The reaction of L with $PtCl_2$(cod) afforded $PtCl_2$(L) (**3**), and crystalline **3**·MeCN is isomorphous to the corresponding palladium complex **1**·MeCN. The ^{31}P NMR $\{^1H\}$ spectrum of **3** showed a singlet at 3.9 with $^1J(^{195}Pt, ^{31}P) = 3735$ Hz. An ORTEP drawing of complex **3** is shown in Fig. 5, and selected bond lengths and angles are given in Table 2. A least-squares plane fitted to the metal and surrounding ligand atoms showed a small deviation of 0.055 Å. The torsion angle Pt–P–C(13)–C(14) = 41.5(3)° indicates that the =CHC_6H_4– unit lies above the $PtCl_2$(P,N) plane.

$PtMe_2$(L) (**4**) was obtained from the reaction of L with $PtMe_2$(cod). The ^{31}P NMR $\{^1H\}$ spectrum of **4** showed a singlet at 24.5 with $^1J(^{195}Pt, ^{31}P) = 1982$ Hz. Complex **4** is not isomorphous to **1** and **3**, although single crystals were grown using the same method. An ORTEP drawing of **4** is shown in Fig. 6. The least-squares plane through the atoms Pt(1), P(1), N(1), C(30) and C(31) shows a mean deviation of 0.032 Å. The two methyl groups are arranged in *cis* positions, and the Pt–C bond lengths are similar. The Pt–P and Pt–N distances are similar to those in **3** (Table 2). The torsion angle Pt–P–C(13)–C(14) = −41.7(4)° indicates that the =CHC_6H_4– unit lies below the $PtMe_2$(P,N) plane.

The alkyl platinum(II) complexes of bidentate chelating *N*,*N*-ligands can react with HgX_2 (X = halide or carboxylate) to give adducts containing a Pt→HgX_2 donor–acceptor bond or oxidative addition products containing a PtX(HgX) group [15]. We decided to use $HgBr_2$ to react with **4** to see if there is a similar reaction. However, in the case of the *P*,*N*-bidentate ligand L, the oxidative addition intermediate could not be isolated, and one of the methyl groups of **4** was displaced by the bromide ligand to form complex **5**, whose ^{31}P NMR $\{^1H\}$ spectrum showed a singlet at 17.0 with $^1J(^{195}Pt, ^{31}P) = 4657$ Hz. When we tried to crystallize **5** in MeCN, twinned crystals were obtained. Diffraction-quality single crystals of **5**·0.75CH_2Cl_2 were subsequently grown by diffusing isopropyl ether into a CH_2Cl_2 solution of **5**.

An ORTEP drawing of **5** is shown in Fig. 7, and selected bond lengths and angles are given in Table 2. The methyl group is *trans* to the nitrogen atom of L. The least-squares plane through the atoms Pt(1), P(1), N(1), C(30) and Br(1) shows a mean deviation of 0.069 Å. The P,N-bite angle at Pt(1) is similar to those in **1**–**4**. The torsion angle is 41.6(9)°, indicating that the =CHC_6H_4– unit lies above the PtMeBr(P,N) plane.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC reference numbers 176292–176298. Received 22 May 2001; accepted 28 February 2002

Abstract

The bis-sulfamide compounds, $SO_2[NHCMe_3]_2$ and $SO_2\{NH[CH(Me)Ph]\}$ were successfully employed as chelating diamide ligands in the synthesis of the tantalum complexes $Ta[N(Me)_2]_3[SO_2(NCMe_3)_2]$ (**1**) and $Ta(NMe_2)_3[SO_2(NCH(Me)Ph)_2]$ (**2**). Compound **1** assumes a distorted trigonal pyramidal geometry in the solid state as determined by an X-ray crystallograpic study. Compounds **1** and **2** are fluxional at room temperature. Variable temperature ^1H NMR was used to investigate the nature of these fluxional processes. In addition, preliminary attempts to generate halide and alkyl derivative of **1** and **2** are presented. Specifically, the reaction of **1** with excess AlR_3 (R = Me or Et), in order to generate alkyl derivatives of **1** led to the isolation of AlR_3 adducts.

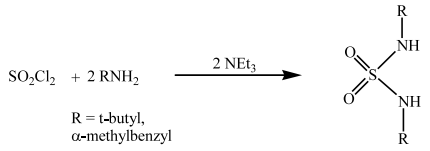
1. Introduction

The organometallic chemistry of early-transition metal compounds has received increased attention in recent years as applications in α-olefin polymerization have grown. A significant portion of this research has focused on metal complexes supported by cyclopentadienyl based ligand sets [1–3], but there is growing interest in the use of complexes with non-cyclopentadienyl ancillary ligands such as dialkoxide [4–6] or diamide ligands [7–17]. Interest in studying chelating-diamide supported Group 4 complexes as polymerization catalysts is in part due to the ease with which the steric and electronic properties of the catalysts can be altered by varying the nitrogen substituants. Several research groups have shown that d^0 Group 4 metal complexes (Ti, Zr, Hf), supported by diamide ligands are active catalysts for the polymerization of α-olefins [8–27].

In response to the growing interest in alternatives to classical metallocene based catalysts, we have become interested in examining the chemistry of a relatively unexplored class of bis-sulfamide ligands [28–31]. The relative ease with which the steric and electronic properties of bis-sulfamides can be varied is evident in their synthesis (Scheme 1). Typically, the synthesis of these ligands is a high yield, one-step process involving the reaction between SO_2Cl_2 and an amine [32,33]. Therefore, many derivatives are readily available by varying the nature of the amine. In addition, upon coordination the inherent electron withdrawing character of the SO_2 backbone should increase the electronic unsaturation at the metal center. In this paper we describe the reactions of the bis-sulfamide ligands $SO_2[NHCMe_3]_2$ and $SO_2\{NH[CH(Me)Ph]\}$ with $Ta(NMe_2)_5$. The molecular structure and variable temperature ^1H NMR studies of $Ta[N(Me)_2]_3[SO_2(NCMe_3)_2]$ (**1**) are also reported.

2. Experimental



2.1. Materials and methods

All experimental procedures were conducted under an inert atmosphere, either in a N_2 filled dry box or by

Scheme 1.

using standard Schlenk techniques. Diethyl ether was distilled from sodium benzophenone ketyl; toluene, hexanes, and pentane were distilled from sodium; dichloromethane was distilled from CaH_2. The distilled solvents were stored under an argon atmosphere and over 4 Å molecular sieves. All NMR solvents were degassed and stored over 4 Å molecular sieves in a N_2 filled drybox. $Ta(NMe_2)_5$ was synthesized according to the improved procedure for the preparation of homoleptic metal amide complexes reported by Jordan et al. [34]. The bis-sulfamide compounds $SO_2[NHCMe_3]_2$ and $SO_2\{NH[CH(Me)Ph]\}_2$ were synthesized according to previously published procedures [28–31].

^1H and ^{13}C NMR spectra were measured at 300 MHz on a Varian VXR-300 spectrometer. The chemical shifts are reported in parts per million (ppm) downfield from tetramethylsilane and referenced to residual proton peaks of the NMR solvents. Mass spectrometry was performed by the UF Department of Chemistry Analytical Services.

2.2. $Ta[NMe_2]_3[SO_2(NCMe_3)_2]$ (1)

To a toluene solution of $Ta(NMe_2)_5$ (3.31 g, 8.24 mmol) at room temperature (r.t.) was added a toluene solution of $SO_2(NHCMe_3)_2$ (1.74 g, 8.24 mmol). No immediate color change was observed. The mixture was allowed to stir for 12 h at r.t. (connected to an oil bubbler to release the $HNMe_2$ produced during the reaction). Removal of the reaction solvent under reduced pressure gave a brown oily solid, which was washed with several portions of hexane to yield 3.86 g (74%) of **1** as a light beige solid. Mass Spec. Calc. For $C_{14}H_{37}O_2N_5TaS$ $[M+H]^+$: 520.2143 *m/e*. Found: (FAB) 520.2143 *m/e*. ^1H NMR (25 °C, C_6D_6): δ 1.51 (s, 18H, $SO_2(NC(CH_3)_3)_2$), 3.09 (s, 18H, $N(CH_3)_2$). ^{13}C NMR (25 °C, C_6D_6): δ 32.83, ($SO_2(NC(CH_3)_3)_2$), 45.16 ($N(CH_3)_2$).

2.3. $Ta(NMe_2)_3[SO_2(NCH(Me)Ph)_2]$ (2)

Compound **2** was synthesized from $Ta(NMe_2)_5$ (2.50 g, 6.23 mmol) and $SO_2(NCH(Me)Ph)_2$ (1.90 g, 6.23 mmol) following the same procedure as was used for the synthesis of compound **1**. The reaction yielded 3.41 g (75%) of **2** as a light brown solid. Mass Spec. Calc. For $C_{22}H_{36}O_2N_5TaS$ $[M+H]^+$: 616.5726 *m/e*. Found: (FAB) 616.5725 *m/e*. ^1H NMR (25 °C, C_6D_6): δ 1.76 (d, 6H, $^3J_{H-H} = 6.9$ Hz, $SO_2(NCH\mathit{Me}(C_6H_5))_2$), 2.75 (s,18H, $N(CH_3)_2$), 5.56 (q, 2H, $^3J_{H-H} = 6.9$ Hz, $SO_2(NC\mathit{H}Me(C_6H_5))_2$), 7.01 (t, 2H, $^3J_{H-H} = 6.9$ Hz, *p*-C_6H_5), 7.09 (t, 4H, $^3J_{H-H} = 7.2$ Hz, *m*-C_6H_5), 7.27 (d, 4H, $^3J_{H-H} = 7.2$ Hz, *o*-C_6H_5). ^{13}C NMR (25 °C, C_6D_6): δ 24.43 ($SO_2(NCH\mathit{Me}(C_6H_5))_2$), 43.92 ($SO_2(N\mathit{C}H$-$Me(C_6H_5))_2$), 55.85 ($N(\mathit{C}H_3)_2$), 126.60, 128.13, 146.50 (aromatic).

2.4. X-ray data collection and structure refinement for 1

Single crystals for X-ray crystallography of $Ta[N(CH_3)_2]_3[SO_2(NC(CH_3)_3)_2]$ (**1**) were grown by slow diffusion of pentane in a saturated toluene solution of **1**. Selected bond lengths and angles are given in Table 1. $C_{14}H_{36}N_5O_2STa$; M 519.49; triclinic; space group P_1; $a = 8.9208(1)$, $b = 10.0987(1)$, $c = 13.7290(1)$ Å; $U = 1044.15(2)$ Å^3; $Z = 2$; $D_{calc} = 1.652$ Mg m^{-3}; $\mu = 5.378$ mm^{-1}; $F(000) = 520$; reflections collected 6924; independent reflections 4634 ($R_{int} = 0.0309$).

Data were collected at 173 K on a Siemens SMART PLATFORM equipped with a CCD area detector and a graphite monochromator utilizing Mo Kα radiation ($\lambda = 0.71073$ Å). Cell parameters were refined using up to 6753 reflections. A hemisphere of data (1381 frames) was collected using the ω-scan method (0.3 v frame width). The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability (maximum correction on I was $< 1\%$). Ψ scan absorption corrections were applied based on the entire data set.

The structure was solved by Direct Methods SHELXTL-5 [35], and refined using full-matrix least-squares. The non-H atoms were treated anisotropically where the hydrogen atoms were calculated in ideal positions and were riding on their respective carbon atoms. Two hundred and nine parameters were refined

in the final cycle of refinement using 4356 reflections with $I > 2\sigma(I)$ to yield R_1 3.04% and wR_2 7.70%, respectively. Refinement was performed using F^2.

3. Results and discussion

The reaction of 2 equiv. of RNH_2 (R = *t*-butyl or α-methylbenzyl) with 2 equiv. of NEt_3 and O_2SCl_2 yields the bis-sulfamide ligands $SO_2[NHC(CH_3)_3]_2$ and $SO_2\{NH[CH(Me)Ph]\}_2$ [28–31]. Unsuccessful attempts to deprotonate either of these ligands using a wide array of bases and deprotonation techniques led us to examine the amine elimination reaction as a means to incorporate them into a metal coordination sphere [8,27,36–38].

Reaction of the bis-sulfamides $SO_2[NHCMe_3]_2$ and $SO_2\{NH[CH(Me)Ph]\}_2$ with $Ta(NMe_2)_5$ for 12 h at room temperature produced the complexes $Ta[NMe_2]_3[SO_2(NCMe_3)_2]$ (**1**), $Ta[NMe_2]_3[SO_2(NCH(Me)Ph]_2$ (**2**) in high yield (75%) (Scheme 2). The room temperature ^1H NMR spectrum of **1** displays two singlets at 1.46 and 3.12 ppm, corresponding to the CMe_3 and NMe_2 groups, respectively. In the proton NMR spectrum of compound **2**, the sulfamide methyl protons appear as a doublet (1.76 ppm) while the NMe_2 protons appear as a singlet (2.75 ppm) and the methine proton resonates as a quartet (5.56 ppm). Since compounds **1** and **2** are pentacoordinate, they can adopt either a square pyramidal or trigonal bipyramidal idealized geometry [39]. Both of these structures have different chemical environments for their NMe_2 groups. The observed equivalency of the NMe_2 groups at room temperature implies the presence of a fluxional process, which equilibrates the NMe_2 groups on the NMR timescale.

In order to determine the nature of the fluxional process, a variable temperature ^1H NMR study was performed on compound **1** (C_7D_8). The ^1H NMR spectra of **1** at various temperatures are shown in (Fig. 1). At −60 °C, the spectrum of **1** has inequivalent CMe_3 peaks (1.50, 1.56 ppm, 9H each) of equal intensity and three NMe_2 resonances (2.95, 2.98, 3.19 ppm) each integrating to six protons. Two of the NMe_2 resonances, 2.95 and 2.98 ppm, coalesce at −35 °C (2.97 ppm). The CMe_3 resonances coalesce at −30 °C whereas the coalesced NMe_2 resonance at 2.97 ppm coalesces with the resonance at 3.19 ppm at −9 °C.

Scheme 2.

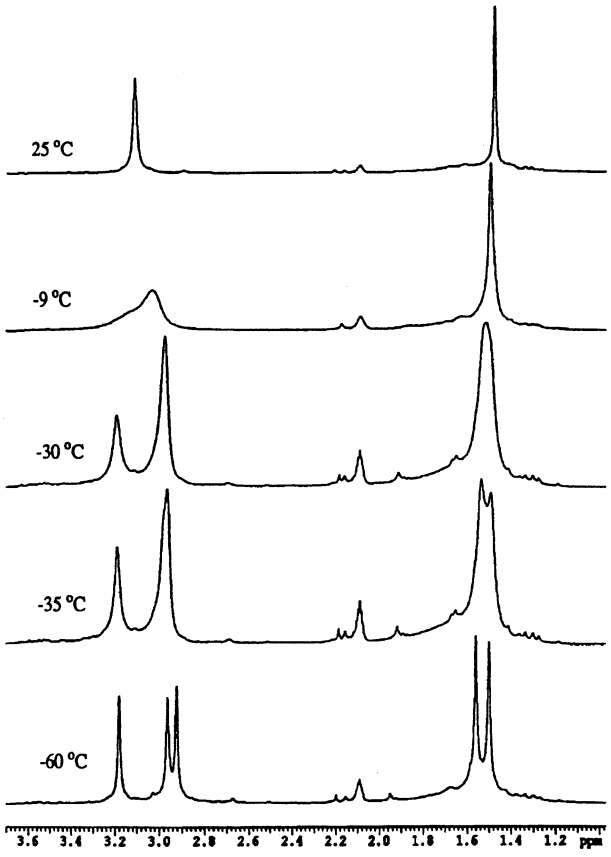

Fig. 1. Variable temperature ^1H NMR spectra of $Ta[N(CH_3)_2]_3[SO_2(NC(CH_3)_3)_2]$ (**1**).

Assuming a trigonal bipyramidal geometry, resolution of the NMe_2 resonance into three peaks instead of two, suggests that at very low temperatures, rotation about the Ta–N bonds of the NMe_2 ligands is slow. Rapid rotation of the equatorial NMe_2 groups at low temperature would produce two peaks in a 2:1 ratio (equatorial:axial). Slow rotation about the Ta–N bonds renders each methyl on the equatorial NMe_2 ligands inequivalent with respect to the other, but equivalent with the adjacent NMe_2 methyl group by a mirror plane that includes the (Fig. 2). The value of $\Delta G^{\ddagger}$ for the coalescence of the NMe_2 (2.95, 2.98 ppm) and the *t*-butyl (1.50, 1.56 ppm) resonances were each estimated to be 12.3 kcal mol^{-1} using the equally populated two-site exchange approximation [40]. Using the unequally populated two-site exchange approximation, the activation energy $\Delta G^{\ddagger}$ for the coalescence of the NMe_2 peaks

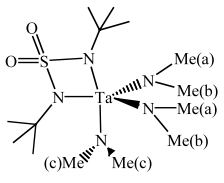

Fig. 2. Proposed structure of **1** to explain the low temperatue ^1H NMR spectrum.

at 2.97 and 3.19 ppm was estimated to be 12.8 kcal mol^{-1}. The similar activation energy values (~12 kcal mol^{-1}) that were calculated for the coalescence of the axial-equatorial NMe_2 groups and the *t*-butyl groups suggest the fluxional process which equilibrates these groups follows a Berry pseudorotation mechanism [39].

A similar variable temperature ^1H NMR study of compound **2** exhibited no significant broadening of the peaks, even at −90 °C. The difference between the dynamic behavior of compounds **1** and **2** may be attributed to the decreased steric bulk of the alkyl substituents of the bis-sulfamide in complex **2**.

The X-ray diffraction study of **1** shows that a trigonal bipyramidal coordination geometry is found in the solid state, which is consistent with the low temperature ^1H NMR spectroscopy of **1**. A molecular drawing of **1** is shown in Fig. 3 and selected bond lengths and angles are presented in Table 1. Compound **1** adopts a distorted trigonal bipyramidal geometry about the Ta metal center with the bidentate sulfamide ligand occupying one axial and one equatorial site. The bite angle of the ligand (67.5°) is smaller than that observed for other bidentate amido complexes reported in the literature due to the four-membered chelate ring. The Ta–N(1) and Ta–N(2) bond lengths of the bis-sulfamide ligand (2.074(3), 2.145(3) Å) are longer than the Ta–N bond lengths of the NMe_2 ligands (1.961(4), 1.965(3), 1.996(4) Å). The angles around N(3) and N(4) and N(5) sum to 360° indicating a trigonal planar geometry at the NMe_2 nitrogen atoms. This suggests that π-donation from the NMe_2 ligands to the metal center is possible and probably plays a role in the observed slow rotation of the NMe_2 groups at low temperature in solution.

In order to explore the reactivity and further derivatization of complexes **1** and **2**, removal of the dimethyl amido ligands was attempted. Attempts to protonate the NMe_2 groups using either Et_3NHCl or $Me_2NH{\cdot}HCl$ or

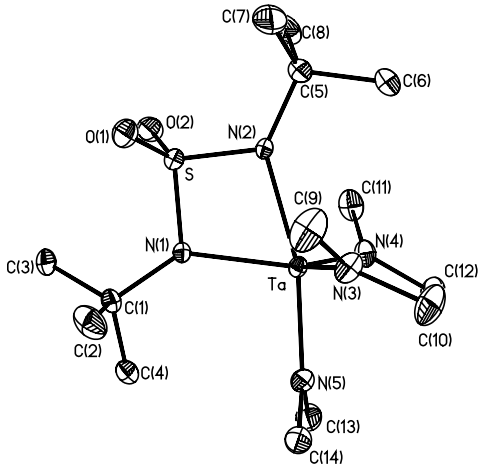

Fig. 3. The structure of $Ta[N(CH_3)_2]_3[SO_2(NC(CH_3)_3)_2]$ (**1**) with the atomic numbering scheme. Ellipsoids are shown at 40% occupancy and the hydrogen atoms have been removed for clarity,

to replace the NMe_2 groups with Cl^- utilizing $SiMe_3Cl$ gave mixtures of uncharacterizable products. Alkyl aluminum reagents have also been useful in converting amido complexes to alkyl derivatives [37,38]. The reaction of compound **1** with either $AlMe_3$ or $AlEt_3$ led to the formation of new complexes, which contain 1 equiv. of AlR_3. It appears that these complexes are coordination complexes between **1** and the aluminum reagent. However, due to inconclusive spectroscopic results and our inability to obtain X-ray quality crystals of these compounds, we do not know whether the AlR_3 groups coordinate to the sulfamide oxygen(s) or the amido N atoms. Further heating of these materials did not lead to characterizable products.

4. Summary

Bis-sulfamide compounds were successfully employed as chelating diamide ligands in the synthesis of the tantalum amido complexes $Ta[NMe_2]_3[SO_2(NCMe_3)_2]$ (**1**) and $Ta(NMe_2)_3[SO_2(NCH(Me)Ph)_2]$ (**2**) via the amine elimination method. Attempts to remove the NMe_2 ligands from either **1** or **2** using Et_3NHCl, $Me_2NH{\cdot}HCl$ or $SiMe_3Cl$ were unsuccessful. The use of AlR_3 reagents to form alkylated derivatives of **1** led to the formation of AlR_3 adduct complexes that have proved difficult to characterize. The synthesis of other metal complexes containing bis-sulfamide ligands is currently being explored.

Abstract

The crystal and molecular structure of a new tetracarboxylato copper(II) dimer [bis(dimethylformamide)tetrakis(μ-formato)dicopper(II)], has been determined by X-ray diffraction methods. The crystal structure consists of a centrosymmetric dimer $[Cu_2(HCOO)_4(dmf)_2]$, where four bidentate formato anions form *syn–syn* bridges between the metal ions which are in a 4+1 environment. Magnetic susceptibility data show that the copper ions are strongly antiferromagnetically coupled with $J = -470$ cm^{-1}. The EPR spectrum shows a characteristic pattern of a triplet state with a D zero field splitting value of 0.27 cm^{-1}. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Copper; Formato; Dinuclear complexes; Antiferromagnetic; EPR

1. Introduction

Extensive work on dimeric copper(II) carboxylates has been reported. Among these copper carboxylates, the copper acetates form a large family with many structurally characterised compounds for which magnetic and spectroscopic properties have been measured [1,2]. In contrast, only a very limited amount of detailed structural data is available for dimeric cupric formato adducts [3]. One of the most attractive puzzles in magneto-structural correlations in dimeric copper carboxylates is why do dimeric copper(II) formato complexes show much larger $-2J$ values (approximately 500 cm^{-1}) than the corresponding copper(II) acetate dimers whose $-2J$ values are approximately 300 cm^{-1}.

With the aim of obtaining a better understanding of this phenomenon we have investigated the structural, spectroscopic and magnetic properties of [bis(dimethylformamide)tetra-μ-formatodicopper(II)] reported here.

2. Experimental

All reagents and chemicals were purchased from commercial sources and used without further purification. Elemental analyses (C, H, N) were carried out at the microanalytical laboratory of the ITQ of the Universidad Politécnica of Valencia.

2.1. Physical measurements

The infrared (IR) spectrum ($\nu = 400$–4000 cm^{-1}) was obtained on KBr pellets using a Mattson Satellite FTIR spectrophotometer. Solid electronic spectra were recorded on samples dispersed in Nujol using a Shimadzu 2101 PC spectrophotometer. Electron paramagnetic resonance (EPR) measurements for ground crystals were carried out on a Bruker ELEXSYS at X-band frequencies. The variable temperature magnetic susceptibility measurement on a microcrystalline sample was

PII: S0277-5387(02)00935-X

carried out on a Quantum Design MPMS2 SQUID susceptometer equipped with a 55 kG magnet, operating at 10 kG in the range of 1.8–400 K. The susceptometer was calibrated with $(NH_4)_2Mn(SO_4)_2\cdot 12H_2O$. Corrections for diamagnetism were estimated from Pascal constants.

2.2. Synthesis of the complex

Prismatic green crystals of $[Cu_2(HCOO)_4(dmf)_2]$ were obtained by slow evaporation of a dmf saturated solution of $Cu(HCOO)_2\cdot 4H_2O$ at room temperature. They were isolated by filtration, washed with dmf and air-dried. Yield: 57%. Anal. Calc. for $C_{10}H_{18}Cu_2N_2O_{10}$: C, 26.5; H, 4.0; N, 6.2. Found: C, 26.4; H, 3.9; N, 6.0%. IR (KBr pellet; cm^{-1}): 2935, 2877 $\nu(CH_3)$; 1629 [ν(C=O)dmf, ν_{as}(COO)]; 1460 ν_s(COO); 1377, 1355 $\delta(CH_3)$; 775 δ(COO). Solid electronic spectra (Nujol) (λ_{max}, nm): 720 (d–d).

2.3. Crystal data

$C_{10}H_{18}Cu_2N_2O_{10}$. Mr = 453.34, triclinic space group $P\bar{1}$, $a = 6.488(3)$ Å, $b = 7.3551(12)$ Å, $c = 9.8309(7)$ Å, $\alpha = 100.25(9)^\circ$, $\beta = 99.212(16)^\circ$, $\gamma = 110.53(2)^\circ$, $V = 419.5(2)$ Å^3, $Z = 1$, Dx = 1.794 g cm^{-3}, Mo Kα radiation (graphite crystal monochromator, $\lambda = 0.7173$ Å), $\mu = 2.586$ mm^{-1}, $F(000) = 228$, $T = 293(2)$ K, final conventional $R_1 = 0.0456$ and $wR_2 = 0.1185$ for 1488 observed reflections and 145 variables.

2.4. X-ray crystal structure determination

Green crystal, size $0.40 \times 0.30 \times 0.18$ mm^3. Throughout the experiment Mo Kα was used with a graphite crystal monochromator on an Enraf Nonius CAD-4 [4] single crystal diffractometer ($\lambda = 0.7173$ Å). The unit cell dimensions were determined from the angular settings of 25 reflections with θ between 2.17° and 25.95°. The space group was determined to be $P\bar{1}$ from no systematic absences (ABSEN, [5]). The intensity data of 3250 reflections, in the *hkl* range (−7, −9, −12) to (7, 9, 12) and limits ($1^\circ < \theta < 25^\circ$), were measured, using the ω–2θ scan technique and variable scan rate with a maximum scan time of 60 s per reflection. The intensity of the primary beam was checked throughout the data collection by monitoring three standard reflections every 60 min. On all reflections profile analyses were performed (PROFIT, Profile Fitting Data Reduction, [6]). Lorentz-polarization corrections were applied and then data were reduced to F_o^2 values. The structure was solved using SIR-92 (A program for crystal structure solution, [7]). Isotropic least-squares refinement on F^2 was made using SHELX-93 [8]. During the final stages of the refinement on F^2 the positional parameters and the anisotropic thermal parameters of the non-H atoms were refined. The hydrogen atoms were located by XHYDEX [9]. The final conventional agreement factors were $R_1 = 0.0456$ and $wR_2 = 0.11185$ for 1488 observed reflections and 221 variables. The function minimised was $[\Sigma(w(F_o^2 - F_c^2)^2)/\Sigma[w(F_o^2)]^2]^{1/2}$, $w = 1/[\sigma^2(F_o^2) + (0.0828P)^2]$ with $\sigma(F_o^2)$ from counting statistic and $P = (F_o^2 + 2F_c^2)/3$. The final difference Fourier map showed a peak of 0.851–0.91 Å^3 for the atom Cu1, the other peaks were no deeper—0.977–0.90 Å^3 from Cu(1). The figures were made by ORTEP-3 (for Windows, [10]). Geometrical calculations were made with PARST [11]. Atomic scattering factors were taken from International Tables of Crystallography [12].

3. Results and discussion

3.1. Spectroscopic properties

In the visible region the diffuse reflectance spectrum is characterised by a very broad band at approximately 13 900 cm^{-1} which can be assigned to unresolved d–d transitions. This spectrum is similar to that reported for $[Cu(HCOO)_2(OH_2)_2]2H_2O$ [13].

The IR spectrum of the compound shows a broad and intense band at 1629 cm^{-1} that must correspond to the ν_{as}(COO) vibration of the bridging formato and to the ν(C=O) of the dmf molecules. The ν_s(COO) vibration of the formato appears at 1377 cm^{-1}. Moreover, the spectrum exhibits characteristic vibrations of the methyl groups of the dmf ligands at 2935, 2877 and 1355 cm^{-1}.

3.2. Crystal structure

Fig. 1 shows an ORTEP drawing of the complex with the atomic numbering scheme. Bond distances and angles are reported in Table 1.

The crystal structure consists of a centrosymmetric dimeric unit of copper atoms bridged by four *syn–syn* $HCOO^-$ ions. Each copper ion is coordinated by four formato oxygens as equatorial ligands and by a dmf molecule, occupying the apex of a square pyramid. The coordination of dmf is through the amide oxygen which is sterically favoured over nitrogen. All Cu–O(formato) bond distances are similar and comparable to those of other cupric carboxylates. The Cu(1)–O(formato) bond lengths are in the range from 1.959(3) to 1.973(3) Å. The apical Cu–O(dmf) bond length [2.131(3)] is longer than the equatorial ones. The Cu(II) ions are displaced out of the mean planes formed by formato oxygen atoms [−1.3991 Å Cu]. The tetragonality value [T, defined as (mean in-plane distance R_S)/(mean out-of-plane distance R_L)] [14] for Cu(1) is 0.92.

The equatorial bond angles around Cu(1) are in the range from 88.42(14)° to 90.80(14)°. The value of τ is 0,

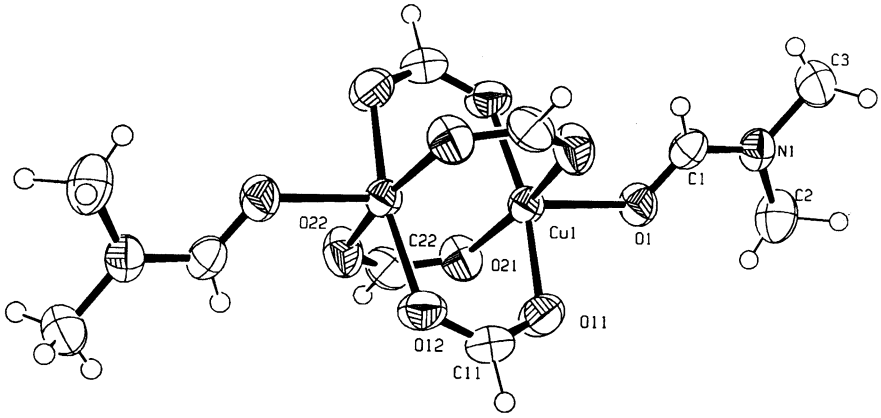

Fig. 1. ORTEP drawing of the $[Cu_2(HCOO)_4(dmf)_2]$ dimer showing 50% probability ellipsoids.

Table 1
Selected bond lengths (Å) and angles (°)

Bond lengths

O(11)–Cu(1)–O(12) [a]	167.50(12)
O(22) [a]–Cu(1)–O(12) [a]	90.80(14)
O(21)–Cu(1)–O(1)	97.68(14)
O(11)–Cu(1)–O(1)	96.43(13)

[a] Symmetry transformations used to generate equivalent atoms: $-x+1, -y+1, -z+1$.

indicating that the coordination polyhedron around the Cu(II) ions is square pyramidal [15].

The Cu–Cu separation [2.6509(19) Å] is very similar to the average value of the other four structurally characterised $[Cu_2(HCOO)_4L_2]$ compounds (L = urea, dioxane, dithiocyanate, DMSO) [3,16,17] and is slightly larger (approximately 0.05 Å) than that found for the cupric acetate monohydrate [18].

The lengths of the Cu–O–C–O–Cu bridges (6.42 Å) are identical (6.44 ± 0.02 Å) for all dimeric cupric carboxylates [16].

3.3. EPR

The X-band EPR spectrum exhibits broad features characteristic of a triplet state with non-negligible zero field splitting (Fig. 2).

The spectra can be analysed with the spin Hamiltonian:

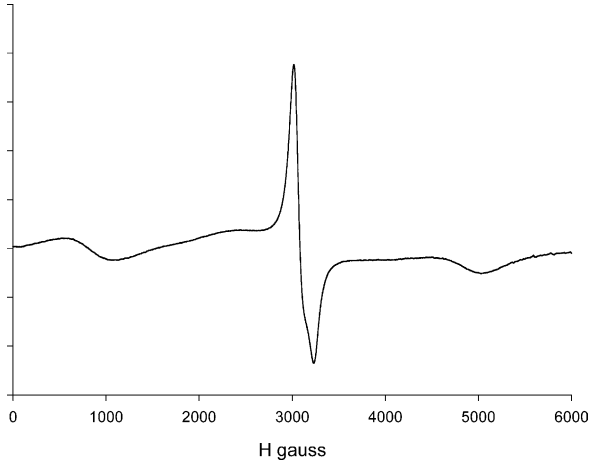

Fig. 2. EPR spectrum of polycrystalline $[Cu_2(HCOO)_4(dmf)_2]$ complex at room temperature.

$$H = \beta HgS + D[S_{z2} - 2/3] + [S_{x2} - S_{y2}]E$$

At the X-band, D is greater than the microwave energy and only two signals are observed, indicating moreover that $E \approx 0$. The two signals corresponds to H_{z1} and H_{z2}. Taking into account the equations proposed by Wasson et al. [19]

$$H_{z1} = (g_e/g_{\|})(H_0 - D')$$

$$H_{z2} = (g_e/g_{\|})(H_0 + D')$$

where $g_e = 2.0023$, $H_0 = h\nu/\beta g_e$ and $D' = D/\beta g_e$. From these expressions, the experimental field positions can be reproduced with $g_{\|} = 2.43$ and $D = 0.27\ cm^{-1}$. The zero field splitting is lower than that reported for $[Cu_2(HCOO)_4(dmso)_2]$ ($D = 0.40\ cm^{-1}$) [3] but similar to that of copper(II) acetate monohydrate ($D = 0.34\ cm^{-1}$) [20] or copper(II) benzoate ($D = 0.33\ cm^{-1}$) [21].

The dipole–dipole contribution, D_{dd}, can be estimated from the following relationship [22]:

$$D_{dd} = \frac{0.650 g_{\|}}{R^3}$$

where the R is the Cu···Cu separation. For this compound, with $R = 2.65$ Å, the dipole–dipole contribution to the experimental D is evaluated to be about 0.205 cm^{-1}. The experimental D is given by $D = D_{dd} + D_{exchange}$, and taking into account that the sign of the experimental D is unknown, a negative sign can be expected for D_{dd} [23], and a positive one for $D_{exchange}$, a $D_{exchange}$ value of 0.478 cm^{-1} is obtained.

3.4. Magnetic properties

The magnetic behaviour of the title compound is illustrated in Fig. 3 by means of a plot of χ_M versus the temperature in the range 100–300 K. The curve shows a strong antiferromagnetic behaviour. The experimental data were fitted to the Bleaney–Bowers equation. The least-squares fitting procedure led to $J = -470$ cm^{-1}, $g = 2.13$, $r_0 = 0.08$[Q1], and $R = 170 \times 10^{-6}$. The absolute value obtained for the singlet–triplet energy gap is similar to that reported for other tetra-μ-formato dicopper adducts and higher than the tetra-μ-acetato dicopper ones [24].

Recently, Rodriguez-Fortea et al. [25] have reported a density functional study of the exchange coupling in carboxylato-bridged dinuclear copper(II) compounds. They compared the J values for several substituents in $[Cu_2(\mu\text{-}RCOO)_4]$ and concluded that the electron-withdrawing groups reduce the strength of the exchange coupling. With respect to the previous studies that suggested a correlation between J and the electronegativity of the atom directly bonded to the carbon atom of the carboxylato group [22,26,27], Rodriguez-Fortea et al. concluded that this correlation is in general valid, but caution is needed when very electronegative atoms are taken into consideration. According to that, it is reasonable that the formato bridge has more exchange coupling than the acetato bridge. Besides, they concluded that the change of the axial ligand induces smaller variations in the coupling constant. They attributed the small changes to indirect effects associated with interactions of the unpaired electrons with lower lying electrons. Another studied factor is the distortion from the square pyramidal to trigonal bipyramidal geometry, which can be determined by the τ parameter. They concluded that for the formato bridge a decrease of the antiferromagnetic coupling occurs when the τ parameter increases. Since the complex is a regular square pyramid ($\tau \approx 0$), the obtained J value must be closed to the maximum expected for this family of compounds.

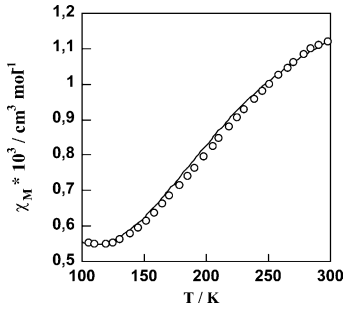

Fig. 3. Experimental χ_M versus T for $[Cu_2(HCOO)_4(dmf)_2]$ compound. The solid line represents the least-squares fit.

4. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 165343. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Reactions of manganese(II) acetate with 2-pyrazine carboxylic acid, 2,6-pyridinedicarboxylic acid and chelidamic acid (4-hydroxypyridine-2,6-dicarboxylic acid) yielded $[Mn(pyr)_2]_n$ (**1**), $[Mn(dipic)]\cdot 1.5H_2O$ (**2**) and $Mn(chedam)]\cdot H_2O$ (**6**), respectively. Reaction of **2** with 2,2′-bipyridine and 1,10-phenanthroline results in the synthesis of $[Mn(dipic)(bipy)]\cdot 2H_2O$ (**3**), $[Mn(dipic)(bipy)_2]\cdot 4.5H_2O$ (**4**) and $[Mn(dipic)(phen)_2]\cdot 2H_2O$ (**5**). Complex **6** reacted with 2,2′-bipyridine and 1,10-phenanthroline to give $[Mn(chedam)(bipy)]\cdot H_2O$ (**7**) and $[Mn(chedam)(phen)_2]\cdot 3H_2O$ (**8**), respectively. Molecular structures for **1**, **4** and **7** were determined by X-ray crystallography. In **1** the structure is essentially polymeric with each pyrazine carboxylate anion coordinated to the manganese ion in a bidentate fashion using one carboxylate oxygen atom and the adjacent nitrogen. The second nitrogen is uncoordinated. For **4** the asymmetric unit consists of one tridentate dipicolinate ligand, two bidentate bipyridine molecules, four full-occupancy water molecules and one half-occupancy water molecule. The structure of **7** contains monomeric [Mn(dicarboxylate)(bipy)H_2O] units in which the Mn(II) ions have very irregular six-coordinate geometry. Spectroscopic, magnetic and physical data for the complexes are presented. All of the manganese complexes catalytically disproportionate hydrogen peroxide in the presence of imidazole. © 2002 Published by Elsevier Science Ltd.

Keywords: Manganese(II) complexes; 2-Pyrazine carboxylic acid; 2,6-Pyridinedicarboxylic acid; Chelidamic acid; Crystal structures; Catalytic disproportionation; Hydrogen peroxide

1. Introduction

The carboxylate group is an important class of ligand in inorganic and bioinorganic chemistry. Metal complexes containing monocarboxylic acids are well known and the publication of many structurally characterised examples of this class of compound has demonstrated the versatility of the carboxylate group as an inner-sphere ligand [1]. The coordination chemistry of dicarboxylic acids is far less developed and indeed structural information for this class of complex is relatively scarce. The main reason for this is due to the fact that dicarboxylic acids generally tend to react with metal salts to yield insoluble polymeric materials which can be difficult to characterise and almost impossible to crystallise. We have shown that reaction of polymeric copper(II), polymeric manganese(II) and polymeric

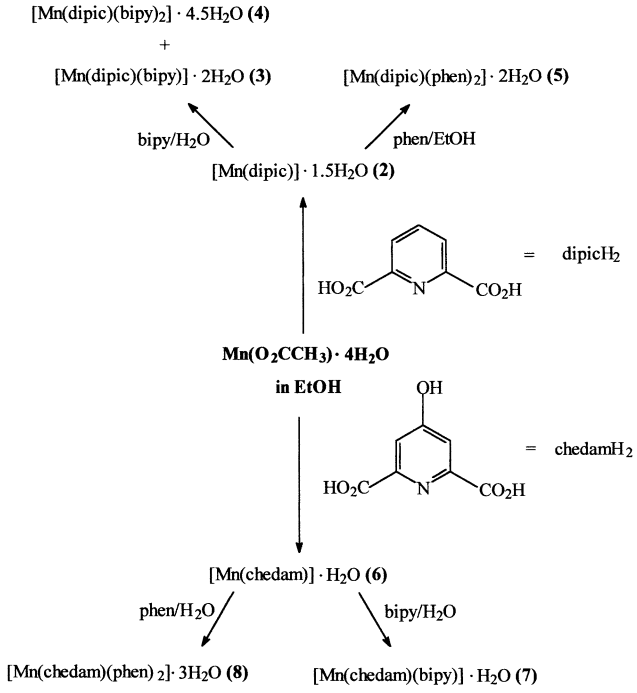
cobalt(II) dicarboxylic acid complexes with the *N*,*N*-donor ligands 1,10-phenanthroline and 2,2′-bipyridine can lead to the synthesis of crystalline compounds which are easily structurally characterised by X-ray methods [2–4]. Furthermore, we have found that the reaction of simple transition metal salts with functionalised carboxylic and dicarboxylic acids leads to the isolation of soluble materials which we have structurally elucidated [5–7]. As well as the contribution that such complexes make to the knowledge of the coordination chemistry of the chemically/biologically important carboxylate ligands, further interest is derived from their potential applications. A wide range of the manganese(II) carboxylate complexes that we have generated exhibit excellent catalytic activity towards the disproportionation of hydrogen peroxide [8]. Such compounds are of interest not only because they mimic the activity of the biologically important mangano-catalases but also a number of them have been shown to catalyse the low temperature peroxide bleaching of fabrics [9].



Herein, we report the synthesis, properties and structures for complexes of the heterocyclic carboxylic and dicarboxylic acids; 2-pyrazine carboxylic acid {pyrH}, 2,6-pyridine-dicarboxylic acid {dipicH_2} and chelidamic acid {chedamH_2} (4-hydroxypyridine-2,6-dicarboxylic acid). The disproportionation of hydrogen peroxide by the complexes is also discussed.

2. Results and discussion

Synthetic routes to the complexes **1**–**8** are shown in Schemes 1 and 2. $[Mn(pyr)_2]_n$ (**1**) was prepared in moderate yield by the reaction of 2-pyrazine carboxylic acid with manganese(II) acetate. Reaction of the acetate with 2,6-pyridinecarboxylic acid in ethanol resulted in the high yield formation of $[Mn(dipic)]\cdot 1.5H_2O$ (**2**). Reaction of **2** with excess 2,2′-bipyridine gave a suspension from which $[Mn(dipic)(bipy)]\cdot 2H_2O$ (**3**) was filtered in moderate yield. $[Mn(dipic)(bipy)_2]\cdot 4.5H_2O$ (**4**) was subsequently isolated from the filtrate. When **2** was reacted with 1,10-phenanthroline in ethanol, yellow/green crystals of $[Mn(dipic)(phen)_2]\cdot 2H_2O$ (**5**) were obtained in moderate yield. Chelidamic acid (4-hydroxypyridine-2,6-dicarboxylic acid) reacted with manganese(II) acetate in methanol to give $Mn(chedam)]\cdot H_2O$ (**6**) in high yield. Complex **6** reacted with 2,2′bipyridine and 1,10-phenanthroline to give good yields of $[Mn(chedam)(bipy)]\cdot H_2O$ (**7**) and $[Mn(chedam)(phen)_2]\cdot 3H_2O$ (**8**), respectively.

Scheme 1.

Scheme 2.

The X-ray structure of $[Mn(pyr)_2]_n$ (**1**) is shown in Figs. 1 and 2 and selected bond and angles are listed in Table 1. In the structure each pyrazine carboxylate anion is coordinated to the manganese ion in bidentate fashion using one carboxylate oxygen atom [O(11) and O(21)] and the adjacent nitrogen [N(11) and N(21)]; the second nitrogen atoms [N(12) and N(22)] are not involved in bonding. The manganese ion achieves six-coordination by coordinating to carboxylate groups in adjacent asymmetric units, forming a two-dimensional polymeric sheet in which the two independent pyrazole anions show different coordination behaviour (Fig. 1).

Symmetry transformations used to generate equivalent atoms:
[a] $x, 0.5-y, 0.5+z$.
[b] $1-x, -y, -z$.

In the first case, the pyrazine carboxylate anion links two manganese ions via a single-atom bridge [Mn–O(21)–MnA 106.96(5)°, Mn–MnA 3.5046(5) Å] and the carbonyl oxygen remains uncoordinated. The second pyrazine carboxylate bridges two manganese ions via *anti*-1,3-carboxylate bridging [Mn–O(11)–C(15)–O(12)–MnB, Mn–MnB 5.646(1) Å]; this pyrazine carboxylate ion is also involved in a π–π interaction with a symmetrically equivalent neighbour (Fig. 2). The net effect is the formation of two-dimensional sheets perpendicular to the *a* axis with no significant interactions between the layers.

The X-ray crystal structure of $[Mn(dipic)(bipy)_2]\cdot 4.5H_2O$ (**4**) is shown in Figs. 3 and 4 and selected bond lengths and angles are listed in Table 2. The asymmetric unit consists of one tridentate dipicolinate ligand, two bidentate bipyridine molecules, four full-occupancy water molecules and one half-occupancy water molecule. The $[Mn(dipic)(bipy)_2]$ complex lies on

a twofold axis, passing through Mn, N3 and C14 so that the bipy groups are *cis* to one another and the metal ion has irregular six-coordinate geometry. All the solvate water molecules and all the carboxylate oxygens of the dipic ligand are involved in hydrogen bonding (Fig. 4, Table 3). The bipy ligands are involved in π–π stacking interactions with neighbouring complex molecules.

The X-ray crystal structure of $[Mn(chedam)(bipy)]\cdot H_2O$ (**7**) is shown in Fig. 5 and selected bond lengths and angles are given in Table 4. The structure contains monomeric $[Mn(dicarboxylate)(bipy)H_2O]$ units in which the Mn(II) ions have very irregular six-coordinate geometry. This arrangement is imposed by the small bite angles of the diacid (O11– Mn–O15, 143.44(4)°) and bipy (72.19(5)°) ligands. Individual molecules are linked into chains running parallel to the *c* axis by hydrogen bonding involving the coordinated water molecule, the phenol group and the carboxylate groups (Fig. 6 and Table 5) and the chains are linked by π–π stacking of the bipy ligands parallel to the *b* axis.

The infrared spectrum of **1** contains prominent $\nu_{OCOasym}$ and ν_{OCOsym} stretching bands around 1588 and 1421 cm^{-1}, respectively. The value of Δ_{OCO} ($\nu_{OCOasym}-\nu_{OCOsym}$) calculated for the complex (167

cm^{-1}) is close to the value expected for a bridging bidentate coordination mode of the carboxylate moiety [10]. The infrared spectrum of **2** contains prominent $\nu_{OCOasym}$ and ν_{OCOsym} stretching bands around 1588 and 1400 cm^{-1}, respectively. The value of Δ_{OCO} ($\nu_{OCOasym} - \nu_{OCOsym}$) calculated for the complex (188 cm^{-1}) is close to the value expected for a monodentate coordination mode of the carboxylate moiety [10]. Its relative insolubility in most common solvents suggests that it may have a polymeric structure. Complex **2** is sparingly soluble in acetone and its molar conductivity ($\Lambda_M = 0.0$ S cm^2 mol^{-1}) suggests that it is a non-electrolyte in this solvent. The IR spectra of complexes **3**, **4** and **5** contain bands attributable to $\nu_{OCOasym}$ and ν_{OCOsym} that give values of 188, 181 and 195 cm^{-1} for Δ_{OCO}, suggesting that the coordination modes for the dicarboxylate ligands in these complexes may be similar. The molar conductivity values for complexes **3** ($\Lambda_M = 0.0$ S cm^2 mol^{-1}) and **4** ($\Lambda_M = 1.64$ S cm^2 mol^{-1}) showed that these compounds are essentially non-electrolytes in ethanol and methanol, respectively. The IR spectra of complexes **6**,**7** and **8** contain bands attributable to $\nu_{OCOasym}$ and ν_{OCOsym} that give values of 148, 188 and 175 cm^{-1} for Δ_{OCO}, suggesting that the coordination modes for the dicarboxylate ligands in **6** may not be the same as those in **7** and **8**. Whereas complexes **7**and **8** are insoluble in most common solvents, **6** readily dissolved in several solvents, further suggesting possible structural differences between it and the other cheledamic acid complexes. The molar conductivity value for an aqueous solution of complex **6** ($\Lambda_M = 300.76$ S cm^2 mol^{-1}) suggests that it dissociates extensively in that solvent.

The room temperature magnetic moments of powdered samples of complexes **1**, **2**, **3**, **6**, **7** and **8** (5.82, 5.72, 5.95, 5.69, 5.89 and 5.99 BM, respectively) were in the range expected for manganese complexes where there is no significant exchange interactions between metal centres [11]. The room temperature magnetic moments for **4** and **5** (6.44 and 6.11 BM, respectively) fall slightly above this range.

We have recently described the synthesis of a series of manganese carboxylate complexes and demonstrated their ability to catalyse the disproportionation of hydrogen peroxide [12]. Apart from the obvious implications that such mimetic systems have for the biologically important mangano-catalases, further applications in areas such as catalytic low temperature bleaching technologies are attracting significant attention [9,13]. The catalytic activity of complexes **1**–**8** towards the disproportionation of hydrogen peroxide was investigated in the presence of the base imidazole (in the absence of the imidazole the complexes were either inactive or very weak catalysts for this reaction). The results from these reactions are summarised in Tables 6 and 7. Table 6 shows the rate of evolution of oxygen from the respective reactions for the complexes over the first 60 min. Examination of Table 7 shows that over the first minute of the reaction, complex **8** appears to be the most efficient catalyst with 4206 molecules of peroxide disproportionated by one molecule of the complex. Complex **2** appears to be the least efficient catalyst over the first minute, with one molecule of the compound knocking down 742 molecules of the peroxide. Significantly, the activity of complex **1** is relatively low, which is surprising as the Mn–Mn separation in this compound (3.5 Å) is similar to that found in the manganocatalases from *Thermus thermophilus* (3.6 Å) [14]. The catalytic activity of these complexes is relatively moderate when compared to that of the best complexes previously made in this laboratory [2]. It should be noted that imidazole itself causes only a very slight disproportionation of the peroxide (Table 6). Such an enhancement of the catalytic activity in the presence of the imidazole has been previously observed in this laboratory [2,12] and indeed by other workers [15]. This may demonstrate the importance of the heterocyclic bases that are known to exist in the vicinity of the active sites of the manganoenzymes [14].

3. Experimental

Chemicals were purchased from commercial sources and used without further purification. IR spectra were recorded in the region 4000–400 cm^{-1} on a Nicolet-400 Impact spectrometer. Magnetic susceptibility measurements were made using a Johnson Matthey Magnetic Susceptibility balance. $[HgCo(SCN)_4]$ was used as a reference. Conductivity readings were obtained using a Ciba Corning model check-mate 90 conductivity meter. Satisfactory microanalytical data for the complexes were reported by the Microanalytical Laboratory, University College Cork, Ireland.

3.1. $[Mn(pyr)_2]_n$ (**1**)

To a solution of 2-pyrazine carboxylic acid {pyrH} (1.22 g, 9.83 mmol) in water (100 cm^3) was added manganese(II) acetate (1.19 g, 4.85 mmol). The resulting mixture was refluxed for 2 h. The product formed as a yellow powder and yellow crystals (**1**) that were filtered off and then dried in air. Yield: 0.75 g (51.17%). Complex **1** was insoluble in dist. H_2O, EtOH, MeOH, acetone, ether and chloroform. *Anal.* Found: C, 39.52; H, 1.92; N, 18.17. Calc.: C, 39.88; H, 2.01; N, 18.60%. IR: 3482.84, 3415.67, 3093.28, 3066.42, 3026.12, 1662.69, 1622.39, 1588.81, 1521.64, 1474.63, 1420.90, 1387.31, 1353.73, 1165.67, 1038.06, 890.30, 850.00, 789.55, 729.10, 635.07, 554.48, 447.01 cm^{-1}. μ_{eff} = 5.82 B.M.

3.2. $[Mn(dipic)]\cdot 1.5H_2O$ (**2**)

To a solution of 2,6-pyridinedicarboxylic acid {dipicH_2} (1.16 g, 6.94 mmol) in ethanol (100 cm^3) was added manganese(II) acetate (1.52 g, 6.20 mmol), and the reaction mixture was refluxed for 2 h. The product formed as a colourless solid. The mixture was allowed to cool to room temperature and then filtered. The product was washed with two small portions of ethanol and then

dried in air. Yield: 1.48 g (96.62%). Complex **2** was partially soluble in warm acetone and insoluble in dist. H_2O, EtOH, MeOH, ether and chloroform. *Anal*. Found: C, 34.13; H, 1.49; N, 5.60. Calc: C, 34.03; H, 2.44; N, 5.66%. IR: 3402.10, 1642.01, 1588.81, 1568.11, 1441.04, 1400.75, 1373.88, 1279.85, 1192.54, 1158.32, 1085.07, 1017.91, 970.22, 823.13, 769.40, 722.39, 661.19 cm^{-1}. $\mu_{eff} = 5.72$ B.M. Λ_M (acetone) = 0 S cm^2 mol^{-1}.

3.3. [Mn(dipic)(bipy)]·2H_2O (**3**) and [Mn(dipic)(bipy)$_2$]·4.5H_2O (**4**)

To a solution of [Mn(dipic)]·1.5H_2O (**2**) (0.50 g, 2.02 mmol) in water (100 cm^3) 2,2'-bipyridine (0.95 g, 6.09 mmol) was added. The resulting mixture was stirred for 4 h. The product formed as a yellow solid that was then filtered off and allowed to dry in air. Yield: 0.29 g (36.98%). Complex **3** was partially soluble in warm EtOH, MeOH and chloroform, and insoluble in dist. H_2O, acetone and ether. *Anal.* Found: C, 46.31; H, 3.94; N, 10.20. Calc.: C, 46.40; H, 3.89; N, 10.82. IR: 3422.26, 3079.64, 1621.85, 1581.55, 1480.78, 1433.75, 1366.57, 1319.55, 1279.24, 1245.65, 1191.91, 1158.32, 1077.70, 1017.24, 956.78, 923.19, 762.69, 735.82, 701.50, 661.19 cm^{-1}. $\mu_{eff} = 5.95$ B.M. Λ_M (EtOH) = 0 S cm^2 mol^{-1}.

The yellow filtrate was reduced to 50 cm^3 on a hot plate for 1 day. Upon standing at room temperature for 1 week the solution turned clear and complex **4** deposited as yellow crystals. The crystals were filtered off and air-dried. Yield: 0.19g (13.54%). Complex **4** was soluble in MeOH and insoluble in distilled H_2O, EtOH, ether, chloroform and acetone. *Anal.* Found: C, 46.89; H, 3.30; N, 10.02. Calc.: C, 52.86; H, 4.60; N, 11.41%. IR: 3405.17, 3073.13, 2355.17, 1620.69, 1574.14, 1474.63, 1439.66, 1356.90, 1274.14, 1078.36, 1010.34, 762.07, 731.03, 661.94 cm^{-1}. $\mu_{eff} = 6.44$ B.M. Λ_M (MeOH) = 1.64 S cm^2 mol^{-1}.

3.4. [Mn(dipic)(phen)$_2$]·2H_2O (**5**)

To a solution of [Mn(dipic)·1.5H_2O] (**2**) (0.50 g, 2.02 mmol) in ethanol (100 cm^3) 1,10-phenanthroline (0.75 g, 3.78 mmol) was added. The resulting mixture was refluxed for 2 h. The product formed as green crystals that were filtered and then dried in air. Yield: 0.49 g (37.84%). Complex **5** was insoluble in dist. H_2O, EtOH, MeOH, acetone, ether and chloroform. *Anal.* Found: C, 60.49; H, 3.66; N, 11.41. Calc.: C, 60.39; H, 3.76; N, 11.36%. IR: 3422.26, 3220.72, 3052.77, 1648.73, 1622.39, 1588.27, 1514.93, 1500.93, 1427.61, 1373.88, 1359.86, 1273.13, 1225.50, 1138.16, 1104.57, 1071.64, 1024.63, 903.73, 876.17, 843.28, 769.40, 722.39, 701.50, 634.32 cm^{-1}. $\mu_{eff} = 6.11$ B.M.

3.5. Mn(chedam)]·H_2O (**6**)

To a solution of chelidamic acid {chedamH_2} (1.01 g, 5.51 mmol) in methanol (100 cm^3) was added manganese(II) acetate (1.34 g, 5.51 mmol), and the reaction mixture was refluxed for 3 h. The product formed as a colourless solid. The mixture was allowed to cool to room temperature and the product was filtered off and dried in air. Yield: 1.29 g (86.05%). Complex **7** was soluble in dist. H_2O and in soluble in EtOH, MeOH, acetone, ether and chloroform. *Anal*. Found: C, 30.67; H, 2.59; N, 5.15. Calc.: C, 30.90; H, 2.50; N, 5.40%. IR: 3407.85, 1577.57, 1429.53, 1348.79, 1133.46, 1032.52, 817.20, 749.91, 642.24, 588.41 cm^{-1}. $\mu_{eff} = 5.69$ B.M. Λ_M (H_2O) = 300.76 S cm^2 mol^{-1}.

3.6. [Mn(chedam)(bipy)]·H_2O (**7**)

To a solution of [Mn(chedam)]·H_2O (**6**) (0.46 g, 1.88 mmol) in water (100 cm^3) 2,2'-bipyridine (0.59 g, 3.77 mmol) was added. The resulting mixture was refluxed for 12 h. The product formed as a yellow solid and crystals that was filtered off and allowed to dry in air. Yield: 0.52 g (66.95%). Complex **7** was insoluble in dist. H_2O, EtOH, MeOH, acetone, ether and chloroform. *Anal.* Found: C, 50.15; H, 3.08; N, 10.39. Calc.: C, 49.77; H, 3.19; N, 10.24%. IR: 3300.19, 3111.78, 3084.86, 2950.28, 2876.26, 2728.29, 2600.37, 2519.63, 1604.49, 1496.82, 1449.72, 1416.07, 1348.79, 1120.00,

1039.25, 897.94, 823.93, 770.09, 749.91, 642.24 cm^{-1}. $\mu_{eff} = 5.89$ B.M.

3.7. [Mn(chedam)(phen)$_2$]·3H$_2$O (8)

To a solution of [Mn(chedam)]·H_2O (**6**) (0.60 g, 2.36 mmol) in water (100 cm^3) 1,10-phenanthroline (0.96 g, 4.84 mmol) was added. The resulting mixture was refluxed for 5 h. The product formed as a yellow powder that was filtered off and dried in air. Yield: 1.27 g (82.79%). Complex **8** was insoluble in dist. H_2O, EtOH, MeOH, acetone, ether and chloroform. *Anal.* Found: C, 57.76; H, 3.12; N, 10.79. Calc.: C, 57.24; H, 3.87; N, 10.77%. IR: 3434.77, 3057.94, 1611.21, 1517.01, 1436.26, 1335.33, 1261.31, 1106.54, 1025.79, 857.57, 823.93, 736.45, 642.24 cm^{-1}. $\mu_{eff} = 5.99$ B.M.

4. X-ray crystallography

Crystal data for complexes **1**, **4** and **7** are summarised in Table 8. Structures **1** and **7** were solved by direct methods, a Patterson tmap was used to solve the structure of complex **4**. All three data sets were refined by full-matrix least-squares on F^2 and the programs used in the structure solution and refinement are contained in the SHELXTL package [16]. All non-hydrogen atoms were refined with anisotropic atomic displacement parameters except for the partial occupancy water molecule in complex 4 (O5w). Hydrogen atoms bonded to carbon were inserted at calculated positions, those bonded to oxygen were located in difference maps, inserted at these positions and not further refined. Hydrogen atoms on the disordered water molecule on complex 4 (O5w) were not included.

4.1. Hydrogen peroxide disproportionation studies

To a solid sample (ca. 10 mg) of the manganese complex was added aqueous H_2O_2 (35% w/w, 10 cm^3, 114 mmol). The mixture was stirred and thermostated at 25 °C and the evolved O_2 was measured volumetrically (volume ± 0.10 cm^3). In cases where imidazole (50 mg) was added this was introduced into the reaction vessel before the addition of H_2O_2.

5. Supplementary material

Crystallographic data have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 164978, 164979 and 164980, respectively. Substituted boat-shaped Co_6 carbonyl cluster derivatives containing a semi-interstitial P atom and both bridging dithiolate and heterocyclic phosphido ligands

Shu-Tang Liu *, Xiang Hu, Fei Chang, Ying-Chun Liu, Er-Run Ding, Bin-Fang Wu, Zhi-Rong Zhao

Department of Chemistry, Inner Mongolia University, Huhhot 010021, People's Republic of China

Received 17 August 2001; accepted 8 January 2002

Abstract

The reaction of $Co_2(CO)_8$ with $Cl[PSCH_2CH_2CH_2S]$ gives the Co_6 cluster $Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}[PSCH_2CH_2CH_2S])(CO)_{12}$ (**5**). X-ray structural analysis of **5** revealed that six Co atoms form a boat-shaped array consisting of a basal square of four cobalt atoms with two opposite edges bridged by two apical Co atoms, a semi-interstitial P atom, a propanedithiolate ligand doubly bridging a basal side and a heterocyclic phosphido ligand bridging the opposite basal edge. Reaction of **5** with PPh_3 results in the formation of the mono-substituted products $(Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}[PSCH_2CH_2CH_2S])(\mu\text{-}CO)(CO)_{10}(PPh_3)$ (**6**) and $(Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}[PSCH_2CH_2CH_2S])(\mu\text{-}CO)(CO)_{11}(PPh_3)$ (**7**). Reaction of $(Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2S)(\mu\text{-}[PSCH_2CH_2S])(CO)_{12}$ (**4**) with PPh_3 at higher temperature results in the formation of the di-substituted cluster $Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2S)(\mu\text{-}[PSCH_2CH_2S])(CO)_{10}\cdot(PPh_3)_2$ (**8**). Reactions of **5** with $P(OEt)_3$ result in the substitution of one or two carbonyl groups to give $(Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}[PSCH_2CH_2CH_2S])(CO)_{11}P(OEt)_3)\}$ (**9**) and $\{Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}[PSCH_2CH_2CH_2S])(CO)_{11}(P(OEt)_3)\}$ (**9′**) with different spectral data from that of (**9**), and $\{Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}[PSCH_2CH_2CH_2S])(\mu\text{-}CO)(CO)_9(P(OEt)_3)_2\}$ (**10**). X-ray structural analysis of 10 identified the sites of phosphite substitution as the two apical Co atoms. A semi-bridging CO group in **10** is located on a basal side. The IR ν(CO) solution spectrum of **10** does indicate the existence of the semi-bridging CO group in the solution as well. © 2002 Published by Elsevier Science Ltd.

Keywords: Crystal structures; Cobalt(I) clusters; Interstitial phosphorus atom; Heterocyclic phosphide; Semi-bridging carbonyl; Substituted site

1. Introduction

The open structures of Co_6 carbonyl clusters which contain an interstitial main group atom have been rarely reported [1,2]. They can be obtained by the insertion of a bulky P atom or a C_2 group into the polyhedral metal arrays, two examples being $(Co_6(\mu_6\text{-}P)(\mu\text{-}CO)_2(CO)_{14})$ (**1**) [3] and $(Co_6(\mu_6\text{-}C_2)(\mu_4\text{-}S)(\mu\text{-}CO)_6(CO)_8$ (**2**) [4]. In **1**, the six metal atoms form a twisted boat arrangement surrounding a semi-interstitial P atom. In **2**, the six metal atoms form a boat-shaped open array which contains a roughly square-planar base with two opposite edges apically bridged by two cobalt atoms. The metal arrangement surrounds a semi-interstitial dicarbide group. We have reported in a previous communication that the reaction of $Co_2(CO)_8$ with $RSPCl_2$ (R = Me, Et) gives the boat-shaped Co_6 carbonyl clusters $(Co_6(\mu_6\text{-}P)(\mu\text{-}SR)_3(CO)_{12})$ (R = Me, (**3**); Et) which contain a semi-interstitial P atom and bridging thiolate ligands [5]. In **3**, the array of the six metal core is similar to that of **2** but with a semi-interstitial P atom in place of the dicarbide group. Another boat shaped (μ_6-P)-containing Co_6 species with a wrongly proposed formula $(Co_6(\mu_6\text{-}P)(\mu_4\text{-}SCH_2CH_2S)(\mu\text{-}[PSCH_2CH_2S])(CO)_{12})$ (**4**) in the previous communication was also reported. We had wrongly imagined that its ligand arrangement pattern might be similar to that in **3**. Since then, more boat-shaped Co_6 carbonyl clusters and their phosphine–

phosphite derivatives which contain a semi-interstitial P atom and both a doubly bridging propanedithiolate and a bridging heterocyclic phosphido ligand $\overline{PSCH_2CH_2CH_2S}$ have been made in our laboratory. Here we report the syntheses and spectral charaterization of the open Co_6 clusters **5**, **6**, **7**, **8**, **9**, **9′** and **10**. The X-ray analysis of clusters **5** and **10** reveal the unusual metal framework geometries and the structural features of P and S-containing ligands.

2. Experimental

2.1. Materials and measurements

All operations were carried out under nitrogen using standard Schlenk techniques. Solvents were purified, distilled from the appropriate drying agents and stored under nitrogen prior to use. Dicobalt octacarbonyl was purchased and the $Cl\overline{PSCH_2CH_2CH_2S}$ was prepared by the literature method [6]. PPh_3 was purchased from Aldrich and $P(OEt)_3$ was made by the literature method [7]. Preparative chromatography was performed on a silica gel column. Infrared spectra were recorded on a Mattson Alpha-Centauri FT-IR spectrophotometer using n-C_6H_{14}–CH_2Cl_2 as solvent. ^1H NMR ($CDCl_3$ as solvent, δ scale relative to $SiMe_4$) and ^{31}P NMR spectra ($CDCl_3$ as solvent, δ scale relative to H_3PO_4) were measured on a Bruker AM-400 instrument and **8** on a BrukerAC-200PFT NMR instrument. FAB MS spectra were recorded on a Finigan MAT 90 instrument using 3-nitrobenzyl alcohol as the matrix. Only the highest mass peaks are given and M^+ = parent ion. Elemental analyses for carbon and hydrogen were conducted on an elemental analyser Perkin–Elmer 2400.

2.1.1. Synthesis of cluster compounds

*2.1.1.1. Synthesis of ($Co_6(\mu_6$-P)(μ-$SCH_2CH_2CH_2S$)-(μ-$\overline{PSCH_2CH_2CH_2S}$)$(CO)_{12}$ (**5**).* $Co_2(CO)_8$ (800 mg, 2.34 mmol) was dissolved in toluene (15 cm^3). A solution of $Cl\overline{PSCH_2CH_2CH_2S}$ (404 mg, 2.34 mmol) in toluene was added dropwise to the $Co_2(CO)_8$ solution and the reaction mixture was stirred at 41 °C for 15 h. After evaporation of the solvent the black residue was dissolved in 3:1 petroleum ether–CH_2Cl_2 v/v, separated by chromatography (eluent: 3:1 petroleum ether–benzene v/v) and recrystallized in 3:1 n-hexane–CH_2Cl_2 v/v (**6**, **7**, **8**, **9**, **9′** and **10** were crystallized using the same solvent mixture) to yield the dark-green cluster compound **5** (200 mg, 26.6%). Spectroscopic data for **5** IR ν(CO): 2077m, 2047vs, 2026vs, 1988m, 1950w cm^{-1}; ^1H NMR: δ 3.31 (d, 6H, $\overline{PSCH_2CH_2CH_2S}$), 2.23–1.26 (m, 6H, $SCH_2CH_2CH_2S$); ^{31}P NMR: δ 811.3 (s, μ_6-P), 322.2 (s, $\overline{PSCH_2CH_2CH_2S}$); FAB MS: M^+ −$PSCH_2CH_2CH_2S$, 826 (Calc. 827). *Anal*. Calc. for $C_{18}H_{12}Co_6O_{12}P_2S_4$ (964.0): C, 22.42; H, 1.24. Found: C, 22.83; H, 1.18%.

*2.1.1.2. Syntheses of ($Co_6(\mu_6$-P)(μ-$SCH_2CH_2CH_2S$)-(μ-$\overline{PSCH_2CH_2CH_2S}$)($\mu$-CO)$(CO)_{10}(PPh_3)$) (**6**) and ($Co_6(\mu_6$-P)($\mu$-$SCH_2CH_2CH_2S$)($\mu$-$\overline{PSCH_2CH_2CH_2S}$)$(CO)_{11}(PPh_3)$) (**7**).* Compound **5** (400 mg, 0.415 mmol) and PPh_3 (280 mg,1.07 mmol) were dissolved in toluene (15 cm^3). The dark–green solution was stirred at 38 °C for 13 h. After evaporation of the solvent the residue was dissolved in 3:1 petroleum ether–CH_2Cl_2 v/v, separated by chromatography and recrystallized to yield the dark-green cluster compound **6** (35 mg, 7%) from the first dark-green band using 3:1 petroleum ether–benzene v/v as eluent and then the cluster compound **7** (30 mg, 6%) from the second green band using 1:1 petroleum ether–benzene v/v as eluent. Spectroscopic data for **6**: IR ν(CO): 2058m, 2022vs, 2017vs, 1990w, 1822w cm^{-1}; ^1H NMR: δ 7.22 (m, 15H, PPh_3), 3.70–3.00 (m, 6H, $\overline{PSCH_2CH_2CH_2S}$), 2.20–1.18 (m, 6H, $\overline{SCH_2CH_2CH_2S}$); FAB MS: M^+ −PPh_3–CO, 909 (Calc. 908); *Anal*. Calc. for $C_{35}H_{27}Co_6O_{11}P_3S_4$ (1198.4): C, 35.06; H, 2.25. Found: C, 35.54; H, 2.60%.

Spectroscopic data for **7**: IR ν(CO): 2058m, 2022vs, 2017vs, 1990w cm^{-1}; ^1H NMR: δ 7.41 (m, 15H, PPh_3), 3.40 (m, 6H, $\overline{PSCH_2CH_2CH_2S}$), 2.63 (m, 6H, $\overline{SCH_2CH_2CH_2S}$); FAB MS: M^+ −3CO, 1115 (Calc. 1114); *Anal*. Calc. for $C_{35}H_{27}Co_6O_{11}P_3S_4$ (1198.4): C, 35.06; H, 2.25. Found: C, 35.51; H, 2.64%.

*2.1.1.3. Synthesis of ($Co_6(\mu_6$-P)(μ-SCH_2CH_2S)(μ-$\overline{PSCH_2CH_2S}$)$(CO)_{10}(PPh_3)_2$ (**8**).* Compound **4** (200 mg, 0.214 mmol) [5], and PPh_3 (280 mg, 1.07 mmol) were dissolved in THF(10 cm^3) and a few drops of Ph_2CONa–THF solution was added to the solution as a catalyst. The mixture was stirred at 47 °C for 10 h. After evaporation of the solvent the black residue was dissolved in benzene and separated by chromatography (eluent: 1:1 petroleum ether–benzene v/v) resulting in a violet eluate which was recrystallized to yield the violet cluster compound **8** (200 mg, 66.6%). Spectroscopic data for **8**: IR ν(CO): 2060m, 2025vs, 2020s, 1990w cm^{-1}; ^1H NMR: 7.40–7.00 (m, 30H, 2 × PPh_3), 3.65 (d, 4H, $\overline{PSCH_2CH_2S}$), 2.63–1.63 (4H, SCH_2CH_2S); ^{31}P NMR: δ 532.5 (s, μ_6-P), 326.8 (s, μ-$\overline{PSCH_2CH_2S}$), 44.5 (s, 2 × PPh_3); *Anal*. Calc. for $C_{50}H_{38}Co_6O_{10}P_4S_4$ (1404.6): C, 34.19; H, 2.71. Found: C, 34.40; H, 2.83%.

*2.1.1.4. Syntheses of {$Co_6(\mu_6$-P)(μ-$\overline{PSCH_2CH_2CH_2S}$)($\mu$-$\overline{SCH_2CH_2CH_2S}$)$(CO)_{11}$-($P(OEt)_3$)} (**9**), {$Co_6(\mu_6$-P)($\mu$-$\overline{PSCH_2CH_2CH_2S}$)($\mu$-$\overline{SCH_2CH_2CH_2S}$)$(CO)_{11}P(OEt)_3$)} (**9′**) and {$Co_6(\mu_6$-P)($\mu$-$\overline{PSCH_2CH_2CH_2S}$)($\mu$-$SCH_2CH_2CH_2S$)($\mu$-CO)-$(CO)_9P(OEt)_3)_2$} (**10**).* Compound **5** (600 mg, 0.622 mmol) was dissolved in toluene (15 cm^3) and then $P(OEt)_3$ (0.54 ml, 3.11 mmol) solution (dissolved in 15

cm^3 toluene) was added dropwise. The mixture was stirred at 40 °C for 18 h. After evaporation of the solvent the black residue was dissolved in 3:1 petroleum ether–CH_2Cl_2 v/v and separated by chromatography. The dark-green cluster compound **9** (41 mg, 6%) was obtained from the first dark-green band using 3:1 petroleum ether–benzene v/v as eluent, the dark-green cluster compound **9′** (25 mg, 3.4%) from the second dark-green band using 2:1 petroleum ether–benzene v/v as eluent and the lighter green cluster compound **10** (20 mg, 2.6%) from the third green band using 1:1 petroleum ether–benzene v/v as eluent.

Spectroscopic data for **9**: IR ν(CO): 2060m, 2025vs, 2012s, 1998w cm^{-1}; ^{1}H NMR: δ 4.02 (m, 6H, $3 \times CH_2$); 2.37 (m, 12H, $SCH_2CH_2CH_2S$ and $\overline{PSCH_2CH_2CH_2S}$), 1.24(t, 9H, $3 \times CH_3$); FAB MS: $M^+ - 3CO$, 1018 (Calc. 1018); *Anal*. Calc. for $C_{23}H_{27}Co_6O_{14}P_3S_4$ (1102.2): C, 25.05; H, 2.45. Found: C, 25.47; H, 2.91%.

Spectroscopic data for **9′**: IR ν(CO): 2065m, 2038vs, 2013vs, 1990w cm^{-1}; ^{1}H NMR: δ 3.76 (m, 6H, $3 \times CH_2$), 2.10 (m, 12H, $SCH_2CH_2CH_2S$ and $\overline{PSCH_2CH_2CH_2S}$), 1.14 (t, 9H, $3 \times CH_3$); ^{31}P NMR: δ 311.3 (s, μ-$\overline{PSCH_2CH_2CH_2S}$), 145.0 (s, $P(OEt)_3$); FAB MS: $M^+ - 5CO$, 962 (Calc. 962); *Anal*. Calc. for $C_{23}H_{27}Co_6O_{14}P_3S_4$ (1102.2): C, 25.05; H, 2.45. Found: C, 25.53; H, 2.94%.

Spectroscopic data for **10**: IR ν(CO): 2055w, 2034w, 2013vs, 1991s, 1823w cm^{-1}; ^{1}H NMR: δ 4.00 (m, 12H, $6 \times CH_2$), 2.63 (m, 12H, $SCH_2CH_2CH_2S$ and $\overline{PSCH_2CH_2CH_2S}$), 1.24(t, 18H, $6 \times CH_3$); ^{31}P NMR: δ 311.2 (s, μ-$\overline{PSCH_2CH_2CH_2S}$), 141.1 (s, $2 \times P(OEt)_3$); FAB MS: $M^+ - 5CO$, 1100 (Calc. 1100); *Anal*. Calc. for $C_{28}H_{42}Co_6O_{16}P_4S_4$ (1240.4): C, 27.10; H, 3.39. Found: C, 27.57; H, 3.81%.

2.1.2. X-ray crystallography and structure determination and refinement of 5 and 10

The X-ray intensities of single crystals **5** ($0.40 \times 0.20 \times 0.15$ mm) and **10** ($0.45 \times 0.30 \times 0.20$ mm) were measured on a Rigaku AFC 6SV diffractometer using graphite–monochromatized Mo Kα radiation ($\lambda =$ 0.71073 Å) in the θ–2θ scan mode. The crystallographic data for clusters **5** and **10** are given in Table 1.

All calculations were performed with the SHELXS-97 program package. Final refinement was conducted through a full-matrix least-squares procedure with non-hydrogen atoms anisotropic and hydrogen atoms isotropic.

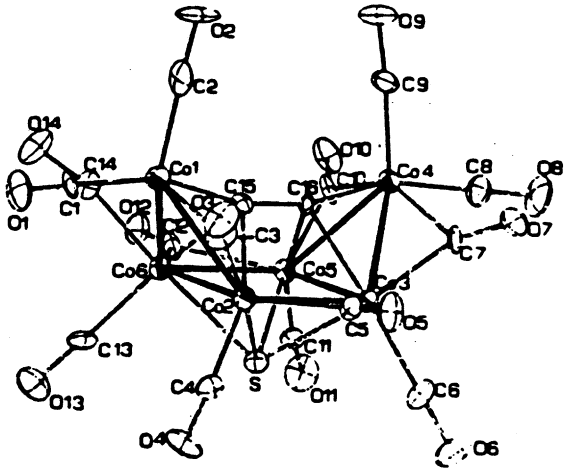
3. Results and discussion

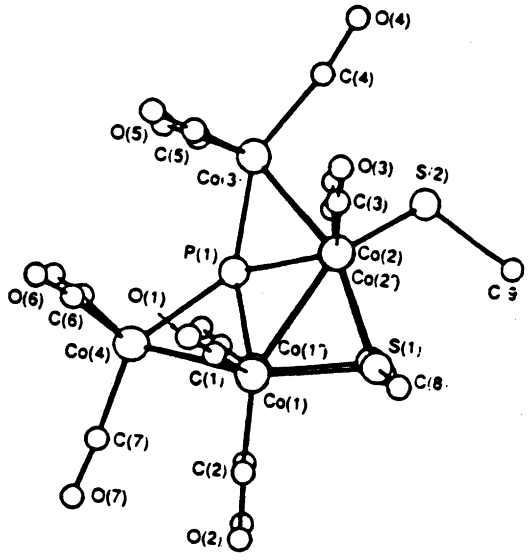
3.1. Syntheses

The reaction of $Co_2(CO)_8$ with $Cl\overline{PSCH_2CH_2CH_2S}$ in toluene at moderate temperature (41 °C) gave the Co_6 cluster **5** in moderate yield (26.6%). The reaction of **5** with PPh_3 in toluene at lower temperature (38 °C) leads to the formation of the phosphine monosubstituted Co_6 clusters **6** and **7** in low yields (7% for **6** and 6% for **7**). The reaction of **4** with PPh_3 in THF at higher temperature (47 °C) results in the formation of the phosphine disubstituted Co_6 cluster **8** in good yield (66%).



The reaction of **5** with $P(OEt)_3$ in toluene at moderate temperature (40 °C) results in substitution of one or two carbonyl groups to give the monosubstituted Co_6 clusters **9** (yield: 6%) and **9′** (yield: 3.4%) and also the disubstituted Co_6 cluster **10** (yield: 2.6%).

The results demonstrate that the reaction at lower temperature (< 40 °C) mainly leads to the formation of the phosphine–phosphite monosubstituted products and that at higher temperature (> 40 °C) mainly leads to the formation of the phosphine–phosphide disubstituted products.



3.2. Description of the structures of clusters 5 and 10

The molecular structures of clusters **5**[1] and **10** are illustrated in Figs. 1 and 2, while selected bond lengths and angles are summarized in Tables 2 and 3, respectively.

The boat-shaped open array of Co_6 atoms in **5** contains a Co_4 basal square with two opposite edges Co(1)–Co(4) and Co(2)–Co(3) bridged by two apical atoms Co(5) and Co(6), respectively, and the metal atoms surround a semi-interstitial P atom. The eight Co–Co bond lengths (2.426(1)–2.677(1) Å) and the eight Co–P bond lengths (2.142(2)–2.299(2) Å) are consistent with the values found in many P-containing cobalt clusters, including **1** and **3** [3,5]. Compound **5** presents an unusual boat-shaped open metal array analogous to that of **2** and **3**. The Co_6 framework of $Co_6(\mu_6\text{-}C_2)$ cluster **2** can be considered to be a finite fragment of metallic cobalt (face-centered cubic and hexagonal close packed) with similar Co–Co distances, Co–Co–Co angles and dihedral angles between triangular and square planes (av. 122° for **2** and 125° for metallic cobalt). The C_2 unit was considered to be inserted into a trigonal–prismatic Co_6 array by breaking an edge and widening the distance between the two apical Co atoms [2]. The dihedral angles between triangular and square planes for 3 (103.5°–106.9°, av. 105.2°) and **5** (104.5°–108.1°, av. 106.3°) are much smaller than that for metallic cobalt and **2**. So, the Co_6 frameworks of **1** and **5** would not be considered to be a finite chunk of metallic cobalt but would be considered as arising from insertion of a P atom into a trigonal prismatic Co_6 array, and the widening degrees between the two apical Co atoms are smaller than that of a C_2 unit. The $Ru_6(\mu_4\text{-}S)$ cluster $\{Ru_6(\mu_4\text{-}S)(\mu_3\text{-}\eta_2\text{-}EtNCSNHEt)(\mu_3\text{-}\eta_2\text{-}EtNCHHEt)(\mu\text{-}CO)_2(CO)_{14}\}$ was reported to present an unusual Ru_6 framework analogous to the boat conformation of cyclohexane (with 109.5° C–C–C angles) but with the dihedral angles 137.3°–143° between Ru triangles and square planes and 54.1°–71.6° triangular Ru interior angles [8]. So neither the Ru_6 framework nor the Co_6 framework of **3** and **5** (with triangular interior angles of 56.4°–61.8°) would be considered to be analogous to the boat conformation of cyclohexane.

2

3

The apical Co atoms bear three terminal carbonyl groups whereas the basal Co(3) and Co(4) bear two and Co(1) and Co(2) only one. The Co(1)–Co(2) side is doubly bridged by a propanedithiolate ligand. We had wrongly proposed that a μ_4-dithiolate ligand with its one S atom bridges the Co(1)–Co(4) edge and the other S atom bridges the opposite Co(2)–Co(3) side in cluster **4** [5], and proposed that a heterocyclic phosphido ligand might be located on the Co(1)–Co(2) side edge such that the ligand arrangements in **4** would look like that in **3**. The real situation is much more complicated. The two donor S atoms of the dithiolate ligand have shown versatile coordination modes in other metal carbonyl polynuclear clusters. For instance, the reaction of

[1] In one crystal structure unit, there are two independent molecules (I and II) having almost the same bond lengths (av. Co–Co distance: 2.5864 Å for I and 2.589 Å for II). The molecule I is chosen to represent cluster 5.

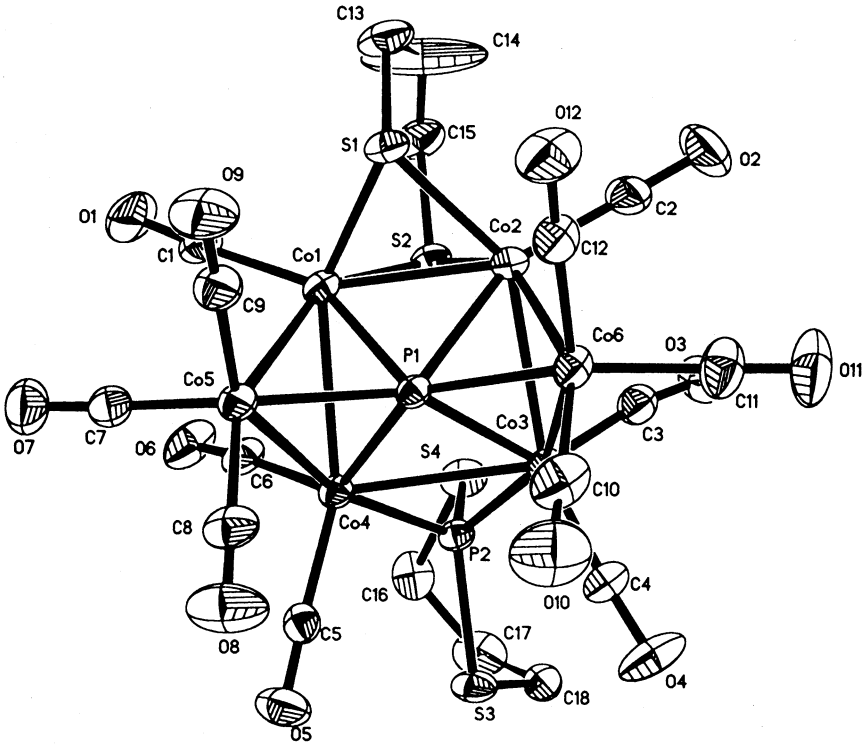


Fig. 1. Molecular structure of $Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}\overline{PSCH_2CH_2CH_2S})(CO)_{12}$ (**5**).

$\{Os_6(CO)_{18-n}\{Me(CN)_n\}\}$ $(n = 1,2)$ with thiirane gives $\{Os_6(\mu_3\text{-}S)(\mu\text{-}SCH_2CH_2S)(CO)_{16}\}$, $(Os_6(\mu_3\text{-}SCH_2CH_2S)(CO)_{17}$ and $\{Os_6(\mu_4\text{-}S(CH_2CH_2S)_3)\}$ [9]. In the products, each of the two donor S atoms can be attached to one, two or three Os atoms.

The Co(3)–Co(4) side of cluster **5**, which lies opposite to the Co(1)–Co(2) side, was bridged by a heterocyclic phosphido ligand. During the synthetic reactions, one ligand precursor $Cl\overline{PSCH_2CH_2CH_2S}$ was cleaved at the Cl–P bond and both P–S bonds to yield the P and

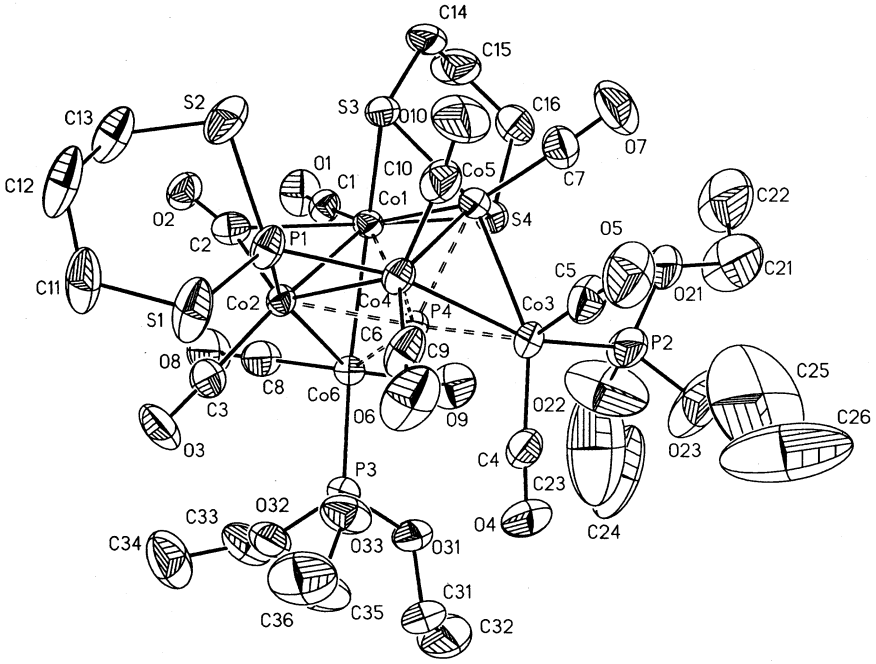

Fig. 2. Molecular structure of $Co_6(\mu_6\text{-}P)(\mu\text{-}SCH_2CH_2CH_2S)(\mu\text{-}\overline{PSCH_2CH_2CH_2S})(\mu\text{-}CO)(CO)_9(P(OEt)_3)_2$ (**10**).

dithiole fragments as ligands (the negative trivalent 5e donor μ_6-P and the negative bivalent 6e donor μ-$SCH_2CH_2CH_2S$, respectively) and another precursor $Cl\overline{PSCH_2CH_2CH_2S}$ was cleaved only at the Cl–P bond to yield the heterocyclic phosphide fragment as the negative univalent 3e donor μ-$\overline{PSCH_2CH_2CH_2S}$ ligand. They are the essential constituents to build the novel 92e boat-shaped $Co(I)_6$ carbonyl cluster **5** which obeys the EAN rule in having 8 Co–Co bonds (on average each of the six Co atoms is in oxidation state + 1 and has 18e) and contains a semi-interstitial P atom and both bridging P and S-containing ligands.

The phoshite substituted cluster **10** presents the boat-shaped open metal array analogous to that of its parent cluster **5**. The X-ray structural analysis of **10** identified the site of phosphide substitution as the apical Co(3) and Co(6) atoms. The eight Co–Co bond lengths (2.443 (2)–2.710 (2) Å) and the ten Co–P bond lengths (2.124 (2)–2.380 (2) Å) in **10** are consistent with the values found in many P-containing cobalt clusters but delicate differences of bond distance between the bonding types are observed, the Co–P bond with 1.5 bridging phosphide donating valence electrons is the shortest bond (av. 2.127 Å); the Co–P bond with the phosphite lone pair electrons is in the middle (av. 2.157 Å); the Co–P bond with 5/6 μ_6-P donating valence electron is the longest bond (av. 2.260 Å).

The X-ray structural analysis of **10** revealed that a semibridging CO group is linked to the basal Co(1) and Co(2) atoms. The unsymmetrical semibridging C(2)–O(2) group mainly belongs to the Co(2) atom with a Co(2)–C(2) bond length of 1.773(8) Å and Co(2)–C(2)–O(2) bond angle of 162.5(7)°, and it is linked to the Co(1) atom with some minor bonding interaction {Co(1)–C(2) bond length, 2.437(8) Å, Co(1)–C(2)–O(2) bond angle, 123.8(6)°}. An explanation for the semibridging posture of one CO ligand can be given in terms of an inequality of metal atom charges caused by the distribution of the dithiole and the phosphido ligands in the molecule [10]. The valence electron numbers around Co(2) are 18 1/3 and around Co(1) are 17 5/6. The Co(2)–Co(1) bond may be considered to be a dative interaction and written as $Co^+(2) \rightarrow Co^-(1)$, and, therefore, the C(2)–O(2) group originally on Co(2) then moves into a semibridging position to help remove some of this excessive electron density at Co(1). There is a partial transference of electron density from a filled d-orbital of the Co(1) atom into one of the π^* orbitals of the C(2)–O(2) group that is principally bonded to the adjacent Co(2) atom.

The inequality of metal atom charges in these open Co_6 clusters would cause the inequality of metal–metal bonds in the basal square also. In cluster **5** the electron deficient Co(1) and Co(2) (with one CO attached) may demand a shorter Co(1)–Co(2) bond (2.426(1) Å) to increase the electron density around its valence shell to balance the deficiency. In contrast, the electron surfeit Co(3) and Co(4) (with two CO attached) results in a longer Co(3)–Co(4) bond (2.677(1) Å). In cluster **10** the electron deficient Co(1) and Co(5) show a shorter Co(1)–Co(5) bond (2.443(2) Å) and the electron surfiet Co(2) and Co(4) shows a longer Co(2)–Co(4) bond (2.710(2) Å). So, the boat-shaped open array of Co_6 atoms in **5** and **10** contain an approximate square planar base that is better described as a trapezoidal base. The average bond lengths of the eight Co–Co bonds in clusters **3**, **5**, **10** are 2.593, 2.586, 2.571 Å, respectively. The shortest value is for cluster **10** reflecting the fact that both the phosphite and semibridging CO ligands in **10** may have a stabilization interaction for this type of Co_6 open structure.

3.3. Spectral characterizations

The IR ν(CO), ^{1}H NMR, ^{31}P NMR and MS spectral data of clusters **5**, **6**, **7**, **8**, **9**, **9′**, and **10** are given in the Section 2 and the spectrometric characterizations are in

agreement with the confirmed structures determined by X-ray analyses. IR ν(CO) and ^{31}P NMR spectra are selected to explain the characterizations as follows.

3.3.1. Infrared ν(CO) spectra

The five terminal ν(CO) infrared active bands of twelve terminal CO groups in the solution spectrum of **5** are observed at 2077, 2047, 2026, 1988 and 1950 cm^{-1}.

The four terminal ν(CO) infrared active bands of ten terminal CO groups in the spectrum of PPh_3 monosubstituted **6** are observed at 2058, 2022, 2017 and 1990 cm^{-1}. One band of the bridging CO group is observed at 1822 cm^{-1}. The analogous four terminal ν(CO) bands are observed at 2058, 2022, 2017 and 1990 cm^{-1} in the spectrum of **7** but no low frequency ν(CO) band of a bridging CO group is observed in its spectrum. So, **6** is a bridging CO containing isomer and **7** is another isomer containing no bridging CO.

The four terminal ν(CO) bands in the spectrum of PPh_3 disubstituted **8** are observed at 2060, 2025, 2020 and 1990 cm^{-1} and no low frequency ν(CO) band of a bridging CO group is observed.

The four terminal ν(CO) bands in the spectra of $P(OEt)_3$ monosubstituted **9** and **9′** (both with eleven terminal CO groups) are observed at 2060, 2025, 2012 and 1988 cm^{-1} and at 2065, 2038, 2013 and 1990 cm^{-1}, respectively. Clusters **9** and **9′** are isomers and the separations of the three higher frequency ν(CO) bands are different from each other (35 and 13 cm^{-1} for **9**, 27 and 25 cm^{-1} for **9′**).

The four terminal ν(CO) bands of nine terminal CO groups in the spectrum of **10** are observed at 2055, 2034, 2013 and 1991 cm^{-1} and one band of the semibridging CO group is observed at 1823 cm^{-1}.

If CO is replaced by phosphine–phosphite, ν(CO) decreases since the latter is a strong σ donor but a weak π-acceptor [11]. The ν(CO) highest frequency bands in the spectra of mono and disubstituted phosphine clusters **6**, **7**, **8** are shifted 17–19 cm^{-1} toward the lower side from that of the parent cluster **5**. The reason is unclear why the disubstituted **8** and the monosubstituted **6** and **7** are observed to have almost the same vibration frequencies of their four CO bands in the spectra. The ν(CO) highest frequency bands in the spectra of the mono, and disubstituted phosphite clusters **9**, **9′** and **10** are observed to shift 17,12 and 22 cm^{-1} toward the lower side from that of the parent cluster **5**, respectively.

3.3.2. ^{31}P NMR spectra

The ^{31}P NMR spectrum of **5** was found to exhibit the μ_6-P singlet at 811.3 and the μ-$\overline{PSCH_2CH_2CH_2S}$ singlet at 322.2 ppm. The ^{31}P NMR spectrum of PPh_3 disubtituted **8** was found to exhibit the μ_6-P singlet at 532.5, the μ-$\overline{PSCH_2CH_2S}$ singlet at 326.8 and the PPh_3 singlet at 44.5 ppm. The ^{31}P NMR spectrum of $P(OEt)_3$ monosubstituted **9′** and disubstituted **10** were found to exhibit the μ-$\overline{PSCH_2CH_2CH_2S}$ singlets at 311.3, 311.2 and the $P(OEt)_3$ singlets at 145.0, 141.1 ppm, respectively. These are in agreement with the X-ray molecular structural determinations of **5** and **10**. The ^{31}P NMR signal will shift to lower field with a paramagnetic deshielding effect for the compounds which have low-lying exited states associated with M–M and M–P bonding systems [12]. For instance, the phosphorus resonance signal of the ligand precursor Cl$\overline{PSCH_2CH_2S}$ occurs at 171.6 but the signal of μ-$\overline{PSCH_2CH_2S}$ in **8** occurs at 326.8 ppm [13]. As the numbers of metal atoms linked to the P atom are increased in the M–P bonding system, the paramagnetic deshielding effect will be increased with the enhancement of valence electrons being donated to the P atom by more metals so the μ_6-P signals are exhibited in the lowest field.

4. Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336-033, e-mail: deposit@ccdc.cam.ac.uk), on request quoting the deposition numbers 148272 and 148273.

Abstract

The reaction between $Ti(OPr^i)_4$ and 8-hydroxyquinoline (HQ) resulted in $TiQ_2(OPr^i)_2$, **1** in 90% yield. Further reaction of **1** with water yielded $[TiQ_2(\mu\text{-}O)]_4\cdot n H_2O$, $\mathbf{2}\cdot nH_2O$, $n = 2$ or 6 depending on whether the sample was dried. The structures of **1** and $\mathbf{2}\cdot 6H_2O$ were determined by X-ray diffraction method. In **1** and **2** the bonding situations around the pseudo-octahedrally coordinated Ti(IV) are very similar. The two oxygen atoms from Q^- ligands are *trans* to each other, while the two nitrogen atoms are *cis* to each other and *trans* to the other two oxygen atoms of OPr^i in **1** and μ-O in **2**. The $[Ti(\mu\text{-}O)]_4$ eight-membered ring is puckered. There is extensive hydrogen bonding of four water molecules with $[TiQ_2(\mu\text{-}O)]_4$, two on each side of the eight-membered ring of $[Ti(\mu\text{-}O)]_4$. The two water molecules on the same face of the eight-membered ring are further hydrogen bonded to another water molecule. A novel feature in **2** is that the plane of each Q^- ligand is parallel to that of another Q^- ligand coordinated to a neighboring Ti(IV) in an eclipsed conformation. The average distance between the corresponding atoms in the parallel Q^- ligands is 3.6 Å. It is an indication that there is a strong non-bonding interaction between each pair of parallel Q^- ligands. The hydrogen bonds and the non-bonding interactions lead to the most severely distorted plane of the $[Ti(\mu\text{-}O)]_4$ eight-membered ring. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

After losing a proton, *8*-hydroxyquinline (HQ) and its derivatives are capable of forming complexes with a large number of both main group [1] and transition metal ions. The complexes of beryllium [2,3] boron, [4–9] magnesium, aluminum and zinc have attracted particular attentions in recent years because of their applications in organic electroluminescence (OEL) devices [10,11]. For example, AlQ_3 [1] is widely used as an electron transport material because it is chemically stable; can be vacuum deposited to form a stable amorphous film without pin-holes and has high light emitting efficiency in a double layer OEL device. The electroluminescent light frequencies of these 8-hydroxyquinolinate complexes are influenced by the central metal ions. For example, tetrakis(2-methyl-8-hydroxyquinolinato)boron(III)$^-$ emits blue light (470 nm) [4], MgQ_2 emits green light (519 nm)[1]; AlQ_3 emits green light (530 nm) [11] and ZnQ_2 emits yellow light (568 nm) [1]. We were curious to find out the influence of Ti(IV), which does not possess d-electrons like the main group ions, on the light emitting properties of the 8-hydroxyquinolinate–Ti(IV) complex. Although to our disappointment, the Ti(IV)–Q complexes do not fluoresce, these novel Ti(IV) complexes have interesting structural features. The preparations and structures of these complexes are reported herein.

2. Results and discussion

The reaction between 8-hydroxyquinoline (HQ) and $Ti(OPr^i)_4$ in dichloromethane resulted in $TiQ_2(OPr^i)_2$, (**1**), in high yield (90%) as indicated in Eq. (1).

$$Ti(OPr^i)_4 + 2HQ \rightarrow TiQ_2(OPr^i)_2(\mathbf{1}) + 2Pr^iOH \quad (1)$$

The light orange product was characterized by ^1H NMR, mass spectrum, elemental analysis and X-Ray structural analysis. It is interesting to point out that the methyl groups in the two isoproproxide groups split into two doublets. These doublets are due to the vicinal couplings ($J = 5$ Hz) to the protons on the central carbons of the isoproproxide groups. The chemical shift difference of these two doublets(0.915 and 1.097 ppm) is 0.182 ppm (72.8 Hz) which is independent of temperature in the range 20–60 °C in $CDCl_3$. Further examination on the structure of **1** reveals that the two methyl groups on each OPr^i group are diastereotopic. Therefore, the methyl groups are chemically non-equivalent.

When **1** was treated with water in dichloromethane, orange crystalline precipitates were obtained. The quality of the crystals was good enough for a X-ray single crystal analysis. The precipitate, after drying in a vacuum oven, has been characterized by ^1H NMR, UV–Vis spectrum, elemental analysis and thermal gravimetric analysis to be $[TiQ_2(\mu\text{-}O)]_4\cdot 2H_2O$ (**2**·$2H_2O$). However, the X-ray structure indicates that there are six water molecules of hydration. Therefore, the heating in vacuum oven led to a loss of four water molecules of hydration. The hydrolysis reaction and the subsequent heating are summarized in Eqs. (2) and (3).

$$4TiQ_2(OPr^i)_2 + 10H_2O \rightarrow [TiQ_2(\mu - O)]_4 \cdot 6H_2O(\mathbf{2} \cdot 6H_2O) + 8Pr^iOH \quad (2)$$

$$[TiQ_2(\mu - O)]_4 \cdot 6H_2O \xrightarrow{\Delta} [TiQ_2(\mu - O)]_4 \cdot 2H_2O(\mathbf{2} \cdot 2H_2O) + 4H_2O \quad (3)$$

The hydration number of this compound after vacuum heating was confirmed by a thermal gravimetric analysis.

2.1. Structure of $TiQ_2(OPr^i)_2$ (1)

The molecular plot of 30% probability of **1** together with the atomic numbering is shown in Fig. 1. The titanium atom is octahedrally coordinated by two nitrogen atoms and two oxygen atoms from the 8-hydroxyquinolinate ligands, as well as two oxygen atoms from the isopropoxide groups. The two isopropoxide groups are *cis* to each other and they are *trans* to nitrogen atoms. The two oxygen atoms in the Q^- ligands are *trans* to each other.

The selected bond distances and bond angles are summarized in Table 1. The Ti–O(Q) distances (1.961 and 1.963 Å) are ostensibly shorter than the Ti–N bond distances (2.248 and 2.251Å). This large difference can be attributed to the double-bond character between Ti and oxygen atoms. The Ti–O(Pr^i) distances (1.798 and 1.783 Å) are significantly shorter than those of Ti–O(Q) distances. This obvious difference in the two types of Ti–O bond distances is due to the *trans* ligand influence because the isopropoxide groups are *trans* to the

N1–Ti1–N2	79.6(2)	N1–Ti1–N2	83.1(5)

nitrogen atoms. The five-membered rings of Ti(IV) and the coordinating atoms in the 8-hydroxyquinolinate ligands may further lead to the longer Ti–O(Q) distances because of possible ring constraint. The angles between the *trans* atoms and Ti are 155° (∠O1–Ti–O2), 165° (∠N1–Ti–O3) and 166°(∠N2–Ti–O4) which are far from the ideal angle of 180°. The reasons for this octahedral distortion can be attributed to the small bite angles (75.9°) of the coordinated 8-hydroxyquinolinate ligands and the large size of the isopropoxide groups (∠O3–Ti–O4: 103°). Looking at the plane formed by N1, O1, O3, O2 and Ti1, opposite to the small bite angle, there is a large angle ∠O2–Ti–O3 (101.2°) to counter balance it. Likewise, opposite to the small bite angle of the other 8-hydroxyquinolinate ligand, the angle ∠O1–Ti–O4 of 101.5° is observed. The dihedral angle between the two 8-hydroxyquinolinate planes is 88.9°. It indicates that the two Q^- planes are almost perpendicular to each other. The titanium atom is out of the Q^- planes only slightly by 0.03 (Q1) and 0.18 Å (Q2).

There are a total of four structurally characterized titanium(IV) complexes containing the 8-hydroxyquinolinate ligand reported in literature: TiQ_2Cl_2, [12] $TiQ_2Cl(\eta^5\text{-}C_5H_5)$ [13], $TiQ_2(OAr)_2$ [14] and $TiQ'_2(OAr)_2$ (OAr: 2,6-di-isopropylphenoxide; Q'^-: 2-methyl-8-hydroxyquinolinate) [14]. The structure of **1** is remarkably similar to those known structures as far as the arrangement of the two 8-hydroxyquinolinate ligands to the metal are concerned. The bonding parameters such as Ti–O, Ti–N bond distances, ∠O–Ti–O, ∠N–Ti–N bond angles and the bite angles of these complexes are compared in Table 2. These parameters show little variation in each compared category. It is noteworthy that the Ti–O–C(Pr^i) angles are far larger than the values found in simple organic ethers. Similar large angles of Ti–O–C(Ar) are also found in $TiQ_2(OAr)_2$ and $TiQ'_2(OAr)_2$ (OAr: 2,6-di-isopropylphenoxide).[14]

2.2. Structure of $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$

There are six water molecules of hydration in the formula of this crystalline compound. It differs from the number of water molecules of hydration in the bulk sample obtained after drying in a vacuum oven. The single crystal of this compound developed cracks easily when left in the open air for a short period of time. This may be due to the loss of some water molecules of hydration.

The molecular plot of $[TiQ_2(\mu\text{-}O)]_4$ at 30% probability of **2** together with atomic numbering are shown in Fig. 2. The tetramer sits on a crystallographic fourfold inversion axis. In other words, it is composed of two inversion related $[TiQ_2(\mu\text{-}O)]$ pairs. The skeleton of the tetramer is a $[Ti(\mu\text{-}O)]_4$ eight-membered ring. Each Ti atom is coordinated to two 8-hydroxyquinlinate ligands via both the nitrogen atoms and oxygen atoms. In addition two bridging oxo ligands also coordinated to

[a] OAr is 2,4,6-trimethylphenoxide, Q'^-: 2-methyl-8-hydroxyquinolinate.
[b] The oxygen atom(s) not in Q^-.

each Ti atom completing the distorted octahedral environment of each Ti atom. Relevant bond distances and bond angles are summarized in Table 1. The Ti–O, and Ti–N distances in **2** are close to the corresponding distances in **1** as well as those of known Ti(IV)–Q complexes (Table 2). The angles around Ti atoms are also remarkably similar to those corresponding angles in **1**. The interplanar angle between the two Q^- ligands is 89.8° which is almost the same as that in **1**.

The skeletal Ti_4O_4 ring is puckered as shown in Fig. 3. The deviations of all atoms from the least-square plane passing through the eight-membered ring are Ti1: −0.26 Å, Ti1a: −0.26 Å, Ti1b: 0.26 Å, Ti1c: 0.26 Å, O3: 0.50 Å, O3a: 0.50 Å, O3b: −0.50 Å, O3c: −0.50 Å. The average deviation from the plane is 0.38 Å. It is clear that the puckering of the ring is extensive and the ring is far from planar. Hydrogen bonding of the water molecules with the oxygen atoms on Q^- ligands as well as the bridging oxygen atoms is shown in Fig. 4. The distances between a representative water oxygen atom O4 with its hydrogen bonded atoms are O4–O2: 2.88(2) Å, O4–O3: 3.05(2) Å and O4–O1*: 3.01(2) Å. These distances indicate that there is a strong hydrogen bonding between O4–O2, and weak hydrogen bonds between O4–O3 and O4–O1*. There are three other symmetry-related water molecules hydrogen bonded in the same fashion. The two oxygen atoms O4, O4* of the two water molecules on the same side of the $[Ti(\mu\text{-}O)]_4$ ring are also hydrogen bonded to another water molecule O5(O5–O4: 2.81(2) Å) which is located on the molecular twofold symmetry axis. The strong hydrogen bonding of O2 and weak hydrogen bonding of O1 to water molecules, resulted in a longer Ti1–O2 distance (1.97(1) Å) than Ti1–O1 (1.94(1) Å).

Careful examination of the orientations of the 8-hydroxyquinolinate ligands reveals that the plane of each Q^- ligand is parallel with the plane of another Q^- ligand coordinated to an adjacent Ti atom. This parallelism can easily be quantified by a small average dihedral angle of 3.5° between these Q^- planes. The parallel Q^- ligands are in an eclipse conformation. Furthermore, the average distance between atoms on the two parallel Q^- planes is 3.6 Å which is close to the sum of van der Waals radii of carbon atoms. Therefore, there

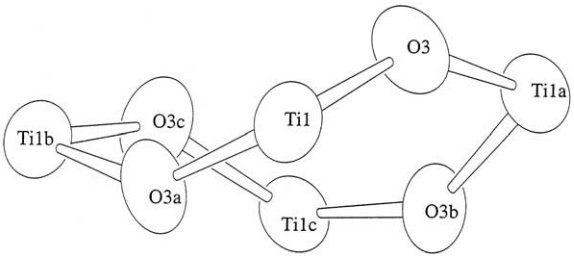

Fig. 3. The puckered conformation of the $[Ti_2(\mu\text{-}O)]_4$ ring in $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$.

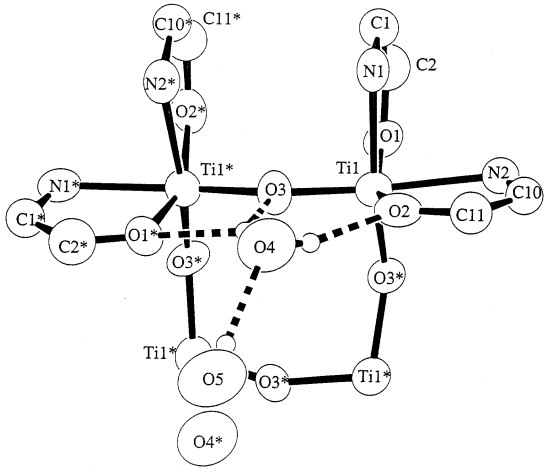

Fig. 4. Hydrogen bonding in $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$. For brevity, only one side of the $[Ti(\mu\text{-}O)]_4$ plane is shown.

are optimal non-bonded interactions in every pair of Q^- ligands. It is likely that these non-bonded interactions, together with hydrogen bonding, are responsible for the special puckered conformation of the $[Ti(\mu\text{-}O)]_4$ ring. The π–π interactions [15] between the pairs of parallel Q^- ligands cannot be important since the eclipsed overlap of the filled π-orbitals on the two Q^- ligands cannot lead to a favorable stabilization energy. The π–π interactions can be significant if the filled π-orbital in one ligand interacts with an empty π*-orbital on the other parallel Q^- ligand. Under this condition, the conformation of the parallel Q^- ligands cannot be eclipsed [15,16] On the other hand, the eclipsed overlap of π-orbitals can lead to significant stabilization when these orbitals are not completely filled [17].

The $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$ molecules pack in a pseudo body-centered cubic arrangement (Fig. 5). One tetramer occupies each corner of the unit cell while another tetramer, rotated about 30° around the *c*-axis, occupies the body center position. Looking down the *a* or *b*-axis the two alternating layer feature (ABABAB–) is obvious. The averaged layer thickness of 8.85 Å (half the length of the *c*-axis) is smaller than the thickness of the hydrated tetramer (10.90 Å), measured from the two tips of the water molecules O5 and O5*. This is because the outer-most water molecule O5 and its symmetry equivalent penetrate into the neighboring layers and point to the central holes that were formed by the groups of four tetramers in the neighboring layer.

There are quite a number of structurally characterized compounds with $[Ti(\mu\text{-}O)]_4$ rings reported. The majority of these complexes contain the cyclopentadienyl ligand or its derivatives coordinated to Ti(IV). In these compounds, each Ti can be viewed as four coordinated if cyclopentadenyl or its derivative is considered to occupy one coordination site. The planarities of the $[Ti(\mu\text{-}O)]_4$ rings of these compounds were analyzed

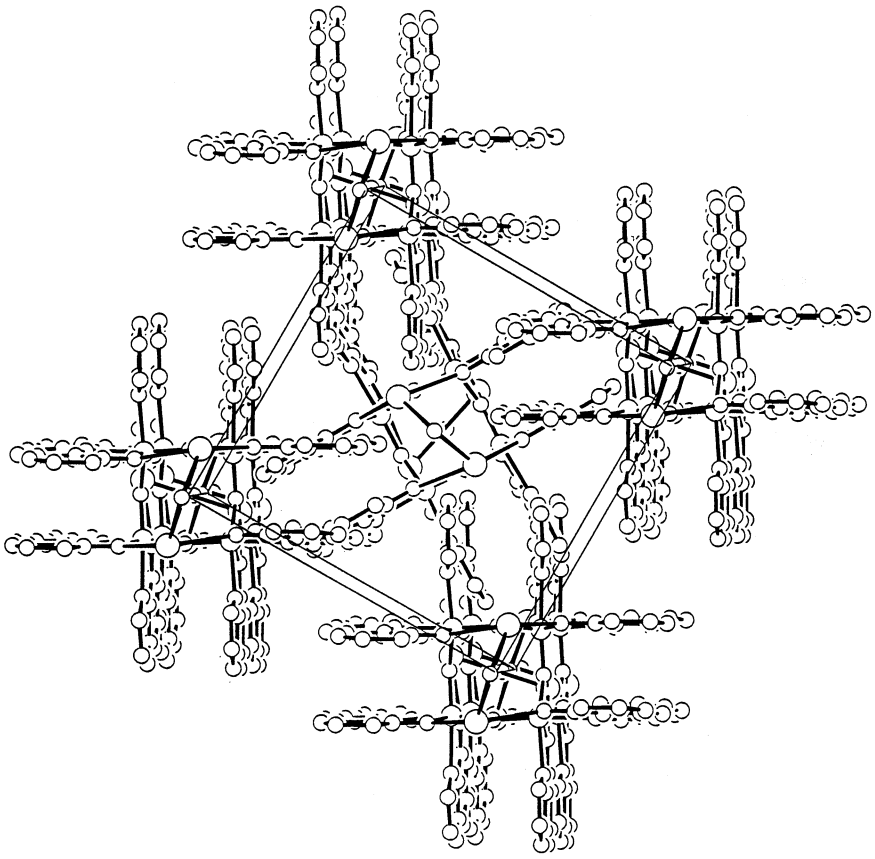

Fig. 5. Pseudo body-centered unit cell packing arrangement of $[TiQ_2(\mu\text{-}O)]_4 \cdot 6H_2O$.

based on the information collected in the Cambridge Structural Database System using Bruker SHELX program. The maximum deviations and the types of atoms above (+) and below(−) the least-square plane of [Ti(μ-O)]$_4$ were used to measure the planarity. The average deviation of all atoms from their least-square plane can also be used to judge whether the [Ti(μ-O)]$_4$ rings is planar. The deviations from planarity for some of the compounds with four coordinated Ti(IV) are given below. [(η^5-C_5Me_5)EtTi(μ-O)]$_4$ [18]: +0.17 Å(Ti), −0.17 Å(Ti), av. 0.09 Å; (η^5-C_5Me_5)$_4F_3$(FAl(CH_2Ph)$_3$)-Ti_4(μ-O)$_4$ [18]: +0.12 Å(Ti), −0.12 Å(Ti), av. 0.07 Å; (η^5-C_5Me_5)$_4$F(FAlMe3)$_3Ti_4$(μ-O)$_4$ [18]: +0.14 Å(Ti), −0.10 Å(O), av. 0.05 Å; [(η^5-C_5Me_5)($FAlMe_3$)Ti(μ-O)]$_4$ [19]: +0.10 Å(Ti), −0.10 Å(Ti), av. 0.05 Å; [(η^5-$C_5H_4SiMe_3$)NCSTi(μ-O)]$_4$ [20]: +0.19 Å(Ti), −0.28 Å(Ti), av. 0.12 Å; [(η^5-C_5Me_5)FTi(μ-O)]$_4$ [21]: +0.03 Å(Ti), −0.03 Å(Ti), av. 0.02 Å; [(η^5-C_5H_5)(O(2,4,6-$C_6H_2Me_3$)Ti(μ-O))$_4$ [22]: +0.46 Å(Ti), −0.44 Å(Ti), av. 0.28 Å. It is clear that the majority of these compounds with four coordinated Ti(IV) have a planar or close to planar [Ti(μ-O)]$_4$ ring. The only exception is [(η^5-C_5H_5)(O(2,4,6-$C_6H_2Me_3$)Ti(μ-O)]$_4$ in which severe distortion from planarity is obvious. It is likely due to the presence of the bulky ligands of 2,4,6-trimethylphenoxide.

In contrast to the four coordinated Ti(IV) compounds with [Ti(μ-O)]$_4$ rings, the structurally characterized six coordinated Ti(IV) compounds with similar rings are rather scarce. Most of them, together with the planarity parameters of the [Ti(μ-O)]$_4$ planes, are given below. [(η^5-N(CH_2COO)$_3$Ti(μ-O))$_4Cs_4$ [23]: +0.12 Å(O), −0.12 Å(O), av. 0.06 Å; [(Me_6acac)$_2$Ti(μ-O)]$_4$ [24]: +0.01 Å(Ti), −0.01 Å(Ti), av. 0.01 Å; [(Cl_2(CH_3CN)$_2$-Ti(μ-O))$_4$ [25]: +0.28 Å(Ti), −0.30 Å(Ti), av. 0.18 Å; [(acac)$_2$Ti(μ-O)Ti(μ-O)(OMe)*c*−(N$MeCH_2CH_2$)$_3$]$_2$ [26]: +0.17 Å(Ti), −0.17 Å(Ti), av. 0.12 Å; [(Oxalato)$_2$Ti(μ-O)]$_4$[NH_4]$_8 \cdot 4H_2O$ [27]: +0.33 Å(Ti), −0.33 Å(Ti), av. 0.24 Å; [(Oxalato)$_2$Ti(μ-O)]$_4Cs_8 \cdot 6H_2O$ [28]: +0.24 Å(O), −0.24 Å(O), av. 0.13 Å. Of these six hexacoordinated Ti(IV) compounds, four of them have planar or nearly planar [Ti(μ-O)]$_4$ rings. The two non-planar compounds have two oxalato ligands coordinated to each Ti(IV) atom. No strong non-bonding interaction among the oxalato ligands can be found. However, both compounds have water molecules of crystallization. Extensive hydrogen bonding exists in these two compounds. The non-planarity can be attributed to the presence of these hydrogen bonds. Therefore, the hydrogen bonding should be one major factor for the non-planarity of **2**. However, the non-bonding interactions must also be important because the distor-

tion from planarity is much more severe in **2**·$6H_2O$ than any known structure with the $[Ti(\mu\text{-}O)]_4$ eight-membered ring.

Fluorescence from both **1** and **2** in chloroform solution or in solid, was not detected. The strong bonding of Q^- ligands to Ti(IV) may be a major factor for the lack of fluorescence. However, a similar strong bonding of Q^- ligands to metal ions also exists in AlQ_3 where the Al–O distances (1.845, 1.847 and 1.857 Å) [29] are also shorter than the Al–N distances (2.073, 2.036 and 2.028 Å) [29], but AlQ_3 has relatively strong fluorescence. We think that the large spin-orbital coupling constant of Ti(IV) relative to that of Al(III) and the involvement of d-orbitals in the bonding of these complexes must be the main reasons why **1** and **2** are non-fluorescent.

3. Experimental

3.1. Physical measurements

^1H NMR spectra were recorded on a Bruker AC-400 spectrometer. Thermal gravimetric analysis was performed on a Seiko SSC 500 Thermal Analyzer under nitrogen stream. UV–Vis spectra were measured on a Perkin–Elmer Lamda-5 spectrophotometer. Elemental analyses were carried out in a Heraeus CHN Rapid Analyzer.

3.1.1. Preparation of $TiQ_2(OPr^i)_2$

$Ti(OPr^i)_4$ (Aldrich) 6 ml (20.4 mmol) was transferred to a 20 ml dichloromethane solution (which was thoroughly dried according to standard procedure) containing 6.0 g (41.3 mmol) HQ (Aldrich). The color of the solution turned orange. The reaction mixture was stirred for 2 h then the solvent was stripped off in a rotary evaporator. Recrystallization of the resulting residue from dichloromethane solution yielded a light orange product. It was dried in a vacuum oven at 70 °C. Yield: 8.45 g (90%). M.p. > 400 °C. δ_H ($CDCl_3$) 0.915(6H, d), 1.097(6H, d), 4.587(2H, t), 6.993(2H, d), 7.092(2H, d), 7.173(2H, t), 7.491(2H, t), 8.053(2H, d) and 8.481(2H, d). (Found: C, 63.31; H: 5.64; N: 6.21. Required for $TiC_{24}H_{26}N_2O_4$: C, 63.44; H: 5.77; N: 6.17%).

3.1.2. Preparation of $[TiQ_2(\mu\text{-}O)]_4\cdot 2H_2O$

To a 40 ml dried dichloromethane solution containing $TiQ_2(OPr^i)_2$ 0.25 g (0.55 mmol), five drops of deionized water were added. After standing for 3 days, orange crystals were obtained by filtration. The crystal were dried in a vacuum oven. Yield 0.153 g (75%). M.p. > 400 °C. λ_{max} nm^{-1} (CH_2Cl_2) 379 (ε dm^{-3} mol^{-1} cm^{-1} 15 700). δ_H (C_6D_6–CD_3OD, 1/1) 6.916 (2H, dd), 7.095 (2H, d), 7.140(2H, d), 7.484(2H, t), 7.870(2H, d), 8.490(2H, d) (Found: C, 58.64; H, 3.99; N, 7.54. $Ti_4C_{72}H_{48}N_8O_{12}\cdot 2H_2O$ requires C, 59.82; H, 3.64; N, 7.75%). Thermal gravimetric analysis indicated that the complex lost 2.7% weight at 53 °C. These data are consistent with a content of two water molecules of hydration in this complex which is expected to be 2.5% theoretically.

3.1.3. X-Ray crystallography

Single crystals of $TiQ_2(OPr^i)_2$ were obtained from a dichloromethane solution by the slow evaporation method. Single crystals of $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$ were obtained directly from its preparative solution. Both crystals of $TiQ_2(OPr^i)_2$ and $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$ were sealed in glass capillaries. Care was taken in the case of $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$ to avoid exposure to air because crystals of $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$ developed cracks easily. Diffraction data measurements were made on a Rigaku AFC6S diffractometer for $TiQ_2(OPr^i)_2$ and an AFC5R diffractometer for $[TiQ_2(\mu\text{-}O)]_4\cdot 6H_2O$ with a graphite monochromater. Empirical absorption corrections were made. The structures were solved by direct methods, [30] and expanded using Fourier techniques. All non-hydrogen atoms in $TiQ_2(OiPr)_2$ were refined anisotropically. However, the weak diffracting nature of the small $[TiQ_2(\mu\text{-}O)]_4$ sample prevents the same treatment. Barely enough data were possible when a rotating anode was used for data collection. Therefore, only non-carbon, non-hydrogen atoms were anisotropically refined. The weak diffracting data (hence less usable data) are also

Abstract

The halogenation of elemental tellurium with SO_2Cl_2 in various solvents has been investigated. $(H_3O)[Te_3Cl_{13}]\cdot 1/2SO_2$ (**1**) and $[(C_4H_8O)_2H][TeCl_5]\cdot(C_4H_8O)$ (**2**) were obtained in CS_2 and THF, respectively. When DMSO is added into the THF solution of tellurium and SO_2Cl_2, $[(Me_2SO)_2H]_2[TeCl_6]$ (**3**) is formed. In the acetonitrile solution tellurium and SO_2Cl_2 form $[Ni(NCCH_3)_6][Te_2Cl_{10}]$ (**4**) in the presence of metallic nickel. All compounds **1**–**4** were characterized by ^{125}Te NMR and by X-ray crystallography. The formation of the anions has been discussed. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Tellurium dichloride; Chloridotellurate anions; X-ray crystallography; NMR spectroscopy

1. Introduction

Chalcogen dihalides EX_2(E = S, Se, Te; X = Cl, Br, I) are useful reagents for synthetic applications. Of the chalcogen dihalogenides SCl_2 is most stable and can be prepared from the elements or by chlorination of S_2Cl_2 [1,2]. While $SeCl_2$ is stable only in the gas phase [3–5], it survives sufficiently long in coordinating solvents to serve as a synthon [6]. At 25 °C it can be stored for hours, and the appearance of Se_2Cl_2 and $SeCl_4$ due to disproportionation is only observed by ^{77}Se NMR after 24 h. $SeBr_2$ can be obtained by halogen exchange between $SeCl_2$ and Me_3SiBr, but disproportionation to Se_2Br_2 is apparent already after 1 h [6].

Tellurium dichloride has been known for over 100 years [7], but only few synthetic routes for the compound have been reported [8–10]. The reaction between $TeCl_4$ and neat hexamethyldisilane seems to be most promising [10]. In CS_2 solution, however, the formation of polymeric $(MeTeCl_3)_n$ was observed [11]. $TeCl_2$ is only stable in the gas phase and the condensation leads to rapid disproportionation to tellurium and $TeCl_4$ [12].

In this work we report the investigation of the reaction of elemental tellurium and SO_2Cl_2 in various solvents in order to explore the plausibility to produce $TeCl_2$ for synthetic applications. It turned out that in the presence of adventitious water tellurium is easily oxidized to the oxidation state IV with the production of a number of anionic species. The products have been characterized by ^{125}Te NMR and X-ray crystallography.

2. Experimental

2.1. General

All reactions were carried out under an argon atmosphere passed through P_4O_{10}. Tellurium (Aldrich), nickel (Merck), and SO_2Cl_2 (Aldrich) were used without further purification. DMSO (Lab-Scan) was dried by stirring over CaH_2 and acetonitrile (Lab-Scan) by distillation over CaH_2 before use. THF (Lab-Scan)

and CS_2 (Merck) were dried by distillation over Na/benzophenone and P_4O_{10}, respectively.

2.2. Spectroscopy

All ^{125}Te NMR spectra were recorded on a Bruker DPX 400 spectrometer at 300 K operating at 126.241 MHz. The spectral width was 95.24 kHz, yielding the resolution of 2.91 Hz per data point. The pulse width was 6.67 μs corresponding to a nuclear tip angle of 30°. The accumulations contained approximately 30 000 transients. All spectra were recorded unlocked. The ^{125}Te chemical shifts are reported relative to a saturated D_2O solution of H_6TeO_6 [$\delta(Me_2Te) = \delta(H_6TeO_6) + 712$].

TOF MS ES negative ion mass spectra were recorded using a Micromass LCT spectrometer at following voltages: capillary 3200 or 4000 V, sample cone from 15 to 30 V, RF lens 200 V, and extraction cone 3 V. Both the desolvation and source temperatures were 120 °C.

2.3. X-ray crystallography

Diffraction data for **1**–**4** were collected on a Nonius Kappa CCD diffractometer at 150 K using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) by recording 360 frames via φ-rotation ($\Delta\varphi = 1°$; two times 20–40 s per frame). Crystal data and the details of the structure determinations are given in Table 1. Lorentz and polarization corrections as well as empirical absorption correction were applied to the net intensities.

All structures were solved by direct methods using SHELXS-97 [13] and refined using SHELXL-97 [14]. After the full-matrix least-squares refinement of the non-hydrogen atoms with anisotropic thermal parameters, the methyl and methylene hydrogen atoms were placed in calculated positions (C–H = 0.98 Å). In the subsequent refinements the hydrogen atoms were riding with the carbon atom they were bonded to. The isotropic thermal parameters of these hydrogen atoms were fixed at 1.5 times to that of the corresponding carbon atom. It was possible, however, to locate the oxonium hydrogen atoms in **1**, and the bridging hydrogen atoms in the cations of **2** and **3**. In the final refinement their positional and isotropic thermal parameters were refined normally. The scattering factors for the neutral atoms were those incorporated with the programs.

2.4. Preparation of samples

2.4.1. $(H_3O)[Te_3Cl_{13}]\cdot 1/2SO_2$ (**1**)

Tellurium (0.458 g, 3.59 mmol) was added into 30 ml of dry CS_2. An excess (1.20 g, 8.89 mmol) of SO_2Cl_2 was added into the resulting suspension during which a clear solution was formed. The mixture was stirred for 2 h during which some white solid was precipitated. Fifty ml of CS_2 was added to dissolve the precipitation. The solution was filtered and the filtrate was concentrated under dynamic vacuum. The crystals for the X-ray structure determination were obtained by cooling the filtrate. After 2 days 0.77 g (72% based on tellurium) of almost colorless crystals were obtained. Spectroscopic data: ^{125}Te NMR (CS_2, 25 °C): $\delta = 1803$ ppm.

2.4.2. $[(C_4H_8O)_2H][TeCl_5]\cdot(C_4H_8O)$ (**2**)

$[(C_4H_8O)_2H][TeCl_5]\cdot(C_4H_8O)$ was prepared by adding 1.380 g (10.23 mmol) of SO_2Cl_2 in 30 ml of THF into 0.522 g (4.09 mmol) of elemental tellurium upon stirring. The mixture was further stirred until the reaction was completed and a clear yellow solution was formed. The solution was concentrated under dynamic vacuum. Yellow crystals of **2** were obtained upon crystallization from the concentrated solution at room temperature (r.t.). The yield is approximately 1.9 g (90% based on tellurium). The rapid decomposition of the product in vacuum precluded the elemental analysis. Spectroscopic data: ^{125}Te NMR (THF, 25 °C): $\delta = 1712$ ppm.

2.4.3. $[(Me_2SO)_2H]_2(TeCl_6)$ (**3**)

SO_2Cl_2 (0.16 ml, 2.00 mmol) and 10 ml of THF were added into 0.255 g (2.00 mmol) of elemental tellurium upon stirring. The solution was further stirred for 60 min after which a 0.06 ml (0.75 mmol) portion of SO_2Cl_2 was added. All tellurium reacted and the solution turned yellow upon further stirring of 15 min. At this point 0.28 ml (4.00 mmol) of DMSO in 10 ml of THF was added into the resulting solution. An immediate pale yellow precipitation was observed with a yield of 0.62 g (95% based on DMSO). The precipitate was filtered, dissolved, and the solution was allowed to stand at r.t. overnight during which yellow crystals were formed. *Anal.* Calc. for $C_8H_{26}O_4S_4TeCl_6$: C, 14.67; H, 4.00. Found: C, 15.05; H, 3.62%. Spectroscopic data: ^{125}Te NMR (THF, 25 °C): $\delta = 1548$ ppm.

2.4.4. $[Ni(NCMe)_6][Te_2Cl_{10}]$ (**4**)

Metallic nickel (0.345 g, 5.88 mmol) and 1.508 g (11.82 mmol) of tellurium were mixed in 40 ml of acetonitrile. Upon addition of 3.995 g (29.60 mmol) of SO_2Cl_2 the color of the solution turned first yellow and then dark green. After stirring for 2 h the solvent was evaporated to dryness under dynamic vacuum. The yield is quantitative. The crystals for X-ray structure determination were obtained by recrystallization at r.t. from acetonitrile. *Anal.* Calc. for $C_{12}H_{18}N_6NiTe_2Cl_{10}$: C, 15.76; H, 1.98; N, 9.19. Found: C, 14.94; H, 1.97; N, 8.59%. Spectroscopic data: ^{125}Te NMR (MeCN, 25 °C): $\delta = 1570$ ppm.

3. Results and discussion

3.1. General

While $SeCl_2$ can conveniently be prepared in coordinating solvents from elemental selenium and SO_2Cl_2 [6], the attempts to treat elemental tellurium with SO_2Cl_2 resulted in the production of chloridotellurate anions in which tellurium is in the oxidation state IV. The reaction route depends on the reaction conditions and is also influenced by the presence of adventitious water. All syntheses are reproducible.

The main products are $(H_3O)[Te_3Cl_{13}]\cdot 1/2SO_2$ (**1**) and $[(C_4H_8O)_2H][TeCl_5]\cdot(C_4H_8O)$ (**2**) in CS_2 and THF, respectively. With the addition of DMSO into the THF solution of the reaction mixture $[(DMSO)_2H]_2[TeCl_6]$ (**3**) is formed. In the presence of elemental nickel in acetonitrile, the reaction produces $[Ni(NCMe)_6][Te_2Cl_{10}]$ (**4**).

The ^{125}Te NMR spectra of all four reaction solutions show only a single resonance each with the chemical shifts of 1803, 1712, 1548, and 1570 ppm for **1**–**4**, respectively. All resonances are expectedly very broad because of the isotopic shifts of the chlorine atoms that are bound to tellurium.

The TOF ES negative ion mass spectra were recorded from every reaction solution. In all cases the most abundant fragment was $TeCl_2^-$ that was assigned on the basis of good agreement between the calculated and observed isotopic distribution. It was also the fragment of highest mass in **1**, **2**, and **3**. In **4** the fragment of highest mass was $TeCl_5^-$.

3.2. Crystal structures

3.2.1. $(H_3O)[Te_3Cl_{13}]\cdot 1/2SO_2$ (1)

The structure of **1** together with the numbering of the atoms is shown in Fig. 1, and the selected bond parameters are presented in Table 2.

The structure of **1** contains discrete $[Te_3Cl_{13}]^-$ and H_3O^+ ions and a disordered SO_2 molecule. The $[Te_3Cl_3]^-$ anion can be thought to be composed of three $TeCl_3^+$ units that are connected together by three bridging μ-Cl^- ligands and by one μ_3-Cl^- ligand that is

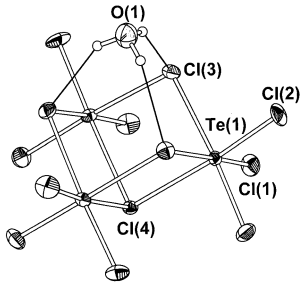

Fig. 1. The molecular structure of $(H_3O)[Te_3Cl_{13}]\cdot 1/2SO_2$ (**1**) indicating the numbering of the atoms. The thermal ellipsoids have been drawn at 50% probability.

coordinated to all three tellurium atoms. The lengths of the terminal Te–Cl bonds Te(1)–Cl(1) and Te(1)–Cl(2) are 2.339(3) and 2.330(4) Å, respectively. The Te(1)–Cl(3) distance of 2.826(2) Å involving a bridging μ-Cl^- ligand is significantly longer than the terminal bonds and the μ_3-Cl^- ligand Cl(4) shows a still longer bond of 2.942(3) Å to tellurium. These values are well in agreement with the corresponding bonds reported for $(Ph_3C)[Te_3Cl_{13}]$ [15,16] and $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ [17]. The terminal Te–Cl bonds span the range of 2.320(5)–2.388(5) Å and 2.313(1)–2.356(1) Å in $(Ph_3C)[Te_3Cl_{13}]$ [15,16] and $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ [17], respectively, those involving the μ-Cl^- ligands show the respective Te–Cl distances of 2.706(5)–2.863(5) Å and 2.798(1)–2.880(1) Å, and the Te–Cl distances involving the μ_3-Cl^- ligand lie in the range of 2.924(5)–2.984(5) Å and 2.913(1)–2.965(1) Å in $(Ph_3C)[Te_3Cl_{13}]$ [15,16] and $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ [17], respectively.

It can be seen from the bond angles in Table 2 that the tellurium atom shows an approximate octahedral coordination and that the anion is a slightly distorted cube with one vertex occupied by the oxonium ion. The O(1)–H(1) bond length is 0.90(1) Å and the H(1)–O(1)–H(1)^a and H(1)–O(1)–H(1)^b bond angles are 106(10)° [see the footnotes in Table 2 for the definition of the symmetry operations *a* and *b*]. The hydrogen atoms of the oxonium ion are involved in weak hydrogen bonds to the bridging chloride Cl(3). The H(1)···Cl(3) contact is 2.6(1) Å. The oxonium oxygen also shows a close contact of 2.39(3) Å to S(1) of the SO_2 molecule.

It is interesting to note that the cation in neither $(Ph_3C)[Te_3Cl_{13}]$ [15,16] nor $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ [17] lies in the open vertex of the cube. In the case of $(Ph_3C)[Te_3Cl_{13}]$ [15,16] there is a close contact between the Ph_3C^+ carbon and the μ_3-Cl^- ligand, and in the case of $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ [17] the $[MeC(H)C(NH_2)O–H\cdots NCCMe_2]^+$ cation interacts through hydrogen bonds of the NH_2 group with one terminal and one μ-Cl^- ligand. These differences in the interionic packing help to understand, why the $[Te_3Cl_{13}]^-$ anion in **1** shows an exact site symmetry of C_{3v}, while the anions in $(Ph_3C)[Te_3Cl_{13}]$ [15,16] and $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ [17] are somewhat distorted from the ideal symmetry.

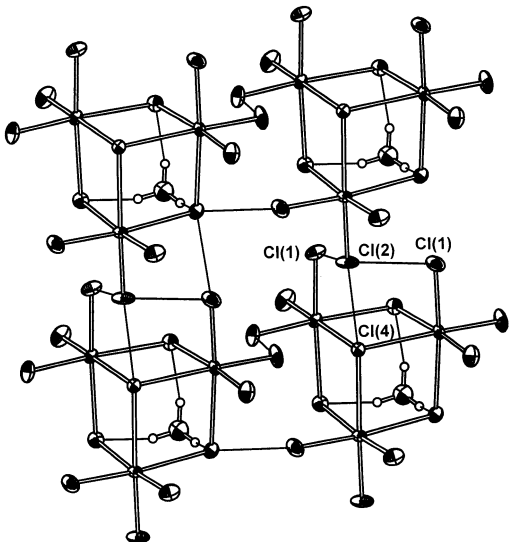

Fig. 2. The packing of the $[Te_3Cl_{13}]^-$ anions in **1**.

It can be seen in Fig. 2 that the anions of **1** are packed into layers involving close Cl···Cl contacts that lie in the range 3.497(6)–3.768(5) Å. It is interesting to note that while the closest Cl···Cl contacts in $(Ph_3C)[Te_3Cl_{13}]$ and $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ are shorter than in **1** {3.328 [15,16] and 3.217(2) Å [17], respectively}, the packing of anions in **1** is more efficient than in either of the two related species. This is reflected by a somewhat higher density of $(H_3O)[Te_3Cl_{13}]\cdot 1/2SO_2$ (2.382 g cm^{-3}) compared with that of $(Ph_3C)[Te_3Cl_{13}]$ {2.127 g cm^{-3} [15,16]} or $[(CH_3)_2CHC(NH_2)(OH)][Te_3Cl_{13}]\cdot(CH_3)_2CHCN$ {2.247 g cm^{-3} [17]} and is a consequence of a significantly smaller cation in **1** that can be incorporated in the cage-structure of the anion.

3.2.2. $[(C_4H_8O)_2H][TeCl_5]\cdot(C_4H_8O)$ (2)

The crystal structure and the numbering of the atoms of **2** is shown in Fig. 3. The selected bond parameters are presented in Table 2. The structure is ionic and is composed of $[(C_4H_8O)_2H]^+$ cations and $[TeCl_5]^-$ anions. In addition there is one discrete THF solvent molecule in the lattice.

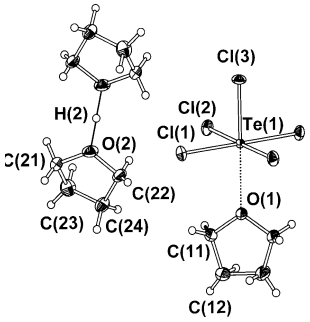

Fig. 3. The molecular structure of $[(C_4H_8O)_2H][TeCl_5]\cdot(C_4H_8O)$ (**2**) indicating the numbering of the atoms. The thermal ellipsoids have been drawn at 50% probability.

The primary coordination sphere of tellurium is a square pyramid. The basal bonds Te(1)–Cl(1) and Te(1)–Cl(2) show the respective lengths of 2.515(1) and 2.516(1) Å. The apical bond Te(1)–Cl(3) is expectedly somewhat shorter [2.355(1) Å]. The basal plane is virtually planar [Σ(Cl–Te–Cl) = 359.1°]. The long Te(1)···O(1) contact of 2.593(4) Å from the solvent molecule completes the octahedral coordination and is consistent with the concept of secondary bonding [18] that has recently been considered for a number of tellurium compounds [19,20]. $(C_8H_8S_2N)[TeCl_5]\cdot 1.5C_4H_8O_2$ [21], $(H_3O)[TeBr_5]\cdot C_4H_8O_2$ [22], and $(AsPh_4)[TeCl_5]\cdot H_2O$ [23] also exhibit a $[TeX_5]^-$ anion with a weak secondary interaction to the dioxane or water oxygen atom. For instance, in $(C_8H_8S_2N)[TeCl_5]\cdot 1.5C_4H_8O_2$ the virtually coplanar basal bonds range 2.494(3)–2.514(3) and the apical Te–Cl bond shows the length of 2.330(4) Å. The secondary Te–O contact is 2.766 Å [21] in agreement with the bond parameters in **2**.

The cation of **2** is a protonated THF dimer $[(C_4H_8O)\cdots H\cdots(OC_4H_8)]^+$. The hydrogen atom H(2) lies at a symmetry element and is thus exactly in the middle of O(2) and its symmetry-related counterpart. The O(2)–H(2) distance is 1.209(3) Å and the O(2)···O(2) separation is 2.418(5) Å. The existence of this kind of protonated dimeric cations with strong hydrogen bonds is well-known and can be exemplified by bis(*N*-nitrosopyrrolidine)hydrogen hexafluorophosphate [24] and $[Me_2NC(H)O\cdots H\cdots O(H)CNMe_2][TeCl_4(OEt)]$ [25]. The $[MeC(H)C(NH_2)O–H\cdots NCCMe_2]^+$ cation that serves as a counterion for one of the $[Te_3Cl_{13}]^-$ structures [17] is also analogous to the dimeric bonding arrangement involving a bridging H^+ ion, as is the dimeric $[Me_2SO–H\cdots OSMe_2]^+$ cation of **3** described below. Reich et al. [23] have suggested that the formation of protonated organic molecules as counterions to halogenidotellurates(IV) is observed, when the electron donating group is more basic than water.

The anions of **2** are chained together involving the solvent THF molecule. In addition to the close Te(1)···O(1) contact to one $[TeCl_5]^-$ anion, there is a Cl(3)···C(12) contact of 3.580(2) Å to another $[TeCl_5]^-$ anion. The closest anion-cation Cl···C distances are 3.672(2) and 3.696(1) Å.

3.2.3. $[(Me_2SO)_2H]_2[TeCl_6]$ (3)

The crystal structure of **3** with the numbering of atoms is shown in Fig. 4, and the selected bond lengths are presented in Table 2. The lattice of **3** consists of discrete $[TeCl_6]^{2-}$ anions and $[(Me_2SO)_2H]^+$ cations. The coordination sphere of tellurium in $[TeCl_6]^{2-}$ is an almost regular octahedron with the Te–Cl bond lengths ranging 2.528(1)–2.547(1) Å. The bond angles are near to 90° ranging 89.30(4)°–91.05(3)°. These values are in

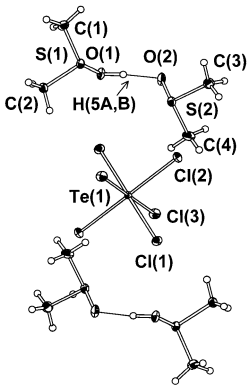

Fig. 4. The molecular structure of $[(Me_2SO)_2H]_2[TeCl_6]$ (**3**) indicating the numbering of the atoms. The thermal ellipsoids have been drawn at 50% probability. Only one hydrogen of the disordered H(5A,B) pair has been displayed.

good agreement with those reported for a large number of species containing the $[TeCl_6]^{2-}$ ion [26].

In an analogous fashion to **2** the cation in **3** is a protonated DMSO dimer. The O(1)···O(2) distance of 2.435(3) Å indicates a relatively strong hydrogen bond. It was possible to detect two electron density maxima along the line connecting O(1) and O(2) and refine the positions of these two hydrogen atoms H(5A) and H(5B) by defining the site occupation factors of 0.5 for both of them (a constant isotropic thermal parameter 0.05 was used in the refinement). Both the O(1)–H(5A) and O(2)–H(5B) bond lengths are 0.9(1) Å with the H(5A)···O(2) and H(5B)···O(1) contacts 1.5(1) Å. The O–H···O bond angles are 175(10)° and 170(5)° for H(5A) and H(5B), respectively.

The crystal structure of $[(Me_2SO)_2H]_2[TeCl_6]$ has also been determined earlier at room temperature [27]. The structure of **3** expectedly shows the same general structural features. In the present low-temperature redetermination, however, it was possible to locate and refine the hydrogen atom positions and establish that the protonation of the two DMSO molecules in the dimeric cation is distributed statistically in the lattice.

3.2.4. *[Ni(NCMe)$_6$][Te$_2$Cl$_{10}$] (4)*

The molecular structure of **4** is shown in Fig. 5 together with the numbering of the atoms. The selected bond lengths and angles of the anion are given in Table 2.

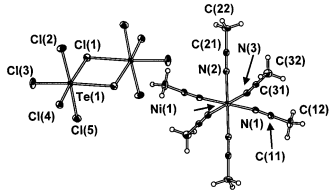

Fig. 5. The molecular structure of $[Ni(NCMe)_6][Te_2Cl_{10}]$ (**4**) indicating the numbering of the atoms. The thermal ellipsoids have been drawn at 50% probability.

The discrete $[Te_2Cl_{10}]^{2-}$ anions consist of two $TeCl_6$ octahedral sharing a common edge. The terminal Te–Cl bond lengths range 2.383(1)–2.352(1) Å. The bridging Cl(1) shows two distances to tellurium, 2.783(1) and 2.909(1) Å. Such an unsymmetrical bridge is a common feature in dinuclear tellurates [28]. The bond angles around tellurium span 87.49(4)°–94.04(4)° indicating a slightly distorted octahedron.

The $[Ni(NCMe)_6]^{2+}$ cation is virtually a regular octahedron. All bond lengths are quite normal for the atoms in question. The anions and the cations form alternating stacks throughout the lattice. The closest cation-anion distances involve the interaction between the chlorido-ligands and the CN group in acetonitrile. The Cl···N contacts range 3.441(3)–3.676(3) Å and the Cl···C contacts 3.336(3)–3.585(4) Å.

3.3. *The structural relationships between the anions and their formation*

All anions formed in this work bear a structural relationship to $TeCl_4$ and to each other. This relationship has initially been proposed by Krebs and Paulat [16] and is presented in Fig. 6. Hasche et al. ([17], and references therein) have also discussed the formation equilibria of the different chloridotellurate anions.

$$3[Te_4Cl_{16}] + 4Cl^- \rightleftharpoons [Te_3Cl_{13}]^-$$

$$4[Te_3Cl_{13}]^- + 4Cl^- \rightleftharpoons 4[Te_2Cl_{10}]^{2-} + [Te_4Cl_{16}]$$

$$[Te_2Cl_{10}]^{2-} + 2Cl^- \rightleftharpoons 2[TeCl_6]^{2-}$$

Hasche et al. [17] suggest that $[TeX_5]^-$ is formed in organic solutions due to disproportionation of TeX_4. This anion is stabilized by the secondary interaction of

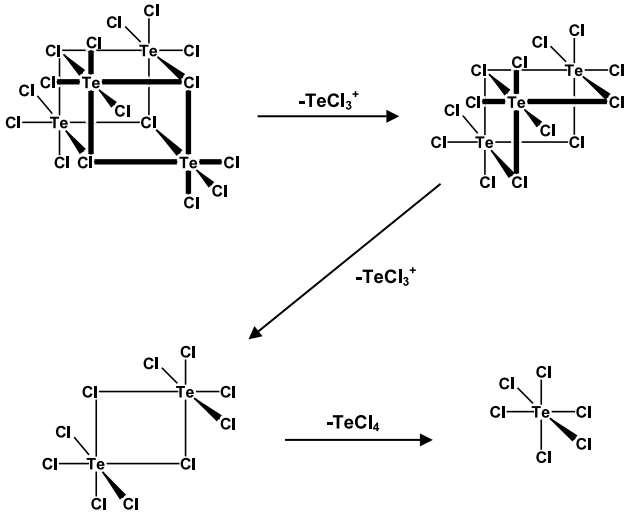

Fig. 6. The structural relationships between the halogenidotellurate anions as suggested by Krebs and Paulat [16].

tellurium to the oxygen atom of the solvent molecules as observed in $(C_8H_8S_2N)[TeCl_5]\cdot 1.5C_4H_8O_2$ [21], $(H_3O)[TeBr_5]\cdot C_4H_8O_2$ [22], $(AsPh_4)[TeCl_5]\cdot H_2O$ [23], and **2**.

These equilibria may well explain the formation of **1**–**4** upon the reaction of elemental tellurium with SO_2Cl_2. It is possible that $TeCl_2$ is an initial product in the reaction, as expected on the basis of the reaction of elemental selenium and sulfuryl chloride in THF that is known to afford $SeCl_2$ in good yields [6]. However, an excess of SO_2Cl_2 needs to be used to facilitate the complete reaction of tellurium. It is possible that in addition to $TeCl_2$ also $TeCl_4$ is formed. Both molecules may play a role in the setting of the above-mentioned equilibria and the isolation of the products **1**–**4**. The solvent and the possible presence of a small amount of residual moisture seem to determine the identity of the main product in each individual case.

4. Supplementary material

Crystallographic information for **1** (excluding tables of structure factors) has been deposited with the Fachinformationzentrum Karlsruhe (FIZ) as supplementary publication number CSD 412153, and that for **2**, **3**, and **4** with the Cambridge Crystallographic Data Center as supplementary publication numbers CCDC 171280-171282, respectively. Copies of the data can be obtained free of charge on application to FIZ, abt. PROKA, 76344 Eggenstein-Leopoldshafen, Germany (tel.: +49-7247-808-205; e-mail: crysdata@fiz-karlsruhe.de), and to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk www:http://www.ccdc.cam.ac.uk).

Received 26 October 2001; accepted 16 January 2002

Abstract

A series of lanthanide–copper coordination polymers with nitrilotriacetic acid (H_3NTA) were synthesized as $[LnCuCl(NTA)(H_2O)_6]ClO_4\cdot H_2O$ [Ln=La (**1**), Ce (**2**), Pr (**3**), Gd (**4**, **4′**), Tb (**5**) and Dy (**6**)] and $[LnCuCl(NTA)(H_2O)_6]ClO_4\cdot 3H_2O$ [Ln=Ho (**7**), Er (**8**), Tm(**9**), Lu (**10**) and Y (**11**)] in aqueous solution. The crystal structures of **1**, **4**, **4′**, **8**, **11** were determined and isomorphous relationships of the others identified. They turned out to be diverse, ranging from a two-dimensional (2D) array for **1** to one-dimensional (1D) chains of three different types (**2**–**4**, **4′**–**6**, and **7**–**11**), as controlled by lanthanide contraction and mixed anions Cl^- and ClO_4^-, which were found to play a crucial role in the formation and stabilization of this series of LnCu polymers. Temperature-dependent magnetic susceptibilities for **1**, **3**, **4**, **5** and **8** were studied. **1** shows a weak ferromagnetic-like behavior, whereas the others exhibit an overall antiferromagnetic feature. © 2002 Elsevier Science Ltd. Keywords: Lanthanide contraction; Anion controlled assembly; Crystal structures; Magnetic properties

1. Introduction

Lanthanide(Ln)-transition metal coordination polymers are of great interest in view of their interesting magnetic properties [1–4]. From a structural viewpoint, lanthanide contraction may have a crucial effect on the formation of 4f–3d complexes. Recently, it was reported that with the ligand 3,5-pyrazoldicarboxylic acid (H_3pdc), three different types of structures (two-dimensional single layer, two-dimensional double layer and three dimensional structures) could be obtained by using different lanthanides from Lu to La [5]. Kahn and coworkers have also carried out systematic studies on a series of $[Ln_2Cu_3]$ heteronuclear complexes with the 1,3-propylene-bis(oxamato) ligand [6]. They observed the lanthanide contraction controlled dimensional structural diversity ranging from two-dimensional honeycomb patterns (Ln=La–Gd) to one-dimensional ladder-like chains (Ln=Tb–Yb). These results suggest that lighter lanthanides tend to form higher-dimensional structures, while heavier lanthanides tend to generate lower-dimensional structures. However, the contraction from light to heavy lanthanides seems to have little effect on the crystal structure of zero-dimensional high nuclearity clusters, such as $[Cu_{12}Ln_6(OH)_{24}(H_2O)_{18}(pyb)_{12}(ClO_4)]^{17+}$ (Ln = Nd, Gd, Y, Sm, Eu, pyb = pyridine betaine) [7] and the heptanuclear clusters $[LnCu_6(\mu_3\text{-}OH)_3(HL)_2(L)_4]\ (ClO_4)_2\cdot 25H_2O$ (Ln = La, Tb, H_2L = iminodiacetic acid) [8].

Nitrilotriacetic acid (H_3NTA) is an important derivative of glycine. However, only a few rare-earth complexes with NTA have been synthesized [9–11], and we first reported two 4f–3d heteronuclear complexes $[LnCuCl(NTA)(H_2O)_6](ClO_4)\cdot H_2O$ (Ln = La, Gd) **1** and **4′** [12]. As an extension of this work, herein we report the synthesis and structural diversity of a series of Ln–Cu–NTA complexes. We found that with a syn-

thetic method similar to that of **1**, two other kinds of different one-dimensional chains could be obtained as $[GdCuCl(NTA)(H_2O)_6](ClO_4)\cdot H_2O$ (**4**) and $[ErCuCl(NTA)(H_2O)_6]\cdot(ClO_4)\cdot 3H_2O$ (**8**), indicating the dimensional diversity controlled by lanthanide contraction in this series of complexes.

Some earlier reports have mentioned the template effect of inorganic anions in studies on the formation of some cluster compounds, e.g. Cl^- in $[Eu_{15}(Cl)(\mu_3\text{-}Tyr)_{10}(\mu_3\text{-}OH)_{20}(\mu_2\text{-}H_2O)_5(OH)_{12}(H_2O)_8](ClO_4)_2\cdot 56H_2O$ [13], $\mu_{12}\text{-}ClO_4^-$ in $[Ln_6Cu_{12}]$ (Ln = Nd, Sm, Gd and Y) [7], and $\mu_6\text{-}O^{2-}$ in $[Ln_6(\mu_6\text{-}O)(\mu_3\text{-}OH)_8(H_2O)_{24}]\cdot(ClO_4)_8\cdot 6H_2O$ [14,15]. In contrast, as monodentate ligands and counter ions, both Cl^- and ClO_4^- ions play crucial roles in the formation of compounds **1** to **11**.

2. Experimental

2.1. Synthesis of the complexes

All the complexes were synthesized by similar procedures. A mixture of $Cu(OH)_2$ (3 mmol) and H_3NTA (3 mmol) was dissolved in 30 ml H_2O, then aqueous solutions of $Ln(ClO_4)_3$ (0.5 M, 1.5 mmol) and $LnCl_3$ (0.5 M, 1.5 mmol), where Ln stands for La, Ce, Pr, Gd, Tb, Dy, Ho, Er, Tm, Lu and Y, were added. The pH value of the reaction mixture was adjusted carefully to approximately 5.0. The solution was filtered, concentrated to 15 ml and left to stand at r.t. Blue crystalline blocks of $[LnCuCl(NTA)(H_2O)_6]\cdot ClO_4\cdot H_2O$ [Ln=La (**1**), Ce (**2**), Pr (**3**), Gd (**4**), Tb (**5**) and Dy (**6**)] and $[LnCuCl(NTA)(H_2O)_6]ClO_4\cdot 3H_2O$ [Ln=Ho (**7**), Er (**8**), Tm(**9**), Lu (**10**) and Y (**11**)] suitable for X-ray crystallography formed after 2 weeks. C, H, N analyses results of the products are listed in Table 1.

2.2. X-ray data collection and structure determination

Crystals of complexes **1**, **4**, **8** and **11** with suitable dimensions were picked out from paraffin oil and sealed into thin-walled capillaries for structure determination. Intensity data were collected on a Siemens P4 diffractometer with Mo Kα radiation in the ω-scan mode. The unit-cell parameters of the complexes were determined from a least-square refinement. Empirical absorption corrections were applied using the XPRED program [16]. The structures were solved and refined with direct methods and difference Fourier syntheses. The structures were further refined with full-matrix least-square calculations using the Siemens SHELXTL/PC system [16]. All non-hydrogen atoms were refined anisotropically. Details of data collection and refinements are listed in Table 2.

2.3. Magnetic measurements

The dc and ac magnetic susceptibility data for crystalline samples were collected on a MAGLAB2000 system in the temperature range from 2 to 300 K. The data were corrected for the diamagnetism of the samples calculated from Pascal's constants.

3. Results and discussion

3.1. Description of structures

Compound **1** consists of a two-dimensional metal-apex honeycomb-like layer with nine-coordinated lanthanum and five-coordinated copper ions located at the apexes of each hexagon [12(a)].

Compound **4** is not a 2D polymer, but a 1D zigzag chain with nine-coordinated gadolinium and five-coordinated copper ions, which was established by X-ray crystallography. An ORTEP view of **4** is shown in Fig. 1. Selected bond lengths and angles are given in Table 3. Similar to **1**, the Cu in complex **4** is also tetradentately chelated by a NTA ligand through O1, O3, O5 and N. The fifth coordination site is occupied by Cl1. Despite the fact that six water molecules (O7–O12) are coordinated to it, Gd is also bidentately chelated by a carboxyl group of NTA through O1 and O2. The last coordination site of Gd is taken up by a carboxyl oxygen atom (O6A) from another NTA ligand. Therefore, each NTA consists of a chelating carboxyl bridge and a *syn–anti* carboxyl bridge over a copper and two different gadolinium ions. The third carboxyl group of NTA is monodentately coordinated to Cu through O3, and O4 is left non-coordinating. The intra-chain Gd···Cu distances in complex **4** is 4.63 (chelation bridge) and 5.72 Å (*syn–anti* bridge). The *syn–anti* and the chelation bridges interconnect the complex into a 1D zigzag chain

[b] $R_w = \{\Sigma[w(F_o^2 - F_c^2)]/\Sigma[w(F_o)^2]\}^{1/2}$.

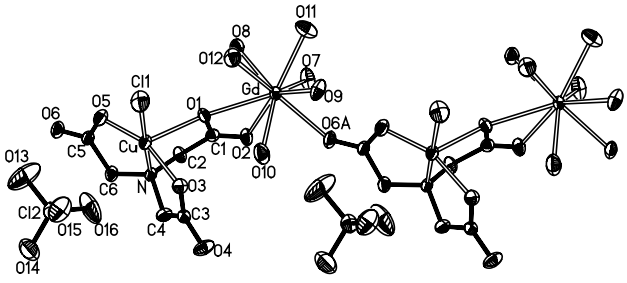

Fig. 1. An ORTEP view of complex **4** showing the connection between Gd^{3+} and Cu^{2+}. Hydrogen atoms and lattice water molecules are omitted for clarity.

(Fig. 2). Under the condition when the concentration of Cl^- was considerably low, we also obtained another Gd–Cu–NTA 1D chain (**4′**) [12(b)], which is a little different from **4**. The structure of **4′** is very similar to that of **4,** except that the carboxyl bridge is *syn–anti* in **4** and *anti–anti* in **4′**. As a result, the crystal system of **4′** is triclinic: space group $P\bar{1}$, $a = 8.483$ Å, $b = 9.642$ Å, $c = 12.838$ Å, $\alpha = 111.17°$, $\beta = 93.52°$, $\gamma = 100.89°$. It is very interesting to find two kinds of Gd–Cu–NTA chains with the same formula and same coordination environments around the metal ions. Since different synthesis methods were employed for **4** and **4′**, it seems that the crystals formed tend to be monoclinic when a higher concentration of Cl^- is used, while a lower concentration of Cl^- is advantageous for the formation of triclinic crystals. The mechanism of crystal formation will be further studied.

As for compounds **8** and **11**, X-ray single crystal diffraction analysis revealed that they are isomorphous.

Symmetry transformations used to generate equivalent atoms: (A) $x, y, z+1$.

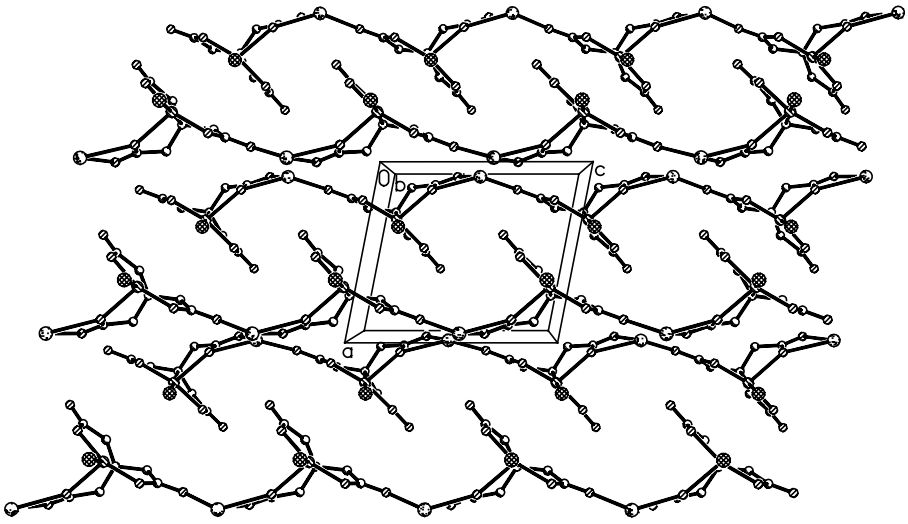

Fig. 2. Viewed along the *c* axis showing the zigzag chains along the *b* axis in **4**. All water molecules and ClO_4^- are omitted for clarity.

Both compounds are 1D chain-like polymers with eight-coordinated lanthanide and five-coordinated copper ions. The ORTEP view of **8** is shown in Fig. 3. Selected bond lengths and angles are given in Table 4. In complex **8**, the coordination environment of Cu is the same as that in **1**, but the environment of Er is different from that of La in **1** and Gd in **4** and **4′**, mainly due to the fact that Er is only eight-coordinated. In addition to six water molecules, Er is only coordinated by two carboxyl oxygen atoms from two different NTA ligands. Thus, each NTA forms a *syn–anti* bridge and an *anti–anti* bridge over one copper and two different erbium ions. The complex is linked into a 1D chain by the *syn–anti* and *anti–anti* bridges of NTA ligands. In general, the length of either the *syn–anti* bridge or the *anti–anti* bridge is much longer than that of the chelating bridge. Both complexes **4** and **4′** contain chelating carboxyl bridges while complex **8** does not. Therefore, the length of chain per unit in **8** (intra-chain Er···Er distance, 10.81 Å) is longer than those in **4** and **4′** (intra-chain Gd···Gd distance: 9.40 Å for **4** and 9.64 Å for **4′**).

Based on the results of elemental analyses and crystal cell parameters (shown in Table 5) for complex **2**, **3**, **5**, **6**, **7**, **9** and **10**, we found that complexes **2** and **3** are isomorphous with **4**, complexes **5** and **6** are isomorphous with **4′**, and complexes **7**, **9** and **10** are isomorphous with **8** and **11**.

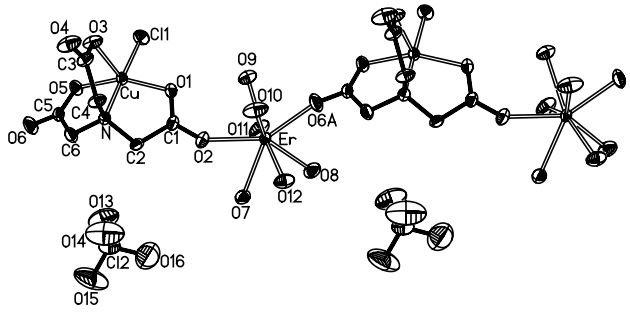

Fig. 3. An ORTEP view of complex **8** showing the connection between Er^{3+} and Cu^{2+}. Hydrogen atoms and lattice water molecules are omitted for clarity.

3.2. Anion controlled assembly

It was found that experiments using either $Ln(ClO_4)_3$ or $LnCl_3$ alone could not give rise to this series of Ln–Cu complexes, suggesting that both Cl^- and ClO_4^- have a synergetic effect on the formation of this series of heteronuclear complexes. On comparing to the Ln_{15} cluster which contains a central Cl^- ion as template and ClO_4^- ions as counter ions [13], the Cl^- ions in the Ln–Cu–NTA complexes are not templates, but are directly coordinate to Cu. Formation of these complexes turned out to be impossible without the presence of Cl^-. The role of ClO_4^- as counter ions may involve it occupying the holes of the honeycomb in complex **1** and the vacuous spaces among the zigzag chains in complex **2**–**11**. The lattices are, therefore, stabilized. Since the size of the Cl^- ion is much smaller than that of ClO_4^-, the lattice may become unstable if the counter ions are changed from ClO_4^- to Cl^-. These facts suggest that the formation of this series of Ln–Cu–NTA complexes is influenced by both Cl^- and ClO_4^-.

3.3. Structural diversity and dimensional change

As all the complexes were synthesized with the same procedure (except for **4′**) except for the use of different starting materials, $Ln(ClO_4)_3$ and $LnCl_3$, the different crystal structures obtained provide a fair assessment of the critical influence of lanthanide contraction. La has the largest ionic radius among all lanthanides. This makes it possible for La^{3+} to be connected to three Cu ions from three different directions through three *anti–*

anti carboxyl bridges of NTA ligands, forming a 2D honeycomb layer. The smaller ionic radii of Ce, Pr and Gd ions only allow them to be connected to two Cu ions from two directions through two carboxyl bridges, forming 1D zigzag chains. Owing to the fact that nine-coordinated ions of Ce, Pr and Gd are more stable than the eight-coordinated ones, one of the carboxyl bridges becomes a chelating bridge in order to satisfy the nine-coordination requirement. As Tb^{3+} and Dy^{3+} are smaller than Ce^{3+}, Pr^{3+} and Gd^{3+}, the length of the chelating bridges in complexes **5** and **6** should be shorter than that in **2**, **3** and **4**. In order to make the chain stable, in **5** and **6** longer carboxyl bridges (*anti–anti bridges*) replace the shorter bridges (*syn–anti* bridges) in **2**, **3** and **4,** and the crystal system changes from monoclinic to triclinic. A point should be made that because of the medium ionic radius of Gd, it might yield either monoclinic or triclinic crystals subject to the concentration of Cl^-. The heavy lanthanides, Ho, Er, Tm, Lu and Y, have the smallest ion radii and higher stability with eight-coordinated ions than with nine-coordinated ones. In this case, chelating bridges are no longer necessary and the carboxyl bridges in complexes **7**–**11** are both μ_2 bridges (*anti–anti* and *syn–anti*).

From the above discussion, it is obvious that various coordination modes of carboxyl groups in NTA, caused by lanthanide contraction, give rise to the diverse structures of the Ln–Cu–NTA complexes. In another word, the structural diversity and dimensional change of the Ln–Cu–NTA complexes are controlled by lanthanide contraction. According to this regularity, it may be suitable to divide all lanthanides (including Y) into four groups according to the crystal structures of their resulting Ln–Cu–NTA complexes. La belongs to group 1, the complexes of which have a 2D layered structure, (orthorhombic $Pca2_1$). Ce to Gd, are in group 2, the complexes of which have a 1D chain structure, (monoclinic, $P2_1$). Gd to Dy, form group 3, and the complexes of which have a different type of 1D chain structure, (triclinic, $P\bar{1}$), form group 4. The lanthanides in groups 1–3 are all nine-coordinated. Gd could be assigned to either group 2 or group 3 because its radius is medium sized. Ho to Lu and Y form group 4, the complexes (a 1D chain structure, triclinic, $P\bar{1}$) where the lanthanides are all eight-coordinated.

3.4. Magnetic properties

The temperature dependence of the magnetic susceptibility in the temperature range 2–300 K at an applied field of 10 kOe (**1**, **3**) or 5 kOe (**4**, **5**, **8**) is shown in Fig. 4, where χ_M is the magnetic susceptibility per LnCu unit. The value of $\chi_M T$ is 0.4 $cm^3\ mol^{-1}$ K at 200 K for **1** and increases very slowly to a maximum of 0.47 $cm^3\ mol^{-1}$ K between 13 and 6 K, then decreases upon further cooling. Fitting the data to the Curie–Weiss law gave $C = 0.398$ $cm^3\ mol^{-1}$ K and $\theta = 2.6$ K, indicative of weak ferromagnetic-like behavior. This might be considered as the result of frustration in the 2D triangular array of antiferromagnetic (AF) interacting copper ions

[a] α-[GdCu] is the complex **4**, β-[GdCu] is complex **4′**.

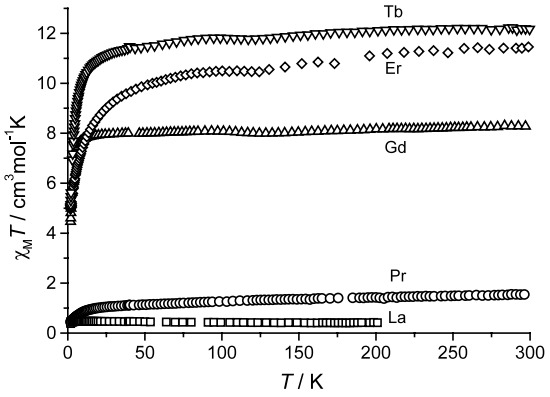

Fig. 4. Temperature dependence of magnetic susceptibility for complexes **1**, **3**, **4**, **8**.

[12(a)]. For other 1D chain compounds **3**, **4**, **5**, **8**, the $\chi_M T$ values are 1.98, 8.28, 12.17, and 11.46 cm^3 mol^{-1} K at 300 K, respectively, which are consistent with the values of 1.87, 8.25, 12.19, 11.87 cm^3 mol^{-1} K, expected for one spin only Cu^{2+} ion and one trivalent rare-earth ion with its *J* quantum number. The $\chi_M T$ of **4** keeps almost a constant above 20 K and decreases remarkably below 10 K, indicating a weak antiferromagnetic coupling between Gd–Cu and/or Gd–Gd at low temperature. The temperature dependence of $\chi_M T$ for **3**, **5**, **8** shows a similar feature: $\chi_M T$ decreases upon cooling, the lower the temperature, the quicker the decrease of $\chi_M T$. The reduction of $\chi_M T$ at low temperature, should mainly arise from the crystal field splitting of Ln^{3+} (here, Pr, Tb, Er) ions, and combine the contribution of the overall antiferromagnetic interactions among the metal ions. However, the nature of the interactions between Ln^{3+} and Cu^{2+} cannot be extracted due to the complication of the system.

As observed in the weak AF interacting 2D LaCu compound **1** [12(a)], field dependent magnetic relaxation was also observed in other 1D LnCu complexes, such as **3** and **4**, shown in Fig. 5. When a dc field (10 kOe for **3**, 5

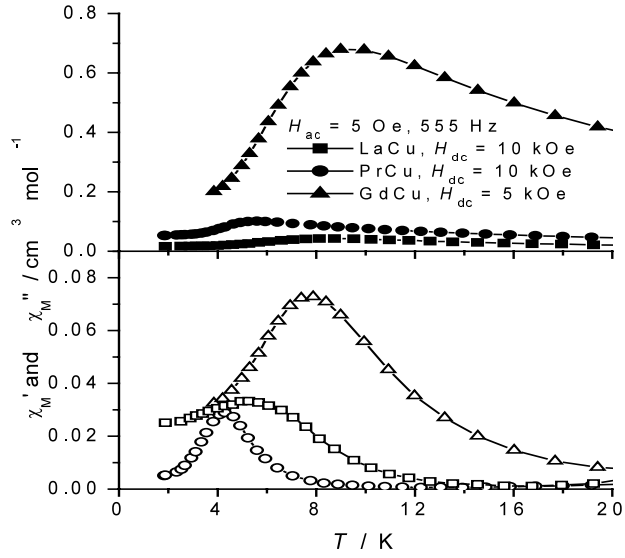

Fig. 5. Temperature dependence of ac magnetic susceptibility for complexes **1**, **3**, **4**, measured at 10 kOe (**1**, **3**) or 5 kOe (**4**) dc field, with 5 Oe, 555 Hz ac field.

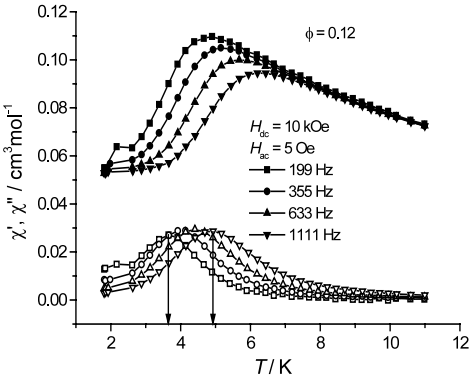

Fig. 6. Temperature dependence of ac magnetic susceptibility for complex **3**, measured at 10 kOe dc field, with 5 Oe ac field at different frequencies (199–1111 Hz).

kOe for **4**) was applied, maxima for ac susceptibility χ' and χ'' are observed, with different peak temperatures (Tp) dependent on the different lanthanide ions. The ac susceptibility is strongly frequency dependent as shown in Fig. 6 for **3**. If we calculate the value of the relative variation of Tp per decade of frequency, $\phi = \Delta T\text{p}/[T\text{p}\Delta(\log f)] = 0.12$, which is distinctly different from the behavior of normal spin glasses ($\phi < 0.1$), and smaller than 1.2 in 2D LaCu (**1**).

The antiferromagnetic (AF) interactions of triangularly arranged metal ions (including inter-chain) should give to rise a spin frustration, which may result in the unusual magnetic relaxation observed in **1**, **3**, and **4**. Similar phenomenon was also observed in other coordination polymers [17].

Abstract

A series of alkyne parallel μ_3-η_2-(//) substituted trinuclear cluster derivatives has been synthesized, containing the alkynes (HC≡CR, R = $SiMe_3$, $SiPh_3$ and *t*Bu) coordinated to Ru_3 and Os_3 units and then converted into the corresponding chemically related acetylide derivatives. A ^{1}H, ^{13}C and ^{29}Si NMR study was carried out for all the complexes and the results are also analyzed in comparison with results of Extended Hückel Molecular Orbital calculations carried out on the complexes and the free alkynes. In the acetylide derivatives, ^{13}C–^{1}H and ^{187}Os–^{1}H couplings involving the hydride, were measured. The ^{13}C–^{29}Si couplings for all the derivatives which contain silicon shows the changes in hybridization of the C_β. The structures of [(μ-H)$Ru_3(CO)_9$(CCR)] (R = $SiMe_3$ and $SiPh_3$) and [(μ-H)$Os_3(CO)_9$(CCR)] (R = $SiPh_3$ and CMe_3) and [$Ru_3(CO)_{10}$(HCCR)] (R = CMe_3) were determined by single crystal X-ray diffraction methods. © 2002 Elsevier Science Ltd. 1. Introduction

The reactions of alkynes with trinuclear metal clusters have been extensively studied [1–10]. The two main coordination modes that have been observed, a parallel μ_3-η^2-(//) and a perpendicular μ_3-η^2-(⊥), have been shown to be dependent on the electron count found in the complex. Thus, the perpendicular mode is found in 46-electron clusters while the parallel one is observed to be present in 48-electron clusters [5–8]. In the case of parallel compounds, [$M_3(CO)_{10}$(μ_3-η^2-(//)-HCCR)] (M = Ru and Os), containing terminal alkynes, these transform into the corresponding acetylide derivatives [$HM_3(CO)_9$(μ_3-η^2-(⊥)-CCR)], (Fig. 1), through the cleavage of the C–H bond, rapidly in the case of ruthenium, more slowly in the osmium compounds [9,11].

The ^{13}C and ^{1}H NMR spectroscopy have been shown to be powerful methods for the assignment of coordination modes for hydrocarbyls [12], but the low natural abundance of the C-13 nuclei combined with the long relaxation times of the coordinated carbon atoms, has limited the studies of coordinated alkynes to cluster units, in particular those reported in the 1970s and early 1980s. Not much information is available on ^{13}C shifts of alkynes or acetylides bonded to trinuclear units [13]. These values could also help to obtain further values of $\delta(C_\alpha)+\delta(C_\beta)$ and $\delta(C_\alpha)-\delta(C_\beta)$, which have been proposed to be related to the total charge alteration in the C≡C triple bond and the polarization of that bond, respectively [14]. More values could also be used to try to evaluate the effect of coordination modes, metal atoms and substituted groups on these values and from there obtain a larger understanding of the reactivity of these systems. The study of shifts and coupling con-

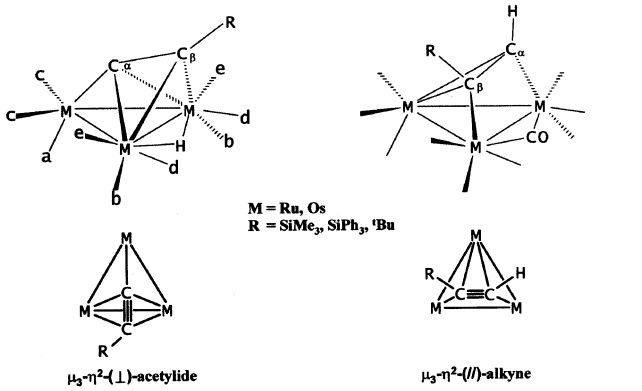

Fig. 1. Structures of the μ_3-η^2-(⊥)-acetylide and μ_3-η^2-(//)-alkyne trinuclear cluster compounds. The carbonyl assignment for compounds **1**–**6** is shown in the acetylide derivative.

stants of the alkyne substituents could also help to determine whether these substituents are affected by the differences in coordination modes.

In an effort to expand the available information on these systems, ^{1}H, ^{13}C and ^{29}Si NMR studies were carried out on both (//)-[$M_3(CO)_{10}(\mu_3$-η^2-HCCR)] and [(μ-H)$M_3(CO)_9(\mu_3$-η^2-CCR)] systems where M = Ru and Os and R = $SiMe_3$, $SiPh_3$ and CMe_3. In the case of acetylide derivatives, ^{13}C–^{1}H of the hydride hydrogen atom and some of the carbonyl groups were also obtained as well as ^{187}Os–^{1}H coupling constants. In the acetylide derivatives, ^{13}C–^{1}H coupling constants for the hydride–acetylide fragment were also measured and ^{1}H–^{13}C couplings between the hydride and some of the carbonyl groups could also be measured. ^{13}C–^{29}Si couplings were obtained in order to attain more information on the changes within the ligand upon coordination to the cluster. EHMO calculations on the 12 compounds were also carried out in order to see whether there is a relationship between calculated charges and experimental NMR chemical shifts. Crystal structures of [$HRu_3(CO)_9$(CCR)] (R = $SiMe_3$ and $SiPh_3$), [$HOs_3(CO)_9$(CCR) (R = $SiPh_3$ and CMe_3) and [$Ru_3(CO)_{10}$(HCCR)] (R = CMe_3) were also obtained and compared with those already described in the literature. Results of these studies are described herein.

2. Results and discussion

2.1. Synthesis

The reactions of terminal alkynes with trinuclear ruthenium and osmium clusters often lead to hydrogen transfer to the metal core and formation of acetylide groups [15]. However, the stabilization of osmium systems containing terminal alkynes coordinated in a (//) mode is possible and seems to be preferred over that of the corresponding ruthenium systems. The (//)-Os_3 systems can then be transformed into the corresponding acetylide derivatives. Very few reports have been published [10,16] of the (//) coordination mode in Ru_3 compounds, in spite of the extensive chemistry carried out on the chemically related acetylide compounds [16]. These few (//)-Ru_3 complexes reported have been usually prepared through the reaction of the activated complex [$Ru_3(CO)_{10}(MeCN)_2$] which permits the preparation of a variety of substituted compounds under mild conditions [17].

Since the synthesis of the acetylide –Ru_3 complexes has been described, reactions of [$Ru_3(CO)_{12}$] with other terminal alkynes HC≡CR (R = $SiMe_3$ and $SiPh_3$), were carried out following the method reported [18] to produce [(μ-H)$Ru_3(CO)_9(\mu_3$-η^2-CCR)] (R = $SiMe_3$, compound **1**, R = $SiPh_3$, compound **2** and R = CMe_3, compound **3**). The corresponding osmium compounds [(μ-H)$Os_3(CO)_9(\mu_3$-η^2-CCR)] (R = $SiMe_3$, compound **4**, R = $SiPh_3$, compound **5** and R = CMe_3, compound **6**), were obtained by heating octane solutions of the parallel derivatives [$Os_3(CO)_{10}$(HCCR)] (compounds **10** [9], **11** and **12**, respectively) prepared by the reaction of [$Os_3(CO)_{10}(MeCN)_2$] with the corresponding alkyne.

As reported [10] for parallel alkyne Ru_3 compounds, the reaction of HC≡CR (R = $SiMe_3$, $SiPh_3$ or ^{t}Bu) with [$Ru_3(CO)_{10}(MeCN)_2$], prepared in situ, yielded [$Ru_3(CO)_{10}$(HCCR)], the (//)-derivatives with R = $SiMe_3$, compound **7**, R = $SiPh_3$, compound **8** and R = ^{t}Bu, compound **9**, which slowly transformed into the acetylide compounds. As an example, the $SiMe_3$ derivative changed from the (//) compound to the acetylide, in 1 h of leaving the solid standing at room temperature in the presence of light. In the dark and at low temperature (−20 °C) the conversion is much slower.

All 12 compounds were characterized by infrared and ^{1}H and ^{13}C NMR spectroscopic methods and ^{29}Si NMR in the case of compounds, which contain silicon groups. Results are given in Tables 1–4. Data on compounds already described (Compounds **3** [18], **4** [9], and **10** [9]) agree with those reported.

As expected, very little difference is observed in the frequency values for the terminal CO stretching bands when moving from one substituent to the other or from one coordination mode to the other. Larger differences are observed in the NMR results, and as observed in other systems [13], ^{13}C chemical shifts for similar compounds appear at higher fields in osmium complexes than in ruthenium ones.

2.2. NMR data for acetylide derivatives (compounds 1–6)

The ^{1}H NMR spectra of compounds **1**–**6** show the presence of a hydride group. Chemical shifts for these hydrides are very similar. Compounds **4**, **5** and **6** show

the presence of satellites due to $^{187}Os-^{1}H$ couplings with J values of 32.5 (compounds **4** and **6**) and 32.6 (compound **5**) Hz. These values are in the same range than those observed in other μ_2-hydride groups [19,20].

^{13}C NMR spectra show that, as reported [13], the chemical shift for C_α is found downfield from that of C_β. This assignment was confirmed in compound **1** by the observation of one bond $^{13}C-^{29}Si$ coupling for C_β while ^{29}Si spectra of **2**, **4** and **5**, showed ^{13}C satellites due to coupling with C_β (a polarization transfer experiment from the methyl group to C_β was carried out in order to augment the C_β signal). Shifts for both C_α and C_β appear in the range reported by Carty and coworkers [13] for this type of acetylide although the value for C_α of compounds **3** and **6** (^{t}Bu derivatives) is observed to be at higher fields than those of the silyl substituted alkynes while the trend for C_β is the opposite one. Furthermore, there are larger differences in chemical shifts of the carbon atoms on going from the free alkyne to the coordinated ones in the ^{t}Bu-acetylene than in the SiR_3 compounds. A much larger separation between C_α and C_β is observed in the silyl substituted compounds than in those containing ^{t}Bu as substituent. In fact the difference in the silyl compounds is larger than that reported for other acetylide compounds [21].

$^{13}C-^{1}H$ couplings with the hydride can be observed for both carbon atoms in some of the compounds. The coupling with C_α is larger than with C_β. In some of the signals due to the carbonyl groups, couplings with the hydride can also be observed. The different types of carbonyl groups in compounds **1**, **2**, **4**, **5** and **6**, were assigned by comparison with those that have been reported for compound **3** [22] as it is shown in Fig. 1. The couplings with the hydride support the assignments since only the carbonyls near the hydride (two bonds),

couple with it. Couplings with COb, and COd show smaller magnitudes than couplings with COe. Therefore, different coupling constant values are explained by different H–M–C angles.

The chemical shift of the quaternary carbon of the ^tBu group show this to be slightly shifted downfield in the complexes with respect to the free alkyne. This trend is also observed in the ^{29}Si spectra.

$^{13}C-^{29}Si$ couplings can be observed in all the compounds. These ^1J values are smaller in the coordinated groups than in the free alkynes and, as expected, the C_β–Si coupling is more affected than the Si–CH_3 coupling. Even though it has been pointed out that a direct relationship between coupling constant values and s character in the bond must be used very cautiously [23]

when one of the atoms involved is large and polarizable, a rehybridization of C_β in compounds **1**–**6** must be expected and a larger sp^2 character seems logical. These is confirmed by the analysis of the values obtained, in free $HC{\equiv}CSiMe_3$ the value of the $^1J_{^{13}C-^{29}Si}$ between the carbon of the methyl group and the silicon atoms is 57 Hz while the coupling alkynic carbon–silicon is 82 Hz. The C_β–Si coupling constant value in compound **1**, 64 Hz, is intermediate between those two values. The same trend is observed in compounds **2**, **4** and **5**.

As can be appreciated in Fig. 2, from the ^{29}Si spectra it was possible to obtain the $^{13}C/^{12}C$ isotope effects on the ^{29}Si chemical shift. Isotope induced shifts, $\Delta\delta^i$, over one bond, have been associated with changes in rotational and vibrational states of the bond under consideration [24,25]. Several studies of isotope effects on different nuclei have been published [26,27], but to our knowledge, nothing has been reported of these type of effects in cluster compounds. This lack of data precludes a more detailed analysis of trends. However, it can be observed that the isotope effect in the compounds reported here, decreases on going from the free ligand to the complexes, and with osmium complexes showing smaller absolute values than ruthenium ones as a consequence of the larger mass of the former.

2.3. NMR data for parallel alkyne derivatives (compounds 7–12)

Proton NMR spectroscopy shows that the chemical shifts for the CH group, move significantly downfield in the coordinated (//) complexes in comparison with the shifts observed in the free ligands. $^{13}C-^1H$ coupling constants of this same group, are much lower on going from the free alkyne to the (//) complex but are very similar in the six complexes. This behavior reflects the rehybridization suffered by the carbon atoms of the alkyne. A similar trend had been previously observed in acetylene-clusters [10,23].

^{13}C NMR of the six compounds show these do not follow a regular trend in the relative position of the carbon atoms of the coordinated alkynes. Depending on the metal and the substituent, their chemical shifts change. Thus, while chemical shift for the carbon of the CH group moves to lower fields in the order ^{t}Bu > $SiMe_3$ > $SiPh_3$; shifts for the CR groups follow the order $SiPh_3$ > $SiMe_3$ > ^{t}Bu, with this last complex being found at much lower fields than the other two. This effect must be a reflection of the higher electronegativity of the ^{t}Bu group.

The quaternary carbon of the ^{t}Bu group also moves downfield on going from the free acetylene to the complexes. The same effect is observed in the ^{29}Si chemical shift of the silyl derivatives. $^1J_{^{13}C-^{29}Si}$ values for compounds **7**, **8**, **10** and **11** range between 64 and 72 Hz. $^{13}C/^{12}C$ isotope effects on the ^{29}Si chemical shift were also observed and follow the same trend observed in acetylide complexes.

The chemical shifts for C_α are found at low fields in both types of compounds, while C_β are shifted to much higher fields when going from the parallel coordination mode to the acetylides. The similarity of the $^{13}C-^{29}Si$

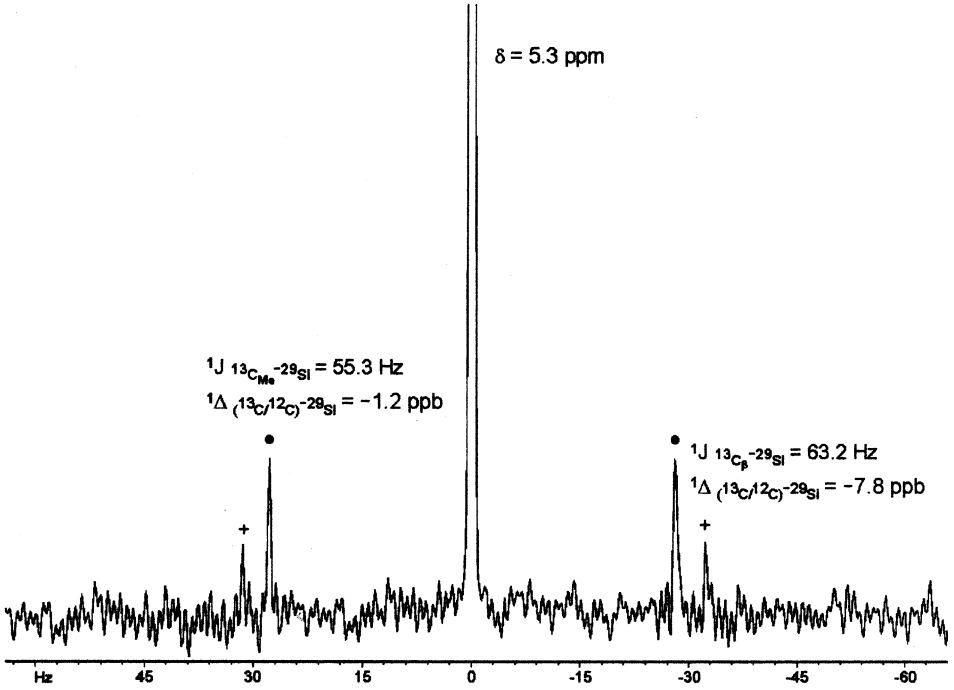

Fig. 2. NMR ^{29}Si spectra for **4**. Negative values are high field isotope shifts.

coupling constants suggests a similar hybridization for C_β.

Given the closely related coordination environment of the two carbon atoms in the alkyne moiety of the (//) systems, the $\Delta\delta$ of these two carbon atoms could be expected to be lower in the (//) systems than in the acetylide ones. Such is the case in the two silyl substituted alkynes both for ruthenium and osmium with $\Delta\delta$ values of around 10 ppm. In the ^{t}Bu derivatives the $\Delta\delta$ (in absolute value) is higher in the (//) derivative than in the acetylide, contrary to what was observed in the silyl compounds. If it is true that $\delta(C\alpha)-\delta(C\beta)$ is related to the polarizability of the CC bond, the $\Delta\delta =$ 67.6 ppm for compound **12**, would suggest that there is a larger polarizability of the CC bond in that complex than in the acetylide derivative, compound **6** ($\Delta\delta = 47.1$ ppm). No values above 100 ppm are observed in other derivatives [21], however, in the silyl acetylides these magnitudes are obtained, therefore, compounds **1** and **3** have the largest polarizability of all.

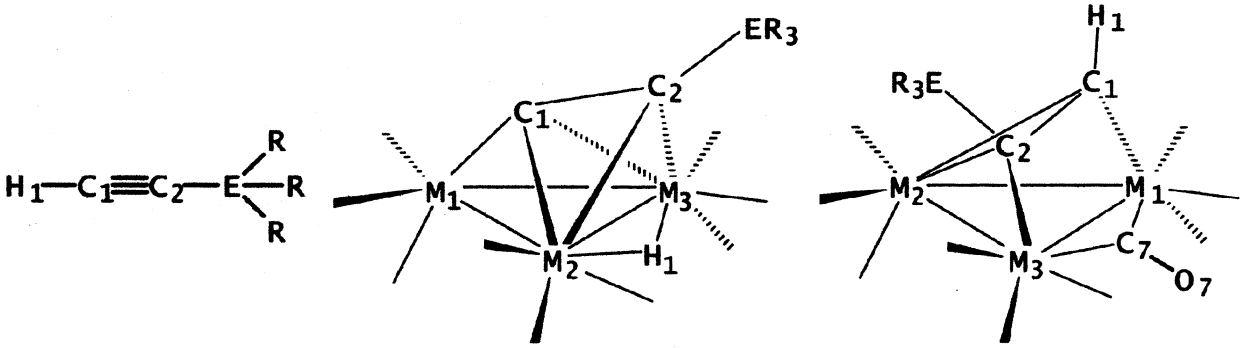
2.4. Theoretical calculations

In order to observe if the reactivity studies described and the NMR trends could be supported with the results of theoretical studies, EHMO calculations were carried out on the 12 complexes and the free alkynes. In the case of those compounds where crystal structure results were available, these were taken as a basis for the calculation. The (//)-complexes which have not been crystallographically characterized, were modeled taking the structure of $[Os_3(CO)_{10}(EtCCEt)]$ [28,29] as a basis.

CNDO theoretical calculations have been carried out in some (//) and ($\perp$) alkyne clusters [30] but no substituents were included in this calculation. Also, EHMO calculations have been reported previously [31] for several trimetal alkyne clusters including heterometallic derivatives, the results described show a good correlation with structures obtained experimentally. When the substituent of the C_β is a methyl group [32] a large difference in charge is described between Cα and Cβ with Cα showing a positive charge and Cβ a negative charge. In general, our results do not yield such differences in charge, (Fig. 3).

Granozzi and coworkers [32] report to have obtained positive charges on the ruthenium atoms, however, we obtain negative values for these. An opposite behavior is observed, in our results, for the osmium derivatives. It is worth noticing that protonation of compound **3**, has been described [33] to occur initially at the metal centers, therefore, a negative charge on the metal atoms makes this result more logical.

It is also interesting to notice that charge on the acetylenic carbon atoms is much more negative in the osmium compounds than in the ruthenium ones. Both in the free ligand and the osmium complexes, the substituted carbon atom (C_β) of the ^{t}Bu compounds, shows a less negative charge, also indicating a larger electronegativity of the ^{t}Bu group. In order to observe if protonation of the osmium acetylide complexes, showed any differences in reaction with protic acids, we carried out the reaction of these compounds with a large excess of trifluoroacetic acid and no reaction was observed to occur, even after 24 h of reaction. This result is thus consistent with the charge distribution obtained in our calculations.



Frontier orbitals from the twelve complexes show that while the LUMO orbitals lie largely on the metal atoms in all cases, there are important differences in the position of the HOMO orbitals. Thus, in the ruthenium complexes, the HOMO orbitals are mainly found on the alkyne ligands. The $SiMe_3$ and ^{t}Bu derivatives have the HOMO situated on the acetylenic carbon atoms, while the $SiPh_3$ derivatives have them on the aromatic rings. In the case of the osmium compounds, the HOMO are also found on the metal atoms with the exception of compound **11** where it is again found on the aromatic rings. EHMO calculations of the free alkynes also show different behavior in the $SiPh_3$ compound where the HOMO orbital is found largely on the aromatic rings while in the other cases, at least part of it, is located on the hydrogen substituted carbon atom of the alkyne.

Osmium (//) complexes show both the HOMO and the LUMO to be lying on the metal atoms while in the (//) ruthenium complexes, the HOMO sit largely on the acetylenic moiety while the LUMO is found on the metal atoms. This might be related to the greater stability of the Os-parallel complexes since the rearrangement towards the acetylide compounds should take place more easily in the case of ruthenium.

In all cases, the HOMO orbitals of the (//) derivatives are observed to be at lower energy values than in the acetylide derivatives, more so in the ruthenium derivatives. The HOMO–LUMO gap is also smaller in the (//) complexes with larger gaps in the osmium complexes than in the ruthenium ones.

2.5. X-ray structures of compounds *1, 2, 5, 6 and 9*

In order to certify there were no important structural differences in the complexes, compounds **1**, **2**, **5**, **6** and **9** were studied by X-ray crystallography. Results are shown in Figs. 4–8 and in Table 5. No significant differences are observed in bond distances and angles in any of the compounds in comparison with the structures already described, compounds **3** [34] and **4** [9]. It is important that although the structure of compound **1** has been reported [35], the data given in this work are the result of the structural results we obtained. Structural details of compound **9** are similar to corresponding values in $[Ru_3(CO)_{10}(HCCH)]$ [11].

Fig. 3. Calculated atomic charges for ligands and compounds **1**–**12**.

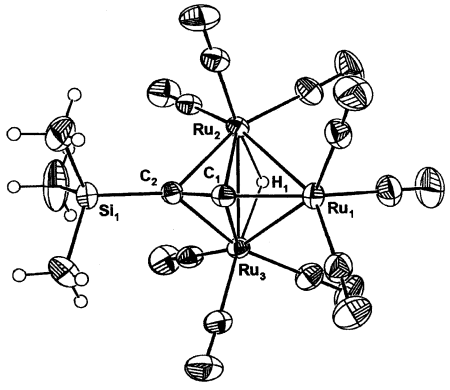

Fig. 4. Molecular structure for compound **1**, including numbering scheme. ORTEPS shown at 40% probability.

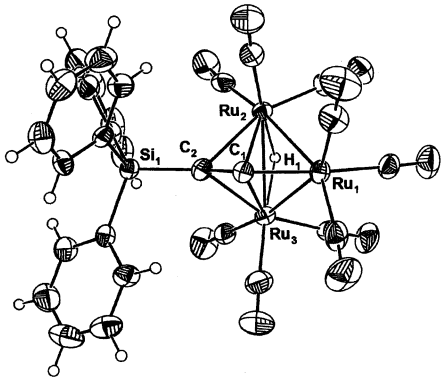

Fig. 5. Molecular structure for compound **2**, including numbering scheme. ORTEPS shown at 40% probability.

The M(1)–C(1)–C(2) angle of the acetylide complexes tends to be in the range of 153°–158° while the C(1)–C(2)–R angle is somewhat smaller, (138°–148° for Ru compounds and about 140° for osmium complexes). The corresponding angles in compound **9** are much smaller (112.6(3)° and 121.8(9)°). Also, in the case of the ruthenium compounds, the larger electronic deformation can be thought to follow the order $SiPh_3 > SiMe_3 > {}^t$Bu while in the osmium derivatives, the trend is the opposite one. The angle formed by the C(1)–C(2) line and the plane formed by the three metal atoms in the acetylides shows different values depending on the metal and the substituent. Thus the two silicon substituted derivatives show larger values than the ^{t}Bu compound in the ruthenium cases while the ^{t}Bu complex shows the largest value for that angle in the osmium compounds.

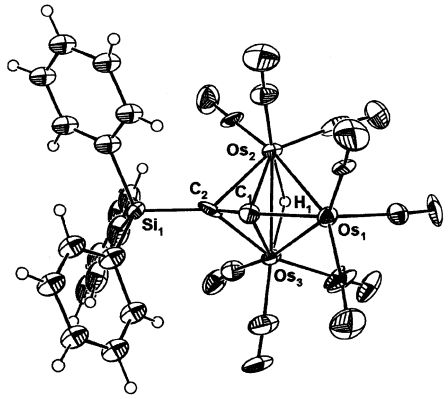

Fig. 6. Molecular structure for compound **5**, including numbering scheme. ORTEPS shown at 40% probability.

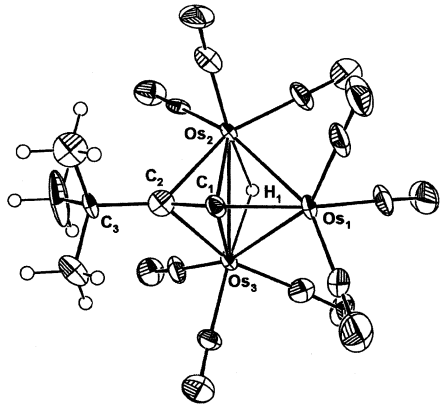

Fig. 7. Molecular structure for compound **6**, including numbering scheme. ORTEPS shown at 40% probability.

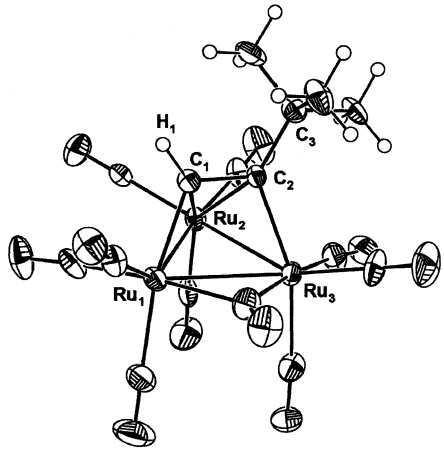

Fig. 8. Molecular structure for compound **9**, including numbering scheme. ORTEPS shown at 40% probability.

A comparison of bond lengths and angles of **5** and **6** with those of $[Os_3(CO)_{10}(EtCCEt)]$ [29] among other (//) complexes [30,36] shows that while the Os–C π interaction, have similar Os–C bond lengths in both (//) and acetylide, the Os–C σ-interaction is slightly shorter in the acetylide complexes. The same trend is observed in the ruthenium compounds **1**, **2** and **9**, in comparison with the structure of $[Ru_3(\mu\text{-}H)_2[\mu_3\text{-}C_2(CO_2Me)_2\}(\mu\text{-}dppm)(CO)_7]$, also a (//) complex [37] although compound **9** shows slightly longer Ru–C σ-bonds. However, it has to be pointed out that angles about the acetylenic carbon atoms show values similar to 120° in the parallel complexes, for example the C–C–R angle is 123.9(18)° in $[Os_3(CO)_{10}(C_2Et_2)]$ and 121.6(4)° for $[Ru_3(\mu\text{-}H)_2[\mu_3\text{-}C_2(CO_2Me)_2\}(\mu\text{-}dppm)(CO)_7]$.

The type of the substituents on Cβ does not affect too much the angle between the C–C bond and the M–M bond. Values go from 87.99(4)° to 89.81(2)°. However, it seems to affect the angle formed by the M_3 plane and the M_2-hydride plane, since values are around 111°–112° in $SiMe_3$ and ^{t}Bu derivatives and around 130° in the two $SiPh_3$ compounds. Hydride positions were calculated by the potential energy method [38].

3. Conclusions

The synthesis of parallel Os_3- and Ru_3-monosubstituted alkyne complexes was accomplished and these compounds were shown to transform into the acetylide complexes. The ^{1}H, ^{13}C and ^{29}Si NMR study of (//)- and acetylide complexes shows important differences in chemical shifts and coupling constants of the acetylenic carbons and the substituents when Ru_3- and Os_3-complexes are found in one coordination mode or the other. The presence of SiR_3 substituents strongly affects the ^{13}C chemical shifts as well as the $\delta(C_\alpha)-\delta(C_\beta)$ values. EHMO calculations also show differences between the two types of coordination modes. Both spectroscopic data and theoretical calculations show that the largest changes in chemical shift and atomic charges are observed in C_β, when changing from one coordination mode to the other. The atomic charges obtained in this work, are consistent with the reactivity of $[(\mu\text{-}H)M_3(CO)_9(CC^tBu)]$ (M = Ru, Os) towards protic acids. Some differences in bond lengths and angles can also be appreciated in the molecular structures of (//) and acetylide derivatives. Angles around C_β change significantly on going from the (//) complexes to the acetylides which could suggest a change in hybridization around this carbon atom. However, $^{13}C-^{29}Si$ coupling constants do not support this change.

4. Experimental

4.1. General procedures

All reactions and other manipulations were carried under a nitrogen atmosphere using standard Schlenk techniques. All solvents were dried and distilled under a

nitrogen atmosphere prior to use. Infrared spectra were recorded on a Perkin–Elmer 2000 spectrometer, and the solvent is indicated in Table 1. NMR spectra were obtained in a JEOL GSX-270, a JEOL Eclipse 400 or a Bruker Avance™ DPX 300 spectrometers, ^{1}H, ^{13}C and ^{29}Si spectra relative to $SiMe_4$, in $CDCl_3$ solution. $[Ru_3(CO)_{12}]$ and $[Os_3(CO)_{12}]$ and the corresponding alkynes, were purchased from Strem and Aldrich and were used without further purification. $[Ru_3(CO)_{10}(MeCN)_2]$ and $[Os_3(CO)_{10}(MeCN)_2]$ were prepared as reported [17,39]. Elemental analysis were carried out in the University of Oviedo, in Spain.

4.2. Synthesis of (//)-[$Ru_3(CO)_{10}(HCCR)$] (compounds 7, 8 and 9)

$[Ru_3(CO)_{10}(MeCN)_2]$ was synthesized as described in the literature (starting with $[Ru_3(CO)_{12}]$, 100 mg, 0.156 mmol) [17] and the product made to react, in situ, with 6 equiv. of the corresponding alkyne (0.939 mmol). These last reactions were carried out in dichloromethane solution, stirring at room temperature (r.t.) for 15 min. After that time, the solvent was evaporated to dryness under vacuum and the residue immediately dissolved in $CDCl_3$ for NMR studies. Conversion was quantitative in all cases. In the case of compound **7**, the solvent was removed to dryness under vacuum and the red solid was left to stand in the light at r.t.; after an hour, the solid had totally transformed into yellow $[(\mu\text{-H})Ru_3(CO)_9(CCSiMe_3)]$, compound **1**.

4.3. Synthesis of [$(\mu\text{-H})Ru_3(CO)_9(CCR)$] (R = $SiMe_3$, $SiPh_3$ and ^tBu) (compounds 1, 2 and 3)

$[Ru_3(CO)_{12}]$ (1 equiv.) (100 mg, 0.156 mmol) was made to react with 6 equiv. of the alkyne (0.939 mmol) in refluxing hexane for 2 h. The solvent was removed under vacuum and the residues purified by silica column or silica thin layer chromatography using hexane (R = $SiMe_3$ or ^tBu) or hexane–$CHCl_3$ (8:2) for compound **2**. Yields: compound **1**, 79%, compound **2**, 85% and compound **3**, 76%. Elemental analysis, Found (calculated): compound **1**, C, 25.72 (25.72); H, 1.60% (1.54); compound **2**, C, 41.50 (41.48); H, 1.91% (1.92); compound **3**, C, 28.55 (28.27); H, 1.46% (1.56).

4.4. Synthesis of (//)-[$Os_3(CO)_{10}(HCCR)$] (compounds **10**, **11** and **12**) and [(μ-H)$Os_3(CO)_9(CCR)$] (R = $SiMe_3$, $SiPh_3$ and ^tBu) (compounds **4**, **5** and **6**)

$[Os_3(CO)_{10}(NCMe)_2]$ (92.5 mg, 0.099 mmol) and the corresponding alkyne (0.595 mmol), were dissolved in dichloromethane in a 1:6 ratio and stirred at r.t. for 15 min. After that time the solvent was removed under vacuum and the residue separated by silica thin layer chromatography using hexane: $CHCl_3$ (9:1) as eluant. Yields of the (//)-$[Os_3(CO)_{10}(HCCR)]$ derivatives varied depending on the substituent (86% if R = $SiMe_3$, 65% if R = $SiPh_3$ and 80% if R = ^{t}Bu). (//) Compounds could be converted to the corresponding acetylide by heating octane solutions of the compounds for 2 h. Yields for these conversions were 49% if R = $SiMe_3$, 45% if R = $SiPh_3$ and 47% if R = ^{t}Bu). Elemental analysis for compound **4**, Found (calculated): C, 18.25 (18.24); H, 0.965 (1.09); for compound **5**, C, 31.20 (31.44); H, 1.31% (1.45); for compound **6**, C, 20.18 (19.91); H, 0.97% (1.11); for compound **11**, C, 31.47 (31.74); H, 1.34% (1.42); for compound **12**, C, 20.18 (20.61); H, 0.92% (1.08).

4.5. Theoretical calculations

Calculations were carried out using Extended Hückel, as implemented on HyperChem [39]. All calculations included d-orbitals for the silicon atoms.

4.6. Crystallographic studies

Crystals of **1**, **2**, **5** and **6** were grown from hexane–CH_2Cl_2 solutions while those of **9** were grown from a $CDCl_3$ solution. Details of the data collection and structure refinement procedures are summarized in Table 6. Data sets were collected in an Enraf–Nonius CAD4 diffractometer except for those of **9**, these were collected in a Nonius Kappa CCD diffractometer. The samples were mounted in capillary tubes. Both structures were solved by direct methods (SHELXS-93) [40]. All non-hydrogen atoms were found in Fourier maps and refined anisotropically. Hydrogen atoms from phenyl and methyl groups were fixed in idealized positions and their positions refined. Absorption corrections were carried out by empirical methods. All calculations were carried out in PC computers.

Synthesis and structural characterization of complexes derived from treatment of gallium trichloride with 3,5-diphenylpyrazole

Zhengkun Yu, Andrey V. Korolev, Mary Jane Heeg, Charles H. Winter *

Department of Chemistry, Wayne State University, Detroit, MI 48202, USA

Received 1 November 2001; accepted 25 February 2002

Abstract

The adduct $GaCl_3(Ph_2pzH)$ (Ph_2pzH, 3,5-diphenylpyrazole) was synthesized in 96% yield upon treatment of equimolar amounts of gallium trichloride with Ph_2pzH in toluene at room temperature. The tetrachlorogallate salt $[Ph_2pzH_2]^+GaCl_4^-$ was obtained in 93% yield by treatment of a 2:1 stoichiometry of gallium trichloride and Ph_2pzH at room temperature, followed by recrystallization from toluene/dichloromethane. The X-ray crystal structures of $GaCl_3(Ph_2pzH)$ and $[Ph_2pzH_2]^+GaCl_4^-$ were determined, and reveal weak hydrogen bond interactions between the nitrogen-bound hydrogen atoms and gallium-bound chlorine atoms. Examination of the formation of $[Ph_2pzH_2]^+GaCl_4^-$ from $GaCl_3(Ph_2pzH)$ and gallium trichloride (1.0 equiv.) revealed that the hydrogen chloride used to form $[Ph_2pzH_2]^+GaCl_4^-$ arises from gallium trichloride-catalyzed chloromethylation of toluene. Under conditions where $[Ph_2pzH_2]^+GaCl_4^-$ was isolated in 82% yield upon treatment of $GaCl_3(Ph_2pzH)$ and gallium trichloride (1.0 equiv.) in toluene/dichloromethane, a mixture of ditolylmethane isomers was isolated in 330% yield based upon gallium trichloride.

Keywords: Gallium pyrazole complexes; Tetrachlorogallate salt; Gallium trichloride; 3,5-diphenylpyrazole

1. Introduction

The coordination chemistry of complexes containing pyrazolato ligands has been extensively studied [1–3]. However, most of this work has focused on transition metal and organolanthanide complexes. Recently, there has been considerable interest in pyrazolato complexes of the Group 13 elements [4–39]. Most of the recent efforts have related to aluminum complexes [4–19]. Pyrazolato complexes of gallium are well known [20–39], although complexes containing bulky alkyl or aryl substituents in the 3- and 5-positions of the pyrazolato ligand have not been reported. Gallium trichloride is a relatively weak Lewis acid [40], but is known to form adducts with many nitrogen donor ligands [41–44]. The development of new source compounds for use in the chemical vapor deposition of metal nitride films is a long-term interest in our group [45], and complexes of gallium with nitrogen heterocyclic ligands may serve as precursors to GaN films [46]. Of relevance to the present work, GaCl-containing precursors have been recently demonstrated to be extremely selective growth species in epitaxial film growth of gallium-based semiconductor materials [47]. In view of our recent reports of aluminum pyrazolato complexes [17–19], we sought to explore the synthesis of new gallium pyrazolato complexes. Herein, we describe the synthesis and structural characterization of products that are obtained upon treatment of gallium trichloride with diphenylpyrazole. Depending on the reaction conditions, the complexes $GaCl_3(Ph_2pzH)$ and $[Ph_2pzH_2]^+GaCl_4^-$ are obtained. The nitrogen-bound hydrogen atoms in these complexes participate in hydrogen bonding to chlorine atoms. $[Ph_2pzH_2]^+GaCl_4^-$ is obtained upon capture of hydrogen chloride by $GaCl_3(Ph_2pzH)$, and it is demonstrated that the hydrogen chloride originates from gallium trichloride-catalyzed chloromethylation of toluene by dichloromethane. To our knowledge, this is the first example of a Friedel–Crafts reaction with dichloromethane that is promoted by any gallium complex. Dichloromethane is a poor electrophile in Friedel–

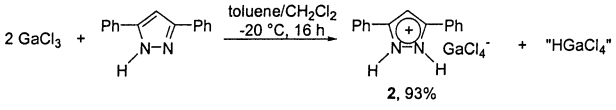
Crafts reactions, and gallium compounds are at best moderate strength Lewis acids that should not be capable of activating dichloromethane [40]. Accordingly, observation of the chloromethylation reaction described herein is surprising.

2. Results and discussion

2.1. Synthesis and characterization

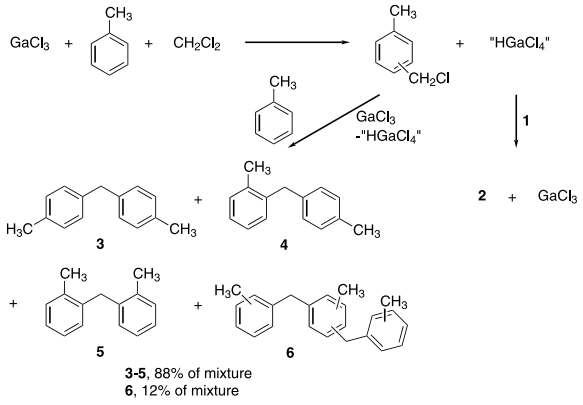
Treatment of gallium trichloride with 3,5-diphenylpyrazole (Ph_2pzH) in a 1:1 molar ratio in toluene at 23 °C led to the formation of the adduct $GaCl_3(Ph_2pzH)$ (**1**), which was isolated as colorless crystals in 96% yield after crystallization from toluene at −20 °C (Eq. (1)). A similar reaction was conducted in an NMR tube in chloroform-*d*. The ^1H NMR spectrum after 24 h indicated that **1** was the only product that formed. The structure of **1** was established by a combination of spectral and analytical data, and by an X-ray crystal structure determination as described below. The ^1H NMR spectrum of **1** in chloroform-*d* showed the nitrogen-bound hydrogen resonance at δ 11.19, consistent with the coordinated Ph_2pzH ligand. The infrared spectrum of **1** revealed a sharp, strong nitrogen–hydrogen absorption at 3350 cm^{-1} and weak nitrogen–hydrogen absorptions between 3274 and 3151 cm^{-1}.



1
96%

(1)

When **1** was prepared using a 1.00:1.00 molar ratio of gallium trichloride and diphenylpyrazole and was recrystallized from toluene, the ^1H and $^{13}C\{^1H\}$ NMR spectra revealed chemically distinct resonances for the two types of phenyl groups present in **1**. Such an observation indicates that cleavage of the gallium–nitrogen bond in **1**, followed by hydrogen atom transfer between the pyrazole nitrogen atoms and recoordination to gallium, is slow on the NMR timescale. In some preparations of **1**, only one type of phenyl group was observed in ^1H and $^{13}C\{^1H\}$ NMR spectra of the product. An NMR tube experiment with recrystallized **1** demonstrated that excess gallium trichloride (up to one full equivalent) had no effect on the ^1H and $^{13}C\{^1H\}$ NMR spectra of **1** in benzene-d_6 at ambient temperature, and two chemically distinct phenyl groups were observed. However, addition of as little as 5% excess diphenylpyrazole to recrystallized **1** led to the observation of a single type of phenyl resonance in the ^1H and $^{13}C\{^1H\}$ NMR spectra at ambient temperature, indicating rapid exchange of the phenyl sites on the NMR timescale. We suggest that the excess diphenylpyrazole promotes the exchange through a low energy associative transition state containing a 5-coordinate gallium center.



As noted above, **1** could be prepared as a single pure product through careful control of the gallium trichloride:diphenylpyrazole stoichiometry, followed by crystallization from toluene. However, treatment of gallium trichloride with Ph_2pzH in a 2:1 ratio in toluene for 0.5 h, followed by recrystallization from toluene/dichloromethane for 16 h at −20 °C, afforded 3,5-diphenylpyrazolium tetrachlorogallate (**2**, 93%) as a colorless crystalline solid (Eq. (2)). The structure of **2** was established by a combination of spectral and analytical data, and by an X-ray crystal structure determination as described below. The ^1H NMR spectrum of **2** in chloroform-*d* revealed the nitrogen-bound hydrogen resonance at δ 12.76. The infrared spectrum showed medium intensity nitrogen–hydrogen absorptions between 3255 and 3174 cm^{-1}, and the electron impact mass spectrum revealed the cation $[Ph_2pzH_2]^+$ with 100% intensity. The microanalysis was consistent with the formulation of **2**. The formation of **2** from **1** and 1.0 equiv. of gallium trichloride was monitored by ^1H NMR in toluene-d_8 and a toluene-d_8/dichloromethane mixture (1.0 ml/0.2 ml) at ambient temperature. After 20 h in toluene-d_8, the only product present was **1**. However, **1** converted to **2** completely over 16 h at ambient temperature when dissolved in 5:1 toluene-d_8/dichloromethane. During this time, the reaction mixture turned deep red and colorless crystals were observed to deposit on the walls of the NMR tube. These observations are consistent with the preparation of **2** outlined above. In addition, new resonances were observed in the ^1H NMR spectrum, suggesting the formation of new organic products.

