminoalane dimers [15,28,30,33,43,44], including the series $[Me_2AlR']_2$ [28], $[Bu^i_2AlR']_2$ [30] and $[R_2AlNMe_2]_2$ [33]. A $[M^+ - Me]$, and not a $[M^+ - Bu^i]$ ion peak is present in **5**. This effect, of cleaving a methyl group off an *iso*-butyl group attached to an aluminum atom, has been observed in the mass spectra of aminoalanes [15]. Also, methyl loss is characteristic for methyl side chains in the EI MS of hydrocarbons [45]. A prominent feature of each mass spectrum is the presence of the monomer peak minus an alkyl group $[R_2AlN(CH_2Ph)_2{}^+ - R]$. This ion peak serves as the base peak for **1** and **4**. The decomposition of the dibenzylamino group is the dominant feature of the mass spectra for **2**, **3**, and **5**, where the base peak is observed at an *m*/*z* ratio of 91 ($C_6H_5CH_2{}^+$, $C_7H_7{}^+$) with related peaks at 65 ($C_5H_5{}^+$), 106 ($C_6H_5CH_2NH^+$), and 120 ($C_6H_5CH_2NHCH_2{}^+$) [43,45]. These mass values are prominent in the EI mass spectrum of dibenzylamine [46]. Selected fragment ion peaks are listed in the Section 2.

3.3. X-ray crystallographic studies

The X-ray crystal data for **2** and **4** are given in Table 1. The ORTEP representations of the two molecular structures for **2** and **4** are shown in Figs. 1 and 2. Selected bond lengths (Å) and angles (°) from the X-ray data are summarized for **1** [27], **2**, and **4** in Table 2. For each of the structures, the Al–N and Al–C bond distances are within the expected range of values for dimeric aminoalanes [15,29,30,47–49]. The C–Al–C, N–Al–N and Al–N–Al angles in the three compounds are highly distorted from tetrahedral, as expected for four-membered rings [15,47]. The internal Al–N–Al and N–Al–N angles are smaller than the external C–Al–C and C–N–C angles, consistent with previously reported values [15,29,30,47–49].

The molecular geometry of the Al_2N_2 ring has been investigated in terms of the influence of different substituent groups on the aluminum and nitrogen atoms. [15,29,30,47–49]. In general, the influence of the substituent bound to the nitrogen has a more pronounced effect on ring geometry than that of the substituent on aluminum. As the steric bulk of the alkyl group attached to the aluminum atom increases, several trends have been observed in a homologous series: an increase in the Al–C bond length; lengthening of the Al···Al non-bonded distance; and a decrease in the N–Al–N bond angle [15,30,47]. Comparison of these parameters for R = Me (**1**), Et (**2**), and Bu^n (**4**) (Table 2) suggests that as the steric bulk of the alkyl group on aluminum is increased from Me to Et or Bu^n, there are only small changes in these parameters. Compounds **2** and **4** have a planar molecular structure with respect to the Al_2N_2 ring, while **1** has a slight deviation from planarity with a fold angle about the N(1)···N(1A) axis of 4.0°. Substitution of a hydrogen atom for a benzyl group on the nitrogen atom in **1** to form $[Me_2AlN(H)CH_2Ph]_2$ (**8**) [34,50] leads to a molecular structure for **8** with a planar Al_2N_2 ring and the benzyl groups in a *trans* orientation. On the average, the molecular structure for **8** has a shorter Al–N bond length than **1** (0.028(6) Å); there is a decrease in the Al–C bond length (0.029(11) Å); and a 2.4(3)° decrease in the N–Al–N bond angle [34]. The molecular structure data for **1**, **2**, and **4** can also be compared with the data for the orthometalated dimer series $[RAlN(CH_2Ph)\text{-}\mu\text{-}(CH_2C_6H_4)]_2$ [26,27] where R = Me, Et, Pr^n, Bu^n and Bu^i. All five molecular structures in the series exhibit planar Al_2N_2 rings. Varying the R group on the aluminum atom in this series has only a minor influence on the Al_2N_2 ring geometry.

The molecular structures of $[Me_2MN(CH_2Ph)_2]_2$ (Al (**1**), Ga (**6**), In (**7**)) are similar in that all three structures belong to the space group, $Cmc2_1$. Each M_2N_2 ring is slightly puckered with angles of fold about the N(1)···N(1A) axis of 4.0, 2.7, and 4.6° for **1**, **6**, and **7**, respectively. The average M–N bond distances for **1**, **6**, and **7** are 1.983(4), 2.044(6), and 2.248(7) Å and the C–M–C angles for **1**, **6**, and **7** are 118.0(4)°, 121.6(7)°, and 129.1(7)°. These bond distances and angles vary with the metal as observed in comparable amino-alanes, gallanes, and indanes [34]. The molecular structures of **1**, **6**, and **7** can also be compared with those of the corresponding adducts, $Me_3M\cdot HN(CH_2Ph)_2$, where M = Al [35], Ga [38], and In [38]. These three adducts crystallize in the same space group $P\bar{1}$, so comparisons of molecular geometry are meaningful. For the adducts as compared with **1**, **6** and **7**, the average C–M–C angles increase in the same order Al < Ga < In with values of 114.2(1)°, 115.5(2)°, and 117.3(4)° and the M–N bond distances also increase in the order Al < Ga < In with values of 2.058(2), 2.151(3), and 2.382(5) Å, respectively. The

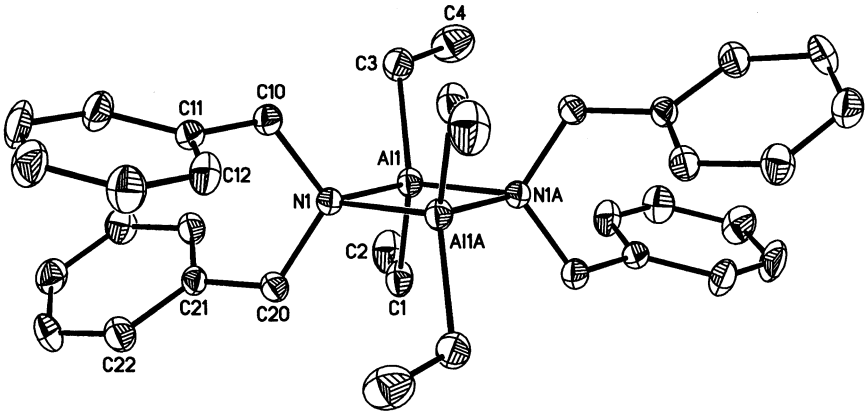

Fig. 1. Molecular structure and atom numbering scheme for $[Et_2AlN(CH_2Ph)_2]_2$ **(2)**. Hydrogen atoms omitted for clarity and thermal ellipsoids at 30% probability.

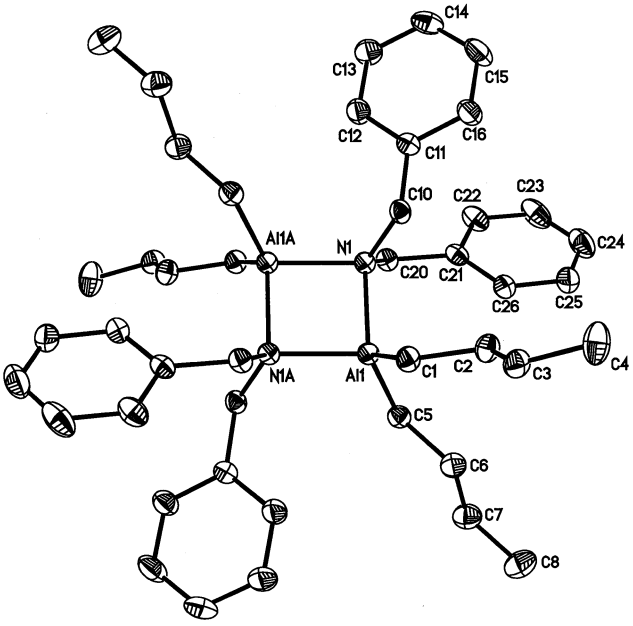

Fig. 2. Molecular structure and atom numbering scheme for $[Bu^n_2AlN(CH_2Ph)_2]_2$ **(4)**. Hydrogen atoms omitted for clarity and thermal ellipsoids at 30% probability.

longer M–N bond lengths for the adducts, as compared with the corresponding dimers, are typical for the two different types of bonding in these main group compounds [51].

4. Supplementary material

Tables of crystallographic data and data collection and structure refinement details have been deposited with the Cambridge Crystallographic Data Center. The CCDC codes are 132622 for $[Et_2AlN(CH_2Ph)_2]_2$ and 132623 for $[Bu^n_2AlN(CH_2Ph)_2]_2$. chemical shifts are reported with respect to 85% H_3PO_4, with downfield shifts considered positive. The SwaN-MR software package [9] was used to treat NMR data. The conductivity of 10^{-3} mol dm^{-3} solutions of the complexes in $MeNO_2$ at 25 °C was measured with a CDM 83 Radiometer.

2.2. Synthesis of complexes

2.2.1. [Fe(=C=C=CPh$_2$){P(OEt)$_3$}$_5$](BPh$_4$)$_2$ (1) and [Fe{C≡CCPh$_2$(OH)}{P(OEt)$_3$}$_5$]BPh$_4$ (3a)

Anhydrous $FeCl_2$ (0.126 g, 1 mmol) and an excess of $P(OEt)_3$ (1 cm^3, 6 mmol) were placed in a three-necked flask (25 cm^3). The suspension was stirred for 1 h and then 10 cm^3 of EtOH and a solution of HC≡CCPh$_2$(OH) (0.208 g, 1 mmol) in 2 cm^3 of EtOH were added. The reaction mixture was stirred for 2 h, treated with an excess of NEt_3 (0.28 cm^3, 2 mmol), and stirred for a further 2 h. The solvent was removed under reduced pressure, giving an oil which was treated with EtOH (4 cm^3) containing an excess of $NaBPh_4$ (0.68 g, 2 mmol). A dark-pink solid, containing both compounds **1** and **3a**, slowly separated out, and was filtered and crystallised fractionally. Typical separation involved the slow cooling to −25 °C of a saturated solution of the mixture of compounds in EtOH (5 cm^3) and enough CH_2Cl_2 to dissolve the solid at room temperature (r.t.). The first solid separated was acetylide **3a**, with yield: ≥ 15%; propadienylidene **1** was obtained with yield: ≥ 40%.

Anal. Calc. for $C_{93}H_{125}B_2FeO_{15}P_5$ (**1**): C, 65.1; H, 7.3. Found: C, 65.2; H, 7.2%. $\Lambda_M = 121.4$ S cm^2 mol^{-1}.

Anal. Calc. for $C_{69}H_{106}BFeO_{16}P_5$ (**3a**): C, 58.7; H, 7.6. Found: C, 58.9; H, 7.5%. $\Lambda_M = 56.7$ S cm^2 mol^{-1}.

2.2.2. [FeCl(=C=C=CPh$_2$){PPh(OEt)$_2$}$_4$]BPh$_4$ (2)

A suspension of anhydrous $FeCl_2$ (0.126 g, 1 mmol) in an excess of $PPh(OEt)_2$ (1.2 cm^3, 6 mmol) was stirred for 1 h and then a solution of HC≡CCPh$_2$(OH) (0.208 g, 1 mmol) in 10 cm^3 of EtOH was added. The reaction mixture was stirred for 2 h and then an excess of NEt_3 (0.28 cm^3, 2 mmol) was added. After 2 h of stirring, the solvent was evaporated to dryness, giving an oil which was treated with EtOH (4 cm^3) containing an excess of $NaBPh_4$ (0.68 g, 2 mmol). A dark-pink solid separated out, and was filtered and crystallised from CH_2Cl_2 (2 cm^3) and EtOH (5 cm^3); yield: ≥ 55%.

Anal. Calc. for $C_{79}H_{90}BFeClO_8P_4$: C, 68.1; H, 6.5; Cl, 2.5. Found: C, 68.0; H, 6.3; Cl, 2.7%. $\Lambda_M = 51.3$ S cm^2 mol^{-1}.

2.2.3. [Fe{C≡CCMePh(OH)}{P(OEt)$_3$}$_5$]BPh$_4$ (3b)

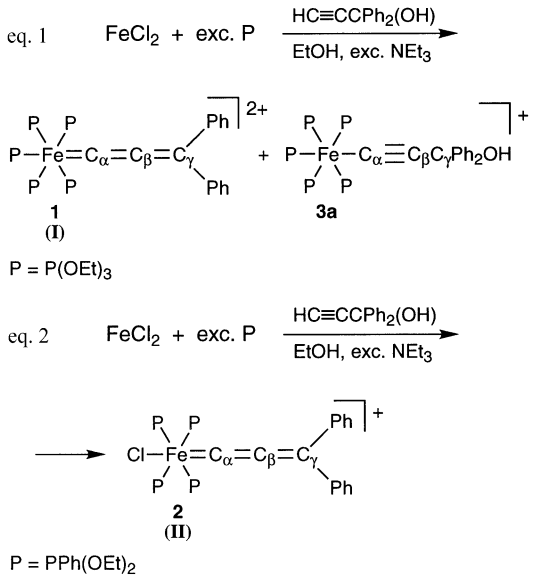
Anhydrous $FeCl_2$ (0.126 g, 1 mmol) and an excess of $P(OEt)_3$ (1 cm^3, 6 mmol) were placed in a three-necked flask (25 cm^3). The suspension was stirred for 1 h and then EtOH (10 cm^3) and HC≡CCMePh(OH) (0.15 g, 1 mmol) were added. The reaction mixture was stirred for 2 h and an excess of NEt_3 (1.4 cm^3, 10 mmol) was added. After 2 h of stirring at r.t., the solvent was removed under reduced pressure, giving a brown oil which was treated with EtOH containing an excess of $NaBPh_4$ (0.68 g, 2 mmol). A brown solid slowly separated out from the resulting solution, which was filtered and crystallised from CH_2Cl_2 (2 cm^3) and EtOH (5 cm^3); yield: ≥ 30%.

Anal. Calc. for $C_{64}H_{104}BFeO_{16}P_5$: C, 56.9; H, 7.8. Found: C, 57.2; H, 8.0%. $\Lambda_M = 50.4$ S cm^2 mol^{-1}.

2.2.4. [Fe(C≡CPh){P(OEt)$_3$}$_5$]BPh$_4$ (3c)

Anhydrous $FeCl_2$ (0.63 g, 5 mmol) and an excess of $P(OEt)_3$ (5.0 cm^3, 30 mmol) were placed in a three-necked flask (50 cm^3), and the resulting suspension was stirred for about 1 h. EtOH (15 cm^3) and then an excess of the appropriate alkyne (15 mmol) were added and the reaction mixture refluxed for 15 min. The solvent was removed under reduced pressure, giving an oil which was treated with EtOH (4 cm^3) containing an excess of $NaBPh_4$ (3.42 g, 10 mmol). A yellow solid slowly separated out, and was filtered and crystallised from CH_2Cl_2 (2 cm^3) and EtOH (5 cm^3); yield: ≥ 35%.

Anal. Calc. for $C_{62}H_{100}BFeO_{15}P_5$: C, 57.0; H, 7.7. Found: C, 56.8; H, 7.8%. $\Lambda_M = 58.5$ S cm^2 mol^{-1}.

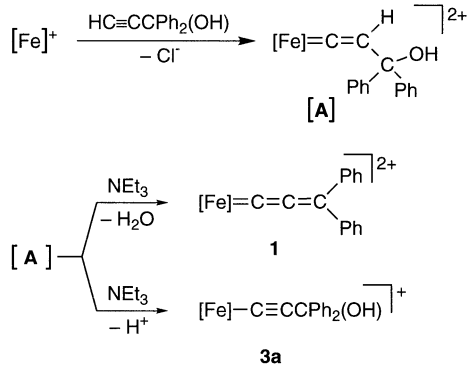


2.2.5. [{Fe[P(OEt)$_3$]$_5$}$_2$(μ-1,4-C≡CC$_6$H$_4$C≡C)](BPh$_4$)$_2$ (4)

An excess of $P(OEt)_3$ (1.0 cm^3, 6 mmol) was added to 0.126 g (1 mmol) of anhydrous $FeCl_2$ in a 25-cm^3 three-necked flask and the resulting suspension stirred for 1 h. Tetrahydrofurane (10 cm^3) and a solution of 1,4-HC≡CC$_6$H$_4$C≡CH (63 mg, 0.5 mmol) in 3 cm^3 in THF were added and, after 2 h of stirring, an excess of NEt_3 (1.4 cm^3, 10 mmol) was further added. The reaction mixture was stirred for 3 h and then the solvent evaporated to dryness under reduced pressure, giving a brown oil which was treated with 4 cm^3 of EtOH. The addition to the resulting solution of an excess of $NaBPh_4$ (0.68 g, 2 mmol) in 2 cm^3 of EtOH caused the separation of an orange–brown solid, which was filtered and crystallised from CH_2Cl_2 (2 cm^3) and EtOH (5 cm^3); yield: ≥ 25%.

Anal. Calc. for $C_{118}H_{194}B_2Fe_2O_{30}P_{10}$: C, 55.9; H, 7.7. Found: C, 56.1; H, 7.8%. $\Lambda_M = 124.5$ S cm^2 mol^{-1}.

3. Results and discussion

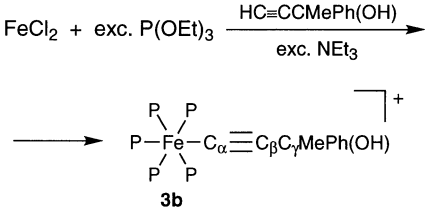


Propadienylidene complexes [Fe(=C=C=CPh$_2$)-{P(OEt)$_3$}$_5$](BPh$_4$)$_2$ (**1**) and [FeCl(=C=C=CPh$_2$)-{PPh(OEt)$_2$}$_4$]BPh$_4$ (**2**) were prepared by allowing iron(II) chloride solutions containing an excess of phosphite to react with propargylic alcohol, as shown in Scheme 1.

Scheme 1.

The reaction depends on the nature of the phosphite, affording pentakis complex **1** with $P(OEt)_3$, or chloro-derivative **2** with $PPh(OEt)_2$. Furthermore, a mixture of propadienylidene **1** and acetylide **3a** (ratio 2.7:1) forms in the case of Eq. (1), and these were separated by fractional crystallisation. The formation of both complexes **1** and **3a** is not surprising, as propargylic alcohol probably tautomerises on the iron centre (Scheme 2), giving a hydroxy-vinylidene [**A**] which, in the presence of NEt_3, can either lose H_2O to give propadienylidene **1** or undergo deprotonation, affording the new acetylide **3a** (Scheme 2).

Phosphite-containing $FeCl_2$ solutions in ethanol probably contain a mixture of phosphite complexes of the type $[FeClP_5]^+$, $FeCl_2P_4$ and $[FeP_6]^{2+}$, analogous to those observed in THF as solvent [10], with the pentakis species predominating in the case of $P(OEt)_3$. Treatment of these solutions with $HC{\equiv}CCPh_2OH$ may afford intermediates of type [**A**], whose reaction with NEt_3 gives final species **1** and **3a**. In contrast, in the case of $PPh(OEt)_2$, a hydroxy-vinylidene of the type $[FeCl\{PPh(OEt)_2\}_4\{{=}C{=}C(H)C(OH)Ph_2\}]^+$ may form, yielding chloropropadienylidene **2** by treatment with NEt_3. However, an acetylide complex of the type $[FeCl\{C{\equiv}CCPh_2(OH)\}\{PPh(OEt)_2\}_4]$ may also form by treatment with NEt_3, but in this case probably in low yield, and this prevents its separation as a solid.



Scheme 2. $[Fe]^+ = [FeClP_5]^+$.

The reactions with $HC{\equiv}CPh_2(OH)$ were also studied in the presence of Brønsted acid (HBF_4, CF_3SO_3H), but no evidence of formatione of propadienylidene complexes was detected. This result is rather surprising, because an acid is generally used to promote the loss of H_2O in hydroxy-vinylidene species to give the $=C=C=CPh_2$ ligand while, in our case, only in the presence of NEt_3 the propadienylidene species **1**, **2** were isolated. Probably, the hydroxy-vinylidene bound to an iron fragment containing phosphites as ancillary ligands requires NEt_3 to give propadienylidene, and the results show as both acid and basic media can promote the loss of H_2O in the reaction of propargylic alcohol.

Propargylic alcohols different from $HC{\equiv}CCPh_2(OH)$, of the type $HC{\equiv}CCPhMe(OH)$, $HC{\equiv}CCH_2(OH)$, or $HC{\equiv}CCHPh(OH)$, also react with phosphite-containing $FeCl_2$ solutions, but afford mixtures of products whose IR spectra exclude the presence of propadienylidene ligands. However, in the case of $HC{\equiv}CCMePh(OH)$, a pale-yellow solid was isolated, which was characterised as the acetylide $[Fe\{C{\equiv}CCMePh(OH)\}\{P(OEt)_3\}_5]BPh_4$ (**3b**) derivative (Scheme 3).

These results on the reactivity of propargylic alcohols with phosphite-containing iron(II) solutions indicate that the nature of both the phosphite ligand and the acetylene play an important role in determining the reaction course and the stoichiometry of the final products. In fact, only with the diphenyl $HC{\equiv}CCPh_2(OH)$ species can propadienylidene complexes **1** and **2** be prepared, containing the pentakis(phosphite) FeP_5 fragment in the case of $P(OEt)_3$ (**1**); with the bulkier $PPh(OEt)_2$ ligand, chloro-species $[FeClP_4(=C=C=CPh_2)]^+$ (**2**) was obtained. Acetylide species **3** can also be prepared, but only in the case of the compound with $P(OEt)_3$ ligand do solid samples result.

Good analytical data were obtained for propadienylidene complexes **1** and **2**, which are purple solids stable in air and in solution of polar organic solvents, where they behave as 2:1 (**1**) or 1:1 (**2**) electrolytes [11].

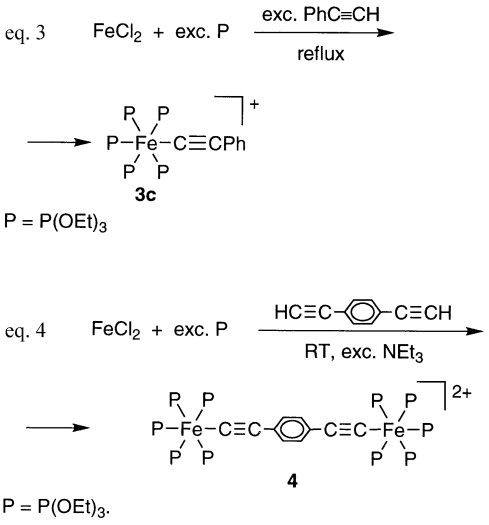
[f] At −70 °C.
[g] In $(CD_3)_2CO$.

The IR and NMR data (Table 1) support the proposed formulation and allow a geometry in solution to be established. The IR spectra show a medium-intensity band at 1950 cm^{-1} for **1** and 1918 cm^{-1} for **2**, attributed to the $\nu_{(C=C=C)}$ of the propadienylidene ligand. However, support for the presence of the =C$_\alpha$=C$_\beta$=C$_\gamma$Ph$_2$ group in the complexes comes from the ^{13}C{^{1}H} NMR spectra, which show the characteristic highly deshielded C$_\alpha$ carbon resonance at 320.0 ppm for **1** and 319.7 ppm for **2**. The spectra also reveal the signals due to the C$_\beta$ and C$_\gamma$ of the propadienylidene ligand at 239.7–230.3 and 152.5–148.4 ppm, respectively.

In the temperature range +20 to −80 °C, the ^{31}P{^{1}H} NMR spectrum of the [Fe(=C=C=CPh$_2$)P$_5$]$^{2+}$ cation **1** appears as an AB$_4$ multiplet, in agreement with geometry (**I**). In contrast, the ^{31}P spectrum of the related complex [FeCl(=C=C=CPh$_2$)P$_4$]$^+$ (**2**) is temperature-

dependent and the sharp singlet which appears at + 20 °C changes as temperature falls and resolves into an A_2B_2 multiplet at −50 °C.

These results are difficult to interpret, because octahedral geometry with the halogenide and propadienylidene ligands in a mutually *cis* position should give an ABC_2- or AB_2C-type multiplet, whereas, in *trans* geometry, a sharp singlet is expected. However, the presence of inequivalent phosphorus *nuclei* at low temperature for **2** may also be interpreted on the basis of *trans* geometry (**II**), in which the four $PPh(OEt)_2$ phosphite ligands are made inequivalent by the different arrangement of the phenyl and ethoxy groups of one phosphite with respect to the other.



Examples of inequivalent phosphorus *nuclei* in octahedral complexes containing four $PPh(OEt)_2$ ligands in a plane have recently been reported for $FeHCl[PPh(OEt)_2]_4$ [6c], $MnH(CO)[PPh(OEt)_2]_4$ [12] and $[ReCl(ArN_2)\{PPh(OEt)_2\}_4]^+$ [13]. These precedents support the hypothesis of the existence, for **2**, of *trans* geometry in which restricted rotation around the Fe–P bond at low temperature makes the phosphite ligands 'two-by-two' inequivalent in the complex.

The IR spectra of acetylide complexes **3a** and **3b** show the $\nu_{(C\equiv C)}$ of the acetylide ligand as a medium-intensity band at 2091 cm^{-1} for **3a** and 2074 cm^{-1} for **3b**. The $^{13}C\{^1H\}$ NMR spectra also confirm the presence of the acetylide ligand in both complexes showing the characteristic C_α and C_β carbon signals at 110.3–103.1 and 120.1–119.2 ppm, respectively (Table 1). They also show the signals of the C_γ carbon atoms at 46.9 (**3b**) and 75.5 ppm (**3a**), and the proton NMR spectrum of **3b** displays a broad signal at 8.65 ppm, attributed to the OH group of the C≡CCMePh(OH) ligand. Lastly, an AB_4 multiplet is present for both complexes in the ^{31}P spectra, in agreement with the proposed formulation.

The results obtained with propargylic alcohols prompted us to extend study to other terminal alkynes. The results are summarised in Scheme 4 and show the formation of pentakis(phosphite) acetylide complexes **3c** and **4**. However, while the mononuclear complexes **3** had previously been prepared by us (except **3c**) following a different method [6], the dinuclear $[\{FeP_5\}_2(\mu\text{-}4,4'\text{-}C\equiv CC_6H_4C\equiv C)]^{2+}$ (**4**) is new, and was isolated as a pale-yellow solid and characterised.

The formation of acetylide in these reactions is not surprising, and probably involves deprotonation of a vinylidene =C=C(H)R intermediate of the type $[Fe\{=C=C(H)R\}P_4]^{2+}$. Such a vinylidene ligand probably formes by a 1,2-hydrogen shift of a coordinate η^2-alkyne group [14–16]. Deprotonation by NEt_3 or an excess of phosphite of the vinylidene intermediate gives the final acetylide derivative.

Analytical and spectroscopic data (Table 1) support the formulation of acetylide complexes **3c** and **4**.

Scheme 4.

The IR spectra of both mononuclear (**3c**) and binuclear (**4**) acetylide complexes show only one medium intensity band, at 2089 and 2085 cm^{-1}, respectively, due to the $\nu_{C\equiv C}$ of the acetylide ligand. The $^{13}C\{^1H\}$ NMR spectra of **3c** also confirm the presence of the RC≡C group, showing the characteristic signals of the C_α and C_β carbon atoms. Lastly, in the temperature range +30 to −80 °C, the ^{31}P spectra of both complexes **3c** and **4** appear as AB_4 multiplets, in agreement with the presence of a pentakis(phosphite) fragment in these acetylide derivatives.

2.1. Synthesis of Cu(II) hinokitiol (1)

Hinokitiol (0.30 g, 1.83 mmol) was dissolved in aq. EtOH (50:50, 50 ml) with stirring. Once dissolved, a solution of copper acetate (0.19 g, 0.95 mmol) was added and the stirring continued. After stirring and gentle heating for 2 h, the green/blue solution was allowed to stand for 1 week after which time the product crystallised from solution as green/blue plate-like crystals. *Anal*. Found (Calc. for $C_{20}H_{22}CuO_4$): C, 61.6 (61.6); H, 5.64 (5.69)%. Selected IR data (cm^{-1}): 1600, 1574 ν(C=O); 1512 ν(C=C); 1286–1228 ν(C–O).

2.2. Synthesis of (hinokitiol)$_2$Cu·(pyridine) (2)

Pyridine (5 ml) was added to a solution of **1** (0.30 g, 0.77 mmol) in $C_6H_5CH_3$ (30 ml). After stirring for 20 min, the solution was cooled to −15 °C whereupon a green solid appeared (0.06 g; 17%). Some crystals suitable for X-ray crystallography were obtained from the filtrate. *Anal*. Found (Calc. for $C_{25}H_{27}CuNO_4$): C, 63.7 (64.0); H, 5.79 (5.76); N, 2.85 (2.98)%. Selected IR data (cm^{-1}): 1583, 1569, 1496 ν(C=O) and ν(C=C); 1261, 1231 ν(C–O).

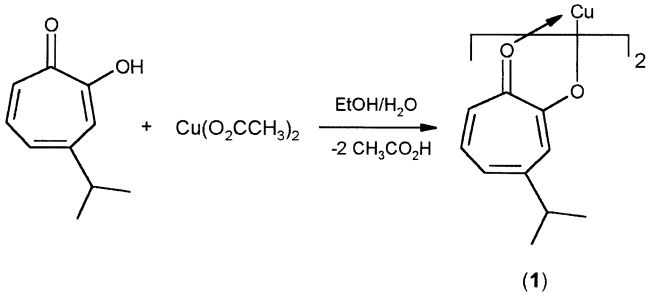
2.3. Synthesis of (hinokitiol)$_2$Cu·(bipyridine) (3)

Bipyridine (1.00 g, 6.25 mmol) was dissolved in $C_6H_5CH_3$ (30 ml) and then added to a solution of **1** (0.40 g, 1.03 mmol) in $C_6H_5CH_3$ (50 ml). The mixture was stirred for 20 min and then left at room temperature for few days, yielding a brown solid (0.44 g, 78%). *Anal*. Found (Calc. for $C_{30}H_{30}CuN_2O_4$): C, 65.5 (65.9); H, 5.48 (5.49); N, 5.83 (5.13)%. Selected IR data (cm^{-1}): 1594, 1554, 1511 ν(C=O) and ν(C=C); 1278, 1199 ν(C–O).

2.4. Crystallography

Suitable crystals of **1** were obtained either from EtOH (modification 1) or from $C_6H_5CH_3$ in the presence of urea (modification 2). Crystals of **2** were obtained from a dilute solution in $C_6H_5CH_3$ (Table 1).

For modification 1 of **1**, crystallographic measurements were made at 293(2) K on a CAD4 automatic four-circle diffractometer in the range $2.40° < \theta < 23.92°$. Data (1685 reflections) were corrected for Lp and 10% decay of the crystal in the X-ray beam. An absorption correction was not applied. In the final least-squares cycles all atoms were allowed to vibrate anisotropically. Hydrogen atoms were included at calculated positions where relevant except for H3, H4, H5 and H7 which were easily located in the penultimate difference Fourier map and refined at a distance of 0.93 Å from the carbon atoms to which they are attached.



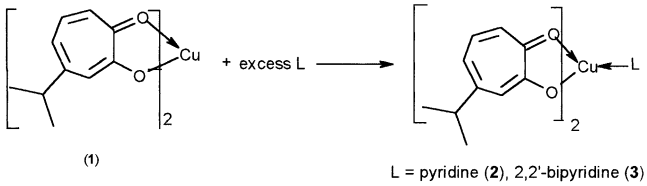
For modification 2 of **1**, crystallographic measurements were made at 150 K on a Nonius Kappa CCD diffractometer in the range $3.80° < \theta < 27.48°$. Data (54 148 reflections) were corrected for Lp, extinction and absorption (max. and min. transmission factors: 1.030 and 0.974, respectively). The asymmetric unit consisted of 2.5 independent molecules. The two full molecules are located proximate to inversion centres and hence dimerise with nearby lattice neighbours. The central copper atom [Cu(3)] in the remaining independent half-molecule is seated on an inversion centre which serves to generate the full molecule in this case. Disorder in one of the isopropyl groups [C(39)/C(40)] was successfully modelled as a 55:45 occupancy ratio. In the final least-squares cycles, all atoms were allowed to vibrate anisotropically and hydrogen atoms were included at calculated positions throughout.

Crystallographic measurements for **2** were made at 293(2) K on a CAD4 automatic four-circle diffractometer in the range $2.24° < \theta < 24.98°$. Data (4337 reflections) were corrected for Lp but not for absorption. In the final least-squares cycles, all atoms were allowed to vibrate anisotropically. Hydrogen atoms were included at calculated positions where relevant.

In all three cases, refinement was based on F_o^2. Software used: SHELXS-86 [19], SHELXL-97 [20], ORTEX [21]. The asymmetric units of **1** (two modifications) and **2** are displayed in Figs. 1–3 along with the atomic numbering scheme. Selected metric data for modification 1 of **1** and **2** are given in the figure captions, while that for modification 2 of **1** are given in Table 2.

3. Results and discussion

Cu(II) hinokitiol (**1**) was synthesised using the method detailed in Eq. (1). After 1 week, a large number of blue plate-like crystals had formed in the solution. Microanalysis of these crystals showed the complex to be anhydrous.



(1)

We have previously noted that copper derivatives of α-hydroxyketones (maltol, hinokitiol etc.) in which the copper is four-coordinate, square-planar geometry are notably anti-bacterially and/or -microbially active, whereas the analogous zinc species, in which the zinc is either five- or six-coordinate, are markedly less so [18].

Table 1
Crystallographic data for **1** and **2**

	1 (modification 1)	**1** (modification 2)	**2**
Empirical formula	$C_{20}H_{22}CuO_4$	$C_{20}H_{22}CuO_4$	$C_{25}H_{27}CuNO_4$

In order to assess the importance of metal coordination number on activity, we have prepared complexes of **1** by reaction with N-donor Lewis bases (Eq. (2)). 1:1 adducts with pyridine (**2**) and 2,2′-bipyridine (**3**) have been isolated, which presumably contain five- or six-coordinate copper, respectively.

(1)

L = pyridine (**2**), 2,2'-bipyridine (**3**)

(2)

3.1. The structure of Cu(II) hinokitiol (*1*)

Cu(II) hinokitiol, prepared as in Eq. (1), was recrystallised from aqueous ethanol, yielding a crystal of approximate dimensions 0.3 × 0.3 × 0.5 mm which was used for data collection. Selected structural data are included in the caption to Fig. 1. This structure will be discussed as modification 1. An attempt to prepare an adduct of **1** with urea in toluene failed, and green crystals of **1** were recovered but whose cell parameters [$a = 16.7420(2)$; $b = 15.5370(2)$; $c = 18.3010(3)$ Å; $\beta = 99.4000(6)°$] were different to those of modification 1 [$a = 9.254(2)$; $b = 9.997(2)$; $c = 11.124(3)$ Å; $\beta = 113.86(2)°$]. This second crystal structure will be dis-

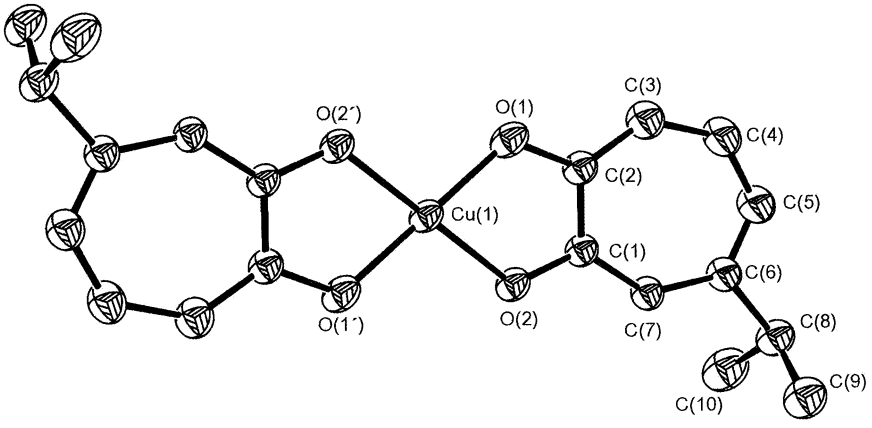

Fig. 1. The asymmetric unit of modification 1 of compound **1** showing the labelling scheme used in the text. Thermal ellipsoids are at the 30% probability level. Selected metrical data: Cu(1)–O(1) 1.904(3), Cu(1)–O(2) 1.900(2), O(1)–C(2) 1.293(5), O(2)–C(1) 1.296(5) Å; O(1)–Cu(1)–O(1′) 180.0, O(2)–Cu(1)–O(2′) 180.0, O(1)–Cu(1)–O(2) 83.84(13), O(1)–Cu(1)–O(2′) 96.16(13), C(2)–O(1)–Cu(1) 113.5(3), C(1)–O(2)–Cu(1) 113.5(3)°. Symmetry related atoms are generated using $-x$, $-y$, $-z$.

cussed as modification 2. Both forms adopt monoclinic $P2_1/c$ (or $P2_1/n$) symmetries.

In modification 1 (Fig. 1), the asymmetric unit comprises half of a molecule, the remaining portion being generated via an inversion centre at the origin on which the copper is sited. The Cu(II) is four-coordinate and in a square-planar environment. The molecule as a whole is essentially planar [maximum deviation from mean plane: 0.029 Å for O(2)]. The Cu–O bonds are equivalent [Cu–O(1), 1.904(3); Cu–O(2), 1.900(2) Å] and the $<$O(1)–Cu–O(2) bond angle is 83.8(1)°. The Cu–O bond lengths are in agreement with other Cu(II) complexes, e.g. Cu(II) erythritol [Cu–O: 1.912(4), 1.922(4) Å] [22]. Both of the C–O bond lengths in **1** compare well with those found in a number of other metal tropolonates, i.e. 1.27–1.30 Å and Zn(II) hinokitiol [1.277(2)–1.306(2) Å] [16]. Furthermore, upon coordination to the Cu(II) the C–O bond lengths become equal [1.293(5), 1.296(3) Å], indicating a similar bond order in both. This is a more symmetric arrangement than the equivalent bonds in hinokitiol itself (C–O: 1.349; C=O: 1.261 Å) [23]. The lengths of the C–C bonds in the hinokitiol ring of **1** are approximately equal (approximately 1.38 Å) with one notable exception. The C(1)–C(2) bond is significantly longer than the others in the ring, indicating that it is not involved to the same extent in the π-electron delocalisation within the C_7 unit. The value of 1.464(6) Å observed for the C(1)–C(2) bond in **1** is closer to that expected for a C(sp^3)–C(sp^3) single bond. For comparison, the π-electron system in hinokitiol is also partially delocalised, though the formal double bonds [C(1)–C(7), C(6)–C(5) and C(4)–C(3); 1.367, 1.355 and 1.364 Å, respectively] are more clearly distinguishable from the formal single bonds [C(7)–C(6), C(5)–C(4) and C(3)–C(2); 1.422, 1.413 and 1.413 Å, respectively] than in **1**. The C(1)–C(2) bond in the ligand (1.469 Å) is, however, significantly longer than the other carbon–carbon bonds and is comparable with that in **1** [23].

In modification 2 of **1**, obtained from toluene in an attempt to prepare a urea adduct, there are two and half molecules in the asymmetric unit; two molecules are in general positions, while half molecule has the copper atom seated on an inversion centre (Fig. 2), as with modification 1. For each molecule, the copper is nominally four-coordinate and in a square-planar environment. The molecule generated by the inversion centre [molecule A, containing Cu(3)] has the isopropyl groups adopting a *trans* configuration and this is also the case for one of the two other molecules [molecule B containing Cu(2)]; in this respect, both molecules replicate the structure of modification 1. However, in the remaining molecule [molecule C containing Cu(1)] the isopropyl groups are *cis* to each other. This is unusual, as for previous structures of α-hydroxyketones, the alkyl groups are *trans* to each other e.g. Zn(hino)$_2$·EtOH [16], Zn(maltol)$_2$ [24], and **2** (*see below*).

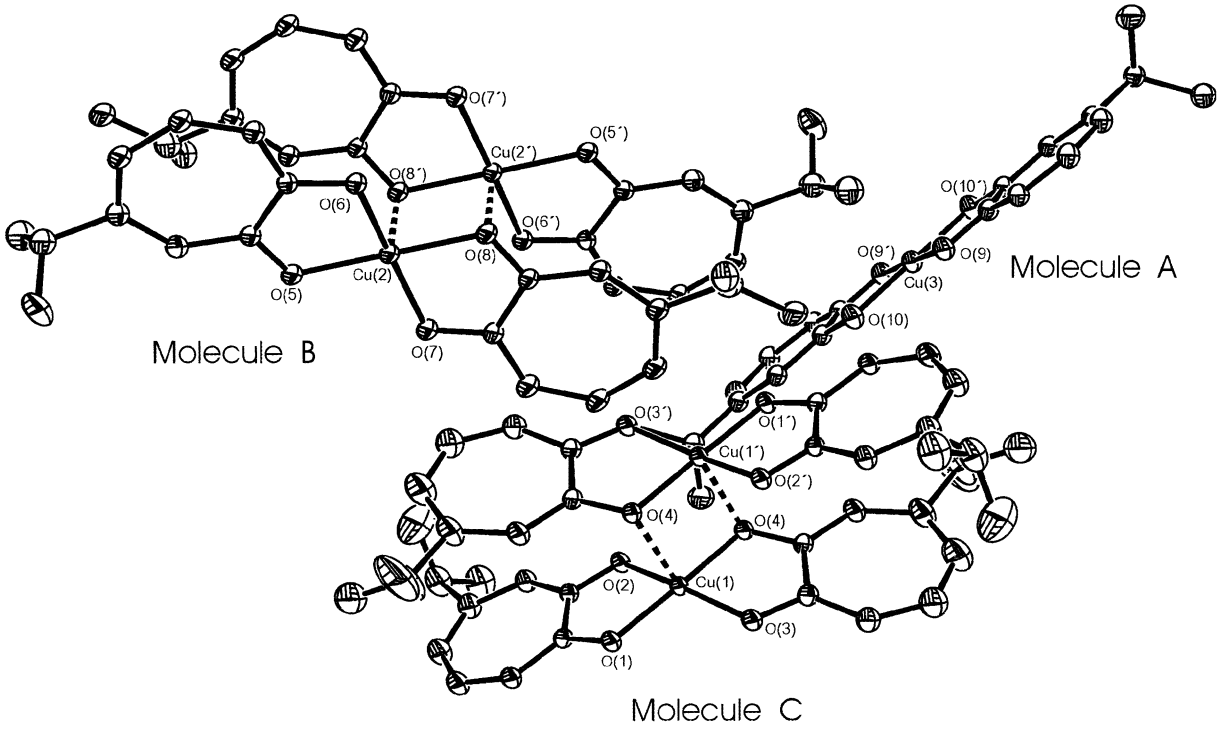

Fig. 2. The asymmetric unit of modification 2 of compound **1** showing the labelling scheme used in the text. Thermal ellipsoids are at the 30% probability level.

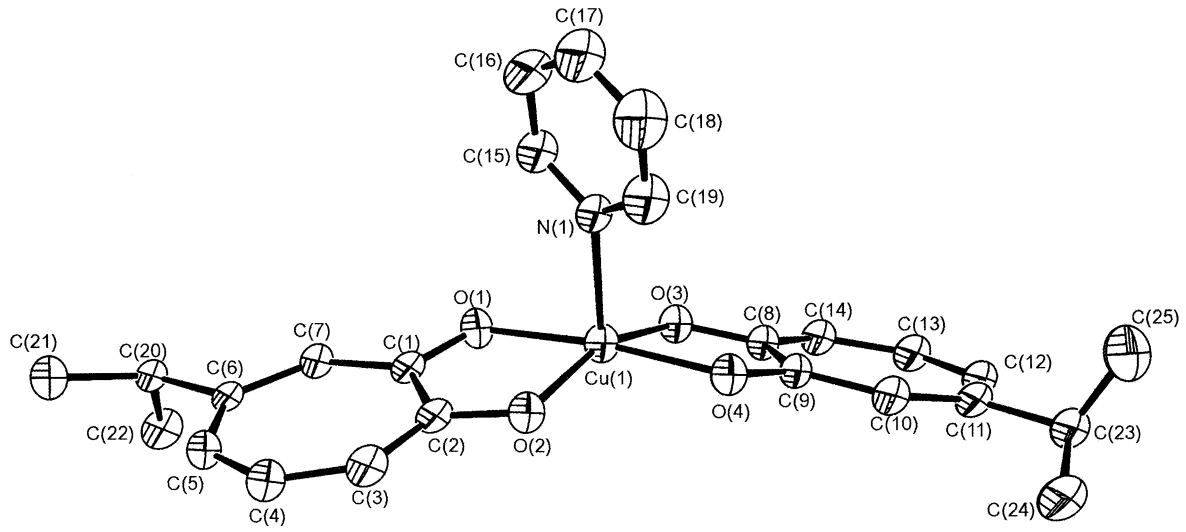

Fig. 3. The asymmetric unit of **2** showing the labelling scheme used in the text. Thermal ellipsoids are at the 30% probability level. Selected metrical data: Cu(1)–O(1) 1.940(3), Cu(1)–O(2) 1.945(3), Cu(1)–O(3) 1.965(3), Cu(1)–O(4) 1.933(3), Cu(1)–N(1) 2.311(5), O(1)–C(1) 1.287(5), O(2)–C(2) 1.278(6), O(3)–C(8) 1.287(5), O(4)–C(9) 1.277(6) Å; O(1)–Cu(1)–O(2) 82.73(14), O(1)–Cu(1)–O(3) 97.28(14), O(1)–Cu(1)–O(4) 172.2(2), O(2)–Cu(1)–O(3) 155.2(2), O(2)–Cu(1)–O(4) 94.3(2), O(3)–Cu(1)–O(4) 82.34(14), O(1)–Cu(1)–N(1) 92.3(2), O(2)–Cu(1)–N(1) 99.0(2), O(3)–Cu(1)–N(1) 105.8(2), O(4)–Cu(1)–N(1) 95.3(2)°.

The two full molecules in modification 2 (B and C) are proximate to inversion centres and hence dimerise with nearby lattice neighbours (Fig. 2). In the dimer based on B, the isopropyl groups sit above each other (eclipsed conformation), while in the dimer of C, they are on opposite sides of the stacked seven-membered rings (staggered conformation). Thus, molecule B minimises repulsions between isopropyl groups within the monomer but maximises it between molecules on dimer formation, while the reverse is true for molecule C.

Table 2
Selected bond lengths (Å) and angles (°) for modification 2 of **1** [a]

Bond angles [b]			
O(1)–Cu(1)–O(2)	84.53(8)	84.27(7)	83.86(7)
O(1)–Cu(1)–O(3)	95.47(8)	97.95(7)	99.15(7)
O(1)–Cu(1)–O(4)	180.0	174.64(7)	177.40(7)
O(2)–Cu(1)–O(3)	180.0	166.88(7)	165.00(8)
O(2)–Cu(1)–O(4)	95.47(8)	93.36(7)	93.55(7)
O(3)–Cu(1)–O(4)	84.53(8)	83.29(7)	83.26(7)

[a] Symmetry transformation used to generate equivalent atoms: $-x, -y, -z$.
[b] Atomic labels refer to molecule C; for molecules A [Cu(3)] and B [Cu(2)], oxygens are O(9, 10) and O(5–8), respectively.

In the non-dimerised molecule A, the Cu–O bond lengths [1.901(2), 1.909(2) Å] are similar than those observed in modification 1 [1.900(2), 1.904(3) Å]. For dimers based on molecules B and C, the intramolecular Cu–O bond lengths [1.915(2)–1.939(2) Å] are longer than those in modification 1 and thus the effect of the dimerisation is similar to the effect of the pyridine coordination, as in **2** (*see below*). The intermolecular interactions [Cu(1)–O(4): 2.476(2); Cu(2)–O(8): 2.511(2) Å] are clearly longer and weaker than the analogous intramolecular bonds, with the eclipsed dimerisation in molecule B manifesting itself in the longer of these two contacts. The intermolecular interactions in both cases do, however, generate almost perfect Cu_2O_2 squares [< Cu(1)–O(4)–Cu(1′): 93.09(6)°; < Cu(2)–O(8)–Cu(2′): 94.80(6)°] at the heart of each dimer.

The coordination chemistry of **1** is thus exceedingly flexible, as both *cis* and *trans* ligand arrangements are possible, as are both monomers and dimers.

3.2. The structure of Cu(II) hinokitiol·pyridine adduct 2

Compound **2** crystallises in the monoclinic space group $P2_1/n$. The copper adopts a square pyramidal geometry with the pyridine in the axial position (Fig. 3),

the copper lies 0.125 Å above the plane of the four oxygen atoms. The Cu–O bond lengths [1.940(3), 1.933(3), 1.945(3), 1.985(3) Å] are longer than those observed in isolated molecules of **1** [1.900(2)–1.909(2) Å]. The structure is similar to the one obtained for $Cu(acrp)_2 \cdot$pyridine (Hacrp: 4-hydroxy-6-methyl-3-[3-dimethylaminoacryloyl]-2*H*-pyran-2-one), and the Cu–N bond [2.311(5) Å] is equivalent with the Cu–N bond of this species [2.310(10) Å] [25].

The electronic spectra of Ni(II) and Cu(II) species incorporating both amines and hinokitiol i.e. $[M(hino)(diamine)]^+$ have been studied [26,27] and such compounds exploited in the extraction of unprotected amino acids [26].

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 181131–181133 for compounds **1** (two modifications) and **2**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.uk or www: http://www.ccdc.cam.ac.uk).

and to obtain information about the simultaneous photoisomerization of both ions we have undertaken an FT IR study of the photoexcited salt that joins both ions. An additional bonus should be the information about the effect of the rather big cation on the IR and thermal behavior (decay) of the anion excited states (c.f. [22] referred to tetrabutylammonium nitroprusside (TBANP)).

2. Experimental

2.1. Preparative

Nitropentaamminecobalt(III) chloride was prepared according to literature [23]. To obtain the title compound (**I**, from now on), the common procedure of mixing equimolar aqueous solutions of silver nitroprusside and of nitropentaamminecobalt(III) chloride was followed. After separation of AgCl, the solution was concentrated in a rotavapor until beginning of crystallization and then it was left at the open air at room temperature to give place to the slow evaporation of enough solvent water to obtain a good crop of crystals.

2.2. X-ray diffraction

Small enough fragments of the crystals were used for X-ray diffraction. Data collection procedure and structure determination methods are summarized in Table 1. Crystal data is also included in the table.

2.3. Irradiation and FT IR spectra

The FT IR spectra of the crystals were recorded with a Bruker IFS 113v spectrophotometer at 2 cm^{-1} resolution. A variable temperature Oxford OX8ITL optical cell was used to cool with liquid nitrogen Nujol mulls of powdered samples spreaded between CsI disks. After recording the low temperature spectra, the samples were irradiated in the cryostat during 3 h with the 488 nm line of an Ar^+ laser (Spectra Physics #166) operated at approximately 100 mW cm^{-2}. Difference spectra allowed the detection of weak new bands. The decay temperatures of the excited species were obtained by heating slowly the samples and monitoring the corresponding NO stretching bands until disappearance.

3. Results and discussion

3.1. Diffraction data and structure solution and refinement

Crystal data and refinement of results are presented in Table 1.

Table 1
Crystal data, structure solution methods and refinement results for $[Co(NH_3)_5NO_2][Fe(CN)_5NO]\cdot 1.5H_2O$

Empirical formula	$C_5H_{18}CoFeN_{12}O_{4.5}$
Formula weight	433.09

[c] Neutral scattering factors and anomalous dispersion corrections.
[d] Structure solved by direct and Fourier methods
[e] Final molecular model obtained by anisotropic full-matrix least-squares refinement of non-hydrogen atoms.
[f] R indices defined as: $R_1 = \Sigma||F_o|-|F_c||/\Sigma|F_o|$, $wR_2 = [\Sigma\, w(F_o^2-F_c^2)^2/\Sigma\, w(F_o^2)^2]^{1/2}$.

All water and most ammonia H-atoms were located in a difference Fourier map. The water H-atoms were refined with Ow–H and H···H distances restrained to 0.82(1) and 1.31(1) Å, respectively, with a common isotropic displacement parameter that converged to $U =$ 0.079(8) Å^2. The ammonia hydrogen atoms were posi-

tioned stereo-chemically and refined with the riding model. During the refinement, the NH_3 hydrogen atoms were allowed to rotate as a rigid group around the Co–NH_3 bond so as to maximize the sum of the electron densities at the three calculated hydrogen positions.

3.2. Crystallographic structural results and discussion

The crystal consists of distinct $[Co(NH_3)_5NO_2]^{2+}$ and nitroprusside units sited at general positions. Atomic fractional coordinates and equivalent isotropic displacement parameters are given in Table 2. Bond distances and angles are included in Table 3. Fig. 1 is an ORTEP [28] drawing of the $[Co(NH_3)_5NO_2]^{2+}$ cation showing the labeling of the non-hydrogen atoms and their displacement ellipsoids.

The cobalt ion is in a distorted octahedral environment, equatorially coordinated with four ammonia ligands [average $d(Co–N) = 1.958(3)$ Å] and axially, with another NH_3 group [$d(Co–N) = 1.975(2)$ Å]; the other axial position is occupied by the NO_2 group, N-bonded to Co at the slightly shorter Co–N bond distance of 1.936(2) Å. The $CoNO_2$ group is practically planar and Y-shaped. This plane is an approximate bisector of the angles formed by opposite couples of adjacent equatorial Co–NH_3 bonds.

Table 2
Atomic coordinates ($\times 10^4$) and equivalent isotropic displacement parameters (Å$^2 \times 10^3$) for $[Co(NH_3)_5NO_2][Fe(CN)_5NO]\cdot 1.5H_2O$

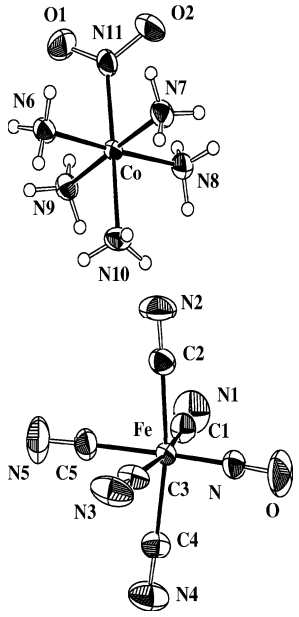

Fig. 1. Molecular plot showing the content of the asymmetric unit of $[Co(NH_3)_5NO_2][Fe(CN)_5NO]\cdot 1.5H_2O$, the labels of the non-H atoms and their displacement ellipsoids at 50% probability level. Metal–ligand bonds are indicated by full lines. The crystallization water molecules are not included in the plot.

The nitroprusside ion has the usual distorted octahedral, pagoda-like, conformation with average Fe–C bond distances of 1.933(3) Å and d(Fe–N) = 1.649(2) Å, in agreement with literature values. [[1,2] and references therein].

One of the water molecules (W1) is at a general crystal position while the other (W2) is sited on a crystallographic twofold axis and exhibits positional disorder.

The solid is stabilized by a network of N–H···N, N–H···O and N–H···Ow bonds, involving as donors the $[Co(NH_3)_5NO_2]^{2+}$ ammonia ligands and as acceptors, nitroprusside cyanide nitrogen atoms [the strongest with d(N6···N5′) = 2.991 Å, ∠(N6–H6B···N5′) = 170.8°], one nitro oxygen atom of a symmetry related $[Co(NH_3)_5NO_2]^{2+}$ complex [the strongest with d(N7···O2′) = 2.972 Å, ∠(N7–H7A···O2′) = 168.3°] and one water oxygen atom [d(N7···O1w′) = 2.928 Å, ∠(N7–H7B···O1w′) = 170.8°]. Further H-bond distances and angles are detailed in the supplementary Table S7.

3.3. Infrared spectra

Infrared spectra of ground state (GS) **I** were recorded at room and at boiling nitrogen temperature. The spectra of the photo-excited compound were run at this later temperature. The main features of the spectra can be immediately assigned to the internal vibrations of the hydration water molecules, the nitroprusside anion and the nitropentaamminecobalt(III) cation.

Wavenumbers of the IR absorption bands and their assignments, based on results of a normal coordinate analysis and Density Functional Theory calculations reported for the nitroprusside anion [8] are presented in Table 4.

Fig. 2 shows the spectra of **I** cooled at 77 K, before and after irradiation with the 488.0 nm line of the Ar^+ laser. After irradiation, new IR bands appear as expected from previous results obtained for the anion [6] and from the isomerization of the cation [29].

Low temperature IR wavenumbers are used in the following discussion of bands.

Bands located at 3644 and 3608 cm^{-1} can be assigned to the anti-symmetric H_2O stretching modes of the two water molecules while the band at 3453 cm^{-1} is probably due to the symmetric mode of one of them. Other bands surely overlap the corresponding band of the other molecule. The single band appearing at 1607 cm^{-1} may be assigned to the bending mode of one of the molecules. For the other one, the same mode, is perhaps overlapped by the NH_3 bending bands.

The water libration bands appear between 790 and 300 cm^{-1} in the IR spectra of other nitroprussides, often overlapped with bands of the anion and in this case with bands of the cation as well. The typical behavior of bands due to these modes are the increase in the intensity and the decrease in half-widths upon cooling, but in the present case it was possible to observe these effects only for the bands located at 433 and 365 cm^{-1}, which can be assigned to these modes. The other bands corresponding to the libration modes may be masked by cation and anion bands.

3.4. Anion bands

3.4.1. CN stretchings

Five features are observed in the low temperature IR spectrum, at 2186 (w), 2165 (sh), 2150 (vs), 2142 (sh) and 2131 (m) cm^{-1}. The weak band at 2186 cm^{-1} could be due to the axial mode of A_1 species under ideal C_{4v} symmetry. As the anions are sited at general C_1 positions in the lattice, the shoulder observed at 2165 cm^{-1} is probably due to the B_1 (under C_{4v} symmetry) equatorial mode activated by the low symmetry of the anions. The strongest band at 2150 cm^{-1} and the shoulder at 2142 cm^{-1} could be due to the doubly degenerated C_{4v} E mode split under C_1 symmetry, originated in the equatorial CN groups, while the medium intense bands at 2131 cm^{-1} could be assigned to the A_1 equatorial mode.

3.4.2. NO and FeNO vibrational bands

Two features are seen in the IR low temperature spectrum in the fundamental NO stretching region, at 1949 and 1912 cm^{-1}, as expected from factor group

Table 4

[d] Intermediate cation.

splitting (66Au, 66Bu under factor group C_{2h} symmetry).

IR bands at 663 and 648 cm^{-1} are assigned to the FeNO bending and FeN stretching modes, respectively. No splitting is observed for these modes.

3.4.3. FeC stretchings and FeCN deformations

Table 4 shows the assignments of bands supposedly due to FeC stretchings, FeCN, CFeC and CFeN deformations. They were made following reference [8].

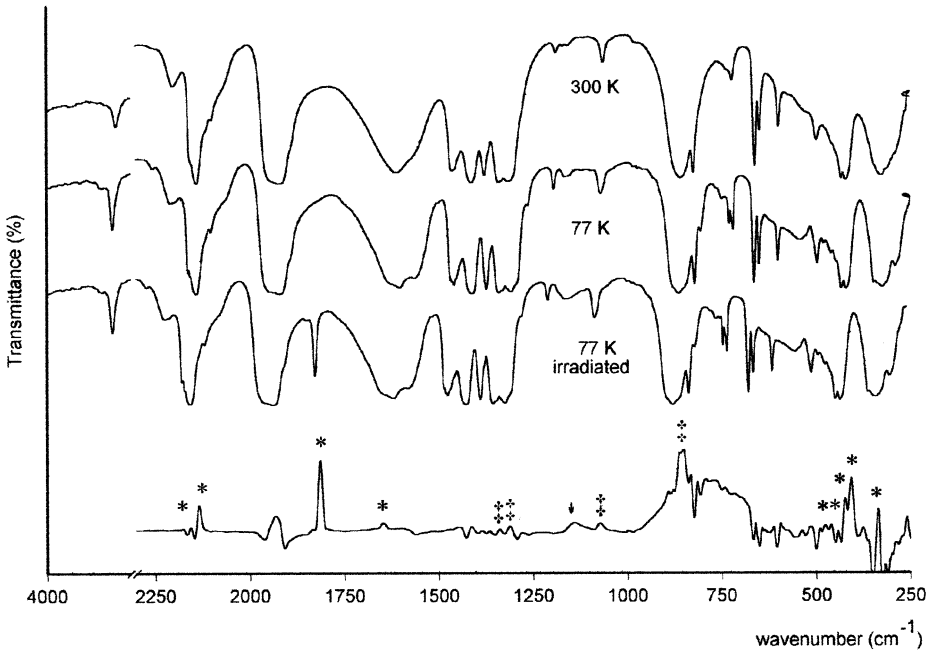

Fig. 2. Infrared spectra of $[Co(NH_3)_5NO_2][Fe(CN)_5NO]\cdot 1.5H_2O$ in the ground state at 300 and 77 K and photoexcited, at 77 K. The difference spectrum between the two last spectra is also included. Features due to MSI and MSII are marked with stars (*) and double crosses (‡), respectively.

3.5. Excited states

3.5.1. Anion

Due to the low concentration of excited states achieved, difference spectra were useful to detect very weak bands. As mentioned above, Fig. 2 shows also the infrared spectrum after irradiation. The irradiation generates two metastable reversible states, MSI and MSII, which can be most easily detected by new bands due to the NO groups. The NO stretching bands of the excited states are shifted to lower wavenumbers in comparison with the ground state band. In general, these bands show downshifts of approximately 110 cm^{-1} for MSI and 300 cm^{-1} for MSII [22].

Three bands due to CN stretchings of the excited states were observed also at lower wavenumbers comparing with the ground sates bands. The average downshift was nearly 8 cm^{-1}.

The new νNO bands due to MSI and MSII of **I** appear at 1814 and 1647 cm^{-1}, respectively, shifted 135 and 302 cm^{-1} with respect to the ground state band located at 1949 cm^{-1} and the decay temperatures are 190 K for MSI and 141 K, for MSII. These values are in agreement with the reported values for other nitroprussides ([22] and references therein) but the MSI νNO downshift is larger than the observed in the other nitroprussides with the exception of the barium salt, for which $\Delta\tilde{\nu}$ is 149 cm^{-1} [30], while the corresponding shift for MSII is the smallest.

It is to be noted that in TBANP, with a big cation, [22] the low decay temperatures of both excited sates (170, 180 and 100, 120 K for MSI and MSII of the dihydrated (DH) and the anhydrous salt, respectively) and the large νNO shifts (118, 122 and 318, 312 cm^{-1}, respectively), were explained by the softness of the structures. In the present case, decay temperatures are larger as well as the MSI νNO shift pointing to a tighter structure as expected from the respective unit cell volumes and Z number (3622.60 $Å^3$ and 3, respectively, for TBANPDH, [22] and 3402.76 $Å^3$ and 8, for **I**). The lower $\Delta\tilde{\nu}$(NO) for MSII remains to be explained.

In the IR spectrum of MSI the δ(FeON) and ν(FeO) modes appear at 573 and 550 cm^{-1}, respectively. The bands expected for the other MSI modes and for MSII are extremely weak, excepting the νFeC_{ax} mode of MSI, which appears as a weak band at 407 cm^{-1}.

3.5.2. Cation

It is known that the photoreaction of the $[Co(NH_3)_5NO_2]^{2+}$ cation in the solid dichloride produces the stable isomeric nitrito species which can be identified by the presence of the IR band at 1055 cm^{-1} due to ν_sNO [29]. Spectral evidence for this isomer in the present cases is the new band located at 1068 cm^{-1}. It was reported that the $(NH_3)_5CoNO_2 \rightarrow (NH_3)_5CoONO$ photoisomerization could probably be an intramolecular process proceeding via a seven-coordinated transition state giving rise to a nitrito compound but with slightly different geometrical parameters from that of the fresh chemically prepared nitrito compound [21]. In another paper about the photochemical nitro–nitrito linkage isomerization [31] the ν_sNO band of a metastable species is reported at 1105 cm^{-1}. In this case, the band due to this species appears at 1140 cm^{-1}. The shift

to higher wavenumbers is perhaps due to the shortening of the N–O distances of the NO_2 group (average: 1.23 Å in [32] and 1.21 Å, in the present case).

3.5.3. TGA, DTA

Thermograms of **I** run under flowing nitrogen show that the dehydration process begins at a relatively low temperature, producing a DTA peak located at 74 °C. The weight loss in this endothermic step corresponds to one and a half water molecules per formula weight (theoretical: 6.4%, measured: 5.8%, mean value).

The following decomposition steps produce two close exothermic DTA peaks at 168.5 and 178.7 °C. The total weight loss is 27.9% (expected: 28.2%) which is due, perhaps, to the evolution of four NH_3 molecules and one of C_2N_2 (the IR spectrum of the residue at this stage showed weak NH_3 bands and bands due to the NO, NO_2 and CN groups). The next steps up to 500 °C occur with a weight change of 27.5% and DTA peaks at 236 °C (endothermic) and at 302.7, 347.4 and 390.9 °C (exothermic).

The infrared spectrum and the X-ray diffractogram of the residue at 500 °C suggest the presence of the mixed oxide $CoFe_2O_4$. The total weight change is in fairly good accordance with the change expected from the following equation (found: 61.0, theoretical: 64.0%), $[Co(NH_3)_5NO_2][Fe(CN)_5NO]\cdot 1.5\ H_2O = 1.5H_2O + 5NH_3 + 5/2C_2N_2 + N_2 + 1/2CoFe_2O_4 + 1/2CoO$. It is to be noted that the composition of the solid residue is speculative.

The solid was further heated up to 900 °C but there was no additional weight change and also, the IR spectrum and the X-ray diffractogram of the residue did not show any modification.

4. Conclusions

$[Co(NH_3)_5NO_2][Fe(CN)_5NO]\cdot 1.5H_2O$ crystallizes in the monoclinic $C2/c$ space group (C_{2h}^6). The anions occupy C_1 sites in the lattice and present the usual distorted octahedral structure and the geometrical parameters (bond distances and angles) as in several nitroprussides. The cation, which has also a distorted octahedral structure, and one water molecule also occupy C_1 sites while the other water molecule is at a C_2 site. The structure of the cation is similar as found in the chloride but the average N–O distance (1.21 Å) seems to be somewhat shorter than reported in [32] (1.23 Å), the difference reflects in the ν_sNO wave numbers (1140 and 1105 cm^{-1}, respectively).

The irradiation of the compound generates the excited states MSI and MSII in the anion. The $\Delta\tilde{\nu}$(NO) wave numbers (difference between the NO stretching of GS and MSI) and the decay temperatures of MSI and MSII are among the greatest measured so far, facts which are assigned to the relatively open structure of the crystal, as done before in the case of tetrabutylammonium nitroprusside dihydrate and anhydrate, which showed a similar behavior [22].

With respect to the cation, irradiation generates the nitrito isomer and the metastable species.

The thermogravimetric results obtained under flowing nitrogen atmospheres pointed to the existence of 1.5 water molecules per formula in the original substance and to the formation of the mixed oxide $CoFe_2O_4$ and of CoO as final solid products. XRD and IRS of the residue seem to confirm the presence of the mixed oxide.

5. Supplementary material

Listings of atomic anisotropic thermal parameters (Table S5), hydrogen atoms positions (Table S6), H-bond distance and angles (Table S7), and calculated and observed structure factor amplitudes (Table S8) are available on request.

under a nitrogen atmosphere: the following step was performed in air. The powder was dissolved in dichloromethane (4 ml), filtered to remove a small amount of insoluble material, treated with hexane and allowed to stand for 1 day at r.t. to give red–brown crystals. The product was found to be insoluble in chloroform, dichloromethane, toluene and dimethylsulphoxide (even with warming). Yield: 0.015 g (22%). IR (KBr) ν(CN) 2160 (s), ν(XCN) 2116 (s), $\nu(O_2)$ 863 (m). *Anal*. Calc. for $C_{47}H_{41}Cl_2N_2O_2P_2Rh$ C, 62.61; H, 4.58; N, 3.11. Found: C, 62.27; H, 4.57; N, 3.13%. The last step (crystallisation in air) could not be relied upon to give a product on every occasion.

2.2. X-ray structure determination

Intensity data were collected on a Bruker SMART 1K CCD area detector diffractometer with graphite monochromated Mo Kα radiation (50 kV, 30 mA). The collection method involved ω-scans of width 0.3°. Data reduction was carried out using the program SAINT+ [19] and absorption corrections were made using the program SADABS [20]. The crystal structure was solved by direct methods using SHELXTL [21]. Non-hydrogen atoms were first refined isotropically followed by anistropic refinement by full matrix least-squares calculation based on F^2 using SHELXTL. All hydrogen atoms were placed geometrically and allowed to ride on their respective parent atoms. The structure contains a disordered dichloromethane molecule; the disorder was resolved by applying a treatment involving three differently orientated molecules as rigid bodies and summing their contributions to unity. Diagrams were generated using SHELXTL and PLATON [22]. Structure and refinement data are given in Table 1.

3. Results and discussion

The complex $[Rh(CN)(O_2)(PPh_3)_2(XNC)]$ Fig. 1 has octahedral geometry with distortions arising from the presence of the O–O bond, which restricts the O–Rh–O angle to 41.77(11)°. The Rh–O and O–O bond lengths (Table 2) are not significantly different from those reported for $[Rh(O_2)\{PPh_2(2\text{-}C_6H_4CHN^iPr)\}_2]BPh_4$ [9] and fall towards the middle of the ranges observed for $Rh(O_2)$ complexes [3–15]. The principal intermolecular interactions are a close contact (2.518 Å) between a phenyl hydrogen (attached to C54) and oxygen O1 (of an adjacent molecule) and several C–H···π [23] interactions.

From the series $[Rh(Y)(PPh_3)_2(XNC)]$ (Y = Cl, N_3, NCO, NCS, $N(CN)_2$, $NCBPh_3$, $CNBPh_3$, CN) the only complex to form an adduct with O_2 is the cyano derivative. The formation of an O_2 adduct involves the transfer of electron density from rhodium to oxygen (to give an Rh(III) peroxo complex [24]), a process favoured by electron-donating ligands on Rh. The CN^- ion, while carrying a negative charge, is not normally considered to be strongly electron-donating, certainly not more so than Cl^- or N_3^-. On two different scales of electron-donating ability (those of Vaska [25], based on carbonyl stretching frequencies of complexes $[M(Y)(PPh_3)_2(CO)]$ (M = Rh, Ir) and Chatt [26], based on the reversible one-electron oxidation potential of $[Cr(CO)_5(Y)]$) the CN^- ligand is rated as less electron-donating than Cl^-, N_3^- and NCO^-. The ability of CN^- to activate the complex *trans*-$[Rh(CN)(PPh_3)_2(XNC)]$ towards reaction with O_2 must, therefore, reside elsewhere, most probably in its polarisability.

The cyano ligand differs from Cl^-, N_3^-, NCO^-, NCS^-, $N(CN)_2^-$ and $NCBPh_3^-$ which, according to Pearson's classification [27], are either hard or borderline, while CN^- is soft, i.e. more polarisable. Although $CNBPh_3$ is also soft it is, in effect, a CN^- modified by attachment of a strong Lewis acid, and its electron-donating ability and polarisability will consequently be reduced. From this perspective the four soft ligands of *trans*-$[Rh(CN)(PPh_3)_2(XNC)]$ can be regarded as con-

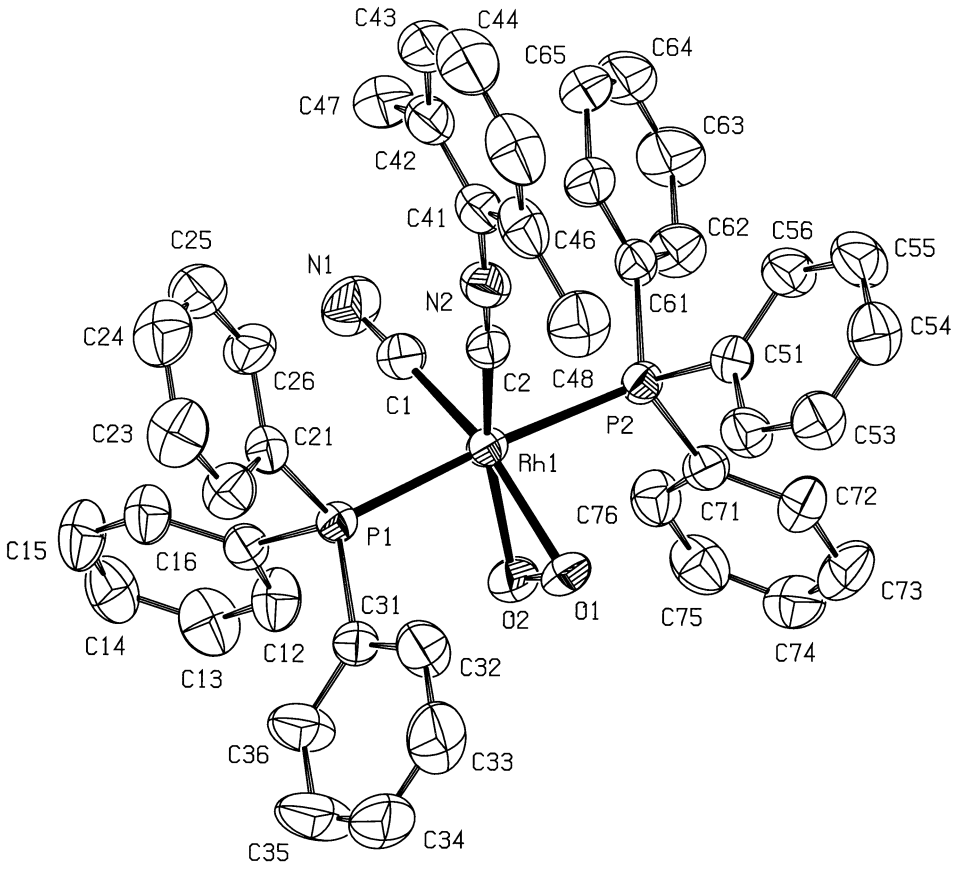

Fig. 1. ORTEP diagram of $[Rh(CN)(O_2)(PPh_3)_2(XNC)](CH_2Cl_2)$; thermal ellipsoids are shown at the 50% probability level; hydrogens and CH_2Cl_2 are omitted.

Table 2
Selected bond lengths (Å) and angles (°) for $[Rh(CN)(O_2)(PPh_3)_2(XNC)](CH_2Cl_2)$

Bond lengths

C(2)–Rh–P(2)	88.79(11)		

ferring enhanced polarisability on rhodium, altering its reactivity so as more to resemble that of iridium, and crossing the threshold at which reaction with O_2 becomes possible. In this context it has been noted by Valentine [28] that the reactivity of Rh(I) towards O_2 is enhanced by strong σ-donor ligands and by polarisable ligands and inhibited by strong π-acceptor ligands (factors which, with important differences, also influence the binding of H_2 by Ir(I) [29]). The carbonyl analogue *trans*-$[Rh(CN)(PPh_3)_2(CO)]$ is unreactive towards oxygen (under ambient conditions) indicating that differences in the σ-donor ability of CO and XNC (CO is a poorer σ-donor) are also important.

2. Experimental

2.1. Materials and methods

All manipulations were performed under aerobic conditions using materials as received, except where indicated otherwise. $NBu^n_4MnO_4$ was prepared as described elsewhere [46], $[Mn_3O(O_2CEt)_6(py)_3](ClO_4)$ was available from previous work [47].

2.2. Syntheses

2.2.1. $Mn(O_2CEt)_2\cdot 0.35H_2O$

To a slurry of $MnCO_3$ (30 g, 0.26 mol) in water (200 mL) was added dropwise propionic acid (25 ml, 0.33 mol). The mixture was stirred for a few days and the unreacted $MnCO_3$ was removed by filtration. The pale brown filtrate was roto-evaporated to dryness to yield a pink solid. The yield was 79%. *Anal.* Calc. (Found) for $Mn(O_2CEt)_2\cdot 0.35H_2O$: C, 34.75 (34.51); H, 5.20 (4.89); N, 0.00 (0.00)%.

2.2.2. $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)\cdot 2EtCO_2H$ (**1**)

A solution of $Mn(O_2CEt)_2\cdot 0.35H_2O$ (757 mg, 3.65 mmol) in water (6 ml) was added to a solution of bpya (356 mg, 2.08 mmol) and NBu_4ClO_4 (520 mg, 1.52 mmol) in propionic acid (25 ml). To the resulting yellow solution was added dropwise a solution of $NBu^n_4MnO_4$ (0.27 g, 0.70 mmol) in MeCN (2 ml) to yield a red solution, which was stirred for ~ 3 h. Addition of Et_2O (200 ml) led to precipitation of a microcrystalline red product that was collected by filtration, washed with Et_2O and dried in vacuo. The yield was 68% based on total available Mn. *Anal.* Calc. (Found) for **1**·2Et-CO_2H: C, 41.72 (41.71); H, 4.84 (4.84); N, 6.21 (6.14)%. To a saturated solution of **1** in MeCN was added toluene (approximately one-fourth of the solution volume) and the mixture left to slowly evaporate at room temperature (r.t.). Crystals suitable for X-ray crystallography deposited over two weeks.

2.3. Crystal structure of *1*

Data were collected on a Bruker Smart 6000 CCD system with a sealed molybdenum source and graphite monochromator. Small crystals were selected from the bulk sample and transferred to the goniostat where they were cooled to −160 °C for data collection and characterization. The data were collected using 10 s frames with an omega scan of 0.30° and corrected for Lorentz and polarization effects. Equivalent reflections were averaged using the Bruker SAINT software, as well as utility programs from the XTEL library ($R_{av} = 0.076$). The space group was *Pbca*. The structure was readily solved using SHELXTL and Fourier techniques. Many of the hydrogen atoms were visible in a difference Fourier map phased on the non-hydrogen atoms. All hydrogen atoms were placed in idealized, calculated positions and treated as fixed atom contributors in the final cycles of refinement. The structure was well ordered with the exception of one $EtCO_2^-$ ligand in which the methyl group was disordered (C47). The MeCN solvent was also found to be in 50% occupancy. A final difference Fourier map was essentially featureless, the largest peak being 0.83 e A^{-3}. The final $R(R_w)$ indices were 3.72(3.92) using 5341 independent reflections with $I > 2.33\sigma(I)$. Crystallographic data are summarized in Table 1.

2.4. Other measurements

^1H NMR spectra were collected on a 300 MHz Varian Gemini 2000 spectrometer and a 500 MHz Varian Inova spectrometer with the protio-solvent signal used as reference. Chemical shifts are quoted on the δ scale (downfield shifts are positive). Cyclic voltammetry was performed in MeCN solution using 0.1 M NBu_4PF_6 as supporting electrolyte using a BAS CV-50 voltammetric analyzer. Electrodes were a glassy carbon working electrode, a platinum wire auxiliary electrode, and a silver wire in a 1 M $AgNO_3$ MeCN solution, connected to the cell solution through a saline bridge, as reference electrode. Dc magnetic susceptibility data were collected on powdered, microcrystalline samples (restrained in eicosane to prevent torquing) with a Quantum Design MPMS-XL SQUID magnetometer equipped with a 5.5 T (55 kG) magnet. A diamagnetic correction to the observed susceptibilities was applied using Pascal's constants. Elemental analyses were performed by Atlantic Microlab.

Table 1
Crystallographic data for $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)\cdot MeCN$ (**1**)

Formula [a]	$C_{43}H_{56}ClMn_4N_7O_{20}$

[b] Mo Kα, graphite monochromator.
[c] $R = 100\ \Sigma\ ||F_o| - |F_c||/\Sigma\ |F_o|$.
[d] $R_w = 100\ [\Sigma\ w(|F_o| - |F_c|)^2/\Sigma\ w|F_o|^2]^{1/2}$ where $w = 1/\sigma^2(|F_o|)$.

3. Results and discussion

3.1. Synthesis and reactivity

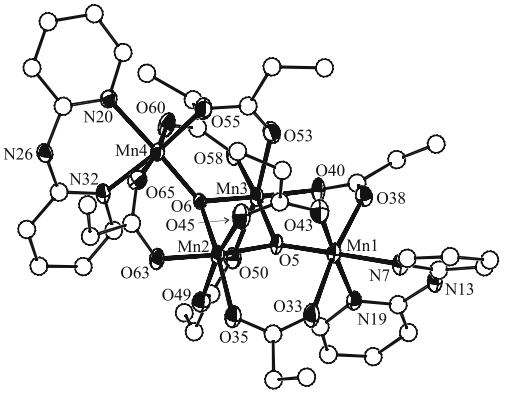
We have recently prepared a number of $Mn_x/O/RCO_2$ aggregates using comproportionation reactions between $Mn(O_2CR)_2$ (R = Me, Et) and MnO_4^- in the presence of a chelating ligand and the corresponding carboxylic acid. This route has provided convenient access to various tetranuclear Mn complexes with trigonal pyramidal or butterfly-like Mn_4 topologies [40]. When $NBu^n_4MnO_4$ in MeCN was added to $Mn(O_2CEt)_2$ in $EtCO_2H/H_2O$ (5:1 v/v) in the presence of bpya and $NBu^n_4ClO_4$, a dark red solution was obtained from which $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ (**1**) was obtained in high yield as a red microcrystalline solid upon addition of Et_2O. The reaction is summarized in Eq. (1).

$$16Mn(O_2CEt)_2 + 4MnO_4^- + 10bpya + 12EtCO_2H \rightarrow 5[Mn_4O_2(O_2CEt)_7(bpya)_2]^+ + 9EtCO_2^- + 6H_2O \quad (1)$$

The crystal structure of **1** (vide infra) shows that bpya is bound in its neutral form, consistent with the acidic conditions of the reaction medium. Since this ligand has been found chelating as a deprotonated anion in a few cases [43,44], the question arose whether under different conditions lacking added acid the ligand would appear in a deprotonated form. The reaction of preformed trinuclear complexes $[Mn_3O(O_2CR)_6(L)_3]^{0,+}$ (L = py, H_2O) with chelating ligands has been used extensively in the past to trigger structural rearrangements leading to higher nuclearity products [45]. With this in mind, the reaction of $[Mn_3O(O_2CEt)_6(py)_3](ClO_4)$ with bpya was investigated. A dark brown solution of the trinuclear complex in MeCN was treated with 1.5 equiv. of bpya, and a red-brown precipitate started to form within minutes. This product was identified as predominantly complex **1** by IR and ^1H NMR spectroscopy.

3.2. Description of the structure of *1*

Crystallographic data for $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ (**1**) are listed in Table 1. A labeled ORTEP representation of the cation of complex **1** is presented in Fig. 1, and selected interatomic distances and bond angles are listed in Table 2. The core consists of four Mn ions bridged by two μ_3-oxide ions, the ensemble having a butterfly-like topology. Approximately octahedral coordination around each Mn(III) is completed by the peripheral ligation, comprising seven μ_2-O_2CEt^- groups and two bpya ligands. One carboxylate is bound only to 'body' Mn ions, Mn2 and Mn3, while each of the other six is bridging a body-wingtip Mn_2 pair. The bpya groups chelate the two wingtip Mn ions Mn1 and Mn4. The cluster possesses virtual C_2 symmetry. Charge considerations indicate the oxidation state +3 for all four metals, as confirmed by the presence of a Jahn–Teller elongation of two *trans* bonds (av. 2.138 Å) at each Mn center, although the equatorial bond distances span a wide range (1.833–2.087 Å). The Mn_4O_2 core contains four different types of Mn···Mn vectors: Mn2 and Mn3 are 2.871(2) Å apart, the body Mn ions are separated from the wingtip ions by averages of 3.307 Å (two carboxylate bridges) and 3.444 Å (one carboxylate bridge), and the Mn1···Mn4 distance is 5.834 Å. The overall structure of this molecule is similar to that of other previously reported clusters with the $[Mn_4O_2]^{8+}$ core [36–40,47] (vide infra), but is the first with a six-membered N-based chelate ring. These six-membered chelate rings are in a boat conformation, as commonly seen for bpya although the extent of the folding varies greatly from compound to compound. The factors determining the exact shape of the chelate ring seem to be mainly steric and possibly involve crystal packing forces as well. The folding of the boat is gauged by the angles between the least-squares plane defined by N_a, N_b, C_b and C_a, and the planes C_a–N_c–C_b and N_a–Mn–N_b, averaging 23.79 and 28.97°, respectively, for complex **1**.



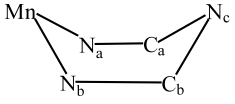


Fig. 1. ORTEP representation of the cation of $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ at the 50% probability level (carbons represented isotropically).

3.2.1. Comparison of *1* with other $[Mn_4O_2]^{8+}$ complexes

As stated above, complex **1** is a new addition to the family of Mn clusters with the butterfly-like $[Mn_4O_2]^{8+}$ core, enlarging the available database of such complexes for identifying correlations between structure and physico-chemical properties. In Table 3 is presented a comparison between the core parameters of **1** and those of $[Mn_4O_2(NO_3)(O_2CEt)_6(bpy)_2](ClO_4)$ (**2**) [40], $[Mn_4O_2(O_2CMe)_7(bpy)_2](ClO_4)$ (**3**) [39] (bpy = 2,2′-bipyridyl), $(NBu^n_4)[Mn_4O_2(O_2CMe)_7(pic)_2]$ (**4**) [36]

(picH = picolinic acid), $[Mn_4O_2(py)_2(O_2CMe)_6(dbm)_2]$ (**5**) [38] (dbmH = dibenzoylmethane) and $[Mn_4O_2(O_2CPh)_6(dpm)_2]$ (**6**) [47] (dpmH = dipivaloylmethane). All these complexes have idealized C_2 symmetry except for **5**, which possesses a crystallographic inversion center and a planar rather than butterfly Mn_4 topology. The main conclusion to be drawn is that core structures of the C_2 molecules are insignificantly affected by the nature of the chelate ligands and are thus all essentially superimposable, with only minor differences between corresponding structural parameters.

3.3. Magnetochemistry

The molar magnetic susceptibility, χ_m, of complex **1** in the solid state was measured under a constant magnetic field of 1 Tesla in the 5–300 K range. A plot of the effective magnetic moment, μ_{eff}, of complex **1** versus temperature is shown in Fig. 2. The value of μ_{eff} is $8.30\mu_B$ at 300 K and gradually diminishes as the temperature is decreased. A sharp increase of the slope is observed at 50 K, below which μ_{eff} decreases much more rapidly to a value of $4.12\mu_B$ at 5 K.

The Heisenberg spin Hamiltonian for complex **1** is given in Eq. (2), where the numbering in Fig. 1 has been employed.

$$\hat{H} = -2(J_{12}\hat{S}_1\hat{S}_2 + J_{13}\hat{S}_1\hat{S}_3 + J_{23}\hat{S}_2\hat{S}_3 + J_{24}\hat{S}_2\hat{S}_4 + J_{34}\hat{S}_3\hat{S}_4 + J_{14}\hat{S}_1\hat{S}_4) \quad (2)$$

From the virtual C_2 symmetry of **1**, it follows that there are two types of 'body-to-wingtip' Mn–Mn interactions. These can be assumed to be equivalent on the basis of the structural parameters, as was done with previous butterfly complexes, and the spin Hamiltonian then simplifies to that in Eq. (3), where J_{wb} is the wingtip-body interaction, J_{bb} is the body–body interaction,

$$\hat{H} = -2J_{wb}(\hat{S}_1\hat{S}_2 + \hat{S}_1\hat{S}_3 + \hat{S}_2\hat{S}_4 + \hat{S}_3\hat{S}_4) - 2J_{bb}\hat{S}_2\hat{S}_3 - 2J_{ww}\hat{S}_1\hat{S}_4 \quad (3)$$

and J_{ww} refers to the wingtip–wingtip interaction. By use of the Kambe vector coupling method [41,42], and the definitions $\hat{S}_A = \hat{S}_2 + \hat{S}_3$, $\hat{S}_B = \hat{S}_1 + \hat{S}_4$ and $\hat{S}_T = \hat{S}_A + \hat{S}_B$, the spin Hamiltonian can be transformed into that in Eq. (4).

$$\hat{H} = -J_{wb}(\hat{S}_T^2 - \hat{S}_A^2 - \hat{S}_B^2) - J_{bb}\hat{S}_A^2 - J_{ww}\hat{S}_B^2 \quad (4)$$

The corresponding expression of the energy of the spin microstates $|S_T, S_A, S_B\rangle$ is given in Eq. (5). There are a total of 85 S_T states, ranging from $S_T = 0$ to 8.

$$E(S_T, S_A, S_B) = -J_{wb}[S_T(S_T+1) - S_A(S_A+1) - S_B(S_B+1)] - J_{bb}[S_A(S_A+1)] - J_{ww}[S_B(S_B+1)] \quad (5)$$

The solid line in Fig. 2 represents the best fit of the experimental data to the theoretical χ_m versus T equation obtained using the energy values in Eq. (5) and the Van Vleck equation. A temperature independent paramagnetism (TIP) term was held constant at 900×10^{-6} cm^3 mol^{-1}. The fitting parameters were $J_{wb} = -3.27$ cm^{-1}, $J_{bb} = -25.66$ cm^{-1} and $J_{ww} = -0.77$ cm^{-1}, with g held constant at $g = 1.99$. These parameters yield a spin ground state of $S_T = 0$, corresponding to $|0,0,0\rangle$. There is a group of five states, including

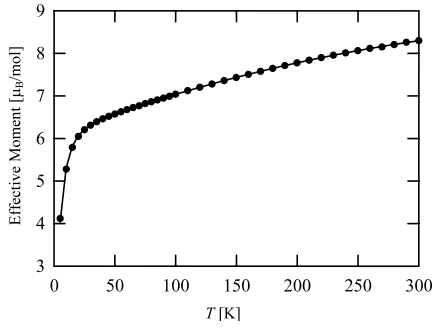

Fig. 2. Plot of effective magnetic moment (μ_{eff}) per molecule vs. T for $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ in a 10.0 kG field. The solid line is a fit of the data to the appropriate theoretical equation; see the text for the fitting parameters.

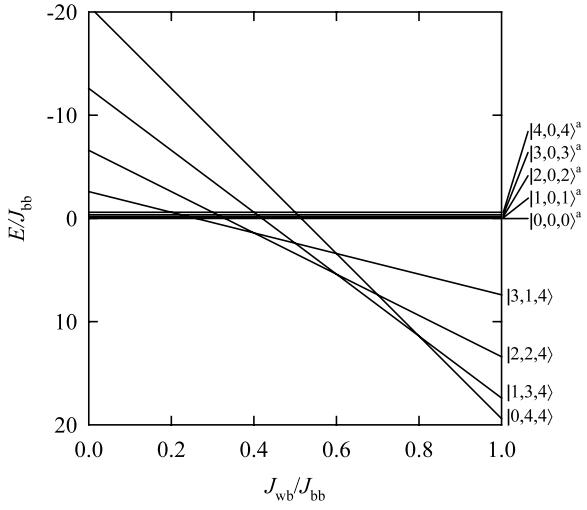

Fig. 3. Relative energy normalized to J_{bb} of the spin-ground state of a $[Mn_4O_2]^{8+}$ system as a function of the ratio J_{wb}/J_{bb} with $J_{ww} = -0.77$ cm^{-1}. For $J_{ww} = 0$, these states would belong to a fivefold degenerate set.

the ground state, within a narrow energy band of 15.3 cm^{-1}, the others being the $|1,0,1\rangle$, $|2,0,2\rangle$, $|3,0,3\rangle$ and $|4,0,4\rangle$ states. This collection of five closely lying spin states becomes degenerate if the weak magnetic coupling between the wing manganese ions (Mn1 and Mn4) is neglected. Although this interaction is very small ($J_{ww} = -0.77$ cm^{-1}), taking it into consideration resulted in a significant improvement of the fit. The introduction of this term results in very small changes to the energies of the different spin states and in the splitting of some groups of states that otherwise would be degenerate, but it strongly influences the behavior of μ_{eff} at very low temperature. The splitting of the ground state caused by this small wing–wing antiferromagnetic interaction leads to a sharp drop of the magnetic moment below 50 K because a diamagnetic state is being populated. Fig. 3 shows the relative energy (normalized to J_{bb}) of the spin ground state for this system as a function of the ratio J_{wb}/J_{bb}, with J_{ww} constant at -0.77 cm^{-1}. This plot shows that the ground-state spin is governed by the J_{wb}/J_{bb} ratio. The value of J_{ww} is assumed to be always very small and it only can affect the ground state when J_{wb}/J_{bb} is sufficiently low, by determining the relative energies of the group of states $|0,0,0\rangle$, $|1,0,1\rangle$, $|2,0,2\rangle$, $|3,0,3\rangle$ and $|4,0,4\rangle$. This is the case in complex **1** ($J_{wb}/J_{bb} = 0.13$), where the drop of μ_{eff} at low temperatures is explained by the existence of the diamagnetic ground state ($|0,0,0\rangle$) that results from the negative value of J_{ww}. A summary of the J_{wb} and J_{bb} parameters found for previously characterized $[Mn_4O_2]^{8+}$ complexes is given in Table 4.

In order to address the question of whether the global rather than a local fitting had been obtained, and to

Table 4
Exchange interaction constants in $[Mn_4O_2]^{8+}$ complexes

Complex	J_{wb} (cm^{-1})	J_{bb} (cm^{-1})	Ref.
$[Mn_4O_2(NO_3)(O_2CEt)_6(bpy)_2]^+$	−1.7	−16.5	[40]
$[Mn_4O_2(O_2CEt)_7(bpya)_2]^+$	−3.3	−25.7	this work
$[Mn_4O_2(O_2CMe)_7(bpy)_2]^+$	−7.8	−23.5	[39]
$[Mn_4O_2(O_2CMe)_7(pic)_2]^-$	−5.3	−24.6	[36]
$[Mn_4O_2(py)_2(O_2CMe)_6(dbm)_2]$	−5.0	−24.9	[38]
$[Mn_4O_2(O_2CPh)_6(dpm)_2]$	−0.4	−27.5	[47]

assess the reliability of the conclusion regarding the ground state of **1**, the relative error surface diagram for this fit was examined. The error surface was generated as a function of J_{wb} (−30.0 to 10.0 cm^{-1}) and J_{bb} (−50.0 to 25.0 cm^{-1}), with J_{ww} and g fixed at −0.77 cm^{-1} and 1.99, respectively. For this, the expression in Eq. (6) was used as the root-mean-square error, where n is the number of data points.

$$\sigma = \sqrt{\frac{\sum(\chi_{calc} - \chi_{exp})^2}{n}} \quad (6)$$

Fig. 4 shows a two-dimensional contour projection of the error surface, showing that the point of minimum error is poorly defined and located within a shallow 'valley'. The area with $\sigma \leq 0.002$ spans approximately the ranges −2 to −4 and −21 to −32 cm^{-1} for J_{wb} and J_{bb}, respectively. Superimposed on top of the contour diagram of Fig. 4 are the lines dividing the {J_{wb}, J_{bb}} space into regions of different ground states. Although the minimum of the error is not very well defined in the surface, it is clear from this plot that the assignment of the spin-ground state is reliable, since the entire region that would contain all reasonable fits is confined within

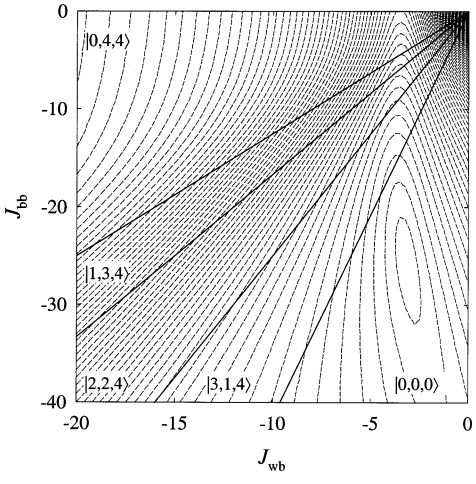

Fig. 4. Error surface of the magnetic susceptibility fit for $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ as a function of J_{wb} and J_{bb}, represented as a contour projection (dashed lines) of the relative error calculated with g and J_{ww} constant at 1.99 and −0.77 cm^{-1}, respectively. Superimposed on the contour diagram are the lines dividing the {J_{wb}, J_{bb}} space into regions of different ground states.

the zone for $S_T = 0$ (or the area where the group of closely lying states |0,0,0⟩, |1,0,1⟩, |2,0,2⟩, |3,0,3⟩, and |4,0,4⟩ have the lowest energy).

The ground state of **1** is in contrast to that of most other $[Mn_4O_2]^{8+}$ complexes [36,38,39] for which the ground state is $S_T = 3$. This emphasizes the importance of the J_{wb}/J_{bb} ratio in determining the ground state of these molecules (Fig. 3). With such a small J_{wb}/J_{bb} ratio (0.13), i.e. $J_{bb} \gg J_{wb}$, the spins of the body Mn ions will be antiparallel-aligned, i.e. $S_A = 0$, and the ground state will then be determined by the interaction of the wingtip Mn ions via the J_{ww} exchange, giving a $S_T = 0$ ground state since J_{ww} is antiferromagnetic. In effect, this |0,0,0⟩ ground state can be described as the result of a weak long-range J_{ww} interaction between the wingtip Mn ions through a strongly coupled, diamagnetic (S_A = 0) central unit. If $J_{ww} = 0$, the ground state is the group of closely spaced states |0,0,0⟩, |1,0,1⟩, |2,0,2⟩, |3,0,3⟩ and |4,0,4⟩, corresponding to two non-interacting Mn(III) ions. The latter situation is approximated in the related complex $[Mn_4O_2(O_2CPh)_6(dpm)_2]$ where the J_{wb}/J_{bb} ratio is only 0.01, J_{ww} is negligible, and the ground state is best described as fivefold degenerate (non-interacting wingtip Mn ions) [47].

3.4. ^1H NMR spectroscopy

Complex **1** is moderately soluble in MeCN and is thus amenable to solution spectroscopic studies. The 500 MHz ^1H NMR spectrum (Fig. 5) was obtained in order to ascertain whether the structure is retained in solution. The spectral data are collected in Table 5. The interpretation of the ^1H NMR spectrum of complex **1** has

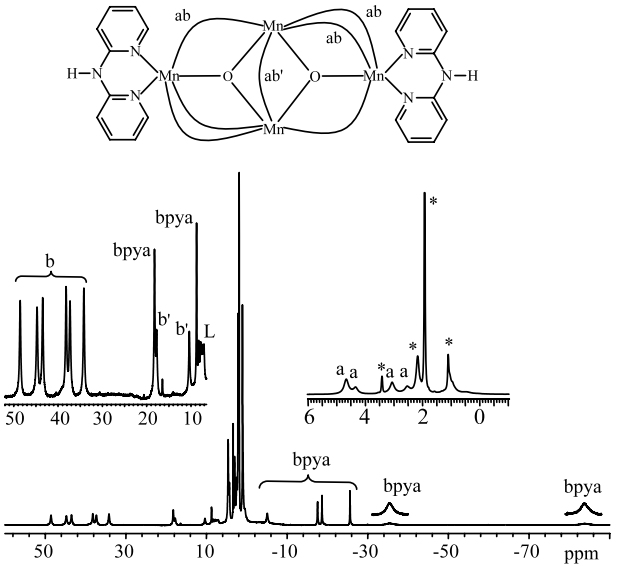

Fig. 5. 500 MHz ^1H NMR spectrum of $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ in CD_3CN; * = $EtCO_2H$, H_2O and MeCN impurities, L = free ligand. Labels a and b refer to propionate CH_3 and CH_2 resonances, respectively.

Table 5
500 MHz ^{1}H NMR data [a] for $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ (**1**) in CD_3CN

a	4.6	bpya	18.3
a	4.3	bpya	8.8
a	3.1	bpya	−5.0
a	2.5	bpya	−17.5
b	48.6(44.7)	bpya	−18.6
b	43.5(38.2)	bpya	−25.5
b	37.3(34.2)	bpya	−35.6
b′	17.8(10.4)	bpya	−83.8

[a] At approximately 23 °C, ppm; *b′* refers to the unique carboxylate bridging the body Mn ions.

benefited from previous spectroscopic studies on the analogous butterfly-like clusters **2**, **3** and **4** [36,39,40].

The ^{1}H NMR spectrum in Fig. 5 exhibits 20 different resonances in addition to the signals from solvent and ligand impurities. This is the number expected if the complex exhibits effective C_2 symmetry in solution. These resonances span a wide range of chemical shifts (−90 to 50 ppm). Four sets of signals in a 2:2:2:1 ratio are observed for the μ_2-O_2CEt groups, according to the scheme shown in Fig. 5. Each of these sets features two peaks from the CH_2 protons, which are diastereotopic, in the 10–50 ppm region, and a singlet from the CH_3 group between 2 and 5 ppm. The two chelating ligands are symmetry-related but all the protons within each bpya group are inequivalent. Accordingly, eight bpya signals are observed, and these display great disparity of linewidths as a result of their different separations from the Mn ions (broadness $\propto r^{-6}$, where r is the Mn···H distance). In addition, these eight resonances are subject to strong paramagnetic shifts to either side of the diamagnetic region, indicating that a π spin-delocalization mechanism is contributing to the coupling of the nuclear and electronic magnetic moments. All these results indicate that the structure of **1** in the solid state is retained in MeCN solution. In contrast, when the cluster is dissolved in DMSO, decomposition takes place, as is evident from the complete loss of the ^{1}H NMR spectral features in this solvent.

3.5. Electrochemistry

Complex **1** was investigated by cyclic voltammetry in MeCN solution with 0.1 M $N^nBu_4PF_6$. The voltammogram of this compound at a scan rate of 100 mV s^{-1} is displayed in Fig. 6. This complex shows a quasi-reversible oxidation process and an irreversible reduction process at 0.71 and −0.20 V versus Fc/Fc^+, respectively. The quasi-reversible oxidation has a peak-to-peak separation of 130 mV and is likely metal-based (Eq. (7)).

$$[Mn_4^{III}O_2]^{8+} - e^- \rightarrow [Mn_3^{III}Mn^{IV}O_2]^{9+} \quad (7)$$

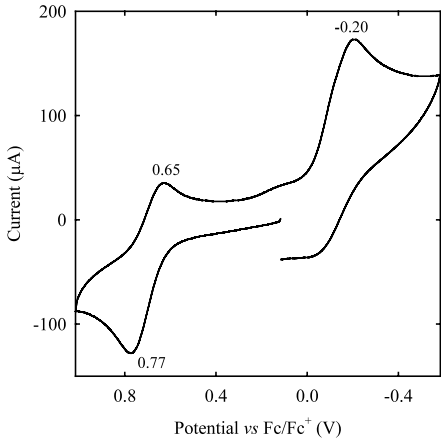

Fig. 6. Cyclic voltammogram at 100 mV s^{-1} for $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ in MeCN containing 0.1 M $NBu^n_4PF_6$.

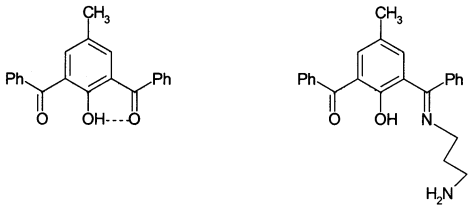
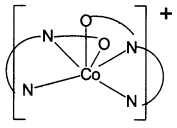
These values are similar to what has been observed previously for the $[Mn_4O_2(O_2CR)_7(L–L)]^+$ (R = Me, Ph; L–L = bpy, phen, 4-4′-Me_2-bpy) complexes reported previously by our group. Thus the non-ligation to Mn of the NH group of bpya results in **1** exhibiting very similar redox properties to the corresponding bpy and phen complexes.

4. Conclusions

The new tetranuclear complex $[Mn_4O_2(O_2CEt)_7(bpya)_2](ClO_4)$ (**1**) forms from the comproportionation reaction between Mn^{II} and Mn^{VII} in propionic acid in the presence of bpya. The title compound is the first crystallographically characterized species containing the ligand bpya bound to manganese. Unlike the majority of previously characterized Mn clusters with a butterfly core, complex **1** possesses a spin ground state of $S_T = 0$. This result emphasizes that only small changes in the relative strength of competing exchange interactions are necessary in a $[Mn_4O_2]^{8+}$ butterfly system for a change of the ground state spin value to occur. ^{1}H NMR spectroscopy has shown that the new complex retains its structure in MeCN solution. Complex **1** is a new addition to the list of crystallographically characterized clusters with the $[Mn_4O_2]^{8+}$ core.



5. Supplementary material



Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 175700 for compound **1**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-

mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) [48].

2. Experimental

All the chemicals were of reagent grade and were used as received. Propane-1,3-diamine and $CoCl_2 \cdot 6H_2O$ were obtained from Aldrich. Solvents were purified by standard methods [14].

2.1. Physical measurements

Elemental analysis was carried out by the University of North London, London, UK. Thermogravimetric analysis was carried out on a DuPont TGA 2950 analyzer in the synthetic air atmosphere with a heating rate of 10 °C min^{-1}. The molar conductance in 10^{-3} mol dm^{-3} MeOH solution was measured using a Global DCM-900 digital conductivity meter. The IR spectra were recorded on a Perkin–Elmer 1720 FT spectrometer in Nujol mulls. The EI and FAB mass spectra (recorded in a 3-nitrophenylmethanol matrix) by use of a VG Autospec spectrometer. The electronic spectra in 10^{-4} mol dm^{-3} MeOH solution were obtained using a Shimadzu UV-160A recording spectrophotometer. The ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded on a 500 MHz Bruker NMR instrument and chemical shifts are relative to $SiMe_4$. Assignments were made using selective decoupling, saturation transfer experiments, 2D double quantum filtered (DQF)-COSY and Nuclear Overhauser effect (NOE) experiments. The signals of phenyl CH carbons were assigned by the DEPT 90° pulse technique. Cyclic voltammograms were run in a nitrogen atmosphere in 10^{-4} M MeOH solution of the complex on an EG & G Versastat II system using platinum as working electrode, Pt wire as auxiliary electrode and SCE as the reference electrode. Tetraethylammonium–perchlorate (TEAP) (0.1 M solution in MeOH) was used as the supporting electrolyte. Scan speeds of 50–200 mV s^{-1} were employed.

2.2. Preparation of 4-methyl-2,6-dibenzoylphenol(mdbp) (*I*)

The precursor (mdbp) **I** was prepared by a literature method [15] (m.p. 159 °C, lit. [15] 160 °C). Crystals suitable for an X-ray study were grown as yellow needles by slow evaporation from the ethanol solution. MS (EI) (*m*/*z*) 316 (100, M), 301 (5, $M-CH_3$), 287 (10, $M-HCO$), 239 (40, $M-Ph$), 211 (15, $M-PhCO$), 161 (40, $M-Ph-PhH$), 105 (65, PhCO), 77 (80). IR (cm^{-1}): 3425 [ν(OH)]; 1658, 1620 [ν(CO)]; 1604 [ν(C–C)ring]; 1575 [ν(C–O)]. UV–Vis (nm) (ε, M^{-1} cm^{-1}) (MeOH): 352 (6000); 255 (24 700). ^1H NMR ($CDCl_3$): δ 2.33 (s, 3H, CH_3); 7.3–7.9 (m, 12H, Ph); 12.02 (s, 1H, OH).

2.3. Template synthesis of $[Co(L)_2](Cl) \cdot NH_2(CH_2)_3NH_2 \cdot 2EtOH$ (*1*)

To a boiling solution of $CoCl_2 \cdot 6H_2O$ (0.952 g, 4.00 mmol) and 4-methyl-2,6-dibenzoylphenol (2.53 g, 8.00 mmol) in ethanol (30 cm^3), an ethanolic solution of the propane-1,3-diamine (0.592 g, 8.00 mmol) was added slowly with constant stirring and the mixture was boiled under reflux for 4 h. The resulting brown solution was cooled to room temperature and allowed to stand for 1 week during which brown crystals formed. The crystals were filtered off, washed with cold ethanol and dried in air. Yield 2.60 g (65%), m.p. 240 °C. *Anal*. Calc. for $C_{55}H_{68}ClCoN_6O_6$: C, 65.84; H, 6.78; N, 8.38. Found: C, 66.00; H, 6.86; N, 8.56%. MS (FAB^+) (*m*/*z*): 801 (CoL_2^+). IR (cm^{-1}): 3448 [ν(OH)]; 3177, 3137 [ν(N–H)]; 1650 [ν(CO)]; 1594 [ν(C=N)]; 1529 [ν(C–O)]. CV data (V): $E_{pc} = -0.67$, $E_{pa} = +0.88$. Λ_M (10^{-3} M, MeOH, 298 K): 85 *S* cm^2 mol^{-1}.

2.4. X-ray structure determination

Yellow needles of the precursor mdbp **I** and brown crystals of complex **1** were grown by slow evaporation from their ethanol solutions. Data were obtained on a Nonius Kappa CCD diffractometer with Mo Kα radiation. Data collection parameters are given in Table 1. No absorption corrections were applied. The structures were solved and refined using SHELXL-97 [16]. The non-hydrogen atoms were refined anisotropically and H atoms in riding mode. Selected bond lengths and angles are listed in Table 2.

3. Results and discussion

3.1. Synthesis and properties

The template condensation of 4-methyl-2,6-dibenzoylphenol (mdbp) **I** with propane-1,3-diamine in the presence of $CoCl_2 \cdot 6H_2O$ in ethanol yields a diamagnetic brown Co(III) complex of composition $[Co(L)_2]Cl \cdot NH_2(CH_2)_3NH_2 \cdot 2EtOH$ (**1**). Presumably an initially formed Co^{II} complex is oxidized by accidentally admitted air.

The molar conductance value in MeOH suggests that it is a 1:1 electrolyte. Elemental analysis is found to be in good agreement with this formulation.

3.2. Thermal study

The presence of chloride ion and a molecule of diamine solvate outside the coordination sphere of the complex is confirmed by dynamic TGA studies. Complex **1** is stable up to 198.3 °C and thereafter it registers a mass loss of 3.3% at 261 °C compared with the theoretical value of 3.54%, which corresponds to the loss of half molecule of chlorine. From 260.6 to 333.4 °C a mass loss of 17.0%, compared with the theoretical value of 16.5% is attributed to the combined loss of two moles of ethanol and one mole of propane-1,3-diamine. After 400 °C the complex starts to decompose and a mass loss of 37% at 441.7 °C corresponds to the loss of one ligand (theoretical value 37.1%). The total mass loss up to 551.6 °C is found to be 90.3%, which shows the formation of cobalt oxide. The high mass of the residue (theory 7.5%) is attributed to carbonaceous matter. Thus the decomposition pattern obtained from TGA curve confirms the proposed formulation of the complex.

3.3. Mass spectrum

The FAB mass spectrum shows the presence of the cationic species $[Co(L)_2]^+$ at *m*/*z* 801.

3.4. IR and electronic spectra

The IR spectrum of the precursor mdbp **I** displays two ν(CO) bands at 1658 and 1620 cm^{-1}, the latter being hydrogen bonded. Complex **1** displays a ν(CO) band at 1650 and a ν(CN) vibration at 1594 cm^{-1}. The bands at 3177 and 3137 cm^{-1} are assigned to ν(N–H) vibrations. The low value of ν(N–H) is attributed to the fact that the NH_2 group is coordinated to the metal. The band at 1530 cm^{-1} has been assigned to the ν(C···O) vibration of the phenol [15] as a consequence of the delocalization of double bond in the chelate ring that has increased the bond order of the phenolic C–O. This is confirmed by the crystal structure determination. A broad band at 3448 cm^{-1} is due to ν(OH) in ethanol molecules occluded in the lattice.

Complex **1** is diamagnetic. The electronic spectrum has three bands at 634, 411 and 243 nm. The first band seems to include a major contribution from the $^1A_{1g} \rightarrow {}^1T_{1g}$ transition, suggesting a distorted octahedral geometry [17]. The other two bands are charge transfer and intraligand transitions, respectively. Strong absorption at higher frequencies precludes observation of other possible ligand field transitions.

3.5. Crystal structure of mdbp *I* and complex *1*

An ORTEP view of the mdbp **I** with the atom numbering scheme is shown in Fig. 1. Selected bond lengths and angles are given in Table 2. The phenolic hydrogen forms a hydrogen bond of length 2.58 Å with atom O(2) of the carbonyl group, essentially similar to that, 2.566(3) Å, in $[(PhCO)_2C_6H_2(OH)_2]$ [10]. The 4-methyl substituent in **I** is unable to participate in intermolecular hydrogen bonding so that the molecules in the lattice are isolated, instead of built into an infinite network like those of the hydroquinone. The C(1)–O(1) [1.360(4) Å] is significantly longer than the C(8)–O(2) [1.235(3) Å] and C(15)–O(3) [1.225(3) Å] distances. Similar distances, mean 1.357(3) Å and 1.232(3) Å are also observed in $[(PhCO)_2C_6H_2(OH)_2]$ [10]. The central carbon C(1) is perfectly planar (sum of bond angles 360.0(3)°). Other features of bond lengths and angles are as expected.

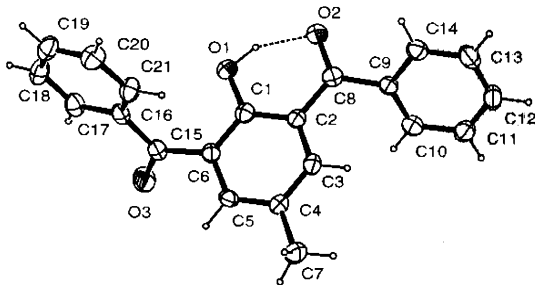

Fig. 1. Molecular structure of 4-methyl-2,6-dibenzoylphenol, mdbp **I**.

The molecular structure of complex **1** is shown in Fig. 2 and another view is given in Fig. 3. The two monoanionic ligands are tridentate, coordinating through amine N, imine N and phenolic O atoms to give a *mer*-CoN_4O_2 octahedral configuration. The two phenolic groups are nearly parallel. The ethanol molecule and the propane-1,3-diamine are disordered and poorly defined, and do not form part of the Co coordination sphere. The phenolic C–O distances in the complex [1.305(8) and 1.317(8) Å] are significantly shorter than that in the ligand **I** [1.360(4) Å] consistent with the infrared data. The average Co–N [1.950(5) Å] and Co–O [1.882(5) Å] bond lengths are in the same range as corresponding values in similar octahedral Co(III) systems [18,19], and significantly shorter than Co^{II}–N and Co^{II}–O bond lengths. For example, the Co–N (peptide) distances range from 2.12 to 2.14 Å and Co–O distances from 2.07 to 2.15 Å in bis-L-histidinate $Co^{II}\cdot H_2O$ [20] and $LCo^{II}_2Br_2\cdot CH_3OH$, in which the N_4O_2 donor set of the macrocyclic ligand L coordinates to two Co atoms [21]. A Co–O distance of 1.98 Å (longer than that in **1**) and Co–N distances from 1.91 to 1.94 Å (similar to those in **1**) have been reported for the *mer*-bis(glycylglycinato)cobalt(III) cation [22]. In general, bite distances of five-membered and six-membered chelate rings are approximately 2.6–2.7 and 2.8–2.9 Å, respectively, and bite angles 84°–88° and 92°–96°,

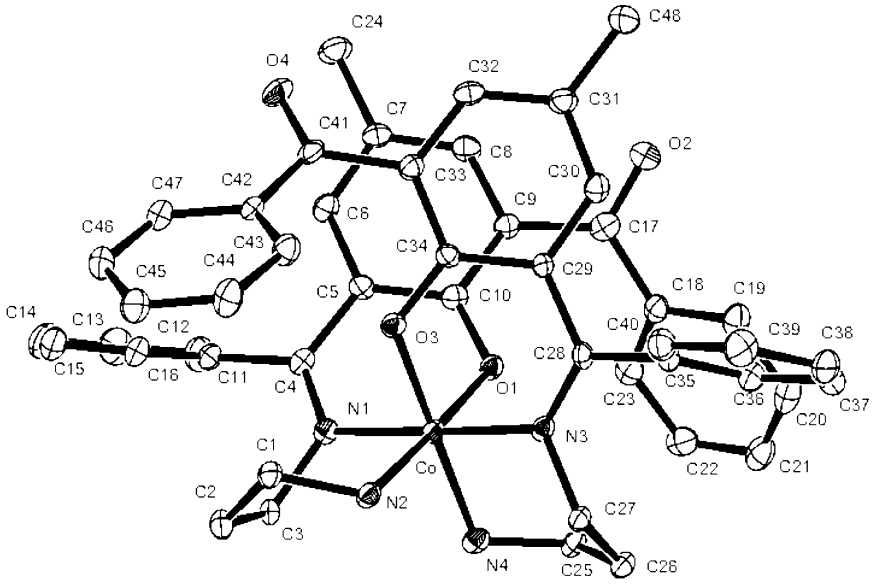

Fig. 2. Molecular structure of the complex $[Co(L)_2]^+$.

respectively [23]. In the present investigation the N···N bite distances (2.74 and 2.76 Å) and the N–Co–N and O–Co–O bite angle, ca. 90°) are in the normal range for six-membered chelate rings and octahedral coordination at the metal. The dihedral angles between the central ring of the Schiff's base and the phenyl rings are 59° and 71° on one side of the complex and 53° and 85° on the other side. There is thus no conjugation between the three aromatic rings with each ligand unit.

3.6. NMR spectra

The ^1H and ^{13}C NMR spectra of **1**, obtained from a sample dissolved in MeOH-d_4, confirmed the presence

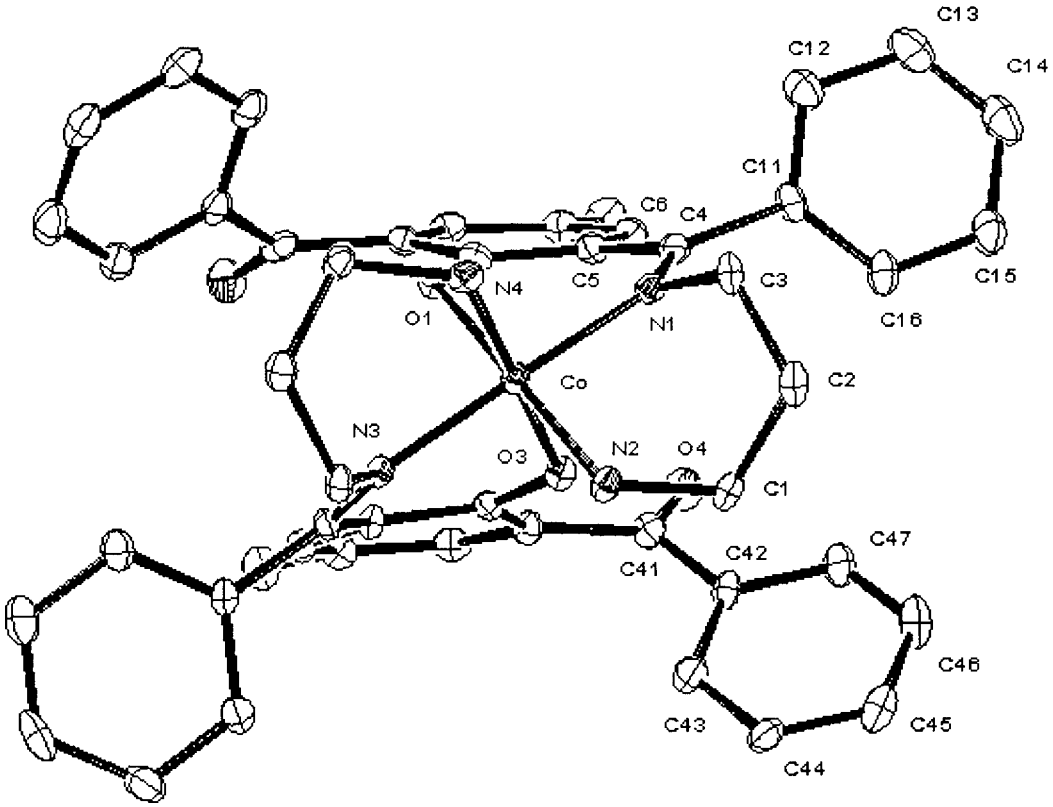

Fig. 3. Another view of the molecular structure of the complex **1**.

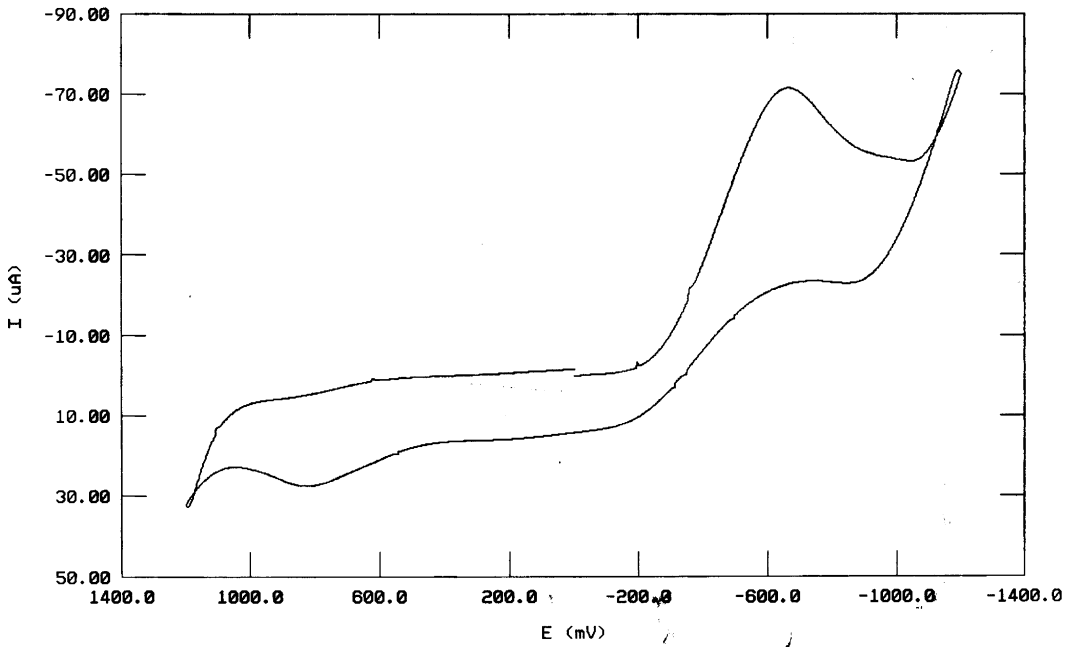

Fig. 4. Cyclic voltammogram of complex **1** (0.1 mM) in MeOH at 200 mV s^{-1}.

of the ion $[CoL_2]^+$. The two ligand fragments, not quite identical in the crystal, appeared to be so in solution, as the ion is freed from packing forces. However, at 298 K, separate signals are obtained for the protons attached to the five carbon atoms of the C^{11}–C^{16} phenyl ring, and separate signals from the six carbon atoms, indicating that rotation of the ring about the C^4–C^{11} bond is slow on the NMR time scale. In contrast, the C^{18}–C^{23} phenyl ring is able to rotate freely. Selective decoupling showed that the signals at δ 7.06 and 7.19 arose from *ortho*-protons at C^{12} and C^{16} attached to the same phenyl ring. A saturation transfer experiment at the highest accessible temperature (336 K) showed that exchange between these protons was beginning to occur on the 1 s^{-1} timescale. As expected, irradiation at the frequency of the protons attached to C^2 caused changes in the signals associated with those attached to C^1 and C^3. Other assignments were made from a 2D double quantum filtered (DQF)-COSY experiment.

Nuclear Overhauser effect (NOE) experiments showed that both the protons attached to C^{12} and those attached to C^{16} are close to the protons on C^6, indicating that the C^{11}–C^{16} and C^5–C^{10} rings are, on average, not far from orthogonal in solution. Further, the protons attached to C^{16} show an NOE at C^2 in the methylene chain and at the *ortho*- protons of the freely rotating ring. These must be those attached to C^{43} and C^{47} in the ligand fragment on the opposite side of the complex. This further confirms that the integrity of the crystal structure is maintained in solution and that rotation of the C^{11}–C^{16} phenyl group is slowed down by the puckering of the $CH_2CH_2CH_2NH_2$ chain. The results suggests that Schiff's bases of the general type discussed here may be sufficiently crowded to make it possible by careful ligand design to fine-tune accessibility to and reducibility of the Co^{III} centre.

3.7. Cyclic voltammetry

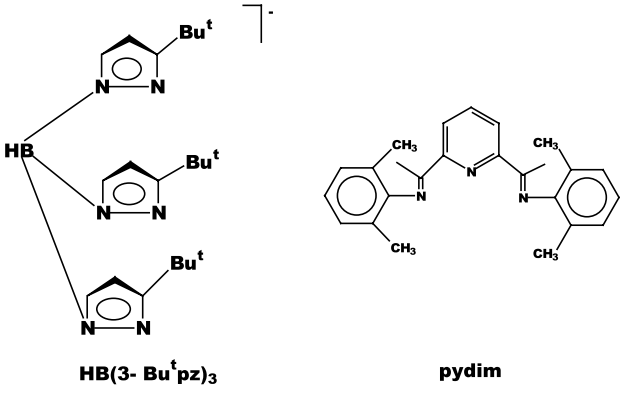
The cyclic voltammogram of complex **1** (Fig. 4) shows one irreversible wave at $E_{pc} = -0.66$ to -0.71 V versus the SCE, with the 50–200 mV s^{-1} scan rates. This is attributed to Co(III) to Co(II) reduction. No anodic peak could be observed even after applying a 200 mV s^{-1} scan rate indicating the irreversible nature of the electrode process. The linear plot of the cathodic peak current (I_{pc}) versus the square root of the scan rate ($v^{1/2}$) passes close to the origin, indicating that the electrode reaction is mainly diffusion controlled. An irreversible anodic peak at $E_{pa} = +0.83$–0.97 V could be assigned to the oxidation of the ligand on the electrode surface.

4. Conclusion

The reaction of cobalt(II) chloride with the unsymmetrical Schiff's base, HL (generated in situ) in the presence of traces of air gave a diamagnetic mononuclear cobalt(III) complex. The structure of $[Co(L)_2]^+$ revealed that the NNO-donor sets of two ligand fragments form a distorted octahedral configuration at Co. The dihedral angles between the central ring of the Schiff base and the phenyl rings showed no conjugation, and NMR experiments indicate that rotation of the phenyl ring adjacent to nitrogen is restricted in solution as well as in the solid state. The values of E_{pc} for the

Co(III)/Co(II) couple range from −0.66 to −0.71 V (vs. SCE).

5. Supplementary material



Tables of atomic coordinates and equivalent isotropic displacement parameters, anisotropic displacement parameters for non-hydrogen atoms, hydrogen coordinates and isotropic displacement parameters have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 176395 for $C_{21}H_{16}O_3$ and 176396 for $C_{55}H_{68}ClCoN_6O_6$. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Scheme 1.

with terminal thiocyanate ligands. The planar bonding substituted pyridine ligand pydim was chosen to contrast the tripodal, facial coordination of pyrazolylborate ligands [12]. We also report the syntheses of two lead thiocyanate complexes of less bulky tris(pyrazolyl)borate ligands. Specifically, the syntheses and solid state structure determinations of the following will be discussed: [HB(3-Bu^{t}pz)$_3$]Cd(NCS), [(Bu^{t}Hpz)$_2$Cd(μ-NCS-*N*,*S*)$_2$]$_n$, {[HB(3,5-Me$_2$pz)$_3$]Pb(μ-NCS)}$_2$, {[HB(pz)$_3$]Pb(μ-NCS)}$_n$, [(pydim)Cd(μ-NCS,*N*,*S*)]$_2$[BF$_4$]$_2$, and [(pydim)Pb(NCS)][BF$_4$]. In the two complexes that are monomeric, the terminal thiocyanate ligands are N-bound.

2. Experimental

2.1. General procedure

All operations were carried out under a nitrogen atmosphere using standard Schlenk techniques and a Vacuum Atmospheres HE-493 dry box. All solvents were dried, degassed, and distilled prior to use. The ^{1}H NMR spectra were recorded on a Varian AM300 or AM400 spectrometer using a broad-band probe. Proton chemical shifts are reported in ppm versus internal Me$_4$Si. Mass spectral data were recorded on a VG 70SQ mass spectrometer. Clusters assigned to specific ions show appropriate isotopic patterns as calculated for the atoms present. Infrared spectra were recorded on a Perkin–Elmer 781 spectophotometer. Anhydrous CdCl$_2$ and KSCN were purchased from Aldrich Chemicals. The compounds 2,6-bis[(2,6-dimethylphenylimino)-methyl] pyridine (pydim), 2,6-bis[1-(2,6-dimethylphenyliimno)ethyl]pyridine (pydimMe$_2$) [14], K[HB(pz)$_3$] [1c], K[HB(3,5-Me$_2$pz)$_3$] [1d], Tl[HB(Bu^{t}pz)$_3$] [1g], [Cd$_2$(thf)$_5$][BF$_4$]$_4$ [2b] and [HB(pz)$_3$]PbCl [3a] were prepared according to published methods.

Note! Cadmium and lead compounds and their wastes are extremely toxic and must be handled carefully!!

2.2. {[HB(3-Bu^{t}pz)$_3$]Cd(II)}[BF$_4$]

[Cd$_2$(thf)$_5$][BF$_4$]$_4$ (0.43 g, 0.50 mmol) and Tl[(HB(3-Bu^{t}pz)$_3$] (0.58 g, 1.0 mmol) were dissolved in thf (20 ml) and allowed to stir for 2 h at ambient temperature. The mixture was filtered and the filtrate was evaporated to leave a white solid (0.25 g, 0.43 mmol, 43%); m.p. = 98–103 °C. ^{1}H NMR (acetone-d_6) δ: 7.68, 6.11 (d, d; 3, 3; J = 2.2 Hz; 4,5-H pz); 1.38 (27, s, Bu^t). FAB$^+$ MS: m/z Calc. for {[HB(3-Bu^{t}pz)$_3$]^{113}Cd}$^+$: 495.1966. Found: 495.1980.

2.3. [HB(3-Bu^{t}pz)$_3$]Cd(NCS) (**1**)

[Cd$_2$(thf)$_5$](BF$_4$)$_4$ (0.43 g, 0.50 mmol) and Tl[HB(3-Bu^{t}pz)$_3$] (0.58 g, 1.0 mmol) were charged into a round bottom Schlenk flask and thf (35 ml) was added to the flask via syringe. A white precipitate immediately formed, the mixture was allowed to stir for 2 h at room temperature (r.t.) and then filtered. The volatiles were removed in vacuo leaving a white solid. This solid and KSCN (0.080 g, 1.0 mmol) were dissolved in thf (20 ml). Immediately, a white precipitate formed, this mixture was allowed to stir for 3 h at r.t. then filtered. The solvent was removed in vacuo to leave a white solid (0.10 g, 0.17 mmol, 17%); m.p. = 135–142 °C. X-ray quality crystals were obtained from hot (50°)/cold(0°) toluene. ^{1}H NMR (acetone-d_6) δ: 7.78, 6.22 (3, 3; d, d; J = 2.2 Hz; 4,5-H pz); 1.39 (27, s, Bu^t). IR (νC≡N, Nujol mull, cm^{-1}): 2103. MS, direct ionization: m/z for M^+ Calc. for {[HB(3-Bu^{t}pz)$_3$]^{113}CdNCS}, 549.1732. Found: 549.1739.

2.4. [(3-Bu^{t}Hpz)$_2$Cd(μ-NCS-S,N)$_2$]$_n$ (**2**)

X-ray quality crystals were obtained from an attempted crystallization, from a layered solution of acetone and hexane, of the product produced in the [HB(3-Bu^{t}pz)$_3$]Cd(NCS) preparation. ^{1}H NMR (acetone-d_6), δ: 7.51 (2, br, 5-H pz); 6.09 (2, br, 4-H pz); 1.35 (18, s, Bu^t).

2.5. {[HB(3,5-Me$_2$pz)$_3$]Pb(μ-NCS)}$_2$ (**3**)

PbCl$_2$ (0.25 g, 0.90 mmol) was dissolved in H$_2$O (15 ml) and added to a thf (15 ml) solution of K[HB(3,5-Me$_2$pz)$_3$] (0.30 g, 0.90 mmol). The mixture was stirred for 0.5 h at which time a white precipitate was formed. The mixture was filtered to leave a white solid. KSCN (0.050 g, 0.50 mmol) was added to the filtrate. This solution was allowed to stir for 6 h at r.t. A white precipitate formed and the mixture was filtered. The solvent was removed in vacuo to leave a white solid, (0.16 g, 31%); m.p. = 296–301 °C (dec). X-ray quality crystals were obtained from a layered solution of CH$_2$Cl$_2$ and hexane. ^{1}H NMR (CDCl$_3$) δ: 5.81 (s, 3,

4-H pz); 2.44 (s, 9, CH_3); 2.30 (s, 9, CH_3). IR: (νC≡N, Nujol mull, cm^{-1}): 2060 and 2020. ES^+/MS: Calc. for $\{[HB(3,5\text{-}Me_2pz)_3]^{207}Pb\}^+$, 505.1770. Found: 505.1776. Calc. for $C_{32}H_{44}B_2N_{14}Pb_2S_2$: C, 34.17; H, 3.94. Found: C, 33.85; H, 4.55%.

2.6. $\{[HB(pz)_3]Pb(\mu\text{-}NCS)\}_n$ (**4**)

$[HB(pz)_3]PbCl$ (0.13 g, 0.30 mmol) was dissolved in thf (10 ml) and KSCN (0.030 g, 0.30 mmol) added to this solution. A white precipitate formed as this mixture was stirred for 6 h at r.t. and the solution was filtered. The solvent was removed in vacuo to leave a white solid, (0.080 g, 57%); m.p. = 222–225 °C. Suitable crystals were obtained from a layered solution of CH_2Cl_2 and hexane. ^1H NMR (acetone-d_6) δ: 7.76, 7.53 (3, 3; s, br; 3,5-H pz); 6.12 (3, s, 4-H pz) IR: (νC≡N, Nujol mull, cm^{-1}): 2084, 2045, 2030, 2004. FAB^+ MS: *m/z* Calc. for $\{[HB(pz)_3]^{207}Pb\}^+$, 419.0805. Found: 419.0796.

2.7. $[(pydim)Cd(\mu\text{-}NCS\text{-}S,N)]_2[BF_4]_2$ (**5**)

$[Cd_2(thf)_5](BF_4)_4$ (0.24 g, 0.25 mmol) and pydim (0.18 g, 0.50 mmol) were charged into a round bottom Schlenk flask and thf (20 ml) was added via syringe. The mixture was allowed to stir for 1 h at r.t. and the solvent was removed to leave a yellow solid. This solid (0.15 g) and KSCN (0.050 g, 0.50 mmol) were dissolved in thf (20 ml) and allowed to stir for 3 h at r.t. This mixture was filtered and the volatiles were removed in vacuo to leave a yellow solid (0.18 g, 55%); m.p. = 260–262 °C (dec). Crystals suitable for X-ray analysis were grown from a layered solution of CH_2Cl_2 and hexane. ^1H NMR (acetone-d_6), δ: 9.03 (2, s, H-imino); 8.81 (1, m, 4-H py); 8.56 (2, d, $J = 7.8$, 3,5-H py); 7.14 (6, m, 3,4,5-H ph); 2.26 (12, s, CH_3). IR (νC≡N, Nujol mull, cm^{-1}): 2110, 2079. FAB^+ MS: *m/z* Calc. for $[(pydim)^{113}Cd]^+$ 509.0674. Found: 509.0668.

2.8. $[(pydimMe_2)Pb(NCS)][BF_4]$ (**6**)

$Pb(acac)_2$ (0.10 g, 0.25 mmol) was suspended in thf (10 ml). The mixture was treated with 54% $HBF_4 \cdot Et_2O$ (0.10 ml, 0.50 mmol) and was allowed to stir for 30 min followed by addition of a thf (10 ml) solution of the $pydimMe_2$ ligand (0.090 g, 0.25 mmol) by cannula transfer. The yellow reaction mixture was heated to 70 °C for 1 h. A solution of KSCN (0.040 g, 0.41 mmol) in thf (10 ml) was added to the reaction mixture and allowed to stir for 12 h at r.t. The mixture was filtered and the solvent evaporated to dryness providing a yellow powder (0.14 g, 0.18 mmol, 72%); m.p. = 224–227 °C. Crystals suitable for X-ray analysis were grown from a layered solution of CH_2Cl_2 and hexane. ^1H NMR (acetone-d_6), δ: 8.91 (3, br, 3,4,5-H py); 7.20 (6, br, 3,4,5-H ph); 2.60 (6, s, (CH_3-imino), 2.24 (12, s, CH_3). IR (νC≡N, Nujol mull, cm^{-1}): 2040 br. FAB^+ MS: Calc. for $[(pydimMe_2)^{207}Pb]^+$ 635.1725. Found: 635.1744.

2.9. X-ray crystal determination for **1**, **2**, **3**, **4**, **5** and **6**

Crystal, data collection, and refinement parameters are collected in Table 1. Colorless crystals of **1**, **2**, **3** and **4** and small yellow crystals of **5** and **6** were epoxied onto the end of a thin glass fiber. X-ray intensity data were measured using a Bruker SMART APEX CCD-based diffractometer system using Mo Kα radiation (λ = 0.71073 Å). All unit cells were initially determined based on reflections harvested from a set of three scans measured in orthogonal wedges of reciprocal space. Subsequently, a hemisphere of data was collected with a scan width of 0.3° in ω and an exposure time of 60 s per frame. The first 50 frames were re-collected at the end of data set to monitor crystal decay. The structures were solved by a combination of direct methods and difference Fourier syntheses, and refined by full-matrix least-squares against F^2, using the SHELXTL software package. The final unit cell constants are based upon the refinement of the XYZ centroids. In all structures, hydrogen atoms were placed in calculated positions and refined using a riding model and an empirical absorption correction based on the multiple measurement of equivalent reflections was applied with the program SADABS.

Systematic absences in the data for **1** were consistent with the space groups *Pnma* and $Pna2_1$. After several unsuccessful initial trials in the centrosymmetric space group *Pnma*, the non-centrosymmetric space group $Pna2_1$ was chosen and confirmed by the successful solution and refinement of the structure. Upon successful solution in $Pna2_1$, a check for missing symmetry was performed with the ADDSYM routine in PLATON, which verified the space group choice with a refined absolute structure (Flack) parameter of −0.003(19). All non-hydrogen atoms were refined with anisotropic displacement parameters including the toluene solvent molecule present in the cell. Crystals of **2** were determined to belong to the monoclinic crystal system. Systematic absences in the diffraction data determined that the space group was $P2_1/n$. Compound **3**, $\{[HB(3,5\text{-}Me_2pz)_3]Pb(\mu\text{-}NCS)\}_2 \cdot 1.5CH_2Cl_2$, crystallizes in the orthorhombic crystal system. Examination of the systematic absences in the data set indicated the space groups *Pnma* or $Pna2_1$. A good solution and refinement was obtained in the space group *Pnma*, revealing two $\{[HB(3,5\text{-}Me_2pz)_3]Pb\}^+$ cations related by mirror symmetry, and bridged by 2 inequiv. SCN^- groups. One SCN^- lies in the mirror plane; the second SCN^- is roughly perpendicular to the intervening plane, with the central carbon (C2) in the mirror plane. Due to the incompatibility of the SCN^- anion with a horizontal

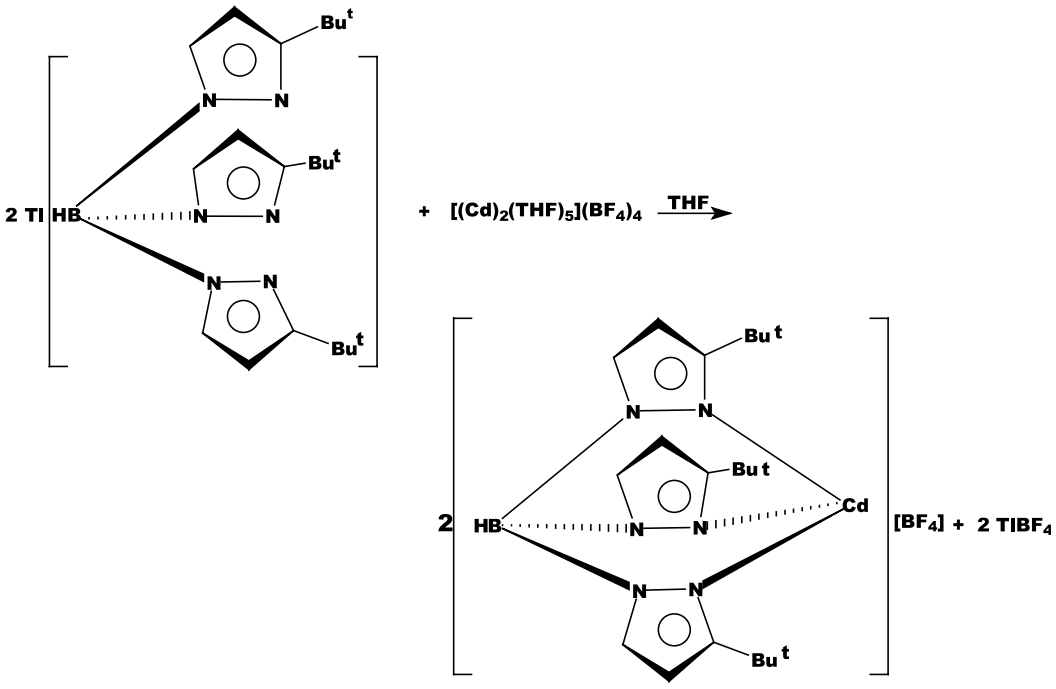
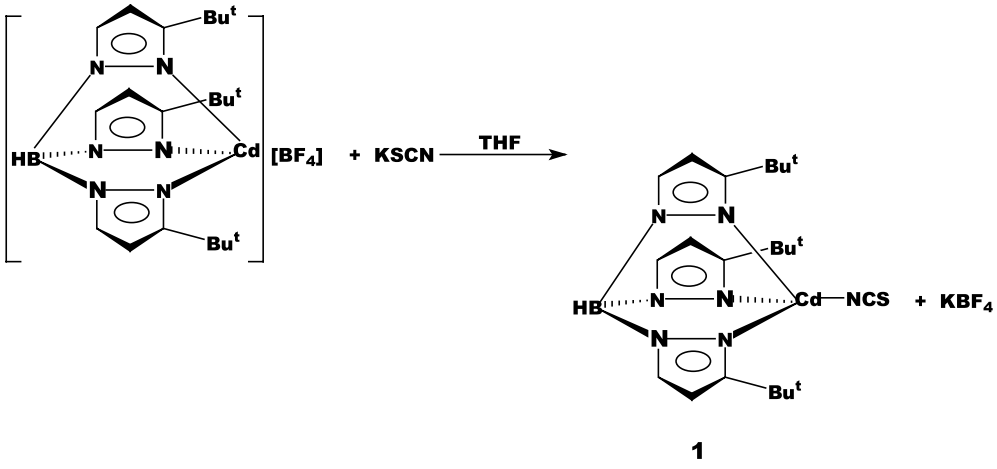
$w = 1/[\sigma^2(F_o^2)+(aP)^2+bP]$, where P is $[2F_c^2+\max(F_o^2, 0)]/3$.



mirror plane, this arrangement results in this perpendicular SCN$^-$ apparently half-occupying two orientations related through the mirror plane, with similar S–C and C–N distances. However, removing the mirror plane relating the two halves of the molecule and refining the structure in *Pna*2$_1$ yielded the same disorder, as well as chemically unreasonable [HB(3,5-Me$_2$pz)$_3$]$^-$ ligand geometry and large correlations between atoms related by symmetry in *Pnma*. Further attempts to remove the disorder by reducing the symmetry even further to monoclinic or triclinic symmetry gave identical results. Therefore, *Pnma* was selected as the correct space group. The similar S2–C2 and C2–N2 distances within the perpendicular SCN$^-$ are an artifact of the disorder. While the displacement ellipsoid of C2 shows elongation along the bond directions, no satisfactory model with C2 off the mirror plane could be found. A total of 1.5 methylene chloride molecules disordered over three positions were located and refined with the aid of three geometrical restraints. Compound **4** crystallizes in the space group *P*2$_1$/*c* as determined from the systematic absences in the intensity data. The asymmetric unit contains three crystallographically inequivalent {[HB(pz)$_3$]Pb}$^+$ cations and three SCN$^-$ counterions and all atoms are on general positions. Crystals of **5** were determined to belong to the monoclinic crystal system. Systematic absences in the diffraction data determined that the space group was *P*2$_1$/c. Compound **6** crystallizes in the triclinic space group *P*$\bar{1}$. The asymmetric unit consists of two [Pb(C$_{25}$H$_{27}$N$_3$)]$^{2+}$ cations, two SCN$^-$ and two BF_4^- counterions, and two CH_2Cl_2 molecules. Comparison of identical reflections measured at the beginning and at the end of the data collection showed an average loss of intensity of 4.1%; a linear decay correction was applied.

All computations were made using SHELXTL NT 5.10 and SADABS software (G. Sheldrick, Bruker AXS, Madison, WI).



3. Results and discussion

3.1. tris(pyrazolyl)borate chemistry

The direct reaction of $CdCl_2$ with 1 equiv. of Tl[HB(3-Bu^{t}pz)$_3$] and KSCN did not produce the desired [HB(3-Bu^{t}pz)$_3$]Cd(NCS) (**1**) complex. The complex was produced in a two step procedure, starting with the reactive compound [Cd$_2$(thf)$_5$](BF$_4$)$_4$ [2b]. Mixing this compound with two equiv. of Tl[HB(3-Bu^{t}pz)$_3$] produces the intermediate {[HB(3-Bu^{t}pz)$_3$]Cd}[BF$_4$].

This intermediate reacts with potassium thiocyanate to yield [HB(3-Bu^{t}pz)$_3$]Cd(NCS) (**1**).

1

Complex **1** is air stable and is soluble in most common solvents. Infrared analysis shows a strong band at 2103 cm^{-1}, indicating the presence of a N-bound, terminal isothiocyante ligand. Reported CN stretching frequencies for terminal cadmium(II) isothiocyanate are in the range of 2059–2108 cm^{-1} [4b,5].

This arrangement was confirmed by a single crystal X-ray analysis. An ORTEP drawing is shown in Fig. 1 and selected bond angles and distances are shown in Table 2. The cadmium(II) site has a N_4 coordination arrangement in a pseudotetrahedral geometry. The chelate rings restrict the intraligand N–Cd–N angles to an average of 88.6°, with interligand N–Cd–N bond angles averaging 126.2°. The Cd–N–C bond angle of the isothiocyanate ligand is significantly bent at 150.7(3)° and the N–C–S bond angle is nearly linear at 178.9(4)°. The Cd–NCS bond distance is 2.107(3) Å, on the short end of the published ranges of analogous

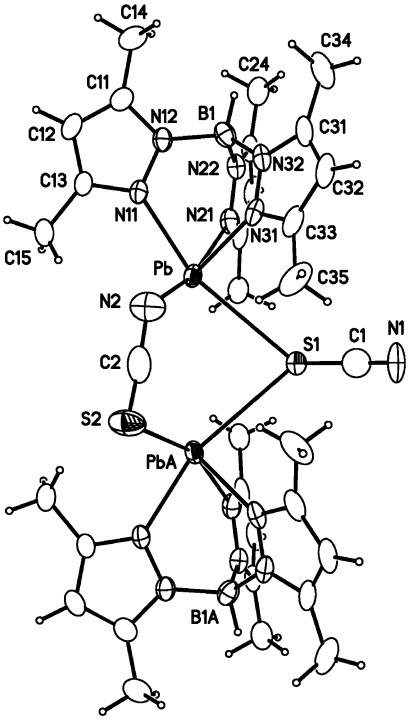
distances for terminal CdNCS groups [4,5,13]. The Cd–N bond distances for the $[HB(3\text{-}Bu^tpz)_3]^-$ ligand are all very similar and average 2.22 Å.

As expected, the sterically demanding 3-*tert*-butyl groups enforce the formation of a tetrahedral, monomeric complex, the first 4-coordinate cadmium(II)-thiocyanate complex to be structurally characterized. In contrast, many cadmium(II)-thiocyanate complexes form intricate networks with bridging thiocyante ligands coordinated to cadmium forming polymeric chains, 2-D sheets and 3-D extended lattices [4,7,14–16].

In our first attempt to crystallize compound **1** from a layered solution of acetone and hexane, the compound we obtained was a decomposition product that was shown by X-ray crystallography to be a polymer, $[(3\text{-}Bu^tHpz)_2Cd(\mu\text{-}NCS)_2]_n$ (**2**). Fig. 2 shows the ORTEP diagram and bond distances and angles are shown in Table 3. The cadmium(II) is six-coordinate, bonding to two *tert*-butyl pyrazole rings located in the axial positions and four doubly bridging thiocyanate ligands in equatorial positions forming a CdN_4S_2 octahedral arrangement. The cadmium(II) is located on an inversion center. The two pyrazole groups coordinate to cadmium with a Cd–N bond distance of 2.286(9) Å, while the N-coordinated SCN^- groups have a Cd–N distance 0.02 Å longer at 2.309(10) Å. The Cd–S distance is normal at 2.762(2) Å. The SCN^- groups are nearly linear at 177.5(9)°. The atoms of the doubly bridging $(\mu\text{-}NCS\text{-}N,S)^-$ groups and the two cadmium(II) form an eight member ring that closely resembles that observed in $[Cd(NCS)_2(CH_3C_5H_4N)_2]_n$ [17], $Cd(NCS)_2\{(C_6H_5CH_2)_2NH\}_2$ [18], and $[Cd(NCS)_2(\text{iso-nicotinamide})_2]$ [19].

Multiple attempts were made to synthesize the tetrahedral lead(II) compound analogous to **1** with the bulky $[HB(3\text{-}Bu^tpz)_3]^-$ ligand, but this complex could not be prepared. The tetrahedral enforcer character of this ligand apparently prevents the formation of a four-coordinate lead(II) complex with a stereochemically active lone pair. The failure to prepare the lead(II) analog of **1** clearly shows the influence of the lone pair.



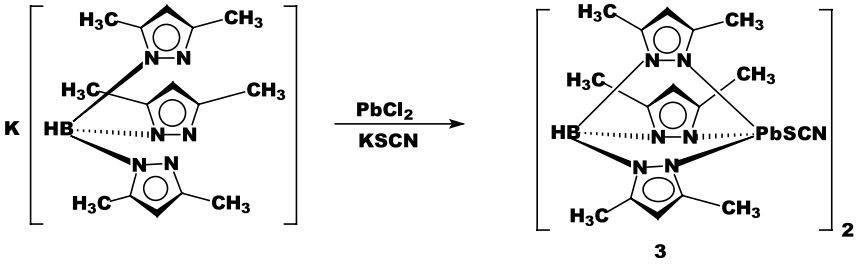


Fig. 3. ORTEP diagram of $\{[HB(3,5\text{-}Me_2pz)_3]Pb(\mu\text{-}NCS)\}_2$ (50% ellipsoids).

In contrast, two new lead(II) compounds with less sterically hindered ligands were prepared. The reaction of equimolar amounts of $PbCl_2$, $K[HB(3,5\text{-}Me_2pz)_3]$ and KSCN in thf yields $\{[HB(3,5\text{-}Me_2pz)_3]Pb(\mu\text{-}NCS)\}_2$ (**3**).

3

This compound is air-stable and soluble in halocarbons, thf, and slightly soluble in aromatic solvents. It has CN stretching frequencies at 2060 and 2020 cm^{-1} indicating bridging SCN^- groups.

Fig. 3 shows the ORTEP diagram of the cation in **3** and selected bond distances and angles are shown in Table 4. The solid state structure of **3** is dimeric with an unusual structure containing both μ-NCS-*S*,*N* and μ-NCS-*S*,*S* bridging SCN^- ligands. The μ-NCS-*S*,*S* ligand is in the mirror plane located between the two metal centers and bridges them through sulfur with relatively long Pb–S bond distance of 3.3277(16) Å [4c,11,20]. The other is in a normal bridging μ-NCS-*S*,*N* bonding one metal through nitrogen and the other through sulfur, but due to the incompatibility of this orientation of the SCN^- anion with a horizontal mirror plane, this perpendicular SCN^- half-occupies two orientations related through the mirror plane. The Cd–N bond distances for the $[HB(3,5\text{-}Me_2pz)_3]^-$ ligand are all similar with a range of 2.381(5)–2.436(5) (average 2.40 Å). Overall, the structure about each lead(II) can be considered octahedral with three sites occupied by nitrogen donor atoms from the $[HB(3,5\text{-}Me_2pz)_3]^-$ ligand with N–Pb–N bond angles restricted by the chelate rings to an average of 77.4°. The sulfur of the symmetrically bridged SCN^- occupies a fourth site while the N and S from the disordered SCN^- share the fifth site.

The remaining octahedral site is generally attributed to a stereoactive lone pair on the lead(II) center. In

general, it is well known that in higher coordinate lead structures, bonds adjacent to the presumed location of the lead(II) lone pair are longer than bonds remote from the lone pair [21]. The structure of **3** is very unique in that the Pb–N bonds of the $[HB(3,5\text{-}Me_2pz)_3]^-$ ligand adjacent to the open site are only 0.03 Å longer, on average, than the *trans* Pb–N bond. For comparison, the three Pb–N bonds adjacent to the open site in the

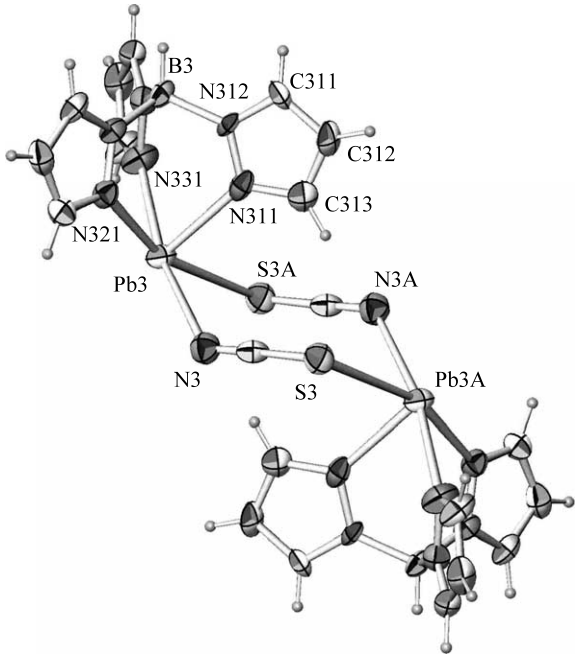

Fig. 5. $\{[HB(pz)_3]Pb(3)(\mu\text{-}NCS\text{-}N,S)\}_2$ units in $\{[HB(pz)_3]Pb(\mu\text{-}NCS)\}_n$.

distorted structure of $[HB(pz)_3]_2Pb$ are 0.24 Å longer, on average, than the *trans* Pb–N bonds [3a]. In addition, the nitrogen atom of the SCN^- ligand in the mirror plane has long range interactions at 3.161(5) Å with both lead(II) centers of an adjacent dimeric unit in the area of this open, sixth site, an unlikely interaction if substantial electron density from the lone pair on lead(II) were present. These results support calculations that indicate that in distorted structures of lead(II) the amount of mixing of the p orbital into the lone pair orbital is small [3g].

The reaction of $[HB(pz)_3]PbCl$ and KSCN in equimolar amounts in thf yields $\{[HB(pz)_3]Pb(\mu\text{-}NCS)\}_n$ (**4**).

rings, Fig. 5, with the two lead units on each side of the sandwich array.

Shown in Fig. 6 is a combined view perpendicular to the view in Figs. 4 and 5. The $\{[HB(pz)_3]Pb(3)(NCS)\}_2$ units are surrounded by two of the infinite chains formed by Pb(1) and Pb(2). There are secondary interactions between the two units, most notably between the bridging N(3) of the dimeric Pb(3) units and Pb(2) at 2.996 Å. There are also π–π stacking interactions between the pyrazolyl groups attached to Pb(1) along the chain and between alternate Pb(2) and Pb(3) pyrazolyl groups attached parallel to this chain ranging from 3.50 to 3.69 Å. Typical interplanar distances for π–π interactions of aromatic groups range from 3.3 to 3.8 Å [22].

3.2. 2,6-bis(imino)pyridine chemistry

Using a method similar to the preparation of the tris(pyrazolyl)borate compound **1**, a new thiocyanate complex of the pydim ligand is prepared starting with

4

This compound is air-stable and soluble in halocarbons, thf, and slightly soluble in some aromatic solvents. It has CN stretching frequencies at 2084, 2045, 2030, 2004 cm^{-1} indicating a complicated bridging arrangement of the SCN^- groups.

The solid state structure was solved crystallgraphically and selected bond distances and angles are shown in Table 5. The structure of this complex is a complicated infinite 2-D layered array in which $\{[HB(pz)_3]Pb\}^+$ groups sandwich a layer of SCN^- ligands with the lead(II) centers oriented toward them. There are three independent $\{[HB(pz)_3]Pb(NCS)\}^+$ units. As shown in the lower part of Fig. 4, $\{[HB(pz)_3]Pb(1)\}^+$ units form a chain connected by $(\mu\text{-}SCN\text{-}S,N)^-$ ligands. There is also a terminal N-bound SCN^- making Pb(1) six-coordinate. The bridging SCN^- groups are also linked through sulfur to the $\{[HB(pz)_3]Pb(2)\}^+$ units on the other side of the sandwich array. The $\{[HB(pz)_3]Pb(3)\}^+$ units are in a centrosymmetric dimeric arrangement with end-on bridging $(\mu\text{-}SCN\text{-}N,S)^-$ ligands forming eight member

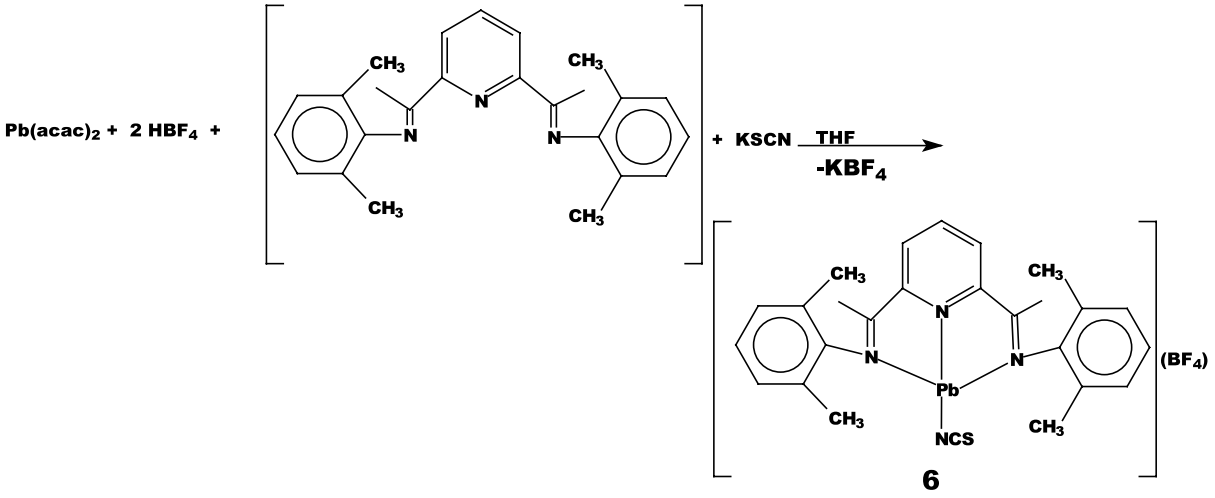
[Cd$_2$(thf)$_5$][BF$_4$]$_4$. This starting material is treated first with the pydim ligand followed by potassium thiocyanate resulting in the formation of [(pydim)Cd(μ-NCS-*S*,*N*)]$_2$[BF$_4$]$_2$ (**5**).

making the overall structure a dimer. The three nitrogen atoms of the planar pyridine ligand occupy three sites in a meridional arrangement, but the intrinsic bite angle of

5



This complex is air-stable in the solution and solid states. It is soluble in acetone, CH_2Cl_2, and chloroform. The infrared spectrum shows CN stretching frequencies of 2078 and 2110 cm^{-1}, indicating that the SCN$^-$ ligands are in bridging positions [5,11].

X-ray crystallography shows that the complex is a dimer. Fig. 7 shows an ORTEP drawing of **5**, and selected bond distances and angles are shown in Table 6. The environment about the cadmium(II) is best described as a distorted octahedron. It is strongly bonded by five donor atoms, with the two bridging thiocyanate groups

the ligand coupled with the large size of the cadmium(II) force a significant distortion from an octahedral arrangement with the *trans* N–Cd–N bond angle of 140.15(16)°. The Cd–N(py) bond (2.256(5) Å) is significantly shorter than the Cd–N(imino) bonds (average 2.45 Å). The bridging SCN$^-$ groups form a N–Cd–S angle much greater than 90° at 123.55(12)° and the SCN$^-$ ligands are nearly linear at 178.9(6)°. The Cd–NCS bond distance is 2.246(6) Å and the Cd–SCN bond distance is 2.5551(17) Å, both typical for this bridging ligand forming an eight membered ring with the two

cadmium(II) [10,14–16]. Within the ring, the Cd(1)–N(1)–C(1) bond angle of 156.35(5)° is much larger than the Cd(1)–S(1)–C(1) bond angle of 99.2(2)°. The sixth coordination site is occupied by a weak interaction from a fluorine of the BF_4^- group.

An analogous lead(II) isothiocyanide complex was synthesized using similar chemistry as outlined in the cadmium synthesis using the pydimMe_2 ligand. In this reaction, $Pb(acac)_2$ was treated with two equiv. of tetrafluorohydroboric acid followed by one equiv. of pydimMe_2 and KSCN to yield a tetra-coordinate lead(II) complex [(pydimMe_2)Pb(NCS)][BF_4] (**6**).

6

This moderately high melting solid compound is air-stable and soluble in halocarbons and acetone. The CN stretching frequency is a broad band centered at 2040 cm^{-1}.

The solid state structure was determined by X-ray crystallography. There are two independent cations in the structure, Fig. 8 shows an ORTEP drawing for one of those, Pb(1), and Table 7 shows the bond angles and distances for both. The primary structures of both cations are similar and are four-coordinate monomeric arrangements. The geometry about lead(II) is irregular, with the N-bound SCN^- ligand oriented basically perpendicular to the N_3Pb plane formed by the donor atoms of the pydimMe_2 ligand and lead(II). The planes of the phenyl rings are also oriented essentially orthogonal to this plane. The Pb–NCS bond distances are short, as would be expected for the low coordinate number for lead(II) of four, at 2.275(7) Å for Pb(1) and 2.333(7) Å for Pb(2). Published Pb–NCS bond distances range from 2.4 to 2.8 Å [11]. The Pb–N–C bond angles are 152.6(7)° and 156.0(7)° while the N–C–S bond angles are nearly linear. In contrast to the cadmium complex **5** and other structures of the pydim ligand [12b], the Cd–N(py) bond (2.466 (6) Å) for Pb(1) is actually longer than one of the Cd–N(imino) bond distances (2.456(6) Å) and only slightly shorter than the other (2.522(6) Å). While the Cd–N(py) bond distance (2.466(5) Å) for Pb(2) is shorter than the average of the Cd–N(imino) bond distances (2.54 Å), the difference is much less than the 0.2 Å distance commonly observed [12]. As expected for the larger size of lead(II) compared with cadmium(II), the three nitrogen atoms of the planar pyridine ligand form even smaller N–Pb–N bond angles with the *trans* N(11)–Pb(1)–N(13) bond angles of only 129.1(2)° for Pb1 and 129.6(2)° for Pb(2).

4. Conclusions

We have prepared and characterized several cadmium(II) and lead(II) thiocyanate complexes containing either tris(pyrazolyl)borate ligands or neutral 2,6-pyridyl-diimine ligands and one thiocyanate ligand per metal. Complex **1**, [HB(3-Bu^{t}pz)$_3$]Cd(NCS), is the first 4-coordinate cadmium(II) isothiocyanate complex to be structurally characterized and contains a short Cd–NCS bond distance (2.107(3) Å). An analogous complex of lead(II) could not be synthesized. It appears that the tetrahedral enforcer character of this ligand prevents the formation of a four-coordinate lead(II) complex with a stereochemically active lone pair and, apparently, a tetrahedral complex isostructural with **1** is energetically unfavorable. The use of less sterically demanding tris(pyrazolyl)borate ligands allowed the preparation

of two interesting new [tris(pyrazolyl)borate]Pb(NCS) complexes. The use of the 3,5-dimethyl substituted ligand produces {[$HB(3,5\text{-}Me_2pz)_3$]Pb(μ-NCS)}$_2$ that has a dimeric structure with both μ-NCS-*S*,*N* and μ-NCS-*S*,*S* bridging SCN^- ligands. The parent ligand produces {[$HB(pz)_3$]Pb(μ-NCS)}$_n$, having an unusual infinite 2-D layered array in which three nonequiv. {[$HB(pz)_3$}Pb}$^+$ groups sandwich a layer of SCN^- ligands, where the overall structure is supported by π–π stacking interaction.