2, 93%

(2)

An experiment was performed in which gallium trichloride (1.0 equiv.) was treated with **1** (1.0 equiv.) in 90:10 toluene/dichloromethane at 20 °C for 16 h. Workup as described in the experimental section afforded **2** in 82% yield. In addition, a brown–red oil was isolated that was identified as three ditolylmethane isomers **3**–**5** (88% of mixture) and eight or more isomers of (methylbenzyl)ditolylmethane **6** (12% of mixture) by GLC/MS and by analysis of the ^1H and $^{13}C\{^1H\}$ NMR spectra of the mixture (Scheme 1). The ^1H NMR spectrum indicated an 84:12:4 mixture of *p*,*p*′-ditolylmethane (**3**), *o*,*p*′-ditolylmethane (**4**), and *o*,*o*′-ditolylmethane (**5**). This identification was based upon comparison with methyl and methylene ^1H NMR chemical shifts that have been previously reported for

Scheme 1. Chloromethylation of toluene.

these compounds [48,49]. The GLC/MS of **3**–**5** all showed a parent ion of mass/charge 196, with a base peak of 181 corresponding to loss of a methyl group from the parent ion. In addition to the ditolylmethane isomers, eight or more methylene resonances were observed between δ 3.82 and 3.87 in the ^{1}H NMR spectrum of the red–brown oil. GLC/MS revealed at least eight minor components exhibiting parent ions of mass/charge 300, with base peaks of 195 corresponding to loss of a methylbenzyl group from isomeric (methylbenzyl)ditolylmethanes. The (methylbenzyl)ditolylmethane mixture was not characterized further, due to the small amount and large number of isomers.

Observation of the mixture containing **3**–**6** suggests that the pathway outlined in Scheme 1 is operant in the formation of **2** under the conditions of excess gallium trichloride. Gallium trichloride-promoted chloromethylation of toluene can proceed to afford *ortho*- and *para*-isomers of chloromethyltoluene as well as '$HGaCl_4$'. As noted in the introduction, this is the first example of a Friedel–Crafts alkylation reaction of dichloromethane that is promoted by any gallium compound. Gallium trichloride is considered to be a moderate strength Lewis acid at best [40], and gallium compounds have been frequently used as Friedel–Crafts reaction catalysts with reactive alkyl halides to avoid side products that are observed with more reactive aluminum-based Lewis acids [50–53]. The direct chloromethylation of aromatic compounds with dichloromethane using aluminum halide catalysts has been well documented [40,54–56]. In addition, an aluminum trichloride-promoted chloromethylation of an aluminum-bound phenoxy group by dichloromethane to give non-aromatic product was described [57]. Several reports have described the chloromethylation of toluene using Lewis acid catalysis and various reactive chloromethyl cation equivalents such as methoxyacetyl chloride, bis(chloromethyl) ether, or chloromethyl methyl ether [58]. Once formed, the intermediate chloromethyl-substituted aromatic compounds rapidly react to form diarylmethane derivatives. In the present work, the intermediate chloromethyltoluene isomers react rapidly with toluene to afford the mixtures of **3**–**5**. The yield of **3**–**5** based upon gallium trichloride is about 330%, thus indicating that the formation of **3**–**5** is catalyzed by a gallium species present in the reaction mixture. The first equivalent of hydrogen chloride generated during the chloromethylation reaction is trapped by **1** to form **2**. Thereafter, the fate of the hydrogen chloride is less clear. '$HGaCl_4$' has been previously described as a diethyl ether adduct [59]. However, the strongest bases remaining after complete formation of **2** are toluene and **3**–**6**. It is possible that the deep red coloration of the reaction solution corresponds to the formation of arenium cations, which are known to be deeply colored in solution [60–63].

The central discovery described herein is the Friedel–Crafts chloromethylation of toluene promoted by **1**, **2**, or some other gallium species present in solution. The fact that gallium compounds can promote rapid Friedel–Crafts alkylation reactions using a poor electrophile such as dichloromethane is surprising in view of the extensive literature in this area [40]. The high solubility of **1** in toluene may be the reason why the chloromethylation reaction proceeds at such a rapid rate. In the present work, the Friedel–Crafts alkylation reaction manifested itself initially through the unexpected formation of **2** when **1** was recrystallized from toluene/dichloromethane mixtures. We expect that similar Friedel–Crafts reactions will occur in systems that contain what are presumed to be weak Lewis acids and poorly electrophilic alkyl halides.

2.2. *Molecular structures of **1** and **2***

The solid-state structures of **1** and **2** were determined by X-ray crystallography. Perspective views are shown in Figs. 1 and 2, crystallographic data are provided in Table 1, and selected bond lengths and angles are listed in Tables 2 and 3.

Complex **1** crystallizes as a monomer with distorted tetrahedral geometry about the gallium center. The Ga–N(1) bond distance is 1.971(2) Å. The nitrogen–hydrogen bond length is 0.759(4) Å. The nitrogen-bound hydrogen participates in intramolecular hydrogen bond-

ing to Cl(3), with a hydrogen-chlorine distance of 2.625(4) Å. The N(2)–H(N2)–Cl(3) angle is 127.96(3)°. There are no significant intermolecular hydrogen bonds. The gallium–chlorine bond distances range from 2.1448(13)–2.1589(15) Å. All three gallium–chlorine bond lengths are identical within the precision of the structure determination, suggesting that the intramolecular hydrogen bond to Cl(3) is weak. The N(1)–Ga–Cl(3) angle (101.56(7)°) is smaller than the related values

for N(1)–Ga–Cl(1) (109.19(8)°) and N(1)–Ga–Cl(2) (111.79(9)°). This distortion may arise from the weak hydrogen bond associated with Cl(3).

Complex **2** crystallizes with a diphenylpyrazolium ion that contains several different hydrogen bonds to the tetrachlorogallate ion. The geometry about the gallium atom is distorted tetrahedral. The gallium–chlorine bond distances range from 2.1521(7) to 2.2032(6) Å, and are slightly longer than the range found in **1** due to the reduced Lewis acidity of the gallium center in the tetrachlorogallate ion. The chlorine–gallium–chlorine angles range between 103.90(3)° and 112.68(3)°. The nitrogen–hydrogen bond lengths are 0.937(5) and 0.827(5) Å. The nitrogen-bound hydrogen atoms are hydrogen-bonded to chlorine atoms of the tetrachlorogallate ion with bond lengths of 2.533(3) ((N1)H···Cl(1)), 2.663(5) ((N1)H···Cl(2′)), and 2.573(4) Å ((N2)H···Cl(2″)). The nitrogen–hydrogen–chlorine angles associated with the hydrogen bonds are 132.88(3)°, 127.68(3)°, and 165.65(3)°, respectively. The nitrogen–hydrogen bond lengths are similar to the value found in **1**. Interestingly, the two chlorine atoms involved in weak hydrogen bonding (Cl(1), Cl(2)) exhibit slightly longer gallium–chlorine bond lengths than the two chlorine atoms that are not involved in hydrogen bonding (Cl(3), Cl(4)). These bond length differences, while small, suggest slightly stronger hydrogen bonding in **2**, compared with **1**. Stronger hydrogen bonding in **2** can be rationalized on the basis of more electrophilic hydrogen atoms and more electron rich chlorine atoms due to the presence of ions in the solid.

The gallium–nitrogen bond length in **1** is very similar to values ranging from 1.97 to 2.00 Å that have been documented in gallium–pyrazolate complexes [20–39]. The X-ray crystal structures of several pyrazolium salts of the formula $[t\text{-}Bu_2pzH]^+X^-$ (X = Cl, Br) have been reported [64,65]. These compounds form distinct dimeric aggregates featuring ten-membered $X_2H_4N_4$ rings in the solid state that are held together by strong, linear N–H···X hydrogen bonding. Ten-membered rings are

present in **2**, but these rings are present as part of an extended hydrogen bonded network, as opposed to the dimeric units in the pyrazolium halide salts. In 3,5-di-*tert*-butylpyrazolium chloride [64,65], the nitrogen–chlorine distance containing the hydrogen bond was 3.057(2) Å, the H···Cl distance was 2.12(3) Å, and the nitrogen–hydrogen–chlorine angle was 175(3)°. By contrast, in **2** the related values were 3.244(2)–3.380(2) Å, 2.533(4)–2.663(4) Å, and 127.68(5)°–165.65(5)°. These values for **2** suggest much weaker hydrogen bonding than is present in 3,5-di-*tert*-butylpyrazolium chloride. The order of hydrogen bonding strength is consistent with the lone pairs of electrons on $GaCl_4^-$ being much less basic than those of chloride ion. Similar weak E–H···X hydrogen bonding (E = O, N; X = halogen) is well established in the solid state structures of other metal halide complexes containing EH fragments within the crystal [66].

3. Experimental

3.1. General considerations

All manipulations were performed under argon using either drybox or Schlenk-line techniques. Gallium trichloride was purchased from Strem Chemical Company. Ph_2pzH was prepared using a reported procedure [67]. ^1H and $^{13}C\{^1H\}$ NMR spectra were obtained at 500 or 300 and 125 or 75 MHz, respectively, in the indicated solvents. Infrared spectra were recorded using KBr discs. Mass spectra were obtained on a Kratos MS-50 spectrometer in the electron impact mode or on a Hewlett–Packard Model 5980 GLC/MS instrument. Elemental analyses were performed by Midwest Microlab, Indianapolis, IN. Melting points are uncorrected.

3.2. Synthesis of $GaCl_3(Ph_2pzH)$ (**1**)

A 100 ml Schlenk flask was charged with a stir bar, gallium trichloride (0.42 g, 2.4 mmol), and diphenylpyrazole (0.52 g, 2.4 mmol). Toluene (30 ml) was added by syringe to form a colorless solution. This mixture was stirred at ambient temperature for 24 h. The volatile components were removed under reduced pressure to afford spectroscopically pure **1** as a white powder (0.91 g, 96%). X-ray and analytical quality crystals were obtained by recrystallization from toluene at −20 °C: m.p. 157–158 °C; IR (KBr, cm^{-1}) 3350 (s), 3274 (w), 3151 (w), 1610 (m), 1569 (s), 1273 (m), 1182 (m), 1108 (m), 1085 (m), 990 (m), 821 (w), 761 (s), 705 (w), 703 (m), 684 (s), 563 (s); ^1H NMR ($CDCl_3$, 23 °C, δ) 11.19 (br. s, 1 H, N***H***), 7.77 (m, 2H, Ph C***H***), 7.65, (m, 2 H, Ph C***H***), 7.57 (m, 3 H, Ph C***H***), 7.51 (m, 3 H, Ph C***H***), 6.91 (d, $J = 3.0$ Hz, 1 H, pyrazole C***H***); $^{13}C\{^1H\}$ NMR ($CDCl_3$, 23 °C, ppm) 156.33 (s, ***C***Ph), 147.39 (s, ***C***Ph), 131.64 (s, *p*-***C***H of Ph), 130.92 (s, *p*-***C***H of Ph), 129.82 (s, *m*-***C***H of Ph), 129.00 (s, *m*-***C***H of Ph), 128.85 (s, *o*-***C***H of Ph), 127.86 (s, *ipso*-***C*** of Ph), 126.34 (s, *o*-***C***H of Ph), 125.39 (s, *ipso*-***C*** of Ph), 105.79 (s, ***C***H of pyrazolato); MS (EI, 70 eV) 220 ($[Ph_2pzH]^+$, 100%).

Anal. Calc. for $C_{15}H_{12}Cl_3GaN_2$: C, 45.46; H, 3.05; N, 7.07. Found: C, 45.68; H, 3.13; N, 6.99%.

3.3. Synthesis of $[Ph_2pzH_2]^+GaCl_4^-$ (**2**)

A 100 ml Schlenk flask, equipped with a stir bar and a rubber septum, was charged with **1** (0.26 g, 0.66 mmol), gallium trichloride (0.12 g, 0.66 mmol), and toluene (10 ml). To this stirred solution was added dichloromethane (0.5 ml). The solution color changed immediately to yellow and deepened to dark red after 0.5 h. The reaction solution was placed in a −20 °C freezer for 16 h. Yellow crystals formed during this time, and a dark red oil separated. The crystals were collected on a medium glass frit and were washed with 1:1 toluene/pentane (18 ml) followed by pentane (18 ml). Vacuum drying afforded white crystals. The washings were combined, producing more white crystals. These crystals were collected on a medium glass frit, washed with pentane (18 ml), and dried under vacuum. The crystals were combined to afford **2** as a colorless solid (0.26 g, 93%): m.p. 135–136 °C; IR (KBr, cm^{-1}) 3255 (m), 3219 (m), 3191 (m), 3174 (m), 1613 (m), 1590 (m), 1262 (w), 1227 (w), 1208 (w), 1188 (w), 1162 (w), 1095 (w), 1070 (w), 1053 (w), 1019 (w), 950 (w), 918 (w), 835 (w),765 (s), 704 (w), 691 (w), 681 (m); ^1H NMR ($CDCl_3$, 23 °C, δ) 12.76 (s, 2H, N***H***), 7.75 (m, 4H, Ph C***H***), 7.62 (m, 6H, Ph C***H***), 7.15 (t, $^4J_{HH} = 3.0$ Hz, 1H, pyrazolato C***H***); $^{13}C\{1H\}$ NMR ($CDCl_3$, 23 °C, ppm) 149.60 (s, pyrazolato ***C***Ph), 132.94 (s, *p*-***C***H of Ph), 130.21 (s, *m*-***C***H of Ph), 126.85 (s, *o*-***C***H of Ph), 123.95 (s, *ipso*-***C*** of Ph), 102.02 (s, ***C***H of pyrazolato); MS (EI, 70 eV) 221 ($[Ph_2pzH_2]^+$, 100%).

Anal. Calc. for $C_{15}H_{13}Cl_4GaN_2$: C, 41.62; H, 3.03; N, 6.47. Found: C, 41.49; H, 3.07; N, 6.55%.

3.4. Isolation of ditolylmethane isomers upon treatment of **1** with excess gallium trichloride

A Schlenk flask was charged with a stir bar, **1** (0.26 g, 0.66 mmol) and gallium trichloride (0.12 g, 0.66 mmol). Toluene (10 ml) was added to the flask to produce a colorless solution. Immediately thereafter, dichloromethane (1 ml) was added. The solution color changed to yellow and deepened to medium red within 0.5 h. The solution was stirred at ambient temperature for 6 h, and the volatiles were removed under reduced pressure to leave a dark red oil. Hexane (20 ml) was added to this oil to afford a pale yellow solution and colorless crystals in the dark red oil. This mixture was kept at ambient temperature for 16 h without stirring. The solution was

decanted from the oily residue, and the oily residue was washed again with hexane (6 ml). The hexane extracts were combined and the volatile components were removed under reduced pressure, leaving a red oil (0.41 g) that was identified as a mixture of **3**–**6** by GLC MS and by correlation of the ^{1}H NMR spectrum with previously reported values for ditolylmethane isomers. For further data, see below and in the text. The hexane-insoluble crystals were collected on a medium glass frit and then washed with 1:1 toluene/hexane (18 ml) and hexane (18 ml). Drying under vacuum for 1 h afforded spectroscopically pure **2** as a pale brown crystalline solid (0.23 g, 82%). The identity of **2** was confirmed by comparison of its ^{1}H and ^{13}C{^{1}H} NMR spectra with those of authentic material described above.

Data for the ditolylmethane mixture:

p,*p*′-ditolylmethane (**3**, 84%): partial ^{1}H NMR ($CDCl_3$, δ) 3.88 (s, C***H***$_2$), 2.29 (s, 2C***H***$_3$) [lit.[28] ^{1}H NMR ($CDCl_3$, δ) 3.89 (s, C***H***$_2$), 2.23 (s, 2C***H***$_3$)]; GLC/MS 196 (M^+, 57%), 181 (M^+–CH_3, 100%).

o,*p*′-ditolylmethane (**4**, 12%): partial ^{1}H NMR ($CDCl_3$, δ) 3.93 (s, C***H***$_2$), 2.28 (s, C***H***$_3$), 2.22 (s, C***H***$_3$) [lit.[27] ^{1}H NMR ($CDCl_3$, δ) 3.93 (s, C***H***$_2$), 2.30 (s, C***H***$_3$), 2.23 (s, C***H***$_3$)]; GLC/MS 196 (M^+, 63%), 181 (M^+–CH_3, 100%).

o,*o*′-ditolylmethane (**5**, 4%): partial ^{1}H NMR ($CDCl_3$, δ) 3.91 (s, C***H***$_2$), 2.28 (s, 2C***H***$_3$) [lit.[28] ^{1}H NMR ($CDCl_3$, δ) 3.91 (s, C***H***$_2$), 2.26 (s, 2C***H***$_3$)]; GLC/MS 196 (M^+, 61%), 181 (M^+–CH_3, 100%).

3.5. X-ray structure determinations of *1* and *2*

Single crystals of **1** and **2** were mounted in thin-walled capillaries under a nitrogen atmosphere. Crystallographic data were collected at room temperature (295 K) on a Siemens–Bruker automated P4/CCD diffractometer with monochromated Mo Kα radiation. Frames (1650) were collected at 10 s and integrated with the manufacturer's SMART and SAINT software. Absorption corrections were applied with Sheldrick SADABS program and the structure was solved and refined using programs of SHELXL-97 [68]. Hydrogen atoms were placed in observed and calculated positions.

4. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, quoting No. 173005 for **1** and No. 173006 for **2**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1233-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Received 16 November 2001; accepted 22 January 2002

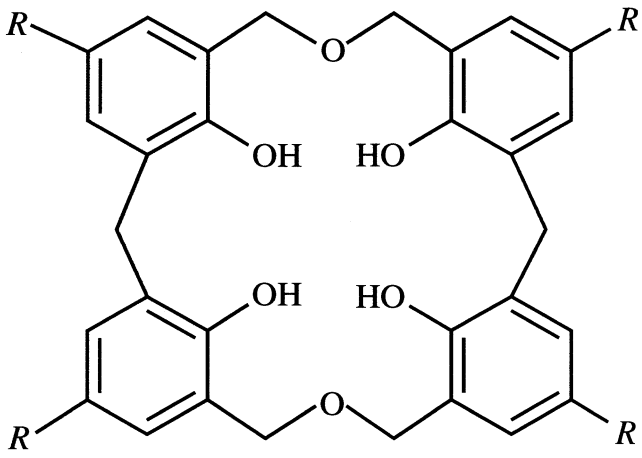
Abstract

Reaction of the expanded calixarenes *p*-*R*-tetrahomodioxacalix[4]arenes (*R* = methyl, phenyl) with uranyl ions in the presence of amines (butylamine, pyrrolidine, triethylamine) gives complexes in which the metal ion is in a distorted square-planar, tetra-phenoxide, equatorial environment. Changes in *para*-substituents and/or in the amine lead to different supramolecular assemblies, resulting in sheets or columns held by hydrogen bonds and cation–π interactions. The importance of primary or secondary amines, able to give divergent hydrogen bonds, to promote such structures, is evidenced. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Uranyl ion; Calixarenes; Homooxacalixarenes; Supramolecular assembly; Crystal structures

1. Introduction

In the course of our investigation of uranyl ion complexes of calixarenes and homooxacalixarenes obtained in a basic medium [1], we have reported previously the first crystal structures of free and complexed *p*-*R*-tetrahomodioxacalix[4]arene (*R* = methyl, *tert*-butyl) [2–4]. In all cases, the conformation of the macrocycle is a distorted *cone* one, held by intramolecular hydrogen bonds involving both phenolic and ether oxygen atoms in the free form, and by internal, tetra-phenoxide uranyl bonding in the complex. We have recently investigated, in the case of the related compound *p*-*R*-hexahomotrioxacalix[3]arene (*R* = methyl, *tert*-butyl), the effect of changes in the base used for deprotonation (and subsequently in the counterion present in the solid state) on uranyl ion complexation [5]. Due to the usual feature of inclusion of the counterion in the macrocycle cavity, these changes result in slight modifications in the homooxacalixarene conformation and in the uranyl ion equatorial coordination geometry, which can be distorted trigonal, tetragonal or pentagonal, depending on the number of coordinating ether oxygen atoms. This study evidenced also the interest of primary or secondary amines as deprotonating agents, due to their ability to be involved in divergent hydrogen bonds and give rise by this way to supramolecular assemblies. We report in the present paper the results of a similar investigation in the case of *p*-*R*-tetrahomodioxacalix[4]arenes with *R* = methyl (L^1H_4) or phenyl (L^2H_4), represented in Scheme 1, and the bases triethylamine (NEt_3), butylamine (NBu) and pyrrolidine (pyr).



2. Results and discussion

The asymmetric unit in $[Hpyr]_2[UO_2(L^1)]\cdot 3H_2O$ **1** comprises two crystallographically independent but nearly identical complex molecules, denoted A and B in the following. As can be seen in Fig. 1 in the case of molecule A, the uranyl ion is in a slightly distorted square-planar equatorial environment, being bound to the four phenoxide groups, with bond lengths in the

Scheme 1. The *p*-*R*-tetrahomodioxacalix[4]arenes under study.

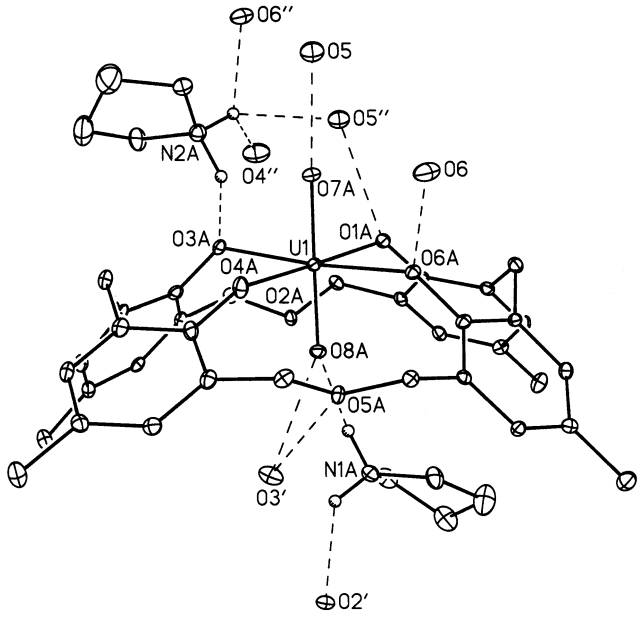

Fig. 1. View of molecule A in $[Hpyr]_2[UO_2(L^1)]\cdot 3H_2O$ **1**. Ellipsoids drawn at the 20% probability level. Hydrogen bonds represented as dashed lines. Ammonium protons drawn as small spheres of arbitrary radii. All other hydrogen atoms omitted for clarity. Symmetry codes: ′, $1-x, 1-y, 2-z$; ″, $1-x, 1-y, 1-z$.

range 2.225(4)–2.306(4) Å [mean value 2.27(3) Å, including both molecules] (Table 1). The uranium atom is consequently in a distorted, axially compressed, octahedral environment. The two ether oxygen atoms are clearly not coordinated, with U···O distances in the range 3.721(4)–3.796(4) Å. The range of $U-O_{phenoxide}$ bond lengths in **1** is comparable to that in the previously reported uranyl complex of *p*-*tert*-butyltetrahomodioxacalix[4]arene **4** (2.252(4)–2.333(4), mean value 2.28(3) Å) [2]. It is also close to the bond lengths in the distorted square–planar uranyl complexes of *p*-*tert*-butyldihomooxacalix[4]arene [2.247(6)–2.275(6), mean value 2.26(1) Å] [6a] and *p*-*tert*-butyltetrahomodioxacalix[6]arene [2.203(5)–2.301(6), mean value 2.26(4) Å] [6b], as well as to those in the more symmetrical uranyl complex of *p*-*tert*-butyltetrathiacalix[4]arene [2.230(2)–2.300(2), mean value 2.27(4) Å] [7a] and even the 'external' uranyl complex of *p*-*tert*-butylcalix[6]arene [2.22(1)–2.31(1), mean value 2.27(4) Å] [7b]. This range thus appears rather independent of the more-or-less regular square–planar geometry, and may be indicative in **1** and **4** of slightly too large donor atoms arrays, preventing the optimal bond length from being reached for all oxygen atoms (narrower ranges are observed for example in the trigonal uranyl complexes of hexahomotrioxacalix[3]arenes [5]). The four donor atoms in **1** define a plane O_4 with a r.m.s. deviation of 0.043 and 0.014 Å in molecules A and B, respectively, and the uranium atoms are located at 0.067(2) and 0.064(2) Å from these mean planes. The distances between the ether oxygen atoms and the O_4 planes are in the range 1.716(6)–2.005(6) Å, which are usual values for non-coordinated ether atoms [5]. The $O_{oxo}-U-O_{phenoxide}$ angles do not deviate much from 90°, but the $O_{phenoxide}-U-O_{phenoxide}$ angles involving adjacent atoms around the macrocycle are significantly different from this value, those between phenolic rings separated by methylenic bridges being smaller than those corresponding to ether bridges (mean values 85.3(4)° and 94.6(3)° in both cases, respectively). The macrocycles in **1** are in the *cone* conformation (a much more regular one than that of uncomplexed L^1H_4 [4]), with dihedral angles between the four aromatic rings and the O_4 plane of 46.4(2)°, 52.5(2)°, 30.3(2)° and 46.5(2)° in molecule A and 46.9(2)°, 49.9(1)°, 43.9(2)° and 30.9(2)° in molecule B. These values span a wider range than in compound **4** [40.0°–48.3°], one of the rings in particular being closer to the mean plane. The ether bridges in both molecules are characterized by *anti* $C-O-C-C_{arom}$ torsion angles [164.6(4)°–170.8(4)°], as in compound **4**. Each complex molecule is accompanied by two protonated pyrrolidine molecules. Both of these counterions possessing two nitrogen-bound protons and, moreover, three water molecules being present for each complex molecule, a most intricated hydrogen bonding pattern is formed (Table 2). In both molecules A and B, one of the pyrrolidinium ions is located near the macrocycle cavity and is hydrogen bonded to the oxo atom directed inwards. These ions are further bonded by their second protons to one or two (bifurcated bond) water molecules. The pyrrolidinium ions located out of the cavities are hydrogen bonded to one phenoxide oxygen atom and possibly, through their second protons, to three water molecules (trifurcated bonds). The water molecules make also hydrogen bonds with oxo, phenoxo and ether oxygen atoms. The resulting tridimensional ar-

rangement displays hydrogen bonded sheets bisecting the planes *ac* and *bc* (Fig. 2).

$[HNEt_3]_2[UO_2(L^2)]\cdot 2CHCl_3$ **2** involves the same tertiary amine as compound **4**, from which it differs by its *para*-substituent, phenyl in **2**, *tert*-butyl in **4**. The asymmetric unit comprises half a complex molecule, the other half being obtained through the binary axis containing the uranyl ion (Fig. 3). The uranyl ion is bound, as in **1** and **4**, to the four phenoxide groups, with U–O bond lengths of 2.276(3) and 2.309(3) [mean value 2.29(2)] Å, the ether oxygen atoms being at a distance of 3.715(3) Å. The mean O_4 plane presents a r.m.s. deviation of 0.081 Å, the uranium atom being at 0.149(2) Å from it. The main geometrical features around the metal ion are identical to those in compounds **1** and **4** and will not be further described. The macrocycle is in a cone conformation but two aromatic rings are much closer to the O_4 plane than the two other ones [dihedral angles 54.44(9)° and 30.62(8)°, respectively]. The dihedral angles between the phenolic rings and their phenyl substituents are 43.1(1)° and 22.5(2)°. The ether bridges correspond to *anti* C–O–C–C_{arom}

Symmetry codes: ′, $1-x, 1-y, 2-z$; ″, $1-x, 1-y, 1-z$; ‴, $x, 0.5-y, 0.5+z$.

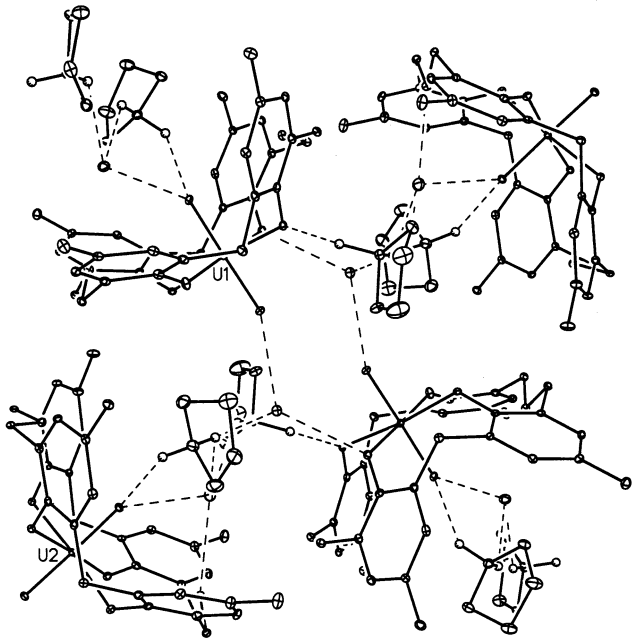

Fig. 2. Partial view of the crystal packing in $[Hpyr]_2[UO_2(L^1)]\cdot 3H_2O$ **1** showing the formation of hydrogen bonded sheets. Ellipsoids drawn at the 10% probability level. Hydrogen bonds represented as dashed lines. Ammonium protons drawn as small spheres of arbitrary radii. All other hydrogen atoms omitted for clarity.

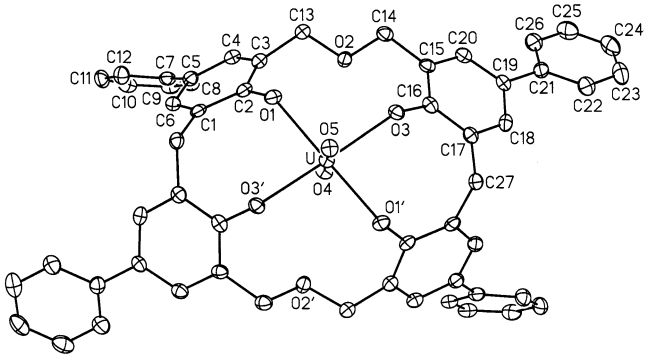

Fig. 3. View of the anionic complex molecule in $[HNEt_3]_2[UO_2(L^2)]\cdot 2CHCl_3$ **2**. Ellipsoids drawn at the 50% probability level. Hydrogen atoms, counterions and solvent molecules omitted for clarity. Symmetry code: ′, $-x, y, 0.5-z$.

torsion angles [−162.3(3)° and 173.4(3)°]. The most original feature is the counterions arrangement and the resulting crystal packing. The triethylammonium ions are not located as they were in compound **4**, i.e. one inside the cavity and hydrogen bonded to an oxo atom and the other outside and linked to a phenoxide group. In compound **2**, the two equivalent ammonium ions are located outside the cavity of the complex molecule to which they are hydrogen bonded through phenoxide oxygen atoms and they are further included in the cavity of the neighboring molecule along the *b*-axis. The location of the counterions, sandwiched between the phenolic rings closer to the mean plane in both neighboring molecules, probably explains the distortion with respect to the *cone* geometry indicated above. The combination of hydrogen bonds and cation–π interactions thus gives rise to a columnar arrangement, as represented in Fig. 4. Several short contacts exist between the carbon atoms of the triethylammonium cation and those of the aromatic rings (either phenolic or phenyl rings) with distances as short as 3.39 Å, comparable to those previously observed in other complexes and discussed in relation with cation–π interactions [5]. Some weaker contacts involve the cations and the phenyl rings of molecules belonging to the neighboring columns, with a shorter distance of 3.80 Å. Few contacts exist between phenolic and phenyl rings from different molecules, the shortest distance being 3.50 Å, and π–π interactions seemingly do not play an important part in this stacking. The disordered chloroform molecules are located in the spaces between the columns.

The complex obtained from the same ligand L^2H_4 and butylamine as a base, $[HNBu]_2[UO_2(L^2)]\cdot(HNBu)\cdot(CH_3COO)\cdot 2H_2O$ **3**, is an example of the ability of primary amines, combined with water molecules, to give rise to extended hydrogen bonded networks, similarly to what is observed with secondary amines in compound **1**.

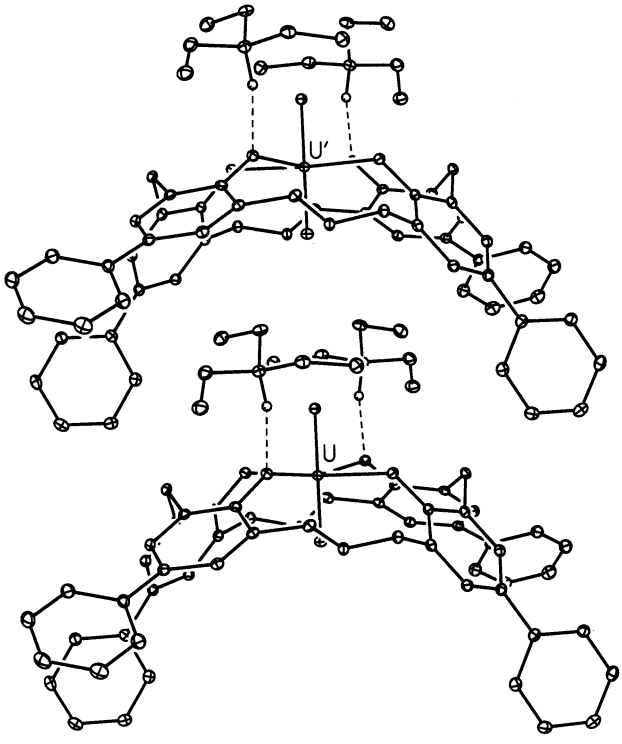

Fig. 4. View of the crystal packing showing the formation of columns along the *b*-axis in $[HNEt_3]_2[UO_2(L^2)]\cdot 2CHCl_3$ **2**. Ellipsoids drawn at the 20% probability level. Hydrogen bonds represented as dashed lines. Ammonium protons drawn as small spheres of arbitrary radii. All other hydrogen atoms and solvent molecules omitted for clarity.

Uranyl complexation in compound **3**, which does not present any crystallographic symmetry, displays the same geometrical features as that in compounds **1**, **2** and **4**, with tetra-phenoxide coordination {range of U–O bond lengths 2.246(6)–2.299(6) [mean value 2.28(2)] Å; ether oxygen atoms at 3.718(5) and 3.678(6) Å from uranium} and a departure of the uranium atom from the O_4 mean plane (r.m.s. deviation 0.023 Å) of 0.118(3) Å. The dihedral angles between the phenolic rings and the O_4 mean plane are 43.0(3)°, 38.9(2)°, 44.7(2)° and 46.8(2)°, evidencing a more regular cone conformation than in compound **2**, and the dihedral angles between phenolic and phenyl rings are 28.4(6)°, 27.1(4)°, 10.8(4)° and 28.4(4)°/29.7(5)° (the last phenyl ring being disordered over two positions). The complex molecule is associated to its two butylammonium counterions and, moreover, an additional butylammonium ion is present, its charge being compensated by that of an acetate ion. Two water molecules complete this assemblage of small molecules and ions. As in compound **1**, all these species and the complex itself are linked by an extended hydrogen bond network, as can be seen in Fig. 5 and Table 2. It can be noted that one of the butylammonium ions [comprising N(3)] is bound to the macrocycle, not directly, but *via* two water molecules [O(11) and O(12)]. As illustrated in Fig. 6, hydrogen bonded undulated sheets parallel to the *bc* plane are formed in **3**, in a way analogous to that in compound **1**, but different from the columnar stacking observed with the same macrocycle in compound **2**. Four species are deeply imbedded in the macrocyclic cavity: two butylammonium ions and the two water molecules. The two butylammonium ions are those corresponding to nitrogen atoms N(1) and N(3), with shortest $C_{ammonium}\cdots C_{phenyl}$ contacts of 3.65 and 3.34 Å, respectively (some shortest contacts between one of the disordered positions of the second cation and one disordered position of a phenyl ring are not physically acceptable and indicate that these two disordered components cannot be occupied simultaneously). These two butylammonium ions occupy the cavity spaces located at the vertical of the methylenic bridges. The spaces at the vertical of the ether bridges are occupied by the two water molecules, each of them being hydrogen bonded to the corresponding ether oxygen atom.

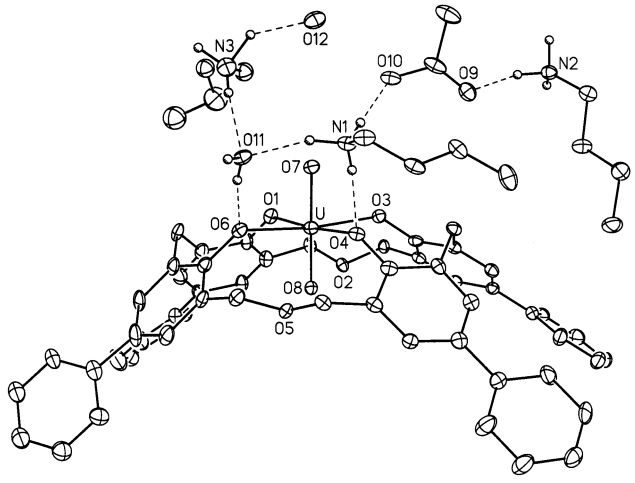

Fig. 5. View of the complex molecule in $[HNBu]_2[UO_2(L^2)]\cdot(HNBu)\cdot(CH_3COO)\cdot 2H_2O$ **3**. Ellipsoids drawn at the 20% probability level. Hydrogen bonds represented as dashed lines. Ammonium and water protons drawn as small spheres of arbitrary radii. All other hydrogen atoms omitted for clarity.

The previous study of *para*-substituent and basic agent replacement in the uranyl complexes of *p*-*R*-hexahomotrioxacalix[3]arene (*R* = methyl, *tert*-butyl) evidenced an effect of these changes on the coordination geometry around the cation, since distorted trigonal, tetragonal and pentagonal equatorial coordinations could be obtained [5]. The propensity of primary and secondary amines (butylamine and dibutylamine) to give rise to hydrogen bonded polymers was also apparent. In the present work, no effect on uranyl coordination is observed, which may be ascribed to the much more stable character of the square planar coordination with respect to the trigonal one. However, the potential of primary and secondary amines for the building of supramolecular assemblies through hydrogen bonding (possibly involving other solvent molecules or ions) and cation–π interactions has been extended and examples have been given of planar or columnar arrangements.

3. Experimental

3.1. Synthesis

The synthesis of L^1H_4 will be described elsewhere [8]. L^2H_4 was prepared as previously reported [9] and purified through column chromatography (silica gel, chloroform–hexane 3:5).

3.1.1. $[Hpyr]_2[UO_2(L^1)]\cdot 3H_2O$ (**1**)

A solution of L^1H_4 (20 mg, 0.037 mmol) and uranyl acetate dihydrate (20 mg, 0.047 mmol) in MeCN (7 ml) was heated to reflux under stirring. Pyrrolidine (150 mg, 1.9 mmol) was then added dropwise. Red–brown crystals suitable for X-ray crystallography separated in a few days.

3.1.2. $[HNEt_3]_2[UO_2(L^2)]\cdot 2CHCl_3$ (**2**)

A solution of L^2H_4 (49 mg, 0.062 mmol) and uranyl acetate dihydrate (30 mg, 0.071 mmol) in MeOH (4 ml) was heated to reflux under stirring. Triethylamine (250 mg, 2.5 mmol) was then added dropwise. The dark-brown solid that separated on slow solvent evaporation at room temperature (r.t.) was recrystallized from $CHCl_3$–MeOH to yield orange crystals suitable for X-ray crystallography.

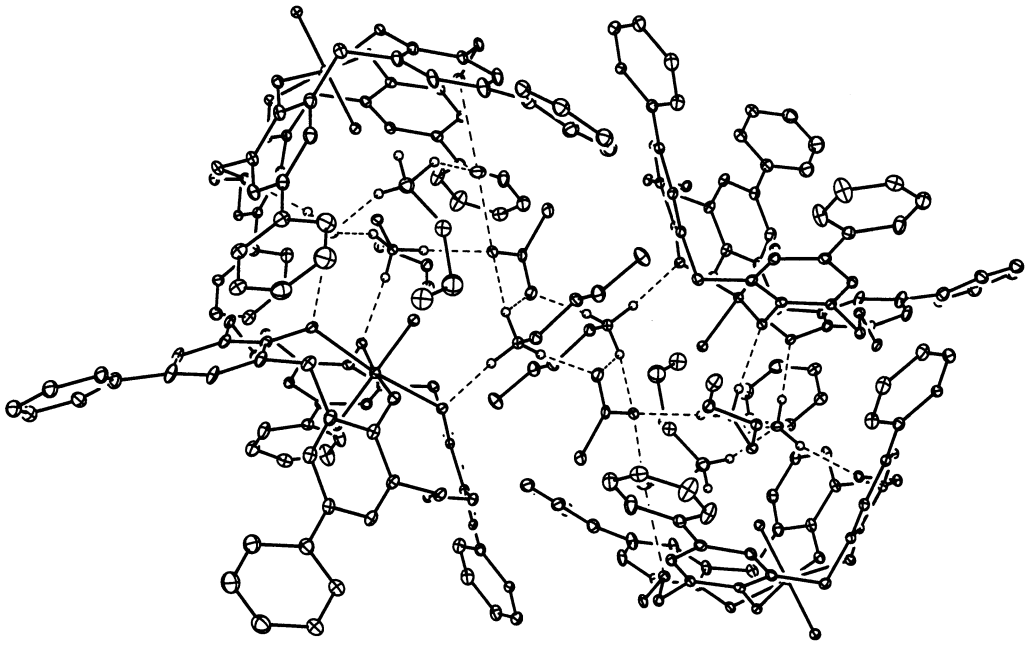

Fig. 6. Partial view of the crystal packing in $[HNBu]_2[UO_2(L^2)]\cdot(HNBu)\cdot(CH_3COO)\cdot 2H_2O$ **3** showing the formation of hydrogen bonded sheets. Ellipsoids drawn at the 10% probability level. Hydrogen bonds represented as dashed lines. Ammonium and water protons drawn as small spheres of arbitrary radii. All other hydrogen atoms omitted for clarity.

3.1.3. $[HNBu]_2[UO_2(L^2)]\cdot(HNBu)\cdot(CH_3COO)\cdot 2H_2O$ (**3**)

A solution of L^2H_4 (15 mg, 0.019 mmol) and butylamine (150 mg, 2.1 mmol) in MeCN (7 ml) was heated to reflux under stirring and uranyl acetate dihydrate (10 mg, 0.024 mmol) was then added gradually. Orange crystals suitable for X-ray crystallography separated in a few days.

3.2. Crystallography

The data were collected at 100(2) K on a Nonius kappa-CCD area detector diffractometer [10] using graphite-monochromated Mo Kα radiation (0.71073 Å). The crystals were introduced in glass capillaries with a protecting 'Paratone' oil (Exxon Chemical Ltd.) coating. The unit cell parameters were determined from the reflections collected on ten frames and were then refined on all data (90 frames, φ-scans, 2° steps). The data were processed with DENZO-SMN [11]. The structures were solved by Patterson map interpretation (compounds **1** and **3**) or by direct methods (compound **2**) with SHELXS-97 [12] and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97 [13]. Absorption effects were corrected empirically with the program DELABS from PLATON [14]. Special features for each structure:

1 The hydrogen atoms bound to nitrogen have been found on the Fourier-difference map, except those bound to N(1B), which have been introduced at calculated positions. The protons of the water molecules have not been found, nor introduced.

2 The chlorine atoms of the chloroform molecule are disordered over two sites which have been refined with some restraints on bond lengths and with occupancy factors constrained to sum to unity. The hydrogen atoms bound to nitrogen and that of the chloroform molecule have been found on the Fourier-difference map.

3 One phenyl substituent and one butylammonium ion were found disordered over two positions, which were refined with occupancy factors constrained to sum to unity. Some restraints on bond lengths have been used and the disordered phenyl rings have been refined as idealized hexagons. The hydrogen atoms bound to nitrogen and oxygen atoms have been found on the Fourier-difference map, except those bound to O(12). The three hydrogen atoms of the disordered butylammonium ion have been kept as found, which clearly does not describe perfectly their disordered nature.

All non-hydrogen atoms were refined with anisotropic displacement parameters, except those of the disordered parts of one butylammonium ion in **3**. All other hydrogen atoms were introduced at calculated positions, except in the disordered parts. The hydrogen atoms were treated as riding atoms with an isotropic displacement parameter equal to 1.2 (OH, NH, CH, CH_2) or 1.5 (CH_3) times that of the parent atom. Crystal data and structure refinement details are given in Table 3. The

Received 8 January 2002; accepted 13 March 2002

Abstract

A 1:1 complex between copper(II) chloride and *cis*-1,3-cyclohexanediol has been synthesized and its crystal structure determined. The structure is composed of two different dinuclear $[CuCl_2(c\text{-}13chd)]_2$ units in which the copper(II) ions are surrounded by the two oxygen atoms of the diol and the two halide ions in a distorted *cis*-square planar arrangement in both cases. A fifth coordination site is occupied by a halide ion in one dinuclear unit for both copper ions and an O atom belonging to the adjacent $CuCl_2(c\text{-}13chd)$ moiety in the other dinuclear unit for both copper ions, thus forming a distorted square pyramidal geometry for the metals in all cases. The ability of $CuCl_2$ to preferentially form a complex with *cis*-1,3-cyclohexanediol renders it amenable to the separation of the *cis*- and *trans*-isomers of 1,3-cyclohexanediol as the *trans*-isomer is not able to form such a complex with $CuCl_2$ and neither are any mixed complexes formed. The crystal structure of *cis*-1,3-cyclohexanediol is also reported for comparative purposes. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

Neutral diols and polyols form relatively unstable complexes with metal ions [1]. The packing of these complexes in the solid state is mainly controlled by second-sphere coordination [2] with hydrogen bonding playing a dominant role [3]. Due to the moderately low coordination ability of these ligands the syntheses of their metal complexes can usually be accomplished only in weakly coordinating solvents. Aprotic solvents such as tetrahydrofuran, 1,2-dimethoxyethane, or acetonitrile generally suffice for this purpose.

The copper(II) halides that form complexes with 1,2-diols do so with varying degrees of stoichiometry. For example, 1 equiv. of copper(II) chloride can complex with 0.5, 1, 1.5, or 2 equiv. of the diols 1,2-ethanediol, *cis*- or *trans*-1,2-cyclohexanediol, *trans*-1,2-cycloheptanediol, or 2,3-dimethyl-2,3-butanediol. The basic structure of these complexes consists of a $CuCl_2$–(diol) complex unit in which the diol is coordinated to copper as a bidentate ligand, and the complex units are linked as dimers or polymers through halogen bridges. If the stoichiometry is 1.5 or 2, only one diol molecule is directly coordinated to the copper(II) ion, and the $CuCl_2$–(diol) units are linked to the uncoordinated diol molecules through hydrogen bonds [4–7]. If the metal has a weakly coordinating counter anion, e.g. sulfate, then the metal ion can retain its coordination number by bonding to more than two diols as in $[Cu(eg)_3]SO_4$, where eg = 1,2-ethanediol [8a]. However, if strongly coordinating solvents such as water are present, mixed complexes such as $[Cu(eg)_2(H_2O)_2SO_4]$ are formed [8b]. The structure of the latter contains eg ligands which act as a bridge between two copper(II) ions. These observations illustrate that the structure of the 1,2-diol complexes depends on the diol used (the size

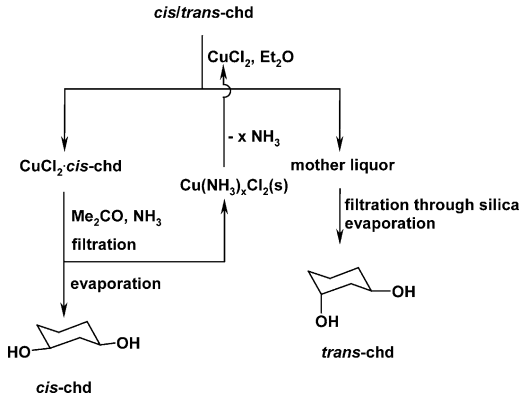
PII: S0277-5387(02)00934-8

and the shape), the metal-to-diol stoichiometry, the solvent, and the counter anion of the metal ion itself.

For 1,3-diols several transition metal complexes have been prepared, although the 1,3-diols are generally weaker ligands than their comparable 1,2-diols [9]. 1,3,5-Substituted triols, such as *per*-*cis*-1,3,5-cyclohexanetriol [10] and 2-ethyl-2-hydroxymethyl-1,3-propanediol [11], form 1:1 complexes with $CuCl_2$. The former is coordinated to copper(II) in a tridentate manner, whilst the latter is a bidentate ligand to the copper(II) ion. Surprisingly, there appear to be no prior structural reports on the metal complexes of non-mixed 1,3-diols. To address this deficiency we have now extended our work on diol coordination chemistry to the copper(II) complexes of 1,3-cyclohexanediols, and it was found that only *cis*-1,3-cyclohexanediol (*c*-13chd), and not the isomeric *trans*-1,3-cyclohexanediol (*t*-13chd), forms a complex with $CuCl_2$. Furthermore, *c*-13chd does so only in a 1:1 stoichiometry.

Metal complexation as a methodology for the separation of isomeric organic compounds has been successfully accomplished previously. For example, various alcohols and phenols have been resolved using anhydrous $CaCl_2$, $CaBr_2$, and $MnCl_2$ as the complexing substrate [12,13]. In particular, mixtures of the *E* and *Z* isomers of α-hydroxyimino phosphonates have been separated by selective complexation to the Cu(II) ion [14]. Furthermore, the commercially available ligand *N*,*N*′-ethylenebis[2-(*o*-hydroxyphenyl)glycine] has been separated into racemic and *meso* isomers via Fe(III) complexes [15]. The complexation of carbohydrates with calcium(II) ion has also been employed for the separation of sugars and polyols on ion-exchange resins [16]. Given the above divergence in complexation between the *cis*- and *trans*-isomers of 1,3-cyclohexanediol towards $CuCl_2$, this approach was explored as a methodology for the separation of the two isomers. In practice it was found to be a simple and practical method for their separation. The crystal structures of both *cis*-1,3-cyclohexanediol and [$CuCl_2$(*c*-13chd)] complex are also described in this work.



2. Results and discussion

2.1. Syntheses and separation

Copper(II) chloride is only slightly soluble in acetonitrile, resulting in a pale yellow solution. Upon the addition of a mixture of *cis*- and *trans*-1,3-cyclohexanediols to the $CuCl_2$ acetonitrile solution, the color of the solution turned green or greenish–yellow depending on the concentration of the diol. The colors of the various solutions are qualitatively indicative of a low coordination power of the diol for copper. The color, though, is temperature-dependent, and the solution changes to a more intense green upon lowering of the temperature. On standing at room temperature green crystals were found to be formed, which were separated by decanting, and the formula was determined to be [$CuCl_2$(*c*-13chd)]. Variation of the $CuCl_2$ to diol ratio and using only *c*-13chd as a ligand did not result in complexes other than the 1:1 complex. If more than 1.8 equiv. of diol was present in acetonitrile solution, uncoordinated diol was also found to crystallize out together with the complex.

The conventional methodology to separate the isomeric *cis*- and *trans*-1,3-cyclohexanediols is by the sole formation of the cyclic acetal for *c*-13chd which is then separated by distillation from the *trans* isomer. The diol *c*-13chd is regenerated by hydrolysis [18], whilst *t*-13chd is recovered, albeit in a compromised state, from the distillation residues. Although quite satisfactory, the methodology requires extensive repurification of the *t*-13chd isomer, which may not be that well separated from the *c*-13chd isomer, and is somewhat cumbersome for the production of the *c*-13chd isomer. Thus the observations just described suggested a possible avenue for creating a practical and possibly general method for the separation of 1,3-diol isomers via the preferential reaction of $CuCl_2$ with *c*-13chd. Indeed, the separation was accomplished successfully in diethyl ether solution; THF and hexane were also tried as solvents but with only limited success. The underlying reason for the success of diethyl ether is that whilst diols are reasonably soluble in ether, Cu(II)–diol complexes on the other hand are only very slightly soluble. This dramatic difference in solubility means that after the formation of the Cu(II)–diol complex, physical separation is afforded simply by filtration. Regeneration of the *c*-13chd isomer was also found to be similarly accomplished by the hydrolysis of the acetals using mild conditions. The complex was dissolved in acetone, and ammonia gas was bubbled through the solution for a few minutes until $Cu(NH_3)_xCl_2$ precipitated out. (Presumably five ammonias are complexed to the copper, i.e. $x = 5$.) The ammine Cu complex was filtered off and the filtrate solution evaporated to produce pure *cis*-1,3-cyclohexanediol. $CuCl_2$ can be regenerated from the $Cu(NH_3)_xCl_2$ complex simply by heating to release the ligand-bound ammonias for subsequent reuse.

Although the ether filtrate after removal of the Cu(II)–diol complex clearly still contained copper(II) ions as indicated by the light green color of the solution, these impurities were readily and easily removed by filtration through silica gel. From this filtrate, essentially pure *t*-13chd was obtained by removal of the solvent. Unfortunately, X-ray quality crystals were not forthcoming from an ethyl acetate solution. Sublimation provided extremely pure and microcrystalline *t*-13chd, but the material readily softened and became oily upon standing, even within a closed vessel (Scheme 1).

Scheme 1.

2.2. The structure of the complex *1*

The solid-state structure of $CuCl_2$(*c*-13chd) is composed of two distinct dinuclear units. The two different dimeric $[CuCl_2(c\text{-13chd})]_2$ units and their atomic numbering are depicted in Fig. 1 which shows that the diol in order to be able to accommodate coordination to the metal must adopt a cyclohexane ring conformation whereby both OH groups are axially orientated, in this case a chair conformation. Clearly, the adoption of a suitable cyclohexane ring conformation in the *trans* isomer for complexation is unfavorable; hence the distinction in the formation of isolatable complexes. In both dinuclear units (**a** and **b**) the copper(II) ions are surrounded by two oxygen atoms of the diol and two halide ions in a distorted *cis*-square planar arrangement. The fifth coordination site in **a** is occupied by a halide ion. In **b** an O atom that belongs to the adjacent $CuCl_2$(diol) unit fulfils the fifth coordination site. Both structures represent a distorted square pyramidal geometry for a metal ion. Selected bond parameters are presented in Table 2. The halide-bridged $[CuCl_2(c\text{-13chd})]_2$ unit is similar to other dinuclear $[CuCl_2(diol)]_2$ complexes that have been described. The neutral OH-bridged structure seen in the other $[CuCl_2(c\text{-13chd})]_2$ dinuclear unit has not been described previously in diol–metal complexes.

Symmetry codes: i = 1−x, 1−y, −z and ii = −x, 1−y, −z.

Structurally, as a result of the different coordinations, there are some distinct differences between the two dinuclear units, as can be seen from Fig. 1. For example, the distances of H-atoms at the top carbons of the chd-ring from the copper atoms are 3.060 Å in **a** and 2.377 Å in **b**, and the O1···O2 and O3···O4 distances are 2.722(6) and 2.674(6) Å, respectively. By comparison, for the Cu(II) complexes of *cis*- and *trans*-1,2-cyclohexanediol the O···O distances in the metal bonded diols are 2.569(4) and 2.571(4) Å, respectively [5]. The longer O···O distances in 1,3-chd complexes are an indication of a different geometric constraint of 1,3-chd compared to that of 1,2-chd in their $CuCl_2$ complexes. Furthermore, the O–Cu–O bond angles, which are 88.0(2)° and 84.25(18)° in **1** and 79.6(1)° in both $CuCl_2$ complexes with the aforementioned 1,2-cyclohexanediols, support the differing geometric constraints of the 1,3- and 1,2-diols under complexation.

The $[CuCl_2(c\text{-13chd})]_2$ units are packed into chains by four OH···Cl hydrogen bonds. The hydrogen bond strength is only moderate, as suggested by a very broad band at 3250 cm^{-1} in the infrared (IR)-spectrum of the compound. The chains are held together by van der Waals' interactions.

2.3. The structure of *cis*-1,3-cyclohexanediol **2**

In the lattice the *c*-13chd molecules (Fig. 2) adopt a chair conformation whereby both OH groups, as expected, are in equatorial positions. The bond parameters are normal and otherwise unexceptional. Both OH hydrogens form intermolecular H-bonds with neighboring molecules (see Fig. 2), and this H-bonding directs the molecules in the layers, which are held together by weak van der Waals interactions.

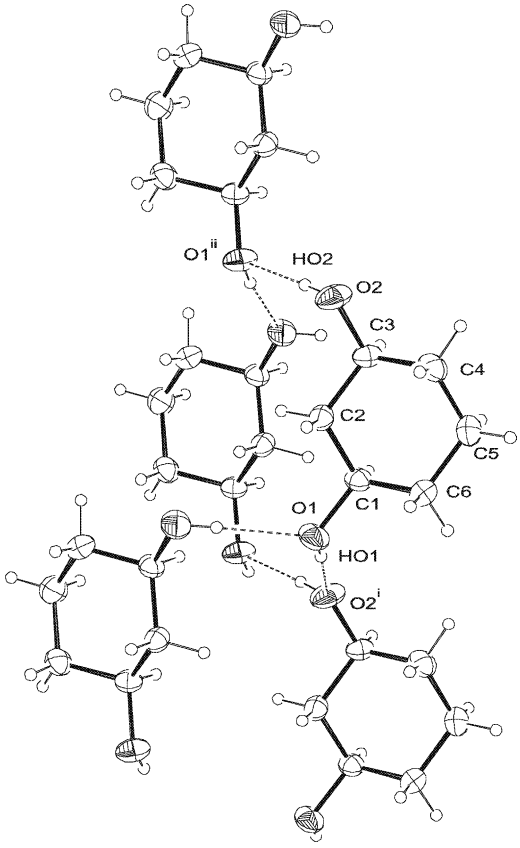

Fig. 2. ORTEP drawing of several *c*-13chd molecules showing the hydrogen bonding system and a part of packing system. The heavy atoms of the asymmetric unit are labeled. Probability ellipsoids are drawn at 30% level. Symmetry codes: i = x, y, z−1 and ii = x−1/2, −y+1/2, z+1/2.

3. Conclusion

$CuCl_2$–(polyol) complexes can be useful intermediaries for the separation of geometric isomeric polyols based on their differing abilities to coordinate the copper(II) cation. The separation potential of such systems is compromised though, when the polyols can form hydrogen bonds to the coordinated OH groups, thus resulting in mixed complexes. In straightforward and limited systems such as the *cis*- and *trans*-1,3-cyclohexanediol isomers, a simple and convenient methodology to separate the two isomers via the copper(II)chloride complex in ether is attainable, as has been amply demonstrated. The method is environmentally acceptable as the solvents, $CuCl_2$, and even the ammonia gas can be recirculated.

4. Experimental

Commercial 1,3-cyclohexanediol is a mixture of *cis* and *trans* isomers of varying proportions. The first 1,3-cyclohexanediol sample from Aldrich (98%) was a 1:1 mixture of isomers according to ^{1}H NMR [17,18] and was used as received for the syntheses. The second sample of 1,3-cyclohexanediol, also from Aldrich (98%), was a mixture of *cis* and *trans* isomers in a 2:1 ratio and was sublimed prior to the separation studies. Solvents were of HPLC grade and used as purchased. $CuCl_2 \cdot 2H_2O$ was held overnight at 120 °C to obtain anhydrous $CuCl_2$.

4.1. Preparation of $CuCl_2 \cdot$ *c*-13chd (method 1)

$CuCl_2$ (793 mg, 5.90 mmol) and commercial 1,3-cyclohexanediol (1.392 g, 11.98 mmol, 1:1 mixture of isomers) were suspended in 20 ml of acetonitrile. The yellow suspension was stored at 4 °C for a week to yield bright green crystals (696 mg, 47% based on copper). The crystals were separated by decanting and washed with ether. IR (Nujol): 3250 (s, v br), 1332 (s), 1281 (vs), 1260 (vs), 1213 (m), 1203 (m), 1101 (vs), 1072 (s), 1007 (m), 943 (vs), 914 (vs), 901 (vs), 873 (m), 839 (s), 777 (m), 720 (s), 708 (s), 617 (w), 536 (w), 444 (m), 421 (m) cm^{-1}. For $C_6H_{12}O_2CuCl_2$: Calc.: Cu, 25.4; Cl, 28.3; Found: Cu, 25.0; Cl, 28.0%.

4.2. Preparation of $CuCl_2 \cdot$ *c*-13chd (method 2)

$CuCl_2$ (50.7 mg, 0.38 mmol) and *cis*-1,3-cyclohexanediol (see preparation below; 61.5 mg, 0.53 mmol) were suspended in 1.0 ml of acetonitrile. The solution, originally yellow, slowly turned green and after overnight at room temperature, the solution yielded bright green, plate-like crystals. After a second night at 7 °C, the crystals were separated by decanting and washed with ether (65 mg, yield 68% based on copper). The IR-spectrum of the sample was identical to the earlier preparation and X-ray diffraction analysis confirmed the structure.

4.3. Separation of *c*-13chd and *t*-13chd

1.80 g of commercial 1,3-cyclohexanediol (15.5 mmol, 1:1 mixture of isomers) and 1.22 g $CuCl_2$ (9.0 mmol) were suspended in 40 ml of diethyl ether, and the suspension was stirred for 2 h to yield a greenish–blue solid and a slightly green solution. The solid, containing $CuCl_2 \cdot$ *c*-13chd and unreacted copper(II) chloride, was filtered off and washed with a small amount of ether (discarded). The solid was then dissolved in 40 ml of acetone and treated with gaseous ammonia precipitating a copper salt, which was removed by filtration and washed with a small amount of acetone. The combined acetone solutions were then evaporated to dryness to obtain 600 mg of *cis*-chd (m.p. 85 °C, lit. 85.5–86 °C [19]). The ether filtrate from above was filtered through a short pad of silica gel and evaporated to yield 1.0 g of *t*-13chd (m.p. 115–117 °C, lit. 117–118 °C [19]). The ^{1}H NMR spectra of both compounds were consistent with previous reports [17,18]. Single crystals of *c*-13chd were grown from ethyl acetate by slow evaporation of the solvent.

4.4. Crystal structure determination

Single-crystal data collections were performed at ambient temperature on a Rigaku AFC5S diffractometer using graphite monochromatized Mo Kα radiation ($\lambda = 0.71069$ Å). The unit cell parameters were determined by least-squares refinement of 25 carefully centered reflections. Data reduction and subsequent calculations were performed with TEXSAN FOR WINDOWS [20]. The data were corrected for Lorenz and polarization effects and for absorption (for **1**) (Ψ-scans [21]). A decay of 3.6% for **1** was also taken into account. The crystal data for compounds **1** and **2**, along with other experimental details, are summarized in Table 1.

The structures were solved by direct methods using the SIR-92 program [22], and full-matrix least-squares refinements on F^2 were performed using the SHELXL-97 program [23]. For **1**, all heavy atoms were refined anisotropically. The CH hydrogen atoms were included at fixed distances with fixed displacement parameters from their host atoms, and the OH hydrogen atoms were refined with fixed displacement parameters. The O–H distances were restrained to 0.82 Å during refinements. For **2**, non-hydrogen atoms were refined with anisotropic displacement parameters, whilst the hydrogen atoms were refined isotropically. Figures were drawn with ORTEP-3 FOR WINDOWS [24].

5. Supplementary material

Crystallographic data (excluding structure factors) for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC no. 170018–170019. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Structures of four types of novel high-valent manganese complexes obtained by the reactions of $KMnO_4$ with tridentate Schiff base ligands

Hideyuki Asada, Minoru Ozeki, Manabu Fujiwara, Takayuki Matsushita *

Department of Materials Chemistry, Faculty of Science and Technology, Ryukoku University, Seta, Otsu 520-2194, Japan

Received 3 August 2001; accepted 26 February 2002

Abstract

X-ray structure analysis revealed that four types of novel manganese complexes, Mn^{IV}(*N*-EtO-sal)$_2$, Mn^{III}(*N*-PhO-sal)(L), [Mn^{IV}(5,6-Benzo-L)$_2$(μ-O)]$_2$ and Mn^{III}(L-4-Me)$_3$ have been found to be obtained by the reactions of $KMnO_4$ with various tridentate Schiff base ligands (*N*-EtOH-salH, *N*-PhOH-salH and its derivatives) in dry MeCN, where *N*-EtOH-salH, *N*-PhOH-salH, LH, 5,6-Benzo-LH and L-4-MeH denote *N*-2-hydroxyethyl-salicylideneamine, *N*-2-hydroxyphenyl-salicylideneamine, 2-(2-hydroxyphenyl)-benzoxazole 2-(2-hydroxynaphthyl)-benzoxazole and 2-(2-hydroxyphenyl)-5-methylbenzoxazole, respectively. The reactions of $KMnO_4$ and *N*-PhOH-salH and its derivatives have especially been found to afford benzoxazole derivatives which may be formed by intramolecular oxidative coupling between the phenolic oxygen atom of aminophenol moiety and the carbon atom of imine moiety. © 2002 Elsevier Science Ltd. Keywords: Tridentate Schiff base ligand; Potassium permanganate; Molecular structures; Photosystem II

1. Introduction

Manganese plays an important role in biological redox systems, which is exemplified by the oxygen-evolving complex of photosystem II (PS II, OEC) in green plants [1–10]. In order to understand its function, a number of oxomanganese clusters with various nuclearity, ligation and number and type of oxo-bridges, have been prepared and studied [11–17]. In particular, there have been many reports on the preparation of structurally characterized di-μ-oxo dimanganese complexes, since the close Mn–Mn distance of OEC (2.7 Å) implies a strong interaction between the manganese atoms of the substructure consistent with a di-μ-oxo dimanganese core. So far, most di-μ-oxo dimanganese(IV) complexes [18–33], such as [Mn^{IV}(salpn)(μ-O)]$_2$ (salpnH_2 = *N*,*N*′-disalicylidene-1,3-diaminopropane) [18–20], have been prepared by the reaction of mononuclear manganese(II) or manganese(III) complexes with dioxygen, hydrogen peroxide or other oxidants. We have reported that a series of di-μ-oxo dimanganese(IV) complexes has been prepared by the one step reaction of $KMnO_4$ with bi- and tetradentate Schiff base ligands in MeCN and characterized in order to mimic OEC [30–34].

In this paper, we describe that the reactions of $KMnO_4$ with tridentate Schiff base ligands, *N*-EtOH-salH, *N*-chxOH-salH, *N*-PhOH-salH and its derivatives, gave four types of manganese complexes: Mn^{IV}(*N*-RO-sal)$_2$, Mn^{III}(*N*-PhO-sal)(L), [Mn^{IV}(5,6-Benzo-L)$_2$(μ-O)]$_2$ and Mn^{III}(L-4-Me)$_3$ where *N*-ROH-X-salH, *N*-Y-PhOH-X-salH, LH, 5,6-Benzo-LH and L-4-MeH denote *N*-2-hydroxy-alkyl-X-salicylideneamine, *N*-2-hydroxy-Y-phenyl-X-salicylideneamine, 2-(2-hydroxyphenyl)-benzoxazole, 2-(2-hydroxynaphthyl)-benzoxazole and 2-(2-hydroxyphenyl)-5-methylbenzoxazole, respectively (R = 1,2-C_6H_{10}, C_2H_4, X = H, 5,6-Benzo, 5-Br and Y = H, 4-Me) [35]. In addition, their molecular structures and a reaction scheme forming benzoxazole derivatives are also described.

2. Experimental

2.1. Preparation of tridentate Schiff base ligands

All of the tridentate Schiff base ligands were prepared and identified according to the literature methods [36,37].

2.2. Preparation of Mn^{IV}(*N*-EtO-sal)$_2$ (Type I)

The manganese(IV) complex, Mn^{IV}(*N*-EtO-sal)$_2$ (**1**) was prepared by the reaction of *N*-EtOH-salH (1.652 g, 10 mmol) and $KMnO_4$ (790 mg, 5 mmol) in MeCN (150 ml) with stirring at room temperature (r.t.). The solution color changed from purple to brown and was allowed to stand in a dark place at r.t. After 12 h, the resulting precipitates were collected on a glass filter and recrystallized from a mixed solvent of CH_2Cl_2 and MeCN. The other type I manganese complexes which use *N*-ROH-X-salH were obtained in the same manner. Single crystals of Mn^{IV}(*N*-EtO-sal)$_2$ (**1**), Mn^{IV}(*N*-EtO-5,6-Benzo-sal)$_2$ (**2**) and Mn^{IV}(*N*-chxO-sal)$_2$ (**3**) were used for X-ray crystallographic determination and their structures are shown in Figs. 1–3, respectively. Elemental analysis data for all of the complexes are given in Table 1.

2.3. Preparation of Mn^{III}(*N*-PhO-sal)(L) (Type II)

The manganese(III) complex, Mn^{III}(*N*-PhO-sal)(L) (**4**) was prepared by the reaction of *N*-PhOH-salH (2.132 g, 10 mmol) and $KMnO_4$ (790 mg, 5 mmol) in MeCN (200 ml) with stirring at r.t. After 12 h, the resulting precipitates were collected on a glass filter and recrystallized from a mixed solvent of CH_2Cl_2 and MeCN. Single crystals of **4** were used for X-ray crystallographic characterization and the structure is shown in Fig. 4. Elemental analysis data are given in Table 1.

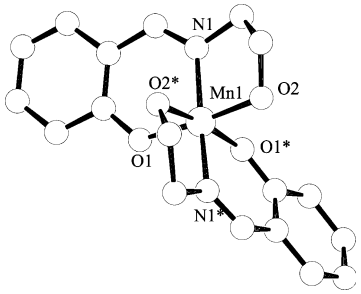

Fig. 1. The molecular structure of Mn^{IV}(*N*-EtO-sal)$_2$ (**1**) with hydrogen atoms omitted for clarity.

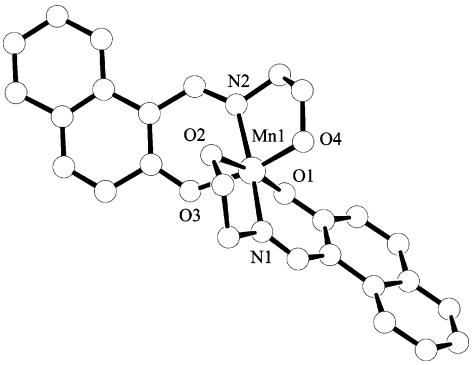

Fig. 2. The molecular structure of Mn^{IV}(*N*-EtO-5,6-Benzo-sal)$_2$ (**2**) with hydrogen atoms omitted for clarity.

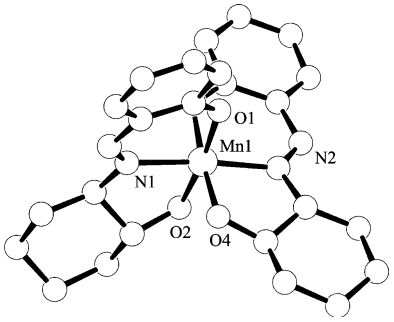

Fig. 3. The molecular structure of Mn^{IV}(*N*-chxO-sal)$_2$ (**3**) with hydrogen atoms omitted for clarity.

2.4. Preparation of [Mn^{IV}(5,6-Benzo-L)$_2$(μ-O)]$_2$ (Type III)

The di-μ-oxo dimanganese(IV) complex, [Mn^{IV}(5,6-Benzo-L)$_2$(μ-O)]$_2$ (**5**) was prepared by the reaction of *N*-PhOH-5,6-Benzo-salH (263 mg, 1.0 mmol) and $KMnO_4$ (80 mg, 0.5 mmol) in MeCN (500 ml) with stirring at r.t. The solution color changed from purple to brown and was allowed to stand in a dark place at r.t. Two weeks later the resulting brownish black crystals were collected on a glass filter. Single crystals of **5** were used for X-ray crystallographic characterization and the structure is shown in Fig. 5. Elemental analysis data are given in Table 1.

2.5. Preparation of Mn^{III}(L-4-Me)$_3$ (Type IV)

The manganese(III) complex, Mn^{III}(L-4-Me)$_3$ (**6**) was prepared by the reaction of *N*-4-Me-PhOH-salH (3.413 g, 15 mmol) and $KMnO_4$ (790 mg, 5 mmol) in MeCN (200 ml) with stirring at r.t. After 12 h, the resulting precipitates were collected on a glass filter and recrystallized from a mixed solvent of CH_2Cl_2 and MeCN. Single crystals of **6** were used for X-ray crystallographic characterization and the structure is shown in Fig. 7. Elemental analysis data are given in Table 1.

Table 1
Elemental analysis of the complexes and ligands

Complex	Formula	Analyses [a]				μ_{eff} (B.M.) [b]
		C (%)	H (%)	N (%)	Mn (%)	
1·1.5MeCN	$C_{22}H_{24}MnN_4O_4$	56.97 (56.96)	5.09 (5.14)	11.26 (11.28)	11.82 (11.86)	3.85
2	$C_{26}H_{22}MnN_2O_4$	62.81 (64.87)	4.84 (4.61)	5.79 (5.82)	10.70 (10.51)	4.02
3·MeCN	$C_{28}H_{33}MnN_3O_4$	62.04 (63.39)	6.53 (6.27)	8.18 (7.92)	10.26 (10.36)	3.88
4·MeCN	$C_{28}H_{20}MnN_3O_4$	66.72 (64.60)	3.79 (3.75)	7.90 (7.98)	10.94 (10.62)	4.80
5·1.25CH_2Cl_2	$C_{69.25}Cl_{2.5}H_{42.5}$ $Mn_2N_4O_{10}$	64.57 (64.52)	3.33 (3.32)	4.58 (4.35)	8.60 (8.52)	2.92
6	$C_{40}H_{30}MnN_3O_6$	69.36 (69.32)	4.07 (4.16)	5.88 (5.78)	7.41 (7.51)	4.87
7	$C_{13}H_9NO_2$	73.51 (73.92)	4.11 (4.30)	6.68 (6.63)		
8	$C_{17}H_{11}NO_2$	77.32 (78.15)	4.52 (4.24)	5.28 (5.36)		
9	$BrC_{13}H_8NO_2$	53.78 (53.82)	2.82 (2.78)	4.82 (4.83)		
10·0.2Me_2CO	$C_{14.6}H_{12.2}NO_{2.2}$	74.13 (74.03)	5.23 (5.19)	5.98 (5.92)

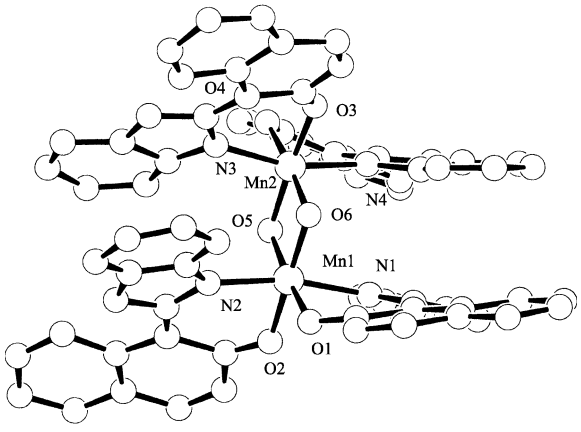

Fig. 5. The molecular structure of $[Mn^{IV}(5,6\text{-Benzo-L})_2(\mu\text{-O})]_2$ (**5**) with hydrogen atoms omitted for clarity.

2.6. Isolation of LH

The bidentate ligand LH (**7**) was isolated from Mn^{III}(*N*-PhO-sal)L (**4**) as follows. To a mixed solvent of *n*-hexane (50 ml) and H_2O (100 ml) containing **4** (500 mg, 1 mmol), glacial acetic acid (1.5 ml) was added and shaken in a separation funnel. The aqueous layer was removed. After the organic layer had been washed with H_2O, it was dried over Na_2SO_4 and evaporated to yield off-white solids. They were recrystallized from *n*-hexane. Other ligands, 5,6-Benzo-LH (**8**), 5-Br-LH (**9**) and L-4-MeH (**10**) were obtained in the same manner from type II-IV complexes where 5,6-Benzo-LH, 5-Br-LH and LH-4-Me denote 2-(2-hydroxynaphthyl)-benzoxazole, 2-(2-hydroxy-5-bromo-phenyl)-benzoxazole and 2-(2-hydroxyphenyl)-5-methylbenzoxazole, respectively. Single crystals of **8** were used for X-ray crystallographic characterization and the structure is shown in Fig. 8. Elemental analysis data for all of the bidentate ligands, X-L-YH, which were isolated from various complexes, are given in Table 1.

2.7. Physical measurements

Elemental analyses were made on a Yanaco Model CHN-CORDER MT-5. UV–Vis and IR spectra were recorded on a Shimadzu Model UV-3100 spectrophotometer and a Shimadzu Model IR-470 infrared spectrophotometer, respectively. Electrochemical studies were performed under argon, using a BAS Model CV-27 voltammograph equipped with a Graphtec Model WX 2400 XY recorder and a standard three-electrode assembly (glassy carbon working, Pt wire auxiliary and Ag–AgCl MeCN 0.1 M *n*-Bu_4NClO_4, TBAP, reference electrode) with 0.1 M TBAP (*n*-Bu_4NClO_4) as the supporting electrolyte. All the redox potentials were corrected to the saturated calomel electrode (SCE).

Magnetic susceptibility measurements were carried out by the Gouy method at r.t.

2.8. X-ray crystallographic measurements

X-ray structure analyses were taken on a Rigaku AFC-7R automatic 4-circle X-ray diffractometer.

Single crystals of all of the manganese complexes and 2-(2-hydroxynaphthyl)-benzoxazole were obtained by recrystallization from a mixed solvent of CH_2Cl_2 and MeCN and *n*-hexane, respectively. The crystals were mounted on a glass capillary. All the data were collected on a Rigaku AFC-7R four circle automated diffractometer with graphite monochromated Cu Kα radiation ($\lambda = 1.54178$ Å) for **1**, **2**, **3**, **4** and **5** and Mo Kα radiation ($\lambda = 0.71069$ Å) for **6** and **8** at 23 °C. Unit-cell parameters were obtained from a least-squares fit of 24 reflections, $25.28^\circ < 2\theta < 51.92^\circ$ for **1**, 25 reflections, $48.40^\circ < 2\theta < 54.36^\circ$ for **2**, $36.89^\circ < 2\theta < 48.54^\circ$ for **3**, $25.38^\circ < 2\theta < 51.40^\circ$ for **4**, 19 reflections, $20.09^\circ < 2\theta < 34.44^\circ$ for **5**, 23 reflections, $22.14^\circ < 2\theta < 24.37^\circ$ for **6** and 14 reflections, $7.17^\circ < 2\theta < 13.67^\circ$ for **8**. Three standard reflections were measured every 150 reflections; they showed no systematic decay throughout the data collection. The data were corrected for Lorentz and polarization effects. All the calculations were carried out using the TEXSAN [38] crystallographic software package. The structures of the complexes and the ligand were solved using direct method for **1**, **2**, **8** (SHELX-86) [39], **3**, **4** (SIR-92) [40], **5** (MULTAN-88) [41], **6** (SIR-88) [42] and expanded using Fourier techniques [43]. These structures were refined by the full-matrix least-squares technique with anisotropic thermal parameters for all non-hydrogen atoms. Hydrogen atoms were introduced in calculated positions but not refined. Crystallographic data for the complexes **1**–**6** and the ligand **8** are summarized in Tables 2 and 3.

2.9. Reagents

The reagents (salicylaldehydes and monoamines) were obtained commercially and used without further purification. $KMnO_4$ was of reagent grade (99.5%). MeCN was purified by distillation over P_4O_{10} twice and then distilled further before use. Other solvents were purified by usual methods.

3. Results and discussion

3.1. Molecular structures

All of the complexes obtained by the reactions of $KMnO_4$ with various tridentate Schiff base ligands are illustrated in Scheme 1, which include the four types of manganese complexes as follows.

3.1.1. Type I complexes

The molecular structures of Mn^{IV}(*N*-EtO-sal)$_2$ (**1**), Mn^{IV}(*N*-EtO-5,6-Benzo-sal)$_2$ (**2**) and Mn^{IV}(*N*-chxO-sal)$_2$ (**3**) are shown in Figs. 1–3, respectively. Selected bond lengths and angles are listed in Table 4. In the case of the tridentate Schiff base ligands *N*-ROH-X-salH, which were obtained by the condensation of X-salicylaldehyde and ethanolamine and/or 1,2-*trans*-cyclohexanolamine, the mononuclear manganese(IV) complexes were obtained. The X-ray crystallographic determination of these manganese(IV) complexes, Mn^{IV}(*N*-RO-X-sal)$_2$, revealed that their configuration has a meridional octahedron. The manganese ion is surrounded by an octahedral N_2O_4 donor set and is at the center of three axes of N(1)–Mn(1)–N(1)*, O(1)–Mn(1)–O(1)* and O(2)–Mn(1)–O(2)* for **1** and N(1)–Mn(1)–N(2), O(1)–Mn(1)–O(2) and O(3)–Mn(1)–O(4) for **2** and **3**. The molecular structures of the present complexes are very similar to those previously reported for $Mn^{IV}L_2^{NO2}$ such as Mn^{IV}(*N*-PrO-sal)$_2$ and Mn^{IV}(*N*-BzO-sal)$_2$, where *N*-PrOH-salH and *N*-BzOH-salH denote *N*-3-hydroxypropyl-salicylideneamine and *N*-2-hydroxybenzyl-salicylideneamine, respectively. Moreover, the bond lengths and angles are very close to those for these manganese(IV) complexes [44–47].

3.1.2. Type II complex

The molecular structure of Mn^{III}(*N*-PhO-sal)(L) (**4**) is shown in Fig. 4. Selected bond lengths and angles are listed in Table 5. In the case of *N*-PhOH-salH, which was obtained by the reaction of salicylaldehyde and *o*-aminophenol, the six-coordinate manganese(III) complex having mixed ligands **4** was isolated. This ligand L, 2-(2-hydroxy-phenyl)-benzoxazole, may be formed by an intramolecular C–O coupling reaction. In the structure of **4**, one nitrogen and two oxygen atoms of *N*-PhOH-salH and the phenolic oxygen atom of the monoanion of L occupy the equatorial plane and a nitrogen atom of the benzoxazole group is placed at the axial position. The *trans* position to the nitrogen atom

of the benzoxazole group is occupied by a phenolic oxygen atom of the neighboring complex with a Mn(1)···O(3)* separation of 2.47 Å, which is considered to be not so strong an interaction. Thus, it can be seen that along the axis of O(3)–Mn(1)···O(3)* the Jahn–Teller effect may be operating on the manganese(III) ion.

3.1.3. Type III complex

The molecular structure of [Mn^{IV}(5,6-Benzo-L)$_2$(μ-O)]$_2$ (**5**) is shown in Fig. 5. Selected bond lengths and angles are listed in Table 5. The reaction of $KMnO_4$ with *N*-PhOH-5,6-Benzo-salH gave the di-μ-oxo dimanganese(IV) complex, [Mn^{IV}(5,6-Benzo-L)$_2$(μ-O)]$_2$ (**5**). This structure consists of two manganese(IV) centers which are bridged by two oxygen atoms to yield a planar Mn_2O_2 core with a Mn–Mn separation of 2.749 Å and two benzoxazole derivatives are coordinated to each manganese atom. Its Mn–Mn separation is relatively long compared with those of the di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff base ligands (2.688(1)–2.732(3) Å) [18–20,30,33] and shorter than those of the di-μ-oxo dimanganese(IV) complexes with bidentate Schiff base ligands (2.756(3)–2.780(2) Å) [31,34].

In the structure of this complex, benzoxazole derivatives around each manganese atom bond via two phenolic oxygen atoms and two nitrogen atoms to complete the roughly octahedral coordination environment. Adoption of this binding model places two phenolic oxygen atoms *trans* and two benzoxazole nitrogen atoms *cis* toward a bridging oxo group, which is similar to the metal center of the di-μ-oxo dimanganese(IV) complexes with tetradentate Schiff bases [Mn^{IV}(μ-sal-*o*-phen)(μ-O)]$_2$ and [Mn^{IV}(μ-salen)(μ-O)]$_2$ [30,33] and the series of [Mn^{IV}(*N*-R-sal)$_2$(μ-O)]$_2$ (R ≥ Et) [31,34]. Moreover, as can be seen in Fig. 5, one of the most interesting features of **5** is two intramolecular close π–π stackings, between one benzoxazole ring and a second one coordinated to another manganese ion, which are coplanar and separated by only 3.54 Å on average (see Fig. 6A and B).

3.1.4. Type IV complex

The molecular structure of Mn^{III}(L-4-Me)$_3$ (**6**) is shown in Fig. 7. Selected bond lengths and angles are listed in Table 5. In contrast to types I–III complexes mentioned above, with *N*-4-Me-PhOH-salH, having a methyl group at the four-position of aminophenol, a roughly octahedral manganese(III) complex, Mn^{III}(L-4-Me)$_3$ was obtained. This means that all of the tridentate Schiff base ligands are converted to a benzoxazole derivative. The metal center is surrounded octahedrally by a N_3O_3 donor set. The bond distances of Mn(1)–N(1) and Mn(1)–N(3) (2.253(8) and 2.261(9) Å, respectively) are longer than that of Mn(1)–N(2) (2.109(8) Å). On the other hand, the differences among the bond distances of Mn(1)–O(1), Mn(1)–O(2), and Mn(1)–O(3) (1.889(7), 1.873(7), and 1.908(3) Å, respectively) are not so large as the differences in the distances of Mn–N bonds. Thus, the Jahn–Teller effect on the manganese(III) ion may occur along the axis containing *trans* nitrogen atoms (N(1)–Mn(1)–N(3)) of benzoxazole groups. Previously, we have reported the molecular structure of the manganese(III) complex with a bidentate Schiff base ligand, Mn^{III}(*N*-Dod-sal)$_3$, where *N*-Dod-salH denotes *N*-dodecyl-salicylideneamine [32]. In this case, three ligands arrange to form a tetragonally distorted octahedron around the manganese atom; such distortion has been ascribed to the Jahn–Teller effect.

3.2. Electronic spectra

Fig. 9 shows the electronic absorption spectra of the complexes **1**, **4**, **5** and **6** in CH_2Cl_2. In the spectra of **4**, **5** and **6**, characteristic absorption bands with high in-

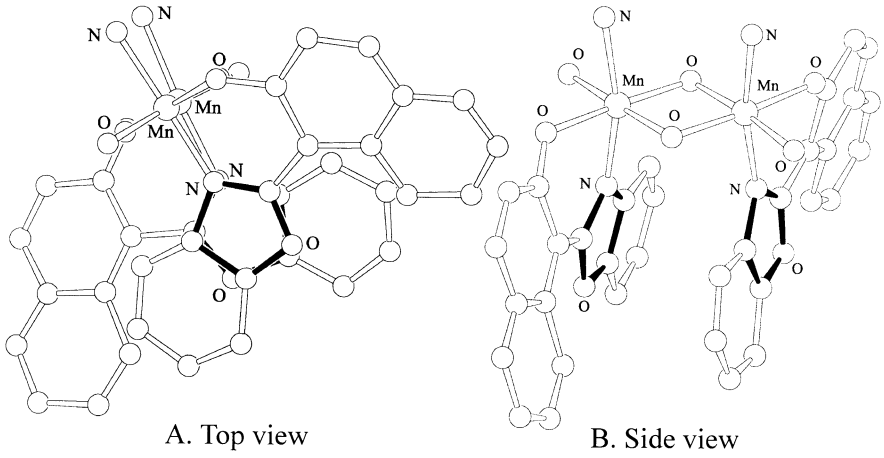

Fig. 6. The intramolecular π–π stacking between benzoxazole rings in **5**.

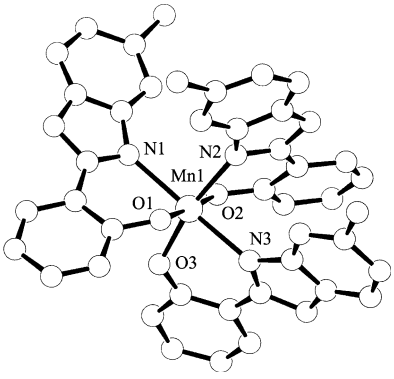

Fig. 7. The molecular structure of $Mn^{III}(L\text{-}4\text{-}Me)_3$ (**6**) with hydrogen atoms omitted for clarity.

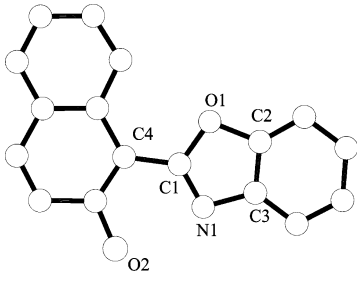

Fig. 8. The molecular structure of the ligand (**8**) with hydrogen atoms omitted for clarity.

tensities around 250–350 nm are observed which are not seen in the spectrum of **1**. These absorption bands can be assigned mainly to ligand transitions due to the benzoxazole groups, which was confirmed by the absorption spectra of the free ligands isolated from these complexes. Moreover, in the spectrum of **5**, high intensity absorption band around 370 nm and moderate ones around 410 and 480 nm are observed. The former absorption bands can be assigned to ligand transitions of the 5,6-Benzo-group, and the latter bands are characteristic for the LMCT from bridging oxygen atoms to the manganese ions [30,31,33,34]. Numerical

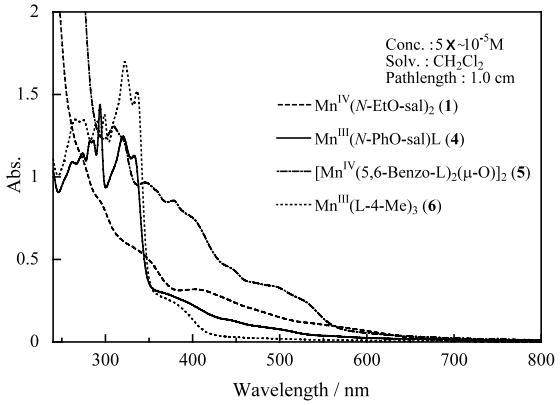

Fig. 9. The electronic absorption spectra of the complexes **1**, **4**, **5** and **6** in CH_2Cl_2.

data for the electronic absorption spectra of all the complexes are listed in Table 6.

3.3. IR spectra

In the IR spectra of the products obtained by the reaction of $KMnO_4$ with *N*-Y-PhOH-X-salH, intense bands around 1250 cm^{-1} were observed, which can be ascribed to the formation of the benzoxazole moiety. Numerical data for the IR spectra of all the complexes are listed in Table 6. It has been reported that IR spectra of di-μ-oxo dimanganese(IV) complexes exhibit sharp absorption bands characteristic for a $Mn_2(\mu\text{-}O)_2$ core in the region around 600–700 cm^{-1}, which can be assigned to the stretching vibrations of $Mn\text{–}O_{oxo}$ bonds [30,31,33,34]. In the IR spectrum of **5**, there are two medium bands at 654 and 633 cm^{-1}. These results suggest that the *N*-PhOH-5,6-Benzo-salH was converted to 5,6-Benzo-LH and formed the di-μ-oxo dimanganese complex.

From the UV–Vis and IR spectra, it can be judged whether the complexes obtained thus include a benzoxazole group as a ligand or not.

Table 6

[a] Five membered ring of benzoxazole moiety.

3.4. Magnetic properties

The magnetic moments per manganese ion of the complexes measured at room temperature are 3.85 μ_B for **1**, 4.02 μ_B for **2**, 3.59 μ_B for **3**, 4.80 μ_B for **4**, 2.92 μ_B for **5** and 4.87 μ_B for **6**. Excepting complex **5**, these values are close to the spin only value of 4.90 μ_B and 3.88 μ_B expected for a magnetically diluted high-spin d^4 manganese(III) ion and d^3 manganese(IV) ions, respectively. For complex **4**, as the manganese ion, located on the axis of nitrogen atom of benzoxazole group, interacts with the phenolic oxygen atom of a neighboring complex, it seems to adopt a dimeric structure. However, the value of its magnetic moment indicates that there is little or no intermolecular antiferromagnetic coupling.

On the other hand, for the di-μ-oxo dimanganese(IV) complex **5**, the magnetic moment per manganese ion of the complex measured at room temperature is 2.92 μ_B. This lower value indicates that an intramolecular antiferromagnetic interaction between the two manganese(IV) ions (d^3) exists in complex **5**. Although this value is slightly higher than those for other di-μ-oxo dimanganese complexes [18–33], it may be caused by the effect of π–π stacking between the benzoxazole moieties of each manganese ion.

3.5. Electrochemical properties

Electrochemical data for all the complexes are listed in Table 6. Quasi-reversible redox waves were observed at −0.44 V for **1**, −0.52 V for **2**, −0.58 V for **3**, −0.36 and +0.87 V for **4**, −0.38 V for **5**, and −0.30 and +0.86 V (vs. SCE) for **6**. The redox waves observed for manganese(IV) complexes **1**, **2**, **3** and **5** can be assigned to the redox couple due to Mn(IV)↔Mn(III). The two redox waves around −0.30 and +0.85 V observed for manganese(III) complexes **4** and **6** can be assigned to the redox couples due to Mn(III)↔Mn(II) and Mn(IV)↔Mn(III), respectively.

3.6. Reactions of $KMnO_4$ with tridentate Schiff base ligands

Fig. 10 shows the absorption spectral changes of a MeCN solution of $KMnO_4$ caused by the addition of a MeCN solution of *N*-PhOH-salH in a 1:2 molar ratio, measured at room temperature. As the intensities of characteristic absorption bands around 550 nm due to $KMnO_4$ were decreased, intensities around 300 nm were significantly increased. These absorption bands can be attributed to the five-membered ring formation of the benzoxazole derivative. Moreover, the spectral changes indicate that this ring formation can take place in the

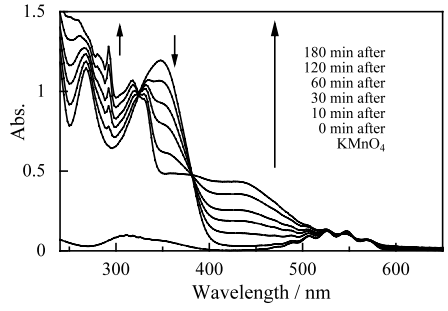

Fig. 10. Spectral changes of a MeCN solution of $KMnO_4$ (5×10^{-4} M) caused by the addition of a MeCN solution of *N*-PhOH-salH. ($KMnO_4$:*N*-PhOH-salH = 1:2, cell length; 1 cm).

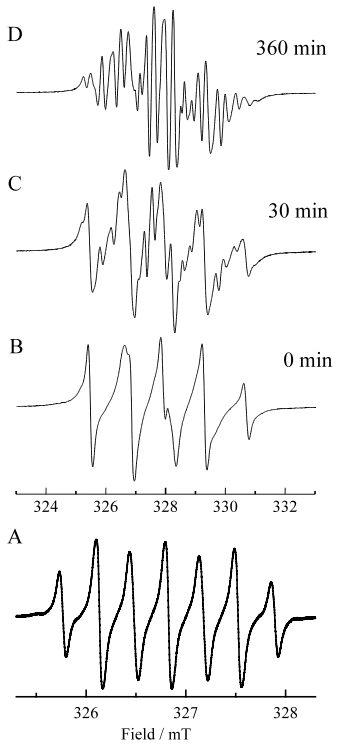

Fig. 11. ESR spectrum of a MeCN solution of $KMnO_4$ in the presence of DMPO (A) and spectral changes during the reaction of $KMnO_4$ and *N*-PhOH-salH (B–D) at 213 K.

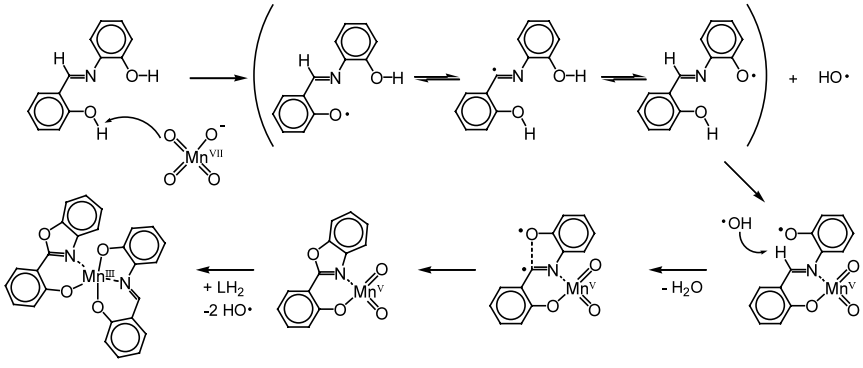

early stages of the reaction of $KMnO_4$ with the tridentate Schiff base ligand.

Oxidation of organic compounds by $KMnO_4$ has been known to proceed via radical formation [48]. Thus, the ESR spectra were measured for the present systems in order to clarify the reaction mechanism. Fig. 11A shows the ESR spectrum of a MeCN solution of $KMnO_4$ plus DMPO (5,5-dimethylpyrroline-N-oxide), which is well-known as a radical trapping agent, measured at 213 K. Seven-line signals centered at $g = 2.0$ were observed. It is conceivable that this signal may be assigned to the DMPO radical which may form by the reaction between DMPO and hydrogen radical, forming by hydrogen abstraction of DMPO by $KMnO_4$. This signal was so stable that further reaction with $KMnO_4$ did not occur.

Next, the ESR spectrum of a MeCN solution of *N*-PhOH-salH plus $KMnO_4$ in the presence of DMPO was measured, as shown in Fig. 11(B). The five-line signals centered at $g = 2.0$ were observed in the early stages of the reaction. Moreover, these signals were split with the passage of time (Fig. 11(C)) and changed to a complicated signal having a hyperfine structure 6 h later (Fig. 11(D)). The ESR spectra for the reaction systems between $KMnO_4$ and other analogous Schiff base ligands, *N*-EtOH-salH and *N*-chxOH-salH and the bidentate one, *N*-Me-salH, which were not oxidized to oxazole derivatives, were measured under almost the same conditions. The ESR spectral changes obtained were similar to that observed for the *N*-PhOH-salH plus $KMnO_4$ system. These results indicate that the signals shown in Fig. 11(B–D) could be attributed to the product formed by the reaction between a phenoxy radical of salicylideneamines and DMPO, which has not yet been identified. Consequently, the reaction of tridentate Schiff base ligands with $KMnO_4$ may be initiated by the hydrogen atom abstraction from the phenol moiety of the ligands to give a phenoxy radical. Scheme 2 shows a tentative reaction pathway for the five-membered ring formation during the reaction of $KMnO_4$ and tridentate Schiff base ligand, *N*-PhOH-salH. In the case of *N*-PhOH-salH, $KMnO_4$ may attack a phenol group of the salicylaldehyde moiety and a phenoxy radical may form. This radical can be stabilized by the aromatic resonance system (π conjugation) and may be delocalized and transferred on the carbon atom of the imino group, which may induce a –N=C–H cleavage to form –N=C, which in turn may couple with a phenoxy radical of an amino phenol moiety to afford a five-membered ring benzoxazole derivative. A further investigation has not been made.

4. Conclusions

Four types of novel manganese complexes can be obtained by the reaction of $KMnO_4$ with various tridentate Schiff base ligands. In the case of *N*-EtOH-

Scheme 2. A tentative reaction pathway for the five-membered ring formation during the reaction of $KMnO_4$ with *N*-PhOH-salH.

salH, the mononuclear manganese(IV) complex, Mn^{IV}(*N*-EtO-sal)$_2$ was obtained. On the other hand, with *N*-PhOH-salH and its derivatives five-coordinate manganese(III) complexes having mixed ligands, Mn^{III}(*N*-PhO-sal)(L), the di-μ-oxo dimanganese(IV) complex, [Mn^{IV}(5,6-Benzo-L)$_2$(μ-O)]$_2$ and the roughly octahedral manganese(III) complex, Mn^{III}(L-4-Me)$_3$ were obtained, depending on the substituents. The reactions between $KMnO_4$ with the tridentate Schiff base ligands have been monitored by UV–Vis and ESR spectroscopies. The results indicate that the five-membered ring formation may proceed via a radical reaction initiated by the oxidation of the ligands with the permanganate ions in the early period of the reaction of $KMnO_4$ with tridentate Schiff base ligands.

5. Supplementary data

Supplementary data are available from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk), deposition numbers 161717 to 161719 for ligand **8** and complexes **3** and **2**, respectively. The complexes **1**, **4**, **5**, **6** are in the CSD with the following refcodes: GAQDUX, GAQFEJ, GAQFUZ and GAQMOA.

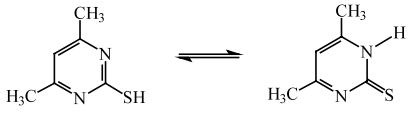
Received 7 September 2001; accepted 19 March 2002

Abstract



The coordination mode of the ambidentate ligand 4,6-dimethylpyrimidine-2-thione (Me_2PymtH) was investigated with respect to the organotin(IV) compounds, namely Me_2SnCl_2, *n*-Bu_2SnCl_2, Ph_2SnCl_2 and Ph_3SnCl. An X-ray crystal structure determination carried out on *cis*-[$Ph_2Sn(Me_2Pymt)$] (**3**) and [$Ph_3Sn(Me_2Pymt)$] (**4**) revealed that the Me_2Pymt^- ligand is N,S-coordinated in both complexes. The Sn(IV) atom is six-coordinated in **3** and five-coordinated in **4**. The similarities observed in the IR, NMR (^1H, ^{13}C) and mass spectroscopy are indicative of a similar behavior of the ligand in all the complexes, thus suggesting a six-coordination in the dimethyltin (**1**) derivative and five-coordination in the dibutyltin (**2**) one. The complexes were characterized by means of elemental analysis, IR, NMR (^1H, ^{13}C) and mass spectroscopic methods. © 2002 Published by Elsevier Science Ltd.

Keywords: Organotin(IV) complexes; Dimethylpyrimidinethione; Crystal structures

1. Introduction

The variety of coordination modes of 4,6-dimethylpyrimidine-2-thione (Me_2PymtH) has been demonstrated in a number of complexes [1] and their biological applications have been of considerable interest for years [2]. Insofar as many organotin(IV) complexes are also noteworthy for the same reason [3], a combination of the two chemistry is an interesting topic to pursue.

The present work deals with the preparation and characterization of four new organotin(IV) complexes with the Me_2PymtH ligand, whose structure is shown below.

Me_2PymtH

This ligand was chosen since it has the potential to form four-, five-or hexacoordinate metal complexes which the polyhedral of these compounds assuming structures that are considerably distorted from ideal configuration. These distorted structures in many organotin(IV) complexes are thought to be due to a number of factors, such as steric requirements, electronic effects arising from different electronegativities of the ligands, intermolecular interactions and crystal packing requirements [4]. Pyridines and pyrimidines substituted with an SH or an OH group at the two or four positions are fundamentally tautomeric heterocyclic system and many experimental studies have been reported [5,6]. The complexes were studied by microanalyses, IR, NMR (^1H, ^{13}C), mass spectroscopy and crystal X-ray diffraction.

2. Experimental

Solvents were purified and dried according to standard procedures. Thiourea, pentane-2,4-dione and organotin(IV) chlorides were obtained from Aldrich and used without further purification. IR spectra were recorded on a Bruker IFS-28 spectrophotometer in the 4000–400 cm^{-1} range using KBr pellets. NMR (^{1}H, ^{13}C) spectra were obtained from a Bruker DPX-200 spectrometer using $CDCl_3$ as the solvent with chemical shifts in parts per million downfield from Me_4Si. The mass spectra were recorded on a Micromass 7070-F instrument, using FAB+Xe at 8 eV and alcohol 3-nitrobenzilic as matrix. Microanalyses were performed in a VARIO EL (Elementar Analysensysteme GmbH) instrument.

2.1. Synthesis

The ligand was prepared according to the literature [2] and the complexes by the following procedure: 0.28 g (2 mmol) of Me_2PymtH was dissolved in 30 ml of THF (freshly distilled) in a Schlenk tube kept under N_2 atmosphere. To the solution, 0.84 ml (6 mmol) of triethylamine (Et_3N) was added via a syringe and the resulting solution was stirred for 30 min. To this solution was added, during 10 min, 1 mmol of the appropriate organotin(IV) species dissolved in 3 ml of THF, and the mixture was refluxed for about 4 h. A white flocculent precipitate identified as triethylamine chloride (Et_3NHCl) was produced and filtered. Slowly evaporation of the solvent led to the appearance of white amorphous crystalline solids with yields of the order 70%. Well formed crystals suitable for X-ray studies were only obtained for complexes **3** and **4** by recrystallization from a 1:1 (v/v) mixture of dichloromethane–*n*-hexane. The microanalyses were performed in a Perkin–Elmer 2400C analyzer, giving for C, H and N the following results: [$Me_2Sn(Me_2Pymt)_2$] (**1**): (m.p. 197–199 °C). *Anal*. Found: C, 40.66; H, 4.78; N, 13.55. Calc. for ($C_{14}H_{20}N_4S_2Sn$): C, 39.37; H, 4.72; N, 13.12%. [$Bu_2SnCl(Me_2Pymt)$] (**2**): (m.p. 212–211 °C). *Anal*. Found: C, 43.32; H, 6.46; N, 6.72. Calc. for ($C_{14}H_{25}ClN_2SSn$): C, 41.26; H, 6.18; N, 6.87%. *cis*-[$Ph_2Sn(Me_2Pymt)_2$] (**3**): (m.p. 202–204 °C). *Anal*. Found: C, 52.17; H, 4.58; N, 10.62. Calc. for ($C_{24}H_{24}N_4S_2Sn$): C, 52.29; H, 4.39; N, 10.16%. [$Ph_3Sn(Me_2Pymt)$] (**4**): (m.p. 206–208 °C). *Anal*. Found: C, 58.67; H, 4.57; N, 5.84. Calc. for ($C_{24}H_{22}N_4S_2Sn$): C, 58.92; H, 4.53; N, 5.73%.

2.2. X-ray studies

Colourless single crystals of compounds **3** and **4** which were suitable for X-ray diffractometric studies were selected and data collected on a Bruker Smart CCD for **3** and an Enraf–Nonius MACH3 for **4**. The data were corrected for absorption effects by an empirical correction (SADABS 7b) (**3**) or using ψ-scans 7a (**4**).

Structural solutions were determined by direct methods [8]. Least-squares full-matrix refinement on F2 was performed using the program SHELXL-97 [8]. All non-H atoms were refined anisotropically. H atoms were calculated and refined as ridding atoms (HFIX [8]). Atomic scattering factors and anomalous dispersion corrections for all atoms were taken from International Tables for Crystallography [9]. Graphics were obtained with ZORTEP [10].

3. Results and discussion

3.1. Infrared spectroscopy

Table 1 shows the assignment of the main IR absorptions of the ligand and its complexes. The Me_2PymtH ligand shows a rather complicated spectrum in the 3100–2600 cm^{-1} range where C–H and N–H stretching absorptions occur. Thus, the spectra of complexes retain those absorptions found in free ligand. The ring stretching vibrations, $\nu(C{=}C)+\nu(C{=}N)$, are shifted to lower frequencies, together with the shift in opposite direction of the ligand band at 1235 cm^{-1}, assigned to mixed $\nu(C{-}S)+\nu(C{-}N)$ absorption bands. These results suggest, in accordance with ^{1}H NMR, an N,S-chelation of the aromatic Me_2Pymt^{-} anion around the Sn(IV) ion. Similar results have been reported for tiolate complexes of 2-PySH (2-mercaptopyridine) and 2-PymSH (2-mercaptopyrimidine) and different metal ions such as Ni(II) [11] and Pt(II) [12], as well as with Re(V) complex of Me_2PymtH [13].

In the IR spectrum of [$Me_2Sn(Me_2Pymt)_2$] the asymmetric Sn–C stretching band at 551 cm^{-1} indicates that this complex has the *trans* arrangement of the methyl groups [14].

3.2. NMR spectroscopy

Table 2 lists ^{1}H chemical shifts for the free ligand Me_2PymtH and its complexes. The ^{13}C NMR spectrum to complex **1** showed a $^{1}J(^{119}Sn{-}CH_3)$ coupling constant of 600 Hz and the ^{1}H NMR spectrum showed one doublet and a singlet in the methyl region occurring at 2.37 and 1.03 [$^{2}J(^{119}Sn{-}CH_3)$ 83 Hz] due to two magnetically non-equivalent methyl groups bonded in $N{=}CH{-}CH_3$ and $Sn{-}CH_3$, respectively. These ^{1}J and ^{2}J coupling constants data can be used to estimate the $CH_3{-}Sn{-}CH_3$ angle in complex **1**, and according to the literature [15,16], two empirical equations can be set up for this estimate:

Table 1
Main IR absorptions (cm^{-1}) for Me_2PymtH and its Sn(IV) complexes

Compound	C.N. [a]	ν(N–H)+ν(C–H)	ν(C=C)+ν(C=N)	ν(C–S)+ν(C–N)
Me_2PymtH		2911	1625, 1569, 1432	1235
$[Me_2Sn(Me_2Pymt)_2]$ (**1**)	6	2916	1578, 1543, 1435	1257
$[Bu_2SnCl(Me_2Pymt)]$ (**2**)	5	2921	1578, 1539, 1437	1257
cis-$[Ph_2Sn(Me_2Pymt)_2]$ (**3**)	6	3038	1579, 1525, 1430	1255
$[Ph_3Sn(Me_2Pymt)]$ (**4**)	5	3038	1584, 1524, 1427	1255

[a] C.N. = coordination number.

Table 2
^1H NMR data in $CDCl_3$ solution[a]

Me_2PymtH	6.49 (s, 1H, C–H); 2.39 (t, 6H, C–CH_3)
$[Me_2Sn(Me_2Pymt)_2]$ (**1**)	6.69 (s, 2H, C–H); 2.37 (d, 12H, C–CH_3); 1.03 (s, 6H, Sn–CH_3) $^2J(^{119}Sn–CH_3)$ = 83/75
$[Bu_2SnCl(Me_2Pymt)]$ (**2**)	(s, 2H, C–H); 2.37 (d, 6H, C–CH_3); 1.64-1.55 (m, 4H, Sn–CH_2–C); 1.42–1.26 (m, 4H, C–CH_2–C); 0.79 (t, 6H, Bu–CH_3)
cis-$[Ph_2Sn(Me_2Pymt)_2]$ (**3**)	7.88–7.26 (m, 10H, Sn–C_6H_5); 6.52 (s, 2H, C–H); 2.18 (s, 6H, C–CH_3)
$[Ph_3Sn(Me_2Pymt)]$ (**4**)	7.80–7.23 (m, 10H, Sn–C_6H_5); 6.55 (s, 2H, C–H); 2.13 (s, 6H, C–CH_3)

[a] s = Singlet, d = doublet, m = multiplet, δ in ppm, J in Hz.

$$^1J(^{119}Sn–^{13}CH_3) = 11.4\theta - 875 \quad (1)$$

$$\theta = 0.0161\{^2J(^{119}Sn–CH_3)\}^2 - 1.32\{^2J(^{119}Sn–CH_3)\} + 133.4 \quad (2)$$

Using ^1J into Eq. (1) and ^2J into Eq. (2), one finds values of θ of 135° and 129°, respectively. These angles values might suggests that in solution the dimethyltin derivative is a distorted *trans* octahedral complex and the basic structural features of the solid-state phase remain in $CDCl_3$ solution. For dibutyl derivative, similar structural considerations in solution might hold.

Similar results were reported for octahedral complexes with analogous *trans* arrangement, namely $[Me_2Sn(dtc)_2]$ [17] [$^2J(^{119}Sn–CH_3)$ 84 Hz and $^1J(^{119}Sn–^{13}CH_3)$ 670 Hz], $[Me_2SnCl_2\cdot(DMSO)_2]$ [15] [$^2J(^{119}Sn–CH_3)$ 86 Hz] and $[Me_2Sn(CH_3COO)_2]$ [18] [$^2J(^{119}Sn–CH_3)$ 82 Hz], where Hdtc = ditiocabamic acid and DMSO = dimethylsulfoxide.

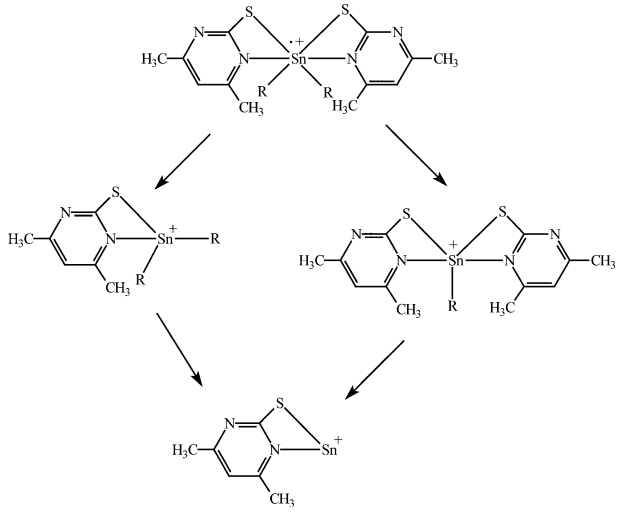

Fig. 1. Fragmentation scheme proposed for complexes **1**–**3**.

3.3. Mass spectroscopy

Table 3 shows the FAB mass spectra of compounds **1**–**4** and Fig. 1 presents a fragmentation scheme proposed for complexes **1**–**3** compatible with literature data [4,19]. The molecular ion for complexes **1**, **3** and **4** were detectable at m/z 429, 553 and 489, respectively.

The spectra of complexes **1** and **3** showed that the base peaks are the ions $R_2Sn(Me_2Pymt)^+$ (R = Me, Ph), in agreement with reported works [4,19]. This contrasts with the spectra of compounds **2** and **4**, in which the base peaks appeared at m/z 882 (not attributed) and m/z 291 (probably due to the ion $Ph_2Sn(H_2O)^+$), respectively.

Table 3
Fragment-ions observed in the FAB mass spectra of compounds **1**–**4**

Fragment-ion	Me_2Sn (**1**) m/z [a] (abundance)	Bu_2Sn (**2**) m/z [a] (abundance)	Ph_2Sn (**3**) m/z [a] (abundance)	Ph_3Sn (**4**) m/z [a] (abundance)
$R_3Sn(Me_2Pymt)^+$				489(8)
$R_2Sn(Me_2Pymt)_2^+$	429(33)		553(15)	
$R_2Sn(Me_2Pymt)^+$	289(100)	373(64)	413(100)	
$RSn(Me_2Pymt)_2^+$	413(16)		258(9)	
$Sn(Me_2Pymt)^+$	259(18)	259(22)	259(24)	259(25)
$(Me_2Pymt)_2^+$	279(9)	279(16)	279(48)

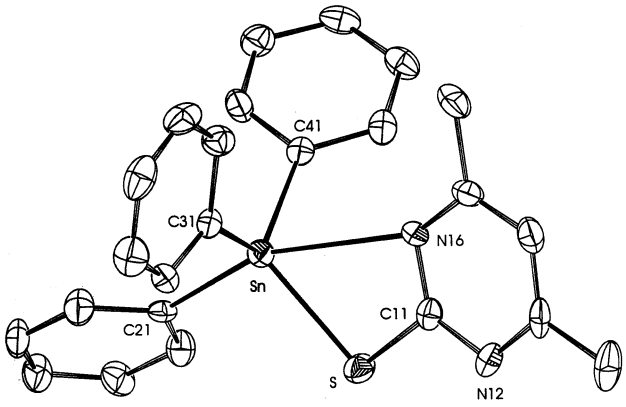

Fig. 3. Perspective view of [$Ph_3Sn(Me_2Pymt)$] (**4**) showing the atom numbering scheme. Displacement ellipsoids are drawn at the 50% probability level.

3.4. X-ray structures of cis-[$Ph_2Sn(Me_2Pymt)_2$] (3) and [$Ph_3Sn(Me_2Pymt)$] (4)

The molecular structures of **3** and **4** are given in Figs. 2 and 3, respectively. Tables 4 and 5 summarize the crystal data and selected bond lengths and bond angles for the two compounds, respectively.

The geometry about Sn(IV) in **3** is best described as a distorted octahedral with the two Me_2Pymt^- anions acting as bidentate ligands with *cis* Ph–Sn–Ph [117.42(13)°] and *cis* S–Sn–S [84.50(3)°] arrangements. The bond distances [2.4476(10); 2.4515(10) Å] in the Sn–S bond lengths found in **3** are shorter than the Sn–S bond distances [2.476(2); 2.485(1) Å], [2.477(3) Å] and [2.487(2) Å] found in [$Ph_2Sn(2\text{-}SPy)_2$] [20], [*n*-$Bu_2Sn(2\text{-}SPy\text{-}5\text{-}NO_2)_2$] [4] and [$Me_2Sn(2\text{-}SPy)_2$] [21], respectively, where 2-SPyH is 2-pyridinethione and 2-SPyH-5-NO_2 is 5-nitropyridinethione.

The Sn–N bond distances [2.754(3) and 3.083(3) Å] found in complex **3** are shorter than the sun of the van der Waals radii (3.75 Å) [20] indicating the bidentate nature of the Me_2Pymt^- ligand. However, these distances are longer than the Sn–N distances [2.636(4); 2.698(3) Å] and [2.702(5) Å] found in [$Ph_2Sn(2\text{-}SPy)_2$] [20] and [$Me_2Sn(2\text{-}SPy)_2$] [21], respectively. Although conclusions are drawn with caution, it would appear most reasonable that the disparate Sn–N bond distances in **3** versus [$Ph_2Sn(2\text{-}SPy)_2$] and [$Me_2Sn(2\text{-}SPy)_2$] [21] is probably due to the electronic effects caused by uncomplexed N(12) and N(22) atoms in complex **3**. The Sn–C bond distances (mean value of 2.12 Å) is typical, and compares favorably with the analogous bond in related compounds, in particular [$Ph_2Sn(2\text{-}SPy)_2$] [20] (2.13 Å) and [$Me_2Sn(2\text{-}SPy)_2$] [21] (2.13 Å), with which it shows striking structural similarities.

The geometry about Sn(IV) in **4** is best described as a strongly distorted trigonal bipyramid (TBP) configuration where two phenyl groups and a S atom are at the equatorial plane while N(16) atom and other phenyl group occupy the axial position.

The Sn–S bond distance [2.433(2) Å] found in **4** is within the range (2.405–2.481 Å) [22,23] recently reported for triphenyltin(IV) thiolates compounds R_3SnL, containing potentially bidentate ligand. Similarly, the Sn–C distances [mean 2.14 Å] agree well with those previously reported [22,23].

The Sn–N bond length [2.835(7) Å] is equal to the length of Sn–N bond [2.836(3) Å] found in [Ph_3Sn(o-quinolinylthiolate)] [22], in which sulfur and nitrogen atoms are bonded to the Sn(IV) atom forming five-membered chelate ring. On the other hand, the Sn–N length in **4** is smaller than that of the Sn–N bond [2.88(5) Å] found in [$Ph_3Sn(2\text{-}Pymt)$] [24], where 2-PymtH is 2-pyrimidinethione, suggesting that the methyl group, C(151), does not cause steric effect. In contrast,

N(16)–Sn–N(26)	160.02(10)	C(11)–S–Sn	94.6(3)
N(16)–Sn–S(1)	55.75(6)	N(12)–C(11)–N(16)	127.7(9)
N(26)–Sn–S(2)	59.71(8)	N(16)–C(11)–S	116.3(7)
N(16)–Sn–S(2)	140.25(6)	N(12)–C(11)–S	115.9(8)
N(26)–Sn–S(1)	144.21(8)	N(12)–C(13)–C(131)	117.9(11)
N(16)–C(11)–S(1)	117.3(3)	N(16)–C(15)–C(151)	115.5(9)
N(26)–C(21)–S(2)	117.6(4)	C(13)–C(14)–C(15)	118.3(11)

the Sn···N interaction [2.920(3) Å], found in [Ph_3Sn(mimt)] [22], where mimtH is 1-methyl-2(3H)-imidazolinethione, slightly distorts the Sn(IV) coordination geometry from that a perfect tetrahedron.

Around the Sn(IV) atom, the S–Sn–C(31), C(31)–Sn–C(41) and C(41)–Sn–S equatorial angles of 110.0(2)°, 116.8(3)°, 115.2(3)° and the N–Sn–C(21) axial angle of 159.7(3)°, are smaller than the ideal trigonal bipyramid angles.

The bite angle of the chelating ligand is similar for both complexes and quite acute, 59.71(8)° for **3** and 59.03(17)° for **4**. In both cases, the phenyl groups (C31 and C41) bend away the coordinate Sn–S bonds, generating an Ph–Sn–Ph angle of 117.42(13)° in the case **3** and 116.8(3)° in **4**.

4. Supplementary data

Crystallographic data (excluding structure factors) for the structures have been deposited with the Cambridge Crystallographic Data Center as supplementary publication nos. 167994 (**3**) and 167995 (**4**). Copies of the data can be obtained, free of change, on application to CCDC, 12 Union road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

A spirocyclic tetraoxyphosphorane with an apically located chlorine in a trigonal bipyramid and its hydrolysis product

Sudha Kumaraswamy, K.C. Kumara Swamy *

School of Chemistry, University of Hyderabad, Hyderabad 500046, A.P., India

Received 11 October 2001; accepted 7 March 2002

Abstract

The spirocyclic (chloro)tetraoxyphosphorane CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$P(Cl)(1,2-$O_2C_6Cl_4$) (**2**) and its hydrolysis product CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$P(O)(OC_6Cl_4-2-OH) (**3**) have been synthesized and characterized by X-ray crystallography and solution state NMR. Unlike the previously reported spirocyclic chlorophosphoranes where chlorine occupies an equatorial position of a trigonal bipyramid (TBP), in **2** it is apical. The hydrolysis product **3** is a hydrogen bonded dimer. Compound CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$P(Cl)[1,2-O_2–3,5-(*t*-Bu)$_2C_6H_2$] (**4**) was also synthesized in a manner analogous to that of **2**. Attempts to isolate structurally characterizable pentacoordinate compounds by reacting CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$PX [X = Cl (**1**), 2,6-$Cl_2C_6H_3O$ (**5**), *cycl*-C_6H_{11}NH (**6**)] with *N*-chlorodiisopropylamine were not successful, although in some cases a pentacoordinate species was detected; the corresponding oxidized products CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$P(O)X [X = Cl (**7**), 2,6-$Cl_2C_6H_3O$ (**8**), *cycl*-C_6H_{11}NH (**9**)] were isolated by this route. Variable temperature (^{1}H, ^{31}P) NMR spectra of **2** have been recorded; at low temperatures, two ^{31}P NMR signals of unequal intensity are seen in the pentacoordinate region. A probable intramolecular process involving equatorial–equatorial↔apical–equatorial (for the eight-membered ring) has been invoked to explain the spectral features. © 2002 Elsevier Science Ltd. Keywords: Phosphoranes; Pentacoordinated; X-ray structures; Hydrogen bonding

1. Introduction

In spirocyclic phosphoranes with phosphorus as a part of a four to seven membered ring, the rings generally prefer apical–equatorial (a–e) sites irrespective of the substituents when phosphorus has a trigonal bipyramidal geometry [1–10]. Thus, in most spirocyclic phosphoranes, the fifth substituent will have to occupy an equatorial position of the trigonal bipyramid (TBP). If the structure has more square (or rectangular) pyramidal (RP) character, the fifth substituent will take an apical position [11,12]. Compounds **I**–**IV** represent some examples involving chlorine as the fifth substituent [2,13–15]. Thus, in the structures of spirocyclic chlorophosphoranes reported so far, the chlorine has been found to be either in an equatorial position of a TBP or in an apical position of an RP [2,13–20]. The sterically hindered eight-membered ring present in **V** is an interesting system in which the a–e and e–e dispositions are equally feasible for the ring, depending on the fifth substituent [21,22]. In this paper we show the utility of such a ring in placing the chlorine at an apical position of a trigonal bipyramidal phosphorus in the spirocyclic phosphorane CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$P(Cl)(1,2-$O_2C_6Cl_4$) (**2**), prepared by starting with CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$PCl (**1**), as evidenced by X-ray crystallography. Hydrolysis of **2** leads to the tetracoordinate compound CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$P(O)(OC_6Cl_4-2-OH) (**3**) that exists in the solid state as a novel hydrogen-bonded dimer (X-ray). Synthesis of CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$P(Cl)(1,2-O_2-3,5-(*t*-Bu)$_2C_6H_2$) (**4**) by a route analogous to that for **2** is also reported herein. In addition, a unique exchange behavior of **2** observed in the variable temperature NMR (^{1}H and ^{31}P) is described. Also described here is our attempt to prepare other chlorophosphoranes by the oxidative addition reaction of CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2$PX [X = Cl (**1**), 2,6-$Cl_2C_6H_3O$ (**5**), *cycl*-

$C_6H_{11}NH$ (**6**)] with *N*-chlorodiisopropylamine in which only the corresponding oxidized products $CH_2(6\text{-}t\text{-Bu-}4\text{-Me-}C_6H_2O)_2P(O)X$ [X = Cl (**7**), 2,6-$Cl_2C_6H_3O$ (**8**), *cycl*-$C_6H_{11}NH$ (**9**)] were isolated.

2. Experimental

Chemicals were procured from Aldrich/Fluka or from local manufacturers; they were purified when required. Solvents were purified according to standard procedures [23]. All reactions, unless stated otherwise, were performed under dry nitrogen atmosphere. ^1H, and $^{31}P\{H\}$ NMR spectra were recorded on a Bruker 200 MHz spectrometer in $CDCl_3$ or $C_6D_5CD_3$ solutions (unless stated otherwise), with shifts referenced to $SiMe_4$ ($\delta = 0$) or 85% H_3PO_4 ($\delta = 0$). Variable temperature ^1H and ^{31}P NMR spectra were recorded in $C_6D_5CD_3$. Elemental analyses were carried out on a Perkin–Elmer 240C CHN analyzer.

2.1. Synthesis of 2 and 3

A mixture of the P(III) precursor $CH_2\{6\text{-}t\text{-Bu-}4\text{-Me-}C_6H_2O\}_2PCl$ (**1**) [δ(P): 153.7] (0.216 g, 0.53 mmol) and *o*-chloranil (0.131 g, 0.53 mmol) was evacuated for 0.5 h. Then dry heptane (5 ml) was added, the mixture heated at 90 °C for 5 min and brought to room temperature (r.t.). After 0.5 h the clear red solution became colorless. It was concentrated to 1 ml and kept at r.t. Crystals of **2** (0.208 g, 60%) were obtained after 1 day. M.p. 206 °C (dec., darkens slightly at 192 °C). ^1H NMR (C_6D_6): δ 1.36 (br s, 18 H, $C(CH_3)_3$), 2.04, 2.09 (2 s, 6 H, $ArCH_3$), 3.86 (d, $J = 14.0$ Hz, 1 H, CH_AH_X), 4.14 (d, $J = 14.0$ Hz, 1 H, CH_AH_X), 6.96–7.03 (m, 4 H, Ar–*H*). ^{31}P NMR (C_6D_6): δ −35.6. *Anal*. Calc. for $C_{29}H_{30}Cl_5O_4P$: C, 53.52; H, 4.61. Found: C, 53.88; H, 4.75%.

Compound **2** was very susceptible to hydrolysis. Exposure to air for approximately 1 day resulted in the formation of **3**, which could be crystallized from dichloromethane–toluene (1:3) mixture in approximately 70% yield. This compound could also be obtained by stirring a solution of **2** in toluene with 1 mol equiv. of water for 18 h and then allowing to crystallize. M.p. 128–130 °C. IR (KBr): 3350–3600 (br) cm^{-1}. ^1H NMR ($CDCl_3$): δ 1.30 (s, 18 H, $C(CH_3)_3$), 2.31 (s, 6 H, $ArCH_3$), 3.96 (d, $J = 16.0$ Hz, 1 H, CH_AH_X), 4.24 (d, $J = 16.0$ Hz, 1 H, CH_AH_X), 7.00–7.29 (m, 4 H, Ar–*H*). ^{31}P NMR ($CDCl_3$): δ −14.5. *Anal*. Calc. for $C_{29}H_{31}Cl_4O_5P$: C, 55.08; H, 4.94. Found: C, 55.21; H, 4.92%.

Compound **4** was prepared in 54% yield in a manner similar to that for **2**. M.p. 204–210 °C. ^1H NMR: δ 0.35, 1.17, 1.23 (3 br s, 36 H, $C(CH_3)_3$), 2.30 (s, 6 H, $ArCH_3$), 3.62 (br d, 1 H, CH_AH_X), 4.48 (br, 1 H, CH_AH_X), 6.70–7.20 (many lines, 6 H, Ar–*H*). ^{31}P NMR: δ −41.3. Within approximately 10 min a hydrolyzed product [δ(P) −15.6] was also observed. Compound **4** was too moisture sensitive and hence elemental analysis was not attempted.

2.2. Isolation of 7–9 from the reaction of $CH_2\{6\text{-}t\text{-Bu-}4\text{-Me-}C_6H_2O\}_2PX$ [X = Cl (1), 2,6-Cl_2-OC_6H_3 (5), NH-cycl-C_6H_{11} (6)] with N-chlorodiisopropylamine

2.2.1. $CH_2\{6\text{-}t\text{-Bu-}4\text{-Me-}C_6H_2O\}_2P(O)Cl$ (7)

To a solution of **1** (0.390 g, 0.96 mmol) in toluene (10 ml) at −30 °C was added a solution of $ClN(i\text{-Pr})_2$ (0.263 g, 1.94 mmol) in toluene (5 ml) during 5 min. The mixture was slowly brought to r.t., stirred overnight and filtered. Concentration to 0.5 ml and addition of heptane (1 ml) afforded **7** as a crystalline solid (0.28 g, 69%). M.p. 155–156 °C. ^1H NMR: δ 1.52 (s, 18 H, $C(CH_3)_3$), 2.07 (s, 6 H, $ArCH_3$), 3.70–4.10 (AB qrt, 2 H, CH_AH_B), 6.81, 7.06 (2 s, 4 H, Ar–*H*). ^{31}P NMR: δ −3.4 (lit. [24] −3.4) [in C_6D_6: −4.6]. *Anal*. Calc. for $C_{23}H_{30}ClO_3P$: C, 65.63; H, 7.18. Found: C, 66.06; H, 7.49%.

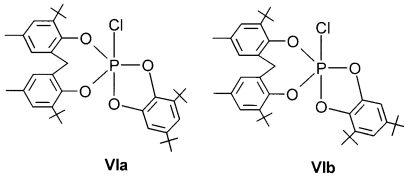
2.2.2. $CH_2\{6\text{-}t\text{-}Bu\text{-}4\text{-}Me\text{-}C_6H_2O\}_2P(O)(2,6\text{-}Cl_2\text{-}OC_6H_3Cl)$ (**8**)

Procedure same as for **7** using **5** [δ(P): 134.8] (0.432 g, 0.81 mmol) and ClN(*i*-Pr)$_2$ (0.222 g, 1.64 mmol). Yield: 0.30 g (67%). M.p. 226 °C. ^{1}H NMR: δ 1.34 (s, 18 H, C(CH_3)$_3$), 2.30 (s, 6 H, ArCH_3), 3.59 (d, $J = 14.2$ Hz, 1 H, CH_AH$_X$), 4.61 (dd, $J = 2.0$, 14.2 Hz, 1 H, CH$_A$$H_X$), 7.04–7.40 (m, 7 H, Ar–H). ^{31}P NMR: δ −21.7. *Anal*. Calc. for $C_{29}H_{33}Cl_2O_3P$: C, 63.62; H, 6.08. Found: C, 64.10; H, 6.15%.

2.2.3. $CH_2\{6\text{-}t\text{-}Bu\text{-}4\text{-}Me\text{-}C_6H_2O\}_2P(O)(NH\text{-}cycl\text{-}C_6H_{11})$ (**9**)

Procedure same as for **7** using **6** [δ(P): 141.5] (0.385 g, 0.82 mmol) and ClN(*i*-Pr)$_2$ (0.225 g, 1.66 mmol). Yield: 0.27 g (68%). M.p. 210 °C. ^{1}H NMR: δ 1.45 (s, 18 H, C(CH_3)$_3$), 1.47–1.49, 1.57–1.68 and 1.70–1.82, 2.15–2.25 (m each, 10 H, cyclohexyl –H), 2.29 (s, 6 H, ArCH_3), 2.95 (dd (?), $J = 9.3$, 13.0 Hz, 1 H, CH_AH$_X$), 3.38–3.58 and 3.50–3.85 (br m, 2 H, CHNH+CHNH), 4.16 (d, $J = 13.0$ Hz, 1 H, CH$_A$$H_X$), 7.21 (s, 4 H, Ar–$H$). ^{31}P NMR: δ −1.8. *Anal*. Calc. for $C_{29}H_{42}NO_3P$: C, 72.02; H, 8.75; N, 2.90. Found: C, 71.88; H, 8.81; N, 2.91%.

Obviously, hydrolysis had occurred in the formation of **7**–**9**. NMR tube experiments were performed in the case of **1** and **6** using C_6D_6 as the solvent at r.t. ^{31}P NMR spectra recorded immediately after the addition of ClN(*i*-Pr)$_2$ showed peaks at δ −15.2 and −38.6, respectively; these peaks may be ascribed to the pentacoordinate species $CH_2\{6\text{-}t\text{-}Bu\text{-}4\text{-}Me\text{-}C_6H_2O\}_2P(N\text{-}(i\text{-}Pr)_2)Cl_2$ and $CH_2\{6\text{-}t\text{-}Bu\text{-}4\text{-}Me\text{-}C_6H_2O\}_2P(N\text{-}(i\text{-}Pr)_2)(NH\text{-}cycl\text{-}C_6H_{11})Cl$, respectively. Over a period of 1–2 days, these peaks disappeared and new peaks at δ −4.6 (in the case of **1**) or −1.8 (in the case of **6**) appeared.



2.2.4. Reaction of **2** with 4-dimethylaminopyridine

Compound **2** (0.410 g, 0.63 mmol) was dissolved in heptane (20 ml) and 4-dimethylaminopyridine (0.154 g, 1.26 mmol) was added to it. The mixture was refluxed for 10 min, solvent removed in vacuo and benzene (carcinogen!) was added to the residue. After warming, the solution was filtered and the filtrate was concentrated to yield a microcrystalline solid (0.130 g). M.p. 206–208 °C. ^{1}H NMR (C_6D_6): δ 1.12 and 1.42 (s each of equal intensity, (18+18) H, C(CH_3)$_3$), 2.05 and 2.12 (s each of equal intensity, (6+6) H, ArCH_3), 3.24 and 3.52 (d each, $J \sim 16.0$ Hz, (1+1) H, CH_AH$_X$), 4.68, 5.21 (dd each, $J \sim 4.0$, 16.0 Hz, (1+1) H, CH$_A$$H_X$), 6.79–7.17 (many lines, (4+4) H, Ar–H). ^{31}P NMR: δ −19.6, −58.1. Due to the moisture sensitive nature, elemental analysis was not taken.

X-ray data were collected on an Enraf-Nonius-MACH3 X-ray diffractometer at 293 K using Mo Kα ($\lambda = 0.71073$ Å) radiation and capillary mounting. The structures were solved by direct methods; [25] all non-hydrogen atoms were refined anisotropically. For the hydrogen atoms bonded to carbon, the riding model was used. The hydrogen atom bonded to the hydroxyl oxygen was located in a difference map. The crystal data are summarized in Table 1.

3. Results and discussion

Compound **2** is synthesized by the oxidative addition of *o*-chloranil to the corresponding phosphite $CH_2\{6\text{-}t\text{-}Bu\text{-}4\text{-}Me\text{-}C_6H_2O\}_2PCl$ (**1**). The ^{31}P NMR chemical shift value confirms that the pentacoordinate structure is preserved in solution (more details discussed below) [8,22]. This compound is quite susceptible towards hydrolysis and exposure to air leads to the hydrolyzed product **3**. Although the reaction of **1** with benzil and 9,10-phenanthrenequinone did not yield any identifiable pentacoordinate compound even upon heating, the reaction with 3,5-di-*t*-butyl-*o*-benzoquinone afforded the moisture sensitive pentacoordinate compound **4**. Two isomers **VIa** and **VIb** differing in the connectivity of oxygens in the five-membered ring are possible, but only one signal is observed in the ^{31}P NMR [δ −41.3].

pounds with *N*-chlorodiisopropylamine [ClN(*i*-Pr)$_2$] is expected to be a pentacoordinate phosphorane with a P(*N*-*i*-Pr$_2$)(Cl) unit [26]. We felt that the sterically hindered eight-membered ring in our system would make it possible to isolate stable species of this type and hence reacted the P(III) precursors $CH_2\{6\text{-}t\text{-Bu-4-Me-}C_6H_2O\}_2PX$ [X = Cl (**1**), 2,6-Cl_2-OC_6H_3 (**5**) and NH-*cycl*-C_6H_{11} (**6**)] with ClN(*i*-Pr)$_2$ (Scheme 1). Immediately after addition of ClN(*i*-Pr)$_2$, in the case of **1** or **6**, a peak is observed in the ^{31}P NMR at −15.2 or −36.6 ppm, respectively; this is ascribable to the corresponding pentacoordinate chlorophosphorane of type **VII**. However, this product rapidly hydrolyzed due to adventitious moisture, leading to the tetracoordinate compounds **7**–**9** as isolable products.

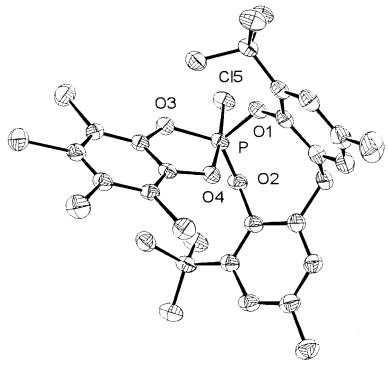
We have been interested in utilizing chlorophosphoranes such as **2** for further reactions. One of the reactions we checked was that of **2** with 4-dimethylaminopyridine to obtain a salt of the type $[CH_2(6\text{-}t\text{-Bu-4-Me-}C_6H_2O)_2P(O_2C_6Cl_4)(NC_5H_4\text{-}4\text{-}NMe_2)]^+[Cl]^-$ containing a P–N bond. In this reaction (done in heptane), the hygroscopic solid obtained had two peaks of equal intensity in the ^{31}P NMR [δ −58.1, −19.7] and the peaks corresponding to the 4-dimethylaminopyridine moiety were not seen in the ^{1}H NMR. Although it is difficult to ascertain the exact structure of this product, it appears to be a species with one phosphorus tetracoordinated and the other pentacoordinated [27,28].

3.1. Structural aspects

The molecular structures of **2** and **3** are depicted in Figs. 1 and 2, respectively. Relevant bond parameters for these two and **1** [29] are given in Table 2. The geometry around phosphorus in **2** can be considered to be essentially a TBP based on the O–P–Cl angle; the chlorine occupies an apical position. The eight-membered 1,3,2-dioxaphosphocin ring spans two of the three equatorial positions. The high electronegativity of chlorine coupled with the flexible nature of the phosphocin ring is thus responsible for the chlorine occupying the apical position.

The P–O bond distances of the eight-membered ring in **2** and **3** are similar but longer than what is observed in

Scheme 1.



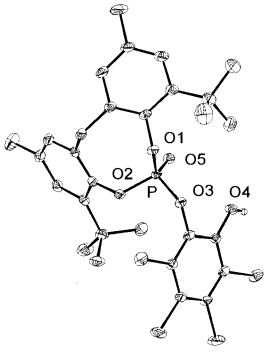


Fig. 1. An ORTEP drawing of **2** showing all non-hydrogen atoms.

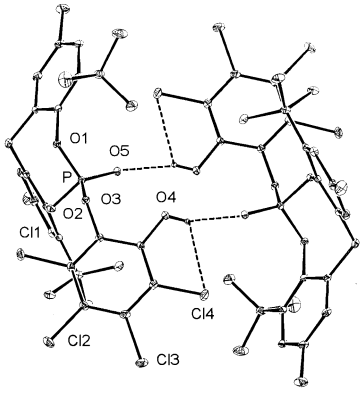

Fig. 2. An ORTEP drawing of **3** showing all non-hydrogen atoms and the OH hydrogen; shown at the bottom is the hydrogen-bonded dimer structure.

the tricoordinate compound **1**. The P–O distances of the five-membered ring are longer than those of the eight-membered ring. The P–Cl distance in **2** is longer than that observed in many other spirocyclic chlorophosphoranes with trigonal bipyramidal geometry, [13,15–18] but this is to be expected since the chlorine in **2** is apically located and such apical bonds are expected to be longer because of the 3c–4e bonds associated with them [30]. The ring angle O(1)–P–O(2) increases in the order: **1** (tricoordinate) < **3** (tetracoordinate) < **2** (pentacoordinate with diequatorial placement). While the

[b] Other angles at phosphorus: O(5)–P–O(1) 115.3(1); O(5)–P–O(3) 119.69(12).

[c] Data for **1** taken from Ref. [29]. We also had performed an X-ray study of this compound; although the *R* values are slightly better in our case the bond parameters are essentially the same as reported.

smaller value in **1** may be attributed to the lone pair on phosphorus trying to occupy more space, the higher value in **2** may be due to the equatorial placement of the eight-membered ring. What is perhaps noteworthy is the flexiblility of this angle (a range of ca. 15° while going from the tricoordinate compound **1** to the pentacoordinate compound **2**).

The eight-membered 1,3,2-dioxaphosphocin ring (Fig. 3) has a boat-chair conformation in **1**–**3**. This feature in **2** is analogous to what was observed by us before when

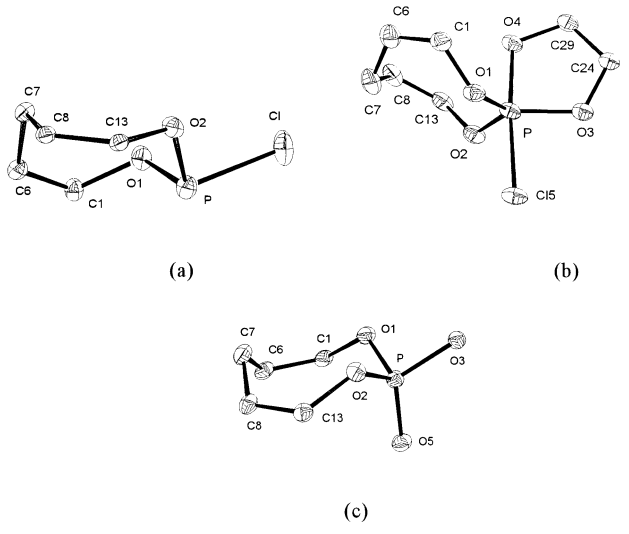

Fig. 3. Selected atoms, highlighting the placement of the substituents on phosphorus and conformation of the eight-membered 1,3,2-dioxaphosphocin ring in (a) **1**, (b) **2** and (c) **3**.

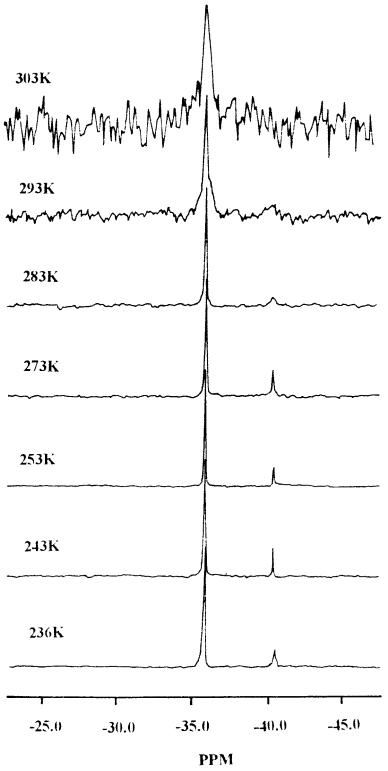
this ring is located diequatorially in a trigonal bipyramidal arrangement [22]. However, for **3**, the boat-chair conformation observed is opposite to that found in the phosphite $CH_2\{6\text{-}t\text{-Bu-4-Me-}C_6H_2O\}_2P(O)H$, [31] phosphate $CH_2\{6\text{-}t\text{-Bu-4-Me-}C_6H_2O\}_2P(O)(OH)$, [32] or the cyclophosphazene $N_4P_4[(4,6\text{-}t\text{-Bu}_2\text{-}C_6H_2O)_2\text{-}CH_2]Cl_6\cdot 1/2C_4H_8Cl_2$ [33]. As can be seen from Fig. 4, it is difficult to define the placement of the other substituents on phosphorus with respect to the eight-membered ring (a–e in the familiar organic terminology). In the tetra-coordinate compound **3** the oxygen atoms O(3) and O(5) are at distances of 1.52 and −1.03 Å from the O(1)–P–O(2) plane; in **1** the chlorine is at 2.028 Å from this plane. In **2**, the atom O(3) is slightly (0.19 Å) away from the O(1)–P–O(2) plane.

Compound **3** exists as a hydrogen-bonded dimer involving O(4)–H and the phosphoryl oxygen O(5) in the solid state [Fig. 2(b)]. However, the O(4)–H(O4)···O(5) angle of 158(4)° is quite far from the expected 180° for a normal hydrogen bond; it is also observed that H(O4) is pretty close to Cl(4) [3.014 Å] of the tetrachlorocatecholate residue although it could have tilted away from this chlorine. This feature, in addition to the lower O(4)–H(O4)···O(5) angle probably suggests that this is a three-center (bifurcated) hydrogen bond [34]. The dimeric structure in **3** contrasts with the intramolecular structure as in **VIII** or intermolecular chain **IX** both of which are phosphates analogous to **3** [35,36].



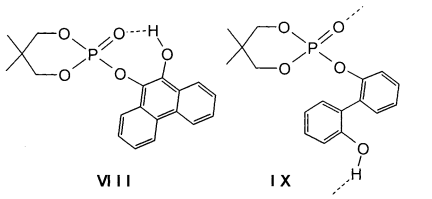


Fig. 4. Variable temperature ^{31}P NMR spectra for **2**.

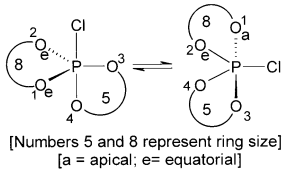

VIII (intramolecular; ref. 35) IX (intermolecular chain; ref. 36)

3.2. Variable temperature NMR behavior

The variable temperature ^{31}P NMR spectra of **2** are shown in Fig. 4. At low temperatures two signals at δ(P) values −35.8 and −40.3 are observed and at >283 K only one peak [δ(P): −35.8] in the pentacoordinate region is observed. We have reported the observation of two ^{31}P NMR signals in compounds of the type CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2P(X)(O_2C_6Cl_4)$ [X = Ph, Me, NMe_2 (<253 K)] [22]. As regards ^{1}H NMR, at 243 K two signals of unequal intensity for the *t*-Bu-*H* [δ 1.10 (minor), 1.32 (major)] as well as ArCH_3 [δ 2.00(major), 2.10 (minor)] protons are observed. In the ArCH_AH_X region the signals for the minor isomer are mostly buried in those due to the major isomer. At 293 K, only one broad signal each for the *t*-butyl and ArCH_3 protons is observed at δ 1.32 and 2.00, respectively. Unfortunately, at higher temperatures (>293 K) decomposition occurred leading to other signals [this is corroborated by ^{31}P NMR at 323 K which showed a signal at −14.5 ppm in addition to the one due to the pentacoordinate peak at −35.8 ppm].

We assign the downfield signal/s in the ^{31}P NMR spectra of **2** to the Cl(apical) isomer and the upfield signal to the Cl(equatorial) isomer on the basis of observations made in the case of CH_2(6-*t*-Bu-4-Me-$C_6H_2O)_2P(X)(O_2C_6Cl_4)$ [X = Me, NMe_2] [22]. Interconversion between these two isomers is possible through the e–e↔ a–e Berry exchange process for the eight-membered ring with O(2) as the pivotal position (Scheme 2). A similar process involving the five-membered ring would involve much higher energy. In the process shown in Scheme 2, the local environment at phosphorus is likely to change significantly [O(1)–P–O(2) angle could vary from 118.0° in the e–e isomer to approximately 90° in the a–e isomer; there will also be significant changes in the P–Cl bond lengths] and hence the ^{31}P NMR chemical shifts can be expected to show a wide difference for the two isomers. The other point is the unequal population of the two isomers; a rationale for this may come through if the individual isomers can be independently isolated.

Scheme 2.

4. Summary

We have provided here an example of a spirocyclic pentacoordinated phophorane with chlorine at the apical site of a TBP; in previous examples of spirocyclic chlorophosphoranes chlorine had occupied either an equatorial site of a TBP or an apical site of a rectangular pyramid. The low temperature ^{31}P NMR spectra for **2** show two signals of unequal intensity; such an observation has not been made in the previously known chlorophosphoranes. A dimeric formulation for the hydrolysis product of **2** involving O–H···O and possible O–H···Cl interactions is described. Thus, this study has further expanded our understanding of the structural preferences of pentacoordinate phosphorus, which in turn is important in the context of nucleophilic substitution reactions at a tetrahedral phosphorus(V) center.

5. Supplementary data

Supplementary data as cif files are available from the CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) on request, quoting the deposition numbers CCDC 171595 and 171596.

Metal–metal bonding trends in mixed-group, face-shared d^3d^3 bioctahedral dimer systems, $M'M''Cl_9^{n-}$

Simon Petrie, Robert Stranger *

Department of Chemistry, The Australian National University, Canberra, ACT 0200, Australia

Received 14 October 2001; accepted 21 March 2002

Abstract

The results of density functional theory (DFT) calculations on a set of binuclear nonachloride complexes $M'M''Cl_9^{4-}$ ($M' = V$, Nb, Ta; $M'' = Cr$, Mo, W) and $M'M''Cl_9^{2-}$ ($M' = Cr$, Mo, W; $M'' = Mn$, Tc, Re), in which each metal possesses a nominal d^3 valence electronic configuration, are reported. When compared with previous studies on same-group dimers (typified by the $M'M''Cl_9^{3-}$ complexes of the chromium triad), the present results display an increased tendency for electron donation from M′ to M″. Structural trends evident for the $M'M''Cl_9^{4-}$ and $M'M''Cl_9^{2-}$ series of dimers are remarkably consistent: weak ferromagnetic coupling between M′ and M″ is the most favorable intermetallic interaction when M″ is a first-row transition metal, antiferromagnetic coupling dominates when M′ is first-row but M″ is second- or third-row, and metal–metal triple bond formation generally yields the lowest-energy structure when neither metal is first-row. These structural trends, and other characteristics of the dimers described here, can be satisfactorily rationalized in terms of the tendency for electron transfer from M′ to M″, coupled with effects due to spin polarization and ligand field splitting of the valence d orbitals on M′ and M″. © 2002 Elsevier Science Ltd. Keywords: DFT calculations; Dinuclear transition metal complexes; Electron transfer; Magnetic coupling; Metal–metal bonding; Spin polarization

1. Introduction

In previous studies [1–7], we have employed DFT to examine metal–metal interactions within face-shared octahedral dimers of the generic formula $M'M''Cl_9^{n-}$. Such dimers exhibit a continuum of metal–metal bonding tendencies ranging from essentially nonbonded to triply bonded structures [8–10]. The broken-symmetry (BS) density functional technique [11] has been found to be especially useful as a method for probing intermetallic interactions in these systems, as is typified by calculations upon the dimers of the Cr(III) triad [1–3]. BS minima corresponding to a weakly coupled structure for $Cr_2Cl_9^{3-}$, possessing a long Cr–Cr separation of 3.22 Å, and a triply-bonded structure for $W_2Cl_9^{3-}$ with a short W–W separation of 2.40 Å, are in excellent agreement with the experimentally determined metal–metal distances in these complexes, and BS calculations on many other complexes also show generally good agreement with experiment.

A feature of the previous studies on same-group d^3d^3 dimers [1–4,6] has been the consistent correlation evident between the energy associated with metal–metal orbital overlap, E_{ovlp}, and the spin polarization (exchange) energy E_{SPE} favoring localization of electrons on the metal centers. Given the very strong correlation between E_{ovlp} and E_{SPE} for same-group dimers of the V, Cr, and Mn triads [2,12], we were motivated to determine whether this correlation was exhibited also by mixed-group d^3d^3 dimers such as $VCrCl_9^{4-}$. While no examples are yet known of experimentally-isolated mixed-group, face-shared complexes, both mixed-valence (e.g. $W(III)W(IV)Cl_9^{2-}$, $[Bu_3P]_3RuCl_3$-$RuCl_2PBu_3$) [13–15] and heterobimetallic (e.g. $CrMoCl_9^{3-}$) [16] face-shared bioctahedra have been structurally characterized, as have a large number of mixed-group bimetallic complexes involving macrocyclic or other bridging ligands. Several studies on such families of compounds have now shown [17–20] that the mode of magnetic coupling in such dimers is strongly

PII: S0277-5387(02)00999-3

dependent on the identity of the two metal atoms. In a preliminary study of the $MW(III)Cl_9^{n-}$ (M = V(II), Cr(III), Mn(IV)) dimers [21], we noted that the lowest-energy structure undergoes a switch from markedly antiferromagnetic ($VWCl_9^{4-}$) to ferromagnetic ($MnWCl_9^{4-}$) coupling, and that this tendency is consistent with the relative magnitudes of spin polarization and ligand-field splittings of the valence d-orbitals on the nominally more highly oxidized metal atom in each case (i.e. respectively, W(III) and Mn(IV)). By surveying a significantly larger group of mixed-metal complexes, the present study affords an opportunity to further test the influence of electron transfer on the mode of magnetic coupling, and on the broader structural characteristics of mixed-group dimers [22].

2. Computational details

All calculations described in this work were performed on Linux-based Pentium III 600 MHz computers using the Amsterdam Density Functional (ADF) program, version ADF-1999 [23], developed by Baerends et al. [24]. All calculations employed the local density approximation (LDA) to the exchange potential [25,26], and the correlation potential of Vosko, Wilk, and Nusair [27], since previous [3,28] and ongoing [29] studies on other anionic metal dimers have shown that this DFT method performs particularly well for the purposes of characterizing the metal–metal interaction in such species. Basis sets for all atoms were triple-ζ quality Slater type orbitals (Type IV). Electrons in orbitals up to and including 2p {Cl}, 3p {V, Cr, Mn}, 4p {Nb, Mo, Tc}, and 4f (but excluding 5s and 5p) {Ta, W, Re} were treated in accordance with the frozen-core approximation. Test calculations, using smaller frozen cores for the various metals, were also performed but were found to yield very minor differences to the fully optimized geometries (with one exception, discussed within the text). Optimized geometries were obtained using the gradient algorithm of Versluis and Ziegler [30]. Calculations for the BS state, $S = 0$, 2, and 3 associated states, and the 'reference state' were performed in C_{3v} symmetry; all such calculations, except for the reference state, were spin-unrestricted. BS calculations employed an asymmetry in the initial spin densities upon the two metal atoms [11]. Potential energy curves for all pertinent states were obtained by optimization of all other structural parameters for the dimers along a series of fixed metal–metal separations.

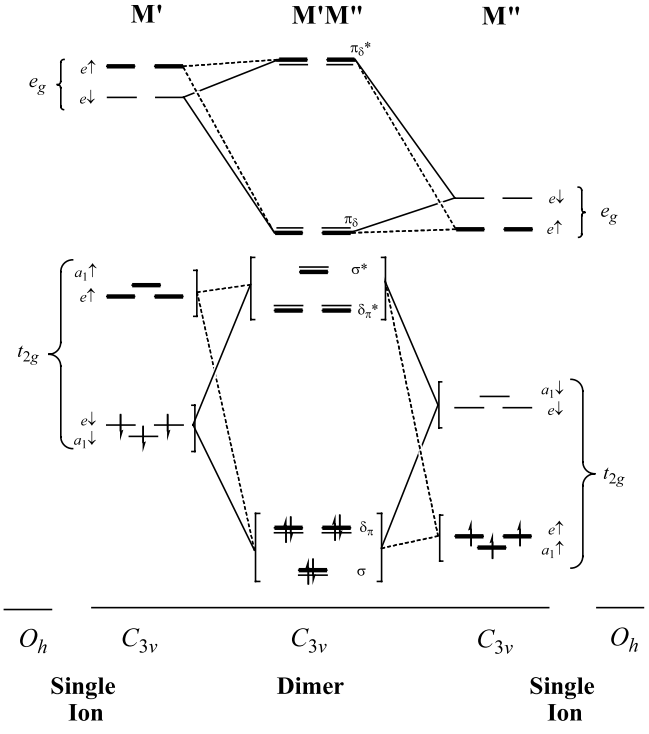

Fig. 1. Representation of localized and delocalized limits for the $S = 0$ BS state of a heteronuclear dimer $M'M''Cl_9^{n-}$. Orbitals are labelled according to the representations of the C_{3v} point group. The energetic ordering of the t_{2g}-derived and e_g-derived orbitals on the two metal atoms permits weak antiferromagnetic coupling, and a d^3d^3 occupation, as the lowest-energy electronic configuration at large intermetallic separations.

3. Results and discussion

3.1. Orbital energies, d-orbital occupancy, and intermetallic interactions: an overview

In a bioctahedral complex $M'M''X_9^{n-}$, the reduction in symmetry (from O_h to C_{3v}) around each metal atom results in a splitting of the t_{2g} orbitals depending on their orientation with respect to the metal–metal axis. Fig. 1 illustrates this principle for a heteronuclear bimetallic complex, depicting both the nonbonded and the triply-bonded limiting cases for the BS state. Due to the disparity between atomic orbital (AO) energies on M′ and M″, the interaction between metal atoms is expected to involve a degree of electron transfer: in the scenario shown here (which is reasonably representative of the species studied in the present work), the imbalance between the orbital energies of M′ and M″ is significant but insufficient to override a d^3d^3 minimum-energy configuration. In the nonbonded case, the t_{2g} orbital splitting produces the symmetry-distinct subsets a_1 and e which have σ and δ_π symmetry ($2/3\delta$, $1/3\pi$), respectively, with reference to the intermetallic axis; stabilization by antiferromagnetic coupling is associated with the splitting of the α- and β-spin orbitals by spin polarization on each metal center. Interaction between the a_1 and e orbitals on neighboring metal centers, for close M–M distances, produces σ, σ*, δ_π and δ_π^* orbitals: here the stabilization results from the energetic

separation between bonding and antibonding orbitals. In the example shown in Fig. 1, stabilization by metal–metal 'polar covalent' bonding exceeds the stabilization offered by antiferromagnetic coupling, and so M–M triple bond formation is favored in this case; but the balance between M–M bond formation and coupling of localized electrons is sensitive to several factors, as we have previously discussed [3].

The tendency to adopt a triply-bonded, singly-bonded, or nonbonded configuration of the two metal centers with increasing M′–M″ separation is most conveniently assessed by comparing three associated pure spin states $S = 0$ (triple bond between M′ and M″, no net excess of α-spin electrons), $S = 2$ (single σ-bond between metals, four α-spin electrons aligned in δ_π and δ_π^* orbitals) and $S = 3$ (no net bonding interaction between metals, six α-spin localized electrons aligned in σ, δ_π, δ_π^*, and σ* orbitals) Orbital occupancies for the $S = 0$, 2, and 3 associated states, and for the hypothetical 'reference state' representing the absence of any stabilization associated with either metal–metal bonding or spin polarization, in which the σ, δ_π, δ_π^*, and σ* orbitals are all half-filled in a spin-restricted calculation [2] are depicted in Fig. 2.

In the discussion which follows, we identify the general bonding trends evident within the set of mixed-group dimers before examining key structural and electronic features of particular dimers. The notation M′ and M″ is used throughout to distinguish between the less highly oxidized (M′) and more highly oxidized (M″) metal atoms within a given mixed-group dimer. We also adopt the convention, pertinent to discussion of electronic configurations and modes of bonding encountered in the $S = 2$ and BS minima, that the unpaired spin density on M″ is always positive (i.e. a net α-spin excess) or zero.

It is perhaps also appropriate to justify the DFT methodology employed in the present study. DFT methods incorporating nonlocal ('gradient') corrections to the exchange and correlation functionals, such as B-LYP, are generally regarded as superior to LDA in their ability to reliably characterize the structural and energetic properties of main-group compounds. There is, however, a sizeable number of studies which have shown that, for certain classes of transition metal compounds (including tetranuclear metal carbonyls [31], mononuclear anionic hexahalide [32] and tetraoxide [33] complexes, and dinuclear halide- [3,29] and oxo-bridged [28] complexes), LDA tends to outperform the gradient-corrected methods on structural, if not energetic, grounds. The transition metal compounds for which LDA performs best are often [32,34,35] but not exclusively [29,31,36–38] anionic species, and in this context the widely-acknowledged 'overbinding' propensity [39] of LDA may be considered to compensate for the absence of stabilizing counterions in these vacuum-phase calculations. While a more rigorous approach would be to pursue calculations including such stabilizing countercharges, either through explicit inclusion of the counterions themselves or via intercalation of point charges at appropriate sites, such calculations are often rather unwieldy (e.g. by not permitting full geometry optimization) or are otherwise subject to a tendency to overemphasize the target species–counterion interaction. In any event, these measures are most likely to influence the metal–*ligand* interaction, whereas it is the metal–*metal* interaction which is the principal focus of the present work; LDA's good performance in characterizing metal–metal interactions has most frequently been explored in the context of polyanionic dimers [3,28], but recent work [29] indicates that such interactions in neutral and cationic metal dimers are also (structurally) better described by LDA than by gradient-corrected methods. Note also that the use of LDA-optimized geometries with gradient-corrected single-point total energies—a combination which has been successfully adopted for several classes of transition metal compounds [31,32,34]—has not been found helpful in the present study, because of the propensity for the

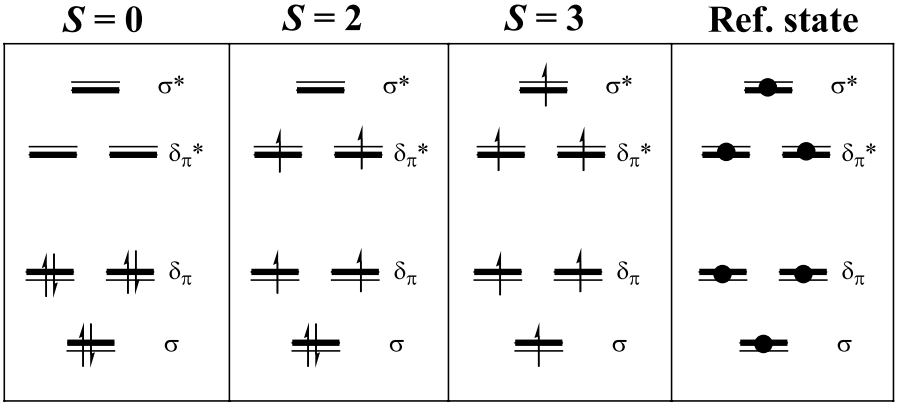

Fig. 2. Representation of t_{2g}-derived orbital occupancy for the $S = 0$, 2, and 3 associated states, and for the reference state, for a generic dimer $M'M''Cl_9^{n-}$.

gradient-corrected methods to favor inappropriately weak metal–metal interactions [3].

3.2. Overall results of calculations upon the mixed-group dimers

Table 1 summarizes the key structural and energetic parameters obtained for the minima of the $S = 0$, 2, and 3 associated states as well as their energies relative to that of the BS minimum for each of the mixed-group dimers.

The spin density calculated for the individual metal atoms is a further diagnostic tool offering useful insights into the electronic structure of the mixed-group dimers. In Table 2, we provide 'covalency-corrected' Mulliken spin densities[40] determined for M′ and M″ for the optimized minima upon the $S = 2$, $S = 3$, and BS potential energy surfaces.

3.3. Trends evident in the $M'M''Cl_9^{n-}$ broken–symmetry potential energy curves

The BS calculations on the mixed-group dimers reveal a trend which is broadly consistent with that already seen for the same-group d^3d^3 $M'M''Cl_9^{n-}$ dimers: that is, dimers in which M′ or M″ is a first-row transition metal (or both M′ and M″ are first-row) exhibit weak antiferromagnetic coupling between M′ and M″ (as evidenced by the unpaired spin densities on the two metal atoms) in complexes characterized by typically large (3.0–3.3 Å) intermetallic separations [41], while dimers in which both M′ and M″ are second- or third-row transition metals yield BS minima characterized by multiple metal–metal bonding (and $\rho_{spin} = 0$ on each metal) and hence small intermetallic distances.

One other result of the calculations deserves comment. For all of the $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$ complexes we find that the BS minimum is not the lowest energy structure: ferromagnetic coupling of M′ and M″ is favored over antiferromagnetic coupling, as diagnosed by the negative E_{rel} value (see Table 1) for the $S = 3$ minimum [41]. This result, which extends our previously reported finding of a ferromagnetically coupled global minimum for $WMnCl_9^{2-}$ [21], is exemplified in Fig. 3, which shows the $S = 0$, 2, 3 and BS potential energy curves for the $TaCrCl_9^{4-}$ dimer. We shall return later below to this 'reversal' of the $S = 3$ and BS minimum energies.

When M″ is not first-row, as noted above, the BS minimum is the lowest-energy species found. In such complexes, weak antiferromagnetic coupling is indicated when the less highly oxidized metal, M′, is first-row, with triple M′–M″ bond formation occurring when M′ is second- or third-row. Potential energy curves for $VMoCl_9^{4-}$ and $NbMoCl_9^{4-}$ (Fig. 4) nicely illustrate the influence of M′ upon the location of the BS minimum: for the V/Mo complex, and similarly V/W (not shown), the $S = 0$, 2 and 3 curves possess minima which are

[a] Covalency-corrected values. The method of covalency correction is described within the text.
[b] Spin densities for the octahedral complexes; these values are not covalency-corrected.
[c] Results for BS(2). For BS(1), values of −1.93 (Ta) and +2.12 (Cr) are obtained.

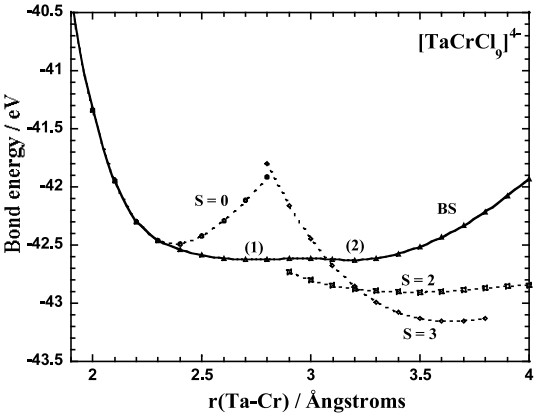

Fig. 3. Potential energy curves for BS and associated states of $TaCrCl_9^{4-}$. Note the presence of two distinct minima (1) and (2) on the BS PES, corresponding to (1) singly-bonded and (2) weakly-coupled metal atoms.

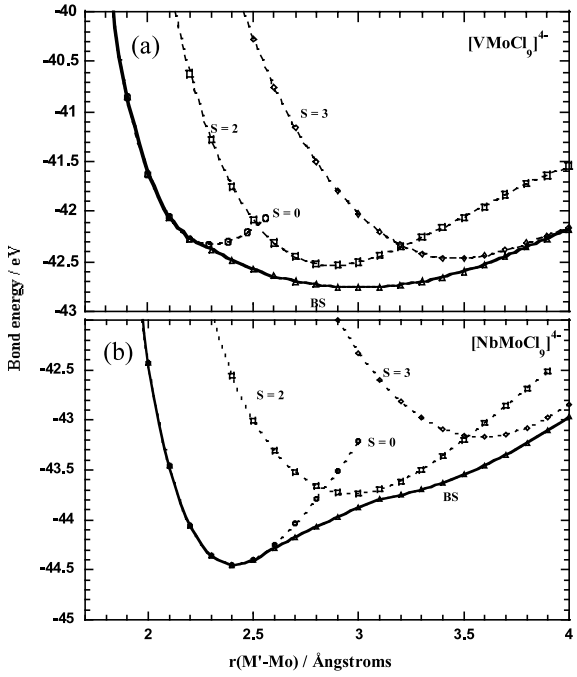

Fig. 4. Potential energy curves for BS and associated states of (a) $VMoCl_9^{4-}$ and (b) $NbMoCl_9^{4-}$. As noted in the text, curves displayed here were obtained with the frozen core on V comprising 1s, 2s, and 2p orbitals, while the frozen cores on Nb and Mo contained all AOs up to 3d.

remarkably close in energy, resulting in a notably shallow BS potential energy curve with a minimum somewhat intermediate between $S = 2$ (σ-bonded) and $S = 3$ (non-bonded), while for the Nb/Mo analogue the $S = 0$ curve is very significantly stabilized (and $S = 2$ to a lesser degree) relative to $S = 3$, due to better overlap between Mo(III) and the larger Nb(II) d orbitals.

A technical point should also be noted with regard to Fig. 4. In this figure we have employed the V '2p' and Nb/Mo '3d' basis sets, where the orbital subshell specifies the highest-lying orbital within the metal atom's frozen core: this approach of 'thawing' the frozen core was found necessary to delivery physically reasonable behavior (i.e. evident repulsion between metal atoms) at intermetallic separations significantly shorter than that of the $S = 0$, 'triply bonded' minimum. This difficulty with the standard (i.e. V '3p' and Nb/Mo

'4p' frozen core) basis sets appears to be important only for M′–M″ separations shorter than those in any of the minima: in only one instance ($VCrCl_9^{4-}$, $S=2$) was there a significant divergence between the 'thawed' (2.97 Å) and 'standard frozen core' (3.3 Å) optimized metal–metal distances. There was no significant difference between 'thawed' and 'standard frozen core' relative energies for the $S=0$, 2, 3, and BS minima for any species.

3.4. Stabilization of ferromagnetic coupling in $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$

For each of the $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$ dimers, the $S=3$ minimum has a total energy lower than that of the BS minimum; furthermore, for M′M″=NbCr, TaCr, and WMn, the $S=2$ structure is also lower in energy than BS, but above $S=3$. The relative energies of the $S=3$ and BS minima indicate that the $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$ dimers are ferromagnetically, rather than antiferromagnetically, coupled. We examine this issue in the molecular orbital (MO) diagrams for $VCrCl_9^{4-}$ and $TaCrCl_9^{4-}$, in Figs. 5–7. These figures also incorporate bar charts indicating the contributions of metallic valence AOs to the key occupied MOs in our DFT calculations.

For the $S=3$ associated state of $VCrCl_9^{4-}$ (Fig. 5), the α-spin $10a_1$, $11a_1$, 13e, and 14e MOs arise from the valence V and Cr AOs, and detailed examination of the composition of these MOs reveals that, for the most part, they remain effectively localized upon either V ($11a_1$) or Cr ($10a_1$ and 13e) with no contamination from the other metal atom. The exception here is the 14e orbital, which is best described as being derived from the V δ_π-symmetry AOs but with significant contamination by the α-spin Cr e_g orbital, which accounts for about 20% of the metal-based character for α-spin 14e. The mixing between the α-spin V δ_π and Cr e_g AOs acts to lower the energy of the 14e MO pair (with a concomitant increase in the energy of the similarly mixed, unoccupied, α-spin 15e MO pair), helping to stabilize the ferromagnetic coupling of the $S=3$ associated state. Furthermore, it is the α-spin 14e level which effectively provides a conduit (by way of the V/Cr AO mixing) for electron transfer from V to Cr in the $S=3$ minimum.

The large metal–metal distance in the BS $VCrCl_9^{4-}$ minimum is consistent with weak antiferromagnetic coupling between V and Cr. Here the valence electrons on V are of opposite spin to those on Cr, and the large spin polarization energies found for each of these first-row TMs (and lower orbital energies for Cr than for V) result in a very large energy separation between the occupied α-spin Cr AOs and the unoccupied vanadium AOs of the same spin. There is thus very little mixing between V and Cr in the α-spin valence MOs, which can be regarded as virtually pure metallic AOs. In contrast, the β-spin AOs on V and Cr are fairly close in energy, and rather more mixing is seen between these: the occupied β-spin $10a_1$ MO is dominated by V, but also significantly contaminated by Cr, $3d_{z^2}$ character, with a

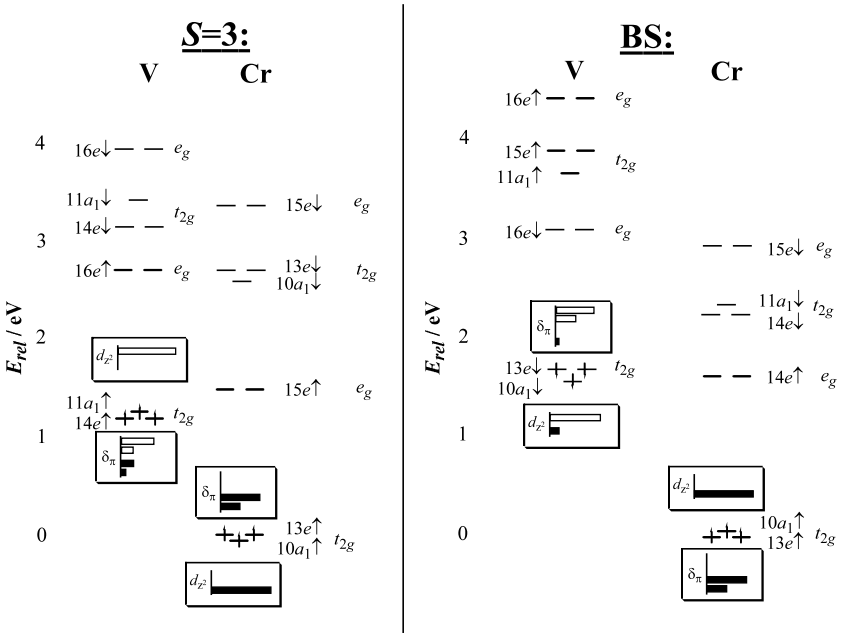

Fig. 5. Electronic configurations of the $S=3$ and broken symmetry minima of $VCrCl_9^{4-}$. In this and subsequent electronic configuration diagrams, the MOs shown, which are labelled according to their hierarchy (excluding 'frozen core' orbitals), are those identified as arising principally from the valence-d AOs of the metal atoms. Metal AO contributions to the occupied MOs are shown as overlaid bar charts, with M′ shown as outlined (white) bars and M″ as filled (black) bars; for a_1- or σ-symmetry MOs, only d_{z^2} content is shown, while for e-symmetry orbitals, the two bars depicted for each metal are: upper bar, $d_{x^2-y^2}$ (or d_{xy}) content; lower bar, d_{xz} (or d_{yz}) content.

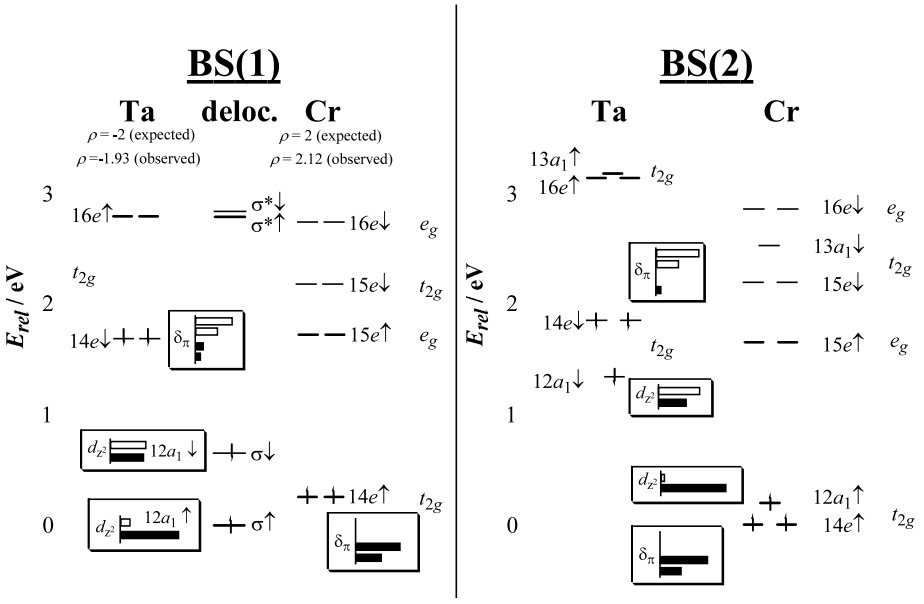

Fig. 6. Electronic configurations of the broken symmetry minima of $TaCrCl_9^{4-}$. The unoccupied α- and β-spin 17e MOs, which correspond to the Ta e_g AOs and which lie more than 1 eV above the highest-energy orbital depicted, are omitted. See Fig. 5 for an explanation of the orbital content bar charts.

converse weighting seen in the unoccupied $11a_1$ MO. Much less contamination is found for the occupied β-spin 13e and unoccupied 14e MOs, despite a similar energy separation, since the AOs concerned lack the direct alignment which exists between the $3d_{z^2}$ orbitals on the two metals. As with $S = 3$, the BS minimum also displays a degree of V → Cr electron transfer, but here it is the β-spin $10a_1$ MO which provides the pathway for this electron migration. We can discern that the β-spin donation manifested in the BS minimum is a less effective method of M′ → M″ electron transfer than is the α-spin donation exhibited by $S = 3$, because the magnitude of the deviation in ρ_{spin} from the expected value of ± 3, on both M′ and M″, is larger for $S = 3$ than for BS (see Table 2). The relative extent of M′ → M″ electron transfer for these two configurations is also consistent with the relative energy separations of the V and Cr AOs involved in the electron transfer: the β-spin $10a_1/11a_1$ gap (implicated in the BS electron transfer) is significantly larger than the α-spin 14e/15e gap (involved in $S = 3$ electron transfer), indicating a greater impediment to electron transfer in the BS electronic configuration.

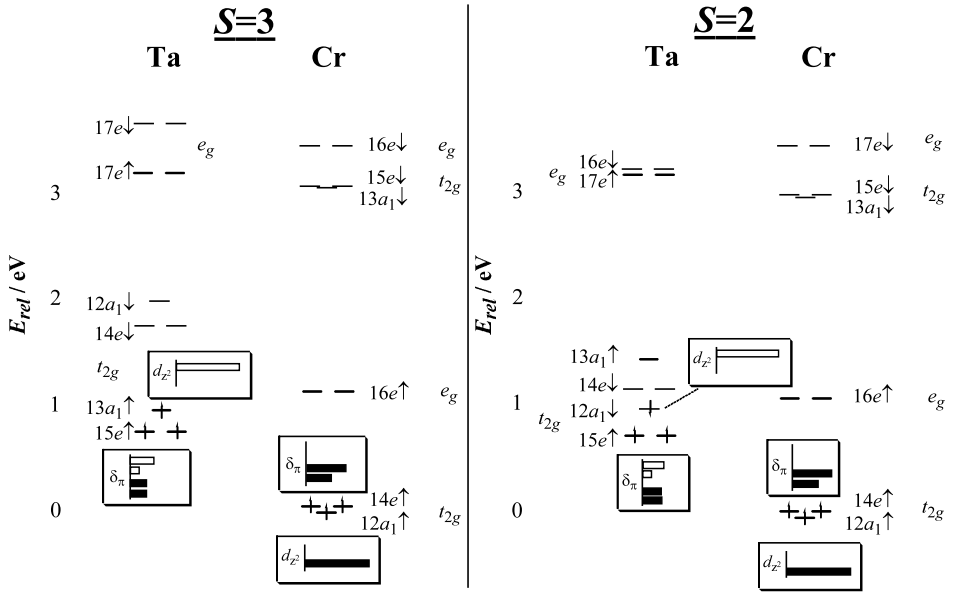

Fig. 7. Electronic configuration of the $S = 3$ and $S = 2$ minima of $TaCrCl_9^{4-}$. See Fig. 5 for an explanation of the orbital content bar charts.

The $TaCrCl_9^{4-}$ BS PES (see Fig. 3) has two local minima at $r(M–M) = 2.77$ Å (BS(1)) and 3.18 A (BS(2)); the two minima and the transition state separating them are all very close in total energy. The bond length for BS(1) is indicative of a Ta–Cr σ bond, while the intermetallic separation in BS(2)—which is marginally the global minimum on the BS surface—is consistent with a weakly coupled antiferromagnetic complex. The BS(2) Ta–Cr distance is also close to that seen in the ferromagnetically-coupled $S = 3$ minimum. Thus, whereas the V/Cr system can be considered a conflict between ferromagnetic and antiferromagnetic coupling, Ta/Cr represents a three-way contest between ferromagnetism, antiferromagnetism, and metal–metal bond formation. Superficial examination of the $TaCrCl_9^{4-}$ $S = 3$ valence MOs in Fig. 6 shows that, as expected, the spin polarization splitting of α- and β-spin orbitals on Cr is much greater than the ligand field splitting of t_{2g}-based and e_g-based orbitals, while for Ta the ligand field splitting is the dominant effect. What influence do these trends have upon the character of the valence MOs in the BS and $S = 3$ states?

For the BS (1) minimum of $TaCrCl_9^{4-}$ (Fig. 6), the M–M distance is suggestive of a metal–metal σ bond. This is reflected in the composition of the MOs, with the a_1-symmetry orbitals identifiable as more-or-less polar σ and σ* delocalized orbitals (the occupied α-spin $12a_1$ is dominated by Cr d_{z^2} character, while the corresponding β-spin $12a_1$ has only a slight excess of Ta d_{z^2} content over Cr) while the *e*-symmetry orbitals are essentially localized on Ta or Cr (although some Cr content is evident in β-spin 14*e*, due to mixing between the Ta and Cr β-spin δ_π-symmetry AOs). While there is clearly a significant degree of overall electron transfer from Ta to Cr, the contributions from α-spin transfer (via $12a_1$) and β-spin transfer (via 14*e*) are of comparable magnitude so that the calculated (covalency-corrected) spin densities on the two metals are very close to the values of −2 and +2, respectively, expected for a straightforward σ-bonded complex.

The longer-bonded BS (2) minimum (Fig. 6) is electronically very similar to BS V/Cr, with the occupied α-spin orbitals ($12a_1$ and 14e) identifiable as the essentially pure t_{2g}-based (σ and δ_π) chromium AOs, while the occupied β-spin $12a_1$ orbital in particular displays very severe mixing between Cr and Ta d_{z^2} AOs.

For the $S = 3$ minimum (Fig. 7), majority-spin $12a_1$, $13a_1$ and 14e occupied MOs display very little mixing between the constituent metal AOs, and these MOs thus correspond, respectively, as the valence Cr $3d_{z^2}$, Ta $5d_{z^2}$, and Cr δ_π-symmetry orbitals. In contrast, severe mixing is found for the α-spin (occupied) 15e and (unoccupied) 16e orbitals, such that these MOs contain virtually equal portions of Ta δ_π-symmetry and Cr e_g character. Since the two electrons occupying the 15e orbital are shared while the other valence electrons are localized, the $S = 3$ state can be considered as involving transfer of a full electron from Ta(II) to Cr(III), resulting in oxidation states of Ta(III) and high-spin Cr(II).

A common feature of the V/Cr and Ta/Cr $S = 3$ and BS minima is the tendency for electron transfer from the vanadium-triad metal to Cr (indeed, all of the various minima for the mixed-group $M'M''Cl_9^{n-}$ dimers show some electron transfer from M′ towards M″). This is the principal factor favoring ferromagnetic coupling when first-row M″ is the recipient of this electron donation: Cr and Mn both have a large spin polarization energy, and this is accentuated when the first-row M″ has an effective share of more than its nominal three valence majority-spin electrons. It is also notable that, while all of the $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$ dimers exhibit a preference for ferromagnetic coupling, no dimer with second- or third-row M″ does so. The lower stability of ferromagnetic coupling when, for example, Cr is replaced by Mo or by W, can be reconciled with the comparatively low spin polarization energies, and high ligand field splitting energies, seen for these larger metal ions. This observed trend is consistent with the mechanism by which we have already accounted for the stabilization of ferromagnetic coupling in $WMnCl_9^{2-}$ [21].

The relative energies of vacant α-spin (e_g) and β-spin (t_{2g}) orbitals on the nominally more highly oxidized metal M″ will help to determine the extent of electron transfer in the longbonded BS and $S = 3$ configurations, which we can gauge from the parameter $\Delta(\rho_{spin})$ as listed in Table 3. This parameter measures the deviation (from the value of $\rho_{spin} = 3$ expected in the absence of electron transfer) of the calculated covalency-corrected spin densities on M′ for the series of $M'M''Cl_9^{4-}$ and $M'M''Cl_9^{2-}$ having longbonded BS minima, and can be considered as a measure of the extent of α-spin ($S = 3$) or β-spin (BS) electron transfer from M′ to M″. We can see that, when M″ is first-row, $\Delta(\rho_{spin})$ is consis-

Table 3
Deviation of absolute covalency-corrected Mulliken spin densities on M′, from the expected value of $\rho_{spin} = 3$, for $S = 3$ and longbonded BS minima of $M'M''Cl_9^{n-}$

M′M″	$\Delta(\rho_{spin})$: $S = 3$ [a]	$\Delta(\rho_{spin})$: BS[a]

WMn	1.26	1.10

[a] $\Delta(\rho_{spin}) = 3 - |\rho_{spin}|$, where ρ_{spin} is the covalency-corrected value as listed in Table 1.

tently larger for $S=3$ than for BS, while when M″ is second- or third-row, $\Delta(\rho_{spin})$ is larger for BS than for $S=3$. This trend is broadly consistent with our expectations based upon the qualitative arguments presented above, and serves to reiterate the preference for ferromagnetic state stabilization by α-spin electron transfer for the $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$ dimers.

3.5. Competition between σ-bonding and electron transfer in the $S=2$ associated state minima

The $S=2$ minima for all of the $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$ dimers exhibit very large M–M separations, not greatly shorter than the $S=3$ values, and so an electronic configuration lacking significant σ-bond character appears to be indicated for the $S=2$ minima for these species. In such an $S=2$ minimum featuring purely localized d electrons, we would expect nominal ρ_{spin} values of 3 ($=3\alpha-0\beta$) and 1 ($=2\alpha-1\beta$) for the two metals. This expectation is not precisely met—$\rho_{spin}(M')<1$ and $\rho_{spin}(M'')>3$ for most of the $S=2$ $M'CrCl_9^{4-}$ and $M'MnCl_9^{2-}$ dimers—but examination of the d-orbital composition for these dimers (for example, $S=2$ $TaCrCl_9^{4-}$ in Fig. 7) indicates that the above description is otherwise fairly accurate. As seen in Fig. 7, the occupied α- and β-spin $12a_1$ orbitals are localized on Cr and Ta, respectively. There is negligible contamination of the (Cr δ_π) α-spin 14e, but significant contamination by Cr e_g AOs of the (nominally Ta δ_π) α-spin 15e MO pair. As with the $S=3$ configuration, the mixing between Ta and Cr in the α-spin 15e orbitals is so extreme that this MO pair in fact possesses about as much Cr content as Ta. It is instructive to contrast the $S=2$ structure and electronic configuration against those of the σ-bonded BS(1) minimum (Fig. 6), to which an $S=2$ associated state would normally be expected to conform. If a BS minimum exists for a σ-bonded dimer, why does the $S=2$ surface not also feature such a minimum?

The same factors which favor antiferromagnetic coupling in the $M'M''Cl_9^{n-}$ (M″ = first-row) dimers also favor $S=2$ associated states for these species which effectively lack any metal–metal bonding. Formation of a σ bond in the $S=2$ associated state of $M'M''Cl_9^{n-}$ (M″ = first-row) permits β-spin electron transfer towards M″ (via the polar M′–M″ σ bond) but mitigates against the spin-polarization stabilization of α-spin orbitals on M″. On the other hand, mixing of the α-spin M′ δ_π and M″ e_g AOs at longer M′–M″ separations provides a means for α-spin electron transfer (enhancing the M″ α-orbital stabilization due to spin-polarization splitting of α- and β-spin orbitals) without any requirement for M′–M″ bond formation. For $TaCrCl_9^{4-}$, it is this M′–M″ α-spin δ_π mixing which drives the elongation of the M′–M″ internuclear separation in the $S=2$ associated state compared with that of the BS(1) geometry.

Analysis of the MO composition also allows us to interpret the observation (see Table 2) that dimers having first-row M′ and second-or third-row M″ (e.g. $CrTcCl_9^{2-}$) are the only complexes in which the $S=2$ spin density on M′ exceeds that on M. A comparison between the Mo/Mn and Cr/Tc $S=2$ dimers is instructive. For Mo/Mn, we obtain $\rho_{spin}(M')$ and (M'') values of 1.05 and 2.87, respectively. For Cr/Tc the situation is reversed: $\rho_{spin}(M')=2.23$, while $\rho_{spin}(M'')=1.62$, a result which appears to run contrary to the expected general tendency of electron transfer from M′ to M″.

The spin density distortions described above arise from the different trends in d-orbital splitting for first-row versus second- and third-row transition metal atoms: ligand field splitting of the t_{2g} and e_g orbitals is significantly greater for second and third row transition metals, while splitting of the α and β orbital energies due to spin polarization is generally greatest for first row TMs. Thus, as reflected in the occupied $10a_1$ orbital compositions in Fig. 8, first-row M″ (e.g., in $S=2$ $MoMnCl_9^{2-}$) is a good α-spin electron acceptor but a poor acceptor of β-spin electron density due to its large spin polarization energy. Conversely, second- or third-row M″ (e.g. $S=2$ $CrTcCl_9^{2-}$) is much more able to accept β-spin, than α-spin, electron density by virtue of its ligand field splitting.

3.6. Overall comparison of $M'M''Cl_9^{4-}$ and $M'M''Cl_9^{2-}$ bonding trends

As noted above, the following statements on mixed-group $M'M''Cl_9^{n-}$ dimers are true for both the V(II)/Cr(III) ($M'M''Cl_9^{4-}$) and Cr(III)/Mn(IV) ($M'M''Cl_9^{2-}$) dimer families:

i) when M″ is first-row, the complexes have ferromagnetic lowest-energy configurations
ii) when M′ (but not M″) is first-row, lowest-energy configurations of the complexes exhibit weak antiferromagnetic coupling between M′ and M″
iii) when neither M′ nor M″ is first-row, complexes show a preference for multiple metal–metal bonding
iv) when M″ is first-row, $S=2$ minima have unexpectedly large M′–M″ interatomic distances, and appear deficient in M′–M″ σ bond character.

Notwithstanding these striking qualitative similarities between the V(II)/Cr(III) and Cr(III)/Mn(IV) families, which are generalized schematically in Fig. 9, there are some significant differences in detail. For example, the preference for ferromagnetic complexes is less marked for M″ = Mn than for M″ = Cr (stabilization of the $S=3$ $VCrCl_9^{4-}$ minimum relative to the antiferromagnetic

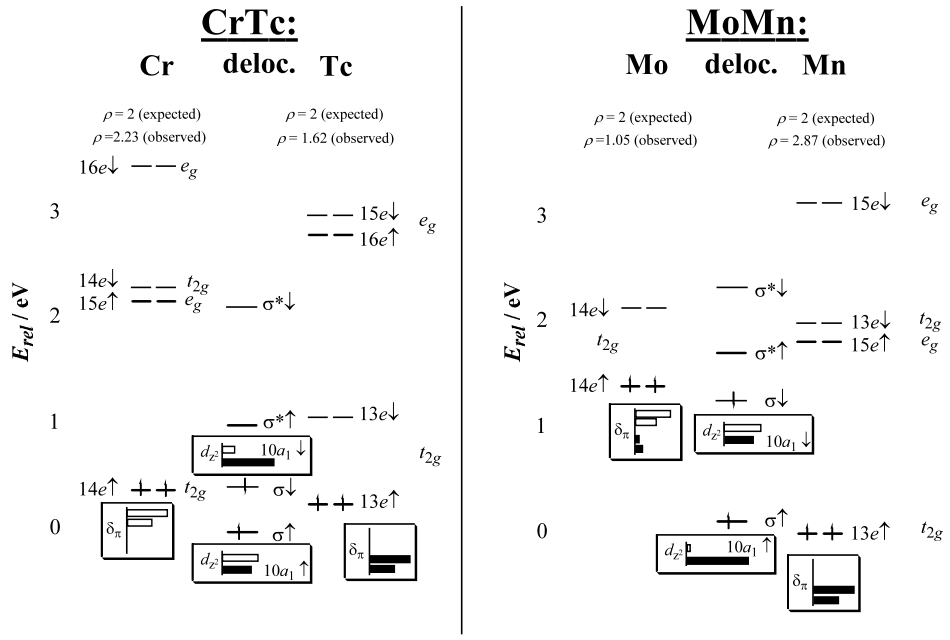

Fig. 8. Electronic configurations of the $S = 2$ minima of $CrTcCl_9^{4-}$ and $MoMnCl_9^{4-}$. See Fig. 5 for an explanation of the orbital content bar charts.

BS minimum is 0.17 eV, whereas the corresponding value for $CrMnCl_9^{2-}$ is only 0.01 eV) [22]. Moreover, we can examine the effect of 'transmuting' the metals such that M′ and M″ both retain their respective row numbers (for example, comparing $VMoCl_9^{4-}$ with $CrTcCl_9^{2-}$, since these are the two complexes having first-row M′ and second-row M″). In such a lateral comparison of the energetic trends across the V(II)/Cr(III) and Cr(III)/Mn(IV) families (see Table 4), it appears that the Cr(III)/Mn(IV) family is more inclined towards weakly-coupled dimers than is the V(II)/Cr(III) family: although the global minima numbers of triply-bonded and weakly-coupled dimers are the same for both families, the total energies of weakly-coupled dimers ($S = 2$, 3, and long M′–M″ bond BS minima) relative to their strongly-bonded counterparts ($S = 0$ minima) are consistently lower for Cr(III)/Mn(IV) mixed triad combinations than for the analogous V(II)/Cr(III) mixed triad combination. As with so many other trends amongst the $M'M''Cl_9^{n-}$ dimers, this observation can be rationalized according to d-orbital size: the larger the d orbitals upon M′ and M″, the greater the strength of any intermetallic bond, and the lower the spin polarization splitting of the valence orbitals of M′ and M″. It is also of interest to note that, while weakly-coupled ($S = 3$, long-bonded BS) and σ-bonded ($S = 2$) minima have generally *shorter* M′–M″ bonds for the Cr(III)/Mn(IV) family than for the V(II)/Cr(III) family, the triply-bonded ($S = 0$) minima exhibit the opposite trend: Cr(III)/Mn(IV) family M′≡M″ bonds are almost invariably *longer* than the corresponding examples from the V(II)/Cr(III) family, again under-

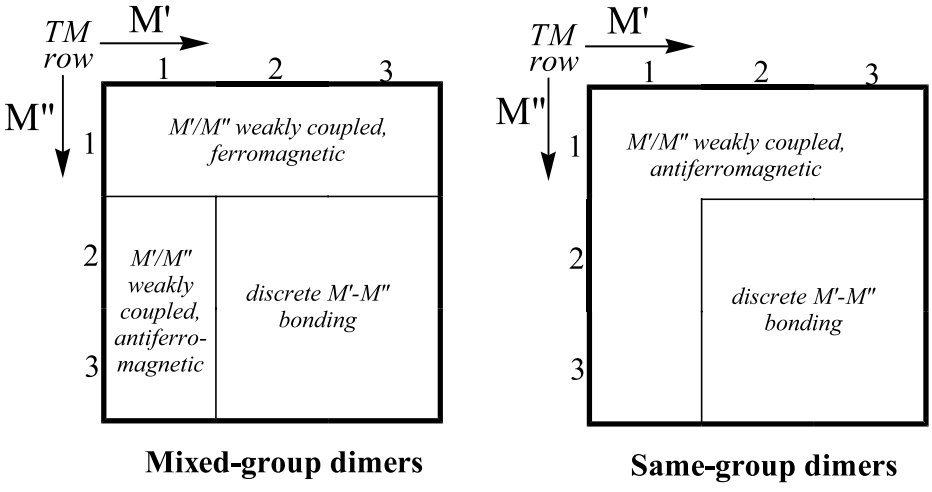

Fig. 9. A summary of metal–metal bonding trends evident for mixed-group and same-group d^3d^3 $M'M''Cl_9^{n-}$ dimers.

Table 4

[a] $\Delta(E_{rel,S=0}[S=2]) = (E[S=2]-E[S=0])_{V(II)/Cr(III)}-(E[S=2]-E[S=0])_{Cr(III)/Mn(IV)}$, where the subscripts V(II)/Cr(III) and Cr(III)/Mn(IV) denote the 'equivalent' family members sharing a given row of this table. The parameters $\Delta(E_{rel,S=0}[S=3])$ and $\Delta(E_{rel,S=0}[BS])$ are defined in an entirely analogous fashion.

[b] For these species, the BS minima are coincident with the respective $S = 0$ minima.

scoring the Cr(III)/Mn(IV) family's generally lower propensity for multiple bond formation via d-orbital σ and δ_π overlap.

3.7. The interplay between spin polarization and d-orbital overlap

Investigating the relationship between d-orbital overlap in the triple-bonded metal dimers, and spin polarization in the weakly antiferromagnetically coupled dimers, has been an important aspect of our previous studies on same-group dimers [1–6]. This has been parametrized in the terms E_{ovlp} and E_{SPE}, which are defined as $E_{ovlp} = E_{ref} - E_{S=0}$ and $E_{SPE} = E_{ref} - E_{S=3}$, where E_{ref}, $E_{S=0}$ and $E_{S=3}$ are the energies of the respective minima for the reference state, $S = 0$, and $S = 3$ associated state potential energy surfaces [2]. The significance of E_{ovlp} and E_{SPE} is that they provide a measure of the stabilization due to metal–metal bond formation through d-orbital overlap, and of stabilization due to spin polarization of localized d-orbital electrons. Plots of E_{ovlp} versus E_{SPE} for the same-group dimers of the Cr(III) and Mn(IV) triads have revealed a consistent linear trend [2]: a large E_{ovlp} value is associated with small E_{SPE} for a given dimer, and as E_{ovlp} is reduced, E_{SPE} increases. This is fully consistent with expectations, since d-orbital overlap leading to bond formation is most effective when the d orbitals are large, while spin polarization of the unpaired electrons is most significant when the d orbitals are small.

We have determined E_{ovlp} and E_{SPE} for the mixed-group dimers (see Table 5). When we analyze these parameters (see Fig. 10), we find that the correlation between E_{ovlp} and E_{SPE} is more-or-less maintained, but adherence to a linear relationship is much more poor for the mixed-group dimers than for their same-group counterparts. This is undoubtedly due, in part, to the effect of electron transfer towards the more highly oxidized metal, which will have a much greater distorting effect than any tendency for electron transfer within the same-group dimers. In this respect, it is worth noting that the most significant 'outliers' for the mixed-group families are, (i) the M′Cr and M′Mn species (where M′ is second- or third-row; labels 1 and 3 on Fig. 10), for which the data points are substantially above the best-fit lines for the respective families; and (ii) the VM″ and CrM″ (with M″ second- or third-row; labels 2 and 4 on Fig. 10), for which the data points lie well below the best-fit lines. Case (i) encompasses the most extreme

[c] $\delta_{SPE} = E_{SPE}(M'M'') - (E_{SPE}(M') + E_{SPE}(M''))$, expressed in eV.

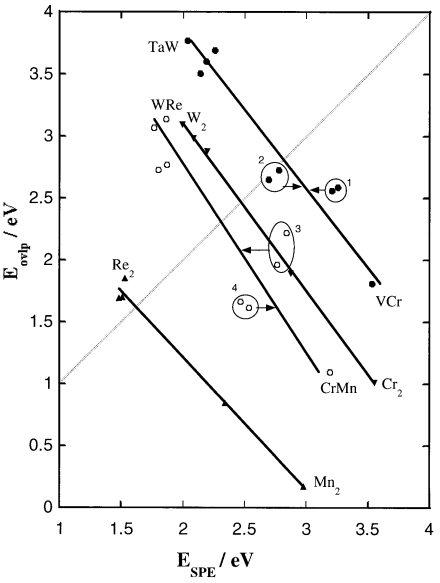

Fig. 10. Graph of E_{ovlp} vs. E_{SPE} (see text for definitions), for the V(II)/Cr(III), Cr(III)/Cr(III), Cr(III)/Mn(IV), and Mn(IV)/Mn(IV) families of $M'M''Cl_9^{n-}$ dimers. Best-fit lines show the general trend within each family, for which the 'terminal' members (i.e. first-row/first-row and third-row/third-row combinations) are labelled; also identified (as numbered ellipses) are groups of significant 'outliers' among the mixed-group dimers [1 = NbCr, TaCr; 2 = VMo, VW; 3 = MoMn, WMn; 4 = CrTc, CrRe]. The dotted line is the boundary between $S = 0$ and 3 absolute stability, which reflects the tendency of dimers to form either multiple metal–metal bonds (upper left section) or weakly coupled complexes (lower right section).

examples of ferromagnetic cf. antiferromagnetic stabilization for each family (in which electron density is transferred from M′ associated with a small spin polarization splitting, to M″ having a large characteristic spin polarization splitting), and we can assume that the effect of electron transfer for these systems is to enhance E_{SPE}; for case (ii), M′ has a larger spin polarization splitting than M″ and so electron transfer will act to diminish E_{SPE} for these species. When these tendencies are accounted for, it appears that the relationship between E_{SPE} and E_{ovlp} for the mixed-group dimers is otherwise broadly similar to that seen for the same-group dimers.

The second noteworthy trend evident in Fig. 10 is due to increasing metal atom oxidation state. We have previously commented [2] that the chromium-triad d^3d^3 dimers display a systematically higher E_{ovlp} term than the corresponding manganese-triad d^3d^3 dimers, in accord with the generally greater spatial extent of d-orbitals for M(III) species than for M(IV), and the mixed-group dimers essentially obey this trend also: the V(II)/Cr(III) data points on Fig. 10 all lie above the best-fit line for the Cr(III)/Cr(III) triad dimers, while (with the exception of WMn, a species heavily influenced by electron-transfer-enhanced ferromagnetic stabilization as noted above) all of the Cr(III)/Mn(IV) family dimers lie between the Cr(III)/Cr(III) and Mn(IV)/Mn(IV) triad dimer best-fit lines, in accord with the trend in d-orbital radii M(II) > M(III) > M(IV) within any given row. The best-fit lines in Fig. 10 also indicate that the change in E_{ovlp} generally exceeds the change in E_{SPE} in moving across a transition row (as can be seen, for example, for the series $VCr \rightarrow Cr_2 \rightarrow CrMn \rightarrow Mn_2$ and $TaW \rightarrow W_2 \rightarrow WRe \rightarrow Re_2$), and this too is consistent with our earlier studies on the same-group dimers [2].

4. Concluding remarks

The various structural and energetic trends reported here for the series of mixed-group, face-shared dimers $M'M''Cl_9^{4-}$ (M′ = V, Nb, Ta; M″ = Cr, Mo, W) and $M'M''Cl_9^{2-}$ (M′ = Cr, Mo, W; M″ = Mn, Tc, Re) can largely be attributed to the interplay between three parameters: the tendency for electron transfer from M′ to M″, the degree of ligand-field splitting Δ for the metal atoms, and the magnitude of the spin-polarization splitting E_{SPE} of the α- and β-spin valence d orbitals on each metal. Our studies on both mixed-group and same-group dimers show that this interplay has consistent results, which may be succinctly summarized: ferromagnetic coupling is adopted in the d^3d^3 $M'M''Cl_9^{n-}$ dimers in which M″ (the more highly oxidized metal) is first-row; weak antiferromagnetic coupling occurs in those dimers in which M′, but not M″, is first-row; and significant metal–metal bonding is always only seen when neither M′ nor M″ is first-row.

[22] We are currently also studying the mixed dimers $M'M''Cl_9^{3-}$ in which M′ and M″ are, respectively, members of the V and Mn triads. For this set of complexes a d^3d^3 configuration requires formal oxidation states of (M′)(II) and (M″)(IV); however, the magnitude of electron transfer seen in the V(II)/Mn(IV) triad mixed dimers is such that these species are best described by d-electron configurations other than d^3d^3, and for this reason we shall report on the V/Mn triad mixed dimers in detail elsewhere.

[40] The raw Mulliken spin densities were corrected by a factor $3/\rho_{M(oct)}$, where $\rho_{M(oct)}$ is the Mulliken spin density obtained for the central metal atom within the isolated high-spin d^3 octahedral complex MCl_6^{n-}. The purpose of this correction factor is to allow for the effect of M–Cl bond covalency within the octahedral complex: covalency reduces the spin density from the value of three expected for a purely ionic complex featuring a d^3 metal atom. We assume for simplicity that the extent of M–Cl bond covalency within the mixed-group dimer is similar to that found for the octahedral complex. This assumption ignores the distorting effect of electron transfer between the two metal atoms within the dimer, but we have previously found that this assumption holds very well within same-group dimers, and within the set of mixed-group dimers described here the sum of the adjusted $\rho(M')$ and $\rho(M'')$ values is always within $\pm 5\%$ of the value of 4.0 expected for the $S=2$ state, while for the $S=3$ state there are only two instances (Mo/Mn and W/Mn) where $\rho(M')+\rho(M'')$ deviates by more than 5% from the expected value of 6.0. We conclude that the 'covalency correction' to the spin densities is essentially appropriate for the mixed-group dimers.
[41] Stabilization of the $S=3$ minimum is systematically more pronounced for the $M'CrCl_9^{4-}$ than the $M'MnCl_9^{2-}$ complexes. The greater preference for $M'CrCl_9^{4-}$ ferromagnetic complexes than for ferromagnetic $M'MnCl_9^{2-}$ species can be rationalized on the basis of the spin polarization energies (SPE) of the metal atoms involved, particularly the relative SPEs for Cr(III) and Mn(IV) [4]. Note that, while the trend in bare metal ions is to d-orbital contraction with increasing oxidation number, the effect of metal-ligand bond covalency is to offset this trend, and the increase in metal-ligand bond covalency in going from Cr(III) to Mn(IV) is sufficient to ensure that the spin polarization splitting for $MnCl_6^{2-}$ is less than that for $CrCl_6^{3-}$.

Coordination chemistry of a new imine-ether ligand, *N*,*N*′-bis(2-pyridylmethylene)-2,2′-(ethylenedioxy)bis(ethylamine): mono-helical and single-helical-strand coordination modes identified by X-ray crystallography

Received 17 October 2001; accepted 11 February 2002

Abstract

A new Schiff base ligand, *N*,*N*′-bis(2-pyridylmethylene)-2,2′-(ethylenedioxy)bis(ethylamine), **L**, and the complexes, [AgL](BF_4) (**1**), $[Zn_2LCl_4]$ (**2**), $[Hg_2LCl_4]$ (**3**), $[Cd_2LI_4]$ (**4**), $[Ni_2L_3](BF_4)_4$ (**5**), and $[M_2L_3](ClO_4)_4$ with M = Co(II) (**6**) Fe(II) (**7**) and Zn(II) (**8**), have been synthesised and characterised crystallographically and spectroscopically. The silver(I) complex **1** consists of a mono-helical structure where one ligand molecule, coordinating in a tetradentate manner, wraps itself around the Ag(I) ion, giving rise to a distorted tetrahedral arrangement. Single-helical-strand binuclear complexes were obtained with zinc(II), mercury(II) and cadmium(II), **2**, **3** and **4**, respectively. Complexes **2** and **3** are isomorphous and both contain one ligand molecule coordinating to two metal atoms via the two pyridylimine N-atoms. The two remaining coordination sites on the metals are occupied by chlorine atoms. In the fivefold coordinate cadmium(II) complex, **4**, the ligand coordinates in a bis-tridentate manner via the two pyridylimine units and the two oxygen atoms. The two remaining coordination sites on the metals are occupied by iodine atoms. It was possible to combine both coordination modes of the ligand, mono-helical and single-helical-strand, in the isomorphous binuclear octahedrally coordinated nickel(II), cobalt(II), iron(II) and zinc(II) complexes, **5**–**8**, respectively. One ligand molecule is wrapped around each metal ion, which in turn are linked by a third ligand molecule, so forming mono-bridged species. © 2002 Elsevier Science Ltd. All rights reserved.

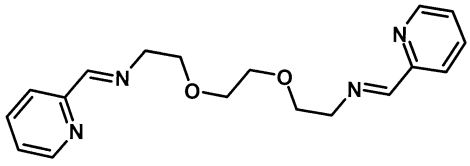
1. Introduction

The design of new nitrogen-donor multidentate ligands, their metallosupramolecular chemistry and the study of their physical properties are of interest not only from the point of view of their potential applications in areas such as catalysis, magnetism, transport processes, sensors or modelling of biological compounds, but also from a strictly structural point of view. The reactivity of transition metals with electron donor organic molecules has been systematically investigated since the last century and continues to be an important area of research [1–7]. One of the main goals today in coordination chemistry is to synthesise molecules with a predefined geometry. To do this, it would be useful to have a library of ligands and a database concerning their characteristics as far as coordination to transition metals is concerned. In this way molecular fragments could be assembled to produce a whole diversity of compounds with predetermined geometry.



The condensation reaction of an aromatic carbaldehyde with a primary amine has been shown to offer an easy and inexpensive way of forming a variety of bis-bidentate and bis-tridentate Schiff base ligands [8–14]. It has previously been shown that such ligands readily lead to the formation of double and triple binuclear helices [8,9]. Already in 1977 the group of Fenton et al. [15] began a series of studies on what they called 'compartmental ligands'. Later [15b] they prepared a

PII: S0277-5387(02)01015-X

series of compartmental Schiff bases using pyrrole units and having two dissimilar 'N_2O_2' or 'N_4' donor sites for metal complexation with different bridges. They were used to study the selective preferences of the metal atom and the effect of the bridge extension. Recently, an interesting 'two-compartmental' receptor ligand capable of moving a metal from one site to another by a change of pH was reported [16]. Bridging amino ether units are commonly used for the formation of macro cyclic ligands [17–19] but only a few acyclic related compounds are known [20–22]. The condensation of pyridine-2-carbaldehyde with the bridging amino ether unit, 2,2′-(ethylenedioxy)bis(ethylamine), resulted in the formation of a new N_4O_2 Schiff base. This is the pyridine analogue of ligand H_2L_8 of reference [15b], which was formed by the condensation of pyrrole-2-carbaldehyde and the same bridging amino ether unit. Lam et al. [22] have recently described the formation of mono-helical zinc(II) and europium(II) complexes of a similar ligand formed by the reaction of 3-(pyridine-2-yl)pyrazole with the same bridging amino ether unit.

L

Here we describe some examples of the coordination chemistry of ligand *N*,*N*′-bis(2-pyridylmethylene)-2,2′-(ethylenedioxy)bis(ethylamine) (**L**) and the characterisation of the different complexes formed, by spectroscopic and crystallographic means.

2. Experimental

2.1. Materials and general methods

All chemicals were used as received without further purification. ^{1}H and ^{13}C NMR spectra were recorded on a Bruker AMX-400 (400 MHz) in CD_3OD. Infrared spectra were measured using a Perkin–Elmer FT IR 1720X spectrometer using KBr pellets. The elemental analysis were carried out by the Ecole d'ingénieurs de Fribourg, Switzerland. No elemental analyses were available for compounds containing Hg, Cd or ClO_4^-. Electron impact (EI) mass spectra were obtained using a DELSI-NERMAG R30-10 system. Electrospray (ESI) mass spectra were performed using a BRUKER FTMS 4.7T BioAPEX II system by the MS-Service at the University of Fribourg. UV–Vis spectrophotometric titration measurements were carried out using a Spectramax-250 Plate Reader (equiped with 96-well microtiter plates) at the Department of Chemistry and Biochemistry, University of Bern. The results were analysed using SOFTMAXPRO 2.2.1 and EXCEL 2000.

Caution! Although no problems were encountered in the present study, perchlorate salts are potentially explosive and should be handled in small quantities with the necessary precautions.

2.2. Synthesis of *N*,*N*′-bis(2-pyridylmethylene)-2,2′-(ethylenedioxy)bis(ethylamine) (*L*)

Pyridine-2-carboxaldehyde (20.93 mmol, 2 ml) was added drop-wise to a solution of methanol (50 ml) containing 2,2′-(ethylenedioxy)bis(ethylamine) (10.46 mmol, 1.53 ml). The mixture was heated at reflux with stirring for 4 h. Removal of solvent under vacuum yielded **L** as a yellow–brown oil which was dried under vacuum for several hours (yield: 3.34 g, 98.0%). ^{1}H NMR (CD_3OD, 400 MHz, ppm): see Table 6. ^{13}C NMR (CD_3OD, 400 MHz, ppm): 163.65, 154.11, 149.28, 137.66, 125.65, 121.79, 70.51, 70.24, 60.65. IR (KBr pellet, cm^{-1}): 2863 (vs), 1651 (s), 1588 (vs), 1568 (m), 1469 (s), 1436 (s), 1353 (m), 1294 (w), 1122 (vs), 993 (m), 776 (s), 618 (m). MS (EI, 70 eV), *m*/*z* (%): 349.3 (LNa+), 327.4 (LH+), 238.3, 219.1, 175.1, 134.1, 106.2. *Anal.* for $C_{18}H_{22}N_4O_2$ (326.39 g mol^{-1}) calc. C 66.24, H 6.80, N 17.16. Found: C 66.00, H 7.09, N 17.17%.

2.3. Synthesis of [*AgL*](*BF*$_4$) (*1*)

$AgBF_4$ (0.1704 mmol, 0.0332 g) in MeOH (15 ml) was slowly added to a methanolic (5 ml) solution of **L** (0.1704 mmol, 0.5 ml of a 0.341 M solution), under N_2 and protected from the light. The colour of the reaction mixture changed immediately to yellow. The solution was refluxed for 2 h and then left undisturbed in the dark for at least 2 weeks, whereupon yellow–green crystals were formed. ^{1}H NMR (CD_3OD, 400 MHz, ppm): see Table 6. IR (KBr pellet, cm^{-1}): 1648 (m), 1589 (s), 1479 (w), 1438 (m), 1308 (m), 1225 (w), 1055 (s), 938 (w), 777 (m), 631 (w). *Anal.* for [AgL](BF$_4$)·2(H_2O)(635.01 g mol^{-1}): calc. C 38.81, H 4.70, N 10.06. Found: C 38.85, H 4.10, N 9.75%.

2.4. Synthesis of [*Zn*$_2$*LCl*$_4$] (*2*)

A very dilute solution of **L** (ca. 0.1 mmol in 10 ml CH_2Cl_2) was introduced into a glass tube and layered with approximately 2 ml MeOH as a buffer zone. A dilute solution of $ZnCl_2$ (ca. 0.25 mmol in 10 ml MeOH) was then added very slowly to avoid possible mixing. The glass tube was sealed and left at room temperature (r.t.). After 2 days pale-yellow plate-like crystals were obtained at the interface of the two solutions. IR (KBr pellet, cm^{-1}): 1654 (s), 1599 (vs), 1474 (m), 1445 (s), 1298 (s), 1222 (m), 1121 (s), 1111 (vs), 1099 (vs), 1091 (s),

1017 (s), 942 (m), 781 (s), 642 (m). *Anal.* for $[Zn_2LCl_4](CH_2Cl_2)\cdot 1/2(MeOH)$ (699.93 g mol^{-1}): calc. C 33.10, H 3.84, N 7.94. Found: C 33.53, H 3.67, N 8.24%.

2.5. Synthesis of $[Hg_2LCl_4]$ (3)

A very dilute solution of **L** (ca. 0.1 mmol in 10 ml CH_2Cl_2) was introduced into a glass tube and layered with about 2 ml MeOH as a buffer zone. A dilute solution of $HgCl_2$ (ca. 0.25 mmol in 10 ml MeOH) was then added very slowly to avoid possible mixing. The glass tube was sealed and left at r.t. After 2 days light-yellow plate-like crystals were obtained at the interface of the two solutions. IR (KBr pellet, cm^{-1}): 1658 (s), 1591 (s), 1472 (m), 1438 (s), 1299 (s), 1220 (m), 1118 (vs), 1106 (s), 1081 (s), 1025 (m), 1010 (m), 930 (m), 784 (s), 636 (m).