It was possible to prepare parallel complexes of both metals using the bulky pydim ligands. However, for cadmium(II) the ligand was not bulky enough to prevent formation of dimeric **5**, [(pydim)Cd (μ-NCS-*N*,*S*)]$_2$[BF_4]$_2$, that has a conventional bridging mode where the two cadmium(II) and two (μ-NCS-*N*,*S*)$^-$ groups form an eight membered ring. It is interesting that compound **1** with a bulky tripodal ligand is monomeric, whereas **5** with a bulky tridentate planar ligand is dimeric. For lead(II), the monomeric complex **6**, [(pydimMe_2)Pb(NCS)][BF_4], formed in which the isothiocyanate ligand is N-bound and the lead(II) has the low coordination number of four. The structure of **6** is very different from **5**, presumably because of the stereoactive lone pair on lead(II).

5. Supplementary material

Crystallographic data for the structures reported in this paper have been deposited at the Cambridge Crystallographic Data Center, CCDC 177361–177366. Copies of the information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

the application of Re compounds and development of radiopharmaceuticals [13]. Therefore, we decided to prepare more suitable S-bridged polynuclear complexes for apparent investigation of the Re^{III} ion.

Generally, *fac*(*S*)-[Ir(aet)$_3$] can be used as a building block for construction of the S-bridged polynuclear structures and has some advantages over *fac*(*S*)-[Rh(aet)$_3$]. For example, electrochemical properties of the Re^{III} ion incorporated into the S-bridged polynuclear structure using spectroelectrochemical techniques can be investigated clearly, since *fac*(*S*)-[Ir(aet)$_3$] shows little absorption in the visible region [8–11]. Moreover, the Ir^{III} complexes tend to indicate shorter metal–metal distances and lower magnetic moments than the corresponding Rh^{III} complexes [9–11], and these characteristic properties seem to be interesting. In this work, a reducing reaction of an acidic mixture of Re^{VII} and *fac*(*S*)-[Ir(aet)$_3$] was attempted. Moreover, a substitution reaction using Re^{III} was applied. The crystal structures of two isomers of $[Re\{Ir(aet)_3\}_2]^{3+}$ were determined by X-ray crystallography. The obtained complexes were characterized on the basis of elemental analysis, ICP, UV–Vis absorption, diffuse reflectance, CD, IR, NMR spectra, molar conductivities and magnetic susceptibilities. Furthermore, the electrochemical behavior for the Re^{III} ion incorporated into S-bridged trinuclear complexes was also investigated.

2. Results and discussion

2.1. Syntheses

The reaction of *fac*(*S*)-[Ir(aet)$_3$] with NH_4ReO_4 in acidic solution (HCl or HBr) using $SnCl_2\cdot 2H_2O$ as a reducing agent at room temperature in the molar ratio of 1:1:2 gave a dark reddish brown solution. The solution was separated into two yellow bands and a purple band using a SP-Sephadex C-25 column. The first two yellow bands were *meso* (**1a**) and racemic (*rac*, **1b**) isomers of $[Re\{Ir(aet)_3\}_2]^{3+}$, whose structures were determined by X-ray diffraction method (vide infra). The purple band was unidentified and it may contain certain Re^{V} species. Of the two yellow bands separated, the crystallization of only the *meso*-isomer was successful. The *rac*-isomer could not be isolated, since a dinuclear Ir^{III} complex, which was confirmed by X-ray crystallography [14], was obtained during this isolation procedure. This means that the Re–S bonds are cleaved, followed by rearrangement during the desaltation, although the *rac*-isomer is relatively stable in water at room temperature.

A more convenient method was developed to isolate *rac*-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1b**), namely, *fac*(*S*)-[Ir(aet)$_3$] reacts with the Re^{III} complex $[Re(Metu)_6]Cl_3$ (Metu = *N*-methylthiourea) [15] in aqueous solution at room temperature in the molar ratio of 1:1. Although both isomers are formed in the reaction mixture (from the column chromatography), as is the case in the reaction using the Re^{VII} ion, the *rac*-isomer could be selectively crystallized as dark brown rod crystals by adding bromide ion to the reaction mixture. Consequently, we could investigate stereochemical, spectrochemical and electrochemical properties of both the *meso*- and *rac*-isomers.

2.2. Structures of complexes

It has been revealed by the X-ray structural analysis that each of the crystals for **1a** and **1b** consists of a complex cation and three bromide anions. Further, the crystals for **1b** contain a water molecule. The total number of anions implies that the entire complex cations are trivalent. This is compatible with the observed molar conductivities in water (420 S cm^2 mol^{-1} for **1a**Br_3 and 384 S cm^2 mol^{-1} for **1b**$Br_3\cdot H_2O$), which are in agreement with those of 1:3 electrolytes, for example *meso*-$[Cr\{Ir(aet)_3\}_2](NO_3)_3\cdot 3H_2O$ (355 S cm^2 mol^{-1}) and *rac*-$[Cr\{Ir(aet)_3\}_2]Br_3\cdot 1.5H_2O$ (369 S cm^2 mol^{-1}) [10].

Perspective views of the complex cations **1a** and **1b** are given in Figs. 1 and 2, and their selected bond distances and angles are listed in Tables 1 and 2, respectively. **1a** and **1b** consist of two approximately octahedral *fac*(*S*)-[Ir(aet)$_3$] units and one Re atom, being complete linear-type S-bridged trinuclear structures, $[Re\{Ir(aet)_3\}_2]^{3+}$. These results are consistent with the plasma emission spectral analysis that gave a value of Re:Ir as 1:2. From the formal charge of the coordinated ligands, it is reasonable to assume that the central Re ions are in oxidation state +3 (d^4-electronic configuration) and situated in an octahedral environment with a $Re^{III}S_6$ chromophore. Considering the absolute configurations (Δ and Λ) of the two terminal *fac*(*S*)-[Ir(aet)$_3$] units, three isomers ($\Delta\Delta$, $\Lambda\Lambda$ and $\Delta\Lambda$) are possible for $[Re\{Ir(aet)_3\}_2]^{3+}$. As shown in Fig. 1, **1a** is the *meso*-isomer with a $\Delta\Lambda$ configuration, having an inversion

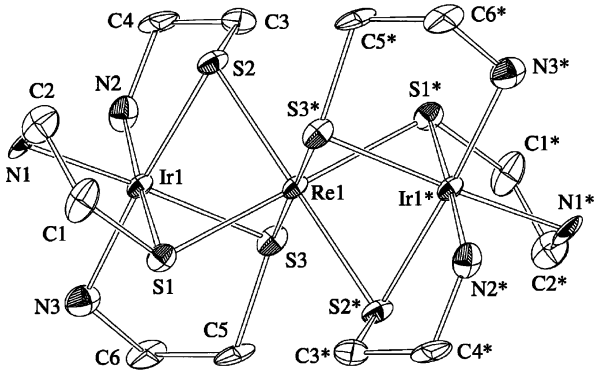

Fig. 1. Perspective view of $\Delta\Lambda$-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1a**) with the atomic labelling scheme (50% probability ellipsoids).

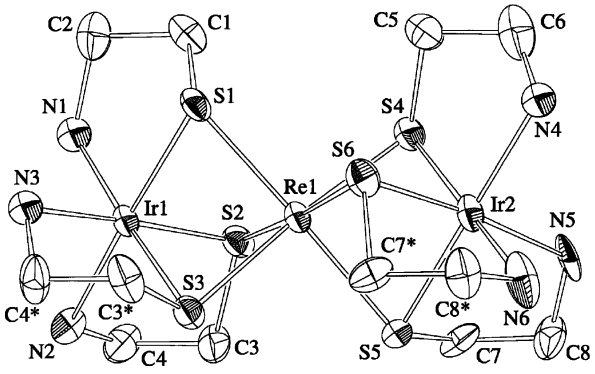

Fig. 2. Perspective view of ΔΛ/ΛΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1b**) with the atomic labelling scheme (30% probability ellipsoids). The overlapped ΛΛ isomer is omitted for clarity.

center on the Re atom. While **1b** is the *rac*-isomer with ΔΔ and ΛΛ configurations (Fig. 2). The O atom of the water molecule in **1b**$Br_3 \cdot H_2O$ seems to participate in hydrogen bonds (N(2)···O(1) = 3.18 Å and Br(2)···O(1) = 3.22 Å). These intermolecular interactions may be related to the selective crystallization of the *rac*-isomer. All of the bridging sulfur atoms in **1a** and **1b** are fixed to the *R* configuration for the Δ unit and the *S* configuration for the Λ unit, which corresponds to the results in all of the reported trinuclear structures [7–12,16].

The bond distances and angles in **1a** and **1b** are similar to each other, suggesting that they are almost independent of the absolute configuration of the two terminal *fac*(*S*)-[Ir(aet)$_3$] units (Tables 1 and 2). The Re–S distances (average 2.401(3) Å in **1a** and average 2.406(1) Å in **1b**) for ΔΛ- and ΔΔ/ΛΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ are slightly longer than those (average 2.383(6) and average 2.386(9) Å) for ΔΛ- and ΔΔ/ΛΛ-$[Re\{Rh(aet)_3\}_2]^{3+}$ [12], reflecting the electron donating ability of the thiolato sulfur atoms of the terminal *fac*(*S*)-[M(aet)$_3$] (M = Ir^{III}, Rh^{III}) units. On the other hand, the Re···Ir distances (2.7961(4) Å for **1a** and average 2.810(2) Å for **1b**) are shorter than the Re···Rh distances (2.8248(9) and average 2.840(2) Å) for the corresponding Rh^{III} isomers [12]. Similar results were observed in the M′–S and M′···M distances for $[M'\{M(aet)_3\}_2]^{3+}$ (M′ = V^{III}, Cr^{III}), whose structures were previously reported for both Ir^{III} and Rh^{III} complexes [9,10].

The Re–S distances in **1a** and **1b** are approximately 0.1 Å longer than the Co–S distances (average 2.297(2) Å) in $[Co\{Ir(aet)_3\}_2]^{3+}$ [8]. However, the Re···Ir distances in **1a** and **1b** are approximately 0.1 Å shorter than the Co···Ir distances (2.906(1) Å) [10] in the Co^{III} complexes. Namely, the *fac*(*S*)-[Ir(aet)$_3$] units are attracted by the Re^{III} ion, and this is obviously apparent in the M′–S–Ir angles (averages 72.52(8)° for **1a**, 72.8(4)° for **1b**, 78.3(1)° for the Co^{III} complex) [10]. The corresponding complexes containing the V^{III} or Mo^{IV} ion, which has an unsaturated t_{2g}-orbital, also indicate acute M′–S–Ir angles (71.12(10)° for V^{III} complex and 69.8(2)° for Mo^{IV} complex) [10,11] than that containing the Co^{III} ion, which has a saturated t_{2g}-orbital. Accordingly, the differences of the distances and angles in the complexes may be related to the electronic state of the central metal ions. Since the bond distances and angles around the Ir^{III} ions indicate no significant differences for all reported trinuclear complexes which have the *fac*(*S*)-[Ir(aet)$_3$] units [8–11], it can be understood that the character of the incorporated metal ion is apparent in the structures.

2.3. Spectrochemical characterization

The UV–Vis absorption, diffuse reflectance and CD spectra of $[Re\{Ir(aet)_3\}_2]^{3+}$ are shown in Fig. 3. The absorption bands of **1b** in water are observed in approximately the same region as the diffuse reflectance bands in the solid state. Further, the absorption spectral patterns of **1a** and **1b** are similar to each other over the whole region, although the intensities of some bands are slightly different. These facts indicate that **1a** and **1b** retain the trinuclear structure in solution.

The most intense band above 45×10^3 cm^{-1} in the UV region corresponds well to the sulfur to Ir^{III} CT band and the bands between 30 and 35×10^3 cm^{-1} to the d–d transition bands due to the terminal *fac*(*S*)-[Ir(aet)$_3$] units, as similar bands were observed in complexes which contain the *fac*(*S*)-[Ir(aet)$_3$] units [8–11]. The bands at approximately 40×10^3 cm^{-1} for **1a** and **1b** are assigned to the sulfur to Re^{III} CT band, as in the case of $[Re\{Rh(aet)_3\}_2]^{3+}$ [12]. The characteristic intense three absorption bands in the region of 12–29 $\times$ 10^3 cm^{-1} are assigned to be arising from the central $Re^{III}S_6$ chromophore. Since the Re^{III} ion belongs to the group of 5d ions known to occur in a strong crystal field octahedral coordination, these bands are thought to depend upon $(t_{2g})^4$ ground state configurations.

The CD spectrum of $(-)^{CD}_{460}$-**1b**, which was optically resolved by the SP-Sephadex C-25 column, shows negative bands at 33.50 and above 45×10^3 cm^{-1}. These CD bands correspond well to the d–d and CT bands for the *fac*(*S*)-[Ir(aet)$_3$] units in the absorption spectra. Although these absorption and CD bands of $(-)^{CD}_{460}$-**1b** are shifted by approximately 5×10^3 cm^{-1} to higher energy than those for the *fac*(*S*)-[Rh(aet)$_3$] units of $[Re\{Rh(aet)_3\}_2]^{3+}$, the CD spectral pattern of $(-)^{CD}_{460}$-**1b** is in agreement with that of ΛΛ-$[Re\{Rh(aet)_3\}_2]^{3+}$ [12]. Accordingly, it seems that the $(-)^{CD}_{460}$-**1b** isomer is ΛΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ and $(+)^{CD}_{460}$-**1b** isomer is ΔΔ-$[Re\{Ir(aet)_3\}_2]^{3+}$. On the other hand, the CD bands, which are observed in the absorption band regions depending on the Re^{III} ion, of $(-)^{CD}_{460}$-**1b** imply that the absolute configuration of the asymmetric sulfur atoms of all *S* configurations from the Λ-*fac*(*S*)-[Ir(aet)$_3$] units affects the environment around the central Re^{III} ion. These bands are shifted by approximately 5×10^3 cm^{-1} to lower energy than those for the Re^{III} ion in the $[Re\{Rh(aet)_3\}_2]^{3+}$ [12], contrary to the case of the bands due to the Ir^{III} ion. Consequently, most absorption and CD bands due to the $Re^{III}S_6$ chromophore in the present Ir^{III} complexes are displayed more clearly than those in the Rh^{III} complexes [12]. For the UV–Vis absorption and CD spectra of **1a** and **1b**, no significant changes with time were observed at least for several hours. This illustrates that the trinuclear structures are fairly stable even under aerobic condition, retaining the oxidation state.

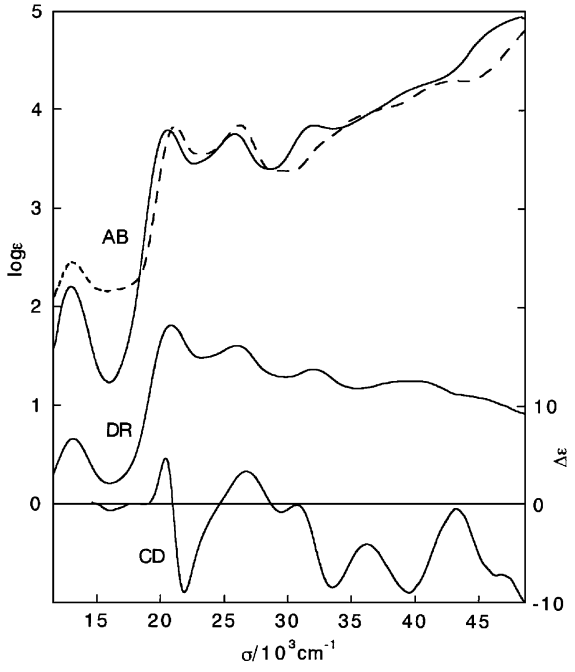

Fig. 3. UV–Vis absorption (AB, log ε), diffuse reflectance (DR, arbitrary scale) and CD (Δε) spectra of ΔΔ-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1a**; ----) and ΛΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ ($(-)^{CD}_{460}$-**1b**; —).

The complexes **1a**Br_3 and **1b**$Br_3 \cdot H_2O$ indicated the typical IR spectral pattern for linear-type S-bridged trinuclear complexes in the range of 4000–400 cm^{-1} [9,11,12]. Namely, the bands due to the vibration mode of the NH_2 group appear between 3500 and 3400 cm^{-1} and those of the CH_2 group between 3200–2900 cm^{-1}. The bands due to the bending mode of NH_2 group are observed around 1600 cm^{-1} and those of the CH_2 group around 1400 cm^{-1}. The fact that these bands in **1a** and **1b** are similar to those in the starting *fac*(*S*)-[Ir(aet)$_3$] support that the terminal units retain their structure during the formation of the S-bridged complexes. On the other hand, the bands in the range of 650–100 cm^{-1} are complicated as observed in $[Re\{Rh(aet)_3\}_2]^{3+}$ [12]. Therefore, it was difficult to assign the bands from the shifts depending upon the Re–S bonds.

2.4. Magnetic properties

The effective magnetic moment for the Re^{III} ion in *rac*-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1b**) is 1.11μ_B, considering a diamagnetic correction (magnetic susceptibility at 296 K is -0.585×10^{-6} cm^3 mol^{-1}) [17]. This value is significantly lower than the spin only value for the $(t_{2g})^4$ configuration. Further, its value is somewhat lower than that (1.32μ_B) in the corresponding Rh^{III} complex *rac*-$[Re\{Rh(aet)_3\}_2]^{3+}$ (**1b**) [12], and similar trend was observed in the effective magnetic moment for the V^{III} ion in $[V\{M(aet)_3\}_2]^{3+}$ (M = Rh^{III}, Ir^{III}) [9]. Mononuclear Re^{III} complexes with a distorted octahedral

coordination often show similar magnetic moments (1.6–2.1μ_B) [18,19]. $[Re(S_2CC_6H_5)_2(S_3CC_6H_5)_2]$, which has a significantly distorted octahedral structure, is diamagnetic and its NMR spectrum showed no paramagnetic shift [20]. Since a similar diamagnetism was also observed for some five coordinate [21] and seven coordinate [19,22] Re^{III} d^4 systems, the consequent distortion as compared with octahedral symmetry could explain the pairing of electrons. In the S-bridged polynuclear structure, however, it is noted that the relatively less distorted octahedral Re^{III} ion (from the X-ray diffraction study) shows lower magnetic moments. These magnetic properties are reflected in the NMR spectral behavior.

In D_2O, each of **1a** and **1b** exhibits six sets of sharp ^1H NMR signals and two ^{13}C NMR signals due to the six aet ligands. This means that the S_6 or D_3 symmetrical S-bridged trinuclear structures observed in the crystals are retained in their aqueous solution. In the ^{13}C–^1H heteronuclear multiple-bond correlation (HMBC) of **1b**, the proton signals at δ 4.47 and 3.05 are coupled with carbon signals at δ 56.58, while the signals at δ 2.60 and 1.45 are coupled with the carbon signals at δ 46.92. Moreover, the signals at δ 4.47 and 3.05 indicate coupling with those of NH_2 protons in ^1H–^1H correlation spectroscopy (COSY). A similar coupling pattern was observed in the HMBC and COSY spectra of **1a**. Accordingly, it can be assigned that the carbon signals at δ 57.62 (**1a**) and 56.58 (**1b**) are due to the CH_2 group neighboring the N atom in the aet ligands, while the signals at δ 44.72 (**1a**) and 46.92 (**1b**) are due to CH_2 group neighboring its S atom. As summarized in Table 3, the chemical shifts of CH_2 groups in the ^{13}C NMR spectra of **1a** and **1b** show some paramagnetic shifts to lower field in comparison with those of diamagnetic $[Co\{Ir(aet)_3\}_2]^{3+}$ [8]. The carbon neighboring sulfur atoms, which coordinate to the Re^{III} ion, indicate especially significant lower shifts (10.98 ppm for ΔΛ isomer and 13.00 ppm for ΔΔ/ΛΛ isomer). However, the degree of paramagnetic shifts in **1a** and **1b** seems to be smaller than those in $[Re\{Rh(aet)_3\}_2]^{3+}$ [12]. A similar trend was also observed in the ^1H NMR chemical shifts.

Table 3
^{13}C NMR chemical shifts (δ (ppm) from DSS in D_2O) for $[M'\{M(aet)_3\}_2]^{3+}$ (M = Ir^{III}, Rh^{III}; M′ = Re^{III}, Co^{III})

ΔΛ-$[Co\{Rh(aet)_3\}_2]^{3+}$	49.89	34.40	[6]
ΔΔ/ΛΛ-$[Co\{Rh(aet)_3\}_2]^{3+}$	50.11	34.62	[6]

Accordingly, it can be considered that the NMR spectral behavior depends upon the effective magnetic moments of the Re^{III} ion in the S-bridged polynuclear structures.

2.5. Electrochemistry

Cyclic voltammetry experiments were performed for the bromide salts of the present $Ir^{III}Re^{III}Ir^{III}$ complexes *meso*- and *rac*-$[Re^{III}\{Ir^{III}(aet)_3\}_2]^{3+}$ (**1a** and **1b**) together with *rac*-$[Re^{III}\{Rh^{III}(aet)_3\}_2]^{3+}$. As summarized in Table 4, each of the voltammograms displays a redox couple in a positive potential region. The observed peak separation (E_{pa}–E_{pc} = 0.07 V) establish that all redox processes are almost reversible, therefore, the complexes retain their trinuclear structure during the redox process. In the $Ir^{III}Re^{III}Ir^{III}$ complexes **1a** and **1b**, the redox wave appeared at a similar position, indicating that the redox potentials are almost independent of the absolute configuration of the terminal *fac*(*S*)-$[Ir(aet)_3]$ units. On the other hand, the $Rh^{III}Re^{III}Rh^{III}$ complex exhibits the redox wave at more positive potential depending on the terminal units. Since the previous trinuclear complexes have shown no waves due to the aet ligands [8–10], all waves given in Table 4 are probably due to the metals. Indeed, the $Ir^{III}Cr^{III}Ir^{III}$ and $Ir^{III}Co^{III}Ir^{III}$ complexes $[M'\{Ir^{III}(aet)_3\}_2]^{3+}$ (M′ = Cr^{III}, Co^{III}) show the redox wave ($E^{0\prime}$ = +0.64 V for Cr^{III} and +0.73 V for Co^{III}) due to the one-electron $Ir^{IV/III}M'Ir^{III}$ redox process, while the corresponding $Rh^{III}Cr^{III}Rh^{III}$ and Rh^{III}-$Co^{III}Rh^{III}$ complexes exhibit a redox wave at +1.01 V due to the one-electron $Rh^{IV/III}M'Rh^{III}$ redox process [8,10]. However, the potentials of the waves observed for the present $Ir^{III}Re^{III}Ir^{III}$ and $Rh^{III}Re^{III}Rh^{III}$ complexes (Table 4) are approximately 0.4 V more negative than those of $Ir^{IV/III}$ (or $Rh^{IV/III}$) redox processes for the previous complexes. Therefore, it is difficult to assign the waves for the present complexes from only the electrochemical measurements.

In order to elucidate the origin of the redox waves for the trinuclear complexes containing the Re^{III} ion, spectroelectrochemical experiments using a thin-layer quartz cell and a platinum mesh electrode were carried out. The absorption spectral change of the representative isomer **1b** of the $Ir^{III}Re^{III}Ir^{III}$ complex in visible region is shown in Fig. 4. The characteristic band at 476 nm, which is assigned as arising from the central $Re^{III}S_6$

Table 4
Redox potentials (E/V vs. Ag/AgCl with scan rate 100 mV s^{-1}) for $[Re^{III}\{M(aet)_3\}_2]^{3+}$ (M = Ir^{III}, Rh^{III})

Complex	$E^{0\prime}$	E_{pa}	E_{pc}
ΔΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1a**)	+0.34	+0.37	+0.30
ΔΔ/ΛΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1b**)	+0.37	+0.40	+0.33
ΔΔ/ΛΛ-$[Re\{Rh(aet)_3\}_2]^{3+}$	+0.60	+0.63	+0.56

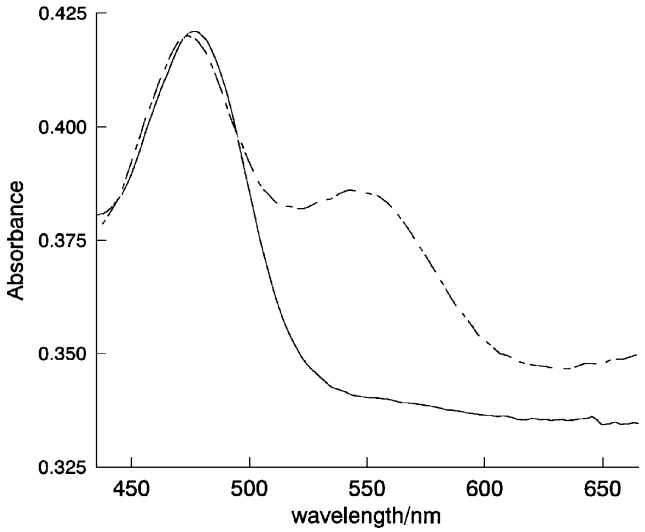

Fig. 4. UV–Vis absorption spectra of ΔΔ/ΛΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1b**) obtained during spectroelectrochemical experiments. Applied potentials vs. Ag/AgCl are: original (—) and +0.75 V for 5 min (–·–·–).

chromophore (vide supra), is observed before electrochemical oxidation. At a potential of +0.75 V, a new absorption band appeared at 542 nm, whereas the band at 476 nm showed no significant changes. Therefore, it is reasonable to assume that the new band at 542 nm is due to an $Ir^{IV}N_3S_3$ chromophore rather than a $Re^{IV}S_6$ one. When the potential was back to 0 V, the new band disappeared and the spectrum coincided well with the original spectrum. This spectroelectrochemical result also confirms the reversibility of the redox processes. Accordingly, it can be assigned that the wave of the cyclic voltammogram for **1a** and **1b** is due to the one-electron $Ir^{IV/III}Re^{III}Ir^{III}$ redox process (Table 4). Namely, the Ir^{III} ions in the present $Ir^{III}Re^{III}Ir^{III}$ complexes are more easily oxidized than those in the corresponding $Ir^{III}Cr^{III}Ir^{III}$ and $Ir^{III}Co^{III}Ir^{III}$ complexes, $[M'\{Ir^{III}(aet)_3\}_2]^{3+}$ [8,10]. This behavior may be related to the fact that the relatively low oxidation state of the Re^{III} ion is stabilized by the terminal *fac*(*S*)-$[Ir(aet)_3]$ units. Similarly, the wave for the $Rh^{III}Re^{III}$-Rh^{III} complex is thought to be dominated by the one-electron $Rh^{IV/III}Re^{III}Rh^{III}$ redox process (Table 4). The difference of the redox potential ($\Delta E^{0\prime} = 0.23$ V) between the $Ir^{IV/III}$ and $Rh^{IV/III}$ processes for the $MRe^{III}M$ complexes is comparable to those for the $MCr^{III}M$ and $MCo^{III}M$ complexes [8,10]. These facts also support the assignment of the redox waves, and the different positions of the $Ir^{IV/III}$ or $Rh^{IV/III}$ process seem to depend on the central Re^{III} ion. On the other hand, the wave due to the $Re^{IV/III}$ redox process could not be observed. Accordingly, it was elucidated that the oxidation state of Re^{III} is highly stabilized in the S-bridged trinuclear structures, $[Re\{M(aet)_3\}_2]^{3+}$ ($M = Ir^{III}$, Rh^{III}).

3. Experimental

3.1. Materials

2-Aminoethanethiolate (Haet) and *N*-methylthiourea (Metu) were purchased from Tokyo Kasei Kogyo Co. Ltd. NH_4ReO_4 was purchased from Soekawa Chemical Co. Ltd. $Na_2[Sb_2(R,R\text{-tart})_2]\cdot 5H_2O$ (H_4tart = tartaric acid) was prepared by the general procedure from $Na_2(R,R\text{-}H_3tart)_2\cdot H_2O$ and Sb_2O_3 (Kanto Chemical Co. Inc). *fac*(*S*)-$[Ir(aet)_3]$ [8,10] and $[Re(Metu)_6]Cl_3$ [15] were prepared by procedures similar to those in the literature. $IrCl_3$, $SnCl_2\cdot 2H_2O$ and the other reagents used were purchased from Wako Pure Chemical Ind. Ltd. All the chemicals were of reagent grade and were used without further purification.

3.2. Preparation of complexes

3.2.1. ΔΛ-$[Re\{Ir(aet)_3\}_2]^{3+}$ (**1a**)

To the colorless solution of NH_4ReO_4 (0.305 g, 1.14 mmol) in 20 cm^3 of 1 mol dm^{-3} (M) HBr or 1 M HCl were added *fac*(*S*)-$[Ir(aet)_3]$ (0.500 g, 1.14 mmol) and $SnCl_2\cdot 2H_2O$ (0.515 g, 2.28 mmol). The dark reddish brown mixture was stirred at room temperature (r.t.) for 1 h. The reaction mixture was subjected to SP-Sephadex C-25 column (Na^+ form) and eluted by 0.5 M NaCl aqueous solution, where upon two yellow bands, *meso* (**1a**) and *rac* (**1b**) isomers and an unidentified purple band were eluted in this order. The *meso* and *rac* bands separated were concentrated by rotary evaporator and partially desalted by the addition of methanol. After the solution was concentrated again, an orange powder of the iodide salt was obtained by the addition of saturated NaI solution. The powder was dissolved in a small amount of water and subjected to QAE-Sephadex A-25 column (Br^- form). The eluate was concentrated by rotary evaporator and kept in the refrigerator after the addition of a few drops of saturated NaBr solution. The *meso*-isomer was separated as dark orange crystals (**1a**), filtered, washed with acetone and dried. Yield: 0.095 g (6.4%). *Anal*. Found: C, 11.13; H, 2.84; Ir, 32.0, N, 6.50; Re, 14.8%. $[Re\{Ir(NH_2CH_2CH_2S)_3\}_2]Br_3\cdot H_2O$ requires C, 11.22; H, 2.98; Ir, 29.9, N, 6.54; Re, 14.5%. Absorption maxima [σ (10^3 cm^{-1}) (log ε (M^{-1} cm^{-1}))]: 12.94 (2.45), 20.97 (3.83), 26.11 (3.84), 32.3sh (3.6), 36.2sh (4.0), 42.84 (4.30). The sh label denotes a shoulder. ^1H NMR spectrum in D_2O (δ (ppm) from DSS): 5.77 (dd, $J = 10.6$ and 5.3 Hz, NH_2), 5.61 (d, $J = 7.0$ Hz, NH_2), 4.69 (d, $J = 12.5$ Hz, NCH_2), 3.12 (dd, $J = 23.3$ and 10.3 Hz, NCH_2), 2.61 (d, $J = 12.0$ Hz, SCH_2), 1.67 (td, $J = 13.6$ and 3.3 Hz, SCH_2). ^{13}C NMR spectrum in D_2O (δ (ppm) from DSS): 57.62 (NCH_2), 44.72 (SCH_2). The *rac*-isomer could not be isolated due to rearrangement to a dinuclear Ir^{III} complex during this procedure (vide supra).

3.2.2. $\Delta\Delta/\Lambda\Lambda$-[Re{Ir(aet)$_3$}$_2$]$^{3+}$ (**1b**)

To a clear bright yellow solution of [Re(Metu)$_6$]Cl$_3$ (1.350 g, 1.625 mmol) in 30 cm^3 of H_2O was added *fac*(*S*)-[Ir(aet)$_3$] (0.675 g, 1.625 mmol). The reddish brown mixture was stirred at r.t. for 1 h. After unreacted materials were filtered off, 2.5 cm^3 of saturated NaBr was added to the filtrate and then kept in a refrigerator overnight. The dark brown rod crystals (**1b**) that appeared, were collected by filtration, washed with acetone and dried. Yield: 0.129 g (16.4%). *Anal*. Found: C, 10.70; H, 3.11; Ir, 26.0, N, 6.32; Re, 13.6%. [Re{Ir($NH_2CH_2CH_2S)_3$}$_2$]$Br_3\cdot 2.5H_2O$ requires C, 10.98; H, 3.15; Ir, 29.3; N, 6.40; Re, 14.2%. Absorption maxima [σ (10^3 cm^{-1}) (log ε (M^{-1} cm^{-1}))]: 12.90 (2.25), 20.42 (3.80), 25.69 (3.76), 31.88 (3.84), 38.5sh (4.1), 45.5sh (4.8). Reflectance maxima (σ (10^3 cm^{-1})): 13.02, 20.70, 26.01, 31.75, 40.32, 45.8sh. The sh label denotes a shoulder. ^{1}H NMR spectrum in D_2O (δ (ppm) from DSS): 5.86 (dd, $J = 10.5$ and 5.3 Hz, NH_2), 5.65 (d, $J = 6.6$ Hz, NH_2), 4.47 (d, $J = 12.7$ Hz, NCH_2), 3.05 (dd, $J = 24.8$ and 13.9 Hz, NCH_2), 2.60 (d, $J = 11.5$ Hz, SCH_2), 1.45 (td, $J = 13.6$ and 3.6 Hz, SCH_2). ^{13}C NMR spectrum in D_2O (δ (ppm) from DSS): 56.58 (NCH_2), 46.92 (SCH_2).

1b was optically resolved by SP-Sephadex C-25 column chromatography, which was eluted with 0.15 M $Na_2[Sb_2(R,R\text{-tartrato})_2]\cdot 5H_2O$ aqueous solution. The bands, which were partially separated, were further eluted with 0.5 M NaCl aqueous solution. Several portions from the lower and upper parts of the band were collected and their CD spectra were measured, which showed the positive or negative CD sign at 460 nm (21.83×10^3 cm^{-1}). The $\Delta\varepsilon$-values of each eluate containing the $(+)^{CD}_{460}$ and $(-)^{CD}_{460}$-**1b** isomers were evaluated on the basis of the absorption spectral data of **1b**$Br_3\cdot 2.5H_2O$. CD extrema for $(-)^{CD}_{460}$ isomer [σ (10^3 cm^{-1}) ($\Delta\varepsilon$ (M^{-1} cm^{-1}))]: 16.20 (−0.74), 20.37 (+5.25), 21.83 (−9.45), 26.75 (+3.39), 29.38 (−0.85), 33.50 (−8.52), 38.97 (−8.64), 45.74 (−6.67).

3.3. Measurements

The elemental analysis (C, H and N) was performed by the Chemical Analysis Center of the University of Tsukuba. The concentrations of Re and Ir in the complexes were determined with a NIPPON Jarell-Ash ICPA-575 spectrophotometer. The UV–Vis absorption spectra were recorded with a JASCO V-560 spectrophotometer and the CD spectra were recorded with a JASCO J-600 spectropolarimeter in aqueous solution. The diffuse reflectance spectrum was recorded by a JASCO V-570 spectrophotometer equipped with an integrating sphere apparatus. The IR spectra were recorded on a JASCO FT IR-550 spectrometer using KBr disks in the range of 4000–400 cm^{-1} and polyethylene pellets in the range of 650–100 cm^{-1}. The ^{1}H and ^{13}C NMR spectra were recorded with BRUKER AM-500 or AM-600 NMR spectrometers in D_2O and the sodium 4,4-dimethyl-4-silapentane-1-sulfonate (DSS) was used as an internal reference. The molar conductance of the complexes was measured with a HORIBA conductivity meter DS-14 in aqueous solution. The magnetic measurement was performed by using a Sherwood Scientific MSB-AUTO susceptibility balance. Electrochemical experiments were performed by a CV-50W apparatus, Bioanalytical Systems, Inc. (BAS) using a platinum-working electrode (BAS, Pt). Spectroelectrochemical experiments were performed by a JASCO CT-10TP multichannel spectrophotometer and a CV-1B apparatus (BAS) using a thin-layer quartz cell and a platinum mesh working electrode. In both electrochemical and spectroelectrochemical experiments, an aqueous (aq.) Ag/AgCl/NaCl (3 M; BAS, RE-1B) and platinum wire were used as reference and auxiliary electrodes. The experiments were conducted in 0.1 M aqueous solution of Na_2SO_4 as a supporting electrolyte. All the measurements were carried out at r.t.

3.4. X-ray crystallography

Red prismatic crystals of **1a**Br_3 were obtained by recrystallization of the isomer from water containing few drops of saturated NaBr solution at r.t. Brown rod crystals of **1b**$Br_3\cdot H_2O$ were obtained from the reaction mixture containing saturated NaBr solution at r.t. or by keeping in a refrigerator. Single crystal X-ray diffraction experiments were performed on a Rigaku AFC-7S four-circle diffractometer with Mo Kα (0.71069 Å) radiation. The intensity data were collected by the ω (**1a**Br_3) or ω–2θ (**1b**$Br_3\cdot H_2O$) scan technique up to 55° (2θ) at 296 K. The crystallographic data and experimental parameters are summarized in Table 5. The structures were determined by a direct method (SIR-92) [23], and refined by full-matrix least-squares techniques. All of the non-hydrogen atoms were refined anisotropically, and all the hydrogen atoms except for those of amino group in **1b**$Br_3\cdot H_2O$ were included in the refinement but restrained to ride on attached atoms [C–H=N–H = 0.95 Å, U(H) = 1.2U(C, N)]. In **1a**Br_3 only Re(1) and Br(2) atoms were constrained to special positions and refined with a site occupancy factor of 0.5. On the other hand, in **1b**$Br_3\cdot H_2O$ two sets of atom peaks corresponding to a pair of enantiomers co-exist in each of four sites in the unit cell. This behavior is often observed in the *rac* isomer of the S-bridged $\Delta\Delta/\Lambda\Lambda$-[M$'_3${M(aet)$_3$}$_2$]$^{3+}$ (M = Co^{III}, Rh^{III}; M$'$ = Ag^I, Au^I) [2,24]. Ir(1, 2), Re(1), Br(1), O(1) and C(1, 2, 5, 6) atoms were constrained to special positions. The site-occupancy factor of each atom except for the Br(2) and C(3, 4, 7, 8) atoms was fixed to 0.5. All of the calculations were performed on an Indigo II computer using the TEXSAN crystallographic software package [25].

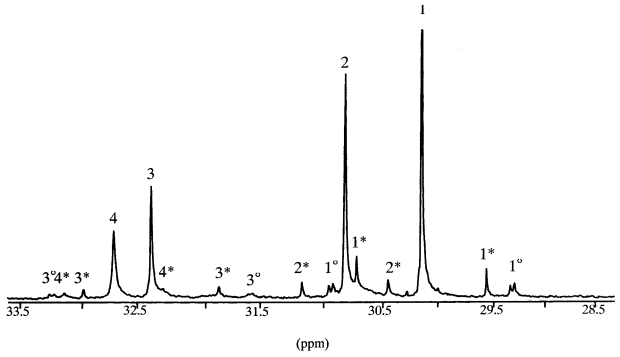
2. Results and discussion

2.1. Synthesis and spectroscopic characterization

Reaction of $[W(CO)_4(NCMe)(PPh_3)]$ with an equimolar quantity of $SnCl_4$ in CH_3CN produced a mixture of oxidative addition products, i.e. tungsten(II) compounds, as observed by $^{31}P\{^1H\}$ NMR spectra (Fig. 1). Four signals at δ_P about 30 ppm indicate the formation of four tungsten(II) compounds containing triphenylphosphine ligands. The intensity ratio of these signals changes slowly during the 1 week NMR measurement, indicating some transformation processes in solution. Two signals at δ_P 30.16 and 32.44, due to the presence of ^{117}Sn ($I = 1/2$, 7.6%) and ^{119}Sn ($I = 1/2$, 8.6%) satellites, and characteristic $^2J_{PSn}$ coupling constants in the range 308–348 Hz [13,14] can be assigned to tungsten(II) compounds containing a W–Sn bond. The intensity of these two signals decreases much faster in time than others. Two other signals at δ_P 30.70 and 32.77 are due to compounds without a W–Sn bond, being the products of the elimination of $SnCl_2$ species from the trichlorostannyl ligand. It is interesting that for the compounds without of a W–Sn bond the value of $^1J_{PW}$ −150 and 170 Hz, respectively—is much smaller than the value of $^1J_{PW}$ for signals due to W–Sn compounds ($^1J_{PW} = 222$ and 235 Hz). This suggests stronger W–P interactions in compounds containing trichlorostannyl ligands than in analogues with chlorine ligands only. Three broad bands in the ν(CO) region (2030–1840 cm^{-1}) of the IR spectra of these compounds suggest the presence of compounds with two and three carbonyl groups [11,13–16]. $^{13}C\{^1H\}$ NMR spectra of these compounds show three groups of carbonyl carbon signals in the region 232–227 ppm. The very narrow ranges of δ_P suggest a similar mutually *cis* position of the CO and PPh_3 ligands in the above tungsten(II) compounds.



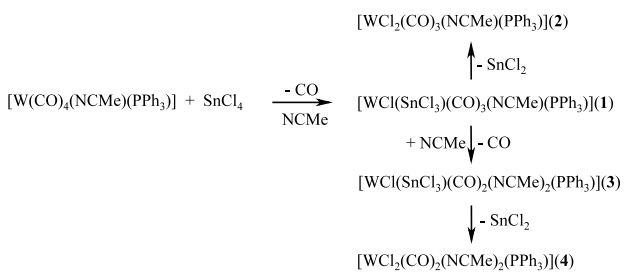


Fig. 1. $^{31}P\{^1H\}$ NMR spectrum showing the mixture of four seven-coordinate tungsten(II) compounds: $[WCl(SnCl_3)(CO)_3(NCMe)(PPh_3)]$(**1**), $[WCl_2(CO)_3(NCMe)(PPh_3)]$ (**2**), $[WCl(SnCl_3)(CO)_2(NCMe)_2(PPh_3)]$(**3**), and $[WCl_2(CO)_2(NCMe)_2(PPh_3)]$(**4**) formed during the reaction of $[W(CO)_4(NCMe)(PPh_3)]$ and $SnCl_4$ in acetonitrile. The signals denoted by an asterisk (*) are due to ^{183}W satellites and by circle (○) are due to ^{117}Sn and ^{119}Sn satellites.

Based on these spectral data, the formation of four seven-coordinate tungsten(II) compounds: $[WCl(SnCl_3)(CO)_3(NCMe)(PPh_3)]$ (**1**), $[WCl_2(CO)_3(NCMe)(PPh_3)]$ (**2**), $[WCl(SnCl_3)(CO)_2(NCMe)_2(PPh_3)]$ (**3**), and $[WCl_2(CO)_2(NCMe)_2(PPh_3)]$ (**4**), can be proposed (Scheme 1).

In reactions carried out in a coordinating solvent, such as acetonitrile, we considered the oxidative addition of $SnCl_4$ to $[W(CO)_4(NCMe)(PPh_3)]$ followed by the dissociation of $SnCl_2$ and the displacement of the CO ligands by the solvent (CH_3CN) molecules. However, during the reaction of $[WCl(SnCl_3)(CO)_3(NCMe)_2]$ with 1 equiv. of PPh_3 in CH_3CN, the formation of a mixture of compounds **3** and **4** was detected due to the presence of ν(CO) bands characteristic for bis(carbonyl) compounds [11,13–16]. Two pairs of ν(CO) bands: 1913(m), 1840(vs) and 1935(m), 1864(vs) cm^{-1}, deriving from compounds **3** and **4**, respectively, were observed in IR spectrum of a solid sample.

Treatment of $[W(CO)_4(NCMe)(PPh_3)]$ with 1 equiv. of $SnCl_4$ in CH_2Cl_2 solution besides compounds **1** and **2** also gave ionic species such as $[HPPh_3]^+$, $[SnCl_6]^{2-}$, and cationic complexes of tungsten(II). One of the cationic complex of tungsten(II) was isolated in crystalline form and X-ray analysis showed it to be $[WH(CO)_3(NCMe)(PPh_3)_2][SnCl_5\cdot MeOH]$ (**5**). The IR spectra (KBr disc) of compound **5** exhibit two sharp ν(CO) bands at 2040(w) and 1939(vs) cm^{-1}; this is fully consistent with the unusual *mer* configuration of the CO groups observed crystallographically. To our knowledge, a similar arrangement of three carbonyl groups has previously been detected only for $[WCl(SnCl_3)(CO)_3(\eta^4\text{-NBD})]$ [17].

The appearance of two carbonyl resonances in the $^{13}C\{^1H\}$ NMR spectrum (125.8 MHz, 293 K) of **5** at an intensity ratio of 2:1, at $\delta_C = 212.09$ and $\delta_C = 208.48$, respectively, conforms with the solid state structure of the distorted capped octahedron and *mer* geometry of the carbonyl groups. The $^{31}P\{^1H\}$ NMR spectrum (121.5 MHz, 293 K) of **5** shows a broad resonance due to 2 equiv. triphenylphosphine ligands at δ_P 25.04 ($^1J_{PW} = 131$ Hz). The ^1H spectra (500 MHz, 293 K) of **5** exhibit a three-line resonance due to a hydride ligand

Scheme 1.

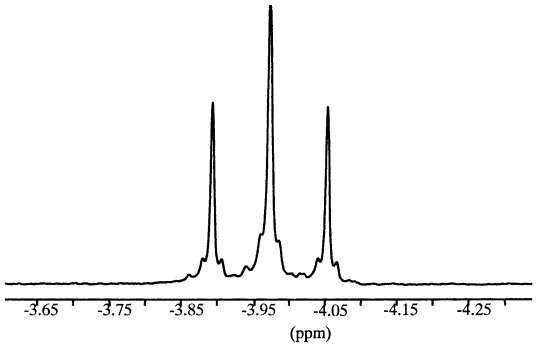

Fig. 2. High field ^{1}H NMR spectrum of the $[WH(CO)_3(NCMe)(PPh_3)_2][SnCl_5\cdot MeOH]$ (**5**) complex obtained at 293 K in CD_2Cl_2, showing the hydride signal at $\delta_H = -3.98$.

at $\delta_H = -3.98$ ($^2J_{PH} = 40$ Hz), which is further split due to a coupling to the tungsten atom ($^1J_{WH} = 13$ Hz) and to the carbonyl carbon atom ($^1J_{CH} = 32$ Hz) (Fig. 2). The $^1J_{WH} = 13$ Hz observed here is much smaller than that for $[^nPr_4N]_4[H_4W_4(CO)_{12}]$ (44.5 Hz [18]), $[Et_4N]_4[W_2(CO)_8(PMe_2Ph)_2]$ (44 Hz [19]), $[Et_4N][(\mu\text{-}H)(\mu\text{-}Ph_2P(CH_2)_4PPh_2)W_2(CO)_8]$ (46.1 Hz [20]), and $[PPN][HW(CO)_4(PMe_3)]$ (54 Hz [21]). In contrast, the $^2J_{PH} = 40$ Hz is about two times higher than observed in those tungsten(0) compounds [18–21], but very close to that found for tungsten(II) compounds such as $[WH(CO)_3(PMe_2Ph)_3]^+$ (47 Hz [22]) and $[WH(SPh)(CO)_3(PCy_3)_2]$ (43 Hz [23]). This suggests that the electronic configuration of the metal atom (d^6 or d^4) can exert influence on W–H interactions. The ^{13}C satellites ($I = 1/2$, 1%) observed on the hydride signal suggest a C–H interaction. The small hydrogen–carbon coupling constant indicates a three-center W–H···C agostic interaction [24,25], which was additionally proved by X-ray structure investigations (see next paragraph).

Similar spectral characteristic to those of compound **5** were shown by the product formed in the reaction of *trans*-$[W(CO)_4(PPh_3)_2]$ and $SnCl_4$ in CH_2Cl_2. Two broad ν(CO) bands at 2030(w) and 1937(vs) in the IR spectrum, a signal at $\delta_P = 25.92$ ($^1J_{PW} = 138$ Hz) in the $^{31}P\{^1H\}$ NMR spectrum and two doublets at $\delta_C = 218.36$ ($^2J_{CP} = 32$ Hz) and $\delta_C = 213.75$ ($^2J_{CP} = 9$ Hz) in the $^{13}C\{^1H\}$ NMR spectrum were observed. These spectral data suggest the formation of the cationic compound of tungsten(II) analogues to **5**. This compound has never been isolated in pure crystalline form, so the counter-ion is unknown. However, during the reaction of *trans*-$[W(CO)_4(PPh_3)_2]$ and $SnCl_4$ in CH_3CN solution, the formation of $[WCl_2(CO)_3(PPh_3)_2]$ as the main product was observed by IR spectra, due to characteristic ν(CO) bands at 2014(s), 1936(vs), and 1894(s) cm^{-1} [11]. In the $^{31}P\{^1H\}$ NMR spectra (CD_3CN, 293 K) of the reaction products, only very low-intensity signals in the range $\delta_P = 32.77–30.16$, assigned to compounds **1**–**4**, were observed. The solubility of $[WCl_2(CO)_3(PPh_3)_2]$ in CD_3CN is probably extremely low.

The oxidative addition reaction of phosphine complexes of tungsten(0) with $SnCl_4$ carried out in dichloromethane is always accompanied by the formation of $[HPPh_3]^+$ cations. The latter species gives a ν(PH) band at 2430 cm^{-1} and other characteristic bands [26–29] at 1114 and 721 cm^{-1} in IR spectra. In ^{1}H NMR spectra of the reaction products containing $[HPPh_3]^+$ cations, a doublet at $\delta_H = 9.36$ with $^1J_{HP} = 526$ Hz can be detected.

From the experimental results we deduce that the reaction course strongly depends on the solvent. When the reaction is carried out in acetonitrile solution, the elimination of $SnCl_2$ from the coordination sphere of tungsten occurs to give neutral compounds. In dichloromethane solution, the elimination of $SnCl_3^-$ anionic ligands takes place yielding cationic compounds of tungsten(II). The $SnCl_3^-$ anion should be oxidized by CH_2Cl_2 [30,31] producing the counterpart anion $[SnCl_5]^-$ or $[SnCl_6]^{2-}$.

2.2. Structure of $[WH(CO)_3(NCMe)(PPh_3)_2][SnCl_5\cdot MeOH]$ (5)

Fig. 3 shows an ORTEP perspective view of compound **5** that includes the atom numbering scheme. Selected interatomic bond distances and angles are summarized in Table 2. The crystal structure of **5** consists of well separated $[WH(CO)_3(NCMe)(PPh_3)_2]^+$ cations and $[SnCl_5\cdot MeOH]^-$ anions. The tungsten atom is in a

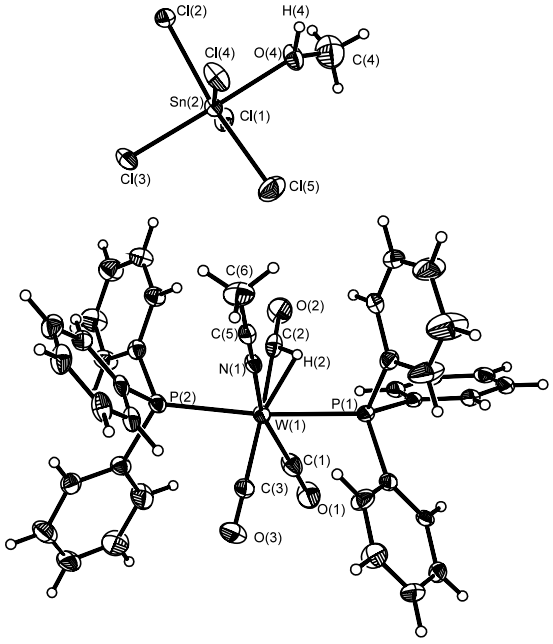

Fig. 3. The crystal structure of $[WH(CO)_3(NCMe)(PPh_3)_2][SnCl_5\cdot MeOH]$ (**5**).

seven-coordinate environment that can be approximately described [32,33] as capped octahedral, with the hydride ligand H(2) capping the triangular face formed by the carbon, nitrogen, and phosphorus atoms (Fig. 4). Within the distorted octahedral description, the two carbon atoms, two phosphorus atoms, and the nitrogen and the carbon atoms are mutually *trans* with C(2)–W–C(3), P(1)–W–P(2), and N(1)–W–C(1) angles of 175.31(18)°, 164.90(4)°, and 160.57(17)°, respectively. The capped octahedral face defined by the angles C(2)–W–N(1) = 90.29(16)°, P(1)–W–C(2) = 88.13(3)°, and P(1)–W–N(1) = 83.16(9)° is a little larger than the opposite face defined by P(2)–W–C(3) = 83.81(13)°, C(3)–W–C(1) = 81.65(19)°, and P(1)–W–C(1) = 78.79(14)°.

The bond lengths from tungsten are not unusual and are of the same order of magnitude as those reported in the literature for related complexes. For example, the average W–P bond length of 2.54 Å is only a little shorter than the values of 2.58 Å (av.) found in the complexes $[WCl(CO)(^tBuC{\equiv}CH)(NCMe)(PPh_3)_2]_2$-$[SnCl_6]\cdot 4NCMe$ [12] and $[WI_2(CO)_3(PEt_3)_2]$ [34]. The average W–C bond length of 2.035 Å, found for the two mutually *trans* carbonyl ligands, is a little longer than a W–C bond length of 1.971(5) Å for a carbonyl ligand in the *trans* position to an acetonitrile ligand. This is in accord with the higher *trans* influence of the CO group as compared with the nitrile ligand. The W–N bond distance of 2.159(3) Å is a little shorter than found in the complexes $[WCl(CO)(^tBuC{\equiv}CH)(NCMe)(PPh_3)_2]_2$-$[SnCl_6]\cdot 4NCMe$ (2.186(6) Å [12]) and $[WCl(SnCl_3)$-$(CO)_3(NCMe)_2]$ (2.18(1) Å [4]). The W–H distance of 1.713 Å in **5** is a little shorter than the W–H distances previously reported for the other tungsten(II) hydrides, e.g. 1.78 Å in $[WH(Cl)(CO)_2(PMe_3)_3]$ [35] and 1.835(36) Å in $[WCl_2(CHCMe_3)(CO)(PMe_3)_2]$ [24]. The H(2)–C(2) distance in **5** is only 0.9992 Å, indicative of a three-centre W–H···C agostic interaction [24,25]. The H(2)–C(2)–W angle is 57.1° and the H(2)–W–C(2) angle is 29.3°. Similar agostic interactions, but involving the α-H of the neopentylidene ligand, have been detected in $[WCl_2(CHCMe_3)(CO)(PMe_3)_2]$, where a C–H distance of 1.053(36) Å, an H–C–W angle of 72.2(20)°, and an H–W–C angle of 33.1(11)° were observed [24]. Interestingly, the carbonyl carbon atom adjacent to the hydride ligand is associated with a little shorter C–O length (1.128(5) Å) than in the other two CO ligands (1.161(5) and 1.143(5) Å).

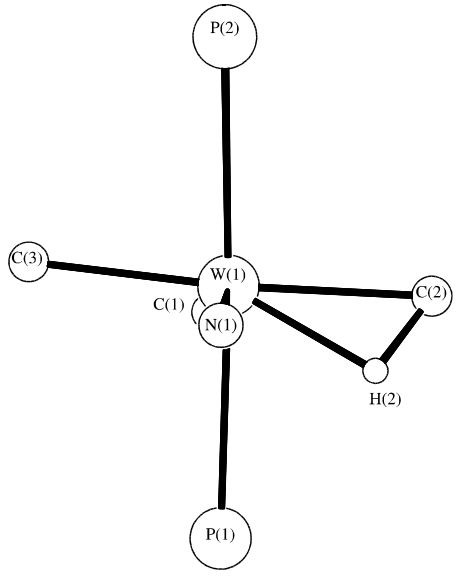

Fig. 4. The coordination sphere of tungsten(II) in $[WH(CO)_3$-$(NCMe)(PPh_3)_2]^+$ cation.

The $[SnCl_5(MeOH)]^-$ anion has irregular octahedral geometry. The *cis* Cl–Sn–Cl angles fall in the range 87.65(4)°–96.25(4)°, while the *cis* Cl–Sn–O angles are smaller (81.66(9)°–86.70(10)°), which is consistent with chlorine having a greater van der Waals radius than oxygen. The Sn(2)–Cl(2) distance of 2.442(1) Å is significantly longer than the remaining four Sn–Cl distances of 2.384 Å (av.). This difference is readily explained in terms of Cl···H interactions. The Cl(2) atom is involved in an intermolecular contact of 3.090(4) Å to H(4). Thus, an alcohol ligand coordinated through the oxygen atom to the tin atom is also hydrogen-bonded to a Cl(2) atom of the $SnCl_5$ counter-ion.

3. Experimental

3.1. General data

All reactions were carried out under nitrogen by standard Schlenk line techniques. The solvents and reagents applied were dried, distilled, and deoxygenated. Solution IR spectra were obtained using KBr or NaCl plates, while solid samples were recorded using KBr pellets on an FT IR model-400 Nicolet instrument. Far-IR spectra were recorded (600–100 cm^{-1}) with a Bruker IFSv instrument in a Nujol mull on a polyethylene film. ^1H, $^{13}C\{^1H\}$, and $^{31}P\{^1H\}$ NMR spectra were recorded on an AMX 300 and 500 MHz Bruker spectrometer. Chemical shifts were referenced against solvent resonance as the internal standard. In ^1H NMR spectra $\delta_H = 1.98$ for CD_3CN and $\delta_H = 5.32$ for CD_2Cl_2 and in ^{13}C NMR spectra $\delta_C = 118.00$ for CD_3CN and $\delta_C = 54.00$ for CD_2Cl_2. ^{31}P NMR spectra were referenced to external 85% H_3PO_4.

3.2. Synthesis of $[W(CO)_4(NCMe)(PPh_3)]$ [8]

$[W(CO)_5(PPh_3)]$ (1.05 g, 1.79 mmol), prepared according to the published procedure [36], was dissolved in acetonitrile (50 cm^3) with continuous stirring under a nitrogen atmosphere in a 100 cm^3 round-bottomed flask

equipped with a quartz window through which the solution was irradiated with an HBO 200 Hg lamp. The course of the reaction was monitored by IR measurements, and photolysis was stopped when the IR band of $[W(CO)_5(PPh_3)]$ at 2073 cm^{-1} had decayed (about 3 h). The solvent was evaporated in vacuum to yield a yellow residue containing $[W(CO)_4(NCMe)(PPh_3)]$ (90%), $[W(CO)_3(NCMe)_2(PPh_3)]$, and $[W(CO)_5(PPh_3)]$ identified by $^{31}P\{^1H\}$ NMR spectra in CD_3CN due to respective signals at $\delta_P = 28.77$, $^1J_{PW} = 240$ Hz [8], $\delta_P = 32.42$, $^1J_{PW} = 222$ Hz, and $\delta_P = 21.24$, $^1J_{PW} = 242$ Hz. Unreacted $[W(CO)_5(PPh_3)]$ was removed from the mixture by extraction to heptane.

3.3. Oxidative addition of $SnCl_4$ to $[W(CO)_4(NCMe)(PPh_3)]$

3.3.1. Reaction in CH_3CN solution

To $[W(CO)_4(NCMe)(PPh_3)]$ (0.83 g, 1.38 mmol) dissolved in 50 cm^3 of acetonitrile was added $SnCl_4$ (0.36 g, 1.38 mmol) by means of a syringe. The mixture was stirred for 4 h, during which time the yellow solution gradually changed to an orange color, while the ν(CO) frequency of the starting tungsten compound disappeared. After the completion of the reaction, the solution was evaporated to dryness and the residue washed with heptane.

IR (KBr disc): ν(CN) 2318(vw), 2287(vw) cm^{-1}, ν(CO) 2031(w), 1935(vs), 1913(sh), 1859(sh), 1840(sh) cm^{-1}; (Nujol): ν(SnCl) broad 330(w) cm^{-1}. ^1H NMR, (CD_3CN, 293 K): $\delta_H = 7.80–7.28$ m (PPh_3), $\delta_H = 2.17$ (CH_3CN). $^{13}C\{^1H\}$ NMR, (CD_3CN, 293 K): δ_C 231.9, 230.69, 226.72 (CO), $\delta_C = 135.14–129.93$d (PPh_3). $^{31}P\{^1H\}$ NMR (CD_3CN, 293 K): $\delta_P = 32.77$, $^1J_{PW} = 170$ Hz, $\delta_P = 32.44$, $^1J_{PW} = 235$ Hz, $^2J_{PC} = 57$ Hz, $^2J_{PSn} = 341$ and 348 Hz, $\delta_P = 30.70$, $^1J_{PW} = 150$ Hz and $\delta_P = 30.16$, $^1J_{PW} = 222$ Hz, $^2J_{PC} = 57$ Hz, $^2J_{PSn} = 308$ and 320 Hz. These spectral data were assigned to the following tungsten(II) compounds: $[WCl(SnCl_3)(CO)_3(NCMe)(PPh_3)]$ (**1**), $[WCl_2(CO)_3(NCMe)(PPh_3)]$ (**2**), $[WCl(SnCl_3)(CO)_2(NCMe)_2(PPh_3)]$ (**3**), and $[WCl_2(CO)_2(NCMe)_2(PPh_3)]$ (**4**).

3.3.2. Reaction in CH_2Cl_2 solution

To $[W(CO)_4(NCMe)(PPh_3)]$ (0.9 g, 1.5 mmol) dissolved in 5 cm^3 of CH_2Cl_2 was added $SnCl_4$ (0.39 g, 1.5 mmol). After 2 h stirring, IR spectroscopy confirmed the reaction to be complete. Volatiles were removed in vacuum to yield an orange solid, which was washed with heptane and dried. The IR spectrum in a KBr disc showed two broad carbonyl bands at 2030(m) and 1930(vs) cm^{-1}, and a shoulder on the former band. The $^{31}P\{^1H\}$ NMR spectra in CD_2Cl_2 showed the formation of a mixture of compounds; very low-intensity ^{31}P signals, decaying over time, were observed at δ_P about 30 ppm and intense signals at δ_P about 25 ppm. Slow crystallization from CH_2Cl_2–CH_3OH–toluene–heptane solution at approximately 273 K gave yellow crystals, which were isolated and fully characterized as $[WH(CO)_3(NCMe)(PPh_3)_2][SnCl_5 \cdot MeOH]$ (**5**). Simultaneously precipitated colorless crystals were identified by X-ray analysis as $[HPPh_3]_2[SnCl_6]$ and *cis*-$[SnCl_4(OPPh_3)_2]$ [37].

Anal. Calc. for $C_{42}H_{38}Cl_5NO_4P_2SnW$: C, 43.39; H, 3.29; N, 1.20. Found: C, 43.30; H, 3.45; N, 1.28%. IR (KBr disc): ν(CN) 2287(vw), ν(CO) 2040(w), 1939(vs) cm^{-1}. ^1H NMR (CD_2Cl_2, 293 K): $\delta_H = 7.90–7.70$d (PPh_3), $\delta_H = 5.85$ (broad) ($HOMe$), $\delta_H = 3.87$ (broad) ($HOMe$), $\delta_H = -3.97$t, $^1J_{HW} = 13$ Hz, $^2J_{PH} = 40$ Hz, $^1J_{HC} = 32$ Hz. $^{13}C\{^1H\}$ NMR, (CD_2Cl_2, 293 K): $\delta_C = 212.09$ (2 CO), $\delta_C = 208.48$ (1 CO), $\delta_C = 127.7$ (CH_3CN), $\delta_C = 35.81$ ($HOMe$), $\delta_C = 5.11$ (CH_3CN). $^{31}P\{^1H\}$ NMR (CD_2Cl_2, 293 K): $\delta_P = 25.04$, $^1J_{PW} = 131$ Hz.

3.4. Reaction of $[W(CO)_4(PPh_3)_2]$ with $SnCl_4$

To $[W(CO)_4(PPh_3)_2]$, prepared in photochemical reaction of $[W(CO)_5PPh_3]$ with PPh_3 [38], (0.18 g, 0.22 mmol) in 25 cm^3 of CH_2Cl_2, 2 equiv. of $SnCl_4$ were added (0.12 g, 0.46 mmol). After 48 h stirring, IR spectroscopy confirmed the reaction to be complete. Volatiles were removed in vacuum to yield an orange solid, which was washed with heptane and dried. The IR spectrum in a KBr disc showed two broad carbonyl bands at 2030(m) and 1937(vs) cm^{-1}. The $^{31}P\{^1H\}$ NMR spectra in CD_2Cl_2 showed the formation of a mixture of new tungsten(II) compounds characterized by ^{31}P signals at $\delta_P = 28.94$ (15%), 25.92, $^1J_{PW} = 138$ Hz (50%) and 25.63 (10%). Signal at $\delta_P = 20.95$, $^1J_{PW} = 244$ Hz (25%) indicates the formation of $[W(CO)_5(PPh_3)]$. In the $^{13}C\{^1H\}$ spectrum, two (2:1) doublets at $\delta_C = 218.36$, $^2J_{CP} = 32$ Hz and $\delta_C = 213.75$, $^2J_{CP} = 9$ Hz were observed. Two additional doublets (1:4) at $\delta_C = 199.19$, $^2J_{CP} = 22$ Hz and $\delta_C = 197.22$, $^2J_{CP} = 7$ Hz proved the presence of $[W(CO)_5(PPh_3)]$. From a CH_2Cl_2 solution of these compounds the colorless crystals of $[HPPh_3]_2[SnCl_6]$ salts always precipitate. IR spectra (KBr, disc): ν(PH) 2430 cm^{-1} and other characteristic bands at 1114, 869, and 721 cm^{-1} [26–29].

3.5. Reaction of $[WCl(SnCl_3)(CO)_3(NCMe)_2]$ with PPh_3 in CH_3CN

To $[WCl(SnCl_3)(CO)_3(NCMe)_2]$ [4] (0.16 g, 0.3 mmol) dissolved in 10 cm^3 of acetonitrile was added PPh_3 (0.7 g, 0.3 mmol) in 5 cm^3 of acetonitrile. The mixture was stirred for 25 min, during which time the ν(CO) frequency of the starting tungsten compound disappeared. After that time the solution was evaporated to dryness and the orange residue washed with heptane. *Anal*. Calc. for $C_{24}H_{21}Cl_4N_2O_2PSnW$ (**3**): C, 34.12; H,

2.51; N, 3.32. Found: C, 34.13; H, 2.68; N, 3.68%. IR (KBr disc): ν(CN) 2339(vw), 2295(vw); ν(CO) 1935(m), 1864(vs) cm^{-1}; $^{31}P\{^{1}H\}$ NMR (CD_3CN): $\delta_P = 32.44$, $^{1}J_{PW} = 235$ Hz, $^{2}J_{PSn} = 341$ and 348 Hz. After prolonged reaction time in acetonitrile the purple crystals of another bis(carbonyl) compound (**4**) were precipitated. IR (KBr disc): ν(CN) 2290(vw), ν(CO) 1914(m), 1840(vs) cm^{-1}.

3.6. Crystal and refinement data for compound 5

Crystal data and relevant refinement details for **5** are presented in Table 1. The yellow crystals of **5** were grown from a CH_2Cl_2–CH_3OH–toluene–heptane (5:0.1:1:10) solution. The crystals were stable enough when handled in an inert atmosphere or coated with a light hydrocarbon oil to protect them from the atmosphere.

Crystal data for **5** were collected on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), μ(Mo Kα) = 3.467 mm^{-1}. The data were corrected for Lorentz and polarization effects. After refinement with isotropic displacement parameters for all atoms, an absorption correction based on the least-squares filled against $|F_c| - |F_o|$ differences was also applied [39].

Minimum and maximum value of the absorption correction factors ranging between 0.726 and 1.495. Data reduction and analysis were carried out with Kuma Diffraction (Wrocław) programs. The structure was solved by heavy-atom methods using the SHELXS-97 program [40] and refined by a full-matrix least-squares method on all F^2 data using the SHELXL-97 program [41] to $R_1 = 0.0305$ and $wR_2 = 0.0691$. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were located according to HFIX procedure using the SHELXL-97 program [41].

4. Supplementary material

Crystallographic data have been deposited at the Cambridge Crystallographic Data Centre with deposition no. 174363. 2. Experimental

All the equipment and procedures used have already been described in the previous papers [3–8]. In particular the synthesis of thiocyanogen and sulfur dicyanide has already been detailed in Refs. [5,6]. The chemical synthesis of polythiocyanogen $[S_2(CN)_2]_x$ has already been reported in Refs. [3,5]. The electrochemical synthesis of polythiocyanogen $[S_2(CN)_2]_x$ has been described both in Refs. [4,7]. The synthesis of all the series of polythiocyanogens $[S_y(CN)_2]_x$ with $y = 1$, 2, 3 and 4 is detailed in the patent of Ref. [8] and/or will be reported in another future work. In the reaction of polythiocyanogens with NaCN or Na_2S we have followed the procedure already described in Ref. [5]. The triazine-based monomeric model compounds trithiocyanuric acid sodium salt has been prepared by reacting trichlorotriazine with sodium sulfide (see Refs. [3–5]). The polymerisation of trithiocyanuric acid with iodine to produce compound **1** of Scheme 1 has been described in Ref. [5]. The procedure to follow the polymerisation of thiocyanogen on a KBr plate described in Ref. [5] has been applied in the present work to follow also the polymerisation of tetrasulfur dicyanide $S_4(CN)_2$.

Scheme 1.

2.1. Preparation of $S_4(CN)_2$ and study of its polymerisation over a KBr plate

In a two necked round bottomed flask with condenser and magnetic stirrer, S_2Cl_2 (2.0 g) was added dropwise to a stirred suspension of $Pb(SCN)_2$ (5.0 g) in CH_2Cl_2 (80 ml) at r.t. For the addition of S_2Cl_2 use was made of a dropping funnel. The reaction is slightly exothermic since CH_2Cl_2 is refluxing at the end of the addition. After having stirred for 1.5 h at r.t. the resulting $PbCl_2$ formed was decanted from the solution. The $S_4(CN)_2$ solution in CH_2Cl_2 shows a maximum at 253 nm followed by a shoulder at about 300 nm. $S_2(CN)_2$ in the same conditions show a maximum at about 250 nm followed by another maximum at 294 nm.

The solution of $S_4(CN)_2$ is reasonably stable for about 1 week if kept in a cool place in a tightly closed flask in the dark. However, if a few drops of the solution are put over a substrate, as soon as almost all the CH_2Cl_2 evaporates a quick polymerisation reaction takes place with the formation of a brick-red–orange solid. Thus a few drops of the solution were placed on a KBr plate and the polymerisation was followed immediately after the almost complete evaporation of CH_2Cl_2. The IR spectral changes are reported in Figs. 1 and 3. A similar procedure has been adopted to follow the polymerisation of $S_2(CN)_2$ after its preparation according to the method reported in Ref. [5]. The spectra of polymerising $S_2(CN)_2$ are reported in Fig. 2.

2.2. Preparation of $S(CN)_2$ and its thermal polymerisation in refluxing acetic acid

AgCN (9.1 g) was suspended in 70 ml of CH_2Cl_2 in the same apparatus described above. Sulfur dichloride SCl_2 (3.3 g) was added dropwise and then the mixture was stirred at r.t. for 1.5 h before the decantation of the AgCl formed. The evaporation of all the solvent at reduced pressure in a water bath leaves a residue of white crystals mixed with orange–red polythiocyanogen. Sublimation of this crude residue gives white tabular crystals on the top of the flask. The FT-IR spectrum of these crystals is perfectly coincident with that reported in Ref. [5] for $S(CN)_2$. The solution of these crystals in acetonitrile shows a maximum at 224 nm and another maximum at 235 nm. A shoulder appears at 324 nm. The residual matter remained in the bottom of the flask after the sublimation appears as a rusty-brown solid. The yield was 1.34 g. The spectrum of this polymeric mass is shown in Fig. 4(D) and it corresponds to that of a polythocyanogen.

The white sublimed crystals (abut 500 mg) were dissolved in 5 ml of acetic acid and refluxed for 15 h. At the end of the thermal treatment the mixture appeared as orange–red. The polymer was insoluble in acetic acid and was recovered by filtration, washed with

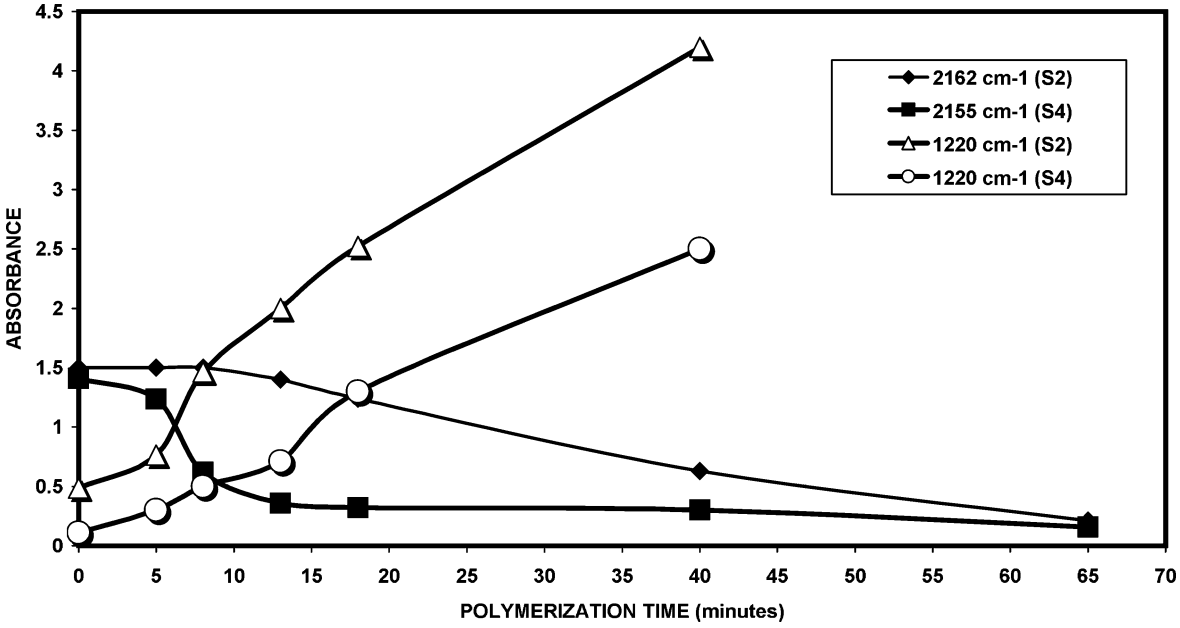

Fig. 1. Kinetics of $S_2(CN)_2$ and $S_4(CN)_2$ polymerisation followed by FT-IR spectroscopy.

abundant water and acetone and left to dry. The yield was almost quantitative. The spectrum of this $[S(CN)_2]_x$ is shown in Fig. 4(C) and corresponds to that of a polythiocyanogen.

2.3. Preparation of the triazine-based model compound **1** (Scheme 1) by the action of S_2Cl_2 over trithiocyanuric acid sodium salt

Trithiocyanuric acid (1.0 g) is dissolved in 20 g of dimethyl sulfoxide (DMSO) and 0.68 g of NaOH are added. The mixture is heated and stirred and becomes bluish-green. On cooling the mass solidifies and a small volume of water (5 ml) was added to re-dissolve the mass. A rapid precipitation of a yellow mass occurred on dropwise addition of S_2Cl_2 (4.0 g) under stirring. The mixture was left overnight and the following day was diluted with acetone and filtered under reduced pressure. The filtrate was washed repeatedly with acetone and dried in air. The yield of recovered bright yellow material was 0.92 g. The FT-IR spectrum of this material is reported in Fig. 6(C) and agrees reasonably with the spectrum of polymeric trithiocyanuric acid prepared by the action of I_2 over $(SH)_3(CN)_3$ Fig. 6(B), Ref. [5].

2.4. Thermal treatments of polythiocyanogens $[S_2(CN)_2]_x$ and $[S_4(CN)_2]_x$ as well as model compound **1** of Scheme 1

The thermal treatment involved the use of 200 mg of each compound, respectively $[S_2(CN)_2]_x$ and $[S_4(CN)_2]_x$ as well as model compound **1** of Scheme 1. Each compound was put into a porcelain crucible with a cap and heated in a muffle at 300 °C for 1 h. After cooling the FT-IR spectra shown in Figs. 6(E) and 7(E and F) have been recorded.

3. Results and discussion

In the previous works [3–8] which were limited only to the study of the structure of parathiocyanogen the polythiocyanogen with $y = 2$ derived from the polymerisation of $S_2(CN)_2$, we have shown that parathiocyanogen does not possess a 1,3,5-triazine-based structure 1 (Scheme 1) as reasonably proposed by other researchers for a number of experimental facts.

i) The FT-IR spectrum of $[S_2(CN)_2]_x$ does not match the spectrum of a 1,3,5-triazine-based polymer prepared through a sure route which has the chemical structure 1 (see Scheme 1) originally expected for parathiocyanogen [3–5].
ii) The ^{13}C NMR spectrum of parathiocyanogen has a relatively broad signal at 186 ppm while trithiocyanuric acid $(SH)_3(CN)_3$ shows a narrow signal at about 145 ppm [4,5].
iii) The electronic spectrum of parathiocyanogen shows a maximum at 267 nm followed by another maximum at 440 nm while the 1,3,5-triazine-based model compound shows a maximum at 275 nm and another peak at about 350 nm [4,5].
iv) The X-ray powder diffraction pattern of $[S_2(CN)_2]_x$ is very peculiar showing only a relatively broad peak at $2\theta = 26$ (Cu Kα) while the triazine-based model compound is dominated by a series of reflections which are similar to those of cyclooctasulfur [5].

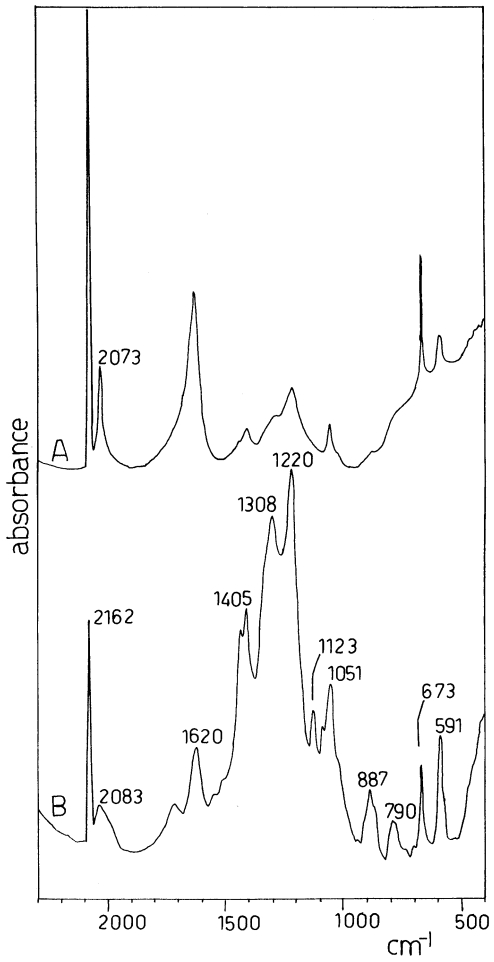

Fig. 2. (A) FT-IR of $S_2(CN)_2$ polymerisation: spectrum taken 7 min after the evaporation of the CH_2Cl_2 solvent from a KBr plate. This is the spectrum of the monomeric thiocyanogen and the incipient polymerisation product (band at 1220 cm^{-1}). (B) FT-IR of $S_2(CN)_2$ polymerisation product 21 min after solvent evaporation.

3.1. Aspects of the polymerisation of sulfur dicyanides (thiocyanogens)

In the present work, we have followed the $S_2(CN)_2$ and the $S_4(CN)_2$ polymerisation by leaving few drops of a fresh solution in CH_2Cl_2 of each pseudohalogen to evaporate spontaneously on a KBr plate and recording by FT-IR the spectral changes as function of time. When almost all the CH_2Cl_2 has been evaporated the polymerisation of the non-volatile pseudohalogen started ($t = 0$) immediately. The spectral changes are summarised in Fig. 1 and show two main trends: the decay in the optical density of the bands associated to the –CN stretching at 2162 and 2073 cm^{-1}, and the concomitant increase of a new main band at about 1220 cm^{-1}. Almost the same trend has been observed for both $S_2(CN)_2$ and $S_4(CN)_2$ as shown in Fig. 1 suggesting that in both cases the –CN groups were the reaction sites and the polymer is deriving just from the reaction of these groups. Visually, the polymerisation can be observed from the fact that the pseudohalogen thin film on the KBr plate becomes yellow, then yellow–orange, orange and red at the end of the reaction. At this final stage the film is hard and brittle.

The details of the spectral evolution during the polymerisation of $S_2(CN)_2$ are illustrated in Fig. 2(A and B). Fig. 2(A) refers to the early polymerisation stages and is dominated by the -CN stretching bands at 2162 and 2073 cm^{-1} as well as the C–S stretching at 670 cm^{-1} [6]. The incipient polymerisation is suggested in Fig. 2(A) by the weak bands at 1405, 1220 and 1051 cm^{-1}. The mentioned bands develop greatly their intensity (see Fig. 2(B)) as the polymerisation goes to completion with the simultaneous decay in intensity of the –CN stretching bands. These new bands are not associated to the 1,3,5-triazine ring formation as will be discussed in the next section.

Of extreme interest are the spectra shown in Fig. 3(A–D) and recorded on $S_4(CN)_2$ at increasing degrees of polymerisation. In fact these spectra show for the first time that also the superior homologue of thiocyanogen $S_2(CN)_2$, namely tetrasulfur dicyanide $S_4(CN)_2$, polymerises exactly as its inferior homologue, suggesting that all the family of the thiocyanogen or sulfur cyanides polymerise in the same fashion. In detail, Fig. 3(A) shows the spectrum of $S_4(CN)_2$ at the beginning of the polymerisation. Again the spectrum is dominated by the asymmetric and symmetric stretching of the –CN group, respectively, at 2155 and 2068 cm^{-1} and by the C–S stretching band at 668 cm^{-1}. The polymerisation involves the gradual development of a band at 1220 cm^{-1} (see Fig. 3(B–D)) which is accompanied by weak bands at 1405 and 1060 cm^{-1}. Simultaneously a decay on the –CN stretching band is observed. The new bands of the polymeric $[S_4(CN)_2]_x$ are located at the same wavenumbers as polymeric $[S_2(CN)_2]_x$ previously discussed. A comparison between the polymerisation kinetics of $S_4(CN)_2$ in comparison to $S_2(CN)_2$ is illustrated in Fig. 1.

Sulfur dicyanide is the most stable molecule of the series of thiocyanogens: it can be isolated as stable crystals. Elsewhere [6] we have discussed the reasons of this unusual stability. However, $S(CN)_2$ is not stable indefinitely. Even at r.t., under the action of moisture, light and heat it is converted into a brick-red polymeric material $[S(CN)_2]_x$. Fig. 4(A) shows the FT-IR spectrum of aged crystals of $S(CN)_2$: they are mixed with the polymeric derivative as suggested by the presence of the broad band at 1242 cm^{-1} together with the –CN band at 2186 cm^{-1} and the C–S band at 678 cm^{-1} due to the monomer. The progression of the polymerisation at r.t. is shown in Fig. 4(B) where, as usual, a reduction of the intensity of the band at 2186 cm^{-1} (–CN stretching) corresponds to the development of the broad band at 1240–1220 cm^{-1}. $S(CN)_2$ can be completely poly-

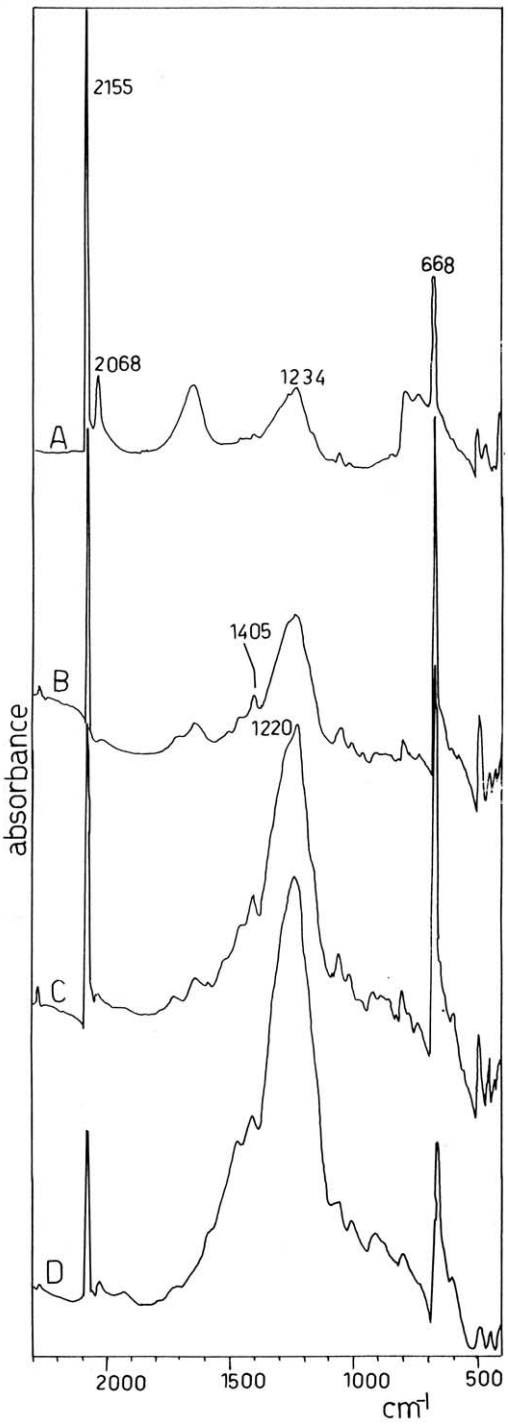

Fig. 3. (A) FT-IR of $S_4(CN)_2$ polymerisation: spectrum taken 5 min after the evaporation of the CH_2Cl_2 solvent from a KBr plate. This is the spectrum of the monomeric tetrasulfur dicyanide and the incipient polymerisation product (band at 1220 cm^{-1}). (B) FT-IR of $S_4(CN)_2$ polymerisation product 10 min after solvent evaporation. (C) FT-IR of $S_4(CN)_2$ polymerisation product 15 min after solvent evaporation. (D) FT-IR of $S_4(CN)_2$ polymerisation product 45 min after solvent evaporation.

merised when heated in refluxing acetic acid; the spectrum of the corresponding $[S(CN)_2]_x$ is shown in Fig. 4(C).

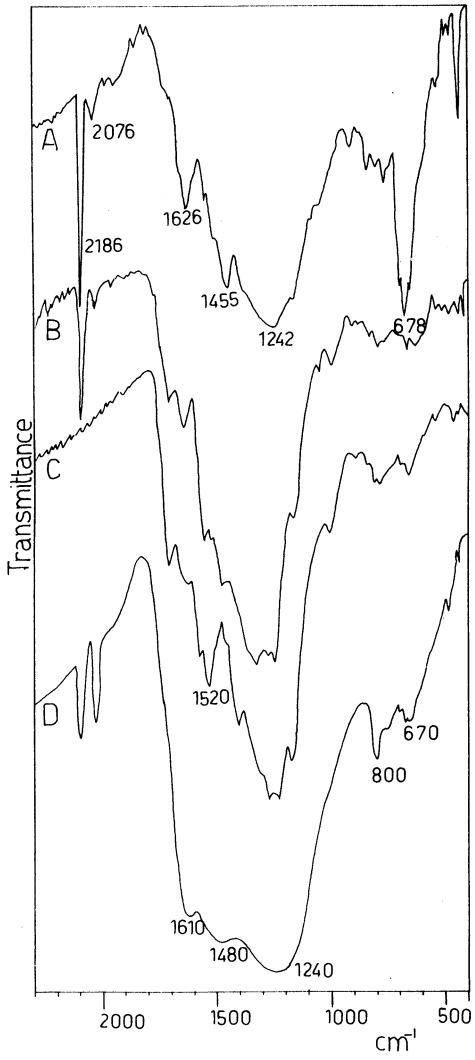

Fig. 4. (A) FT-IR of partially polymerised $S(CN)_2$. (B) FT-IR of polymerised $S(CN)_2$ at r.t. after several weeks. (C) FT-IR of polymerised $S(CN)_2$ after refluxing in acetic acid for 15 h. (D) FT-IR of polymerised $S(CN)_2$ formed in the bottom of the flask after the thermal treatment for the sublimation recovery of pure $S(CN)_2$.

The experimental evidences are now sufficient to affirm that all the sulfur cyanide family $S_y(CN)_2$ polymerise in the same way yielding polymers whose general structure may be described by the general formula:

$[S_y(CN)_2]_x$ with y and integer 1, 2, 3, 4, ...

and x an high number but unknown

All the polythiocyanogens show the same spectrum essentially characterised by a very strong and broad band centred at about 1220 cm^{-1} and by several other minor bands. Fig. 5 illustrates the concept by comparing the spectra of $[S_2(CN)_2]_x$, $[S_3(CN)_2]_x$ and $[S_4(CN)_2]_x$: it is clear the spectral identity and thus the structural identity of these polymers.

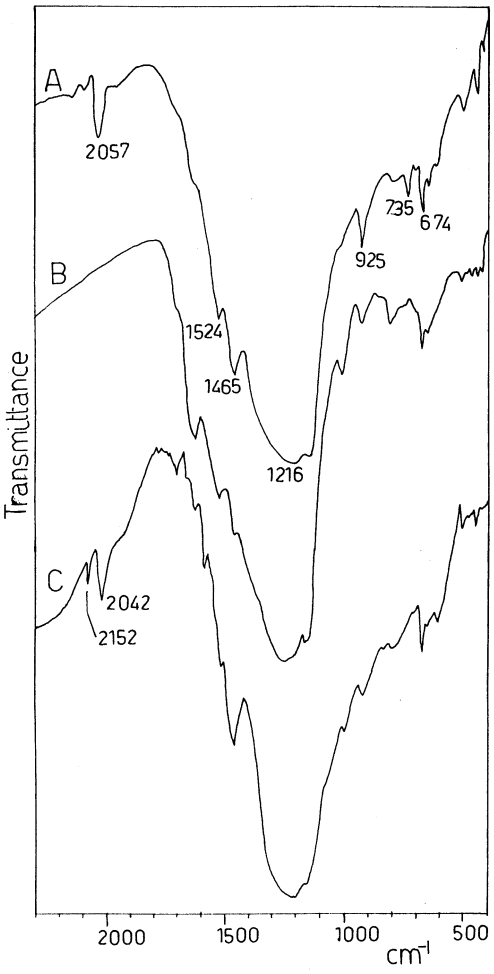

Fig. 5. (A) FT-IR of polymerised $S_2(CN)_2$: polythiocyanogen $[S_2(CN)_2]_x$. (B) FT-IR of polymerised $S_3(CN)_2$: polythiocyanogen $[S_3(CN)_2]_x$. (C) FT-IR of polymerised $S_4(CN)_2$: polythiocyanogen $[S_4(CN)_2]_x$.

Thus the provisory conclusions we can draw at this stage is that despite the different length of the sulfur bridges connecting the –CN end groups, the latter polymerise in the same way. Therefore, it appears that the –CN groups are transformed into derivatives having the same chemical structure. Since nitrile groups are prone to trimerise into 1,3,5-triazine rings, the simplest explanation for the polymerisation of all sulfur dicyanides is the formation of 1,3,5-triazine rings connected together by sulfur bridges. The length of the sulfur bridges depends on the original chain length of the starting monomeric sulfur dicyanide. This interpretation has been proposed by Feher et al. in 1956 [9].

3.2. The FT-IR spectra of the 1,3,5-triazine-based polymers with sulfur bridges do not match the spectra of polythiocyanogens

As illustrated in Scheme 1 we have prepared trithiocyanuric acid by reacting trichlorotriazine with disodium sulfide and we have polymerised the trithiocyanuric acid by the action of iodine or by reacting the sodium salt of trithiocyanuric acid with sulfur monochloride (Scheme 1, structure 1). In the last two cases we have obtained through two different sure routes the chemical structures expected from the polymerisation of sulfur cyanides or thiocyanogens, supposing that they trimerise into triazine rings. Fig. 6(A–C) illustrate the FT-IR spectra of both trithiocyanuric acid (Fig. 6(A)) and its polymers with S_2 (Fig. 6(B)) and polysulfide bridges (Fig. 6(C)): if we compare these spectra with those of $[S_y(CN)_2]_x$ for instance shown in Fig. 5, it appears immediately evident that the polythiocyanogens cannot have the triazine-based structure. First of all the triazine-based structure is characterised by the out-of plane bending of the triazine ring which is located at 783 and 751 cm^{-1} in the monomeric trithiocyanuric acid (Fig. 6(A)) and is shifted to higher wavenumbers after the polymerisation. In fact the triazine ring bending appears at about 823 cm^{-1} in Fig. 6(B and C) both referring to the polymeric triazine structure 1 (Scheme 1). This characteristic band is weak or completely absent in the case of the $[S_y(CN)_2]_x$ (see Fig. 5). Other characteristic triazine bands present in the spectrum of Fig. 6(A) are the very strong bands at 1540 and 1362 cm^{-1} respectively due to quadrant and semicircle triazine ring stretch [10]. After polymerisation these two bands are still detectable at 1480 and 1242 cm^{-1}, shifted to shorter wavenumbers (see Fig. 6(B and C)). In any case these spectra cannot be compared with those of polythiocyanogens of Fig. 5. Thus, once again structure 1 is not the structure of polythiocyanogen.

3.3. Some chemical aspects of polythiocyanogens: their reaction with sodium sulphide and sodium cyanide

Although polythiocyanogens do not display the same FT-IR spectra of the triazine-based polymer, they are reduced to polymeric trithiocyanuric acid (Structure 1, Scheme 1) when they are treated with sodium sulfide in water solution (see Ref. [5]). This is evident by comparing Fig. 7(A) and especially Fig. 7(B) with the spectra of Fig. 6(C and B). This is the first indication that polythiocyanogens undergo a structural isomerisation to a triazine-based polymer. Thus the Na_2S treatment causes the passage from structure 4 to 1.

Another interesting reaction, which can be observed on the polythiocyanogens, involves their treatment with NaCN. Sodium cyanide is able to abstract sulfur from the polysulfide bridges of structure 4, with the consequent formation of NaSCN, causing the passage from structure 4 to 2 of paracyanogen (see Scheme 1). This is documented by the spectra of Fig. 7(D and E) which should be compared with the IR spectra of the pristine samples shown in Fig. 5. The formation of paracyanogen $(CN)_x$ by sulfur abstraction from polythiocyano-

gens $[S_y(CN)_2]_x$ is suggested by the development of new bands at 1630–1640 and at about 1500 cm^{-1} which

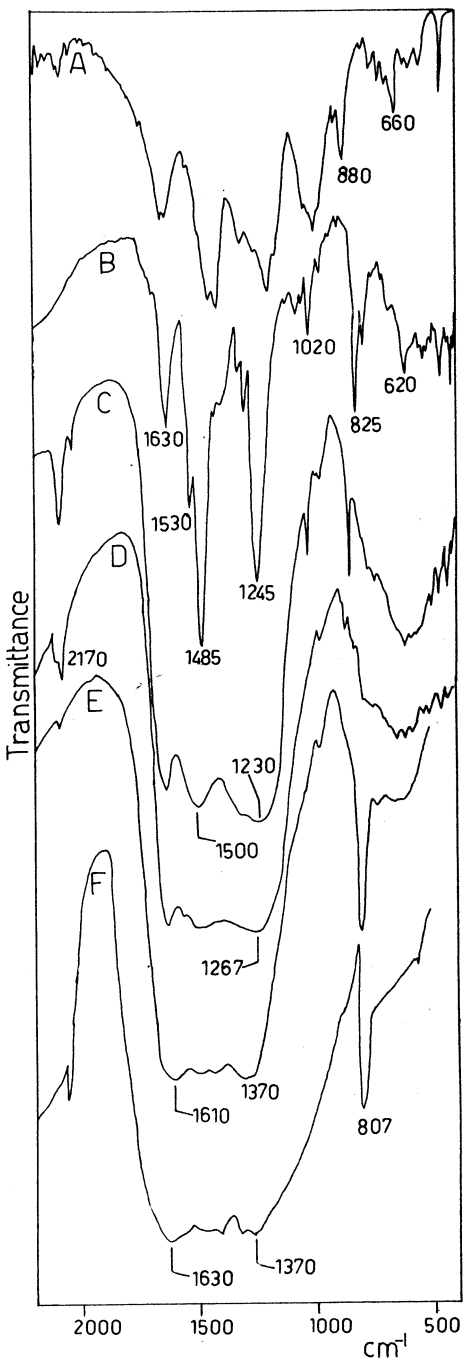

Fig. 7. (A) FT-IR of polythiocyanogen $[S_2(CN)_2]_x$ after the treatment with Na_2S according to Ref. [5]. The spectrum is now that of 1,3,5-triazine-based model compound **1** of Scheme 1; compare with Fig. 6(B and C). (B) FT-IR of polythiocyanogen $[S_4(CN)_2]_x$ after the treatment with Na_2S according to Ref. [5]. The spectrum is now that of 1,3,5-triazine-based model compound 1 of Scheme 1; compare with Fig. 6(B and C). (C) FT-IR of polythiocyanogen $[S_2(CN)_2]_x$ after the treatment with NaCN according to Ref. [5]. The spectrum is now that of paracyanogen structure 2, Scheme 1. (D) FT-IR of polythiocyanogen $[S_4(CN)_2]_x$ after the treatment with NaCN according to Ref. [5]. The spectrum is now that of paracyanogen structure 2, Scheme 1. (E) FT-IR of polythiocyanogen $[S_2(CN)_2]_x$ after thermal treatment at 300 °C. The spectrum is now that of paracyanogen structure 3, Scheme 1. reach the same intensity as the band at 1220 cm^{-1} as shown in the spectra of Fig. 7(C and D).

The other aspect, which links again (by chemical behaviour) the triazine, based polymer and the polythiocyanogens is the treatment with sodium cyanide of the former (according to Ref. [5]). In fact when the polymeric triazine compound (structure 1, Scheme 1) is treated with NaCN, sulfur abstraction occurs as well because of the formation of NaSCN and the IR spectrum changes into that of paracyanogen $(CN)_x$ as illustrated in Fig. 6(D). This spectrum is characterised by the intense and broad band at 1640–1450 cm^{-1} and by the triazine ring band at 878 cm^{-1} but by the absence of the intense band at 1230–1260 cm^{-1} observed in the paracyanogen obtained from polythiocyanogens. Therefore, the triazine-based polymer of structure 1 is transformed into the triazine isomer of paracyanogen (structure 3 of Scheme 1) when treated with NaCN. Conversely, the polythiocyanogens with structure 4 are converted into ladder paracyanogen of structure 2 upon NaCN treatment.

Elsewhere [11–13] we have already discussed about paracyanogen $(CN)_x$ and about its formation from the photopolymerisation of dicyanogen $(CN)_2$ and about the synthesis and the existence of a triazine-based isomer of paracyanogen having structure 3, in addition to the well known ladder paracyanogen of structure 2 (Scheme 1). The spectrum of Fig. 6(D) is analogous to the IR spectrum of the triazine-based isomer of paracyanogen $(CN)_x$ with structure 3 of Scheme 1 which we have prepared through a sure route [11–13].

Furthermore, the thermal treatment at 300 °C of both the polythiocyanogens and the triazine-based polymer transform both these macromolecules into paracyanogen as clearly suggested by the spectra of Figs. 6(E) and 7(E and F), with release of detectable free sulfur vapours. After this thermal treatment there are no doubts about the fact that both the polythiocyanogens having structure 4 and the triazine polymer of structure 1 have been transformed into paracyanogen. In fact the spectra of Figs. 6(E) and 7(E and F) are completely comparable with those of the paracyanogen prepared by Bircumshaw et al. [14]. It is of particular interest that all the spectra just mentioned show an intense band at 807 cm^{-1} which could be assigned also to a triazine ring and hence the paracyanogen formed from both the model compound and the polythiocyanogens may be the triazine isomer of Scheme 1 structure 3.

3.4. Further reflections and discussions about the structure of polythiocyanogens

Among the data discussed in the preceding paragraph, these are still some puzzling result concerning the structure assignment of the polythiocyanogens. In fact the treatment with sodium sulfide of $[S_y(CN)_2]_x$ favours the idea that polythiocyanogens may have structure 5 instead of structure 4 (Scheme 1) where we have represented a polymer with triazine rings having both possible tautomers (thioketo and sulfidic form). In this context it is useful to recall that thiocyanic acid is an unstable molecule and trimerises to trithiocyanuric acid which is in tautomeric equilibrium with its trithioketo form (isothiocyanuric acid trimer) as illustrated in Scheme 1 structure 6.

Structure 5 reported in Scheme 1 is in fact able to justify why the polythiocyanogens show an FT-IR spectrum different from that of triazine polymers with structure 1. The strong band at 1220 cm^{-1} in fact could reasonably be assigned to the thioketo group C=S which absorb just in this spectral region [15]; additionally the spectrum of 1,3,5-triazine-2,4,6-trithione shows a strong band at 1140 cm^{-1} which is shifted to 1210 cm^{-1} in the parent compound 1,3,5-triazine-2,4-amino-6-thione [15]. Moreover in these compounds the triazine ring bending is weak or absent, as in the case of polythiocyanogens spectra of Fig. 5. Structure 5 for polythiocyanogens may also be able to explain their orange and red colour since the chromophore will be just the C=S group and the quinoid structures associated (see structure 5). Of course, with structure 1 it is almost impossible to explain the orange–red colour of polythiocyanogens.

Thus it appears reasonable to think that when the sulfur dicyanides polymerise, they form triazine rings containing also thioketonic groups as shown in Scheme 1 structure 5. The treatment of these polymers with sodium sulfide causes the rearrangement of the structure 5 to the structure 1 (Scheme 1). The treatment with NaCN, being an alkaline agent probably causes the passage from structure 5 to 1 and simultaneously causes the partial abstraction of sulfur from the polysulphidic bridges connecting the triazine rings leading to both structure 1 with $y = 1$ or directly to structure 3 (see Scheme 1) which is the structure of the triazine-isomer paracyanogen. However, in the previous paragraph we have already shown that the treatment of polytiocyanogens with NaCN is leading to paracyanogen with the ladder structure 2 and not with the triazine isomer with structure 3. Thus this fact strongly supports structure 4 for polythiocyanogens rather than structure 5.

Furthermore, the strong heating of both polythiocyanogens and also the triazine-based model polymer (structure 1) causes the extrusion of sulfur and the passage to structure 3 in both cases. This fact does not necessarily support structure 5 for polythiocyanogens since one can expect a rather easy decomposition and thermal depolymerisation from structure 5 rather than its rearrangement to structure 3.

Additional data, which are against structure 5 for polythiocyanogens, are provided by ^{13}C NMR spectroscopy. We have already excluded that the polythiocyanogens have a triazine-based structure 1 because the

trithiocyanuric acid shows a peak at 145 ppm while $[S_2(CN)_2]_x$ shows a broad peak at 186 ppm [4,5]. Thus the newly proposed structure 5 is not correct because it requires at least two ^{13}C NMR signals: one for the C=S group which is expected at about 200 ppm or at lower field and the triazine signal at 145 ppm. Since we have recorded only a unique peak at 186 ppm [5], it is now allowed to drop the structure 5 as the corrected structure for polythiocyanogens.

In our previous works we have proposed a linear structure for polythiocyanogen $[S_2(CN)_2]_x$. The possible linear structures are 7 and 8 (see Scheme 1) and have also been proposed by Skorobogatova et al. [16]. However structure 8 can be phased out because the ^{13}C NMR of $[S_2(CN)_2]_x$ shows only one peak at 186 ppm while from structure 8 two different ^{13}C signals are expected but have not been observed [4,5]. Furthermore, the –SCN stretching band is not always present in the IR spectra of polythiocyanogens and if present is always weak while for structure 8 it is expected to be strong.

Structure 7 is coherent with the ^{13}C NMR spectrum of $[S_2(CN)_2]_x$ but it appears to be not extremely stable. The criticism against this structure is that it could easily undergo a crosslinking reaction with adjacent chains so that it cannot survive for long time under the form of 7 but other more complex networked structures should be derived easily from 7.

The discovery that all polythiocyanogens $[S_y(CN)_2]_x$ have essentially the same IR spectrum and hence the same chemical structure also creates problems with structure 7 since it becomes difficult to explain why the introduction of a different number of sulfur atoms in the polymer backbone does not alter at all either the FT-IR spectrum or the UV spectra of the series.

In fact, the introduction of more than one sulfur atom in the chain structure 7 must necessarily reduce the conjugation along the chain and the electronic spectra should change abruptly by passing from $y = 1$ to 2 and then to $y > 2$ but this is not observed experimentally for all the polythiocyanogen series as outlined in Fig. 8, where the electronic spectra in DMSO are very similar to each other from $y = 1$ to 4 showing essentially two absorption bands in all series. One of the absorption bands is located at about 270 nm and other one in the range of 375–410 nm. Moreover the colour of all the polythiocyanogen series is invariably orange to brick-red but if structure 7 is correct we should expect a gradual shift from red to orange, to yellow, to pale yellow as the length of the sulfur bridge increases for $y \to \infty$.

3.5. Attempt to interpret the spectral data and the chemical data in a unique coherent model

All the discussion in the previous paragraphs has shown that structure 5 is not satisfactorily describing the structure of polythiocyanogens, although it has some merit. Conversely, structure 8 and especially structure 7 which were originally proposed by us [3–5] and by

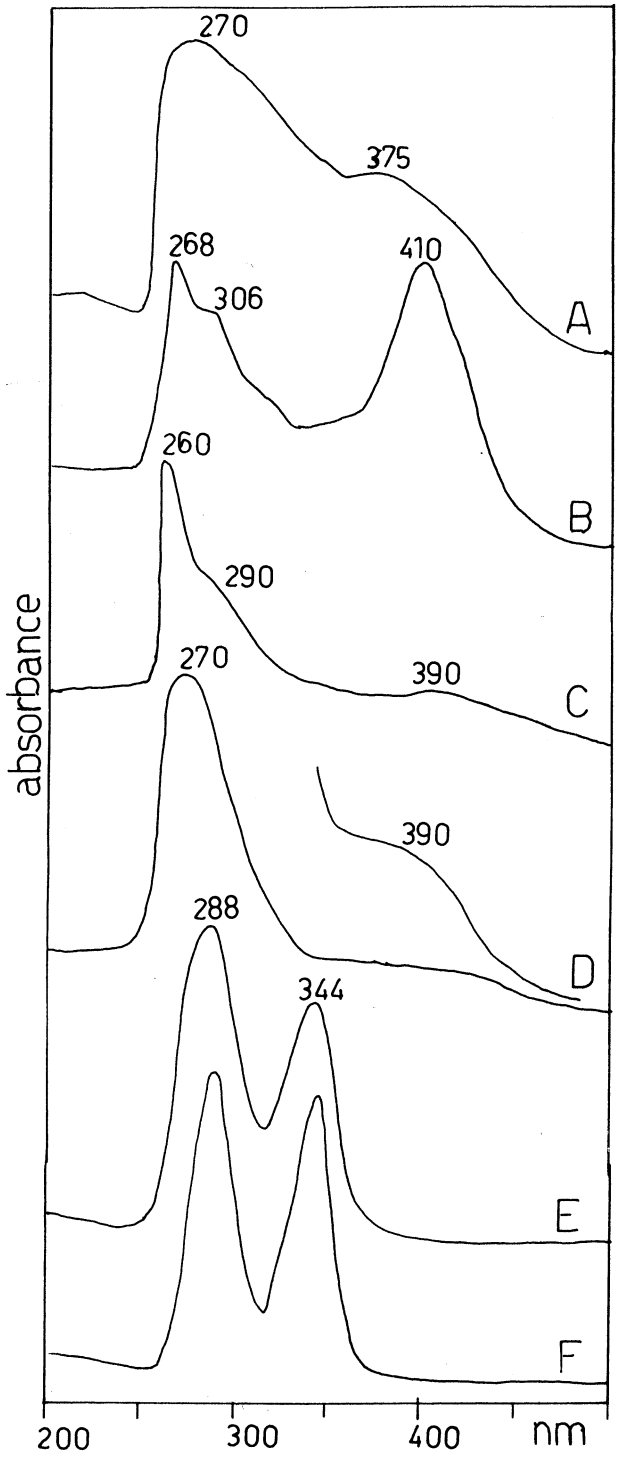

Fig. 8. (A) Electronic spectrum of $[S(CN)_2]_x$ in DMSO solvent. (B) Electronic spectrum of $[S_2(CN)_2]_x$ in DMSO solvent. (C) Electronic spectrum of $[S_3(CN)_2]_x$ in DMSO solvent. (D) Electronic spectrum of $[S_4(CN)_2]_x$ in DMSO solvent. (E) Electronic spectrum of trithiocyanuric acid in DMF solvent. (F) Electronic spectrum of compound **1** of Scheme 1 in DMF solvent.

others [16] present too many flaws in front of the experimental data available. Thus the structure of polythiocyanogens can be represented as structure 4 of Scheme 1. Let us summarise the reason for this choice and proposal:

i) dicyanogen NC–CN can be considered the most inferior homologue of the polythiocyanogen series of $[S_y(CN)_2]_x$; in fact when $y = 0$ we get $[(CN)_2]_x$. It polymerise thermally [14] and under the action of the UV light [11–13] into a polymer having essentially a polypyrazino–pyrazine ladder structure 2 (see Scheme 1). The ladder structure 2 is a little bit of an idealised structure because recently ourselves [11,13] and other authors [17,18] have proposed a more disordered structure derived from structure 2. However, in the frame of our discussion here we can utilise the structure 2. In normal conditions dicyanogen does not polymerise into the polytriazine structure 3 [11,13,17,18].

ii) Therefore, it is reasonable to think that also the superior homologues of dicyanogen, those containing S (so that when $y > 0$ the general formula is $[S_y(CN)_2]_x$) should polymerise in the same fashion of dicyanogen giving polyazomethine chains connected together by sulfur bridges (structure 4, Scheme 1) rather than the triazine rings of structure 1. Many experimental facts can be explained with this model.

iii) First of all, the structure 4 proposed for polythiocyanogens explains well both the FT-IR spectra and the electronic spectra of the series and the fact that these spectra appear exactly the same for all the polythiocyanogen series. Concerning the strong infrared band at about 1220 cm^{-1} we should not anymore advocate the thioketonic C=S stretching band which has been postulated in the case of structure 5. Instead the band at 1220 is due to the polyazomethine chain which, due to the tight sulfur crosslink of structure 4, causes the shift of this band from 1600 to 1450 cm^{-1} (typical paracyanogen band, see Refs. [11–14]) to about 1250–1220 cm^{-1}. Furthermore, structure 4 explains well the electronic spectra of polythiocyanogens of Fig. 8 and the colour of these polymeric compounds which does not change as function of the sulfur chain length. The polyazomethyne chain of structure 4 is a sequence of single and double bonds and this explains well the long wavelength transition at 380–410 nm observed in the electronic spectra of Fig. 8(A–D) for all the polythiocyanogen series. Thus, the polyazomethyne chain is the chromophore for all the polythiocyanogen series. As expected, the triazine-based structure 1 cannot display any transition at so long wavelengths due to the lack of conjugated chains. In fact, both the compound having structure 1 and the parent compound trithiocyanuric acid (structure 6) show the longest transition at only 344 nm (see Fig. 8(E and F)). In the case of the alternative structure 5 for polythiocyanogen series we were forced to introduce the ad hoc hypothesis of the presence of the thioketo (C=S) groups which should cause the transition at 400 nm or even at longer wavelength.

iv) The ^{13}C NMR spectrum of polythiocyanogen $[S_2(CN)_2]_x$ shows a unique broad band at 186 ppm [5]. The paracyanogen ^{13}C MAS NMR spectrum appears at about 158–150 ppm [17] while the spectrum of triazine ring shows just one unique sharp carbon signal at 145 ppm [4]. Initially we have thought that the signal at 186 ppm was the proof for the linearity of $[S_2(CN)_2]_x$ but in the preceding section we have explained the reasons which have led us to abandon the linear structure 7: the intrinsic instability of that structure together with the fact that it cannot explain many properties of all $[S_y(CN)_2]_x$. At this point, the peculiar peak at 186 ppm is assigned to the carbon atoms present in the azomethine chains connected with sulfur bridges of structure 4 (Scheme 1). The connection of the azomethine chains with sulfur bridges causes a deshielding of the carbon atoms which appear at 20 ppm downfield in comparison to the usual chemical shift of an azomethine chain not connected with sulfur. In fact the azomethine chain is expected to give a ^{13}C NMR signal at about 167 ppm in imines, oximes and hydrazones [19] and it is reported to appear at 158–150 ppm in the solid state spectra of paracyanogen. Thus a shift of 20 ppm downfield is expected for sulfur substitution [19] and leads to a value just at about 186 ppm as experimentally found.

v) The treatment of the polythiocyanogen series with NaCN causes the formation of ladder parathiocyanogen as suggested by the FT-IR spectra of Fig. 7(C and D) confirming that the correct structure of polythiocyanogen is 4 of Scheme 1. Conversely, the triazine-based polymer with structure 1 is transformed into the triazine-isomer of paracyanogen with structure 3 when treated with NaCN. The thermal treatment of both polythiocyanogens with structure 4 and the triazine polymer with structure 1 involves the elimination of sulfur and causes their transformation into paracyanogen with presumable structure 3 as documented by FT-IR spectroscopy (Figs. 6(E) and 7(E–F)). There is no clear mechanism for the passage from structure 2 to 3, but the FT-IR of the thermally processed polythiocyanogens suggest that the final structure is structure 3, the same obtained by thermal processing of the triazine-based structure 1 (see discussion in the

preceding sections). The sodium sulfide treatment of the polythiocyanogen series converts structure 4 into 1. This is again the passage from a ladder structure to a triazine structure and is documented by the FT-IR spectra of Fig. 7(A and B). Sulfur abstraction may cause the direct isomerisation and cyclisation from structure 4 to 3 although the mechanism is not yet clear.

4. Conclusions

On the basis of a considerable body of experimental facts which have been reviewed step-by-step the conclusion has finally been reached that polythiocyanogens of $[S_y(CN)_2]_x$, the red–orange polymeric materials derived from the polymerisation of the thiocyanogens or sulfur cyanides of $S_y(CN)_2$ (with y an integer 1, 2, 3, 4...) have the structure 4 of Scheme 1. This structure is characterised by two long polyazomethine chains connected together by sulfur bridges of different length. The linear structure originally proposed has now been rejected due to various reasons including the experimental evidences.

scopic properties of perchlorate complexes containing trivalent rare earth ions. The perchlorate anion (ClO_4^-) has been chosen due to its poor ability to coordinate to metal ions; this is useful for the investigation of the influence of ligands on metal ions in solution in the absence of anionic interference. However, in some compounds [13–15] vibrational spectroscopy and conductance data have shown that some perchlorate groups are coordinated to the rare earth ion as monodentate or chelating bidentate ligands. The formation of the complexes between the perchlorate group and RE^{3+} ions has been explained in terms of hard acid–base interactions, which are predominantly electrostatic. Furthermore, the coordination sphere of the rare earth ions is large enough to accept several bonds, which favour the competition between the perchlorate anion and water or organic solvents. A detailed study on the perchlorate anion and its coordination modes in complexes was reported by Pascal and Favier [16].

N-(2-Pyridyl)acetamide and some related amides serve as model compounds for the study of polypeptides and proteins conformation, their vanadium(III) and oxovanadium(IV/V) complexes also have been used to investigate the interaction between vanadium and proteins in biological systems [17]. Some complexes between transition metals and trivalent rare earth ions with *N*-(2-pyridyl)acetamide and derived ligands were previously characterized and studied, showing that this ligand is chelating bidentate to the metal ions by using heterocyclic pyridinic nitrogen and oxygen amide atoms [18–20]. Recently, theoretical studies [21] of the complexes containing trivalent rare earth ions and pyridine and amide as ligands indicate that the metal–ligand interaction increases with the electron donating character of the substituent.

Perchlorate complexes of Eu with *N*-(2-pyridyl)acetamide ligand [20] showed high luminescence and it was observed by vibrational spectroscopy and conductance data that the ClO_4^- anions were not coordinated to the metal.

This work describes the synthesis, characterization and study of the influence of the methyl group in the 3, 4 and 6 positions on the pyridine ring of the *N*-(2-pyridyl)acetamide ligand in the luminescent properties of the Eu(III)-complexes with these ligands.

2. Experimental

2.1. Synthesis of the ligands and Eu(III)-perchlorate complexes

The *x*-mpa ligands (where mpa = *N*-[methylpyridyl]acetamide and $x = 3$, 4 and 6) were synthesized by the method described by Bould and Brisdon [19]. A mixture of 0.048 mol of 2-amino *x*-methylpyridine and 0.06 mol of Ac_2O was heated on a steam bath and remained under stirring. After 30 min, water ($\sim$100 ml) was added to the mixture to hydrolyze the excess of Ac_2O. The resulting solution was maintained under stirring for 1 h. The AcOH formed in the mixture was neutralized with $NaHCO_3$ and the ligand was extracted from the solution with $CHCl_3$ solvent. The solid product was recrystallized from ether to give large colorless crystals with efficiency of 70% and dried under in a desiccator vacuum over anhydrous $CaCl_2$.

The Eu(III)-perchlorate complexes were prepared by direct reaction between ethanolic solutions of the ligand and Eu(III)-perchlorate, in the molar ratio ligand–metal of 3:1, at room temperature (r.t.) and under stirring. The complexes precipitated immediately after addition of the Eu(III)-perchlorate solution, which were filtered, washed with EtOH and dried in vacuum in a desiccator. The complexes are not hygroscopes, except for the one with the 6-mpa ligand.

2.2. Measurements

The ^1H NMR spectra of the ligands were recorded on a Varian Unit 300 MHz spectrometer in $CDCl_3$ at r.t. with TMS as an internal standard.

The IR absorption spectra of solid samples were recorded in the range of 400 up to 4000 cm^{-1} in KBr plates using a Perkin–Elmer model 180 spectrophotometer. The Raman spectra of the complexes were obtained using a Renishaw Raman spectrometer. The laser power was approximately 7 mW.

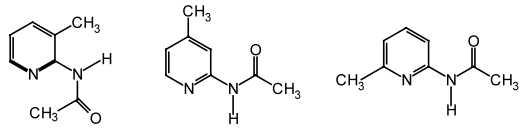
The carbon, hydrogen and nitrogen percentages were obtained from elemental analyses. The Eu(III) content was determined by complexometric titration with EDTA (0.01 mol l^{-1}) using xylenol orange as indicator.

The conductance measurements of the complexes were carried out in methanolic millimolar solution at r.t. using an equipment composed of a Leeds and Northrup 4760 resistance box, a 2370 a.c. pointer galvanometer and a cell with $K_C = 0.00962$ cm.

The thermogravimetric curves were recorded on a Shimatzu model TGA thermobalance at a heating rate of 10 °C min^{-1} in a nitrogen dynamic atmosphere of 10 ml min^{-1} from r.t. to 900 °C.

The luminescence spectra were obtained using a spectrofluorimeter Spex 212L with a 450 W xenon lamp. The signal was detected using a water-cooled Hammamatsu R928 photomultiplier. The excitation spectra were obtained using both monochromator and lamp corrections. The luminescence spectra were obtained at room and liquid nitrogen temperature using a detector mode correction. This apparatus was fully controlled by a DM3000F spectroscopic computer.

3. Results and discussions



3.1. Characterization

The ^{1}H NMR data for the free ligands are summarized in Table 1. The 4- and 6-mpa ligands data have been interpreted in terms of a planar structure where the pyridine ring is trans to the methyl of the amide group (*Z* configuration), this is shown in Fig. 1(b and c), respectively. These configurations are stabilized due to strong dipole–dipole interactions between the pyridine ring and the acetamide group [22]. This supposition is in agreement with the presence of three protons at downfield ($\sim$8.25 ppm) due to the deshielding by larger anisotropic effects from the carbonyl group on these protons. On the other hand, for the 3-mpa ligand, the presence of a substituent on the aromatic ring may produce a deviation from the planarity between the aromatic ring and the amide group to relieve the steric hindrance between 3-methyl pyridine ring and amide group.

The chemical shift of the acetyl methyl protons observed for the 3-mpa ligand (2.27 ppm) compared to those 4- (2.36 ppm) and 6-mpa (2.44 ppm) ligands is indicative that the acetyl methyl protons are situated in a region close to the plane of the pyridine ring where the shielding effect is operative [22]. These results indicate that the 3-mpa ligand has a conformation close to that illustrated in Fig. 1(a).

The rare earth percentages in the complexes were determined by complexometric titration with ethylenediaminetetraacetic acid disodium salt (EDTA) in aqueous solution. Whereas carbon, hydrogen and nitrogen contents were determined by microanalytical procedures. C, H, N and Eu(III) percentages (found/calculated) for $Eu(ClO_4)_3(x\text{-mpa})_n$ with the respective ligands are: 3-mpa (C, 31.93/32.01; H, 3.90/4.03; N, 9.42/9.33; Eu(III), 16.76/16.87%), 4-mpa (C, 32.46/32.01; H, 3.78/4.03; N, 9.82/9.33; Eu(III), 16.80/16.87%) and 6-mpa (C, 25.61/25.42; H, 2.68/3.53; N, 7.46/7.27; Eu(III), 20.24/20.34%). These data are consistent with the stoichiometries suggested.

According to the results of molar conductivities of a 10^{-3} M methanol solution, all complexes be have as 2:1 electrolytes, suggesting the coordination of only one perchlorate group to the Eu(III) ion. These results indicate that these complexes present two general formulae $[Eu(ClO_4)(x\text{-mpa})_3](ClO_4)_2$ (where $x = 3$ and 4) and $[Eu(ClO_4)\ (6\text{-mpa})_2](ClO_4)_2$.

(a) (b) (c)

Fig. 1. Molecular conformation of the *N*-[*x*-methylpyridyl]acetamide ligands: (a) 3-mpa; (b) 4-mpa; and (c) 6-mpa.

The IR (infrared) absorption spectral data of the free ligands and Eu(III)-perchlorate complexes are summarized in Table 2. It was observed the absence of broad bands around 3500 cm^{-1} (νOH) indicating that the coordination compounds with *x*-mpa ligands are anhydrous. The bands in the IR region used to diagnose the coordination of the ligands to the Eu(III) ion were those the amide I band (mainly of νC=O), amide II band (νC–N and δN–H), νC=C, νC=N and deformation modes of pyridine ring. If coordination occurs through the oxygen of the amide group, a shift of the amide I band to lower frequency is expected and, consequently, the amide II band will shift to a higher frequency, as compared with the spectrum of the free ligand. If coordination occurs through the nitrogen of the pyridine ring, a shift to higher frequencies of the νC=C and νC=N stretching and deformation bands of the pyridine ring is expected [19].

The amide I band in the complexes compared to the bands of the free ligands shows a displacement to lower frequencies, suggesting that the amide group is coordinated in all the complexes through the carbonyl oxygen atom. The νC=C and νC=N stretching and one deformation band of the pyridine ring around 620 cm^{-1} are shifted to higher frequencies upon coordination with the Eu(III) ion indicating that coordination also occurs through the pyridine nitrogen. Thus the *N*-(*x*-methyl 2-pyridyl)acetamide ligands have acted as chelating agents coordinating to the metal ion through both nitrogen pyridine and oxygen atoms.

The IR and Raman vibrational spectroscopies offer precious information about bonding modes of the perchlorate anion [16]. The ClO_4^- group in the ionic form has T_d symmetry and in the of IR spectral region

Table 1
^{1}H NMR chemical shifts of the free *N*-[methyl 2-pyridyl]acetamide ligands in $CDCl_3$

Ligands	δ (ppm)						
	Py–CH_3	CH_3–(C=O)	3-proton	4-proton	5-proton	6-proton	N–H
3-mpa	2.21	2.28		7.57	7.11	8.22	9.57
4-mpa	2.19	2.36	6.88		8.11	8.14	10.22
6-mpa	2.16	2.44	6.89	7.59	8.01		8.84

Table 2
Assignments in the IR spectra of the amide group and pyridine ring of the free and coordinated ligand in the Eu(III)-perchlorate complexes

Compounds	Amide I ν(C=O) [a]	Amide II	νC=C and νC=N (ring) [b]	δC=C and δC=N (ring) [c]
3-mpa	1669	1549	1592, 1457	620
$[Eu(3\text{-mpa})_3(ClO_4)](ClO_4)_2$	1658	1576	1617, 1466	637
4-mpa	1668	1550	1613, 1568	617
$[Eu(4\text{-mpa})_3(ClO_4)](ClO_4)_2$	1657	1533	1622, 1479	630
6-mpa	1661	1549	1600, 1458	619
$[Eu(6\text{-mpa})_2(ClO_4)](ClO_4)_2$	1653	1553	1630, 1458	629

[a] Very strong.
[b] Strong.
[c] Weak.

between 1200 and 1000 cm^{-1}, a strong broad band is generally observed, corresponding to the triply degenerate frequency ν_3. Under coordination to the metal ion the ClO_4^- ion is expected to undergo a lowering in the symmetry. If one or two of oxygen atoms are coordinated its T_d symmetry is lowered to C_{3V} or C_{2V} splitting the ν_3 band in the IR spectrum to give a doublet or triplet, respectively.

The IR spectra of the complexes with the 3- and 4-mpa ligands showed two strong bands well defined around 1088 and 1115 cm^{-1}, while in the Raman spectra these bands appear around 1077 and 1126 cm^{-1}. This can be assigned to the splitting of the frequency ν_3 of the ClO_4^- group, i.e. this group is acting as a monodentate ligand. On the other hand, the IR spectrum of complex with the 6-mpa ligand presented an additional band around 1174 cm^{-1} that is assigned to the lowering of the symmetry (C_{2V}) of the ClO_4^- group due to coordination to the rare earth ion through two oxygen atoms. These data are agreement with the molar conductance data indicating that in all complexes only one perchlorate group is coordinated to the Eu(III) ion.

The TG curves were obtained for the complexes $[Eu(ClO_4)(x\text{-mpa})_3](ClO_4)_2$ (where $x = 3$ and 4). The curves do not present weight loss in the temperature interval 25–180 °C, indicating that the complexes containing the 3- and 4-mpa ligands are anhydrous corroborating the IR data. On the other hand for the range 180–400 °C weight loss occurs in three consecutive stages, where the quantitative analyze on this interval show a good correlation between the experimental and calculated values considering releases of the all three ligands, it is in concordance with data of elemental analyses. In the next stage, in the temperature range from 400 to 900 °C, the thermal decomposition of the Eu(III)-perchlorate is observed. However, the TG curves are very complex in this interval, making it difficult to assign on the reaction that the perchlorate group undergoes. The thermogravimetric study on the complex containing the 6-mpa ligand is not possible due to its high hygroscopicity.

3.2. Photoluminescence study

Fig. 2 presents the excitation spectra of the complexes in the range of 250–500 nm at 77 K monitored at 612 nm. These spectral data present narrow absorption bands originated from f^6-configuration of the Eu(III) ion corresponding to the $^7F_0 \rightarrow {}^5H_4$ ($\sim$360 nm), $^7F_0 \rightarrow {}^5G_6$ ($\sim$375 nm), $^7F_0 \rightarrow {}^5L_6$ ($\sim$394 nm), and $^7F_0 \rightarrow {}^5D_2$ ($\sim$462 nm) transitions, while the broad absorption bands refer to the ligands. The spectra (Fig. 2(a and b)) corresponding to the $[Eu(ClO_4)(3\text{-mpa})_3](ClO_4)_2$ and $[Eu(ClO_4)(4\text{-mpa})_3](ClO_4)_2$ complexes are similar, but they are different from the one with the 6-mpa ligand (Fig. 2(c)). It is observed that the complexes with 3- and 4-mpa ligands present their maxima around 290 nm while the complex containing the 6-mpa ligand present a maximum around 320 nm.

The emission spectra recorded at 77 K in the region of the $^5D_0 \rightarrow {}^7F_J$ transitions (where $J = 0$–4) in the range 560–720 nm by exciting at the $^7F_0 \rightarrow {}^5L_6$ transition around 394 nm are shown in Fig. 3. The profiles of the

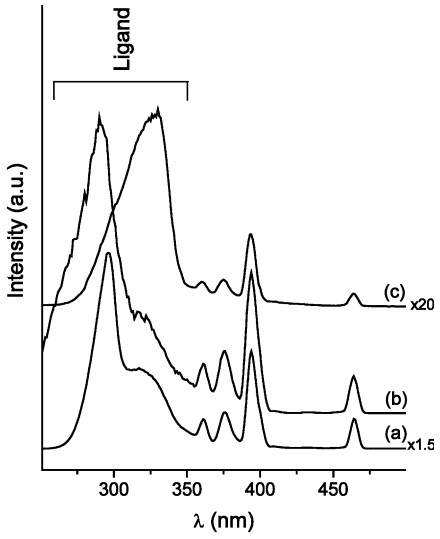


Fig. 2. Excitation spectra of the $[Eu(ClO_4)(x\text{-mpa})_3](ClO_4)_2$ complexes with ligands: (a) 3-mpa; (b) 4-mpa; and (c) $[Eu(ClO_4)(6\text{-mpa})_2](ClO_4)_2$.

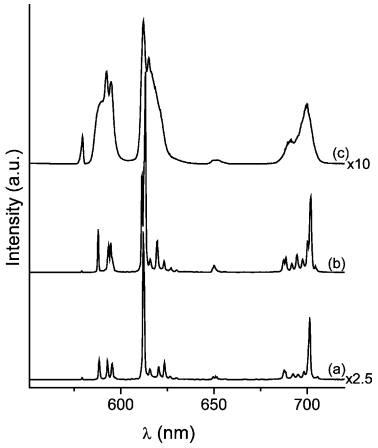

Fig. 3. Emission spectra of the complexes $[Eu(ClO_4)(x\text{-mpa})_3](ClO_4)_2$ with: (a) 3-mpa; (b) 4-mpa; and (c) 6-mpa with general formula $[Eu(ClO_4)(6\text{-mpa})_2](ClO_4)_2$.

spectra of the complexes with the 3- and 4-mpa ligands consist of sharp and defined bands. In contrast, the emission spectrum of the complex with the 6-mpa ligand shows broadened bands.

As shown in Fig. 3, the emission spectra of the complexes with the 3- and 4-mpa ligands present only one sharp peak in the region of the $^5D_0 \rightarrow {}^7F_0$ transition indicating the presence of a single chemical environment around the Eu(III) ion. The presence of three components assigned to the magnetic dipole allowed $^5D_0 \rightarrow {}^7F_1$ transition is consistent with a ligand field perturbation of low symmetry. All the electronic $^5D_0 \rightarrow {}^7F_J$ transitions are split in the maximum of $(2J+1)$-components, $J = 0$ (one band), 1 (three bands) and 4 (nine bands), but in the case of $J = 2$ there are seven bands more than $(2J+1 = 5)$ components (Fig. 3).

Fig. 3 shows two satellite bands in region of the $^5D_0 \rightarrow {}^7F_2$ hypersensitive transition (around 626 and 630 nm) for the complexes with the 3- and 4-mpa ligands (Table 3). The Eu-complexes present two additional low intensity bands at 1301 and 1387 cm^{-1}, for the 3-mpa ligand, and at 1322 and 1398 cm^{-1} for the 4-mpa ligand where the $^5D_0 \rightarrow {}^7F_0$ transition was taken as reference. They are assigned to vibronic transitions due to the coupling between the electronic and vibrational transitions from the $^7F_2$ and ν(C–N–CO) and ν(C–C) stretching, respectively, even though they could also be interpreted in terms of an electronic Raman effect as in Ref. [4]. The vibrational (IR and Raman) and electronic (emission) spectra of the $[Eu(ClO_4)(4\text{-mpa})_3](ClO_4)_2$ complex are presented in Fig. 4.

The Ω_2 and Ω_4 experimental intensity parameters were determined from the emission spectra (Fig. 3) based on the $^5D_0 \rightarrow {}^7F_2$ and $^5D_0 \rightarrow {}^7F_4$ electronic transitions of the Eu(III) ion, and they are estimated according to equation [23,24]

Table 3
Energies of the $^5D_0 \rightarrow {}^7F_J$ transitions ($J = 0$–4) (in cm^{-1}) observed in the emission spectra of the complexes $[Eu(ClO_4)(x\text{-mpa})_3](ClO_4)_2$ ($x = 3$ and 4) and $[Eu(ClO_4)(6\text{-mpa})_2](ClO_4)_2$, at 77 K

[a] Vibronic transitions. The $^5D_0 \rightarrow {}^7F_3$ transition was not assigned in this study due to its very low intensity.

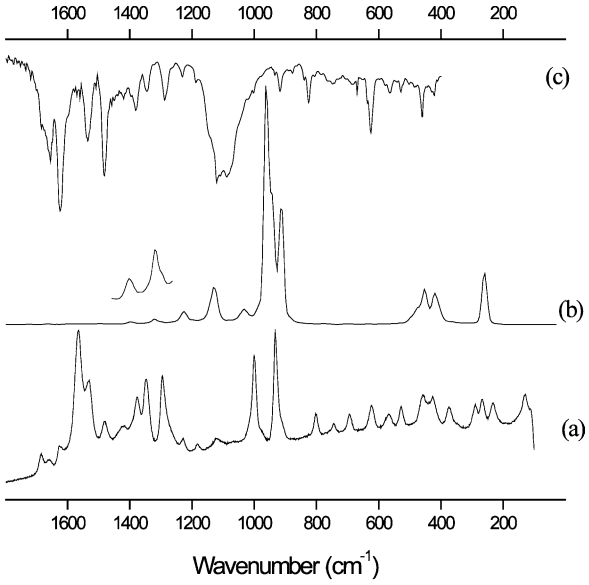

Fig. 4. IR (top) and Raman (bottom) spectra of the $[Eu(ClO_4)(4\text{-mpa})_3](ClO_4)_2$ complex and comparison with the emission spectrum (middle) recorded at 77 K. The energy of the $^7F_0$ level of the Eu(III) ion was taken as the origin.

$$A_{0J} = \frac{4e^2\omega^3}{3\hbar c^3}\,\chi \sum_{\lambda}\,\Omega_{\lambda}\langle {}^7F_J||U^{(\lambda)}||{}^5D_0\rangle^2 \qquad (1)$$

where, $\lambda = 2$ and 4, A_{0J} is the coefficient of spontaneous emission, χ is the Lorentz local field correction term that is given by $n(n^2+2)^2/9$ with the refraction index $n = 1.5$ and $\langle {}^7F_J||U^{(\lambda)}||{}^5D_0\rangle^2$ are the square reduced matrix

elements whose values are 0.0032 and 0.0023 for $J=2$ and 4, respectively. Since the intensity of a magnetic dipole transition ($^5D_0 \rightarrow {}^7F_1$) is relatively insensitive to the ligand field around of the Eu(III) ion, so that it may be used as internal standard to avoid the difficulty in experimental measurement of absolute emission intensities. The experimental coefficients of spontaneous emission, A, to be used in Eq. (1) are obtained according to the relation

$$A_{0J} = A_{01}\left(\frac{I_{0J}}{I_{01}}\right)\left(\frac{\nu_{01}}{\nu_{0J}}\right) \quad (2)$$

where I_{01} and I_{0J} are the integrated intensities of the $^5D_0 \rightarrow {}^7F_1$ and $^5D_0 \rightarrow {}^7F_J$ transitions ($J=2$ and 4) with ν_{01} and ν_{0J} energy baricenters, respectively. The coefficient of emission spontaneous, A_{01} in Eq. (2) is given by the expression $A_{01} = 0.31 \times 10^{-11}(n)^3(\nu_{01})^3$, and its value is estimated to be around 50 s^{-1} [25].

The Ω_2 and Ω_4 intensity parameters for the three complexes are presented in Table 4. The values of the Ω_2 parameters ($\sim 6.5 \times 10^{-20}$ cm^2) and the band profiles for the compounds with 3- and 4-mpa ligands are very similar, suggesting a similar chemical environment around the Eu(III) ion in these complexes.

When we compare the value of the Ω_2 parameter for the x-mpa complexes it is observed that in the compound with the 6-mpa ligand it is smaller than in the compounds containing the 3- and 4-mpa ligands. This might be expected on the basis of a steric effect of the methyl group on the pyridyl ring, decreasing the interaction between the N-pyridyl and the Eu(III) ion. Besides, the presence of only two 6-mpa ligands and one perchlorate group acting as bidentate ligands leads to a six-coordination complex, conferring a smaller electric dipole character to the $^5D_0 \rightarrow {}^7F_2$ transition. The hydrated salt presents the smallest value of the Ω_2 parameter compared with the complexes containing the 3-, 4- and 6-mpa ligands (Table 4) because the $^5D_0 \rightarrow {}^7F_2$ transition in octahedral complexes is formally forbidden owing to the electric dipole selection rules in centrosymmetric compounds.

From the luminescence decay curves for all the complexes (Fig. 5) we have determined the lifetime values (Table 4) of the emitting $^5D_0$ level of Eu(III) at room temperature as described in Ref. [24]. The short lifetime ($\tau = 0.078$ ms) of the emitting $^5D_0$ level in the salt precursor $[Eu(H_2O)_6](ClO_4)_3$ compared with the Eu-complexes (around $\tau = 0.270$ ms), presented in Table 4, is associated with the non-radiative decay channel due to vibronic coupling with the vibrations of the H_2O molecules.

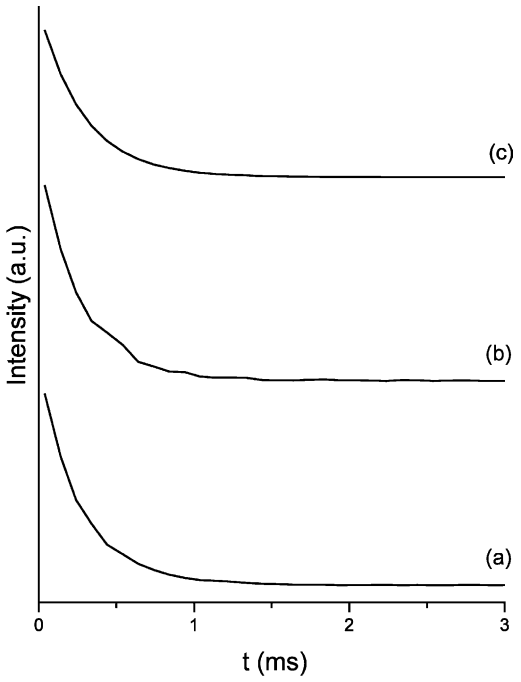

Fig. 5. Luminescence decay curves at room temperature of the emitting $^5D_0$ level of the Eu(III)-perchlorate complexes with ligands: (a) 3-mpa; (b) 4-mpa; and (c) 6-mpa.

The lifetime, non-radiative (A_{nrad}) and radiative (A_{rad}) rates are related through the following equation

$$A_{tot} = \frac{1}{\tau} = A_{rad} + A_{nrad} \quad (3)$$

where A_{rad} rates were obtained by summing over the radiative rates A_{0J} for each $^5D_0 \rightarrow {}^7F_J$ transitions ($A_{rad} = \Sigma_J\, A_{0J}$).

The quantum efficiency of the emitting $^5D_0$ level can be defined by

Table 4
Photoluminescent data of the complexes of the Eu(III)-perchlorate with acetamide ligands in solid state

Compounds	Ω_2	Ω_4	R_{02}	A_{rad}	A_{nrad}	A_{tot}	τ	η
$[Eu(H_2O)_6](ClO_4)_3$	1.1	4.7	0.003	155	12 573	12 728	0.078	1.2
$[Eu(ClO_4)(3\text{-mpa})_3](ClO_4)_2$	6.6	8.8	0.005	381	3364	3745	0.267	10.2
$[Eu(ClO_4)(4\text{-mpa})_3](ClO_4)_2$	6.5	9.1	0.002	382	3281	3663	0.273	10.4
$[Eu(ClO_4)(6\text{-mpa})_2](ClO_4)_2$	2.6	3.0	0.036	174	3322	3496	0.286	5.0

The experimental intensity parameters Ω_λ (10^{-20} cm^2), R_{02}, lifetimes τ (ms), radiative emission coefficient A_{rad} (s^{-1}), non-radiative emission coefficient A_{nrad} (s^{-1}), and quantum efficiency η (%) were obtained at room temperature (around 298 °C).

[a] Refs. [25,26].

$$\eta = \frac{A_{rad}}{A_{rad} + A_{nrad}} \quad (4)$$

We made a comparison between the 3-, 4- and 6-mpa complexes by considering that these three ligands are very similar. Table 4 shows that the complexes with 3- and 4-mpa ligands exhibit quantum efficiencies twice higher than the complex with 6-mpa, which is due to the higher radiative decay rates in the former case. As mentioned above, the smallest value of the quantum efficiency, which corresponds to the hydrated Eu(III)-perchlorate salt, is due to multiphonon relaxation by coupling to the OH vibration, quenching considerably its luminescence. For the sake of comparison the complexes in solid state bis(dibenzylsulfoxide)trithenoyltrifluoacetonateeuropium(III) has highest quantum efficiency ($\eta = 70\%$) that those with 3-, 4- and 6-mpa complexes indicating that non-radiative processes are operative [26–28].

Table 4 shows also the R_{02} intensity parameter, which is the ratio between the intensities of the $^5D_0 \rightarrow {}^7F_0$ and $^5D_0 \rightarrow {}^7F_2$ transitions. The R_{02} parameter may give information on the J-mixing effect associated with the $^5D_0 \rightarrow {}^7F_0$ transition as described in detail in Refs. [29,30]. In this case, this effect is mainly due to the mixing between the $^7F_2$ manifold and the $^7F_0$ level though the rank-two components of the ligand field. By comparison between the three Eu(III)-perchlorate complexes, the following order for the magnitude of the J-mixing effect is proposed: 6-mpa $\gg$ 3-mpa $>$ 4-mpa.

4. Conclusion

In this work we synthesized new Eu(III)-perchlorate complexes with 3-, 4- and 6-methyl substituted ligands derived from N-[2-pyridyl]acetamide. The elemental analyses, TG and molar conductivities data suggested that the complexes present the formula $Eu[(ClO_4)(x\text{-mpa})_3](ClO_4)_2$, with $x = 3$ or 4, and $Eu[(ClO_4)(6\text{-mpa})_2](ClO_4)_2$. The IR spectra showed that the amide ligands are coordinated to the Eu(III) ion by the oxygen atom of the amide group and the nitrogen atom of the pyridyl ring and that one perchlorate group coordinates to the Eu(III) ion as a monodentate ligand in the complexes with the 3- and 4-mpa ligands and as a bidentate ligand in the complex with the 6-mpa ligand. The emission spectra show only one peak for the $^5D_0 \rightarrow {}^7F_0$ transition indicating the presence of a single chemical environment around the Eu(III) ion. The detailed analysis in the region corresponding the $^5D_0 \rightarrow {}^7F_2$ transition showed the presence of satellite bands that were attributed to vibronic transitions due to the resonance between the energies of the νC–N–CO and νC–C stretching and the electronic $^7F_2$ level of the Eu(III) ion. This result was confirmed by the IR and Raman spectra of the compounds.

The Ω_2 intensity parameter for the $[Eu(ClO_4)(6\text{-mpa})_2](ClO_4)_2$ compound is smaller than for the complexes with the 3- and 4-mpa ligands. This was interpreted in terms of steric effect of the methyl group on the pyridyl ring, which decreases the interaction between the N-pyridyl and the Eu(III) ion. The $[Eu(H_2O)_6](ClO_4)_3$ precursor salt shows the smallest value of the Ω_2 parameter compared with all the complexes (Table 4) due to the fact the $^5D_0 \rightarrow {}^7F_2$ transition occurs in a chemical environment with point symmetry very close to (O_h).

The complexes obtained exhibit small values of the quantum efficiencies, η, indicating that energy transfer from (ClO_4^-) group and x-mpa ligands (where $x = 3$, 4 and 6) to Eu(III) ion is not very efficient compared with $[Eu(TTA)_3(DBSO)_2]$ complex suggesting that non-radiative processes are operative possibly due to vibronic coupling with the vibrations of the N–H on the amide group.

about the co-ordination chemistry of the Group 12 elements with this ligand. We have earlier reported [15] that DMPP does not form 2:1 complexes with mercury(II) halides due to the steric bulk of the phosphine ligand. The structures of the 1:1 complexes vary from weakly linked dimers for the chloride and bromide to a distorted trigonal planar monomer for the iodide, the latter being the first example of the monomeric 1:1 tertiary phosphine mercury(II) iodide complex. All three complexes have secondary interactions with one of the *ortho*-methoxy oxygen atoms on each ring [15].

Bowmaker and coworkers [21] have formed complexes of unusual stoichiometries with TMPP and mercury(II) halides. ^{31}P NMR studies of 1:1 solutions of the phosphine and the metal salts in acetonitrile showed the presence of $[(TMPP)HgX]^+$ and $[(TMPP)_2Hg]^{2+}$ cations, both with $[Hg_2X_6]^{2-}$ counterions, and with the amount of the first relative to the second increasing from chloride to iodide. These complexes thus have empirical formulae $TMPP(HgX_2)_2$ and $(TMPP)_2Hg_3X_6$, respectively, both having a P:Hg ratio <1:1. In an attempt to isolate the former complexes, solid complexes for X-ray structural and vibrational spectroscopic studies were obtained by adding a solution of the phosphine ligand in acetonitrile to a *suspension* of HgX_2 in the same solvent in a 1:2 molar ratio. For the chloride and bromide, complexes were isolated which analysed for $(TMPP)_4Hg_7X_{14}$ and which were shown by vibration spectroscopy to be essentially equimolar mixtures of $[TMPPHgX^+]_2[Hg_2X_6]^{2-}$ and $[(TMPP)_2Hg]^{2+}[HgX_6]^{2-}$. X-ray structural determination of a crystal obtained from the solid product from the chloride reaction confirmed the formulation as $[(TMPP)_2Hg][Hg_2Cl_6]$ having a slightly different crystal structure [21] to that found for $(Me_3P)_2(HgI_2)_3$ [16]. The cation was significantly distorted from linearity (P–Hg–P, 166.51(9)°) due to interactions with the *ortho*-methoxy oxygen atoms. For the iodide $[TMPPHgI^+]_2[Hg_2I_6]^{2-}$ was isolated, its formulation being confirmed spectroscopically [21].

Herein we report the results of our studies of the reactions of ethanolic solutions of HgX_2 (X = Cl, Br, I) and TMPP in a variety of proportions and the crystal structures of monomeric $(TMPP)HgX_2$ (X = Br, I) and $(TMPP)(HgI_2)_2$.

2. Experimental

Mercury(II) chloride, bromide and iodide, reagent grade, were used without further purification. The ligand, tris(2,4,6-trimethoxyphenyl)phosphine, was prepared as described previously [22] by reaction of 1,3,5-trimethoxybenzene with butyllithium, followed by the addition of triphenylphosphite in diethyl ether. After hydrolysis a white crystalline solid was obtained on recrystallisation from hot ethanol; m.p. 159–162, lit. 158–160 °C [17].

Melting points were obtained using an electrothermal melting point apparatus and are uncorrected. Elemental analyses were carried out by the Sheffield University Centre for Chemical Instrumental Analytical Services. ^{31}P NMR spectra were recorded as solutions in dimethylsulfoxide-d_6 using a Bruker AMX 400 spectrometer at 161.97 MHz with chemical shifts referenced to 85% H_3PO_4. Raman spectra were acquired by excitation with at 785 nm (300 mW) solid-state laser using a Renishaw Raman System 1000 spectrometer which comprised an integral Raman microscope (Olympus BH2 system), a stigmatic single spectrograph and a Peltier-cooled CCD detector (400 × 600) pixels. The holographic notch filters allowed a lower spectral limit of ~ 120 cm^{-1}.

2.1. Preparation of complexes

The complexes were prepared using solutions of the phosphine ligand and the mercury(II) halide, both separately dissolved in hot ethanol. Precipitation occurred almost immediately and the complexes were filtered off and dried in vacuo. A typical synthesis is described below. For 1:1, 1:2 and 2:3 (P:Hg) ratios of reactants used, the ligand was added to the metal salt whereas for the 2:1 ratio of reactants, the reverse order of addition was used. However, in the case of chloride it was found to be necessary for the formation of the 1:1 complex to add the mercury salt to the phosphine. Quantities of materials used and ratio of reactants, together with analytical data for the products isolated, their appearance and melting points are reported in Table 1.

2.1.1. Tris(2,4,6-trimethoxyphenyl)phosphine–dibromomercury(II)

Tris(2,4,6-trimethoxyphenyl)phosphine (0.399 g, 0.75 mmol) dissolved in warm ethanol (50 cm^3) was added with stirring to mercury(II)bromide (0.270 g, 0.75 mmol) also dissolved in warm ethanol (50 cm^3) with stirring. The white precipitate which formed almost immediately was filtered off and dried in vacuo as white needles; m.p. 250–251 °C. *Anal.* Found: C, 36.38; H, 3.87. Calc. for $C_{33}H_{27}OPHgBr_2$: C, 36.32; H, 3.72%.

2.2. X-ray crystallography

Crystals suitable for X-ray study were grown by slow evaporation of ethanolic solutions of the complexes, mounted on glass fibres and intensity data collected. A summary of crystal data, data collection strategy and model refinement parameters are given in Table 2. The structures of $TMPPHgX_2$ (X = Br (**I**), I (**II**)) and $TMPP(HgI_2)_2$ (**III**) were solved by direct methods

(SHELXS-97 [23]) and refined using SHELXL-97 [23]. Non hydrogen atoms were refined anisotropically, whilst hydrogens were refined isotropically in idealised positions with temperature factors tied to the values of their parent atom. Large residual peaks are observed approximately 1 Å from the mercury centres in **III** and are attributed to absorption effects.

3. Results and discussion

The results described herein both complement and contrast with those reported by Bowmaker and coworkers [21] for reactions of TMPP solutions with *suspensions* of mercury(II) halides, both in acetonitrile. We have examined reactions of TMPP on the metal halide in a variety of ratios (Table 1) in ethanol solutions. All complexes were only sparingly soluble and readily precipitated out. For reactions involving the ligand and HgX_2 in 1:1, 1:2 and 2:3 molar ratios the ligand solution was added to the halide solution (except in one case for the chloride, vide infra), while for reactions involving the phosphine in a greater molar ratio than the metal halide, the reverse order of addition was used.

When the solutions of the ligand and mercury(II) halides were mixed in 1:1 ratio, the 1:1 complexes were readily isolated for the bromide and iodide which have been shown herein to be monomeric due to the steric bulk of the tertiary phosphine ligand. Despite repeated attempts for the chloride, when the ligand ethanolic solution was added to metal halide solution, in every case the known [21] 2:3 complex, $(TMPP)_2(HgCl_2)_3$ was isolated. This latter complex was structurally characterised by Bowmaker and co-workers [21], a crystal having been obtained from the reaction of TMPP and a suspension of $HgCl_2$ in MeCN in a 1:2 molar ratio, though the bulk material appeared to be an equimolar mixture of the above compound and $(TMPP)(HgCl_2)_2$. However when an equimolar solution of $HgCl_2$ was added to the phosphine, also in ethanol, the 1:1 complex precipitated from solution as a white powder which was characterised by carbon and hydrogen analyses (Table 1). Unfortunately, recrystallisation of this material, in an attempt to obtain crystals suitable for X-ray study, resulted in isolation of the known complex [21] $(TMPP)_2(HgCl_2)_3$. The other 2:3 complexes $(TMPP)_2(HgX_2)_3$ (X = Br, I), which may be formulated as $[(TMPP)_2Hg][Hg_2X_6]$ like the chloride [21], were obtained readily by reaction of the phosphine and metal halide in a 2:3 ratio (Table 1). Recrystallisation of the bromide and iodide from hot ethanol resulted in isolation of the 1:1 complexes.

When TMPP and HgX_2 were mixed in a 3:2 ratio no analogues of $(Me_2EtP)_3(HgCl_2)_2$ [24] were obtained, due to the steric bulk of the ligand, and only the previously described $(TMPP)HgX_2$ (X = Br, I) and $(TMPP)_2(HgCl_2)_3$ were isolated. The reaction between the tertiary phosphine and mercury(II) halides in a 1:2 ratio in ethanol resulted in the isolation of $(TMPP)_2(HgX_2)_3$ (X = Cl, Br), whereas for the iodide, $(TMPP)(HgI_2)_2$ was isolated (Table 1). This complements Bowmaker's NMR findings [21] that 1:1 solutions of the phosphine and mercury (II) halides in MeCN contain $TMPP(HgX_2)_2$ and $(TMPP)_2(HgX_2)_3$, both given an ionic formulation, with the amount of the former to the latter increasing from chloride to iodide. They were also able to isolate this particular complex and formulated it as the ionic compound $[TMPPHgI]_2[Hg_2I_6]$ from spectroscopic data. However our X-ray structural analysis shows that these units are linked together via a single bridging iodine between two mercury atoms.

In contrast to reactions with DMPP [15] we were readily able to isolate the 2:1 complex $(TMPP)_2HgX_2$ (X = Cl, Br, I) (Table 1), presumably due to the stronger basicity of TMPP (pK_a, 11.02) compared to DMPP (pK_a, 9.33) [18] as the two phosphines have similar steric requirements. However, the second ligand must be weakly held as recrystallisation, to obtain suitable crystals for X-ray structural examination, yielded the 1:1 complexes for the bromide and iodide, and $(TMPP)_2(HgCl_2)_3$ for the chloride.

The X-ray crystal structures of $(DMPP)HgX_2$ (X = Cl, Br, I) showed a trend from very weakly linked halogen-bridged dimeric structures (X = Cl, Br) to a monomeric trigonal planar arrangement for the iodide. All three show additional interactions between mercury and one of the *ortho*-methoxy oxygen atoms on each ring [15]. An attempt to compare this series with the corresponding TMPP complexes were unsuccessful as unfortunately recrystallisation of $(TMPP)HgCl_2$ resulted in the formation of $(TMPP)_2(HgCl_2)_3$ whose structure has been reported [21]. However, recrystallisation of the corresponding bromide (**I**) and iodide (**II**) yielded crystals suitable for X-ray study. Crystallographic data for **I** and **II** are shown in Table 2 and selected bond lengths and angles in Table 3. The structures of **I** and **II** (Figs. 1 and 2, respectively) are both highly distorted trigonal planar monomeric molecules with a shorter Hg–P distance (2.420(4) (**I**), 2.437(2) (**II**) Å) than in the corresponding DMPP complexes (2.4490 (12), 2.4656(16) Å, respectively [15], reflecting the stronger donor capacity of TMPP, larger size of iodide and also the better donor capability of iodide to mercury compared to bromide. These are however longer than in the corresponding triphenylphosphine complex [6,13], despite the much higher pK_a of TMPP (11.02) [18] compared to Ph_3P (2.73) [19], due to the buttressing effect of the *ortho*-methoxy groups.

In contrast to its DMPP analogue [15], a weakly linked halogen-bridged dimer, in which the two bridging distances differ somewhat (2.6272(6), 2.9195(6) Å) with

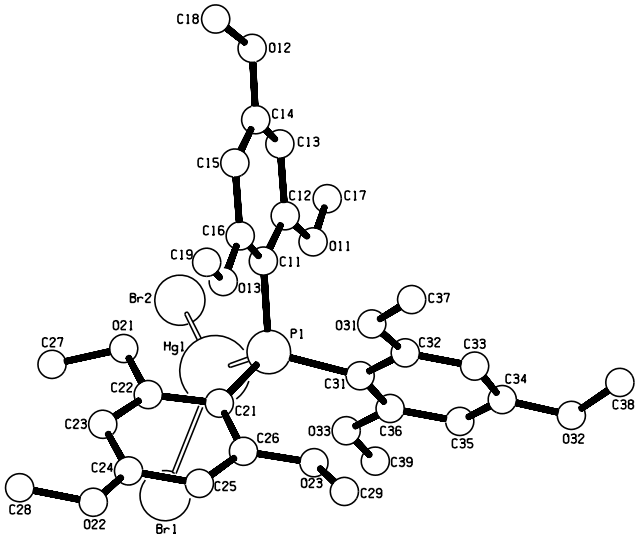

Fig. 1. The molecular structure of monomeric $TMPPHgBr_2$.

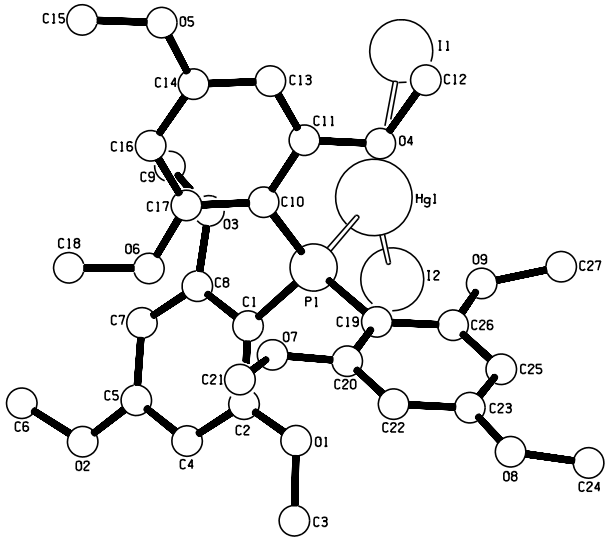

Fig. 2. The molecular structure of monomeric $TMPPHgI_2$.

one of these similar to the terminal Hg–Br bond length (2.6129(6) Å), $TMPPHgBr_2$ is monomeric (Fig. 1). The only other structurally characterised monomeric tertiary phosphine–mercury(II) bromide complex, bis(triphenylphosphonio)isophosphindolide–$HgBr_2$ [25], contains a shorter Hg–P bond still (2.399(2) Å). There are however other marked differences in the structures of these two monomeric complexes. In the phosphindolide complex the mercury atom displays almost T-shaped co-ordination geometry with the two Br–Hg–P angles differing significantly (157.7(1)°, 96.4(1)°) as also do the two Hg–

Br distances (2.491(1), 2.737(1) Å) and thus the complex could almost be formulated as $[R_3PHgBr]^+Br^-$. In contrast the TMPP complex described herein, whilst also showing planarity round mercury, contains much more similar Hg–Br distances (2.528(3), 2.637(3) Å). Additionally, whilst the two P–Hg–Br angles are somewhat different (138.47(14)°, 117.48(14)°) and larger than the Br–Hg–Br angle (103.79(10)°) they are more akin to trigonal planarity around mercury, albeit somewhat distorted due to the bulk of the phosphine ligand. There are no intermolecular Hg–Br distances less than 4 Å.

In $TMPPHgI_2$ the I–Hg–I angle (111.37(2)°) is approximately 8° greater than the corresponding angle in the bromide (103.79(10)°) reflecting the greater steric bulk of iodide and is ~4° smaller than in monomeric $DMPPHgI_2$ due to the stronger basicity of TMPP compared to DMPP resulting in a shorter Hg–P bond distance. This results in a reduction of both P–Hg–I angles of ~4° so that the P–Hg–I angles are still very asymmetric (113.92(4)°, 133.35(4)°), as in the bromide, due to strong interactions with the central mercury and one of the oxygens of the *ortho*-methoxy groups on each phenyl ring. These contacts (Table 3) are within the sum of the van der Waals radii for mercury and oxygen and can thus be considered as bonding interactions. Hence the co-ordination round mercury is raised to six although the overall geometry is significantly distorted from a regular octahedral arrangement.

The structure (Fig. 3) of complex **III** of empirical formula $(TMPP)(HgI_2)_2$ is somewhat different from that suggested previously [21] from spectroscopic data. In contrast to $[(TMPP)_2Hg]^{2+}[Hg_2Cl_6]^{2-}$, in which the presence of the two bulky phosphine ligands forces approximate linearity about the attached mercury atom and also precludes any interaction with neighbouring halogens, the presence of only one phosphine bonded to mercury in **III** does allow such an interaction to occur. Thus we have shown that **III**, rather than being described as the discrete ions $[(TMPP)HgI^+]_2[Hg_2I_6]^{2-}$ suggested from ^{31}P NMR and vibrational spectroscopic data [21], consists of the discrete molecular unit (TMPP)HgI(μ-I)HgI(μ-I)$_2$HgI(μ-I)HgI(TMPP). There are no Hg–I interactions between these units of less than 4 Å. Thus the centrosymmetric structure contains a double halogen bridge between mercury atoms in the central Hg_2I_6 core with one of the two terminal iodines on each mercury linked via a single bridge to a (TMPP)HgI unit. This single bridge (3.0705(7) Å) is slightly longer than the terminal Hg(1)–I(2) (2.6192(7) Å) and Hg(2)–I(3) (2.6862(7) Å) distances and is much shorter than the single iodine bridge (3.417(2) Å) linking $(Me_3P)_2Hg^{2+}$ cations to $Hg_2I_6^{2-}$ in $(Me_3P)_2(HgI_2)_3$ [16] but it is much closer to the bridging distances in the asymmetric Hg_2I_6 core (2.8037(8), 2.9787(7) Å). Such asymmetry in HgX_2Hg bridges has been noted previously in 1:1 dimers $(R_3PHgX_2)_2$ [6,7,10,13,14] and in $(Ph_4P)_2Hg_2I_6$ (2.864(1), 2.962(1) Å) [26]. The Hg–P distance (2.408(2) Å) is shorter than in (II) resulting from less steric crowding round mercury because of Hg1–I1 being longer than both of the Hg–I distances in (II). The angles in the Hg_2I_2 bridge are similar to those found in $(Ph_4P)_2Hg_2I_6$ [26] but the external angles around Hg2 are ~5° more distorted from tetrahedral due to the additional bonding to Hg1. Atoms P, Hg1, I1 and I2 are coplanar (deviation from least squares mean plane = 0.0055(10) Å) though there is considerable distortion of these atoms from trigonal planar geometry both due to bonding to Hg2 and also strong interactions of Hg1 with one of the *ortho*-methoxy oxygen atoms on each of the phenyl rings (2.667(6), 2.869(5), 3.207(6) Å). In all three complexes the geometry of the phosphine is not significantly altered from that of the free ligand [22].

3.1. Vibrational spectra

Important Raman bands in the 600–100 cm^{-1} region are summarized in Table 4 and displayed in Figs. 4–7. The assignment of the vibrational spectral features of a range of R_3PHgX_2 complexes has previously been correlated with their full crystal and molecular structures [6,27]. The structural variety found for the TMPP complexes described herein gives rise to differences in Raman spectra. There are several bands that are common to all spectra which are assigned to the skeletal vibrations of the phosphine ligand. However, there are clear differences, especially in the 300–100 cm^{-1} region, which may be assigned to terminal and bridging ν(HgX) modes, sym and anti-sym ν(HgX) and ν(HgP) stretching vibrations. For the 1:1 centrosymmetric dimer $[(R_3P)_2Hg_2X_4]$ (X = Cl, R = Ph, Pr, 1,2,5-triphenylphosphole; X = Br, R = Ph_3P; X = I, R = Bu_3P, 1-phenyl,3,4-dimethylphosphole), whose structures have been crystallographically determined [6,13,27], group theory predicts one ν(HgP), one $\nu(HgX_t)$ and two $\nu(HgX_b)$ vibrations and when the inversion centre is lost the number of possible bands is doubled. However these are not always all observed, so that vibrational spectral data do not give a very clear indication of the exact symmetry of the dimer [27]. The terminal and bridging ν(Hg–Cl) stretching modes (Fig. 4, Table 4) for the 1:1 $HgCl_2$ complex described herein may be assigned at 283 and 253 cm^{-1} respectively with ν(HgP) either below the cut off of the notch filters or hidden beneath the multicomponent band observed between 100 and 300 cm^{-1}. Thus this indicates that this is a halogen bridged dimer with the closeness of the bridging and terminal modes being ascribed to very weak bridging, as found in the DMPP complexes [15]. A different pattern and intensity of bands arises for the bromide and iodide species, which have Raman bands of much higher intensity than for the chloride. Bromide and iodide have diminished ability as bridging groups and the X-ray structure of

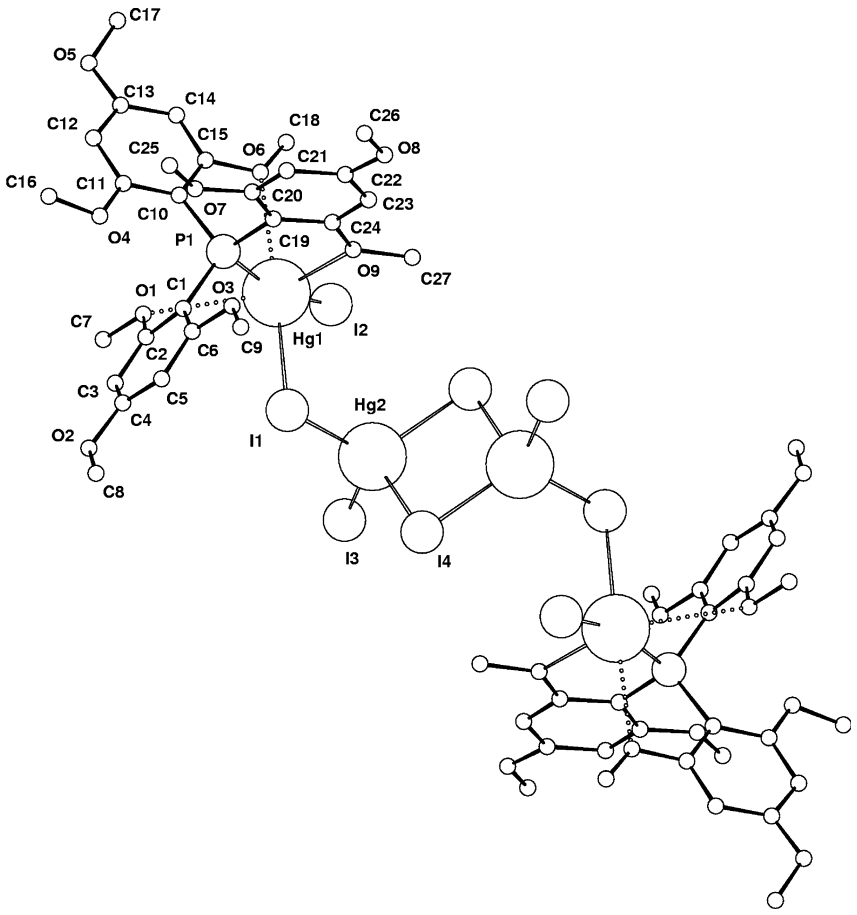

Fig. 3. The molecular structure of $(TMPP)_2(HgI_2)_4$.

these has shown them to be monomeric. Thus, for $TMPPHgX_2$ (X = Br, I) only a symmetric and anti-symmetric ν(Hg–X) stretching vibration are predicted which should have very similar band positions with the possibility of these bands overlapping. A single band was observed for both these complexes found at 176 (bromide) and 140 cm^{-1} (iodide). The iodo complex ν(Hg–I) mode is very asymmetric indicating that further bands are probably beneath the overall band structure. The ν(Hg–P) band was not observed for these complexes probably due to the cut-off of the notch filter.