2.6. Synthesis of $[Cd_2LI_4]$ (4)

A very dilute solution of **L** (ca. 0.1 mmol in 10 ml CH_2Cl_2) was introduced into a glass tube and layered with approximately 2 ml MeOH as a buffer zone. A dilute solution of CdI_2 (ca. 0.25 mmol in 10 ml MeOH) was then added slowly to avoid possible mixing. The glass tube was sealed and left at r.t. After 2 days, light-yellow plate-like crystals were obtained at the interface of the two solutions. IR (KBr pellet, cm^{-1}): 1661 (s), 1594 (vs), 1476 (m), 1442 (s), 1302 (s), 1221 (m), 1106 (s), 1091 (vs), 1077 (s), 1012 (m), 934 (m), 925 (m), 779 (s), 638 (m).

2.7. Synthesis of $[Ni_2L_3](BF_4)_4$ (5)

To a solution of **L** (3 equiv., 0.341 mmol, 1 ml of a solution 0.341 M, 30 ml MeOH) was added 0.054 g of $NiCl_2\cdot 6H_2O$ (2 equiv., 0.227 mmol). The colour of the reaction mixture changed immediately to light orange. The solution was refluxed for 2 h. $[NH_4][BF_4]$ (0.0476 g, 4 equiv., 0.454 mmol) were then added. The clear solution was heated for a further 2 h, cooled and filtered to avoid any impurity, and allowed to slowly evaporate. After 1 week, light orange needle-like crystals of the complex were obtained. The same compound was also obtained by slow diffusion of $Ni(BF_4)_2$ in MeOH over $NaClO_4$ in MeOH and **L** in CH_2Cl_2 in a glass tube. IR (KBr pellet, cm^{-1}): 1647 (m), 1599 (s), 1481 (m), 1448 (m), 1308 (m), 1058 (vs), 777 (m), 643 (w). *Anal.* for $[Ni_2L_3](BF_4)_4\cdot(H_2O)$ (1461.8 g mol^{-1}): calc. C 43.83, H 4.77, N 11.36. Found: C 43.89, H 4.25, N 10.86%.

2.8. Synthesis of $[Co_2L_3](ClO_4)_4$ (6)

A solution of **L** (0.423 mmol, 3 ml of a solution 0.141 M, 30 ml MeOH) was slowly added, under N_2, to a solution of $Co(ClO_4)_2\cdot 6H_2O$ (0.282 mmol, 0.1031 g) in 10 ml MeOH. The colour of the reaction mixture changed immediately to deep orange–red and a precipitate appeared in some minutes. Ten ml MeCN were then added in order to dissolve the precipitate. The orange–red clear solution was heated at reflux during 2 h and an excess of $NaClO_4$ in 10 ml MeOH was added (0.211 mmol, 0.03 g). The solution was refluxed for a further 2 h. After filtration, slow evaporation of the solution yielded orange–red rod crystals. The same compound could also be obtained by slow diffusion of a methanolic solution containing a mixture of $Co(ClO_4)_2\cdot 6H_2O$ and $NaClO_4$ over a solution of **L** in CH_2Cl_2. The addition of $LiClO_4$ or $KClO_4$ did not lead to the formation of any crystals. IR (KBr pellet, cm^{-1}): 1645 (m), 1599 (s), 1480 (m), 1447 (m), 1309 (m), 1084 (vs), 776 (m), 623 (s).

2.9. Synthesis of $[Fe_2L_3](ClO_4)_4$ (7)

A solution of **L** (3 equiv., 0.341 mmol, 1 ml of a solution 0.341 M, 30 ml MeOH) was slowly added, under N_2, to a methanolic (50 ml) solution of $Fe(ClO_4)_2\cdot 6H_2O$ (2 equiv., 0.227 mmol, 0.0082 g). The colour of the reaction mixture changed immediately to deep purple. The solution was refluxed for 2 h, filtered to avoid any impurity, diluted with more MeOH and allowed to evaporate slowly. After approximately 2 weeks, very small purple needle-like crystals were obtained. The same compound was also obtained by slow diffusion of $Fe(ClO_4)_2\cdot 6H_2O$ in MeOH over $NaClO_4$ also in MeOH and **L** in CH_2Cl_2 in a glass tube under N_2. IR (KBr pellet, cm^{-1}): 1615 (m), 1599 (w), 1474 (m), 1448 (m), 1302 (m), 1093 (vs), 771 (w), 623 (m).

2.10. Synthesis of $[Zn_2L_3](ClO_4)_4$ (8)

A very dilute solution of **L** (ca. 0.1 mmol in 10 ml CH_2Cl_2) was introduced into a glass tube and layered with approximately 2 ml MeOH as a buffer zone. A dilute solution of $Zn(ClO_4)_2$ (ca. 0.25 mmol in 10 ml MeOH) was then added very slowly to avoid possible mixing. The glass tube was sealed and left at r.t. After approximately 2 weeks, small light-yellow needle-like crystals were obtained at the interface of the two solutions. IR (KBr pellet, cm^{-1}): 1652 (m), 1599 (s), 1482 (m), 1446 (m), 1310 (m), 1093 (vs), 777 (m), 624 (s).

2.11. X-ray data collection, structure solution and refinement

Crystals of compounds **1**, **2**, **4**, **5**, **6**, **7**, and **8** were mounted on a Stoe Imaging Plate Diffractometer System equipped with a one-circle φ goniometer and a graphite-monochromator. Data collection was per-

formed using Mo Kα radiation ($\lambda = 0.71073$ Å). Two hundred exposures (3 min per exposure) were obtained at an image plate distance of 70 mm (resolution D_{min}–D_{max} 14.23–0.87 Å) with $0° < \varphi < 200°$ and with the crystal oscillating through 1° in φ. For compound **3**, a crystal was mounted on a Stoe STADI4 four-circle diffractometer. Intensity data were measured using graphite-monochromated Mo Kα radiation ($\lambda =$ 0.71073 Å). The ω–2θ scan technique was used for data collection in the range $2.97° < \theta < 25.50°$. The cell parameters were determined by a least-squares treatment of the setting angles of 20 reflections, and their equivalents, with $12.5° < \theta < 14.5°$. The intensity of the two standard reflections measured every 60 min was found to decrease by less than 2%. The structures were solved by either Patterson or direct methods using SHELXS-97 [23] and refined by full-matrix least-squares on F^2 with SHELXL-97 [24]. The hydrogen atoms were included in calculated positions and treated as riding atoms using SHELXL-97 default parameters. All non-hydrogen atoms were refined anisotropically. Complex **1** crystallised in the non-centrosymmetric group *Cc* and was refined as a racemic twin [25] (BASF = 0.37(3)). It crystallised with one highly disordered BF_4^- anion with occupancies of 0.5 for all of the fluorine atoms (F1 to F4 and $F1^a$ to $F4^a$). Part of the ligand was also found to be disordered with occupancies of 0.4 and 0.6 for atoms C9, C10 and $C9^a$, $C10^a$, respectively. The thermal parameters for the fluorine atoms were constrained to be equal in the refinement process. Complex **2** was a twinned crystal with more than 40% overlapped reflections. The reflections relating to the major twin component were used for structure analysis. No disorder was observed in compounds **2**, **3** and **4** and an empirical absorption correction using the DIFABS routine in PLATON [26] was applied. One molecule of dichloromethane per molecule of complex was found for structure **4**. For compound **7**, only a very small crystal was available and it was shown to be isomorphous with compounds **5**, **6** and **8**. The number of observed reflections was too small to permit the complete refinement of this compound, nevertheless, the unit cell parameters were refined and the heavy atom and the main backbone atomic positions were located. The structure is not presented in detail. In compounds **5**, **6** and **8**, one ligand (one pyridine ring and the ether chain) molecule presents conformational disorder. The disordered atomic positions were refined with occupancies of 0.47 for **5**, 0.56 for **6** and 0.44 for **8**, and their thermal parameters were constrained to be equal in the refinement process. The two perchlorate anions were also highly disordered. The thermal parameters for the disordered oxygen atoms were constrained to be equal. The Cl–O bond distances as well as some of the N_{im}–C distances, were constrained to their theoretical values. In compound **5**, the BF_4^- anions were highly disordered and were refined with occupancies of 0.5 for the F atoms. Further crystallographic details are summarised in Tables 1 and 2. Selected bond lengths and bond angles are listed in Tables 3–5.

3. Results and discussion

3.1. Spectral characterisation

The formation of ligand **L** was followed by NMR spectroscopy until the complete disappearance of the aldehyde and the amine proton signals (9.83 and 1.63 ppm, respectively). The ^{1}H NMR spectra of **L** displays five sets of resonances in the aromatic region (Table 6). As the ligand is symmetrical each set of resonances was assigned to a given pair of equivalent H's; one for the imine H's and four for the pyridine H's (ddd (Ha), ddd (Hb), ddt (Hc) and td (Hd)). Two supplementary signals were observed in the CH_2 region, in the form of a multiplet and a singlet, corresponding to the alkane chain protons. The ^{1}H NMR spectrum for the silver complex (**1**) is compared with the corresponding spectrum of the free ligand in Table 6. The ^{1}H NMR spectrum of **1** shows five signals in the aromatic region for the symmetrically coordinated ligand **L** and two more resonance sets in the CH_2 region. The signals were displaced to higher or lower chemical shifts depending on the H-atom. The largest displacement was found, as expected, for the imine hydrogen atom signal due to the coordination of the N_{im}-atom to the metal. Compounds **2**, **3** and **4** were insoluble in all common organic solvents.

The infrared spectra for ligand **L** and compounds **1**–**8** exhibit the characteristic imine, C–N, C–C(pyridine) and C–O–C vibrational frequencies. A small (ca. 10–15 cm^{-1}) shift to higher or lower frequencies was observed in the metal complexes compared with the corresponding frequencies for the free ligand. For compounds **5**–**8**, the vibrational bands of the perchlorate or BF_4^- anions (very strong for all four compounds) overlapped with the C–O–C bands. The perchlorate bands were found in the region of 1084–1093 cm^{-1}, and for the BF_4^- anion at 1058 cm^{-1}, showing typical values for uncoordinated anions.

Complexes **1**, and **5**–**8**, were soluble in several organic solvents, such as methanol and acetonitrile. The positive ESI MS spectrum of **1** in acetonitrile indicated the presence of only one peak at *m*/*z* 435, and was assigned to cation $[AgL]^+$, which corresponds to the solid state cation. The positive ESI MS spectra of **7** and **8** in acetonitrile, and **5** and **6** in methanol–acteonitrile, appear to be more complicated. Each spectrum is composed of several peaks of different intensity. The cation $\{[ML](ClO_4)\}^+$ could clearly be identified in the respective spectra, at *m*/*z* 483 for **5**, 484 for **6**, 481 for **7**,

intensity peak at m/z 1083 was assigned to a binuclear species $\{[Zn_2L_2](ClO_4)_3\}^+$.

UV–Vis spectrophotometric titrations of ligand **L** in ethanol ([**L**] = 125 μm) were carried out with the metal salts, $AgNO_3$, $Co(BF_4)_2\cdot 6H_2O$, $Fe(ClO_4)_2\cdot 6H_2O$, $Zn(ClO_4)_2$, and $Ni(ClO_4)_2\cdot 6H_2O$. The metal concentration was varied from 0 to 300 μM in eight steps. Upon addition of $AgNO_3$ the ligand π–π* band at 270 nm was progressively displaced to 280 mm. The presence of an isosbestic point at 265 mm was indicative of a clean reaction. In the case of Ni^{2+}, Co^{2+} and Zn^{2+} the ligand band was shifted to 280–285 mm but the isosbestic point at approximately 270 nm was poorly defined. Titration with $Fe(ClO_4)_2\cdot 6H_2O$ was carried out with the metal concentration varying from 0 to 300 μM in 31 steps. The spectra are shown in Fig. 1. An intense band in the UV region due to the ligand π–π* transitions was observed,

and the metal-to-ligand charge-transfer (MLCT) bands were observed in the Visible region of the spectrum. During the titration, the ligand band was gradually displaced to 280 nm and suffered a hyperchromic effect. A new band appeared at 349 nm and increased in intensity with increasing concentration of Fe^{2+}. Finally a new band emerged at 562 nm and increased in

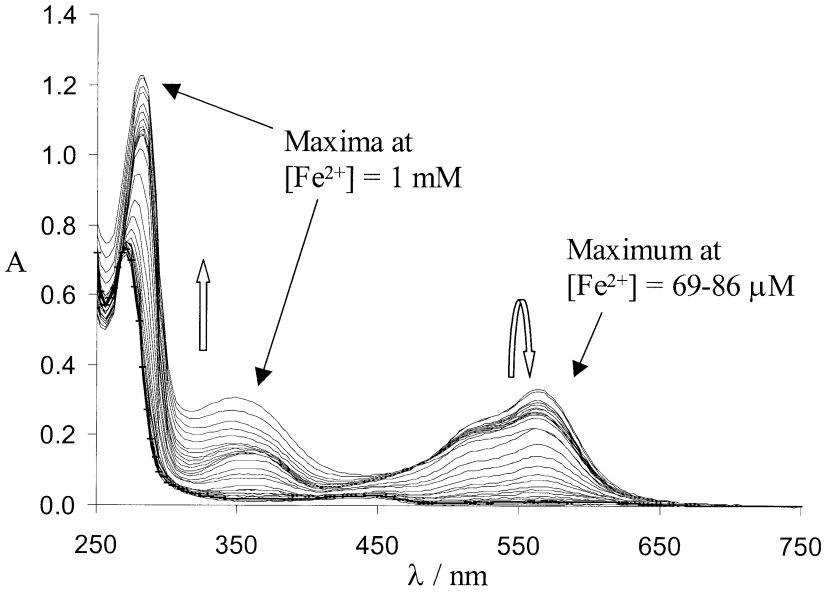

Fig. 1. Spectrophotometric titration of **L** with Fe^{2+} in EtOH.

intensity until the metal concentration reached 69 μM. On continued addition of Fe^{2+} the absorption maximum decreased until the [Fe^{2+}] was 86 μM, after which it decreased only slightly. The diminution in intensity became more pronounced for concentrations greater than 108 μM. This was associated with a net decrease in the intensity of the purple colour of the solution. An isosbestic point appeared at 268 nm, until the metal concentration reached 69 μM. With increasing metal concentration it disappeared, but then a second isosbestic point appeared at 478 nm. This could be indicative of a switch from one species to another. The metal concentration of 69–86 μM corresponds approximately to a M:L ratio of 2:3, which is the same ratio found for the deep purple solid-state species $[Fe_2L_3]^{4+}$. The following solution equilibria can be proposed:

$$2Fe^{2+} + 3L \rightleftharpoons [Fe_2L_3]^{4+} + Fe^{2+} \rightleftharpoons 3[FeL]^{2+}$$

Admitting that the concentration of the $[Fe_2L_3]^{4+}$ species is approximately 3.45×10^{-5} (half of 69 μM) and with $l = 0.5$ cm, a ε value of approximately 19 400 at $\lambda = 562$ nm can be estimated [27]. Compound **7** contains two Fe^{2+} ions; hence the ε value per Fe^{2+} ion is approximately 9700. This can be compared with the value of 11 000 at 510 nm found for the d^6 low-spin mononuclear complex tris–phenanthroline–iron(II) [28]. Hence, it is reasonable to suppose that the Fe^{2+} ion is also in the low-spin state. This is also in agreement with the short Fe–N_{py} bond distances, typical for low-spin iron(II), observed in the solid-state structure (see Table 9). This type of Schiff base ligand does indeed induce high *ligand fields* around the metal and hence it is reasonable to propose that the metal is mainly in the low-spin state. The ^{1}H NMR spectrum of complex **7** (purple crystals in CD_3OD) was poorly resolved. This may be due to the coexistence in solution of both low- and high-spin species.

3.2. X-ray crystallography

3.2.1. Structure of [AgL](BF$_4$) (1)

The reaction of **L** with $AgBF_4$ in a 1:1 ratio lead to the formation of a mononuclear complex. The structure can be considered as a mono-helical complex with the silver atom encapsulated by a single ligand molecule (Fig. 2).

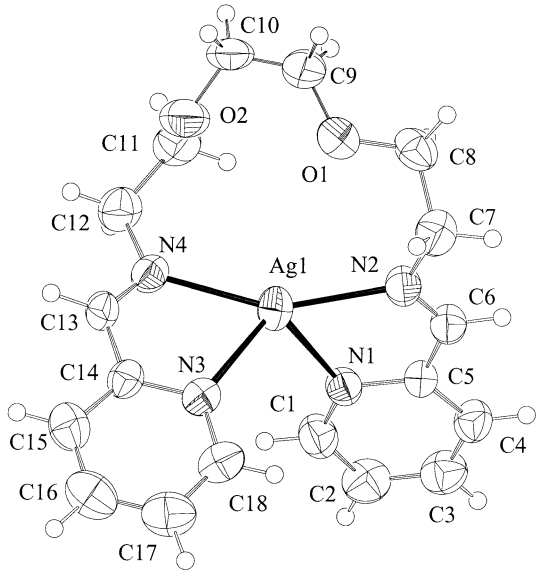

Fig. 2. The molecular structure of cation $[AgL]^+$ (**1**) showing the crystallographic numbering scheme and thermal ellipsoids at 50% probability level.

A number of examples of mono-helical complexes with different ligand molecules have been published [22,29–33]. The silver atom has a distorted tetrahedral geometry and is coordinated to the two pyridylimine units of one ligand molecule. Selected bond distances and bond angles are given in Table 3. The N_{py}–Ag–N_{im} bite angles are very narrow, 72.5(2)°. The average Ag–N_{py} bond length of 2.398(4) Å is significantly longer than the standard value of 2.299 Å [34], while the average Ag–N_{im} bond distance of 2.264(4) Å, is considerably shorter than the standard value for Schiff bases, 2.403 Å [34], see Table 3. The helicity is caused by a twist of **L** about the very flexible C–O–C–C–O–C chain linking the two pyridylimine units. Selected dihedral angles are given in Table 7. The complex crystallises in a non-centrosymmetric space group and in the crystal the molecules stack up the *b*-axis. Molecules with one sense of chirality stack in the one direction (> > > > >) while those with the opposite sense of chirality stack in the opposite direction (< < < < <).

3.2.2. Structure of compounds $[M_2LX_4]$, where M = Zn(II) for 2, Hg(II) for 3 and Cd(II) for 4 and X = Cl^- for 2 and 3 and I^- for 4

The reaction of **L** with $ZnCl_2$, $HgCl_2$ and CdI_2, using diffusion techniques (see Section 2) and in dilute conditions, gave in a few days, crystals of these centrosymmetric binuclear complexes (Figs. 3 and 4). Their overall structures can be considered as single-helical-strand, as clearly illustrated in Fig. 4 for complex **4**. In **2** and **3**, which are isomorphous, the metal atoms (Zn(II) and Hg(II), respectively) are four-coordinate with very distorted tetrahedral geometry and are coordinated to one pyridylimine unit and to two chlorine atoms (Fig. 3). Selected bond distances and bond angles are given in Table 4, and select dihedral angles and inter-planar distances in Table 7. The five-membered chelate pyridylimine ring forces the bond angle, N_{py}–M^{2+}–N_{im}, to be almost 70°, much smaller than the theoretical value of 109° for an ideal tetrahedron. In **2**, the Zn to O1 distance is very long, 2.705(5) Å, compared with the typical Zn–O bonding distance of 2.093 Å [34]. In **3**, it is reasonable to consider that the O-atom participates in the coordination sphere of the metal as the Hg–O distance of 2.823(10) Å is comparable to the literature values of 2.825, 2.909 and 2.935 Å [34]. In **4** the Cd atom is five-coordinate with a distorted square-pyramidal coordination geometry (Fig. 3(a)). Here the Cd-atom adds to its coordination sphere the ether function of the ligand, distance Cd–O is 2.666(5) Å. This is only slightly longer than the standard Cd–O distance of 2.569 Å [34]. The trigonality index τ is 0.42, indicating that the coordination geometry around the Cd^{2+} ion can be described as half-way between an ideal square-pyramidal geometry ($\tau = 0$) and an ideal trigonal-bipyramidal geometry ($\tau = 1$) [35]. The structures of **2** and **3** differ from that of **4** in their overall conformation. In **2** and **3**, the two pyridine rings are strictly parallel while in **4** the bridge is more twisted and the pyridine rings are almost perpendicular to one another (see Table 7). Compound **4** is also more compact than compounds **2** and **3** with the metal centres being separated by 6.645(1) Å in **4** compared with 7.409 (2) Å in **2**, 7.429 (9) Å in **3**. In all three compounds the pyridylimine unit is nearly planar. The pyridine and chelate ring dihedral angles are less than 4°, and the metal atoms are displaced by less than 0.25 Å from the mean plane of the pyridine ring (Table 7).

3.2.3. Structure of compounds $[M_2L_3](X)_4$, where M = Ni(II) for 5, Co(II) for 6, Fe(II) for 7 and Zn(II) for 8 and X = BF_4^- for 5 and ClO_4^- for 6, 7 and 8

The four compounds were obtained either by refluxing a methanolic solution containing 3 equiv. of **L** with 2 equiv. of the correspondent metal salt or by slow diffusion of a methanolic solution of the metal salt into a solution of **L** in dichloromethane. Complexes **5**–**8** have a metal-to-ligand ratio of 2:3 and were obtained even when this ratio was varied. They combine the two coordination modes observed for complexes **1** and **2**–**4**, that is mono-helical and single-helical-strand (see Fig. 5) for complex **8**. One ligand molecule is wrapped around each metal ion, which in turn are linked by a third ligand molecule, giving rise to mono-bridged species. In this way, the metal is coordinated to three pyridine N-atoms and three imine N-atoms. Selected bond distances and bond angles are given in Table 5 and select dihedral angles and inter-plane distances in Table 8. The metals are octahedrally coordinated with distorted octahedral geometry. The distortion is essentially due to the narrow N_{py}–M–N_{im} bite angles (ca. 77°) imposed by the ligand.

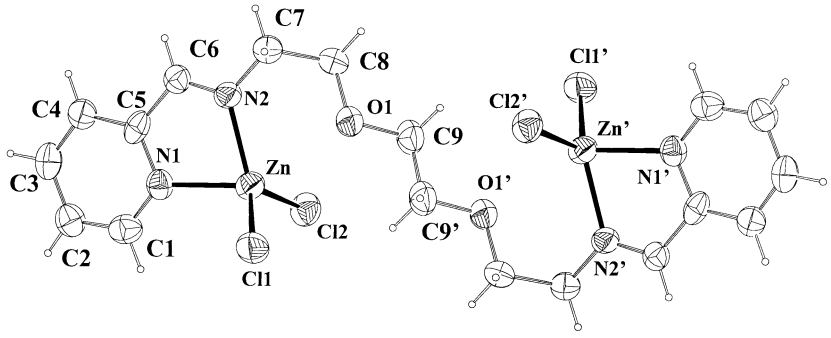

Fig. 3. The molecular structure of complex $[Zn_2LCl_4]$ (**2**), showing the crystallographic numbering scheme and thermal ellipsoids at 50% probability level. (See Table 4 for symmetry operation.)

The metal centres are separated by distances between 7.859(2) and 8.055(2) Å.

It can be seen from Tables 7 and 8 that in complexes **2**–**8**, the metal atoms are only slightly displaced from the best plane through the pyridine rings, and that the pyridine and chelate rings are almost perfectly co-planar, with the dihedral angles varying from 2.6° to 7.1°. The average $C{=}N_{im}$ bond distance of 1.266(4) Å, is close to the standard value of 1.279 Å for a Schiff base system [34]. The average $C_{py}{-}C_{im}$ bond distance, 1.469(4) Å, is close to the standard value of 1.476 Å found for a conjugated system [34]. The $N_{py}{-}M{-}N_{im}$ bite angles vary from 70.5(4)° to 78.6(3)° (see Tables 4 and 5). The standard values [34] for the $Metal{-}N_{py}$ and $Metal{-}N_{im}$ bond distances are compared with the values found in complexes **1**–**8** in Table 9. In the case of complexes **1**–**4** not all the standard values are available. However, it is interesting to note here that the observed $M{-}N_{py}$ bond distances are longer than the standard values and that this trend is reversed for the $M{-}N_{im}$ bond distances. For the first row transition metal complexes, **5**–**8**, the $M{-}N_{py}$ and the $M{-}N_{im}$ bond distances for individual complexes are very similar. However, it can be seen that the $M{-}N_{py}$ bond distances are shorter than the standard values while the $M{-}N_{im}$ bond distances are either similar or longer than the standard values (see Table 9). The difference in the relative M–N bond distances with respect to the standard values, for compounds **1**–**4** compared with compounds **5**–**8**, is probably due to steric overcrowding in the latter.

4. Conclusions

As expected, the ligand **L** was found to be very flexible and reacted readily with transition metals. Two different coordination modes of the ligand were possible; mono-helical and single-helical-strand. Depending on the geometrical preferences of the metal these coordination modes can either be observed separately or combined in the same complex. With silver(I) a mono-helical complex **1** was formed rather than a polymeric structure. With zinc(II), mercury(II) and cadmium(II) single-helical-strand complexes, **2**, **3** and **4**, respectively, were obtained. Finally with the first row transition metals, which favour octahedral coordination, both mono-helical and single-helical-strand coordination modes are present in complexes **5**–**8**. This result was surprising as frequently binuclear complexes

of this type of ligand, with a M:L ratio of 2:3, and with metals having predilection for octahedral geometry, form triple helical arrangements [8,9]. The flexibility of the central spacer obviously plays an important role and it also appears that the type of complex formed depends upon the counterion used for the reaction. In the case of Zn(II), two different complexes, **2** and **8,** were obtained using chloride or perchlorate, respectively, as counterions. The chloride atoms prefer to coordinate to the metal centre while with $Zn(ClO_4)_2$ the metal prefers to coordinate to the nitrogen atoms only, with an octahedral geometry. Interestingly the mono-helical zinc(II) complex recently obtained by Lam et al. [22] was synthesised using anhydrous $ZnCl_2$ but $NaClO_4$ was later added to the refluxed solution in absolute ethanol. There the zinc atoms are also coordinated to the ether O-atoms with typical Zn–O bond distances of 2.203–2.211 Å. In the case of the pyrrole analogue of **L**, described by Bailey et al. [15b], only a mononuclear copper(II) complex was reported. These studies are being extended to the synthesis of related ligands with different central spacers and chelating units, in order to explore ways in which the ligand flexibility can be controlled.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structures **1**–**8** have been deposited with the Cambridge Crystallographic Data Centre as supplementary

publication nos. Structure and properties of tetraaquabis(hydrogenmaleato)iron(II)

Rama K. Barman, Rajesh Chakrabarty, Birinchi K. Das *

Department of Chemistry, Gauhati University, Guwahati 781 014, Assam, India

Received 22 October 2001; accepted 6 March 2002

Abstract

The title compound tetraaquabis(hydrogenmaleato)iron(II), $Fe(C_4H_3O_4)_2(H_2O)_4$ (**1**) forms large orange-coloured crystals that are remarkably stable against air-oxidation and weight loss until ~160 °C. Crystal structure analysis of compound **1** has been performed by single crystal X-ray diffraction. The basic octahedral complex consisting of two centrosymmetrically related monodentate hydrogenmaleato ligands and four water molecules coordinated to Fe(II) remains firmly hydrogen-bonded through intra- and inter-molecular interactions to form a robust three-dimensional network structure in the solid state. Comparison between the simulated and experimental powder X-ray diffraction patterns confirms bulk purity of the product. The solid-state UV–Vis–NIR spectrum for this yellow–orange compound shows bands at 227, 383 (broad) and 917 (broad) nm among which the last one is assignable to the expected $^5T_{2g} \rightarrow {}^5E_g$ band for octahedral Fe(II) complexes. The variable temperature magnetic susceptibility measured for compound **1** in the 2–300 K range shows Curie–Weiss behaviour with weak antiferromagnetic interactions occurring at low temperatures as observed from the $\chi_M T$ versus T curve and a Weiss constant of −2.4 K found from the $1/\chi_M$ versus T plot. An aqueous solution prepared by dissolving crystalline samples of **1** is indefinitely stable in air and it is possible to recover **1** from the solution. The yellow–orange solution displays nearly identical redox stability ($E_{1/2} = 0.15$ V vs. Ag/AgCl) with the well-known $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ couple. © 2002 Published by Elsevier Science Ltd.

1. Introduction

Investigations on the salts of the *cis* and *trans* isomers of 1,4-butenedioic acid are not extensive. Although a few crystal structure analyses on such compounds are available in the literature, the intimate details of the truly intricate structures have remained by and large obscure. These two dicarboxylic acids, maleic and fumaric acid, may bind to a metal ion in either the monoanionic or dianionic form, and given with the possibility of the resulting ligands to act as mono-, bi-, tri-, and tetra-dentate ligands, formation of a variety of compounds displaying a plethora of interesting structures and properties could easily be imagined. In recent times the salts of dicarboxylic acids, including those of fumaric acid, have been found to display porous metal-organic network structures [1].

An example of metal maleate complexes, copper(II) maleate hydrate, is known to display ferromagnetic behaviour resulting from the complicated layered structure of this polymeric compound [2]. In this compound the maleato ligand coordinates in a tetradentate fashion, utilising all four carboxyl oxygen atoms present in the dianion, to produce two-dimensional sheets that finally link through hydrogen bonds to one another to form a three-dimensional structure [3] essential for ferromagnetism [4]. In the case of copper(II) hydrogenmaleate tetrahydrate, the hydrogenmaleate anions remain fully uncoordinated to the metal centre [3a]. Herein we describe the detailed structure and magnetic properties of tetraaquabis(hydrogenmaleato)iron(II), $Fe(C_4H_3O_4)_2(H_2O)_4$ (**1**) where the monoanion of maleic acid acts as a monodentate ligand. Ferrous fumarate is extensively used in commercial medicinal formulations to provide iron supplement to anaemic bodies [5], but the corresponding maleate salt remains largely unknown. On the other hand, several metal hydrogenmaleates, including that of ferrous iron, are known [6,7], but the physico-chemical properties of most of the

PII: S0277-5387(02)01002-1

compounds remain unexplored. Although some properties of ferrous hydrogenmaleate tetrahydrate have been previously described [8], the details of its crystal and molecular structure and the correlation of the properties with the structure remain unpublished. In fact, a previous structural report [7] on the compound does not take into account the intermolecular hydrogen-bonding interactions that are likely to play an important role in determining the properties of such metal salt hydrates. To our knowledge, the title compound represents the only structurally characterised example of simple salts or salt hydrates formed by 1,4-butenedioic acid anions with iron in any of its oxidation states. In fact, a search of chemical and structural databases indicates that crystal structure analyses have not so far been published for any complex of iron other than **1** in which either maleato or fumarato ligands remain coordinated to iron through one or more of its oxygen atoms. Compounds of interesting compositions such as calcium tris(maleato)ferrate(III) [9] and $[Fe_3O(OOCCH{=}CHCOOH)_6]OH\cdot 3H_2O$ [10] are known in the literature, but the details of their structure are yet to be published.

2. Experimental

2.1. Materials and methods

All materials were used as obtained from commercial sources. Electrolytic iron powder was purchased from Loba Chemie (India). Infrared (IR) spectrum in the mid-IR region (4000–450 cm^{-1}) was recorded using a Perkin–Elmer 1600 spectrometer. While the solution UV–Vis spectrum was recorded on a Perkin–Elmer Lambda 40 spectrophotometer, the UV–Vis–NIR (200–2600 nm) diffuse-reflectance spectrum for compound **1** in the solid state was obtained using a Shimadzu UV-3101PC scanning Spectrophotometer. $BaSO_4$ powder was used as reference (100% reflectance). Absorption data were calculated from the reflectance data using the Kubelka–Munk function ($a/S = (1-R)^2/2R$ where a is the absorption coefficient, R the reflectance and S the scattering coefficient) [11]. For obtaining the cyclic voltammogram of **1** a computer controlled BAS-100 electrochemical analyser was used. In the three-electrode set-up of the electrochemical cell, the redox potential measured on a platinum microelectrode (in conjunction with a Pt counter electrode) was referenced to an Ag/AgCl electrode. Electrochemical response was measured at 22 °C at the scan rates of 20 and 50 mV s^{-1} for an approximately 10^{-3} M solution of **1** in the presence of $NaClO_4$ (0.1 M) as the supporting electrolyte. Under similar experimental conditions the Fe(III)/Fe(II) couple of potassium hexacyanoferrate(II), was observed at a potential +0.12 V against the Ag/AgCl electrode. Magnetic susceptibility data for **1** were obtained as a function of temperature using an MPMS Quantum Design SQUID magnetometer in the 2–300 °C range. Susceptibility data were corrected for diamagnetism. Details of X-ray crystallographic procedures are given below in a separate section.

2.2. Preparation of $Fe(C_4H_3O_4)_2(H_2O)_4$ (1)

Electrolytic iron powder (0.28 g, 5 mmol) is heated with a solution of maleic acid (1.74 g, 15 mmol) in water (10 ml) under reflux for 2 h to dissolve the iron completely. The resulting solution is filtered and the filtrate is allowed to stand for 24 h at room temperature (r.t.). The orange crystals formed at the bottom of the beaker are filtered off, washed with a small volume of cold water under suction, and dried in air. Yield: 0.76 g (42%). *Anal.* Calc. for $C_8H_{14}O_{12}Fe$: C, 26.61; H, 3.91; Fe, 15.64. Found: C, 26.88; H, 3.74; Fe, 16.49 (titrimetric)%. UV–Vis–NIR spectral data (λ_{max}, nm): (i) aqueous solution: 340 (sh), 947 (br); (ii) solid state: 227, 383(br), 917(br), 1120(sh). IR spectral data (cm^{-1}): 3491(sh), 3412(s), 3054(w), 2932(m), 2852(w), 1680(m), 1618(sh), 1559(s), 1489(s), 1362(s), 1222(m), 1087(br), 897(w), 866(m), 744(s), 669(s), 497(s) [sh, shoulder; s, strong; m, medium; w, weak; br, broad].

2.3. X-ray crystallographic procedures

The thick orange crystals of compound **1** directly obtained from the reaction mixture are suitable for single crystal X-ray diffraction experiments. A relatively large crystal was mounted on a glass fibre for intensity data collection using graphite monochromatized Mo-Kα radiation on a Bruker SMART Platform CCD Diffractometer. Several sets of frames covering a random area of the reciprocal space were collected using 0.3° steps in ω at a detector to sample distance of ~5 cm. Data acquisition, extraction and reduction and empirical absorption correction were performed using the programs SMART, SAINT and SADABS [12], respectively. The structure solution (direct methods) and refinement (full-matrix least-squares) were carried out with the SHELX-97 suite [13] of crystallographic programs. The correct assignment of the triclinic centrosymmetric space group for **1** was made on the basis of successful solution and well-behaved refinement of the structure. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were located in difference Fourier maps and refined with isotropic displacement parameters. The structural diagrams were drawn using the programs ORTEP-3 and PLUTON available in WINGX [14].

2.3.1. Crystal data

Columnar crystal, $1.03 \times 0.52 \times 0.44$ mm, $[Fe(C_4H_3O_4)_2(H_2O)_4]$, $a = 5.2785(8)$ Å, $b = 7.3987(11)$ Å, $c = 9.3016(14)$ Å, $\alpha = 109.249(2)^\circ$, $\beta = 104.727(2)^\circ$, $\gamma = 93.366(2)^\circ$, $V = 327.62(9)$ Å^3, $\lambda = 0.71073$ Å, triclinic, $P\bar{1}$, $Z = 1$, Bruker SMART CCD platform diffractometer, 3633 reflections of which 1440 unique, $R_{int} = 0.0212$, 96.1% completeness of data to $2\theta = 55^\circ$, $R_1^\dagger = 0.0227$, $wR_2^\dagger = 0.0612$, refinement against all 1440 reflections based on F^2 for 126 parameters, GoF* = 1.046. $^\dagger wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$; $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$, *GoF $= S = \{\Sigma[w(F_o^2 - F_c^2)^2]/(n-p)\}^{1/2}$].

The powder X-ray diffraction pattern was recorded using a Rigaku-Denki/RW400F2 (Rotaflex) rotating-anode powder diffractometer. The calculated powder pattern was generated from the refined atom coordinates using the CERIUS^2 software [15].

3. Results and discussion

3.1. Synthesis and properties

Reaction of iron powder with aqueous maleic acid is rapid at refluxing temperature. The resulting solution is stable against air-oxidation. Yellow–orange crystalline columns and crystals of irregular shape, some of which are over 5 mm in the longest dimension, of compound **1** form slowly when the cooled reaction mixture is allowed to stand at room temperature.

$$Fe + 2C_4H_4O_4 + 4H_2O = Fe(C_4H_3O_4)_2(H_2O)\ \ (\mathbf{1}) + H_2\uparrow$$

For molar ratios higher than 1:3 between the reactants, formation of colourless crystals of maleic acid was observed and due to the similar solubility property of these crystals, purification of **1** was found to be difficult. Vithal and Jagannathan [8] prepared this compound using a 1:4 molar ratio of the reactants under somewhat different conditions. Analogous compounds of manganese [16], cobalt and nickel were previously obtained for crystallographic work by treating MCO_3 with aqueous maleic acid [6].

The crystalline, non-hygroscopic solid of [Fe(hydrogenmaleate)$_2$(H$_2$O)$_4$] (**1**) is indefinitely stable against air-oxidation and water loss. In fact, thermogravimetric data show that there is no loss of water until ~ 160 °C. Slow dissolution of the crystals of **1** in water leads to a slightly acidic (pH 4.2) air-stable solution from which the crystals can be grown again in a slightly different morphology. The solution obtained by dissolving **1** is electrically conducting in nature and the high value of conductivity (equivalent conductance falls in the range of values expected for aqueous 10^{-3} M solutions of 1:2 electrolytes) can be explained by invoking the formation of $[Fe(H_2O)_6]^{2+}$ upon dissolution in water. But this leaves the orange–yellow colour, in contrast to the expected pale green colour of the hexaaqua cation, of the solution unexplained. It seems likely that because the orange colour of the solution could only result from charge-transfer transitions between metal and ligand orbitals, the hydrogenmaleato anions may not dissociate fully in water with the high solution conductivity arising from a partial dissociation of the acidic protons of the coordinated ligands. While the charge-transfer absorption is seen as a shoulder around ~ 340 nm, the expected $^5T_{2g} \rightarrow {}^5E_g$ transition appears as a weak, broad absorption band at 947 nm in the UV–Vis–NIR spectra of compound **1**. The solid state UV–Vis–NIR spectrum (Fig. 1) of compound **1** also shows these absorption features as two broad bands at 383 and 917 nm along with a strong red-shifted UV absorption at 227 nm due to the $\pi \rightarrow \pi^*$ transition of the C=C bond of the hydrogenmaleato ligands. The NIR band with a shoulder at lower energy is strikingly similar to an electronic spectrum of Fe^{2+} [17], and the splitting of this d–d band for high-spin Fe(II) may be attributed [8,17] to a splitting of the excited state in a permanently distorted ligand field. This appears to be acceptable because our structural data to be detailed below show that the Fe^{2+} centre in complex 1 is indeed in a low symmetry environment.

An aqueous solution of **1** was studied by cyclic voltammetry in the presence of $NaClO_4$ as a supporting electrolyte. The observed $E_{1/2}$ value of +0.15 V versus Ag/AgCl is low compared with the values known for aqueous acidic solutions of Fe^{2+}, and is nearly the same with the reduction potential found for the $Fe(CN)_6^{3-}$/$Fe(CN)_6^{4-}$ couple under similar experimental conditions. The quasi-reversible nature ($\Delta E_p = 227$ mV, $i_c/i_a = 0.986$ and $\Delta E_p = 257$ mV, $i_c/i_a = 0.951$ at 20 and 50 mV s^{-1}, respectively) of the electrochemical response is indicative of sluggish electron transfer for the oxidation of Fe^{2+} to Fe^{3+}. Resulting kinetic barrier for the redox process involving the Fe(III)/Fe(II) couple appears to be responsible for the stability of iron(II) in compound **1** against aerial oxidation, a commonly accepted redox property of the ferrocyanide ion in aqueous solution.

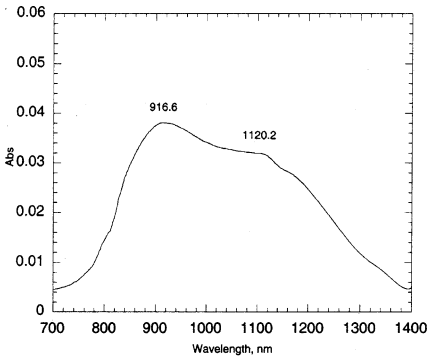

Fig. 1. Electronic spectrum of compound **1** in the near-IR region.

The KBr phase infrared spectrum of $Fe(O_2CCH{=}CHCO_2H)_2(H_2O)_4$ (**1**) displays bands assignable to the presence of the hydrogenmaleato and aqua ligands. Observation of the O–H vibrations at low energies is suggestive of their participation in hydrogen-bonding interactions. The bands at 2932 and 2852 cm^{-1} may also be of similar origin traceable to the likely presence of strong intramolecular hydrogen bonding between the –COOH and $–COO^-$ groups of the hydrogenmaleate anions. The C=O stretching frequency for the acid end of the hydrogenmaleato ligand could be assigned to the medium intensity band at approximately 1680 cm^{-1}. But there are several overlapping bands on the low energy side of this band and accurate assignment of bands to specific stretching vibrations is difficult to make. Assuming the absorption at $\sim$1620 cm^{-1} (the corresponding band for maleic acid is known to occur at 1640 cm^{-1}) to be due to the C=C stretch, the stronger absorptions at 1559 and 1489 cm^{-1} could be traced to the ν_{asym}(carboxyl) and ν_{sym}(carboxyl) vibrations, respectively. More detailed assignment of infrared absorption by a coordinated maleate dianion has been attempted earlier [7,18].

3.2. Crystal structure

Details of the solid-state structure of the compound have been determined by X-ray diffraction. An ORTEP presentation of the molecular structure of **1** is shown in Fig. 2 and a list of selected geometrical parameters are presented in Table 1. The iron atom in $Fe(C_4H_3O_4)_2(H_2O)_4$ (**1**) lies at a crystallographic centre of symmetry (1/2, 0, 1/2). The $HO_2CCH{=}CHCO_2^-$ ligands in the complex are *trans* to one another. However, the effective point symmetry of the central metal atom is only C_i. In spite of this low symmetry the metal complex at hand may, however, be conveniently considered to be approximately octahedral in structure. The Fe–O distances of 2.086(1) and 2.154(1) Å for the aqua ligands

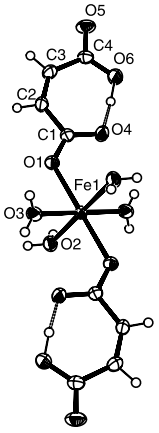

Fig. 2. An ORTEP view of $[Fe(C_4H_3O_4)_2(H_2O)_4]$ (**1**) at 50% probability. Hydrogen atoms are shown by spheres of arbitrary radius.

Table 1

Symmetry transformation used to generate equivalent atoms: #1 $-x+1, -y, -z+1$.

and 2.162(1) Å for the carboxyl group show the distorted nature of the FeO_6 octahedron. The expected C=O distance [O5–C4 = 1.231(2) Å] for the acid end (–COOH) is about 0.07 Å shorter compared with the C–O in O=C–O–H. The former distance is also shorter compared with the C–O distances for the coordinated $–COO^-$ group. The O4···O6 intra-molecular hydrogen bond distance of 2.428(2) Å is the shortest of all distinct hydrogen bonds (Table 2). The geometrical constraint of keeping the hydrogen bond as linear as possible [$\angle$ O4···H7–O6, 174(4)°] for the maximisation of bonding ($d_{O6–H7}$: 1.04 Å and $d_{O4\ldots H7}$: 1.39 Å compared with the other O–H distances in the range of 0.74–0.81 Å) leads to the formation of a seven-member ring for each of the hydrogenmaleate anions. Structure of **1** is similar to that of $[M(C_4H_3O_4)_2]\cdot 4H_2O$ (M = Ni, Zn and Mn) [6,16]. Considering the ionic radii of the metal ions involved, the M–O distances in these compounds are comparable to those in **1**. The intramolecular hydrogen bond mentioned above for **1** is also similar in length with those in the other compounds, but the O–H···O bond angle is much closer to the ideal 180° for **1** compared with that in the Mn compound [$\angle$ O···H–O: 165(7)°] [16] and is nearly identical with the corresponding angle in the Zn analogue for which hydrogen atom positions

Symmetry transformations used to generate equivalent atoms: #1 $-x+1, -y, -z+1$; #2 $-x+1, -y, -z+2$; #3 $-x, -y, -z+1$; #4 $-x+1, -y+1, -z+2$; #5 $x-1, y-1, z-1$.

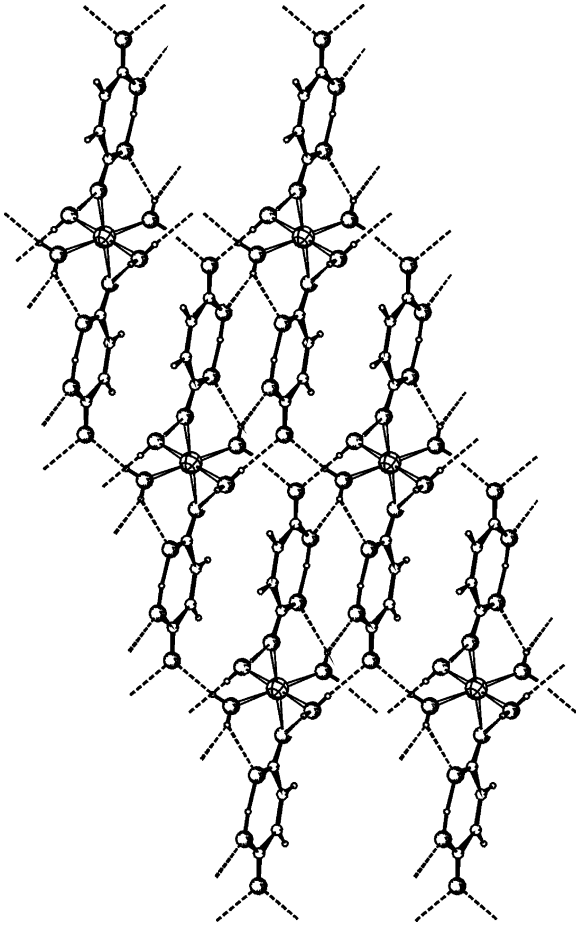

Fig. 3. Crystal packing diagram of $[Fe(C_4H_3O_4)_2(H_2O)_4]$ (**1**) viewed along *a*-axis showing the details of hydrogen-bonding interactions.

have been determined by a more appropriate neutron diffraction analysis [6]. For the example of copper(II) hydrogenmaleate tetrahydrate, the hydrogenmaleate ions present as charge-compensating anions are merely hydrogen bonded to the water molecules that form the tetraaqua copper(II) coordination sphere [3a]. The comparable intra-molecular O···O hydrogen bond distance in this compound is 2.409(3) Å, which is marginally shorter than that in compound **1**. The hydrogen atoms were not located in this structure.

Crystal packing diagram of the discrete $Fe(C_4H_3O_4)_2(H_2O)_4$ molecular units of **1** are given in Fig. 3. All O and O–H groupings participate in hydrogen-bonding and one hydrogen atom (H6) is involved in bifurcated hydrogen-bonding. The resultant supramolecular network thus assumes a rigid three-dimensional structure. The hydrogen-bonded architecture presents approximately hexagonal pores with shortest and the longest void dimensions of 4.8 and 9.4 Å (Fig. 4). A more detailed analysis of the hydrogen-bonding interactions in isostructural compounds, based on neutron diffraction studies on $Zn(C_4H_3O_4)_2(H_2O)_4$, has been made by Sequeira et al. [6].

Purity of the bulk sample of **1** has been confirmed by comparing the simulated powder X-ray diffraction pattern based on the atom coordinates obtained from single crystal X-ray analysis with the experimental pattern. Apart from the fact that the two most intense peaks in the two patterns (Fig. 5) have different d-spacings, both XRD patterns are very similar in appearance to suggest that both patterns tally well with one another.

3.3. Magnetic behaviour

Variable temperature magnetic susceptibility data on compound **1** have been measured in the 2–300 K range.

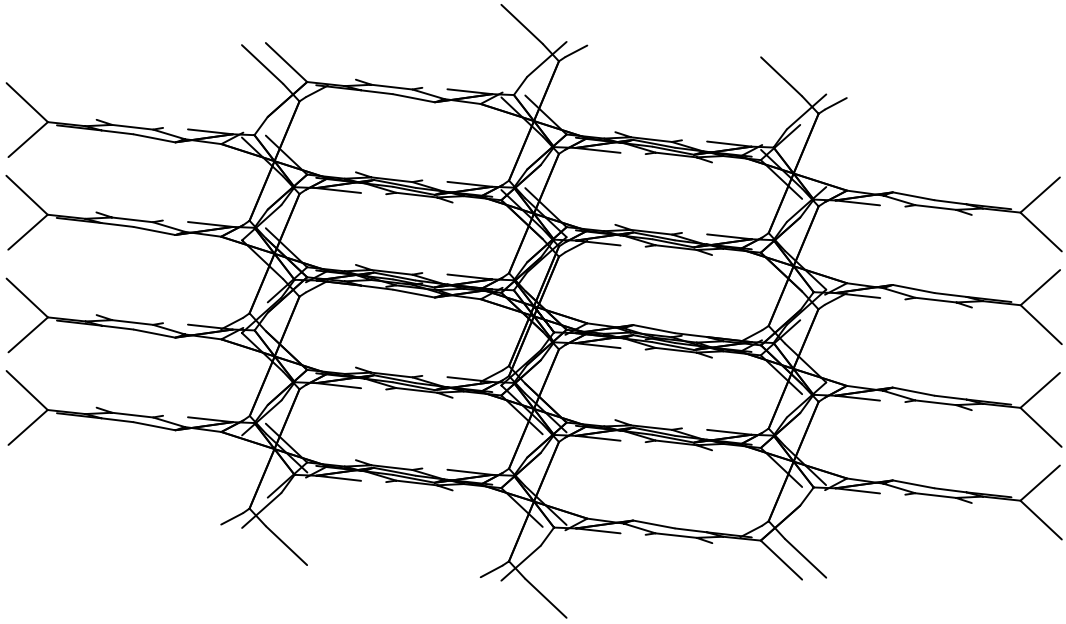

Fig. 4. A view of the supramolecular porous network in **1**.

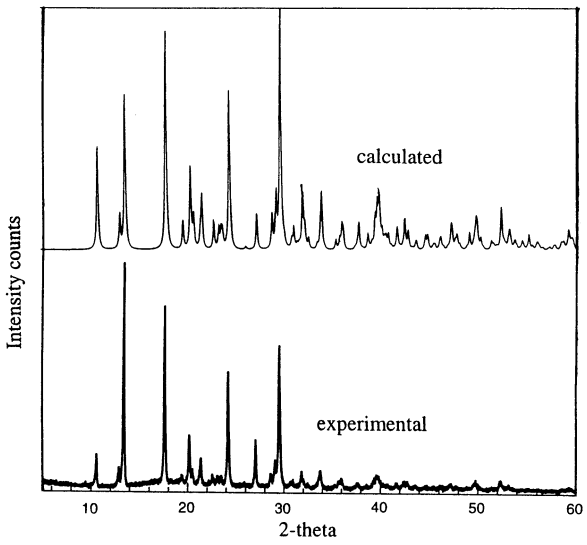

Fig. 5. Observed and calculated powder X-ray diffraction patterns for $[Fe(C_4H_3O_4)_2(H_2O)_4]$ (**1**).

The straight line obtained for the $1/\chi_M$ versus T plot (Fig. 6) makes an intercept with the T axis at -2.4 K. This indicates that the compound remains a Curie–Weiss paramagnet down to very low temperatures. Around 30 K the μ_{eff} ($=5.25$ BM at 300–30 K) value of high-spin iron(II) starts to decrease slowly to reach a minimum value of 3.4 BM at 2 K. Porollo et al. [7] reported two μ_{eff} values of 5.83 and 5.71 BM, respectively, at 290 and 80 K for this compound without indicating whether any antiferromagnetic interaction was involved. The μ_{eff} value for **1** obtained by us appears to be well within the minimum and maximum of such values commonly observed for high-spin iron(II) complexes [19]. The reduction in the μ_{eff} value at low temperatures is suggestive of progressive spin pairing with decreasing temperature. That the high-spin iron(II) complex weakly couples through antiferromagnetic exchange interactions is seen from the negative Weiss constant as well as the downward behaviour of the $\chi_M T$ versus T curve (please see inset in Fig. 6) below ~ 30 K [4]. Although our attempts to obtain a good fit of the data with well-established equations for magnetic susceptibility were unsuccessful, we are of the view that the unpaired electrons couple weakly in an antiferromagnetic manner through the hydrogen-bonded network, because of the lack of covalent bonds to connect the metal centres and also due to the fact that the shortest distance separating the iron(II) centres is over 5 Å in the crystal lattice.

4. Conclusions

The work reported in the paper indicates that detailed knowledge of the crystal structure even for a simple compound such as **1** may prove useful in understanding some bulk properties of the compound in the solid state. Intermolecular association through hydrogen-bonding phenomena may lead to enhanced redox stability of Fe(II) and to weak antiferromagnetism at low temperature.

5. Supplementary material

Cyclic volammogram and crystallographic data for compound **1** in CIF format are available from the authors. CIF is deposited with the Cambridge Crystallographic Data Centre, CCDC (No. 172028). The

Received 24 October 2001; accepted 15 April 2002

Abstract

Two ternary complexes [Cu(ala–gly)(isocyt)(H_2O)]·H_2O (**1**) and [Cu(L-tyr–gly) (isocyt)]·3H_2O (**2**) have been prepared and characterised by X-ray diffraction, optical, ESR and IR spectral data. Both compounds exist as slightly distorted square-planar complexes, with the four co-ordination sites occupied by the tridentate peptidic dianion [oxygen carboxylic O(7), nitrogen amidic N(13) and nitrogen aminic N(10)] and the N(3) of the pyrimidine base. In complex **1**, obtained as a racemic compound, an additional weak axial interaction exists between the oxygen of a water molecule OW1 and the copper atom [Cu–OW1 distance 2.50 Å]. Spectroscopic data are in accordance with the crystal structures. The isocytosine ligand is approximately orthogonal to the Cu–peptide moiety independently of the nature of the lateral chain. This disposition of the nucleobase contrasts with the coplanarity of the previously described Cu(II)–glygly–creatinine complex. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Cu(II) complexes; Ternary complexes; Peptide–Cu(II)–isocytosine complexes; Isocytosine complexes

1. Introduction

The present study is a continuation of our work on ternary metal complexes with peptides and nucleobase related ligands [1–3]. A considerable number of X-ray crystallographic studies on glycylglycinato–copper(II)–cytosine or isocytosine have been reported but X-ray diffraction crystallographic studies on ternary copper(II) complexes containing other peptides are scarce [3–7]. This fact could be related to some experimental difficulties in the preparation of gly-X and X-gly copper(II) ternary compounds and only one copper(II) ternary complex, [Cu(L-tyr–gly)(phen)]·3H_2O has been structurally described [8].

In a previous paper [3] two glycylglycinato isocytosine copper(II) complexes were structurally characterised. Primary co-ordination spheres of copper(II) were very similar to the previously described cytosine [4] and cytidine [5] related compounds. Moreover, additional intramolecular interactions NH_2(glygly)···O=C(pyrimidine) and intermolecular interactions COO(glygly)···NH(pyrimidine) are present. To obtain direct evidence for specific ligand-peptide interactions and the influence of the nature of the lateral chain in the formation and stabilisation of the ternary complex, two new (X-gly)–copper(II)–isocytosine compounds: [Cu(ala–gly)(isocyt)(H_2O)]·H_2O (**1**) and [Cu(L-tyr–gly)(isocyt)]·3H_2O (**2**) have been synthesised and characterised.

2. Experimental

Reagents were used as received from Aldrich.

The synthesis of these type of ternary complexes Cu(peptide)(isocytosine) strongly depends on the nature of the peptide moiety. In our hands we have explored the preparation of the corresponding ternary complexes with gly-D,L-ala, gly–L-ala, gly–L-val, gly–L-phe, gly–

L-tyr, gly–L-trp and L-val–gly, modifying the reaction conditions (solvent, temperature, stoichiometry of the reagents, pH and reaction time). Unfortunately, all these experiments were unsuccessful yielding the binary copper compounds. Only with L-ala–gly and L-tyr–gly it has been possible to isolate ternary complexes.

2.1. Preparation of [Cu(ala–gly)(isocyt)(H_2O)]·H_2O (**1**)

Isocytosine (0.11 g, 1 mmol) was added, while stirring, to a 3 ml aqueous solution containing $CuSO_4 \cdot 5H_2O$ (0.25 g, 1 mmol) and L-ala–gly (0.15 g, 1 mmol). The mixture was treated with 2 ml of NaOH 1 N and then heated on a steam bath up to boiling and filtered. The resulting solution was allowed to stand at room temperature (r.t.) for a few days until blue crystals of the racemic compound were formed. These crystals were filtered off and air dried (yield: 17%). The complex exhibits a mass decrease between 79 and 133 °C corresponding to the loss of two water molecules per formula unit (mass loss calc., 10.1%; mass loss found, 10.1%). *Anal.* Found: C, 30.47; H, 4.76; N, 19.50. Calc. for $C_9H_{17}CuN_5O_6$: C, 30.47; H, 4.79; N, 19.75%. IR(KBr, cm^{-1}): 282m, 337w, 439w(br), 459s, 577s, 713m, 766w, 790vw, 820s, 877m, 919w, 941w(br), 982m(br), 1020w, 1057m, 1086m, 1099m, 1236m, 1288s, 1399s(br), 1434w, 1465m, 1498m, 1597s(br), 1635s(br), 1683s(br), 3664m(sp). UV–vis (water): λ 639 (ε 94), 284 (5.1×10^3), 261 nm (5.1×10^3 dm^3 mol^{-1} cm^{-1}). Λ_M (Ω^{-1} cm^2 mol^{-1}) of 10^{-3} M in water, 20 °C = 11.6

2.2. Preparation of [Cu(L-tyr–gly)(isocyt)]·3H_2O (**2**)

[Cu(L-tyr-gly)] was freshly prepared by addition of 0.12 g (0.5 mmol) of L-tyr–gly in 1 ml of NaOH 1 N to an aqueous solution (4 ml) containing 0.12 g (0.5 mmol) of $CuSO_4 \cdot 5H_2O$. The resulting suspension was heated for 10 min on a steam bath (85 °C). After cooling the precipitate was filtered off and dried (yield: 89%). To a suspension of 0.10 g (0.33 mmol) of crude [Cu(L-tyr–gly)] in 2 ml of distilled water, heated on a steam bath (70 °C), 0.04 g (0.33 mmol) of isocytosine were added. The temperature of the steam bath was increased to boiling and subsequently the suspension was stirred for 20 min without heating. The blue precipitate was filtered off and air dried (yield: 73%). The product was partially redissolved in hot water and suitable crystals for X-ray diffraction were obtained by slow evaporation for a few days at room temperature. The complex exhibits a mass loss between 27 and 201 °C corresponding to the loss of three water molecules per formula unit (mass loss calc., 11.6%; mass loss found, 10.9%). *Anal.* Found: C, 38.66; H, 5.07; N, 14.96. Calc for: $C_{15}H_{23}CuN_5O_8$: C, 38.75; H, 4.95; N, 15.07%. IR (KBr, cm^{-1}): 288w, 352vw, 373w, 438w, 503w, 544w, 563vw, 577w, 598w, 630vw, 713vw, 731vw, 759vw, 810m, 824m, 854w, 889w, 907vw, 951w, 996vw, 1019m, 1058vw, 1083m, 1117w, 1174vw, 1205vw, 1234w, 1273m, 1300m, 1378m(br), 1401vw, 1431w, 1447w, 1499m(sh), 1513m, 1576s(br), 1613s, 1663m(br), 1689m, 3273vw, 3336w. UV–vis (water): λ 634 (ε 96), 281(sh) (6.9×10^3), 276 nm (7.0×10^3 dm^3 mol^{-1} cm^{-1}). Λ_M ($\Omega^{-1}cm^2$ mol^{-1}) of 10^{-3} M in water, 20 °C = 16.5.

2.3. Physical measurements

Elemental analyses of the complexes were carried out using a Carlo Erba model 1106 microanalyzer. The infrared spectra (KBr pellets) were recorded on a PE 683 with an infrared data station PE 1600 and the electronic spectra were registered on a PE 552 spectrophotometer. Thermogravimetric data in the temperature range from 30 to 700 °C were recorded in a flowing nitrogen atmosphere (heating rate 10 °C min^{-1}) on a PE TGA-2 thermobalance. ESR spectra were recorded at X-band frequencies with a Bruker ESP-300E spectrometer at 298 K. Magnetic measurements were carried out on powdered samples with a pendulum-type magnetometer (Manics DSM8). Diamagnetic corrections were estimated from the Pascal tables.

2.4. Crystallographic studies

X-ray data for single crystals of **1** and **2** were collected on an Enraf Nonius CAD4 diffractometer using monochromatic Mo Kα radiation ($\lambda = 0.71069$ Å). The cell parameters and space group were determined from a least squares refinement of 25 reflections randomly searched. Data collection was realised with scan ω–2θ technique.

The WINGX program [9] was used for applying Lorentz-polarization, decay and ψ-scan empirical absorption corrections. The structures were solved by direct methods and refined by a full-matrix least-squares method using the SHELX97 programs [10]. Non-H atoms were anisotropically refined. H atoms were positioned in calculated positions, except those in water molecules, which were localised in Fourier difference maps. Isotropic thermal vibration of the H-atoms were fixed to 1.2–1.5 times the U_{iso} of the bonded atom. Crystal parameters, data collection details and results of the refinements are summarised in Table 1.

3. Results and discussion

In order to explore specific ligand–peptide interactions and the influence of the lateral chain in the formation and stabilisation of the ternary complex, we have been working on the system Cu–(peptide)–iso-

cytosine. As indicated in the experimental section, the preparation of copper(II) ternary complexes with more complex peptides than glygly presents important difficulties and we have been unsuccessful to obtain the complete family of these compounds. In our hands, we should mention that the nature of the peptide show a great influence in the synthesis of these ternary complexes. Thus, peptides like gly-X (gly-D,L-ala, gly–L-ala, gly–L-val, gly–L-phe, gly–L-tyr and gly–L-trp) have not allowed us to isolate the ternary compound. Contrarily, with X-gly peptides it is possible to obtain the desired complexes and two new compounds were obtained: [Cu(ala–gly)(isocyt)(H$_2$O)]·H$_2$O (**1**) and [Cu(L-tyr–gly)(isocyt)]·3H$_2$O (**2**). It is interesting to note that the reaction conditions for the obtention of the ternary complex with L-ala–gly yield the racemic [Cu(ala–gly) (isocyt)(H$_2$O)]·H$_2$O (**1**) probably due to the high basicity involved in the synthesis. Unfortunately, it has not been possible to isolate the binary Cu(L-ala–gly) to perform the synthesis of the ternary complex in a non-basic conditions.

3.1. Crystal structures

The molecular structures of the compounds are shown in Fig. 1 and Fig. 2. Selected bond distances and angles are given in Table 2.

The crystal structure of **1** presents two molecules per asymmetric unit, having opposite chiralities at C(12).

The complexes [Cu(ala–gly)(isocytosine)(H$_2$O)]·H$_2$O (**1**) and [Cu(L-tyr–gly) (isocyt)]·3H$_2$O (**2**) present a slight distorted square-planar geometry with the four co-ordination sites occupied by the tridentate peptidic dianion [O(7), N(13) and N(10)] [Cu–O(7): 2.020(13) and 2.042(13); Cu–N(13): 1.922(16) and 2.095(15); Cu–N(10): 1.905(17) and 1.883(18) Å for **1** and Cu–O(7): 1.986(2); Cu–N(13): 2.014(3); Cu–N(10): 1.892(3) Å for **2**] and the N(3) [Cu–N(3) 2.003(17) and 2.008(17) Å for **1** and 2.000(3) Å for **2**] of the isocytosine (Figs. 1 and 2). The structures of these two complexes **1** and **2** are similar to the previously described isocytosine complex [Cu(gly–gly)(isocyt)]·2H$_2$O (**3**). Moreover, as observed in compound **3**, additional interactions Cu–water molecules, are present in **1**, although the distance Cu···OW is shorter [2.59 and 2.50 Å for **1** and 2.70 Å for **3**]. On the other hand, in complex **2**, the distances Cu–N(13)

C(12)–N(13)–Cu(1)	108.3(10) and 108.2(10)	109.6(2)

[2.023(8) Å for **3**] and Cu–O(7) [2.008(7) Å for **3**] are shorter than in [Cu(gly–gly)(isocyt)]·2H_2O (**3**). In both complexes the distance Cu–N(3) [1.949(7) Å for **3**] is larger than in **3**. The peptide dianion in **1** and **2** show similar angles as observed in other ternary complexes [Cu(glygly)(isocytosine)]·2H_2O (**3**) [3], [Cu(glygly)(6-methylisocytosine)]·H_2O (**4**) [3], [Cu(glygly)(cytosine)] (**5**) [4] and [Cu(glygly)(cytidine)] (**6**) [5]. Complex **2** show a hydrogen bond N(13)(peptide)–H···O(4)=C(pyrimidine ring) at 2.59 Å and an ancillary interaction Cu–O(8)(other complex unit) [Cu–O(8)*, 2.566(3) Å] similar to those observed in other complexes [3–5] but in complex **1**, neither a hydrogen bond N(13)(peptide)–H···O(4)=C(pyrimidine ring) nor ancillary interactions Cu–O(8) (other complex unit) are observed. The crystal structure of **1** is formed by direct interactions between different complex units [N(13)–H···O*(8)=C: 2.29 and 2.19 Å and N(1)–H···O**(8)=C: 1.70 and 2.03 Å] jointly with interactions through a water molecule [N(2)–H···O(W1): 2.206 and 1.842 Å; O(W1)···O*(11): 2.653 and 2.810 Å] similar to that observed in complex **2** where the crystal packing is dominated by a network of H–bonds through one [N(1)–H···O(21)–H···O*(11): 1.91 and 1.90 Å], two [N(1)–H···O(21)···H–O(23)–H···O*(4): 1.91, 1.92 and 1.96 Å] or three [N(1)–H···O(21)···H–O(23)···H–O(22)–H···O*(11): 1.91, 1.92, 1.88 and 1.946 Å] water molecules, besides other direct interactions between two different complex units [N(2)–H···O*(8): 1.96 Å; O(18)–H···O*(7): 1.89 Å].

These results and the previously described [3] show that the ligand is approximately orthogonal to the Cu–peptide moiety independently of the nature of the lateral chain. Moreover, this disposition contrasts with the corresponding Cu(II)–glygly–creatinine complex [1] where, although the distance between the carboxylic oxygen (O=C) and the aminic nitrogen (H_2N–C) of these two ligands is practically the same (4.5±0.1 Å) the torsion angle that implies Cu(II)–peptide and ligand moieties is completely different. Thus, creatinine adopts a nearly planar disposition with two strong intramolecular H-bonds contrarily to isocytosine that present a nearly orthogonal disposition (Fig. 3).

3.2. IR and electronic absorption

As observed in other N(3) metal co-ordinated isocytosine complexes [3], the strong band assigned to ν[C(4)=O] (1679 cm^{-1} for isocytosine) is shifted to higher frequencies (1683 cm^{-1} for **1** and 1689 cm^{-1} for **2**) upon complexation, ruling out direct O(4) binding of isocytosine to the metal ion. In C(2)=O bonded cytosine complexes [11], the ν(C=O) peak is shifted to lower frequencies. The most noticeable changes in frequency are observed on the bands related to the isocytosine ring stretching. The peaks appearing at 1518 and 1476 cm^{-1} assigned to ν(ring), νC–C+νC=N+ν C–N+νN–H in the free ligand [12–16], are shifted to lower frequencies (1498 and 1465 cm^{-1} for **1**, 1513 and 1499 cm^{-1} for **2**) and the intensity of the band at 1476 cm^{-1} decrease noticeably in both complexes. Similar behaviour in these ν(ring) bands have been observed and attributed to co-ordination of isocytosine to the metal ion through the N(3) [3]. In the lower frequency region the new bands at

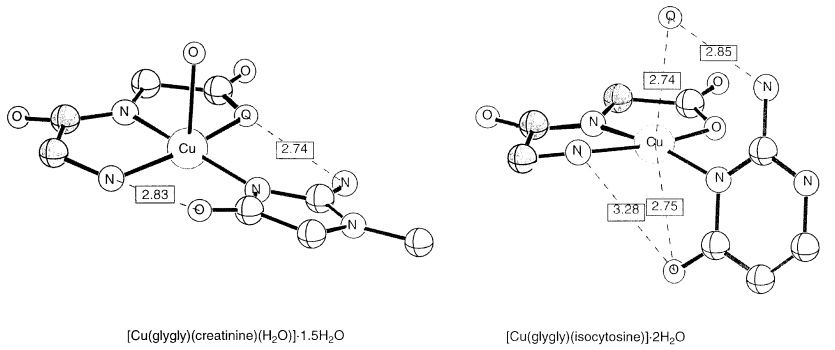

Fig. 3. Isocytosine vs. creatinine: they have similar structure moiety (O=C–N=C–NH_2) but present two different ways of interaction with peptide–Cu(II) binary compounds.

337, 282 cm^{-1} (for **1**) and 288 cm^{-1} (for **2**) are tentatively assigned to ν(Cu–N) [17].

The compounds yield blue solutions in water. The d–d transition spectra of the complexes show broad bands centred at 639 nm ($\varepsilon = 94$), 634 nm ($\varepsilon = 96$) for the isocytosine complexes **1** and **2**, respectively, that are suggestive of approximate square pyramidal geometry about Cu(II) as observed in other Cu(II) peptide complexes [1,18–20]. The π–π* transition bands corresponding to the isocytosine (263sh, $\varepsilon = 3.7 \times 10^3$ and 284, $\varepsilon = 4.5 \times 10^3$) exhibit, in the complex **1**, similar values of intensity and energy (261, $\varepsilon = 5.1 \times 10^3$ and 284, $\varepsilon = 5.1 \times 10^3$) and, in the complex **2**, an increase in intensity and energy (276, $\varepsilon = 7.0 \times 10^3$ and 281, $\varepsilon = 6.9 \times 10^3$). For these complexes, the Λ_M (10^{-3} M) values in water at 20 °C [11.6 (for **1**) and 16.5 (for **2**)] imply the presence of non-electrolyte-type species [21].

3.3. ESR spectra and magnetic properties

The effective magnetic moments $\mu_{eff} = 1.85$ BM (**1**) and 1.72 BM (**2**) at room temperature are normal for magnetically diluted d^9 systems. The X-band ESR spectra of a polycrystalline powder of complexes **1** and **2** recorded at 298 K show a single broad band centred at $g = 2.12$ and 2.11, respectively. Signals of both ESR spectra could be generated by the overlapping of the three components of g according to a rhombically distorted symmetry, particularly in the case of complex **1** in which a small anisotropic feature in $g_\perp$ component is observed.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 172038 and 172037 for **1** and **2,** respectively. Copies of this information mat be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www:http://www.ccdc.cam.ac.uk).

Abstract

Four new oxalato complexes of copper(II) of composition $[Cu(dmen)ox(H_2O)]_2$ $[Cu(dmen)_2](ClO_4)_2$ (**1**) (dmen = *N*,*N*-dimethylethylenediamine, H_2ox = oxalic acid), $[(Cu(dmen)H_2O)_2ox](ClO_4)_2 \cdot H_2O$ (**2**), $[Cu(tmen)(H_2O)(ox)Cu(aep)(H_2O)](ClO_4)_2$ (**3**) (tmen = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, aep = 2-(2-aminoethyl)pyridine) and $[(Cu(dben)NO_3)_2ox]$ (**4**) (dben = *N*,*N*′-dibenzylethylenediamine) have been prepared and characterised by IR and UV–Vis spectroscopies and magnetic measurements. The crystal structure of $[Cu(dmen)ox(H_2O)]_2[Cu(dmen)_2](ClO_4)_2$ (**1**) has been determined by single-crystal X-ray analysis. The structure of **1** contains a neutral $[Cu(dmen)ox(H_2O)]$ complex, a cationic $[Cu(dmen)_2]^{2+}$ complex and perchlorate anions. The copper(II) atom of the neutral $[Cu(dmen)ox(H_2O)]$ unit possesses a distorted square-pyramidal environment with two oxygen atoms of oxalate and two nitrogen atoms of dmen in the basal plane and an oxygen atom of a water molecule in the apical position. The copper(II) atom of the cationic $[Cu(dmen)_2]$ unit shows a square-planar environment with four donor nitrogen atoms of two molecules of dmen. The temperature dependence of magnetic susceptibility for compounds **2**–**4** was measured. Magnetochemical measurements show that copper(II) ions in compounds **2**–**4** are antiferromagnetically coupled through the oxalate bridge, $J = -157$, -175 and -167 cm^{-1} ($H = -2JS_1S_2$, $S_1 = S_2 = 1/2$) for **2**, **3** and **4**, respectively. © 2002 Elsevier Science Ltd. Keywords: Copper(II) complexes; Oxalato complexes; Oxalato-bridged complexes; Magnetic properties; Crystal structures

1. Introduction

Binuclear copper(II) complexes with the oxalate dianion (ox) acting as a bis-bidentate bridging ligand are suitable model compounds for magneto-structural correlations. General trends of magnetic behaviour of these compounds are well established, the oxalate bridge being very efficient in transmission of the antiferromagnetic interactions between the two copper(II) atoms. Julve at al. [1,2] described a theory predicting the magnetic interactions in oxalato bridged Cu(II) complexes. Many binuclear copper(II) mixed-ligand complexes with oxalate as bridging ligand have been structurally characterised and it was found copper(II) can be five- or six-coordinated [2–30]. It was demonstrated that μ-oxalato-dicopper(II) complexes possesses *J*-values approximately from 0 to -200 cm^{-1} ($H = -2JS_1S_2$, $S_1 = S_2 = 1/2$). Further, it is known that complexes with tetragonal pyramidal geometry at both copper centres with oxalate coordinated in the basal plane give rise to *J*-values near -200 cm^{-1} [2,6,8,11,13,24,25,28–30]. A weak interaction (the observed *J*-values are in the range from $+1.1$ to -37.4 cm^{-1}) was found in the case of octahedral, trigonal bipyramidal or tetragonal pyramidal (with one oxygen atom of oxalate coordinated in the basal plane and the other in the apical position) arrangements of copper(II) atoms [9,17,23,25]. Recently, we prepared and characterised binuclear μ-oxalato copper(II) complexes $[(Cu(1,3\text{-pn}))_2ox](ClO_4)_2$ (1,3-pn = 1,3-diaminopropane)

($J = -127$ cm^{-1}), [(Cu(ept))$_2$ox](ClO$_4$)$_2$ (ept = *N*-(2-aminoethyl)-1,3-diaminopropane) [31], [(Cu(aep)-H$_2$O)$_2$ox](NO$_3$)$_2$ (aep = 2-(2-aminoethyl)pyridine) ($J = -160$ cm^{-1}), [(Cu(ept))$_2$ox](NO$_3$)$_2$·H$_2$O [28], [(Cu(medpt))$_2$ox](ClO$_4$)$_2$ (medpt = 3,3′-diamino-*N*-methyl-dipropylamine) ($J = +1.9$ cm^{-1}), [(Cu-(medpt))$_2$ox](NO$_3$)$_2$·2 2/3H$_2$O [29] ($J = -2.6$ cm^{-1}), [(Cu(trimeen)H$_2$O)$_2$ox](ClO$_4$)$_2$·2H$_2$O (trimeen = *N*,*N*,*N*′-trimethylethylenediamine) ($J = -172$ cm^{-1}), [(Cu(trimeen)H$_2$O)$_2$ox](NO$_3$)$_2$·2H$_2$O ($J = -168$ cm^{-1}) and [(Cu(dieten)H$_2$O)$_2$ox](ClO$_4$)$_2$·H$_2$O (dieten = *N*,*N*′-diethylethylenediamine) ($J = -172$ cm^{-1}) [30].

We have extended the series of amine ligands by dmen (*N*,*N*-dimethylethylenediamine) and dben (*N*,*N*′-dibenzylethylenediamine) with the aim to prepare new binuclear μ-oxalato copper(II) complexes. Therefore, we carried out the reaction of copper(II) perchlorate (or copper(II) nitrate), the appropriate amine and sodium oxalate and prepared binuclear μ-oxalato copper(II) complexes [(Cu(dmen)H$_2$O)$_2$ox](ClO$_4$)$_2$·H$_2$O (**2**) and [(Cu(dben)NO$_3$)$_2$ox] (**4**). Our attempts to prepare the analogous complexes [(Cu(dmen)H$_2$O)$_2$ox](NO$_3$)$_2$ and [(Cu(dben)H$_2$O)$_2$ox](ClO$_4$)$_2$ led only to non-reproducible products. Surprisingly, the reaction of copper(II) perchlorate, *N*,*N*-dimethylethylenediamine, sodium oxalate and potassium cyanate in aqueous solution did not result in a complex with oxalato or cyanato bridging ligands but the mononuclear oxalato complex [Cu(dmen)ox(H$_2$O)]$_2$[Cu(dmen)$_2$](ClO$_4$)$_2$ (**1**).

Julve et al. [2] prepared an interesting binuclear oxalato-bridged complex with non-equal copper(II) centres (each copper atom is coordinated by a different blocking ligand) of composition [Cu(tmen)(H$_2$O)(ox)-Cu(dien)](ClO$_4$)$_2$ (tmen = *N*,*N*,*N*′,*N*′-tetramethylethylenediamine, dien = diethylenetriamine). With the aim to extend the series of these compounds we tried the reaction [Cu(tmen)ox]·4H$_2$O, copper(II) perchlorate and 2-(2-aminoethyl)pyridine (aep) that results in the formation of the complex [Cu(tmen)(H$_2$O)(ox)Cu(aep)-(H$_2$O)](ClO$_4$)$_2$ (**3**).

The prepared compounds were characterised by elemental analysis, IR and UV–Vis spectroscopies and magnetic susceptibility measurements. The crystal structure of the complex [Cu(dmen)ox(H$_2$O)]$_2$[Cu(dmen)$_2$]-(ClO$_4$)$_2$ (**1**) has been determined by a single-crystal X-ray analysis.

2. Experimental

2.1. Chemicals and methods

The starting material Cu(ClO$_4$)$_2$·6H$_2$O was obtained by the reaction of basic copper(II) carbonate and HClO$_4$ (Carlo Erba) in aqueous solution (the reaction mixture was concentrated to crystallisation, the solid was filtered off and dried at 35 °C under an infralamp). *N*,*N*-dimethylethylenediamine, *N*,*N*′-dibenzylethylenediamine and 2-(2-aminoethyl)pyridine (Aldrich), sodium oxalate and Cu(NO$_3$)$_2$·3H$_2$O (Lachema Brno) and KOCN (Fluka) were used without further purification. Compound [Cu(tmen)ox]·4H$_2$O was prepared according to the literature [2].

Elemental analyses (C, H, N) were performed on a Fisons EA1108 CHN instrument. Absorption UV–Vis spectra (33 000–11 000 cm^{-1}) were recorded on a SPECORD M40 instrument in Nujol, IR spectra (4000–400 cm^{-1}) on a SPECORD IR 80 instrument using the Nujol technique. The magnetic susceptibilities were measured in the temperature range liquid nitrogen to room temperature (r.t.) by the Faraday method on the balance constructed in Nicholas Copernicus University (complexes **3** and **4**) and in Palacký University (complex **2**) with Hg[Co(NCS)$_4$] as a calibrant [32]. The molar susceptibilities of all complexes were corrected for diamagnetism using Pascal's constants [33].

Crystals of [Cu(dmen)ox(H$_2$O)]$_2$[Cu(dmen)$_2$](ClO$_4$)$_2$ (**1**) of X-ray quality were obtained from water by slow evaporation of solvent at r.t. The reflections were collected at 150 K on a four-circle κ-axis KUMA KM-4 diffractometer. The structure was solved by the heavy method using atom the program SHELXS-97 [34]. All non-hydrogen atoms were refined anisotropically [35] by a full-matrix least-squares with the weight procedure $w = [\sigma^2(F_o^2) + (w_1P)^2 + w_2P]^{-1}$, where $P = [F_o^2 + 2F_c^2]/3$, $w_1 = 0.0740$, $w_2 = 3.4700$. Parameters of all hydrogen atoms were refined isotropically. The crystal data and structure refinement details for [Cu(dmen)ox(H$_2$O)]$_2$[Cu(dmen)$_2$](ClO$_4$)$_2$ (**1**) are given in Table 1, whereas selected bond lengths and angles are listed in Table 2.

2.2. Syntheses

Caution! Perchlorates and perchlorate salts of metal complexes with organic ligands are potentially explosive. A small amount of material only should be prepared and it should be handled with care.

2.2.1. [Cu(dmen)ox(H$_2$O)]$_2$[Cu(dmen)$_2$](ClO$_4$)$_2$ (1)

A solution of 0.22 g (2.71 mmol) of KOCN and 0.36 g (2.69 mmol) of sodium oxalate in 25 cm^3 of water was added to a solution of 2.00 g (5.40 mmol) of Cu(ClO$_4$)$_2$·6H$_2$O and 0.59 cm^3 (5.37 mmol) of *N*,*N*-dimethylethylenediamine in 10 cm^3 of water. After 1 h of stirring the reaction mixture was concentrated to crystallisation in a water bath. The obtained dark blue crystals were filtered off and dried in air. The yield was 0.6 g (45%).

2.2.2. [(Cu(dmen)H$_2$O)$_2$ox](ClO$_4$)$_2$·H$_2$O (2)

A solution of 0.18 g (1.34 mmol) of sodium oxalate in 15 cm^3 of water was added to a solution of 1.00 g (2.70

mmol) of Cu(ClO_4)$_2$·6H_2O and 0.30 cm^3 (2.73 mmol) of *N*,*N*-dimethylethylenediamine in 25 cm^3 of water. The resulting dark blue solution was concentrated to 15 cm^3 to crystallisation by heating. A small amount of solid formed was discarded. The filtrate was allowed to stand overnight. The light blue microcrystals were filtered off, washed with a small amount of water and dried in air. The yield was 0.35 g (40%).

2.2.3. [Cu(tmen)(H_2O)(ox)Cu(aep)(H_2O)](ClO_4)$_2$ (**3**)

A solution of 0.50 g (1.35 mmol) of Cu(ClO_4)$_2$·6H_2O and 0.16 cm^3 (1.34 mmol) of 2-(2-aminoethyl)pyridine in 20 cm^3 of water was added to a solution of 0.46 g (1.35 mmol) of [Cu(tmen)ox]·4H_2O in 15 cm^3 of water. The resulting dark blue solution was concentrated to 10 cm^3 to crystallisation by heating. A small amount of light blue powder formed was discarded. The filtrate was allowed to stand overnight. The obtained blue polycrystalline product was filtered off and dried in air. The yield was 0.2 g (22%).

2.2.4. [(Cu(dben)NO_3)$_2$ox] (**4**)

A solution of 0.14 g (1.04 mmol) of sodium oxalate in a minimum amount of water was added to a solution of 0.50 g (2.07 mmol) of Cu(NO_3)$_2$·3H_2O and 0.49 cm^3 (2.08 mmol) of *N*,*N*′-dibenzylethylenediamine in ethanol (25 cm^3) and water (10 cm^3). The reaction mixture was filtered and the filtrate was allowed to stand overnight. The blue microcrystalline product was filtered off, washed with water and ethanol and dried in air. The yield was 0.7 g (85%).

3. Results and discussion

3.1. Structure of complex *1*

The structure of [Cu(dmen)ox(H_2O)]$_2$[Cu-(dmen)$_2$](ClO_4)$_2$ (**1**) is made up of neutral [Cu(dmen)-ox(H_2O)] units, cationic [Cu(dmen)$_2$]$^{2+}$ units and un-

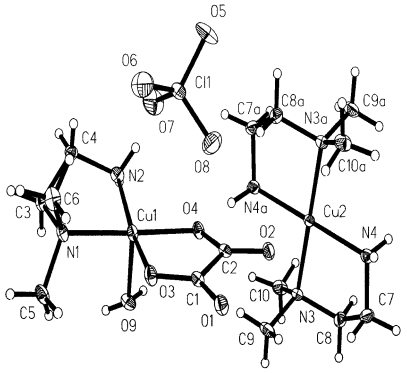

Fig. 1. A view (thermal ellipsoids are drawn at 40% probability level) of [Cu(dmen)ox(H_2O)]$_2$[Cu(dmen)$_2$](ClO_4)$_2$ (**1**).

coordinated perchlorate anions (Fig. 1). The $[Cu(dmen)ox(H_2O)]$ complex, $[Cu(dmen)_2]^{2+}$ cation and perchlorate anion, in a 2:1:2 molar ratio, coexist. The copper atom of the neutral $[Cu(dmen)ox(H_2O)]$ unit shows a distorted square-pyramidal environment with the two oxygen atoms of oxalate and two nitrogen atoms of dmen building the basal plane and an oxygen atom of a water molecule in the apical position. The in-plane Cu–N and Cu–O bond lengths ranges from 1.940(3) to 2.022(3) Å and the axial Cu–O bond distance 2.345(3) Å is significantly longer than the in-plane Cu–N and Cu–O bond lengths. The value of the τ parameter (17.9) [36] discloses a square-pyramidal shape of the coordination polyhedron (ideal τ value for square-pyramidal situation is 0 and for trigonal bipyramidal situation is 100). The copper atom of the cationic $[Cu(dmen)_2]^{2+}$ unit is situated on a crystallographic centre of symmetry and shows a square-planar environment with four nitrogen atoms from two molecules of dmen. The one Cu–N bond length (1.994(3) Å) is shorter than the other Cu–N bond length (2.095(3) Å). This difference may be explained by steric hindrance from the methyl groups bonded to donor nitrogen atom.

The neutral complex $[Cu(dmen)ox(H_2O)]$ has square-pyramidal arrangement around the copper(II) atom with the two oxygen atoms of oxalate and two nitrogen atoms of *N*,*N*-dimethylethylenediamine forming the basal plane and an oxygen atom of a water molecule in the apical position as in the analogous complex $[Cu(L)ox(H_2O)]$ (L = *N*,*N*′-dimethylethylenediamine) [37] (its structure has been known since 1973).

3.2. IR and UV–Vis

The characteristic IR spectra group vibrations of the complexes prepared are as follows: $\nu_3(ClO_4)$ 1056–1100 cm^{-1} (s), $\nu_4(ClO_4)$ 624–620 cm^{-1} (s), $\nu_{asym}(OCO)$ 1642–1668 cm^{-1} (s) and $\delta(OCO)$ 752–788 cm^{-1} (m). These values are consistent with coordinated oxalate [7,12,38,39] and uncoordinated perchlorate [28,29,40] anions.

The UV–Vis absorption spectra of Cu(II) complexes are characterised by a strong band in the range 11 000–16 000 cm^{-1} corresponding to a d–d transition [41]. In the present compounds, the maxima for **1** (16 250), **2** (16 450), **3** (14 900) and **4** (15 700 cm^{-1}) with ε_{max} (mol^{-1} dm^3 cm^{-1}; per Cu) equal to 62 (**1**), 115 (**2**), 140 (**3**) and 103 (**4**), respectively, correspond to this band.

3.3. Magnetic properties

The magnetic susceptibility of the mononuclear complex $[Cu(dmen)ox(H_2O)]_2[Cu(dmen)_2](ClO_4)_2$ (**1**) was measured at r.t. only. The observed value of the magnetic moment (1.82μ_B per Cu) is in accordance with the literature data for magnetically diluted compounds of copper(II).

The variable-temperature magnetic moment and magnetic susceptibility in the range 84–295 K (compound **2**) and 78–298 K (compounds **3** and **4**) for solid samples is shown in Figs. 2–4. The magnetic moment are dependent on temperature and decreases from 1.31–1.40 μ_B (per Cu) at 298 (or 295) K to 0.29–0.30 μ_B (per Cu) at 78 (or 84) K (see Tables 3 and 4). This implies rather strong antiferromagnetic coupling mediated by the oxalate bridge.

Magnetic measurements show that complexes **2**–**4** behave like a common copper(II) dimers ($H = -2JS_1S_2$, $S_1 = S_2 = 1/2$) (see Figs. 2–4). The molar magnetic susceptibility was expressed by the modified Bleaney–Bowers equation allowing for the presence of paramagnetic impurity [42]:

Table 4
Magnetic properties of the complexes

Complex	μ_{eff} (per Cu)/T[μ_B] (K)	J (cm^{-1})	g	P (%)
$[Cu(dmen)ox(H_2O)]_2[Cu(dmen)_2](ClO_4)_2$ (**1**)	1.82/294			
$[(Cu(dmen)H_2O)_2ox](ClO_4)_2 \cdot H_2O$ (**2**)	1.40/295–0.30/84	−157	2.150	0
$[Cu(tmen)(H_2O)(ox)Cu(aep)(H_2O)](ClO_4)_2$ (**3**)	1.31/298–0.30/78	−175	2.108	1.63
$[(Cu(dben)NO_3)_2ox]$ (**4**)	1.35/298–0.29/78	−167	2.123	0.86

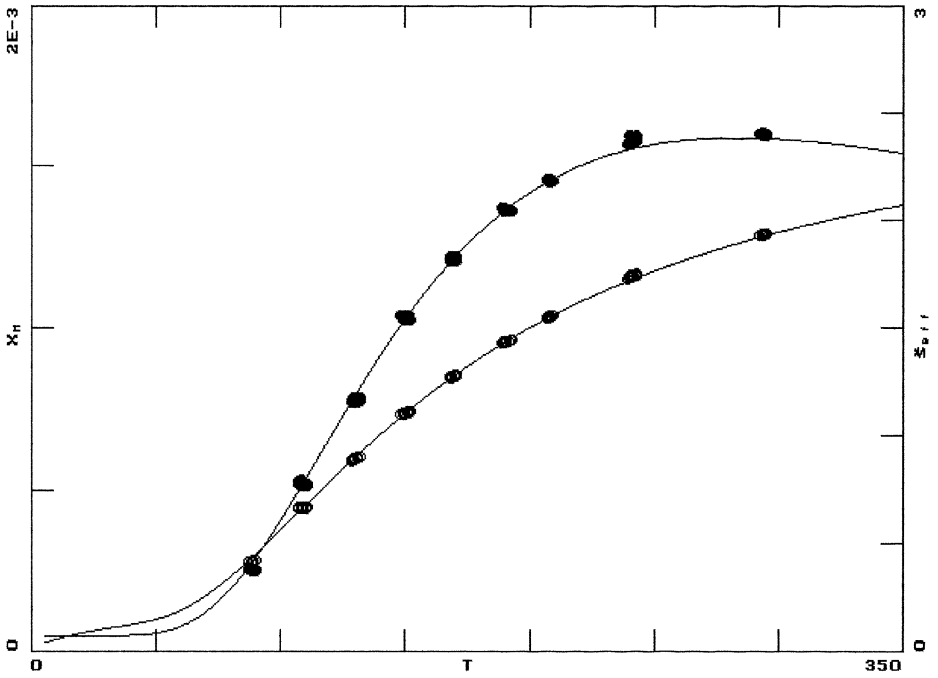

Fig. 2. Variation of corrected molar magnetic susceptibility (●) and effective magnetic moment (○) per mole of $[(Cu(dmen)H_2O)_2ox](ClO_4)_2 \cdot H_2O$ (**2**) complex with temperature. The circles are the experimental points, the solid lines are theoretical lines.

$$\chi_M^{corr} = 2(Ng^2\beta^2/3kT)[1 + 1/3\ \exp(-2J/kT)]^{-1}(1 - P) + (Ngi_i^2\beta^2/4kT)P + N\alpha$$

where χ_M^{corr} is the corrected molar magnetic susceptibility per copper(II) dimer, P is the mole fraction of the monomeric copper(II) impurities, g_i is the average g factor of the impurity which was fixed at 2.15 throughout the present study, $-2J$ is the singlet-triplet separation, $N\alpha$ is the temperature independent paramagnetism equal to 120×10^{-6} cm^3 mol^{-1} (per dimer), and the other symbols have their usual meanings. The best fit parameters J, g and P, were obtained by using a non-linear least-squares program. The exchange integral does not depend on the g_i value within range 2.1–2.2 and $N\alpha$ within the reasonable range, whereas changes on g-value and P are negligible. As a convenient statistical indicator of the quality of the least-squares fits, the discrepancy index σ_{dis} ($\sigma_{dis} = [\Sigma(\chi_{obs} - \chi_{calc})^2/$

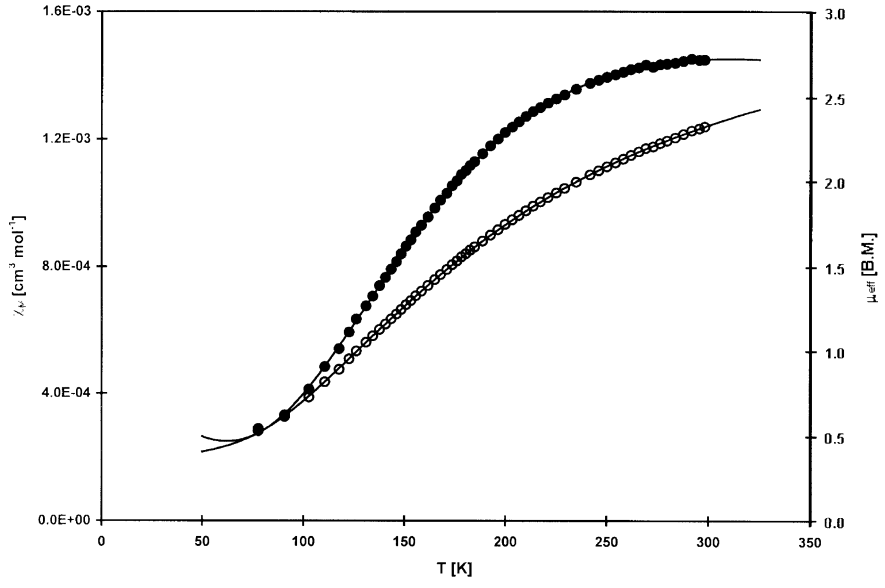

Fig. 3. Variation of corrected molar magnetic susceptibility (●) and effective magnetic moment (○) per mole of $[Cu(tmen)(H_2O)(ox)Cu(aep)(H_2O)](ClO_4)_2$ (**3**) complex with temperature. The circles are the experimental points, the solid lines are theoretical lines.

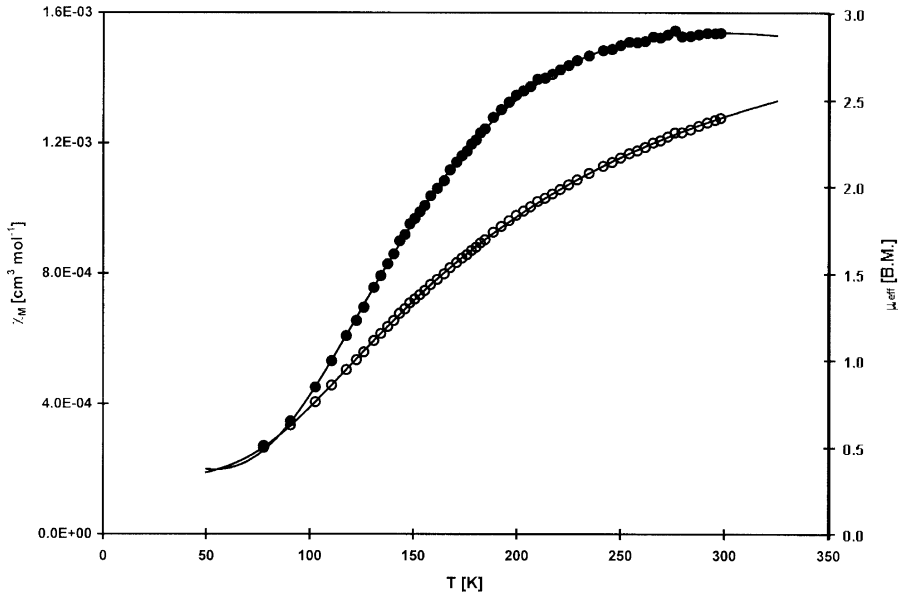

Fig. 4. Variation of corrected molar magnetic susceptibility (●) and effective magnetic moment (○) per mole of [(Cu(dben)NO_3)$_2$ox] (**4**) complex with temperature. The circles are the experimental points, the solid lines are theoretical lines.

$\Sigma(\chi_{obs})^2]^{1/2}$) was employed. The least-square fit (see Table 4) of the data yields $J = -157$ cm^{-1} ($\sigma_{dis} = 3.99 \times 10^{-3}$), $J = -175$ cm^{-1} ($\sigma_{dis} = 3.08 \times 10^{-3}$) and $J = -167$ cm^{-1} ($\sigma_{dis} = 4.74 \times 10^{-3}$) ($H = -2JS_1S_2$, $S_1 = S_2 = 1/2$) for **2**, **3** and **4**, respectively.

Hence, the compounds **2**–**4** exhibit a strong antiferromagnetic exchange interaction that can be explained by the tetragonal pyramidal coordination of copper with oxalate oxygen atoms in basal positions, so that the x^2-y^2 magnetic orbital on Cu is directed ideally for overlap with the oxalate sigma orbitals [1,2]. The observed J-values for **2** (−157), **3** (−175) and **4** (−167 cm^{-1}) are similar to those of [(Cu(L)H_2O)$_2$ox](ClO$_4$)$_2$ (L = *N*,*N*-diethyl-1,2-diaminoethane) ($J = -150$ cm^{-1}) [24], [(Cu(L)H_2O)$_2$ox](ClO$_4$)$_2$·H_2O (L = *N*,*N*′-diethyl-1,2-diaminoethane) ($J = -172$ cm^{-1}) [30], [(Cu(aep)(H_2O))$_2$ox](ClO$_4$)$_2$ ($J = -160$ cm^{-1}) [28] or [(Cu(tmen)H_2O)$_2$ox](ClO$_4$)$_2$·1.25H_2O ($J = -193$ cm^{-1}) [2]. These four complexes [2,24,28,30] contain the square pyramidal arrangement of copper(II) with bridging oxalate and bidentate amine coordinated in the basal plane. The water oxygen atom is coordinated in the apical position. The square pyramidal coordination with oxalate oxygen atoms and blocking diamine nitrogen atoms in basal positions is supposed for complexes **2**, **3** and **4**, too.

Abstract

A chloride substitution reaction of a bis(imido) molybdenum(VI) complex, [Mo(Nmes)$_2$Cl$_2$(dme)] (dme = 1,2-dimethoxyethane) with KTp* (Tp* = hydrotris(3,5-dimethyl-1-pyrazole)borate) in THF resulted in [Tp*Mo(Nmes)$_2$Cl] **1** in good yield. The analogous methylated complex [Tp*Mo(Nmes)$_2$(CH_3)] **2** was formed by reaction of **1** with 1 equiv. of CH_3MgCl in THF, while [Tp*Mo(Nmes)$_2$(OH)] **3** was conveniently produced from **2** in the presence of wet methanol under aerobic conditions. The complexes were characterized by ^{1}H NMR and IR spectroscopy. The molecular structures of complexes of **1** and **3** have been determined by X-ray single crystal analyses. The crystal structures of the complexes show that the three nitrogen atoms of Tp* are not equidistant from the respective Mo(VI) centers. Each Mo(VI) centre of **1** and **3** is in a distorted octahedral coordination geometry with a facially co-ordinated Tp* and two Nmes ligands. The complexes of **1** and **3** contain linear imido ligands © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Pyrazole; Mononuclear bis(imido) Mo(VI) complexes; X-ray crystal structures

1. Introduction

Tris(pyrazolyl)borate is a facially co-ordinating ligand similar to 6e$^-$ donors such as L_{OR} and Cp* ligands (L_{OR} = [η^5-(C_5H_5)Co{P(OR)$_2$(O)}$_3$]; Cp* = pentamethylcyclopentadienyl). The substitution of groups on the pyrazoles can control the steric and electronic effects of the ligand on the metal center [1–5]. Also, the sterically encumbering nature of the Tp* ligand compared with Cp* is widely known and explored in high activity for catalyst systems [6–8].

Imido ligands attached to transition metals form multiple bonds, which may be used to stabilize high oxidation state metals [9,10]. Certain imido complexes can readily be prepared by adding a primary amine to a molybdenum-oxo complex and removing water. Convenient synthetic entries into bis(imido) [11–17] and chelating bis(imido) [18,19] molybdenum(VI) complexes have been reported and [Mo(TADDAMINat)Cl$_2$(dme)] (TADDAMIN = {(4S,5S)-2,2-dimethyl-α,α,α′,α′-tetraphenyl-1,3-dioxolan-4,5-dimethanamine}) [20] containing a chiral diimido ligand is known as a catalyst for C–C and C–N bond formation.

[TpMo(Nmes)$_2$Cl] (Tp = hydrotris(pyrazolyl)borate) and [(L_{OEt})Mo(Nmes)$_2$Cl] (L_{OEt} = [η^5-(C_5H_5)Co{P(O-C_2H_5)$_2$(O)}$_3$]) [21] have been synthesized by the treatment of [Mo(Nmes)$_2$Cl$_2$(dme)] with KTp or NaL_{OEt}, but are not fully characterized. The related bis(imido) molybdenum complex [Tp*Mo(N′Bu)$_2$Cl] [22] was synthesized and its structure was identified by X-ray crystallography. However, studies of the reactivity of bis(imido) molybdenum complexes are limited. The related dioxomolybdenum(VI) complexes [Tp*Mo-(O)$_2$Cl] [22,23] and [Tp*Mo(O)$_2$(R)] [24,25] (R = CH_3 or $CH_2Si(CH_3)_3$) were also reported. Significantly, we have obtained products containing alkyl and hydroxy

groups from the further reactions with **1** and we report herein the syntheses, molecular structures and reactivities of [Tp*Mo(Nmes)$_2$X] (X = Cl, CH_3 or OH).

2. Experimental

2.1. General

All manipulations were carried out with standard Schlenk techniques under argon. KTp* [26,27] and [Mo(Nmes)$_2$Cl$_2$(dme)] [21] were prepared according to literature procedures. All other chemicals were of reagent grade and the solvents were distilled and degassed under argon prior to use. Elemental analyses were performed by the Chemical Analysis Laboratory of the Korea Basic Science Institute at Kyungpook National University. The ^{1}H NMR spectra were recorded on a Varian 300 NMR spectrometer at ambient temperature. The IR spectra (KBr, pellet) were recorded on Mattsion, Galaxy 7020A spectrophotometers.

2.2. Synthesis of bis(imido)complexes

2.2.1. Synthesis of [Tp*Mo(Nmes)$_2$Cl] (*1*)

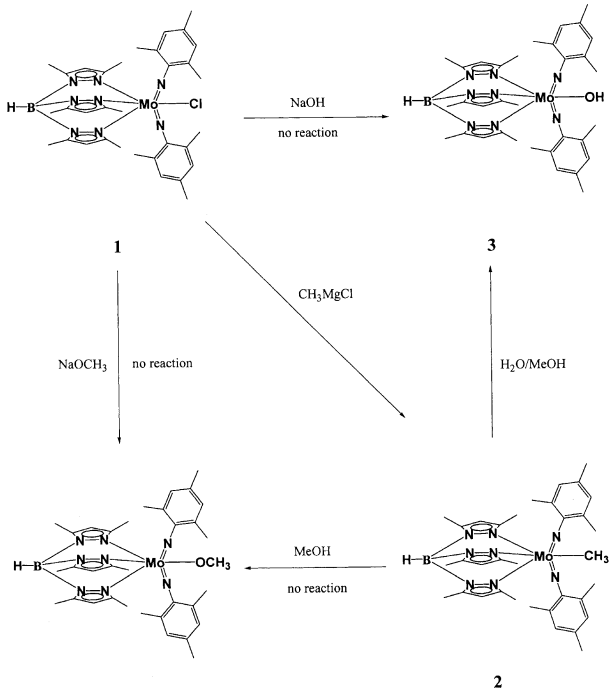
To a mixture of KTp* (2.64 g, 7.90 mmol) and [Mo(Nmes)$_2$Cl$_2$(dme)] (4.11 g, 7.90 mmol) was added 150 ml of THF with stirring and the solution was then left to stir at room temperature (r.t.) for 4 days. The resulting green solution was filtered in air and the filtrate was dried in vacuo. The green solid was extracted with Et_2O and dried to afford a dark green solid. Yield 3.80 g (70%). (Found: C, 56.87; H, 6.38; N, 16.13. $C_{33}H_{44}BClN_8Mo$ requires C, 57.03; H, 6.38; N, 16.12%); ν_{max} (cm^{-1}) 2924m, 2523w, 1601w, 1542m, 1447s, 1414s, 1369s, 1274vs, 1209s, 1070m, 1043w, 969w, 855w, 786w, 648w cm^{-1}; δ_H(300 MHz; $CDCl_3$; $SiMe_4$) 6.70 (2H, s, $Me_3C_6H_2$), 6.45 (2H, s, $Me_3C_6H_2$), 5.68 (1H, s, 4-$Me_2C_3N_2H$), 5.65 (2H, s, 4-$Me_2C_3N_2H$), 2.74 (6H, s, 3-$Me_2C_3N_2H$), 2.37 (3H, s, 3-$Me_2C_3N_2H$), 2.29 (12H, s, *o*-$Me_3C_6H_2$), 2.15 (6H, s, *p*-$Me_3C_6H_2$), 1.98 (3H, s, 5-$Me_2C_3N_2H$), 1.12 (6H, s, 5-$Me_2C_3N_2H$).

2.2.2. Synthesis of [Tp*Mo(Nmes)$_2$(CH$_3$)] (*2*)

Complex **1** (1.70 g, 2.45 mmol) was dissolved in 50 ml of THF, cooled in a dry ice–acetone bath. 3 M CH_3MgCl in THF (0.82 ml, 2.45 mmol) was added slowly by syringe. The dark green solution was allowed to warm to r.t. and the solution stirred for 1 day. The resulting solution was filtered off and the solvent was removed in vacuo. The dark green solid was extracted with Et_2O and dried in vacuo. Yield 1.21 g (73%). (Found: C, 60.67; H, 7.18; N, 16.43. $C_{34}H_{47}BN_8Mo$ requires C, 60.54; H, 7.02; N, 16.61%); δ_H(300 MHz; $CDCl_3$; $SiMe_4$) 6.76 (2H, s, $Me_3C_6H_2$), 6.56 (2H, s, $Me_3C_6H_2$), 5.61 (2H, s, 4-$Me_2C_3N_2H$), 5.54 (1H, s, 4-$Me_2C_3N_2H$), 2.87 (6H, s, 3-$Me_2C_3N_2H$), 2.54 (6H, s, *p*-$Me_3C_6H_2$), 2.21 (3H, s, 3-$Me_2C_3N_2H$), 2.12 (6H, s, *o*-$Me_3C_6H_2$), 2.11 (6H, s, *o*-$Me_3C_6H_2$), 2.06 (3H, s, 5-$Me_2C_3N_2H$), 1.81 (3H, s, CH_3), 1.63 (6H, s, 5-$Me_2C_3N_2H$).

Attempts to obtain [Tp*Mo(Nmes)$_2$(CH$_2$(CH$_3$)$_2$Ph)] from the reaction of **1** with $CH_2(CH_3)_2PhMgCl$ failed.

2.2.3. Synthesis of [Tp*Mo(Nmes)$_2$(OH)] (*3*)



Complex **2** (0.50 g, 0.74 mmol) was dissolved in a mixture of wet methanol (50 ml) and acetone (10 ml), and the solution was stirred at ambient temperature for 1 day. The yellow solution gradually deposited a yellow green solid, which was filtered off and dried in air. Yield 0.37 g (74%). (Found: C, 58.87; H, 6.68; N, 16.53. $C_{33}H_{45}BN_8OMo$ requires C, 58.55; H, 6.67; N, 16.55%); ν_{max} (cm^{-1}) 3404m. br, 2955m, 2923w, 2855w, 1543m, 1447m, 1370w, 1303m, 1278vs, 1211m, 1069m, 1040m, 971m, 854m, 812m 649w cm^{-1}; δ_H(300 MHz; $CDCl_3$; $SiMe_4$) 6.67 (2H, s, $Me_3C_6H_2$), 6.48 (2H, s, $Me_3C_6H_2$), 5.64 (3H, s, 4-$Me_2C_3N_2H$), 2.53 (6H, s, 3-$Me_2C_3N_2H$), 2.34 (3H, s, 3-$Me_2C_3N_2H$), 2.29 (6H, s, *o*-$Me_3C_6H_2$), 2.31 (6H, s, *o*-$Me_3C_6H_2$), 2.23 (6H, s, *p*-$Me_3C_6H_2$), 2.03 (3H, s, 5-$Me_2C_3N_2H$), 1.26 (6H, s, 5-$Me_2C_3N_2H$).

2.3. Crystal structure determination of *1* and *3*

A dark green crystal of **1** and a yellow green crystal of **3** suitable for X-ray diffraction study were obtained from acetonitrile solution and mounted on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Unit cell dimensions with e.s.d. were determined by least-squares using 25 well-centered reflections in the range of 10°–13°. A total of 6932 unique reflections for **1** were collected in the range of 1.68°–25.47° ($-13 \le h \le 13$, $0 \le k \le 29$, $0 \le l \le 15$) and those (7158) for **3** were collected in the range where ($0 \le h \le 10$, $0 \le k \le 29$, $-21 \le l \le 21$) in the ω–2θ scan mode. The intensities of the reflections were corrected for Lorentz and polarization effects. Crystal data, data collection and refinement for **1** and **3** are listed in Table 2. Data reductions were carried out using a MOLEN program package; a decay correction based on the intensities of two standard reflections and monitoring every hour was performed; empirical absorption corrections were applied based on Ψ scans [28]. The structures in $P2_1/c$ for **1** and **3** were determined by direct methods and refined by full-matrix least-squares using SHELXS-97 and SHELXL-97 program packages [29,30] using reflections with $I > 2\sigma(I)$. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were constrained by using riding modes. The final cycle of the refinement yielded to $R = 0.055$ and $wR = 0.143$ for **1** and $R = 0.037$ and $wR = 0.103$ for **3**.

3. Results and discussion

A bis(imido) molybdenum complex [Tp*Mo(Nmes)$_2$Cl] was prepared using a similar synthetic procedure to that for [TpMo(Nmes)$_2$Cl]. The dark green crystals of **1** were obtained after recrystallization in acetonitrile and its structure was determined by the X-ray diffraction method. Complex **2** was prepared by the reaction of **1** with 1 equiv. of CH_3MgCl in THF at −78 °C, but [Tp*Mo(Nmes)$_2$($CH_2C(CH_3)_2Ph$)] was not obtained using a similar procedure. Complex **3** was readily obtained from an acetone solution of **2** wet methanol mixture but was not directly produced from NaOH as shown Scheme 1. Attempts to obtain the complex [Tp*Mo(Nmes)$_2$(OCH_3)] from reaction of **1** or **2** with $NaOCH_3$ or MeOH failed. The view of the molecular structure of **1** with the atomic labelling scheme is shown in Fig. 1. Selected bond lengths and angles for **1** are given in Table 1 and the molybdenum atom is in a distorted octahedral geometry surrounded by N(3), N(5) and N(7) nitrogen atoms of Tp*, N(1) and N(2) nitrogen atoms of Nmes and one chlorine atom. While the Mo–N(3), Mo–N(5) and Mo–N(7) bond lengths [2.296(3), 2.325(3) and 2.176(3) A] are slightly shorter than those [2.321(3), 2.472(3) and 2.201(3) Å] in [Tp*Mo(N^{t}Bu)$_2$Cl] [22], the Mo–N(1) and Mo–N(2) bond lengths [1.772(3) and 1.765(3) Å] are somewhat longer than those [1.746(3) and 1.739(3) Å] in [Tp*Mo(N^{t}Bu)$_2$Cl] [22]. The Mo–N bond lengths of Tp* trans to the Nmes ligands are elongated by about 0.135 Å on comparison with that trans to the chloro ligand, which is showing a trans influence. The opening of the bond angle [N(1)–Mo–N(2) 104.7(1)°] is the main distortion of the coordination geometry around the metal center which is similar to that [105.4(2)°] in [Tp*Mo(N^{t}Bu)$_2$Cl] [22]. Both imido ligands are linear having Mo–N(1)–C(1) and Mo–N(2)–C(10) bond angles [177.8(3)° and 174.6(3)°], within the range 160°–180° by comparison with those [170.4(9)° and 164.2(9)°] of [(L_{OEt})Mo(Nmes)$_2$Cl] [21].

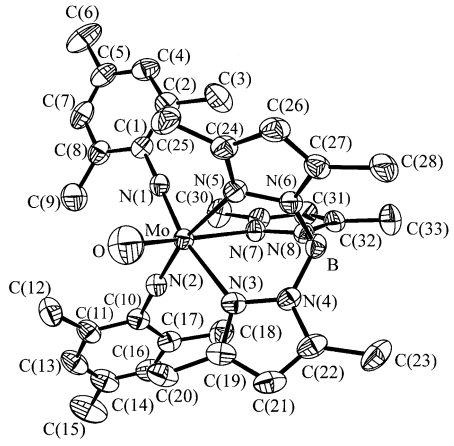

Fig. 2. Molecular structure with the labelling scheme for compound **3**.

The coordination geometry around the Mo atom in **3** is octahedral with three nitrogen atoms of Tp* occupying one face of the octahedron and with two nitrogen atoms of Nmes and one oxygen atom of the hydroxy group occupying the opposite face. The bond lengths of Mo–N(3), Mo–N(5) and Mo–N(7) [2.333(3), 2.357(3) and 2.228(3) Å] are slightly longer than those in **1**, but are similar to those in [Tp*Mo(N^{t}Bu)$_2$Cl] [22]. The Mo–N bond lengths of Tp* trans to the Nmes ligands in **3** are 0.117 Å longer than that trans to the OH ligand. The differences between Mo–N bond lengths for Tp* trans to OH and Nmes ligands in **3** are smaller than that in **1**(0.135Å). The bond angles of N(1)–Mo–N(3), N(2)–Mo–N(5) and N(7)–Mo–O [166.4(1)°, 164.0(1)° and 158.1(1)°] are comparable with those [166.0(1)°, 166.1(1)° and 161.89(8)°] in **1** and those [160.0(1)°, 166.5(1)° and 163.0(1)°] in [Tp*Mo(N^{t}Bu)$_2$Cl] [22]. Both imido ligands can be considered linear having Mo–N(1)–C(1) and Mo–N(2)–C(10) bond angles [175.2(3)° and 177.6(3)°] within the range expected for the related d^0 M(NR) linkages [24,25].

Complexes of **1** and **3** are slightly soluble in hydrocarbon solvents and soluble in THF, $CHCl_3$ and other common polar solvents. Complex **2** is soluble in Et_2O, benzene and toluene. The complexes of **1** and **3** are stable in air for several weeks without noticeable decomposition but **2** decomposed in air within several hours. The ^{1}H NMR spectrum of **1** shows two singlets in a 1:2 ratio at 5.68 and 5.65 ppm for the three 4-H protons of the 3,5-dimethylpyrazolyl groups of Tp*, which are close to those at 5.87 and 5.71 ppm in [Tp*Mo(N^{t}Bu)$_2$Cl] [22]. The ^{1}H NMR spectrum of **2** shows two singlets in a 2:1 ratio for the three 4-H protons of the 3,5-dimethylpyrazolyl groups of Tp* at 5.61 and 5.54 ppm and the ^{1}H NMR of **3** shows a singlet for the three 4-H protons of the 3,5-dimethylpyrazolyl group at 5.64 ppm. The ^{1}H NMR spectra from the 4-H protons of the 3,5-dimethylpyrazolyl of Tp* for **1**, **2** and **3** are shown in Fig. 3. A singlet of one 4-H proton of 3,5-dimethylpyrazole trans to Cl is at low field and a singlet for the 2 equiv. 4-H protons trans to the Nmes ligands is upfield for **1**, while a singlet for two 4-H protons trans to the Nmes ligands is at low field and a singlet for one 4-H proton trans to the methyl group is at up field for **2**, in contrast to **1**. These facts are due to the different trans influences from Cl, methyl and Nmes ligands. However, the ^{1}H NMR of **3** shows a singlet for all three 4-H protons due to the equivalent trans influences of OH and Nmes ligands in comparison with **1** and **2**.

Abstract

Three zinc(II) halide complexes ZnL_2X_2 (X = Cl, Br, I; L = 4-methoxylbenzaldehyde thiosemicarbazone) have been synthesized and characterized by spectroscopic techniques. The complexes exhibit powder SHG efficiency approximately ten times higher than that of urea. The molecular hyperpolarizabilities are calculated to be -2.6×10^{-30} esu for the free ligand L, and -4.6×10^{-30}, -6.2×10^{-30}, -10.1×10^{-30} esu for the three zinc complexes, respectively. The former two complexes crystallize in the noncentrosymmetric space group *Aba*2, whilst ZnL_2I_2 crystallizes in the centrosymmetric space group $P2_1/c$ and does not exhibit any SHG efficiency. The zinc(II) atom in these complexes is tetrahedrally coordinated by two neutral sulfur atoms from the corresponding thiosemicarbazones and two halide anions. The relationships between the molecular structures and nonlinear optical properties were studied based on theoretical calculation and experimental determination methods. © 2002 Elsevier Science Ltd. 1. Introduction

Nonlinear optical materials exhibiting efficient second-harmonic generation (SHG) at short wavelengths are needed in the fields of high-density optical recording, laser printing, and optical measurement systems and for other applications [1,2]. Compact all-solid-state devices based on the frequency doubling of diode-pumped laser have the potential to meet industrial needs such as efficiency, reliability, and low costing. Recently efficient continuous-wave (cw) green and blue SHG was demonstrated with inorganic crystals such as KTP [3], $KNbO_3$ [4], and β-barium borate (BBO) [5]. The properties of these inorganic devices [5] have made them suitable for practical use. On the other hand, numerous organic SHG materials with nonlinearity superior to that of inorganic materials have been investigated [6,7]. However, only a few organic compounds with large hyperpolarizability (β) have been developed into useful bulk crystalline materials for practical applications [8,9].

Ideally the large nonlinearities of π-conjugated organics and favorable crystal growth characteristics and mechanical properties of ionic salts would be combined into a single NLO crystal [10–17]. Extended π-conjugated networks in organic systems with the largest nonlinearities invariably have significant absorption in the visible portion of the spectrum. Consequently, for SHG into the blue-near-UV regions, more transparent and less extensively delocalized organics must be considered (e.g. urea), albeit at the expense of decreasing the nonlinearity. Semiorganics have the potential for combining the high optical nonlinearity and chemical flexibility of organics with the physical ruggedness of inorganics. Also, for obtaining the materials with large

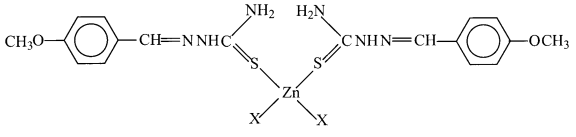
χ^2, optimization of both the molecular, first hyperpolarizability and their orientation in the bulk should be considered. Towards this end, we have explored a class of crystals in which urea or urea analogs have been stoichiometrically incorporated into an inorganic salt [18–20]. In continuation of these studies, we reported herein the design, synthesis, crystal structure and nonlinear optical properties of zinc halide complexes derived from 4-methoxylbenzaldehyde thiosemicarbazone. The structure of the complexes is shown in Scheme 1.

2. Experimental

All chemicals used were of analytical grade. The solvents were purified by conventional methods.

2.1. Physical measurements

Elemental analysis data were obtained using a Perkin–Elmer 240 analyzer. Infrared spectra were recorded from KBr discs in the range 4000–400 cm^{-1} on a Nicolet FT IR-170SX instrument. Electronic absorption spectra were obtained on a Shimadzu UV-3100 spectrophotometer in DMF solution (1.0×10^{-4} mol dm^{-3}). Solid-state electronic spectra were obtained by the reflection technique on a Shimadzu UV 240 spectrophotometer using MgO as the reference material. DSC and TG of the compounds were carried out using a Perkin–Elmer DSC-2C Differential Scanning Calorimeter and TGS-2 Thermogravimetric Analyzer. The samples were heated at the rate of 20 K min^{-1} in an inert nitrogen atmosphere. The decomposition temperature of the free ligand and its zinc complexes are shown in Table 1.



2.2. Synthesis

2.2.1. Preparation of the ligand

4-Methoxylbenzaldehyde thiosemicarbazone (L) was prepared by reacting equimolar amounts of 4-methoxylbenzaldehyde and thiosemicarbazone in hot ethanol.

2.2.2. Preparation of ZnL_2Cl_2

Ethanol solution of (0.42 g, 2 mmol) and zinc chloride (0.69 g, 2 mmol) were mixed. The colorless crystalline solid formed after refluxing for 4 h was isolated and dried in vacuo over P_4O_{10}. Yield: 0.78 g (90%). Crystals

suitable for X-ray structure analysis were obtained by slowly evaporating an ethanol solution in air. IR data (KBr disc): 3158 (s, N–H), 1607, 1535 (s, C=N), 980 cm^{-1} (s, C=S). UV–Vis: λ_{max} (log ε): 326 nm (3.69). Found: C, 39.3; H, 4.4; N, 15.0; $C_{18}H_{24}N_6O_2S_2ZnCl_2$ Calc.: C, 39.0; H, 4.1; N, 15.2%.

2.2.3. Preparation of ZnL_2Br_2

The complex was synthesized by the same procedure, but from $ZnBr_2$ (yield: 73%). IR data (KBr disc): 3159 (s, N–H), 1604, 1532 (s, C=N), 985 cm^{-1} (s, C=S). UV–Vis: λ_{max} (log ε): 328 nm (3.72). Found: C, 33.5; H, 3.6; N, 13.2; $C_{18}H_{24}N_6O_2S_2ZnBr_2$ Calc.: C, 33.4; H, 3.4; N, 13.0%.

2.2.4. Preparation of ZnL_2I_2

The complex was synthesized by the same procedure, but from ZnI_2 (yield: 69%). IR data (KBr disc): 3289 (s, N–H), 1598, 1548 (s, C=N), 1020 cm^{-1} (s, C=S). UV–Vis: λ_{max} (log ε): 334 nm (3.71). Found: C, 19.4; H, 2.9; N, 7.4; $C_{18}H_{24}N_6O_2S_2ZnI_2$ Calc.: C, 19.1; H, 2.7; N, 7.4%.

2.3. X-ray crystallography and structure solution

The relevant crystal data and structural parameters are summarized in Table 2. Selected bond distances and angles are shown in Tables 3 and 4, respectively. The intensities of ZnL_2Cl_2 was collected at 294 K on a MSC/Rigaku RAXIS-IIC imaging plate diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) from a rotating anode operating at 50 kV, 90 mA ($2\theta_{max} = 55.2°$); 60 oscillation frames in the range of 0–180°, expose 8 min per frame for those compounds. Absorption corrections were made using the ABSCOR program based on Fourier-coefficient fitting to the intensities of symmetry-equivalent reflections [21–23].

The structures of ZnL_2Cl_2 was solved by direct methods. All non-hydrogen atoms were refined anistropically by full-matrix least-squares. Hydrogen atoms were placed in calculated positions (C–H = 0.96 Å), assigned fixed isotropic thermal parameters and allowed to ride on their respective parent atoms. The contributions of these hydrogen atoms were included in the structure-factor calculations. All the computations were

carried out using the SHELXTL-PC program package [24]. Analytical expressions of neutral-atom scattering factors were employed, and anomalous dispersion corrections were incorporated [25].

The data for $[ZnL_2I_2]$ were collected on a Siemens SMART CCD area detector diffractometer equipped with Mo Kα radiation using ω-scan mode. The data collection covered over a hemisphere of reciprocal space by a combination of three sets of exposures; each set had a different ϕ angle (0.88° and 180°) for the crystal and each exposure of 30 s covered 0.3° in ω. The crystal-to-detector distance was 4 cm and the detector swing angle was −35°. Coverage of the unique set is over 99% complete. Crystal decay was monitored by repeating thirty initial frames at the end of data collection and analyzing the duplicate reflections and was found to be negligible.

The unit cell parameters were determined using SMART (Siemens, 1996a) [26]. The three sets of data collected were reduced using the program SAINT (Siemens, 1996b) [27]. The structure was solved with direct methods using the program SHELXTL (Sheldrick, 1997) [28]. All the non-hydrogen atoms were located from the trial structure and then refined anisotropically with SHELXTL using full-matrix least-squares procedure. A weighting scheme of $w = 1/[\sigma^2(F_o^2)+(0.0422P)^2+2.1119P]$, where $P = (F_o^2+2F_c^2)/3$ was applied. The hydrogen atom positions were fixed geometrically at calculated distances.

2.4. Nonlinear optical property measurements

The second order nonlinear optical intensities are estimated by measuring powder samples of 76–154 μm diameter in the form of pellet. The thickness of a pellet is about 0.8 mm. The experimental arrangement for the nonlinear optical properties utilizes a M200 high power Mode-Locked Nd:YAG laser with 200 ps pulse at a repetition rate of 5 Hz. The selected wavelength is 1064 nm. After the selection of the wavelength, the laser beam is split into two parts, one to generate the second harmonic signal in the sample and the other to generate the second harmonic signal in the reference (urea pellet). According to the principle proposed by Kurtz and Perry [29], SHG efficiency can be estimated as 7.6 and 13.2 times higher than that of urea for complexes ZnL_2Cl_2 and ZnL_2Br_2, respectively. However, no SHG response was observed for ZnL_2I_2.

3. Results and discussion

3.1. Spectroscopic characterization

The new Schiff base ligand L was prepared by the reaction of thiosemicarbazide with 4-methoxylbenzaldehyde in a 1:1 molar ratio. The ligand can, in principle, exhibit thione–thiol tautomerism, since it contains a thioamide –HN–C=S functional group [30–32]. The ν(S–H) band at 2570 cm^{-1} is absent from the IR

spectra of the Schiff-base, but ν(N–H) at approximately 3150 cm^{-1} is present, indicating that in the solid state the ligand remains as the thione tautomer. After refluxing the free ligand and zinc halide in ethanol solution, a colorless crystalline solid was formed. It has been shown [33] that the thiosemicarbazide molecule itself exists in the *trans* configuration and while complexing in this configuration, it behaves as a monodentate ligand, bonding only through the sulfur atom. Gerbeleu et al. [34] have shown that bonding may also occur through the hydrazine nitrogen and the amide nitrogen, if the sulfur center is substituted. In most of the complexes studied the thiosemicabazone function coordinates to the metal ion in the *cis* configuration [35], as a bidentate ligand bonding through the thione–thiol sulfur atom and hydrazine nitrogen atom in bidentate manner. The most common stereo chemistries encountered in bidentate thiosemicarbazone complexes are centrosymmetric octahedral and square-planar, so in order to obtained a noncentrosymmetric complex molecule, it is necessary to ensure that the thiosemicarbazone behaves as a monodentate sulfur ligand. HSAB consideration dictates that the softer acid character of Zn(II), Cd(II)and Hg(II) exhibit higher stability constants with this class of sulfur ligands, because of the formation of strong σ-bonds as well as d(π)–d(π) bonds by donation of a pair of electrons to ligands. So it can be expected that the zinc halide complexes might be monodentate S-bonded. The explanation was supported by the IR and UV–Vis spectra of the zinc complexes, which are quite similar to those of the corresponding ligand L, especially with the presence of ν(N–H) at approximately 3150 cm^{-1}.

3.2. Thermal stabilities for the ligand and its zinc complexes

Thermal stabilities for the ligand and its zinc complexes were determined by DSC and TG. The data for them are given in Table 1. From the table, it can be seen that both melting point and decomposition temperature of the complexes are higher than those of their free ligand. So it can be concluded that coordination of the ligand to the metal ion results in greater thermal stability.

3.3. Crystal structure for ZnL_2Cl_2

The ORTEP drawing of ZnL_2Cl_2, with numbering scheme is shown in Fig. 1. The unit cell contents of the complex is shown in Fig. 2. The coordination geometry of the zinc atom is distorted tetrahedral with the two sulfur atoms from the neutral thiosemicarbazone ligand forming bond angles around the Zn(1) in the range of 104.5°–113.2°. The ligand (except the amino atom N(1) is almost planar (mean deviations from the best plane being ca. 0.074 Å). The dihedral angle between the two ligand planes is 75.7°.

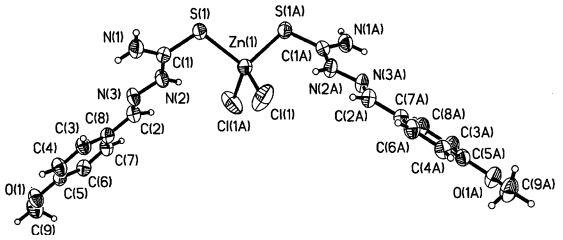

Fig. 1. Molecular structure and atom numbering of ZnL_2Cl_2. The thermal ellipsoids are drawn at the 50% probability level.

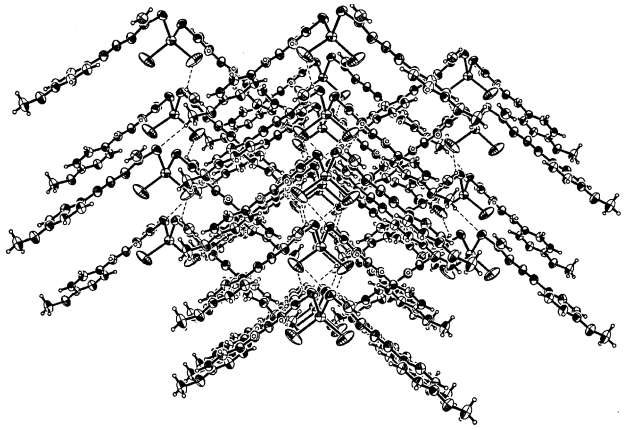

Fig. 2. Packing diagram for ZnL_2Cl_2 viewed approximately along the *c* axis.

The thiosemicarbazone moiety in the complex shows *E* configuration about both C(2)–N(3) and C(1)–N(2). The hydrogen atoms attached to the imine nitrogen atoms N(2) and N(5) are also in cis-configuraion with the sulfur atoms. The six hydrogen atoms attached to amino nitrogen atoms N(1), N(2), N(4) and N(5) have the potential to form donor hydrogen bonds. The two hydrogen atoms attached to the imine nitrogen atoms N(2) and N(5) form intramolecular hydrogen bond with the chloride atoms Cl(1) and Cl(2) (distances of 3.235(7) and 3.215(7) Å for N(2)···Cl(1) and N(5)···Cl(2), respectively and angles around corresponding hydrogen atoms are 152.9(4)° and 152.4(4)°, respectively). Analyses of intermolecular contacts indicated that the hydrogen atoms attached to amino nitrogen atoms N(1) and N(4) formed donor hydrogen bonds of the types N(1)–H(1b)···O(2a) $(-0.5+x, -0.5+y, 1+z)$ and N(4)–H(4b)···O(1b) $(-0.5+x, 0.5+y, z-1)$. The N···O separations are approximately 3.02 and the N–H···O angles are approximately 154°. There are also two intermolecular contacts which can be considered as hydrogen bonds, although the contacts are approximately 3.40 Å. [3.397(8) Å, N(1) and Cl(2c) $(-0.5+x, 0.5-y, 0.5+z)$; 3.405(8) Å, N(4)···Cl(1d) $(-0.5+x, 0+0.5-y, -0.5+z)$], since the bond angles around the corresponding hydrogen atoms are 158.2(5)° and 158.8(5)°, respectively.

The data in Table 3 show that all the bond distances in the side chain of the thiosemicarbazones are intermediate between formal single and double bonds, pointing to extensive electron delocalization over the entire moiety. Examination of the structural data for thiosemicarbazones [36] and their metal complexes [37–40] shows that the N(1)–C(1) and C(1)–S(1) bonds in L^- are longer than those in the neutral form L (1.34 vs. 1.31 and 1.73 vs. 1.71 Å on average, respectively), whereas the N(2)–C(1) bond is shorter than that in L (1.35 vs. 1.33 Å on average).

3.4. Crystal structure for ZnL_2I_2

The crystals contain individual $ZnL_2^2I_2$ neutral molecules. A perspectives drawing with atom-labeling scheme is shown in Fig. 3. Each metal atom is tetracoordinated by two monodentate L ligands bonded through the S atoms, and two terminal iodine atoms (Table 4). The Zn–S and Zn–I distances are almost equal; thus the strong distortion in the tetrahedral environment of the four donor atoms is explained on the basis of strong stereo interactions between the two L ligands in each complex. The Zn–S distance (Table 4) in the complex is in the range of those found for metal–S terminal bonds in other complexes [35]. Zn–I distances are also in the range of those found in other Zn(II) iodine complexes with terminal Zn–I bonds.

3.5. Nonlinear optical properties

Based on MNDO Hamitanian [41] and PM3 parametrization [42] with the MOPAC program package [43], the molecular hyperpolarizability, β_μ, the vector component along the dipole moment direction, of the organic ligand are calculated to be -2.6×10^{-30} esu for the free ligand L, and -4.6×10^{-30}, -6.2×10^{-30}, -10.1×10^{-30} esu for the three zinc complexes, respectively. The molecular hyperpolarizabilities β_μ of organic ligands and their complexes are comparable with that of *p*-nitroaniline (PNA, 6.3×10^{-30}). The absolute values are much greater than that of urea (0.14×10^{-30} esu). This result is easily understood, since the ligand in the free state and in the zinc complexes both present

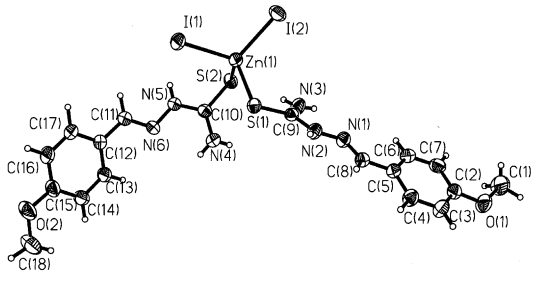

Fig. 3. Molecular structure and atom numbering of ZnL_2I_2. The thermal ellipsoids are drawn at the 50% probability level.

extensive electron delocalization in the whole system with long conjugation length between the donor and acceptor. The negative sign of β_μ can be explained by the smaller dipole moment of the lowest excited state than that of the ground one. The microscopic second-order susceptibility β values of zinc complexes seems to be twice as larger than that of the free ligands. This suggests that the two ligands in complexes may contribute equally to the microscopic second-order nonlinearity of complexes. The β_u value can also be understood by their contribution from lower-energy transition. The linear absorption spectra of the ligand and the zinc complexes in DMF solution exhibit only one intense band near 325 nm. The optical transition associated with this band is mainly the contribution of $\pi^*\leftarrow\pi$ and $\pi^*\leftarrow n$ transitions of nonbonding electron pairs of N and S atoms according to the analysis of molecular orbital components for the ligand and zinc complexes, which are the excitation mainly responsible for the NLO response [19].

Apart from the discussions above, the crystal structures and their alignment is important for the enhancement of nonlinear optical response. The noncentrosymmetric crystals of ZnL_2Cl_2 (molecular dipole moment $\mu=0.39$ D) and ZnL_2Br_2 ($\mu=1.27$ D) serve to hold the molecules in the head-to-tail fashion which give rise to effective dipolar orientation for near-optimum second-order harmonic generation. However, the complex ZnL_2I_2 ($\mu=2.29$ D) showed no SHG response due to its centrosymmetric space group in crystallization, although it has the largest microscopic second-order nonlinear susceptibility. As predicted by PM3 method, the large ground dipolar moment of an isolated molecule in these crystals can lead to strong dipole–dipole interaction and then result in dimers or anti-paralleled molecular alignment in the crystal. Therefore, the centrosymmetric crystals show vanishing SHG efficiency.

Several conclusions can be drawn from the experimental determinations and theoretical calculations above. Combining the conjugated thiosemicarbazide containing donor group with a distorted inorganic tetrahedral center, we may design and synthesize various metal complexes, which possess a large second-order microscopic and macroscopic nonlinear optical (NLO) property. For example, the complexes ZnL_2X_2 (X = Cl, Br, I) have larger molecular hyperpolarizability and greater thermal stability than those of their free ligand. It is interesting to find that the zinc halides are deliquescent whereas the zinc halide thiosemicarbazone complexes are moisture free. The molecules of ZnL_2Cl_2 and ZnL_2Br_2 are arranged noncentrosymmetrically in the crystalline state to have macroscopic second-order nonlinear optical response. Unfortunately, the molecules of $[ZnL_2I_2]$ crystallize centrosymmetrically, leading to vanishing SHG activity. These are associated with

their molecular dipole moment. The results above might give us a general guideline in the synthesis of new nonlinear optical materials. The complexes in this report, are almost colorless, transparent and easy to form crystals. They are also mechanically and thermally stable, thereby making them suitable to be used as potential or practical NLO materials.

4. Supplementary material

Crystallographic data have been deposited with the CCDC (12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk; www: http://www.ccdc.cam.ac.uk) and are available on request quoting the deposition number CCDC145742 for ZnL_2Cl_2; CCDC145743 for ZnL_2I_2.

Abstract

A lead(II) complex with 1,10-phenanthroline (phen) containing two different anions has been synthesized using a direct synthetic method and characterized by IR and CHN elemental analysis. The structure of $[Pb(phen)(_2OCCH_3)(NCS)]_2$ was confirmed by X-ray crystallography. The single crystal X-ray data of this compound shows the complex to be dimeric as a result of acetate ligand bridging. The Pb atom has an unsymmetrical six-coordinate geometry, being coordinated by three nitrogen atoms of 1,10-phenanhroline and the thiocyanate ligand and three oxygen atoms of the acetate ligand. The arrangement of the 1,10-phenanhroline, acetate and thiocyanate ligands exhibits a coordination gap around the Pb(II) ion, occupied possibly by a stereoactive lone pair of electrons on lead(II), with the coordination around lead atoms being hemidirected. There is a $\pi-\pi$ stacking interaction between the parallel aromatic rings that may help to increase the 'gap' in the coordination geometry around the Pb(II) ion. © 2002 Published by Elsevier Science Ltd.

Keywords: Hemidirected; Lead(II) complexes; Thiocyanate ligands; Crystal structures

1. Introduction

The coordination chemistry of lead(II) with N and O-donor ligands has been investigated in the past decade and frequently discussed in regard to the the coordination and stereoactivity of the valence shell lone electron pairs [1–8]. Extensive recent structural studies of lead(II) compounds [9,10] in particular have provided a basis for rather detailed analysis of the evidence for coordination sphere distortions which may be a consequence of the presence of such electron pairs. It appears that in complexes of lead(II) (and probably in those of related species such as Tl(I) [11,12] and Bi(III) [13,14]), the nature and form of the coordination sphere are generally determined by a number of factors, possibly lone pair-bond pair repulsions is important, so that seemingly minor differences in ligands can have quite marked effects upon the coordination stereochemistry. Since the presence of a lone pair is not directly detected but it is inferred on the basis of the spatial distribution of donor atoms surrounding the metal, the identification of these donor atoms is fundamental to the analysis of any particular system. Interestingly, this alone is not a straightforward process. An interesting point is that crystal packing may affect the size and extent of the lone-pair in the coordination sphere. Building new molecular species and modifying their architectures in order to control their physical properties has been a topic for many research groups. Different ligands have been used to bridge in lead(II) complexes, like acetate [2,10,15], thiocyanate [10] or nitrate [16]. The thiocyanate ligand presents an ambidentate ability with an end-on and end-end coordination mode and the acetate ligand presents bridging coordination of both acetate oxygen atoms.

The recent reports of the crystal structures of $Pb(phen)(O_2CCH_3)(O_2ClO_2)$ [2] and $Pb(phen)(O_2CCH_3)(O_2NO)$ [15] described the presence of bridging acetate and its influence upon the coordination stereochemistry of the lead(II) ion and also on their polymeric structures. In the present paper, we report the synthesis and characterization of a dimeric mixed-ligand lead(II) complex of acetate and thiocyanate ligands.

2. Experimental

2.1. Physical measurements

IR spectra were recorded as Nujol mulls using Perkin–Elmer 597 and Nicolet 510P spectrophotometers. Microanalyses were carried out using a Heraeus CHN-O-RAPID.

2.2. Preparation of [Pb(phen)(O_2CCH_3)(NCS)]

The complex was prepared by dissolving lead(II) acetate (0.36 g, 1 mmol) and potassium thiocyanate (0.097 g, 1 mmol) in distillation water and adding an alcoholic solution of 1,10-phenanhroline ligand, (0.2 g, 1 mmol). The resulting solution was stirred for 5 h at room temperature (r.t.), then it was allowed to stand for 2–3 days in a refrigerator (ca. 6 °C). White crystals of the desired product precipitated, which were filtered off, washed with acetone and ether and air dried (0.356 g yield 70%), m.p. 215 °C. found C, 35.61; H, 2.18; N, 8.43: calculated for $C_{15}H_{11}N_3O_2PbS$; C, 35.65; H, 2.18; N, 8.32%. IR (cm^{-1}) selected bands: 740(s), 1010(s), 1480(s), 1590(s), 1618(s), 2040(vs), 3040(w). Branched tube method: 1, 10-Phenanthroline (0.2 g, 1 mmol) was placed in one arm of the branched tube and a mixture of lead(II) acetate (0.36 g, 1 mmol) and potassium thiocyanate (0.097 g, 1 mmol) in the other. Methanol was carefully added to fill both arms, then the tube was sealed and the ligand-containing arm immersed in a bath at 60 °C while the other was at ambient temperature. After 10 days, white crystals, (m.p. 215 °C) had deposited in the cooler arm.

2.3. Crystallography

2.3.1. Crystal data and refinement details

[Pb(phen)(O_2CCH_3)(NCS)]$_2$. $C_{30}H_{22}N_6O_4Pb_2S_2$, M 1009.04, triclinic, Space group $P\bar{1}$, $a = 8.1581(13)$, $b = 9.0697(15)$, $c = 11.0187(17)$ Å, $\alpha = 68.089(3)$, $\beta = 82.769(3)$, $\gamma = 74.970(3)^\circ$, $V = 730.1(2)$ Å^3, D_c ($Z = 1$ f.u.) 2.295 mg m^{-3}, $F(000)$ 472. Specimen: 0.40 × 0.4 × 0.4 mm; $T_{max,\ min} = 0.9621$, 0.2333, N 12255, N_0 3789, $R = 0.0344$, $R_w = 0.0929$.

2.3.2. Determination of the structure

Crystallographic measurements were made at 140(2) K using a Siemens R3m/V diffractometer. The intensity data were collected within the range $1.99^\circ \le \theta \le 29.58^\circ$ using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Accurate unit cell parameters and an orientation matrix for data collection were obtained from least-squares refinement. Intensities of 12 255 unique reflections were measured, from which 3789 with $I > 2\sigma(I)$ were used in the refinement. The structure was solved by direct methods and refined by full-matrix least-squares techniques on F^2.

The positions of hydrogen atoms were idealized and included in the calculations of the structure factors as fixed contributions. Each hydrogen atom was assigned an isotopic thermal parameter. R, R_w, with goodness-of-fit on F^2 $1.088R = 0.0344$, $R_w = 0.0929$. The final difference density map showed a maximum peak and hole of 3.032 and −2.625 e Å^{-3}. Corrections for the Lp effects as well as the empirical correction for absorption using the SADABS programs were applied. All structural calculations were carried out with a PDP-11/23+computer using the SDP-PLUS program package [17,18].

Crystal data and structure refinement are given in Table 1. Selected bond lengths and angles are given in Table 2. Anisotropic thermal parameters, observed and calculated structure factors, full lists of bond distances, bond angles and torsion angles are given as supplementary material. ORTEP diagrams and a perspective view of the packing in the unit cells are shown in Figs. 1 and 2.

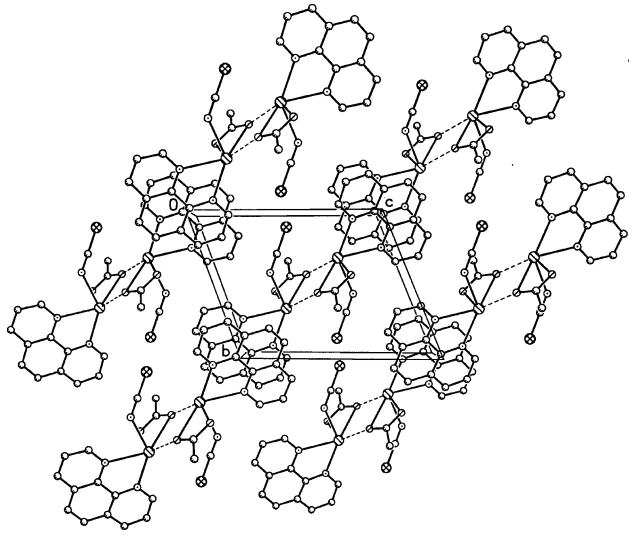

Fig. 2. The unit cell and showing π–π stacking interactions in [Pb(phen)(O_2CCH_3)(NCS)].

3. Discussion

3.1. Synthesis

Reaction between 1,10–phenantroline (phen) and an equimolar mixture of lead(II) acetate and potassium thiocyanate by diffusion along a thermal gradient in methanol solution (the branched tube method), provided crystalline material analyzing as [Pb(phen)(O_2CCH_3)(NCS)]. Attempts to isolate [$(phen)_2$Pb(O_2CCH_3)(NCS)] were not successful and each time, the 1:1 adduct was isolated.

3.2. Crystal structure of [Pb(phen)(O_2CCH_3)(NCS)]$_2$

The crystal structure of this compound consists of dimeric units of [Pb(phen)(O_2CCH_3)(NCS)]$_2$. Each lead atom is chelated by the nitrogens of 1,10-phenanthroline with Pb–N distances of 2.564 and 2.663 Å, and bonded to the thiocyanate with a Pb–N distances of 2.511 Å and also the oxygen atoms of an acetate ligand with Pb–O distances of 2.322 and 2.674 Å. The coordination number in this complex is five (two from the 'phen' ligand, one from thiocyanate and two from the acetate ligand) and the weak interaction of lead(II) with oxygen atoms of an adjacent molecule produce dimer units in the solid state. In fact each Pb atom in this structure with five normal bonds forms two 'weak' Pb···O bonds. Only one of them is symmetry independent and the exact distances is Pb1···O2 = 3.190 Å (Table 2). The presence of a lone pair of electrons on the lead atom is apparently the reason that the bridging interactions are so long.

Determination of the structure of this material by X-ray crystallography (Table 1) showed the complex in the solid state (Fig. 1) to be a dimeric species with various similarities to the polymeric structures of [Pb(phen)(O_2CCH_3)(O_2ClO_2)], [Pb(phen)(NO_3)$_2$(OH_2)] and the dimeric structure of [Pb(phen)(O_2CCH_3)$_2$].

The Pb_2O_2 rings which share edges with PbOCO quadrilaterals to make the dimer core are similar to the central Pb_2O_2 rings of dimeric [Pb(phen)(O_2CCH_3)$_2$] [10], polymeric [Pb(phen)(O_2CCH_3)(O_2ClO_2)] [2] and [(phen)Pb(O_2CCH_3)(O_2NO)] [15], though the long edge of the rings in [Pb(phen)(O_2CCH_3)(NCS)]$_2$ (3.190 Å) is considerably longer than in [Pb(phen)(O_2CCH_3)(O_2NO)]$_n$ (2.804 Å), [Pb(phen)(O_2CCH_3)(O_2ClO_2)]$_n$ (2.736 Å), but shorter than [Pb(phen)(O_2CCH_3)$_2$]$_2$ (3.366 Å). This is consistent with the assumption that the thiocyanate anion should be a stronger ligand than nitrate and perchlorate and weaker ligand than the acetate anion, ($CH_3COO^- > NCS^- > NO_3^- > ClO_4^-$). The arrangement of nitrate and acetate anions suggest a gap or hole in the coordination geometry around the metal ion the [N(1S)–Pb–N(1) angle is 141.12°], occupied possibly by a stereoactive lone pair of electrons on lead(II). The

observed shortening of the Pb–N and Pb–O bonds on the side of the Pb(II) ion opposite to the putative lone pair (2.564 and 2.322 Å) compared with 2.663 and 2.674 Å adjacent to the lone pair) supports the presence of this feature [19]. Hence, the geometry of the nearest coordination environment of every lead atom is likely caused by the geometrical constraints of the coordinated 1,10-phenanhroline ligand, the acetate and thiocyanate anions and by the influence of a stereochemically active lone pair of electrons in an hybrid orbital on the metal atom. Such an environment leaves space for bonding of oxygen atoms of an acetate anion from an adjacent molecule (Fig. 2).

The possible stereochemical activity of the lone pair in divalent lead compounds has recently been discussed by Shimoni-Livny et al. based on a thorough review of crystal data available in the Cambridge Structural Database (CSD) [20]. They classify lead coordination as holodirected which refers to complexes in which the bonds to ligand atoms are directed throughout the surface of an encompassing sphere, while hemidirected refers to those cases in which the bonds to ligand atoms are directed throughout only part of the coordination sphere, leaving a gap in the distribution of bonds to the ligand. The latter, present in all Pb(II) compounds with coordination number 2–5, is quite common in Pb(II) compounds with coordination numbers 6, 7 and 8, and does not exist in lead complexes with higher coordination numbers, here holodirected geometry is the rule. For the structure described here, coordination around the lead atoms is hemidirected with a significant gap trans to the chelating acetate and thiocyanate ligands. The two lone pairs on two lead atoms in a dimeric unit are trans. The striking similarity of $[Pb(phen)(O_2CCH_3)(O_2ClO_2)]_n$ and $[Pb(phen)(O_2CCH_3)(O_2NO)]_n$ with $[Pb(phen)(O_2CCH_3)(NCS)]_2$ is that, there is a π–π stacking interaction [21,22] (charge-transfer arrays) between the parallel aromatic rings belonging to adjacent chains in all three compound, as shown in Fig. 2. A question is, do the π–π stacking interactions between the parallel aromatic rings help to increase the 'gap' in coordination geometry around the metal ion or does the 'gap' arising from the 'stereochemical activity' of valence shell lone electron pairs help to form π–π stacking? The 'gap' in $[Pb(phen)(O_2CCH_3)(O_2ClO_2)]_n$ [2], $[Pb(phen)(O_2CCH_3)(O_2NO)]_n$ [15], and $[Pb(phen)(O_2CCH_3)(NCS)]_2$ is more than in $[(phen)_2Pb(NO_3)_2]$ [10], $[(phen)_2Pb(NO_3)(NCS)]$ [23] and $[(phen)_2Pb(ClO_4)_2]$ [10]. The π–π stacking interactions are rarely observed in complexes with a ratio of ligand to metal of 2:1. In both 1:1 and 2:1 ratios there is a gap and this is greater for 1:1 than in 1:2. It may be that the increased gap to the influence of π–π stacking of aromatic units in these cases.

4. Supplementary material

Complete bond lengths and angles, coordinates and displacement parameters have been deposited at the Cambridge Crystallography Data Centre. Supplementary data are available on request, quoting the deposition number 174596, from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk; www: http://www.ccdc.cam.ac.uk).

Acknowledgements

Support of this investigation by Tarbiat Modarres University is gratefully acknowledeged. We thank the Institute of Organoelement Compounds of the Russian Academy of Science for determining the crystal structure by X-ray crystallography.

Abstract

Reaction between 8-aminoquinoline and benzenesulfonyl, toluene-4-sulfonyl and naphthalene-2-sulfonyl chlorides in a basic medium leads to the formation of the corresponding sulfonamides. Reaction of these sulfonamides with Ni(II) salts leads to the formation of the corresponding complexes, with a NiL_2 stoichiometry. Determination of the crystalline structure by X-ray diffraction shows an octahedral environment for the Ni(II) ions, sulfonamides acting as bidentate ligands and two solvent molecules completing the octahedral coordination. The spectroscopic and magnetic properties of these compounds are also discussed. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Nickel complexes; Sulfonamide complexes; 8-Aminoquinoline; X-ray crystal structures

1. Introduction

Coordination chemistry of nickel with ligands containing N-donor atoms has been widely studied in the literature and in recent years such studies have been mostly addressed to ligands with a biological interest, such as peptides [1,2]; the Ni(II)-promoted hydrolysis of these peptides has been one of the aims of these sorts of studies [3]. Recent findings showing the role of Ni(II) ions in several processes taking place in living organisms (where it is coordinated by N-donor ligands) have been probably the origin of these studies [4]. However, complexes of this ion with sulfonamides are not well known, and only a few examples have been described in the literature [5], despite the fact that complexes formed by sulfonamides and other transition metal cations, especially copper, have been studied, probably because they may act as chemical nucleases [6–9].

In the present paper, we describe the synthesis of three new sulfonamides derived from 8-aminoquinoline and benzenesulfonyl, toluene-4-sulfonyl and naphthalene-2-sulfonyl chlorides, which have then been used as ligands to coordinate Ni(II) ions.

2. Experimental

2.1. Materials and methods

8-Aminoquinoline and the sulfonyl chlorides were provided by Aldrich and Fluka, respectively, and all reagents were of analytical grade.

Chemical analyses for carbon, hydrogen and nitrogen were performed on a 2400 elemental analyzer from Perkin–Elmer. Nickel was determined on an ICP spectrometer (Perkin–Elmer model 2380 Plasma 2).

FT-IR spectra were recorded using KBr mulls and a Perkin–Elmer FT-IR 1730 instrument. Electronic spectra were recorded on a Shimadzu 8452A diode spectrophotometer.

Molecular masses were measured by Servicio de Masas (Universidad Autónoma de Madrid, Spain) by the FAB method with samples held on a nitrobenzyl alcohol (NBA) matrix.

Magnetic susceptibility measurements at room temperature (r.t.) were taken with a fully automatized AZTEC DSM8 pendulum-type susceptometer. Mercury tetrakis(thiocyanate)cobaltate(II) was used as a susceptibility standard. Corrections for diamagnetism were estimated from Pascal's constants.

2.2. Synthesis of the ligands

The sulfonamides were prepared by direct synthesis between 8-amino quinoline with the corresponding sulfonyl chloride, using pyridine as solvent. The procedure is as follows: 5 mmol 8-amino quinoline and 5 mmol sulfonyl chloride are dissolved in 10 ml pyridine and the mixture is heated under reflux at 110–120 °C for 30 min. The solution is then left to cool down to 70 °C and is added to a beaker containing 10 ml water. A brown precipitated is formed; this is filtered and washed with distilled water until all pyridine has been removed. Yield is 85–90%.

Analytical data: For N-quinolin-8-yl-benzenesulfonamide, Hqbsa: Found: C, 63.30; H, 4.04; N, 10.25%. Calculated for $C_{15}H_{12}N_2O_2S$: C, 63.37; H, 4.25; N, 9.85%. For N-quinolin-8-yl-*p*-toluenesulfonamide, Hqtsa: Found: C, 64.38; H, 4.69; N, 9.47%. Calculated for $C_{16}H_{14}N_2O_2S$: C, 64.44; H, 4.73; N, 9.43%. For N-quinolin-8-yl-naphthalene-2-sulfonamide, Hqnsa: Found: C, 68.08; H, 4.07; N, 8.32%. Calculated for $C_{19}H_{14}N_2O_2S$: C, 68.24; H, 4.22; N, 8.38%. The most significant IR bands are listed in Table 3. λ_{max} nm (ε, M^{-1} cm^{-1}): 250 (16 000), 320 (7000).

2.3. Synthesis of the nickel complexes

Although direct synthesis between the sulfonamide and the metallic salt is possible with the copper complexes [6], addition of a base is required in the case of the Ni derivatives in order to deprotonate the sulfonamidate nitrogen atom. So 1.5 mmol sulfonamide are dissolved in 75 ml DMF and 2 ml NH_3 2 M are added. Then a solution containing 0.75 mmol Ni(II) chloride dissolved in 25 ml methanol is slowly added dropwise to the former solution. Once the addition has been completed, the original green color of the solution becomes enhanced. Upon very slow evaporation of the solvent, green crystals (suitable for structural determination by X-ray diffraction) were obtained.

Analytical data: $[Ni(qbsa)_2(H_2O)(MeOH)]$: Found: C, 55.31; H, 4.21; N, 8.43; Ni, 8.92%. Calculated for $NiC_{31}H_{28}N_4O_6S_2$: C, 55.13; H, 4.18; N, 8.29; Ni, 8.69%. MS: $m/z = 625$ $[M]^+$

$[Ni(qtsa)_2(H_2O)_2]$: Found: C, 56.01; H, 4.47; N, 8.33; Ni, 8.39%. Calculated for $NiC_{32}H_{30}N_4O_6S_2$: C, 55.75; H, 4.39; N, 8.13; Ni, 8.52%. MS: $m/z = 652.1$ $[M]^+$

$[Ni(qnsa)_2(H_2O)_2]$.2DMF: Found: C, 57.91; H, 4.91; N, 9.06; Ni, 6.55%. Calculated for $NiC_{44}H_{44}N_6O_8S_2$: C, 58.22; H, 4.89; N, 9.26; Ni, 6.47%. MS: $m/z = 725$ $[M]^+$.

The most significant IR bands are listed in Table 3. λ_{max} nm (ε, M^{-1} cm^{-1}): 266 (18 000), 370 (12 000), 585 (20), 785 (30).

2.4. X-ray data collection and processing

A green needle crystal of $[Ni(qtsa)_2(H_2O)_2]$ was mounted on an Enraf Nonius CAD4 automatic drifractometer to be used for the structure determination. X-ray diffraction data for $[Ni(qbsa)_2(H_2O)(MeOH)]$ and $[Ni(qnsa)_2(H_2O)_2]\cdot 2DMF$ were collected on a four circle Seifert XRD 3003 SC diffractometer. Data of these Ni(II) complexes were collected at r.t. using Cu Kα radiation and the $\omega-2\theta$ scan technique. The unit cell parameters were determined by least-squares refinement on the 2θ values of 25 strong well centered reflections in the range $13.5° < \theta < 27°$ for $[Ni(qtsa)_2(H_2O)_2]$ and $8° < \theta < 20°$ for $[Ni(qbsa)_2(H_2O)(MeOH)]$ and $[Ni(qnsa)_2(H_2O)_2]\cdot 2DMF$ compounds. Scattering factors for neutral atoms and anomalous dispersion correction for Ni, C, N, O and S were taken from 'International Tables for X Ray Crystallography' [10]. The structures of $[Ni(qtsa)_2(H_2O)_2]$ and $[Ni(qbsa)_2(H_2O)(MeOH)]$ were resolved by direct methods and refined in the monoclinic space groups $P2_1/c$ and $C2/c$, respectively. The structure of $[Ni(qnsa)_2(H_2O)_2]\cdot 2DMF$ was resolved by Patterson methods and refined in the monoclinic space group $P2(1)/n$. Full-matrix least-squares refinement with anisotropic thermal parameters for non-H atoms was carried out by minimizing $\omega(F_o^2-F_c^2)^2$. Refinement on F^2 for all reflections, weighted R factors ($R\omega$), and all goodness-of-fit S are based on F^2, while conventional R factors (R) are based on F; R factors based on F^2 are statistically about twice as large as those based on F, and R factors based on all data will be even larger.

Most of the calculations for $[Ni(qtsa)_2(H_2O)_2]$ were carried out using CAD4-EXPRESS [11] software for data collection, GENHKL [12] program for data reduction, SHELX-97 [13] to refine the structure and PLATON [14] for molecular graphics. All calculations for $[Ni(qbsa)_2(H_2O)(MeOH)]$ and $[Ni(qnsa)_2(H_2O)_2]\cdot 2DMF$ were performed using CRYSOM [15] software for data collection, X-ray8O [16] for data reduction, SHELXTL™ [17] to resolve and refine the structure and to prepare material for publication.

Crystal data and some details of the structural determination are given in Table 1. Table 2 shows some selected geometrical information.

3. Results and discussion

The synthetic route used to prepare the sulfonamides can be depicted as in Scheme 1 for N-quinolin-8-yl-naphthalene-2-sulfonamide, Hqnsa.

Deprotonation of the sulfonamide takes place in an ammonia medium to yield the sulfonamidate anion, qnsa$^-$, which readily reacts with Ni(II) ions to form complexes with a NiL_2 stoichiometry, although solvent molecules also exist completing the coordination around the Ni(II) cations.

3.1. Description of the crystal structures

As it could be readily expected, the local environment around the Ni(II) cations is very similar in all three cases, with a distorted octahedral structure (Figs. 1–3). The coordination polyhedron is formed by four N atoms from both sulfonamide molecules (one nitrogen atom from the sulfonamide group, and another from the quinoline group), which act as bidentate ligands, together with two oxygen atoms from two water molecules. The sulfonamide molecule forms a stable five-member ring with the metal cation. It should be noticed that the hydrogen atoms from the water molecules are not shown in the structural formula of the complex, [Ni(qnsa)$_2$(H$_2$O)$_2$]·2DMF, as they were not located by X-ray diffraction.

Selected bond distances and angles are summarized in Table 2. Only minor differences can be seen in the local environment of the nickel ions among the three complexes prepared, as expected bearing in mind that the organic chains differentiating the three ligands studied are rather far away from the coordinating (donor) sites of these molecules. From the bond angles given, it can be also concluded that the distortion is not too severe, the angle between *trans* atoms being close to 180°, and that between *cis* atoms close to 90°.

The most significant distortions are observed for the complex [Ni(qsba)$_2$(H$_2$O)(MeOH)], where two different molecules (water and methanol) complete the octahedral coordination around the Ni(II) cation, opposite to the findings for the other complexes, where two water molecules exist. Consequently, the O1–Ni–O2 angle decreases to 85.3°, with respect to the values determined

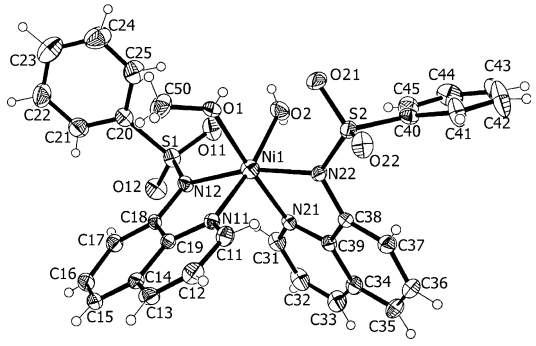
N(12)–Ni–O(2)	99.9(3)	98.1(17)	97.9(3)
N(22)–Ni–O(2)	90.1(3)	91.0(17)	88.7(3)

for the other two complexes (88.0° and 87.0°); similarly, the N11–Ni–O2 angle also decreases (171.7° vs. 177.43° and 176.6°), while angle N21–Ni–O2 is slightly larger (93.2° instead of 88.1° and 90.8°).

As expected, the angle formed by the Ni(II) cation with the two N atoms belonging to the same ligand molecule (N11–Ni–N12 and N21–Ni–N22) remain constant in all three complexes, although small differences are seen for angles formed between N atoms from both ligands (e. g. N11–Ni–N21), probably as a consequence of the changes in other angles commented above. The Ni–N(sulfonamidate) distances are also slightly larger than the Ni–N(quinoline) ones. In any case, the bond and angle distances measured for these complexes are very similar to those previously reported [5,18] for complexes similar to those prepared here.



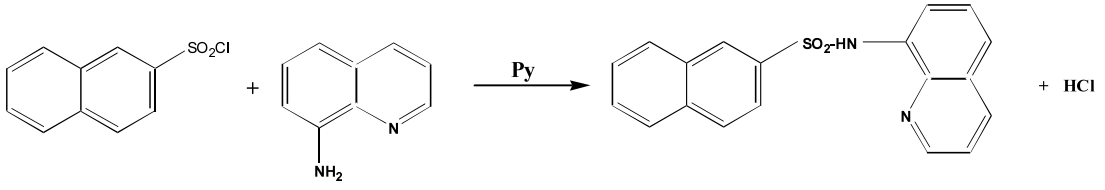


Fig. 1. Molecular structure of $[Ni(qbsa)_2(H_2O)(MeOH)]$ showing the atom numbering scheme.

3.2. FT-IR spectroscopy

Data are summarized in Table 3. It should be noticed that the removal of the band at 3260 cm^{-1}, due to the N–H stretching mode, in the complexes demonstrates the deprotonation of the N(sulfonamide) atom. It should also be mentioned that the splitting of bands due to the symmetric and antisymmetric stretching modes of the SO_2 group, probably because of the different spatial orientation of the S=O bonds upon coordination of the sulfonamide to the metal cation. Both bands shift approximately 30 cm^{-1} downwards when passing from the ligands to the complexes,

probably due to a charge transfer from the deprotonated, negatively-charge N atom to the oxygen atom of the sulfonyl group [7]; consequently, the double bond character of the S=O group results larger in the free ligands than in the complexes.

The remaining bands are recorded in close positions both for the ligands and for the complexes, except the band due to the S–N stretching mode, which shifts approximately 30 cm^{-1} upwards, thus confirming the donor role of the N atom. Overall, the positions are similar to those previously reported for similar compounds [19].

3.3. Magnetic susceptibility and electronic spectra

The effective magnetic moments at room temperature of the complexes are in the range 2.95–3.13 BM, in agreement with the octahedral environment around the Ni(II) cations. These values are only slightly larger than that corresponding to the spin-only value (2.83 BM), thus suggesting an orbital contribution by mixing of the ground state with low energy excited states, or because the ground state is orbitally degenerated.

The two intense bands recorded in the electronic spectra of the complexes at 266 and 370 nm are probably due to charge transfer processes. The two bands at 785 and 585 nm are recorded in the ranges usually expected for transitions $^3A_{2g} \rightarrow {}^3T_{1g}$ and $^3A_{2g} \rightarrow {}^3T_{1g}(P)$, respectively, of octahedral Ni(II) (d^8) complexes [20].

4. Supplementary material

Complete lists with atomic coordinates, anisotropic displacement parameters, bond lengths and angles have been deposited at the Cambridge Crystallographic Data Center, 912 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) [CCDC 173676, 173677, 173866].

Received 16 December 2001; accepted 19 March 2002

Abstract

Diadduct complexes of the mixed-valent form of diruthenium tetraacetate, $[Ru_2(\mu\text{-}O_2CCH_3)_4L_2](PF_6)$, with L = urea (**1**), 1,1,3,3-tetramethylurea (tmu) (**2**) and 1,1,3,3-tetramethyl-2-thiourea (tmtu) (**3**) have been synthesized and characterized by elemental analysis, IR and UV–Vis spectroscopy, magnetic susceptibility, cyclic voltammetry and X-ray crystallography. Compound **1** crystallizes as a co-diadduct system from 1-propanol in which both $[Ru_2(\mu\text{-}O_2CCH_3)_4(urea)_2]^+$ and $[Ru_2(\mu\text{-}O_2CCH_3)_4(1\text{-}propanol)_2]^+$ cations are present in the unit cell. Complex **3** displays a very long Ru–S bond of 2.610(2) Å and is only the second example of a sulfur-donor adduct of a diruthenium tetracarboxylate that has been structurally characterized. Electrochemical measurements on **2** and **3** show them to have reduction potentials of −487 and −541 mV (vs. Fc/Fc^+), respectively, which is in the range of moderate to strong axial donor adducts despite the long Ru–S bond in **3**. Reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ with thiourea yields a 1:1 complex, $[Ru_2(\mu\text{-}O_2CCH_3)_4(thiourea)](PF_6)$, which from solubility and infrared evidence appears to be a polymer in which the thiourea bridges through the sulfur and one of the amine nitrogens. © 2002 Elsevier Science Ltd. 1. Introduction

Paddle-wheel complexes of the type $[Ru_2(\mu\text{-}O_2CR)_4L_2]X$, where L = an axially bound Lewis base, R = an alkyl or aryl group and X = a non-coordinating counterion, have received considerable attention over the last 25 years [1–3]. Until recently the most common Lewis base used was an O-donor such as H_2O, THF or $OPPh_3$. Our group has expanded this somewhat in including a significant number of N-donors [4,5] and the first structurally characterized cases of such adducts containing a P-donor [6] and an S-donor [7]. Reactions of diruthenium tetracarboxylates with various phosphines had already received significant attention but were always hampered by rapid axial to equatorial migration followed by Ru–Ru bond rupture [1–3]. Far less attention has been focussed on S-donor adducts and their properties. We report here on the thiourea and tetramethylthiourea (tmtu) derivatives.

Another area which has had limited study is the axial interaction of ligands of biological relevance with the $[Ru_2(\mu\text{-}O_2CR)_4]^+$ core. Dunbar et al. [8,9] investigated the reaction of 9-ethylguanine with $Ru_2(\mu\text{-}O_2CCH_3)_4Cl$ and found that it displaced two of the bridging acetates. Gangopadhyay and Gangopadhyay [10] synthesized an adenine containing polymer, $[Ru_2(\mu\text{-}O_2CCH_3)_4(adenine)]_x$, in which the adenine bridges adjacent dimers through N^9 and N^3 (or N^1) and a distinct diadduct containing adenosine, $[Ru_2(\mu\text{-}O_2CCH_3)_4(adenosine)_2]Cl$, most likely bound to the ruthenium through N^7. However, no structural characterization of either derivative was reported and doubt about the actual structures remains. Recently the crystal structure of $[Ru_2(\mu\text{-}O_2CC_6H_4\text{-}p\text{-}OMe)_4(2\text{-}mimH)_2](ClO_4)$ where 2-mimH = 2-methylimidazole was reported [11]. It was found that the axial 2-mimH ligands were oriented in a

PII: S0277-5387(02)00998-1

cis fashion and that there was weak H-bonding between the NH group of the imidazole ring and an oxygen on the perchlorate counterion. In light of the activity shown by $Ru_2(\mu\text{-}O_2CCH_3)_4Cl$ and other derivatives [12,13] against certain cancer cell lines we are beginning an extensive study on the axial and equatorial interaction of various biologically relevant ligands with the diruthenium core. The reactions with urea and tetramethylurea (tmu) are reported here.

2. Experimental

2.1. General procedures

1-Propanol, 2-propanol and diethyl ether were used as received. 1,2-Dichloroethane (dce) was distilled from CaH_2 prior to use. Urea, 1,1,3,3-tetramethylurea (tmu), thiourea and 1,1,3,3-tetramethyl-2-thiourea (tmtu) were used as received. The compounds $Ru_2(\mu\text{-}O_2CCH_3)_4Cl$ and $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ were prepared using literature procedures [14,15]. Infrared spectra were recorded on a Bruker IFS25 or a Bio-Rad FTS-175 spectrophotometer as KBr discs. UV–Vis spectra were recorded in methanol or 1,2-dichloroethane using a Varian 2300 or Varian 100 spectrophotometer. Effective magnetic moments were determined at room temperature (r.t.) using a Johnson Matthey MSB-1 magnetic susceptibility balance with $HgCo(SCN)_4$ as a calibrant ($\chi_g = 16.17 \times 10^{-6}$ c.g.s.) [16]. Cyclic voltammetry was performed in 1,2-dichloroethane and/or dichloromethane using a BAS CV-50W voltammetric analyzer. The cell system consisted of a platinum button working electrode, platinum wire auxiliary electrode and an Ag/AgCl reference electrode. The ferrocene/ferrocenium couple was used as an internal reference and was consistently measured at 392 mV versus Ag/AgCl. Measurements were normally performed on a 2 mM solution of the complex with 0.100 M $[CH_3(CH_2)_3]_4NPF_6$ as the supporting electrolyte. All solutions were purged with argon for 15 min prior to each scan. Elemental analyses were performed by Canadian Microanalytical Service Ltd., Delta, BC, Canada. X-ray data were collected and the structures solved at the DalX X-ray facility, Dalhousie University, Halifax, NS, Canada.

2.2. Synthesis of $[Ru_2(\mu\text{-}O_2CCH_3)_4(urea)_2](PF_6)$ (**1a**)

$[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ (0.100 g, 0.16 mmol) was dissolved in 4 ml of 2-propanol. An excess of urea (0.038 g, 0.64 mmol) dissolved in 4 ml of 2-proponal was added dropwise with stirring to the first solution. An orange–brown precipitate slowly formed and the solution was allowed to stir for a further 15 min. It was then filtered, washed with 1 ml of cold 2-propanol and dried in vacuo. Additional product could be obtained by adding diethyl ether to the remaining solution. Recrystallization of the product was afforded from hot 2-propanol. Ligand to metal ratios of 0.5:1–6:1 were tried with all giving the same formulation and a 4:1 ratio (described above) giving the optimal yield. Yield = 0.080 g (71%). *Anal*. Calc. for $C_{10}H_{20}F_6N_4O_{10}PRu_2$: C, 17.07; H, 2.86; N, 7.96. Found: C, 17.39; H, 2.78; N, 7.67%. IR (KBr, cm^{-1}): 3474 (s), 3362 (m), 2930 (m), 1648 (s), 1600 (s), 1565 (m), 1452 (s), 1402 (s), 1351 (w), 1156 (m), 1044 (m), 843 (s), 693(s), 563 (m). UV–Vis: λ (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$) (methanol): 332 (1800), 420 (950). $\mu_{eff} = 4.1$ B.M.

2.3. Synthesis of $[Ru_2(\mu\text{-}O_2CCH_3)_4(urea)_2](PF_6)$/ $[Ru_2(\mu\text{-}O_2CCH_3)_4(1\text{-propanol})_2](PF_6)$ (**1b**)

Attempts to grow crystals of (**1a**) from 2-propanol that were suitable for X-ray diffraction studies proved unsuccessful, however, we were able to obtain good crystals from 1-propanol. These turned out to be a co-crystallized system of (**1a**) and the solvent (1-propanol) diadduct (see Section 3.2).

2.4. Synthesis of $[Ru_2(\mu\text{-}O_2CCH_3)_4(tmu)_2](PF_6)$ (**2**)

$[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ (0.100 g, 0.16 mmol) was dissolved in 15 ml of 1,1,3,3-tetramethylurea (tmu). The solution was gently heated to completely dissolve the solid. Stirring was continued for 1 h at r.t. Diethyl ether was then added slowly to precipitate the tan colored product. The product was filtered and dried in vacuo. The complex could be recrystallized by diffusion of diethyl ether into a 1,2-dichloroethane (dce) solution of the product. Crystals suitable for X-ray diffraction were also obtained in this fashion. Yield = 0.116 g (89%). *Anal.* Calc. for $C_{18}H_{36}F_6N_4O_{10}PRu_2$: C, 26.51; H, 4.45; N, 6.87. Found: C, 26.44; H, 4.39; N, 6.75%. IR (KBr, cm^{-1}): 2935 (m), 1614 (s), 1551 (s), 1445 (s), 1411 (s), 1357 (m), 1333 (m), 1237 (w), 1163 (m), 1070 (m), 843 (s), 693 (s), 558 (m). UV–Vis: λ (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$) (dce): 302 (2320), 436 (880). $\mu_{eff} = 4.0$ B.M.

2.5. Synthesis of $[Ru_2(\mu\text{-}O_2CCH_3)_4(tmtu)_2](PF_6)$ (**3**)

$[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ (0.050 g, 0.08 mmol) was dissolved in a 3 ml of 2-propanol. 1,1,3,3-Tetramethyl-2-thiourea (tmtu) (0.021 g, 0.16 mmol) in 3 ml of 2-propanol was added with stirring and allowed to react for 5 min. The resulting light brown precipitate was filtered and dried in vacuo. Yield = 0.030 g (44%). *Anal.* Calc. for $C_{18}H_{36}F_6S_2N_4O_8PRu_2$: C, 25.44; H, 4.27; N, 6.60; S, 7.53. Found: C, 25.39; H, 4.25; N, 6.35; S, 7.47%. IR (KBr, cm^{-1}): 2936 (m), 2855 (w), 1543 (m), 1437 (s), 1387 (s), 1266 (m), 1163 (m), 1102 (s), 1046 (w),

841 (s), 691 (s). UV–Vis: λ (nm) (ε, dm^3 mol^{-1} cm^{-1}) (dce): 393 (2220), 475 (1130). $\mu_{eff} = 3.8$ B.M.

Recrystallization of **3** from 1,2-dichloroethane (dce) by diethylether diffusion led to the formation of plate-like crystals of the disolvate (**3**)·2dce. Compound **3** can be regenerated by rigorous drying, however, crystal integrity is lost.

2.6. Reaction of $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ with thiourea (tu) and formation of the polymeric $[Ru_2(\mu\text{-}O_2CCH_3)_4(tu)]_x(PF_6)_x$ (**4**)

Reactions of $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ with thiourea in various alcohols at stoichiometries of 0.5:1 to 4:1 led, in all cases, to the rapid formation of a dark brown insoluble solid. A typical reaction giving optimum yield of this solid was carried out as follows. $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ (0.100 g, 0.16 mmol) was dissolved in 4 ml of 2-propanol to which was added 0.013 g (0.16 mmol) thiourea in 3 ml of 2-propanol. A dark brown precipitate formed immediately. The solution was allowed to stir for 5 min, filtered, washed thoroughly with 2-propanol and dried in vacuo. The product was found to be insoluble in most organic solvents. Yield = 0.084 g (80% based on above formulation). *Anal.* Calc. for $C_9H_{16}F_6SN_2O_8PRu_2$: C, 16.39; H, 2.45; N, 4.25; S, 4.86. Found: C, 16.09; H, 2.61; N, 4.33; S, 5.06%. IR (KBr, cm^{-1}): 3396 (m), 3210 (m), 3186 (m), 2924 (m), 1661 (s), 1624 (s), 1536 (s), 1448 (m), 1406 (s), 1102 (w), 1038 (w), 918 (s), 853 (s), 696 (s). $\mu_{eff} = 4.0$ B.M.

2.7. X-ray crystallography

All crystals (**1b**, **2** and **3**·2dce) were mounted in glass capillaries and measurements were made at r.t. on a Rigaku AFC5R diffractometer with graphite monochromated Cu Kα radiation and a rotating anode generator. Procedures for crystal indexing, data collection and data reduction for this instrument were routine and have been described elsewhere [15]. Corrections were made for the effects of absorption anisotropy as well as Lp effects. A correction for secondary extinction was applied in all cases.

All three structures were solved by direct methods and expanded using Fourier techniques [17,18]. All data processing was performed using TEXSAN [19] except for the refinement of complex **1b** which was done using SHELX-97 [20]. Neutral atom scattering factors were taken from Cromer and Waber [21]. The values of the mass attenuation coefficients are those of Creagh and Hubbell [22]. For complex **2** and **3**·2dce anomolous dispersion effects were included in F_{calc} [23] and the values for $\Delta f'$ and $\Delta f''$ were those of Creagh and McAuley [24]. Crystallographic parameters for the three structures discussed are given in Table 1. Bond lengths and angles are presented in Tables 2–4.

3. Results and discussion

3.1. Synthesis

The synthesis of complexes **1**, **3**, and **4** was carried out in a similar fashion in 2-propanol using a simple axial ligand substitution reaction [4] displacing H_2O in the starting $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ complex with the desired ligand normally in a 2:1–4:1 ligand:metal ratio. The optimum yields of complex **4** were obtained using a 1:1 ratio. Complex **2** was synthesized by using the neat 1,1,2,2-tetramethylurea (tmu) ligand as solvent with precipitation of the product afforded by the addition of diethyl ether. Satisfactory elemental analyses were obtained for all of the thoroughly dried compounds with that of compound **4** being consistent with a 1:1 ligand to complex ratio which is evidence for a possible polymeric structure. Complex **1** was successfully recrystallized from 1-propanol as the co-diadduct system **1b** and **2** and **3**·2dce were obtained from diethyl ether diffusion into a solution of the complex in 1,2-dichloroethane. Complex **4** could not be recrystallized satisfactorily as it was only found to be soluble in DMSO and pyridine in which it decomposed.

3.2. Structure of $[Ru_2(\mu\text{-}O_2CCH_3)_4(urea)_2](PF_6)$/ $[Ru_2(\mu\text{-}O_2CCH_3)_4(1\text{-}propanol)_2](PF_6)$ (**1b**)

Complex **1b** crystallizes in a triclinic system ($P\bar{1}$). Selected bond lengths and angles are listed in Table 2. An ORTEP diagram of each diadduct is shown in Fig. 1. Fig. 2 presents the unit cell diagram which clearly shows the presence of the two distinct diadducts, namely $[Ru_2(\mu\text{-}O_2CCH_3)_4(urea)_2](PF_6)$ and $[Ru_2(\mu\text{-}O_2CCH_3)_4(1\text{-propanol})_2](PF_6)$. Co-crystallization of more than one diadduct is not common but has been seen on four previous occasions. Each of these earlier cases have their own unique characteristics and a brief discussion of each will help to put complex **1b** in context.

McCann et al. [25] synthesized the complex salt, $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2][Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]$, which in the crystal structure was found to contain the $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(C_2H_5OH)_2]^+$ cation and the $[Ru_2(\mu\text{-}O_2CC_6H_5)_4(HSO_4)_2]^-$ anion. These ions linked together in an infinite polymeric chain by a modest hydrogen-bond (2.77 Å) between the ethanol oxygen of one dimer and the hydrogensulfate oxygen of another. Handa et al. [26,27] recently investigated the magnetic properties of two compounds that display co-crystallized adducts. The first, $[Ru_2(\mu\text{-}O_2CCMe_3)_4(tempo)_2][Ru_2(\mu\text{-}O_2CCMe_3)_4(H_2O)_2](BF_4)_2$ where tempo = 2,2,6,6-tetramethylpiperidine-1-oxyl, contains the two

[a] $R = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[b] $R_w = [(\Sigma w(|F_o| - |F_c|)^2/\Sigma wF_o^2)]^{1/2}$.
[c] $R_1 = \Sigma||F_o| - |F_c||/\Sigma|F_o|$.
[d] $wR_2 = [\Sigma w(F_o^2 - F_c^2)^2/\Sigma w(F_o^2)^2]^{1/2}$.

cationic diadducts $[Ru_2(\mu\text{-}O_2CCMe_3)_4(tempo)_2]^+$ and $[Ru_2(\mu\text{-}O_2CCMe_3)_4(H_2O)_2]^+$ and two BF_4^- ions. No evidence of any interactions between the two cations is mentioned. In the second case, $[Ru_2(\mu\text{-}O_2CCMe_3)_4(nitme)_2][Ru_2(\mu\text{-}O_2CCMe_3)_4(H_2O)_2](BF_4)_2$ where nitme = 2,4,4,5,5-pentamethyl-4,5-dihydro-1H-imidazolyl-1-oxyl 3-oxide, the two cations are linked by hydrogen-bonds (2.81 Å) between the N–O groups of the nitme and the water molecules on $[Ru_2(\mu\text{-}O_2CCMe_3)_4(H_2O)_2]^+$ leading to an infinite zig-zag chain. An interesting system investigated by Jimenez-Aparicio et al. [28], $Ru_2(\mu\text{-}O_2CCH_2OEt)_4Cl\cdot H_2O$, showed not only the distinct cationic species $[Ru_2(\mu\text{-}O_2CCH_2OEt)_4(H_2O)_2]^+$ and the anionic $[Ru_2(\mu\text{-}O_2CCH_2OEt)_4Cl_2]^-$ but also the infinite chain $\{Ru_2(\mu\text{-}O_2CCH_2OEt)_4Cl\}_x$ where the Cl^- links adjacent dimers, all in the same crystal lattice.

In the present study the nature of complex **1b** most closely resembles that of Handa's first complex as we have two distinct cations, $[Ru_2(\mu\text{-}O_2CCH_3)_4(urea)_2]^+$ and $[Ru_2(\mu\text{-}O_2CCH_3)_4(1\text{-propanol})_2]^+$ with two PF_6^- anions. While there is no evidence of any significant axial ligand to axial ligand interaction between the cations in **1b** there is a weak hydrogen-bonding interaction (3.18(1) Å) between the urea nitrogen N(2) and an oxygen, O(9), on the equatorial acetate of the 1-propanol containing diadduct and a stronger interaction (2.786(8) Å) between the 1-propanol oxygen, O(10) and an acetate oxygen, O(4), on the urea adduct. The Ru–Ru and Ru–O_{eq} bond lengths in the two cations are typical for these types of compounds [3] as are the two Ru–Ru–O_{axial} bond angles. The Ru–O_{ax}(urea) bond, (Ru(1)–O(5) = 2.245(5) Å) and the Ru–O_{ax}(1-propanol) bond (Ru(1)–O(10) = 2.268(6) Å) are comparable to the tetraacetato complexes $[Ru_2(\mu\text{-}O_2CCH_3)_4(DMSO)_2](PF_6)$ (Ru–O_{ax} = 2.243(5) Å) and $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ (Ru–O = 2.279(4) Å), respectively [15]. The Ru(1)–O(5)–C(5) bond angle of 134.6(5) Å (urea cation) is somewhat larger than might be expected, possibly due to the hydrogen-bonding mentioned above, whereas the Ru(2)–O(10)–C(10) (1-propanol cation) angle is 123.2(6) Å. In both cases the axial ligands are arranged in an anti geometry with respect to each other.

3.3. Structure of $[Ru_2(\mu\text{-}O_2CCH_3)_4(tmu)_2](PF_6)$ (2)

Complex **2** crystallizes in the monoclinic system ($P2_1/c$) with a center of inversion lying between the two Ru atoms. Selected bond lengths and angles are given in Table 3 and an ORTEP diagram is shown in Fig. 3. The bonding parameters in this complex are similar to those of the urea diadduct in complex **1b** with the Ru–Ru and Ru–O_{eq} bond lengths and the Ru–Ru–O_{ax} bond angle falling into the typical ranges and the axial tmu ligands

Table 2

arranged in an anti fashion. The Ru–O_{ax}(tmu) bond (Ru(1)–O(5) = 2.249(4) Å) is essentially identical to the ruthenium–urea bond in complex **1b**. Although one might have expected it to be shorter due to the stronger Lewis basicity of tmu versus urea, the steric bulk introduced by the four methyl groups may hinder a closer approach. It is also worthy of note that the Ru(1)–O(5)–C(5) bond angle of 125.3(4)° is smaller than the corresponding bond angle in the urea diadduct in **1b**.

3.4. Structure of $[Ru_2(\mu\text{-}O_2CCH_3)_4(tmtu)_2](PF_6)\cdot 2dce$ (**3**)·2dce

Complex **3**·2dce crystallizes in the triclinic system ($P\bar{1}$). Selected bond lengths and angles are presented in Table 4 and an ORTEP diagram is given in Fig. 4. This is the second example of a structurally characterized sulfur-donor adduct of a diruthenium carboxylate. The first, $[Ru_2(\mu\text{-}O_2CCH_3)_4(tht)_2](PF_6)$ where tht = tetrahydrothiophene, was reported earlier by our group [7]. Fig. 4 clearly shows co-ordination of the tmtu ligands through the sulfur atom. The Ru–Ru bond (2.301(2) Å) is slightly longer than is typical for these types of complexes and is second only to the very strong axial donor adduct, $[Ru_2(\mu\text{-}O_2CCH_3)_4(PCy)_2](PF_6)$ (Cy = cyclohexyl), in which Ru–Ru is 2.427(1) Å [6]. The Ru–O_{eq} bonds and the Ru–Ru–S bond angle are normal for these compounds. As with the $[Ru_2(\mu\text{-}O_2CCH_3)_4(tht)_2](PF_6)$ complex in which the Ru–S bond was very long at 2.627 Å, the Ru–S bond in **3** is long at 2.610(2) Å. A similar argument can be used here as for the tht adduct in that there appears to be a strong *trans*-effect across the Ru–Ru bond and very little π-backbonding from the metal centers to the sulfur [7]. Finally the Ru(1)–S(1)–C(5) bond angle is quite small, in compar-

ison with the similar angle in the urea type derivatives **1b** and **2**, at 104.9(3)°.

3.5. IR spectroscopy

All four compounds show the characteristic symmetric ν_{sym}(COO) and asymmetric ν_{asym}(COO) carboxylate stretches in the 1380–1450 cm^{-1} region and $\nu(PF_6^-)$ in the range 840–855 cm^{-1} [15]. Of more interest, however, is the nature of the axial ligand binding. A summary of all the bands and assignments mentioned in this section is given in Table 5.

Let us consider the urea, **1**, and tmu, **2**, derivatives first. Bands above 3000 cm^{-1} in **1** can be assigned to N–H stretching frequencies with the band at 2930 cm^{-1} due to the C–H stretch of the acetate methyl groups. In **2** no bands are seen above 3000 cm^{-1} and the C–H stretching frequency is observed at 2935 cm^{-1}. The $\nu_s(C=O)$ values for **1** (1648 cm^{-1}) and **2** (1614 cm^{-1}) represent a decrease in the stretching frequencies from free urea (1683 cm^{-1}) and free tmu (1640 cm^{-1}) [29–31] of 35 and 26 cm^{-1}, respectively. CO stretching frequencies are expected to decrease (by as much as 110 cm^{-1}) when coordination to the metal occurs through the oxygen [29]. Coordination through the nitrogen should

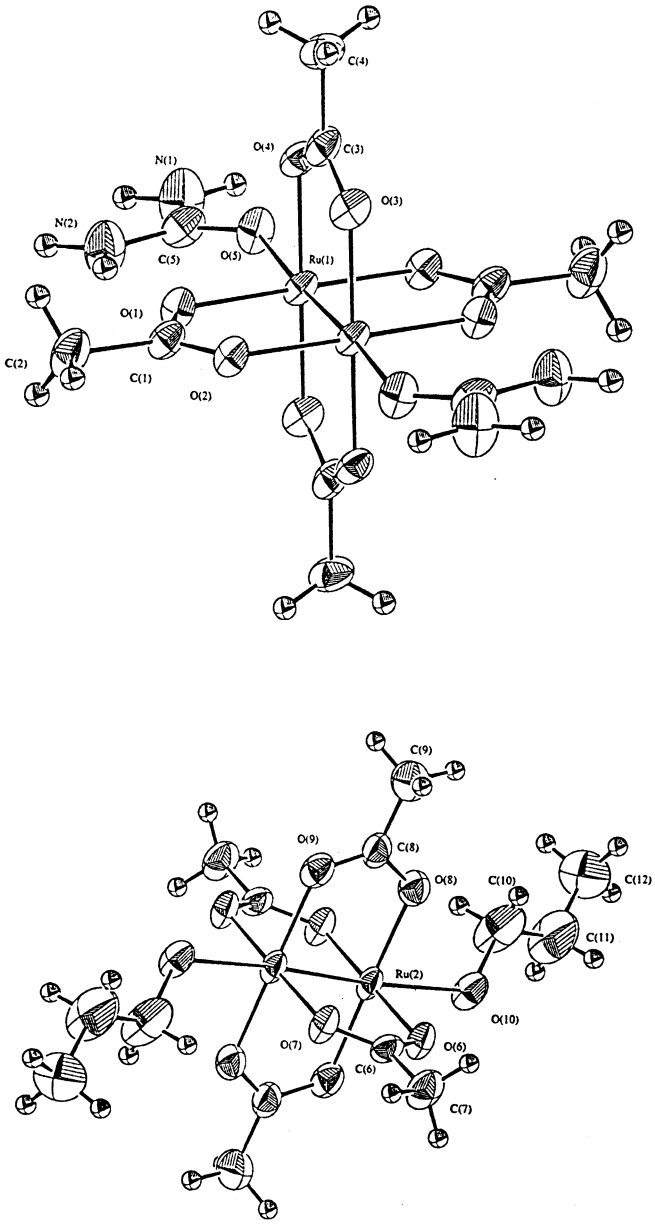

Fig. 1. ORTEP drawing of **1b** showing the $[Ru_2(\mu\text{-}O_2CCH_3)_2(urea)_2]^+$ cation (top) and the $[Ru_2(\mu\text{-}O_2CCH_3)_2(1\text{-propanol})_2]^+$ cation (bottom). The PF_6^- counterion has been omitted for clarity.

lead to an increase in $\nu_s(C=O)$. The band at 1600 cm^{-1} in **1** (absent in **2**) is assigned to an NH_2 bending mode. This is virtually identical to the value for the free urea ligand (1599 cm^{-1}) [32,33]. It has been shown previously that this band remains relatively constant upon urea coordination through oxygen [29,33,34]. The bands at 1565 and 1551 cm^{-1} in complexes **1** and **2**, respectively, are assigned to the antisymmetric N–C–N stretching vibration which has a value of 1506 cm^{-1} in free urea [32,33] and 1499 cm^{-1} in free tmu [30]. An increase of this frequency upon coordination is also consistent with bonding through oxygen.

Let us now consider the tmtu, **3**, and thiourea, **4**, derivatives. As was the case with **2**, complex **3** shows no

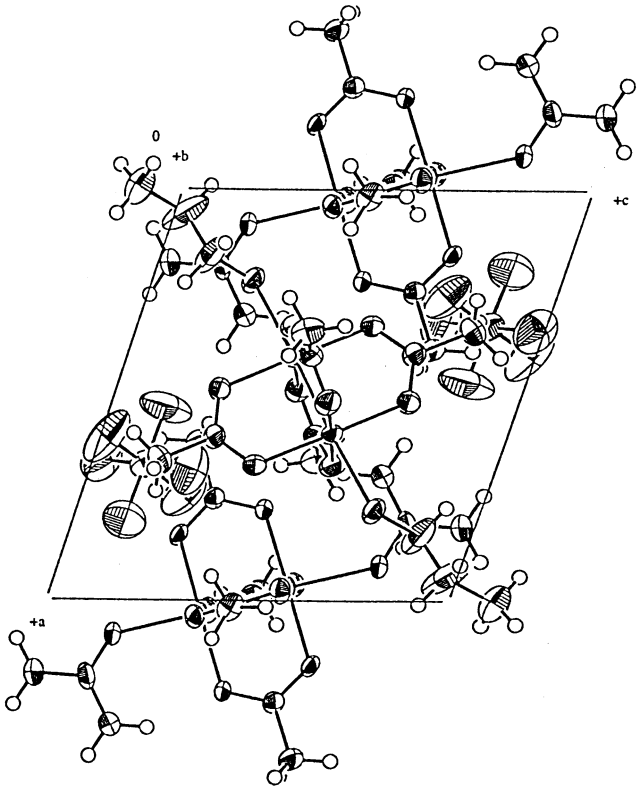

Fig. 2. View of the unit cell looking down the *b*-axis of **1b** showing the two unique diadducts present.

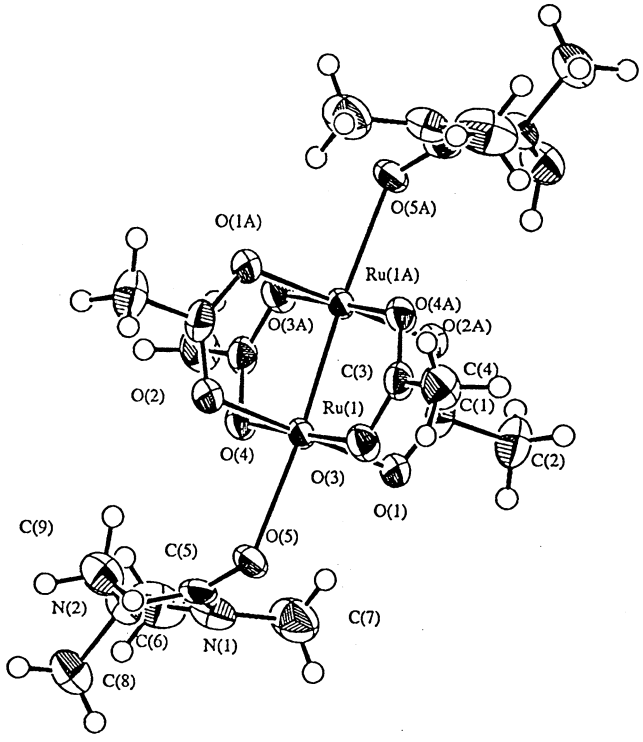

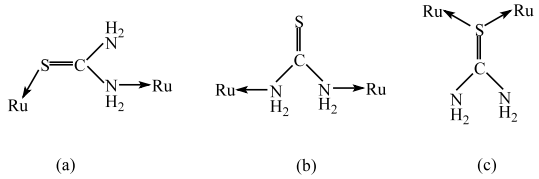

Fig. 3. ORTEP drawing of the $[Ru_2(\mu\text{-}O_2CCH_3)_2(tmu)_2]^+$ cation in **2**. The PF_6^- counterion has been omitted for clarity.

bands above 3000 cm^{-1} (no N–H stretching) and a band at 2936 cm^{-1} due to C–H stretching. Complex **4** shows bands characteristic of both of these modes at 3396, 3210 and 3186 cm^{-1} for N–H and at 2924 cm^{-1} for C–H. It is important to note that there are several N–H stretching modes for **4** and the two lowest lie at lower frequencies than those for **1** and those for free thiourea. According to Nakamoto [29] and Yamaguchi [34] this suggests that there may be coordination through nitrogen rather than (or as well as) sulfur. In the NH_2 bending region **4** shows two strong bands at 1661 and 1624 cm^{-1} which is indicative of two different NH_2 environments, possibly bound and unbound [34]. As with complex **2**, complex **3** shows an antisymmetric N–C–N stretch at 1543 cm^{-1} which is higher than the value for the free tmtu ligand of 1504 cm^{-1} [30]. In complex **4** there is also a positive shift from the free ligand value of 1470–1536 cm^{-1}. In both cases this is indicative of coordination through the sulfur. Finally we consider the two stretching modes due, primarily, to the C=S double bond. In free tmtu these lie at 1126 and 718 cm^{-1} and both are shifted to lower frequencies (1102 and 691 cm^{-1}) upon complexation. This is consistent with a reduction in the double bond character and coordination through the sulfur. In **4** the results are not as clear as there is a shift to higher frequency for ν_1(C=S) from 1083 to 1102 cm^{-1} and to a lower frequency for ν_2(C=S) from 730 to 696 cm^{-1}. The band in **4** at 1102 cm^{-1} is very weak and previous results have been ambiguous in that slight increases are seen despite coordination still taking place at sulfur [34,35]. The decrease in ν_2(C=S) points to bonding through sulfur.

The ligand coordination modes for complexes **1**, **2**, and **3** are clear from the X-ray structures and the infrared data supports this. For compound **4** we can only speculate for now. Assuming that a polymer (or oligomer) is formed, and the elemental analysis and solubility properties appear to support this, there are three likely bridging modes for thiourea. These are shown in Scheme 1. It would appear from the arguments presented above that bridging mode (a) is the most likely as it accommodates both sulfur and nitrogen coordination.

3.6. UV–Vis spectroscopy and magnetic susceptibility

The electronic spectra of complexes **1**–**3** have been recorded in methanol (for **1**) and dce (for **2** and **3**). All of

Scheme 1.

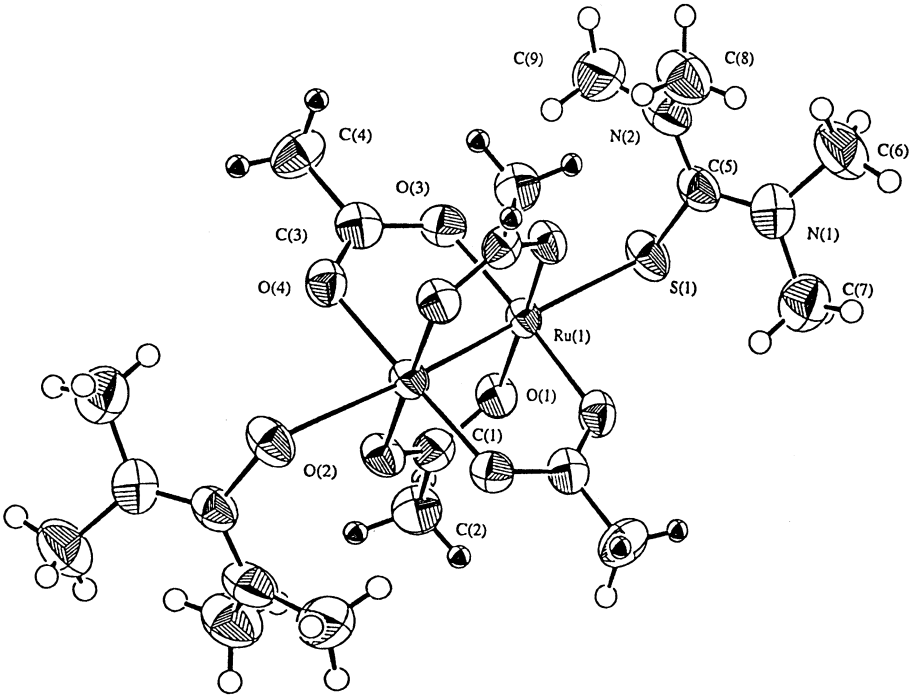

Fig. 4. ORTEP drawing of the $[Ru_2(\mu\text{-}O_2CCH_3)_2(tmtu)_2]^+$ cation in **3**·2dce. The PF_6^- counterion and the dce molecules of solvation have been omitted for clarity.

the complexes display a distinctive electronic transition in the visible in the range 420–475 nm due to a π(RuO, Ru_2) → π*(Ru_2) transition and another in the UV in the range 300–395 nm assigned to a π(axial O or S) → π*(Ru_2) transition [3]. It should be noted that both of the bands for **3** (475 and 393 nm) are red-shifted somewhat from the corresponding bands in **1** (420 and 332 nm) and **2** (436 and 302 nm). A similar shift to lower energies has been seen in the only other S-donor adduct to date, $[Ru_2(\mu\text{-}O_2CCH_3)_4(tht)_2](PF_6)$ [7]. Complex **4** was insoluble in most solvents to obtain a reasonable spectrum. Dissolution in DMSO or pyridine caused decomposition.

The magnetic moment of each complex was measured in the solid state at room temperature and found to be in the range 3.8–4.1 B.M. This is consistent with the ground-state configuration $\sigma^2\pi^4\delta^2(\pi^*\delta^*)^3$ and three unpaired electrons [3].

[c] C=S stretching + N–C–N stretching [34].

3.7. Electrochemistry

As complex **1** is not sufficiently soluble in an appropriate non-coordinating solvent, measurements carried out in coordinating solvents such as water or methanol suffer from the ambiguity of which is the electroactive species: complex **1**, the solvent-donor adduct or a mixture of the two. For example, cyclic voltammetry measurements on **1** in aqueous media (0.100 M $NaClO_4$) versus Ag/AgCl reference yielded an essentially reversible redox couple at $E_{1/2} = 72$ mV ($\Delta E_p = 68$ mV) at a scan rate of 100 mV s^{-1}. This is the same value as was found for $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$, $[Ru_2(\mu\text{-}O_2CCH_3)_4(DMF)_2](PF_6)$, and $[Ru_2(\mu\text{-}O_2CCH_3)_4(DMSO)_2](PF_6)$ which were measured under identical conditions [15]. This is almost certainly due to substantial hydrolysis of the complexes, with the measured value being essentially that for the $[Ru_2(\mu\text{-}O_2CCH_3)_4(H_2O)_2](PF_6)$ adduct. Subsequent measurements of the DMF and DMSO adducts in the non-coordinating solvents dichloromethane and/or 1,2-dichloroethane showed substantially different values [4].

Complexes **2** and **3** were not hampered by this solubility problem and could readily be measured in 1,2-dichloroethane allowing for direct comparison to several previously measured adducts. Both complexes displayed one quasi-reversible one-electron reduction at a scan rate of 100 mV s^{-1}. For complex **2** this occurred at −487 mV (vs. Fc/Fc^+) with an anodic to cathodic potential separation (ΔE_p) of 123 mV. Complex **3** showed a similar reduction at −541 mV (vs. Fc/Fc^+) with $\Delta E_p = 93$ mV. Table 6 summarizes these results and puts them in the context of selected donor adducts measured under similar conditions. The trend of decreasing $E_{1/2}$ values with increasing Gutmann donor number of the axial ligand has been discussed elsewhere [4]. What we are primarily interested in here is where complex **2** and **3** fit into this trend. With a Gutmann donor number of 31 for tmu [36] complex **2** fits the trend quite nicely, lying between L = DMSO (D.N. = 29.8) and L = pyridine (D.N. = 33.1). The potential for complex **3** lies substantially lower than **2** with a value close to that for L = 4-methylpyridine (D.N. = 35.1). As there is no documented donor number value for tmtu a direct comparison cannot be made and structurally the long Ru–S bond (2.610(2) Å) makes the low $E_{1/2}$ value and hence strong donor character somewhat surprising. However, if one compares the tmtu adduct with the tetrahydrothiophene (tht) adduct ($E_{1/2} = -322$ mV) there is structural consistency. The tht adduct has a longer Ru–S bond (2.627 Å) and shorter Ru–Ru bond (2.285 Å) than complex **3** (Ru–Ru = 2.301 Å). This implies that **3** forms a stronger axial bond and more electron density is transferred into the metal centers leading to an increased population of the antibonding orbitals, a longer Ru–Ru bond and hence a lower $E_{1/2}$ value.

4. Conclusion

We have synthesized and fully characterized three (complexes **1**–**3**) new Lewis base adducts of diruthenium(II,III) tetraacetate and partially characterized a fourth (**4**) which appears to be of a polymeric or oligomeric nature. Complex **1** crystallizes from 1-propanol as a rare example of co-solvent diadduct system and complex **3** is only the second known example of a diruthenium tetracarboxylate sulfur-donor adduct. While there is no significant intramolecular hydrogen-bonding in **1** there is evidence for intermolecular H-bonding between the urea nitrogen and an acetate of the 1-propanol diadduct as well as between the 1-propanol oxygen and an acetate oxygen of the diurea adduct. The X-ray structures for **1**–**3** are supported by the infrared and electronic spectroscopy. The cyclic voltammetry of complexes **2** and **3** displays one quasi-reversible reduction, consistent with earlier studied Lewis base adducts [4,6,7]. Despite the long axial Ru–S bond in **3** the electrochemistry implies that tmtu is a moderately strong donor, comparable to 4-methylpyridine.

Evidence for **4**'s polymeric nature comes from its solubility properties and the metal complex to ligand stoichiometry which is shown to be 1:1 from the elemental analysis. IR spectroscopy provides partial evidence that the thiourea ligand in **4** is acting as a bridge between adjacent $[Ru_2(\mu\text{-}O_2CCH_3)_4]^+$ groups and that bridging occurs through both the S and N atoms, but this is not conclusive. Decomposition of **4** in an excess of strong solvents such as DMSO and pyridine is also consistent with the breakdown of a diruthenium tetracarboxylate polymer [39]. Assuming **4** is a polymer, some key questions do remain. What is the exact nature

of the thiourea bridge? Why doesn't the urea analogue form a polymer? Are there significant magnetic and/or electronic interactions through the bridge? We are currently attempting to answer these questions by synthesizing adducts of partially methylated derivatives of thiourea, using slow diffusion processes to grow crystals of **4** and investigating the low temperature magnetic susceptibility of all the compounds.

5. Supplementary material

Crystallographic data (CIF) files for the structural analyses of **1**, **2**, and **3** have been deposited with the Cambridge Crystallographic Data Centre (12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk)), and are available on request quoting the deposition numbers 175390 for **1**, 175391 for **2**, and 175392 for **3**.

Received 3 January 2002; accepted 27 March 2002

Abstract

Using a bidentate heterocyclic ligand with mixed hard–soft nitrogen donor set [L^5 = 2-(3,5-dimethylpyrazol-1-ylmethyl)pyridine] two types of copper(II) complexes have been synthesized and characterized: (i) $[Cu(L^5)_2][ClO_4]_2 \cdot H_2O$ (**1**) and (ii) $[Cu(L^5)_2X][ClO_4]$ ($X = Cl^-$ (**2**), NCS^- (**3**) and N_3^- (**4**)). Structural analysis of **1** reveals that its unit cell consists of a 1:1 mixture of square planar $[Cu(L^5)_2]^{2+}$ (coordination by two pyrazoles and two pyridines) and tetragonal $[Cu(L^5)_2(H_2O)_2]^{2+}$, having additional weak interaction with the water molecules in the axial positions. Preliminary X-ray structural analysis of **3** with a poor data set, which is not reported here, revealed that the thiocyanate group is S-coordinated. For each complex the stereochemistry of the copper(II) centre has been investigated in the solid state as well as in MeCN solution, by absorption and EPR spectroscopy. In the polycrystalline state as well as in MeCN solution complex **1** displays axial EPR spectra having a $d_{x^2-y^2}$ ground state. However, solid samples of **2**–**4** exhibit rhombic EPR spectral features, characteristic of a compressed d_{z^2} ground state. In the solution phase (80 K) **2** exhibits an isotropic signal; **3** and **4** exhibit axial spectra, characteristic of a $d_{x^2-y^2}$ ground state. The observed $E_{1/2}$ values for the Cu^{II}–Cu^{I} redox couple [cyclic voltammetry: MeCN solution; V vs. saturated calomel electrode (SCE)] are fairly positive: 0.41 (**1**), 0.29 (**2**), 0.30 (**3**) and 0.19 (**4**). © 2002 Elsevier Science Ltd. 1. Introduction

Investigations of the coordination chemistry of copper(II) with chelating ligands continue to be stimulated by interest in developing models for copper proteins and in understanding the factors which give rise to the relationship between the coordination geometry and the nature of the donor atoms and redox potentials [1–6]. As a result of 'plasticity effect' due to Jahn–Teller active ground state, copper(II) forms compounds of coordination number 4–6 with many kinds of irregular coordination geometries. The geometry of the coordination polyhedron around copper(II) is also influenced by subtle ligand characteristics: ligand constraints/flexibility, steric hindrance and the strength of the donor atoms. Systematic variation of Cu^{II} stereochemistry provides an opportunity to identify the effect of ligands' electronic and/or imposed steric factors responsible for subtle stereochemical preferences for a particular molecular structure, associated electronic structure and reactivity behaviour.

In the past few years we have investigated [7–13] the coordination chemistry using nonplanar bi- and tridentate heterocyclic ligands (L^1–L^5) to control the stereochemistry at metal centres, including copper(II) [10,11,13]. These ligands contain both pyridine (soft) and pyrazole (hard) donors in a given ligand system. However, their electronic communication is prevented due to placement of methylene spacer(s) between the rings. The effects of such an electronic feature and the

PII: S0277-5387(02)01014-8

presence of methyl substituents near the donor site (L^2, L^3 and L^5) were revealed in the structural and electronic properties of transition-metal centres. We [10,11,13] and others [14,15] have demonstrated that using ligands L^1, L^3 or L^5 the coordination polyhedra around mononuclear Cu^{II} centres could be systematically tuned. X-ray crystallographic investigations on $[Cu(L^3)X_2]$ ($X = Cl^-$, Br^- or SCN^-) [14,15], $[Cu(L^3)(N_3)_2]$ [13], $[Cu(L^3)(ONO)(OClO_3)]$ [13], $[Cu(L^3)(L^5)][ClO_4]_2$ [11] and $[Cu(L^5)_2(ONO)][ClO_4]$ [10] complexes have given credence to our expectation. These observations prompted our interest in the synthesis of bis-ligand $Cu^{II}N_4$ complexes of L^5 to probe the coordination geometry around copper(II). To reveal stereochemical changes around the Cu^{II} centre by coordination of the bidentate ligand L^5 with additional binding of simple inorganic anions, we have synthesized complexes like dark violet $[Cu(L^5)_2][ClO_4]_2\cdot H_2O$ (**1**) and green $[Cu(L^5)_2X][ClO_4]$ ($X = Cl^-$ (**2**), NCS^- (**3**) and N_3^- (**4**)) and determined the crystal structure of **1**. Interestingly, the crystal structure of **1** reveals that it contains a 1:1 mixture of square planar $[Cu(L^5)_2]^{2+}$ and tetragonal $[Cu(L^5)_2(H_2O)_2]^{2+}$, having weak interaction with the water molecules in the axial positions. This paper is also concerned with the spectral and redox properties of these complexes. Given the scarcity [7,10,11,13–15] of structural investigation of copper(II) complexes with this class of ligands, the structural information on the bis-ligand complex **1** would be of interest to rationalize the chemical significance of the results observed.

2. Experimental

2.1. Materials

All chemicals were obtained from commercial sources and used as received. Solvents were purified/dried following standard procedures [10,11,13]. The ligand L^5 and tetra-*n*-butylammonium perchlorate were synthesized as before [9,10].

2.2. Synthesis of copper(II) complexes

2.2.1. $[Cu(L^5)_2][ClO_4]_2\cdot H_2O$ (1)

To a magnetically stirred solution of $Cu(ClO_4)_2\cdot 6H_2O$ (0.1 g, 0.27 mmol) in EtOH (3 cm^3) a solution of the ligand L^5 (0.1 g, 0.54 mmol) in EtOH (3 cm^3) was added dropwise. The resulting clear blue solution was stirred for 15 min and kept in air for slow evaporation. After 12 h, a dark violet microcrystalline solid that formed was collected by filtration, washed thoroughly with EtOH and dried in vacuo. Recrystallization was achieved from MeCN/EtOH to afford a dark violet product (yield: approximately 60%). *Anal.* Found: C, 40.2; H, 4.2; N, 12.7. Calc. for $C_{22}H_{28}N_6O_9Cl_2Cu$: C, 40.3; H, 4.3; N, 12.8%. IR (KBr, cm^{-1}, selected peaks): 3400 ν(OH), 1085, 620 $\nu(ClO_4^-)$. Conductivity (MeCN, $\approx 10^{-3}$ mol dm^{-3} solution at 298 K): $\Lambda_M = 286\ \Omega^{-1}\ cm^2\ mol^{-1}$ (expected range [16] for 1:2 electrolyte: 220–300 $\Omega^{-1}\ cm^2\ mol^{-1}$). UV–Vis: λ_{max} (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 950 (sh), 602 (80), 350 (sh), 262 (sh) (MeCN); 980 (sh), 505, 364, 273 (Nujol mull). μ_{eff} (MeCN, 298 K) 1.87 μ_B. Variable-temperature magnetic moment data (T/K, μ_{eff}/μ_B): 300, 1.88; 280, 1.86; 260, 1.87; 240, 1.86; 220, 1.87; 200, 1.86; 180, 1.85; 160, 1.85; 140, 1.83; 120, 1.82; 100, 1.77; 81, 1.81. Cyclic voltammetry (V vs. SCE; MeCN): $E_{1/2} = 0.41$ V, $\Delta E_p = 120$ mV and $E_{pc} = -0.56$ V.

2.2.2. $[Cu(L^5)_2Cl][ClO_4]$ (2)

2.2.2.1. Method A. To a magnetically stirred solution of **1** (0.1 g, 0.153 mmol) in MeCN (8 cm^3) was added dropwise a solution of $Et_4NCl\cdot xH_2O$ (0.025 g, 0.153 mmol) in H_2O. The green reaction mixture thus obtained was allowed to stand for 3 days in air. Green crystals thus obtained were washed thoroughly with water and dried in vacuo (yield: approximately 98%). *Anal.* Found: C, 46.2; H, 4.5; N, 14.6. Calc. for $C_{22}H_{26}N_6O_4Cl_2Cu$: C, 46.1; H, 4.5; N, 14.7%. IR (KBr, cm^{-1}, selected peaks): 1100, 620 $\nu(ClO_4^-)$. Conductivity (MeCN, $\approx 10^{-3}$ mol dm^{-3} solution at 298 K): $\Lambda_M = 132\ \Omega^{-1}\ cm^2\ mol^{-1}$ (expected range [16] for 1:1 electrolyte: 120–160 $\Omega^{-1}\ cm^2\ mol^{-1}$). UV–Vis: λ_{max} (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 980 (sh), 710 (160), 355 (800), 280 (sh), 260 (8270) (MeCN); 980 (br), 720 (br), 620 (sh), 370 (sh), 271 (Nujol mull). μ_{eff} (MeCN, 298 K) 1.90 μ_B. Variable-temperature magnetic moment data (T/K, μ_{eff}/μ_B): 300, 1.90; 280, 1.87; 260, 1.87; 240, 1.87; 220, 1.88; 200, 1.86; 180, 1.84; 160, 1.85; 140, 1.82; 120, 1.79; 100, 1.77; 81, 1.75. Cyclic voltammetry (V vs. SCE; MeCN): $E_{1/2} = 0.29$ V, $\Delta E_p = 180$ mV and $E_{pc} = -0.66$ V.