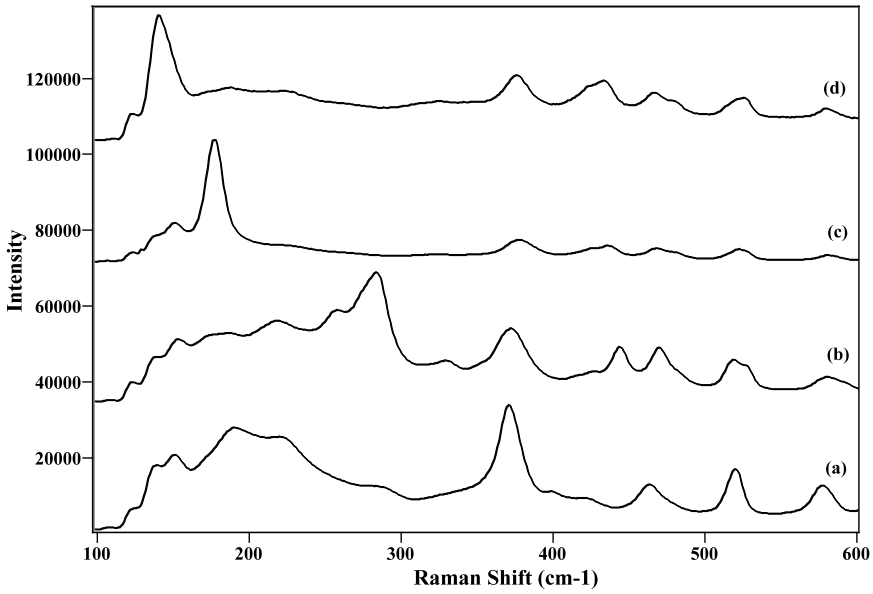

Fig. 4. Raman spectra of the 1:1 complexes ((a) TMPP, (b) chloride (c) bromide and (d) iodide).

The 2:1 complexes $[L_2HgX_2]$ in principle should give one ν(Hg–X) symmetric and one anti-symmetric mode and two ν(Hg–P) modes. However this was not observed for all of the complexes (Fig. 5). The chloride did not give well resolved bands which could be ascribed to ν(Hg–Cl) and it seems likely that it has decomposed in the laser beam like 1-phenyl –3,4-dimethylphosphole-mercury(II)chloride [27]. The bromide complex shows only one clearly visible ν(Hg–Br) mode at 157 cm^{-1}, however there is spectral intensity seen as a shoulder which may be obscuring further bands. The iodo complex shows only a single very intense band at 150 cm^{-1} which can clearly be ascribed to ν(Hg–I) as also found in a range of other tertiary phosphine–mercury(II)iodide complexes [27]. In the spectra of all three complexes no clear ν(Hg–P) band can again be observed.

The spectra of the 2:3 complexes $(TMPP)_2(HgX_2)_3$ which may be formulated as $[Hg(TMPP)_2][Hg_2X_6]$ on the basis of the crystal structure of X = Cl [21] are shown in Fig. 6 and assignments listed in Table 4. The spectra do not contain bands ascribed to $[TMPPHgX]^+$ which was found to be present in products crystallised from 2:1 solutions of HgX_2 and TMPP in MeCN. For the iodide the main component in such mixtures was described as $[TMPPHgI]_2[Hg_2I_6]$ whereas the chloride and bromide systems were believed to consist of mixtures of analogues of the above and $[Hg(TMPP)_2]$-

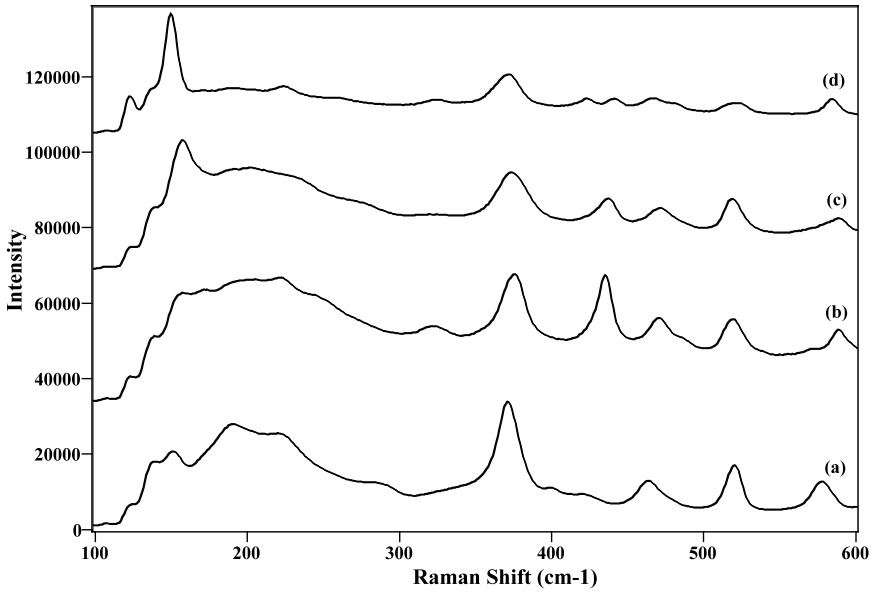

Fig. 5. Raman spectra of the 2:1 complexes ((a) TMPP, (b) chloride (c) bromide and (d) iodide).

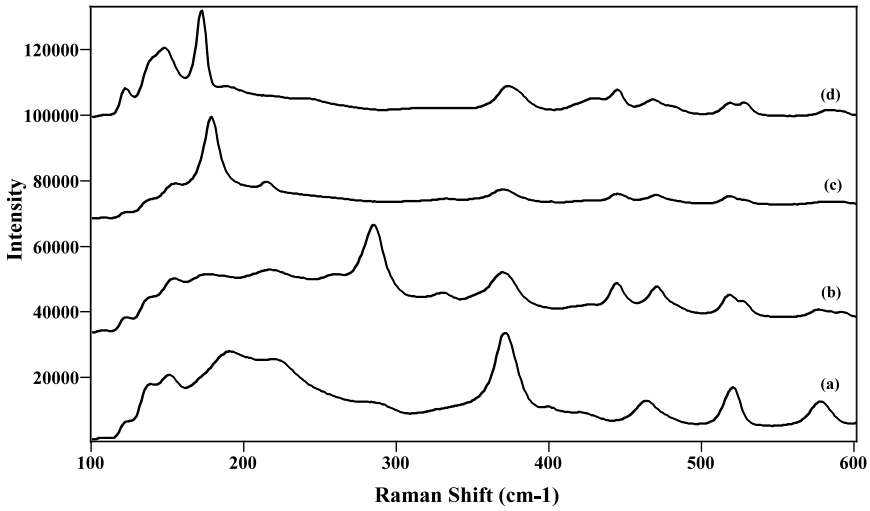

Fig. 6. Raman spectra of the 3:2 complexes ((a) TMPP, (b) chloride (c) bromide and (d) iodide).

$[Hg_2X_6]$ (X = Cl, Br) [21]. The solid 2:3 chloro complex isolated here contains bands due to terminal and bridging Hg–Cl vibrations at 285 and 258 cm^{-1}(Table 4). Only a single intense band was observed for the bromide complex at 178 cm^{-1}. The corresponding iodo complex showed three bands at 172 cm^{-1} (terminal) and 147 and 140 cm^{-1} (bridging) which are close to the assignments for one of the components $[Hg(TMPP)_2]$-$[Hg_2X_6]$ (X = Br, I) in the mixed complexes [21] and can thus be ascribed to the $[Hg_2X_6]^{2-}$ ion. Thus the vibrational spectra of all three 2:3 complexes confirm their formulation as $[Hg(TMPP)_2][Hg_2X_6]$.

The spectrum of the 1:2 iodo complex and assignments agree well with those discussed for this complex previously although formulated as $[TMPPHgI]_2[Hg_2I_6]$ [21]. Thus, the terminal Hg1–I1 vibration is found as a strong band at 171 $cm^{-1}$and the terminal Hg–I vibration of the central Hg_2I_6 core at 146 cm^{-1} although, due to its asymmetry, there is the possibility of further bands beneath the 147 cm^{-1} mode. The bridging Hg–I vibrations occur below the cut off point of the instrument.

3.2. Solution ^{31}P NMR spectra

^{31}P NMR spectral data for $TMPPHgX_2$, $(TMPP)_2(HgX_2)_3$ (X = Cl, Br, I) and $TMPP(HgI_2)_2$ as solutions in DMSO are listed in Table 5. All were only sparingly soluble but showed two central peaks due to components containing the non-magnetic isotopes of mercury, indicating the presence of two species in solution. Also present were small satellites from coupling of ^{31}P to ^{199}Hg which has nuclear spin, $I = 1/2$ and natural abundance of 16.8%. The parameters are non-halogen dependent and remain essentially constant for one of the species in solutions of all seven compounds and must be ascribed to $[(TMPP)_2Hg]^{2+}$ as found for 1:1 solutions of the ligand and mercury(II) halides in

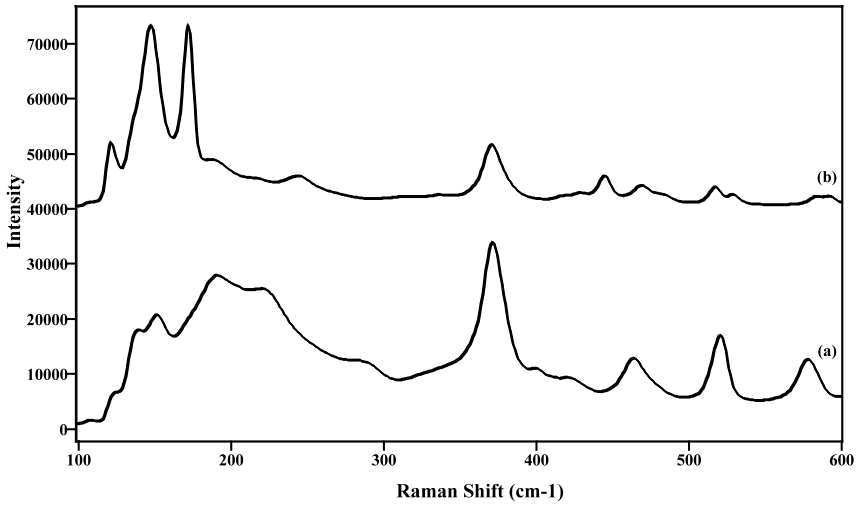

Fig. 7. Raman spectrum of the 1:2 iodo complex ((a) TMPP (b) iodide).

Table 5
^{31}P NMR spectral data

	δ/ppm	^1J (^{31}P^{199}Hg)/Hz	δ/ppm	^1J (^{31}P^{199}Hg)/Hz
$TMPPHgCl_2$	−35.54	5087	−33.54	9278
$TMPPHgBr_2$	−35.55	5149	−30.12	8486
$TMPPHgI_2$	−35.49	5251	−28.00	6939
$(TMPP)_2(HgCl_2)_3$	−35.43	5180	−34.36	9295
$(TMPP)_2(HgBr_2)_3$	−35.39	5168	−32.16	8580
$(TMPP)_2(HgI_2)_3$	−35.39	5239	−28.22	7631
$TMPP(HgI_2)_2$	−35.47	5282	−28.20	7656

MeCN solutions [21]. The other species present are halogen dependent and show the expected trend of chemical shift with $J(^{199}Hg-^{31}P)$ decreasing from chloride to iodide.

For the 1:1 complexes all of the chemical shifts and coupling constants are much greater than for other R_3PHgX_2 complexes [27,28] due to the much greater basicity of TMPP. Although others [21] have ascribed the halogen dependent peaks as due to $[TMPPHgX]^+$, in view of our crystallographic data, we believe that they are simply due to $[TMPPHgX_2]$. The ratio of the non-halogen to the halogen dependent peaks is ~2:1 for X = Cl, 1:1 (Br) and 1.6:1 (I).

For $(TMPP)_2(HgX_2)_3$ the dominant species (ratio ~2.2:1) for the chloride was $[(TMPP)_2Hg]^{2+}$ while for the bromide and iodide the non-halogen: halogen ratio of peaks was ~3.2:1 and 1:1, respectively. The chemical shifts and coupling constants for the chloride and bromide were very close to those of the corresponding 1:1 complexes and, as the vibrational spectra do not contain bands due to $[TMPPHgX]^+$ [21] this indicates the presence of $[TMPPHgX_2]$ (X = Cl, Br) as the halogen containing species. The chemical shift and coupling constant for the iodide were very similar to those of $TMPP(HgI_2)_2$ indicating the presence in both cases of the same species in solution which is likely to be the covalent dimer, $(TMPP)HgI(\mu\text{-}I)HgI(\mu\text{-}I)_2HgI(\mu\text{-}I)HgI(TMPP)$, determined crystallograpically.

4. Conclusion

Reaction of TMPP with mercury(II) halides in varying molar ratio in ethanol solutions produces complexes with a variety of stoichiometries. Crystal structure determinations has proved the uncommon monomeric nature for the 1:1 complexes containing bromide and iodide while ^{31}P NMR studies have shown the presence of significant amounts of both halogen dependent and non-halogen dependent species in DMSO solution.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 169399 for compound **I**, 169400 for compound **II** and 178058 for compound **III**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

2. Experimental

2.1. Investigation in the solid state

2.1.1. Preparation of the complexes

The hydrochloride 5-hydroxymethyl-4-methylimidazole (Aldrich Europe) was alkalized with a $KHCO_3$ solution. The free imidazole base was extracted with 1-BuOH.

The Cu(II) and Ni(II) complexes of 4-CH_2OH–5-CH_3im were prepared in aq. solution. Thus, to a solution of 8 mmol of the imidazole base, a solution containing 2 mmol of the particular metal nitrate was added. The crystals of the Cu(II) complex were navy-blue, while those of the Ni(II) complex were dark-violet. Results of the elemental analyses are as follows: Cu(II) complex: C, 37.9; H, 5.0; N, 22.2. Calc. for $CuL_4(NO_3)_2$: C, 37.76; H, 5.07; N, 22.02%. Ni(II) complex: C, 38.0; H, 5.0; N, 22.4. Calc. for $NiL_4(NO_3)_2$: C, 38.05; H, 5.11; N, 22.19%.

2.1.2. Physical measurements

Elemental analyses were run on a Model 240 Perkin–Elmer CHN analyser. The IR spectra were recorded on a Perkin–Elmer 180 (spectral range 50–4000 cm^{-1}) spectrophotometer in Nujol and in KBr pellets. The far-IR spectra were obtained in Nujol mulls sandwiched between polyethylene plates. The electronic spectra (5000–30 000 cm^{-1}) were recorded on a Cary 5 UV–Vis–NIR spectrophotometer in Nujol mulls.

The EPR spectra were recorded on a Bruker ESP 300E (Bruker, Germany) spectrometer operating at X-band and equipped with the Bruker NMR gaussmeter ER 035M and the Hewlett-Packard microwave frequency counter HP 5350B. EPR parameters were calculated by computer simulation of the experimental spectra using Bruker's WIN-EPR SimFonia Software Version 1.25.

2.1.3. Crystal data

X-ray measurements were performed on a Kuma KM4 diffractometer. The structures were solved by direct methods using the SHELXS-86 [11] and SHELXS-97 [12] programs and refined by full-matrix least-squares methods using the SHELXL-93 [13] and SHELXL-97 [14] programs (respectively for the Cu(II) and Ni(II) complexes). Details of the crystal data and refinement for the studied compounds are collected in Table 1.

Table 1

2.2. Solution studies

2.2.1. Potentiometric measurements

Potentiometric measurements of the metal-ion systems were carried out using a PHM-84 pH meter (Radiometer) and a GK 24001 C combination electrode placed in a glass vessel thermostatted at 298 K in a solution of a constant ionic strength $I = 0.5$ mol dm^{-3} maintained with KNO_3. The electrode was calibrated by means of a HCl solution of known titre with a KOH solution. The concentration of the protonated ligand (HL^+) in stock solutions used in potentiometric titrations was 0.20 mol dm^{-3}.

In the three series of measurements the metal–HL^+ molar ratios were 1:4, 1:8 and 1:10. The titration with the base was conducted in triplicate, over the pH range 2.5–7.1. The dissociation constants of the conjugate acid and stability constants, β_n, of the complexes were refined by the SUPERQUAD program.

2.2.2. Spectroscopic measurements

The visible-range absorption spectra of the Cu(II) and Ni(II) complexes in aq. solutions were recorded on a Specord M-500 (Carl Zeiss, Jena) spectrophotometer. The solutions were prepared in an analogous manner to those for the potentiometric titrations. The initial metal concentrations were 0.05 mol dm^{-3}. The highest concentration of the protonated ligand was 0.20 mol dm^{-3}.

3. Results and discussion

3.1. Investigation in the solid state

3.1.1. Molecular structure of the Cu(II) and Ni(II) complexes

The molecular structure of the Ni(II) complex together with the atom labelling is shown in Fig. 1. The molecular packing of $[Ni(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$ in the unit cell is presented in Fig. 2. The angles and bond lengths for both complexes are collected in Tables 2 and 3.

On account of the tautomeric transformation of the hydrogen atom, which is bonding with the pyrrole nitrogen atom >NH in the heterocyclic ring, imidazole substituted at positions 4 and 5 occur in two forms, 5(4)-CH_2OH–4(5)-CH_3im. The determined molecular structure of the Cu(II) and Ni(II) complexes reveals that the 4-CH_2OH–5-CH_3im tautomer is involved in complexation. In the co-ordination compounds, this ligand has a dual nature. Namely, two molecules act as monodentate ligands co-ordinating through the 'pyridynic' atom of the imidazole ring, whereas the remaining two are bidentate ligands, where the oxygen atom of the hydroxymethyl group acts as another electron donor. Consequently, the immediate surrounding of the central ion is made up of four nitrogen atoms of the imidazole rings and two oxygen atoms of the hydroxymethyl groups (CuN_4O_2 and NiN_4O_2 chromophores).

The shape of the co-ordination polyhedron of the Cu(II) ion is that of a slightly distorted tetragonal bipyramid. The copper–nitrogen bond lengths are 1.981(2) and 2.050(2) Å, and the angles between bonds lying in this plane are 90.3(1)° and 89.7(1)°, thus differing from a right angle by ±0.3°. The elongated copper–oxygen bonds are 2.496(2) Å long each. The O(11)–Cu–N(21) and O(11)–Cu–N(21a) angles are, respectively 93.6(1)° and 86.4(1)°. On account of chelation, the O(11)–Cu–N(11) and O(11)–Cu–N(11a) angles are deformed to 75.8(1)° and 104.2(1)°, respectively.

In the Ni(II) complex, the bonds between the central ion and the nitrogen atoms are slightly longer than those in the Cu(II) complex, namely 2.046(1)° and 2.108(1) Å. The bonds with the oxygen atoms are 0.385 Å shorter, being 2.141 Å each.

In the *xy* co-ordination plane, the nitrogen–nickel–nitrogen angles are 89.4(1)° and 90.6(1)°, whereas those of N(21a)–Ni–O(11) and N(21)–Ni–O(11) are, respectively 87.7(1)° and 92.3(1)°. The largest distortion of the octahedral environment of the Ni(II) ion is caused by the N(11)–Ni–O(11) and N(11a)–Co–O(11) angles being equal to 80.2(1)° and 99.8(1)°, respectively.

In the aforementioned complexes the non-co-ordinating $-CH_2OH$ group is involved in two intramolecular hydrogen bonds, one with the oxygen atom of the

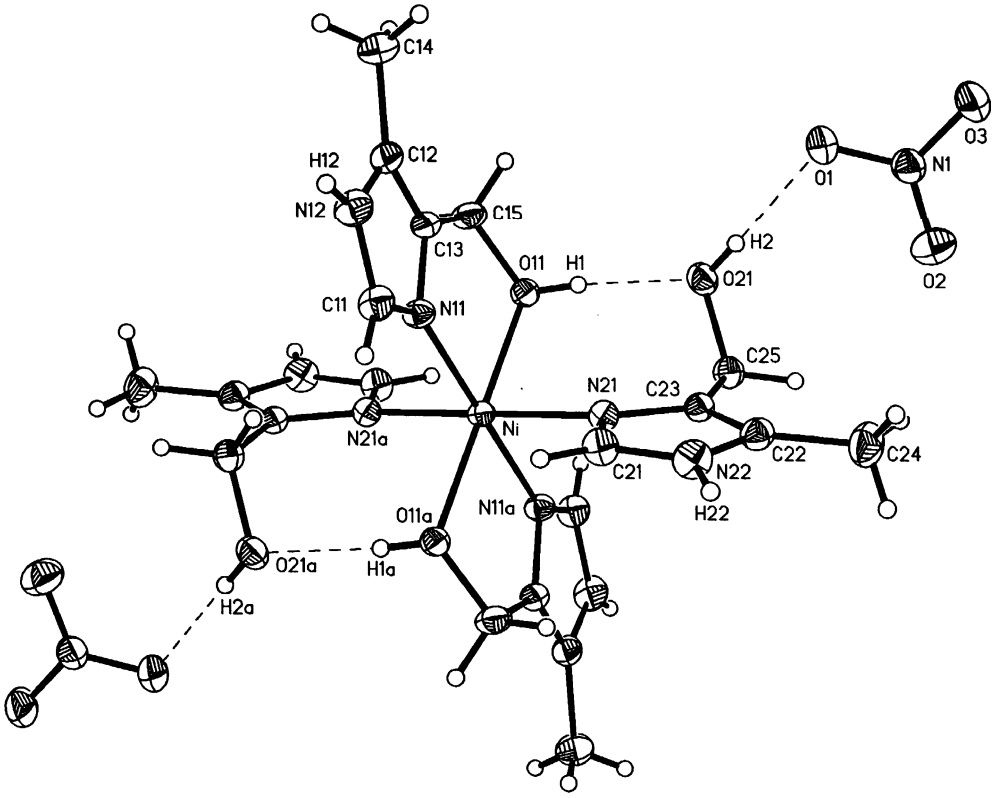

Fig. 1. The molecular structure of the Ni(II) complex with 4-hydroxymethyl-5-methylimidazole, $[M(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$.

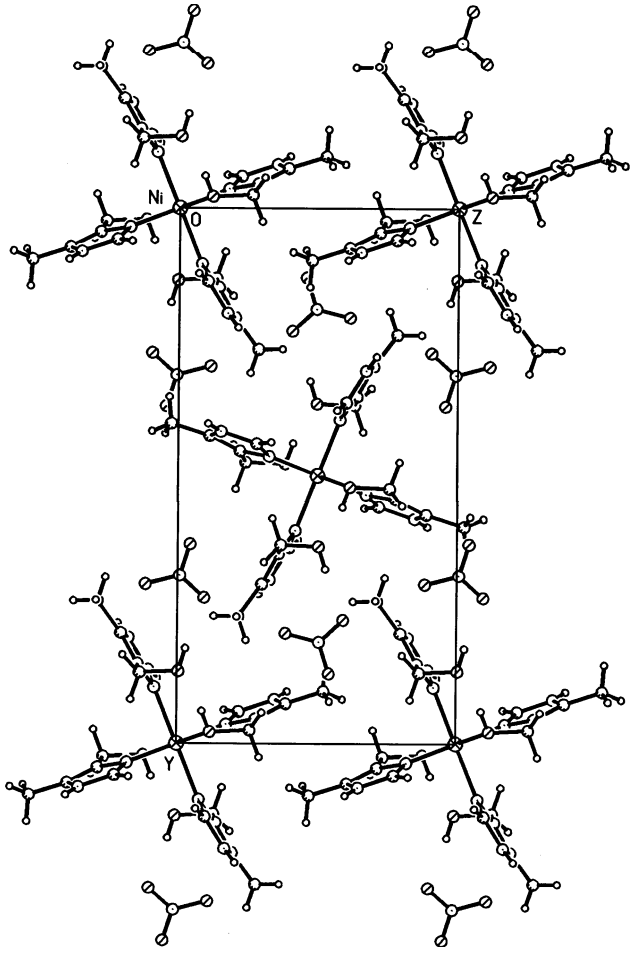

Fig. 2. Molecular packing of $[Ni(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$ in the unit cell.

nitrate group and the other with the hydrogen atom of the hydroxyl group of the bidentate azole ligand. Both the lengths and angles between the bonds are shown in Tables 4 and 5.

3.1.2. The IR spectra

Interpretation of the IR and far-IR spectra was based on changes in the spectra of the complexes relative to that of non-complexed 4-CH_2OH–5-CH_3im. Those of both studied complexes are in accord with their structure. Involvement of the 'pyridine' nitrogen atom of the imidazole ring in co-ordination is highlighted by displacement of the band assigned to ν(C=C) conjugated with ν(C=N) from 1499 (free ligand) to 1510 cm^{-1} for the Cu(II) complex and to 1506 cm^{-1} for the Ni(II) complex. The metal–nitrogen bond was identified on the basis of the far-IR spectra in which double bands at 302, 279 and 298, 283 cm^{-1} for the Cu(II) and Ni(II) complexes, respectively, have been assigned to ν(M–N). Co-ordination through the oxygen atom of the hydroxymethyl group shifts the ν(OH) band from 3415 cm^{-1} (free base) down to 3327 cm^{-1} in the Cu(II) complex

Table 2

and 3337 cm^{-1} in the Ni(II) complex. Again, a strong sharp ν(C–O) peak in the spectrum of the free base at 1004 cm^{-1} is split in that of the Cu(II) complex into two bands emerging at 993 and 1024 cm^{-1} due to the dual nature of the hydroxymethyl group in this complex. One of the split bands can be assigned to the hydroxymethyl group co-ordinated to the central ion, while the other to the non-co-ordinated group. In the spectra of the Ni(II) complex, this band is not displaced.

In the IR spectra of both complexes, there are two new bands which are missing in the spectrum of the free base. One of these, at 1385 cm^{-1}, is very strong and sharp, and the other, at 812 cm^{-1} is weak. Both the shape and position of the latter is typical for the nitrate group non-co-ordinated to the central ion [15].

3.1.3. EPR spectra of $[Cu(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$ complex

The EPR spectrum of polycrystalline $[Cu(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$ presents a slightly anisotropic line (Fig. 3(a)). A very weak resolution of the parallel orientation peak and the lack of copper hyperfine splitting is most likely caused by spin–spin interaction between Cu(II) paramagnetic centres at a relatively small distance (7.238 Å). In the case of the Cu(II) complex with the analogous ligand donor set from four 1-benzyl-2-hydroxymethylimidazoles this distance is 9.580 Å and distinctly resolved copper hyperfine struc-

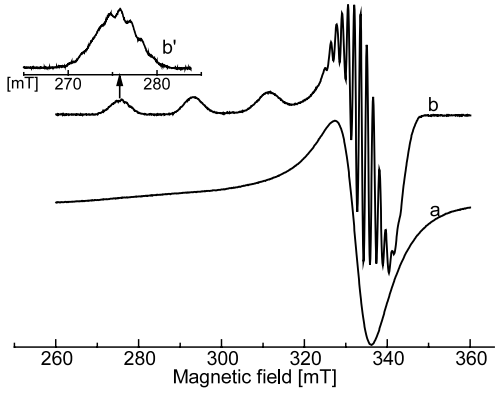

Fig. 3. EPR spectra of $[Cu(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$: (a) polycrystalline; (b) in methanolic frozen solution at 77 K (b′ is an amplified peak of copper hyperfine coupling).

the EPR spectrum at 77 K exhibits hyperfine splittings due to interaction with both copper and nitrogen nuclei (Fig. 3(b and b′)). The values of EPR parameters ($g_\parallel = 2.263$ and $A_\parallel = 185 \times 10^{-4}$ cm^{-1}) are characteristic of tetragonally elongated octahedral geometry of the complex, in agreement with the Cu(II) environment determined by crystal structure analysis. The ^{14}N hyperfine splittings at the peaks due to copper hyperfine coupling of parallel orientation (Fig. 3(b′)) and at the high field peak of perpendicular orientation (Fig. 3(b)) result from strong interaction between four nitrogen donors and Cu(II). The EPR parameters of the complex characteristically differ from those found for the complex with similar chelate rings around Cu(II) provided by four 1-benzyl-2-hydroxymethylimidazole ligands (with $g_\parallel = 2.277$ and $A_\parallel = 175 \times 10^{-4}$ cm^{-1}) [8]. A decrease of $g_\parallel$ and an increase of $A_\parallel$ values may be assigned to higher donor properties of 4-hydroxymethyl-5-methylimidazole ($pK_a = 7.14$) as compared to 1-benzyl-2-hydroxymethylimidazole ($pK_a = 6.58$) [8] taking into account that the axial positions are occupied in a similar way in both complexes.

3.1.4. d–d Electronic spectra

The previously described spatial configuration of the CuN_4O_2 chromophore is closely related to the shape and

position of the visible absorption spectrum. The absorption band at 18 100 cm^{-1} is broad, diffuse and asymmetric. With tetragonal Cu(II) complexes such a shape of the spectrum results from superposition of three component bands. Their exact positions established by means of the Gaussian distribution are at 11 600, 14 400 and 18 900 cm^{-1} In addition, the EPR survey shows that the ground state of the Cu(II) ion in the complex is within the $d_{x^2-y^2}$ orbital (spectroscopic state $^2B_{1g}$). Consequently, the identified absorption bands can be assigned as the $^2B_{1g} \rightarrow {}^2A_{1g}$, $^2B_{1g} \rightarrow 2B_{2g}$ and $^2B_{1g} \rightarrow {}^2E_g$ transitions, respectively [16].

For the octahedral Ni(II) complexes the crystal field theory predicts three spin permissible electronic transitions, namely $^3A_{2g}(F) \rightarrow {}^3T_{2g}(F)$ (ν_1), $^3A_{2g}(F) \rightarrow {}^3T_{1g}$ (ν_2) and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$ (ν_3) [17]. In the d–d spectra of the Ni(II) complex, the low-energy absorption due to the first transition appears in the near-IR at $\nu_1 = 11\,700$ cm^{-1}. The next two bands appear in the visible range, at $\nu_2 = 18\,100$ and $\nu_3 = 28\,600$ cm^{-1}.

3.2. Investigation in aqueous solution

Under the adopted experimental conditions, the dissociation constant of protonated 4-CH_2OH–5-CH_3im is 8.08×10^{-8} (pK_a 7.09). The base is thus a one order of magnitude weaker base than its alkyl counterpart, 4,5-dimethylimidazole (pK_a 8.19).

The complexation of the Cu(II) and Ni(II) ions was studied over the pH range 2.5–7.1. The determined stability constants of consecutive complexes are collected in Table 6. Percent molar contributions of particular complexes in aqueous solution, calculated on the basis of β_n, are presented in Fig. 4. As seen in Table 6, despite the fact that 4-CH_2OH–5-CH_3im is a weaker Brönsted base than 4,5-dimethylimidazole, it forms complexes of higher stability (missing β_n constants for the Ni(II)—4,5-dimethylimidazole complexes precludes making similar comparison for this central ion). In order to identify factors affecting stability of the hydroxymethylimidazole complexes, substitution constants, $\log {}^*\beta_1 = \log \beta_1 - pK_a$ have been determined. These constants represent the tendency of the ligand towards complexation after elimination of the basicity effect. For the Cu(II) complexes of 4-CH_2OH–5-CH_3im, the $\log {}^*\beta_1$ value is a respective 1.28 units

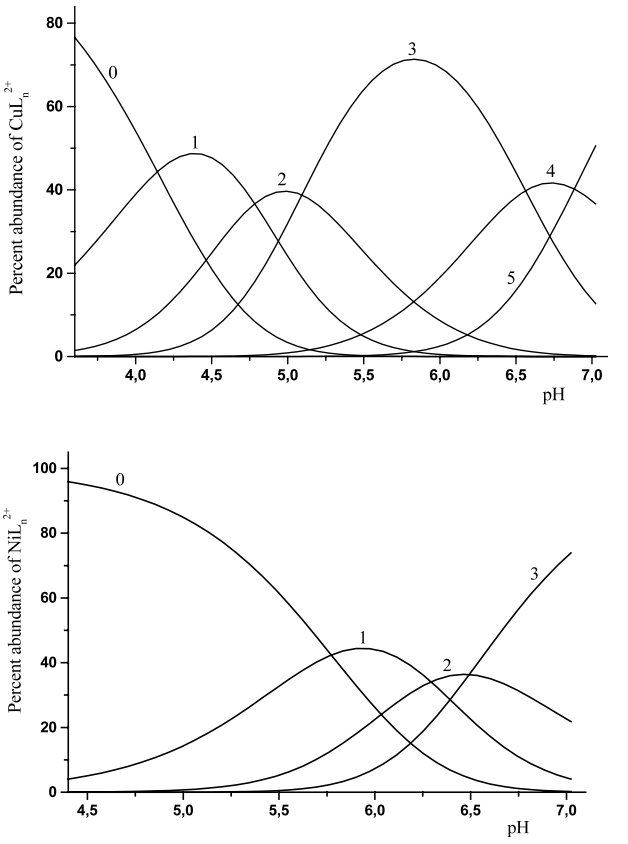

Fig. 4. Distribution diagrams of complexes formed in the M^{2+}-4-hydroxymethyl-5-methylimi-dazole (M^{2+}=Cu^{2+} and Ni^{2+}) systems as a function of pH at 298 K and $I = 0.5$ mol dm^{-3}. The number in the diagrams mean n in ML_n^{2+}.

higher than for their 4,5-dimethylmidazole counterparts. The enhanced stability of the complexes due to substitution of the methyl group for the hydroxymethyl ones can be explained in terms of an additional participation of the oxygen atom in the co-ordination bond. Consequently, the enhanced stability of the 4-CH_2OH–5-CH_3im complexes is an outcome of the possibility of formation of five-member chelate rings under involvement of both the nitrogen and oxygen atoms. Quantitative analysis of $\log(K_1/K_2)$ does not indicate the existence of typical, strong chelates in solution because the metal–oxygen bond is weak and easily broken. Formation of this chelate is not accompanied by loss of a proton from the hydroxymethyl group. This interpretation is in accord with studies of

Table 6
Stability and substitution constants $\log {}^*\beta_1$ of the 4,5-dimethylimidazole and 4-hydroxymethyl-5-methylimidazole complexes in aqueous solution [a]

Ligand	Central ion	$\log \beta_1$	$\log \beta_2$	$\log \beta_3$	$\log \beta_4$	$\log \beta_5$	$\log \beta_1^*$	Reference
4,5-Dimethyl imidazole ($pK_a = 8.19$)	Cu^{2+}	3.72	6.92	9.55	10.78		−4.47	[18]
4-Hydroxymethyl-5-methylimidazole ($pK_a = 7.14$)	Ni^{2+}	2.32(1)	4.12(1)	5.72(2)				this work
	Cu^{2+}	3.95(1)	7.26(2)	10.26(2)	11.79(3)	13.00(2)	−3.19	

[a] At 298 K, ionic strength $I = 0.5$ mol dm^{-3} (KNO_3).

Table 7
Position of absorption bands of Cu(II) and Ni(II) complexes with 4-hydroxymethyl-5-methylimidazole in aqueous solution

Ligand	Absorption band position (cm^{-1})		
	Ni(II)		Cu(II)
	$^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$	$^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$	$^2E_g \rightarrow {}^2T_{2g}$
H_2O	15 200	25 300	12 600
4-Hydroxymethyl-5-methylimidazole	16 000 ($e = 6.1$)	26 800	15 900 ($e = 69$)

these complexes in the solid state. It was shown that Cu(II) and Ni(II) were bonded to four molecules of the ligand, two of which are unidentate and the remaining two are bidentate (chelate). With the Cu(II)–4-CH_2OH–5CH_3im complexes, remarkable is the enhanced stability of the first three complexes and a distinct weakening of the fourth complex. One might thus speculate that the metal–oxygen bonds are weak and, after inclusion of four ligand molecules into the coordination sphere of the central ion, they are broken. Similar variations in the consecutive stability constants have been noted with the 1-alkyl-2-hydroxymethylimidazole complexes [1–3,8].

The structure of the Cu(II) and Ni(II) complexes with 4-CH_2OH–5-CH_3im in aqueous solution was established on the basis of their visible spectra. Formation of the Cu(II) and Ni(II) complexes is accompanied by an increase in the mean molar absorptivity and a hypsochromic shift of the maximum. Both the shape and position of the absorption bands as well as the magnitude of the mean molar absorptivity (Table 7) indicate the presence of hexacoordinate tetragonal Cu(II) as well as pseudo-octahedral Ni(II) complexes in aqueous solution [17].

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 179897 and 179898 for compounds $[Cu(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$ and $[Ni(4\text{-}CH_2OH\text{–}5\text{-}CH_3im)_4](NO_3)_2$, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

2. Experimental

2.1. Materials and measurements

All solvents were reagent grade and purified according to the standard procedure [7]. All chemicals used in syntheses were of reagent grade and used without further purification. The dithiadiazamacrocycle [8], cyanogen-di-*N*-oxide [9], $[Cu(CH_3CN)_4]$ PF_6^- [10] and 1,2-bis(2-chloroethoxy)benzene [11] were prepared as described previously. ^1H, ^{13}C NMR and IR spectra were recorded on a Varian XL-200 and on a Perkin–Elmer 1600 FT IR spectrometer, respectively. Fast atom bombardment mass spectra were recorded on a Varian MAT 711 and VG Zapspec spectrometers using *m*-nitrobenyl alcohol as the matrix. The elemental analysis and metal contents of the complexes were determined on a Hewlett-Packard 185 CHN analyzer and on a Unicam 929 AA spectrometer.

2.2. Synthesis of 1,2-dinitro-4,5-bis(2-chloroethoxy)benzene (**2**)

Concentrated HNO_3 (13.5 ml, 70%) was added dropwise to a solution of **1** (5.0 g, 21 mmol) at room temperature (r.t.) over 1 h, then the mixture was stirred for 7 h at 60 °C. After the end of this period, the reaction mixture was cooled to r.t., filtered off, washed with water and cold ethanol, and then dried in vacuo. The crude product was recrystallized from methanol to yield pale yellow crystals. Yield: 6.0 g, 86.8%, melting point (m.p.) 102 °C. Found (Calc. for $C_{10}H_{10}N_2O_6Cl_2$): C, 37.14 (36.93); H, 3.29 (3.07); N, 8.40 (8.61)%. ^1H NMR (DMSO-d_6, ppm): δ 7.81 (s, 2H, Ar–H), 4.52 (t, 4H, CH_2O), 4.05 (t, 4H, CH_2Cl). IR (KBr, cm^{-1}); 3031 (Ar–H), 2978 (C–H), 1337 (NO_2), 1288–1223 (Ar–O–C), 678 (C–C1). EI MS (*m*/*z*): 324 $[M]^+$.

2.3. Synthesis of 1,2-dinitro-4,5-bis(2-iodoethoxy)benzene (**3**)

Compound **2** (4.5 g, 13.8 mmol) was dissolved in dry acetone (100 ml) containing anhydrous NaI (8.29 g, 55.2 mmol) under an argon atmosphere and refluxed for 29 h. After a while, the solution turned cloudy and then solid product precipitated. Then the reaction mixture was cooled to r.t. and the precipitate was filtered off and washed with dry acetone. The mother liquor and the washing solvents were combined and evaporated to dryness under reduced pressure. The crude product was purified by column chromatography using silica gel. The elution was carried out successively with petroleum–ether–ethyl acetate [(6:1), $R_f = 0.58$] to yield yellow needle crystals. Yield: 5.77 g, 84.4%, m.p. 112 °C. Found (Calc. for $C_{10}H_{10}N_2O_6I_2$); C, 23.38 (23.63); H, 2.17 (1.96); N, 5.35 (5.51)%. ^1H NMR (DMSO-d_6, ppm): δ 7.67 (s, 2H, Ar–H), 4.41 (t, 4H, CH_2O), 3.52 (t, 4H, CH_2I). IR (KBr, cm^{-1}): 3055 (Ar–H), 2883 (C–H), 1369 (NO_2), 1291–1224 (Ar–G–C), 662 (C–I), FAB MS (*m*/*z*): 507 $[M+1]^+$.

2.4. Synthesis of dinitro substituted dioxadithiadiazamacrobicycle (**5**)

A 500 ml round-bottom flask containing dry acetonitrile–DMF mixture (3:1) (200 ml) and fitted with a condenser was evacuated, refilled several times with argon and connected to a vacuum-line. Under argon, the flask was charged with **4** (1.32 g, 4 mmol) and finely ground anhydrous Cs_2CO_3 (3.24 g, 9.92 mmol) and the mixture was stirred at r.t. A solution of **3** (2.03 g, 4 mmol) in dry acetonitrile (80 ml) was added to this mixture and the reaction mixture was stirred at r.t. for 94 h. The reaction was monitored by TLC [chloroform–acetone–petroleum ether (4:6:1), $R_f = 0.51$]. At the end of this period, the reaction mixture was filtered and washed with dry chloroform and then the combined solution was evaporated to dryness under reduced pressure. The crude product was crystallized from chloroform–ethyl ether to yield yellow crystals. Yield: 1.36 g, 58.36%, m.p. 239 °C. Found (Calc. for $C_{28}H_{30}N_4O_6S_2$): C, 57.94 (57.73); H, 4.94(5.15); N, 9.39 (9.39)%. ^1H NMR (DMSO-d_6, ppm): δ 7.62 (s, 2H, Ar–H), 7.15–7.03 (m, 8H, Ar–H), 4.20 (t, 4H, CH_2O), 4.14 (s, 4H, $ArCH_2$), 3.47 (m, 8H, NCH_2), 2.69 (t, 4H, SCH_2). ^{13}C NMR (DMSO-d_6): δ 151.38, 139.27, 135.92, 132.71, 131.67, 128.59, 127.87, 126.23, 107.44, 66.94, 60.01, 52.74, 32.85. IR (KBr, cm^{-1}): 3055 (Ar–H), 2923–2786 (C–H), 1375 (NO_2), 1288–1218 (Ar–O–C). FAB MS (*m*/*z*): 583 $[M+1]^+$.

2.5. Synthesis of diamine substituted dioxadithiadiazamacrobicycle (**6**)

Palladium (10%)–activated carbon (1.25 g) was added to a solution of **5** (1.7 g, 2.92 mmol) in dry dioxane (100 ml) at 60 °C and 5.2 ml of anhydrous hydrazine was then added dropwise at reflux temperature. The reaction mixture was refluxed and stirred for 15 h. The extent of the reaction was monitored by using TLC [petroleum–ether–acetone (1:2), $R_f = 0.88$]. The reaction mixture was filtered through Celite as an extraction agent and concentrated to 15 ml under reduced pressure and then was allowed to stand in a refrigerator at −18 °C overnight. The colorless crystalline product was collected by filtration and washed with cold ethanol and diethyl ether and then dried in vacuo. Yield: 1.0 g, 65.78%, m.p. 181 °C. Found (Calc. for $C_{28}H_{34}N_4O_2S2$): C, 64.53 (64.36); H, 6.36 (6.51); N, 10.89 (10.72)%. ^1H NMR ($CDCl_3$, ppm): δ 7.22 (s, 2H, Ar–H), 7.04–6.97 (m, 6H, Ar–H), 6.31 (s, 2H, Ar–H), 4.30 (m, 4H, Ar–OCH_2), 3.88 (m, 4H, Ar–CH_2), 3.58 (s, 4H, NH_2), 3.27

(m, 8H, CH_2–N), 2.61 (m, 4H, CH_2–S). ^{13}C NMR ($CDCl_3$, ppm): δ 148.15, 146.67; 129.88, 128.21, 128.12, 127.83, 125.93, 122.89, 103.87, 65.82, 59.54, 53.41, 33.92. IR (KBr, cm^{-1}): 3349 (NH_2), 3053 (Ar–H), 2958–2852 (C–H), 1605 (N–H), 1234–1199 (Ar–O–C). FAB MS (m/z): 522.1 $[M]^+$.

Caution: Anhydrous hydrazine is potentially hazardous. While working with this chemical, half-mask respirators should be used and the reaction should be performed in a very well ventilated system. The system should be handled with caution.

2.6. Synthesis of dioxime (*H_2L*)

A solution of cyanogen-di-*N*-oxide (**7**) prepared from (*E*,*E*)-dichloroglyoxime (0.31 g, 2 mmol) in dichloromethane (20 ml) and an aqueous solution of Na_2CO_3 (10 ml, 0.5 M), was added to a cold solution (−15 °C) of **6** (1.44 g, 2 mmol) in dichloromethane (40 ml) under argon atmosphere. The reaction was continued for 12 h at the above mentioned temperature and the pale brown product formed separated by filtration, washed with dichloromethane and diethyl ether, and then dried in vacuo. The purification of this compound was performed by using column chromatography with chloroform as the eluent ($R_f = 0.62$). Yield: 0.83 g, 68.9%, m.p. 282 °C (dec.). Found (Calc. $C_{30}H_{34}N_6O_4S_2$): C, 59.24 (59.40); H, 5.40 (5.61); N, 14.05 (13.86)%. ^1H NMR (DMSO-d_6, ppm); δ 10.22 (s, 2H, OH), 9.30 (s, 2H, NH), 732–7.03 (m, 10H, Ar–H), 4.29 (m, 4H, Ar–O–CH_2), 3.83 (m, 4H, Ar–CH_2), 3.39 (m, 8H, CH_2–N), 2.62 (m, 4H, CH_2–S). ^{13}C NMR (DMSO-d_6, ppm): δ 145.28, 143.92, 133.53, 131.36, 129.61, 128.46, 127.83, 123.25, 114.97, 104.37, 67.45, 60.08, 54.32, 35.11. IR (KBr, cm^{-1}): 3318 (N–H), 3245 (O–H), 3043 (Ar–H), 2922–2793 (C–H), 1639 (C=N), 1601 (N–H), 1265–1153 (Ar–O–C), 948 (N–O), FAB MS (m/z): 607.2 $[M+1]^+$.

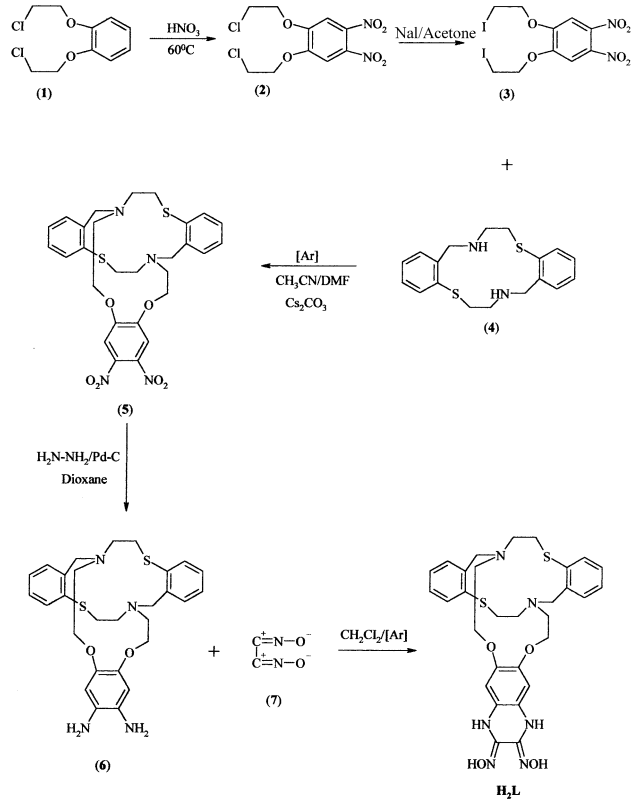
2.7. Synthesis of [Ni(HL)$_2$] (*8*)

A solution of $NiCl_2 \cdot 6H_2O$ (0.15 g, 0.625 mmol) in ethanol (10 ml) was added to a solution of **H_2L** (0.75 g, 1.25 mmol) in ethanol (75 ml) at 60 °C, a distinct change in color from pale brown to orange and a decrease in the pH of the solution was observed. While heating and stirring at the above mentioned temperature, an equivalent amount of ethanolic solution of triethylaminc (0.1 M) was added and an orange precipitate of **8** formed. After heating the mixture for 2 h in a water-bath, the precipitate was filtered off, washed several times with water, ethanol and diethyl ether and then dried in vacuo. Yield: 0.68 g, 86%, m.p. 274 °C (dec.). Found (Calc. for $C_{60}H_{66}N_{12}O_8S_4Ni$): C, 56.92 (56.75); H, 5.37 (5.20); N, 13.01 (13.24); Ni, 4.38 (4.62)%. ^1H NMR (DMSO-d_6, ppm): δ 16.97 (s, 2H, O–H–O), 9.37 (s, 4H, NH), 7.43–7.11 (m, 20H, Ar–H), 4.36 (m, 8H, Ar–O–CH_2), 3.89 (m, 8H, Ar–CH_2), 3.46 (m, 16H, CH_2–N), 2.78 (m, 8H, CH_2–S). IR (KBr, cm^{-1}): 3334 (N–H), 3054 (Ar–H), 2917–2823 (C–H), 1709 (O–H–O), 1625 (C=N), 1605 (N–H), 1252–1138 (Ar–O–CH_2), 936 (N–O). FAB MS (m/z): 1269.2 $[M+1]^+$.

2.8. Synthesis of [Ni(LBF$_2$)$_2$ (*9*)

A suspension of **8** (0.63 g, 0.5 mmol) in 50 ml of freshly distilled dry acetonitrile was brought to reflux temperature in an argon atmosphere. An equivalent amount of boron–trifluoride etherat complex (0.41 ml) was added with continuous stirring to this suspension, which changed its color to red immediately. After refluxing for 30 min., the solvent was evaporated to dryness. Then the dark red crude product was dissolved in 10 ml dry acetonitrile and allowed to stand in a refrigerator at −18 °C overnight, whereupon the compound crystallized from the solution. The red crystallized product was collected by filtration, washed with cold acetonitrile and diethyl ether and then dried in vacuo. Yield: 0.32 g, 47%, m.p. 253 °C. Found (Calc. for $C_{60}H_{64}N_{12}O_8S_4\ B_2F_4Ni$); C, 52.58 (52.77); H, 4.87 (4.69); N, 12.12 (12.31); Ni, 4.46 (4.30)%. ^1H NMR (DMSO-d_6, ppm): δ 9.25 (m, 4H, NH), 7.34–6.79 (m, 20H, Ar–H), 4.52 (m, 8H, Ar–O–CH_2), 3.98 (m, SH, Ar–CH_2), 3.44 (m, 16H, CH_2–N), 2.74 (m, 8H, CH_2–S). IR (KBr, cm^{-1}): 3419 (N–H), 3059 (Ar–H), 2935–2827 (C–H), 1654 (C=N), 1258–1141 (Ar–O–C), 940 (N–O), 1112 (B–O), 885 (B–F). FAB MS (m/z); 1362.3 $[M]^+$.

2.9. Synthesis of [Cu$_2$Ni(LBF$_2$)$_2$](PF$_6$)$_4$ (*10*)



A solution of $[Cu(CH_3CN)_4]PF_6$ (0.11 g, 0.29 mmol) in dry acetonitrile (20 ml) was added to a solution of **9** (0.24 g, 0.15 mmol) in dry acetonitrile (80 ml) under an oxygen-free nitrogen atmosphere at 45 °C. Then the reaction was refluxed and stirred under nitrogen for 4 h. The end of the reaction was determined by TLC [*n*-butanol–acetic acid–water (4:1:5), $R_f = 0.33$]. After cooling to r.t. the reaction mixture was concentrated to 10 ml under reduced pressure. The reaction mixture was allowed to stand at −18 °C overnight whereupon the product crystallized from the solution. The reddish brown crystallized product was collected by filtration, washed with cold ethanol, acetonitrile and diethyl ether and then dried in vacuo. Yield: 0.19 g, 61.5%, m.p. 144 °C Found (Calc. for $C_{60}H_{64}N_{12}O_8S_4B_2P_2F_{16}NiCu_2$): C, 40.57 (40.41); H, 3.41 (3.59); N, 9.29 (9.41); Ni, 3.59 (3.29); Cu, 6.94 (7.13)%. ^1H NMR (DMSO-d_6, ppm): δ 8.29 (m, 4H, NH), 7.38–6.81 (m, 20H, Ar–H), 4.63 (m, 8H, Ar–O–CH_2), 4.12 (m, 8H, Ar–CH_2), 3.55 (m, 16H, CH_2–N), 2.91 (m, 8H, CH_2–S). IR (KBr,

cm^{-1}): 3365 (N–H), 3059 (Ar–H), 2919–2825 (C–H), 1653 (C=N), 1607 (N–H), 1272–1142 (Ar–O–C), 1085 (B–O), 897 (B–F), 845 $(PF_6)^-$, FAB MS (*m*/*z*); 1777 $[M+1]^+$.

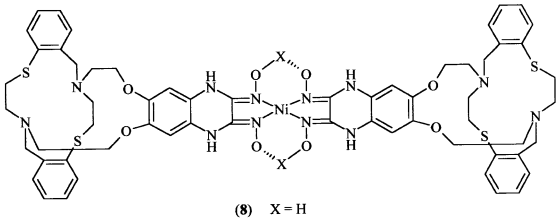
3. Results and discussion

The preparation of the target heterotrinuclear complex **9** was synthesized in a seven-step (Scheme 1) sequence from 1,2-bis(2-chloroethoxy)benzene [11]. The conversion of **1** to the dinitro derivative (**2**) was accomplished in 86.8% yield. In the ^{1}H NMR spectrum of **2**, the presence of the singlet at $\delta = 7.81$ ppm showed that dinitration had occurred. The mass spectrum (EI) of this compound showed a dominant peak at $m/z =$ 324, which corresponds to $[M]^+$. This compound was easily converted to the diiodo derivative **3** by reaction with NaI in dry acetone and the yield of the conversion reaction was very high (84.4%). The ^{1}H NMR resonances of **3** are very similar to those of the precursor compound **2** except the proton resonances connected to iodo atoms. The fast atom bombardment EI of **3** also supports the replacement of chlorine by iodide, with the peak at $m/z = 507$ $[M+1]^+$.

The macrobicyclization reaction **5** was performed by starting from the 14-membered macrocycle **4** [8] and **3** using Cs^+ as a promoter [12] and in acetonitrile–DMF

Scheme 1.

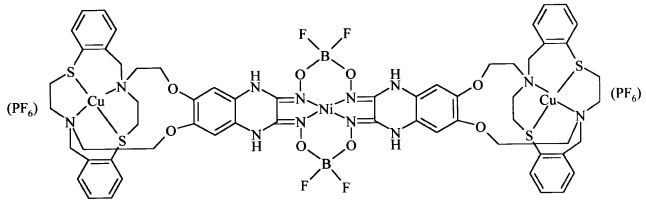
mixture at r.t. in a Schlenk system connected vacuum-line under argon. The macro-bicycle compound was isolated in 58.36% yield, crystallized a mixture of chloroform–ethyl ether and characterized. Analytical and spectroscopic data of **5** clearly confirm the success of the macrobicyclization reaction. The new signals due to methylene and aromatic protons at $\delta = 4.20$ and 7.62 ppm, respectively, confirm the formation of **5.** The disappearance of NH chemical shifts and N–H stretching vibration in the IR spectrum of this compound also suggests the desired macrobicycle. Proton-decoupled ^{13}C NMR spectral data are also in good agreement with the proposed structure (Scheme 1). The new resonances belonging to dinitro substituted phenyl and methylene carbons at $\delta = 151.38$, 139.27, 135.92 and 66.94 ppm, respectively, that can be attributed to the macro-cyclization have occurred. The value of the molecular ion observed shows good agreement with the calculated value for **5** ($m/z = 583$ $[M+1]^+$).



The diamine compound **6** was prepared in 65.78% yield by reduction [13] of the corresponding dintro compound **5** with palladium-activated charcoal and anhydrous hydrazine, which was sufficiently stable to make characterization. The amine **6**, apparently sensitive to both light and air, is colorless and darkens as expected when it is left to standing at r.t. In the ^{1}H NMR spectrum of **6**, there is a broad signal at $\delta = 3.58$ ppm due to the aromatic amine protons. A comparison of the proton resonances of **5** and **6** resulted in an upfield shift of the aromatic proton. The ^{13}C NMR spectrum for **6** also supported this situation and was consistent with the proposed formulation. The disappearance of the Ar–NO_2 (1375 cm^{-1}) stretching and appearance of Ar–NH_2 stretching (3349 cm^{-1}) and bending vibrations (1605 cm^{-1}) indicate completion of the reduction. On the other hand, the EI (FAB) of **6**, which shows a molecular ion peak at $m/z = 522.1$ $[M]^+$, confirms the proposed structure.

The preparation **H_2L** has been accomplished as described [14] in 68.9% yield by the reaction of **6** with cyanogen-di-*N*-oxide (**7**) at -15 °C in dichloromethane media. In the ^{1}H NMR spectrum of **H_2L**, the deuterium exchangeable protons of the OH and NH groups appear as two singlets at $\delta = 10.22$ and 9.30 ppm, respectively. More detailed information about the structure of **H_2L** is provided by its ^{13}C NMR spectrum. The carbon resonance of amidoxime is found to be at the higher field value of $\delta = 143.92$ ppm compared with the values for the aldo- and ketooximes [15]. The equivalent carbon and proton signals of the azomethine and hydroxyimino groups confirm the (*E*,*E*) form of *vic*-odioxime [16].

The FAB EI of this ligand exhibited an intense peak at $m/z = 607.2$ $[M+1]^+$, which is in accord with the expected formulation.



It was found that when on equivalent amount of nickel(II) chloride hexahydrate is used as the Ni(II) salt, the mononuclear Ni(II) complex **8** of **H_2L** is obtainable in a good yield (86.0%) (Scheme 2). It is interesting to note that this complexation reaction does not occur in the macrobicyclic moieties under the same conditions, which we attributed to greater affinity of the Ni(II) oxime promoting oxime nucleophile formation. In the ^{1}H NMR spectrum of **8**, only slight differences between those of the ligand and its Ni(II) complex were observed. While the chemical shifts of deuterium exchangeable NH protons were observed at $\delta = 9.37$ ppm, the intramolecular hydrogen bridging O–H–O protons have been shifted to a lower field at $\delta = 16.97$ ppm as expected [17]. Since a distinct decrease in the pH of the solution was observed during complex formation, deprotonation of the ligand with subsequent *N*,*N*′-chelation with the (*E*,*E*)-dioxime groups occurs **8**. The weak band at 1709 cm^{-1} assigned to the intramolecular hydrogen bonded bending vibrations in the IR spectrum also indicates the same formation [18], The FAB EI of this complex showed the expected molecular ion peak at $m/z = 1269.2$ $[M+1]^+$.

The template synthesis of the BF_2^+-capped nickel(II) complex **9** was performed in 47% yield by adding borontrifluoride ethyl ether complex to a refluxing suspension of **8** in acetonitrile media. The hydrogen bridging protons were replaced by BF_2^+ groups. In the ^{1}H NMR spectrum of **9**, the hydrogen bonding protons disappeared after the replacement with $BF_2'^+$. This new group causes the resonances of **9** to shift down-field relative to those of the precursor nickel(II) complex. The disappearance of the characteristic O–H–O bending vibrations when substituting the hydrogen bonds with BF_2^+ also confirm the formation of **9**. On the other hand, an upward shift of the C=N stretching vibration was observed due to the strong electron-withdrawing influence of the difluoroboron-linked group incorporated in this macrocycle [19]. The molecular ion peak at $m/z = 1362.3$ $[M]^+$ in the FAB EI of this compound also supports the proposed formulation.

(8) X = H

(9) X = BF_2

(10)

Scheme 2.

In order to synthesize the heterotrinuclear complex $[Cu_2Ni(LBF_2)_2](PF_6)_2$ (**10**), the reaction of mononuclear complex **9** with a solution of $[CucCH_3CN)_4]PF_6$ was carried out in 61.5% yield. In this product Ni(II) is still coordinated to the dioxime groups, and the two Cu(I) ions are coordinated to two dithiadiaza hetero atoms of macrobicycles [20] according to the analytical and spectroscopic data. The ^{1}H NMR spectrum of **10** is largely similar to those of the precursor compound **9**, but the expected shifts due to complexation with Cu(I) cations belonging to macrobicyclic units such as CH_2–N and CH_2–S are significant. In the IR spectrum of **10**, the resonances at 845 and 563 cm^{-1}, assigned to $[PF_6]^-$, support a structure in which the PF_6^- ions are not coordinated to the Cu(I) cations [21]. The EI of **10** was obtained by the FAB technique using a matrix (matrix: *m*-nitrobenzyl alcohol) in the region of the molecular ion peak at $m/z = 1777$ $[M+1]^+$.

4. Conclusions

We have presented a novel *o*-dinitrobenzene containing macrobicyclic unit as a starting material and its conversion to macrobicycle substituted *o*-phenylenediamine and also to the quinoxaline substituted (*E*,*E*)-dioxime. Starting form **H_2L** and $NiCl_2 \cdot 6H_2O$, the mono-nuclear nickel(II) complex was prepared. We succeeded in other transition metal binding to the macrobicyclic cavities of $N_2S_2O_2$ macrocycles by Cu(I) cations, causing a distinct change in the spectral data compared with those of the diazadithiadioxamacrobicycle substituted compounds. The approach described here allows the preparation of a wide number of homo or hcterotrinuclear complexes whose properties will be a subject of heavy metal extraction from aqueous media to organic solvents.

compound in the 2–300 K region have been studied as well.

2. Experimental

Pyridine derivative ligands were purchased from the Aldrich or BDH companies and other chemicals are of analytical grade quality.

Abbreviations for the pyridine ligands are given as a footnote under Table 1.

2.1. Preparation of complexes

2.1.1. $[Ni(4\text{-}Etpy)_4(N_3)]PF_6$ (**1**)

This complex was prepared by mixing an aqueous solution of $Ni(NO_3)_2\cdot 6H_2O$ (2.0 mmol) dissolved in 10 cm^3 water and 4-Etpy (5.0 mmol) in approximately 15 cm^3 ethanol followed by KPF_6 (2.0 mmol, 3 cm^3 water) and NaN_3 (1.5 mmol, in ca. 3 cm^3 water). The final clear solution mixture was allowed to stand in an open beaker over several days until good quality blue crystals of the complex deposited.

2.1.2. $[Ni(py)_4(N_3)]PF_6$

This complex was prepared by mixing $Ni(NO_3)_2\cdot 6H_2O$, pyridine, KPF_6 and NaN_3 in the molar ratio of 1:6:1.5:1, respectively, in approximately 30 cm^3 aqueous-ethanol medium. The final clear solution mixture was allowed to stand over several days to produce the complex as a blue microcrystalline powder.

2.1.3. $[Ni(4\text{-}Mepy)_4(N_3)]PF_6$

This complex was prepared in a crystalline form by adding an ethanol solution (10 cm^3) of 4-Mepy (4.0 mmol) to an aqueous solution (10 cm^3) of $Ni(NO_3)_2\cdot 6H_2O$ (1.5 mmol), followed by addition of KPF_6 (2.0 mmol, in ca. 2 cm^3 water) and NaN_3 (1.0 mmol, in ca. 2 cm^3 water). The final clear solution mixture was heated for several minutes and then allowed to stand over several days.

2.1.4. $[NiL_4(N_3)]PF_6$; for L = 3-Clpy and 3-Brpy

These complexes were prepared in powder form by mixing 3-Clpy or 3-Brpy, $Ni(NO_3)_2\cdot 6H_2O$, KPF_6 and NaN_3 in a molar ratio of 6:1:1.5:1, respectively, in approximately 30 cm^3 water–ethanol medium, and the final mixture allowed to stand over several days in the open air. Trials to crystallize the powder products from water or ethanol, failed to produce crystalline complexes.

2.1.5. $[Ni(3\text{-}hydpy)_4(N_3)]PF_6$

This complex was prepared by mixing $Ni(NO_3)_2\cdot 6H_2O$,3-hydpy, KPF_6 and NaN_3 in the molar ratio of 2:3:4:1.5, respectively, in approximately 30 cm^3 aqueous-ethanol medium and allowing the final mixture to stand over several days to produce a micro-crystalline powder of the complex. Molar ratios of the components other than that given above produce a mixture of the desired complex with the 1:4 nickel(II) azide complex. The elemental analyses of the isolated complexes are given in Table 1.

2.2. Physical measurements

The experimental procedures and instruments used for physical measurements were described previously [16].

2.3. X-ray crystallography

A modified STOE four-circle diffractometer was used for the single X-ray measurement. Orientation matrix and lattice parameters were obtained by least-squares refinement of 42 reflections ($9.3^\circ < \theta < 14.8^\circ$). Data were collected at 293(2) K, using graphite-monochromatized Mo Kα radiation ($\lambda = 0.71069$ Å) and the ω-scan technique. The data were corrected for Lorentz-polarization and intensity decay (16% observed intensity decay of three control reflections). The structure was solved by direct methods and subsequent Fourier analysis. Anisotropic displacement parameters were applied to non-hydrogen atoms in full-matrix least-

squares refinement based on F^2. The hydrogen atoms were assigned with common isotropic displacement factors and included in the final refinement cycles by use of geometrical restraints. Analytical expressions of neutral atom scattering factors were employed and anomalous dispersion corrections were incorporated. The program DIFABS [17] and the SHELXTL/PC-V 5.03 [18] program package were used for computations. Crystal data: empirical formula: $C_{28}H_{36}F_6N_7NiP$, formula weight = 674.32; triclinic; space group: $P\bar{1}$, a = 11.600(3), b = 15.188(6), c = 20.496(6) Å; α = 95.22(3)°, β = 106.35(2)°, γ = 107.04(3)°; V = 3253.1(18) Å^3; Z = 4; D_{calc} = 1.377 g cm^{-3}, μ (Mo Kα) = 0.710 mm^{-1} crystal size = 0.35 × 0.22 × 0.17 mm; 1153 reflections, 786 parameters; R_1 = 0.0777, R_{int} = 0.0290.

3. Results and discussion

3.1. Preparation of the complexes

Nickel(II) nitrate hexahydrate interacts with pyridine derivative ligands in the presence of sodium azide and potassium hexafluoro phosphate in aqueous-ethanol media giving the nickel(II) azido complexes collected in Table 1. Such reactions are very sensitive to the ratio between azide and PF_6^- ions. A small amount of the azide ion higher than PF_6^- ion, leads to the isolation of nickel(II) azido complexes, usually 1:4, rather than the desired complex containing the PF_6^- ion. Our trials to prepare such cationic complexes with pyridine derivative ligands other than those mentioned in Table 1, resulted in the isolation of 1:4, nickel(II) azide: ligand complexes. Crystals of the cationic complex in case of L = 4-Mepy were found to be twins rather than single crystals.

All the isolated complexes are soluble in one or more of the following solvents; water, MeOH, EtOH, acetone, DMF and DMSO. Aqueous solutions of these complexes behave as 1:1 electrolytes (molar conductance in the range of 105–128), a result which is suggestive of the ionic nature of these complexes in aqueous solutions.

3.2. IR and electronic spectra

The IR spectral results for these complexes are collected in Table 2. These spectra show bands that can be assigned to the PF_6^- anions [19] as follows: 550–560 (ν4), 740–750 wm (ν1) and 845–850 vs, br (ν3) (all values are in cm^{-1}). These results meet the criteria for non- coordinated PF_6^- anions, as described previously [19] and are consistent with the structure of complex (**1**) (see later). The spectra of all complexes show a single or slightly split very strong band in the 2070–2090 cm^{-1} range due to the ν_{as} (N_3) mode. We could not locate any absorption band in the 1360–1270 cm^{-1} range, associated with the ν_s (N_3) mode in these complexes. The disappearance of the latter band is a strong evidence of the symmetric nature of the azido bridges [20,21] not only in complex (**1**) as shown by the X-ray structure analysis described later but also for all other complexes. In the far IR region we tentatively assigned the bands in the 300–250 and 240–210 cm^{-1} ranges [22,23] to νNi–N(azide) and νNi–N(L), respectively.

The electronic spectral data given in Table 1, for solid complexes mulled in Nujol are consistent with six-coordination around nickel(II) atoms. All these spectra exhibit a weak band or shoulder in the region of 376–465 nm, and a strong band in the vicinity of 590–610 nm, associated with $^3A_{2g}(F) \rightarrow {}^3T_{2g}(P)$ and $^3A_{2g}(F) \rightarrow {}^3T_{1g}(F)$ transitions, respectively, as found for other six-coordinated complexes involving substituted pyridines [24,25].

3.3. Structure of [Ni(4-Etpy)$_4$(N$_3$)](PF$_6$) complex (1)

Figs. 1 and 2 illustrate the principal structural features of complex (**1**), and selected bond distances and angles are collected in Table 3. The structure of **1** consists of 1D nickel-azido chains, isolated by PF_6^- anions, which are found in the interchain space. In the chain structure each nickel(II) atom is coordinated by four nitrogen atoms from the four pyridine ligands and two nitrogen atoms from two μ-1,3-azide bridges in an octahedral trans arrangement. The four nitrogen atoms of the

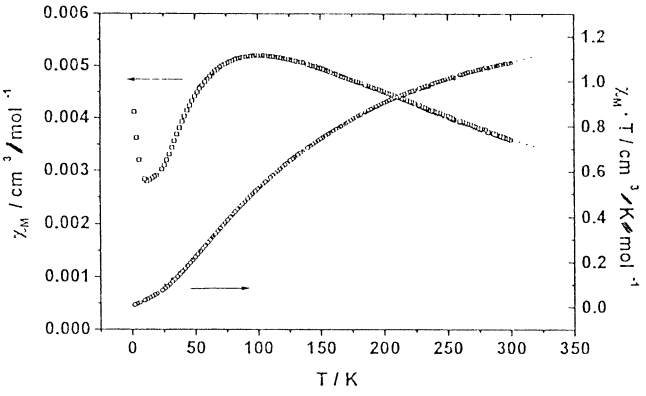

Fig. 2. Susceptibility data for compound **1**. Dotted lines show the best fit using a single average J parameter. Solid line show the best fit obtained using a ring of nine Ni(II) centers and three J superexchange parameters (see text).

pyridine ligands are in the same plane (maximum deviation from the plane = 0.03 Å); the coordination of the μ(1,3) azide bridge is slightly asymmetric; the Ni–N–N angles are 135.6(4)° and 140.3(4)°. The torsion angles are: Ni(2B)–N(31B)···N(31)–Ni(2) = 180.0°, Ni(1)–N(11)···N(11A)–Ni(1A) = 180.0° and Ni(1)–N(21)···N(23)–Ni(2) = 133.4°. The first two are a consequence of the inversion centers which are occupied by central azido atoms N(12), N(32). The four Ni–N (L) distances are almost equal [2.117–2.132 Å] as well as the Ni–N(N_3) bond lengths [2.096–2.124 Å]. The azido ligand itself is symmetrical and linear (Table 3) within the experimental error. This structure is very close to the corresponding structure of $[Co(4\text{-Mepy})_4(N_3)]PF_6$, although the latter crystallizes in the monoclinic, space group, $P2_1/c$ and the Co–N–N angles are symmetrical [135.3(3)° and 133.0(3)°] [16].

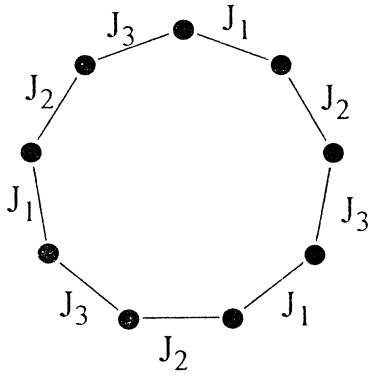
Symmetry codes; (a) $-x+1, -y+2, -z+1$ (b) $-x, -y+1, -z$.

A single μ(1,3) bridging azide has previously been found in the cation in $[Ni_2(Me_4Cyclam)_2(N_3)_3]I$ [26]. Furthermore, X-ray analysis of $Mn(acac)_2N_3$ has established the presence of single μ(1,3) azide bridge which links adjacent metal atoms to form polymeric chains of six-coordinate Mn(II) polyhedra [27]. The structure of the present complex resembles that of catena-μ(N_3)–[Ni(Cyclam)]$ClO_4 \cdot H_2O$ (Cyclam = 1,4,8,11-tetraazo-cyclotetradecano) (**2**) [28] which features six-coordinate Ni(II), trans arrangement, 1D nickel azide chains and ClO_4^- anions. Complex (**2**) differs in the asymmetric arrangement of the azido bridges: the two Ni–N–N angles are 140.7(3)° and 128.2(3)°. The azide ligand itself is asymmetric [N_1–N_2 = 1.178(5), N_2–N_3 = 1.138(5) Å], as well as the bond lengths of the two Ni–N(azide) distances being longer [2.165 and 2.172 Å] than the four Ni–(Cyclam) distances [2.059–2.073 Å].

3.4. Magnetic data for complex (*1*)

The magnetic behavior of compound **1** plotted as $\chi_M T$ versus T is shown in Fig. 2 (the data represent duplicated values from two separate preparations). As

suggested by the presence of end-to-end (EE) azido bridges between the Ni(II) centers, the magnetic behavior of compound **1** indicates overall antiferromagnetic superexchange interactions: $\chi_M T$ at room temperature is 1.03 cm^3 K mol^{-1} and on cooling $\chi_M T$ tends to zero at low temperature. The susceptibility plot shows a well-defined maximum at 102 K.



Structural data show a set of three different azido bridges in a regular alternating arrangement along the chain and so same kind of alternating superexchange parameters J_1, J_2 and J_3 should be assumed as a starting point for the analysis of the magnetic behavior. As was previously published [29] the J value is highly sensitive to the bond parameters involving the bridging region: the antiferromagnetic contribution to the superexchange parameter J increases for lower Ni–N–N bond angles, giving the maximum contribution at 108°, and simultaneously shows a strong dependence on the Ni–N–N–N–Ni torsion angle, giving the maximum J values for the planar arrangement (torsion 180°). Deviation from these optimal bond parameters implies a decrease in the overlap between the e_g atomic orbitals and the non-bonding MOs of the bridge and a decrease in the antiferromagnetic component of J. MO extended-Huckel calculations performed with the CACAO program [30] on the previously described model and using the experimental bond angles shows a semi-quantitative approach to this assumption following the Hoffmann model [31], Table 4, in which it is assumed that the antiferromagnetic contribution to the J parameter is proportional to Δ^2, Δ being the gap between the pairs of symmetric and antisymmetric MOs built from the e_g atomic orbitals and the adequate orbitals of the bridge. In Table 4 the relevant structural parameters in the bonding region together with the calculated Δ and Δ^2 values for the three kinds of bridges present along the chain.

Following the above rules, the greater J_3 value should be expected for the bridge Ni(2′)–N(31′)–N(32)–N(31)–Ni(2), an intermediate J_1 value for the bridge Ni(1)–N(11)–N(12)–N(11′)–Ni(1′) and the lower J_2 value is expected for the bridge Ni(1)–N(21)–N(22)–N(23)–Ni(2) on the bases of the bond parameters summarized in Table 4.

Several expressions have been proposed for the analytical fit of alternating 1-D systems with local spin $S = 1$, but all cases are limited to only two J parameters [32]. As a first approach to the J superexchange parameters, a fit using the analytical expression for a homogeneous system with local spin $S = 1$ on the Hamiltonian $H = -JS_1S_2$ in the range 75–300 K, gave an average value of $-55.2(1)$ cm^{-1} and $g = 2.42$, Fig. 2. A more detailed approach may be performed by using the full-matrix diagonalization procedure applied to a ring of nine Ni atoms with the alternance of J_3- J_2- J_1 superexchange parameters [33], Scheme 1. This procedure may be applied only up to the maximum region because the number of chosen paramagnetic centers is odd. The best fit parameters were $J_3 = -65.0$, $J_1 = -35.0$ and $J_2 = -52.7$ cm^{-1}, R agreement factor 3.4×10^{-4} ($R = \Sigma (\chi_M^{calc} - \chi_M^{exp})^2 / \Sigma (\chi_M^{exp})^2$), in good accordance with the expected J values gradation. Therefore, it should be noted that the accurate calculation of the J superexchange parameters for a system of this kind implies a large degree of vagueness. The accurate fit should be performed by using larger rings of 12 or 15 paramagnetic centers, but the size of the matrix and the time of calculation make this not possible to apply to these models.

4. Supplementary data

Further details of the crystal structure investigation are available from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 IEZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or

Scheme 1.

Table 4
Relevant structural parameters for the three different bridges of compound **1**

Ni–N–N (°)	Ni–N_3–Ni torsion (°)	Δ	Gap	Δ^2	Gap
Ni(2′)–N(31′)–N(32)–N(31)–Ni(2)	128.7	180	0.497	0.247	128.7
Ni(1)–N(11)–N(12)–N(11′)–Ni(1′)	135.6	180	0.399	0.159	135.6
Ni(1)–N(21)–N(22)–N(23)–Ni(2)	128.6	133.4	0.279	0.078	140.3

Δ^2 Parameter is equal to the gap $(E\phi(z^2_{(s)}) - E\phi(z^2_{(d)})^2$ which is directly related to the antiferromagnetic component of J in the Hoffmann model.

2.1. $Ga(^tBu)_2(OPh)(pyz)\cdot(PhOH)$ (1)

Solid $[(^tBu)_2Ga(\mu\text{-}OPh)]_2$ (0.10 g, 0.18 mmol) and, as received, pyrazine (35 mg, 0.43 mmol) were combined in a round bottom flask. The combined powders changed color from white to yellow over a few minutes. Toluene (15 ml) was added to the flask and the resulting solution stirred for 12 h. Pentane (10 ml) was layered on to the solution, and upon cooling to −30 °C white crystals along with a small quantity of yellow crystals were deposited. ^{1}H NMR characterization of the white crystals showed it to be unreacted $[(^tBu)_2Ga(\mu\text{-}OPh)]_2$ [5]. The yellow crystals were suitable for X-ray analysis.

2.2. $[(^tBu)_2Ga(H_2O)(\mu\text{-}OH)Ga(^tBu)_2]_2(\mu\text{-}OC_6H_4O)\cdot 4(2\text{-}Mepy)$ (2)

A solution of $[\{(^tBu)_2Ga\}_2(\mu\text{-}OC_6H_4O)]_8$ (0.25 g, 0.53 mmol) in degassed wet 2-picoline (30 ml) was allowed to stir for a day. The solution was cooled to −30 °C overnight yielding colorless crystals suitable for single crystal X-ray analysis. Yield: 0.406 g, 37%. m.p. 98 °C (dec.). MS (EI, %): *m/z* 1229 ($M^+ - {}^t$Bu, 60). IR (cm^{-1}): 3349 (br m), 2952 (m), 2937 (m), 2867 (m), 2828(s), 2753 (w), 2694 (w), 1601(w), 1492 (s), 1457 (m), 1388 (w), 1298 (w), 1214 (s), 1199 (s), 1005 (w), 841 (m), 812 (m), 787 (m), 752 (m). ^{1}H NMR ($CDCl_3$): δ 8.51 [1H, d, J(H–H) = 4.0 Hz, NC*H*], 7.59 [1H, t, J(H–H) = 6.5 Hz, *p*-C*H*], 7.16 [1H, d, J(H–H) = 5.5 Hz, *m*-C*H*], 7.11 [1H, t, J(H–H) = 7.5 Hz, *m*-C*H*], 6.7 (1H, s, OCC*H*), 2.57 (3H, s, CH_3), 1.13 [9H, s, C(CH_3)$_3$], 1.11 [9H, s, C(CH_3)$_3$]. ^{13}C NMR ($CDCl_3$): δ 158.6 (O*C*), 149.2 (N*C*H), 136.6 (*p*-*C*H), 123.6 (*m*-*C*H), 120.8 (OC*C*H), 31.1 [C(*C*H$_3$)$_3$], 24.6 (*C*H$_3$), 24.5 [C(*C*H$_3$)$_2$].

2.3. X-ray data collection, solution and refinement

Data for compounds **1** and **2** were collected at 298 K on a Bruker CCD SMART system, equipped with graphite monochromated Mo Kα radiation (λ = 0.71073 Å) and corrected for Lp effects. The structures were solved using the direct methods program xs [6] and difference Fourier maps and refined by using full-matrix least-squares methods. All non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms involved in hydrogen bonding were located in the electron difference map. Hydrogen atoms bound to carbon were introduced in calculated positions and allowed to ride on the attached carbon atoms [d(C–H) = 0.95 Å]. Refinement of positional and anisotropic thermal parameters led to convergence (see Table 1).

3. Results and discussion

Reaction of $[(^tBu)_2Ga(\mu\text{-}OPh)]_2$ with wet pyrazine ($N_2C_4H_4$, pyz), followed by crystallization from toluene–pentane, results in the isolation of small quantity of yellow crystals of $Ga(^tBu)_2(OPh)(pyz)\cdot(PhOH)$ (**1**). The formation of compound **1** may be rationalized by assuming that the pyrazine cleaves the Ga_2O_2 core and allows for the formation of the monomeric Lewis acid–base complex, $Ga(^tBu)_2(OPh)(pyz)$. Subsequent, hydrolysis, or direct hydrolysis of $[(^tBu)_2Ga(\mu\text{-}OPh)]_2$ yields PhOH and presumably the ubiquitous hydroxide compound, $[(^tBu)_2Ga(\mu\text{-}OH)]_3$ [7,8]. The phenol thus formed, hydrogen bonds to the most basic ligand in the system, the terminal aryloxide in $Ga(^tBu)_2(OPh)(pyz)$.

The structure of $Ga(^tBu)_2(OPh)(pyz)\cdot(PhOH)$ (**1**) is shown in Fig. 1; selected bond lengths and angles are given in Table 2. The bond lengths and angles about gallium are within the ranges observed for related compounds [5,9]. The geometry about the phenoxide oxygen [O(1)], as measured by the N(1)–Ga(1)–O(1)–C(1) torsion angle (131.2°), is significantly different from $Ga(^tBu)_2(OPh)(py)$ (180°) [2], as a result of an O···H–O hydrogen bond to the phenol. The O(1)···O(30) distance of 2.64 Å is comparable to the typical range observed for such interactions (2.57–2.69 Å) [10].

If the synthesis of $[(^tBu)_2Ga(2\text{-}Mepy)]_2(\mu\text{-}OC_6H_4O)$ is attempted without sufficiently drying the 2-Mepy,

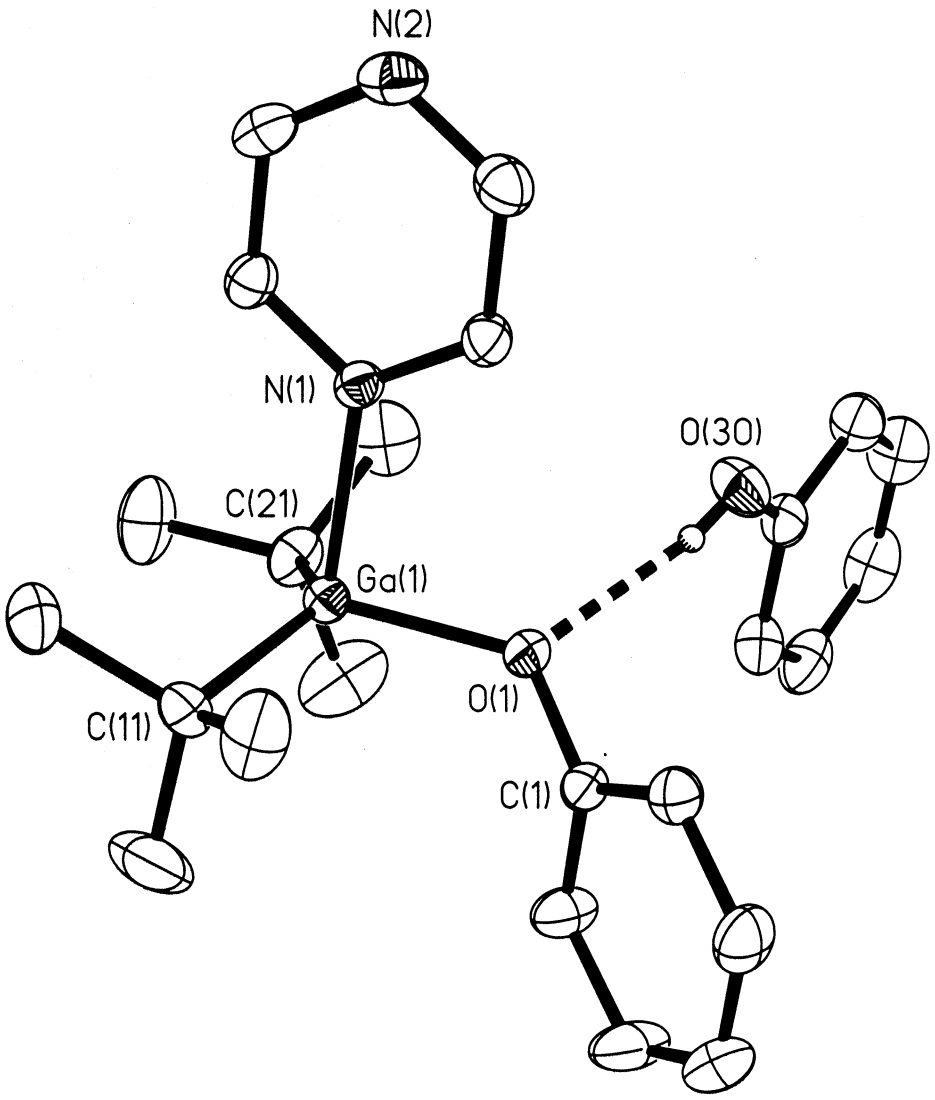

Fig. 1. Molecular structure of $Ga(^tBu)_2(OPh)(pyz)\cdot(PhOH)$ (**1**) showing the intra-molecular hydrogen bond. Thermal ellipsoids shown at the 20% level, and hydrogen atoms bound to carbon are omitted for clarity.

partial hydrolysis occurs, yielding the tetra-gallium compound, $[(^tBu)_2Ga(H_2O)(\mu\text{-}OH)Ga(^tBu)_2]_2(\mu\text{-}OC_6H_4O)\cdot 4(2\text{-Mepy})$ (**2**). The IR spectrum of compound **2** indicates the presence of hydrogen bonding with a very broad signal at 3350 cm^{-1} and an N–H stretch at 3050 cm^{-1}. Unfortunately, no signals could be assigned to the hydroxide and/or water ligands in the ^1H NMR spectrum, presumably due to H-bonding effects [11].

The solid state structure of compound **2** is shown in Fig. 2; selected bond lengths and angles are given in Table 3. The centrosymmetric structure of compound **2**

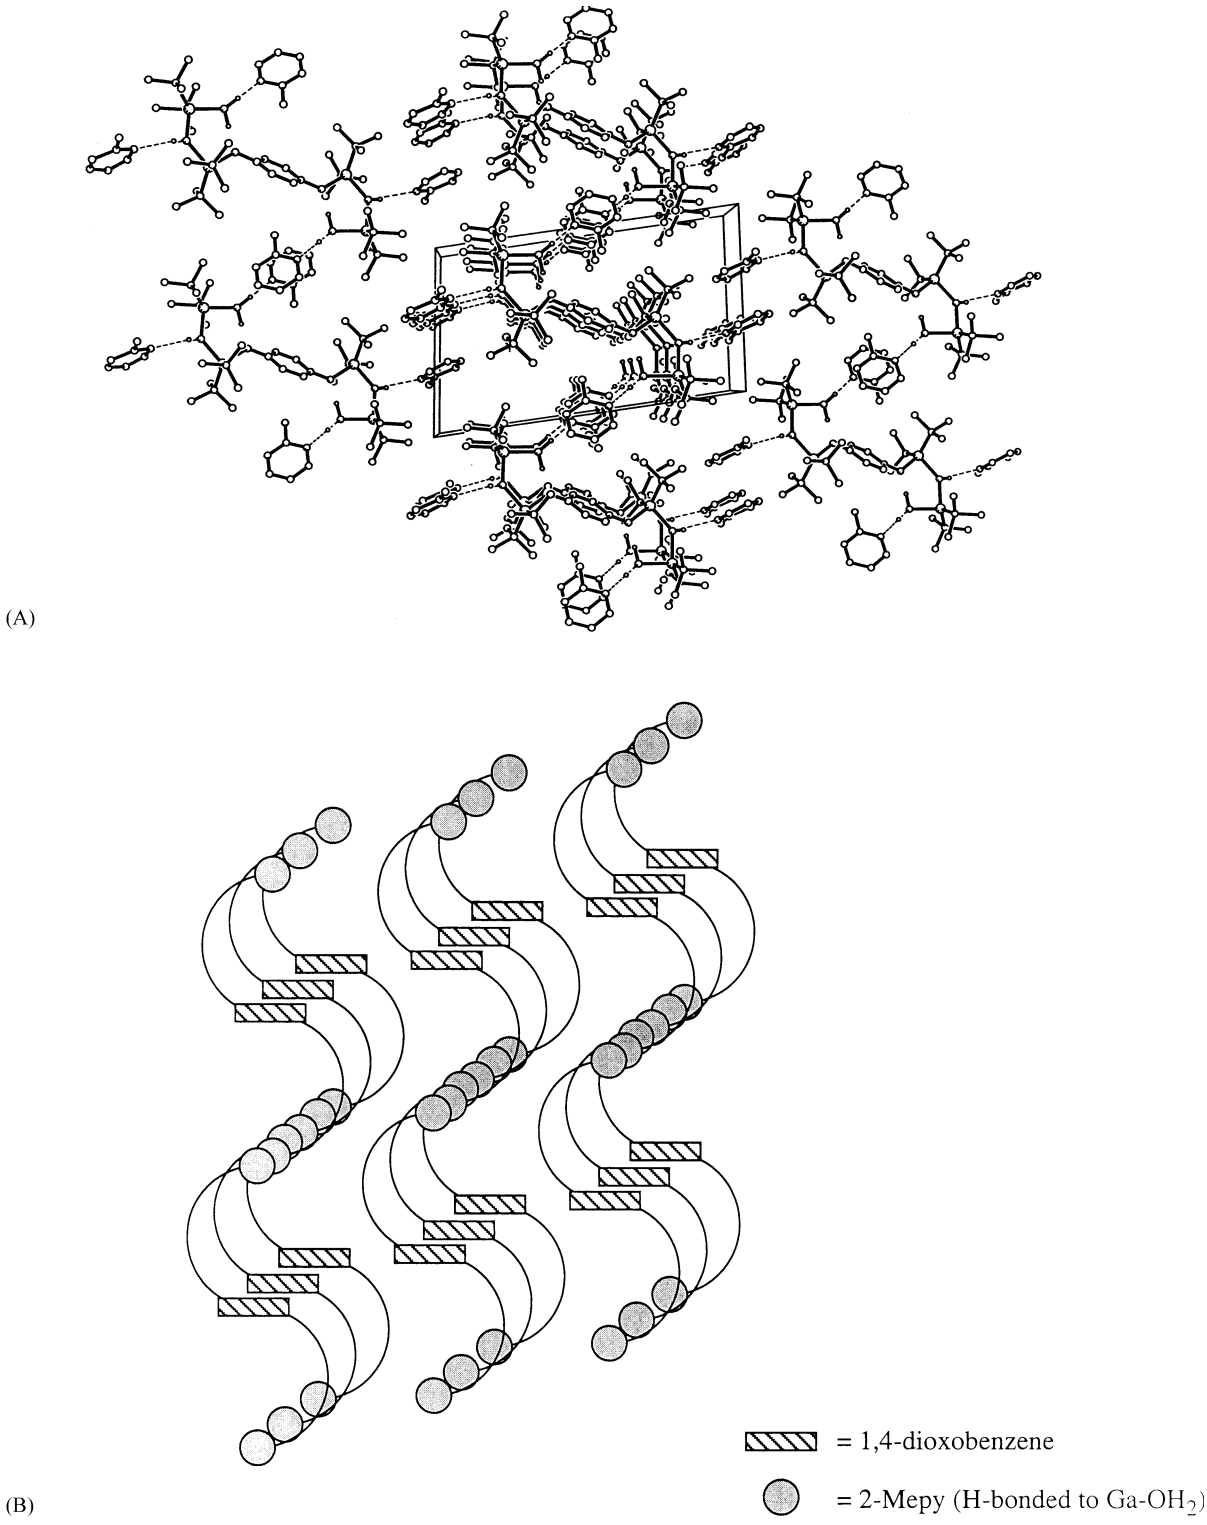
consists of a $[(^tBu)_2Ga]_2(\mu\text{-}OC_6H_4O)$ core to which two $Ga(^tBu)_2(H_2O)(OH)$ moieties are coordinated via bridging hydroxides. Each of the terminal water ligands is hydrogen bonded to an aryloxide's oxygen, resulting in a six-membered O–Ga–O–Ga–O–H cycle. Each water ligand is also hydrogen bonded to a 2-Mepy ligand of crystallization. As a result, the molecule is stabilized through both intra- and inter-molecular hydrogen bonding, see Fig. 2.

The O(1)···O(3) distance (2.50 Å) associated with the intra-molecular hydrogen bond is significantly shorter than typical O–H···O hydrogen bonds (2.57–2.69 Å), and close to the values found for a strong H-bond [10]. The O(3)···N(1S) distance (2.65 Å) is shorter than observed for transition metal aqua complexes (2.71–2.72 Å) [12]. This observation is in line with the known acidity of the coordinated water ligands in $[Ga(H_2O)_6]^{3+}$. There have been several recent examples of coordinated water molecules undertaking two intra-molecular hydrogen bonds [13], two inter-molecular hydrogen bonds [14], or one intra- and one inter-molecular hydrogen bonding interaction [12,15].

The Ga(1)–O(2) and Ga(2)–O(2) distances [1.963(4) and 1.945(4) Å, respectively] are typical for a gallium hydroxide (approximately 2.00 Å), rather than a gallium oxide (1.87–1.89 Å) [16], suggesting that there is negligible contribution from the Zwitter ionic ($O^-\cdots H\text{–}N^+$) form. The Ga(1)–O(2)–Ga(2) angle associated with the bridging hydroxide [137.0(2)°] is within the range previously observed for similar six-membered cyclic systems [132.0(3)°–143.0(2)°] [7,17]. The hydrogen bond between 2-Mepy and the bridging hydroxide [O(2)···N(7S) = 2.95 Å] is significantly longer than for the water ligand (2.65 Å). Furthermore, the O(2)···N(7S) interaction appears to be weaker than the intra-molecular gallium hydroxide···amine interaction in $(^tBu)_2Ga(o\text{-}C_6H_4NMe_2)(\mu\text{-}OH)Ga(^tBu)[o\text{-}C_6H_4N(O)Me_2]$ (2.80 Å) for which a significant Zwitter ionic contribution is proposed [13].

As illustrated in the crystal packing diagram of compound **2**, the orientation of the 2-Mepy ligand hydrogen bonded to the water ligands allows for a series of π-stacking interactions between adjacent molecules, see Fig. 3. The result of this hydrogen bonding is the formation of a series of molecular 'S's' along the crystallographic *a*-axis. On the basis of the hierarchical levels of crystal architecture [18], the structure of compound **2** may be described as a series of head-to-tail (*primary* level) interactions, creating a series of corrugations (*secondary* level) which are coplanar but contain no inter-layer contacts (*tertiary* level). A sche-



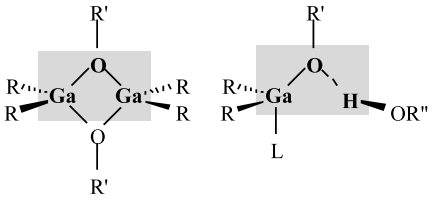


Fig. 3. Crystal packing of $[(^tBu)_2Ga(H_2O)(\mu\text{-}OH)Ga(^tBu)_2]_2(\mu\text{-}OC_6H_4O)\cdot 4(2\text{-Mepy})$: (**2**), (a) as viewed along the crystallographic *a*-axis; and (b) a schematic representation, demonstrating the series of molecular 'S's' created by a combination of hydrogen bonding and π-stacking.

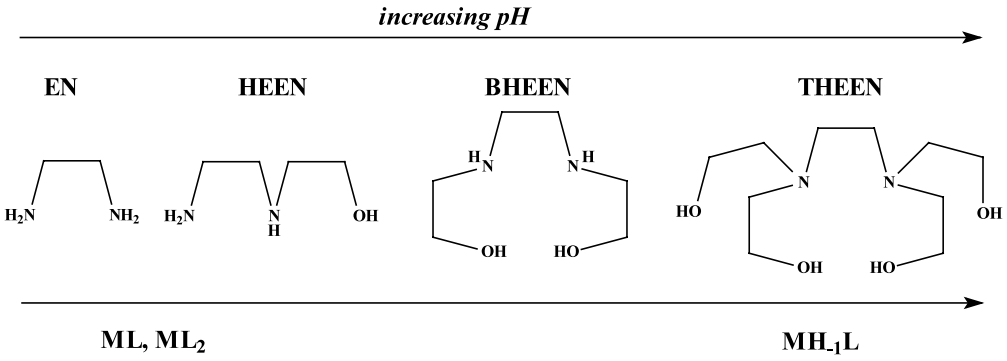
matic representation of the crystal packing is shown in Fig. 3(b).

Both compounds **1** and **2** show examples of strong hydrogen bonding to the oxygen atom of a terminal aryloxide ligand. We have previously observed that the basicity of terminal Group 13 aryloxides is sufficient to enolize ketones [19]. It is possible to consider the hydrogen bonding to the aryloxides in compounds **1**

and **2** as an isolobal analog [20] of a bridging alkoxide compound. In particular, the Ga(1)–O(1)···H(30) unit (see **I**) may be considered analogous to a bridging alkoxide unit, Ga(μ-OR)Ga (**II**). This analogy has some precedent since we have previously shown by ^{17}O NMR spectroscopy that Group 13 metals and a proton have similar electronegativities with regard to oxygen [21].

4. Supplementary material



Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 178641 and 178642 for compounds **1** and **2**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

$$2Cu(ClO_4)_2 6H_2O + 2H_4THEEN + 2OH^- \rightarrow [Cu(H_3THEEN)ClO_4]_2 + 8H_2O$$

An aqueous 20 ml solution of $(CuClO_4)_2 \cdot 6H_2O$ (0.02 mol) and NaOH (0.02 mol) was prepared. To this was added a mixture of *N*,*N*,*N*′,*N*′-tetrakis(2-hydroxyethyl)ethylenediamine (0.01 mol) and 15 ml deionised water at 60 °C. The solution was stirred for a further 2 h at 60 °C and then left to cool down to room temperature. Slow evaporation yielded blue crystals after 4 days. The crystals were collected by filtration and air-dried.

Anal. Calc. for $C_{10}H_{23}ClCuN_2O_8$: C, 30.16; H, 5.82; N, 7.03. Observed: C, 30.14; H, 5.97; N, 6.92%.

3. Data collection

Intensity data were collected at −100 °C on a Bruker SMART [5] 1K CCD area detector diffractometer with graphite monochromated Mo Kα radiation (50 kV, 30 mA). The collection method involved ω-scans of width 0.3°. Data reduction was carried out using the program SAINT+ [6] and absorption corrections were made using the program SADABS [7]. The crystal structure was solved by direct methods using SHELXTL [8]. Non-hydrogen atoms were first refined isotropically followed by anisotropic refinement by full matrix least-squares calculation based on F^2 using SHELXTL. Hydrogen atoms were positioned geometrically and allowed to ride on their respective parent atoms. All the CH_2 hydrogen positions were calculated while the hydroxyl hydrogens (H_{200}, H_{300} and H_{400}) were placed from the Difference Fourier map and refined isotropically. These hydrogen atoms are all involved in extensive hydrogen bonding. Diagrams and publication material were generated using SHELXTL and PLATON [8,9]. No disorder models were required for the ClO_4^- ion (Fig. 1).

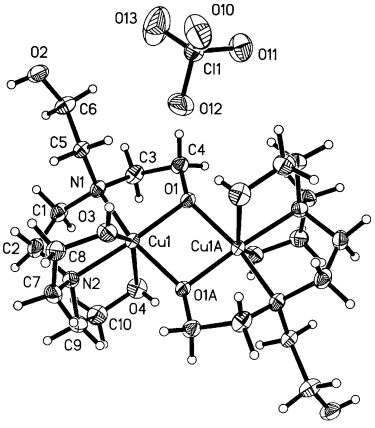

Fig. 1. The molecular structure of the copper complex of THEEN, showing the atom-labeling scheme and 50% probability displacement ellipsoids.

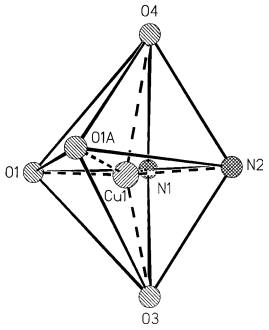
The X-ray structure is that of a dimer comprising two $[CuH_3THEEN]^+$ monomers bonded by the formation of a Cu_2O_2 ring across an inversion centre. The complex utilizes the hydroxylate oxygens to form two Cu–O–Cu bridges. Oxygen O(1) is binucleating serving to bridge between the copper centers. The Cu(1)–Cu(1A) and O(1)–O(1A) transannular distances are 2.958 and 2.540 Å and the O(1)–Cu(1)–O(1A) and Cu(1)–O(1)–Cu(1A) angles are 81.30° and 98.71°, respectively. Coordination to the copper center occurs via two amine nitrogen atoms (N(1) and N(2)) and three oxygen atoms (O(1), O(3) and O(4)). The coordination polyhedron is best interpreted as a distorted octahedron rather than the distorted square-pyramidal coordination reported for $[CuH_3THPED]^+$ [4]. The sixth coordination site completing the octahedral coordination geometry includes the oxygen donor O(1A) of the symmetry related $[CuH_3THEEN]^+$ monomer that forms the second of the two metal–oxygen–metal bridges (Fig. 2).

Oxygen atoms in the Cu_2O_2 ring have shortened bond lengths of 1.940 and 1.959 Å to the Cu(II) ion in comparison to the oxygen atoms (O(3) and O(4)) that occupy the axial positions defining the principal axis. These longer bond lengths of 2.332 and 2.674 Å are associated with characteristic Jahn–Teller distortions observed for copper coordination compounds. The shorter Cu(1)–O(1) and Cu(1)–O(1A) bonds imply deprotonation of the oxygen atoms of the hydroxyethyl moieties and compare favourably with copper to oxygen bond lengths of negatively charged oxygen donors reported for the Cu(II) complex of EDTA [11]. Chelation of the Cu(II) ion by THEEN forms four chelate rings as one of the hydroxyethyl pendant donor moeities does not form part of the coordination sphere. This may be due to steric influences arising from H–H non-bonded interactions of adjacent chelate rings [12].

Early studies of the stereochemistry of five-membered chelate rings were based on metal complexes of ethylenediamine. These studies established geometric requirements necessary for the metal–ethylenediamine chelate ring that would afford a strain-free structure [13]. In these calculations ideal bond lengths were used and the



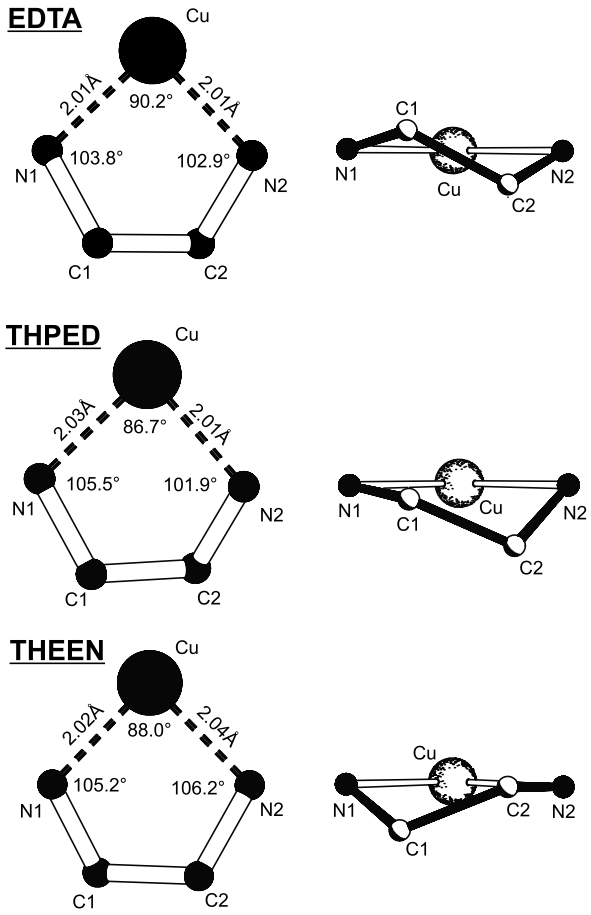


Fig. 2. Distorted octahedral coordination sphere of Cu(II) on complexation to THEEN.

M–N–C bond angle was selected to be 109.5°, comparable to the value observed in the chair conformation of cyclohexane, which minimizes H–H non-bonded interactions on adjacent carbon atoms. An N–M–N angle of 86.2° and a dihedral angle of 48.8° was calculated if the M–N distance is taken as 2.00 Å. The above parameters determined by Corey and Bailar [13] essentially defined a strain-free, five-membered metal–ethylenediamine chelate ring. Orama et al. [4] reported a N–Cu–N angle of 86.8° in their structure of the Cu(II) complex of THPED that is comparable to the calculated value above, however, it must be noted that their Cu–N(1)–C(1) and Cu–N(2)–C(2) angles are 105.5° and 101.9°, respectively. These angle deviations are accompanied by a similar difference in the dihedral angle of 50.6° as compared to the calculated 48.8°. The deviations arise as a result of the geometric inability of the ethylenediamine ring to accommodate the N–M–N and M–N–C angles simultaneously at their required values, but minimizes the angle strain by altering the dihedral angle as a function of M–N bond length, thereby changing the bite size [13,14]. This phenomenon has been used to explain why larger metal ions prefer five-membered chelate rings while smaller metal ions prefer six-membered chelate rings [14,15]. The 'asymmetric envelope' conformation observed for $[CuH_3THPED]^+$ due to deviations of the carbon atoms towards the same side of the N–Cu–N plane [4] is not observed for the $[CuH_3THEEN]^+$ monomer. Carbon C(2) however is nearly contained within the N(1)–Cu(1)–N(2) plane and its deviation is only 0.04 Å. The effect of this conformation is to flatten the ethylenediamine chelate ring as can be concluded from the dihedral angle of 46.8° compared to 55.9° for [CuEDTA] where the carbon atoms C(1) and C(2) of the ethylenediamine chelate ring distinctly deviate to opposite sides of the plane of the metal ion and the two nitrogen donors by 0.25 and 0.45 Å, respectively (Scheme 3).

The decreased puckering of the ethylenediamine chelate ring has been explained as a function of M–N length were the ring flattens for short M–N values, decreasing the bite size [12–14]. The bite sizes of the ethylenediamine chelate ring for the Cu(II) structures of EDTA, THPED and THEEN are 2.848, 2.787 and 2.821 Å, respectively. The Cu–N bond lengths for the same structures are also comparable which reinforces the idea that the ring flattening can in this case be attributed in principal to the conformations adopted by the ethylenediamine ring in the THPED and THEEN structures of the copper complexes.

An analogous analysis of the three ethanolamine–metal chelate rings in $[CuH_3THEEN]^+$ reveals similar results although differences between C–N and C–O bond lengths and coordination geometries of nitrogen and oxygen donors must be appreciated [16,17,19]. The chelate ring formed by the hydroxyethyl pendant arm

Scheme 3. Comparison N–M–N and M–N–C angles and M–N bond lengths of the ethylenediamine chelate ring in the copper complexes of EDTA, THPED and THEEN. Orientations of the carbon atoms of the ethylenediamine chelate ring relative to the N–M–N plane.

containing the O(1) donor adopts a conformation that strongly resembles that of the ethylenediamine chelate ring in $[CuH_3THPED]^+$. Carbon atoms C(3) and C(4) both deviate to the same side of the N(1)–Cu(1)–O(1) plane by 0.85 and 0.34 Å, respectively. Similarly the Cu(1)–N(1)–C(3) and Cu(1)–O(1)–C(4) angles deviate significantly from the strain-free value and are 100.51° and 113.25°, respectively, compressing the N(1)–Cu(1)–N(2) angle to 84.9°. The fact that O(1) is a binucleating donor in the Cu_2O_2 ring influences the geometric requirements of the chelate ring. The Cu(1)–O(1) bond length (1.940 Å) is significantly smaller than that of Cu(1)–O(3) (2.332 Å) or Cu(1)–O(4) (2.674 Å). Decreased puckering of the chelate ring, as seen from a dihedral angle of 41.39°, accommodates the shorter bond length adjusting the bite size to 2.674 Å which is the smallest in $[CuH_3THEEN]^+$. The reduced bite size forces the opening of the Cu(1)–O(1)–C(4) angle to 113.25°. Chelate rings including the larger Cu–O bonds are more open and puckered to facilitate the larger bite size requirements. The Cu(1)–O(3) and Cu(1)–O(4)

Table 4
Hydrogen bonds for $[Cu(H_3THEEN)ClO_4]_2$ (Å and °)

D–H	d(D–H)	d(H···A)	DHA	D(D···A)	A	Symmetry
O(3)–H(300)	0.780	1.990	174.28	2.766	O(2)	$[-x, y+\frac{1}{2}, -z+\frac{1}{2}]$
O(4)–H(400)	0.770	2.282	142.95	2.934	O(12)	$[-x+1, -y+1, -z+1]$
O(4)–H(400)	0.770	2.338	127.40	2.872	O(1)	$[-x+1, -y+1, -z+1]$
O(2)–H(200)	0.798	2.039	162.42	2.810	O(12)	$[-x, y-\frac{1}{2}, -z+\frac{1}{2}]$

bonds along the axial positions contribute to the bite sizes of 2.831 and 2.908 Å for their chelate rings with dihedral angles of 54.97° and 52.48°, respectively. Different conformations are adopted by these rings and atoms C(9) and C(10) are oriented towards a single side of the O(4)–Cu(1)–N(2) plane that mimics the asymmetric envelope conformation, however atoms C(7) and C(8) deviate to opposite sides of the N(2)–Cu(1)–O(3) plane and more closely resemble the conformation of the ethylenediamine bridge in the Cu(II) complex of EDTA. Both intermolecular and intramolecular hydrogen-bonding occurs in the $[Cu(H_3THEEN)ClO_4]_2$ structure. Intermolecular hydrogen-bonding clarifies the observed orientation of the uncoordinated hydroxyethyl pendant arm and the involvement of the perchlorate anions with coordinated O(4) hydroxyethyl moiety. Intramolecular hydrogen-bonding occurs between O(1) in the Cu_2O_2 ring and H(400) on the O(4) donor forming the longest Cu–O bond length in this structure (Table 4; Fig. 3).

Thermodynamic data for THPED [2,18] and THEEN [18] shows a marked increase in stability of THPED complexes compared to complexes of THEEN. Increasing the number of hydroxypropyl groups over hydroxyethyl groups results in an increased stability. Inductive effects of the additional electron releasing methyl groups makes the O-donor a better nucleophile and more attracted to an electron deficient metal ion (Table 5).

The $[CuH_3THPED]^+$ complex has an average Cu–O bond length of 2.058 Å, substantially shorter than that for $[CuH_3THEEN]^+$ at 2.316 Å; for their respective coordination geometries. The bite sizes of the chelate rings adjust accordingly and chelate rings are generally flatter for $[CuH_3THPED]^+$. The architectural difference between the ligands lies in the C-alkyl substituents adjacent to the oxygen pendant donors of THPED. Effects on complex stability by the addition of alkyl

Table 5

groups to ligands, has been documented [19,20] as has their ability to affect metal ion selectivity. Steric destabilization derived from alkyl substitution may outweigh favourable contributions to complex stability by inductive effects. Unfavourable steric contributions in the coordination polyhedron of THPED arising from the bulkier 2-hydroxypropyl pendant groups are absent in the THEEN complex that may facilitate dimerisation for complexes of smaller metal ions. A dimeric structure observed for Ti^{IV}THPED suggests that larger metal ions are more readily able to tolerate steric crowding produced by bulky pendant donors, and multinuclear complexes of the type observed for the open-chain β-amino alcohols such as THEEN and THPED are feasible. The ligands THEEN and THPED however, have identical donor sets and the Cu(II) complexes indicate that metal ion size may not be the only factor contributing towards dimerisation. The effects of steric crowding due to pendant donors need to be understood for successful syntheses of multinuclear complexes of open-chain ligands bearing 2-hydroxyalkyl pendant groups.

4. Supplementary material

Crystallographic data for the structure analysis has been deposited with the Cambridge Crystallographic

Data Centre, CCDC No. 175807 for compound ($Cu(H_3THEEN)ClO_4]_2$). Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

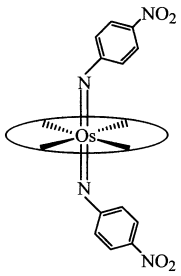

Fig. 1. Drawing of $Os(TTP)(NC_6H_4NO_2)_2$. For clarity, the porphyrin ring is depicted as an ellipse.

received. The alkenes were distilled under nitrogen or recrystallized prior to use. Ultraviolet–Visible (UV–Vis) spectra were recorded with a Hewlett Packard 8452A diode array spectrophotometer. The temperature of the cell compartment was maintained to ± 0.2 °C using a constant temperature bath. Gas chromatography/mass spectrometry (GC–MS) data was obtained with a Hewlett Packard 5890 Series II gas chromatograph.

2.1. Reaction with phosphines, PY_3

Toluene solutions of $Os(TTP)(NC_6H_4NO_2)_2$ and $PMe_{3-x}Ph_x$ ($x = 0$, 1, 2, 3) or $P(OMe)_2Ph$ were allowed to reach thermal equilibrium in a constant temperature bath prior to each run. After equilibration to the desired temperature, the solutions were combined in a cuvette that had also been thermally equilibrated. The rate of the reaction was followed by monitoring the decrease in absorbance of $Os(TTP)(NC_6H_4NO_2)_2$ at 576 nm. The initial concentration of $Os(TTP)(NC_6H_4NO_2)_2$ was 7.5×10^{-5} M. The reactions were run under pseudo first order conditions with $[PY_3] \gg Os(TTP)(NC_6H_4NO_2)_2$. The initial concentration of phosphine was varied between 0.01 and 0.29 M. Although the solutions were typically prepared in a glovebag under 1 atm. of N_2, the same kinetic data was obtained if the solutions were prepared under 1 atm. of air.

2.2. Reaction with alkenes

All reactions were performed under nitrogen. The alkenes studied were dimethyl fumarate, styrene, *cis*-cyclooctene, and 2,3-dimethylbutene. Three reaction conditions were examined. In each case, approximately 500 equiv. of alkene were used. The first set of conditions involved the combination of alkene and $Os(TTP)(NC_6H_4NO_2)_2$ in C_6H_{14} or $C_6H_5CH_3$ at room temperature. Since no reaction was observed by thin layer chromatography or by UV–Vis spectroscopy after 4 h, the solutions were heated to reflux and the reactions were monitored for an additional 2 h. The third set of conditions involved the combination of alkene and $Os(TTP)(NC_6H_4NO_2)_2$ in C_6H_6 or $C_6H_5CH_3$ followed by irradiation with a 450 W Hanovia lamp for 1 h.

3. Results and discussion

Reactivity studies of $Os(TTP)(NC_6H_4NO_2)_2$ suggest the two *p*-nitrophenyl imido ligands coordinated to the osmium porphyrin are mildly electrophilic in character. Treatment of $Os(TTP)(NC_6H_4NO_2)_2$ with excess phosphine, PY_3, yields $Os(TTP)(PY_3)_2$ [17] and the corresponding phosphinimine identified by GC–MS.

$$Os(TTP)(NC_6H_4NO_2)_2 + \text{excess } PY_3 \rightarrow Os(TTP)(PY_3)_2 + 2O_2NC_6H_4N{=}PY_3$$

Clean isosbestic points at 419 and 431 nm indicate the absence of any long-lived intermediate.

The kinetics of the reaction were studied by monitoring the decrease in absorbance of $Os(TTP)(NC_6H_4NO_2)_2$ at 576 nm. At this wavelength, $Os(TTP)(NC_6H_4NO_2)_2$ has a modest absorption ($\log \varepsilon = 4.4$) [16] whereas $Os(TTP)(PY_3)_2$ does not absorb. The reaction was performed under pseudo first order conditions with $[PY_3] \gg Os(TTP)(NC_6H_4NO_2)_2$. Plots of $\ln|A_t - A_\infty|$ versus time were linear over four half lives with slopes equal to the pseudo first order rate constant, k_{obs}, where A_t is the absorbance at time t and A_∞ is the absorbance once the reaction has reached completion. Under the reaction conditions described, no loss in absorbance of $Os(TTP)(NC_6H_4NO_2)_2$ was observed in the absence of PY_3. At each concentration of PY_3, two or three independent runs were performed and the average k_{obs} was calculated. Plots of average k_{obs} versus $[PY_3]$ were linear with slopes equal to the second-order rate constants, k_2, Table 1. Saturation kinetics was not observed even at high PY_3 concentrations, $[PY_3] = 0.20$ M. The lack of saturation kinetics suggests an initial equilibrium to form an adduct between $Os(TTP)(NC_6H_4NO_2)_2$ and PY_3 does not occur, or if it does, reactants are highly favored and the equilibrium constant is small.

The enthalpies, $\Delta H^\ddagger$, and entropies, $\Delta S^\ddagger$, of activation for PMe_2Ph and $PMePh_2$ were determined by measuring k_2 at three different temperatures and using the Eyring equation. A plot of $\ln(k_2/T)$ versus $1/T$ yields a slope equal to $-\Delta H^\ddagger/R$, where R is the universal gas constant, and a y-intercept equal to the sum of $\ln(k'/$

Table 1

PY_3	$10^4\ k_2$ ($M^{-1}\ s^{-1}$) [a]	θ (°) [b]	pK_a [c]	pK_a' [d]

h) and $\Delta S^{\ddagger}/R$ where k' is Boltzmann's constant and h is Planck's constant. The enthalpies of activation were 42 ± 1 and 25 ± 1 kJ mol^{-1} and the entropies of activation were -135 ± 20 and -210 ± 20 J mol^{-1} K^{-1} for PMe_2Ph and $PMePh_2$, respectively. Due to experimental difficulties such as the high volatility of PMe_3 and the slowness of reaction for PPh_3 and $P(OMe)_2Ph$, activation parameters were not determined for the other phosphines. The negative values for the entropies of activation are consistent with an associative mechanism [18].

Several authors have examined the relationship between rate constants for associative reactions involving phosphine nucleophiles and the stereoelectronic properties of phosphines [19–22]. In general, data for these reactions give a good fit to the following relationship:

$$\log k_2 = \alpha + \beta X + \gamma\theta$$

The first term, α, is related to the intrinsic reactivity of the metal complex. The second term, βX, is related to the electronic properties of the incoming phosphine, and the third term, $\gamma\theta$, where θ is Tolman's cone angle [19], is related to the steric properties of the phosphine. In early studies, pK_a values were used for X [19,20]. However, the use of this term as a measure of basicity was found insufficient [21,22]. More recent analyses have used values of χ [21] or pK_a' [22] for X. χ values are derived from infrared data whereas pK_a' values are derived from pK_a values, corrected for hydration effects. In all cases, the protocol for stereoelectronic analysis involves plotting log k_2 versus X (where $X = pK_a$, χ, or pK_a') for isosteric or nearly isosteric phosphines. The resulting plot is called an electronic profile and since the nucleophiles used have identical or nearly identical cone angles, γ can be assumed to be zero and the slope equals β. A subsequent plot of (log $k_2-\beta X$) versus θ yields a steric profile. In systems where steric effects are important, the steric profile has a horizontal region at low values of θ for nucleophiles small enough not to show any steric effects, i.e. phosphines with cone angle below some threshold cone angle, $\theta < \theta_{th}$, followed by a region with a linear downward slope for phosphines with cone angles above the threshold angle, $\theta > \theta_{th}$ [21,22].

Using the analysis suggested by Chen and Poë [22], an electronic profile was prepared by plotting log k_2 versus pK_a' (Fig. 2), for the nearly isosteric phosphines, PMe_3, $P(OMe)_2Ph$, and PMe_2Ph. The non-zero slope in Fig. 2 indicates the basicity of PY_3 affects the rate of imido ligand transfer. $P(OMe)_2Ph$, the least basic of the three isosteric phosphines, exhibits a much smaller k_2 than PMe_3 or PMe_2Ph. The slope of this line equals β. Deviations from linearity may be due to experimental design. All of the PY_3 solutions were prepared from neat reagents except for the PMe_3 solutions, which were prepared from a purchased 1.0 M solution. The true concentration of this solution was not confirmed and

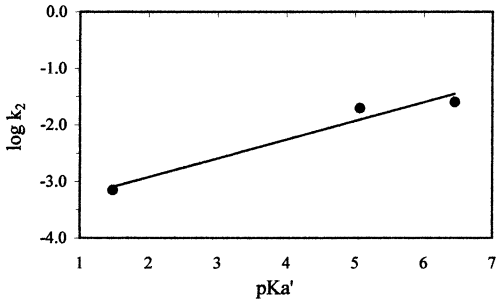

Fig. 2. Electronic profile, plot of log k_2 versus pK_a'.

may have been less than 1.0 M due to the high volatility of PMe_3. In this case, a smaller than expected k_2 value would be observed.

A subsequent plot of log k_2^{o} [22] versus θ was prepared (Fig. 3). The shape of this steric profile indicates the steric properties of the incoming nucleophile affect the rate of imido ligand transfer. If steric properties were not important, all of the data points would lie on a horizontal line. An estimate for the threshold cone angle (125°) is the intersection of the horizontal and downward sloping parts of the steric profile [22].

Similar stereoelectronic analyses have been reported for oxo ligand transfer to PY_3 from an oxorhenium(VII) complex [23], a molybdenum dithiolene species [24], and *trans*-$Ru(TMP)O_2$ [25] where TMP is the dianion of 5,10,15,20-tetramesitylporphyrin. However, this type of stereoelectronic analysis has not been reported for imido ligand transfer to PY_3. Although osmium imido complexes are relatively common and several are known to transfer their imido ligands to phosphines [11,14], no kinetic studies have been reported. A kinetic study has been reported for the reaction of PMe_2Ph and a ruthenium porphyrin complex possessing one imido ligand, Ru(tbpp)(NR) where tbpp is the dianion of 5,10,15,20-tetrakis(p-*tert*-butylphenyl)porphyrin [10]. Using similar concentrations of complex as used in this study, the reaction demonstrates saturation kinetics at relatively low phosphine concentrations, [PMe_2Ph] < 0.002 M. The proposed mechanism for the ruthenium system involves reversible binding of the phosphine to

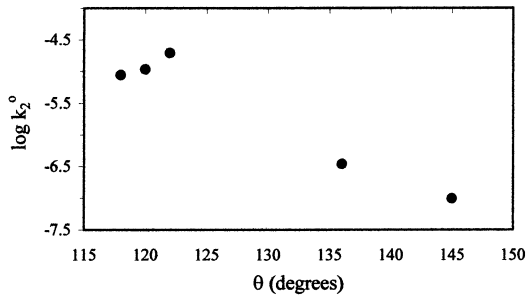

Fig. 3. Steric profile, plot of log k_2^{o} versus θ where log k_2^{o} equals log $k_2-\beta$ (p$K_a'+4$) [22].

the nitrogen of the imido ligand followed by a rate-limiting irreversible intramolecular imido-group transfer. Since only one phosphine was examined, a stereoelectronic analysis could not be performed.

Although $Os(TTP)(NC_6H_4NO_2)_2$ transferred the *p*-nitrophenyl imido ligands to phosphines, no reaction was observed with a variety of alkenes. Four alkenes were studied and varied from electron poor dimethyl fumarate to electron rich 2,3-dimethylbutene. No reaction was observed with 500 equiv. of alkenes at room temperature, at refluxing hexane or toluene, or photolysis with an ultraviolet lamp.

These results suggest the two *p*-nitrophenyl imido ligands coordinated to the osmium(VI) porphyrin are mildly electrophilic in character. Upon addition of a good nucleophile such as PY_3, imido ligand transfer occurs to form a phosphinimine and $Os(TTP)(PY_3)_2$. Both the basicity and the steric properties of PY_3 affect the rate of reaction with the most basic, least sterically hindered phosphines yielding the fastest rates of reaction. Imido ligand transfer does not occur to alkenes. This reactivity is similar to the reactivity of other osmium imido [11,14] complexes whereby reactions only occur with good nucleophiles. In contrast, ruthenium imido complexes are known to react with both phosphines [10] and alkenes [12].

sulfate (G.R., E. Merck) with barium nitrate (G.R., E. Merck) and standardised by oxidation with $KBrO_3$ in presence of dilute H_2SO_4 [19]. We found this solution to be stable for at least 6 months when kept at low temperature ($\sim$5–10 °C) and in dark. Aqueous solutions of $NaNO_3$ (G.R., E. Merck) was standardised by passing through a Dowex 50W X-8 strong cation exchange resin in the H^+ form and titrating the liberated acid with standard NaOH to a phenolphthalein end-point. All measurements were made at 25 °C and $I = 1.0$ mol dm^{-3} ($NaNO_3$). All solutions were prepared in water which was deionised and then double distilled.

2.2. Physical measurements and kinetics

All absorbance versus time data were recorded with a Shimadzu (1601 PC) spectrophotometer using 1.00 cm quartz cells. The kinetics was monitored in situ in the 'kinetic mode' of the instrument at 420 nm in the electrically controlled thermostated (25.0 ± 0.1 °C) cell-housing (CPS-240A). In this mode the change in absorbance is automatically and continuously recorded. Hydroxylamine solution (adjusted to the desired pH) was directly injected in to the spectrophotometer cell containing other components of the reaction mixture kept at the same pH. The desired concentration of the complex and reducing agent was achieved after mixing. The ionic strength (I) was maintained at 1.0 mol dm^{-3} ($NaNO_3$). The solution pH values were adjusted with $HClO_4$ or NaOH. Although the measured pH is usually defined in terms of the activity of hydrogen ions, we used the hydrogen ion concentration by calibrating the pH electrode with analytically prepared solutions as described earlier [20].

2.3. Stoichiometric measurements

The stoichiometry was measured under kinetic conditions by estimating excess hydroxylamine spectrophotometrically. Excess hydroxylamine was mixed with the complex in the pH range 4.0–6.0. After the reaction mixtures turned colourless indicating complete reduction of Ag(III) to Ag(I), pH of the mixtures were made to $\sim$2. A solution of $Fe_2(SO_4)_3$ at pH $\sim$ 2 was then added in each set and after a few minutes excess 2,2′-bipyridyl solution (at pH $\sim$ 2) was added. The resulting red $[Fe(bipy)_3]^{2+}$, generated by the quantitative reduction of excess Fe(III) by hydroxylamine was measured [21] at 523 nm ($\varepsilon = 8500$ dm^3 mol^{-1} cm^{-1}) after proper dilution.

3. Results and discussions

3.1. Preliminary observations

Within the time span of the reactions the autodecomposition [22] of the silver(III) complex is insignificant. No silver(I) catalysis was found in the reactions below pH $\sim$ 5.0. Above this pH, addition of $AgNO_3$ in the reaction mixture produces a faint blackish suspension probably due to metallic silver and/or silver oxide and thus Ag^+ catalysis, if any, was examined below pH $\sim$ 5.0. No external buffer was used in the kinetic measurements since buffering (by acetate for example) affects the spectra of the complex; specific interaction of buffer with the complex was thus indicated. Even in the absence of an external buffer, the media pH before and after the reactions did not change by more than 0.05 units.

3.2. Stoichiometry and reaction products

Stoichiometric experiments under kinetic conditions indicate 1:1 reaction between the redox partners (Table 1). The principal conversion may then be represented by Eq. (1).

$$2Ag(III) + 2NH_2OH \rightarrow 2Ag(I) + N_2O + H_2O + 4H^+ \quad (1)$$

Immediately after completion of reaction (absorbance < 0.01 at 380 nm), all Ag^+ was precipitated as AgCl and removed by filtration. From the filtrate, the free ligand, ethylenebis(biguanide), was quantitatively isolated [23] as the sparingly soluble [ethylenebis(biguanide)]copper(II) sulfate, and the amount of Cu(II) thus held was estimated iodometrically after decomposing the Cu(II) complex. The results showed that more than 95% of the free ligand (H_2L) was recovered.

The complicated redox chemistry of hydroxylamine in solution has been studied extensively [15]. It was observed that hydroxylamine is most commonly oxidised to N_2O [24–26]. Oxidation to N_2, NO_2^-, NO_3^- and NO are relatively rare [16,24–26]. ESR spectroscopy has established the formation of the $H_2NO^\bullet$ radical in the oxidation of NH_2OH with one-electron oxidants [27]. The ultimate oxidation product varies depending on the mode of decay (Eq. (3)) of $H_2NO^\bullet$

Table 1
Stoichiometric results for the oxidation of N(−I) by the silver (III) complex [a]

$[Ag(III)]_T$ (mmol dm^{-3})	$[N(-I)]_T$ (mmol dm^{-3})	pH	$[N(-I)]_{left}$ (mmol dm^{-3})	$\Delta[N(-I)]_T/\Delta[Ag(III)]_T$
0.15	0.30	3.8	0.17	0.87
	0.40	4.0	0.26	0.93
	0.50	4.9	0.34	1.07
0.30	0.80	5.0	0.48	1.07
	1.20	4.6	0.94	0.87
0.50	1.00	4.9	0.52	0.96
	1.50	3.9	1.05	0.90
				Average = 0.97 ± 0.10.

[a] $T = 25.0$ °C; $I = 1.0$ mol dm^{-3} ($NaNO_3$).

radical under different conditions [15]. Thus $H_2NO^{\bullet}$ may decay to N_2 (Eq. (2)) or may be further oxidised (Eq. (3)) to HNO, which dimerises to *cis*- and *trans*-hyponitrous acid [28]. The *trans* form is more stable than the *cis*- form, decomposes into N_2O [29]. With strong oxidants such as Mn^{3+}(aq) or Ag^{2+}(aq), present in excess, the free radical is further oxidised to NO_3^- [30].

$$H_2NO^{\bullet} \rightarrow 0.5N_2 + H_2O \quad (2)$$

$$H_2NO^{\bullet} \rightarrow HNO + H^+ + e^- \quad (3)$$

$$2HNO \rightarrow H_2N_2O_2 \rightarrow N_2O + H_2O \quad (4)$$

Thermodynamic oxidising strength of the title complex under investigation is moderate [4,11]. Hence N(III) or N(V) is not an expected oxidation product.

3.3. Kinetics

No immediate spectral change was observed on mixing hydroxylamine with the Ag(III) complex over the entire range of experimental pH. However, the absorbance at $\lambda \geq 380$ nm gradually decreases to less than 0.01. Trace metal ions [31] in solution strongly catalyse the oxidation of hydroxylamine and affects both rate and the oxidation product. Ambient light sometime also plays a definite role [32]. We measured some k_0 values in presence of added ethylenebis(biguanide) [1.0 mmol dm^{-3}] and found to be identical with its absence within experimental uncertainties, and we observed no effect of diffused light in our system. The $\log_{10}$(absorbance) versus time plots were found to be linear for more than 90% of reactions and the pseudo first-order rate constants, k_0, defined by Eq. (5) were obtained from the least-squares slopes of these plots.

$$-d[Ag(III)]/dt = k_0[Ag(III)] \quad (5)$$

Any initial drop in absorbance for faster reactions can be computed from the time of mixing of solutions (~ 4 s) and the observed first-order rate constants. Averages of the k_0 values from at least three runs were taken and individual runs were reproducible within 3%. Detailed data of the kinetics of the process were obtained as a function of pH and total NH_2OH (defined as $[N(-I)]_T$, which is $[NH_2OH]+[NH_3OH^+]$) and some representative data are summarised in Table 2. Over the entire pH range studied the reaction shows a clear first-order dependence on $[N(-I)]_T$ and there is no $[N(-I)]_T$ independent term. The following changes in the reaction conditions had, within the limits of experimental uncertainties, no influence on the values of k_0: a fivefold variation in [Ag(III)] from 0.1 to 0.5 mmol dm^{-3}, addition of $AgNO_3$ (studied up to 0.01 mol dm^{-3}), variation of ionic strength maintained by $NaNO_3$ or $NaClO_4$ in the range 0.1–1.0 mol dm^{-3}, the occasional shaking of the spectrophotometer cell, presence or

Table 2

[a] $T = 25.0$ °C, $I = 1.0$ mol dm^{-3}; [complex] = 0.15 mmol dm^{-3}.

absence of dissolved oxygen, and a variation in the monitoring wavelength in the range 380–480 nm.

No polymer is formed when 6% (v/v) acrylonitrile is added to the reaction mixture and whole reaction course is epr silent. There is thus no evidence for the formation of detectable amounts of free radicals or other paramagnetic species during the reaction. However, one can not conclude from these observations as to whether the reactions of Ag(III) with hydroxylamine are one or two electron processes, because the radicals produced from one-electron oxidation of hydroxylamine may react in a very fast manner with Ag(III) before they can escape into the bulk solvent, thus evading detection.

A plot of k_0 versus pH has a bell shape (Fig. 2). Such a pH dependence indicates the involvement of two or more acid–base equilibria [33]. Considering the values for the acid dissociation constants of the complex in aqueous solution [34] (K_{a_1} and K_{a_2}, which are 1.58×10^{-4} and 5.01×10^{-7} mol dm^{-3}, respectively) and K_a ($= 1.0 \times 10^{-6}$ mol dm^{-3}), the acid dissociation constant [35] of NH_3OH^+, the scheme in Eqs. (3)–(8) provide a reasonable explanation for the kinetic observations.

$$[Ag(H_2L)]^{3+} \overset{K_{a_1}}{\rightleftharpoons} [Ag(HL)^{2+} + H^+ \quad (6)$$

$$[Ag(HL)]^{2+} \overset{K_{a_2}}{\rightleftharpoons} [AgL]^+ + H^+ \quad (7)$$

$$NH_3OH^+ \overset{K_a}{\rightleftharpoons} NH_2OH + H^+ \quad (8)$$

$$[Ag(H_2L)]^{3+} + NH_2OH \overset{k_1}{\rightarrow} \text{Products} \quad (9)$$

$$[Ag(HL)]^{2+} + NH_2OH \overset{k_2}{\rightarrow} \text{Products} \quad (10)$$

$$[AgL]^+ + NH_2OH \overset{k_3}{\rightarrow} \text{Products} \quad (11)$$

From these, expression (12) can be derived where the fraction of the complex present as $[Ag(H_2L)]^{3+}$ is given by Eq. (13) and the fraction of $[N(-I)]_T$ present as NH_2OH is given by Eq. (14).

$$k_0[H^+]^2/([N(-I)]_T\alpha_1\alpha_2) = k_1[H^+]^2 + k_2K_{a_1}[H^+] + k_3K_{a_1}K_{a_2} \quad (12)$$

$$\alpha_1 = [H^+]^2/([H^+]^2 + K_{a_1}[H^+] + K_{a_1}K_{a_2} \quad (13)$$

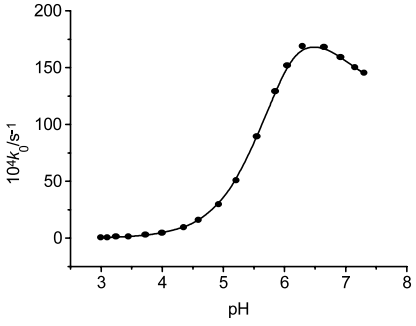

Fig. 2. Dependence of k_0 on pH at 25.0 °C, $[Ag(III)]_T = 0.15$ mmol dm^{-3}, $[N(-I)]_T = 3.0$ mmol dm^{-3}, $I = 1.0$ mol dm^{-3} ($NaNO_3$). The solid line represents the fit of Eq. (12).

$$\alpha_2 = K_a/(K_a + [H^+]) \quad (14)$$

Non-linear fitting of left-hand-side of Eq. (12) with $[H^+]$ yielded k_1, $k_2K_{a_1}$ and $k_3K_{a_1}K_{a_2}$. Using known values of K_{a_1} and K_{a_2}, the rate constants k_2 and k_3 were evaluated. All these second-order rate constants are presented in Table 3 which reproduced all k_0 within 5%.

It may also be noted that in the pH interval 3.00–4.60, the second dissociation of the Ag(III) complex (K_{a_2}) can be neglected and Eqs. (9) and (10) are sufficient to represent the observed first-order rate constants. On the other hand, in the higher pH range 6.30–7.30 the first dissociation of the Ag(III) complex (K_{a_1}) can be neglected and only Eqs. (10) and (11) may account for the observed situation. The second-order rate constants evaluated in this manner agreed nicely with the values represented in Table 3 within 7%.

3.4. Mechanism

The observed sequence $k_1 > k_2 > k_3$ indicates that protonation of the oxidant increases its kinetic reactivity whereas the opposite is true for protonation of the reductant. Majority of the other known redox systems also follow a similar trend [36,37]. The trend was observed earlier for the oxidation [12] of N(III) with the title Ag(III) complex. In the present investigation we found that the conjugate acid NH_3OH^+ is kinetically inactive towards the Ag(III) complexes under investigation and its conjugate bases, whereas HNO_2 was active, though to a much lesser extent than NO_2^- towards the reduction of the Ag(III) complex. We anticipate that an unfavourable charge interaction between the cationic silver(III) complexes with NH_3OH^+ makes the situation a different one. A molecule with a free electron pair should have a greater affinity for cation than would another positively charged ion.

One may use Marcus cross relation [38], $k_{12} = (k_{11}k_{22}K)^{1/2}$ to identify the nature of electron transfer. The equilibrium constant K of the one-electron transfer between $[Ag(H_2L)]^{3+}$ and NH_2OH may be calculated from the known redox potentials of $[Ag(H_2L)]^{3+/2+}$ couple (0.43 V) [4,11] and NH_2OH–NH_2OH^+ (−0.42 V) [39]. The self-exchange rate constant for the couple NH_2OH–NH_2OH^+ is 5×10^{-13} dm^3 mol^{-1} s^{-1} [39] and the maximum possible self-exchange rate for

Table 3
Second-order rate constants (in dm^3 mol^{-1} s^{-1}) for the oxidation of N(−I) by the Ag(III) complex [a]

Reaction	Rate constant
$[Ag(H_2L)]^{3+} + NH_2OH$	$k_1 = 20.1 \pm 1.0$
$[Ag(HL)]^{2+} + NH_2OH$	$k_2 = 12.5 \pm 0.60$
$[AgL]^+ + NH_2OH$	$k_3 = 4.35 \pm 0.50$

[a] [Complex] = 0.15 mmol dm^{-3}, $I = 1.0$ mol dm^{-3} ($NaNO_3$), $T = 25.0$ °C.

$[Ag(H_2L)]^{3+/2+}$ couple is $10^{6.6}$ [13]. Using these values, the calculated maximum value of k_{12} becomes $\sim 1.7 \times 10^{-3}$ dm^3 mol^{-1} s^{-1}, much lower than the experimentally observed value (20.1 dm^3 mol^{-1} s^{-1}), which refutes one-electron outer sphere pathway as the rate-determining step. This is not unexpected in light of the remarkably low NH_2OH–NH_2OH^+ self-exchange rate coupled with a near zero E° value for the one electron reaction.

It is well documented that hydroxylamine (NH_2OH) can co-ordinate to higher valent metal ions [40–42]. The electron affinity of the Ag(III) in the present complex is high [43] as established by X-ray photoelectron spectroscopic measurements that the Ag(III) centre has a high degree of positive charge and it is known from structural [44–46] and kinetic [6,7] studies that the complex undergoes axial co-ordination with alcohols, H_2O_2, SO_4^{2-}, NO_3^- or even ClO_4^-. We thus anticipate a similar co-ordination of NH_2OH to the Ag(III) centre and subsequent electron transfer.

4. Conclusions

Reduction of the complex cation $[Ag(H_2L)]^{3+}$ may proceed via a Ag^+- catalysed path and/or an uncatalysed path depending on the nature of the reductant. Only the uncatalysed path is detectable in the oxidation of N(−I), N(III) [12], alcohols [6], ascorbic acid [10] and Fe^{2+}(aq) [11] by this complex. The catalysed path involves a Ag^+–Ag^0 cycle (for HCO_2H [5], $N_2H_5^+$ [8] and H_3PO_2 [9]) or a Ag(I)–Ag(II) cycle (for H_2O_2 [7]). Predominance of the uncatalysed or catalysed path depends on a critical balance of thermodynamic and also on kinetic factors, but grossly speaking when the reductant is powerful [47] like HCO_2H, $N_2H_5^+$ or H_3PO_2 or a good ligand for Ag(III), then catalysed path dominates. We observed that below pH $\sim$ 5.0 hydroxylamine does not react with Ag^+ over a long period and we observed no Ag^+ catalysis in our reactions. Below pH 3.0, hydroxylamine was found to be kinetically inactive towards the reduction of the title complex which indicates absence of any possible $[Ag(H_2L)]^{3+}$–NH_3OH^+ path. We found that NH_3OH^+ is kinetically inactive but the conjugate base, NH_2OH, a neutral species reacts with the charged Ag(III) complexes. An indirect outcome of these types of reacting species may be the innocent influence of media ionic strength on the rate of reactions. All the reaction paths k_1, k_2 and k_3 possibly involve inner-sphere processes. It cannot be concluded at this stage whether the reaction involves one- or two-electron changes.

allowing determination of its structure by X-ray diffraction.

2. Experimental

2.1. Materials and methods

All amino acids were used in the L form and were purchased from Fluka. Other reagents (i.e. $Ba(OH)_2$, CS_2, $Cu(NO_3)_2 \cdot 3H_2O$, $CuCl_2 \cdot 2H_2O$) and the organic solvents were from Fluka (pa) as well. Chemical analyses for carbon, hydrogen and nitrogen were performed on a 2400 elemental analyser from Perkin–Elmer. Barium and copper were determined on an ICP spectrometer Perkin–Elmer model 2380 Plasma 2. IR spectra were recorded using KBr mulls and a Perkin–Elmer instrument. Electronic spectra were recorded in aqueous solution on Shimadzu UV-240 double beam and Hewlett–Packard 8452A diode spectrophotometers. The room temperature (r.t.) magnetic moment was measured by the Faraday method on a AZTEC DSM8 pendulum-type susceptometer and electron paramagnetic resonance spectra were recorded at X-band frequencies with a Bruker ER200D. The water content in the complexes was determined by thermal analysis using a Perkin–Elemer TGA-7 thermobalance and a DTA-7 differential thermal analysis apparatus, both operating at a heating rate of 5 $^{\circ}C\ min^{-1}$ and under oxygen as the reaction atmosphere.

2.2. Preparation of the barium dithiocarbamates

The dithiocarbamate ligands have been prepared in the form of the barium salts through reaction of the corresponding amino acid with CS_2 in a basic medium ($Ba(OH)_2$), following the method described elsewhere [3]. The use of the barium salts permits larger yields (ca. 85%) than if sodium salts are used, due to their low solubility in ethanol. The general formula of the salts is $Ba(dtc\text{-}a.a.) \cdot H_2O$, where a.a. stands for the amino acid; the existence of the crystallisation water molecule has been checked by thermogravimetric and differential thermal analysis of the barium salts. These salts are very soluble in water, but insoluble in organic solvents.

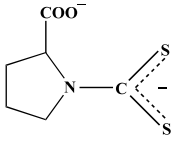
2.3. Preparation of the copper complexes

The copper complexes have been prepared by direct reaction between the dithiocarbamate barium salts and soluble Cu(II) salts (nitrate or chloride), results being different depending on the precise nature of the amino acid (with an alcohol or an amide group, or proline). The method was as follows: 0.8 mmol of the dithiocarbamate are dissolved in 25 ml H_2O and dropwise added to a magnetically stirred solution containing 0.4 mmol Cu(II) soluble salt in 25 ml H_2O. For compounds **1**–**5** (see Table 1) the solution immediately darkens when addition starts, finally giving a dark brown precipitate, which is separated by filtration. Elemental chemical analysis results are given in Table 1; yields ranged between 40 and 45% in all cases.

The proline derived compound (**6**) behaves differently. The solution changes to a dark green colour and precipitation only takes place after strong concentration, by slow evaporation of water or in a vacuum dessicator; the yield was 70–75% in this case. Unfortunately, we failed to crystallise this compound, despite its solubility in water. However, well defined crystals were obtained upon addition of a second ligand, ethylenediamine (en), leading to formation of a mixed, more stable complex. This was obtained as follows: 2.2 mmol of the barium salt of the proline derived dithiocarabamate are dissolved in 25 ml H_2O; the solution is strongly magnetically stirred and 2.2 mol Cu, dissolved in 25 ml H_2O, and 2.2 mmol ethylenediamine are added. After completing the addition, a green precipitate is formed (compound **7**), which is separated by filtration. After standing for 3 days at r.t., the supernatant liquid forms green, needle-like, crystals whose elemental chemical analysis data and FTIR spectrum coincide with those of the precipitate. It is worth noting the presence of an ethanol molecule in the composition of this compound as evidenced by X-ray diffraction (see below), which probably was present in the starting barium salt (precipitated in ethanol medium). The presence of crystal-

lisation water molecules has been checked in all cases by thermogravimetric and differential thermal analyses.

2.4. Crystal structure determination



A dark green prismatic crystal of [Cu(en)(EtOH)$(H_2O)_3$][Cu(dtc-pro)$_2$] was mounted on a glass fiber and used for data collection. Crystal data were collected at 291(2) K, using a Bruker SMART CCD 1000 diffractometer. Graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) was used throughout. The data were processed with SAINT [11] and corrected for absorption using SADABS (transmissions factors: 1.000–0.573) [12]. The structure was solved by direct methods using the program SHELXS-97 [13] and refined by full-matrix least-squares techniques against F^2 using SHELXL-97 [14]. Positional and anisotropic atomic displacement parameters were refined for all non-hydrogen atoms of the anion and the copper atom of the cation, and isotropic displacement parameters for the other cation atoms. The cation atoms are disordered over two positions; the occupancy factor for each was initially refined, resulting in a value of 0.50(6) for each. Hydrogen atoms, except those bonded to oxygen atoms, were placed geometrically and positional parameters were refined using a riding model. Isotropic atomic displacement parameters for hydrogen atoms were constrained to be 1.2 (1.5 for methyl groups). Atomic scattering factors were obtained from 'International Tables for X-ray Crystallography' [15]. Molecular graphics were obtained from PLATON [16] and SCHAKAL [17]. A summary of the crystal data, experimental details and refinement results are listed in Table 2.

Table 2
Crystal data and structure refinement for [Cu(en)(EtOH)$(H_2O)_3$][Cu(dtc-pro)$_2$]

Empirical formula	$C_{16}H_{34}Cu_2N_4O_8S_4$
Formula weight	665.79
Temperature (K)	293(2)

Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	3243/0/154
Goodness-of-fit on F^2	0.974
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0914$, $wR_2 = 0.2032$
R indices (all data)	$R_1 = 0.1607$, $wR_2 = 0.2322$
Largest difference peak and hole (e Å^{-3})	1.638 and −1.346

3. Results and discussion

Reaction of Cu(II) salts with dithiocarbamates derived from α-amino acids possessing alcohol or amide groups leads to reduction of the metal cation to Cu(I), probably through oxidation of the dithiocarbamate to the corresponding disulfide. An additional feature of the compounds prepared with serine, threonine and tyrosine arises from the presence of an alcohol group in their structures, which becomes deprotonated, thus providing a total formal charge of −3 to the corresponding ligands. However, such a reduction does not takes place with the proline compound, a Cu(II) complex being formed. This results further confirms that the reduction ability of dithiocarbamates depends on the nature of the organic chain linked to the NCS_2^- moiety, as previously observed for some dithiocarbamate complexes of Mo [8,10]. Probably, the fact that the nitrogen atom belongs to the organic ring (Scheme 1) decreases its electron donor ability towards the sulfur atoms, thus decreasing their reducing ability.

Scheme 1. Schematic representation of proline dithiocarbamate.

3.1. IR spectra

The positions of the main FT-IR bands recorded for all seven complexes synthesised are given in Table 3. The band close to 1490 cm^{-1} is due to the stretching of the C–N group of the NCS_2^- moiety; its position corresponds to a partial double bond character, and is recorded in the range previously reported for similar compounds [18,19]. The band designated as ν(N–C′) in the table corresponds to the vibration of the two N–C bonds within the five members ring, and corresponds to single N–C bonds. The additional band at 1044 cm^{-1} in complex **7** is due to the ethylenediamine ligand.

The bands recorded in the region corresponding to the C–S vibrations are typical of a bidentate bonding of the dithiocarbamate unit to the metal cation [18,19], and

Table 3
Vibrational frequencies (cm^{-1}) for selected absorption bands in the IR spectra

Complex	ν(C–N)	ν(N–C′)	ν_{as}(C–S)	ν_s(C–S)	$\nu_{as}(COO^-)$	$\nu_s(COO^-)$	$\rho(COO^-)$	ν(S–Cu)
1 $Ba[Cu(dtc\text{-}asn)]_2\cdot 4H_2O$	1484	1112	927	622	1589	1396	548	337
2 $Ba[Cu(dtc\text{-}gln)]_2\cdot 4H_2O$	1488	1107	939	614	1577	1396	541	328
3 $Ba[Cu_2(dtc\text{-}ser)]_2\cdot 2H_2O$	1499	1172	928	609	1602	1385	556	326
4 $Ba[Cu_2(dtc\text{-}thr)]_2\cdot 3H_2O$	1498	1177	936	608	1606	1383	556	328
5 $Ba[Cu_2(dtc\text{-}tyr)]_2\cdot 3H_2O$	1513	1233	901	612	1609	1373	538	327
6 $Ba[Cu(dtc\text{-}pro)_2]\cdot 3H_2O$	1472	1164 1139	940	659	1598	1382	487	345
7 $[Cu(en)(EtOH)(H_2O)_3][Cu(dtc\text{-}pro)_2]$	1489	1173 1152 1044	952	661	1598	1381	487	339

the vibration of the sulfur–copper bond gives rise to a band close to 330 cm^{-1} in all complexes synthesised [18–20]. The bands close to 1600 and 1390 cm^{-1} are due to the antisymmetric and symmetric vibrations of the carboxylate groups.

3.2. Crystal structure of $[Cu(en)(EtOH)(H_2O)_3][Cu(dtc\text{-}pro)_2]$

In addition to the other experimental data described above, X-ray diffraction for this complex shows both the cation and the anion are coordination compounds. Most significant structural parameters are given in Table 4 and the molecular structure of both ions are shown in Fig. 1(a and b).

As shown in this figure, the copper is coordinated by four sulfur atoms in the anion $[Cu(dtc\text{-}pro)_2]^{2-}$, giving rise to a local symmetry of D_{2h} around the metallic site, as the SCS angles are lower than 90° (otherwise the local geometry would approach D_{4h}). The four Cu–S distances are almost coincident, as well as the C–S distances, thus confirming the bidentate nature of the dithiocarbamate ligand; actually, the C–S distances are close to 1.71 Å, similar to the values previously reported for other dithiocarbamates [21], including the barium salt of glycine dithiocarbamate [22]. The C–N distance, 1.312 Å, is also similar and in agreement with a marked double bond character. However, the –SCS– angle is about 6° smaller in the copper complex than in the glycine dithiocarbamate (as the barium salt), i.e. the angles become somewhat closed upon coordination to copper. Overall, the bond angles and bond distances are rather similar to those reported for Cu complexes with alkyldithiocarbamates [23].

In the other complex subunit, $[Cu(en)(EtOH)(H_2O)_3]^{2+}$, Cu(II) is hexacoordinated, with a distorted octahedral symmetry. The aquo ligands stand in a *fac* symmetry, and two of the three water molecules are in the same plane as the nitrogen atoms of the ethylenediamine ligand; the oxygen atom of the third water molecule is 0.27 Å further out than the other two, and that of the ethanol molecule is even further out, probably because of the tetragonal distortion favoured for this configuration (d^9), according to the Jahn–Teller

effect. The two Cu–N (from ethylenediamine) distances are also different, probably because of packing effects in the crystalline state and/or in order to minimise repulsions with the other ligands.

3.3. Electronic and ESR spectra

Compounds **1**–**5** are diamagnetic and do not show well defined bands in the visible region, but the absorption extends almost in all the visible range. On the contrary, the proline complexes show a broad, ill defined, absorption band centred at about 630 nm for compound **6** and at 615 nm for compound **7**, with an extinction coefficient of 100 M^{-1} cm^{-1}, that should correspond to transits from lower energy levels to dx^2-y^2 [24]. An additional band at 430 nm ($\varepsilon = 3500$ M^{-1} cm^{-1}) is recorded for both complexes and can be assigned to a S→Cu charge transfer process. These two compounds are paramagnetic, the effective magnetic moments being 1.78 and 1.76 BM for complexes **6** and **7**, respectively, very close to the value calculated for the spin-only moment, 1.73 BM, thus suggesting only weak, if any, spin-orbit coupling [25]. Cu^{2+} possesses an orbitally non-degenerate ground state in the Jahn–Teller distorted polyhedra and hence essentially a spin-only magnetic moment; deviations are due to admixtures of very small orbital contributions of excited states via spin-orbit coupling.

The ESR spectra for both proline complexes are included in Fig. 2; no fine structure was observed in either case. That for compound **6** is axial, with ESR parameters deduced from simulation [26] of $g_{\parallel} = 2.09$, $g_{\perp} = 2.03$ and $g_o = 2.07$. The spectrum corresponding to compound **7** corresponds to a mixture of two Cu(II) ions (d^9 configuration) under two different surroundings, as it can be considered as being formed by two

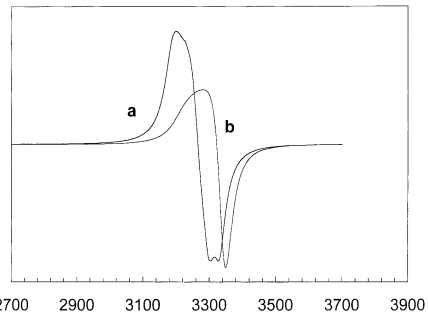

Fig. 2. Experimental polycrystalline X-band ESR spectra at 298 K of the copper complexes: (a) $[Cu(en)(EtOH)(H_2O)_3][Cu(dtc\text{-}pro)_2]$, (b) $Ba[Cu(dtc\text{-}pro)_2]\cdot 3H_2O$.

axial quasi-isotropic spectra, unable to be simulated, with average values of $g_o = 2.08$ and 2.06 for both Cu atoms [25].

4. Supplementary material

Complete lists with atomic coordinates, anisotropic displacement parameters, bond lengths and angles have been deposited at the Cambridge Crystallographic Data Centre [CCDC 178510], 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

A B

Fig. 1. (A) Structural formula of naphthalocyanine; and (B) skeletal representation of bis(naphthalocyaninato) rare earth sandwich complexes $M(2,3\text{-}Nc)_2$.

iono-electronics [5,6]. By the continuous efforts of Jiang and co-workers to develop new examples of sandwich compounds, a series of homoleptic and heteroleptic sandwich rare earth complexes containing naphthalocyanine ligands have been reported based on newly developed methodology [7–12].

Although naphthalocyanine derivatives have been known for a long time, relatively little is known of their vibrational spectroscopic properties. In 1984, Kaplan et al. reported the IR characteristics of the most intense absorptions of some Nc metal complexes [13]. Yanagi et al. investigated the IR spectra of various Nc complexes of Zn, Al, Ga, and V in 1992 and 1993 [14]. Aroca and co-workers also studied the vibrational spectra (IR, Raman, resonance Raman, surface enhanced resonance Raman) for free base $H_2(2,3\text{-}Nc)$ and copper complex Cu(2,3-Nc) following their intensive work on phthalocyanine counterparts [15]. Very recently, the group of Campos-Vallette tried to interpret the structure of free base naphthalocyanine and a series of naphthalocyaninato metal complexes on the basis of their FT-IR and Raman spectroscopic investigation [16]. Before the report on IR spectroscopic characterization of some bis(naphthalocyaninato) rare earth compounds [17], the sole relevant report concerning the vibrational properties is that of L'Her who attributed a strong band at approximately 1330 cm^{-1} to the stretching vibration of the pyrrole rings of naphthalocyanine in $Lu(2,3\text{-}Nc)_2$ and Lu(Pc)(2,3-Nc) [18]. Since 1999, Jiang, Arnold, and Homborg have started to pay attention to the vibrational spectroscopic characterization of Nc rare earth sandwich complexes and have briefly reported the Raman spectra for several bis(naphthalocyaninato) rare earth complexes [19,20]. The aim of the present paper is not only to add more information on the Raman spectroscopy of naphthalocyanine but also to give insight into the influence of the rare earth ionic size on the Raman spectra of naphthalocyanine in the sandwich compounds. Herein we describe the Raman spectroscopic characteristics of naphthalocyanine anions in the bis(naphthalocyaninato) rare earth compounds $M(2,3\text{-}Nc^*)_2$ [$M = Ce\cdots Lu$ except Nd and Pm, Y; $Nc^* = Nc(t\text{Bu})_4$] by means of excitation by laser sources at 632.8 and 785 nm. It is worth noting that the Raman spectra of several bis(naphthalocyaninato) rare earth compounds under excitation by 632.8 nm radiation have been recorded previously [19]. For the purpose of systematic comparison with those under 785 nm laser excitation and re-assignment of some vibrational modes, the spectra of the complete set of compounds discussed in this paper were re-measured under 632.8 nm excitation and their spectra are in good accordance with the previous measurements [19,20].

2. Experimental

Bis(naphthalocyaninato) rare earth complexes $M(2,3\text{-}Nc^*)_2$ [$M = La\cdots Lu$ except Nd and Pm, Y; Nc^* = 3(4),12(13),21(22),30(31)-tetra(t-butyl)-2,3-naphthalocyanine, $Nc(t\text{Bu})_4$] were prepared according to the reported procedures [8]. Raman spectra were recorded on a few grains of the solid samples with approximately 4 cm^{-1} resolution using a Renishaw Raman Microprobe, equipped with a Spectra Physics Model 127 He–Ne laser excitation source emitting at a wavelength of 632.8 nm and a Renishaw diode laser emitting at 785 nm, and a cooled charge-coupled device (CCD) camera. An Olympus BHZ-UHA microscope was attached and was fitted with three objective lenses ($\times 10$, $\times 20$, $\times 50$). For these experiments, the $\times 10$ objective was employed giving a spot size on the sample of about 5 μm. Laser power at the sample was approximately 0.08 mW. Spectra of excellent quality were obtained in approximately 3 min.

3. Results

In bis(phthalocyaninato) rare earth complexes $M(Pc)_2$, the single crystal X-ray diffraction structural data have shown that the rare earth cation is at the centre of two Pc ligands facing each other in a staggered arrangement. In the solid state, these compounds can be assumed to belong to the D_4 or D_{4d} point-groups depending on the skew angle between the two macrocyclic rings. There has been no crystallographic report on the molecular structure of bis(naphthalocyaninato) metal complexes as systematic research on these complexes has not been pursued until the recent work of Jiang and co-workers [7]. However, according to the recently reported molecular structures of mixed (octaethylporphyrinato)(naphthalocyaninato) rare earth double-deckers M(OEP)(2,3-Nc) (M = Pr, Nd, Sm, Eu,

Gd, Y, Tm, Lu), the skew angles between OEP and 2,3-Nc macrocyclic ligands in the whole series of rare earth compounds remain unchanged at 45° in order to minimize the non-bonding interactions between the fused benzene rings of Nc and the β-ethyl groups of OEP [8,21]. Therefore, it is reasonable to assume that the skew angle between two Nc rings in M(2,3-Nc)$_2$ is near 45° due to the same reason. The equilibrium geometry of M(2,3-Nc)$_2$ should be D_{4d} group symmetry when the skew angle is 45° or D_4 when the skew angle is not 45°. This needs direct confirmation from X-ray molecular structure analysis in future. The actual materials M(2,3-Nc*)$_2$ [Nc* = Nc(tBu)$_4$] contain more than one isomer due to the alternative locations of the *tert*-butyl groups. However, for each substituted Nc ring and the central rare earth metal atom, a local C_{4v} symmetry should be seen and the interpretation of the observed vibrational spectra could be assisted by this approximation. In the Raman spectra of Zr[Pc(tBu)$_4$]$_2$, only frequencies corresponding to the characteristic fingerprint vibrations of the Pc macrocycle were observed and *tert*-butyl vibrations were very weak or absent [22]. Moreover, because both laser lines used in our experiments appear to enhance modes associated with the aromatic macrocycles (see below), the *tert*-butyl groups will be ignored in our subsequent analysis. Even the unsubstituted naphthalocyaninato metal fragment with 81 atoms and 237 normal vibrational modes is a tremendous challenge for the vibrational spectroscopist. For a C_{4v} M(2,3-Nc) fragment there will be only 31 A_1 totally symmetric modes that dominate the spontaneous Raman spectra. The other Raman active modes include $30B_1+30B_2+118E$, which will show a number of new frequencies in the resonance Raman scattering in view of the Herzberg–Teller mechanism. Despite the large number of fundamental vibrational modes, the Raman spectra of these double-decker complexes are composed of a small number of bands, as shown in Figs. 2 and 3.

Based on their intensive research on the vibrational spectra of both phthalocyanine and naphthalocyanine compounds, Aroca and co-workers found that the following three groups of characteristic phthalocyanine or naphthalocyanine vibrations dominate their IR and Raman spectra [15,23,24]. In the spectral region from 400 to 1000 cm^{-1}, the vibrations are mainly composed of the dihedral plane deformations involving the aromatic C–H groups (wagging and torsion vibration) which are normally seen in the IR spectra, and ring radial vibrations of the isoindole moieties and the macrocycle which show strong Raman signals. Aromatic in-plane C–H vibrations are responsible for the IR and resonance Raman spectra of phthalocyanine molecules in the region of 1000–1300 cm^{-1}, with the exception of the pyrrole ring vibration at about 1140 cm^{-1}. Vibrational frequencies in the range of 1320–1650 cm^{-1} are derived from isoindole ring stretches and the aza group stretch, for which the pyrrole stretching vibrations at approximately 1330 and 1510 cm^{-1}, and *ortho*-substituted benzene (or naphthalene) stretchings at approximately 1560, 1590, and 1610 cm^{-1} or above can be distinguished by frequency and relative intensity.

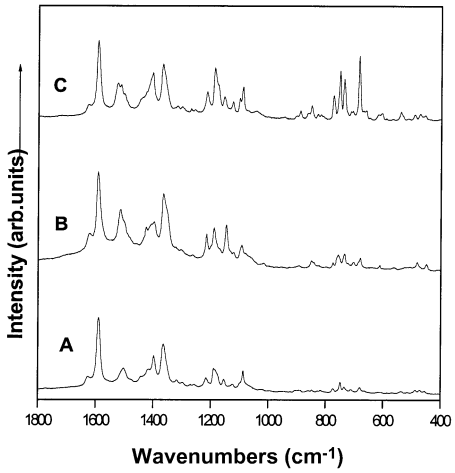

Fig. 2. Raman spectra of M(2,3-Nc*)$_2$ [Nc* = Nc(tBu)$_4$]: (A) M = Ce; (B) Gd; (C) Lu with excitation at 632.8 nm.

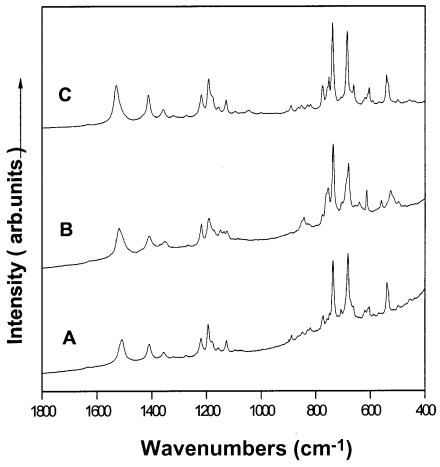

Fig. 3. Raman spectra of M(2,3-Nc*)$_2$ [Nc* = Nc(tBu)$_4$]: (A) M = Ce; (B) Gd; (C) Lu with excitation at 785 nm.

3.1. Raman characteristics of M(2,3-Nc)$_2$ [M = Ce···Lu except Nd and Pm, Y; Nc* = Nc(tBu)$_4$] with excitation by laser line at 632.8 nm*

Fig. 2 compares the Raman spectra obtained with laser excitation at 632.8 nm of three compounds M(2,3-Nc*)$_2$ [M = Ce, Gd, Lu; Nc* = Nc(tBu)$_4$], typical for the light, middle, and heavy rare earths, respectively. The observed Raman spectroscopic frequencies of naphthalocyanine for M(2,3-Nc*)$_2$ were partially assigned by analogy with the Raman characteristics of

bis(phthalocyaninato) rare earth counterparts [19,20] and naphthalocyanine derivatives [13–16]. Due to the similar electronic structure and electronic absorption properties among the whole series of bis(naphthalocyaninato) rare earth compounds, all these compounds show similar Raman characteristics, so the results have been summarized in the shortened form given in the Table 1. The naphthalene stretchings around 1592 cm^{-1} appear as the most intense band. The Nc breathing mode in M(2,3-Nc*)$_2$ appears as a weak band at approximately 681–684 cm^{-1}, which gains intensity gradually from M = Ce to Lu and shows a trend to blue-shift slightly along with the decrease of rare earth radius. The pyrrole stretching gives two peaks at approximately 1154 and 1500 cm^{-1}. The former one remains unchanged at approximately 1154 cm^{-1} as a single weak peak whereas the latter one seems to be blue-shifted along with the rare earth contraction. It must be pointed out that this latter peak overlaps with the aza stretch vibration at approximately 1520 cm^{-1} and thus appears as a shoulder for M(2,3-Nc*)$_2$ from M = Ce to M = Tm. Only in the spectra of the smallest rare earth bis(naphthalocyaninato) compounds M(2,3-Nc*)$_2$ (M = Yb, Lu) is this vibration apparent as a well-separated band at 1512 and 1513 cm^{-1}, respectively. The sensitivity of this vibrational mode to the central metal radius in the complexes suggests that it must contain significant C=N aza character and therefore is assigned to the coupling of pyrrole C=C and aza C=N stretches, which is consistent with the point of Melendres on the same vibrational mode of phthalocyanine derivatives [25]. The weak bands in the region from 400 to 1000 cm^{-1} are assigned to the ring radial vibrations of the isoindole moieties and the naphthalocyanine macrocycle. One of these at 750 cm^{-1} is due to the aromatic naphthalocyanine C–H wagging, which also gains intensity along with the decrease of rare earth size from Ce to Lu just as does that at 684 cm^{-1} due to the Nc ring breathing. The frequencies with weak and medium intensity observed in the spectral region of 1050–1280 cm^{-1} are attributed to the in-plane naphthalocyanine C–H bending vibrations. The remaining vibrations in 1320–1650 cm^{-1} range are isoindole stretch, aza group, and naphthalene stretch as organized in Table 1. In this group, except for the above-mentioned frequency at 1503–1513 cm^{-1} derived from the coupling of pyrrole C=C and aza C=N stretches, the C=N aza group stretch exhibits a weak shoulder band at approximately 1515 cm^{-1} for Ce(2,3-Nc*)$_2$ and a weak separated band at 1524 cm^{-1} for Lu(2,3-Nc*)$_2$. The most intense vibration at approximately 1592 cm^{-1} and a very weak shoulder at approximately 1625 cm^{-1} are assigned to the naphthalene stretches in M(2,3-Nc*)$_2$ (M = Ce···Lu except Nd and Pm, Y) by analogy with those of bis(phthalocyaninato) rare earths and monomeric naphthalocyaninato metal compounds [19,20,23]. In our preliminary report on the Raman spectra of M(2,3-Nc*)$_2$, we tentatively assigned the intense band at approximately 1370 cm^{-1} to the pyrrole vibration [19]. However, according to its appearance with a shoulder at approximately 1340 cm^{-1} and the sensitivity of this frequency to the nature of the rare earth ion, we now revise our assignment of the broad band centred at 1364–1369 cm^{-1}, and attribute it to the overlapped vibrations of the naphthalene stretching with some contributions from the pyrrole stretchings. This has been verified by the corresponding characteristics of the same band in M(OEP)(2,3-Nc). For the early rare earth double-deckers in the series M(OEP)(2,3-Nc) (M = La···Gd except for Ce and Pm), with excitation at 632.8 nm, a broad band locating at 1363–1364 cm^{-1} was attributed to the naphthalene stretching vibrations, whose shoulder at approximately 1340 cm^{-1} was assigned to the pyrrole stretchings. For late rare earth compounds M(OEP)(2,3-Nc) (M = Tb···Lu, Y), the two well-separated bands respectively at 1346–1350 and 1361–1364 cm^{-1} were undoubtedly assigned to pyrrole stretchings and naphthalene stretchings, respectively [26].

Under excitation by the laser line at 632.8 nm, the vibrations at 681–684 cm^{-1} assigned to the Nc breathing, 1357–1361 cm^{-1} due to the naphthalene stretchings, 1409–1415 cm^{-1} attributed to the isoindole stretchings, and 1517–1530 cm^{-1} contributed from the aza stretchings in the Raman spectra of M(2,3-Nc*)$_2$ shift slightly to higher energy along with the decrease of rare earth radius, clearly showing the rare earth size effect. A weak vibrational band at 878–886 cm^{-1} in the IR spectra of bis(phthalocyaninato) rare earths M(Pc)$_2$ has also been found to be sensitive to the central rare earth metal size and was thus attributed to the metal–

[a] Extremes of observed frequencies for medium or strong bands over the series M = Ce···Lu (except Nd, Pm); Y, values in parentheses are for the Gd complex where its frequency lies outside the quoted range.

nitrogen vibration by Isago and Shimoda [27]. This seems to be in line with the assignment of the same vibration at 886 cm^{-1} to the metal–nitrogen bond in the IR spectra of monomeric phthalocyaninato metal complexes according to Kobayashi [28] and Kenn [29]. However, in the present work, the frequency near 890 cm^{-1} shows no dependence on size (this is also true when recording the Raman spectra with excitation by the laser line at 785 nm). A vibration in the range of 849–854 cm^{-1} does seem to show such a trend, shifting slightly from 849 for Ce(2,3-Nc*)$_2$ to 853 cm^{-1} for Lu(2,3-Nc*)$_2$. It seems that the present results support the points of Shurvell [30] and Janczak [31] who associated the band in the range of 810–830 cm^{-1} with the metal–ligand vibration. Anyway, more theoretical and experimental efforts are necessary to make clear assignment of the frequencies in the region from 800 to 900 cm^{-1} to the metal–nitrogen vibration.

As noted previously, strong fluorescence occurred when trying to measure the Raman spectrum of La(2,3-Nc*)$_2$ using excitation at 632.8 nm.

3.2. *Raman characteristics of M(2,3-Nc*)$_2$ [M = Ce···Lu except Nd and Pm, Y; Nc* = Nc(t Bu)$_4$] with excitation by laser line at 785 nm*

Using the excitation laser line at 785 nm, as shown in Fig. 3 and summarized in the Table 1, the macrocyclic ring deformation and ring radial vibrations between 400 and 900 cm^{-1} in the Raman spectra of M(2,3-Nc*)$_2$ are selectively intensified. This is in good accordance with the Raman characteristics of bis(phthalocyaninato) rare earth analogues [19,20]. The Nc breathing at approximately 682 cm^{-1} and the aromatic C–H wagging at approximately 738 cm^{-1} are the most intense bands. The intense band due to the naphthalene stretches around 1592 cm^{-1} under 632.8 nm excitation is absent whereas the vibration at approximately 1637 cm^{-1} remains as a very weak band. Similar to those excited with 632.8 nm laser line, the frequencies of the coupling of pyrrole C=C and aza C=N stretches at 1508 cm^{-1} and the aza stretch in the region above 1520 cm^{-1} overlap to form a broad band. For the bis(naphthalocyaninato) complexes of larger rare earths such as Ce and Pr, the contribution from coupling of pyrrole C=C and aza C=N stretches dominates the frequencies and the two overlapped vibrations show a broad weak band at 1508 and 1507 cm^{-1}, respectively. For metals heavier than Sm, the frequency of the two overlapped vibrations is dominated by the contribution of the aza stretches and a relatively intense and broad band shifts from 1512 for Sm(2,3-Nc*)$_2$ to 1524 cm^{-1} for Lu(2,3-Nc*)$_2$. Obviously, the application of the 785 nm laser line adds intensity to this vibration and its frequency is clearly also dependent on the size of the metal ion. The broad, weak band locating at 1357–1361 cm^{-1} is assigned to the overlapped vibrations of pyrrole and naphthalene stretchings by analogy with those under 632.8 nm excitation.

Under 785 nm laser line excitation, the vibrations at 681–685 cm^{-1} assigned to the Nc breathings, 1357–1361 cm^{-1} due to the naphthalene stretchings, 1409–1413 cm^{-1} attributed to the isoindole stretchings, and 1517–1530 cm^{-1} contributed from the aza stretch in the Raman spectra of M^{III}(2,3-Nc*)$_2$ [Nc* = Nc(t Bu)$_4$] are shifted to higher energy along with the ionic radius contraction. For instance, a linear correlation exists between the frequency of the aza stretchings at approximately 1530 cm^{-1} and the tervalent rare earth ionic radii, as shown in Fig. 4.

4. Discussion

The Raman spectra of this series of compounds are clearly quite sensitive to the frequency of the exciting radiation, and in particular there are dramatic changes in relative intensities of various bands. The electronic absorption spectra of M(2,3-Nc*)$_2$ [M = Ce, Gd, Lu; Nc* = Nc(t Bu)$_4$] which are typical representatives of the UV–Vis spectra of the light, middle, and heavy rare earth complexes, respectively, are shown in Fig. 5 [7]. The spectral features resemble those of bis(phthalocyaninato) rare earth complexes except that all absorption bands are significantly red-shifted in the Nc series due to the extended conjugation. It is worthwhile to describe briefly the assignments of these electronic absorption bands [7]. The spectra consist of a broad Soret region peaking at 328–334 nm, an intense band in the region 767–799 nm described as the $Nc^{\bullet -}$ Q(0, 0) band (i.e. a transition from the singly-occupied orbital to the LUMO), and the intermediate region which includes the Q(1, 0) band and the 'π-radical anion band' (593–648 nm), representing transitions from lower levels to the SOMO. As the ionic radius of the tervalent metal decreases from La to Lu, the Soret band of M(2,3-Nc*)$_2$

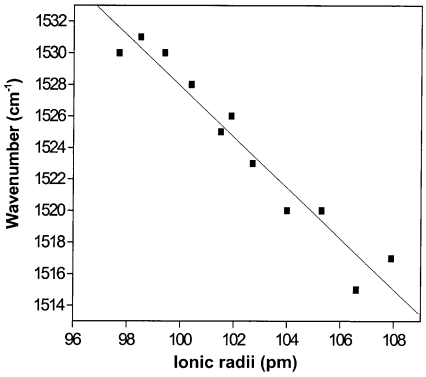

Fig. 4. Plot of wavenumber of the aza stretching scattering of M(2,3-Nc*)$_2$ [Nc* = Nc(t Bu)$_4$] at approximately 1530 cm^{-1} with excitation at 785 nm as a function of the ionic radius of M^{III}.

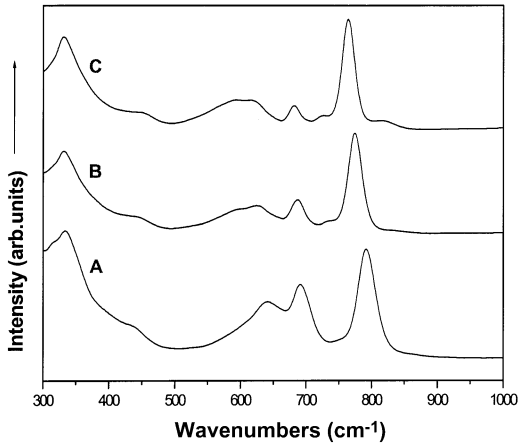

Fig. 5. Electronic absorption spectra of M(2,3-Nc*)$_2$ [Nc* = Nc(tBu)$_4$] (A) M = Ce, (B) Gd, (C) Lu in $CHCl_3$.

remains almost unchanged but the Q band and π-radical anion band are shifted to the blue [7]. As indicated from the electronic absorption, IR, and ^{1}H NMR spectra, bis(naphthalocyaninato) cerium exists in the form Ce^{III}(2,3-Nc*$^{2-}$)(2,3-Nc*$^{\bullet -}$) [Nc* = Nc(tBu)$_4$], the same as other analogues in the rare earth series [7,32]. It must be noted that in either bis(phthalocyaninato) double-deckers Ce(Pc′)$_2$ (Pc′ = Pc, Pc*) or mixed (porphyrinato)[(na)phthalocyaninato) double-deckers Ce(Por)(P) (P = Pc, 2,3-Nc) the cerium appears to exist in a mixed III/IV valency according to the recent work of Jiang, Ng, and Homborg [32,33].

The 632.8 nm laser line is far away from resonance with the most intense Q band at 767–799 nm of M(2,3-Nc*)$_2$, but is in near-resonance with the π-radical anion band and therefore would be expected to enhance particular vibrational modes. On the other hand, the 785 nm laser line is apparently in closer resonance with the intense Q band. According to the IR investigation, the unpaired electron in M(2,3-Nc*)$_2$ does delocalize over both naphthalocyanine macrocyclic ligands at a rate faster than the vibrational time scale [3,4,7,17,34]. Similarly, the Raman spectra of bis(naphthalocyaninato) rare earth(III) complexes can be attributed solely to the naphthalocyanine monoanion radical Nc*$^{\bullet -}$. This conclusion is in line with that of Tran-Thi from the Raman spectroscopic study of Gd(Pc)$_2$ [35]. When the laser excitation (632.8 nm) is well away from resonance with the Q band absorption, the strongly enhanced Raman band at approximately 1592 cm^{-1}, which is assigned to the naphthalene stretch of Nc ring, is a typical feature of naphthalocyanine monoanion radical Nc*$^{\bullet -}$, in M(2,3-Nc*)$_2$ [Nc* = Nc(tBu)$_4$]. On the other hand, when using excitation by the laser line at 785 nm, the band at approximately 1520 cm^{-1} with contributions from the aza C=N stretches, is a prominent Raman marker band for the naphthalocyanine anion Nc*$^{\bullet -}$. Moreover, the most intense band under 632.8 nm excitation (approximately 1592 cm^{-1}) is absent from these spectra.

Under excitation by either frequency, the vibrations at approximately 680 cm^{-1} assigned to the Nc breathings, approximately 1360 cm^{-1} derived from naphthalene stretchings, 1400 cm^{-1} contributed from isoindole stretchings, 1503 cm^{-1} due to the coupling of pyrrole C=C ring and aza C=N stretches, and 1515–1524 cm^{-1} contributed from the aza stretches, are sensitive to the central metal size, and are all slightly blue-shifted along with the decrease of rare earth radius. According to the recent theoretical work of Smith [36] on the IR and Raman spectra of ZnPc, the 'naphthalene stretching' band near 1360 cm^{-1} is actually from the out-of-phase indole ring expansions and the naphthalene ring deformations. Based on their theoretical investigations into the vibrational spectra of ZnPc, among the Raman active A_1 and B_1 modes, the scatterings at 1417, 1483 and 1517 cm^{-1} have been assigned to vibrations involving the aza C=N stretches. The strengths of these bonds could be easily affected by the ionic radius of the central metal and their frequencies are thus dependent on metal ionic size in the Raman spectra of phthalocyaninato metal complexes. In the sandwich-type bis(phthalocyaninato) metal complexes, X-ray single crystal molecular structure analyses have demonstrated that the degree of distortion of the Pc rings in the double-decker molecules containing different sized metal ions arises mainly from the extent of tilting of the isoindole sub-units using the bridging aza N atom as hinge [37]. Therefore, not only the scatterings at 1503 and 1515–1524 cm^{-1} but also that around 1400 cm^{-1} should be overlapped vibrations containing some contribution also from aza C=N stretches. Any modes involving the pyrrole ring nitrogens which are coordinated to the central metal ion could potentially be size-sensitive, such as the peak at approximately 1360 cm^{-1}, if it is a vibration involving pyrrole stretches coupled with the out-of-phase indole ring expansions and the naphthalene ring deformations. In view of the above, the reassignment of this band is reinforced.

Under both laser line excitations, the Raman characteristics of naphthalocyanine in Ce(2,3-Nc*)$_2$ correspond well with those of its tervalent rare earth analogues, confirming the tervalent nature of cerium in Ce(2,3-Nc*)$_2$ which is also implied by other spectroscopic techniques.

From a simplistic viewpoint, the trends in frequency of the electronic absorption bands seem to be largely responsible for the gradual changes seen in the relative intensities of some of the Raman lines, as the laser frequency more or less coincides with the most intensely absorbing region of the electronic spectrum. In order to understand and generalize the effects of changing excitation frequencies on the individual vibrational modes, we require a deeper knowledge of the electronic

structure of these complexes as well as more comparative data on other series of compounds. In a subsequent paper, we will describe the Raman characteristics of two sets of heteroleptic naphthalocyanine/porphyrin double-deckers [26].

Finally, it is worth noting that examination of our data indicates that several of the Raman bands for $Gd(2,3\text{-}Nc^*)_2$ do not correspond with those of other rare earth counterparts. This spectroscopic anomaly, however, has also been revealed in the electronic [7a] and IR [34a] absorption characteristics of the same compound compared with its analogues of the remaining rare earths in the lanthanide series. The reason might be related to the special $4f^7$ electronic configuration of Gd^{3+} but actually is not clear at this stage.

2. Experimental

2.1. Materials and physical measurements

All chemicals and solvents used in the syntheses were of reagent grade and were used without further purification. Distilled water was used for all procedures. IR spectra were recorded on a Perkin–Elmer Paragon 1000 FT-IR spectrophotometer as KBr pellets. Solution electronic spectra were obtained on a JASCO Uvidec 610 spectrophotometer. Solid-state spectra were measured by diffuse reflectance method on a Shimadzu UV2401 PC/DRS spectrophotometer. Room temperature (r.t.) magnetic susceptibilities were measured with a Johnson Matthey MK-II magnetic balance, and the variable temperature magnetic susceptibility data on powder samples were obtained in the range 5–300 K by using a Quantum Design MPMS-7 SQUID magnetometer with 0.5 T external magnetic field. The diamagnetic corrections were evaluated from Pascal's constants. Electrochemical measurements were accomplished with a three electrode potentiostat BAS-100BW system. A hanging mercury dropping electrode was used as the working electrode. The counter electrode was a coiled Pt wire and a Ag/AgCl electrode was used as a reference electrode. Cyclic voltammetric data were obtained in dimethylformamide (DMF) solution with 0.10 M tetraethylammonium perchlorate (TEAP) as supporting electrolyte at 20.0 ± 0.1 °C. The solution was degassed with high purity nitrogen prior to carrying out the electrochemical measurements. Elemental analyses (C, H, N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of $[Ni(H_2L)Cl_2]Cl_2 \cdot 2H_2O$ (2)

Compound **1** was obtained in a manner similar to the procedure described in Ref. [12]. To a MeOH solution (100 ml) of $NiCl_2 \cdot 6H_2O$ (11.9 g, 0.05 mol) was added *N*,*N*′-bis(2-aminoethyl)ethylenediamine (7.3 g, 0.05 mol), 1,2-diaminocyclohexane (5.7 g, 0.05 mol) and 37% HCHO (16.2 g, 0.2 mol). The mixture was heated to reflux for 1 day and then cooled to r.t. After an excess amount of HCl has been added, the mixture was placed in a refrigerator to complete the crystallization. The violet crystals were filtered off, washed with MeOH, and dried in air. Yield: 8.5 g (31%). *Anal*. Found: C, 35.22; H, 7.04; N, 15.28. Calc. for $C_{16}H_{38}Cl_4N_6NiO_2$: C, 35.13; H, 7.00; N, 15.36%. IR (KBr, cm^{-1}): 3212 (νNH). Magnetic moment (μ_{eff}): 2.94 μ_B at 20.0 ± 0.1 °C.

2.3. Preparation of $[Ni_2(L)_2(N_3)_4] \cdot 5H_2O$ (3)

To a MeCN solution (20 ml) of **2** (274 mg, 0.5 mmol) was added NaN_3 (65 mg, 1 mmol) and the mixture refluxed for 1 h. The solution was filtered to remove the KCl. The filtrate was allowed to stand for a few days, a quantity of violet crystals precipitated. These were collected by filtration and dried in air. Yield: 105 mg (73%). *Anal*. Found: C, 38.85; H, 7.64; N, 33.72. Calc. for $C_{32}H_{74}N_{24}Ni_2O_5$: C, 38.73; H, 7.52; N, 33.87%. IR (KBr, cm^{-1}): 3242 (νNH), 2037 (νN_3). Magnetic moment (μ_{eff}): 2.95 μ_B at 20 ± 0.1 °C.

2.4. Preparation of $[Ni(L)(tp)] \cdot 2H_2O$ (4)

A $CHCl_3$ solution (20 ml) of **2** (274 mg, 0.5 mmol) was allowed to diffuse into an aq. solution (5 ml) of sodium terephthalate (186 mg, 1 mmol) in a tube for several days. Pink crystals formed at the water | $CHCl_3$ interface. Crystals were collected by filtration and dried in air. Yield: 0.3 g (72%). *Anal*. Found: C, 50.68; H, 7.03; N, 14.67. Calc. for $C_{24}H_{40}N_6NiO_6$: C, 50.81; H, 7.11; N, 14.81%. IR (KBr, cm^{-1}): 3203 (νNH), 1569 (νCOO).

2.5. X-ray crystallography

Single-crystals of **2**, **3** and **4** were mounted at 293 K on an Enraf–Nonius CAD4 diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71069$ Å) and operating the ω–2θ scan mode. Unit cell parameters and orientation matrix were determined by least-squares treatment of the setting angles of 25 reflections. The intensity data were corrected for Lp effects. Empirical absorption corrections were carried out using φ-scan. The structures were solved by direct methods [13] and refined by full-matrix least-squares on F^2 [14]. All non-hydrogen atoms were anisotropically refined. For **2**, four H aoms bound to N(1), N(2), N(5) and N(6) atoms were found from the difference Fourier and they were refined isotropically, but the H atoms of two water molecules were not located. For **3**, positional parameters of all H atoms except for Ow(1), Ow(2), Ow(3) and Ow(4) atoms were calculated geometrically and constrained to ride on their attached atoms with $U_{iso}(H) = 1.2U_{eq}$(C or N), but the H atoms of Ow(5) were not located. For **4**, all H atoms were placed in calculated positions allowing to ride on their attached atoms with

$U_{iso}(H) = 1.2U_{eq}$(C or N). The water hydrogen atoms were not located. Crystallographic data and refinement results for the compounds are summarized in Table 1.

3. Results and discussion

3.1. Description of the structures

An ORTEP drawing of $[Ni(H_2L)Cl_2]Cl_2 \cdot 2H_2O$ (**2**) with the atomic numbering scheme is shown in Fig. 1. Selected bond distances and angles are listed in Table 2. The complex cation contains one cyclohexane subunit in the five-membered chelate ring and two 1,3-diazacyclopentane subunits in the six-membered chelate rings. The water molecules are disorderd. The complex has a distorted octahedral coordination geometry with two secondary and two tertiary amines of the macrocycle and two axial chloride ions. The macrocyclic ligand takes the most stable *trans*-III configuration. The 1,3-diazacyclopentane ring moiety assumes an envelope conformation with the N–C–C–N torsion angles of −18.2(4)° and −18.9(4)°, respectively. The 1,3-diazacyclopentane subunits of the complex are also protonated toward the uncoordinated tertiary N(5) and N(6). The Ni–N bond distances range from 2.060(3) to 2.121(3) Å, and the average of the four distances is 2.092(2) Å. These values are comparable to those of other octahedral nickel(II) complexes of 14-membered polyaza macrocyclic ligands [15–17]. The average Ni–N (secondary) distance of 2.065(2) Å is significantly shorter than the average Ni–N (tertiary) distance of 2.119(2) Å, indicating comparatively strong coordination. The N–Ni–N angles (93.8(1)° and 94.5(1)°) of six-membered chelate ring are much larger than the N–Ni–N angles (86.2(1)° and 85.8(1)°) of the five-membered chelate rings. The axial Ni–Cl distances of 2.490(1) and 2.512(1) Å can be compared to that found in $[Ni(cyclam)Cl_2]$ (2.510(1) Å) [18]. Furthermore, the axial Ni–Cl linkage is bent slightly off the perpendicular to the NiN_4 plane by 0.4°–7.1°. It is also interesting to observed that the average N(5)–C (1.503(3) Å) and N(6)–C (1.508(3) Å) distance involving the uncoordinated tertiary nitrogens is approximately 0.03 Å longer than the average N(3)–C

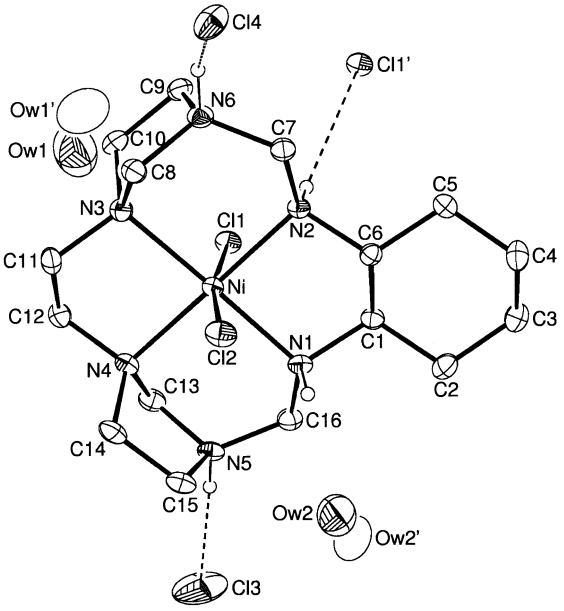

Fig. 1. An ORTEP diagram of $[Ni(H_2L)Cl_2]Cl_2\cdot 2H_2O$ (**2**) with the atom-numbering scheme (30% probability ellipsoids shown). The dotted lines indicate the hydrogen bonds.

(1.484(3) Å) and N(4)–C (1.478(3) Å) distance involving the coordinated tertiary nitrogens. This result may be attributed to the sp^3 hybridization by protonation of the uncoordinated tertiary nitrogen atoms. Interestingly, the coordinated chloride forms hydrogen bond with the secondary amine of the macrocycle ($Cl(1)^{i}\cdots N(2)$ 3.506(4) Å, 152(4)°; symmetry code: (i) $-x, -y, -z$). Furthermore, the non-coordinated chlorides form hydrogen bonds with the uncoordinated tertiary nitrogens ($Cl(3)\cdots N(5)$ 2.999(4) Å, 171(5)° and $Cl(4)\cdots N(6)$ 2.967(4) Å, 145(5)°) and with the water molecules ($Cl(3)^{ii}\cdots Ow(1)$ 3.213 Å, $Cl(4)\cdots Ow(1)'$ 3.118 Å, $Cl(3)^{iii}\cdots Ow(2)$ 2.949 Å and $Cl(3)^{iii}\cdots Ow(2)'$ 3.307 Å; symmetry codes: (ii) $-x, -y, 1-z$; (iii) $-1+x, y, z$).

An ORTEP drawing of $[Ni_2(L)_2(N_3)_4]\cdot 5H_2O$ (**3**) with the atomic numbering scheme is shown in Fig. 2. Selected bond distances and angles are listed in Table 3. There are two crystallographically independent complexes, in each of which revels an asymmetric unit. The structure of **3** shows that the nickel atom is coordinated by the two secondary and two tertiary amines of the macrocycle and that the axial positions are bonded by two nitrogen atoms of the azide ligands. The average bond distance of two axial Ni(1)–N and Ni(2)–N is similar (2.179(2) and 2.185(2) Å) and longer than the average distance of $Ni(1)N_4$ and $Ni(2)N_4$ plane (2.078(2) and 2.074(2) Å), giving an axially elongated octahedral geometry. The average Ni–N (tertiary) distance of

2.093(2) Å is significantly longer than that of Ni–N (secondary) (2.058(2) Å). The axial Ni(1)–N and Ni(2)–N linkages are bent slightly off the perpendicular to the NiN_4 planes by 0.3°–6.3° and 0.6°–6.5°, respectively. The apical Ni–N bond distance and Ni–N–N angles related to the azide ligands are similar to the observed for $[Ni(dttd)(N_3)_2]$ (dttd = 3,14-dimethyl-2,6,13,17-tetraazatricyclo-[14,4,$0^{1.18}$,$0^{7.12}$]docosane) [15] and $[Ni(tmtt)(N_3)_2]$ (tmtt = 2,5,9,12-tetramethyl-1,4,8,11-tetraazacyclo-tetradecane) [16]. Both azide groups which act monodentate ligands are slightly asymmetric and linear within the experimental error. In contrast to **1**, the N–C bond distances of the uncoordinated tertiary amines are significantly shorter than other N–C single bond distances. This result supports an sp^2-like hybridization of the uncoordinated nitrogen atoms [11,19].

An ORTEP diagram of $[Ni(L)(tp)]\cdot 2H_2O$ (**4**) with the atomic numbering scheme is shown in Fig. 3. Selected bond distances and angles are listed in Table 4. The nickel atom occupies a distorted octahedral coordination geometry in which the macrocycle, two water molecules and two *trans* tp ligands have assembled around each nickel center. The average Ni–N (tertiary) distance of 2.094(4) Å is much longer than the average Ni–N (secondary) distance (2.028(5) Å). The average NiN_4 distance of 2.061(3) Å is similar to that found **3** and shorter than the average Ni–O (carboxylate oxygen) distance (2.152(4) Å), indicating an axially elongated octahedron in the one-dimensional chain direction. The axial Ni–O linkage is bent slightly off the perpendicular to the NiN_4 plane by 0.5°–4.5°. The coordination of the benzenedicarboxylato bridge is slightly asymmetrical; the two Ni–O(1)–C(17) and Ni–O(3)–C(21) angles are 135.8(5)° and 139.3(5)°, respectively. The Ni···Ni′ distance across the polymer backbone is 11.526 Å. The dihedral angles (α) between the plane of the benzene ring and carboxylate group are 5.1° and 11.2°. Moreover, the dihedral angles (β) between the plane of the carboxylate group and NiN_2O_2 plane are 6.0° and 15.0°, respectively. Furthermore, the average N(5)–C (1.477(6) Å) and N(6)–C (1.463(6) Å) distance involving the uncoordinated tertiary nitrogen atoms is significantly shorter than

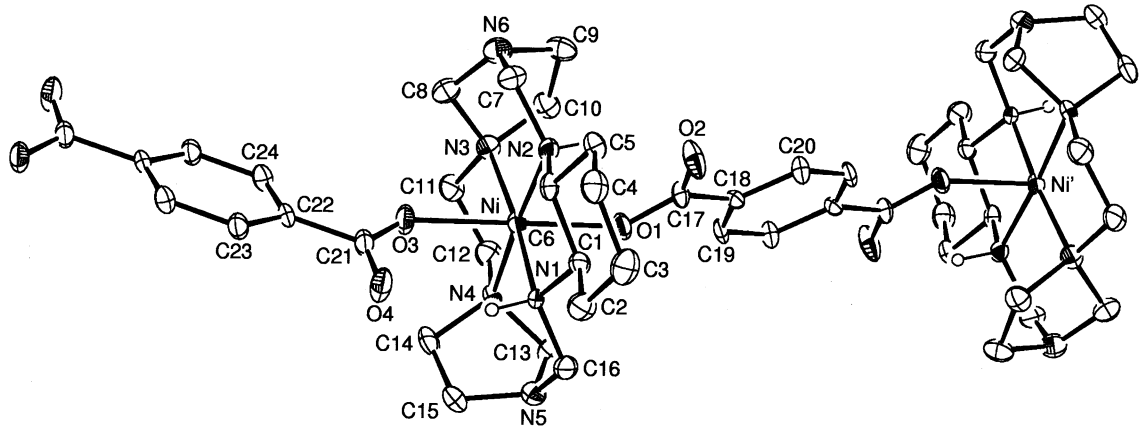

Fig. 3. An ORTEP diagram of $[Ni(L)(tp)]\cdot 2H_2O$ (**4**) with the atom-numbering scheme (30% probability ellipsoids shown). Two water molecules are omitted for clarity.

Table 4

N(4)–Ni–O(1)	87.3(2)		

other N–C single bond distances, which indicate the sp^2-like hybridization of the uncoordinated N(5) and N(6) atoms [11,19].

3.2. Characterization of the nickel(II) complexes

The spectroscopic data of the complexes are listed in Table 5. The visible spectra of the complexes **2**–**4** in acetonitrile, DMF and the solid state show two bands at 542–556 and 845–859 nm which assigned to the spin-allowed d–d transitions $^3A_{2g}\rightarrow{}^3T_{1g}$ and $^3A_{2g}\rightarrow{}^3T_{2g}$, respectively [20]. The IR spectrum of **2** shows ν(NH) band at 3212 cm^{-1} associated with secondary amines of the macrocycle. Visible absorptions are found at 554 nm in the solid state, and at 556 and 554 nm respectively in acetonitrile and DMF solution, consistent with a distorted octahedral nickel center. However, a visible band in water shows at 458 nm, indicative of a square-planar geometry. Compound **3** reveals ν(NH) band at 3242 cm^{-1} associated with secondary amines and a strong band at 2037 cm^{-1} due to the azide stretching mode. Complex **3** exhibits a broad visible band in the solid state (547 nm), acetonitrile (551 nm) and DMF (548 nm), again consistent with a distorted octahedral environment. However, this band shifts to higher energy (463 nm) in water, indicative of a significantly structural change (square-planar geometry) in solution. The IR spectrum of **4** reveals ν(NH) of the secondary amines and ν(COO) of the carboxylate at 3203 and 1569 cm^{-1}, respectively. The diffuse reflectance absorption spectrum of **4** reveals a broad band at 540 nm, which is the characteristic spectrum expected for a high-spin d^8 nickel(II) ion in an octahedral environment [21]. However, it dissolves in water (456 nm) and decomposes into the building block, consistent with the square-planar complex $[Ni(L)](ClO_4)_2$ [12].

Table 5
Electronic spectral data [a]

Complex	State	λ_{max} nm ($\varepsilon = M^{-1}\ cm^{-1}$)
$[Ni(L)](ClO_4)_2$ (**1**) [b]	H_2O	456 (121)
	CH_3CN	459 (116)

	DMF	542 (11), 848 (sh)
	Solid	540, 845

[a] Solutions = water, acetonitrile and DMF; solid = diffuse reflectance.
[b] Ref. [12].

Cyclic voltammetric data for the nickel(II) macrotetracyclic complexes in DMF solution are given in Table

Table 6
Cyclic voltammetric data [a]

Complex	Potentials (V) vs. Ag/AgCl	
	M(II)/M(III)	M(II)/M(I)
$[Ni(L)](ClO_4)_2$ (**1**)	+0.955(i) [b]	−0.789(i) [b]
$[Ni(H_2L)Cl_2]Cl_2\cdot 2H_2O$ (**2**)	+0.739	−0.524(i) [b]
$[Ni_2(L)_2(N_3)_4]\cdot 5H_2O$ (**3**)	+0.742(i) [b]	−1.083(i) [b]
$[Ni(L)(tp)]\cdot 2H_2O$ (**4**)	+0.815(i) [b]	−0.460(i) [b]

[a] Measured in 0.10 M TEAP–DMF solution at 20.0±0.1 °C.
[b] i, irreversible.

6. A typical cyclic voltammogram of **2** is shown in Fig. 4. The complexes exhibit two one-electron waves corresponding to Ni(II)/Ni(III) and Ni(II)/Ni(I) processes. It is of interest to compare the redox potentials for the nickel(II) complexes containing the organic ligands. The oxidation potentials for **2**, **3** and **4** are considerably less positive than that for the square-planar $[Ni(L)](ClO_4)_2$ (**1**). This fact can be attributed to the coordination of the organic ligands. It has been noted that when the organic ligands of the macrotetracyclic nickel(II) complexes are coordinated to the metal ion the attainment of Ni(III) is made easier. Meanwhile, although the complexes **2**, **3** and **4** have a similar average NiN_4 bond distance, the reduction potential for **3** is much more negative than that for **2** and **4**. This result may be due to the π-donor ability of the coordinated organic ligands. The above results, together with the crystal structures and the electronic spectra, clearly show that the organic ligands are coordinated to the metal ion.

The effective magnetic moments (μ_{eff}) of **2** and **3** in the solid state are 2.94 and 2.95 μ_B at room temperature, which are consistent with a d^8 electronic configuration in an octahedral geometry. The magnetic susceptibility (χ_m) of **4** was measured from 5 to 300 K. The magnetic

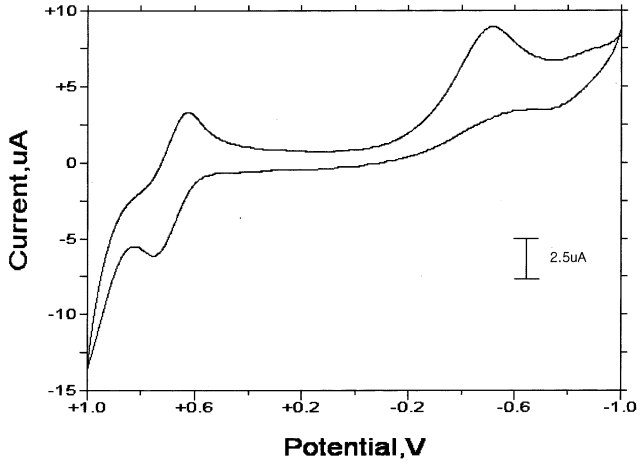

Fig. 4. Cyclic voltammogram of $[Ni(H_2L)Cl_2]Cl_2\cdot 2H_2O$ (**2**) in 0.10 M TEAP–DMF solution at 20.0±0.1 °C. The scan rate is 100 mV s^{-1}.

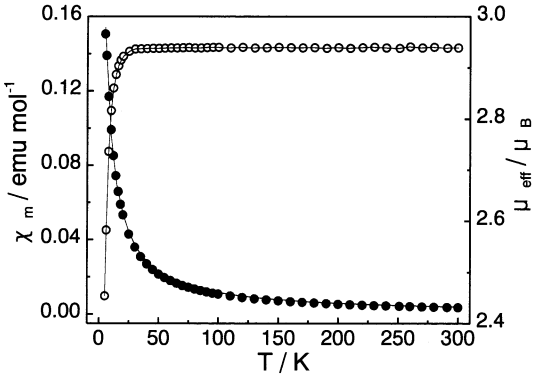

Fig. 5. Plots of χ_m vs. T (●) and μ_{eff} vs. T (○) for **4**. The solid line represents the best fit of the experimental data.

properties of the complex are given in Fig. 5 in the form of χ_m and μ_{eff} versus T show a very weak antiferromagnetic behavior. Compound **4** has a room-temperature magnetic moment ($\mu_{eff} = 2.94\ \mu_B$) close to the spin-only value for nickel(II). However, the magnetic moments gradually decrease with decreasing temperature, suggesting the presence of an antiferromagnetic coupling between the nickel(II) centers, which are clearly bridged by the carboxylate group. The magnetic susceptibility data are analyzed by Fisher's model for the classical spin chain system ($S = 1$ and $H_{chain} = -J\ \Sigma\ S_i \cdot S_{i+1}$) [22].

$$\chi_m = \{N\beta^2 g^2 S(S+1)/3kT\}\{(1+u)/(1-u)\}$$

with

$$u = \coth[JS(S+1)/kT] - [kT/JS(S+1)]$$

The parameters giving the best-fit were obtained using a nonlinear regression analysis with $g = 2.19(1)$, $J = -1.18(3)$ cm^{-1} and $R = 5.2 \times 10^{-3}$ ($R = [\Sigma\ (\chi_{obs} - \chi_{calc})^2/\Sigma\ \chi^2_{obs}]^{1/2}$). The value of the weak antiferromagnetic coupling observed in compound **4** is similar to those previously reported through bridging carboxylato in the nickel(II) chains $[Ni(dttd)(tp)]\cdot 2H_2O$ ($J = -1.37$ cm^{-1}) [23] and $[Ni(dttd)(PDC)]\cdot 2H_2O$ (PDC = 2,5-pyridinedicarboxylate) ($J = -1.47$ cm^{-1}) [23]. This fact can be understood in terms of the large intramolecular Ni···Ni′ distance and dihedral angles.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 179227–179229 for compounds **2**–**4**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

2. Experimental

2.1. General

The following chemicals were purchased from commercial sources and used without further purification: $Na_2MoO_4{\cdot}2H_2O$ (Fluka), $NaAsO_2$ (Fluka), pyridine (Fluka), $Co(acac)_2$ (Fluka) and H_2O_2 (Fluka). All reactions and manipulations were carried out in air. The infrared spectra (4000–400 cm^{-1}) were recorded from KBr pellets on a Perkin–Elmer FT IR 1720 X spectrophotometer. Micro-analytical data were obtained from the Laboratoire de Chimie Pharmaceutique et Organique Propédeutique de l'Université de Genève, Switzerland.

2.2. Preparations

2.2.1. $[NC_5H_6]_5[Mo_8^{VI}O_{26}(OH)]{\cdot}3H_2O$ (anion **1**)

$Na_2MoO_4{\cdot}2H_2O$ (1.48 g, 6×10^{-3} mol) and pyridine (1 ml, 1.2×10^{-2} mol) were dissolved in water (8 ml), and the pH of the solution was adjusted to 5.0 by dropwise addition of diluted hydrochloric acid (2 M). The solution was heated to 130 °C in a pressure Schlenk tube (250 ml) for 2 days. Then the solution was filtered and cooled to 4 °C. The colourless crystals of the product, obtained after some days, were filtered off, washed with water and acetone and dried in vacuo. Yield: 60%. Found: C, 18.44; H, 2.54; N, 4.28. Calc. for $C_{25}H_{42}N_5Mo_8O_{30}$: C, 18.14; H, 2.25; N, 4.23%. IR (KBr): ν (cm^{-1}) 1635(m), 1605(m), 1539(m), 1487(s), 889(vs), 823(vs), 797(s), 749(m), 678(s), 608(w).

2.2.2. $[C_5H_6N]_6[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}O_{34}]{\cdot}3H_2O$ (anion **2**)

$Na_2MoO_4{\cdot}2H_2O$ (1.48 g, 6×10^{-3} mol), $NaAsO_2$ (1.56 g, 1.2×10^{-2} mol) and pyridine (1 ml, 1.2×10^{-2} mol) were dissolved in water (15 ml), and the pH of the solution was adjusted to 5.0 by dropwise addition of diluted hydrochloric acid (2 M). Then the solution was heated at 130 °C in a pressure Schlenk tube for 2 days. After this period, the deep-blue solution was filtered hot and cooled to 4 °C. The resulting light-blue crystals (obtained overnight) were filtered off, washed with water and acetone and dried in vacuo. Yield: 38% (based on Na_2MoO_4). Found: C, 16.84; H, 2.15; N, 3.78. Calc. for $C_{31}H_{42}N_6As_2Mo_9O_{37}$: C, 17.22; H, 2.07; N, 4.02%. IR (KBr): ν (cm^{-1}) 2084(w, br), 1633(m), 1605(m), 1530(m), 1485(s), 931(s), 858(vs), 845(vs), 748(m), 676(s), 649(s), 607(s).

2.2.3. $[C_5H_6N]_{10}[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}O_{34}\{Co(C_5H_5N)_2(H_2O)_3\}][HAs^{III}As^{V}Mo^{V}Mo_8^{VI}O_{34}]{\cdot}8H_2O$ (anions **3** and **2**)

A solution of $Co(acac)_2$ (38.65 mg, 0.147 mmol) in 4 ml of water was added to 10 ml of an aqueous solution of $[C_5H_6N]_6$**2** (300 mg, 0.147 mmol). The resulting pink solution was refluxed for 3 h. Then the solution was filtered hot and cooled to 4 °C. After several weeks light brown crystals of the product were isolated by filtration and dried in vacuo. Yield: 70% (based on **2**). Found: C, 16.77; H, 2.07; N, 3.89. Calc. for $C_{60}H_{78}N_{12}CoAs_4Mo_{18}O_{71}$: C, 16.63; H, 2.19; N, 3.88%. IR (KBr): ν (cm^{-1}) 2079(w, br), 1634(m), 1603(m), 1531(m), 1485(s), 932(s), 860(vs), 780(w), 750(m), 704(w), 680(m), 645(s), 607(m).

2.2.4. $[NBu_4]_3[As^{V}Mo_{12}^{VI}O_{40}]{\cdot}0.5H_2O_2$ (anion **4**)

A solution of NBu_4Br (316 mg, 0.98 mmol) in 5 ml of water was added to a well stirred aqueous solution (8 ml) of $[NC_5H_6]_6$**2** (200 mg, 0.098 mmol). Immediate precipitation of a light blue solid was observed. After stirring the mixture for 10 min, the precipitate, which is the tetrabutylammonium salt of **2**, was isolated on a medium-porosity filter, washed successively with 5 ml of water, 5 ml of acetone and 5 ml of diethylether and dried in vacuo. Then the isolated $[NBu_4]_6$**2** (230 mg, 0.078 mmol) was dissolved in acetonitrile (5 ml); to this solution aqueous H_2O_2 (35%, 0.05 ml, 1.56 mmol) was added dropwise. The colour changed immediately from light green to yellow. After stirring this solution for 16 h at room temperature (r.t.), 5 ml of ether were added, which caused the crystallisation of the product over several hours at r.t. The yellow crystals were isolated, washed with ether and dried in vacuo. Yield: 63% (based on **2**). Found: C, 22.01; H, 4.35; N, 3.89. Calc. for $C_{96}H_{217}N_6As_2Mo_{24}O_{85}$: C, 21.89; H, 4.15; N, 1.60%. IR (KBr): ν (cm^{-1}) 2962(m), 2933(w), 2873(w), 963(s), 898(vs), 856(m), 792(vs), 619(w).

2.3. X-ray crystallography

Relevant crystallographic data for compounds **1**, **2**, **3** and **4** are summarized in Table 1. The intensity data were collected at −120 °C on a Stoe Image Plate Diffraction system using Mo Kα graphite monochromated radiation ($\lambda = 0.71073$). The structures were solved by direct methods using the program SHELXS-97 [25] and refined by full-matrix least-squares on F^2 with SHELXL-97 [26]. The compound **1** crystallises with five pyridinium cations and three water molecules. The compound **2** crystallises with six pyridinium cations and three water molecules (four positions, two of them being half occupied). The position of the arsene hydrogen atom is derived from difference Fourier maps and freely refined while the remaining hydrogen atoms are fixed in their theoretical positions and refined as riding atoms using SHELXL-97 default parameters. An absorption correction was applied using DIFABS ($T_{min} = 0.331$, $T_{max} = 0.759$). The measured crystal of compound **3** contains co-crystallised $[(HAs_2Mo_9O_{34})\{Co(NC_5H_5)_2(H_2O)_3\}]^{4-}$ and $[HAs_2Mo_9O_{34}]^{6-}$ anions, ten pyridi-

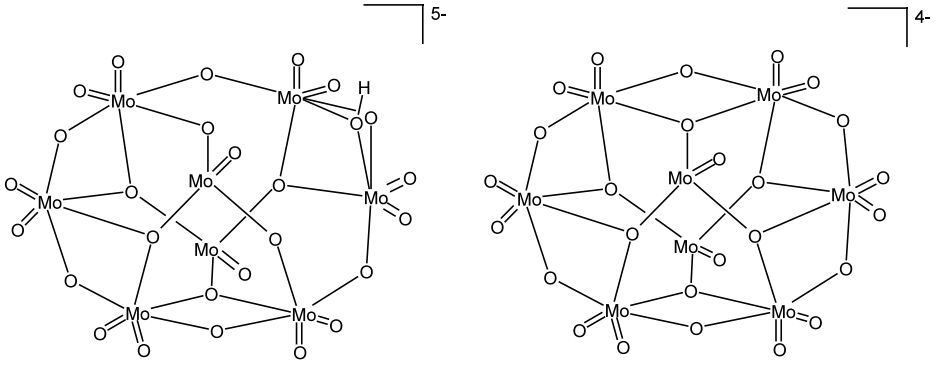
nium cations and eight water molecules. The two clusters anions occupy the same space in the crystal structure which is realised by a half occupation of the attached $Co(NC_5H_5)_2(H_2O)_3$ fragment to the cluster framework. At the same time, a pyridinium cation and two water molecules (disordered over three position), also being half occupied, use the same space than the $[Co(NC_5H_5)_2(H_2O)_3]^{2+}$ fragment. The position of the arsene hydrogen atom is derived from difference Fourier maps and fixed while the remaining hydrogen atoms are fixed in their theoretical positions and refined as riding atoms using SHELXL-97 default parameters. An absorption correction was applied using DIFABS ($T_{min} = 0.454$, $T_{max} = 0.821$). For $[NBu_4]_3$**4** there are two highly symmetrical positively charged complex molecules in the unit cell [molecule 1 (As1, Mo1-6) possessing C_2 symmetry and molecule 2 (As11, Mo11-16) possessing C_i symmetry] together with six $[NBu_4]^+$ cations. It was also possible to locate, what we assume to be, half a molecule of H_2O_2 in the unit cell. Selected bond lengths for **1**, **2**, **3** and **4** are given in Table 2.

3. Results and discussion

The metamolybdate anion $[MoO_4]^{2-}$ is known to undergo condensation in acidic media to give a variety of isopolyoxomolybdates(VI), the major species being $[Mo_7O_{24}]^{6-}$ at pH below 6 [27]. Careful adjustment of acidity, concentration and temperature, often coupled with slow crystallisation, can lead other polyoxomolybdates(VI) based on fused MoO_6 octahedra. In particular, three different octamolybdate isomers (α, β, γ), $[Mo_8O_{26}]^{4-}$, have been isolated and structurally characterised [28]. Surprisingly, we now found the anion $[MoO_4]^{2-}$ to react in aqueous solution at pH 5 with pyridine under hydrothermal conditions to give a new hydroxo octamolybdate anion, $[Mo_8^{VI}O_{26}(OH)]^{5-}$ (**1**), which crystallises as pyridinium salt. The structure of **1** derives from that of the α-isomer of $[Mo_8^{VI}O_{26}]^{4-}$ by replacing two oxygen–molybdenum bonds by a additional hydroxo bridge (Fig. 1).



Selected bond distances of the new isopolyoxomolybdate are shown in Table 2. The structure of **1** consists of a ring of six octahedra capped by two tetrahedra (Fig. 2). Each octahedron has Mo–O bonds in the range of 1.898–1.914 Å for short, 1.916–1.998 Å for medium and 2.205–2.473 Å for long bonds. All molybdenum atoms in the ring have two terminal Mo–O(t) bonds in the short range (1.694–1.723 Å) indicating the double bond character. The capping MoO_4 units have two kinds of Mo–O bonds: Mo–O(t) (1.651–1.730 Å) and Mo–O(μ_3) (1.668–1.707 Å), and in the case of Mo(4) there are two Mo–O(μ_2) bond (1.665 and 1.668 Å), because with respect to the parent α-octamolybdate anion, two Mo(4)–O bond are opened and replaced by a new hydroxo bridge bewteen Mo(1) and Mo(2). Both ring and capping MoO_4 tetrahedral units have O–Mo–O angles in the ranges of 70.6–168.8 and 107.8–111.9°, respectively. Anion **1** can be regarded as an association of a barely perturbed α-$[Mo_8^{VI}O_{26}]^{4-}$ anion and an OH^- anion, the resulting bonds Mo(1)–O(5) and

Mo(2)–O(5) are longer (2.473 and 2.430 Å) than those of the Mo(1)–O(4) and Mo(2)–O(4) bonds (1.905 and 1.937 Å) of the neighbouring oxo bridge. In the unit cell of **1**, the five pyridinium cations are crystallographically independent and have no bonding interaction with the $[Mo_8^{VI}O_{26}(OH)]^{5-}$ anion. The hydroxyl H-atom of atom O(5) was located from a difference Fourier map and held fixed with $U_{iso} = 1.5U_{eq}(05)$ Å^2.

The thermal reaction of sodium metaarsenite with sodium molybdate in pyridine and water at 130 °C

$[Mo^{VI}{}_8O_{26}(OH)]^{5-}$ (**1**) α-$[Mo^{VI}{}_8O_{26}]^{4-}$

Fig. 1. Comparison of anion **1** with the known α-octamolybdate.

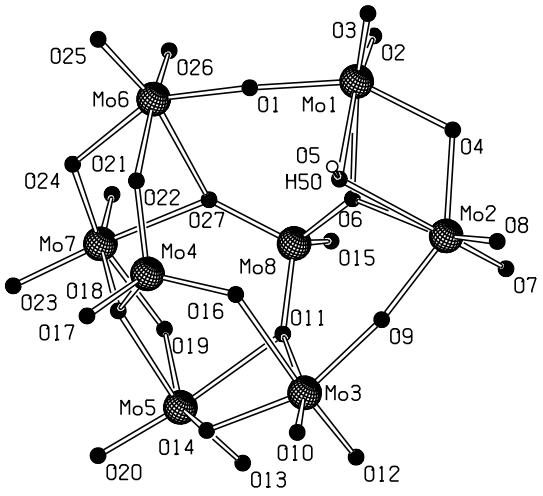

Fig. 2. ORTEP plot of $[Mo_8^{VI}O_{26}(OH)]^{5-}$ (**1**).

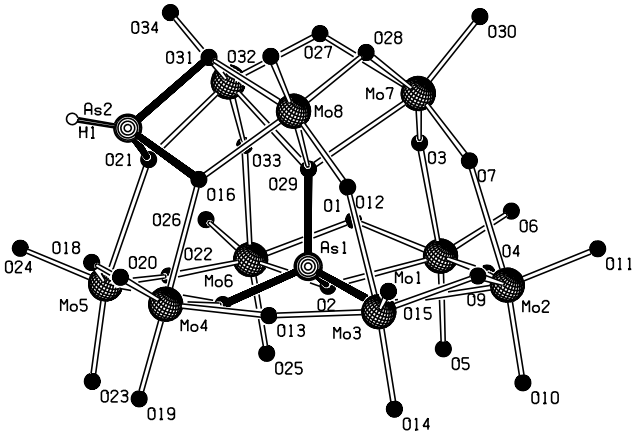

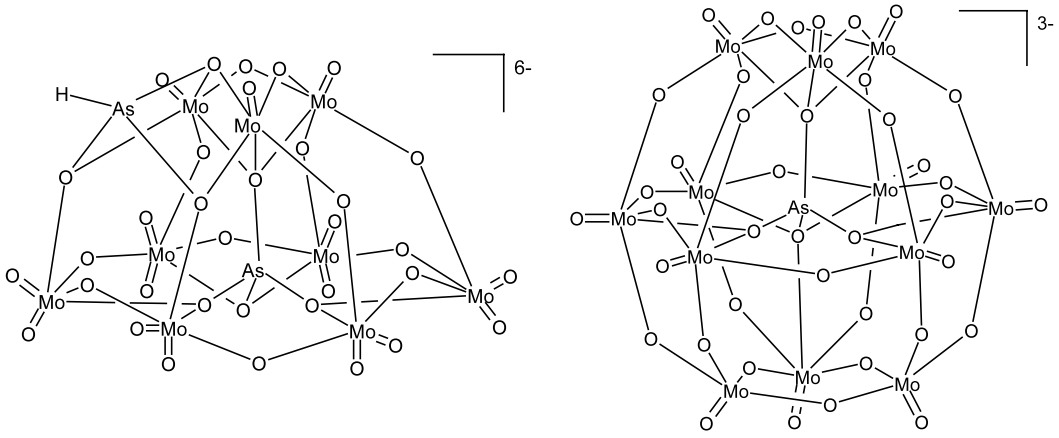

Fig. 3. ORTEP plot of $[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}O_{34}]^{6-}$ (**2**).

gives after 48 h a clear blue solution. When this solution is allowed to stand for 12–16 h at 4 °C, colourless crystals of the pyridinium salt of $[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}O_{34}]^{6-}$ (**2**) are obtained. The infrared spectrum of **2** exhibits characteristic ν(Mo–O), ν(Mo–O–Mo) and ν(As–O–Mo) absorptions in the region between 950 and 600 cm^{-1}. A weak absorption of 2084 cm^{-1} is assigned to the ν(As–H) vibration. In accordance with the presence of a Mo(V) centre, the ^1H NMR spectrum shows **2** to be paramagnetic.

A single-crystal X-ray structure analysis of $[C_5H_6N]_6$**2** reveals the presence of crystal water (3 equiv.). The molecular anion $[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}O_{34}]^{6-}$ (**2**) shown in Fig. 3, is the second example of a monocapped trivacant 1:9 Keggin species. Its structure derives from the trivacant α-Keggin anion by removing three edge-sharing MoO_6 octahedra and by capping a trioxygen face of three remaning MoO_6 octahedra with an AsH group (Fig. 4), while the anion $[As^{III}As^{V}Mo_9^{VI}O_{34}]^{6-}$ published recently [20] derives from the β-Keggin structure.

The anion structure reveals the presence of a central AsO_4 tetrahedron which shares its four oxygen atoms with one Mo_3O_{13} group and three Mo_2O_{10} groups. These Mo_3O_{13} and Mo_2O_{10} groups are in turn joined to each other by corner-sharing, three Mo_2O_{10} groups form a 12-membered Mo_6O_6 ring, each Mo_2O_{10} group of this ring shares two oxygen atoms with a MoO_6 octahedron of the Mo_3O_{13} group. The anion is capped by a HAs group, and this group shares its oxygen atoms with four MoO_6 octahedra. The central AsO_4 tetrahedron has As(1)–O bond distances in the range of 1.675–1.710 Å. The triply bridging oxo group O(29) exhibits angles with the Mo_3O_{13} group of As(1)–O(29)–Mo(7) 122.14(11), As(1)–O(29)–Mo(8) 122.18(12) and As(1)–

$[HAs^{III}As^{V}Mo^{V}Mo^{VI}{}_8O_{34}]^{6-}$ (**2**) α-$[As^{V}Mo^{VI}{}_{12}O_{40}]^{3-}$

Fig. 4. Comparison of **2** with the α-Keggin anion.

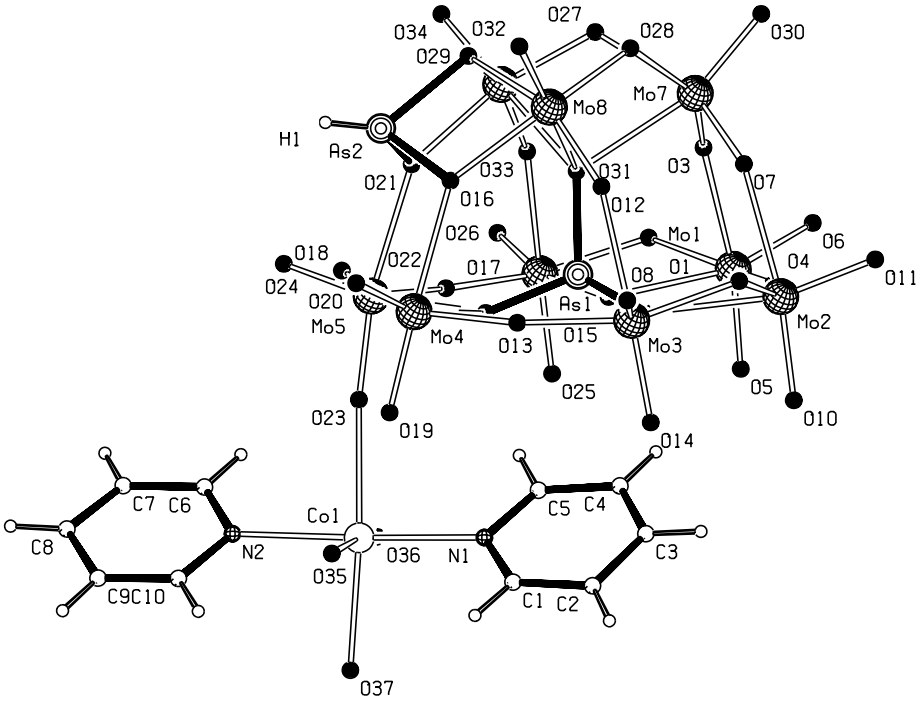

Fig. 5. ORTEP plot of $[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}\ O_{34}\{Co(C_5H_5N)_2(H_2O)_3\}]^{4-}$ (**3**).

O(29)–Mo(9) 123.49°. The AsH group has two short As–O bond distances of 1.802(2) Å [As(2)–O(21)] and 1.810(2) Å [As(2)–(O16)] and one long As–O bond distance of 1.897(2) Å [As(2)–O(31)]. The O(31) associated with the long As–O bond is bonding two MoO_6 octahedra with bond angles: As(2)–O(31)–Mo(9) [97.95(11)°], As(2)–O(31)–Mo(8) [97.24(10)°] and Mo(9)–As(2)–Mo(8) [113.58(10)°]. The other oxygen atoms O(16) and O(21) associated with the short As–O distances are bonding one Mo_2O_{10} group with bond angles of: As(2)–O(16)–Mo(8) [106.34(12)°], As(2)–O(16)–Mo(4) [111.12(11)°], Mo(8)–O(16)–Mo(4) [139.93(12)], As(2)–O(21)–Mo(9) [104.58(11)°], As(2)–O(21)–Mo(8) [109.61(11)°] and Mo(9)–O(21)–Mo(8) [142.39(11)°].

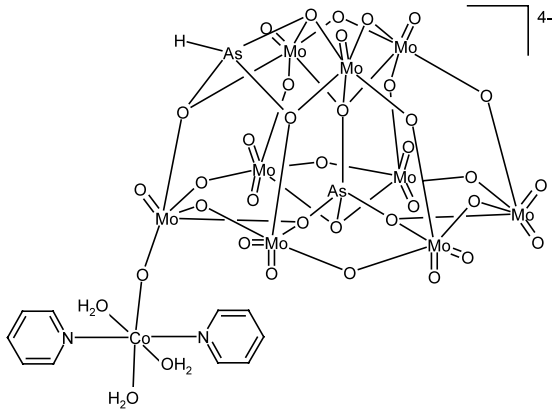

Fig. 6. Anion $[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}\ O_{34}\{Co(C_5H_5N)_2(H_2O)_3\}]^{4-}$ (**3**).

The charge of **2**, determinated by valence sum calculations based on the bond distances associated with the Mo centres [29], confirmed that the electrons are effectively delocalised throughout the cluster. The oxidation state of eight of the nine Mo atoms is +6 ($\Sigma s = 5.8$–5.9) while one Mo atom is the oxydation state of +5 ($\Sigma s = 5.5$). The As (1) atom associated with the AsO_4 tetrahedron is in the oxidation state of +5, while

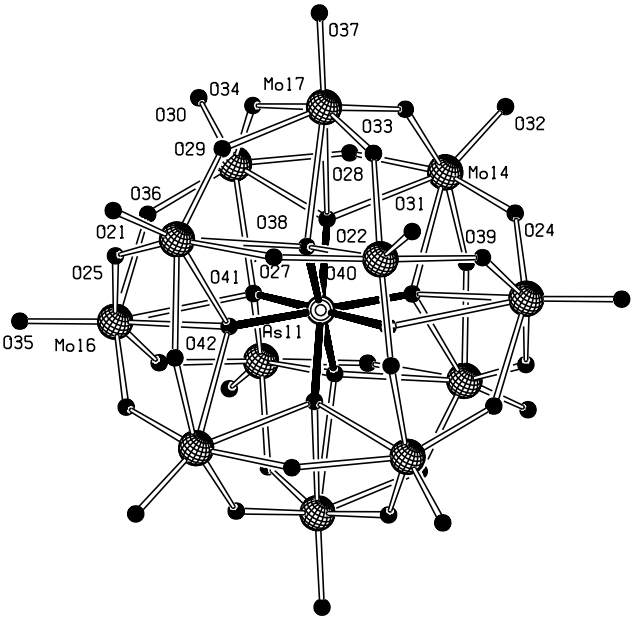

Fig. 7. ORTEP plot of $[As^{V}Mo_{12}^{VI}\ O_{40}]^{3-}$ (**4**). The central arsenic atom is coordinated to four disordered oxygen atoms; the eight positions of which are occupied to 50%.

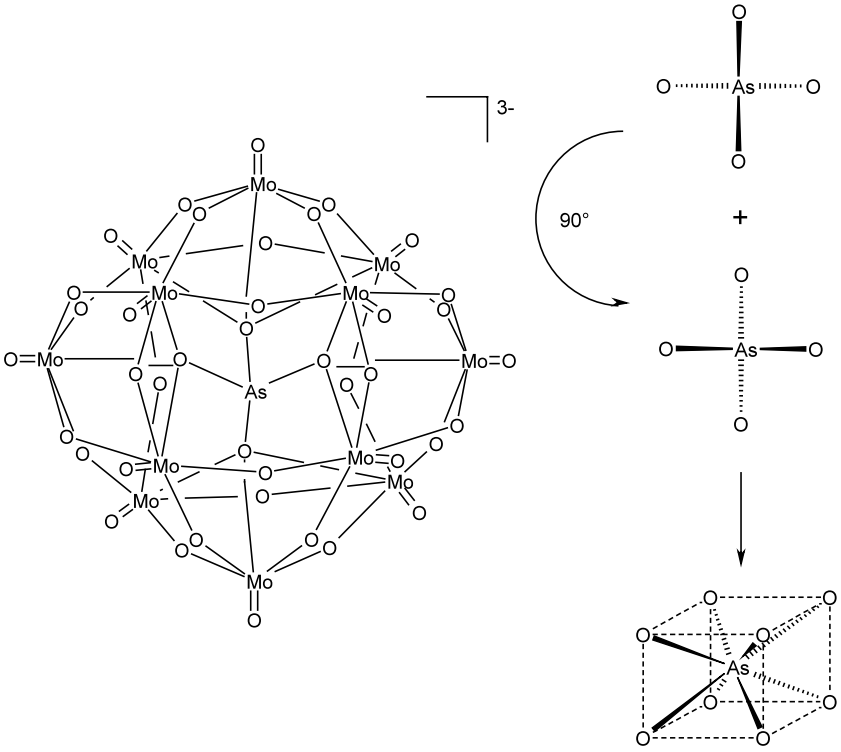

Fig. 8. Disorder in anion **4** (two of the three independent anions of the unit cell).

As(2) is in the oxidation state of +3, which explains the six negative charges of **2**.

$[C_5H_6N]_6$**2** reacts in aqueous solution with Co^{2+} (in variable amounts) at 100 °C to give the new arsenomolybdate anion $[HAs^{III}As^{V}Mo^{V}Mo_8^{VI}O_{34}\{Co(C_5H_5N)_2(H_2O)_3\}]^{4-}$ (**3**) (Fig. 5) which crystallises together with **2** as pyridinium salt. The ν(As–H) vibration is found as a weak, broad absorption at 2079 cm^{-1}. Because of the paramagnetism of **2** and **3**, a well-resolved ^1H NMR spectrum could not be recorded.

The molecular structure of **3**, solved by a single-crystal X-ray structure analysis of the pyridinium salt, is shown in Fig. 6; selected bond distances are given in Table 2. The structure of **3** derives from that of **2** by attaching a $Co(C_5H_5N)_2(H_2O)_3$ fragment to a terminal oxo ligand. The Mo(5)–O(23) distance is 1.724(6) Å, which is longer than the Mo(5)–O(23) distance found in **2** [1.711(3) Å]. In **3** the cobalt atom Co has an octahedral environment with the bond angles: O(36)–Co(1)–O(23) [84.6(3)°], N(1)–Co(1)–O(23) [91.2(4)°], N(2)–Co(1)–O(23) [87.1(5)°] and N(1)–Co(1)–O(37) [94.5(4)°], the Co–O(23) distance being 2.291(7) Å. In general, the Mo–O(t) and the Mo–O bond distances in **3** remain unaffected in relation to **2**. The charge of **3** is determinated by valence sum calculations [29] which explains the four negative charges of the anion.

The anion $[As^{V}Mo_{12}^{VI}O_{40}]^{3-}$ (**4**) is obtained by adding an excess of aqueous H_2O_2 to acetonitrile solution of $[NBu_4]_6$**2** at 20 °C. It crystallises after several hours at 4 °C as the tetrabutylammonium double-salt. A single-crystal of the tetrabutylammonium salt was analysed by X-ray crystallography; it turned out to contain the known [30] α-Keggin anion with three independent anionic molecules in the unit cell two of which being disordered. The structure of **4** is shown in Fig. 7; selected bond distances are given in Table 2. The structure is disordered because of the location of the As atom on a center of inversion, incompatible with the tetrahedral symmetry of the α-Keggin unit. This disorder leads to the apparent presence of eight oxygen atoms (50% occupancy) surrounding the central arsenic atom at the vertices of a cube, which is composed of two inverted AsO_4 tetrahedron (Fig. 8). This type of disorder has already been encountered a few times for heteropolyoxomolybdates [31] and was first described by Evans and Pope [32].

Chemically identical bond distances and angles vary only slighty with the exception of Mo–O(As) and As–O(Mo) bonds. For the α-Keggin anion structure reported [30], these distances are in the range of 2.356–2.369 and 1.658–1.666 Å, respectively. In comparasion to these values, the distances in **4** (Mo–O(As) (2.387–2.449 Å), As–O(Mo) (1.613–1.691 Å) are slightly larger. The Mo–O(t) bonds remains unaffected. The Mo–O–Mo angles are in the range of 139.8(5)–140.5(5)° which are sligthly smaller than the Mo–O–Mo angle for the α-Keggin structure. The charge of the anion is deduced from the number of tetrabutylammonium cations,

together with an examination of the Mo–O bond lengths and a calculation of bond valence sums [29].

4. Supplementary material

The crystallographic data for compounds **1**, **2**, **3** and **4** have been deposited with the Cambrigde Crystallographic Data Centre as supplementary publication: No. CCDC 166546 (**1**), CCDC 166547 (**2**), CCDC 166548 (**3**) and CCDC 166549 (**4**). 2. Experimental

2.1. Materials and methods

Reactions were carried out in dry solvents under a dinitrogen atmosphere using Schlenk techniques. Chemicals were obtained from commercial sources. The precursor complex $[(\eta^6\text{-}p\text{-cymene})RuCl_2]_2$ was prepared by a literature method [19]. The chiral Schiff base (HL*) was prepared by condensation of 3,5-di-*t*-butyl-2-hydroxybenzaldehyde (Aldrich) and (*S*)-α-methylbenzylamine (Fluka) using a method reported for the preparation of (*S*)-(α-methylbenzyl)salicylaldimine [20]. Solvents were purified by standard procedures [21]. Elemental analysis was performed on a Perkin–Elmer model 2400 CHN analyzer. NMR measurements were carried out using a Bruker AMX 400 MHz spectrometer.

2.2. Preparation of *[(η⁶-p-cymene)Ru{2-O-(3,5-di-t-Bu)C₆H₂CH=NCH(Me)Ph}Cl] (1)*

A 200 mg (0.33 mmol) quantity of $[(\eta^6\text{-}p\text{-cymene})RuCl_2]_2$ was reacted with 225 mg (0.66 mmol) of the Schiff base (HL*) and 0.14 cm^3 (1.0 mmol) of NEt_3 in 15 cm^3 CH_2Cl_2 under stirring for 3 h at 0 °C. The orange–red solution was filtered and the filtrate was reduced to a volume of ~2 cm^3. *n*-Hexane (10 cm^3) was added to the solution to precipitate the complex which was isolated and thoroughly washed with *n*-hexane and finally dried in vacuum. Yield: 360 mg (0.59 mmol, 90%). *Anal.* Found: C, 65.41; H, 7.05; N, 2.42. Calc. for $C_{33}H_{44}ClNORu$: C, 65.24; H, 7.25; N, 2.31%. ^{1}H NMR data for the major diastereomer (88%) in $CDCl_3$ at 293 K (δ, ppm; multiplicity; $^3J_{HH}$, Hz): *p*-cymene ligand, 1.05, 1.16 (d, 7.2, CH*Me*$_2$); 2.16 (s, Me); 2.75 (sp, 6.0, *CH*Me$_2$); 4.84, 4.88, 5.06, 5.24 (d, 6.0, ring H); Chiral Schiff base, 1.21, 1.42 (s, CMe_3); 1.82 (d, 6.8, C*–Me); 5.82 (q, 6.0, C*–H); 6.68, 7.24 (s, ring C_6H_2); 7.45 (m, C*–Ph); 7.84 [s, N=CH (imine)]. ^{1}H NMR data for the minor diastereomer (12%) in $CDCl_3$: 0.82, 0.84 (d, 7.2, CH*Me*$_2$); 2.36 (s, Me); 2.90 (sp, 6, *CH*Me$_2$); 5.02, 5.19, 5.41, 5.44 (d, 6.0, ring H); Chiral Schiff base, 1.18, 1.21 (s, CMe_3); 1.96 (d, 6.8, C*–Me); 5.65 (q, 6.0, C*–H); 6.48, 7.35 (s, ring C_6H_2); 7.40 (m, C*–Ph); 7.58 (s, imine H) [s, singlet; d, doublet; q, quartet; sp, septet; m, multiplet]. The ^{1}H NMR spectrum at 233 K in $CDCl_3$ showed a shift only for the *p*-cymene ring protons. The data for the cymene ring protons of the major isomer at 233 K are: 4.75, 4.90 (d, $^3J_{HH} = 4.1$ Hz); 5.11, 5.33 (d, $^3J_{HH} = 5.2$ Hz).

2.3. Crystallographic analysis for *[(η⁶-p-cymene)Ru{2-O-(3,5-di-t-Bu)C₆H₂CH=NCH(Me)Ph}Cl] (1)*

Single crystals suitable for X-ray diffraction were grown by a slow diffusion technique in which *n*-hexane was layered above the CH_2Cl_2 solution of **1** at −5 °C under a dinitrogen atmosphere. A crystal of approximate size $0.41 \times 0.53 \times 0.56$ mm was mounted on a glass fiber with epoxy cement. Unit cell dimensions were obtained using twenty centered reflections in the θ range 8.16–17.77 on an Enraf–Nonius CAD4 diffractometer equipped with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The intensity data were collected by ω–2θ scan mode within $2^\circ \le 2\theta \le 50^\circ$ for $0 \le h \le 11$, $-10 \le k \le 12$, $-20 \le l \le 20$ in the triclinic crystal system. Out of 5696 unique reflections, 5317 with $I > 2\sigma(I)$ were used for structure solution and refinement. Data were corrected for Lorentz and polarization effects.

The structure was solved in the triclinic space group $P1$ by the combination of Patterson and Fourier techniques and refined by full-matrix least-squares. The PLATON checks on the $P1$ structure suggested that it could be described in the centrosymmetric space group $P\bar{1}$, where there was an almost perfect match for all the non-hydrogen atoms except the methyl carbons C19 and C52 that are attached to the chiral C18 and C51 atoms, respectively. This ruled out the $P\bar{1}$ space group. All non-hydrogen atoms were refined anisotropically. The hydrogen atom positions were generated and assigned isotropic thermal parameters using a riding model. The hydrogen atoms' numbering was same as the carbon they are attached to. An absorption correction was made to the data using DIFABS after obtaining the complete structural model [22]. In the final cycle of refinement, each ruthenium atom was found to have a residual peak of ~1.2 e Å^{-3} situated ~1.0 Å from the metal center. These two residual peaks had no significant effect on the structural parameters and were left as such. The final refinement was converged to $R_1 = 0.0408$ and $wR_2 = [\Sigma\, w\{(F_o^2 - F_c^2)^2/\Sigma\, w(F_o^2)^2\}]^{1/2} = 0.1097$ with a weighting scheme: $w = 1/[\sigma^2(F_o^2) + (0.0963P)^2 + 0.0711P]$, where $P = (F_o^2 + 2F_c^2)/3$ [*R* indices (all data): $R = 0.0433$, $wR = 0.1124$] using 667 parameters and 5696 data. The goodness-of-fit on F^2 was 1.066 and the maximum shift/e.s.d. was 0.001. The highest peak in the final ΔF map, other than those two residual peaks near ruthenium, was 0.96 e Å^{-3}. All calculations were done using PC versions of the SHELX system of programs [23]. The perspective view of the molecules were obtained using ORTEP [24].

2.3.1. Crystal data

$C_{33}H_{44}ClNORu$ **1** (**1a**, **1b**), $M = 607.2$, triclinic, space group $P1$ (no. 1), $a = 9.638(4)$, $b = 10.138(3)$, $c = 17.599(6)$ Å, $\alpha = 84.13(1)^\circ$, $\beta = 80.89(1)^\circ$, $\gamma = 63.87(4)^\circ$,

$U = 1523.4(9)$ Å^3, $F(000) = 636$, $Z = 2$, $D_{calc} = 1.324$ g cm^{-3}, Mo Kα radiation, $\lambda = 0.71073$ Å, μ (Mo Kα) = 6.27 cm^{-1}, $T = 293(2)$ K.

3. Results and discussion

3.1. Synthesis and ^{1}H NMR spectra

The complex [(η^6-*p*-cymene)Ru(L*)Cl] (**1**) has been prepared as a diastereomeric mixture of two species **1a** and **1b** from a reaction of [(η^6-*p*-cymene)$RuCl_2]_2$ with the N,O-donor chiral Schiff base (*S*)-HO-2-(3,5-di-*t*-Bu)C_6H_2CH=NCH(Me)Ph and NEt_3 in CH_2Cl_2 at 0 °C. The complex is moderately stable in the solid state but unstable in a solution phase. The ^{1}H NMR spectral data in $CDCl_3$ suggest a 1:1 molar ratio of the *p*-cymene and the Schiff base ligand in **1**. The spectral features indicate the presence of two diastereomers in a 88:12 ratio (Fig. 1). The *p*-cymene ring protons appear as doublets in the range δ 4.8–5.4 ppm. The methyl and isopropyl methyl protons of *p*-cymene are observed as singlet and doublets in the δ range 2.2–2.4 and 1.7–2.0 ppm, respectively. The septet corresponding to the isopropyl proton appears at ~2.8 ppm. The *t*-butyl, C*–Me and C*–H protons of the Schiff base display signals in the respective δ ranges 1.2–1.6, 1.7–1.9 and 5.6–5.8 ppm. The peaks in the aromatic region are assignable to the imine proton and the phenyl ring protons of the Schiff base. The diastereomeric ratio remains the same in the spectra recorded at 233 K with a minor shift of the *p*-cymene ring protons along with a minor broadening of the signals.

3.2. Crystal structure

The crystals of complex **1** belong to the triclinic space group $P\bar{1}$ (no. 1) with two molecules in the unit cell. The structure was refined with the expected S_C-configuration of the chiral carbon of the Schiff base ligand. The ruthenium atom configuration is obtained using a priority sequence: η^6-*p*-cymene > Cl > O(L*) > N(L*) [25]. The structure consists of two diastereomers in a 1:1 molar ratio having (R_{Ru}, S_C)- and (S_{Ru}, S_C)-configurations. The ORTEP views of the molecules differing in metal configuration are shown in Fig. 2. Selected bond distances and angles are given in Table 1. The molecular species (R_{Ru}, S_C)-**1a** and (S_{Ru}, S_C)-**1b** consist of a *p*-cymene ligand showing η^6-mode of bonding, a terminal chloride and a bidentate N,O-donor chelating chiral Schiff base ligand.

A general observation in the molecular structures of the diastereomers **1a** and **1b** is the presence of non-covalent CH–π attractive interaction involving the phenyl group attached to the chiral carbon and two *p*-cymene ring protons [10,26–28]. While the distances from H(6) and H(7) to the centroid of the phenyl group (C^0_{Ph}) attached to the chiral carbon are 3.183 and 3.859

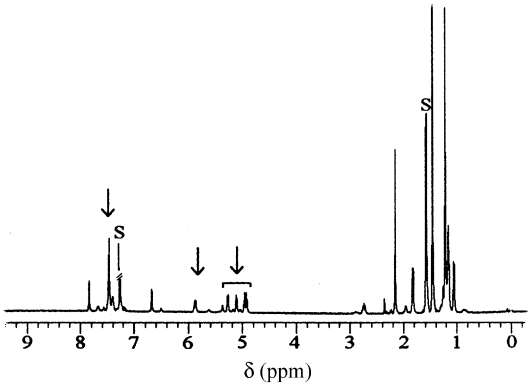

Fig. 1. ^{1}H NMR spectrum of complex **1** in $CDCl_3$ at 293 K displaying a diastereomeric ratio of 88:12. Arrows in the spectrum indicate diagnostic signals used for the 2D measurements (S, solvent peaks).

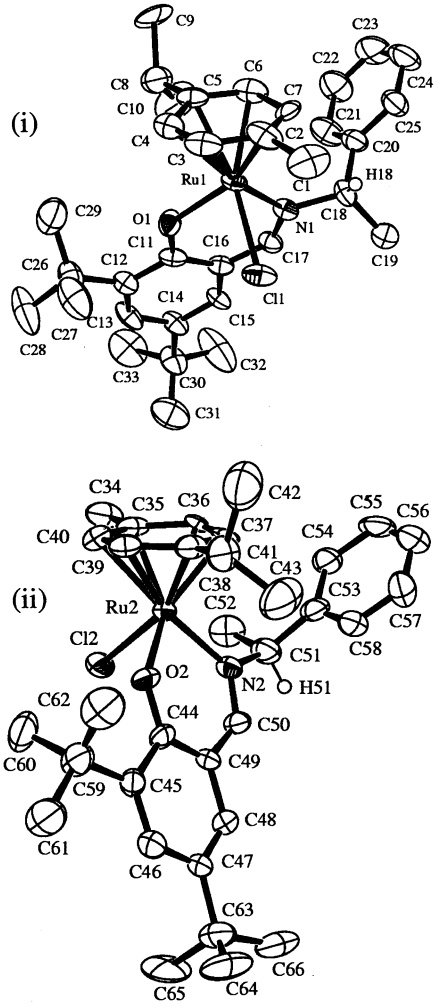

Fig. 2. ORTEP view of the two diastereomers (R_{Ru}, S_C)-**1a** (i) and (S_{Ru}, S_C)-**1b** (ii) showing thermal ellipsoids at the 50% probability level along with the atom numbering scheme.

N(1)–Ru(1)–C^0_{1a}	132.8(9)	N(2)–Ru(2)–C^0_{1b}	134.1(9)
Cl(1)–Ru(1)–C^0_{1a}	127.2(9)	Cl(2)–Ru(2)–C^0_{1b}	126.9(3)

[a] C^0_{1a} and C^0_{1b} are the centroids of the η^6-*p*-cymene rings in molecules **1a** and **1b**, respectively.

Å, the separation between the C^0_{Ph} and the cymene ring protons H(3), H(4) is ~7 Å. In **1a**, the H(6) and H(7) atoms are likely to be involved in CH–π interaction. In **1b**, the H(36) and H(37) atoms are involved in CH–π interaction [$C^0_{Ph}\cdots$H(36), 3.584; $C^0_{Ph}\cdots$H(37), 2.922; $C^0_{Ph}\cdots$H(39), H(40), ~7 Å]. Such an interaction restricts the number of diastereomers to two with the methyl group (C*–Me) or the proton (C*–H) attached to the chiral carbon orienting themselves differently with respect to the cymene group.

In the (R_{Ru}, S_C)-diastereomer, the distances from the centroid of the *p*-cymene ring to the H and Me attached to the chiral carbon are 3.627 and 5.419 Å, respectively. The H atom attached to C* has a 'proximal' geometry with respect to the *p*-cymene ring. In the (S_{Ru}, S_C)-diastereomer, the $C^0_{1b}\cdots$H(51) and $C^0_{1b}\cdots$C(52) spatial separations are 5.124 and 4.387 Å. Another structural feature is the proximity of H(18) to the Cl atom in **1a** [Cl(1)···H(18), 3.431; Cl(1)···C(19), 4.252 Å], while the methyl group in the other diastereomer lies in the proximity of the chloride [Cl(2)···C(52), 3.496; Cl(2)···H(51), 4.360 Å]. From the steric point of view, the diastereomer with a (R_{Ru}, S_C)-configuration having H(18) in proximity to the chloride atom is expected to be the thermodynamically more stable species compared with the (S_{Ru}, S_C)-diastereomer having C*–Me near the Cl atom [10].

3.3. 2D NMR spectra

The crystal structure of **1** shows the presence of two diastereomers having (R_{Ru}, S_C)- and (S_{Ru}, S_C)-configurations in a 1:1 ratio. The solution ^{1}H NMR spectrum of the crystalline sample in $CDCl_3$ displays the presence of two diastereomers in a 88:12 ratio. The ^{1}H NMR data are not adequate enough for an unequivocal determination of the metal configuration of the diastereomers in the solution phase. We have thus made investigations using 2D NMR spectroscopy, which has enabled us to analyze the diastereomeric mixture of **1** in solution.

The presence of a rapid inter-conversion between the diastereomers in **1** is observed in the 2D ROESY spectra at 293 K showing exchange cross peaks. Such an exchange, however, reduces considerably at 233 K. The NOE cross peaks involving the C*–Ph and two *p*-cymene ring protons suggest the presence of CH–π interaction in the solution phase (Fig. 3(a)). This interaction imposes restriction of rotation around the C*–N single bond. It is again observed that the C*–H proton in the major isomer which appears as a quartet at δ 5.8 ppm displays cross peaks with the cymene ring protons (Fig. 3(b)). The C*–Me protons of the major isomer do not show any such cross peaks with the cymene ring protons. This is indicative of a close proximity of the C*–H moiety to the cymene ring while the C*–Me is away from the same in the major diastereomer. The 2D NMR spectral features suggest a (R_{Ru}, S_C)-configuration for the major diastereomer in solution.

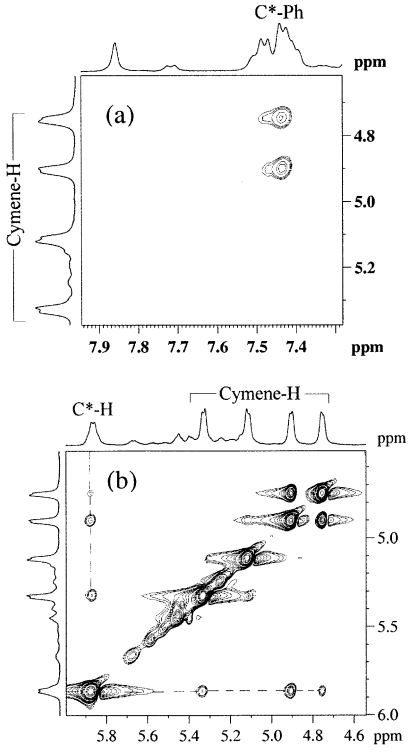

Fig. 3. The 400 MHz ^{1}H ROESY spectrum of **1** in $CDCl_3$ at 233 K for the major diastereomer showing (a) CH–π interaction and (b) the cross peaks involving the C*–H and the *p*-cymene ring protons.

The crystal structure shows the separations of the hydrogen atoms H(3), H(4), H(6) and H(7) of the *p*-cymene ring from the H(18) atom attached to the chiral carbon in the (R_{Ru}, S_C)-diastereomer as 5.071, 5.602, 3.413 and 2.235 Å, respectively. It is likely that the H(7) atom because of its proximity would interact strongly with H(18). The intensity of the NOE cross peaks helps us to assign the protons involved in this interaction. The peak, observed at δ 4.90 ppm in the ^{1}H NMR spectrum at 233 K in $CDCl_3$, is assignable to H(7). The atoms H(6) and H(7) show NOE cross peaks with the phenyl group attached to C* due to the CH–π interaction (Fig. 3(a)). The signal at δ 4.75 ppm is assignable to the H(6) atom of the cymene ring. The up-field shift of the H(6) and H(7) protons is possibly due to the shielding effect caused by the phenyl group involved in the CH–π interaction. Interestingly, the H(6) proton having a distance of 3.4 Å from H(18) shows only a weak interaction while the H(3) atom which appears at δ 5.33 ppm displays a relatively stronger interaction with H(18). This suggests a dynamic process to be operative in solution by which the H(3) proton may come closer to H(18). The peak at δ 5.11 ppm is assignable to the H(4) proton as it shows NOE cross peaks to the methyl protons [H(1A)–H(1C)] of the *p*-cymene ligand. The 2D NMR spectral studies have been done with only the major diastereomer as the proton signals of the minor species (12%) are not found to be suitable for the NOE measurements.

4. Conclusions

We have prepared and structurally characterized a new diastereomeric (η^6-arene)ruthenium(II) complex [(η^6-*p*-cymene)Ru{2-O-(3,5-di-*t*-Bu)C_6H_2CH=NCH(Me)Ph}Cl] (**1**). The complex crystallizes in the triclinic space group *P*1 with two diastereomers (R_{Ru}, S_C)-**1a** and (S_{Ru}, S_C)-**1b** in a 1:1 ratio in the unit cell. Complex **1**, however, shows the presence of two diastereomers in a 88:12 ratio in $CDCl_3$ as evidenced from the ^{1}H NMR spectrum. Both the diastereomers are stabilized by non-covalent CH–π attractive interaction involving the phenyl group attached to the chiral carbon and two hydrogen atoms of the *p*-cymene ring. The di-*t*-butyl group on the chiral ligand has caused a marginal enrichment of the d.e. to 76 from the 70% d.e. reported for its salicylaldimine analogue [7].

The 2D NMR spectra of the complex displays spatial interaction of the *p*-cymene ring protons with the proton(s) of either the C*–H of (R_{Ru}, S_C)-**1a** or the C*–Me of (S_{Ru}, S_C)-**1b**. The major diastereomer shows NOE cross peaks that are indicative of a 'proximal' arrangement of the C*–H proton to the cymene ring. This suggests a (R_{Ru}, S_C)-configuration for the major diastereomer in solution. The 2D NMR spectroscopic results along with the single crystal X-ray structural data have enabled us to unequivocally determine the metal configuration in the major diastereomer of **1** in solution.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre (CCDC), CCDC No. 178110 for complex **1**. Copies of the information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Scheme 1.

These Ni(II) dithiophosphate can coordinate one or two additional donor molecules forming five- and six-coordinate adducts, respectively [12–15]. *Trans*-octahedral complexes [16–19], e.g. $Ni\{S_2P(OR)_2\}_2{\cdot}2Py$ and *cis*-octahedral complexes [20–26], e.g. $Ni\{S_2P(OR)_2\}_2{\cdot}$bipy have also been structurally characterized. The ring-opening of the Laweson's reagent $(ArP(S)S)_2$ ($Ar = p$-$MeOC_6H_4$) [27] has been induced by reaction with alcohols and sylanols [28] generating dithiophosphonic acids and under appropriate conditions a new route to obtain dithiophosphonate complexes. Although, the reactivity of the Laweson's reagent has received much attention, the reactions of these substrates with transition metal ions have been explored scarcely [29,30]. In this paper we describe the simple 'one-pot' synthesis, as well as their spectroscopic and structural characterization, of novel dithiophosphate and dithiophosphonate complexes of pentacoordinate Ni(II) containing the $[Ni([12]aneN_3)]^{2+}$ fragment ([12]aneN$_3$ = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene ([12]aneN$_3$-mc1) and its 9-methyl derivative ([12]aneN$_3$-mc2)) the first pentacoordinate derivatives with these ligands and a different ancillary ligand.

2. Experimental

2.1. General methods

C, H, N and S analyses were carried out with a microanalyzer Carlo Erba model EA 1108. Infrared (IR) spectra were recorded on a Perkin–Elmer 16F PC FT-IR spectrophotometer using Nujol mulls between polyethylene sheets. The UV–Vis spectra (in C_3H_6O) were recorded on a Hitachi 2000V spectrophotometer for 300–800 nm range. The ^1H NMR spectra of $(CD_3)_2CO$ solutions were recorded on a Bruker model AC 200E or a Varian Unity 300 spectrometer. Fast atom bombardment (FAB) mass spectra were run on a Fisons VG Autospec spectrometer operating in the FAB$^+$ mode. Conductance measurements were performed with a Crison 525 conductimeter (in C_3H_6O solution, $c \approx 10^{-3}$ mol dm^{-3}). All chemicals were purchased from Aldrich and were used without further purification. Solvents were dried and distilled by general methods before use. The complexes $[Ni([12]aneN_3)(\mu\text{-}OH)]_2(PF_6)_2{\cdot}$([12]aneN$_3$ = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene ([12]aneN$_3$-mc1) and its 9-methyl derivative ([12]aneN$_3$-mc2) were prepared by procedures previously described [31,32]. The *O*,*O*′-dialkyldithiophosphoric acids [33], $HS(S)P(OR)_2$ and (4-methoxyphenyl)-*O*-alkyldithiophosphonic acids [28], $HS(S)P(p\text{-}CH_3OPh)(OR)$ were prepared according reported methods, with slight modifications.

2.2. Syntheses

2.2.1. [Ni([12]aneN$_3$-mc1){S$_2$P(OR)$_2$}][PF$_6$] (R = Me (1), Et (2), ^{i}Pr (3))

$[Ni([12]aneN_3\text{-}mc1)(\mu\text{-}OH)]_2(PF_6)_2$ (0.15 g, 0.17 mmol) was added to a solution of *O*,*O*′-dialkyldithiophosphoric acid (0.34 mmol) in the corresponding alcohol (20 ml), and the mixture was stirred at room temperature (r.t.) for 24 h. The solvent was removed under reduced pressure to approximately 10 ml and Et_2O (20 ml) was added to the solution which was then cooled to −18 °C for 24 h. The resulting green solid was filtered off, washed with Et_2O and air-dried.

Complex **1**: Yield: 74%. *Anal*. Found: C, 29.2; H, 5.6; N, 7.4; S, 11.0. Calc. for $C_{14}H_{31}F_6N_3NiO_2P_2S_2$: C, 29.4; H, 5.5; N, 7.3; S, 11.2%. Λ_M: 109 S cm^2 mol^{-1}. 2.3. Determination of the X-ray crystal structure of compounds 2 and 9

Crystals of [Ni([12]aneN_3-mc1){$S_2P(OEt)_2$}][PF_6] (**2**) suitable for X-ray diffraction studies were grown from C_3H_6O/Et_2O liquid diffusion and crystals of [Ni([12]aneN_3-mc1){S_2P(*p*-CH_3OPh)(O^iPr)}][PF_6] (**9**) were obtained by slow evaporation of an C_3H_6O solution. In both cases, crystals were mounted on glass fibres and transferred to a Siemens P4 diffractometer. The crystallographic data are summarised in Table 1.

Cell constants were refined from 60 (**2**) and 56 (**9**) reflections in the 2θ range 10°–25°. The structures were solved by direct methods and refined anisotropically on F^2 [34]. Hydrogen atoms were included using a riding model.

3. Results and discussion

3.1. Dithiophosphate and dithiophosphonate complexes

The *O*,*O*′-dialkyldithiophosphoric acids, HS(S)P$(OR)_2$, and (4-methoxyphenyl)-*O*-alkyldithiophosphonic acids, HS(S)P(*p*-MeOPh)(OR), are monoprotic acids and their deprotonation gives anions which can be trapped by a metal substrate to form new complexes [2]. On the other hand, previous work demonstrated that $[Ni([12]aneN_3)(\mu\text{-}OH)]_2^{2+}$ ([12]aneN_3 = 2,4,4-trimethyl-1,5,9-triazacyclododec-1-ene ([12]aneN_3-mc1) [31] and its 9-methyl derivative ([12]aneN_3-mc2) [32]) are useful precursors for the preparation of salicylaldiminate [35], β-ketoiminate [36], 2-pyridonate [37] and heterocyclic-2-thionate [38] complexes. Thus, the synthesis of *O*,*O*′-dialkyldithiophosphate and *O*-alkyldithiophosphonate complexes proceeds smoothly via a 'one-pot' method according to equations (i–iv) shown in Scheme 2. Typically, *O*,*O*′-dialkyldithiophosphoric acids were prepared by reaction of the appropriate alcohol with P_4S_{10} eq. (i) followed by the neutralization of the resulting acid with the hydroxo precursor $[Ni([12]aneN_3)(\mu\text{-}OH)]_2(PF_6)_2$ eq. (iii), *O*,*O*′-dialkyldithiophosphate complexes **1**–**6** were obtained. The ring opening of Laweson's reagent used in the formation of the complexes requires a nucleophilic agent that is the same solvent, for example ROH in eq. (ii). Therefore, (4-methoxyphenyl)-*O*-alkylphosphonate derivatives (**7**–**12**) are prepared by the acid–base reaction between the hydroxo complexes and the corresponding (4-methoxyphenyl)-*O*-alkyldithiophosphonic acids in the same alcohol [eq. (iv)]. The new complexes exhibit conductance values corresponding to 1:1 electrolytes in acetone [39].

Scheme 2. Syntheses of nickel complexes and proton labelling.

3.2. IR spectra

The IR spectra show the bands attributable to [12]aneN$_3$-mc1 and [12]aneN$_3$-mc2 ligands and the two strong characteristic bands due to the $[PF_6]^-$ anion, at normal frequencies [38]. The IR spectra of **1**–**6** exhibit two bands the in the regions 1164–1100 and 1076–950 cm^{-1} which could be assigned to the ν[(P)–O–C] and ν[P–O–(C)] vibrations, respectively, whereas for complexes **7**–**12** appear between 1116 and 1034 and around 1020 cm^{-1}, respectively [40,41]. The bands due to ν_{asym}(P–S) and ν_{sym}(P–S) vibrations fall in the range 672–652 and at 558 cm^{-1}, respectively, in the spectra of complexes **1**–**6** and in the range 664–629 and around 545 cm^{-1} for complexes **7**–**12** [40,41]. The bands at 452 cm^{-1} for complexes **1**–**6** and around 445 cm^{-1} for complexes **7**–**12** can be assigned to ν(Ni–S) vibrations.

3.3. Electronic spectra

The electronic spectra of the complexes in acetone solution are all similar and show bands in the 650 and 400 nm regions which could be assigned to $^3B_1(F) \rightarrow {}^3E(F)$ and $^3B_1(F) \rightarrow {}^3A_2, {}^3E(P)$ transitions, respectively [42]. Both λ_{max} values and molar absorptivities are consistent with a pentacoordinate environment around Ni(II) [38].

3.4. ^{1}H NMR spectroscopy

The representative proton NMR spectra for complexes **1** and **11** are shown in Fig. 1. The ^{1}H NMR spectra for complexes **1**–**12** exhibit relatively sharp hyperfine shifted signals spanning from approximately 340 to −40 ppm. The spectra show the resonance line pattern observed for the [12]aneN$_3$-macrocycle ligands that has been assigned on the basis of previous studies of nickel macrocyclic complexes [35–38]. The α-methylene protons shift downfield whereas the β-methylene protons shift upfield with regard to the diamagnetic position probably because of spin polarization mechanisms [43]. Equatorial protons are expected to experience larger contact shifts than axial protons and therefore the most downfield resonances are due to α-CH$_{eq}$ and the most upfield ones to β-CH$_{eq}$ [44]. The isotropically shifted ^{1}H NMR signals observed for methyl groups (2-Me, 4-Me(a, b) and 9-Me–N) can be initially assigned by inspection of their peak areas as well as alkyl groups of *O*,*O*′-dialkyldithiophosphate and *O*-alkyldithiophosphonate ligands. However, the resonances of alkyl and phenyl groups of dithiophosphate and dithiophosphonate ligands farther to the nickel atom have the smaller shift with regard to the diamagnetic position and all these resonances are downfield to TMS.

3.5. Crystal structures of complexes *2* and *9*

The crystal structures of **2** and **9** have been determined by single-crystal X-ray diffraction. ORTEP views of the structures together with atom-numbering schemes are shown in Fig. 2 (**2**) and Fig. 3 (**9**). Selected bond lengths and angles are given in Tables 2 and 3.

The crystal structure determination revealed that green crystals of **2** consist of [Ni([12]aneN$_3$-mc1)-$(S_2P(OEt)_2]^+$ cations and $[PF_6]^-$ anions. The structure shows the presence of two independent molecules. In each one, the nickel atom is pentacoordinate, with a square pyramid arrangement of the chelating atoms. The three nitrogen atoms of the N$_3$-macrocycle occupy the apical position and two adjacent basal ones, whereas the other two basal positions correspond to the *O*,*O*′-dialkyldithiophosphate group. The coordination geometry around the nickel atoms are distorted square pyramidal with the basal plane formed by N1, N2, S1

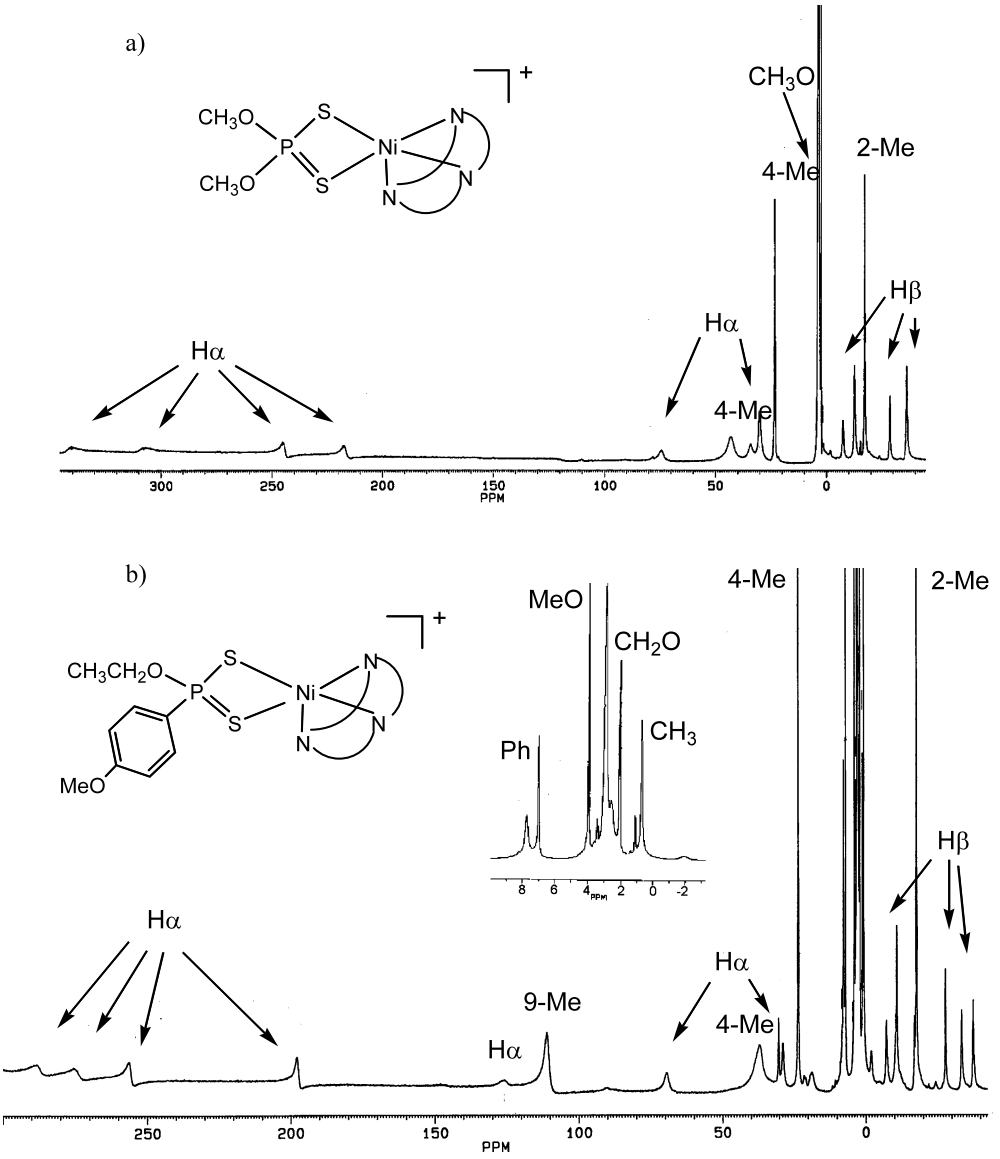

Fig. 1. ^{1}H NMR spectra (in d_6-acetone solution at room temperature) of **1** (a) and **11** (b).

and S2 and N4, N5, S3 and S4 (Table 2). The r.m.s.d. of these planes are 0.171 and 0.181 Å, respectively. The Ni1 and Ni2 atoms are 0.336 and 0.338 Å out of the corresponding basal plane towards the apical N3 or N6 atom. The Ni–[12]aneN$_3$-mc1 distances are not significantly different (2.018–2.059 Å) in contrast with

$[Ni([12]aneN_3\text{-mc2})(hp)]^+$ (hp = 2-pyridonate) where there are two Ni–N distances (2.057 and 2.044 Å) longer than the other (2.002 Å) [37]. The two Ni–S bond lengths are similar, 2.4338(9) and 2.5005(9) Å, or 2.4436(9) and 2.4831(9) Å) as previously found for five-coordinate adducts [12–15]. The P–S bond lengths are also similar (1.9765(12) and 1.9913(11) Å or 1.9767(12) and 1.9839(13) Å) suggesting a delocalized P–S π bond. The P–S distances are comparable with those found in the five-coordinate adducts [12–15].

The X-ray structural analysis of compound **9** showed a monomeric nickel complex in which the nickel atom is bonded to three nitrogen atoms of the macrocycle and to two sulfur atoms of the *O*-alkyldithiophosphonate ligand in a distorted square pyramidal geometry (Fig. 3). The nickel atom is 0.319 Å out of the basal plane defined by N1, N2, S1 and S2. The r.m.s.d of this plane is 0.261 Å. The Ni–N distances (2.027–2.055 Å) are similar to those found in **2** as well as the Ni–S distances (2.4020(9) and 2.5222(8) Å). However, the Ni–S bond distances are longer than that observed in homoleptic square-planar complexes [29,30]. The P–S bond lengths are also comparable with those found in **2** (2.0092(11) and 2.0037(11) Å), that is in accordance with delocalization of the P–S π bond over the S–P–S fragment. However, these distances are comparable with those found in *trans*-square-planar homoleptic nickel complexes with similar ligands [29,30]. To our knowledge, this complex is the first pentacoordinate ditiophosphonate Ni(II) derivative crystallographically characterised.

4. Conclusions

This work shows that mononuclear dithiophosphate $[Ni([12]aneN_3)(S_2P(OR)_2]\cdot(PF_6)$ and dithiophosphonate $[Ni([12]aneN_3)\{S_2P(p\text{-}CH_3OPh)(OR)\}](PF_6)$ complexes of pentacoordinate Ni(II) containing the $[Ni([12]aneN_3)]^{2+}$ fragment can be conveniently prepared by acid–base reactions between the a hydroxo precursor and the corresponding *O*,*O*′-dialkyldithiophosphoric acid $HS(S)P(OR)_2$ or (4-methoxyphenyl)-*O*-alkyldithiophosphonic acid in the corresponding alcohol as solvent. All these compounds have been fully characterised by means of spectroscopic and diffractometric techniques. The mild reaction conditions and high yields allows the introduction of dithiophosphate and dithiophosphonate ligands in the five-coordination environment of Ni(II).

5. Supplementary material

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 175301 and 175302 for complexes **2** and **9**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

phosphides have received attention as potentially interesting nanomaterials [16]. It is anticipated that such nanomaterials may have interesting mechanical, optical and electrical properties [17]. They are also known to be catalysts of alkylation reactions [18].

Here we report the first instance of a tin phosphide film prepared by dual source atmospheric pressure chemical vapour deposition (APCVD).

2. Experimental

Nitrogen (99.99%) was obtained by BOC and used as supplied. Coatings were obtained on SiO_2 coated float glass. APCVD experiments were conducted on $150 \times 45 \times 3$ mm^3 pieces of glass using a flat bed cold walled APCVD reactor. The glass was cleaned prior to use by washing with petroleum ether (60–80 °C) and isopropanol and then dried in air. A graphite block containing a Whatman cartridge heater was used to heat the glass substrate. The temperature of the substrate was monitored by a Pt–Rh thermocouple. Independent thermocouple measurements indicated that temperature gradients of up to 50 °C were observable at 600 °C across the surface of the glass. The rig was designed so that four independent gas lines could be used. All gas handling lines, regulators and flow valves were made of stainless steel and were $\frac{1}{4}''$ internal diameter except for the inlet to the mixing chamber and the exhaust line from the apparatus that were $\frac{1}{2}''$ in diameter. In these experiments three gas lines were used. Gases came directly from a cylinder and were preheated by passing along 2-m lengths of stainless steel tubing, which were curled and inserted inside a tube furnace. The temperatures of all the gas inlet lines were monitored by Pt–Rh thermocouples and Eurotherm heat controllers.

Tin(IV) chloride (99.99%) was obtained from the Aldrich Chemical Company and used without further purification and was placed into a stainless steel bubbler. The bubbler was heated to 35 °C by a heating jacket and $SnCl_4$ introduced into the gas streams by passing hot nitrogen gas through the liquid. $PCyc^{hex}H_2$, $PCyc^{hex}{}_2H$, $PCyc^{hex}{}_3$ and $PhPH_2$ were purchased from Strem Chemicals and used without further treatment. The two components of the system were mixed by the use of two concentric pipes of $\frac{1}{4}''$ and $\frac{1}{2}''$ diameter, respectively. The inner pipe being 3 cm shorter than the outer pipe. The concentric pipes were attached directly to the mixing chamber of the coater. Gas flows were adjusted using suitable regulators and flow controllers. The exhaust from the reactor was vented directly into the extraction system of a fume cupboard. All of the apparatus was baked out with nitrogen at 150 °C for 30 min before use. Deposition experiments were conducted by heating the horizontal bed reactor and the bubblers to the desired temperatures before diverting the nitrogen line through the bubbler and hence to the reactor. Deposition experiments were timed by use of a stopwatch and were conducted typically for 1 min. At the end of the deposition only nitrogen was allowed to flow over the glass substrate until the substrate was sufficiently cool to handle (approximately 60 °C). Cool, coated samples were handled and stored in air. The large coated glass sample was cut into smaller samples (1×1 cm^2), for analysis by X-ray photoelectron spectroscopy (XPS), energy dispersive X-ray analysis (EDXA), scanning electron microscopy (SEM), electron probe, transmission/reflectance and UV absorption studies. Larger pieces of glass (4×4 cm^2) were used for sheet resistance, X-ray powder diffraction, contact angle and Scotch tape tests.

X-ray powder diffraction patterns were measured on a Siemens D5000 diffractometer using filtered (Cu Kα1, $\lambda = 1.5406$ Å) radiation in the reflection mode using glancing angle incidence (1.5°). SEM was obtained on a Hitachi S570 instrument. EDXA was obtained using a JEOL 35-CF instrument. Electron microprobe analysis was obtained on a JEOL EMA and referenced against Sn and P standards. X-ray photoelectron spectra were recorded with a VG ESCALAB 220I XL instrument using a focused (300 μm spot) monochromatic Al Kα radiation at a pass energy of 20 eV. Scans were acquired with steps of 50 meV. A flood gun was used to control charging and the binding energies were referenced to an adventitious C 1s peak at 284.6 eV. Depth profiling measurements were obtained by using Ar beam sputtering.

UV–Vis spectra were obtained using a Helios double beam instrument. Reflectance and transmission spectra were recorded between 300 and 1150 nm by a Zeiss miniature spectrometer. Measurements were standardised relative to an Rh mirror (reflectance) and air (transmission). Raman spectra were acquired on a Renishaw Raman system 1000 using He–Ne laser of wavelength 632.8 nm. The Raman system was calibrated against the emission lines of Ne. Contact angle experiments were determined by measuring the spread of a 1 μl droplet of water and applying a simple trigonometric program. Electrical properties were determined by using a four-probe device.

3. Results

APCVD of tin phosphide films were achieved on glass substrates from the dual source CVD reaction of $SnCl_4$ or $SnBr_4$ and a substituted phosphine ($PCyc^{hex}H_2$, $PCyc^{hex}{}_2H$, $PCyc^{hex}{}_3$ or $PhPH_2$). The process was studied at different substrate temperatures and flow rates of precursor (Table 1).

No film could be grown at substrate temperatures below 400 °C, uniform films were obtained at 500 °C

Table 1
Experimental conditions and microanalytical results

Substrate temperature (°C)	Nitrogen flow through SnX_4 bubbler (l min^{-1}) (SnX_4) [bubbler temperature (°C)]	Nitrogen flow through R_xPH_{3-x} bubbler (l min^{-1}) (R_xPH_{3-x}) [bubbler temperature (°C)]	Nitrogen flow of make up gas (l min^{-1})	EDAX and electron probe analysis
500	0.5 ($SnCl_4$) [35]	0.5 ($PCyc^{hex}H_2$) [120]	1.4	$SnP_{0.40}$

500	0.2 ($SnCl_4$) [35]	0.8 ($PCyc^{hex}H_2$) [120]	1.0	$SnP_{0.40}$
500	0.3 ($SnCl_4$) [35]	0.3 ($PCyc^{hex}H_2$) [120]	1.0	$SnP_{1.00}$
500	0.8 ($SnCl_4$) [35]	0.2 ($PCyc^{hex}H_2$) [120]	1.0	Sn
550	0.3 ($SnCl_4$) [35]	0.3 ($PCyc^{hex}H_2$) [120]	1.0	$SnP_{1.00}$
600	0.3 ($SnCl_4$) [35]	0.3 ($PCyc^{hex}H_2$) [120]	1.0	$SnP_{1.00}$
500	0.3 ($SnCl_4$) [35]	0.3 ($PhPH_2$) [145]	1.0	$SnP_{0.66}$
500	0.3 ($SnCl_4$) [35]	0.5 ($PhPH_2$) [145]	1.0	$SnP_{1.33}$
600	0.3 ($SnCl_4$) [35]	0.5 ($PhPH_2$) [145]	1.0	$SnP_{1.00}$
600	0.3 ($SnCl_4$) [35]	0.7 ($PCyc_2^{hex}$ H) [250]	0.7	$SnP_{0.66}$
600	0.3 ($SnCl_4$) [35]	1.8 ($PCyc_2^{hex}$ H) [250]	0.2	$SnP_{1.00}$
600	0.5 ($SnBr_4$) [200]	0.3 ($PCyc_3^{hex}$) [120]	0.8	$SnP_{1.00}$
600	0.4 ($SnBr_4$) [200]	0.4 ($PCyc_3^{hex}$) [120]	0.8	$SnP_{1.33}$

and above. The films grown from the dual source CVD reaction of $SnCl_4$ or $SnBr_4$ and a substituted phosphine ($PCyc^{hex}H_2$,$Cyc^{hex}{}_2H$, $PCyc^{hex}{}_3$ or $PhPH_2$) were opaque in colour, although those grown at higher temperatures had a blue tint. The films appeared unreflective. The films prepared at higher temperatures exhibited some birefringence due to thickness effects. All of the films passed the Scotch tape test. They could not be marked with a wet towel but could be marked with a brass stylus or steel scalpel. The films prepared at higher precursor flow rates showed some 'pin holing' due to gas phase nucleation. The films showed no optical change after storage in air for 3 months.

Raman microscopy was used to investigate all of the films. In all cases no Raman scattering due to the films was observed. It is thought that tin phosphides are poor Raman scatters, indeed a sample of Sn_4P_3 purchased form Aldrich gave no Raman spectra. In the samples prepared using $PCyc^{hex}H_2$ and $PhPH_2$ no free carbon was detected by Raman. This was not the case with films prepared using $PCyc^{hex}{}_2H$ and $PCyc^{hex}{}_3$ where free carbon was present in the films. No Raman scattering was observed from the film due to the presence of tin oxides. In previous work we have shown that even trace amounts of tin oxides (SnO_2 or Sn_3O_4) give strong Raman patterns [19].

Compositional analysis of the films was determined by EDXA and electron probe measurements (summarised in Table 1). The results show that the films are free of chlorine (or bromine if $SnBr_4$ was used) and contain only tin and phosphorus. In all cases some breakthrough to the underlying glass was observed. This was corrected for based on a sample of plain glass. These results show that it is possible to create films with a selection of stoichiometries, ranging from $SnP_{1.33}$ to $SnP_{0.40}$. The analysis showed that there was a slight variation in composition across the surface of the glass substrate, for example films with composition $SnP_{1.33}$ had a composition of $SnP_{1.00}$ at the extreme edges, this correlates with the measured temperature gradient across the glass substrate. Area maps indicate that particles containing tin and phosphorus are made (Fig. 1), and that no oxygen is present in these particles.

SEM analysis of the films showed that the deposition reaction proceeded via an island growth mechanism. The majority of samples consisted of microspheres of tin phosphide covering the majority of the surface. Two representative samples are shown in Fig. 2.

The optical properties of the films were studied by reflectance/transmission measurements and UV absorption between 400 and 1100 nm. All samples showed a shift in the absorption edge relative to the plain glass

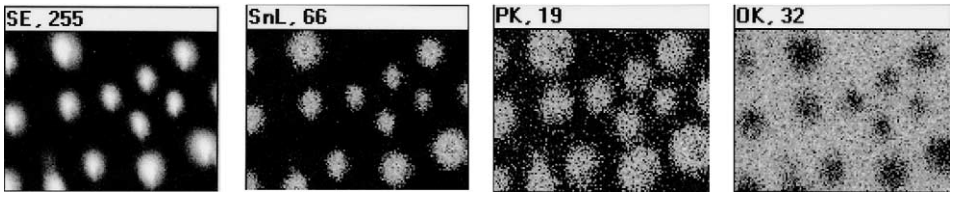

Fig. 1. EDXA area maps of tin phosphide particles. The lighter colours indicate a higher concentration of the specific element. The key on each caption SE, secondary electron image; SnL, tin L X-ray line; PK, phosphorus K X-ray line; OK, oxygen K X-ray line. The numbers 255, 66, 19 and 32 indicate the uncorrected counts per second for each X-ray line.

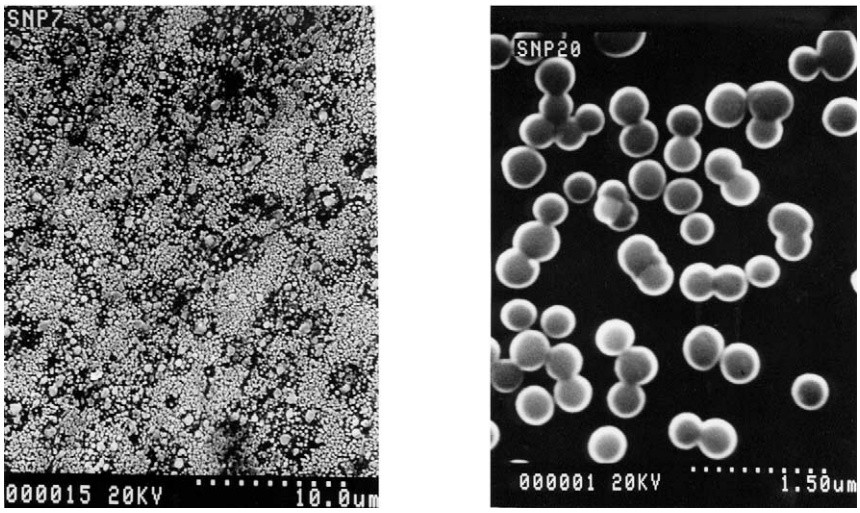

Fig. 2. Scanning electron microscope pictures of tin phosphide films formed from the APCVD reaction of tin tetrachloride and monocyclohexylphosphine at 600 °C.

substrate. The films showed minimal reflectivity (2%), less than the substrate (10%). The transmission spectra were indicative of hazing; this is due to scattering by particles in the film of a similar size to the wavelength of the light.

XPS measurements on a sample of $SnP_{1.00}$ composition, revealed binding energy shifts of 487.2 and 133.6 eV for Sn $3d_{5/2}$ and P $2p_{3/2}$, respectively. These are in reasonable agreement with previous values published in the literature concerning nanoscale Sn_4P_3[6] of 487.6 eV for Sn $3d_{5/2}$ and 134.1 eV for P $2p_{3/2}$. A sample of composition $SnP_{0.40}$ revealed similar binding shifts of 487.2 and 133.8 eV for Sn $3d_{5/2}$ and P $2p_{3/2}$, respectively. The XPS peak profiles for both samples (Fig. 3) are consistent with one environment for both tin and phosphorus. There is no evidence for the presence of tin oxides from the XPS profiles.

The tin phosphide films were X-ray amorphous. Sheet resistance measurements indicated that the films were insulating. The films were shown to have contact angles of 70°–80°. This contact angle did not change significantly after irradiation with 254 nm UV light for 1 h. This contact angle is similar to that of plain glass 50°–75°.

4. Discussion

Reaction of $SnCl_4$ (or $SnBr_4$) and a substituted phosphine ($PCyc^{hex}H_2$, $PCyc^{hex}{}_2H$, $PCyc^{hex}{}_3$ or $PhPH_2$) under APCVD affords opaque films of tin phosphide on glass substrates. The tin phosphide films were shown in most cases to be tin rich, although it was possible to make the stoichiometric compound tin monophosphide when equimolar quantities of precursor were introduced into the gas phase.

The films were found to be insulating. This is because of grain boundary effects due to the island growth mechanism.

The mechanism of this reaction was not determined in this study. It is likely that HCl is produced in the reaction as well as $Cyc^{hex}Cl$ or PhCl (depending on the

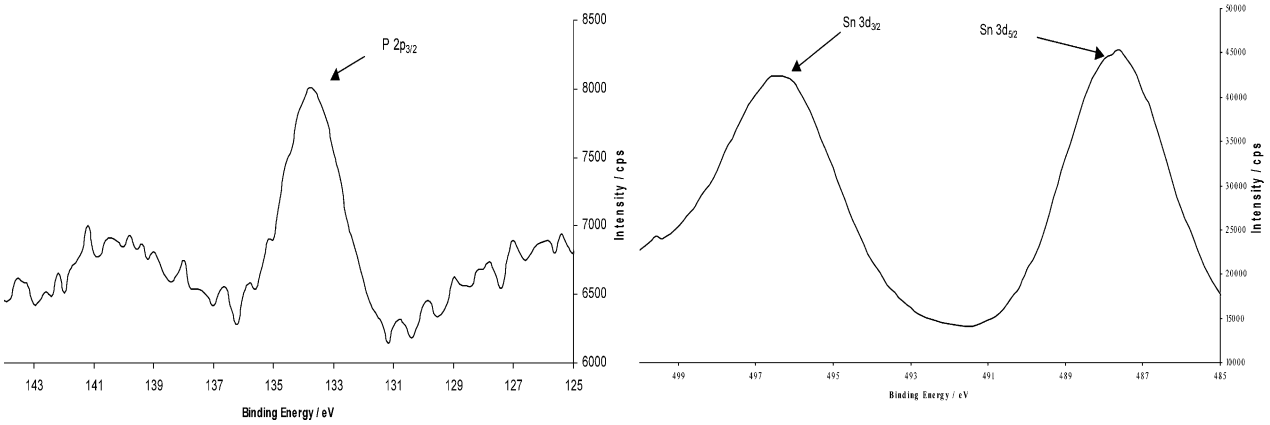

Fig. 3. The XPS peak profiles for a $SnP_{1.00}$ sample showing on the left, the phosphorus $2p_3$ region and on the right, the tin $3d_{5/2}$ and $3d_{3/2}$ region.

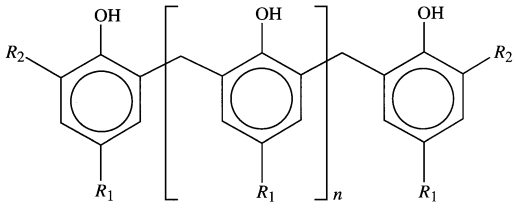
phosphine precursor used) [20]. It is plausible that the reaction occurs via the formation of a adduct as some material was recovered from the exhaust which was not starting material. Previous work also suggests that similar deposition process occur via adducts [21].

These films show no Raman spectra. They shift the absorption edge of, and undergo less transmission and reflection than SiO_2 coated glass due to scattering haze. EDAX and electron probe results suggest that the composition over the surface of the glass is similar. SEM shows that whilst various morphologies are possible, one predominates in samples of tin phosphide films.

There is no variation of film stoichiometry with different precursors. It was noted that distinct phases ($SnP_{1.33}$, $SnP_{1.00}$, $SnP_{0.66}$ and $SnP_{0.40}$) were seen and no intermediate phases were observed. Higher nitrogen flow rates had the effect of lowering the phosphorus content of the resultant films. Using di- and tri-substituted phosphines required higher substrate temperatures (600 °C) for films to form. Where films did form at lower substrate temperatures (500 °C) with the di- and tri-substituted phosphines they were lower in phosphorus content than those formed at higher substrate temperatures.

5. Conclusion



Reaction of $SnCl_4$ (or $SnBr_4$) and a substituted phosphine ($PCyc^{hex}H_2$, $PCyc^{hex}{}_2H$, $PCyc^{hex}{}_3$ or $PhPH_2$) under APCVD affords opaque films of tin phosphide on glass substrates. The films show good surface coverage, adhesion and reasonable uniformity. Tin phosphide films with a range of stoichiometries ($SnP_{0.40}$–$SnP_{1.33}$) could be obtained; these were all opaque in appearance and electrical insulators.

Acknowledgements

The authors wish to thank the EPSRC for funding and Pilkington for a CASE award to RB and for glass. The EPSRC are also thanked for providing financial assistance in the purchasing of the Raman spectrometer.

Scheme 1. The polyphenols under study.

CH_3CN, while on recrystallizing **3** from CCl_4 a solvate was obtained, **3**·1/3(CCl_4), denoted **3s** hereafter. The triphenol **4** has been synthesized as previously reported [4c,d] and single crystals were obtained by slow evaporation of a $CHCl_3$–CH_3CN (1:1) solution.

2.1.1. [HDABCO]$_2$[UO_2(**3**–2H)$_2$]·2H_2O (**7**)

The diphenol **3** (32 mg, 0.086 mmol) and a slight excess of DABCO (23 mg, 0.205 mmol) were dissolved in $CHCl_3$ (100 ml). Uranyl nitrate hexahydrate in slight excess with respect to the 1:2 metal–ligand stoichiometry (25 mg, 0.050 mmol) in CH_3OH (30 ml) was then added dropwise, giving immediately an orange solution which was refluxed for 10 min. Orange crystals of low quality but suitable for X-ray crystallography deposited after several recrystallizations from $CHCl_3$, CH_3CN, CH_3OH and mixtures of these solvents.

2.1.2. [HDABCO]$_2$[UO_2(**4**–2H)$_2$]·2CH_3CN (**8**)

The triphenol **4** (350 mg, 0.738 mmol) and a large excess of DABCO (420 mg, 3.75 mmol) were dissolved in $CHCl_3$–CH_3CN (120 ml). Uranyl nitrate hexahydrate in slight excess with respect to the 1:2 metal–ligand stoichiometry (200 mg, 0.40 mmol) in CH_3CN (30 ml) was then added dropwise, giving immediately a dark orange solution, which deposited in a few days orange crystals suitable for X-ray crystallography.

2.2. Crystallography

The data were collected on a Nonius Kappa-CCD area detector diffractometer [5] using graphite-monochromated Mo Kα radiation (0.71073 Å). The crystals were introduced in Lindemann glass capillaries with a protecting 'Paratone' oil (Exxon Chemical Ltd) coating. The unit cell parameters were determined from the reflections collected on ten frames and were then refined on all data. The data were processed with DENZO-SMN [6]. The structures were solved from Patterson map interpretation (compound **7**) or by direct methods (all other compounds) with SHELXS-97 [7] and subsequent Fourier-difference synthesis, and refined by full-matrix least-squares on F^2 with SHELXL-97 [8]. Absorption effects in compounds **3s**, **7** and **8** were empirically corrected with the programs DELABS (**3s**, **7**) and MULABS (**8**) from PLATON [9]. Special details for each compound are as follows:

Compound **2**. All non-hydrogen atoms were refined with anisotropic displacement parameters. All hydroxy protons but one were found on the Fourier-difference map (one of them disordered over two positions, each corresponding to a possible hydrogen bond).
Compounds **3s** and **4**. All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydroxy protons were found on the Fourier-difference map.
Compound **7**. One *tert*-butyl group was found disordered over two positions, which have been refined with occupation parameters constrained to sum to unity. All non-hydrogen atoms were refined with anisotropic displacement parameters, except the disordered ones. Restraints on bond lengths, angles and displacement parameters were applied to the badly resolved HDABCO ions. The hydroxy and ammonium ion protons were not found, nor introduced.
Compound **8**. One *tert*-butyl group was found disordered over two positions, which have been refined with occupation parameters constrained to sum to unity. All non-hydrogen atoms were refined with anisotropic displacement parameters, except the disordered ones. The hydroxy and ammonium ion protons were found on the Fourier-difference map.

All the carbon-bound hydrogen atoms were introduced at calculated positions, except in the disordered parts. All hydrogen atoms were treated as riding atoms with an isotropic displacement parameter equal to 1.2 (OH, NH, CH, and CH_2) or 1.5 (CH_3) times that of the parent atom. Crystal data and refinement details are reported in Table 1. The molecular plots were drawn with SHELXTL [10]. All calculations were performed on a Silicon Graphics R5000 workstation.

3. Discussion

3.1. Uncomplexed polyphenols

Compounds **2** and **3** pertain to the family of *bis*(hydroxymethylated) diphenols (R_2=CH_2OH). The structure of the analogous compound with *iso*-propyl *para*-substituents R_1 has previously been described [11]. Compared with *ortho*-unsubstituted diphenols (R_2=H) [2,12], which crystallize as hydrogen bonded dimers or chains, the hydroxymethyl groups add further possibi-

lities of intra- or inter-molecular hydrogen bonding. The asymmetric unit in the crystal structure of **2** contains two independent but nearly identical molecules with intramolecular hydrogen bonds linking three successive oxygen atoms. The intermolecular hydrogen bonding pattern gives rise to double chains or ribbons directed along the *a*-axis, as illustrated in Fig. 1. The asymmetric unit in the trigonal 3:1 tetrachlorocarbon solvate of compound **3**, **3s**, includes one diphenol molecule and a third of a CCl_4 molecule located on a ternary axis. The intramolecular hydrogen-bonding pattern is identical to that in compound **2**. The trigonal arrangement gives rise to layers parallel to the *ab*-plane held by intermolecular hydrogen bonds. The bonds involving one of the terminal oxygen atoms and its symmetry-related counterparts around the $\bar{3}$-axis lead to the formation of a trigonal $(OH)_6$ pattern, as represented in Fig. 2, whereas the CCl_4 molecules are located on the 3-axis and are surrounded, in projection along this axis, by three diphenol molecules linked by hydrogen bonds. The crystal structure of compound **4** has previously been briefly described [11], but to the best of our knowledge, no detailed data have been published. This structure is essentially similar to that of the related triphenol **5** previously published [2], with formation of dimers held by cyclic (isodromic) hydrogen bonds, and it will not be described further herein.

3.2. Uranyl complexes

$[HDABCO]_2[UO_2(\mathbf{3}–2H)_2]\cdot 2H_2O$ (**7**) crystallizes with one complete and two halves complex molecules in the repeat unit of the triclinic cell. The three molecules are quite similar, at least regarding the main features of the complex core, molecule A (represented in Figs. 3 and 4) being pseudo-centrosymmetric and the uranium atom in molecules B and C being located on a symmetry center. The uranium atoms are bound to four deprotonated phenolic groups, which gives the usual slightly distorted square-planar equatorial environment (Table 2). The U–O distances are in the range 2.217(4)–2.285(11) [mean value 2.25(2)] Å and the uranium atom in molecule A is at 0.061(6) Å from the mean plane defined by the four donor atoms. Numerous hydrogen bonds involve the diphenol and water molecules (Table 2). In molecule A, an intramolecular hydrogen bond links the hydroxymethyl oxygen atom O4A and the deprotonated phenolic atom O5A of the other coordinated molecule. As a result, the two ligand molecules are closer one to the other on the side of this bond, which is reflected by an O2A–U1–O5A angle [85.5(4)°] smaller than O1A–U1–O6A [97.8(5)°]. In molecules B and C, where such a bond does not occur, the O–U–O angles involving adjacent phenoxide oxygen atoms deviate little from 90° [89.0(5)°–91.0(5)°]. The dihedral angles between adjacent aromatic rings are 73.3(6)° and 77.6(6)° in molecule A, 79.6(7)° in molecule B and 71.4(6)° in molecule C. These values are larger than that in the compound **1**·0.5DABCO·0.5H_2O, but are in the range usual in diphenols with more or less distorted 'butterfly' conformations [2]. The dihedral angles between the phenolic rings and the mean O_4 plane defined by the coordinating atoms are 52.4(5)°, 49.1(4)°, 48.1(5)° and 36.9(6)° in molecule A, 44.1(7)° and 44.9(6)° in molecule B and

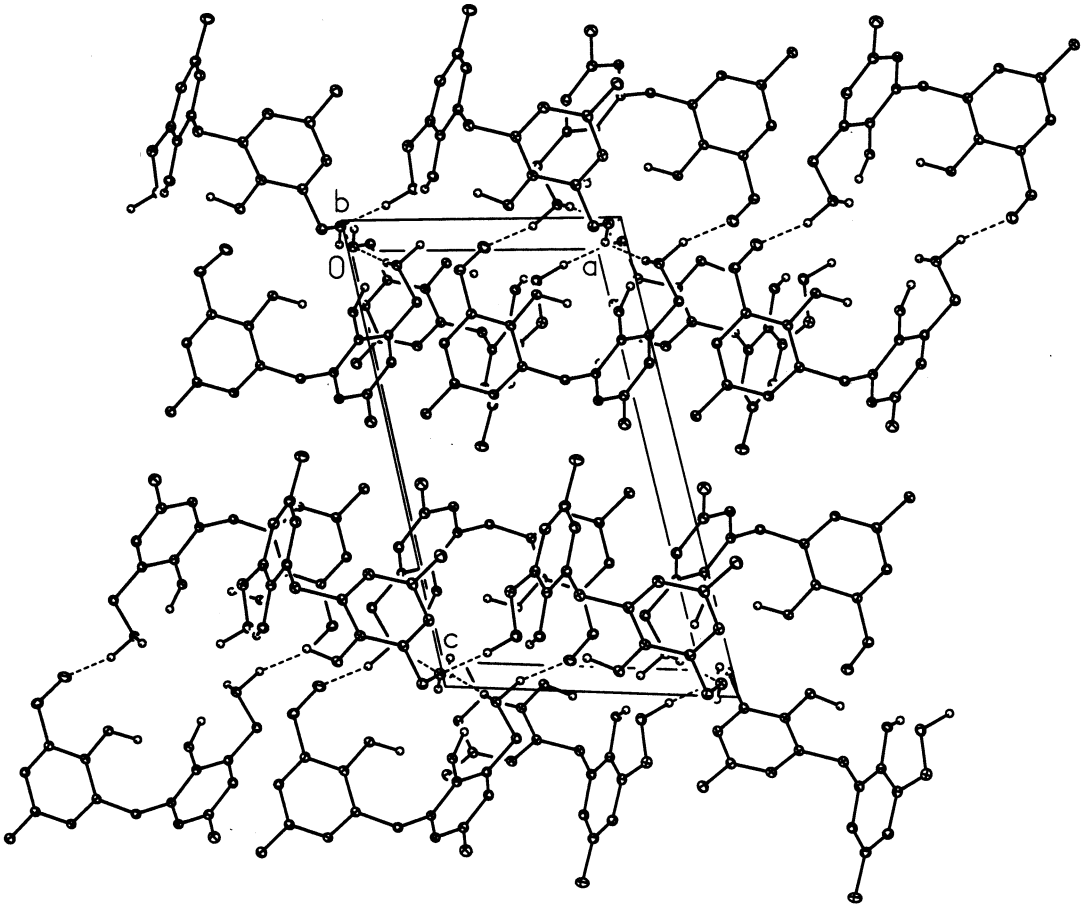

Fig. 1. View of the packing in compound **2**. Hydrogen bonds are represented as dashed lines and hydrogen atoms as small spheres of arbitrary radii (intramolecular hydrogen bonds and carbon-bound hydrogen atoms are omitted for clarity). Hydrogen atoms are omitted for clarity. Ellipsoids are drawn at the 10% probability level.

43.5(6)° and 47.7(5)° in molecule C. In each molecule, the two protonated DABCO counterions are hydrogen bonded to the two oxo atoms of the uranyl ion, each on one side of the equatorial plane. They are further located near the cup built by the two phenolic rings of each ligand and near one other phenolic ring pertaining to a neighboring complex. The interactions involved in this arrangement will be discussed below.

$[HDABCO]_2[UO_2(\mathbf{4}–2H)_2]\cdot 2CH_3CN$ **8** crystallizes in the monoclinic space group $P2_1/c$, with only half a molecule in the repeat unit, the uranium atom being located on the symmetry center (Figs. 5 and 6). Each ligand is bound by two phenoxide oxygen atoms only and is in this way equivalent to a diphenol with regard to complexing properties, as in the previously reported complex $[HDABCO]_2[UO_2(\mathbf{5}–2H)_2]\cdot CH_3OH$ **9** [2]. This behavior has been discussed in relation with the complexing properties of calixarenes, and in particular those of calix[6]arene [2]. An obvious difference with complex **9** is the relative position of the two ligands with respect to the central cation. Complex **9** does not possess any symmetry and the two ligands are such that the two uncomplexed phenolic moieties are surprisingly located on the same side of the complex. On the other hand, these two remaining units are diametrically located in the centrosymmetric complex **8**, which seems a more likely geometry in terms of steric interactions. The uranyl ion in **8** is bound to two phenoxide oxygen atoms and their symmetry-related counterparts, with bond lengths of 2.207(8) and 2.297(7) Å. Such different bond lengths have already been observed in compounds **7** (see above) and **9** [mean values 2.18(1) and 2.27(1) Å], which has been attributed in the latter case to some distortion of the complex core due to the repulsion between the two uncomplexed phenolic units (the usual values for tetra-phenoxide bound uranyl in calixarene complexes are close to 2.23 Å). In the present case, the difference between the two values is the same (with a slight increase of both), but the previous explanation does not hold true any more. A repulsion between O4 and O2′ is also unlikely, the distance between these atoms being 3.61(1) Å [for comparison, the O2···O3 distance is 3.16(1) Å]. The most plausible origin is the presence of the strong hydrogen bond between O3 and

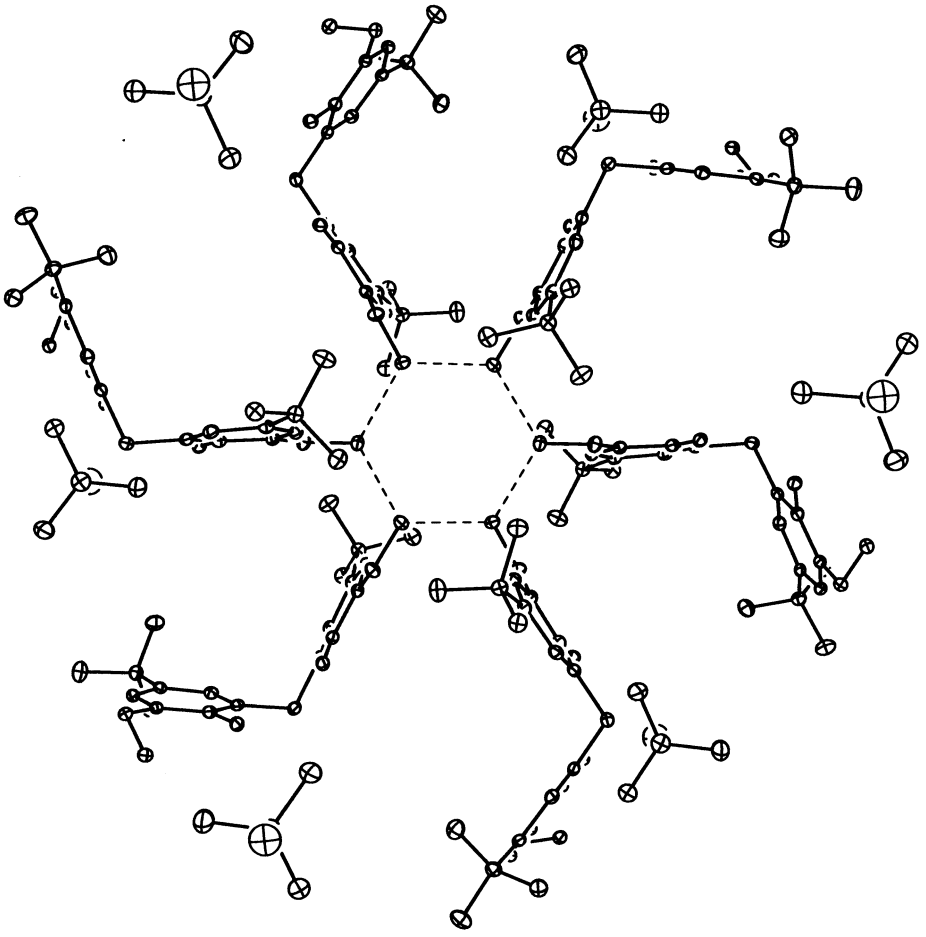

Fig. 2. View of the trigonal arrangement in the *ab*-plane in compound **3s**. Intermolecular hydrogen bonds are represented as dashed lines. Hydrogen atoms are omitted for clarity. Ellipsoids are drawn at the 20% probability level.

O4, which likely diverts some electronic density from the former atom. In comparable calixarene complexes, the U–O bond lengths appear also to be slightly larger when hydrogen bonding is present, in the absence of any other identifiable cause, but this effect is probably often hindered by other effects inducing an asymmetry in the coordination sphere, such as the ligand geometric constraints. The U1–O5A distance in complex **7** is a

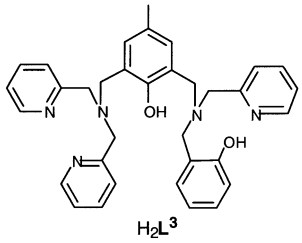
short one, in spite of the involvement of O5A in a strong hydrogen bond. The difference with complex **8** is that, in **7**, the donor atom in the hydrogen bond pertains to the second ligand in the complex molecule, and not to the same one as in **8**, which implies a slightly different geometry (see above). The O–U–O angles involving adjacent phenolic oxygen atoms of the coordination

sphere do not deviate much from 90° in **8**, whereas a strong deviation was observed in compound **9**, one of the angles, involving one oxygen atom from each ligand, being as large as 100.6(4)° as a result of the repulsion between the two uncomplexed phenol units. The four-phenoxide oxygen atoms and the uranium atom in **8** define a plane, the phenolic oxygen atoms O4 and O4′ being at a distance of 1.11(2) Å on each side of it. The conformation of the triphenol is the one that has been termed *trans* or *anti* [11], the first and third aromatic rings being on either side of the plane defined by the central ring. The dihedral angles between adjacent aromatic rings are 80.4(4)° and 75.3(4)°, i.e. larger than in complex **9** (range 62.4°–74.5°) and the dihedral angles between the two bonding phenolic rings and the mean O_4 plane defined by the coordinating atoms are 43.1(3)° and 50.4(3)°. The torsion angles φ and χ, as defined for calixarenes [13], correspond to a sequence of distorted *gauche* angles $-++-$, identical to that in complex **9** or in the uncomplexed ligands **4** and **5**. It may be considered as rather surprising that the conformation of so flexible a molecule does not change much upon uranyl complexation. In this respect, uranyl bonding by two phenoxide groups does not differ much from an intramolecular hydrogen bond from a purely geometric viewpoint. Such a similarity in the geometries of uncomplexed and uranyl-complexed ligands has already been observed in the case of several calixarenes. Some preorganization effects due to hydrogen bonding in cyclic and acyclic polyphenols may be assumed in such cases.

The location of the $HDABCO^+$ cations in **8** is similar to that in complexes **7** and **9**, with the formation of a N–H···O(oxo) hydrogen bond. The counterion is further located in the cup formed by the two bonding phenolic groups. We have discussed in previous papers the interactions involved in the inclusion of ammonium counterions in the cavity of calixarene complexes [14]. In the present cases, the ammonium···oxo hydrogen bond is certainly of a primary importance in the counterion location, but this does not prevent some weak interactions being involved as well. The shortest distances observed between the carbon and nitrogen atoms of the HDABCO ions and the centroids of the aromatic rings may reveal these interactions. In complex **7**, these shortest contacts are 3.56 Å for carbon atoms in α positions with respect to the charged nitrogen and aromatic rings of the cup of the same complex molecule, 3.54 Å for carbon atoms and aromatic rings of neighboring molecules and 3.84 Å for nitrogen atoms and aromatic rings of the cup. In compound **8**, the corresponding values are 3.38, 3.88 and 3.97 Å, respectively. Such distances are in a range indicative of possible cation–π interactions [14,15]. These interactions may be at the origin of the rather strong deviation of the N–H···O(oxo) bond from linearity (144° around H in compound **8**), the HDABCO ion being tilted towards the aromatic rings of the cup. Besides, some weaker CH–π interactions [16,17] may also be present: in compound **8** for example, one of the hydrogen atoms linked to the HDABCO carbon atom more imbedded in the cup is possibly involved in a hydrogen bond with the neighboring aromatic ring, with a H···centroid distance of 2.41 Å and a C–H···centroid angle of 172.5°.



4. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC no. 182688 (**2**), 182689 (**3s**), 171000 (**4**), 182690 (**7**) and 171001 (**8**). Copies of the information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

H_2L^3

2. Experimental

2.1. Materials and measurements

Elemental analyses were carried out by the University of Sheffield microanalytical service. Infrared spectra were recorded as KBr discs or as liquid films between NaCl plates, using a Perkin–Elmer 297 (4000–600 cm^{-1}) or a Perkin–Elmer 1600 (4000–400 cm^{-1}) infrared spectrophotometer. Positive ion fast atom bombardment (FAB) mass spectra were recorded using a Kratos MS80 or a VG PROSPEC spectrometer (the matrix used was 4-nitrobenzyl alcohol).

The proligand 2,6-bis[((2-pyridylmethyl)-aminomethyl)-6-((2-hydroxybenzyl)(2-pyridylmethyl))-aminomethyl]-4-methylphenol (H_2L^3) was prepared by the method of Neves et al. [4]

2.2. Synthesis of complexes

The complexes were prepared by dissolving H_2L^3 (1 equiv.) in a warm methanolic solution (15 cm^3) and then adding NEt_3 (2 equiv.) and $Zn(OAc)_2\cdot 2H_2O$ (2 equiv.). The solution was refluxed for 60–90 min and 2 equiv. of the requisite alkali metal salt were added ($NaBF_4$, $NaClO_4$ or KPF_6). The solutions were cooled and crystals removed for analysis; the bulk sample was then recovered by filtration, washed and dried in vacuo.

The bulk sample of $[Zn_2L^3(OAc)(OH_2)](BF_4)\cdot 2MeOH\cdot H_2O$ (**1**) was prepared from H_2L^3 (112 mg, 0.2 mmol), $Zn(OAc)_2\cdot 2H_2O$ (88 mg, 0.4 mmol) and $NaBF_4$ (44 mg, 0. 4 mmol). Yield: 96 mg (52%). MS (+veFAB): *m/z*: 732 (100%) $[Zn_2L3(OAc)]^+$, 692 (17%) $[Zn_2L^3(OH)]^+$. IR (KBr disc, ν (cm^{-1})): 1608($C{=}N_{pyr}$), 1581(C=C–Ar), 1565(ν_{as}OAc), 1446(ν_sOAc), 1059(BF_4). *Anal*. Calc. for $C_{38}H_{48}BF_4N_5O_8Zn_2$: C, 49.5; H, 5.4; N, 7.6. Found: C, 49.2; H, 5.2; N, 7.7%.

The bulk sample of $[Zn_2L^3(OAc)(OH_2)](ClO_4)\cdot 2MeOH\cdot H_2O$ (**2**) was prepared from H_2L^3 (347 mg, 0.6 mmol), $Zn(OAc)_2\cdot 2H_2O$ (275 mg, 1.2 mmol) and $NaClO_4$ (176 mg, 1.2 mmol). Yield: 352 mg (63%). MS (+veFAB): *m/z*: 732 (100%) $[Zn_2L3(OAc)]^+$. IR (KBr disc, ν (cm^{-1})): 1608($C{=}N_{pyr}$), 1582(C=C–Ar), 1569(ν_{as}OAc), 1432(ν_sOAc). *Anal*. Calc. for $C_{38}H_{48}ClN_5O_{12}Zn_2$: C, 48.9; H, 5.2; N, 7.5. Found: C, 48.2; H, 5.0; N, 7.8%.).

The bulk sample of $[Zn_2L^3(OAc)(OH_2)](PF_6)\cdot MeOH\cdot 2H_2O$ (**3**) was prepared from H_2L3 (119 mg, 0.22 mmol), $Zn(OAc)_2\cdot 2H_2O$ (97 mg, 0.44 mmol) and KPF_6 (81 mg, 0. 44 mmol). Yield: 135 mg (64%). MS (+veFAB): *m/z*: 732 (24%) $[Zn_2L3(OAc)]^+$, 692 (25%) $[Zn_2L3(OH)]^+$. IR (KBr disc, ν (cm^{-1}))): 1609($C{=}N_{pyr}$), 1582(C=C–Ar), 1568(ν_{as}OAc), 1446(ν_sOAc). *Anal*. Calc. for $C_{37}H_{47}F_6N_5O_8PZn_2$: C, 46.0; H, 4.9; N, 7.3. Found: C, 45.8; H, 4.9; N, 7.2%.

2.3. X-ray crystallography

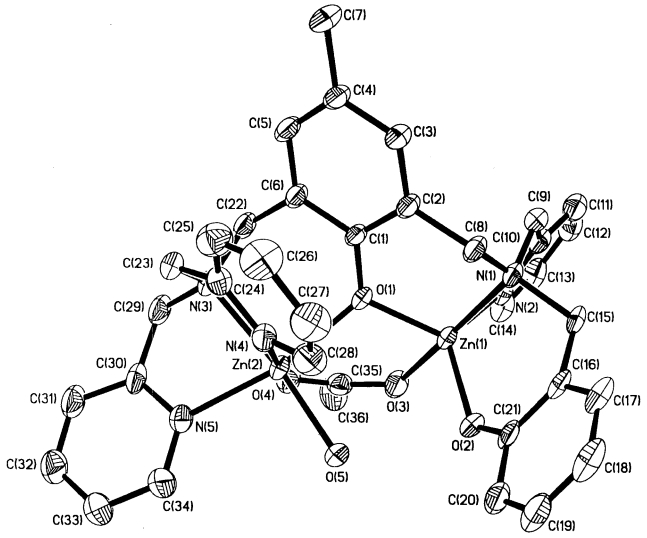
Crystal data: $C_{38}H_{48}BF_4N_5O_8Zn_2$: $M = 920.36$. Crystallises from CH_3OH as colourless blocks; crystal dimensions $0.24\times0.24\times0.10$ mm. Triclinic, space group $P\bar{1}$, $a = 10.9887(13)$, $b = 13.1778(16)$, $c = 15.7302(19)$ Å, $\alpha = 67.418(2)^\circ$, $\beta = 77.199(2)^\circ$, $\gamma = 83.622(2)^\circ$. $U = 2050.1(4)$ $Å^3$, $Z = 2$, $D_{calc} = 1.491$ Mg m^{-3}, Mo Kα radiation ($\lambda = 0.71073$ Å), μ(Mo Kα) = 1.245 mm^{-1}, $F(000) = 952$. Data collected were measured on a Bruker Smart CCD area detector with an Oxford Cryosystems low temperature system at 150 K. Cell parameters were refined from the setting angles of 72 reflections (θ range 1.43°–28.34°). Reflections were measured from a hemisphere of data collected of frames each covering 0.3° in omega. Of the 13 000 reflections measured, all of which were corrected for Lorentz and polarisation effects and for absorption by semi empirical methods based on symmetry-equivalent and repeated reflections (minimum and maximum transmission coefficients 0.7544 and 0.8856), 7283 independent reflections exceeded the significance level $|F|/\sigma(|F|) > 4.0$. The structure was solved by direct methods and refined by full matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model (including torsional freedom for methyl groups) and with U_{iso} constrained to be 1.2 (1.5 for methyl groups) times U_{eq} of the carrier atom. Refinement converged at a final $R_1 = 0.0529$ ($wR_2 = 0.1531$, for all 9274 data, 525 parameters, mean and maximum δ/σ 0.000, 0.000) with allowance for the thermal anisotropy of all non-hydrogen atoms. Minimum and maximum final electron density: −1.096 and 1.108 e $Å^{-3}$. A weighting scheme $w = 1/[\sigma^2(F_o^2)+(0.1000P)^2+0.00P]$ where $P = (F_o^2+2F_c^2)/3$ was used in the latter stages of refinement. Complex scattering factors were taken from the program package SHELXTL as implemented on the Viglen Pentium computer [5].

3. Results and discussion

H_2L^3 was synthesised by the method of Neves et al. [4] and reacted with zinc(II) acetate in methanol. The

dizinc(II) complexes $[Zn_2L^3(OAc)(OH_2)](BF_4)\cdot 2MeOH\cdot H_2O$ (**1**), $[Zn_2L^3(OAc)(OH_2)](ClO_4)\cdot 2MeOH\cdot H_2O$ (**2**) and $[Zn_2L^3(OAc)(OH_2)](PF_6)\cdot MeOH\cdot 2H_2O$ (**3**) were isolated after metathesis with the appropriate alkali metal salt. Colourless crystals of **1** and **2** suitable for X-ray structural determination were obtained on standing. The MS of all the complexes showed peaks at $m/z = 732$ affirming the presence of the dinuclear core $[Zn_2L^3(OAc)]^+$ and those of complexes **1** and **3** showed further peaks at $m/z = 692$ indicating the presence of $[Zn_2L^3(OH)]$. In the IR spectra the difference between the absorption bands for $\nu_{asym}(OAc)$ and $\nu_{sym}(OAc)$ is in the range 119–137cm^{-1} suggesting the presence of an acetato-bridge in all of the complexes [6].

The molecular structure of the monocation from **1** [**A**], is shown in Fig. 1 with selected bond lengths and angles given in the caption to the figure. The structure shows that the complex is donor atom, geometry and co-ordination number asymmetric with one five-co-ordinate zinc atom [Zn(1)] and one six-co-ordinate Zn atom [Zn(2)]. There is an endogenous cresolato bridge and an exogenous *syn–syn* acetato bridge at the dinuclear centre and a water molecule is co-ordinated to Zn(2). Two molecules of methanol and one of water are also present in the structure.



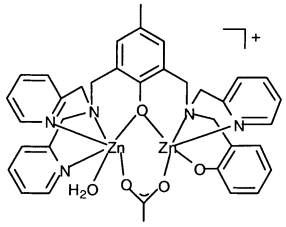


Fig. 1. ORTEP drawing of the molecular structure of the monocation from **1**, $[Zn_2L3(OAc)(OH_2)]^+$. Thermal ellipsoids for the non-hydrogen atoms are drawn at the 50% probability level. Selected bond lengths and angles at the zinc(II) atom. Zn(1)–O(1), 1.975(2); Zn(1)–O(2), 1.971(2); Zn(1)–O(3), 2.034(2); Zn(1)–N(1), 2.164(2); Zn(1)–N(2), 2.069(3); Zn(2)–O(1), 2.103 (2); Zn(2)–O(4), 2.077(2); Zn(2)–O(5), 2.063(2); Zn(2)–N(3), 2.179(2); Zn(2)–N(4), 2.158(3); Zn(2)–N(5), 2.176(3); Zn(1)–Zn(2), 3.4260(6) Å. N(1)–Zn(1)–O(3), 170.28(9)°; O(1)–Zn(1)–N(2), 123.66(9)°; N(2)–Zn(1)–O(2), 125.42(9)°; O(2)–Zn(1)–O(1), 110.64(9)°; Zn(1)–O(1)–Zn(2), 114.25(9)°; N(4)–Zn(2)–O(4), 171.16(9)°; O(1)–Zn(2)–N(5), 166.25(9)°; O(5)–Zn(2)–N(3), 168.43(10)°; O(1)–Zn(2)–O(5), 97.16(8)°; O(5)–Zn(2)–N(5), 96.45(9)°; N(3)–Zn(2)–N(5), 77.11(10)°; N(3)–Zn(1)–O(1), 89.79(9)°.

[A]

Zn(1) is five-co-ordinate with an N_2O_3 co-ordination environment provided by the bridging cresolato-O and acetato-O donor atoms [O(1) and O(3)], a pendant phenolato-O donor atom [O(2)], an articular tertiary aminic-N atom [N(1)] and a pendant pyridinyl-N atom [(N2)]. The degree of trigonality (τ) at Zn(1) is 0.75 and represents a distorted trigonal bipyramidal co-ordination geometry [a perfect geometry has $\tau = 1$ and a perfect square pyramidal geometry has $\tau = 0$] [7]. The cresolato bridge is non-symmetric [Zn(1)–O(1), 1.97; Zn(2)–O(1), 2.10 Å] as is the acetato bridge [Zn(1)–O(3), 2.03; Zn(2)–O(4), 2.08 Å]. The largest angle at Zn(1) is O(3)–Zn(1)–N(1), 170.3°, indicating that a bridging acetato-O atom and the articular aminic-N atom occupy the axial positions. The Zn–N_{pyr} interaction (2.07 Å) is shorter than the The Zn–N_{amine} interaction (2.16 Å). The distribution of bond lengths and angles at Zn(1) is closely similar to that reported for the corresponding Zn atom in the complex $[Zn_2L^2(OAc)(OH_2)]\cdot CH_3CO_2H$ (**4**) derived from the symmetric compartmental ligand H_3L^2 which has pairs of pendant pyridyl and phenolic pendant arms providing two N_2O_2 donor sets [3]. The τ value for the polyhedron at Zn(1) in **4** is 0.63 indicating a larger distortion from ideal geometry than that found in **1**.

Zn(2) is in a distorted octahedral geometry with an N_3O_3 donor set derived from the bridging cresolato-O and acetato-O donor atoms [O(1) and O(4)], an articular tertiary aminic-N atom [N(3)], two pendant pyridinyl-N atoms [N(4) and N(5)] and the O-atom [O(1W)] The three *trans*-axial angles at Zn(2) are 171.2° [O(4)–Zn(2)–N(4)], 166.3° [O(1)–Zn(2)–N(5)], and 168.4° [N(3)–Zn(2)–O(5)]. The co-ordinated water molecule is bound *trans*- to the articular tertiary amine N-atom as was found for the N_2O_4 donor set at the corresponding Zn atom in complex **4** [3]. The Zn–O distances at Zn(2) average 2.08 Å and the Zn–N distances at this Zn atom average 2.17 Å, both are slightly longer than the corresponding distances at Zn(1).

Fig. 2 presents a schematic comparison of the (μ-cresolato)(μ-acetato) cores in complexes **1**, **2** and **4** and clearly shows the similarity between them. In each complex the cresolato bridge is non-symmetric with the acetato bridge being more symmetric. The inter-metallic separations [Zn(1)···Zn(2)] are closely similar being 3.43 (**1**); 3.40 (**2**) and 3.41 Å (**4**).

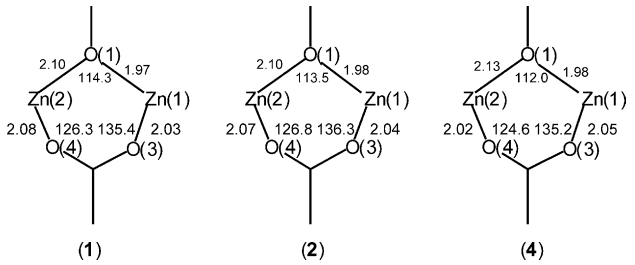

Fig. 2. Comparison of the (μ-cresolato)(μ-acetato) cores in complexes **1**, **2** and **4** (bond lengths are given in Å and bond angles in °).

The crystal structure of complex **2** was also solved. The structure and dimensions of the cation $[Zn_2\mathbf{L}3(OAc)(OH_2)]^+$ were closely similar to those for the cation from **1** and so the crystallographic data has been deposited electronically [8]. No crystals suitable for X-ray analysis were obtained for complex **3** but it is likely the cation in this structure will closely resemble those in complexes **1** and **3**.

4. Conclusions

The formation of co-ordination number asymmetric dinuclear zinc(II) complexes of the unsymmetrical compartmental proligand $H_2\mathbf{L}^3$ follows the reaction pattern observed for dinuclear zinc(II) complexes of the symmetrical proligands $H\mathbf{L}^1$ and $H_3\mathbf{L}^2$. It is interesting to note that the co-ordinated water molecule in complexes **1** and **2** is bound at the Zn atom that resides in the nitrogen-rich binding compartment. This parallels the bound water molecule found at catalytic Zn sites in hydrolytic enzymes where the most common donor is the imidazole N-atom from histidine residues [9]. Although the asymmetric complexes above have the necessary features-a bound, and, therefore, polarisable, water molecule at one zinc atom adjacent to an available co-ordination site at the second zinc [10] to serve as plausible models for hydrolytic enzymes study of this property has been hindered by the relative insolubilities of the complexes after isolation. The most efficient solvent for dissolution is DMSO and as this is a strongly co-ordinating solvent it is likely that the solvent would co-ordinate to the metal at the expense of the water and could also block the vacant co-ordination site at the second zinc atom. Both of these events would severely affect the course of any hydrolysis of substrate, such as phosphate esters and would not necessarily be directly relevant to enzymatic activity, which occurs in aqueous media. If is, therefore, essential that the complexes should be made more soluble in aqueous media and to that end it is suggested that the attachment of polar groups, such as sulphonate, to the ligand perifery should facilitate the solubility of the complexes in aqueous media [11] and permit kinetic studies to be carried out under more enzymatic conditions.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre CCDC No. 173827 [complex **1**]. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: (internat.) +44-1223-336033; e-mail: deposit@ccda.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We thank the BBSRC for a studentship (to D.B.) and the EPSRC for funds towards the purchase of the diffractometer.

$[Cu(DLM)_2(H_2O)_2](ClO_4)_2$ [17], complexes showing the $[M^{II}L_2(H_2O)_2]X_2$ formula display the octahedral cation $[ML_2(H_2O)_2]^{2+}$ in which the ligands are arranged in *trans* positions. In a few compounds, as $[CdL_2(NO_3)_2]$ [14] and halide complexes [15,18,19], the counteranion is coordinated to the metal ion, the relative position of the donor atoms always being *trans*.

Now, the preparation and characterization of a number of perchlorate complex salts with divalent cobalt, nickel, copper, zinc, cadmium and mercury ions are reported. The crystal structures of $[Cu(MLM)_2(H_2O)_2](ClO_4)_2$, $[Zn(MLM)_2(H_2O)_2](ClO_4)_2$ and $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$ have been determined by X-ray diffraction methods. The presence of a hydrogen in N3-position promotes a different H-bond scheme respect to previous perchlorate complex salts with 1,3-dialkyllumazines [13,17].

2. Experimental

2.1. Synthesis

The ligands MLM and MLMD were obtained according to literature procedures [20] and characterized through analysis, ^{1}H NMR and IR spectroscopy [21]. The coordination compounds were prepared by reaction of metal perchlorate and the pteridine ligand (M/L = 2:1) in MeCN (50 ml) heating at 40–50 °C (CAUTION: perchlorate salts are dangerous and must be handled with care), except to Hg/MLM in which the solvent was water. The mixed Cu(II) complex was obtained adding 1 mmol of copper perchlorate to $\frac{1}{2}$ mmol of MLM and MLMD ligands dissolved in MeCN solution (approximately 50 ml). In some cases, after several hours, a solid was obtained and in the others, after standing at room temperature (r.t.) for several days, the solutions gave different solids. Only the complexes $[Cu(MLM)_2(H_2O)_2](ClO_4)_2$, $[Zn(MLM)_2(H_2O)_2](ClO_4)_2$ and $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$ were obtained as single crystals suitable for X-ray diffraction. The solids were filtered off, washed with a small amount of EtOH and Et_2O and air-dried.

Analytical data were as follows (%): $Co(ClO_4)_2(MLM)_2\cdot 2H_2O$ (orange): *Anal.* Found: C, 26.05; H, 2.61; N, 18.00. 2.2. Instrumentation

Microanalyses of C, H and N were performed in the Fisons-Instruments EA-1008; the water content of the complexes was determined from the TG plot. TG and DSC studies were carried out under pure air on a SHIMADZU system (TGA-50 thermobalance and DSC-50 differential scanning calorimeter) using approximately 5 mg of sample and a 20 °C min^{-1} heating rate in the TG and 10 °C min^{-1} in the DSC plots. Infrared (IR) spectra were measured on a Perkin–Elmer FT-IR 1760-X (KBr pellets, 4000–400 cm^{-1}) and on a Bruker FT-IR VECTOR 22 spectrophotometer (polyethylene pellets, 600–180 cm^{-1}). ^{13}C and ^{1}H NMR spectra were recorded using a Bruker DPX-300 apparatus (DMSO-d_6 solutions). The ESR spectra were obtained in the X-band at r.t. on a Bruker ESP 300E apparatus, with a microwave frequency of 9.79 GHz and a modulation frequency of 100 kHz. Magnetic measurements were carried out on a Manics DSM-8 system between 77 and 290 K. Reflectance diffuse spectra (200–1200 nm) were recorded on a Perkin–Elmer UV–Vis–NIR Lambda-19 machine using a $BaSO_4$ pellet as reference.