2.2.2.2. Method B. To a magnetically stirred solution of $Cu(ClO_4)_2\cdot 6H_2O$ (0.050 g, 0.135 mmol) in MeCN (1 cm^3) was added dropwise a solution of L^5 (0.050 g, 0.27 mmol) in MeCN (2 cm^3). After 2 min of stirring the

resulting blue solution, a solution of $Et_4NCl \cdot xH_2O$ (0.029 g, 0.18 mmol) in H_2O (1 cm^3) was added dropwise and the resulting faint greenish-blue solution was stirred for an additional 1 h at 298 K. It was then left for slow evaporation in air. After 2 days fine needle-like light blue crystals precipitated, which were collected by filtration, washed with water and dried in vacuo (yield: approximately 65%).

2.2.3. $[Cu(L^5)_2(SCN)][ClO_4]$ (3)

2.2.3.1. Method A. A similar procedure as that for **2** was followed with KSCN (0.015 g, 0.153 mmol). (yield: approximately 95%). *Anal.* Found: C, 46.5; H, 4.4; N, 16.5. Calc. for $C_{23}H_{26}N_7ClSO_4Cu$: C, 46.4; H, 4.4; N, 16.5%. IR (KBr, cm^{-1}, selected peaks): 2105, 2060 ν(CN) of NCS^-; 1100, 620 $\nu(ClO_4^-)$. Conductivity (MeCN, $\approx 10^{-3}$ mol dm^{-3} solution at 298 K): $\Lambda_M = 154\ \Omega^{-1}\ cm^2\ mol^{-1}$. UV–Vis: λ_{max} (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 950 (sh), 690 (140), 412 (1100), 254 (11 470), 224 (21 300) (MeCN); 712, 390, 268 (Nujol mull). μ_{eff} (MeCN, 298 K) 1.82 μ_B. Cyclic voltammetry (V vs. SCE; MeCN): $E_{1/2} = 0.30$ V, $\Delta E_p = 140$ mV and $E_{pc} = -0.64$ V.

2.2.3.2. Method B. To a magnetically stirred solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.050 g, 0.135 mmol) in MeCN (2 cm^3) was added dropwise a solution of L^5 (0.050 g, 0.27 mmol) in MeCN (3 cm^3). After stirring for 2 min, a solution of KSCN (0.013 g, 0.135 mmol) in EtOH (2 cm^3) was added dropwise to generate a dark green solution. After 1 h it was left for slow evaporation in air. After 2 days, green crystals that precipitated were collected by filtration, washed with water and dried in vacuo (yield: approximately 75%).

2.2.3.3. Method C. To a magnetically stirred solution of **2** (0.02 g, 0.035 mmol) in MeCN (3 cm^3) was added dropwise an aqueous solution (1 cm^3) of KSCN (0.004 g, 0.041 mmol) and the resulting solution was allowed to stand for 2 days. Green crystals that precipitated were collected by filtration, washed with water and dried in vacuo (yield: approximately 96%).

2.2.4. $[Cu(L^5)_2(N_3)][ClO_4]$ (4)

2.2.4.1. Method A. A similar procedure as that for **2/3** was followed with NaN_3 (0.015 g, 0.153 mmol) (yield: approximately 95%). *Anal.* Found: C, 45.6; H, 4.4; N, 21.7. $C_{22}H_{26}N_9ClO_4Cu$: C, 45.6; H, 4.5; N, 21.8%. IR (KBr, cm^{-1}, selected peaks): 2042, 2005 $\nu(N_3^-)$ of N_3^-; 1080, 620 $\nu(ClO_4^-)$. Conductivity (MeCN, $\approx 10^{-3}$ mol dm^{-3} solution at 298 K): $\Lambda_M = 144\ \Omega^{-1}\ cm^2\ mol^{-1}$. UV–Vis: λ_{max} (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$): 717 (370), 425 (1950), 417 (2350), 254 (9500) (MeCN); 800, 440, 270 (Nujol mull). μ_{eff} (MeCN, 298 K) 1.85 μ_B. Cyclic voltammetry (V vs. SCE; MeCN): $E_{1/2} = 0.19$ V, $\Delta E_p = 260$ mV and $E_{pc} = -0.65$ V.

2.2.4.2. Method B. To a magnetically stirred solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.050 g, 0.135 mmol) in MeCN (2 cm^3) was added dropwise a solution of L^5 (0.050 g, 0.27 mmol) in MeCN (3 cm^3). After stirring the resulting blue solution for 2 min, a solution of NaN_3 (0.009 g, 0.135 mmol) in H_2O (3 cm^3) was added dropwise to generate a dark green solution. After 1 h it was filtered and left for slow evaporation in air. After 3 days, green crystals that precipitated were collected by filtration, washed with water and dried in vacuo (yield: approximately 70%).

2.2.4.3. Method C. A similar procedure as that for **3** was followed with NaN_3 (0.015 g, 0.035 mmol) (yield: approximately 95%).

Caution! Perchlorate salts of compounds containing organic ligands are potentially explosive.

2.3. Measurements

Elemental analyses (C, H, N) were obtained at the Microanalysis Service Centre of the Department of Inorganic Chemistry, Indian Association for the Cultivation of Science, Kolkata. Infrared spectra were recorded on a Perkin Elmer M-1320 spectrophotometer using KBr discs or Nujol mulls. Electronic spectra were recorded using a Perkin Elmer Lambda 2 spectrophotometer. Solution electrical conductivity measurements (298 K) were carried out at a concentration of $\sim 1 \times 10^{-3}$ $dm^3\ mol^{-1}\ cm^{-1}$ with an Elico (Hyderabad, India) Type CM-82 T conductivity bridge. Variable temperature (81–300 K) magnetic susceptibility measurements in the solid state were performed using a locally-built Faraday balance [17] comprising an electromagnet with constant gradient pole caps (Polytronic Corporation, Mumbai, India), an ultravacuum Sartorius M25-D/S Balance (Germany), a closed-cycle refrigerator and a Lake Shore temperature controller (Cryo Industries, USA). All measurements were made at a fixed main field strength of ~ 10 kG. Solution state magnetic susceptibility was obtained by the NMR technique of Evans [18] in MeCN with a PMX-60 JEOL (60 MHz) NMR spectrometer. Susceptibilities were corrected for the diamagnetic contribution [19]. Cyclic voltammograms were recorded at 298 K on a PAR model 370 electrochemistry system consisting of a model 174A polarographic analyzer with a model 175 universal programmer. A planar Beckman platinum electrode (model 39273) was used as the working electrode. All potentials were measured referenced to SCE; no corrections were made for junction potentials.

2.4. Structure determination and refinement

A violet crystal of **1** was used for data collection (θ–2θ scan technique) on an Enraf Nonius CAD-4-Mach four-circle diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Lattice parameters were obtained from least-squares analyses of 25 machine-centred reflections. A total of 5306 reflections were measured of which 4986 were unique and 3104 reflections with $I > 3\sigma(I)$ were used in the structure refinement.

2.4.1. Crystal data

$C_{22}H_{28}Cl_2CuN_6O_9$, $M = 654.54$, triclinic, space group $P\bar{1}$, $a = 9.824(5)$, $b = 10.208(7)$, $c = 14.750(1)$ Å, $\alpha = 90.39(6)$, $\beta = 104.51(4)$, $\gamma = 95.72(5)^\circ$, $V = 1424(2)$ Å^3, $Z = 2$, $D_c = 1.485$ g cm^{-3}, $\mu = 10.1$ cm^{-1}.

Data were corrected for Lorentz-polarization effects; anomalous dispersion was applied for all non-hydrogen atoms and analytical absorption corrections were also applied. The structure was solved initially with SIR-92 and refined isotropically with the SHELX-97 package incorporated in WINGX 1.61 crystallographic collective package [20]. Using the XTAL 3.2 crystallographic software package [21], anisotropic refinements were performed by full-matrix least-squares procedure on F, where the function minimized was $\Sigma w(F_o - F_c)^2$ with $w = 1$. The positions of the hydrogen atoms were calculated assuming ideal geometries, but not refined. Except for O atoms, which were refined isotropically, all other atoms were refined with anisotropic thermal parameters. The ClO_4^- anions were disordered; eight peaks were located as possible oxygen positions, each of them was given a site occupation factor of 0.5. We could not locate the hydrogen atoms of the water molecule. The final cycle of refinement included 371 variable parameters and converged with $R = 0.074$, $R_w = 0.079$, $S = 2.071$, final difference Fourier synthesis: $-0.68 \leq \Delta\rho \leq 0.78$ e Å^{-3}.

3. Results and discussion

3.1. Synthesis and properties

Dark violet bis-ligand copper(II) complex $[Cu(L^5)_2][ClO_4]_2 \cdot H_2O$ (**1**) was readily prepared by the stoichiometric reaction of $[Cu(H_2O)_6][ClO_4]_2$ with L^5 in EtOH. Green anion-bound complexes $[Cu(L^5)_2X][ClO_4]$ (X = Cl^- (**2**), NCS^- (**3**) and N_3^- (**4**)) were prepared in MeCN–H_2O/EtOH mixture by (i) reaction between **1** and $Et_4NCl \cdot xH_2O$, KSCN or NaN_3 in a 1:1 molar ratio and (ii) direct reaction of $[Cu(H_2O)_6][ClO_4]_2$, L^5 and $Et_4NCl \cdot xH_2O$, KSCN or NaN_3 in the molar ratio 1:2:1. Complexes **3** and **4** were also prepared from the reaction between **2** and KSCN or NaN_3 in the molar ratio 1:1. Microanalytical, IR [11,22] and conductivity data (in MeCN, **1** behaves as a 1:2 electrolyte and **2**–**4** behave as 1:1 electrolytes) are in conformity with the suggested formulations for **1**–**4**. For **1** an interesting observation is that it reacts with Br^- ion giving rise to green colouration, which was revealed during KBr pellet formation for IR studies. This inspired us to explore the possibility of synthesizing anion-bound complexes and successful synthesis of **2**–**4** from **1**, is the outcome of such an effort. Complex **1** is highly soluble in MeCN, MeOH, DMF and moderately soluble in $MeNO_2$ and Me_2CO, however, generating blue solutions. Complexes **2**–**4** are highly soluble in MeCN and DMF.

In order to determine unambiguously the structure of the bis-ligand complex **1**, a single-crystal structure determination was undertaken (vide infra). Although we succeeded in growing single crystals of **3**, the X-ray data collected at 295 K using such a crystal [monoclinic, space group $P2_1$ (no. 4); $a = 9.465(3)$, $b = 18.364(7)$, $c = 15.496(9)$ Å, $\beta = 102.7(4)^\circ$, $V = 2628(2)$ Å^3, $Z = 4$] has not allowed us to solve the structure satisfactorily, due to a poor data set. However, the presence of $[Cu(L^5)_2(SCN)][ClO_4]$ is clearly observable in the difference Fourier map. The asymmetric unit contains two such units, and in each molecule the copper(II) centre is distorted towards trigonal bipyramidal and the thiocyanate group is S-coordinated in the equatorial plane [23].

3.2. Description of the structure of $[Cu(L^5)_2][ClO_4]_2 \cdot H_2O$

The asymmetric unit of the crystal of the complex $[Cu(L^5)_2][ClO_4]_2 \cdot H_2O$ contains a 1:1 mixture of square planar $[Cu(L^5)_2][ClO_4]_2$ and tetragonal $[Cu(L^5)_2(H_2O)_2][ClO_4]_2$. The molecular structures of both the cations together with the atom numbering scheme used are shown in Fig. 1. Relevant bond distances and angles are given in Table 1. In each $[Cu(L^5)_2]^{2+}$ cation the copper(II) ion sits on a crystallographically imposed centre of inversion, with the two pyridyl [N1 and its symmetry related N1′ for Cu(1); N1a and N1a′ for Cu(2)] and two pyrazole [N3 and its symmetry related N3′ for Cu(1); N3a and N3a′ for Cu(2)] nitrogens in mutually *trans* positions. The coordination angles very slightly deviate from the ideal angle of 90° (Table 1). The water molecules are not in contact distances with the Cu(1) centre [Cu(1)–O(1w) distance 10.82(1) Å]. For the Cu(2) centre two extremely long interactions with the O atoms of water molecules in the axial positions is clearly observable (Fig. 1(b)). The observed Cu(2)–O(1w) bond distance [2.729(8) Å] can at most be regarded as semi-coordination [24,25], then the structure would correspond to CuN_4O_2 coordination. Each cation is thus effectively a four-coordinate bis-ligand complex and the geometry of the copper(II) centre is square planar. The Cu–N(pyridyl) and Cu–N(pyrazole) bond distances are

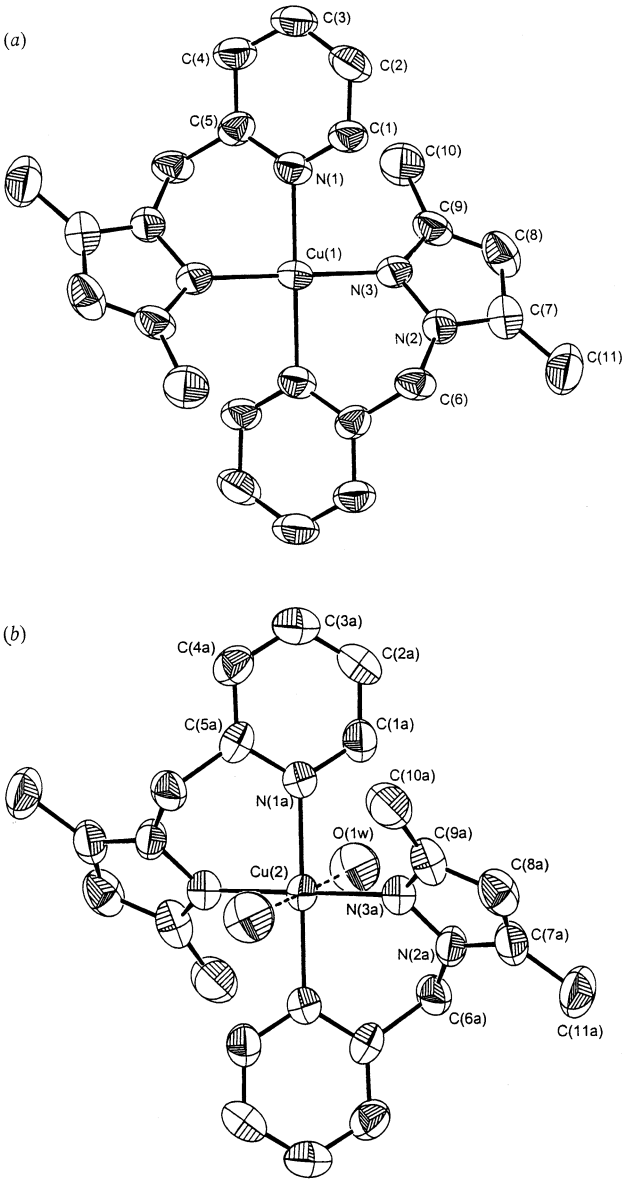

Fig. 1. Molecular structure of (a) $[Cu(L^5)_2]^{2+}$ and (b) $[Cu(L^5)_2(H_2O)_2]^{2+}$ in the unit cell of $[Cu(L^5)][ClO_4]_2 \cdot H_2O$ (**1**). The thermal ellipsoids are at the 50% probability level. Hydrogen atoms are omitted.

Table 1
Selected bond distances (Å) and bond angles (°) for $[Cu(L^5)_2][ClO_4]_2 \cdot H_2O$ (**1**)

Bond lengths			
Cu(1)–N(1)	2.026(7)	Cu(2)–N(1a)	2.029(8)
Cu(1)–N(3)	1.981(8)	Cu(2)–N(3a)	1.990(7)
Bond angles			
N(1)–Cu(1)–N(3)	92.3(3)	N(1a)–Cu(2)–N(3a)	92.0(3)
N(1)–Cu(1)–N(3′)	87.7(3)	N(1a)–Cu(2)–N(3a′)	88.0(3)

2.026(7) and 1.981(8) Å for Cu(1) and 2.029(8) and 1.990(7) Å for Cu(2), respectively. The Cu–N(pyridyl) distances are longer than Cu–N(pyrazole) distances (Table 1). The observed behaviour is in line with this trend and the distances are also in good agreement with values observed in $[Cu(L^3)(ONO)(OClO_3)]$ [13] and $[Cu(L^3)(NCS)_2]$ [14]. The pyridyl and pyrazole rings are each planar. However, a pyridyl ring of a given ligand is twisted to a pyrazole ring by an angle of $\sim 57^\circ$ or $\sim 65^\circ$. Thus, the six-membered chelate rings exist in boat conformations [7,10].

Within the present class of non-planar pyrazolylmethylpyridine ligands, the structure of **1** has two distinct noteworthy features. This is for the first time the metric parameters of a mononuclear copper(II) complex with coordination solely by two chelating ligands L^5 have become available. To the best of our knowledge, this is the second report of two different cationic copper(II) coordination geometries in the same unit cell, one four-coordinate and the other six-coordinate. The other report [25] demonstrated the existence in the same unit cell one hexa-coordinate and the other penta-coordinate cations.

3.3. Absorption spectral properties

The electronic spectra of complexes **1**–**4** were measured both in the solid state (dispersed in mineral oil mull) and in MeCN solution (Section 2). The diffuse reflectance spectrum of **1** displays a visible band at 505 nm, suggestive of a predominantly square planar stereochemistry [26], in conformity with the X-ray structural result. In MeCN solution it displays a band due to a d-d transition at 602 nm. This indicates a square pyramidal geometry [26] around Cu^{II}, implying that in going from solid to the solution phase, a stereochemical change around Cu(II) from square planar to square pyramidal has occurred. For **2**, the solid state reflectance spectrum displays two overlapping bands in the region 600–1000 nm. Similar behaviour was observed for $[Cu(L^1/L^3)Cl_2]$ [11], exhibiting Cu_2Cl_2 core formation (vide infra). For **3** and **4** broad absorptions are observed at 710 and 800 nm, respectively. This is indicative of a distorted trigonal bipyramidal geometry around Cu^{II} [26]. However, in MeCN solution the positions of the d–d transition are 710 nm (**2**), 690 nm (**3**) and 717 nm (**3**). The observed blue shift implies that a change in copper(II) stereochemistry has occurred in going from solid to solution (vide infra) and the effect is more pronounced in the case of **4**.

3.4. EPR spectral properties

To extract more information about the stereochemistry at the copper(II) centre, the X-band EPR spectra of all the complexes have been recorded as microcrystalline solids (at 298 and at 80 K) and in frozen MeCN solution or as glass at 80 K. The data are summarized in Table 2.

Table 2
EPR spectral data for the complexes [a]

Compound	Medium	$g_{\|}$	$A_{\|}$	$g_{\perp}$	g_1	g_2	g_3
1 $[Cu(L^5)_2][ClO_4]_2\cdot H_2O$	polycrystalline powder at 298 K	2.214	207	2.048			
	polycrystalline powder at 80 K	2.209	214	2.043			
	MeCN solution at 80 K	2.232	198	2.063			
2 $[Cu(L^5)_2Cl][ClO_4]$ [b]	polycrystalline powder at 298 K				2.222	2.149	2.014
	polycrystalline powder at 80 K				2.192	2.150	2.007
3 $[Cu(L^5)_2(SCN)][ClO_4]$	polycrystalline powder at 298 K				2.192	2.143	2.011
	polycrystalline powder at 80 K				2.190	2.146	2.010
	CH_2Cl_2–C_6H_7 solution (2:1 v/v) at 80 K	2.269	169	2.061			
4 $[Cu(L^5)_2(N_3)][ClO_4]$	polycrystalline powder at 298 K				2.173	2.131	2.017
	polycrystalline powder at 80 K				2.175	2.134	2.013
	CH_2Cl_2–C_6H_7 solution (2:1 v/v) at 80 K	2.250	163	2.050			

[a] $A_{\|}$ values are in $\times 10^{-4}$ cm^{-1}. For the complex $[Cu(L^5)_2(ONO)][ClO_4]$ in CH_2Cl_2–C_6H_7 solution (2:1 v/v) at 80 K the EPR parameters: $g_{\|} = 2.266$, $A_{\|} = 169 \times 10^{-4}$ cm^{-1}, $g_{\perp} = 2.060$.
[b] $g_{iso} = 2.121$ in MeCN/MeCN–C_6H_7 solution (1:1 v/v) at 80 K.

Complex **1** exhibits in the solid state as well as in MeCN solution, axial spectra typical for monomeric tetragonal copper(II) species with $d_{x^2-y^2}$ ground-state ($g_{\|} > g_{\perp} > 2.0$) [26]. The behaviour of **1** in the polycrystalline state at 298 K is displayed in Fig. 2. For **1**, the change from solid state to MeCN solution affects the EPR spectral parameters only slightly. A convenient EPR spectral empirical index is the $g_{\|}/A_{\|}$ ratio [27], which provides information about distortion in the geometry around copper(II). For **1**, an increase in $g_{\|}$ and a decrease in $A_{\|}$ rendering the ratio to increase from 103 cm (solid state at 80 K) to 113 cm (MeCN solution at 80 K), however, is clearly observable. This indicates that the copper environment in **1** has been modified in solution due to increased in-plane ligand-field strength or increased axial interaction. It is well known [28] that as the axial interaction in copper(II) complexes increases, ν_{max} of the ligand-field spectral band decreases (vide supra), $g_{\|}$ increases and $A_{\|}$ decreases (Table 2). For **1**, the axial interaction, manifested by giving blue solutions in common organic solvents, is clearly weak.

The polycrystalline EPR spectra of **2**–**4**, in contrast to that of **1**, displayed rhombic pattern from which three distinct g values ($g_1 > g_2 > g_3$) could be derived. The behaviour of **2** at 298 K is displayed in Fig. 2. The fact that the lowest g-value is < 2.03 indicates that these complexes have a compressed rhombic site with a d_{z^2} ground state [26]. For **2**–**4** the values of R [$= (g_2-g_3)/(g_1-g_2)$] [26] at 298 K are 1.85, 2.69 and 2.71, respectively. The observed R values, which are > 1, also justify the fact that these complexes have a predominant d_{z^2} ground state [26]. Interestingly, for **2** the frozen MeCN solution spectrum is isotropic. This could be due to a relaxed (more toward octahedral) coordination sphere, due to the existence of a 'pseudo dimeric structure' with additional coordination of a Cl^- ion

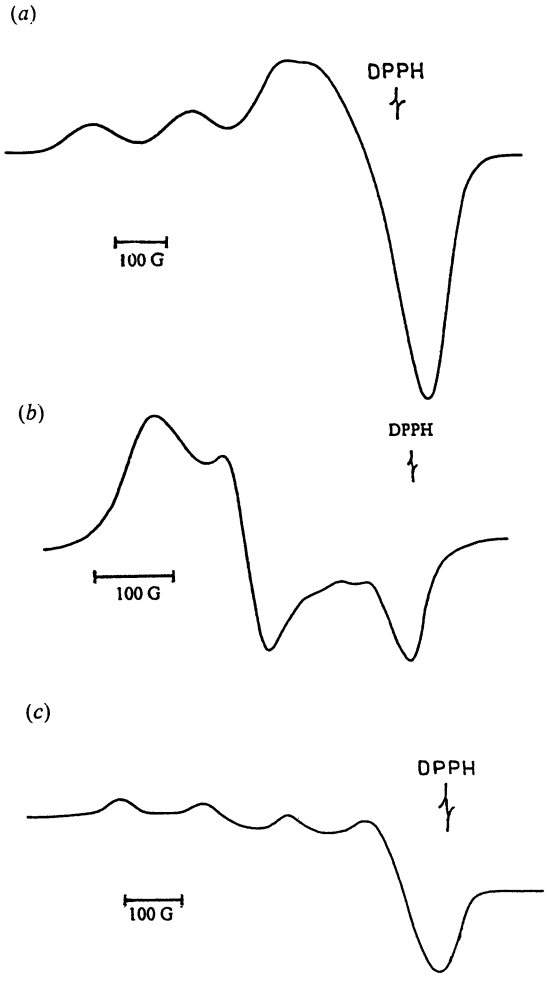

Fig. 2. X-band EPR spectra of (*a*) $[Cu(L^5)_2][ClO_4]_2\cdot H_2O$ (**1**) in the polycrystalline state at 298 K, (b) $[Cu(L^5)_2Cl][ClO_4]$ (**2**) in the polycrystalline state at 298 K and (c) $[Cu(L^5)_2(SCN)][ClO_4]$ (**3**) in CH_2Cl_2–C_6H_7 glass (2:1 v/v) at 80 K.

from a Cu(II) centre to a nearby Cu(II) centre. The existence of such a Cu_2Cl_2 core is well documented in Cu^{II} coordination chemistry, including our own report [29]. However, for **2**, such an interaction must be very weak (cf. magnetism data). Given the results at hand for **2**, we are not in a position to comment more specifically on this behaviour. It should be mentioned here that the complex $[Cu(L^3)(ONO)(OClO_3)]$ [13] behaved similarly. On the other hand, complexes **3** and **4** in 2:1 (v/v) CH_2Cl_2–C_7H_8 glass (80 K) show well resolved four-line tetragonal spectra, characteristic of a $d_{x^2-y^2}$ ground state (Fig. 2 and Table 2). In fact, the spectra are closely similar to that of the structurally characterized square pyramidal complex $[Cu(L^5)_2(ONO][ClO_4]$ ($g_{\|}/A_{\|} = 134$ cm, under identical experimental conditions) [10]. We can therefore infer that the Cu^{II} centre in $[Cu(L^5)_2(SCN)][ClO_4]$ assumes a tetragonal geometry in MeCN solution (cf. absorption spectral result), implying a structural change in going from solid to solution. Given the X-ray structures of $[Cu(L^3)(L^5)][ClO_4]_2$ [11] and $[Cu(L^5)_2(ONO)][ClO_4]$ [10] we believe that in the square pyramidal geometry one of the pyrazole groups acts as the axial ligand. The EPR spectra for the present complexes indicate that it adopts a similar geometry in frozen solution (barring the behaviour of **2** in solution) despite the fact that in the solid state the Cu^{II} geometry of **3** and **4**, is considerably distorted from square pyramidal towards trigonal bipyramidal. Presumably the energy difference between square pyramidal and trigonal bipyramidal geometries is small, and at lower temperature there is a shift toward square pyramidal geometry. Similar changes in stereochemistry have been observed for other Cu^{II} complexes [1].

3.5. Magnetic properties

To confirm whether or not compound **2** is a monomer, we decided to investigate its variable-temperature (81–300 K) magnetic susceptibility behaviour in the solid state using the Faraday method. We have also done temperature-dependent measurement for bis-ligand complex **1**, for which the X-ray structure is available. The complexes followed the Curie–Weiss law. The $1/\chi_M$ versus T plots are linear. The effective magnetic moments of the complexes in the solid state at 300 K are 1.88 and 1.90 μ_B for **1** and **2**, respectively. The solution-state values for all the complexes lie in the range 1.8–2.0 μ_B, expected for copper(II) complexes in a magnetically dilute environment [26] Thus, in the absence of X-ray structural proof, the temperature-dependent magnetic studies clearly demonstrate the mononuclear nature of **2**.

3.6. Redox properties

Cyclic voltammetric measurements of the copper(II) complexes **1**–**4** were carried out in MeCN at a platinum working electrode. Each complex displayed chemically reversible ($i_{pc}/i_{pa} \approx 1$) and electrochemically quasireversible (ΔE_p, in the range 120–260 mV) redox waves corresponding to the reduction of copper(II) to copper(I). The observation of larger ΔE_p values for these complexes is expected given the differing stereochemical requirements of the Cu^{II} and Cu^{I} states [30]. For each complex a second redox process was also observed. This reduction, which was irreversible, led to a copper stripping peak in the subsequent oxidation cycle, indicative of decomposition of a zerovalent complex to elemental copper at the platinum electrode. Such an effect has been described for closely similar complexes [10,11,13].

Interestingly, compared to similar types of complex the $E_{1/2}$ values (V vs. SCE) for the present complexes are fairly positive [10,11,13,15]. The factors [2,10,31–35] which contribute to tune the Cu^{II}–Cu^{I} reduction potentials are: (i) the flexibility of or constraints imposed by the chelating ligands, which might favour a geometry preferred by one metal ion oxidation state, but not the other, (ii) the types of the coordinated donor atoms (i.e. O vs. N vs. S, etc.), (iii) the coordination geometries of the copper sites and (iv) hydrophobicity in the copper complex environment. The complexes **1**–**4**, including previously reported complex $[Cu(L^5)_2(ONO)][ClO_4]$ [10], have given us an unique opportunity to pinpoint each subtle effect. (i) On the cyclic voltammetric time scale, the formation of the comparatively stable copper(I) complex upon reduction will mostly require concomitant distortion of the square planar arrangement of the complex toward a tetrahedral geometry. The flexible ligand L^5 must be contributing to the geometrical requirement. (ii) For a given ligand L^5, the $E_{1/2}$ values for the present solvent-/anion-bound complexes are significantly more positive in the order: MeCN (0.41) > NCS^- (0.30) > Cl^- (0.29) > N_3^- (0.19). In this series **1** has the highest $E_{1/2}$ value. This is possibly because reduction of the Cu^{II} centre to Cu^{I} is expected to trigger a decrease in coordination number from five to four. It is understandable that a weaker axial bond would facilitate bond dissociation and hence electron addition and makes the reduction potential more positive.

The complex $[Cu(L^5)_2(ONO)][ClO_4]$ [10] exhibits a Cu^{II}–Cu^{I} wave at −0.32 V, albeit irreversible, under identical conditions. As the nitrito group in $[Cu(L^5)_2(ONO)][ClO_4]$ [10] or the NCS^- group in **3** [23] is coordinated in the equatorial position it is reasonable to assume that in **2** and **4** the X^- anions are present in the equatorial position, as well. For the mononuclear copper(II) complexes with the composition $[Cu(L^5)_2$-

(X)][ClO_4], a stronger equatorial ligation by X^- is expected to bring about an increase in repulsion between the $d_{x^2-y^2}$ orbital and X^-, which in turn would lead to an increase in the energy of the $d_{x^2-y^2}$ orbital. This would make the addition of an electron into this orbital difficult, i.e. the $E_{1/2}$ values would be more cathodic. It is worth noting here that the Cu–ONO bond distance in [$Cu(L^5)_2$(ONO)][ClO_4] is quite short [2.091(5) Å] [10]. As the Cu^{II}–SCN bond is quite long ($\approx$2.37 Å) [23] the observed trend $ONO^- < NCS^-$ is thus justifiable. Moreover, the S-bound NCS^- group in **3** raises the $Cu^{II}-Cu^{I}$ redox potential by destabilizing the copper(II) state. It is worth noting here that thioether coordination behaves similarly [5]. If we assume a similar Cu–Cl bond distance ($\approx$2.34 Å) as that observed in [$Cu(L^3)Cl_2$] [15], then the observed trend in $E_{1/2}$ values between **2** and **3** is understandable. (iv) Complex **2** exhibits a more negative $E_{1/2}$ value than **1**, undoubtedly caused by the presence of the anionic chloride ligand, which favours ligation to Cu^{II} compared to MeCN [34].

Interestingly, it is well documented that pyrazole-containing complexes have more positive $E_{1/2}$ values than the corresponding pyridine complexes [35]. This is illustrated by comparing (in MeCN) complex **1** (0.41) with [CuL_2][ClO_4]$_2$ [L = di(2-pyridyl)methane] (0.25) [36]. This result suggests that the pyrazole-containing ligands are weaker ligands than the pyridine ones and that the coordination environment of the complexes is softer for the pyrazole complexes. The presence of methyl substituents near the donor site provides 'environmental effects' [11,32]. We believe that the comparatively higher Cu^{II}–Cu^{I} redox potential observed for **1**–**4** is primarily due to reduced ligand field strength exerted around the copper(II) centre by the ligand L^5. Generally speaking, these ligands (L^1–L^5) do not possess good σ-donor ability to stabilize the copper(II) centre [7].

4. Conclusions

Although numerous four, five and six-coordinate mononuclear copper(II) complexes are known in the literature, examples of such structural varieties with non-planar heterocyclic ligands having both soft and hard donor sets are quite uncommon. In this investigation we have provided examples of such complexes with a pyridyl and pyrazole containing bidentate ligand L^5. Interestingly, the crystal structure reveals that [$Cu(L^5)_2$][ClO_4]$_2$·H_2O contains a 1:1 mixture of square planar $[Cu(L^5)_2]^{2+}$ and tetragonal $[Cu(L^5)_2(H_2O)_2]^{2+}$, having additional weak interaction with the water molecules in the axial positions. The properties in the solid state have been systematically compared with those in MeCN solution, revealing that the structure of these complexes in solution is predominantly square pyramidal. Taken together the results presented here and that recently reported [10,11,13–15], indicate that a change in the nature of the anion can substantially influence the geometry (square pyramidal or trigonal bipyramidal) and Cu^{II}–Cu^{I} redox potentials of the copper(II) complexes. This tuning of ligand makeup and resulting metal complex will continue to be useful in the design of desired reactivity [6,30,33,34]. The effects of various factors, which contribute to tune the Cu^{II}–Cu^{I} reduction potentials, have been carefully analyzed. These ligands considerably stabilize the copper(I) state over Cu(II), due to reduced donation by the pyrazole groups. In essence, the bidentate ligand L^5 having non-communicable hard–soft N-donor sets offers a wealth of interesting copper chelate chemistry.

5. Supplementary material

Full tables of bond lengths and angles, tables of non-hydrogen and hydrogen atomic coordinates, anisotropic thermal parameters for non-H atoms as well as hydrogen atom parameters have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 171047. Abstract

The thermodynamic parameters for the interactions of $MeSnBr_3$ with *para*- and *meta*-substituted *meso*-tetraphenylporphyrins ($H_2T(4\text{-}X)PP$; $X = OCH_3$, CH_3, H, Cl, NO_2 and $H_2T(3\text{-}X)PP$; $X = CH_3$, Cl) have been studied. The formation constants have been elucidated by using spectrophotometric titration and computer SQUAD program data refinement. The adducts of composition 2:1 and 1:1 of $MeSnBr_3$ to $H_2T(4\text{-}X)PP$ with stability constants K_1 and K_2 coexist in solution, but *meta*-substituted porphyrins form adducts of the composition 1:1 of $MeSnBr_3$ to $H_2T(3\text{-}X)PP$ with stability constant K_1. Formation constants decrease with decreasing electron donation of *para*-substituted porphyrins as follow: $H_2T(4\text{-}CH_3O)PP > H_2T(4\text{-}CH_3)PP > H_2TPP > H_2T(4\text{-}Cl)PP > H_2T(4\text{-}NO_2)PP$. Despite the electron donation of the methyl group, $H_2T(3\text{-}Cl)PP$ forms more stable adducts than $H_2T(3\text{-}CH_3)PP$ with $MeSnBr_3$. © 2002 Published by Elsevier Science Ltd.

Keywords: Porphyrins; Sitting–Atop complexes; Methyltin(IV) tribromide; Organotin(IV) halide adducts; Tin compounds; Spectral method

1. Introduction

Thermodynamics of organotin(IV) halides adducts with various uni- and bidentate ligands [1–4], specially with biological systems, have been the subject of lots of studies [5–9]. In addition, a particularly attractive idea in the kinetics and mechanism of metallation of free base porphyrins is that of the Sitting–Atop (SAT) complexes [10,11]. In 1960, Fleischer and Wang [10] first proposed the so-called Sitting–Atop complexes as intermediates of metallation of the protoporphyrin dimethyl ester in chloroform. According to the SAT idea the metallation of free base porphyrin begins with a pre-equilibrium step involving partial bonding of the metal ion to two of the pyrrolenine nitrogens to form an intermediate, the so-called Sitting–Atop complex, in which two protons on the pyrrole nitrogens still remain. Some controversy exists as to whether this kinetically detected complex is of the Sitting–Atop type or is best represented as an outer-sphere ion pair [12]. Recently Funahashi et al. [13–15] have succeeded in the direct detection of SAT complexes of *meso*-tetraphenylporphyrin (H_2TPP), *meso*-tetrakis(4-chlorophenyl)porphyrin ($H_2T(4\text{-}Cl)PP$), *meso*-tetramesitylporphyrin (H_2TMP), and octaethylporphyrin (H_2OEP), with the Cu(II) ion in acetonitrile as solvent. Continuing these encouraging studies for the direct characterization of SAT complexes, led us to investigate the organotin(IV) halide adducts with a number of free base *para*-substituted *meso*-tetraphenylporphyrins, $H_2T(4\text{-}X)PPs$, in non-basic solvents. With a suitable selection of acceptor species and solvent, we successfully prepared some adducts of diorganotin(IV) dichlorides as the acceptor with free base *para*-substituted *meso*-tetraphenylporphyrin as the donor [16], these adducts have structures close to SAT complexes. Here we believe that tetraarylporphyrin as a bidentate bridging ligand makes a bridge between two molecules of organotin(IV) halide and produces a stable Sitting–Atop adduct.

In the earlier works we investigated the interactions of R_2SnCl_2, (R = Me [17], Et and Bu [18]) with tetraar-

ylporphyrins. The present work is on the investigation of thermodynamic parameters for the interaction of methyltin(IV) tribromide with H_2TPP (*meso*-tetraphenylporphyrin), H_2T(4-Cl)PP (*meso*-*tetrakis*-(*4*-chlorophenyl)porphyrin), H_2T(3-Cl)PP (*meso*-*tetrakis*-(*3*-chlorophenyl)porphyrin), H_2T(4-NO_2)PP (*meso*-*tetrakis*-(*4*-nitrophenyl)porphyrin), H_2T(4-CH_3)PP (*meso*-*tetrakis*-(*4*-methylphenyl)porphyrin), H_2T(3-CH_3)PP (*meso*-*tetrakis*-(*3*-methylphenyl)porphyrin) and H_2T(4-CH_3O)PP (*meso*-*tetrakis*-(*4*-methoxyphenyl)porphyrin) in chloroform as solvent.

2. Experimental

2.1. Reagents

Benzaldehyde and *para*- and *meta*-substituted benzaldehydes (Merck and Fluka) were used as received. Pyrrole (Fluka) was distilled before use. Propionic acid and chloroform (Merck) employed for the synthesis and the purification of porphyrins were used as received. Me_4Sn (Fluka) was used without further purification. Chloroform solvent for UV–Vis measurements was distilled over K_2CO_3 before use.

2.2. Instrumental

UV–Vis measurements were carried out on a JASCO V-530 UV–Vis spectrometer equipped with a LAUDA Ecoline RE 104 thermostat.

2.3. Preparations

Methyltin(IV) tribromide was prepared by the reaction between Me_4Sn and anhydrous $SnBr_4$, and purified by sublimation [19]. H_2T(4-X)PP; X = OCH_3, CH_3, H, Cl, NO_2 and H_2T(3-X)PP; X = CH_3, Cl were prepared and purified by usual methods [20–22].

2.4. General method

UV–Vis measurements were carried out by the titration method at 5.0, 10.0, 15.0, 20.0 and 25.0 ± 0.1 °C. In a typical measurement, 2.5 ml solution of H_2TPP (5×10^{-6} M) in chloroform was titrated by $MeSnBr_3$ (6.25×10^{-4} M). UV–Vis spectra were recorded in the range of 396–710 nm approximately 10 min after each addition. In this range of spectra, about 20–30 wavelengths that have suitable variations of absorbance were selected, and the formation constants and other thermodynamic parameters of adduct formation were calculated. Formation constants were calculated by squad program [23,24].

3. Results

On addition of $MeSnBr_3$ to a solution of porphyrin in chloroform its purple color changes to green. This change is due to adduct formation between $MeSnBr_3$ and the porphyrins. These adduct formations are reversible and show a different order of stability with respect to temperature. For example rising of the temperature to 60 °C caused the [$(MeSnBr_3)_2H_2$T(4-Cl)PP], Fig. 2, and [$(MeSnBr_3)_2H_2$T(4-NO_2)PP] adducts to return to $MeSnBr_3$ and free bases H_2T(4-Cl)PP and H_2T(4-NO_2)PP, respectively. Dissociation of [$(MeSnBr_3)_2H_2$TPP] and [$(MeSnBr_3)_2H_2$T(4-CH_3)PP] at this temperature occurred to a lesser extent, while the [$(MeSnBr_3)_2H_2$T(4-CH_3O)PP] adduct showed a high degree of stability with respect to temperature. Interactions of $MeSnBr_3$ with porphyrins were studied by means of UV–Vis spectrophotometry.

By interaction of tetraarylporphyrins with $MeSnBr_3$ Lewis acid the original peaks of the tetraarylporphyrins (Soret band and Q bands) undergo considerable changes with a range of isosbestic points. For example by addition of $MeSnBr_3$ to H_2T(4-CH_3O)PP, Fig. 1, the original peaks of the free base (421, 518, 556, 589 and 646 nm) were diminished and two new peaks appeared at (456 and 696 nm) with isosbestic points around 428, 480, 574, 598 nm. Table 1 gives the original peaks of free base porphyrins and new peaks produced by addition of $MeSnBr_3$ to a solution of porphyrins in chloroform. It seems that the positions of the adduct peaks mainly relate to a step of the adduct formation which leads to a deformation of the porphyrin plane and other steps only exert a minor effect on the λ_{max} of the adducts. On the other hand, since the distortion of porphyrin plane occurred during the 1:1 adduct formation, the attachment of the second Lewis acid is not accompanied by a significant displacement in the position of these bands (about 2–4 nm shift to longer wavelength for the Soret band). This statement can be better understood by comparison of electronic absorption spectra of a planar free base porphyrin such as 5,10,15,20-tetrabutylporphyrin; UV–Vis (CH_2Cl_2): Soret band (417 nm) and Q bands (520, 555, 600, 659 nm) with a severely ruffled (distorted) one like free base 5,10,15,20-tetrakis(*tert*-butyl)porphyrin: Soret band (446 nm) and Q bands (552, 596, 628, 691 nm) [25]. This example clearly shows that the observed bathochromic shift resulted mainly from distortion of the porphyrin structure.

However λ_{max} (corresponding to the Soret band) of electronic absorption spectra of adducts and also the positions of the isosbestic points change by a limited range of wavelengths (about 2–6 nm) during adduct formation. It is noticeable while there are a few (2–4 nm) displacements for the Soret band of adducts from the beginning up to completion of adduct formation, this displacement reached 20–45 nm upon completion of

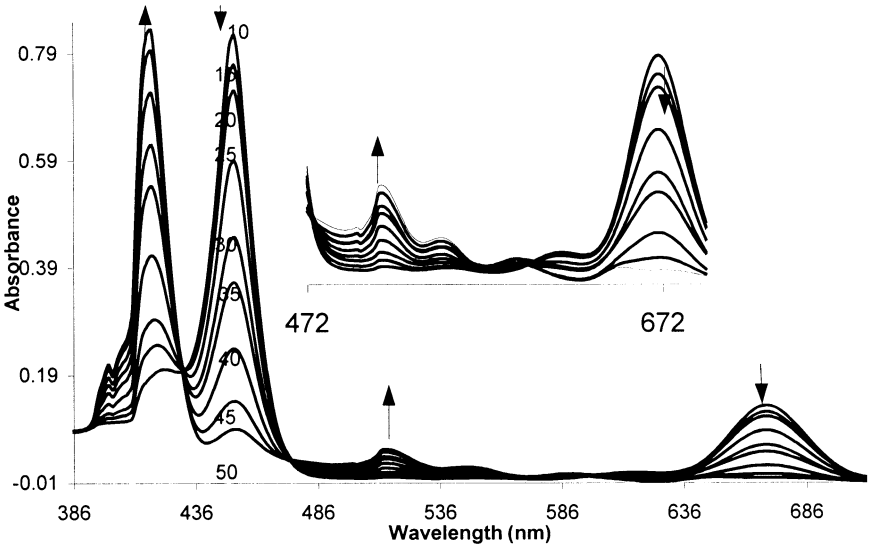

Fig. 2. Temperature dependence spectra of: $(MeSnBr_3)_2H_2T(4\text{-}Cl)PP$ adduct. By addition of $MeSnBr_3$ (6.25×10^{-4} M) to 2.5 ml of the solution of $H_2T(4\text{-}Cl)PP$ (2.5×10^{-6} M) in chloroform in a UV–Vis cell at 5 °C, the $(MeSnBr_3)_2H_2T(4\text{-}Cl)PP$ adduct was formed. Then the composition of the cell remained constant and the temperature was raised to 60 °C stepwisely, isosbestic point around 430, 476, 570, 596 nm. This spectrum has a similarity to the previous work on acidic dissociation of ClHg–TPP–HgCl complex [30], in which ClHg–TPP–HgCl returned to H_2TPP and $HgCl_2$.

the reaction for the band that appeared beyond 660 nm for different adducts.

The thermodynamic parameters were studied for these interactions and formation constants were determined at several temperatures by analyzing the concentration and the temperature dependence of UV–Vis electronic absorptions spectra by the SQUAD program. These absorption spectra were analyzed by using the following mole ratios of acid to base as models of interaction between $MeSnBr_3$ and a typical porphyrin: (1) formation of the 1:1 adduct; (2) formation of the 2:1 adduct; (3) simultaneous formation of the 1:1 and 2:1 adducts. The fit of the model to the experimental data, 15 points, is measured by the sum of the squares of the deviations of the experimental points from the point calculated by the model. For *para*-substituted porphyrins the proposed model is the coexistence of 2:1 and 1:1 adducts of acceptor to donor and in the case of *meta*-substituted porphyrins only 1:1 adducts have the best fitting and the produced error sum of squares was between 10^{-2} and 10^{-3}. The mole ratio plot of these adducts has good agreement with the stoichiometry

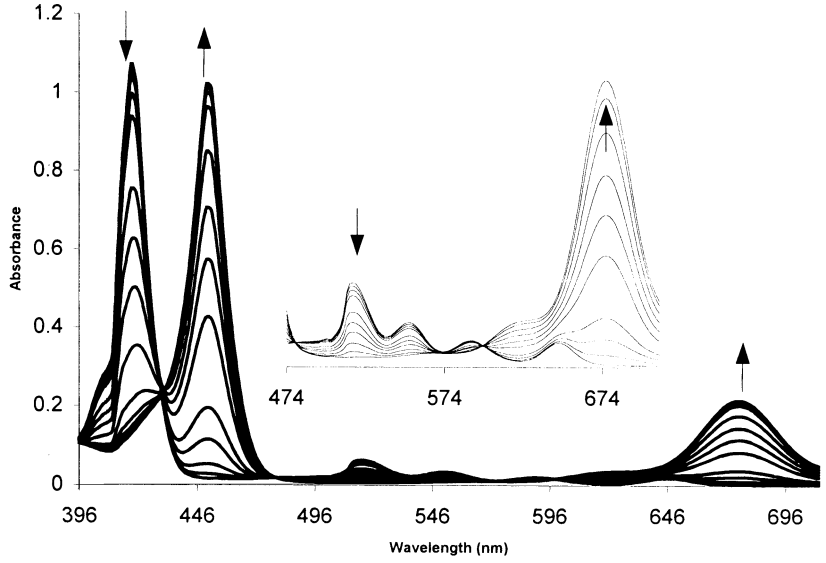

Fig. 1. Titrametric absorption spectra of $H_2T(4\text{-}CH_3O)PP$ with $MeSnBr_3$ in chloroform; 396–710 nm bands appeared at 450 and 476 nm are related to the adduct. Inset expanded of 474–710 nm region. Isosbestic points around 428, 480, 574, 598 nm.

Table 1
UV–Vis peaks λ ($CHCl_3$/nm) of the free bases $H_2T(X)PP$ and their adducts with $MeSnBr_3$

Compound	Wavelength (nm)				
H_2TPP	417	514	549	589	646
$(MeSnBr_3)_2H_2TPP$	448				666
$H_2T(4\text{-Cl})PP$	418	514	550	590	646
$(MeSnBr_3)_2H_2T(4\text{-Cl})PP$	452				670
$H_2T(3\text{-Cl})PP$	418	514	550	590	646

4. Discussion

4.1. $(MeSnBr_3)_2H_2T(4\text{-}X)PP$ adducts

The data of Table 2 show that the equilibrium constants of the adducts undergo a regular increase from $H_2T(4\text{-}NO_2)PP$, $H_2T(4\text{-Cl})PP$, H_2TPP, $H_2T(4\text{-}CH_3)PP$ to $H_2T(4\text{-}CH_3O)PP$. For example at 5 °C we have the following order of formation constants:

$(MeSnBr_3)_2H_2T(4\text{-}NO_2)PP < (MeSnBr_3)_2H_2T(4\text{-Cl})PP < (MeSnBr_3)_2H_2TPP < (MeSnBr_3)_2H_2T(4\text{-}CH_3)PP < (MeSnBr_3)_2H_2T(4\text{-}CH_3O)PP$

$\log K_1 \quad 3.13 < 5.31 < 5.68 < 6.30 < 6.58$

$\log K_2 \quad 3.55 < 6.10 < 6.65 < 7.31 < 7.70$

Tables 4 and 5 show the thermodynamic parameters obtained for the interactions of $MeSnBr_3$ with $H_2T(4\text{-X})PP$ in chloroform.

The successive adducts $(MeSnBr_3)(H_2T(4\text{-X})PP)$ and $(MeSnBr_3)_2(H_2T(4\text{-X})PP)$ have negative values of ΔH° and ΔS°.

4.2. $(MeSnBr_3)H_2T(3\text{-}X)PP$ adducts

The data of Table 3 show that interactions in the $(MeSnBr_3)H_2T(3\text{-Cl})PP$ system are stronger than $(MeSnBr_3)H_2T(3\text{-}CH_3)PP$. For example at 5 °C we have the following order of formation constants:

$(MeSnBr_3)H_2T(3\text{-}CH_3)PP < (MeSnBr_3)H_2T(3\text{-Cl})PP$

$\log K_1 \quad 6.30 < 8.42$

Table 6 shows the thermodynamic parameters obtained for the interactions of $MeSnBr_3$ with $H_2T(3\text{-X})PP$ in chloroform. The negative values of ΔH° are indicating favorable adduct formations, but a negative entropy contribution is unfavorable for adduct formation.

Our results are in agreement with a pre-equilibrium step as demonstrated by previous studies on the kinetics of incorporation of some divalent metal ions into the free base porphyrins. Tanaka et al. [26] have studied the incorporation of Cu(II), Zn(II) and Cd(II) in the free base H_2TPP in DMF. They suggested a pre-equilibrium between metal ions and H_2TPP prior to metal insertion and proton release. Their values of K were 1.6×10^4 M^{-1} for Cu(II), 7.2×10^2 M^{-1} for Zn(II), and no kinetic evidence for complex formation was found for Cd(II). Pasternack's group [27] kinetically found a $K = 5$ M^{-1} for Cu(II)–H_2TPP reaction in DMSO. Hambright and Rabinson [28] obtained the following values of K (M^{-1}) for Zn(II) SAT complexes with tetraphenylporphyrin (12.3×10^3), tetrakis(2,6-difluorophenyl)porphyrin (2.8×10^3), tetra(4-aminophenyl)porphyrin (7.7×10^3), tetrakis(4-*N*,*N*-dimethylaminophenyl)porphyrin (6.0×10^3) and tetra(4-hydroxyphenyl)porphyrin

(9.5×10^3) in DMF as solvent [29]. They suggested that metal ions and porphyrins formed an intermediate with composition [M–H_2P; M = Zn(II), Cd(II), Cu(II)] [26–29] in which coordination of H_2P with metal ion causes a deformation of the porphyrin plane in such a manner that a second metal ion is more readily able to incorporate into this bent porphyrin structure on the opposite side. Then formation of M–H_2P–Zn follows by dropping the Zn(II) ion into the porphyrin cavity [26–29]. These studies show that SAT stability has a strict dependence on the basicity of the solvent. But here attending to the non basic properties of our solvent and more importantly because of our bulky Lewis acids ($MeSnBr_3$), which could not drop into the porphyrin cavity under these conditions we deal with more stable SAT complexes. Comparing the results in Tables 2–6 with results given in our last works [17,18], the present adducts are more stable than the corresponding adducts with dialkyltin(IV) dichlorides. This greater stability of adducts returns to the higher acceptor property of $MeSnBr_3$ compared to R_2SnCl_2 Lewis acids. The results in Tables 2–6 show that the kind and the the position of substituent (X) on phenyl rings of $H_2T(X)PP$ significantly influences the interactions of the corresponding porphyrin with $MeSnBr_3$. We think that primarily 1:1 adduct formation, [$(MeSnBr_3)H_2T(4\text{-}X)PP$], for *para*-substituted porphyrins induces a distortion in the porphyrin plane; this deformation enhances the coordinating ability of the nitrogen lone pairs by directing them away from the central porphyrin cavity. Therefore, the distorted porphyrin readily accepts the second $MeSnBr_3$ molecule on the opposite side and eventually favors the formation of the 2:1 adduct [$(MeSnBr_3)_2H_2T(4\text{-}X)PP$], so we are dealing with a $K_2 > K_1$ for these adducts. Both the free energy and the enthalpies of adduct formation become more negative through the series $H_2T(4\text{-}NO_2)PP$, $H_2T(4\text{-}Cl)PP$, H_2TPP, $H_2T(4\text{-}CH_3)PP$ to $H_2T(4\text{-}CH_3O)PP$, which indicates stronger interactions and favoring adduct formations with increasing electron donation of free base porophyrins along this series.

In the case of $H_2T(3\text{-}X)PP$ porphyrins a behavior different to $H_2T(4\text{-}X)PP$ was observed. Our studies give acceptable results only for formation of 1:1 adducts between *meta*-substituted porphyrins and $MeSnBr_3$, perhaps steric hindrance arising from *meta*-substituents prevents the attachment of a second $MeSnBr_3$ molecule to $H_2T(3\text{-}X)PP$ on the opposite side. Also the greater magnitude of the binding constants, K_1, for the corresponding *meta*- relative to K_1 of *para*-substituted porphyrins is probably due to a more distorted structure of *meta*- free base than the corresponding *para*- isomer that increases the N-lone pairs coordinative property toward the first $MeSnBr_3$ molecule. It seems that this distortion depends on the weight and the bulkiness of the substituent, so that the weightier groups lead to better deformation in porphyrin structure and a greater tendency for 1:1 adduct formation.

Adducts have negative values of ΔH°, ΔS° and ΔG°. Generally, the negative values of ΔS° refer to an associative reaction between donor and acceptor and has an unfavorable contribution on adduct formation. These results show the following order for interactions of *para*- and *meta*-substituted porphyrin with methylti-

Phosphine nickel(0) π-complexes with vinylcyclosilazane —synthesis and structure

Hieronim Maciejewski *, Maciej Kubicki, Bogdan Marciniec, Agnieszka Sydor

Faculty of Chemistry, Adam Mickiewicz University, Grunwaldzka 6, 60-780 Poznań, Poland

Received 8 January 2002; accepted 13 March 2002

Abstract

Synthesis, spectroscopic (^{1}H, ^{13}C, ^{31}P, ^{29}Si NMR) characterisation and X-ray structure of the first nickel(0) π-complex with vinylcyclosilazane [{Ni(PPh$_3$)}$_2${μ-(η-CH$_2$=CH(Me)Si(μ-NH))$_4$}] (**1a**) have been presented. This is the first report on the structure of a TM complex with a vinylsilazane ligand. Complex **1a** is synthesised by the reaction of [Ni(cod)$_2$] with cyclotetra (vinylmethylsilazane). The complex occupies a special position of the space group $P2_1/c$ on the centre of symmetry that lies in the middle of the cyclotetrasilazane ring. The coordination of nickel is close to triangular one. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Nickel(0); Vinylcyclosilazane complexes; Crystal structure

1. Introduction

The recent interest in the chemistry of transition metal olefin complexes containing vinyl derivatives of organosilicon compounds as π-ligands is fully justified not only by the particular nature of the bond between vinylsilicon derivatives and transition metals, but mainly by the possible application of this kind of complex as catalysts in hydrosilylation of olefins [1]. Hydrosilylation is also used to a much greater extent in industry to produce crosslinked products [2]. Such processes generally require the use of highly active platinum—containing catalysts. One class of platinum compounds used as hydrosilylation catalysts includes Pt(0) complexes containing vinyl-siloxane ligands. An example is the Karstedt's catalyst, which contains both bridging and chelating divinyl ligands [{Pt(η-CH$_2$=CHSiMe$_2$)$_2$O}$_2${μ-(η-CH$_2$=CHSiMe$_2$)$_2$O}] [3,4]. Besides showing a high catalytic activity, this complex is also a good starting compound for synthesis of other platinum(0) π-complexes. The treatment of the Karstedt's catalyst with maleic anhydride, styrene or divinyltetramethyldisiloxane gave [{Pt(η-CH$_2$=CHSiMe$_2$)$_2$O}{η^2-CHC(O)OC(O)CH}] [4], [{Pt(η-CH$_2$=CHSiMe$_2$)$_2$O}-(η^2-CH$_2$=CHPh)] [4] and [{Pt(η-CH$_2$=CHSiMe$_2$)$_2$O}-{η^2-(CH$_2$=CHSiMe$_2$)$_2$O}] [5].

Due to the fact that tertiary phosphine ligands play a crucial role in many industrially important metals—catalysed organic reactions, phosphine metal—vinylsilicon complexes were also synthesised [6,7]. The reaction between Karstedt's catalyst [{Pt(LL)}$_2$(μ-LL)] (where LL = {CH$_2$=CHSiMe$_2$}$_2$O) and mono-, bis- or tris(tertiary phosphine) led to complexes of the type [Pt(LL)(PR$_3$)] [6], [{Pt(LL)}$_2$(DIPHOS)] or [{Pt(LL)}$_3$(TRIPHOS)] [7], respectively. Moreover there is arousing interest in complexes with cyclic π-vinylsilicon ligands. Cyclotetrakis[vinyl(methyl)siloxane] has been used to generate the platinum complex [{Pt(PPh$_3$)}$_2${μ-(η-CH$_2$=CH(Me)Si(μ-O))$_4$}] acting as a hydrosilylation catalyst equivalent to Karstedt's catalyst [2,5,9].

The cost of platinum compounds has stimulated much research to check other transition metal compounds as potential hydrosilylation catalysts. By analogy to Karstedt's catalyst, the nickel complex [{Ni(η-CH$_2$=CHSiMe$_2$)$_2$O}$_2${μ-(η-CH$_2$=CHSiMe$_2$)$_2$O}] was obtained and showed high catalytic activity in the hydrosilylation and related reactions (dehydrogenative coupling especially of vinyl derivatives) [10]. In analogy to platinum

PII: S0277-5387(02)01001-X

complexes, those of the type [Ni(LL)(PR_3)] were also prepared [6,7]. Very recently, nickel complexes with cyclotetrasiloxane [{Ni(PR_3)}$_2${μ-(η-CH_2=CH(Me)Si-(μ-O))$_4$}] were synthesised and the X-ray structure of one of them was determined [11]. There are also well known platinum or nickel complexes with vinylsilanes (i.e. vinyltrimethylsilane [12,13] or divinyldimethylsilane [7]) used as ligands, however, the application of vinyl derivatives of silazane as ligands in organometallic chemistry has been rather rare. Hitherto only two examples of the synthesis of nickel complexes with linear divinyltetramethyldisiloxane, i.e. [{Ni(η-CH_2=CHSiMe_2)$_2$NH}$_2$ {μ-(η-CH_2=CHSiMe_2)$_2$NH}] and [Ni(PR_3)(η-CH_2=CHSiMe_2)$_2$NH}], have been reported in Ph.D. Theses [8,14], however, they have not been fully characterised and their crystallographic structures have not been resolved.

In this paper, we present a synthetic procedure, spectroscopic characterisation and X-ray structure of phosphine–nickel complexes with vinylcyclosilazane ligands. To the best of our knowledge this is the first example of a fully characterised TM complex with a vinylsilazane ligand.

2. Experimental

2.1. General procedures

All reagents were dried and purified before use by the usual procedures. [Ni(cod)$_2$] was prepared as described in literature [15]. Other chemicals were purchased from Fluka. The NMR spectra (^{1}H, ^{13}C, ^{31}P, ^{29}Si) were recorded on a Varian XL 300 spectrometer. In all cases C_6D_6 was used as a solvent.

2.2. Synthesis of complexes

2.2.1. [{Ni(PPh_3)}$_2${μ-(η-CH_2=CH(Me)Si(μ-NH))$_4$}] (**1a**)

Cyclotetrakis [vinyl(methyl)silazane] (2 ml) was added slowly to a stirred red suspension of [Ni(cod)$_2$] (0.5 g, 1.8 mmol) and PPh_3 (0.47 g, 1.8 mmol) in diethyl ether (10 ml) at ambient temperature, yielding a yellow solution. The reaction mixture was allowed to stir overnight. The volatiles were removed in vacuo to give a yellow oil, which was extracted into pentane (2 × 2 ml). The extract was filtered through Celite. The filtrate was concentrated, then set aside at −30 °C to yield a yellow solid compound (0.66 g, 0.72 mmol, 79%). Yellow crystals of **1a** suitable for X-ray diffraction, were grown from benzene at ambient temperature over a period of 24 h.

^{1}H NMR (C_6D_6, 298 K, 300 MHz,) δ 0.09 (s, 12H), 2.68 (td, 4H), 3.04 (dd, 8H), 7.08–7.76 (m, 30H); $^3J(^1H_1-^1H_2) = 12.0$ Hz, $^3J(^1H_1-^1H_3) = 16.0$ Hz, $^3J(^1H_1-^{31}P) = 4.6$ Hz, $^3J(^1H_2-^{31}P) = 7.7$ Hz, $^3J(^1H_3-^{31}P) = 6.0$ Hz.

^{13}C NMR (C_6D_6, 298 K, 125.8 MHz); δ 2.66 (s, CH_3), 60.66 (d, =CH–), 62.93 (s, =CH_2), 129.00–134.00 (m, Ph), $^2J(^{13}C_1-^{31}P) = 6.7$ Hz.

^{29}Si NMR (C_6D_6, 298 K, 99.4 MHz); δ −12.07(d), $^3J(^{29}Si-^{31}P) = 3.8$ Hz.

^{31}P NMR (C_6D_6, 298 K, 101.2 MHz); δ 38.59.

2.2.2. [{NiP(C_6H_4Me-4)$_3$}$_2${μ-(η-CH_2=CH(Me)Si(μ-NH))$_4$}] (**1b**)

Compound **1b** (0.76 g, 0.74 mmol, 82%) was prepared in a similar manner to **1a**, except that P(C_6H_4Me-4)$_3$ was used in the place of PPh_3. Yellow crystals of **1b** were obtained by recrystalisation from benzene, at ambient temperature.

^{1}H NMR (C_6D_6, 298 K, 300 MHz); δ 0.15 (s, 12H), 2.10 (s, 9H), 2.72 (td, 4H), 3.12 (dd, 8H), 6.90–7.34 (m, 24H).

^{13}C NMR (C_6D_6, 298 K, 125.8 MHz); δ 2.39 (s, CH_3), 21.58 (s, CH_3), 58.28 (s, =CH–), 61.86 (s, =CH_2), 127.90–139.22 (m, tol).

^{29}Si NMR (C_6D_6, 298 K, 99.4 MHz); δ −12.57 (d).

^{31}P NMR (C_6D_6, 298 K, 101.2 MHz); δ 39.24.

2.2.3. [{NiP(C_6H_{11}-c)$_3$}$_2${μ-(η-CH_2=CH(Me)Si(μ-NH))$_4$}] (**1c**)

Compound **1c** (0.65 g, 0.66 mmol, 72%) was prepared in a similar manner to **1a**, except that P(C_6H_{11}-c)$_3$ was used in the place of PPh_3. Yellow crystals of **1c** were obtained by recrystalisation from benzene at ambient temperature.

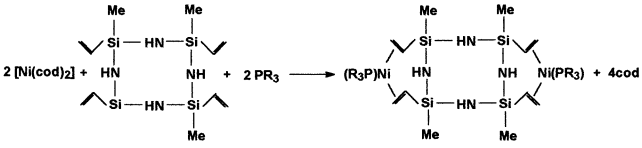
^{1}H NMR (C_6D_6, 298 K, 300 MHz); δ 0.17 (s, 12H), 1.21–1.82 (m, 33H), 2.63 (td, 4H), 3.08 (dd, 8H).

^{13}C NMR (C_6D_6, 298 K, 125.8 MHz); δ 2.54 (s, CH_3), 26.23–35.54 (m, C_6H_{11}-c), 59.76 (s, =CH–), 61.34 (s, =CH_2).

^{29}Si NMR (C_6D_6, 298 K, 99.4 MHz); δ −12.94(d).

^{31}P NMR (C_6D_6, 298 K, 101.2 MHz); δ 38.27.

2.3. Crystal structure determination of **1a**



Diffraction data from a yellow, prism-shaped crystal with dimensions 0.2 × 0.2 × 0.15 mm, sealed in a glass capillary, were collected on a KUMA KM4CCD diffractometer [16] at room temperature (r.t.), using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). The data collection was performed in six separate runs in order to cover the symmetry-independent part of the reciprocal space. The ω-scan was used with a step of 0.75°, two reference frames were measured after every 50 frames, they did not show any systematical changes either in the peaks positions or in their intensities. A total of 782 frames was collected, giving 22 024 reflections up to $2\theta = 60°$. The unit-cell parameters were determined by the least-squares treatment

of the setting angles of 2400 highest-intensity reflections, chosen from the whole experiment. The Lorentz and polarisation corrections were applied [17], and then the reflexes were merged and corrected for absorption ($A_{min} = 0.747$, $A_{max} = 0.767$) with Sortav [18]. The merging procedure produced 6003 unique data with R_{int} of 0.13. The structure was solved by direct methods with SHELXS-97 program [19], and refined with full-matrix least-squares by SHELXL-97 [20]. Non-hydrogen atoms were refined anisotropically, hydrogen atoms were generated geometrically and were refined as a 'riding model' with their U_{iso} parameters set at 1.2 times U_{eq} of the appropriate carrier atom. Selected geometric parameters are listed in Table 1.

Crystallographic data for $[Ni_2(PPh_3)_2(Si_4N_4C_{12}H_{28})]$: empirical formula $Ni_2P_2Si_2N_4C_{48}H_{58}$, monoclinic, space group $P2_1/c$, $a = 13.5628(17)$ Å, $b = 9.7290(12)$ Å, $c = 18.605(2)$ Å, $\beta = 90.349(10)^\circ$, $V = 2454.9(5)$ Å^3, $Z = 2$, $d_x = 1.332$ g cm^{-3}, μ(Mo Kα) = 0.97 mm^{-1}, $F(000) = 1032$, $R(F)$ $[F_o > 4(F_o)] = 0.057$, $wR(F^2) = 0.127$, where $w^{-1} = [\sigma^2(F_o)^2 + (0.01P)^2 + 5P]^{-1}$, $P = (\mathrm{Max}(F_o{}^2, 0) + 2F_c{}^2/3)$, $S = 1.29$, $(\Delta/\sigma)_{max} = 0.001$ in the last cycle of refinement, $\Delta\rho_{max} = 0.42$ e Å^{-3}, $\Delta\rho_{min} = -0.35$ e Å^{-3}.

3. Results and discussion

The reaction of $[Ni(cod)_2]$ with cyclotetra(vinylmethylsilazane) in the presence of tertiary phosphine was effective for the preparation of the corresponding phosphine nickel–vinylcyclosilazane complexes according to the following equation.

1a R = C_6H_5, **1c** C_6H_{11}-c

1b C_6H_4Me-4,

The above reaction seems to be a very simple and convenient route to synthesise various phosphine complexes with vinylsilicon ligands. As mentioned earlier, the nickel phosphine complexes with cyclotetra(vinylmethylsiloxane) $[\{Ni(PR_3)\}_2\{\mu\text{-}(\eta\text{-}CH_2{=}CH(Me)Si(\mu\text{-}O))_4\}]$ (**2**) (where $R = C_6H_5$ (**a**), C_6H_4–Me (**b**) and c-C_6H_{11} (**c**)) were synthesised previously [11].

[a] Symmetry transformations used to generate equivalent atoms: $-x+1$, $-y$, $-z+1$.

All kinds of analyses of the crystalline yellow complexes **1a**–**c** have brought satisfactory results. The NMR spectra taken for complexes **1a**–**c**, were very similar to those for complexes **2a**–**c**. The NH signal was not observed in the spectra which is consistent with the ^{1}H spectrum obtained for hexamethyldisilazane [21].

The ^{1}H NMR spectra of **1a**–**c** reveals one signal from the methyl group and two signals from the vinyl group in the region appropriate for vinylsilicon complexes of this type. The ^{13}C NMR spectra also confirm the structure of complexes **1a**–**c**. These spectra showed one signal assigned to the methyl carbons and the signals corresponding to the vinyl carbons at frequencies lower than those observed for the free ligand. The ^{31}P NMR spectra of each of the complexes obtained revealed a single signal. The signals in these spectra showed some differences in positions, depending on the type of phosphine used, however, they always appeared in the region typical of a coordinated phosphine. The values of spectroscopic chemical shifts in ^{1}H, ^{13}C and ^{31}P NMR spectra for complexes **1a**–**c** are quite similar to those for complexes **2a**–**c**, but some differences are observed in the ^{29}Si NMR spectra. For the complexes with vinylsiloxane ligands, the ^{29}Si NMR spectrum showed signals at -24 ppm but in the spectra of complexes with vinylsilazane these signals were observed at -12 ppm. The difference depends on the nature of the vinylsilicon compounds used.

The crystal structure of **2b** is very similar to that one established for **1a.**

The complex **1a** lies in a special position of the space group $P2_1/c$, on the centre of symmetry that lies in the middle of the cyclotetrasilazane ring. The coordination of nickel is close to a triangular (regarding the middlepoints of the double bonds as coordination centres), however, some degree of pyramidalization can be noticed. The sum of the angles around nickel is 358.2(3)° and the Ni1 atom is displaced by 0.156(5) Å from the plane defined by P1, X1 and X2 (X1 and X2 denote the middlepoints of C1A–C1B and C2A–C2B

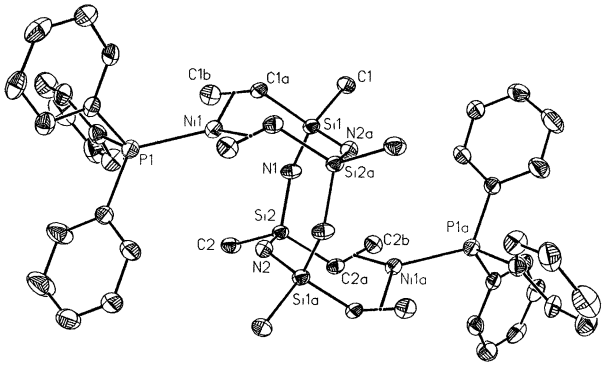

Fig. 1. The thermal ellipsoid view of the complex **1a** (at 50% probability level) with the numbering scheme [23]. The hydrogen atoms are omitted for clarity.

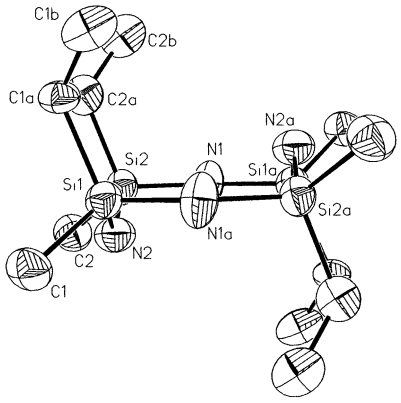

Fig. 2. The conformation of the tetrasilazane ring. The thermal ellipsoids are drawn at 50% probability level, only symmetry-independent atoms are labelled.

double bonds, respectively). The Ni–P bond length of 2.175(3) Å is within the range for short Ni–P bonds (the Ni–P lengths distribution is bimodal [22]).

The eight-membered silazane ring adopts the chair conformation; six atoms N1, Si2, Si1, N1′, Si2′ and Si1′ are almost perfectly coplanar (the prime denotes the atoms created by the centre of symmetry), with the largest deviation from the least-square plane of 0.012(5) Å, while the N2 and N2′ atoms are tilted out of this plane by + and −0.729(9) Å, respectively, (Figs. 1 and 2). This different character of N1 and N2 nitrogen atoms is reflected in differences of the Si–N–Si angles: 132.7(5)° for N1 and 129.7(5)° for N2, while the Si–N bond lengths are almost equal with the mean value of 1.720(2) Å. The methyl substituents are in quasi-equatorial positions, and the vinyl ones in quasi-axial ones (cf. Table 1).

The phenyl rings are planar within experimental error, the mean value of the C_{ar}–C_{ar} bond length is 1.380(7) Å, and agrees well with the typical value. The mutual disposition of these rings can be described by the dihedral angles between their least-squares planes A/B 85.1(4)°, B/C 72.6(4)°, A/C 82.8(3)°, where A, B, and C denote the rings with C11, C21, and C31 atoms, respectively. The crystal packing is determined mainly by van der Waals interactions.

4. Conclusions

1) Nickel complexes of the type $[\{Ni(PR_3)\}_2\{\mu\text{-}(\eta\text{-}CH_2{=}CH(Me)Si(\mu\text{-}NH))_4\}]$ are the first examples of TM complexes with vinylsilazane whose crystal structure has been determined.
2) The NMR and crystal structure data obtained have proved that the compounds **1a**–**c** and **2a**–**c** are similar. They both are binuclear nickel(0) complexes with a inversion centre at the mid-point of the chair-shaped $(SiO)_4$ or $(SiNH)_4$ ring.

3) Phosphine nickel(0) π-complexes with vinylcyclosilazane ligands seem to be promising potential catalysts for hydrosilylation and related reactions; the catalytic aspects will be considered in a separate paper.

5. Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge, CB2 1EZ (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk; or www: http://www.ccdc.cam.ac.uk) on request, quoting the deposition number CCDC 168038.

Synthesis of silver(I) complexes of thiones and their characterization by ^{13}C, ^{15}N and ^{107}Ag NMR spectroscopy

Anvarhusein A. Isab *, Saeed Ahmad, Mohammed Arab

Department of Chemistry, King Fahd University of Petroleum and Minerals (KFUPM), Dhahran 31261, Saudi Arabia

Received 8 January 2002; accepted 28 March 2002

Abstract

Silver(I) complexes of thiones (L), $[LAgNO_3]$ and $[AgL_2]NO_3$ have been prepared and characterized by elemental analysis, IR and NMR (^1H, ^{13}C, ^{15}N and ^{107}Ag) spectroscopy. An upfield shift in the C=S resonance of thiones in ^{13}C NMR and downfield shifts in N–H resonances in ^1H and ^{15}N NMR are consistent with the sulfur coordination to silver(I). In ^{107}Ag NMR, the $AgNO_3$ signal is deshielded by 300–500 ppm on its coordination to thiones. Greater upfield shifts in ^{13}C NMR are observed for $[LAgNO_3]$ compared with $[AgL_2]NO_3$ complexes, whereas the opposite trend is observed for ^1H, ^{15}N and ^{107}Ag chemical shifts. © 2002 Elsevier Science Ltd. Keywords: Silver(I) complexes; Thiones; NMR studies

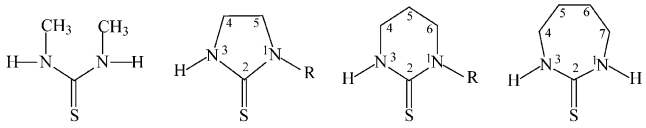
1. Introduction



Complexes of heterocyclic thiones such as imidazolidine-2-thione (Imt), diazinane-2-thione (Diaz) and their derivatives with transition metals are of interest in bioinorganic chemistry because of the search for simple model compounds for metal proteins [1,2]. In view of this, Cu(I) [3], Ag(I) [4,5], Au(I) [6–8], Hg(II) [9] and Cd(II) [10] complexes with thiones have been widely studied in recent years. In our previous work on silver-thione complexes, we reported the synthesis and spectroscopic characterization of various $[LAgNO_3]$ (where L = Imt, Diaz and their derivatives) [4] and $Ag(Tu)_xNO_3$ (Tu = thiourea and $x = 1$–4) complexes [11]. The present report describes the synthesis of silver(I) complexes of the stoichiometry, $[AgL_2]NO_3$ for a series of thiones and their characterization by ^{13}C, ^{15}N and ^{107}Ag NMR spectroscopy. The results of ^{15}N and ^{107}Ag NMR for $[LAgNO_3]$ complexes are also presented. Among $[LAgNO_3]$ complexes, $[DmTuAgNO_3]$ and $[DiapAgNO_3]$ were not reported earlier. The main goal of the study is to provide a data base of ^{13}C and ^{107}Ag NMR spectra for silver(I) complexes of thiones.

The structures of the thiones used in this study are described in Scheme 1.

2. Experimental

2.1. Chemicals

N,*N*′-dimethylthiourea, methanol, acetone, acetonitrile and DMSO-d_6 were obtained from Fluka Chemical Co. The thione ligands were synthesized according to

(a) (b-f) (g-h) (i)

Scheme 1. (a) *N*,*N*′-dimethylthiourea (DmTu); (b) R = H; imidazolidine-2-thione (Imt); (c) $R = CH_3$; *N*-methylimidazolidine-2-thione (MeImt); (d) $R = C_2H_5$; *N*-ethylimidazolidine-2-thione (EtImt); (e) $R = C_3H_7$; *N*-propylimidazolidine-2-thione (PrImt); (f) R = *i*-C_3H_7; *N*-(*i*-propyl)imidazolidine-2-thione (*i*-PrImt); (g) R = H; 1,3-diazinane-2-thione (Diaz); (h) $R = C_2H_5$; *N*-ethyl-1,3-diazinane-2-thione (EtDiaz); (i) 1,3-diazipane-2-thione (Diap).

the procedure described in the literature (by the addition of CS_2 to diamines in ether and then heating the resulting adduct at 100–110 °C for 2–3 h, followed by its crystallization in methanol) [12,13]. The ligands Imt and Diaz contain 2–3% ^{15}N labelled nitrogen (by using a mixture of ^{15}N labelled and unlabeled diamine in preparation of thiones).

2.2. Preparation of complexes

All the complexes were prepared by adding thiones in methanol (20–25 ml) to $AgNO_3$ in 15 ml acetonitrile in the required molar ratios and stirring for 15 min. For the complexes of DmTu, Imt and Diaz ligands, white or yellow precipitates were formed on mixing the two solutions (dark brown for [ImtAgNO$_3$]), which were filtered and washed with methanol. The $[Ag(Diaz)_2]NO_3$ complex was crystallized from a water-methanol mixture. For the complexes of MeImt, EtImt, PrImt, *i*-PrImt and EtDiaz mixing resulted in a colorless or yellow solution. White or yellow solids were obtained on evaporation of the solvent. In the case of EtImt and *i*-PrImt the products were washed with water and acetone. $[Ag(EtDiaz)_2]NO_3$ was isolated from acetone. The experimental yield of the products was around 60–70% (40% for $[Ag(EtDiaz)_2]NO_3$]). The elemental analyses, melting points (m.p.) and molar conductance of the complexes are given in Table 1.

2.3. NMR measurements

The ^1H NMR spectra were obtained on a JEOL JNM-LA 500 NMR spectrometer operating at a frequency of 500.00 MHz. The ^{13}C NMR spectra were obtained at the frequency of 125.65 MHz with ^1H broadband decoupling at 297 K. The spectral conditions were: 32 K data points, 0.967 s acquisition time, 1.00 s pulse delay and 45° pulse angle.

The ^{15}N NMR spectra were recorded at 50.55 MHz using 2.1 M $NH_4^{15}NO_3$ in D_2O as an external reference, which lies at 375.11 ppm relative to pure CH_3NO_2, 380.2 ppm [14]. The spectral conditions for ^{15}N were: 32 K data points, 0.721 s acquisition time 2.50 s delay time, 60° pulse angle and 15 000 scans.

The ^{107}Ag NMR spectra were obtained at the frequency of 20.13 MHz using 10 mm low frequency probe with 9.1 M aqueous $AgNO_3$ as an external reference. The spectral conditions were: 32 K data points, 1.02 s acquisition time, 6.0 s delay time, 45° pulse angle and approximately 4000 scans.

3. Results and discussion

Selected IR spectroscopic vibrational bands for the free ligands and their silver(I) complexes are given in Table 2. A low frequency shift in the ν(C=S) band and a high frequency shift in ν(N–H) band in the complexes compared with free ligands indicate the existence of

Table 2

[a] λ, in mho cm^2 mol^{-1} (for free silver nitrate in DMSO, $\lambda = 38.0$ mho cm^2 mol^{-1}).

thione forms in the solid state. A sharp band around 825 cm^{-1} for NO_3^- bending was observed for all the complexes indicating that NO_3^- ion is not coordinated [5,15].

The molar conductivity measurements in DMSO show that for $[LAgNO_3]$ complexes, the NO_3^- ion is weakly coordinated except in the complexes of Diaz, EtDiaz and Diap. For $[AgL_2]NO_3$ complexes, the conductance values lie in the range acceptable for a 1:1 electrolyte except in EtDiaz and DmTu complexes, which indicates that these two complexes are polymeric (Table 1). The polymeric structure of $[Ag(DmTu)_2]ClO_4$ is already known [16].

The ^1H and ^{13}C NMR chemical shifts of 0.10 M solutions of the complexes in DMSO-d_6 are summarized in Table 3. In ^1H NMR spectra of the complexes, the N–H signal of thiones became less intense upon coordination and shifted downfield by 0.7–1.0 ppm from their positions in free ligands. The deshielding of the N–H proton is related to an increase of the π electron density in the C–N bond upon complexation [17]. The appearance of a N–H signal shows that the ligands are coordinating to silver(I) via the thione group.

In all complexes, the C-2 resonance appears upfield by 4–7 ppm compared wth free ligands in accordance with the data observed for other complexes of Cu(I), Ag(I) and Au(I) with heterocyclic thiones [3–7]. The upfield shift is attributed to a lowering of the >C=S bond order upon coordination and a shift of N→C electron density producing partial double bond character in the C–N bond [17,18]. The upfield shift decreases as the number of ligands attached to silver(I) increases from one in $[LAgNO_3]$ to two in $[AgL_2]NO_3$. This is because of the increase in number of electronegative groups attached to silver(I). A small shift of 1–2 ppm is observed in other carbon atoms, which shows that the nitrogen atoms are not involved in coordination. In the complexes of Imt and its derivatives a deshielding effect is observed at C-4/5 while in Diaz and EtDiaz complexes, a deshielding effect is observed at C-4 and C-6, but C-5 bears a shielding effect. The deshielding at C-4/6 is due to an increase in π character of the C–N bond.

The difference in shielding at C-2 is related to the strength of the metal-sulfur bond, which arises from the back donation of silver(I) to sulfur [17]. In mono complexes, the smallest C-2 shift, amounting to 5.18 ppm was detected in [*i*-PrImtAgNO$_3$], while the greatest one was found in [DiapAgNO$_3$]. Among the bis complexes, the DmTu complex with the most significant shift in C-2 was found to be the most stable. From Table

[a] Resonances due to nonequivalent CH_3 groups.
[b] N–C3.
[c] ^{13}C Resonances for these complexes in a 50:50 (v/v) mixture of DMSO and acetone are reported in Ref. [4]; the values given here are in DMSO and are mentioned to show a comparison with other complexes.

3, it can be seen that as the size of the ring is increasing the shift difference at C-2 also increases. Thus, Diap forms more stable complexes with $AgNO_3$ compared with Imt and Diaz. Also, for the complexes of *N*-ethyl derivatives (EtImt and EtDiaz), the shift is greater for EtDiaz complexes than for the EtImt one. Changing the group at the *N*-1 position has a little effect on the C-2 shift.

The ^{15}N NMR chemical shifts of Imt, Diaz and their complexes are given in Table 4. The ^{15}N NMR of the complexes shows an opposite trend compared with that observed in ^{13}C NMR. The ^{15}N NMR signal shifts towards downfield position on coordination consistent with an increase in double bond character of the C–N bond [17]. A similar observation was found in other silver(I) and gold(I) complexes of thiones [5,11,19]. As found in ^{13}C NMR, a greater shift in ^{15}N NMR is observed for Diaz complexes compared with those of Imt (Tables 3 and 4). The ^{15}N signal undergoes a slight shift suggesting that the nitrogen of thiones is not involved in bonding with silver(I) [11,19]. The metal binding through nitrogen involves an upfield shift of at least 50 ppm as is observed in some Pt(II) complexes [20,21].

In ^{107}Ag NMR the signal for $AgNO_3$ is deshielded by 166 ppm when recorded in DMSO compared with that in aqueous solution showing that the ^{107}Ag chemical shift is not only sensitive to the nature of ligands but is also affected by changing the solvent. The complexation with thiones shifts the signal further downfield by approx. 300–500 ppm. This very large reduction in shielding indicates the silver(I) binding to sulfur of the thiones [22]. In the case of bonding through nitrogen a smaller shift of around 100 ppm would have been observed in ^{107}Ag NMR [22]. This provides a clear evidence that thiones bind to silver(I) through sulfur only. The ^{107}Ag chemical shifts of all the complexes are listed in Table 5. For $[LAgNO_3]$ type complexes, two categories of ^{107}Ag chemical shifts are found, one around 500 ppm and the other around 600 ppm or greater. The larger downfield shifts suggest that the compounds should be polymeric, since the electronegative ligands are coordinating from both sides of the metal ion. The smaller shifts for MeImt, EtImt, PrImt and *i*-PrImt indicate that they are forming monomeric complexes. For Imt and its derivatives, ^{107}Ag chemical shifts are greater in bis complexes than for mono complexes, while for DmTu and Diaz, the trend is opposite. The opposite trend suggests that they exist in the form of polymers or involve some change in the geometry of the complex. The same trend was observed for $[Ag(Tu)_xNO_3]$ complexes ($x = 1$–4), which are also polymeric [11,23,24]. The crystal structure of $[Ag(DmTu)_2]ClO_4$ also shows that the compound is polymeric, having a tetrahedral geometry around silver(I) [16]. The more downfield shifts for bis complexes than for mono complexes are because of the increase in the number of electronegative groups attached to silver(I). The ^{107}Ag NMR chemical shifts for the complexes are comparable to the reported complexes of other thiones with the same stoichiometries [5,11].

Table 4
^{15}N NMR chemical shifts of Imt, diaz and their silver(I) complexes in DMSO-d_6

Species	δ (^{15}N)
Imt	112.24

EtImt	480.15	645.15
PrImt	506.97	
i-PrImt	489.58	650.27
Diaz	708.73	678.00
EtDiaz	612.01	731.01
Diap	664.04	

In this study we have shown that thiones react with silver nitrate to form complexes of the type, $[LAgNO_3]$ and $[AgL_2NO_3]$ in which the ligands exist in thione form both in solution as well as in the solid state. The study provides useful information about the nature of bonding in silver(I) complexes. The chemical shifts for different complexes presented here are useful, especially if the ^{107}Ag NMR is used to study silver(I) complexes with sulfur containing biological ligands.

Copper(II) complexes of 1,3-dithian-2-ylidenemalonate: doubly layered 2D sheet induced by alkali metal ions

Jung Su Park, Kyoung-Tae Youm, Moo-Jin Jun *

Department of Chemistry, Yonsei University, Seoul 120-749, South Korea

Received 8 January 2002; accepted 6 March 2002

Abstract

Novel doubly layered 2D sheets of $M_2[Cu(DTAYM)_2(H_2O)_m]\cdot nH_2O$ (M = K, $m = 0$, $n = 2$ for compound **1**; M = Na, $m = 1$, $n = 4$ for compound **2**; M = Rb, $m = 1$, $n = 2$ for compound **3**) have been synthesized and characterized by single crystal X-ray structure studies. In compounds **1**, **2** and **3** the alkali metal ions hold each layer by binding oxygen donor atoms from hydrated water and DTAYM. Basic frameworks are an oxo-bridged dimer for **1** and monomers for **2** and **3** of which the apical site is occupied by hydrate water. © 2002 Published by Elsevier Science Ltd.

Keywords: Alkali metal ions; Doubly layered 2D sheet; Copper(II) complexes

1. Introduction

There has been great interest in the coordination chemistry of alkali metal ions since the fact was discovered that macrocyclic polyethers have been found to act as efficient ligands for alkali metals. Many works have focused on understanding the vital role played by alkali metal ions in biological systems, followed by exploiting macrocyclic multidentate ligands such as crownethers, cryptands and the relates [1]. Recently alkali metal aggregates of metal complexes ligating donor atom rich ligands have been studied [2]. In view of structural studies many examples of multidimensional polymers induced by alkali metals have been reported [3,4]. In some instances they show remarkable magnetic properties [5], which are caused by the high coordination number of alkali metals [6]. One of the strategies in making heterometallic coordination polymers containing alkali metals is that complexes with residual donor atoms such as oxygen, nitrogen or sulfur are designed. In this respect the ligand 1,3-dithian-2-ylidenemalonate (DTAYM) should be a particularly promising one in that it has many binding sites (four oxygen and two sulfur atoms). The complex, $[MnCu(MTM)_2(H_2O)_2\text{-}(CH_3OH)_2]_n$, a transition–transition metal aggregate containing bis(methylthio)methylidene)malonate (MTM) which is similar to DTAYM, affords a ferrimagnetic layered compound where four carboxylates of two MTM ligands bridge Mn and Cu atoms in a *syn-anti* bonding mode [7]. Here we report $M_2[Cu(DTAYM)_2(H_2O)_m]\cdot nH_2O$ (M = K, $m = 0$, $n = 2$ for compound **1**; M = Na, $m = 1$, $n = 4$ for compound **2**; M = Rb, $m = 1$, $n = 2$ for compound **3**), all of which show doubly layered 2D sheet frameworks in the solid state.

2. Experimental

2.1. Materials

DTAYM was prepared by the hydrolysis of the diethylester of DTAYM with an equivalent of $Ba(OH)_2$ in MeOH at boiling temperature [8]. Elemental analyses (C, H, O, S) were performed with Elementa Analysensysteme GmbH Vario EL instrument by Korea Basic Science Institute Seoul branch Lab.

2.2. Synthesis

2.2.1. $K_2[Cu(DTAYM)_2]\cdot 2H_2O$ (**1**)

$CuSO_4\cdot 5H_2O$ (0.25 g, 1 mmol) and K_2SO_4 (0.175 g, 1 mmol) were added to a solution of Ba(DTAYM) (0.711 g, 2 mmol) in H_2O (30 ml). After vigorous stirring for 2 h, the white precipitate ($BaSO_4$) was removed by filtration. The filtrate was evaporated to dryness and then the resultant solid was dissolved in MeOH (30 ml), the resulting solution was filtered, concentrated to a half of its original volume and left undisturbed for a week. Single crystals were separated. Yield: 91% (based on Ba(DTAYM)). *Anal*. Calc. for $C_{14}H_{16}CuK_2O_{10}S_4$: C, 27.37; H, 2.63; O, 26.05; S, 20.88. Found: C, 27.43; H, 2.89; O, 26.32; S; 20.52%.

2.2.2. $Na_2[Cu(DTAYM)_2(H_2O)]\cdot 4H_2O$ (**2**)

Compound **2** was prepared via a similar method as that for compound **1**, using Na_2SO_4 (0.284 g, 2 mmol) in place of K_2SO_4. After removing $BaSO_4$ the filtrate was concentrated to approximately half of its original volume under reduced pressure and layered with MeOH slowly. After a day single crystals were separated and washed with MeOH, acetone and air-dried. Yield: 85% (based on Ba(DTAYM)). *Anal*. Calc. for $C_{14}H_{22}CuNa_2O_{13}S_4$: C, 26.43; H, 3.49; O, 32.70; S, 20.16. Found: C, 26.80; H, 3.37; O, 33.05; S, 20.49%.

2.2.3. $Rb_2[Cu(DTAYM)_2(H_2O)]\cdot 2H_2O$ (**3**)

Compound **3** was prepared via a similar method as that for compound **2**, using Rb_2SO_4 (1.534 g, 2 mmol) instead of Na_2SO_4. Yield: 89% (based on Ba(DTAYM)). *Anal*. Calc. for $C_{14}H_{18}CuO_{11}Rb_2S_4$: C, 23.19; H, 2.50; O, 24.27; S, 17.69. Found: C, 22.87; H, 2.75; O, 24.51; S; 17.58%.

2.2.4. X-ray diffraction measurement

All the X-ray data were collected on Enraf–Nonius CAD-4 automated diffractometer with Mo Kα radiation ($\lambda = 0.71073$ Å) at ambient temperature. The orientation matrix and unit cell dimensions were determined from 25 machine-centered reflections in the 2θ range from 15 to 25°. The variation of intensities were monitored with repeated check of intensities of three reflections every 1 h during the data collection period. An absorption correction was applied by an empirical ψ-scan on two or three reflection planes with a κ-value near 90°. A direct method (SHELX-86) [9] was employed to locate heavy atoms and subsequent cycles of Fourier map and least-square refinements located the other atoms (SHELX-97) [10]. Hydrogen atoms were included in the structure factor calculation using a riding model. All the calculations were carried out using a VAX and a PC. Detailed crystal parameters and procedural information corresponding to data collection and structure refinement are given in Table 1.

3. Result and discussion

DTAYM is a very feasible ligand in that it has four oxygen atoms (two carboxylates) and two sulfur atoms, which are potential donors to act as a metal acceptor. A similar ligand, MTM, coordinates to a Pt(II) ion via one of the three distinct modes of O, O′-, O, S′- and S, S′-chelation [8]. Recently, it has been reported that selective affinity of oxygen and sulfur of similar derivative, bis(ethylthio)methylenepropanedithiolate (BETMP) to particular metal ions gives the trinuclear complex $[[(dach)Pt(BETMP)]_2[Cu(BF_4)_2]]$ which is dimerized in MeOH to give an inorganic tennis ball via a non-covalent interaction [11]. As mentioned above, DTAYM is a donor-rich ligand which can give unpredictable polymorphs.

The reaction of Ba(DTAYM) with Cu(II) ion and M_2SO_4 (M = Na, K, Rb) affords compounds **1**, **2** and **3**.

Symmetry operation: #1: $-x$, $-y+1$, $-z+2$; #2: $x-1$, y, z; #3: $-x+1$, $-y$, $-z+2$; #4: $-x+1$, $-y+1$, $-z+2$; #5: $x+1$, y, z; #6: $-x$, $-y$, $-z+2$.

All of the complexes show U-shaped frameworks like horseshoes, which face each other. This inward connection is caused by the alkali metal ions, hydrated water and oxygen from DTAYM, resulting in a doubly layered 2D sheet. Selected bond lengths and angles are listed in Table 2 for **1**, Table 3 for **2** and Table 4 for **3**. In compound **1** the elucidative framework is horseshoes in which the copper ion is surrounded by five oxygens (four from DTAYM (O1, O3, O5, O7) and the rest from neighboring DTAYM ligands (O1#1)). As a result the basic framework of **1** is a bis-μ-oxo-bridged dimer. The length of Cu–O1#1 and bond angle of O1–Cu–O1#1 are 2.418(4) Å and 80.11(18)°, respectively. These dimers are aggregated via an interaction of potassium ions and oxygen atoms. As shown in Fig. 1, the environment of each potassium ion is different, where K1 has the coordination number of seven. K1 ions are bridged by two hydrated water and two carboxylate groups. More interestingly two carboxylate groups bridge two K1 ions in a *syn–syn* bonding mode and hydrated waters (OW1)

bridge two K1 ions in a μ-mode. The distance between K1 (K1–K1#4) is 3.612(4) Å and the rest of the coordination environment is completed with η^2-chelating of another carboxylate and η^1-bonding of the other carboxylate group. The coordination number of K2 is five, where the oxygen atoms from the carboxylate group chelate the potassium ion in a η^2-mode, one of which bridges the other potassium ion to form a bis-μ-oxo K_2O_2 plane. As a result these interactions induce the doubly layered 2D sheets (Fig. 2).

In the case of compounds **2** and **3**, the interacting patterns are somewhat different from that of the compound **1**. The basic unit of the double layer is composed of the asymmetric units of **2** and **3** as a monomer, where an hydrated water occupies an apical site of the copper ion and four oxygen atoms from DTAYM complete the five coordination environment of the Cu atom.

In compound **2**, the Na1 ion lies coplanar against the least-squared plane made up of O1, O3, O5 and O7 and Na2 is located above that plane to interact with apically occupied water and the oxygen atoms belonging to a neighboring monomer and hydrated waters (Ow1, Ow4), resulting in doubly layered 2D sheet frameworks. The coordination number of sodium ions (Na1 and Na2) is six (Figs. 3 and 4). Ow3 bridges Na1 and Na1#6 with an angle of 180°, which is related by an inversion symmetry operation. Sodium ions (Na1 and Na2#2) are bridged through Ow1 and O4#4 via a bis-μ-oxo-bridging mode to afford a bent plane composed of Na1, Na2#2, Ow1 and O4#4. The resultant dihedral angle between the Na1, Ow1, O4#4 plane and the Na2#2, Ow1, O4#4 plane is 126.19°.

It is very interesting to see the position of the

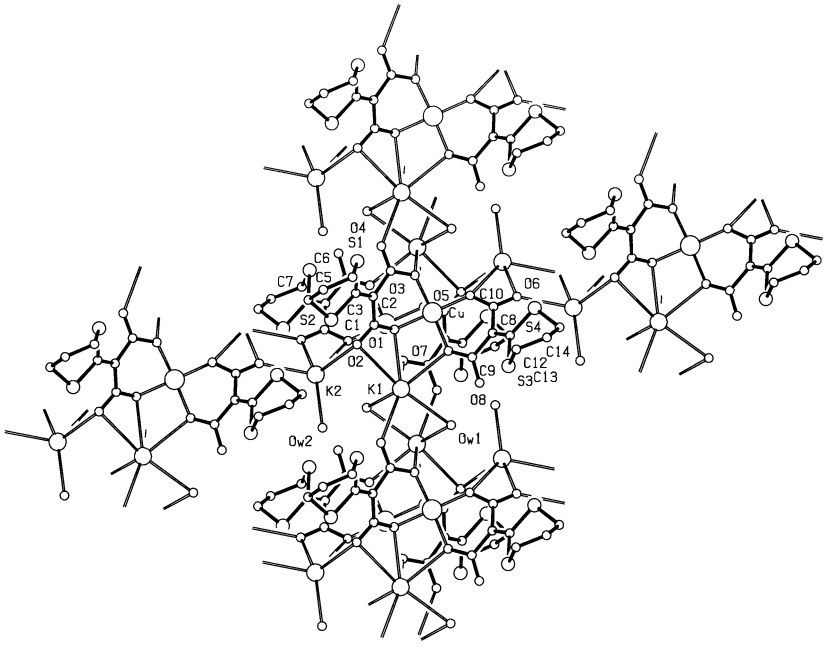

Fig. 1. Extended structure of **1** showing binding mode of K ions [12]. All hydrogen atoms are omitted for clarity.

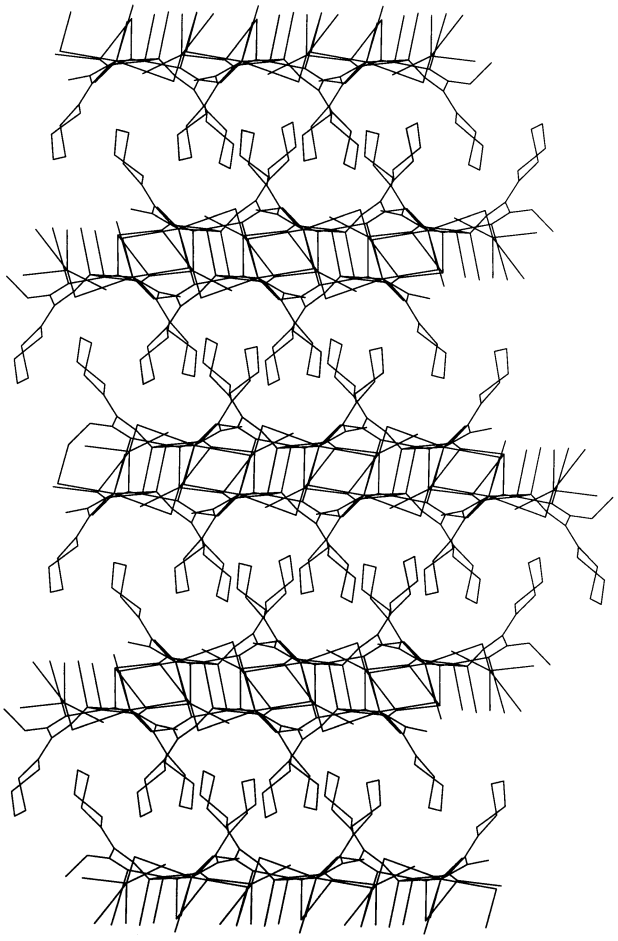

Fig. 2. Doubly layered 2D sheet as viewed from the [100] side plane of coordination polymer.

rubidium ions in compound **3**. Here the apically occupied water (O9) pushes down the face of copper ions and hold the rubidium ions a μ-3 mode. The angle of ∠Rb1–O9–Rb2 is 167.53(17)°, and the Rb1 lies in the bisect plane against the O3–Cu–O5 plane. The Rb2 ion interacts with only O1 atom in the asymmetric unit of compound **3**. The coordination numbers of Rb1 and Rb2 are seven and six, respectively (Fig. 3). Rb1 ions are bridged through hydrate waters (Ow1) and two carboxylate groups via a *syn–syn* bonding mode, as is the case for the Rb2 ions. But the distances between the rubidium ions are quite different. Whereas Rb1 ions are separated by approximately 4.48 Å, the length between two Rb2 ions (Rb(2)–Rb(2)#5) is 3.8458(17) Å. As a result these interactions in compounds **2** and **3** induce doubly layered 2D sheets similar to compound **1**.

In summary, the affinity of the alkali metal ions to oxygen atoms plays a pivotal role for all compounds to afford doubly layered 2D sheets where all oxygen atoms and alkali metal ions protrude inward in the double layer.

Abstract

The crystal structures of two mono(dpyam)copper(II) complexes, $[Cu(dpyam)(NO_2)_2]$ (**1**) and $[Cu(dpyam)(H_2O)_2(SO_4)]$ (**2**) and two dithiocyanate compounds containing bis(dpyam)copper(II) units, $[Cu(dpyam)_2(NCS)](SCN)\cdot 0.5DMSO$ (**3**) and $[Cu(dpyam)_2(SCN)_2]$ (**4**) have been determined by X-ray crystallography. The second orthorhombic form of the monomeric Cu(II) complex **1** was obtained by the reaction of di-2-pyridylamine (dpyam) with CuCl and $NaNO_2$ in water–methanol solution. Each copper(II) ion in **1** exhibits a tetrahedrally-distorted square base of the CuN_2O_2 chromophore, with off-the-z-axis coordinated nitrito groups weakly bound in approximately axial positions. Complex **2** is an example of a polymeric copper(II) derivative containing the bidentate bridging sulfate ligand in the long-bonded axial positions. Each copper(II) ion in **2** shows an elongated tetragonal octahedral stereochemistry. The CuN_4N' chromophore of **3** involves a square-based pyramidal structure, slightly distorted towards a trigonal bipyramidal stereochemistry, $\tau = 0.13$. One of the SCN^- anions is bonded to the copper(II) ion via the N atom in the axial position of the square pyramid. Complex **4** is centrosymmetric and octahedrally elongated, with the SCN^- anions coordinating in axial positions via the S atom. The structures of complexes **1**–**4** and their ESR and electronic reflectance spectra are compared with those of related complexes. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

Reported complexes of copper(II) and bidentate mono(chelate) ligands with mono- and divalent oxyanions may be grouped in many classes for each type of oxyanions depending on the coordinating nature. Complexes with monovalent oxyanions formulated as $Cu(chelate)(OXO)_2\cdot nH_2O$ or $Cu(chelate)(OXO)(OYO)\cdot nH_2O$, where OXO and OYO = NO_2^-, NO_3^-, ClO_4^-, $CH_3CH_2COO^-$, CH_3COO^- or $HCOO^-$, exhibit three classes of local molecular structures: (A) monomeric tetrahedrally-distorted elongated octahedron with an extremely asymmetric bidentate coordination of both oxyanions [1–10]; (B) polymeric elongated tetragonal (or rhombic) octahedron with the nearly symmetric bidentate coordination of a basal oxyanion and the bridging bidentate coordination in the axial positions of the second one [10–13] and (C) dimeric tetrahedrally-distorted square pyramid with monodentate and bidentate bridging oxyanions [8,14]. While complexes with divalent oxyanions formulated as $Cu(chelate)(OZO)\cdot nH_2O$, where OZO = CO_3^{2-} and SO_4^{2-}, involve five classes of local molecular structures: (I) monomeric distorted square-based pyramid with bidentate oxyanions [15]; (II) polymeric distorted square-based pyramid with the tridentate bridging oxyanions [16]; (III) monomeric square-based pyramid with unidentate oxyanions [17]; (IV) polymeric elongated octahedron with

PII: S0277-5387(02)01011-2

bidentate bridging oxyanions [18,19]; (V) dimeric distorted square-based pyramid with double bridges of tridentate oxyanions [20]. In order to continue exploring the coordinating and bridging natures of mono- and divalent oxyanions on these types of complexes, [Cu(dpyam)$(NO_2)_2$] (**1**) and [Cu(dpyam)$(H_2O)_2(SO_4)$] (**2**) complexes were prepared and the structures investigated and compared with other relevant complexes.

More interesting of **1** is that it was reported by us in 1999 to crystallize in orthorhombic form of the $P2_12_12_1$ space group but the title complex **1** of the same composition shows differences both in color and electronic spectra. We have characterized this second form crystallographically and found that it crystallized in space group $Pca2_1$ of the orthorhombic system. Both forms were each unique in their unit cell content and their local molecular environments. Herein we have reported differences in their molecular geometries and their spectroscopic properties.

The bis(chelate)copper(II) complexes formulated as Cu(chelate)$_2$XY, with chelate being 2,2′-bipyridyl (bpy) and 1,10-phenanthroline (phen) and X, Y various counter anions, coordinated or not, are known to display a large variation of non-regular stereochemistry [1,21] with a large number of investigated structural data [22–26]. Structural data are more limited for the corresponding complexes in which the chelate is the more flexible di-2-pyridylamine (dpyam) [24,27a,27b,28–35]. In order to examine the chelate function of bpy or phen and the more flexible dpyam ligand upon the range of stereochemistries observed in this family of complexes, this paper also reports the crystal structures and electronic properties of two bis(dpyam) complexes [Cu(dpyam)$_2$(NCS)](SCN)·0.5DMSO (**3**) and [Cu(dpyam)$_2$(SCN)$_2$] (**4**) and these are compared with other analogous complexes.

2. Experimental

All reagents were commercial grade materials and were used with out further purification. Elemental analyses (C, H, N) were performed by the Microanalytical Service of Science and Technological Research Equipment Centre, Chulalongkorn University on a Perkin–Elmer PE2400 CHNS/O Analyzer. The infrared spectra were recorded on a Biorad FTS-7/PC FTIR spectrophotometer as KBr pellets in the 4000–450 cm^{-1} region. Solid-state (diffuse reflectance) electronic spectra were recorded as polycrystalline samples on a Perkin–Elmer Lambda2S spectrophotometer over the range 8000–18 000 cm^{-1}. The X-band ESR spectra were recorded on polycrystalline samples at room temperature (r.t.) with a JEOL ESR JES-RE2X spectrometer (operating at the X-band) by the service of Scientific and Technological Research Equipment Centre, Chulalongkorn University.

2.1. Preparation

2.1.1. Preparation of [Cu(dpyam)$(NO_2)_2$] (1)

A solution of CuCl (99 mg, 1.0 mmol) in 25 ml water was mixed with a solution of dpyam (85.5 mg, 0.5 mmol) in 25 ml methanol and 69 mg (1.0 mmol) of solid $NaNO_2$ were added to the mixed solution. Bright green needle crystals were deposited when allow to stand for slow evaporation in air. They were filtered off, washed with mother liquor and were dried in air. Yield approximately 60%. *Anal.* Calc. for $C_{10}H_9CuN_5O_4$: C, 36.76; H, 2.78; N, 21.43. Found: C, 36.68; H, 2.70; N, 21.39%.

The first form of **1** (compound **5**) was also reprepared following the method previously described [7] for spectral comparison to that of **1**, starting differently with the $Cu(O_2CCH_3)_2·H_2O$: dpyam: $NaNO_2$ ratio of 1:2:4 in methanolic aqueous solution (20:30 ml). Dark green crystals were obtained as [Cu(dpyam)$(NO_2)_2$]. Yield approximately 83%. *Anal.* Calc. for $C_{10}H_9CuN_5O_4$: C, 36.76; H, 2.78; N, 21.43. Found: C, 36.82; H, 2.83; N, 21.50%.

2.1.2. Preparation of [Cu(dpyam)$(H_2O)_2(SO_4)$] (2)

2.1.2.1. Method a. To a stirring aqueous solution (75 ml) containing $CuCl_2·2H_2O$ (169 mg, 1.0 mmol) and $Na_2S_4O_6$ (307 mg, 1.0 mmol), a solution of dpyam (171 mg, 1.0 mmol) in MeOH (20 ml)–DMSO (35 ml) mixed solvent was added. The solution was heated to approximately 40 °C with continuous stirring for 3 h. A light green precipitate was filtered off resulting in a light green filtrate. From the light green solution, light green needle crystals were deposited on slow evaporation at r.t. Yield approximately 48%. *Anal.* Calc. for $C_{10}H_{13}CuN_3O_6S$: C, 32.74; H, 3.57; N, 11.46. Found: C, 32.80; H, 3.65; N, 11.51%.

2.1.2.2. Method b. To a stirring aqueous solution (15 ml) containing $CuSO_4·5H_2O$ (250 mg, 1.0 mmol) and $Na_2S_2O_3·5H_2O$ (268 mg, 1.0 mmol), a solution of dpyam (171 mg, 1.0 mmol) in MeOH (10 ml) was added. The solution was heated with continuous stirring for 15 min. Light green precipitates were developed and filtered off. The solids were dissolved in DMSO (50 ml) with heating and stirring for 14 h resulting in a bluish-green solution. On slow evaporation at r.t., light green needle crystals of **2** were obtained. Yield approximately 40%.

2.1.3. Preparation of [Cu(dpyam)$_2$(NCS)](SCN)·0.5DMSO (3)

The complex [Cu(dpyam)$_2$(NCS)](SCN)·0.5DMSO (**3**) was prepared by adding a hot solution of dpyam (0.34 g, 2.0 mmol) in 20 ml methanol to a hot DMSO solution (20 ml) of Cu(SCN) (0.12 g, 1.0 mmol). Dark green and rod-like crystals of [Cu(dpyam)$_2$(SCN)$_2$] (**4**) deposited together with the green, rectangular-shaped crystals of **3**, which were separated by hand. Yield approximately 50%. *Anal.* Calc. for $C_{24}H_{24}N_8CuOS_3$: C, 49.23; H, 3.77; N, 19.97. Found: C, 49.17; H, 3.69; N, 19.92%.

2.1.4. Preparation of [Cu(dpyam)$_2$(SCN)$_2$] (4)

The complex [Cu(dpyam)$_2$(SCN)$_2$] (**4**) was prepared by adding a hot solution of dpyam (0.34 g, 2 mmol) in 30 ml ethanol to a hot aqueous solution (30 ml) containing $Cu(CH_3CO_2)_2·H_2O$ (0.18 g, 1 mmol) and KSCN (0.19 g, 2 mmol). Dark-green and rod-like crystals of **4** were formed after a few days. Yield approximately 92%. *Anal.* Calc. for $C_{22}H_{18}N_8CuS_3$: C, 50.61; H, 3.48; N, 21.46. Found: C, 50.55; H, 3.53; N, 21.41%.

The complex [Cu(dpyam)$_2$Br$_2$]·2H$_2$O (**6**) was reprepared in order to compare its electronic spectrum to that of the present compound **4**. This compound was structurally reported [29] but there was no electronic reflectance spectrum reported. Complex **6** was prepared by adding a hot solution of dpyam (0.34 g, 2.0 mmol) in 20 ml methanol to a hot aqueous solution (30 ml) of $CuBr_2$ (0.22 g, 1 mmol). Dark green needle-like crystals of **6** were formed after slow evaporation at r.t. for several days. Yield approximately 86%. *Anal.* Calc. for $C_{20}H_{22}N_6CuBrO_2$: C, 39.92; H, 3.69; N, 13.97. Found: C, 39.86; H, 3.74; N, 14.01%.

2.2. Crystallography

Reflection data for complexes **1**–**4** were collected at 293 K on a 1K Bruker SMART CCD area-detector diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at a detector distance of 4.5 cm and swing angle of $-35°$. A hemisphere of the reciprocal space was covered by a combination of three sets of exposures; each set had a different ϕ angle (0, 88, 180°) and each exposure of 30 s for all complexes except that of **1** (35 s), covered 0.3° in ω. Data reduction and cell refinements were performed using the program SAINT [36]. An empirical absorption correction by using the SADABS [37] program was applied, which resulted in transmission coefficients ranging from 0.705 to 1.000 for **1**, 0.723 to 1.000 for **2**, 0.806 to 1.000 for **3** and 0.908 to 1.000 for **4**. The structures were solved by direct methods and refined by full-matrix least-squares method on F^2_{obs} with anisotropic thermal parameters for all non-hydrogen atoms using the SHELXTL-PC V 5.03 [38] software package. All hydrogen atoms in **1** and **2** were located by difference synthesis and refined isotropically, except hydrogen atoms of a water molecule in **2** and nine dpyam hydrogens in **1** which are geometrically fixed and allowed to ride on attached atoms. The methyl hydrogens of DMSO were not located but the bond parameters of DMSO are reasonable with average S–O and S–C distances of 1.563 and 1.663 Å, respectively. The molecular graphics were created by using SHELXTL-PC. The crystal and refinement details for complexes **1**–**4** are listed in Table 1. Selected bond lengths and angles are given in Tables 2–5. Figs. 1–4 illustrate the structures of complexes **1**–**4**, respectively, and the atom numbering scheme used.

3. Results and discussion

3.1. Structure of [Cu(dpyam)(NO$_2$)$_2$] (1)

The structure of **1** (Fig. 1) consists of a neutral [Cu(dpyam)(NO$_2$)$_2$] unit. The local molecular structure of the copper(II) ion involves a tetrahedrally-distorted elongated octahedral $CuN_2O_2O'_2$ chromophore. The dpyam ligand bonds symmetrically in-the-plane with Cu–N distances of 1.970(2) and 1.984(2) Å, and a N(1)–Cu–N(2) dpyam bite angle of 93.5(1)°. Two oxygen atoms from each nitrite group also bond in-the-plane with Cu–O distances of 1.984(2) and 2.012(2) Å, forming a markedly tetrahedral distorted square base with the dihedral angle of 38.6(1)° at which the N–Cu–N and O–Cu–O planes cross. The four N(1), N(2), O(2), O(3) basal donor atoms are out from their least-squares plane as 0.474(1), −0.472(1), −0.476(1), 0.475(1) Å, respectively. The second oxygen atom from each nitrite group are bent towards the Cu atom to complete the fifth and sixth coordination sites in the approximately axial positions at longer distances of 2.471(2) and 2.535(2) Å and with an O(1)–Cu–O(4) angle of 128.6(3)° which is markedly less than 180°, giving the extremely distorted octahedron.

There are no unusual bond lengths or bond angles in the dpyam ligand [39]. The separate pyridine rings are planar, (r.m.s.d. 0.003 and 0.005 Å) and the dihedral angle is 6.0(1)°. The nitrite ions show the expected geometry, with the longer N–O bonds involved in coordination with respect to the weakly coordinated N–O bonds (1.276(2) and 1.222(2) Å, and 1.267(2) and 1.230(2) Å, respectively, for both nitrite groups). However, the variations are less than that found in a purely monodentate nitrite (1.290 and 1.207 Å) [40]. In addition, the angles at the in-plane oxygen atoms [106.9(2)° and 109.4(2)°] are intermediate between the value of 119.5° in the monodentate nitrito-complex [40] and of 93°–100° in the bidentate nitrito-complex [41]. The angles at the nitrogen atoms of the nitrite groups

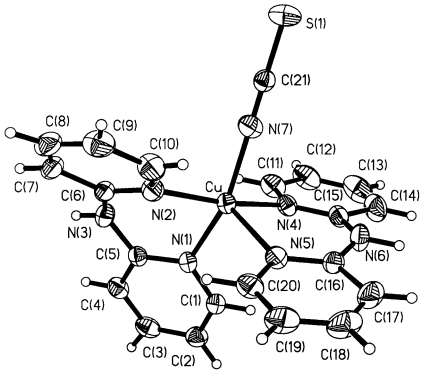

Fig. 3. The molecular structure of $[Cu(dpyam)_2(NCS)](SCN)\cdot 0.5DMSO$ (**3**).

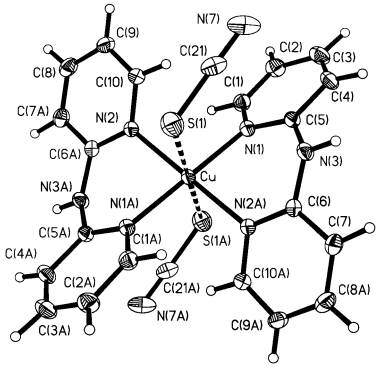

Fig. 4. The molecular structure of $[Cu(dpyam)_2(SCN)_2]$ (**4**).

[113.0(2)° and 113.7(2)°] are between that found in the purely monodentate nitrito-coordination (115.0°) [40] and the bidentate nitrito-coordination (111°–112°) [41,42]. Consequently, the coordination mode of the weakly coordinated oxygen atoms to the copper in **1** is intermediate between the purely monodentate nitrito-coordination [40] and the bidentate nitrito-coordination [41].

The coordination geometry of the nitrite groups in **1** is similar to that of the first previous reported isomer **4** [7]. The planes of the dinitrite groups in each complex are almost perpendicular to each other [87.0(3)° for **1** and 82.0(2)° for **4**]. In spite of the same composition of the orthorhombic system for both complexes, their local molecular geometries around the copper(II) ions are not comparable, with a slightly more elongated and asymmetric coordination in the axial positions for **1** [2.471 and 2.535 Å, $\Delta O = 0.068$ Å for **1**, and 2.431 and 2.469 Å, $\Delta O = 0.038$ Å for **4**]. Both complexes have significant differences in the tetrahedral twist of the basal plane [38.6(1)° in **1** and 31.2(2)° in **4**], the O(1)–Cu–O(4) angle [128.6(3)° in **1** and 133.7(2)° in **4**] and the dihedral angle

between pyridine rings [6.0(1)° in **1** and 25.6(2)° in **4**]. These cause differences in the electronic spectra of both complexes and these differences in the local molecular arrangements of **1** and **4** arise due to a difference of the packing forces in the lattices of both complexes. Another closely related complex is observed in the dimeric tetranitrito copper(II) complex, $[Cu(dpyam)(NO_2)_2]_2 \cdot 2CH_3CN$ [8] containing double bridges of asymmetrically-O-bridging nitrito groups and the asymmetrically-bidentate chelating nitrito ligands. The coordination around each copper atom in this compound is best described as tetrahedrally-distorted elongated octahedral with off-the-*z*-axis coordination in the axial positions rather than the distorted square pyramidal geometry described by the authors. The local molecular structure is comparable to those of **1** and **4** but with a larger O–Cu–O axial angle of 144.6(1)° and a reasonably lower tetrahedral twist [deviations of basal atoms from the mean plane: 0.209(3), 0.223(3), 0.557(5), 0.217(3)] [8]. The dihedral angle of 23.1(1)° between pyridine rings also corresponds to the lesser tetrahedral twist with respect to that of **1** (6.0°) and is not too different from that of **4** (25.6°).

The N–H groups [N(3)–H] of both complexes **1** and **4** are involved in intermolecular hydrogen bonds. In **1**, the N–H group is involved in a N–H···O hydrogen bonds with an oxygen atom of the nitrite (O(4)) group which is translated one unit cell along the '*c*' direction. Where as in **4**, it is involved in N–H···N hydrogen bond with the nitrite [N(4)] group of the molecule which is translated one unit cell along the '*a*' direction.

3.2. Structure of $[Cu(dpyam)(H_2O)_2(SO_4)]$ (2)

The asymmetric unit of **2** consists of the neutral $[Cu(dpyam)(H_2O)_2(SO_4)]$ complex unit. The local molecular structure of the copper(II) ions involves the six coordinate $CuN_2O_2O_2'$ chromophore, with elongated tetragonal octahedral stereochemistry (Fig. 2). The basal planes with four nearly equal short bonds involve two pyridyl nitrogen atoms from dpyam ligand [Cu–N, 2.011(8) and 2.015(7) Å] and two oxygen atoms from each water molecule [Cu–O, 2.012(7) and 1.999(6) Å]. These basal planes are linked into an infinite chain by the bidentate bridging sulfate group. The two donor atoms from the almost-symmetrically-bridging sulfate groups occupy axial positions above and below the CuN_2O_2 planes, with Cu–O distances of 2.447(9) and 2.482(9) Å, giving the tetragonality (T) of 0.815. The four in-plane ligand atoms are reasonably planar (r.m.s.d. = 0.195 Å), with a slight tetrahedral twist [dihedral angles between CuN_2 and CuO_2 planes = 15.8(1)°]. The axial O–Cu–O angle is 172.5(4)°. The separate pyridine rings are planar and the dpyam ligands as a whole are nearly planar [dihedral angle between pyridine rings is 3.5(2)°].

The S–O distances of the coordinated O atoms are shorter [1.448(9) and 1.477(9) Å] than those of the uncoordinated oxygen atoms [1.461(7) and 1.517(7) Å], except that of the coordinated S(1)–O(6) [1.477(9) Å]. However, the internal geometry of the sulfate anion is quite regular in spite of their coordinations. Both the bond distances and angles are not too different and are within the range for ionic sulfate [43]. The six O–S–O angles vary from 107.5° to 112.8°. These deviations may be due to the hydrogen-bonding network involving all water molecules, non-coordinated sulfate oxygen atoms and the dpyam amino groups.

The structure of **2** is comparable to those of $[Cu(en)(H_2O)_2(SO_4)]$ [18] and $[Cu(bpy)(H_2O)_2(SO_4)]$ [19], all of which involve polymeric chain structures with bidentate bridging sulfate groups. However, they differ from the square pyramidal monomeric complex, $[Cu(tmen)(H_2O)_2(SO_4)] \cdot H_2O$ [17] in which the coordination geometry (4+1) around copper consists of a water molecule at the apex and four base sites occupied by two nitrogen atoms from the chelated diamine and two oxygen atoms from a monodentate sulfate and a second water molecule. In comparison to the copper(II) complexes with the divalent carbonate anion, they exhibit the marked difference both in the nature of coordinating and bridging modes between the carbonate and sulfate anions, and the local molecular geometries [15,16,20]. However, the structure of **2** with the divalent bidentate bridging sulfate group is similar to those of complexes with monovalent oxyanions, $[Cu(dpyam)(NO_3)_2]$ [10], $[Cu(dpyam)(O_2CCH_3)(ClO_4)]$ [11], $[Cu(dpyam)(O_2CCH_3)(NO_3)]$ [12] and $[Cu(dpyam)(O_2CCH_2CH_3)(NO_3)]$ [13], all of which involve polymeric chain structures with bidentate bridging nitrate or perchlorate groups.

3.3. Structure of $[Cu(dpyam)_2(NCS)](SCN) \cdot 0.5DMSO$ (3)

The asymmetric unit of **3** consists of a $[Cu(dpyam)_2(NCS)]^+$ cation, a thiocyanate ion and a half molecule of disordered, non-coordinated dimethylsulfoxide. The cation involves a five coordinate CuN_4N' chromophore, with an approximately trigonal bipyramidal stereochemistry, Fig. 3 [21]. The out-of-plane bond lengths, Cu–N(2) and Cu–N(4), are not significant different, with values of 1.997(3) and 2.017(3) Å. The in-plane bond lengths, Cu–N(1), Cu–N(7) and Cu–N(5), are significantly different, with values of 2.017(3), 1.976(4) and 2.164(3) Å, respectively. The N(1,2) dpyam ligand is thus nearly symmetrically coordinated, but the N(4,5) dpyam ligand is very asymmetrically coordinated. The CuN_4N' chromophore stereochemistry is distorted from regular trigonal pyramidal. The N(2)–Cu–N(4) (α_8) angle of 166.2(1)° is significantly different from 180° and is distorted away from the Cu–N(7) direction [44].

The in-plane angles, N(1)–Cu–N(7) (α_1), N(5)–Cu–N(7) (α_2) and N(1)–Cu–N(5) (α_3), are all significantly different from 120°, namely 158.6(2)°, 103.9(1)° and 97.4(1)°, respectively.

The largest in-plane angle of 158.6(2)° lies opposite the longest in-plane bond length, namely, the Cu–N(5) bond. This could be taken as the basal angle of a square-based pyramidal stereochemistry with elongation in the Cu–N(5) direction. The τ-value defined to describe the degree of trigonal distortion is 0.13 $\{\tau = (\alpha_8 - \alpha_1)/60\}$ [25]. As the regular trigonal bipyramid and square-based pyramid have τ values of 1.00 and 0.00, respectively, the stereochemistry of the CuN_4N' chromophore of **3** is best described as square-based pyramidal, with a slight trigonal distortion, rather than square pyramidal distorted trigonal bipyramidal [44]. The Cu(II) ion is displaced 0.31 Å from the N(1), N(2), N(4), N(7) basal plane. There are unusual bond lengths and bond angles in the coordination of the dpyam ligands [39]. The dihedral angles between the pyridine rings within the same dpyam ligand, are 31.1(1)° and 11.5(3)° and the N–Cu–N bite angles of the N(1,2) and N(4,5) dpyam ligands are 87.4(1)° and 88.9(2)°, respectively. The full mean planes of the dpyam ligands are inclined to each other at 62.3(1)°.

The non-coordinated thiocyanate group is well-ordered with C–N and C–S distances of 1.168(9) and 1.620(7) Å, compared with the coordinated isothiocyanato moiety C–N and C–S distances of 1.157(5) and 1.622(4) Å, respectively. Those of the isothiocyanato group are comparable to those reported for $[Cu(phen)_2(NCS)](ClO_4)$ (1.138 and 1.629 Å, respectively) [26a]. The crystal structure is stabilized by cooperative hydrogen bonds N–H···O (DMSO) and N–H···N (NCS counterion).

The τ-value of 0.13 for the trigonal bipyramidal distorted square-based pyramidal (TBDSBP) CuN_4N' chromophore of **3** is the lowest value found in the five-coordinated bis(dpyam)copper(II) complexes known to date. Most close geometries are the chromophores of $[Cu(dpyam)_2(NCS)]^+$ cation ($\tau = 0.18$) [33], $[Cu(dpyam)_2Cl]Cl\cdot 4H_2O$ ($\tau = 0.25$) [30], $[Cu(dpyam)_2(NCO)]_2(SO_4)(dpyam)_2\cdot H_2O$ ($\tau = 0.30$) [28] and $[Cu(dpyam)_2Cl]_2I_2\cdot 2CH_3CN$ ($\tau = 0.32$) [29]. The geometry of the last compound should be TBDSBP rather than distorted trigonal bipyramidal as previously reported [29]. In the corresponding compounds $[Cu(dpyam)_2Cl]Cl$ ($\tau = 0.57$) [32] and $[Cu(dpyam)_2I]_2I(ClO_4)$ ($\tau = 0.63$ and 0.65) [31] the trigonal bipyramidal geometry is considerably more pronounced, giving the square-based pyramidal distorted trigonal bipyramidal (SBPDTB) stereochemistry. There is a substantial number of monomeric five-coordinated $[Cu(bpy \text{ or } phen)_2X]^+$ complexes with coordination geometries ranging from TBDSBP ($\tau = 0.19$–0.22) to SBPDTB ($\tau = 0.56$–0.80) and to near regular trigonal bipyramidal (RTB) ($\tau > 0.80$–1.00) [25]. These series of cation distortion isomers have been used to suggest a structural pathway from a RTB ($\tau = 1.0$) to distorted square-based pyramidal ($\tau = 0.0$) stereochemistry [25] and suggest that **3** forms a point in a most extensive ($\tau = 0.13$) structural pathway for the CuN_4N' chromophore.

Most of the complexes of the bpy or phen ligand mentioned above have geometries ranging from SBPDTB to near RTB ($\tau \approx 0.6$–1.0). Only two complexes have very close to TBDSBP geometry, namely, $[Cu(phen)_2Cl](BPh_4)$ ($\tau = 0.19$) [25b] and $[Cu(phen)_2Br](BPh_4)$ ($\tau = 0.22$) [25d]. The more closely related CuN_4N' chromophores from these complexes also involve the above geometric range, e.g. $[Cu(bpy)_2(NCS)](NO_3)$ ($\tau = 0.89$) [45], $[Cu(bpy)_2(NCS)](NCS)$ ($\tau = 0.65$) [46], $[Cu(bpy)_2(NCS)](BF_4)$ ($\tau = 0.61$) [47], $[Cu(bpy)_2(NH_3)](BF_4)_2$ ($\tau = 0.77$) [48] and $[Cu(phen)_2(NCS)](ClO_4)$ ($\tau = 0.81$) [26a]. It thus appears that the near RSBP and TBDSBP geometries may be better attained with di-2-pyridylamine as ligands.

3.4. Structure of $[Cu(dpyam)_2(SCN)_2]$ (4)

The complex **4** involves an elongated centrosymmetric octahedral geometry of the six-coordinate CuN_4S_2 chromophore of a neutral $[Cu(dpyam)_2(SCN)_2]$ unit. The copper ion is equatorially bonded to two bidentate dpyam ligands [Cu–N = 2.020(1) and 2.036(1) Å] and axially, weakly bonded to the thiocyanato group (S-bonded) [Cu–S = 2.944(1) Å] giving an elongated tetragonal octahedral stereochemistry with the tetragonality (T = mean in-plane Cu–N distance/mean out-of-plane Cu–S distance) of 0.69. The basal CuN_4 plane is exactly planar, attributed to the large dihedral angle of 41.8(1)° between the pyridine rings of the dpyam ligand. The N–Cu–N bite angle of the dpyam ligands is 86.2(1)°.

The coordination chemistry of the thiocyanato group (S-bonded) in the six-coordinate complex **4** differs from those of the five-coordinate complexes $[Cu(bpy)_2(NCS)]Y$, $Y = SCN^-$ [46], NO_3^- [45] and BF_4^- [47], $[Cu(phen)_2(NCS)](ClO_4)$ [26a], $[Cu(dpyam)_2(NCO)](SO_4)_{0.5}\cdot dpyam\cdot(H_2O)_{0.5}$ [28] and the present complex **3**, involving the isothiocyanato or isocyanato coordination (N-bonded). The five-coordinate and six-coordinate complex units, $[Cu(dpyam)_2(NCS)]^+$ and $[Cu(dpyam)_2(NCS)_2]$, respectively, of the compound $[Cu(dpyam)_2(NCS)_{1.5}(ClO_4)_{0.5}][Cu(dpyam)_2(NCS)]_2(ClO_4)_2$ [33] also involve the N-bonded isothiocyanato group. Hence, complex **4** is rare example involving the S-bonded SCN^- group as in general, Class A metals (first transition series) form M–N bonds, whereas Class B metals form M–S bonds [23,24,25a,25b]. This could be understood as the S-bonded coordination mode in **4** give rises to the N–H···N (NCS) hydrogen bonds in order to stabilize the crystal structure.

The elongated centrosymmetric octahedral geometry found in **4** ($T = 0.69$) has also been observed in the $[Cu(dpa)_2]X_2$ (X = *O*-tricyanoethyleneoate) [49], $[Cu(dpyam)_2(NCS)_2]$ ($T = 0.83$) [33] and $[Cu(dpyam)_2(OH_2)_2](PF_6)_2$ ($T = 0.82$) [27a] complex units and complexes $[Cu(dpyam)_2(NO_3)_2]$ ($T = 0.81$) [33], $[Cu(dpyam)_2(Br)_2]\cdot 2H_2O$ ($T = 0.65$) [29] and $[Cu(dpyam)_2(OH_2)_2](SO_4)\cdot 7H_2O$ ($T = 0.81, 0.82$) [50]. The complexes $[Cu(dpyam)_2(CF_3SO_3)_2]$ ($T = 0.81$) [27a] and $[Cu(dpyam)_2(OH_2)_2](S_4O_6)$ ($T = 0.82$) [27a], which are although not centrosymmetric, also have structures similar to the above complexes. The equatorial Cu–N distances in these complexes range from 1.983 to 2.047 Å. The planar equatorial CuN_4 plane is only possible because of the flexibility of the dpyam ligands. This results in a great range of values of the dihedral angles between the pyridine rings, which are comparable for all complexes (35.6°–46.5°). The N–Cu–N bite angles within these complexes are also comparable (85.3°–86.4°). An analogous coordination geometry has not been found in complexes with the less flexible bpy and phen ligands. Complexes $[Cu(bpy)_2(O_2ClO_2)](ClO_4)$ [50] and $[Cu(bpy)_2(F_2BF_2)](BF_4)$ [50] although involving the six-coordinated elongated octahedral chain structure are not centrosymmetric and involve a strong tetrahedral distortion (dihedral angles = 37.9° and 44.6°, respectively). The coordination geometries in $[Cu(bpy)_2(NO_3)](NO_3)\cdot H_2O$ [51] and $[Cu(phen)_2Br]Br\cdot 2H_2O$ [52] are totally different from those of the closely related dpyam complexes $[Cu(dpyam)_2(NO_3)_2]$ [33] and $[Cu(dpyam)_2Br_2]\cdot 2H_2O$ [29], respectively. The former involves a distorted bicapped square pyramidal geometry of the CuN_4OO' chromophore with a marked asymmetric bidentate coordination of the nitrato group while the latter involves the five-coordinate CuN_4Br complex of the near RTB geometry with a slight distortion towards the square-based pyramidal geometry ($\tau = 0.87$). Hence, the analogous coordination geometry has not been found in complexes with the less flexible bpy or phen ligand. These observations demonstrate a noticeable difference between the chelate functions of bpy or phen and the more flexible dpyam ligand.

3.5. ESR spectra

The polycrystalline ESR spectrum of **3** is axial with $g_{//} \gg g_{\perp} > 2.0 = 2.310 \gg 2.054 > 2.0$, consistent with a $d_{x^2-y^2}$ ground state for the distorted square-based pyramidal geometry of the CuN_4N' chromophore [21]. This type of ESR spectrum is similar to those of **1**, **2** and **4** which also are of the axial type, consistent with a $d_{x^2-y^2}$ ground state for the tetrahedrally-distorted elongated tetragonal octahedral geometry with off-the-*z*-axis coordination in the axial positions of **1** and the elongated tetragonal octahedral stereochemistry of **2** and **4**.

3.6. Electronic and IR spectra

The significant crystallographic differences between **1** and **5** are reflected in their color (bright green for **1** and dark green for **5**) and their electronic spectra. The electronic reflectance spectra of **1** and **5** involve a broad peak ranging from 11 500 to 13 500 cm^{-1} (centered at ca. 12 500 cm^{-1}) for **1** and 13 300 to 14 400 cm^{-1} (centered at ca. 13 890 cm^{-1}) for **5**. The lower frequencies in electronic spectrum of **1** are consistent with the higher tetrahedral twist of the equatorial plane in **1** compared with **5** [7]. The most relevant feature of the IR spectra in complexes **1** and **2** is the evidence for the coordination of the nitrite and sulfate anions, respectively. As some interest regions are obscured by absorption peaks deriving from dpyam, the precise assignment, which we have usually made, is by comparison with the prepared $[Cu(dpyam)_2Cl]Cl$ complex. The IR spectrum of **1** shows two strong bands at 1370 and 1140 cm^{-1} and a medium peak at 860 cm^{-1} corresponding to the $\nu_{as}(NO_2)$, $\nu_s(NO_2)$ and $\delta(NO_2)$ absorption bands, respectively [1,7,53]. The latter appears to be superimposed on a weak intensity dpyam peak. The IR spectrum of the present batch of **5** has peaks at 1365, 1180 and 860 cm^{-1} for $\nu_{as}(NO_2)$, $\nu_s(NO_2)$ and $\delta(NO_2)$, respectively [7] in which the latter two peaks are superimposed on the lower intensity dpyam peaks.

The light green complex **2** exhibits a single broad band at 13 700 cm^{-1} with a poorly resolved shoulder at 10 260 cm^{-1}. The local molecular geometry around the copper(II) ion in **2** is very comparable to that of the relevant polymeric chain complex, $[Cu(dpyam)(NO_3)_2]$ involving the monovalent nitrate oxyanions [10], but with a higher tetrahedral twist (15.8° in **2**) than the dinitrate complex (7.0° and 3.8° for both units). Consequently, complex **2** exhibits lower energies in the electronic spectrum than the dinitrate complex. The higher tetrahedral twist of the basal planes results in the smaller dihedral angle between the pyridine rings [3.5° in **2**, and 10.0° and 6.1° in the dinitrate complex]. The IR spectrum of **2** shows a strong band (ν_3) splitting into 1160, 1140 and 1115 cm^{-1} and a medium band (ν_4) at 619 cm^{-1} attributed to the coordinated sulfate group [1,19].

The polycrystalline electronic reflectance spectrum of **3** shows a high-energy peak at 15 740 cm^{-1}, with a low-energy peak at lower intensity at 10 660 cm^{-1}, consistent with the near RSBP with a slight trigonal distortion of **3** ($\tau = 0.13$) [25], and similar to that of the closely related CuN_4N' chromophore in $[Cu(dpyam)_2(NCO)]_2(SO_4)\cdot(dpyam)_2\cdot H_2O$ (14 230 and 10 630 cm^{-1}) ($\tau = 0.30$) [28]. The IR spectrum of **3** shows a strong band ($\nu_{as}(CN)$) splitting into three bands at 2100, 2080 and 2055 cm^{-1}, several weak bands ($\nu_s(CS)$) at 820, 795, 745 cm^{-1} and several weak bands ($\delta(NCS)$) at 485, 475 and 470 cm^{-1}. The splitting into several peaks of the

frequencies in **3** could imply two distinct crystallographic sites of a coordinated isothiocyanate group and a free thiocyanate anion. The bands at 2055(ν_{as}(CN)), 745(ν_s(CS)) and 485(δ(NCS)) cm^{-1} may be attributed to the free ligand [43a]. However, the ν_s(CS) and δ(NCS) bands are rather weak and some are partially obscured by the presence of the dpyam ligand in the same region. Hence the ν_{as}(CN) frequencies are used as a criteria to determine the bonding type of the SCN^- group, which are generally lower in N-bonded complexes than S-bonded complexes [43a].

The electronic spectrum of **4** involves an asymmetric broad peak occurring at 16 700 cm^{-1} with some evidence for a possible low-energy shoulder at approximately 14 080 cm^{-1}, consistent with its stereochemistry, and similar to those of the comparable structures in $[Cu(dpyam)_2X_2]$, $X = Br^- \cdot 2H_2O$ (17 200 cm^{-1}) [27b], $CF_3SO_3^-$ (18 120, 15 430(sh) cm^{-1}) [27a], NO_3^- (17 870, 14 700(sh) cm^{-1}) [24,27b]. That of the most similar complex $[Cu(dpyam)_2Br_2]\cdot 2H_2O$ (**6**) prepared in the present work also shows an asymmetric broad peak at 16 790 cm^{-1} with some evidence for a low-energy shoulder at approximately 14 170 cm^{-1}. The suggested one-electron ground state configuration is $d_{x^2-y^2} > d_{z^2} > d_{xy} > d_{xz} \approx d_{yz}$ for the complexes. For complexes **2**–**4**, the transitions may be assigned as the $d_{z^2} \rightarrow d_{x^2-y^2}$ transition for the low-energy peak and the d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ transition for the high-energy peak, with the position of the $d_{xy} \rightarrow d_{x^2-y^2}$ transition being uncertain. The single broad peak in **1** may be assigned as the d_{z^2}, d_{xy}, d_{xz}, $d_{yz} \rightarrow d_{x^2-y^2}$ transition. The IR spectrum of **4** appears as a strong band (ν_{as}(CN)) splitting into two peaks at 2140 and 2110 cm^{-1} and two weak bands at approximately 810–790 (ν_s(CS)) and 470 (δ(NCS)) cm^{-1}, corresponding to the S-bonded thiocyanato groups in **4**.

While this paper was accepted, we noted that the structure of $[Cu(dpyam)_2(SCN)_2]$ (**4**) has been published as a short communication in *Acta Chem. Scand.* (1999) 53, 634. This is to indicate the duplication of the structure **4**.

4. Supplementary material

Crystallographic data for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication no. CCDC No. 168990, 168991, 169167 and 169168 for structures **1**–**4**, respectively. Copies of the data can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk www: http://www.ccdc.cam.ac.uk).

Abstract

A series of Ag(I) complexes, [Ag(X)L], where X is the anion of 2,2,6,6-tetramethyl-3,5-heptanedione (tmhdH), 2,2,7-trimethyl-3,5-octanedione (tmodH), 2-sila-2,2,6,6-tetramethyl-3,5- heptanedione (tmshdH), 5-mercapto-2,2,6,6-tetramethyl-4-hepten-3-one (*S*-tmhdH), 5-mercapto-2,2,7-trimethyl-4-octen-3-one (*S*-tmodH), or 5-amino-2,2,6,6-tetramethyl-4-hepten-3-one (*N*-tmhdH) and L = triphenylphosphine (PPh_3) or tri-*n*-butylphosphine (PBu_3), were prepared by treatment of silver nitrate with either the diketone derivative in the presence of a base or with the preformed sodium salt of the diketone derivative. The thermal properties of the new complexes were investigated for potential application in chemical vapor deposition (CVD) processes. Results of thermogravimetric analysis showed that the vast majority of the silver complexes have little promise for CVD, since the ligands dissociate at elevated temperatures without volatilization. The first ever reported single crystal X-ray diffraction studies of silver complexes, with simple, ancillary, non-fluorinated β-diketonate supporting ligands, revealed [Ag(tmhd)(PPh_3)] (**1a**) to be monomeric and [Ag(*S*-tmhd)(PPh_3)]$_2$ (**4a**) to be dimeric in the solid state, respectively. © 2002 Elsevier Science Ltd. Keywords: Silver(I) complexes; Non-fluorinated β-diketonate ligands; Monothio-β-ketonate; β-Ketoiminate; Chemical vapor deposition; Crystal structures

1. Introduction

Currently, there is ongoing interest in the search for electroluminescent materials. Applications range from lighting appliances, such as fluorescent tubes, to display apparatus such as cathode ray tubes or projection television [1]. One of the most rapidly advancing and growing areas is the development of thin film electroluminescent displays. Inorganic phosphor materials currently are widely used in these applications, while research on organic phosphors is ongoing [2]. The most commonly employed phosphor, the ZnS–Mn with SrS–Ce combination, generates red and green output by filtering the yellow emission from the ZnS–Mn couple while the SrS–Ce couple provides a bluish green light [3]. Unfortunately, the SrS–Ce couple is only a weak blue emitter and as such, a need remains for the development of brighter blue sources. Recent work suggests SrS–Cu is a suitable alternative, with a good blue emission with CIE color coordinates of $x = 0.15$ and $y = 0.23$ [3,4]. Codoping of the SrS–Cu couple with Ag gave an even truer blue color with $CIE_x = 0.17$, $CIE_y = 0.13$ [3,5]. However, the strategy for silver doping is currently limited by a lack of suitable volatile silver-containing precursors.

One of the techniques for preparation of thin films of these phosphors is metallo-organic chemical vapor deposition (MOCVD). As such, precursor volatility and stability are important issues for doping strategy. Research on the preparation of stable, yet volatile, complexes is central to the development of new, more efficient MOCVD precursors.

β-Diketonates and allied derivatives are among the most common ancillary ligand types for the preparation

of MOCVD precursors. Structural variations of the supporting β-diketonate ligand can impart desired chemical and physical properties to the precursor complex as well as modulate the volatility. Introduction of a second, supporting ligand in a ternary complex can have complementary effects, while improving the stability of the complex. Combination of both strategies clearly can lead to highly desirable enhancements in performance for MOCVD.

Previously, the preparation of silver β-diketonate complexes for use in MOCVD have focused on fluorinated β-diketonate ligands, such as hfac (anion of 1,1,1,5,5,5-hexafluoro-2,4-pentanedione) and fod (anion of 2,2-dimethyl-6,6,7,7,8,8,8-heptafluoro-3,5-octanedione) [6]. While these ligands impart volatility to the Ag complexes, a crucial property for applications in MOCVD, fluoride ion contamination in the resultant films is frequently observed. The initial aim of the present study was to investigate alternatives to the use of fluorinated silver β-diketonates for MOCVD applications. Although there were some previous studies that indicated that silver complexes containing non-fluorinated β-diketonate ligands had limited volatility [7], we decided to explore a much wider range of structural alterations to the β-diketonate backbone, including unsymmetrically substituted ligands, as well as those in which silylated substituents were incorporated or in which an oxygen donor atom was replaced by sulfur [8] or imino nitrogen [9]. The replacement of one of the oxygen donor atoms of the β-diketonate was investigated, since such ancillary ligands might facilitate reduction of oxygen contamination, which accompanies the MOCVD processing of silver β-diketonates. We report here the synthesis and physical characterization of a series of binary and ternary silver complexes, [Ag(X)] and [Ag(X)L], where X is the anion of 2,2,6,6-tetramethyl-3,5-heptanedione (tmhdH), 2,2,7-trimethyl-3,5-octanedione (tmodH), 2,2,6,6-tetramethyl-2-sila-3,5-heptanedione (tmshdH), 5-mercapto-2,2,6,6-tetramethyl-4-hepten-3-one (*S*-tmhdH), 5-mercapto-2,2,7-trimethyl-4-octen-3-one (*S*-tmodH), or 5-amino-2,2,6,6-tetramethyl-4-hepten-3-one (*N*-tmhdH) and L is triphenylphosphine (PPh_3) or tri-*n*-butylphosphine (PBu_3). We also present structural results on the first two non-fluorinated β-diketonate silver complexes characterized by single crystal X-ray diffraction.

2. Experimental

2.1. Materials and physical measurements

Unless otherwise noted, all experiments were performed under an inert atmosphere of nitrogen utilizing standard Schlenk techniques or in a Vacuum Atmospheres drybox filled with nitrogen. Reagents and solvents obtained commercially were of reagent grade and used as received unless otherwise noted. Tetrahydrofuran (thf), toluene, and anhydrous diethyl ether (Et_2O) were distilled from sodium–benzophenone ketyl under nitrogen. Pentane and hexane were distilled from sodium–benzophenone–diglyme under nitrogen. The β-diketone tmshdH was prepared according to our procedure [10], while tmodH was made analogously by condensing 3-methylbutyryl chloride with pinacolone in the presence of lithium diisopropylamide. The heteroatom substituted β-diketone derivatives, *S*-tmhd [8], *S*-tmod [8], and *N*-tmhd [9] were prepared by literature procedures. The sodium salts of the β-diketonate compounds were prepared by modification of the literature procedure for Na(hfac) [11].

^1H, ^{13}C, and ^{19}F NMR spectra were recorded on a Gemini-300 MHz NMR spectrometer at 300, 75.46, and 282.3 MHz, respectively. TGA data were obtained on a TA Instrument TGA 2050 Thermogravimetric Analyzer. Sample sizes were 1–3 mg. The ramp rate was 5.0° min^{-1} and the nitrogen purge rate was 100 cm^3 min^{-1}. Elemental analyses were performed by MHW Laboratories.

2.2. [Ag(tmhd)] (**1**)

This complex was prepared following a slight modification of the literature procedure [12]. Under an inert atmosphere, a stirring slurry of $AgNO_3$ (0.42 g, 2.5 mmol) in acetonitrile (0.14 ml) and methanol (5 ml) was cooled to 0 °C. To this slurry was added a solution of tmhdH (0.55 ml, 2.6 mmol) and triethylamine (0.35 ml, 2.5 mmol) in methanol (5 ml). The mixture was stirred at 0 °C for 1 h and then filtered quickly. The white-colored silver complex was washed with methanol and dried in vacuo. Yield: 0.40 g (55%). *Anal.* Calc. for $C_{11}H_{19}AgO_2$: C, 45.38; H, 6.58. Found: C, 45.52; H, 6.39%. ^1H NMR (C_6D_6): δ 5.71 (s, 1H, C(O)C*H*C(O)), 1.06 (s, 18H, ^tBu–CH_3). ^{13}C NMR (C_6D_6): δ 201.6 (*C*=O), 90.7 (C(O)*C*HC(O)), 39.4 (*C*(CH_3)$_3$), 27.4 (C(*C*H_3)$_3$).

2.3. [Ag(tmhd)(PPh_3)] (**1a**) (method A)

A stirred slurry of **1** (0.21 g, 0.72 mmol) and triphenylphosphine (0.19 g, 0.71 mmol) in toluene (10 ml) was cooled to 0 °C. The mixture was stirred at 0 °C for 1 h giving a clear solution. Removal of the solvent in vacuo afforded the silver complex as an off-white solid. Yield: 0.33 g (83%). *Anal.* Calc. for $C_{29}H_{34}AgO_2P$: C, 62.94; H, 6.19. Found: C, 62.78; H, 6.09%. ^1H NMR (C_6D_6): δ 7.28–6.88 (m, 15H, C_6H_5), 6.06 (s, 1H, C(O)C*H*C(O)), 1.49 (s, 18H, ^tBu–CH_3). ^{13}C NMR (C_6D_6): δ 200.4 (*C*=O), 134.3 (d, $^2J_{CP} = 17.0$ Hz, *o*-*C* Ph), 132.1 (d, $^1J_{CP} = 35.8$ Hz, *ipso*-*C* Ph), 130.4 (*p*-*C*

Ph), 129.0 ($^3J_{CP} = 10.4$ Hz, *m-C* Ph), 88.5 (C(O)*C*HC(O)), 42.4 (*C*(CH_3)$_3$), 29.4 (C(*C*H_3)$_3$).

2.4. [Ag(tmhd)(PPh$_3$)] (**1a**) (method B)

Na(tmhd) (0.45 g, 2.2 mmol) was dissolved in Et_2O (15 ml) and added to a stirred slurry of $AgNO_3$ (0.37 g, 2.2 mmol) and triphenylphosphine (0.57 g, 2.2 mmol) in Et_2O (15 ml). The mixture was allowed to react for 24 h forming a gray slurry. The volatile components were removed in vacuo affording the crude product. Extraction with toluene (2 × 20 ml), followed by filtration and evaporation in vacuo, gave the silver complex as a white solid. Yield: 1.2 g (56%). The ^{1}H NMR spectrum of the product was identical to that formed via Method A.

2.5. [Ag(tmhd)(PBu$_3$)] (**1b**)

Tri-*n*-butylphosphine (1.0 ml, 4.0 mmol) was added to a stirred slurry of **1** (1.2 g, 4.0 mmol) in toluene (45 ml) at 0 °C. The mixture was stirred at 0 °C for 1 h giving a red–brown solution. Removal of the toluene in vacuo afforded the silver complex as a reddish brown oily liquid. Yield: 1.8 g (93%). *Anal.* Calc. for $C_{23}H_{46}AgO_2P$: C, 55.98; H, 9.40. Found: C, 55.82; H, 9.29%. ^{1}H NMR (C_6D_6): δ 5.82 (s, 1H, C(O)C*H*C(O)), 1.42 (s, 18H, ^{t}Bu–CH_3), 1.32–1.22 (m, 18H, PCH_2CH_2-CH_2CH$_3$), 0.88 (t, 9H, $^3J_{HH} = 6.9$ Hz, PCH$_2$CH$_2$CH$_2$-CH_3). ^{13}C NMR (C_6D_6): δ 198.9 (*C*=O), 87.2 (C(O)*C*HC(O)), 42.1 (*C*(CH_3)$_3$), 29.5 (C(*C*H_3)$_3$), 27.9 (d, $^3J_{CP} = 6.0$ Hz, PCH$_2$CH$_2$*C*H$_2$CH$_3$), 25.9 (d, $^1J_{CP} =$ 14.8 Hz, P*C*H$_2$CH$_2$CH$_2$CH$_3$), 24.7 (d, $^2J_{CP} = 13.8$ Hz, PCH$_2$*C*H$_2$CH$_2$CH$_3$), 14.0 (PCH$_2$CH$_2$CH$_2$*C*H$_3$).

2.6. [Ag(tmod)] (**2**)

This complex was prepared using a similar procedure as that for **1**, starting with $AgNO_3$ (0.51 g, 3.0 mmol) and tmodH (0.59 g, 3.2 mmol). Yield of white solid: 0.57 g (66%). *Anal.* Calc. for $C_{11}H_{19}AgO_2$: C, 45.38; H, 6.58. Found: C, 45.58; H, 6.54%. ^{1}H NMR (C_6D_6): δ 5.43 (s, 1H, C(O)C*H*C(O)), 2.12–1.96 (m, 1H, ^{i}Bu–C*H*), 1.93 (s, 1H, ^{i}Bu–CH_2), 1.91 (br s, 1H, ^{i}Bu–CH_2), 1.05 (s, 9H, ^{t}Bu–CH_3), 0.80 (d, 6H, $^3J_{HH} = 6.6$ Hz, ^{i}Bu–CH_3). ^{13}C (C_6D_6): δ 201.1 (*C*=O), 194.1 (*C*=O), 95.9 (C(O)*C*HC(O)), 47.7 (^{i}Bu–*C*H$_2$), 39.3 (*C*(CH_3)$_3$), 27.3 (C(*C*H_3)$_3$), 26.2 (^{i}Bu–*C*H), 22.5 (^{i}Bu–*C*H$_3$).

2.7. [Ag(tmod)(PPh$_3$)] (**2a**)

This complex was prepared by a similar method to that for the preparation of **1a** (Method A). Triphenylphosphine (0.12 g, 0.46 mmol) was added to a stirred slurry of **2** (0.13 g, 0.46 mmol) in toluene (15 ml) at 0 °C. The mixture was stirred at 0 °C for 1 h, after which the toluene was removed in vacuo. Trituration of the oily residue with pentane gave the silver complex as a gray solid. Yield: 0.20 g (79%). *Anal.* Calc. for $C_{29}H_{34}AgO_2P$: C, 62.94; H, 6.19. Found: C, 62.77; H, 6.24%. ^{1}H NMR (C_6D_6): δ 7.28–6.86 (m, 15H, C_6H_5), 5.82 (s, 1H, C(O)C*H*C(O)), 2.60–2.45 (m, 1H, ^{i}Bu–C*H*), 2.41 (br s, 2H, ^{i}Bu–CH_2), 1.47 (s, 9H, ^{t}Bu–CH_3), 1.12 (d, 6H, $^3J_{HH} = 6.0$ Hz, ^{i}Bu–CH_3). ^{13}C NMR (C_6D_6): δ 199.9 (*C*=O), 194.1 (*C*=O), 134.3 (d, $^2J_{CP} = 16.9$ Hz, *o-C* Ph), 131.9 (d, $^1J_{CP} = 36.8$ Hz, *ipso-C* Ph), 130.5 (d, $^4J_{CP} = 1.9$ Hz, *p-C* Ph), 129.0 (d, $^3J_{CP} = 10.7$ Hz, *m-C* Ph), 94.3 (C(O)*C*HC(O)), 53.2 (^{i}Bu–*C*H$_2$), 41.9 (*C*(CH_3)$_3$), 29.3 (C(*C*H_3)$_3$), 27.2 (^{i}Bu–*C*H), 23.3 (^{i}Bu–*C*H$_3$).

2.8. [Ag(tmod)(PBu$_3$)] (**2b**)

This complex was prepared by a similar method to that for **1b**, instead utilizing tri-*n*-butylphosphine (0.11 ml, 0.42 mmol) and **2** (0.13 g, 0.46 mmol). Yield of reddish–black oily liquid: 0.20 g (97%). *Anal.* Calc. for $C_{23}H_{46}AgO_2P$: C, 55.98; H, 9.40. Found: C, 56.12; H, 9.30%. ^{1}H NMR (C_6D_6): δ 5.66 (s, 1H, C(O)C*H*C(O)), 2.51–2.36 (m, 1H, ^{i}Bu–C*H*,), 2.29 (br s, 2H, ^{i}Bu–CH_2), 1.38 (s, 9H, ^{t}Bu–CH_3), 1.21–1.01 (complex, 24H, PCH_2CH_2CH_2CH$_3$ and ^{i}Bu–CH_3), 0.80 (t, 9H, $^3J_{HH} = 6.9$ Hz, PCH$_2$CH$_2$CH$_2$CH_3). ^{13}C NMR (C_6D_6): 199.3 (*C*=O), 193.5 (*C*=O), 93.9 (C(O)*C*HC(O)), 53.1 (^{i}Bu–*C*H$_2$), 41.6 (*C*(CH_3)$_3$), 29.2 (C(*C*H_3)$_3$), 27.9 (d, $^3J_{CP} = 5.6$ Hz, PCH$_2$CH$_2$*C*H$_2$CH$_3$), 27.1 (^{i}Bu–*C*H), 25.7 (d, $^1J_{CP} = 18.4$ Hz, P*C*H$_2$CH$_2$CH$_2$CH$_3$), 24.4 (d, $^2J_{CP} = 14.2$ Hz, PCH$_2$*C*H$_2$CH$_2$CH$_3$), 23.3 (^{i}Bu–*C*H$_3$), 13.8 (PCH$_2$CH$_2$CH$_2$*C*H$_3$).

2.9. [Ag(tmshd)] (**3**)

A mixture of $AgNO_3$ (0.92 g, 5.4 mmol) in CH_3CN (0.5 ml) and CH_3OH (11 ml) at 0 °C was transferred by cannula to a cooled flask containing a stirring mixture of tmshdH (1.15 g, 5.7 mmol), triethylamine (0.8 ml, 5.7 mmol), and CH_3OH (11 ml) at 0 °C. Immediate formation of white precipitate was observed. The mixture was stirred at 0 °C for an hour, filtered and the precipitates washed with minute amounts of cold CH_3OH. The pale colored precipitates darkened over time even at −25 °C and were used immediately for the preparation of the ternary complex **3a**. Yield: 0.33 g (20%).

2.10. [Ag(tmshd)(PPh$_3$)] (**3a**)

A mixture of **3** (0.14 g, 0.46 mmol) and triphenylphosphine (0.12 g, 0.46 mmol) in Et_2O (30 ml) was stirred at 0 °C for 3 h. Removal of the solvent at 0 °C gave a light brown powder. Yield: 0.25 g (95%). *Anal.* Calc. for $C_{28}H_{34}AgO_2PSi$: C, 59.05; H, 6.02. Found: C, 59.27; H, 5.99%. ^{1}H NMR ($CDCl_3$): δ 7.50–7.34 (m, 15H, C_6H_5),

5.80 (s, 1H, C(O)C*H*C(O)), 1.16 (s, 9H, ^{t}Bu–CH_3), 0.17 (s, 9H, Si–CH_3).

2.11. [Ag(S-tmhd)] (4)

A yellow slurry of $AgNO_3$ (0.26 g, 1.5 mmol) and Na(*S*-tmhd) (0.34 g, 1.5 mmol) in thf (20 ml) was stirred for 24 h giving a dark gray mixture. The solvent was removed in vacuo and the residue extracted with toluene (20 ml). Filtration and removal of all volatiles in vacuo gave the silver complex as a yellow brown solid. Yield: 0.38 g (81%). *Anal.* Calc. for $C_{11}H_{19}AgOS$: C, 43.01; H, 6.23. Found: C, 42.91; H, 6.02%. ^{1}H NMR ($CDCl_3$): δ 6.74 (s, 1H, C(O)C*H*C(S)), 1.31 (s, 9H, ^{t}Bu–CH_3), 1.10 (s, 9H, ^{t}Bu–CH_3). ^{13}C NMR ($CDCl_3$): δ 206.9 (*C*=O), 173.5 (*C*=S), 118.2 (C(O)*C*HC(S)), 44.7 (*C*$(CH_3)_3$), 42. (*C*$(CH_3)_3$), 31.0 (C(*C*$H_3)_3$), 27.2 (C(*C*$H_3)_3$).

2.12. [Ag(S-tmhd)(PPh$_3$)] (4a)

A slurry of $AgNO_3$ (0.26 g, 1.5 mmol), Na(*S*-tmhd) (0.33 g, 1.5 mmol) and triphenylphosphine (0.39 g, 1.5 mmol) in thf (20 ml) was stirred for 44 h giving a lemon yellow slurry. The solvent was removed in vacuo and the residue extracted with toluene (25 ml). Filtration and removal of all volatiles in vacuo gave the silver complex as a lemon yellow solid. Yield: 0.61 g (72%). *Anal.* Calc. for $C_{29}H_{34}AgOPS$: C, 61.16; H, 6.02. Found: C, 61.32; H, 6.15%. ^{1}H NMR ($CDCl_3$): δ 7.60–7.30 (m, 15H, C_6H_5), 6.85 (s, 1H, C(O)C*H*C(S)), 1.36 (s, 9H, ^{t}Bu–CH_3), 1.14 (s, 9H, ^{t}Bu–CH_3). ^{13}C NMR ($CDCl_3$): δ 205.5 (*C*=O), 134.1 (d, $^2J_{CP} = 16.6$ Hz, *o*-*C* Ph), 131.4 (d, $^1J_{CP} = 34.6$ Hz, *ipso*-*C* Ph), 130.6 (d, $^4J_{CP} = 1.9$ Hz, *p*-*C* Ph), 128.9 (d, $^3J_{CP} = 10.4$ Hz, *m*-*C* Ph), 113.6 (C(O)*C*HC(S)), 44.5 (*C*$(CH_3)_3$), 44.4 (*C*$(CH_3)_3$), 31.5 (C(*C*$H_3)_3$), 27.7 (C(*C*$H_3)_3$).

2.13. [Ag(S-tmhd)(PBu$_3$)] (4b)

A mixture of $AgNO_3$ (0.20 g, 1.2 mmol), Na(*S*-tmhd) (0.26 g, 1.2 mmol) and tri-*n*-butylphosphine (0.30 g, 1.1 mmol) in thf (20 ml) was stirred for 24 h giving a yellow mixture. The solvent was removed in vacuo and the residue extracted with toluene (20 ml). Filtration and removal of all volatiles in vacuo gave the silver complex as a yellow brown oil. Yield: 0.56 g (96%). *Anal.* Calc. for $C_{23}H_{46}AgOPS$: C, 54.22; H, 9.10. Found: C, 54.42; H, 8.86%. ^{1}H NMR ($CDCl_3$): δ 6.74 (s, 1H, C(O)C*H*C(S)), 1.61–1.32 (complex, 18H, PCH_2CH_2-CH_2CH$_3$), 1.29 (s, 9H, ^{t}Bu–CH_3), 1.07 (s, 9H, ^{t}Bu–CH_3), 0.85 (t, 9H, $^3J_{HH} = 7.2$ Hz, PCH$_2$CH$_2$CH$_2$CH_3). ^{13}C NMR ($CDCl_3$): δ 204.8 (*C*=O), 185.0 (*C*=S), 113.4 (C(O)*C*HC(S)), 43.7 (*C*$(CH_3)_3$), 43.5 (*C*$(CH_3)_3$), 30.8 (C(*C*$H_3)_3$), 27.2 (d, $^3J_{CP} = 5.6$ Hz, PCH$_2$CH$_2$*C*H$_2$CH$_3$), 27.1 (C(*C*$H_3)_3$), 24.8 (d, $^1J_{CP} = 18.8$ Hz, P*C*H$_2$CH$_2$-CH$_2$CH$_3$), 23.7 (d, $^2J_{CP} = 14.3$ Hz, PCH$_2$*C*H$_2$CH$_2$CH$_3$), 13.1 (PCH$_2$CH$_2$CH$_2$*C*H$_3$).

2.14. [Ag(S-tmod)] (5)

This complex was prepared by the same method as for **4**, instead using $AgNO_3$ (0.26 g, 1.5 mmol) and Na(*S*-tmod) (0.34 g, 1.53 mmol). Yield of dark yellow brown product: 0.36 g (76%). *Anal.* Calc. for $C_{11}H_{19}AgOS$: C, 43.01; H, 6.23. Found: C, 43.18; H, 6.03%. ^{1}H NMR ($CDCl_3$): δ 6.48 (s, 1H, C(O)C*H*C(S)), 2.34 (s, 1H, ^{i}Bu–CH_2), 2.32 (s, 1H, ^{i}Bu–CH_2), 2.24–2.05 (m, 1H, ^{i}Bu–C*H*), 1.09 (s, 9H, ^{t}Bu–CH_3), 0.85 (d, 6H, $^3J_{HH} = 6.3$ Hz, ^{i}Bu–CH_3). ^{13}C NMR ($CDCl_3$): δ 204.8 (*C*=O), 120.7 (C(O)*C*HC(S)), 59.3 (^{i}Bu–*C*H$_2$), 43.6 (*C*$(CH_3)_3$), 27.8 (^{i}Bu–*C*H), 27.0 (C(*C*$H_3)_3$), 22.4 (^{i}Bu–*C*H$_3$).

2.15. [Ag(S-tmod)(PPh$_3$)] (5a)

This complex was prepared analogously to **4a** using $AgNO_3$ (0.26 g, 1.5 mmol), Na(*S*-tmod) (0.33 g, 1.5 mmol) and triphenylphosphine (0.39g, 1.5 mmol). Yield of yellow–brown product: 0.71 g (83%). *Anal.* Calc. for $C_{29}H_{34}AgOPS$: C, 61.16; H, 6.02. Found: C, 61.34; H, 5.87%. ^{1}H NMR ($CDCl_3$): δ 7.46–7.26 (m, 15H, C_6H_5), 6.45 (s, 1H, C(O)C*H*C(S)), 2.33 (bs, 2H, ^{i}Bu–CH_2), 2.27–2.04 (m, 1H, ^{i}Bu–C*H*), 1.01 (s, 9H, ^{t}Bu–CH_3), 0.82 (d, 6H, $^3J_{HH} = 6.3$ Hz, ^{i}Bu–CH_3). ^{13}C NMR ($CDCl_3$): δ 204.6 (*C*=O), 133.9 ($^2J_{CP} = 16.6$ Hz, *o*-*C* Ph), 131.8 (d, $^1J_{CP} = 30.2$ Hz, *ipso*-*C* Ph), 130.3 (*p*-*C* Ph), 128.8 (d, $^3J_{CP} = 10.0$ Hz, *m*-*C* Ph), 117.6 (C(O)*C*HC(S)), 59.7 (^{i}Bu–*C*H$_2$), 43.5 (*C*$(CH_3)_3$), 28.4 (^{i}Bu–*C*H), 27.3 (C(*C*$H_3)_3$), 22.3 (^{i}Bu–*C*H$_3$).

2.16. [Ag(S-tmod)(PBu$_3$)] (5b)

Na(*S*-tmod) (0.26 g, 1.2 mmol) was added to a stirring slurry of $AgNO_3$ (0.20 g, 1.2 mmol) and tri-*n*-butylphosphine (0.30 ml, 1.1 mmol) in thf (20 ml). The reaction mixture was allowed to react for 24 h, resulting in a gray slurry. The volatile components were removed in vacuo affording the crude product. Extraction with toluene (20 ml) followed by filtration and evaporation in vacuo gave the silver complex as an orange brown oily liquid. Yield: 0.42 g (72%). *Anal.* Calc. for $C_{23}H_{46}AgOPS$: C, 54.22; H, 9.10. Found: C, 54.12; H, 9.27%. ^{1}H NMR ($CDCl_3$): δ 6.47 (s, 1H, C(O)C*H*C(S)), 2.33 (s, 1H, ^{i}Bu–CH_2), 2.31 (s, 1H, ^{i}Bu–CH_2), 2.25–2.05 (m 1H, ^{i}Bu–C*H*), 1.60–1.31 (complex, 18H, PCH_2CH_2-CH_2CH$_3$), 1.07 (s, 9H, ^{t}Bu–CH_3), 0.80 (d, 6H, $^3J_{HH} = 6.3$ Hz, ^{i}Bu–CH_2), 0.79 (t, 9H, $^3J_{HH} = 7.2$ Hz, PCH$_2$CH$_2$CH$_2$CH_3). ^{13}C NMR ($CDCl_3$): δ 203.7 (*C*=O), 179.2 (*C*=S), 119.7 (C(O)*C*HC(S)), 59.8 (^{i}Bu–*C*H$_2$), 43.3 (*C*$(CH_3)_3$), 28.7 (^{i}Bu–*C*H), 27.6 (d, $^3J_{CP} = 5.6$ Hz, PCH$_2$CH$_2$*C*H$_2$CH$_3$), 27.4 (C(*C*$H_3)_3$), 25.5 (d, $^1J_{CP} = 13.6$ Hz, P*C*H$_2$CH$_2$CH$_2$CH$_3$), 24.4 (d, $^2J_{CP} = 13.3$ Hz,

$PCH_2CH_2CH_2CH_3$), 22.5 ($^{i}Bu-CH_3$), 13.6 ($PCH_2CH_2CH_2CH_3$).

2.17. [Ag(N-tmhd)(PPh$_3$)] (6a)

A stirring slurry of $AgNO_3$ (0.13 g, 0.77 mmol) and Na(*N*-tmhd) (0.16 g, 0.78 mmol) was dissolved in Et_2O (20 ml). A solution of triphenylphosphine (0.20 g, 0.76 mmol) in Et_2O (40 ml) was added. The reaction mixture was allowed to react for 24 h resulting in a gray slurry. The volatile components were removed in vacuo affording the crude product as a black solid. Extraction with toluene (2×20 ml) followed by filtration and evaporation in vacuo gave the silver complex as a salmon pink colored solid. Yield: 0.24 g (56%). *Anal.* Calc. for $C_{29}H_{35}AgNOP$: C, 63.05; H, 6.39. Found: C, 63.22; H, 6.50%. ^{1}H NMR ($CDCl_3$): δ 7.44–7.16 (m, 15H, C_6H_5), 5.32 (s, 1H, C(O)C*H*C(NH)), 1.14 (s, 9H, $^{t}Bu-CH_3$), 1.12 (s, 9H, $^{t}Bu-CH_3$). ^{13}C NMR ($CDCl_3$): δ 205.3 (*C*=O), 173.5 (*C*=NH), 133.8 (d, $^2J_{CP} = 16.4$ Hz, *o*-*C* Ph), 131.8 (d, $^1J_{CP} = 29.2$ Hz, *ipso*-*C* Ph), 130.1 (*p*-*C* Ph), 128.6 (d, $^3J_{CP} = 9.8$ Hz, *m*-*C* Ph), 86.4 (C(O)*C*HC(NH)), 41.9 ($C(CH_3)_3$), 35.9 ($C(CH_3)_3$), 28.7 ($C(CH_3)_3$), 27.8 ($C(CH_3)_3$).

2.18. [Ag(N-tmhd)(PBu$_3$)] (6b)

A stirred mixture of $AgNO_3$ (0.20 g, 1.18 mmol) and (*N*-tmhd) (0.24 g, 1.18 mmol) was dissolved in thf (10 ml). Tri-*n*-butylphosphine (0.31 ml, 1.18 mmol) was added and the mixture stirred for 18 h. All volatiles were removed from the resulting greenish black mixture. Extraction of the residue with toluene (2×20 ml) followed by filtration and evaporation in vacuo gave the silver complex as a reddish brown oil. Yield: 0.51 g (88%). *Anal.* Calc. for $C_{23}H_{47}AgNOP$: C, 56.10; H, 9.62. Found: C, 55.95; H, 9.49%. ^{1}H NMR ($CDCl_3$): δ 10.2 (br s, 1H, N*H*), 5.18 (s, 1H, C(O)C*H*C(NH)), 1.53–1.21 (complex, 18H, $PCH_2CH_2CH_2CH_3$), 1.04 (s, 9H, $^{t}Bu-CH_3$), 0.98 (s, 9H, $^{t}Bu-CH_3$), 0.75 (t, 9H, $^3J_{HH} = 6.9$ Hz, $PCH_2CH_2CH_2CH_3$). ^{13}C NMR ($CDCl_3$): δ 204.9 (*C*=O), 173.4 (*C*=NH), 86.2 (C(O)*C*HC(NH)), 41.7 ($C(CH_3)_3$), 35.8 ($C(CH_3)_3$), 28.6 ($C(CH_3)_3$), 27.7 ($C(CH_3)_3$), 27.4 (d, $^3J_{CP} = 2.9$ Hz, $PCH_2CH_2CH_2CH_3$), 24.8 (d, $^1J_{CP} = 16.6$ Hz, $PCH_2CH_2CH_2CH_3$), 24.0 (d, $^2J_{CP} = 13.5$ Hz, $PCH_2CH_2CH_2CH_3$), 13.3 ($PCH_2CH_2CH_2CH_3$).

2.19. X-ray crystallography

Crystals of **1a** and **4a** suitable for X-ray diffraction studies were obtained by dissolving the corresponding complex in thf and layering pentane over the solution. The mixture was cooled to -35 °C, while allowing the pentane to diffuse slowly through the mixture. Crystals formed over a period of five to nine days (yield of **1a**: 30%; yield of **4a**: 75%). X-ray data were collected at ambient temperature using a Bruker R3m diffractometer in the $\omega-2\theta$ mode with variable scan speed (3–20 ° min^{-1}) and graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Check reflections were measured every 200 reflections during data collection and gave no indication of crystal decay. Data were corrected for background, attenuators, Lorentz and polarization effects in the usual fashion [13]. A semi-empirical absorption correction was applied to **4a** using the Ψ-scan method.

Both structures were solved by direct methods and refined by full matrix least-squares procedures on $|F^2|$ with the SHELXTL Plus package of programs. All non-hydrogen atoms were refined anisotropically; hydrogen atom positions were calculated geometrically and fixed at a C–H distance of 0.96 Å and were not refined. Crystal data and further data collection parameters are summarized in Table 1.

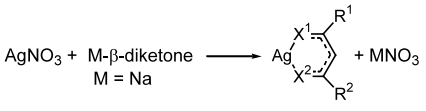
3. Results and discussion



3.1. Synthesis

Two routes were employed for the syntheses of the binary silver complexes, [Ag(X)]. For complexes **1** (X = tmhd), **2** (X = tmod), and **3** (X = tmshd), a modification of the method of Wakeshima [13] was employed. In this approach, $AgNO_3$ was reacted with the β-diketone in the presence of a base (Eq. (1)). Alternatively for **4** (X = *S*-tmhd) and **5** (X = *S*-tmod), the complexes were readily formed by displacement of nitrate using the sodium salt of the β-diketonate derivative (Eq. (2)) [14]. The method described in Eq. (1) was somewhat preferable, in that it afforded spectroscopically pure products, suitable for further reaction with neutral coordinating ligands to form ternary complexes (vide infra). On the other hand, separation of the silver product obtained in Eq. (2) from unreacted sodium β-diketonate was difficult due to the similar solubilities of these substances in most solvents. Attempts to prepare the complexes via reaction of Ag_2O with the β-diketone, as described for hfac [7], failed to provide the desired compounds. This result may be attributed to the decreased acidity of the nonfluorinated β-diketones relative to the fluorinated analogs.

1: $R^1 = R^2 = t$-Bu
2: $R^1 = t$-Bu, $R^2 = i$-Bu
3: $R^1 = t$-Bu, $R^2 = SiMe_3$

4: X^1 = O, X^2 = S, $R^1 = R^2 = t$-Bu
5: X^1 = O, X^2 = S, $R^1 = t$-Bu, $R^2 = i$-Bu
6: X^1 = O, X^2 = NH, $R^1 = R^2 = t$-Bu

(2)

Ternary complexes, [Ag(X)L], were prepared in two ways. In the first method, reaction of Ag(tmhd) **1**, Ag(tmod) **2**, and Ag(tmshd) **3** with 1 equiv. of PPh_3 or PBu_3 gave the corresponding desired complexes **1a**–**3a** (L = PPh_3) and **1b**–**2b** (L = PBu_3) in >80% yield. The complexes are air-stable; the PPh_3 derivatives were white to grayish-white in color, while the PBu_3 compounds were orange or reddish-brown viscous liquids, perhaps due to slight amounts of oxidation products. In all cases, good elemental analyses [15] and NMR spectroscopic data were obtained, so contamination must have been quite small. Slight downfield shifts of the CH resonance of the β-diketonate ligands were observed in the ^{1}H NMR spectra, while slight upfield shifts were found for the carbonyl and CH carbon atoms in the ^{13}C NMR spectra, upon coordination of the phosphine ligands. Although slight darkening occurred over long periods of time, no changes were observed in the NMR spectra of the compounds.

Complex **1a** could also be obtained by direct reaction of $AgNO_3$ with Na(tmhd) in the presence of PPh_3. This method was employed successfully for the preparation of [Ag(X)L], X = *S*-tmhd, L = PPh_3 **4a** or PBu_3 **4b**; X = *S*-tmod, L = PPh_3 **5a** or PBu_3 **5b**. The complexes were air-stable, yellow to yellow–brown compounds, probably due to the coloration of the ligands. The ^{1}H NMR resonance for the CH resonance of the monothio-β-diketonate ligands in the silver complexes experienced a downfield shift compared to the corresponding silver β-diketonate complexes, a result previously noted by Musso and coworkers for an analogous silver complex [16]. We also observed a downfield shift of the CH resonance in the ^{13}C NMR spectra of the coordinated ligands upon sulfur substitution.

Attempts to isolate pure Ag(*N*-tmhd) proved unsuccessful, perhaps due to ease of hydrolysis [17]. However, [Ag(*N*-tmhd)L], L = PPh_3 **5a** or PBu_3 **5b** could be prepared in acceptable yield by direct reaction of $AgNO_3$ with Na(*N*-tmhd) in the presence of the appropriate phosphine ligand. The CH resonance of the β-diketoiminate ligands in **5a** and **5b** was slightly upfield of the chemical shifts observed for the β-diketonate analogs, **1a** and **1b**, in both the ^{1}H and ^{13}C NMR spectra.

3.2. Thermal studies

Thermogravimetric analysis was employed to determine the suitability of the silver complexes for MOCVD processing. Experiments were conducted at atmospheric pressure under a nitrogen purge. Typical temperatures of maximum weight loss were in the range of 160–240 °C. For most of the complexes, weight loss was accompanied by residues in the TGA pan, the amount of which was comparable to the theoretical percentage of silver present in the complex. In fact in some cases, the residue appeared to be a silver mirror. Evidently, these complexes lose the ancillary ligands upon heating, without significant volatilization of the intact complex. One exception was **1b**, which had maximum rate of weight loss at 204 °C and a residue of only 11% (theoretical %Ag, 22%). Thus, at atmospheric pressure, the majority of the studied complexes showed little utility for MOCVD applications.

3.3. X-ray diffraction studies

While numerous solid-state structures have been reported for silver complexes supported by fluorinated β-diketonate ligands [6a,6b,6c,6f,6h,6f,6h,7,17–23], we

have determined the first structures of ternary silver complexes containing either a non-fluorinated β-diketonate or a monothio-β-diketonate ligand.

The asymmetric unit for [Ag(tmhd)(PPh_3)] **1a** contains one molecule of the mononuclear complex. The geometry is best described as highly distorted trigonal planar (Fig. 1); selected bond lengths and angles are summarized in Table 2. Ag(1), P(1), O(1), and O(2) are planar to within ±0.066 Å; the silver atom is 0.18 Å out of the plane defined by the three donor atoms of the ligands.

Structural features for **1a** are reminiscent to those reported for similar, three-coordinate analogs, [Ag(hfac)L], L = PMe_3 [6a,6b,6c], MeNC [6f], and PPh_3 [17]. Comparisons to the latter complex are probably most fruitful. The silver atom in **1a** is unsymmetrically bonded to the tmhd ligand with the Ag(1)–O(1) bond almost 0.08 Å longer than Ag(1)–O(2). Not surprisingly, the longer Ag–O bond occurs on the side of the complex with the smaller P–Ag–O angle (Table 2 and Fig. 1). Similar results are observed for [Ag(hfac)(PPh_3)] [17]. The reasons for these distortions are not clear, though sterics may play a part; the hfac ligand is more symmetrically coordinated in [Ag(hfac)L], L = PMe_3 [6a,6b,6c] and MeNC [6f]. The Ag–O bonds in **1a** are slightly shorter than those observed for [Ag(hfac)(PPh_3)] (2.218 (5) and 2.341(5) Å) [17], which can be attributed to the absence of the electron-withdrawing trifluoromethyl substituents. However, no appreciable lengthening of the C–O bonds of the tmhd ligand was observed for **1a**. The Ag–P bond length in **1a** is comparable to those in previously reported monomeric, three-coordinate silver β-diketonate complexes [6a,6b,6c,6f,17]. The packing diagram shows a head-to-tail stacking of β-diketone ligands for adjacent molecules. Stacking of phenyl rings is also observed for alternating molecules.

The asymmetric unit for [Ag(*S*-tmhd)(PPh_3)] **4a** contains two crystallographically independent halves of centrosymmetric dimers; thus, the triclinic unit cell contains two dimers. Selected bond lengths and angles are collected in Table 3. To our knowledge, **4a** is the first complex for which a monothio-β-diketonate serves as a bridging ligand [24,25], though a weak, long-range bridging interaction is observed in a Hg(II) monothio-β-diketonate complex [9].

The two dimers of **4a** have similar overall structures (see Fig. 2 for dimer molecule 1). The *S*-tmhd ligands in both **4a** dimers can be considered to be bridging in a μ_4:η^2,η^2 mode, that is analogous to that seen for the hfac ligands in [Ag(hfac)L]$_2$, where L is 1,5-dimethyl-1,5-cyclooctadiene [18] or diglyme [19a]. The dihedral angle between the planes defined by the bridging *S*-tmhd ligands in each dimer is a crystallographically-enforced 0.00°. The Ag···Ag distances in the dimers are

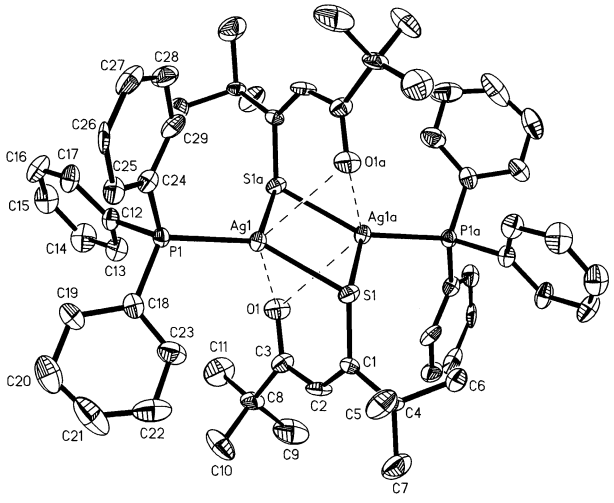

Fig. 2. Molecular structure for and atom numbering scheme for dimer molecule 1 for **4a**. Hydrogen atoms are omitted for clarity.

2.929(2) and 2.900(2) Å, for dimer molecules 1 and 2, respectively.

The Ag–S bond lengths for the dimers of **4a** are clearly within bonding range, but are somewhat longer on average than those observed in silver clusters containing bridging thiolate ligands [26] or for metal-to-sulfur bond distances in comparable, monomeric monothio-β-diketonate complexes involving metals from the second and third transition series [9,24]. The Ag–O distances are longer than the Ag–S bonds and include one long and one very long interaction per silver center from different bridging *S*-tmhd ligands. These interactions are weak at best; if the longer interaction is ignored, then the geometry about each silver ion is distorted tetrahedral. On the other hand, each silver ion can be considered to be distorted trigonal planar, if all Ag–O bonds are omitted. Interestingly, the shorter Ag–O bond distance is similar to that found in monomeric [Hg(*S*-tmhd)$_2$], a linear complex with two weak Hg–O interactions [9]. The Ag–P bond distances in the **4a** dimers are somewhat longer than those found for **1a** and [Ag(hfac)(PPh$_3$)] [17], presumably due to increased steric congestion in the dimers.

4. Conclusions

We have presented a series of silver complexes containing non-fluorinated β-diketonate derivatives. These complexes are air-stable, though slightly light and temperature sensitive. We have also reported on the first solid-state structures for this class of complexes, including [Ag(tmhd)(PPh$_3$)] **1a** and [Ag(*S*-tmhd)(PPh$_3$)] **4a**. The former is a monomeric, three-coordinate complex, while the latter is a dimer with two bridging *S*-tmhd ligands.

In general at atmospheric pressure, the complexes under study decompose without volatilization to give silver via loss of the supporting ligands. One exception was **1b**, [Ag(tmhd)(PBu$_3$)], which exhibited some ability to volatilize before total decomposition. We note that while our work was in progress, Edwards, et al. reported on the utility of [Ag(X)(PPh$_3$)] complexes for CVD processes, where X is various β-diketonate or β-ketoiminate ligands [17]. This group found a significant variation in volatility and quality of deposited silver films as a function of X. While many silver β-diketonate derivatives, [Ag(X)L], including those in the present study, are either too ionic [22] or too unstable to be employed for CVD applications, it appears that judicious choice of X and L ancillary ligands will possibly allow for useful complexes to be obtained [6f,17,20,21].

5. Supplementary material

Full lists of crystallographic data for **1a** (CCDC 169487) and **4a** (CCDC 169488), including atomic coordinates, bond lengths and angles, and anisotropic thermal parameters have been deposited with the Cambridge Crystallographic Data Center. Copies of this information may be obtained from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1233-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Received 14 January 2002; accepted 18 March 2002

Abstract

The crystal structure of a trinuclear iron monoiodoacetate complex was determined. Although it has been incorrectly characterized as $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]$, the correct chemical formula turned out to be $[Fe(III)_2Fe(II)O(O_2CCH_2I)_6(H_2O)_3]$-$[Fe(III)_3O(O_2CCH_2I)_6(H_2O)_3]I$ (**1**). The two kinds of Fe_3O molecules ($Fe(III)_2Fe(II)O$ and $Fe(III)_3O$) are crystallographically indistinguishable. All the Fe atoms are crystallographically equivalent because of a crystallographic threefold symmetry. Heat capacities of **1** seem to exhibit no thermal anomaly in the temperature range 5.5–309 K, although the valence detrapping phenomenon has been observed in this temperature range. This fact indicates that the valence-detrapping phenomenon in **1** occurs without any phase transition, leading **1** to a glassy state, probably because the crystal of **1** is just like a solid solution of distorted mixed-valence $Fe(III)_2Fe(II)O$ molecules and permanently undistorted $Fe(III)_3O$ molecules which may act as an inhibitor for a cooperative valence-trapping. © 2002 Elsevier Science Ltd. 1. Introduction

^{57}Fe Mössbauer spectra of mixed-valence trinuclear iron carboxylate complexes $[Fe(III)_2Fe(II)O(O_2CR)_6L_3]$ (R: substituent group, L: monodentate neutral molecule) have been known to exhibit a temperature-dependent valence transformation between a valence-detrapped state at high temperatures and a valence-trapped state at low temperatures in the solid state [1]. Recent studies on this type of complex have shown that the valence trapping-detrapping process is accompanied by phase transitions [2] and that the mixed-valence state observed by ^{57}Fe Mössbauer spectroscopy is sensitively affected by the solid state environment [3]. It has been observed that the solvent molecule in crystals of solvated acetate complexes, $[Fe_3O(O_2CCH_3)_6L_3]S$ (S: solvate molecule), can modulate the lattice dynamics and can determine the rate of intramolecular electron transfer [3].

The valence detrapping phase transition has also been found in non-solvated mixed-valence trinuclear iron carboxylate complexes, $[Fe_3O(O_2CR)_6L_3]$ [4]. The cyanoacetate complex $[Fe_3O(O_2CCH_2CN)_6(H_2O)_3]$ [5] is an appropriate substance for the study of valence-detrapping phase transitions because of the lack of solvate molecules. From the crystal structure determinations above and below T_c, a clear change in the molecular-core structure formed by three iron atoms from an equilateral triangle to an isosceles triangle was observed for the first time. The most essential factor controlling the valence-trapping phenomenon (not valence-trapping phase transition) has been suggested to be the electric

dipole moment ascribed to the distorted Fe_3O molecule itself in this complex [5].

In the course of our investigations, we found that the monoiodoacetate-aqua complex previously reported as $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]$ [6] is an unusual compound. Its correct formula turned out to be $[Fe(III)_2Fe(II)O(O_2CCH_2I)_6(H_2O)_3][Fe(III)_3O(O_2CCH_2I)_6(H_2O)_3]I$ (**1**). Two types of (mixed-valence and homo-valence) Fe_3O clusters coexist in the same crystal, just like a solid solution. In the case of the mixed-valence solid solutions, $[Fe(III)_2Fe(II)_{1-x}Co(II)_xO(O_2CCH_3)_3(py)_3]\cdot py$ [7], it has been found that the Fe_2CoO molecule acts as unusual quenched disorder for the valence trapping phase transition, hindering the ordering of trapped-valence Fe_3O molecules in the solid solution even before the percolation threshold is reached [8]. Adachi et al. [8] examined the effect of doping of permanently distorted Fe_2CoO molecules in the mixed-valence Fe_3O complex, which exhibits a cooperative valence trapping phase transition. The present system can be regarded as a solid solution of a Fe_3O complex doped with permanently undistorted Fe_3O monocations, although the undoped crystal of each complex has not been isolated. Thermal properties of such a system are of great interest and will give some insight into the valence trap-detrapping phenomenon. In the present paper, we report the single crystal structure determination and heat capacity measurement of **1**.

2. Experimental

2.1. Compound preparation

2.1.1. $[Fe(III)_2Fe(II)O(O_2CCH_2I)_6(H_2O)_3][Fe(III)_3O(O_2CCH_2I)_6(H_2O)_3]I$ (**1**)

A solution of CH_2ICO_2H (50.2 g, 0.27 mol) and NaOH (3.4 g, 0.066 mol) in 50 ml of water was added to a solution of $FeCl_2\cdot 4H_2O$ (13.2 g, 0.066 mol) in 50 ml of water. The resulting mixture was allowed to stand for several weeks in air. Black needle-like crystals were filtered off, washed with water and acetone, and dried under a nitrogen atmosphere. *Anal.* Found: C, 10.46; H, 1.25; I, 58.22. Calc. for $C_{24}H_{36}O_{32}Fe_6I_{13}$: C, 10.22; H, 1.29; I, 58.47%.

2.2. Crystal structure determination

All measurements were made by using graphite monochromated Mo Kα (0.71069 Å) radiation and a rotating anode generator (40 kV, 150 mA) on a Rigaku AFC-5R diffractometer at 296 K. A crystal with dimensions of $0.20 \times 0.20 \times 0.50$ mm^3 cut from a long needle-like crystal was mounted on the end of a glass fiber by epoxy cement. Data collection was made by using the ω–2θ scan to a maximum 2θ value of 55.0°.

Table 1

R_w [b]	0.114

[a] $R_1 = (\Sigma||F_o|-|F_c||)/(\Sigma|F_o|)$.
[b] $R_w = [\Sigma w(|F_o|-|F_c|^2)/(\Sigma w|F_o|^2)]^{1/2}$.

The structure was solved by direct method SHELXS-86 [9] and expanded by using Fourier techniques. An intense peak found in the difference Fourier map was regarded as the I^- ion. None of the refinements locating the other possible atoms such as O, Na and Cl could converge with any reasonable thermal parameters. All the non-hydrogen atoms were refined anisotropically. Hydrogen atoms of iodoacetate ligands were located in idealized positions of the tetrahedral methylen group with a fixed distance of 0.95 Å by calculation but not refined. Hydrogen atoms of water could not be located. Crystallographic data are presented in Table 1. Selected bond lengths and angles are summarized in Tables 2 and 3, respectively. The final positional parameters are provided as Supporting Information in CIF format.

2.3. Heat capacity measurement

Heat capacity measurements between 6 and 309 K were made with a home-built adiabatic microcalorimeter [10,11]. The mass of the sample **1** used for the calorimetry was 2.50608 g, but we determined molar heat capacities by assuming as if it were 1.77650 mmol of $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]I_{0.5}$. A small amount of helium gas was sealed in the calorimeter cell to aid the heat transfer.

3. Results and discussion

The mixed-valence Fe_3O type complex with monoiodoacetate anion was first reported by Yakubov et al. [12,13], and a valence detrapping phenomenon was observed by ^{57}Fe Mössbauer spectroscopy. Sato et al. [6] also studied the crystalline sample of this complex and observed a valence detrapping phenomenon by ^{57}Fe

Mössbauer spectroscopy. At 8.5 K two quadrupole split doublets were observed and ascribed to a high-spin Fe(II) and a high-spin Fe(III). With increasing temperature, two doublets became indistinguishable and seemed to coalesce into one broad peak at room temperature, but there was a peculiar feature in the Mössbauer spectra, i.e. the area ratio of Fe(II) and Fe(III) seemed to be much smaller than 1/2 even at liquid helium temperature. Unfortunately, however, there has been no structure report on this complex, so as to solve the mysterious situation, before the present structure determination.

An ORTEP plot of **1** is shown in Fig. 1. There is only one independent molecular site in the crystal. The ratio of Fe_3O complex site and I^- ion site is 2:1 owing to the crystallographic necessity. As the occupancy factor of each site is 1.0, the chemical formula of **1** should be

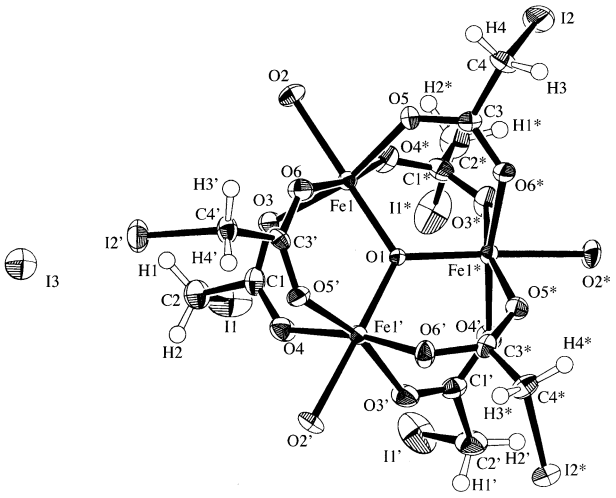

Fig. 1. ORTEP drawing of **1**. The thermal ellipsoids are drawn at the 50% probability level. This molecular structure is a time average and space average of two kinds of molecules.

$[Fe_3O(O_2CCH_2I)_6(H_2O)_3]_2I$. To maintain the whole charge balance, the crystal of **1** should consist of two kinds of Fe_3O complexes, $[Fe(III)_2Fe(II)O(O_2CCH_2I)_6(H_2O)_3]$ and $[Fe(III)_3O(O_2CCH_2I)_6(H_2O)_3]I$ in the ratio of 1:1. Probably these two kinds of Fe_3O complexes are arranged in the crystal with some regularity, but they are crystallographically indistinguishable. It is very likely that the source of I^- ion is monoiodoacetic acid. The elimination of I^- ion from $CH_2ICO_2^-$ may occur in the reaction mixture. It was difficult to distinguish the present complex from $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]$ by elemental analysis, because there is no significant difference in the contents of C and H between **1** and $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]$. For example, the calculated values for $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]$ ($C_{12}H_{18}O_{16}Fe_3I_6$) are C, 10.70; H, 1.35; I, 56.52%. The difference on the contents of I is insignificant beyond the experimental error of approximately 0.3%. Since the correct formula was found to be different from that of the normal mixed-valence Fe_3O type complex, the ^{57}Fe Mössbauer spectrum of **1** should be re-analyzed by assuming the existence of two Fe_3O complexes: one quadrupole split doublet ascribed to high spin Fe(III) at any temperatures, and an $Fe(III)_2Fe(II)O$ complex showing temperature-dependent spectra from valence trapped at low temperature to valence detrapped at room temperature.

The selected bond lengths are listed in Table 2. It has been established that the Fe–(μ_3-O) distance determined by single crystal X-ray structure determination well corresponds to the 'effective' valence state of the Fe atom [1]. For example, the distances Fe(II)–O = ~2.0 Å and Fe(III)–O = ~1.85 Å are observed in a fully trapped Fe_3O complex at room temperature. Recently, the longest and the shortest distances for a mixed-valence Fe_3O complex were reported for $[Fe_3O(O_2CC-$

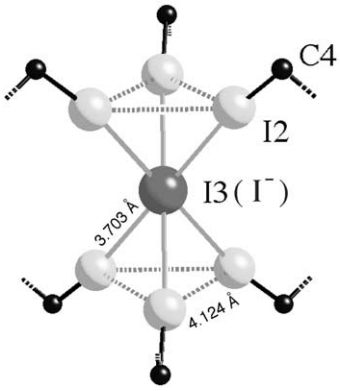

Fig. 2. Bicapped trigonal antiprism structure constructed by the I^- ion and surrounding six I atoms of $CH_2ICO_2^-$.

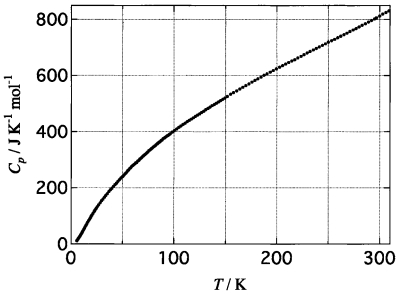

Fig. 3. Plot of the molar heat capacity of $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]I_{0.5}$ vs. temperature.

$Me_3)_6(py)_3]$: 2.046 Å attributable to Fe(II)–O (28 K) and 1.824 Å attributable to Fe(III)–O (10 K) [14]. In the case of a valence fluctuation system, the Fe–O distance shows an intermediate value depending on the mixing ratio of Fe(II) and Fe(III) at each Fe site, because the single crystal structure determination provides a space and/or time averaged structure. In a valence detrapped system, the Fe–(μ_3-O) distance of a molecule with crystallographic threefold symmetry is usually $\sim$1.9 Å, corresponding to a weighted-average of the three distances in a trapped molecule, while those of a Fe_3O molecule located on a crystallographically lower symmetric site are usually in a range between 1.85 and 2.0 Å and exhibit a temperature dependence [3,15]. The three distances sometimes exhibit a curious temperature dependence [15], but finally they become close to one at 2.05 Å and two at 1.85 Å at low temperature [3,5,15]. On the other hand, the Fe(III)–O length in $Fe(III)_3O$ complex is $\sim$1.9 Å, slightly longer than that in a mixed-valence molecule. These lengths are known to be slightly varied by some anisotropy effect or packing force [1]. In the case of **1**, all the Fe–(μ_3-O) lengths are 1.896 Å at room temperature. This value is close to both the Fe(III)–O length in a $Fe(III)_3O$ complex and the averaged length in a $Fe(III)_2Fe(II)O$ complex.

It is worth stating here about another interesting feature of the structure. Fig. 2 illustrates a bicapped trigonal antiprism structure constructed by the I^- ion and surrounding six I atoms of monoiodoacetate ligands. The interatomic distance of $I^-\cdots I$ is 3.703 Å and the shortest $I\cdots I$ distance in the bicapped trigonal antiprism is 4.124 Å. These distances are much longer than 2.715 Å, the intramolecular I–I distance of I_2 in the solid sate, implying no chemical bond between the I atoms and I^- ion. However, they are close to the shortest interatomic approaches between the I_2 molecules, 3.50 Å within the layer and 4.27 Å between layers, in solid I_2 [16], indicating a contact of van der Waals radius.

The molar heat capacities under constant pressure, C_p, of **1** at temperatures between 5.5 and 309 K are plotted in Fig. 3 and listed in Table 4. It has so far been known that the valence trapping phase transition takes place below room temperature in any mixed-valence Fe_3O complexes which have crystallographic threefold symmetry at room temperature as a result of valence fluctuation [2,3,5]. If some ordering of Fe_3O molecules takes place in **1**, the entropy change of $(R \ln 3)/2 = 4.567$ J K^{-1} mol^{-1} per mole of $[Fe_3O(O_2CCH_2I)_6(H_2O)_3]I_{0.5}$ should be observed as some type of thermal anomaly. However, neither phase transition nor thermal anomaly was observed in the measured temperature region, although the valence detrapping phenomenon has been observed in the same temperature region based on ^{57}Fe Mössbauer spectroscopy [6]. This is copmprehensible if the crystal of **1** becomes glassy state at low temperatures. In that case, the permanently undistorted $Fe(III)_3O$ cations will act as an inhibitor for the cooperative lattice distortion due to the electron trapping. As there is no phase transition in **1** below room temperature, the crystallographic threefold symmetry will remain at low temperatures even if the mobile electron ceases to itinerate. At low temperatures, the orientational motion of the distorted Fe_3O molecules due to the intramolecular electron transfer will be randomly frozen in three directions, implying a glassy state. Only this situation can explain how **1** interconvertes between the valence-trapped and valence-detrapped states without any phase transition or any thermal anomaly.

Diphosphazane supported platinum(II) triflate, amine, and amido complexes: synthesis and X-ray crystal structures

Aibing Xia, Paul R. Sharp *

125 Chemistry, University of Missouri, Columbia, MO 65211, USA

Received 24 January 2002; accepted 19 March 2002

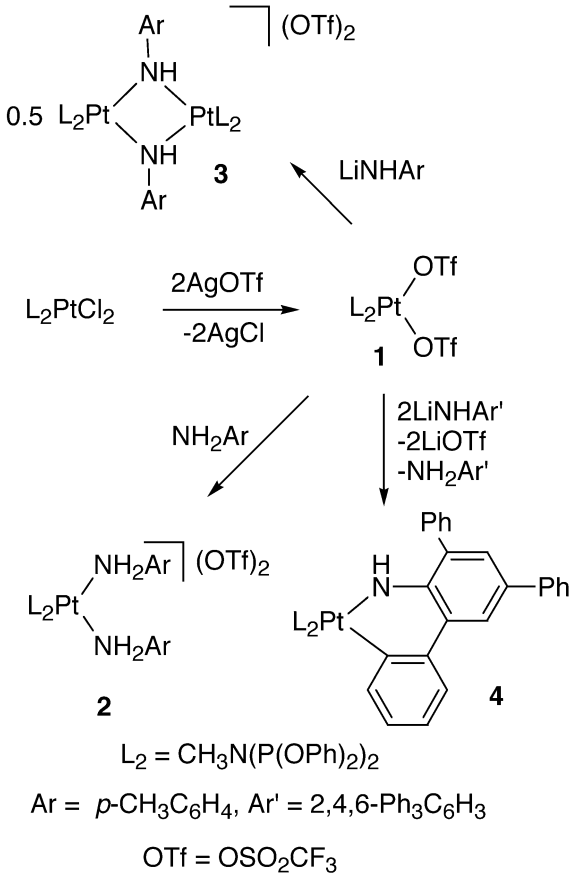
Abstract

Treatment of L_2PtCl_2 ($L_2 = MeN[P(OPh_2)]_2$) with $AgSO_3CF_3$ gives the triflate complex $L_2Pt(SO_3CF_3)_2$ (**1**). Addition of 2,6-dimethylaniline to **1** in CH_2Cl_2 gives the monomeric diamine complex $[L_2Pt(NH_2Ar)_2](SO_3CF_3)_2$ (**2**, $Ar = 2,6\text{-}Me_2C_6H_3$), while reaction of **1** with lithium 2,6-dimethylanilide gives the dimeric bridging amido complex $[L_2Pt(\mu\text{-}NHAr)]_2(SO_3CF_3)_2$ (**3** $Ar = 2,6\text{-}Me_2C_6H_3$). Cyclometalation is observed when **1** is treated with lithium 2,4,6-triphenylanilide yielding the neutral complex $L_2Pt\{NH[2\text{-}(3,5\text{-}Ph_2C_6H_2)C_6H_4]\}$ (**4**). The structures of all four complexes were determined by X-ray diffraction methods. All display the expected four-coordinate square planar Pt geometry. The amine (**2**) and amido (**3**) complexes show N–H hydrogen bonding to the triflate anions. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Amido; Amine; Triflate; Platinum; Diphosphazane; Cyclometalation

1. Introduction

Late transition metal amido complexes [1] have attracted considerable interest for their potential in organic synthesis [2] and for their usefulness as synthetic precursors [1,3,4]. Platinum(II) and palladium(II) amido complexes have been widely studied and their structural features and reactivities found to be influenced by differences in the supporting ligands [2,5,6]. A common feature of amido complexes is a relatively high amido ligand electron density. Since one of our major interests is deprotonation of amido ligands to imido ligands we are interested in factors that reduce amido ligand electron density and enhance acidity. Diphosphazanes ($RN(PX_2)_2$) are versatile supporting ligands that can be easily modified on both nitrogen and phosphorus centers to tune steric and electronic properties [7]. Here we report the synthesis and structures of several platinum(II) complexes, including amido complexes, employing the supporting diphosphazane ligand $MeN[P(OPh)_2]_2$.



2. Results and discussion

The high lability of the triflate ligand makes metal triflate complexes excellent synthetic precursors [8]. The triflate complex $L_2Pt(SO_3CF_3)_2$ (**1**) is readily obtained from the reaction of L_2PtCl_2 ($L_2 = MeN[P(OPh)_2]_2$) [9] with $AgSO_3CF_3$ in CH_2Cl_2 at ambient temperatures (Scheme 1). The ^{31}P NMR signal of the diphosphazane ligand shifts upfield by about 36 ppm (from 43.5 ppm for the dichloride to 7.5 ppm for the triflate). Along with this upfield shift, the Pt–P coupling constant increases almost 1000 Hz (from 5036 to 6008 Hz). These data imply a stronger P–Pt interaction consistent with the expected weaker *trans*-influence of the triflate ligand [10]. An X-ray crystal structure analysis of **1** (Fig. 1, Table 1) shows the expected square planar Pt center with a *cis*-disposition of the triflate ligands. Selected distances and angles are given in Table 2. There are two known structures of Pt(II) triflate complexes with a phosphorus ligand *trans* to the triflate ligand. The most closely related to **1** is the diphosphine complex $\{1,2\text{-}(PMePh)_2C_6H_4\}Pt(OTf)_2$ [11]. The Pt–O bond lengths in this complex are 2.142(9) and 2.091(8) Å, similar to those in **1** (2.080(3) and 2.096(3) Å). The Pt–O–S angles of 136.1(5)° and 131.1(6)° are slightly greater than those in **1** (130.19(17)° and 128.06(16)°). The more open Pt–

Scheme 1.

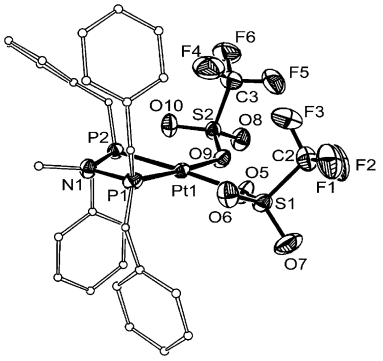

Fig. 1. ORTEP drawing of $L_2Pt(SO_3CF_3)_2$ (**1**). Hydrogen atoms are omitted for clarity. Atoms, except phenoxide atoms and the N–Me carbon (arbitrary spheres), are represented by 50% probability thermal ellipsoids.

O–S angle of $\{1,2\text{-}(PMePh)_2C_6H_4\}Pt(OTf)_2$ may result from steric crowding. Such factors are absent in **1** with its smaller bite angle diphosphazane and less sterically demanding OPh phosphorus substituents. The second complex for comparison is the diphosphine complex $\{(C_2F_5)_2PCH_2CH_2P(C_2F_5)_2\}Pt(Me)(OTf)$ [12]. The Pt–O distance (2.090(6) Å) and the Pt–O–S angle (130.2(3)°) in this complex are almost identical to those of **1** suggesting minimal steric congestion, as in **1**.

As expected, the triflate ligands of **1** are labile and **1** reacts readily with 2,6-dimethylaniline at ambient temperature to afford the diamine complex $[L_2Pt(NH_2Ar)_2](SO_3CF_3)_2$ (**2**, Ar = 2,6-$Me_2C_6H_3$). Complex **2** gives a ^{31}P NMR signal at 16.5 ppm with a Pt–P coupling constant of 4900 Hz. This decrease in the Pt–P coupling constant from that of **1** and L_2PtCl_2 is indicative of the stronger *trans*-influence of the amine ligand relative to the triflate and chloride ligands [10]. The NH peak is observed in the ^1H NMR spectrum of **2** at 7.04 ppm (CD_2Cl_2), shifted downfield by about 2 ppm from that of the free ligand in the same solvent. An X-ray crystal structure analysis of **2** (Fig. 2, Table 1) shows the expected square planar Pt center with a *cis*-disposition of the amine ligands. The amine ligands interact with the two triflate anions through bifurcated hydrogen bonds. Metrical parameters are given in Table 3. Comparison structures with mononuclear *cis*-P_2PtN_2 cores are mostly limited to complexes incorporating the amine nitrogen in a chelate ring. An exception is the simple ammonia complex *cis*-$[(Ph_3P)_2Pt(NH_3)_2](NO_3)_2$ [13]. This complex shows a similar hydrogen bonding pattern of the coordinated amine to the counter anion, and an average Pt–N distance of 2.098(9) Å. Structures incorporating the amine into a chelate ring have average Pt–N distances ranging from 2.07(11) to 2.110(8) Å [14]. The Pt–N distances of **2** are in this range (2.118(4) and 2.129(4) Å).

Attempts to deprotonate **2** with $LiN(SiMe_3)_2$ to obtain an amido complex were not successful. ^1H NMR spectra of the reaction mixtures showed the loss of the diphosphazane N–Me triplet signal indicating disruption of the diphosphazane ligand, probably through nucleophilic attack on the phosphorus center.

As an alternative to the formation of an amido complex by deprotonation of **2**, **1** was treated with lithium 2,6-dimethylanilide in THF at −30 °C. The amido-bridged dimer $[L_2Pt(\mu\text{-}NHAr)]_2(SO_3CF_3)_2$ (**3**, Ar = 2,6-$Me_2C_6H_3$) was obtained as the only isolated product with anilide to Pt ratios of 1:1–2:1 (Scheme 1). Complex **3** gives a ^{31}P signal at 29.9 ppm with a Pt–P coupling constant of 4628 Hz. The ^1H NMR spectrum shows an N–H peak at 4.93 ppm, an upfield shift compared with the monomeric diamine complex **2** and suggestive of greater electron density on the nitrogen centers in the anilido dimer **3**. However, this shift is lower than that observed for analogous diphosphine complexes (4.6–2.6 ppm) [6] suggesting that the reduced donor properties of the diphosphazane ligand result in less electron density at the amido ligand. An X-ray crystal structure analysis of **3** (Figs. 3 and 4, Table 1) shows the expected edge-shared dimer with a *syn*-orientation of the amido aryl groups. One triflate anion is hydrogen-bonded to the amido groups. The Pt_2N_2 core is slightly bent at the N–N hinge. Factors involved in the bending of di-bridged d^8-square-planar dimers of

this type have been studied [15]. Selected bond distances and angles are given in Table 4 and are similar to those of related structurally characterized amido complexes with $P_2Pt(\mu\text{-}N)_2PtP_2$ cores [6,16].

Previous work has shown that $[L_2Pt(\mu\text{-}NHAr)]_2^{2+}$ complexes can be converted to imido complexes by deprotonation if L_2 is the small bite-angle ligand $(Ph_2P)_2NMe$ [3]. We, therefore, anticipated that **3**, with its more weakly donating $[(PhO)_2P]_2NMe$ ligand, would deprotonate even more readily to produce an imido complex. However, treatment of **3** with $LiN(SiMe_3)_2$ does not give an imido complex but rather appears to lead to disruption of the diphosphazane ligand. As in the attempted deprotonation of **2** (see above), this is indicated by the loss of the N–Me triplet signal in the ^1H NMR spectrum of the reaction mixture.

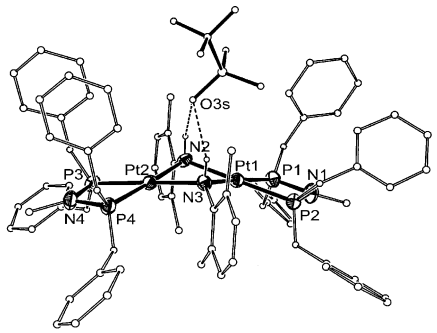

Fig. 3. ORTEP drawing of the cationic portion of $[L_2Pt(\mu\text{-}NHAr)]_2(SO_3CF_3)_2$ (**3**, Ar = 2,6-$Me_2C_6H_3$). Hydrogen atoms, except the N–H hydrogen atoms, are omitted for clarity. All atoms, except phenoxide atoms and the N–Me carbon (arbitrary spheres), are represented by 50% probability thermal ellipsoids.

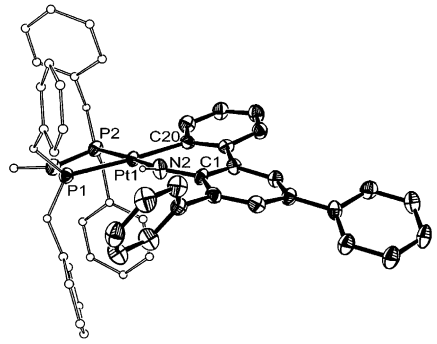

Fig. 4. ORTEP drawing of the cationic portion of $L_2Pt\{NH[2\text{-}(3,5\text{-}Ph_2C_6H_2)C_6H_4]\}$ (**4**). Hydrogen atoms, except the amine hydrogen atoms, are omitted for clarity. Atoms, except phenoxide atoms and the N–Me carbon (arbitrary spheres), are represented by 50% probability thermal ellipsoids.

P1–N1–P2	99.7(3)		

$L_2Pt\{NH[2\text{-}(3,5\text{-}Ph_2C_6H_2)C_6H_4]\}$ (**4**) was obtained (Scheme 1). The ^{31}P NMR spectrum of **4** shows two doublets ($J_{P-P} = 49.1$ Hz) at 70.8 ppm ($J_{P-Pt} = 3920$ Hz) and 95.9 ppm ($J_{P-Pt} = 1959$ Hz). The high-shift doublet with the small Pt–P coupling constant is assigned to the phosphorus atom *trans* to the carbon atom consistent with the strong *trans*-influence of a carbon anion [10]. An X-ray crystal structure analysis of **4** (Fig. 4, Table 1) confirms the cyclometalation of the amido ligand. Selected distances and angles are given in Table 5. Remarkably, despite the commercial availability of the aniline, this is apparently only the second report of a transition metal complex formed from this aniline [17]. This is in sharp contrast to other terphenyl ligands, [18] the related phenol, 2,6-$Ph_2C_6H_3OH$, [19] and other substituted anilines, [20] which have been used for the preparation of a number of metal complexes. Cyclometalations, like that observed here, have been reported with the phenoxo ligand 2,6-$Ph_2C_6H_3O$ for a number of early transition metals [19] and for Sn [21] and Ge [22].

Two possible pathways to cyclometalation product **4** are considered in Scheme 2. Both begin by formation of the amido triflate complex $L_2Pt(NHAr')(OTf)$. This species may loose a triflate anion to generate the three-coordinate species $[L_2Pt(NHAr')]^+$ (**A**). (A

Scheme 2.

Ni(II) analog of **A** has been isolated [23]). Three-coordinate species are thought to be required for significant cyclometalation rates in Pt(II) systems [24]. The second pathway requires formation of the terminal imido complex $L_2Pt{=}NAr'$ (**B**) either by deprotonation of $L_2Pt(NHAr')(OTf)$ (or **A**) or formation of $L_2Pt(NHAr')_2$ followed by elimination of H_2NAr'. Addition of the C–H bond across the Pt–N double bond, a process known for terminal early transition metal imido complexes, [25] would then yield **4**. Although never observed, terminal Pt(II) oxo complexes analogous to **B** have been postulated [26] and a Ni(II) analog of **B** has been recently reported [23]. Given the lack of evidence for imido complex **B**, we favor the well-established [24] electrophilic cyclometalation through three-coordinate **A**. However, future work will be directed at establishing the possible existence of **A** with aryl groups that are less susceptible to cyclometalation and supporting ligands (L_2) that discourage approach of the aryl group to the Pt center.