2.3. Crystallography

Crystal data and structure refinement details are given in Table 1. Intensity data were measured at 173 K on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71070$ Å). The structure was solved by direct methods using the SHELXTL program package [22]. Refinement was carried out using SHELXL employing full-matrix least-squares methods on F^2. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed in their ideal positions.

3. Results and discussion

3.1. X-ray structural study of the complexes

The $[Cu(MLM)_2(H_2O)_2](ClO_4)_2$ and $[Zn(MLM)_2(H_2O)_2](ClO_4)_2$ complexes are isostructural; the molecular unit of Zn/MLM complex with numbering scheme is shown in Fig. 1. Selected bond distances and angles are listed in Table 2. It is readily seen that both complex salts are primarily ionic in nature, consisting on $[ML_2(H_2O)_2]^{2+}$ cations and perchlorate anions. Both metal ions are encircled by six donating centres. Four of these atoms are two N5 and two O4 atoms from the bidentate lumazine derivative ligands, which are linked to the metal ion as usual, producing two chelate rings of five members. The coordination sphere is completed by

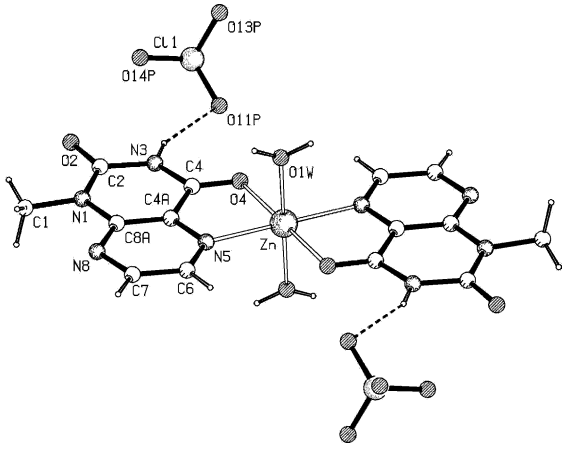

Fig. 1. Molecular unit and numbering scheme of $[Zn(MLM)_2(H_2O)_2](ClO_4)_2$.

Table 2

two water molecules directly bonding to the metal centre.

The six-coordinated copper ion is equatorially bonded to two N5 atoms of MLM ligands and two water oxygens and axially bonded to two O4 MLM atoms. The coordination geometry around the copper ion can be described as an elongated tetragonal octahedral of the CuN_2O_4 chromophore with the tetragonality of 0.91. The observed distortions are due to the Jahn–Teller effect. The complex $[Zn(MLM)_2(H_2O)_2](ClO_4)_2$ exhibits a roughly regular octahedral geometry in which the Zn–N and Zn–O distances (see Table 2) are not significantly different to each other, ranging from 2.115(1) to 2.122(1) Å.

In the Cu/MLM and Zn/MLM complexes, the O4–M–N5 bite angle of the lumazine derivative ligands is similar (see Table 2) and the normalized *bite* is approximately 1.29. Following Kepert [23], the bidentate ligands that form five-membered chelate rings and have relatively large normalized bites ($b \sim 1.2$–1.5) normally form undistorted *trans* structures, like is a familiar pattern in this kind of complexes [12–19].

The bonding parameters for the organic ligands are very close to those found for previously reported bidentate lumazine derivatives [10–19]. The C2–O2 distances are a little shorter than that of C4–O4 because of the involvement of the O4 atom in the coordination. The angle between pyrazine and pyrimidine rings is 1.9° (Cu/MLM) and 1.5° (Zn/MLM), so the lumazine ligands are roughly planar. The greatest deviations from the mean plane in the lumazine derivative occur in the N1 for the endocyclic atom and in the C1 for the exocyclic ones. Each organic ligand and the five-membered chelate ring are quasi-coplanar because the least-squares plane defined by the pteridine skeleton and the chelate rings (M–O4–C4–C4A–N5) define acute angles of 0.7° and 0.5° in the Cu/MLM and Zn/MLM, respectively. Pteridine moieties are parallel but not coplanar being distanced by 0.050 (Cu/MLM) and 0.022 Å (Zn/MLM) to each other.

The geometrical data of hydrogen bonds in the Cu/MLM and Zn/MLM complexes are summarized in Table 3 and a stereoview of the copper complex is shown in Fig. 2. In both complexes, a three-dimensional network is produced by two OW–H···O(ClO_4^-) hydrogen bonds and N3–H3···O(ClO_4^-) ones. The disordered perchlorate anions are located between zig-zag layers of the complexes and are hydrogen bonded to either the water molecules or to the N3 atom of lumazine ligands, as shown in Fig. 2.

In Fig. 3, the molecular drawing and numbering scheme for the monomeric unit of $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$ is shown and in Table 4, selected bond distances and angles are given. This complex differs from related complexes [14,17] because it contains two different lumazine derivatives and one

acetonitrile molecule directly linked to the metal ion. Both lumazine ligands are bonded to the copper ion through the N5 and O4 atoms.

As it is shown in Fig. 3, the metal ion is surrounded at distances of approximately 2.0 Å by two N5 atoms from

pteridine ligands in a *trans* arrangement, a water molecule and the N-coordinated acetonitrile defining a regular square-plane. In addition to these, in a roughly perpendicular tetragonal axis, two O4 atoms from lumazine ligands are placed at distances-to-metal very different to each other and the four square-plane donor atoms. The apical Cu–O42 and Cu–O41 distances are significantly different with $\Delta O_{42,41} = 0.265$ Å. The ratio between apical and equatorial bond lengths is 1.21, which is smaller than that needed (≥ 1.4) to force a square-planar complex [23].

The larger Cu–O41 distance (2.293(3) Å), if compared with the Cu–L bond lengths in the equatorial plane, must be attributed to the Jahn–Teller effect whereas the larger Cu–O42 distance (2.558(3) Å) must be due, in addition to the Jahn–Teller effect, to the O42 atom cannot be involved in direct bonding along the z-axis, but is close enough to the z direction to involve at least some weak or semi-coordination of the O42 atom to the Cu(II) ion. Consequently, the stereochemistry of the Cu/MLM/MLMD complex should not be considered to involve a five coordination, but six-coordinate elongated octahedral with a 4+1+1* -type coordination [24,25]. If the weak interaction between Cu(II) and O42 is not considered, the copper centre displays a slightly distorted square-pyramidal stereochemistry ($\tau = 0.03$) [26], with atoms N51, N52, N1D and O1W arranged in the basal plane.

The effect of both electronic and steric hindrances of the ligands can be seen in the opening of the L–M–L angles of the respective metallocyclic rings. The five-membered chelate rings, with an angle type O–M–N, have values of 73.1(1)° in the MLM and 78.7(1)° to MLMD ligand. The chelate rings are roughly coplanar (4.4°) and the greatest deviations from the mean plane of the pteridine ligands are in the O2 in both ligands for the exocyclic atoms and C2 (MLM) and N1 (MLMD) for the endocyclic ones.

The Cu–N1D–C2D bond angle 177.5(3)° is slightly distorted from the expected value for a sp hybridised nitrogen atom (180°). The N1D–C2D bond lengths of 1.13(5) Å compare well with the literature values [27] for coordinated acetonitrile and are a little shorter than the value found for the free acetonitrile 1.157 Å.

The monomeric units are connected through the N–H···O and O–H···O hydrogen bonds (see Table 5) in a similar way than the above mentioned Cu(II) and Zn(II) complexes, in which one perchlorate anion is bonded to the N31 and the water molecules and the other is not involved in the hydrogen bonds network. In addition to the N3–H···O(ClO_4^-) hydrogen bond, the crystal structure is packed via the strong involvement of the coordinated water molecule in the H-bond scheme, since it is linked with two perchlorate anions and the O2 oxygen from MLMD moiety through a bifurcated hydrogen bond in which the D–H···A angle (109°) is too smaller than the other ones (approximately 180°). The hydrogen bonds generate two-dimensional networks which are packed by van der Waals interactions following the a-axis as it is shown in Fig. 4.

3.2. Thermal and spectral studies

The study of the thermal decomposition of these compounds in air has been carried out from their TG and DSC plots. These indicate the water molecules are lost in only one clearly defined step in the TG plot, but, in most cases, the corresponding endothermic effect in the DSC plot is splitted, indicating the non-equivalence of all water molecules. In all cases, the weight losses agree well with those expected for the elimination of solvent molecules. The dehydrated intermediates are stable at temperatures up to 300 °C. At this point, an abrupt weight loss occurs as consequence of the

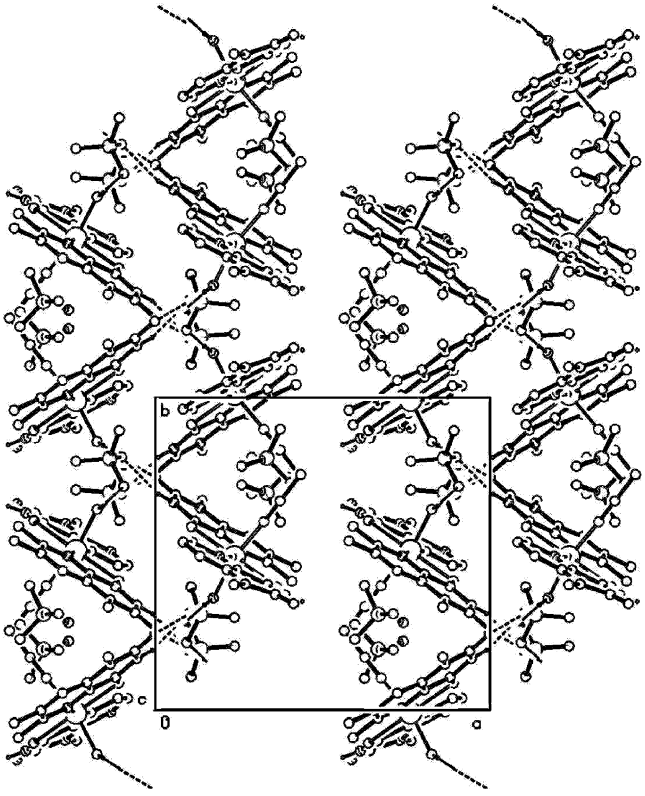

Fig. 4. Packing scheme of the hydrogen-bonded network in the complex $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$ viewed down the [0 0 1] direction. Hydrogen atoms of methyl groups are omitted for clarity.

combustion of the organic matter and the sharp decomposition of perchlorate anions. The pyrolysis finishes at 400 °C, leaving as final residue the corresponding oxides, as it has been corroborated from the corresponding IR spectrum, but it was not possible to calculate the experimental total weight loss because there are material losses from the crucible.

In the 3500–2800 cm^{-1} region, the IR spectra show the ν(O–H), ν(N–H) and ν(C–H) bands. The $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$ complex shows a weak ν(C≡N) band at 2330 cm^{-1} due to the presence of coordinated acetonitrile [28] which is shifted to upper wavenumber with respect its position in the free acetonitrile (2255 cm^{-1}), this shift is consistent with the shortening in the C≡N distance upon coordination.

The bands assignable to the C=C, C=N and C=O stretching vibrations are shifted respect to their position in the spectra of uncoordinated MLM and MLMD. The vibrational activity of carbonyl groups is coupled and appears as two bands. The higher (1700–1730 cm^{-1}) is mainly due to ν(C2=O) and the other one (1650–1680 cm^{-1}) must be assigned to ν(C4=O). In all MLM complexes, both bands are strong shifted with respect to their position in the IR spectrum of the free ligand whereas in the MLMD complexes the shifts are weaker. These displacements are due to the different H-bond scheme found in the free MLM and MLMD; thus, in the free MLM, dimeric units are produced via O2···H3–N3 hydrogen bonds, whereas in the MLMD ligand, these H-bonds are established through the O4 atom. Therefore, in the MLMD complexes, the participation of the O4 atom in the coordination sphere induces a weaker shift than in the MLM complexes. The spectra also show a strong ν(Cl–O) band splitted into three peaks between 1150 and 1090 cm^{-1} and the δ(O–Cl–O) band at 626 cm^{-1} assignable to the perchlorate anions [29].

Within experimental error, NMR spectra of zinc, cadmium and mercury complexes display signals at the same values of chemical shift than the free ligands, clearly indicating that these compounds may undergo strong solvolysis. Although, an alternative explanation based on the π-electronic density is unchanged upon coordination cannot be discarded.

The room temperature powder ESR spectra of $[Cu(MLM)_2(H_2O)_2](ClO_4)_2$ and $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$ are axial with $g_{\parallel} \gg g_{\perp} > 2.0$ [24,30]. The g values of Cu/MLM complex are $g_{\parallel} = 2.38$ and $g_{\perp} = 2.09$, corresponding to elongated tetragonal octahedral CuN_2O_4 chromophore and the $d_{x^2-y^2}$ ground state. The G-parameter, calculated from the relation $G = (g_{\parallel} - 2)/(g_{\perp} - 2)$ in the axial-elongated complex Cu/MLM has a value of 4.3. This indicates the absence of interaction between the copper centres in the solid state and a rhombic symmetry with the local tetragonal axes aligned or slightly misaligned, as it is expected from the structural data. In the $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$ complex only the $g_{\perp}$ (2.03) value can be measured that it is consistent with an square-pyramidal coordination sphere around Cu(II) ion and the single unpaired electron is located in an essentially $d_{x^2-y^2}$ orbital. In the $Cu(MLMD)_2(ClO_4)_2 \cdot 3H_2O$ complex, the ESR spectrum at room temperature is apparently isotropic with g_i of 2.17 value.

The electronic reflectance spectra (see Table 6) of the Co(II) complexes show two d–d bands assignable to the transitions $^4T_{2g}(F) \leftarrow {}^4T_{1g}$ and $^4T_{1g}(P) \leftarrow {}^4T_{1g}$ in a d^7 (high spin) system in octahedral symmetry. The transition $^4A_{2g}(F) \leftarrow {}^4T_{1g}$ value has been calculated by means of the algebraic Dou's method [31]. The transitions bands, B and Δ_o values are characteristic of Co(II) at the octahedral site. In the Ni(II) complexes, three bands can be observed due to $^3T_{2g}(F) \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow A_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$ transitions typical from octahedral Ni(II) complexes. The values of B are about 55% respect of those for the free ions, indicating there is a high degree of covalence in the metal–ligand bonds [31,32].

The Cu(II) complex spectrum shows a broad and asymmetric band centred at 13 300 (Cu/MLM), 13 800 (Cu/MLMD) and 14 300 cm^{-1} (Cu/MLM/MLMD). This band is typical for distorted octahedral Cu(II) complexes [32]. In each case, the band was deconvoluted

[a] Calculated by means of algebraic method (from Ref. [31]).

into Gaussian component bands in the visible region. Starting from a set of six peaks, computer iteration processes for experimental curves fitting were carried out to minimize the standard deviation from the calculated ones, reaching a standard deviation of approximately 0.003 absorbance units. Thus, three peaks for all copper spectra were obtained. In the Cu/MLM (15 000, 13 300 and 11 200 cm^{-1}) and Cu/MLMD (14 600, 11 600 and 9300 cm^{-1}) complexes, these bands are assignable to the transitions between the Jahn–Teller splitted t_{2g} and e_g orbitals [24]. The deconvolution of the spectrum of the Cu/MLM/MLMD complex gives four peaks at 15 300, 13 300, 11 400 and 9100 cm^{-1}, which could be assigned to the four d–d transitions expected for the orbital distribution in a tetragonal 4+1+1* geometry.

The molar susceptibility values at different temperatures for the Co/MLM and Co/MLMD complexes have been successfully fitted to the Curie–Weiss law. Whereas the Co/MLMD displays a Curie's behaviour, in the Co/MLM complex, the θ value (−67(5) K) could indicate a slightly antiferromagnetic interaction. The magnetic moments in the Co(II) complexes are 4.9(3) and 4.52(1) MB in the Co/MLM and Co/MLMD, respectively; these values are quite different from the spin-only value due to the orbital contribution expected in the octahedral d^7 (high spin) systems. The molar susceptibility values at room temperature for the Ni(II) and Cu(II) complexes were measured. In these complexes, where no orbital contribution to the magnetic moment must be expected, the μ_{eff} values measured differ only slightly from the spin-only moment (2.83 and 1.73 MB in Ni(II) and Cu(II) complexes, respectively) and are in accordance with the existence of magnetically dilute monomeric units [33].

4. Supplementary material

Supplementary material including all atomic coordinates, anisotropic displacement parameters for non-hydrogen atoms and all interatomic distances and bond angles have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 181136–181138 for compounds $[Cu(MLM)_2(H_2O)_2](ClO_4)$, $[Zn(MLM)_2(H_2O)_2](ClO_4)$ and $[Cu(MLM)(MLMD)(H_2O)(CH_3CN)](ClO_4)_2$, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1233-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

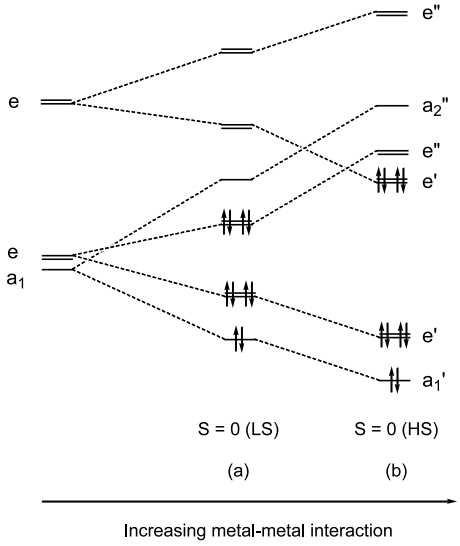
d^5d^5 system $M_2Cl_9^{3-}$ (M = Fe, Ru, Os) to include the heterobimetallic dimers $FeRuCl_9^{3-}$, $FeOsCl_9^{3-}$ and $RuOsCl_9^{3-}$. In addition, we apply methodology developed previously in the context of d^nd^n dimers ($n = 1$–3) to assess trends in metal–metal bonding in terms of three fundamental electronic factors, ligand field splitting, spin polarization energy and overlap of the metal orbitals.

2. Computational details

All calculations described in this work were performed on Linux-based Pentium III computers using the 1999 release of the AMSTERDAM DENSITY FUNCTIONAL (ADF) program developed by Baerends et al. [4]. The local density approximation to the exchange potential was used, along with the correlation potential of Vosko, Wilk and Nusair [5]. The LDA was used throughout as previous work has shown that incorporation of non-local corrections to the exchange-correlation potential leads to generally poorer agreement with experiment, particularly in relation to metal–metal distances [1c]. A double-ζ Slater type orbital basis set extended with a single d-polarization function was used to describe the chlorine atoms, while all metals were modeled with triple-ζ basis sets. Electrons in orbitals up to and including 2p {Cl}, 3p {Fe}, 4p {Ru,}, 5p {Os} were treated in accordance with the frozen-core approximation. Geometries were fully optimized using the algorithm of Versluis and Ziegler [6]. Calculations for the LS $S = 0$, 1 and HS $S = 0$, 5 states, were performed in a spin-unrestricted manner using D_{3h} (homobimetallic) or C_{3v} (heterobimetallic) nuclear symmetry of the molecule. In the BS calculations, all symmetry elements connecting the two metal centers were removed, resulting in overall C_{3v} point group symmetry. In addition, an asymmetry in the initial spin density was introduced using the modifystartpotential key. Potential energy curves for the BS and other spin states were generated by freezing the metal–metal separation and optimizing all other structural parameters independently.

3. Results and discussion



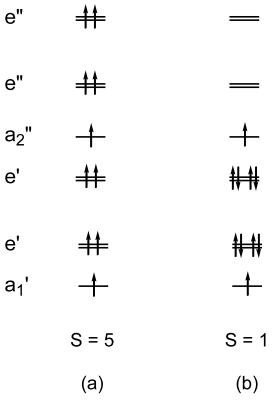
3.1. Modes of electronic coupling in $M_2Cl_9^{3-}$ dimer complexes

In this section, we first present a qualitative description of the various possible coupling schemes for two d^5 metal ions in a confacial array, and establish appropriate single determinant wavefunctions to describe the electronic states involved. The calculated energies of these states are then compared for the homo- ($Fe_2Cl_9^{3-}$, $Ru_2Cl_9^{3-}$ and $Os_2Cl_9^{3-}$) and heterobimetallic ($FeRuCl_9^{3-}$, $FeOsCl_9^{3-}$ and $RuOsCl_9^{3-}$) species. The latter offer an additional degree of complexity, as it is possible for the two metal ions to be in different single-ion spin states ($S = 5/2$ or $S = 1/2$). The various dimer states for the homobimetallic systems have been described elsewhere, but a systematic description is justified here to provide a framework for the subsequent description of dimer states for the heterobimetallic species.

3.2. Homobimetallic dimers

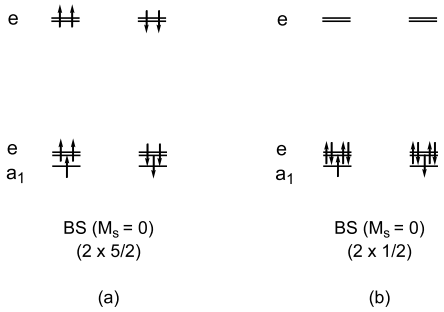
3.2.1. Strongly coupled limit

Where all electrons are delocalized over both sides of the molecule, the metal-based orbitals split as shown in Scheme 1. The local C_{3v} symmetry splits the t_{2g} orbitals on each metal center into a_1 and e subsets having, respectively, σ and δ_π ($^1/_3\pi + {}^2/_3\delta$) symmetry relative to the metal–metal axis. The e_g orbitals do not split and transform as another e subset with $^2/_3\pi + {}^1/_3\delta$ symmetry, denoted π_δ. In a D_{3h}-symmetric confacial array, the t_{2g} orbitals form metal–metal bonding and antibonding molecular-orbitals of $a_1'(\sigma)$, $e'(\delta_\pi)$, $e''(\delta_\pi^*)$ and $a_2''(\sigma^*)$ symmetry, while the higher lying e levels form $e'(\pi_\delta)$ and $e''(\pi_\delta^*)$ bonding and antibonding combinations. Depending on the relative magnitude of the ligand-field splitting and the metal–metal interaction it is possible, in principle, to identify two limiting situations. If the metal–metal interaction is relatively weak, the occupied orbitals (*) bonding and antibonding combinations. Depending on the relative magnitude of the ligand-field splitting and the metal–metal interaction it is possible, in principle, to identify two limiting situations. If the metal–metal interaction is relatively weak, the occupied orbitals (a_1', e' and e'') all originate from the t_{2g} subshell, and the metal–metal bond order is 1. To emphasize its



Scheme 1.

descent from the LS configuration of the single ion, it is denoted $S = 0$ (LS) (Scheme 1(a)). In contrast, if the metal–metal interaction is very strong, the metal–metal bonding π_δ orbital may fall below δ_π^*, resulting in a formal metal–metal bond order of 5. This state is denoted $S = 0$ (HS) (Scheme 1(b)) to emphasize the fact that it correlates with a HS single ion configuration.

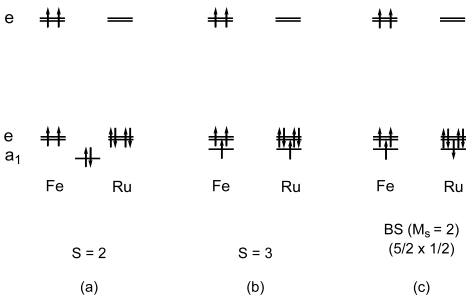


3.2.2. Weakly-coupled limit

In the limit of weak coupling between the single ions, the metal-based electrons remain localized on opposite sides of the dimer. Coupling of two $S = 5/2$ single ions gives rise to dimer states with total spin $S = 5$, 4, 3, 2, 1 and 0, while two $S = 1/2$ single ions combine to give dimer states with $S = 1$ and 0. Only the states with maximum multiplicity for each coupling mode ($S = 5$ and $S = 1$, respectively) can be described by single determinant wavefunctions (see Scheme 2(a) and (b)). In the $S = 1$ case, the determinant with the unpaired electrons in the a_1' and a_2'' orbitals is used because it correlates directly with the M–M σ bonded configuration in the delocalized limit.

In contrast, the singlet state arising from coupling of two $S = 1/2$ single ions is properly described by a linear combination of two single determinant wavefunctions, while its counterpart from coupling of two $S = 5/2$ ions requires a total of 252 single determinants. It has, however, been shown that in either case, a single-determinant BS wavefunction of the type shown in Scheme 3 provides a close approximation, in energetic terms, to the true singlet antiferromagnetic states [3]. To emphasize the fact that this BS wavefunction is an eigenfunction of $\boldsymbol{S_z}$ but not of $\boldsymbol{S^2}$, and, therefore, does not represent a pure singlet spin state, it is denoted BS ($M_s = 0$). Whilst it is possible to obtain an estimate of the true singlet energy by spin projection, we have shown in related cases that the difference between this and BS ($M_s = 0$), in the limit of weak coupling, is not large [1]. In this study, where the emphasis is on qualitative trends, no attempt has, therefore, been made to obtain spin-projected energies. In the context

Scheme 2.



Scheme 3.

of this work, the most important point to note is that the BS wavefunctions for both high-spin (Scheme 3(a)) and low-spin (Scheme 3(b)) limits are represented by the same electronic configuration, $a_1^{1/1}e^{2/2}e^{2/2}$ (the numbers on either side of the '/' indicate the number of electrons of α and β spin). As a consequence, the same BS configuration can encompass both weakly coupled high- and low-spin situations. Moreover, it also correlates with both $S = 0$ (HS) and $S = 0$ (LS) in the delocalized limit, and so can also encompass the complete range of metal–metal interactions, from strong to weak coupling. This extreme flexibility provides a powerful tool in investigating changes in metal–metal interaction, allowing us to define a single electronic configuration that can encompass all possible limiting behaviors of the dimer manifold. The flexibility does, however, present a problem, in that it is often difficult to unambiguously define the precise nature of the coupling at any given point on the BS potential energy surface. In this context, the ferromagnetically coupled states of maximum multiplicity (single-determinants) provide, through their energetic proximity to the BS state, a useful indicator of the precise nature of the coupling. Thus, where the $S = 5$ state, which is derived unambiguously from two $S = 5/2$ single ions, lies close to its BS counterpart, then the latter must be formed from antiferromagnetically coupled $S = 5/2$ single ions. Likewise, where the $S = 1$ state lies close to BS state, the latter is formed by antiferromagnetic coupling of two $S = 1/2$ ions.

3.2.3. Heterobimetallic dimers

Where the two metal centers in a heterobimetallic dimers share a common spin state ($S = 5/2$ or $S = 1/2$), the limiting single-determinant wavefunctions are as described above. In the case where one ion is low-spin and the other high-spin, however, a different series of dimer states arises. In the low-spin $S = 1/2$ state, the t_{2g}-based orbital of e symmetry is fully occupied, and, therefore, cannot participate in any magnetic coupling. As a result, the only coupling pathway is through the orbitals of a_1 symmetry, giving rise, in the strongly coupled limit, to a single metal–metal σ bond. In such circumstances, the molecular ground state will be a

Scheme 4.

quintet ($S = 2$), well described by the single determinant wavefunction shown in Scheme 4(a).

In the weakly coupled limit, the coupling of one $S = 5/2$ single ion with one with $S = 1/2$ results in dimer spin states with $S = 3$ and 2. Once again the state of maximum multiplicity is well described by a single determinant, denoted $S = 3$ in Scheme 4(b), but its ferrimagnetic counterpart, $S = 2$, is not. It is, however, possible to construct a BS wavefunction (Scheme 4(c)) that will closely approximate the energy of the true $S = 2$ state. Unlike the broken symmetry states for the symmetric systems, the inequivalence of the single-ion spin states leaves four residual unpaired electrons. The BS wavefunction illustrated in Scheme 4(c) is, therefore, denoted BS ($M_s = 2$) to distinguish it from the BS states in the symmetric systems, BS ($M_s = 0$). Significantly, the $S = 2$ and BS ($M_s = 2$) states share a common electronic configuration in C_{3v} symmetry, and so the latter has the flexibility to describe both strongly and weakly coupled limits, as well as all intermediate situations. In fact, because the two ends of the dimer are now physically different, it is not possible to enforce electron delocalization through the imposition of the full nuclear symmetry, as it was in the homobimetallic cases. Consequently, it is not possible to unambiguously evaluate the energy of the delocalized $S = 2$ case in the same way as it was possible to evaluate $S = 0$ (HS) and $S = 0$ (LS). As a result, only the energy of the BS ($M_s = 2$) state, and not $S = 2$, is reported in subsequent discussions.

In summary, we have identified a number of electronic states, all of which can be adequately represented by a single determinant, that defines the limiting behavior of a dimer containing two d^5 single ions. In species where the ions share a common spin state, we have identified the BS ($M_s = 0$) state, along with its ferromagnetic counterparts $S = 1$ and $S = 5$ as potentially important in the weakly coupled limit, and $S = 0$ (HS) and $S = 0$ (LS) at the strongly coupled limit. Where the spin states differ we have identified two further states, BS ($M_s = 2$) and its ferromagnetic counterpart, $S = 3$. Any one of these states may constitute the global minimum in a given system, and, in the following section, we report energies for each of them for all possible combinations of metals of the iron triad.

Calculated minima for all states described above are listed in Table 2. In our previous detailed analysis of the potential energy curves for $Ru_2Cl_9^{3-}$ and $Os_2Cl_9^{3-}$, [3] we noted that the BS minimum was identical to that in the $S = 0$ (LS) state, indicating that there was no driving force for electron localization, and, therefore, that the dimers were stabilized by a covalent σ bond between the metal ions. The data contained in Table 2 confirm that the situation is very similar in $RuOsCl_9^{3-}$, the preference for LS configurations on both metal centers ensuring that the $S = 0$ (LS) state lies lowest in energy and, analogous to $Ru_2Cl_9^{3-}$ and $Os_2Cl_9^{3-}$, the ground state geometry corresponds to a metal–metal σ bonded structure.

In contrast, the BS minimum for $Fe_2Cl_9^{3-}$ is almost identical, structurally and energetically, with the $S = 5$ state, confirming that the ground state contains weakly antiferromagnetically coupled $S = 5/2$ single ions. In both $FeRuCl_9^{3-}$ and $FeOsCl_9^{3-}$, the most stable state is $S = 3$, indicating that the Fe center retains an $S = 5/2$ single ion state while the heavier metal ions prefer to adopt a low-spin configuration. The BS ($M_s = 2$) is relatively close in energy, confirming the weak coupling between the two metal ions. In contrast, the BS ($M_s = 0$) state, where both ions are forced to adopt the same spin state (either high or low), lies much higher in energy. Moreover, the energy is identical to that of the $S = 0$ (LS) state, rather than $S = 0$ (HS), indicating that the both adopt a LS, rather than HS, state. This observation is consistent with the greater energy required to promote a Ru^{3+} ion from LS to HS than to promote an Fe^{3+} from HS to LS (see later discussion and also reference [3]).

The greater stability of the $S = 3$ state relative to BS ($M_s = 2$) is, at first sight, somewhat surprising, as the half-filled orbitals of a_1 symmetry on each center should provide an effective superexchange pathway, stabilizing the ferrimagnetic BS ($M_s = 2$) state. The origin of this apparent anomaly can be traced to the very strong spin polarization induced on the bridging chloride ligands by the HS Fe^{3+} ion. The occupation of the Fe–Cl σ antibonding orbitals with spin-α electrons, causes a considerable leakage of spin density onto the bridging ligands, resulting in the net destabilization of the spin-β manifold of π-donor orbitals relative to their spin-α counterparts. Donation of π electron density from the bridging ligand into the vacant orbital in the t_{2g} shell of the LS Ru^{3+} ion is, therefore, most effective when the vacancy is also in the spin-β manifold, as the energy separation between donor and acceptor orbitals is then minimized. The spin polarization of the bridging ligands, therefore, favors ferromagnetic coupling, with the result that the $S = 3$ state is the global minimum.

The calculated energies of the various spin states provide us with an overview of the global minimum in each case, and, therefore, of periodic trends in metal–metal bonding. They do not, however, allow us to evaluate the relative importance of metal–metal interactions, ligand-field splitting and spin polarization in dictating these trends. In the following section, we extend a model previously used to analyze the bonding in $d^n d^n$ dimers ($n = 1$–3) [1b,1e] to evaluate the contributions of these three distinct electronic mechanisms. We begin with review of the factors that determine the ground spin states of the octahedral monomers, MCl_6^{3-} [3], where metal–metal interactions are obviously absent. We then extrapolate to the dimer systems, where metal–metal bonding emerges as a perturbation. Much of the following section rests on the definition of appropriate reference states where one or more of the three electronic factors noted above are effectively removed. It is important to emphasize that these reference states are artificial constructs designed to afford insight into the fundamental nature of the bonding, and are not intended to represent any real electronic state of the molecule.

3.2.4. MCl_6^{3-} complexes

The energetic separation of high-spin ($S = 5/2$) and low-spin ($S = 1/2$) states of $FeCl_6^{3-}$, $RuCl_6^{3-}$ and $OsCl_6^{3-}$ is summarized in Table 2. From these data, it is clear that, consistent with experiment, the iron complex adopts a high-spin ground state, while the Ru and Os analogues are low spin. In the closed energy cycle shown in Fig. 1, we define two additional reference states, where the circles indicate that the electrons are of undefined spin (achieved in a computational sense by performing a spin-restricted calculation). The resulting closed cycle illustrates the fact that the nature of the ground state depends on the relative magnitudes of three terms. The ligand-field energy, denoted LFE, takes into account the energy required to promote two electrons from the t_{2g} orbital to e_g, as well as the difference in coulombic repulsion between the LS and HS configurations. The spin-polarization energies for the LS state, SPE(LS), and HS state, SPE(HS) reflect the difference in energy between unrestricted and restricted energies for the same configuration. From the cycle, we can derive the following relationships:

$$\mathrm{LFE} = E_{\mathrm{ref}}(\mathrm{HS}) - E_{\mathrm{ref}}(\mathrm{LS})$$

$$\mathrm{SPE(LS)} = E_{\mathrm{ref}}(\mathrm{LS}) - E(\mathrm{LS})$$

$$\mathrm{SPE(HS)} = E_{\mathrm{ref}}(\mathrm{HS}) - E(\mathrm{HS})$$

where E(LS) and E(HS) are the calculated energies for the d^5 octahedral MCl_6^{3-} LS and HS states, respectively, using spin-unrestricted density functional theory. Based on the above definitions, the position of the LS/HS equilibrium, i.e. the energetic difference between LS and HS configurations, can be expressed as:

$$\Delta E(\mathrm{HS/LS}) = E(\mathrm{HS}) - E(\mathrm{LS})$$
$$= \mathrm{LFE} + \mathrm{SPE(LS)} - \mathrm{SPE(HS)}$$

As written, the position of the HS/LS equilibrium is defined to be a positive quantity when the LS configuration is favored.

The calculated values of LFE, SPE(LS), SPE(HS) are also collected in Table 2 for the hexachloride complexes. The ligand-field term, LFE, follows the trend anticipated on the basis of the greater radial extent of the 4d and 5d orbitals, increasing dramatically by over 40% from Fe to Ru with only a minor increase of approximately 5% from Ru to Os. The opposite trend is observed in both the spin-polarization terms, corresponding to a 40% reduction from Fe to Ru and a further 10% reduction from Ru to Os. For $FeCl_6^{3-}$, the large SPE(HS) term is clearly responsible for maintaining a HS configuration. For $RuCl_6^{3-}$ and $OsCl_6^{3-}$, the lower spin-polarization energies and significantly larger ligand-field terms result in positive values for ΔE(HS/LS) and thus LS ground states. Based on the data given in Table 2, the trend towards LS ground states in the heavier metals is due to approximately equal changes in the spin-polarization and ligand-field energies.

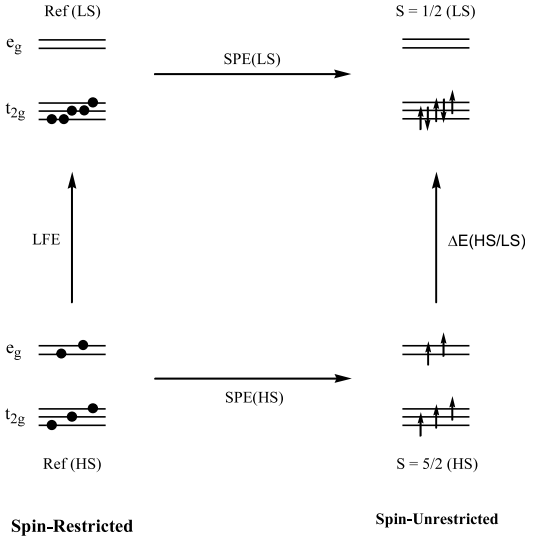


Fig. 1. Closed-energy cycle for HS/LS equilibrium in octahedral d^5 MCl_6^{3-} (M = Fe, Ru, Os) complexes.

3.2.5. Factors effecting electron localization in dimers

In our earlier work involving d^3d^3 dimers, where the single ions are by definition low-spin, we showed that the extent of delocalization of the metal-based electrons is dictated by two terms, namely spin-polarization energy, favoring localization of the metal-based electrons, and the energy associated with metal–metal orbital overlap, favoring delocalization. These two terms are in direct opposition and, therefore, the

position of the localized/delocalized equilibrium depends on their relative magnitudes. The driving force for electron delocalization is determined by the relative energies of the $S = 0$ and $S = S_{max}$ associated states. The depth of the $S = 0$ curve at short metal–metal distances, where the metal-based electrons are delocalized, is a measure of the stabilizing effects of metal–metal orbital overlap. In contrast, the depth of the $S = S_{max}$ curve at large metal–metal distances, where there is the maximum number of unpaired electrons on each metal center, is associated with the stabilizing influence of spin-polarization. Absolute estimates for the energetic contributions of these terms can, however, only be obtained by defining an appropriate reference state, analogous to those shown for MCl_6^{3-}, where both metal–metal bonding and spin polarization were factored out.

For d^5d^5 systems, it is necessary to define two reference states, depicted on the LHS of Figs. 2 and 3, one for low-spin dimer configurations $[(a_1')^1(e')^4(e'')^4(a_2'')^1]$, the other for high-spin $[(a_1')^1(e')^2(e'')^2(a_2'')^1(e')^2(e'')^2]$. In each case, all metal–metal bonding and antibonding orbitals are equally occupied to ensure a formal bond order of zero, and the use of spin-restricted theory ensures that there is no energetic contribution from spin polarization. In the LS case, the ΔE_{ovlp} and ΔE_{spe} terms represent the difference in energy between the LS reference state and the $S = 0$ (LS) and $S = 1$ associated states, respectively. Similarly, for the HS configuration, the ΔE_{ovlp} and ΔE_{spe} terms denote the difference in energy between the HS reference state and the $S = 0$ (HS) and $S = 5$ associated states. In either case, the difference $\Delta E_{ovlp} - \Delta E_{spe}$ quantifies the driving force for delocalization of the metal-based electrons. It only remains then to make a connection between the HS and LS reference states. The dimer ligand field term, ΔE_{LF}, is defined as the difference between the spin-restricted energies of the LS and HS d^5d^5 reference states

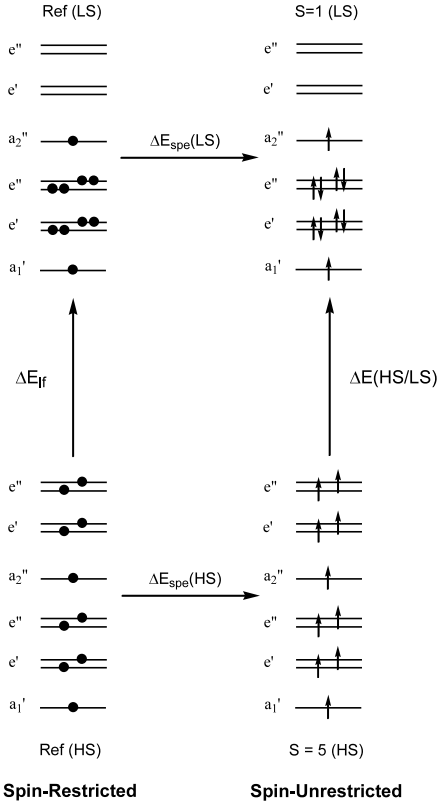

Fig. 2. Closed-energy cycle for the HS/LS equilibrium in d^5d^5 $M_2Cl_9^{3-}$ (M = Fe, Ru, Os) complexes.

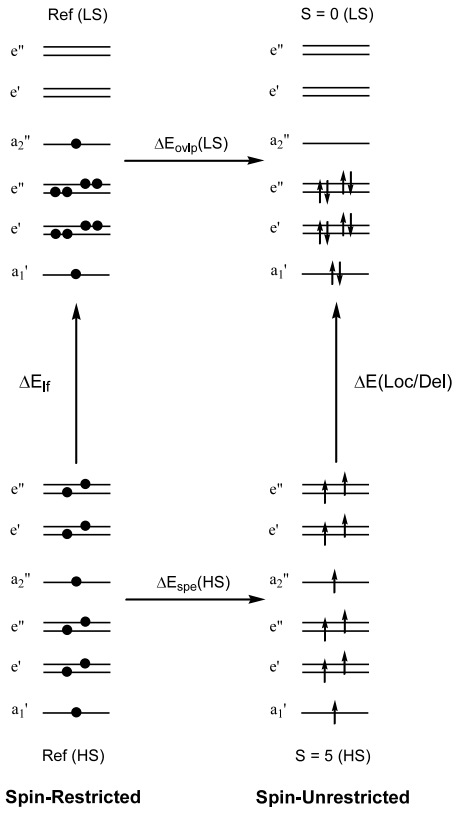

Fig. 3. Closed-energy cycle for the Loc/Del equilibrium in d^5d^5 $M_2Cl_9^{3-}$ (M = Fe, Ru, Os) complexes.

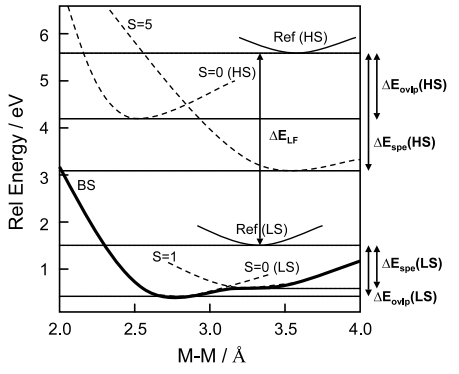

Fig. 4. Schematic representation of the potential energy curves for the BS and $S = 0$ (LS), $S = 1$, $S = 0$ (HS) and $S = 5$ associated states and the energetic terms involved in the HS/LS and Loc/Del equilibria in d^5d^5 $M_2Cl_9^{3-}$ dimers.

and, in the absence of any interaction between the component MCl_6^{3-} fragments, should equal approximately twice the appropriate octahedral ligand field term (Table 2). An appreciation of the energetic terms described above can be gained from Fig. 4 where a schematic representation of the potential energy curves for the LS, HS and reference states are plotted as a function of the metal–metal separation.

The various terms described above, ΔE_{ovlp}, ΔE_{spe} and ΔE_{LF}, along with the difference $\Delta E_{ovlp} - \Delta E_{spe}$, can be simply extracted from the data in Table 1, and are summarized in Table 3 for the LS and HS configurations of all six dimers. For both LS and HS configurations, the progressive reduction in ΔE_{spe} and increase in both ΔE_{ovlp} and ΔE_{LF} going down the group can be rationalized on the basis of the increased dilation of the 4d and 5d metal orbitals relative to 3d. As found in previous studies, the ΔE_{spe} term for the dimer is very close to the sum of the single-ion spin-polarization energies for the constituent metals. A prominent feature of the data given in Table 3 is the large ΔE_{spe} terms compared with ΔE_{ovlp} for the HS complexes. Thus, the $\Delta E_{ovlp} - \Delta E_{spe}$ terms are all negative implying that in the HS state, the metal-based electrons remain strongly localized. In the LS case, the $\Delta E_{ovlp} - \Delta E_{spe}$ terms are much smaller. The negative value for $Fe_2Cl_9^{3-}$ indicates that this complex would prefer to remain localized, even if the Fe^{3+} ions were forced to adopt low-spin configurations. In contrast, the Ru and Os complexes yield positive values for $\Delta E_{ovlp} - \Delta E_{spe}$ corresponding to delocalized electrons and thus metal–metal σ bonded structures.

To quantify both the LS/HS and localized/delocalized equilibria, use is made of the closed-cycle energy diagrams in Figs. 2 and 3 which detail the energetic quantities involved in going from a localized HS ($S = 5$) d^5d^5 dimer to either a localized ($S = 1$) or delocalized ($S = 0$) LS dimer. The alternate energy cycles involving a delocalized HS d^5d^5 dimer are not considered as the data in Table 2 indicate that such a state [$S = 0$ (HS)] is highly unfavorable energetically. On the basis of Fig. 2, the following expression can be written for the energy change, ΔE(HS/LS), associated with conversion from a localized HS to a localized LS d^5d^5 dimer,

$$\Delta E(\mathrm{HS/LS}) = \Delta E_{LF} - \Delta E_{spe}(\mathrm{HS}) + \Delta E_{spe}(\mathrm{LS}) \quad (1)$$

where ΔE(HS/LS) is defined to be positive when a LS localized ground state is favored. In an analogous fashion, the energy change associated with conversion from a localized HS to a delocalized LS d^5d^5 dimer (Fig. 3) can be written as:

$$\Delta E(\mathrm{Loc/Del}) = \Delta E_{LF} - \Delta E_{spe}(\mathrm{HS}) + \Delta E_{ovlp}(\mathrm{LS}) \quad (2)$$

where again ΔE(Loc/Del) is defined to be positive when a LS delocalized ground state is favored. On the basis that Eq. (1) quantifies the tendency to adopt a LS ground state in the absence of any delocalization of the metal-based electrons, it, therefore, defines the pure HS/LS equilibrium of the dimer. Eq. (2) on the other hand, quantifies the influence of metal–metal bonding on the HS to LS transition.

From the data in Table 3, values of ΔE(HS/LS) and ΔE(Loc/Del) can be calculated and are summarized in Table 4. For the Fe complex, both these values are negative indicating that $Fe_2Cl_9^{3-}$ prefers to be HS with the metal-based electrons localized, largely as a consequence of the large spin-polarization energy for this system but also because of a smaller ligand field term. For the Ru and Os analogues and all three heterobimetallic complexes, the calculated values of ΔE(HS/LS) and ΔE(Loc/Del) are positive and, therefore, these complexes are predicted to be LS with the metal-based electrons delocalized in a metal–metal σ bond. The change in ΔE(HS/LS) from $Fe_2Cl_9^{3-}$ to $Ru_2Cl_9^{3-}$ is substantial, just under 4.5 eV, and can be attributed to a 2.74 eV (40%) reduction in spin-polarization energy compared with $Fe_2Cl_9^{3-}$ accompanied by a 1.79 eV (35%) increase in the ligand field energy. An additional but smaller increase in both ΔE(HS/LS) and ΔE(Loc/Del) is observed in passing from $Ru_2Cl_9^{3-}$ to $Os_2Cl_9^{3-}$. This trend is again consistent with the increased radial dilation of the 5d orbitals compared with 4d, which leads to a further reduction in the spin-polarization energy and increases in both orbital overlap and ligand field terms. Not unexpectedly, $FeRuCl_9^{3-}$, $FeOsCl_9^{3-}$ and $RuOsCl_9^{3-}$ are essentially intermediate between their homobimetallic counterparts.

Table 4
High-spin/low-spin and localized/delocalized equilibria data (eV) for d^5d^5 $M_2Cl_9^{3-}$ (M = Fe, Ru, Os) complexes

Complex	ΔE(HS/LS)	ΔE(Loc/Del)
$Fe_2Cl_9^{3-}$	−1.27	−1.58
$Ru_2Cl_9^{3-}$	+3.00	+3.47
$Os_2Cl_9^{3-}$	+3.66	+4.33
$FeRuCl_9^{3-}$	+0.96	+1.00
$FeOsCl_9^{3-}$	+1.20	+1.30
$RuOsCl_9^{3-}$	+3.33	+3.91

In our earlier studies of d^3d^3 $M_2Cl_9^{n-}$ dimers of the Cr and Mn triads, a linear dependence of ΔE_{ovlp} on ΔE_{spe} was observed [1b]. The same trend is also found for the Fe triad. This dependence can be rationalized on the basis that both terms are sensitive to the dilation of the metal-based orbitals. As the orbitals expand going down a group, ΔE_{ovlp} increases due to the greater metal–metal orbital overlap. Conversely, ΔE_{spe} decreases due to the magnetic electrons on each metal being on average further apart. Furthermore, as can be seen from Fig. 5, an almost exact linear relationship is observed between ΔE_{spe}(HS) and ΔE_{LF}. This relationship is analogous to the dependence of ΔE_{ovlp} on ΔE_{spe} in the sense that the ligand-field term is also a measure of the orbital overlap, in this case between the metal-based orbitals and the ligand array.

The interdependence of ΔE_{spe}, ΔE_{ovlp} and ΔE_{LF} and their involvement in the expressions for ΔE(HS/LS) and ΔE(Loc/Del), suggests a possible connection between

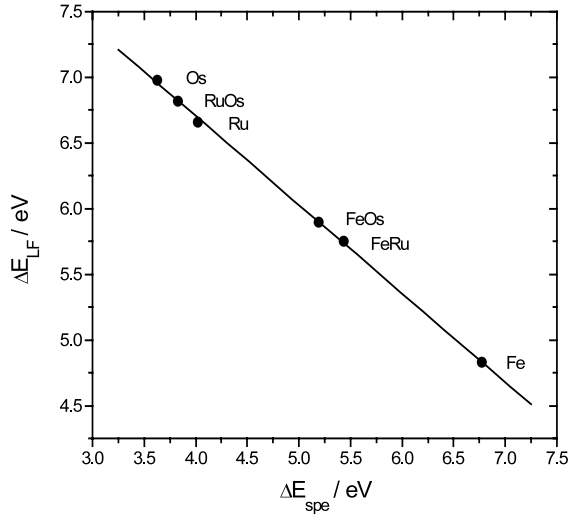

Fig. 5. Plot showing the dependence of the dimer ligand-field energy, ΔE_{lf}, on the spin-polarization energy, ΔE_{spe}, for d^5d^5 $M_2Cl_9^{3-}$ (M = Fe, Ru, Os) complexes.

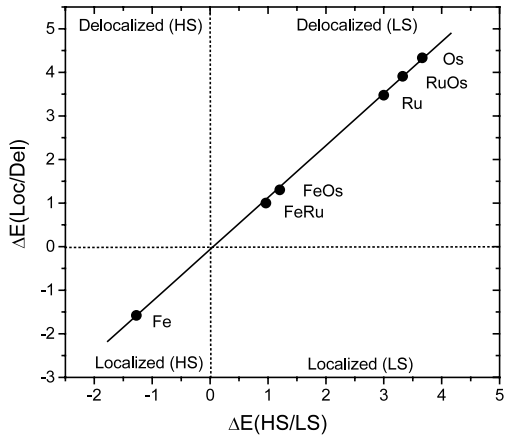

Fig. 6. Plot showing the dependence of the Loc/Del equilibrium, ΔE(Loc/Del), on the HS/LS equilibrium, ΔE(HS/LS), for d^5d^5 $M_2Cl_9^{3-}$ (M = Fe, Ru, Os) complexes.

the HS/LS and localized/delocalized equilibria. Indeed, from Fig. 6, a strong linear correspondence is apparent between these two equilibria with all complexes except $Fe_2Cl_9^{3-}$ falling into the LS-delocalized quadrant. The correlation implies that the onset of metal–metal bonding is intimately linked to the HS/LS crossover in these complexes and that neither delocalized HS or localized LS d^5d^5 dimer structures are likely to occur. Further comment is necessary in relation to the heterobimetallic systems $FeRuCl_9^{3-}$ and $FeOsCl_9^{3-}$. Although these two complexes are located midway between their homobimetallic counterparts, close to the crossover between LS-delocalized and HS-localized regimes, on the basis of Fig. 6, they should still possess LS-delocalized structures. However, as pointed out earlier, our calculations reveal that the global minimum in both complexes corresponds to an intermediate $S = 3$ spin state where the Fe adopts a HS configuration while the Ru or Os centers are LS.

4. Conclusion

The HS/LS and localized/delocalized equilibria in homo- and hetero-bimetallic d^5d^5 face-shared $M_2Cl_9^{3-}$ (M = Fe, Ru, Os) dimers, as defined by the energetic quantities ΔE(HS/LS) and ΔE(Loc/Del), respectively, are found to exhibit a strong linear dependence which can be attributed to their mutual dependence on the single-ion spin-polarization energy. The conclusion drawn from this correlation is that metal–metal bond formation necessitates a crossover from a HS to LS configuration and, therefore, neither delocalized HS or localized LS d^5d^5 structures are likely to occur.

have isolated one solid complex and characterized it by means of elemental analysis, thermal behavior and IR and diffuse reflectance spectroscopies.

2. Experimental

2.1. Reagents and instrumentation

All chemicals were of analytical grade and were used without further purification. Caffeic acid, $VOSO_4 \cdot 5H_2O$ and $VOCl_2 \cdot 2H_2O$ (50% aqueous solution) were purchased from Sigma, Merck and Carlo Erba, respectively.

IR spectra of powdered samples were measured with a Bruker IFS 66 FTIR-spectrophotometer from 4000 to 400 cm^{-1}, using the KBr pellet technique. Electronic absorption spectra were recorded on a Hewlett–Packard 8453 diode-array spectrophotometer, using 1 cm quartz cells. Diffuse reflectance spectra were recorded with a Shimadzu UV-300 instrument, using MgO as an internal standard. Thermogravimetric (TG) and differential thermal analysis (DTA) were performed on a Shimadzu system (models TG-50 and DTA-50, respectively), working in an oxygen flow (50 ml min^{-1}) and at a heating rate of 10 °C min^{-1}. Sample quantities ranged between 10 and 20 mg. Al_2O_3 were used as a DTA standard.

Vanadium contents were determined by atomic absorption, C and H were determined using a Carlo Erba EA 1108 elemental analyzer, and sodium by flame photometry.

2.2. Potentiometric titrations

The EMF measurements were performed with a Schott Gerate TS165 pH meter and the added volumes were measured using a Techware (Sigma) Digitrate (25 ml). Volume of titrated aliquotes was always 25 ml.

$VOSO_4 \cdot 5H_2O$ was used without further purification and dried at 60 °C until constant weight. The 'formula weight' was re-calculated ($VOSO_4 \cdot 4.84\ H_2O$, 250.12) on the basis of a TG analysis before preparing the solutions. NaCl was dried until constant weight and stored over $CaCl_2$ All solutions were made in freshly boiled tridistilled water cooled under a constant flow of nitrogen. The solutions were freshly prepared prior to their use. Diluted solutions of HCl (Merck p.a.) were standardized against TRISMA-base (hydroxymethyl aminomethane). Diluted NaOH solutions were prepared from a saturated NaOH solution and standardized against the HCl. In order to assess the degree of carbonate contamination the Gran's method [11] was used. Cell compartments were kept at 25 ± 0.1 °C with circulating water from a thermostated bath. The ionic strength was fitted at 0.150 M with NaCl in the solutions. The glass electrode was calibrated separately in a solution with known $[H^+]$ before and after each titration.

2.2.1. L^{3-}–H^+ system

Ligand solutions were titrated in the absence of metal to determine the dissociation constant values (pK_a). Two series of titrations were performed in different conditions:

a) Vessel: 5 mM Caf–5 mM H^+; burette: 20 mM NaOH, pH range: 2.3–11.
b) Vessel: 10 mM Caf–40 mM OH^-, burette: 50 mM HCl, pH range: 12–2.1.

2.2.2. VO^{2+}–L^{3-}–H^+ system

In order to determine the formation constants of the VO^{2+}–Caf^{3-}–H^+ system, further titrations of vanadium–ligand solutions were performed in the pH range 2.3–11.3. Different experimental conditions were used:

a) Vessel: 2.5 mM VO^{2+}–5 mM Caf–5 mM H^+; burette: 20 mM and 40 mM NaOH.
b) Vessel: 5 mM VO^{2+}–5 mM Caf–5 mM H^+, burette: 40 mM NaOH.

The formation constants denoted β_{pqr} correspond to the general notation:

$$pM^{2+} + qL^{3-} + rH^+ \rightleftharpoons (M^{2+})_p(L^{3-})_q(H^+)_r$$

A value of $pK_w = 13.76$ (corresponding to $\log \beta_{00-1} = -13.76$) was assumed for the experimental conditions ($T = 298$ K, $I = 150$ mM).

2.3. Synthesis

All the operations were carried out under high-purity dry argon atmosphere and using standard Schlenk techniques.

2.3.1. Sodium caffeate

To a solution of caffeic acid (0.180 g, 0.999 mmol) in methanol (20 ml), sodium methoxide was added until the pH of the solution raised to 8. Addition of toluene in excess gave a solid precipitate, which was filtered, washed with toluene and dried in air. Yield: 82%.

2.3.2. $Na_3[VOCaf(OH)_2] \cdot 3H_2O$

Caffeic acid (0.180 g, 0.999 mmol) was added to a solution of $VOCl_2 \cdot 2H_2O$ (0.348 ml, 1.00 mmol) in water (10 ml). Solid NaOH was added to the solution until a final pH 12 was reached. Absolute ethanol (50 ml) was added to the stirred solution and a green precipitate was formed. It was filtered off, washed with ether and dried under argon atmosphere.

Yield: 65%. *Anal.* Calc. for $C_9H_{13}O_{10}Na_3V$: C, 26.90; H, 3.24; Na, 17.20; V, 12.72. Found: C, 27.10; H, 3.15; Na, 17.30; V, 12.65%.

3. Results

3.1. Potentiometric titrations

Acidity constants for caffeic acid were determined from titrations using pKas values and BEST calculation programs [12]. In the experimental conditions only the first two deprotonation constants ($pK_{a1} = 4.51$, $pK_{a2} = 8.67$) could be calculated. These results are in accordance with the reported data [9]. The third deprotonation constant was optimized using SUPERQUAD program, taking a starting pK_a value of 13.0, according to the literature [9]. The calculated pK_{a3} value was 12.50. On this basis, L^{3-} has been considered as the proper component of the system. To estimate the formation constants of the ternary system VO^{2+}–L^{3-}–H^+ the data collected from two sets of titrations were analyzed with BEST and SUPERQUAD [13].

The usual criteria for this kind of programs (CHI^2 and R values, standard deviations, etc.) were used to select the equilibrium model of speciation. The results were compared with spectroscopic measurements.

In Table 1 the proposed model for the ternary system and the corresponding β values for the species are shown. The species distribution as a function of pH was obtained with SPECIES program and is depicted in Fig. 1.

Calculation also indicates the presence of some VO^{2+} hydrolysis species: $M(OH)_3^-$ ($\log \beta_{10-3} = -17.90$) and $M_2(OH)_5^-$ ($\log \beta_{20-5} = -21.85$). No precipitation of VO^{2+} hydrolysis products was observed during the experiences. A more complete model, including other monomeric and dimmeric complex species (ML_2H_4, ML_2H_2, MLH_2, MLH, ML, M_2L_3) was considered in a first attempt of calculation. Nevertheless, several species have to be excluded to improve the fitting with experimental data.

Table 1
Composition, notation and formation constants (β) for the VO^{2+}–L^{3-}–H^+ system (0.150 M NaCl, 25 °C) [a]

Species	Formula	log β
011	LH	12.50
012	LH_2	21.17
013	LH_3	25.68
110	ML	16.52
11-1	MLH_{-1}	11.10
11-2	MLH_{-2}	0.79
120	ML_2	29.42
320	M_3L_2	39.67
210	M_2L	20.30

[a] In the final calculation log β for vanadium hydrolysis products were −17.90 and −21.85 for MH_{-3} and M_2H_{-5}, respectively.

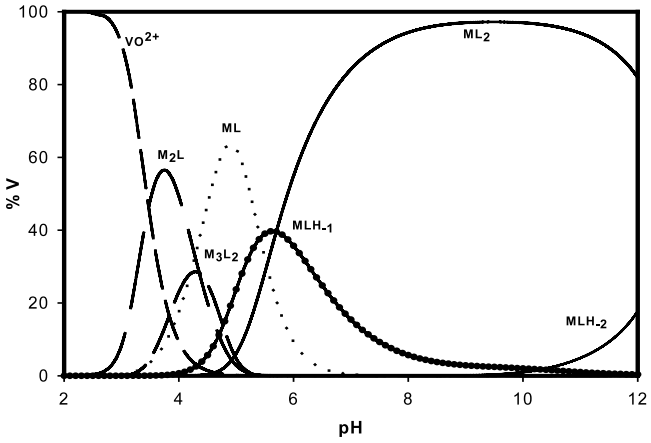

Fig. 1. Species distribution for the vanadyl (IV)–caffeic acid system (2.5/5.0 mM) as a function of pH at 25 °C, $I = 0.150$ M NaCl.

3.2. UV–Vis spectra

The UV–Vis spectrum of the ML_2 species has been calculated on the basis of the spectrum of 4 mM:1 mM L:M solution. In this conditions the species distribution shows a 99.9% of (120) complex at pH 8.3. The resulting bands are located at 800(sh), 728(sh), 620 ($\varepsilon = 168$ M^{-1} cm^{-1}) and 536(sh) nm. Upon consideration of the species distribution model, different solutions with variable total vanadyl concentration, and V:L ratio were prepared at determined pH values. The respective UV–Vis spectra were registered. The percentage of each species present in solution was calculated from the distribution curves and used to estimate the corresponding electronic spectra. The positions of the electronic band maxima of the complexes in solution are listed in Table 2. The extinction coefficient values are not shown because their calculated errors have no statistical significance.

3.3. IR spectrum

Table 3 shows the main characteristic bands of caffeic acid, sodium caffeate and the solid complex. The strong band at 1619 cm^{-1} is assigned to (C=O) stretching of

Table 2
UV–Vis calculated spectra of the VO^{2+}–L^{3-}–H^+ system

Complex	λ (nm)
ML	724, 586
MLH_{-1}	> 820, 716
MLH_{-2}	> 820, 776, 706
ML_2	800(sh), 728(sh), 620, 536(sh)
M_2L	766, 644
M_3L_2	> 800, 722, 524

Table 3
Assignments of some characteristic IR bands (cm^{-1}) of caffeic acid, sodium caffeate and $Na_3[VOCaf(OH)_2]\cdot 3H_2O$

Caffeic acid	Sodium caffeate	$Na_3[VOCaf(OH)_2]\cdot 3H_2O$	Assignments
1644 (vs)	1644 (vs)	1634 (s)	ν(C=C)
1619 (vs)			ν(COOH)
	1572 (vs)	1567 (s)	$\nu_{as}(COO^-)$
1450 (vs)	1444 (vs)	1487 (s)	ν(ring)
	1395 (vs)	1392 (s)	$\nu_s(COO^-)$
1218 (s)	[a]	1260 (s)	ν(CO), phenol
		955 (s)	ν(V=O)

vs: Very strong, s: strong.
[a] Masked.

the –COOH group in the free ligand. In the sodium salt this band disappears and the spectrum shows two new bands located at 1572 cm^{-1} (ν_{as} COO^-) and 1395 cm^{-1} (ν_s COO^-). Similar behavior is observed in the complex spectrum where the bands appear at 1567 and 1392 cm^{-1}, respectively.

The band related to the ring stretching, located at 1450 cm^{-1} (vs) in caffeic acid, remains unaltered in the caffeate anion but is shifted to higher energy values in the vanadyl complex spectrum. A similar shift is observed in the ν(CO, phenol) band, located at 1218 cm^{-1} in the acid and at 1260 cm^{-1} in the vanadyl complex.

The band at 955 cm^{-1} in the solid complex has been assigned to V=O stretching. This value is lower than that of $VOSO_4\cdot 5H_2O$ [14].

3.4. Thermogravimetric behavior

The thermal behavior of the solid complex was investigated by means of TG and DTA measurements under a flowing O_2 atmosphere up to 1100 °C.

The dehydration begins early and covers a temperature range between 18 and 231 °C, with an observed mass loss of 13.96%, in agreement with the calculated value of 13.46%. This process is accompanied by a weak endothermic DTA signal located at 67 °C that corresponds to the loss of three water molecules:

$$Na_3[VOCaf(OH)_2]\cdot 3H_2O \xrightarrow{O_2} Na_3[VOCaf(OH)_2] + 3H_2O$$

After the release of water, a complex degradation process of the remaining material is observed. It shows, at least, five consecutive TG steps:

1) Between 231 and 402 °C (with a weak exothermic DTA signal at 368 °C).
2) Between 402 and 633 °C (exothermic DTA signal at 505 °C).
3) 633 and 737 °C (strong exothermic DTA signal at 677 °C);
4) 737 and 830 °C (exothermic DTA signal at 781 °C).
5) The last pyroliysis step is extended between 830 and 1100 °C and is accompanied by an exothermic DTA peak at 1009 °C. After this last mentioned process, weight constancy is attained. The total observed mass loss is of 54.2%, in very good agreement with the theoretically expected (54.1%) according to the following equation:

$$Na_3[VOCaf(OH)_2]\cdot 3H_2O \xrightarrow{O_2} Na_3VO_4 + \text{volatile products}$$

The generation of the ortovanadate as the final residue was confirmed, unambiguously by IR spectroscopy.

4. Discussion

4.1. Potentiometric titrations

From the potentiometric results, it can be seen that complexation occurs in a wide pH range, depending on the total concentration of the components and the M:L ratio. This observation is in agreement with the spectroscopic results. Even at M:L 1:1 ratio and total concentration 5 mM, potentiometric titration curves of caffeic acid with and without vanadyl(IV) are not superimposable from pH 3, indicating that complex formation starts at low pH values.

The species present in solution in the acidic region involve coordination of the metal to the fully deprotonated ligand. This fact indicates that both carboxylic and phenolic protons are more strongly acidic in the vanadyl complexes than in the free ligand (see pK_a values above). According to Rheder and Rieger [15] this effect can be explained through the delocalization of the electron pair generated by deprotonation in a molecular orbital extended onto the metal.

This model can be compared with the speciation of Cu(II)–L^{-3}–H^+ system, previously reported [9]. In the 3–4 pH range, the $CuLH_2$ complex, which involves only the carboxylate donor groups in the metal coordination, has been identified. The analogous $VOLH_2$ should be discarded from the model in order to improve the fitting parameters. In contrast to other metal-carboxylate complexes, vanadyl(IV)-carboxylate compounds were difficult to be obtained by the usual methods [16,17] due to their tendency to form polymeric species. These complexes show particular magnetic properties as a consequence of anisotropic antiferromagnetic exchange along infinite linear chains of interacting spins [18]. The calculated equilibrium constants denote the preference to form M_3L_2, M_2L, ML_2 and ML complexes in solution in the VO^{2+}–Caf system.

4.2. Spectroscopic Measurements

4.2.1. UV–Vis spectra

The visible spectra of VO^{2+}–caffeate system (see Table 2) show strong similarities with those of vanadyl(IV) linked to catecholate-like ligands (cat) [19,20]. In this type of complexes both species $VO(cat)_2^{2-}$ and $V(cat)_3^{2-}$ exist, but the equilibrium is displaced to the 1:2 species at higher pH [4]. In contrast, for VO^{2+}-Caffeate system in very strongly basic solutions, the involvement of the third ligand in the coordination sphere of vanadium is not observed, probably due to the steric hindrance of the carboxylate group. Moreover, the air oxidation of $V(cat)_3^{2-}$ to $V(cat)_3^{-}$ is not easily detected (the blue color remains unaltered) while the air oxidation of caffeate complexes, either in solution or in solid state, is immediately observed due to the development of a brown color.

However, the system behaves in a similar manner to that of catechol [19]. At pH 4–5 the main species is ML and at higher pH is ML_2 for a ligand to metal ratio of 1:2. The UV–Vis spectrum calculated for ML is similar to that of [VO(cat)]. For ML_2, the spectrum shows additional bands at the red side, probably due to the interaction of the carboxylate moiety of caffeic acid with the sixth position of the coordination sphere of the metal center. This last behavior may have connection with the higher stability of this species in comparison with the copper analogues [9]. In the alkaline region (pH > 10), the hydrolysis of ML_2 takes place generating mixed hydroxo complexes: MLH_{-1}, MLH_{-2}. The bands in the electronic spectra of these complexes appear at low energy (> 820 nm).

The experimental conditions for solid complex precipitation were selected from the species distribution curves Fig. 2. It can be seen that for VO:Caf: 100:100 mM, the main species at pH 12.0 is MLH_{-2}. The position of the bands in the diffuse reflectance spectrum of the solid (> 800, 780, 690 nm) were coincident with the calculated for the UV–Vis spectrum. The elemental analysis, the thermal behavior and the IR characterization (see below) also support the proposed complex composition: $Na_3[VOCaf(OH)_2]\cdot 3H_2O$. The complex is oxygen sensitive either in solution or in solid state, but it is indefinitely stable under inert atmosphere.

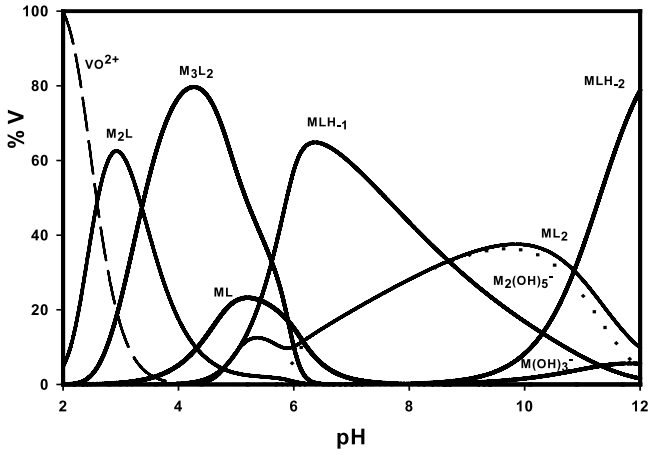

Fig. 2. Species distribution for the vanadyl (IV)–caffeic acid system (100/100 mM) as a function of pH at 25 °C, $I = 0.150$ M NaCl.

4.2.2. IR spectrum

IR spectroscopy has been a powerful tool in the analysis of the purity of the solid samples. When the complex was prepared in the presence of small quantities of oxygen, an additional band located at 1717 cm^{-1} was observed. This band is indicative of the oxidation of the OH groups to ketone of the catechol moiety [21].

Copper et al. [19] has also reported an infrared evidence for quinone formation by oxidation of catechol by atmospheric oxygen. The band located at 892 cm^{-1} is related to ketone formation. We have also detected this band in the experiments described above. Working under Ar atmosphere, ketone formation together with the oxidation of the metal center was avoided.

The frequency difference observed in the sodium caffeate spectrum between the bands ν_{as} COO^- and ν_s COO^- ($\Delta\nu$) is 177 cm^{-1}. This value is in accordance with the presence of an ionic carboxylate group. In the solid complex the $\Delta\nu$ value (175 cm^{-1}) indicates that the carboxylate group remains in an ionic form without coordination to the metal center.

The behavior of the ring stretching bands denotes that deprotonated OH groups of the catecholate-like part of the ligand are involved in the coordination to the vanadium atom.

The shift of the V=O band to lower frequencies compared with vanadyl sulfate spectrum has been observed in other catechol–vanadyl complexes. It implies a weakening of the V=O bond as a consequence of the strong σ electron donation of the ligand to antibonding orbitals of the V=O group [19,20].

2. Experimental

All manipulations were routinely performed under nitrogen atmosphere using Schlenk tubes and vacuum line techniques with dried and distilled solvents. Hexafluoroisopropanol (hfipH) (Aldrich) was stored over molecular sieves and used as received. The Ce(IV) hexafluoroisopropoxide adducts were obtained as previously reported by us [15]. XPS experiments were performed with an Escalab 200R (VG Scientific) spectrometer using the monochromated Kα Al radiation as excitation source. SEM images were collected on a Hitachi S800 spectrometer. XRD data were collected on a Siemens D 5000 diffractometer using the Cu Kα radiation.

2.1. Crystallography of 1 and of 2

Suitable crystals of **1** were grown directly from the reaction medium, those of **2** were obtained by recrystallization in petroleum ether. The crystals were fixed at a glass fiber with paratone. Data collection was made on a Nonius CCD diffractometer at 123 K. Three thousand seven hundred thirty-eight reflections were measured for **1** and 12 721 reflections of which 8787 were unique were measured for **2**. Cell parameters were refined using DENZO [16]. Compound **1** crystallizes in the monoclinic system (*C*2/*c* group) whereas **2** crystallizes in the triclinic system ($P\bar{1}$ group). The structures were solved by direct methods and refined by least-squares using SHELXTL [17]. All non-H atoms were refined anisotropically giving the values of *R* listed in Table 1. Hydrogen atoms position were calculated at theoretical positions and refined isotropically riding on C. The distribution of the C–F bond lengths is quite large due to disorder phenomena which are also illustrated by high thermal factors and a large residual density.

2.2. Decomposition experiments

Compounds **1** and **2** were sublimed and decomposed in a hot-wall, dynamic vacuum reactor with argon flow. The precursor reservoir was charged with 200–300 mg of compound and maintained at about 150 °C; the furnace temperature was 550 °C and the pressure was 5×10^{-3} bar, the decomposition took place over a 4–8 h period. About 15% in weight of residue remained in the source reservoir after this time. After removing the residue, a flow of water-saturated argon (water bubbler at room temperature) was introduced and the furnace was maintained at 550 °C for over 8 h.

3. Results and discussion

3.1. Synthesis and molecular structures of Ce(hfip)$_4$(TMEDA) (1) and of Ce(hfip)$_4$(diglyme) (2)

The alcohol exchange reaction between cerium isopropoxide $Ce_2(OPr^i)_8(Pr^iOH)_2$ and hexafluoroisopropanol (hfipH = $OHCH(CF_3)_2$) (1:8 stoichiometry) in THF at room temperature afforded a cerium hexafluoropropoxide THF adduct Ce(hfip)$_4$(THF)$_2$. The high Lewis acidity of fluoroalkoxides makes, however, this adduct extremely prone to hydration. Ligand exchange with polydentate Lewis bases such as TMEDA and diglyme $MeO(CH_2CH_2O)_2Me$ provided more stable adducts. Those were characterized (FT-IR, ^{1}H and ^{19}F NMR) by comparison with authentic samples as previously reported [15]. Their FT-IR spectra are characterized by very intense broad absorption bands around 1290–1100 cm^{-1} corresponding to the C–F vibrations. Additional sharp bands due to the coordinated Lewis base are present as well but they are shifted downfield with respect to the free ligand. The absorption bands of the Ce–OR bonds are observed below 600 cm^{-1}.

The ligand exchange reactions between Ce(hfip)$_4$(THF)$_2$ and chelating ligands afforded derivatives

being more air stable, the order of stability being $Ce(hfip)_4(TMEDA) < Ce(hfip)_4(diglyme) \ll Ce(hfip)_4(bipy)_2$. All these compounds are volatile and sublime unchanged (no loss of the Lewis base occurs during volatilization). Compound **1** is more favorable than **2** in terms of melting point (155 vs. 234 °C) whereas their volatility properties are comparable (sublimation around 70 °C under 10^{-4} mm of Hg). Their solubility properties make them suitable as precursors for liquid injection CVD. By contrast to barium and yttrium derivatives with various ligands [4], no rationale and predictive trends could be established by analysis of the relationship between sublimation temperatures and molecular weight data. However, for derivatives having similar formula, the volatility appears to be in favor of the hfac derivatives with the ranking hfac > hfip > fdh > thd > fod. $Ce(hfip)_4$(diglyme) has a volatility comparable to that of $Ce(hfac)_3$(dedg) (dedg = diethyldiglyme) [10].

Compounds **1** and **2** were characterized by low temperature single crystal X-ray diffraction. Their structures are depicted in Figs. 1 and 2 for **1** and **2**, respectively. Selected bond lengths and angles are collected in Tables 2 and 3. The coordination polyhedron of the hexacoordinated cerium atom is quite distorted with angles ranging from 69.6(3)°—the bite angle of the bidentate ligand—to 170.5(3)°. The Ce–O distances have values of 2.115(5) and 2.152(6) Å, the shortest ones being *trans* to the Ce–N coordination bonds of 2.624(7) Å. Data on Ce–N bond distances are scarce. The Ce–N coordination bond observed for **1** are shorter than those reported for $[Ce_2(O^iPr)_6(\mu,\eta^2\text{-}OC_2H_4NMeC_2H_4NMe)_2]$ but where the metal is heptacoordinated [18]. The shortest intramolecular cerium–fluorine distance corresponds to Ce···F(210) with a value of 3.754 Å. Four other Ce···F–C distances are found in the range 4.128–4.332 Å, each of the fluoroisopropoxide ligand providing either one or two

fluorine for these interactions. Activation of carbon–fluorine bonds by metallic species has been observed in a number of complexes giving short M···F–C interactions [19]. The shortest distance is much longer than the Ce–O bond lengths or the sum of the van der Waals radii ($\sim$3.20 Å) and than the interactions found for barium derivatives (usually 3–3.20 Å) [12]. The Ce···F(210) interaction might however account for the opening of the O(1)–Ce–O(1)# angle [108.7(3)°]. Some intramolecular F···N interactions involving F(111), F(112), F(200) are also observed (4.137–4.259 Å). These interactions are much longer than the Ce–F bond distances reported for cerium fluoride derivatives such as $NH_4[CeF_2(PO_4)]$ for instance [20].

The molecular structure of the Ce(hfip)$_4$(diglyme) adduct **2** is based on a heptacoordinated metal center since all oxygens of the diglyme are involved in coordination. Such a coordination number was observed for $Ce_4O(OPr^i)_{14}$ [21]. The Ce–O(hfip) bond lengths are similar to those of **1** [2.122(4)–2.139(5) Å] and are much shorter than the Ce–O bond distances involving the diglyme ligand [2.582 Å av.]. The stereochemistry around the metal corresponds to a trigonal prism capped by one of the oxygen O(1) of the glyme. The metric parameters of the diglyme ligand are in agreement with the literature body [9,10]. The shortest Ce···F distance [with F(17)] has a value of 4.060 Å but additional Ce···F distances having values below 4.31 Å are observed with eight other fluorine atoms.

The Ce–OR bond distances are, for both complexes, quite short, although longer than those observed for non-fluorinated terminal Ce–OR alkoxides (2.088 Å av. for $[Ce_2(OPr^i)_8(PriOH)_2]$) [22]. They are shorter than those observed for the $[Ce(hfip)_6]^{2-}$ anion [2.183(5)–2.208(5) Å]. The Ce–O–(hfip) angles display values of [156.7(7)°–166.5(7)°] and [149.4(5)°–174.2(5)°] for **1** and **2**, respectively. Those are large by comparison to most other hexafluoroisopropoxide derivatives [143.3(5)°–156.5(5)° for $[Ce(hfip)_6]^{2-}$] and nearly comparable to those observed for non-fluorinated OR ligands which are considered to be more prone to π-bonding [23]. These large Ce–O–C angles do, however, not prevent interaction of the fluorine atoms with the metal center. These interactions shield the positive charge of the metal and reduce its electrophilic character. Its is noticeable that metal–fluorine interactions are generally absent in the solid state structures of fluorinated β-diketonate complexes in which the coordination number of the metal is usually higher than for fluorinated alkoxide adducts [10].

3.2. CVD experiments

Deposition experiments were achieved at various temperatures using an horizontal cold wall reactor under dynamic vacuum ($4–5 \times 10^{-3}$ bar). Compounds **1** and **2** were transported into the vapor phase at 120–140 °C. No deposits were observed below 500 °C and depositions were thus conducted at a temperature of 550 °C for **1** and **2**. Films were homogeneous, white and displayed poor mechanical properties. They were characterized by XPS in the range 0–1000 eV and gave similar spectra in terms of peak energies and profile for both compounds (Fig. 3(a) and (b)). The Ce3d spectra displayed peaks due to Ce^{4+} and Ce^{3+} atoms namely those of ceria CeO_2 and of fluoride, CeF_3, the latter being predominant. Indeed the F1s spectra showed a peak at 684.5 eV and the O1s spectra displayed a broad peak at 530 eV representing the O^{2-} contributions of Ce^{3+}–O and Ce^{4+}–O bonds. Under similar experimental conditions, the amount of cerium oxide was slightly higher for the diglyme adduct (42%) than for the TMEDA one (33%) by measuring the relative intensity of peak u‴ in the Ce3d$_{3/2}$ region [24]. Subsequent heating at 550 °C under a water-saturated argon atmosphere allowed to convert CeF_3 into CeO_2 as shown by the XPS pattern (Fig. 3(c)). The latter compares with that reported for an authentic CeO_2 sample [25] and no

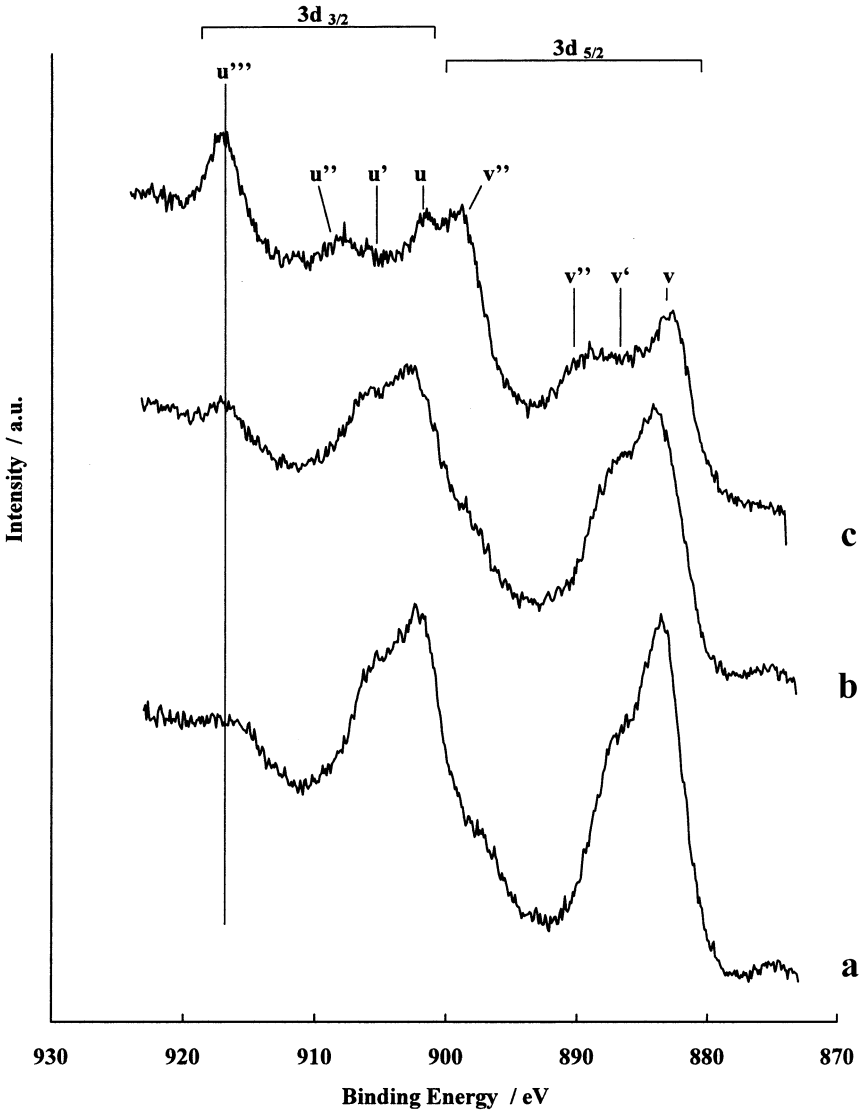

Fig. 3. Ce3d XPS patterns of films obtained from: (a) $Ce(hfip)_4(TMEDA)$ (**1**), (b) $Ce(hfip)_4(diglyme)$ (**2**), (c) **2** with water-saturated argon treatment at 550 °C.

peaks assigned to fluorine could be detected. These films were homogeneous, colorless with very good transparency (transmittance of 90–95% in the range 350–900 nm) and displayed good mechanical properties (tested by applying cellophane tapes to the coated substrate). SEM data featured a smooth film but with small cracks resulting probably from the elimination of the fluorine residues. The thickness was estimated from cross sectional SEM pictures to be around 20 nm and XRD experiments indicated that the films were amorphous.

The formation of cerium(III) fluoride indicates cleavage of the C–F bonds. Although fluorine contamination has been observed for systems without M...F interactions in the ground-state structure, this process is probably assisted here by the metal–fluorine interactions which weaken the C–F bonds but was not further investigated. It should be noted that while fluorine contamination of oxide films is generally undesirable, pure metal fluorides have many desirable properties of their own and cerium fluoride is involved in the formulation of γ-scintillations [26]. Thus production of pure metal fluoride films has its own relevance.

4. Supplementary material

Tables of coordinates, of thermal parameters, of bond lengths and angles have been deposited at the Cambridge Crystallographic Data Base Centre. CCDC reference numbers: 171191 for **1** and 171192 for **2**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 IEZ, UK (fax: +44-1223-336033; e-

mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We thank Mr. P. Delichere and Mr. G. Wicker for XPS and SEM experiments, respectively.

2. Experimental

2.1. General

All chemicals and solvents were of AR grade and obtained from commercial sources. Tetrahydrofuran was freshly distilled over sodium under argon before use. Other solvents and liquid reactants were dried by storage over molecular sieves. The complex $[ReBr(CO)_5]$ was prepared according to reported procedures [8]. All reactions were carried out using standard Schlenk techniques under purified nitrogen. Infrared spectra were recorded on a Perkin–Elmer 1600 FT IR Spectrometer or a Bio-Rad FT IR Spectrometer. The reactions were monitored by solution IR spectroscopy, and were considered to be complete when there was no more change in the ν(C–O) pattern. Proton NMR spectra were recorded on a Bruker AMX 500 MHz spectrometer. The ^{1}H chemical shifts are reported in ppm downfield of tetramethylsilane. Elemental analyses were performed by the Microanalytical Laboratory of the Department of Chemistry of the National University of Singapore. The molecular weight analysis of complex **1** was performed by Galbraith Laboratories, Inc. using the three-point vapour pressure osmometry method; the sample was dissolved in dichloromethane at 27 °C. Cytotoxicity tests were carried out as previously reported [7].

2.2. Synthesis of $[Re(\eta^2\text{-}Me_2NCH_2CH_2O)(CO)_3(\mu\text{-}OH)Re(\eta^2\text{-}Me_2NCH_2CH_2OH)(CO)_3]$ (1)

A solution of $[Re_2(CO)_{10}]$ (130 mg, 0.2 mmol) in freshly distilled THF (10 ml) was added at room temperature (r.t.) to a solution of $Me_3NO{\cdot}2H_2O$ (67 mg, 0.6 mmol) and $Me_2NCH_2CH_2OH$ (0.1 cm^3, 89 mg, 1.0 mmol) in THF–MeOH (20 ml, 1:1, v/v). The solution was stirred for 4 h at ambient temperature. Following solvent removal in vacuo, the product was recrystallised from dichloromethane–hexane mixture by slow evaporation at r.t. Yield: 133 mg (90% based on Re). (Found: C, 22.9; H, 3.0; N, 3.8. $C_{14}H_{22}N_2O_9Re_2$ requires C, 22.9; H, 3.0; N, 3.8%); $\tilde{\nu}_{max}$ (cm^{-1}) (CO) 2014s, 1894vs (CH_2Cl_2); δ_H (CD_2Cl_2) 4.33 [1H, dq, H(8B)] (see Fig. 1 for the labelling scheme for the hydrogen atoms), 4.21 [1H, dd, H(12A)], 3.93 [1H, td, H(8A)], 3.68 [1H, td, H(12B)], 3.04 [6H, s, H(10A)–H(10C) and H(13A)–H(13C)], 2.98 [1H, td, H(11B)], 2.85 [3H, s, H(9A)–H(9C)], 2.80 [3H, s, H(14A)–H(14C)], 2.60 [1H, td, H(7A)], 2.23 [2H, tt, H(7B) and H(11A)]; MW found: 1492, calcd. 1470 (for dimer).

When the reaction was carried out in pure THF instead of a THF–MeOH mixture as the solvent, complex **1** was also formed, but in 55% yield (based on Re). Analogous reactions of $[Re_2(CO)_{10}]$ with other ω-aminoalcohols, $Me_2N(CH_2)_nOH$ ($n = 3$, 4, 6), in THF–MeOH mixture were also attempted, but in all these cases intractable oils were obtained.

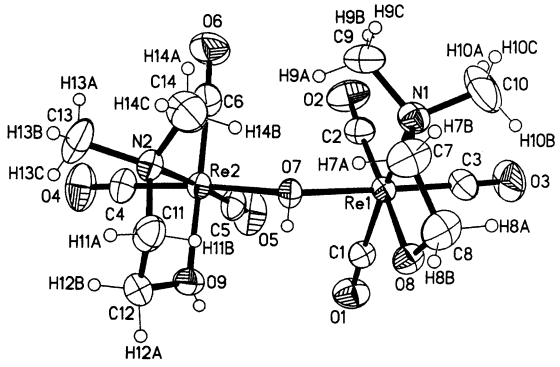

Fig. 1. Crystal structure of $[Re(\eta^2\text{-}Me_2NCH_2CH_2O)(CO)_3(\mu\text{-}OH)Re(\eta^2\text{-}Me_2NCH_2CH_2OH)(CO)_3]$ (**1**).

2.3. Synthesis of $[Re_3(\mu_3\text{-}OH)(\mu\text{-}OH)_2(\mu\text{-}OCH_2CH_2NMe_2H)(CO)_9]$ (2)

2.3.1. Method 1

The procedure was similar to that for the synthesis of complex **1** except that methanol was replaced by water, and that the product was recrystallised from acetone–water mixture by slow evaporation at 0 °C. Yield: 43 mg of **2** (as the acetone solvate) (29% based on Re).

2.3.2. Method 2

A 1 M solution of $Na[OCH_2CH_2NMe_2]$ in THF (0.25 cm^3, 0.25 mmol), prepared by the reaction of $Me_2NCH_2CH_2OH$ with sodium metal, was added to a THF solution (10 cm^3) of $[ReBr(CO)_5]$ (103 mg, 0.25 mmol). The resultant solution was stirred for 18 h, after which the solvent was removed in vacuo. The product was recrystallised from acetone–water mixture as above. Yield: 52 mg (55% based on Re). (Found: C, 23.15; H, 2.62; N, 1.40. $C_{22}H_{32}NO_{16}Re_3$ requires C, 23.49; H, 2.87; N, 1.24%; $\tilde{\nu}_{max}$ (cm^{-1}) (CO) 2026w, 2011m, 1893vs (acetone); δ_H (acetone-d_6) 4.44 (2H, t, OCH_2), 4.03 (1H, br s, NH), 3.32 (2H, t, NCH_2), 3.08 (6H, s, Me_2N).

2.4. X-ray crystallography

Pale yellow crystals of complex **1** were grown from dichloromethane–hexane mixture by slow evaporation at r.t. Colourless crystals of complex **2** were grown from acetone–water mixture by slow evaporation at 0 °C. Crystals of **2** desolvate quite readily on isolation, and were thus sealed in quartz capillaries with the mother liquor during data collection. Data collection was carried out at ambient temperature on a Siemens SMART CCD diffractometer using Mo Kα radiation (λ 0.71073 Å). The data were corrected for absorption effects using the SADABS program [9]. Crystal and

refinement data for complexes **1** and **2** are summarised in Table 1.

The structures of the two complexes were solved by direct methods and difference Fourier maps. Full-matrix least-squares refinements (on F^2) were carried out with anisotropic thermal parameters for all non-hydrogen atoms, using all of the unique data. The hydrogen atoms of the two hydroxyl groups of complex **1** were located in a difference map, and their positional and isotropic thermal parameters were refined independently. All other hydrogen atoms were introduced in calculated positions and refined using the riding model. Computations were carried out using the SHELXTL software package [10]. Selected geometric parameters of the complexes are given in Tables 2 and 3.

2.5. Cytotoxicity tests

Complexes **1** and **2** and the compounds $[NBu^n_4][ReO_4]$ and $[NEt_4]_2[ReBr_3(CO)_3]$ were tested for cytotoxic activity by homogenising the compounds as a 1 mg ml^{-1} solution in 0.05% Tween 80/H_2O. These solutions were sterilised by passing them through an acrodisc (0.45 μm). The cell lines investigated (Table 4) were maintained by literature techniques [11]. The NCI protocol was used to assess the cytotoxicity of the test compounds and standard drugs in each cell line [11]. The number of cells were determined by the trypan blue exclusion technique [11] and the percent inhibition of growth for each concentration of compound was calculated and averaged ($N = 4$). The percent inhibition was plotted against the log of the concentration of compound and the ED_{50} value (concentration of compound in μg ml^{-1} inhibiting 50% of cell growth) estimated. Solid tumour cytotoxicity was determined using crystal violet/MeOH and read at 580 nm (Molecular Devices) [12]. An ED_{50} value of less than 4 μg ml^{-1} was required for significant activity for inhibition of cell growth [11].

3. Results and discussion

3.1. Synthesis of $[Re(\eta^2\text{-}Me_2NCH_2CH_2O)(CO)_3(\mu\text{-}OH)Re(\eta^2\text{-}Me_2NCH_2CH_2OH)(CO)_3]$ (**1**)

Complex **1** is easily synthesised in high yield by the reaction of $[Re_2(CO)_{10}]$ with $Me_2NCH_2CH_2OH$ and $Me_3NO{\cdot}2H_2O$ (1:5:3) in a mixture of THF and MeOH at room temperature. This reaction can be described as an oxidative alkoxylation of $[Re_2(CO)_{10}]$, and is analogous to the oxidative methoxylation of $[Re_2(CO)_{10}]$ by methanol in the presence of Me_3NO [13]. Interestingly, no methoxo group is incorporated into complex **1** despite the fact that a large excess of methanol is present in the reaction mixture. The presence of methanol is, however, important, since complex **1** is obtained at a

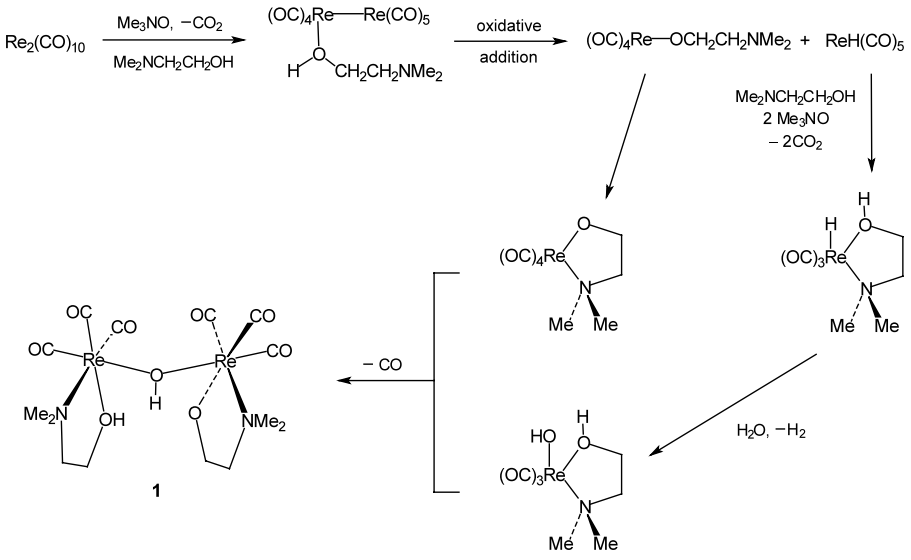
much lower yield if the reaction is performed in THF instead of a THF–MeOH mixture. The source of the bridging OH group in complex **1** is probably $Me_3NO\cdot 2H_2O$. Increasing the proportion of water in the reaction mixture, however, leads to the formation of complex **2** instead (see below).

The mechanism for the formation of complex **1** is proposed in Scheme 1. This mechanism is analogous to that proposed for the formation of $[Re_2(\mu\text{-}OMe)_2(\mu\text{-}PP)(CO)_6]$ (PP = diphosphine) in the reactions of diphosphines with $[Re_2(CO)_{10}]$ and $Me_3NO\cdot 2H_2O$ in THF–MeOH mixture [13]. The mechanism requires the initial substitution of a CO group by the hydroxyl oxygen, followed by oxidative addition of the coordinated H–$OCH_2CH_2NMe_2$ molecule across the Re–Re bond. Since THF solvates the hydroxyl group but not the amino group, it would favour the coordination of the amino group to rhenium, thereby inhibiting the reaction pathway depicted in Scheme 1. Methanol, on the other hand, can solvate both the hydroxyl group and the amino group; it thus increases the probability of the coordination of the hydroxyl group of $Me_2NCH_2CH_2OH$ to rhenium, thereby facilitating the formation of complex **1**. Methanol may also catalyse an alternative pathway for the formation of the $[Re(\eta^2\text{-}OCH_2CH_2NMe_2)(CO)_4]$ intermediate (Scheme 2).



Complex **1** cannot be obtained from the reaction of $Me_2NCH_2CH_2OH$ with aqueous $[NEt_4]_2[ReBr_3(CO)_3]$,

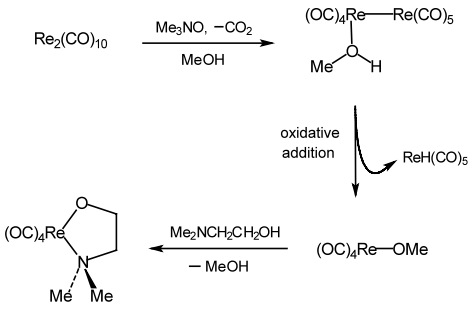
[a] ED_{50} values refer to the concentration of the compound inhibiting 50% of cell growth. A value of less than 4 μg ml^{-1} is required for significant activity for inhibition of cell growth [11].

[b] 6-MP, 6-mercaptopurine; Ara-C, cytosine β-D-arabinofuranoside.



Scheme 1.

which yields the known compounds [2] $[NEt_4][Re_3(\mu_3\text{-}OH)(\mu\text{-}OH)_3(CO)_9]$ (**3**) (when one molar equivalent of aminoalcohol is used) or $[NEt_4][Re_2(\mu\text{-}OH)_3(CO)_6]$ (**4**) (when excess aminoalcohol is used) instead. The complex $[ReBr_3(CO)_3]^{2-}$ is known to react in aqueous solution as $[Re(H_2O)_3(CO)_3]^{+}$, with three labile water ligands [2]. In mildly alkaline medium, the aqua ion reacts to form $[Re_3(\mu_3\text{-}OH)(\mu\text{-}OH)_3(CO)_9]^{-}$, which is in turn converted into the ion $[Re_2(\mu\text{-}OH)_3(CO)_6]^{-}$ in more strongly alkaline medium [2]. The formation of compounds **3** and **4** in the reaction of $Me_2NCH_2CH_2OH$ with aqueous $[NEt_4]_2[ReBr_3(CO)_3]$ can thus be attributed to the basicity of the aminoalcohol.

3.2. Crystal structure of $[Re(\eta^2\text{-}Me_2NCH_2CH_2O)(CO)_3(\mu\text{-}OH)Re(\eta^2\text{-}Me_2NCH_2CH_2OH)(CO)_3]$ (1)

The molecule of **1** (Fig. 1) consists of a $\{Re(\eta^2\text{-}Me_2NCH_2CH_2O)(CO)_3\}$ and a $\{Re(\eta^2\text{-}Me_2NCH_2CH_2OH)(CO)_3\}$ fragment bridged by one OH ligand. To our knowledge, complex **1** is the first structurally characterised singly-bridged dinuclear rhenium hydroxo carbonyl complex. Most other dinuclear rhenium hydroxo–alkoxo carbonyl complexes, e.g. $[Re_2(\mu\text{-}OR)_3(CO)_6]^{-}$ (R = H, Me, Et, Ph) [3a,5,14] $[Re_2(\mu\text{-}OH)(\mu\text{-}OPh)_2(CO)_6]^{-}$ and $[Re_2(\mu\text{-}OR)_2(\mu\text{-}PP)(CO)_6]$ [PP = diphosphine or ethylenebis(phosphino) moiety; R = H, Me, Et, Ph] [3,15] are stabilised by three bridges between the Re(I) centres.

Scheme 2.

Each Re(I) centre is octahedrally coordinated to three *fac*-carbonyl ligands, the (μ-OH) group, and one chelating aminoalkoxide/aminoalcohol ligand. The Re(I) octahedra are staggered, and the Re–(μ-O)–Re angle [127.8(1)°] is much larger than those observed in the triply-bridged complexes $[Re_2(\mu\text{-}OR)_3(CO)_6]^{-}$ (ca. 94°) and $[Re_2(\mu\text{-}OR)_2(\mu\text{-}PP)(CO)_6]$ (ca. 104°) [3,15]. The large Re–O–Re angle of **1** may be attributed to the steric repulsion between the rhenium coordination spheres. It is also noteworthy that the sterically demanding aminoalkoxo moieties are both on the exterior of the V-shaped Re(1)–O(7)–Re(2) unit, i.e. only the *syn*, *exo* conformation is observed. Steric factors probably also account for the preference for a hydroxo-, rather than a methoxo-bridge for the Re atoms in complex **1**. The Re(1)–O(7) and Re(2)–O(7) bond lengths [2.164(3) and 2.157(3) Å, respectively] fall within the range observed in $[Re_2(\mu\text{-}OR)_3(CO)_6]^{-}$ and $[Re_2(\mu\text{-}OR)_2(\mu\text{-}PP)(CO)_6]$ complexes (2.14–2.19 Å) [3,15].

Complex **1** can also be described as a *syn* geometrical isomer with respect to the relative positions of the alkoxo oxygen atoms and those of the amino groups. The two {Re–N–C–C–O} rings are arranged such that N(1) is nearly eclipsed with N(2) and O(8) is nearly eclipsed with O(9). In principle, it is possible for a geometrical isomer with N(1)–O(9) eclipsed and N(2)–O(8) eclipsed to exist. The observed configuration for **1** is probably favoured because it facilitates the formation of cyclic hydrogen-bonded dimers (Fig. 2). Virtually all of the dimers persist in solution at room temperature, as

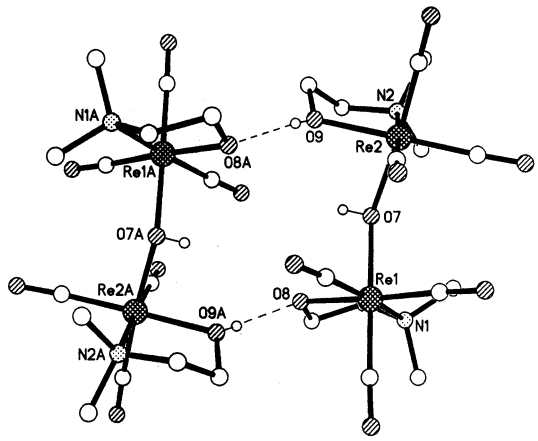


Fig. 2. Hydrogen-bonded dimer of complex **1**.

verified by molecular weight analysis in CH_2Cl_2 solution.

3.3. ^1H NMR spectroscopic studies of complex *1*

The room-temperature ^1H NMR spectrum of **1** shows seven separate signals for the methylene protons and three different signals for the methyl protons. The combination of ^1H–^1H through-bond and through-space interactions, revealed by COSY and NOESY experiments, established that all the above signals are due to protons belonging to the same molecule (Figs. 3 and 4). The NMR results thus indicate, together with the molecular weight measurement results, that the solid-state structure of complex **1** is maintained in solution, and no other stereoisomers of complex **1** are present.

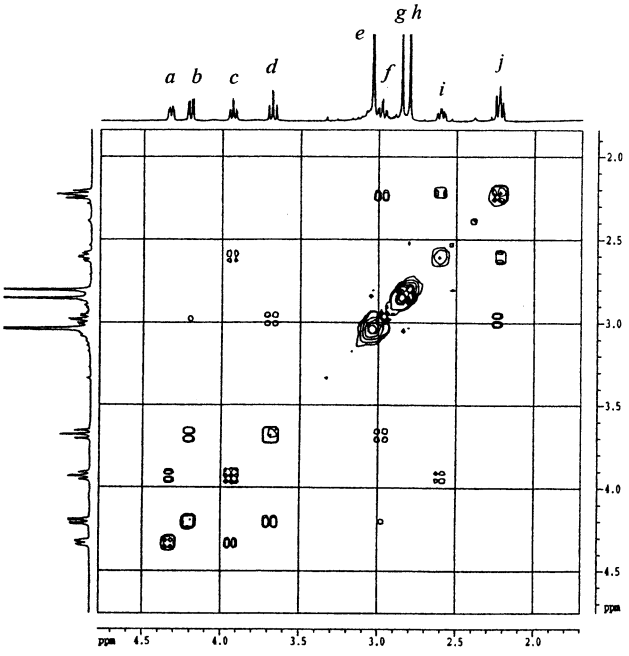

Fig. 3. The ^1H–^1H COSY NMR spectrum (500 MHz, r.t., CD_2Cl_2) of complex **1**. Signal assignments: (a) H(8B), (b) H(12A), (c) H(8A), (d) H(12B), (e) H(10A)–H(10C) and H(13A)–H(13C), (f) H(11B), (g) H(9A)–H(9C), (h) H(14A)–H(14C), (i) H(7A), (j) H(7B) and H(11A).

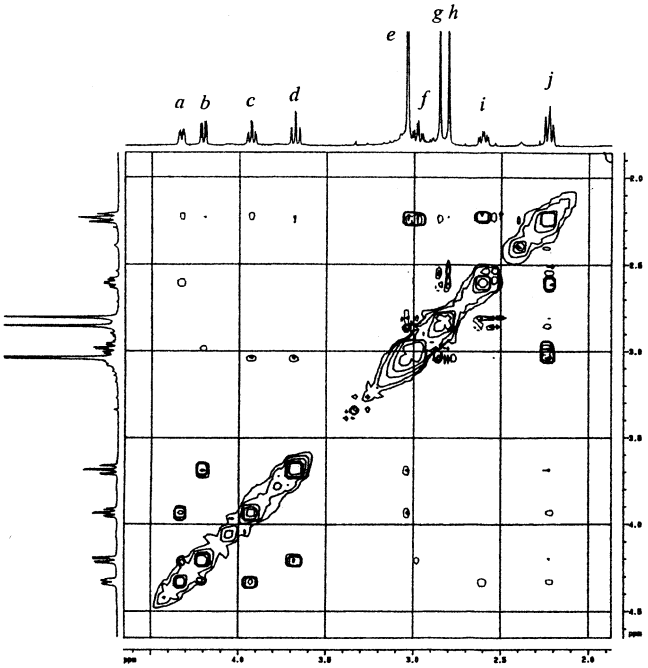

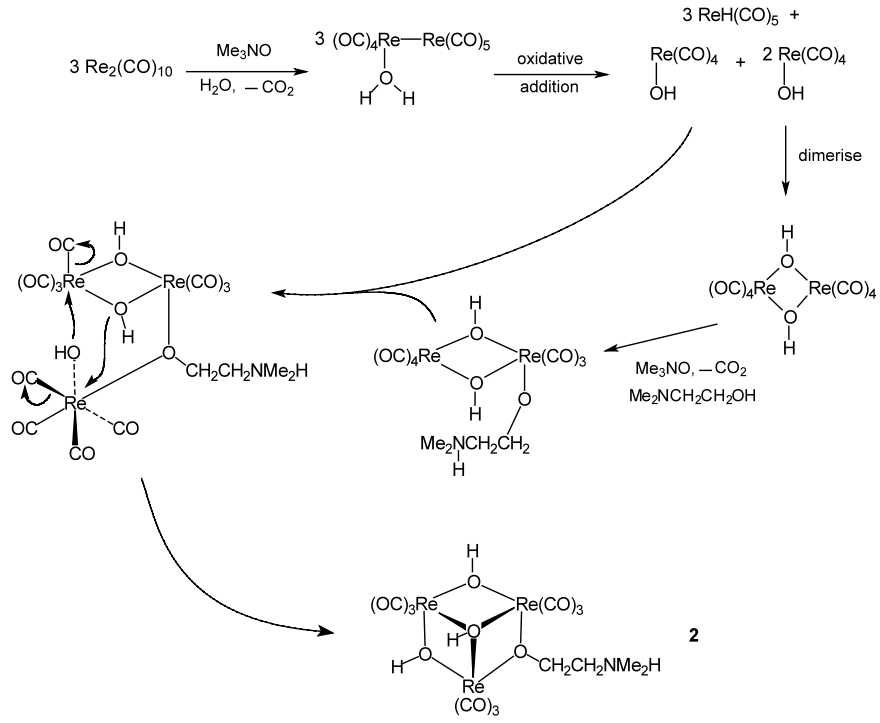

Fig. 4. The ^1H–^1H NOESY NMR spectrum (500 MHz, r.t., CD_2Cl_2) of complex **1**. Signal assignments: (a) H(8B), (b) H(12A), (c) H(8A), (d) H(12B), (e) H(10A)–H(10C) and H(13A)–H(13C), (f) H(11B), (g) H(9A)–H(9C), (h) H(14A)–H(14C), (i) H(7A), (j) H(7B) and H(11A).

3.4. Synthesis of $[Re_3(\mu_3\text{-}OH)(\mu\text{-}OH)_2(\mu\text{-}OCH_2CH_2NMe_2H)(CO)_9]$ (*2*)

Complex **2** was synthesised in similar way as **1**, except MeOH was changed to H_2O. Complex **2** can also be synthesised by the reaction of $[ReBr(CO)_5]$ with $Me_2NCH_2CH_2ONa$ (1:1), followed by recrystallisation from acetone–water mixture. It belongs to the family of $[Re_3(\mu_3\text{-}OR)(\mu\text{-}OR)_3(CO)_9]^-$ complexes (R = H, Me) [2,4]; in this case one of the μ-OR groups is ($OCH_2CH_2NMe_2H$), so the entire molecule is neutral.

The mechanism for the formation of complex **2** by the $[Re_2(CO)_{10}]$ route is proposed in Scheme 3, and is analogous to the mechanism proposed for the formation of the complex $[Re_3(\mu_3\text{-}OMe)(\mu\text{-}OH)_2(\mu\text{-}OMe)(CO)_9]^-$ in the reaction of $[Re_2(CO)_{10}]$ with $Me_3NO\cdot 2H_2O$ and MeOH [4a]. In the reaction of $[ReBr(CO)_5]$ with $Me_2NCH_2CH_2ONa$, displacement of bromide by the aminoalkoxide probably occurs first to generate the intermediate complex $[(OC)_5ReOCH_2CH_2NMe_2]$, which then undergoes hydrolysis and aggregation to form complex **2** during recrystallisation from acetone–water mixture.

Scheme 3.

3.5. Crystal structure of $[Re_3(\mu_3\text{-}OH)(\mu\text{-}OH)_2(\mu\text{-}OCH_2CH_2NMe_2H)(CO)_9]$ (2)

The crystal structure of **2** is depicted in Fig. 5. It contains an Re_3 triangular core held together by one ammonioalkoxo and two hydroxo bridges and face-capped by a hydroxo group. There being no Re–Re bonds, the coordination sphere of each Re atom is completed by three carbonyl ligands.

The hydrogen atom on the ammonio nitrogen (H1A) is involved in intramolecular N–H···O hydrogen-bonding with a bridging OH group. In addition, each of the three OH groups of **2** is hydrogen-bonded to one acetone solvate molecule via an O–H···O linkage.

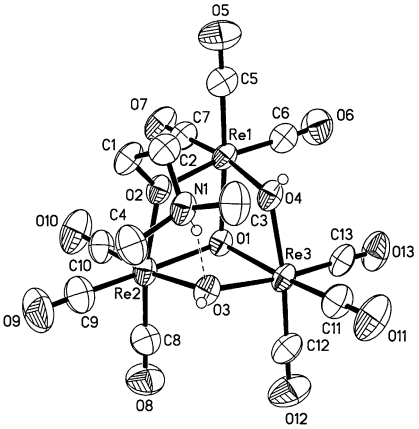

Fig. 5. Crystal structure of $[Re_3(\mu_3\text{-}OH)(\mu\text{-}OH)_2(\mu\text{-}OCH_2CH_2NMe_2H)(CO)_9]$ **2**.

Thus, each molecule of **2** is associated with three acetone solvate molecules exclusive to itself. The structural features of **2** are otherwise similar to those of the analogous $[Re_3(\mu_3\text{-}OR)(\mu\text{-}OR)_3(CO)_9]^-$ complexes (R = H, Me) [2,4].

3.6. Cytotoxicity

Complexes **1** and **2** were generally effective in reducing the growth of the suspended murine and human leukaemias and lymphoma, as well as the HeLa suspended uterine carcinoma cells (Table 4). The compounds were, however, much more selective in inhibiting the growth of tumours derived from human solid cancers. This pattern of cytotoxic activity is similar to that of the rhenium alkoxo complexes $[Re_2(\mu\text{-}OR)_3(CO)_6]^-$ (R = H, Me, Et, Ph), $[Re_2(\mu\text{-}OH)(\mu\text{-}OPh)_2(CO)_6]^-$, $[Re_2(\mu\text{-}OR)_2(\mu\text{-}dppf)(CO)_6]$ [dppf = 1,1′-bis(diphenylphosphino)ferrocene; R = H, Me, Ph] and *fac*-$[Re(OPh)(\eta^2\text{-}dppf)(CO)_3]$ [7]. However, complexes **1** and **2** (average ED_{50} for MCF-7 = 3.36 μg ml^{-1}) show much higher activity against MCF-7 breast cancer cells than the rhenium alkoxo complexes (average ED_{50} for MCF-7 = 9.96 μg ml^{-1}) [7]. Complex **1** is also active against more of the solid tumour cell lines (KB nasopharynx, MCF-7 breast, HCT-8 ileum and SK2 melanoma) than the alkoxo complexes, and complex **2** is especially active against 1-A9 ovary cancer cells.

The compounds $[NBu^n_4][ReO_4]$ and $[NEt_4]_2[ReBr_3(CO)_3]$ were also screened for their cytotoxicity to provide a comparison with complexes **1** and **2**. The

anion $[ReBr_3(CO)_3]^{2-}$ readily hydrolyses in aqueous media [2] to $[Re(H_2O)_3(CO)_3]^+$, which, together with $[ReO_4]^-$, are likely metabolic products of **1** and **2** in cells. It is possible that the cytotoxic activities of **1** and **2** are actually due to their metabolic products rather than the complexes themselves. From Table 4 it can be seen that the compounds $[NBu^n_4][ReO_4]$ and $[NEt_4]_2[ReBr_3(CO)_3]$ were also very active against the suspended cell lines and very selective when it came to the solid tumours. The selectivity patterns of $[NBu^n_4][ReO_4]$ and $[NEt_4]_2[ReBr_3(CO)_3]$ against the solid tumours were, however, quite different from those of **1** and **2**, suggesting that the latter complexes are active on their own.

It is noteworthy that all the compounds tested showed no activity against non-cancerous human fibroblast cells (Table 4). This is an important property for any chemotherapeutic agent since harmful side-effects of the treatment will be minimised.

Whilst it would be premature to draw any definite conclusions on the molecular mechanism responsible for the activity of compounds **1** and **2**, it seems probable that they would bind to DNA bases or side-chains of amino acid residues in peptides and proteins after displacement of the labile ligands, e.g. hydroxide and aminoethanol. It is noteworthy that the related complexes $[Re_2(\mu\text{-}OH)_3(CO)_6]^-$, $[Re_2(\mu\text{-}OH)(\mu\text{-}OPh)_2(CO)_6]^-$, $[Re_2(\mu\text{-}OMe)_2(\mu\text{-}dppf)(CO)_6]$ and $[Re_2(\mu\text{-}OPh)_2(\mu\text{-}dppf)(CO)_6]$ have been shown to interfere with nucleic acid metabolism at multiple enzyme sites in L1210 lymphoid leukaemia cells, and cause DNA strand scission after 60 min incubation [7]. The hydroxo, alkoxo and phenoxo ligands in these complexes have been shown to be labile by electrospray mass spectrometric studies [16]. The lability of the bromide ligands of $[ReBr_3(CO)_3]^{2-}$ is also well-documented [2], and may account for its cytotoxicity by similar arguments.

4. Summary and conclusions

Two new rhenium(I) carbonyl complexes containing the 2-(dimethylamino)ethoxo group, $[Re(\eta^2\text{-}Me_2NCH_2CH_2O)(CO)_3(\mu\text{-}OH)Re(\eta^2\text{-}Me_2NCH_2CH_2OH)(CO)_3]$ (**1**) and $[Re_3(\mu_3\text{-}OH)(\mu\text{-}OH)_2(\mu\text{-}OCH_2CH_2NMe_2H)(CO)_9]$ (**2**), have been synthesised in good yields. The presence of the amino group results in interesting new structural frameworks and hydrogen-bonding motifs exhibited by these complexes. The new complexes also show significant activity against a range of cancer cell lines. Studies on the reactivities of complexes **1** and **2** toward representative Lewis bases, e.g. diphosphines, DNA bases, amino acids, are under way.

5. Supplementary material

Supplementary crystallographic data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition numbers 160945 for **1**, and 160946 for **2**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

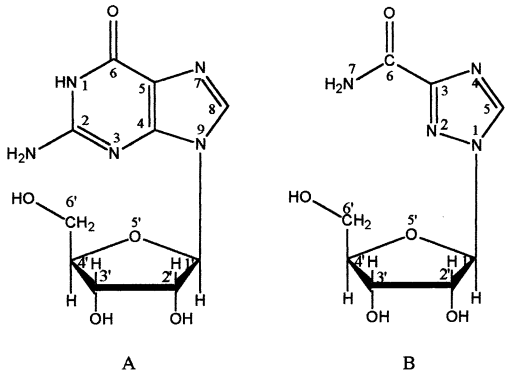

Fig. 1. IUPAC numbering schemes of: (A) guanosine; and (B) ribavirin.

The purpose of the presented work was to isolate new Pt(II) compounds which show similar activity to cisplatin and carboplatin, but have an additional functional group which can be linked to a carrier substances. Therefore, our research was focused on complexes bearing the ribavirin and dmso ligand, which is expected to improve water solubility of the complex and might influence better diffusion through membranes. To the best of our knowledge, it is the first report on mixed Pt(II) complexes with an antiviral agent (1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide) and dmso.

2. Experimental

2.1. Chemicals

Dipotassium tetrachloroplatinum(II) and dmso were purchased from Aldrich, and the inorganic salts of analytical grade from POCh Gliwice (Poland). Ribavirin was obtained according to the reported method [13], while *cis*-$[PtCl_2(dmso)_2]$ was prepared from the reaction of K_2PtCl_4 in aq. solution and dmso [22].

2.2. Instrumentation

IR spectra were obtained with a Perkin–Elmer 2000 FTIR spectrometer using KBr discs for the 400–4000 cm^{-1} range and polyethylene ones for 100–400 cm^{-1}. ^1H, ^{13}C, ^{195}Pt and ^{15}N–^1H NMR HETCOR spectra were detected on a Bruker DRX 500 spectrometer, in the latter case by Gradient Heteronuclear Single-Quantum Coherence. Samples were dissolved in dmf-d_7; the concentration of samples were 0.01 M for ^1H, ^{13}C, ^{195}Pt and 0.1 M for ^{15}N, the temperature was 295 K. The reference standard was TMS (internal) for ^1H or ^{13}C and CH_3NO_2 (external) for ^{15}N. ^{195}Pt chemical shifts were referenced relative to an external sample of 0.1 M K_2PtCl_4 in D_2O ($\delta = -1624$ ppm). C, H, N contents were determined by semimicroanalysis, whereas platinum was determined by a spectrophotometric method on a Specord M40 Carl Zeiss Jena ($\lambda = 400$ nm).

2.3. Synthesis

2.3.1. Preparation of Pt(II) complexes

A suspension of *cis*-$[PtCl_2(dmso)_2]$ (0.222 g; 0.53 mmol) in MeOH 15 ml was treated with the stoichiometric amount of ribavirin (0.129 g; 0.53 mmol) dissolved in 20 ml MeOH–water (1:1) solution, stirred at room temperature for 1 day and filtered. The filtrate was left for crystallisation and after 3 days white crystals of the complex precipitates, which were washed with C_3H_6O, Et_2O and dried in vacuum over P_2O_5. The results of elemental analyses for **1** were (% Calc./Found): Pt (34.2/33.9), C (20.7/20.7), N (9.7/9.2), H (3.7/3.7). Yield: 73%.

By slow crystallisation from water–MeOH mixture (1:1) white crystals of **1** and **2** suitable for X-ray structure analysis were obtained.

2.4. Crystal data

Two different crystals of $[PtCl(dmso)(N^4N^7\text{-rib})]\cdot H_2O$ (**1**) and $[PtCl(dmso)(N^4N^7\text{-rib})]\cdot 2H_2O$ (**2**) were selected after examination under a microscope. The X-ray measurements were carried out for a $0.10 \times 0.10 \times 0.15$ mm crystal of **1** with a Kuma KM-4 CCD diffractometer using graphite-monochromated Mo Kα radiation at 293 K. Ten thousand one hundred and twenty-five reflections were collected for the θ range 2.75°–26°. Data reduction and analysis were carried out with the Kuma Diffraction (Wroclaw) programs. The reflection data for **2** were collected in the range 3.23°–25° on the same diffractometer (Mo Kα radiation) at 100 K. No absorption correction was applied. Both structures were solved by heavy-atom methods (program SHELXS-97 [23]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL-97 programs [24]. Non-hydrogen atoms were refined with anisotropic thermal parameters. The crystallographic data for **1** and **2** are listed in Table 1.

3. Results and discussion

3.1. Discussion of the crystal structure

Selected bond distances and angles for **1** and **2** are listed in Table 2. The molecular geometry of **1** and **2** with the atom numbering scheme are presented in Figs. 2 and 3. Both complexes revealed square-planar coordination geometry for Pt atoms.

The coordination sites in **1** and **2** are occupied by one chloride atom, the sulfur atom of dmso, N(4) nitrogen of the triazole ring and N(7) nitrogen of the deproto-

nated carboxamide group. The structures of **1** and **2** demonstrate distortions from the square geometry with N–Pt–N a chelate angle of 79.2(2)° and 80.0(2)°, respectively. The remaining X–Pt–Y angles are greater than 90°, being of 96.3° (**1**) and 97.3° (**2**) for N(4)–Pt–S due to the bulky dmso ligand. The sulfur atoms in dmso ligands are in an approximate tetrahedral environment. The Pt–S–O angles of 117.0(2)° for **1** and 115.9(3)° for **2** are larger than Pt–S–C (109.1°–111.6°) in comparison to the values observed in other Pt–dmso complexes [26]. The S=O length for **2** 1.493(7) Å is appreciably longer compared to 1.468(4) Å in **1**. It may be supposed that this difference is closely associated with the O(3′)-H(3′)···O(3) = S$^{(i)}$ hydrogen bond in the crystal structure of **2**. The Pt–N(7) bond distance (2.041(4) Å) in **1** appears to be significantly longer than the Pt–N(4) bond distance of 2.009(4) Å. On the other hand in **2** the analogous bond distances are almost the same (2.032(7), 2.2028(7)). This discrepancy can be related to the hydrogen bond interaction N(7)–H(7)···O(1) in **1**. The bond distances and angles of the coordinated 1-β-D-ribofuranosyl-1,2,4-triazole-3-carboxamide are similar to those found in two crystalline forms of ribavirin [27] and in a Cu(II) complex [15], except the internal ring angles centred at N(4), C(3) and C(5). These angles are larger at N(4) and smaller at C(3) and C(5) in both **1** and **2** as compared to the neutral ligand [27], most probably due to the metallation at N(4). The geometry of carboxamide group is also affected by deprotonation

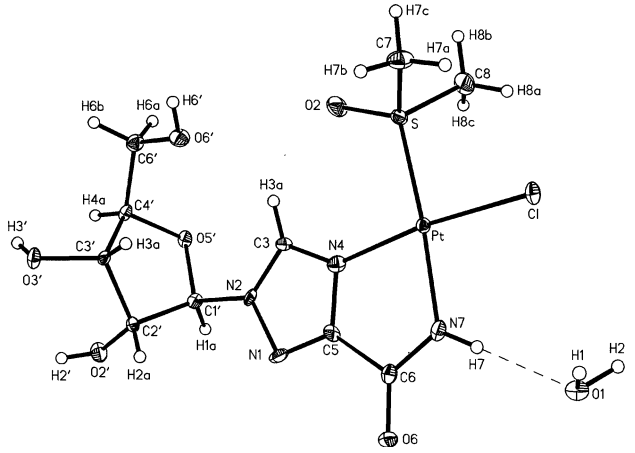

Fig. 2. The ORTEP [25] drawing of [PtCl(dmso)(N^4N^7-rib)]·H_2O (**1**).

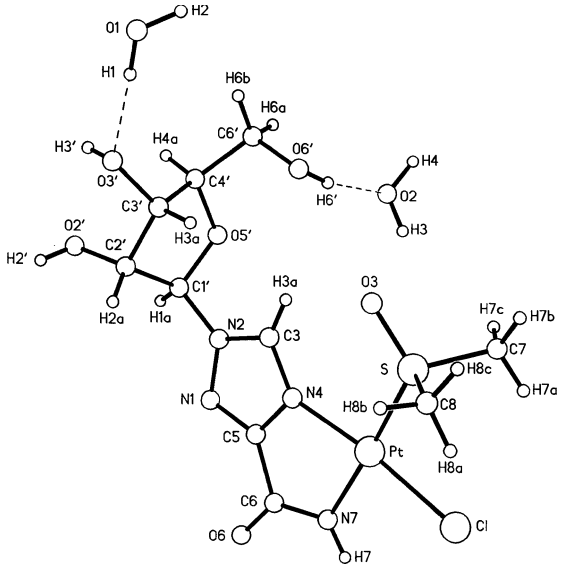

Fig. 3. The ORTEP [25] drawing of [PtCl(dmso)(N^4N^7-rib)]·$2H_2O$ (**2**).

and coordination. While forming the chelate ring, the N(7)–C(6)–C(5) angle decreases from 116.0° and 116.8° for two forms of free ribavirin [27] to 110.0° in **1** and 110.6° in **2**. Similarly, the N(4)–C(5)–C(6) angle decreases from 121.2° and 122.1° in the uncoordinated ligand to 117.8° and 118.5° for **1** and **2**, respectively, whereas the C(5)–C(6)–O(6) angle is almost unaffected. The glycosidic torsion angle χ defined by O(1′)–C(1′)–N(1)–C(5) is 2.0(6)° (**1**) and 39.5(1)° (**2**) compared to 10.4° and 119.0° in ribavirin [27] and −112.6° in the Cu(II) complex [15]. These differences are considered to arise from intermolecular interactions rather than the metal ion influence. The crystal packing is formed through the three-dimensional hydrogen bond network. The intermolecular hydrogen bonding networks in both structures are extensive (Figs. 4 and 5). Specifically in **2** almost all possible sites on the Pt complex are involved in hydrogen bonding, e.g. each of the hydroxy groups of the sugar moiety act both as donor and acceptor. On the other hand in **1** the monohydrate water molecule forms bridges between four symmetry-related complex molecules. A detailed geometry of all hydrogen bonds in the two crystal structures is presented in Table 3.

3.2. NMR results

All the measurements were performed in dmf-d_7, due to the poor solubility or decomposition reaction of the Pt(II) complex in other solvents (dmso-d_6, acetone-d_6, D_2O). When [PtCl(rib)(dmso)] was left for 1 h in dmso-d_6, ribavirin was displaced by the solvent because of the strong trans-labilizing effect of the sulfur ligands. The assignment of signals for both ligand and complex was based on the heteronuclear correlation technique (HETCOR). For NMR analysis we used IUPAC numbering schemes of ribavirin (Fig. 1(B)).

The ^1H, ^{13}C, ^{15}N and ^{195}Pt NMR data of [PtCl(dmso)(N^4N^7-rib)]·H_2O (**1**) are listed in Tables 4–6.

The signal of H(5) was detected at 8.94, whereas $N(7)H_2$ protons in the free ribavirin spectrum appear at 7.86 and 7.60 ppm as singlets due to the interaction with the oxygen atom from carboxy. Ribose protons (H(1′)–H(4′) and H(5′)) in the free ligand have been observed as multiplets in the range 5.95–3.73 ppm (Table 4).

Symmetry codes for **1**: (i) $-x+0.5,\ -y+1,\ z+0.5$; (ii) $-x,\ y-0.5,\ z+1.5$; (iii) $x-0.5,\ -y+0.5,\ -z+1$; (iv) $x+0.5,\ -y+0.5,\ -z+1$. Symmetry codes for **2**: (i) $-x+1,\ y+0.5,\ -z-0.5$; (ii) $-x+0.5,\ -y,\ z-0.5$; (iii) $x-0.5,\ -y+0.5,\ -z$; (iv) $-x,\ y-0.5,\ -z-0.5$.

Protons H(5) and N(7)H_2 are sensitive to the nature of the complex, hence coordination of ribavirin caused significant shift of the free ligand signals, H(5) (+0.55 ppm), N(7)H (−1.42 ppm) or (−1.16) (Table 4). The upfield shift of N(7)H can be related to the deprotonation of the carboxamide group and coordination to the Pt(II) ion. The magnitude of N(7)H and H(5) coordination shifts comes out from the close proximity of these protons to the central ion linked via N(4) and N(7). Metallation of ribavirin by Pt(II) ions also results in downfield shifts of the ribose protons signals, which can be related to the lower negative charge on the hydrogen atoms (Table 4). Resonances of CH_3 groups in dmso molecules appeared at 3.56 ppm, which is typical for the sulfur-bonded ligands [28]. It is noteworthy that no $^{195}Pt\{^{1}H\}$ spin–spin interaction has been detected.

Upon coordination, the resonances of C(3) and C(5) are shifted upfield (−0.4, −2.4 ppm) which can be related to the charge increase in the heterocyclic ring. This can be rationalised as a result of π-back donation from the Pt(II) d^8 electron system to the unsaturated heterocyclic ring. The downfield shift (+2.8 ppm) of

C(6) can be related to the σ electron withdrawal upon NH coordination. In ^{13}C NMR the largest coordination shifts were observed at carbon atoms which are in close proximity to the coordination centre (Table 5), which is in favour of coordination via N(4), N(7) atoms.

^{15}N resonances are very useful in determination of coordination sites of heterocyclic rings [29–32], however in the case of this ligand, the assignment is not straightforward. In order to determine the coordination sites of ribavirin, we have measured ^{15}N–^{1}H HETCOR spectra of the free ligand and **1**.

The ^{15}N NMR data and assignment for the ligands and complex **1** are collected in Table 6. From the magnitude of the coordination shift (Δ), it is evident that the Pt(II) linkage affects most significantly N(4) and N(7) resonances which are shifted upfield approximately 92.7 ppm and downfield 18.4 ppm, respectively. The downfield shift of the N(7) signal can be caused by two simultaneous effects i.e. coordination and deprotonation of the carboxamide group. Hence we can unambiguously indicate that the complexation occurs via these nitrogen atoms in solution.

The ^{195}Pt resonance of **1** was observed at −3103 ppm. This value is very close to that reported in the literature for *cis*-[PtCl(Xpy)$_2$(dmso)] where Xpy = 2-, 2,5-, 2,6-halogenopyridines, (−2876– −3042 ppm) [33]. This range is characteristic for the square-planar Pt(II) complexes in which two adjacent corners are occupied by two nitrogen atoms and the other positions by dmso and chloride. A spectrum of **1** exhibits ^{195} Pt resonances shifted downfield 373 ppm in relation to the starting platinum complex, *cis*-[PtCl$_2$(dmso)$_2$]. The downfield coordination shift can be explained by the charge displacement from (σ-donation) ribavirin to the metal centre caused by Pt–N bond formation. The ^{195}Pt signals of **1** have been detected as broad singlets, their half-line widths being approximately 460 Hz. Such values are relatively high, compared to those found for $[PtCl_4]^{2-}$ ions (approximately 110 Hz) [34], which most likely can be related to the quadrupolar interactions between ^{195}Pt and ^{14}N nuclei.

3.3. IR spectroscopy

Absorption bands of ribavirin in the spectra of **1** are affected by coordination. The characteristic band of νC=O vibration appeared at 1639 cm^{-1}, whereas NH vibration at 1620 cm^{-1}. In a spectrum of the free ligand the former band was found at 1658 and 1625 cm^{-1}. The frequencies of the ribavirin absorption band is shifted approximately 19 cm^{-1} towards lower frequencies upon coordination in comparison to the spectrum of free ribavirin. The sharp absorption band at 1130 cm^{-1} indicates S-bonded dmso, as reported for this soft coordination centre [35,36]. The spectrum of **1** has exhibited one new strong absorption band at 347 cm^{-1}. A similar frequency was detected in the spectra of Pt(II) with ammonia, pyridine (py) or imidazole (imH) [37], where it was assigned to a Pt–Cl stretching vibration.

4. Conclusion

Presented results of X-ray and spectral analyses revealed the same coordination site (N(4), N(7)) of ribavirin both in the solid state and dmf-d_7 solution. The crystal structure of **1** and **2** indicates that the Pt(II) ions have the square-planar geometry with chelating bonded ribavirin (N(4), N(7)), S-bonded dmso and chloride anion. The way of ribavirin bonding is different from described carboxamide analogs where the majority of the complexes revealed Pt(II) bonded via N, O atoms. An extensive intermolecular hydrogen bond network is evident in both hydrates. The coordination sphere of **1** is stable only in dmf solution which allows NMR studies.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic

Data Centre, CCDC Nos. 168127 and 168128 for compounds **1** and **2**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

could be found that present its synthesis by chemical methods, using different precursors. Niobium ammonium oxalate, $(NH_4)H_2[NbO(C_2O_4)_3]\cdot 3H_2O$, was used in the synthesis of fine $NaNbO_3$ powders by the Pechini method [8,9], and by thermal decomposition of a precursor obtained through solvent evaporation [10]. Kinomura et al. have prepared $NaNbO_3$ by hydrothermal reaction of $Na_8[Nb_6O_{19}]\cdot 13H_2O$ with NaOH and found a new metastable phase with ilmenite-type structure, that was obtained pure in a very narrow temperature and concentration region [11]. Also, $NaNbO_3$ has been obtained by evaporation of a solution of $Na_7H[Nb_6O_{19}]$ under a CO_2 atmosphere [12]. An old report states that crystals of $NaNbO_3$ were obtained by boiling a suspension of Nb_2O_5 in NaOH for about 20 min, but no synthetic details were provided [13]. To our knowledge, no report referring the synthesis of $NaNbO_3$ by hydrothermal reaction of Nb_2O_5 with NaOH has been published.

The synthesis of $KNbO_3$ through the hydrothermal reaction of Nb_2O_5 with KOH has already been reported [14,15]. Depending on the KOH concentration and temperature, that reaction may provide $KNbO_3$, $K_4Nb_{16}O_{17}\cdot 3H_2O$ or complete dissolution of the initial niobium oxide [14,15]. These studies were mainly concerned with the synthesis of the oxides and the dissolution of Nb_2O_5 in the alkaline solutions was only briefly mentioned.

Potassium hexaniobates of general formula $K_{8-x}H_x[Nb_6O_{19}]\cdot nH_2O$, $x = 0$–3, have been prepared before and some spectroscopic data has been published [6,16]. They are usually obtained by crystallization or precipitation from aqueous alkaline solutions of Nb(V) with pH 9–14 [16–19].

We report here the hydrothermal synthesis of microcrystalline, single phase $NaNbO_3$ through the reaction of commercial Nb_2O_5 with NaOH, at 200 °C. Different concentrations and NaOH:Nb_2O_5 molar relations were examined. In the conditions used for the synthesis of $NaNbO_3$, the use of KOH in place of NaOH leads to solubilization of the initial Nb_2O_5. From these solutions, solids like $K_6H_2[Nb_6O_{19}]\cdot 13H_2O$ or niobic acid were obtained. This procedure allows, thus, preparation of alkaline solutions of Nb(V) without need of the cumbersome technique of fusion of mixtures of Nb_2O_5 with alkali.

2. Experimental

2.1. Reagents and methods

All chemicals and solvents were used as received. Decarbonated water was used. Nb_2O_5 (99.5%) was purchased from Aldrich. NaOH and KOH were pro analysi grade.

Elemental analysis for Nb, Na and K were performed by ICP spectrometry (University of Aveiro, Central Laboratory of Analysis). Thermogravimetric analyses were carried out in air between 25 and 800 °C at a heating rate of 5 °C min^{-1}, on a Mettler M3 thermobalance equipped with a TC 10A microprocessor.

Infrared absorption spectra were recorded on a Mattson 7000 FTIR spectrometer, using KBr pellets. Raman measurements were performed with solid samples in a Bruker RFS 100/S FT-Raman spectrometer, equipped with a Nd:YAG laser emitting at 1064 nm. The spectra were obtained in the 200–1200 cm^{-1} range, using the following settings: power at the sample, 50 mW; resolution, 4 cm^{-1}. X-ray powder diffraction patterns were measured on a RigakuD–Max III instrument, using Cu Kα, radiation in the range $2\theta = 3°$–$130°$. Powder X-ray diffraction patterns were indexed with the POWDERX package [20] and the unit cells were indicated by the TREOR90 indexing program [21]. Cell parameters were refined using the program RIETICA 1.6.7A, by B.A. Hunter. Scanning electron microscope images (SEM) were recorded on a Hitachi S-4100 microscope.

2.2. General procedure for hydrothermal reaction of Nb_2O_5 with MOH, M = K, Na

Nb_2O_5 (0.1 or 0.2 g) and an aqueous solution of MOH (20 cm^3) with concentration corresponding to molar ratio MOH:Nb_2O_5 between 2 and 75 were placed in a Teflon lined cylindrical autoclave (60 cm^3 capacity), and introduced in an oven pre-heated to 200 °C for a predetermined period of time. After cooling down (under running cold water), any solid residue was separated by filtration or centrifugation, washed with water and ethanol and dried in a desiccator under vacuum. To the filtrate, absolute ethanol was added and any precipitated solid was filtered, washed with very cold ethanol–water (50%) and ethanol and dried under vacuum. Care should be taken to prevent contamination with carbonates.

2.3. Specific synthetic procedures

2.3.1. $NaNbO_3$

The reaction of Nb_2O_5 and NaOH was performed as described in 2.2, using molar ratios NaOH:Nb_2O_5 between 35 and 67 and 6–24 h reaction time. After cooling down, the obtained solid was separated by filtration, washed and dried as described above. *Anal.* Found: (Calc.): Nb, 56.2 (56.7); K, 14.2 (14.0)%.

2.3.2. $K_6H_2[Nb_6O_{19}]\cdot 13H_2O$

The reaction of Nb_2O_5 (0.2 g) and KOH was performed as described in Section 2.2, with a molar ratio KOH:$Nb_2O_5 = 60$ and 24 h reaction time. After cooling down, any insoluble residue was eliminated by

centrifugation. To the obtained solution was added an equal volume of absolute ethanol and the precipitated solid was filtered, washed successively with very cold ethanol–water (50%) and ethanol and dried under vacuum.

Anal. Found: (Calc.): Nb, 39.8 (41.8); K, 17.2 (17.6); H_2O, 17.7 (17.6)%. Infrared spectra (cm^{-1}): ν(Nb–O_t) 859 (vs); ν(Nb–O_b), 788 (m), 670 (s), 528 (s); ν(Nb–O_c) 418 (s), 400 (s). Raman spectra (cm^{-1}): ν(Nb–O_t) 900 (vs), 850 (m), 829 (m); ν(Nb–O_b), 679 (m), 535 (m); δ(O_b–Nb–O_b) 284(s), 217(s).

2.3.3. $Nb_2O_5 \cdot nH_2O$

The reaction of Nb_2O_5 and KOH was performed as described for the previous compound. After filtration of the insoluble residue, HCl 1 mol dm^{-3} was added until complete precipitation of the white solid formed. The solid was separated by centrifugation, washed repeatedly with water, followed by ethanol and left in a desiccator.

3. Results and discussion

Hydrothermal reactions of Nb_2O_5 with aqueous alkali metal hydroxides, MOH, M = Na, K, were performed at 200 °C and autogenic pressure in an autoclave and the obtained solids and solutions studied. Time of reaction and molar ratio mol(MOH):mol(Nb_2O_5) were systematically varied.

3.1. Reactions with NaOH

Experiments were performed with molar ratios NaOH:Nb_2O_5 between 3 and 67 and different time of reaction (6–48 h). After cooling, an abundant white solid material was found inside the autoclave. The composition of these powders varied with reaction conditions. In most cases, the mass of solid obtained suggested that little dissolution had occurred.

Fig. 1 presents the X-ray patterns of reaction products obtained after 6 h. In those solids $NaNbO_3$ was first identified by comparison of the correspondent powder X-ray diffractogram with published data [22]. For the molar ratio NaOH:Nb_2O_5 = 9 the obtained $NaNbO_3$ was contaminated with Nb_2O_5, but synthesis of single phase $NaNbO_3$ was achieved for the higher molar ratio. The same results were observed for 24 h reactions. Further reaction time did not lead to any improvement. The electron micrographs of the powders obtained from the reactions performed with molar ratios NaOH:Nb_2O_5 = 67 and different reaction times are shown in Fig. 2. They show small parallelepiped crystals of different sizes with length smaller than about 1.5 μm. By analysis of the powder X-ray diffraction patterns an orthorhombic unit cell was found, with $a = 5.510(2)$, $b = 5.569(1)$, $c = 15.533(6)$ Å. At room temperature, $NaNbO_3$ crystallizes in a pseudoperovskite phase, frequently referred as phase P [23], that has been indicated as orthorhombic [13,24–27] but also as monoclinic [28].

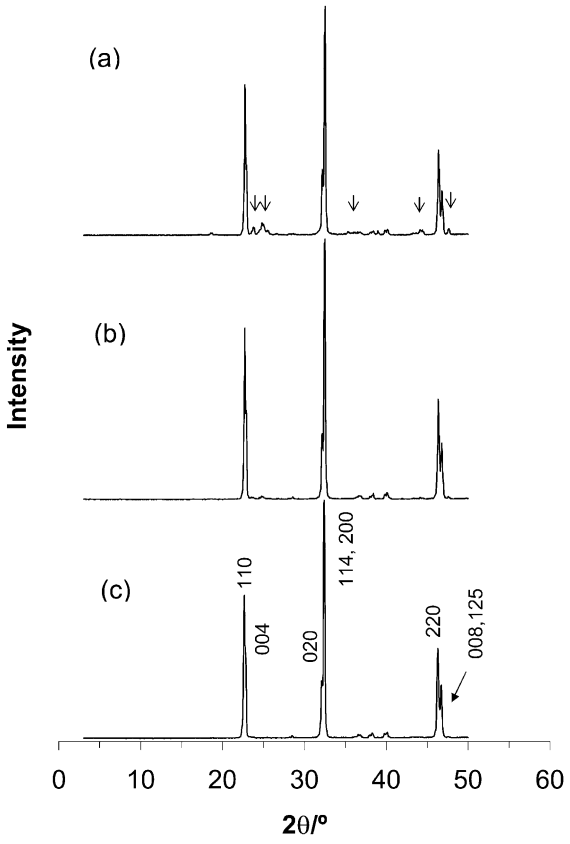

Fig. 1. X-ray powder diffraction patterns of products obtained after 6 h hydrothermal reaction, with different ratio mol(NaOH)–mol(Nb_2O_5): (a) 9; (b) 34; (c) 67. Mass of Nb_2O_5 used: 0.2 g. Main peaks corresponding to $NaNbO_3$ are indexed in (c). Arrows indicate Nb_2O_5 impurity.

The infrared spectrum of $NaNbO_3$ is distinct from that of the initial Nb_2O_5, presenting a broad strong peak at 640 cm^{-1}, with a shoulder near 780 cm^{-1} and one medium band at 372 cm^{-1} with a shoulder at lower frequency. This spectrum compares well with that of powders prepared by other techniques [7,29].

Some experiments were performed using $Nb_2O_5 \cdot nH_2O$ (obtained by the method described in Section 2.2) instead of Nb_2O_5 (NaOH:Nb_2O_5 ratio approximately equal to 60, 24 h). $NaNbO_3$ was also the product obtained.

The direct synthesis of $NaNbO_3$, from Nb_2O_5 and aqueous NaOH, at 200 °C, under hydrothermal conditions, represents thus an easy method of preparation of this compound. This method eliminates the need of using high temperature reactions, calcination steps, or less accessible precursors. It compares well with published procedures starting from $Na_8[Nb_6O_{19}] \cdot 13H_2O$ [11] or $Na_7H[Nb_6O_{19}] \cdot 15H_2O$ [12], as preparation of

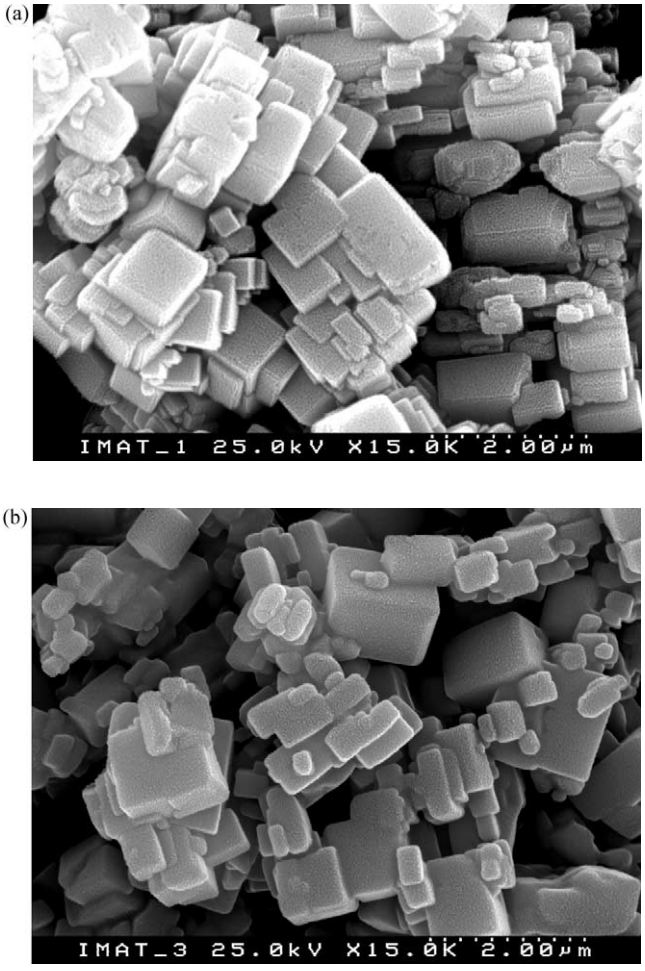

Fig. 2. Electron micrographs of powders obtained from reactions performed with mol(NaOH)–mol(Nb_2O_5) = 67 and different reaction times: (a) 24 h; (b) 48 h.

these starting materials is not necessary. Our work is not in accordance with the only report that claims that crystals of $NaNbO_3$ were obtained by boiling a suspension of Nb_2O_5 in NaOH for about 20 min [13], as longer periods of time at higher temperatures were found to be necessary. It is possible that a hydrated form of niobium pentoxide had been used. $Nb_2O_5{\cdot}nH_2O$ is known for being more reactive than Nb_2O_5. We have confirmed that the hydrothermal reaction of niobic acid with NaOH yields also $NaNbO_3$, but the study of the best reaction conditions was not performed in this work.

We observed that commercial niobium oxide had an insoluble residue that never dissolved in the reactions with KOH (see Section 3.2). It is possible that this residue may not react also with NaOH. However, we could not identify any impurity in the prepared $NaNbO_3$ by any of the used techniques and thus be sure of its presence or absence. This residue was eliminated during the preparation of $Nb_2O_5{\cdot}nH_2O$ and, thus, synthesis starting with niobic acid may lead to purer products. Otherwise, the preparation of $Nb_2O_5{\cdot}nH_2O$ introduces an extra procedure in the synthetic pathway of no particular advantage.

3.2. Reactions with KOH

The reaction of Nb_2O_5 with aqueous KOH under hydrothermal conditions had been previously used to successfully prepare $KNbO_3$ [14,15] and $K_4Nb_6O_{17}{\cdot}3H_2O$ [15]. The work here presented concerns mainly the dissolution of niobium pentoxide in aqueous KOH, as this reaction provides an interesting new process of obtaining alkaline solutions of Nb(V). We were particularly interested in observing if solutions prepared by hydrothermal dissolution of Nb_2O_5 could be used to perform standard niobium chemistry, like preparation of potassium hexaniobates [16,17] or niobic acid [3–5].

In the conditions here reported, it was found that Nb_2O_5 was practically all dissolved after 24 h reaction if the molar ratio KOH:Nb_2O_5 was larger than 35 (molar ratio between 2 and 75 were evaluated). Extra time or increase of the molar ratio did not eliminate a small amount of an insoluble residue always present. That residue could not be obtained in the necessary quantities for identification and was considered as an insoluble phase of the commercial reagent used. When the reaction time was equal or less than 8 h or the molar ratio smaller than 35, a solid was obtained in reasonable amounts, which was found by powder X-ray diffraction to be mostly un-reacted Nb_2O_5. Reaction times between 8 and 24 h were not monitored.

When solubilization was almost complete the solid residue was eliminated and ethanol added to the filtrate. In all cases, the formation of a white precipitate was observed. Elemental analysis of the obtained solids yielded a K:Nb molar ratio near 1.0. The correspondent infrared spectra and Raman showed in the 400–900 cm^{-1} region the characteristic pattern of the hexaniobate anions, $H_xNb_6O_{19}{}^{(8-x)-}$, assigned to Nb=O and Nb–O–Nb stretching vibrations [6,16,30–32]. Reasonably pure $K_6H_2[Nb_6O_{19}]{\cdot}13H_2O$ was obtained from solutions prepared with an initial molar ratio KOH:Nb_2O_5 = 60 (see Section 2). The correspondent infrared and Raman spectra are shown in Fig. 3. Mixtures with other hexaniobates, like $K_7H[Nb_6O_{19}]{\cdot}nH_2O$, could not be ruled out in other conditions. Identification of the degree of protonation cannot be done with certainty by infrared spectroscopy, as the values of the frequencies of hexaniobate anions have been found to depend slightly on protonation and on the degree of hydration of the salts, for a given cation [6,16]. The anions $H_xNb_6O_{19}{}^{(8-x)-}$, $x = 0$–3 are known to exist in aqueous solutions with pH in the 8.5–14 region [5,17]. Studies of the preferential conditions of precipitation of some potassium hexaniobates have been published [16,17] and were not pursued in this work.

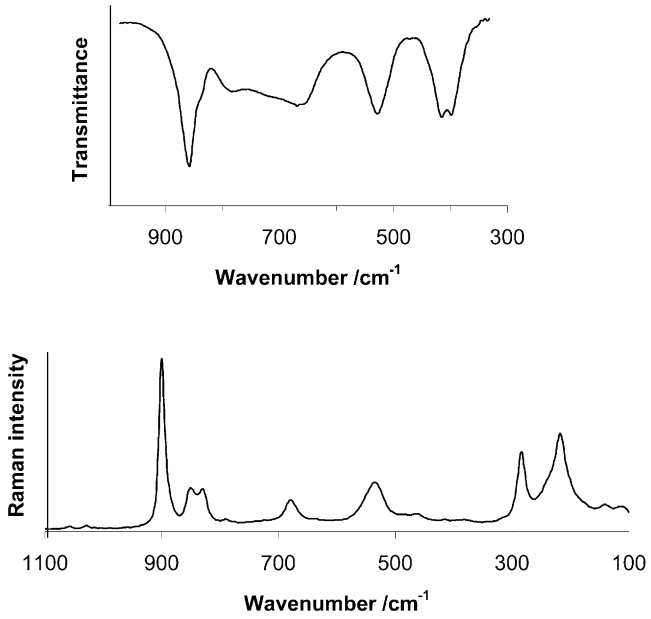

Fig. 3. Vibrational spectra of $K_6H_2[Nb_6O_{19}]\cdot 13H_2O$: (a) infrared spectrum; (b) Raman spectrum.

$K_6H_2[Nb_6O_{19}]\cdot nH_2O$ was obtained in the form of crystalline, slightly agglomerated powders (Fig. 4). The corresponding X-ray powder diffraction pattern is presented in Fig. 5(a). Indexation of this will be presented elsewhere. Of the possible salts $K_{8-x}H_x[Nb_6O_{19}]\cdot nH_2O$, only for $K_8[Nb_6O_{19}]\cdot 10H_2O$ has the powder X-ray diffraction patterns been published [33], but this was never observed for our compounds. Calcinations of $K_6H_2[Nb_6O_{19}]\cdot nH_2O$ at 800 °C yielded $KNbO_3$ as the only product, identified by its X-ray powder diffractogram match with the ICDD database [34] (Fig. 5(b)) and confirmed by elemental analysis (EDAX). This result is in accordance with equation (1), thus confirming the molecular stoichiometry of the prepared potassium hexaniobate.

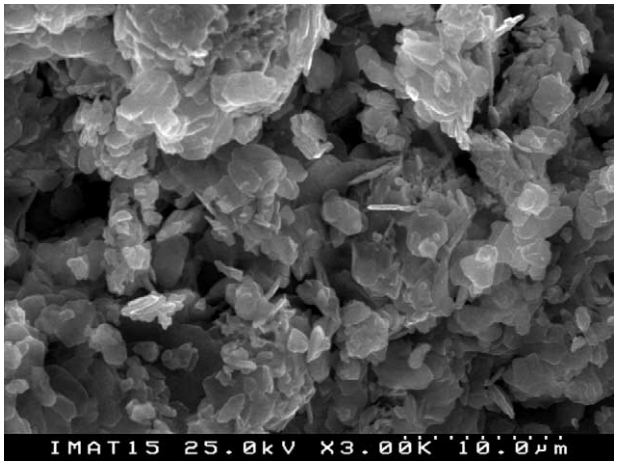

Fig. 4. Electron micrograph of $K_6H_2[Nb_6O_{19}]\cdot 13H_2O$.

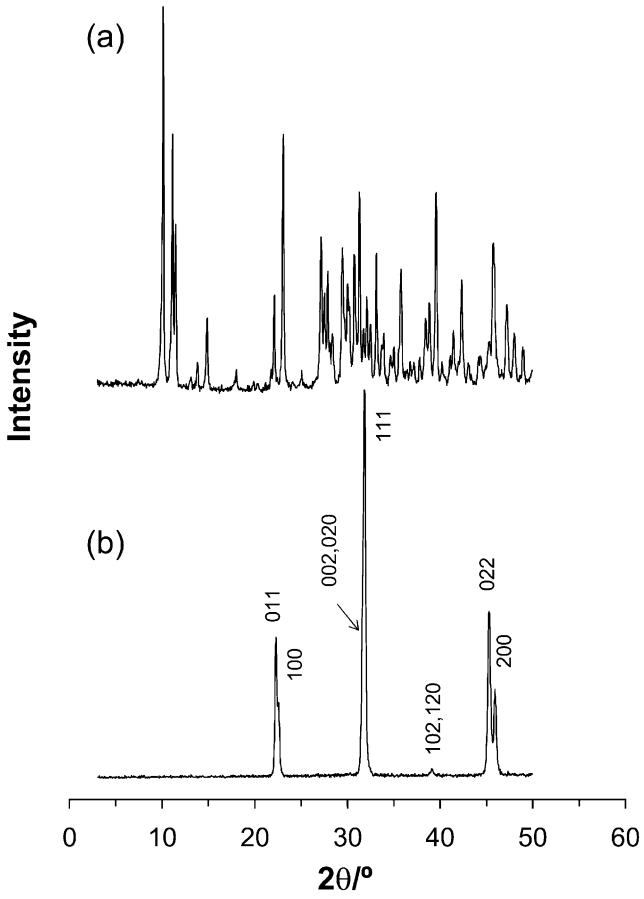

Fig. 5. X-ray powder diffraction patterns of (a) $K_6H_2[Nb_6O_{19}]\cdot 13H_2O$ and (b) $KNbO_3$ (orthorhombic, $a = 3.968(1)$, $b = 5.691(1)$, $c = 5.700(1)$ Å) obtained by calcinations of $K_6H_2[Nb_6O_{19}]\cdot 13H_2O$ at 800 °C.

$$K_6H_2[Nb_6O_{19}]\cdot 13H_2O \rightarrow 6KNbO_3 + 14H_2O \quad (1)$$

Even when Nb_2O_5 did not dissolve extensively, addition of ethanol to the filtrate originated solids with the hexaniobate anions, as determined by infrared spectroscopy. If HCl was added to the filtrate, instead of ethanol, precipitation of hydrated niobium pentoxide was observed, as expected [3,4]. We have used this method to prepare $Nb_2O_5\cdot nH_2O$ used in the reactions with NaOH (see Section 3.1).

The oxide Nb_2O_5 has a complicated structural chemistry and occurs in several polymorphs [35,36]. The commercial solid used was found to be a mixture of forms where the main components were identified by powder X-ray diffraction as being a low-temperature orthorhombic phase and a M-form [37]. The reactivity of the different modifications was not the same and thus the form of Nb_2O_5 identified by X-ray diffraction when the reactions (either with KOH or NaOH) were not complete varied with experimental conditions. The infrared spectra of different samples of un-reacted Nb_2O_5, obtained from the experiments with KOH, were, however, very similar, presenting three broad strong bands centered around 827, 710 and 513 cm^{-1}

with several weak, poorly resolved, peaks on the larger wavenumber side.

The insolubility of the different forms of niobium pentoxide in common aqueous acids and bases has been recognized for many years as a characteristic of these oxides. The solubilization of Nb_2O_5 in KOH solutions, under hydrothermal conditions at 200 °C offers great advantage, as it is experimentally easy and does not need the use of high temperatures. It has been reported that dissolution was obtained with shorter reaction times [14] than those here described, but this was obtained in a stirred reactor with a different range of reagent concentrations. In this work, the conditions used were identical to those in the preparation of $NaNbO_3$ (Section 3.1). Under these conditions, formation of $KNbO_3$ or $K_4Nb_6O_{17}\cdot 3H_2O$ [14,15] was never detected. Comparison of the results here presented with those previously published [14,15] seems to imply that different factors (concentration of KOH solution, KOH:Nb_2O_5 molar ratio and experimental settings) influence the outcome of the studied reactions.

3.3. Final remarks

It is interesting to note that the method and conditions of attack of Nb_2O_5 described in this work provided different results when NaOH or KOH were used. Soluble potassium and sodium hexaniobates, of general formula $M_{8-x}H_x[Nb_6O_{19}]\cdot nH_2O$, are well known [3]. Potassium hexaniobates are, generally, more soluble in water than the corresponding sodium salts and thus sodium hexaniobates are frequently obtained by cation metathesis, starting with solutions of the potassium analogues [3]. Muller et al. have studied a series of sodium hexaniobates prepared by reaction of niobic acid with NaOH [6,38]. Different solubility and thermal stability of these salts may explain the different results observed.

In conclusion, we have found that the hydrothermal reaction of Nb_2O_5 with NaOH at 200 °C can be used in the synthesis of $NaNbO_3$ under milder conditions than by the ceramic method. A low temperature form, described previously as stable up to 365 °C [26,27], was obtained. Under similar conditions, reactions of Nb_2O_5 with KOH allowed the preparation of solutions containing soluble potassium hexaniobates by a more convenient process than the traditional method of fusion of mixtures of the niobium oxide with KOH or other potassium salts.

Acknowledgements

We are grateful to Dr. M.R. Soares for assistance with the X-ray diffraction analysis. Thanks are also due to the University of Aveiro and Center of Inorganic and Materials Chemistry (FCT) for financial support of this work.

2. Experimental

Methanol (99.8%, anhydrous), copper(II) acetate monohydrate (98+%) and nitric acid (trace metal grade) were obtained from commercial sources and used as received. UV–Vis spectra were recorded using matched quartz cells on a Shimadzu UV2101 PC spectrophotometer. IR spectra were recorded on a Mattson Galaxy 5000 FT-IR spectrometer. GC-MS data were obtained using a Varian Saturn 2100D instrument, and inductively coupled plasma emission data were recorded and analyzed using a Thermo Jarrell Ash Atom Scan 25 instrument and associated software.

2.1. Synthesis of copper(II) methoxide

In a typical experiment, a glass vial was charged with 24.5 mg (0.123 mmol) of copper(II) acetate monohydrate and 5.0 ml of methanol. After stirring, the vial was placed into a Teflon-lined stainless steel autoclave and heated to 110 °C for three days. Upon opening the autoclave, dark purple block-shaped crystals of **1** were observed on the bottom and sides of the vial. No other solid product was evident, and the supernatant liquid was colorless. The vial containing the crystals and mother liquor was capped with a rubber septum and attached to the Schlenk line via a needle. Under argon, the mother liquor was withdrawn and analyzed by UV–Vis and GC-MS. These experiments clearly indicated the presence of methyl acetate in the mother liquor. The crystals remaining in the vial after removal of the mother liquor were washed with several 5 ml portions of methanol under argon. No observable change occurred during the washing or subsequent evacuation of the vial.

2.2. Spectroscopic characterization of copper(II) methoxide

A sample of the washed crystalline material described above was ground under methanol to produce a fine slurry. Several drops of the slurry were placed on a sodium chloride plate in an argon-filled chamber that was subsequently evacuated. When the methanol had evaporated from the slurry, the chamber was filled with argon and brought to the IR spectrometer, the sample cavity of which had been purged with nitrogen gas. The salt plate was mounted in the spectrometer and a spectrum matching that of copper(II) methoxide [1,2] was recorded. The sample cavity was then opened to the air and spectra were recorded at approximately five-minute intervals, during which time the bands ascribed to copper methoxide were replaced by a broad O–H band typical of a hydrogen-bonded O–H stretch and other unidentified signals.

2.3. Inductively coupled plasma emission spectroscopic analysis.

The synthesis of **1** was carried out using a 24.7 mg (0.124 mmol) sample of copper(II) acetate monohydrate. After reaction, the mother liquor was transferred to a Schlenk flask that was then subjected to dynamic vacuum until no solvent was evident. The residue was dissolved in nitric acid and diluted to 50.00 ml with deionized water. Analysis of this solution against a 10.00 ppm Cu standard indicated a Cu concentration of 0.157 ppm with a standard deviation of 0.005 ppm. This corresponds to 1.24×10^{-4} mmol Cu in the entire analyte solution.

2.4. Crystallography

Crystal evaluation and data collection were performed on a Bruker CCD-1000 diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å). A purple block-shaped crystal with approximate dimensions $0.45 \times 0.14 \times 0.12$ mm, obtained directly from the reaction vial, was mounted under oil on the tip of a glass capillary. The crystal was mounted in a stream of nitrogen gas at 173(2) K and centered in the X-ray beam.

Crystal Data: $C_2H_6CuO_2$ (formula weight = 125.61), tetragonal, space group $P4_2/mbc$, $a = 8.1848(6)$ Å, $c = 5.8770(4)$ Å, $V = 393.71(5)$ Å^3, $Z = 4$, $\rho_{calc} = 2.119$ g cm^{-3}, $F(000) = 252$, μ (Mo Kα) = 5.356 mm^{-1}. Initial cell constants were obtained from three series of ω scans at different starting angles. Each series consisted of 50 frames collected at intervals of 0.3 in a 15° range about ω with an exposure time of 20 s per frame. The final cell constants were calculated from a set of 1084 strong reflections. Data were collected by use of the hemisphere data collection routine. A total of 3205 data were harvested by collecting three sets of 30-s frames with 0.3° scans in ω. Data were corrected for Lorentz and polarization effects. An absorption correction was performed and was based on fitting a function to the empirical transmission surface as sampled by multiple equivalent measurements [5]. Systematic absences in the diffraction data were consistent with the space groups $P4_2bc$ and $P4_2/mbc$. The E-statistics strongly suggested the centrosymmetric space group $P4_2/mbc$ that yielded chemically reasonable and computationally stable refinement results [6]. A solution by direct methods provided most of the non-hydrogen atoms from the E-map. The remaining non-hydrogen atoms were located in an alternating series of least-squares and difference Fourier maps. Non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in the structure factor calculation at idealized positions and were allowed to ride on the neighboring atoms with relative isotropic displacement coefficients. A total of 3205

reflections were collected, 224 of which were independent [$R_{int} = 0.0300$] in the range $3.52^\circ < \Theta < 26.38^\circ$. The data were 100% complete over this range. The final least squares refinement on F^2 yielded $R_1 = 0.0204$ ($wR_2 = 0.0713$) for 179 reflections having $I > 2\sigma(I)$, where $wR_2 = \Sigma[w(F_o^2 - F_c^2)]/\Sigma[(wF_o^2)^2]^{1/2}$; $R_1 = \Sigma\Delta/\Sigma(F_o)$, $\Delta = |(F_o - F_c)|$. The Cu atom occupies three crystallographic twofold axes while the carbon and oxygen atoms reside on a crystallographic mirror plane.