3. Experimental

3.1. General procedures

Experiments were performed under a nitrogen atmosphere in a Vacuum Atmospheres Corp. drybox. Solvents were dried by standard techniques and stored under nitrogen over 4 Å molecular sieves. The compounds 2,6-dimethylaniline, 2,4,6-triphenylaniline, and $AgSO_3CF_3$ were purchased from Aldrich or Acros Chemicals and were used as received. The lithium anilides were prepared from the anilines and $LiBu^n$ (2.5 M) in hexane. $L_2 = MeN[P(OPh)_2]_2$ and L_2PtCl_2 were prepared by literature procedures [9]. NMR spectra were recorded on a Bruker AMX-250 spectrometer. ^1H NMR (250 MHz) and ^{13}C NMR (62.9 MHz) spectra are referenced to TMS or to solvent impurities referenced back to TMS. ^{31}P NMR (101 MHz) spectra are referenced to external 85% H_3PO_4. All NMR shifts are in ppm with negative shift upfield from the reference. Spectra were recorded at ambient temperatures (22 °C) unless otherwise indicated. Melting points are uncorrected.

3.2. Preparation of $L_2Pt(OTf)_2$ (**1**)

Silver trifluoromethane sulfonate (0.257 g, 1.00 mmol) was added to a suspension of L_2PtCl_2 (0.365 g, 0.500 mmol) in 2.0 ml of CH_2Cl_2. The mixture was stirred at ambient temperature overnight and then filtered. Addition of Et_2O (10 ml) to the filtrate afforded a white precipitate of the product. This was collected by filtration, washed twice with Et_2O (3 ml), and dried in vacuo to give 0.400 g (83.5%) of white solid. Colorless single crystals suitable for X-ray diffraction were obtained from CH_2Cl_2–Et_2O. *Anal*. Calc. (Found): C 33.90 (34.12), H 2.42 (2.41), N 1.46 (1.49)%. M.p.: 180–182 °C. ^1H NMR (CD_2Cl_2): 2.91 (t, $^3J_{H-P} = 13.3$ Hz, 3H, Me), 7.20–7.41 (m, 20H, phenyl). ^{13}C NMR (CD_2Cl_2): 31.71 (s, Me), 120.92 (t, $J_{C-P} = 2.4$ Hz, C_{ortho} of Ph), 127.85 (s, C_{para} of Ph), 131.15 (s, C_{meta} of Ph), 149.39 (t, $J_{C-P} = 4.0$ Hz, C_{ipso} of Ph). ^{31}P (CD_2Cl_2): 7.49 ($J_{P-Pt} = 6008$ Hz).

3.3. $[L_2Pt(NH_2Ar)_2](SO_3CF_3)_2$ (**2**, $Ar = 2,6\text{-}Me_2C_6H_3$)

2,6-dimethylaniline (0.032 g, 0.260 mmol) was added to a solution of $(L_2Pt)(OTf)_2$ (0.126 g, 0.132 mmol) in CH_2Cl_2 (2 ml). The solution was stirred for 2 h at ambient temperature. Addition of Et_2O (10 ml) afforded a white precipitate of the product. This was collected by filtration, washed twice with Et_2O (3 ml), and dired in vacuo (0.135 g, 85.4%). Colorless single crystals suitable for X-ray diffraction were obtained from CH_2Cl_2–Et_2O. *Anal*. Calc. (Found): C 43.08 (42.87), H 3.78 (3.87), N 3.50 (3.50)%. M.p.: 196–200 °C. ^1H NMR (CD_2Cl_2): 1.75 (t, $^3J_{H-P} = 12.0$ Hz, 3H, Me), 2.67 (s, 12H, Me), 7.04 (s, overlapped with Ph, NH), 6.87–7.49 (m, 30H, Ph). ^{13}C NMR (CD_2Cl_2): 15.00, 18.11, 110.09, 119.63, 124.53, 126.95, 127.62. ^{31}P (CD_2Cl_2): 16.47 ($J = 4909$ Hz).

3.4. $[L_2Pt(\mu\text{-}NHAr)]_2(OTf)_2$ (**3**, $Ar = 2,6\text{-}Me_2C_6H_3$)

A solution of lithium 2,6-dimethylanilide (0.010 g, 0.079 mmol) in THF (1 ml) was added to a solution of $(L_2Pt)(OTf)_2$ (0.039 g, 0.040 mmol) in THF (1 ml) at −30 °C. The mixture was kept at −30 °C overnight then warmed to ambient temperatures and the volume reduced in vacuo. Et_2O (10 ml) was added and the resulting precipitate was filtered and washed with Et_2O (3 ml) to afford the pale yellow solid product (0.020 g, 50%). Yellow crystals for the X-ray analysis were obtained from DME–$^iPr_2O$. M.p.: 205–208 °C. ^1H NMR (CD_2Cl_2): 2.13 (t, $^3J_{H-P} = 12.0$ Hz, 6H, Me), 2.42 (s, 6H, Me), 3.52 (s, Me), 4.93 (bs, 2H, NH), 6.73–7.45 (m, 26H, Ph). ^{13}C NMR (CD_2Cl_2): 19.18, 22.97, 120.14, 120.21, 127.34, 129.10, 130.80, 130.99, 131.44, 149.49. ^{31}P (CD_2Cl_2): 29.93 ($J_{P-Pt} = 4628$ Hz).

3.5. $L_2Pt\{NH[2\text{-}(3,5\text{-}Ph_2C_6H_2)C_6H_4]\}$ (**4**)

A solution of lithium 2,4,6-triphenylanilide (0.013 g, 0.040 mmol) in THF (1 ml) was added to a solution of $(L_2Pt)(OTf)_2$ (0.020 g, 0.020 mmol) in THF (1 ml) at −30 °C. The mixture was kept at −30 °C overnight and the volume was reduced under reduced pressure. Et_2O (10 ml) was added and the precipitate was filtered and washed with Et_2O (3 ml) to afford a pale yellow solid

(0.010 g, 50%). Yellow crystals for the X-ray analysis were obtained from DME–$^{i}Pr_2O$. M.p.: 196–200 °C. ^{1}H NMR (CD_2Cl_2): 3.00 (t, $^{3}J_{H-P} = 8.0$ Hz, 3H, Me of L_2), 6.60 (1H, NH), 6.64–7.74 (38H, Phenyl). ^{13}C NMR (CD_2Cl_2): 14.27, 126.62, 126.72, 127.28, 127.77, 128.33, 128.62, 128.66, 129.10, 129.38, 131.10, 140.18, 140.95, 141.25. ^{31}P (CD_2Cl_2): 70.80 ($^{2}J_{P-P} = 49.1$ Hz, $J_{P-Pt} =$ 3920 Hz, *trans* to N), 95.86 ($^{2}J_{PP} = 49.1$ Hz, $J_{P-Pt} =$ 1959 Hz, *trans* to C).

4. Supplementary data

Full crystal structure information has been deposited with the Cambridge Crystallographic Data Center (deposition numbers CCDC 178035-CCDC 178038). Copies of this information are available upon request from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We thank the Division of Chemical Sciences, Office of Basic Energy Sciences, Office of Energy Research, US Department of Energy (Grant DF-FG02-88ER13880) for support of this work. A grant from the National Science Foundation provided a portion of the funds for the purchase of the NMR (CHE 9221835) equipment.

Preface

Thermodynamics of Metal Complexes ISMEC XII, Parma, Italy, June 6–9, 2001

This special Issue of POLYHEDRON contains the contributions presented at the Meeting ISMEC 2001 (XII Italian–Spanish Congress on Thermodynamics of Metal Complexes and XXVIII Congress of the Italian 'Gruppo di Termodinamica dei Complessi', GTC). The Meeting has taken place at the University of Parma, Italy from the 6th to 9th of June 2001. The articles are dedicated to the members of the group that have recently retired or are going to retire: Professors Giorgio Ostacoli (University of Turin), Carla Riolo Bertoglio (University of Pavia), Fernando Pulidori (University of Ferrara), Vincenzo Carunchio (University of Rome, La Sapienza), Piero Paoletti (University of Florence), and Antonio Braibanti (University of Parma). Vincenzo Carunchio has described the history of the development of the thermodynamics of Metal Complexes, and of GTC in particular, in his article published in this Issue. The personal scientific contributions by these researchers who, for about three decades, have taken part to the activities of the Group since its foundation, are documented by the titles of their papers contained in the list of publications of the GTC (the updated list can be requested from Professor Diego Ferri, University of Naples, Italy, e-mail: ferri@chemistry.unina.it). Their researches have permitted to obtain significant achievements in the field of thermodynamics of metal complexes from the integrated points of view of inorganic, analytical and physical chemistry.

The human participation to the activities of the Group lives in the memory of all those who have had the opportunity to meet them or to work with them. It is continuously renovated by the contacts they maintain after retirement.

The warm applause by the whole assembly of participants and Academic Authorities that has accompanied the assignment to them of dedicated medals has been the best reward offered to the senior researchers by their Italian and Spanish friends and pupils.

Metal complexes: from pioneers to the GTC

Vincenzo Carunchio *

Department of Chemistry, University 'La Sapienza' Piazzale Aldo Moro 5, 00185 Rome, Italy

Received 1 October 2001; accepted 29 October 2001

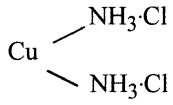
Abstract

The lecture takes into consideration the main and significant stages of the history of metal complexes. The story begins with the first empirical observations at the end of the XVIII Century, to the attempts for explaining some supposed anomalous behaviours, to the different interpretations by Jorgensen and Werner, to the Ziegler and Natta's achievements. Particular attention is devoted to the development of the study of complex formation equilibria in solution, and kinetic of complexation reactions. Together with these historical passages, consideration is also given to the different scientific fields in which the study of metal complexes gave a noteworthy contribution to increase in knowledge by suggesting some original solutions and supporting other fields of research, especially in biochemistry. With the aim of keeping alive the interest on the fundamental researches in these fields, the Group of Thermodynamics of Complexes (GTC) was constituted in Italy in 1973. The GTC has organised yearly congress and some summer schools, and has produced a wealth of scientific papers. © 2002 Published by Elsevier Science Ltd.

Keywords: Complex history; Complex pioneers; Thermodynamics group; Coordination chemistry

We were taught that 'History is Master of Life', and presuming this saying is correct, its scope can be extended also to the life of that small portion of knowledge represented by the 'Group of Thermodynamics of Complexes' (GTC), that was founded mainly with the aim of preserving the heritage of experiences on this subject, both those already collected, and those yet to be realised. An outline of the articulated history of the complexes, which in its initial phases alterned between critical and fascinating, may be a valid support for the 'complex researchers'.

The term, 'complex', as well as the general concept of 'complex' appear for the first time in the literature in an article by Werner in 1893 [1]. He introduced such innovation being pressed by the obvious desire of every researcher to provide an explanation for everything that he has under study, all the more so when the observed phenomenon appears strange or, at least, anomalous and unpredictable. In that case the attention was focused on solutions containing particular salts, which reacting with one another did not maintain their original chemical properties, but presented new and different ones.



In the previous literature there had been references describing casual events of this type but they were presented with no explanations at all or by interpretations that the later chemists could not accept. The first report of an event that can be related with a metal complex dates back at the beginning of the XVIII century, and refers to the case of a manufacturer from Berlin. He, combining potassium cyanide with iron cyanide, casually obtained a dark blue stain, (also called soluble Prussian Blue) and a blue precipitate (Prussian blue). In later times, they were attributed the formulae $KFe(III)[Fe(II)(CN)_6]$ (soluble) and $Fe(III)_4[Fe(II)(CN)_6]_3$ (precipitate), respectively. The moiety enclosed in squared parentheses is just the 'complex' with secondary valence recognised by Werner. Nevertheless the first article that in the literature [2] refers to a real preparation of a complex mentions $CoCl_3 \cdot 6NH_3$, obtained by Tassaert in 1798. The properties of such compound were pretty peculiar because they were different from those of each single component, but at the time such phenomenon could not find an explanation consistent with current knowledge. The possibilities of combination of these two stable compounds, alleg-

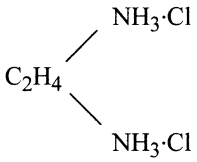
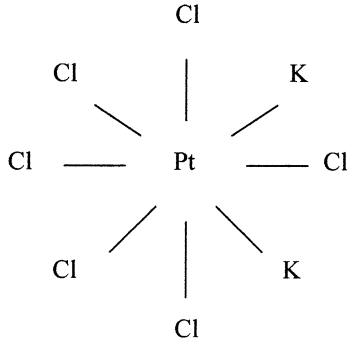
PII: S0277-5387(02)00961-0



edly having saturated (primary) valences, such as $CoCl_3$ and NH_3, represented an incentive to conduct further researches aimed at the comprehension of the behaviour of some apparently anomalous other salt.

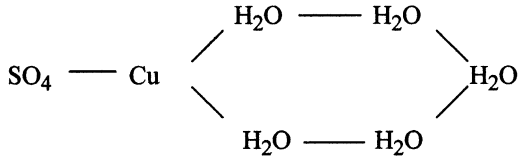
We find also further references to the formation of compounds included in the typology of the complexes, however, they were accompanied with elementary and not convincing explanations which often seemed to depend on the prevailing culture of the organic chemistry. To recall some examples, we can mention the case of the copper(II) complex prepared by Graham (1837), who postulated, the following formula:



This structure, nevertheless, allowed for no explanation for a metal/amine ratio higher than 1:2.

Another example to be mentioned is a platinum(II) compound obtained by Odling (1870), proposing a sort of analogy between a metal and an ethylene group.

Another interesting attempt to explain the structure of a compound on the basis of the ratio of the elements was proposed by Horstman (1885) for $2KCl–PtCl_4$ in which the metal is attached in the same manner to six atoms of chlorine and two of potassium.



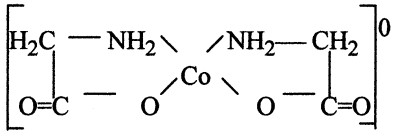
In the meantime, Reset [3] in 1844 and Peyrone [4] in 1845 described almost contemporaneously two compounds responding to the same stoichiometrical ratio ($Pt(NH_3)_2Cl_2$), but presenting different properties. The news of these compounds gave rise to contrasting exchanges of opinion, since the concept of isomerism for the complexes had not yet been achieved.

Summarizing what said before, in the literature we may find several references to such findings of compounds of this kind 'on a chance basis', although, as mentioned above, it was only in 1893 that Werner started to refer to them as 'complexes'. The metal atom (particularly transition metal) was considered as the centre of a whole system, so that we might very easily set the molecules connected or coordinated to it at the corners of an octahedron. Specifically, Werner introduced the concept that metal atoms have two types of valence, primary and secondary. Every metal tends to satisfy both types of valence. The secondary valence is directed toward fixed positions, which form a coordination polyhedron. It is worth noting that Werner introduced also the term 'coordination number', used until today, as well as the entire nomenclature to indicate the complexes. Werner was awarded Nobel Prize in 1913 for such achievements. In this manner he revolutionised-as was later stated by Pauling- the original global concept of valence, giving rise to new 'dissociated' (or 'articulated') concepts, to which we still make reference to today, although obviously in terms of the modern electronic structure of the atoms.

A concrete attempt to interpret analogous compounds was tried also in 1886 by S.M. Jorgensen [5], another pioneer of the chemistry of complexes. Jorgensen, prompted by organic chemistry, supported 'the theory of the chain', the same one that in 1869 inspired Blomstrand [6] to propose for hexamminocobalt(II) a linear formula similar to that of a hydrocarbon,

$Cl–NH_3–NH_3–NH_3–Co–NH_3–NH_3–NH_3–Cl$

It is no wonder that, according to this view, for some compounds, as for example the cupric(II) sulphate pentahydrate, the following ring-structure was proposed:



The diversity of opinions between Werner and Jorgensen gave rise to an increase in the development of knowledge relevant to the complexes that, independently from the result of the dispute, the two chemists' names are often recalled together as the pioneers of this branch of the science. In this regard, it is interesting to mention Basolo and Pearson [7] who, in the introduction of their well-known text 'Mechanisms of inorganic reactions' propose an imaginaring meeting between the two famous competitors, a meeting that during their lifetime they did not have the opportunity to arrange.

During the first stage of the historical development of Werner's theory, a notable confirmation derived from the experimental demonstration of the variation of the electric conductivity. In tetramminoplatinum(II), $Pt(NH_3)^{+2}$, the gradual substitution of the chloride ions for ammonia molecules produces a modification of the charge, while maintaining the unity of the 'complex-

ion'. The occasion for this demonstration occurred to Werner as a result of the enunciation of the theory of the electrolytic dissociation, which Arrhenius was formulating in that period. The coordinated complex ion exists as a unit in the solution and the stepwise substitution occurs as a consequence of equilibria between the central metal (in general a transition metal) and one or more ligand. The binding of neutral ligands to the metal ion was explained by introducing the idea of 'coordinative' or 'dative' bond. These coordinated compounds gave rise to the widely used definition of Coordination Chemistry for the study of metal complexes.

During the first 20 years of the XX century, the methods of synthesis of the complexes witnessed considerable development, and the discussions on the relative structures were thoroughly analysed. Among them, particularly those referring to the isomers, determined a definite progress in highlighting the diversities (both logic and real) presented by compounds sharing the same stoichometry but holding different properties, as those previously mentioned [3,4]. And on this occasion too, the culture of organic chemistry inspired concrete analogies for debates and definitions.

Significant progress was also made through the process involving the 'chelation' and related applications [8], although it was a long time before the actual interpretation was arrived at. In fact, the current term, as well as its relevant meaning, was proposed as late as 1920 by Morgan and Drew [9]. The methods of preparation, however, were already known for many of the compounds, even if not yet classified as 'chelates', and Ley [10] had referred some of these electrically neutral complexes as 'metal complex salts' as long ago as 1904:

Subsequently Lewis, [11] in order to interprete the complexation reactions proposed considering them as 'acid–base reactions' in which the metal ions are the acids and the ligands are the bases.

The studies focused particularly on the synthesis and on the structural properties of the complexes were continually growing. Nevertheless, interest in those compounds could not be confined to those targets, albeit of utmost importance.

This very long initial period, which we can actually define as a 'period of pioneers', was the prelude to new phases. After the Second World War, coordination chemistry was undergoing tremendous development mainly under the leadership of inorganic chemists. The main factor, however, was undoubtedly that coordination chemistry is a branch tending to integrate the whole of chemistry. The physical chemists studied the spectroscopic, theoretical, electrochemical, thermochemical, structural and crystallographic properties. The inorganic chemists studied the preparative, spectrochemical, magnetic and structural properties. The organic chemists contributed with preparation of ever new and complicated ligands, and with the study of kinetic, mechanistic, and catalytic properties. The analytical chemists provided the search for new complexing agents for precipitation and spectroscopic identification, and devoted their attention to speciation in solution searching for modern and sophisticated instrumental and computational methods. Subsequently the basic research was intensified both to reach a better comprehension of the experimental data and to obtain some benefits in the applications by means of the implementation of some various scientific and technological branches in a more rational and clear way.

An ever-increasing role was being played by the study of the mechanisms of metal–ligand interactions. Consequently, the studies on the thermodynamics and kinetics of the complexes increased. They represent a large portion of the chemical research, being the basis for fruitful use of application in different areas and for providing large interpretative contributions to other branches of the basic research. Precious contributions to the thermodynamics were developed by the prestigious schools of Bjerrum, Biedermann, Sillen, and Schwarzenbach. The school of Guttmann analysed the effects of the solvent on the equilibria. Other scientists (Ingold, Basolo) addressed themselves successfully to the study of the kinetics of the coordination compounds in solution, the main goal being to identify the mechanism of substitution reactions. This period of intense research on coordination compounds produced a considerable development, and led to technological improvements in organic chemistry, in electrochemistry through the development of processes of controlled and guided electrodeposition, as well as in analytical chemistry.

We have to recall here the studies on thermal analysis of the solid state complexes developed in particular by the School of Duval, already well known scientist for its thermoanalytical researches in geology and in the area of the materials. Other groups, first of all that of Wenndlandt' further developed these types of research.

Greater perspectives were opened for the use of the complexes in industry, first of all for the catalytic activity presented by some of them. Ziegler and Natta, in particular, were awarded the Nobel Prize for Chemistry in 1963 for their success in the stereospecific polymerisation of ethylene at low pressure in the presence of a complex of aluminium and titanium as catalyst.

Biochemistry, pharmacology and industrial production as well as environmental problems, in addition to

the application in analytical chemistry can be considered the main branches where the complexes have given rise to a considerable impact.

A very important subject of the research studies is the role that the metal ions exert upon the biological activity of the organism, by means of complexing, and in particular on the enzymatic activity. The best known coordination compounds in biological systems consist of ions of a transition metal and, as ligands, of atoms of nitrogen of a tetrapyrrole system. For example, it is absolutely necessary for the relevant complexing and activation of molecular oxygen, that a metal centre in the protein is responsible for the storage and transport of the oxygen itself as in hemocyanins, hemoglobin, hemerythrin and others. The same holds for some enzymes as oxigenase and oxidase.

In a number of biological systems the coordination compounds exert a function of great relevance since they constitute, in many systems, the active site for some essential process for the life of the cells. The catalytic functioning of about one third of all known enzymes requires the presence of a metal ion. The metal, more or less closely connected with the protein moiety of the enzyme, participates in the process either by binding to the substrate, thus activating it for the reaction, or through redox reactions by means of reversible variations of the oxidation state of the metal.

In this comprehensive view of innovative aspects, a newer frontier for research has been opened up under the stimulation of the large universe represented by the biothecnologies, which—as is well known—have given rise to a very considerable increase in every field connected to them. This trend has resulted as being particularly useful for the enzymatic systems, to which a considerable attention has been devoted in order to study the effects caused by the occurrence of certain cations on the coordination sites present in the enzyme molecules.

At cell level the sequence of the redox reactions is controlled by systems present in the cytochrome C, consisting of iron complexed in a porphyrin ring that shifts from the reduced to oxidised state and back, during the transport of the electrons. Beyond that, studies on the biomodel have been undertaken in order to interpret the effect produced by the presence of different kinds of ligands on the cobalt oxidation as well as on the formation and stability of oxygenated intermediate species [12–15]. It is also worthwhile to recall the mechanism activated by the main plants' photoreceptors and, above all, in vegetal biology. The well-known photosynthetic action of the chlorophyll is due to its structure in which one atom of magnesium is coordinated to the nitrogens of four pyrrolic rings, analogous to that of haemoglobin.

In the bio-medical field the main results from the study of the complexes have been attained through the examination of the interactions of the metal ions with several biologically active substances. Often the amount of data collected leads to a major awareness of the action mechanism that represents the base for the application to practical problems, mainly in the pharmacological field. In fact, the possibility of using inorganic compounds as pharmaceutical agents has been known for centuries. Nevertheless, the interest in 'bio-inorganic medical chemistry' is mainly related to the recent therapeutic innovating features achieved using, for example, radioactive and not radioactive metal complexes employed in imagery diagnosis, lithium compounds in neurology, complexes of gold in reumathology and, above all, some coordination compounds for anti-tumour action. This is the case of bleomycin [16–22], an antibiotic of the family of the glycopeptide derivates used in the Hogkin's lynphoma as well as in skin, head, and neck carcinomas. Its action seems to be connected to the formation of complexes as the copper(II), which is able to penetrate the tumour cells where, through a process of de-complexing, it causes the scission of the DNA strain. The major contribution to the use of coordination compounds in therapy is represented by the discovery [23] of the activity of the *cis*-diamminedichloroplatinum(II) (*cis*-DDP or *cis*-Platinum), on the tumours of the head, neck or genital-urinary apparatus. From this discovery, research studies were performed, with the purpose of identifying anti-tumor properties of 'new' coordination compounds as well as organo-metal compounds with ions other than Platinum [24].

The knowledge of the thermodynamic properties of the complexes species allows for metal ions to be used for regulating the concentration of biologically active substances in the living organism, but also as vehicles of medicaments through the cell membranes. In fact, it may be necessary to examine the properties of the complexes in more depth by identifying the chemical species effectively present in the solutions, that is their 'speciation'. These further studies have made possible to explain the effects of particular elements in fluids that represent the basis of the investigations, particularly in environmental refluents and in biological fluids. Their contribution to the interpretation of relevant and specific effects, in environmental chemistry is of vital importance. They represent the best interpretation of the causes of the deviations from normal state and consequently of the study of protective and curative applications. By means of speciation, it is possible to know the behaviour of a metal in solution, because of the different chemical–physical forms in which it 'actually' exists. Through the thermodynamic study of the equilibria in solution we obtain the knowledge of the real species and, from the values obtained, we can find out the number, the nature and the concentration of the different species that exist in the solution investigated

[25]. The knowledge of such data is of the utmost importance on account of its potential benefits in dealing with contaminating agents and constitutes a tool for solving problems related to the mobility of metals, in addition to explaining, rationalising and highlighting the potential toxic features of the species. These latter are also particularly relevant in the case of heavy metals.

The study of toxicity for living organisms is also connected to 'speciation', since the permeability of the cell membrane is different according to the species coming in contact with it. In particular, the toxicity of the metal in water solution was investigated, mainly in connection with unicellular organism as algae and phytoplankton. The toxicity of the free-metal ion emphasised as has that of the neutral stable complexes of a lipophilic type [26], able to penetrate directly the layer of cell membranes in which they are soluble.

The knowledge of 'speciation' of an environmental system is particularly important both for theoretical and implementation [27] purposes. In fact, it is possible to interpret or to predict the performance of a natural system and potentially to plan interventions upon it in terms of both resolution or prevention, merely by knowing the relationships and mutual influences of the chemical components, as well as the physical parameters that characterise such a system.

In the field of analytical chemistry, new, important applications have been carried out following the studies on complexation, which have proved to be of particular advantage regarding two subjects: (1) as titration indicators of metal ions, as murexide, or 'eriochrome black T'; (2) as reagents in colorimetry for the qualitative and quantitative analysis, such as dithizone, dimethylglyoxime, hydroxyquinoline, cupferron, *o*-phenanthroline. In most cases, the resulting coordination compounds are chelates, as for example in the quantitative volumetric analysis. As far as these complexometric titrations are concerned, many reactions lead to the formation of soluble complexes but only a few of them can be used for analytical purposes since they must meet the fundamental requirements for the volumetric analysis, quickness, univocality and fulfilment. It is also worthmentioning that, apart from those related to the formation of halogenic (as with Hg(II)) or cyanidric (as with Ag (I)) complexes, the reactions mainly used for complexometric titrationd analysis are those involving chelation [28]. In accordance with that, the term 'chelometry' identifies the related part of volumetry.

In the titrations of metal ions of different types, the multidentate ligands are used more frequently, since it is possible to find in their structures different donor atoms, as oxygen and nitrogen. Among those, the best known is ethylene-diamminetraacetic acid (EDTA) that, being able to form stable chelates with almost all the polivalent metal cations, is used for the direct determination, of ions, as for Ca^{2+}, Mg^{2+}, Zn^{2+}, Bi^{3+}, Fe^{3+}, Co^{2+}. Other multidentate chelating agents are diethylenetriaminepentaacetic acid (DTPA), which provides a better result than the EDTA in the titrations of cations with a high coordination number, cyclohexanediamine tetraacetic acid (CyDTA), whose complexes are, in contrast, characterised by a partial liability, and some other synthesised products, including, for example, tris-(2pyridylmethyl) amine (TPA). We may take into account that in different analytical methods applied to matrixes containing many species the reagents play a determining role since, through them, it is possible to 'sequestrate', in a selective manner, the ions provoking interferences.

We have already mentioned the outstanding success attained by the Nobel Prizewinners Ziegler and Natta in the synthesis of the isotactic polypropylene, a compound of great relevance both for scientific and industrial applications. Their great success was not achieved by chance but was the result of thorough research involving the chemistry of the complexes since almost all processes in the chemical industry are based on the implementation, selection and application of catalysts. Thus, in the literature we find reports of several reactions indicating complexes, or, rather, the metal ions that form coordination compounds with the substrata, acting as catalysts. We also need to say here that, when the catalysed reaction of the metal ion is completed, the catalyst can be recovered also, although in most cases in an oxidation state different from the initial one and coordinated to groups that are different from the initial ones.

The reaction catalysed by hydrogen ions can be activated also by metal ions able to produce the formation of chelates with the substrata. There are several examples of this, ranging from the reaction of the bromuration of acetacetic ester catalysed by copper ion [29] to decarboxylation of some keto-acids, such as 'oxalacetic acid', or the hydrolysis of esters and amides of α-aminoacids.

The complexes also play a fundamental role as catalysts in the processes of hydrogenation and of the acid-catalysed reactions. Such reactions find their main application in food industry and in particular in the production of edible fats starting from oils of animal or vegetal origin, varying in mono and poly-unsaturated fatty acids.

The coordination compounds are also involved in the mechanism of condensation leading to the production of molecules that are important from an industrial point of view. We have, for example, acrylonitrile, starting from acetylene and from hydrocyanic acid in the presence of copper chloride as a catalyst [30], or derived from acrylic acid obtained from the reaction of carbon monoxide and water, alcohol, or amines, with carbonyl nickel as a catalyst.

Another subject of great interest is the use of transition metal complexes as catalysts in the oxidation reactions. The catalytic oxidation of hydrocarbons in the presence of oxygen, in fact, finds a considerable number of applications. In industry, mention can be made of those conducted on the *p*-xylene [31] for producing acids, used in the production of polymers for synthetic fibres, as well as those for the production of hydroperoxides, used as sources of free radicals for their function of starter in the polymerisation reactions [32,33].

In the light of what has been said above, it is clearly important to know the chemistry of the complexes in solution for: (1) the interpretations of some interactions that can explain the mechanism of the reactions, in which the complexes are involved, and (2) some applications in specific fields, for which the data collected through such study provide basic information for the planned targets. It is reasonable to assess that further research on coordination compounds will lead to further knowledge of the interpretations and applications involving chemistry as a whole. This support provided by the thermodynamic and kinetic studies of the complexes in solution will also lead to their application in the many and varied fields in which chemistry is directly or indirectly interested.

I was with the purpose of contributing to further studies in this field, requiring deep commitment and engagement, that the Group of Thermodynamics of the Complexes, 'GTC' was founded in 1973, in Italy, just in Parma, by researchers from a sizeable number of Italian universities. The GTC was constituted to create a common background to increase specific knowledge, and to compare with the experiences of the individual members by means of debates. Distinguished by the qualified experience of its members, the Group has attained important international recognition, without being bound by the bureaucracy of statutes or rigorous regulations. GTC has had the resolve and the tenacity to remain operational for the last 28 years. GCT each year is seeking confrontation in a Congress, having found interests and met challenges that go well beyond any barriers that may exist between various academic fields. This is confirmed, on the one hand, by its extremely friendly and fruitful relationship with the corresponding groups in the Spanish universities, and, on the other, by the high number of publications of its members. The GTC's main policy is to foster and intensify basic research by the setting up of 'Summer Schools', which are held with the purpose of providing constant updating through didactics.

I would like to end with a much appreciated quotation by Professor Luigi Sacconi, one of the most eminent scientists involved in the chemistry of complexes: 'The aim of fundamental research is, mainly, to understand'.

Received 11 December 2001; accepted 25 January 2002

Abstract

Cadmium(II) and zinc(II) complexes with the chelating agents *meso*-2,3-dimercapto succinic acid, *meso*-monomethyl dimercapto succinate, *meso*-dimethyl dimercapto succinate and the related methylmercapto acetate and mercapto succinic acid were studied potentiometrically in 0.1 M KCl at 25 °C. Models and hypotheses of coordination for the solution complexes are proposed. IR characterisation and stoichiometry of the solid state compounds evaluated by elemental analysis are presented. The obtained formation constants, together with the previously measured ionisation constants of the ligands, were used to compute pCd and pZn values and then to evaluate the effectiveness of the studied chelating agents in binding Cd(II) and Zn(II) in intoxication treatments.

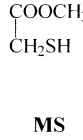
1. Introduction



The use of chelating agents in heavy metal intoxication treatment is a very complex field that requires the collaboration of several branches of Science. The main contribution of Chemistry to this field is the determination of both coordination models and formation constants of complexes between metal ions and chelating agents to compare the strength and characteristic of the formed complexes. In the coordination processes using chelating agents in vivo, it should be taken into account that there is always competition for the coordinating positions between toxic and essential metal ions such as calcium(II), magnesium(II), zinc(II), manganese(II), iron(III) or copper(II) [1,2]. For this reason, it is of great interest from a chemical point of view to study the chelating agent coordination with both toxic and essential metal ions. In recent years our group has focused on the thermodynamic study of the complexation of DMSA (*meso*-2,3-dimercapto succinic acid) and some derivatives with platinum group metals [3,4]. DMSA is a widely used oral chelating agent with two kinds of binding positions involved in metal coordination: the carboxylic and mercapto groups [5–7]. However, DMSA hydrophilicity prevents it from permeating cell membranes and entering into cells. For this reason, it would be useful to study the mono and dimethyl DMSA ester derivatives which, apart from being good chelating agents, are also more lipophylic compounds.

In this paper, the equilibrium studies of complexation between Zn(II) and Cd(II) with DMSA, mono and dimethyl dimercapto succinates, and the other structurally related molecules shown in Table 1 are presented. Zinc is the second more abundant trace metal in the human body [1] and can be considered as non-toxic to humans [8]. It is essential for the structure, regulation, and/or catalytic action of over 300 enzymes, as for example those responsible for DNA and RNA synthesis [9]. It has also a physiological action in collagen synthesis, bone metabolism, immune system integrity, anti-inflammatory action and protection against free radicals [10]. As a consequence, zinc should not be removed by chelating agents used *in vivo*. Cadmium, on the contrary, is a very toxic metal widely used in many

industrial processes to produce batteries, plastic, pigments and semiconductors [1]. It is estimated that humans absorb 5% of ingested cadmium, while absorption of cadmium by the lungs (cigarette smoke) is approximately 10–40% [1]. Immediately after systemic entrance, cadmium localises intracellularly and kidney, liver, lung and pancreas [11] are the main organs for its accumulation. In the kidneys it has a 30-year biological half-life causing renal dysfunction [1]. Other syndromes produced by cadmium toxicity are: hepatic injury, lung damage, bone defects dependent on altered calcium metabolism [12], mutagenic and carcinogenic effects [13,14]. Orally administered DMSA has been shown to reduce intestinal cadmium uptake but, to mobilise aged cadmium depots from the liver or kidney, monoalkylesters or monoalkylamides derivatives of *meso*-2,3-dimercapto succinic acid have been proved to be more effective chelators [15,16]. The main aim of this work is to compare quantitatively the strength of the Cd(II) and Zn(II) complexes formed with DMSA, alkyl ester derivatives and related molecules to evaluate the efficiency of these compounds in cadmium removal and in the possible side-effects on the zinc level. This study follows previous works on the complexation of DMSA [17–23] or other related molecules[24–26] with Cd(II) and Zn(II) and can provide insights into the proposed complexation models.

2. Experimental

2.1. Reagents

HCl standard solution, KOH, $CdCl_2$, $ZnCl_2$, KCl, methylmercapto acetate, mercapto succinic acid, *meso*-2,3-dimercapto succinic acid were Aldrich products; *meso*-monomethyl dimercapto succinate and *meso*-dimethyl dimercapto succinate were synthesised according to Gerecke [27]. The purity of the synthesised compounds was checked by elemental analysis with a CHN-S Fisons instrument and by ^{13}C NMR and IR spectra. The commercial compounds were used without further purification. Due to their redox properties, the solutions of mercapto-compounds were prepared daily by dissolving weighed amounts with freshly double-distilled water saturated with Argon. Potassium hydroxide carbonate free solutions were prepared according to Albert [28].

2.2. Potentiometric measurements

Titrations were performed on a Dosimat 665 Metrohm automatic titrator connected to a Metrohm 654 pH meter. A thermostated glass-cell was used equipped with a magnetic stirring system, a Metrohm combined LL Unitrode glass electrode, a thermometric probe, a microburet delivery tube, and an inlet-outlet tube for Argon. The solutions (20 ml at ionic strength 0.1 M KCl) were titrated at 25 °C with carbonate-free KOH, whose titre was checked daily. The electrode was calibrated for hydrogen ion concentration by titration of HCl with KOH; the resulting data were analysed with Gran [29] procedure using our granplot program. We titrated, for each ligand, 20 ml ligand–metal mixtures with KOH 0.1 M using ligand 10^{-3} M and metal variable in order to have 4:1, 2:1, 4:3 and 1:1 ligand–metal molar ratios. Ionisation and formation constants were calculated by the psequad [30] program operating on the experimental data (ml, $-\log[H^+]$). Since the analysis of results led us to assume polymeric complexes, we repeated the measurements at four different ligand concentrations (1×10^{-4}, 4×10^{-4}, 7×10^{-4} and 1×10^{-3} M) using the same scheme as above i.e. 4:1, 2:1, 4:3 and 1:1 ligand–metal molar ratios.

2.3. Synthesis of metal complexes

2.3.1. Zinc complexes

A mixture of 50 mmoles (or 100 mmoles in the case of 2:1 molar ratio) of ligand and 50 mmoles of zinc chloride in ethanol was left for 1 h in reflux under nitrogen. The resulting solution was evaporated to dryness under vacuum to give a white solid product, which was washed with a 1:1 isopropanol–ethyl ether mixture, and filtered off to dryness under vacuum. In both 1:1 and 2:1 molar ratio preparations the same

products were obtained. In the case of MS ligand colourless oil was obtained.

2.3.2. Cadmium complexes

A mixture of 50 mmoles (or 100 mmoles in the case of 2:1 molar ratio) of ligand and 50 mmoles of cadmium chloride in water was stirred under nitrogen for 1 h. Freezing this solution, a solid residue was obtained and filtered off under vacuum, washed with cool water, and then dried under vacuum. In both 1:1 and 2:1 molar ratio preparations the same products were isolated.

2.4. IR measurements

IR spectra were recorded with a Perkin–Elmer 983 instrument in the range $4000 \div 180$ cm^{-1} using KBr pellets for solid compounds, and CsI disks for liquid compounds.

3. Results and discussion

The ionisation constants of the five ligands, previously determined [31], are reported in Table 2. Since the studied equilibria involve formation of polynuclear complexes we took the measurements at four different metal concentrations ranging from 10^{-4} to 10^{-3} M and for each metal concentration at four different metal–ligand ratios. For each system the data relative to all the performed titrations (4×4) were processed at the same time using psequad program.

The estimated models and related formation constants for zinc and cadmium are reported in Tables 3 and 4, respectively. The solid complexes obtained as reported in Section 2.3 were characterised by IR spectroscopy to give evidence of SH and COOH group involvement in complex formation, and the frequencies of the significant bands are reported in Table 5.

[a] Values in parentheses are S.D. in units of the last significant figure.

3.1. Zinc complexes

Examined ligands form 1:1 and 2:1 complexes with Zn(II) except MS that also forms a $[ZnL_3]^{-}$ complex. Polymeric structures must be assumed in the majority of cases. The distribution curves for zinc(II) complexes at 1:1 molar ratio are reported in Fig. 1.

The lower stability (complex formation starting at pH > 5) of complexes with ligands characterised by a single SH group (MS and MSA) is observed, compared with those with ligands having two SH groups, already formed at pH 4. The 2:2 complexes with monothiolic ligands can be hypothesised as in Scheme 1(A) and Scheme 2(A), in which two zinc atoms in a tetrahedral configuration are joined by two bridging sulfur atoms. Four water molecules complete metal coordination in the first case, while only two water molecules are required for MSA where a COO^{-} group per ligand binds zinc forming a five membered ring.

Their different configurations as well as the total charges (2+ for MS and 2-for MSA) determine their pH behaviour: $[Zn_2L_2]^{2+}$ with MS loses protons from the

Table 5
Frequencies of significant IR bands of zinc and cadmium complexes

Ligand	Pure ligand (cm^{-1})	Zn complex (cm^{-1})	Stoichoimetry	Cd complex (cm^{-1})	Stoichoimetry
MS	2570–2550 (SH)	broad bands	oil product	no SH band	CdLCl
MSA	2570–2550 (SH) 1700 (COOH)	1700 (COOH) 1600 (COO–Zn)	$ZnLH\cdot 2H_2O$	1700 (COOH) 1570 (COO–Cd)	CdLH
DMSA	2550–2525(SH) 1700 (COOH)	1700 (COOH) 1600 (COO–Zn)	$Zn_2LHCl\cdot 3H_2O$	2550 (SH) 1700 (COOH) 1537–1340 (COO–Cd)	$CdLH_2$
MMS	2550–2515(SH) 1730 ($COOCH_3$) 1700 (COOH)	1730 ($COOCH_3$) 1600 (COO–Zn)	Zn_2LCl	1730 ($COOCH_3$) 1575 (COO–Cd)	Cd_2LCl
DMS	2520 (SH) 1730 ($COOCH_3$)	2525 (SH) very weak 1630–1730 ($COOCH_3$)	ZnLHCl	1730–1675 ($COOCH_3$)	CdL

four coordinated water molecules at pH 7.50, 8.16 (two protons) and 9.62, while $[Zn_2L_2]^{2-}$ with MSA ionises at pH 8.48 and 9.44. At higher pH, the monodentate MS forms both ZnL_2 and $[ZnL_3]^-$ complexes (Scheme 1(B)), being this last the prevailing species at 4:1 molar ratio. The bidentate MSA besides $[Zn_2L_2]^{2-}$ forms only $[ZnL_2]^{4-}$, whose structure is proposed in Scheme 2(B).

We were not able to obtain a solid compound with MS. The structure of the white solid obtained with MSA, characterised by elemental analysis as $ZnLH\cdot 2H_2O$, is analogous to that presented in Scheme 2(A), protonated on the two uncoordinated carboxylates. This agrees with IR findings: the SH bands at 2570–2550 cm^{-1} of pure ligand totally disappear while the COOH band at 1700 cm^{-1} decreases with the simultaneous appearance of a band at 1600 cm^{-1} assigned to a coordinated COO^-.

The greater stability of $[Zn_2L_2H_2]^{2-}$ with DMSA compared with that of $[Zn_2L_2]^{2-}$ with MSA implies a coordination through both S^- groups as reported in Scheme 3. This structure suits the pK values 4.4 and 6.4, which can be attributed to COOH ionisation from a

Scheme 3.

MMS

Scheme 4.

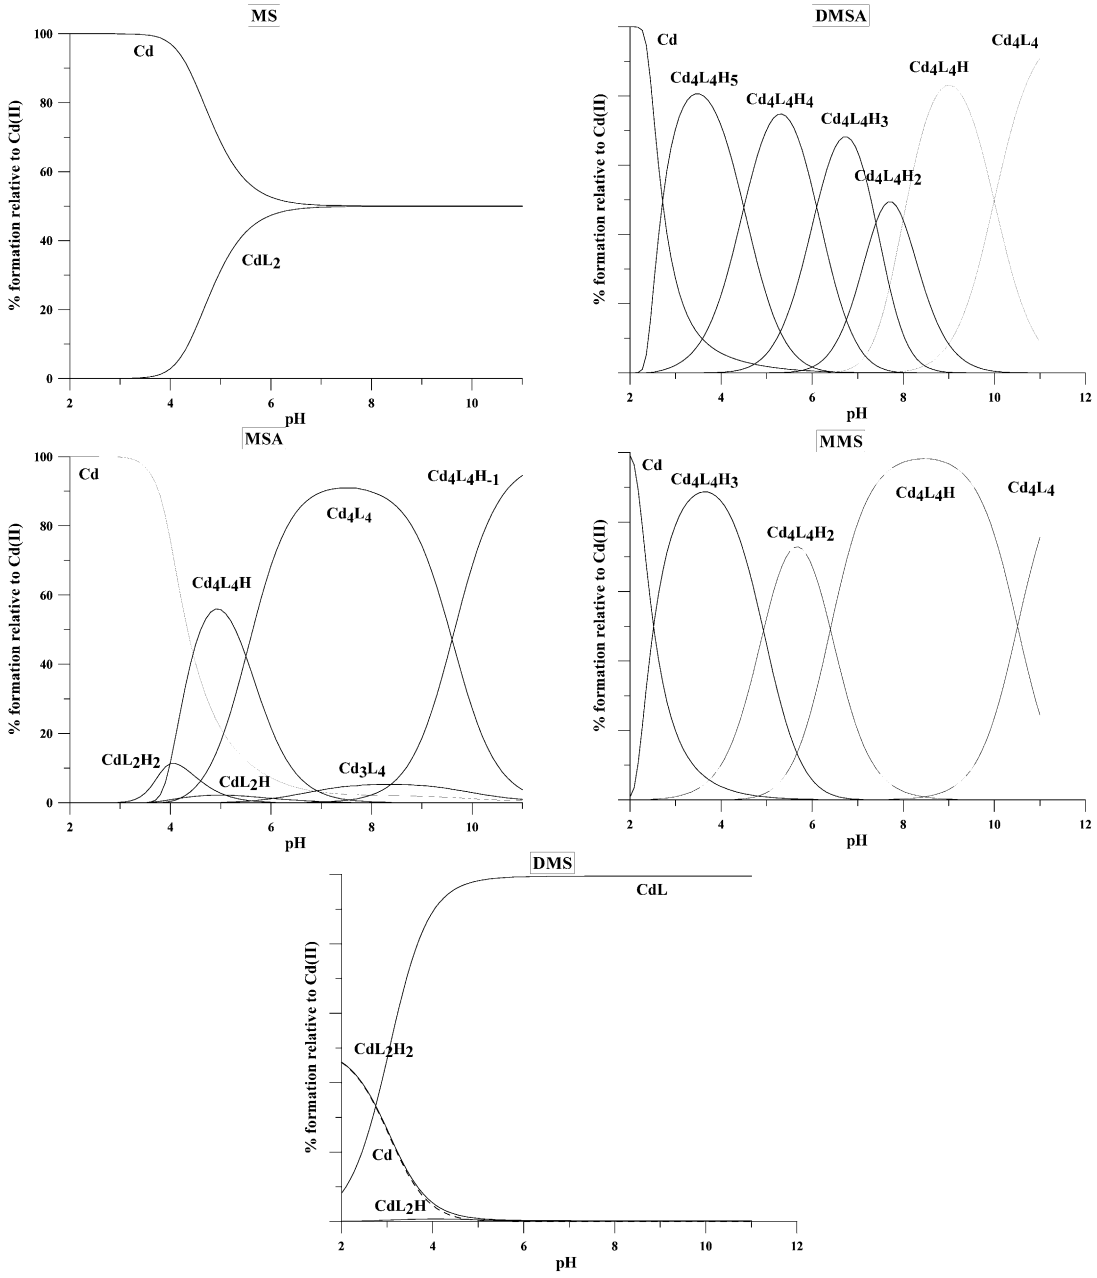

Fig. 2. Distribution curves for Cd(II) complexes versus pH, calculated with concentrations of Cd(II) and ligands 1 mM.

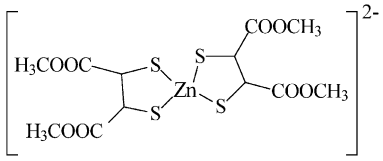
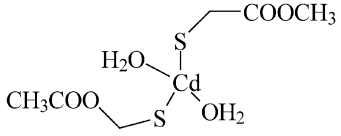
negatively charged molecule. The obtained solid compound with DMSA, characterised as $Zn_2LHCl\cdot 3H_2O$, does not correspond to the solution model.



A polymeric structure, Scheme 4(A), has to be invoked for $[Zn_4L_4H]^{3-}$ with MMS; the first pK 5.3 agrees with the carboxylic group ionisation, while the value 9.2 can be ascribed to one coordinated water molecule. In the $[Zn_2L_4H_2]^{6-}$ structure, Scheme 4(B), two MMS molecules coordinate via both thiolato groups and two via a S^- alone. The isolated compound, as in DMSA case, involves zinc coordination by a single thiolato group and it does not correspond to the solution model.

At any metal ratio, a $[ZnL_2]^{2-}$ complex is formed by DMS in which zinc is coordinated by both S^- groups as suggested in Scheme 5. At molar ratios lower than 2:1 excess zinc precipitates as hydroxide at pH > 6.5. In a different way from DMSA and MMS, only a zinc per ligand is coordinated in the solid compound, via a S^- group.

3.2. Cadmium complexes



The distribution curves of cadmium(II) complexes are reported in Fig. 2. Also in this case, the greatest stability

DMS

Scheme 5.

MS

Scheme 6.

of complexes of ligands with two thiolic groups is evident.

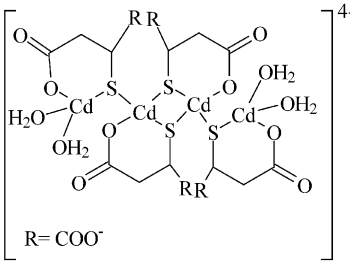
At any molar ratio MS forms only the CdL_2 complex, Scheme 6. The much higher stability of CdL_2 than ZnL_2 prevents formation of 2:1 and 3:1 complexes. A CdLCl compound was isolated in the solid state.

As with zinc, cadmium forms with MSA 1:1 and 1:2 polymeric complexes. In the proposed structure for $[Cd_4L_4]^{4-}$, Scheme 7(A), the inner cadmium(II) ions are linked by two S-bridges while the coordination sphere of the external ions is completed by two water molecules. All four ligands coordinate both by thiolato and carboxylate groups. Moreover a $[Cd_3L_4]^{6-}$ complex is formed, Scheme 7(B), where all the ligands coordinate again by thiolato and carboxylate groups. A solid compound of formula CdLH, analogous to ZnLH, was obtained.

The cadmium(II) tendency to form polymeric structures of multiplicity four was confirmed by DMSA

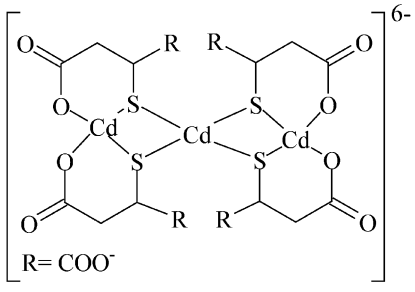
Table 6
pZn and pCd, for the studied ligands, defined according Raymond [32]

	pZn	pCd
MS	6.0	7.0
MSA	6.0	6.1
DMSA	7.9	7.9
MMS	8.2	9.5
DMS	10.1	18.7



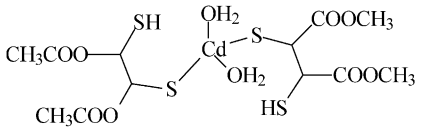
complexes, for which a structure similar to that in Scheme 4(A) for $[Zn_4L_4H]^{3-}$ can be proposed. IR spectrum of the solid $CdLH_2$ suggests a coordination via one S^- and one COO^- group.

A structure as in Scheme 4(A) could be proposed again for 4:4 MMS complexes. The $[Cd_4L_4H_3]^-$, existing at pH < 4, loses the first two protons at pH 4.93 and 6.40, starting from 1-and 2-charged molecules. This behaviour is similar to that of DMSA in which the reactions $[Cd_4L_4H_5]^{3-} \rightarrow [Cd_4L_4H_4]^{4-} \rightarrow [Cd_4L_4H_3]^{5-}$ take place at pH 4.5 and 6.1 but starting from 3-and 4-charged molecules. A structure similar to that for Zn(II) in Scheme 4(B), can be proposed for $[Cd_2L_4H_4]^{4-}$. In this case the two protons on carboxylic groups are removed at pH 5.74 and 6.70, due to the high negative charge on the complex, and the third from the SH group at pH 7.99. A solid Cd_2LCl compound was isolated, analogous to the Zn_2LCl.

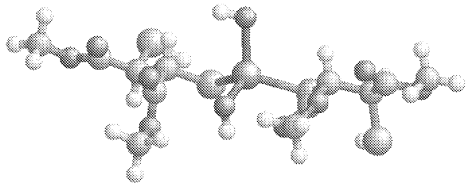


In excess of the dimethylated DMS cadmium forms CdL_2H_2 coordinated by only one thiolato group per ligand, Scheme 8, while at higher pH is coordinated by both thiolato groups as in Scheme 5. At 1:1 molar ratio the prevailing compound is CdL, coordinated by both thiolato groups, with the same stoichiometry of the solid compound.

MSA



A



B

Scheme 7.

DMS

Scheme 8.

In literature solution equilibria between zinc(II) and DMSA has been studied by different authors; leaving out the oldest [17,18] the models and the numerical values of recent works [19,21,23] are in good agreement with our results. A good agreement has been also found with MSA results [24,25]. No other ligand is reported, except DMS whose equilibria with zinc(II) were examined [26] in a water-ethanol 50% mixture. No comparison with literature was possible for cadmium(II) since its complexes have been scarcely studied (DMSA [19] and MSA [25] at 37 °C). We only remark that with these two ligands we had to assume polymeric structures.

4. Conclusions

The evaluation of the clinical success of a ligand involves the knowledge of the amount of chelated metal ions. This amount depends on binding properties of the ligand at physiological pH, taking into account the competition of the proton towards the same binding sites. To compare the effectiveness of ligands we made use of pM introduced by Raymond [32]. It is defined as the concentration, expressed as negative logarithm, of free metal ion in a solution at pH 7.4 that is 10 μM in ligand and 1 μM in metal. A high pM value signifies that the ligand is a successful chelating agent. In Table 6 we report the pCd and pZn values for the studied ligands. On the basis of these values we can state that monothiolic, different from dithiolic ligands, are not good chelators. The dithiolic ligands can be classified in the order DMSA < MMS ≪ DMS, according to their efficiency, that increases with methylation of carboxylic groups. Methylation has two cooperative effects, one inductive and one electrostatic. These two effects act synergistically, the first increasing the strength of S–Cd bond and the second decreasing proton competition. Furthermore, methylated compounds have different behaviour in vivo for their different lipophilicity, which should allow them to pass through cellular membranes.

Cd(II) complexation in aqueous solution with dipyridine- and phenanthroline-containing polyamine macrocycles

Andrea Bencini *, Antonio Bianchi *, Patrizia Fornasari, Claudia Giorgi, Piero Paoletti *, Barbara Valtancoli

Department of Chemistry, University of Florence, Via della Lastruccia 3, 50019-Sesto Fiorentino, Firenze, Italy

Received 10 September 2001; accepted 1 October 2001

Abstract

The coordination features toward Cd(II) of four phenanthroline-containing and three dipyridine-containing macrocyclic polyamines have been studied by means of potentiometric and spectrophotometric UV–Vis measurements in aqueous solutions. All ligands form stable 1:1 metal complexes. The stability constants of the Cd(II) are generally lower than those reported for Cd(II) complexes with aliphatic macrocyclic polyamines containing the same number of nitrogen donors. This effect is mainly related to the stiffening of the ligands, due to the insertion of a large and rigid heteroaromatic moiety within the aliphatic polyamine framework. This structural feature does not allow the nitrogen donor to achieve an optimal arrangement around the metal ion. The decreased stability is often accompanied by facile protonation of the complexes, suggesting that some amine groups are not involved in metal binding. © 2002 Elsevier Science Ltd. Keywords: Macrocycles; Cadmium; Polyamines; Dipyridine; Phenanthroline

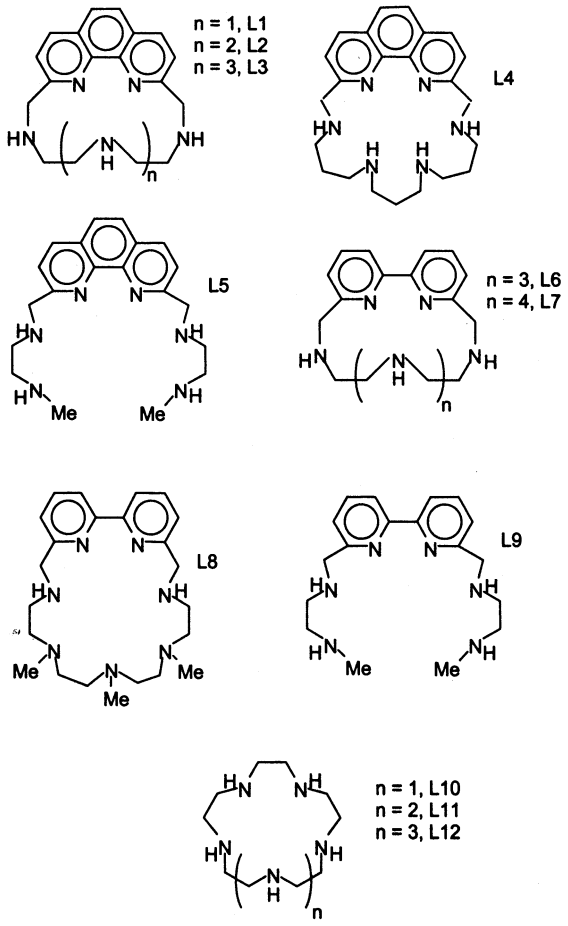
1. Introduction

Macrocyclic ligands may contain central hydrophilic cavities, ringed with electronegative binding atoms, and exterior frameworks exhibiting hydrophobic behavior [1–15]. The hydrophobic exteriors may allow them to solubilize metal ions in nonaqueous solvents or in membrane media, resulting in their employment as models for carrier molecules in the study of active ion transport phenomena as well as in their potential use as sequestering agents for metals of environmental importance, such as Pb(II) or Cd(II). The coordination features of several saturated polyamine macrocycles have been investigated in order to design selective binding agents for these metals [16–26].



Earlier, we reported the synthesis of a series of macrocyclic polyamine ligands containing a dipyridine or a phenanthroline unit, namely **L1**–**L4** [24,27–29] and **L6**–**L8** [30]. These heteroaromatic moieties can provide a further binding site for metal cations. Furthermore, these units are rather rigid, and may provide two aromatic nitrogens whose unshared electron pairs may act cooperatively in binding cations.

Previous studies on Cu(II) [28,31], Zn(II) [27,32,33], Ni(II) [34] and Pb(II) [24] coordination have shown that the heteroaromatic nitrogens are generally involved in metal coordination. Only in the case of Pb(II) complexation, however, this structural feature leads to an enhancement of the stability of the complexes with respect to the saturated polyamine ligands with the same number of nitrogen donors, such as **L10**–**L12**, containing an ethylendiamine unit which replaces the heteroaromatic moiety ([3*k*]aneN$_k$ series) [35]. This was attributed to the higher affinity of the heteroaromatic nitrogens toward the soft Pb(II) ion than aliphatic amine groups [24]. On the contrary, in the case of Cu(II) [28], Zn(II) [27,32,33] and Ni(II) [34], the replacement of an ethylendiamine chain of **L10**–**L12** with a dipyridine or a phenanthroline unit gives rise to a destabilization of the complexes. The rigidity of these heteroaromatic units, in fact, does not allow all the nitrogen donors to bind simultaneously to the smaller Cu(II), Zn(II) or Ni(II) ions.

We have now extended this analysis to Cd(II), in order to further elucidate the relationship between the structural features of these ligands and their coordination properties. In this paper we report a potentiometric and UV spectrophotometric study on the interaction with this metal in aqueous solutions. The coordination features of the two open-chain polyamines **L5** and **L9** [26,36], which contain a phenanthroline or a dipyridine unit, are also analyzed. The results are compared with those previously obtained with saturated polyazacycloalkanes not containing heteroaromatic units, such as **L10**–**L12** [35].

2. Experimental

2.1. General procedures

Ligands **L1** and **L2** [24], **L3** [28], **L4** [29], **L5** and **L9** [36], **L6**–**L8** [30] were obtained as previously reported.

2.2. EMF measurements

Equilibrium constants for the complexation reactions were determined by pH-metric measurements ($pH = -\log [H^+]$) in 0.1 mol dm^{-3} NMe_4Cl at 298.1 ± 0.1 K, by using the potentiometric equipment that has been already described [37]. The combined glass electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free NaOH solutions and determining the equivalent point by the Gran's method [38], by which you may determine the standard potential E°, and the ionic product of water ($pK_w = 13.83(1)$ at 298.1 K in 0.1 mol dm^{-3} NMe_4Cl, $K_w = [H^+][OH^-]$). Also 1×10^{-3}–2×10^{-3} mol dm^{-3} ligands and metal ion concentrations were employed in the potentiometric measurements performing three titration experiments (about 100 data points each one) in the pH ranges 2.5–10.5. Protonation constants of ligands are from references [33] (**L1** and **L2**), [28] (**L3**), [29] (**L4**), [27] (**L6**), [25] (**L7** and **L8**) and [26] (**L5** and **L9**). The computer program HYPERQUAD [39] was used to calculate equilibrium constants from e.m.f. data. All titrations were treated either as single sets or as separated entities, for each system, without significant variation in the values of the determined constants.

2.3. Spectrophotometric measurements

Absorption spectra were recorded on a Perkin–Elmer Lambda 9 spectrophotometer. HCl and NaOH were used to adjust the pH values that were measured on a Metrohm 713 pH meter.

3. Results and discussion

Cd(II) coordination by ligands **L1**–**L4** and **L6**–**L8** was studied by means of potentiometric measurements and the formation constants of the complexes formed in aqueous solutions are listed in Tables 1 and 2 for the phenanthroline and dipyridine complexes, respectively. The stability constants of the complexes with **L5** and **L9** are reported for comparison [26].

Considering the data in Tables 1 and 2, some general features can be outlined.Firstly, all ligands form mononuclear $[CdL]^{2+}$ complexes (**L** = **L1**–**L9**) in aqueous solutions. The data analysis with the program HYPERQUAD [39] under our experimental conditions revealed 1:1 stoichiometries for all the species detected. The stability constants of the **L1**–**L9** complexes are generally lower than those of the corresponding complexes with polyamine ligands with the same number of nitrogen donors but not containing heteroaromatic units [35]. Secondly, with the exception of **L1**, Cd(II) forms stable complexes with protonated species of the ligands. **L3**, **L4**, **L5**, **L6** and **L9** can bind up to three protons in aqueous solution, while **L7** can also form a tetraprotonated species $[CdL7H_4]^{6+}$. Consequently, protonated species of the complexes are often present in solution at neutral or slightly acidic pH values. Some exemplifying distribution diagrams are reported in Figs. 1 and 2.

Table 1
Formation constants of the Cd(II) complexes with the phenanthroline-containing ligands **L1**–**L5** (0.1 M NMe_4Cl, 298.1 K)

Reaction	L1	L2	L3	L4	L5 [a]
$Cd^{2+} + L = [CdL]^{2+}$	17.30(1) [b]	16.91(1)	15.89(2)	10.82(1)	16.03(2)

3.1. Cd(II) complexation by phenanthroline-containing polyamines

The phenanthroline-containing ligands **L1**–**L3** present aliphatic chains, linking the 2, 9 positions of phenanthroline, with an increasing number of amine groups separated by ethylenic spacers. In Fig. 3 the logarithms of the stability constants corresponding to the general reaction $Cd^{2+} + \mathbf{L} = [Cd\mathbf{L}]^{2+}$ are plotted for the phenanthroline-containing polyamines **L1**–**L3** and for the macrocycles of the $[3k]aneN_k$ series containing the same number of nitrogen donors (**L10**–**L12**) [35]. Although ligands **L1**–**L3** show a good ability to coordinate Cd(II), the stability constants of their complexes are remarkably lower than those of the complexes with macrocycles of the $[3k]aneN_k$ series with the same number of donors. This would be ascribed, in principle, to the different binding ability of phenanthroline and/or to steric effects exerted by this heteroaromatic unit, which replaces, in **L1**–**L3**, one ethylenic chain of **L10**–**L12**. In order to get further information on the role played by the phenanthroline unit in Cd(II) coordination, the reaction of complex formation was followed by means of UV spectra recorded on aqueous solutions containing ligands and Cd(II) in various molar ratios. Metal binding by 1,10 phenanthroline usually does not change the position of the typical UV band of this heterocycle at 270 nm, but leads to a marked change in the molar absorbance [24,26,28]. For instance, in the case of **L1** the aromatic moiety gives a rather sharp band

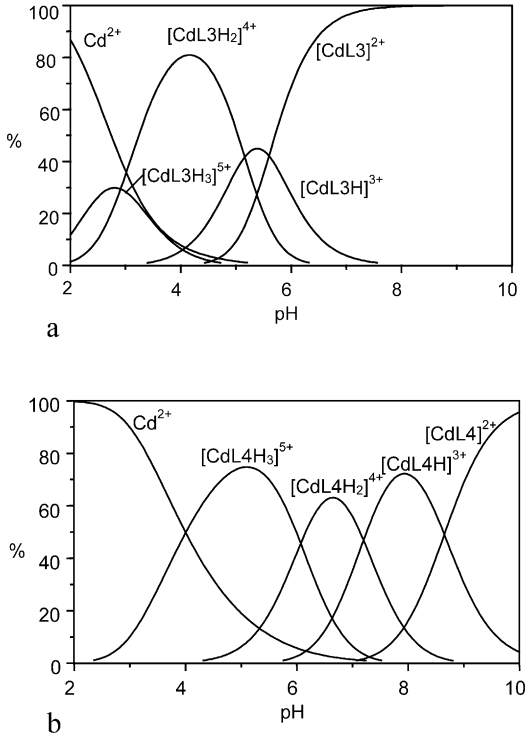

Fig. 1. Distribution diagrams of the species for the systems **L3**/Cd(II) (a) and **L4**/Cd (b) (NMe_4Cl 0.1 mol dm^{-3}, 298.1 K, $[\mathbf{L3}] = [\mathbf{L4}] = [Cd^{2+}] = 1 \times 10^{-3}$ M).

at 273 nm ($\varepsilon = 21\,200$ dm^3 mol^{-1} cm^{-1}). Solutions containing **L1** and increasing amounts of Cd(II) at neutral pH values, up to 1:1 molar ratio, show a marked decrease of the absorbance. A linear correlation between the ε values and the Cd(II):**L1** ratio is found up to 1:1 molar ratio (in this condition $\lambda_{max} = 273$, $\varepsilon = 17\,400$ dm^3 mol^{-1} cm^{-1}). Similar decreases of the ε values in presence of Cd(II) are also found for the other phenanthroline-containing ligands, as summarized in Table 3. These data account for the involvement of the phenanthroline moiety in metal coordination in the $[Cd\mathbf{L}]^{2+}$ complexes in aqueous solution. On the other hand, 1,10-phenanthroline and the aliphatic amine *N*,*N*′-dimethyl-ethylendiamine show almost equal binding ability toward Cd(II) (log $K = 4.9$ and 5.2 for the equilibrium $Cd^{2+} + \mathbf{L} = [Cd\mathbf{L}]^{2+}$ with **L** = 1,10 phenan-

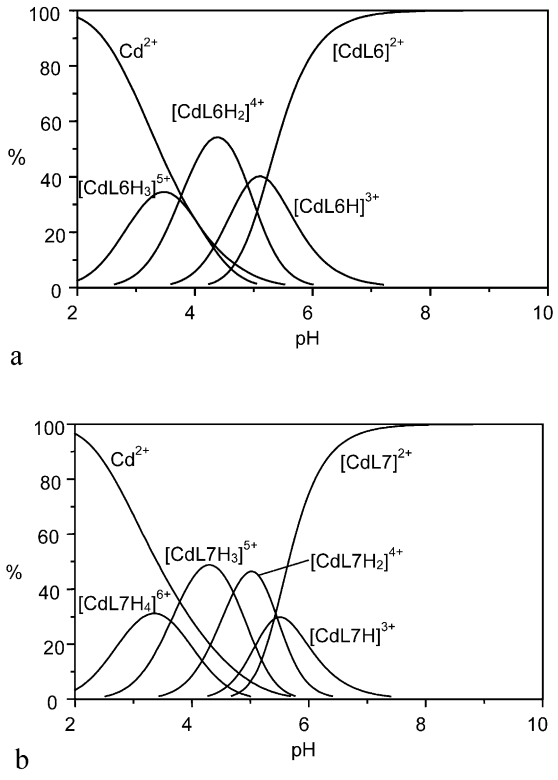

Fig. 2. Distribution diagrams of the species for the systems **L6**/Cd(II) (a) **L7**/Cd (b) and **L9**/Cd(II) (c) (NMe_4Cl 0.1 mol dm^{-3}, 298.1 K, [**L6**] = [**L7**] = [**L9**] = $[Cd^{2+}] = 1 \times 10^{-3}$ M).

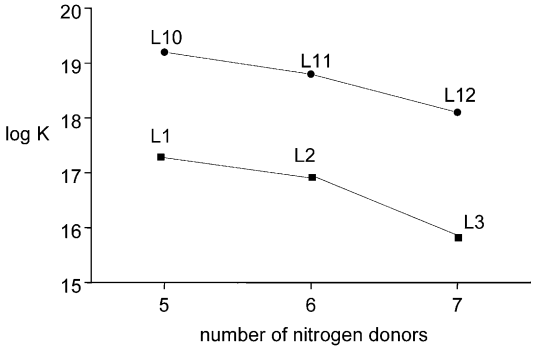

Fig. 3. Plot of the stability constants of Cd(II) complexes with phenanthroline-containing ligands **L1**–**L3** (■) and with [3*k*]aneN$_k$ macrocycles **L10**–**L12** (●) as a function of the number of nitrogen donors.

throline and *N*,*N*′-dimethyl-ethylendiamine, respectively) [40]. This consideration suggests that the lower stability of the **L1**–**L3** complexes cannot be simply ascribed to the different binding ability of phenanthroline with respect to an ethylediamine chain, but it is mainly ascribed to the stiffening of the macrocyclic structure, due to the insertion of a large and rigid heteroaromatic unit, which does not allow all the nitrogen donors to achieve an optimal arrangement around the metal ion.

Comparing the formation constants of the Cd(II) complexes with the **L1**–**L3** ligands, the stability slightly decreases on passing from the pentadentate **L1** to the hexadentate **L2**, while a larger decrease is observed for **L3** (Table 1 and Fig. 3). The small decrease in stability experienced by **L2** with respect to **L1** may be explained considering that a nitrogen donor in the **L2** complex is weakly bound, or not bound, to the metal. The formation of a monoprotonated $[Cd\mathbf{L2}H]^{3+}$ complex, not observed in the case of the **L1** complex, confirms this hypothesis. For **L3**, assuming that the metal is coordinated, once again, by only five out of the seven nitrogens, two amine groups would remain uncoordinated. These nitrogens should be located either far from each other or in adjacent positions, yielding respectively the formation of two eight-membered chelate rings or of one eleven-membered chelate ring. Both possibilities may account for the lower stability of the $[Cd\mathbf{L3}]^{2+}$ complex with respect to that of $[Cd\mathbf{L2}]^{2+}$, but the second one is in contrast to the fact that the two first stepwise protonation constants of $[Cd\mathbf{L3}]^{2+}$ have similar values. Interestingly, the electronic spectra recorded at pH 5 and 4, where the $[Cd\mathbf{L3}H]^{3+}$ and $[Cd\mathbf{L3}H_2]^{4+}$ predominate in solution (Fig. 1(a)), are almost equal ($\lambda_{max} = 273$, $\varepsilon = 17\,530$ dm^3 mol^{-1} cm^{-1} at pH 5 and $\lambda_{max} = 273$, $\varepsilon = 17\,700$ dm^3 mol^{-1} cm^{-1} at pH 4) to that of the $[Cd\mathbf{L3}]^{2+}$ complex ($\lambda_{max} = 273$, $\varepsilon = 17\,400$ dm^3 mol^{-1} cm^{-1}), indicating that these two protonation steps take place on nitrogen donors of the aliphatic pentaamine chain. This fact is not surprising, considering the by far higher basicity of secondary amine groups with respect to the phenanthroline nitrogens [41].

Ligand **L4** contains four aliphatic amine groups separated by propylenic chain. The spectral features of this complex (Table 3) account for the involvement of the phenanthroline nitrogen in metal binding. Ligand **L4**, however, forms a Cd(II) complex which is remarkably less stable than **L2**, where the four amine groups are spaced by ethylenic chains. Actually, open-chain or macrocyclic tetraamines containing propylenic chains linking the nitrogen donors usually form less stable Cd(II) complexes than the corresponding ligands with ethylenic chains (for instance log $K = 14.32$ for the formation of the Cd(II) complex with 1,4,7,10-tetraazacyclododecane, while log $K = 12.65$ in the case of the Cd(II) complex with 1,5,9,13-tetraazacyclohexadecane) [40]. This fact is usually ascribed to the formation of larger chelate ring, due to the larger bite of the propylenic chain with respect to the ethylenic ones. The resulting molecular strain may also lead to a weak interaction of some nitrogen donors with the metal, as testified by the tendency of the $[Cd\mathbf{L4}]^{2+}$ to form protonated species (Table 1 and Fig. 1(b)). The constants for successive additions of H^+ to the $[Cd\mathbf{L4}]^{2+}$ complex are far higher than those of $[Cd\mathbf{L2}]^{2+}$ and $[Cd\mathbf{L3}]^{2+}$, due to the larger +I inductive effect exerted

Table 3
UV–Vis data of phenanthroline-containing ligands **L1**–**L5** and their Cd(II) complexes

	L1	**L2**	**L3**	**L4**	**L5**
λ (nm) [ε ($dm^3\ mol^{-1}\ cm^{-1}$)]	273 [21 200]	267 [24 200]	273 [21 200]	264 [27 900]	271 [27 000]
	$[Cd\mathbf{L1}]^{2+}$	$[Cd\mathbf{L2}]^{2+}$	$[Cd\mathbf{L3}]^{2+}$	$[Cd\mathbf{L4}]^{2+}$	$[Cd\mathbf{L5}]^{2+}$
λ (nm) [ε ($dm^3\ mol^{-1}\ cm^{-1}$)]	273 [17 400]	270 [18 500]	270 [18 600]	269 [22 700]	266 [20 200]

by the propylenic chains with respect to ethylenic chains. Furthermore, propylenic linkages can also better minimize the electrostatic repulsion between charged ammonium groups, leading to a stabilization of the protonated forms of the complex.

As previously found in the case of **L3**, the electronic spectra recorded in the pH range 8–5, where the formation of protonated species $[Cd\mathbf{L4}H_n]^{(n+2)+}$ occurs (Fig. 1(b)), are almost equal to that of $[Cd\mathbf{L4}]^{2+}$, indicating that protonation takes place on aliphatic amine groups.

The open-chain ligand **L5** contains two ethylendiamine side arms linked to the 2,9 positions of phenanthroline. The stability of its Cd(II) complex is somewhat lower than the corresponding complex with **L2**, which can be considered the cyclic ligand analogous to **L5**. The higher stability observed for the complexes with cyclic ligands with respect to the corresponding acyclic ligands is generally ascribed to the 'macrocyclic effect' [2,6]. It should be noted, however, that in the present case the extent of the macrocyclic effect is rather small, the stability constant of the **L2** complex being less than one log. unit higher than that of the **L5** complex. For instance, the formation constant of the Cd(II) complex with the aliphatic macrocyclic hexamine **L10** is approximately 3 log units higher than that of the complex with the corresponding acyclic hexamine 1,14-bis(methylamino)-3,6,9,12-tetraazatetradecane [42]. Among the factors that determine the macrocyclic effect, cyclic ligands usually offer preorganized binding sites, with a preformed optimal disposition of the donors for metal binding to the metal, while the open-chain ligands would rearrange themselves to coordinate the metal cation, with a consequent energy cost. On the other hand, a previous study on the metal binding features of **L5** [26] showed that the particular molecular architecture of this ligand gives rise to a preformed coordinating 'cleft', delimited by the phenanthroline unit and the two ethylendiamine side-arms, where the metal ions can be lodged with a low energetic cost for the process of ligand rearrangement upon metal complexation. On the contrary, as discussed above, the rigid macrocyclic ligand **L2** does not seem to offer to the metal an optimal arrangement of the donors, and severe conformational stress could accompany the formation of its Cd(II) complex. Although other factors, such ligand and metal desolvation in the process of complex formation, may contribute to the macrocyclic effect, i.e. to the stabilization of the complex with macrocycle **L2**, the effect of 'ligand preorganization' would not favor the formation of the complex with the cyclic ligand **L2**, giving a reasonable explanation to the observed low difference in stability between the **L2** and **L5** complexes.

3.2. Cd(II) complexation by dipyridine-containing polyamines

A similar binding ability is shown by 2,2′-dipyridine toward Cd(II) with respect to 1,10-phenanthroline ($\log K = 4.9$ and 4.6 for the equilibrium $Cd^{2+} + \mathbf{L} = [Cd\mathbf{L}]^{2+}$ with **L** = 1,10-phenanthroline and 2,2′-dipyridine, respectively) [40]. Although in 2,2′-dipyridine the two aromatic rings can rotate along the C–C axis which connects the two pyridine units, X-ray crystallographic studies on Cu(II) [36], Zn(II) [27] and Pb(II) [25] coordination by ligands **L6**–**L9** showed that in their complexes the two heteroaromatic nitrogens are bound to the metal with an almost coplanar disposition of the two pyridine moieties. On the basis of these considerations it is expected that the present dipyridine-containing polyamines show similar binding features with respect to the corresponding phenanthroline-containing ligands. Actually, the stability constants of the complexes with **L6** and **L9** (Table 2) are almost equal to those previously found for **L3** and **L5**, where the dipyridine unit of **L6** and **L9** is simply replaced by a phenanthroline one.

The protonation behavior of $[Cd\mathbf{L6}]^{2+}$ and $[Cd\mathbf{L9}]^{2+}$ is also similar to that found for the $[Cd\mathbf{L3}]^{2+}$ and $[Cd\mathbf{L5}]^{2+}$ complexes, with rather high equilibrium constants for the successive addition of the first and the second H^+ to the complexes. As suggested for $[Cd\mathbf{L3}]^{2+}$, it can be proposed that, at least in the case of the $[Cd\mathbf{L6}]^{2+}$ complex, two nitrogen donors are not involved, or at least weakly involved, in metal coordination, and facile protonation may occur on these amine groups.

As previously observed in the case of Zn(II) binding [27], Cd(II) coordination by the dipyridine unit leads to marked changes in the absorption spectra of the ligands, with the appearance of a new red-shifted absorption band at approximately 305 nm. This new band can be used as a diagnostic tool to prove the effective involvement of dipyridine in metal binding. Fig. 4 reports the electronic spectra of **L6** and its Cd(II) complexes at different pH values. The remarkable red shift of the UV band observed with the formation of $[Cd\mathbf{L6}]^{2+}$ indicate that dipyridine is indeed coordinated to the metal. Similar features are also found in the spectra recorded at acidic pH values (c and d spectra in Fig. 4), where the mono- and diprotonated $[Cd\mathbf{L6}H]^{3+}$ and $[Cd\mathbf{L6}H_2]^{4+}$ species predominates in solution (Fig. 2(a)), suggesting that the heteroaromatic nitrogens are still involved in Cd(II) coordination. The first two protonation steps of the complex, therefore, occur on the nitrogens of the aliphatic chain. Similar results are also found for the other dipyridine-containing ligands; Table 4 summarizes the spectral features of **L6**–**L9** and their Cd(II) complexes.

Ligand **L7** displays a molecular architecture similar to **L6**, containing a longer hexamine chain linking the 6, 6′ positions of 2,2′-dipyridine. The addition of a nitrogen donor and the increased length of the aliphatic chain determine a marked decrease of the stability of the $[Cd\mathbf{L7}]^{2+}$ complex with respect to the $[Cd\mathbf{L6}]^{2+}$ complex. This result can be explained assuming that, as in $[Cd\mathbf{L6}]^{2+}$, only five out of the eight nitrogen donors of **L7** are coordinated to the metal, leading to the formation of one or more large chelate rings, containing uncoordinated nitrogen atoms. This hypothesis is confirmed by the rather high values of the first three protonation constants of $[Cd\mathbf{L7}]^{2+}$. As previously found for $[Cd\mathbf{L6}]^{2+}$, protonation of the complex does not significantly change the shape and position of the band at 304 nm in the UV spectrum, indicating that protonation takes place on aliphatic amine groups.

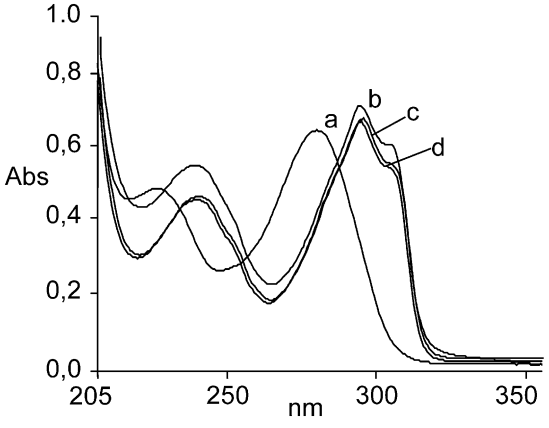

Fig. 4. UV spectra of **L6** and its Cd(II) complex at different pH values. **L6** at pH 11 (a); $[Cd\mathbf{L6}]^{2+}$ at pH 10 (b), at pH 5.2 (c) and at pH 4.5 (d).

Table 4
UV–Vis data of dipyridine-containing ligands **L6**–**L9** and their Cd(II) complexes

	L6	**L7**	**L8**	**L9**
λ (nm)	288	290	288	290
[ε ($dm^3\ mol^{-1}\ cm^{-1}$)]	[11 700]	[12 300]	[12 200]	[12 400]
	$[Cd\mathbf{L6}]^{2+}$	$[Cd\mathbf{L7}]^{2+}$	$[Cd\mathbf{L8}]^{2+}$	$[Cd\mathbf{L9}]^{2+}$
λ (nm)	304	304	304	305
[ε ($dm^3\ mol^{-1}\ cm^{-1}$)]	[14 030]	[12 550]	[13 770]	[13 200]

The macrocyclic ligand **L8** contains a pentaamine aliphatic moiety. The only structural difference with respect to **L6** is the presence of methyl groups on the three central nitrogens of the pentaamine chain. This apparently small structural modification strongly affects the stability of the Cd(II) complex, leading to a remarkable decrease of the formation constant with respect to the complex with **L6**. This fact can be related to the electronic and steric effects of N-methylation. N-methylation, in fact, reduces the σ-donating properties of the amine groups, due to the absence of M–N–H···O hydrogen bonds to the solvent, that make them weaker σ-donors [43]. Furthermore, steric hindrance due to the insertion of methyl groups within the ligand framework can cause elongation of the M–N bond as well as distortions of the coordination sphere of the metal in its complexes and thus reduces the overall metal–ligand interaction [43].

4. Concluding remarks

Phenanthroline- and dipyridine-containing macrocycles and open-chain ligands generally form stable water-soluble 1:1 Cd(II) complexes. In all the complexes under investigation the two heteroaromatic nitrogens are involved in metal coordination. Although the binding ability of 1,10-phenanthroline and 2,2′-dipyridine toward Cd(II) is similar to that of an ethylendiamine chain, the insertion of these large and rigid heteroaromatic units within a macrocyclic framework lead to a decrease of the thermodynamic stability of the complexes, i. e., the stability constants are lower than those reported for Cd(II) complexes with cyclic aliphatic polyamines containing the same number of nitrogen donors. This effect is mainly due to the stiffening of the macrocyclic structure, which does not allow the nitrogen donor to achieve an optimal arrangement around the metal ion. Among ligands **L1**–**L3**, the stability of the complexes decreases from **L1** to **L3**. The potentiometric results indicate that in the $[Cd\mathbf{L1}]^{2+}$ complex all nitrogens are involved in metal coordination, while in $[Cd\mathbf{L2}]^{2+}$ and $[Cd\mathbf{L3}]^{2+}$ some of the amine groups are

weakly bound or not bound to the metal. Other structural modifications, such as replacement of the ethylenic chain connecting the amine groups with propylenic linkages or methylation of some nitrogen donors further decrease the complex stability.

The decreased stability is generally accompanied by facile protonation of the complexes, suggesting that some nitrogen donors are not involved in metal binding. In the protonated complexes the acidic protons are located on the aliphatic amine groups, due to their higher basicity with respect to the heteroaromatic nitrogens.

Received 27 September 2001; accepted 16 October 2001

Abstract

The thermodynamic functions for the complexation of Ag(I) by the following diamines: *N*,*N*-dimethyldiethylenediamine (*N*,*N*-dmen), *N*,*N*-dimethyl-1,3-propanediamine (*N*,*N*-dmtn) and *N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediamine (tmtn) have been determined in dimethylsulfoxide (dmso) by potentiometric and calorimetric techniques at 298 K and 0.1 mol dm^{-3} ionic strength (NEt_4ClO_4). Only mononuclear complexes are formed (AgL_j^+, $j = 1, 2$) where the ligands act as monodentate or chelate agents. All the complexes are enthalpy stabilized whereas the entropy changes counteract the complexation. The different basicities and steric requirements of both the ligands and complexes formed together with the size of the chelate rings are taken into account to discuss the results presented here. © 2002 Elsevier Science Ltd. Keywords: Silver(I); *N*-methylated polyamines; Complexes; Dimethylsulfoxide; Thermodynamics

1. Introduction

In the last few years there has been a great deal of interest in the field of complex formation of metal ions with neutral N-donors in water [1–8] as well as in nonaqueous or mixed solvents [9–17]. The aim of these works has been to improve the knowledge of the coordination chemistry of soft and hard metal ions with these ligands, to investigate the strong influence of different basicities and steric properties of the ligands on the stability and nature of the complexes and to design ligands for selective complexation of metal ions.

These studies have now also attracted renewed interest as the coordination properties of open chain polyamines towards different cations have been taken as models allowing direct comparison with corresponding macrocyclic systems [18].

In particular many papers have reported data concerning Group 11 metal complexation with these ligands [1,3,7,12,16,17]. These data have shown that the coordination properties of amines towards these ions may be modulated through the number and the basicity of nitrogen atoms present in the ligand, the different chelate ring sizes the ligands can form, the different N-functionalization and the nature of the solvent.

In this context and as an extension of previous works, we report here the results of a thermodynamic study on the complex formation of Ag(I) with the following diamines in the aprotic solvent dimethylsulfoxide (dmso): *N*,*N*-dimethyldiethylenediamine (*N*,*N*-dmen), *N*,*N*-dimethyl-1,3-propanediamine (*N*,*N*-dmtn) and *N*,*N*,*N*′,*N*′-tetramethyl-1,3-propanediamine (tmtn).

The ligands have been chosen in order to provide further information on how the different alkylation and/or the different size of the potential chelate rings formed may affect their coordination ability toward metal ions. For this purpose also a comparison with data previously reported on Ag(I) complex formation with similar diamines possessing the same skeleton, but differently methylated, i.e. ethylenediamine (en) [12c], *N*,*N*′-dimethylethylenediamine (dmen) [12e], *N*,*N*,*N*′*N*′-tetramethylethylenediamine (tmen) [12e] and 1,3-propanediamine (tn) [12c], will be carefully taken into account.

Potentiometric and calorimetric measurements have been used to obtain the free energy and enthalpies of the

reactions, respectively. All measurements have been performed at 298 K in an ionic medium adjusted to 0.1 mol dm^{-3} with NEt_4ClO_4 as neutral salt. ^1H NMR spectroscopy has been used to provide insight into the coordination modes of the ligands.

2. Experimental

Anhydrous silver perchlorate was obtained from $AgClO_4 \cdot H_2O$ (Fluka puriss) as described previously [12a]. Dimethylsulfoxide (Fluka >99%) was purified by distillation according to the described procedures [12a] and stored over activated 4 Å molecular sieves. The background salt NEt_4ClO_4 was recrystallized twice from MeOH and dried at 110 °C. The ligands *N*,*N*-dmen (Aldrich 95%), *N*,*N*-dmtn (Aldrich 99%) and tmtn (Aldrich 98%) were purified by fractional distillation [19].

The Ag(I) solutions were prepared from anhydrous $AgClO_4$ and freshly distilled dmso. (*Warning*! Although we encountered no problems when handling $AgClO_4$, metal perchlorates solvated by dmso are powerful explosives under certain conditions [20] and should be handled with caution!)

The metal concentration in these solutions was checked by potentiometric titrations with chloride. Solutions of the ligands were prepared by dissolving weighted amounts in the anhydrous solvent. NEt_4ClO_4 was used to obtain the required ionic strength.

All the solutions were prepared afresh before each experiment in a MB Braun 150 glove box under atmosphere of dry nitrogen. The water content in the solutions, typically 10–20 ppm, was determined by a Metrohm 684 KF Coulometer.

2.1. Potentiometric measurements

All measurements were carried out in the MB Braun 150 glove box in a thermostated cell maintained at 298.0 ± 0.1 K. The experimental data required for the determination of the stability constants of the complexes were the equilibrium concentrations of the Ag(I) ion, which were obtained from the emf of a galvanic cell previously described [12a]. The emf were measured by means of an Amel 338 pH meter equipped with a Metrohm 6.0328.000 Ag electrode as a working electrode and a Metrohm 6.0718.000 Ag electrode as a reference. An experimental run consisted in collecting many equilibrium data points when solutions of silver perchlorate ($2.00 < C^\circ_M < 20.0$ mmol dm^{-3}) were titrated with solutions of the ligands ($50 < C^\circ_L < 200$ mmol dm^{-3}). Titrations were performed with at least three different initial Ag(I) concentrations and some titrations were carried out in duplicate to verify the reproducibility of the system. The electrode couple was periodically checked in dmso solutions containing no coordinating ligands. In the concentration range $10^{-6} < [Ag^+] < 10^{-2}$ mol dm^{-3}, the emf values varied with the metal ion concentration according to Nernst's law.

The computer program HYPERQUAD [21] was used for the calculation of the stability constants.

2.2. Calorimetric measurements

A Tronac model 87-558 precision calorimeter was employed to measure the heat of reaction. The calorimeter was checked by titration of tris(hydroxymethyl)aminomethane (tham) with a standard solution of HCl in water. The experimental value of the heat of neutralization of tham was found to be $\Delta H^\circ = -47.61$ kJ mol^{-1}, in good agreement with the accepted value of -47.53 ± 0.13 kJ mol^{-1} [1].

The calorimetric titrations were performed at 298.00 ± 0.02 K by adding known volumes of ligand solutions ($50 < C^\circ_L < 200$ mmol dm^{-3}) to 20 ml of Ag(I) solution ($2.00 < [Ag^+] < 20.0$ mmol dm^{-3}). The heats of dilution of the reactants, determined in separate runs, were found negligible. The least-squares computer program LETAGROP KALLE [22] was used for the calculation of the enthalpy changes.

2.3. NMR measurements

^1H NMR spectra were recorded at 298 K on a Brucker AC 200F QNP spectrometer. ^1H chemical shifts refer to $SiMe_4$. Measurements were performed on dmso-d_6 solutions containing the dissolved salt $AgClO_4 \cdot 4$dmso (approximately 20 mmol dm^{-3} in Ag^+) and the ligand *N*,*N*-dmtn in the molar ratio $R_c = C_L/C_M = 0.5$. Analogous measurements were carried out on a solution containing only the ligand concerned.

3. Results

The computer treatment of the potentiometric data shows that the best fit is obtained when the mononuclear species reported in Table 1 are taken into account. In the table, the overall stability constants and free energies of formation, with the limits of error indicated, are listed for the reactions: $Ag^+ + jL \rightleftharpoons AgL_j^+$ ($j = 1, 2$; L is the ligand concerned). In Fig. 1, the distribution of Ag(I) between the different complexes as a function of the ligand-to-metal ratio, $R_c = C_L/C_M$, is plotted for all the systems studied.

The experimental data obtained from the calorimetric measurements are reported in Fig. 2 as Δh_v, the total heats of reaction per mole of metal ion versus R_c.

From an examination of the shape of these curves some conclusions can be drawn about the prevalent

The errors quoted correspond to three standard deviations. [a]Ref. [12c]. [b]Ref. [12e].

coordinated species formed, which are consistent with the information obtained from the analysis of the potentiometric data.

For Ag(I)–tmtn system, the splitting of the curves is only indicative of formation of weak complex(es), whereas for Ag(I)–*N*,*N*-dmen and *N*,*N*-dmtn systems the enthalpy data which coincide up to $R_c = 1$, slightly diverge at the inflection point ($R_c = 2$) and superimpose at higher R_c values can be easily explained by the formation of only two successive, almost equally stable, mononuclear complexes.

The enthalpy values and the overall stability constants in Table 1 were used to calculate the full lines in Fig. 2. The match of the experimental data is quite good indicating that all the systems are satisfactorily described. Also in Table 1, the stability constants and the thermodynamic functions for the complexation reactions of Ag(I) by the ligands en [12c], dmen, tmen [12e] and tn [12c] previously determined in dmso are reported, for comparison.

Fig. 3 shows the ^{1}H NMR spectra of *N*,*N*-dmtn and of its [Ag(*N*,*N*-dmtn)]$^+$ complex in dmso-d_6.

4. Discussion

As a consequence of the formation of strong covalent Ag(I)–N bonds and the relatively weak solvation of the species [9] favourable enthalpy values are obtained whereas the entropy terms oppose the complex formation.

In a previous work [12e] the drop in the stability constant values between en, dmen and tmen, all behaving as chelating agents, was explained as due to: (i) the

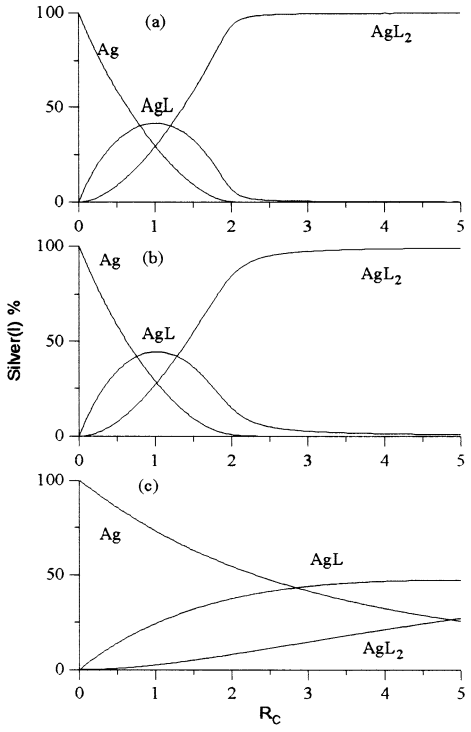

Fig. 1. The percent distribution of the metal ion in the Ag(I)–diamine systems in dmso at $C^{\circ}_{Ag} = 10$ mmol dm^{-3}. (a) *N*,*N*-dmen; (b) *N*,*N*-dmtn; (c) tmtn.

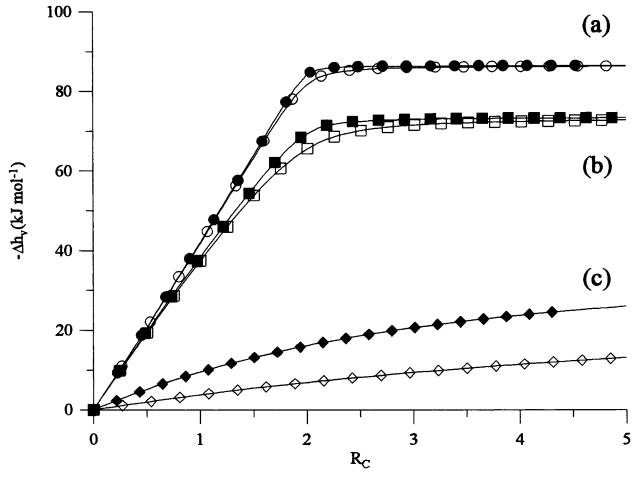

Fig. 2. The total molar enthalpy changes, Δh_v, as a function of $R_c = C_L/C_M$ for Ag(I)–diamine systems in dmso. (a) *N*,*N*-dmen: (○) 5.10, (●) 19.85 mmol dm^{-3} in Ag^+; (b) *N*,*N*-dmtn: (□) 4.85, (■) 19.98 mmol dm^{-3} in Ag^+; (c) tmtn: (◇) 4.91, (◆) 19.55 mmol dm^{-3} in Ag^+. Only some of the experimental points, chosen at random, have been plotted. The solid lines have been calculated from the values of β_j and $\Delta H^{\circ}_{\beta_j}$ in Table 1.

different basicity of amino group, which decreases in the order $-NH_2 > -NHR > -NR_2$ in dmso [23]; (ii) the elongation of M–N bonds, as a consequence of the steric hindrance of the ligands [7]; and (iii) the decreased solvation of the complexes as a consequence both of their increased radii and of the minor extent of hydrogen bonding brought about by the *N*-alkylated amines [7].

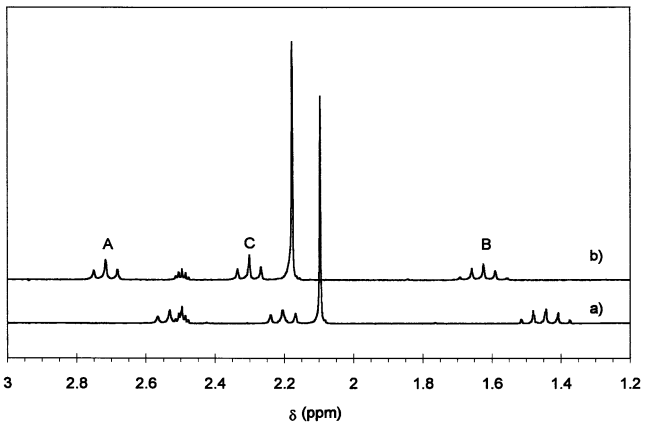

Fig. 3. ^{1}H NMR spectra at 298 K of: (a) *N*,*N*-dmtn = 10.1 mmol dm^{-3}; (b) $C^{\circ}_{Ag} = 20.0$, *N*,*N*-dmtn = 10.1 mmol dm^{-3} in dmso-d_6.

The log β_1 value here reported for the Ag(I)–*N*,*N*-dmen system is about of the same order of magnitude as that of dmen: this indicates that the ligand behaves as bidentate as confirmed by the enthalpy and entropy values.

It is of interest to note that the major difference in the thermodynamic values between dmen and *N*,*N*-dmen lies in the entropy term which is less unfavourable for the latter system. This points out that no great differences in the medium M–N bond strength are found when changing two secondary nitrogens with one primary and one tertiary ones whereas the asymmetric *N*-methylation in *N*,*N*-dmen influences the first step of complexation from an entropic point of view.

Evidently, both the ligand and the complex formed should be seen as less hydrogen bonded by the dmso molecules with respect to dmen system where the solvent may well interact with alongside –NHR groups, due to the formation of less crowded solvates.

The thermodynamic data associated with the second complexation step indicate that in the AgL_2 complex the ligand behaves also as bidentate. The higher exothermic enthalpy value of the second complexation step, ΔH°_{K2}, as compared with ΔH°_{K1} is probably due to a particular desolvation occurring in the first step of complexation: the enthalpy needed for desolvating causes the ΔH°_{K1} to be less exothermic than ΔH°_{K2} in spite of the larger exothermicity associated to the Ag(I) interaction in the first complexation step. This hypothesis is confirmed by the unfavourable high stepwise entropy term which is also in line with the above mentioned relatively scanty outer sphere solvation of the $[Ag(N,N\text{-dmen})]^+$ complex.

As far as *N*,*N*-dmtn is concerned, the thermodynamic data are somewhat ambigous in indicating the ligand coordination mode, i.e. if it acts as mono- or bi-dentate.

A comparison of the data previously reported for monoamines [12a,12b] and tn [12c] in dmso shows that: (i) the values of log β_1 and ΔH°_1 for *N*,*N*-dmtn are

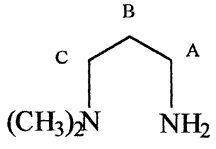
slightly more favourable and the ΔS°_1 value much more unfavourable than those found previously for the monodentate *n*-butylamine (*n*-but) ($\log \beta_1 = 3.58$; $-\Delta H^{\circ}_1 = 31.4$ kJ mol^{-1}; $-\Delta S^{\circ}_1 = 37.3$ J mol^{-1} K^{-1} [12b]; (ii) $\log \beta_1$ for *N*,*N*-dmtn is about two orders of magnitude lower than that found for tn and ΔH°_1 about half the enthalpy value for tn, which has been found to be linearly chelated to Ag(I) [12c], whereas the same differences between the two chelated en and dmen are much less important (see Table 1).

Point (i) seems to indicate that *N*,*N*-dmtn is able to act as a chelating agent, whereas point (ii) seems to imply a different conclusion. Nevertheless the trend in thermodynamic functions discussed in (ii) should also be due to different geometric requirements in Ag(I)–*N*,*N*-dmtn and Ag(I)–tn systems. In fact, as mentioned above, tn was found to behave as linear bidentate in dmso according with the observed fact that large metal ions such as Ag(I) and Hg(II) will tend to have low coordination numbers and therefore large N–M–N angles [24]: this is an exception to the general behaviour of metal ions whose coordination numbers tend to become higher as metal ions become larger, behaviour which generally favours five-membered chelate ring formation more than six-membered ones [24].

As a consequence of this exception, the decreased complex stability expected for large metal ions when chelate ring size is changed from five- to six-membered, is not observed when Ag(I) is considered (see also data reported in Table 1 for en and tn systems) but, on the contrary, an increase in complex stability occurs.

In conclusion, the trend in the thermodynamic data here reported seems to indicate that, if the ligand acts as bidentate, the tetrahedral configuration of the Ag(I) solvate [9] is retained: likewise, when *N*-methyl groups are present in *N*,*N*-dmtn other steric requirements are added to the six-membered chelate ring formed which prevents Ag(I) from being coordinated linearly.

The ^{1}H NMR spectra of *N*,*N*-dmtn and of its Ag(I) complex may be of some help in investigating the coordination mode of the ligand concerned. In Fig. 3, a $\Delta\delta$ ($\Delta\delta = \delta_{complex} - \delta_{ligand}$) of about 0.1 is observed for both *N*-methyl groups (from 2.18 to 2.08) and the CH_2 (C) (see Scheme 1) (from 2.32 to 2.22) whereas the $\Delta\delta$ of CH_2 (A) is about 0.2 ppm (from 2.72 to 2.52).



For comparison also the ^{1}H NMR spectra of the monodentate *n*-but and of its Ag(I) complex were collected and it was observed that the multiplet signal of CH_2 (at 1.30) in γ position with respect to $-NH_2$ is unaffected by complexation. The small downfield shift of CH_2 (C) (and of methyl protons) observed in Ag(I)–*N*,*N*-dmtn system should be therefore taken as reflecting an interaction between the $-NR_2$ moiety and the metal ion.

Nevertheless, this M–NR_2 interaction is weak, given that the formation of a six-membered chelate ring, normally more strained than that of a five-membered ring in a tetrahedral arrangement [24], is assisted by a tertiary, low basic, amino group [23]. The weakness of this interaction is supported not only by the values of the thermodynamic functions associated to [Ag(*N*,*N*-dmtn)]$^+$ formation, but also by the absence of polynuclear species which have usually been found to be formed in dmso when chelating ligands having primary nitrogen atoms separated by more than two methylene groups were considered [12c,12d].

The thermodynamic parameters associated to the second complexation step are very close to those corresponding to the formation of [Ag(*n*-but)$_2$]$^+$ complex ($\log \beta_2 = 7.34$; $-\Delta H^{\circ}_2 = 71.5$ and $-\Delta S^{\circ}_2 = 99.6$) [12b], thus indicating that *N*,*N*-dmtn behaves as monodentate in this complexation step.

For tmtn system, the data clearly indicate that the ligand behaves as monodentate in both the complexation steps: the $\log \beta_1$ value is even lower than that found for Ag(I)–tributylamine (tribut) system ($\log \beta_{1\ tribut} = 2.2$) [17]. The enthalpy value for 1:1 Ag(I)–tribut complex has not been reported: therefore the most reliable comparison with literature data is with the enthalpy values relative to the secondary monodentate dibutylamine (dibut) which are, respectively $\Delta H^{\circ}_1 = -31.80$ and $\Delta H^{\circ}_2 = -61.60$ kJ mol^{-1} for the 1:1 and 1:2 Ag(I)–dibut complexes [12b]. These values are certainly much more favourable than those found for tmtn system further confirming monodentation.

In conclusion, it is of interest to note that symmetric dimethylation of an amino group in a potential six-membered *N*,*N*-dmtn chelate ligand reverses the peculiar feature of silver ion to form more stable six-membered chelate rings with respect to five-membered chelate ones, strongly influencing the efficiency of the ligands concerned toward Ag(I). In the case of the tetramethylated 1,3-propanediamine the low basicity of the tertiary amino groups and the important steric requirement of the ligand even prevent chelation.

Abstract

A competion method is proposed to characterize natural metal complexes present in a high salinity spring water. The competitor is a strong complexing resin containing the iminodiacetic group, Chelex 100. Its sorbing properties towards the metal ions here considered, Cu(II), Mn(II) and Al(III), are well known and could be quantified through K^*, the ratio of the concentration of the metal in the resin phase to that of the free metal in solution. It can be calculated for the considered metal ion for the particular experimental conditions. From the fraction of metal experimentally sorbed on the resin it is possible to obtain information about the distribution of the metal in the original water solution. Two different methods are proposed. In the resin titration (RT), different volumes of sample are treated with the same amount of resin. RT allows to determine the total metal concentration and the reaction coefficient of that metal in solution. In the ligand titration (LT), the free metal is added stepwise into the original sample, and the ligand concentration and the complexation constant are determined. This was done by the Ruzic linearization method, modified to take unto account the variation of the pH of the solution. Also the data from RT were elaborated by the modified Ruzic linearization. The study of metal ions distribution among different chemical species by the combined methods is discussed in detail. The three metal ions in the considered high salinity water were found to be mainly combined in complexes with high complexation constant. The concentration of the strong ligands involved was near to that of the metals. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Natural metal complexes; Natural ligands; Resin titration; Ligand titration; Chelex 100

1. Introduction

The metal ions in natural waters can be complexed by ligands of different nature and concentration, for instance inorganic anions, included OH^-, and organic molecules or ions, at low and high molecular weight. The metal ions can be also adsorbed or combined in micellar particles [1,2]. This distribution among different species determines the geochemical mobility, bioavailability and toxicity of heavy metals in natural waters. The stability of the species is very important, since the most toxic form is often the free metal ion, and the weak species which are easily dissociated.

The stability of the metal complexes in aqueous solution can be determined by a number of well established experimental methods [3], but most of them can not be applied for the direct investigation of natural waters, due to the very low concentration of the metal ions and of the ligands and to the complexity of these samples. This is the reason why these investigations are usually carried out in model solutions, under exactly controlled conditions, and usually at relatively high concentration of metals and ligands. The results are transferred to the real systems, as for instance natural waters, using dedicated calculation programs. Obviously this can be done only if the system is exactly characterized, i.e. if the nature and the total concentration of all the metals and the ligands are exactly known. This is only seldom true in the case of natural waters. The experimental methods which can be used for the direct determination of the stability of the metal complexes in

PII: S0277-5387(02)00969-5

solution must be specific and with a low detection limits. For this reason they are often based on some kind of preconcentration procedures. For instance in the widely used voltammetric methods ASV and CSV [4,5] the metal is concentrated at the working electrode in the first step of the determination. Other preconcentration methods are based on the sorption of a species on a solid phase, for example the metal ions on an ion exchange resin [6,7]. In this way, the labile fraction of a metal ion in a sample is obtained. This is an operationally defined quantity, which has been found to be correlated to the toxicity of a metal [6].

In this work, a method is proposed based on the sorption of a metal ion on a complexing resin. The metal ions complexed by the active groups present in the resin are strongly sorbed, and can be specifically separated also from complex matrices, for instance natural waters [8–10]. By this method it is possible to evaluate the concentration of free metal ion in solution, in the presence of the resin, based on the experimental determination of the concentration of metal ion sorbed on the resin, c, according to Eq. (4) described later on. To illustrate the application of the method, a natural water was considered, with a very complex composition. It is a high salinity spring water, whose main components are reported in Table 1. The sodium and chloride concentration is higher than in seawater, the alkaline earth metals are also present at high concentration. Sulfide is present at high concentration immediately after drawing the sample from the spring. Then its concentration decreases due to the bacterial activity, which transforms it into sulfur and sulfate.

An investigation method similar to that here proposed has been previously applied in the case of some synthetic solutions [11] and freshwaters [8,9], for different metal ions. In this investigation, it is used for the determination of the complexation of copper(II), manganese(II) and aluminium(III) in the particular sample describe above.

1.1. Description of the method

The complexation of a metal in a given solution can be considered characterized, from a thermodynamic point of view, when the concentration of the ligands and the complexation constant are known. This can be done for instance by the simple method proposed by Ruzic and van der Berg [12,13]. This method is widely used in environmental determinations. Here the ligand concentration is usually not known, and it must determined together with the conditional complexation constant.

Suppose that the following complexation equilibrium is set up in solution, where I is the natural ligand, M is the metal and charges are omitted, here and in the following:

$$\mathrm{M} + \mathrm{I} \rightleftarrows \mathrm{MI} \quad K_{\mathrm{M(I)}} = \frac{[\mathrm{MI}]}{[\mathrm{M}]c_{\mathrm{I}}'} \tag{1}$$

where $K_{\mathrm{M(I)}}$ is the conditional equilibrium coefficient and c_{I}' is the total concentration of the not complexed ligand.

The reaction coefficient $\alpha_{\mathrm{M(I)}}$ pertinent to this complexation, as defined by Ringbom [14], is:

$$\alpha_{\mathrm{M(I)}} = \frac{c_{\mathrm{M}}}{[\mathrm{M}]} = 1 + K_{\mathrm{M(I)}}c_{\mathrm{I}}' \tag{2}$$

Considering the mass balance of I, $c_{\mathrm{I}} = c_{\mathrm{I}}' + [\mathrm{MI}]$, and the mass balance of M, $c_{\mathrm{M}} = [\mathrm{M}] + [\mathrm{MI}]$, the following relationship is obtained, from which both c_{I} and $K_{\mathrm{M(I)}}$ can be evaluated:

$$\frac{[\mathrm{M}]}{[\mathrm{MI}]} = \frac{1}{K_{\mathrm{M(I)}}c_{\mathrm{I}}} + \frac{[\mathrm{M}]}{c_{\mathrm{I}}} \tag{3}$$

In the method originally proposed by Ruzic and van den Berg, [M], the concentration of free, uncomplexed metal ion was determined by voltammetric techniques, as ASV and CSV, which have the required low detection limits. Here the concentration of free metal ion in solution in equilibrium with a complexing resin can be evaluated by the following relationship [15]:

$$[\mathrm{M}] = \frac{cV}{wK^*} \tag{4}$$

where c is the concentration of the metal ion sorbed on the resin.

The mass balance of M is in this case $c_{\mathrm{M}} = c + [\mathrm{M}] + [\mathrm{MI}]$, since the metal ion is partially sorbed on the resin. The evaluation can be done only if the metal is partially sorbed on the resin, so that a properly selected resin must be used. It has been previously shown [8,11] that this is so when $\alpha_{\mathrm{M(I)}}/K^*$ ranges between 0.1 and 10 w/V (V is the volume of the solution phase, and w that of the solvent in the resin phase). K^* is the ratio of the

concentration of metal ion sorbed in the resin phase to the concentration of the free metal ion in the solution phase. The accurate knowledge of K^* is required for the evaluation of [M] by Eq. (4). It can be obtained either experimentally or by calculation, if the sorption equilibria are known, as described in a number of previous works [8,11].

The reaction coefficient $\alpha_{M(I)}$ can be evaluated from the concentration of sorbed metal c from the relationship:

$$c = \frac{c_M}{1 + \frac{\alpha_{M(I)} V}{K^* w}} \quad (5)$$

It should be considered that $K_{M(I)}$ is a conditional equilibrium coefficient, since the ligand I not complexed with the metal ion M can be present in different forms, and in particular at different protonation degree. In this case its value depends on the acidity of the solution. The complexation constant, independent of the pH, is $K_{M(I)t}$ which is correlated to the conditional equilibrium coefficient by the following relation:

$$K_{M(I)t} = \frac{[MI]}{[M][I]} = \frac{K_{M(I)}\, c_I'}{[I]} = K_{M(I)}\,(1 + \sum \beta_{ap}[H]^p) \quad (6)$$

where β_{ap} is the p-protonation constant of the ligand I, to form the p-protonated species, H_pI, and $c_I'/[I]$ is the reaction coefficient of the I form of the ligand, α_I.

If $K_{M(I)}$ depends on the acidity, the reaction coefficient, $\alpha_{M(I)}$, too changes with the pH. The following simplified relationship can be obtained:

$$\log \alpha_{M(I)} = \log \frac{c_I' K_{M(I)t}}{\beta_{an}} + n\mathrm{pH} \quad (7)$$

holding for $\alpha_{M(I)}$ and $\alpha_I \gg 1$. n is the average number of protons linked to I in the considered pH range. It can also have fractional values. If $K_{M(I)}$ depends on the acidity, Eq. (3) (Ruzic linearization) strictly holds only when the acidity is constant. In the present investigation, a modification of the original equation is proposed, to take into account the pH variations. It is obtained by substituting Eqs. (4) and (6) into Eq. (3) and assuming for simplicity that $[M] \ll c_M - c$:

$$\frac{cV}{(c_M - c)K^*[H]^n w} = \frac{1}{\frac{K_{M(I)t}}{\beta_{an}}\, c_I} + \frac{cV}{c_I\, K^*[H]^n w} \quad (8)$$

From the parameters of the straight line obtained by considering the two variables $cV/(c_M - c)K^*[H]^n w$ and $cV/K^*[H]^n w$ (n has the value experimentally found by Eq. (7)) the concentration of the ligand I in solution (c_I) and the complexation constant are evaluated.

1.2. Procedures

In this investigation two procedures were used to obtain the information:

1.2.1. Resin titration (RT)

[M] and [MI] are varied by changing the ratio V/w, while c_M is kept constant. Different fractions of the metal ion are sorbed on the resin at different V/w, so that the metal ion is actually titrated by the resin. This is the reason for the name of the method. This procedure was used in the case of different natural waters [10,16], to determine the value of the reaction coefficient $\alpha_{M(I)}$. The total concentration of metal ion in solution, which is labile for the considered resin, c_M, can also be evaluated. The concentration of the metal sorbed on the resin is given by Eq. (5), where the two unknown quantities are c_M and $\alpha_{M(I)}$. The reaction coefficient is an interesting quantity for the characterization of the stability of the complex.

1.2.2. Ligand titration (LT)

[M] is varied by adding increasing concentrations of metal ion M to the sample. Here the ligands are titrated by the added metal ion. The ligand titration (LT) is widely used in the investigation of the complexing capacity of natural waters, often in connection with amperometric techniques for the determination of the labile metal [4,5,13]. The LT of copper(II) and aluminium(III) in freshwater [10] and synthetical solutions [15] using complexing resins was described. Eq. (8) is applied to obtain the required information about c_I and $K_{M(I)}$.

2. Experimental

2.1. Chemicals

All the reagents were of analytical reagent grade.

The spring water was analyzed without any modification of the sample, after filtration on 0.22 μm polycarbonate Nucleopore filter.

Chelex 100 (Na-form, 50–100 mesh) was obtained from Bio-Rad Laboratories, Richmond, CA. Its capacity (mmoles of active groups per g of dry resin), and the amount of water sorbed under different conditions were previously determined [11,17].

Chelex-100 in Na^+ form was transformed in H^+ form as previously reported [16].

2.2. Instrumentation

The determination of the metal concentrations was made by AAS. A Shimadzu AA-6601 G/GFA 6500 electrothermal atomic spectrometer with Shimadzu

autosampler ASC 6100 was used for Al(III), Cu(II) and Mn (II) determinations. L'vov platform pyrolytic graphite tube was used and analysis was performed according to operating instruction of the producer [9].

When the concentration was sufficiently high a Perkin–Elmer 1100 B flame AAS was used, following the standard condition of the operating instruction of the producer.

The concentration of H^+ in the solution phase was measured potentiometrically by a combined glass electrode (Orion 9102 SC, saturated KCl filling solution) standardized in H^+ concentration by the standard addition method in NaCl 1.1 M solution. The standard potential $E^{\circ\prime}$ was determined by the Gran linearization as described elsewhere [11,16].

2.3. Experimental procedure

All the titrations were made dividing the sample in a number of subsamples (5–8), whose volume ranged from 25 to 100 ml. Each subsample was contacted with a measured amount of resin, from 0.2 to 0.5 g of dry resin. In the case of RT the subsamples had different volumes, while all other variables were the same. In the case of LT only the total concentration of the metal was varied. In both cases, the subsamples were equilibrated at the considered acidity, and after 12 h the liquid phase was separated by filtration, the resin rapidly washed with water and eluted with 10 ml of HNO_3 0.1 M. The concentration of the metal ion in the eluting solution was determined by AAS. By this technique the required low detection limits were obtained.

2.4. Evaluation of K*

This quantity, which is of foundamental importance for the investigation of the speciation by the method proposed, was calculated as previously described from the sorption equilibria of the metals on Chelex 100, which have been investigated elsewhere [8,9,17]. As a matter of fact the knowledge of the exchange coefficient of the considered metal on Chelex 100 is required for the evaluation of K^*. The exchange coefficients are calculated from the intrinsic complexation constants of the metal, on the basis of the Gibbs–Donnan model for the resin [18,19].

The intrinsic complexation constants of copper(II), manganese(II) and aluminium(III), used in this investigation, have been previously reported [8,9].

Table 2
Concentration of some metals in the solid phase collected in a 0.22 μm filter after the filtration of 1 l of the high salinity water sample

	μmol l^{-1}
Iron	52.5
Calcium	21.7
Magnesium	14.0
Copper	1.82
Manganese	2.67
Aluminium	9.11

Concentrations of metal ions are referred to the volume of the filtered sample.

3. Results and discussion

3.1. Resin titration of the high salinity spring water

The complexation of copper(II), manganese(II) and aluminium(III) in a high salinity spring water was investigated by the resin titration (RT) procedure, as described under 'Methods'. The major constituents of this water sample are reported in Table 1. The speciation investigation was performed in solution, after filtration through a 0.22 μm filter. In Table 2 the concentration of copper, manganese and aluminium retained in the filter is reported. It was determined by AAS, after dissolution with concentrated HNO_3 (3 ml) of the filtrate obtained from 1 l of sample. A large amount of copper(II) and aluminium(III) is in the solid fraction, while manganese is almost totally in the solution phase, as seen by comparing these results with the concentration of the metals in the solution phase (see Table 4).

The strongly sorbing resin Chelex 100 was used for RT, since in the considered sample a high concentration of competing metals, like alkaline hearth metals, is present.

The results of the RT of the solution phase are reported in Fig. 1, which shows the concentration of metal ion sorbed in the resin phase c against the volume of the solution phase, at constant amount of resin. The data for the three metals were obtained by the same resin equilibration, determining the concentration of the sorbed metals in the same eluate, as described in the experimental section. This is very convenient since informations about different metals can be obtained at the same time. The average acidity was pH 5.6, but it ranged from 5.08 to 6.06 in the different subsamples, as reported in Table 3. The pH of the subsamples, obtained spontaneously after equilibration with the resin, was much lower, since Chelex 100 was used in the H^+ form, and this H^+ is almost completely exchanged for other ions, in particular the alkaline earth metals, which are present at high concentration in the sample here considered. The acidity is partially neutralized by addition of NaOH, up to the final pH reported in Table 3. This neutralization is poorly reproducible, and very time consuming, so that it is practically impossible to obtain subsamples at the same final acidity. For this reason a data treatment is used which takes into account the pH variations among the different subsamples (see

Table 4
Results of RT of the high salinity water sample

	c_{tot} (mol l^{-1})	$\alpha_{M(I)}$ at pH 5.6 [a]	n [b]	log $c_I' K_{M(I)t}/\beta_{an}$ [c]	$K_{M(I)}c_I$ [d]

Eq. (8)). The values of K^* which have been used for the three metals are those reported in Table 3.

The fact that K^* varies with the conditions is usually observed, also for Chelex 100. It is important for the accuracy of the method to know the value of K^* exactly at the operating conditions.

Table 3
Final pH of the subsamples of the high salinity water, after equilibration with 0.3 g of Chelex 100 in H^+ form and after control of the acidity

V (ml)	Ph	K^*(Cu)	K^*(Mn)	K^*(Al)
50	5.69	3.9×10^{11}	$5.7\ 10^{2}$	4.3×10^{7}
100	5.58	2.3×10^{11}	$3.7\ 10^{2}$	2.4×10^{7}
150	6.06	2.0×10^{12}	$2.7\ 10^{3}$	3.4×10^{8}
200	5.08	2.4×10^{10}	$8.9\ 10^{1}$	1.9×10^{6}
250	6.32	6.2×10^{12}	$8.3\ 10^{3}$	1.7×10^{9}
300	5.22	4.5×10^{10}	$1.2\ 10^{2}$	3.9×10^{6}

Calculated K^* values at the operating conditions are reported for the three metal ions.

The RT curves of each metal are fitted by Eq. (5), whose parameters c_M and $\alpha_{M(I)}$ are evaluated assuming that $\alpha_{M(I)}/K^*$ is constant. The results are reported in Table 4 as c_{tot} and $\alpha_{M(I)}$ at an intermediate pH. The reaction coefficient $\alpha_{M(I)}$ at different pH was evaluated, and the function log $\alpha_{M(I)}$ versus pH is reported in Fig. 2 for the three metals. It is a straight line, as expected from Eq. (7), whose slope indicates the number of protons removed from the ligand I when the metal ion combines. The ordinate at the origin is related to the stability of the complexes formed in solution.

The parameters of the straight lines corresponding to Eq. (7) are reported in Table 4 for each metal ion. Different values of n are obtained for the three metals, in the same pH range, indicating that probably different ligands are involved in the respective complexation. In the case of manganese a value of $\alpha_{M(I)}$ near to 1 indicates that it is not correct to use the simplified Eq. (7) for this metal. The parameters obtained are reported in Table 4 as well, together with those of the other metals.

The reaction coefficients $\alpha_{M(I)}$ of the three metals have widely different values. It is very high in the case of copper(II), as previously found in some seawater samples [16]. Also aluminium has a high reaction coefficient, somewhat higher than that ascribable to the hydrolysis (log $\alpha_{hydr} = 4.0$ at pH 5.6 [9]), while the reaction coefficient of manganese corresponds to the free metal ion, or to a very weak complexation.

An attempt was made to determine stability constant and the concentration of ligands responsible for the

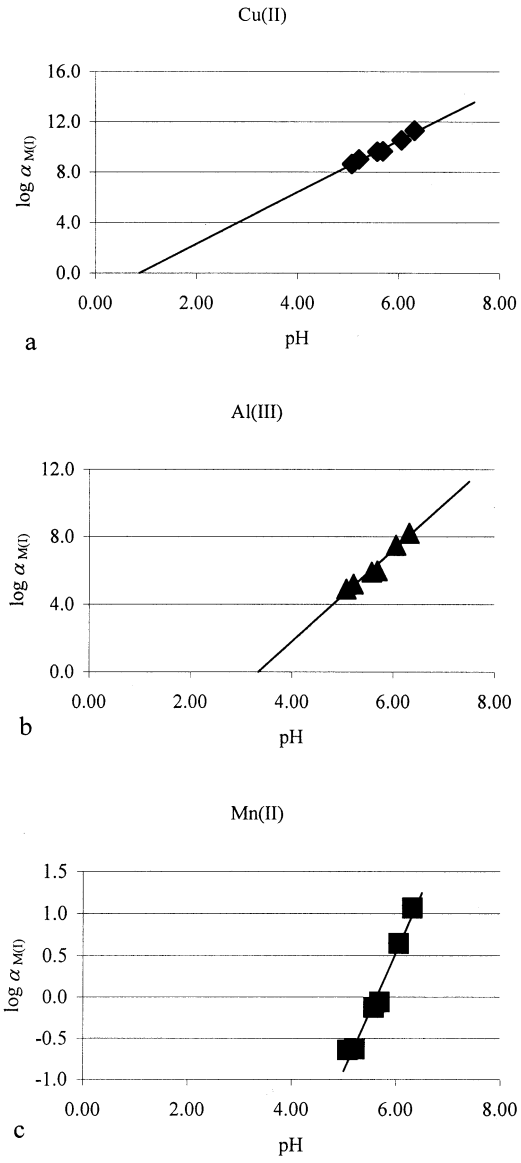

Fig. 2. Log $\alpha_{M(I)}$ at different pH of the subsamples, obtained from the RT (Eq. (7)). Graph (a) copper Graph (b) aluminium Graph (c) manganese.

complexation, by treating the data of RT by a method similar to that proposed by Ruzic in the early 1980s [12]. A modification of the equation originally proposed was used, as shown in Eq. (8), to take into account the pH variations in the different subsamples.

The results obtained in the present investigation are reported in Table 5. The ordinate at the origin was negative in the case of copper(II) and aluminium(III).

The negative intercept indicates that the complexation constant in solution $K_{M(I)}$ is too high to be evaluated by the proposed procedure. It should be observed that the fraction of sorbed metal was low for both the metals, lower than 0.1 in the majority of the points obtained by RT. The high imprecision of the metal ion determination when a low concentration is sorbed on the resin is responsible for the irreproducibility of the ordinate a the origin. In both these cases, the slope is significantly different from 0, and thus the concentration of the ligands could be evaluated. It was, respectively, 3.9×10^{-8} M for copper(II) and 3.8×10^{-7} M for Al(III). These ligands are at concentration close to that of the metal ions, forming complexes of very high stability, whose conditional complexation constants at pH 5.6 can be evaluated to be approximately 1.0×10^{17} (copper) and 2.5×10^{12} (aluminium).

The slope of the straight line in the case of manganese is not significantly different from zero. This indicates that the ligand of manganese (if any ligand is present, detectable by the proposed method) is at concentration much higher than that of the metal ion ($c_I \gg [MI]$). Obviously in this situation the concentration of the ligands can not be evaluated. The ordinate at the origin is significantly different from 0. In this case the fraction of sorbed metal ranged from 0.79 to 0.33, so it is always significant. From the ordinate at the origin $c_I K_{M(I)t}$ was evaluated to be 0.58, a value near to that obtained by the log $\alpha_{M(I)}$ versus pH straight line.

3.2. Ligand titration of the high salinity spring water

To investigate the presence of other ligands, a LT of the high salinity spring water sample was carried out with manganese(II) and copper(II). This could not be done with aluminium since a precipitate was formed when aluminium(III) was added to the solution as titrant. The same was observed in the case of copper(II) at concentration higher than 2×10^{-5} M. The LT was carried out independently for each metal ion. The data of the titration are reported in Table 6. The pH of each subsample is also shown, together with other informations of interest for the considered LT. In this procedure too it was experimentally difficult to maintain the same acidity in all the subsamples. On the other hand, the pH variation may allow us to obtain other information about the complexation, i.e. the dependence of the reaction coefficient on the acidity, as in the case of RT. Here again, as described above, log $\alpha_{M(I)}$ for each pH can be obtained, and the parameters n and log $c_I' K_{M(I)t}/\beta_{an}$ of Eq. (7) can be evaluated. They are reported in Table 7, together with the other results of the LT, obtained by Eq. (8).

In the case of copper(II) only a concentration of titrant up to 1.6×10^{-5} M could be considered, since at higher concentration a precipitate was formed. The fraction of metal sorbed never exceeded 10%, so it is evident that strong complexes are formed in solution and the ligands are far from being saturated by the added copper(II). For these reasons the quantitative evaluation of the ligand concentration and stability constant was affected by a high inaccuracy, as discussed elsewhere [15].

[a] Acidity of the different subsamples.
[b] f is the fraction of metal ion sorbed on the resin (c/c_M).

However, the quantity $\log c_I K_{M(I)t}/\beta_{an}$ can be evaluated from the ordinate at the origin of Eq. (7), and is reported in Table 7. The value has a high uncertainty, due to the fact that the fraction of sorbed metal is lower than 10%. If it has any meaning, the value of $\log c_I' K_{M(I)t}/\beta_{an}$ is very near to that determined by RT, (see Table 4). On the contrary the concentration of the ligands can not be determined, even if it can be said that they are at concentration higher than that of the maximum amount of copper added for the titration. In any case these ligands are not the strong ligands detected by RT, which are at a concentration very near to that of the metal.

In the LT with manganese(II) both c_I and $K_{M(I)t}/\beta_{an}$ (see Eq. (8)) could be determined, even if with a large uncertainty. A considerably high fraction of metal was always sorbed on Chelex 100, and the last metal additions were sorbed as expected if the ligand were completely saturated. It has been previously shown [15] that in this situation accurate values can be obtained for $K_{M(I)}$ and c_I. The results are reported in Table 7. The concentration of the ligands is higher than that of the metal ion, as expected from RT. Considering the results obtained from the modified Ruzic linearization, the quantity $\log c_I' K_{M(I)t}/\beta_{an} = -6.7$ is probably not significantly different from that obtained by RT, considering the high uncertainty. This confirms that the same complexes are detected by the two methods. The reaction coefficient, evaluated at pH 5.56, is 11.4 with a standard deviation (S.D.) of 5.9, obtained by the error propagation. Thus the hypothesis on which Eq. (7) is based should hold. The reaction coefficient of the species of manganese in the high salinity water here examined is slightly higher than that ascribable to the complexation produced by the major inorganic components, since the conditional complexation constant can be evaluated to be 2.9×10^{5}.

4. Conclusions

Some interesting results have been obtained in the investigation of some metal ions complexation in a high salinity spring water.

The reaction coefficient of aluminium obtained by RT was found to be somewhat higher than that due to the hydrolytic species, which are usually believed to be the most important aluminium species in natural waters. As an example, the strongly complexing synthetic ligand EDTA has a conditional complexation constant with aluminium of 4.7×10^{11} at pH 6 [20], which is only slightly lower than that here determined. This is the

Table 7

[a] Slope not significantly different from 0.

opposite of what observed in the case of manganese, whose conditional complexation constant with EDTA at these conditions is $10^{9.24}$ [20], much higher than that found here. Very strong are also the complexes of copper(II), and detected by RT. The conditional complexation constant was around 10^{17}, while that of EDTA is 1.5×10^{14} [20]. Other ligands of copper(II) were detected by the LT procedure, which are at concentration higher than 1.6×10^{-5} M, and must have a conditional stability constant lower than 2.4×10^{11}. This is true also considering that the LT was carried out at a pH lower than that of the RT. The complexing properties of the ligands of copper(II) detected by LT could be near to that of EDTA, since the conditional complexation constant Cu-EDTA at pH 4 is 2.4×10^{10}. The comparison with EDTA for the three metals is only reported as an example. It is likely that different ligands are involved for copper(II), manganese(II) and aluminium(III) complexation in the considered sample.

The methods based on the sorption of a metal ion on a complexing resin are useful for the characterization of the metal ion complexation in natural waters, at the very low concentration, and to detect metal ligands.

The characterization consists in the determination of the reaction coefficient, of the concentration of the ligands, and of the complexation constant. Informations about the dependence of the complexation equilibria on the acidity of the solution can be obtained, if the experiments are performed at different acidities. Of course the accuracy of the results depends on the accuracy of the knowledge of the sorption equilibria, since the evaluations are based on the existing relationship between the concentration of free metal in solution and that sorbed on the resin phase in equilibrium conditions, shown by Eq. (4).

The reproducibility of the experimental method is also important, and it should be improved to obtain more reliable results. Best and more complete information is obtained when the experiment is properly set up, by using a suitable resin and proper conditions, as for instance acidity and V/w. Only those complexes with $\alpha_{M(I)}$ ranging from 0.1 to 10 K^*w/V can be detected and investigated. The metal ion combined in complexes with $\alpha_{M(I)}$ lower than 0.1 K^*w/V are completely sorbed on the resin, while those with $\alpha_{M(I)}$ higher than 10 K^*w/V are not sorbed at all [15].

For instance in the sample here considered a better characterization of the strong complexes of copper and aluminium should be obtained by changing the conditions of the experiment, in particular by decreasing V/w. In this paper, the results obtained by a standard procedure are reported, which in any case give us interesting information about the considered sample. On the basis of this preliminary knowledge, most suitable conditions can be selected for a most accurate characterization.

In this paper, the results obtained using Chelex 100 are reported. This resin strongly sorbs the heavy metal ions, and makes it possible the detection of very strong complexes, which are hardly observed by other methods. This is interesting, since for instance the presence of strong ligands in solution increases the mobility of the metals, and has an influence on the toxicity. Usually strong complexes are less toxic than the weak complexes and the free metal ions.

Abstract

The synthesis of the flexible ligand 2,6-bis-{[bis-(2-aminoethyl)amino]methyl}-benzene (**L1**) is reported. The basicity behavior of the ligand in aqueous solution was studied by potentiometry (25 °C, $I = 0.15$ mol dm^{-3}, Me_4NCl). **L1** behaves as pentaprotic base ($\log K_1 = 10.39(2)$, $\log K_2 = 9.72(1)$, $\log K_3 = 9.11(1)$, $\log K_4 = 8.72(1)$, $\log K_5 = 2.03(2)$). The stability constants for Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and Pb(II) complexes were determined by potentiometry under the same experimental conditions and they were compared with those of ligands **L2** having the same two tri-amine subunits linked by a phenol, rather than a benzene, spacer. **L1** forms mono nuclear species with $\log K_{ML} = 9.65(1)$ for Co(II), 13.92(1) for Ni(II), 17.59(1) for Cu(II), 10.45(1) for Zn(II) and 9.24(1) for Cd(II) and binuclear species with $\log K_{M2L} = 15.28(1)$ for Co(II), 19.24(3) for Ni(II), 28.32(2) for Cu(II), 16.94(1) for Zn(II) and 14.88(1) for Cd(II). The role of the benzene and phenol as spacers of two amine functions in metal ion coordination is discussed. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

Due to the key roles they play in a variety of fields, binuclear transition metal complexes and ligands capable to form them have been attracting interest from the standpoints of synthetic and biological chemistry [1–4]. Various hydrolytic metal-enzymes contain two divalent transition metal ions in close proximity, forming their active site [5–12]. For this reason, the distance between the two metals is the crucial feature allowing the cooperation of both metal ions in the active center. Recently, we reported the synthesis and the coordination properties toward M(II) metal cations of the non-cyclic ligand **L2** (Chart 1) containing a phenol moiety separating two *triaza*-polyamine fragments, highlighting its capability to assemble two transition metal ions in close proximity [13]. In this way, the two metals cooperate to bind a new species (OH^-, Cl^-, $R–O^-$, N_3^-, O_2, and other), which are coordinated in a bridge disposition between the two metals [13–15]. **L3** includes the same two tri-amine moieties but in this case, they are separated by the anisolic group (Chart 1). The presence of this spacer permits the formation of binuclear complexes with various M(II) metal ions in which, the two metals are far from each other; in this way, they can bind secondary ligands independently to saturate their coordination sphere [16]. To learn more about the structural parameters needed to obtain a bimetallic center using simple triamine subunits, we designed the new ligand **L1**, which has a different rigid spacer linking two amine moieties. The acid–base behavior and the coordination properties toward M(II) transition cations of this ligand were determined and are reported and compared with the coordination properties of **L2** toward the same M(II) cations.

Ligands

2. Experimental

2.1. Synthesis

The synthesis of ligands **L1** was obtained following the procedure reported in Scheme 1. 2,6-bis(Bromomethyl)-benzene (**1**) [19] and *N*,*N*′-imminodiethylene-bis-phthalimide (**2**) [20] were prepared as previously described. Solvents and starting materials were used as purchased.

Scheme 1. Synthetic pathway followed to obtain compound **L1**.

2.1.1. 2,6-bis{[bis(2-Phthalimidoethyl)amino]methyl}benzene

Over a period of 3 h, a solution of **1** (2.6 g, 0.01 mol) in 200 cm^3 of dimethylformamide was added to a refluxing suspension of **2** (7.3 g, 0.02 mol) and of Na_2CO_3 (5.3 g, 0.05 mol) in 250 cm^3 of dimethylformamide. The reaction mixture was maintained under reflux for a further 3 h. Subsequently, the mixture was cooled to room temperature (r.t.) and the resulting suspension was filtered. The solution was concentrated to 100 cm^3 under reduced pressure and poured into cold water (500 cm^3), obtaining the product as a white solid. Yield: 7.4 g (89%). *Anal*. Calc. for $C_{48}H_{40}N_6O_8$: C, 69.55; H, 4.86; N, 10.14. Found: C, 69.4; H, 4.8; N, 10.1%. ^{1}H NMR ($CDCl_3$, 25 °C): 2.74 (t, 8H), 3.39 (s, 4H), 3.72 (t, 8H), 6.51 (t, 1H), 6.79 (d, 2H), 6.89 (s, 1H), 7.71 (m, 16H) ppm.

2.1.2. 2,6-bis{[bis-(2-Aminoethyl)amino]methyl}benzene (*L1*)

2,6-bis{[bis-(2-Phthalimidoethyl)-amino]methyl}-benzene (4.1 g, 5.0 mmol) was suspended in HCl 6 M (50 cm^3). The reaction mixture was maintained under reflux for 1 day. Subsequently, the mixture was cooled to r.t. and the resulting suspension was filtered to eliminate the phthalic acid. The solution was evaporated under reduced pressure to give a white solid, which was recrystallized with hot ethanol, achieving **L1** as *hexa*-hydrochloride salt. Yield: 2.2 g (83%). *Anal*. Calc. for $C_{16}H_{38}N_6Cl_6$: C, 36.45; H, 7.26; N, 15.94. Found: C, 36.6; H, 7.4; N, 15.8%. ^{1}H NMR D_2O, (pH 3, 25 °C): 3.42 (m, 16H), 4.46 (s, 4H), 7.60 (m, 3H), 7.68 (s, 1H) ppm. ^{13}C NMR 35.3, 50.7, 59.2, 131.7, 132,0 134.0, 134.7 ppm.

2.2. General

2.2.1. NMR spectroscopy

^{1}H and ^{13}C NMR spectra were recorded on a Bruker AC-200 instrument, operating at 200.13 and 50.33 MHz, respectively. Peak positions are reported in relation to TMS ($CHCl_3$) or HOD at 4.75 ppm (D_2O). Dioxane was used as reference standard in ^{13}C NMR spectra (δ = 67.4 ppm).

2.2.2. UV–Vis spectroscopy

UV absorption spectra were recorded at 298 K on a Varian Cary-100 spectrophotometer equipped with a temperature control unit.

2.2.3. Potentiometric measurements

Equilibrium constants for complexation reactions were determined by pH-metric measurements (pH = $-\log[H^+]$) in 0.15 mol dm^{-3} Me_4NCl at 298.1 ± 0.1 K, using the fully automatic equipment that has already been described; the EMF data were acquired with the

PASAT computer program [21]. The combined glass electrode was calibrated as a hydrogen concentration probe by titrating known amounts of HCl with CO_2-free Me_4NOH solutions and determining the equivalent point by Gran's method [22], which gives the standard potential E° and the ionic product of water ($pK_w = 13.73(1)$ at 298.1 K in 0.15 mol dm^{-3} Me_4NCl, $K_w = [H^+][OH^-]$). Ligand and metal ion concentrations of 1×10^{-3}–2×10^{-3} were employed in the potentiometric measurements, performing at least three measurements in the pH range 2–11. The HYPERQUAD [23] computer program was used to process the potentiometric data. All titrations were treated either as single sets or as separate entities, for each system, without significant variation in the values of the determined constants.

3. Results and discussion

3.1. Synthesis

The synthetic pathway used to obtain ligand **L1** is depicted in Scheme 1. The reaction of 2,6-bis(bromomethyl)-benzene (**1**) with 2 equiv. of *N*,*N*′-iminodiethylenebisphthalimide (**2**), in the presence of a base gives the intermediate molecule 2,6-bis[[bis-(2-phthalimidoethyl)-amino]methyl]-benzene in high yield. The cleavage reaction of the phthalic groups was carried out with HCl 6 M, obtaining **L1**, after the work up, as hydrochloride salt.

3.2. Solution studies

3.2.1. Basicity

Table 1 summarizes the basicity constants of **L1** with those of **L2** [15], potentiometrically determined in 0.15 mol dm^{-3} Me_4NCl aqueous solution at 298.1 K. **L1** can bind up to five protons under the experimental conditions used. The first four protonation steps lead to a slight decrease in the log *K* values: from $\log K_1 = 10.39 - \log K_4 = 8.72$, while a greater decrease in the log *K* value was observed for the fifth protonation step (see Table 1).

Table 1
Equilibrium constants (298.15 K, $I = 0.15$ mol dm^{-3}, Me_4NCl) for the protonation equilibria of **L1** and **L2** in aqueous solution

Reaction	Log *K*	
	L1	**L2**
$L + H^+ = HL^+$	10.39(2) [a]	10.49 [b]
$HL^+ + H^+ = H_2L^{2+}$	9.72(1)	9.68
$H_2L^{2+} + H^+ = H_3L^{3+}$	9.11(1)	9.21
$H_3L^{3+} + H^+ = H_4L^{4+}$	8.72(1)	7.59
$H_4L^{4+} + H^+ = H_5L^{5+}$	2.03(2)	2.31

[a] Values in parentheses are the S.D. on the last significant figure.
[b] Values from [15].

Considering the number of the protonation sites and their localization, this trend in the constant values can be easy explained in terms of minimization of the electrostatic repulsion between positive charges in the protonated species. In other words, the first four protons, binding the four primary amine functions, occupy positions far from each other and thus experience little charge repulsion. On the contrary, the fifth proton must be bound to a nitrogen atom (a tertiary amine) having the two other nitrogens of the same subunit protonated; this situation implies significant charge repulsion and is the cause of the drop in the log *K* value for the fifth protonation step. The differences between the stepwise basicity constants $\log K_1 - \log K_2 = 0.67$, $\log K_2 - \log K_3 = 0.61$ and $\log K_3 - \log K_4 = 0.39$ are similar to the critical and statistical value of $\Delta pK_a = pK_2 - pK_1 = 0.6$ of the successive dissociation of H_2L species having 2 equiv. but not-interacting dissociable protons. These data suggest that the four primary amines do not interact and they behave independently to the protonation processes. Furthermore, the first four protonation constants of **L1** are very similar to the first two basicity constants of diethylenetriamine, indicating again the independency of the two amine subunits [17]. In contrast, the differences of stepwise protonation constants of **L2**, show different values (0.81, 0.47, 1.59 logarithmic units, respectively) due to the interaction between the protonable sites during the protonation processes, produced by the insertion of the phenolic moiety.

3.2.2. Coordination of metal ions

The coordination behavior of **L1** towards the bipositive metal cations Mn(II), Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and Pb(II) was potentiometrically studied in 0.15 mol dm^{-3} NMe_4Cl aqueous solution at 298.1 K and the data are reported in Table 2. For comparison, the binding properties of ligand **L2** towards the same metal cations are reported in Table 3. The data for **L2** were taken from the literature or determined under the same experimental conditions used for **L1**. **L1** forms stable mono and binuclear complexes with Co(II), Ni(II), Cu(II), Zn(II), and Cd(II); in addition, Mn(II) and Pb(II) are bound by **L2**, forming both mono and binuclear species.

The trends of the log *K* values for the addition of one M(II) ion to the neutral species are reported in Fig. 1; they are in agreement with the Irving–Williams sequence, although for the same metals **L2** always shows higher addition values than **L1**.

This behavior can be explained taking into account the fact that **L2** contains the phenolic function, which provides one more active coordination site in the ligand, thus permitting a better stabilization of the metal ion.

Table 2

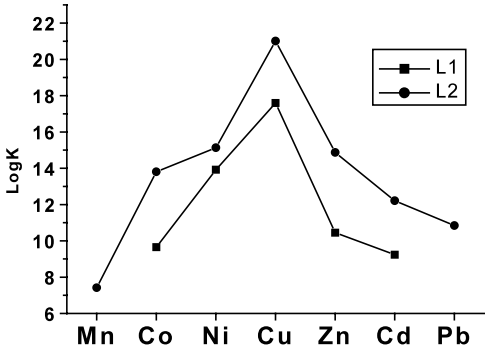

Fig. 1. Trend of the formation constants (log K) for the mononuclear species $[ML]^{2+}$ of **L1** (■) and **L2** (●).

As already demonstrated, the phenol of **L2** is involved in the coordination with its deprotonated form even at low pH values; in the mononuclear $[MH_{-1}L2]^{+}$ species the metal is probably bound by it and by three nitrogen atoms of one tri-amine subunit. Moreover, Tables 2 and 3 report the formation of complexed protonated species for all $[ML]^{2+}$ species; they easily give the $[MLH_2]^{4+}$ species indicating that the two protons are located on donor atoms not involved in the coordination of the metal ion. The molecular topology of the ligands, which have two symmetrical tri-amine subunits kept apart by a rigid spacer, can justify this behavior since it prevents the two tri-amine moieties from simultaneously binding

the same metal ion, leaving one of the units involved in the protonation process unbound.

The molecular topology also facilitates the formation of binuclear species; however, because the subunits are close to each other and not independent, the addition of the second metal ion is affected by the presence of the first one and is less favorable, as reported in Tables 2 and 3. It is of note that the addition of the second metal ion takes place on the $[MH_{-1}\mathbf{L2}]^{+}$ species for **L2**, again highlighting the involvement of the phenolate in stabilizing the mononuclear species. The log K values for the addition of the second metal ions (Fig. 2) reveal that **L2** again shows higher addition constant values than **L1**. This is again due to the fact that **L2** provides a further binding site, since it is well know that the phenolate is able to simultaneously bind two metal ions in a bridge disposition [13–15,18].

All the mononuclear species $[M\mathbf{L1}]^{2+}$ have a great tendency to form *mono*-hydroxo species, indicating that the coordination requirement of the metal ion is not satisfied by the donor atoms present in the molecule. Comparison of the data for the addition of one OH^{-} to the *mono*-nuclear species shows that, while **L1** forms $[M\mathbf{L1}OH]^{+}$ species with all the metal ions, in the case of **L2** the monohydroxo species are present only for the Ni(II) species (see Table 3). This once again indicates the better saturation of the coordination sites of the metal by **L2** than **L1**.

The binuclear species of both ligands show the addition of at least one hydroxide to the $[M_2\mathbf{L1}]^{4+}$ or $[M_2H_{-1}\mathbf{L2}]^{3+}$ species, respectively, (the precipitation of hydroxo species of Ni(II) prevents detection of the addition of OH^{-} to the binuclear complex of **L1**). The addition constants of the first OH^{-} are always greater for **L2** than for **L1** by about two logarithmic units for the binuclear species of the metal ions of the first transition row. On the contrary, the addition process of the OH^{-} to the Cd(II) and Pb(II) binuclear species of **L2** shows log K values that are similar between them and also similar to the value found for the addition of the anion to the Cd(II) binuclear species of **L1**. Moreover, while the addition of a second hydroxide was observed only for the Mn(II) and Co(II) binuclear species of **L2**, this speciation was found for all the metal ions except for Ni(II), for the above reason, in the case of **L1.** This different behavior for the hydroxylated binuclear species can be ascribed to the different disposition of the two metals in the complexes of **L1** or **L2**. In the case of **L1** the two metals are independent and quite far from each other; in this way, the addition of one hydroxide to form the *mono*-hydroxylated species takes place only in one of the two metal ions, while the other one remains unaffected and tends to bind a second hydroxide anion. This is confirmed by the similar values for the addition of the second hydroxide to such species (see Table 2). In the case of **L2**, the two metals are most likely brought close to each other by forming the phenolate bridge; therefore, the first hydroxide anion can be bound in a bridge disposition by both metal ions, giving rise to higher addition constant values and moreover, at the same time saturating their coordination requirement. This assumption is contradicted in the cases of Cd(II) and Pb(II) binuclear complexes of **L2**, where the larger dimension of the ions probably prevents the formation of the hydroxo-bridge. In other words, the presence of the phenolate oxygen bridging two metal ions of the first transition row permits the assembling of two metals close to each other, allowing them to cooperate to bind molecules having two close lone pairs such hydroxide anion; on the contrary, this cooperation is unfavorable for the bigger Cd(II) and Pb(II) metal ions; in the case of **L1**, where the spacer does not have binding properties, the two amine subunits show independent coordination behavior. In this case, each metal ion must fulfil its coordination requirement on each side of the molecule by using external donor atoms; indeed, all of the metal ions investigated form binuclear *di*-hydroxo species (see Table 2).

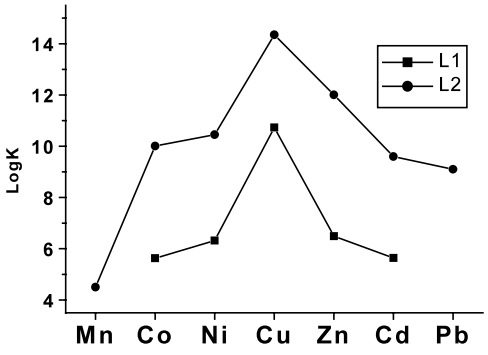

Fig. 2. Trend of the addition constants (log K) for the second M(II) ions to the mononuclear species of [**ML1**] (■) and $[MH_{-1}\mathbf{L2}]$ (●).

3.3. Conclusions

The insertion of benzene (**L1**) instead of phenol (**L2**) as spacer to separate two triamine units produces changes in the coordination properties of the two resulting ligands towards metal cations, exalting the compartmental behavior of **L1** as compared with **L2**. The basicity constants of both ligands are approximately the same in aqueous solution, while the formation constants of the *mono*- and *bi*-nuclear species with the M(II) metal ions studied are always higher for the phenolic ligand **L2** than **L1**. This is ascribed to the presence of one more coordination site in **L2** due to the oxygen of the phenol, which moreover has the possibility to bridge two metal ions in the binuclear species, furnishing a further coordination site. However, **L1** forms stable binuclear complexes with many of the ions

investigated. The metal is coordinated by a single triamine sub-unit of the ligand in both *mono*- and binuclear complexes; in the *mono*-nuclear species, the other amine subunit remains unbound. In all cases, however, the metal ions show an unsaturated coordination environment; for this reason, these species are able to bind at least another ligand, giving rise to cascade complexes. The presence of the phenolic function in **L2** gives binuclear complexes in which the two metal ions are located close to each other due to the formation of one metal–oxygen–metal phenol bridge; on the contrary, this situation is unfavorable for the binuclear species of **L1** in which the benzene spacer exalts the compartmental behavior of the ligand, due to the long distance between the two metal ions. In this way, the two metal centers of **L2** can cooperate to bind a substrate, while the same centers in **L1** are able to bind substrates independently in order to saturate their coordination requirement.

Calculation of organic solvent–water partition coefficients of iron–sulfur protein models

Francisco Torrens *

Institut Universitari de Ciència Molecular, Universitat de València, Dr Moliner 50, E-46100-Burjassot, València, Spain

Received 6 June 2001; accepted 29 October 2001

Abstract

A method is presented that permits semiquantitative estimation of the partitioning of many solutes between many pairs of media. As an example, the organic solvent–water partition coefficients P are calculated. The only needed parameters are the dielectric constant and molecular volume of the organic solvent. $Fe_4S_4Cys_n$ models of high-potential FeS proteins are studied. The Gibbs free energies of solvation and partition coefficients for $Fe_4S_4Cys_n$ are calculated. The organic solvent–water partition coefficients for 1-octanol P_o, cyclohexane P_{ch} and chloroform P_{cf} decrease 4.41, 6.22 and 4.60 log units per cysteine (Cys) ligand, respectively. P_o results are compared with CDHI calculations and P_{ch} and P_{cf} results are compared with calculations carried out with a method by Leo et al. With these reference methods, P_o, P_{ch} and P_{cf} decrease 4.12, 4.70 and 5.63 log units per Cys ligand, respectively. log P_o, log P_{ch} and log P_{cf} mean relative errors (MRE) are 17, 26 and −16%, respectively. These represent a MRE of 9% but a mean unsigned relative error (URE) of 19%. For Fe_4S_4, P_o, P_{ch} and P_{cf} are close to 0 log unit. On varying the number of Cys units, the structures show hydrophobic moments indicative of particularly amphipathic structures as Fe_4S_4Cys. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Solvation parameter model; Partition coefficient; Hydrophobic moment; Iron–sulfur protein; Mixed-valence non-integer oxidation number; Cysteine ligand

1. Introduction

High-potential iron–sulfur proteins (HiPIPs) are a class of small electron-transfer metalloproteins that have been predominantly found in purple sulfur bacteria [1–8]. The cubane [4Fe–4S] cluster of HiPIPs is widespread in nature, functioning in electron transfer, catalytic or other roles in various proteins including ferredoxins, hydrogenase, aconitase and gene regulatory proteins. In addition, the [4Fe–4S] cluster is an element of more complex centers such as the P-cluster of nitrogenase. HiPIPs are amenable to study by a variety of biophysical techniques and are thus important paradigms in elucidating the structural determinants of the physicochemical properties of both [4Fe–4S] clusters and, more generally, biological metallocenters.

As their name implies, HiPIPs have relatively high midpoint reduction potentials, varying between 50 and 450 mV. The cluster of the reduced HiPIP has an overall charge of +2 and a net spin of 0. Mössbauer spectra indicate that the iron atoms are in equivalent, $Fe^{2.5+}$, oxidation states. The oxidized HiPIP cluster, with an overall charge of +3 and a net spin of 1/2, is made up of two antiferromagnetically coupled spin pairs. One spin pair consists of two Fe^{3+}, whereas the other consists of two $Fe^{2.5+}$. The chemical shift of the βCH_2 protons of the cluster cysteine (Cys) ligands and their temperature dependence are consistent with this interpretation. Extensive nuclear magnetic resonance (NMR) work demonstrates that the position of the spin pairs within the protein framework varies from one HiPIP to another and may be determined by the relative reduction potentials of the individual iron atoms. A third oxidation state of the [4Fe–4S] cluster possesses a charge of +1. This corresponds to the reduced ferredoxin cluster and has only been observed in HiPIPs when the protein is partially denatured.

The valence distribution within the 4-Fe cluster of oxidized HiPIPs is not well understood and may be

relevant to elucidating the factors determining the redox potential. The cluster contains two Fe^{3+} ions and a mixed-valence $Fe^{2.5+}$ pair [9,10]. The cluster of HiPIP II from *Ectothiorhodospira halophila* is the best understood system: its electron spin resonance spectrum at 4 K is consistent with an $S = 1/2$ ground state [11], and magnetic Mössbauer data indicate that this $S = 1/2$ state is the result of antiferromagnetic coupling between the mixed-valence pair and the Fe^{3+} pair, the former having a larger subspin than the latter [12,13]. This arises because the hyperfine coupling with ^{57}Fe of $Fe^{2.5+}$ has a regular sign while that of Fe^{3+} has a reversed sign, indicative of negative and positive $\langle S_z \rangle$ for the $Fe^{2.5+}$ pair and for the Fe^{3+} pair, respectively. This interpretation of the electronic structure of the oxidized cluster of HiPIP II from *E. halophila*, which is also valid for model compounds, is consistent with NMR data [14,15]. The NMR spectrum of this protein possesses two clearly divided sets of four signals arising from Cys βCH_2 proton signals, one set being upfield and the other, downfield [16]. This spectrum was interpreted by assigning a negative $\langle S_z \rangle$ to the $Fe^{2.5+}$ pair, thus accounting for the dawnfield hyperfine shifts of the βCH_2 protons of the Cys ligated to the $Fe^{2.5+}$ pair, and a positive $\langle S_z \rangle$ to the Fe^{3+} pair, accounting for the upfield hyperfine shifts of the βCH_2 protons of the Cys ligated to the Fe^{3+} pair [17,18]. With increasing temperature, the upfield shifted signals move rapidly toward the diamagnetic region of the spectrum, and at infinite temperature, their shifts extrapolate to far downfield. This behavior, which was termed pseudo-Curie, is observed because the excited states of the Fe^{3+} ions, which increase in population, have negative $\langle S_z \rangle$ [19].

In all other characterized HiPIPs, only one of the two Cys bound to the Fe^{3+} ions has upfield-shifted βCH_2 protons, while the βCH_2 protons of the other Cys are downfield shifted, albeit to a lesser extent than those of the Cys bound to the $Fe^{2.5+}$ ions [20–22]. The temperature dependence of the latter pair of signals is of anti-Curie type. The signals of both pairs extrapolate far downfield at infinite temperature. These data were interpreted by assuming the existence of an equilibrium between two electronic distributions in the cluster; both distributions have $Fe^{2.5+}$ and Fe^{3+} pairs, but one $Fe^{2.5+}$ ion in one distribution becomes Fe^{3+} in the other and vice versa [23]. This equilibrium is fast on the NMR time scale. According to this interpretation, the Fe^{3+} ion, which exists transiently in the $Fe^{2.5+}$ state, induces a small downfield shift on the Cys proton signals. Conversely, the $Fe^{2.5+}$ ion, which exists transiently in the Fe^{3+} state, induces a downfield shift, which, while still sizable, is smaller than that induced by the 100% $Fe^{2.5+}$ ion.

Bertini et al. performed the sequence-specific assignment of ligand Cys protons of oxidized, recombinant HiPIP I from *E. halophila* [24]. They investigated the unfolding properties of HiPIP from *Chromatium vinosum* [25] and compared them with those of other proteins representative of various classes of FeS proteins [26].

The present model is an extension of the solvent-dependent conformational analysis program (SCAP) 1-octanol–water model to organic solvents. It uses extended versions of the functional forms developed in that work [27]. The method was previously applied to the calculation of the organic solvent–water partition coefficients of porphyrins, phtahlocyanines, benzobisthiazoles, fullerenes, acetanilides, local anaesthetics [28], lysozyme [29], barbiturates, polystyrene [30] and hydrocarbons [31]. In this work, $Fe_4S_4Cys_n$ $(0 \leq n \leq 4)$ models of HiPIP have been studied. Section 2 presents the improvements in the solvation model. Section 3 is devoted to the results. The last section summarizes the conclusions.

2. Solubilities and partition coefficients for general organic solvents

SCAP is based on the model of Hopfinger parameterized for the 1-octanol–water solvent pair with solute molecules composed of H, C, N, O, F, S, Cl and Br, and containing a wide variety of functional groups [32,33]. SCAP was initially used to calculate the Gibbs free energy of solvation of molecules. From these data and with the equation

$$RT \ln P = \Delta G^{\circ}_{solv}\ (\text{water}) - \Delta G^{\circ}_{solv}\ (\text{1-octanol}) \qquad (1)$$

one can calculate the logarithm log P at a given T which is taken as 298 K. R is the gas constant, and ΔG°_{solv} (1-octanol) and ΔG°_{solv} (water) (in kJ mol^{-1}) are the standard-state free energies of solvation of a given solute considered in 1-octanol and water, respectively.

SCAP manages up to four fitting parameters for a given solvent: (1) n, maximum number of solvent molecules allowed for filling the solvation sphere; (2) Δg°, variation of Gibbs free energy associated with the extraction of one solvent molecule out of the solvation sphere; (3) R_v, radius of the solvation sphere and (4) V_f, free volume available for a solvent molecule in the solvation sphere. In order to generalize SCAP for a different organic solvent, it was decided not to fit new parameters, because of the lack of available experimental data for many solvents. Instead, the four parameters of 1-octanol have been used, but modified taking into account the effect of only the new dielectric constant and molecular volume on the original parameters of 1-octanol.

For a general organic solvent (e.g. cyclohexane), the maximum number of solvent molecules allowed to fill the solvation sphere is related to the molecular volume of the solvent molecule as

$$n_s = n_o \left(\frac{V_s}{V_o}\right)^{\log\frac{n_o}{n_w}/\log\frac{V_o}{V_w}} \quad (2)$$

where V_o, V_w and V_s are the molecular volumes of 1-octanol, water and a general organic solvent, respectively; n_o, n_w and n_s are the maximum numbers of molecules of 1-octanol, water and a general organic solvent, respectively, allowed to fill the solvation sphere.

The variation in the standard Gibbs free energy associated with the extraction of one solvent molecule out of the solvation sphere Δg_s° is calculated using the generalized Born equation,

$$\Delta g_s^\circ = \Delta g_o^\circ \frac{1-\frac{1}{\varepsilon_s}}{1-\frac{1}{\varepsilon_o}} = \Delta g_o^\circ \frac{\varepsilon_o(\varepsilon_s-1)}{\varepsilon_s(\varepsilon_o-1)} \quad (3)$$

where ε_o and ε_s are the relative dielectric constants [34]. Previous results for benzene suggested a variation of only 80% of that (Eq. (3)). However, the calculation of more molecules showed that it is a better rule to expand this variation up to 100%.

The radius of the solvation sphere is related to the molecular volume of the solvent molecule as

$$R_{v,s} = R_{v,o}\left(\frac{V_s}{V_o}\right)^{1/3} \quad (4)$$

Finally, the free volume available for a solvent molecule in the solvation sphere is related to the molecular volume of the solvent molecule as

$$V_{f,s} = V_{f,o}\frac{V_s}{V_o} \quad (5)$$

The only parameters needed are the relative dielectric constant ε and molecular volume V_s of the organic solvent. V_s values have been calculated with a new version of our program TOPO version 2001 [35], which includes an actualized database of van der Waals radii [36]. In the present work, the following values have been used: $\varepsilon = 10.34$ (1-octanol), 2.023 (cyclohexane) and 4.806 (chloroform); $V_s = 155.0$ (1-octanol), 93.4 (cyclohexane) and 72.1 Å^3 (chloroform) [37]. The 1-octanol is a linear molecule, very mobile, and thus it has very different volumic properties than the cyclohexane and the chloroform.

The algorithm of Kyte and Doolittle has been used to calculate the hydropathy profile of the structures [38]. The hydrophobicity of each molecule is calculated from its atomic contributions as:

$$H = \sum_{i=1}^{M} h_i$$

where h_i is the hydrophobicity of atom i and the sum extends to the number of atoms in the molecule, M.

The hydrophobic moment calculation is based on the Eisenberg et al. formula:

$$\mu = \left[\left(\sum_{i=1}^{M} h_i \cos\delta_i\right)^2 + \left(\sum_{i=1}^{M} h_i \sin\delta_i\right)^2\right]^{1/2}$$

where the gyration angle δ_i is the successive angle between an atom and the next, around the z axis [39–41]. For instance, δ increases 97° in the successive C^α atoms of an α-helical structure (Fig. 1). This hydrophobic moment is a widely used method for determining amphipathic helices in a protein [42,43].

3. Calculation results and discussion

The free energies of solvation, partition coefficients and hydrophobic moment for $Fe_4S_4Cys_n$ $(0 \le n \le 4)$ models of HiPIP are reported (Table 1). The organic solvent–water partition coefficients P_o, P_{ch} and P_{cf} decrease monotonically 4.41, 6.22 and 4.60 log units per Cys ligand, respectively. Notice that for values of $\log P < 3$, more than 99.9% of the solute is in the aqueous phase. Therefore, some results predict a negligible quantity of solute in the organic phase. The value $1-\log P_{ch}$ is greater than the Avogadro number exponent 23 ($P_{ch} < 10^{-23}$). This means that no solute molecule would be present in the organic solvent to allow experiments for validation. However, all the log P figures are only kept for the purpose of comparison along the series. P_o results are on the same order of magnitude as CDHI computations [44]. P_{ch} and P_{cf} results are on the same order of magnitude as calculations carried out with a method by Leo et al. [45]. With these reference methods, P_o, P_{ch} and P_{cf} decrease monotonically 4.12, 4.70 and 5.63 log units per Cys ligand, respectively. log P_o, log P_{ch} and log P_{cf} mean relative errors (MRE) are 17, 26 and −16%, respectively. These represent globally a MRE of 9%. However,

[a] Gibbs free energy of solvation in water (kJ mol^{-1}).
[b] Gibbs free energy of solvation in 1-octanol (kJ mol^{-1}).
[c] Gibbs free energy of solvation in cyclohexane (kJ mol^{-1}).
[d] Gibbs free energy of solvation in chloroform (kJ mol^{-1}).
[e] P_o is the 1-octanol–water partition coefficient.
[f] CDHI, calculations carried out with a method developed by Kantola et al.
[g] P_{ch} is the cyclohexane–water partition coefficient.
[h] Calculations carried out with a method developed by Leo et al.
[i] P_{cf} is the chloroform–water partition coefficient.
[j] μ is the hydrophobic moment.

this result should be taken with care because the mean unsigned relative error (URE) is 19%. The error for chloroform is rather smaller than for cyclohexane. This is due to the greater similarity in relative dielectric constant between the former solvent and 1-octanol. In particular, for Fe_4S_4 the three P are close to 0 log unit.

On the other hand, the hydrophobic moment μ differentiates well the $Fe_4S_4Cys_n$ structures. On varying the number of Cys units, the structures show μ values indicative of particularly amphipathic structures as Fe_4S_4Cys.

4. Conclusions

From the previous results the following conclusions can be drawn.

1) The three organic solvent–water P for $Fe_4S_4Cys_n$ ($0 \leq n \leq 4$) models of HiPIP decrease approximately 5.1 log units per Cys ligand. With reference methods the three P decrease 4.8 log units per Cys ligand. log P_o, log P_{ch} and log P_{cf} MRE are 17, 26 and −16%, respectively. These represent a MRE of 9% but a URE of 19%.
2) The organic solvents similar to 1-octanol in relative dielectric constant are those that are best modeled by SCAP.
3) The hydrophobic moment μ differentiates well $Fe_4S_4Cys_n$ structures. On varying the number of Cys units, the structures show μ indicative of particularly amphipathic structures as Fe_4S_4Cys. An extension of the present study to other proteins would give an insight into a possible generality of this conclusion. Further work is in progress on the characterization of lysozyme.

Abstract

Due to the increasing interest in the use of biomasses from agriculture as removing agents for heavy metals in waste effluents, we present here a joint potentiometric and ^{13}C MAS and cross polarization-magic angle spinning NMR (CP-MAS NMR) study on cork interaction with Cu(II) and Ni(II). Through potentiometry we were able to distinguish two kind of interactions, a stronger one which involves protonated sites on cork and a second that allows hydroxide precipitation of the bound metal ion into the cork structure. NMR signal analysis suggests a specific metal complexation on the carbohydrate moieties of polymeric cork matrix. The ^{13}C MAS NMR suggests that the dynamics in the MHz range and the overall arrangement of polymeric matrix is not affected by metal binding; and the spin relaxation times $T_{1\rho}(^{1}H)$ and $T_{1\rho}(^{13}C)$ show that no significant difference of relaxation processes in the KHz range is introduced by metal coordination. © 2002 Published by Elsevier Science Ltd.

1. Introduction

Considering the harmful effects of heavy metals, it is necessary to almost totally remove them from waste effluents. When contaminants are in low concentrations chemical precipitation, reverse osmosis and other methods can become inefficient. In these conditions, adsorption is one of the best options. Heavy metal adsorption from wastewater is generally achieved with polymer resins, activated carbon, activated alumina, which are expensive and non-regenerable. In the last decade many studies have been carried out to evaluate the metal removal potential of different kinds of biomass. Increasing attention has been devoted to the use of biomass generated from the waste by-products of agriculture or industry, such as sun-flowers stalks [1], apple wastes [2], pine, yohimbe and cork barks [3,4]. In one of our recent studies, cork wastes generated from wine cork manufacture were found to be efficient in the removal of Ni(II) and Cu(II) from aqueous solutions [4]. In this study, the influence of pH, NaCl and metal concentration on metal uptake was investigated, and maximum adsorption for both metals was found at around pH 6–7; an increase of NaCl concentration caused a decrease of metal removal. Absorption isotherms were expressed by the non-competitive Langmuir model. The metal binding mechanism responsible for metal uptake is, however, unknown: mechanisms like complexation, coordination, chelation, ion exchange, physical adsorption, inorganic microprecipitation or a combination of any of them might be involved [5].

The cork bark of *Quercus suber* L. is widely used for stoppers; floor and wall insulation from noise and temperature; decoration, etc. The main polymeric components of cork are suberin (40%), lignin (22%) and polysaccharides (cellulose and hemicellulose 20%). The remainder comprises waxes, tannins and other extractable compounds [6]. Cork has been extensively studied by solid state ^{13}C NMR spectroscopy, and information

was obtained on the polymeric structure and dynamics of the main components of untreated cork [7–10], but to our knowledge no studies have yet been performed on metal cork interactions. The aim of this work is the investigation of the role of chemical groups in the different cork components in Ni(II) and Cu(II) uptake. This study has been carried out characterizing the cork bark before and after metal uptake. The Ni(II) and Cu(II) affinities toward cork polymeric matrix were investigated by potentiometric titrations, while the structure and local dynamics of the cork samples in the absence and in the presence of these paramagnetic metal ions were studied by means of solid state ^{13}C MAS and cross polarization-magic angle spinning NMR (CP-MAS NMR).

2. Experimental

2.1. Reagents

Cork wastes were kindly supplied by the company Oller Germans, Cassà de la Selva (Catalunya). Cork was ground and sifted to the desired particle size (20–40 and >20 mesh) and used without further treatment. $NiCl_2 \cdot 6H_2O$, $CuCl_2$, KCl, NaOH and HCl volumetric standard 0.1 N solutions and ICP standards for Cu and Ni 1000 mg l^{-1} were Aldrich products. Metal ion solutions were prepared by dissolving proper amounts of chlorides in bidistilled water.

2.2. Cork metal uptake

In order to study by potentiometry and NMR the behavior of cork containing metal we prepared the samples at different metal concentrations in the following way: 0.5 g of cork was put into 50 ml of variable metal concentration solutions and shaken with a magnetic stirrer for 24 h. Metal concentrations lay in the range 0.03–1.0 M for potentiometry and 0.24 and 1.0 M for NMR measurements. Then, the samples were vacuum filtered through a Gooch number 1, and abundantly rinsed with bi-distilled water to remove the not bound metal ions. These experiments were performed with cork of two different particle sizes, 20–40 and >20 mesh. The second size was chosen for the following experiments since it gave more reliable results.

2.3. Potentiometric titrations

Untreated and metal treated 0.125 g cork samples were suspended in 20 ml of a solution 0.1 M KCl and titrated both with 0.1 M NaOH and with 0.1 M HCl, added stepwise each 30 s (100 points). This time delay allows reproducible titration curves (without any differences from those, for example, with 120 s of time delay). Titrations were performed on a DOSIMAT 655 Metrohm automatic titrator connected to a Metrohm 654 pH-meter, in a glass cell thermostated at 25 °C, equipped with a magnetic stirring system, a Metrohm glass electrode for highly alkaline solutions, and a microburet delivery tube. The electrode was calibrated daily for hydrogen ion concentration by titrating standard HCl with carbonate free 0.1 M NaOH; the resulting potentiometric data were analyzed with Gran procedure [11] using our GRANPLOT program. The results of potentiometric titrations were processed with the PSEQUAD program[12] operating on the experimental data (titrant volume, $\log[H^+]$). These data were processed simplifying the system as a single phase one.

2.4. ICP-AES measurements

The ICP measurements were made on a Liberty 200 ICP Varian spectrometer set up with Argon plasma flow at 15 l min^{-1}; with auxiliary gas flow 1.5 l min^{-1}; at a power 1.0 kW. The sample was aspired at a flow of 1.0 ml min^{-1} through a nebulizer of the V-grove type. Atomic emissions were determined at 324.7 for Cu and 231.6 for Ni. No spectral interferences were observed. Fresh working calibration solutions were prepared by properly diluting the commercial standards with double distilled water. Calibrations, within the expected ranges for each element, were obtained with nine equally spaced concentrations.

2.5. NMR studies

Solid-State ^{13}C NMR spectra were obtained on a Varian 400 Unity Inova spectrometer operating at 100.57 MHz, equipped with 7 mm CPMAS probeheads by a cross-polarization tecnique (CP) with magic-angle spinning (MAS). A matched Hartmann–Hann condition was established by using radio-frequency field of 38 KHz for ^1H and 152 KHz for ^{13}C. The rotor was spun at spinning rate (frequency) of 4 KHz and, working at room temperature (r.t.), a contact time of 1000 μs was applied to obtain polarization transfer. An acquisition time of 0.010 s and the 90° pulse of 6.6 ms were used. Chemical shifts of CP-MAS spectra were originally obtained with respect to the methylene carbon resonance of solid adamantine, 38.3 ppm with respect to Me_4Si, measured before each measurement. Proton spin-lattice relaxation times in the rotating frame, $T_{1\rho}H$, were determined in a CP-MAS experiment from the decay of the carbon signal as a function of d3, the time before cross polarization. The $T_{1\rho}H$ values were calculated from exponential fits (proton signal height) versus time d3. Carbon rotating-frame relaxation time, $T_{1\rho}C$, were measured by recording the ^{13}C signal as a function of carbon spin-lock time following cross polarization. Value of $T_{1\rho}C$ were determined from

exponential fits (carbon signal height) versus spin-lock time. For these studies cork samples previously contacted with 0.24 and 1.0 M metal (nickel and copper) solutions were used.

3. Results and discussion

In a previous work [4], the Langmuir isotherm model provided a maximum uptake of 2.64 $mg \cdot g^{-1}$ for Cu(II) and 4.09 $mg \cdot g^{-1}$ for Ni(II) at pH 6. Further metal desorption from biomaterials was observed using HCl as eluent, up to 90% for Cu(II) and 10% for Ni(II). To better quantify these last results, in the present work we have examined more thoroughly the behavior of pure cork before and after metal absorption when subjected to acid and basic treatments. Therefore, different cork samples, according to Section 2.2, suspended in 20 ml of 0.1 M KCl, were titrated both with 0.1 M HCl and 0.1 M NaOH. The titration plots for nickel and copper treated samples are presented in Figs. 1 and 2 for acid and basic titrations, respectively. These titrations allow interesting conclusions to be made, although some differences are found among similar samples in repeated experiments, to be ascribed both to non-homogeneous cork and to different contacts between solution and stirred sample.

As can be seen from the acid titration curves in Fig. 1, the pure cork curve lies above that of KCl. This implies that suspended cork binds H^+ on some basic groups, according to the reaction Cork $+ H^+ \rightleftharpoons H^+$ Cork. The dashed curve can be reproduced by assuming a concentration of basic groups equal to 0.1 mmoles l^{-1}, which corresponds to $\sim 1.6 \cdot 10^{-5}$ moles of basic groups per gram of cork. The curves of metal treated cork start at acidic pH 4.5–5 and then overlap the reference KCl solution curve.

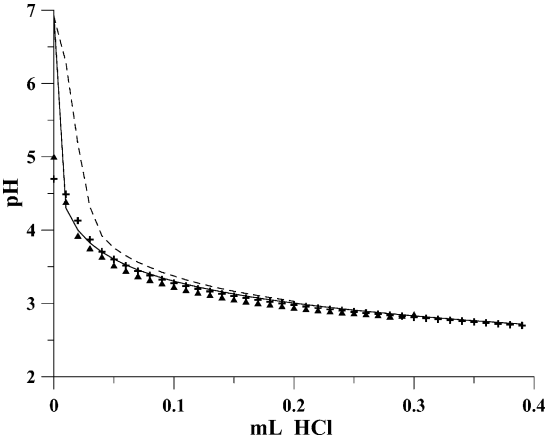

Fig. 1. Titration curves with 0.1 M HCl of 20 ml of 0.1 M KCl in which 0.125 g of cork samples were suspended: untreated (dashed line), treated with (■) Cu(II) and (▲) Ni(II) and titration curve of 0.1 M KCl alone (full line).

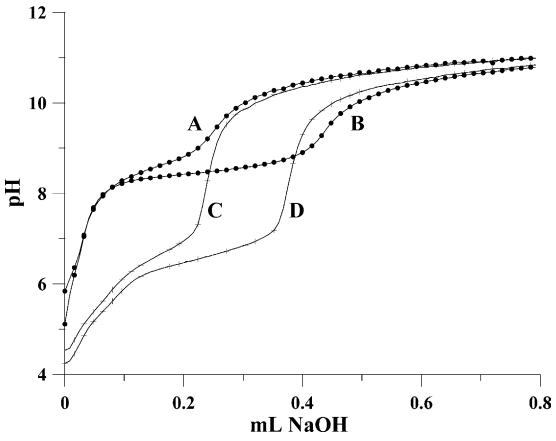

Fig. 2. Titration curves with NaOH 0.1 M of 20 ml of 0.1 M KCl in which were suspended 0.125 g of cork, (A) treated with Ni(II) 0.24 M; (B) with Ni(II) 1.0 M; (C) with Cu(II) 0.24 M; and (D) with Cu (II) 1.0 M.

The starting acidity and the curve shapes imply that cork binds the metal ions via some acidic groups, therefore, releasing H^+ ions which are bonded by free basic sites on cork. The titration protons, which compete for the same binding sites, release the metal ions coordinated by cork, as quantified by ICP-AES analysis. These measurements showed that all coordinated metal ions are totally released, contrary to that observed for nickel in our previous study[4]. This can be attributed to the used ionic strength KCl 0.1 M, i.e. to K^+ competition with copper and nickel for the same binding sites. The data shown in Fig. 2 for the basic titration show that (a) curves A and B for nickel are characterized by a first part (0.09 ml of added base) whose width does not depend on the previous cork treatment, and by a second part, attributed to the formation of nickel hydroxide at pH $\sim$ 8.5, whose width instead depends on nickel concentration; (b) a similar trend is observed for curves C and D relative to copper(II), taking into account copper(II) hydroxide formation at pH $\sim$ 6.6; (c) it must be pointed out that the titration curve of untreated cork did not show easily titrable acidic groups (less than pK 9).

These plots were fitted, using the PSEQUAD program [11] for the calculation of solution equilibria, by assuming the models and the concentration reported in Table 1.

These models can be interpreted assuming that during the preliminary treatment the metal ions are coordinated by cork via some acidic groups which, due to metal coordination, lose their protons that transfer to less basic sites. Therefore, the first part of the curve can be considered proportional to the maximum concentration of tightly bound metal. In the second part we observe, on the other hand, the precipitation of metal hydroxides, at the same pH values as solutions of the same ionic strength. The hydroxide formation involves less

Table 1
Models and concentrations assumed for fitting the curves in Fig. 2 with PSEQUAD program

	Curve	Cork acidic sites	Metal hydroxide	Model	Log β
Ni	A	2.5×10^{-4}	4.8×10^{-4}	HCork(site3)	6.9
	B	2.7×10^{-4}	9.2×10^{-4}	$Ni(OH)_2$	−17.1
Cu	C	$(3.0+3.0) \times 10^{-4}$	2.8×10^{-4}	Hcork(site1), Hcork(site2)	4.8, 5.8
	D	$(3.0+3.0) \times 10^{-4}$	6.4×10^{-4}	$Cu(OH)_2$	−13.3

In the third and fourth columns cork titrable protons (different sites with proper pK values) and metal titrable as hydroxydes are reported, respectively.

tightly bound metal ions, whose amount depends on Cu(II) or Ni(II) concentrations in the preparative procedure. It should be noted that hydroxide formation takes place inside the cork framework, since no turbidity appears in the titration vessel. This second kind of interaction is also favored for Ni(II) with respect to Cu(II).

As far as NMR measures are concerned, Fig. 3(a) shows the ^{13}C CP-MAS NMR spectrum of a cork sample. The attribution of the observed peaks, collected in Table 2, corresponds to that found in previous works [8,13,14]. The intense signals at 30 and 33 ppm originate from suberin chain methylens; the peak $a(3.0+3.0)t$ 56 ppm corresponds to O–CH_3 groups from suberin, lignin or hemicellulose. The signals in the range 62–105 ppm are due to the carbohydrate and to the aliphatic carbons of suberin and/or lignin, while the unsaturated and aromatic ring carbon signals appear in the 105–148 ppm range. Finally, the peak at 173 ppm is attributed to the ester groups of suberin and hemicellulose or to carboxyls in aromatic structures of suberin and/or lignin and in uronic acids.

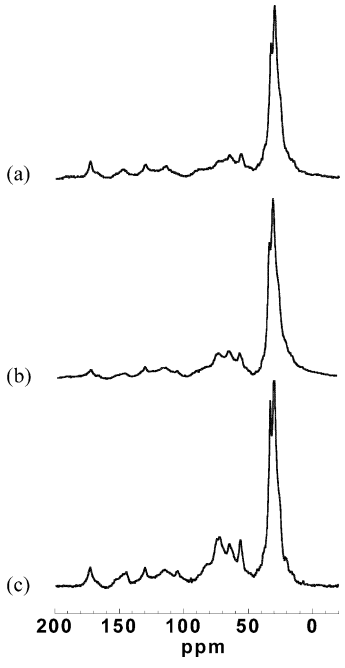

Fig. 3. ^{13}C CP-MAS NMR spectra of untreated (a), and treated cork with aqueous solutions of Ni(II) 0.24 M (b) and 1.0 M (c).

Adding aqueous Ni(II) or Cu(II) to cork particles resulted in beyond detection broadenings of a part of the signals at 72 and 105 ppm suggesting that a specific complexation occurs between each of these paramagnetic metal ions and, especially the carbon-hydrated moieties of the polymeric matrix, which originates an electron dipole-nuclear dipole relaxation. In Fig. 3(b and c), such broadening is shown as an example for the Nickel-cork sample. It can be clearly seen that when contacting cork with increasing concentrations of Ni(II) the peaks at 72 ppm and 105 ppm progressively disappear, while the remaining resonances do not show any appreciable effect.

To investigate possible changes in the structure and/or dynamics of those polymeric domains not involved in the binding with the paramagnetic metal ions, ^{13}C MAS NMR spectra of a cork sample in the absence and in the presence of nickel were performed as a function of the recycle delay between spectral acquisitions. As shown in Fig. 4(a) (I–IV), shortening the recycle delay from 50 to 0.1 s causes a progressively large decrease of signal intensities of carbon atoms with the longest relaxation times in the MHz range, especially the signals at 173 and 80 ppm.

A comparison between the ^{13}C MAS NMR spectra of Fig. 4(a) (I–IV) and Fig. 2(b) (I–IV) indicates that very similar behaviour occurs in the Ni(II) treated cork sample, suggesting that the dynamics in the MHz range and possibly the overall arrangement of the polymeric matrix is not affected by the metal binding.

Additional information on the dynamics of the polymeric domains in these samples was obtained from the spin relaxation times $T_{1\rho}(^1H)$ and $T_{1\rho}(^{13}C)$, which are sensitive to the motions in the KHz range. More specifically, the former is affected by ^1H spin diffusion and, therefore, depends on the neighbouring spin reservoirs, while the latter gives information on the site- and arrangement-specific motions. The average $T_{1\rho}$'s are collected in Table 2. Comparing the data for the untreated and treated cork it can be seen that, within experimental error, no important differences exist in the efficiency of the relaxation processes in the KHz range for the polymeric domains of the two samples.

Table 2
$T_{1\rho}(^{13}C)$ and $T_{1\rho}(^{1}H)$ of cork untreated and treated with an aqueous solution of 1 M Ni(II)

The determination of mineral acidity excess in solutions containing Ga(III), Al(III), Bi(III)

Diana Amorello, Vincenzo Gambino, Vincenzo Romano *, Roberto Zingales

Abstract

A new procedure is proposed to carry out volumetric determinations of the strong acid content of a solution in the presence of inorganic cations such as Ga^{3+}, Al^{3+}, Bi^{3+} which, showing in aqueous solution an acidic behaviour, introduce non negligible interferences in these determinations. Before the acid–base titration, an equivalent amount of a ligand, such as dihydrogen ethylendiamino tetraacetate is added, in order to strongly complex the cation masking it toward the successive addition of a strong base. Interferences are thus removed, and the volumetric determination of the strong acid excess plus the hydrogen ions set free from the ligand, as a consequence of the complex forming reaction, can be accurately carried out, in the presence of a colorimetric indicator. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Solutions; Equilibria; Cations; Hydrolysis; Titration; Masking

1. Introduction

It is well known that the sharpness index at the equivalence point in the titration of a strong acid with a strong base is lowered by the presence of a weak acid. This lowering will be the greater, the greater the strength of the weak acid, and the greater the ratio of its concentration to that of the strong acid [1].

The same problem arises, of course, when dealing with a mixture of a strong acid and a salt whose cation shows acidic properties such as, for instance, Fe^{3+}, Al^{3+}, Ga^{3+}.

Aqueous solutions of these cations must often be prepared by adding an excess of a strong acid to avoid the formation of slightly soluble hydrolysis products [2]. Moreover, their salts are commonly hygroscopic and the small quantities of retained water can give rise to the formation of hydrolysis products long before their dissolution.

When investigating complex or hydrolysis equilibria involving these cations, the analytical composition of both the metal and the hydrogen ions content of the stock solutions must be accurately known, both for the metal and the hydrogen ions content. This could be accomplished by mixing known amounts of the solution components in a high degree of purity. Concerning the commercially available salts of the hydrolizable cations, these often contain small quantities of the mineral acid excess used in the process of their preparation and crystallisation. So, the composition derived from the amount of the mixed chemicals to give the stock solution may result erratic, and accurate analytical procedure become obliged.

Usually, the analysis of the cation does not give great difficulties, but its behaviour as a weak acid can make the determination of the strong acid excess troublesome, just for the reasons above discussed.

This problem must not be under-evaluated, because for example in the study of the hydrolysis equilibria, even a slight error in the strong acid analytical excess content of the stock solution can generate a wrong assumption for the hydrolysis model. For instance, this systematic error, which is different at the different metal ion concentrations, can suggest a polynuclear hydrolysis model even if only mononuclear species are present.

We met this problem in the study of gallium(III) hydrolysis, when analysing the stock solution of $Ga(ClO_4)_3$ containing some $HClO_4$ excess. To avoid

the occurrence of these troubles, we thought to change the free Ga^{3+} ion in a stable complex ion, so that the titration of the perchloric acid excess could be carried out as the titration of the strong acid alone. The ligand chosen was the EDTA ion (Y^{4-}) which was introduced into the solution in the usual form of $Na_2H_2Y\cdot H_2O$.

2. The method

In order to test the method we had to prepare an aqueous solution of defined Ga(III) content, moreover containing a known amount of H^+.

As already discussed, this can be done by mixing chemicals of high purity: under this respect, gallium(III) chloride appears to be the best choice, as it can be prepared by direct reaction of metallic gallium with gaseous hydrochloric acid [3]; gaseous acid is preferred to its aqueous solutions, as its excess can be easily completely removed from the reaction mixture, leaving an anhydrous product, free from any contaminant.

An accurately weighed amount of metallic gallium was put into a multi-necked vessel kept at 190 °C in which gaseous dry HCl was driven to quantitatively convert the metal into its chloride. To avoid losses of the quite volatile solid $GaCl_3$, the vessel was kept under water reflux. Once the reaction was completed, the residual gaseous HCl was removed from the reaction vessel by passing a stream of dry, purified nitrogen. Then, after cooling, a defined amount of a standard HCl solution was introduced into the vessel through the reflux by means of a weight burette. The chloride was completely dissolved and the so obtained solution quantitatively transferred to a volumetric flask and diluted to the mark.

The Gallium content (C_M) of this solution was checked by titration with standard EDTA according to [4] (see Section 4). The agreement was quite good, differences being less than 0.1%. The hydrochloric acid excess content (C_H) of this solution was determined by means of the potentiometric and volumetric acid–base titrations, which form our proposed method.

To a measured amount of the solution, standard EDTA of concentration C_L was added, in order to have a ratio $C_L/C_M = 1$. In this way, gallium(III) ions were stoichiometrically converted into the stable Gallium–EDTA complex [5], setting free two hydrogen ions for each gallium ion, according to reaction (1):

$$Ga^{3+} + H_2Y^{2-} = GaY^- + 2H^+ \quad (1)$$

So the hydrolysable species was masked, and only a strong acid, whose total concentration was equal to $C_H + 2C_M$, was left in solution. The stepwise addition of a strong base solution should now give rise to a strong acid–strong base titration curve.

The vessel containing the solution was equipped with a glass (GE) and a saturated calomel electrode (SCE), and the potentiometric titration carried out by stepwise additions of a standard NaOH solution C_b molar. The e.m.f. of cell (G)

G.E.|Solution|S.C.E (G)

was read after each addition, waiting long enough (5 min) to have steady e.m.f. values.

An example of the so obtained titration curves is reported in Fig. 1. It can be seen that the curve exhibits two sharp jumps, one for $C_b = 2C_M + C_H$ and another one, larger, for $C_b = 3C_M + C_H$.

If the potentiometric titration is carried out including thymol blue or phenolphthalein indicators, a sharp change of colour can be observed at the second jump. No indicator seems to be useful for detecting the first jump observed in the potentiometric titration curve.

3. Results and discussion

According to our hypothesis on the occurrence of reaction (1), the first jump in the mentioned curve can be explained as corresponding to the titration of the hydrogen ions due to the mineral acid excess (C_H), plus those made free in reaction (1) which are equal to $2C_M$. The second pH jump in the titration curve can be ascribed to the completion of a second acid–base titration. As the moles of added base, going from the first to the second inflection point, are exactly equal to the moles of Gallium ion, we can ascribe it to a reaction involving the gallium–EDTA complex, such, for instance:

$$[GaY]^- + OH^- = [GaYOH]^{2-} \quad (2)$$

We do not have elements to decide if reaction (2) is an OH^- addition to $[GaY]^-$ or a proton extraction from a water molecule bound to $[GaY]^-$ [6].

We want to emphasise that the differences of the NaOH volumes used between the second and the first jump gives $C_b = C_M$ and is a further check of the Gallium content analysis.

In Table 1 some results of different titrations with colorimetric or potentiometric detection of the end point are summarised. It can easily be seen that the match between the expected and the measured value is quite good (differences not higher than 0.1–0.2%) for Ga(III) solutions.

Once we succeeded in checking the validity of the proposed analytical method, we turned to the original problem of preparing a stock solution of $Ga(ClO_4)_3$ containing an excess of perchloric acid. As the previously reported methods suffer the inconvenience of giving solid $Ga(ClO_4)_3$ contaminated by small amounts of chloride ions and perchloric acid [7], we tried a

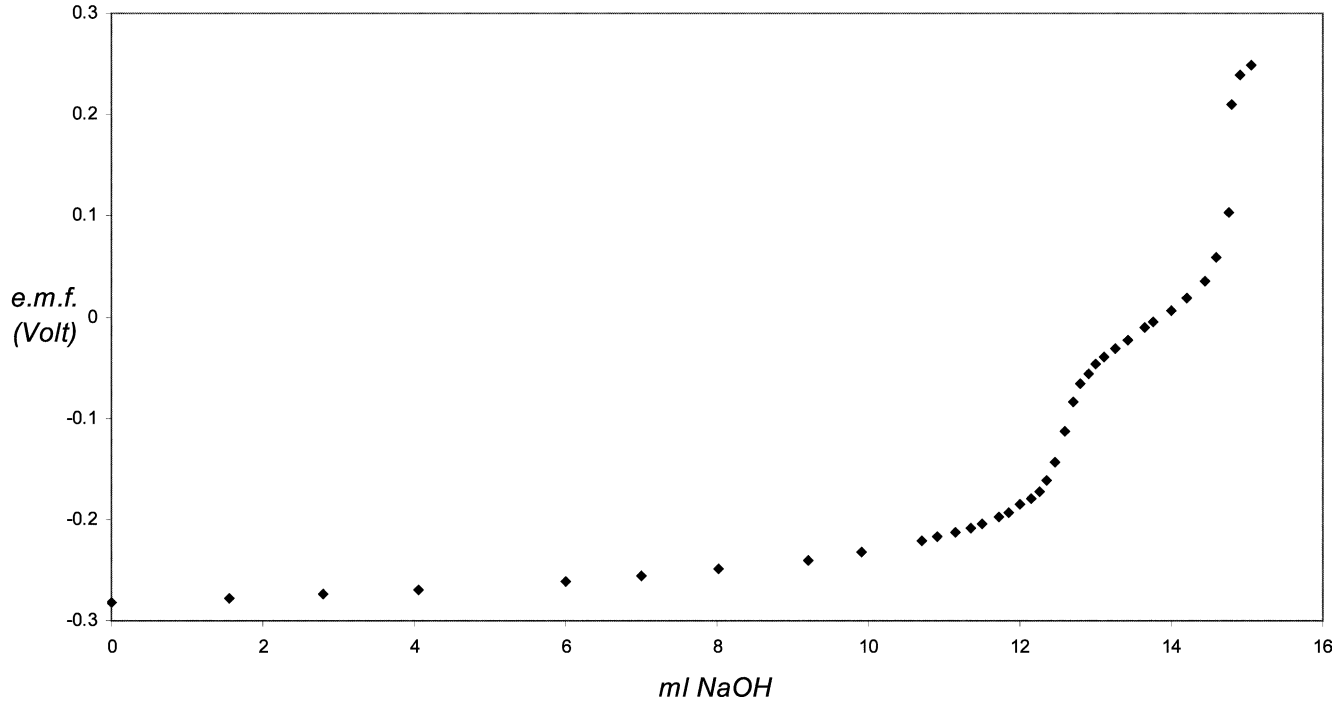

Fig. 1. Potentiometric curve for the titration of hydrochloric acid with standard sodium hydroxide, in the presence of a known amount of gallium(III) ions masked by means of EDTA.

different approach. A weighed amount of metallic Gallium was dissolved in a slight excess of a hot redistilled HBr solution. A platinum wire was dipped into the liquid gallium pool to speed up its dissolution. When this was completed, the obtained gallium(III) bromide complex, probably $[GaBr_4]^-$, was then converted into gallium(III) perchlorate, by treating it with a measured slight excess of a $HClO_4$ solution. Bubbling gaseous ozone into the solution, kept at about 90 °C, bromide ions were oxidised to bromine. The bromine excess was then driven off by a nitrogen stream. This long procedure led to unavoidable slight losses of the solution components and finally gave a stock $Ga(ClO_4)_3$ solution containing a slight excess of $HClO_4$. In it, C_M and C_H could be determined, using the above described method.

Finally, we decided to check if the method could be applied to other cations, especially the trivalent ones, which show similar acidic properties. To an acidic solution of Al(III) ions, the equivalent amount of a Na_2H_2Y solution was added, warming it near to boiling for about 2 min, and then cooling to room temperature. The solution was then titrated in the presence of phenolphtalein, giving good agreement between expected and measured values (see Table 1).

A slight different behaviour is shown by the Bi(III) solutions, for which the titration curve shows only one jump giving evidence that the reaction with NaOH and

Table 1
C_H values in metal salt solutions obtained by volumetric titrations with colorimetric detection of the end point

Cation	Weight of analysed solution (g)	C_H found (in mol kg^{-1} of solution)	Expected value
Ga^{3+}	0.6299	0.493	
	0.5622	0.495	
	0.5917	0.492	
Average		0.493 ± 0.001	0.493 ± 0.001
Al^{3+}	2.0147	0.615	
	2.1412	0.617	
	1.6822	0.615	
Average		0.616 ± 0.001	0.612 ± 0.001
Bi^{3+}	1.4368	0.757	
	1.5401	0.760	
	1.9922	0.759	
Average		0.759 ± 0.002	0.758 ± 0.001

H_2Y^{2-} proceeds only to the formation of BiY^- so that the acid excess is given by $C_H = C_b - 2C_M$. No evidence could be detected of any further reaction with OH^- ions.

The data reported quite clearly indicate that the proposed masking method can give accurate values in the determination of the acid excess content of gallium, aluminium and bismuth salt solutions either by potentiometric or volumetric titrations in the presence of colour indicators. Due to its simplicity, we are confident that the method will give accurate results also in the presence of any strong mineral acids such as sulphuric, nitric, hydrobromic.

This fact is important and probably extendible to other ions whose perchlorates are usually obtained in the presence of an unknown slight acid excess, added to suppress the hydrolysis of the metal ions. In fact it exists a great variety of chelating ligands which can mask completely most ions already before the equivalence point, so making it possible the acid excess determination.

An accurate knowledge of the title of this acid excess is important to get accurate data when studying for example, complex formation or ion hydrolysis equilibria. As we will show in a coming paper, the usual method of carrying out the titration of a metal ion and hydrogen ion mixture with a strong base, detecting the end point with a Gran plot [8] gives systematically higher titles, which can result in a wrong hydrolysis model, wrong equilibrium constants and chemical artefacts.

4. Experimental

All the solutions were prepared using water twice distilled from an alkaline solution of potassium permanganate.

Their composition, if not specified, has been determined using standard methods of analysis [4,9].

4.1. Gallium(III) chloride solution

This solution has been prepared as above detailed; although these procedures allowed us to know the correct composition of the solution from the steps of its preparations, anyway a check was carried out.

Gallium (III) content was determined by EDTA titration, following two different procedures: the first consisted in the addition of a measured excess of a standard EDTA solution, buffering the mixture at pH 9 and then back titrating with a standard zinc sulphate solution, in the presence of Black Eriochrome T as indicator, following the details reported in [10]. In the second procedure, the gallium solution was buffered at pH 3.5, boiled and then titrated with standard EDTA in the presence of PAN as indicator [11]. Both methods gave results agreeing with the expected value, into the experimental uncertainties.

The chloride content was determined argentimetrically, according to [12]. In this case too the found chloride concentration agreed with the expected one. Moreover, as a further check, the H^+ ion excess could be estimated according to

$$C_H = C_{Cl} - 3C_M \quad (3)$$

which gave C_H values in excellent agreement with those obtained with the here proposed method and with the expected ones, reported in Table 1.

4.2. Aluminium(III) solution in perchloric acid

A weighed amount of potassium aluminium sulphate, $KAl(SO_4)_2$, was dissolved in a weighed amount of water containing a known amount of perchloric acid. Its aluminium content was determined by adding a measured excess of a standard EDTA solution, boiling for a couple of minutes, cooling to room temperature and back titrating the excess with a standard zinc sulphate solution, in the presence of Black Eriochrome T as indicator, following the details reported in [13].

4.3. Bismuth(III) solution in perchloric acid

A weighed amount of $Bi(NO_3)_3 \cdot 5H_2O$ was dissolved in a weighed amount of water containing a known amount of perchloric acid. Its bismuth content has been determined adding a measured excess of a standard EDTA solution which was then back titrated with standard zinc sulphate, as above.

4.4. Sodium hydroxide solutions

Their title was determined by titration with a standard perchloric acid solution, standardised, at its time, against potassium hydrogen carbonate. A weighed amount of this solid was dissolved in water and treated with the solution to be standardised; the mixture was boiled just before the equivalence point to drive off the formed carbon dioxide. A mixed indicator was used, consisting of three volumes of methyl red and one volume of bromocresol green; it turned from green to red at pH near 7.

4.5. EDTA solutions

In the proper volume of water, it was dissolved a weighed amount of the disodium salt, which had been stored overnight in an oven at 80 °C. Its content was checked by titration with standard zinc sulphate [13].

4.6. Potentiometric titrations

Cell (G) was used, containing one Ingold GE and one Ingold reference SCE, connected to a Keithley model 624 high impedance electrometer, giving e.m.f. values on a digital display.

Evaluation of chemical equilibria with the use of artificial neural networks

Josef Havel *, Přemek Lubal, Marta Farková

Department of Analytical Chemistry, Faculty of Science, Masaryk University, Kotlářská 2, 611 37 Brno, Czech Republic

Received 6 June 2001; accepted 22 October 2001

Abstract

Multivariate calibration with experimental design (ED) and artificial neural networks (ANN) modeling can be used to estimate equilibria constants from any kind of protonation or metal–ligand equilibrium data like potentiometry, polarography, spectrophotometry, extraction, etc. The method was tested on evenly or randomly distributed experimental error-free data and data with random noise and the results show that even rather higher experimental errors do not influence significantly the prediction power and correctness of ANN prediction. ANN with appropriate ED can provide accurate prediction of stability constants with the relative errors in the range of $\pm 4\%$ or smaller while the approach is very robust. Comparison with a hard model evaluation based on non-linear regression techniques shows excellent agreement. Proposed ANN method is of a general nature and, in principal, can be adopted to any analytical technique used in equilibria studies. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Artificial neural networks; Experimental design; Stability constants; Metal complexes; Ion selective electrodes; Metal–ligand equilibria

1. Introduction

Protonation and/or metal–ligand equilibria play substantial role in analytical, organic and/or other chemistries, especially bio-organic or bio-inorganic and theirs knowledge is substantial to understand chemical processes.

During the second half of the last century great effort was devoted to the development of computational methods for the determination of protonation or complexation equilibria. From single graphical methods used from the beginning, almost solely computer-aided methods are used now. A good overview of solution equilibria computation can be found elsewhere ([1,2] and references therein).

In spite of the fact that many computer programs has been developed, still the problem of chemical model determination (stability constants, stoichiometry of complexes, etc.) is alive. Mostly potentiometry, spectrophotometry, extraction, NMR, etc. experimental techniques are used, while computation is based on so called 'hard' modeling, solving mass balance equations while stability constants are searched for by a computer-aided 'curve fitting' applying general least-squares method and suitable optimizing technique.

The aim of this work was to study other alternatives for evaluation of equilibrium data. We have turned our attention towards the artificial intelligence methods among which artificial neural networks (ANN) are increasingly applied in chemistry. As for basic review we refer here to a paper by Gasteiger and Zupan [3]. ANN represent so called 'soft' modeling without the need to know or establish a mathematical model. Recently, ANN has successfully been applied in capillary zone electrophoresis [4–6], for modeling in ion chromatography [7] or in electrokinetic micellar chromatography [8] without necessity to know or determine physicochemical parameters.

In chemical equilibria Havel et al. showed recently that another 'soft' modeling method, partial least-squares (PLS) multivariate calibration method, can be used to evaluate equilibrium data in potentiometry [9]. ANN has been successfully applied in differential pulse polarography to evaluate equilibria for fully inert [10] or labile [11] metal complexes. The purpose of this work

PII: S0277-5387(02)00955-5

was to study the possibility of applying ANN for the chemical equilibria computation from a general point of view for any kind of data.

In order to calculate the unknown parameters from a data set, the programs such as LETAGROP, SQUAD, POLET [2,12,13], OPIUM [14] were prepared. In 1950s Sillén created the theory of normalized projection maps [15–19]. A survey is given of graphical methods for the determination of unknown parameters from a data set by fitting normalized curves. By the application of the 'hard' programs is in every iterative cycle solved mass balance (equations system). By normalized projection maps using, once we are getting normalized graphs no more mass balance is necessary to solve. If we have calculated projection maps, it is possible to predict the required parameters immediately. If we train a neural network, we get corresponding weights and biases. We use this trained network for consecutive determinations the parameters. Every determination is ready at once, immediately. We do not solve mass balance equations (only once, when we train the neural network).

2. Theoretical

2.1. Experimental design

Experimental designs (ED) are methods, based on statistics, for making plan of experiments. The use of ED strongly reduces the number of needed experiments. The most important aspect of statistical ED is that they provide a strict mathematical framework for changing all pertinent factors simultaneously, and achieve this in a small number of experimental runs. There are various types of ED [20]. The selection of a specific type of design depends primarily on both the nature and the extent of the information we want to obtain.

2.2. Artificial neural networks

One of the most common is the feedforward neural network of multilayer perceptrons. The training data for this network contain examples (patterns) of inputs together with the corresponding outputs, and the network learns to infer a relationship between the two.

The network consists of artificial neurons sorted in input layer, hidden layer(s) (one or more) and output layer. Input neurons accept the input data characterizing each observation, output neurons provide the predicted value or pattern, and hidden neurons neither receive inputs directly nor provide output values directly. Neurons are connected by weights, which are modified in the course of network operation. Each neuron has an activity level that is determined by an input signal received from the other units in the network.

The use of ANN consists of two steps: 'learning' and 'prediction'. In the 'learning' phase the optimum structure, weight coefficients and biases are searched for. These parameters are found from a training data set. After the 'learning' phase the network can be used to predict (calculate) the outputs from an arbitrary set of inputs. Although the 'learning' phase can be quite lengthy, once trained, the network produces prediction almost instantaneously.

The input neurons activities introduce the inputs to the neural networks. The hidden and output neurons activities are defined by the relations:

$$x_i = t(\xi_i) \tag{1}$$

$$\xi_i = \sum_j w_{ij} x_j + \upsilon_i \tag{2}$$

where υ_i is the bias, w_{ij} is the weight and ξ_i is the sum of the weighted inputs (see Fig. 1).

Function $t(\xi)$ is so called transfer function with these properties:

1) t: $R \rightarrow (0, 1)$ is a continuous and monotonously increasing function;
2) $t(\xi) \rightarrow 0$ for $\xi \rightarrow -\infty$ and $t(\xi) \rightarrow 1$ for $\xi \rightarrow \infty$.

Commonly, the sigmoid function for $t(\xi)$ is used:

$$t(\xi) = \frac{1}{1 + e^{-\xi}} \tag{3}$$

The aim of the neural network training is by the changes of weights and biases to minimize the error E:

$$E = \sum_{i=1}^{r} E^{(i)} = \frac{1}{2} \sum_{i=1}^{r} (\underline{x}_0^{(i)} - \underline{\hat{x}}_0^{(i)})^2 \tag{4}$$

where r is the number of input–output vector pairs in the training set, $\underline{\hat{x}}_0^{(i)}$ is required output vector and $\underline{x}_0^{(i)}$ is the neural network response to the adequate input vector.

The error E can be minimized for example using gradient methods. Most often the steepest descent method is used. The weights and the biases are changed by the relations:

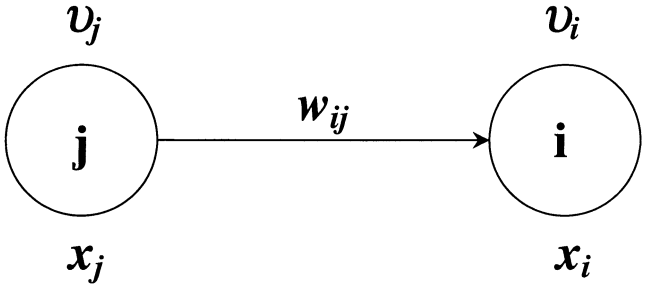

Fig. 1. Two neurons from the neighboring layers of the feedforward multilayer neural network, their activities, biases and the weight between them.

$$w_{ij}^{(k+1)} = w_{ij}^{(k)} - \mu\frac{\partial E}{\partial w_{ij}} + \mu\Delta w_{ij}^{(k)} \quad (5)$$

$$\vartheta_j^{(k+1)} = \vartheta_j^{(k)} - \lambda\frac{\partial E}{\partial \vartheta_j} + \mu\Delta\vartheta_j^{(k)} \quad (6)$$

$$\Delta v_j^{(k)} = v_j^{(k)} - v_j^{(k-1)} \quad (7)$$

$$\Delta w_{ij}^{(k)} = w_{ij}^{(k)} - w_{ij}^{(k-1)} \quad (8)$$

where k is the iteration number, λ the learning rate, $\mu\Delta w_{ij}^{(k)}$ and $\mu\Delta v_j^{(k)}$ are the momentum members. The minimization process is done until no improvement of root mean square (RMS) is observed.

RMS error is used to follow minimizing process. To obtain this value the individual errors are squared, added together, divided by the number of individual errors, and then square rooted. RMS gives a single number which summarizes the overall error (equals to squared sum of residuals divided by $N \times M$ and squared root of):

$$\mathrm{RMS} = \sqrt{\frac{\sum_{i=1}^{N}\sum_{j=1}^{M}(t_{ij} - y_{ij})^2}{N \times M}} \quad (9)$$

where t_{ij} are elements of the matrix for the training or the test set, y_{ij} are elements of the output matrix of the neural network, N is the number of patterns and M is the number of outputs for the training or the test set.

A standard technique is to train the network using one data set (training set). For a check that the network is able to perform well on previously-unseen data is necessary to have also a verification set not used in training. As training progresses, the RMS value for the training set drops, and providing training is minimizing the true error function, the RMS value for the verification set drops too. If the RMS value for the verification set stops to decrease, or starts to rise, this indicates that the network is starting to overfit the data. It is necessary to stop training in this case.

2.3. Computer data treatment

The data were processed on a Pentium PC computer using ANN TRAJAN 3.0 software package [21]. POLET [2,12,13], LETAGROP, SQUAD and OPIUM [14] programs were used for the simulation of experimental data needed for training ANN or for the treatment of experimental data.

3. Results and discussion

3.1. Case (1) potentiometry–dissociation of a weak acid in two steps with two near pK values

In this case, we have studied the possibility to use ANN modeling for normalized potentiometric data.

Let us consider an acid which splits off consecutively two protons:

$$H_2L \rightleftarrows H^+ + L^-H^- \quad K_{a1}$$

$$H_2L \rightleftarrows 2H^+ + L^{2-} \quad K_{a1} \times K_{a2}$$

We can define Z as a function of pH:

$$Z = \frac{c_H - 10^{-pH} + 10^{pH-pK_w}}{c_L}$$

where c_H is analytical concentration of protons, c_L the analytical concentration of acid present in solution and pK_w is the negative decadic logarithm of ionic product of water.

A pattern is a curve consisting of a number of data, each one being a Z value calculated at pH value for adequate pK_1 and pK_2 values. Number of pH values selected in pH range 1–6 was 21.

The pK_1 and pK_2 values are selected according to the ED used. In this way the error-free training set containing 13 patterns was generated. The training set is shown in the Fig. 2. Then four patterns as a test set were randomly generated.

The Z values were used as input for the ANN, the pK_1 and pK_2 values were used as output. The ANN architecture was searched for automatically by the TRAJAN program computation and then used further for the training process and the prediction, as well. This architecture (21:6:2) is shown in Fig. 3. We have also tried 'manual' search of the best architecture with the same result as using Trajan Automatic Network Designer. As training algorithm we have usually used Back Propagation (BP). Other training algorithms were tried too (Conjugate Gradients, Levenberg-Marquardt, and Quick Propagation) but the same results were obtained. Therefore, BP was used throughout the paper. In this

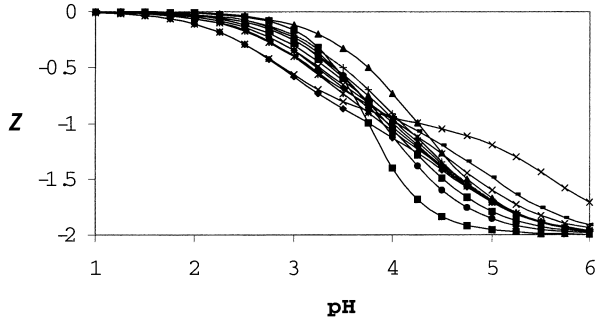

Fig. 2. Normalized Z-pH data concerning Case (1) of two overlapping protonation equilibria.

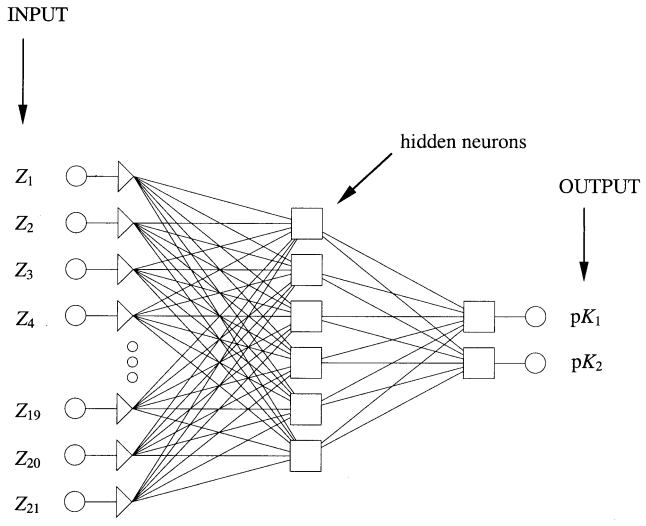

Fig. 3. Optimal ANN architecture (21:6:2) applicable for modeling Z-pH data and estimation of near pK_a values in Case (1).

case, number of epochs needed was 1200. For this value no overtraining was observed (Fig. 4). Table 1 shows the corresponding weight matrix. The RMS value obtained for the training set was 0.0352, the value for the test set was 0.0359. The predicted and correct pK_1 and pK_2 values for the test set are given in Table 2.

In the next stage, the simulated patterns with random noise were generated. Using a random number generator, error values were obtained (normal distribution with S.D. 0.001 and 0.01, respectively) and then were added to the error-free data in the patterns of the test set. The ANN structure with weights obtained on the error-free data was used to evaluate the ANN resistance to the noise. The results obtained for the test sets are seen in Table 2. The RMS values (0.03184 and 0.0306, respectively) are near to the value for error-free test set and the results obtained can be regarded as highly satisfactory. In addition, as it can be seen, the agreement was also achieved with the results obtained by OPIUM program [14] (Table 2).

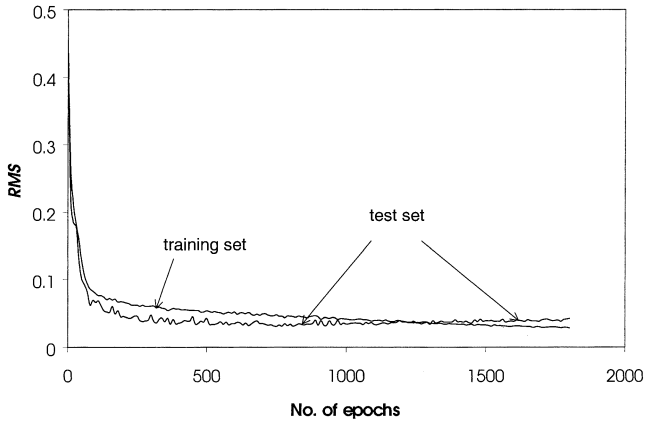

Fig. 4. Demonstration of the convergency of BP algorithm for optimal ANN architecture.

3.2. Case (2) determination of equivalence point and simultaneous glass-electrode calibration in potentiometry

3.2.1. Stage (A)

As the example, titration of acetic acid (p$K_a = 4.56$, p$K_w = 13.78$, $I = 0.1$ M) of initial concentration c_{HA} ($V_0 = 5$ ml, $T = 298.15$ K) with 0.1 M sodium hydroxide using a glass electrode was chosen. The task was to determine c_{HA}, electrode potential E_0 and electrode slope g from real titration curve in one step.

The input vector contains the electrode potential values measured for equidistant additions of sodium hydroxide solution in the range from 0 to 1.3 ml (totally 66 values).

The three-level factorial design for three parameters in combination with a star design for three parameters were used and for each combination of c_{HA}, E_0 and g values 32 titration curves were calculated by OPIUM software package [14] for a simulated titration generating always 66 values of emf for 66 additions of sodium hydroxide solution. Error-free training set containing 32 patterns was then generated by simulation using program, ten patterns randomly generated were used as a verification set and four patterns randomly generated were used as a test set. Example of selected titration curves is given in Fig. 5.

Values of the emf were used as inputs for the ANN, while c_{HA}, E_0 and g parameters of the electrode were used as outputs. Suitable ANN architecture for modeling was selected automatically by the TRAJAN program and used further for the training process. The optimal architecture found was (66:27:3). The RMS value for the training set was 0.00022, for the verification set 0.00065 and for the test set 0.00075. The predicted and given c_{HA}, E_0 and g values for the test set are given in Table 3.

In the next stage, the simulated patterns with random noise were generated. Using a pseudo-random numbers generator, error values with normal distribution were obtained and then were loaded to the error-free data in the patterns of the test set. The ANN structure with weights obtained on the error-free data was used to evaluate the ANN resistance to the noise. The results obtained for the test sets are seen in Table 3. In order to compare results obtained from hard modeling, the noise loaded data were treated by OPIUM program. The results are comparable (Table 3) and show that ANN are able to predict acid concentration, electrode potential and the slope of the electrode while the prediction errors are acceptable and within common experimental errors.

3.2.2. Stage (B)

A weak acid with dissociation constant pK_a in aqueous solution showing dissociation constant of water pK_w were titrated with sodium hydroxide ($c = 0.1$ M) using a glass electrode. The acids of initial concentration

Remark: i1–i21 are order numbers of input neurons, h1–h6 are order numbers of the hidden neurons and o1–o2 are order numbers of output neurons.

c_{HA} ($V_0 = 5$ ml, $T = 298.15$ K) were titrated, while electrode potential E_0 and electrode slope g were studied.

The input vector contains the electrode potential values calculated for volumes of volumetric solution added from 0 to 1.3 (in sum 66 values).

The pK_a, pK_w, c_{HA}, E_0 and g values are selected according to the ED used. Training set containing 480 error free titration curves (patterns) was generated by simulation using program. Then 50 patterns were randomly generated as a verification set and two patterns were randomly generated as a test set.

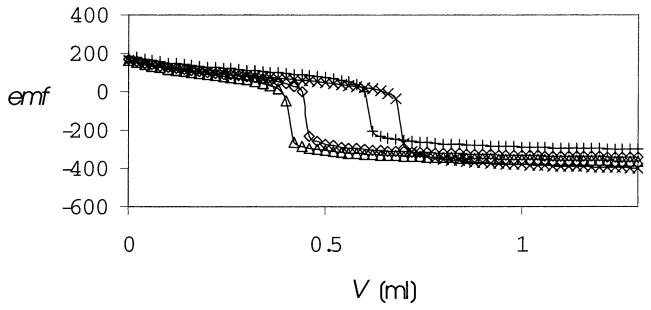

Fig. 5. Selected titration curves concerning Case (2A).

Values of the emf were used as inputs for the ANN, while pK_a, pK_w, c_{HA}, E_0 and g parameters of the electrode were used as outputs. Suitable ANN architecture for modeling was selected automatically by the TRAJAN program and used further for the training process. This architecture was (66:12:5). The RMS value for the training set was 0.005227, for the verification set 0.006166 and for the test set 0.00648. The average prediction errors for these three sets are given in Table 4. The predicted and given pK_a, pK_w, c_{HA}, E_0 and g values for the test set are compared in Table 5.

Table 4
Comparison of average prediction errors for the determination of five parameters (pK_a, pK_w, c_{HA}, E_0 and g) concerning potentiometric titration

Type of set	Estimated parameters				
	pK_a	pK_w	c_{HA}	E_0	g

Verification	1.32%	1.27%	0.90%	0.18%	−2.08%
Test	−3.10%	0.27%	2.03%	−0.26%	0.13%

Results given for training, verification and test sets (Case 2B).

Then the simulated patterns with random noise were generated. Using a random number generator, error values were obtained (normal distribution with S.D. 0.1, 0.3, 0.6, 1.2 and 3 mV corresponding with pH uncertainity 0.002, 0.006, 0.01, 0.02 and 0.05, respectively) and then were added to the error-free data in the patterns of the test set. The ANN structure with weights obtained on the error-free data was used to evaluate the ANN resistance to the noise. The results obtained for the test sets are seen in Table 5. In addition, the results are similar to those obtained by OPIUM program.

The results show that ANN are able to predict pK_a, pK_w, c_{HA}, E_0 and g values with sufficient accuracy.

3.3. Case (3) NMR

Nuclear magnetic resonance (NMR) spectroscopy is a powerful tool for the determination of structural information of complexes in solution. It can also be used for the determination of equilibrium constant of species present in solution. As example, we took example of dissociation constant determination of hydrogen cyanide followed by means of ^{13}C NMR spectroscopy [22].

The input vector contains the chemical shift as observed values were calculated for 56 pH values from 2 to 13.

The δ_{HA}, δ_A (both measured in ppm) and pK_a values were selected according to the three-level factorial design. This design is demonstrated in the Fig. 6. In this way, the error-free learning set containing 27 patterns was created. Then six patterns as a test set were randomly generated.

Observed values of chemical shift were used as inputs for the ANN, the δ_{HA}, δ_A and pK_a values were used as outputs. The optimal ANN architecture (56:16:3) was found by computing using the TRAJAN program and was then used further for the training process and data evaluation. The RMS value for the training set was 0.05897, for the test set 0.0601. The predicted and given δ_{HA}, δ_A and pK_a values for the test set are in Table 6.

In the next stage the simulated patterns with random noise were generated. Using a random generator, appropriate values of noise with normal distribution were calculated and were then loaded to the error-free data in test set patterns. Optimal ANN structure with weights obtained on the error-free data was then applied to evaluate with ANN approach to study the resistance of the method with respect to the noise level. The results obtained for the test sets by means of ANN and OPIUM program are given in Table 6.

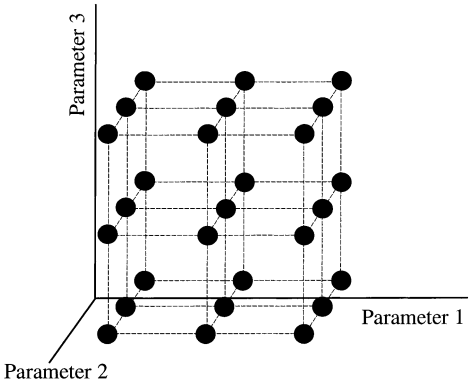

Fig. 6. Scheme of a three-level factorial design for three parameters used in Case (3).

The RMS values obtained were 0.06038 and 0.08332, respectively. The increase in the RMS values when increasing the level of noise is not very large. The results obtained with ANN are acceptable and then indicate that ANN approach is usable for NMR data evaluation.

Further the evaluation of experimental data was accomplished. Results obtained can be seen from Table 6 and can be regarded as highly satisfactory. The difference between the expected and ANN predicted value is within the experimental errors.

3.4. Case (4) potentiometry-determination of uranyl hydrolytic constants

The hydrolytic reaction of uranyl can be written

$$pUO_2^{2+} + qH_2O \overset{K_{h,pq}}{\rightleftarrows} (UO_2)_p(OH)_q^{2p-q} + qH^+$$

where the equilibrium hydrolytic constant is defined as

$$K_{h,pq} = [(UO_2)_p(OH)_q^{2p-q}][H^+]^q[UO_2^{2+}]^{-p}$$

We will continue in abbreviating hydrolytic species using their indices in brackets (p, q).

As training data, 192 curves for ANN were simulated by means of OPIUM package for the following parameters: uranyl concentration 2, ..., 100 mM, $-\log[H^+]$ 3, ..., 5, $\log K_{2-2} = -5.8$, ..., -6.5, $\log K_{3-4} = -12.6$, ..., -13.2, $\log K_{3-5} = -16.5$, ..., -17.2. The following Z function

$$Z = \frac{c_{OH} - K_w/[H^+] + [H^+]}{c_U}$$

where c_{OH} is analytical concentration of hydroxide ions, c_U is analytical concentration of uranyl present in solution, K_w is the ionic product of water under given experimental conditions and $[H^+]$ is concentration of free protons which can be determined e.g. by glass electrode. Z-function is dependent on parameters mentioned above. The change of parameters was proposed according to central composite design. The simulated data are presented in Fig. 7. As data for ANN verification, 50 curves were generated under the same conditions as for training data but for different values. Experimental data [23] were then evaluated using simulated curves of the training set by ANN approach.

For ANN computation, a trial set $(c_M, -\log[H^+], Z)_n$ was used as input data while the output data were $-\log K_{2-2}$, $-\log K_{3-4}$, and $-\log K_{3-5}$. The architecture of ANN was optimized and it was found to be (33:3:3). The results of experimental data evaluation by means of ANN were compared with the results obtained by POLET program. The results of experimental data analysis by soft and hard model technique are given in Table 7 and it is evident that ANN approach is giving good agreement with 'hard' computing.

4. Conclusions

The use of ANN multivariate calibration approach to estimate stability constants tested on error-free data and on data with random noise shows high rigidity of ANN method to random errors, while equilibrium constants can be obtained with sufficient accuracy and the results do not differ significantly from the correct values or those obtained by a general regression optimization programs.

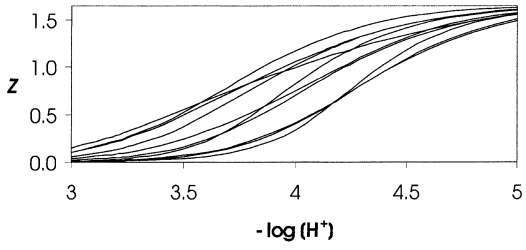

Fig. 7. Simulated ($-\log[H^+]$, Z) curves concerning hydrolysis of uranium with experimental points concerning Case (4). For the sake of clarity, only each 20th curve of the total number of curves are given (total number of the curves was 192).

The method proposed is quite general and, in principal, can be applied for evaluation of any kind of experimental data in equilibria studies.

On the base of ED-ANN, 'normalized equilibrium data base' can be created. Once evaluated (trained) it can yield the equilibrium constants very fast without solving mass balance equations, for any data with the same chemical model. This can be a completely general and NEW approach towards equilibrium data evaluation.

Abstract

The interactions of lanthanide(III) ions with the following oxygen- and mixed oxygen–nitrogen-donor ligands: 2-methoxyethylamine (**L1**), 2-aminoethanol (**L2**), 2-methoxyethylether (**L3**), di(ethyleneglycol) (**L4**), 2,2′-oxydiethylamine (**L5**) and 1,5-diaminopentane (**L6**) have been investigated in dimethylsulfoxide (DMSO) at 298 K and $I = 0.1$ mol dm^{-3} (Et_4NClO_4). Calorimetric and ^{1}H NMR results show that **L1**–**L4** and **L6** are not able to complex Ln(III) ions. **L5** is shown to be able to bind heavier Ln(III) ions (Ln=Ho–Lu). Potentiometric and calorimetric measurements have been carried out to obtain the Ln(III)–**L5** thermodynamic parameters of complexation. All the complexes are formed in exothermic reactions being the entropy terms generally negative or slightly positive. Comparison between the complexing abilities of **L1** and **L5** shows that at least two $-CH_2CH_2NH_2$ side-arms added to an ether function are needed to promote effective interaction between an ether O atom and Ln(III) ions in the high coordinating solvent DMSO. The results are discussed in terms of different donor properties and solvation of –NR– and –O– groups towards metal ions. A comparison with data previously obtained in DMSO for the complex formation of Ln(III) with the purely N donor diethylenetriamine (dien) is made. © 2002 Elsevier Science Ltd. All rights reserved.

1. Introduction

The past decade has witnessed a growth in research into the coordination chemistry of lanthanide(III) ions, due to the importance of their compounds in homogeneous and heterogeneous catalysis [1], in biochemistry as luminescent probes [2], in analytical chemistry as ion-selective reagents [3], in NMR as shift reagents [4] and, as shown by recent studies, in magnetic resonance imaging (MRI) [5], where they are used as contrast reagents. Their development also concerns the fields of glass, ceramics, magnets, optics and electronics [6] and also extends to studies as catalytic active metals in synthetic hydrolases [7].

This enlargement in the scientific and technological interest of lanthanides consequently means that additional information concerning particular aspects of their coordination chemistry is of interest and usefulness.

So far, much attention has been paid to the aqueous solution chemistry of lanthanides, which is dominated by their oxophilicity, most ligands containing carboxylato or phosphinato oxygen donors [1,8–10]. In this context, only slightly basic N-donors have been studied in water, as strongly basic amines do not survive hydrolysis [9,11]: these studies have shown that amines are poor donors for lanthanides in water whereas, when incorporated into aminocarboxylates or aminophosphonate, they form quite stable Ln(III) complexes, much more stable than the analogous oxoacids [10].

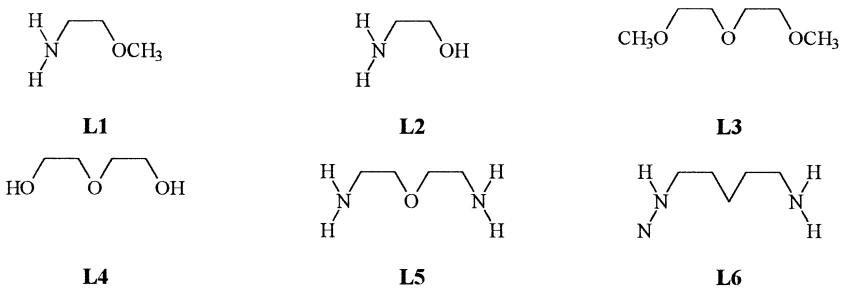
Recently, some attention has been also paid to non-aqueous media, where strongly basic ligands can be more easily investigated [12–14]. In particular, our resaerch group has recently studied [15] the thermodynamic and luminescent properties of lanthanide(III) complexes with linear amines and polyamines in the following solvents of differing coordinating properties [16,17]: dimethylsulfoxide (DMSO), (donor number, DN = 29.8), acetonitrile, an, (DN = 14.1), and *N*,*N*′-dimethylformamide (DMF) (DN = 26.6). These studies have shown that: (i) the formation constants of LnL_j complexes in DMSO (L = en, $J = 1–3$; L = dien and trien, $j = 1, 2$) increase almost linearly with the increasing atomic number of the metal ion, indicating ion–dipole interactions; (ii) complex formation in all aprotic solvents is accompanied by high negative enthalpy and entropy values, as a consequence of strong Ln–N coordination and relatively weak desolvation of the species; (iii) strong chelate effects are at play, as complex stability increases with the N atoms present in the ligand concerned; (iv) solvation effects greatly influence complex formation in such a way that complexes unstable in DMSO are stabilized in DMF and, to a greater extent, in an.

Up to date, few studies concerning the affinity of Ln(III) ions for the ether or alcohol O-function inserted in neutral ligands have been reported in water or other strong donor solvents such as DMF [13,14,18] or DMSO [19,20]: in the latter solvent, the formation of stable lanthanide (III) complexes with cryptands 4,7,13,16,21,24-hexaoxa-1,10-diazabicyclo[8.8.8]hexacosane and 4,7,13,16,21-pentaoxa-l,10-diazabicyclo[8.8.5]tricosane, claimed by some authors [19], has been ruled out by independent experimental evidence [20]. However, data on Ln(III) interactions with neutral macrocycles containing O and other heteroatoms, N or S, in less coordinating solvents such as propylenecarbonate (4-methyl-l,3-dioxolan-2-one, pc) or acetonitrile (an) show that lanthanides have considerable affinity not only for –NH– but also for –O– functions, though maintain a greater preference for –NH– coordination [13,14,21].

With the aim of improving our understanding of Ln(III) behavior towards the coordination of the neutral oxygen atom in strong donor solvents, we present here an investigation on the interactions of some oxygen- and mixed oxygen–nitrogen-donor ligands with some lanthanide(III) ions in DMSO. The ligands studied are 2-methoxyethylamine (**L1**), 2-aminoethanol (**L2**), 2-methoxyethylether (**L3**) di(ethyleneglycol) (**L4**) and 2,2′-oxydiethylamine (**L5**) (Scheme 1). They were chosen as being able to form five-membered chelate rings, which should maximize their complexing ability [22]. In order to clarify if the ether function in **L5** contributes to stabilizing Ln(III)–2,2′-oxydiethylamine complexes or if it simply acts as a spacer between the amino groups, some experimental measurements were carried out in DMSO to verify the complexing ability towards lanthanides(III) of 1,5-diaminopentane (**L6** in Scheme 1), were the O atom of **L5** is substituted by a $–CH_2–$ moiety.



A number of preliminary experiments, run using solutions of moderately high concentrations of the above-mentioned ligands proved that (see Section 3) only **L5** shows some affinity for lanthanide ions: the present thermodynamic investigation was therefore focused on the study of **L5** complexation with the heavier Ln(III) ions ($Ln=Ho^{3+}–Lu^{3+}$), as their high charge density should maximize ion–dipole interactions.

The stability constants of the complexes formed by metal ions with **L5** were obtained by means of potentiometric measurements using the method of competitive reactions [23]: silver(I) was the auxiliary metal ion. The method requires the preliminary determination of the stability constants of the silver(I) complexes with **L5** [23]. Enthalpy changes were determined by direct calorimetric titration.

The present study was performed at 298 K by adjusting the ionic medium to 0.1 mol dm^{-3} with tetraethylammonium perchlorate as supporting electrolyte. To provide insight into the nature of Ln(III)–**L5** coordination, spectroscopic NMR studies were also performed.

2. Experimental

Warning! Although we did not have any problems, organic solvates of perchlorate salts are powerful

Scheme 1.

explosives and should be handled with great caution! [24]

$Ln(III)(ClO_4)_3 \cdot n$DMSO (n decreasing almost regularly from 7.9 for La to 7.1 for Lu) were prepared, crystallized and characterized as described earlier [15a]. Stock anhydrous solutions of the salts were prepared by dissolving weighed amounts of the adducts in anhydrous DMSO. The metal ion concentration in the stock solution was determined by complexometry with EDTA [25].

Silver (I) perchlorate (Fluka puriss × H_2O) and NEt_4ClO_4 (Fluka purum >99%) were dehydrated and purified as previously described [26].

DMSO (Fluka >99%) was distilled under reduced pressure [27] and stored with 4 Å molecular sieves in dark bottles.

Pure 1,5-diaminopentane was obtained by distillation under reduced pressure of the commercial product (Aldrich 95%) [27]. 2-Methoxyethylamine (Aldrich 99%), 2-aminoethanol (Aldrich 99+%), 2-methoxyethylether (Aldrich 99%) and di(ethylene glycol) (Aldrich 99%) were dehydrated with 4 Å molecular sieves and used without further purification.

The free base 2,2′-oxydiethylamine (**L5**) was obtained by percolation of an aqueous solution of the dihydrochloride salt (Aldrich 97%) through an Amberlite-IRA-400(OH) ion exchange resin. Water was then removed from the eluate by distillation and the anhydrous product (purity >99% by gas chromatography) was finally obtained by distillation under reduced pressure.

Stock solutions of the ligands were prepared by dissolving weighed amounts of the pure substances in anhydrous DMSO. All solutions were prepared and stored in a glove box under controlled atmosphere of N_2 (H_2O <2 ppm). The water content in the stock solutions (10–30 ppm) was determined on a Metrohm 684 KF coulometer.

2.1. Potentiometric measurements

Data for calculating the stability constants of the Ln(III)–2,2′-oxydiethylamine complexes were obtained by monitoring the equilibrium concentration of silver(I) in solutions containing different initial concentration of silver(I)–lanthanide(III) and known concentrations of the ligands. All measurements were carried out in a thermostatted cell maintained at 298.0±0.1 K. The e.m.f. values were collected by means of a data acquisition system using an Amel model 338 pH-meter equipped with a Metrohm 6.0328.000 silver electrode as working electrode and a Metrohm 6.0718.000 silver electrode as reference. Typically, a titration run was carried out by adding known volumes of the ligand solution ($100 < C^\circ_L < 300$ mmol dm^{-3}) to 20 ml of a lanthanide(III)–silver(I) solution ($5 < C^\circ_{Ln} < 33$ mmol dm^{-3}; K $C^\circ_{Ag} < 10$ mmol dm^{-3}).

The e.m.f. values of cells containing Ln^{3+} and Ag^+ ions proved that the silver(I) electrode behaved in DMSO according to Nernst's law in the range $10^{-5} < [Ag] < 10^{-2}$ mol dm^{-3}. To exclude moisture, all titrations were performed in a dry MB Braun 150 glove box. The computer program HYPERQUAD [28] was used for the calculation of the stability constants.

2.2. Calorimetric measurements

A Tronac model 87-558 precision calorimeter was employed to measure reaction heats. The calorimeter accuracy was checked by titration of tris(hydroxymethyl)aminomethane (THAM) with a standard solution of HCl in water. The experimental value of the neutralization heat of tham was found to be $\Delta H^\circ = -47.58$ kJ mol^{-1}, in good agreement with the accepted value of -47.53 ± 0.13 kJ mol^{-1} [9].

Calorimetric titrations were performed at 298.00±0.02 K by adding known volumes of ligand solutions ($30 < C^\circ_L < 120$ mmol dm^{-3}) to 20 ml of lanthanide(III) ($5 < C^\circ_{Ln} < 33$ mmol dm^{-3}) solutions. The dilution heats of the reactants, determined in separate runs, were found to be negligible. The LETAGROP KALLE least-squares computer program [29] was used to calculate enthalpy changes.

2.3. NMR measurements

^{1}H NMR spectra were recorded at 298 K on a Brucker AC 200F QNP spectrometer.^{1}H chemical shifts refer to $SiMe_4$. Measurements were performed on DMSO-d_6 solutions containing the metal ions (~33 mmol dm^{-3}) and the ligands in the molar ratio $R_c = C_L/C_M = 0.3$. Analogous measurements were carried out on solutions containing only the ligand concerned.

3. Results

The overall stability constants obtained after the minimization procedure of the potentiometric data, with the limits of error indicated, are listed in Table 1 for reactions $M + jL \rightleftarrows ML_j$ ($M = Ln^{3+}$, **L** = **L5**). Computer treatment of experimental data showed that the best fit was achieved when one (Ho) or two (Er–Lu) successive mononuclear complexes formed.

Fig. 1 shows plots of $\bar{n}$, the average number of ligands per metal ion, versus $-\log[\mathbf{L}]$ for the formation of **L5** complexes of Ho^{3+} and Lu^{3+}, where [**L**] is the free ligand concentration. The relationship $\bar{n} = (C_L - \bar{n}' C_{Ag} - [\mathbf{L}])/C_M$ was used to calculate $\bar{n}$, where $\bar{n}'$ is the average number of ligands bound to silver(I) ion and C_L is the analytical ligand concentration. The values of

Only some experimental points chosen at random are plotted. Full curves are calculated from the stability constants in Table 1.

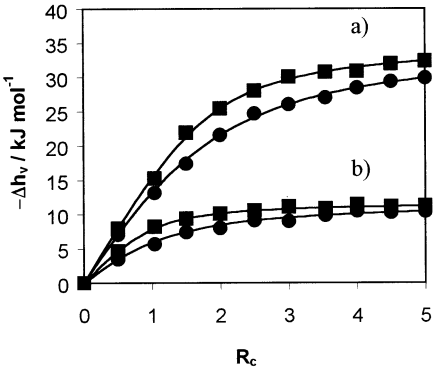

Fig. 2. Total molar enthalpy changes, Δh_v, as a function of $R_c = C_L/C_M$ for (a) Lu(III)- and (b) Ho(III)–**L5** systems. Total Ln(III) concentrations in mmol dm^{-3}: (a) (●) 9.96, (■) 30.10; (b) (●)11.6, (■) 32.7. Only some experimental points chosen at random are plotted. Full curves calculated from stability constants and enthalpy changes in Table 1.

$\bar{n}'$ and [**L**] were obtained from the measured free silver(I) concentration calculated from e.m.f. data and the stability constants of the silver(I) complexes with **L5** previously obtained [30].

The complex–formation curves in Fig. 1, almost superimposing, show that neither polynuclear nor mixed complexes form in appreciable amounts in the adopted conditions [23].

The total reaction heats per mole of metal ion, Δh_v, are reported as a function of $R_c = C_L/C_M$ in Fig. 2 for Ho and Lu, respectively. The experimental reaction heats and overall stability constants of Table 1 were used to calculate the full lines in Fig. 2. The fit of the experimental data is quite good, indicating that the systems are satisfactorily described. As the results for the other lanthanides are quite similar, they are not reported here. Calorimetric measurements carried out on the lanthanide(III)–**L1**–**L4** and **L6** systems gave negligible reaction heats, indicating that no appreciable interactions exist between Ln(III) ions and these ligands in DMSO. This evidence is further supported by the ^{1}H NMR measurements on DMSO solutions of ligands alone and on solutions also containing Lu(III): the shapes and chemical shifts of the signals observed in the latter solutions did coincide with those observed in the solutions containing the ligands alone.

Fig. 3 shows that a difference exists between the ^{1}H NMR spectrum of **L5** and that of its [Lu**L5**]$^{3+}$ complex in DMSO-d_6. From the values of the stability constants and from the used Lu(III) concentration, one can calculate that at $R_c = 0.3$ the percentual of 1:1 Lu(III)–**L5** complex formed was about 90%.

4. Discussion

The experimental data (see above) clearly show **L1**–**L4** and **L6** cannot interact with Ln(III) ions in DMSO.

The following considerations are applied to explain, ligand by ligand, their inability to interact with Ln(III) ions: (i) it has previously been shown that the chelate ring size of non-macrocyclic ligands plays an important role in controlling the affinity and selectivity for metal

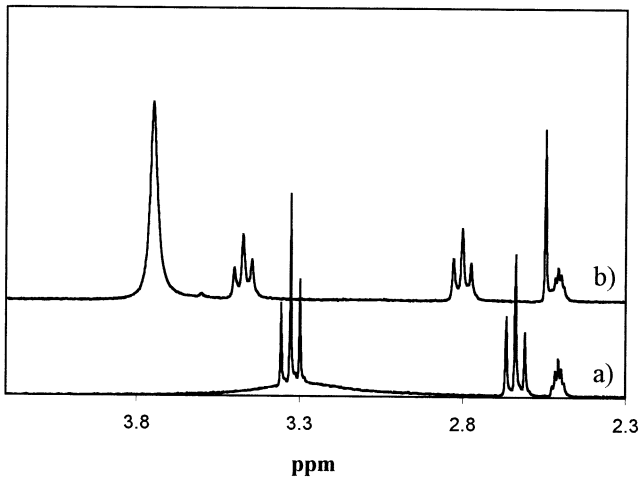

Fig. 3. NMR spectra at 298 K of: (a) **L5** = 11.0 mmol dm^{-3}; (b) $C^{\circ}_{Lu} = 33.2$, **L5** = 11.0 mmol dm^{-3} in DMSO-d_6.

ions [22], and in particular that increasing the number of the $-CH_2-$ groups separating the N atoms decreases the stability of block f lanthanide(III) complexes with polyaminocarboxylates in water [31] and of uranyl(VI) complexes with polyamines in DMSO [32], the stability of these complexes being maximized when five-membered chelate rings are formed. Evidently the eight-membered chelate ring that **L6** should have formed in the hypothesis of chelate complex formation is greatly hindered and so no Ln(III)–complex(es) is(are) form. The lack of interaction not only of L6 but also of **L1**–**L4** with Ln(III) ions is also in line with the observed inability of monoamines to coordinate block f ions in DMSO [15f, 32]; (ii) the absence of interactions between metal ions and **L3** or **L4**, oxygen donors having the same molecular framework as dien or **L5**, shows that purely O-donors do not exhibit any affinity for Ln(III) in DMSO. Many factors must be considered when attempting to explain ligand affinity for metal ions, i.e. donor strength of donor atoms, strain effects in the formation of chelate rings, steric and inductive effects of substituents, and the role of donor group orientation [22,33]. Strain energy effects in five-membered chelate rings, whether they contain oxygen or nitrogen donors, are similar [33a] and the role of donor group orientation may not be important in interactions with f-block lanthanide ions. The important difference between O- and N-donor ligands is that neutral oxygen donors are not better bases than DMSO, as the relative basicity of saturated neutral oxygen donors, measured in the gas phase, decreases in the order DMSO > ROH > ROR [34a,34b], this trend being retained, for example, in aqueous solution [34c]. For most metal ions, nitrogen donors are generally better donors than DMSO [16,17,34,35]. Since the ligand donor atoms must compete with DMSO for coordination sites on metal ions, the poorer basicity of alcohols and ethers with respect to the solvent is probably responsible for the results obtained here, despite the potential chelate effect which the ligand should cause; (iii) the fact that potential chelate ligands such as **L1** and **L2**, containing both nitrogen and oxygen atoms, cannot interact with Ln(III) ions shows that the cooperativity of one N and one O atom is not efficient enough to create a chelate in DMSO [16,17,34]. Otherwise, when **L5** is concerned, the coordination of Ln(III) ions is possible and one or two complexes are formed. Certainly, on the basis of the above discussed inability of **L6** to complex lanthanide(III), in this case the –O– group must be active part in the complex formation.

The ^{1}H NMR spectra of **L5** (A_2X_2 system) and of its lutetium complex (AA′XX′ system) reported in Fig. 3 show a $\Delta\delta$ ($\Delta\delta = \delta_{complex} - \delta_{ligand}$) of about 0.2 ppm for both $-CH_2-$ protons near the O atom (from 3.32 in the free ligand to 3.48 in the complex) and $-CH_2-$ protons near the amino function (from 2.63 to 2.80): despite the downfield shift is low, this shift should be considered as a possible diagnostic tool of the interaction of –NH– and –O– donor groups with the central metal ion.

One interesting piece of evidence which emerges from this study is that complex formation depends on a synergic effect between donor groups in the ligand: at least two $-CH_2CH_2NH_2$ side-arms added to an ether function are needed to make the ligand capable of forming two five-membered chelate rings, giving rise to effective interaction between O atom and Ln(III) ions.

The complex formation of Ln(III) ions with **L5** is always accompanied by negative enthalpy changes, which are typical of aprotic solvent reactions involving complexation by neutral ligands [13,15,18,21,26,36]. This behavior has already been observed in other Ln(III)–amine systems in DMSO [15] and has been interpreted as the formation of complexes in which interactions of metal ions with donor atoms are quite strong and fully capable of compensating the energy required to set off from the co-ordination sphere of the metal ion one or more solvent molecules. As lanthanides are strongly solvated in DMSO [15a], this implies that inner-sphere complexes are formed.

The entropy terms are generally negative or, when positive, only slightly favorable. This is in accord with the formation of complexes generally involving large conformational entropy losses not, or only slightly, compensated by gains due to desolvation of reacting species. That is, when neutral ligands are considered, complex formation does not cause substantial modifications in the metal-charge ordering effect of the bulk solvent, and thus no large positive entropy changes take place [36].

The data in Table 1 and Fig. 4 show that the stability constants of 1:1 Ln(III)–**L5** complexes increase almost regularly with the increasing charge density of the metal ions, indicating that the ion–dipole character of the

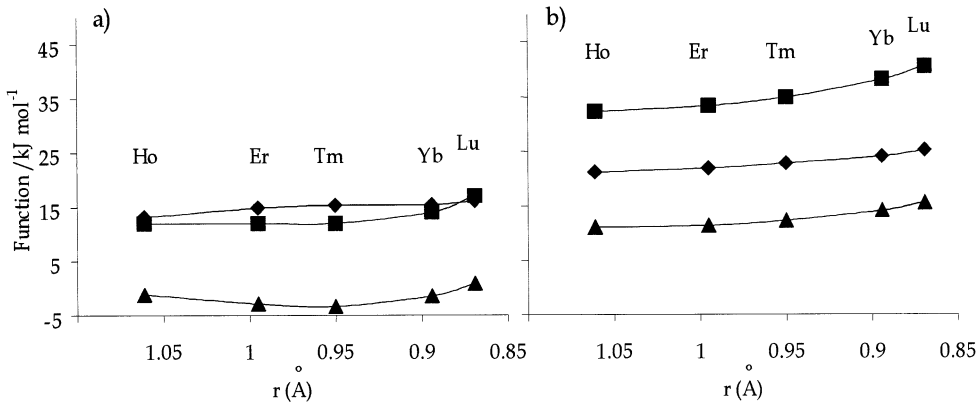

Fig. 4. Thermodynamic functions for 1:1 complex formation of (a) Ln(III)–**L5** and (b) Ln(III)–dien [15c] systems at 298 K and $I = 0.1$ mol dm^{-3}. (◆) $-\Delta G^{\circ}_{\beta 1}$; (■) $-\Delta H^{\circ}_{\beta 1}$; (▲) $-T\Delta S^{\circ}_{\beta 1}$.

interaction is an important feature of these complexes. Similar behavior was observed (Fig. 4) for the formation of Ln(III)–dien complexes in DMSO 15b. The stabilities of the complexes of **L5** are lower than those of dien. This is reasonably due to two main factors: the intrinsic higher basicity of the central –NH– group in dien with respect to that of –O– group in **L5** [16,17,34]; the lower solvation energies of the complexes formed by **L5** [33,37], due to the presence of an ether function which cannot give rise to hydrogen bonds with the solvent, like the –NH– group in dien. The magnitude of enthalpy gains for the formation of the lanthanide(III)–**L5** complexes are much lower than those found for homologous dien complexes. Certainly, the decreased strength of the Ln(III)–O interaction with respect to that of Ln(III)–NH is reflected in this result, but other effects should also be considered to explain this enthalpy trend and, even more, to provide deeper insight into the entropy values. As mentioned above, the entropy term for 1:1 complex formation contributes in a slightly favorable way to complex formation (apart from the Lu(III)–**L5** system), whereas the contribution of entropy always opposes it in Ln(III) dien systems (Fig. 4).

Solvation of **L5** is certainly less considerable than that of dien, because of the lesser hydrogen bonding with the solvent: this effect alone would increase the net enthalpy gain and decrease the entropy term for Ln(III)–**L5** systems with respect to dien ones and therefore it does not explain the trend in the data reported here. As both **L5** and dien are probably responsible for the removal of the same number of solvent molecules from the first solvation sphere of the metal ion, these results may be explained by taking into account the effect that –NH– substitution with the –O– group has on the outer-sphere solvation energy of the resulting complexes.

In particular, it is to be considered that the minor extent of hydrogen bonding of **L5** should also cause less outer-sphere solvation energy of the metal complex [37], reflected in a lower enthalpy gain and a less unfavorable entropy term.

From the thermodynamic data and for the reasons discussed above (point (i) at the beginning of discussion), it may be presumed that **L5** acts as a tridentate also in ML_2 complexes. The higher exothermic enthalpy value of the second complexation step, ΔH°K2, compared with ΔH°K1 is probably due to a particular kind of desolvation occurring in the first complexation step: the enthalpy required for desolvating causes ΔH°K1 to be less exothermic than ΔH°K2, in spite of the greater exothermicity associated with the Ln(III) interaction in the first step.

Abstract

The interaction of La(III), Gd(III), and Yb(III) with Tris((2,3-dihydroxybenzylamino)ethyl)amine) (TRENCAT) was investigated by means of potentiometric measurements in 0.1 mol dm^{-3} aqueous solution of sodium perchlorate at 25 °C. The formation of complexes between the partially protonated ligand and lanthanides has been observed and the values of their formation constants are reported. © 2002 Elsevier Science Ltd. 1. Introduction

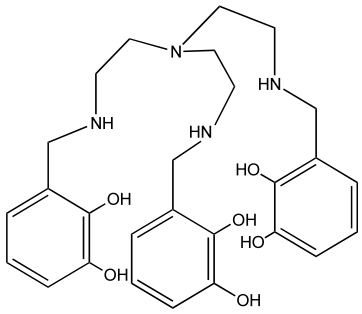
In the last few years, many multidentate ligands of several kinds have been prepared in the quest for lanthanide(III) complexes useful in the medical field. The greatest interest focuses on the use of these complexes, gadolinium compounds in particular, as contrast agents in magnetic resonance imaging (MRI) [1].

For this purpose, the most stringent requirement for these complexes is good thermodynamic stability. Enhanced stability has generally been achieved by introducing two or more carboxyl groups in various positions into the frame of the ligand, together with other neutral donor groups.



While a large number of publications regarding this kind of polycarboxyl ligands reveal growing interest, only a few studies on the interaction of lanthanides(III) with ligands bearing a phenol group as possible anion donor have been published. The main reason why this kind of ligand is less appealing than polycarboxyl ones is the low acidity of the hydroxyl group. In most cases, lanthanide ions, which are themselves weak Lewis acids in water, are not as competitive as hydrogen ions towards the phenol group, so that Ln(III) ions, unable to create stable complexes with phenol ligands, show a marked tendency to form hydroxo complexes in solution. Nevertheless, it has recently been demonstrated that the introduction of phenol groups into a well preorganised structure allows the ligand to form strong lanthanide(III) complexes [2].

In line with these findings, in our most recent publication [3] we demonstrated the very high complexing power of Tris((2,3-dihydroxybenzylamino)ethyl)amine (TRENCAT; a new ligand containing three catechol groups linked via ethylene moieties to the backbone of Tris(2-aminoethyl)amine) towards 'hard' cations like thorium(IV) and H^+ (Scheme 1).

The present study extends investigations to some trivalent lanthanide ions. To verify the effect of lanthanoid contraction, three metal ions were chosen. Two (La^{3+} and Yb^{3+}) occupy the extremes of the lanthanide series and the third (Gd^{3+}) lies in the middle. The study, carried out with the potentiometric technique in water at 25 °C with 0.1 M $NaClO_4$ as ionic medium, yielded the

Scheme 1. Schematic drawing of TRENCAT

formation constants of all the metal species involved in the detected equilibria.

As already reported [3], TRENCAT is a potentially hexa-protic acid. However, in the experimental conditions adopted here, deprotonation of only one of the two weak acid functions of each catechol group could be studied. Accordingly, in the following discussion, neutral TRENCAT is called H_3L and the fully protonated form H_6L^{3+}. In the latter form, protons are presumed to be bound only to the secondary nitrogens of the molecule, as the tertiary one could not be protonated in our experimental conditions ($p[H+] > 2$) [2].

2. Experimental

2.1. Reagents

Stock solutions of lanthanoid perchlorates were prepared by dissolving the appropriate oxide (Aldrich $>99.9\%$ pure) in a small excess of perchloric acid. Working solutions were prepared from stock solutions by dilution. Metal ion concentration was determined by titration with EDTA using Xylenol Orange as indicator and acetate buffer [4]. The concentration of free perchloric acid in the lanthanide(III) solutions was determined by Gran's potentiometric method [5].

The stock solution of perchloric acid was prepared by dilution of concentrated perchloric acid (Aldrich 70% ACS reagent) with doubly-distilled deionised water and standardised by titration with Tris(hydroxymethyl)aminomethane (Aldrich, ultrapure grade).

Diluted sodium hydroxide solutions were prepared from a saturated NaOH solution (50% NaOH, 50% H_2O) left standing in a polyethylene bottle for several days. Standardisation of these solutions was carried out with potassium hydrogenphthalate (Aldrich, ACS acidimetric standard).

A stock solution of sodium perchlorate was prepared with recrystallised reagent grade product (Fluka, puriss. p.a. ACS). The solution titre was obtained by ion-exchange analysis on a cationic resin in the hydrogen form.

The trihydrochloride monohydrate salt of the ligand was prepared and purified as already reported [3].

2.2. Apparatus

Potentiometric measurements were carried out at 25 °C in solutions in which the total concentration of sodium ion was maintained at 0.1 mol dm^{-3} by adding a standard $NaClO_4$ solution. A 50-ml glass cell with a thermostated water jacket maintained the temperature at 25 ± 0.1 °C.

Potentiometric measurements were performed on a Metrohm (model 654) pH-meter equipped with a Metrohm 6.0204.100 combined glass electrode. The original electrode filling solution (3 mol dm^{-3} KCl) was replaced with a 100 mmol dm^{-3} NaCl solution to avoid clogging of the electrode frit glass septum by $KClO_4$. The electrode was calibrated (25 ml of $NaClO_4$ 0.1 mol dm^{-3} titrated with standard 0.1 mol dm^{-3} $HClO_4$) before each titration, in order to measure hydrogen ion concentration H^+ and liquid-junction potential E_j.

The computer-controlled potentiometric apparatus collected e.m.f. data (ΔE) at intervals determined by the data collection criterion, i.e. $\Delta E = 0.0$ mV for 2 min, a value usually reached within 3–7 min.

2.3. Procedures

The experimental method consisted of potentiometric titrations of the ligand acid in the presence of metal ion, by adding standard NaOH solution. Ligand solutions were prepared immediately prior to experiments with deoxygenated water, as ligands may slowly oxidise in aerated solutions. Six titrations with the following initial concentrations of lanthanide(III) ($C_M°$) and ligand ($C_L°$) were carried out: ($M = La^{3+}$) $C_M°/C_L° = 0.55/0.55$, 0.29/0.58; ($M = Gd^{3+}$) $C_M°/C_L° = 0.50/0.49$; 0.50/1.00; ($M = Yb^{3+}$) $C_M°/C_L° = 0.56/0.56$; 0.29/0.56 mmol dm^{-3}/mmol dm^{-3}. The low concentrations adopted in these experiments were imposed by the poor solubility of the unprotonated neutral ligand.

Stability constants for lanthanide(III)–TRENCAT complexes were obtained with the help of the SUPERQUAD computer program [6]. Only data points for which the absence of a solid phase was clearly assessed were considered in data processing. The six protonation constants of the ligand (log β_n ($1 \le n \le 6$) 11.23, 21.84, 31.59, 40.10, 47.68, 54.00), previously reported [3], were used as input data to evaluate the formation constants of the metal complexes.

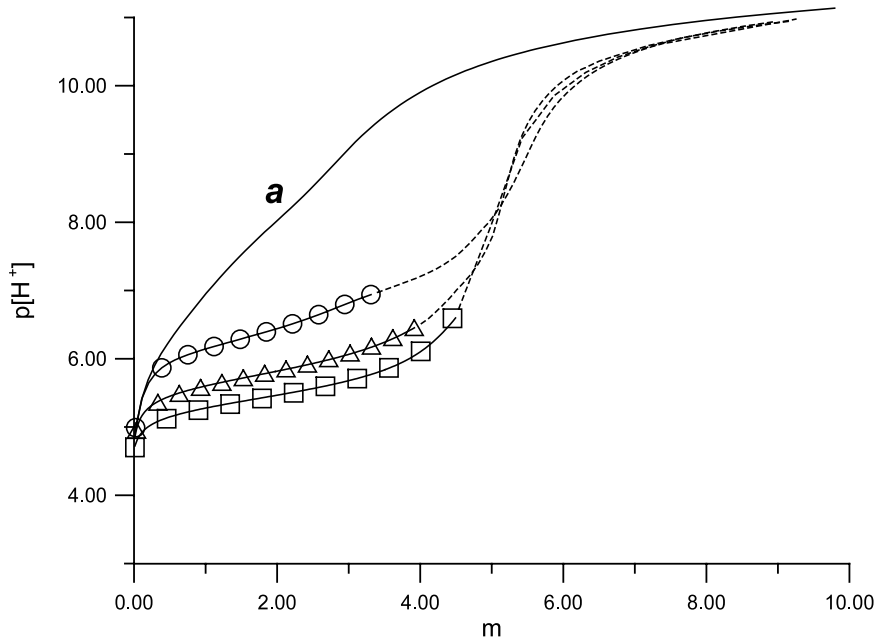

Fig. 1. Titration curves of H_6L^{3+} in absence (***a***) and presence of metal ions La^{3+} (○), Gd^{3+} (△) and Yb^{3+} (□). For all curves, Ln^{3+}–H_6L^{3+} ratio was 1/1.

3. Results and discussion

Fig. 1 compares p[H^+] versus m (m = moles of NaOH per mole of metal ion) for each Ln^{3+}–TRENCAT system studied. Open symbols (○, △, □) represent equilibrium points collected when no solid phase was present in solution. Dashed lines represent points collected when solid phase was or might be present in solution. Line ***a***, which represents p[H^+] as a function of m (m = moles of base per mole of ligand) for a solution in which only the ligand was present, was calculated with the protonation constants reported above.

Qualitatively, Fig. 1 gives the following indications: (i) TRENCAT has considerable affinity for lanthanide ions (as clearly illustrated by the difference in the shapes of the titration curves of the ligand alone and those in which Ln^{3+} is present); (ii) the stability of the complexes depends to a significant extent on the charge density of the metal ion (Yb^{3+} complexes form at the lowest pH values and La^{3+} at the highest); (iii) due to complexation reactions, more than three protons are set free per mole of ligand before a solid phase forms in solution. On the basis of these preliminary observations, many sets of possible lanthanide(III)–TRENCAT complexes were tested by the minimisation program. Table 1 lists the stability constants which best represent the experimental data. MH_2L^{2+} and MH_3L^{3+} are the main species for low p[H^+] regions (see Fig. 2). At higher p[H^+] these complexes lose protons, as depicted in Eqs. (1a) and (1b):

$$MH_3L \leftrightarrows MH_2L + H \quad \log K_M = -7.28_{La},\ -5.91_{Gd},\ -6.51_{Yb} \tag{1a}$$

$$MH_2L \leftrightarrows MHL + H \quad \log K_M = -6.97_{La},\ -6.66_{Gd},\ -5.20_{Yb} \tag{1b}$$

giving, before precipitation, a complex (MHL) in which the neutral ligand has lost two protons. It may be a matter of debate exactly which of these protons are removed, as they may be either the more acid ones, for which pK_a values may be evaluated, or catechol ones, for three of which the deprotonation values are unknown. Naturally, the two hypotheses lead to clearly distinct structures for the resulting complexes (MH_2L and MHL). In the first case, the metal ion is 'encapsulated' in the upper cavity of the ligand. In the second case, Ln^{3+} remains outside the nitrogen–oxygen cage. Starting from the initial 'capped' configuration, it forms five-membered chelate rings in sequence, being at-

M(TRNS) + TRNS ⇆ M(TRNS)$_2$	6.34	7.69	9.73

Data for TRNS ($\mu = 0.16$, 25 °C) taken from Ref. [2].

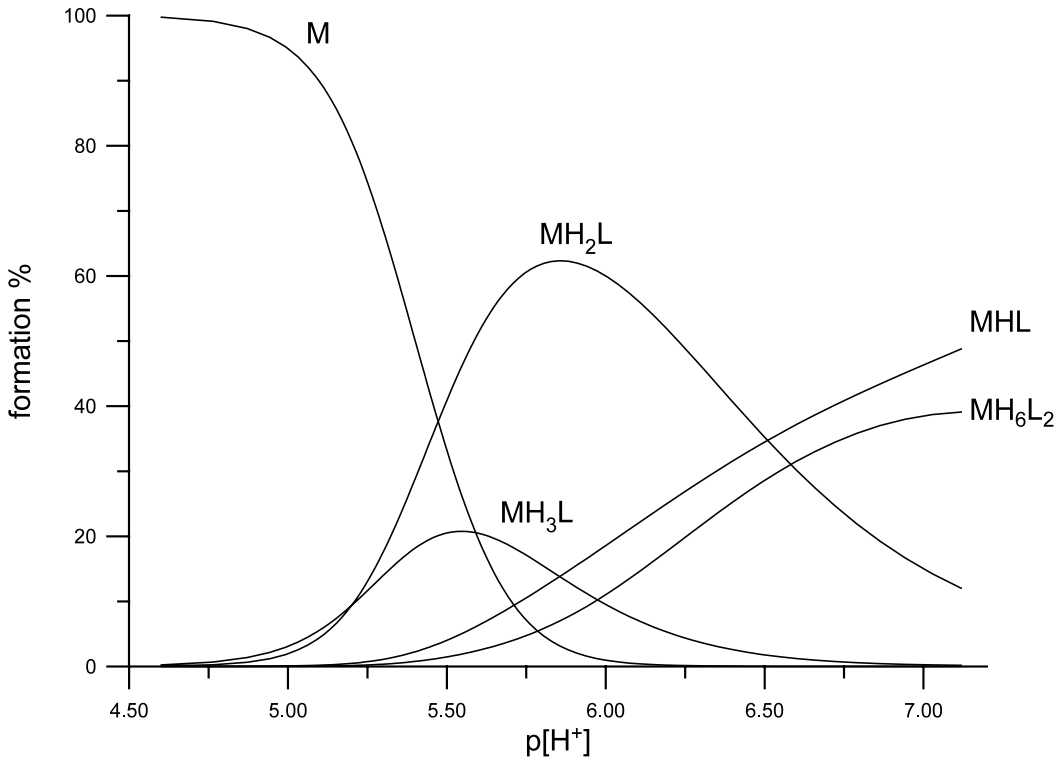

Fig. 2. Speciation diagram calculated for a 1/2 = Yb^{3+}–TRENCAT system. [Yb^{3+}] = 0.5 mmol dm^{-3}.

tracted, step by step as the p[H^+] increases, into the lower cavity formed by the three catechol units.

From the electrostatic point of view, the 'encapsulated' configuration does not appear to be probable. This is because the stability of 'hard' cation complexes depends mainly upon the difference in electrical charge density of the interacting species (either ions or neutral atoms): i.e. the larger the difference, the stronger the interaction. Thus, in the 'encapsulated' configuration, Ln^{3+} would interact with neutral nitrogen and, in the more reliable 'capped' version, with negatively charged oxygens.

Table 1 compares the stability constants of the lanthanide(III) complexes formed by triprotonated TRENCAT and TRNS [tris((2-hydroxy-5-sulfobenzylamino)ethyl) amine [2], a parent compound of TRENCAT containing sulfophenol instead of catechol units.

The stability of the 'capped' complexes formed by TRENCAT, higher ($\Delta \log \beta = 0.67$ for Yb^{3+}) or much higher ($\Delta \log \beta = 1.29$ and 1.82 for La^{3+} and Gd^{3+}, respectively) than that of TRNS complexes, reflects the stabilising effect of the phenol in *ortho* which probably forms chelate complexes, favouring co-ordination of lanthanides to TRENCAT. In addition, formation of stronger 1:1 complexes: (i) removes the anomalous behaviour in the formation constants observed for TRNS complexation ($K_2 > K_1$): in this case, K_1 is always higher than K_2; (ii) allows much easier deprotonation of two of the three highly basic catechol hydrogens of the molecule. Reactions 1a and 1b show that complete deprotonation of catechol takes place at nearly physiological pH levels. This is an important result when we consider these ligands as potential candidates for the formation of very stable lanthanide complexes, for use as contrast agents in magnetic resonance imaging.

Abstract

The new open-chain polyazaalkanes ligands L^1, L^2, L^3 and L^4 functionalised with one or two pyrene groups were synthesised and characterised and their potential use as selective cation and anion sensing chemosensors studied. Solution studies by potentiometric methods were carried out in the presence of the metal cations Cu^{2+} and Zn^{2+} in acetonitrile–water (70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate, 25 °C) The results are compared with those reported for the analogous non-functionalised ligand triethylentetraamine (*tta*). The fluorescence behaviour of the ligands L^1–L^4 has been studied as a function of the pH in the presence of the metal cations Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+} in acetonitrile–water 70:30 v/v mixtures. The Zn^{2+} and Cd^{2+} cations enhance the fluorescence emission of the L^1–L^4 chemosensors at basic pH, whereas Cu^{2+} induce quenching of the fluorescence emission at acid pH. The fluorescence behaviour of L^1–L^4 receptors was also studied as a function of the pH in acetonitrile–water 70:30 v/v in the presence of anions. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Polyazaalkanes ligand; Fluorogenic receptors; Chemosensors

1. Introduction

The development of chemosensors is an area of current interest [1–3]. This usually involves the design and synthesis of molecules containing binding sites and signalling subunits able to display selective changes in observable features such as colour [4–6], fluorescence emission intensity [7–10], electrochemical shifts [11–13], etc upon guest binding. Chemosensors showing fluorescence emission changes are of interest due to the usually low detection limits that can be reached using fluorimetric techniques. Among different coordinating environments polyamines have been used as binding sites for both cations and anionic species. Polyamines are known to form stable complexes with metal cations and are good receptors for anions. The functionalisation of polyamines with fluorescent groups such as anthracene has resulted in systems that act as chemosensors for transition metal ions and anions [14–16]. In fact, anthracene is one of the fluorescent groups most widely used in the development of fluorescent chemosensors. In contrast, other aromatic hydrocarbons have been less studied as fluorescent signalling subunits. We report here the synthesis and characterisation of new open-chain polyazaalkanes functionalised with pyrene groups, and have studied the fluorescence behaviour of these receptors in the presence of metal cations and anions in acetonitrile–water 70:30 v/v (0.1 mol dm^{-3} tetrabutylammonium perchlorate, 25 °C) in order to find pH ranges of selective response.

2. Experimental

2.1. Physical measurements

The fluorescence behaviour was studied with a FS900CDT Steady State T-Geometry Fluorimeter, Edinburgh Analytical Instruments. All solution for photophysical studies were previously degassed. The concentration of ligands and metal ion were approxi-

mately 1.0×10^{-4} mol dm^{-3} in acetonitrile–water (the metal ions were perchlorate or nitrate salts of Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+}). In all photophysical studies the data were collected at fixed values of $\lambda_{ex} = 340$ nm and $\lambda_{em} = 395$ nm. The ^{1}H NMR spectra were recorded with Varian Gemini spectrometer. Chemical shifts were reported in parts per million downfield from TMS. Spectra taken in $CDCl_3$ were referenced to residual $CHCl_3$.

Potentiometric titrations were carried out in acetonitrile–water (70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate, 25 °C) for L^1, L^2, L^3 and L^4 using a reaction vessel water-thermostatted at 25.0 ± 0.1 °C under nitrogen. The titrant was added by a Crison microburete 2031. The potentiometric measurements were made using a Crison 2002 pH-meter and a combined glass electrode. A PC computer automatically controlled the titration system. The electrode was calibrated as a hydrogen concentration prove by titration of well-known amounts of HCl with CO_2-free KOH solution and determining the equivalent point by the Gran's method [17] which gives the standard potential E'° and the ionic product of water ($K'_w = [H^+][OH^-]$). The computer program SUPERQUAD [18] was used to calculate the protonation and stability constants. The titration curves for each system (ca. 250 experimental points corresponding to at least three titration curves, pH −log[H] range investigated 2.5–10.5, concentration of the ligand and cations was ca. 1.1×10^{-3} mol dm^{-3}) were treated either as a single set or as separated entities without significant variations in the values of the stability constants.

2.1.1. Synthesis of receptors L^1–L^4

1-Pyrenecarboxaldehyde, the correspondent open-chain polyamine and 20 g of molecular sieve (3 Å) were heated to reflux in dry dichlorometane (100 ml) for 2 h. The solution was filtered off, evaporated to dryness, dissolved in dry ethanol (100 ml) and the imine obtained as an orange oil reduced with $NaBH_4$ at reflux under argon for 2 h and then 16 h at room temperature (r.t.). The resulting solution was evaporated to dryness, dissolved in dichloromethane and washed with NaOH 1 M (3 × 25 ml). HCl 35% was added dropwise to the dichloromethane phase until total precipitation of the final product in its chlorohydrate form. The yellow–orange solid was filtered off, washed with dichloromethane and dried in vacuum.

2.1.2. Synthesis of 1-(1-methylpyrenyl)-1,4,7,10-tetraazadecane (L^1)

1-Pyrenecarboxaldehyde (500 mg, 2.17 mmol), triethylentetraamine (*tta*; 2020 mg, 10.85 mmol) and reduction of the imine with $NaBH_4$ (125 mg, 3.26 mmol) give, after HCl treatment, 1-(1-methylpyrenyl)-1,4,7,10-tetraazadecane in its tetraprotonated form (935 mg, 85%). NMR ($CDCl_3$): ^{1}H δ 2.50–2.85 (m, 12H), 4.44 (s, 2H), 7.93 (m, 3H), 8.12 (m, 4H), 8.34 (d, 2H). ^{13}C δ 46.83 (CH_2), 48.70 (CH_2), 49,15 (CH_2), 49.17 (CH_2), 49.25 (CH_2), 49.52 (CH_2), 51.70 (CH_2), 123.16 ($C_{16}H_9$), 124.60 ($C_{16}H_9$), 124.91 ($C_{16}H_9$), 124.97 ($C_{16}H_9$), 125.01 ($C_{16}H_9$), 125.81 ($C_{16}H_9$), 126.89 ($C_{16}H_9$), 127.39 ($C_{16}H_9$), 127.51 ($C_{16}H_9$), 128.96 ($C_{16}H_9$), 130.57 ($C_{16}H_9$), 130.76 ($C_{16}H_9$), 131.24 ($C_{16}H_9$), 133.88 ($C_{16}H_9$). HRMS. Calc. for $C_{23}H_{32}N_4Cl_4$ 506.6422, obs. 506.4434.

2.1.3. Synthesis of 1,10-bis(1-methylpyrenyl)-1,4,7,10-tetraazadecane (L^2)

1-Pyrenecarboxaldehyde (1000 mg, 4.34 mmol), *tta* (405 mg, 2.17 mmol) and reduction of the imine with $NaBH_4$ (410 mg, 10.85 mmol) give, after HCl treatment, 1,10-bis(1-methylpyrenyl)-1,4,7,10-tetraazadecane in its tetraprotonated form (1250 mg, 80%). NMR ($CDCl_3$): ^{1}H δ 2.57 (s, 4H), 2.68 (t, 4H), 2.80 (t, 4H), 4.37 (s, 4H), 7.93 (m, 6H), 8.10 (m, 8H), 8.28 (d, 4H). ^{13}C δ 49,11 (CH_2), 49.18 (CH_2), 51.65 (CH_2), 123.16 ($C_{16}H_9$), 124.60 ($C_{16}H_9$), 124.92 ($C_{16}H_9$), 125.01 ($C_{16}H_9$), 125.81 ($C_{16}H_9$), 126.91 ($C_{16}H_9$),126.97 ($C_{16}H_9$), 127.39 ($C_{16}H_9$), 127.40 ($C_{16}H_9$), 127.49 ($C_{16}H_9$), 128.93 ($C_{16}H_9$), 130.55 ($C_{16}H_9$), 130.64 ($C_{16}H_9$), 130.71 ($C_{16}H_9$), 130.75 ($C_{16}H_9$), 131.21 ($C_{16}H_9$), 131.24 ($C_{16}H_9$), 132.85 ($C_{16}H_9$), 133.85 ($C_{16}H_9$). HRMS. Calc. for $C_{40}H_{42}N_4Cl_4$ 720.6135, obs. 720.5537.

2.1.4. Synthesis of 1-(1-methylpyrenyl)-1,4,7,10,13-pentaazatridecane (L^3)

1-Pyrenecarboxaldehyde (220 mg, 0.95 mmol), tetraethylenpentaamine (890 mg, 4.70 mmol) and reduction of the imine with $NaBH_4$ (60 mg, 1.43 mmol) give, after HCl treatment, 1-(1-methylpyrenyl)-1,4,7,10,13-pentaazatridecane in its pentaprotonated form (483 mg, 87%). NMR ($CDCl_3$): ^{1}H δ 2.50–2.90 (m, 16H), 4.45 (s, 2H), 7.97 (m, 3H), 8.12 (m, 4H), 8.35 (d, 2H). ^{13}C δ 46.79 (CH_2), 49.10 (CH_2), 49.16 (CH_2), 49.24 (CH_2), 49.25 (CH_2), 49.30 (CH_2), 49.49 (CH_2), 51.72 (CH_2), 123.19 ($C_{16}H_9$), 124.63 ($C_{16}H_9$), 124.90 ($C_{16}H_9$), 124.94 ($C_{16}H_9$), 125.03 ($C_{16}H_9$), 125.79 ($C_{16}H_9$), 126.92 ($C_{16}H_9$), 127.41 ($C_{16}H_9$), 127.53 ($C_{16}H_9$), 129.00 ($C_{16}H_9$), 130.58 ($C_{16}H_9$), 130.73 ($C_{16}H_9$), 131.26 ($C_{16}H_9$), 133.86 ($C_{16}H_9$), 137.95 ($C_{16}H_9$). HRMS. Calc. for $C_{25}H_{38}N_5Cl_5$ 585.8764, obs. 585.8033.

2.1.5. Synthesis of 1,13-bis(1-methylpyrenyl)-1,4,7,10,13-pentaazatridecane (L^4)

1-Pyrenecarboxaldehyde (1640 mg, 7.10 mmol), tetraethylenpentaamine (670 mg, 3.55 mmol) and reduction of the imine with $NaBH_4$ (400 mg, 10.65 mmol) to give, after HCl treatment, 1,13-bis(1-methylpyrenyl)-1,4,7,10,13-pentaazatridecane in its pentaprotonated form (2350 mg, 83%). NMR ($CDCl_3$): ^{1}H δ 2.60–2.69 (m, 12H), 2.79 (t, 4H), 4.39 (s, 4H), 7.90–8.15 (m, 14H),

8.28 (d, 4H). ^{13}C δ 49,05 (CH_2), 49.13 (CH_2), 51.60 (CH_2), 123.16 ($C_{16}H_9$), 124.58 ($C_{16}H_9$), 124.91 ($C_{16}H_9$), 125.00 ($C_{16}H_9$), 125.80 ($C_{16}H_9$), 126.92 ($C_{16}H_9$), 126.97 ($C_{16}H_9$), 127.39 ($C_{16}H_9$), 127.40 ($C_{16}H_9$), 127.48 ($C_{16}H_9$), 127.54 ($C_{16}H_9$) 128.96 ($C_{16}H_9$), 130.56 ($C_{16}H_9$), 130.76 ($C_{16}H_9$), 131.24 ($C_{16}H_9$), 133.88 ($C_{16}H_9$). HRMS. Calc. for $C_{42}H_{48}N_5Cl_5$ 800.1431, obs. 800.1846.

3. Results and discussion

Reaction of the corresponding amine and 1-pyrenecarboxaldehyde gave Schiff-base derivatives that were reacted without further purification with $NaBH_4$ to obtain the receptors L^1, L^2, L^3 and L^4 (see Scheme 1) [19]. The receptors were isolated in their chlorohydrate form. ^1H NMR spectra of the receptors show pyrenyl protons in the 7.5–8.5 range and CH_2 groups as multiplets between 2.5 and 3.0. ^{13}C NMR, elemental analysis and mass spectra of L^1–L^4 were also in agreement with the proposed formulation.

v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate, 25 °C). Table 1 shows the protonation constants. Both L^1 and L^2 behave as tetra-protic bases and their basicity constants are similar to those obtained for other open-chain tetraazaalkanes [20]. Table 2 shows the complex stability constants found for L^1 with Cu^{2+} and for L^2 with Cu^{2+} and Zn^{2+}. For Cu^{2+} similar stability constants have been obtained for both L^1 and L^2 ligands. The logarithms of the stability constant for the formation of the complexes $[Cu(L^1)]^{2+}$ and $[Cu(L^2)]^{2+}$ are 13.50 and 13.70, respectively. These values are similar to those obtained for the formation of copper complexes with the analogous tetraamine 1,12-diferrocenyl-2,5,8,11-tetraazadodecane (L^5) (analo-

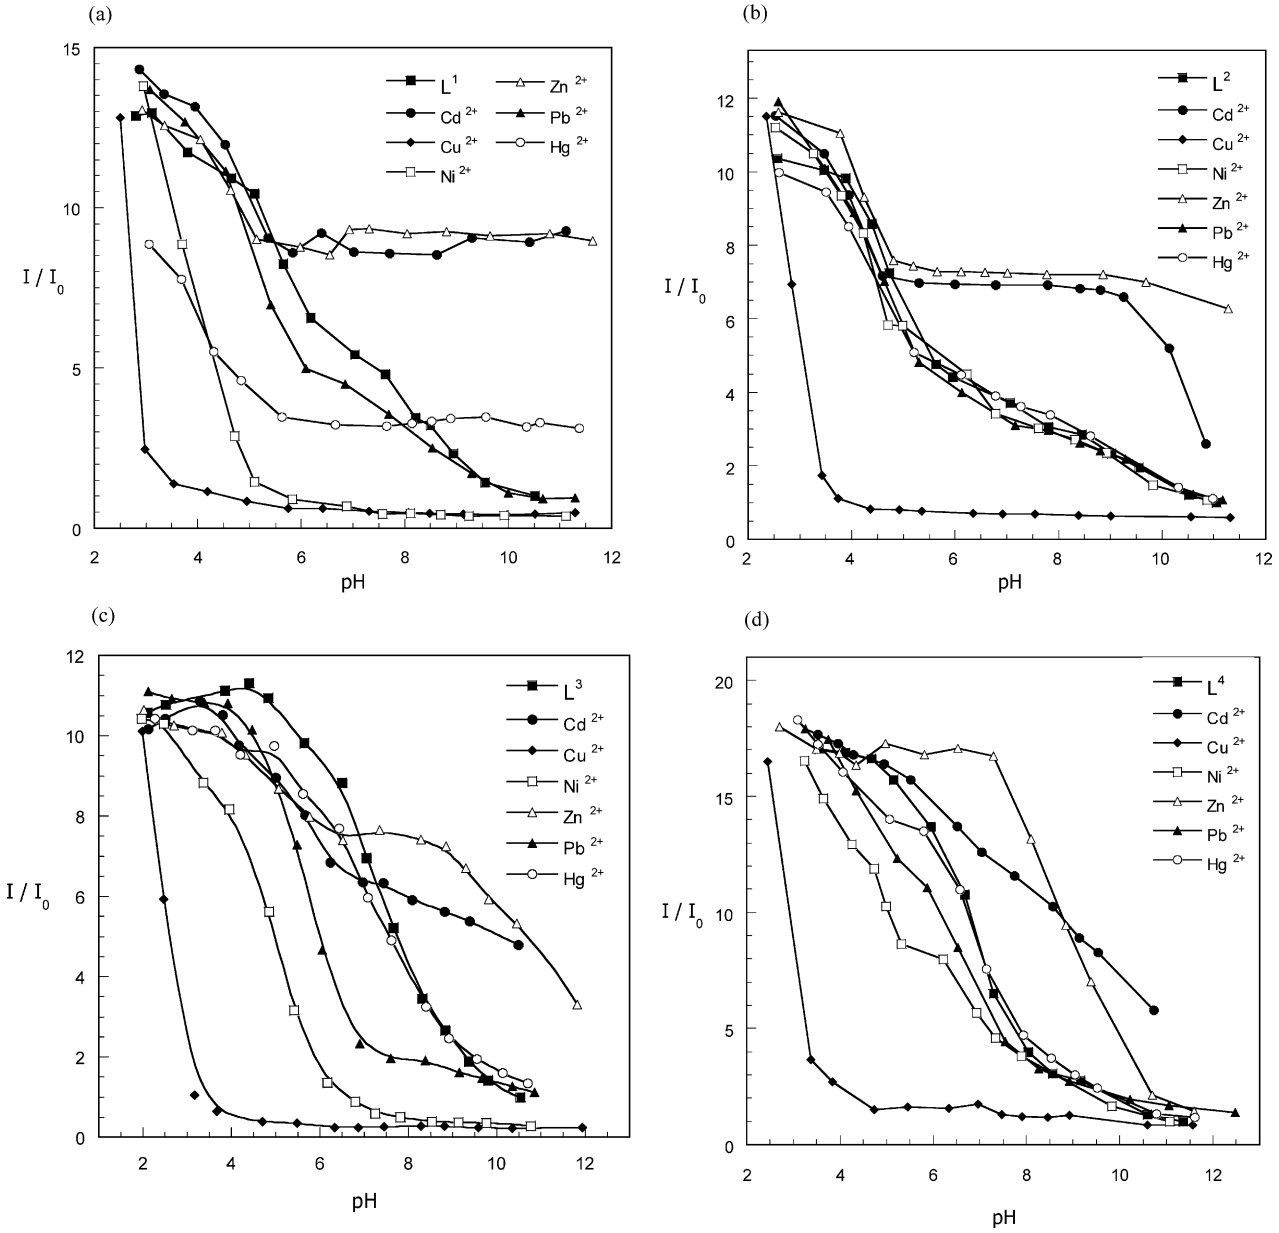

Fig. 1. Fluorescence emission intensity vs. pH for the systems (a) L^1–H^+–M^{2+}, (b) L^2–H^+–M^{2+}; (c) L^3–H^+–M^{2+} and (d) L^4–H^+–M^{2+}. M^{2+}=Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+} (λ_{ex} = 340 nm, λ_{em} = 395 nm).

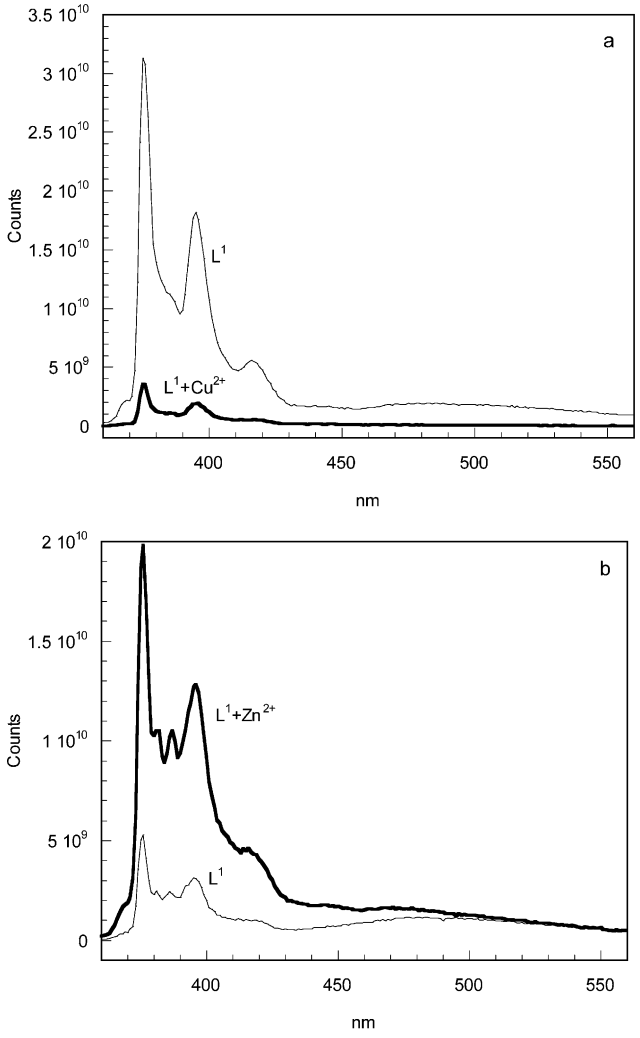

Fig. 2. Fluorescence emission spectra for (a) L^1 and L^1 in the presence of Cu^{2+} cation at pH 3.0, (b) L^1 and L^1 in the presence of Zn^{2+} cation at pH 9.0 ($\lambda_{ex} = 340$ nm, concentration of ligand and metal ions were equal and approximately 1.0×10^{-4} mol dm^{-3}).

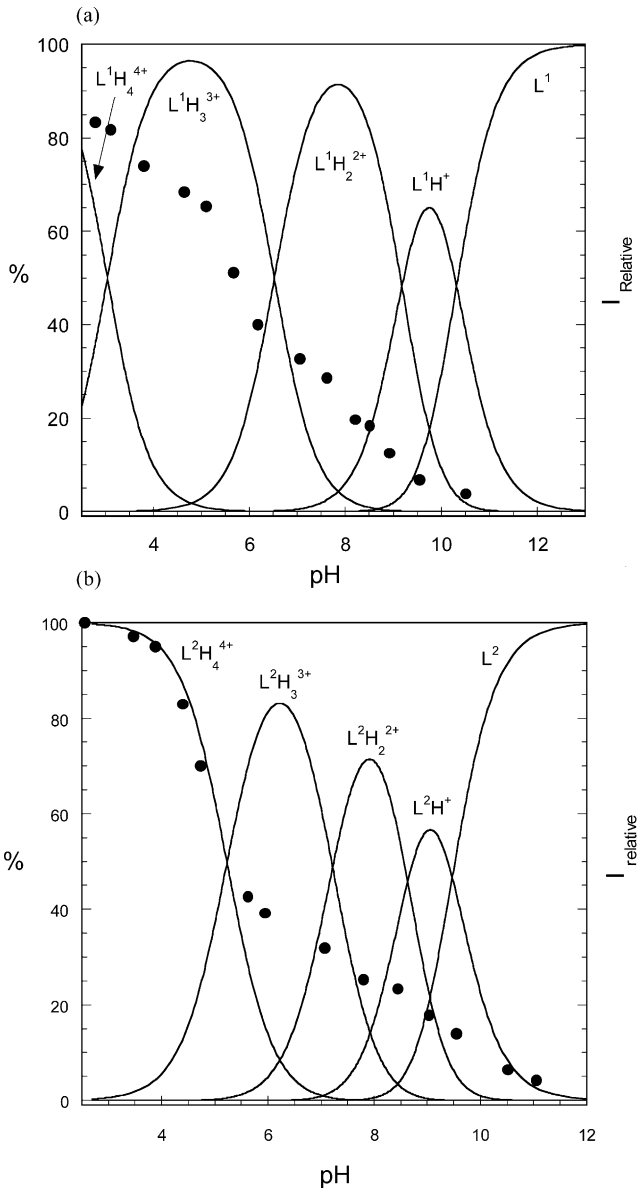

Fig. 3. Distribution diagrams of the species for (a) L^1–H^+ and (b) L^2–H^+ (full line) and the fluorescence emission titration curves (●) for those systems (concentration of L^1 and L^2 were equal and approximately 1.0×10^{-4} mol dm^{-3}, acetonitrile–water 70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate, 298.1 K).

gous to L^2 but functionalised with ferroceneylmethyl groups) [20]. In this case, the logarithm of the constant for the formation of the $[Cu(L^5)]^{2+}$ complex was 14.34 in water. These values obtained for L^1 and L^2 with copper are remarkably lower that than found for the analogous non-functionalised ligand *tta* [20]. In water, the logarithm of the stability constant found for the formation of the $[Cu(tta)]^{2+}$ complex was 20.4. Despite the use of a different solvent, this large difference between the stability constants of L^1, L^2 and that of the *tta* with Cu^{2+} could be attributed to the different number of nitrogens coordinating the metal cation. Thus, the logarithm of the first protonation step of the species $[Cu(L)]^{2+}$ $\{[Cu(L)]^{2+} + H^+ = [Cu(HL)]^{3+}$, $\log K = 7.12$ for L^1 and $\log K = 7.28$ for $L^2\}$ are larger than the logarithm of the third protonation step of the corresponding ligand $\{(H_2L)^{2+} + H^+ = (H_3L)^{3+}$, $\log K = 6.53$ for L^1 and 7.12 for $L^2\}$. In contrast, the $[Cu(tta)]^{2+}$ complex shows a logarithm for the first protonation constant lower than the third protonation of the free *tta* amine (3.5 and 6.67, respectively), indicating that the protonation of the $[Cu(tta)]^{2+}$ complex involves the cleavage of M–N bonds and suggesting that the number of nitrogens coordinating the Cu^{2+} cation in the $[Cu(tta)]^{2+}$ complex is four. This is not the case for $[Cu(L)]^{2+}$ ($L = L^1$ or L^2) for which the stability constants suggested that the number of coordinated nitrogens are less than four. The large difference in stability constants between *tta* and L^1 or L^2 (due to the different number of coordinated nitrogens atoms to the metal cation) has to the attributed to the

presence of bulky pyrene groups in the functionalised L^1 and L^2 receptors. The logarithm of the stability constant for the formation of the $[Zn(L^2)]^{2+}$ complex is much lower than that found for Cu^{2+}. A detailed study of the stability constants for the L^2–Zn^{2+}–H^+ system also suggests that the number of nitrogen atoms coordinating the Zn^{2+} metal cation in the $[Zn(L^2)]^{2+}$ complex is less than four.

5. Cation sensing

The cation sensing behaviour of receptors L^1, L^2, L^3 and L^4 in the presence of the metal ions Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+} was studied in acetonitrile–water 70:30 v/v as a function of the pH. The relative fluorescence intensity versus pH for L^1, L^2, L^3 and L^4 are shown in Fig. 1(a–d), respectively. The fluorescence emission of the receptors L^1–L^4 is pH-dependent. Maximum fluorescence emission was found for all receptors at acidic pH (when protonated). At basic pH there is a partial quenching. This is a similar behaviour to that found for analogous open-chain polyazaalkanes functionalised with anthrylmethyl groups [21]. At basic pH there is a photo-induced electron transfer form the lone pair of the nitrogen atom from the amines to the photo-excited pyrene group. When the pH is acid, the amines are protonated and the photo-induced electron-transfer process from the nitrogen to the pyrene is inhibited [22].

In the presence of metal ions three different behaviours are observed; namely, fluorescence enhancement, fluorescence quenching and no effect. Fluorescence enhancement is observed at basic pH for the diamagnetic cations Zn^{2+} and Cd^{2+} [23]. For all four receptors there is an enhancement of the fluorescence in the 7–10 pH range in the presence of these two cations. The maximum enhancement is observed for L^1 at pH 10–11 (enhancement factor of ca. 10). In contrast to this enhancement behaviour some other metal ions induce in all receptors a fluorescence quenching. This is the case for the paramagnetic cations Cu^{2+} and Ni^{2+} [24]. The quenching is more remarkable for Cu^{2+}. There is also a fluorescence quenching in the presence of Ni^{2+} for the receptors L^1, L^3, and in a lesser extension for L^4. At acid pH there is a remarkable selective sensing of Cu^{2+} using

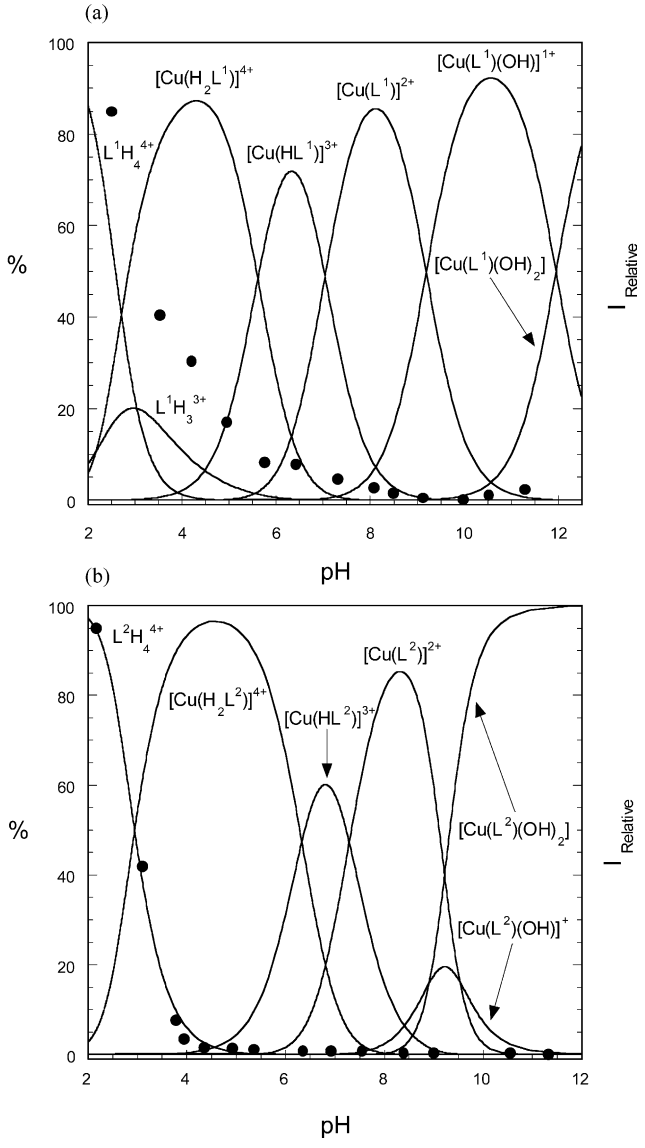

Fig. 4. Distribution diagrams of the species for (a) L^1–Cu^{2+}–H^+ and (b) L^2–Cu^{2+}–H^+ (full line) and the fluorescence emission titration curves (●) for those systems (concentration of L^1, L^2 and Cu^{2+} were equal and approximately 1.0×10^{-4} mol dm^{-3}, acetonitrile–water 70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate, 298.1 K).

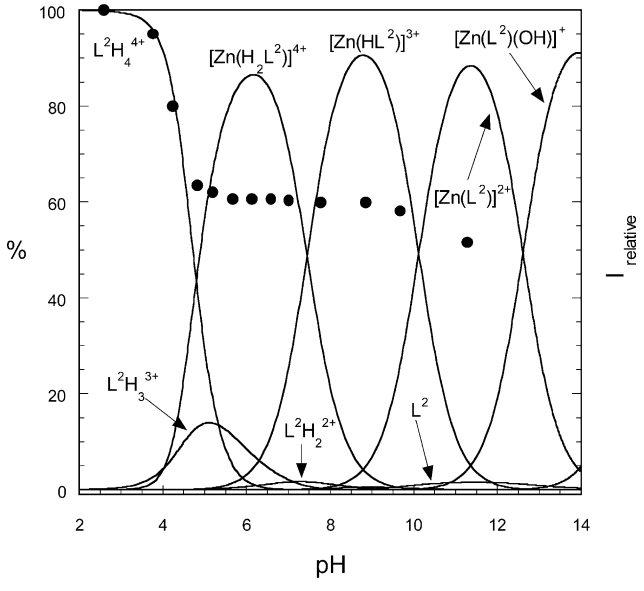

Fig. 5. Distribution diagrams of the species for the L^2–Zn^{2+}–H^+ system (full line) and the fluorescence emission titration curves (●) for those systems (concentration of L^2 and Zn^{2+} were equal and approximately 1.0×10^{-4} mol dm^{-3}, acetonitrile–water 70:30 v/v, 0.1 mol dm^{-3} tetrabutylammonium perchlorate, 298.1 K).

receptor L^2. A quenching factor of approximately 8 is found for Cu^{2+}, whereas other metal cations (Ni^{2+}, Zn^{2+}, Cd^{2+}, Hg^{2+} and Pb^{2+}) do not change the fluorescence behaviour of the L^2 receptor. Neither Hg^{2+} nor Pb^{2+} have any remarkable effect on the fluorescence emission of L^2 and L^4. Addition of Hg^{2+} to a solution of L^1 results in a partial fluorescence quenching in the 3–8 pH range, whereas Pb^{2+} has little effect. In contrast, receptor L^3 is able to sense Pb^{2+} in the pH range 5–9 whereas Hg^{2+} does not induce any effect. Emission spectra of L^1 in the absence and in the presence of Cu^{2+} and Zn^{2+} cations at different pH values (pH 3.0 for the system L^1+Cu^{2+} and pH 9.0 for the system L^1+Zn^{2+}) are shown in Fig. 2.

Fig. 3 shows the distribution diagrams of the L^1–H^+ and L^2–H^+ systems and the fluorescence emission (in arbitrary units) of L^1 and L^2 as a function of the pH. From this figure it can be seen that the fluorescence emission intensity increases remarkably when the species $(H_2L^1)^{2+}$, $(H_3L^1)^{3+}$ and $(H_4L^1)^{4+}$ exists. The maximum fluorescence emission is observed for the tetraprotonated species $(H_4L^1)^{4+}$. For L^2 a similar behaviour is observed. Fig. 4 shows the distribution diagram for the L^1–Cu^{2+}–H^+ and L^2–Cu^{2+}–H^+ systems and the relative fluorescence emission as a function of the pH. The maximum fluorescence emission is found when the metal cation is not coordinating the ligand at acid pH. When the pH is basified an abrupt decrease of the fluorescence emission is observed. This corresponds to coordination of the copper cation. Thus the species $[Cu(L)(OH)_2]$, $[Cu(L)(OH)]^+$, $[Cu(L)]^{2+}$, $[Cu(HL)]^{3+}$ and $[Cu(H_2L)]^{4+}$ quench the fluorescence emission significantly. Fig. 5 shows the distribution diagram for the L^2–Zn^{2+}–H^+ system and the fluorescence emission. The fluorescence behaviour of the Zn^{2+} species is very different to that of the Cu^{2+} cation and the $[Zn(L)(OH)_2]$, $[Zn(L)(OH)]^+$, $[Zn(L)]^{2+}$, $[Zn(HL)]^{3+}$ and $[Zn(H_2L)]^{4+}$ species do not quench the fluorescence significantly as do the analogous copper complexes. This is a similar behaviour to that reported for polyazaalkanes functionalised with anthracene [21–24].

6. Anion sensing

The fluorescence behaviour of receptors L^1, L^2, L^3 and L^4 was studied as a function of the pH in the presence of the anions chloride, bromide, iodide, sulfate, phosphate and ATP. Despite the well-known ability of the polyamines to act as anion receptors, the curve of the fluorescence emission intensity versus pH of L^1–L^4 is not modified in the presence of those anions. This contrasts with the selective ATP sensing found for related systems containing anthryl signalling subunits [25].

7. Conclusions

We have synthesised and characterised the new ligands L^1, L^2, L^3 and L^4 containing pyrene groups as signalling subunits and amino groups as binding sites. The protonation, coordination and fluorescence behaviour of those ligands has been studied in acetonitrile–water 70:30 v/v mixtures. The new ligands have proved to be suitable chemosensors for the fluorimetric sensing of certain metal cations. All four receptors show a remarkable fluorescence enhancement at basic pH in the presence of the Zn^{2+} and Cd^{2+} metal cations. Addition of Cu^{2+} to acidic solutions of the L^1–L^4 receptors results in a remarkable quenching of the fluorescence emission.

Abstract

A method based on the use of capillary zone electrophoresis (CZE) is proposed for the determination of the heterologous protein bovine pancreatic trypsin inhibitor (BPTI) expressed in yeast. *Saccharomyces cerevisiae* cells were transformed with plasmid pCB235U and the amount of inhibitor expressed in yeast was measured both in the culture medium (supernatant) and the cell extract. Supernatant samples were investigated by the CZE method preceded by affinity chromatography (the BPTI yield was between 2 and 5 μg ml^{-1}); direct determination of BPTI in cell extract was performed taking advantage of the complex formation of BPTI and trypsin (BPTI yield was 5 μg ml^{-1}). © 2002 Elsevier Science Ltd. Keywords: Capillary electrophoresis; Hydrophobic interaction chromatography; Heterologous protein; BPTI; *Saccharomyces cerevisiae*

1. Introduction

Bovine pancreatic trypsin inhibitor (BPTI), commonly known as aprotinin, is widely used in clinical and biochemical research; it is a strongly basic protein (isoelectric point close to 10.5, $M_r = 6512$ Da) with a remarkable stability to heat, acid or basic treatment, organic solvents and proteolytic degradation; it strongly inhibits trypsin as well as various trypsin-like enzymes [1].

Various immunological or enzyme assays for the determination of the polypeptide concentration were proposed [2–6]. Immunological assays [2–4] are specific and highly sensitive, but they require relatively complex and time-consuming sample preparations. Furthermore, immunological methods show a non-linear calibration function, which does not go through the origin: calibration based on non-linear standard curves is tedious, and reproducibility varies over the measuring range. The enzymic methods [1,5,6] are based on the BPTI inhibition of bovine trypsin-catalysed hydrolysis of an appropriate chromogenic substrate, under defined conditions, followed by spectrophotometric detection. BPTI undergoes a reversible reaction with bovine trypsin at about pH 8.0 to form a very stable complex with 1:1 stoichiometry [1]. These procedures can only be used with relatively pure inhibitor samples; they also posses rather low sensitivity, involve an indirect determination procedure and are limited by competition between the substrate and the inhibitor for the active center of the enzyme.

Therefore, the development of economical, time-saving, routine, direct assay systems which allow a reliable estimation of BPTI in various biological matrices is of interest. In previous papers [7–11] we have considered the direct determination of BPTI in pre-purified solutions, by using various HPLC columns with different hydrophobicities. In a recent work [12], carried out by capillary zone electrophoresis (CZE), we describe the effects of inhibitor interaction with trypsin on the electrophoretic pattern.

It is known that the yeast *Saccharomyces cerevisiae* is recognized as an ideal eukaryotic microorganism used for biological and genetic studies: BPTI is representative of the class of proteins well suited to yeast expression

and it has been studied as a model system for the folding of globular polypeptide domains and for secretion [13,14]. Owing to higher efficiency and resolution, shorter analysis time and the lower operating cost of CZE technique in comparision with HPLC, in particular when highly complex matrices are examined, and availing ourselves of previous experience, we developed a CZE approach to the direct determination of BPTI expressed in different laboratory strains of *S. cerevisiae*.

In this paper, we propose a direct electrophoretic assay which allows a reliable routine estimation of effective inhibitor concentrations in such biological matrices. The method permits a specific and direct determination of BPTI; the analysis of the inhibitor is accomplished without the use of any substrate and is effective in very diluted solution.

2. Experimental

2.1. Reagents and materials

Buffer 1: 0.1 M sodium phosphate buffer [NaH_2PO_4–Na_2HPO_4], pH 7.2. Buffer 2: 0.1 M sodium phosphate buffer [H_3PO_4–$Na_2H_2PO_4$], pH 2.5. Buffer 3: 1: 2 dilution (0.05 M) of buffer 2. Buffer 4: 0.1 M sodium hydrogencarbonate in 0.5 M sodium chloride, pH 8.3.

HPLC grade ammonium sulphate and buffer 2 were purchased from Bio-Rad (Richmond, VA, USA); bovine Trypsin was from Sigma (St. Louis, MO, USA) and native BPTI, as physiologic solution, was from Istituto Behring (Scoppito, L'Aquila, Italy). All other chemicals were of analytical grade.

A stock solution of bovin trypsin was prepared by dissolving the appropriate amount of commercial enzyme in buffer 2 to yield a 1 mg ml^{-1} solution. A stock solution of native BPTI was prepared by diluting 100 μl of physiologic solution with 900 μl of buffer 1. Working standard solutions were prepared by diluting stock solutions with the appropriate buffer. Stock and standard solutions were stored at 4 °C when not in use. Information concerning the stabilities of stock and standard solutions has been previously reported [7–12].

Bovine trypsin was bound to cyanogen bromide (CNbr)-activated Sepharose 4B according to the method of the manufacturer (Pharmacia, Uppsala, Sweden); prolonged washing cycles of the affinity chromatography column (Econo columns, 10 × 1.0 cm I.D. (Bio-Rad)) with solutions of alternately high and low pH were necessary to obtain an accettable HPLC background.

S. cerevisiae strains, RSY12 and RS112, constructed by Robert H. Schiestl (UCLA, Los Angeles, CA, USA) were available in our laboratory. The BJ5464 strain was provided by K. Dane Wittrup (MIT, Cambridge, MA, USA). Yeast strains were transformed with the plasmid pCB235U which was obtained from K. Dane Wittrup (MIT); yeast transformation was performed as described by Gietz and Schiestl [15]. Liquid and solid media were prepared according to a standard procedure [16].

All the strains of *S. cerevisiae* were maintained in complete medium. They were grown for 24 h in a culture medium containing glucose and then were resuspended in a medium containing galactose to induce expression of BPTI. Yeast cells (10^8 cells ml^{-1}) were inoculated in 20–50 ml liquid medium lacking uracile plus galactose for 24 h at 30 °C. The cells (5×10^9) were collected by centrifugation at 4390 g for 5 min and washed with ultrapure water; the cell extract was prepared as described by Kimmerly et al. [17]. Subsequently, the cells were incubated for 96 h at 30 °C in galactose medium, the culture was centrifuged and the supernatant collected for analysis.

Cell extracts were either stored at −70 or at −20 °C; whereas the supernatants were stored at 4 °C. All chemicals were stored as recommended by the manufacturer. Water used in every operation was deionized through a Milli-Q water purification system (Millipore, Bedford, MA, USA).

Before injecting cell extract in CZE each sample was clarified to avoid formation of colloidal suspensions; for this purpose samples were ultracentrifuged through a 0.2 μm Anopore Plus filter (Whatman). All solutions were filtered through a Millipore 0.45 μm filter.

2.2. Apparatus and operating conditions

2.2.1. Chromatography

Hydrophobic interaction chromatography (HIC) measurements were carried out using a LKB Pharmacia DfB HPLC System One which includes a LC 2249 gradient pump, variable-wavelength 2141 monitor connected to a 2221 integrator (LKB-Pharmacia). The UV detector was operated at 220 nm. A Model 7125 sample injector (Rheodyne, Cotati, CA, USA) equipped with 100-μl loop was used. The separations were performed by a TSKgel Phenyl-5PW (TosoHaas), at room temperature (r.t.) and a flow-rate of 1.0 ml min^{-1} with a 30 min linear salt-gradient from 100% high salt buffer (buffer 1, 1.8 M ammonium sulphate) to 100% low-salt buffer (buffer 1). The mobile phase as well as all the solutions were filtered through a 0.45 μm cellulose acetate filter (Millipore). When necessary, the eluted fractions were recovered by means of a Pharmacia Frac-100 Collector.

2.2.2. Electrophoresis

The CZE experiments were performed with a Biofocus 2000 Capillary Electrophoresis System (Bio-Rad) equipped with a non-coated silica capillary (total length = 50 cm, length to detector 45.5 cm and internal diameter = 50 μm).

The following optimised operating conditions were selected. The capillary was conditioned prior to its first use by flushing with 0.1 M NaOH (15 min), ultrapure water (10 min), buffer 2 (10 min), ultrapure water (5 min) and finally running buffer (15 min). The running buffer was buffer 3 with a voltage of 20 kV. Samples were injected by hydrodynamic injection at 5 psi × s. Electropherograms were recorded at 200 nm. The capillary was flushed with buffer 3 before starting daily experiments (15 min) and between two separations (3 min); it was filled with ultrapure water when not in use. Triplicate injections of the solution were performed and average corrected peak areas (area/migration time) were used for the quantitation. All experiments were carried out at 20 °C.

3. Procedures

3.1. Analysis of yeast supernatant

A known volume of sample (20–50 ml) was adjusted to pH 8.0 and applied to the trypsin-Sepharose 4B column (bed volume ca. 1.0 ml), previously equilibrated with buffer 4. The column was washed with at least ten bed volumes of starting buffer to remove unbound substances prior to elution. BPTI, tightly bound to the immobilized trypsin, was fully recovered in a 5.0 ml calibrated flask by elution, in order, with the following volumes and concentrations of phosphoric acid: 0.8 ml (0.01 M), approximately 1.0 ml (1.0 M) and 2.0 ml (0.01M). After adjustment of the pH to the value of 2.5, the resulting solution was brought to the mark with ultrapure water and appropriate aliquots were injected into the CZE capillary or in HIC column. The concentration of BPTI was determined from a calibration curve of peak areas versus amounts (μg) of inhibitor, constructed from directly injected BPTI standard solutions.

3.2. Analysis of cell extract

To a known volume of sample (3 ml) 1.0 M phosphoric acid was added to bring the pH value to approximately 2.5 and the mixture was gently stirred for 10 min. The precipitate was removed by centrifugation (4390 *g*) for 40 min and the supernatant was further centrifuged through a 0.2 μm Anopore Plus membrane filter to drive away the persistent cloudiness. The pH value of the resulting clear solution was adjusted to approximately 7.0 and a moderate excess (10–20 μmol) trypsin was added to allow the rapid formation of the BPTI–trypsin complex. The mixture was collected in a 5 ml calibrated flask and brought to the mark with buffer 3. An aliquot of the resulting solution was assayed by CZE; the concentration of the inhibitor was determined by calibrated additions of BPTI to standard solutions containing trypsin.

4. Results and discussion

In order to produce BPTI, *S. cerevisiae* cells were transformed with the expression vector pCB235U. Selection of transformed yeast cells was carried out in solid medium lacking uracile; BPTI expression was induced by growth in galactose conditions. By contrast, no BPTI presence was detected in cells grown under glucose conditions. BPTI expression led to secretion into the culture medium and to intracellular accumulation.

4.1. Analysis of yeast supernatant

The proposed procedure includes a specific isolation of BPTI on immobilized trypsin; this step is followed by analysis by CZE technique.

Preliminary experiments were carried out under the same conditions used for the analysis of BPTI by HIC [9–11]. The possibility of determining the inhibitor by direct injection of an aliquot of the yeast supernatant solution was discarded, because the chromatogram obtained from injected fresh galactose medium, where the inhibitor has not been induced, already showed a wide absorption in the time range where the BPTI peak appears. Instead, the chromatographic peak for BPTI was obtained by injecting an aliquot of the solution resulting after the passage of the yeast supernatant through the column of immobilized trypsin (Fig. 1,

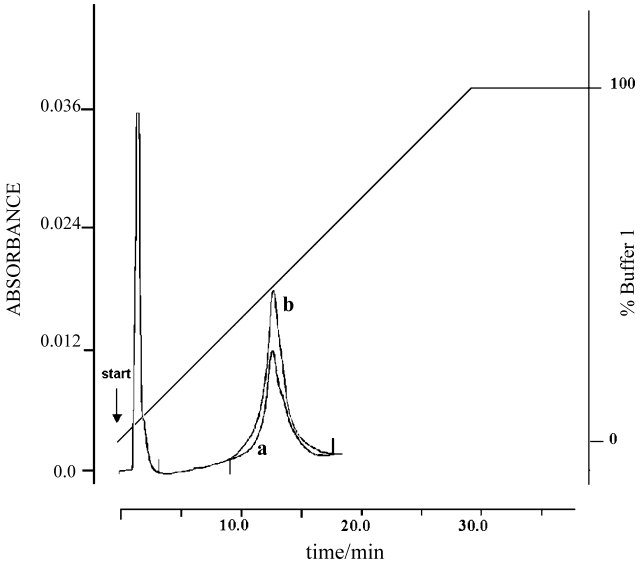

Fig. 1. Chromatogram of heterologous BPTI (29.5 μg ml^{-1}) before (curve a) and after addition of native BPTI (100 μl, 4×10^{-6} M) (curve b). Conditions: TSKgel Phenyl-5PW column; flow rate, 1.0 ml min^{-1} with 30 min linear gradient ammonium sulphate 1.8–0 M in 0.1 M sodium phosphate buffer (pH 7.2); volume injected 100 μl; $\lambda = 280$ nm.

curve a). The peak ascribed to the inhibitor appeared at the expected retention time; an identically shaped peak, without distortions, was obtained (Fig. 1, curve b) from the injection of another aliquot of the same solution, spiked with the standard solution of the inhibitor.

Owing to the enrichment effect resulting from the affinity chromatography step, the possibility of revealing the BPTI signal by CZE technique was considered. Fig. 2(a) shows the electrophoretic peak: its migration time coincides with the previously reported time [12].

To ascertain that no other components interfered with BPTI, 50 ml of a freshly prepared galactose medium (blank) was subjected to the procedure described in this work: the results demonstrated that even high sample volumes do not produce interfering peaks.

A calibration equation for the external addition method was previously established [12] by the regression of the peak area on standard concentration with a correlation coefficient higher than 0.9998. The limit of determination, defined here as the lowest injected amount of BPTI that gave a 5:1 signal-to-noise ratio, was 2 μg ml^{-1}.

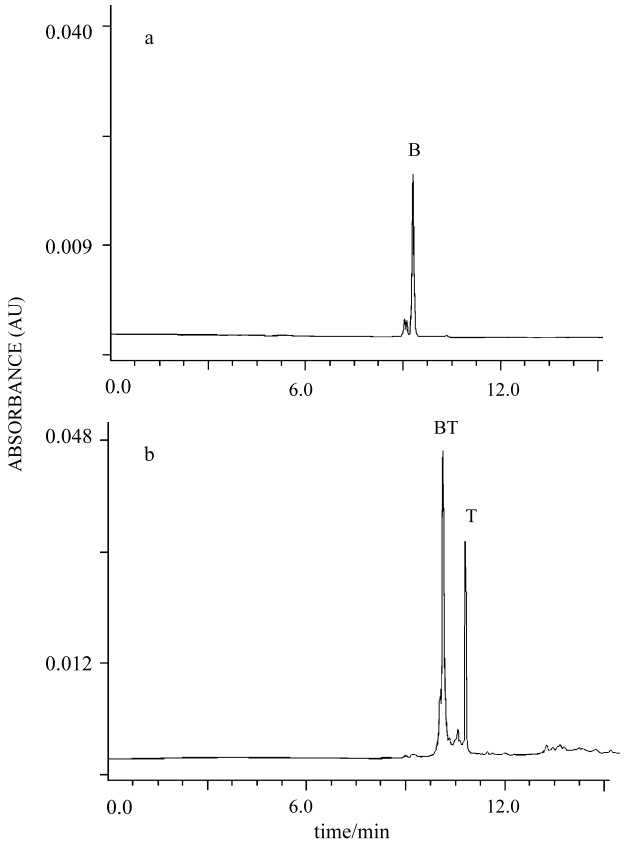

Fig. 2. (a) Electropherogram of heterologous BPTI (B) (1.0×10^{-5} M); (b) electropherogram of the same sample in the presence of bovine trypsin (T) in excess (2.5×10^{-5}); BT represents the inhibitor–trypsin complex. Conditions: 50 μm × 50 cm non-coated silica capillary containing 0.05 M sodium phosphate buffer (pH 2.5). Hydrodynamic injection at 5 psi × s; $V = 20$ KV; $T = 20$ °C; $\lambda = 200$ nm.

Recoveries of BPTI from spiked fresh galactose medium samples were determined in duplicate at BPTI concentrations 5.0 and 10.0 μg ml^{-1}. An identical series of BPTI amounts in buffer standard solution provided the 100% values. Three injections for each sample, test and reference, were performed. The mean (±S.D.) recovery from the six determinations over the calibration range indicated was 99.2 ± 1.24%.

From the results of the described experiment it was concluded that sensitivity due to the preconcentration of the inhibitor; accuracy, precision and freedom from interference make the described procedure a suitable routine tool for monitoring the levels of BPTI in yeast supernatant. Table 1 shows the results obtained by applying the method to the supernatant collected from *S. cerevisiae* strains (RSY12, RS112, BJ5464); the expression levels ranged between 2 and 5 μg ml^{-1}.

4.2. Analysis of cell extract

A fast determination of BPTI in cell extracts obtained from BJ5464 strain was considered representative of all *S. cerevisiae* strains analyzed. In fact, the three strains (RSY12, RS112, BJ5464) showed almost the same profile when analyzed either by CZE or HIC, thus indicating that cell extract and supernatant have nearly the same composition.

A typical electropherogram obtained from cell extract treated as described under 'Procedures', but with no added trypsin, is reported in Fig. 3(a). The electrophoretic profile shows numerous peaks; however, the high efficiency and resolution achieved by CZE technique enabled us to single out peak B as that due to the inhibitor we looked for. This assumption was supported through spiking experiments with a BPTI standard solution and by comparison of the electrophoretic pattern with that displayed by the yeast extract from cells grown on a glucose medium (i.e. under no induction conditions). Decisive confirmation was achieved through the analysis of the BPTI-trypsin complex. As it has recently been demonstrated [12], the electrophoretic signal of the complex BPTI–trypsin appears at a migration time somewhere between those of pure BPTI and trypsin. When increasing amounts of

Table 1
Yield of inhibitor (BPTI) produced by different strains of *S. cerevisiae* both in supernatant and cell extract

Strain	Amount of BPTI (μg ml^{-1})	
	Supernatant	Cell extract
RSY12	4.8	n.d
RS112	2.2	n.d
BJ5464	4.2	5.0

n.d: Not determined.

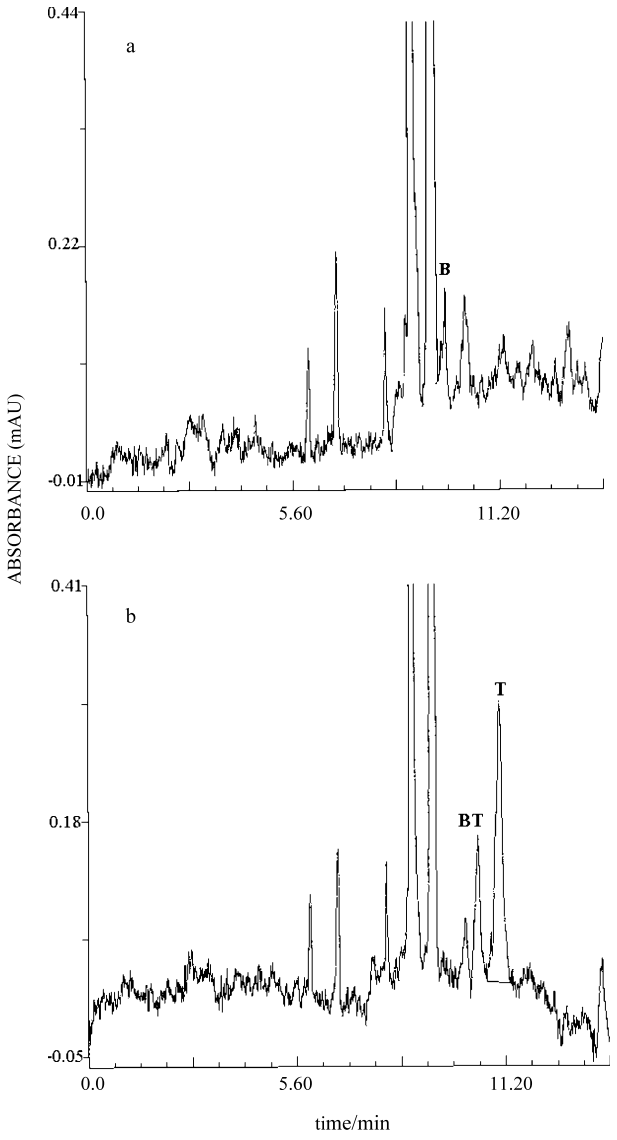

Fig. 3. (a) Electropherogram of cell extract, amount of BPTI (B) 1.6 μg ml^{-1}; (b) Electropherogram of the same sample in the presence of bovine (T) trypsin in excess; BT represents the inhibitor–trypsin complex. Electropherogram obtained from cell extract treated as described under 'Procedures'. Conditions: 50 μm × 50 cm non-coated silica capillary containing 0.05 M sodium phosphate buffer (pH 2.5). Hydrodynamic injection at 5 psi × s; $V = 20$ KV; $T = 20$ °C; $\lambda = 200$ nm.

trypsin are added to a solution containing BPTI, the corresponding electrophoretic patterns show the progressive decrease of the BPTI peak and the increase of the complex peak: in the presence of excess trypsin the disappearance of the BPTI peak is paralleled by the increase of the trypsin peak. The same result was obtained with heterologous BPTI (Fig. 2(b)).

By adding excess trypsin to the solution of cell extract, the corresponding electropherogram shows (Fig. 3(b)) a change with respect to that reported in Fig. 3(a) which agrees upon the appearance and disappearance of the described peaks. The wider area of the complex peak allows an enhancement of the sensivity of the determination.

A calibration curve was constructed for the BPTI–trypsin complex from a series of standard working solutions (2–20 μg ml^{-1}) of BPTI to which an excess (five times molar concentration of inhibitor) of trypsin was added. The analytical recovery was found to be almost complete, the correlation coefficient (six points) being 0.9994. Limits of determination (0.5 μg ml^{-1}), limits of quantitation (1 μg ml^{-1})and coefficient of variation $< 4.0\%$ were ascertained by a series of experiments. In order to evaluate the possible matrix effect, the method of standard addition was used for the determination of BPTI in the cell extract. The calibration curves obtained by standard addition to the sample and by using external standard solutions were significantly parallel; owing to the limited number of determinations, the standard addition method was preferred. Each peak area was measured three times: the mean BPTI level in the cell extract was found to be 5.0 μg ml^{-1}.

The results obtained from the series of experiments performed to determine the amount of BPTI expressed into both the supernatants and the cell extract area are summarized in Table 1.

5. Conclusions

The results of the chromatographic and electrophoretic experiments in the biological matrices described above show that heterologous BPTI produced by the *S. cerevisiae* expression/secretion system is indistinguishable from the natural material. We have been able to detect and quantify low levels of BPTI with a direct method which is simpler and more rapid than the commonly used immunological assays. Given the increasing interest in genetically modified microorganisms and plants, which involve heterologous proteins, other experiments are in progress to apply the CZE method to detect specific heterologous proteins directly in yeast extracts.

Abstract

Uranyl–oxalate complex equilibrium in aqueous solution was studied by UV–Vis spectrophotometry. Due to high spectra correlation, derivative spectrophotometry was also applied during the search for the best chemical model. The absorption spectra of all the complexes were calculated and found in a good agreement with theoretical considerations. Overall protonation constants of oxalate, necessary for accurate calculation of uranyl–oxalate formation constants, were also determined under the same conditions and the following values were obtained $\log K_1 = 3.83 \pm 0.01$; $\log K_2 = 4.92 \pm 0.01$. Stability constants determined for the $[(UO_2)_p(C_2O_4)_q]^{2p-2q}$ species were: $\log \beta_{11} = 6.31 \pm 0.02$, $\log \beta_{12} = 11.21 \pm 0.07$, $\log \beta_{13} = 13.8 \pm 0.04$, $\log \beta_{23} = 18.5 \pm 0.2$, $\log \beta_{25} = 28.5 \pm 0.1$ ($I = 3.0$ M $NaClO_4$; 25 °C). The equilibrium constants were extrapolated to infinite dilution by applying specific ion interaction theory (SIT) and are the following: $\log \beta_{11}{}^0 = 7.41 \pm 0.01$, $\log \beta_{12}{}^0 = 11.80 \pm 0.02$, $\log \beta_{13}{}^0 = 13.96 \pm 0.07$. Formation of polynuclear $[(UO_2)_2(C_2O_4)_3]^{2-}$ and $[(UO_2)_2(C_2O_4)_5]^{6-}$ species was proved and confirmed independently by conductometry and vapor pressure osmometry. © 2002 Published by Elsevier Science Ltd.

1. Introduction

Modeling of chemical processes governing the migration of actinides and fission products requires reliable thermodynamic data concerning metal ion complexation. Knowledge of uranyl–oxalate complexation equilibrium is important as oxalate can be formed in nuclear waste depositories by decomposition of organic compounds. It is known that in aqueous solution, uranyl reacts with oxalate forming $[UO_2(C_2O_4)_n]^{2-2n}$ ($n = 1$–3) complexes and a great effort has been made to determine the reliable values of the stability constants under different conditions. Also protonated complexes were mentioned in the literature [1,2] to explain different grades of complexation as a function of pH. Potentiometry [3], solvent extraction [1,4], Raman spectroscopy [5], etc. methods have been used and the system is apparently well known. However, the stability constant of the complex $[UO_2(C_2O_4)_3]^{4-}$, $\log \beta_{13}$, is still not well established and there is great discrepancy in literature values. In 1969, using UV-spectrophotometry, Havel [6] determined a value for $\log \beta_3 = 11.0$ confirming the decrease of stepwise constants ($\log K_{11} = 5.99$, $\log K_{12} = 4.65$, $\log K_{13} = 0.36$ in 1 M $NaClO_4$). Also, structural–theoretical considerations with regard to the actual value of $\log K_{13}$ conclude that this should be relatively small, since a third oxalate is expected to bind differently to the uranyl than the first two oxalate molecules do [7]. Furthermore, studies of single-crystal X-ray diffraction of the mono-, bis- and trisoxalato dioxouranium(VI) compounds in solid state have been made [8–11] and they show that the third oxalate is actually bound differently.

Recently, Ferri et al. [12,13] developed a second kind electrode, based on the $Hg_2(C_2O_4)(s)$–Hg couple, which was used to determine the stability constants of $[UO_2(C_2O_4)_n]^{2-2n}$ ($n = 1$–3) complexes in 1, 2 and 3 M $NaClO_4$, ascribing the variation of $\log \beta_3$ (14.0 in 1 M and 15.2 in 3 M $NaClO_4$) to the different ionic strength employed. In that study, the third stepwise formation constant is $\log K_{13} = 3.45$ in 1 M $NaClO_4$ [12].

In spite of the fact that uranyl polynuclear complexes such as $M_2[(UO_2)_2(C_2O_4)_3]\cdot nH_2O$ with M = NH_4, K, Cs, Tl, and $M_6[(UO_2)_2(C_2O_4)_5(H_2O)_2]\cdot nH_2O$ with M = N_2H_5, NH_4, Na, K, Cs have also been known for a long

PII: S0277-5387(02)00947-6

time [8,14–16], their possible formation in aqueous solution has always been neglected. The only information published so far concerns the reaction (A)

$$[(UO_2)_2(C_2O_4)_5]^{6-} = 2\,[UO_2(C_2O_4)_2]^{2-} + C_2O_4^{2-} \quad (A)$$

with an equilibrium constant $K = 5 \times 10^{-7}$ [17].

Spectrophotometric study of the uranyl–oxalate system is complicated by photolysis and numerous investigators have studied it [2,18–22]. An UV–Vis spectrophotometric study of uranyl species also has to deal with high correlation of absorption spectra as this has been observed not only for hydrolyzed uranium(VI) species [23,24], but also for uranium(VI)–selenate complexes [25].

The aim of this paper is to perform a detailed multiwavelength spectrophotometric study (in UV–Vis range) in order to verify uranyl–oxalate stability constants, applying computational methods and investigating systematically the possible formation of polynuclear and protonated complexes in aqueous solution.

2. List of symbols

All the concentrations are expressed as molarities (mol dm^{-3}). c_L, total concentration of $C_2O_4^{2-}$; c_M, total concentration of UO_2^{2+} and $[H^+]$ the free hydrogen ion concentration. The equilibria of interest are:

$$rH^+ + C_2O_4^{2-} = H_rC_2O_4^{r-2} \quad (B)$$

$$pUO_2^{2+} + qC_2O_4^{2-} + rH = [(UO_2)_p(C_2O_4)_qH_r]^{2p-2q+r} \quad (C)$$

for which the equilibrium constants, expressed in terms of the concentrations, are defined by Eqs. (1)–(2):

$$K_r = [H_rC_2O_4^{r-2}][C_2O_4^{2-}]^{-1}[H^+]^{-r} \quad (1)$$

$$\beta_{pqr} = [(UO_2)_p(C_2O_4)_qH_r^{2p-2q+r}][UO_2^{2+}]^{-p}[C_2O_4^{2-}]^{-q} \times [H^+]^{-r} \quad (2)$$

For simplicity, β_{pq} means $r = 0$ and β_q means $p = 1$, $r = 0$.

3. Experimental

3.1. Chemicals

Stock solution of uranium(VI) perchlorate (1.66 M) was prepared as described elsewhere [23]. Sodium oxalate, potassium oxalate and oxalic acid, purity pro analysis, were purchased from Lachema (Brno, Czech Republic) and used as such without any further purification. Sodium perchlorate (from the same company) was recrystallized twice and traces of metals removed according to the procedure [26] and air-dried. Stock solution of 8.77 M $NaClO_4$ was analyzed, by drying defined volumes of the solution in a drying box at 120 °C to constant weight. Traces of perchloric acid in sodium perchlorate solution were determined by potentiometry. Concentrated perchloric acid (70%) was from Merck (Darmstadt, Germany).

3.2. Synthesis of $K_6[(UO_2)_2(C_2O_4)_5(H_2O)_2]\cdot 8H_2O$

The compound was prepared from a concentrated aqueous solution of $UO_2(C_2O_4)\cdot 3H_2O$ and $K_2C_2O_4\cdot H_2O$ mixed in stoichiometric ratio 2:3. The mixture was heated and then partly evaporated at 60 °C and formed crystals were isolated [8].

3.3. Apparatus

All emf and absorbance measurements were performed at 25.0 ± 0.2 °C, using $NaClO_4$ at constant perchlorate concentration, $[ClO_4^-] = 3.00$ M. A combined glass electrode 01-29 B of Monokrystaly (Turnov, Czech Republic) was used, in which the inner saturated potassium chloride solution of reference electrode was replaced with 3 M sodium perchlorate saturated with silver chloride. The emf of the cell was measured to ± 0.2 mV with a Radelkis OP-208 Precision Digital pH-meter (Budapest, Hungary). The electrode parameters were determined titrating a known amount of diluted perchloric acid by a standard sodium hydroxide solution also in 3 M $NaClO_4$. The free hydrogen-ion concentrations, $[H^+]$, were determined by calculating the $-\log[H^+]$ values from the measured emf by means of Eqn. (3),

$$E = E^\circ - g\log[H^+] + E_j \quad (3)$$

where, E° is the potential of the cell at $\log[H^+] = 0$, g the Nernstian slope given by the term $2.30259(RT/F)$ and E_j the liquid junction potential.

Spectrophotometric measurements were done on a single-beam, diode-array, HP 8452A spectrophotometer of Hewlett–Packard (Palo Alto, USA). A quartz cell with 1 cm of path-length was used.

3.4. Preparation of the solutions for experiments

Two different methods were used to mix oxalate and uranium(VI). In one method, the total uranyl plus oxalate concentration ($c_L + c_M$) was kept constant, while the total oxalate concentration (c_L) was varied (continuous variation or Job's method). In the other method, the total uranyl concentration (c_M) was kept constant, while the oxalate concentration was varied (molar-ratio method). In each experiment, the pH was fixed either with $HClO_4$ or NaOH and the emf was measured after every mixing. At least one of the quantities $-\log[H^+]$,

$c_M + c_L$ or c_M was varied in the different experiments. This represented more than 90 000-absorbance values for about 640 different spectra (solutions).

The vapor-pressure osmometry (VPO) measurements were done with a thermostated osmometer of Knauer (Berlin, Germany) and conductivity was measured with a conductometer type OK-104 and an electrode for conductivity type OK-0902P, Radelkis (Budapest, Hungary).

3.5. Computation

The number of light-absorbing species was estimated by SIBYLA [27] factor analysis program. The equilibria constants were calculated and refined with SQUAD [28], LETAGROP-SPEFO [29] or with OPIUM [30] least-squares programs. All experimental points were given unit weight in the least-square refinement. Hence, we had to use approximately the same number of experimental points in the regions where the different complexes were predominant.

The derivative spectra were calculated either with the standard software provided in HP-spectrophotometer or with a spreadsheet based on the Savitzky–Golay algorithm [31] and its corrections [32]. No differences in calculated derivative spectra were observed. First and third derivative spectra were calculated using a sixth order polynomial, while for second and fourth derivative, a fourth order polynomial was used. In all the cases, a 13-point convolution operation was employed.

4. Results and discussion

Equilibria in H^+–$C_2O_4^{2-}$–UO_2^{2+} system can be described by a general reaction (C). In order to make realistic and correct evaluation of uranium–oxalate equilibria, reliable values of oxalate protonation constants are needed and they have therefore been carefully checked.

4.1. H^+–oxalate system

The values of oxalate protonation constants in 3 M $NaClO_4$ were checked by spectrophotometry. As traces of carbonate in sodium hydroxide were absorbing strongly in the same region as oxalate, the protonation constants of oxalate were determined via titration of diluted sodium oxalate with perchloric acid.

An initial volume equal to 40 ml of 0.001 M of sodium oxalate was titrated with 0.1 or 0.8 M perchloric acid. The UV-spectra for 59 different hydrogen-ion concentrations and wavelengths in the range 200–250 nm (step 1 nm) were measured. The value of $-\log[H^+]$ was varied from 6.7 to 0.7 and the total concentration of oxalate was varied from 1.0 to 0.61 mM. An example of selected data is given in Fig. 1.

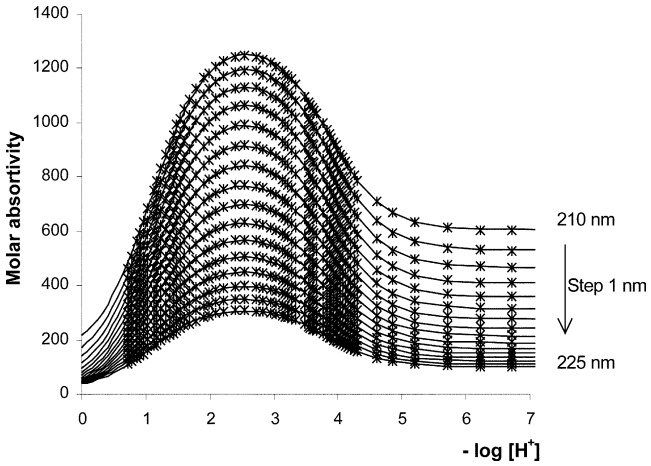

Fig. 1. The apparent absortivity of oxalate (A/c_L, where $c_L = 0.6$–1.0 mM) vs. $-\log[H^+]$. The stars are experimental points and the solid lines were calculated using the protonation constants ($\log K_1 = 3.83 \pm 0.01$and $\log K_2 = 4.92 \pm 0.01$) and molar absortivities obtained in this work.

Protonation constants were calculated with a SQUAD computer program and the complete data matrix (1770 absorbances) was evaluated with OPIUM. The resulting logarithmic constants agree up to the second decimal. Satisfactory agreement of protonation constants obtained in this work (Table 1) with those of literature was reached. For further calculations, the values $\log K_1 = 3.83$ and $\log K_2 = 4.92$ ($pK_{a1} = 1.09$, $pK_{a2} = 3.83$) were used.

4.2. Uranium(VI)–oxalate system

An example of absorption spectra in visible range concerning uranyl complexation with oxalate in acid solutions is given in Fig. 2. We have chosen to work at pH 4, as hydrolysis of uranyl ion or the formation of mixed uranyl–hydroxo–oxalate species [8,13] can thus be neglected. Increasing oxalate:uranyl ratio, the absorption bands of uranyl are more intense and a slight

shift toward higher wavelengths is observed. Results of factor analysis (FA) are summarized in Table 2. A factor is considered significant if the variance is larger than 0.01% [27]. Hence, the variance test suggests three factors. The fourth column holds the residual standard deviation of absorbance, $s_k(\mathbf{A})$. This value accepts a factor if the corresponding $s_k(\mathbf{A})$ is larger than the standard deviation of the measured absorbance. For two factors ($k = 2$), $s_k(\mathbf{A})$ is 0.00334 AU (absorbance units) which is larger than estimated experimental noise (± 0.001–0.002). Therefore, three factors (species) are needed to explain the data sufficiently as the spectra are very similar (and perhaps correlated).

Derivative spectra from the first up to the fourth derivative with the aim to prove the number of species formed in solution were also used. In this case, the value of the rank of derivative spectra matrices was also found to be equal to three. FA was applied systematically throughout the work also for other data.

Concluding, FA of normal and derivative spectra confirms the formation of three absorbing species in acid solution, which might be UO_2^{2+} and 1:1, 1:2 $[UO_2(C_2O_4)_n]^{2-2n}$ complexes.

4.3. Continuous variation method (CVM)

In spite of the fact that stoichiometry of uranium(VI)–oxalate species is well known, continuous variation method was applied here as a way to study the formation of 1:1 complex in acid solutions and the possible occurrence of protonated species. Job's plots for $c_L + c_M = 16.6$ mM and different pH are presented in Fig. 3. It is observed that as pH increases, the maximum shifts towards higher values of oxalate molar fraction. It means that in addition to 1:1 complex, complexes with a higher number of oxalates are starting to be formed. Selected data of CVM were treated by SQUAD program to determine the formation constants and testing

Experimental data: 38 spectra × 41 wavelengths (350–470 nm, step 3 nm); uranyl concentration: 4.1, 8.3 and 16.6 mM; oxalate concentration, 0–36 mM; $1.2 < -\log[H^+] < 3.7$.

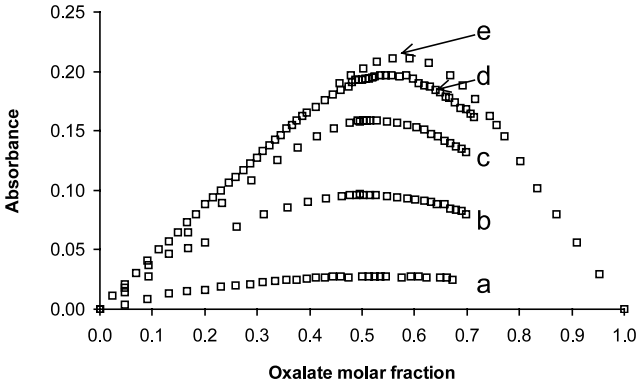

Fig. 3. Continuous variation curves (350 nm) for uranyl–oxalate system at $c_L + c_M = 16.6$ mM and different $-\log[H^+]$ values: (a) 0.0; (b) 0.5; (c) 1.0; (d) 1.5; (e) 2.4.

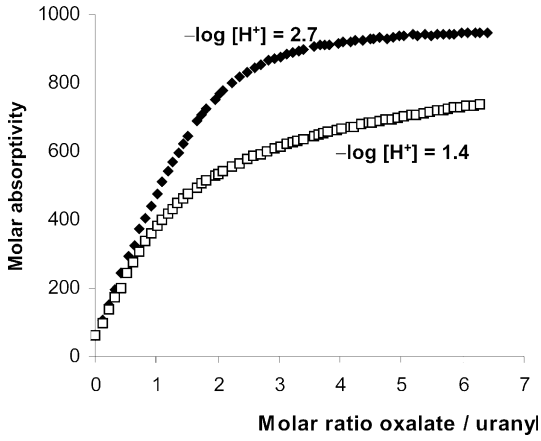

Fig. 4. Apparent molar absorbtivity of uranium(VI) (A/c_M, where, $c_M = 1.7$ mM) at 300 nm vs. ligand to metal molar-ratio.

different protonated species. No protonated species was accepted. The results of computation are presented in Table 3. For the experiments carried out at $-\log[H^+] = 1.5$, it was possible to calculate also $\log \beta_{12}$ in addition to $\log \beta_{11}$. Negligible difference in $\log \beta_{11}$ at $-\log[H^+] = 0.5$, 1.0 and 1.5 proves no formation of protonated complexes, which was also verified by factor analysis. The higher absorbances for higher pH and other changes in the range $0.5 < -\log[H^+] < 3.0$ are satisfactorily explained on the bases of acid–base equilibria involving oxalate and binary uranyl–oxalate complexes.

4.4. Molar-ratio method

In molar-ratio method, the total uranyl concentration is kept constant, pH was fixed (but measured through the whole experiment), and the concentration of oxalate was varied. Two examples of molar-ratio curves for 1.7 mM uranyl and different pH are shown in Fig. 4. Data matrix was divided to several parts according to uranyl concentration and also subdivided according to either the pH or the ligand to metal ion molar-ratio (θ). In each division and subdivision the data were evaluated, i.e. different species were tested and constants calculated with SQUAD program. Addition of 1:2 complex (uranium(VI):oxalate) greatly improved the fit. The initial calculations allowed rationalizing the data selection and implementing a good strategy for the final test of models and constants refinement. In the second evaluation stage, a typical calculation started with two sets of data for one metal concentration. The first set was a matrix (usually with $\theta \leq 3$ for pH 1.5 and $\theta \leq 1.5$ for pH 2.0) for the refinement of β_{11} and β_{12}. In the next step (generally with the remaining data) β_{12} and β_{13} were refined with β_{11} fixed together with the molar absortivities of 1:1 complex (obtained from previous experiments). Then returning to the first data to refine β_{11} while β_{13} and the molar absortivities of 1:3 complex were fixed. In this calculation step, the parameters of complex 1:2 were either fixed or refined. The whole procedure was repeated three to four times until the whole set of stability constants remained unchanged.

The results for different experiments and data subsets presented in Table 4 were calculated assuming only mononuclear species. In this table, the presence of 1:3 complex, $[UO_2(C_2O_4)_3]^{4-}$ was examined. Experiment 1 in Table 4 contains spectra in the UV-range (300–349 nm), where no new band is observed. Evaluation of experiments 2 and 3 takes data in the visible range, where different bands are observed (cf. Fig. 2). Different data were evaluated in this way with similar results, while $\log \beta_{13}$ obtained was lower than 14. Generally, these results show acceptable consistency among $\log \beta$ values, although some slight discrepancy for $\log \beta_{12}$ values was observed. Finally, the recommended values of the present work are presented in Table 5. These values were chosen among the several results obtained and considered reliable on the basis of not only statistical parameters but also following the species spectra and the relationship between experimental conditions and constants refined.

Table 3
Equilibrium constants, $\log \beta_{pq}$, for the reactions $p\,UO_2^{2+} + q\,C_2O_4^{2-} = [(UO_2)_p(C_2O_4)_q]^{2p-2q}$ $(p = 1)$ determined from data of continuous variation method ($c_L + c_M = 16.6$ mM) in a 3.00 M $NaClO_4$ ionic medium at 25 °C

$-\log[H^+]$	Formation constants
1.5	$\log \beta_{11} = 6.26 \pm 0.05$
	$\log \beta_{12} = 11.4_2 \pm 0.1_3$
1.0	$\log \beta_{11} = 6.25 \pm 0.01$
0.5	$\log \beta_{11} = 6.2_6 \pm 0.1_8$

The uncertainties of $\log \beta_{pq}$ values are given as a S.D. obtained in the least-square refinement of data. Each input file contained 24 spectra with 41 wavelengths (350, 353, …, 470 nm) and SQUAD program was used.

Table 4
Equilibrium constants, $\log \beta_{pq}$, for the reactions $p UO_2^{2+} + q C_2O_4^{2-} = [(UO_2)p(C_2O_4)q]^{2p-2q}$ ($p = 1$) determined from data of molar ratio method in a 3.00 M $NaClO_4$ ionic medium at 25 °C

Model	Experiment 1	Experiment 2	Experiment 3
$\log \beta_{11}$	6.19 ± 0.01	6.38 ± 0.02	6.25 ± 0.02

U	5.77×10^{-3}	1.04×10^{-4}	6.80×10^{-4}

The uncertainties of $\log \beta_{pq}$ values are given as a S.D. obtained in the least-square refinement of data. Experiment 1. Data matrix: 24 spectra (solutions) × 50 wavelengths (300, 301, ..., 349 nm). $c_M = 1.7$ mM; $5.0 < c_L < 10.2$ mM for $-\log[H^+] = 1.4$ and $3.4 < c_L < 15.1$ mM for $-\log[H^+] = 2.7$. Experiment 2. Data matrix: 24 spectra (solutions) × 25 wavelengths (398, 401, ..., 470 nm). $c_M = 4.1$ mM; $4.3 < c_L < 18.9$ mM for $-\log[H^+] = 1.3$ and $4.0 < c_L < 18.9$ mM for $-\log[H^+] = 2.3$. Experiment 3. Data matrix: 24 spectra (solutions) × 41 wavelengths (350, 353, ..., 470 nm). $c_M = 8.3$ mM; $16.7 < c_L < 33.3$ mM for $-\log[H^+] = 1.3$ and $17.4 < c_L < 36.1$ mM for $-\log[H^+] = 2.7$.

5. Search of the presence of polynuclear complexes

Similar strategy as described above was used to investigate whether the formation of polynuclear species takes place in solution or not. The starting file involved absorbance data for lower uranyl and oxalate concentrations and in the next stage higher concentrations were included (where complexes different from 1:1 and 1:2 might be formed). The candidates being examined to improve the fit were: $[UO_2(C_2O_4)_3]^{4-}$, $[(UO_2)_2(C_2O_4)_3]^{2-}$ and $[(UO_2)_2(C_2O_4)_5]^{6-}$ species. Stoichiometry of soluble polynuclear complexes was suggested by the composition of such complexes, obtained in solid state via synthesis [8]. Other dimers, such as $[(UO_2)_2(OH)_2(C_2O_4)_2]^{2-}$, suggested by Ferri et al. [13] but in much more basic conditions than those we used here, are of low probability and therefore were not tested.

In addition to normal spectra, up to fourth derivative spectra were used here to test the different models. As an example, the results corresponding to first derivative, similar to the other derivative orders, are presented in Table 6. It can be seen that the addition of the polynuclear species improves the fit. Although the improvement is not too high, it is statistically significant. The stability constant of equilibrium (A) given by Grinberg et al. [17] can be used to estimate $\log \beta_{25} = 28.7$, which agrees very well with the calculated value of the present work (Table 5).

The spectra for the individual species presented in Fig. 5 concord with theoretical considerations. The absorption spectrum of a solution of synthesized $K_6[(UO_2)_2(C_2O_4)_5(H_2O)_2]\cdot 8H_2O$ compound was measured and the spectrum matched well with that calculated in this work for 2:5 complex, as well as with the spectrum of $(N_2H_5)_6[(UO_2)_2(C_2O_4)_5]\cdot 2H_2O$ as published by Govindarajan et al. [16].

Equilibrium constants, log β_{pq}, for the reactions $pM+qL=M_pL_q$ (where, M is UO_2^{2+} and L is $C_2O_4^{2-}$) determined in a 3.00 M $NaClO_4$ medium at 25 °C. In all models log $\beta_{11}=6.29\pm0.03$ was kept constant. *, Compare to log $\beta_{25}=28.7$, recalculated from [17]. The uncertainty (in parentheses) is equal to once the e.s.d. in the least-squares refinement of the experimental data. Data matrix: 24 first derivative spectra (solutions) × 41 wavelengths (396, 398, …, 476 nm). $c_M=8.3$ mM: $9.9<c_L$ mM^{-1} <36.5 for $-\log[H^+]=1.3$ and $8.9<c_L$ mM^{-1} <35.2 for $-\log[H^+]=3.4$; $c_M=16.6$ mM: $16.6<c_L$ mM^{-1} <33.2 for $-\log[H^+]=1.2$ and $16.9<c_L$ mM mM^{-1} <23.2 for $-\log[H^+]=2.2$. The protonation constants, log K_r, for the reactions $rH^+ + C_2O_4^{2-} = H_rC_2O_4^{r-2}$ from this work are equal to log $K_1=3.83\pm0.01$ and log $K_2=4.92\pm0.01$.

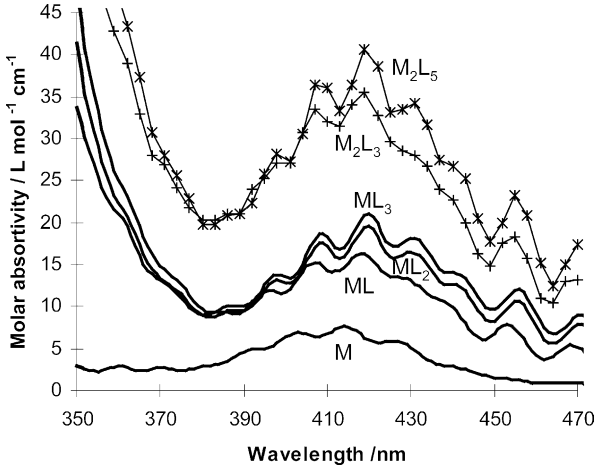

Fig. 5. Calculated spectra of individual species (M is UO_2^{2+} and L is $C_2O_4^{2-}$).

5.1. Vapor-pressure osmometry (VPO) and conductivity experiments

In order to independently check the formation of polynuclear complexes, these two techniques was applied in order to study the behavior of more concentrated solutions of uranyl and oxalate (in absence of $NaClO_4$, i.e. without constant ionic strength).

Solutions of $K_2C_2O_4$ and $UO_2(NO_3)_2$ in ratio 2:3 were prepared at concentrations suited to be studied by VPO, in the limit of their solubility. As shown in Fig. 6(a), a deviation from linearity in VPO experiments for mixtures 2:3 uranium(VI)–oxalate is observed for approximately 0.060 M uranium(VI) (0.180 M oxalate) and higher concentrations.

A saturated solution (ca. 47 g l^{-1}) of $K_6[(UO_2)_2(C_2O_4)_5(H_2O)_2]\cdot 8H_2O$ was used to prepare different dilutions, for which VPO and conductivity measurements were made. Conductivity results are shown in Fig. 6(b) and deviation from linearity is observed both in VPO and conductivity experiments at about 0.030 M uranium(VI) (0.150 M oxalate) and higher concentrations.

The deviation of the linearity in these experiments can be explained by the formation of polynuclear species. Concluding, the presence of polynuclear compounds in aqueous solution might be observed at 0.060 M uranium(VI) or higher concentrations. Rather low improvement of the fit to the spectrophotometric equilibrium data after introducing polynuclear species might be due to the low concentration of these species at the conditions investigated and spectra correlation. The stability constants determined for 2:3 and 2:5 complexes should be regarded as an upper limit of their real values. Studies at the suggested concentrations (0.060 M uranium(VI) or higher) cannot be made at 1 or 3 M $NaClO_4$ since both sodium oxalate and $UO_2(C_2O_4)$ compound are barely soluble at high ionic strength.

Distribution diagram of uranium as a function of oxalate concentration is presented in Fig. 7. Complex 2:3 is a minor species and it explains why most of the previous authors overlook its formation. Polynuclear 2:5 complex is present simultaneously with 1:2 and 1:3 complexes, which explains the discrepancies found in the literature, particularly for the β_{13} value. The relative stability of the 1:3, 2:3 and 2:5 complexes may be explained on the basis of their structures as investigated in solid state. In 2:5 complex, uranyl groups are five-coordinated by oxygen atoms of three oxalate ions, resulting in an approximately pentagonal bipyramidal coordination for uranium. Two oxalate groups are chelating as bidentate (1,4-coordination), while the third one acts as a bridging bidentate (1,4-coordination) [16]. The peculiarity of 1:3 complex is that uranyl group is

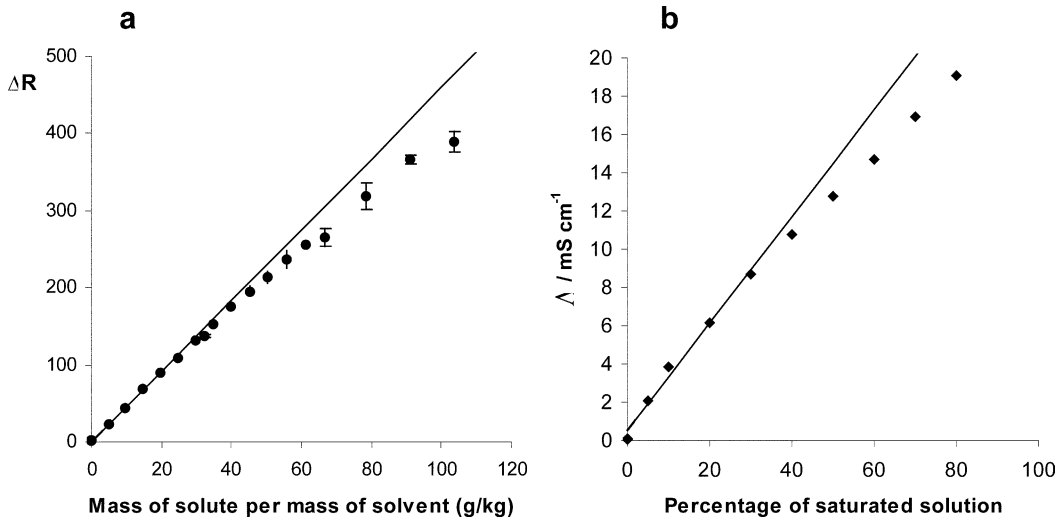

Fig. 6. (a) Vapor pressure osmometry. The solute is a mixture of uranyl nitrate and potassium oxalate in ratio 2–3. The straight line represents the linear regression of the first five points. Three S.D. are shown. (b) Conductivity measurements. The solute is $K_6[(UO_2)_2(C_2O_4)_5(H_2O)_2]\cdot 8H_2O$ and an aqueous saturated solution contains approximately 47 g l^{-1}. The straight line represents the linear regression of the first five points.

not five, but six-coordinated by oxygen atoms of three oxalate ions, one of which is chelating bidentate with 1,3-coordination to give an unique four-membered ring among this family of complexes [11]. The main distinctive characteristic of 2:3 complex (at least as observed in the cell of its crystal form) is that the bridging oxalate is quadridentate, 1,4-coordinated to two uranium atoms [14,15]. All these structural properties fit nicely with the relative stability of 1:3, 2:3 and 2:5 complexes.

5.2. SIT analysis

The extrapolation of experimental stability constants to zero ionic strength was done using specific ion interaction theory (SIT) [7,36,37]. The basic SIT equation for uranyl–oxalate system is

$$\log {}^{*}\beta_{pq} - \Delta z^2 \times D - n \log a(H_2O) = \log {}^{*}\beta^{0}_{pq} - \Delta\varepsilon \times I_m \quad (4)$$

where, ${}^{*}\beta_{pq}$ is a conditional stability constant, Δz^2 the

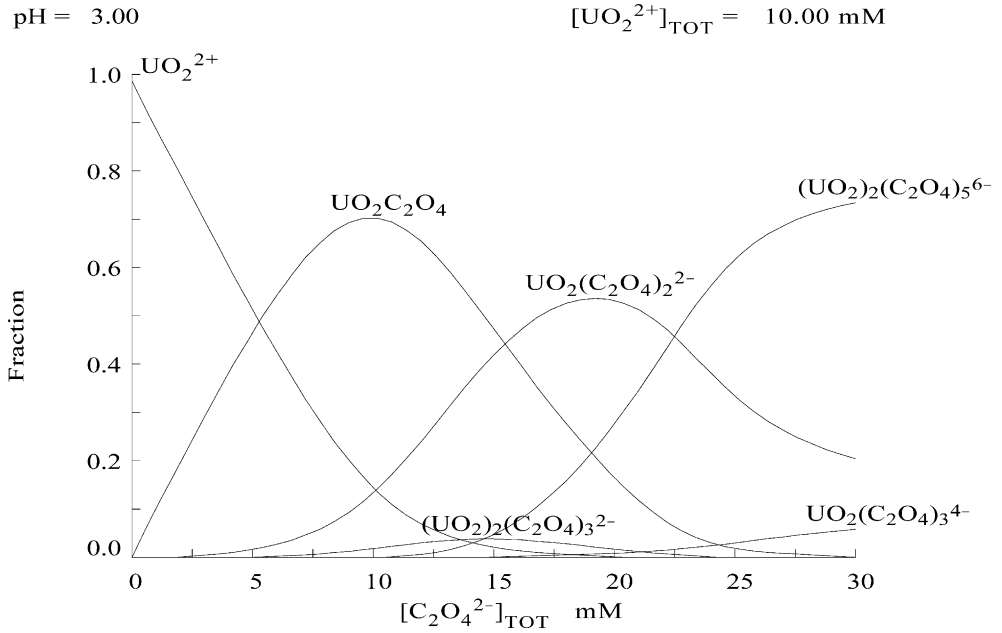

Fig. 7. Distribution diagram for solutions of $[UO_2^{2+}]_{total} = 10$ mM, pH 3 and $[C_2O_4^{2-}]_{total}$ varying from 0 to 30 mM at 25 °C.

charge change in course of reaction, D the Debye–Hückel term, ${}^{*}\beta_{pq}{}^{0}$ the thermodynamic constant at zero ionic strength, $\Delta\varepsilon$ the change of ion interaction coefficients of species involved in the reaction, and I_m is ionic strength in molality scale.

Applying Eq. (4) to uranyl–oxalate system, the following equations are obtained

$$\log \beta_1 + 8D = \log \beta_1{}^{0} - \Delta\varepsilon' \times I_m \quad (5)$$

$$\log \beta_2 + 8D = \log \beta_2{}^{0} - \Delta\varepsilon'' \times I_m \quad (6)$$

$$\log \beta_3 + 0D = \log \beta_3{}^{0} - \Delta\varepsilon''' \times I_m \quad (7)$$

where

$$\Delta\varepsilon' = \varepsilon(UO_2(C_2O_4),\ Na^+ + ClO_4{}^-) - \varepsilon(UO_2{}^{2+},\ ClO^{4-}) - \varepsilon(C_2O_4{}^{2-},\ Na^+) \quad (8)$$

$$\Delta\varepsilon'' = \varepsilon(UO_2(C_2O_4)_2{}^{2-},\ Na^+) - \varepsilon(UO_2{}^{2+},\ ClO^{4-}) - 2\varepsilon(C_2O_4{}^{2-},\ Na^+) \quad (9)$$

$$\Delta\varepsilon''' = \varepsilon(UO_2(C_2O_4)_3{}^{4-},\ Na^+) - \varepsilon(UO_2{}^{2+},\ ClO^{4-}) - 3\varepsilon(C_2O_4{}^{2-},\ Na^+) \quad (10)$$

In order to apply SIT analysis, we need reliable data for different ionic strengths. The system uranium(VI)–oxalate has been studied by means of different experimental techniques in perchlorate as inert supporting electrolyte (Table 5). However, the stability constants in some of those papers [1,34] are lower in comparison with other values. These discrepancies can be ascribed either to some side reactions (e.g. photochemical decomposition of uranium(VI) oxalate), incorrect evaluation of experimental data or wrong chemical model. The formation of protonated species MHL and $M(HL)_2$ was deduced from pH dependence of stability constants obtained [1] but it was not detected by another experimental technique allowing determination of chemical structure in solution (e.g. NMR, EXAFS, etc.). Furthermore, the species are not formed under the experimental conditions given in that paper and, as it was proved here, the stability constants are not dependent on the solution acidity. Hence the stability constants were recalculated as a weighted average of values taken from paper [1] and the new values are given in Table 5. As it can be seen in some cases, there is a large difference between old and new estimates of stability constants.

The experimental stability constants found in literature for various ionic strengths up to 9 M $NaClO_4$ were evaluated (Table 5) and then the chosen values were treated using SIT [7] and following parameters were obtained: $\log \beta_1{}^{0} = 7.41_4 \pm 0.01_4$, $\Delta\varepsilon' = -0.230 \pm 0.004$ kg mol^{-1}, $\log \beta_2{}^{0} = 11.79_6 \pm 0.02_4$, $\Delta\varepsilon'' = -0.462 \pm 0.006$ kg mol^{-1}. Using the ion interaction coefficient $\varepsilon(UO_2{}^{2+},\ ClO_4{}^-) = 0.46 \pm 0.03$ kg mol^{-1} [36] and $\varepsilon(C_2O_4{}^{2-},\ Na^+) = -0.07_9 \pm 0.01_2$ kg mol^{-1} [38], the ion interaction coefficients $\varepsilon(UO_2(C_2O_4),\ Na^+ + ClO_4{}^-) = 0.15_1 \pm 0.03_3$ kg mol^{-1} and $\varepsilon(UO_2(C_2O_4)_2{}^{2-},\ Na^+) = 0.07_2 \pm 0.06_1$ kg mol^{-1} are obtained. The stability constant $\log \beta_3{}^{0} = 13.96_4 \pm 0.06_7$ was obtained by extrapolation to zero ionic strength using $\Delta\varepsilon''' = -0.23 \pm 0.05$ kg mol^{-1} for the formation of uranium(VI) tricarbonate complex [36] and then calculated as weighted average of four values ([12,13] and this work). The extrapolated stability constants at zero ionic strength are in a good agreement with those obtained by Ferri et al. ($\log \beta_1{}^{0} = 7.38 \pm 0.07$, $\log \beta_2{}^{0} = 11.7_2 \pm 0.1$, $\log \beta_3{}^{0} = 13.6 \pm 0.2$) [13]. In addition, the value of ion interaction coefficient $\varepsilon(UO_2(C_2O_4),\ Na^+ + ClO_4{}^-)$ is not zero as it has to be assumed according to SIT but it is comparable with other values obtained for other chemical species [7] ($\varepsilon(CdCl_2{}^0,\ Na^+ + ClO_4{}^-) = 0.15 \pm 0.02$ kg mol^{-1}, $\varepsilon(CdCl_2{}^0,\ Na^+ + ClO_4{}^-) = 0.15 \pm 0.02$ kg mol^{-1}, $\varepsilon(CdCl_2{}^0,\ Li^+ + ClO_4{}^-) = 0.23 \pm 0.05$ kg mol^{-1}, $\varepsilon(CdI_2{}^0,\ Na^+ + ClO_4{}^-) = 0.25 \pm 0.05$ kg mol^{-1}, $\varepsilon(Hg(OH)_2{}^0,\ Na^+ + ClO_4{}^-) = 0.06 \pm 0.05$ kg mol^{-1}, $\varepsilon(HgCl_2{}^0,\ Na^+ + ClO_4{}^-) = 0.06 \pm 0.03$ kg mol^{-1}, $\varepsilon(PbCl_2{}^0,\ Na^+ + ClO_4{}^-) = 0.13 \pm 0.02$ kg mol^{-1}).

The stability constants for uranium(VI)–oxalate at zero ionic strength are much lower than analogous complexes of uranyl-carbonate ($\log \beta_1{}^{0} = 9.67 \pm 0.05$, $\log \beta_2{}^{0} = 16.9_4 \pm 0.1_2$, $\log \beta_3{}^{0} = 21.60 \pm 0.05$ [36,37]) due to its five membered chelate ring in comparison with the four membered one in the case of carbonate.

6. Conclusions

In uranium–oxalate system, the formation of $[(UO_2)_p(C_2O_4)_q]^{2p-2q}$ complexes with composition (p, q) = 1:1, 1:2, 1:3, 2:3 and 2:5 was found and their equilibrium constants determined. Stability constants of mononuclear complexes ($p = 1$, $q = 1$–2), agree with those of Ferri et al. [13]. The difference concerning $\log \beta$ of 1:3 complex at 3 M $NaClO_4$ can be explained by the competing formation of polynuclear 2:3 and 2:5 complexes. The occurrence of polynuclear species in aqueous solution (reported before only in solid state) was also confirmed by conductometry and vapor-pressure osmometry. Absorption spectra of all uranyl–oxalate complexes were calculated and were found to be in good agreement with theoretical considerations.

Abstract

The acidity parameter in bile acid systems was re-examined in an attempt to unify the many contrasting results reported in the literature. Discrepancies originate not only through differences in experimental approaches but mainly through the peculiar behaviour of bile acids and their salts, which can be present in aqueous solution as monomers, or simple and/or mixed aggregates. The acidity (and the pK_a values) of bile acid could also be affected by parameters which do not usually play a major role (e.g. hydroxy groups, far from the reaction centre). The microenvironment, where the bile acid is partitioned (e.g. inside a mixed micelle), also makes the carboxyl group less acidic than it would commonly be, considering only structural factors. When the system is made simpler, avoiding problems of solubility and self-aggregation (e.g. in mixed solvents), unconjugated and glycine-conjugated bile acids display acidity behaviour which matches their molecular structure. © 2002 Published by Elsevier Science Ltd.

Keywords: Acidity parameter; Aqueous solution; Hydroxy groups; Glycine-conjugated bile acids

1. Introduction

Bile acids are a group of acidic compounds, which are present in biological fluid mostly in their ionised form; they are produced by cholesterol (and, therefore, possess its steroid skeleton) and are responsible for its transport in the intestine via formation of mixed micelles or vescicles, composed also of phospolipids. In a physiological medium bile salts interact not only with cholesterol but also with fairly soluble lipid materials such as fatty acids and hydrophobic drugs, since, above a narrow range of concentration value (CMC), they self-associate to form micelles, which are able to solubilise or emulsify endogenous and exogenous materials and, therefore, to improve their transport and absorption or, in any case, to prevent their precipitation [1–4].

Bile acids are synthesised in the liver as unconjugated C-24 carboxylic acids and, after amidation, are secreted into the bile. They are exclusively amidated with glycine and taurine and accumulated in these forms. The most relevant bile acids in humans are the two primary bile acids i.e. cholic acid, 3α7α12α tri-hydroxy-5β-cholan-24-oic acid and chenodeoxycholic acid, 3α7α di-hydroxy-5β-cholan-24-oic acid; by the action of intestinal bacterial 7-dehydrogenase enzyme they are converted, respectively, to deoxycholic acid, 3α,12α di-hydroxy-5β-cholan-24-oic acid and lithocholic acid, 3α monohydroxy 5β-cholan-24-oic acid [4]. Most of the physical chemistry studies dealing with their behaviour in aqueous solution in terms of micelle formation and the little accurate data on solubility, acidity and other properties has only recently been defined [5–11].

On the other hand little data is available regarding their action towards hydrogen or metal ions [12–24].

Moreover, the importance of having experimental data as close as possible to a physiological medium greatly limited the possibility of obtaining results with thermodynamic meaning. In addition the behaviour in solution of these acids (poorly soluble in water) and anions (self-aggregated in micelles) imposed non-canonic experimental conditions or suggested the use of indirect approaches to the determination of acidity constants, that, therefore, appear as a set of scattered values. These could have been interpreted as not very precise if the values were not read in the light of the different conditions used for measurements or if the micro-environment surrounding the molecules during

the determinations was not taken into account. In the classic review regarding bile acid chemistry and physiology [4] very different pK_a values are still wrongly reported among a class of unconjugated bile acids and these data lead to misinterpretation of their physiopathological role [5].

In a previous paper [25] we preliminarily reported and discussed the difference in behaviour between monomers and aggregates, the latter playing an important role in the optimisation of bile acid functions in biological systems, in such a way as to represent a preorganised and privileged substrate for reaction with hydrophilic species, such as, for instance, hydrogen or metal ions, not only for hydrophobic substances.

In this paper, by reviewing the suggestions and considerations that have emerged during more than 30 years of experimental work on these topics, we wish to discuss the influence of the surrounding medium on the acidity constant of bile acids and that of the experimental conditions, in an attempt to find a relationship between the values obtained in different conditions by different authors and establish the 'true' pK_a value for bile acid systems.

2. The bile acid molecule

Bile acids consist of a steroid nucleus, containing 1, 2 or 3 hydroxy groups, that differentiate the single compounds by number, position and orientation; they also bear a short side chain terminating with a carboxy group, that can be free (unconjugated bile acid, UCBA), conjugated with the glycine (GCBA) or taurine (TCBA). Irrespective of their structure the terms bile salt or bile acid anion both refer to the ionised forms, which is the form present in solution in most of the physiological medium [1].

Thus the steroid structure of a bile acid is identified by the hydroxy groups: e.g. a pattern such as 3α, 7α, 12α indicates the moiety typical of the cholic acid (CA, for the unconjugated form), that remains unchanged when the side chain carboxylic group binds, through a peptide moiety –CONH–, to glycine (glycocholic acid, GCA) or taurine (taurocholic acid, TCA). Different bile acids of the same class do not, therefore, differ due to the nature of the acidic group; researchers took advantage of this fact, using the most soluble compounds for each class for measurements and extending the results to all others [1].

3. Behaviour in aqueous solution

UCBA and GCBA are rather poorly soluble in water in their unionised form; while TCBA, bearing the strongly hydrophilic sulphonic group, does not display problems for solubility in water in both forms [5,6]. The water solubility of the bile acids is also influenced by the nature of their solid state; see, for example, the difference between two di-hydroxy bile acids, such as 3α7α and 3α7β di-hydroxy epimers [26,27].

Solubility increases with the pH according to the anionic species formation; a CMpH can be defined, whose value represents the lowest pH, which ensures a sufficiently high concentration of the ionised form to originate micelles:

$$\mathrm{CMpH} = \mathrm{p}K_a + \log(\mathrm{CMC}/S_w)$$

where S_w is the water solubility of the unionised form. This parameter is related to the dissolution of a bile acid when orally administered as a solid and in dissociated form (see for instance the UCDA administration for gallstone dissolution) [11].

Bile salts behave in aqueous solutions as association colloids. They are atypical surface active agents: in this class of compounds the molecular polarity originates from a dissimilarity between the two faces of the steroid rings: the one containing the hydroxy groups is defined as α-face; while the one formed by the hydrocarbon skeleton is the β-face [28]. The aggregation occurs via a 'back-to-back' contact between the β-faces of two monomers to minimise the contact with water of these hydrophobic surfaces (primary micelles) [28].

In most of the physiological bile acids all the hydroxy groups are oriented in the same direction, even if other bile acids present not in human but in other animal species present a structure in which the continuity of the hydrophobic β-face is partially interrupted by the presence of hydroxyls, which are no longer oriented in the α-face. Typical examples are represented by ursodeoxycholic acid (UDCA), 3α7β di-hydroxy-5β-cholan-24-oic acid and ursocholic acid (UCA), 3α7β12α trihydroxy-5β-cholan-24-oic acid.

Aggregation starts above a so-called critical micelle concentration (CMC). The CMC values are affected by the number, position and orientation of hydroxyls, and bile acids, like those reported above, exhibit high CMC values with respect to conventional bile acids (compare UDCA vs. CDCA and CA vs. UCA) [5,29].

The aggregation number is generally low and micelles can increase their size and number as the bile salt concentration increases; as a consequence, the aggregation is not really co-operative and critical.

In other words in bile salt micelles the hydrophobic effect is weak, since the molecular size and the mode of association prevent the building of large and compacted structures. The term CMC, however, is widely used, even though it also refers to a (narrow) concentration range rather than to a single concentration, as is usually reported. Dimers represent the starting and more frequent form of association, especially for hydrophilic bile salt (such as cholate). Electrostatic repulsion of

charged groups does not occur in dimerisation since the charged chains are positioned as far as possible from each other, that is diagonally opposite in a dimer structure [29].

Association could also be present at low concentrations, and may even not be detectable when using in a appropriate techniques; the study of the isolated monomers can, therefore, be carried out only at very low concentrations, below the CMC. In most cases the concentration ranges useful for acidity constant determination are too low and too narrow to allow accuracy. Moreover, the low solubility in water of the unionised forms for UCBA and GCBA limit direct determinations in water.

This introduction is necessary to understand the results obtained with bile salts towards hydrogen ions as well as heavy metal ions and the differences between monomers and aggregates, since many parameters undergo a fairly sharp change around the CMC.

4. Hydrolysis

At low concentrations the bile salts behave like a 1:1 electrolyte. Since UCBA are weak acids, the pH of the sodium deoxycholate (which is a 3α12α UCBA) aqueous solutions steadily increases with concentration, as expected. When aggregates start to form, pH shows a dramatic increase, as a consequence of a higher hydrolysis reaction, as if the strength of the acid undergoes a sudden drop after the aggregation [30]. In fact, when anions in large aggregates are forced into a closer spatial contiguity than that of monomers in solution, an increased electrostatic repulsion occurs. To attenuate this repulsion, some surface charges are protonated by water and consequently produce OH^- ions. At the same time, an electrode sensitive to sodium ions reveals a parallel increase of activity of Na^+ ions, that, as a consequence of the protonation, are freed from the micellar surroundings. It must be pointed out that deoxycholate forms the largest micelles of all bile salts examined and its behaviour is opposite to that of cholate.

These results suggest that a bile salt micelle can be considered a polyanion, like that formed by the ionisation of a poly(carboxylic acid), where single components are kept together by hydrophobic effects, rather than by covalent bonds, such as in the polymer, and where a polyelectrolyte effect operates to increase the affinity of the anion groups towards protons. In this particular polyanion, charged and uncharged groups coexist, solvated by the ions present in the original salt form. When a charged group is protonated, precipitation of the poorly soluble unionised form does not occur immediately, despite its low solubility: this is maintained in solution, precisely because of its participation in this assembled structure. This can, at the same time, explain the resistance to precipitation of the protonated bile acid after an abrupt decrease of pH [31].

This fact has some practical implications, since simple measurements of pH, as a function of concentration, could be sufficient to determine the CMC of bile salts without invasive techniques or the addition of extraneous substances to the system. This fact also explains the possibility of obtaining different acidity constants when the concentration is above or below the CMC, which, therefore, represents a critical concentration border around which a bile salt exists in different forms (monomer/micelle) affecting the experimental results. Qualitatively this suggests that the acidity of a bile acid (when in micelles) is a function of the aggregation degree and, therefore, of all the parameters affecting the aggregation, such as, for instance, concentration and nature of electrolytes controlling the ionic strength.

5. Acidity constant of aggregates

$C_{tot} = CMC$ represents the highest concentration of the monomer, which remains rather constant also at $C_{tot} > CMC$, where excess bile salts self aggregate and the solution contains monomer and aggregates. At $C_{tot} = 0.1$ M, a proton added by titration more frequently encounters a micellar rather than a monomer bile salt anion. Previous data concerning pK_a values [32] did not take into account possible differences between monomers and aggregates; therefore, acid–base titrations provided different results depending on the total concentration used (in parentheses): deoxycholate: 5.3 (2 mM); 6.3 (23 mM); chenodeoxycholate: 5.88 (2 mM); 6.18 (23 mM); glycocholate: 3.95 (2 mM); 3.8 (20 mM); glycodeoxycholate: 4.69 (2 mM); 4.77 (20 mM); glycochenodeoxycholate: 4.23 (1.5 mM); 4.20 (76 mM).

Let us consider the difference between cholate and chenodeoxycholate, two UCBA having 3α7α12α and 3α7α hydroxy groups, respectively. The first one contains three hydroxy groups and is known to form only dimers in a large concentration range. In this case the poly-electrolyte effect can be considered practically negligible, since, according to the 'back-to-back' aggregation, the charged chains are completely separated from each other and behave independently as far as their affinity to protons is concerned. By titrating this system it was observed that the acidity constant is unaffected by the total concentration of cholate (at least in the concentration range examined, where the system remains homogeneous) and its value ($pK_a = 5.02$) concords with the value expected for the structure of such an acid: that is an aliphatic carboxylic acid, where the steroid moiety has very limited influence on the acidic behaviour, like a simple alkyl group [33,34].

On the contrary, chenodeoxycholate (that is a 3α7α UCBA, more hydrophobic than cholate) forms aggregates of a larger size and in this case the polyelectrolyte effect plays a major role: the observed pK_a value (6.38) is much higher than that expected from the structure of the monomer. The carboxylate groups, kept together in the structure of a micelle, display a synergetic affinity to protons. The assembly of monomers by hydrophobic effect is very efficient, since during titration the precipitation of unionised species is slowed down; protonated monomers are kept solubilised as long as the system globally maintains a favourable hydrophilic/hydrophobic balance: also metastable, the system allows the collection of precise experimental data [33,34].

These results confirm that intra and intermolecular interactions affect acidity: acidity constants determined in these conditions are thus also a function of the hydroxy groups, despite their distance from the reaction centre and a completely aliphatic bonding system. In fact they are involved in the formation of secondary micelles, mainly by intermicellar hydrogen bonds, and are responsible for the aggregation number of micelles [35–38].

6. Acidity constant of monomers

At the same time, however, it is well known that an aliphatic structure, such as that of the steroid ring and its substituents, especially when far from the reaction centre, should not have any influence; the acidity constant should be the same for each bile acid in each bile acid class.

To minimise the polyelectrolyte effect, which alters the behaviour of the anions, and to study the behaviour of monomers different approaches were used.

First, acidity constants were measured [39] in a mixed solvent (methanol/water 50% w/w), where the hydrophobic effect does not operate and aggregation does not occur, since both bile acids and bile salts are freely soluble.

As expected, within the UCBA class, where the side chain bears a carboxyl group, all the components display the same acidity constant; steroid hydroxy does not influence the acidity. They are too far from the reaction centre and their inductive or mesomer effects cannot be transmitted through the aliphatic structures of the steroid ring. This test was carried out only with UCBA, available in a very large variety of structures [40].

A second approach [41] considered potentiometric measurements in mixed solvents of different composition and extrapolation of experimental data to a zero content of the organic solvent, that is to pure water. Using two different solvent systems (DMSO and methanol) and two bile acid classes (UCBA and GCBA), values in agreement with each other, both for cholic and glycocholic acid, were obtained. The pK_a value (5.05) for the UCBA is a little higher that that of the GCBA (3.91), because of the -I effect of the peptide group near the acidic centre. This pair of values was confirmed also for deoxycholic and glycodeoxycholic acid [41].

Finally we carried out direct potentiometric measurements on UCA, a 3α7β12α tri-hydroxy semi-synthetic bile acid. This compound has both a high CMC and solubility in water, thus allowing reliable direct data, without the possible interference of aggregates, formation of precipitate or presence of organic solvent. Titration of the sodium salt afforded a value of 4.76 (25 °C and 0.1 M NaCl), which concords very well with previous values obtained by extrapolation and without controlling the ionic strength; moreover the measured $\Delta H = +0.1$ Kcal mol^{-1} can be easily associated with the ionisation of a mono-carboxyl aliphatic acid. The same results were obtained with cholic acid [19].

More recently an interesting result was obtained [42] again using a semisynthetic sodium bile salt, namely UDCA , whose two hydroxy groups were sulphated, giving rise to an anion with three negative charges, freely soluble in water. By titrating the carboxylate group in carefully controlled conditions (0.25 M KCl or Et_4NI, at 25 °C) the following was found: absence of monomeric species in the solution, either protonated or complexed; initial presence of a completely deprotonated dimer (L_2^{6-}) that converts into partially (HL_2^{5-} and $H_2L_2^{4-}$) protonated forms in the course of titration. The values obtained for the acidity constants (5.25 and 4.80) refer to the protonation of the two carboxylate groups [42].

These results suggest a few comments.

It is not clear whether the formation of a dimer found for this compound, at the concentrations used, is a general feature for each bile salt or peculiar to this particular compound: nevertheless, this fact suggests [42] that experimental conditions for the study of isolated monomers of bile salts must be carefully controlled since the association cannot simply be ignored, even in a dilute solution of bile salts and especially at high ionic strength.

The effect of the ionic strength on the CMC is dependent on the nature of the electrolyte, since it was reported that the disulphated ursodeoxycholate forms a complex with K^+ ions. In addition this fact suggests the need to specify the nature of the electrolyte used in every experiment with bile salts and to control the occurrence of unforeseen interactions between the cations of the electrolyte and the bile salt anions (monomer or micelle).

7. Influence of the medium

Previous data suggested that the different acidity of monomers and aggregates originates from the micro environment surrounding the centre of the reaction [43,44].

As a consequence, the differences observed in the case of cholic acid when inserted into mixed micelles with phosphatidylcholine or bound to serum albumin are not surprising: these results were obtained measuring the ^{13}C chemical shift of the C24 of the carboxyl group, as a function of pH [43,44].

Different pK_a values can be found for the same compound according to the nature of the medium: the ionisation ability of a bile acid tends to decrease as far as the hydrophobicity of the medium surrounding the acidic group increases, as a consequence of increasing difficulty for the anion to be solvated.

Cholic acid shows an apparent pK_a 4.98 in 2 mM solution in water (below CMC), 5.2 in 3 mM solution cholic acid solubilised in 90 mM sodium taurocholate, 5.5 in 100 mM solution (above CMC) [46] and two values in phospholipid vesicles as 3 wt.% were 6.8 for the first and 7.3 for the second. This last value is attributed to the molecules inside the layer of the vesicle, the carboxyl group being more shielded than that on the outside [45]. Finally cholic acid bound to albumin has an apparent p$K_a \approx 4.2$. These values overlap those found for the oleic acid in similar experimental conditions, suggesting that the state of ionisation of carboxyl carbon of fatty acids strongly depends on the surrounding medium: a hydrophobic environment destabilised a charged moiety, increasing its affinity for hydrogen and metal ions [45].

8. Affinity for Me^{2+} ions

The affinity of bile salts also increases towards the metal cations when in the form of aggregates [46–53]. Metal ions form complexes with small aggregates that can saturate the solution or remain in solution as colloidal species. Measurements were carried out by polarographic techniques. This first behaviour is typical of hydrophobic bile salts; the precipitation, as a consequence of the formation of very simple (dimers?) and poorly soluble species, is accompanied by a marked decrease of the metal ion concentration (in most cases the precipitation of a salt was observed); in the second case, the depletion of the metal ion in the solution is less pronounced, because hydrophilic complexes are formed and solubilisation and a clarification of the system is observed, as the bile salt concentration increases due to the formation of more soluble complexes with larger bile salt aggregates [53–55].

Solubilisation occurs when larger aggregates are formed and the basicity of the system increases: when this ability is scarce, the bile salt is not able to maintain metal ions in the solution, forming soluble complexes [54]. This can be the case of ursodeoxycholate that only forms aggregates of a small size. During ursotherapy to dissolve cholesterol gallstones, bile is enriched with this exogenous bile acid, increases its ability to interact with cholesterol, but decreases the solubilising ability for metal ions, which can precipitate in an insoluble form. In fact long-term ursotherapy leads to the formation of a thin film of calcium carbonate on gallstones and prevents continuing solubilisation. But when the pool of bile acids has the physiological composition [55], precipitation of complexes or salts with heavy metal ions is very rare, this system displaying a notable buffering action towards the activity of hydrogen and heavy metal ions in bile [53–58].

9. Conclusions

Each bile acid of the UCBA and GCBA classes behaves like common aliphatic carboxylic acids, when the experimental conditions cancel its peculiarities (poor solubility for the acids and self aggregation for the anions). Due to their acidic strength, TCBA were not

Table 1
Chemical and physical properties of some bile acids and salts at 25 °C [56–58]

Bile acids	Symbol	Hydroxy group	log P	CMC (mM)	Solubility (μM)	CMpH (mM)
Cholic	CA	3α7α12α	2.02	11	273	6.71
Taurocholic	TCA	3α7α12α	–	6	–	–
Glycocholic	GCA	3α7α12α	1.65	10	32	5.72
Ursocholic	UCA	3α7β12α	0.92	39	1670	6.73
Hyocholic	HCA	3α6α7α	2.80	8	45	7.53

Lithocholic	LA	3α	–	–	–	–

Table 2
pK_a values for the cholic acid under different experimental conditions

pK_a	Experimental conditions	References
5.02	Above CMC	[10,11]
5.21	At 22 mM	[4]
5.5	At 80 mM	[4]
4.98	Below CMC (2 mM)	[18]
6.30	Aqueous methanol 50% v/v	[12,13]
5.05	Extrapolated from potentiometric measurements in aqueous methanol and DMSO	[14]
I = 6.8; II = 7.3	Phospholipid vesicles	[19]
5.2	In 3 mM sodium taurocholate	[18]

examined here. Precise pK_a for any taurine conjugates are not yet known; they will probably be between −1.5 and +1.5 [28].

Some pK_a values for the cholic acid are summarised in Tables 1 and 2 for comparison.

When in aggregated form, anionic micelles can refer to single anions as a polycarboxylic polymer relates to its monomers: in both cases the polyelectrolyte effect increases the affinity of the anion to protons (or metal ions) and higher pK_a are found.

A hydrophobic environment destabilises charged moieties, increasing their affinity for protons to acquire an uncharged form: again higher pK_a values are produced. Different values obtained for the same compounds, in different situations, must be related to the experimental conditions, and each value has an intrinsic meaning.

Received 23 October 2001; accepted 3 December 2001

Abstract

N-Benzoylthioureas have been reported to form complexes with gold (III) and palladium (II) and other transition metals. In this study, an *N*-benzoyl-*N*′,*N*′-diethylthiourea (**3f**) ligand was used in the solvent extraction of palladium(II) and gold(III) from aqueous chloride media (0.1 mol l^{-1} NaCl). The distribution coefficient was determined as a function of both metal concentration in the aqueous phase and extractant concentration in the organic phase. The experimental distribution data were numerically analysed by LETAGROP-DISTR software in order to obtain the thermodynamic model corresponding to the metal extraction. It is found that pH does not affect the metal extraction process in the 1–2 pH range. Synthesis of the palladium benzoyl thiourea complexes was carried out by mixing quantities of metal and ligand solutions in methanol in a 1:2 ratio stoichiometric. Yields of 74 and 80.9% were obtained for the Pd-3c and Pd-3f complexes. In order to confirm the formation of the palladium complexes, NMR, FTIR and MS analyses were performed. From MS analyses a complex stoichiometry 1:2 (metal:ligand) was confirmed. The formation of crystals of palladium *N*-benzoyl-*N*′,*N*′-diethylthiourea complex (Pd-3f) in the methanolic solution allows the characterisation of the complex structure by XRD. The resulting structure is described and discussed. Bis(1,1,-diheptadecyl-3-benzoyl-thioureate)palladium(II) (Pd-3c) and bis(1,1,-diheptadecyl-3-benzoyl-thioureate)palladium(II) (Pd-3f) were used as ionophores in polymeric membrane electrodes. Their potentiometric responses to different anionic metal chlorocomplexes are evaluated and discussed taking into consideration the results obtained in the liquid–liquid distribution studies. A nernstian response was only obtained for $AuCl_4^-$ (PDL = 8.8×10^{-8}) and $PdCl_4^{2-}$ (PDL = 1.5×10^{-4} M) with a selectivity coefficient of $K^{pot}_{AuCl_4^-,\ PdCl_4^{2-}} = -3.4$, calculated taking $AuCl_4^-$ as being the primary anion. © 2002 Elsevier Science Ltd. 1. Introduction

The development of selective extractants for the separation and concentration of precious metals at trace levels reflects an increasing need for these metals to be recovered and analysed. Chelating extractants have been found to be more selective than solvating reagents and anion exchangers, and, in accordance with Pearson's theory [1], better performance is obtained with sulfur-containing compounds in the cases of Au(III) and Pd(II). Of the extractants containing soft atoms, a novel group of benzoylthioureas has been reported to form complexes with Cu, Fe(III), Pb, Ni, Zn, Cd, Co, Ag, Pd, Hg and Au [2]. In particular, *N*-benzoyl-*N*′,*N*′-diheptadecylthiourea (**3c**) and *N*-benzoyl-*N*′,*N*′-diethylthiourea (**3f**) (see Fig. 1) have been successfully used in the extraction of copper(II) [3] and gold(III) [4] from acidic media. These reagents have also been implemented in a solid supported liquid membrane system for the selective

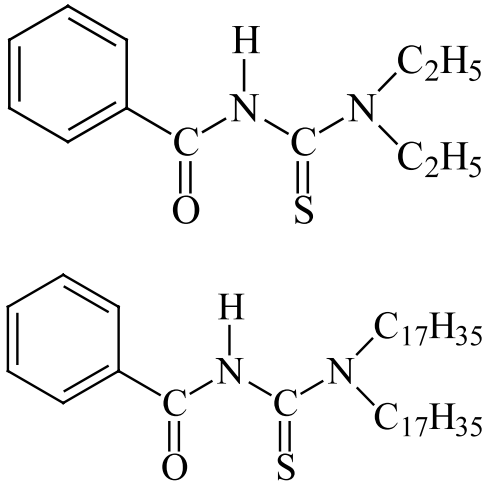

Fig. 1. Chemical structure of the ligands *N*-benzoyl-*N*′,*N*′-diheptadecylthiourea (**3c**) and *N*-benzoyl-*N*′,*N*′-diethylthiourea (**3f**).

transport of palladium(II) [5] and gold(III) [6]. Recently, the field of organic extractant applications has broadened since metal complexes of reagents used in solvent extraction have also been studied in the development of polymeric membrane electrodes taking advantage of the specific interactions between the carrier, i.e. the metal complex and the target ion. This is the case of several metallomacrocyclic and organometallic compounds, for example metalloporphyrin [7] and vitamin B_{12} [8] derivatives, as well as silver(I)–thiourea complexes [9] and several M–triisobutylphosphine sulfide complexes (M = Au, Ag or Hg) [10–12].

In this study, the thermodynamic characterisation of the solvent extraction of palladium(II) and gold(III) from aqueous chloride media by *N*-benzoyl-*N*′,*N*′-diethylthiourea in $CHCl_3$ is undertaken in order to determine the stoichiometry of the complexes formed in the organic solution and their corresponding extraction constants.

Taking advantage of the palladium complexation properties of these ligands, the solid complexes bis-(1,1,-diheptadecyl-3-benzoyl-thioureate)palladium(II) (Pd-3c) and bis(1,1,-diheptadecyl-3-benzoyl-thioureate)palladium(II) (Pd-3f) were obtained and isolated from a mixture of ethanol–methanol solutions. The metallic compounds were characterised and the structure of the crystal Pd-3f was redetermined by means of XRD and compared with previous published results [13]. Pd-3c and Pd-3f were used as ionophores in an ISE system and the potentiometric response of the ion selective membrane to the aqueous chlorocomplexes of precious metals was studied. The selectivity of the potentiometric response is related to the distribution of the metal between the solution and the membrane phases [14].

2. Experimental

2.1. Reagents and solutions

N-benzoyl-*N*′,*N*′-diheptadecylthiourea (**3c**) and *N*-benzoyl-*N*′,*N*′-diethylthiourea (**3f**) were synthesised by Professor Beyer et al. [15]. Organic solutions of these ligands were prepared in $CHCl_3$ (HPLC grade, Panreac, Spain).

Stock solutions of the metals were prepared from the solid compounds, Na_2PdCl_4 (Aldrich, UK) and $HAuCl_4$ (Fluka, Switzerland). Working solutions were prepared by dilution and appropriate volumes of NaCl and HCl standardised solutions were added to adjust the ionic strength (0.1 M) and the H^+ concentration to the desired value.

Pro analysis-grade Na_2PdCl_4 (Aldrich), methanol (Fluka) and ethanol (Fluka) were used for the synthesis of solid palladium complexes Pd-3c and Pd-3f.

High molecular weight poly(vinylchloride) (PVC) and *o*-nitrophenyl octyl ether (*o*-NPOE), used to prepare the polymeric membranes, were purchased from Fluka.

All other reagents were of analytical grade (Panreac, Spain) and all standard solutions and buffers were prepared with deionised (Milli-Q, Millipore, Bedford, USA) distilled water.

2.2. Apparatus

A Labinco rotary mixer was employed to agitate aqueous and organic solutions.

A Spectra A-300 atomic absorption spectrometer (Varian, Australia) was employed to analyse the metal remaining in the aqueous phase.

All pH measurements were carried out using a pH-meter GLP 22 (Crison, Spain) equipped with a combined electrode model 50-02 (Crison).

IR spectra, which were obtained through the use of with KBr pellets, were recorded on a Satellite FTIR equipped with a WINFIRST LITE software package form Mattson Instruments.

The ^1H NMR and ^{13}C NMR spectroscopy was performed on a Brucker DPX200. Samples were run in CD_3CN (for Pd-3f) or $CDCl_3$ for (Pd-3c).

Elemental analyses were performed using a CHNS-O elemental analyser EA-1108 from Fisons.

ESI MS spectra were obtained with a Finnigan AQA™ (ThermoQuest, Manchester, UK). The temperature of the probe was 170 °C and the voltage of the source was 30 eV. The mobile phase was a mixture of acetonitrile:water 70:30 and the flow rate 150 μl min^{-1}.

X-Ray data were collected on a Nonius CAD4 single-crystal diffractometer Potentiometric responses were measured with a digital pH/mV meter (micropH-2002, Crison) and registered on a Yokogawa (LR 4120, Japan) strip-chart recorder. In order to test different

units simultaneously, we used a custom built three-way commuter.

2.3. Procedure for the liquid–liquid distribution studies

Experiments were carried out by shaking equal volumes (10 ml) of the aqueous and organic phases at known concentrations in stoppered glass tubes. After equilibrium was reached, the liquid phases were separated and an aliquot was taken from the aqueous phase for analysis by atomic absorption spectrometry (AAS). Equilibrium time was determined in preliminary experiments by measuring the metal content in the aqueous phase as a function of time until the metal concentrations in the aqueous solutions did not vary. The equilibrium times needed for the extraction of gold and palladium were 16 h and 5 h, respectively. The equilibrium metal concentration in the organic phase was calculated as the difference between the initial and remaining concentrations in the aqueous phase. In some experiments, metal concentration in the organic phase was determined after stripping in order to verify the mass balance.

The initial metal concentration in the aqueous phase was varied from 1×10^{-4} to 1×10^{-3} mol l^{-1} and the total ligand (**3f**) concentration in the organic phase was varied within the range 1×10^{-5}–1×10^{-3} mol. l^{-1}. In order to study the pH dependence of the extraction process, experiments were performed with the aqueous solution at both pH 1 and 2. All experiments were performed at least in duplicate at a controlled room temperature (r.t.) of 22 ± 1 °C.

2.4. Preparation of compounds Pd-3f and Pd-3c

Stoichiometric quantities of metal and ligand in a 1:2 ratio were mixed in order to prepare the Pd-3c and Pd-3f complexes [16]. *N*-benzoyl-*N*′,*N*′ -diheptadecylthiourea palladium complex was obtained by dropwise addition of a methanolic solution of 0.333 mmol of Na_2PdCl_4 to an ethanolic solution of the ligand (0.665 mmol). The mixture was then shaken during 10 min and left to precipitate at −22 °C. The resulting dark yellow solid was vacuum filtered and washed with methanol. *N*-benzoyl-*N*′,*N*′-diethylthiourea (**3f**) palladium complex was prepared following the same steps as for Pd-3c. In this case, 0.250 mmol of Na_2PdCl_4 was added to a 0.500 mmol **3f** ligand resulting in the formation of orange crystals.

2.5. Procedure for crystal structure determination

Unit cell dimensions were determined from the angular settings of 25 reflections in the $10 \leq \theta \leq 15°$ range. The space group was inferred by systematic absences to be $P2_1/n$. Intensities were measured using the ω–2θ scan technique with a scan angle of 1.5° and a variable scan rate of 60 s per reflection. The intensity of the primary beam was checked throughout the collection by monitoring three standard reflections every 60 min. Profile analysis was performed on all reflections [17]. Symmetry-equivalent reflections were averaged and Lorentz and polarisation corrections were applied. The structure was solved by direct methods using SHELXS-97 [18]. Isotropic least-square refinement on F^2 was obtained using SHELXS-97 [19]. During the final stages, all positional parameters and the anisotropic temperature factors of all the non-H atoms were refined. The H-atoms were located by Fourier difference synthesis and refined free or riding with common isotropic thermal parameters. The function minimised was $[(\Sigma w F_o^2 - F_c^2)/\Sigma w(F_o^2)]^{1/2}$ where $w = 1/[\sigma(F_o^2) + (0.0661P)^2 + 1.3168P]$ and with $\sigma(F_o^2)$ from counting statistics and $P = (\text{Max}(F_o^2, o) + 2*F_c^2)/3$. Atomic scattering factors were taken from International tables for X-ray Crystallography [20]. Plots were made with the EUCLID package [21]. Geometrical calculations were made with PARST [22]. Relevant crystal and refinement data are collected in Table 1. All calculations were made at the Scientific Computer Centre of the University of Oviedo and on the X-ray group computers.

2.6. Procedure for the potentiometric measurements

Solvent polymeric membranes were prepared by mixing the ionophore (2 wt.%), the plasticiser (66 wt.%) and the polymer, PVC (32 wt.%). The mixture was dissolved in 1 ml THF and cast in a 16 mm i.d. glass ring [23]. The solvent was allowed to evaporate overnight and a membrane was obtained from which 16 mm diameter disks were cut and mounted on a Phillips IS-561 electrode body (Glassblaserei, W. Moller, Switzer-

land). In this study, between calibrations we stored electrodes which were either dry or soaked in diluted 10^{-4} M Pd(II) chloride solution after having tested different conditioning solutions (10^{-3} or 10^{-4} M Pd(II) chloride) for periods of between 2 h and 24 h without observing any significant improvement in their slope and stability.

The membranes were conditioned for between 2 h and 24 h in 10^{-3} or 10^{-4} M $PdCl_4^{2-}$ solutions or were kept dry.

An Orion double-junction Ag–AgCl electrode (90-02-00) was used as the reference electrode. The outer compartment was filled with the same solution as in the test solution.

Different volumes of standard analyte solutions were added to a 10.0 ml aliquot of 0.100 M KCl–HCl pH 3.0 to determine the response of the ISE to precious metal chlorocomplexes. Differences in potential were measured with the pH/mV meter and registered on the strip-chart recorder. All experiments were carried out in a thermostatic cell at 25.0 ± 0.1 °C. Calibration plots were obtained by representing the potential of the electrode versus the logarithm of the concentration of the analyte in the sample solution. Response time was calculated as the time elapsed to be within 1 mV of the steady-state potential. Analytical parameters, i.e. slope of the linear portion, practical detection limit (PDL), linear range, operational lifetime and selectivity coefficients were determined in accordance with IUPAC recommendations [24–26].

3. Results and discussion

3.1. Liquid–liquid extraction

The metal distribution coefficient (D) between the organic and aqueous phase was calculated as the ratio of total metal concentration in both phases:

$$D = \frac{[\text{Metal}]_{org}}{[\text{Metal}]_{aq}} \quad (1)$$

The experimental data are presented in Figs. 2 and 3 in the form of log D versus log[*3f*] for several concentrations of the metals and at different initial pH of the aqueous solutions. The great extractability of both metals, especially gold(III), with **3f** has restricted the metal and ligand concentration ranges which can be used as when the metal content is low, errors in the analysis lead to inaccurate D values. The dependence of the metal extraction processes on pH range 1–2 was studied varying the proton concentration in the aqueous phase while keeping the total concentration of chloride at 0.1 mol l^{-1}. As seen in Fig. 3 there is no dependence of the gold(III) and palladium(II) extraction by **3f** on the pH.

In order to determine the composition and formation constants of the extracted species, the distribution data was analysed using LETAGROP-DISTR software [27]. The best set of equilibrium constants for a given model is found by a numerical analysis based on the minimisation of the square sum, U, defined as:

$$U = \sum_N (\log D_{calc} - \log D_{exp})^2 \quad (2)$$

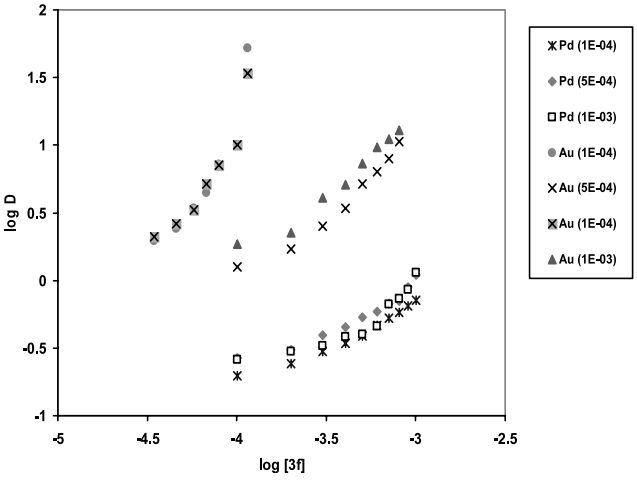

Fig. 2. Experimental distribution data of gold(III) and palladium(II) at pH 1. The total ligand concentration in the organic phase was varied from 3.16×10^{-5} to 1×10^{-3} M.

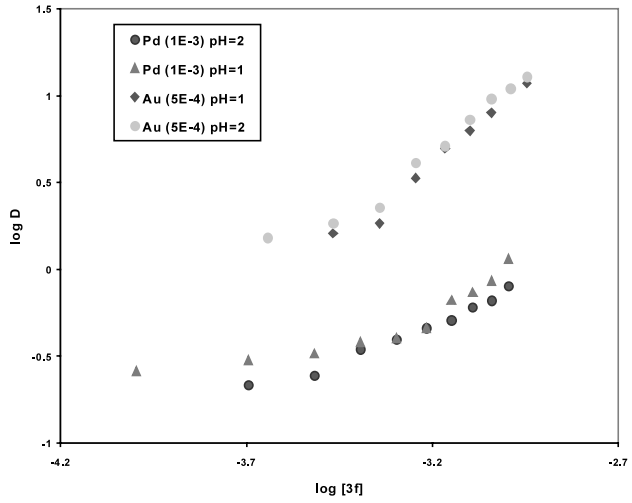

Fig. 3. Experimental distribution data of gold(III) and palladium(II) as a function of pH. The total ligand concentration in the organic phase was varied from 1.0×10^{-4} to 1.0×10^{-3} M.

where D_{exp} represents the experimental values of the distribution coefficient and D_{calc} is the corresponding value calculated by the program solving the mass balance equation for the ligand, the metal and H^+, assuming a proposed set of chemical species and formation constants. N_p is the number of experimental points.

In the experimental conditions used in this work (0.1 M NaCl and low pH), palladium and gold are present in the aqueous solution as the chlorocomplexes $PdCl_4^{2-}$ and $AuCl_4^-$ and the experiments were performed at such low metal concentration that only mononuclear species are present. Then, the metal extraction reaction can by described by using the following equation:

$$MeCl_4^{n-} + qH^+ + rL_{(org)} \Leftrightarrow MeCl_sH_qL_{r(org)} + (4\text{-}s)Cl^- \quad (3)$$

By considering ideal behaviour in the organic phase and assuming the activity coefficients of the aqueous solution to be constant, the equilibrium constant of the reaction can be written as:

$$K_{qr} = \frac{[MeCl_sH_qL_r]_{org}[Cl^-]^{(4-s)}}{[MeCl_4^{n-}][H^+]^q[L]^r_{org}} \quad (4)$$

The distribution coefficient, D, for metal extraction can be expressed by:

$$D = \sum_1^q \sum_1^r K_{qr}[H^+]^q[L]^r_{org}[Cl^-]^{(4-s)} \quad (5)$$

Hence, a plot of log D versus log L would give a preliminary estimation of the stoichiometric coefficients by slope analysis [28]. The values obtained from this graphical treatment were considered as the starting point of the numerical calculations and were introduced into the input of the program along with the constants related to the equilibria involved in the system i.e. hydrolysis of the metal, formation of the metal chlorocomplexes. The results of the numerical analysis are given in Table 2. The goodness-of-fit for any model may be evaluated from the values of U and σ (log D) defined as σ (log D) $= (U/N-N_K)^{1/2}$ where N_K is the number of constants to be adjusted.

The best fit to the experimental data is given by models consisting of one species with a 1:1 stoichiometry i.e. $AuCl_3L$ and $PdCl_2L$. As can be seen in Table 2, the model formed by the species with stoichiometries 1:1 and 1:2 (metal:ligand) gave the same values of U and σ as the models formed by the 1:1 species. This result means that the addition of the 1:2 species to the latter model did not improve the fit of the data and, hence, the most realistic model is that composed by 1:1 species.

Previous studies on gold(III) solvent extraction from aqueous chloride media by *N*-benzoylthiourea derivatives [4] found that the species responsible for gold extraction by **3f** in cumene was $AuCl_3L_2$ and its extraction constant log $K_2 = 5.9 \pm 0.4$. In our case, the use of chloroform, which is more polar than cumene, favours the formation of 1:1 species. Mühl et al. [2] studied the extraction of palladium and gold (10^{-4} M) with *N*-benzoyl-*N*′,*N*′-dibuthylthiourea (**3e**) in benzene, whose concentration was varied from 2.5×10^{-4} to 10^{-2} M. From the representation of log D versus log[*3e*], they obtained slopes of two for palladium and approximately one for gold which indicated the formation of a palladium species of 1:2 (metal:ligand) stoichiometry and a 1:1 gold: ligand complex. The differences in the results of Mühl et al. with respect to the stoichiometry of the palladium species is attributable to the higher ligand concentrations at which they have conducted their experiments.

The extraction of gold by *N*-benzoylthiourea derivatives can take place after the reduction of gold(III) to gold(I) by the ligand as was found in the characterisa-

tion by XRD of the crystal obtained by mixing a $AuCl_4^-$ solution with a solution of **3f** in $CHCl_3$ [29]. The 1:1 (gold:ligand) complex formed has a Au(I) centre, one ligand molecule in which the sulfur atoms are oxidised and one chloride atom.

3.2. Spectral properties

The IR spectra of the complexes Pd-3c and Pd-3f described in this work are assigned in the Section 2. Comparison of these spectra with those of ligands **3c** and **3f** (not shown here) reveals the absence of the bands corresponding to the N–H and C=O bonds which were present in the ligands. The resonance signals in the ^1H NMR and in the ^{13}C NMR spectra can be assigned easily (see Section 2). The disappearance of the N–H signal in the ^1H NMR spectra and the shift in the ^{13}C NMR spectra of the signals assigned to the C–O and C–S bonds, which in the complex appear close together, shows once more the co-ordination of the palladium through the O and S atoms of the ligand.

The ES^+ MS spectrum of the Pd-3f complex shows a peak at $m/z = 577.4$ which corresponds to a 1:2 (metal:ligand) stoichiometry. In Fig. 4, the experimental and calculated isotopic patterns of compound Pd-3f (which agree with the presence of the Pd atom in the complex) are depicted showing the complete correlation between them. The high degree of fragmentation of Pd-3c makes it difficult to interpret the mass spectrum (not shown).

3.2.1. X-ray structure determination

In order to achieve more accurate solid state structural data for the complex compound, the crystal structure of Pd-3f was determined. The structure found agrees with previously published results [13]. In Tables 1 and 3, the crystallographic data and selected bond length and angles are presented. That the new determination is a significant improvement is shown by the *R* factor, the hydrogen atom locations and the refinement of the H bonding description, and the overall decrease in e.s.d. Fig. 5 shows the molecular structure of the complex with the atomic labelling.

3.2.2. Potentiometric results

Potentiometric responses to $PdCl_4^{2-}$ have been accurately determined in 0.10 M KCl–HCl pH 3.0, which was chosen to ensure that more than 95% of the added analyte was in the $PdCl_4^{2-}$ form. The influence of the membrane composition and working conditions on the electrode response to this palladium chlorocomplex was evaluated by systematically changing certain variables. Both palladium ionophores (Pd-3c and Pd-3f) were tested and a significantly greater signal stability was achieved when Pd-3c was used as the ionophore. The drift in potential obtained with Pd-3f membranes is explained by the leaching of the ionophore into the test solution due to the lower lipophilicity of ligand **3f** in comparison to **3c**, which has longer alkylic side chains (see Fig. 1). Subsequent experiments were mainly focussed on Pd-3c based membrane ISEs. Preliminary experiments were undertaken in order to evaluate the optimum composition of the liquid membranes and their conditioning. No significant improvement in the slope and stability of the electrodes was made by varying the time and the composition of the conditioning solution. The best reproducibility of the Nerstian response was obtained with 2 wt.% Pd-3c as the ionophore and *o*-nitrophenyl octyl ether (*o*-NPOE) as the solvent mediator.

After testing all precious metal chlorocomplexes (Fig. 6), a Nernstian response was only obtained for $AuCl_4^{2-}$ and $PdCl_4^{4-}$ in 0.100 M KCl pH 3.0 medium. $RhCl_5(H_2O)^{2-}$, $PtCl_6^{2-}$ and $PtCl_4^{2-}$ did not give any response and, therefore, would not have interfered in the measurement of $PtCl_4^{2-}$ in a mixed PGM solution. The calibration parameters for $AuCl_4^-$ potentiometric responses were determined by using the optimum working conditions described above for $PtCl_4^{2-}$. The electrodes, with membranes containing 2% of Pd-3c ionophore, presented Nernstian slopes of 59.6 ± 1.9 mV per decade for $AuCl_4^-$. However, the sensitivity and linear dynamic range are very different for the two chlorocomplexes. The measured PDL value for $AuCl_4^-$ was 8.8×10^{-8} M while for $PdCl_4^{2-}$ it was only 2×10^{-4} M. A selectivity coefficient of $K^{pot}_{AuCl_4^-,\ PdCl_4^{2-}} = -3.4$ was calculated taking $AuCl_4^-$ as being the primary anion. These selectivity coefficients were calculated by the matched potential method [30,31]. The greater response of the ISE system for gold is a result of the higher extraction constant obtained for gold in the liquid–liquid system.

4. Conclusions

Solutions of *N*-benzoyl-*N*′,*N*′-diethylthiourea (**3f**) in $CHCl_3$ were used in the solvent extraction of gold (III)

and palladium (II) from aqueous chloride media (0.1 M NaCl) giving high extraction rates especially for gold. By treating equilibrium data with the LETAGROP-DISTR software we have concluded that gold and palladium extraction can be explained by the formation of 1:1 (metal:ligand) species with extraction constants of log K ($AuCl_3L$) = 4.07 and log K ($PdCl_2L$) = 3.73. The pH of the aqueous solution does not affect the metal extraction process in the 1–2 pH range

The solid complexes bis(1,1,-diheptadecyl-3-benzoyl-thioureate)palladium(II) (Pd-3c) and bis(1,1,-diheptadecyl-3-benzoyl-thioureate)palladium(II)Pd-3f were prepared and isolated from a mixture of ethanol–methanol solution obtaining yields of 74 and 80.9%,

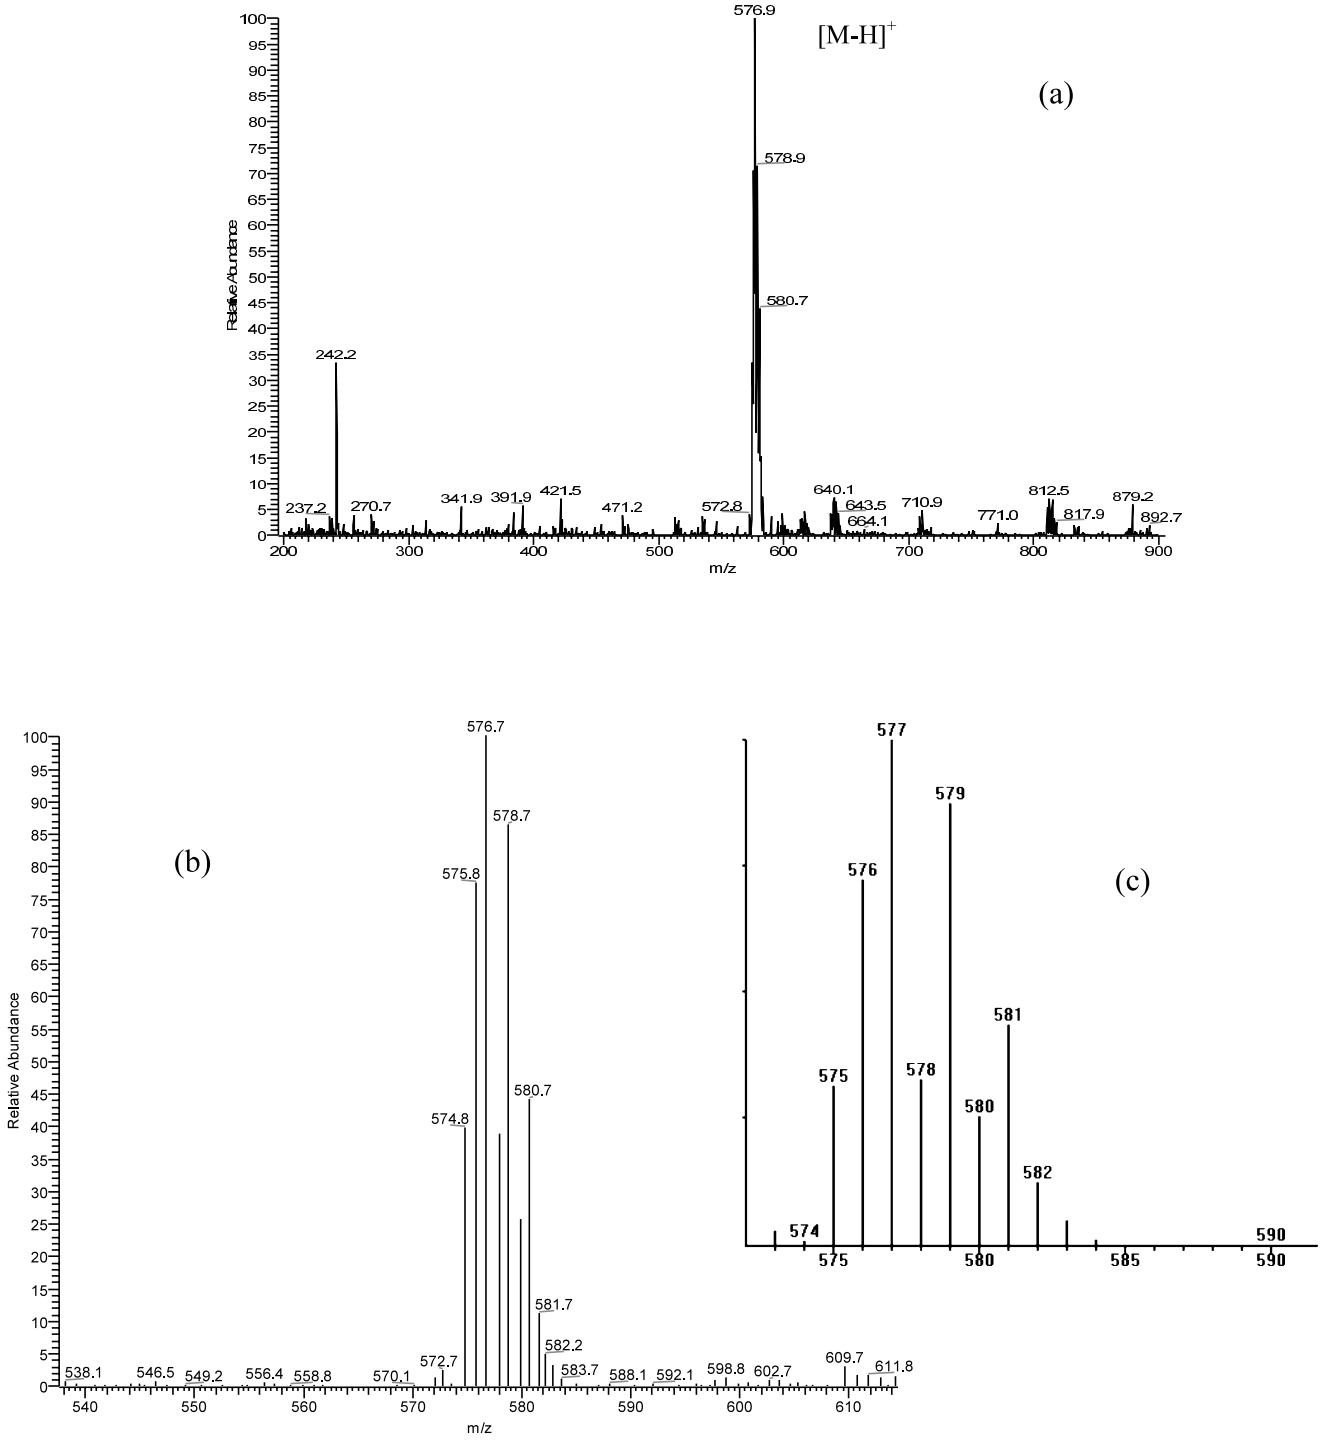

Fig. 4. ES^+ MS mass spectra of Pd-3f. Comparison of the (b) found and (c) calculated isotopic pattern of compound Pd-3f.

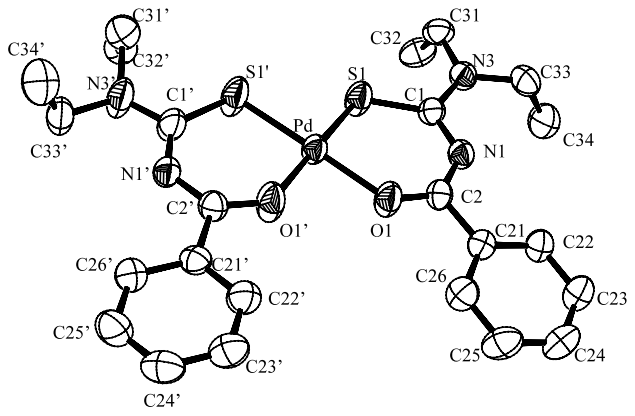

Fig. 5. Molecular structure of bis(1,1,-diheptadecyl-3-benzoylthiourea)palladium(II) with the atom numbering scheme.

respectively. The characterisation of these complexes was performed by NMR, FTIR and MS analyses and their stoichiometry was confirmed to be 1:2 (metal:ligand) by MS.

The structure of the Pd-3f crystal was redetermined by means of XRD. The *R* factor, hydrogen atom locations and the refinement of the H bonding description, and the decrease in e.s.d. are significant improvements.

The Pd-3c and Pd-3f complexes were used as ionophores in the development of polymeric membrane electrodes. The membranes prepared with 2% of Pd-3c gave Nernstian responses to $PdCl_4^{2-}$ and $AuCl_4^-$, with an average of -30.9 ± 0.8 mV per decade and a PDL of 1.5×10^{-4} M for palladium, and a slope of -59.6 mV per decade and a PDL of 8.8×10^{-8} M for gold.

5. Supplementary data

Further details of the complex Pd-3f structure determination are available as a cif (crystallographic information file) magnetic file from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) on request quoting deposition number 172658.

Abstract

The relationships between statistical thermodynamics and equilibrium constants, either cumulative, stepwise or specific site constants are investigated. In order to show the link between equilibrium constants and statistical thermodynamic microscopic properties, a distinction has been introduced between non-reacting and reacting systems. The non-reacting systems are those for which continuous statistical distributions of enthalpies can be assumed. The distribution function can be obtained as an integral of the interparticle potential extended to the whole ensemble. Molecular partition functions ζ_A, are used to describe the properties of the ensembles. The reacting ensemble is represented by distinct distributions of enthalpies, each distribution being grouped around a mean value. Each level is representative of one species. Around each mean level the distribution is continuous as in non-reacting ensembles. The reacting ensemble of particles is described by a grand canonical molar partition function $Z_M = (1+k\gamma(i)[A])^t$ where k is the specific site constant, $\gamma(i)$ is the cooperativity function, [A] is the concentration of free ligand, and the power t indicates the maximum number of i sites in one class. The specific site constant k is proportional to the affinity of binding and is related to the depth of the minimum of the potential function. The factor γ_i is the cooperativity factor given by the value of the cooperativity function $\gamma(i)$ at the ith level and indicates how the depth of the potential function is affected by previous binding of a ligand. The values of the stability constant and cooperativity factor can be optimized by a computer program. The derivatives of the partition function Z_M with respect to ln[A] correspond to the formation function $\langle n \rangle$ (first derivative) and to the buffer capacity B_C (second derivative). The derivatives of the partition function Z_M with respect to temperature are reaction enthalpy ΔH (first derivative with $-(1/T)$) and apparent heat capacity $\Delta C_{p,app}$ (second derivative with ln T). The denaturation heat obtained by integration of $\Delta C_{p,app}\, dT$ for many proteins explains why the denaturation enthalpy depends linearly upon T. © 2002 Elsevier Science Ltd. 1. Introduction

Statistical thermodynamics provides a bridge linking the thermodynamic properties of a macroscopic system to molecular parameters of its microscopic constituents; thus giving a molecular basis to the thermodynamic laws.

Materials in bulk will contain some multiple of Avogadro's number (e.g. 10^{10} or higher) of particles (atoms, molecules, or their constituent nuclei and electrons). We will refer to such collections of particles as macroscopic (experimental) systems where we use the term 'system' to refer to any collection of material particles enclosed by a boundary. Anything not included in a defined system is considered as the surroundings. Any macroscopic system, therefore, has a microscopic model description, i.e. a description in terms of properties of its individual particles. A macroscopic system such as one drop of water, or 1 carat of diamond corresponds to a model containing many microscopic particles or elements.

2. Non-reacting and reacting systems

Appropriate relationships between macroscopic experimental properties and motions of collection of molecules can be found not only for gases but also for liquids, solids, and solutions. We have now investigated the relationships between equilibrium constants, either

cumulative, stepwise, or specific site constants, in solution and the properties of statistical thermodynamic ensembles. In order to establish the correspondence between real macroscopic systems and molecular models it has been necessary to distinguish between non-reacting and reacting systems [1–4].

The non-reacting systems are represented by ensembles of cells for which continuous distributions of enthalpies can be assumed. The distribution function of energy or enthalpy can be obtained as an integral of the interparticle potential extended to the whole ensemble. Molecular partition functions ζ_A appropriate to microcanonical, canonical and grand canonical ensembles, respectively, are used to describe the properties of the ensembles.

The reacting system is represented by an ensemble of cells presenting distinct distributions of energies or enthalpies; each distribution being grouped around a mean energy or enthalpy value. Each mean level is representative of one species. Around each mean level the distribution is continuous as in non-reacting ensembles.

The fundamental assumption of the statistical approach to thermodynamics is that the behaviour of materials in bulk can be described by appropriate averages obtained from sums or powers of activities of the constituent parts. By reference to a solution, we can imagine a subdivision of the whole volume of the solution in a very large number of microscopic cells. Each cell has its own energy and the mean energy can be obtained as the mathematical average of the sum of single energies. Each cell has its own concentration c_i; then the concentration of the typical cell from an ensemble of n cells is obtained by taking the nth root (i.e. geometrical average) of the product of n concentrations.

The possible configurations of a system where the total energy E is given by the sum of all the energies of the particles

$$E = \sum_i n_i \varepsilon_i \tag{1}$$

are given by the Boltzmann distribution, whereby the probability p_i of state i is

$$p_i = \exp(-\varepsilon_i/k_B T)/\sum_i \exp(-\varepsilon_i/k_B T) \tag{2}$$

and is equal to the ratio n_i/N between the population n_i of the ith state and the total number N of states ($k_B = 1.381 \times 10^{-23}$ J K^{-1} is the Boltzmann constant).

The denominator of Eq. (2) is the partition function

$$\zeta = \sum_i \exp(-\varepsilon_i/k_B T) \tag{3}$$

of the system and indicates how the particles are distributed over the different states.

The total internal energy of a macroscopic system is the sum of the kinetic and potential energy associated with the various active modes of motion of the individual microscopic particles together with the sum of the microscopic potential energies resulting from interactions between the particles. We assume that there is a distribution of kinetic energies among the individual particles and among their several modes of motion and that the kinetic energy of a single particle is constantly changing as a result of energy exchange occurring during collisions or in the coupling of internal motions. This distribution of energies can be related to the model of an ideal gas. The ideal gas is assumed to be formed by a large set of particles with mass m and velocity u. There is no net interaction (either attractive or repulsive) between molecules. The volume of the molecules is very small with respect to the volume V of the container. Any molecule has equal statistical probability to be found in any part of the volume. On the other hand not all the molecules have the same and constant velocity and the directions of the motion of these molecules are completely random.

The distribution of energy can be also calculated by assuming that it is quantized. The energy levels for a single molecule can be calculated by quantum mechanics methods. In principle, the energy level of any molecule can be calculated, although the actual computation can be very difficult and in many cases is not yet possible.

For an ideal gas the energy levels of a molecule can be assigned, with good approximation, to translational, rotational, and electronic motion. The spacing between energy levels is smallest for translational energy levels and largest for electronic levels. The values of the energy levels can be calculated from quantum mechanics and the partition function can be obtained (for volume $V = abc$)

$$\zeta = (2\pi m k_B T/h^2)^{3/2} V \tag{4}$$

that can be written

$$\zeta = V/\Lambda^3 \tag{5}$$

where

$$\Lambda = (2\pi m k_B T/h^2)^{-1/2} \tag{6}$$

has the dimension of length and is called the thermal wavelength. Correspondingly, Λ^3 is a length to the third power and hence a volume. This continuous distribution of energies is a distinctive example of a non-reacting system. The identification of volume in Eq. (6) as 'dilution' volume qualifies it as an entropy probability factor $\zeta = \exp(S/R)$ (see Section 3). The expression (4) shows how the exponential probability factor is a function of the kinetic energy $(m/2)u^2$.

3. Potential functions and non-reacting systems

The fundamental problem in statistical mechanics is to find a relationship between the interparticle interactions and the energy differences contained in the partition function. The possibility to predict thermodynamic properties of liquids resides in finding accurate potential functions to describe the interparticle interactions [5].

Intermolecular potential theory is based upon two assumptions: (i) that intermolecular potentials are a function of internuclear separations (Born–Oppenheimer approximation), (ii) that the total potential energy of a system of N atoms whose nuclei are at positions $\boldsymbol{r}_1, \ldots \boldsymbol{r}_i, \ldots \boldsymbol{r}_N$ may be written (in the absence of external fields) as a sum of two-body; three-body, four-body,... potential functions

$$\Phi(\boldsymbol{r}_1, \ \ldots \ \boldsymbol{r}_i, \ \ldots \boldsymbol{r}_N) = \sum_{i<j} \phi^{(2)}(\boldsymbol{r}_{ij}) + \sum_{i<j<k} \phi^{(2)}(\boldsymbol{r}_{ij}, \ \boldsymbol{r}_{jk}, \boldsymbol{r}_{ik}) + \ldots \tag{7}$$

In general we can truncate the series to the two-body potential [$\Sigma\phi^{(2)}$] and calculate the canonical partition function

$$Z_N = \{((\Lambda^3)^N/(N!)\ldots \mathrm{d}\mathbf{r}_1 \ldots \mathbf{r}_N) \exp[-\Phi(\mathbf{r}_1 \ldots \mathbf{r}_N)]/k_\mathrm{B}T\} \tag{8}$$

It is assumed that the particles are obeying the laws of classical mechanics. The partition function is divided by $N!$ because it refers to a collection of indistinguishable particles. The most realistic two-body potential function is the Lennard–Jones (12, 6) potential

$$\phi(\boldsymbol{r}) = 4\eta[(\sigma/r)^{12} - (\sigma/r)^6] \tag{9}$$

In this potential, σ is a measure of the diameter of the particle and η gives the potential at its minimum. The microscopic enthalpy η is related to the microscopic energy ε by $\eta = \varepsilon + p\phi$, where ϕ is the microscopic volume accessible to one molecule. The shape of the potential curve is that reported in Fig. 1. The total energy produced by two-body interactions between the particles is transformed into kinetic energy which is measured by an entropy increase. It is worth noting that the partition function for non-reacting systems can be an extremely large number [6].

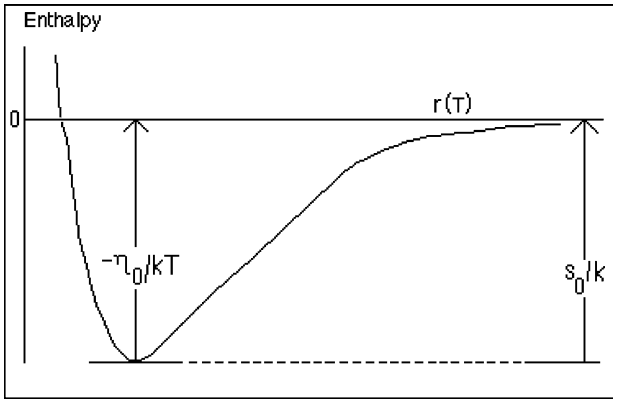

Fig. 1. Potential function in non-reacting ensemble.

The non-reacting system can be represented by the partition function which can be derived with respect to temperature to give an average enthalpy

$$-\partial \ln \zeta/\partial(1/T) = \sum\nolimits_i (\eta_i/k_\mathrm{B})\{\exp(-\eta_i/k_\mathrm{B}T)/\sum\nolimits_i \exp(-\eta_i/k_\mathrm{B}T)\} = \langle \eta_i/k_\mathrm{B} \rangle = \langle H/R \rangle \tag{10}$$

where

$$\zeta = \sum\nolimits_i \exp(-\eta_i/k_\mathrm{B}T) \tag{11}$$

is the partition function of the system. The ensemble can be represented by the mean enthalpy value with average partition function $\zeta_\mathrm{av} = \exp(-\langle \eta \rangle/k_\mathrm{B}T)$. Note that the derivation of $\ln \zeta_\mathrm{av}$ with respect to $(1/T)$ leads to the same result as the derivation of $\ln \zeta$ (cfr. Eq. (10)). The multiplicity of the state ω, i.e. the number of accessible states (cfr. dilution factor below), is an entropy factor

$$\omega = \sum\nolimits_i \exp(s_i/k_\mathrm{B}) \tag{12}$$

In non-reacting systems, $\zeta = \omega$, which means that the partition function is a measure of the probability of the state and corresponds to the number of accessible states. Therefore, the following equality holds

$$\exp(-\langle \eta \rangle/k_\mathrm{B}T) = \exp(\langle s/k_\mathrm{B} \rangle) \tag{13}$$

The distribution of enthalpies, as well as that of entropies, of a non-reacting ensemble is continuous, centred around the most probable state. According to Eq. (13) in the diagram of Fig. 1, the total energy $(-\eta/k_\mathrm{B}T)$ of each elementary process is transformed into kinetic energy (s/k_B). The intermolecular interactions do not give origin to definite compounds.

The partition function of a non-reacting ensemble is suited to represent the thermal properties of the system. For example, the isobaric heat capacity C_p is by definition the quantity of heat supplied to one mole of substance (or solute) necessary to increase by 1 °C the temperature of the substance. More immediately, the specific heat capacity applies to 1 g of substance. This experimental quantity corresponds, for the model, to the derivative of Eq. (10) and, therefore, to the double derivative of the partition function

$$\partial \langle H/R \rangle/\partial T = -\partial^2 \ln \zeta/\partial(1/T)\partial T = C_\mathrm{p}/R \tag{14}$$

On the other hand, it can be shown that the variance of enthalpy is

$$\mathrm{var}(H) = C_\mathrm{p}RT^2 \tag{15}$$

By calculating the dispersion of enthalpy as the square

root of variance, the mean enthalpy can be written

$$\langle H\rangle = 5/2RT \pm (C_p R)^{1/2} T \quad (16)$$

The non-reacting ensemble can be open to exchange of matter. Therefore, the partition function (Eqs. (11)–(13)) is expressed as the function of the multiplicity factor ω, which represents the dependence upon the dilution. In order to show the relation between the multiplicity and an experimental quantity such as the concentration or its reciprocal, the dilution, we can refer to Fig. 2. In (a) the dilution of solute A in (conventional) standard state d_1 indicates a ratio of one molecule A in every 5 cells, whereas in (b) the dilution is d_2 and it has been increased to one molecule A in every 14 cells ($d_2 = 2.8d_1$). The state d_2 (corresponding to a larger number of accessible states) is more probable than the state d_1. The dilution is an entropy factor because it is a probability factor which measures the trend of the molecules to occupy the maximum accessible volume [7]. In fact, any non-reacting solute moves towards less occupied cells, so that it becomes as sparse as possible. The more diluted solution is, therefore, the more probable state. The change of probability is measured on a molar scale by an entropy change corresponding to a dilution change

$$\mathrm{d}S = R\ \mathrm{d}\ \ln\ 1/[\mathrm{A}] = R\ \mathrm{d}\ \ln\ d_\mathrm{A} \quad (17)$$

On the molecular scale, the change of entropy is

$$\mathrm{d}s = k_\mathrm{B}\ \mathrm{d}\ \ln\ \omega \quad (18)$$

where ω is the number of accessible states or multiplicity.

Not only a change of dilution but also a change of temperature in non-reacting systems produces a change of entropy, which is proportional to the isobaric heat capacity $C_{p,A}$ of the solute A. In fact

$$\mathrm{d}S = C_{p,A}\ \mathrm{d}\ \ln\ T \quad (19)$$

By equating Eqs. (17) and (19) we obtain a virtual change of dilution produced by a change of temperature

$$-R\partial\ \ln[\mathrm{A}]/\partial\ \ln\ T = C_{p,A}/R \quad (20)$$

which can be called thermal equivalent dilution [8]. This principle raises a question: Can we assume that the thermal equivalent dilution is an experimental demonstration of the so-called ergodic hypothesis whereby the 'mean toss over time' (temperature) is equal to the 'mean toss over space' (dilution)? On the other hand, it has been asserted that Maxwell–Boltzman statistics with corrections for the quantum character of energy changes and the indistinguishable nature of molecules, works perfectly well when we consider systems of non-interacting molecules [9].