3. Results and discussion

We have found that treatment of copper(II) acetate monohydrate with methanol for three days at 110 °C produces exceptionally well-formed deep purple block-shaped crystals of copper(II) methoxide with no other solid products. These crystals are indefinitely stable under the mother liquor or pure methanol at room temperature. They also appear to be stable for at least several hours under argon or vacuum. In the air in absence of methanol, the crystals decompose rapidly, undergoing an irreversible color change to light blue. Interestingly, if the amount of copper acetate reacting in 5.0 ml of methanol is raised above 25 mg, the yield of purple crystals is drastically decreased and a large amount of uncharacterized brown/black solid forms. Further, no reaction is observed if the same starting material is left to stand in methanol under argon for 11 days, indicating that solventothermal conditions are necessary for the facile synthesis of **1** by this reaction.

3.1. Description of the crystal structure of copper(II) methoxide

After preliminary identification of the identity of the purple crystalline product as copper(II) methoxide, confirmation was achieved via single crystal X-ray methods. In the structure of **1**, infinite one-dimensional chains of copper atoms with bridging methoxide ligands run parallel to the crystallographic *c*-axis in the tetragonal space group $P4_2/mbc$. The copper atoms in **1** are each coordinated by four oxygen atoms in a distorted square planar fashion. The methyl groups on either side of the one-dimensional chain tip in alternating directions away from the mean copper–oxygen plane in a 'zig–zag' arrangement, and the copper atoms are arranged in a linear fashion with respect to one another. A segment of this coordination polymer is shown in Fig. 1. Fig. 2 is a view down the crystallographic *c*-axis showing the orientation of the chains with respect to one another. Fig. 3 presents a view looking down the crystallographic a axis, illustrating the orientation of the methyl groups in **1** with respect to the linear arrangement of copper atoms. Selected bond distances and angles are reported in Table 1.

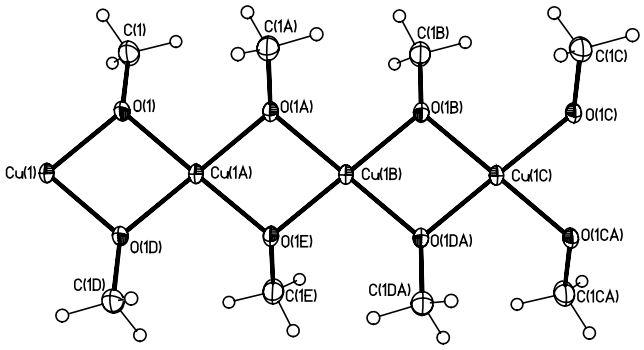

Fig. 1. A section of the infinite one-dimensional chain in **1**, with ellipsoids drawn at the 50% probability level.

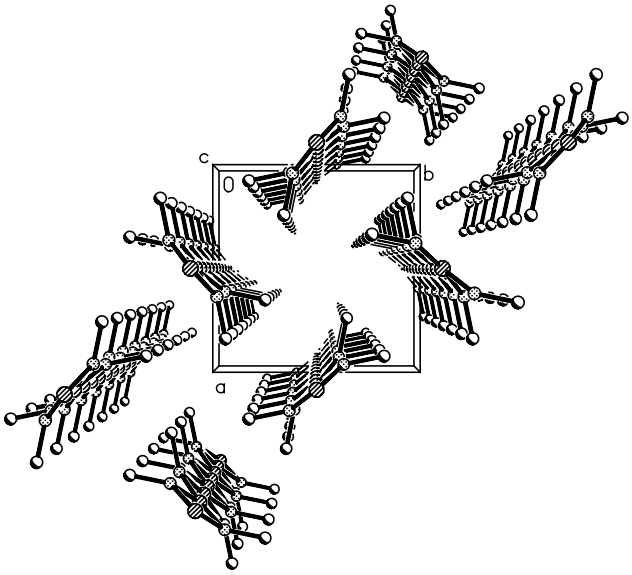

Fig. 2. A view down the crystallographic *c*-axis in the lattice of **1**.

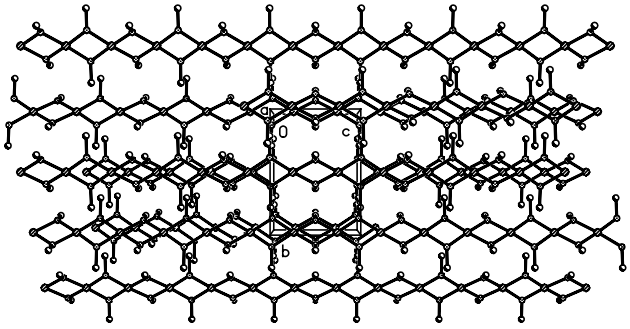

Fig. 3. A view down the crystallographic *a*-axis in the lattice of **1**.

The bridging of copper atoms by methoxide ligands is a common structural motif, but the infinite chain structure determined for **1** is novel. The structure of **1** can be thought of as the most basic of all methoxide-bridged Cu coordination compound structures. A search of the Cambridge Structural Database [7] for compounds containing methoxide ligands bridging copper

Table 1
Selected bond lengths (Å) and bond angles (°) for **1**

Bond lengths			
Cu(1)–O(1)	1.915(1)	O(1)–C(1)	1.417(3)
Bond angles			
O(1)–Cu(1A)–O(1A)	100.5(1)	C(1)–O(1)–Cu(1)	124.22(8)
O(1)–Cu(1A)–O(1D)	79.80(9)		

atoms, limited to structures with final R values of 5% or lower and no disorder yielded 26 hits. Among these structures, the average Cu–O distance was 1.93(2) Å and the average Cu–Cu separation 3.0(1) Å. Both the Cu–O bond distance and Cu–Cu separation in **1**, 1.915(1) and 2.9385(2) Å, respectively, compare well with these parameters.

3.2. Discussion of the synthetic reaction and products

The only solid product of the synthesis is **1**, as confirmed by IR spectroscopy**.** Analysis of the mother liquor by inductively coupled plasma emission spectroscopy showed only a minute trace of copper, corresponding to about 0.1% of the copper in the starting material. This indicates that the conversion of copper(II) acetate to copper(II) methoxide is essentially quantitative, as there are no reasonable volatile copper-containing products. A UV–Vis spectrum of the mother liquor was transparent in the visible region, showing only an absorbance attributable to methyl acetate, the presence of which was confirmed by GC-MS. We believe that the methyl acetate forms via a classical condensation reaction whereby methanol and acetic acid react with elimination of water and concomitant formation of the ester. This observation strongly suggests that acetate ions, present in solution due to the use of copper acetate as the copper source, are responsible for deprotonation of methanol. It is not clear what role, if any, copper atoms may play in this process. Nonetheless, the overall pathway by which **1** and methyl acetate form can be summarized as shown in Scheme 1.

This work has confirmed initial suppositions of a methoxide-bridged polymeric structure for copper(II) methoxide [1], well supported from the beginning by observed physical properties. What is not clear is whether the initial suggestion of a three-dimensional coordination polymer (as opposed to the crystallographically-determined one-dimensional structure) was in fact in error, or rather that the present conditions result in the formation of a different phase of copper methoxide than those that had been prepared and characterized previously. This question will be difficult to answer conclusively, as none of the previously reported synthetic conditions lead to products that are suitable for complete structural characterization by X-ray methods.

$$CH_3OH + CH_3COO^- \leftrightarrows CH_3O^- + CH_3COOH$$
$$n(Cu^{2+}) + 2n(CH_3O^-) \rightarrow [Cu(OCH_3)_2]_n$$
$$CH_3COOH + CH_3OH \rightarrow CH_3COOCH_3 + H_2O$$

Scheme 1.

The observed stability of **1** under methanol, even in the presence of a significant amount of water (present because of the use of hydrated copper acetate as starting material) is somewhat surprising and worthy of note. The observation that a sample of **1** identified in the nitrogen-purged sample cavity of an IR spectrometer decomposes rapidly upon the introduction of air is, however, consistent with the known air sensitivity of copper methoxide in the absence of solvent.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 178855. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

Acknowledgement is made to the donors of The Petroleum Research Fund, administered by the ACS, for support of this research**.** The authors thank Dr. Paul J. Taylor and Dr. Paul D. Miller of UW-La Crosse for assistance with ICP analysis and GC-MS, respectively.

the spectra were obtained at ambient temperature (approximately 24 °C). EPR measurements were taken on a Bruker ESP300 EPR spectrometer with the following settings: modulation amplitude, 1G; modulation frequency, 100 KHz; time constant 163.84 ms; scan time, 83.886 s; receiver gain, 6.32×10^3 unless otherwise noted. The frequency is calibrated using frequency meter. The solvents were purged with nitrogen before use.

3,5-Di-*t*-pentylsalicylaldehyde (**1**) is prepared by modification of a reported method [11] and is reported elsewhere, together with the preparation of ligand **2** [12].

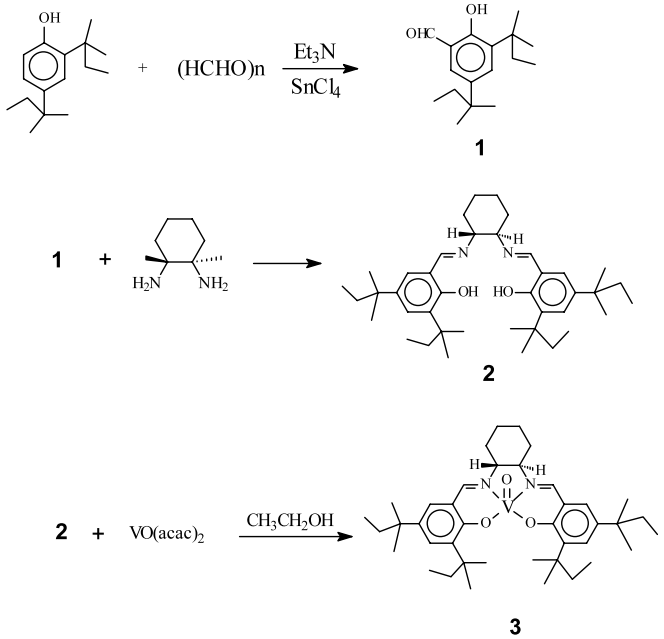
Preparation of vanadyl complex **3**: in dry EtOH (10 cm^3), salen schiff base ligand **2** (1.000 g, 1.66 mmol) and vanadyl(IV) acetylacetonate [$VO(acac)_2$, 0.467 g, 1.76 mmol] were stirred at room temperature for 8 h. The volume of ethanol was reduced and a green solid was filtered and washed with cold EtOH to afford vanadyl complex **3** (1.04 g, 94%). The analytical sample was obtained with recrystallization from a mixture of C_6H_{14} (hexane) and $CHCl_3$, and dried over P_2O_5 for 24 h. *Anal.* Calc. for $C_{40}H_{60}N_2O_3V$: C, 71.93; H, 9.06; N, 4.20; Found: C, 72.00; H, 9.11; N, 4.20%.

2.2. Crystal structure determination

Crystals suitable for X-ray determination were obtained by slow evaporation of a C_6H_{14}–$CHCl_3$ (1:1, v/v) solution. $C_{46}H_{74}N_2O_3V$: $3 \cdot C_6H_{14}$, $M = 710.93$, triclinic, space group P_1, $a = 10.2439(1)$, $b = 14.4771(2)$, $c = 14.8782$ (2) Å, $\alpha = 68.655(1)°$, $\beta = 85.059(1)°$, $\gamma = 87.060(1)°$, crystal size $0.493 \times 0.221 \times 0.136$ mm, λ(Mo Kα) 0.71073 Å, $Z = 2$, $D_c = 1.153$, $F(000) = 772$, μ(Mo Kα) = 2.81 cm^{-1}.

2.2.1. Data collection

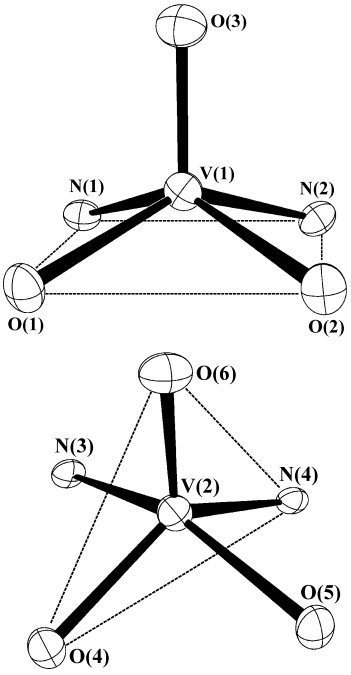
Absorption correction calculated using SADABS with maximum and minimum transmission factors of 0.9628 and 0.8740, respectively; intensity data were collected on a Bruker 1K CCD platform diffractometer; A total of 20271 reflections were collected, of which 14809 independent reflections ($R_{int} = 0.03341$) were observed with $1.47° < \theta < 28.24°$ and used in all the calculations. The unit cell dimensions were determined by a least-square fit of 2θ angles for 8192 reflections.



2.2.2. Structure analysis and refinement

The structure was solved by direct methods and subsequent Fourier difference techniques, and refined anisotropically, by full-matrix least-squares, on F^2 using SHELXTL 5.1. Hydrogen atoms were calculated from ideal geometry with coordinates fixed and temperature factors varied. Weights based on counting-statistics were used (based on $w^{-1} = \sigma^2(F_o^2) + (0.0844P)^2 + 0.34P$, where $P = [\mathrm{Max}(F_o^2, 0) + 2 \times F_c^2)/3]$). The last least-square cycle was calculated with 1002 parameters and 14809 reflections. For 10713 reflections with $I > 2\sigma(I)$, $R(F)$ was 0.0596, R_w (F^2) 0.1441 with goodness-of-fit 1.011 where R_w is defined by $R_w(F^2) = [\Sigma(\omega(F_o^2 - F_c^2))^2 / [\Sigma(\omega(F_o^2)^2]^{1/2}$ and GoF defined by $\mathrm{GoF} = [\Sigma(\omega(F_o - F_c))^2/13807]^{1/2}$. For all reflections, $R(F)$ was 0.0919, $Rw(F^2)$ 0.1654. The maximum $\Delta/\sigma = 0.000$, the deepest hole is −0.425 e $Å^{-3}$ and the highest peak is 0.446 e $Å^{-3}$. Full crystallographic data are given in the supporting materials.

3. Results and discussion



The new vanadyl complex **3** was prepared from the reaction of $VO(acac)_2$ with salen ligand **2** in ethanol (Scheme 1). The important feature of this ligand is to possess *t*-pentyl (Pn) groups at the 3, 5-positions of the aromatic rings. Due to the presence of these bulky components, the vanadyl complex has excellent solubility in most of the commonly used organic solvents such as THF, acetone, chloroform, and methylene chloride. The needle-like crystals of the vanadyl complex were obtained from a mixture of hexane and chloroform solvents.

The crystal structure revealed by X-ray determination showed that there are two independent molecules, referred to as **A** and **B**. Selected bond distances and angles in central metal coordination were listed in Table 1. There is a striking difference in the chromophore coordination geometry in **A** and **B** molecules. Two N–V bonds in **A** are nearly symmetrical with almost equal bond length (~2.06 Å), and so are the two V–O bonds

Scheme 1. Synthesis of salen ligand with *t*-pentyl groups and salen VO complex.

Table 1
Selected bond lengths (Å) and angles (°) in the vanadium geometry

N(2)–V(1)–O(1)	143.56 (17)	N(4)–V(2)–O(4)	131.11 (16)

(~ 1.93 Å). However, they are seriously distorted in **B**. One V–O bond is noticeably longer than the other (1.944 vs. 1.903 Å), and so is the V–N bond (2.09 vs. 2.058 Å). In addition, vanadium is approximately centered in **A**, it is not in **B**. Both shorter N(3)–V(2) and O(4)–V(2) bonds clearly suggest that vanadium is deviated from the center in **B**.

The other significant distortion is bond angles involving basal atoms and V=O in the molecule **B**. There is about 10° deviation between two O=V–O (~ 115° vs. 105°). In addition, the same order of deviation is also found between two O=V–N (~ 101° vs. 112°). In contrast, almost symmetrical angles between two O=V–O (~ 110°) or two O=V–N (~ 105°) are observed in **A** (Fig. 1).

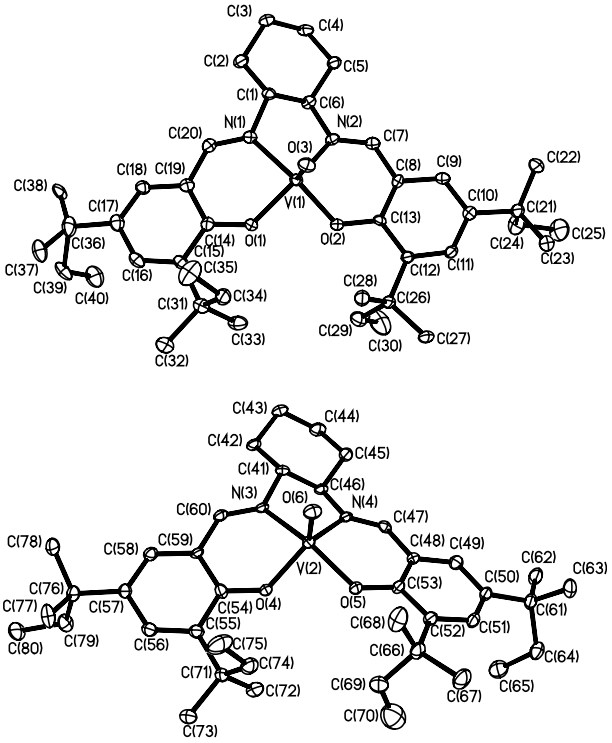

Fig. 1. ORTEP drawings of molecules **A** (top) and **B** (bottom).

It has been suggested that square-pyramidal complex should exhibit apical atom-basal atom in the range of 90°–113° [13], a diagnostics for tbp configuration when the angles exceed the range. The molecule **A** has all the O=V-basal atom angles in this range, fitting into the description of square-pyramidal (sp) geometry. The molecule **B**, on the other hand, has one O=V-basal atom angle beyond this range. Noticeably, the O(6)–V(2)–O(4) is 115.78°, suggesting that the geometry is not exactly square-pyramidal, and may be distorted to tbp, an alternative configuration for a five-coordinated complex.

Another important feature in the molecule **B** is the N(3)–V(2)–O(5) angle. The ideal angle should be 180° for a standard tbp complex with an unconstrained ligand, normally monodentate. When the ligand becomes multidentate, this angle is bent because of the ring restraint upon coordination. For example, in a structurally defined tbp Schiff base vanadyl complex, bis[*N*-(4-chlorophenyl)salicylaldehydeneiminato]oxovanadium (IV) [(Cl-Salim)$_2$VO] where the ligand is a bidentate Schiff base, this value was reported to be 159.1° [14]. It has been speculated that a more restrained ligand should lead to a further decrease in this angle. The salen ligand is an ideal ligand that should offer more restraint due to the tetradentate nature. The smallest value (152.81°) found in this complex appears to provide a direct correlation between ligand restraint and angle distortion with the following deviation trend: tetradentate ligand > bidentate ligand > monodentate.

For practical consideration, it is highly unlikely that a vanadyl complex with a multiple dentate ligand will have a perfect tbp configuration. The extent of such trigonality can be quantitatively described by the τ index, with value of zero for a perfect sp (no trigonality), and a unit for a perfect tbp [15,16]. The τ index is defined by $(\beta-\alpha)/60$ to give molecule **B** a τ value of 0.36 where α (131.11) and β (152.81) are diagonally basal angles. The character of trigonality is obvious when comparison is made against molecule **A** which has a τ value of almost zero. Using the same analysis, the τ value for the tbp-defined $(Cl\text{-}Salim)_2VO$ is 0.43 [17]. This number provides a quantitative insight that more trigonality character is possessed by a complex with bidentate ligands than with a tetradentate ligand, a complimentary description to the diagnosis using O=V-basal atom angles.

The tbp distorted geometry in molecule **B** could be caused by crystal packing although the exact reason is yet to be understood. The lack of two species coexisting in solution strongly suggests the possibility.

The complex in solution clearly shows two bands in the region from 377 to 624 nm due to d–d transition of square-pyramidal vanadyl. The vanadyl complexes can usually accept a sixth ligand to vanadium in the axial position *trans* to the oxygen atom. When this happens, the d–d transition bands will be solvent-dependent. However, some factors can have profound impact on this interaction. We have previously reported that a large displacement of vanadium from the basal plane would make the external ligand more difficult to gain access to the site, leading to weak or no interaction at all [18]. It has been speculated here that the steric effect from the bulky group, in particular, from the 3-position will hamper the approach of the external ligand to the vanadium atom in the sixth position. Fig. 2 shows that in solid state the two ethyl moieties from *t*-pentyl groups in the 3,3′-positions are already opposite to each other due to steric effect. To test this, two solvents, acetonitrile and pyridine, have been chosen. The donating ability of a solvent, defined by $D_{I/II}$ [19], is 2.60 for acetonitrile, a weak donating solvent and 4.40 for pyridine, a strong donating solvent. It has been found that the two bands appear at 377 ($\varepsilon=8151$) and 622 nm ($\varepsilon=162$) in acetonitrile, at 379 (9574) and 623 nm ($\varepsilon=155$) in pyridine, respectively. Clearly, there is no significant shift of absorption bands in both weak and strong donating solvents, suggesting that it is unlikely that there is any strong interaction between vanadium and the donating molecule. The bulky groups indeed appear to have an impact on the approach of the donating solvent to the vanadium.

The A values from EPR also appear to have no significant changes in these two solvents. The $A_{\parallel}$ and $A_{\perp}$ values obtained at -78 °C are also essentially unchanged (Fig. 3, Table 2). It needs to be pointed out that the complex in acetonitrile at low temperature tends to crystallize out, but, both $A_{\parallel}$ and $A_{\perp}$ values can be obtained to be fairly accurate. In addition, more A values from chloroform have been added for comparison. These data are consistent with the suggestion that there is no strong interaction between vanadium and donor molecules, even at low temperature. The anisotropic g values are evidently consistent again. The $g_{\parallel}$ and $g_{\perp}$ values are around 1.96 and 2.00, respectively, in all solvents. The current tensor and g values in solution are consistent with the presence of square-pyramidal configuration. The lack of two sets of peaks in the $A_{\parallel}$ region further suggests that the formation of the tbp geometry is probably a solid state phenomena, and molecule **B** is relaxed into **A** in solution.

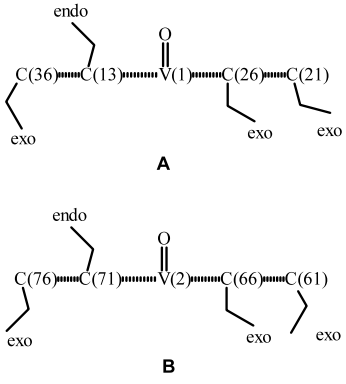

Fig. 2. Schematic representation of orientation of bulky *t*-pentyl groups in both molecules **A** and **B** in solid state.

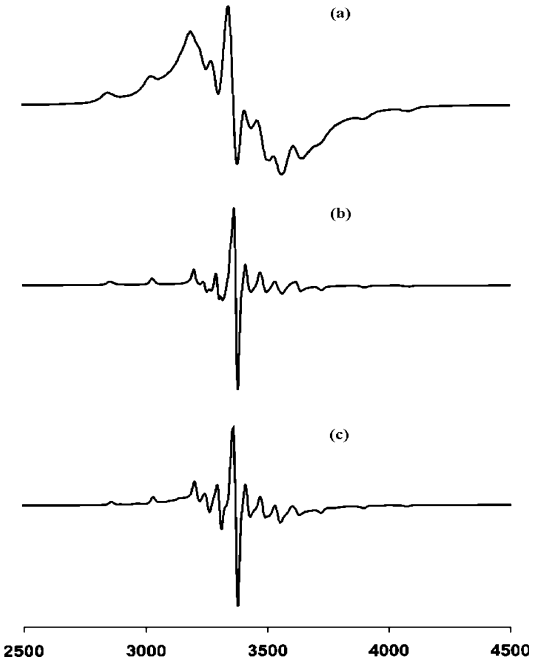

Fig. 3. Low temperature (liquid nitrogen) EPR spectra in various solvents: (a) acetonitrile; (b) pyridine; (c) chloroform.

Table 2
EPR data in various solvents

Solvent	A_o[a]	$A_\parallel$[b]	$A_\perp$[b]	g_0	$g_\perp$	$g_\perp$
Acetonitrile	97.05	171.07	61.58	1.9851	1.9609	1.9973
Pyridine	96.08	171.61	61.06	1.9853	1.9594	1.9983

[a] In Gs, obtained at ambient temperature.
[b] In Gs, obtained at liquid nitrogen temperature.

In conclusion, the two configurations in a chiral vanadyl complex have been identified. One is almost symmetrical regarding coordination chromophore, which leads to square-pyramidal configuration, while the other is unsymmetrical, which leads to distorted tbp configuration. The tetradentate ligand constraint causes significantly large angle deviation between two axial bonds in the tbp configuration. The lack of finding these two species in solution suggests that this may be a solid state phenomena. Square-pyramidal vanadyl complex is only one species found in solution. Steric effect from bulky substituents at the 3-positions prevents donor molecules from interacting with metal centers.

4. Supplementary material

The supplementary material is available from the Cambridge Crystallographic Data Center, CCDC No. 162359 for compound **3**. Fig. 1. Some of the ligands discussed in the text; note that $(py)_2C(OH)_2$, $(py)_2C(OR)(OH)$ and all three anions do not exist as free species but exist only in their complexes.

ions are bridged by anionic ligands present in the complexes, e.g. Cl^- or SCN^-.

Completely different and much more interesting (for cluster chemistry) coordination modes are seen when ligands $(py)_2C(OR)(OH)$ and $(py)_2C(OH)_2$ become deprotonated. Upon deprotonation, the former becomes monoanionic, while the latter can function either as monoanion or dianion. The presence of deprotonated hydroxy groups within $(py)_2C(OR)O^-$, $(py)_2C(OH)O^-$ and $(py)_2CO_2^{2-}$ (Fig. 1) leads to a great coordinative flexibility, due to the well known ability of the negatively charged oxygen to bridge two or three metal ions. The monoanionic forms usually bridge two (μ_2) or three (μ_3) metal ions, while the dianionic form can bridge as many as five metal sites. The ability of these forms to adopt a variety of coordination modes has resulted in the isolation of clusters with nuclearities ranging from 4 to 14 [11–13]. It is not known [14] whether the coordination of the oxygen to the metal center occurs *after* the hydration/alcoholysis reaction or *prior* to this reaction; in the former case there is a polarization effect of the metal upon the hydroxy group leading to its deprotonation, while in the latter case there is a direct activation of the carbonyl group towards nucleophilic attack.

Our groups are engaged in developing the polynuclear 3d-metal chemistry of di-2-pyridyl ketone [12,13]. Our main contribution to this area is twofold: firstly, the realisation that $(py)_2C(OH)_2$ can be doubly deprotonated leading to structurally impressive clusters [12] and, secondly, the incorporation of end-on azido ligands into the chemistry of $(py)_2CO_2^{2-}$ and $(py)_2C(OH)O^-$/$(py)_2C(OR)O^-$ as a means to introduce specifically ferromagnetic components in the superexchange schemes, thus increasing the ground-state S values of clusters [12,13].

We recently reported [12] that the reaction of $Co(O_2CMe)_2\cdot 4H_2O$ with $(py)_2CO$ and NaN_3 (9:4:2, 2:1:1 ratios) in DMF under heating led to the nonanuclear cage $[Co_9(N_3)_2(O_2CMe)_8\{(py)_2CO_2\}_4]$ (**1**), in which the nine Co^{II} atoms adopt a topology of two square pyramids sharing a common apex. Salient features of the structure are the unique η^1,μ_4 coordination mode of the azido ligands, the μ_5 coordination mode of $(py)_2CO_2^{2-}$ and the extremely rare coordination number 8 for the Co^{II} atom lying at the common apex of the pyramids. The magnetic study revealed ferromagnetic coupling mediated by the azido bridges giving a total S value of seven times the local spin and leading to a high-spin ferrimagnetic system.

We were interested to study whether and how the nature of the carboxylate ligands affects the structural and magnetic identity of the products resulting from the $Co^{II}/RCO_2^-/N_3^-$ reaction mixtures in DMF. For example, we wondered if replacement of acetates with benzoates in this reaction mixture would give a cluster structurally and magnetically similar to **1**. In this report, we describe the identity, single-crystal X-ray structure and magnetic properties of the product from the $Co^{II}/PhCO_2^-/N_3^-$ reaction mixture in DMF.

2. Experimental

2.1. Preparation of $[Co_4(N_3)_2(O_2CPh)_2\{(py)_2C(OH)O\}_4]\cdot 2DMF$ (2)

DMF (20 ml) was added to a solid mixture containing $Co(O_2CPh)_2$ (0.18 g, 0.60 mmol), $(py)_2CO$ (0.06 g, 0.31 mmol) and NaN_3 (0.02 g, 0.31 mmol). The solid dissolved upon stirring under heating to give a dark blue solution. The solution was allowed to stand undisturbed at room temperature for 3 days. Well-formed, X-ray quality pink crystals of the product appeared within this period. The crystals were collected by filtration, washed with DMF and Et_2O, and dried in vacuo over silica gel. Yield: 40% [based on $(py)_2CO$]. *Anal.* Found: C, 50.8; H, 3.9; N, 14.8. Calc. for $C_{64}H_{60}Co_4N_{16}O_{14}$: C, 50.8; H, 4.0; N, 14.8%. Complex **2** can also be isolated by employing an 1:1:0.5 $Co(O_2CPh)_2$–$(py)_2CO$–NaN_3 molar ratio.

Caution: azide salts are potentially explosive and should be handled in small quantities.

2.2. Physical measurements

Magnetic susceptibility measurements were carried out for a polycrystalline sample of **2** with a SQUID susceptometer working in the range 2–300 K under magnetic fields of approximately 0.1 T. Diamagnetic corrections were estimated from Pascal Tables. IR spectra (4000–400 cm^{-1}) were recorded from KBr pellets on a Nicolet 520 FTIR spectrometer.

2.3. X-ray crystallography

Analyses on pink prismatic single crystal of **2** were carried out with an MAR345 diffractometer with image plate detector. Intensities were collected with graphite

monochromatized Mo Kα radiation. A summary of the crystallographic data is reported in Table 1. Unit cell parameters for **2** were determined from automatic centering of 8219 reflections ($3^\circ < \theta < 30^\circ$) and refined by the least-squares method. Five thousand and twenty-four reflections were measured in the range $2.81^\circ < \theta < 28.87^\circ$. Three thousand nine hundred and three reflections were assumed as observed applying the condition $I > 2\sigma(I)$. Lp but no absorption corrections were made.

The structure was solved by direct methods using the SHELXS computer program [15] and refined by full-matrix least-squares method, with the SHELX-97 computer program [16] using 5024 reflections. The function minimized was $\Sigma\, w||F_o|^2-|F_c|^2|^2$, where $w=[\sigma^2(I)+(0.0655P)^2]^{-1}$, and $P=(|F_o|^2+2|F_c|^2)/3$. f, f' and f'' were taken from *International Tables of X-ray Crystallography* [17]. Sixteen hydrogen atoms were located from a difference synthesis and 12 H atoms were computed. All were refined with an isotropic temperature factor equal to 1.2 times the equivalent isotropic temperature factor of the bonded atom. A riding model was used for computed hydrogen atoms. The number of parameters refined was 507. Max. shift/esd = 0.002. Mean shift/esd = 0.000.

3. Results and discussion

3.1. Synthesis

As stated in Section 1, the initial goal of this work was the preparation of a cobalt(II) benzoate cluster with a structure and magnetic properties similar to those of **1**. Our general synthetic approach for the isolation of heteroleptic $RCO_2^-/(py)_2CO_2^{2-}/N_3^-$ metal clusters is to react an excess of the metal carboxylate with $(py)_2CO$ and N_3^- in DMF under heating [12]. Obviously $(py)_2C(OH)_2$ is fully deprotonated by the basic carboxylate groups and polynuclear $M^{II}/RCO_2^-/(py)_2CO_2^{2-}/N_3^-$ complexes result from the reactions [as long as the RCO_2^-–$(py)_2CO$ ratio is high enough to leave an amount of nonprotonated RCO_2^- in the reaction mixture], given the fact that the RCO_2^-, $(py)_2CO_2^{2-}$ and azido ligands can potentially adopt a variety of terminal and bridging modes.

Reaction of $Co(O_2CPh)_2$ with $(py)_2CO$ and NaN_3 (2:1:1 molar ratio) in DMF under heating resulted in a blue solution from which the pink tetranuclear complex $[Co_4(N_3)_2(O_2CPh)_2\{(py)_2C(OH)O\}_4]\cdot 2DMF$ (**2**) was isolated in moderate yield. We did not try to optimize the yield. The low to moderate yield in our experiments is presumably a consequence of the crystallization method (see Section 2.1). The extremely slow evaporation of the solvent (DMF) at room temperature and the relatively short time ($\sim$3 days) of the storage of the open reaction flask before filtration may both be responsible for the obtained yields. The stoichiometric reaction is represented by Eq. (1):

$$4Co(O_2CPh)_2 + 4(py)_2CO + 4H_2O + 2NaN_3 + 2DMF \xrightarrow[T]{DMF} \underset{\mathbf{2}}{[Co_4(N_3)_2(O_2CPh)_2\{(py)_2C(OH)O\}_4]\cdot 2DMF} + 4PhCO_2H + 2NaO_2CPh \quad (1)$$

Surprisingly, a seemingly subtle change in the reaction conditions that gave complex **1** (i.e. changing the acetates with benzoates) led to a dramatic change in the type of complex produced. Complex **1** is a nonanuclear cage containing doubly deprotonated $(py)_2CO_2^{2-}$ ligands, whereas **2** is a tetranuclear cluster containing singly deprotonated $(py)_2C(OH)O^-$ ligands. Further increase in the 'base' ($PhCO_2^-$) to 'acid' ['$(py)_2C(OH)_2$'] ratio, either by increase of the $Co(O_2CPh)_2$–$(py)_2CO$ molar ratio from 2:1 to 3:1 or by employment of external $PhCO_2^-$s, and longer reaction times did not give any evidence for the formation of a complex containing dianions $(py)_2CO_2^{2-}$ as ligands. We strongly believe that the

lower basicity of $PhCO_2^-$ (the pK_a value of its conjugate acid, $PhCO_2H$, is 4.19) compared to $MeCO_2^-$ (pK_a of $MeCO_2H = 4.75$) is responsible for the inability of $PhCO_2^-$s to doubly deprotonate '$(py)_2C(OH)_2$' and the failure to isolate the benzoate analogue of **1**.

Use of external hydroxides (LiOH, Me_4NOH) to help double deprotonation of the *gem*-diol form of $(py)_2CO$ complicates the reaction mixture leading to non-crystalline hydroxo products with poor analytical results.

Looking for an alternative method of preparing the benzoate analogue of **1**, we anticipated that complex **1** would be capable of acetate substitution on treatment with $PhCO_2H$. Such a reactivity pattern is consistent with the known acidities of the RCOOH molecules as reflected in the pK_a values (see above) and the probable mechanism [18] involves protonation of bound acetates by more acidic $PhCO_2H$ molecules, followed by their displacement by generated $PhCO_2^-$s. Such ligand substitution reactions have been widely used in metal carboxylate cluster chemistry [18,19]. Unfortunately, we could not confirm this type of reactivity for **1**. Addition of excess of $PhCO_2H$ to **1** in MeOH or DMF gives a mixture of products (including **2**) depending on the reaction conditions; the separation of these products was impossible.

With the identity of **2** established by single-crystal X-ray crystallography (vide infra), a modified preparative procedure (not reported in detail in Section 2) was devised by adjusting the $Co(O_2CPh)_2$–$(py)_2CO$–NaN_3 reaction ratio in DMF from 2:1:1 to 1:1:0.5 (Eq. (1)). We have also found that heating is not necessary for the preparation of **2**.

3.2. Description of structure

A plot of the structure of the tetranuclear compound $[Co_4(N_3)_2(O_2CPh)_2\{(py)_2C(OH)O\}_4]\cdot 2DMF$ (**2**) is shown in Fig. 2(a). Fig. 2(b) emphasizes the core of the tetranuclear molecule and shows the numbering scheme. Selected distances and angles are listed in Table 2.

The structure consists of centrosymmetric tetranuclear molecules. The four Co^{II} atoms are located at four corners of a defective double cubane (two cubanes sharing one face and each missing one vertex, see Fig. 2(b)) and bridged by means of two end-on (η^1,μ_2) azido ligands and O atoms from the $(py)_2C(OH)O^-$ anions. Peripheral ligation is provided by two O atoms of the terminal benzoate ligands and the N atoms of the eight 2-pyridyl rings. Atoms O(1) of two $(py)_2C(OH)O^-$ ligands are triply bridging with distances to Co^{II} atoms of 2.225(2), 2.155(2) and 2.015(2) Å for Co(1)–O(1), Co(2)–O(1) and Co(2)#1–O(1), respectively. The Co(1)–O(1)–Co(2) and Co(1)–O(1)–Co(2)#1 angles are 97.4(1)° and 96.2(1)°, respectively. Atoms O(3) of the two other $(py)_2C(OH)O^-$ ligands are doubly bridging with distances of 2.012(2) and 2.154(2) Å to Co(1) and Co(2)#1, respectively. The Co(1)–O(3)–Co(2)#1 angle is 98.5(1)°. One O atom of each $(py)_2C(OH)O^-$ ligand remains protonated and unbound to the metals. Therefore, two $(py)_2C(OH)O^-$ ions adopt the η^1:η^3:η^1:μ_3 coordination mode and the other two bind with the η^1:η^2:η^1:μ_2 mode (Fig. 3). Co(1) and Co(2) are also bridged by the N(1) atom of the η^1, μ_2 azido ligand (end-on). The Co(1)–N(1) and Co(2)–N(1) distances are 2.158(2) and 2.103(2) Å, respectively. The Co(1)–N(1)–Co(2) angle is 101.1(1)°. The azido ligand is practically linear with a N(1)–N(2)–N(3) angle of 179.5(3)°.

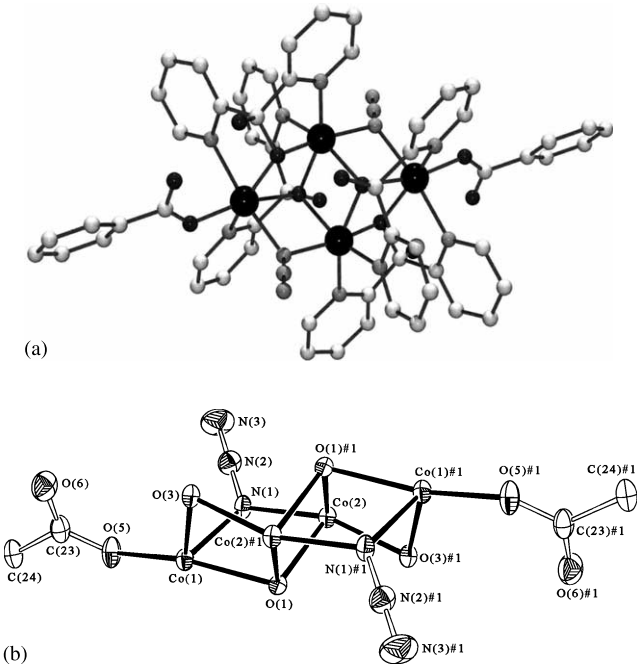

Fig. 2. (a) Plot of $[Co_4(N_3)_2(O_2CPh)_2\{(py)_2C(OH)O\}_4]\cdot 2DMF$ (**2**); the solvate DMF molecules have been omitted. (b) Labelled plot of the defective, double-cubane core present in complex **2**.

The metal ions have distorted octahedral geometries. The Co(1) octahedral coordination is completed by the N(4) and N(6) atoms of two $(py)_2C(OH)O^-$ ligands, and the O(5) atom of the terminal benzoate ligand. The Co(2) octahedral coordination is completed by the N(5)#1 and the N(7)#1 atoms of two $(py)_2C(OH)O^-$ ligands with Co(2)–N(5)#1 and Co(2)–N(7)#1 distances of 2.168(2) and 2.079(2) Å, respectively.

3.3. IR spectroscopy

The presence of DMF in **2** is manifested by a medium-intensity band at 1669 cm^{-1} and a weak band at 645 cm^{-1}, assigned to ν(C=O) and δ(OCN), respectively [20]. The absence of shifts of these bands in the complex, when compared with the corresponding bands in the spectrum of free DMF [21], implies that there is no interaction between DMF and the Co^{II} atoms. The complex exhibits an intense band at 2076 cm^{-1},

Symmetry transformations used to generate equivalent atoms: #1 $-x+2$, $-y$, $-z+1$.

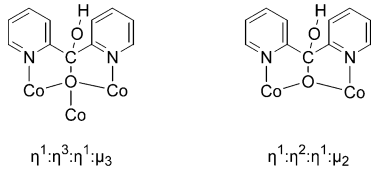

Fig. 3. The crystallographically established coordination modes of the $(py)_2C(OH)O^-$ ligands in complex **2**.

assigned to the asymmetric stretching mode of the azido ligands [13]. The strong bands at 1601 and 1388 cm^{-1} are assigned to the ν_{as}(COO) and ν_s(COO) modes, respectively [22]; the former should also involve a pyridine stretching character. The difference Δ [$\Delta = \nu_{as}(COO) - \nu_s(COO)$] for **2** (213 cm^{-1}) is more than that for NaO_2CPh, as expected for the monodentate mode of carboxylate ligation [22]. The spectrum of **2** also exhibits a strong band at 3445 cm^{-1}, assignable to $\nu(OH)_{(py)_2C(OH)O^-}$. The broadness and relatively low frequency of this band are both indicative of hydrogen bonding.

3.4. Magnetochemistry

The $\chi_M T$ product versus T of **2** in the 300–2 K range is shown in Fig. 4 (χ_M is the corrected molar magnetic susceptibility per tetramer). $\chi_M T$ increases quickly on cooling from 10.8 cm^3 K mol^{-1} at 300 K to a maximum of 16.9 cm^3 K mol^{-1} at 11 K, and then decreases to 14.6 cm^3 K mol^{-1} at 2 K. χ_M increases upon cooling and does not have any maximum in the temperature range studied. The overall behaviour of **2** corresponds to a ferromagnetically coupled system. The strong ferromagnetic interaction in **2** is confirmed by the molar magnetization measurement at 2 K, which shows a quick increase of $M/N\beta$ by increasing the external field, arriving to a final value of 10.37 at 5.0 T (Fig. 5). This strong coupling between Co(2) and Co(1) permits us to assume that the interactions through the η^1,μ_2-N_3^- and the μ-O^- bridge with the Co(1)–O(1)–Co(2) angle of 97.4(1)° are both ferromagnetic, indicating a magnetic behaviour similar to that found for the structurally related Co(II) derivatives $[Co_4(\eta^1,\mu_2\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OMe)O\}_2]\cdot 2H_2O$ (**3**) [13] and $[Co_4(\eta^1,\mu_2\text{-}N_3)_2(H_2O)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OMe)O\}_2](BF_4)_2\cdot 4H_2O$ (**4**) [11]. All three complexes have the same defective double-cubane core. Analysis of the coupling constants for a high-spin rhombic cobalt(II) tetramer is not possible by means of an effective Hamiltonian based on four $S = 3/2$ spins, due to the large anisotropy of this ion [11,13]. At low temperature the local spin of Co^{II} is closer to $\frac{1}{2}$, and then the low temperature data are better defined as an $S_T = 2$ system with a large g_{eff} value.

3.5. Synthetic aspects of the $Co^{II}/(py)_2CO/N_3^-$ reaction system

Complex **2** is structurally related to complexes $[Co_4(\eta^1,\mu_2\text{-}N_3)_2(N_3)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OMe)O\}_2]\cdot 2H_2O$ (**3**) [13] and $[Co_4(\eta^1,\mu_2\text{-}N_3)_2(H_2O)_2\{(py)_2C(OH)O\}_2\{(py)_2C(OMe)O\}_2](BF_4)_2\cdot 4H_2O$ (**4**) [11], prepared from the $Co(O_2CMe)_2\cdot 4H_2O/(py)_2CO/NaN_3$ (1:1:1, 1:2:2, 1:3:3, 1:2:4, 1:4:4) and $CoCl_2\cdot 6H_2O/(py)_2CO/NaN_3/NaBF_4$ (1:1:0.5:0.5) reaction mixtures, respectively, in $MeOH/H_2O$. All three complexes have a defective, double-cubane motif. There are two chemical

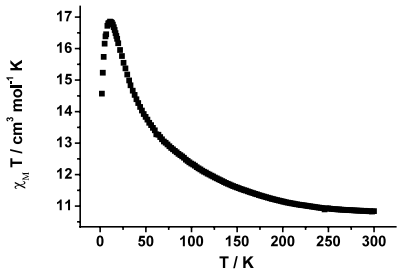

Fig. 4. $\chi_M T$ plot vs. T for compound **2**.

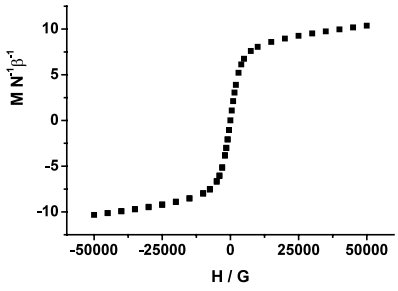

Fig. 5. Plot of the magnetization ($M/N\mu_B$) vs. H for **2** at 2 K.

differences along the series which have no structural effect. First, complexes **3** and **4** have two $(py)_2C(OH)O^-$ and two $(py)_2C(OMe)O^-$ ligands; this is a consequence of MeOH present in the reaction systems that lead to **3** and **4**. Second, the two terminal monodentate ligands differ in the three complexes; these are $PhCO_2^-$ ions in **2**, N_3^- ions in **3** and H_2O molecules in **4** (giving rise to a cationic species). The presence of benzoate ligands in **2** is a result of the high $PhCO_2^-$–N_3^- ratio used (4:1), whereas the presence of the two terminal azide ligands in **3** can be explained by the lower $MeCO_2^-$–N_3^- ratios used (2:1, 1:1, 1:1.5, 1:2) in the reaction mixtures. The existence of aqua ligands in the structure of **4** is certainly due to the presence of BF_4^- ions in the reaction system; the latter favour formation of cationic species.

4. Supplementary material

Further details (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 180597 for compound **2**. Copies of the data may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccd.cam.ac.uk).

dinuclear ruthenium terpyridine complexes using the α,α′-diimine based neutral bridging functions NC_5H_4–CH=N–$(C_6H_4)_n$–N=CH–H_4C_5N ($n = 1$, 2), L. Although the bridging functions (L) are stable enough in the free state [28,29], during the reaction with $Ru(trpy)Cl_3$ (trpy = 2,2′:6,2″-terpyridine) one of the imine functions of L has been selectively hydrolyzed. This in turn leads to the formation of ruthenium monoterpyridine complexes of the type $[Ru^{II}(trpy)(L')Cl]^+$ (**1**) where L′ corresponds to NC_5H_4–CH=N–$(C_6H_4)_n$–NH_2 ($n = 1$, 2).

Herein we report the stepwise syntheses of the complexes, $[Ru^{II}(trpy)(L')Cl]^+$ (**1**) → $[Ru^{II}(trpy)(L')H_2O]^{2+}$ (**2**) → $[Ru^{IV}(trpy)(L')O]^{2+}$ (**3**), crystal structures of L^1 and **1a**, and the chemical–electrochemical reactivities of the complexes including the catalytic/electrocatalytic behaviors of the in situ generated oxo species (**3**). The specific role of the electronic nature of L′ in **1**–**3** in comparison with the analogous ancillary functions present in other known ruthenium monoterpyridine complexes have been noted.

2. Experimental

2.1. Materials

The starting complex $Ru(trpy)Cl_3$ and the ligands L^{1-2} were prepared according to the reported procedures [30,28]. 2,2′:6,2″-terpyridine was obtained from Aldrich, USA. Other chemicals and solvents were reagent grade and used as received. Alumina (neutral) was used for column chromatography. For spectroscopic and electrochemical studies HPLC grade solvents were used. Water of high purity was obtained by distillation of the deionized water from $KMnO_4$. Sodium perchlorate for electrochemical work in aqueous medium was recrystallized from water.

2.2. Physical measurements

UV–Vis spectra were recorded by using a Shimadzu-2100 spectrophotometer. FT-IR spectra were taken on a Nicolet spectrophotometer with samples prepared as KBr pellets. Solution electrical conductivity was checked using a Systronic 305 conductivity bridge. Magnetic susceptibility was checked with a PAR vibrating sample magnetometer. NMR spectra were obtained with a 300 MHz Varian FT spectrometer. Cyclic voltammetric, differential pulse voltammetric and coulometric measurements were carried out using a PAR model 273A electrochemistry system. Platinum wire working and auxiliary electrodes and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. The supporting electrolyte was $[NEt_4]ClO_4$ and the solute concentration was approximately 10^{-3} M. The half-wave potential E°_{298} was set equal to $0.5(E_{pa}+E_{pc})$, where E_{pa} and E_{pc} are anodic and cathodic cyclic voltammetric peak potentials, respectively. A Pt wire-gauze working electrode was used in coulometric experiments. All experiments were carried out under a dinitrogen atmosphere and were uncorrected for junction potentials. The elemental analyses were carried out with a Carlo–Erba (Italy) elemental analyzer. Solution emission properties were checked using a SPEX-fluorolog spectrofluorometer. X-ray data were collected by using a Nonius MACH 3 four-circle diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å).

2.3. Preparation of complexes

The complexes $[Ru(trpy)(L')(Cl)](ClO_4)\cdot 2H_2O$ (**1a** and **1b**) were prepared by following a general procedure. Details are mentioned for the complex **1a**.

2.4. *[Ru(trpy)(L′)(Cl)]$ClO_4\cdot 2H_2O$ (1a)*

The starting complex $Ru(trpy)Cl_3$ (100 mg, 0.227 mmol) was taken in 25 ml of hot EtOH. The preformed bridging ligand L^1 (65 mg, 0.228 mmol) was added to the above solution and the mixture was heated to reflux for 14 h. The solvent was removed under reduced pressure. The residual mass was dissolved in a minimum volume of MeCN and saturated aq. $NaClO_4$ solution was added. The solid product thus obtained on cooling was filtered and washed with ice-cold water followed by cold EtOH. The crude product was purified by using an alumina (neutral) column. Initially the side product, $[Ru(trpy)_2](ClO_4)_2\cdot 2H_2O$ was eluted by CH_2Cl_2–MeCN (5:2) mixture. The pink colored complex, **1a** was eluted by CH_2Cl_2–MeCN (5:3) mixture. Another fraction of the pink solution corresponding to **1a** was eluted later by CH_2Cl_2–MeCN (1:1) from the same column. The complex **1a** thus obtained from the two different batches were further purified separately by following the same above procedures in order to remove any trace of $[Ru(trpy)_2](ClO_4)_2\cdot 2H_2O$ impurity. Similarly the $[Ru(trpy)_2](ClO_4)_2\cdot 2H_2O$ complex obtained from the above column was also purified again in order to make it free from **1a**. The two pink colored solutions thus obtained separately from the same column were found to exhibit identical spectral and electrochemical features. Evaporation of the solvent mixture resulted in pure solid complexes, **1a** and $[Ru(trpy)_2](ClO_4)_2\cdot 2H_2O$. Yield: **1a** (95.0 mg, 61%) and $[Ru(trpy)_2](ClO_4)_2\cdot 2H_2O$ (15 mg, 10%). *Anal*. Calc. for **1a**: C, 46.15; H, 3.73; N, 11.97. Found: C, 46.31; H, 3.45; N, 12.22%. Λ_M/Ω^{-1} ($cm^2\ mol^{-1}$) in MeCN at 298 K: 148. *Anal*. Calc. for **1b**: C, 50.90; H, 3.89; N, 10.80. Found: C, 50.52; H, 3.32; N, 11.02%. Λ_M/Ω^{-1} ($cm^2\ mol^{-1}$) in MeCN at 298 K: 140.

2.5. [Ru(trpy)(L′)(H$_2$O)](ClO$_4$)$_2$·2H$_2$O (2a)

The aqua complexes (**2**) were prepared from the corresponding chloro species using excess $AgNO_3$. Details are mentioned for **2a**.

Silver nitrate (120 mg, 0.70 mmol) was added to the aqueous solution of the chloro complex, [Ru(trpy)(L′)(Cl)]ClO$_4$·2H$_2$O (**1a**) (100 mg, 0.14 mmol in 15 ml water) and the solution was heated to reflux for 2.5 h. It was then cooled and the precipitated AgCl was filtered off through a sintered glass crucible (G-4). The volume of the filtrate was reduced to 5 ml and saturated aq. $NaClO_4$ solution was added to it. The mixture was kept in the refrigerator overnight. The solid product (**2a**) thus obtained was filtered and washed with ice-cold water and dried in vacuo over P_4O_{10}. Yield: 78 mg (70%). *Anal*. Calc. for **2a**: C, 41.34; H, 3.60; N, 10.71. Found: C, 40.92; H, 3.33; N, 10.37%. Λ_M/Ω^{-1} (cm^2 mol^{-1}) in MeCN at 298 K: 230. *Anal*. Calc. for **2b**: C, 46.06; H, 3.75; N, 9.77. Found: C, 46.59; H, 3.43; N, 10.11%. Λ_M/Ω^{-1} (cm^2 mol^{-1}) in MeCN at 298 K: 240.

2.6. X-ray structure determination

The single crystals of L^1 were grown by slow diffusion of a CH_2Cl_2 solution of L^1 in C_6H_{14} followed by slow evaporation. The single crystals of **1a** were obtained by slow diffusion of the MeCN solution of **1a** in C_6H_6 followed by slow evaporation. Significant crystal data and data collection parameters are listed in Table 1. The structures were solved by direct methods using SHELXS-86 and refined by full-matrix least-squares on F^2 using SHELXL-97 [31].

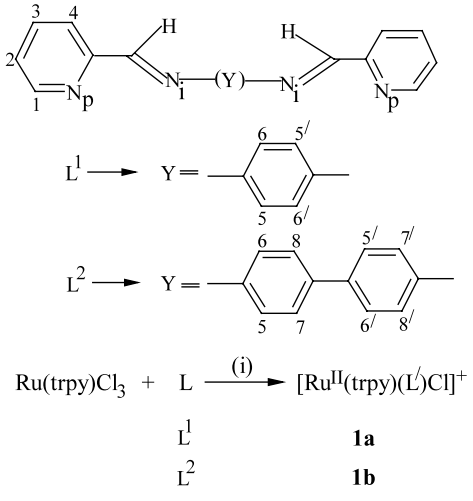
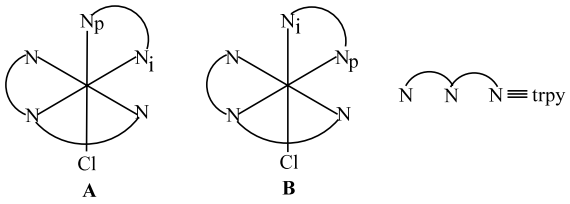
3. Results and discussion



3.1. Synthesis

The bridging ligands L^1–L^2, used for the present study differ primarily with respect to the length of the spacers (Scheme 1). The ligands are designed with the intention of holding two Ru(trpy)Cl units through the terminal N$_p$ (N$_p$ = pyridine nitrogen) and N$_i$ (N$_i$ = imine nitrogen) donor centers of L. However, the reaction of L with the starting complex Ru(trpy)Cl$_3$ in a 1:2 mole ratio in ethanol solvent results in a monomeric species of the type [Ru(trpy)(L′)Cl]$^+$, **1** where L′ corresponds to NC$_5$H$_4$CH=N–(C$_6$H$_4$)$_n$–NH$_2$ ($n = 1$, **1a**; $n = 2$, **1b**) (Scheme 1).

During the course of the reaction one of the imine functions of the preformed bridging ligands (L) has been selectively hydrolyzed and the resulting mononucleating fragment of the bridging moiety (L′) leads to the formation of **1** (Scheme 1). The complexes have been isolated as their dihydrated perchlorate salts, [Ru^{II}(trpy)(L′)Cl]ClO$_4$·2H$_2$O (**1**).



Under identical reaction conditions (Scheme 1) but in the absence of ruthenium precursor Ru(trpy)Cl$_3$, the preformed bridging functions (L) are found to remain intact, implying the effective role of the metal fragment in transforming L → L′ in **1**.

The synthesis of **1** by using a 1:2 mole ratio of L and Ru(trpy)Cl$_3$ is always observed to be accompanied by the formation of a [Ru(trpy)$_2$]$^{2+}$ complex in an approximately 1:1 ratio. However, the use of a 1:1 mole ratio of L and Ru(trpy)Cl$_3$ reduces the yield of [Ru(trpy)$_2$]$^{2+}$ to an appreciable extent {**1**–[Ru(trpy)$_2$]$^{2+}$, 6:1, Section 2}. In order to minimize the perpetual formation of the undesired product [Ru(trpy)$_2$]$^{2+}$, the 1:1 mole ratio of L and Ru(trpy)Cl$_3$ had always been selectively used.

Scheme 1. (i) EtOH, heating, N$_2$.

Although the unsymmetrical nature of L′ in **1** leads to the possibility of the simultaneous formation of two isomers **A** and **B**, here the reaction (Scheme 1) systematically results in one particular isomeric product (see NMR). The existence of the isomeric form **B** has been confirmed by single-crystal X-ray structure for **1a** (see later). Based on the similar spectral features of **1a** and **1b** (see later), we believe that the complex **1b** also exists in same isomeric form **B**.

The aqua complexes $[Ru^{II}(trpy)(L')(H_2O)]^{2+}$ (**2**) have been isolated as their dihydrated perchlorate salts from the corresponding chloro complexes (**1**) in the presence of excess aqueous $AgNO_3$.

The oxo-complexes $[Ru^{IV}(trpy)(L')(O)]^{2+}$ (**3**) can be generated in solution state by chemical oxidation of the aqua species (**2**) using excess ceric solution in 1 (N) H_2SO_4. The isolation of the pure oxo derivative (**3**) in the solid state has not been successful as in the absence of Ce^{IV} ion the oxo-species reduces back to the parent aqua species (see later).

The isolated chloro (**1**) and aqua (**2**) complexes are diamagnetic and show 1:1 and 1:2 conductivities, respectively (Section 2). The complexes exhibit satisfactory elemental analyses (Section 2).

3.2. Crystal structures of $NC_5H_4CH{=}N{-}(C_6H_4){-}N{=}CHC_5H_4N$ (L^1) and $[Ru(trpy)(L')Cl](ClO_4)$ (**1a**)

The single crystal X-ray structure of L^1 is shown in Fig. 1. It shows that each half of the molecule is related to the other half by symmetry. Selective bond distances and angles are listed in Table 2. The bond distances and angles match well with the standard values.

The crystal structure of $[Ru(trpy)(L')Cl](ClO_4)$ (**1a**) is shown in Fig. 2. Selective bond distances and angles are listed in Table 2. The terpyridine group coordinates to the ruthenium center in a meridional fashion with the ligand L′ in a *cis* orientation. The chloride ligand is *trans* to the imine nitrogen (N_i) of L′ (structure **B**). The central Ru–N(1) distance [1.978(9) Å] of terpyridine is shorter than the terminal Ru–N(2)/Ru–N(3) distances, 2.080(9) Å [14–16]. Correspondingly, the geometrical strain of the meridionally disposed terpyridine ligand is reflected in the short *trans* angle, 159.0(4)° [14–16]. The Ru^{II}–N(5) [imine nitrogen, 2.057(10) Å], Ru–N(4) [pyridine nitrogen of L′, 2.097(10) Å] and Ru^{II}–Cl [2.414(3) Å] distances in **1a** are in agreement with those of reported similar complexes [16–20,32,33].

The cationic molecules are packed in a zigzag manner with anions (ClO_4^-) in between the zip when viewed down the *a*-axis (Fig. 3). Both the hydrogens of the pendant amine group are involved in hydrogen bonding. Hydrogen H(6A) forms hydrogen bonds with the chlorine atom Cl(1) $[-x+3/2, y-1/2, -z+1/2]$ of Ru–Cl, N(6)–H(6A)···Cl(1) = 2.543 Å while H(6B) forms hydrogen bonds with the oxygen atom O(2) of

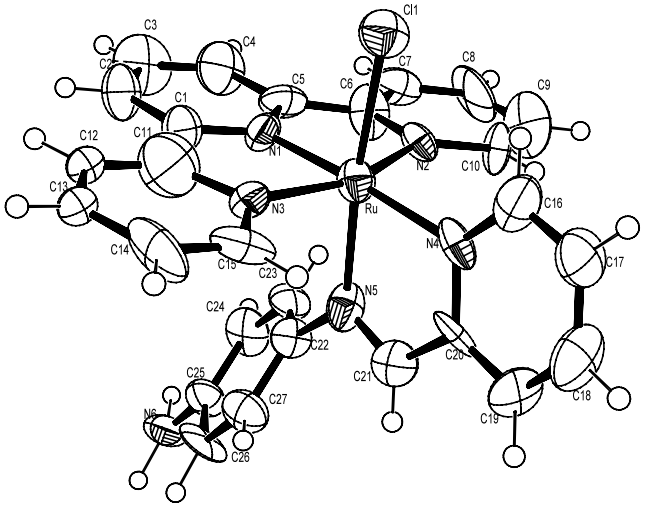

Fig. 2. An ORTEP diagram for $[Ru^{II}(trpy)(L')Cl]ClO_4$ (**1a**). Atoms are drawn at 50% probability.

the translated perchlorate anion moiety, N(6)–H(6B)···O(2) = 2.123 Å (Table 3). The Cl(2)–O(2) distance of 1.372 Å is longer compared to the other Cl–O distances in the ClO_4^- anion which may be due to its involvement in the hydrogen bonding.

3.3. Spectral properties

The ν(C=N) stretching frequency of the coordinated L′ has been observed near 1600 cm^{-1}. The bands due to ionic perchlorate and ν(Ru–Cl) have appeared near 1100/630 and 300 cm^{-1}, respectively.

The ^1H NMR spectra of the free ligands (L) in $CDCl_3$ (Fig. 4(a)) exhibit the signals corresponding to half of the molecule as expected due to the internal symmetry. The complexes (**1a** and **1b**) in DMSO-d^6 solvent display the expected 22 and 26 signals, respectively (Fig. 4(b and c)). The signals due to the NH_2 group [which is absent in the free ligands (Fig. 4(a))], the pendant phenyl ring(s) and the azomethine (–CH=N–) function of L′ appear in isolated regions and are therefore assigned. On the other hand the signals due to the terpyridine ligand and the pyridine fragment of L′ are found to overlap severely which essentially restricts the identification of the individual protons. However, the direct comparison of the intensity of these proton signals with that of the clearly observable NH_2 protons or –CH=N– proton reveals the presence of the calculated number of protons in both the complexes.

Electronic spectral data of the isolated complexes **1a**, **1b**, **2a** and **2b** are listed in Table 4. The complexes display moderately strong MLCT transitions in the visible region ($\lambda_{max} > 500$ nm for **1** and approximately 470 nm for **2**) and strong intra ligand transitions in the UV region (Fig. 5) [34,35]. The observed order of MLCT band energy, **1**(Cl^-) < **2**(H_2O) (Table 4, Fig. 5) is due to relative stabilization of the dπ(Ru) state while moving from $Cl^- \rightarrow H_2O$.

The replacement of one strong π-acidic tridentate trpy ligand from the $[Ru(trpy)_2]^{2+}$core by L′ and Cl^- decreases the MLCT transition energy reasonably {the MLCT transition of $[Ru(trpy)_2]^{2+}$ appears at 478 nm [36]}, however the MLCT transition energy remains almost unaltered when the combination of L′/H_2O is used to replace one trpy group from the $[Ru(trpy)_2]^{2+}$core.

The MLCT transition energy of the aqua derivative, **2a** varies reasonably depending on the nature of the coordinating solvents [37], however little variation has been observed in case of **2b** (Table 4).

The other known ruthenium terpyridine aqua complexes $[Ru(trpy)(L'')(H_2O)]^{2+}$ incorporating analogous

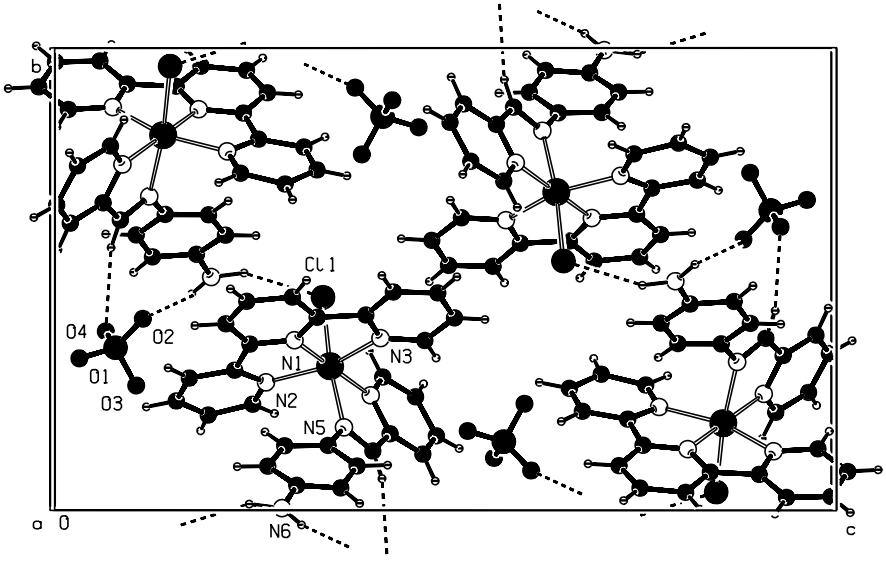

Fig. 3. Packing diagram of the molecule $[Ru^{II}(trpy)(L')Cl]ClO_4$ (**1a**) viewed down the *a*-axis.

nm; quantum yield (Φ_{em}): **1a**, 0.03; **1b**, 0.015, Fig. 5, (inset). The observed emissions are believed to have originated from the ^{3}MLCT excited states [38]. The quantum yields (Φ_{em}) of the emission processes were measured in the MeOH–EtOH (1:4 v/v) glass at 77 K relative to $[Ru(bpy)_3]^{2+}$ for which $\Phi_{em} = 0.35$ [39].

3.4. Electron-transfer properties

Redox properties of the complexes **1** and **2** have been studied in acetonitrile and water, respectively using a platinum working electrode at 298 K. Representative voltammograms are shown in Fig. 6. The chloro complexes **1a** and **1b** display reversible ruthenium(III)–ruthenium(II) couples, E°_{298}, V (ΔE_p, mV) at 0.80 (90) and 0.85 (90) versus SCE, respectively. Thus the ruthenium(III)–ruthenium(II) potential increases with the increase in number of phenyl rings in the ligand framework (L′). Although the complexes (**1**) can be coulometrically oxidized to the corresponding ruthenium(III) congeners ($\mathbf{1}^+$), the oxidized species are found to be unstable at room temperature. The observed ruthenium(III)–ruthenium(II) potential of **1** is comparable to that of $[Ru(trpy)(bipyridine)Cl]^+$ (0.81 V) [18] but less anodic compared to those of analogous complexes incorporating other types of *N*,*N*-donors based ancillary functions such as, $[Ru(trpy)\{3,6\text{-di(pyrid-2-yl)pyridazine}\}Cl]^+$ (0.89–1.04 V) [19]; $[Ru(trpy)(azopyridine)Cl]^+$ (1.10–1.24 V) [15] and [Ru(trpy)(2,2′-bipyrazine)Cl] (1.07 V) [18]. Thus the π-acceptor strength of L′ in **1** can be considered to be appreciably closer to that of the bipyridine ligand.

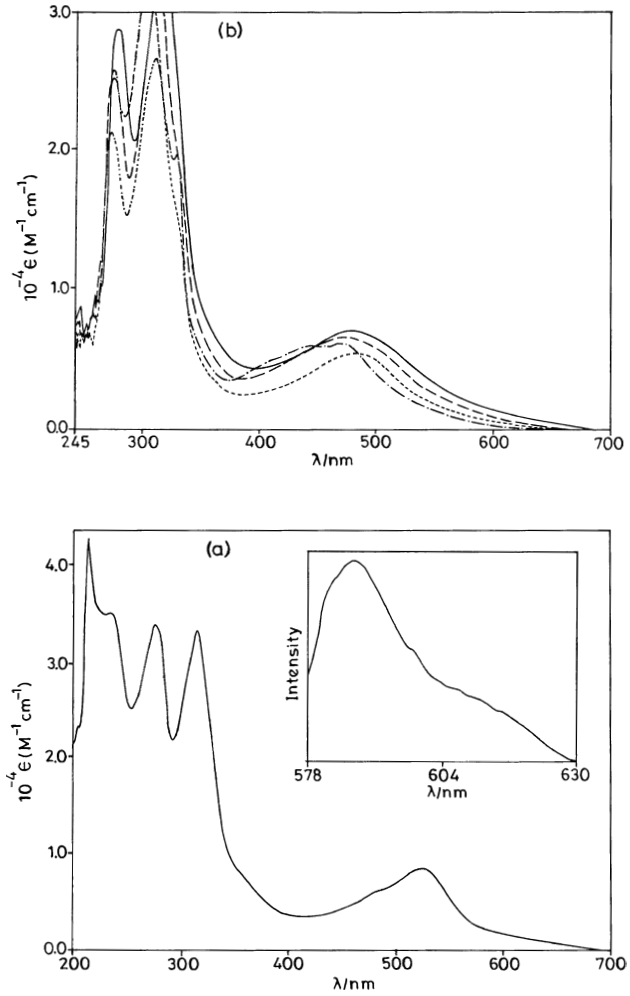

Fig. 5. Electronic spectra of: (a) $[Ru^{II}(trpy)(L')Cl]ClO_4\cdot 2H_2O$ (**1a**) in acetonitrile. Inset shows emission spectrum of $[Ru^{II}(trpy)(L')Cl]ClO_4\cdot 2H_2O$ (**1a**) in EtOH–MeOH 4:1 (v/v) at 77 K; (b) $[Ru^{II}(trpy)(L')(H_2O)](ClO_4)_2\cdot 2H_2O$ (**2a**) in DMF (—), MeOH (----), H_2O (------), CH_3CN (-·-·-).

The complex, **1a** exhibits one irreversible reduction, E_{pc} at −1.09 V and **1b** displays one quasi-reversible reduction, E°_{298}, V (ΔE_p, mV), at −0.96 (190). These are believed to be terpyridine based reductions [40].

Cyclic voltammograms of the aqua species (**2a** and **2b**) have been recorded in aqueous medium in the pH range 1–12. The complexes exhibit one quasi-reversible oxidative response each at the positive side of SCE (Fig. 6(b)). The potentials of the responses are observed to decrease linearly with the increase in pH (Fig. 6(c)). The electron–proton content of the redox processes over the pH range 1–12 have been estimated from the slopes of the experimentally derived potential–pH plots (Fig. 6(c)) [21]. In the pH ranges 1–9 and >9.0, the potentials change at the rate of approximately 60 and 30 mV, respectively per unit change in pH. Therefore, the redox processes in the pH range 1–9 and >9 are associated with $2e^-/2H^+$ and $2e^-/H^+$ oxidation processes, respectively (Eqs. (1) and (2)) [19–21]. The pK_a

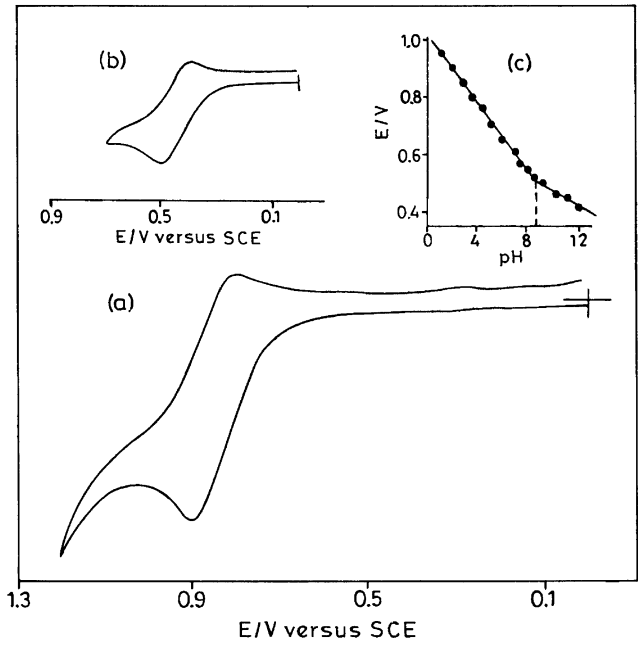

Fig. 6. Cyclic voltammograms of: (a) $[Ru^{II}(trpy)(L')Cl]ClO_4\cdot 2H_2O$ (**1b**) in acetonitrile; (b) $[Ru^{II}(trpy)(L')(H_2O)](ClO_4)_2\cdot 2H_2O$ (**2b**) in water at pH 9.5; and (c) variation of Ru^{IV}/Ru^{II} couple with pH in water for **2b**.

values of the complexes **2a** and **2b**, calculated from the intersection point of the two curves in E versus pH graphs (Fig. 6(c)), are 9.0 and 8.7, respectively. The values are in good agreement with the pK_a data (9.1 for **2a** and 9.0 for **2b**) determined separately by

$$[Ru^{II}(trpy)(L')(H_2O)]^{2+} \rightarrow [Ru^{IV}(trpy)(L')(O)]^{2+} + 2e^- + 2H^+ \quad (1)$$

$$[Ru^{II}(trpy)(L')(OH)]^{+} \rightarrow [Ru^{IV}(trpy)(L')(O)]^{2+} + 2e^- + H^+ \quad (2)$$

spectrophotometric titrations using sodium hydroxide. The pK_a values of the similar monoterpyridine aqua complexes $[Ru(trpy)(L'')(H_2O)]^{2+}$, L″ = 2,2′-bipyridine, 1,10-phenanthroline, 2,2′-bipyrazine, 3,6-di(pyrid-2-yl)pyridazine, tetramethylene diamine, and azopyridine are 9.7, 9.6, 8.8, 10.3, 10.2 and 7.9–8.5, respectively [15,18–20]. Thus, as far as the acidity of the coordinated aqua molecule is concerned, the present set of complexes (**2a** and **2b**) are closest to the bipyrazine derivative.

Similar proton coupled electron-transfer processes have been observed in case of bipyrazine [18] and 3,6-di(pyrid-2-yl)pyridazine [20] complexes. However, the bipyridine analogue shows two step processes in the acidic region, $[Ru^{II}(trpy)(bpy)(H_2O)]^{2+} \rightarrow [Ru^{III}(trpy)(bpy)(OH)]^{2+} + e^- + H^+$ and $[Ru^{III}(trpy)(bpy)(OH)]^{2+} \rightarrow [Ru^{IV}(trpy)(bpy)(O)]^{2+} + e^- + H^+$ [21]. On the other hand the azopyridine analogue exhibits $2e^-/2H^+$-transfer process specifically in the highly acidic region [15]. Therefore, electron-transfer behavior of the ruthenium terpyridine aqua species is primarily controlled by the acidity of the coordinated H_2O molecule or in other words the electronic aspect of the ancillary functions.

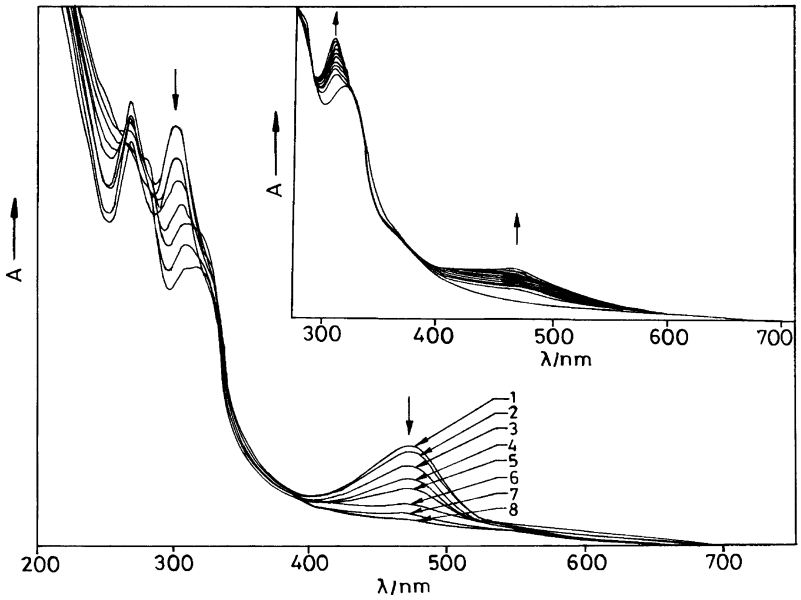
3.5. *Chemical oxidation of $[Ru^{II}(trpy)(L')(H_2O)]^{2+}$ (**2**) → $[Ru^{IV}(trpy)(L')(O)]^{2+}$ (**3**): role of **3** in catalyzing the water oxidation process*

Chemical oxidation of the aqua complex (**2**) by excess aqueous ceric solution in 1 (N) H_2SO_4 leads to the spontaneous formation of a yellow colored species. The intensity of the MLCT band of $[Ru(trpy)(L)(H_2O)]^{2+}$ near 470 nm is found to decrease systematically on progressive addition of Ce^{IV} solution with the concomitant development of a new band near 320 nm (Fig. 7). The plots of absorbance versus $[Ce^{IV}]/[\mathbf{2}]$ show that approximately 4.0 mole ratio of Ce^{IV}: **2** is needed for the complete oxidation of the aqua species.

Considering the observed electrochemical concerted $2e^-/2H^+$ oxidation process of the aqua complexes in acidic solution (Eqs. (1) and (2)) it can be assumed that the chemical oxidation of **2** also leads to the formation of the same oxo-species, Eq. (3).

$$[Ru^{II}(trpy)(L')(H_2O)]^{2+} + 2Ce^{4+} \rightarrow [Ru^{IV}(trpy)(L')(O)]^{2+} + 2e^- + 2H^+ + 2Ce^{3+} \quad (3)$$

The oxo-complexes (**3**) thus formed are found to reduce back partially to the parent aqua derivatives (**2**). The MLCT band at 474 nm, characteristic of the aqua species, develops slowly with time but levels off before attaining the calculated intensity of the standard aqua species (Fig. 7, inset). The percent conversion of the oxo (**3**) to aqua (**2**) for **3a** and **3b** are calculated to be 63 and 69%, respectively. The further addition of acidic Ce^{+4} solution into the mixture of **2** and **3** oxidizes the solution completely to the oxo-state and the cycle follows. Therefore, the oxo-species is stable only in presence of excess oxidant. The observed partial conversion of oxo to aqua species possibly can account for the need of excess ceric rather than the 1:2 mole ratio of **2**–Ce^{IV} as expected from the stoichiometric oxidation reaction (Eq. (3)). The partial conversion of oxo to aqua species has essentially precluded the isolation of the oxo-complexes in the pure solid state. The observed conversion of the oxo to aqua species and the subsequent reverse reaction, aqua to oxo on further addition of Ce^{4+} can be best explained on the basis of earlier observations [15,17,41] i.e. the involvement of the chemically generated oxo-species in the catalytic water splitting reaction (Scheme 2). It may be noted that in the case of the azopyridine analogue, the oxo complex was found to transform quantitatively to the aqua species and the backward process, aqua to oxo was observed on further addition of Ce^{4+}. Therefore, as far as water splitting is concerned the present oxo-species (Scheme 2) is much less efficient as compared to the corresponding azopyridine deriva-



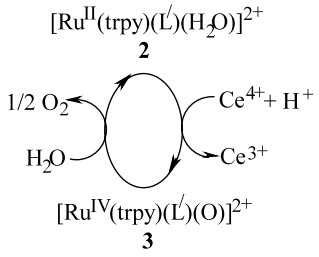


Fig. 7. Change in absorbance of $[Ru^{II}(trpy)(L')(H_2O)](ClO_4)_2\cdot 2H_2O$ (**2a**) as a function of $[Ce^{IV}]$. Ratio of $[Ce^{IV}]$–**2a** = (1) 0:1, (2) 0.5:1, (3) 1:1, (4) 1.5:1, (5) 2:1, (6) 2.5:1, (7) 3:1, (8) 3.5:1. Inset shows time evolution of the electronic spectra of a changing solution of $[Ru^{IV}(trpy)(L')(O)]^{2+}$ (**3a**) → $[Ru^{II}(trpy)(L')(H_2O)]^{2+}$ (**2a**) in water [1 (N) H_2SO_4] at 298 K. The arrows indicate increase or decrease in band intensities as the reaction proceeds.

Scheme 2.

tive, which is certainly due to the greater π-acceptor character of the azopyridine function.

3.6. Electrocatalytic oxidation of benzyl alcohol

The cyclic voltammetric experiments of the aqua species $[Ru(trpy)(L')(H_2O)]^{2+}$ (**2**) in the presence of benzyl alcohol have been studied in order to examine the role of the electrogenerated $[Ru(trpy)(L')(O)]^{2+}$ (**3**) towards the oxidaton of benzyl alcohol [18–20,42–44]. The cyclic voltammogram of **2b** at pH 9.58 is shown in Fig. 8. Under identical experimental conditions the voltammogram of benzyl alcohol does not show any appreciable current (Fig. 8). However, the voltammogram of **2** in the presence of benzyl alcohol displays substantially excess anodic current as compared to that of the standard **2** (Fig. 8). Thus the oxidation of **2** to **3** is followed rapidly by the reaction (Scheme 3) and the regenerated **2** is reoxidized before it can diffuse away from the electrode surface.

Therefore, the electrogenerated **3** is involved in catalyzing the benzyl alcohol oxidation process. A similar electrocatalytic behavior has been reported in case of the corresponding bipyrazine and 3,6-di(4-methylpyrid-2-yl)pyridazine complexes [18–20]. Here catalytic current increases with the increase in ratio of [benzyl alcohol]/[**2**] as expected and maximum catalytic current is observed in case of 25:1 ratio of [benzyl alcohol]/[**2**]. The catalytic effect has been quantifiedly based on the experimentally observed excess current (i_{ex}) with respect to the current only due to the catalyst (i_{ct}) (same catalyst concentration has been used for both the standard and the mixture containing the substrate) at a particular potential (Eq. (4)) (Fig. 8) [45]. Here i_o is the observed current for

$$i_{ex} = i_o + i_d - i_{ct} \quad (4)$$

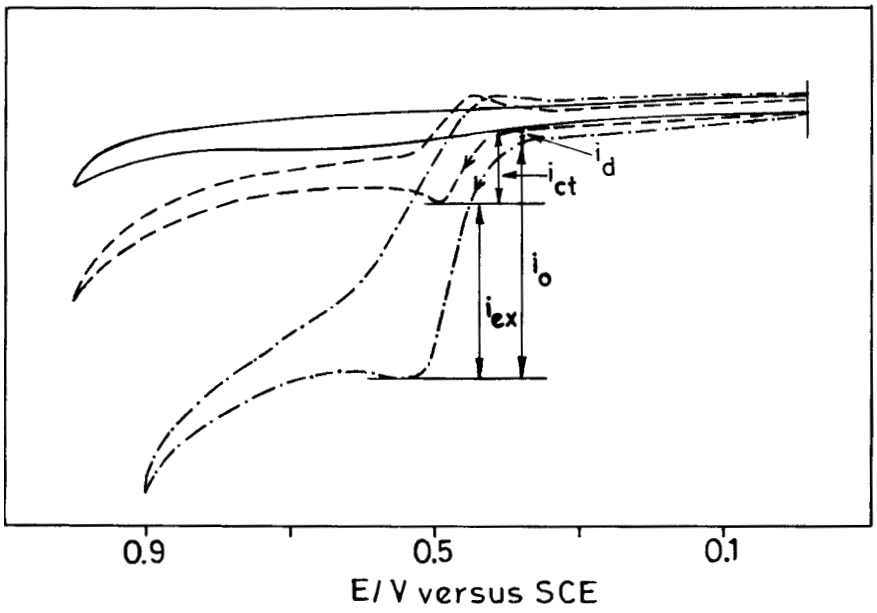
the mixture and i_d is the difference in current between the catalyst and the catalyst + substrate at the concerned base line potential. The turnover numbers (t) of the processes

$$t = i_{ex}/i_{ct} \quad (5)$$

(Scheme 3; Fig. 8) calculated by using Eq. (5) are found to be 2.7 and 2.3 for **3a** and **3b**, respectively. Further studies on the catalytic aspect of **3** are in progress.

4. Conclusion

The role of α,α′-diimine based ancillary (L′) functions in the ruthenium monoterpyridine [Ru-trpy] core (**1**–**3**) have been scrutinized with special reference to the chemical and electrochemical behaviors of the oxo species $[Ru(trpy)(L')(O)]^{2+}$ (**3**). The ruthenium(III)–



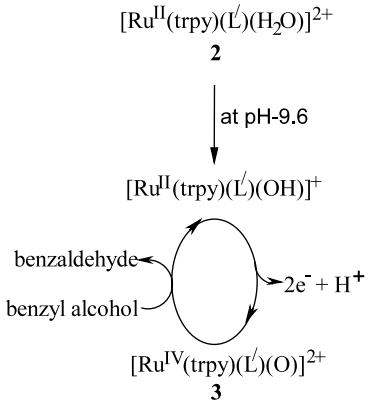


Fig. 8. Cyclic voltammograms of benzyl alcohol in water (20.32×10^{-3} M) (—); $[Ru^{II}(trpy)(L')(H_2O)](ClO_4)_2 \cdot 2H_2O$ (**2b**) in water at pH 9.58 (0.96×10^{-3} M) (----) and the mixture of the two taken at the same concentrations (-·-·-).

Scheme 3.

ruthenium(II) potential of the chloro species $[Ru(trpy)(L')(Cl)]^+$ (**1**) is comparable to that of the corresponding bipyridine complex but less anodic compared to the analogous complexes incorporating 3,6-di(pyrid-2-yl)pyridazine, bipyrazine and azopyridine ancillary functions. The aqua complex $[Ru(trpy)(L')(H_2O)]^{2+}$ (**2**) undergoes one-step-$2e^-/2H^+$ and $2e^-/H^+$ transformations in the acidic and basic regions, respectively to the corresponding oxo-species $[Ru(trpy)(L')(O)]^{2+}$ (**3**) like the bipyrazine and 3,6-di(pyrid-2-yl)pyridazine derivatives. The chemically generated oxo-species (**3**) catalyzes the water oxidation process like the azopyridine derivative but much less efficiently. The electrochemically generated oxo-species (**3**) is found to be effective in catalyzing the oxidation of benzyl alcohol like the bipyrazine and 3,6-di(pyrid-2-yl)pyridazine derivatives. The present study therefore emphasizes the serious impact of the electronic aspect of the ancillary functions in directing the reactivity pattern of the ruthenium monoterpyridine aqua species.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 170396–170397 for compounds **1a** and L^1. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

dissociation constant of the ternary complex. Both en and phen are strong coordinated bidentate ligands but en is flexible, having tetrahedral nitrogens whereas phen has rigid, planar nitrogens.

2. Experimental

2.1. Materials

$Ni(NO_3)_2 \cdot 6H_2O$, ethylenediamine, 1,10-phenanthroline and $NaClO_4$ were purchased from Merck. Ethylenediamine was distilled and standarised by a potentiometric titration against standard HCl solution (Merck). 1,10-Phenanthroline was crystallised before use. 2,2′,2″-Triaminotriethylamine was obtained from TCI. The buffers used were *N*-(2-hydroxyethyl)piperazine-*N*′-2-ethanesulfonic acid (HEPES, $pK_a = 7.75$) and {[tris(hydroxymethyl)methyl]amino}propane (TAPS, $pK_a = 8.4$). Sodium perchlorate was used to maintain the ionic strength. All other chemicals and solvents were of reagent grade and used without any purification.

2.2. Synthesis of complexes

2.2.1. Caution

Perchlorate salts of metal complexes with organic ligands are potentially explosive materials and should be handled with care.

The ternary complexes of $[Ni(tren)(H_2O)_2]^{2+}$ with ethylenediamine and 1,10-phenanthroline were prepared in the following way.

2.2.2. Ni(tren)(NO3)2

$Ni(NO_3)_2 \cdot 6H_2O$ (1 g, 3.4 mmol) was dissolved in 100 ml of EtOH and then 0.5 g (3.4 mmol) of tren in 50 ml EtOH was added drop-wise with stirring. During the addition the colour changed from green to blue. The reaction mixture was stirred continuously for 2 h and after that kept in a refrigerator for 5 h. A precipitate was formed and filtered off. The ppt was washed with water, EtOH and Et_2O thoroughly and dried over P_2O_5. The product was recrystallised from hot EtOH. Deep blue crystals were formed. Yield: 68%.

2.2.3. [Ni(tren)(en)](ClO4)2 (**a**)

Ethylenediamine (0.4 g, 2.5 mmol) in 50 ml EtOH was added into a solution of 0.8 g (2.4 mmol) $[Ni(tren)](NO_3)_2$ in 50 ml EtOH with continuous stirring. The colour changed from blue to purple. The reaction mixture was stirred for 2 h at room temperature and then cooled in freezer for complete precipitation. The nitrate salt product was collected by filtration and washed with EtOH and Et_2O. The product was dried over P_2O_5.

The dried product was dissolved in EtOH and 10 ml saturated aq. solution of $NaClO_4$ added. A precipitate was formed immediately and filtered off. The residue was washed with water and EtOH thoroughly and dried over P_2O_5. The product was recrystallised from 1:3 CH_3CN–H_2O mixture. Purple colour crystals were formed. The yield was 55%. Elemental analysis: Found (Calc.): C, 20.62 (20.70); H, 5.53 (5.61); N, 18.22 (18.12)%.

2.2.4. [Ni(tren)(phen)](ClO4)2 (**b**)

$Ni(tren)(NO_3)_2$ (0.8 g, 2.4 mmol) was dissolved in 50 ml EtOH and then added dropwise a solution of 0.5 g (2.5 mmol) 1,10-phenanthroline in 50 ml EtOH. The reaction mixture was stirred continuously for 3 h. The brown crystals of nitrate salts were precipitated out. They were filtered and washed with water and EtOH.

The crystals were dissolved in EtOH and 10 ml saturated aq. solution of $NaClO_4$ was added. The perchlorate salt was precipitated immediately and washed with water and EtOH thoroughly. The product was recrystallised from 1:2 CH_3CN–H_2O. The yield was 48%. Elemental analysis: Found (Calc.): C, 37.11 (37.01); H, 4.44 (4.45); N, 14.48 (14.39)%.

2.3. Physical measurements

Spectral data were obtained using the following instruments: Bomen MB100; UV spectra, Hitachi 3410. The kinetic studies were carried out using a Union Giken RA-401 stopped-flow spectrophotometer equipped with a Union RA-415 rapid-scan attachment at 25.0 ± 0.1 °C. The reactions were monitored at a definite wavelength, 254 nm for en and at 343 nm for the phen reaction path.

2.4. X-ray crystal structure and analysis

X-ray quality crystals were obtained by slow evaporation of an EtOH solution of $[Ni(tren)(en)](ClO_4)_2$ (**a**) and $[Ni(tren)(phen)](ClO_4)_2$ (**b**) at 298 K (crystal size: $[Ni(tren)(en)](ClO_4)_2$, $0.79 \times 0.29 \times 0.20$ mm and $[Ni(tren)(phen)](ClO_4)_2$, $0.60 \times 0.40 \times 0.20$ mm). Data were collected on a Siemens SMART-CCD diffractometer with graphite monochromatised Mo Kα radiation ($\lambda = 0.71073$). The ORTEP of the crystals are shown in Figs. 1 and 2. A summary of the crystallographic data and structure refinement parameters is given in Table 1. The bond lengths and angles within the coordination sphere of the nickel ion are listed in Table 2 for **a** and Table 3 for **b**. The data were corrected for absorption effects by an empirical method. Systematic absences led to the identification of space groups *Pccn* (orthorhombic crystal system) for **a** and *Pbca* (orthorhombic crystal system) for **b**. Of the 45 294 (**a**) and 26 893 (**b**) collected reflections, 9061 and 5441 with $I > 2\sigma(I)$ were used for

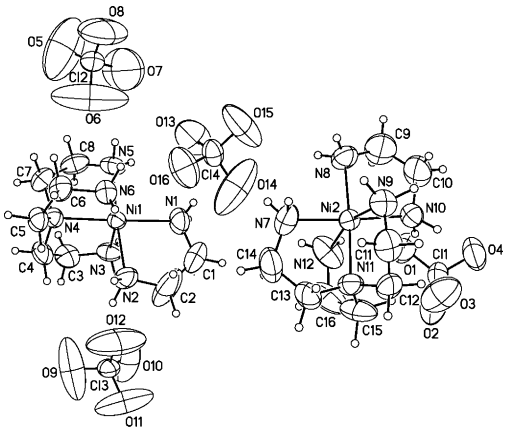

Fig. 1. ORTEP view of $[Ni(tren)(en)](ClO_4)_2$.

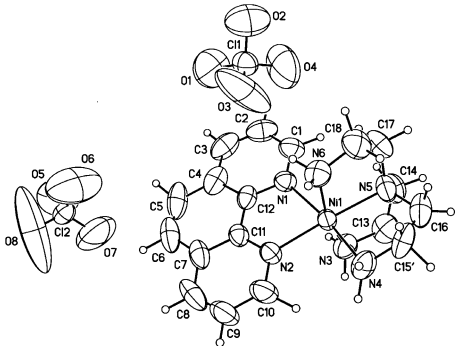

Fig. 2. ORTEP view of $[Ni(tren)(phen)](ClO_4)_2$.

the structure solutions, respectively. In both cases structures were solved by direct method [11]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were located in calculated positions and refined isotropically. The final full-matrix least-squares refinements on F^2, including 9061 (**a**) and 5441 (**b**) reflections with $I > 2\sigma(I)$, adjusting 452 (**a**) and 326 (**b**) parameters, converged at R_1 and wR_2 indices of 0.0606 and 0.1788 for **a**, 0.0676 and 0.2232 for **b**. All calculations were carried out using the PC Version SHELXTL [12].

3. Results and discussion

3.1. Synthesis

$Ni(tren)(NO_3)_2$ was prepared by the reaction of $Ni(NO_3)_2 \cdot 6H_2O$ and tren in a 1:1 ratio. In aqueous solution $Ni(tren)(NO_3)_2$ is diaquated. The water molecules are *cis*-oriented. In the presence of bidentated ligands it forms ternary complexes. Ethylenediamine and 1,10-phenanthroline were considered as symmetrical *N*,*N*-bidentate chelating ligands. Thus $[Ni(tren)(en)](ClO_4)_2$ and $[Ni(tren)(phen)](ClO_4)_2$ were prepared when $Ni(tren)(NO_3)_2$ was reacted with en and phen in EtOH solution, followed by the addition of saturated aqueous $NaClO_4$ solution to give the perchlorate salts, respectively. The complexes have been characterised by X-ray crystallographic methods.

3.2. Molecular structures

The crystal structures of ternary complexes **a** and **b** are shown in Figs. 1 and 2 and bond parameters are listed in Tables 2 and 3, respectively. The coordination around nickel is approximately octahedral.

3.2.1. $[Ni(tren)(en)](ClO_4)_2$ (**a**)

An ORTEP view of the molecular structure of the complex along with the atom-labelling scheme, including the perchlorate ions and H-atoms attached with C- and N-atoms is shown in Fig. 1. The structure consists of two independent units of the $[Ni(tren)(en)]^{2+}$ cation

Ni(1)–N(5)	2.109(4)	Ni(1)–N(6)	2.132(5)
Ni(1)–N(3)	2.112(4)	Ni(1)–N(1)	2.194(4)
Bond angles			
N(2)–Ni(1)–N(5)	176.66(2)	N(3)–Ni(1)–N(6)	162.40(2)
N(2)–Ni(1)–N(3)	96.68(2)	N(4)–Ni(1)–N(6)	94.98(2)
N(5)–Ni(1)–N(3)	83.66(2)	N(2)–Ni(1)–N(1)	78.65(2)
N(2)–Ni(1)–N(4)	94.24(2)	N(5)–Ni(1)–N(1)	104.68(2)
N(5)–Ni(1)–N(4)	82.43(2)	N(3)–Ni(1)–N(1)	87.03(2)
N(3)–Ni(1)–N(4)	92.85(2)	N(4)–Ni(1)–N(1)	172.82(2)
N(2)–Ni(1)–N(6)	98.43(2)	N(6)–Ni(1)–N(1)	87.15(2)
N(5)–Ni(1)–N(6)	81.78(2)		

which have also been found in $[Ni(tren)(O_2CCH_3)]^+$ [13]. Selected bond lengths and angles are given in Table 2. The metal centre possesses a distorted octahedral geometry with a NiN_6 chromophore with two en-N, three primary tren-N and one tertiary tren-N. The *trans* bond angles, N(1)–Ni(1)–N(4), 176.25(2)° and N(5)–Ni(1)–N(2) 175.67(2)°, and *cis* bond angles, N(4)–Ni(1)–N(2), 101.14(2)° and N(1)–Ni(1)–N(5), 93.68(2)°, support that N(1), N(2), N(4) and N(5) constitute the equatorial square base of the octahedron. The other *trans* bond angle, N(6)–Ni(1)–N(3), is 163.03(2)°. The Ni–N(tren) bond lengths of $[Ni(tren)(en)]^{2+}$ are normal and essentially equivalent with the reported values [13,14]. The bond lengths of Ni(1)–N(3), 2.158(4) and Ni(1)–N(6), 2.150(4) Å are essentially higher than the other Ni(1)–N bond lengths (Table 2). So it is clear that N(3) and N(6) are in the axial sites of the octahedron. The other two chelate rings, Ni(1), N(3), C(3), C(4), N(4) and Ni(1), N(6), C(6), C(5), N(4) are appreciably orthogonal with respect to the equatorial chelate rings of the square base of the octahedron. The bond angle between en nitrogens is 82.02° which is comparable with the reported bond angle, 81.90° of the $Ni(en)_3^{2+}$ [15] complex. The bond distances Ni(1)–N(1) and Ni(1)–N(2) are 2.095(4) and 2.142(4) Å, respectively. Both are en nitrogens but the later bond distance is longer than former. This is due to the fact that N(2) is *cis*-oriented to a sterically hindered tertiary tren nitrogen.

3.2.2. *[Ni(tren)(phen)](ClO4)2*

A perspective view of the complex cation with the atom numbering scheme, including the perchlorate ions and H-atoms attached to C- and N-atoms is shown in Fig. 2. The structure consists of a $[Ni(tren)(phen)]^{2+}$ cation. The charge of the nickel is satisfied by the perchlorate ions outside of the coordination sphere. Selected bond lengths and angles are listed in Table 3. The structure of the complex is distorted octahedral with a NiN_6 chromophore with two phen-N, three primary tren-N and one tertiary tren-N. The phenanthroline chelate ring, Ni(1), N(1), C(12), C(11), N(2) is planar and it is appreciably orthogonal to the chelate rings, Ni(1), N(6), C(18), C(17), N(5), dihedral angle 95.6° and Ni(1), N(5), C(14), C(13), N(3), dihedral angle 83.4°. The chelate ring, Ni(1), N(5), C(16), C(15), N(4) is inclined to the phenanthroline plane by an angle of 6.9°. The *trans* bond angles, N(2)–Ni(1)–N(5), 176.66(2)° and N(4)–Ni(1)–N(1), 172.82(2)° and *cis* bond angles, N(5)–Ni(1)–N(1), 104.68(2)° and N(2)–Ni(1)–N(4), 94.24(2)° support that N(1), N(2), N(4) and N(5) constitute the equatorial square base of the octahedron. The other *trans* bond angle, N(3)–Ni(1)–N(6), is 162.40(2)°. The Ni–N(tren) bond lengths of this complex are almost equivalent with the reported values [13,14]. The bond lengths of Ni(1)–N(6), 2.132(5) and Ni(1)–N(3), 2.112(4) Å support that N(3) and N(6) of the tren-N are in the axial positions of the octahedron. The N(1) of the phenanthroline ligand suffers some steric effects, created by the tertiary tren-N which is in the *cis*-position, causing the long Ni(1)–N(1) (= 2.194(4) Å) bond distance compared to Ni(1)–N(2) (= 2.074(4) Å). Four chelate angles, N(2)–Ni(1)–N(1), N(5)–Ni(1)–N(3), N(5)–Ni(1)–N(6), N(5)–Ni(1)–N(4) are 78.65(2)°, 83.66(2)°, 81.78(2)° and 82.43(2)°, respectively. Since all tren-N do not face similar environments, the bite angles are so different.

3.3. Kinetic studies

3.3.1. Ethylenediamine

Reactions were carried out with a 10-fold excess of en concentrations than $[Ni(tren)(H_2O)_2]^{2+}$ over a pH range of 7.32–8.26. HEPES and TAPS were used as buffers. The ionic strength was 0.10 ± 0.01 M. Under these conditions, the reaction is first-order in $[Ni(tren)(H_2O)_2]^{2+}$ and is reversible. The observed rate constants are listed in Table 4. The rate equation is expressed as in Eq. (2) with L = en and T = tren. Assuming that L remains constant, Eq. (2)

$$-\frac{d[NiT]}{dt} = k_f[L][NiT] - k_d[NiTL] \quad (2)$$

integrates to Eq. (3) where $[NiT]_e$ and $[NiT]_i$ are the equilibrium and initial concentrations, respectively. The observed pseudo-first-order rate constants (k_{obsd}) at different pH versus en

$$k_{obsd} = k_f[L] + k_d = -\frac{2.303}{t}\log\frac{[NiTL^{2+}]_e - [NiTL^{2+}]}{[NiT^{2+}]_e - [NiT^{2+}]_i} \quad (3)$$

Table 4

concentrations are plotted in Fig. 3 and provide straight line according to Eq. (3) in each case. The k_f and k_d values are obtained from the slope and intercept of straight lines, respectively and the data are given in Table 5.

The en concentration becomes significant at high pH where k_{obsd} depends on both Hen^+ and en concentrations. Reactions of these two species with $[Ni(tren)(H_2O)_2]^{2+}$ to produce the ternary complex are expressed as Eqs. (4) and (5). Eq. (3) can be written as the sum of two

$$NiT(H_2O)_2^{2+} + en \underset{k^{NiT}}{\overset{k^{en}_{NiT}}{\rightleftharpoons}} NiT(en)^{2+} + 2H_2O \quad (4)$$

$$NiT(H_2O)_2^{2+} + Hen^+ \underset{k^{NiT(en)}_{H}}{\overset{k^{Hen}_{NiT}}{\rightleftharpoons}} NiT(en)^{2+} + H^+ + 2H_2O \quad (5)$$

formation terms involving the two reactive forms of the bidentate ligand as well as the reverse terms for each pathway as shown in Eq. (6). Multiple linear regression analysis of Eq. (6)

$$k_{obs} = k^{en}_{NiT}[en] + k^{Hen}_{NiT}[Hen^+] + k^{NiT(en)} + k^{H}_{NiT(en)}[H^+] \quad (6)$$

$$\frac{k_{obs}}{[en]} = k^{en}_{NiT} + k^{Hen}_{NiT}K^{H}_{1}[H^+] + \frac{k^{NiT(en)}}{[en]} + k^{H}_{NiT(en)}\frac{[H^+]}{[en]} \quad (7)$$

cast in the form shown in Eq. (7) with $K_1^H = [Hen^+]/[H^+][en] = 7.76 \times 10^9$ M^{-1} [16]. Regression analysis of Eq. (7) using only the first three terms on the right hand

Table 5
Rate constants for the forward reaction (k_f) and reverse reaction (k_d) of $[Ni(tren)(H_2O)_2]^{2+}$ with en at 25.0 ± 0.1 °C and $\mu = 0.10$ M (NaCl)

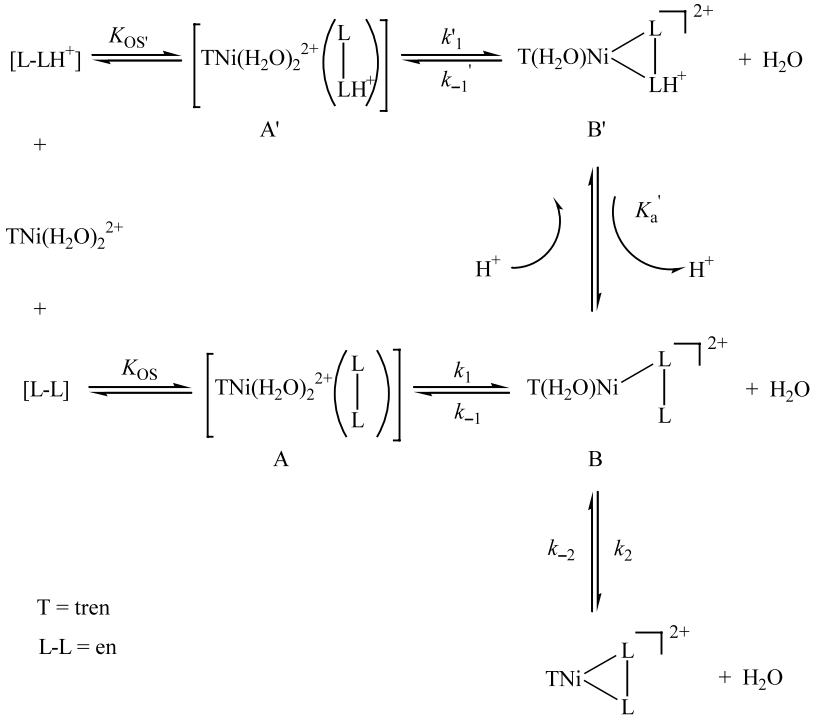
[b] Predicted from Eq. (7).

side yielded the values of k^{en}_{NiT}, k^{Hen}_{NiT} and $k^{NiT(en)}$, given in Table 6.

The Eigen–Tamm mechanism (Scheme 1) has been used successfully as a model for predicting complex formation rates for many systems [17]. Differences seen by comparison of experimental formation rate constants to those predicted from the Eigen–Tamm mechanism are used to reveal the presence of other factors which effect the formation rate. The complex formation reactions of $[Ni(tren)(H_2O)_2]^{2+}$ with en and Hen^+ follow the mechanism represented in Scheme 1. If the usual assumptions are made that: (i) the outer-sphere formation and dissociation reactions are rapid; (ii) the steady-state approximation is applied to the singly bonded intermediates B and B′; and (iii) the protonation equilibrium is rapid compared to other steps; the formation rate expression can be written for the two forward pathways as shown in Eqs. (8) and (9). The factor 2/6 is due to

$$k^{L}_{NiT} = \frac{2}{6}\frac{K_{OS}k_1k_2}{k_{-1} + k_2} \tag{8}$$



$$k^{HL}_{NiT} = \frac{2}{6}\frac{K_{OS}k'_1k_2}{k'_{-1}K'_H[H^-] + k_2} \tag{9}$$

the number of available coordination sites on $[Ni(tren)(H_2O)_2]^{2+}$ relative to $[Ni(H_2O)_6]^{2+}$.If the ring closure step is fast compared with step A to B, then $k_2 > k_{-1}$ and Eq. (8) simplifies to Eq. (10); the formation rate constants may be predicted from calculated values of K_{OS} and independent measurements of k^{-H_2O} ($= k_1$).

$$k^{L}_{NiT} = \frac{2}{6}K_{OS}k_1 \tag{10}$$

k^{Hen}_{NiT} could be predicted by using either Eq. (9) or Eq. (10), depending upon the relative sizes of k_2 and $k_{-1}K'_H[H^+]$. A plot of $(k_{obsd} - k^{NiT(en)})/[en]$ versus $[H^+]$ (Fig. 4) provides a straight line and the slope of the line give the value of $k^{Hen}_{NiT(en)}$ which is independent of $[H^+]$. Incorporating the steric factor, 14 [18] and intramolecular hydrogen bonding factor, 3 [19], K_{OS}, 0.044 [2] and k^{-H_2O}, 9×10^6 [5] in Eq. (10), the predicted k^{Hen}_{NiT} is corroborated with the experimental value (Table 6). The steric factor value is also applicable for the reaction of en with $[Ni(tren)(H_2O)_2]^{2+}$since the unprotonated end of Hen^+ is the initial reaction site.

To predict the k^{en}_{NiT} value either Eq. (8) or Eq. (10) are useful and this is dependent on k_2 and k_{-1}. In both cases an ICB factor must be incorporated because the reaction proceeds through an internal conjugate base

Scheme 1.

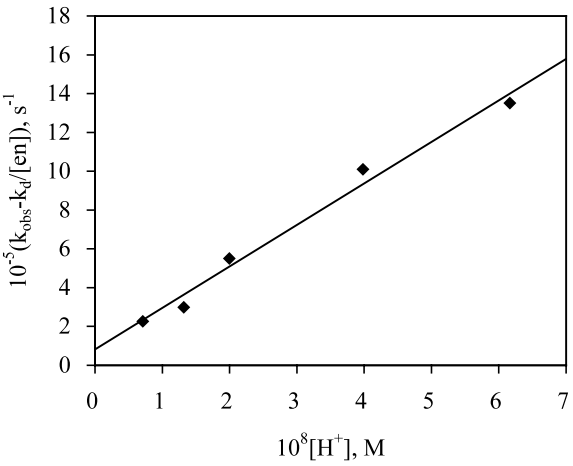


Fig. 4. A plot of $(k_{obsd}-k_d)/[en]$ versus $[H^+]$ for the reaction of $[Ni(tren)(H_2O)]^{2+}$ + en ($\mu = 0.10$ M, 25.0 ± 0.1 °C).

mechanism. Incorporating an ICB factor, 193, a steric factor, 14, K_{OS}, 0.16 [2] and the value of k^{-H_2O}, Eq. (10) predicts a value of k^{en}_{NiT} (Table 6) which is 20 times larger than the experimentally observed value. Thus Eq. (10) is not applicable and the initial bond formation is not the rate-determining step.

If the complex formation path follows as stated in Scheme 1 and the rate-determining step k_2 i.e. the ring closure step, can be calculated from Eq. (8), incorporating $k_{-1} = 1.2 \times 10^5$ [2] and all other parameters are the same as used before in Eq. (10), the found value of k_2 is 3.07×10^3 s^{-1} which is very low compared to the k_2 value 2.2×10^5 s^{-1}, of the en and $Ni(en)_2^{2+}$ reaction [20]. The causes behind the low value of k_2 may be due to: (i) the three en segments are tied on the same nitrogen of tren and ring closure occurs in that side where tertiary tren-N is bonded; (ii) the existence of a conformation-angle-distortion (CAD) effect. The crystal structure of $[Ni(tren)(en)]^{2+}$ reveals that the bond angle formed between the en nitrogens and nickel is 82.02°. The structure also shows that the chelate bite angles between tren nitrogens with nickel varies from 81.84° to 83.14°. Thirdly the crystal structure of $[Ni(tren)(NO_2)_2]\cdot H_2O$ provides a bond angle between the two NO_2^- ligands and nickel of 86.3° [14]. This indicates that the coordinated tren to nickel forces a bite angle 86.3° onto the two open coordination sites. It does not affect the initial bond formation of en but imposes considerable strain when en undergoes ring closure in $Ni(tren)^{2+}$. But this CAD effect is comparatively low compared to those found in the reaction of $[Ni(trien)(H_2O)_2]^{2+}$ with en, because the coordination of trien to nickel forces a bite angle of 92.7° on $Ni(trien)^{2+}$ involving the two open coordination sites. Thus the formation rate constants k^{en}_{NiT} and k^{Hen}_{NiT} for the reaction of $[Ni(tren)(H_2O)_2]^{2+}$ are larger than those of $[Ni(trien)(H_2O)_2]^{2+}$ (Table 7); on the other hand, the dissociation rate constant, $k^{NiT(en)}$, for the reaction of $[Ni(tren)(H_2O)_2]^{2+}$ is smaller than that of $[Ni(trien)(H_2O)_2]^{2+}$ (Table 7).

Table 7
Rate constants values for $[Ni(tren)(H_2O)_2]^{2+}$-en and $[Ni(trien)(H_2O)_2]^{2+}$-en systems at 25.0 ± 0.1 °C and $\mu = 0.10$ M (NaCl)

	$[Ni(tren)(H_2O)_2]^{2+}$-en	$[Ni(trien)(H_2O)_2]^{2+}$-en [a]

3.3.2. 1,10-Phenanthroline

The kinetics of ternary complex formation between $[Ni(tren)(H_2O)_2]^{2+}$ and phen were studied over a pH range from 7.18 to 7.53 both with and without buffer, covering a phen concentration range of $(2.00–5.00) \times 10^{-3}$ M at 25.0 ± 0.1 °C and $\mu = 0.1$ M (NaCl). All reactions were carried out with at least a 10-fold excess of phen to $[Ni(tren)(H_2O)_2]^{2+}$. The observed pseudo-first-order constants are given in Table 8. Under these

conditions, $[Ni(tren)(phen)]^{2+}$ is formed completely and follows the rate expression in Eq. (11) with L = phen and T = tren. A plot of k_{obsd}, versus phen concentrations follow Eq. (12) and are shown in Fig. 5. The obtained rate constants are listed in Table 9.

$$-\frac{d[NiT]}{dt} = k^{L}_{NiT}[NiT][L] - k_d[NiTL] \quad (11)$$

$$k_{obsd} = k^{L}_{NiT}[L] + k_d \quad (12)$$

In the formation reactions involving Ni(II), the Eigen–Tamm mechanism has been found to hold. As shown in Scheme 2, $NiT(H_2O)_2^{2+}$ is $[Ni(tren)(H_2O)_2]^{2+}$, L–L is phen, species II is an outer-sphere complex, species III is mono-coordinated and species IV is chelated.

Like bipyridine [21], the reaction of phen with $[Ni(tren)(H_2O)_2]^{2+}$ follows the reversible path. Assuming that: (1) the outer-sphere reaction is rapid ($K_{OS} = k_1/k_{-1}$); and that (2) the singly bonded species is a steady-state intermediate, then the formation rate constant can be written as shown in Eq. (13).

$$k^{phen}_{NiT} = \frac{K_{OS}k_2k_3}{k_{-2} + k_3} \quad (13)$$

If the ring closure (k_3) is much faster than the bond rupture (k_{-2}) of species III, then the initial complex formation (k_2) is the rate limiting and the formation rate constant could be predicted as Eq. (14). The statistical factor of 2/6 accounts for the number of available coordination sites of $[Ni(tren)(H_2O)_2]^{2+}$ relative to $[Ni(H_2O)_6]^{2+}$.

$$k^{phen}_{NiT} = \frac{2}{6} K_{OS}k_2 \quad (14)$$

The rate constant values of Ni–polyamine complexes with en, bpy and phen are displayed in Table 10. The effect of coordinated tren on the formation reaction is evaluated by comparing experimental and predicted values. The predicted value is obtained by incorporating $K_{OS} = 0.16$ and $k_2 = 9 \times 10^6$ in Eq. (14). The very low

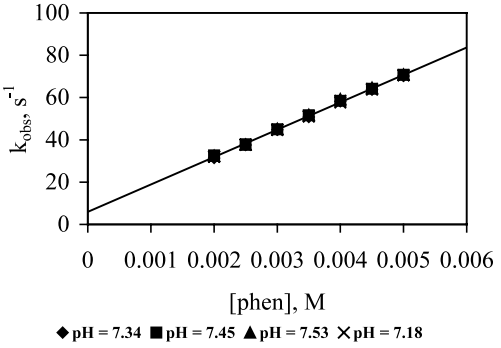

Fig. 5. Dependence of k_{obsd} upon [phen] for reaction of $[Ni(tren)(H_2O)]^{2+}$ + phen ($\mu = 0.10$ M, 25.0 ± 0.1 °C): runs with buffers (◆, ■, △); run without buffer (×). Solid line is least-squares best fit of the points.

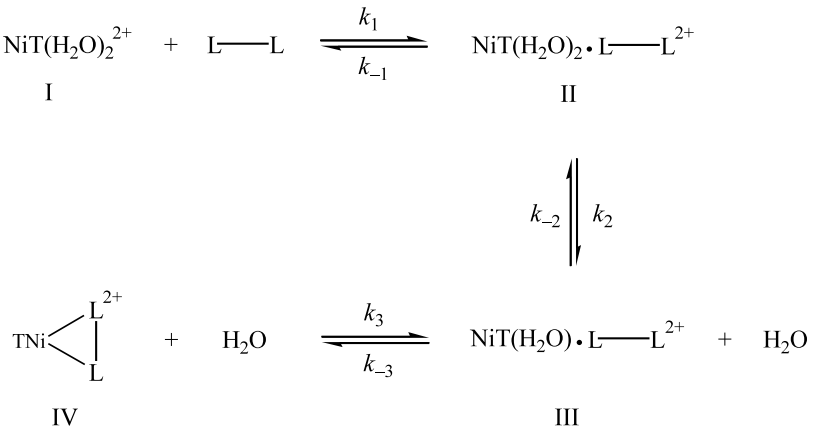
Table 9
Rate constants for the forward reaction (k_f) and reverse reaction (k_b) of $[Ni(tren)(H_2O)_2]^{2+}$ with phen at 25.0 ± 0.1 °C and $\mu = 0.10$ M (NaCl)

pH	10^4 k_f (M^{-1} s^{-1})	k_b (s^{-1})
7.18	1.29	5.84
7.34	1.30	5.42
7.45	1.29	6.36
7.53	1.31	5.86



basicity of phen offers a negligibly small ICB contribution to the rate [1]. As listed in Table 10, the predicted value is about 37 times larger than the experimental value of k^{phen}_{NiT}. Further, the experimental rate constant values of phen and bpy reacting with $[Ni(tren)(H_2O)_2]^{2+}$, $[Ni(trien)(H_2O)_2]^{2+}$, $[Ni(cyclen)(H_2O)_2]^{2+}$ are almost identical and 30–84 times less than that of predicted values for all of those reactions. Those differences indicate that the coordinated ligands exert a decelerating effect on the complexation of the attacking bpy or phen and suggest that ring closure contributes to the rate of formation. Thus, the rate-determining step is the formation of the second Ni–N bond. The coordinated tren increases the lability at the remaining coordination sites and increases the monodentate phen dissociation rate constant (k_{-2}). In addition, the steric effect of the coordinated tren blocks the formation of the second Ni–N bond so that ring closure contributes to the rate.

The formation rate constant for the reaction of phen with $[Ni(H_2O)_6]^{2+}$ and the water exchange rate constant of $[Ni(H_2O)_6]^{2+}$ are 1.6×10^3 M^{-1} s^{-1} and 3.2×10^4 s^{-1}, respectively [22,23]. The coordinated tren increases the rate of water loss of Ni(II) by a factor of about 280, but phen reacts only eight times faster with $[Ni(tren)(H_2O)_2]^{2+}$ than with $[Ni(H_2O)_6]^{2+}$. The relatively low rate of reaction between $[Ni(tren)(H_2O)_2]^{2+}$ and phen is due to the steric blocking of coordinated tren.

As shown in Table 10, the rate constants of the phen or bpy reaction with $[Ni(tren)(H_2O)_2]^{2+}$, $[Ni(cyclen)(H_2O)_2]^{2+}$ and $[Ni(trien)(H_2O)_2]^{2+}$ are similar. These results indicate that the steric effect of coordinated tren upon the formation reaction of its Ni(II) complex with phen is very similar to those of coordinated cyclen and trien.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 176793–176794 for compounds **a** and **b**, respectively. Copies of this information may be obtained free of charge from The Director,

mol) in MeCN (30 ml). Orange needles slowly crystallised.

Analysis for $FeCl_3$(*N*-methylimidazole)$_3$: $C_{12}H_{18}Cl_3FeN_6$ requires C, 35.27; H, 4.44; N, 20.57. Found: C, 34.85; H, 4.27; N, 19.92%.

Mer-[$FeCl_3$(terpy)] (**3**) and [$FeCl_3$(imidazole)$_4$] (**6**) were prepared similarly by adding a warm solution of the ligand (0.10 g; 0.49×10^{-3} mol (terpy) or 1.72×10^{-3} mol (imidazole)) in MeCN (40 ml) to a solution of $FeCl_3$ (0.08 g; 0.49×10^{-3} mol) in MeCN (8 ml); (**3**) formed yellow crystals and (**6**) yellow to orange diamonds.

Analysis for $FeCl_3$(terpy): $C_{15}H_{11}Cl_3FeN_3$ requires C, 45.55; H, 2.81; N, 10.63. Found: C, 45.44; H, 2.76; N, 10.64%.

Analysis for $FeCl_3$(imidazole)$_4$: $C_{12}H_{12}Cl_3FeN_8$ requires C, 35.45; H, 3.96; N, 20.67. Found: C, 34.50; H, 4.26; N, 19.81%.

Mer-[$FeCl_3$(tptz)] (**4**) was obtained as yellow–orange crystals from the addition of a warm solution of the ligand (0.12 g; 0.385×10^{-3} mol) in MeCN (20 ml) to a solution of $FeCl_3$ (0.06 g; 0.37×10^{-3} mol) in MeCN (2 ml). X-ray crystallography confirms the presence of 1 molecule of MeCN and $\frac{1}{2}$ molecule of H_2O in the lattice of the crystal studied.

Analysis for $FeCl_3$(tptz): $C_{18}H_{12}Cl_3FeN_6$ requires C, 45.55; H, 2.55; N, 17.71; $C_{20}H_{16}Cl_3FeN_6O_{0.5}$ ($FeCl_3$(tptz)·MeCN·$\frac{1}{2}H_2O$) requires C, 45.79; H, 3.07; N, 18.69. Found: C, 43.10; H, 2.79; N 16.51%.

[$FeCl_3$(3-methylpyrazole)$_4$] (**5**) was prepared by the addition of 3-methylpyrazole (0.10 g; 1.22×10^{-3} mol) to a solution of $FeCl_3$ (0.08 g; 0.49×10^{-3} mol) in MeCN (8 ml). Well formed orange–red crystals slowly crystallised. Analysis for $FeCl_3$(3-methylpyrazole)$_4$: $C_{16}H_{24}Cl_3FeN_8$ requires C, 39.16; H, 4.93; N, 22.84. Found: C, 38.76; H, 4.76; N, 22.39%.

[$FeCl_3$(3-methylpyrazole)$_3$] was prepared by the literature method [1], by addition of 3-methylpyrazole (0.40 g; 4.88×10^{-3} mol) to a solution of $FeCl_3$ (0.30 g; 1.85×10^{-3} mol) in EtOH (5 ml). An oil initially formed, which changed to an orange solid on scratching the glass.

Analysis for $FeCl_3$(3-methylpyrazole)$_3$: $C_{12}H_{18}Cl_3FeN_6$ requires C, 35.27; H, 4.44; N, 20.57. Found: C, 34.01; H, 4.28; N, 19.76%.

2.2. X-ray crystallography

Full spheres of diffraction data for **1**, **2**, **3** and **4** were collected on a Bruker APEX 2000 CCD diffractometer at 150 K. Data for **5** were measured at 190 K on a Bruker P4 diffractometer. All data sets were collected using graphite monochromated Mo Kα radiation ($\lambda = 0.7107$ Å) and the reflections were corrected for Lp and absorption effects. The structures were solved by Patterson methods using the program SHELXS [8] and refined by full-matrix least squares on F^2 using SHELXTL [9]. All hydrogen atoms were included in calculated positions (C–H = 0.96 Å) with isotropic displacement parameters set to $1.5U_{eq}$(C) for the methyl groups and $1.2U_{eq}$(C) for all other hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters.

Crystal data are presented in Table 1, with important bond lengths and angles in the metal's co-ordination sphere listed in Table 2.

3. Results and discussion

3.1. Description of the structures

3.1.1. *mer*-[$FeCl_3$(pyrazole)$_3$] (**1**)

This molecule (Fig. 1) has six co-ordination of iron with bond angles showing slight distortion from a regular octahedral geometry (*cis* N–Fe–N 84.97(5)° and 85.95(5)°; *trans*-N–Fe–N 170.90(5)°; *cis* Cl–Fe–Cl 90.81(2)° and 94.77(2)°; *trans*-Cl–Fe–Cl 174.42(2)°). The mutually *trans*-Fe–N bonds are virtually identical in length at 2.1186(14) and 2.1195(13) Å, shorter than that *trans*-to chlorine, where Fe–N is 2.1721(13) Å. This indicates a greater *trans*-influence for chloride. As far as the Fe–Cl distances are concerned, Fe–Cl (3) (*trans*-to nitrogen) is 2.3053(5) Å, shorter than the mutually *trans*-Fe–Cl bonds of 2.3185(5) and 2.3548(5) Å. A possible explanation for the discrepancy in Fe–Cl bond length between 'equivalent' bonds lies in Cl···H–N hydrogen-bonding. Cl(1), involved in the greater Fe–Cl bond length, has intramolecular hydrogen bonds at 2.461 and 2.628 Å as well as an intermolecular one at 2.555 Å, whilst Cl(2) has an intramolecular hydrogen bond at 2.585 Å and an intermolecular one at 2.686 Å. M–Cl moities have been shown to be good hydrogen-bond acceptors [10] and there is X-ray and neutron-diffraction evidence for intramolecular hydrogen-bonding causing strong N–H···Cl interactions in another pyrazole complex, *trans*-[$NiCl_2$(pyrazole)$_4$], leading to long Ni–Cl distances [11]. Similarly, in $(NH_4)_2$[$FeCl_5(OH_2)$], there is considerable variety in Fe–Cl distances. Apart from a short Fe–Cl bond *trans*-to water (2.323(1) Å), the other Fe–Cl distances are 2.350(1), 2.3838(8), 2.3828(8) and 2.390(1) Å. The first-named is regarded as unperturbed; the others are all lengthened (by up to 0.04 Å) owing to hydrogen-bonding [12].

The only '$FeCl_3$(N-donor)$_3$' complex previously characterised crystallographically is mer-[$FeCl_3$(py)$_3$]·py [3],where the respective Fe–Cl distances were 2.306(2) Å *trans*-to N and 2.326(2) Å *trans*-to Cl; there was a more striking difference in Fe–N distance, at 2.168(5) Å *trans*-to N and 2.274(6) Å *trans*-to Cl.

	2.1186(14)	2.1353(15)	2.1335(13)	2.1928(15)	2.140(4)
Fe–N (*trans*-Cl)	2.1721(13)	2.1526(15)	2.1021(13)	2.1104(15)	

[a] The Fe atom of compound **5** is located on a centre of symmetry and therefore there is one unique Fe–Cl1 and two Fe–N distances.

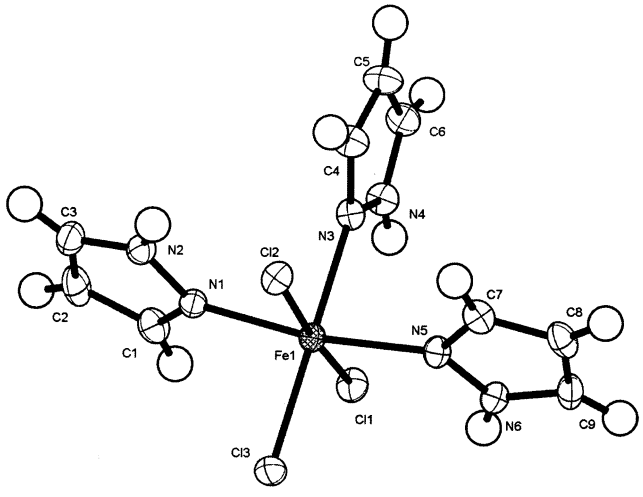

Fig. 1. Molecular structure of **1** showing the atom label scheme. Displacement ellipsoids are shown at the 50% level. H atoms are shown as spheres of arbitary radius.

The Fe–Cl bond lengths in these compounds are substantially shorter than those in $[FeCl_6]^{3-}$ ions, such as in $[Co(NH_3)_6]\cdot[FeCl_6]$ where it is 2.3926(3) Å, where the lengthening, even in comparison with salts of the $[FeCl_5(OH_2)]^{2-}$ ion, has been ascribed to Cl···Cl repulsions in a congested coordination sphere [13].

3.1.2. *mer*-[$FeCl_3$(*N*-methylimidazole)$_3$] (**2**)

The molecule is similar in structure to (**1**) (Fig. 2). Here the *cis* N–Fe–N angles are 85.21(6)° and 88.05(6)°; *trans*-N–Fe–N 172.88(6)°; *cis* Cl–Fe–Cl 91.354(19)° and 93.619 (18)°; trans-Cl–Fe–Cl 174.86(2)°. The mutually *trans*-Fe–N bonds are again very similar in length at 2.1247(16) and 2.1353(15) Å, shorter than that *trans*-to chlorine, where Fe–N is 2.1526(15) Å, again indicating a greater *trans*-influence for chloride. The iron–chlorine distance *trans*-to nitrogen Fe–Cl(1) is 2.3151 (5) Å, shorter than the other two mutually trans-Fe–Cl bonds of 2.3527(5) and 2.3871(5)

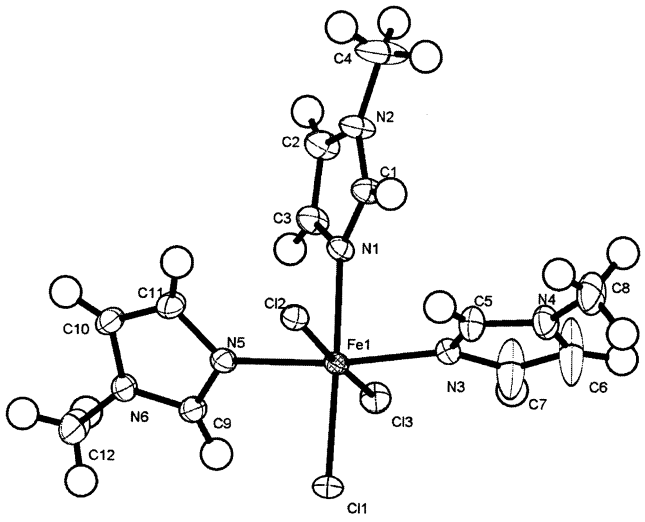

Fig. 2. Molecular structure of **2** showing the atom label scheme. Displacement ellipsoids are shown at the 50% level.

Å. The only H···Cl contact below 2.7 Å is Cl(2)···H(5)–N(5) at 2.641 Å.

3.1.3. *mer*-[$FeCl_3$(terpy)] (**3**)

A mer-geometry is enforced on this complex by the tendency of a co-ordinated terpyridyl ligand to adopt a near-planar geometry when tridentate (Fig. 3). *Mer*-[$FeCl_3$(terpy)] exhibits a greater distortion from regular octahedral geometry than the pyrazole and methylimidazole complexes, due to the steric demands of the terpyridyl ligand. However, the N–Fe–N angles subtended by two neighbouring nitrogens in the same ring, at 74.89° and 75.00(5)°, are very similar to those in the $[FeCl_2(bipy)_2]^+$ cation (74.9(1)° and 75.2(1)°) and in the $[FeCl_4(bipy)]^-$ anion (74.6°) [14]. The presence of the three nitrogen donor atoms in the terpy complex leads to a N(1)–Fe–N(3) angle of 149.84(5)°. The chlorides

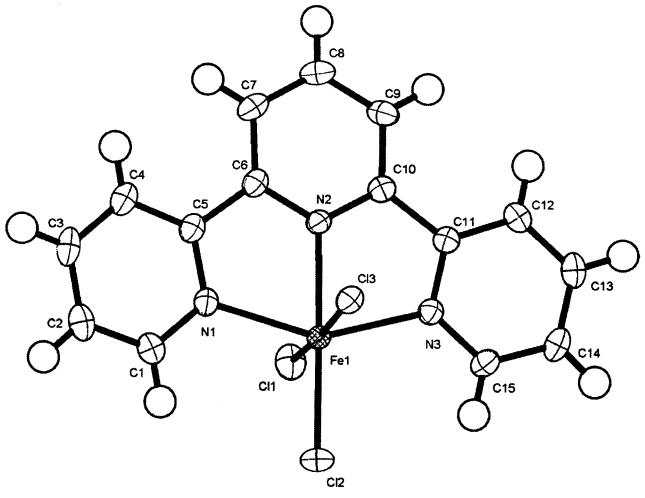

Fig. 3. Molecular structure of **3** showing the atom label scheme. Displacement ellipsoids are shown at the 50% level.

are less constrained, so that in contrast the Cl–Fe–Cl angles are nearer to the regular octahedral angles, at 90.902(19)° and 94.58(2)° (*cis*) and 174.468(17)° (*trans*).

Another consequence of the linkage between the three pyridine rings in *mer*-[$FeCl_3$(terpy)] is the short Fe–N (2) distance trans-to chlorine (2.1021(13) Å) which is shorter than the mutually trans-Fe–N distances (2.1335(13) and 2.1267(14) Å), in the opposite sense to the *trans*-influence observed in the pyrazole complex, but which clearly is an imposed consequence of bringing N(1) and N(3) close enough to iron to bond. In the similarly six co-ordinate *cis*-$[FeCl_2(bipy)_2]^+$ cation, Fe–N distances *trans*-to N lie in the range 2.126–2.144 Å, whilst *trans*-to chlorine they fall into a narrower 2.174–2.178 Å range (2.187–2.199 Å in $[FeCl_4(bipy)]^-$).

The Fe–Cl distances in *mer*-[$FeCl_3$(terpy)], however, observe the expected pattern, with Fe–Cl (2) *trans*-to N (2.2526(5) Å) being shorter than the Fe–Cl(1) and Fe–Cl(3) distances of 2.3150(5) and 2.3743(5) Å, respectively; the range in distances is, however, rather large. The discrepancy between the mutually *trans*-Fe–Cl distances is again noticeable; however, one possible explanation lies in C–H···Cl–Fe interactions, as Cl(3) has 3 C–H··· contacts at <2.8 Å against none for Cl(1).

In the comparable *cis*-$[FeCl_2(bipy)_2]^+$ cation, the Fe–Cl distance *trans*-to N are 2.254–2.282 Å (in the $[FeCl_4]^-$ and $[FeCl_4(bipy)]^-$ salts), whilst in the $[FeCl_4(bipy)]^-$ anion, the Fe–Cl distances are 2.305–2.310(2) Å (*trans*-to N) and 2.371–2.374(2) Å *trans*-to Cl.

The layer structure has a repeat sequence every 4th layer with the shortest C···C contact of 3.421 Å; this may be compared with the interlayer spacing in graphite of 3.35–3.44 Å [15]. The *trans*-Cl atoms fit into holes in the terpy layers above and below.

3.1.4. [$FeCl_3$(tptz)] (**4**)

This compound has a similar co-ordination geometry (Fig. 4) to *mer*-[$FeCl_3$(terpy)], with a 'central' Fe–N distance of 2.1104(15) Å and other Fe–N distances of 2.1774(15) and 2.1928(15) Å. Fe–Cl *trans*-to N is 2.2487(6) Å, with other Fe–Cl distances being 2.3228(6) and 2.3473(5) Å.

The N–Fe–N angles subtended by two neighbouring nitrogen atoms in the same ring, at 72.84(6)° and 73.55(5)°, are very similar to those in [$FeCl_3$(terpy)]. The N(1)–Fe–N(5) angle, at 146.29(6)°, is similar to that in the terpy complex [149.84(5)°] whilst there is a similar pattern in the Cl–Fe–Cl angles at 91.69(2)° and 93.09(2)° (*cis*) and 174.84(2)° (*trans*).

There are a number of short Cl···H contacts, with a notable discrepancy between the intra molecular Cl1···H1 and Cl1···H13 distances of 3.076 and 3.249 Å, respectively, where more similar values might be expected; the discrepancy may be due to the effects of a

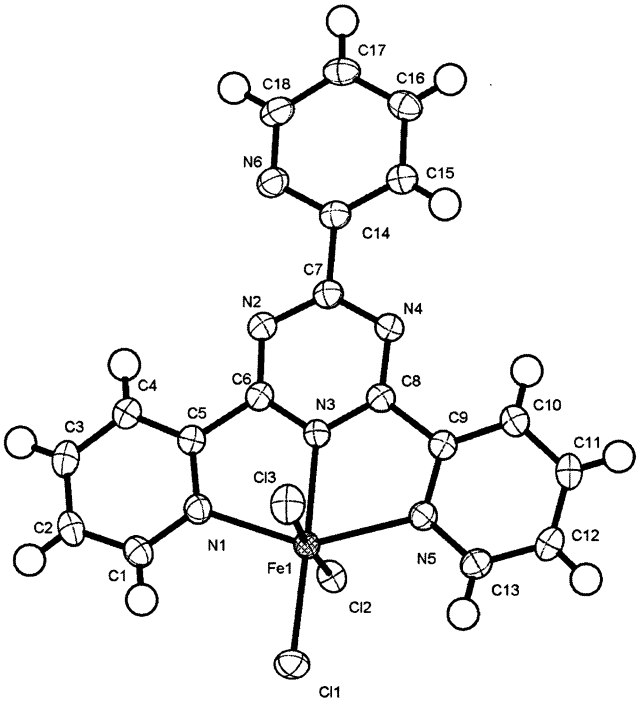

Fig. 4. Molecular structure of **4** showing the atom label scheme. Displacement ellipsoids are shown at the 50% level.

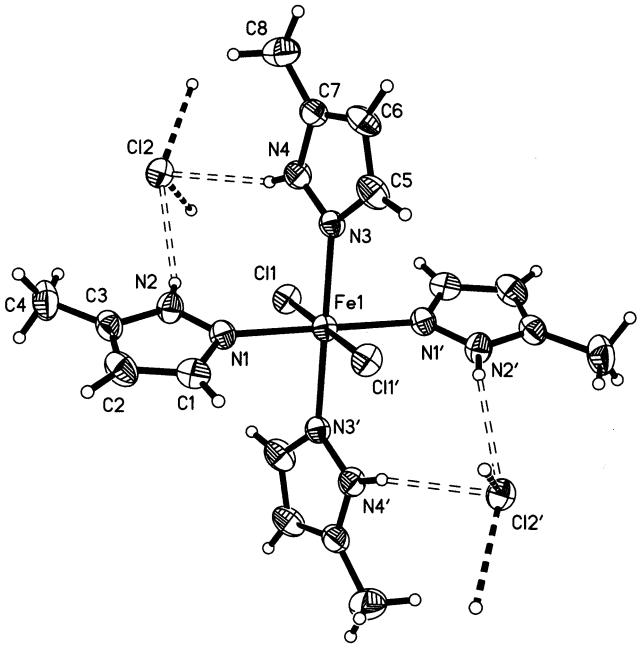

Fig. 5. Molecular structure of **5** showing the atom label scheme. Displacement ellipsoids are shown at the 50% level.

number of intermolecular hydrogen bonds, notably short distances being Cl2···H17′ 2.775; Cl1···H12′ 2.782; Cl2···H2′ 2.905; Cl2···H3′ 2.914; Cl3···H15′ 3.078 and Cl3···H16′ 3.102 Å. There is a molecule of MeCN in the lattice, as well as a half-molecule of water per formula unit; the MeCN is involved in a short N···H contact with $CH_3CN\cdots H(11)$–C(11) at 2.49 Å.

3.1.5. *trans*-[$FeCl_2$(3-methylpyrazole)$_4$]Cl (**5**)

The structure of this compound (Fig. 5) exhibits similarities to the recently reported *trans*-[$FeCl_2$(imidazole)$_4$]Cl·thf·H_2O [5] but there are differences too. The Fe atom is located on a center of symmetry as is Cl(1) and the methylpyrazoles. The Fe–N distances at 2.137–2.140(4) Å and Fe–Cl at 2.3183(13) Å are unsurprising and compare with respective values of 2.125–2.140(5) and 2.355(2) Å, respectively for the *trans*-$[FeCl_2(\text{imidazole})_4]^+$ ion. The mutually *trans*-Fe–Cl distances are rather similar to the corresponding Fe–Cl distances in (**1**–**3**), which fall in the range 2.3150–2.3871 Å, the longer ones being lengthened by Q–H···Cl–Fe interactions (Q = N, C).

The structure is linked by strong N–H···Cl hydrogen bonds. Each chloride ion is involved in two hydrogen bonds (Cl2···H2a = 2.470 and Cl2···H4a = 2.411 Å) to mutually *cis*-3-methylpyrazole ligands (shown as solid dash lines in Fig. 5) and in two further bonds to neighbouring complex cations (shown as open dash lines). In contrast, the imidazole complex is described [5] as 'having no significant cation–anion interactions'. The imidazole groups are aligned nearly parallel to the Cl–Fe–Cl axis, as in the pyrazole complex.

3.1.6. *trans*-[$FeCl_2$(imidazole)$_4$]Cl (**6**)

The poor quality of crystals obtained from this reaction meant that no satisfactory refinement of the data was possible ($R = 0.258$), probably because of unresolved disorder due to solvent molecules in the lattice. It was clear, however, that the structure was *trans*-$[FeCl_2(\text{imidazole})_4]^+\cdot Cl^-$, with dimensions in the cation similar to those in *trans*-[$FeCl_2$(imidazole)$_4$]+ $Cl^-\cdot$thf·H_2O [5].

4. Discussion

We attempted to synthesise new complexes by reaction of the N-donor ligands with a solution of anhydrous $FeCl_3$ in MeCN, reasoning that a labile complex [$FeCl_3(MeCN)_x$] ($x \sim 3$) would be a suitable synthon from which weakly bound nitrile ligands would be readily displaced by N-donors and obviate problems encountered in solvents used hitherto such as ethanol or propanone. Though not successful in every case, this method led to the isolation of complexes with pyrazole, 3-methylpyrazole, imidazole and *N*-methylimidazole; although [$FeCl_3$(pyrazole)$_3$] was synthesised by this route, in the event superior crystals were obtained by recrystallisation from $MeNO_2$. We also observed colour changes indicating complex formation with 4-methylpyrazole and 3,5-dimethylpyrazole, but were unable to isolate crystalline material; we were also able to extend

the method to isolate suitable crystals of the terpyridyl and 2,4,6-tris(2-pyridyl)-1,3,5-triazine complexes.

The complex isolated from the reaction of $FeCl_3$ with 3-methylpyrazole in MeCN was *trans*-[$FeCl_2$(3-methylpyrazole)$_4$]Cl (**5**), in contrast to earlier syntheses carried out in ethanol, when molecular [$FeCl_3$(3-methylpyrazole)$_3$] was formed [1]. The earlier synthesis of [$FeCl_3$(3-methylpyrazole)$_3$] was found to be reproducible, but it is not possible to isolate crystals suitable for X-ray diffraction.

The one-step synthesis of *mer*-[$FeCl_3$(terpy)] by this route represents a considerable improvement over the previously reported three-step method [16], which involved prior preparation of $[Fe(terpy)_2]^{2+}$, its oxidation to $[Fe(terpy)_2]^{3+}$ followed by reaction with Cl^- to afford [$FeCl_3$(terpy)]. Apart from ultimate confirmation of its nature by its crystal structure and microanalyses, our material had a similar peak in the far-IR spectrum [16] due to νFe–Cl at 343 cm^{-1} comparable with the earlier reported value for [$FeCl_3$(terpy)] of 353 cm^{-1}.

Four of the six complexes characterized have structures of the *mer*-[$FeCl_3L_3$] type (L = pyrazole, *N*-methylimidazole, $\frac{1}{3}$terpy, $\frac{1}{3}$tptz), which has hitherto not been well represented. A number of octahedral $FeCl_3$ complexes are known where a *fac*-geometry is enforced by the steric requirements of the ligand making it occupy a face; such systems include *fac*-[$FeCl_3$(L)] (L = 1,3,5-trimethyltriazacyclohexane [17a]; 1,3,5-trithiazacyclononane [17b]; di(2-pyridyl)methylamine (DPMA) [17c]; (bis(pyridin-2-ylmethyl)amine) [17d]; bis(2-pyridylmethyl)amine) (BPA) [17e]. However, meridional systems have been characterized before, such as *mer*-[$FeCl_3(py)_3$]·py [3] and *mer*-[$FeCl_3$L] (L = 2,6-bis(*N*-(2-pyridylethyl)iminomethyl]-4-methylphenolate), which contains a $FeCl_3N_2O$ co-ordination sphere [18]. Whilst the ligands terpy and tptz enforce a *mer*-geometry, in principle either a *fac*- or *mer*-isomer could be obtained for a [$FeCl_3L_3$] complex where L is a monodentate ligand; so far, only the *mer*-isomer has been obtained with these N-donors (L = py, *N*-methylimidazole, pyrazole) and this is presumably due to the desire of the bulky N-donor ligands to mimimise repulsions between them.

Otherwise, there can be a fine balance of forces dictating whether a *fac*- or *mer*-isomer is obtained. Thus, reaction of $FeCl_3$ with phen gives a complex of 1:1 stoichiometry $FeCl_3$(phen). Its recrystallisation from methanol gives *fac*-[$FeCl_3$(phen)(MeOH)], whilst recrystallisation from presumably wet MeCN gives *fac*-[$FeCl_3$(phen)(H_2O)] [14,19a]; in contrast, recrystallisation from DMF affords *mer*-[$FeCl_3$(phen)(DMF)] (DMF = dimethylformamide) [19b]. Even in a relatively non-polar solvent, reaction of $FeCl_3$ with a Lewis base can lead to a number of species in solution, some neutral and some ionic, possibly resulting from self-ionisation. Thus a spectrophotometric study of solutions of $FeCl_3$ in pyridine identified the presence of at least three complexes, neutral [$FeCl_3py_n$] ($n = 3$, presumably), $[FeCl_4]^-$ and (by implication) $[FeCl_2py_n]^+$ ($n \sim 4$) with the first named predominating, as the solution was essentially a non-electrolyte [20]. The choice of solvent can affect the identity of the complex isolated, thus reaction of $FeCl_3$ with pyridine N-oxide (pyO) in ether yielded [$Fe(pyO)_3Cl_3$] whilst in ethanol $[Fe(pyO)_4Cl_2]^+$ $[FeCl_4]^-$ ('$Fe(pyO)_2Cl_3$') was obtained [21].

Ultimately the nature of the complex isolated will depend upon the balance of a number of factors, including the concentration of each species and its solubility, as well as steric requirements of the ligand.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 183556–183560, for compounds **1**–**5**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; email: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We are very grateful to Dr J.C. Anderson of the University of Nottingham for helpful discussions and for assistance with the collection of far-IR data, and to T.F. Spencer of the University of Nottingham for microanalytical data.

1:2 molar ratio, an untreatable mixture was obtained, instead of the expected intramolecularly bonded complex, whereas reaction in a 1:4 molar ratio gave compounds with the diphosphine acting as a chelating ligand.

2. Experimental

2.1. Safety note: caution

Perchlorate salts of metal complexes with organic ligands are potentially explosive. Only small amounts of these materials should be prepared and handled with great caution.

The synthesis of complexes **1**, **2** and **8** has been reported previously by us [30]. Solvents were purified by standard methods [31]. Chemicals were reagent grade. The phosphines PPh_3, $P(p\text{-}MeOC_6H_4)_3$, $P(p\text{-}NMe_2C_6H_4)Ph_2$ and *cis*-$Ph_2PCH{=}CHPPh_2$ were purchased from Aldrich-Chemie. Microanalyses were carried out using a Carlo Erba Elemental Analyser, Model 1108. IR spectra were recorded as Nujol mulls or polyethylene discs on a Perkin–Elmer 1330 and Mattson spectrophotometer. NMR spectra were obtained as $CDCl_3$ solution and referenced to $SiMe_4$ (^1H, $^{13}C\{^1H\}$) or 85% H_3PO_4 ($^{31}P\{^1H\}$) and were recorded on a Bruker AC-200F spectrometer. All chemical shifts were reported downfield from standards. The FAB-MS were recorded using a VG Quatro mass spectrometer with a Cs ion gun; 3-nitrobenzyl alcohol was used as the matrix. Conductivity measurements were made on a CRISON GLP 32 conductimeter using 10^{-3} mol dm^{-3} solutions in dry MeCN.

2.2. Preparation of [1,3-{Pd[2,3,4-(MeO)$_3$C$_6$HC(H)=NCH$_2$](OAc)(PPh$_3$)}$_2$C$_6$H$_4$] (3)

To a suspension of **1** (50 mg, 0.061 mmol) in C_3H_6O (approximately 15 cm^3), triphenylphosphine (32 mg, 0.122 mmol) was added. The solution was stirred for 24 h at room temperature, after which a yellow precipitate appeared, which was filtered off, washed with cold C_3H_6O, dried in vacuo, and recrystallized from $CHCl_3$/*n*-C_6H_{14}. Yield: 75%. *Anal*. Found: C, 60.3; H, 4.7; N, 2.2. $C_{68}H_{66}N_2O_{10}P_2Pd_2$ requires: C, 60.7; H, 4.9; N, 2.1%. IR: $\nu_{as}(COO) = 1580$s; $\nu_s(COO) = 1380$s; $\nu(C{=}N) = 1610$m cm^{-1}. 3. Results and discussion

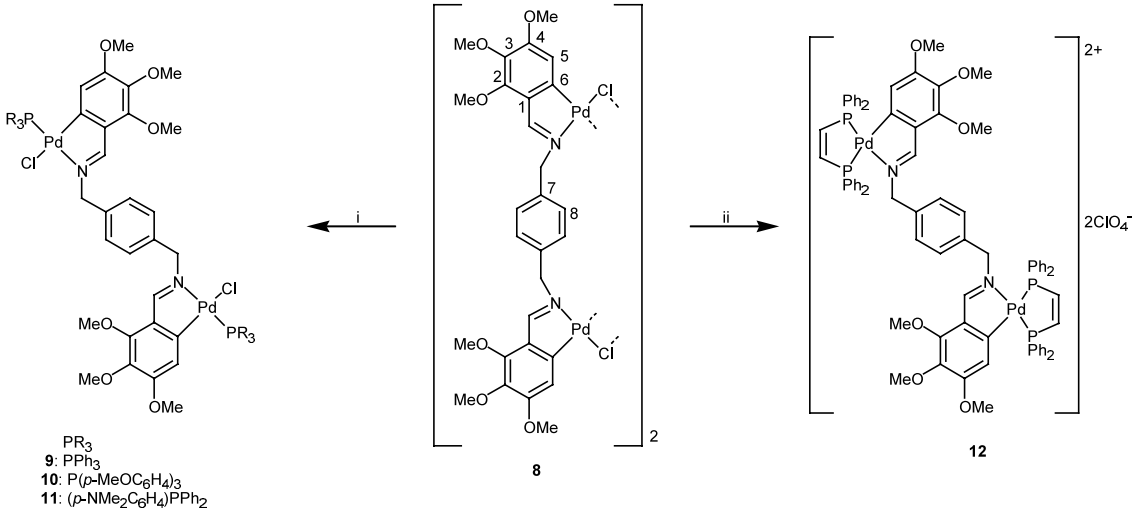
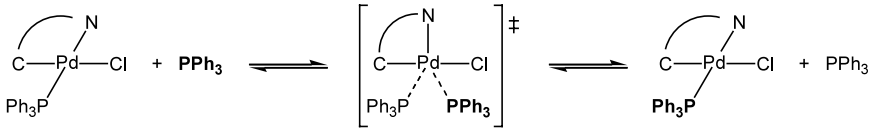
For the convenience of the reader the compounds and reactions are shown in Schemes 1 and 2. The compounds described in this paper were characterized by elemental analysis (C, H, N) and by IR spectroscopy and by ^{1}H, $^{31}P\{^1H\}$ NMR and, in part, $^{13}C\{^1H\}$ NMR spectroscopy and FAB mass spectrometry (data in the Section 2).



The reaction of complex **1** [30] with triphenylphosphine in a 1:2 molar ratio gave the doubly cyclometallated complex [1,3-{Pd[2,3,4-(MeO)$_3$C$_6$HC(H)=NCH$_2$](OAc)(PPh$_3$)}$_2$C$_6$H$_4$] (**3**), after cleavage of the two acetate-bridging ligands. The IR spectrum of **3** showed the ν(C=N) stretch at 1610 cm^{-1}, shifted to lower wavenumbers (as compared to the free ligand) due to N-coordination of the imine [32,33]. The IR spectrum also showed strong bands assigned to the symmetric and asymmetric ν(COO) vibrations, in agreement with those expected for monodentate acetate ligands [34] (see Section 2). The *H*C=N and H5 resonances in the ^{1}H NMR spectrum were coupled to the phosphorus nucleus [δ 8.07 and 5.70, respectively; J(HP) = 8.3 and 5.9 Hz, also, respectively], and in the $^{31}P\{^1H\}$ NMR spectrum, the phosphorus resonance appeared as a singlet at δ 41.2 in accordance with the symmetric nature of the complex. These data are indicative of a phosphorus *trans* to nitrogen geometry [35–38]. The relative position of the phosphine ligand in the coordination sphere of the palladium atom was confirmed by the highfield shift of the signal corresponding to the C(4)–OMe group, due to shielding by a phenyl ring from the phosphine [35–38]. In complex **1**, the signals assigned to the diastereotopic CH_2 protons in the ^{1}H NMR spectrum appeared as two doublets, due to the hindered rotation of this group. However, only one rather broad resonance at δ 4.85 was assigned to the methylene group in complex **3**, after cleavage of the intramolecular-bridges. The $^{13}C\{^1H\}$ NMR spectrum of **3** showed the high-frequency shift of the resonances corresponding to the HC=N, C6 and C1 carbons, evidencing formation of the cyclometallated ring [39,40].

The synthesis of complexes **2** and **8** has been described previously by us [30]. Reaction of **2** and **8** with the tertiary monophosphines PPh_3, P(*p*-$MeOC_6H_4)_3$ and P(*p*-$NMe_2C_6H_4$)Ph_2 gave the doubly cyclometallated complexes [1,3-{Pd[2,3,4-(MeO)$_3$C$_6$HC(H)=NCH$_2$](Cl)-(PR_3)}$_2$C$_6$H$_4$] (PR_3 = PPh_3, **4**; P(*p*-$MeOC_6H_4)_3$, **5**; P(*p*-$NMe_2C_6H_4$)Ph_2, **6**) and [1,4-{Pd[2,3,4-(MeO)$_3$C$_6$HC(H)=NCH$_2$](Cl)-(PR_3)}$_2$C$_6$H$_4$] (PR_3 = PPh_3, **9**; P(*p*-$MeOC_6H_4)_3$, **10**; P(*p*-$NMe_2C_6H_4$)Ph_2, **11**), respectively, which were fully characterized (see Section 2). The spectroscopic features of these complexes are similar to those described for **3**. Thus, the IR spectra was in accordance with coordination of the HC=N group. The ^{1}H NMR spectra showed the coupling of the HC=N and H5 resonances to the ^{31}P nucleus and the $^{13}C\{^1H\}$ NMR spectra also showed the high-frequency shift of the resonances corresponding to the HC=N, C6 and C1 carbons. In all the cases, the FAB-MS rendered clusters of peaks whose isotopic patterns were in agreement with $[M]^+$ and/or $[M-PR_3]^+$ fragments.



The reaction of the **4** with PPh_3 in a 1:2 molar ratio did not yield the expected non-cyclometallated complex, with two phosphine ligands coordinated to palladium and the Pd–N bond cleaved [37,41]. The ^{1}H NMR spectra of the reaction mixture in $CDCl_3$ showed the resonances corresponding to the HC=N and H5 resonances as singlets (no coupling to the ^{31}P nucleus was observed). This behavior is characteristic of the non-cyclometallated complexes, where in the absence of Pd–

Scheme 3.

N bond the metallated ring can rotate about the Pd–C vector so that its plane is at 90° to the palladium coordination plane and coupling of the H5 proton to the ^{31}P nucleus is absent [37,41]. Furthermore, the $^{31}P\{^{1}H\}$ spectrum did not show the expected singlet. In order to clarify this controversy the ^{1}H and $^{31}P\{^{1}H\}$ spectra of the reaction mixture were recorded at different temperatures. The $^{31}P\{^{1}H\}$ spectrum at 223 K showed two slightly broad resonances at δ 43.0 and −6.3 corresponding to complex **4** and free PPh_3, respectively. At 298 K the signals coalesced and at 323 K a broad resonance at approximately δ 20 appeared. The ^{1}H NMR spectra showed the progressive broadening of the HC=N and H5 resonances on cooling, however no coupling to phosphorus was observed even at 223 K. These results seem to indicate that although the Pd–N was not cleaved, a fast exchange between coordinated and free PPh_3, which could proceed through the typical substitution reaction mechanism in square-planar d^8 complexes, is responsible for the absence of the PH coupling [42,43] (see Scheme 3).

The reaction of **2** and **8** with the tertiary diphosphine *cis*-$Ph_2PCH{=}CHPPh_2$, in a 1:4 molar ratio yielded the doubly cyclometallated complexes [1,3-{Pd[2,3,4-$(MeO)_3C_6HC(H){=}NCH_2$]($Ph_2PCH{=}CHPPh_2$-*P*,*P*)}$_2C_6H_4$][ClO_4]$_2$ (**7**) and [1,4-{Pd[2,3,4-$(MeO)_3C_6HC(H){=}NCH_2$]($Ph_2PCH{=}CHPPh_2$-*P*,*P*)}$_2C_6H_4$][ClO_4]$_2$ (**12**), respectively, as air-stable solids which were fully characterized (see Section 2). In the ^{1}H NMR spectra of the complexes the resonance corresponding to the HC=N protons appeared as a doublet, showing coupling only to the phosphorus atom *trans* to the imine nitrogen atom [29,44]. However, the H5 resonance showed coupling to both ^{31}P nuclei [29,44]. Only one set of signals appeared for each proton, as proof of the symmetric nature of the complexes. The $^{31}P\{^{1}H\}$ spectra showed two doublets for the 2 non-equivalent phosphorus atoms. In the $^{13}C\{^{1}H\}$ the signal assigned to C6 was a doublet due to coupling to the *trans* ^{31}P nucleus [approximately 122 Hz] [45]. The FAB-MS of the complexes showed a cluster of peaks at 1495 amu corresponding to the $[M]^+$ fragments.

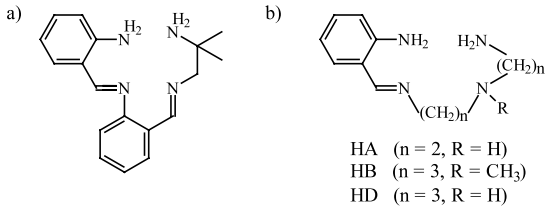

Fig. 1. Structural formulae: (a) for the Cummins ligand [6], (b) for ligands of the present study.

incorporate singly condensed products of 2-aminobenzaldehyde and triamines (Fig. 1(b)).

2. Experimental

2.1. Reagents

1,5-Diamino-3-azapentane, 1,7-diamino-4-azaheptane and 1,7-diamino-4-methyl-4-azaheptane were dried over potassium hydroxide, distilled and fractions boiling in ranges of 206–208, 110–122/6 mm and 105–106 °C/5 mm, respectively, were collected. 2-Aminobenzaldehyde was obtained from 2-nitrobenzaldehyde and purified by the method described elsewhere [7]. Nickel(II) iodide monohydrate has been obtained by recrystallization of anhydrous NiI_2 from water and gentle drying.

2.2. Ligands

2.2.1. 1-(2′-Aminophenyl)-2,5-diaza-7-amino-1-heptene, HA

To a rapidly stirred solution of 1,5-diamino-3-azapentane (3.26 g, 0.031 mol) in MeOH (50 ml) a solution of freshly purified 2-aminobenzaldehyde (3.72 g, 0.031 mol) in MeOH (50 ml) was slowly added over a period of 1 h. The solvent was removed from the mixture in vacuo to give an oily residue. Mass spectrum of the product showed a prominent peak at $m/z = 206$, which may be assigned to the molecular ion. 1-(2′-Aminophenyl)-2,6-diaza-6-methyl-9-amino-1-nonene, HB, and 1-(2′-aminophenyl)-2,6-diaza-9-amino-1-nonene, HD, were obtained in a similar way as HA. Mass spectra of the reaction products revealed molecular ions at $m/z =$ 248 and 234, respectively. Structural formulae of ligands are shown in Fig. 1(b).

2.3. Complexes

Complexes were prepared by the reaction of preformed HA, HB and HD ligands with nickel(II) chloride, nitrate and perchlorate hexahydrates, nickel(II) iodide monohydrate and palladium(II) chloride. The following method was used. To a vigorously stirred solution of the corresponding metal salt (3 mmol) in MeOH (25 ml) was slowly added the HA or HB or HD ligand (3 mmol) in MeOH (25 ml). After 2–3 h of stirring the precipitate was filtered off washed with MeOH and dried over molecular sieves. Crystals of $NiAClO_4$ suitable for X-ray investigations were obtained using a slow diffusion of diisopropylether vapor into acetonitrile solution of the complex, but those of NiBI by slow recrystallization of that compound from acetonitrile solution.

Caution: One of the complexes reported here was isolated as a perchlorate salt. We worked with them dissolved in DMSO and acetonitrile solvents and also as solid without any accident. In spite of this the potentially explosive behavior of perchlorate salts necessitates extreme care in their handling.

2.3.1. 1-(2′-Iminophenyl)-2,5-diaza-7-amino-1-heptenonickel(II) perchlorate, $NiAClO_4$

Black amorphous powder, soluble in DMSO and acetonitrile but sparingly soluble in alcohols. Yield: 40%. *Anal*. Calc. for $C_{11}H_{17}ClN_4NiO_4$: C, 36.6; H, 4.9; N, 15.4. Found: C, 36.5; H, 4.9; N, 15.4%. IR (KBr, cm^{-1}): 3387, 3302, 3205 (ν_{N-H}), 1615 ($\nu_{C=N}+\nu_{C=C}$), 1538 (ν_{C-N}), 1090, 620 (ν_{ClO_4}). DRS, λ_{max} (nm): 425, 550 (the latter with a shoulder extending far to the red). PAS, λ_{max} (nm): 450 (broad band with shoulder extending to the red) (Fig. 2). Absorption spectrum in DMSO, λ_{max} (nm), ε (M^{-1} cm^{-1}): 285 (3200), 318 (1840), 450 (1660). ^1H NMR in DMSO-d_6 [ppm vs. TMS, r.t., s, singlet; d, doublet; t, triplet; m, multiplet; dd, doublet of doublets; dt, doublet of triplets; td, triplet of doublets; tt, triplet of triplets; br, broad; hydrogen atom attached to the ith carbon atom (Ci) is denoted as Hi, but that attached to jth nitrogen atom (Nj) as H_Nj]: H_N1, 4.739 (s, 1H); H_N3, 5.417 (s, 1H); H_N4a, 4.144 (dt, 1H); H_N4b, 3.506 (dd, 1H); H2, 6.636 (d, 1H, $^3J = 8$ Hz); H3, 6.939 (td, 1H, $^3J = 8$ Hz, $^4J = 1.5$ Hz); H4, 6.232 (td, 1H, $^3J = 8$ Hz, $^4J = 1.2$ Hz); H5, 7.159 (dd, 1H, $^3J = 7$ Hz); H7, 7.848 (s, 1H); H8a, 3.676 (td, 1H, $^2J = 13$ Hz, $^3J = 3$ Hz); H8b, 3.625 (dd, 1H); H11b, 2.436 (t, 1H); signals of H9a, H9b, H10a, H10b and H11a overlap

giving rise to a 5H multiplet in the 2.58–2.62 ppm region.

2.3.2. 1-(2′-Iminophenyl)-2,5-diaza-7-amino-1-heptenonickel(II) chloride, NiACl

Red plates after recrystallization from MeOH, soluble in DMSO, hot acetonitrile and MeOH. Yield: 34%. *Anal*. Calc. for $C_{11}H_{17}ClN_4Ni$: C, 44.2; H, 5.9; N, 18.7. Found: C, 44.1; H, 5.7; N, 18.7%. IR (KBr, cm^{-1}): 3245, 3185, 3098 (ν_{N-H}), 1613, 1595 ($\nu_{C=N}+\nu_{C=C}$), 1541 (ν_{C-N}). DRS, λ_{max} (nm): 430, 450. PAS, λ_{max} (nm): 470. Absorption spectrum in DMSO, λ_{max} (nm), ε (M^{-1} cm^{-1}): 285 (2950), 319 (1530), 450 (1580). ^{1}H NMR in DMSO-d_6 (ppm, r.t.): H_N1, 4.778 (s, 1H); H_N3, 5.558 (s, 1H); H_N4a, 4.172 (s, 1H); H_N4b, 3.552 (s, 1H); H2, 6.674 (d, 1H, $^3J=8$ Hz); H3, 6.937 (t, 1H, $^3J=7$ Hz); H4, 6.230 (t, 1H, $^3J=7$ Hz); H5, 7.160 (d, 1H); H7, 7.848 (s, 1H); H8a and H8b, 3.62-3.72 (m, 2H); H9a, H9b, H10a, H10b, H11a and H11b overlap giving rise to a 6H multiplet in 2.36–2.78 range.

2.3.3. 1-(2′-Iminophenyl)-2,5-diaza-7-amino-1-heptenonickel(II) nitrate, NiANO$_3$

Red brown plates after recrystallization from methanol, soluble in DMSO, hot acetonitrile and methanol. Yield: 38%. *Anal*. Calc. for $C_{11}H_{17}N_5NiO_3$: C, 40.6; H, 5.2; N, 21.4. Found: C, 40.5; H, 5.3; N, 21.5%. IR (KBr, cm^{-1}): 3261, 3122, 3090 (ν_{N-H}), 1615 ($\nu_{C=N}+\nu_{C=C}$), 1541 (ν_{C-N}), 1380, 1041, 710 ($\nu_3+\nu_1+\nu_{4(NO_3)}$). DRS, λ_{max} (nm): 450. PAS, λ_{max} (nm): 470. Absorption spectrum in DMSO, λ_{max} (nm), ε (M^{-1} cm^{-1}): 285 (3180), 320 (1710), 450 (1640). ^{1}H NMR in DMSO-d_6 (ppm, r.t.): H_N1, 4.750 (s, 1H); H_N3, 5.472 (tt, 1H); H_N4a, 4.177 (dt, 1H, $^2J=10.7$ Hz, $^3J=5.6$ Hz); H_N4b, 3.531 (dd, 1H, $^2J=10.7$ Hz, $^3J=5.3$ Hz); H2, 6.635 (d, 1H, $^3J=8$ Hz); H3, 6.935 (td, 1H, $^3J=8$ Hz, $^4J=1.7$ Hz); H4, 6.228 (td, 1H, $^3J=7.5$ Hz, $^4J=1.3$ Hz); H5, 7.159 (dd, 1H, $^3J=8$ Hz, $^4J=1.7$ Hz); H7, 7.848 (s, 1H); H8a, 3.672 (td, 1H, $^3J=14$ Hz; $^3J=6$ Hz); H8b, 3.628 (dd, 1H); H9a and H10b, 2.55–2.57 (m, 2H); H9b, H10a and H11a, 2.61–2.77 (m, 3H); H11b, 2.418 (tt, 1H). ^{13}C NMR in DMSO-d_6 (ppm vs. TMS): 158.7, 151.5, 131.2, 130.0, 118.8, 115.7, 111.7, 62.1, 50.7, 49.8, 44.8.

2.3.4. 1-(2′-Iminophenyl)-2,5-diaza-7-amino-1-heptenopalladium(II) chloride, PdACl

Golden color needles after recrystallization from MeOH. Yield: 20%. *Anal*. Calc. for $C_{11}H_{17}ClN_4Pd$: C, 38.1; H, 4.9; N 16.1. Found: C, 38.2; H, 5.0; N, 16.3%. IR (KBr, cm^{-1}): 3250, 3187, 3107 (ν_{N-H}), 1617, 1592 ($\nu_{C=N}+\nu_{C=C}$), 1520 (ν_{C-N}). DRS, λ_{max} (nm): 412, 485. Absorption spectrum in DMSO, λ_{max} (nm), ε (M^{-1} cm^{-1}): 448 (3160). ^{1}H NMR in DMSO-d_6 (ppm, r.t.): H_N1, 6.524 (s, 1H); H_N3, 6.679 (br. s., 1H); H_N4a, 4.912 (tt, 1H); H_N4b, 4.607 (td, 1H); H2, 6.727 (d, 1H, $^3J=8$ Hz); H3, 7.001 (t, 1H, $^3J=7$ Hz); H4, 6.190 (t, 1H, $^3J=7$ Hz); H5, 7.206 (d, 1H, $^3J=8$ Hz); H7, 7.982 (s, 1H); H8a and H8b, 4.01–4.10 (m, 2H); H9a, H9b, H10a, H10b, H11a and H11b overlap giving rise to a 6H multiplet in the 2.82–3.00 range. ^{13}C NMR in DMSO-d_6 (ppm vs. TMS): 161.7, 157.3, 133.6, 117.4, 112.6, 110.3, 54.6, 54.2, 51.4, 49.5.

2.3.5. 1-(2′-Iminophenyl)-2,6-diaza-6-methyl-9-amino-1-nonenonickel(II) iodide, NiBI

Greenish black needles after recrystallization from acetonitrile solution. Yield: 37%. *Anal*. Calc. for $C_{14}H_{23}IN_4Ni$: C, 38.8; H, 5.4; N 12.9. Found: C, 38.9; H, 5.4; N, 12.8%. IR (KBr, cm^{-1}): 3267, 3177, 3104 (ν_{N-H}), 1617, 1592 ($\nu_{C=N}+\nu_{C=C}$), 1520 (ν_{C-N}). DRS, λ_{max} (nm): 440, 670sh. PAS, λ_{max} (nm): 450, 650. Absorption spectrum in DMSO, λ_{max} (nm), ε (M^{-1} cm^{-1}): 285 (3180), 439 (1620), 598 (68). ^{1}H NMR data listed in Table 4.

2.3.6. 1-(2′-Aminophenyl)-2,6-diaza-9-amino-1-nonenonickel(II) dichloride, Ni(HD)Cl$_2$

Pale green precipitate. Yield: 35%. *Anal*. Calc. for $C_{13}H_{22}Cl_2N_4Ni$: C, 42.6; H, 6.3; N 15.2. Found: C, 42.4; H, 6.4; N, 15.0%. IR (KBr, cm^{-1}): 3345, 3151, 3072 (ν_{N-H}), 1636 (δ_{NH_2}), 1611, 1593, 1572 ($\nu_{C=N}+\nu_{C=C}$). DRS, λ_{max} (nm): 412. PAS, λ_{max} (nm): 350sh, 430sh, 620. Absorption spectrum in DMSO, λ_{max} (nm), ε (M^{-1} cm^{-1}): 314 (460), 425 (240), 587 (20). The effective magnetic moment measured in MeOH + 1% cyclohexane is 3.17.

2.3.7. 1-(2′-Aminophenyl)-2,5-diaza-9-amino-1-nonenonickel(II) dinitrate, Ni(HD)(NO$_3$)$_2$

Brownish green needles. Yield: 37%. *Anal*. Calc. for $C_{13}H_{22}N_6NiO_6$: C, 37.4; H, 5.4; N, 20.2. Found: C, 37.4; H, 5.3; N, 20.4%. IR (KBr, cm^{-1}): 3329, 3303, 3230, 3223, 3117 (ν_{N-H}), 1637 (δ_{NH_2}), 1614, 1577 ($\nu_{C=N}+\nu_{C=C}$) 1421, 1308, 1044 ($\nu_3+\nu_{1(NO_3)}$). DRS, λ_{max} (nm): 420, 550. PAS, λ_{max} (nm): 440sh, 560. Absorption spectrum in DMSO, λ_{max} (nm), ε (M^{-1} cm^{-1}): 314 (260), 425 (240), 564 (18), 950 (6). The effective magnetic moment in MeOH + 1% cyclohexane determined by the Evans' method is 3.19.

2.4. Measurements

Carbon, hydrogen and nitrogen contents were determined on a Carlo Erba MOD 1106 elemental analyzer. Field desorption mass spectra were recorded with a Mat 711 spectrometer. FT-IR spectra of solid samples (KBr pellets) were run on a Bruker IFS 66, and electronic spectra on the Perkin–Elmer LAMBDA 18 spectrophotometer. ^{1}H and ^{13}C NMR spectra were obtained with a Varian Unity Plus 500 MHz spectrometer. Photoacoustic spectra were measured using a MTEC Model 200 Photoacoustic Detector.

2.5. Magnetic moments

The magnetic moment, μ, of each of Ni(HD)X_2 complexes was determined in methanol solution by the method of Evans [8] using in the experiment co-axial tubes, the outer containing solvent and cyclohexane as indicator and the inner-solvent, cyclohexane and the paramagnetic complex. The difference in proton resonance frequencies of cyclohexane present in the outer and inner tubes, $\Delta\nu$, could be read out accurately from the spectrum and allowed to obtain effective magnetic moments using the relationship $\mu = a(T\Delta\nu/c)^{1/2}$ [9], where T is temperature, c the concentration of the paramagnetic substance and a the proportionality constant obtained from Evans relations [8]. Magnetic moment of NiBI has been obtained in DMSO-d_6 using hexamethyldisiloxane as a reference.

2.6. X-ray investigations

The structures of $NiAClO_4$ and NiBI were determined. Crystal data and refinement details are provided in Table 1. Data for both the complexes were obtained with Mo Kα radiation using the Nonius Kappa CCD diffractometer. Structures were solved using direct methods with SHELXS-97 [10] and refined by full-matrix least-squares using the SHELXL-97 [11] with anisotropic thermal parameters for the non-hydrogen atoms. Hydrogen atoms on the carbon and nitrogen atoms were included in calculated positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached.

3. Results and discussion

Each of the NiAX (X = Cl, NO_3, ClO_4), Ni(HD)X_2 (X = Cl, NO_3), NiBI and PdACl complexes was obtained after addition of a corresponding metal salt to the preformed product of monocondensation of a diprimary triamine with 2-aminobenzaldehyde in 1:1 mole ratio like in the preparative procedure of the [Cu(HB)I]I complex comprising undeprotonated HB ligand [12]. Microanalytical data showed that HA and HB ligands were coordinated in singly deprotonated forms while the HD ligand reacted intact with Ni(II) retaining all its hydrogen atoms. It is worthy to note a striking difference in color of nickel complexes comprising perchlorate and iodide counterions as compared with those with nitrate and chloride counterions. $NiAClO_4$ and NiBI are black, the latter with a faint green tint, respectively, but NiAX (X = Cl, NO_3) complexes are red brown.

3.1. Infrared and electronic spectra

Separate peaks in the 3050–3350 cm^{-1} region of IR spectra of solid compounds were assigned to N–H stretching vibrations and their number does not exceed the number of NH stretching frequencies characteristic either for non-deprotonated or deprotonated ligand. Five bands in this region for Ni(HD)$(NO_3)_2$ may be attributed to asymmetric and symmetric stretching vibrations of both NH_2 groups and to the NH stretching of the secondary amino group. The approximately 1637 cm^{-1} bands which occur in the spectra of Ni(HD)X complexes has been assigned to deformation (scissoring) vibrations of the aromatic amino group. The 1617–1592 cm^{-1} frequencies may be assigned to C=C and azomethine C=N vibrations. However, single bands in the 1541–1538 cm^{-1} region or 1520 cm^{-1} which occur only in the spectra of Ni and Pd complexes comprising deprotonated ligands may be attributed to C–N stretch-

ing vibrations of the bond connecting deprotonated amino nitrogen with carbon atom of the aromatic ring, since order of that bond evaluated as 1.57 on the basis of Pauling's formula[1] [13], bond length data for single and double C–N bonds [14] and C1–N1 bond length in $NiACIO_4$ is comparable to the order (1.70) of aldimine C=N bond for that compound. A broad band at 1090 and a sharper one at 620 cm^{-1} for $NiACIO_4$ are attributed to the perchlorate v_3 and v_4 vibrations, respectively [15]. A lack of any splitting would be consistent with a non-coordinated, tetrahedral ClO_4 [16]. Broad and intense bands at 1421, 1308 and 1044 cm^{-1} in the spectrum of $Ni(HD)(NO_3)_2$ suggest that both the nitrate anions are coordinated since these bands may be assigned to IR active v_3 (split into two components) and v_1 vibrations which as expected will occur when the symmetry of that anion is lowered to C_{2v} or less [17]. The nitrate group of $NiANO_3$ gives rise to one strong and broad band at 1380 cm^{-1} and low intensity bands at 1041 and 710 cm^{-1} which may be attributed to v_3, v_1, v_4 vibrations of weakly interacting nitrate.

The reflectance (DRS) and photoacoustic (PAS) spectra of solid chelates have been recorded, the latter are presented in Fig. 2. The photoacoustic spectroscopy has been included in the study since it gives a direct information about the optical-absorption bands even when the surface of solid material is not highly reflective [18] as in the case of black complexes obtained in this work. All the complexes show intensive absorptions (285–320 nm) which may be assigned to π–π* transitions of the co-ordinated aldimine group and those which incorporate A or B ligands exhibit also intense bands in the 450–500 nm region. The d–d bands expected for planar complexes in the latter region [19] are not resolved but obscured by charge transfer transitions like the bands occurring at 481 and 495 nm in related complexes: *N*,*N*′-ethylenebis(2′-iminobenzaldimino)nickel(II) [Niamben] and *N*,*N*′-propylenebis(2′-iminobenzaldimino)nickel(II) [Niambtn], respectively [20]. Unexpectedly band of the solid $NiACIO_4$ and NiBI complexes show a much higher absorption above 600 nm than the NiAX (X = Cl, NO_3) complexes. To gain information on structural reasons for the occurrence of unusual spectroscopic properties we determined the crystal and molecular structures of $NiACIO_4$ and NiBI complexes by X-ray diffraction studies. These studies showed (vide infra) a planar for $NiACIO_4$ and planar-to-tetrahedral distorted metal configuration for NiBI, and significantly shorter contacts between Ni(II) and aromatic carbon atoms of a neighboring unit in the former and between two nickel ions in an asymmetric unit in the latter compound. These short contacts may facilitate intermolecular charge transfer transitions which account for the intense absorption above 600 nm in solid $NiACIO_4$ and in NiBI with that difference that absorption overlaps the lowest field d–d band in the latter compound. In spite of different colors of solid $NiACIO_4$ (black) and NiAX (X = Cl, NO_3; red) complexes the spectra of their DMSO solutions are similar and do not show absorption above 600 up to 1000 nm in consistency with planar coordination [21]. However, concentrated solutions of $NiACIO_4$ in acetonitrile are black and became red after dilution, what suggests the presence of associated forms in concentrated solution. In contrast to NiAX, the NiBI and $Ni(HD)X_2$ (X = Cl, NO_3) complexes show weak low-energy bands in the 540–800 nm region. The 598 nm band of NiBI in DMSO solution has been assigned to a metal d–d band shifted to the red in consequence of planar-to-tetrahedral distortion and weakening of the ligand field strength. Two low energy bands and one UV band which occur at 314, 564 and 950 nm for $Ni(HD)(NO_3)_2$ could be assigned to d–d transitions in a octahedral field providing that the magnitude of that field may be approximated as a weighted average of octahedral fields associated with each set of N and O ligands separately, according to the rule of averaged environment [22]. The lowest energy band gives then $10Dq$ (10 504 cm^{-1}) which compares well with the value of that parameter (10 640 cm^{-1}) calculated on the basis of equation:

$$Dq = \{9(v_2 + v_3) - [81(v_2 - v_3)^2 - 16v_2v_3]^{1/2}\}/340$$

The equation was obtained by reduction of Dou's equation [23] to a more convenient form. Wave numbers v_2 and v_3 of 587 and 314 nm bands, respectively, for $Ni(HD)Cl_2$ led to a comparable $10Dq$ value (10 626 cm^{-1}). For octahedral stereochemistry the magnetic moment for Ni(II), μ_{eff} is given by the expression $\mu_{eff} = \mu_{s.o.}(1 - \alpha\lambda/10Dq)$ [24] where λ is the spin–orbit coupling constant and $\mu_{s.o.}$ is the spin only moment. Using μ_{eff} of 3.19, 3.17 and the evaluated Dq values we obtained λ values of approximately −340 and −320 cm^{-1} for $Ni(HD)(NO_3)_2$ and $Ni(HD)Cl_2$, respectively, as compared with the free ion value of −320 cm^{-1}.

3.2. NMR spectra

Diamagnetic NiAX and PdACl complexes have been characterized by ^1H and ^{13}C NMR ($NiANO_3$ and PdACl) spectroscopy. In all cases, the spectra show the simultaneous occurrence of two set of signals which are attributable on the one hand to the substituted benzaldimine entity and on the other hand to the aliphatic part of the ligand. Protons which are bonded to nitrogen atoms give rise to separate bands which were

[1] Fractional bond orders, n, were calculated according to the formula $\log n = [d(1) - d(n)]/c$, where $d(1)$ and $d(n)$ are the distances of single and n-ple bond, respectively, and c is a constant to be determined.

identified by using deuterium exchange and H–H connectivities established by the ^1H–^1H COSY experiment. Splitting of each H3 and H4 signal into two doublets and one triplet shows two unequal *ortho* couplings (9.5 and 7.6 Hz for H3) and one *meta* coupling (ca. 1 Hz for both H3 and H4 atoms) and are consistent with the *ortho* disubstitution of the benzene ring. Resonance frequencies of H2 (ca. 6.65 ppm) and H4 (6.23 ppm) indicate shielding of these protons in NiAX and PdACl complexes affected by mesomeric (+) effect of the deprotonated amino group acting as an electron donor substituent. The complexity of multiplets observed in the aliphatic part of the spectrum *i.a.* due to the chirality of the coordinated secondary amino group provide evidence of rigidity of the MA(II) ionic species in solutions. Resonance signals of primary (H_N4a at ca. 4.16, and H_N4b at ca. 3.53 ppm), deprotonated primary (H_N1 at ca. 4.76 ppm) and secondary amino (H_N3 at ca. 5.48 ppm) protons for NiAX complexes are shifted upfield in the PdACl complex to 4.912 ppm (H_N4a), 4.607 ppm (H_N4b), 6.524 ppm (H_N1) and 6.679 ppm (H_N3). These shifts imply stronger N–Pd interaction and better stabilization of the partial negative charge on the nitrogen by Pd(II) versus Ni(II). The farthest downfield signal and the next one in ^{13}C NMR spectrum (at 158.7 and 151.5 ppm) for $NiANO_3$ and (at 161.7 and 157.3 ppm) for PdACl may be assigned to the chemical shifts of aldimine (C7) and aromatic (C1) carbon atom since these atoms are strongly deshielded on account of polarization of their carbon–nitrogen bonds which like in $NiACLO_4$ (vide infra) may be of comparable order (>1.5).

Chemical shifts of NiB^+ protons are spread over approximately 16 ppm (at 325 K). Resonance signals of protons except those of aromatic ring are broadened relative to the same protons in diamagnetic NiAX complexes. The observed spin–spin coupling between aromatic ring protons made their resonances readily assignable. Disappearance of two singlets at 0.77 ppm (two-proton signal) and at 2.356 ppm (one-proton signal) at 325 K after addition of D_2O to the solution of NiBI allowed assigning these signals to NH_2 and NH protons, respectively. Relative ^1H–^1H connectivities established by the COSY experiment allowed assigning the remaining resonances. The data presented in Table 4 show that NiBI proton resonance frequencies decrease or increase with increasing temperature depending on the position of proton in the molecule. The difference in chemical shift of a NiBI proton relative to the shift of proton occupying the same position in the diamagnetic reference, $NiANO_3$, the ($\delta-\delta'$) value in Table 4, is shown to be positive or negative. Clear downfield or upfield shifts of signals from the diamagnetic reference in addition to the line broadening effects are thought to arise because of a weak paramagnetic properties of NiBI in DMSO-d_6 solution. Weak paramagnetism may be the result of spin equilibrium between low spin, close to square planar and high spin presumably tetrahedral NiB^+ and five-coordinate NiBI forms, in which the high spin forms are in low concentration. A rapid interconversion of the paramagnetic into diamagnetic species will result that the paramagnetic spin density is distributed over a large number of NiB^+ ions and becomes 'diamagnetically diluted'. The differences between the chemical shifts of NiBI protons and those of diamagnetic reference (Table 4) seem to arise mainly due to contact interactions since pseudocontact interactions in paramagnetic Ni(II) complexes are judged to be very small [25a]. The Table 4 data suggest that the unpaired spin density is spread over the whole organic ligand and that contact shifts which cause shielding and deshielding effects alternate in sign by going from H3 to H6 owing to spin correlation effects like contact shifts of succeeding ring protons in paramagnetic bis(*N*,*N*′-diethylaminotroponeimino)nickel(II) [25b]. Molar susceptibility and magnetic moment for NiBI were determined in DMSO-d_6 solution (0.04 M) by the method of Evans. The Table 5 data show that there is an increase in magnetic moment, in the fraction of high spin form ($N_{h.s.}=\mu^2/\mu^2_{h.s.}$, where $\mu_{h.s.}$ is assumed to be 3.3 μ_B) and in the planar⇄tetrahedral equilibrium constant [$K_{eq}=N_{h.s.}/(1-N_{h.s.})$] with the increase in temperature. The thermodynamic parameters of the equilibrium ($\Delta G^\circ=4.7\pm0.1$ kJ mol^{-1}, $\Delta H^\circ=1.8\pm0.2$ kJ mol^{-1}, $\Delta S^\circ=-9\pm2$ J mol^{-1} K) were obtained from standard equations as described previously [26].

3.3. Crystal structures

3.3.1. $NiACLO_4$

A perspective view of the asymmetric unit is shown on Fig. 3, while the selected bond distances are given in Table 2. The crystal structure consists of discrete $Ni(C_{11}H_{17}N_4)^+$ cations and perchlorate anions. The HA is singly deprotonated at the aromatic amino group and binds Ni(II) atom through four nitrogen atoms. The geometry of metal coordination sphere is distorted square planar, the sum of bond angles at the Ni(II) atom is 359.9(5)°. The nitrogen atoms lie exactly in plane (their maximal deviation from least-squares plane

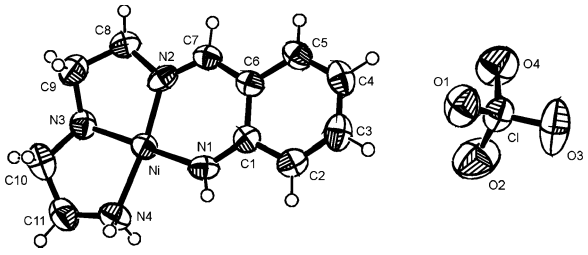

Fig. 3. The structure of the $NiACLO_4$ asymmetric unit with atom numbering scheme. Displacement ellipsoids are drawn at the 30% probability level; H atoms are drawn as spheres of arbitrary radii.

The apostrophy sign denotes atoms belonging to the other crystallographically independent molecule.

is 0.002 Å) and are arranged at the corners of an irregular quadrangle reflecting the difficulty of the ligand to span square planar coordinative positions. The Ni(II) atom resides a little out [0.029(2) Å] of the N1–N4 plane. The structure comprises one six and the two five-membered chelate rings. The six-membered metallocycle involving the 2-iminobenzaldimino moiety is practically coplanar with the N1–N4 coordination plane (dihedral angle 1.5°). Both the five membered metallocycles are in envelope conformation one on C9 the other on C10. Both C9 and C10 atoms are on the same side of the least-squares plane defined by the remaining 14 non-hydrogen atoms constituting the cationic unit and are separated from that plane by −0.633(4) and −0.594(4) Å, respectively. The Ni–N1 and Ni–N2 distances (Table 2) are significantly shorter and the N1–Ni–N2 angle a little more obtuse [94.2(2)°] than the corresponding quantities reported for planar Ni(II) complexes comprising deprotonated 2-aminobenzylideneimino ligands being 1.857(6), 1.878(9) Å and 92.5° for Niambpn [*N*,*N*′-2-methylethylenebis(2′-iminobenzaldimino)nickel(II)] [27] and 1.860(7), 1.923(7) Å and 90.1(3)° for Niambtn [*N*,*N*′-propylenebis(2′-iminobenzaldimino)nickel(II)] [28], and 1.81(1), 1.89(1) Å for Cummins’ complex [6], respectively. The Ni–N3 and Ni–N4 distances (Table 2) comparable with the average Ni–N bond length (1.92 Å) found in low spin $Ni(en)_2$ complex [29] are a little below the Ni–N (primary amine) distance in Cummins’ complex [1.94(1) Å] and the averaged values reported recently for four coordinate planar Ni(II) tetraamine complexes (1.95 Å) [30] and (1.94 Å) [31]. Perchlorate anion does not directly interact with Ni(II) (Ni···O distances exceed 4.7 Å) but is involved in hydrogen bonding interactions with amino hydrogens of the aliphatic part of the ligand. Geometric details of these bonds are given in Table 3. The closest intermolecular approaches in the structure excluding pairs of atoms participating in hydrogen bonding interactions, occur between Ni(II) and both the $C4^j$ and $C5^j$ atoms of the aromatic ring [symmetry code in (*j*): $-x$, $-y$, $-z$) and are by 0.62 and 0.52 Å less, respectively, than the corresponding radius sum [32].

3.3.2. *NiBI*

Each asymmetric unit contains two crystallographically independent NiBI moieties related by the pseudo-twofold rotation axis. The molecular structure of one independent ionic pair is shown in Fig. 4. Pairs of crystallographically independent complex cations are linked with crystallographically independent iodide anions by hydrogen bonds to give an $[NiB]_2I_2$ four ion assembly, which may be considered the motif that crystallized (Fig. 5). Geometric details of these bonds are listed in Table 3. Proton donors in that assembly are both the undeprotonated and deprotonated amino groups of the coordinated ligand, and the proton acceptor is only the iodide anion in accordance with the Etter’s rule [33], that best proton donors and best proton acceptors will bind to one another. A shorter separation of nickel atoms (4.125 Å) than the sum of their

[e] Equilibrium constant.

van der Waals radii (4.60 Å) may suggest a weak Ni···Ni interaction within the asymmetric unit. The unit cell contains eight $[NiB]_2I_2$ assemblies. In the structure we find nickel(II) atoms four coordinated by the nitrogen atoms of singly deprotonated Schiff base ligand. The coordination geometry about the nickel atom may be described as planar with significant tetrahedral distortion in contrast to the reported by us earlier square pyramidal coordination in the related [CuBI]I complex [12]. Deviations of the plane defining atoms N1, N2, N3 and N4 from the least-squares plane through these atoms being 0.214, −0.198, 0.187, −0.202 Å, respectively, and the

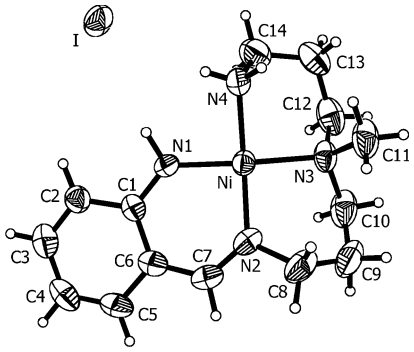

Fig. 4. The structure of one of the independent NiBI complex molecule with atom numbering scheme. Displacement ellipsoids are drawn at the 30% probability level; H atoms are drawn as spheres of arbitrary radii.

acute angle of 41.4° between Ni, N1, N2 and Ni, N3, N4 planes in comparison with that angle anticipated for tetrahedral (90°) and for planar (0°) coordination geometry indicate a marked tetrahedral character of this distortion. The nickel atom is displaced from the N1, N2, N3, N4 plane by 0.046 Å. The distorted arrangement of coordinating atoms results in a twisting of the Schiff base backbone so that least-squares plane through Ni, N1, N2, C1, C6, C7 atoms makes an angle of 39.35° with the least-square plane through Ni, N3, N4, C12, C13, C14. The Ni–N1 and Ni–N2 bond distances fit the ranges of 1.827–1.860 and of 1.812–1.925 Å, respectively, observed in $NiAClO_4$, Niambpn [27] and Niambtn [28] complexes. The Ni–N3 bond distance is markedly longer

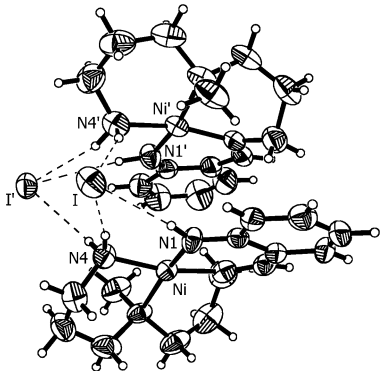

Fig. 5. The structure of the $(NiB)_2I_2$ aggregate showing hydrogen bonding arrangement.

than the nickel tertiary amino nitrogen separation (1.951 Å), whereas the Ni–N4 distance compares well with the nickel primary amino nitrogen bond length in the planar nickel(II) complex with aliphatic tetraamines [30,31]. The NiBI comprises three chelate rings. The ring incorporating N1 and N2 atoms is approximately planar, deviations of plane defining atoms do not exceed 0.134 Å. Cremer and Pople parameters [34] like puckering amplitude 0.789 Å, and $\theta = 91.0^\circ$, $\phi = 87.49^\circ$ angles show that the central chelate ring (with N2 and N3 atoms) is approximately in twist-boat conformation. It is worthy to note the proximity of certain aromatic rings in the crystal. The shortest approach of gravity centers of two aromatic rings of 5.25 Å was found for that ring which occupies equivalent position x, y, z and the other $-x$, $1-y$, $1-z$.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC 180372 for 1-(2′-iminophenyl)-2,5-diaza-7-amino-1-heptenonickel(II) perchlorate and CCDC 180373 for 1-(2′-iminophenyl)-2,6-diaza-6-methyl-9-amino-1-nonenonickel(II) iodide. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Cu(II), Ni(II), Co(II), Zn(II), Cd(II) were isolated and characterized.

VI X=O, R=NO_2; VIa X=O, R=Ph;
VII X=S, R=NO_2; VIIa X=S, R=Ph;
VIII X=NTs, R=NO_2; VIIIa X= NTs, R=Ph;

VI - VIII

Compounds of the types (**VI**, **VIa**–**VIII**, **VIIIa**) possess a potential tetradenticity. On their basis, little known polynuclear metal chelates can be isolated. Variations of different donor centers (–N, –O, –S) and substituents (R = $-NO_2$, –Ph) can be carried out in the frameworks of the same molecule.

It is well known that, in addition to the nature of metal center and ligand, the applied synthetic technique influences considerably the type, structure, and properties of metal complexes [23–26]. In this respect, two methods were used: chemical (metal acetates as source of metal centers) and electrochemical (sacrificial metal anode).

2. Experimental

2.1. Materials and equipment

IR spectra were recorded by the spectrophotometer Specord-71 (the samples were prepared in as nujol mulls). ^{1}H NMR spectra were measured in DMSO-d_6 solutions (TMS standard) using Varian UNITY 300. The EPR spectra of the powders were obtained with the ER-9 (Zeiss) equipment in the temperature interval 77–300 K, and those of the solutions were made in DMF at 77 K (in low-temperature glass). Effective magnetic moments were determined by the Faraday method in the crystalline phase at 77–300 K with equipment made at Rostov State University [27]. Hg[Co(CNS)$_4$] was used as a calibration standard. Calculations of molar magnetic susceptibility were performed by taking into account the diamagnetic properties of ligands and the available theoretic data for organic species [28].

2.2. Synthetic techniques

The bis-[(2-oxy-, mercapto-, *N*-tosylamino)aniles] of nitro- and phenylmalondialdehyde (**VI**, **VIa**–**VIII**, **VIIIa**; X = O, S, NTs; R = NO_2, Ph), used as ligands, were obtained as follows. A solution of *o*-aminophenol hydrochloride or *o*-aminothiophenol hydrochloride or 2-(*p*-toluenesulfamine)aniline hydrochloride (0.02 M in each case) in 10 ml of MeOH was added to a solution of sodiumnitro(phenyl)malonic aldehyde (0.01 M) in MeOH (10 ml). The precipitate formed was treated with a solution of KOH in MeOH to achieve pH 7, filtered, washed with MeOH (3 × 3 ml) and dried in air. Yield was in the range of 70–78%.

A solution of *o*-aminothiophenol hydrochloride (0.02 M) in 10 ml of MeOH and a solution of metal acetate in 15 ml of MeOH was added to a 0.01 M solution of sodium nitromalondialdehyde in 20 ml of the MeOH–dioxane mixture (1:1). The mixture was refluxed for 1 h. The solid formed was filtered, washed (3 × 10 ml) with a hot mixture of MeOH–dioxane (1:1), and dried under vacuum at 150 °C.

Both chemical and electrochemical techniques were applied in order to obtain metal chelates. The chemical synthesis was carried out by refluxing MeOH–dioxane solutions of ligands and acidified MeOH solutions of their corresponding metal acetates (molar ratio metal–ligand 1:2.5). In the case of Ni(II) and Co(II) complexes, a MeOH solution of equimolar quantity of KOH was added to neutralize produced CH_3COOH. The precipitates formed were filtered, washed with MeOH, and dried under vacuum at 120 °C. Yields were in the range of 50–80%.

The electrochemical synthesis of the metal complexes [24,29–31] was carried out in an electrochemical cell containing a MeOH solution of the ligand (10^{-3} mol in 30 ml of MeOH). A copper sheet was used as a sacrificial anode while a platinum wire was used as a cathode. $LiClO_4$ was used as supporting electrolyte. The electrolysis was performed with a current of 20 mA and initial voltage of 20 V during 4 h at room temperature. The precipitates formed were filtered, washed with hot MeOH (3–5 ml) and dried under vacuum at 150 °C. Yield was in the range of 70–80%. The characteristics of the compounds obtained are presented in Table 1.

3. Results and discussion

According to the data of elemental analysis, all metal complexes synthesized with the studied bis-azomethines **VI**, **VIa**–**VIII**, **VIIIa** have the general formula M_3L_2, corresponding to trinuclear structures, independently of the synthetic method applied (Table 1, compounds **5**–**20**). Their IR spectra contain changes indicating chelate formation [32]: disappearance of valent oscillations of acidic protons of –OH and NH groups and a decrease of frequencies of oscillations of the conjugated C=N and C=C bonds (Table 2).

The chelate structure of Zn(II) and Cd(II) trinuclear complexes (Table 1, compounds **19** and **20**) was also confirmed by ^{1}H NMR spectroscopy data. The spectrum of 3 **VIII** (X = NTs, R = NO_2) contain peaks of protons of the methyl groups of tosyl fragments at δ = 2.23 ppm (s, 6H, $2CH_3$). The following peaks are observed: at 7.0–9.4 {aromatic protons δ = 7.0–7.5

[a] Obtained electrochemically.

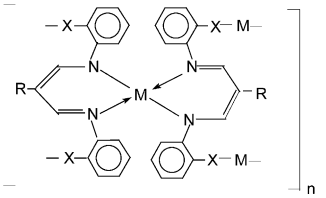
ppm (m, 16H, $4C_6H_4$)}, 8.3 (2H, 2NHTs in NH–Ts groups), and 9.4 ppm (s, 2H, =CH–NH–, –CH=N–, singlet peak of methyne protons). The protons of the NH group of the –NH–CH= fragment are revealed at $\delta = 12.0$ ppm (t, 1H, NH, $^3J(-NH-CH=) = 6$ Hz) in the form of a triplet peak with vicinal constant 6 Hz.



The ^1H NMR spectrum of the bis-azomethine complex (19 **VIII**) Zn_3L_2 does not contain peaks at $\delta = 12$ ppm of N–H protons, as well as the peak at $\delta =$ 8.3 ppm of the protons of the NH–Ts-fragment. This fact testifies for a substitution of the protons in the ligand system by the metal during formation of the complex chelate type. In other respects the spectra of Zn_3L_2 (19 **VIII**) correspond to the ligand's spectrum: δ (ppm) 2.23 (s, 12H, $4CH_3$), 6.76 (t, 4H, $4C_6H_4(3)$, $^3J = 8$ Hz), 6.84 (t, 4H, $4C_6H_4(4)$, $^3J = 8$ Hz), 6.98 (d, 4H, $4C_6H_4(2)$, $^3J = 8$ Hz), 7.12 (d, 8H, $4C_6H_4(2'6')$, $^3J = 8$ Hz), 7.28 (d, 4H, $4C_6H_4(5)$, $^3J = 8$ Hz), 7.8 (d, 8H, $4C_6H_4(3'5')$, $^3J = 8$ Hz), 9.15 (s, 4H, 2(=CH–NH–, –CH=N–).

The complex (20 **VIII**) Cd_3L_2 shows analogous ^1H NMR spectral data, confirming the chelate type of the formation of the complex: δ (ppm) 2.23 (s, 12H, $4CH_3$), 6.76 (t, 4H, $4C_6H_4(3)$, $^3J = 8$ Hz), 6.84 (t, 4H, $4C_6H_4(4)$, $^3J = 8$ Hz), 6.94 (d, 4H, $4C_6H_4(2)$, $^3J = 8$ Hz), 7.2 (d, 12H, $4C_6H_4(5)$, $4C_6H_4(2'6')$), 7.92 (d, 8H, $4C_6H_4(3'5')$, $^3J = 8$ Hz), 9.24 (t, 4H, (=CH–NH–, –CH=N–), $^3J(^{111}Cd-^1H) = 12$ Hz).

The composition M_3L_2 of the products formed may correspond to the chelate structures of any of two types: trinuclear (**IX**) or polymeric (**X**) complexes.

IX

X

The magnetic properties of complexes **IX** and **X** should be considerably different: the trinuclear clusters **IX** have a definite spin–spin exchange interaction of the antiferromagnetic type between the paramagnetic centers, which is impeded in the polymeric structures **X** [33]. In this respect, the study of structures of coordination units, as well as the inner-sphere influence of various heteroatoms (X) and substituents (R) on the physicochemical characteristics of the metal chelates obtained, was carried out using magnetochemical and EPR-spectral data.

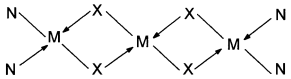
It was established that the experimental effective magnetic moments $\mu_{eff.exp.}$ of all isolated copper complexes (Table 1, compounds **5**–**13**) at room temperature have magnitudes which are slightly lower as compared to the ones of pure spins (1.73 B.M.). The study of temperature dependence of their magnetic properties at 80–300 K revealed a symbiotic decrease of $\mu_{eff.exp.}$ with temperature (Table 3). This fact testifies the presence of a spin–spin exchange interaction of the antiferromagnetic type between Cu(II) ions. Such phenomena are characteristic for bi- and polynuclear structures and correlated with the trinuclear structure **IX** [34].



It is well known that magnetic properties of polynuclear complexes are determined by both their electronic structure and the geometric positions of the metal center and the ligands [33]. The presence of three paramagnetic centers in the molecule of a complex compound assumes several variants in their mutual positions, for example: in the tops of the equilateral triangle (D_{3h} symmetry), isosceles triangle (C_{2V} symmetry) or in the straight line ($C_{\infty V}$). A definite character of the spin–spin exchange interaction corresponds to each variant.

Good coincidence of the experimental and theoretical magnetic moments ($\mu_{eff.exp.}$ and $\mu_{eff.theor.}$, Table 3), calculated by using the model of isotropic exchange interaction of Geisenberg–Dirak–van Vlek [34], in approximation of the linear chain ($C_{\infty V}$), testifies that

the selected configuration (**IX**) is optimal for describing the mentioned exchange effects.

Deviation from the trinuclear structure **IX** was noted only for copper complexes with ligands **VI** and **VIII** containing the substituent R = NO_2. The molar ratio of the paramagnetic impurity (F) in these complexes, i.e. the polymeric form **X**, is 0.2 and 0.58, respectively (Table 3).

A considerable part of the polymeric form **X** in the copper complex with the ligand **VIII** is probably caused, additionally to the influence of the electron-acceptor substituent (R = NO_2), by the spatial conditions, created by bulky N–Ts fragments. A comparison of exchange parameters of bis-azomethines **VI**, **VIa**–**VIII**, **VIIIa** represents a peculiarity of magnetic properties of these compounds, caused by the nature of the bridge atoms X.

XI

X=O, S, N–Ts

As it is seen in Table 3, the constant of exchange interaction (J) is practically double on its absolute magnitude for complexes with bridge S atoms in comparison with those with O atoms. Taking into account the isostructural character of these compounds, it is possible to suppose that more considerable exchange interactions occur through the S-bridges due to the existence of free d-orbitals in S-atoms. It is known that the presence of sulfur atoms in a binuclear complex could lead to such strong increase of the exchange antiferromagnetic interaction that the complex becomes practically diamagnetic even at room temperature [33].

It is also necessary to mention the considerable value (conductivity) of spin–spin exchange interactions, occurring through X = N atoms ($J < -300$ cm^{-1}) (Table 3). Evidently, the identity of atoms of chelate and bridge connection in the coordination unit CuN_4 in comparison with the chelate environment in CuN_2O_2, as well as the presence of the sulfur atoms in the tosyl fragment, leads to maximum exchange between copper ions.

The magnitudes of exchange effect depend also on the character of the substituent R in the aldehyde fragment of ligands. They are considerably higher (Table 3) for the chelates with ligands **VIa**, **VIIa**, **VIIIa** (where R = Ph) in comparison with **VI**, **VII**, **VIII** (where R = NO_2). As it is seen, the role of electronic effects, created by R-substituents, is considerable for the existence of structures **IX** or **X**, as for magnetochemical characteristics of the complexes. This emphasizes the good electronic conductivity of the bond system and testifies indirectly for the planarization of trinuclear metal chelates. It was noted [35] that the introduction of a nitro group into the malondialdehyde fragment of bis-aryhydrazones could lead to a ferromagnetic exchange interaction between the copper ions.

The EPR spectral studies of copper complexes, obtained by both methods with all examined ligands at 80–300 K, confirm and complete the magnetochemical data. All EPR spectra of crystalline samples contain peaks of low intensity. The isotropic form of the peaks ($g = 2.117$–2.124), absence of hyperfine structure and anisotropy, typical for $S > 1/2$ state, testify for a composition of complexes having unusual number of copper atoms. This conclusion is also confirmed by the dependence of the intensity and the form of the spectra on the temperature. When the temperature is decreased from 300 to 80 K, the intensity and asymmetry of the peaks is increased. This fact could be related to an increase of occupancy of the spin level $S = 1/2$ and decrease of occupancy of the level $S = 3/2$ in trinuclear copper complexes with antiferromagnetic exchange interaction Cu–Cu–Cu (Fig. 1).

For complexes with even number of copper atoms, the decrease of temperature would lead to a decrease of the intensity of EPR peaks as a result of the increase of occupancy of the level ($S = 0$, in the case of antiferromagnetic exchange Cu–Cu). It is also necessary to mention that for O- and S-containing complexes (Table 1, compounds **7**–**12**) the intensity of EPR peaks of frozen DMF solutions is higher than those of the powders of these compounds. Such an effect is absent in the case of copper complexes with the ligand **VIII** (Table 1, X = NTs, compounds **13**–**15**). This fact could be related with both inner-molecular and inter-molecular exchange interaction of O- and S-containing chelates, taking place in crystals. At 77 K the inter-molecular interaction disappears.

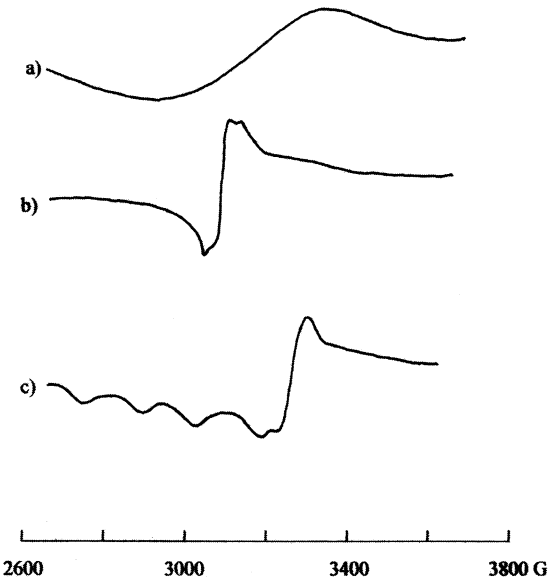


Fig. 1. X-band ESR spectra: a) polycrystalline **7** at room temperature, b) polycrystalline **7** at 80 K, c) **13** in DMF at 80 K

Absence of inter-molecular exchange effects in crystalline copper complexes with the ligands **VIII** and **VIIIa** (X = NTs) is, evidently related with spatial difficulties, caused by bulky tosyl groups. Spatial strains in these complexes leads also to their weak dissociation in DMF solution: in the frozen solutions of the complexes, additionally to intensive peaks of trinuclear metal chelates the anisotropic spectrum of a mononuclear copper complex ($g_{\parallel} = 2.211$, $g_{\perp} = 2.062$, $A_{\parallel} = 138$) with a hyper-fine structure on one copper nucleus ($I = 3/2$) is observed (Fig. 1). The magnitudes of the parameters of anisotropic spectrum of this mononuclear complex testify that the copper atom is in a distorted tetrahedral environment of nitrogen atoms [36]. Evidently, the spatial factor of tosyl groups is also an obstacle for its planarization.

The nickel and cobalt chelates show at room temperature the magnetic moments characteristic for high-spin ions (Table 1, compounds **14**, **15**, **17**, and **18**). Varying the temperature from 80 to 300 K, the magnitudes of $\mu_{\text{eff.exp.}}$ for these compounds are practically unchanged. Such magnetic properties of Ni(II) and Co(II) chelates can be explained taking into account the fact that the metal ions in a trinuclear chain **XI** are non-equivalent and have different electronic configuration. Really, two terminal ions have coordination units NiN_2X_2 and should be low-spin. At the same time, the central ion, arranged in a coordination unit of non-chelating bridge X-atoms (NiX_4), has a distorted high-spin tetrahedral structure. The resulting magnetic moment of complexes should correspond to the normal paramagnetism of one high-spin ion of Ni(II) and should practically not depend on the change of temperature that it is really observed.

Magnetic properties of Co(II) complexes can be interpreted using the same point of view. Taking into account the non-equivalency of three Co(II) ions in metal chelates, their $\mu_{\text{eff.exp.}}$ magnitudes should be 3.5–4.5 B.M., this corresponds to the experimental data (Table 1, compounds **17** and **18**).

4. Conclusions

The trinuclear metal chelates (M_3L_2) containing new tetradentate ligands β-aminovinylketones with aryl substituents with NTs, OH and SH groups at the nitrogen atom were obtained by conventional chemical and direct electrochemical synthesis. Magnetochemical and EPR studies testify for preferential realization of trinuclear structures with a spin–spin interaction of the antiferromagnetic type.

dinuclear precursory species was also investigated and reported in this work.

(bta)

2. Experimental

2.1. Syntheses and preparation of compounds

Benzotriazole (btaH) was commercially purchased (1*H*-1,2,3-benzotriazole; 99%) and recrystallized from hot ethanol–water. The lithium benzotriazolate salt was prepared as described previously [6,8]. All other chemicals and organic solvents employed in the syntheses were analytical reagent grade and were used without further purification. Deionized water was used throughout the experiments.

The syntheses of *trans*-$[RuCl_2(NH_3)_4]Cl$ [13], $Ru(Hedta)H_2O$ [14], $Ru(Hedta)(btaH)$ [15] and $Li_n[Ru(edta)(L)]^{n-}$ ($L = btaH$, $n = 1$; $L = bta$, $n = 2$) [8–10] were based on the literature methods. The purity and characterization of the final products were assessed by means of elemental analysis, electronic spectroscopy and electrochemistry.

2.1.1. *trans*-$[Ru^{II}(NH_3)_4(btaH)_2](PF_6)_2$

The preparation of the mononuclear precursor was performed by an adaptation of the procedure published earlier for the pyrazine [16–19] analogue: 55 mg of *trans*-$[RuCl_2(NH_3)_4]Cl$ (0.20 mmol) were dissolved in approximately 5 ml of deionized water and reduced for 30 min with zinc amalgam, under an argon atmosphere. Then, the deep yellow solution of *trans*-$RuCl_2(NH_3)_4$ was anaerobically transferred by syringe techniques to a recipient containing 0.60 g of benzotriazole (5.0 mmol). The final orange solution was treated with approximately 5 ml of a concentrated solution of ammonium hexafluorophosphate, yielding a yellow precipitate. The solid product was collected on a filter, washed with cold ethanol and dried in vacuum for a couple of days in the presence of anhydrous calcium chloride. *Anal.* Found: C, 20.2; H, 3.5; N, 19.5. Required for $[Ru(NH_3)_4(C_6H_5N_3)_2](PF_6)_2\cdot H_2O$ ($MM = 715.4$ g mol^{-1}): C, 20.2; H, 3.4; N, 19.6%.

2.1.2. *trans*-$Na[(bta)(NH_3)_4Ru^{II}(bta)Ru^{III}(edta)]$

The unsymmetrical mixed-valent dinuclear complex was prepared and characterized in aqueous solutions. In the electrochemical experiments, 18 mg of *trans*-$[Ru(NH_3)_4(btaH)_2](PF_6)_2\cdot H_2O$ (2.5×10^{-2} mmol) was added into 5.0 ml of a deaerated, buffered solution (pH 7.0; pipes 5.0×10^{-2} M; where pipes = 1,4-piperazinediethanesulfonic acid) containing 12 mg of $Ru(Hedta)(H_2O)\cdot 4H_2O$ (2.5×10^{-2} mmol). The pH of the solution was adjusted to 9.0 by the controlled addition of 3.0 M sodium hydroxide solution under an argon atmosphere. The initial yellow mixture became brownish immediately and, eventually, deeply red at the completeness of the acid–base titration. In the spectroelectrochemical experiments, the aqueous solutions were also prepared as described above. However, 36 mg of *trans*-$[Ru(NH_3)_4(btaH)_2](PF_6)_2\cdot H_2O$ (5.0×10^{-2} mmol) and 24 mg of $Ru(Hedta)H_2O\cdot 4H_2O$ (5.0×10^{-2} mmol) were used instead.

The complex was also isolated in the solid form, for comparison purposes. The procedure was similar to the method reported for the pyrazine derivative [16] and consisted of mixing stoichiometric amounts of the starting complexes in aqueous solutions and, then, precipitating with the addition of acetone. Further treatment of the solid was carried out as described for the mononuclear precursor. *Anal.* Found: C, 30.2; H, 4.5; N, 19.3. Required for $Na[Ru(NH_3)_4(C_6H_4N_3)_2\text{-}Ru(C_{10}H_{12}N_2O_8)]\cdot 3H_2O$ ($MM = 871.8$ g mol^{-1}): C, 30.3; H, 4.4; N, 19.3%.

2.1.3. *trans*-$Na_2[(NH_3)_4Ru^{II}\{(bta)Ru^{III}(edta)\}_2]$

Analogously to the dinuclear species, the symmetrical mixed-valent trinuclear complex was prepared and characterized in aqueous solutions. All the solutions were generated by mixing the precursors *trans*-$[Ru(NH_3)_4(btaH)_2](PF_6)_2\cdot H_2O$ and $Ru(Hedta)(H_2O)\cdot 4H_2O$, at the 1:2 molar ratio, in 5.0 ml of deoxygenated buffer solution (5.0×10^{-2} M pipes; pH 7.0). Nevertheless, the employed amount of each starting complex for electrochemistry was half the quantity used for spectroelectrochemistry, in order to give solutions of the trinuclear complex with concentrations of 5.0×10^{-3} and 1.0×10^{-2} M, respectively. The pH of the mixture was then adjusted to 9.0 by addition, under argon, of 3.0 M sodium hydroxide, yielding a purple product.

To obtain the compound in the solid form, stoichiometric amounts of the starting species were mixed in aqueous solutions, at pH above 9, and precipitated with acetone after reaction. Further procedure was identical to the above description for the precursory complexes. *Anal.* Found: C, 29.6; H, 4.2; N, 15.0. Required for $Na_2[Ru(NH_3)_4(C_6H_4N_3)_2\{Ru(C_{10}H_{12}N_2O_8)]\cdot 4H_2O$ ($MM = 1302.0$ g mol^{-1}): C, 29.5; H, 4.0; N, 15.1%.

2.1.4. Preparation of solutions

For the physical measurements, 5.0×10^{-3} M (cyclic voltammetry) or 1.0×10^{-2} M solutions (spectroelectrochemistry) of the complexes were prepared in pipes buffer at the required pH (pH 7–10). The final pH was adjusted by adding microvolumes of 3.0 M sodium

hydroxide or hydrochloric acid. Sodium trifluoroacetate (0.10 M) and potassium nitrate (0.25 M) were employed as supporting electrolytes in cyclic voltammetry and spectroelectrochemistry, respectively. Solutions of Na(tfa) (where tfa = trifluoroacetate) were prepared by titration, up to neutrality, of diluted solutions (0.10 M) of trifluoroacetic acid with 3.0 M sodium hydroxide.

2.1.5. General precautions

In order to minimize the absorption by water in the near-infrared (NIR) region of the spectra, D_2O was used as solvent. All measurements at pH above 6.5 were run under an inert atmosphere of argon, to avoid further oxidation processes involving the edta–ruthenium(III) complex [20].

2.2. Physical measurements

Electronic spectra were recorded either on a Hewlett–Packard 8453 diode-array spectrophotometer or on a Guided-Wave 260 fiber-optic instrument.

Cyclic voltammetry measurements were carried out using a PAR 283 potentiostat. A conventional three-electrode arrangement consisting of a glassy carbon working electrode, a Luggin capillary with a Ag/AgCl (1.0 M KCl) reference electrode ($E^\circ = +0.222$ V vs. SHE, standard hydrogen electrode) and a platinum wire as the auxiliary electrode, was used. Cyclic voltammograms were recorded at sweep rates of 10–500 mV s^{-1}. The sample solutions were thoroughly degassed with argon prior to each measurement. $E_{1/2}$ values given in this paper are uncorrected for junction potentials.

Spectroelectrochemical measurements in the UV–Vis region were carried out using a PAR 366 bi-potentiostat in parallel with the diode-array spectrophotometer. A three-electrode system was specially designed for a rectangular quartz cell of 0.25 mm internal optical length. A gold minigrid was used as a transparent working electrode, in the presence of a small Ag/AgCl (1.0 M KCl) reference electrode and a platinum auxiliary electrode. The OTTLE cell was located directly in the spectrophotometer, and the absorption was monitored during the electrolysis.

Spectroelectrochemical measurements in the NIR region were performed by using a fiber-optic probe for in situ monitoring in a quartz, flat bottom, electrochemical cell. The fiber-optic probe was placed perpendicularly to the mirror surface of the platinum electrode, which was kept approximately 0.2 mm from the bottom, providing a constant optical length.

pH measurements were monitored with a Digimed MD21 digital pH meter. Calibration was carried out by using commercial standard buffers.

Elemental analyses were obtained by the Microanalytical Laboratory of the Institute of Chemistry, University of São Paulo.

2.3. Computational calculations

Semiempirical molecular calculations were carried out as described in details elsewhere [21,22], by using Zerner's geometric implementation of the Intermediate Neglect Differential Overlap method (ZINDO/1) [23] within the HYPERCHEM™-5.1 program from Hypercube Inc. [24]. The default resident parameterization was kept. Quantum mechanics geometry optimizations were performed at the RHF (Restricted Hartree–Fock) and UHF (Unrestricted Hartree–Fock) levels for the low-spin, closed-shell (Ru^{II}) and open-shell (Ru^{III}) ground state species, respectively. The starting nuclear coordinates used here were obtained from the geometry optimizations at molecular mechanics level by using the MM+ module, a modified MM2 force field [25] within HYPERCHEM™. A gradient of 1×10^{-2} cal $Å^{-1}$ mol^{-1} was set as a convergence criterion in all the molecular mechanics and quantum calculations, which were processed on a PC WINDOWS® platform with a Pentium® III microprocessor.

3. Results and discussion

Despite the emphasis on the mixed-valence di- and trinuclear systems, the characterization of the mononuclear precursor was found to be necessary in order to understand the properties of the polynuclear complexes.

Note: since herein all derivatives containing the tetraammineruthenium(II/III) fragment are *trans* with regard to their coordination geometry, the *trans* prefix which should appear as a notation along with the formulas was neglected in this section.

3.1. Mononuclear complexes

Analogously to pentaamminechlororuthenium(II) [26], the starting complex $Ru^{II}Cl_2(NH_3)_4$ reacts promptly in an aqueous solution to form $[Ru^{II}(H_2O)_2(NH_3)_4]^{2+}$ (**1**). This aqua complex is labile and easily exchanges the ligand water in the presence of N-heterocyclic ligands, yielding the corresponding disubstituted species Eq. (2).

$$[Ru(H_2O)_2(NH_3)_4]^{2+} + L \rightleftharpoons [Ru(H_2O)(NH_3)_4(L)]^{2+} + H_2O \quad (1)$$

$$[Ru(H_2O)(NH_3)_4(L)]^{2+} + L \rightleftharpoons [Ru(NH_3)_4(L)_2]^{2+} + H_2O \quad (2)$$

In the particular case with L = benzotriazole, the two-step formation reaction of $[Ru(NH_3)_4(btaH)_2]^{2+}$ follows $k_1 = 1.9 \pm 0.2 \times 10^2$ M^{-1} s^{-1} and $k_2 = 0.28 \pm 0.03$ M^{-1} s^{-1} ($T = 25 \pm 1$ °C; $I = 0.10$ M; pH 4.5) [27]. This result shows that the second step is rather slower than

the first substitution, which can be interpreted in terms of the so-called *trans* effect. The reaction mechanism is essentially dissociative, near the S_N1 limit [27].

The cyclic voltammograms of the benzotriazole-disubstituted complex in a slightly acidic solution (pH 4.5) exhibited a single reversible wave couple with $E_{1/2} = 0.20$ V (vs. SHE). In acidic medium, the oxidized species displays a red color, and its absorption spectrum in the Vis region shows a single band at 510 nm (2.1×10^3 M^{-1} cm^{-1}), which was assigned to a ligand-to-metal charge transfer (LMCT) involving the transition $\pi(\text{btaH}) \rightarrow d\pi(Ru^{III})$. The corresponding reduced species absorbs at 425 nm (9.0×10^3 M^{-1} cm^{-1}), whose band was associated with a metal-to-ligand charge transfer (MLCT) related to the $d\pi(Ru^{II}) \rightarrow \pi^*(\text{btaH})$ transition.

If the pH of a solution of $[Ru(NH_3)_4(btaH)_2]^{2+}$ is raised to 8.5–9.0, its color changes from yellow to dark orange. Such variation was ascribed to the deprotonation of the coordinated ligands, as shown in Eqs. (3) and (4).

$$[Ru(NH_3)_4(btaH)_2]^{2+} \rightleftharpoons [Ru(NH_3)_4(btaH)(bta)]^{+} + H^{+} \quad (3)$$

$$[Ru(NH_3)_4(btaH)(bta)]^{+} \rightleftharpoons Ru(NH_3)_4(bta)_2 + H^{+} \quad (4)$$

Both pK_a values for the equations above were determined ($pK_{a1} = 6.0$ and $pK_{a2} = 8.6$) by means of spectrophotometric titrations, whose acid–base equilibrium constants are equivalent to 1.0×10^{-6} and 2.5×10^{-9} M, respectively [27]. The calculations of K_{a1} and K_{a2} followed a method of graphical analysis for successive equilibria [28].

The constants indicate a substantial stabilization of $[Ru(NH_3)_4(btaH)(bta)]^{+}$ ($pK_a = 6.0$) over the uncoordinated anion, since the pK_a of the free ligand is 8.38 ± 0.03 ($T = 25$ °C; $I = 0.0$) [29]. On the other hand, the second deprotonation of the complex reflects no additional stabilization on the involved ligand within $Ru(NH_3)_4(bta)_2$ ($pK_a = 8.6$). Indeed, the latter process occurs with a slight destabilization in comparison with the free benzotriazolate. That is because the extra charge from the first deprotonation is partially transmitted through the $L \rightarrow Ru \rightarrow LH$ axis, increasing significantly the electron density on the LH molecule and, consequently, the nucleophilicity. In addition to the manifestation of *trans* effects, the π-back-donation features of the Ru(II) ion ($4d^6$; low-spin) attenuate the acid character of the complex.

The cyclic voltammograms of the complex are also sensitive to the pH of the solution, with redox potentials ($E_{1/2}$) ranging from 0.20 V at pH 4.5 (protonated complex) to ~0.05 at pH > 9 (deprotonated complex). By using these reduction potentials for the couples $[Ru^{III/II}(NH_3)_4(btaH)_2]^{3+/2+}$ and $[Ru^{III/II}(NH_3)_4(bta)_2]^{+/0}$, respectively, and assuming that $pK_{a1} = 6.0$, the value of pK_{a2} was estimated from the square thermodynamic cycle as 8.5, which is in accordance with the value (8.6) obtained by spectrophotometry. Electronic spectra from spectroelectrochemical measurements at pH 9.5 showed a MLCT absorption band at 410 nm (7.0×10^3 M^{-1} cm^{-1}), associated with the $d\pi(Ru^{II}) \rightarrow \pi^*(\text{bta})$ transition in $Ru^{II}(NH_3)_4(bta)_2$, and a LMCT band at 515 nm (2.2×10^3 M^{-1} cm^{-1}), attributed to the transition $\pi(\text{bta}) \rightarrow d\pi(Ru^{III})$ in the species $[Ru^{III}(NH_3)_4(bta)_2]^{+}$.

For assignment purposes and comparison with the mononuclear $[Ru(NH_3)_4(L)_2]^{n+}$ complexes, the redox potentials for the starting species (L = Cl^- and H_2O) are given: −0.18 and 0.02 V, respectively [18]. In addition, the MLCT lambda and the half-potential for the analogue containing L = pyrazine (pz) are 485 nm [19] and 0.78 V [18].

The set of results shown above point at the same time to the σ/π-donor electronic character of the anion benzotriazolate (comparable with imidazole derivatives [8,9,15]), and the π-acceptor character of neutral benzotriazole (which places it close to pyridine [18,19,30]), as revealed by their redox properties. These features are stressed below in the context of the mixed-valence chemistry and the characteristics of benzotriazolate as a bridging ligand.

Unlike some monosubstituted ruthenium [10,11] and iron [12] complexes with benzotriazole or benzotriazolate (in aqueous solutions), no evidence of linkage isomerism was observed herein for the disubstituted species $[Ru^{III/II}(NH_3)_4(btaH)_2]^{3+/2+}$ or $[Ru^{III/II}(NH_3)_4(bta)_2]^{+/0}$. As a matter of fact, linkage isomers were also recently observed in organic solutions for *cis*-$[Ru^{III/II}Cl(bpy)_2(btaH)]^{2+/+}$ but not for the disubstituted complex, *cis*-$[Ru^{III/II}(bpy)_2(btaH)_2]^{3+/2+}$ [31]. Therefore, the set of systems studied with benzotriazole clearly shows that disubstitution of complexes of both types *cis*- and *trans*-$[MX_4L_2]$ inhibits the expected isomerization reaction: $M-\{\kappa N(1)-L\} \rightleftharpoons M-\{\kappa N(2)-L\}$ (L = btaH or bta) [32]. This particular aspect of such systems will be explored in a separate work.

In the light of theoretical studies [31], the isomer $[(NH_3)_4Ru^{III/II}\{\kappa N(1)\text{bta}\}_2]^{+/0}$ should most likely exist, due to a higher basicity–donicity on the nitrogen atom N(1). Hence, since there is an electrochemical indication on the presence of a single species at both oxidation states (at several pH), only the mentioned $\kappa N(1)$ isomer is to be considered herein.

Prior to advancing to the next sections on polynuclear complexes based on the mononuclear species introduced above, another important issue concerning the structure of this precursor must be addressed. That is because it has two possible molecular geometries: C_{2h} and C_{2v}. In fact, other isomers of lower symmetry can exist, and their presence depend on the reciprocal/relative rotation of both ligands around the *trans* (L–M–L) axis. Based on structural data for similar compounds, which show

that the coplanar conformation prevails in the most electronically stable structures, only the two mentioned major symmetries were taken into account in this consideration.

In order to gain some theoretical insight into the relative stability of the isomers, quantum calculations at the semiempirical level (see Sections 2 and 2.3 for computational details) were carried out by assuming both molecular symmetries: C_{2h} (isomer **A**) and C_{2v} (isomer **B**); see illustration in Fig. 1.

According to ZINDO results for the geometry-optimized molecules, the isomer **A** is about 3 kcal mol^{-1} more stable than isomer **B**. On the basis of this argumentation, only the structure **A** was considered for the assumptions of this work.

3.2. Dinuclear complexes

The mixture of $[(btaH)Ru^{II}(NH_3)_4(bta)]^+$ with $[Ru^{III}(edta)(H_2O)]^-$ at the molar ratio 1:1 in aqueous solution yields, at pH around 7, a deeply brownish species. The reaction was promoted by adding slowly a solution of $[Ru^{III}(edta)(H_2O)]^-$ over another containing $[(btaH)Ru^{II}(NH_3)_4(bta)]^+$ at the same concentration and, then, adjusting the pH of the buffered mixture to 9.0 under an argon atmosphere. At these medium conditions, the cyclic voltammograms exhibited two reversible wave couples of identical intensities, displaying linear response with respect to the square root of the scan rates. The calculated half-potentials ($E_{1/2}$) are $E_1 = 0.15$ V and $E_2 = -0.21$ V versus SHE, both with $\Delta E_p = 60$ mV.

By comparison of these results with the redox potentials for the Ru^{III}/Ru^{II} couple in the reagents $Ru(NH_3)_4(bta)_2$ (0.05 V) and $[Ru(edta)(H_2O)]^-$ (−0.05 V; Section 3.3) under similar conditions, the formation of a new unsymmetrical dinuclear complex, formulated as $[(bta)(NH_3)_4Ru^{II}(bta)Ru^{III}(edta)]^-$, was

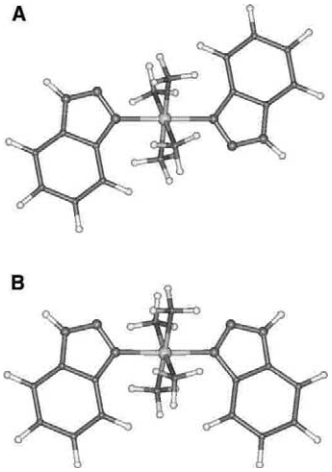

Fig. 1. Theoretical molecular structure for the C_{2h} (**A**) and C_{2v} (**B**) geometric isomers of the complex *trans*-$[Ru(NH_3)_4(btaH)_2]^{2+}$.

electrochemically evidenced. Therefore, the two redox potentials E_1 and E_2, which are separated by $\Delta E_{1/2} = 0.36$ V, refer to the following monoelectronic reduction steps:

$$(bta)Ru_a^{III}(bta)Ru_b^{III} + e^- \rightleftharpoons [(bta)Ru_a^{II}(bta)Ru_b^{III}]^- \quad (5)$$

$$[(bta)Ru_a^{II}(bta)Ru_b^{III}]^- + e^- \rightleftharpoons [(bta)Ru_a^{II}(bta)Ru_b^{II}]^{2-} \quad (6)$$

where $Ru_a = \{Ru(NH_3)_4\}$ and $Ru_b = \{Ru(edta)\}$.

As for the analysis of these potentials, an increase of ~0.2 V on the $E_{1/2}$ value for the couple $[Ru^{III/II}(NH_3)_4(bta)_2]^{+,0}$ was realized following the binding of $[Ru^{III}(edta)]^-$. In contrast, the dimer formation is accompanied by a decrease of more than 0.1 V on the value of $E_{1/2}$ for $[Ru^{III/II}(edta)(bta)]^{2-,3-}$ (−0.09 V; [15]). These observations reflect the influence of the π-backbonding effects through the Ru_a^{II}–bta bonding, induced by the Ru_b^{III} fragment attached to the bridging ligand. The same trend applies to the charge-transfer properties to be discussed below.

Another important indication of the existence of a dinuclear complex comes from the presence of a strong electronic absorption band in the NIR region. Given the redox states of the starting mononuclear and aqua complexes (Ru^{II} and Ru^{III}, respectively), this observation is consistent with the formation of a mixed-valent species, where the NIR band is related to the intervalence charge-transfer (IVCT) transition.

Spectroelectrochemistry in the NIR region confirmed that the band at 1510 nm appears only if the system is submitted to a potential between E_1 and E_2, with the absorption reaching the maximum intensity (1.6×10^3 M^{-1} cm^{-1}) around −0.03 V, the middle point between the two redox potentials (E_1 and E_2) obtained from the cyclic voltammograms. Under potentials above or below that value, the absorptivity decreases gradually up to the complete disappearance of the band at positive (> 0.4 V) and negative (< −0.5 V) regions.

The spectroelectrochemical behavior described above is dependent on the presence of a reduced (Ru_a^{II}) and an oxidized (Ru_b^{III}) redox center, which is coherent with an IVCT process inherent to the mixed-valent species:

$$[(bta)Ru_a^{II}(bta)Ru_b^{III}]^- \xrightarrow{h\nu} [(bta)Ru_a^{III}(bta)Ru_b^{II}]^- \quad (7)$$

Following the photo-induced intervalence transfer, an inverse electron transfer process through a thermal pathway is expected to take place (i.e. $[(bta)Ru_a^{III}(bta)Ru_b^{II}]^- \rightarrow [(bta)Ru_a^{II}(bta)Ru_b^{III}]^-$), since the system is unsymmetrical and there is a driving force, ΔG° or ΔE_0 (see comparison for the reduction potentials of each moiety), favoring the electronic isomer $[(bta)(NH_3)_4Ru^{II}(bta)Ru^{III}(edta)]^-$.

The thermodynamic stability of the mixed-valent complex relative to the isovalent species can be estimated from the comproportionation equilibrium constant (K_c) associated with the reaction:

$$(bta)Ru_a^{III}(bta)Ru_b^{III} + [(bta)Ru_a^{II}(bta)Ru_b^{II}]^{2-} \rightleftharpoons 2\,[(bta)Ru_a^{II}(bta)Ru_b^{III}]^{-} \quad (8)$$

Calculation of K_c [33] by assuming a redox separation ($\Delta E_{1/2}$) of 0.36 V results a value of 1.2×10^6, which corresponds to a comproportionation free energy (ΔG_c) of -8.3 kcal mol^{-1}.

In spite of the high stability of the mixed-valent complex, as shown by the thermodynamic parameters, according to the criteria established by the perturbational formalism of Hush [34] this system features localized oxidation states (class II, within the classical Robin–Day scheme [35]) if one takes into account the fact that (i) the experimental half-bandwidth (5.5×10^3 cm^{-1}) is larger than the theoretical [34,36] value (3.9×10^3 cm^{-1}); (ii) the IVCT band is solvatochromic (even though the solubility of the complex is very poor in organic solvents, preventing a more systematic solvent-dependence study to be performed).

Based on these considerations, the Mulliken–Hush theory [34] applies adequately to the estimation of the electronic coupling energy (H_{ab}) ground state electron delocalization degree (α^2) from the observed IVCT band parameters, through the Eqs. (9) and (10), respectively [34,36].

$$H_{ab} = 2.05 \times 10^{-2} \left(\frac{\varepsilon_{max} \Delta \bar{\nu}_{1/2} \bar{\nu}_{max}}{d^2} \right)^{1/2} \quad (9)$$

$$\alpha^2 = \left(\frac{H_{ab}}{\bar{\nu}_{max}} \right)^2 \quad (10)$$

In these formulas, the energy at the maximum optical absorption (ν_{max}), the molar absorptivity (ε_{max}), and the bandwidth at half-height ($\Delta\nu_{1/2}$) for the IVCT band of the mixed-valent species, $[(bta)(NH_3)_4Ru^{II}$-$(bta)Ru^{III}(edta)]^-$ are 6.6×10^3 cm^{-1}, 1.6×10^3 M^{-1} cm^{-1}, and 5.5×10^3 cm^{-1}, respectively. The electron transfer distance d is roughly assumed to be the metal–metal geometric separation (5.7 Å) and was extracted from the theoretical calculations (see Sections 2 and 2.3 for computational details).

The H_{ab} and α^2 parameters were, in this way, calculated as 870 cm^{-1} and 0.017, respectively. Even though this system exhibits a trapped-valence configuration, the magnitude for the resonance energy, H_{ab} is quite remarkable for this type of complex, surpassing most of similar class II systems and approaching some values previously reported for mixed-valence systems with charge delocalization [9]. In this context, an illustrative comparison is provided below along with the trinuclear species.

In addition to the NIR band, the spectral changes in the UV–Vis region were also monitored by means of spectroelectrochemical experiments. The results can be summarized as follows: if the applied potential corresponds to the fully oxidized species, $Ru_a^{III}Ru_b^{III}$, then two bands are observed at 610 nm (1.2×10^3 M^{-1} cm^{-1}) and $\sim$380 nm (1.0×10^3 M^{-1} cm^{-1}); they were assigned to LMCT bands associated with the chromophores $\{Ru^{III}(NH_3)_4(bta)_2\}$ and $\{Ru^{III}(edta)(bta)\}$, respectively, by analogy with the spectra and the redox potentials of the mononuclear species (Table 1 and Section 3.1). In contrast, for the fully reduced species, $Ru_a^{II}Ru_b^{II}$, a single absorption band is defined at 455 nm (2.3×10^3 M^{-1} cm^{-1}); it arises simultaneously with the disappearance of the band at 610 nm and thus corresponds to the MLCT on the ammine moiety, $\{Ru^{II}(NH_3)_4(bta)_2\}$. The analogous band for the edta moiety occurs below 350 nm and is probably obscured by the intraligand $\pi \rightarrow \pi^*$ transitions.

At potentials applied in the intermediate dominion delimited by E_1 and E_2, i.e. upon electrolytic generation of the mixed-valent state, a rather more complex spectrum is displayed in the range from 350 to 550 nm. By using deconvolution methods, it was shown that one of the bands refers to the shift of the LMCT band for $\{Ru^{III}(edta)(bta)\}$ to 540 nm ($\sim 8.0 \times 10^2$ M^{-1} cm^{-1}) by virtue of the reduction of the ammineruthenium fragment, which in turn promotes the energy raise of the π-HOMO levels of benzotriazolate (L_b) by means of π-backbonding interactions. The same reasoning explains why the MLCT band for $\{Ru(NH_3)_4(bta)_2\}$ appears shifted (with regard to the fully reduced dimer) to the red (500 nm). Such redox behavior in the UV–Vis region is typical of a mixed-valent species with significant electronic coupling [8,9], and is caused by the perturbation of the frontier orbitals/electronic levels at each of the donor–acceptor centers in reference to the isovalent reduced and oxidized species (Table 1).

3.3. Trinuclear complexes

The mixture of $Ru^{II}(NH_3)_4(bta)$ and $[Ru^{III}(edta)(H_2O)]^-$ at the 1:2 molar ratio in basic (pH > 9) aqueous solutions reacts to yield a purple product, which was found to be the trinuclear complex. Like previous procedure [16,17], excess $[Ru(edta)(H_2O)]^-$ (ca. 1 equiv.; 1:3 molar ratio) was added to the solutions to ensure the completeness of the substitution reactions (Eqs. (11) and (12)), although the use of stoichiometric amounts also gives the quantitative formation of the very stable mixed-valent trinuclear species.

$$(bta)Ru_a^{II}(bta) + [Ru_b^{III}(H_2O)]^- \rightleftharpoons [(bta)Ru_a^{II}(bta)Ru_b^{III}]^- + H_2O \quad (11)$$

$$[(bta)Ru_a^{II}(bta)Ru_b^{III}]^- + [Ru_b^{III}(H_2O)]^- \rightleftharpoons [Ru_a^{II}\{(bta)Ru_b^{III}\}_2]^{2-} + H_2O \quad (12)$$

The cyclic voltammograms of a 1:3 mixture, for instance, display three pairs of reversible waves (labeled

[d] Ref. [15].
[e] Ru ($d_\pi \rightarrow d_\sigma$) transition [15].
[f] $Ru(II) \rightarrow L_p$.
[g] $Ru(II) \rightarrow L_b$.
[h] $L_b \rightarrow Ru(III)$.
[i] $L_p \rightarrow Ru(III)$.
[j] It must be taken into account the fact that the absorptivity of this transition is about twice the one of the dinuclear analogue due to the two terminal non-interacting {Ru(edta)(bta)$^-$} moieties.

as **I**, **II**, and **III** in Fig. 2) with half-potentials at 0.15, −0.05 and −0.22 V, respectively. The waves **III** present current intensities twice higher than waves **I** (Fig. 2).

By analogy with the $E_{1/2}$ values for the mono- and dinuclear species (Table 1), the observed potentials were assigned to the following redox couples:

$$\textbf{(I)}\ [Ru_a^{III}\{(bta)Ru_b^{III}\}_2]^- + e^- \rightleftharpoons [Ru_a^{II}\{(bta)Ru_b^{III}\}_2]^{2-} \quad (13)$$

$$\textbf{(II)}\ [Ru_b^{III}(H_2O)]^- + e^- \rightleftharpoons [Ru_b^{II}(H_2O)]^{2-} \quad (14)$$

$$\textbf{(III)}\ [Ru_a^{II}\{(bta)Ru_b^{III}\}_2]^{2-} + 2e^- \rightleftharpoons [Ru_a^{II}\{(bta)Ru_b^{II}\}_2]^{4-} \quad (15)$$

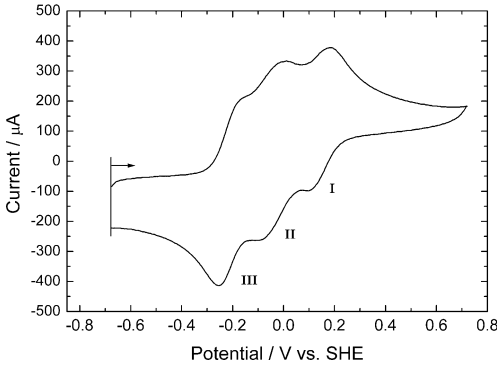

Fig. 2. Cyclic voltammograms of *trans*-$[(NH_3)_4Ru\{(bta)Ru(edta)\}_2]^{n-}$ ($n = 1$, 2, or 4) in aqueous solutions ($c = 2.0 \times 10^{-2}$ M; *I*, KNO_3 0.25 M; pH 9.5).

Despite the quite significant electronic interaction between the adjacent terminal (Ru_b) and central (Ru_a) redox centers (whose potentials are indeed rather similar to the ones for the dinuclear species), the direct communication between the identical peripheral ruthenium–edta units must be negligible, since there is no measurable split in their half-potentials ($\Delta E_{1/2} < 30$ mV) and thus they are both reduced practically at the same redox potential (−0.22 V), as can be deduced from the voltammograms (Fig. 2).

NIR spectroelectrochemistry showed that the IVCT spectral features are also similar to the dinuclear species (Fig. 3), with a strong absorption band at 1530 nm ($1.9 \times 10^3\ M^{-1}\ cm^{-1}$) under application of potentials between **I** and **III** (mixed-valent state; $Ru_b^{III}Ru_a^{II}Ru_b^{III}$). At potentials above **I** or below **III**, the absorptivity vanishes gradually due to the electrolytic generation of the fully oxidized, $Ru_b^{III}Ru_a^{III}Ru_b^{III}$, and fully reduced species, $Ru_b^{II}Ru_a^{II}Ru_b^{II}$, respectively, which do not absorb in the NIR region (Fig. 3).

As mentioned, the electrochemical and NIR spectral properties presented above for the di- and the trinuclear complexes are quite similar. The main changes that arises upon passing from $[(bta)Ru_a^{II}(bta)Ru_b^{III}]^-$ to $[Ru_b^{III}(bta)Ru_a^{II}(bta)Ru_b^{III}]^{2-}$ are basically (i) an increase of 10 mV on the redox separation $\Delta E_{1/2}$ (0.37 V) between E_1 (**I**) and E_2 (**III**), due to a cathodic shift of the half-potential centered on the Ru_b center, (ii) a lower-energy shift of 20 nm and an increase of absorptivity

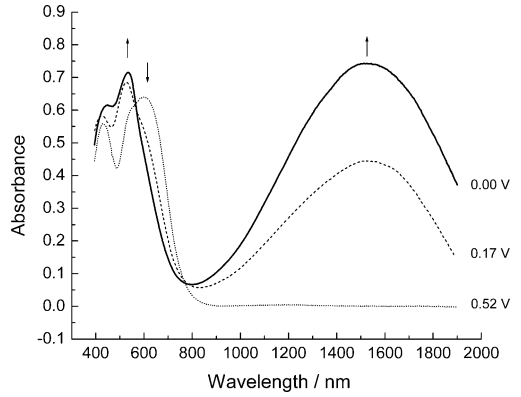

Fig. 3. Electronic spectra of *trans*-$[(NH_3)_4Ru\{(bta)Ru(edta)\}_2]^{n-}$ ($n = 1$, 2, or 4) in D_2O solutions under application of potentials ($c = 2.0 \times 10^{-2}$ M; I, KNO_3 0.25 M; pH 9.5; $l = 0.24$ mm; applied potentials vs. SHE are indicated in the figure).

($\Delta\varepsilon_{max} = 3 \times 10^2$ M^{-1} cm^{-1}) on the IVCT band. These slight differences can be rationalized partially in terms of coordination effects of the additional negatively charged ruthenium–edta unit with regard to the dinuclear precursor, and partially by an enhancement of electron delocalization following the increasing nuclearity of the system.

By taking the properties of the IVCT band ($\nu_{max} = 6.5 \times 10^3$ cm^{-1}, $\varepsilon_{max} = 1.9 \times 10^3$ M^{-1} cm^{-1}, and $\Delta\nu_{1/2} = 5.6 \times 10^3$ cm^{-1}) and the theoretical intermetallic distance ($d = 5.7$ Å; see illustration in Fig. 4) into the Eqs. (9) and (10), the parameters H_{ab} and α^2 were calculated as 945 cm^{-1} and 0.021, respectively. These results are rather interesting because they reveal that the extent of electronic coupling (and so the delocalization) is significantly enlarged in the symmetrical trinuclear system. Its mixed-valence properties are summarized in Table 2 along with the dinuclear species and other literature analogues, for comparison purposes.

As discussed briefly in Section 3.2, although these systems behave consistently with a localized oxidation states description (on the Hush model basis), the magnitude of H_{ab} is remarkable for both mixed-valent di- and trinuclear complexes. An illustrative comparison is provided by the trinuclear analogue with pyrazine as bridging ligand, $[Ru_b^{III}(pz)Ru_a^{II}(pz)Ru_b^{III}]$, whose spectra display no evidence of IVCT band (i.e. with absorption higher than 1×10^2 M^{-1} cm^{-1}) in the NIR region [16], which means that the electronic coupling is negligible in that system (in this case, the large $\Delta E_{1/2}$ of ca. 0.6 V shown in Table 2 comes primarily from the redox asymmetry of the complex). Besides, the systems reported herein are very stable at all the isovalent and mixed-valent states with respect to disproportionation, whereas the literature analogues are electrostatically unstable at some of the oxidation states, as is the case of the pyrazine example given by the replacement of the terminal units Ru_b with pentacyanoferrate ions, i.e. $[(CN)_5Fe^{II}(pz)Ru_a^{III}(pz)Fe^{II}(CN)_5]^{3-}$ [17]. An additional notice within this perspective comes from the fact that the pyrazine-derivatives are symmetrical and linear [39], while the benzotriazolate-bridged systems are symmetrical and nonlinear.

The results of UV–Vis spectroelectrochemistry resemble the ones for the dinuclear species, and were interpreted on the basis of assignments made in the previous section. The redox/charge-transfer data were collected in Table 1 in order to make the comparison easier (the spectra are shown in Fig. 5). Variations in reduction potentials, LMCT and MLCT energies can be plausibly explained as a function of the synergistic charge-transfer and cooperative π-acid–base or π-back-bonding effects on each species, and are compatible with a greater perturbation at the mixed-valent state.

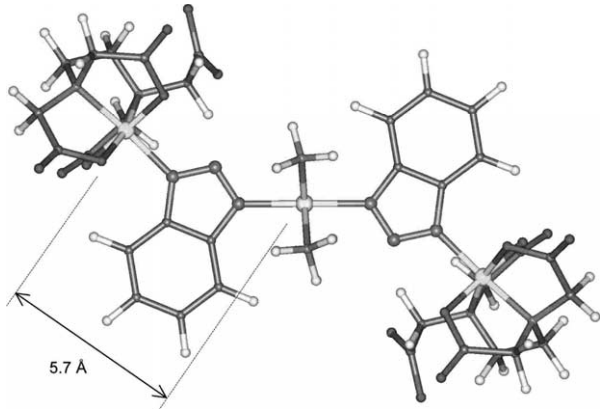

Fig. 4. Theoretical molecular structure of the symmetrical (C_2) trinuclear complex, *trans*-$[(NH_3)_4Ru\{(bta)Ru(edta)\}_2]^{2-}$.

4. Concluding remarks

The current investigation of mono-, di-, and trinuclear complexes with ammine- and edta–ruthenium units leads to the conclusion that polymetalic derivatives

containing benzotriazolate as a bridging ligand exhibit electronic interactions suitable for the design of multicomponent supramolecular systems with conductor linkers [40].

An interesting feature of the complexes reported herein is that the electron communication between the adjacent (donor–acceptor) centers increases slightly with the nuclearity of the system. In this perspective, molecular wires can be devised via a combination of appropriate metallic units to act as building/ending blocks interconnected by the electron-rich benzotriazolate mediator. Unlike pyrazine-bridged polynuclear complexes [16,17], which afford linear polymer-like chains [39], the extended molecular systems bridged by benzotriazolate can provide a 'zigzag' type of wires.

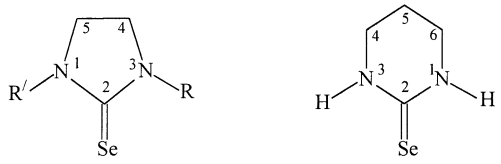
integration of the CN^- resonances in the ^{13}C NMR. Although the complexes of thiones with gold(I) have been studied extensively [17–19], there is no known report describing the synthesis of gold(I) complexes of selenones (except that of selenourea) [20]. The complexation of gold(I) with selenium containing ligands is important since selenocysteine is present at the active binding site of the enzyme, Se-glutathione peroxidase and gold(I) is known to be a strong inhibitor for the catalytic activity of Se-glutathione peroxidase [21–23]. The structures of the selenones used in this study and their resonance assignments are described in Scheme 1.

2. Experimental



2.1. Chemicals

AuCN, using ^{13}C and ^{15}N labelled KCN (99% enriched) was prepared according to the published procedure [5]. Acetone, MeCN and DMSO-d_6 were obtained from Fluka Chemical Co. All the selenones were synthesized according to the procedure described in the literature [24,25].

2.2. Preparation of complexes

AuCN was suspended in C_3H_6O and an equimolar amount of the selenone in MeCN was added. The mixture was stirred for almost half an hour (in the case of Et_2ImSe, it was stirred for 1 day), after which a colorless solution was obtained. The solution was filtered and kept in a refrigerator for crystallization. As a result, white crystalline products were obtained with 50–60% yield.

The elemental analyses of all the complexes are given in Table 1.

(a) R = R′ = H; Imidazolidine-2-selenone (ImSe)

(b) R = H, R′ = CH_3; N-methylimidazolidine-2-selenone (MeImSe)

(c) R = H, R′ = C_2H_5; N-ethylimidazolidine-2-selenone (EtImSe)

(d) R = H, R′ = *i*-C_3H_7; N-(*i*-propyl)imidazolidine-2-selenone (*i*-PrImSe)

(e) R = H, R′ = C_6H_5; N-phenylimidazolidine-2-selenone (PhImSe)

(f) R = R′ = C_2H_5; N,N′-diethylimidazolidine-2-selenone (Et_2ImSe)

(g) R = H; 1,3-Diazinane-2-selenone (DiazSe)

Scheme 1.

Table 1
Elemental analyses of the [>C=Se–Au–CN] complexes

Complex	Found (Calc.)%			M.p. (°C)
	C	H	N	
ImSeAuCN	13.36 (12.91)	1.70 (1.63)	11.12 (11.30)	168 (dec.)
MeImSeAuCN	15.75 (15.55)	2.19 (2.09)	10.69 (10.89)	172 (dec.)
EtImSeAuCN	18.05 (18.01)	2.65 (2.52)	10.12 (10.50)	140 (dec.)
i-PrImSeAuCN	20.58 (20.30)	2.99 (2.92)	10.46 (10.15)	160 (dec.)
PhImSeAuCN	26.63 (26.74)	2.37 (2.40)	9.85 (9.36)	165 (dec.)
Et_2ImSeAuCN	22.62 (22.44)	3.31 (3.29)	9.89 (9.82)	110–111
DiazSeAuCN	16.17 (15.55)	2.22 (2.09)	10.90 (10.89)	119–121

All the complexes are written in the nonionic form, since on the basis of elemental analysis the ionic and nonionic forms cannot be distinguished.

2.3. Spectroscopic measurements

The solid state IR spectra of the ligands and their cyano gold(I) complexes were recorded on a Perkin–Elmer FTIR 180 spectrophotometer using KBr pellets over the range 4000–400 cm^{-1}.

The ^1H NMR spectra were obtained on a JEOL JNM-LA 500 NMR spectrometer operating at a frequency of 500 MHz. The ^{13}C NMR spectra were obtained at the frequency of 125.65 MHz with ^1H broadband decoupling at 297 K. The spectral conditions were: 32 K data points, 0.967 s acquisition time, 1.00 or 30.00 s pulse delay and 45° pulse angle. ^{13}C chemical shifts (relative to TMS) were assigned according to the references given in the literature for analogous thiones [17,19].

The ^{15}N NMR spectrum was recorded at 50.55 MHz using $NH_4^{15}NO_3$ as an external reference, which lies at 375.11 ppm relative to pure CH_3NO_2, 380.2 ppm [26]. The spectral conditions for ^{15}N NMR were: 32 K data points, 0.721 s acquisition time 2.50 s delay time, 60° pulse angle and approximately 10 000 scans.

T_1 values for the ^{13}C nuclei were measured only for CN^- carbons in [ImSeAuCN] and $[Au(CN)_2]^-$ using the inversion recovery method. The average values obtained are 4.0 and 5.1 s, respectively. Based on these T_1 values, a delay time of 30.0 s was used to record the ^{13}C NMR spectra of all the complexes so that the spectra could be integrated quantitatively.

2.4. Determination of equilibrium constant (K_{eq})

Equilibrium constants (K_{eq}) were calculated using relative intensities (I) of cyanide resonances of [>C=Se–Au^{13}C^{15}N] and $[Au(^{13}C^{15}N)_2]^-$ complexes, in the ^{13}C NMR, which gives the relative concentrations of both species;

$$K_{eq} = (I[Au(^{13}C^{15}N)_2]^-) \times (I[Au(>C{=}Se)_2]^+)/(I[>C{=}Se{-}Au^{13}C^{15}N])^2 \quad (2)$$

Where,

$I[Au(^{13}C^{15}N)_2]^- = I[Au(>C{=}Se)_2]^+$

Each K_{eq} value is the result of at least seven measurements.

3. Results and discussion

3.1. IR Studies

Table 2 lists the significant IR bands of free selenones and their gold(I) complexes. The ν(C=Se) vibration, which occurs around 600 cm^{-1} for the free ligands [27], shifts towards lower frequency upon complexation, in accordance with the data observed for the analogous thione complexes [17]. Another important vibrational band observed in IR spectra of the selenones is the ν(NH), which appears around 3200 cm^{-1}. Upon coordination to AuCN this band shifts to higher wave numbers with some exceptions. The presence of a band around 3200 cm^{-1} in free ligands as well as in the complexes indicates the existence of the selenone form of the ligands in the solid state. One or two bands around 2100 cm^{-1} corresponding to CN^- stretches are observed in IR spectra of all the complexes. For the complexes of ImSe and DiazSe only one ν(CN) mode was observed, which appeared at a lower frequency (by approximately 150 cm^{-1}) compared to free AuCN. For the rest of the complexes, two stretching bands (asymmetric and symmetric) are observed for the CN^- group which are characteristic of $[Au(CN)_2]^-$ (since the NC–Au–CN bond angle in $[Au(CN)_2]^-$ is found to be less than 180°) [7,8].

Several studies on the crystal structures of cyanogold(I) complexes show that these complexes exist as monomers and in the nonionic form in the solid state [2–4]. However, the crystal structures of two of the complexes, [DmTu–Au–CN] [8] and [CEP–Au–CN] [7] show that they exist as ionic complexes, $[Au(DmTu)_2]^+$-$[Au(CN)_2]^-$ and $[Au(CEP)_2]^+[Au(CN)_2]^-$, respectively, in the solid state. We prepared these two complexes in our laboratory and in the IR spectra of these complexes, it was observed that they possess two bands corresponding to the CN^- stretch. For the other cyano(thione)gold(I) complexes only one ν(CN) band was observed [17]. Thus it is established that the complexes which show only one CN^- stretch in IR exist as nonionic complexes (i.e. as [L–Au–CN]), while those which possess two CN^- bands exist in the form (i.e. as $[AuL_2]^+[Au(CN)_2]^-$. The IR spectra of $[Au(CN)_2]^-$ and a representative complex are shown in Fig. 1.

The appearance of one ν(CN) peak for the complexes [ImSeAuCN] and [DiazSeAuCN], indicates that these two complexes exist in the nonionic form. The appearance of two ν(CN) bands for the other five selenone complexes suggests that they exist in the ionic form (i.e. as $[Au(>C{=}Se)_2]^+[Au(CN)_2]^-$) in the solid state, similar to $[Au(CEP)_2]^+[Au(CN)_2]^-$ and $[Au(DmTu)_2]^+[Au(CN)_2]^-$ [7,8].

3.2. NMR studies

In solution, the complexes were characterized by ^1H, ^{13}C and ^{15}N NMR in DMSO-d_6. All the complexes were observed to undergo the ligand scrambling reactions in solution similar to that shown in Eq. (1). In ^1H NMR the N–H signal was broadened upon coordination and a downfield shift of 0.7–1.0 ppm was observed for the N–H proton of all the ligands. The appearance of the N–H signal in ^1H NMR of all ligands after complexation shows that the ligands are coordinating in the selenone form in solution. The ^1H NMR chemical shifts of N–H protons and ^{13}C NMR chemical shifts of all the ligands and their gold(I) complexes are given in Table 3. In ^{13}C NMR, no significant change in the chemical shifts of the ligands upon complexation was observed except in the C-2 resonance (Table 3). A shift of 9–13 ppm for the C-2 resonance indicates that in all the complexes, gold(I) is bonded to the selenone ligands through the selenium atom only. In the case of bonding through nitrogen, a considerable shift of the C-4 resonance would have been observed, but there is only a slight shift in C-4.

Table 2
IR frequencies, ν(cm^{-1}) of the selenones and their cyanogold(I) complexes

Species	ν(C=Se) of ligands	ν(C=Se) of complexes	ν(NH) of ligands	ν(NH) of complexes	ν(CN) of complexes

The ligand scrambling reactions of the cyano(selenone)gold(I) complexes were followed by ^{13}C NMR and were further characterized by ^{15}N NMR spectroscopy. Some representative ^{13}C and ^{15}N spectra are shown in Fig. 2. The ^{13}C and ^{15}N NMR shifts of the CN^- group for all the selenone complexes are given in Table 4. In the CN^- region of the ^{13}C spectrum, two intense resonances were observed for all the complexes (Fig.

[a] In methanol.

The $[Au(CN)_2]^-$ resonance appears as a triplet with an average coupling constant of 5.9 Hz. The triplet appearance of the $[Au(^{13}C^{15}N)_2]^-$ resonance is because the $^{13}C-^{15}N$ coupling in $[Au(^{13}C^{15}N)_2]^-$ follows the AA′XX′ spin system as described in the previous studies [11–13]. The $^{13}C^{15}N$ resonance due to [>C=Se–Au–$^{13}C^{15}N$] complexes is a doublet with the $^1J_{C\text{-}N}$ values given in Table 4. Separate resonances for selenone ligands in [>C=S–Au–CN] and $[Au(>C=S)_2]^+$ species were not observed either due to their rapid exchange or the chemical shifts of the two species are overlapped so that they cannot be resolved.

The results of the ^{15}N NMR studies are consistent with the ^{13}C NMR data. The ^{15}N NMR also showed two resonances for the CN^- nitrogen corresponding to equilibrium (3) (Fig. 2c). The resonance at 284.1 was a triplet of $[Au(^{13}C^{15}N)_2]^-$ (as observed in the ^{13}C spectrum) with an average coupling constant of 5.9 Hz. The other resonance is a doublet due to $^{13}C-^{15}N$ coupling in the [>C=Se–Au–$^{13}C^{15}N$] complexes. The ^{15}N chemical shift is very much affected by the change of solvent. When the ^{15}N spectrum of ImtAuCN, a thione analogue of ImSeAuCN (Imt = imidazolidine-2-thione), was taken in methanol, the $[Au(CN)_2]^-$ resonance was observed at 264.7 ppm [9].

3.3. Evaluation of equilibrium constant (K_{eq})

Equilibrium constants (K_{eq}) were determined for the [>C=Se–Au–CN] complexes at 297 K using 0.025 M concentration of each complex in DMSO-d_6. The average K_{eq} values calculated for the complexes using Eq. (2) are given in Table 4 and for comparison, K_{eq} values of some known cyanogold(I) complexes are also given.

In the scrambling reactions of cyanogold(I) complexes of phosphines, it was observed that the basicity of the phosphine is the most important factor which affects K_{eq} [5], although K_{eq} is also affected by external factors such as ionic strength [5,9]. An increase in K_{eq} was observed with an increase in basicity of the phosphine. As shown in Table 4, the K_{eq} values for the cyanogold(I) complexes of selenones are found to be much larger than for the complexes of other ligands. The larger K_{eq} values indicate that the selenones are more basic towards Au(I) compared to phosphines and thiones. A shift of 9–13 ppm in the C-2 resonance also indicates that they are very strong σ donors. It seems that greater donation of electron density to gold(I) would result in a stronger Au–CN bond. This should lead to an easier formation of $[Au(CN)_2]^-$, resulting in a larger value of K_{eq}. In the case of R_3PAuCN complexes, π accepting ability of phosphines stabilizes the Au–P bond and thus would result in a lower value of K_{eq}. This shows that the selenones are weaker π acceptors compared to phosphines and thiones. A comparison of the K_{eq} value for scrambling of Cy_3PSeAuCN with its sulfur analogue, Cy_3PSAuCN (Table 4) further suggests that the K_{eq} values for the selenones complexes should be greater than the complexes of their sulfur analogues (thiones). Moreover, since five of the eight complexes being reported exist in the solid state as ionic complexes, in solution the ionic form will also be more populated resulting in a larger value of K_{eq}. Thus the order of ability of different L–Au–CN complexes undergoing disproportionation is, [>C=SeAuCN] > [R_3PSeAuCN] > [>C=SAuCN] > [R_3PAuCN] ≥ [R_3PSAuCN].

In the scrambling reactions of cyano(phosphine)gold(I) complexes [5,6], it was observed that with increasing basicity of phosphines, δ ^{13}C for CN^- in R_3PAuCN also increased due the increased π bond character in the Au–C bond, while there was a decrease in δ ^{15}N. However, in the present study, δ ^{13}C and ^{15}N for CN^- and the coupling constants, $^1J_{C-N}$ in all the complexes are very close showing that the difference in their basicity is small. Table 4 shows the highest value of δ ^{13}C for a CN^- resonance DiazSe–AuCN indicating that it is the most basic, while Et_2ImSe–AuCN with the lowest $\delta^{13}C$ is the least basic among the selenones. The least basicity of Et_2ImSe–AuCN is due to its inability to exhibit the selenol–selenone equilibrium. However, the greater δ ^{13}C and smaller ^{15}N of selenone complexes compared to that of thione ones indicate that selenones are comparatively more basic than thiones.

4. Conclusion

In this study we have shown that some of the cyanogold(I) complexes of selenones exist as nonionic complexes and some as the ionic species in the solid state as proved by IR spectroscopy. However, in solution all cyano(selenone)gold(I) complexes undergo dissociation showing an equilibrium between ionic and nonionic species. The equilibrium constants (K_{eq}), measured for the scrambling of selenone complexes, have the highest values compared to those observed for all other reported complexes.

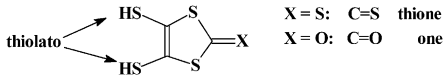

Fig. 1. X = S: H_2dmit; X = O: H_2dmio.

expected, only small structural differences are found between dmit and dmio complexes when these 1,2-dithiolato ligands merely act as chelates, as in [Q][R_2SnX(dmit)] and [Q][R_2SnX(dmio)] [9,10], [Q]$_2$[Sn(dmit)$_3$] and [Q]$_2$[Sn(dmio)$_3$] [11], as well as [Q][Zn(dmit)$_2$] and [Q][Zn(dmio)$_2$] [12]. However, when the chalcogen atoms are involved in secondary bonding, structural differences are realised as is the case with the pair, Me_2Sn(dmit) and Me_2Sn(dmio) [9,13].

A series of bis(1,3-dithiole-2-one-4,5-dithiolato)antimonate(1-) complexes, [Q][Sb(dmio)$_2$] (**3**) have been prepared and the structures of two complexes, (**3**: Q = NEt_4 and DMP), have been determined and are now reported. These are compared with the structures of the previously reported (**1**: Q = NEt_4, DMP and PPh_4) as well as with those of the new compounds, (**1**: Q = NBu_4 and $AsPh_4$).

2. Experimental

2.1. General

NMR spectra were run on Bruker 250 and 300 MHz instruments, IR spectra on Nicolet Magna 760 FTIR, Philips Analytical PU9800 and Nicolet Fourier-transform spectrometers and UV–Vis spectra on a Varian–Cary 1E UV–Vis instrument. Melting points (m.p.) were measured on a Melt–TempII instrument and a Kofler hotstage and are uncorrected. Elemental analyses were obtained using a Perkin–Elmer 2400 Instrument or from Butterworth Laboratories Ltd, Middlesex. The compounds, (ferrocenylmethyl)trimethylammonium iodide, [$FcCH_2NMe_3$]I [14], [Q]$_2$[Zn(dmit)$_2$] (Q = NBu_4 and $AsPh_4$) and [Q]$_2$[Zn(dmio)$_2$] (Q = NEt_4, DMP, $FcCH_2NMe_3$ and PPh_4) [12,15] were prepared by published procedures.

2.1.1. Synthesis of *1* and *3*

These were prepared by a procedure similar to that previously used for (**1**: Q = NEt_4, PPh_4 or DMP) [2,3]. Reactions between $SbBr_3$–NaSCN and [Q]$_2$[Zn(dmit)$_2$] or [Q]$_2$[Zn(dmio$_2$] gave the target products in yields generally greater than 60% after recrystallisation. The procedure used for (**1**: Q = $AsPh_4$) is given as an illustration.

2.1.2. Compound (*1*: *Q* = *AsPh*$_4$) from [*AsPh*$_4$][*Zn*(*dmit*)$_2$]

To a solution of NaSCN·$2H_2O$ (0.351 g, 3 mmol) in acetone (20 cm^3) was successively added a solution of $SbBr_3$ (0.36 g, 1 mmol) in acetone (20 cm^3) and a solution of [$AsPh_4$]$_2$[Zn(dmit)$_2$] (1.22 g, 1 mmol) in acetone (35 cm^3). The reaction mixture was stirred for 30 min after the addition of [$AsPh_4$]$_2$[Zn(dmit)$_2$], the solvent removed by rotary evaporation and the crude product recrystallised from acetone to give dark green–black crystals (blocks), m.p. 185–187 °C. *Anal.* for (**1**: Q = $AsPh_4$). Found: C, 40.2; H, 2.3. $C_{30}H_{20}AsS_{10}Sb$ requires C, 40.1; H, 2.2%. ^{1}H NMR (DMSO-d_6, 300 MHz): δ: 7.8–7.9(m, aryl-H). ^{13}C NMR (DMSO-d_6, 75.5 MHz): δ: 121.5, 131.5, 133.7 and 134.9(aryl-C), 132.7(C=C), 212.2(C=S). IR (KBr, cm^{-1}): 1437 (C=C), 1053, 1014(C=S), 883(C–S). IR (CsI, cm^{-1}): 516, 482, 463, 398, 360, 351, 323, 289, 279, 270, 246, 223.

2.1.3. Compound (*1*: *Q* = *NBu*$_4$) from [*NBu*$_4$]$_2$[*Zn*(*dmit*)$_2$]

The product was recrystallised from DMSO as dark red crystals (needles): m.p. 168–170 °C. *Anal.* for (**1**: Q = NBu_4). Found: C, 34.8; H, 4.9; N, 1.8. $C_{22}H_{36}NS_{10}Sb$ requires C, 34.9; H, 4.8; N, 1.9%. ^{1}H NMR (DMSO-d_6, 300 MHz): δ 0.93(t, 12H, J(^{1}H–^{1}H) = 7.2 Hz, CH_3), 1.30(m, 8H, CH_2), 1.57(m, 8H, CH_2), 3.18(t, 8H, H_2C–N). ^{13}C NMR (DMSO-d_6, 75.5 MHz): δ 13.5(CH_3), 19.2(CH_2), 23.1(CH_2), 57.6(CH_2), 132.4(C=C) and 211.5(C=S). IR (KBr, cm^{-1}): 1437(C=C), 1063, 1016(C=S), 889(C–S). IR (CsI, cm^{-1}): 526, 519, 462, 441, 390, 343, 329, 300, 288, 266, 246, 219.

2.1.4. Compound (*3*: *Q* = *NEt*$_4$) from [*NEt*$_4$]$_2$[*Zn*(*dmio*)$_2$]

The target product was recrystallised from acetone as a dark green–black crystalline solid, m.p. 193–195 °C. Yield: 0.57 g (67%). *Anal.* for (**3**: Q = NEt_4). Found: C, 27.6; H, 3.5. $C_{14}H_{20}NO_2Sb$ requires C, 27.5; H, 3.3%. ^{1}H NMR (DMSO-d_6, 250 MHz): δ: 1.2 (t of t, 12H, J(^{1}H–^{1}H) = 7.2 Hz, Me of cation), 3.2 (q, 8H, J(^{1}H–^{1}H) = 7.5 Hz, CH_2N of cation). ^{13}C NMR (DMSO-d_6, 63 MHz): δ: 8.7(Me), 53.0(CH_2N), 119.9(C=C), 195.4(C=O). IR (CsI, cm^{-1}): 2075, 1660, 1607, 1473, 1391, 1365, 1171, 1000, 883, 786, 755, 545, 462, 365, 338, 321, 280, 257, 172.

2.1.5. Compound (*3*: *Q* = *DMP*) from [*DMP*]$_2$[*Zn*(*dmio*)$_2$]

The target product was recrystallised from acetone as a dark green–black crystalline solid, m.p. 182–183 °C. Yield: 0.58 g (68%). *Anal.* for (**3**: Q = DMP). Found: C, 26.7; H, 1.7; N, 2.5. $C_{13}H_{10}NO_2S_8Sb$ requires C, 26.4; H, 1.7; N, 2.4%. ^{1}H NMR (DMSO-d_6, 250 MHz): δ: 2.6 (s, 3H, Me of cation), 4.3 (s, 3H, MeN of cation), 7.9 (d, 2H, J(^{1}H–^{1}H) = 6.2 Hz, C_3 and C_5), 8.8 (d, 2H, J(^{1}H–^{1}H) = 6.6 Hz, C_2 and C_6). ^{13}C NMR (DMSO-d_6, 63 MHz): δ: 23.1(Me), 48.8(MeN), 120.0(C=C), 129.7, 146.2, 159.9 (aromatic-C), 195.4(C=O). IR (CsI,

cm^{-1}): 1771, 1660, 1641, 1605, 1517, 1471, 1295, 1189, 885, 877, 816, 803, 752, 695, 542, 486, 460, 366, 333, 318, 279, 252, 174, 154.

2.1.6. Compound (3: Q = Ph_4P) from $[PPh_4]_2[Zn(dmio)_2]$

The target molecule was recrystallised from acetone as a black crystalline solid, m.p. 173–175 °C. Yield: 0.88 g (66%). *Anal.* for (**3**: Q = Ph_4P). Found: C, 43.5; H, 2.6. $C_{30}H_{20}O_2PS_8Sb$: requires C, 43.8; H, 2.4%. ^{1}H NMR (DMSO-d_6, 250 MHz): δ: 7.8 (m, 12H, *m*-H + *p*-H), 8.0 (m, 8H, *o*-H). ^{13}C NMR (DMSO-d_6, 63 MHz): δ: 118.6 (C=C), 120.0 ($J(^{31}P-^{13}C) = 88.5$ Hz, C_i), 132.0 [$J(^{31}P-^{13}C) = 12.2$ Hz, C_m], 136.1 ($J(^{31}P-^{13}C) = 11.0$ Hz, C_o), 137.0($^{31}P-^{13}C) = 2.2$ Hz, C_p), 195.3(C=O). IR (KBr, cm^{-1}): 1660, 1610, 1585, 1471, 1434, 1104, 995, 885, 752, 686, 526, 460.

2.1.7. Compound (3: Q = $FcCH_2NMe_3$) from $[FcCH_2NMe_3]_2[Zn(dmio)_2]$

The target molecule was recrystallised from acetone as a dark orange–green solid, m.p. 203–205 °C. Yield: 0.78 g, (60%). *Anal.* for (**3**: Q = $FcCH_2NMe_3$): C, 32.0; H, 3.0; N, 1.7. $C_{20}H_{20}NO_2FeS_8Sb$ requires C, 32.4; H, 2.7; N, 2.0%. ^{1}H NMR (DMSO-d_6, 250 MHz): δ: 2.9 (s, 9H, Me of cation), 4.2 (s, 5H, unsubstituted cp-H), 4.4 (s, 4H, substituted cp-H), 4.5 (s, 2H, CH_2N). ^{13}C NMR (DMSO-d_6, 63 MHz): δ: 53.0(Me), 67.1(CH_2N), 70.6(unsubstituted cp-C), 71.7, 73.6, 74.7(substituted cp-C), 119.9(C=C), 195.3(C=O). IR (KBr, cm^{-1}): 1666, 1610, 1479, 1467, 867, 825, 482, 464.

2.2. Crystallography

2.2.1. Data collection

For (**3**: Q = NEt_4 or DMP) unit cell and intensity data were obtained at 293 and 150 K, respectively, on the Delft Instruments FAST diffractometer of the EPSRC's crystallographic service at Cardiff. Unit cells were determined and the data collected using the routines ENDEX, REFINE and MADONL of the MADNES software [16] and data reduction carried out using ABSMAD [17]. Full procedural details are available elsewhere [18]. The triclinic cell determined initially for (**3**: Q = NEt_4) was found to correspond to a C-centred monoclinic cell and the cell dimensions were adjusted accordingly and the intensity data re-indexed with the row-wise transformation matrix −1 −1 0; −1 1 0; 0 0 −1. In both cases correction for absorption was made using XABS-2 [19].

Unit cell and intensity data for (**1**: Q = NBu_4) and (**1**: Q = $AsPh_4$), both at 150 K, were obtained by means of the Enraf Nonius KappaCCD area detector diffractometer of the EPSRC's crystallographic service at Southampton. The entire process of data collection, cell refinement and data reduction was accomplished by means of the programs DENZO [20] and COLLECT [21]. Correction for absorption was by means of SORTAV [22].

2.2.2. Structure solution and refinement

The direct methods approach of SHELXS-97 [23] provided solutions for the structures of (**1**: Q = NBu_4) and (**3**: Q = NEt_4 or DMP), while the structure of (**1**: Q = $AsPh_4$) was solved by the heavy atom method using SHELXS-86 [23]. Structure refinement in all cases was by means of SHELXL-97 [24]. In the case of (**1**: Q = $AsPh_4$) correction for extinction was applied with k in the formula: $F_c^* = kF_c[1 + 0.001 \times F_c^2\lambda^3/\sin(2\theta)]^{1/4}$ taking the value 0.0035(5). In all four cases, all non-H atoms were refined anisotropically and in the final stages H atoms were introduced in calculated positions and refined with a riding model. Special action was required to deal with disorder in two of the Bu groups of the counter cation of (**1**: Q = NBu_4) and the centrosymmetric symmetry of the cation sites in (**3**: Q = NEt_4) and (**3**: Q = DMP). Further details of data collection and structure refinement are available in Table 1.

3. Results and discussion

3.1. General

The dmit complexes, (**1**: Q = NBu_4 and $AsPh_4$), were prepared from $[Q]_2[Zn(dmit)_2]$ and $SbBr_3$–NaSCN in acetone, using a previously reported procedure [2]. A related procedure was used to obtain (**3**: Q = NEt_4, DMP, PPh_4 or $FcCH_2NMe_3$) from $[Q]_2[Zn(dmio)_2]$ and $SbBr_3$–NaSCN. The complexes have little solubility in non-coordinating solvents: the NMR spectra were run in DMSO-d_6 for this reason. The values of ν(C=C) for **1** and **3** are generally found in the regions 1430–1443 and 1455–1470 cm^{-1}, respectively, while the d^{13}C(C=C) NMR values are between 132.4–133.9 and 118.6–120.0 ppm, respectively. Spectral data for the C=S groups in **1** ν(C=S) 1016–1026 cm^{-1} and δ ^{13}C(C=S) 211.5–213.3 ppm: values for C=O in **3** are ν(C=O) 1660–1667 and 1605–1610 $cm^{-1}$and δ ^{13}C (C=O) 195.3–195.4 ppm.

3.2. Crystal structures

In what follows, the geometry of the previously published structures of (**1**: Q = NEt_4, DMP or PPh_4) [2,3] is described in terms of values obtained by the use of PLATON [25] applied to cif data extracted from the Cambridge Structural Database [26] at the Chemical Database Service of the EPSRC at Daresbury [27] with the atomic coordinates unchanged but with the atoms relabelled for conformity with the new structures presented here.

Complexes **1** and **3** are, in all cases, ionic species exhibiting only electrostatic cation–anion interactions.

The cations have their usual geometries and are not discussed further. The V-shape (Table 2) of the anions in **1** and **3** is shown, along with the numbering scheme used, in Fig. 2. The bond lengths and angles within dmit, in **1**, and dmio, in **3**, vary little from complex to complex. The central C=C bond of each of the ligands and its attached S constitutes a planar entity with Sb and the C=O or C=S atoms displaced from this plane by varying amounts as shown in Table 2. In all complexes each of the two chelating dmit–dmio ligands is asymmetrically bound to Sb (Table 3) with shorter and longer Sb–S bond lengths in the range 2.4679(18)–2.527(3) and 2.529(3)–2.7311(6) Å, respectively, both of which can be compared with the PLATON [25] estimate of the sum of the covalent radii of Sb and S of 2.48 Å. As indicated in the Introduction, the complex, $[NEt_4][Sb(1,2\text{-}S_2C_6H_4)_2]$, has been reported [7] to have non-interacting anions and have a pseudo 5-coordinate Sb centre, if one coordination site is assumed to be occupied by the antimony lone pair. The dithiolato ligands in $[NEt_4][Sb(1,2\text{-}S_2C_6H_4)_2]$ [7] are also asymmetrically bonded to Sb, with Sb–S bond lengths of 2.4400(7) and 2.6093(7), in one chelate, and 2.4450(7) and 2.6266(8) Å, in the other and are, therefore, comparable with those in **1** and **3**.

In all of the complexes **1** and **3** antimony also forms two weaker bonds to chalcogen atoms of neighbouring anions with Sb–S and Sb–O, in the range 3.271(4)–3.4968(16) and 3.131(5)–3.285(3) Å respectively (cf. PLATON [25] estimates of sums of van der Waals radii for Sb and S and Sb and O and of covalent radii of Sb

and O of 4.06, 3.78 and 2.14 Å, respectively). These link the anions into 2D sheets or chains and in some cases, along with S···S or S···O contacts shorter than the sum of van der Waals radii (3.60 or 3.32 Å, respectively), into 3D networks in a manner described in more detail below.

In all of the structures discussed here, the anions are confined to layers whose orientation is indicated compound by compound in Table 3 and which are stacked alternating with parallel layers of counter cations. The simplest case, the anion layer in isostructural (**1** and **3**: Q = NEt_4), is clearly evident in Fig. 3(a). Here the disposition of the anions is entirely due to the C-centred nature of the unit cell so that all the anions within a single layer at $z = 1/4$ or 3/4 point in the same direction along b. Adjacent anion layers are then related to one another by crystallographic centres of symmetry or equivalently by the operation of the c-glide of the space group $C2/c$, thus inverting the orientation of the anions from one layer to the next. Contacts between anion layers as S3···S5^{i} (i: $1/2-x$, $1/2-y$, $-z$) at 3.556(5) Å in (**1**: Q = NEt_4) and S3···S1^{i} (i: $-x$, $-y$, $1-z$) and S3···O1^{ii} (ii: $-1/2-x$, $-1/2-y$, $1-z$) at 3.550(3) and 3.317(5) Å, respectively, in (**3**: Q = NEt_4) complete the connectivity.

In all of the other compounds discussed in this paper the secondary Sb–S and Sb–O bonds interconnect the anions to form chains. This is brought about in two stages leading to three different situations (Fig. 3(b–d), Tables 3 and 4). In the first stage one atom, X′ in Table 3, i.e. a symmetry related equivalent of thione S5 in (**1**: Q = NBu_4, $AsPh_4$, PPh_4 and DMP) or of thiolato S2 in (**3**: Q = DMP), bonds to Sb to form a centrosymmetric dimer in which inevitably a pair of parallel and head to tail ligands overlap to a greater or lesser extent (ring pairs a–a′ in Table 4). The second stage involves further contacts, Sb–X″ where X″ (Table 3) is a second and different symmetry related eqivalent, relative to the original Sb, of the same thione S5 as before for (**1**: Q = NBu_4, $AsPh_4$ and PPh_4), or symmetry equivalent thione S, S10, or one-O, O1, in (**1**: Q = DMP) [2] or (**3**: Q = DMP), respectively. These connect the anions in (**1**: Q = NBu_4, $AsPh_4$ and PPh_4) (Fig. 3(b)) and (**3**: Q = DMP) (Fig. 3(c)), to form linear double chains in which the face to face ligands, including their chelate function, are now μ^3 bridging species while the other ligands, protruding on either side of the spine of the double

[e] Form of plane parallel to anion (and cation) layers.

chain, are purely chelating. In (**1**: Q = DMP) [2], on the other hand, the secondary Sb–S10 bond, which was overlooked in the original report of this structure, creates a chain in the form of a succession of loops, Fig. 3(d), and both ligands are now μ^2 bridges while still chelating.

In the case of (**1**: Q = $AsPh_4$) and (**1**: Q = PPh_4) [3], which are isostructural despite the different labelling of the cell edges, there is no significant contact between the linear chains within or between the layers and adjacent layers being related to one another purely by cell translation are all identical. In (**1**: Q = NBu_4), which is isostructural with (**2**: Q = NBu_4) [4], there is likewise no significant contact between the chains but adjacent anion layers are now related by the operation of the *n*-glide of the space group $P2_1/n$. In (**1**: Q = DMP) [2], there is no significant contact between the anion layers, once again related by cell translation and, therefore, all identical, where the looped chains are opposed face to face but within the layers edge to edge contacts between the chains as S5···$S5_i$ (*i*: $1-x, 3-y, 2-z$) and S5···$S9^{ii}$ (ii: $1+x, 1+y, z$) at 3.387(4) and 3.544(4)Å, respectively, are found (Fig. 3(d)). Also present here between the chains within the layer is limited overlap of centrosymmetrically related pairs of loop forming ligands comprising C4–C6 and S6–S10 (ring pair b–b′

Table 4
Ring overlaps in terms of PLATON [25] π–π interaction parameters (Å, °) and lateral displacements, O

	Ring pair [a] [symmetry operation]	A	α	β	β'	B	B'	O [b]
(**1**: Q = NBu_4)	a–a′ [vii]	3.534	0	12.80	12.80	3.447	3.447	0.779
(**1**: Q = $AsPh_4$)	a–a′ [viii]	3.512	0	13.37	13.37	3.417	3.417	0.811
(**1**: Q = PPh_4) [c]	a–a′ [x]	3.541	0	13.02	13.02	3.450	3.450	0.798
(**1**: Q = DMP)	a–a′ [xii]	4.245	0	33.50	33.50	3.540	3.540	2.359
	b–b′ [xiii]	5.571	0	48.99	48.99	3.654	3.654	4.205

	d–d′ [x]	4.960	0	51.73	51.73	3.072	3.072	3.894
	e–e′ [vii]	4.068	0	40.14	40.14	3.110	3.110	2.622

[a] Rings defined as: (a) C1, C2, S4, C3, S3; (b) C4, C5, S7, C6, S6; (c) the DMP ring; (d) C4, C5, S8, C6, S7; (e) Sb, S1, C1, C2, S2. Symmetry operations as in Table 3, plus: xiii: $-x, 1-y, 1-z$; xiv: $1-x, 2-y, 1-z$; xv: $2-x, 1-y, -z$.

[b] Calculated as $(A^2-B^2)^{1/2}$ for all except in (1: Q = DMP) for the a–c′ overlap, which was calculated as $[A^2-(B+B')^2/4]^{1/2}$. The overlap of rings x and y with centroids Cg_x and Cg_y and points F_x (or F_y) defined as the foot of the perpendicular from Cg_x (or Cg_y) to the plane of ring y (or x) is defined in the manner used by PLATON [25] in terms of the following: distances Cg_x–Cg_y (A); Cg_x–F_x (B) and Cg_y–F_y (B') and angles between the ring planes (α); Cg_y–Cg_x–F_x (β) and Cg_x–Cg_y–F_y (β'). If the rings are related to one another by the operation of a crystallographic centre of symmetry they are by definition parallel to one another and hence $\alpha = 0$, $\beta = \beta'$ and $B = B'$.

[c] Ref. [3].

[d] Ref. [2].

in Table 4). More significant is π–π overlap between the DMP counter cation and the dimer forming ligand (ring pair a–c′ in Table 4). In (**3**: Q = DMP) there is yet again no significant contact between chains within or between layers. However, in this case the use of thiolato S2 in dimer formation promotes overlaps d–d′ and e–e′ (Table 4) within the essentially linear double chains.

3.3. Geometry at Sb

In all of the complexes **1** and **3**, Sb forms six bonds in two groups as four strong intra- and two weaker inter-anion bonds. Inclusion of the Sb lone pair results in pseudo seven-coordinate geometry probably pentagonal bipyramidal in form (see reference [28]). In contrast, the antimony geometry in $[NEt_4][Sb(1,2\text{-}S_2C_6H_4)_2]$ is reported to be pseudo trigonal bipyramidal [7]. The site of the lone pair in compounds (**1**: Q = NBu_4 or $AsPh_4$) is assumed to be as shown in Fig. 4(b) and is exactly the same, allowing for the changed atom numbering scheme, as that previously reported for (**1**: Q = PPh_4) [3]. In all three complexes, the lone pairs on centrosymmetrically related Sb atoms are directed away from one another on opposite sides of the centrosymmetric Sb_2S_2 rings and are in equatorial sites between S5′ and S7. The S5′–Sb–S7 angles [X″–Sb–S(D) in Table 3] are less than twice the ideal ligand–M–ligand angle of 72° but are perceived as sufficiently large [$>126.70(4)°$] to accommodate the lone pair. The axial atoms are S5″ and S6 with angles at Sb [X′–Sb–S(C)] of 168.58(5)°, 179.409(19)° and 178.9(2)°, respectively.

The situation in (**3**: Q = DMP) is similar with the lone pair between O1′ and S6 (Fig. 4(d)). The angle O1′–Sb–S6 is only 119.47(14)° but still regarded as large enough to accommodate the lone pair. The axial atoms are now S2′ and S5 making an angle of 165.56(8)° at Sb which also shows a greater departure from the ideal than the corresponding angles in the previous cases.

The location of the lone pair in isostructural (**1** and **3**: Q = NEt_4) is not so simply or obviously determined. In the earlier report on the structure of (**1**: Q = NEt_4) [2], it was considered to be in an equatorial site between the two Sb–S5 inter-anion bonds, i.e. directed along the crystallographic twofold axis (Fig. 4(a)). It then bisects an angle of only 103.54(13)° which appears extremely small to accommodate it. However, the estimate of this angle has been increased by positing [2] an increase to that of ϕ (Fig. 5), which is achieved if the inter-anion bonds from Sb are directed toward p-orbitals on S (or O) rather than directly toward the atoms. The equivalent bond angle in (**3**: Q = NEt_4) is still less at 100.6(2)° but the same argument regarding the use of ϕ applies here also. The difference between ϕ and the X–Sb–X bond angle (X = S5 or O1) for the same orbitals increases as the Sb–X bond lengths decrease and the inter-anion bonds Sb–S5 and Sb–O1 are the shortest of all inter-anion bonds found in **1** and **3**. Thus the impact of considering orbital overlap rather than direct atom to atom vectors to determine bond direction and hence bond angles will be greatest for these two complexes. With the lone pairs in equatorial sites directed along the twofold axis as just described the axial sites are then occupied by S2 atoms which form the longest intra-anion bonds in these complexes which is appropriate for their perceived axial status. The angle they form, while only about 158°, is, however, the largest subtended at Sb.

Bearing in mind the twofold axial symmetry of these last two complexes, alternative dispositions of the lone pair can also be envisaged. In (**3**: Q = NEt_4) the bond

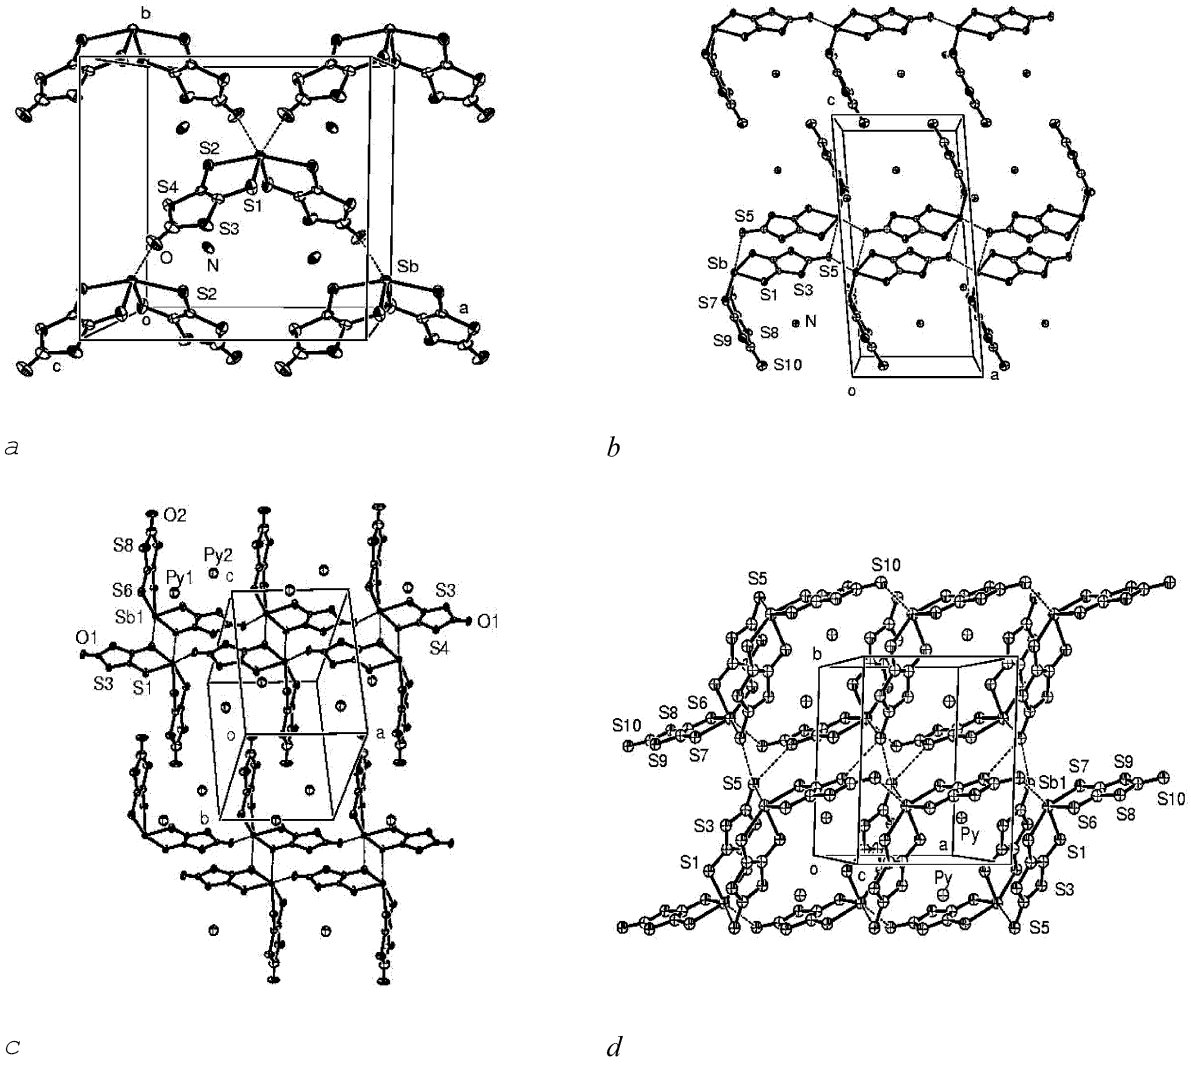

Fig. 3. Anion layers in (a) (**3**: Q = NEt_4], (b) (**1**: Q = NBu_4), (c) (**3**: Q = DMP) and (d) (**1**: Q = DMP) [2]. In all cases only selected atoms are labelled and in a generic manner i.e. lacking symmetry relationships which are instead given in Table 3. Cations are crudely represented either by N or for DMP by the centroid. Atoms are shown as 50% ellipsoids [isotropic atoms for (**1**: Q = DMP)] and the cell edges are labelled. Dashed lines represent Sb–X (X = thione S or one-O) bonds or, in (d), S···S contacts.

angles O1′–Sb1–S2 = O1″–Sb1–S2′ = 128.96(11)°, associated with axial pairs O1″–S1 and O1′–S1′ with *trans*-axial angle 147.36(10)°, are sufficiently large to accommodate the lone pair more easily. If the lone pair occupies only one of these sites the axial symmetry is destroyed but, if the lone pair on Sb occupied an orbital of *d*-type character, it would no longer concentrate electron density towards a single notional coordination site. A similar situation obtains for (**1**: Q = NEt_4) and, see below, (**1**: Q = DMP). Dispersal or smearing out of the lone pair electron density in this way is also consistant with the comparatively short inter-anion Sb–X bonds observed in these complexes.

While crystallographic symmetry does not apply in the case of the remaining complex (**1**: Q = DMP) the atom pairs S1–S6, S2–S7 and S5′–S10′ approximate twofold axial symmetry in their disposition (Fig. 4(c)). On this basis the situation in (**1**: Q = DMP) with angles S10′–Sb–S5′ [103.4(2)°], S2–Sb–S7 [159.5(2)°], S10′–Sb–S7 [121.8(2)°] and S5′–Sb–S2 [123.2(2)°] relates to that in (**3**: Q = NEt_4) and (**1**: Q = NEt_4) with corresponding angles of similar magnitude.

4. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC numbers 174409–174412. Copies of this information may be obtained free of charge from

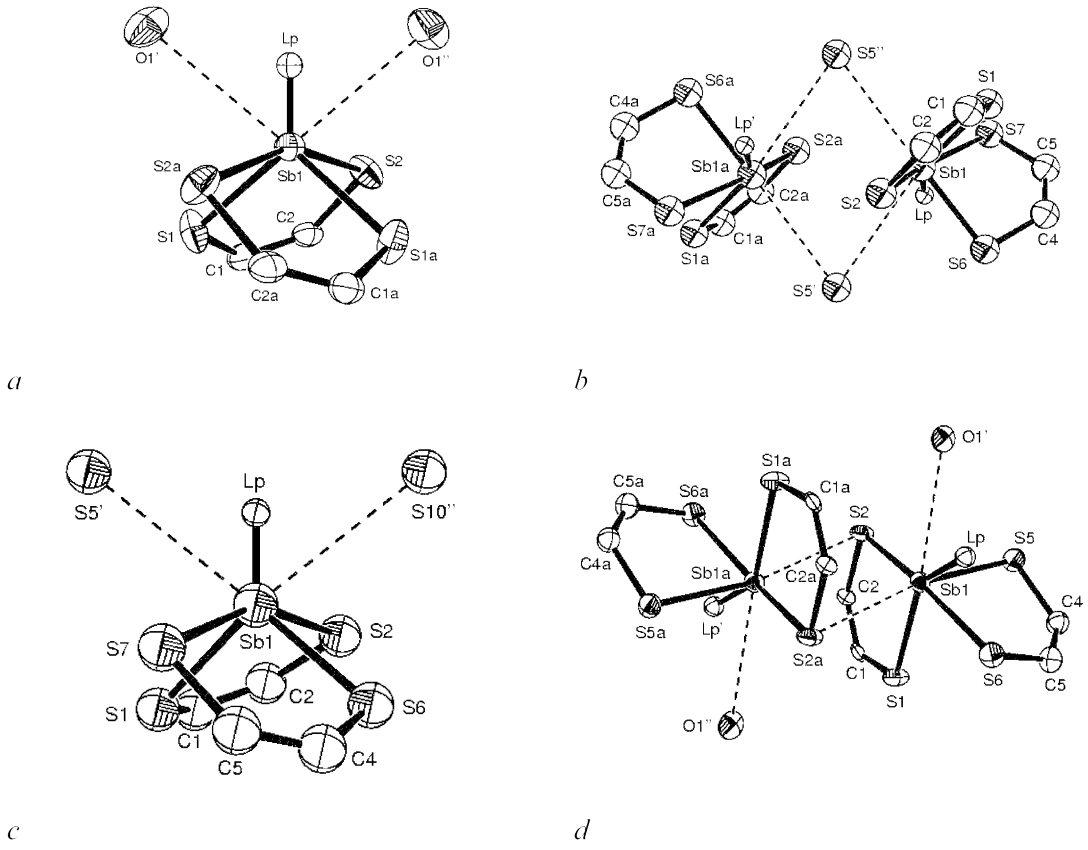

Fig. 4. Representations of the co-ordination of Sb including the stereochemically active lone pair (Lp and where appropriate the centrosymmetrically related Lp′) in (a) (**1**: Q = NEt_4) and (**3**: Q = NEt_4); (b) (**1**: Q = NBu_4, PPh_4 or $AsPh_4$) [the example shown is (**1**: Q = PPh_4)]; (c) (**1**: Q = DMP) and (d) (**3**: Q = DMP). In (a), (b) and (d) the suffix 'a' marks atoms related by symmetry to atoms without suffix. For clarity the ligands providing the primary coordination of Sb are indicated only in terms of the 5-membered chelate rings thus formed.

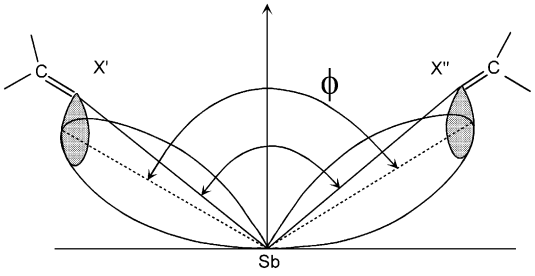

Fig. 5. Comparison of the angle, ϕ, from overlap of Sb and S (or O) orbitals with the S–Sb–S (or O–Sb–O) bond angle.

thetic procedures to clusters of middle and late 3d metals in moderate oxidation states with interesting structural and magnetic properties. One of our routes takes advantage of the observation that the 1:1 reactions between metal(II) β-diketonates and benzotriazole (btaH, **I**) or ring-substituted (with non-donor groups) benzotriazoles (RbtaH) lead to incomplete replacement of the β-diketonato ligands by the deprotonated benzotriazoles and large heteroleptic 3d metal cages. Restricting further discussion to nickel(II) chemistry, the systematic investigation of the [Ni(β-diketonate)$_2$L$_2$]–RbtaH reaction mixtures has led to three families of polynuclear complexes: [Ni$_5$(OH)(acac)$_4$(Rbta)$_5$(H$_2$O)$_4$] [18,19], [Ni$_5$(dbm)$_4$(Rbta)$_6$(Me$_2$CO)$_4$] [20] and [Ni$_9$(bzac)$_6$(Rbta)$_{12}$(MeOH)$_6$] [20] (L = H$_2$O, EtOH; acacH = acetylacetone; bzacH = benzoylacetone; dbmH = dibenzoylmethane; RbtaH = 5-methyl-, 6-methyl-, 5,6-dimethyl- and 5-chlorobenzotriazole, or benzotriazole). The families of the Ni$_5$(OH), Ni$_5$ and Ni$_9$ clusters possess the intermediate-spin ground states [$S = 0$, $S = 1$], [$S = 1$, $S = 2$] and [$S = 2$, $S = 3$], respectively. Thus, the benzotriazolate ligands are important players in the field of polynuclear transition metal chemistry.

However, the main reason for which several groups [21–27], involving our group [28–31], have been exploring the coordination chemistry of btaH over the last 25 years is the anticorrosion action of this compound and its benzene ring-substituted derivatives toward certain metals, particularly copper and its alloys [32–37]. Inorganic chemists study the chemical, physical and structural properties of model complexes to probe several aspects of corrosion inhibitors, to understand the complicated surface chemistry that leads to corrosion inhibition and to create new inhibitors more efficient than btaH.

btaH, I

btaOH, II

More recently [38–40], our efforts have turned towards the use of benzotriazoles, substituted on the azole ring with donor groups, to see how incorporation of this ligand type might affect the structures and physical properties of the products. The first ligand employed was 1-hydroxybenzotriazole (btaOH, **II**), a well-known peptide-coupling additive [41], which exhibits corrosion inhibitive properties toward Cu [42,43] and Fe [44]. The synthetic investigation of the [Cu$_2$(O$_2$CMe)$_4$(H$_2$O)$_2$]–btaOH reaction system in MeOH resulted in the isolation of the three-dimensional (3D), diamond-like coordination polymer [Cu(btaO)$_2$(MeOH)]$_n$ (**1**), which is a soft magnet exhibiting two critical temperatures at 6.4 and 4.4 K [38]. Later [39], the reaction of Ni(NO$_3$)$_2$·6H$_2$O with btaOH in aqueous NH$_3$–DMF yielded the trinuclear complex [Ni$_3$(btaO)$_6$(NH$_3$)$_6$] (**2**). Reaction of zerovalent manganese with btaOH and NH$_4$SCN in DMF has recently allowed the isolation of the one-dimensional (1D) polymer [Mn$_3$(btaO)$_2$(SCN)$_4$(DMF)$_8$]$_n$ (**3**) [40].

The flexibility of the 1-hydroxybenzotriazolate ligand (btaO$^-$) observed in the structures of **1**–**3** prompted us to explore further the coordination properties of this anionic ligand with the goal of isolating large clusters. It seemed logical to us that a good starting point of our efforts would be the synthetic investigation of the [Ni(β-diketonate)$_2$L$_2$]–btaOH reaction systems; analogous reaction systems, involving RbtaHs instead of btaOH, had led to the synthesis of the penta- and nonanuclear heteroleptic nickel(II) clusters mentioned above. Here we report the preparation, spectroscopic characterization, X-ray crystal structure and magnetic properties of the structurally novel heptanuclear complex [Ni$_7$(OH)$_2$(acac)$_8$(btaO)$_4$(H$_2$O)$_2$]·MeCN·0.9H$_2$O (**4**·MeCN·0.9H$_2$O), which is the product from the [Ni(acac)$_2$(H$_2$O)$_2$]–btaOH reaction mixture in MeCN.

2. Experimental

2.1. General and physical measurements

All manipulations were performed under aerobic conditions using materials (reagent grade) and solvents as received. Compound [Ni(acac)$_2$(H$_2$O)$_2$] was prepared as described elsewhere [45].

Microanalyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Service using an EA 1108 Carlo Erba analyzer. Nickel analysis was carried out by EDTA titration. IR spectra (4000–500 cm^{-1}) were recorded on a Perkin–Elmer 16 PC FT spectrometer with samples prepared as KBr pellets. Solid-state (diffuse reflectance, 800–300 nm) electronic spectra were recorded on a Varian, Cary 3 instrument. Magnetic susceptibility measurements were carried out on a polycrystalline sample of **4**·H$_2$O in the 300–3 K temperature range using a Quantum Design SQUID susceptometer. The applied magnetic field was 1000 G. The experimental magnetic susceptibilities were corrected for the diamagnetic response using Pascal's constants. The solid-state EPR spectrum of the complex at 4 K was recorded on a Bruker ER 200D-SRC X-band spectrometer, equipped with an Oxford ESR 9 cryostat.

Safety note: Benzotriazoles and benzotriazolate complexes are potentially explosive, and caution should be exercised in handling such compounds. However, the small quantities used in this study were not found to present a hazard.

2.2. Preparation of $[Ni_7(OH)_2(acac)_8(btaO)_4(H_2O)_2]\cdot MeCN\cdot 0.9H_2O$ ($\mathbf{4}\cdot MeCN\cdot 0.9H_2O$)

Solid btaOH·H_2O (0.11 g, 0.7 mmol) was dissolved with stirring in a pale green solution of [Ni(acac)$_2$(H_2O)$_2$] (0.50 g, 1.7 mmol) in MeCN (20 ml) under reflux. The reflux was continued for a further 30 min after dissolution. The resulting deep green solution was layered with an 1:1 mixture (25 ml) of *n*-hexane and Et_2O. Slow mixing yielded light green–blue crystals (some of them were of X-ray quality), which were collected by filtration, washed with cold MeCN and Et_2O, and dried in air. Yields as high as 75% were obtained. The crystals were found to lose solvent readily, and they were kept in the mother liquor until a suitable crystal had been found for X-ray crystallography. The latter established the formulation $\mathbf{4}\cdot MeCN\cdot 0.9H_2O$; the dried analysis sample analyzed for $\mathbf{4}\cdot H_2O$. *Anal.* Found: C, 42.2; H, 4.3; N, 9.3; Ni, 23.2. Calc. for $C_{64}H_{80}N_{12}O_{25}Ni_7$: C, 42.0; H, 4.4; N, 9.2; Ni, 22.5%. IR data (KBr pellet, cm^{-1}): 3390mb, 3074w, 2996w, 2920w, 1598s, 1518s, 1454m, 1398sb, 1262s, 1198m, 1166m, 1140w, 1116m, 1018s, 928s, 852w, 766m, 746s, 670w, 646w, 614sh, 584m, 540sh. Solid-state (diffuse reflectance) electronic spectral data (λ_{max}, nm): 690, 400.

2.3. X-ray crystallography

A light green–blue crystal of $\mathbf{4}\cdot MeCN\cdot 0.9H_2O$ was mounted in a capillary filled with drops of mother liquid. Diffraction measurements were made on a $P2_1$ Nicolet diffractometer upgraded by Crystal Logic using Ni-filtered Cu radiation. Complete crystal data and parameters for data collection and processing are reported in Table 1. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centred reflections in the range $24° < 2\theta < 54°$. Three standard reflections, monitored every 97 reflections, showed less than 3% intensity fluctuation and no decay. Lorentz, polarization and Ψ-scan absorption corrections were applied using CRYSTAL LOGIC software.

The structure was solved by direct methods using SHELXS-86 [46] and refined by full-matrix least-squares techniques on F^2 with SHELXL-93 [47]. Hydrogen atoms of C(42), C(52) and C(62) of the acac$^-$ ligands were located by difference maps and refined with isotropic thermal parameters. The hydrogen atoms on the hydroxo and aqua ligands were located by difference maps and refined in fixed positions. All the rest hydrogen atoms were introduced at calculated positions as riding on bonded atoms. All non-hydrogen atoms were refined anisotropically, except those of the solvent H_2O molecules which were refined isotropically with occupation factors fixed at 0.30.

3. Results and discussion

3.1. Synthesis

The preparation of compound $\mathbf{4}\cdot MeCN\cdot 0.9H_2O$ was achieved via the reaction of [Ni(acac)$_2$(H_2O)$_2$] with btaOH·H_2O in MeCN under reflux. The preparation is summarized in Eq. (1).

$$7[Ni(acac)_2(H_2O)_2] + 4\ btaOH\cdot H_2O + MeCN \xrightarrow[T]{MeCN} \underset{\mathbf{4}\cdot MeCN\cdot 0.9H_2O}{[Ni_7(OH)_2(acac)8(btaO)4(H_2O)_2]\cdot MeCN\cdot 0.9H_2O} + 6\ acacH + 13.1\ H_2O \quad (1)$$

Obviously btaOH is deprotonated by the basic acac$^-$ groups. The excess of [Ni(acac)$_2$(H_2O)$_2$] used in the reaction leaves an amount of nonprotonated acac$^-$ in the mixture and the heptanuclear cluster results from the acac$^-$–btaO$^-$ ligand 'blend'.

The exact metal to ligand molar ratio does not affect the identity of the product in MeCN provided that the

acac$^-$ to btaOH ratio is large; thus complex **4**·MeCN·0.9H_2O is the only product from the 4:1 and 3:1 reactions between [Ni(acac)$_2$(H_2O)$_2$] and btaOH·H_2O in MeCN.

The same product can be isolated from Me_2CO. The 7:4 reaction of [Ni(acac)$_2$(H_2O)$_2$] and btaOH·H_2O in refluxing Me_2CO results in a blue–green solid which, on the basis of microanalytical, IR and UV–Vis data, appears to be [$Ni_7(OH)_2(acac)_8(btaO)_4(H_2O)_2$]·$H_2O$ (**4**·H_2O).

Temperature is a particularly important synthetic parameter for the isolation of **4**. If the reaction mixtures in MeCN or Me_2CO are not refluxed, they yield non-hydroxo species with non-reproducible analytical results.

Complex **4** is moderately soluble in MeOH under heating, but it is readily soluble in DMF and DMSO.

3.2. IR and UV–Vis spectra

In the IR spectrum, the heptanuclear cluster exhibits a broad band of medium intensity at 3390 cm^{-1} assignable [48] to $\nu(OH)_{OH^-H_2O}$. The broadness and relatively low frequency of this band are both indicative of strong hydrogen bonding. A series of four bands is found in the 1600–1390 cm^{-1} region. Contributions from benzotriazolate ν(C=C) and ν(C=N) vibrations would be expected in this region [19], but overlap with the $\nu(C{=}C)_{acac^-}$, $\nu(C{=}O)_{acac^-}$, $\delta(CH)_{acac^-}$ and $\delta_d(CH_3)$ bands [48] renders assignments difficult. The strong band at 1018 cm^{-1} is assigned to the $\rho_r(CH_3)$ mode of the acac$^-$ ligands [48]. The bands in the 1200–1100 cm^{-1} are associated with the ν_{as}(N···N···N), ν_s(N···N···N) and ν(N–O) modes of vibration [26,38–40] but detailed assignments seem impossible. Most probably the band at 1166 cm^{-1} is due to ν(N–O) [38–40]. This band is shifted to lower wavenumbers in **4** compared with its frequency (1224 cm^{-1}) in the IR spectrum of potassium salt of 1-hydroxybenzotriazolate, btaOK. Such a large shift to lower frequencies was also observed [38,40] in the spectra of **1** and **3**, where the deprotonated oxygen is a donor atom.

The solid-state UV–Vis spectrum of **4** exhibits d–d maxima typical [49] of octahedral nickel(II). The bands at 690 and 400 nm are assigned to the spin-allowed transitions $^3A_{2g}\rightarrow{}^3T_{1g}$(F) and $^3A_{2g}\rightarrow{}^3T_{1g}$(P), respectively, under O_h symmetry. The wavelengths are in accord with Ni(II) chromophores rich in O-donors [49].

3.3. Description of structure

A plot of the molecular structure of **4**·MeCN·0.9H_2O is shown in Fig. 1 and selected interatomic distances and angles are collected in Table 2.

The complex crystallizes with a pseudo twofold axis passing through Ni(1) and the middle of the Ni(2)···Ni(3) distance. The heptanuclear assembly is held together by two μ_3-OH$^-$ ions [O(2), O(3)], two terminal H_2O molecules, two η^2:η^1:η^1:μ_4-btaO$^-$ ligands (or 4.211 using Harris notation [50]), two η^1:η^1:μ_2-btaO$^-$ ligands (or 2.011 using Harris notation [50]) which use only their nitrogen atoms for coordination, four chelating η^2-acac$^-$ groups (or 1.11), two η^1:η^2:μ_2-acac$^-$ groups (or 2.21) and two η^2:η^2:μ_3-acac$^-$ groups (or 3.22). According to Harris notation, the binding mode of a ligand is referred to as $X.\ Y_1Y_2Y_3\ldots Y_n$, where X is the overall number of metals bound by the whole ligand and each value of Y refers to the number of metal ions attached to the different donor atoms. The ordering of Y is listed by the Cahn–Ingold–Prelog priority rules, hence here O before N. Therefore, for the 1-hydroxybenzotriazolate ligands of **4**·MeCN·0.9H_2O there will be three values of Y, as there are three donor atoms. Similarly for the acetylacetonate ligands there will be two values of Y, as there are two donor atoms. The notation for the hydroxo and aqua ligands includes one Y value. The seven bonding modes of the ligands, and the Harris notation to describe these modes, are given in Fig. 2.

The btaO$^-$ ligands binding with the 4.211 mode are those involving O(11) and O(21), and they bridge the tetrads Ni(1), Ni(3), Ni(4), Ni(6) and Ni(1), Ni(2), Ni(5), Ni(7), respectively. The btaO$^-$ ligands binding with the 2.011 mode are those involving O(1) and O(31), and they bridge the pairs Ni(2), Ni(4) and Ni(3), Ni(5), respectively. The four chelating acac$^-$ groups are those involving the oxygen atoms O(41), O(42)/O(43), O(44)/O(47), O(48)/O(53), O(54) and they are parts of the coordination spheres of Ni(2), Ni(6), Ni(3) and Ni(7), respectively. The two μ_2 (2.21) acac$^-$ ligands involve the oxygen atoms O(51), O(52)/O(55), O(56) and they bridge the Ni(4), Ni(6)/Ni(5), Ni(7) pairs through O(51) and O(56), respectively. The two acac$^-$ ligands adopting the 3.22 mode are those containing the oxygen atoms O(45), O(46)/O(49), O(50) and they bridge the Ni(1), Ni(4), Ni(6) and Ni(1), Ni(5), Ni(7) triads, respectively. The hydroxo ligands bridge the triads Ni(1), Ni(2), Ni(4) and Ni(1), Ni(3), Ni(5). Thus, the central metal ion of the cluster [Ni(1)] is attached exclusively to six bridging oxygen atoms [O(2), O(3), O(46), O(49), O(11), O(21)].

All terminal, i.e. chelating, acetylacetonate ligands form short Ni–O bonds, with a range of 1.969(9)–2.013(7) Å. For the μ_2 acac$^-$ ligands, the bridging Ni–O bonds [2.036(7)–2.104(6) Å] are longer than the terminal ones [1.988(8) and 2.004(7) Å]. Each of the acac$^-$ ligands adopting the 3.22 mode forms three relatively short Ni–O bonds [2.039(7)–2.084(6) Å], whereas one bridging atom [O(45), O(50)] forms a long bond [2.213(6) and 2.230(7) Å, respectively] to the non-chelated Ni(II) atom [Ni(6) and Ni(7), respectively]. The Ni–O bonds to the bridging hydroxides [average value:

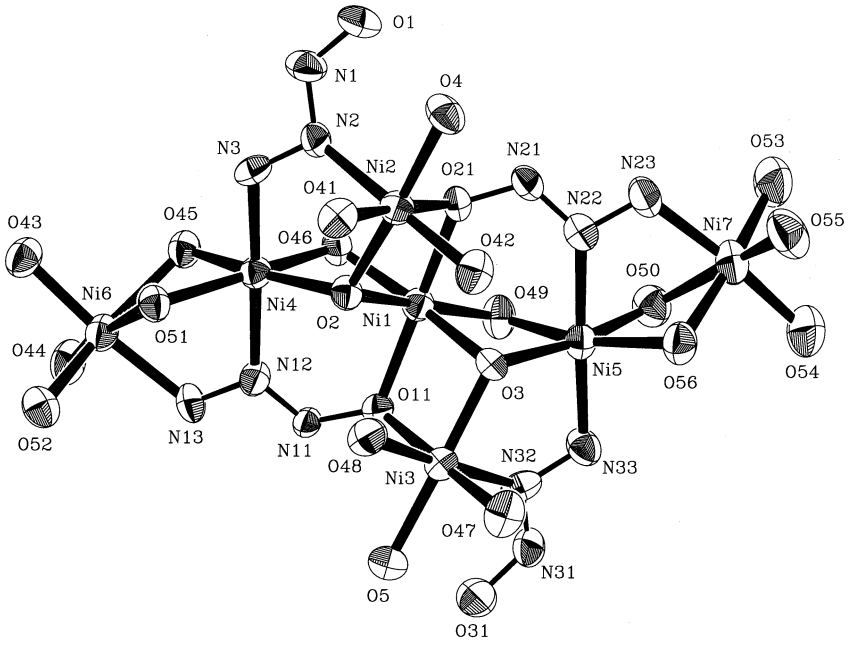

Fig. 1. ORTEP view of **4**·MeCN·0.9H_2O with 50% thermal ellipsoids showing the atom labeling scheme. To avoid congestion, all carbon atoms and the solvate molecules have been omitted. Atoms O(1), O(11), O(21) and O(31) belong to the deprotonated 1-hydroxybenzotriazolate (btaO$^-$ ligands). Atoms O(2) and O(3) belong to the hydroxo ligands, while the coordinated water oxygen atoms are O(4) and O(5). Each of the pairs O(41), O(42)/O(43), O(44)/O(45), O(46)/O(47), O(48)/O(49), O(50)/O(51), O(52)/O(53), O(54)/O(55), O(56) belongs to a different acac$^-$ ligand.

2.033(6) Å] are slightly shorter than those to the terminal aqua ligands [average value: 2.066(7) Å]. The four Ni–$N_{\mu_4\text{-btaO}-}$ bond lengths [2.076(8)–2.097(8) Å] are almost equal, while each μ_2 btaO$^-$ ion forms one strong [2.026(8) and 2.035(9) Å] and one weaker [2.157(8) and 2.171(8) Å] bond to the Ni(II) atoms. The Ni–N distances are generally within the normal range observed for other structurally characterized nickel(II)-benzotriazolate complexes [19,20,39].

The metal centres have distorted octahedral geometries; the chromophores are NiO_6 for Ni(1), NiO_5N for Ni(2), Ni(3), Ni(6) and Ni(7) and *trans*-NiO_4N_2 for Ni(4) and Ni(5).

The crystal structure is stabilized by a strong, intermolecular hydrogen bond involving one coordinated H_2O molecule [O(4)] as donor and the deprotonated 1-hydroxybenzotriazolate oxygen O(31) as acceptor (Table 3). There are also intramolecular hydrogen bonds (Table 3). Of particular interest are the two very strong hydrogen bonds with the coordinated H_2O oxygens O(4) and O(5) as donors and the deprotonated 1-hydroxybenzotriazolate oxygens O(1) and O(31), respectively, as acceptors.

Complex **4** is only the second structurally characterized Ni(II) complex comprising three different types of acac$^-$-ligation, the first example being the well-known trinuclear species $[Ni_3(acac)_6]$ [51].

Complex **4** joins a small family [52–57] of structurally characterized, discrete heptanuclear Ni(II) clusters with O- and/or N-ligation.

The structures displayed by the 3d-metal heptanuclear complexes containing N- or O-donors are mostly irregular [11]. There are a number of 'metallacrowns' [53,58–63], vertex-sharing double cubanes [64–67], oxo-centred vertex-sharing bitetrahedra [68,69], one example where two Mn_4O_2 butterfly units are fused together by sharing of one wing-tip Mn(III) atom [70] and three examples from cobalt chemistry [11] where the metal core can be derived from a square-based pyramid, capped on one edge of the square base and on the neighboring triangular face by two further Co(II) atoms. However, many other heptanuclear compounds [11,71–74] have no easily describable core. Complex **4** is no exception; the seven Ni(II) atoms do not seem to define any established topology.

3.4. Magnetochemistry

The magnetic susceptibility of **4**·H_2O was measured in the 3.0–300 K temperature range. The $\chi_M T$ product (χ_M is the corrected molar magnetic susceptibility per heptamer) decreases from a value of 7.28 $cm^3\ mol^{-1}$ K at 300 K to a value of 2.1 $cm^3\ mol^{-1}$ K at 3.0 K (Fig. 3). The spin-only value for seven uncoupled Ni(II) atoms is 7.66 $cm^3\ mol^{-1}$ K for $g = 2.1$ (this g value is reasonable for polynuclear Ni(II) species [52,75]), close to the experimental value at r.t.

Complex **4** has not any crystallographic symmetry; therefore, in principle, for this cluster there are a large number of independent exchange interactions. This

would lead to the fit being vastly over-parameterized in any computational model. Therefore, we decided to attempt to fit the data using the simplest possible coupling scheme. The best simple model to fit the susceptibility data is a 3-J model. The magnetic model that was used is shown graphically in Fig. 4. Only the monoatomic O bridges (derived from the OH^-, $acac^-$ and $btaO^-$ ligands) have been taken into consideration for more effective coupling, and the exchange interactions are defined mainly according to the Ni–O–Ni angle and the distance between the Ni(II) atoms. Exchange interactions for distances more than 4 Å were excluded. The corresponding zero-field Hamiltonian is given in Eq. (2).

$$H = -2J_1[S_1(S_3 + S_2) + S_7S_5 + S_4S_6] - 2J_2[S_1(S_5 + S_4)] - 2J_3(S_2S_4 + S_3S_5) \quad (2)$$

Due to the low symmetry of the cluster, an efficient procedure [76] was applied using irreducible tensor operators and point symmetry classification of the functions. Following this procedure the exchange matrix, initially of size 2187×2187, is formed by S-block matrices with a maximum size of 105×105. By fixing the value of g to 2.0, the fitting parameters are $J_1 = 0.45$ cm^{-1}, $J_2 = 11.0$ cm^{-1} and $J_3 = -13.7$ cm^{-1}. The theoretical curve is shown in Fig. 3 as a solid line. Table 4 gives selected bond lengths and angles according to Fig. 4.

When we considered a 4-J model using the Hamiltonian given in Eq. (3)

$$H = -2J_1[S_1(S_3 + S_2)] - 2J_2[S_1(S_5 + S_4)] - 2J_3(S_2S_4 + S_3S_5) - 2J_4(S_7S_5 + S_4S_6) \quad (3)$$

no improvement of the fit was succeeded and the values of the J_1, J_4 parameters were almost equal ($J_1 \approx J_4$). For the same reason we did not use zero-field terms in the Hamiltonian, although it seems that they play an important role in the low-temperature limit.

The obtained J values are in agreement with magnetostructural correlations found in nickel(II) clusters [19,77–81]. The negative (antiferromagnetic) value of J_3 is explained by the fact that both Ni(2)–O(2)–Ni(4)

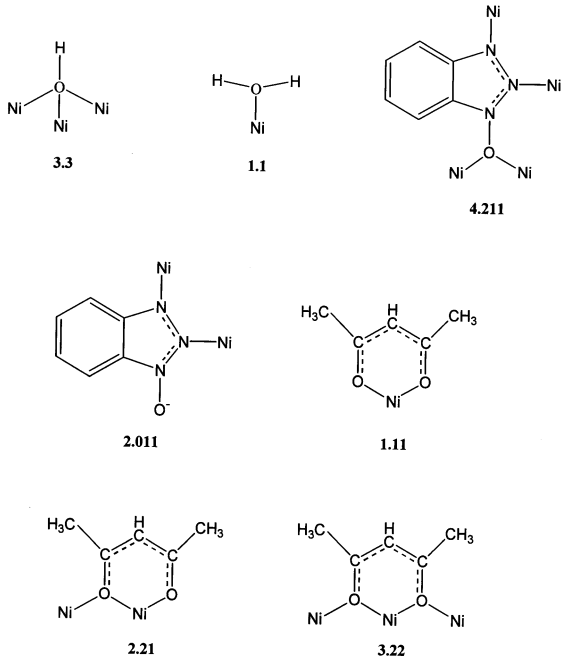

Fig. 2. The seven different coordination modes of the ligands present in the heptanuclear cluster, and the Harris notation [50] to describe these modes.

and Ni(3)–O(3)–Ni(5) angles (119.9°, 121.1°) are well above the limit (approximately 100°) from which the Ni–μ_3(OH^-)–Ni interactions become antiferromagnetic [19,75,79–82]. The ferromagnetic values of J_1 and J_3 are in agreement with the relatively small (< 100°) Ni–O–Ni bond angles within the Ni(1)···Ni(3), Ni(1)···Ni(2), Ni(5)···Ni(7), Ni(4)···Ni(6), Ni(1)···Ni(5) and Ni(1)···Ni(4) pairs, see Table 4.

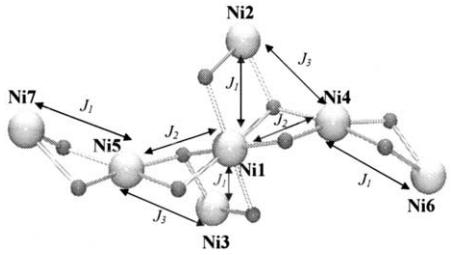

Fig. 4. The simplified magnetic model used for **4** with the monoatomic O bridges and the exchange pathways between the Ni(II) atoms at distances < 4 Å. The numbering scheme used for the Ni(II) atoms is the same with that used in Fig. 1.

According to the J values the ground state of the system is $S = 1$ with two excited states, $S = 0$ and $S = 2$, very close to it (0.57 and 1.19 cm^{-1}, respectively).

In order to validate the correctness of the fit, a simulation of the magnetization data at 4 K was carried out employing the parameters deduced from the fitting of the susceptibility data. As it can be seen in Fig. 5, the model reproduces the behavior of the magnetization versus field quite well.

The presence of a state with an integer spin which is thermally populated at 4 K is confirmed by the EPR spectrum of **4** (Fig. 6), which shows a transition centred at approximately 800 G due to small zero-field splitting effects. A HF-EPR spectrum is needed to resolve the broad line to proceed to a satisfactory interpretation.

4. Conclusions and perspectives

The 3d-metal β-diketonates–benzotriazoles chemistry seems to continue its promise as a source of polynuclear complexes with interesting structures and properties. When the 3d-metal is copper(II) this general reaction system gives pentanuclear clusters of the general formula $[Cu_5(L–L)_4(bta)_6]$, where L–L represents various diketonate ligands [21,22]. When the 3d-metal is nickel(II) the products of this general reaction system are the

$Ni_5(OH)$, Ni_5 and Ni_9 clusters [18–20] mentioned in the Introduction; the structures of the products depend mainly on the nature of the β-diketonate ligand. Complex **4** is a new addition in the Ni(II)–β-diketonates–benzotriazoles family of clusters. From a synthetic inorganic viewpoint, the isolation of **4** shows that it is possible to generate Ni(II) clusters with nuclearities significantly different than those known to date (Ni_5, Ni_9) by perturbations to the Ni(II)–β-diketonate–benzotriazole reaction system, in the present case, the introduction of a donor substituent group in the azole ring of benzotriazole. From the magnetic viewpoint, an attempt was made to fit the data of a compound of high nuclearity ($Ni(II)_7$). The ground state is $S = 1$ with $S = 0$ and $S = 2$ low-lying excited states.

Compound **4** is the seventh structurally characterized complex of any metal containing btaO$^-$ ligands. Compounds **1**, **2** and **3** (see Section 1), synthesized by our group [38–40], are coordination complexes (Werner-type). The other three compounds are the organometallic complexes $[Os_3H(CO)_{10}(btaO)]$ (**5**), $[Os_3(C{=}NHPr^n)(CO)_{10}(btaO)]$ (**6**) and $[Os_3(C{=}NHCH_2Ph)(CO)_{10}(btaO)]$ (**7**) containing bridging hydrido (**5**) or bridging aminocarbyne (**6**, **7**) ligands [83]. The 1-hydroxybenzotriazolate(−1) ligand (btaO$^-$) adopts four different coordination modes in the seven compounds, conveniently shown in Fig. 7; for the reader's convenience, we have incorporated in Fig. 7 the bonding modes exhibited by the btaO$^-$ ligands in **4** (although these modes were also shown in Fig. 2). In the 3D coordination polymer **1**, both btaO$^-$ ions adopt the bonding mode 2.101, i.e. they function as bidentate bridging ligands with N(3) and the deprotonated oxygen being the ligating atoms [38]. In the trinuclear complex **2**, all the btaO$^-$ ions bind with the 2.011 mode with the uncoordinated, deprotonated oxygen participating in hydrogen bonding with the ammine ligands [39]. In the 1D coordination polymer **3**, the btaO$^-$ exhibits the coordination mode 3.201. As described in Section 3.3, the btaO$^-$ ligands adopt two different coordination modes in **4**; two bind with the 4.211 mode and two with the 2.011 mode. It is clear that only the 2.011 mode is found in more than one compounds, i.e. in **2** and **4**–**7**. The coordinative flexibility of btaO$^-$ observed in the structures of **1**–**7** makes this ion a versatile new ligand

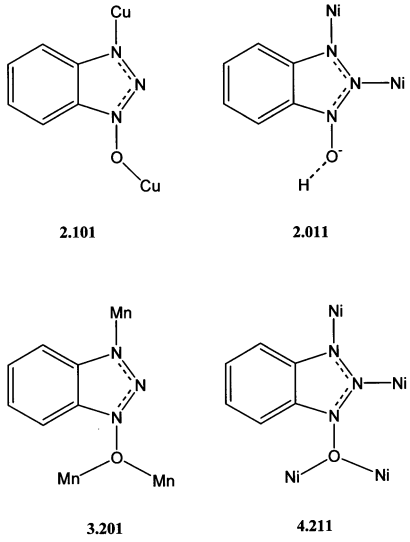

Fig. 7. The crystallographically established coordination modes of the 1-hydroxybenzotriazolate(−1) ligand (btaO$^-$).

for a variety of objectives/advantages, including variable denticity levels, high-nuclearity cluster formation, linking of clusters into 2D, 2D and 3D polymeric arrays, 3d–4f mixed-metal chemistry and ferromagnetic exchange interactions.