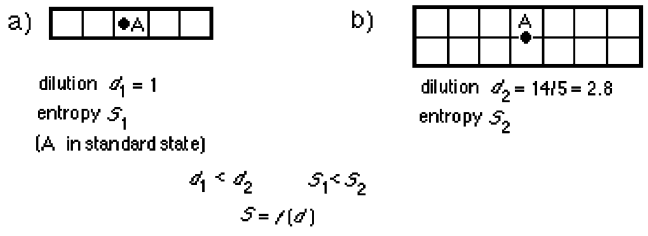

Fig. 2. Dilution and entropy: $d = \exp(S/R)$. (a) The dilution of solute A is d_1 (one molecule A every 5 cells. (b) Dilution of solute A is d_2 (one molecule A every 14 cells) ($d_2 = 2.8d_1$).

4. Reacting systems

The reacting system is composed of two or more non-reacting ensembles of energy (or enthalpy) levels. Each non-reacting sub-system represents a continuous distribution of energies, at constant volume, or of enthalpies, at constant pressure. Examples of the latter subsystems are those represented by the integral of Eq. (8) and by the partition function of Eq. (12). Each group of energies or enthalpies is centred about its mean value $\langle \varepsilon/k_\mathrm{B}T\rangle$ or $\langle \eta/k_\mathrm{B}T\rangle$ and the same holds for mean entropy $\langle s/k_\mathrm{B}\rangle$ and mean free energy $\langle \gamma/k_\mathrm{B}T\rangle$, respectively.

Therefore the whole partition function, by taking 1 the probability of occupation of the ground level is

$$Z_\mathrm{M} = 1 + \exp(-\Delta\gamma/k_\mathrm{B}T) \quad (21)$$

The distribution of molecules is of the order of moles and on this scale the exponential term can be written by multiplying numerator and denominator of the exponent by N_L (Avogadro number)

$$Z_\mathrm{M} = 1 + \exp(-\Delta G/RT) \quad (22)$$

The potential function of the reacting system can be represented in Fig. 3 where the total energy corresponds to the enthalpy change ($\Delta H/RT$), the kinetic energy to the entropy change ($\Delta S/R$) and the potential energy to the free energy change ($\Delta G/RT$). Note that the entropy change is not equal to the enthalpy change, which is different from the non-reacting systems.

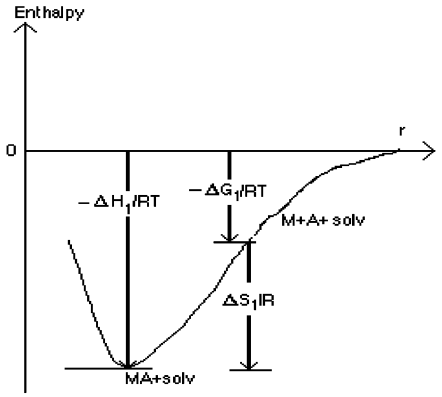

Fig. 3. Potential energy function in a reacting system.

Following the line of Poland [10], I want to find the relation between this kind of partition function employed as molecular descriptor and experimental quantities, such as analytical total amounts, equilibrium constants and site constants. The total analytical amount of molecules in a system with a receptor M and a ligand A forming mononuclear complexes MA, MA_2, MA_3... is represented by the sum of all the species containing M

$$[T_M] = [M] + [MA] + [MA_2] + \ldots + [MA_i] \ldots + [MA_t] \quad (23)$$

where $t = i(\max)$ is the number of binding sites of the receptor M. By dividing by [M] we obtain

$$Z_M = 1 + [MA]/[M] + [MA_2]/[M] + \ldots + [MA_i]/[M] + \ldots + [MA_t]/[M] \quad (24)$$

which has the same structure of the partition function of Eq. (22), provided that each exponential free energy term corresponds to a concentration ratio and, hence, to a relative probability of occupation [11,12]. In fact, the binding of M with iA is ruled by a cumulative binding constant

$$\beta_i = [MA_i][M]^{-1}[A]^{-i} \quad (25)$$

and, therefore, each term

$$\beta_i[A]^i = [MA_i][M]^{-1} \quad (26)$$

can be substituted for each term of Eq. (24), thus obtaining ($\beta_0 = 1$)

$$Z_M = 1 + \beta_1[A] + \beta_2[A]^2 + \ldots \beta_i[A]^i \ldots + \ldots \beta_t[A]^t \quad (27)$$

Each term of Eq. (27) corresponds to an exponential factor $\exp(-\Delta G_i/RT)$ where $-\Delta G_i$ is the free energy change for the binding of M with iA. At [A] = 1, we obtain the cumulative standard free energy change for each step i

$$\exp(-\Delta G_i^\circ/RT) = \beta_i \quad (28)$$

The cumulative binding constant depends on the site affinity constant. The affinity of A to M is measured by the site binding constant k which, in the absence of cooperativity, should be the same for every site of the same class. The whole probability of binding as a function of site constant k can be obtained as the tth power of the probability of binding to one site

$$Z_M = (1 + k\gamma(i)[A])^t \quad (29)$$

where $\gamma(i)$ is a cooperativity function which depends on the cooperativity between sites. The cooperativity is the average weakening (the most general cases) of affinity when other sites are previously occupied by the ligand. The product of Eq. (29) can be transformed to a polynomial and written

$$Z_M = \sum_i m_i\{k\gamma_i[A]\}^i \quad (30)$$

where m_i is the statistical factor and γ_i the cooperativity factor i.e. the value of the cooperativity function of the ith term. Each term of Eq. (30) corresponds to each term of Eq. (27) and hence

$$\beta_i = m_i\{k\gamma_i\}^i \quad (31)$$

The cumulative constant is therefore a function of the statistical factor m_i, of the site constant k, and of the cooperativity factor γ_i. The statistical factor m_i is a dilution indicator depending on the multiplicity of the site in one class and, as such, is an entropy factor. The specific site constant k is proportional to the affinity of binding and is related to the depth of the minimum of the potential function and on the change in kinetic energy. The factor γ_i is the cooperativity factor given by the value of the cooperativity function $\gamma(i)$ at the ith level

$$\gamma(i) = \exp(-b(i-1)) \quad (32)$$

and indicates how the depth and distance of the minimum of the potential function are affected by previous binding of a ligand.

When self-association takes place, the partition function is no longer exactly proportional to the total stoichiometric amount $[T_M]$. In fact, the partition function is composed of as many terms as independent species in solution and, in case of self-association, $Z_M < [T_M]/[A]$ (see Eq. (47b)). When there are more classes of sites, then the partition function becomes a product of probability functions

$$Z_M = (1 + k_1\gamma(i_1)[A])^{t(1)}(1 + k_2\gamma(i_2)[A])^{t(2)} \quad (33)$$

If there is self-association, the molecules, for instance with three M, are considered as a combination between M (receptor) and 2M (ligands).

5. Derivatives of partition function and observables

The partition function as a whole is equal to an exponential probability factor

$$\exp(-\Delta G_i/RT) = Z_M \quad (34)$$

The derivative of $\ln Z_M$ with respect to the variable ln[A] is therefore a change of free energy and corresponds, for mononuclear complexes, to the formation function of Bjerrum

$$\partial \ln Z_M/\partial \ln[A] = \langle n \rangle \quad (35)$$

where $\langle n \rangle$ measures the number of ligand bound per molecule of receptor against ln[A]. The plot is practically a titration curve and the elementary area

$$\langle n \rangle \, \mathrm{d} \ln[A] = \mathrm{d}(-\Delta G_i/RT) \quad (36)$$

is the differential of free energy [13]. By integration between [A] = 0 and [A] = 1, provided that the satura-

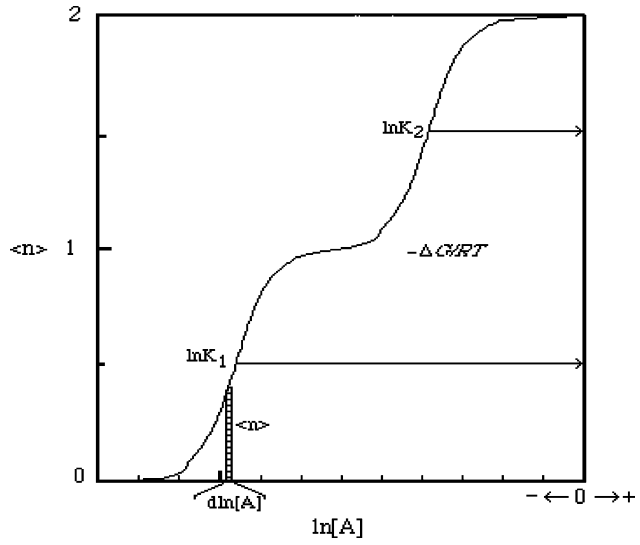

Fig. 4. The integral area below the formation curve is proportional to $-\Delta G_t/RT$.

tion of receptor has been reached, we obtain (Fig. 4)

$$\int_{[A]=0}^{[A]=1} \langle n\rangle \, \mathrm{d}\ln[A] = -\Delta G_t/RT \tag{37}$$

where

$$-\Delta G_t/RT = \ln \beta_t \tag{38}$$

is the free energy change for the whole reaction

$$M + tA = MA_t \tag{39}$$

The formation fraction of each species is

$$\beta_i[A]^i/Z_M = \alpha_i \tag{40}$$

and the formation function can be rewritten as a sum of formation fractions

$$\langle n\rangle = \sum_{i=1}^{i=t} i\alpha_i \tag{41}$$

that can be rearranged to a double summation

$$\langle n\rangle = \sum_{i=1}^{i=t} \sum_{i=i}^{i=t} \alpha_i \tag{42}$$

In the case, for example, with $t=2$, $\langle n\rangle = (\alpha_1+\alpha_2)+(\alpha_2)$ which, when multiplied by d ln[A] and integrated, yields the whole area corresponding to free energy $-\Delta G_t/RT$ as the sum of two areas (Fig. 5), each of which corresponds to one $\ln K_i$. This $\ln K_i$ is the stepwise constant for the ith step. In fact, by recalling Eq. (38)

$$\sum_{i=1}^{i=t} \ln K_i = \ln \beta_t \tag{43}$$

The differences between the areas are proportional to

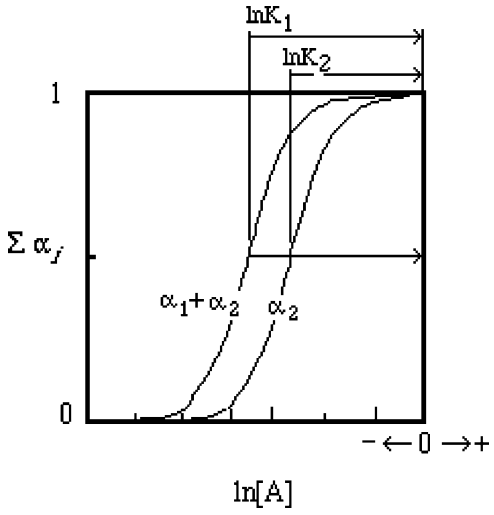

Fig. 5. The cumulative fraction curves delimit areas proportional to $-\Delta G_i/RT$ for each step.

the logarithm of the statistical factor and to the logarithm of the cooperativity factor.

The stepwise constants, however, are not indicative of the real ligation process. In fact, successive binding of ligands to the sites of the receptor (Fig. 6) takes place by rearrangement of the previous bonds [13]. For instance, when the second ligand binds, the bond (if the cooperativity is negative) of the first ligand is weakened and becomes equal to that of the second one. In terms of potential function, this means that the mean minimum of the well is less deep and further from the origin for both ligands The cooperativity might be also positive and the bond lengths would become uniformly shorter.

6. Cooperativity function

In order to verify the model of specific site affinity constant and class cooperativity function, we can recall Eqs. (42) and (43) and calculate

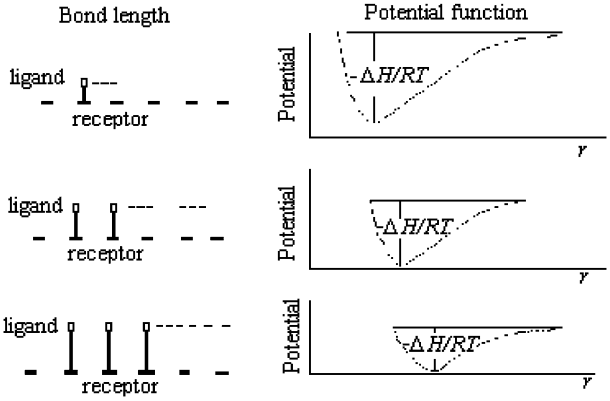

Fig. 6. Successive binding of ligands produces weakening of all the bonds. The reduction of the potential function well is represented on the right.

$$\ln K_{\gamma} = (1/i)(\ln \beta_t \ln m) = \ln k - \ln \gamma(i)$$
$$= \ln k - (i-1)b \quad (44)$$

whereby we calculate the mean cooperativity per site at each binding step and, by extrapolation to $i=1$, the specific site affinity constant. Then by plotting this function [13] against $(i-1)$, a straight line should be obtained with slope b. This behaviour has been observed for several sets of experimental data such as the cumulative constants for complexes Ni(II)–ammonia, Cu(II)–bovine serum albumin (BSA), Co(II)–ammonia, Ni(II)–hydrazine, and Cd(II)–ammonia. The determination of the cooperativity function with cooperativity factor b for BSA is reported in Fig. 7. The Scatchard function

$$\partial \ln Z_{\mathrm{M}}/\partial[\mathrm{A}] = \langle n \rangle/[\mathrm{A}] \quad (45)$$

plotted against $\langle n \rangle$ is a straight line with slope proportional to the site constant k whenever there is no cooperativity, i.e. when the sites are independent. The Scatchard function, however, is curved downward with respect to the straight line of non-cooperativity when the cooperativity is negative and upward when the cooperativity is positive. By applying to the original data of the cumulative constants the cooperativity factor calculated according to Eq. (45), the curve is transformed into a straight line (Fig. 8).

7. Site affinity constants and cooperativity coefficients

In a sufficiently general case, we can assume that there are three independent components M, A, and H forming complexes $\mathrm{M}_P\mathrm{A}_Q\mathrm{H}_R$ defined by the cumulative constants

$$\beta_{PQR} = [\mathrm{M}_P\mathrm{A}_Q\mathrm{H}_R][\mathrm{M}]^{-P}[\mathrm{A}]^{-Q}[\mathrm{H}]^{-R} \quad (46)$$

We can describe the thermodynamic state of the system by means of three partition functions, Z_{M}, Z_{A}, and Z_{H}, respectively

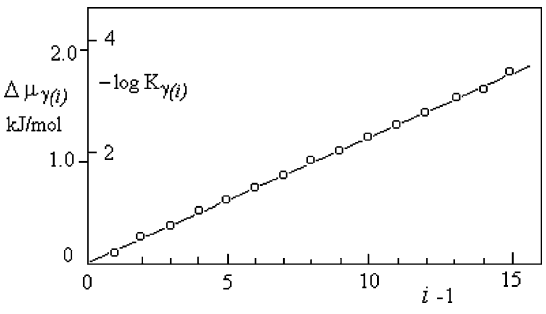

Fig. 7. The cooperativity function reported against $(i-1)$ shows a slope corresponding to b of Eq. (44).

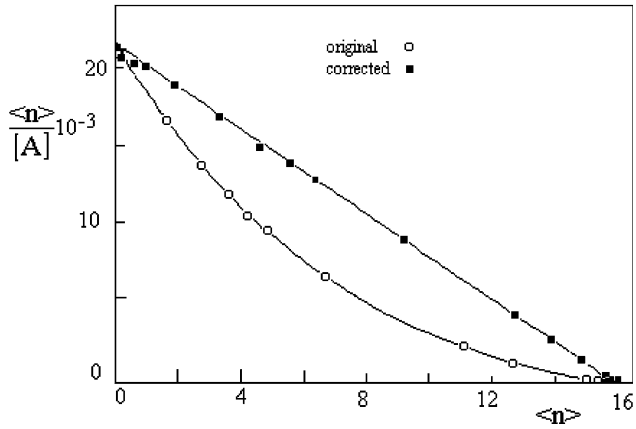

Fig. 8. Scatchard function calculated with original and corrected data of cumulative constants for BSA (Bovine Serum Albumin).

$$Z_{\mathrm{M}} = \sum_{P=1}^{P_t}\sum_{Q=0}^{Q_t}\sum_{R=0}^{R_t}\beta_{PQR}[\mathrm{M}]^{(P-1)}[\mathrm{A}]^{Q}[\mathrm{H}]^{R} \quad (47a)$$

$$Z_{\mathrm{A}} = \sum_{P=0}^{P_t}\sum_{Q=1}^{Q_t}\sum_{R=0}^{R_t}\beta_{PQR}[\mathrm{M}]^{P}[\mathrm{A}]^{(Q-1)}[\mathrm{H}]^{R} \quad (48a)$$

$$Z_{\mathrm{H}} = \sum_{P=0}^{P_t}\sum_{Q=0}^{Q_t}\sum_{R=1}^{R_t}\beta_{PQR}[\mathrm{M}]^{(P-1)}[\mathrm{A}]^{Q}[\mathrm{H}]^{(R-1)} \quad (49a)$$

where P_t, Q_t, and R_t are the maximum values of the indexes P, Q, and R, respectively. The total balance equations become

$$[T_{\mathrm{M}}] = [\mathrm{M}]\{Z_{\mathrm{M}}\} + [\mathrm{M}]\{\partial Z_{\mathrm{M}}/\partial[\mathrm{M}]\} \quad (47b)$$
$$[T_{\mathrm{A}}] = [\mathrm{A}]\{Z_{\mathrm{A}}\} + [\mathrm{A}]\{\partial Z_{\mathrm{A}}/\partial[\mathrm{A}]\} \quad (48b)$$
$$[T_{\mathrm{H}}] = [\mathrm{H}]\{Z_{\mathrm{H}}\} + [\mathrm{H}]\{\partial Z_{\mathrm{H}}/\partial[\mathrm{H}]\} \quad (49b)$$

Each cumulative constant in Eqs. (47a), (48a) and (49a) can be expressed as sums of terms as in Eq. (31) which are functions of statistical factor, site constant of the class j, and cooperativity coefficient $\gamma_{i,j} = \exp(b_j(i-1))$ of the i element of class j. Therefore, it is possible to express the mass balance equations Eqs. (47b), (48b) and (49b) via Eqs. (47a), (48a) and (49a) as functions of the variables k_j and $\gamma_{i,j}$. The derivatives of the mass balance equations with respect to the variables k_j and $\gamma_{i,j}$ can be calculated analytically. Then these derivatives can be employed to construct the normal equations necessary to refine the values of the site constants and of the cooperativity coefficients by means of a non-linear least-squares optimization procedure. A computer program called SITECON has been prepared [14]. This program has been employed to calculate the affinity site constant and the cooperativity constant in a set of titrations of polyamines [15]. The values of the cumulative equilibrium constants calculated by introducing the values of the site constant and of the cooperativity coefficient obtained in the refinement have been compared with (see Table 1) values of the cumulative constants obtained by direct refinement by the computer method

SUPERQUAD [16]. In the series of aliphatic diamines, the value of the cooperativity factors b obtained in the refinement shows a negative cooperativity effect decreasing with the increase of the molecular length (Table 2). This conforms to the hypothesis that the reciprocal influence of the two binding sites is smaller the greater is the distance between them. The question can be raised whether the cooperativity effect, which is a free energy difference, is purely enthalpic or partially enthalpic and partially entropic. The results obtained so far are not conclusive in this respect.

8. Partition function derivatives: buffer capacity and heat capacity

The formation function, which is the first derivative of partition function with respect to ln[A] can be derived again, thus obtaining, as the second derivative, the buffer capacity B_C. The buffer capacity is an element of the matrix formed by the second derivatives of the partition function. The B_C values of the different parts are important features of the titration curve. It is important, however, to emphasize that the buffer capacity is the second derivative of ln Z_M

$$B_C = \partial^2 \ln Z_M / \partial(\ln[A])^2 \quad (50)$$

and as such it indicates the spreading (variance) of the free energy around values of ln β_t. The buffer capacities are independent for each cumulative constant and are a good indicator of the multimodal distribution of the reacting ensemble (Fig. 9).

In the cases where there is only one site, the formation function is identical with the molar fraction α_1 of the complex and its derivative with ln[A] can be rewritten as

$$B_C = \partial\alpha_1/\partial \ln[A] = \alpha_1(1-\alpha_1) \quad (51)$$

whereby B_C becomes the convolution of α_1 with its complement to unity. Because of this property, every cumulative curve can be convoluted with its own complement to unity to produce a set of buffer capacity curves, one curve for each ln β_t.

Every constant either cumulative or stepwise can be derived with respect to the reciprocal temperature thus yielding the reaction enthalpy for the corresponding reaction

$$(\partial \ln K_i/\partial(-1/T))_p = (\Delta H_{i,i-1}/R) \quad (52)$$

or

$$(\partial \ln \beta_i/\partial(-1/T))_p = (\Delta H_i/R) \quad (53)$$

where $\Delta H_{i,i-1}$ is the enthalpy of the reaction $MA_{i-1} + A = MA_i$ and ΔH_i is the enthalpy of the reaction $MA_{i-1} + iA = MA_i$. By further derivation with respect to T, we obtain the heat capacity

$$\partial^2 \ln \beta_i/\partial(-1/T)\partial T = \partial^2 \ln\beta_i/\partial(\ln T)^2 = (\Delta C_{p,i}/R) \quad (54)$$

If the equilibrium constant matches exactly the species involved, then $(\Delta H_i/R)$ is constant $(\Delta C_{p,i} = 0)$. By plotting ln β_i against $(1/T)$ we obtain a straight line whose slope yields the reaction enthalpy. If, however, other reactants are involved in the reaction but are not explicitly included in the equilibrium constant, particularly the solvent, then the enthalpy is altered by the contribution of these reactants and we do not obtain a constant slope any more $(\Delta C_{p,i} \neq 0)$, but rather a curve at a variable slope.

The partition function can be also derived with respect to ln T thus obtaining another element of the

[a] Data from Ref. [16].

derivative matrix. The first derivation with respect to ln T yields the molar fraction obtained from the change of temperature α_T

$$(\partial \ln(1+k[\mathrm{A}])/\partial(\ln T))_\mathrm{p} = (1/R)\{(\Delta H_i/T) - n_\mathrm{A} C_{\mathrm{p,A}}\}\alpha = (1/R)\alpha_T \quad (55)$$

and the second derivation yields

$$(\partial^2 \ln(1+k[\mathrm{A}])/\partial(\ln T)^2)_\mathrm{p} = (1/R)\alpha_T(1-\alpha_T)\{(\Delta H_i/T) - n_\mathrm{A} C_{\mathrm{p,A}}\} \quad (56)$$

which by comparison with Eq. (51) can be recognized as an apparent (buffer) heat capacity.

$$(\partial^2 \ln(1+k[\mathrm{A}])/\partial(\ln T)^2)_\mathrm{p} = (1/R)\Delta C_{\mathrm{p,app}} \quad (57)$$

Therefore, we obtain an explicit expression for the apparent heat capacity $\Delta C_{\mathrm{p,app}}$

$$\Delta C_{\mathrm{p,app}} = \alpha_T(1-\alpha_T)\{(\Delta H_{\mathrm{reac}}/T) - n_\mathrm{A} C_{\mathrm{p,A}}\} \quad (58)$$

This heat capacity is called *apparent* because it is dependent not only upon the heat supplied to the system to increase the temperature by one degree but also upon the endogenous heat produced or absorbed by the advancement of the reaction produced by the change of temperature. (We recall that the definition of molar heat capacity is the amount of heat supplied to the system necessary to increase the temperature of one mole of substance by one degree).

By multiplication of Eq. (58) by dT and integration (Fig. 10) between the limits T_1 (beginning of the reaction) and T_2 (end), we obtain the denaturation heat Q_{den}

$$Q_{\mathrm{den}} = \Delta H_{\mathrm{reac}} - n_\mathrm{A} C_{\mathrm{p,A}} T_{\mathrm{av}} \quad (59)$$

where T_{av} has been substituted for the mean temperature between T_1 and T_2. If the reaction is denaturation with water as ligand the result is

$$\Delta H_{\mathrm{den}} = (\Delta H^\circ + n_\mathrm{w} T_{\mathrm{den}} C_{\mathrm{p,w}}) \quad (60)$$

where T_{den} has been substituted for the mean temperature. This means that, according to this model, the denaturation enthalpy is changing linearly with the temperature following the expression

$$\Delta H_{\mathrm{den}} = \Delta H^\circ + \Delta C_\mathrm{p} T_{\mathrm{den}}, \quad (61)$$

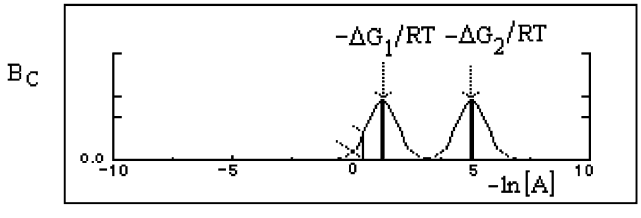

Fig. 9. Buffer capacity B_C as indicative of a multimodal distribution in a reacting system.

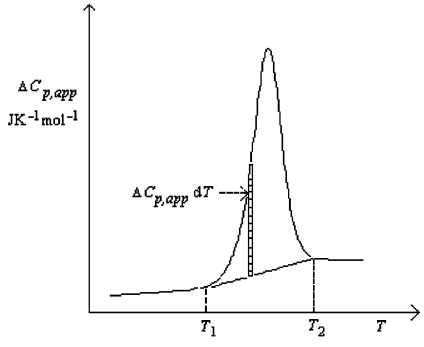

Fig. 10. Denaturation calorimetric profile for one-step process.

with ($\Delta C_p \neq 0$)

$$\Delta C_p = n_w C_{p,w} \tag{62}$$

It is then possible from the slope of the line ΔH_{den} against T to obtain the number n_w of water molecules involved in the denaturation process, by assuming $C_{p,w} = 75.38$ J K^{-1} mol^{-1}. The real changes in $C_{p,w}$ between 0 and 100 °C are very small and no appreciable error ($< 0.2\%$) is introduced by assuming a constant value and hence a non-reacting system. These calculations have been applied [17] to several sets of data of different origin and in any case the number of water molecules has been calculated. An example is represented in Fig. 11. The values n_w of water molecules calculated for different proteins range from 66.8 for β-lactoglobulin to 283 for ribonuclease. It depends on the size of the molecule, on the pH, and the hydrophobic character of the substituents.

Similarly for micelles [17], by plotting the micellization enthalpy against T, a straight line is obtained with negative slope, thus indicating that $n_w < 0$. This is in accordance with a possible mechanism of micellization opposite to that occurring in denaturation, whereby the separated chains are initially surrounded in the solution by a cavity which has been produced by some water molecules relaxed during the solubilization process. When the two hydrophobic moieties come close to one another, they need a volume which is smaller than the sum of the original cavities. As a consequence, a certain number n_w of released water molecules need to be restructured to occupy the available space.

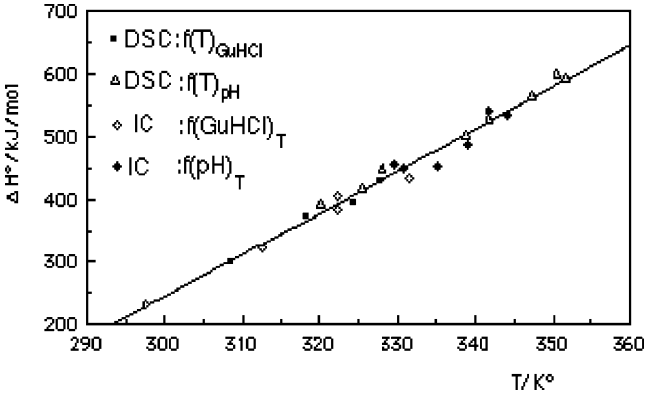

Fig. 11. Denaturation enthalpy of HEW lysozyme versus T. (Data from Ref. [18].) DSC, differential scanning calorimetry (denaturation by varying the temperature T at various constant concentrations of GuHCl or at various constant pH). IC, isothermal calorimetry (denaturation by adding GuHCl or by changing pH at various constant temperatures T).

9. Probability space, thermodynamic space, and energy space

The partition function belongs to the probability space and through Eq. (34) can be transformed into a function of the thermodynamic space [4]

$$\ln Z_M = -\Delta G/RT \tag{63}$$

The thermodynamic space is the domain of the relative changes of probability. In the thermodynamic space, the function can be expanded in a Taylor series following the maximum entropy method [19–21]. The logarithmic function can be written

$$\ln Z_M = (\ln Z_M)_0 + \sum\nolimits_n M^{(n)} x^n \tag{64}$$

where $(\ln Z_M)_0$ is the value of the function at the centre of expansion, x is a thermodynamic variable that can be either ln[A], ln T, or $1/T$, and $M^{(n)}$ is the nth derivative of the function with respect to the variable chosen

$$M^{(n)} = \partial^n \ln Z_M / \partial x^n \tag{65}$$

For instance, if $x = (\ln[A] - \ln[A]_0)$, then the first moment is given by $\langle n \rangle$ of Eq. (35) and the second moment by the buffer capacity B_C of Eq. (50). Higher moments can be calculated as derivatives of the partition function with respect to ln[A]. Poland has shown how this expansion can be used to calculate the partition function starting from the knowledge of the higher moments [19].

If the variable is $x = (\ln T - \ln T_0)$, then the first moment is given by Eq. (55) and the second moment by Eq. (57). If the variable is $x = (1/T - 1/T_0)$, then the first moment is the reaction enthalpy of Eq. (52) and the second moment is a function of the heat capacity $C_p^* = T^2 C_p$ [22]. An application of the variable $x = (1/T - 1/T_0)$ has been given in the study of the dependence upon the temperature of the protonation constant of carboxylic acids [23]. On the other hand, by multiplication of both members of Eq. (63) by RT, we perform a transformation to the energy–affinity space

$$-RT \ln Z_M = \Delta G \tag{66}$$

for which the derivative with respect to the variable $x = T$ is

$$M^{(1)} = \partial(\Delta G)/\partial x = \partial(\Delta H - T\Delta S)/\partial x = -\Delta S \tag{67}$$

It is possible, however, to expand the function ΔH, which is to conform to the energy space, in a Taylor series, for which the first moment is the heat capacity ΔC_p and higher moments can be calculated by expanding the heat capacity as a function of $x = (T - T_0)$. Poland [20,21] has shown how the expression for heat capacity as the function of the variable x can be used to calculate the enthalpy by integration, starting from the knowledge of the moments of heat capacity.

atom by the N(9) donor (as mono-dentate) [1,3,4,7,9,10] or in a μ-N(3),N(9) bridging mode (oligomers) [2,5,6,8]. Such coordination modes in non-substituted adenine species are understood on the basis that the N(9) donor atom is the most basic among its five nitrogen atoms, followed by N(1) [1]. Interestingly a single metal–N(3)–adenine coordination has been proved in the structure of [Ni(AdeH)(tren)Cl]Cl [11] and [Pd(thiacyclophane)(AdeH)]BF_4 [12]. A variety of structures concerning adeninium(1+) and adeniniun(2+) ions (for this latter, four inorganic salts [13–15]) are also known. Compounds which have $AdeH_2^+$ cation are a broad variety of salts with inorganic or organic counter-anions as well as adeninium(1+)–metal complexes of nickel(II) [16], copper(II) [8–10], zinc(II) [17–19] cadmium(II) [20] and silver(I) [21]. In the Cd(II) derivative the $AdeH_2^+$ ligand acts as a bridge, with an unexpected μ-N3,N7 coordination mode [20]. In Ag(I) complexes, $AdeH_2^+$ ion links the metal by N(9) atom [21], whereas in Ni(II) [16] and Zn(II) [17–19] derivatives the donor is unusually the N(7) atom. Keeping this in mind, as a part of the laboratory work for our students in Inorganic Aspects of Biological Processes [22], the following proposal was made: to carry out the reaction of AdeH and aqua(dihydrogen-ethylenediaminetetraacetato)copper(II), [Cu(H_2EDTA)(H_2O)], an acid-complex derivative of ethylenediaminetetraacetic acid (H_4EDTA) whose structure was reported by Stephens a long time ago [23]. In this octahedral complex the pentadentate H_2EDTA^{2-} ligand has one coordinated and one free acetic arms. We could expect that this acidic complex should react with neutral AdeH to give the $AdeH_2^+$ ion. This adeninium(1+) ion could or could not bind the copper(II) atom. In this latter case it probably replaces the aqua ligand, which in the parent complex is among the four closest donors. The best way to find definitive answers to these hypotheses is to perform the X-ray structure determination of the corresponding reaction product. In this connection, we have carried out the synthesis, structure and properties of the title compound.

2. Experimental

All chemicals were commercially available products of reagent grade and used without further purification.

2.1. Synthesis of title compound *1*

Adeninium [aqua(ethylenediamine-*N*,*N*,*N*′-triacetato-*N*′-acetic acid)copper(II) dihydrate} (**1**) ($AdeH_2$)[Cu(HEDTA)(H_2O)]·$2H_2O$, was obtained by reaction of $Cu_2CO_3(OH)_2$ (221 mg, 1 mmol, Probus or Aldrich) and H_4EDTA (588.5 mg, 2 mmol, Sigma) in water (100 ml) in a Kitasato flask, by heating (15 min, $t < 50$ °C) and stirring under reduced pressure (to remove the CO_2, by-product). The resulting blue solution was stirred and heated at 60 °C during 30 min. After leaving it to cool to room temperature (r.t.), it was slowly filtered (without vacuum, to remove a very small amount of CuO) on an Erlenmeyer flask. Adenine (270 mg, 2 mmol) was added to this clear blue solution and stirred. No appreciable change of colour occurs in the solution, which was filtered without vacuum on crystallisation device. By slow evaporation of the clear solution at r.t. (1–2 weeks), crystals of compound **1** were observed. First poly-crystals were removed by filtration. The evaporation of the remaining solution (partially covered with a plastic film) gives many well-shaped crystals of the desired product suitable for X-ray diffraction studies. Several fractions of the product were collected by filtration, washed with cold water and air-dried. The blue compound is stable at r.t. without apparent water loss. It can be re-crystallised at r.t. from water. Yield: 980 mg (90%). $C_{15}H_{25}CuN_7O_{11}$: Calc.: H 4.64, C 33.18, N 18.06. Found: H 5.13, C 32.99, N, 18.19%. Calc. Cu 11.7. Found: Cu 17.6% (EDTA complexometry [24]). If the solution of compound **1** became microbiologically contaminated, ethanol should be added, the solution covered with a plastic film, filtered without vacuum 2 or more days after, and left to evaporate as before. Using a molar ratio Cu(II)/H_4EDTA/AdeH 1:1:2, a pale blue powder of the type Cu(EDTA)·$(AdeH_2)_2$·nH_2O is also obtained. However, no suitable crystals for X-ray diffraction studies of such compound have yet been obtained. The analytical data of this product is close to a 1:2 metal/ligand molar ratio, but at the present time it seems not consistent enough to a well-defined stoichiometry.

2.2. Crystal structure determination

A blue prismatic crystal of (AdeH)[Cu(HEDTA)(H_2O)]·$2H_2O$ was mounted on a glass fibre and used for data collection. Crystal data were collected at 291(2) K, using a Bruker SMART CCD 1000 diffractometer. Graphite monochromated Mo Kα radiation ($\lambda =$ 0.71073 Å) was used throughout. The data were processed with SAINT [25] and corrected for absorption using SADABS (transmission factors: 0.9189–0.6729) [26]. The structure was solved by direct methods using the program SHELXS-97 [27] and refined by full-matrix least-squares techniques against F^2 using SHELXL-97 [28]. Positional and anisotropic atomic displacement parameters were refined for all non-hydrogen atoms. Hydrogen atoms were located unambiguously from difference Fourier maps and refined isotropically. Atomic scattering factors from 'International Tables for X-ray Crystallography' [29]. Molecular graphics were obtained with the program PLATON [30]. A summary of the crystal data, experimental details and refinement results are listed in Table 1.

Table 1
Crystal data and structure refinement for compound **1**

Empirical formula	$C_{15}H_{25}CuN_7O_{11}$

Largest difference peak and hole (e Å^{-3})	0.394 and −0.394

2.3. Physical measurements

Elemental analysis was performed on a Fisons–Carlo Erba EA 1108 microanalyser (C, H, N) or by standard EDTA complexometry (Cu). The infrared spectrum was obtained by the KBr disc technique on a JASCO FT-IR 410 instrument. TG analysis (pyrolysis) of the studied compound (295–875 K) in air flown (100 ml min^{-1}) and corresponding IR spectra of evolved gasses were recorded using a Shimazu Thermobalance TGA-DTG-50H coupled with an FT-IR Nicolet Magna 550. Electronic (reflectance) spectrum (175–3300 nm) was obtained in a Varian Cary-5E spectrophotometer. RSE spectrum of a polycrystalline sample was recorded without magnetic dilution in a spectrophotometer Bruker ESP 300E (X band) at r.t. Magnetic susceptibility was measured at the temperature range 80–300 K using a Manics DM magnetometer. The susceptometer was calibrated with mercury tetrakis(thiocyanato)cobaltato(II). Corrections for the diamagnetism (-271.47×10^{-6} cm^3 mol^{-1}) were estimated from Pascal's constants [31]. Experimental susceptibilities were also corrected for the temperature-independent paramagnetism (60×10^{-6} cm^3 mol^{-1}).

3. Results and discussion

3.1. Cu(II) coordination, conformation of ligands and crystal packing in compound 1

Bond lengths and angles of the copper(II) coordination in the complex $[Cu(HEDTA)(H_2O)]^-$ of compound **1** are listed in Table 2. Structural data of the adeninium(1+) ion are given in Table 3. Hydrogen bonding data of the studied crystal are showed in Table 4. The studied compound consists of a salt of the complex anion $[Cu(HEDTA)(H_2O)]^-$ and the adeninium(1+) cation with two non-bonded to the metal water molecules (Fig. 1). The copper(II) atom exhibits a distorted octahedral coordination supplied by a penta-dentate $HEDTA^{3-}$ anion and one aqua ligand. This coordination polyhedron is of the general type 4+1 and closely related to those reported for the parent complex $[Cu(H_2EDTA)(H_2O)]$ [23] (hereafter compound **2**) and the bimetallic derivative $Ag[Cu(HEDTA)(H_2O)]\cdot H_2O$ [32] (hereafter compound **3**). The metal falls at 0.083(1) Å from the mean plane P-1 [O1,O11,O15,N12] of the four closest donor atoms (0.075(1) and 0.13(1) Å in compounds **2** and **3**, respectively). In the three compounds which we are considering now, the partially protonated EDTA ligand acts as pentadentate giving a Cu(II)–ethylendiamine-like ring (E ring) and three Cu(II)–glycinato-like rings (one of them is a Cu(II)–glycine-like ring in compound **2**). Two of these three rings are so-called R rings (nearly perpendicular to the plane P-2 [Cu1,N11,N12]), and the

other, is a G ring (nearly coplanar to P-2) [32,33]. The G ring is more strained than the R ones [34], as the corresponding bond angles on the metal atom reveal (73.2° for the G ring, and 79.2 and 85.6° for R1 and R2 rings involving the O(18), O(15) and O(11) donor atoms, respectively). The free carboxymethyl arm in the three compounds could be considered as an 'opened G ring'.

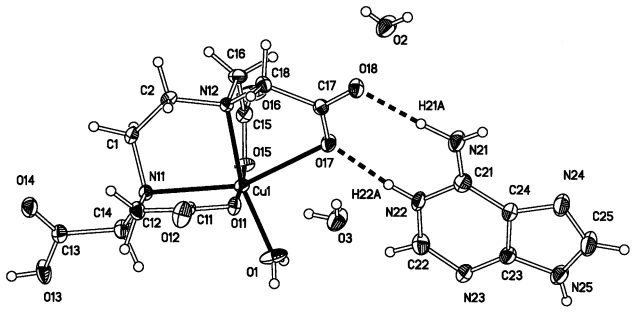

Fig. 1. Asymmetric unit in the crystal of $(AdeH_2)[Cu(HEDTA)(H_2O)]\cdot 2H_2O$ (compound **1**) with the numbering scheme. The two rather linear hydrogen bonds involved in the cation–anion recognition are depicted as dashed links.

Among the three methylene groups linked to the same N atom, those of the E and G rings fall to the same side of the plane P-2, and that of the R ring, to the opposite side [33]. The partially protonated EDTA ligand exhibits in **1** a E,G/R conformation, as in all mononuclear octahedral metal–EDTA chelates [33]. The E ring is puckered. The G and R1 rings have unsymmetrical envelope conformations whereas the R2 ring adopts a less common puckered form [35].

On the other hand, assuming that the N–H bond in neutral AdeH corresponds to the most basic N9 atom (formula 1) and was reported for the crystal structure of the free base [36]), the protonation of the adenine is made in the called N1 atom (formula 2). Indeed, such N1 protonation has been reported for the crystal structure of the adenine hydrochloride *hemi*-hydrate [37] and all known structures involving the adeninium(1+) cation. The N1 protonation is consistent with the C(21)–N(22)–C(22) bond angle (123.4(3)°) which is larger than that of the free base by 4.7°. A similar difference (5°) corresponds to the Ni(II)-bounded adeninium in $[Ni(NTA)(AdeH_2)(H_2O)]\cdot 2.5H_2O$ [16]. The adeninium(1+) cation is planar within ±0.025(1) Å.

In contrast to all other known Cu(II)–adeninium derivatives [8–10], which have coordinated adenium(1+) ligand, compound **1** consists, as referred above, of a salt. This means that the complex **2** reacts with AdeH to give the anion $[Cu(HEDTA)(H_2O)]^-$ which seems unable to recognise the cation $AdeH_2^+$ by means of a complexation process (for example, by a substitution reaction of aqua by the adeninium(1+) ligand). In contrast, Aoki et al. [16] have proved that the octahedral anion diaqua(nitrilotriacetate)nickel(II) recognises selectively the adeninium(1+) ion forming the neutral complex adeninium-aqua(nitrilotriacetato)nickel(II) (described as $[Ni(NTA)(H_2O)(AdeH_2)]_2\cdot 5H_2O$ in the crystalline state [16]) where the unusual Ni–N7($AdeH_2^+$) bond is reinforced by an intra-molecular

bond between an exocyclic N–H bond and one or two O-carboxylate atoms of the NTA ligand. Remarking that complexes $[Ni(NTA)(H_2O)_2]^-$ and $[Cu(HEDTA)(H_2O)]^-$ are both octahedral anions, we suggest that the difficulty of the latter in accepting the adeninium(1+) ion as a 'secondary' ligand arises from steric constraints favouring the recognition by the formation of an ion pair stabilised by inter-ionic hydrogen bonds. Consistently, the data of Table 4 reveal that, among others, there are two rather linear hydrogen bonds [the 'onium' $N(22)^+$–H(22A)···O(17) and exocyclic N(21)–H(21A)···O(18) interactions] where the adeninium(1+) ion acts twice as H-donor for the two O atoms of the same carboxylate group of the $HEDTA^-$ (Figs. 1 and 2). A detailed analysis [38] of the short aromatic ring–ring interactions (with centroid–centroid distances < 6.0 Å and its angles with the normal to the stacked ring planes, β and $\gamma < 60°$) reveals that such ion pairs recognise themselves to form aggregates $\{(AdeH_2)[Cu(HEDTA)(H_2O)]\}_2$ by a π,π-ring stacking interaction (Fig. 2). In the present case, for symmetry reasons, such interaction is displayed by the parallel six-membered rings of two adjacent $AdeH_2^+$ ions (symmetry code $\#5 = -x, -y, 1-z$). With a centroid–centroid vector of 3.39 Å and slipping angles (between the centroid–centroid vector and the normal to each stacked plane) $\beta = \gamma = 10.1°$, the inter-planar distance is 3.34 Å. Such stacking is rather close to, but not strictly, a 'face-to-face' interaction. In addition of the two referred inter-ionic hydrogen bonds, the remaining polar bonds (O–H from the $HEDTA^{3-}$ carboxyl group or water molecules and heterocyclic and exocyclic N–H of $AdeH_2^+$ ion) interact with carboxylate or water O atoms or adeninium N3 and N7 atoms (see Table 4). These hydrogen bonds involve nine different asymmetric units building the crystal as an extensive 3D network. The shortest hydrogen-bridges (2.638–2.672(4) Å) are those involving the aqua ligand, the free carboxylic group of $HEDTA^{3-}$ and both heterocyclic N–H bonds of $AdeH_2^+$ ion.

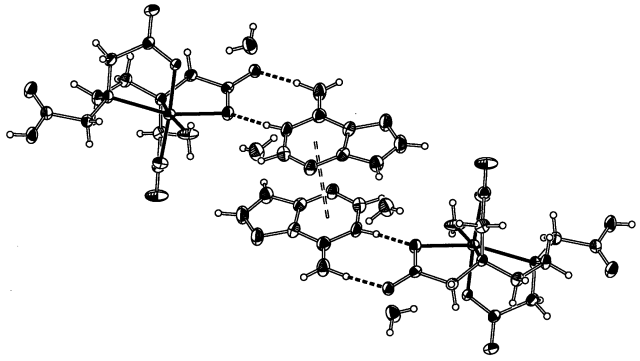

Fig. 2. Formation of aggregates $\{(AdeH_2)[Cu(HEDTA)(H_2O)]\}_2$ by anti-parallel π,π-stacking interaction between adeninium(1+) cations in the crystal of $(AdeH_2)[Cu(HEDTA)(H_2O)]\cdot 2H_2O$.

The structural results reported here offer a definitive answer to the main question of the aim of the present work. In this context, we can also consider that hypoxanthine (6-hydroxopurine) is unable to bind directly to the Ni–NTA chelate, because it has not the possibility to form an appropriate inter-ligand hydrogen bond, whereas the hypoxanthinato(1−) ion acts as a bridging ligand in $[\{Cu(tren)\}_2(\mu\text{-hypoxanthinato})](ClO_4)_3$ (tren = tris(2-aminoethyl)amine) [1] because each tren ligand forms an inter-ligand hydrogen bond with the bridging base. In addition, the Ni–NTA chelate is unable to coordinate the cytosinium(1+) ion because of the protonation of the 'N3' donor, but three inter-ligand hydrogen bonds are used in the inter-ionic recognition process in the salt (cytosinium)$[Ni(NTA)(H_2O)_2]\cdot 2H_2O$ [16]. This latter compound resembles the compound **1** in the out-spherical attachment of the protonated base to the metal chelate. However, it should be noted that the cytosynium(1+) ion has not an available N-heterocyclic donor, whereas the N-heterocyclic coordination of the adeninium(1+) ion to the copper(II) [8–10] and other metal ions [11,12] is well known.

3.2. Properties of compound *1*

The TG/DTG analysis of compound **1** (5.834 mg, 20 °C min^{-1}, in air flown) reveals its thermal decomposition in four steps. Selected FT-IR spectra of the evolved gasses are shown in Fig. 3. The first one (115–180 °C, maximum rate of weight loss at 151 °C, experimental weight loss 6.980% > calculated for $2H_2O$ 6.636%) is due to the loss on non-coordinated water, and lead to a starting actual 'TG-formula' $(AdeH_2)[Cu(HEDTA)(H_2O)]\cdot 2.1H_2O$ (FW 544.747; calculated weight loss 6.945% for $2H_2O$, in good agreement with the experimental value 6.980%). The second step (180–310 °C, weight loss of 36.582%) corresponds reasonably to the estimated loss (35.453%) of the aqua ligand and the pyrolysis of the free carboxymethyl arm ($-CH_2COOH$) and two acetate arms ($-CH_2COO^-$) from $HEDTA^{3-}$ ligand. Consistently, only water loss is observed during the first step, whereas FT-IR spectra during the second step show bands of H_2O, CO_2 and CO. The third step (310–440 °C) produces H_2O, CO_2, N_2O, and lower amounts of NH_3 and CO, whereas the last step (440–480 °C) gives H_2O, CO_2, N_2O, NO and a little CH_4 and NH_3. These steps correspond to the overlapped pyrolysis of the $HEDTA^{3-}$ residue and $AdeH_2^+$ ligand, giving a residue of CuO (experimental 14.651% and calculated 14.602% for the TG-formula). It seems rather improbable that the adeninium(1+) ion pyrolyses at so higher temperatures (> 300 °C) and perhaps adeninate(1−) is formed before this process occurs.

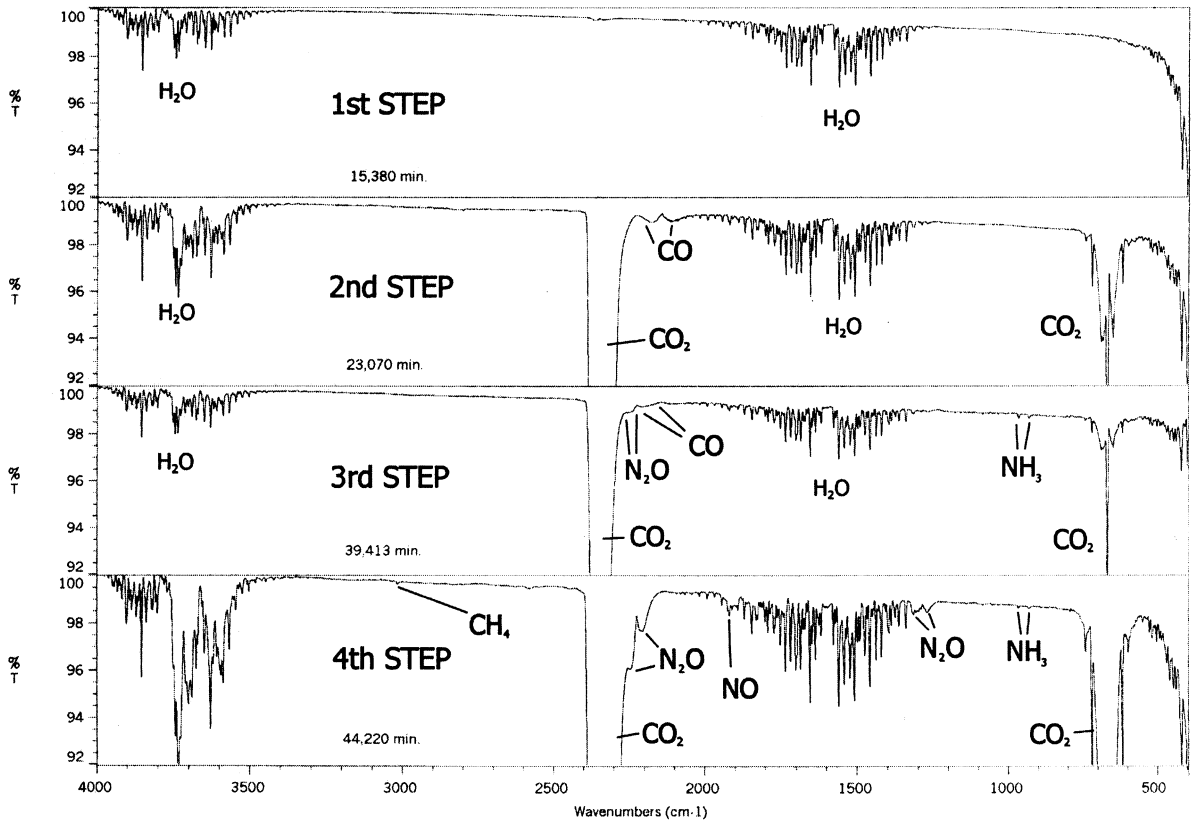

Fig. 3. Selected FT-IR spectra for identification of evolved gasses in the four steps of decomposition and pyrolysis of $(AdeH_2)[Cu(HEDTA)(H_2O)]\cdot 2H_2O$.

The IR spectrum has many peaks and bands expected for contributions of water and/or aqua, $HEDTA^{3-}$ and $AdeH_2^+$ ligands. Tentative assignments (in cm^{-1}) are as follows: $\nu_{as}(H_2O)$, 3440; $\nu_s(H_2O)+\nu_{as}(NH_2)$, 3356; $\nu_s(NH_2)$, 3242; the N^+–H chromophore gives a typical series of peaks in the range 2800–2250 [39] (six peaks in this case), including one at 2760 of $\nu(N^+–H)$; $\nu(C{=}O)$ of hydrogen bonded –COOH, 1720 and 1693; $\delta(H_2O)+\nu_{as}(COO)$, 1595; $\delta(NH_2)$ and $\delta(N^+–H)$, 1537 (shoulder) and 1495 (peak), respectively; $\nu(C–O)+\delta(O–H)$ of –COOH, 1404; and $\nu_s(COO)$, 1381. A large difference $\Delta=\nu_{as}(COO)-\nu_s(COO)=214\ cm^{-1}$ suggests the main ionic character of the Cu(II)–O(carboxyl) bonds [40]. The electronic spectrum shows an unsymmetrical d–d band at $\nu_{max}=13\,260\ cm^{-1}$ (with a shoulder $\sim 8360\ cm^{-1}$) in agreement with the elongated octahedral chromophore $CuNO_3+N+O$. The powder ESR spectrum at r.t. is *quasi*-isotropic type with $\sim g_{//}=2.17>g_{av}=2.14>\sim g_{\perp}=2.13>2.03$, which yields no useful g value information but is in accordance with a d_{x2-y2} Cu(II) ground state, long metal–metal separations (Cu(1)–Cu(1^i) = 7.053(1) Å) and local molecular axes clearly misaligned in the crystal [41]. A plot of χ data versus T (K) ($T=79$–290 K) is linear ($1/\chi=(1/C)T-(\theta/C)$ with a statistical r^2 factor of 0.9965) according to a Curie–Weiss behaviour, $\chi=C/(T-\theta)$ [31]. The Curie constant is $C=0.43$ K emu mol^{-1} with Weiss constant of $\theta=7.46$. The estimated value of μ_{eff} for Cu(II) atom is 1.86 BM, according to the structure reported here.

4. Concluding remarks

We can consider that the chelated anions $[Cu(HEDTA)(H_2O)]^-$ and $[Ni(NTA)(H_2O)_2]^-$ [16] display different mechanisms to recognise the adeninium(1+) ion. The former by means of an ion pair stabilised by two inter-ionic hydrogen bonds, and the latter, as a secondary ligand also reinforced by an inter-ligand NTA–$AdeH_2^+$ hydrogen bond. In addition, ion-pairs of compound **1** recognise themselves forming a slightly slipped π,π-stacking interaction between the six-membered rings of anti-parallel symmetry related adjacent $AdeH_2^+$ cations. In contrast, such aromatic π,π-ring stacking seems not to take part in the crystal packing of the related compound $[Ni(NTA)(AdeH_2)(H_2O)]\cdot 2.5H_2O$ [16].

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre CCDC No. 172659 for compound $(AdeH_2)[Cu(HEDTA)(H_2O)]\cdot 2H_2O$. Copies of this information may be obtained free of charge form The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

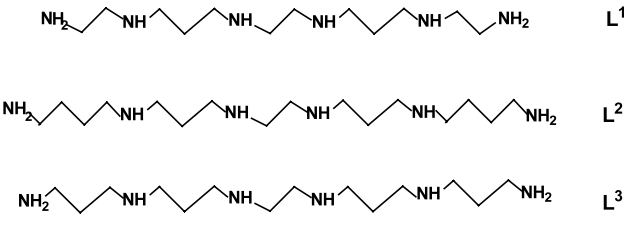
Received 24 October 2001; accepted 20 November 2001



Abstract

The synthesis of the two new linear hexa-amines, 3,7,10,14-tetraazahexadecane-l,16-diamine (L^1) and 5,9,12,16-tetraazaicosane-l,20-diamine (L^2) has been reported. Ligand protonation and Cu(II) and Zn(II) coordination have been studied in aqueous solution by means of potentiometric, microcalorimetric (298.1 K, $I = 0.1$ mol dm^{-3}) and spectrophotometric (UV–Vis, ^{1}H and ^{13}C NMR) measurements. The species present in solution and their stability constants have been determined. L^1 forms mono- and binuclear complexes in aqueous solution with Cu(II). In the $[ML^1]^{2+}$ complexes, the metal ion is coordinated by five nitrogen atoms, while in the $[ML^2]^{2+}$ complexes the metal ion is four-coordinate. This different behavior is explained in terms of the different numbers of methylene groups between adjacent nitrogen atoms. © 2002 Elsevier Science Ltd. All rights reserved.

Keywords: Linear polyamines; Metal complexes; Polyamine complexes

1. Introduction

In recent years [1] much effort has been devoted to the synthesis and characterization of large macrocyclic polyamines such as those in the series [3k]aneN$_k$ (k = 5–12) [2] and their complexes. These ligands are able to hold more than one metal ion inside the ring structure. The ligands are sufficiently flexible so that they can wrap themselves around various metal ions in a way that achieves an optimal match between the stereochemical requirements of both metal and ligand atoms [3–5]. Also, the protonated forms of these ligands are able to encapsulate anions [6]. Recently, some of us [7–9] reported that linear polyamines containing a similar number and type of nitrogen donor atoms have very similar metal coordination chemistry, both in terms of the equilibrium speciation and of the stabilities of the different complexes formed, though there are much more data for macrocyclic polyamines than for linear ones. It has been shown that cyclic polyamines which produce a sequence of alternating five- and six-membered rings form stronger complexes than ligands which produce all five-membered or all six-membered chelate rings [10,11]. In order to get further insight into the chemistry of long open-chain polyamines we have synthesized the two ligands L^1 and L^2, which differ in the size of the chelate rings that may be formed and have examined the formation of complexes of these ligands with Cu(II) and Zn(II).

2. Experimental

2.1. Synthesis of 3,7,10,14-tetraazahexadecane-l,16-diamine (L^1) and 5,9,12,16-tetraazaicosane-1,20-diamine (L^2)

The synthesis of compounds L^1 and L^2 was carried out by the general synthetic route depicted in Scheme 1.

Perhydro-4,5,8a,10a-tetraazaphenanthrene (**1**) was prepared as previously described [12].

2.2. Synthesis of 4,5-bis(phthalimidoalkyl)-perhydro-4,5,8a,10a-tetraazaphenanthrene

To a solution of **1** (3.9 g, 20 mmol) in 60 cm^3 of dry CH_3CN, K_2CO_3 (200 mmol) and a solution of ω-bromoalkylphthalimide (40 mmol) in 50 cm^3 of CH_3CN were added. The reaction mixture was refluxed for 3 days. After reaction, the base was filtered, washed with CH_2C1_2 (3×10 cm^3) and solvents evaporated in vacuo. The resulting solid was recrystallized in CH_3CN affording L^1 and L^2 as white crystals. For L^1 alkyl = ethyl: yield 50% (the mono phthalimidoethyl adduct was also formed and separated by recrystallization from CH_3CN). NMR ^{13}C ($CDCl_3$): 168.3 (CO), 133.6, 132.3, 122.8 (C_{ar}), 79.7 (C_{aminal}), 56.6, 53.1, 50.8, 44.8 (NCH_2), 36.8 (CH_2N_{phth}), 19.9 ($NCH_2CH_2CH_2N$).

For L^2 alkyl = butyl: yield 92%. NMR ^{13}C ($CDCl_3$): 168.3 (CO), 133.6, 132.1, 122.9 (C_{ar}), 80.3 (C_{aminal}), 56.7, 53.4, 49.9, 45.2 (NCH_2), 37.8 (CH_2N_{phth}), 26.3, 26.1 ($CH_2CH_2CH_2CH_2$), 19.4 ($NCH_2CH_2CH_2N$).

2.3. General procedure for deprotection of $L^{1\prime}$ and $L^{2\prime}$: synthesis of ligands L^1 and L^2

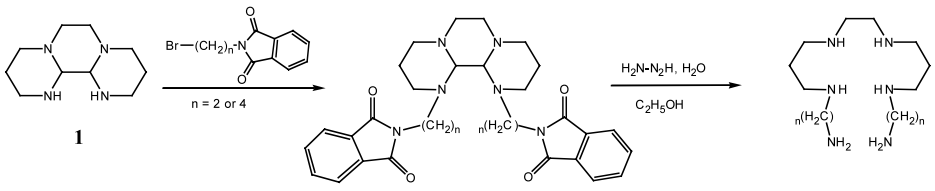
4,5-Bis(phthalimidoalkyl)-perhydro-4,5,8a,10a-tetraazaphenanthrene (10 mmol), hydrazine monohydrate (30 cm^3) and ethanol (90 cm^3) were refluxed overnight. After cooling, the white precipitate was filtered and the solvent rotary evaporated. The resulting oil was stirred in chloroform and the white precipitate formed was filtered. After evaporation of the solvent, hexaamine was isolated as colorless oil. These compounds were converted into the corresponding hydrochloride salts using the classical procedure (EtOH–HCl) and then recrystallized from EtOH–H_2O.

3,7,10,14-Tetraazahexadecane-1,16-diamine hexahydrochloride [$L^1 \cdot 6HCl$]: white crystals (yield 82%). NMR ^{13}C (D_2O): 47.8, 47.7, 47.2, 46.0, 38.3 (CH_2N), 25.5 ($NCH_2CH_2CH_2N$). $C_{12}H_{32}N_6 \cdot 6HC1 \cdot (479.19)$: Calc.: C, 30.08; H, 7.99; N, 17.54; Cl, 44.39; Found: C, 30.03; H, 7.77; N, 17.37; Cl, 44.68%.

5,9,12,16-Tetraazaicosane-1,20-diamine hexahydrochloride [$L^2 \cdot 6HCl$]: white crystals (yield 95%). NMR ^{13}C (D_2O): 50.0, 48.0, 47.2, 46.0, 41.7 (CH_2N), 26.8, 25.6, 25.5 ($NCH_2CH_2CH_2CH_2N$ and $NCH_2CH_2CH_2N$). $C_{16}H_{40}N_6 \cdot 6HCl \cdot (535.29)$: Calc.: C, 35.90; H, 8.66; N, 15.74; Cl, 39.74; Found: C, 35.73; H, 8.55; N, 15.56; Cl, 39.68%.

Caution: Perchlorate salts of metal complexes with organic ligands are potentially explosive; these compounds must be handled with great caution.

2.4. Preparation of $[CuL^1](ClO_4)_2$



A solution of $Cu(ClO_4)_2 \cdot 6H_2O$ (37 mg, 0.1 mmol) in water (5 cm^3) was slowly added to a solution of $L^1 \cdot 6HCl$ (48 mg, 0.1 mmol) in water (10 cm^3). The pH was adjusted at 10.0 with NaOH and $NaClO_4$ (100 mg) was added to the resulting solution. The complex was obtained as a blue powder by slow evaporation of this solution at room temperature. Yield: 40 mg (76.5%) (Found: C, 27.6; H, 6.2; N, 16.1%. Calc. for $C_{12}H_{32}Cl_2CuN_6O_8$: C, 27.57; H, 6.17; N, 16.07%.)

2.5. Preparation of $[CuL^2](ClO_4)_2$

This compound was synthesized from L^2 (53.5 mg, 0.1 mmol) and $Cu(ClO_4)_2 \cdot 6H_2O$ (37 mg, 0.1 mmol) following the procedure given above for $CuL^1(ClO_4)_2$. Yield: 46 mg (79.5%) (Found: C, 33.2; H, 7.0; N, 14.5%. Calc. for $C_{16}H_{40}Cl_2CuN_6O_8$: C, 33.19; H, 6.96; N, 14.51%.).

2.6. Potentiometric measurements

A combined Ingold 405 S7/120 electrode was calibrated in terms of pH ($pH = -\log[H^+]$) by titrating a known amount of HCl with CO_2-free NMe_4OH solution; Gran's method [13] was applied to determine the

L2: n=4

Scheme 1.

standard electrode potential E°, and the ionic product of water: $pK_w = 13.83(1)$. Stability constant titrations were carried out in a 0.1 mol dm^{-3} NMe_4Cl medium at 298.1 K using equipment and procedures which have been already described [14]. Ligand and metal ion concentrations were in the range 1×10^{-3}–2×10^{-3} mol dm^{-3}, and the $[M^{2+}]$ was varied in the range $0.8[L] < [M^{2+}] < 1.5[L]$. At least four titrations, each with about 150 data points, were performed for each system. The pH range covered was 2.5–10.5. The stability constants were derived with the aid of the computer program HYPERQUAD [15]; the values obtained are shown in Tables 1, 3 and 4.

2.7. Microcalorimetric measurements

The enthalpies of both ligand protonation and metal ion complexation reactions were determined in 0.1 mol dm^{-3} Me_4NCl solution by means of an automated system composed of a Thermometric AB thermal activity monitor (model 2277) equipped with a perfusion–titration device and a Hamilton Pump (model Microlab M) coupled with a 0.250 cm^3 gas-tight Hamilton syringe (model 1750 LT). The microcalorimeter was calibrated by determining the enthalpy of reaction of strong base (Me_4NOH) with strong acid (HCl). The value obtained, $-13.55(5)$ kcal mol^{-1} was in good agreement with the literature value [16]. As a further check the enthalpies of protonation of ethylenediamine (en) were determined by addition of a Me_4NOH solution (0.15 mol dm^{-3}, addition volumes 15 μl) to acidified solutions of en (5×10^{-3} mol dm^{-3}, 1.5 cm^3). For heats of complexation, acidified solutions containing a ligand (5×10^{-3} mol dm^{-3}, 1.5 cm^3) and a metal ion were titrated with Me_4NOH solution. Corrections for the heats of dilution were applied. The corresponding enthalpies of reaction were determined from the calorimetric data by least-squares fitting using the AAAL computer program [17]. At least three titrations (each with about 120 data points) were performed for each system.

Values in parentheses are S.D. in the last significant figure.

2.8. NMR measurements

^1H and ^{13}C spectra in D_2O solution were recorded at 298 K and different pD values using a Varian Unity 300 MHz spectrometer. In the ^1H NMR spectra, peak positions are taken relative to HOD at 4.75 ppm. ^1H–^1H and ^1H–^{13}C 2-dimensional correlation experiments were performed to assign the signals. pD was adjusted by adding small amounts of 0.01 mol dm^{-3} NaOD or DCl solution. The pH was calculated from the measured pD value using the following relationship [18]:

$$pH = pD - 0.40$$

3. Results and discussion

The ligand L^1 has the sequence 2,3,2,3,2 of methylene groups between nitrogen atoms and is capable, in principle, of forming a sequence of alternating 5- and 6-membered rings in a metal-ion complex. L^2 has the sequence 4,3,2,3,4 and, therefore, may also form 7-membered rings. The thermodynamic data for protonation and complexation are shown in Tables 1–4, together with data for the related hexa-amine L^3 which has the methylene group sequence 3,3,2,3,3 [19].

3.1. Protonation

Each hexa-amine can accept up to six protons in a regular sequence over the pH range 2.5–11, as shown in Fig. 1. For each protonation step, except the first one, the protonation constant values increase in the order $L^2 > L^3 > L^1$. This sequence can be rationalized in terms of inductive and charge minimization effects, as has been discussed previously [19–23]. The higher basicities of L^2 compared with those of L^1 is also reflected by the higher $-\Delta H^\circ$ values in each protonation step, except the last step, illustrated in Table 2.

The enthalpy terms are favorable for all protonation steps. The entropy terms are favorable for the first three

protonation steps, much less favorable for the fourth and fifth ones and unfavorable for the last one.

The location of attachment of each proton during the protonation sequence has been determined by relating ^1H and ^{13}C chemical shifts to calculated solution compositions. Firstly, individual resonances were assigned on the basis of ^1H–^1H homonuclear and ^1H–^{13}C heteronuclear correlation experiments, as shown in ligand drawing 1.

Then, changes in chemical shift were correlated with changes in concentration on the speciation diagrams, Fig. 1.

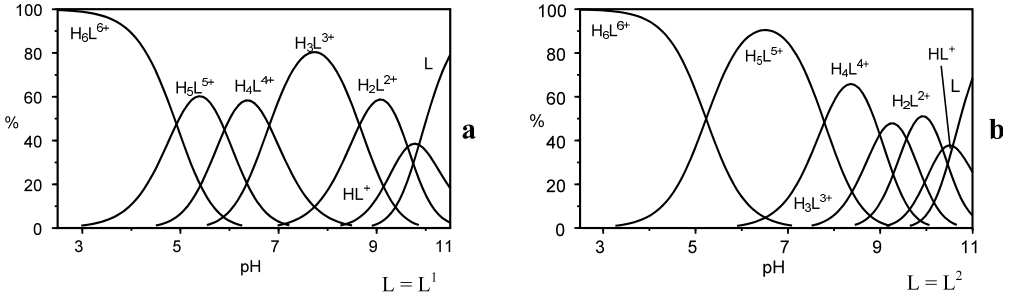

Fig. 1. Distribution diagrams of the protonated species formed by L^1 and L^2 as a function of pH (NMe_4Cl 0.1 mol dm^{-3}, 298.1 K).

At pH 11 the unprotonated amine, L^1, predominates in solution and the ^{13}C spectrum exhibits six peaks, at 28.97 (C4), 40.32 (Cl), 46.90 (C3), 47.10 (C5), 48.07 (C6), and 51.16 (C2). The ^1H spectrum of L^1 at this pH shows a quintuplet at 1.61 ppm (integrating to four protons and attributed to the protons, H4, of the central methylene group in a $-(CH_2)_3-$ group), a multiplet at 2.55 (8 protons), for the protons H3 and H5, a singlet at 2.65 (four protons, H6) and a multiplet at 2.70 ppm (H1 and H2). These spectral features indicate a time-averaged C_{2V} symmetry. This symmetry is preserved throughout the pH range investigated.

Fig. 2(a) and (b) show the ^1H and ^{13}C NMR chemical shifts of L^1 as a function of pH. In the pH range 11–8.5, where the first two protons bind to the ligand, the signal of H1, which is α to N1, shows the largest downfield shift. In ^{13}C NMR spectra of polyamines, it is known that the signal of a carbon atoms β to a nitrogen atom shifts upfield when that nitrogen atom is protonated [24]. The signal of the carbon atom C2, which is β to N1, displays the most pronounced upfield shift. These spectral features suggest that the first two protonation steps involve the primary nitrogens N1 and N1′, as would be expected considering that primary amines are more basic than secondary amines in aqueous solutions.

The third protonation step occurs in the pH range 8.5–7. In the ^1H NMR spectra H5 and H6 show the largest downfield shift whilst C4 and C6 show the largest upfield shift in the ^{13}C spectra. This protonation step therefore occurs at N3 and N3′. In the structure of $[H_3L^1]^{3+}$ each protonated nitrogen atom is separated from the next one by the unprotonated N2 and N2′, an arrangement which minimizes the electrostatic repulsion between charged $-NH_2^+-$ groups.

The atoms N2 and N2′ are protonated when $[H_4L^1]^{4+}$ and $[H_5L^1]^{5+}$ are formed, in the pH range 7.5–5. The protonation process is accompanied by significant shift of the H2, H3, C1 and C4 resonances. Below pH 5 protonation occurs on N3 and N3′ with an upfield shift of the C6 and C4 signals.

The ^1H and ^{13}C NMR spectra of L^2 indicate that this polyamine also has time-averaged C_{2V} symmetry over the whole of the observed pH range. The variation of chemical shift with pH is illustrated in Fig. 3.

With L^2, the first four protons go onto N1, N1′, N2 and N2′, as indicated by the way the resonances associated with H1, H4, H5, C2, C3, and C6 move with pH. This protonation sequence is different from that of L1. The main reason for this difference is the presence of two more methylene groups between N1 and N2. This has the effect increasing the distance between N1 and N2 and so decreasing the electrostatic repulsion when both atoms are protonated. Also N2 is slightly more basic due to inductive effects. Obviously the last two protons must go onto N3 and N3′ and this is confirmed by the movements of H7, H8, C6 and C8 signals in the region pH < 7.

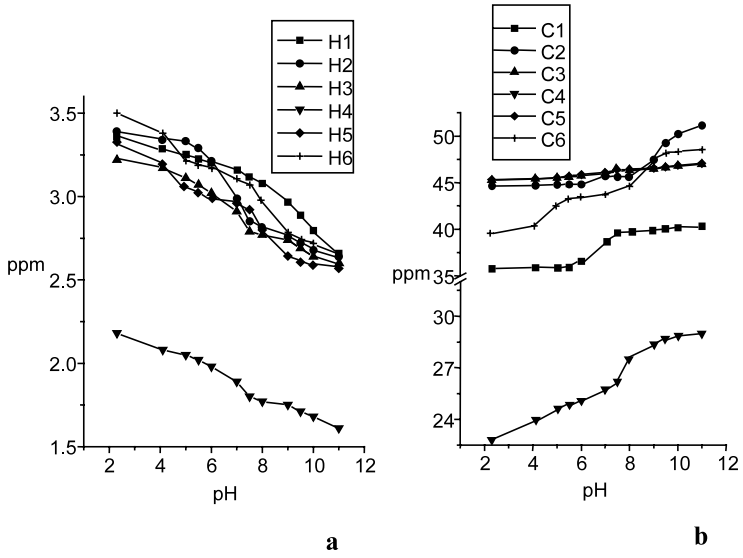

Fig. 2. (a) ^{1}H and ^{13}C (b) NMR chemical shifts of the L^1 signals as a function of pH.

3.2. Complexes of L^1 and L^2 with Cu(II)

Both ligands form the expected 1:1 complex CuL. The complexes can accept two protons to form $[CuLH]^{3+}$ and $[CuLH_2]^{4+}$ or an hydroxyl ion to form $[CuL(OH)]^{+}$. In addition binuclear complexes are formed with L^1 but not L^2 whereas a tris-protonated complex is formed with L^2 but not L^1. Stability constants and enthalpies are in Table 3 and speciation diagrams are in Figs. 4 and 5.

All the indications are that $[CuL^1]^{2+}$ is a 5N-coordinate species whereas L forms only 4N-coordinated complexes.

(i) K_{CuL} for L^2 is much lower than K_{CuL} for L^1. The difference is much larger than might be expected on the basis of ring-size differences and this suggests that $[CuL^2]^{2+}$ has a lower coordination number than $[CuL^1]^{2+}$.

(ii) The constant for the first protonation of the $[CuL]^{2+}$ ($L = L^1$ or L^2) complex is higher than those corresponding to the third protonation of the free amine. These data point out that the first protonation step of the complex occurs on a nitrogen atom not involved in metal coordination. The constant for the second protonation of the complex $[CuHL^1]^{3+}$ is smaller than those of the fourth protonation step of the free amine therefore in the $[CuL^1]^{2+}$ complex the copper ion is probably pentacoordinated. On the other hand the log K value for the protonation of $[CuHL^2]^{3+}$ is equal to

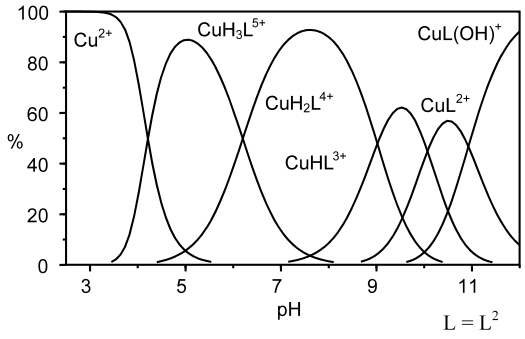

Fig. 4. Distribution diagrams of the species for the systems L^2–Cu(II) ($[L^2] = [Cu^{2+}] = 1 \times 10^{-3}$ mol dm^{-3}) as a function of pH (NMe_4Cl 0.1 mol dm^{-3}, 298.1 K).

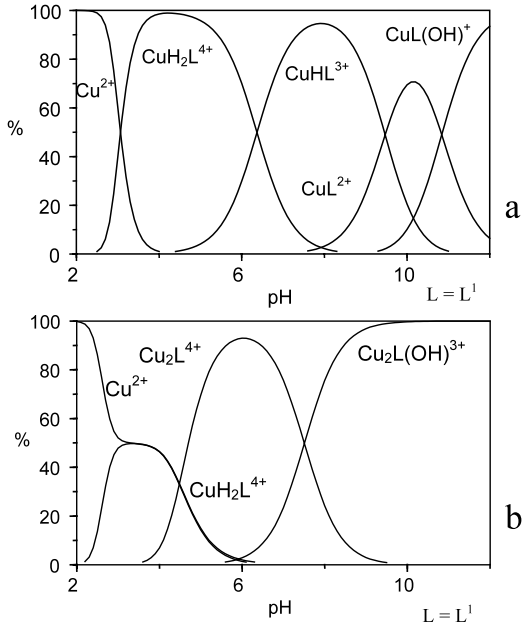

Fig. 5. Distribution diagrams of the species for the systems L^1–Cu(II) ($[L^1] = [Cu^{2+}] = 1 \times 10^{-3}$ mol dm^{-3} (a), $[L^1] = 1 \times 10^{-3}$ mol dm^{-3} and $[Cu^{2+}] = 2 \times 10^{-3}$ mol dm^{-3} (b) as a function of pH (NMe_4Cl 0.1 mol dm^{-3}, 298.1 K).

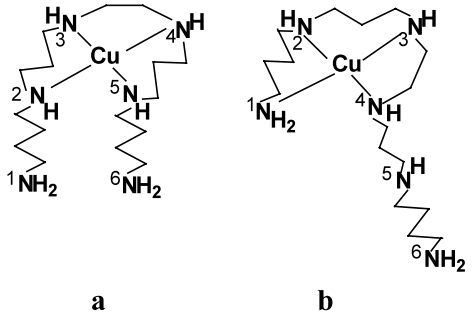
that for fourth protonation of the free ligand. These data suggest that in the $[CuL^2]^{2+}$ complex two of the nitrogens of L^2 remain uncoordinated.

(iii) The UV–Vis spectra of solutions in conditions where the species $[CuH_2L^2]^{4+}$, $[CuHL^2]^{3+}$ and $[CuL^2]^{2+}$, respectively, predominate all show a broad band at the same position and with the same intensity (λ_{max} 560 nm, ε 180 dm^3 mol^{-1}), suggesting that the copper ion environment is the same in all three complexes. However, the complex $[CuH_3L^2]^{5+}$ has a different spectrum (λ_{max} 610 nm, ε 110 dm^3 mol^{-1}), consistent with a decrease in ligand field strength due to the detachment of a nitrogen donor atom.



(iv) The UV–Vis spectrum of the species $[CuL^1]^{2+}$ (λ_{max} 538 nm, ε 110 dm^3 mol^{-1}) is consistent with the Cu(II) ion having a 5N- environment with a stronger ligand field splitting than in the 4-N complex formed with L^2.

v) The enthalpy of formation of $[CuL^1]^{2+}$ (116.6 kJ mol^{-1}) is comparable to the enthalpy of formation of the complex of Cu(II) with the linear polyamine 1,4,7,10,15-pentaazatridecane (105 kJ mol^{-1}) which is known to act as a pentadentate ligand towards Cu(II) [19].

It is interesting to note that even though the ligand L^1 could form a hexadentate complex with alternating 5- and 6-membered chelate rings, it does not do so, but instead forms a pentadentate complex. By comparison, the Cu(II) complex with the ligand 1,16-dimethyl-1,4,7,10,13,16-hexaazahexadecane [19,25,26], which forms a pentadentate complex with all 5-membered rings has a stability constant of log $K = 21.6$, which is almost the same as for the ligand L^1. The greater stability of complexes with alternating chelate ring sizes is well established with macrocyclic ligands, which effectively form square–planar complexes. L^2, which could form a 7-membered ring in fact only donates four nitrogen atoms.

In the structure of $[CuL^1]^{2+}$ one nitrogen atom, presumably at the end of the chain is not attached to the metal. In the structure of $[CuL^2]^{2+}$ two nitrogen atoms are unattached. Two proposed structures for this complex are reported in Fig. 6. The metal ion can be coordinated by four secondary nitrogen atoms (N2, N3, N4 and N5, see Fig. 6(a)) or by the terminal nitrogen atom Nl and the three adjacent secondary donors (N2, N3 and N4, see Fig. 6(b)). The spectral and potentiometric data do not allow us to discern between these two hypothesis.

The formation of binuclear complexes with L^1 has a clear analogy with the inclusion of two metal ions in large macrocyclic polyamines. A reasonable structure would have both copper atoms coordinated by three nitrogen atoms. The binuclear complex $[Cu_2L^1]^{4+}$ has a very high stability constant for the formation of the hydroxo complex $[Cu_2L^1(OH)]^{3+}$ (log $K = 6.32$ compared with the value of 2.99 for the formation of the

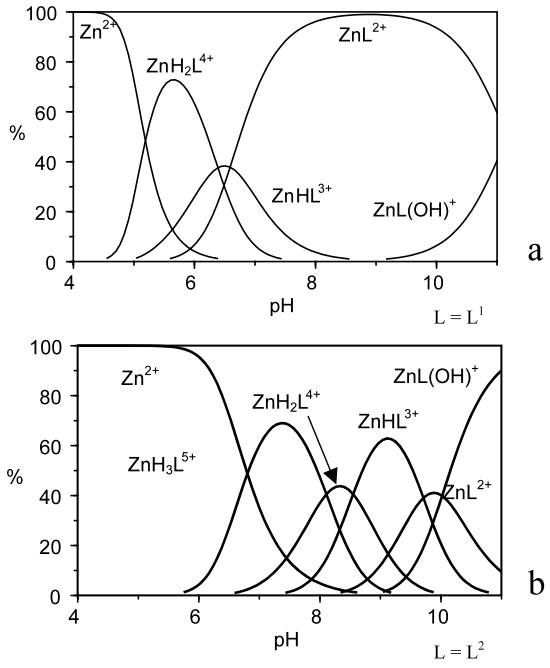

Fig. 7. Distribution diagrams of the species for the systems L^1–Zn(II) (a) and L^2–Zn(II) (b) ($[L^1] = [L^2] = [Zn^{2+}] = 1 \times 10^{-3}$ mol dm^{-3}) as a function of pH (NMe_4Cl 0.1 mol dm^{-3}, 298.1 K).

mononuclear hydroxo complex.). This suggests that the hydroxo group is bridging between two Cu(II) ions, so that both have a N_3O 4-coordinate environment.

3.3. Complexes of L^1 and L^2 with Zn(II)

Thermodynamic data for the complexes formed by Zn(II) with L^1 and L^2 are given in Table 4 and speciation diagrams are illustrated in Fig. 7. The main difference between Zn(II) and Cu(II) coordination is that the Zn(II) complexes are weaker and all mononuclear. Otherwise the coordination chemistry appear to be similar, with L^1 forming a 5-N complex and L^2 forming a 4-N complex. The complexes $[ZnL^1]^{2+}$ and $[ZnL^2]^{2+}$ can both accept two protons or an hydroxyl group whereas the latter can also accept a third proton. The complex $[ZnL^2]^{2+}$ is much less stable than $[ZnL^1]^{2+}$; this is clearly due to the fact that the formation of the complex with L^2 is much less exothermic. As with the Cu(II) complexes this difference in stability is a reflection of the fact that the 5th nitrogen atom necessarily forms an unfavorable 7-membered ring if it coordinates.

Received 25 October 2001; accepted 20 December 2001

Abstract

Complex-formation equilibria of the tetrapeptide Lys–Gly–His–Lys with the Cu(II) and the Ni(II) ions have been studied in aqueous solution, at $I = 0.1$ mol dm^{-3} (KNO_3) and $T = 25$ °C. Protonation and complex-formation constants have been potentiometrically determined. The structure of the main complex species is discussed on the basis of thermodynamic data obtained by direct calorimetry as well as the CD, ESR and electronic spectra. The participation of two amide nitrogens in complex-formation is suggested for both the metal ions, while no evidence supports the participation of the ε-NH_2 side groups of Lys residues in coordination. © 2002 Elsevier Science Ltd. 1. Introduction

Secreted Protein, Acidic and Rich in Cysteine (SPARC) is a matricellular calcium-binding glycoprotein, which mediates the cell–matrix interactions without covering any primarily structural role [1,2]. It is the product of a single-copy gene and its sequence has been highly conserved during vertebrate evolution and among species, with the mammalian, amphibian and avian proteins showing more than 70% amino acid identity [3]. SPARC is highly expressed during embryonic development while its expression in the adult is generally associated with tissues undergoing remodelling or renewal, also as a response to injury. It has also been reported as product of some tumours and this result has been associated to the SPARC activity in angiogenesis [4]. The human protein consists of 286 residues divided into three distinct domains [5]. The N-terminal domain is an acidic region which binds several calcium ions with low affinity. The second domain is a Cys-rich, follistatin-like (FS) domain (residues 53–137), in which all the Cys residues are disulfide-bonded and with an N-linked complex carbohydrate at Asn99. This domain is characterised by the presence of two copper binding sites, the strongest of which contains the sequence Lys–Gly–His–Lys (KGHK) (residues 120–123). Both KGHK and longer peptides containing this sequence and deriving from the proteolysis of SPARC have been recognised to regulate angiogenesis in vitro and in vivo [6]. Domain III (residues 138–286) is largely α-helical and contains high-affinity calcium binding sites.

The side-chain amino group of Lys residues is a potential donor group for oligopeptide and protein coordination to metal ions [7]. Literature data on this topic are growing, but real ability of this group to participate in metal-complex formation is still a vexed question. No evidence of ε-NH_2–metal ion binding has been observed for Cu(II)/Lys [8] and Ni(II)/dipeptide [9] complexes. On the other hand, recent investigations on the complex-formation equilibria of Lys-containing oligopeptides with the Cu(II) ion [10–12], supported the hypothesis that the ε-NH_2 of Lys residue interacts with copper, but only at alkaline pH; no deprotonation of ε-NH_2 (and subsequent interaction with copper) was found at neutral pH, thus supporting the hypothesis that, under physiological conditions protonated Lys residue of

PII: S0277-5387(02)00952-X

metallo-peptides can act as an 'anchor' for biological receptors [13].

In the present paper, the complex-formation equilibria of the tetrapeptide Lys–Gly–His–Lys (Fig. 1) with both, Cu(II) and the Ni(II) ions have been investigated, at $I = 0.1$ mol dm^{-3} (KNO_3) and $T = 25$ °C. Protonation and complex-formation constants have been potentiometrically determined; formation enthalpies have been measured by direct solution calorimetry; complex-formation model and species stoichiometry have been carefully checked by means of UV–Vis absorption, CD and ESR spectroscopies. On the basis of the obtained data, the structures of the complex species have been discussed.

2. Experimental

KGHK was a high purity product (Sigma) and was used without further purification. Cu(II) nitrate and Ni(II) chloride were extra pure Merck products.

Aliquots (2.5 cm^3) of sample solution, containing suitable amounts of the metal ion, the ligand, HNO_3 (when the initial pH value needed to be adjusted) and KNO_3 (to adjust the ionic strength to 0.1 mol dm^{-3}) were potentiometrically titrated with standard NaOH, in the pH range 3.0–11.0 (or till a precipitate or opalescence was observed in solution), in a thermostatted potentiometric vessel ($T = 25.0$ °C). Metal ion concentration ranged from 1×10^{-3} to 3×10^{-3} mol dm^{-3}, and metal to ligand ratios were 1:1.1 with Cu(II), while it was 1:3.5 with Ni(II). A minimum of three pairs of potentiometric titrations for each system were performed.

CD, ESR and UV–Vis spectra were recorded on solutions of the same composition as above, varying the pH by addition of suitable amounts of standard NaOH or HNO_3, under potentiometric control. Spectra every 0.5 pH units were recorded.

Calorimetric titrations were performed by means of an Isoperibolic Calorimeter (Tronac), at 25.0 °C, by addition of standard HNO_3 to solutions of ionic strength equal to 0.1 mol dm^{-3} (KNO_3). The sample solution volume was 2.5–2.8 ml. The ligand concentration ranged from 2×10^{-3} to 4×10^{-3} mol dm^{-3}; the metal-to-ligand ratios were 1:1.1 and 1:2 for the Cu(II) and Ni(II) ions, respectively. For protonation and Cu(II) complex-formation studies at least three pairs of calorimetric titrations containing not less than 250 experimental points were utilised to calculate the thermodynamic quantities. The slow complex-formation kinetics, encountered in the Ni(II)/KGHK system, did not allow the normal calorimetric titrations. In fact, the isoperibolic method requires a maximum run time of about 30 min, calibrations included. Only one titrant addition was then performed during each run and the total heat was recorded after a suitable waiting time. The same experiment was repeated eight to ten times, in order to cover the desired pH range (5.0–6.0). Three series of measurements were performed on different sample solutions.

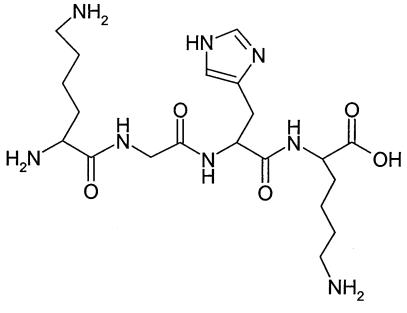

Fig. 1. Structure of Lys–Gly–His–Lys.

Further experimental details, equipment and software used are reported elsewhere [11].

Throughout, the complex species are indicated by means of the corresponding stoichiometric indexes pqr, referred to the equilibrium $pM + qL + rH = M_pL_qH_r$.

3. Results and discussion

3.1. Protonations

Thermodynamic data for KGHK protonation are reported in Table 1.

The most basic groups are the two Lys-residue ε-amino groups: the corresponding protonation constants are slightly higher and slightly lower than those of free Lys [8], respectively. The same is true for the corresponding enthalpies, which are always favourable. Entropy changes, however, are ambiguous in their sign: negative for the first protonation process and positive for the second. This difference should not be due to the position of the two Lys-residues (which are potentiometrically and calorimetrically indistinguishable). In fact, literature data concerning protonation of Lys residues in oligopeptides do not significantly depend on the nature of the other neighbouring amino acids of the chain [14]. Some role is certainly played by the different ligand charge during the first and the second protonation step. Moreover, the formation of an intramolecular hydrogen-bond, between the two side ε-amino groups, as a consequence of the first protonation, could explain the corresponding thermodynamic parameters. However, further investigation is required to confirm such hypothesis.

The terminal amino group is less basic than the ε-amino group of Lys residue due to the former's proximity to the electron-withdrawing carbonyl group of the first peptidic bond. The corresponding pK value is 1.8 U lower than that of free Lys [8]. As a consequence

Table 1
Thermodynamic parameters for KGHK protonation steps, at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3)

Residue	Donor group	log K	$-\Delta G^\circ$ (kJ mol^{-1})	$-\Delta H^\circ$ (kJ mol^{-1})	ΔS° (J mol^{-1} K^{-1})
Lys	$NH_2(\varepsilon)$	10.97 (6)	62.6 (3)	69 (3)	−23 (15)
Lys	$NH_2(\varepsilon)$	10.16 (8)	57.9 (5)	41 (3)	59 (11)

Lys_4	COO^-	3.0 (1)	17.1 (7)		

of the formation of peptide linkage, the imidazolic-nitrogen pK value is about 0.3 U higher than the corresponding values of His (6.03) [15]. This difference is mainly of entropic nature. Finally, the terminal carboxylic-group protonation-constant is in agreement with literature data on oligopeptides.

3.2. Cu(II)/Lys–Gly–His–Lys complexes

As the distribution diagram shows (Fig. 2), coordination starts under pH 4, with the 110 complex formation. The concentration of this species reaches its maximum at pH 5, binding all the Cu(II) ion and remaining the only species in solution up to pH 7. At higher pH values, the 110 complex undergoes three deprotonation steps leading to the species 11-1, 11-2 and 11-3. The log $K^{110}_{11\text{-}1}$ value is compatible with the deprotonation of a bound water molecule, while the following log $K^{11\text{-}1}_{11\text{-}2}$ and log $K^{11\text{-}2}_{11\text{-}3}$ values are very close to the protonation pK values of the two side Lys residues (see Table 1), suggesting that no interaction occurs between the ε-NH_2 groups and the copper ion. The corresponding ΔH°_{step} and ΔS°_{step} values, which can be computed from Table 2, can be considered in agreement with this suggestion, taking into account the high standard deviations. If the above hypothesis is true, neither the complex geometry nor the donor-atom set should vary when pH is raised from 5 to 11. This conclusion is fully supported by spectroscopic results, reported in Figs. 3 and 4 and summarised in Table 3.

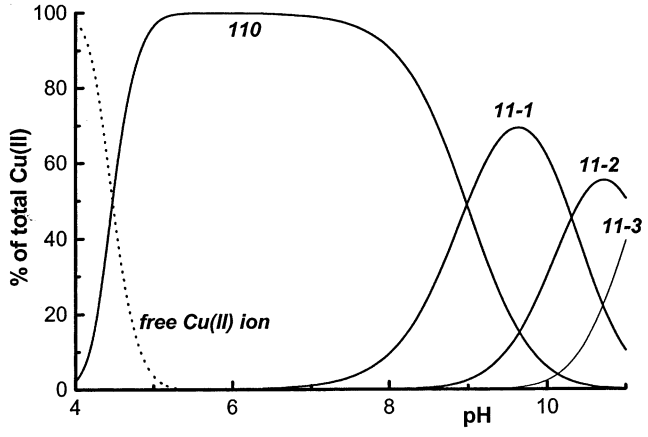

Fig. 2. Distribution diagram of Cu(II)/KGHK complexes, $T = 25$ °C, $I = 0.1$ mol dm^{-3} (KNO_3); [Cu(II)] = 3.0×10^{-3} mol dm^{-3}; [KGHK] = 3.3×10^{-3} mol dm^{-3}.

Absorption spectra (Fig. 3) are characterised by the onset of one single band, due to complex-formation, the intensity of which increases from pH 4 to 5, remaining then constant up to pH 11 (see also Table 3). The wavelength of maximum absorption is 524 nm, very close to the value of 530 nm, which can be computed by means of the empirical formula developed by Sigel and Martin [16] for the coordination of four nitrogen atoms to Cu(II) (α-NH_2, $2N^-$ and N_{Im}). CD spectra (Fig. 4) exhibit an oppositely signed curve for the d–d transition (as His-containing peptides usually do), with the negative extremum centred at 580 nm and the positive one at 495 nm. This result is consistent with the hypothesis of four nitrogen atoms involved in coordination. A CT band at 306 nm is also present in the CD spectra: it can be ascribed to the coordination of deprotonated amido nitrogens to copper. An additional negative band is present, at 272 nm, attributable to an α-$NH_2 \rightarrow$ Cu(II) CT transition. It is remarkable that neither the band shape nor the position depends on pH, but only the signal intensity, as already found for the UV–Vis absorption. Finally, a similar behaviour is also shown by ESR spectra, giving constant $A_{||}$ and $g_{||}$ values, in the pH range 4–11 (see Table 3); such values are once again compatible with the hypothesis of a 4N complex.

The most likely structure hypothesis for the 1:1 Cu(II)/KGHK complex is shown in Fig. 5. In this complex the ligand binds the copper ion in a tetradentate way, i.e. by means of its terminal amino group, the first two [deprotonated] amido nitrogens and the side imidazolic group. This way of coordination is typical of oligopeptides containing His in third position, like Gly–Gly–His (GGH) [17], for which it has also been observed that the 11-2 complex (corresponding to the 110 complex in the present Cu/KGHK system, where the ligand contains two additional-protonated-side chains) is the only species in solution, even in the presence of a ligand excess. The above structural hypothesis is also supported by the results of an X-ray study on the crystal structure of Cu(II)/Gly–Gly–His–N-methylamide 1:1 complex [18]. In order to compare the stability of the corresponding Cu(II) complexes in the two systems, it is useful to compute the respective

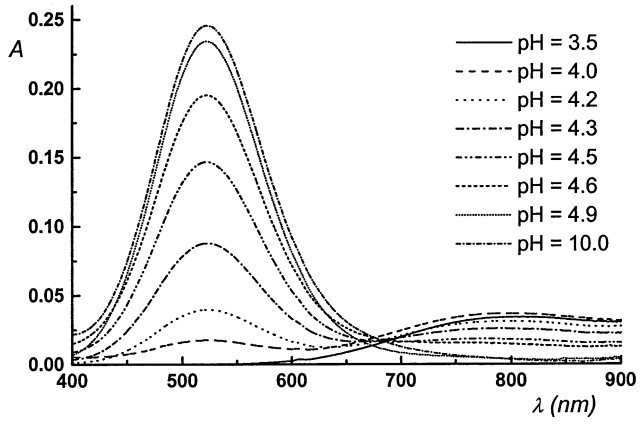

Fig. 3. Absorption spectra of Cu(II)/KGHK solutions. [Cu(II)] = 3.0×10^{-3} mol dm^{-3}, [KGHK] = 3.3×10^{-3} mol dm^{-3}, $T = 25$ °C, $I = 0.1$ mol dm^{-3} (KNO_3).

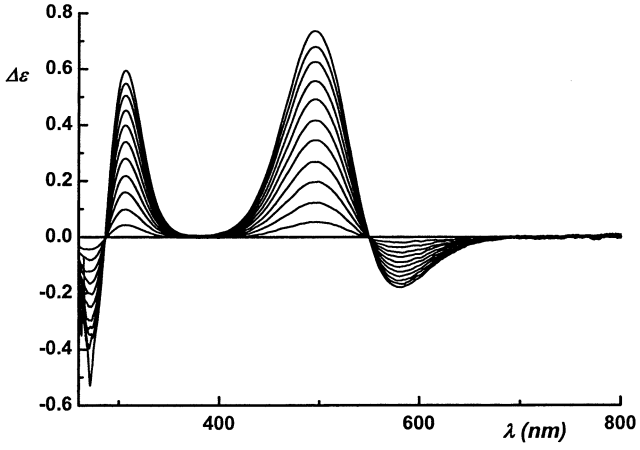

Fig. 4. Circular Dichroism spectra of Cu(II)/KGHK solutions. [Cu(II)] = 3.0×10^{-3} mol dm^{-3}, [KGHK] = 3.3×10^{-3} mol dm^{-3}, $T = 25$ °C, $I = 0.1$ mol dm^{-3} (KNO_3).

log K^* values (log $K^* = \log \beta_{pqr} - pK_{\alpha\text{-}NH2} - [\Sigma pK_{\varepsilon\text{-}NH2}] - pK_{N\text{-}imidazole}$, where pqr is 110 in the case of KGHK and 11-2 for GGH), which measure the binding strength of the ligand, 'normalised' for the basicity of the donor sites and for the presence of additional protonated groups [7]. The computed values are the following: $\log K^*_{Cu(II)/GGH} = -16.43$ [17] and $\log K^*_{Cu(II)/KGHK} = -15.13$ (Table 2). These data show that KGHK is a Cu(II) ligand stronger than GGH: the former's K^* value is higher than the latter's of more than one magnitude order. However, KHGK is weaker than other albumin-like chelators containing the hydroxymethylserine (HmS) residue, like HmS–HmS–His ($\log K^*_{Cu(II)/HmS-HmS-His} = -13.12$ [19]). The extra-stability of the Cu(II)/HmS–HmS–His complex has been ascribed to electronic effects which render the terminal amino group of the ligand more acidic than the imidazole nitrogen and the amido nitrogens much more effective donors [19]. Additional intramolecular interactions among the side chains of the ligand and the metal ion have been excluded in the case of HmS–HmS–His [19]; the same is reasonable here, where no evidence was found for the participation of the ε-amino groups in complex formation (see above). The substitution of Gly with Lys as first residue and the presence of an additional amino acid in the polypeptidic chain most likely influences the basicity of the donor atoms and the complexing strength of KGHK with respect to GGH. Unfortunately, complex-formation enthalpies for GGH or HmS–HmS–His are not available. A systematic study on other peptidic ligands, containing His in the third position, could shed more light on these phenomena, but is beyond the aim of the present work.

3.3. Ni(II)/Lys–Gly–His–Lys complexes

Ni(II)/KGHK coordination starts from pH 5, where the solution colour starts to change from pale blue–green to yellow and the 110 complex is formed. This species, less stable than the corresponding Cu(II) complex, reaches its formation maximum at pH 6, binding the 100% of the Ni(II) ion present in solution; it remains the only species in the whole investigated pH range. Similar results were previously been reported for the Ni(II)/GGH [17] and Ni(II)/HmS–HmS–His systems [19], except for the formation of low amounts of some minor protonated species, not found with KGHK (see Table 2). To compare the Ni(II)/KGHK, Ni(II)/GGH and Ni(II)/HmS–HmS–His complex stabilities, the corresponding log K^* values can, once again, be computed: $\log K^*_{Ni(II)/GGH} = -21.31$ [17], $\log K^*_{Ni(II)/KGHK} = -19.42$, $\log K^*_{Ni(II)/HmS-HmS-His} = -17.92$ [19]). As in the case of copper complexes,

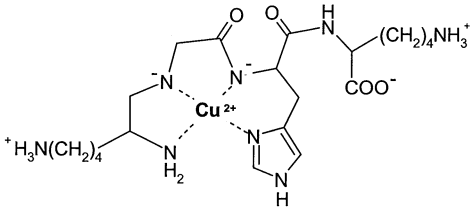

Fig. 5. Structural hypothesis for the complex [Cu(II)/KGHK]$^+$, in aqueous solution.

HmS–HmS–His is the strongest ligand, while KGHK binds the nickel ion with more efficacy than GGH, in the whole investigated pH range. Electronic spectra of Ni(II)/KGHK solutions (Fig. 6) show a single absorption band the intensity of which steadily increases from pH 4 to 6, then remaining constant up to pH 10. The wavelength of maximum absorption is 420 nm, in agreement with the values found for GGH (423 nm [17]) and HmS–HmS–His (420 nm [19]), as well as for other peptides giving a 4N square-planar coordination [16]. Matching results were obtained by CD spectroscopy (see Fig. 7). As in the case of copper complexes discussed above, KGHK should bind the nickel ion in a tetradentate way, i.e. by means of its terminal amino group, the imidazole and two deprotonated amide nitrogens, which provide a strong ligand field leading to singlet ground state Ni(II). No evidence has been found for the involvement of the ε-NH_2 side groups of the two Lys residues in Ni(II) coordination. These hypotheses are in good agreement with the corresponding ΔH°_{110} value, shown in Table 2 (last row). In fact, subtracting the contribution of the two side-amino-group protonations (−110 kJ mol^{-1}, Table 1), a cleansed value of −24 kJ mol^{-1} is obtained; it is very close to the double of the $\Delta H^\circ_{11\text{-}1}$ value for the Ni(II)/

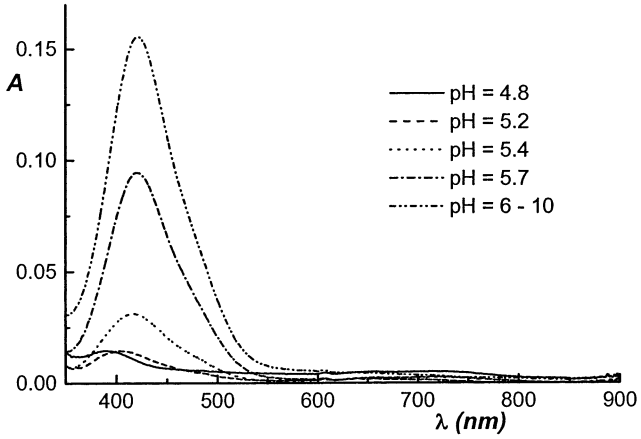

Fig. 6. Absorption spectra of Ni(II)/KGHK solutions. [Ni(II)] = 1.0×10^{-3} mol dm^{-3}, [KGHK] = 3.5×10^{-3} mol dm^{-3}, T = 25 °C, $I = 0.1$ mol dm^{-3} (KNO_3).

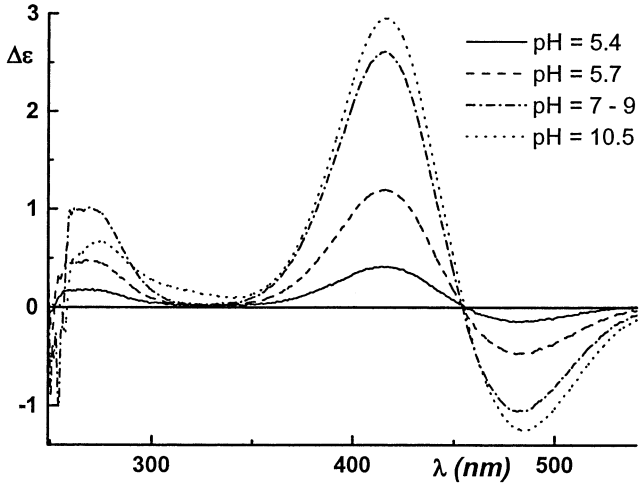

Fig. 7. Circular Dichroism spectra of Ni(II)/KGHK solutions. [Ni(II)] = 1.0×10^{-3} mol dm^{-3}, [KGHK] = 3.5×10^{-3} mol dm^{-3}, T = 25 °C, $I = 0.1$ mol dm^{-3} (KNO_3).

Gly–Ala system [9], which accounts for the formation of one Ni(II)–NH_2 and one Ni(II)–N^- bonds. Moreover, such a ΔH°_{110} value is very close to the corresponding value for the Cu(II)/KGHK system, also reported in Table 2. These results suggest that the lower stability of the Ni(II) complex could be ascribed to a more unfavourable entropic contribution, possibly due to the higher rigidity of the Ni(II) geometry.

4. Conclusions

The tetrapeptide KGHK binds both the Cu(II) and the Ni(II) ions in a tetradentate fashion, forming mono-complexes in the whole investigated pH range; the formation of neither bis-complexes nor polynuclear species has been observed. KGHK binds both the Cu(II) and Ni(II) ions more strongly than GGH, although the complex geometry and the donor-atom set are the same in both the cases. This extra-stability can be ascribed to electronic effects caused by the different side chains on the peptide backbone, which influence the amido-nitrogen donor capability. In fact, the two ε-NH_2 groups of Lys residues proved not to be involved in coordination.

purification of the inhibitors carried out by a variety of techniques like ultrafiltration, gel chromatography, ion-exchange. Unfortunately many of them are time consuming or associated with appreciable loss of analyte, thus requiring the treatment of a huge quantity of urine samples to obtain the desired amount of product. Moreover, the inhibitor of interest is always analyzed by enzymic-spectrophotometric assay, which is indirect and non-specific.

Another example of enrichment is the one proposed [18] for UTIs concentration by foam fractionation. This is a type of adsorptive bubble separation technique (adsubble technique [19]) in which surface-active substances, such as proteins and enzymes [20] because of their strong amphipathic nature, are removed from the solution by selective adsorption at the surface of bubbles rising through the solution forming a foam at the top of the solution.

Within adsubble techniques, bubble extraction process used to preconcentrate inorganic species [21–23] appears as a promising technique that could be applied to large samples to concentrate analytes from very diluted solutions obtaining quantitative recoveries.

In this paper we describe a three-step procedure including preconcentration of UTIs by bubble extraction, binding to immobilized trypsin, recovery and separation of the inhibitors at controlled pH by affinity chromatography. This procedure displays a unique capability for retaining full bioactivity of the isolated components. For the direct monitoring of the inhibitors at the intermediate and final steps we adopted a RP-HPLC method developed by our research group [24,25].

2. Experimental

2.1. Reagents and materials

All chemicals were of the highest purity available and were stored, when necessary, as recommended. Aprotinin, bovine pancreas trypsin, Nα-Benzoyl-L-arginine *p*-nitroanilide (L-BAPNA, a cromogenic substrate for trypsin and other proteolytic enzymes) and antifoam A were obtained from Sigma Chemicals (St. Louis, MO, USA). Water was distilled once and then further purified by a Milli-Q purification system (Millipore Systems, Bedford, MA, USA).

2.2. Human urine samples

Urine obtained from healthy volunteers was collected in flasks containing sodium azide (0.02%, w/v) and stored at −20 °C before it was processed.

2.3. Buffer solutions

Buffer solution A (pH 2.2): 10.0 mM H_3PO_4 in 0.2 M $NaClO_4$. Buffer solution B (pH 8.3): 0.1 M Tris–HCl in 0.5 M NaCl. Buffer solution C (pH 3.5): 0.1 M CH_3COONa–CH_3COOH in 1.0 M NaCl.

2.4. Inhibition assays

Inhibition assays were performed by an enzymic-spectrophotometric method based on the inhibition by UTIs of the trypsin-catalysed hydrolysis of L-BAPNA, followed at 405 nm, which takes advantage of the stable complex that UTIs form at approximately pH 8.0 with the enzyme. The UTI concentration in the sample was determined from the decrease in the trypsin activity caused by the sample using aprotinin as standard [26]. For absorbance measurements a Perkin–Elmer H.200 spectrophotometer was used.

2.5. Bubble extraction

The apparatus for bubble extraction utilizing a hydrodynamic trap principle has already been described [22]. In this series of experiments, a column having loading capacity of 5 l was employed.

2.6. Chromatography

Trypsin-affinity chromatography was performed as previously reported [27] taking care of washing the affinity gel phase to obtain an acceptable chromatographic background; econo-columns (1.0 × 10 cm from Bio-Rad) were used.

To perform chromatographic analyses, a Twincle Model JASCO Liquid Chromatograph was used. The instrument equipment included: VL-614 injector loop capacity 100 μl; JASCO Model Uvidec 100-III variable wavelength UV-detector connected to a Chromatopac C-R3A data elaborator; JASCO Model GP-A30 Gradient Programmer.

The chromatographic column was kept in a Violet Thermostat Clar 0.55. Buffer solutions were filtered through a 0.45 Millipore filter, and mobile phases were deareated by helium bubbling. When necessary, the eluted fractions were recovered using a Pharmacia Frac-100 collector.

2.6.1. Chromatographic conditions

Column: LiChrosorb RP18, 250 × 4.6 mm I.D (Merck); temperature: 30 ± 0.1 °C; flow rate: 1.0 ml min^{-1}; injection volume: 100 μl; elution: isocratic step over 15 min with mobile phase 1 (buffer solution A–acetonitrile, 70:30) and then linear gradient with phase mobile 2 (buffer solution A–Acetonitrile, 40:60); detection UV: 200 nm.

3. Procedure

The proposed procedure was experimented with urine collected from healthy volunteers and involved the following steps.

3.1. Step A—preconcentration

For UTIs enrichment and collection a bubble extraction apparatus was used equipped with a column having a loading capacity of 5 l (Fig. 1). The column was filled at the lower end with a detachable section furnished with a gas sparger of fine porosity (G 4), ending in its upper part with a coning tapering at its outlet which fitted for about 1.5 cm above the collected liquid level. A 0.5 l separating funnel was employed as the collecting vessel.

The column was filled with urine and an aqueous dispersion (100 μl in 10 ml) of Fluka Antifoam A was added and ran along the wall of the collecting vessel before its assembly. The gas (N_2) flow was then regulated to obtain the proper run of foam: a flow rate of about 20–30 ml min^{-1}, measured by a soap-bubble flowmeter, was found effective. The suitable operation time of enrichment was about 90–120 min.

3.2. Step B—binding of the inhibitors

The urine collected (ca. 200 ml) was transferred to a vessel, adjusted to pH 8.3 with 2.0 N NaOH, and centrifuged for 10 min at $4390 \times g$.

The supernatant and washings were percolated through a trypsin-Sepharose 4B column (bed volume ca. 1.0 ml; loading capacity approximately 200 nmol of active trypsin) previously equilibrated with buffer solution B. The eluate was then passed through two other econo-columns identical to the first and used in series. The three columns were then washed with at least ten bed volumes of the same buffer solution to remove unbound substances prior to UTIs elution.

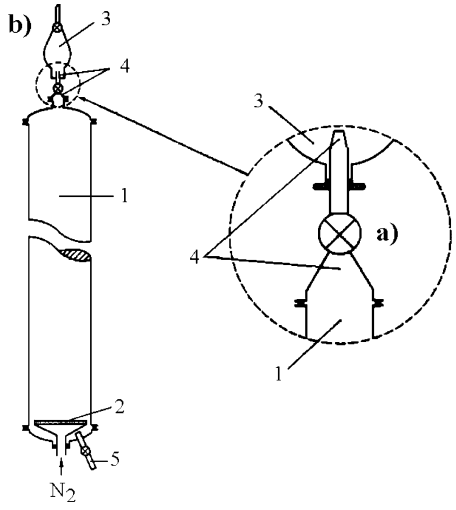

Fig. 1. Bubble extraction apparatus. Experimental set up: 1 column; 2 sparger; 3 collecting funnel; 4 trapping device, 5 column solution outlet.

3.3. Step C—elution at controlled pH values

The first trypsin-Sepharose column was subjected to elution (flow rate: 1 ml min^{-1}) with buffer solution C. The eluate containing UTI_{72} and UTI_{18} was collected in a 250 ml calibrated flask (flask 1). The same column was then subjected to elution with 0.8 ml of 1.0 M H_3PO_4 and buffer solution A; the eluate containing UTI_6 was collected in a 5 ml calibrated flask (Flask 2). From the other two econo-columns the remaining UTI_{72} and UTI_{18} were recovered in flask 1 by eluting any column with 0.8 ml of 1.0 M H_3PO_4 and buffer solution A.

4. Results and discussion

In urine samples of healthy individuals, the Kunitz-type inhibitor (UTI_{72}) occurs at low concentration, approximately 0.3 μmol l^{-1}, which is, however, far higher than that of the Kazal-type (UTI_6), approximately 3 nmol l^{-1}. Bubble extraction combined with affinity chromatography appears promising for the enrichment and separation of considered inhibitors from biological fluids.

As already reported, the extraction bubble apparatus operates substantially by dividing the liquid solution into two portions: the lower part constituting the fractionation column and the upper one the enriched solution. Surface-active substances as proteins, owing to gas bubbling, are progressively transferred from the column into the collecting vessel together with an easy collection of the enriched solution. When biological fluids, as urine, are manipulated according to this technique an antifoam should be added to prevent production of foam excess that can come out from the collecting vessel.

In affinity chromatography the optimal elution conditions are determined by protein stability and strength of binding of UTI types to the adsorbent. Desorption is generally effected by pH decrease because the pH variation alters the ionization degree of the charged groups at the binding site. In our previous studies [24,25], UTIs were desorbed from immobilized trypsin with buffer solution pH 2.2 (Fig. 2). As the inhibitors showed different affinities to immobilized trypsin, in this study UTI_{72}, UTI_{18} and UTI_6 were sequentially eluted at pH 3.5 and 2.2, respectively, in order to obtain a selective separation. When the trypsin inhibitor-binding capacity of the column is exceeded, the UTI_6 is found to bind preferentially to the column at the expense of the UTI_{72} and UTI_{18}. Consequently, under our experimen-

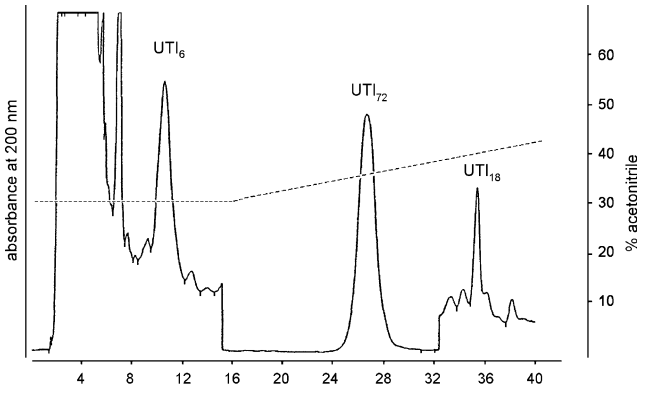

Fig. 2. Separation of UTIs resulting by pH 2.2 elution of a trypsin-Sepharose 4B column after passage of urine sample. See Section 2 for chromatographic conditions.

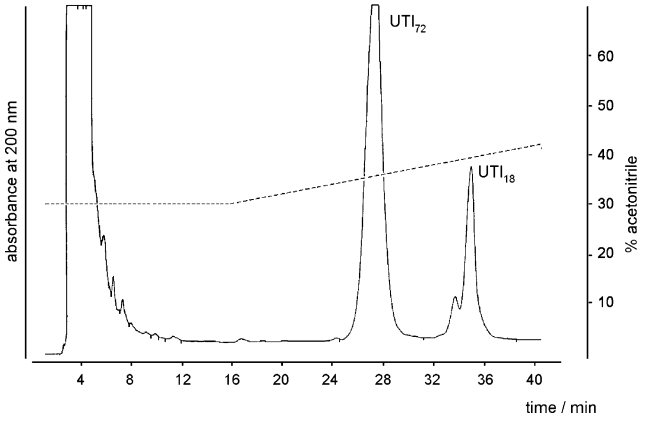

Fig. 3. Chromatogram of solution from flask 1, containing UTI_{72} (and its degradation product UTI_{18}) only. Chromatographic conditions as in Fig. 2.

tal conditions, UTI_6 was found only in the first immobilized trypsin column. UTI_{72} and UTI_{18} were removed from the column by eluting with buffer solution pH 3.5. After passage of about 150 ml of buffer solution C, the decrease until disappearance of the two inhibitors in the eluate was monitored. For this purpose, a 100 μl aliquot of the eluate was tested by RP-HPLC injection. A total elution volume of about 200 ml was found to be effective in any case. The complete

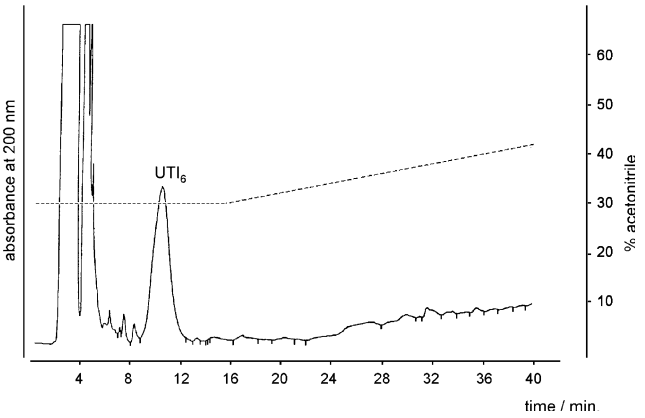

Fig. 4. Chromatogram of solution from flask 2, containing UTI_6 only. Chromatographic conditions as in Fig. 2.

recovery of UTI_6 was achieved by eluting the first column with 0.8 ml of 1.0 M H_3PO_4 and buffer solution A. Finally, flasks 1 and 2 contained only UTI_{72}, UTI_{18} and UTI_6, respectively, as confirmed by the analyses performed by our RP-HPLC method (Figs. 3 and 4).

The analytical recovery of the two inhibitors from urine was determined by inhibition assays and by chromatographic measurements. Each test was performed by comparison of the response obtained by analysis of 200 ml of urine processed without any preconcentration step, which provided the 100% value, with that obtained from 5000 ml of the same urine processed as described, after suitable correction for precocentration factors. The results are shown in Table 1: for both inhibitors, the recoveries were higher than 70%, and the retaining of bioactivity was tested.

The preconcentration step is particular suitable for Kazal-type recovery, owing to the low concentration of this inhibitor in urine of healthy individuals. Some authors processed samples of urine obtained from subjects affected by particular diseases with very high amounts of the inhibitor (ca. 1 mg $^{-1}$): in this instance our procedure could be simplified, avoiding the preconcentration step.

Concluding, the proposed procedure is advantageous for its speed, specificity and, chiefly, for the reliability of monitoring.

Table 1
Recovery of Kazal-type and Kunitz-type inhibitors from human urine (%)

Experiment number	Kazal-type (UTI_6)		Kunitz-type (UTI_{72})	
	By chromatographic measurement	By inhibition assay	By chromatographic measurement	By inhibition assay
1	80	77	91	88
2	78	80	85	87
3	71	73	86	84
4	75	72	92	90

containing species, such as HPO_4^{2-}, ATP and ADP, in forming metal-ion complexes.

Few thermodynamic data have been reported for the formation of PCr complexes and those that have are so contradictory that it is stated that the published data do not meet the criteria required for a critical selection in the NIST database [3]. Formation constants have been published for MgPCr [4] and $KPCr^-$ [5], but nothing has been reported for $NaPCr^-$. This is strange as the sodium and potassium complexes of ATP and ADP are usually quite similar [3,6]. Another disquieting aspect of the published data is the small difference between the formation constants of MgPCr and $KPCr^-$, since with analogous ligands magnesium complexes are much more stable than the corresponding potassium complexes [3,6].

Information regarding the stability of PCr complexes is essential for the determination of the concentrations of the species present in the cytosolic medium. We have, therefore, undertaken a systematic study, using ^{31}P NMR spectroscopy, of complexation of the phosphate ligands PCr, ATP, ADP and AMP with the three cations Na^+, K^+ e Mg^{2+}, under physiological conditions ($T = 37$ °C and $I = 0.25$ M). We now report the results for phosphocreatine.

2. Experimental

2.1. Chemicals

$Na_2PCr \cdot 4.5H_2O$ (Sigma) was used without further purification (Calc. for $C_4H_{17}N_3O_{9.5}PNa_2$, C, 14.29; H, 5.10; N, 12.50. Found: C, 14.20; H, 5.21; N, 12.50%). The ^{31}P NMR spectra of this substance show that hydrolysis is negligible in aqueous solution as the intensity of the phosphate ion signal was always less than 1% of the total integrated intensity. Analytical grade reagents (Merck) were used to prepare stock solutions of Me_4NCl, NaCl, KCl and $MgCl_2$ using weighed amounts of solute and solvent. D_2O (99.8%, Merck) and reagent grade Bu_4NCl (Fluka) and Bu_4PCl (50% aqueous solution, Merck) were used as supplied.

2.2. NMR measurements

$^{31}P\{^1H\}$ NMR spectra were recorded at 81.02 MHz using a Bruker AC 200 spectrometer. The probe temperature was 37.0 ± 0.2 °C. Field frequency stabilisation was established by using as solvent H_2O–D_2O (80:20 by volume). All chemical shifts are reported in ppm toward higher frequency relative to external 85% aqueous H_3PO_4. No corrections were made for differences in bulk susceptibly in the various samples. Digital resolution was 0.216 Hz per point. In all cases $\pi/3$ pulses were used. The feed was accumulated in 32 k data points with zero filling to 64 k data points before Fourier transformation. The acquisition time was 4.62 s.

2.3. Spectra and compositions of the solutions used

At least ten solutions were prepared for each system. Solutions were stored at approximately 4 °C to prevent hydrolysis. The concentration of Na_2PCr was approximately 0.02 mol dm^{-3} in all solutions. The concentrations of the metal halides (NaCl, KCl and $MgCl_2$) ranged between zero and the concentration corresponding to an ionic strength of 0.25 mol dm^{-3}. Where necessary, the solutions were made upto constant ionic strength of 0.25 mol dm^{-3} by addition of Me_4NCl for the NaCl–PCr and KCl–PCr systems or NaCl for the $MgCl_2$–PCr system. A further series of 11 replicate solutions in the NaCl–PCr system was prepared, but with Bu_4PCl added as an internal reference and replacing Me_4NCl by Bu_4NCl.

2.4. Computational procedures

In the course of this work the new computer program HYPNMR-2000 has been written and developed. This is a generalised program for the determination of stability constants from NMR chemical shift data in systems where exchange is rapid on the NMR time-scale. It has a novel structure. The main program is written in VISUAL BASIC and runs as a typical WINDOWS application. The main program contains extensive facilities for data input and preliminary calculations including the possibility of interactive data fitting with graphical displays of observed and calculated data. The stability constant refinement is a compiled FORTRAN module, called from the main program, which is based on the earlier HYPNMR program [7]. The refinement module reads data from an input file and records the results of the computation in an output file. On termination of the refinement the output file is automatically opened in the main program and is displayed in a customised viewer.

HYPNMR-2000 can handle any number of individual resonances, including resonances from more than one nucleus, such as ^{13}C and ^1H, at the same time. There are no limitations on the number of reagents or stability constants that can be specified. Further details are available at http://www.chem.leeds.ac.uk/people/peter_gans/hypnmr.htm.

3. Results and discussion

All spectra showed a single narrow resonance, as illustrated in Fig. 1. This indicates that all the species related to phosphocreatine are in rapid equilibrium on the NMR time-scale. Confirmation of this state of affairs is provided by the smooth variation of the

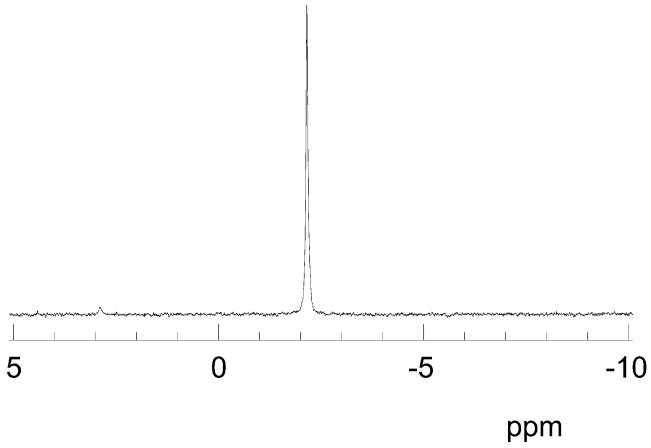

Fig. 1. ^{31}P NMR spectrum of a solution containing Na_2PCr 0.020 mol dm^{-3}; $T = 37$ °C and $I = 0.25$ mol dm^{-3}, made up with Me_4NCl.

chemical shift with changes in concentration of the metallic cations: with Na^+ and K^+ there is a slight drift to low field with increasing metal ion concentration and

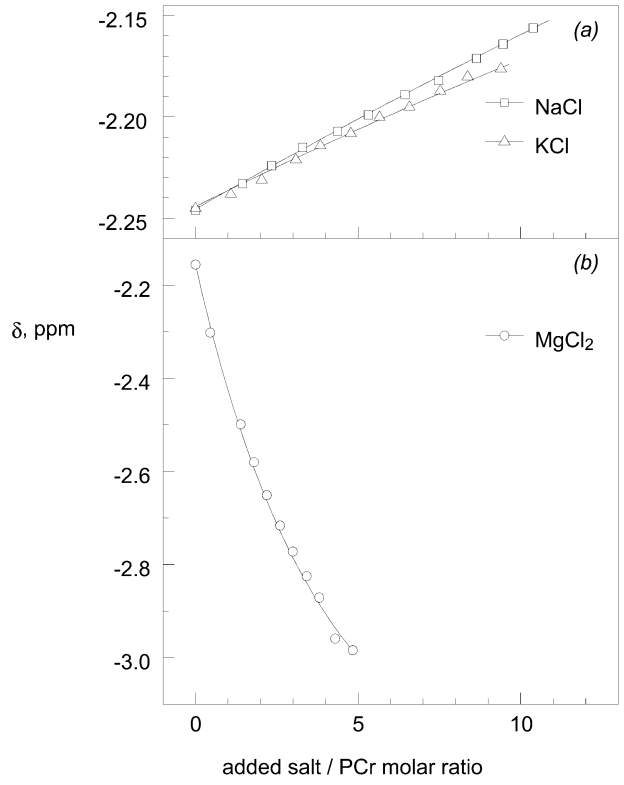

Fig. 2. ^{31}P chemical shifts of phosphocreatine at 37 °C as a function of added salt–phosphocreatine molar ratio. Hollow symbols represent the experimental points, solid lines refer to calculated titration curves. Chemical shifts were calculated on the basis of a constant analytical concentration of PCr equal to the average in each system: 0.01944 mol dm^{-3} for NaCl, and 0.2075 for KCl and $MgCl_2$. (a) Experimental values and titration curves for the systems NaCl–PCr and KCl–PCr, ionic strength adjusted with Me_4NCl; (b) experimental values and titration curve for the system $MgCl_2$–PCr, ionic strength adjusted with NaCl.

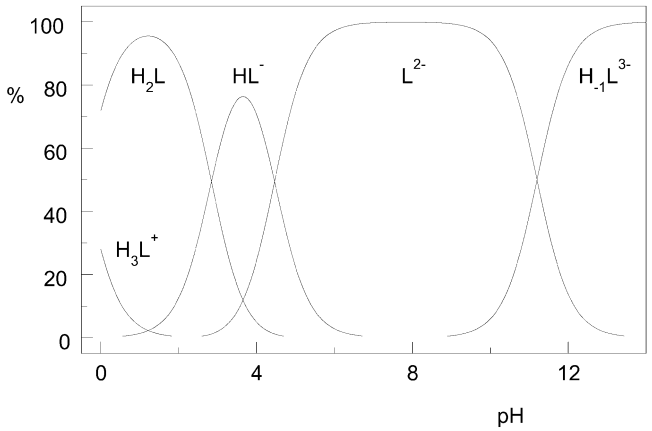

Fig. 3. Hyss distribution diagram of phosphocreatine as a function of pH. The pK_a values were taken from Ref. [8].

with Mg^{2+} there is a marked displacement to high field. These trends are illustrated in Fig. 2.

Four protonation constants have been determined for phosphocreatine [8]. The three pK_a values, −0.41, 2.84 and 4.46, were assigned to dissociation of one proton from the $-PO_3H_2$ group, dissociation of the carboxyl group proton and dissociation of a second proton from the phosphate group, respectively. The fourth pK_a value, 11.2, relates to further deprotonation of PCr^{2-}. A diagram showing the distribution of the species as a function of pH is shown in Fig. 3. This diagram, produced by the program HYSS-2000 [9], shows that PCr^{2-} is the only species present between pH 7 and pH 9. With the same program the pH of an aqueous solution of 0.02 mol dm^{-3} Na_2PCr is calculated to be 7.80 with PCr^{2-} being present at a relative concentration of more than 99.9%. These results mean that any protonated or deprotonated form of PCr^{2-} is present in negligible concentration and can, therefore, be ignored.

The stability constants for $NaPCr^-$, $KPCr^-$ and MgPCr were determined with the aid of the program HYPNMR-2000 by fitting all the data points (with unit weights) with the further inclusion of a stability constant for MgCl (log $K = 0.43$) [5] as a constant entity. The refined stability constants are shown in Table 1. The

$Mg^{2+} + PCr^{2-} \rightarrow MgPCr$	1.43 ± 0.03	1.6 ± 0.2 [b]

[a] From [5]; $T = 25$ °C, $I = 0.15$ mol dm^{-3}.
[b] From reference [4]; $T = 30$ °C, in 0.1 mol dm^{-3} *N*-ethylmorpholine buffer at pH 8.0.

value obtained for the complex MgPCr is in satisfactory agreement with a previous determination [4], but with the complex $KPCr^-$ our value is much smaller that the published value [5]. For $NaPCr^-$ there is no previously reported value for comparison and the value is quite similar to that of the potassium complex, as expected.

The chemical shifts of PCr^{2-}, $NaPCr^-$, $KPCr^-$ and MgPCr were refined along with the stability constants. The values found are -2.264 ± 0.001, -0.9 ± 0.6, -1.4 ± 0.3 and -3.44 ± 0.03 ppm, respectively.

Agreement between observed and calculated resonances is excellent, as indicated by a value of 0.00085 ppm for the S.D. on all the residuals. The calculated resonances are also shown on Fig. 2. The good agreement also provides confirmation that the only complexes formed have 1:1 metal:PCr stoichiometry.

Although the fit of the experimental data is very good the standard deviations calculated for both stability constants and chemical shifts of the sodium and potassium complexes are rather large. The main reason for this is that these complexes are rather weak so that even in the most concentrated solutions the degree of formation is small, 7.7% for NaCl–PCr and 8.7% for KCl–PCr. The magnesium complex is stronger and the degree of formation is much larger (reaching a maximum of 61%) so the standard deviations of both stability constant and chemical shift are an order of magnitude smaller.

Two assumptions underlie the results given in this work. Firstly, that the magnetic susceptibility of the medium was not affected by the progressive replacement of Me_4NCl by NaCl or KCl or of NaCl by $MgCl_2$. Secondly, that the Me_4N^+ cation does not associate with PCr^{2-}. The validity of these assumptions was tested by replicating the NMR measurements in the series NaCl–PCr with two significant differences: Bu_4PCl was added as an internal standard for the measurement of chemical shifts and Bu_4NCl was used instead of Me_4NCl for the background electrolyte. It is generally accepted that the tetrabutylammonium ion does not associate with phosphate-containing ligands [10,11]. The ^{31}P chemical shift of the tetrabutylphosphonium ion was found to be constant, 34.2456 ± 0.0009 relative to external 85% H_3PO_4. This shows that variation of solution composition over the experimental range has no significant effect on bulk magnetic susceptibility. The second assumption was tested by comparing the calculated stability constants. With the tetrabutylammonium salt log K was found to be -0.4 ± 0.3. This value is practically the same as the value obtained with the tetramethylammonium salt which demonstrates that neither cation interacts significantly with PCr.

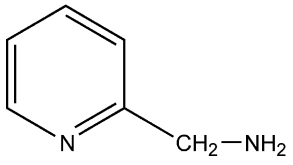
pounds have afforded various structural co-relations. For example, IDA (or IDA-like) conformation changes from *fac*- to *mer*-conformation when aqua is replaced in $[Cu(IDA)(H_2O)_2]$ (or a related chelate) by a monodentate N-heterocyclic imidazole (Him) or Him-derivative. Subsequently, a *mer*- to *fac*-IDA (or IDA-like) conformation is systematically observed going from these 1/1/1 Cu–IDA–N-heterocyclic donor compounds [1c,2–11] to others having a 1/1/2 Cu–IDA–N-heterocyclic donor ratio [12,13] or closely related complexes [14–17]. Some of these later compounds [14,15,17] reveal in addition that in the secondary ligand there is a preference of the N-heterocyclic donor for the *trans*-position to the Cu–N(IDA or IDA-like) bond. In this broad context, we became increasingly interested on new mixed-ligand copper(II) complexes having a *N*-R-IDA derivative with a R non-chelatable [16,17] or chelatable [18]18a aromatic side chain as primary ligand, and various N-heterocyclic secondary ligand of remarkable aromaticity. These kinds of mixed-ligand complexes could be 'structural model systems' with possibilities of displaying 'aromatic π,π-stacking interaction's. Such weak interactions are extensively studied because they seem to play essential roles in molecular recognition processes and in supra-molecular assemblies of relevant biological (and non-biological) systems [19,20].

It is well known that 2-(aminomethyl)pyridine or α-picolyamine (pca) acts as *N,N*-bidentate diamine ligand for copper(II) in $[Cu(pca)_3]Cl_2\cdot Cl_2CH_2$ [21a] and in several 'mixed-ligand' complexes (such as, $[Cu(pca)_2(H_2O)_2]Cl_2$ [21b] or $[Cu(pca)_2(L)_2]$ (L = various anions) both in solution and/or in solid state [21c,21d,21e,21f,21g,21h,21i]. Pyridyl π,π-stacking interactions have recently been reported for a polymeric non-chelated pca–silver(I) complex [22]. In this sense, a suggestive H_2IDA-derivative (as primary ligand) is the anion of *N*,*N*-bis(carboxymethyl)-2-(aminomethyl)pyridine or *N*-(2-pyridylmethyl)iminodiacetic acid (H_2pmda), namely *N*-(2-pyridylmethyl)iminodiacetate(2-) (hereafter pmda) (Schemes 1 and 2).

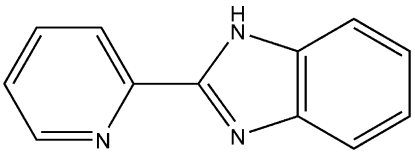
The stability constants of pmda-complexes in solution have been reported for a large variety of mono-(Li, Na, Ag, Tl), di-(alkaline-earths, Mn, Fe, Co, Ni, Cu, Zn, Cd, Hg, Pb), tri-(lanthanide series, Am, Cm) and tetravalent (vanadyl) metal ions [23]. As expected, the tripodal pmda ligand forms a very stable Cu(II) chelate (log $K = 14.2$ at 20 °C) [23d,23h,23i]. Crystal structure reports on pmda-derivatives are surprisingly limited to one dinuclear complex of iron(III) [24], two vanadium

Scheme 1. H_2IDA.



Scheme 2. H_2pmda.

compounds [25] and a tricarbonyl–technetium derivative [26]. In these cases pmda acts as tetradentate, but no mention is made of 'aromatic ring stacking' interactions. In contrast, we have recently found that in the polymeric structure of $\{[Cu(pmda)]\cdot 2H_2O\}_n$ there is a multi-π,π-stacking interaction between pyridyl rings of the complex chains [18b]. This paper deals with the synthesis and molecular and crystal structure of the free acid (H_2pmda·0.5H_2O) and of two pmda–copper(II) chelates having pca or 2-(2′-pyridyl)benzimidazole (Hpb) as secondary ligand. The aim of the present work is to study the coordination preferences of N donor atoms of these unsymmetrical diamines to the *trans*-position versus the Cu–N(tertiary amino pmda) bond. The inter-ligand aromatic ring π,π-stacking interactions in the studied compounds are also discussed (Schemes 3 and 4).



2. Experimental

2.1. Synthesis of the acid H_2pmda·0.5H_2O

The pmda ligand has been obtained as free acid by reaction of potassium chloroacetate and pca in aqueous alkaline solution at room temperature (r.t.). In a standard essay the solution of chloroacetic acid (79.36 g, 0.84 mol) in 200 ml of water was stirred and cooled in a salt–ice bath. A solution of KOH (94.08 g, 1.68 mol) in 200 ml of water was drop-wise added. To the resulting alkaline solution pca (41.24 ml, 0.40 mmol) was slowly added and the mixture was left to react in a 500 ml cooled flask in the dark for 2 weeks. HCl 6N (33 ml) was added to neutralize the solution, which was concentrated under reduced pressure and cooled (salt–ice bath) to remove KCl (by-product, 40 g). HCl 6N was newly added to fit the pH near 2.5. The desired acid precipitates and is removed by filtration. An additional amount of HCl 6N was added to the mother liquor (pH ~4) to bring down the pH to 2.5. A new amount of

Scheme 3. Pca.

Scheme 4. Hpb.

H_2pmda was removed by filtration. The product was re-crystallized in a hot fifty–fifty ethanol–water mixture, filtered and air-dried. Many well-shaped prismatic crystals of H_2pmda·0.5H_2O suitable for crystallographic work were obtained in this way. This product can also be re-crystallized from water or water:methanol (1:4). Yield: 50.38 g, 54%. *Anal.* Calc. for $C_{10}H_{12}N_2O_4$·0.5H_2O: C, 51.50; H, 5.62; N, 12.01. Found: C, 51.41; H, 5.68; N, 11.96%. Alternative syntheses of this acid were reported in the literature [23i,27]. ^{1}H NMR (300 MHz, *d*6-DMSO; δ, ppm): 3.47 (s, 4H), 3.97 (s, 2H), 7.27 (m, 1H), 7.53 (d, 1H), 7.77 (m, 1H), 8.46 (d, 1H) and 11.99 (exchangeable H). ^{13}C NMR (d_6-DMSO; δ, ppm): 54.44 (N–CH_2–COO^-), 59.01 (C_{arom}–CH_2–N), 122.29, 122.71, 136.64, 148.44 and 158.98 (C_{arom}), and 172.47 (–COO^-). FTIR spectrum (cm^{-1}): 3449, ν(OH); 3110, $\nu(CH_{arom})$; 3065 and 3002 $\nu_{as}(CH_2)$; 2964, $\nu_s(CH_2)$; 1690 and shoulders, ν(C=O), pyridyl ring breathing I and $\delta(H_2O)$; 1595, ν_{as}(COO) and pyridyl ring breathing II; 1480, pyridyl ring breathing III; 1437, pyridyl ring breathing IV, and 1389, ν_s(COO). TG+FTIR of pyrolysis gasses: In a dry-air flow it becomes nearly anhydrous (water: 0.58% exp., calc. 3.86%) and the anhydrous sample gives three pyrolytic steps (190–575 °C) with production of H_2O, CO_2, CO, NH_3 and N_2O. The decomposition starts by de-carboxylation of a free carboxylic group (190–200 °C).

2.2. Synthesis of [Cu(pmda)(pca)]·3H_2O

The stoichiometric reaction of bluish copper(II) hydroxycarbonate ($Cu_2(CO_3)(OH)_2$) and (H_2pmda·0.5H_2O) in water yields a blue solution of the complex [Cu(pmda)(H_2O)$_2$] (from which a polymeric solid {[Cu(pmda)]·2H_2O}$_n$ could be obtained [18b]). In a typical essay a mixture of 466.4 mg (2.0 mmol) of H_2pmda·0.5H_2O and 221.1 mg (1.0 mmol, Probus) of $Cu_2CO_3(OH)_2$ in 150 ml of water was heated and stirred under controlled vacuum (to remove the CO_2, by-product). The solution was stirred and heated at 60 °C for 30 min, left to cool at r.t. and then slowly filtered to remove any insoluble by-product (mainly a small amount of CuO). The clear blue solution was stirred and 0.21 ml (2 mmol, Aldrich) of pca was dropwise added. By slow evaporation of the solution at r.t. the volume was reduced to a few millilitres, and then isopropanol and acetone was added just to initiate the precipitation. The crystallization device was covered with a watch glass and slowly evaporated. A very variable and limited amount of needle-shaped crystals of the desired product (compound **1**) were formed, many of them being poly-crystals. Some single crystals were picked up for the X-ray diffraction study. The remaining product was filtered-off and air-dried for elemental analysis and FTIR spectral characterization. Frequently the reaction mixture is degraded, probably by pca oxidation, which is observed from a change from blue to greenish color. These changes are promoted by heating. Yield: < 5%. *Anal*. Calc. for $C_{32}H_{48}Cu_2N_8O_{14}$: C, 42.90; H, 5.40; N, 12.51. Found: C, 42.96; H, 5.44; N, 12.56%. The FTIR spectrum (cm^{-1}): ~3400 and 1629, ν and $\delta(H_2O)$; 3263, 3130 and 1571, ν_{as}, ν_s and $\delta(NH_2)$; 3083 and 3058, $\nu(CH_{arom})$; 2978, $\nu_{as}(CH_2)$; 2863, $\nu_s(CH_2)$; 1680, pyridyl ring breathing I; 1608, ν_{as}(COO) and pyridyl ring breathing II; 1482, pyridyl ring breathing III; 1446 or 1438, pyridyl ring breathing IV; and 1394, ν_s(COO). Δ(COO) = 214 cm^{-1}.

2.3. Synthesis of [Cu(pmda)(Hpb)]·5H_2O

To a clear blue solution of pmda–Cu(II) complex prepared in 200 ml of water, as referred before, 390.5 mg of Hbp (1 mmol, Aldrich) was added. The mixture was stirred 48 h at r.t. and filtered, and the blue solution was left to evaporate in a crystallization device. After 2 weeks, blue crystals of the desired product (compound **2**) were formed, some of them suitable for X-ray crystallography. The product was collected by filtration, washed with water and ethanol, and air-dried. Successive amounts of **2** can be collected. The product can be re-crystallized several times from water. Yield: 75%. *Anal*. Calc. for $C_{22}H_{29}CuN_5O_9$ C, 46.27; H, 5.12; N, 12.26; Cu, 11.13. Found: C, 46.46; H, 5.46; N, 12.48; Cu, 10.93% (EDTA complexometry [1,15]). FTIR spectrum data (cm^{-1}): ~3420 $\nu_{as}(H_2O)$; 3263(broad), $\nu_s(H_2O)$ and ν(NH) of Hpb; 3098 and 3060, $\nu(CH_{arom})$; 2977 and 2926, $\nu_{as}(CH_2)$; 2861 and 2813, $\nu_s(CH_2)$; 1639, pyridyl ring breathing I and $\delta(H_2O)$; 1613, ν_{as}(COO) and pyridyl ring breathing II; 1598, ν_{as}(COO); 1541, δ(NH) of Hpb; 1482, pyridyl ring breathing III; 1443 or 1425, pyridyl ring breathing IV; 1394 and 1382, ν_s(COO). Δ(COO) = 219–216 cm^{-1}.

2.4. X-ray data collection, solution of the structures and refinement

2.4.1. Acid H_2pmda·0.5H_2O

A colorless prismatic crystal of H_2pmda·0.5H_2O was mounted on a glass fibre and used for data collection. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the diffraction data from 25 reflections in the range of $12.152° < \theta < 42.972°$ in an Enraf–Nonius CAD4 diffractometer [28]. Data were collected at 293 K using Cu

Kα radiation ($\lambda = 1\,54\,184$ Å) and the ω-scan technique and corrected for Lorentz and polarization effects [29]. A semi-empirical absorption correction (Psi-scans) was made [30]. The structure was solved by direct methods [31], which revealed the position of all non-hydrogen atoms, and refined on F^2 by a full-matrix least-square procedure using anisotropic displacement parameters [32]. All hydrogen atoms were located from difference maps and refined isotropically. Atomic scattering factors were taken from the International Tables for X-ray Crystallography [33]. Molecular graphics plotted from PLATON-98 [34]. A summary of the crystal data, experimental details and refinement results is given in Table 1.

2.4.2. *[Cu(pmda)(pca)]·3H$_2$O and [Cu(pmda)(Hpb)]·5H$_2$O (compounds **1** and **2**)*

Crystallographic data for these two blue compounds were collected on a Bruker Smart CCD diffractometer at 293 K using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å), and were corrected for Lorentz and polarization effects. The frames were integrated with the Bruker SAINT [35a]; software package and the data were corrected for absorption using the program SADABS [35b]. The structures were solved by direct methods using the SHELXS-97 program [36]. All non-hydrogen atoms were refined with anisotropic thermal parameters by full-matrix least-squares calculations on F^2 using the program SHELXL-97 [37]. The position of most H atoms was calculated geometrically and included in structure factor calculations, but in compound **2** the H atom bonded to N23 was located in difference maps and its position was refined isotropically. Crystal data and structure refinement parameters are listed in Table 1. Molecular graphics were obtained using SHELXTL [38].

2.5. Physical measurements

NMR spectra were recorded in a Bruker AM300 spectrophotometer. Infrared spectra were obtained by the KBr disc technique on a JASCO FTIR 410 instrument. In addition the TG (pyrolysis) of studied compounds and analysis of evolved gasses were recorded (295–775 K) in air flow (100 ml min^{-1}) using a Shimazu Thermobalance TGA-DTG-50H coupled with an IRFT Nicolet Magma 550 (and mass spectrometer Fisons Thermolab). Electronic (reflectance) spectra (175–3300 nm) were obtained in a Cary 5E spectrophotometer.

RSE spectra of a polycrystalline sample were recorded without magnetic dilution in a spectrophotometer Bruker ESP 300E (X band) at r.t. The magnetic susceptibility of **I** was measured at the temperature range 80–300 K using a Manics DM magnetometer. The susceptometer was calibrated with mercury tetrakis(thiocyanato)–cobaltato(II). Corrections for the diamagnetism ($122 \cdot 10^{-6}$ cm^3 mol^{-1}) were estimated from Pascal constants [39]. Experimental susceptibilities were also corrected for the temperature-independent paramagnetism (60×10^{-6} cm^3 mol^{-1} per Cu(II) atom) [40].

3. Results and discussion

3.1. Description of the structures

Bond lengths and angles between non-hydrogen atoms and hydrogen bond distances and angles of H_2pmda·0.5H_2O are given in Table 2. Fig. 1 shows a drawing of two adjacent symmetrically related units, with the numbering scheme. According to the relative magnitude of its pK_a values (for example, p$K_0 = 2.65$, p$K_1 = 2.74$ and p$K_2 = 8.16$ for a proton dissociation from H_3pmda$^+$, H_2pmda and Hpmda$^-$, respectively, at $I = 0.1$(KNO_3) and 25 °C [23d]) the molecule of this diamino-diacid will exist as a zwitterion in solution of polar solvents. Such dipolar ions H_2pmda$^{\pm}$ are also found in the crystal, as it has usually been observed for a variety of free amino-polycarboxylic acids [41].

Two structural features of the studied amino-polycarboxylic acid are of major interest. First, is the conformation intra-stabilised by a trifurcated hydrogen bond formed by the 'onium' proton with two carboxylate atoms, O(12) and O(22), and the pyridyl atom N(2) as 'acceptors'. In accordance, its planar pyridyl ring forms similar dihedral angles with the planes of both carboxylic (86.2°) and carboxylate (89.3°) groups. Similar kind of zwitterions have been largely referred for the structure of a variety of amino-polycarboxylic acids such as iminodiacetic acid [41]. The presence of similar trifurcated hydrogen bonds governing a zwitterion conformation is also known, for example, in the crystal structures of β-(hydroxyethyl)iminodiacetic acid (H_2heida) [42] and nitrilopropionicdiacetic acid (H_3npda) [43], both with appropriate O-acceptor atoms in the 'third arm'. In H_2heida the 'onium' hydrogen atom interacts with two O-carboxyl and one O-alcoholic atoms, whereas in H_3npda three O-carboxyl atoms interact with the onium N–H$^+$ group. Second, pyridyl rings from pairs of adjacent dipolar ions H_2pmda$^{\pm}$ (related by the symmetry code #2 = ii = $1/2-x$, $-1/2-y$, $2-z$) lie parallel and stacked (dihedral angle between planes $\alpha = 0.2°$) at a distance of 3.57(1) Å (Fig. 1). This

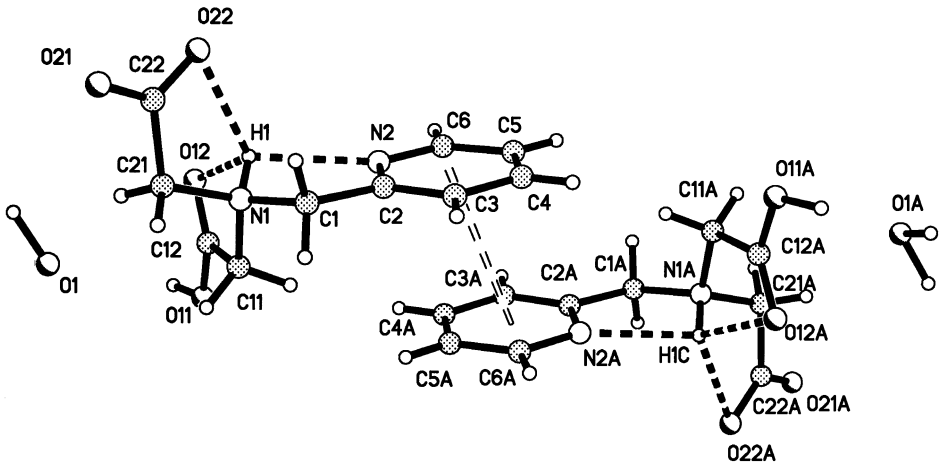

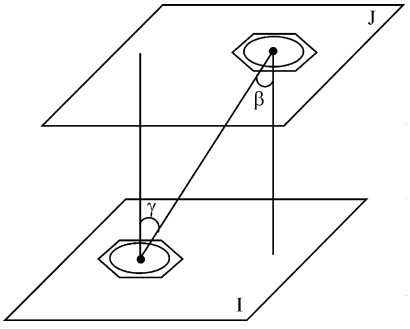

Fig. 1. Structure of the acid *N*-(2-pyridylmethyl)iminodiacetic acid hemi-hydrate showing the stacking between pyridyl rings of two adjacent zwitterions, which are intra-stabilised by a tri-furcated hydrogen bond.

Scheme 5. β and α angles in a ring–ring π,π-stacking interaction.

π,π-interaction will have a significant σ,π-contribution because of the long centroid–centroid distance (3.94 Å) and the remarkable displacement between the stacked rings (angles of the centroid–centroid vector with the perpendicular to each stacked ring plane are $\beta = \gamma =$ 25.0°; see scheme 5 below). In addition, each zwitterion acts as H-donor to an adjacent one (related by the symmetry code #1 = $i = x, -y+1, z-1/2$; see Table 2). These latter –COOH···$^{-}$OOC–hydrogen bonds and the ring–ring stacking interactions generate a 2D framework with the carboxyl groups toward the external surfaces and stacked pyridyl rings toward the inside (Fig. 2). In the crystal, each water molecule forms two symmetry related and equivalent hydrogen bonds of the type O(1)–H(10)···O(21)#1 (Table 2) toward opposite sides connecting the closest external faces of two adjacent bi-layers (Fig. 2) (Scheme 5).

Since the internal geometry of the ligands could be considered normal (see appropriate refs. for pmda [24–26], pca [21,22] and Hpb [44]), only coordination bond lengths and selected *trans*-angles of (α-picolylamine)(*N*-(2-pyridylmethyl)iminodiacetato)copper(II) thi-hydrate

([Cu(pmda)(pca)]·3H_2O, compound **1**) and (2-(2′-pyridyl)benzimidazole)(*N*-(2-pyridylmethyl)iminodiacetato)copper(II) pentahydrate ([Cu(pmda)(Hpb)]·5H_2O, compound **2**) are listed in Tables 3 and 4, respectively.

The asymmetric unit of compound **1** (Fig. 3) consists of a pair of crystallographically independent molecules [Cu(pmda)(pca)], very similar from a chemical point of view, and six non-coordinated water molecules. Coordination bond lengths (averaged, in Å): Cu–N(aliphatic) 2.064(2), Cu–O(equat.) 1.966(2), Cu–O(apex) 2.399(2) and Cu–N(py ring) 2.529(3) to pmda; Cu–N(py ring) 1.990(2) and Cu–N(primary amino) 2.015(2) to pca ligand. The closest four donors around the copper(II) atom are both N atoms of pca, and the N aliphatic and one O carboxyl atoms of pmda. It is remarkable that the N(pyridyl) and one O carboxyl atom from pmda occupy the apexes of the asymmetrically elongated coordination of copper(II). Two main structural features arise from this structure: (1) the conformational flexibility of the tripodal tetradentate pmda ligand, which occupy two equatorial and two apical coordination sites (instead of three equatorial and an apical ones), and (2) the coordination preference of the *N*(pyridyl)-heterocyclic atom from the secondary pca ligand to occupy the *trans*-position to the Cu–N(aliphatic) bond of pmda.

Compound **2** has one complex molecule and five water molecules in the asymmetric unit (Fig. 4). In this complex, the pmda exhibits a tripodal tetradentate role occupying three equatorial sites and one apical donor site, whereas the *N*,*N*-bidentate Hpb ligand supplies one equatorial atom and one apical donor atom. The structure of the compound **2** shows the preference of the *N*(imidazolyl) donor versus the *N*(pyridyl) donor of

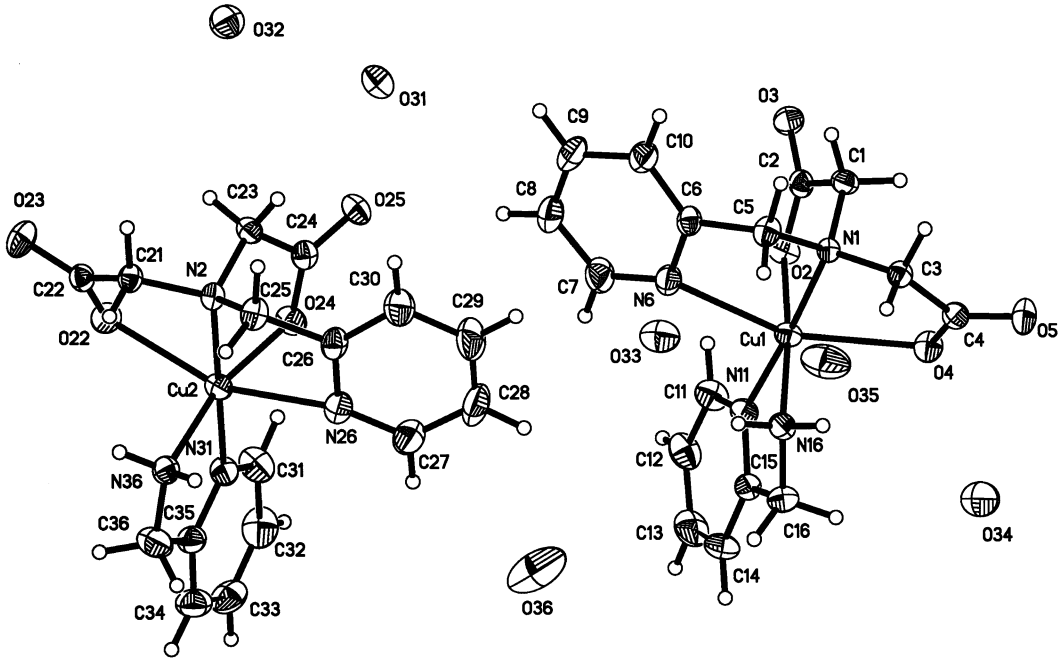

Fig. 3. Asymmetric unit in the crystal of compound **1**, [Cu(pmda)(pca)]·3H_2O, showing the two crystallographically independent complex units and the six independent water molecules.

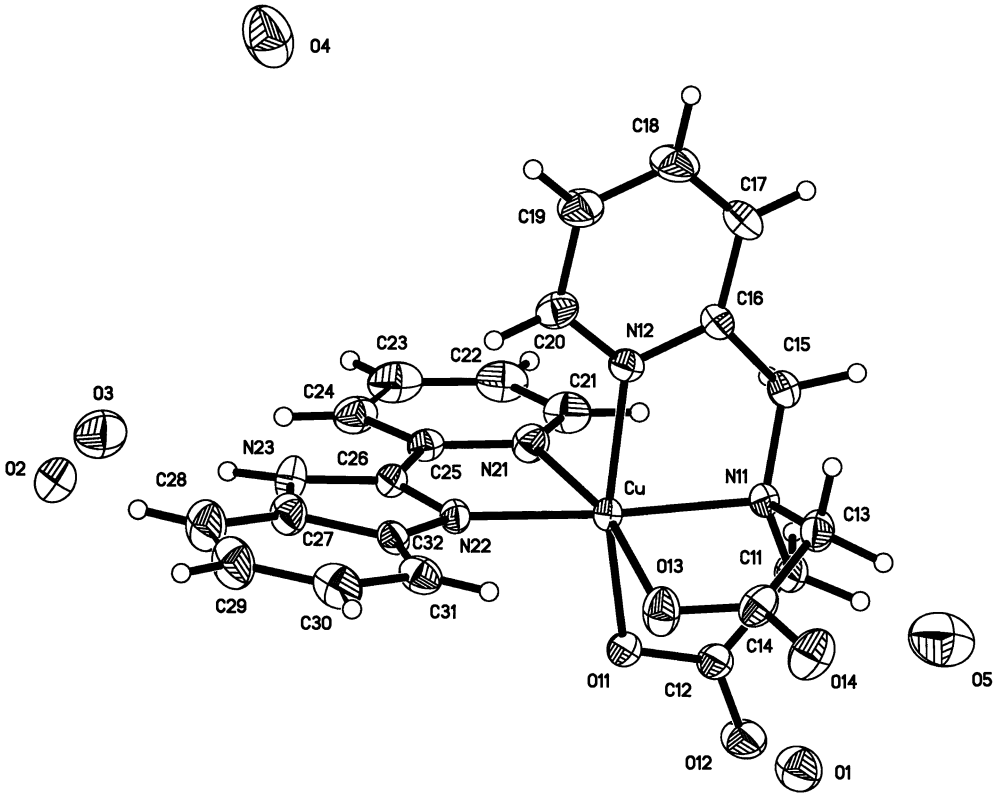

Fig. 4. Asymmetric unit in the crystal of [Cu(pmda)(Hpb)]·5H_2O (compound **2**).

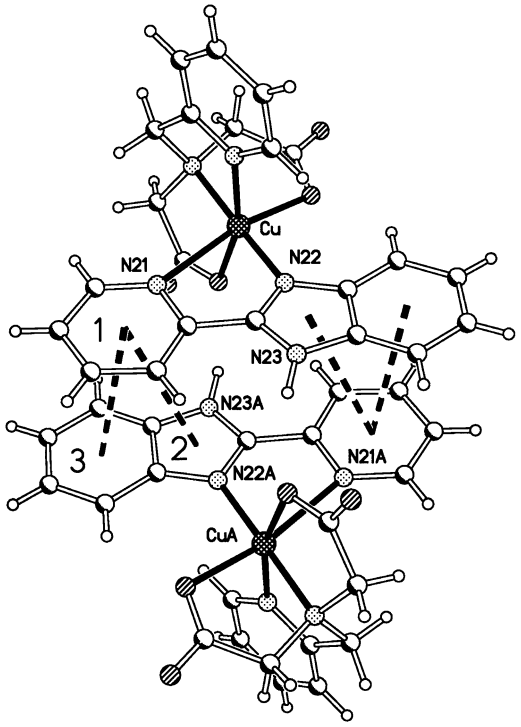

Fig. 5. Aromatic ring–ring π,π-stacking interaction between Hpb ligands of a pair of adjacent molecules in the crystal of [Cu(pmda)(Hpb)]·5H_2O (compound **2**).

Hpb to occupy one among the four closest donor atoms in the distorted octahedral coordination of copper(II) atom; that is just in *trans* to the Cu–N(1) bond of the tertiary amino atom of pmda ligand. In this crystal, pairs of adjacent complex molecules (symmetry related by the code $i = 2-x,\ 1-y,\ z$) have the corresponding Hpb ligands anti-parallel stacked at 3.41 Å (Fig. 5). This π,π-stacking interaction relates approximately the pyridyl ring (ring 1) of each Hpb ligand with the five and six-member rings of the benzimidazolyl moiety from the stacked Hpb ligand (rings 2 and 3, respectively). The analysis of this stacking interaction gives the following structural parameters. Centroid–centroid distances dc_1–$dc_2 = 3.67$ Å and dc_1–$dc_3 = 3.56$ Å. The dihedral angle between stacked rings (α) and angles β and γ of the c–c vector to the normal to the first and second planes (see Scheme 5) are $\alpha = 5.3$, $\beta = 25.6$ and $\gamma = 21.9^\circ$ for planes of rings 1 and 2, and $\alpha = 5.6$, $\beta = 17.2$ and $\gamma = 16.6^\circ$ for planes of rings 1 and 3. The perpendicular distances from the centroid of the ring 1 to the planes 2 and 3 are 3.40 and 3.41 Å, respectively. The perpendicular distances from the centroid of the ring 2 or 3 to the plane of ring 1 are 3.31 and 3.40 Å, respectively. These structural parameters for the stacking between Hpb ligands are consistent with a π,π-interaction with some σ,π-contribution [20]. The crystal is supposedly built linking

pairs of complex molecules and water molecules in a hydrogen-bonding array.

In both complexes the copper(II) atom falls in a distorted and asymmetrically elongated octahedral coordination (type 4+1+1), with the four shortest R_S bonds and the two out-of-plane or *trans*-apical longest R_L bonds. In compound **1** there is a remarkable difference in the asymmetry of two molecules, as reflected by the *trans*-apical R_L bond lengths and the tetragonality (T = mean in-plane distance/mean out-of-plane distance) [45] of 0.828 and 0.802 for Cu(1) and Cu(2), respectively. In this complex the individual and the averaged tetragonality (mean $T = 0.815$) falls below that of compound **2** ($T = 0.839$), which has also rather different *trans*-apical R_L bond distances, Cu–O(13) and Cu–N(21). Consequently, the overall elongation of the copper(II) coordination polyhedron is higher in **1** (with lower T) than in **2**.

In the new mixed-ligand Cu(II) complexes, the pmda ligand acts as a tripodal tetradentate as referred in all known structures of complexes with this chelating agent and other metal ions [24–26]. However, the conformation of pmda ligand around the copper(II) in reported chelates is different, because it supplies two equatorial and two apical donors (in **1**) or three equatorial and one axial donors (see above). We found surprising that in compound **1** the rather flexible pca diamine occupies two among the four closest coordination sites around the copper(II) atom, whereas in compound **2** the very rigid Hpb heterocyclic diamine supplies one equatorial and one axial N donors. This apparent controversy can be rationalised considering that both pmda conformations enable the formation of two types of metal-glycinate rings in the complexes studied here. These are the G ring (nearly coplanar to the plane [Cu, N, N] and more strengthened) and the R ring (nearly perpendicular to the plane [Cu, N, N] and less constrained). In the compounds considered here, the G ring falls approximately coplanar with a mean plane P defined by metal and three N donors (two from the pmda ligand and the other from the auxiliary diamine ligand). In contrast, the R ring is roughly perpendicular to the G ring and to the mean plane P of the Cu and three N atoms.

3.2. Properties of compound 2

3.2.1. Thermal stability

The TG-DTA diagram of compound **2** showed that the studied compound loses all non-bonded to the metal water molecules in air-dry flow before starting the pyrolytic decomposition (190 °C) of the anhydrous complex (5.469 mg, 10 °C min^{-1}) in two overlapped processes. The infrared spectra of evolved gasses in the first step (190–235 °C) showed a significant production of CO_2, H_2O and N_2O. The lost weight corresponds approximately to the pyrolysis of the pmda–IDA moiety (calc. 27.045%, exp. 28.572%). The second step (235–405 °C) shows the decomposition of remaining organic fragments (with production of CO_2, CO, H_2O and N_2O) to yield CuO (exp. 17.584%, calc. residue 16.539%).

3.2.2. Electronic and ESR spectra

The electronic spectrum of **2** shows a d–d band with $\nu_{max} = 13\,320$ cm^{-1} with shoulder at 9000 cm^{-1} and intensity baricenter near 12 500 cm^{-1}. These values are in accordance with a distorted octahedral chromophore CuN_2O_2+N+O (type 4+1+1) [45]. A polycrystalline sample of this compound gives an axial ESR spectrum that is 'reverse' in type ($g_{//} = 2.06 < g_{\perp} = 2.19$) with the lowest g value significantly above 2.00. This behaviour is referred as an antiferrodistortive ordering [45] with total misalignment of the CuN_2O_2+O+N cromophores in the crystal lattice, and is consistent unambiguously with a d_{x2-y2} ground state for the copper(II) atom.

3.2.3. Magnetic susceptibility

A plot of χ data versus T(K) ($T = 79$–290 K) is linear ($1/\chi = (1/C)T - (\theta/C)$ with a statistical r^2 factor of 0.9987) according to a Curie–Weiss behaviour, $\chi = C/(T-\theta)$ [39,45]. The Curie constant is $C = 0.437$ K emu mol^{-1} with Weiss constant of $\theta = 5.45$. The estimated value of μ_{eff} for Cu(II) atom is 1.87 BM. The ESR spectrum and the magnetic susceptibility data are in accordance with the structure reported here and a $Cu\cdots Cu^{ii}$ separation of 7.165(1) Å (symmetry code: ii = $-x$, $1-y$, $-z$).

4. Concluding remarks

From the molecular recognition point of view, it is interesting to note the way in which an inter-molecular hydrogen bond and the pyridyl–pyridyl π,π-stacking interaction co-operate to build the 2D molecular framework of zwitterions in the crystal of H_2pmda·0.5H_2O. The pyridyl–pyridyl inter-planar stacking distance in the free acid (3.57(1) Å) is larger than in compounds $\{[Cu(pmda)]\cdot 2H_2O\}_n$ (3.19(1) Å) [18b] and [2-(aminomethyl)-pyridine]silver(I) nitrate (3.21(1) Å [22]). It is noteworthy that compounds **1** and **2** do not involve the pmda pyridyl ring in aromatic π,π-stacking forces, whereas compound **2** displays such inter-ligand interactions between adjacent Hpb heterocycles to recognize itself forming pairs of complex units. The most important structural consequence of the insertion of a *N*-(α-pycolyl) arm in the IDA skeleton is an efficient increase of denticity from three (IDA) to four (pmda). In addition, the studied Cu(II) complexes reveal a remarkable conformational flexibility of the tripodal tetradentate pmda ligand. As for the coordination

preference for the *trans*-position to the Cu–N(aliphatic) bond, these structures enable to propose the following donor order N(imidazolyl) > N(pyridyl) > N(aliphatic).

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 129246 for H_2pmda·0.5H_2O, CCDC No. 172576 for [Cu(pmda)(pca)]·3H_2O (compound **1**) and CCDC No. 172577 for [Cu(pmda)(Hpb)]·5H_2O (compound **2**). Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or www:http://www.ccdc.cam.ac.uk).

to better explain thermodynamic data in terms of microscopic interactions and to understand the role of intra- and/or intermolecular hydrogen bonding on the structure, we have synthesized and studied the aqueous solutions of some potassium salts of 3-((alkylcarbonyl)amino)-4-hydroxybenzoic acid ($KAHB_n$) and 4-((alkylcarbonyl)amino)- benzoic acid ($KPAB_n$) [4]. The present work is devoted to the study of potassium salts of *p*-*n*-hexylbenzoic acid (HBA), *p*-*n*-heptylbenzoic acid (HEBA), *p*-*n*-octylbenzoic acid (OBA) and it is aimed to understand the role played by the amido group bridging the benzoic moiety and the alkyl chain.

2. Experimental

2.1. Materials

p-*n*-Hexylbenzoic acid (HBA), *p*-*n*-heptylbenzoic acid (HEBA), *p*-*n*-octylbenzoic acid (OBA), were prepared at Department of Chemistry of Kyushu University, as already described [2]. The purity of the reagents was checked by elemental analysis and gas chromatography. Inorganic chemicals of analytical reagent grade were used without further purification. Freshly boiled doubly distilled water, stored under nitrogen, was used throughout. Potassium hydroxide solutions (ca. 2 and 0.2 mol l^{-1}) were prepared by diluting the content of Merck Titrisol ampoules with the proper quantity of water and standardized with potassium hydrogen phthalate (C. Erba; dried at 120 °C).

The surfactant solutions were prepared under nitrogen adding to the acid the quantity of KOH needed both to neutralize the carboxylate group and to reach the required excess of hydroxide ion in the final solution (KOH 0.1 m excess). Solution concentrations are expressed as molality, m (mol kg^{-1}).

2.2. Measurements

The enthalpies of dilution were measured by means of the Thermometric TAM (flow mixing cell) microcalorimeter, equipped with 221 Nano Amplifier, at 298 K. The freshly prepared surfactant solutions, kept before injection at the experimental temperature by means of a Heto cryothermostatic bath, were diluted into the 'mixing' measuring cell of the microcalorimeter in ratio 1:1 by using CO_2-free water. The injection of the solutions and of water into the calorimeter was done by means of a Gilson peristaltic pump, Minipuls 2, and their flows were determined by weight.

Densities of the solutions were measured by a vibrating tube densimeter (PAAR DMA602) controlled by an IBM personal computer, calibrated with water and air. The temperature was kept constant at ± 0.002 °C by a Heto proportional temperature controller.

3. Results

The experimental data have been expressed in terms of apparent and partial molar quantities of the solute, as is usual in solution thermodynamics, assuming the infinite dilution as reference state.

With reference to this state, we recall [1,5–10] that, the molar enthalpy of dilution, ΔH_d, is given by:

$$\Delta H_d = \Phi_{L,f} - \Phi_{L,i} \quad (1)$$

where Φ_L is the apparent molar relative enthalpy and the indexes f and i stand for the final and initial concentrations, respectively.

For ionic surfactant in the premicellar region:

$$\Phi_L = A_L m^{1/2} + B_L m + C_L m^{3/2} \quad (2)$$

where A_L is the limiting Debye–Huckel slope for relative enthalpies, accounting for the long range electrostatic solute–solute interactions. Parameters B_L and C_L are averaged on the experimental points in the premicellar region.

In the micellar region, the apparent molar enthalpies are evaluated by means of equation 1 and by graphical interpolation.

The partial molar enthalpies L_2 are determined by drawing the best curve for the apparent molar enthalpies versus m and then by calculating the partial molar quantities as $\Delta(m\Phi_L)/\Delta m$ from points interpolated at regular intervals.

The heats of dilution and apparent and partial molar enthalpies at 298 K, obtained by means of Eq. (1)–(2), for the compounds under study are listed in Tables 1–3. In Figs. 1 and 2, the plots of the apparent and partial molar enthalpies, respectively, as a function of molality for the different chain length are shown.

The apparent molar volumes, V_Φ of surfactants were calculated by means of the following equation:

$$V_\Phi = \frac{M}{d} - \frac{10^3(d - d_o)}{m d d_o} \quad (3)$$

where d is the density of the solution of molality m, M is the molecular weight of the surfactants and d_o is the density of the KOH 0.1 m solution.

4. Discussion

In the literature, dissolution and micellization of HBA and OBA in aqueous solution were examined by the phase rule in relation to the solution pH [2]. The experimental data were interpreted under the light of

the mass action model to obtain the micellization constant K_n, the micelle aggregation number n, and the number of counterion bound per micelle, m. In presence of undissolved acid as a separate phase, the pH plays a role similar to that of temperature, because the concentration of the dissociated anion showing surface active properties increases linearly with $1/a_{H^+}$ till to a range of values (micellar pH range) at which micellization starts. This pH range, as the cmc, is typical of the insoluble acid under study. This paper deals with the potassium salts of the above mentioned acids and of HEBA, in KOH 0.1 m excess, i.e. when the concentration of the undissociated acid is negligible and hydrolysis is avoided. In the same conditions we studied, as mentioned before, the enthalpic properties of the potassium salts of PAS_n, PAB_n, and AIB_n solutions [1,4]. The comparison of the behavior of the above mentioned compounds in the same conditions could give

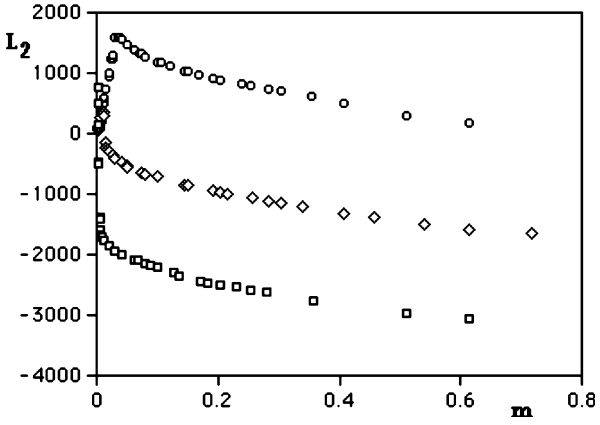

Fig. 2. Partial molar relative enthalpies (L_2, J mol^{-1}) of potassium salts of *p*-*n*-hexylbenzoic acid (KHB, empty squares), *p*-*n*-heptylbenzoic acid (KHEB, empty rhombs), *p*-*n*-octylbenzoic acid (KOB, empty circles) in KOH 0.1 m as a function of surfactant molality, *m*.

us information about the role played by the different fragments of the molecule in the micellization process. In Fig. 1 and in Tables 1–3, the curves of the apparent molar enthalpies versus *m* at 298 K are reported for different chain lengths. The general trends concord with the expectations for ionic surfactants: the curves, after increasing in the premicellar region, tend to level off at concentrations above the cmc, where they are almost parallel. The lowering of the curves in the micellar region is proportional to the number of carbon atoms in the alkyl chain. It is possible to extract the group contribution of the $-CH_2-$ group in the postmicellar region: it results -1.6 kJ mol^{-1} per $-CH_2-$. This value is comparable with that obtained in the case of cationic surfactants [6]. This group contribution proves to apply specifically to the methylene group and to be independent of the charge in the polar head, too.

It is very interesting to evaluate the effect of the amido group, bound in para position in respect to the carboxylic moiety, by the comparison of the trends of the compounds under study with those of potassium 4-((alkylcarbonyl)amino)- benzoate ($KPAB_n$) [4]. In Fig. 3, as an example, the comparison between the apparent molar enthalpies versus *m* of the terms having seven carbon atoms in the alkyl chain is reported. The effect of the substitution of a methylene group by an amido group results in a strong increase in hydrophilicity for the $KPAB_n$: the effect is comparable with that brought about by a removal of a methylene group in the alkyl chain. The group contribution results $+1.7$ kJ mol^{-1}. The electron withdrawing amido group behaves as a part of the polar head. Some of us have shown for a series of dodecyl cationic surfactants with the same counterion that, from the trends of the apparent and

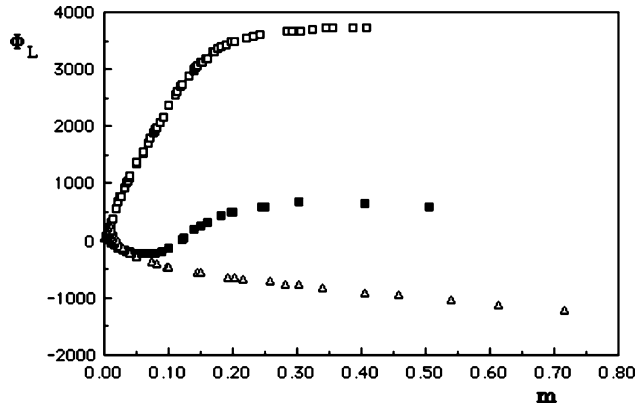

Fig. 3. Comparison between apparent molar enthapies (Φ_L, J mol^{-1}) as a function of molality, m of potassium salts of *p*-*n*-heptylbenzoic acid (KHEB, empty triangles), 4-((hexylcarbonyl)amino-benzoic acid ($KPAB_7$, full squares) [4] and 4-((hexylcarbonyl)amino-2-hydroxybenzoic acid ($KPAS\text{-}C_7$, empty squares) in KOH 0.1 m [1].

partial molar enthalpies, a sort of 'charge delocalization scale' for the polar head could be obtained. The more delocalized is the charge, the more similar is the behavior to that of non-ionic surfactants [10]. The same observation seems to hold also for the anionic surfactants, as shown in Fig. 3.

In the case of cationic surfactants, we have studied the effect of an amido group in meta position by comparing *N*-alkylpyridinium (C_nPC) and *N*-alkylnicotinamide chlorides (C_nNAC). It has been shown that when the amido group is bound in three position to the pyridinic ring, it acts in the opposite way, strongly enhancing the hydrophobicity of the C_nNAC surfactants [10].

4.1. Changes in thermodynamic properties upon micelle formation

In order to obtain the changes in thermodynamic properties upon micellization, we have applied a pseudo-phase transition model, in which the aggregation process is considered like a phase transition, taking place at equilibrium. In this model, it is assumed that, at the cmc, the partial molar properties present a discontinuity due to the formation of a pseudo-phase. The micellization parameters are obtained by extrapolating at the cmc the trends of partial molar properties before and after cmc [1,5–10]. Rather sharp changes occur around the cmc, but they are never discontinuous, especially for surfactants with short hydrophobic chains. In order to evaluate the micellization enthalpy change, ΔH_m of the compounds under investigation, we have to know the values of the cmc. Previous studies on solubility and micelle formation of *p*-*n*-alkylbenzoic acids have shown that the cmc values at the critical micelle pH were 4.80×10^{-2} at 298 K for NaHBA and 1.30×10^{-2} for NaOBA at 308 K [2]. The experimental conditions of this work are very different both as pH value at which only the basic dissociated form is present and as counterion (K^+ instead of Na^+). So it is reasonable to expect that also the cmc values are different. We have evaluated the cmc by a thermodynamic method, assuming as cmc the abscissa of the first inflection point of the curves of Φ_L versus m. The values so obtained for the cmc and the micellization enthalpies of the compounds under investigation are reported in Table 4.

The logarithms of the cmc are nicely linearly correlated (see Fig. 4) with the number of carbon atoms, the slope of the straight line so obtained being proportional to the free energy of transfer of each $-CH_2-$ from the aqueous phase to the micellized state. It results $-1.27kT$ per$-CH_2-$. This value appears to be a slightly greater quantity (in terms of absolute value) than that reported in ref [11]. The difference could be explained in terms of higher ionic strength, reducing the electrostatic repulsion between the polar head groups. The reported micellization enthalpies for the studied compounds are linearly correlated with the number of carbon atoms in the alkyl chain. It is, therefore, possible to extract a group contribution for the methylene group: thus we have -1.5 kJ mol^{-1} per group, which is comparable with that obtained in the case of potassium 3-((alkyl-

Table 4
Critical micelle concentration (cmc), enthalpy changes for the micellization process (ΔH_m) and partial molar volume in micellar phase (V_s) for the surfactants studied

	KOB	KHEB	KHB
Cmc (mol kg^{-1})	0.0016	0.0069	0.020
L_{2m} (kJ mol^{-1})	+0.714	+0.390	+0.980
L_{2s} (kJ mol^{-1})	−1.429	−0.181	+1.847
ΔH_m (kJ mol−1)	−2.143	−0.571	+0.857
V_s (cm^3 mol^{-1})	201	184	167

Indices m and s stand for the value of the quantity for the monomer and for the micelle, respectively.

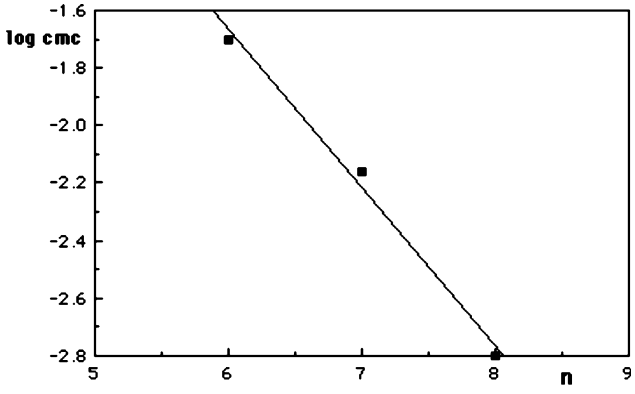

Fig. 4. Log cmc, obtained as the abscissa of the first inflection point of the curves of Φ_L vs. m, as a function of the number of carbon atoms, n in the alkyl chain for the compounds under investigation in the experimental conditions.

carbonyl)amino)-4-hydroxybenzoates (–1.4 kJ mol^{-1} per group) and 4-((alkylcarbonyl)amino)-benzoates (–1.33 kJ mol^{-1} per group) [4], but greater than the average group contribution obtained in the case of cationic surfactants (−1.1 kJ mol^{-1} per group) [6].

In Table 4 partial molar volumes of the surfactants under study in micellar phase are also reported. It is easy to see that the values differs by 17 cm^3 mol^{-1} per $-CH_2-$. The $-CH_2-$ group contribution obtained in micellar region is the same as that obtained for pyridine and nicotinamide type cationic surfactants [6].

5. Conclusions

The study of thermodynamic properties of the aqueous solutions of potassium salts of KHB, KHEB, KOB in KOH 0.1 m has shown that also in the case of anionic surfactants derived from benzoic acid, the group contribution of the $-CH_2-$ is additive both in the plateau (−1.6 kJ mol^{-1} per $-CH_2-$) and in the micellization enthalpy changes (−1.5 kJ mol^{-1} per group). The values are comparable with those obtained in the case of cationic surfactants and for similar anionic compounds in the same experimental conditions. The behavior of the compounds under study was compared with that of the potassium salts of 4-((alkylcarbonyl)amino)-benzoic acids, in order to understand the role played by the amido group bridging the benzoic moiety and the alkyl chain. Thus, we see that the amido group behaves as a part of the polar head, strongly increasing the hydrophilicity of the molecule.

or base, etc.) and substrate (proton or metal or ligand) as the functions of affinity constants, k_j and cooperativity coefficients, b_j, respectively, specific for each class of sites.

The probability of state of a solution referred to one mole of reacting receptor is given by:

$$Z_A = \exp(-\Delta G/RT) \quad (1)$$

The joined probability of the state of a solution of a receptor A with t binding sites for ligand H in one class is represented by the product of t factors, each representing the probability of single binding:

$$Z_A = \exp(-\Delta G/RT) = (1 + k\gamma(i)[H])^t \quad (2)$$

where k is the site constant and $\gamma(i)$ is the cooperativity function:

$$\gamma(i) = \exp\{b(i-1)\} \quad (3)$$

When we refer to one class, we can drop the index j. The Newton binomial of the RHS of Eq. (2) produces a polynomial with $t+1$ terms:

$$Z_A = \sum_{i=0}^{t} m_i(k\gamma_i[H])^i \quad (4)$$

where $m_i = t!/\{(t-i)!i!\}$is the multiplicity factor (an entropic factor) that indicates the number of possible microspecies and γ_i is the cooperativity factor that is the value of the cooperativity function at the protonation step i. The microspecies are isomeric complexes AH_i with ligand H occupying equivalent binding sites [19,20].

When two classes, p and q are present with $t(p)$ and $t(q)$ binding sites for the same ligand, respectively, the joined probability of the state of the solution is a product of polynomials:

$$Z_A = (1 + k_p\gamma_p[H])^{t(p)}(1 + k_q\gamma_q[H])^{t(q)} \quad (5)$$

The self-association of receptor units A_1, A_2, $A_{i+1}\ldots A_t$ can be considered a complexation between the first A as the receptor with $(t-1)$ sites and the successive A as the ligands.

For one class of sites without self-association, the probability of the state is given by the polynomial of Eq. (4) that can be rewritten in the form of a summation of cumulative constant terms multiplied by powers of concentrations:

$$Z_A = \sum_{i=0}^{t} \beta_i[H]^i \quad (6)$$

By comparison with Eq. (4), we obtain the cumulative constant β_i as:

$$\beta_i = m_i(k\gamma_i)^i \quad (7)$$

The determination, therefore, of the site affinity constant k for a class is connected to the determination of the cumulative binding constants β_i. For example, the cumulative formation constant of the complex HA in a class with three sites is $\beta_1 = 3\gamma_1 k$, where three is the multiplicity factor, m_1 and $\gamma_1 = 1$ is the cooperativity factor. The formation constant of the complex AH_2 in the same class with three sites is $\beta_2 = 3\gamma_2 k^2$, where three is the multiplicity factor m_2 and $\gamma_2 = \exp b$ is the cooperativity factor. The formation constant of the complex AH_3 in the same class with three sites is $\beta_3 = \gamma_3 k^3$, where one is the multiplicity factor m_3 and $\gamma_3 = \exp 2b$ is the cooperativity factor.

There is one partition function for each component of the system. If the complexes are of type $H_P A_R$ there are two partition functions, namely Z_H and Z_A.

The relationships between partition functions and total analytical concentrations $[T_H]$ and $[T_A]$, respectively, are given by:

$$[T_A] = [A]\{Z_A\} + [A]\{\partial Z_A/\partial[A]\} \quad (8)$$

$$[T_H] = [H]\{Z_H\} + [H]\{\partial Z_H/\partial[H]\} \quad (9)$$

These equations show how one can calculate the analytical quantities T_H and T_A from the partition functions and hence from the cumulative constants. On the other hand, being the cumulative constant function of the site constant k and of cooperativity coefficient b through Eq. (6), then the analytical quantities T_H and T_A can be calculated as functions of these variables (k and b) too.

If the binding of a ligand to the receptor is not affected by the presence of other ligands already bound, the cooperativity factors are all equal to unity ($b = 0$), the cumulative constants are functions of the site affinity k and of the statistical factor m_i only. The latter is a calculated quantity (cf. Eq. (4)) and not a variable. When the cooperativity takes place, the affinity of the ligand for the receptor site can be enhanced (positive cooperativity) or depressed (negative cooperativity) by previous occupation of sites. The cooperativity effect can be accounted for by introducing a cooperativity function $\gamma_j(i)$ for each class j.

By taking the logarithms of Eq. (7), one can calculate [21] a mean affinity constant devoid of statistical factor:

$$\ln K_{\gamma(i)} = (1/i)(\ln \beta_i - \ln m_i) = \ln k - \ln \gamma_i = \ln k - (i-1)b \quad (10)$$

By plotting $\ln K_{\gamma(i)}$ against $(i-1)$, a straight line is obtained with slope b. The validity of the cooperativity function thus obtained can be checked by means of the Scatchard function:

$$\langle n\rangle/[A] = \{\sum_i im_i\{k_{\gamma_i}\}^i[H]^{i-1}\}/\{\sum_i m_i\{k_{\gamma i}[H]\}^i\} = \{\sum_i i\beta_i[H]^{i-1}\}/\{\sum_i \beta_i[H]^i\} \quad (11)$$

The Scatchard diagram with cooperativity is characterised by a concavity upward if the cooperativity is

negative ($\gamma < 1$), or downward if the cooperativity is positive ($\gamma > 1$). The diagram, is a straight line when there is no cooperativity effect ($\gamma = 1$). The Scatchard function can be corrected for cooperativity, obtaining the corrected Scatchard function $\langle n_{corr}\rangle/[A]$

$$\langle n_{corr}\rangle/[A] = \{\sum_i im_i\{k\}^i[H]^{i-1}\}/\{\sum_i m_i\{k[H]\}^i\} = \{\sum_i i\beta_{i,corr}[H]^{i-1}\}/\{\sum_i \beta_{i,corr}[H]^i\} \quad (12)$$

This function is calculated by introducing the constants $\beta_{i,corr}$:

$$\beta_{i,corr} = \beta_i/(\gamma_i)^i \quad (13)$$

corrected for cooperativity effect, by dividing each β_i by the corresponding i-th power of cooperativity factor. If the correction is valid, then the curved plot should be transformed into a straight line.

The existence of the cooperativity function makes the cumulative constants β_i dependent from one another through the affinity constant k_j and cooperativity coefficient b_j. The use, therefore, of the cumulative constants β_i as independent variables in a refinement process by least-squares procedures should be avoided because it is biased. A new algorithm has been proposed [22,23] whereby the independent variables to be refined are class site constants k_j and class cooperativity coefficients b_j. The algorithm has been obtained by introducing the appropriate types of expressions of Eqs. (5) and (3) for Z_H and Z_A into the Eqs. (8) and (9), respectively. It is thus possible to calculate explicitly the derivatives $\partial[T_H]/\partial k_j$, $\partial[T_H]/\partial(\exp b_j)$, $\partial[T_A]/\partial k_j$, $\partial[T_H]/\partial(\exp b_j)$ of the functions T_H and T_A, with respect to the variables to be refined. A set of normal equations for least-squares calculations can be set up where the unknown are the increments to the variables that minimise the difference between observed and calculated values of both T_H and T_A. The program SITECON calculates these increments and has been tested for several systems [23,24]. In this work, this program has been applied to the potentiometric data for the protonation of polyamines. The compounds to be studied have been chosen on the basis of the increasing number of classes and sites in each class.

3. Experimental

The experimental data have been obtained by potentiometric titrations of aqueous solutions of aliphatic polyamines at $T = 298$ K and ionic medium $I = 0.1$ KCl.

3.1. Materials

Ethylenediamine dihydrochloride (Aldrich 98%), 1,3-diaminepropane dihydrochloride (Aldrich 98%, melting point (m.p.) 246°–250°), 1,4-diaminebutane dihydrochloride (Aldrich 97%, m.p. 280°), 1,5-diaminopentane dihydrochloride (Aldrich 99%, m.p. 260°–262°), 1,4-diaminebutanone dihydrochloride (Aldrich 99% m.p. 221°), 1,3-diamine-2-hydroxypropane (Aldrich 95%), diethylenetriamine (Acros 98%, m.p. 90°), triethylenetetramine tetrachloride (Aldrich 97%, m.p. 269°–270°), *N*-(2-hydroxyethyl)ethylenediaminetriacetic acid (Acros 99%), Ethylenediaminetetracetic acid (Aldrich 98.5%). All the compounds have been recrystallized from water. Bidistilled water was used as solvent, deairated by N_2 stream.

3.2. Measurements

Sensor Electrode: Glass electrode (CRISON 52–50). Reference Electrode: Calomel electrode (RADIOMETER REF 401) with 0.1 KCl bridge, ionic medium: KCl 0.1 M. The titrations have been performed by an automatic potentiometric apparatus. The concentration of titrant KOH has been determined by titration of a weighed amount of potassium hydrogen phthalate. The standard potential of the electrometric chain E_0 and pK_w have been determined every day by titration with KOH solution of a fixed volume of hydrochloric acid of known concentration. The neutralisation point was determined by a computer program based on Gran's method [25]. The concentration of polyamine solutions to be titrated has been obtained by weight. The temperature has been maintained constant at 298 K by thermostatting the circulating water by a ISCO CRIOTERM 190 (precision ± 0.1). The volume of the liquid in the cell has been measured at 25 °C (usually 50 ml).

3.3. Calculations

The titration data (emf and volume), the total analytical concentrations $[T_A]$ and $[T_H]$ the guessed value of site constants k_j and cooperativity factors b_j are the input data of the program SITECON. The program refines the values of k_j and $\exp b_j$, by successive iterations. SITECON can be operated on a personal computer in DOS.

4. Results and discussion

The program SITECON was employed to calculate the affinity site constants and the cooperativity parameters in the set of titrations of polyamines (Table 1). In order to identify the classes of sites, the sets of cumulative protonation constants β_i were obtained by means of

SUPERQUAD algorithm [26]. By using the β_i so obtained, it has been possible to calculate and plot the Scatchard function $\langle n\rangle$/[H] as the function of $\langle n\rangle$. An example is given in Fig. 1 for the compound DIEN. The diagram shows that there are two classes of sites, without cooperativity as shown by the two straight lines. The Scatchard plot of the compound TRIEN shows how this compound presents two classes of sites with two sites each. In the first class, the most basic sites, there is no cooperativity, whereas in the second class there is high cooperativity. After having refined the site constants, the values of the cumulative equilibrium constants were calculated with the values of the constants, k_j and of the cooperativity coefficients, b_j. These cumulative constants were compared with the values of the cumulative constants obtained by direct refinement by the program SUPERQUAD (Table 2).

The values of the site constants, k_j and of the cooperativity coefficients, b_j obtained in the refinement are reported in Table 3 and compared with the values of the site constants and cooperativity coefficients obtained graphically by applying Eq. (10). The values of b_j were then used to calculate the corrected cumulative constants $\beta_{i,\mathrm{corr}}$, according to Eq. (13) and then the corrected Scatchard plot (Table 4). The curve is transformed into a straight line. An example is given for the compound EN in Fig. 2.

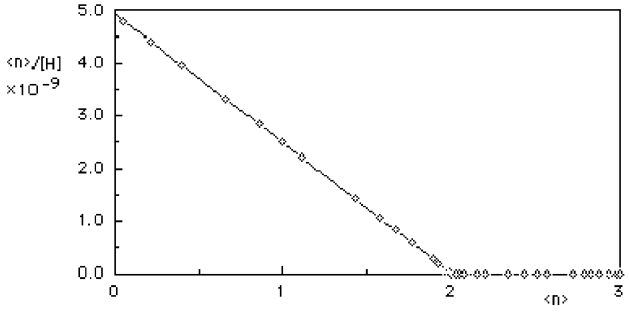

Fig. 1. Scatchard plot for DIEN: two classes and no cooperativity.

The values of b are on the same scale of the natural logarithm of equilibrium constant. Therefore b can be transformed into cooperativity potential, $\Delta\mu_\gamma$ in kJ mol^{-1} scale according to

$$\Delta\mu_\gamma = -bRT \tag{14}$$

We can examine the changes of $\Delta\mu_\gamma$ at $T = 298$ K for the protonation of the amine group $-NH_2$ in the amines of Table 1. By considering the series, $_2HN-(CH_2)_n-NH_2$ with $n = 2$, 3, 4, 5, we observe that these compounds show a mild exponential decrease of the cooperativity effect with the increase of the molecular length (Fig. 3). ($\ln(\Delta\mu_\gamma) = -0.7194n_C + 4.1799$, with $r^2 = 0.9819$). This conforms to the idea that the reciprocal influence of the two sites is smaller the greater is the distance between them. On the contrary, the site affinity constant is scarsely affected by the chain length.

The cooperativity effect can be compared in other analogous or partially analogous molecules. The difference between the site constants in DAB (1,4-diaminebutanone) can be compared with cooperativity in EN (ethylenediamine): the two compounds show a remarkable difference of cooperativity but this could be due to intrinsically different site affinities of the two nitrogens in DAB which are not structurally equivalent. The comparison of PD (1,3-diaminepropane) and DAHP (1,3-diaminehydroxypropane) shows a similar behaviour for the two compounds. On the other hand, we can consider the polyamines DIEN (diethylenetriamine) and TRIEN (triethylenetetramine); the external $-NH_2$ groups do not show any cooperativity. The two

[a] Carboxylic groups.

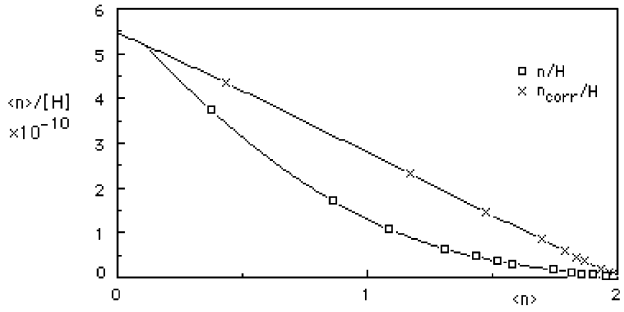

Fig. 2. Scatchard plots for EN: the corrections for cooperativity effect transform the curve into a straight line.

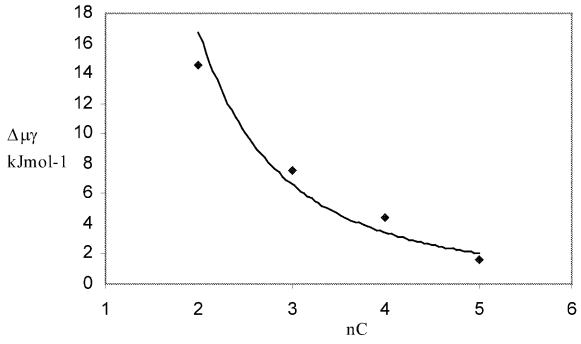

Fig. 3. Cooperativity potential, $\Delta\mu_\gamma$ ($T = 298$ K) in diamines as the function of the chain length.

compounds are structurally similar in the sense that, in both, aliphatic chains containing alternating $-CH_2-CH_2-$ and weakly basic $-NH-$ groups, separate the external $-NH_2$ sites. The two compounds do not show any cooperativity between the external $-NH_2$ groups. It seems that a screen interrupts the electrostatic interaction between the sites. The interaction between the adjacent $-NH-$ groups in TRIEN is highly negatively cooperative. Finally the comparison of HEDTA (*N*(hydroxyethyl)ethylenediaminetriacetic acid) and EDTA (ethylenediaminetetracetic acid) provides evidence for a substantially homogeneous behaviour of the cooperativity between the basic sites, although much higher than that of ethylenediamine. This cooperativity enhancement is due to the influence of the carboxylic substituents.

The values of the site affinity constants are specific for nitrogen sites and can be compared with those of corresponding monoamines [27] as shown in Table 5. The comparison between amine of correspondent chain length shows how the substitution of $-NH_2$ for $-CH_3$ produces a weakening effect, which is lower, the longer the distance from the basic site ($\Delta\log k$ $-RNH_2$). The weakening effect of the charged groups $R-NH_3^+$ can be calculated directly from the cooperativity coefficients divided by 2.303 ($\Delta\log k$ $-RNH_3^+$). The division brings the cooperativity coefficients to the scale of σ_x Hammett constants [28].

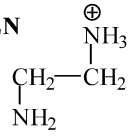
The weakening effect of one protonated site over the neighbouring sites can be evaluated by means of the cooperativity coefficient b or from the site constants of the different classes. For instance, in EN with primary amine group, the site constant is $\log k = 9.634$ and the cooperativity coefficient $b = -2.557$. The affinity constant after cooperativity becomes $\log k = 8.702$. It is then possible to evaluate the Taft [29] constant of the protonated or unprotonated substituent by assuming an equation set up by Barlin and Perrin [30]

$$\log k = 11.59 - 1.89 \sum \sigma_R^* \tag{15}$$

The values thus obtained are reported in Table 6, together with substituent constants for secondary and tertiary amines. For secondary and tertiary amines, the Eq. (15) becomes:

$$\log k = 11.59 - 1.89 \sum \sigma_R^* \tag{16}$$

where the additivity rules have been assumed to hold. The calculation of the protonation constant at secondary nitrogen in the symmetric compound DIEN gives a Taft constant $\Sigma\,\sigma^* = 2\sigma_R^*$ from which a value σ_R^* for the single substitutent $(R'H^+) = (H_3N^+-(CH_2-)_2)$ can be obtained. Then this value can be used to calculate, by subtraction from $\Sigma\,\sigma^*$, the contribution of the longer moiety in the asymmetric compound TRIEN.



Where tertiary amine groups appear as in EDTA, an average $\sigma^*_{\langle R\rangle} = (1/3)\Sigma\,\sigma_R^*$ can be obtained.

5. Conclusions

The computer program SITECON was applied to the protonation equilibria of polyamines; it is based on a function of affinity constant, k_i and cooperativity coefficient, b_i specific for each class of sites. Thus, the evaluation of the cooperativity potential $\Delta\mu_\gamma = -RTb_i$ can be made. The cooperativity potential between two basic sites depends on the length of the molecule i.e. on the distance between sites and can be attributed to electrostatic interactions. Binding of a proton to one site yields a weaker electrostatic attraction by the second site for the next proton. Introduction of basic $-NH_2-$ groups in the chains between the sites exerts a screening effect removing the cooperative effect. The addition to the basic sites of EDTA and HEDTA of carboxylic groups enhances the cooperativity effect. The cooperativity coefficient divided by 2.303 brings the cooperativity effect to the scale of the base weakening effects as expressed by the Hammett equation and Taft equation. It is then possible to calculate Taft substituent constants σ^* for substitution in primary, secondary and tertiary amines.

Scheme 1.

complexes formed strongly depends on metal cation, ligand–metal ratios, and pH of the solution [13].

Carnosine forms complexes with metals of the first transition metal series [13]. Thus, with Zn^{II}, complexes in the ratio metal–ligand 1:1 such as $[ZnLH]^{2+}$ and $[ZnL]^{+}$ which show [14,15] interesting pharmacological activity, are formed [16]. With Cu^{II}, complexes of the type $[CuLH]^{2+}$, $[CuL]^{+}$, $[CuLH_{-1}]^{0}$, $[Cu_2L_2H_{-2}]^{0}$ [13,17,18] and $[CuL_2]$ [19] are found. It has also been shown that the Cu^{II}-carnosine complex possesses a SOD-like activity [20]. For Co^{II}, complexes $[CoLH]^{2+}$, $[CoL]^{+}$ and $[CoLH_{-1}]^{0}$ are found [14,21]. The structure of the Co^{III} mixed ligand complex $[Co(Hcar)(en)(H_2O)]Cl_2 \cdot H_2O$, (Hcar = carnosine, en = etilenediamine) shows that carnosine is coordinated through the deprotonated peptide nitrogen, one carboxylic oxygen and the N^1 atom of the imidazole ring [22]. Studies with other metals such as Ni^{II} [14], Mn^{II}, Mg^{II}, Ca^{II} and Sr^{II} [23] and Cd^{II} [24] have also been carried out.

The interaction of carnosine with the biologically relevant oxovanadium (IV) [25–29] has been investigated by means of ENDOR techniques in frozen solutions [30] and electron absorption spectroscopy at high ligand–metal ratios, in the pH range 6.0–8.5 [31], suggesting the formation of the complex $[VO(car)_4(H_2O)]^{2+}$ with the coordination of the imidazole group of four different ligand molecules. Spectra, however, obtained in the pH range 2.0–4.0, point out a coordination through oxygen atoms of the carboxylate group [31]. The study of complex species formation in aqueous solution in order to determine the stability constants of the complexes formed has not been carried out so far.

In a recent work [32] we have investigated the oxovanadium(IV)–glutathione system in aqueous solution both potentiometrically and spectrophotometrically. The experimental data were analysed by means of least-square computer program LETAGROP: version NERNST [33,34] (potentiometric data) and version SPEFO [35] (spectrophotometric data). Similarly, in this work we have performed an investigation of the oxovanadium(IV)–carnosine system in aqueous solution in the pH range 2.0–9.0 by means of emf and UV–Vis measurements.

2. Experimental

2.1. Materials

Vanadyl(IV) sulfate trihydrate (99.99+%, Aldrich) and L-Carnosine (99%, Sigma) were used as supplied. The solutions of HCl and KCl were prepared by dissolving the respective acid and salts (Merck, analytical grade) in doubly glass-distilled water that has been boiled in order to remove dissolved CO_2. A carbonate-free hydroxide solution (NaOH) were prepared from an ampoule of Titrisol Merck and standardized against potassium hydrogen phthalate. The emf and spectrophotometric UV–Vis measurements were carried out in aqueous solution at ionic strength 0.15 mol dm^{-3} in KCl. Argon free of O_2 and CO_2 was used.

2.2. Emf measurements

We have used ionic strength 0.15 ($I = 0.15$ mol dm^{-3} KCl ionic medium) that is typical for biological systems. However, due to the low stability of the carnosine complexes with first row transition metals [13,14], the study of complex formation at pH 5–7 is not possible since precipitation of hydrolytic species of oxovanadium(IV) occurs. Therefore, ligand–metal ratios up to 60:1 were employed to repress the hydrolysis and to study the pH range 5–7. This high ligand–metal ratio implies that C_L increases to 0.344 mol dm^{-3} and consequently the ionic strength is not mantained practically constant. Due to this, we have carried out experiments at ionic strength $I = 1.5$ mol dm^{-3} in KCl for the ratio ligand–metal 60:1, to confirm the suitability of the model of complex species present in solution and the order of magnitude of the values of stability constants.

We have proceeded as follows.

At low ligand–metal ratios, $6 \leq R \leq 25$, C_B 0.0084–0.0124 mol dm^{-3} and C_L 0.071–0.214 mol dm^{-3} for vanadium(IV) and carnosine, respectively, the potentiometric study was carried out in the pH range 2.5–5 (acid zone) and 7–9 (basic zone), since precipitation occurs between pH 5 and 7 in the experimental conditions stated above.

For ligand–metal (R) ratios ≥ 60, the precipitation was not observed in the pH range 5–7. Thus, for $R \geq 60$ the study was carried out in the pH range 2.5–9 using concentrations of the vanadium(IV) and carnosine in the range 0.0047–0.0058 and 0.330–0.344 mol dm^{-3}, respectively.

Finally at ionic strength $I = 1.5$ mol dm^{-3} in KCl we have confirmed the model (ligand–metal ratio 60:1) of the species present in solution and the order of magnitude of the values of the stability constants.

The symbols used in the present paper are the same as those adopted in previous works [36–41].

The emf and UV–Vis measurements were done using the following instruments: pH meter Radiometer PHM85, Crisson Microbur 2031 piston buret, titration vessel Crisson, thermostat bath Heto, Shimadzu UV-2101 PC spectrophotometer. The sealed 100 ml thermostated double-walled glass titration vessel was fitted with a Red Rod combined pH electrode Radiometer PHG201-7 and titrant inlet, magnetic stirrer, inert argon atmosphere inlet and outlet tubes. The titrant was delivered through an immersed capillary tip from the piston buret. The temperature was maintained at 25.00(1) °C by regular circulation of water from the thermostat bath.

The measurements have been carried out by means of the cell REF//S/EV, where REF = Hg–Hg_2Cl_2(calomel)–saturated KCl solution; S = equilibrium solution and EV = glass electrode. At 25 °C the emf (mV) of this cell follows Nernst's equation $E = E^\circ + Jh + 59.16 \log h$, where h represents the free hydrogen ion concentration, E° the standard potential and J a constant which takes into account the liquid junction potential [39].

The experiments were carried out as follows [40]: a fixed volume of 0.100 mol dm^{-3} HCl was titrated with succesive additions of 0.100 mol dm^{-3} NaOH until near neutrality, in order to get the parameters E° and J. Then, determined weights of carnosine and $VOSO_4$ were added, in this order. Finally, the titration was continued from pH 2–2.5 to 8.5–9 with NaOH 1.000 mol dm^{-3}.

The ionization constants of carnosine have been determined by means of the LETAGROP program at $I = 0.15$ mol dm^{-3} and $I = 1.5$ mol dm^{-3} in KCl. The pK_i values obtained are listed in Table 1 and compared with other literature data at different ionic strength and temperature [44–48]. Fig. 1 shows the formation function Z (pH) [36–41], where Z represents the average number of H^+ associated per mole of carnosine (HL), according to the reaction $L^- + pH^+ \rightleftarrows H_pL^{(p-1)+}$, β_{pr}. The curve shows the formation of the species HL ($Z = 1$), H_2L^+ ($Z = 2$) and H_3L^{2+} ($Z = 3$).

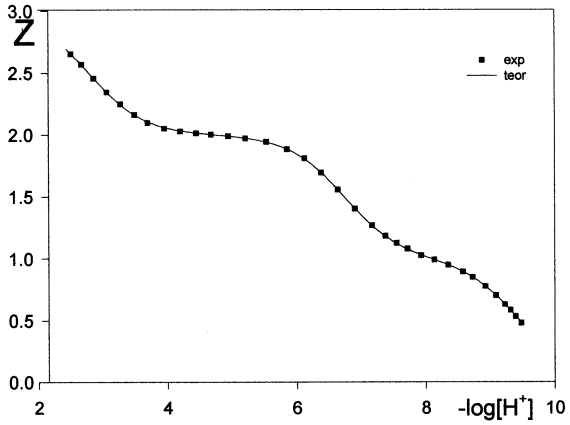

Fig. 1. Z, average number of H^+ associated per mol of the deprotonated carnosine, according the reaction $L^- + pH^+ \rightleftarrows H_pL^{(p-1)+}$, in 0.15 mol dm^{-3} KCl ionic medium at 25 °C. The continuous–draw curve made using the stability constants of Table 1.

We have also carried out theoretical calculations of the pK_i of the carnosine using PALLAS 3.0 program [42]. The method of calculation is based on the consideration that the substituents in the parent compound produce free energy changes that are linearly additive. This assumption led to the Hammet and Taft equations [43], which are the starting points of pK_i predictions (Table 1).

Subsequently, the system VO^{2+}-carnosine was studied according to the reaction

$$pH^+ + qVO^{2+} + r\,L^- \rightleftarrows [H_p(VO)_q(L)_r]^{(2q-r+p)+}, \quad \beta_{pqr}$$

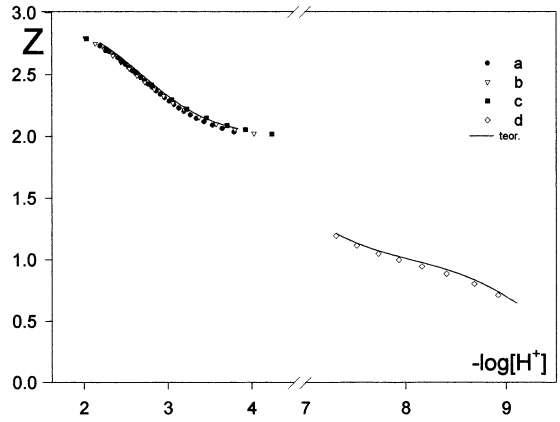

Fig. 2. Z, average number of H^+ associated per mol of deprotonated carnosine L^- vs. pH, according to the reaction $p\,H^+ + q\,VO^{2+} + r\,L^- \rightleftarrows [H_p(VO)_q(L)_r]^{(2q-r+p)+}$, in 0.15 mol dm^{-3} KCl ionic medium at 25 °C and the following B and R ranges: 0.0084 mol dm$^{-3} \leq B \leq$ 0.0124 mol dm^{-3} and $6 \leq R \leq 25$. The continuous-draw curve was made using the stability constants (Table 2, minimising Z_f). (a, b) $R =$ 15/1, $B = 0.01$ mol dm^{-3}, (c, d) $R = 15/1$, $B = 0.0084$ mol dm^{-3}.

As a consequence of the high L–M ratio used, the experimental data are practically situated on the same theoretical curve of the ligand (Fig. 2), similarly to the study of the glutathione–oxovanadium(IV) system [32]. This fact constitutes the main difficulty in the interpretation of this system. The buffer capacity of the ligand prevents detecting the stoichiometry (p, q, r) of the VO^{2+}-carnosine complexes, overlapping it.

The experimental data were analysed by means of both LETAGROP program [33,35] and LETAGROP/FONDO treatment [49,50]. LETAGROP minimizes the function $Z_C = (H-h)/C$ whereas LETAGROP/FONDO minimizes the function $Z_f = ((H-h)-\Sigma p c_{p01})/(L-\Sigma c_{p01})$, (reference L^-) where c_{p01} represents the equilibrium concentrations of the ligand species, in order to eliminate the excess of ligand.

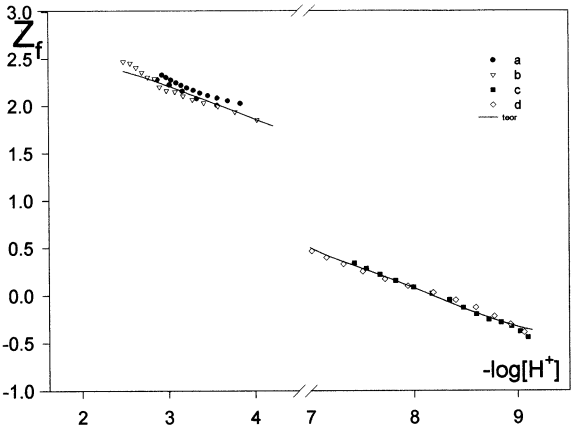

Fig. 3. Z_f $(= (BZ-\Sigma p c_{p01})/(L-\Sigma c_{p01}))$ average number of H^+ associated per mol of deprotonated carnosine L^- as VO^{2+}–carnosine complexes vs. pH, according the reaction $p\,H^+ + q\,VO^{2+} + r\,L^- \rightleftarrows [H_p(VO)_q(L)_r]^{(2q-r+p)+}$, in 0.15 mol dm^{-3} KCl ionic medium at 25 °C. The continuous–draw curve was made using the stability constants (Table 2, minimizing Z_f). (a) $R = 6/1$, $B = 0.0123$ mol dm^{-3}, (b, c) $R = 10/1$, $B = 0.0113$ mol dm^{-3}, (d) $R = 6/1$, $B = 0.012$ mol dm^{-3}.

In both treatments, the model best fitting the experimental data, for ligand–metal ratio $6 \leq R \leq 25$, was that formed by species 512, 412 and 312 for the acid zone (Table 2, $2.5 \leq$ pH ≤ 5), and for species 112, 012 and-112 for the basic zone (Table 2, $7 \leq$ pH ≤ 9). In Fig. 3, we can observe: the formation in acid zone of species 512, ($Z \approx 2.5$, pH ≈ 2.5); 412 with H_2L^+ ligand, ($Z_f \approx 2$, pH ≈ 3.5); and species 312, ($Z_f \approx 1.5$, pH ≈ 4.5). The species 112, ($Z_f \approx 0.5$, pH ≈ 7.3) with HL and L^- as ligands, species 012 with L^- ligand, ($Z_f \approx 0$, pH ≈ 8.3); and -112, with L^- and L^{2-} ligands, ($Z_f \approx -0.5$, pH $\approx$ 9), in basic zone. Complexes with $Z_f \approx 1$ were not observed due to the precipitation of the oxovanadium(IV) hydroxide.

The precipitation of oxovanadium(IV) hydroxide in the pH range 5–7 makes impossible the determination of the stability constant for the species 212. At the ligand–metal ratios $R \geq 60$ the precipitation of the hydroxide was not observed. Therefore, we carried out the titrations in the ratio L–M 60:1. The analyses of the experimental data by LETAGROP allowed us to determine the value of the formation constant corresponding to the complex 212 (Table 2). Although with such an excess of ligand, the values obtained are not so precise, they are in the same order of magnitude as the values obtained for log β_{pqr} at smaller L–M ratios (≤ 25).

In the calculations the hydrolytic species of VO^{2+} $[VO(OH)]^+$ and $[V_2O_2(OH)_2]^{2+}$ were considered [51,52]. In agreement with Baes and Mesmer [51], by means of the equations 10.5 and 10.6, we calculated the following values:

	$I = 0$	$I = 0.15$ mol dm^{-3}	$I = 1.5$ mol dm^{-3}
$[VO(OH)]^+$	−5.67	−5.98	−6.44
$[V_2O_2(OH)_2]^{2+}$	−6.67	−6.98	−7.44

which were used in the calculations.

Fig. 4 shows the species distribution diagram of the system VO^{2+}–carnosine as a function of pH, at $B =$ 0.011 mol dm^{-3} and R 60:1.

2.3. Spectrophotometric measurements

The spectrophotometric measurements were performed using the same experimental conditions (concentration ranges and ligand–metal ratios) as those used in the potentiometric study.