Very recently Winpenny reported [1] that the idea of synthesizing polynuclear compounds without strictly designing the final product is an extremely productive means of producing new polymetallic cages. In this approach, termed 'serendipitous assembly' (as a contrast to the designed assembly approach), the element of strict design is absent. In contrast to designed assembly, ligands are used that display several different coordination modes. Much interesting synthetic work can arise where results, originally obtained by chance, are exploited through design. It is clear that the structure of **4** is not a structure we would choose to design. Therefore, the isolation of this complex has been achieved in the context of serendipitous assembly. Since the blend of nickel(II) with $acac^-$ and $btaO^-$ generated an interesting cluster, a rational extension of the work presented here is to look at other 3d-metals, for example manganese(II) and cobalt(II). Another rational extension is to try to find out if the Ni(II)–β-diketonate–$btaO^-$ blend can be extended fruitfully to other β-diketonate ligands, e.g. dbm^-, $bzac^-$.

We wish to do a last comment on the anticorrosion properties of btaOH (**II**). The corrosion inhibitive properties of benzotriazole (btaH, **I**) have been attributed to the 3.111, i.e. μ_3, coordination of its conjugate base, bta^-, that leads to the formation of a tight, close-packed, inert surface polymer [21,26,35–37]. The anticorrosion action of btaOH [42–44] may be associated with the capability of its conjugate base, $btaO^-$, to bridge three (as in **3**) or four (as in **4**) metal ions.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Centre, CCDC No. 102274 for complex **4**·MeCN·$0.9H_2O$. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1233-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

ture with RE(III) and M(II) ions (RE = rare-earth element, and M = d-block metal) [8–12].

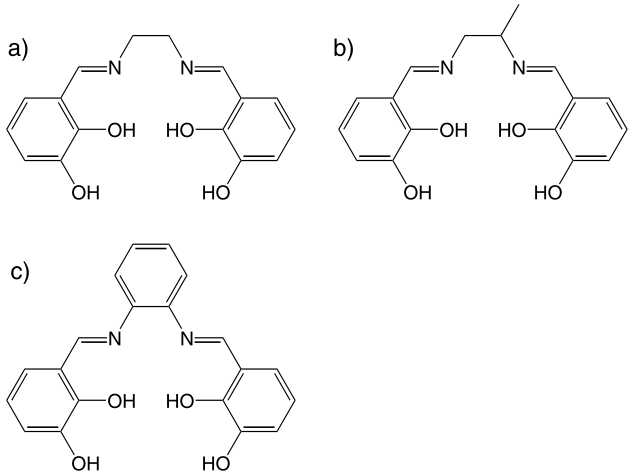
In order to change the flexibility of the ligand, various diamines were used as a bridging chain of ethylene, propylene and *o*-phenylene. When the bridging chain has a π-conjugated system, such as *o*-phenylene, the ligand is considered to have a rigid frame, and the coordinating structure of the ligand must be planar. The d-block ions of Ni(II) and Zn(II) prefer their coordination structure to be square-planar and tetrahedral, respectively. Therefore, the coordination structure of the cavity at the O_4 site of the ligand is affected by the structure of the N_2O_2 site around the M(II) ion in the complex (Scheme 1). In other words, it is assumed to be possible to control the coordinating structure around the RE(III) ion by changing the d-block metal ions, M(II), and the bridging chains. In this paper, please note that the transition metal free structure is referred as 'vacancy', but it is not a real meaning; an H^+ may be placed at that site.

There are cases in which magnetically diluted single crystals are hard to obtain, Gd(III) ions serve as a probe in a biological system or the structure of the complexes in solution are of interest. We are also attempting to develop a method for investigating the properties of the Gd(III) complexes in a disordered system using the EPR technique. Therefore, the frozen solutions of the complexes were used for the investigation.

Scheme 1. The schematic coordination structure around the transition metal ion and the gadolinium ion. The structures are (a) planar for Ni, (b) tetrahedral distortion by Zn.

2. Experimental

2.1. Materials



All of the chemicals used were commercially obtained, and no further purifications were performed. The ligands used in this study are shown in Scheme 2. The Gd(III) complexes with the Schiff base ligand were synthesized by the usual method [8–12]. The obtained ligands and the Ni and Zn complexes were examined by IR and NMR spectra [11,15]. Complex formations with the Gd(III) ion were confirmed by the EPR and IR spectra. In order to obtain the complex $[GdNi(osalph)]^+$, both synthetic procedures, a one-pot reaction and a two-step reaction, gave the same product, which was confirmed by the IR spectra.

2.2. UV–Vis absorption spectra

The UV–Vis absorption spectra were measured by a continuous variational method in order to investigate the complex formation between the metal ions and the ligands. The concentrations of the Ni(II) solution and the H_4osalph solution were approximately 10^{-4} mol l^{-1} with methanol as a solvent. The spectra were recorded using a Hitachi U-2001 spectrophotometer at room temperature (r.t.).

2.3. EPR measurement

The EPR spectra were observed using a JEOL RE3X X-band EPR spectrometer with a liquid-nitrogen dewar. Typical measurement conditions involved a temperature of 77 K and a microwave power of 5–20 mW. Frozen dimethylsulfoxide (dmso) solutions of the Gd(III) complexes were used for observing the EPR spectra. This solvent was chosen for the appropriate solubility of the

Scheme 2. The structure of the ligands used in this study. (a) H_4osalen, (b) H_4osalpn, (c) H_4osalph.

complexes, and it was also confirmed to form a glassy matrix by the spectral pattern of EPR. The magnetic fields were measured using a EFM-2000AX field meter (Echo Electronics Co., Ltd.), and the microwave frequencies were determined by a Mn^{2+} marker.

2.4. Molecular orbital calculations

In order to study the structures of the Gd(III) complexes, ab initio molecular orbital (MO) calculations were performed. The model complexes used here were $[YNi(osalen)]^+$, $[YZn(osalen)]^+$ and [YH(osalen)], where the structures were assumed to have C_2 symmetry. The complexes with the osalph ligand were also calculated. It can be mentioned that the ionic radii of Y and Gd are comparable, and that the unpaired electrons of the spin octet system in the Gd will bring an unessential difficulty in the MO calculation. The optimized geometries, where a local energy minimum was achieved, of these model complexes were obtained by the RHF method using a 3-21G basis set. All calculations were done using the GAMESS program package [13] on a CONVEX SPP1000 at the Computer Center of Hirosaki University. PLUTON was used to draw the molecular structures [14].

3. Results and discussion

3.1. Structure of the complexes

The ligands used in this study have two kinds of metal coordination site, an N_2O_2 coordination site and an O_4 site. Sakamoto et al. [9–12] and Casellato et al. [15] reported that the d-block metal ions were coordinated by the N_2O_2 site, while the rare-earth ions were coordinated by the O_4 site. The former group discussed the hardness of the metal ions and the C=N stretching frequencies of the complexes. The latter group showed the crystal structures of $[Cu(H_2osalen)]$ and $[YCu(osalen)](NO_3)$ with IR and NMR data; the structures of these are considered to be similar to those of the corresponding Ni(II) complexes. Here, the structures of the synthesized complexes were confirmed by IR, ^1H and ^{13}C NMR, and the continuous variational method applied for the absorption band at the visible region. The optimized structures of the model complexes obtained by the ab initio MO calculations also give useful information about the structure of the O_4 coordination site.

According to both the hardness and the size of the cavity at the N_2O_2 and O_4 sites of the ligands, it is considered that the rare-earth ion prefers to be coordinated at the latter, while the d-block ion is coordinated in the former. This is suggested by the following experimental data.

Table 1
C=N stretching frequencies of the Gd(III)–M(II)–osalR complexes [a] in cm^{-1}

Ligands	H_4osalen	H_4osalpn	H_4osalph
Metal free	1632.0 (1640 [b], 1632 [c])	1631.2	1617.0
Ni(II)	1618.7 (1626 [b], 1610 [c])	1619.6	1614.0
Zn(II)			1616.0
Gd(III)	1636.0 (1634 [c])	1638.4	1618.0
Gd(III)–Ni(II)	1619.1		1614.4 (1612.3 [d])
Gd(III)–Zn(II)			1613.0

[a] Chloride as a counter anion.
[b] Ref. [15].
[c] Ref. [11].
[d] This work, PF_6^- salt.

Table 1 shows that the C=N stretching frequencies of the ligand were shifted lower when a metal ion was coordinated, and the observed shift in the C=N stretching frequencies was larger in coordinating a d-block metal ion than coordinating a rare-earth ion. These IR data are consistent with the reported results [11,15], and are shown in Table 1, indicating that the d-block ion is coordinated at the N_2O_2 site which neighbors to the C=N bond.

The ^1H and ^{13}C NMR data are summarized in Tables 2 and 3, where those for H_4osalen show good agreement

[a] Signals of the bridging phenylene cannot separate from those of osal unit.

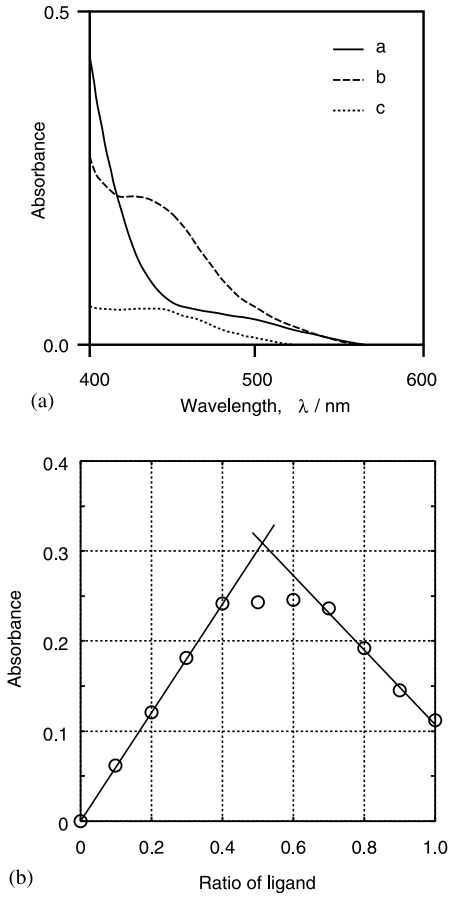

Fig. 1. Plot for the continuous variation method with H_4osalph and Ni(II) ion, and UV–Vis absorption spectra. (a) Absorption spectra at various ligand ratios. The ratio of the ligand is (a)1.0, (b) 0.5, (c) 0.1. (b) Observed wavelength, 437.0 nm; solvent, methanol; concentration, approximately 10^{-4} mol l^{-1}; temperature, r.t.

with the reported values [15]. The chemical-shift values of the metal complexes are different from those of the ligands; for example, the chemical-shift values for [M(H_2osalph)] (M = Ni(II), Zn(II)) have changed from that for H_4osalph, which indicates a complex formation. Furthermore, [M(H_2osalph)] (M = Ni(II), Zn(II)) shows only ten peaks for the ^{13}C NMR spectra; this means that these complexes are symmetric. The chemical-shift values for these Ni(II) and Zn(II) complexes are different. It is also shown that the structures of these complexes are different, assuming that the Ni(II) complex has a planar structure while that of Zn(II) is a tetrahedrally distorted one (vide infra). These NMR results also point out the magnetic properties of the Ni(II) complexes; that these coordination complexes are diamagnetic, i.e. the Ni(II) ions have a low-spin ground state.

A new absorption band at approximately 450 nm appeared for a mixture of the solution of the Ni(II) ion and that of H_4osalph; the band was not seen either in the solution of the Ni(II) ion or in that of the ligand. This band is then thought to arise from the formation of the Ni(II)–H_2osalph complex (Fig. 1(a)). The optical density at 437 nm versus the ratio of the contents of the Ni(II) ion and the H_4osalph ligand is plotted in Fig. 1(b). These results show that the complex formation between the Ni(II) ion and the ligand occurs in a 1:1 molar ratio.

As a conclusion of the above results, it is strongly suggested for the M(II)–H_2osalR system that only a single d-block ion was coordinated to the one site of the compartmental ligand (N_2O_2 site), and that the other binding site remains free for the other rare-earth ion.

In the next step, the three-dimensional structure of the Gd(III)–M(II) complexes and the local environment around the Gd(III) ion were of interest. Ni(II) and Zn(II) were used for the d-block metal ion, M(II), which was introduced to the N_2O_2 site of the complexes; they are considered to take a square-planar and a tetrahedral coordination structure, respectively. The coordination structure around the Gd(III) ions will strongly be affected by these d-block metal ions, where the structures are illustrated in Scheme 1.

We did not think about the bridged dimer reported by Casellato et al. [15]. If the dimeric structure was formed, the line-shape of its EPR spectrum should be different from that of the $S = 7/2$ system, and/or the line-width might be too broad to observe the signals, because of the magnetic interaction between the nearest Gd(III) ions. It is considered enough to rationalize the observed spectra being caused by the Gd(III) complexes (vide infra).

In order to estimate the structure of the Gd(III)–M(II)–osalR complexes, ab initio MO calculations

were carried out, and then the optimized geometry of the model complexes of $[YNi(osalen)]^+$, $[YZn(osalen)]^+$ and $[YH(osalen)]^0$ were obtained, where C_2 symmetry was assumed. Moreover, the complexes with osalph ligand were also calculated. The selected bond lengths, bond angles, and dihedral angles obtained by the MO calculations are listed in Table 4 and the stereo views of $[YM(osalen)]^{n+}$ ($M = Ni^{2+}$, $n = 1$; $M = Zn^{2+}$, $n = 1$; $M = H^+$, $n = 0$) are shown in Fig. 2. The bond lengths of M–N, M–O, and Y–O are essentially same between $[YM(osalen)]^{n+}$ and $[YM(osalph)]^{n+}$, though the bond angles with respect to the metal coordination sphere (both M and Y) are different.

The most remarkable difference between osalen and osalph can be seen in dihedral angles. The dihedral angles are used to measure the distortion of the coordinating structure around the metal ion. The dihedral angles around the d-block metal ion sites show that the angle for (N1–Ni–O1)–(N2–Ni–O2) is 6.0° for the osalen complex and 6.4° for the osalph complex, and that for (N1–Zn–O1)–(N2–Zn–O2) is 30.4° and 23.4°, respectively. These results represent the properties of Ni(II) and Zn(II) well, where the coordination structure around the Ni(II) ion is planar, while that of Zn(II) is tetrahedrally distorted. Furthermore, it is interesting that the distortion around Zn(II) is smaller because of the rigidity of the *o*-phenylene bridge. In addition to that, the dihedral angles around the Y(III) ion in the osalen complex were determined as (O1–Y–O3)–(O2–Y–O4) to be 21.8° for M(II) = Ni(II), 33.2° for M(II) = Zn(II), and 50.1° for $M(II) = H^+$, while in the osalph complex, 12.5°, 33.6°, and 52.6°, respectively (see Table 4). These results indicate that the coordination structure around the Y(III) ion, which is a model of the rare-earth ion, has more distortion in $[YZn(osalR)]^+$ than in $[YNi(osalR)]^+$. It is interesting that the coordination structure around the Y(III) ion for [YH(osalR)] has a greatly distorted structure, too. The

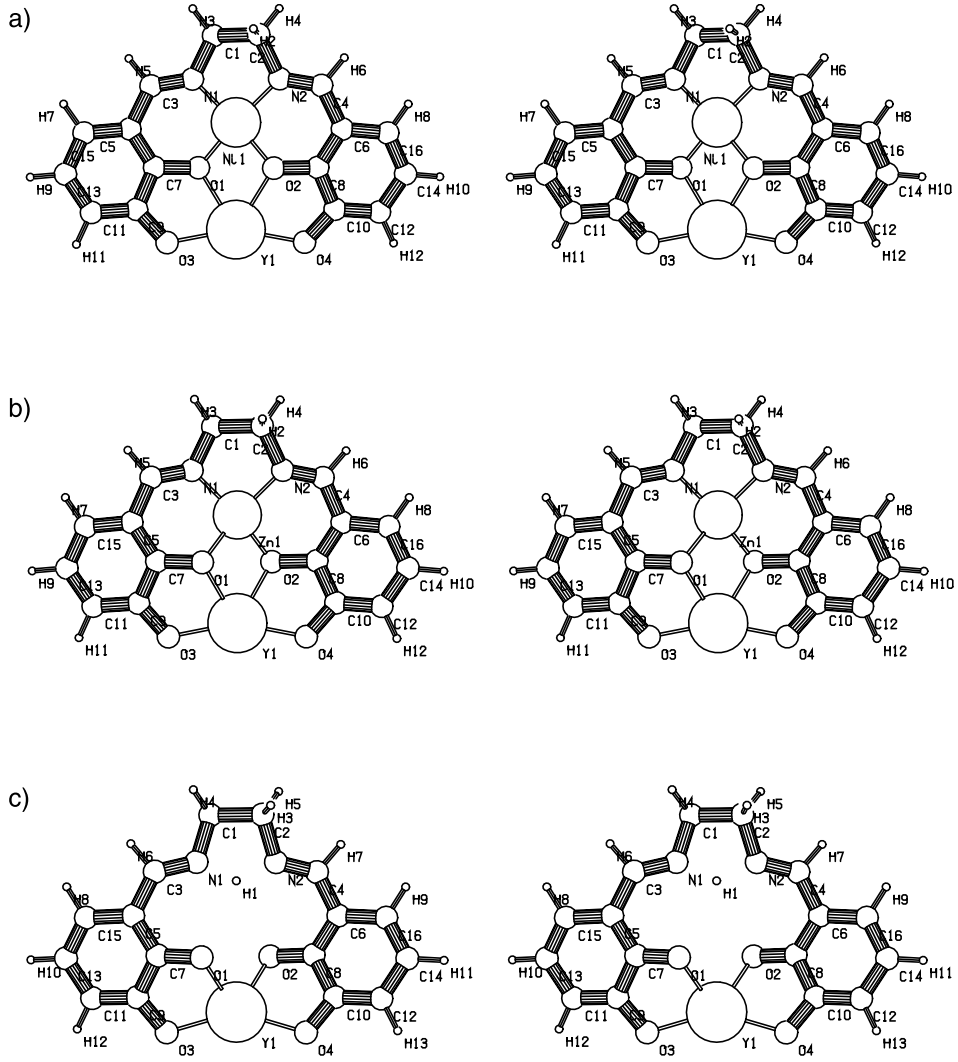

Fig. 2. Stereo views of $[YM(osalen)]^n$ [14]. a) M = N, $n = +1$; b) M = Zn, n = +1; c) M = H, $n = 0$. These structures were obtained from RHF/3-21G MO calculations.

vacant N_2O_2 site (where $M(II) = H^+$) is thought to be a site where it would be possible to arrange the donor atoms around the rare-earth ion with less strain, because the flexibility of the ligand does not restrict the structure of the complex. The effect of the *o*-phenylene bridge is also interesting, that the coordination sphere around M(II) is lesser distorted in osalph ($M(II) = Zn(II)$ and H^+), but it is not around Y(III). While in the Y–Ni–osalph complex, the dihedral angle (O1–Y–O3)–(O2–Y–O4) is smaller than the osalen complex. These results indicate that the rigidity of the bridging R also affects the coordination sphere around the Y(III) ion. It is important to conclude that the coordination structure around the Gd(III) ion is able to be controlled by the d-block metal ion through the structure of the compartmental ligand unit.

It is certainly important that the coordination number of the rare-earth ions is not only four, like some of the d-block ions, but can possibly number in six or more. By those means, it was obvious that the above model calculation did not give the whole coordination sphere of the Gd(III) ion of the Gd(III)–M(II)–osalR complex in solution. The solvent molecules and/or the counter anions may occupy the fifth site and more of the Gd(III) ion. For example, the chloride anion may easily be accessible to the additional fifth and sixth coordination site of the Gd(III) ion in the $[GdNi(osalen)]^+$ complexes, where the osalen-ligand has a more planar structure around the rare-earth ion than that of the Zn-including or the metal-free complex. Because of the rigidity of the osalph-ligand, the dihedral angle (O1–Y–O3)–(O2–Y–O4) of $[YNi(osalph)]^+$ is smaller than others, indicating that the ligand in $[GdNi(osalph)]^+$ is more planar around the coordination sphere of the Gd(III) ion. In any case, it is clear that the coordination structure of these additional donors is also controlled by the d-block metal ions. In addition, the changes in the structure of the compartmental ligands also makes it possible to rearrange the structures of the additional coordinating atoms which come from anions and/or solvents around the Gd(III) ion.

3.2. EPR spectra

The observed X-band EPR spectra are shown in Fig. 3. Strong signals were easily obtained in the wide range of 100–800 mT at 77 K. The properties of the line-shapes of these spectra were essentially similar to those of the Gd(III)-β-diketonate complexes [5]. Furthermore, though the d-block ions were changed in our Gd(III)-M(II) complexes (M(II) = Ni(II), Zn(II) and vacancy), the dominant line-shapes of the spectra were not changed, which means that the Ni(II) ion has a low-spin as a ground state. It was also pointed out that the complexes without the Gd(III) ion, [M(H_2osalR)], show the normal NMR spectra (Tables 2 and 3), which indicates that all the d-block ions used in this study are diamagnetic. These results suggest that the diamagnetic d-block ions play a role as a building block, and the complexes for which we observed the EPR spectra have the electron spin $S = 7/2$.

The X-ray structural analyses and the magnetic properties of some related RE(III)–M(II) complexes with the H_4osalR ligand were reported [15–17]. Casellato et al. said that the mononuclear [Cu(H_2osalen)] complex forms a square-planar configuration around the Cu(II) ion [15]. Costes et al. determined that the ground state of their Gd(III)–Ni(II) complex has $S = 9/2$; in other words, the Ni(II) ion is in a high-spin state [16,17]. So as in the Casellato's Cu(II) case, our Ni(II)-including complexes are expected to have the square-planar coordination structure around the Ni(II) ion. However, in contrast to the Costes' case, the Ni(II) in our complex is diamagnetic, as shown by the NMR and EPR spectra. Consequently, it can be considered that the observed EPR signals are only due to the Gd(III) ion.

As was mentioned above, the observed line-shapes of the EPR spectra of the Gd(III)–M(II) complexes are essentially similar to those of the Gd(III)-β-diketonate complexes [5]. The latter complexes are known to have

some negatively charged β-diketonates as ligands, and the Gd(III) ions are surrounded by the oxygen atoms. Hence the former complexes are supposed to have a similar local environment around the Gd(III) ions as the latter complexes.

In Fig. 3(b–d), the EPR spectra of the [GdM(osalph)]$^{n+}$ complexes with various diamagnetic d-block M(II) ions, such as Ni(II), Zn(II), and a vacancy, are displayed. It can be seen that the detailed line-shape of the spectra differs from each other upon changing the d-block ion M(II). These results indicate that the local environments around the Gd(III) ion are changed, and are controlled by the d-block ion.

Though the accurate spectral line-shapes are varied, the line-shape of [GdZn(osalph)]$^{+}$ and that of [GdH(osalph)]^{0} are essentially similar, whereas that of [GdNi(osalph)]$^{+}$ is different. Both [GdZn(osalph)]$^{+}$ and [GdH(osalph)]^{0} have a single peak at approximately 230 mT in their EPR spectral line-shape (Fig. 3(c–d)), while [GdNi(osalph)]$^{+}$ has a split peak at the corresponding position (Fig. 3(b)). Furthermore, only the latter spectrum has a shoulder at approximately 450 mT. The similarity in the spectral line-shapes of the former two suggests a similarity in the local environment around the Gd(III) ion. The optimized structures of both [GdZn(osalph)]$^{+}$ and [GdH(osalph)]^{0} obtained from the MO calculation have a tetrahedral distorted coordination sphere (Table 4). The EPR data of those complexes can be explained by the MO results.

In Fig. 3(a–b), the EPR spectra of the [GdNi(osalR)]$^{+}$ complexes with various compartmental ligands are shown. The EPR spectron of [GdNi(osalen)]$^{+}$ shows a broad peak at approximately 220 mT (Fig. 3(a)), while that of [GdNi(osalph)]$^{+}$ has a split peak at approximately 250 mT (Fig. 3(b)). The line-shape of the obtained EPR spectra is different, when the bridging chain R is changed. Due to the the rigid π-conjugated system of the phenylene bridge, [GdNi(osalph)]$^{+}$ is expected to have a planar coordination structure around the Gd(III) ion, however, the coordination structure around Gd(III) in the [GdNi(osalen)]$^{+}$ complex, which has an ethylene bridge, may be slightly distorted. This flexibility in the ligand is very interesting. Unfortunately, the complex having a longer alkyl chain, trimethylene, was reported to have a Ni(II) in a high-spin state [16,17]. Consequently, it is suggested that the coordination structure around the Gd(III) ion is able to be governed by the bridging chain in the ligand, through the structure around the Ni(II) ion.

In Fig. 3(d–f), the EPR spectra of the [GdH(osalR)] complexes are shown. The obtained spectra are very similar to each other. These results strongly suggest that the coordination structure of the Gd(III) ion is equivalent in these three complexes, though the bridging chain R is varied. Indeed, when the d-block ion site is vacant, the local environment around the Gd(III) ion is considered to be less restricted. Furthermore, the angle of O(1)–Y–O(2) for the calculated structure of the [YH(osalen)] complex is much larger than that for the others, indicating that the osalen^{4-} ligand is very flexible. This means that the local environment is determined by the nature of the Gd(III) ion itself when the ligand is flexible. The calculated structure for [YH(osalen)] shows that the O_4-donating atoms are arranged in a tetrahedral coordination structure (Fig. 2(c), Table 4) with a large steric distortion at the N_2O_2 vacant site.

EPR spectral simulations are required to determine the EPR parameters and for more precise discussions. However, we have not obtained good results so far, because there was a distribution in the structure of the complexes in solution which causes a distribution in the EPR parameters, or there was a D-strain which causes a m_S-dependent linewidth [5,18–21]. For these reasons, qualitative discussions only were achieved here. A study on the EPR spectral simulations of the Gd(III) complexes for the frozen solution system requires a great deal of computer power, and is in progress.

4. Concluding remarks

The EPR spectra of Gd(III) complexes with the compartmental ligands, osalR^{4-}, and d-block ions M(II), such as Ni(II), Zn(II), and a vacancy, were measured here. It was confirmed by some experimental results and by the optimized structure obtained by MO calculations that the structures of the rare-earth binding site were the O_4 site, and were changed by changing M and R. It is interesting that the obtained EPR spectra clearly reflect the local environment of the Gd(III) ions. In other words, various line shapes of the EPR spectra can be observed when the d-block ion M and the bridging chain R are changed. This means that the coordinating structures around the Gd(III) ions can be controlled by the compartmental ligands and d-block ions, and that the 4f-electrons of the Gd(III) ion are affected by the coordinating ligands and their structures, though the 4f-electrons are shielded by the outer-shell electrons.

Acknowledgements

tobenzoxazol. This is an unsaturated heterocycle which exists both in solid and in polar solution in the thione tautomeric form with a protonated N-atom [9a,10]. Bzoxsh is structurally related to biologically important bases and several transition-metal complexes have been described in the literature [9].

2. Experimental

2.1. Physical measurements and instrumentation

Ligand dissociation reactions were followed through conventional kinetics using a Hewlett-Packard Model 8452A diode-array spectrophotometer in MeOH/H_2O (75:25%) thermostated solutions. All experiments were performed under pseudo-first-order conditions and the reactions were monitored for 5–6 half-lives. Dissociation of the substituted pentacyanoferrates takes place to a very small extent at room temperature. The kinetics were investigated in the presence of the compounds L = dimethylsulfoxide (dmso), pyridine (py) for Fe^{III} and *N*-methylpyrazinium for Fe^{II}. These have strong affinities for pentacyanoferrate group, allowing the dissociation reactions to be safely followed [3,5a]. The rates of substitution were studied as a function of 7–10 different concentrations of L at a fixed bzoxsh concentration. First-order rate constants were determined by four different mathematical methods: least-squares or the infinite absorbance method, Guggenheim, Kezdy–Swinbourne and a non-linear fitting [12], with excellent result agreement. Second-order rate constants were calculated from literature data (for Fe^{II}) and from the thermodynamic cycle presented in this work. Temperature dependence of the rate dissociation constants was studied in the range of 10–30 °C.

Cyclic voltammetry measurements were carried out with a Princeton Applied Research Potentiostat model 273A. A Pt disc electrode was employed for the measurements at an ionic concentration of 0.5 mol dm^{-3} kept constant with tetrabutylammonium tetrafluoroborate. A Ag/$AgNO_3$ ($[Ag^+] = 0.01$ mol dm^{-3} in an MeCN solution of $Bu^t_4NBF_4$ 0.1 mol dm^{-3}) along with a Pt wire were used as reference and auxiliary electrodes, respectively. Typical experiments were conducted with a 2.5×10^{-3} mol dm^{-3} complex concentration in MeOH/H_2O (75:25%) solutions at ambient temperature.

2.2. Materials

$Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ was prepared from sodium nitroprusside as described in the literature [11]. The yellow product was stored in the dark at −15 °C. *Anal*. Calc. for $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$: C, 18.4; H, 2.8; N, 25.8. Found: C, 18.0; H, 2.1; N, 24.6%.

The purity of the 2-mercaptobenzoxazole (Aldrich) was confirmed by elemental analysis. *Anal*. Calc. for C_7H_5NOS: C, 55.6; H, 3.3; N, 9.3. Found: C, 56.1; H, 3.3; N, 8.9%.

Solutions of the aquapentacyanoferrate(II) complex were always freshly prepared using Schlenk techniques. $Na_3[Fe(CN)_5NH_3]\cdot 3H_2O$ was dissolved in dinitrogen-saturated water, mixed with three parts of MeOH (to give a total iron concentration of $1–5 \times 10^{-4}$ mol dm^{-3}) and enough sodium perchlorate to keep the ionic strength at 1.00 mol dm^{-3}. Solid 2-mercaptobenzoxazole (bzoxsh) was always dissolved in excess (20-fold) to avoid competing reactions with small amounts of free NH_3 coming from the starting material.

Solutions of the aquapentacyanoferrate(III) complex were also freshly prepared by oxidizing $[Fe^{II}(CN)_5(H_2O)]^{3-}$ (obtained by dissolving the ammine complex in water) with PbO_2 in dinitrogen-saturated water. The excess of PbO_2 was filtered off and three volumes of MeOH were added. After correction of the ionic strength, solid bzoxsh was added, resulting in a clear deep-green solution.

3. Results and discussion

Typical spectral changes for the reaction of $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$ with dmso and of $[Fe^{II}(CN)_5(bzoxsh)]^{3-}$ with *N*-methylpyrazinium are illustrated in Fig. 2. The concentrations used gave well-defined and reproducible first-order kinetic plots. Dmso is suitable because it forms a very stable and colorless complex with pentacyanoferrate(III) [3] and the reaction was studied following the decay of the band of the reactant at 706 nm. The same procedure was applied when pyridine was the attacking reagent as the $[Fe^{III}(CN)_5(py)]^{2-}$ complex is faintly yellow and absorbs at 410 nm. For the dissociation reactions involving Fe^{II}, the formation of the blue $[Fe^{II}(CN)_5(N\text{-methylpyrazinium})]^{2-}$ was monitored at 690 nm. The dissociation kinetics exhibited good pseudo-first-order behavior during at least two half-lives, with the attacking L always present in large excess over the iron complex ($10^2–10^3$-fold).

According to the general mechanism for the dissociation reactions in pentacyanoferrate complexes [5a] we can write:

$$[Fe^{III/II}(CN)_5(bzoxsh)]^{2/3-} \underset{k_f}{\overset{k_d}{\rightleftharpoons}} [Fe^{III/II}(CN)_5(H_2O)]^{2/3-} + bzoxsh$$

$$[Fe^{III/II}(CN)_5(H_2O)]^{2/3-} + L \underset{k_{-L}}{\overset{k_L}{\rightleftharpoons}} [Fe^{III/II}(CN)_5(L)]^{2-/3-} + H_2O$$

where the loss of bzoxsh is the rate-determining step.

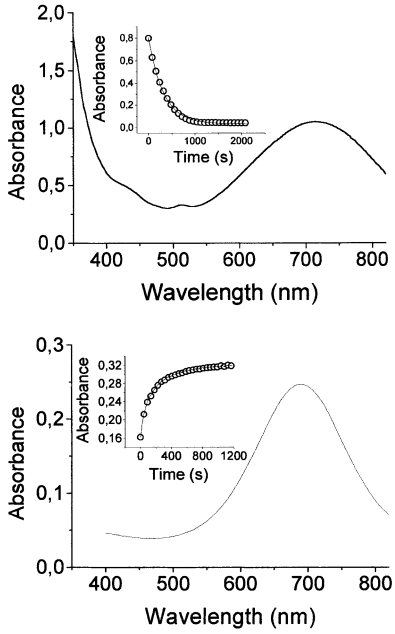

Fig. 2. UV–Vis spectra of $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$ (top) and $[Fe^{II}(CN)_5(N\text{-methylpyrazinium})]^{2-}$ in MeOH/H_2O 75:25 (v/v); Inset shows typical first-order kinetic curves: scatter, experimental data; line, non-linear first-order exponential fit. Top shows the absorbance decay of the 706 nm band typical of $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$ after reaction with dmso; Bottom shows the increase of the 690 nm band when $[Fe^{II}(CN)_5(bzoxsh)]^{3-}$ reacts with *N*-methylpyrazinium.

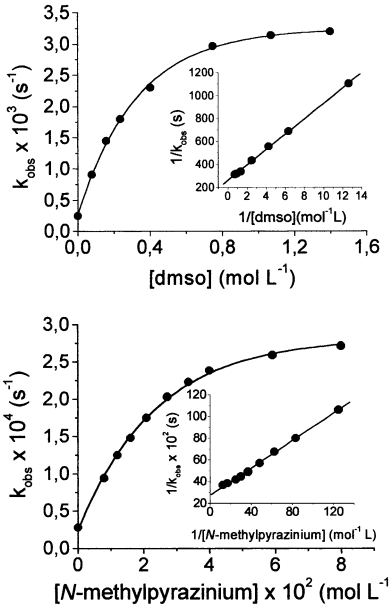
Assuming a steady-state approximation for $[Fe(CN)_5(H_2O)]^{2/3-}$ the observed rate constant and its reciprocal form (if $k_{-L} \ll k_d$) are given by Eqs. (1) and (2):

$$k_{obs} = \frac{k_f k_{-L}[bzoxsh] + k_L k_d[L]}{k_f[bzoxsh] + k_L[L]} \quad (1)$$

$$\frac{1}{k_{obs}} = \frac{k_f[bzoxsh]}{k_L k_d[L]} + \frac{1}{k_d} \quad (2)$$

The expression (Eq. (1)) is coherent with the saturation curve of k_{obs} versus L and Eq. (2) with the linear behavior of the reciprocal form as seen in Fig. 3. Since the rates of formation of $[Fe(CN)_5L]^{3-}$ are completely independent of the nature of the entering ligand, as expected for a limiting SN_1 mechanism, we calculated a medium value of $k_f^{II} = 290$ dm^3 mol^{-1} s^{-1} from published results for neutral ligands at the same ionic strength. k_f^{II} and (L) used for calculation were: 240 (dmso), 212 (imidazole), 184 (histidine) [6], 354 (4-picoline), 365 (pyridine), 295 (isonicotinamide) and 380 (pyrazine) [3]. The stability constant K_f^{II} was calculated as k_f^{II}/k_d^{II} from the formation and dissociation reactions. K_f^{III} was calculated from the measured electrochemical potentials and the following redox cycle:



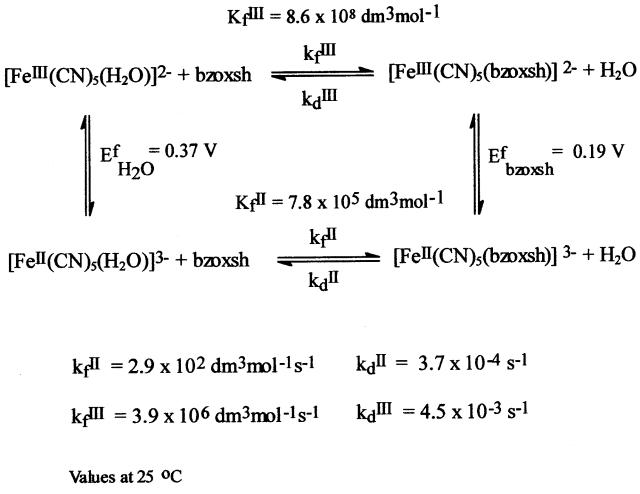


Fig. 3. Plot of k_{obs} versus attacking ligand concentration, showing rate saturation. Top: reaction of $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$ with dmso. Bottom: $[Fe^{II}(CN)_5(bzoxsh)]^{3-}$ reacts with *N*-methylpyrazinium. Inset shows double reciprocals for determination of k_d.

where $K_f^{III} = K_f^{II}\{\exp[(nF/RT)(E^f_{bzoxsh} - E^f_{H_2O})]\}^{-1}$.

The results for bzoxsh are similar to those described for other neutral ligands. This holds for k_f^{II} (240–400 dm^3 mol^{-1} s^{-1}) and K_f^{II} (10^2–10^6 dm^3 mol^{-1}) [3,5a,6]. K_f^{III} is out of the range of 10^{-2}–10^6 dm^3 mol^{-1} and this is consistent with the lower limit of the formal reduction potential, E^f_{bzoxsh} (Table 1). The relative strength of the Fe–L bond can be related with the basicity of L as suggested by Eldik et al. [13]. The higher the sigma-donor capacity of L the lower the lability of the Fe–L bond. However, pK_a values represent only the sigma part of metal–ligand interactions. As can be seen from Table 1, the dissociation constants (k_d) are not much sensitive to large variations of pK_a (compare, for example pyrazine with histidine). This can be explained

Table 1

Table 2
Temperature dependence of the rate constant for the dissociation of $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$

Temperature (°C)	$10^4\ k_d$ (s^{-1})
10	5.69
15	11.5
20	22.9
25	45.6
30	81.4

if we consider that both the σ-donor and back-bonding have the same effect on the substitution rate of L in a pentacyanoferrate complex, making it more inert. Back-bonding is bigger for less basic L. The $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$ complex is approximately 10 times more labile than the reduced form, a result consistent with the lack of back-bonding for the Fe^{III} ion. The same argument can be used to explain the higher observed lability of $[Fe^{III}(CN)_5(dmso)]^{2-}$ over $[Fe^{II}(CN)_5(dmso)]^{3-}$ ($k_d^{III} = 2.5 \times 10^{-4}\ s^{-1}$ [this work] versus $7.5 \times 10^{-5}\ s^{-1}$ [3]). In this case preferential π-back-bonding stabilization of the Fe^{II}–dmso complex is an important factor being also probably responsible also for the high value of K_f^{II} (Table 1).

Interestingly, bzoxsh appears to behave as a fair π-acceptor as well as a strong σ-donor ligand, as it stabilizes both oxidation states of pentacyanoferrate complexes. This bonding behavior is also observed for histidine, imidazole and 2-mercaptopyridine (2-mpy). Considering the thermodynamic stability of the complexes, although both the pK_a values of bzoxsh (S–H group) and pyridine are similar, bzoxsh is a weaker π-acceptor, consistent with the significantly lower value of E^f_{bzoxsh} and the high value of K_f^{III}. Conversely, pyridine shows greater stabilization of the pentacyanoferrate(II) ion over the oxidized form (Table 1).

The dissociation constants observed for $[Fe^{III}(CN)_5(py)]^{2-}$ and $[Fe^{II}(CN)_5(py)]^{3-}$ are 1.5×10^{-5} [this work] and $1.1 \times 10^{-3}\ s^{-1}$ [5a], respectively, showing that pyridine prefers the hard Fe^{III} ion, the back-bonding interactions having less importance here.

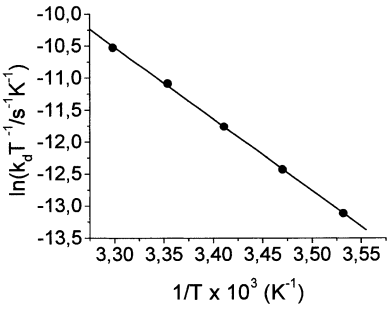

Fig. 4. Eyring plot for the reaction of $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$ with pyridine.

The effect is very pronounced, $[Fe^{III}(CN)_5(py)]^{2-}$ being much more inert than its reduced form.

If we compare the k_d^{III} values for the $[Fe^{III}(CN)_5L]^{2-}$ complexes, we can establish the following order of increasing lability: py ($1.5 \times 10^{-5}\ s^{-1}$) < dmso ($2.5 \times 10^{-4}\ s^{-1}$) < bzoxsh ($4.5 \times 10^{-3}\ s^{-1}$). This result suggests that bzoxsh is bound to Fe^{III} through the soft sulfur atom. If the coordination were through the nitrogen atom, we would expect the complex to be as inert that of pyridine. When k_d^{II} values are compared, the order is dmso ($7.5 \times 10^{-5}\ s^{-1}$) < bzoxsh ($3.7 \times 10^{-4}\ s^{-1}$) < py ($1.1 \times 10^{-3}\ s^{-1}$), emphasizing the importance of back-bonding in the stabilization of these Fe^{II} compounds.

Completing the investigation of the less studied $[Fe^{III}(CN)_5L]^{n-}$ series, activation parameters for the dissociation reaction of $[Fe^{III}(CN)_5(bzoxsh)]^{2-}$ were determined (Fig. 4 and Table 2). They are $\Delta S^{\#} = +11.4\ J\ K^{-1}\ mol^{-1}$ and $\Delta H^{\#} = 93.3\ kJ\ mol^{-1}$, typical of a dissociative type mechanism.

We hope that these results will help fill the gap in the kinetic data available for pentacyanoferrate(III).

the contributions by the 5,6-disubstitutions in the phen frameworks in more detail, we have determined the crystal structures of $[CuCl(dmphen)_2]PF_6$ (**1**) and $[CuCl(phendione)_2]PF_6 \cdot H_2O$ (**2**) under the regulated condition with the same monodentate co-ligand and counteranion. The crystal structures of **1**, **2** and $[CuCl(phen)_2]PF_6$, in which the structure of $[CuCl(phen)_2]PF_6$ was already determined [10], are discussed in relation to their absorption and reflectance spectral, and electrochemical behaviors.

2. Experimental

2.1. Materials

$CuCl_2 \cdot 2H_2O$, 1,10-phenanthroline monohydrate and NH_4PF_6 were purchased from Wako Pure Chemical Ind. Co., Ltd. 5,6-Dimethyl-1,10-phenanthroline was obtained from Aldrich Chemical Co., Inc. The other chemicals were purchased from Wako Pure Chemical Ind. Co., Ltd., Aldrich Chemical Co., Inc., or Tokyo Chemical Co., Ltd. All of the chemicals were of reagent grade and were used without further purification. 1,10-Phenathroline-5,6-dione was synthesized as described in the literature [15]. $[CuCl(phen)_2]PF_6$, which was used for the comparative studies on spectroscopic and electrochemical properties of the present complexes, was prepared by a modified method from the literature [10].

2.2. Preparations of the complexes

2.2.1. Synthesis of $[CuCl(dmphen)_2]PF_6$ (*1*)

This complex was prepared by a similar method to that for $[CuCl(phen)_2]PF_6$ [10]. To a solution containing dmphen (0.052 g, 0.25 mmol) in 20 ml EtOH was added a solution of $CuCl_2 \cdot 2H_2O$ (0.021 g, 0.13 mmol) in 10 ml EtOH, and the mixture was stirred at room temperature (r.t.) for 20 h. After removing any undissolved materials by filtration, a solution containing NH_4PF_6 (0.41 g, 2.5 mmol) in 10 ml EtOH was added to the filtrate. The whole was stirred for 1 day and the resulting green fine crystals were collected by filtration. The crystals were recrystallized from CH_3CN and a well-formed crystal was used for the X-ray structural analysis. Yield: 0.072 g (88%). *Anal.* Found: C, 50.92; H, 3.66; N, 8.48%. Calc. for $C_{28}H_{24}N_4F_6PClCu$ (**1**): C, 50.73; H, 3.69; N, 8.41%. UV–Vis: ν_{max} (10^3 cm^{-1}) (ε, mol^{-1} dm^3 cm^{-1}) (MeCN): 10.27 (141), 13.72 (190), 29.41 (1775), 36.10 (49 500), 44.05 (48 600). Diffuse reflectance spectrum: ν_{max} (10^3 cm^{-1}): 10.22, 13.35, 28.74, 31.85, 35.09. EPR: $g_{\|} = 2.02$, $g_{\perp} = 2.11$ (solid, 140 K); 2.12 (MeCN solution, 140 K). Cyclic voltammetry (MeCN): $E^{\circ\prime} = -0.39$ V.

2.2.2. Synthesis of $[CuCl(phendione)_2]PF_6$ (*2*)

This complex was prepared by a similar method to that for $[CuCl(dmphen)_2]PF_6$ (**1**). To a solution containing phendione (0.10 g, 0.50 mmol) in 20 ml EtOH was added a solution of $CuCl_2 \cdot 2H_2O$ (0.043 g, 0.25 mmol) in 10 ml EtOH, and the mixture was stirred at r.t. for 20 h. After removing any undissolved materials by filtration, a solution containing NH_4PF_6 (0.82 g, 5.0 mmol) in 10 ml EtOH was added to the filtrate. The whole was stirred for 1 day and the resulting green fine crystals were collected by filtration. Recrystallization was accomplished by slow diffusion of ether into a solution of the compound in CH_3CN. A well-formed crystal was used for the X-ray structural analysis. Yield: 0.16 g (92%). *Anal*. Found: C, 41.16; H, 2.30; N, 8.00%. Calc. for $C_{24}H_{14}N_4O_5F_6PClCu$ (**2**): C, 41.78; H, 2.31; N, 7.97%. UV–Vis: ν_{max} (10^3 cm^{-1}) (ε, mol^{-1} dm^3 cm^{-1}) (MeCN): 10.24 (112), 13.76 (179), 28.65 (2440), 33.22 (15 200), 39.68 (52 000). Diffuse reflectance spectrum: ν_{max} (10^3 cm^{-1}): 10.12, 13.89, 27.40, 31.55, 38.02. EPR: 2.10 (solid, 140 K); 2.11 (MeCN solution, 140 K). Cyclic voltammetry (MeCN): $E^{\circ\prime} = -0.79$, -0.14 V.

2.3. Measurements

Electronic absorption and diffuse reflectance spectra were recorded with JASCO Ubest V-560 and V-570 spectrophotometers, respectively. EPR spectra were measured with a Bruker EMX-T ESR spectrometer. Electrochemical measurements were made with a CV-50W apparatus (Bioanalytical Systems, Inc.; BSI) using a platinum disk as working electrode. The Ag/AgCl/MeCN electrode (BSI) and a platinum wire were used as reference and auxiliary electrodes, respectively. These experiments were conducted at r.t. in a 0.1 mol dm^{-3} MeCN solution of Bu_4N as a supporting electrolyte, and at concentrations of the complexes or ligand with 1.0 mmol dm^{-3}. Elemental analyses (C, H, N) were performed by the Analysis Center of the University of Tsukuba.

2.4. X-ray structure determination

Intensity data for **1** and **2** were collected on the Rigaku RASA-7S four-circle diffractometer with graphite-monochromatized Mo Kα radiation ($\lambda = 0.71069$ Å). The structures were solved by the direct method using SIR92 and refined by the full-matrix least-squares method using a TEXSAN program package [16]. All calculations were performed on an Indigo II computer. Crystal data for **1** = $C_{28}H_{24}N_4F_6PClCu$, F.W. = 660.49, triclinic, space group $P\bar{1}$ (#2), $a = 11.497(3)$, $b = 14.526(4)$, $c = 8.750(2)$ Å, $\alpha = 100.23(2)^\circ$, $\beta = 112.20(2)^\circ$, $\gamma = 88.35(2)^\circ$, $V = 1330.2(5)$ $Å^3$, $Z = 2$, $D_{calc} = 1.649$ g cm^{-3}, $\mu = 1.051$ mm^{-1}, crystal size $0.23 \times 0.33 \times 0.58$ mm, trans. factors 0.88–1.00, 6385

reflections measured ($2\theta_{max} = 55.0°$), 4302 observed reflections [$I > 2.00\sigma(I)$] used in the refinement, $R = 0.053$, $Rw = 0.071$ and GOF = 1.81 for 370 parameters. Crystal data for **2** = $C_{24}H_{14}N_4O_5F_6PClCu$, F.W. = 682.36, monoclinic, space group $P2_1/c$ (#14), $a = 13.167(7)$, $b = 14.225(8)$, $c = 15.171(3)$ Å, $\beta = 114.06(3)°$, $V = 2594(2)$ Å^3, $Z = 4$, $D_{calc} = 1.747$ g cm^{-3}, $\mu = 1.095$ mm^{-1}, crystal size $0.15 \times 0.15 \times 0.20$ mm, trans. factors 0.96–1.00, 6200 reflections measured ($2\theta_{max} = 55.0°$), 1913 observed reflections [$I > 2.00\sigma(I)$] used in the refinement, $R = 0.056$, $Rw = 0.065$ and GOF = 1.41 for 442 parameters.

3. Results and discussion

3.1. Crystal structures

The X-ray structural analyses revealed that each of **1** and **2** consists of a discrete monovalent complex cation and one PF_6^- anion, and that **2** additionally involves one H_2O molecule. As shown in Fig. 1, both of the complex cations in **1** and **2** possess five-coordinated environments with $CuClN_4$ chromophores similar to that in $[CuCl(phen)_2]PF_6$ [10]. Namely, each of the Cu atoms in **1** and **2** is coordinated by four N atoms from two phen frameworks and one Cl atom. As shown in Table 1, however, the Cu–Cl distances in **1** (2.257(1) Å) and **2** (2.250(2) Å), which are almost identical with each other, are significantly shorter than that in $[CuCl(phen)_2]PF_6$ (2.294(2) Å). Furthermore, the values of differences between the longest and shortest Cu–N bond distances, ΔCu–N = 0.188(3) Å for **1** and 0.190(7) Å for **2**, are considerably different from that for $[CuCl(phen)_2]PF_6$ (0.156(4) Å) [17]. These suggest that the geometries around Cu(II) centers in **1** and **2** are fairly distinct from that in $[CuCl(phen)_2]PF_6$. The largest angle around the Cu(II) center (β: N3–Cu–N1 = 170.8(1)° for **1**, 173.7(3)° for **2**) is considerably different from the second-largest one (α: N2–Cu–Cl = 150.13(8)° for **1**, 154.0(2)° for **2**). This implies that the geometries around Cu(II) centers in **1** and **2** are of distorted square-pyramidal or trigonal-bipyramidal one. Since the angular structural index parameter, $\tau = (\beta - \alpha)/60$, is evaluated by the two largest angles ($\alpha < \beta$) in the five-coordinated geometry [18], the value of $\tau = 0.34$

[a] Ref. [10].

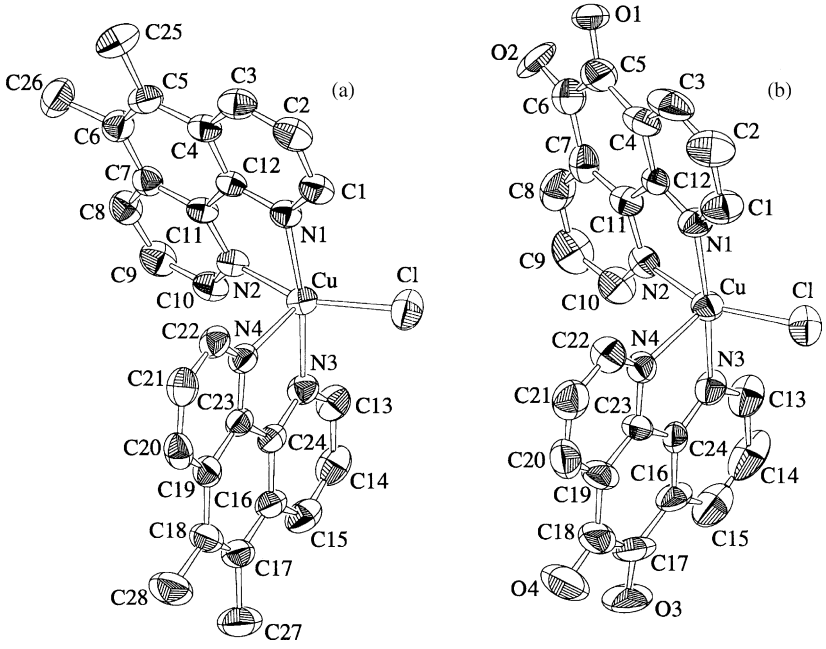

Fig. 1. Perspective views of the complex cations in **1** (a) and **2** (b) with the atomic labeling schemes (ellipsoids at 50% probabilities).

for **1** or 0.33 for **2** seems to indicate a distorted square-pyramid. This is in marked contrast to the unsubstituted phen complex, $[CuCl(phen)_2]PF_6$, with a distorted trigonal-bipyramidal geometry ($\tau = 0.73$) [10].

In both crystals of **1** and **2**, no PF_6^- anions are close enough to interact with the Cu(II) centers in the complex cations, as in the case of $[CuCl(phen)_2]PF_6$ [10]. As shown in Fig. 2(a), however, one dmphen framework in the complex cation in **1** is in close proximity to that in the other complex cation accompanied by the formation of a dimeric unit. Namely, the interplane distance and angle between the neighboring two dmphen frameworks are 3.356(7) Å and 0.000(1)°, respectively, indicating the interaction between the two π-electronic systems of dmphen frameworks. Although slight differences due to the O atoms on the 5- and 6-positions of phen are recognized for the interactions between the π-electronic systems in **2**, the formation of a dimeric unit based on the interaction between the adjacent two phendione frameworks (interplane distance: 3.36(1) Å, interplane angle: 0.000(3)°) occurs as in the case of **1** (Fig. 2(b)). However, the morphology of interactions between the π-frameworks in **1** and **2** is obviously distinguishable from that in $[CuCl(phen)_2]PF_6$, in which each of the two phen frameworks interacts with one phen framework in the adjacent complex cation to form a polymeric chain [10]. Considering these facts, it can be concluded that the five-coordinated geometries of these complexes are appreciably governed by the interactions between the π-frameworks. Since the interactions of π-frameworks are significantly dependent on the steric and electronic natures of the substituents, the five-coordinated geometries of the present complexes seem to be brought by the introductions of the substituents into the phen frameworks.

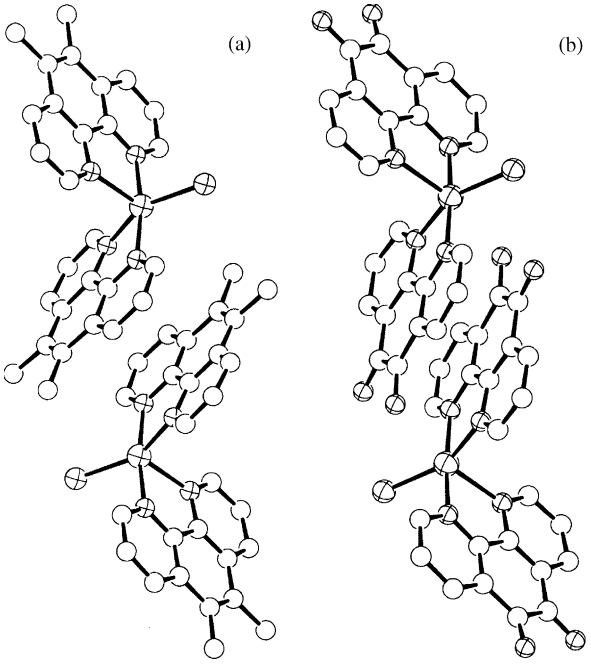

Fig. 2. Dimeric structures in the crystalline state of **1** (a) and **2** (b).

3.2. Electronic absorption and diffuse reflectance spectral behaviors

The reflectance spectrum of $[CuCl(phen)_2]PF_6$ exhibits single peak due to the $d_{xz} \approx d_{yz} \rightarrow d_{z^2}$ transition at 12.10×10^3 cm^{-1} accompanied by a shoulder due to the $d_{x^2-y} \rightarrow d_{z^2}$ transition at 10.50×10^3 cm^{-1} [19], as reported by Hathaway et al. [10]. In the UV region, the complex shows additional four bands at 27.47, 30.40, 33.22, and 35.84×10^3 cm^{-1}. Among these bands, the corresponding band to the 27.47×10^3 cm^{-1} one is also observed for $[CuCl(bpy)_2]Cl$ (bpy = 2,2′-bipyridine) with a different kind of π character [18]. Therefore, the 27.47×10^3 cm^{-1} band of $[CuCl(phen)_2]PF_6$ can be assigned as a Cl-to-Cu CT transition [20,21]. The remaining bands in the UV region seem to be mainly due to the π–π* transitions localized on the phen frameworks. While similar spectral patterns in the UV region are also recognized for **1** and **2**, both complexes exhibit well-resolved two peaks due to the d–d transitions (10.22 and 13.35×10^3 cm^{-1} for **1**, 10.12 and 13.89×10^3 cm^{-1} for **2**) in contrast to $[CuCl(phen)_2]PF_6$. These spectral features seem to reflect differences from $[CuCl(phen)_2]PF_6$ in the geometries around Cu(II) centers and the resulting one-electron ground-state configurations of **1** and **2** [10]. In MeCN, the absorption spectra of **1** and **2** exhibit similar spectral patterns to the reflectance spectra, indicating almost the same geometries around the Cu(II) centers as in the crystalline state. On the other hand, the d-d bands for $[CuCl(phen)_2]PF_6$ are observed as the well-resolved two components, which are appeared at similar energies to those for **1** and **2**. This implies that the geometry around the Cu(II) center of $[CuCl(phen)_2]PF_6$ in solution is distinct from that in the crystalline state and is considered to be rather similar to those of **1** and **2** with a distorted square-pyramid. This is supported by the results of the EPR spectral measurements for the present complexes. Namely, for instance, the anisotropic spectral pattern for the polycrystalline sample of $[CuCl(phen)_2]PF_6$ is slightly different from that in frozen MeCN solution, but seems to be rather similar to that for the polycrystalline sample of **1** with a distorted square-pyramidal geometry [19]. It is suggested therefore that the geometries around the Cu(II) centers of these complexes in the crystalline state are significantly governed by the lattice forces.

3.3. Electrochemical properties

The cyclic voltammogram at platinum disk electrode for $[CuCl(phen)_2]PF_6$ displays only one reversible

Cu(II)/Cu(I) redox couple with $E^{\circ\prime} = -0.37$ V [19]. While **1** also shows the redox couple in a similar potential region, the value of $E^{\circ\prime}$ (-0.39 V) is of slightly negative compared with that for $[CuCl(phen)_2]PF_6$. It is known that the redox potential for Cu(II)/Cu(I) process is shifted to more negative as the electron-donating ability of the substituents on the phen framework becomes higher [14]. Accordingly, it can be regarded that a slight difference in the Cu(II)/Cu(I) redox couple between $[CuCl(phen)_2]PF_6$ and **1** is due to the electron-donating methyl groups on 5- and 6-positions at phen framework. Contrary to the cases of these complexes, **2** shows two reversible redox couples with $E^{\circ\prime} = -0.79$ and -0.14 V in the negative potential region. Among these redox couples, the one with $E^{\circ\prime} = -0.79$ V is also observed for the free phendione ligand [22], and can be assigned as the redox process in the phendione. Although the couple with $E^{\circ\prime} = -0.14$ V of **2** can be regarded as the Cu(II)/Cu(I) redox process, the potential is located on rather positive region than $[CuCl(phen)_2]PF_6$ and **1**. This seems to reflect the characteristic electronic nature of **2** due to the electron-withdrawing substituents on 5- and 6-positions at phen framework. It can be concluded, therefore, that the electrochemical properties of these complexes are significantly influenced by the electronic characters of the substituents on the phen frameworks.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 181117 and 181118 for **1** and **2**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

complexes of the most common di- and tripeptides were first recorded more than three decades ago [7–11] and the most important conclusions were reviewed by Sigel and Martin [12]. It was found that these metal ions form stable, tetragonal $[MH_{-2}L]^{-}$ complexes with tripeptides via the coordination of the terminal amino, two deprotonated amide nitrogen and carboxylate oxygen donor functions. The non-coordinating side chains (e.g. Ala or Leu) do not affect the binding modes of these complexes and the CD spectra can be easily explained by the use of a double octant or hexadecant sector rule [7,12]. Donor atoms in the side chains of peptides, however, can alter the coordination modes of complexes and this is reflected in characteristic changes of the CD spectra.

The metal binding of thioether donor functions of methionyl residues is among the most contradictory issues of metallopeptide chemistry. Thioether donor atoms are among the major metal binding sites in blue copper proteins and in some other metalloenzymes, but the thioether donor groups are generally considered as weakly or non-coordinating side chains in the complexes of the first row transition elements [12]. It was found in our previous study on copper(II) and nickel(II) complexes of tripeptides of methionine that coordination of the sulfur atoms depends on both the number and the position of methionyl residues in the peptide sequence [13]. The results were obtained from combined potentiometric, UV–Vis and EPR measurements and indicated a weak, *axial* or *equatorial* coordination of the sulfur atoms. Metal ion coordinations of N-terminal methionyl residues were also reported in copper(II) and nickel(II) complexes of some dipeptides [14–16], and in some cases these observations were supported by CD measurements [16]. Soft metal ions, like palladium(II), have much higher affinity to thioether binding. As a consequence, the sulfur atoms in the di- and tripeptides of methionine are the primary ligating groups towards palladium(II) [17–21]. Complex formation reactions between palladium(II) and peptides are generally monitored by NMR spectroscopy and in the case of methionine and its derivatives, relatively little information has been gained from CD measurements [18–20].

These data on metal complexes of peptides containing methionyl residues revealed that metal ion coordination of the thioether functions depends on several crucial factors, including the nature of the metal ion and location of the thioether donor atoms. The results were generally obtained from potentiometric studies supported by UV–Vis and EPR or NMR measurements. CD spectra have been reported for several dipeptide complexes, but tripeptides or higher oligomers have not been studied yet. In this paper, we report the results of CD spectroscopic measurements on the copper(II), nickel(II) and palladium(II) complexes of tripeptides containing methionine in all possible locations. The measurements were aimed to reveal the high sensitivity and applicability of CD spectroscopy for the structural elucidation of metal ion–peptide complexes and the results provide a significant contribution to the better understanding of metalloenzymes [1].

2. Experimental

2.1. Materials

The optically pure di- and tripeptides Gly-L-Met, L-MetGly, L-AlaGly, L-MetGlyGly, Gly-L-MetGly, Gly-L-AlaGly, GlyGly-L-Met, L-MetGly-L-Met, L-Met-L-Met-L-Ala and L-Met-L-Met-L-Met were purchased from Bachem and used without further purification. The concentrations of the peptide stock solutions were checked by potentiometric titrations and the pK values of the ligands were reported earlier [13,21]. Stock solutions of copper(II) and nickel(II) chlorides were prepared from analytical grade reagents and their concentrations were determined gravimetrically via the precipitation of oxinates. Palladium(II) complexes were prepared from $K_2[PdCl_4]$ obtained from Fluka.

2.2. CD studies

CD spectra were recorded on a JASCO J-810 spectropolarimeter using 1 or 10 mm cells in the 200–800 nm range with metal ion concentration of 3×10^{-4}–1×10^{-2} mol dm^{-3} in aqueous solution. The pH was varied by adding small portions of either 0.2 mol dm^{-3} KOH or 0.2 mol dm^{-3} HNO_3 to the solution of the metal complexes. All CD spectra are reported as the difference in molar absorptivity ($\Delta\varepsilon = \varepsilon_l - \varepsilon_r$). All experiments were performed at room temperature, near 22 °C.

The CD spectra of the individual complexes were calculated by means of a general computational program PSEQUAD [22], using the original spectra and the total concentrations of metal ion, ligand, hydrogen ion and the potentiometrically determined stability constants.

2.3. Determination of stability constants

The stability constants of peptide complexes were defined by Eqs. (1) and (2) and determined from CD spectroscopic measurements.

$$pM + qH + rL \rightleftharpoons M_pH_qL_r \quad (1)$$

$$\beta_{pqr} = \frac{[M_pH_qL_r]}{[M]^p[H]^q[L]^r} \quad (2)$$

The calculation of the stability constants were performed for copper(II)–tripeptide systems by the use of

the general computational program PSEQUAD [22]. The original spectra, the total concentrations of the metal ion and ligand and the pH values or the total hydrogen ion concentrations were used as the primary input parameters for calculations. The CD spectra of the same samples were taken at 7–10 different pH values in the pH range 3.5–9.0 and $\Delta\varepsilon$ values belonging to 50–60 different wavelengths were used for calculation from each spectrum.

3. Results and discussion

3.1. Copper(II) complexes

Stability constants of the copper(II) and nickel(II) complexes of tripeptides containing methionyl residues have already been reported from potentiometric studies [13]. These data show a very close similarity in the complex formation reactions of the six tripeptides and a good correlation with any other tripeptides containing non-coordinating side chains [12,23]. In all cases, the metal ion speciation of the copper(II) complexes was characterised by the successive formation of the species $[CuL]^+$, $[CuH_{-1}L]$ and $[CuH_{-2}L]^-$ (Fig. 1). The metal binding sites of these species were described by the (NH_2, CO), (NH_2, N^-, CO) and (NH_2, N^-, N^-, COO^-)-coordination modes, respectively.

CD spectra of the copper(II)–tripeptide systems were measured in equimolar solutions and Fig. 2 is used to demonstrate the differences in the measured CD spectra obtained by increasing the pH values in the copper(II)–GlyMetGly system. Although the measured CD spectra always corresponded to a mixture of different complexes in accordance with the distribution curves, the CD spectra of the individual species $[CuL]^+$, $[CuH_{-1}L]$ and $[CuH_{-2}L]^-$ could be derived from the recorded CD spectra by using PSEQUAD program (Fig. 3). The CD data from these optimized spectra for all the major species are collected in Table 1. It is evident that the species $[CuL]^+$, $[CuH_{-1}L]$ and $[CuH_{-2}L]^-$ have significantly different chiroptical properties (Fig. 3 and Table 1), and in all cases, the Cotton effects (CEs) observed in the wavelength range 280–800 nm can be assigned to three different types of transitions: d–d (500–800 nm), N^-(amide)→Cu(II) (280–310 nm) and S(thioether)→Cu(II) transitions (320–360 nm). The NH_2→Cu(II) CT bands were generally observed in the range 250–280 nm but they overlapped with intraligand transitions and the corresponding parameters could not be accurately determined. In addition, the amino groups are coordinated in all species in the whole pH range, thus the changes in NH_2→Cu(II) transitions are not characteristic of the different coordination modes of the complexes.

3.1.1. Species $[CuL]^+$

The formation of the species $[CuL]^+$ is accompanied with a low intensity negative CE in the d–d absorption bands (Table 1 and Fig. 3). This is in agreement with the previous findings of Sigel and Martin [12], which states that the ability of metal ions to sense asymmetry on a nearby side chain is transmitted in the decreasing order: N^-(amide) > NHCO(amide) > COO^- > NH_2. The low intensity of the CEs in the visible range and the lack of any N^-→Cu(II) CT transition below 300 nm strongly

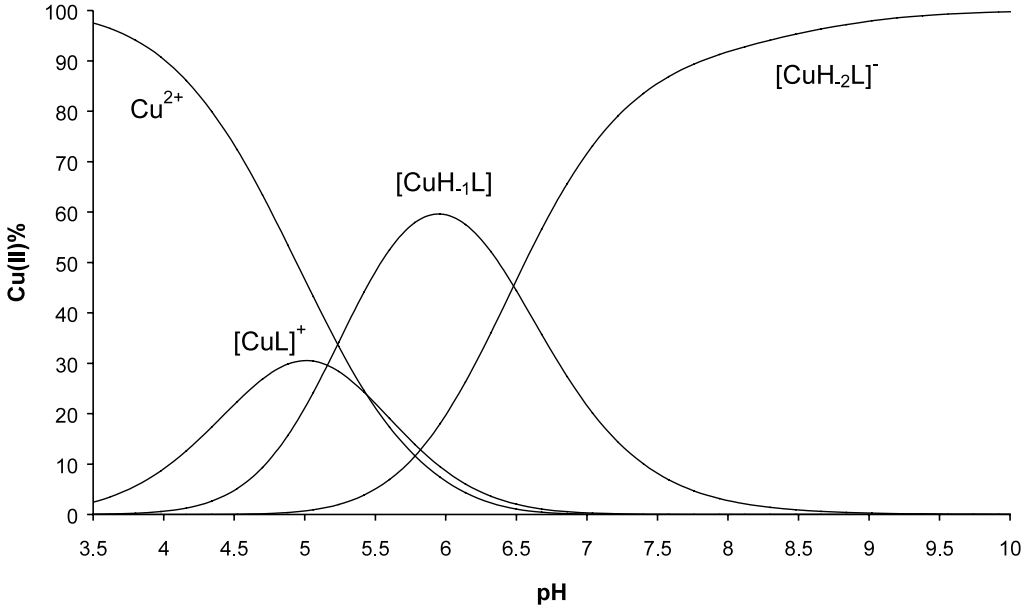

Fig. 1. Concentration distribution of the species formed in copper(II)–GlyMetGly system as a function of pH ($c_{Cu(II)} = c_{GlyMetGly} = 4 \times 10^{-3}$ mol dm^{-3}).

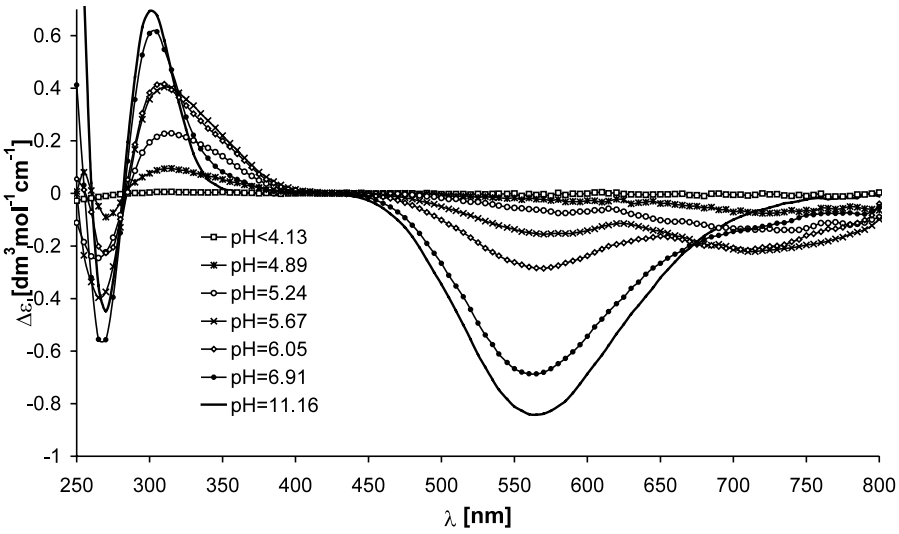

Fig. 2. CD spectra measured in equimolar solutions of copper(II) and GlyMetGly as a function of pH ($c_{Cu(II)} = c_{GlyMetGly} = 1 \times 10^{-2}$ mol dm^{-3}).

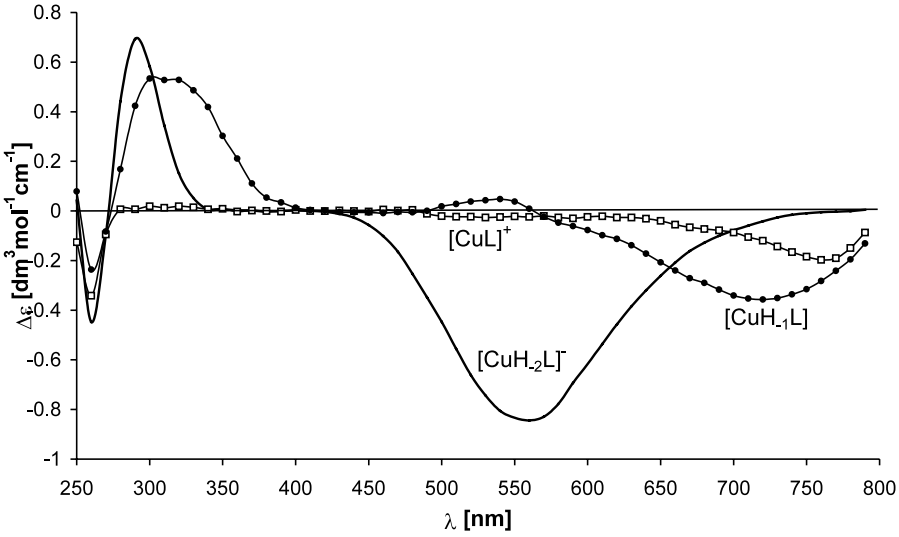
support the (NH_2, CO) binding mode in all $[CuL]^+$ species. There are, however, characteristic differences in the CD spectra of $[CuL]^+$ around 330 nm. A moderately intense CT band with a negative CE is developed in all tripeptide complexes containing N-terminal methionyl residues. These CEs can be attributed to the S(thioether)→Cu(II) CT transitions supporting the *axial* coordination of the thioether residues (Scheme 1a). The intensities of these transitions are changing via maximum curves in the function of pH and the locations of the maxima correspond to the highest concentration of $[CuL]^+$.

3.1.2. Species $[CuH_{-1}L]$

The species $[CuH_{-1}L]$ was formed in a medium pH range ($4.5 < pH < 8$) and it was characterised by the coordination of the terminal amino and the deprotonated nitrogen atoms of the subsequent amide groups [13]. The visible absorption spectra of $[CuH_{-1}L]$ exhibit a broad, single absorption band around 630–650 nm in agreement with the coordination of two nitrogen donor atoms [4,5]. In most cases, the CD of the d–d transitions are, however, split into a low intensity negative (700–730 nm) and an even less intense positive (540–570 nm) CE. The highest intensities of these CD extrema were obtained for the copper(II) complexes of tripeptides containing internal methionyl residues, supporting the above mentioned coordination mode and the increased ability of the amide nitrogen to transmit chiral information. The $N^- \rightarrow Cu(II)$ CT transitions were observed in all systems and the intensities followed the same trends. The S(thioether)→Cu(II) CT bands were developed only in the $[CuH_{-1}L]$ species of peptides containing internal methionyl residues. In this case, the



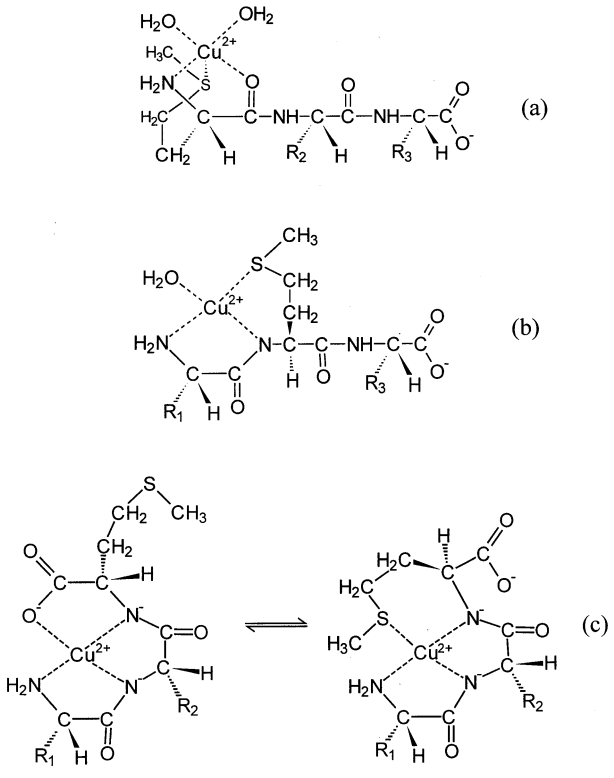


Fig. 3. Optimized CD spectra of the individual species $[CuL]^+$, $[CuH_{-1}L]$ and $[CuH_{-2}L]^-$ formed in the copper(II)–GlyMetGly system and calculated with the program PSEQUAD by using the measured CD spectra and the stability constants.

Scheme 1.

S(thioether) → Cu(II) transitions were, however, observed in the form of a positive CE, appearing as a red-shifted shoulder on the $N^- \rightarrow Cu(II)$ CT transitions. The change in the sign of CE strongly suggests a different binding mode, namely, an *equatorial* coordination of the thioether residue as represented by Scheme 1b. The absence of this transition in the copper(II) complexes of Gly-L-AlaGly provides further support for the thioether coordination of internal Met residues in $[CuH_{-1}L]$ species.

3.1.3. Species $[CuH_{-2}L]^-$

The stability constants, UV–Vis and EPR spectral parameters of $[CuH_{-2}L]^-$ complexes of different tripeptides were reported to be very similar to each other, while CD spectra of these species (Fig. 4) revealed significant differences. The CD data obtained for the complexes of tripeptides with two or three optically active residues make it possible to assess the so-called additivity rule [12]. For instance, the comparison of the data for the d–d transitions of the species $[CuH_{-2}L]^-$ in Table 1 and Fig. 4 reveals that in the case of tripeptides with one methionyl residues, the intensities of the d–d and $N^- \rightarrow Cu(II)$ CT transitions are changing in the following order: GlyMetGly > GlyGlyMet ≫ MetGlyGly. The CD intensities of the studied complexes are collected in Table 2 for both d–d (560 nm) and CT (300 nm) transitions. Table 2 shows that the measured intensities of the d–d transitions for MetGlyMet and MetMetMet complexes gave good agreement with the calculated ones. The additivity is also reasonable for MetMetAla, but in this case the exact comparison would require the consideration of the data for GlyGlyAla. Similar observations on the addi-

Table 2
CD intensities measured at 300 and 560 nm for the $[CuH_{-2}L]^{-}$ complexes of tripeptides

Ligand	300 nm		560 nm	
	Measured	Calculated [a]	Measured	Calculated [a]
GlyAlaGly	+0.49		−0.84	
GlyMetGly	+0.69		−0.86	
GlyGlyAla [b]	no data		−0.42	
GlyGlyMet	−0.67		−0.68	
MetGlyGly	+0.37		−0.01	
MetGlyMet	−0.26	−0.30	−0.61	−0.69
MetMetAla	+0.50		−1.27	−1.29
MetMetMet	−0.20	+0.38	−1.60	−1.55

The choosen wavelengths are characteristic of the CT and d–d transitions and are aimed to certify the validity of the additivity rule.
[a] Calculations are based on additivity rule [12].
[b] Data from Ref. [12].

tivity of CD transitions have already been reported for the copper(II) complexes of tripeptides of alanine and leucine [10].

Moreover, the CD spectra recorded in the near UV range show marked differences both in the signs and intensities of CD extrema. In the case of the tripeptides containing N-terminal and/or internal Met residues (GlyMetGly, MetGlyGly and MetMetAla), only the $N^{-}\rightarrow Cu(II)$ CT transitions are observed. These data reflect a significant positive CE and the additivity also holds for these transitions. However, in the case of tripeptides containing C-terminal Met residues (GlyGlyMet, MetGlyMet and MetMetMet), the $N^{-}\rightarrow Cu(II)$ and $S\rightarrow Cu(II)$ transitions overlap, which makes the interpretation of data more complex. Our previous EPR studies on the same systems proved that in the case of C-terminal methionyl residues an *axial/equatorial* equilibrium is possible for the thioether binding (Scheme 1c.). It was also concluded from the EPR data that the *axial* coordination is much favoured for MetMetMet as compared to the other peptides [13]. Previous CD data reported for the copper(II) complexes of tripeptides with C-terminal alanine or leucine residues showed a negative CE in the $N^{-}\rightarrow Cu(II)$ CT transitions upon the coordination of two amide functions and their additivities were also well established [9]. The data in Tables 1 and 2 reveal very similar tendencies for GlyGlyMet and MetGlyMet, whereas MetMetMet exhibits very significant deviation from the additivity. This difference can probably be explained by the differences in the coordination modes of the thioether residues in various complexes. The data in Table 1 unambiguously prove that *axial* coordination of thioether residues are accompanied with a significant negative, whereas *equatorial* coordination with a less intense positive CE.

The measured CD spectra of the Cu(II)–tripeptide systems also allow the calculation of the stability constants. Details of these calculations were given in Section 2, while the final data are collected in Table 3 and compared with the stability constants determined by potentiometric titrations [13]. The agreement of potentiometric and CD spectroscopic data is excellent in almost all the cases, which supports that besides structural characterisation, CD spectroscopy is a very sensitive tool for determination of metal ion speciation of peptide complexes.

3.2. Nickel(II) complexes

Complex formation processes between nickel(II) ions and tripeptides are characterised by the formation of a diamagnetic, square planar $[NiH_{-2}L]^{-}$ complex which exists as the major species in slightly alkaline solutions

Table 3
Stability constants of copper(II) complexes of tripeptides determined by potentiometric and CD spectroscopic methods

Ligand	Species	pH-metric data from Ref. [13]	CD spectra
GlyAlaGly	$[CuL]^+$	5.18	5.2 (1)
	$[CuLH_{-1}]$	−0.14	−0.01 (9)
	$[CuLH_{-2}]^-$	−6.76	−6.67 (9)
GlyMetGly	$[CuL]^+$	5.06	4.8 (1)
	$[CuLH_{-1}]$	−0.10	−0.23 (2)
	$[CuLH_{-2}]^-$	−6.58	−6.51 (2)

	$[CuLH_{-1}]$	−0.26	−0.27 (6)
	$[CuLH_{-2}]^-$	−6.17	−6.34 (4)

Standard deviations of the last digits are in parenthesis.

[12,23]. In the case of tripeptides of methionine, the formation of these species have already been reported, containing (NH_2, N^-, N^-, COO^-)-coordinated central nickel(II) ions without any involvement of the thioether residue in the metal binding [13]. The formation of an octahedral (NH_2, CO)-coordinated species, $[NiL]^+$, was also detected at low pH values in all cases. Thioether coordination was proposed only in these $[NiL]^+$ complexes of tripeptides containing N-terminal methionyl residues.

The evaluation of the CD spectra of the nickel(II)–tripeptide complexes supports the published structures obtained by the combined application of potentiometric and UV–Vis measurements [13]. Moreover, CD investigations provide some additional information on the binding properties of the ligands and reveal significant differences in the spectral behaviour of these tripeptide complexes (Table 4). The S → Ni(II) CT transitions are found only in the $[NiL]^+$ complexes of tripeptides that contain N-terminal methionyl residues. The intensities of these CD transitions are increasing with the increasing number of Met residues (MetMetMet > MetMetAla > MetGlyGly), suggesting that the coordination of the metal ion to the thioether group of the N-terminal methionine may help the subsequent metal binding of the other thioether functions. Considering the high number of free coordination sites in the octahedral

Table 4
Parameters of CD extrema ($\lambda(\Delta\varepsilon)$) calculated from the CD spectra of nickel(II)–tripeptide complexes measured at different pH values

Ligand	Species	$N^- \rightarrow Ni(II)$	S → Ni(II)	d–d
MetGlyGly	$[NiL]^+$		261 (+0.13)	
	$[NiLH_{-2}]^-$	237 (−2.45)		495 (−0.22); 424 (+0.38)
GlyMetGly	$[NiLH_{-2}]^-$	250 (+8.35)		479 (−1.50)
GlyGlyMet	$[NiLH_{-2}]^-$	236 (+1.89)		454 (−1.27)
MetMetAla	$[NiL]^+$		257 (+0.23)	
	$[NiLH_{-2}]^-$	250 (+9.30)		475 (−2.96)
MetMetMet	$[NiL]^+$		253 (+0.60)	
	$[NiLH_{-2}]^-$	248 (+8.77)		474 (−3.06)

$[NiL]^+$ complexes, the coordination of more than one sulfur atom is possible.

The species $[NiH_{-2}L]^-$ is exclusively formed in all the studied nickel(II)–tripeptide systems above pH 9. The UV–Vis spectra of these complexes are almost the same for all tripeptides, exhibiting a rather intense absorption maximum at $\lambda_{max} = 429 \pm 2$ nm. The CD spectra of these species are, however, much more sophisticated, and always contain d–d and $N^- \rightarrow$ Ni(II) CT transitions around 470 and 250 nm, respectively. Moreover, the intensities of these CD extrema reveal quite significant differences depending on the number and location of methionyl residues. The $[NiH_{-2}L]^-$ complexes of tripeptides containing internal methionyl residues show strong CE at around 250 nm due to their $N^- \rightarrow$ Ni(II) CT transitions, while this CE is significantly less intense in the case of tripeptides without internal methionyl residues. This observation agrees with earlier results published on the nickel(II) complexes of tripeptides containing non-coordinating side chains where the highest intensities were always reported for the ligands containing the optically active residue in internal position [9]. However, for the peptides of methionine, the effect of the internal residues is much more enhanced than that of other side chains, which is most likely due to the effect of the non-coordinated thioether residues.

The results obtained for the d–d transitions of the square-planar $[NiH_{-2}L]^-$ complexes show a very high similarity to those of the corresponding tetragonal copper(II) complexes. Thus, the transmission of the asymmetry from the optically active residues is decreasing in the order: GlyMetGly > GlyGlyMet ≫ MetGlyGly, which is manifested in a decrease in the CD intensities of the d–d transitions. The d–d CD intensities of the peptides containing three optically active residues (MetMetAla and MetMetMet) are much stronger which is in accordance with the calculated value [475 nm (+2.81)] assuming the additivity of CD intensities.

3.3. Palladium(II) complexes

Numerous studies have been reported in the literature on the palladium(II) complexes of simple dipeptides of methionine and the results unambiguously prove that the thioether donor functions are the primary metal binding sites [17–21,24–26]. The structures of the palladium(II) complexes of the ligands containing methionine in C-terminal or internal positions were described by the (NH_2, N^-, S)- or (NH_2, N^-, N^-, S)-coordination modes [21]. The coordination chemistry of N-terminal methionine peptides was reported to be more complicated due to the formation of polynuclear species. Most of these observations were based upon ^1H NMR measurements which requires concentrated solutions (at least 10^{-2} mol dm^{-3}). In contrast, CD measurements of these systems can be carried out at a concentration less than 3×10^{-4} mol dm^{-3}. Several CD spectra were reported for the simple dipeptides of methionine and *S*-methyl-L-cysteine [19,20] but a systematic study for the CD characterisation of di- and tripeptides of methionine is not yet available in the literature. In this study, we performed CD measurements on the palladium(II) complexes of the dipeptides GlyMet and MetGly and the tripeptides GlyMetGly and GlyGlyMet with various pHs and metal ion to ligand ratios.

The characteristic CD spectra obtained in equimolar acidic (pH $\approx$ 3) solutions of $K_2[PdCl_4]$ and GlyMet, GlyMetGly or GlyGlyMet are shown in Fig. 5. The CD data of the palladium(II) complexes of GlyMet and GlyMetGly reflect a close similarity to each other below 370 nm, but they are distinctly different from those of MetGly and GlyGlyMet. It is also noteworthy that the CD spectra of the Pd(II)–GlyMet and –GlyMetGly systems are significantly different from Pd(II)–GlyAla (375 nm (−0.80) and 320 nm (+0.25)) reported by Wilson and Martin [11]). These observations clearly indicate the existence of the (NH_2, N^-, S)-coordination mode in the palladium(II) complexes of GlyMet and GlyMetGly in agreement with previous results from NMR studies [21]. The stoichiometric compositions of the corresponding species in solution can be given as $[PdH_{-1}L]$ or $[PdL]^+$ ($=[PdH_{-1}LH]^+$) depending on the pH because the non-coordinating carboxylate group is protonated in acidic solutions. The fourth coordination sites of palladium(II) ions are certainly available for the monodentate binding of any complexing agents present in solution. In equimolar samples, this results in species like $[PdH_{-1}L(H_2O)]$, $[PdH_{-1}LCl]$, $[PdH_{-1}L(OH)]^-$ depending on the chloride concentration and pH of the solutions. In agreement with these expectations, the change of pH or increasing chloride concentration of solutions does not induce substantial shifts of the CD extrema of Pd(II)–GlyMet or –GlyMetGly systems, and there is no change in the shape of the absorption bands at all. Similar observations were obtained with an excess of di- or tripeptide ligands, supporting that the second ligand is coordinated monodentately via the thioether residues in acidic solutions ($[PdL_2]=[Pd(H_{-1}L)(LH)]$ and via the deprotonated amino group at higher pH values ($[PdH_{-1}L_2]^-=[Pd(H_{-1}L)(L)]^-$). Our previous NMR studies on the bis(ligand) complexes of these peptides clearly indicated the existence these (S)- or (N)-bonded isomers [21].

The CD spectra of Pd(II)–GlyGlyMet system is characterised by a relatively intense negative CE ($\Delta\varepsilon = -1.15$) at 290 nm. This is entirely different from those reported for the palladium(II)–GlyGlyAla system: 335 nm (−1.00) and 290 nm (+0.37) [11]. In agreement with the previous findings from NMR measurements [21] these data strongly support the existence of the

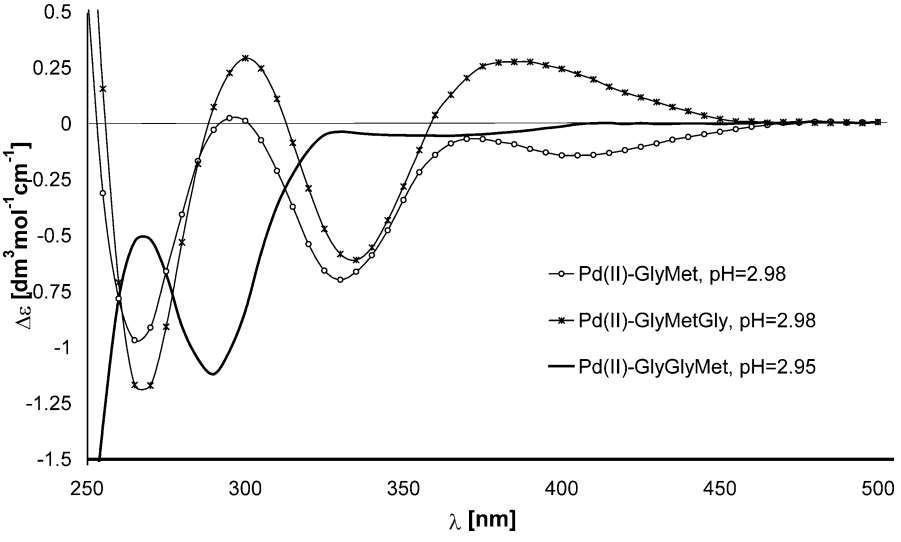

Fig. 5. CD spectra of the palladium(II) complexes of GlyMet, GlyMetGly and GlyGlyMet obtained in equimolar solutions ($c = 4 \times 10^{-4}$ mol dm^{-3}).

(NH_2, N^-, N^-,S)-coordination mode in the $[PdH_{-2}L]^-$ species of GlyGlyMet. It is also important to note that the CD spectrum measured in equimolar solutions at pH 3 and shown in Fig. 5 does not show any change when increasing or decreasing pH or adding an excess of ligand, which provides an unambiguous proof for the outstanding thermodynamic stability of the palladium(II) complexes of peptides containing methionyl residues as the third amino acid in the peptide sequence.

In contrast to the above-mentioned findings, the CD spectra of the palladium(II)–MetGly system exhibit very significant changes in the function of pH values and metal ion to ligand ratios. These spectral changes are best represented by Fig. 6 where the CD spectra of Pd(II)–MetGly = 1:2 samples are plotted in the function of pH. It can be seen from Fig. 6 that the CD spectra obtained in acidic solutions ($2.06 < pH < 6.61$) are the same and the spectral parameters show a good agreement with those of bis(ligand) complexes of palladium(II) with methionine [11]. Namely, the CD transitions occurred at $\lambda = 381$ and 305 nm ($\Delta\varepsilon = +0.62$ and -2.56, respectively) for MetGly in this study and $\lambda =$ 379 and 300 nm ($\Delta\varepsilon = +0.32$ and -1.80, respectively) for L-methionine. In agreement with the previous NMR studies [17], these observations strongly support the bidentate (NH_2, S)-coordination of the N-terminal Met residues in the bis(ligand) complexes of palladium(II). Thermodynamic data for the outstanding stability of this type of coordination have been reported recently [27]. As a consequence, the coordinatively saturated bis(ligand) complexes of palladium(II) are formed under strongly acidic conditions and their CD spectra remains intact because deprotonation of the non-coordinated carboxylic functions do not have any effect on the CD parameters. Characteristic changes of the CD spectra are, however, observed above pH 7, suggesting a significant change in the coordination modes of the ligands. The appearance of an isobestic point at 345 nm strongly supports the presence of two species in the pH range 7–10. It should also be considered that the spectral parameters of Pd(II)–MetGly = 1:2 system at $pH > 10$ are reminiscent of those of Pd(II)–AlaGly [350 and 301 nm ($\Delta\varepsilon = -0.50$ and -0.41) for MetGly and 360 and 279 nm (-0.32 and -0.35) for AlaGly], suggesting the bidentate (NH_2, N^-) binding mode in the palladium(II) complexes of both peptides above pH 10 [21,28].

The changes of the CD spectra in the equimolar solutions of palladium(II) and MetGly are more complicated because of the formation of polynuclear species. The CD spectra obtained in strongly acidic solutions ($pH < 3$) correspond to the bidentate chelation via the amino and thioether donor functions in mononuclear complexes. An increase in pH results in very significant changes both in the locations and intensities of the CD transitions but neither isobestic points nor saturation of spectra can be observed in equimolar samples at the studied pH values. The previous NMR experiments [17] were interpreted by the deprotonation and coordination of amide groups resulting in (NH_2, N^-, COO^-)-coordination with sulfur bridging at the fourth coordination site. A further increase in pH leads to hydroxo complex formation, but these can also be polynuclear via hydroxo and/or thioether bridging.

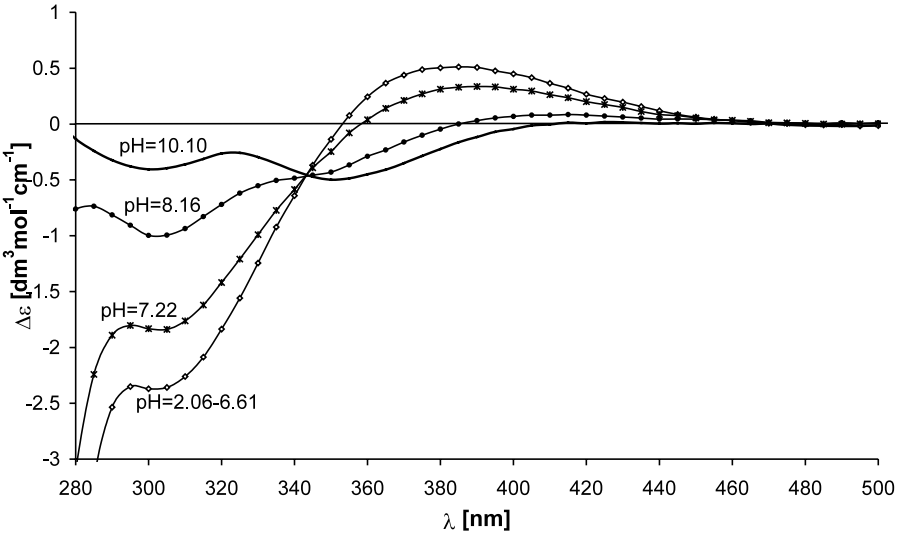

Fig. 6. CD spectra of the palladium(II) complexes of MetGly obtained in 1:2 metal ion to ligand ratio at different pH values ($c_{Pd(II)} = 4 \times 10^{-4}$ mol dm^{-3}).

4. Conclusions

The results presented in this paper provide clear evidence that CD spectroscopy is a valuable, fast and relatively simple experimental technique for the structural characterisation of peptide complexes. In the case of the copper(II) complexes of tripeptides, the results gave an unambiguous proof for the weak metal ion coordination of thioether donor functions depending on the number and location of methionyl residues. Although, similar observations have already been reported on the basis of UV–Vis and EPR measurements [13], CD spectroscopy have three major advantages compared to those techniques: (i) d–d transitions, $S\rightarrow$ Cu(II) and $N^{-}\rightarrow$Cu(II) CT transitions are generally well separated and easily observable; (ii) the intensities of the individual transitions depend on the location of the optically active residue or on the nature of the coordinating donor atoms; (iii) the results obtained for the $S\rightarrow$Cu(II) CT bands indicate that the *axial* and *equatorial* coordination of thioether residues results in the different signs of the CE providing an unambiguous proof for the conformation in solution.

It has been shown for copper(II) complexes that the CD data of metal complexes can be used for the determination of stability constants. In general, this is true for any spectroscopic technique, but the application of UV–Vis spectroscopy is very limited, because of the broad, unresolved absorption bands of copper(II) complexes. The sensitivity of EPR spectroscopy is much better, but it can be applied only for selected metal ions. It is well demonstrated that changes of pH values have a very significant impact on the CD spectra. Moreover, these spectral changes can involve the changes of the sign of CD extrema, which makes CD spectroscopy a very sensitive tool for the characterisation of metal ion speciation and provide a unique possibility for the detection of species present in low concentration. A further advantage of the application of CD spectroscopy comes from the fact that pH-potentiometry can only be applied if complexation is accompanied by a change in pH values. It is not the case for the monodentate coordination of thioether ligands, but CD spectroscopy can be an adequate method even for these systems.

In the case of square-planar, diamagnetic species (e.g. tripeptide complexes of nickel(II) and any palladium(II) complex), the application of NMR spectroscopy is probably as informative as CD spectroscopy. The NMR measurements, however, require the use of relatively high concentrations (≥ 0.01 mol dm^{-3}), while 10–100 times lower concentrations can be used in CD measurements. This makes the investigation of peptide complexes possible, when the ligands are available in very small quantities. On the other hand, the combined application of CD and NMR spectroscopies provides a valuable tool for structural studies in a wide concentration range, e.g. for the detection of different oligomers.

complexes have shown interesting cytotoxic activity [9], similar behaviour may be expected by the Zn(II) complexes that we have synthesized and studied also for this purpose. In fact, Zn(II) is recognized to be essential for life, being present in several naturally occurring metalloenzymes; then its metal complexes should be investigated as potential cytotoxic agents.

2. Results and discussion

2.1. Molecular and crystal structure of trichloro(1-methylpiperazin-1-ium-N^4)zinc(II), [$ZnCl_3(H_2Meppz)$] (1)

Selected bond distances and angles of complex **1** are reported in Table 1 and the molecular structure is depicted in Fig. 1. The crystals of [$ZnCl_3(H_2Meppz)$] are isomorphous with those of [$CoCl_3(H_2Meppz)$] [7], in particular they are both zwitterionic (amphiionic) species being the HMeppz ring protonated at the N2 nitrogen atom, both show the piperazine ring in the characteristic chair conformation and both possess the same distorted tetrahedral geometry compressed along the metal–nitrogen bond [7].

The Zn–N(1) distance of 2.078(3) Å is shorter than the Zn–N distance of 2.102(5) Å found in (1,3,5,7-tetraazaadamantane)trichlorozincate(II) anion, $[\{(CH_2)_6N_4\}ZnCl_3]^-$ [10], the only known complex that shows the aminotrichlorozinc(II) group N–$ZnCl_3$ with a N atom of an aliphatic amine. This is probably due to the steric hindrance exerted by the hydrogen atoms bonded to C_1^b atom of the adamantine ring towards the Zn(II)–N bond.

The three Zn(II)–Cl distances [Zn–Cl(1) = 2.257(1), Zn–Cl(2) = 2.264(2) and Zn–Cl(3) = 2.228(1) Å] are in the normal range usually observed in N–$ZnCl_3$ complexes [10–19], but become slightly longer when the corresponding chlorine atom is involved in strong hydrogen bonding [7]. In fact, Zn–Cl(3) is the shortest distance as Cl(3) is not involved in any hydrogen bond.

Table 1
Selected bond distances (Å) and angles (°) in trichloro(1-methylpiperazin-1-ium-N^4)-zinc(II), [$ZnCl_3(H_2Meppz)$] (**1**)

Bond lengths			
Zn–N(1)	2.078(3)		
Zn–Cl(1)	2.257(1)		
Zn–Cl(2)	2.264(1)		
Zn–Cl(3)	2.228(1)		
Bond angles			
N(1)–Zn–Cl(1)	104.18(7)	C(1)–N(1)–Zn	111.3(2)
N(1)–Zn–Cl(2)	104.27(7)	C(4)–N(1)–Zn	114.5(2)
N(1)–Zn–Cl(3)	107.69(8)	Cl(1)–Zn–Cl(3)	112.94(4)
Cl(1)–Zn–Cl(2)	113.56(4)	Cl(2)–Zn–Cl(3)	113.20(4)

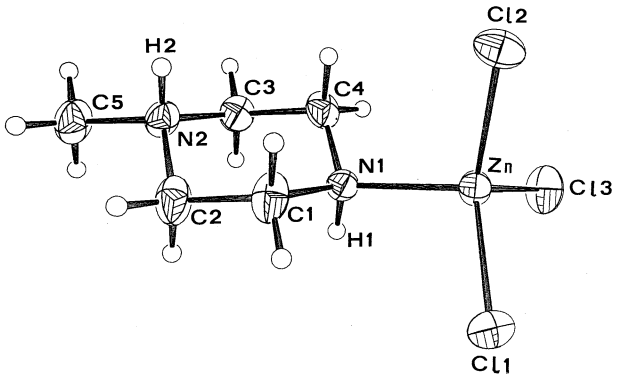

Fig. 1. ORTEP drawing of the [$ZnCl_3(H_2Meppz)$] complex (**1**) showing the atom numbering scheme. For clarity the hydrogen atoms are shown as spheres of arbitrary radius.

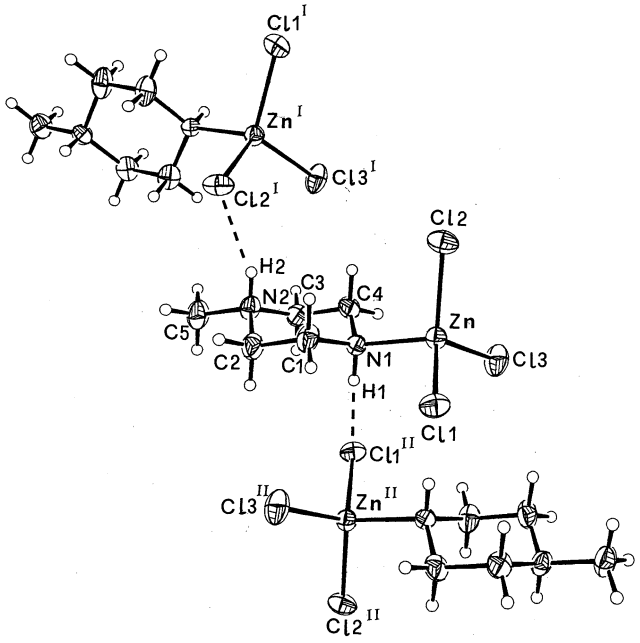

Fig. 2. ORTEP drawing of the [$ZnCl_3(H_2Meppz)$] complex (**1**) showing the two N–H···Cl hydrogen bonds connecting the fundamental molecule (in the middle) with the two molecules at ($I = 1/2+x$; $1/2-y$; $1/2+z$) (top) and at (II = $-x$; $-y$; $2-z$) (bottom).

The structure consists of discrete [$ZnCl_3(H_2Meppz)$] molecules held together by N^+–H···Cl intermolecular hydrogen bonds (Fig. 2), thus giving rise to the same crystal packing of [$CoCl_3(H_2Meppz)$] complex [7]. The parameters of the two very strong N^+–H···Cl intermolecular hydrogen bonds are (prior to calculations the N(2)–H(2) and N(1)–H(1) bond lengths were normalized to 1.033 Å): (i) $H(2)\cdots Cl(2)^I = 2.156(3)$ Å, $N(2)\cdots Cl(2)^I = 3.137(4)$ Å, $N(2)^+–H(2)\cdots Cl(2)^I = 157.8(3)°$; (ii) $H(1)\cdots Cl(1)^{II} = 2.373(3)$ Å, $N(1)\cdots Cl(1)^{II} = 3.361(3)$ Å, $N(1)–H(1)\cdots Cl(1)^{II} = 159.4(2)°$.

Table 2
Selected bond distances (Å) and angles (°) in trichloro(1,4-dimethylpiperazin-1-ium-N^4)-zinc(II), $[ZnCl_3(HMe_2ppz)]$ (**2**) [a]

Bond lengths			
Zn–N(1)	2.117(5)		
Zn–Cl(1)	2.258(1)		
Zn–Cl(2)	2.232(2)		
Bond angles

2.2. Molecular and crystal structure of trichloro(1,4-dimethylpiperazin-1-ium-N^4)zinc(II), $[ZnCl_3(HMe_2ppz)]$ (2)

Selected bond lengths and angles of complex **2** are reported in Table 2 and the molecular structure is illustrated in Fig. 3. Also the crystals of $[ZnCl_3(HMe_2ppz)]$ are isomorphous with those of $[CoCl_3(HMe_2ppz)]$ [7]; in particular they are both zwitterionic (amphiionic) species being the 1,4-dimethylpiperazine ring protonated at the N2 nitrogen atom, both show the piperazine ring in the characteristic chair conformation and both possess the same distorted tetrahedral geometry but different from that of complex $[ZnCl_3(H_2Meppz)]$ and of course of $[CoCl_3(H_2Meppz)]$. In fact, analogously to $[CoCl_3(HMe_2ppz]$ [7], the bulky $-ZnCl_3$ group is coordinated to the axial position of piperazine ring instead of the less hindered equatorial position. This event produces two short intramolecular non-bonding H···Cl distances: H(2)A···Cl(2) = 2.821(4) Å and H(4)A···Cl(1) = 2.910 (4) Å and, in addition, a very long Zn–N coordination bond, Zn–N(1) = 2.117(5) Å, while that observed in complex **1** is only 2.078(3) Å. Similarly to the $[CoCl_3(HMe_2ppz]$

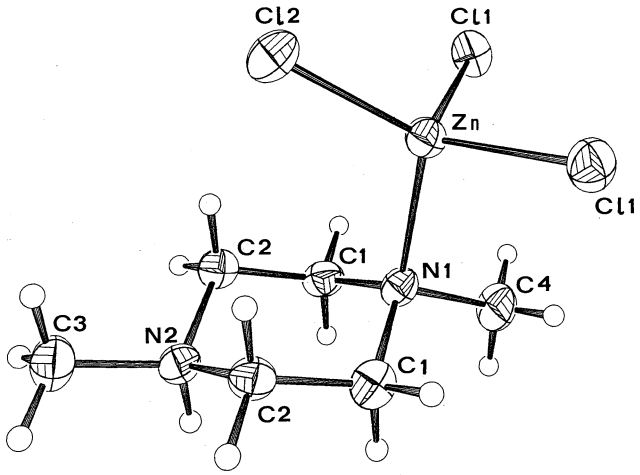

Fig. 3. ORTEP drawing of the $[ZnCl_3(HMe_2ppz)]$ complex (**2**) showing the atom numbering scheme. For clarity the hydrogen atoms are shown as spheres of arbitrary radius.

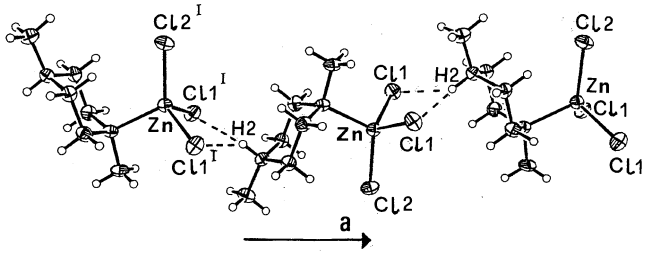

Fig. 4. ORTEP drawing of the $[ZnCl_3(HMe_2ppz)]$ complex (**2**) showing the symmetrical three-centre

hydrogen bond connecting molecules positioned across the mirror plane at $y = 1/4$ and running along the a-axis. Symmetry transformation: ($I = -1/2+x, 1/2-y, 1/2-z$).

complex [7], the crystal packing consists of discrete $[ZnCl_3(HMe_2ppz]$ molecules held together by a strong symmetrical (imposed by the space group symmetry) three-centre hydrogen bond as shown in Fig. 4, with the following parameters (prior to calculations the N(2)–H(2) bond length was normalized to 1.033 Å): H(2)···Cl(1)^I = 2.520(2) Å, N(2)···Cl(1)^I = 3.283(4) Å, N(2)$^+$–H(2)···Cl(1)^I = 130.18(3) Å.

2.3. The N–$ZnCl_3$ group and the Zn–N bond

The tetrahedral or distorted tetrahedral N–$ZnCl_3$ group is very uncommon in literature when N belongs to an aliphatic amine but is more common when N belongs to an aromatic ring. So far the only known aminotrichlorozinc(II) species is the (1,3,5,7-tetraazaadamantane)trichlorozincate(II) anion $[\{(CH_2)_6N_4\}ZnCl_3]^-$ [10]. The Zn–N distances are, on average, shorter when N is aromatic rather than aliphatic, in fact, for example, they are: 2.020(2) Å in [trichloro(7-methyladenine-N^9)zinc(II)]$^-$ anion [11]; 2.040(3) Å in Zn(thiamine)$Cl_3 \cdot 0.4H_2O$ [12]; 2.050 Å in 9-methyladeninium) trichloro(9-methyladenine)-zinc(II) [13]; 2.054(3) Å in trichloro-(purinium)-zinc(II) [14]; 2.055(8) Å in trichloro(*N*-4′-pyridyl)-4-ethoxypyridinium)-zinc(II) [15]; 2.073(11) Å in trichloro(8-aza-adeninium)-zinc(II) [16]; 2.079(2) Å in trichloro-adeninium-zinc(II) form(ii) [17]; 2.091(1) Å in (adeninium-N)-trichloro-zinc(II) [18]; 2.094(2) Å in trichloro-adenium-zinc(II) form(i) [19].

Another interesting aspect of the N–$ZnCl_3$ group is its ability to form hydrogen bonds, usually involving only two chlorine atoms.

Among the numerous [1,4-dimethylpiperazinium]$^{2+}$ $[MX_4]^{2-}$ complexes (M(II) = Fe(II), Co(II), Zn(II); X = Cl^-, Br^-) studied by Kemnitz et al. [20–23], we want to remember the $[H_2Me_2ppz][ZnCl_4]$ [20] and $[H_2Me_2ppz][ZnBr_4]$ [21] complexes; their structures

consist of discrete, slightly distorted, $[MX_4]^{2-}$ tetrahedral and centrosymmetric $[H_2Me_2ppz]^{2+}$ dications, in the chair form, held together by electrostatic forces and hydrogen bonds. They are formed as charged species because the syntheses were carried out in concentrated HCl and HBr solutions, while our complexes are formed at basic pH for the presence of piperazine free bases, thus metal atom may bind the piperazine nitrogen atom instead of the X^- anion. So far, only two complexes, namely *N*,*N*′-bis(6-(2-hydroxymethyl)-pyridylmethyl)-piperazine zinc(II) nitrate and dichloro-*N*,*N*′-bis(6-(2-hydroxy-methyl)pyridylmethyl)piperazine zinc(II), possessing a Zn(II)–N(piperazine) bond of 2.238(4) and 2.232 (4) Å, respectively, are reported in literature [24]. No comparison with our complexes is possible because they differ for coordination geometry, coordination number and donor site. Our complexes are distorted tetrahedral (c.n. = 4) with NCl_3 donor set, and those in Ref. [24] are distorted square-pyramidal (c.n. = 5) with O_3N_2 donor set.

2.4. Formation of isomorphous and isostructural Zn(II) and Co(II) complexes

The formation of isomorphous and isostructural Co(II) and Zn(II) coordination compounds is common enough and occurs in particular with the c.n. = 4, (pseudo)tetrahedral [25] or with c.n. = 6, (pseudo)octahedral [26]. In addition, other geometries with c.n. = 5 are sometimes observed, namely (pseudo)trigonal bipyramidal [27] or (pseudo)square-pyramidal [28].

The factors favouring such a phenomenon are: (i) the similarity of Zn(II) and high spin Co(II) ionic radii in various environments (0.74, 0.72 Å with c.n. = 4, 0.78, 0.79 with c.n. = 5 and 0.88, 0.89 Å with c.n. = 6, respectively); (ii) the easy formation of (pseudo) tetrahedral, octahedral and pentacoordinate compounds for both the ions. On the contrary, the factors contrasting this phenomenon are the easy oxidation of Co(II) to Co(III) complexes and the impossibility of forming Zn(III) complexes. In fact, tetrahedral species containing $Co(II)O_4$, $Co(II)S_4$ or $Co(II)S_xO_{4-x}$ cores oxidize very easily while complexes containing $Co(II)N_4$ and $Co(II)N_2O_2$ cores are more difficult to oxidize.

2.5. Infrared spectra of complexes 1 and 2

Table 3 summarizes the most significant IR absorption frequencies of complexes **1** and **2** compared with those of free HMeppz and Me_2ppz ligands. The attribution of vibrational modes is consistent with that reported in literature [7,14,15,29] and with the molecular structure now determined.

The ν(N–H) frequency, occurring at 3266 cm^{-1} in free HMeppz, decreases to 3188 cm^{-1} in complex **1** ($\Delta = 78$ cm^{-1}). This frequency shift, due to both metal co-ordination and hydrogen bond formation, has been observed also in the isostructural $CoCl_3$(HMeppz) complex ($\Delta = 89$ cm^{-1}) [7] and in the $CuCl_3$(HMeppz) ($\Delta = 121$ cm^{-1}) complex [8].

The modest change observed in both complexes for the skeleton vibrational and deformation modes in respect to those of the free ligands is consistent with a little distortion of the chair conformation upon coordination.

Finally, in the far-IR region, in agreement with other authors [14,15,29] the absorptions at 315ms and 301sh cm^{-1} (complex **1**) and at 312w and 301s cm^{-1} (complex **2**) are assigned to the ν(Zn–Cl) stretching frequencies while the bands at 278s cm^{-1} and at 276m cm^{-1} are assigned to the ν(Zn–N) stretching frequency for complex **1** and complex **2**, respectively. All the other features of infrared spectra are analogous to the isostructural Co(II) complexes [7].

3. Experimental

3.1. Materials and laboratory equipment

Commercial reagent grade chemicals 2-methylpiperazine(HMeppz), 1,4-dimethylpiperazine (Me_2ppz) (98%,

[a] $\nu(N^+–H)$ band is overlapped by the large ν(C–H) absorption in the 3100–3020 cm^{-1} region.

Acros) and anhydrous $ZnCl_2$ (Fluka) were used without further purifications.

IR spectra were performed as KBr pellets with a Perkin Elmer 598 spectrometer in the 4000–600 cm^{-1} region and as Nujol mulls with a Nicolet 5Sxc FT-IR (20 far IR) spectrometer in the 600–50 cm^{-1} region.

3.2. X-ray single-crystal studies

Experimental details of crystal structure determinations including crystal data, data collection, structure determination and refinement for complexes **1** and **2** are listed in Table 4. X-ray data were collected on a Philips PW 1100/20 diffractometer equipped with a graphite-monochromated Mo Kα radiation using the θ–2θ scan technique. Cell parameters were determined using 21 reflections. The intensities were corrected for Lorentz, polarization and absorption factors utilizing the program RIFLUP-80 [30]. Absorption measurements were made using a Ψ-rotation method [31]. Structure determinations were performed with SHELXL-86 [32], refinements were carried out with SHELXL-97 [33] and geometrical calculations were performed with PARST [34] set of programs. Molecular graphics were drawn using ORTEX [35] programs.

3.3. Syntheses

3.3.1. Trichloro(1-methylpiperazin-1-ium-N^4)zinc(II), [$ZnCl_3(H_2Meppz)$] (1)

The complex was synthesized by adding dropwise under stirring a solution of anhydrous $ZnCl_2$ (0.136 g, 1 mmol) in 10 ml EtOH to a solution of 1-methylpiperazine (HMeppz) (0.113 ml, 1 mmol) in 10 ml EtOH. A white powder compound precipitates and the solution was stirred for 2 h and then cooled to room temperature. The solid product was filtered, washed with EtOH–Et_2O (1:2 v/v) and dried under vacuum for 2 h and at 70°C for 8 h. Then, complex **1** was nearly quantitatively extracted from the precipitate by refluxing CH_3CN at 80°C for 7 h (solubility in $CH_3CN \sim 0.5$ mg ml^{-1}). After filtration, the solution was allowed to evaporate slowly for 5 days. The uncoloured parallelepiped crystals were filtered off, washed with CH_3CN–EtOH (1:1 v/v) and dried under vacuum. M.p. 262.3–263.5°C (decomp.). Yield: 0.177 g., 0.65 mmol. Found: C, 21.98; H, 4.87; N, 10.22; Cl, 38.95%. Calculated for $C_5H_{13}Cl_3N_2Zn$: C, 22.01; H, 4.80; N, 10.27; Cl, 38.97%. Good quality well-formed single crystals suitable for X-ray structure determination, were obtained after 2 weeks by recrystallization from CH_3CN using the Et_2O vapour diffusion technique.

[b] $wR_2 = \{\Sigma w[(F_o^2 - F_c^2)^2]/\Sigma\,[w(F_o^2)^2]\}^{1/2}$.

3.3.2. Trichloro(1,4-dimethylpiperazin-1-ium-N4)zinc(II), [$ZnCl_3(HMe_2ppz)$] 2

This complex was prepared and recrystallized following the same procedures used for complex **1** except for 1,4-dimethylpiperazine (Me_2ppz) (0.138 ml, 1 mmole) instead of HMeppz. M.p. 268.1–269.9 °C (dec.). Yield: 0.189 g, 0.66 mmol. Found: C, 25.08; H, 5.31; N, 9.72; Cl, 37.02. Calc. for $C_6H_{15}Cl_3N_2Zn$: C, 25.12; H, 5.27; N, 9.76; Cl, 37.06%.

4. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic

Data Centre, CCDC Nos. 184085/184086 for compounds **1** and **2**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

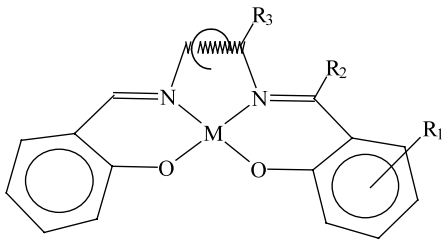

Fig. 1. The simplest symmetric Schiff's base framework. Conformational flexibility is to be induced by the systematic expansion of the alkyl chain between the imine moieties $-(CH_2)_n-$, $n = 2, 3, 4$. To avoid steric and electronic influences from substituent groups around the ligand R_1, R_2 and R_3 will be kept to their simplest protic form.

throughout the process occurring. Once again it is possible that Schiff's base complexes (Fig. 1) could meet the stringent demands on this concept. Due to the multidentate nature of the ligands, the formation constants for their complexes are high thus preventing ligand exchange. As the donor atoms are pre-organised within the ligand detrimental donor atom scrambling cannot occur. Thus, the prospect exists to develop functionally and conformationally active Schiff's base complexes based on the common geometries displayed by many transition metals (Fig. 2).

Although there may be a wealth of prior information on the synthesis of Schiff's base complexes, some of which encompass aspects of the concept being put forward here, many of these reports were designed to serve other needs and consequently many of the key examples, structures or connectivities remain absent [1,16–22]. As such, the important trends required to demonstrate the principles of conformational active complexes remain unclear. Within this study the field of view must be limited to identify the problems and potential of the concept. Thus, to service the conformational changes described in Fig. 2 we need only re-visit the chemistry of nickel, copper and zinc in the first

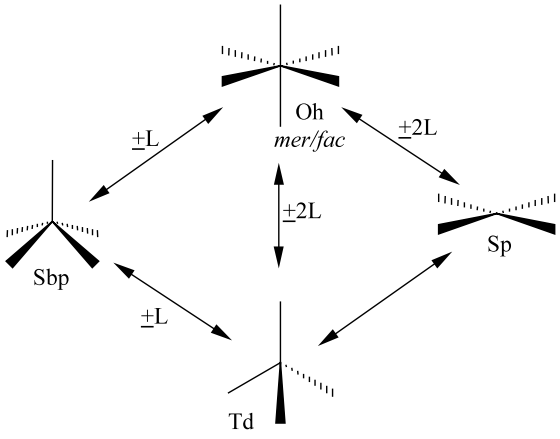

Fig. 2. Conformational geometries available to tetradentate Schiff's base ligands coordinated to late transition metals (Ni, Cu, Zn). Td: tetrahedral; Oh: Octahedral; Sbp: square based pyramid and Sp: square-planar.

instance. To avoid any contribution from additional steric or electronic effects, we have reduced the ligands to their simplest, symmetric, protic forms (Fig. 1; R_1, R_2, $R_3 = H$). Similarly to avoid more complex reorganisation at the metal centre, flexibility has been limited to the alkyl chain between the imine moieties, hence the use of the salicylidene unit. Even here it has been possible to further limit the study to the more inflexible ethylenediamine and the potentially more flexible 1,3-propane and 1,4-butane diamines thus generating a central chelate ring of five, six and seven members, respectively.

The initial survey of the three chosen ligands with the three metal cations identified is best conducted from the perspective of the metal as this allows a clear analysis of the specific co-ordination preferences which occur as the alkyl chain between the imine moieties increases in size. A further factor in this choice is the previous publication [16–21] of the required series of complexes for four coordinate copper(II) requiring us to only complete the fragmentary data sets for six coordinate nickel [20,22–25] and five coordinate zinc [26–28]. This, however, remains a substantive task. As such we have found it necessary to limit the report here to an analysis of the nickel complexes only, principally *N*,*N*′-bis(salicylidene)-1,4-butanediamine nickel (NiSalbu), leaving the analysis of the zinc complexes and the overall comparison for the following report. Thus within this report we focus on the structural analysis of the nickel complexes of Salbu. To fully delineate the structural patterns linking the well established *N*,*N*′-bis(salicylidene)-1,2-ethylenediamine nickel (NiSalen) with the hitherto uncharacterised NiSalbu we have sought to also increase our structural knowledge on the sparsely [20,24,25] studied *N*,*N*′-bis(salicylidene)-1,3-propanediamine nickel (NiSalpr) system.

2. Experimental

Unless otherwise stated, all chemicals were commercially obtained. Magnetic measurements were determined using an MSB1 Magnetic susceptibility balance. *N*,*N*′-bis(salicylidene)-1,3-propanediamine (Salpr), *N*,*N*′-bis(salicylidene)-1,4-butanediamine (Salbu), were prepared by standard methods. Briefly, 2 mol equiv. of salicylaldehyde (20 ml) were mixed with 1 mol equiv. of the required amine in methanol (80 ml). The resulting solution was refluxed for an hour, filtered while hot and allowed to cool, whereupon, copious amounts of yellow crystal began to form. These were collected, washed with diethylether and allowed to air dry. Yields were typically 70% or better.

Found: C, 72.35; H, 6.38; N, 9.90. Salpr $C_{17}H_{18}O_2N_2$ requires: C, 72.32; H, 6.43; N, 9.92%.

^{1}H NMR: δ_H (400.1 MHz; solvent $CDCl_3$) 2.1 (q, 2H, $-CH_2-$), 3.7 (t, 4H, $-CH_2-$), 6.9 (m, 4H, arom), 7.3 (m, 4H, arom), 8.4 (s, 2H, –CH=), 13.5 (br s, 2, OH). Melting point (m.p.): 52 °C (54–55 °C, lit. [29]).

Found: C, 72.76; H, 6.95; N, 9.58. Salbu $C_{18}H_{20}O_2N_2$ requires: C, 72.95; H, 6.80; N, 9.45%.

^{1}H NMR: δ_H (400.1 MHz; solvent $CDCl_3$) 1.8 (q, 4H, $-CH_2-$), 3.6 (t, 4H, $-CH_2-$), 6.9 (m, 4H, arom), 7.3 (m, 4H, arom), 8.4 (s, 2H, –CH=), 13.5 (br s, 2, OH). M.p.: 89 °C (91 °C, lit. [30]).

2.1. Ni(Salbu)

Salbu (0.59 g, 2.0 mmol) was dissolved in methanol (50 ml) to which was added nickel acetate tetrahydrate (0.5 g, 2.0 mmol). The mixture was refluxed for an hour whereupon a green precipitate formed. The solid was collected by filtration. The mother liquor was set aside. The resulting solid was then washed with water, methanol and diethylether. Yield 0.3 g, 41%.

Found: C, 60.75; H, 5.23; N, 7.59. Ni(Salbu) $C_{18}H_{18}O_2N_2Ni_1$ requires: C, 61.23; H, 5.14; N, 7.93%. $\mu_{eff} = 2.3$ BM.

Crystal suitable for X-ray analysis were obtained directly from the methanol mother liquors over a prolonged period as the solution slowly evaporated. However, these were found to be {[Ni(Salbu)$HOCH_3$]$_2$(μOAc)$_2$Ni}.

2.2. {[Ni(Salbu)$HOCH_3$]$_2$(μOAc)$_2$Ni}

Salbu (0.59 g, 2.0 mmol) was dissolved in methanol (50 ml) to which was added nickel acetate tetrahydrate (0.75 g, 3.0 mmol). The mixture was refluxed for an hour whereupon a green precipitate formed. The solid was collected by filtration, washed with water, methanol and diethylether and allowed to air dry. Yield 0.6 g, 62%.

Found: C, 48.04; H, 5.06; N, 5.70. {[Ni(Salbu)$HOCH_3$]$_2$(μOAc)$_2$Ni}·5H_2O· $C_{42}H_{60}O_{15}N_4Ni_3$ requires: C, 48.64; H, 5.83; N, 5.40%. $\mu_{eff} = 5.17$ BM.

The complex was only sparing soluble in methanol and suitable single crystals could not be grown. However, suitable crystals for X-ray analysis were obtained from DMF–methanol 1:5 solution. However, these were found to be consistent with the DMF adduct.

Found: C, 53.44; H, 5.55; N, 8.05. Expected for {[Ni(Salbu)Me_2NCOH]$_2$(μOAc)$_2$Ni}·$C_{42}H_{56}O_{10}N_6Ni_3$: C, 53.69; H, 5.48; N, 8.16. $\mu_{eff} = 5.18$ BM.

2.3. {[Ni(Salpr)$HOCH_3$]$_2$(μOAc)$_2$Ni}

Salpr (0.56 g, 2.0 mmol) was dissolved in methanol (80 ml) to which was added nickel acetate tetrahydrate (0.5 g, 2.0 mmol). The mixture was refluxed for an hour whereupon a green precipitate formed. This was collected, washed with water, methanol and diethylether. Yield 0.3 g, 45%.

Found: C, 47.91; H, 4.69; N, 5.26. {[Ni(Salpr)-$HOCH_3]_2(\mu OAc)_2Ni\}\cdot 5H_2O\cdot C_{40}H_{56}O_{15}N_4Ni_3$ requires: C, 47.62; H, 4.60; N, 5.55%. $\mu_{eff} = 5.17$ BM.

A portion of this material was recrystalised from pyridine–diethylether to give yellow–brown crystals suitable for X-ray analysis identified as {[Ni(Salpr)-$NC_5H_3]_2(\mu OAc)_2Ni\}$.

Found: C, 58.04; H, 4.87; N, 8.83. {[Ni(Salpr)-$NC_5H_5]_2(\mu OAc)_2Ni\}\cdot NC_5H_5\cdot C_{53}H_{53}O_8N_7Ni_3$ requires: C, 58.29; H, 4.89; N, 8.98%.

A second portion of $\{[Ni(Salpr)HOCH_3]_2(OAc)_2Ni\}\cdot 5H_2O$ was recrystallised from pyridine saturated with $PbCl_2$ using vapour diffusion from diethylether again affording crystals suitable for X-ray analysis.

Found: C, 44.73; H, 3.64; N, 8.17. {[Ni(Salpr)-$(NC_5H_5)_2]PbCl_2\}\cdot NC_5H_5\cdot C_{32}H_{31}O_2N_5Cl_2Ni_1Pb_1$ requires: C, 45.09; H, 3.66; N, 8.22%.

2.4. X-ray analysis

All measurements were conducted with a Nonius Kappa CCD diffractometer at 123 K using graphite monochromated Mo Kα radiation on suitable crystals mounted on glass fibres. Details of the data collection and refinements are given in Table 1. The structures were solved by direct methods [31]. The non-hydrogen atoms were refined anisotropically except for the disordered carbon sites in the butane backbone of $\{[Ni(Salbu)DMF]_2(\mu OAc)_2Ni\}$, which were treated isotropically. In all cases the refinement converged satisfactorily.

3. Results and discussion

Within the family of ligands under study, complexes of Salbu remain the poorest characterised. Reports of the nickel(II) adducts remain sparse and even those products obtained have yet to be unequivocally characterised structurally. Apart from an early report of a diamagnetic form [32], which will undoubtedly be square-planar, the exact structure of the dominant paramagnetic green form is still open to speculation. These considerations not-withstanding, the early reports [2,32] clearly suggest that our desire to construct *mer* and *fac* confomers[1] of Ni(Salbu) adducts should be attainable. Sadly we were unable to isolate samples of the red diamagnetic form. Furthermore, although we were able to prepare a bulk amorphous sample of Ni(Salbu) consistent with that of Holm [2], we were frustrated by its lack of solubility and were unable to isolate suitable samples for structural analysis. However, from the mother liquors we did retrieve a small number of crystals suitable for analysis by X-ray methods. These were structurally characterised initially in the hope that they were representative of the bulk. Clearly, however, this was not the case, as instead of Ni(Salbu) we obtained the structure of {[Ni(*fac*-Salbu)MeOH]$_2$(μOAc)$_2$Ni} (Fig. 3). Although a somewhat slightly disappointing result, this rogue complex is still the first structurally characterised NiSalbu containing species. As a consequence of this result we were prompted to produce this complex by a more rational route using a 3:2 ratio of nickel acetate and the Schiff's base. Typical of these species, its solubility in common solvents were again found to be poor. We were, however, able to isolate crystalline materials from methanol–DMF (5:1). However, in contrast to the complex obtained from the methanol liquors, that obtained from DMF (Fig. 4) was found to be the *mer* form, i.e. {[Ni(*mer*-Salbu)DMF]$_2$(μOAc)$_2$Ni} indicative that slow ligand exchange and Schiff's base reorganisation (*fac* ⇒ *mer*) had taken place at the metal centre.

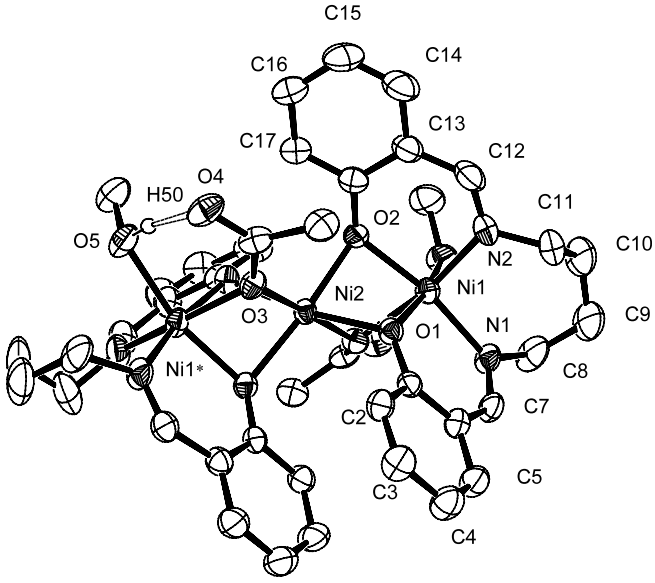

Fig. 3. The structure of {[Ni(Salbu)MeOH]$_2$(μOAc)$_2$Ni}. The key bond lengths and angles for the Salbu regions are given in Table 2. Each of the nickel atoms sit in slightly distorted octahedral geometry ($<$O5–Ni1–O1, 164.9° Salbu; $<$O3–Ni2–O3′, 176.9°; O2–Ni2–O2′, 171.7°). The structure is presented to show the *fac* arrangement of the salicylidene units and the hydrogen bonding between the methanol Hydrogen (H50) and the acetate unit (O4).

[1] The terms *mer* and *fac*, properly used, describe the positions of three identical ligands within an octahedral complex. This nomenclature is employed here to include the relative positions of the four donor atoms of these tetradentate Schiff's base ligands. Thus, *mer* is used to imply a ligand lying meridionally around the metal centre with the other ligands occupying the *trans* positions. *Fac* implies that the four donors occupy one face of the metal allowing the remaining ligands to lie *cis* to one another.

3.1. {Ni(fac-Salbu)MeOH}$_2$(μOAc)$_2$Ni}

The structure of the nickel adduct of Salbu (Fig. 3) roughly follows the reported structure of {[Ni(Salpr)DMSO]$_2$(μOAc)$_2$Ni} [24] and {[Ni(Salpr)DMF]$_2$(OAc)$_2$Ni} [25] insofar as we have a trimetallic complex comprising two Ni(Salbu) moieties bridged by a third nickel bonded to the four oxygens of the two Schiff's base moieties (Fig. 3). The three nickel atoms all sit in slightly distorted octahedral environment. The environment around the Ni(Salbu) moieties is completed by a coordinated methanol and an oxygen from the acetate bridge. In turn the central nickel's coordination sphere is completed by the two bridging acetates. Holding the methanol ligand *cis* to the acetate bridge via hydrogen bonding (O4···H50; 172.6 pm) forces the Salbu moiety to adopt the *fac* configuration. As will be seen below removing the hydrogen-bonding interaction allows the Salbu ligand to adopt the *mer* configuration. This interaction influences the bonding around the acetates such that the acetate bridge is formed using a single oxygen (O3) rather than the entire carboxylate bridge (O=C–O–) as is found in the Salpr complexes [24,25]. The key bond lengths and angles for the Schiff's base motif are given in Table 2 and collectively described below.

3.2. {[Ni(mer-Salbu)DMF]$_2$(μOAc)$_2$Ni}

In contrast to the *fac* complex described above (Fig. 3), the structure obtained for {[Ni(*mer*-Salbu)DMF]$_2$(OAc)$_2$Ni} (Fig. 4) more closely follows that of the previously reported structure of {[Ni(Salpr)DMSO]$_2$(OAc)$_2$Ni} [24] and {[Ni(Salpr)DMF]$_2$(OAc)$_2$Ni} [25]. In this instance the acetate bridge adopts the more familiar μO–C–O form and consequently the distance between the nickel centres increases from 282.8 pm for the *fac* complex (Fig. 3) to 307.6 pm for the *mer* complex. This distance is, however, comparable at 304.8 pm to the homologous Ni(Salpr) adduct [25]. Although it is evident that the ligand exchange process which formed this species is accompanied by a geometric change at the nickel Schiff's base centre, it remains unclear if the DMF adopts the position *trans* to acetate ($<173.5°$) due to the lack of hydrogen bonding or whether it is a simple consequence of the ligand exchange process. That the Salbu ligand is confined to the equatorial plane by the axial nature of the DMF forces the seven membered ring to adopt a flat point chair conformation, with C_9 and C_{10} being juxtaposed to the N–Ni–N unit. The Salbu ligand is more cumbersome than Salen or Salpr and significant disorder is encountered in the alkyl chain between the imines of the structure at these two carbons. Consequently the N–Ni–N angle at nickel is forced wider (103.7°) than that found in the analogous Salpr complex (97.9°) [25].

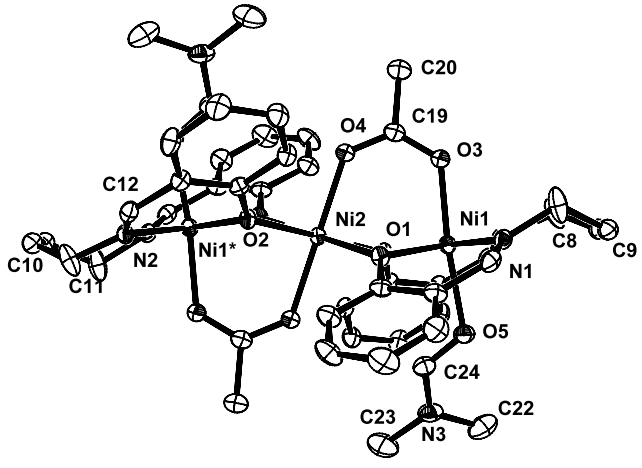

Fig. 4. The structure of {[Ni(Salbu)DMF]$_2$(μOAc)$_2$Ni}. The key bond lengths and angles for the Salbu regions are given in Table 2. Each of the nickel atoms sit in an octahedral geometry ($<$O3–Ni–O5, 173.4°; O4–Ni2–O4′, 180.0°; O1–Ni–O1′, 180.0°). The structure is presented to show the *mer* arrangement of the salicylidene units. In the absence of hydrogen bonding, the acetate unit reverts to its more common bridging mode.

We have been remarkably successful in obtaining two structurally characterised six coordinate NiSalbu complexes which provide a unique view of the Salbu ligand in both the *mer* and *fac* conformations. It is evident that the Ni(OAc)$_2$ bridge unit has an important effect on the *mer*–*fac* conformation via a stablising effect of the hydrogen-bonding between the adjacent axial ligand and itself. Thus there is some concern that the bridge unit may also profoundly affect the bond length and bond angles (Table 2) of the Ni(Salbu) moiety, bearing in mind that it is the behaviour of the Schiff's base environment around the metal cation which is the central theme of this work. It was deemed appropriate, therefore, to look at the effect of the Ni(OAc)$_2$ unit on the adjacent Schiff's base ligand in more detail. As we had been unable to structurally characterise either of the Ni(Salbu) complexes reported [2,32] which are free of the Ni(OAc)$_2$ unit, we moved to the use of Ni(Salpr) where complexes free of Ni(μOAc)$_2$ units were available for comparison with their respective more complex forms.

3.3. {[Ni(Salpr)NC$_5$H$_5$]$_2$(μOAc)$_2$Ni}

A sample of the {[Ni(Salpr)MeOH]$_2$(μOAc)$_2$Ni} complex was prepared and recrystallised from pyridine in an initial attempt to sequester the unwelcome nickel unit. From this system we obtained good quality crystals which, on analysis revealed an identical motif to the parent complex, i.e. a trimetallic systems comprising two Ni(Salpr) units bridged by a nickel acetate (Fig. 5), but with the octahedral geometry around the nickels within the Schiff's base motif now being completed by a

Table 2

The < O–M–N angles are used to depict the geometry within the metal ligand plane. The M–N and M–O distances are presented to indicate that there is minimal change in the metal to ligand bond nature. The torsion angles associated with the di-imine backbone and aromatic planes are used to show how the ligand contorts to accommodate the desired geometry at the nickel centre.

coordinating pyridine. The acetate units in this complex are observed to bridge via the carboxylate unit in a manner similar to that discussed above for {[Ni(*mer*-Salbu)DMF]$_2$(μOAc)$_2$Ni}. Sadly the association of the central nickel at the Schiff's base oxygen's is maintained. However, it would seem that the presence strong donors (DMSO, DMF or pyridine) and the additional nickel acetate unit (cf. Ni(Salpr) [20,24,25], Table 2) although inducing an increase in the M–O distances as expected has minimal effect on the bond angles at the nickel centres within the Schiff's base complex. The small

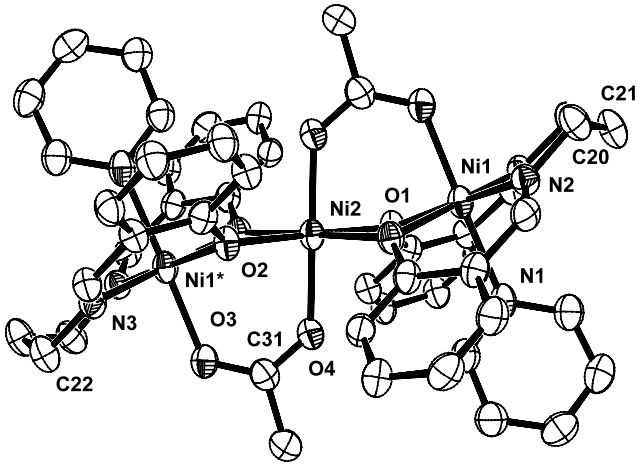

Fig. 5. The structure of {[Ni(Salpr)NC_5H_5]$_2$(μOAc)$_2$Ni}. The key bond lengths and angles for the Salpr regions are given in Table 2. Each of the nickel atoms sit in an octahedral geometry (< N1–Ni–O3, 175.8°; O4–Ni–O4′, 180.0°; O1–Ni–O2, 180.0°).

increase in the bond lengths (M–O; M–N; Table 2) within the Ni(Salpr) motif due to the presence of the included nickel, allows the metal within the Schiff's base moiety to adopt a slightly greater degree of planarity by approximately 3°–4° (Table 2). Consequently we believe that the bond angles and distances found for the *mer* and *fac* Ni(Salbu) complexes above will only have been increased to a similar but small extent (~2%) by the presence of the bridging $Ni(OAc)_2$ unit.

It is noteworthy that the homologous {[Ni(Salpr)MeOH]$_2$(μOAc)$_2$Ni} does not adopt the *fac* configuration via the formation of hydrogen bonds but remains in the *mer* form. At this juncture this behaviour is ascribed to the Salpr unit which will preferentially wish to be in the chair conformation. Thus it can be suggested that whereas hydrogen bonding does stabilise the structure of {[Ni(Salbu)MeOH]$_2$(μOAc)$_2$Ni} (Fig. 3), there remains some contribution to this conformation from the ligand and its need to accommodate a seven membered ring at the nickel centre.

3.4. {Ni(Salpr)$(NC_5H_5)_2$}$PbCl_2$

We remain perplexed by the stability of the central nickel acetate and reasoned that our choice of competing ligand (pyridine) may not have been suitable for the task envisaged. Thus rather than remove the nickel acetate an attempt was made to replace it within the motif using lead(II) chloride. Remarkably introducing lead chloride into the re-crystallising solvent we were

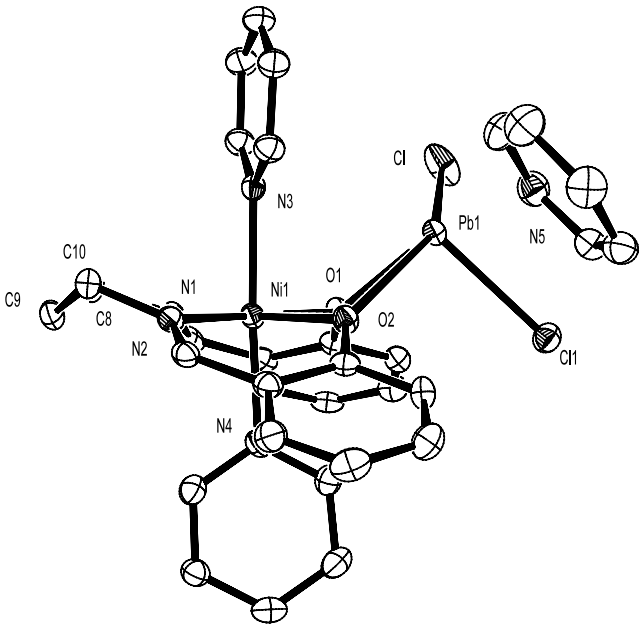

Fig. 6. The structure of $\{[Ni(Salbu)(NC_5H_5)_2]PdCl_2\}.NC_5H_5$. The key bond lengths and angles for the Salbu regions are given in Table 2. The lead atom sits in a heavily distorted tetrahedral environment (Pb–O1, 236.3 pm; Pb–O2, 267.7 pm; O1–Pb–O2, 64.52°). There is a long-range interaction to the pyridine solvent (Pb–N5 300.6 pm).

successful in removing the nickel acetate moiety. However, as a consequence of this action the Ni(Salpr) moiety was transferred to the lead centre forming $\{Ni(Salpr)(NC_5H_5)_2\}PbCl_2$ (Fig. 6). This is an intriguing result, which suggests that Schiff's base complexes can be considered to be neutral ligands, which are capable of undergoing exchange processes. The data presented in Table 2 indicates that the presence of the larger cation again does not profoundly affect the bond distances or angels around the metal Schiff's base moiety. Significantly the O–Ni–O angle at the Schiff's base centre (83.8°) is not significantly larger than that found in the absence of a metal (78.4°) and is curiously smaller than found in the parent nickel (85.0°) complexes discussed above. This result further confirms that although the nickel acetate unit is present in the solid state structures of Salpr and Salbu complexes (Table 2), there remains significant freedom within the key Schiff's base complex. Should the ligand wish to adopt a specific conformation i.e. *mer*–*fac*, the presence of the internal metal cation will be unlikely to prevent this from occurring.

4. Concluding remarks

The isolation of the two Ni(Salbu) complexes completes the matrix of motifs which can be constructed between Salen, Salpr and Salbu and nickel. To highlight the effect of the increasing size of the alkyl chain between the imine moieties we have focused on a small selection of structural elements within these species (Table 2). These are the geometry at the metal centre (M–N and M–O distance; O–M–N angles), the dihedral angle around the imines of the central chelate (N–C···C–N) and the orientation of the aromatic rings with respect to one another. These factors demonstrate how the local environment around the metal distorts to accommodate the increasing internal chelate ring and how the ligand itself adjusts should the metal centre maintain is preferred geometry.

The popular Salen motif has limited conformational flexibility and is confined to the equatorial plane. The N_2O_2 plane about the nickel is distorted only to a minimal extent with the major strain being taken up by the torsion in the ethylene bridge unit ($<$CN–NC of 20.8° and 14.1°, respectively [22,23]). Although the Salpr ligand may be expected to have slightly greater flexibility the propensity of the central chelate ring to adopt a chair conformation generates a motif with less distortion than the Salen system. Consequently, in the five examples cited in Table 2, the torsion angles have fallen to values very close to 0°. As anticipated, extending the di-imine chelate to a seven membered ring does re-introduces strain. In one instance $\{[Ni(Salbu)MeOH]_2(\mu OAc)_2Ni\}$, the Salbu ligand flips into a facial orientation which has a concomitant impact on the torsion angles and the aromatic planes (Fig. 3). For the alternative meridial species the strain is transferred to the tetramethylene backbone manifesting itself as disorder at C_9 and C_{10} (Fig. 4). However, in all cases (Salen, Salpr and Salbu) the planar geometry around the nickel centre is conserved at the expense of the ligand most notably for the *mer* and *fac* Ni(Salbu) complexes.

From the data above it is obvious that within the nickel family of complexes it is possible to obtain a variety of coordination geometries. However, it would seem that Salbu is capable of supporting the broadest range and furthermore that the potential exists for interconversion (Fig. 7) between motifs. The missing element in the scheme is a structurally characterised five coordinate species similar to $[Ni(Salpr)OH_2]$ [33] which is inferred to exists as the intermediate in the *mer*–*fac* re-organisation. However, that Salbu is content to support five coordinate geometries of this type will become clearer in the following study on zinc complexes which have a marked preference for this geometry.

Schiff's base complexes have been in the literature for over 150 years. Most workers rely on them to provide a stable, rigid chelating environment for metals and consequently workers have kept faith with Salen and five membered rings. The realisation that Salbu has the potential to move between conformations illicits the prospect of conformationally active complexes which should have an rich, interesting and independent chemistry worthy of greater exploration.

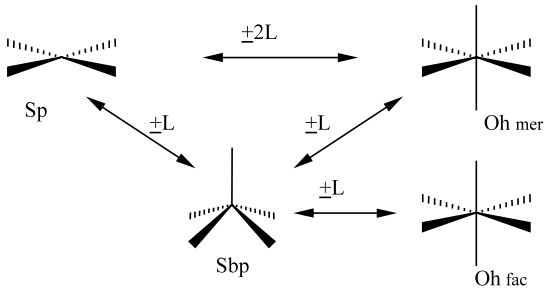

Fig. 7. Conformational geometries available to the Salbu complexes of Nickel. Sp: square-planar, Sbp: square based pyramid and Oh: Octahedral.

5. Supplementary material

Supplementary information are available form The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) on request quoting the deposition numbers 182534–182537.

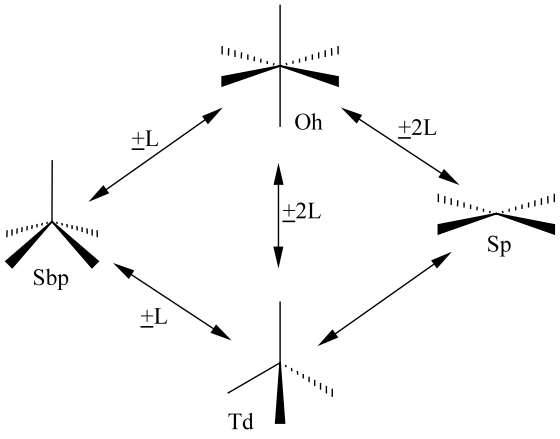

Fig. 1. Conformational geometries available to tetradentate Schiff's base ligands coordinated to late transition metals (Ni, Cu, Zn). Td: tetrahedral; Oh: Octahedral; Sbp: square based pyramid and Sp: square-planar.

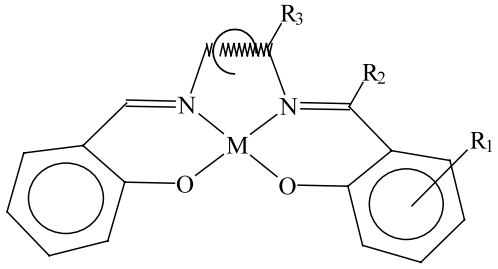

Fig. 2. The simplest symmetric Schiff' base framework. Conformational flexibility is induced by the systematic expansion of the alkyl chain between the two imine moieties; $-(CH_2)_n-$, $n = 2, 3, 4$. To avoid steric and electronic influences from substituent groups around the ligand R_1, R_2 and R_3 will be kept to their simplest protic form.

the preferred octahedral geometry of the metal cation coupled with the stability of the chair conformation of the six membered Ni(Salpr) chelate. This limited structural variety contrasts markedly with that of Salbu, which formed both *mer* and *fac* octahedral complexes[1] (Eq. (1)).

$$\{[Ni(fac-Salbu)HOCH_3]_2(\mu OAc)_2Ni\} \xrightarrow{DMF} \{[Ni(mer-Salbu)Me_2NCOH]_2\text{-}(\mu OAc)_2Ni\} \quad (1)$$

Coupled with the structural preference of Salbu for octahedral geometries with nickel, it is also reported to support a planar four coordinate geometry [7] similar to Salen [2] and Salpr [4]. However, a more complete picture of the structure of these Salbu moieties within a four coordinate environment can be obtained by extending the remit to include the established structures of divalent copper [4,8–12]. Here a definite trend from planar (Salen, Salpr) to a distorted tetrahedral environment (Salbu) was observed as the alkyl chain between the two imine moieties increases in length (Fig. 1). Thus it is clear that Salbu is also capable of adopting either a square-planar (nickel) or a tetrahedral (copper) motif at the behest of the metal centre.

Thus, we have a complete picture of the chosen ligand system within a four and six coordinate environment (Figs. 1 and 3). Consequently, the missing element in the concept put forward is a clear understanding of the chosen ligand's behaviour in a five coordinate environment. Since Zinc demonstrates a marked preference for this geometry, its complexes with the ligand set have been identified as the third important structural motif (Fig. 1) for our initial studies. Although Schiff's base complexes of zinc have been known for many years [13–15], surprising they still remain very poorly characterised structurally. In a comparable earlier study to that presented here Batley and Graddon [15] attempted to delineate the structural preferences of these complexes using spectroscopic methods. Their early study suggested that as the alkyl chain between the two imine moieties increases in length ($n \geq 3$, Fig. 2) the complexes change structural preference from a five coordinate configuration (e.g. $[Zn(salen)OH_2]$ [16]) to a more complex polymeric form. However, more recently two structural reports on Zn(salpr) complexes have appeared [17,18] in which the zinc atom adopts a five coordinate environment.

These recent conflicting studies suggest that the structural patterns available to zinc may be more complex and divergent than previously thought. Consequently, this study seeks to characterise the key parent zinc complexes derived from Salen, Salpr and Salbu such that the structural preferences of zinc can be clearly identified. Combining this information with that derived from the previous study [1] on nickel and copper should make it possible to generate a complete picture of the behaviour of the chosen ligands within a four, five and six coordinate environment.

2. Experimental

Unless otherwise stated, all chemicals were commercially obtained.

N,*N*′-bis(salicylidene)-1,2-ethylenediamine (Salen), *N*,*N*′-bis(salicylidene)-1,3-propane-diamine (Salpr), *N*,*N*′-bis(salicylidene)-1,4-butanediamine (Salbu), were prepared by standard methods. Briefly: 2 mol equiv. of salicylaldehyde (20 ml) were mixed with 1 mol equiv. of the required diamine in methanol (80 ml). The resulting

[1] The terms *mer* and *fac*, properly used, describe the positions of three identical ligands within an octahedral complex. This nomenclature is employed here to include the relative positions of the four donor atoms of these tetradentate Schiffs base ligands. Thus, *mer* is used to imply a ligand lying meridionally around the metal centre with the other ligands occupying the *trans* positions. *Fac* implies that the four donors occupy one face of the metal allowing the remaining ligands to lie *cis* to one another.

solution was refluxed for an hour, filtered while hot and allowed to cool, whereupon copious amounts of yellow crystal began to form. These were collected, washed with diethyl-ether and allowed to air dry. Yields were typically 70% or better.

Expected for Salen $C_{16}H_{16}O_2N_2$: C, 71.62; H, 6.01; N, 10.44. Found: C, 71.19; H, 6.02; N, 10.43%. Melting point (m.p.): 124 °C (124 °C, lit [19]).

^{1}H NMR (400.1 MHz, $CDCl_3$) δ 4.0 (s, 4H, CH_2), 6.9 (m, 4H, arom), 7.3 (m, 4H, arom), 8.4 (s, 2H, –CH=), 13.2 (br s, 2H –OH).

Expected for Salpr $C_{17}H_{18}O_2N_2$: C, 72.32; H, 6.43; N, 9.92. Found: C, 72.35; H, 6.38; N, 9.90%. M.p.: 52 °C (54–55 °C, lit [20]).

^{1}H NMR (400.1 MHz, $CDCl_3$) δ 2.1 (q, 2H, CH_2), 3.7 (t, 4H, CH_2), 6.9 (m, 4H, arom), 7.3 (m, 4H, arom), 8.4 (s, 2H, –CH=), 13.5 (br s, 2H, OH).

Expected for Salbut $C_{18}H_{20}O_2N_2$: C, 72.95; H, 6.80; N, 9.45. Found: C, 72.76; H, 6.95; N, 9.58%. M.p.: 89 °C (91 °C, lit [13]).

^{1}H NMR (400.1 MHz, $CDCl_3$) δ 1.8 (q, 4H, CH_2), 3.6 (t, 4H, CH_2), 6.9 (m, 4H, arom), 7.3 (m, 4H, arom), 8.4 (s, 2H, –CH=), 13.5 (br s, 2H, OH).

2.1. Zn(Salen)

Zinc acetate dihydrate (0.44 g, 2.0 mmol) were dissolved in methanol (50 ml). Salen (0.54 g, 2.0 mmol) was added and the solution brought to reflux. The mixture was heated for 2 h during which time a lemon yellow precipitate formed. The solid was recovered from the hot liquor by filtration. Yield 0.5 g; 75%.

Expected for $Zn(Salen)\cdot C_{16}H_{14}O_2N_2Zn_1$: C, 58.26; H, 4.28; N, 8.49. Found: C, 57.89; H, 4.09; N, 8.28%.

A small amount of this material was recrystallised from pyridine–diethylether by vapour diffusion, affording crystals suitable for X-ray analysis.

Expected for $[Zn(Salen)NC_5H_5]\cdot C_{21}H_{19}O_2N_3Zn_1$: C, 61.40; H, 4.66; N, 10.23. Found: C, 60.97; H, 4.61; N, 10.21%.

2.2. Zn(Salpr)

Zinc acetate dihydrate (0.44 g, 2.0 mmol) were dissolved in pyridine (25 ml). Salpr (0.56 g, 2.0 mmol) was added and the solution allowed to stir for 24 h during which time a very pale yellow precipitate formed. The solid was recovered by filtration and recrystalised from dichloromethane–diethylether by vapour diffusion. Yield 0.3 g; 43%.

Expected for $Zn(Salpr)\cdot 0.5CH_2Cl_2\cdot C_{17.5}H_{17}O_2N_2Cl_1Zn_1$: C, 54.15; H, 4.41; N, 7.22. Found: C, 54.45; H, 4.84; N, 7.15%.

2.3. Zn(Salbu)

Zinc acetate dihydrate (0.44 g, 2.0 mmol) were dissolved in pyridine (25 ml). Salbu (0.59 g, 2.0 mmol) was added and the solution allowed to stir for 48 h. The mixture was treated with diethylether to produce a pale lemon yellow powder, which was recovered by filtration. Yield 0.3 g; 42%.

Expected for $Zn(Salbu)\cdot C_{18}H_{14}O_2N_2Zn_1$: C, 60.10; H, 5.04; N, 7.79. Found: C, 60.45; H, 5.15; N, 7.85%.

Crystals suitable for X-ray analysis were obtained by treating the dichloromethane extract with THF using vapour diffusion methods. However, the sample isolated in this manner was identified as $\{[Zn(Salbu)]_2(OAc)_2Zn\}$.

Expected for $\{[Zn(Salbu)]_2(OAc)_2Zn\}\cdot C_{40}H_{42}O_8N_4Zn_3\cdot H_2O$: C, 52.60; H, 4.82; N, 6.08. Found: C, 52.21; H, 4.88; N, 5.77%.

2.4. {[Zn(Salbu)]$_2$(OAc)$_2$Zn}

Salbu (0.59 g, 2.0 mmol) was dissolved in methanol (50 ml) to which was added zinc acetate dihydrate (0.66 g, 3.0 mmol). The mixture was refluxed for 2 h, allowed to cool and the solvent removed. The resulting white powder was recrystallised from dichloromethane–THF by vapour diffusion. Yield 0.34 g, 38%.

Expected for $\{[Zn(Salbu)]_2(OAc)_2Zn\}$ $C_{40}H_{42}O_8N_4Zn_3$: C, 53.21; H, 4.66; N, 6.20. Found: C, 52.97; H, 4.77; N, 6.10%.

2.5. X-ray analysis

All measurements were conducted with a Nonius Kappa CCD diffractometer at 123 K, using graphite monochromated Mo Kα radiation, on suitable crystals mounted on glass fibres. Details of the data collection and refinements are given in Table 1. The structures were solved by direct methods [21]. The non-hydrogen atoms were refined anisotropically. In all cases the refinement converged satisfactorily.

3. Results and discussion

Similarly to many other workers the synthesis of zinc complexes of Salen, Salpr and Salbu was relatively straightforward to prepare. The complexes forthcoming from solution were essentially pure amorphous solids. Typically, however, their solubility remained poor and great difficulty was encountered in their re-crystallisation. Although Zn(Salen) could be re-crystallised from pyridine to form the desired five coordinate $[Zn(Salen)NC_5H_5]$ complex, the corresponding Salpr and Salbu complexes refused to behave in a similar manner. Resorting to the synthesis of Salpr and Salbu in pyridine

in an attempt to force the donor solvent into the fifth coordination site still generated complexes devoid of pyridine (consistent with Batley et al. [15]). Curiously, however, the material derived from this reaction lead to the formation of a dichloromethane soluble [Zn(Salpr)] complex which could be crystallised and fully characterised. Once again, the Salbu species refused to mirror the behaviour of its lower homologue. However, as a consequence of our aggressive behaviour towards this material we were able to isolate suitable crystals of a minor product $\{[Zn(Salbu)]_2(OAc)_2Zn\}$ which we were subsequently able to prepared by more rational means. Thus although we were capable of synthesising a series of five coordinate zinc complexes, the structural homology between them is somewhat more complex than initially anticipated.

3.1. $[Zn(Salen)NC_5H_5]$

The structure obtained for $[Zn(Salen)NC_5H_5]$ (Fig. 3) was the expected square based pyramidal configuration isostructrual with the monohydrate of Hall et al. [16]. In both compounds association occurs alternately between the bases of adjacent Salen units and the apical substituents (H_2O, pyridine). However, unlike the monohydrate the distance between the co-planar pyridine rings (330 pm) in $[Zn(Salen)NC_5H_5]$ support the view that the pyridine ligands are π-stacked in the bulk solid. For $[Zn(Salen)NC_5H_5]$ the zinc sits within the body of the pyramid approximately 33 pm from the base as defined by the Salen ligand donor atoms. The N_{py}–Zn distance at 208.8 pm is commensurate with the nitrogen donors (208.7 pm) in the chelate. At the apex of the pyramid the pyridine ligand lies at an angle of 172.1°

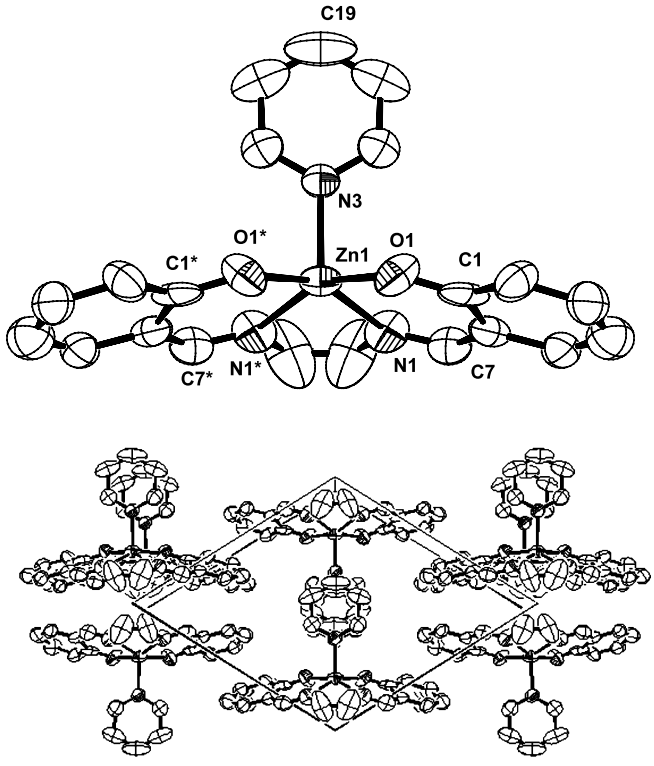

Fig. 3. (Above): The pyramidal structure of $[Zn(Salen)NC_5H_5]$. The key bond lengths are given in Table 2. The large displacement ellipsoids of C13 and C14 indicate their relative freedom of movement. Attempts to model this motion as disorder over a number of sites failed. (Below): The arrangement of the molecules in the unit cell showing the base to base orientation of the Salen and π-stacking of the pyridine ligands.

to the N_{py}–Zn axis and is tilted in the direction of and parallel to the oxygen donor atoms. The orientation of

the pyridine is again reflected by the angles at the N_{py}–zinc which are 105.2° (∠ N_{py}–Zn–N) and 99.8° (∠ N_{py}–Zn–O), respectively. The torsion angles around the aromatic planes and the di-imine chelate ring (Table 2) confirm that the structure of the pyridine adduct is generally more regular than the monohydrate. Selected bond distances and angles within the Salen framework are shown in Table 2 and discussed collectively below.

3.2. {Zn(Salpr)}$_2$

Extending the alkyl chain between the two imine moieties by one methylene unit induces a profound change in the structure of the complex isolated. The material synthesised in pyridine and recrystallised from dichloromethane was found to be devoid of pyridine instead favouring a dimeric arrangement. However, the structure obtained for Zn(Salpr) can still be described in a manner which is consistent with a five coordinate environment. The dimeric structure (Fig. 4) contains three distinct Zn–O distances (195.5, 204.1 and 209.2 pm). As expected the shortest of these is found for the bond between the zinc and the unbridged oxygen (Zn1–O1). However, of some surprise is that the Zn–O distance to the oxygen derived from the adjacent ligand is shorter than to the oxygen within the chelating Salpr unit. This observation substantiates the view of this complex as a five coordinate dimer. This finding in itself was surprising not just because the complex was prepared deliberately in pyridine but also because the analogous copper and nickel complexes have been

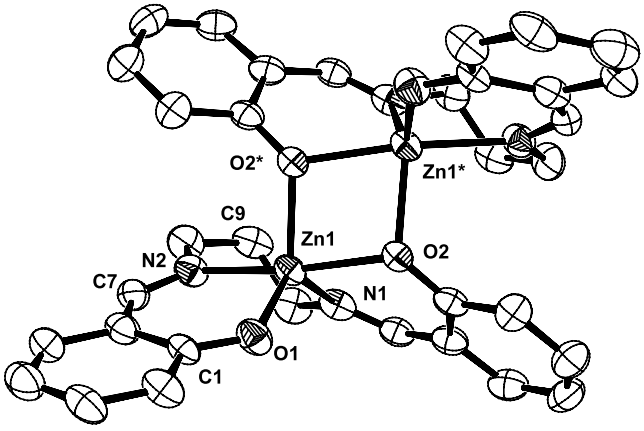

Fig. 4. The dimeric structure of [Zn(Salpr)] showing the Zn_2O_2 core. The key bond lengths are given in Table 2.

reported, where the fifth coordination site is filled by a bridging oxygen [22] or a water ligand [23,24] (Table 2). The facial arrangement of the Zn(Salpr) units and formation of oxygen bridges significantly distorts the pyramidal shape (c.f. [Ni(Salpr)OH_2] and [Cu(Salpr)OH_2]) and consequently the ∠ O2–Zn–O2* is highly constrained (77°).

The motif retrieved here for Zn(Salpr) closely follows that predicted by Batley and Graddon [15]. However, the system characterised by us is dimeric rather than polymeric and there is a far stronger association between the zinc units than might have been predicted. Considering the lack of solubility of the bulk material it is thought that the species structurally characterised here