The VO^{2+}–carnosine system in the acidic range gives blue solutions which are slightly more intense in colour than that corresponding to an aqueous solution of the VO^{2+} [53,54], and its spectrum shows a band at 625 nm and another band more intense at 764 nm (Fig. 5). The spectrum of $[VO(H_2O)_5]^{2+}$ (C_{4v} geometry) presents

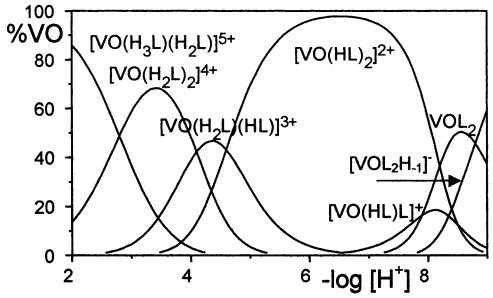

Fig. 4. Species distribution diagram as a function of pH for $B = 0.011$ mol dm^{-3} and ligand–metal $R = 60/1$, in 0.15 mol dm^{-3} KCl ionic medium at 25 °C. Calculated from β_{pqr} values of 512, 412, 312, 112, 012 and −112, Table 2, $R = 6/1,10/1$ and 212 value, Table 2, $R = 60/1$.

three bands corresponding to $b_2 \rightarrow e$, $b_2 \rightarrow b_1$ and $b_2 \rightarrow a_1$ transitions (the latter generally obscured by overlapping with a charge transfer band) [55]. When carboxylate coordinates to oxovanadium(IV) the $b_2 \rightarrow e$ and $b_2 \rightarrow b_1$ bands shifts to the red and to the blue, respectively, due to the stronger ligand crystal field [56]. When the pH is higher than 4 (ratios $\geq 60:1$), the band $b_2 \rightarrow b_1$ is shifted at 480–500 nm and therefore the solution turns dark blue (Fig. 5(a)). The band $b_2 \rightarrow e$ is also shifted to the red. Finally at pH > 7 both bands disminish their intensity to an amber colour (Fig. 5(b)).

Using the program LETAGROP/SPEFO [35,57] for the treatment of the UV–Vis data (pH, B, C, $(D)_{N\lambda})_{NSOL}$, where D is the absorptivity of each solution, Nλ is the number of wave lengths and NOSL is the number of solutions, we select one group of NOSL = 37 solutions and NL = 10 wave lengths at the following ranges: $2.0 \leq pH \leq 4.3$, $0.006 \leq B \leq 0.012$ mol dm^{-3} and $6 \leq R \leq 15$. This analysis gives β_{pqr} values of the same order of magnitude than the *emf* data (Table 2), being its value for the 412 species the stability constant determined with greater precision. But, in the basic zone the values of equilibrium constants could not be determined with enough precision. Fig. 5(b) shows the spectra for $B = 8.4\ 10^{-3}$ mol dm^{-3} and $R = 15/1$. As in this ratio precipitation occurs at pH ≈ 4.5, we could not obtain absorptivity data in the range $4.5 \leq pH \leq 7$.

However, for $R = 60/1$ the hydrolysis is repressed and precipitation is not observed. In this conditions we can see the spectra in this zone ($4.5 \leq pH \leq 7$) in Fig. 5(a).

The spectrophotometric data in the ligand–metal ratio 60/1 and pH range $2.19 \leq pH \leq 9.14$ were analysed by LETAGROP/SPEFO [35,37], using four different zones four λ: 440–485, 585–630, 758–780 and 830–875 nm, respectively (Table 2). The values obtained for log β_{pqr} corresponding to the complexes 412, 312, 212, 112 and 012, are, in general more precise than those obtained from potentiometric data. In particular, the value obtained log β_{212} is good (Table 2).

3. Results and discussion

3.1. Ionization constants of the carnosine

The pK_i constants of the carnosine, HL, (25 °C, $I =$ 0.15 and 1.5 mol dm^{-3} in KCl) are presented in Table 1. The pK_1 corresponds to the deprotonation of the carboxylate group in the species H_3L^{2+}; pK_2 corresponds to the deprotonation of the protonated N^3 imidazole group in the species H_2L^{+}; and pK_3 corresponds to the deprotonation of the NH_3^+ group, in the species HL. The deprotonation of the amide group –CONH– becomes important mainly in the presence of the cation metals [13].

3.2. Stability constants of the complexes formed

From β_{pqr} (Table 2) and β_{pr} constants of the carnosine (Table 1), the formation constants of the complex species formed can readily be calculated according to the following equilibria (Table 3).

The log K value for the species $[VOL_2]$ of the present work (see Table 3) is in agreement with the value reported in the literature for $[CuL_2]$ complex (log $K =$ 14.4) in the carnosine–copper(II) system [19].

The values calculated for pK_i corresponding to the ionization of the protonated complexes are displayed in Table 4.

Taking into account pK_i values of carnosine (Table 1), we can deduce that pK_{a_1} (Table 4) corresponds to the deprotonation of the carboxylic group (Scheme 2). The species distribution diagram (Fig. 4) indicates that the specie $[VO(H_2L)_2]^{4+}$ is the most important in the pH range 3–4. The electronic spectra (Fig. 5(a and b)) up to pH 4 is in accordance with the coordination through oxygen donors [13,31]. The carboxylate group and the oxygen of the peptide group of the carnosine molecules only occupy a part of the coordination site, whereas the remaining ones are occupied by water molecules [31]. The application of SPEFO-LETAGROP program to the spectrophotometric data (Fig. 5(b)) allows to obtain a good value for the stability constants of 412 complex, $[VO(H_2L)_2]^{4+}$ (Table 2). In the specie $[VO(H_3L)(H_2L)]^{5+}$, the ligand H_3L^{2+} (Scheme 2) only can coordinate through oxygen of the peptide group. The values of log K for species $[VO(H_3L)(H_2L)]^{5+}$ and $[VO(H_2L)_2]^{4+}$ (Table 3) indicate that carnosine is a weak complexing agent toward VO^{2+}. The electronic spectra in the ligand–metal ratio 60/1, pH range 5–7 (Fig. 5(a)) change widely, with an increase of the spectral intensity. In pH range 4–7, the band $b_2 \rightarrow b_1$ is shifted [55] to 480–500 nm (solution dark blue) and the band $b_2 \rightarrow e$ is shifted [55] to the red. These changes in the spectra can be explained by the coordination of the N^3 imidazol nitrogen (Scheme 2). The application of SPEFO-LETAGROP program to the spectrophotometric

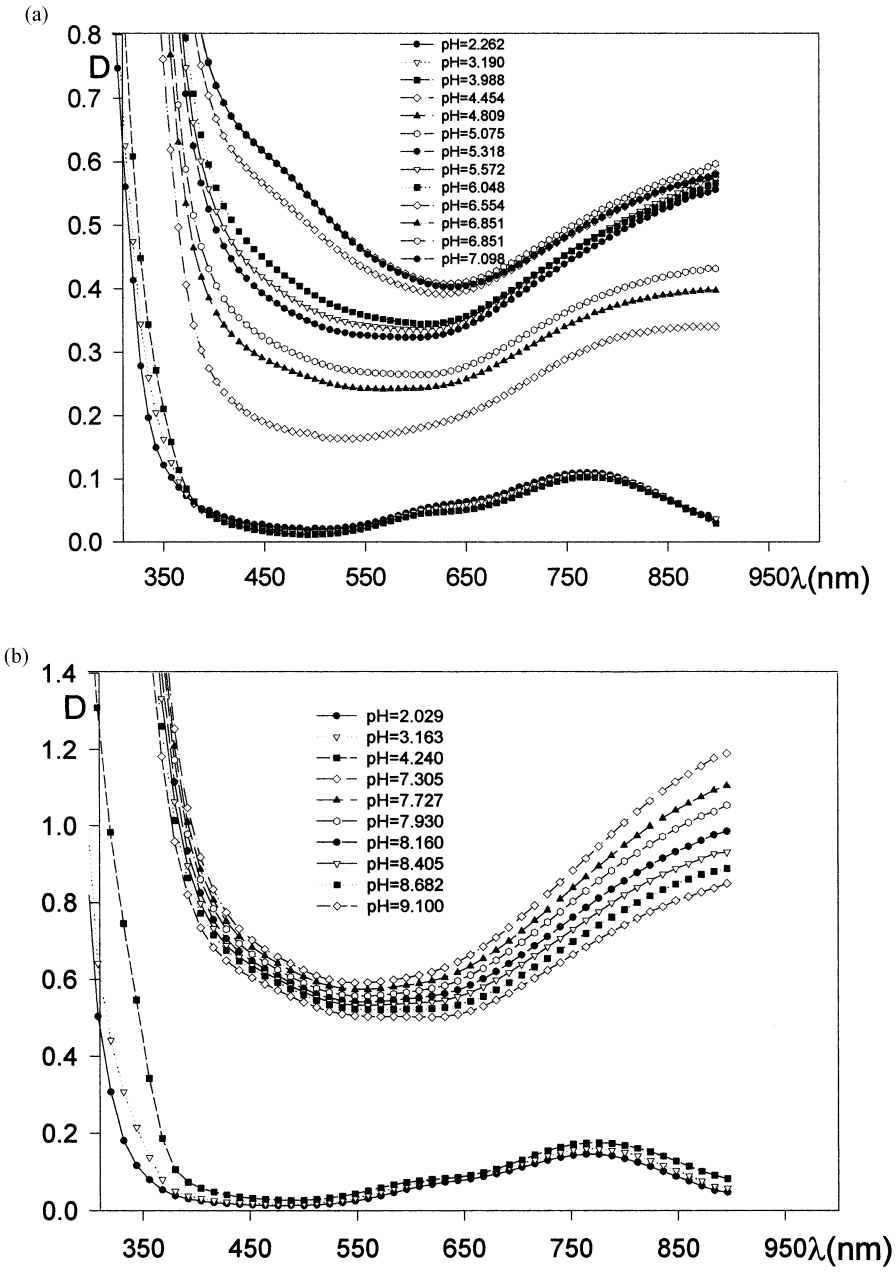

Table 3

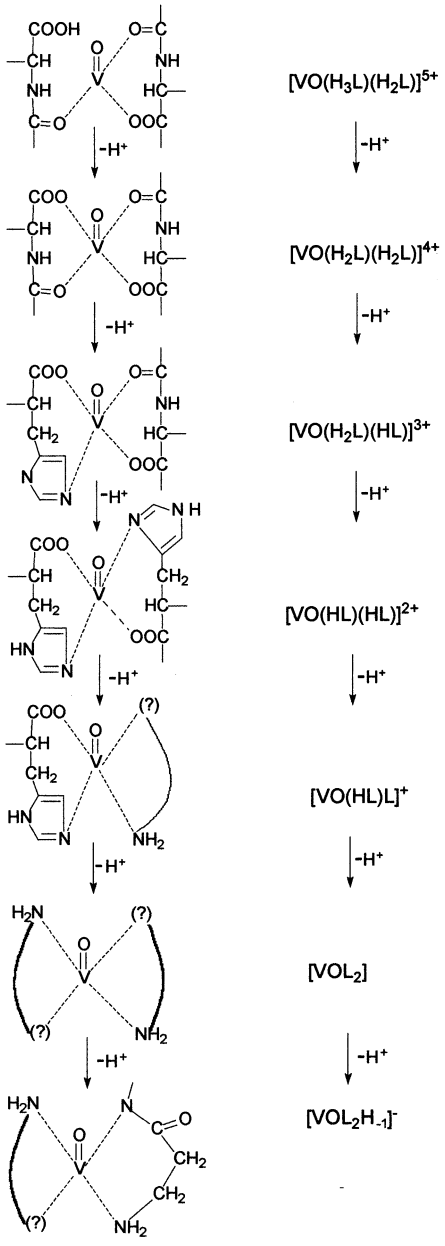

Pqr	Equilibrium	log K
512	$VO^{2+} + H_3L^{2+} + H_2L^{+} \rightleftarrows [VO(H_3L)(H_2L)]^{5+}$	~4
412	$VO^{2+} + 2\ H_2L^{+} \rightleftarrows [VO(H_2L)_2]^{4+}$	~4
312	$VO^{2+} + H_2L^{+} + HL \rightleftarrows [VO(H_2L)(HL)]^{3+}$	6.5
212	$VO^{2+} + 2\ HL \rightleftarrows [VO(HL)_2]^{2+}$	8.6
112	$VO^{2+} + HL + L^{-} \rightleftarrows [VO(HL)L]^{+}$	9.5
012	$VO^{2+} + 2\ L^{-} \rightleftarrows [VOL_2]$	11.2

data in the ligand–metal ratio 60/1 (Table 2) permits to obtain good values for the stability constants of the complexes 312, $[VO(H_2L)(HL)]^{3+}$, and 212, $[VO(HL)_2]^{2+}$. The formation of the complexes $[VO(H_2L)(HL)]^{3+}$ and $[VO(HL)_2]^{2+}$ in the pH range 4–7 can be observed in the species distribution diagram (Fig. 4). Comparing pK_{a_2} and pK_{a_3} (Table 4) with pK_2 (Table 1) we can deduce that the N^3 imidazole atom of the carnosine is involved in coordination to VO^{2+} (Scheme 2), as stated in other work [31]. The HL, species which represents carnosine with a protonated amino group (NH_3^+), also coordinates through the N^3 imidazole nitrogen to Cu^{II} [13]. The species $[VO(HL)_2]^{2+}$ is the most important of the complexes formed in carnosine-oxovanadium(IV) system in accordance with the species distribution diagram, (pH 5–7

Table 4

	pK_{a_i}
$[VO(H_5L_2)]^{5+} \rightleftarrows [VO(H_2L)_2]^{4+} + H^+$	pK_{a_1} ~ 3
$[VO(H_4L_2)]^{4+} \rightleftarrows [VO(H_3L_2)]^{3+} + H^+$	pK_{a_2} ~ 4
$[VO(H_3L_2)]^{3+} \rightleftarrows [VO(HL)_2]^{2+} + H^+$	pK_{a_3} 4.5
$[VO(H_2L_2)]^{4+} \rightleftarrows [VO(HL_2)]^{+} + H^+$	pK_{a_4} 8.5
$[VO(HL_2)]^{+} \rightleftarrows [VOL_2] + H^+$	pK_{a_5} 8
$[VOL_2] \rightleftarrows [VOL_2H_{-1}]^{-} + H^+$	pK_{a_6} 8.7

(Fig. 4)). However, the value of the formation constant (Table 3) indicates that the complex is not very stable since it is necessary a high ratio ligand–metal to avoid the precipitation of the hydroxide.

Scheme 2.

At pH > 7, the electronic spectra (Fig. 5(b), ratio ligand–metal 15:1, similar spectra in ratio 60:1) show that the intensity of the bands diminish, indicating a change of the coordination of the ligand. The curve Z_f(pH) (Fig. 3) and species distribution diagram (Fig. 4) show the formation of the complexes $[VO(HL)L]^+$, $[VOL_2]$ and $[VOL_2H_{-1}]$ in the range pH 7–9. The values of the pK_{a_4} and pK_{a_5} (Table 4) (comparing them with pK_3 of the carnosine (Table 1)) indicate a weak interaction of the nitrogen atom of the amino group with VO^{2+} in the complexes $[VO(HL)L]^+$ and $[VOL_2]$ (Scheme 2). The formation of the complex with a $Z_f = -0.5$ (Fig. 3) can be due either to hydrolysis of the hydroxocomplex $[VOL_2(H_2O)]$ [31] or to the coordination of the deprotonated N-atom of the peptide group –CONH–. The value of the pK_{a_6} (Table 4) is in better agreement with the deprotonation of the peptide nitrogen atom (Scheme 2). In a potentiometric and ^{51}V NMR study in aqueous solution of the H^+-vanadate(V)-L-α-alanyl–L-histidine system [58], the coordination through the amino nitrogen (NH_2), peptide nitrogen and carboxylate oxygen in the complexes (1, 1, 1) and (0, 1, 1) has been proposed. The coordination of the nitrogen atom of the peptide group is also proposed in other work [59]. For the carnosine–copper(II) system, in species $[CuHL]^{2+}$, the ligand behaves as monodentate, coordinating only through N^3 imidazole atom; in the species $[CuL]^+$ the coordination involves the participation of the terminal amino group and deprotonated peptide N-atom; in the species $[CuLH_{-1}]^0$ moreover coordination through N^3 imidazole nitrogen is observed. In the dimeric $[Cu_2L_2H_{-2}]^0$ complex, the carboxylate is also coordinated: each Cu^{II} is coordinated to N-amino, N-peptide, N^3 imidazole nitrogens and to a carboxylate oxygen [13,17].

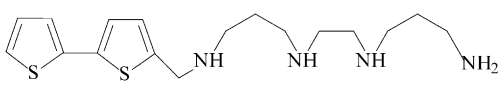
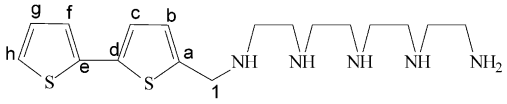
polyamine chain to a bithiophene unit through thenylic carbons. In many ways, these novel products might be considered as an initial approach for designing more soluble oligothiophene compounds with interesting properties. In this respect and focusing on future potential applications in the fields of pharmacology and that of sensory materials, some co-ordination studies in aqueous solution with metal ions have been carried out.

2. Experimental



2.1. Materials

The starting materials for the synthesis of **L1** and **L2** were purchased from commercial sources and used without further purification. The solvents were dried using standard techniques.



All solutions used in the pH-metric and electrochemical studies have been prepared using milipore H_2O.

The CO_2-free NaOH and HCl, solutions used in the potentiometric measurements were prepared following the procedure reported in ref. [9].

2.2. Synthesis

2.2.1. 2,2′-Bithiophene-5-carboxaldehyde (*1*)

This compound was obtained by a modification of the procedure described in ref. [10] for the preparation of bis(5-formyl-2-thienyl)methane using 2,2′-bithiophene (0.5 g, 3.2 mmol), $POCl_3$ (9.4 mmol) and DMF (9.4 mmol) as starting materials. Yield: 43%, δ_H (300 MHz, $CDCl_3$, J in Hz) 7.09 (t, $J = 4$, 1H), 7.25 (d, $J = 5$, 1H), 7.38 (d, $J = 5$, 2H), 7.68 (d, $J = 4$, 1H), 9.88 (s, 1H); δ_C

(300 MHz, $CDCl_3$) 124.5, 126.4, 127.3, 128.6, 136.3, 137.5, 141.9, 147.4, 182.8.

Synthesis of compounds **L1** and **L2** has been accomplished as described in Ref. [11] for the preparation of some related compounds containing anthracene units.

2.2.2. *N-(3-aminopropyl)-N′-3-(2,2′-bithien-5-ylmethyl)aminopropylethane-1,2-diamine (**L1**)*

*2.2.2.1. **L1**·4HCl.* 1,5,8,12-Tetraazadodecane (1.25 g, 7.2 mmol) and 2,2′-bithiophene-5-carboxaldehyde (0.70 g, 3.6 mmol) were dissolved in ethanol (25 ml) and allowed to react for 24 h at room temperature (r.t.). Then, $NaBH_4$ (0.14 g, 3.6 mmol) was added portionwise and the resulting solution kept for 24 h at r.t. The solvent was distilled off under reduced pressure and the residue treated with water and extracted with dichloromethane (3 × 100 ml). Then, it was dried over Na_2SO_4 and the solvent removed by rotatory evaporation. The final residue was dissolved in ethanol and treated with an excess of aqueous HCl. The yellowish precipitate formed was filtered off and dried under vacuum. Yield: 11%, m.p. 265–270 °C (Found: C, 40.7; H, 6.2; N, 10.9. Calc. for $C_{17}H_{31}S_2N_4Cl_4$: C, 40.9; H, 6.5; N, 11.2%); δ_H (400 MHz, D_2O, J in Hz) 1.99–2.04 (m, 4H), 2.9 (t, $J=8$, 2H), 2.9–3.15 (m, 6H), 3.36 (s, 2H), 4.36 (s, 2H), 6.98 (dd, $J=5$, $J=1$, 1H), 7.07 (d, $J=4$, 1H), 7.12 (d, $J=4$, 1H), 7.20 (dd, $J=5$, $J=1$, 1H), 7.29 (dd, $J=5$, $J=1$, 1H); δ_C (400 MHz, D_2O) 22.8, 23.9, 36.6, 43.2, 43.5, 43, 45.2, 45.3, 45.4, 45, 124.3, 125.0, 126.2, 128.5, 130.0, 132.3, 136, 140.1; FAB mass spectrum: m/z 353 ($[M+H]^+$).

2.2.3. *N-(2-aminoethyl)-N″-2-(2,2′-bithien-5-ylmethyl)aminoethyl diethylen-1,4,7-triamine (**L2**)*

*2.2.3.1. **L2**·5HCl.* To prepare this compound the same procedure was used as for **L1**. Yield: 17%, m.p. 270–272 °C (Found: C, 37.7; H, 6.1; N, 12.9. Calc. for $C_{17}H_{33}S_2N_5C_{15}$: C, 37.2; H, 6.1; N, 12.8%); δH (400 MHz, D_2O) 3.23–3.41 (m, 16H), 4.44 (s, 4H), 7.02 (dd, $J=5$ Hz, $J=1$ Hz, 1H), 7.14 (d, $J=4$ Hz, 1H), 7.17 (d, $J=4$ Hz, 1H), 7.25 (dd, $J=5$ Hz, $J=1$ Hz, 1H), 7.35 (dd, $J=5$ Hz, $J=1$ Hz, 1H); δ_c (300 MHz, D_2O) 36.2, 43.4, 43.7, 44.5, 44.7, 45.1, 45.2, 45.4, 45.6, 124.3, 125.0, 126.2, 128.5, 129.0, 132.5, 140.0, 140.0; FAB mass spectrum: m/z 368 ($[M+H]^+$).

2.3. Spectroscopy

The ^1H and ^{13}C NMR spectra were recorded on Varian UNITY 300 and UNITY 400 spectrometers, operating at 299.95 and 399.95 MHz for ^1H and at 75.43 and 100.58 MHz for ^{13}C, respectively. The spectra were obtained at r.t. in $CDCl_3$ or D_2O solutions. For the ^{13}C NMR spectra the $CDCl_3$ signal or the dioxane (67.4 ppm) were used as a reference standard and for the ^1H spectra, the solvent signal. Adjustments to the desired pH values were made using drops of DCl or NaOD solutions. The pH was calculated from the measured pD values using the correlation, pH = pD − 0.4 [12]

2.4. Electromotive force measurements

The potentiometric titrations were carried out at 298.1 ± 0.1 K using NaCl 0.15 mol dm^{-3} as supporting electrolyte. The experimental procedure and the potentiometric equipment (burette, potentiometer, cell, stirrer, microcomputer, etc.) have been fully described elsewhere [13]. The acquisition of the emf data was performed with the computer program PASAT [14]. The reference electrode was an Ag–AgCl electrode in saturated KCl solution. The glass electrode was calibrated as a hydrogen-ion concentration probe by titration of previously standardised amounts of HCl with CO_2 free NaOH solutions. The equivalent point was determined by the Gran's method [15], which gives the standard potential, $E^{\circ\prime}$, and the ionic product of water [$pK_w = 13.73(1)$]. The concentration of the different metal ions solutions employed was determined gravimetrically by standard methods. The computer program HYPERQUAD [16] was used to calculate the protonation and stability constants. The pH range investigated was 2.5–10.5 and the concentration of the different metal ions and of **L1** and **L2** ranged from 1×10^{-3} to 5×10^{-3} mol dm^{-3}. The different titration curves for each system (ca. 150 experimental points corresponding to at least three measurements) were treated either as single or as separate sets without significant variations in the values of the stability constants. Finally, the sets of data were merged together and treated simultaneously to give the final stability constants.

2.5. Electrochemistry

Cyclic voltammograms (CV) were obtained using a BAS CV50 W equipment. Linear scan (LSV) and differential pulse voltammograms (DPV) were performed with a Metrohm E506 polarecord. Glassy carbon (0.120 cm^2 surface) was used as a stationary working electrode, a platinum wire was used as the counter electrode, and an aqueous saturated calomel reference electrode (SCE), separated from the bulk solution by a salt bridge containing the solvent and supporting electrolyte, only was used as a reference electrode. Prior to series of experiments, the working electrode was cleaned and activated. Pre-treatment was performed in blank solutions by applying +1.50 V versus SCE for 10 min followed by −1.0 V for 1 min. Before each run, the electrodes were polished with an

aqueous suspension of alumina on a soft surface, dried and cleaned.

Single-sweep conditions were used for cyclic voltammetry, the potential scan rate ranging from 0.1 to 50 mV s^{-1}. For DPV, a potential scan rate of 4 mV s^{-1} was used; pulse amplitude was 10 mV.

Electrochemical experiments were performed under an argon atmosphere in solutions of $Cu(NO_3)_2 \cdot 6H_2O$ or $CuCl_2 \cdot 2H_2O$ prepared with doubly distilled water. As supporting electrolytes were used solutions of 0.15 M NaCl and 0.15 M $NaClO_4$, being their pH adjusted to the required value by adding the appropriate amounts of $HClO_4$ and/or NaOH.

3. Results and discussion

3.1. Acid–base behaviour

The protonation trends of **L1** and **L2** (see Ligand Drawing) have been studied in 0.15 mol dm^{-3} NaCl at 298.1 ± 0.1 K. In Table 1 are presented the logarithms of the stepwise basicity constants of the new compounds conjointly with those of the analogue compounds containing an anthracene unit (**L3** and **L4**) [10]. By means of comparison, the constants for the corresponding open-chain non-terminally substituted polyamines **L5** and **L6** have also been included [17].

In order to discuss the data, it is helpful to separate the polyamines in two groups according to the nature of the polyamine chain. When propylenic units are present, slight differences in the individual basicity constants have been found, being the overall basicity of the polyamine **L5** the highest of this group. **L1**, **L3** and their counterpart **L5**, all of them with four basic centres, present relatively large constants for the first three protonation steps and a much lower one for the last protonation. This trend of the stepwise protonation constants can be largely interpreted in terms of minimisation of coulombic repulsions among same sign charges [18]. Thus, the possibility of arranging the first three protons binding **L1**, **L3** and **L5** in non-neighbouring nitrogen atoms together with the presence of the two propylenic chains makes the electrostatic repulsions not very large at this stage. However, the fourth protonation step yields an important basicity decrease because it has to occur necessarily adjacent to two already protonated nitrogen atoms. Another point to be considered is the great resemblance between the data of the compounds with an anthracene unit and the one with the bithiophene fragment, particularly in the values of the three last constants. This would imply that the type of aromatic unit does not seem to be an important factor in defining the acid–base behaviour of these two ligands (**L1** and **L3**).

On the other hand, while the basicity trend of **L4** and **L6** can be explained also in terms of coulombic repulsion, the behaviour of **L2** is rather different. Indeed, according to the literature [19], **L4** and **L6** containing an odd number of nitrogen atoms present two groups of constants, so that their protonation constants decrease sharply upon passing from the third to fourth step; the difference between $\log K_{H_3L}$ and $\log K_{H_4L}$ being approximately 3 logarithmic units. However, for **L2** such a jump is not observed and the decrease in the values on the successive constants are more steady. The largest drop in basicity is observed with the fifth protonation of the ligand. After going through the individual constants, the large basicity of **L2** can be especially attributed to the two last protonations, which are much higher than expected. Therefore, in the ligands with only ethylenic chains the bithiophene unit plays a significant role on its basicity. This observation could be related with the electron-rich characteristic of the thiophene ring [20], and with its much more robust π-conjugation than in related systems.

In order to clarify this point we have carried out a variable pH NMR study of **L2**. The protonation pattern inferred from the displacements of the chemical shifts with the pD values reproduces the one observed in analogous systems [17]. At this respect, a noticeable information stems from changes on the ^{1}H or ^{13}C

Table 1
Logarithms of the stepwise protonation constants and global basicity for **L1**–**L6** at 298.1 ± 0.1 K

Reaction [a]	**L1** [b]	**L2** [b]	**L3** [d]	**L4** [d]	**L5** [e]	**L6** [e]

resonances corresponding to the nucleus in position 1 (for the labelling, see ligand drawing), which is the one that acts as a link between the chain and the aromatic system (thenylic carbon or protons). In this way, the ^1H resonance for the protons linked to this carbon does not change very much on going from the pH region where the free ligand predominates (pH > 11) to the one where the existence of the monoprotonated form prevails; this indicates that the first equivalent of added acid protonates mainly the primary nitrogen of the chain. However, the second equivalent (pH 9.5–10.0) induces a large upfield shift on this signal, suggesting this proton is located on the nitrogen closest to the aromatic fragment (thenylic nitrogen). Finally, the remaining positive charges should enter successively at the middle of the chain. In spite of the fact that the aliphatic signals are the most affected by protonation, the aromatic signals result also affected. In these bithiophenic systems slight upfield movements when the pH becomes more basic are observed on the doublets attributed to H_b and H_c (see ligand drawing), so they seem to be affected by the protonation of nitrogen linked to thenylic carbon [21–23].

4. Metal co-ordination

4.1. Emf measurements

Table 2 reports the stability constants for the formation of Cu^{2+} and Zn^{2+} complexes of ligands **L1** and **L2**. Following the same criteria used in the discussion of the protonation data we have also included in this Table the values for the related ligands **L3**–**L6**.

At first glance, the collected data reveal that **L1** forms $[ML]^{2+}$ and $[MHL]^{3+}$ species with both metal ions, while for **L2** an additional $[CuH_2L]^{4+}$ species is detected. In the ligand containing propylenic units the stability tendency of the copper complexes is **L5** > **L3** > **L1**. In this way, the lower stability of $[Cu(\mathbf{L1})]^{2+}$ and $[Cu(\mathbf{L3})]^{2+}$ with respect to that of $[Cu(\mathbf{L5})]^{2+}$ is a well documented fact based on the different kind of nitrogen donors present in these molecules [9,16]. Effectively, **L5** is a molecule which has two primary amino groups at both ends, in **L1** and **L3** one of such nitrogens has been linked to a bulky hydrophobic substituent through a methylene group. This affects the solvation of the molecules and consequently the stability of their complexes. The close stability displayed by $[Cu(\mathbf{L1})]^{2+}$ (log $K = 18.54(5)$ and $[Cu(\mathbf{L3})]^{2+}$, in which full involvement of all the nitrogen atoms in the co-ordination of the metal ion was ascertained by its X-ray crystal structure [10], suggests a similar co-ordination environment in both complexes. The previous copper data analysis can be extrapolated for the Zn^{2+} complex with the exception of the reverted **L1**–**L3** stability; $[Zn(\mathbf{L1})]^{2+}$ is slightly more stable than $[Zn(\mathbf{L3})]^{2+}$.

The behaviour of the Cu^{2+}–**L2** complexes is particularly different. The complex $[Cu(\mathbf{L2})]^{2+}$ is remarkably more stable than the analogous one $[Cu(\mathbf{L4})]^{2+}$ with the anthracene derivative (Table 2). Although the differences in stability are not as large as in the case of Cu^{2+}, the $[Zn(\mathbf{L2})]^{2+}$ complex is also more stable than $[Zn(\mathbf{L4})]^{2+}$. The stability of the $[Cu(\mathbf{L2})]^{2+}$ species is closer to that displayed by the open-chain polyamine

L6, although slightly higher. The higher stability of $[Cu(\mathbf{L2})]^{2+}$ with respect to $[Cu(\mathbf{L4})]^{2+}$ might be ascribed to the full involvement of all the nitrogen atoms in the co-ordination to the metal ion in the first case. The reduced protonation constant of $[Cu(\mathbf{L2})]^{2+}$ with respect to $[Cu(\mathbf{L4})]^{2+}$ lends support to this point. The slightly higher apparent stability of $[Cu(\mathbf{L4})]^{2+}$ with respect to $[Cu(\mathbf{L6})]^{2+}$ can be related to its higher basicity. The Zn^{2+} complexes of this ligand follow the tendency previously advanced for **L1** which denotes higher stability of the complex with the bithiophene unit with respect to that with the anthracenyl fragment. Although it is difficult to explain such behaviour, factors like participation of the sulfur atoms of the bithiophene ring in the stabilisation of the complexes cannot be discarded.

4.2. Electrochemistry of the Cu^{2+}–*L1* system

The electrochemical activity of **L1** in aqueous solution is confined to oxidation processes which develop close to +1.0 V versus SCE. As described in the literature [5], this electrochemical behaviour would be attributable to two successive one-electron transfer steps coupled with a nucleophilic attack of water. On the contrary, at negative potentials coupled reduction and protonation processes occur at −1.2 V, according to the general scheme proposed for aromatic systems [24–26].

The electrochemical response of the Cu^{2+}–**L1** system has been studied by linear scan, cyclic, and differential pulse voltammetry in the 3–11 pH range. At low scan rates, the CVs exhibit two well defined cathodic peaks at −0.32 (C_1) and −0.58 (C_2) V versus SCE followed by anodic peaks at −0.51 (A_2) and −0.20 (A_1) V, as depicted in Fig. 1.

The cyclic voltammetric pattern remains essentially unchanged upon repetitive cyclic voltammetry and the voltammetric response of freshly prepared solutions remains unchanged with time, denoting the absence of kinetic complications. Peak potentials and peak currents are essentially pH-independent in the pH range where the species $[Cu(\mathbf{L1})]^{2+}$ predominates (pH 7−11). Moreover, no changes in the C_1–A_1 couple are detected if the potential sweep is reversed in the first scan before the appearance of the peak C_2. On increasing the potential scan rate, v, the peak C_1 decreases whereas the peak C_2 increases. Although it is not easy to find an explanation for this behaviour, it could be suggested that the C_1 and C_2 peaks must correspond to the reduction of different Cu(II) species for which a relatively slow inter-conversion equilibrium occurs (Eq. (1)). Neither colour decoloration nor changes in the electrochemical response have been detected after the storage of well deareated solutions of an excess of ligand in the presence of a wire of metallic copper, we can conclude that no stable intermediate Cu(I) species are formed. Then, a dual CE mechanism involving Cu(II) complexes with different co-ordination environment can be proposed:

$$Cu^{II}L \overset{k}{\rightarrow} (Cu^{II}L)' \quad (1)$$

$$Cu^{II}L + 2e^- \rightleftarrows Cu^0 + L \quad (2)$$

$$(Cu^{II}L)' + 2e^- \rightleftarrows Cu^0 + L \quad (3)$$

These data are confirmed by differential pulse voltammetry, a technique that allows an increased peak

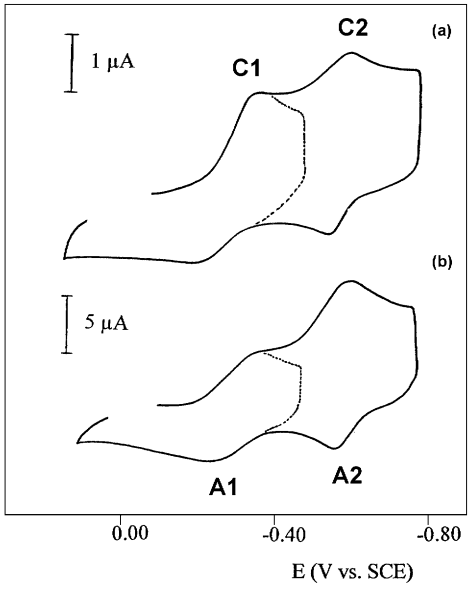

Fig. 1. GCE cyclic voltammograms for a 0.15 M NaCl solution containing $Cu(NO_3)_2 \cdot 6H_2O$ (0.40 mM) plus **L1** (0.85 mM) at pH 8.95. (a): $v = 5$ mV s^{-1}; (b): $v = 50$ mV s^{-1}. Dotted lines represent the CVs when the potential scan is reversed at −0.45 V vs. SCE.

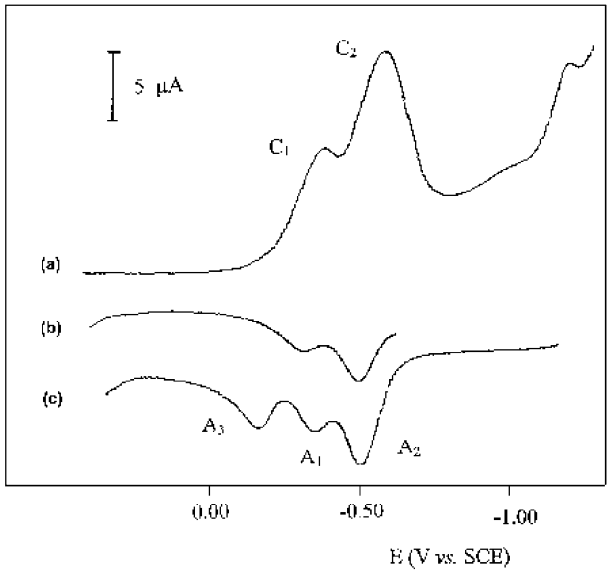

Fig. 2. DPVs for a 0.15 M NaCl solution containing $Cu(NO_3)_2 \cdot H_2O$ (0.30 mM) plus **L1** (0.35 mM) at pH 9.50. (a) Cathodic scan starting at +0.50 V; (b) anodic scan starting from −0.60 V; (c) anodic scan starting from −1.20 V. GCE; $v = 20$ mV s^{-1}; $\Delta U = 80$.

resolution. As can be seen in Fig. 2(a) for the Cu^{2+}–**L1** system, cathodic DPVs exhibit peaks at −0.38 (C_1) and −0.58 (C_2) V clearly separated and followed by a ligand-centred reduction at potentials close to −1.2 V. Interestingly, anodic DPVs depend on the starting potential. As shown in Fig. 2(b), for anodic scans starting from −0.6 V, anodic peaks A_1 and A_2 appear at −0.38 and −0.52 V.

In contrast, on starting the potential scan at −1.2 V, a third peak, A_3, appears at −0.18 V (Fig. 2(c)). Since the ligand is partly reduced at the potentials applied at the beginning of the scan, it appears that Cu^{2+} atoms can also co-ordinate with the reduced ligand, **L***. Thus, the anodic peaks A_1 and A_2 must correspond to the inverse/reverse of processes described by Eqs. (2) and (3), while peak A_3 is attributable to the oxidation reaction described by Eq. (4):

$$Cu^0 + \mathbf{L}^* \rightleftarrows Cu^{II}\mathbf{L}^* + 2e^- \quad (4)$$

This electrochemical behaviour differs from that previously described for macrocyclic thiophenophane ligands for which relatively stable Cu(I) intermediates were detected [23]. Although additional electronic, steric and solvation factors can be adduced to discuss the relative stability of Cu(II) and Cu(I) complexes [27–31], the difference between the cyclic thiophenophane **L7** [23] (see Ligand Drawing) and **L1** could be explained by balancing the number of donor atoms which co-ordinates the metal ion and the flexibility of the polyamine chain. Effectively, the presence of the aromatic spacer supplies rigidity enough to prevent the simultaneous co-ordination of both thenylic nitrogen and so, in the macrocyclic system, the maximum number of nitrogens able to co-ordinate the Cu^{2+} ions would be three. This situation would provide the adequate geometry required for the stabilisation of Cu(I) complexes. On the contrary, in the most flexible linear polyamine chain **L1** the co-ordination of copper probably would take place through four nitrogen atoms and consequently, there are major difficulties to satisfy the structure demanded for the stabilisation of Cu(I) species. The notable destabilisation of Cu(I) complexes observed for macrocyclic polyamines containing biphenyl spacers [32] and for macrocyclic benzene-containing ligands upon incorporation of an axial ligand [33] are consistent with the foregoing considerations.

5. Conclusions

The bithiophene open-chain polyaminic ligands here described show several interesting properties. Firstly, the synthesis, although it does not provide a very high yield is straight forward and allows obtaining the products on a large scale. The basicity and the metal ion studies denote the amphipilic characteristics of the compounds although the chelating characteristics of the parent polyamines are preserved a large extent. All these factors make these compounds promising candidates for potential applications with different purposes.

Abstract

The 3A-deoxy-3A-(2-methylaminopyridine)-2A(*S*),3A(*R*)-β-cyclodextrin (CDampy3) was synthesized and characterized by NMR spectroscopy. The proton and copper(II) complex formation and stability of this new β-cyclodextrin derivative were determined by potentiometric and calorimetric investigations, carried out in aqueous solution at 25 °C and $I = 0.1$ mol dm^{-3} (KNO_3). The ΔH° and ΔS° values allowed to bring to light the role of the hydrogen bond between the amine and the hydroxyl groups in the basicity decrease of NH group of this 3-functionalized β-cyclodextrin. The comparison between the log K values of copper(II) complexes with CDampy3 and those of 6-deoxy-6-(2-methylaminopyridine)-β-cyclodextrin (CDampy6) allowed to determine the donor atoms involved in the coordination to metal ion. The high stability constant of $[Cu(CDampy3)]^{2+}$ in comparison with $[Cu(CDampy6)]^{2+}$ was attributed to the involvement of the OH groups in the binding to copper(II) ion. © 2002 Elsevier Science Ltd. Keywords: Cyclodextrins; Copper(II) complexes; 2-Methylaminopyridine

1. Introduction

Cyclodextrins (CDs) are cyclic oligosaccharides consisting of six or more α-D-glucopyranose units, which have attracted interest in a variety of contexts [1–6]. The direct coordination of native cyclodextrins to the metal ion has been found only for some metal ions because of the poor coordinating ability of their hydroxy groups [7–10]. The secondary OHs act as coordinating groups in the characterized complexes. The only metal complexes with high stability constants described are derivatives in which, the cyclodextrin torus serves as a framework for attaching complexing functional groups [11–33]. In this context mainly six-functionalized cyclodextrins metal complexes have been synthesized and fully characterized [12,15–18,21–28]. This in spite of the fact that the first metallo-enzyme model by cyclodextrins, 'Breslow enzyme' [30], has been the nickel(II) complex with a functional group attached to a secondary alcohol group on the secondary face of CD. Furthermore a CD 3-derivative cobalt(III) complex in comparison to the analogous six-derivative shows larger activity as hydrolase model [15,16]. The reason for the less extensive investigation on the secondary side derivatives is related to the fact that, primary hydroxyl groups are more nucleophilic than secondary OHs and they are easily modified into other functional groups. The secondary side is more crowded than the primary side due to the presence of twice the number of hydroxyl groups [1,2]. Hydrogen bonds between the 2-OH and 3-OH make these OHs less flexible and less reactive. The C-3 functionalization gives chemical modification of

functionalized unit in altrose and furthermore the tosylation of cyclodextrin, useful starting reaction, is a low yield reaction. New synthetic routes have been reported to give with high yield the CD tosylate [35]. In order to investigate on the complexing features of three-derivatives, recently the thermodynamic characterization of three-functionalized cyclodextrin with ethylendiamine and of its copper(II) complexes have been reported by our group [33]. The ability of this class of derivatives to complex the metal ion with 2-OH of the functionalized ring in addition to the donor atoms present of the functionalizing moiety has been brought to light. The stability constant of copper(II) complex constant complex formation of the CDen3 is larger than that of the analogous six-derivative. To further investigate on the three-derivative properties, we report the potentiometric and calorimetric investigations on a new three-functionalized derivative, the 3A-deoxy-3A-(2-methylaminopyridine)-2A(*S*),3A(*R*)-β-cyclodextrin (CDampy3) (Fig. 1). The formation and stability of copper(II) complexes of CDampy3 were characterized by means of potentiometric measurements.

2. Experimental

2.1. Material

Commercially available reagents were used directly unless otherwise noted. TLC was carried out on silica gel plates 60F-254 (Merck). Cyclodextrin derivatives were detected with UV light and the anisaldehyde reagent. Merck lichroprep RP-8 (40–60 mm) was used for reversed phase column chromatography. NMR spectra were performed at 25 °C in D_2O on a Bruker AC-200 spectrometer. DSS was used as an external standard.

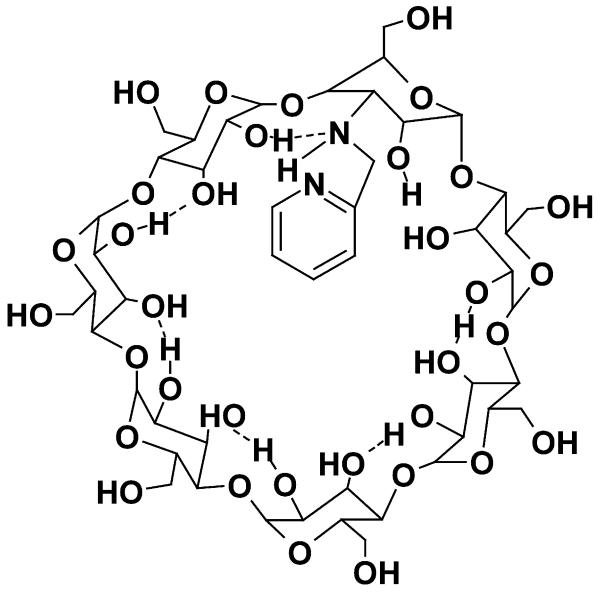

Fig. 1. 3A-deoxy-3A-(2-methylaminopyridine)-2A(*S*),3A(*R*)-β-cyclodextrin.

2.2. Synthesis of 3A-deoxy-3A-(2-methylaminopyridine)-2A(S),3A(R)-β-cyclodextrin

A solution of 500 mg of 2-CDOts [34,35] and 970 mg of $NaHCO_3$ in 7 ml of water was stirred at 60 °C for 3.5 h. The formed epoxide was not isolated. The 2-methylaminopyridine (ampy) in excess was directly added to the solution. The reaction mixture was stirred under nitrogen at 60 °C for 5 h. The solution was evaporated to dryness in vacuo, precipitated in acetone, and purified by elution from a column (35 × 900 mm) of CM-Sephadex C-25 column (NH_4^+ form) with water 1 l, then with a 0–0.25 M NH_4HCO_3 linear gradient (total volume 2 l). The appropriate fractions were concentrated to give CDampy3, $Rf = 0.46$ (5/3/1 PrOH–H_2O–NH_3), yield: 45%.

^{1}H NMR (D_2O, 200 MHz): 2.97 (dd,1H, H-3A), 3.34–4.05 (m, 40H, H-2,H-4, H-5, H-6, H-3), 4.28 (m, 1H, H-5A), 4.76 (d, 1H, H-1A) 4.95–5.10 (m, 6H, H-1), 8.46 (d, 1H, H-1 of pyridine ring), 7.84 (t, 1H, H-3 of pyridine ring), 7.46 (d, 1H, H-4 of pyridine ring), 7.36 (m, 1H, H-2 of pyridine ring).

^{13}C NMR: 160.57 (C-2 py), 151.1 (C-6 of py), 140.9 (C-4 of py), 126.0,125.7 (C-3,5 of py), 106.1 (C-1A), 104.5-104 (C-1 CD), 83.7 (C-4 CD), 78.6 (C-3A CD), 75.9–74.6 (C-2,3,5 CD), 62.9–62.8 (C-6 CD), 54 (CH_2).

2.3. Potentiometric and calorimetric measurements

Copper(II) nitrate was prepared from copper(II) basic carbonate by adding a slight excess of HNO_3. Stock solution concentration was determined by EDTA titrations with a murexide indicator. The concentrations of HNO_3 and KOH stock solutions were determined by titration with the primary standard *tris*(hydroxymethyl)aminomethane (THAM) and potassium hydrogen phthalate, respectively. Potassium nitrate (Suprapur Merck) was used without further purification. All solutions were prepared with doubly distilled water.

Stability constants for proton and copper(II) complexes were calculated from potentiometric titrations carried out at 25 °C (total volumes: 2.5 cm^3). Duplicate or triplicate titrations were carried out at 1:1 and 1:2 Cu–L ratios, with KOH. The KOH solution was added using Hamilton burettes equipped with 0.25 or 0.50 cm^3 syringes. pH changes were measured using a combined Metrohm 125 microelectrode, standardised on the pH $-\log[H^+]$ scale by titrating HNO_3 solutions with CO_2 free KOH. The ionic strength of all solutions was 0.1 mol dm^{-3} (KNO_3).

ΔH° values were determined by calorimetric titrations using a LKB TAM 2277 instrument in isothermal condition at $T = 25.000 \pm 002$.

Other details were as previously described [13,18].

2.4. Calculations

Calculations for the electrode system E° values, ligand purity, and HNO_3 excess in the metal stock solution were performed using the Gran method [36] or the least-squares ACBA computer program [37]. All other potentiometric data were handled using the program SUPERQUAD [38], thus minimizing the error-square sum of the differences between measured and calculated electrode potentials. In this paper, errors in stability constant values are expressed as three times standard deviations. The ΔH° values of complex formation were calculated by the DOEC program [39]. Distribution diagram for the copper(II)–CDampy3 system (1:1 ratio, $c = 5 \times 10^{-3}$ mol dm^{-3}) was calculated by the DISDI program.

3. Results and discussion

The new ligand CDampy3 was synthesized in good yield from the 2-deoxy-2-[(*p*-tosyl)oxy]-β-cyclodextrin treated with an aqueous solution of $NaHCO_3$ to give 2,3-manno-epoxide. Ampy was added in excess to the mixture containing the epoxide. The CDampy3 was isolated by chromatography. As described in the literature [40,41], the ring opening of the manno-epoxide generally gives rise to derivative in position three having modified altrose residue. The ^{1}H NMR were assigned by COSY. The introduction of one altroside into the cyclodextrin caused unequivalency of the glucose units in the NMR spectrum. After the three-functionalization in addition to the two groups of peaks observed in the 4.1–3.5 ppm region due to the CD protons, peaks are present at 2.97 and 4.28 ppm due to the H-3A and H-5A (A is the functionalized ring). All the other protons of the modified ring are easily assigned on the COSY spectra.

3.1. Proton and copper(II) binary complexes: formation, stability and bonding details

The generalized formation reaction of the ligand with protons and copper(II) ions is given in Eq. (1), where L is CDampy3. For the sake of clarity, charges on the copper(II) complexes have been omitted.

$$m\mathrm{Cu}^{2+} + l\mathrm{L} + h\mathrm{H} \rightleftarrows \mathrm{Cu}_m\mathrm{L}_l\mathrm{H}_h \quad (1)$$

The stability constant β_{mlh} is defined in Eq. (2).

$$\beta_{mlh} = \frac{[\mathrm{Cu}_m\mathrm{L}_l\mathrm{H}_h]}{[\mathrm{Cu}^{2+}]^m[\mathrm{L}]^l[\mathrm{H}]^h} \quad (2)$$

Analysis of the titration data for CDampy3 in the absence of copper(II) provides the formation constants for amino and pyridine nitrogen protonation (Eqs. (3) and (4)).

$$\mathrm{L} + \mathrm{H}^+ \rightleftarrows \mathrm{LH}^+ \quad (3)$$

$$\mathrm{L} + 2\mathrm{H}^+ \rightleftarrows \mathrm{LH}_2^{2+} \quad (4)$$

The proton and copper(II) complex formation constants determined in this study are given in Table 1 together with those found for 6-deoxy-6-(2-methylaminopyridine)-β-cyclodextrin (CDampy6) [18], 2-aminomethylpyridine (ampy) [42], *N*-methyl-2-aminomethylpyridine (CH_3ampy) [42]. The equilibria necessary to fit the experimental titration curves for the solutions of copper(II) complex formation with the CDampy3 under study are given in Eqs. (5)–(8).

$$\mathrm{Cu}^{2+} + \mathrm{L} \rightleftarrows \mathrm{CuL} \quad (5)$$

$$\mathrm{Cu}^{2+} + \mathrm{L} \rightleftarrows \mathrm{CuLH}_{-1} + \mathrm{H}^+ \quad (6)$$

$$\mathrm{Cu}^{2+} + \mathrm{L} \rightleftarrows \mathrm{CuLH}_{-2} + 2\mathrm{H}^+ \quad (7)$$

$$2\mathrm{Cu}^{2+} + 2\mathrm{L} \rightleftarrows \mathrm{Cu}_2\mathrm{L}_2\mathrm{H}_{-2} + 2\mathrm{H}^+ \quad (8)$$

The complex formations are listed in Table 2, together with those of CDampy6 [18], ampy [42] and CH_3ampy [42].

The log K for the amino group protonation of CDampy3 (6.35) is about 2.5 log units lower than that for ampy (8.74) and CH_3ampy (9.01) and slightly lower than that of CDampy6 (6.86). The decrease in the amino nitrogen basicity of this latter CD isomer derivative was attributed to the proximity of the NH group to the cavity, in agreement with what previously reported for this type of functionalized cyclodextrins [13,18,21,43]. The main difference between the two CDampy isomers consists in the involvement of the NH group of CDampy3 in the hydrogen bonding network between the 2-OH and the 3-OH groups that stabilizes the toroidal structure of the β-CD (Fig. 1). Thus the low basicity of the NH group can be attributed to the existence of this hydrogen bond that is destroyed in the formation of the monoprotonated species. At the same time this cleavage of the hydrogen bond should imply a significant decrease of rigidity of the cavity, with a sort of collapse of the toroidal structure.

The comparison between the enthalpy and entropy changes (Table 1) associated to the proton complex formation of the two CDampy isomers support what suggested on the basis of the differences in log K values. In fact the ΔH° value of $[(\mathrm{CDampy3})\mathrm{H}]^+$ species (−1.7 kcal mol^{-1}) is less exothermic than that of $[(\mathrm{CDampy6})\mathrm{H}]^+$ species (−9.3 kcal mol^{-1}) due to the fact that the lone pair of the NH group of CDampy3 is less available to interact with the proton than the amino

Table 1

residue of CDampy6. The much less favourable enthalpy changes of [(CDampy3)H]$^+$ accompanying the break-up of the hydrogen bond is counterbalanced by the unusually large entropy change. The ΔS° value reflects the conformational change associated with the monoprotonated species. The larger rim of the β-CD partially loses the rigid ordered structure due to hydrogen bonding network to assume a more flexible partly disordered conformation. The altrose unit could interconvert easily in the $^4C_1$ or $^0S_2$ conformation, in a similar way to altrocyclodextrin [44]. The thermodynamic data bring to light this change, namely by the positive ΔS° value of [(CDampy3)H]$^+$ (23 cal mol^{-1} °) higher not only than that of [(CDampy6)H]$^+$ (0.2 cal mol^{-1} °), but also of ampy and CH_3ampy (Table 1). The decrease of basicity is much less marked in the second protonation step of CDampy3 with respect to CDampy6 as well as the ampy and CH_3ampy. For the second protonation step, ΔH° values are more or less equal and the slight differences in ΔS° values can be attributed to small effects of the cavity environment.

[Cu(CDampy3)]$^{2+}$ is the major species from pH 3 to 5, then CDampy3 forms monomeric and dimeric deprotonated species (Fig. 2). Comparing the stability constant values of the copper(II) mono complexes of the two CDampy isomers with those of the analogous species of ampy and CH_3ampy, the higher stability of these latter follows the differences in the basicity of the amine groups (Table 2). Despite similar basicity CDampy3 displays a stability constant value higher than that of CDampy6 in the CuL species. It is necessary to invoke the involvement of the OH groups of the larger rim of the β-CD to explain this behavior (Fig. 3(a)). Increasing the pH, this tendency of the OH groups to bind to copper(II), verified for other three-functionalized derivatives of CD [7–10] and for some diaminoalcohols [45], is evident in the mono- and bis-deprotonated species as well as in the dimeric species. Structures of copper(II) complexes with native β-CD have been reported, showing the involvement of OH groups [10]. On this basis, the complexation of the deprotonated 2-OH of the A ring can be hypothesized to explain the high stability constant for the [Cu(CDampy3)H_{-1}]$^+$ species. Analogously it is reasonable to suggest that the deprotonated 2-OH group of the A and G rings could coordinate the copper(II) ion (Fig. 3(c)). A possible structure of dimeric species [Cu_2(CDampy3)$_2H_{-2}$]$^{2+}$ is sketched in Fig. 4, as reported for some amino alcohol complexes [45]. The inclusion of the pyridine ring into the CD cavity could stabilize this species.

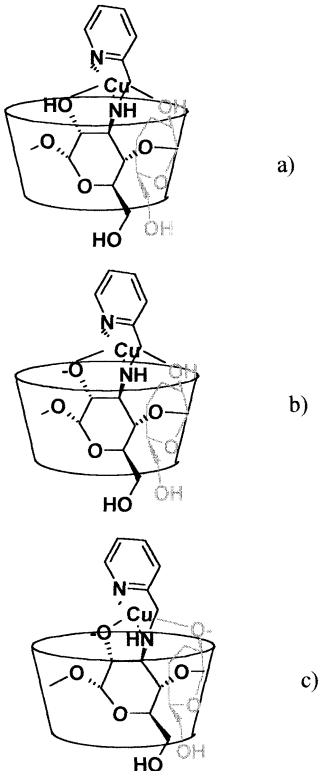

Fig. 3. Schematic representation of $[Cu(CDampy3)]^{2+}$ (a), $[Cu(CDampy3)H_{-1}]^{+}$ (b), $[Cu(CDampy3)H_{-2}]$ (c) species.

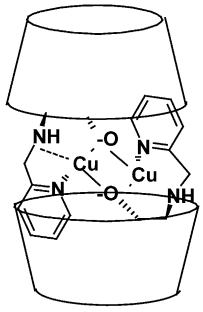

Fig. 4. Schematic representation of $[Cu_2(CDampy3)_2H_{-2}]^{2+}$ species.

4. Concluding remarks

A number of thermodynamic investigations have been carried out on proton and metal complex formation of six functionalized derivatives [13,16–18,21–26,32]. Thus the features of six amino derivatives in terms both of basicity and of complexing ability have been widely explored. The thermodynamic data here reported deals with the protonation and complexation reaction of three functionalized β-cyclodextrin. The involvement of functionalizing group on the C-3 carbon in the H-bond formation has been verified by calorimetry. The OH groups adjacent to the altrose unit, that is the 2-OH of A and 2-OH of G ring, seem bind to the metal ion in the deprotonated form and in the native form, thus determining high complexation stability constants if compared with the analogous six derivatives. These results could be used in the rationalization of the features of three and of six derivatives in the enzyme mimicking [12].

takes place through the oxygen and pyrazolate bridge. In Ten Hoedt's study the distortion of the geometry around the Cu atom from square planar toward tetrahedral was considered as the main reason for the small J value, and in Manzur's study the exchange mechanism was explained by the countercomplementary effect without molecular orbital analysis [13]. In this study, we have synthesized a similar tetranuclear copper(II) complex $[Cu_4(pz)_4L_2]\cdot(ClO_4)$ (LH = 1,3-diamino-2-propanol, Hpz = pyrazole) and investigated its crystal structure and magnetic properties. Molecular orbital analysis of the compound have been done by the ab initio restricted Hartree–Fock molecular orbital method [14] to determine the influence of bridging ligands between the metal ions on the magnetic superexchange interaction and to explain the main reason of the weak antiferromagnetic coupling.

2. Experimental

2.1. Synthesis of $[Cu_4(pz)_4L_2]\cdot(ClO_4)$

The copper(II) complex was synthesized by mixing $Cu(ClO_4)_2\cdot 6H_2O$ (0.741 g, 2 mmol) with pyrazole (0.136 g, 2 mmol) in methanol at room temperature (r.t.), followed by the addition of 1,3-diamino-2-propanol (0.090 g, 1 mmol) and triethylamine (0.304 g, 3 mmol) in a methanol-water mixture (5:1, 50 ml). The product is well formed dark blue crystals (yield 0.11 g ca. 49%). *Anal*. Found: C, 23.9; H, 3.5; N, 18.7. Calc. for $C_{18}H_{30}ClCu_4N_{12}O_6$: C, 24.0; H, 3.4; N, 18.8%. Absorption spectra [λ_{max} (nm) (ε, $dm^3\ mol^{-1}\ cm^{-1}$)]: (DMF solution) 275 (14 500), 345 (6270), 604 (600).

CAUTION! Perchlorate salts of metal complexes are potentially explosive and should be handled in small quantities with care.

2.2. Crystal structure determination and refinement

X-ray data collection was carried out on an Enraf-Nonius CAD4 diffractometer [15] using a single crystal with dimensions $0.20 \times 0.15 \times 0.10$ mm with graphite monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). Precise unit cell dimensions were determined by least-squares refinement on the setting angles of 25 reflections ($2.52^\circ \leq \theta \leq 13.83^\circ$) carefully centered on the diffractometer. Data were collected at 298 K using the ω–2θ scan technique. A total of 4520 reflections were recorded, with Miller indices $h_{min} = -11$, $h_{max} = 5$, $k_{min} = -11$, $k_{max} = 0$, $l_{min} = -20$, $l_{max} = 20$.

2.2.1. Crystal data

$C_{18}H_{30}ClCu_4N_{12}O_6$, $M = 449.8$, monoclinic, space group $P2_1/c$, $a = 9.490(1)$, $b = 9.221(2)$, $c = 16.980(3)$ Å, $\beta = 95.83(1)^\circ$, $V = 1478.2(4)$ $Å^3$, $Z = 2$, $D_{calc} = 2.021$ g cm^{-3}, $\mu = 29.82$ cm^{-1}, $F(000) = 904$.

The structure was solved by direct methods using SHELXS-97 [16] and refined by full-matrix least-squares and Fourier techniques using SHELXL-97 [17]. The positions of the H atoms bonded to C atoms were calculated (C–H distance 0.96 Å), and refined using a riding model, and H atom displacement parameters were restricted to be $1.2U_{eq}$ of the parent atom. Final $R(F^2)$ and $wR(F^2)$ factor as were 0.0340 and 0.0753 and goodness-of-fit = 1.002 for 244 parameters using the I values of 1929 ($I > 2\sigma(I)$) reflections. The highest and the lowest peaks in the final difference map were 1.066 and -0.614 e $Å^{-3}$.

2.3. Susceptibility measurements

Magnetic susceptibility measurements of the powdered sample were performed on a Faraday-type magnetometer consisting of a CAHN D-200 microbalance, a Leybold Heraeus VNK 300 helium flux cryostat and a Bruker BE 25 magnet connected with a Bruker B-Mn 200/60 power supply in the temperature range 4.5–306.8 K. Details of the apparatus have already been described [18]. Diamagnetic corrections of the molar magnetic susceptibility of the compound were applied using Pascal's constants [1]. The applied field was ≈ 1.2 T. Magnetic moments were obtained from the relation $\mu_{eff} = 2.828(\chi T)^{1/2}$.

2.4. Measurements

Chemical analyses were performed by the Scientific and Technical Research Council of Turkey. The UV–Vis spectra of the title compound were recorded on a Perkin–Elmer Lambda-2 spectrophotometer using 1 cm quartz cells and solution concentrations of 10^{-4} mol l^{-1}.

3. Results and discussion

3.1. X-ray crystal structure

A perspective drawing of the title compound is shown in Fig. 1 [19] and consists of a tetranuclear copper(II) complex and perchlorate anion which is bound to the tetrameric unit by hydrogen bonds. Selected bond lengths and angles are summarized in Table 1. In the solid state, the title compound resides on an inversion center so that only half of the molecule is crystallographically unique. The structure contains a pair of dimeric units. The two copper(II) centers are bridged by the alkoxide oxygen atom of the ligand and a pyrazolate ligand and these two dimeric units are linked by two pyrazolate ligands, Cu(1) is bound to Cu(2) and Cu(1a) is bound to Cu(2a) to give the investigated tetrameric copper(II) complex.

In the title compound two different types copper coordination geometry is observed. The coordination around the Cu(1) center (or Cu(1a)) can be described as almost planar formed by N(2), N(4), N(5) and O(1). The maximum deviation of the atoms from the least-squares plane does not exceed 0.04 Å. The deviations of the atoms from the least-squares plane are as follows: N(2) = 0.039(2), N(4) = −0.021(2), N(5) = 0.039(2), O(1) = −0.030(2) Å, while Cu(1) deviates by −0.027(2) Å. However, a small in-plane distortion is reflected by the bond angles N(4)–Cu(1)–O(1) = 179.6(1)° and N(5)–Cu(1)–N(2) = 167.3(2)°. The coordination geometry around the Cu(2) center (or Cu(2a)) is tetrahedrally distorted square planar. The Cu(2) atom is coordinated by N(3), N(6), N(1a) and O(1a). The tetrahedral distortion is evidenced with the distances of the five atoms from the least-squares plane through the atoms: N(3) = −0.331(3), N(6) = 0.361(2), N(1a) = −0.347(2), O(1a) = 0.441(2), Cu(2) = −0.124(2) Å. Besides that the tetrahedrally distorted square planar geometry is reflected by trans-atom bond angles smaller than 180°: N(3)–Cu(2)–O(1a) = 174.4(2)° and N(6)–Cu(2)–N(1a) = 166.7(2)°.

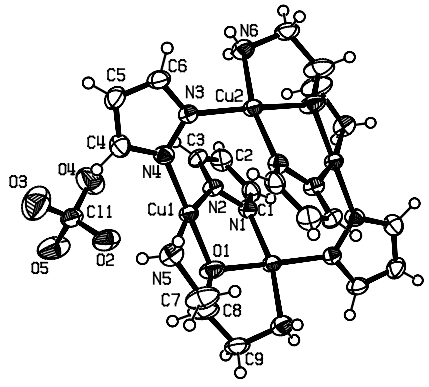

Fig. 1. View of the molecule. Displacement ellipsoids are plotted at the 50% probability level and H atoms are presented as spheres of arbitrary radii.

Table 1
Selected bond lengths (Å) and angles (°) characterizing the inner coordination sphere of the copper ions (see Fig. 1 for labelling scheme adopted)

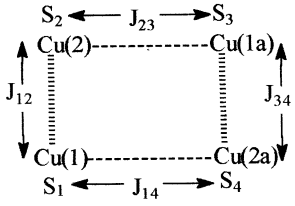
Bond lengths	
N(1)–Cu(2)	1.959(4)
N(2)–Cu(1)	1.963(4)
N(3)–Cu(2)	1.958(4)
N(4)–Cu(1)	1.948(3)
N(5)–Cu(1)	2.024(4)
N(6)–Cu(2)	2.021(4)
O(1)–Cu(1)	1.921(3)
O(1)–Cu(2)	1.935(3)
Bond angles	
Cu(1)–O(1)–Cu(2)	113.4(2)
O(1)–Cu(1)–N(4)	179.6(2)
O(1)–Cu(1)–N(2)	84.6(2)
N(4)–Cu(1)–N(2)	95.8(2)
O(1)–Cu(1)–N(5)	83.3(2)
N(4)–Cu(1)–N(5)	96.4(2)
N(2)–Cu(1)–N(5)	167.3(3)
O(1a)–Cu(2)–N(3)	174.4(2)
O(1a)–Cu(2)–N(1)	84.5(2)
N(3)–Cu(2)–N(1a)	96.8(2)
O(1a)–Cu(2)–N(6)	82.7(2)
N(3)–Cu(2)–N(6)	96.3(2)
N(1a)–Cu(2)–N(6)	166.7(2)

In the structure, the four copper atoms are situated at the corners of a nearby rectangle with side lengths of 3.223(2)Å (Cu(2)–Cu(1a)) and 3.575(2)Å (Cu(1)–Cu(2)). Cu(1)–Cu(2)–Cu(1a) and Cu(2)–Cu(1)–Cu(2a) angles are 88.8(2)° and 91.2(2)°, respectively. The Cu–O–Cu bridging angle is 113.4(2)° in the super-exchange pathway and in good agreement with data of similar compounds [12,13].

3.2. UV–Vis spectroscopic properties

We have investigated the UV–Vis spectroscopic properties of the title compound to gain insight into the coordination geometry of the title compound. The spectra of the complex were recorded in DMF in the range 250–700 nm. UV–Vis spectroscopic studies revealed that the title compound has ligand-metal charge transfer band at $\lambda = 345$ nm. The bands near 275 nm are attributed to $\pi \rightarrow \pi^*$ transitions within the ligands. A broad d–d transition is observed at near 605 nm is indicative of a square-based geometry around copper(II).

3.3. Magnetic properties



Magnetic susceptibility measurements for a powdered sample of the complex were performed by the Faraday method in the temperature range 4.5–306.8 K. The

observed and calculated magnetic moment ($\mu_{eff} = 2.828 (\chi T)^{1/2}$) decreases with decreasing temperature. The μ_{eff} value per copper center at room temperature is 2.49 μ_B for the title compound. This value is higher than the spin-only value of 1.73 μ_B for a copper(II) ion; this means that the title compound is weakly antiferromagnetically coupled. The magnetic susceptibilities and the effective magnetic moments versus temperature are shown in Fig. 2. The title compound shows a maximum in magnetic susceptibility at approximately 208 K which is typical of antiferromagnetic behavior. The rapid increase in magnetic susceptibility at low temperatures is due to the presence of a small amount of monomeric impurity (1%) which are commonly encountered in such systems [20].

The molar magnetic susceptibility is calculated by using the isotropic (Heisenberg) exchange Hamiltonian which was first used by Kambe for this purpose [21] (Eq. (1)).

$$H = -2\sum_{ij} JS_i \cdot S_j \quad (1)$$

In keeping with the structure of the title compound, the magnetic data were analyzed with the spin Hamiltonian for a rectangular system of four S = 1/2 spins.

$J_{12} = J_{34} = J_1$ and $J_{14} = J_{23} = J_2$

J_1 and J_2 values cannot be determined separately by a fitting procedure. This may show that as a result of antiferromagnetic coupling only the first two lowest energy levels (S = 1 first excited state and S = 0 ground state) are thermally populated at temperatures up to ≈ 300 K. Consequently, the tetrameric complex can be described magnetically as a two-energy level model. Therefore, the experimental data were fitted to the Bleaney–Bowers equation [22] which is used for copper dimers. A fixed value of 60×10^{-6} cm^3 mol^{-1} per Cu atom was employed for the temperature-independent paramagnetism (N_a) contribution. This fit leads to $J = -98.5$ cm^{-1}, $g = 1.96$, $x_p = 1\%$. x_p is the molar fraction of a monomeric impurity.

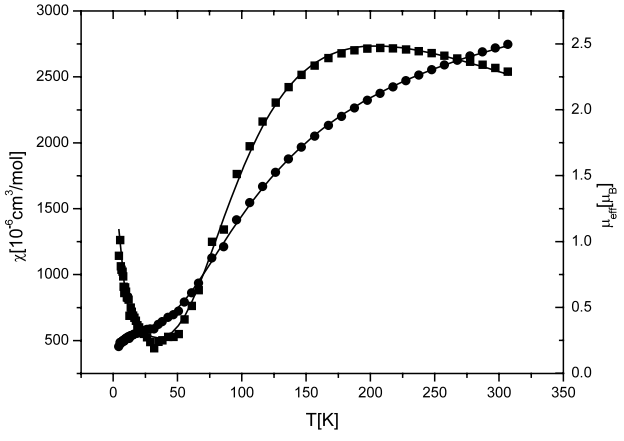


Fig. 2. Molar susceptibility (■) and effective magnetic moment (●) per copper(II) vs. temperature curve.

The good quality of fit to the dimer equation supports that only the first singlet–triplet gap is accessible in magnetic susceptibility measurements. This treatment also shows that two J values (J_1 and J_2) are strongly different from each other. Consequently, the title compound can be considered as being composed of two weakly associated pairs of dimers. At this point, we should decide which of the possible magnetic exchange pathway is more important, Cu(1)–Cu(2a) via the oxygen and pyrazolate bridge or Cu(1)–Cu(2) via the secondary pyrazolate bridge.

3.4. Magnetostructural correlations

Magnetostructural correlations have been established for dinuclear copper(II) complexes in the last two decades [4,5,23–25]. All these correlations show that a linear relationship exists between exchange integral and the Cu–O–Cu bridging angle [4]. This factor also influences the sign of the exchange interaction. In all cases the bridging angle at the point where the sign of the exchange interaction changes is nearly the same, namely 97.5° ±1°. In the title compound the Cu–O–Cu angle is larger than 100° (Cu(1)–O(1)–Cu(2a) = 113.4(2)°). Therefore, if magnetostructural correlations of dinuclear copper(II) complexes are considered for the title compound, antiferromagnetic interactions would be expected. In addition, recent studies have shown that antiferromagnetic interactions via pyrazolate bridges are weaker than substituted oxide bridges [26–29]. As a result of the above conclusions and owing to the shorter bond distance of Cu(1)–Cu(2a) than the bond distance of Cu(1)–Cu(2), the alkoxide oxygen can be considered as a main pathway of magnetic exchange interaction. So, the magnetic super exchange interaction via the oxygen and pyrazolate bridge for Cu(1)–Cu(2a) are a more important pathway than via the secondary pyrazolate bridges between Cu(1) and Cu(2) or Cu(1a) and Cu(2a). However, when we consider the linear dependency between 2J and the Cu–O–Cu bridging angle, as reported by Hatfield et al. [4] the 2J value of the title compound is relatively small. In the case of similar tetranuclear copper(II) complexes, weak antiferromagnetic coupling have been also observed [12,13].

In this study, we considered overlap interactions between the metal d-orbitals and ligand orbitals by molecular orbital calculations to explain the weak antiferromagnetic coupling of the title compound.

The sign and the magnitude of the coupling constant is influenced by bridging ligands between the metal ions because of the various types of overlap interactions between the metal d-orbitals and the ligand orbitals. The difference in the magnitude of the coupling constant may be explained by metal–ligand overlap interactions. Single μ-alkoxo-bridged dinuclear copper complexes are antiferromagnetically coupled [30,31]. When the Cu–O–Cu angle is larger than 90°, in such systems the d_a overlap with oxygen p_x is larger than d_s with p_y, so d_a and d_s split as illustrated in (Fig. 3(a)). Thus, $d_a{}^{I}$ and $d_s{}^{I}$ molecular orbitals are formed. The larger energy seperation of $d_a{}^{I}$ and $d_s{}^{I}$ gives a stronger antiferromagnetic interaction. In the presence of a second bridging ligand according to the orbital symmetries, $d_a{}^{I}$ and $d_s{}^{I}$ interact with antisymmetric (ψ_a) and symmetric (ψ_s) combinations of ligand orbitals, respectively. This interaction forms new molecular orbitals $d_a{}^{II}$ and $d_s{}^{II}$ (Fig. 3(b)). The energy difference between the two new molecular orbitals ($d_a{}^{II}$ and $d_s{}^{II}$) determines the magnitude of the $-2J$ value [32].

According to Hoffmann, the second bridging ligand can act in a complementary or countercomplementary fashion with the alkoxide oxygen atom to enhance or attenuate the strength of the antiferromagnetic coupling [32]. We investigated the overlap interaction between the HOMO's of the pyrazolate nitrogens and the magnetic d-orbitals to understand the influence of the pyrazolate ligand (see Fig. 4). Molecular orbitals of the pyrazolate ion have been calculated by the ab initio restricted Hartree–Fock method using the GAUSSIAN-98 computer program [14]. STO-3G [33] minimal bases sets were adopted for the carbon and nitrogen atoms. The HOMO's are expressed in terms of LCAO's in the appendix for the title compound.

Nishida et al. [34] showed that the energies of $d_a{}^{II}$ and $d_s{}^{II}$ depend on two factors (i) energies of the interacting

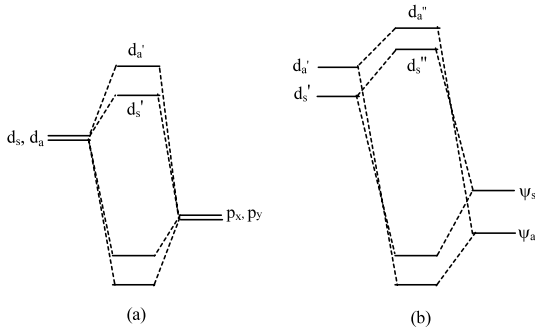

Fig. 3. The orbital energy level diagrams showing the interaction between the magnetic orbitals and bridging group orbitals (a) for single-alkoxide-bridged system; (b) for additional bridging ligand.

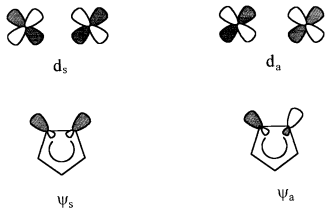

Fig. 4. Orbital symmetry combinations of metal d-orbitals and pyrazolate HOMOs.

orbitals and (ii) the overlap integrals between the interacting orbitals. When ψ_s is higher in energy than ψ_a, the energy gap between $d_a{}^{II}$ and $d_s{}^{II}$ is decreased. In our complex, since the orbital energy of ψ_s is higher than that of ψ_a by 0.260 eV, the energies of the interacting orbitals cause the pyrazolate bridge to work in a countercomplementary fashion with the alkoxide bridge. In additon, overlap integrals of the interacting orbitals is an important factor to increase or decrease the energy separation of $d_a{}^{II}$ and $d_s{}^{II}$. If ψ_s overlaps more effectively with d_s than ψ_a with d_a, the overlap integrals of the interacting orbitals may affect the pyrazolate bridge to act in a countercomplementary fashion with the alkoxide bridge again.

We determined approximate values for the overlap integrals $S(d_a,\psi_a)$ and $S(d_s,\psi_s)$ and calculated the difference between $S(d_a,\psi_a)$ and $S(d_s,\psi_s)$ for the title compound. The rigorous definition and the process of the calculation are given in the Appendix A. The difference between $S(d_a,\psi_a)$ and $S(d_s,\psi_s)$ is denoted as $S(a-s)$.

In the case of the title compound $\alpha = 5.8°$,

$$\begin{aligned} S(a-s) &= S(d_a,\ \psi_a) - S(d_s,\ \psi_s) \\ &= 0.1556(\cos(11.6)) \cdot S(3d,\ 2s) \\ &\quad - 0.0425(\sin(11.6)) \cdot S(3d_p,\ 2p_p) \\ &\quad - 0.3916(\cos(11.6)) \cdot S(3d_s,\ 2p_s) \end{aligned} \tag{5}$$

The rough overlap integrals are evaluated by using data from Jaffe and Kuroda [35,36]: $S(3d,\ 2s) \approx 0.04$, $S(3d_p,\ 2p_p) \approx 0.02$, $S(3d_s,2p_s) \approx 0.06$. For the title compound $S(a-s)$ is negative,

$$S(d_s,\ \psi_s) > S(d_a,\ \psi_a)$$

According to factor (ii) the pyrazolate bridge acts in a countercomplementary fashion to reduce the energy seperation between $d_a{}^{II}$ and $d_s{}^{II}$.

In the title compound, the energy spacing of the pyrazolate HOMO's indicates that the pyrazolate ligand and alkoxide oxygen act in a countercomplementary fashion. Since the symmetric molecular orbitals overlap is more effective (note that $S(a-s)$ is negative) this overlap factor supports the energy factor. Thus, the weak antiferromagnetic coupling of the complex is interpreted in terms of the countercomplementary effect

of the different bridging ligands which participate in the super-exchange interactions.

4. Concluding remarks

The title compound can be considered as being composed of two weakly associated pairs of dimers. The magnetic exchange interaction occurs more possibly via the alkoxide oxygen and pyrazolate bridge. The observed relatively weak antiferromagnetic exchange within the tetranuclear compound is explained by the countercomplementary behavior of the bridging pyrazolate ion which participates in the super-exchange interaction with alkoxide oxygen by means of ab initio restricted Hartree–Fock molecular orbital calculations.

5. Supplementary material

Further details of the structure determination, including atomic coordinates, bond lengths and angles, thermal parameters of all non-hydrogen atoms for the structure are available on request as supplementary material from The Director, Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http//www.ccdc.cam.ac.uk) (CCDC deposition number, 162126).

Acknowledgements

We thank Professor Dr. W. Haase for giving us the opportunity to do of magnetic susceptibility measurement. This work was supported by the Research Fund of the University of Ankara under grant number 98-25-00-03.

Appendix A: Determination of the orientation of magnetic d-orbitals

The orientation of the magnetic d-orbitals was determined according to Nishida [34]. In order to fulfill the requirement of maximum overlapping, the following function was minimized:

$$F(\alpha) = \alpha^2 + \beta^2 + \gamma^2 + \delta^2 \quad (1')$$

where, α, β, γ and δ are the angles formed by the coordination bonds and the axes of the d-orbitals (Fig. 5).

For the title compound, when the value of

$$\beta = \alpha + 90 - 95.76$$

$$\gamma = \alpha + 180 - 95.76 - 96.36$$

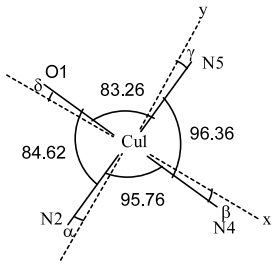

Fig. 5. Projection of Cu1 and donor atoms onto the best plane formed by these atoms (the broken lines are the axes of the magnetic d-orbital) for the title compound.

$$\delta = \alpha + 270 - 95.76 - 96.36 - 83.26$$

are used in Eq. (1), Eq. (1) becomes

$$F(\alpha) = \alpha^2 - 11.63\alpha + 52.25 \quad (2)$$

$$\frac{dF(\alpha)}{d\alpha} = 2\alpha - 11.63 \quad \alpha = 5.8^\circ$$

Determination of overlap integrals between d_s and ψ_s and between d_a and ψ_a:

The HOMOs are expressed in terms of LCAOs in Eqs. (3) and (4) for the title compound

$$\psi_s = 0.1272[s(N1) + s(N2)] + 0.2865[p_x(N1) - p_x(N2)] + 0.3167[p_y(N1) + p_x(N2)] \quad (3)$$

$$\psi_a = 0.2372[s(N1) - s(N2)] + 0.1221[p_x(N1) + p_x(N2)] + 0.0920[p_y(N1) - p_y(N2)] \quad (4)$$

According to Nishida, when the x and y axes in Fig. 5 are rotated by α, the d_1-orbital is expressed in terms of the new coordinate system as

$$d_1 = (\cos(2\alpha))d_{x^2-y^2} + (\sin(2\alpha))d_{xy} \quad (5')$$

The ψ_s and ψ_a orbitals of the pyrazolate ion can be expressed as the sum of the orbitals on N1 and N2 and the neigbouring carbon atoms

$$\psi_s = \phi_{s1} + \phi_{s2} + \phi_{sc} \quad (6)$$

$$\psi_a = \phi_{a1} + \phi_{a2} + \phi_{ac} \quad (7)$$

These orbitals can be expressed in terms of the new coordinate system in which the y axis is on the Cu1–N2 bond.

$$\phi_{s1} = 0.1272[s(N1) + s(N2)] + 0.2865[(\cos 30)p_x + (\sin 30)p_y] + 0.3167[-(\cos 60)p_x + (\sin 60)p_y]$$

$$\phi_{s1} = 0.1272s + 0.0897p_x + 0.4176p_y \quad (8)$$

From Eqs. (5) and (8)

$$S(d_1, \phi_{s1}) = 0.1272(\cos(2\alpha)) \cdot S(3d, 2s) + 0.0897(\sin(2\alpha)) \cdot S(3d_p, 2p_p) + 0.4176((\cos(2\alpha)) \cdot S(3d_s, 2p_s)$$

Since $d_s = (d_1 - d_2)/2^{1/2}$ and $S(d_2, \phi_{s2}) = -S(d_1, \phi_{s1})$

$$S(d_s, \psi_s) = 2S(d_1, \phi_{s1})/2^{1/2}$$

The overlap integral can be expressed as

$$\begin{aligned} S(d_s, \psi_s) = {} & 0.1796(\cos(2\alpha)) \cdot S(3d, 2s) \\ & + 0.1269(\sin(2\alpha)) \cdot S(3d_p, 2p_p) \\ & + 0.5906((\cos(2\alpha)) \cdot S(3d_s, 2p_s) \end{aligned} \quad (9)$$

In a similar way, $S(d_a,\psi_a)$ was obtained as follows

$$\begin{aligned} S(d_a, \psi_a) = {} & 0.3352(\cos(2\alpha)) \cdot S(3d, 2s) \\ & + 0.0844(\sin(2\alpha)) \cdot S(3d_p, 2p_p) \\ & + 0.1990((\cos(2\alpha)) \cdot S(3d_s, 2p_s) \end{aligned} \quad (10)$$

where α is the angle between the Cu–N bond vector and the nearest lobe of the local magnetic d-orbital.

the published methods [19]. The infrared spectra (4000–400 cm^{-1}) were recorded from KBr disks with a SHIMADZU IR-470 spectrometer. UV–Vis spectra of the ligands and complexes were recorded on a JASCO model 7850 spectrophotometer. ^1H NMR spectra were obtained using a Bruker DRX 500 AVANCE spectrometer.

2.2. Preparation of $WOS_3Cu_3Pz_3Cl$ (**1**)

$[NH_4]_2[WOS_3]$ (0.2 g, 0.6 mmol) was partially dissolved in analar acetone (50 ml). Solid CuCl (0.12 g, 1.2 mmol) was added to the solution and the mixture was stirred at room temperature for 45 min. in an erlenmeyer flask. This produced a yellow–orange solution. Pyrazole (0.16 g, 2.3 mmol) was added to this solution and the mixture was stirred for another 2 h. The precipitate was filtered off and the filtrate was vacuum evaporated to dryness, leaving a yellow-orange solid. This product was washed with diethyl ether (2×2 ml) and vacuum dried for 6 h. Yield 55%. *Anal.* Calc. for $C_9H_{12}ClCu_3N_6OS_3W$: C 14.87, H 1.65, N 11.56. Found: C 14.6, H 2.0, N 12.0%.

2.3. Preparation of $[PPh_4]_4[\{WOS_3(CuCNSe)_3\}_2]$ (**2**)

$[PPh_4]_2[WOS_3]$ (0.2 g, 0.2 mmol) was partially dissolved in analar acetone (70 ml). Solid CuCl (0.06 g, 0.61 mmol) and KSeCN (0.09 g, 0.6 mmol) were added to the solution and the mixture was stirred for 12 h. A small amount of yellow precipitate was removed by filtration. Yellow crystals suitable for X-ray crystallography were obtained by slow evaporation of the solvent; they were washed with diethyl ether and air dried. Yield 60%. *Anal.* Calc. for $C_{102}H_{80}Cu_6N_6O_2P_4S_6Se_6W_2$: C 41.38, H 2.72, N 2.84. Found: C 41.0, H 2.8, N 2.8%.

2.4. Attempted preparation of $[PPh_4]_2[Co(WO_2S_2)_2(CuNCS)_2]$

The method was similar to that for **2**. $[PPh_4]_2[Co(WO_2S_2)_2]$ (0.245 g, 0.189 mmol) [20] was dissolved in acetonitrile (50 ml). Solid CuCl (0.752 g, 0.75 mmol) and KSCN (0.732 g, 0.75 mmol) were added to the solution. The resulting mixture was stirred for 5 h. and then filtered. The filtrate was vacuum evaporated to dryness. A solution of this complex in dichloromethane is unstable and storing the solution at room temperature (r.t.) in air deposited a few crystals identified crystallographically as $[PPh_4]_2[Cu(NCS)_4]$. Yield and analysis were not measured.

2.5. X-ray crystallography

Crystal data together with other relevant information on the structure determinations are listed in Table 1. All measurements were made on a Bruker SMART CCD diffractometer with narrow frames (0.3° in ω). Mo Kα radiation ($\lambda = 0.71073$ Å) was employed for data collection at 160 K. Absorption corrections were based on the high redundancy of symmetry-equivalent and repeated reflections. The structures were solved by direct methods and refined by full-matrix least-squares on all F^2 values. Non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in calculated positions and refined with isotropic displacement parameters, riding on their parent atoms. The dimeric bridged anion of compound **2** lies on an inversion center, while the monomeric anion of compound **3** has crystallographic twofold rotation symmetry. In compound **1**, twofold disorder with relative occupancies 0.533:0.467(16) was resolved for one Cu atom and its attached Pz ligand; refinement involved restraints on the geometry and displacement parameters of the disordered ligand, and the disorder reduces the overall precision of the structure. Programs were standard Bruker AXS control and integration software, SADABS [21] and SHELXTL [22].

3. Results and discussion

3.1. Infrared spectra

The infrared spectrum of complex **1** shows bands at 3100–3400, 1516, 1462, 1132, 1060 and 759 cm^{-1} characteristic of the pyrazole ligands. The W–S stretching frequency of $[WOS_3]^{2-}$ in the complex (433 cm^{-1}) is shifted to a lower frequency relative to that for free $[WOS_3]^{2-}$ (470 cm^{-1}, ammoniun salt) [19]. This indicates a decrease in the stretching force constant, showing that the $[WOS_3]^{2-}$ ligand is coordinated through the sulfur atoms. Furthermore, the W–O stretching frequency (as expected when W–O is terminal) shifts to higher frequency (905–916 cm^{-1}) compared with the average ν(W–O) frequency of free $[WOS_3]^{2-}$ (860 cm^{-1}).

In the infrared spectrum of complex **2**, two bands are found for the ν(CN) stretching mode at 2084 cm^{-1} (for bridging SeCN ligands) and 2048 cm^{-1} (for terminal N-bonded SeCN ligands). This assignment was confirmed by the crystal structure of the complex. The terminal ν(W–O) stretching freqency has been identified as a strong absorption band at 922 cm^{-1} in accordance with literature values [23]. The band at 429 cm^{-1} is assigned to the stretch of the W–S bridges.

The infrared spectrum of complex **3** exhibits a ν(CN) band at 2075 cm^{-1}, which indicates monodentate N-coordination of the SCN^- anion to the Cu^{2+} ion [24].

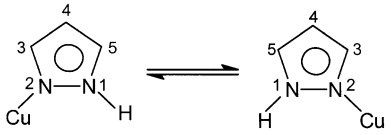
3.2. Solution spectroscopic studies

3.2.1. Electronic spectra



The UV–Vis spectrum of complex **1** shows the existence of $[WOS_3]^{2-}$ in the cluster by the internal transitions of this anion. The major peak in the electronic spectrum of $WOS_3Cu_3Pz_3Cl$ (345 nm) is red-shifted from the position of this transition in the free $[WOS_3]^{2-}$ ion (334 nm). The spectrum of the complex also shows a shoulder in the region 212–203 nm, which corresponds to the $d\pi \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions [25]. The UV–Vis spectrum of complex **2** is essentially the same as that of complex **1**.

3.2.2. ^1H NMR spectrum

Though the polymeric structure of the title compound **1** was established in the solid state by X-ray crystallography, it was of interest to investigate both the integrity and rigidity of this structure in solution.

The proton magnetic resonance spectrum of the complex in d^6-acetone indicates magnetic equivalence of the H3 and H5 protons of the pyrazole ring at r.t. The spectrum exhibits resonances at 7.9 ppm (br, H-3, 5; Pz) and 6.6 ppm (H4, Pz). This result indicates that rapid exchange is occurring between coordinated copper and the H1 proton of the pyrazole ring (Scheme 1).

^{1}H NMR spectra were recorded down to −65°C in d_6-acetone. The integrals of these resonances are in the ratio of 2:1 (H3, H5: H4). The r.t. ^{1}H NMR spectrum also exhibits three broad peaks at 7.38, 7.50 and 7.61 ppm, which are due to the N–H proton of the pyrazole rings. As the temperature decreases from r.t. to −65 °C, the spectrum shows 1:1 resonances at 7.45 ppm (H3) and 7.8 ppm (H5) due to the non-equivalent H5 and H3 protons of the pyrazole ring, which would indicate proximity to the slow exchange limit between coordinated copper and the N–H proton of the pyrazole ring. The ^{1}H NMR spectrum at −65 °C also exhibits a resonance at 6.2 ppm due to H4, and three other resonances at 7.4, 7.5 and 7.6 ppm due to the N–H proton of pyrazole rings.

Scheme 1.

3.2.3. ^{13}C NMR spectrum

The ^{13}C NMR spectrum of the complex in DMSO at r.t. exhibits two main resonances at 105.23 and 134.65 ppm. The resonance at 105.23 ppm is assigned to C4 and the resonance at 134. 65 ppm is assigned to C3 and C5 of the pyrazole ring. This result agrees with the ^{1}H NMR spectrum, which also indicates that rapid exchange of the coordinated copper and N–H proton of the pyrazole ring is occurring at r.t.

3.3. Description of crystal structures

3.3.1. Crystal structure of $WOS_3Cu_3Pz_3Cl$

Views of a single monomer and the polymeric arrangement of this complex are presented in Figs. 1 and 2, respectively. Table 2 lists selected bond distances (Å) and angles (°), excluding any involving the minor disorder component.

In the complex, there are two distinctly different coordination geometries about copper atoms. The Cu(1) and Cu(3) atoms have a distorted trigonal planar geometry with bond angles ranging from 109.8(2)° to 126.8(2)° and they are coordinated by two sulfur atoms from thiometallate ligands with average Cu–S distances of 2.244 Å, and one nitrogen atom from a pyrazole ring with a Cu–N distance of 1.93(2) or 1.961(12) Å, while Cu(2) has a distorted tetrahedral arrangement with bond angles ranging from 96.9(3)° to 122.4(4)° and coordination by two sulfur atoms from thiotungstate with an average Cu–S distance of 2.228 Å and one nitrogen atom from pyrazole ring with a Cu–N distance of 1.974(11) Å. The fourth ligand atom is Cl^- with a Cu–Cl distance of 2.472(4) Å. The Cu–Cl distance is in the range previously reported for tetrahedral copper(I) geometry [26]. Cl(1) has a weak interaction with a neighboring copper atom at 2.781 Å, linking the anions together into infinite chains (Fig. 2). Bonds involving Cu with primary four coordination are somewhat longer than those for three-coordinate Cu.

The coordination of pyrazole to copper appears to have only minor effects on the structure of the pyrazole molecule. The N=N bond distance of 1.35(1) Å [6] in the uncoordinated pyrazole molecule shows little change [1.344(16), 1.355(13) and 1.359(17) Å] on forming a terminal Cu–N bond in the title compound.

In this complex all metal atoms and sulfur atoms form an incomplete cubane-type framework (the WS_3Cu_3 fragment); the eighth vertex opposite W is vacant. Completion of the pseudo-cubane would either involve rare fivefold coordination for Cu(I), or would displace the chloro ligand from its asymmetric bridging role linking the molecules into a polymeric chain. Around

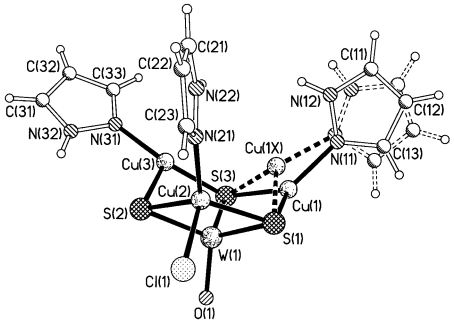


Fig. 1. Structure of the asymmetric unit of $WOS_3Cu_3Pz_3Cl$, with atom labeling, showing the disorder of one copper atom and one Pz ligand.

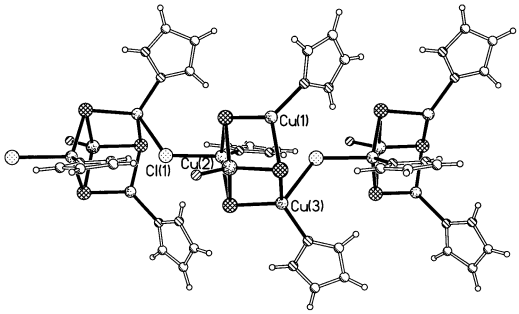

Fig. 2. The polymeric chain structure of $WOS_3Cu_3Pz_3Cl$ formed by chloro bridges, with the Cu and Cl atoms of the basic monomer unit labeled.

S(3)–Cu(3)–S(2)	107.37(15)		

two dozen such structures are known (containing either W or Mo), all with halide or pseudo-halide as the eighth vertex. In compound **1**, the W atom has a distorted tetrahedral coordination geometry with one terminal O and three μ_3-S atoms. Thus the $[WOS_3]^{2-}$ ion acts as a bidentate ligand toward each copper atom, as has been predicted from the vibrational spectrum. All atoms of the WS_3Cu_3 core are distributed in three planar four-membered rings, having the central W atom as common point.

The W–O distance of 1.731(11) Å is typical for a W=O double bond. The average W–S bond length, 2.262 Å, falls in the range of a typical W–S single bond.

The O–W–S angles range from 110.2(4)° to 111.8(5)°, whereas the three S–W–S angles range from 107.82(2)° to 108.25(4)°. Clearly, the W atom has basically retained

the pseudo-tetrahedral geometry of the free $[WOS_3]^{2-}$ anion. The inter-metal Cu···W distances range from 2.603(4) to 2.713(5) Å, and are sufficiently short to permit a direct Cu–W interaction.

Of about 50 structures in the Cambridge Structural Database [27] containing a MOS_3Cu_3 core (M = Mo or W), including those with the eighth vertex of the cube occupied, the majority are monomeric with terminal ligands attached to Cu. Dimers are formed through halide or thiocyanate bridges, and cyanide ligands give polymers. Although there are several known structures with pyridine as a ligand for Cu, compound **1** is the first reported cluster of this kind to contain pyrazole.

3.3.2. Crystal structure of $[PPh_4]_4[\{WOS_3(CuNCSe)_3\}_2]$

This complex is isostructural with $[PPh_4]_4[\{MoOS_3(CuNCS)_3\}_2]$ [28]. The cluster ion consists of two nest-shaped $[WOS_3(CuNCSe)_3]^{2-}$ fragments connected by a pair of CuNCSeCu bridges to form centrosymmetric dimers (Fig. 3). The $[WOS_3(CuNCSe)_3]^{2-}$ anion has a WS_3Cu_3 chromophore with atoms at seven vertices of a trigonally distorted cube; the eighth vertex, opposite W, is vacant. W is tetrahedrally coordinated by one terminal O^{2-} ligand and by three bridging S^{2-} ligands, each of which also bonds to two Cu atoms. In this anion two distinctly different coordination geometries of copper exist. The Cu(1) and Cu(2) atoms adopt trigonal planar geometry (coordinated by two S^{2-} and one $NCSe^-$ ligand bonded via its N atom), while Cu(3) adopts distorted tetrahedral geometry (coordinated by two S^{2-} and one $NCSe^-$ ligand bonded via N, the fourth ligand atom being Se of a $NCSe^-$ ligand of a neighboring anion, acting as a bridge).

The W–O distance of 1.736(3) Å is typical for a W=O double bond. The three W–S bonds, 2.2569(10)–2.2815(10) Å, fall in the range of a typical W–S single bond. The O–W–S angles range from 110.29(10)° to 111.74(10)°, whereas the three S–W–S angles range from 107.53(4)° to 108.46(4)°. Thus, the W atom has retained the pseudo-tetrahedral geometry of the free $[WOS_3]^{2-}$ anion. Cu–S bond lengths range from 2.2540(11) to 2.3111(11) Å, Cu–N from 1.881(4) to 1.909(4) Å, Cu···W distances from 2.6513(5) to 2.6998(6) Å; Cu–Se is 2.6467(7) Å. Bonds involving four-coordinate Cu are somewhat longer than those for three-coordinate Cu. The CuNCSe linkages are essentially linear at C, and only slightly bent at N. The selenocyanate bridges are markedly bent at Se. Table 3 gives selected bond lengths and bond angles for the anion.

Symmetry operation for primed atoms (twofold rotation axis): $-x+1, y, -z+1/2$.

3.3.3. Crystal structure of $[PPh_4]_2[Cu(NCS)_4]$

The crystal structure consists of $[PPh_4]^+$ cations and discrete $[Cu(NCS)_4]^{2-}$ anions (Fig. 4). The bond lengths and bond angles (Table 4) in the $[Cu(NCS)_4]^{2-}$ anion indicate that the copper atom has an only slightly distorted tetrahedral coordination geometry, which is rare for Cu(II) compounds and much more common for Cu(I), and the NCS^- ligands are bonded via their N atoms. N–Cu–N bond angles range from 104.90(18)° to 112.01(17)°. Cu–N distances range from 1.945(3) to 1.959(3) Å. The CuNCS linkages are essentially linear at C and only slightly bent at N. In a previously reported salt of the same anion, this has a geometry intermediate between tetrahedral and square planar, with two opposite N–Cu–N angles of 135.0° and 139.5° [29]; it thus appears to be quite flexible, depending on the counter-ion and crystal packing interactions.

4. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 164129 for compound **1**, 164128 for compound **2**, and 164127 for compound **3**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1IZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

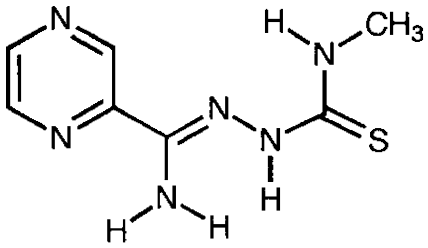

Fig. 1. Representation of pyrazineformamide N(4)-methylthiosemicarbazone, HPzAm4M.

addition of another 25 ml of MeOH, the mixture was refluxed for a minimum of 4 h. Slow evaporation of the MeOH produced the orange pyrazineformamide N4-methylthiosemicarbazone, HPzAm4M, NMR (DMSO-d_6): N(2)H at $\delta = 10.18$, N(4)H at $\delta = 9.72$, N–CH_3 at $\delta = 3.02$ (d), NH_2 at $\delta = 6.95$; m.p., 234–235 °C.

$[Zn(AmPz4M)]_2$ was prepared by electrochemical oxidation of zinc in a solution of HPzAm4M (0.186 mmol, 39.0 mg) in CH_3CN (40 ml) containing 10 mg of tetraethylammonium perchlorate for 1 h at 5 mA. A loss of 6.1 mg of the anode resulted. $[Cd(AmPz4M)]_2$ was prepared by electrochemical oxidation of cadmium in a solution of HAmPz4M (0.25 mmol, 52.5 mg) in CH_3CN (50 ml) containing 10 mg of tetraethylammonium perchlorate for 1 h at 5 mA. A loss of 13.4 mg of the anode resulted.

2.2. X-ray data collection and reduction

Orange crystals of HPzAm4M obtained by slow evaporation of ethanol, dark orange prismatic crystals of $[Zn(PzAm4M)_2]$ grown from MeCN and red prismatic hygroscopic crystals of $[Cd(PzAm4M)_2]$ obtained from MeCN were mounted on glass fibers and used for data collection. Data were collected on a Nonius MACH 3 diffractometer (HPzAm4M) or Bruker Smart CCD area-detector diffractometer at ambient conditions using Cu Kα radiation ($\lambda = 1.54184$ Å) for HPzAm4M and Mo Kα radiation ($\lambda = 0.71073$ Å) for $[Zn(PzAm4M)_2]$ and $[Cd(PzAm4M)_2]$. The structures were solved by direct methods [11] which revealed the position of all non-hydrogen atoms, and refined on F^2 by full-matrix least-square procedure using anisotropic displacement parameters [12]. The hydrogen atoms attached to carbons in the three compounds were located in their calculated positions and were refined using a riding model; the hydrogens attached to nitrogens were found and refined isotropically. Atomic scattering factors were taken from the International Table for X-ray Crystallography [13] and molecular graphics are from PLATON (HPzAm4M) [14] or ORTEP [15].

3. Results and discussion

The molecular structures of HPzAm4M, $[Zn(PzAm4M)_2]$ and $[Cd(PzAm4M)_2]$ are shown in Figs. 2–4, respectively. Table 1 has summaries of crystal data and intensity collection for the three compounds. A selection of bond distances and angles in the thiosemicarbazone fragment and coordination sphere of these complexes are listed in Tables 2 and 3. Hydrogen-bonding interactions for the three compounds are listed in Table 4 and their mean plane deviations, atoms showing the greatest deviation for each plane and the angles between planes are shown in Table 5.

3.1. Crystal structure of HPzAm4M

HPzAm4M crystallizes in the monoclinic space group $P2_1/c$ like 2-pyridineformamide N4-methylthiosemicarbazone, HAm4M [7], while 2-formylpyridine N4-methylthiosemicarbazone, HFo4M, crystallizes in the orthorhombic space group $P2_12_12_1$ with $Z = 4$ [16]. However, HAm4M [7] crystallizes with four unique molecules in the unit cell and $Z = 16$ compared with $Z = 4$ for HPzAm4M. HPzAmM, HAm4M and HFo4M are all E with respect to the imine C=N bond, the conformation that is most often found for heterocyclic N4-alkylthiosemicarbazones [16]. Like other heterocyclic N4-alkylthiosemicarbazones [7,16], the arrangement with respect to the N–C(S) bond, which has considerable double bond character, is also E. This allows for a weak interaction by N14H (Fig. 2) with the imine nitrogen, N12 and another weak interaction occurs between one of the N15 hydrogens and the pyrazine nitrogen, N11, that is unique to these recently studied heterocyclic amide thiosemicarbazones [7]. The bond distances for the thiosemicarbazone moiety of HPzAm4M, HAm4M [7] and HFo4M [16] are not very different except that the two amide thiosemicarbazones, HPzAm4M and HAm4M, have a C17–S1 bond that is approximately 0.05 Å longer and the C17–N13 and

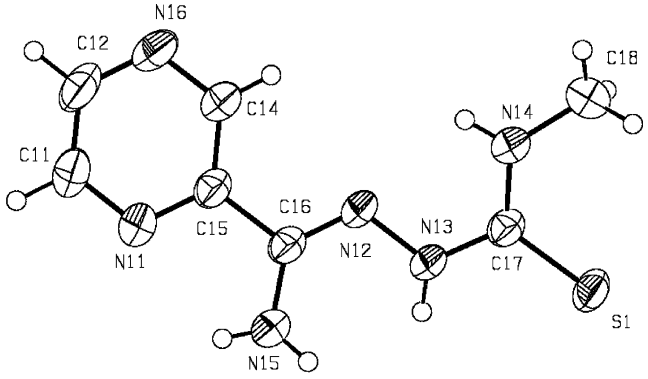

Fig. 2. ORTEP drawing of HPzAm4M with atom numbering scheme and displacement ellipsoids at 50% probability level.

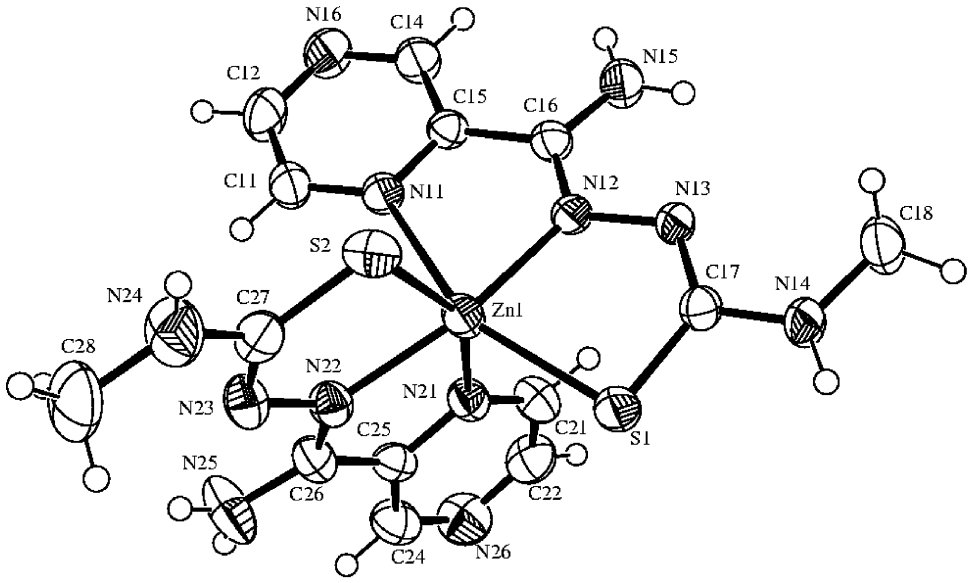

Fig. 3. ORTEP drawing of $[Zn(PzAm4M)_2]$ with atom numbering scheme and displacement ellipsoids at 50% probability level.

C17–N14 bonds are marginally shorter suggesting greater delocalization of electron density. While HPzAm4M and HAm4M have C15–C17–N12 bond angles of approximately 116°, this angle is more than 120° for HFo4M [16], which is consistent with a recent report comparing the structures of 4-formylpyridine and 4-acetylpyridine N(4)-methyl- and N(4)-ethylthiosemicarbazones [17]. The remainder of the thiosemicarbazone bond angles in HPzAm4M, HAm4M [7] and HFo4M [16] are more similar.

As indicated previously, two weak intramolecular hydrogen bonds, N14–H14···N12 and N15–H15B···N11, are present in HPzAm4M. Although the arrangement of HFo4M [16] is the same, the N14–H14···N12 interaction was not found because of the inductive effect of a the aldehyde hydrogen compared with the electron donating amino function. In the four unique molecules of HAm4M, the N14–H14···N12 interaction has an average non-bonding distance of 2.575(5) Å and average angle of 113(4)° which are similar to the values for HPzAm4M (Table 4). The distances and angles for the N15H15B···N11 interaction are essentially the same for HPzAm4M and HAm4M. Unique to HPzAm4M is that H14 is also involved in an interaction with the second nitrogen of the pyrazine ring, N16, which is weaker, based on the H14···N distances, than its intramolecular interaction with N12. The second N15 hydrogen, H15A, interacts weakly with the thione sulfur of a second neighboring molecule.

The thiosemicarbazone moiety of HPzAm4M, C16–N12–N13–C17–S1–N14, has a larger mean plane deviation (Table 5) than HAm4M, 0.0339 Å. The mean plane of the pyridine ring forms an angle of 9.912(12)° with the thiosemicarbazone moiety mean plane, which is smaller than found for HAm4M, 14.1(4)°.

3.2. Crystal structure of [Zn(PzAm4M)$_2$] and of [Cd(PzAm4M)$_2$]

In both complexes, the metal center has a coordination number of six binding the imine and the pyridine nitrogen atoms, as well as the thiolato sulfur, of two anionic tridentate thiosemicarbazone ligands. The coordinated polyhedron about the metal in both complexes is distorted octahedral with the two ligands in a meridional arrangement. This distortion from octahedral symmetry is illustrated by the three angles defined by pairs of *trans* donor atoms and the metal atom, in the range of 151.77(6)°–155.91(9)° for $[Zn(PzAm4M)_2]$ and 138.23(7)°–142.10(5)° for $[Cd(PzAm4M)_2]$, significantly different from 180°. The small bite angle of chelate rings is the main source of distortion as found previously with Group 12 metal complexes, as well as iron(III), cobalt(III) and nickel(II) complexes with bis(heterocylic thiosemicarbazone) metal centers [7a]. The bond angles (Table 3) of the two ligands, which involve the metal ions, are similar in the two complexes, and, in particular, those angles involving donor atoms within the same ligand. The greatest difference occurs in comparing analogous angles between the two ligands; for example, S1–Zn1–N22 is 115.08(7)°, but S2–Zn1–N12 is 112.29(7)°. The difference is even larger in $[Cd(PzAm4M)_2]$, S1–Cd1-N22 is 136.07(5)° and S2–Cd1–N12 is 130.97(5)°. As would be expected due to the larger size of cadmium(II) compared with zinc(II), the bond angles involving the metals ions in the two complexes are significantly different.

In both complexes the M–N(imine) bonds (i.e. M–N12, M–N22) are the shortest metal–ligand distances and in $[Cd(PzAm4M)_2]$ the Cd–S distances are longer than the Cd–N(pyridine) distances. However, in $[Zn(PzAm4M)_2]$ the Zn–S and Zn–N(pyridine) bond distances are similar. $[Fe(Am4M)_2]ClO_4$ and $[Co(Am4M)_2]ClO_4$ have the same order of ligand bond distances [7a] as $[Cd(PzAm4M)_2]$. To date the only zinc and cadmium complexes of HAm4M for which we have obtained crystals are four-coordinate, $[Zn(Am4M)OAc]_2$ and five-coordinate $[Cd(HAm4M)Cl_2]\cdot DMSO$ [18]. Compared with the bond distances of the thiosemicarbazone moiety of HPzAm4M, the following bond distances have been altered in $[Zn(PzAm4M)_2]$ and $[Cd(PzAm4M)_2]$: C17–S1 (and C27–S2) is longer consistent with it formally changing from a double bond to a single bond, N13–C17 (and N23–C27) is shorter consistent with it formally changing from a single bond to a double bond and C17–N14 (and C27–N24) is marginally longer. The remaining bond distances of the thiosemicarbazone moiety, as well as C16–N15 (and C26–N25) are unchanged in the two complexes from their distances in HPzAm4M. The bond angles of the thiosemicarbazone moieties (Table 3) also are different in the two complexes than in HPzAm4M; N13–C17–S1 (and N23–C27–S2) and N14–C17–S1 (and N24–C27–S2) show the largest differences.

These complexes of 2-pyridineformamide thiosemicarbazones feature hydrogen-bonding involving the amide hydrogens, $N15H_2$ [7,18]. One of the hydrogens from both ligands in $[Zn(PzAm4M)_2]\cdot 2CH_3CN$ is involved in hydrogen-bonding, one to sulfur of the other ligand in a neighboring molecule, and the other to the nitrogen of an acetonitrile solvent molecule. In $[Cd(PzAm4M)_2]\cdot 0.5CH_3CN$ only N25–H25...S1 is present, and it is substantially weaker than the analogous interaction in $[Zn(PzAm4M)_2]\cdot 2MeCN$. Unique to these pyrazine thiosemicarbazones is hydrogen-bonding to the second ring nitrogen, N16. Both complexes, as well as HPzAm4M, involve the atom in an intermolecular interaction and it is either of comparable strength or a stronger interaction in the complexes.

Formation of the anion on coordination retains the planarity of the thiosemicarbazone moiety in the two complexes. The average of the mean planes of the two ligands in $[Zn(PzAm4M)_2]$ is less than that of HPzAm4M, but the mean plane average of the two ligands in $[Cd(PzAm4M)_2]$ is comparable to HPzAm4M. Both ligands in each complex have angles between the mean planes of the pyrazine ring and the thiosemicarbazone moiety that are marginally less than

found for HPzAm4M. This is expected because of the greater conjugation present in the anionic ligand compared with the neutral molecule.

4. Supplementary material

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-172573 for HPzAm4M, and, CCDC-172574 for $[Zn(PzAm4M)_2]\cdot 2CH_3CN$, and CCDC-172575 for $[Cd(PzAm4M)_2]\cdot 0.5CH_3CN$. Copies of available material can be obtained, free of charge, on application to the Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: +44-1223-336033 or e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

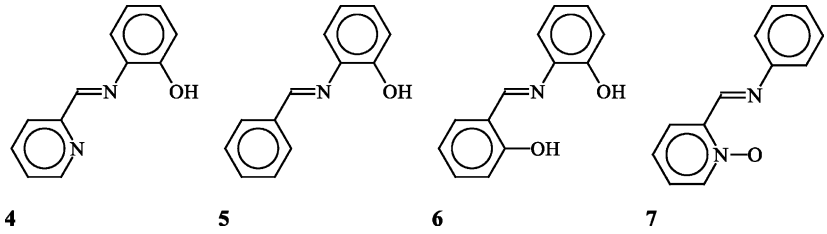
containing one [4] or two pyNO groups [5] were investigated. Finally, since 1989 more complex ligands with the pyNO fragment have appeared in the literature. Besides linear tridentate, tetradentate and potentially pentadentate chelating ligands [6], the syntheses of penta-, hexa- and heptadentate tripodal ligands were described [7]. Recently, some macrocyclic systems were synthesised, which contain two pyNO groups and which are able to form binuclear complexes [8].

We have studied Cu(II) complexes of 2,2′-bipyridine N,N′-dioxide (bipyO) [9] and of 1,10-phenanthroline N-oxide [10]. For bipyO, the first structurally characterised couple of binuclear Cu(II) isomers with and without a pyridine N-oxide bridge was reported. The magnetic properties of these isomers stimulated our general interest in pyridine N-oxide ligands and in the magnetism of the corresponding transition metal complexes. We, therefore, began to undertake a systematic study on such systems [11].

The present contribution deals with the spectral and structural properties of Cu(II) complexes formed with the tridentate Schiff base ligand 2-(*o*-hydroxyphenyliminomethyl)pyridine N-oxide (Hpoxap) prepared according to Scheme 1. Some preliminary data on these complexes have been already reported [12].

2. Experimental



2.1. Preparation of the ligands

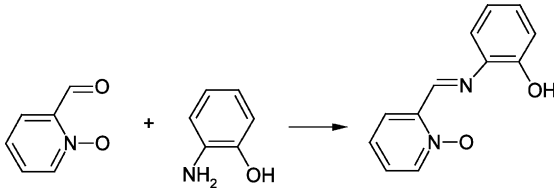
2.1.1. Hpoxap

A solution of 15.5 g (11.0 mmol) of 2-pyridinecarboxaldehyde N-oxide, monohydrate (prepared by the method of Jerchel [13]) in 150 cm^3 of EtOH was added to a solution of 12.0 g (11.0 mmol) of freshly recrystallised *o*-aminophenol in 50 cm^3 of EtOH at room temperature (r.t.) under stirring. The resulting solution was heated to 60–70 °C until a yellow Schiff base began to precipitate. The mixture was cooled to r.t. under stirring. After 2 h the solid was filtered, washed with EtOH and air-dried. Yield 17.2 g (73%). *Anal*. Found: C, 67.43; H, 4.62; N, 13.23. Calc. for $C_{12}H_{10}N_2O_2$: C, 67.28; H, 4.70; N, 13.08%. Melting point (m.p.), 204–205 °C.

2.1.2. Other ligands

The remaining ligands, namely 2-(*o*-hydroxyphenyliminomethyl)pyridine (**4**), *N*-phenyl-methylidene(*o*-aminophenol) (**5**), 2-(*o*-hydroxyphenyliminomethyl)phenol (**6**), and 2-(phenyliminomethyl)pyridine *N*-oxide (**7**) were prepared according to literature recipes [14,15] (Eq. (2)).

4 **5** **6** **7** (2)



2.2. Preparation of the complexes

2.2.1. Cu(poxap)(OAc) (*8*)

A solution of 2.00 g (10 mmol) of $Cu(OAc)_2.H_2O$ in 150 cm^3 of EtOH was slowly added to the mixture of 2.14 g (10 mmol) of Hpoxap in 90 cm^3 of EtOH under rigorous stirring at r.t. The dark red suspension was stirred and slowly heated for 10 min. After that stirring at r.t. was continued for 60 min. The dark solid product was filtered, washed twice with EtOH and air-dried. Yield 2.96 g (88%). *Anal*. Found: C, 50.01; H, 3.67; N, 8.27; Cu, 19.02. Calc. for $C_{14}H_{12}N_2O_4Cu$: C, 50.07; H, 3.60; N, 8.34; Cu, 18.92%. Cube-shaped crystals, suitable for X-ray structure determination, were received from the mother liquid after 6 weeks.

2.2.2. Cu(poxap)(H_2O)(NO_3) (*9*)

A solution of 1.62 g (7 mmol) of $Cu(NO_3)_2 \cdot 3H_2O$ in 25 cm^3 of ethanol was added to the mixture of 1.50 g (7 mmol) of Hpoxap in 100 cm^3 of boiling EtOH under rigorous stirring. The solution became dark red and

Scheme 1. Preparation route of Hpoxap.

crystals were formed in few seconds. The mixture was cooled to r.t. under stirring within 2 h. The solid product was filtered, washed with EtOH and air-dried. Yield 2.28 g (91%). *Anal*. Found: C, 40.30; H, 3.03; N, 11.67; Cu, 17.82. Calc. for $C_{12}H_{11}N_3O_6Cu$: C, 40.40; H, 3.11; N, 11.78; Cu, 17.81%. Brownish-red needles, suitable for X-ray structure determination, were received by the slow diffusion of diethylether vapour into the solution of the complex **9** in EtOH during 4 months.

2.2.3. Remaining complexes Cu(poxap)(BF_4) (**10**), Cu(poxap)(H_2O)(SiF_6)$_{0.5}$ (**11**), Cu(poxap)(ClO_4) (**12**)

These complexes were prepared according to the procedure described for **9**. Yield for **10**, 85%. *Anal*. Found: C, 39.82; H, 2.51; N, 7.69; Cu, 17.33. Calc. for $C_{12}H_9N_2BCuF_4O_2$: C, 39.64; H, 2.50; N, 7.07; Cu, 17.48%. Yield for **11**, 90%. *Anal*. Found: C, 38.57; H, 2.88; N, 7.47; Cu, 16.73. Calc. for $C_{12}H_{11}N_2CuF_3O_3Si_{0.5}$: C, 39.40; H, 3.03; N, 7.66; Cu, 17.48%. Yield for **12**, 89%. *Anal*. Found: C, 38.53; H, 2.39; N, 7.47. Calc. for $C_{12}H_9N_2ClCuO_6$: C, 38.31; H, 2.41; N, 7.45%.

2.3. Instrumentation

IR spectra were recorded in the 200–4000 cm^{-1} range in Nujol suspension between CsI windows (Philips, PU 9800 FT-IR spectrometer). DRIFT spectra were recorded in the 3000–15 000 cm^{-1} range (Nicolet, Magna 750 FTIR spectrometer).

Electronic solution spectra were recorded in the range 11 000–31 000 cm^{-1} (Zeiss, Specord M 40, and Hewlett-Packard, model 8451).

Conductivity measurements—Radelkis, OK-104.
Powder diffraction patterns were scanned using the STOE, STADI-P apparatus.
Electron spin resonance spectra were recorded at X-band frequency (Bruker, SRC 200D).

The mass magnetisation was measured using the SQUID magnetometer at the field $B = 0.1$ T as well as at the AC susceptometer (LakeShore, model 7221). This was converted to the molar magnetic susceptibility and corrected: (i) for the underlying diamagnetism evaluated on the basis of Pascal constants (χ_{dia}(**8**) $= -1.83 \times 10^9$ m^3 mol^{-1} and χ_{dia}(**9**) $= -1.87 \times 10^9$ m^3 mol^{-1}); (ii) for the temperature-independent paramagnetism per copper atom ($\chi_{TIP} = +0.75 \times 10^9$ m^3 mol^{-1}). The effective magnetic moment is calculated as usual: $\mu_{eff}/\mu_B = 798(\chi'_{mol}T)^{1/2}$ where the SI units are employed.

2.4. X-ray structure determination

Single-crystal data collection was performed with an Enraf–Nonius CAD-4 diffractometer [16]. The unit cells were determined by least-squares refinements from θ values of 25 accurately measured reflections. Intensities were recorded with an ω–2θ scan technique, and graphite-monochromated Mo Kα radiation was used. Corrections for Lorentz polarisation and ψ empirical absorption were applied. The crystallographic data are given in Table 1.

The structures were solved by direct methods [17] and all the positions of the non-hydrogen atoms were obtained from the Fourier map. The positions of the hydrogen atoms of the coordinated water molecule in **9** were also obtained from the Fourier map. Refinements were carried out by common least-squares methods [18]. The positions of hydrogen atoms other than water hydrogen atoms were refined with fixed distances from the parent carbon atoms. The function minimised

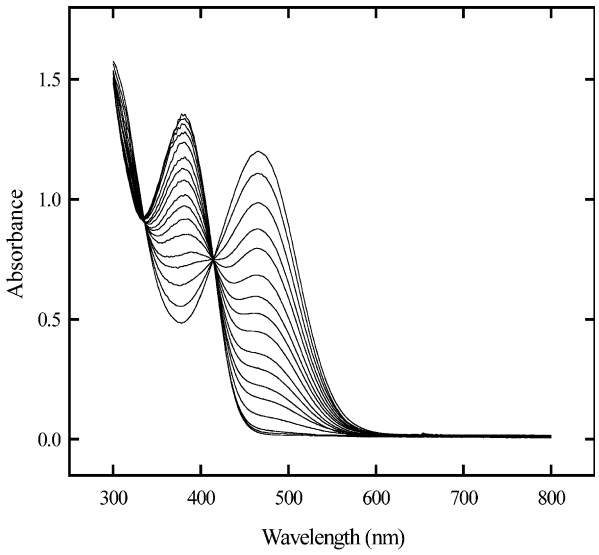

Fig. 1. Titration of Hpoxap with Bu_4NOH in 50% *i*-PrOH/MeOH.

during the least-squares refinements was $\Sigma w(|F_o|-|F_c|)^2$, where $w = 1/[\sigma^2(F_o^2)+(0.0427P)^2+0.0166P]$ for **8**, and $w = 1/[\sigma^2(F_o^2)+(0.0376P)^2+0.1151P]$ for **9**, with $P = (F_o^2+2F_c^2)/3$.

3. Results and discussion

3.1. Electronic spectra of Hpoxap and of the complexes in solution

A yellow solution of Hpoxap in MeOH ($\lambda_{max} = 382$ nm) turns orange–red after deprotonation and a new band appears at 464 nm (Fig. 1). For comparison, the absorption spectra of compounds **4**, **5** and **6** were recorded in MeOH and analogous spectral changes were observed upon addition of base (the absorption maxima were shifted to lower energies). The addition of copper(II) or zinc(II) acetate caused the same sort of red shift (Table 2). Similar shifts of the absorption bands were already described for oxovanadium, chromium and aluminium complexes with **4** and/or **6** [19]. No spectral changes were observed for compound **7** upon addition of NaOH. It is important to note that this is in line with the appearance of new bands in the orange–red range due to phenolate formation and charge transfer from the phenolate oxygen [14,20].

As shown in Table 3, Hpoxap and the poxap anion are subject to solvatochromism.

The UV–Vis spectra of the various complexes Cu(poxap)X ($X^- = NO_3^-$, OAc^-, ClO_4^-, $1/2SiF_6^{2-}$) provide the following information: (i) the strong CT absorption covers the d ← d bands of copper; (ii) there is no anion effect on the spectra (Table 3); (iii) the complex Cu(poxap)(OAc) is subject to solvatochromism. These findings mean that the counteranions X are obviously not coordinated to the copper(II) in solution and the coordination sphere is formed by the anionic ligand poxap and possibly completed by solvent molecules.

The data obtained for the molar conductance of the complexes Cu(poxap)X ($X^- = NO_3^-$, OAc^-, ClO_4^-, $1/2SiF_6^{2-}$, BF_4^-) are in the range typical for 1:1 electrolytes [21] (Table 3). The somewhat lower value of Λ for the acetate complex could indicate that this complex dissociates only partially at the given concentration.

3.2. Crystal structures of Cu(poxap)(OAc) (**8**) and Cu(poxap)(H_2O)(NO_3) (**9**)

Figs. 2 and 3 present views and the atom numbering of Cu(poxap)(OAc) and Cu(poxap)(H_2O)(NO_3), respectively. The coordinates of all atoms are contained in Section 4.

In both structures, copper atoms have approximately square-planar coordination formed by two oxygen atoms and one nitrogen atom from the chelating anionic ligand poxap and one oxygen atom (labelled O(3)) from the acetate anion for **8** or water molecule for **9**. In both complexes the ligand poxap is almost planar. Bond angles around the copper atom for both complexes are similar and are probably determined by the ligand geometry.

In **8**, Cu(1) and O(3) lie in the calculated mean plane of the ligand without significant deviations (Table 4). The plane formed by the non-hydrogen atoms of the acetate anion is almost perpendicular to the $Cu(poxap)^+$ fragment (dihedral angle of 88.1°) with a rather long distance (2.745(1) Å) between O(4) and Cu(1). The O(4) oxygen deviates from the theoretically calculated apical position towards copper by 33.4°. This means that the acetate anion can be considered as a monodentate ligand.

In **9**, the copper atom is five-coordinate with the O(5) atom of the nitrate anion in the apical position, thus completing the square-pyramidal surrounding of the copper. The fragment $Cu(poxap)^+$ possesses some deviation from planarity. For the best fit calculations the Plane 3 was chosen, which is formed by the ligand poxap without the O(2) atom. The deviations of Cu(1)

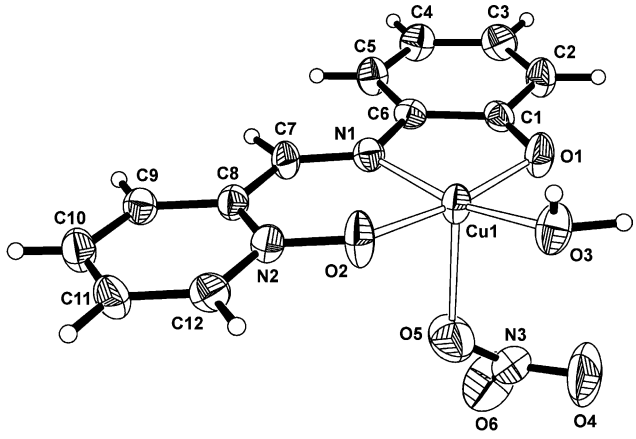

Fig. 3. View of the [Cu(poxap)(H_2O)(NO_3)] (**9**) molecule.

(−0.030 Å), O(2) (0.25 Å) and O(3) (0.40 Å) from this plane were calculated (Table 4). The Cu(1) atom lies nicely in the plane. The deviations of O(2) and O(3) lead to a dihedral angle of 7.6° between Plane 3 and 4 (defined by the four basal donor atoms). The position of Cu(1) is 0.18 Å below Plane 4. It means it is slightly shifted towards the apical O(5) donor. The O(5) atom deviates only by 3.6° from the regular axial position with respect to copper.

It seems to be a common feature of pyridine N-oxides **1** and phenolates **2** that the oxygen atom can deviate from the mean plane of the aromatic ring [22]. However, in **8** and **9**, this deviation is small. The dihedral angle between the N–O group and the normal to the pyridine ring is 92.9° for **8** and 93.9° for **9**, instead of 90°. The values for the N(2)–O(2)–Cu(1) bond angles are 128.4(3)° for **8**, and 127.4(3)° for **9** (Table 5). The relative small deviation of oxygen from the pyridine plane together with the observed values of the N(2)–O(2)–Cu(1) angles and the location of the central Cu(II) atom in the plane of the chelating ligand indicates the sp^2 character of the N-oxide oxygen donor atom.

While the crystal packing of **8** is determined only by van der Waals forces (the nearest interatomic distances between neighbouring molecules Cu(poxap)(OAc),

O(4)···H(7) 2.384(3), O(4)···H(9) 2.506(4), O(2)···H(10) 2.531(5), O(1)···H(12) 2.428(3) and O(3)···H(14) 2.533(3) Å, are too long to be considered as interactions), the molecular packing of **9** is affected by two different types of hydrogen bonds.

One hydrogen bond between coordinated water and the phenolic oxygen atom of the neighboring molecule (O(3)···O(1)′ distance is 2.685(1) Å and O(1)′···H(31)–O(3) angle is 158.3(1)°) forms a dimer. Molecules Cu(poxap)(H_2O)(NO_3) are related centrosymmetrically

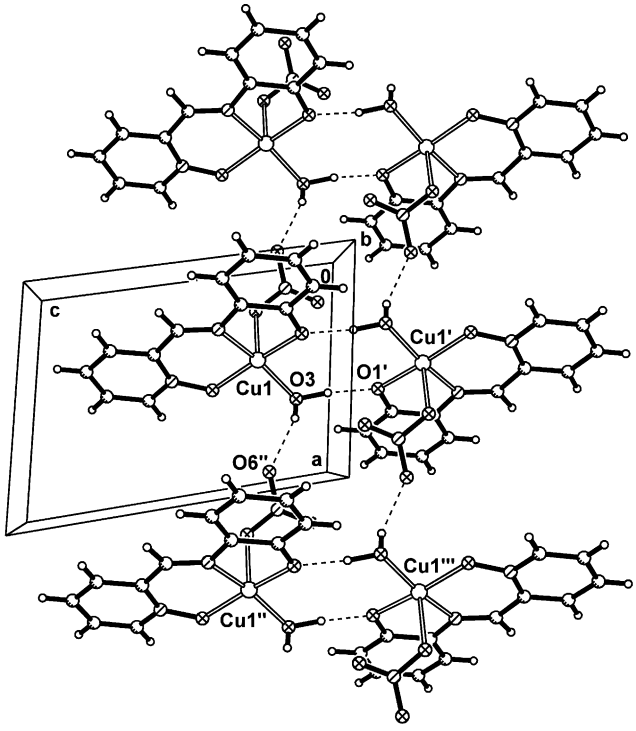

Fig. 4. Crystal packing of **9**. Projection along the *b* axis showing a formation of a 'ladder' structure via a net of hydrogen bonds.

to each other in the dimer. The least-square planes of the neighbouring Cu(poxap)(H_2O)$^+$ fragments in the dimeric unit are parallel as a result of the centre of inversion and separated by 0.12(4) Å.

The dimers are joined into a polymeric chain of dimers (Fig. 4) through another type of hydrogen bond between the other hydrogen atom of coordinated water and the oxygen atom of the apically coordinated nitrato group (O(3)···O(6)″ distance is 2.691(1) Å and O(6)″···H(32)–O(3)) angle is 159.8(1)°).

3.3. ESR spectra

The r.t. X-band ESR spectra of polycrystalline **8** and **9** exhibit signals typical for axial spectra ($g_{||} = 2.19$ and $g_{\perp} = 2.05$ for **8** and $g_{||} = 2.25$ and $g_{\perp} = 2.06$ for **9**) of copper(II) ions with a $d_{x^2-y^2}$ ground state. In frozen ethanol solution (80 K) the hyperfine structure of the $g_{||}$ component is clearly resolved ($g_{||} = 2.26$, $A_{||} = 181$ G and $g_{\perp} = 2.05$ for **8** and $g_{||} = 2.27$, $A_{||} = 173$ G and $g_{\perp} = 2.05$ for **9**). The frozen solution spectrum of **9** exhibits a well resolved feature of medium intensity at $g = 1.90$, which might be attributed to a component of a pair of zero-field split transitions, indicating the presence of a binuclear species in solution. This band disappeared after the addition of pyridine, but the axial character of the spectrum was not affected ($g_{||} = 2.25$, $A_{||} = 177$ G and $g_{\perp} = 2.05$). This indicates that pyridine can substitute the water molecule in the equatorial position and break the hydrogen bonds forming binuclear units. It must be pointed out that no half-field signal was found for solid compound **9**.

3.4. Powder diffraction patterns

As it will be evidenced later, compound **9** exhibits unusual magnetic behaviour. However, the powder sample has been under investigation and thus an important question arises: is the structure of the powder material identical with that determined for the single crystal? For that reason the powder diffraction patterns have been scanned twice: for the original sample of **9a** and a freshly prepared sample of **9b** by the same recipe. According to Fig. 5, the experimental diffraction patters match the theoretical prediction based upon the atomic positions known from the single-crystal data.

3.5. Magnetic data

The temperature variation of the molar magnetic susceptibility and the effective magnetic moment for **8** and **9** is shown in Fig. 6.

The monomeric complex **8** shows features typical for isolated copper(II) ions possessing $s = 1/2$: (i) the almost constant effective magnetic moment at higher temperature being close to the spin-only value of 1.73 μ_B; (ii) some drop at low temperature due to intermolecular interactions of the antiferromagnetic nature. The fitting procedure for the Curie–Weiss law of the form $\chi_{mol} = (N_A\mu_0\mu_B^2/k)g_{eff}^2 s(s+1)/[3(T-\Theta)]$ gave $g_{eff} = 2.092$ and $\Theta = -0.74$ K (discrepancy factor $R = 0.01$).

Complex **9** exhibits features typical for copper(II) dimers: (i) at high temperature the effective magnetic moment reaches the spin-only limit (per copper ion); (ii) on cooling the magnetic susceptibility passes through a maximum and then turns down to zero indicating the singlet ground state of the dimer, $S = 0$; (iii) at very low temperature the vanishing susceptibility of the dimer is superimposed by the Curie-like signal of the paramagnetic impurity. In calculating the molar magnetic susceptibility a doubled value of the formula weight resulting from the single-crystal X-ray analysis has been applied. The fitting procedure for the Bleaney–Bowers equation $\chi_{mol} = (N_A\mu_0\mu_B^2/kT)g_{eff}^2[(1-x_{PI})2/(3+\exp(-J/kT))+2x_{PI}s(s+1)/3]$ gave $g_{eff} = 1.96$, $J/hc = -26.6$

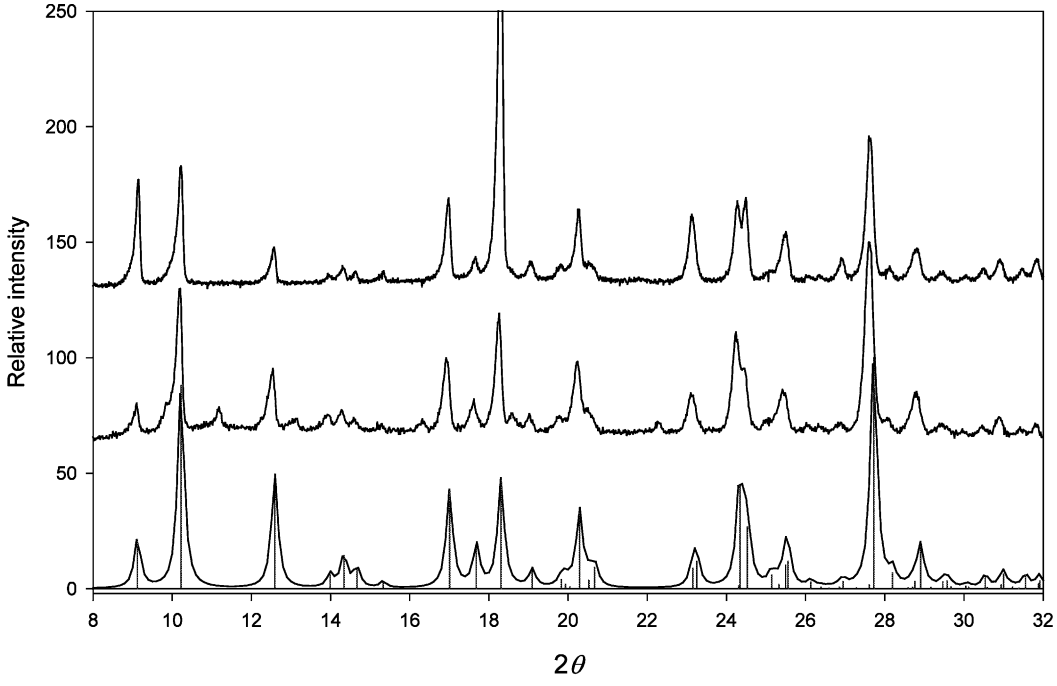

Fig. 5. Experimental powder diffraction patterns for **9b** (top) and **9a** (centre); theoretical patterns—bottom.

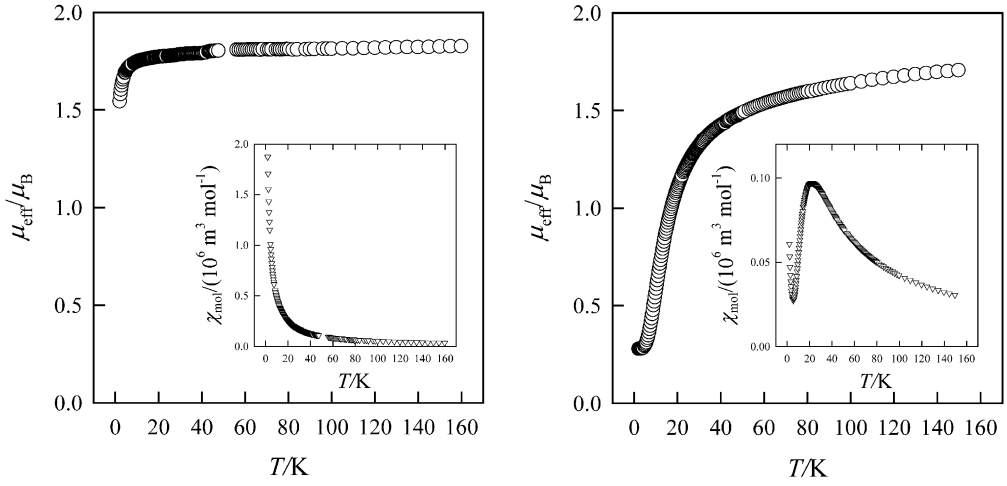

Fig. 6. Temperature dependence of the effective magnetic moment for **8** (left) and **9** (right, per monomer). Inset—the molar magnetic susceptibility.

cm^{-1} and the mole fraction of the paramagnetic impurity $x_{PI} = 0.030$ ($R = 0.028$). The used model [23,24] is partially successful since it does not account for the ladder-type arrangement of the copper(II) centres. The abstraction from the inter-dimer exchange interaction may be the origin of the sub-normal value of the g-factor. The negative value of the coupling constant matches the available experimental data [25–27].

The AC susceptibility data taken for the freshly prepared sample **9b** match perfectly the SQUID data for the sample **9a**. No new information or altered conclusions can be drawn from them except the important statement that the synthesis and the properties of the complex **9** are reproducible.

3.6. IR spectra

The IR spectra of the complexes were studied to obtain more information on the O-coordination of the pyridine N-oxide from the shift of the N–O stretching frequency, relative to the free ligand. Shifts of the (NO) bending vibration could also support the oxygen–metal

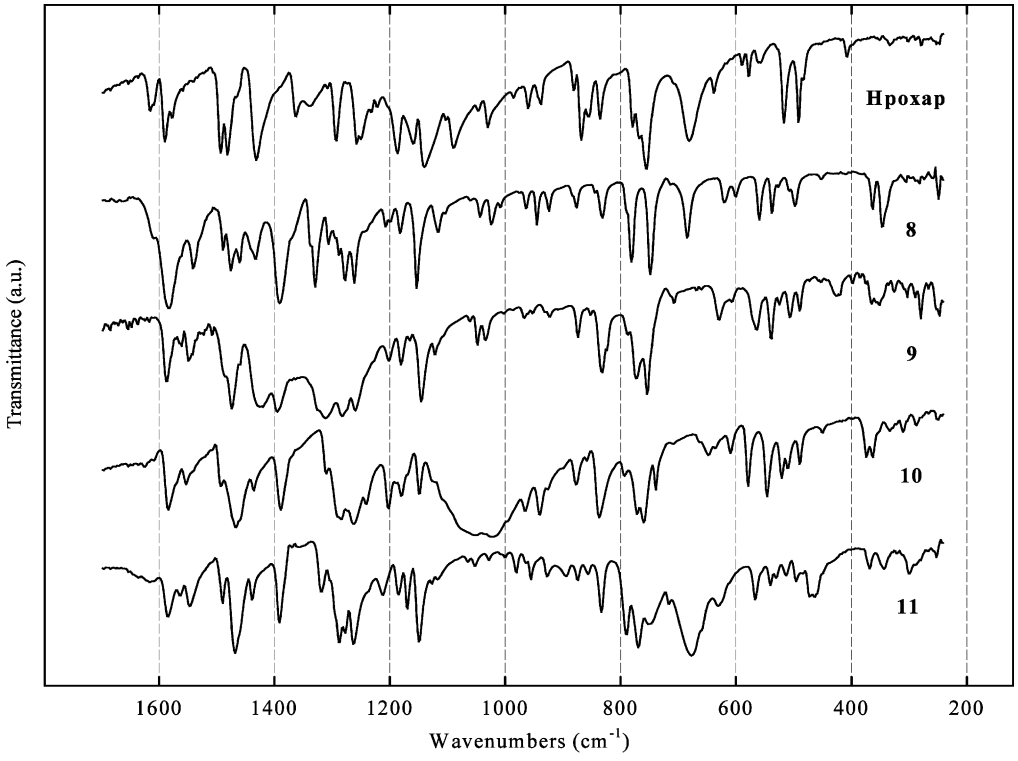

Fig. 7. IR spectra of Hpoxap and its Cu(II) complexes measured in Nujol suspension between CsI windows (absorptions from Nujol were subtracted).

coordination. Unfortunately, even for simple substituted pyridine N-oxides, there are different assignments for the N–O group in literature [28].

The present ligand Hpoxap has a rather complicated IR spectrum (Fig. 7). To assign the observed absorptions, the IR spectrum of Hpoxap was compared with those of **4**, **5** and **7**. Spectra of all four compounds were also simulated (gas phase) using the standard semi-empirical AM1 method of quantum chemistry [29] for better understanding of possible vibrations.

The simulations showed that, the ν(NO) frequency of Hpoxap is shifted to energies, higher than it is usually assumed for substituted pyridine N-oxides [3–6]. The calculated ν(NO) frequency is indeed close to the C=N stretching mode. This supports the assignments recommended by Thornton and Watkins [28]. In addition, ν(NO) is strongly combined with CN pyridine ring stretching. Even more complicated is the identification of the NO bending mode, which is dominated by CN pyridine ring stretching. The combined vibration (with the minor contribution due to the NO bending) should occur in the region of combined ν(ring)/γ(CH) vibrations.

The observed vibrations of the ligands and complexes studied together with the suggested assignments are listed in Table 6. These assignments are:

i) The ν(C=N) vibration is observed in the region 1590–1624 cm^{-1} for the free ligands and is shifted approximately 2–8 cm^{-1} to lower energies for complexes **8**, **9**, **10** and **11**.
ii) There is single vibration at 1615 cm^{-1} in the ν(ring) region (1600–1400 cm^{-1}) of Hpoxap, which disappears upon coordination and new vibrations at about 1550 cm^{-1} appear in the IR spectra of the complexes. These absorptions are assigned as ν(NO). A similar behaviour is observed for a strong band at 1516 cm^{-1} in the spectrum of **7**.
iii) A strong absorption at approximately 1430 cm^{-1}, assigned as ν(CN) aromatic ring vibration, is found in the spectra of all ligands (except of **5**, which does not contain any pyridine ring).
iv) The complexes exhibit a very strong ν(C–O) vibration at approximately 1390 cm^{-1}. No absorption at 1390 cm^{-1} is found neither for Hpoxap nor for the other ligands. In contrast, there are two medium intensity vibrations at 1362 (ν(C–O)), and 1339 cm^{-1} (δ(O–H)) found for Hpoxap as well as for **4** and **5**, but not for **7** (**7** does not contain the phenolic group). Due to the deprotonation of Hpoxap the broad peak at 1339 cm^{-1} disappears upon complexation. The shift of ν(C–O) to higher energies can be explained by an increase of electron density between C and O atoms after the deprotonation of Hpoxap.
v) The bending NO vibration is usually misaligned in the literature. Simulations of IR spectra yielded three combined absorptions. The one with the highest energy is a combination of NO bending mode with the aromatic ring stretching and should be observed in the range of aromatic ring stretching (1300–950 cm^{-1}). In this range a very strong band at 1140 cm^{-1} is found for Hpoxap (and a medium band at 1142 cm^{-1} for **7**, but no for **4**, nor for **5**). In the complexes Cu(poxap)X, this band shifts to

[b] An overlap with ν(C=N–).

slightly higher energy (Table 6). Two another absorptions with a contribution of NO bending mode were not localised, but should be found at lower energies in the range of the ring breathing modes.

vi) The contribution of the anions X to the IR spectra of complexes Cu(poxap)X is clearly observable. The assignment of the ν(COO) vibrations in **8** is possible after a detailed band shape analysis. Compared with the spectra of the other complexes, the absorption at 1582 cm^{-1} is broader possibly due to the overlap of ν_a(COO) with ν(C=N). A shoulder at approximately 1440 cm^{-1} could be assigned to the ν_s(COO) vibration. In **9**, the splitting of $\nu_3(NO_3)$ was observed (1426 and 1312 cm^{-1}) as a product of the symmetry lowering of the nitrato group. The value of 114 cm^{-1} for the splitting is consistent with the monodentate character of the coordinated nitrato anion [30]. Complex **10** exhibits a very broad and strong band in the range 980–1100 cm^{-1}, which corresponds to non-coordinated BF_4^- anion. Analogously, the anion SiF_6^{2-} is most probably not coordinated in **11**, due to the appearance of strong bands (677, 463 and 473 cm^{-1}), which are almost identical with those found for Na_2SiF_6.

4. Supplementary material

Crystallographic data (X-ray data in *.cif files) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 165961 for compound **8** and CCDC No. 165962 for compound **9**. Copies of this information may be obtained from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

novel family of rod-shaped supramolecular materials. If the geometrical arrangement holds for the coordination polymers formed from PyPN and silver alkylsulfonates, the polymers would be expected to take a hairy-rod structure, which is composed of a rigid-rod polymer backbone and alkylsulfonate anions as the side chains.

In this paper we report the formation and organization behavior of novel coordination polymers with hairy-rod structure by self-assembling of PyPN and silver alkylsulfonates (AgC_{12}, AgC_{14}, AgC_{16} and AgC_{18}).

2. Experimental

2.1. Materials

Hexakis(4-pyridylmethoxy)cyclotriphosphazene (PyPN) was synthesized from the reaction of hexachlorocyclotriphosphazene with sodium 4-pyridylmethoxide prepared from 4-pyridinemethanol (Koei Chemical) and NaH in THF, according to the method reported previously [21]. Silver alkylsulfonates (silver dodecylsulfonate (AgC_{12}), silver tetradecylsulfonate (AgC_{14}), silver hexadecylsulfonate (AgC_{16}) and silver octadecylsulfonate (AgC_{18})) were prepared from the corresponding sodium alkylsulfonates and $AgNO_3$ [24]. Other reagents and solvents were commercially available and used without further purification.

2.2. Preparation of coordination polymers

A DMSO solution (5 ml) of PyPN (51 mg, 6.5×10^{-5} mol) was added dropwise to a stirred DMSO solution (15 ml) of AgC_{12} (70 mg, 1.9×10^{-4} mol) at room temperature (r.t.). The resulting precipitate was redissolved in acetonitrile solution at 80 °C and slowly cooled to r.t. giving white solids (PyPN–AgC_{12}). Similarly, other coordination polymers (PyPN–AgC_{14}, PyPN–AgC_{16} and PyPN–AgC_{18}) were obtained. PyPN–AgC_{12} was obtained in 52% yield. *Anal.* Found (Calc. for $C_{72}H_{111}N_9Ag_3O_{15}P_3S_3$): C, 46.37 (46.61); H, 5.90 (6.03); N, 6.82 (6.79)%. FT-IR (KBr, cm^{-1}): 2923, 2852, 1618, 1241, 1192, 1055–1035. PyPN–AgC_{14} was obtained in 35% yield. *Anal.* Found (Calc. for $C_{78}H_{123}N_9Ag_3O_{15}P_3S_3$): C, 47.79 (48.30); H, 6.50 (6.39); N, 6.56 (6.50)%. FT-IR (KBr, cm^{-1}): 2920, 2850, 1618, 1241, 1193, 1055–1035. PyPN–AgC_{16} was obtained in 53% yield. *Anal.* Found (Calc. for $C_{84}H_{135}N_9Ag_3O_{15}P_3S_3$): C, 49.60 (49.85); H, 6.58 (6.72); N, 6.19 (6.23)%. FT-IR (KBR, cm^{-1}): 2919, 2848, 1618, 1240, 1192, 1055–1035. PyPN–AgC_{18} was obtained in 42% yield. *Anal.* Found (Calc. for $C_{90}H_{147}N_9Ag_3O_{15}P_3S_3$): C, 51.10 (51.28); H, 6.95 (7.03); N, 6.05 (5.98)%. FT-IR (KBr, cm^{-1}): 2919, 2848, 1618, 1241, 1192, 1055–1035.

2.3. Measurements

Elemental analyses were carried out with a Perkin–Elmer 240C elemental analyzer (Advanced Instrumentation Center for Chemical Analysis, Ehime University). FT-IR spectra were recorded on a JASCO FT-IR 230 spectrophotometer applying the KBr pelleting techniques. Wide-angle X-ray diffraction patterns were obtained on a Rigaku RINT 2000 diffractometer using graphite-monochromated Cu Kα radiation (40 kV, 20 mA). Differential scanning calorimetry (DSC) was done using a Shimadzu DSC-50 calorimeter in sealed aluminum pans at a heating rate of 10 °C min^{-1}.

3. Results and discussion

The supramolecular materials obtained by self-assembling of hexakis(4-pyridylmethoxy)cyclotriphosphazene (PyPN) and silver alkylsulfonates were stable indefinitely in air, and are insoluble in water and common organic solvents such as acetone, methanol, chloroform and tetrahydrofuran. Combination of PyPN and sodium alkylsulfonates did not give rise to supramolecular assemblies, suggesting that the present supramolecular materials are not formed through the formation of the salt of alkylsulfonate anions with PyPN. This is supported by the fact that the band at 994 cm^{-1} of PyPN remains as a shoulder in the FT-IR spectrum of PyPN–AgC_{16} (Fig. 2), because the band at 993 cm^{-1} of the pure poly(4-vinylpyridine) disappears completely on fully protonation of the pyridyl groups [25]. We have already shown that the pyridyl groups of PyPN coordinate to the Ag^+ ion for the coordination polymer obtained from PyPN and $AgNO_3$ from extended X-ray absorption fine structure (EXAFS) measurements [23]. In the FT-IR spectrum of PyPN–AgC_{16}, the peak at 1605 cm^{-1}, assignable to free PyPN disappeared and shifted to 1618 cm^{-1} (Fig. 2), indicating that all of the pyridyl units in PyPN, participate in the coordination bonding with Ag^+. A similar result was obtained for the other polymers. From elemental analysis and ^1H NMR spectra, the stoichiometry was shown to be PyPN/silver alkylsulfonates = 1:3 for all supramolecular assemblies. These suggest that the coordination bonding with an alternating sequence of one PyPN and three silver alkylsulfonates gives supramolecular (coordination) polymers composed of $[PyPN{\cdot}3Ag^+]_x{\cdot}3x(SO_3C_nH_{2n+1})$, as shown in Fig. 1.

FT-IR spectra also provide information about the conformation of the alkyl chains in the coordination polymers (Fig. 3). The C–H asymmetric and symmetric bands of the alkyl chains for PyPN–AgC_{16} and PyPN–AgC_{18} are observed at 2919 and 2848 cm^{-1}, respectively, indicating that the alkyl chains are in all-*trans* conformation [26,27]. These bands for PyPN–AgC_{14},

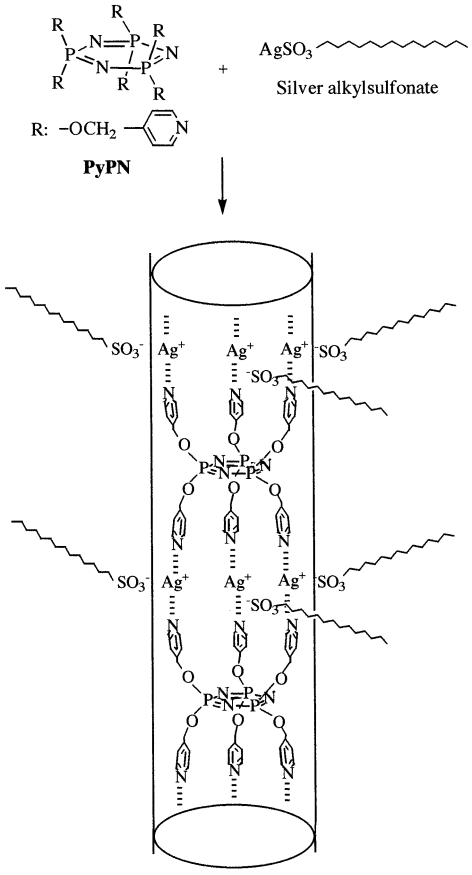

Fig. 1. Formation of coordination polymers by supramolecular assembly of PyPN and silver alkylsulfonates.

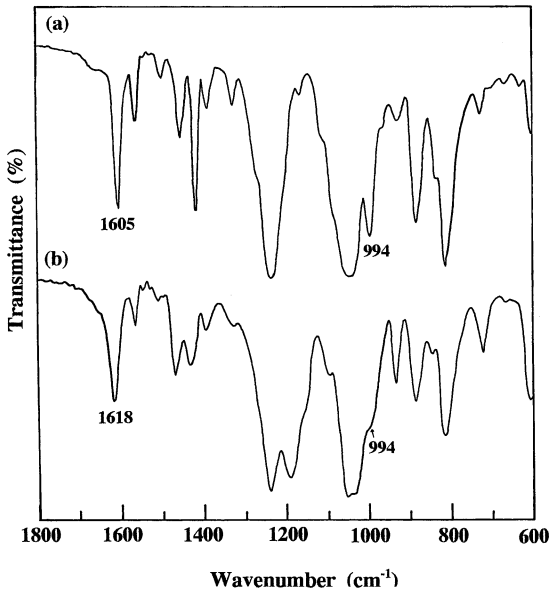

Fig. 2. FT-IR spectra of PyPN (a) and PyPN–AgC_{16} (b).

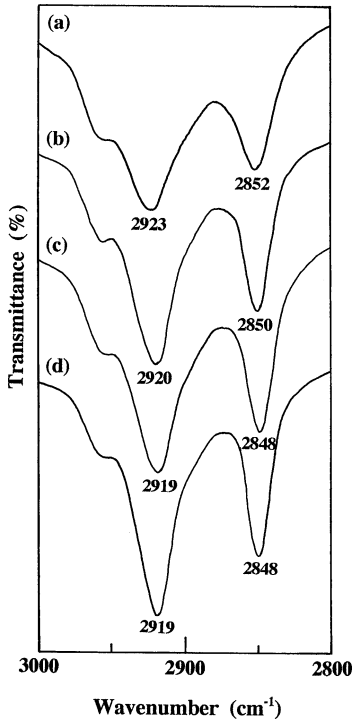

Fig. 3. FT-IR spectra of the coordination polymers in the 2800–3000 cm^{-1} region: (a) PyPN–AgC_{12}, (b) PyPN–AgC_{14}, (c) PyPN–AgC_{16} and (d) PyPN–AgC_{18}.

which were observed at 2920 and 2850 cm^{-1}, suggest that the alkyl chains are almost in extended form. In contrast, PyPN–AgC_{12} gave the C–H stretching bands at higher frequencies of 2923 and 2852 cm^{-1}, indicative of disordered packing of the alkyl chains involving a considerable amount of gauche conformers [26,27].

X-ray diffraction (XRD) patterns for the coordination polymers, PyPN–AgC_n ($n = 12$, 14, 16, 18) are shown in Fig. 4 and the diffraction data are listed in Table 1. The low-angle diffraction comes from the characteristic lattice repeat, i.e. the long range ordering of the polymers, whereas the wide-angle region is indicative of the surfactant alkyl side-chain packing, i.e. the short range ordering [28,29].

PyPN–AgC_{14}, PyPN–AgC_{16} and PyPN–AgC_{18} exhibited peaks centered at Bragg spacings of 4.4, 4.4 and 4.0 Å, and 4.4, 4.0 and 3.8 Å, respectively. These peaks indicate that the alkyl chains in the coordination polymers are organized in the crystal lattice. The spacings of 4.4 and 4.0 Å were in agreement with the values reported for poly(γ-alkyl-L-glutamates) with ten or more carbon atoms in the side chains, which are believed to indicate triclinic packing of the alkyl chains [15].

For the PyPN–AgC_{18} system, three sets of Bragg spacing were observed, one set with the primary reflection at 26.0 Å together with a second order at 13.0 Å, another set having the first-order reflection located at 23.9 Å and second-order at 12.1 Å, and the last set having the first-order reflection located at 21.0

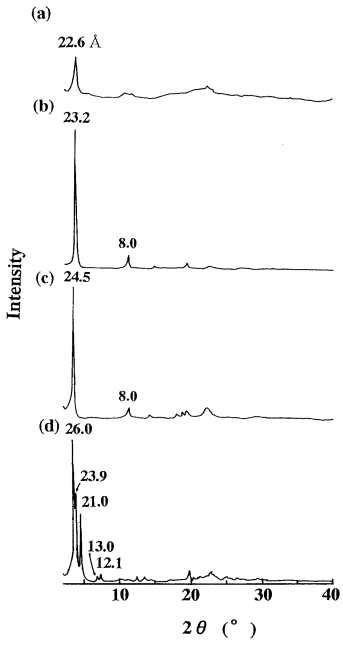

Fig. 4. X-ray diffraction patterns of the coordination polymers: (a) PyPN–AgC_{12}, (b) PyPN–AgC_{14}, (c) PyPN–AgC_{16} and (d) PyPN–AgC_{18}.

Table 1
X-ray diffraction data of the coordination polymers

Sample	Representative X-ray diffraction			
	Before heating		After heating (150 °C)	
	Long spacing	Short spacing	Long spacing	Short spacing
PyPN–AgC_{12}	22.6			
PyPN–AgC_{14}	23.2	4.4	22.6	
PyPN–AgC_{16}	24.5	4.4, 4.0	23.9	4.4, 4.0
PyPN–AgC_{18}	26.0, 23.9, 21.0	4.4, 4.0, 3.8	25.2	4.4, 3.9

Å. Muller has shown in XRD studies of $C_{18}H_{38}$ and $C_{20}H_{42}$, the coexistence of crystalline modification such as α-hexagonal phase and β-triclinic phase [30]. PyPN–AgC_{18} exhibited endothermic transitions, which correspond to the melting of the side-chain crystallites, at 67, 73, 83 °C in its DSC heating curve (Fig. 5). This result is consistent with the observation of the peaks due to the short range packing in the XRD pattern. Taking into consideration the three sets of Bragg spacing and the three melting points of the side-chain crystallites for PyPN–AgC_{18}, it seems reasonable to assume that the alkyl side-chains in PyPN–AgC_{18} organize themselves in multiple crystalline modifications.

PyPN–AgC_{12}, PyPN–AgC_{14} and PyPN–AgC_{16} showed a peak with a Bragg spacing of 22.6, 23.2 and 24.5 Å in the small angle region of their XRD patterns, respectively, although the peak of PyPN–AgC_{12} was

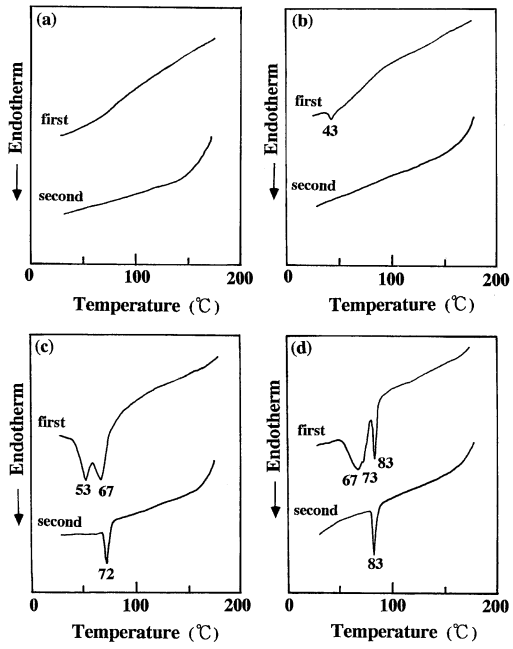

Fig. 5. DSC heating curves of the coordination polymers: (a) PyPN–AgC_{12}, (b) PyPN–AgC_{14}, (c) PyPN–AgC_{16} and (d) PyPN–AgC_{18}.

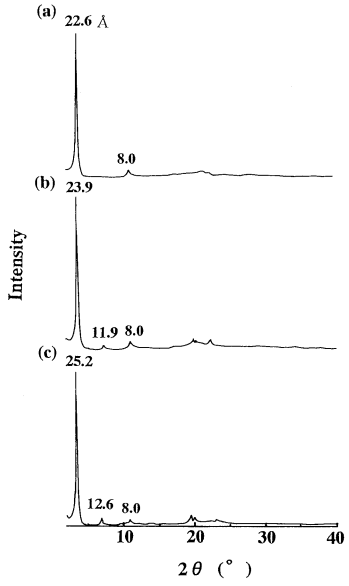
very broad compared to that of the other polymers. When the coordination polymers were heated up to 150 °C, the Bragg spacing of PyPN–AgC_{14}, PyPN–AgC_{16} and PyPN–AgC_{18} decreased from 23.2 to 22.6, 24.5 to 23.9 and 26.0 to 25.2 Å, respectively (Fig. 6). The DSC second heating curves of these coordination polymers were also different from the DSC first heating curves. These behaviors could be attributed to the disordering and reorganization of the alkyl side chains bound to the polymer backbones by the heating and the subsequent cooling process.



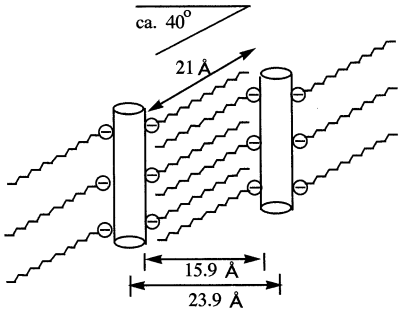


Fig. 6. X-ray diffraction patterns of the coordination polymers after heating up to 150 °C: (a) PyPN–AgC_{14}, (b) PyPN–AgC_{16} and (c) PyPN–AgC_{18}.

The XRD profile of heated PyPN–AgC_{18} was identified by a single reflection with a Bragg spacing of 25.2 Å together with a second-order peak of 12.6 Å. This result suggests that PyPN–AgC_{18}, with a hairy-rod structure [31] i.e. the skeleton is a cylindrical rod consisting of alternating PyPN and three Ag^+ ions bearing alkylsulfonate anions as the side chain, self-organizes into a lamellar structure. The hairy-rod structure is formed by the preference of metal anion (Ag^+)–pyridyl group interaction over the salt formation of the sulfonate anion with the pyridyl group [32], as mentioned above. In the case of PyPN–AgC_{16}, a peak with a spacing of 11.9 Å that corresponds to the second-order spacing of 23.9 Å appeared clearly, showing that the heating treatment brings about a more ordered packing of the hairy-rod coordination polymers and, consequently, the lamellar interface is more sharply defined [33]. PyPN–AgC_{14} did not exhibit a second-order peak of the spacing of 22.6 Å, but the difference (1.30 Å) of the spacing between PyPN–AgC_{14} and PyPN–AgC_{16} is equal to that between PyPN–AgC_{16} and PyPN–AgC_{18}. The above results imply that the PyPN–AgC_{16} and PyPN–AgC_{14} also take a lamellar packing in analogy with PyPN–AgC_{18}. In the XRD patterns of both PyPN–AgC_{16} and PyPN–AgC_{14}, a peak with the spacing of 8.0 Å was observed (Figs. 4 and 6), but, at present, the origin remains unclear.

On the other hand, from the results of FT-IR and XRD measurements, PyPN–AgC_{12} seems distinctly not to form a lamellar structure. In the DSC curve of PyPN–AgC_{12}, an endothermic peak was not observed in both first and second scans, indicative of the absence of a crystalline state of side-chains. It appears that the dodecyl side chains are too short to crystallize.

The orientation of the alkyl side-chains with respect to the polymer backbone in the lamellar structure can be guessed from the dependence of the long period spacing on the number of methylene groups in the side chain. In the case of comb-like polymers [34], the increment of lamellar thickness with side chain length is reported to be about 1.25 Å per methylene group if the alkyl chains are fully extended and perpendicular to the polymer backbone. The increment is less than 1.25 Å if the side chains are tilted. In the coordination polymers composed of PyPN and silver alkylsulfonates, the increment of lamellar thickness with side chain length is estimated to be about 0.65 Å per methylene group, indicating that the alkyl chains are tilted with respect to the polymer backbone. For the PyPN–AgC_{16} assembly, the diameter of rod with the alternating sequence of PyPN and three Ag^+ ions is about 8 Å [23], and the length of fully extended hexadecylsulfonate ion is about 21 Å. Thus, the experimental value (23.9 Å) of the long period of the lamellar of PyPN–AgC_{16} suggests that the alkyl chains of neighboring polymers should be interdigitated and tilted with respect to the polymer backbone by about 40° (Scheme 1).

Scheme 1. Packing model of the lamellar structure of PyPN–AgC_{16}.

Finally, we describe the thermal stability of the coordination polymers composed of PyPN and silver alkylsulfonates. In the second scans for all coordination polymers, an exothermic process occurs from about 170 °C (Fig. 5), indicating the decomposition of the coordination polymers. The temperature of decomposition was higher than that of PyPN (100 °C). The pure PyPN shows an endothermic melting peak at 75 °C, but melting of PyPN is not visible in the DSC curves of the coordination polymers. These indicate that PyPN becomes thermally stable in the coordination polymers with hairy-rod structure. In the DSC curves, an endothermic peak due to the coordination bond scission was not observed. Thus, the coordination polymers decompose due to the pyrolysis of PyPN in the polymers rather than the scission of the coordination bond.

4. Conclusions

The self-assembly of hexakis(4-pyridylmethoxy)cyclotriphosphazene (PyPN) and silver alkylsulfonates through the combination of coordination bonding and ionic interaction has generated novel supramolecular hairy-rod polymers. These coordination polymers with hairy-rod structure were self-organized into ordered structures that depend on the variation of the length of alkyl side chains. The tetradecyl, hexadecyl and octadecyl side chains bound to the rod-shaped coordination polymer composed of PyPN and Ag^+ ions can crystallize intermolecularly, leading to the organization into a lamellar structure. On the basis of the present results, we would now like to go on to exploit new supramolecular rigid-rod polymers controlled nanoscale structures.

4, although NMR studies show that often the solutions contain a mixture of species. The isolated complexes were identified by a combination of analysis, IR, ^{1}H, $^{31}P\{^{1}H\}$ and ^{45}Sc NMR spectroscopy, which also revealed that many retain lattice solvent even after prolonged drying in vacuum. The very poorly soluble $ScF_3 \cdot 1/2H_2O$ did not react with Ph_3PO or Me_3PO in boiling ethanol or acetone even with extended reaction times.

2.2. $[ScX_2(Ph_3PO)_4]X$

The reaction of $ScX_3 \cdot nH_2O$ with Ph_3PO in ethanol in molar ratios 1:3–6 resulted in white $[ScCl_2(Ph_3PO)_4]Cl$, $[ScBr_2(Ph_3PO)_4]Br$ and yellow $[ScI_2(Ph_3PO)_4]I$ (Table 1). Attempts to isolate $[ScX_3(Ph_3PO)_3]$ using low ScX_3:Ph_3PO ratios or other solvents were unsuccessful. The presence of six-coordinate cations with O_4X_2 donor sets was confirmed by an X-ray crystal structure of $[ScBr_2(Ph_3PO)_4]Br \cdot 1/2Et_2O$, which (Fig. 1, Table 2)

Table 1
^{45}Sc and $^{31}P\{^{1}H\}$ NMR data [a]

	$^{45}Sc(w_{1/2}$ (Hz))	$^{31}P\{^{1}H\}$	Solvent
$[ScCl_2(Ph_3PO)_4]Cl$	75(850)	34.5	CH_2Cl_2–$CDCl_3$
$[ScCl_3(Ph_3PO)_3]$ [b]	121(1400)	34.0, 33.0	CH_2Cl_2–$CDCl_3$
$[ScBr_2(Ph_3PO)_4]Br$	108(4500)	35.8	CH_2Cl_2–$CDCl_3$
$[ScCl(Me_3PO)_5]Cl_2$	47.0(250)	56.0, 54.5	$MeNO_2$–$CDCl_3$
$[ScCl_2(Me_3PO)_4]Cl$ [b]	85.0(360)	54.0(?)	$MeNO_2$–$CDCl_3$
$[Sc(Me_3PO)_6]Br_3$ [c]	4.4(sept)	57.0(eight lines)	$MeNO_2$–$CDCl_3$
$[ScBr(Me_3PO)_5]Br_2$ [b]	51.5(850)	56.5, 55.0	$MeNO_2$–$CDCl_3$
$[Sc(Me_3PO)_6]I_3$ [c]	4.2(sept)	57.0 (eight lines)	$MeNO_2$–$CDCl_3$
$[Sc(Ph_3AsO)_4Cl_2]Cl$	96(4000)		CH_2Cl_2–$CDCl_3$
$[Sc(Ph_3AsO)_4Br_2]Br$	140(20 000)		CH_2Cl_2–$CDCl_3$
$[Sc(Me_3AsO)_6]Cl_3$	56(80)		$MeNO_2$–$CDCl_3$
$[Sc(Me_3AsO)_6]Br_3$	56(70)		$MeNO_2$–$CDCl_3$
$[Sc(Me_3AsO)_6]I_3$	56(70)		$MeNO_2$–$CDCl_3$
$[ScCl_3(Ph_2MePO)_3]$	123(1100)	40.5, 42.5	CH_2Cl_2–$CDCl_3$
$[ScCl_2(Ph_2MePO)_4]Cl$ [b]	80(2000)	42.4	CH_2Cl_2–$CDCl_3$
$[ScBr_2(Ph_2MePO)_4]Br$	100(8000)	41.0	CH_2Cl_2–$CDCl_3$

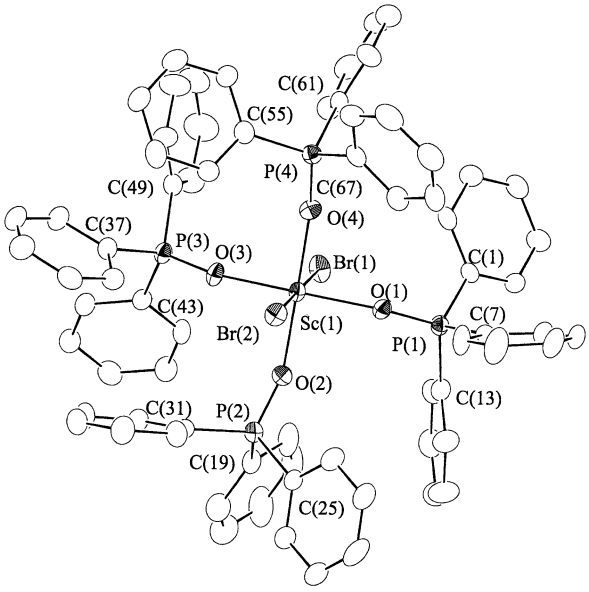

Fig. 1. View of the cation in $[ScBr_2(Ph_3PO)_4]Br \cdot 1/2Et_2O$ showing the atom numbering scheme. Ellipsoids are drawn at the 40% probability level and H atoms omitted for clarity.

reveals a *trans* octahedral cation with Br–Sc–Br very close to linear 179.04(5)° and Br–Sc–O 88.6(3)°–91.3(3)°. The angles Sc–O–P are variable approximately 154–166°. The Sc–O(P) distances, approximately 2.07 Å, are very similar to the values [7] in $[Sc(Ph_3PO)_2(NO_3)_3]$ or $[Sc(Ph_2MePO)_4(NO_3)_2]^{+}$, whilst the Sc–Br distances 2.652(1), 2.661(1) Å appear to be the first reported. The IR spectrum of each complex contains one very strong broad feature in the range 1150–1130 cm^{-1} assignable as ν(PO), which may be compared with 1195 cm^{-1} in the 'free' ligand [7]. In CH_2Cl_2 solution $[ScCl_2(Ph_3PO)_4]Cl$ approximates to a 1:1 electrolyte[1] and in the $^{31}P\{^{1}H\}$ NMR spectrum there is a main feature at δ 34.5 attributed to the tetrakis(Ph_3PO) complex, and weaker features at 26.0 (Ph_3PO), 34.0, 33.0. The corresponding ^{45}Sc NMR spectrum has a broad resonance at δ 75 and a weaker broader resonance at δ 121. Addition of excess Ph_3PO to these solutions results in the loss of the weaker

$^{31}P\{^{1}H\}$ NMR features at 34.0 and 33.0 and the ^{45}Sc NMR resonance at 121 which are attributed to *mer*-$[ScCl_3(Ph_3PO)_3]$. In the presence of excess Ph_3PO, $[ScCl_2(Ph_3PO)_4]Cl$ is the only complex present in significant amounts, but in its absence some decomposition into *mer*-$[ScCl_3(Ph_3PO)_3]$ occurs. Even a large excess of Ph_3PO fails to produce substitution of further chloride ligands, in contrast to the corresponding yttrium systems [10]. The $^{31}P\{^{1}H\}$ NMR spectra of $[ScX_2(Ph_3PO)_4]X$ (X = Br or I) in CH_2Cl_2 solution show only a single resonance in each and the conductances do not change significantly on addition of Ph_3PO, consistent with $[ScX_2(Ph_3PO)_4]X$ as the only species present. The ^{45}Sc NMR spectrum of the bromide confirms this with a broad feature at δ 108, but the ^{45}Sc resonance of the iodo-complex is extremely broad (δ ca. 200, $w_{1/2}$ ca. 20 000 Hz) and whilst the δ value is reasonable for a O_4I_2 set, the line-width could clearly obscure any other species present.

2.3. $[ScCl(Me_3PO)_5]Cl_2$ and $[Sc(Me_3PO)_6]X_3$ (X_3 = Br or I)

The reaction of $ScX_3 \cdot nH_2O$ with Me_3PO in a 1:6 molar ratio in ethanol gave $[Sc(Me_3PO)_6]X_3$ (X = Br or I), but only $[ScCl(Me_3PO)_5]Cl_2$ for the lightest halide. The complexes are insoluble or poorly soluble in chlorocarbons, alcohols or acetone, but dissolve in nitromethane. In nitromethane solution, the ^{1}H, $^{31}P\{^{1}H\}$ and ^{45}Sc NMR spectra of $[ScCl(Me_3PO)_5]Cl_2$ show a mixture of species present, which can be identified as $[ScCl(Me_3PO)_5]Cl_2$, $[ScCl_2(Me_3PO)_4]Cl$ (in ca. equal amounts), Me_3PO and some unassigned minor species. In the presence of excess Me_3PO, only $[ScCl(Me_3PO)_5]Cl_2$ (δ $^{45}Sc = 47$) is present in large amounts, but two weak resonances at δ ^{45}Sc 11 and 4 are also seen, the latter due to a small amount of $[Sc(Me_3PO)_6]^{3+}$ (see below). The molar conductivity of a 10^{-3} mol dm^{-3} solution in $MeNO_2$ is 117 Ω^{-1} cm^2 mol^{-1}, intermediate between 1:1 and 1:2 electrolytes and this increases with addition of Me_3PO to 180 Ω^{-1} cm^2 mol^{-1}, showing that excess phosphine oxide shifts the equilibrium in favour of the pentakis complex. An attempt to extract the chloride ligand from $[ScCl(Me_3PO)_5]Cl_2$ with $SbCl_5$ in the presence of Me_3PO was unsuccessful. Dissolution of $[Sc(Me_3PO)_6]Br_3$ in $MeNO_2$ also produces a mixture of complexes which can be identified by the NMR spectra as $[Sc(Me_3PO)_6]^{3+}$ (δ ^{45}Sc 4.5, δ $^{31}P\{^{1}H\}$ 56.5), $[ScBr(Me_3PO)_5]^{2+}$ (δ ^{45}Sc 51.5, δ $^{31}P\{^{1}H\}$ 56.0, 55.0), Me_3PO, and a minor species at δ 11 in the ^{45}Sc NMR spectrum. Addition of excess Me_3PO shifts the equilibria in favour of $[Sc(Me_3PO)_6]^{3+}$, although very small amounts of the other complexes remain evident. In contrast to the initial solution where the resonances of $[Sc(Me_3PO)_6]^{3+}$ in both ^{45}Sc and $^{31}P\{^{1}H\}$ NMR spectra are broad with ill-defined coupling, in the presence of excess Me_3PO well resolved couplings are seen (Fig. 2) confirming the presence of the quadrupolar scandium in a cubic symmetry environment where relaxation is slow. The trends are continued in $[Sc(Me_3PO)_6]I_3$ in that the $[Sc(Me_3PO)_6]^{3+}$ cation is the only major species in solution even in the absence of added Me_3PO (there is also a feature at δ 11 in the ^{45}Sc spectrum). The weak feature in the ^{45}Sc NMR spectra of all three complexes at δ approximately 11 is attributed to a solvento-complex $[Sc(Me_3PO)_{6-n}(MeNO_2)_n]^{3+}$ since the resonance is suppressed by addition of Me_3PO, and moreover is absent if the spectra are recorded in Me_2CO solution (although solubility in acetone is very poor).

2.4. $[ScX_2(Ph_3AsO)_4]X$

The reaction of $ScX_3 \cdot nH_2O$ with Ph_3AsO in 1:4 molar ratio in ethanol gave the *trans*-$[ScX_2(Ph_3AsO)_4]X$ (X = Cl or Br) complexes. The iodide complex failed to give reproducible analytical data, it would appear to be obtained with a mixture of polyiodide–iodide counter-anions, although spectroscopically the cation seems analogous to those with the lighter halides (cf. $[YI_2(Ph_3AsO)_4]I_5$) [9]. The identity as *trans* octahedral

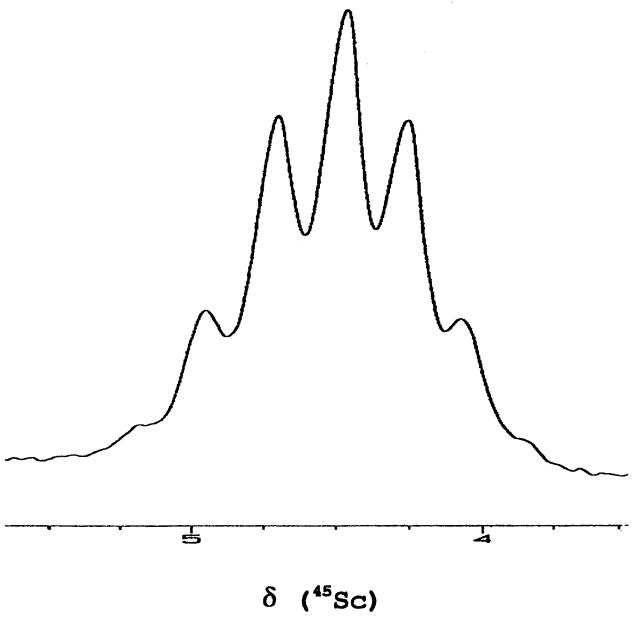

Fig. 2. ^{45}Sc NMR spectrum of $[Sc(Me_3PO)_6]^{3+}$ in $MeNO_2$ at 295 K in the presence of excess Me_3PO.

[1] CH_2Cl_2 has rarely been used as a solvent for conductivity measurements and in the standard review (W.J. Geary, Coord. Chem. Rev., 7 (1971) 81), some doubts were raised about its value for this purpose. We have used it here and in previous papers (refs [7–9]) to correlate with the NMR data obtained in CH_2Cl_2 solution, and with the typical conductances for the electrolyte types established using appropriate tetra-alkylammonium salts.

Table 3
Selected bond lengths (Å) and angles (°) for $[ScCl_2(Ph_3AsO)_4]Cl$

Bond lengths			
Sc(1)–Cl(1)	2.562(4)	Sc(1)–Cl(2)	2.545(4)
Sc(1)–O(1)	2.079(7)	Sc(1)–O(3)	2.059(7)
Sc(1)–O(2)	2.089(7)	Sc(1)–O(4)	2.063(7)
As–O	1.651(7)–1.668(7)		
Bond angles			
Cl(1)–Sc(1)–Cl(2)	179.8(1)	Cl–Sc(1)–O	88.6(3)–91.3(3)
Sc(1)–O(1)–As(1)	146.6(4)	Sc(1)–O(3)–As(3)	147.3(5)
Sc(1)–O(2)–As(2)	145.4(5)	Sc(1)–O(4)–As(4)	147.5(5)

cations was established by the X-ray structure of $[ScCl_2(Ph_3AsO)_4]Cl$ (Table 3, Fig. 3). Like the Ph_3PO complex (above) the scandium cation is *trans* octahedral with bond angles at scandium very close to those of a regular octahedron. The Sc–Cl distances 2.562(4), 2.545(4) Å are approximately 0.15 Å longer than observed in $[ScCl_3(thf)_3]$ [10] or scandium chloride complexes of crown ethers [11]. The Sc–O(As) distances are very similar to those [8] in the eight-coordinate $[Sc(Ph_3AsO)_4(NO_3)_2]^+$, but the Sc–O–As angles (Table 3) are rather more acute than the Sc–O–P angles in $[ScBr_2(Ph_3PO)_4]^+$. In CH_2Cl_2 solution the complexes are 1:1 electrolytes and the conductances increase little in the presence of added ligand. For $[ScCl_2(Ph_3AsO)_4]Cl$ the ^{45}Sc NMR spectrum is a broad ($w_{1/2}$ 4000 Hz) resonance at δ 96 and there was no evidence for any dissociation into a tris(Ph_3AsO) complex (compare $[ScCl_2(Ph_3PO)_4]Cl$ above). The ^{45}Sc NMR spectrum of $[ScBr_2(Ph_3AsO)_4]Br$ has a very broad resonance ($w_{1/2}$ 18 000 Hz) centred at approximately δ 140 ($\pm$20), whilst we have been unable to observe a ^{45}Sc resonance from the iodocomplex.

2.5. $[Sc(Me_3AsO)_6]X_3$

The reaction of $ScX_3 \cdot nH_2O$ with Me_3AsO in boiling ethanol readily affords the hexakis(Me_3AsO) complexes; the contrast with $[ScCl(Me_3PO)_5]Cl_2$ is notable. The complexes are characterised by a sharp singlet in the ^1H NMR spectra at approximately δ 2.1, and a sharp ^{45}Sc NMR signal at δ 56. The IR spectra show three strong bands in the region 925–840 cm^{-1} attributable to ν(As–O) and methyl rocking modes. These data compare well with those reported [7] for $[Sc(Me_3AsO)_6](NO_3)_3$, and the presence of $[Sc(Me_3AsO)_6]^{3+}$ cations was confirmed by an X-ray crystal structure of $[Sc(Me_3AsO)_6]Br_3$ (Fig. 4, Table 4). As expected the dimensions of the cation are very similar to those reported previously for the corresponding nitrate salt

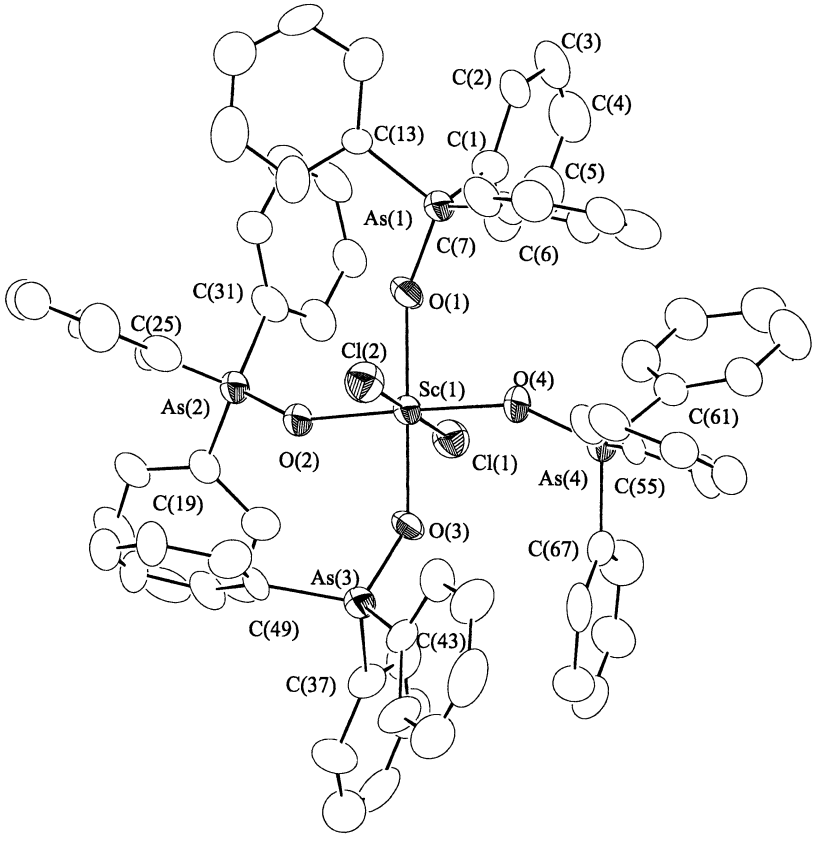

Fig. 3. View of the cation in $[ScCl_2(Ph_3AsO)_4]Cl$ showing the atom numbering scheme. Ellipsoids are drawn at the 40% probability level and H atoms omitted for clarity.

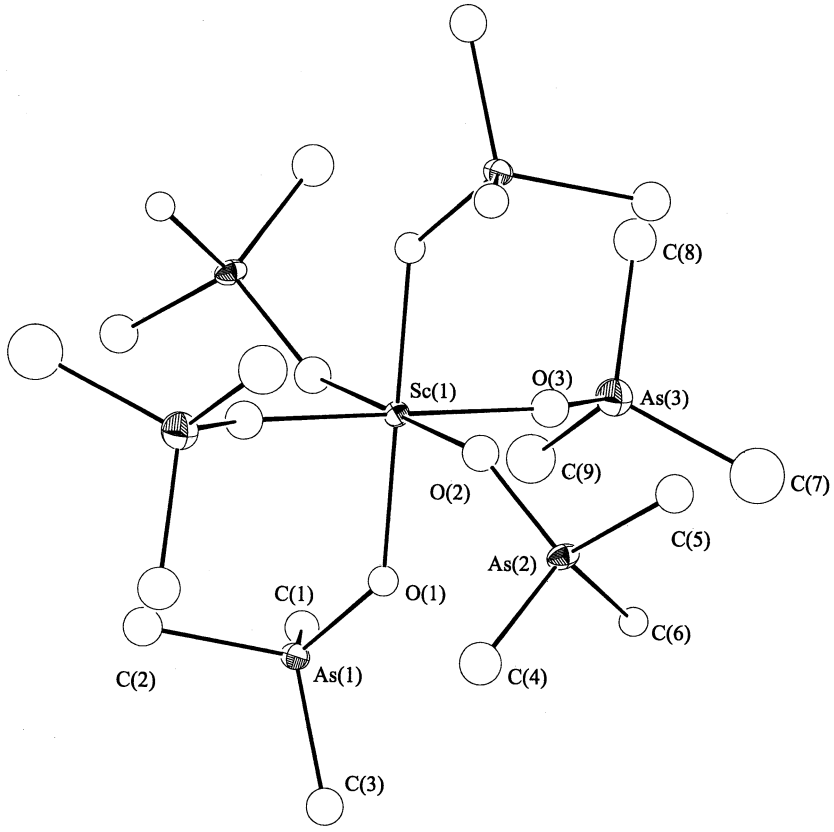

Fig. 4. View of the cation in $[Sc(Me_3AsO)_6]Br_3$ showing the atom numbering scheme. Ellipsoids are drawn at the 40% probability level. The Sc(1) is located on a centre of symmetry.

Table 4
Selected bond lengths (Å) and angles (°) for $[Sc(Me_3AsO)_6]Br_3$

Bond lengths			
Sc(1)–O(1)	2.08(2)	Sc(1)–O(3)	2.11(2)
Sc(1)–O(2)	2.11(2)		
As–O	1.65(2)–1.69(2)		
Bond angles			
O(1)–Sc(1)–O(2)	89.5(6)	Sc(1)–O(1)–As(1)	133.8(9)
O(1)–Sc(1)–O(3)	90.5(7)	Sc(1)–O(2)–As(2)	132.6(10)
O(2)–Sc(1)–O(3)	88.3(6)	Sc(1)–O(3)–As(3)	146.3(10)

[8], but the structure serves to confirm the ScO_6 environment with uncoordinated bromide ions. All three complexes are 3:1 electrolytes in 10^{-3} mol dm^{-3} $MeNO_2$ solution, although the conductivities increase a little on addition of Me_3AsO, possibly indicating some small amounts of coordination of halide, which is suppressed by excess ligand. However, only for $[Sc(Me_3AsO)_6]Cl_3$ is there any NMR evidence for a second complex in $MeNO_2$ solution, with a very weak singlet at δ 2.05 in the ^1H, and a broad weak feature at δ 84 in the ^{45}Sc spectrum, which we propose are due to small amounts of $[ScCl(Me_3AsO)_5]^{2+}$, although this is $\sim$5% of the concentration of the hexakis-complex.

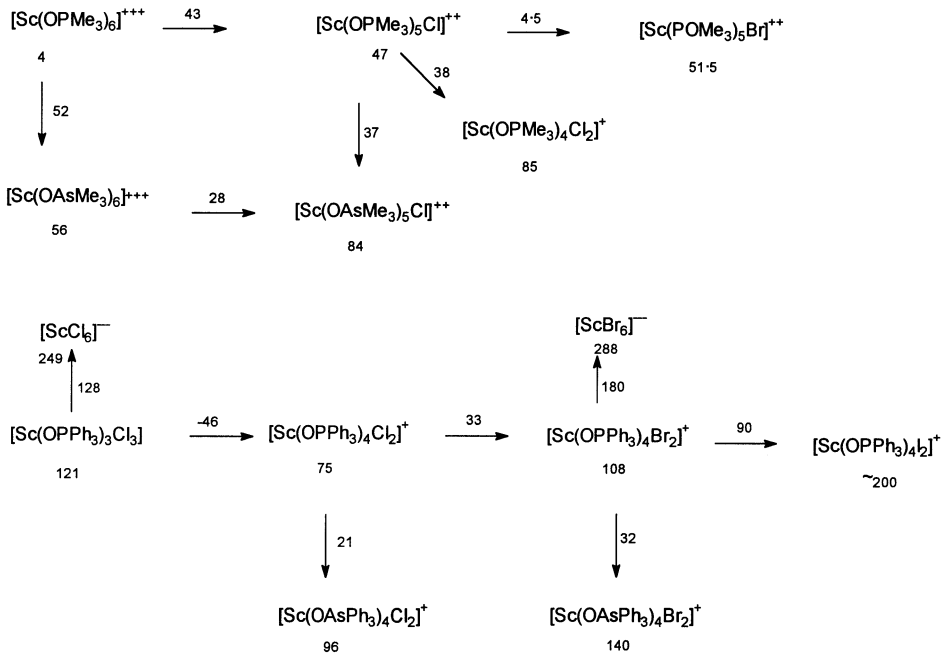
2.6. $[ScCl_3(Ph_2MePO)_3]$ and $[ScBr_2(Ph_2MePO)_4]Br$

Isolation of pure complexes containing Ph_2MePO proved difficult and attempts to obtain reproducible products from the $ScI_3 \cdot 8H_2O$–Ph_2MePO system in either ethanol or acetone were unsuccessful. The white solid isolated from the reaction of hydrated $ScCl_3$ with Ph_2MePO in ethanol or acetone was identified as the $[ScCl_3(Ph_2MePO)_3]$ complex by analysis. In CH_2Cl_2 solution this complex partially rearranges into $[ScCl_2(Ph_2MePO)_4]^+$ readily identified by a combination of ^{45}Sc and $^{31}P\{^1H\}$ NMR spectroscopy. A small amount of Ph_2MePO is also present and there are weak features in the ^{45}Sc NMR spectrum which have no corresponding resonances in the $^{31}P\{^1H\}$ NMR spectrum. From the NMR spectra the two scandium species are tentatively assigned as *mer*-$[ScCl_3(Ph_2MePO)_3]$ and *trans*-$[ScCl_2(Ph_2MePO)_4]^+$ isomers. Addition of excess Ph_2MePO to the solution converts the scandium to the $[ScCl_2(Ph_2MePO)_4]^+$ and this is accompanied by the expected increase in conductance. In contrast the bromide complex isolated was $[ScBr_2(Ph_2MePO)_4]Br$, and in solution in CH_2Cl_2 this appears to be the only significant species present and the conductance is that of a 1:1 electrolyte, showing that $[ScBr_3(Ph_2MePO)_3]$ does not form.

2.7. ^{45}Sc NMR data

The use of ^{45}Sc and ^{31}P NMR spectroscopy to identify solution species has been discussed in previous sections. There are advantages and disadvantages to both nuclei in these systems. The $I = 1/2$ ^{31}P nucleus is very sensitive, but the chemical shifts vary little between complexes in each ScX_3–R_3PO system, and coincidence or only partial resolution of resonances is a concern when identifying minor species or isomers present. The ^{45}Sc nucleus is also inherently very sensitive, but the line widths (Table 1) vary greatly and in some systems this also causes problems. The ^{45}Sc NMR spectra often show a number of weak and usually sharp resonances in addition to those of the major species, which we tentatively assign to hydrolysis/solvolysis impurities in solution, although there remains the possibility that some are due to other isomers of the phosphine oxide complexes. In situ ^{45}Sc NMR studies by Kirakosyan et al. [12,13], on $ScCl_3$–$(RO)_3PO$ (L) systems (R = Me, Et or Bu) identified a range of complexes including $[ScClL_5]^{2+}$, *cis*- and *trans*-$[ScCl_2L_4]^{2+}$, *fac*- and *mer*-$[ScCl_3L_3]$, *cis*- and *trans*-$[ScCl_4L_2]^{-}$. In these phosphate systems the line-widths are much smaller than in the present phosphine oxides and often partial resolution of ^{45}Sc–^{31}P couplings were seen. The line widths in the present complexes increase Cl < Br ≪ I and in several cases we were unable to observe resonances from the iodo-complexes. There is also a significant increase in line-width $R_3PO < R_3AsO$ in the halide systems. The broad lines indicate that the electric field gradient is substantial, promoting fast quadrupolar relaxation of the ^{45}Sc nucleus. The increasing line width Cl → Br → I is predictable as the disparity in electron density increases between the hard O (of Ph_3AsO) and the increasingly soft halide, but clearly the effect is much greater than in the Ph_3PO analogues. We have shown elsewhere [8] that the donor power towards oxophilic metals is $R_3AsO > R_3PO$ and this is manifested here in increased electric field asymmetry. The ^{45}Sc NMR chemical shifts show systematic trends with donor set (Table 1, Scheme 1) the $\delta(^{45}Sc)$ shifting to high frequency with halide Cl → Br → I and $R_3PO \rightarrow R_3AsO$. This pattern is also seen in the ^{89}Y NMR shifts of the yttrium analogues [9]. As discussed above, only for $[Sc(Me_3PO)_6]^{3+}$ were ^{31}P–^{45}Sc couplings resolved (Fig. 2). We also note that intermolecular exchange with added R_3PO or R_3AsO is slow on the NMR time-scales in these systems.

3. Conclusions



All the scandium halide complexes isolated are based upon six-coordinate metal centres. The results also suggest that the affinity of scandium for chloride is much greater than for the heavier halides; compare $[ScCl(Me_3PO)_5]Cl_2$ and $[Sc(Me_3PO)_6]X_3$ (X = Br or I), and that $[ScX_3(R_3PO)_3]$ form only with X = Cl. Comparison with the yttrium halide systems [9] shows that whilst both metals form $[MX_2(Ph_3EO)_4]X$ (E = As or P), in the presence of excess Ph_3PO, the yttrium systems also form $[YX(Ph_3EO)_5]^{2+}$, whereas we have no evidence for pentakis complexes in the scandium systems. This is probably due to the smaller radius of scandium ($r = 83$ vs. 106 pm for Y) which may be unable to accommodate more than four bulky Ph_3EO ligands. For both metals the affinity for R_3AsO is greater than for R_3PO.

4. Experimental

Multinuclear NMR spectra were obtained on a Bruker DPX400 at 161.9 MHz ($^{31}P\{^1H\}$) and referenced to external 85% H_3PO_4, 97.2 MHz (^{45}Sc) and referenced to 1 mol dm^{-3} $Sc(NO_3)_3$ in water at pH 1. Other physical measurements were made as before [7]. Ph_3PO, Ph_2MePO, Ph_3AsO (Aldrich) and Me_3PO (ALFA) were used as received. Me_3AsO was made by H_2O_2 oxidation of Me_3As in diethyl ether and purified by sublimation in vacuo [8]. $ScF_3 \cdot 1/2H_2O$ was made by precipitation from aqueous solutions of $Sc_2(SO_4)_3$ and NaF, washed with water and dried in vacuo. $ScBr_3 \cdot 6H_2O$ was prepared by evaporating Sc_2O_3 with 48% HBr, and recrystallising the product from H_2O. Yield 79% (Found: Br, 60.8. Calc. for $ScBr_3 \cdot 6H_2O$: Br, 61.0%). $ScCl_3 \cdot 6H_2O$ and $ScI_3 \cdot 8H_2O$ were made by metathesis of aqueous solutions of scandium sulfate and the appropriate barium halide, removal of the precipitated $BaSO_4$, and evaporation to dryness in vacuo. $ScCl_3 \cdot 6H_2O$ yield 90% (Found: Cl, 40.8. Calc. for $ScCl_3 \cdot 6H_2O$: Cl, 41.0%). $ScI_3 \cdot 8H_2O$ yield 86% (Found: I, 66.7. Calc. for $ScI_3 \cdot 8H_2O$: I, 66.8%).

4.1. $[ScCl(Me_3PO)_5]Cl_2$

Ice-cold ethanol solutions (10 cm^3) of $ScCl_3 \cdot 6H_2O$ (0.13 g, 0.5 mmol) and Me_3PO (0.28 g, 3.0 mmol) were mixed, stirred for 1 h and then concentrated to approximately 5 cm^3 and refrigerated overnight. The white solid was filtered off and dried in vacuo. Yield 0.24 g, 63%. (Found: C, 29.7; H, 8.1. Calc. for $C_{15}H_{45}Cl_3O_5P_5Sc$: C, 29.4; H, 7.4%). IR (cm^{-1}) (CsI disc): 2964w, 2896w, 1421w, 1360w, 1299m, 1182w, 1109br,vs (PO), 959s, 872s, 845m, 762s, 682m, 559w, 427s. ^1H NMR (300 K, CD_3NO_2): 1.5(d) $^2J(^{31}P-^1H) = 14$ Hz (Me_3PO); 1.90(d) $^2J(^{31}P-^1H) = 14$ Hz ($[ScCl_2(Me_3PO)_4]^+$); 1.8(d) [4H] 1.70(d) [H] $^2J(^{31}P-^1H) = 14$ Hz ($[ScCl(Me_3PO)_5]^{2+}$). $^{31}P\{^1H\}$ NMR ($MeNO_2$) 36.5 (Me_3PO), 54.0 ($[ScCl_2(Me_3PO)_4]^+$), 54.5 [P], 56.0 [4P] $[ScCl(Me_3PO)_5]^{2+}$). ^{45}Sc NMR ($MeNO_2$) 47.0 ($[ScCl(Me_3PO)_5]^{2+}$), 84.5

Scheme 1. Systematic trends in the ^{45}Sc NMR chemical shifts. The values under formulae are the chemical shift, values over arrows the chemical shift differences. Data for the hexahaloscandate ions are taken from Ref. [6].

($[ScCl_2(Me_3PO)_4]^+$). Λ_M (10^{-3} mol dm^{-3} $MeNO_2$) = 117 Ω^{-1} cm^2 mol^{-1}, +XS Me_3PO 180.

4.2. $[Sc(Me_3PO)_6]Br_3$

A solution of $ScBr_3\cdot 6H_2O$ (0.20 g, 0.50 mmol) in ice-cold ethanol (10 cm^3) was treated with Me_3PO (0.28 g, 3.0 mmol) in ethanol (5 cm^3), resulting in an immediate white precipitate. After stirring for 1 h, the solid was filtered off and dried in vacuo. Yield 0.29 g, 54%. (Found: C, 25.2; H, 6.6. Calc. for $C_{18}H_{54}Br_3O_6P_6Sc$: C, 25.8; H, 6.5%). IR (cm^{-1}) (CsI disc): 2964w, 2897w, 1422m, 1361w, 1312m, 1299m, 1183w, 1110vbr s (PO), 960s, 872s, 762m, 682m, 428s, 418s. ^1H NMR (300 K, CD_3NO_2): 1.5(d) $^2J(^{31}P-^1H) = 14$ Hz (Me_3PO); 1.85(d) $^2J(^{31}P-^1H) = 14$ Hz ($[Sc(Me_3PO)_6]^{3+}$); 1.70(d) [H], 1.85(d) [4H] $^2J(^{31}P-^1H) = 14$ Hz ($[ScBr(Me_3PO)_5]^{2+}$). $^{31}P\{^1H\}$ NMR ($MeNO_2$) 36.5 (Me_3PO), 56.5(m) ($[Sc(Me_3PO)_6]^{3+}$), 56.0 [4P], 55.0 [P] ($[ScBr(Me_3PO)_5]^{2+}$). ^{45}Sc NMR ($MeNO_2$) 51.5 ($[ScBr(Me_3PO)_5]^{2+}$), 4.5 ($[Sc(Me_3PO)_6]^{3+}$). Λ_M (10^{-3} mol dm^{-3} $MeNO_2$) = 179 Ω^{-1} cm^2 mol^{-1}, +XS Me_3PO 221.

4.3. $[Sc(Me_3PO)_6]I_3\cdot EtOH$

Me_3PO (0.14 g, 1.5 mmol) and $ScI_3\cdot 8H_2O$ (0.11 g, 0.25 mmol) were dissolved separately in boiling ethanol (2×5 cm^3) and the solutions mixed to yield a pale yellow precipitate. After stirring for 1 h this was filtered off and dried in vacuo. Yield 0.14 g, 67%. (Found: C, 24.2; H, 6.1. Calc. for $C_{20}H_{60}I_3O_7P_6Sc$: C, 23.6; H, 5.9%). IR (cm^{-1}) (CsI disc): 3480br, 2964w, 2898w, 1421m, 1360w, 1312m, 1299m, 1184w, 1108vbr s (PO), 957s, 871s, 761m, 681m, 427s. ^1H NMR (300 K, CD_3NO_2): 1.1(t) [3H], 3.4(q) [2H] (EtOH), 1.88(d) [54H] $^2J(^{31}P-^1H) = 13$ Hz ($[Sc(Me_3PO)_6]^{3+}$); 1.82–1.78(br). $^{31}P\{^1H\}$ NMR ($MeNO_2$) approximately 57.5(s) ($[Sc(Me_3PO)_6]^{3+}$). ^{45}Sc NMR ($MeNO_2$) 4.0 ($[Sc(Me_3PO)_6]^{3+}$), 9.0. Λ_M (10^{-3} mol dm^{-3} $MeNO_2$) = 189 Ω^{-1} cm^2 mol^{-1}, +XS Me_3PO 242.

4.4. $[ScCl_2(Ph_3PO)_4]Cl$

Warm (60 °C) ethanol solutions (10 cm^3) of $ScCl_3\cdot 6H_2O$ (0.13 g, 0.5 mmol) and Ph_3PO (0.55 g, 2.0 mmol) were mixed, concentrated to approximately 10 cm^3 and then refrigerated for 1 h. The white solid was filtered off and dried in vacuo. Yield 0.35 g, 50%. (Found: C, 68.4; H, 4.7. Calc. for $C_{72}H_{60}Cl_3O_4P_4Sc$: C, 68.4; H, 4.8%). IR (cm^{-1}) (CsI disc): 3055w, 1624w, 1591w, 1439m, 1358w, 1191w, 1152s (PO), 1122s, 1091s, 1046w, 1029w, 999m, 751m, 726s, 697s, 544s, 473m, 460m, 445m, 430m. ^1H NMR ($CDCl_3$) 7.0–7.9(m). $^{31}P\{^1H\}$ NMR (CH_2Cl_2) 34.5 ($[ScCl_2(Ph_3PO)_4]^+$), 34.0 [2P], 33.0 [P] ($[ScCl_3(Ph_3PO)_3]$), 26.0 (Ph_3PO). ^{45}Sc NMR (CH_2Cl_2) 76 ($[ScCl_2(Ph_3PO)_4]^+$), 121 ($[ScCl_3(Ph_3PO)_3]$). Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 17 Ω^{-1} cm^2 mol^{-1}, +XS Ph_3PO 22.

4.5. $[ScBr_2(Ph_3PO)_4]Br\cdot CH_2Cl_2$

A solution of $ScBr_3\cdot 6H_2O$ (0.39 g, 1.0 mmol) in ice-cold ethanol (10 cm^3) was added to Ph_3PO (1.11 g, 4.0 mmol) in ethanol (5 cm^3) and stirred for 1 h. The

solution was refrigerated and the white solid filtered off and dried in vacuo. It was recrystallised by dissolving in CH_2Cl_2 and diffusion of diethyl ether. Yield 0.84 g, 60%. (Found: C, 59.0; H, 4.5. Calc. for $C_{73}H_{62}Br_3Cl_2O_4P_4Sc$: C, 59.1; H, 4.2%). IR (cm^{-1}) (CsI disc): 3056w, 1620w, 1591w, 1438m, 1358w, 1188w, 1137s(PO), 1120s, 1084s, 1028m, 1000m, 750m, 725s, 692s, 547s, 465m, 454m, 426w, 317m, 306m, 269m, 255m. ^1H NMR ($CDCl_3$) 7.0–7.6(m) [30H], 5.2 [H] (CH_2Cl_2). $^{31}P\{^1H\}$ NMR (CH_2Cl_2) 35.8. ^{45}Sc NMR (CH_2Cl_2) 108. Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 21 Ω^{-1} cm^2 mol^{-1}, +XS Ph_3PO 23.

4.6. $[ScI_2(Ph_3PO)_4]I{\cdot}2H_2O$

This was made similarly to the chloride analogue, as a pale yellow solid. Yield 44%. (Found: C, 54.7; H, 3.7. Calc. for $C_{72}H_{64}I_3O_6P_4Sc$: C, 54.9; H, 4.1%). IR (cm^{-1}) (CsI disc): 3466br, 3054w, 1624w, 1590w, 1438m, 1359w, 1187w, 1132s(PO), 1122s, 1073s, 1027m, 999m, 750m, 725s, 693s, 543s, 464m, 452m, 425w. ^1H NMR ($CDCl_3$) 7.0–7.7(m) [60H], 1.7 [4H] (H_2O). $^{31}P\{^1H\}$ NMR (CH_2Cl_2) 38.0. ^{45}Sc NMR (CH_2Cl_2) approximately 200 vbr. Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 22 Ω^{-1} cm^2 mol^{-1}.

4.7. $[ScCl_2(Ph_3AsO)_4]Cl{\cdot}2EtOH$

An ethanol solution (5 cm^3) of Ph_3AsO (0.32 g, 1.0 mmol) was added to a solution of $ScCl_3{\cdot}6H_2O$ (0.06 g, 0.25 mmol) in boiling ethanol (10 cm^3). The mixture was concentrated to 5 cm^3 and refrigerated overnight. The white solid was separated and dried in vacuo. Yield 0.24 g, 64%. (Found: C, 58.9; H, 4.5. Calc. for $C_{76}H_{72}As_4Cl_3O_6Sc$: C, 59.5; H, 4.7%). IR (cm^{-1}) (CsI disc): 3407br, 3055w, 1583w, 1485m, 1440m, 1358w, 1187w, 1162w, 1089s, 1070w, 1027m, 999m, 908vs (AsO), 883m, 745s, 692s, 480s, 458m. ^1H NMR ($CDCl_3$) 7.0–7.7(m) [60H], 1.2(t) [6H], 3.4(q) [4H] (EtOH). ^{45}Sc NMR (CH_2Cl_2) 96. Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 20 Ω^{-1} cm^2 mol^{-1}, +XS Ph_3AsO 24.

4.8. $[ScBr_2(Ph_3AsO)_4]Br{\cdot}5H_2O$

$[ScBr_2(Ph_3AsO)_4]Br{\cdot}5H_2O$ was made similarly (54%) (Found: C, 51.4; H, 3.6. Calc. for $C_{72}H_{70}As_4Br_3O_9Sc$: C, 51.9; H, 4.3%). IR (cm^{-1}) (CsI disc): 3400br, 3051w, 1654m, 1582w, 1485m, 1440s, 1354w, 1185m, 1162w, 1088s, 1027w, 999m, 883s (AsO), 762s, 744s, 691s, 482s, 473s, 457m, 413m. ^1H NMR ($CDCl_3$) 7.1–6.6(m) [60H], 1.8(br) [11H] (H_2O). ^{45}Sc NMR (CH_2Cl_2) approximately 140. Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 19 Ω^{-1} cm^2 mol^{-1}, +XS Ph_3AsO 23.

4.9. $[ScI_2(Ph_3AsO)_4]I$

$[ScI_2(Ph_3AsO)_4]I$ was made similarly as a mustard coloured solid (46%). Not obtained analytically pure see text. IR (cm^{-1}) (CsI disc): 3300m, 1636w, 1439m, 1359w, 1185w, 1161w, 1088s, 1027w, 998m, 883s,br (AsO), 739s, 690s, 477m, 457m, 419m. ^1H NMR ($CDCl_3$) 7.15–7.7(m). ^{45}Sc NMR (CH_2Cl_2) not observed. Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 20 Ω^{-1} cm^2 mol^{-1}, +XS Ph_3AsO 23.

4.10. $[Sc(Me_3AsO)_6]Cl_3$

Scandium chloride hydrate (0.05 g, 0.19 mmol) was dissolved in boiling ethanol (10 cm^3) and added to a solution of Me_3AsO (0.21 g, 1.5 mmol) in ethanol (10 cm^3), resulting in a white suspension. The solution was concentrated to approximately 10 cm^3 and the white solid filtered off and dried in vacuo. Yield 0.13 g, 71%. (Found: C, 22.1; H, 5.6. Calc. For $C_{18}H_{54}As_6Cl_3O_6Sc$: C, 22.3; H, 5.6%). IR (cm^{-1}) (CsI disc): 2981w, 2904w, 1418m, 1359w, 1295w, 1269m, 1114w, 924s, 874s, 844s, 647s, 420m. ^1H NMR (300 K, CD_3NO_2): 2.1(s), 2.05(w). ^{45}Sc NMR ($MeNO_2$) 56.0 ($[Sc(Me_3AsO)_6]^{3+}$), 84(vw) ($[ScCl(Me_3AsO)_5]Cl_2$). Λ_M (10^{-3} mol dm^{-3} $MeNO_2$) = 214 Ω^{-1} cm^2 mol^{-1}, +XS Me_3AsO 251.

4.11. $[Sc(Me_3AsO)_6]Br_3$

$[Sc(Me_3AsO)_6]Br_3$ was made similarly. Yield 62%. (Found: C, 19.0; H, 5.0. Calc. for $C_{18}H_{54}As_6Br_3O_6Sc$: C, 19.6; H, 5.0%). IR (cm^{-1}) (CsI disc): 2982w, 2920w, 1653w, 1418m, 1359m, 1268m, 1088m, 926s, 874s, 846s, 648s, 420m. ^1H NMR (300 K, CD_3NO_2): 2.05(s). ^{45}Sc NMR ($MeNO_2$) 56.0 ($[Sc(Me_3AsO)_6]^{3+}$). Λ_M (10^{-3} mol dm^{-3} $MeNO_2$) = 239 Ω^{-1} cm^2 mol^{-1}, +XS Me_3AsO 281.

4.12. $[Sc(Me_3AsO)_6]I_3{\cdot}3H_2O$

A solution of $ScI_3{\cdot}8H_2O$ (0.10 g, 0.17 mmol) in warm (60 °C) ethanol (10 cm^3) was added to a solution of Me_3AsO (0.14 g, 1.0 mmol) resulting in immediate precipitation of a yellowish solid. After stirring for 1 h this was filtered off and dried in vacuo. Yield 0.11 g, 53%. (Found: C, 15.8; H, 3.9. Calc. for $C_{18}H_{60}As_6I_3O_9Sc$: C, 16.7; H, 4.6%). IR (cm^{-1}) (CsI disc): 3440br, 2978w, 2902w, 1647w, 1417m, 1359w, 1265m, 1088w, 921s, 872s, 844s, 646s, 420m. ^1H NMR (300 K, CD_3NO_2): 2.1(s) [10H], 2.05(vw) 1.7 [H] (H_2O). ^{45}Sc NMR ($MeNO_2$) 56.0 ($[Sc(Me_3AsO)_6]^{3+}$). Λ_M (10^{-3} mol dm^{-3} $MeNO_2$) = 253 Ω^{-1} cm^2 mol^{-1}, +XS Me_3AsO 280.

4.13. $[ScCl_3(Ph_2MePO)_3]\cdot H_2O$

Solutions of $ScCl_3\cdot 6H_2O$ (0.06 g, 0.25 mmol) and Ph_2MePO (0.16 g, 0.75 mmol) in boiling acetone (2×10 cm^3) were mixed resulting in a white suspension. Hexane (10 cm^3) was added and the white sticky solid separated and stirred with diethyl ether for 24 h. The white powder was dried in vacuo. Yield 0.17 g, 59%. (Found: C, 56.8; H, 5.1. Calc. for $C_{39}H_{41}Cl_3O_4P_3Sc$: C, 57.2; H, 5.0%). IR (cm^{-1}) (CsI disc): 3420br, 3056w, 2913w, 1643m, 1439s, 1359w, 1143s(PO), 1127sh, 1099m, 1028w, 998w, 901s, 783m, 746s, 720m, 696s, 517s, 507sh, 429w. ^1H NMR ($CDCl_3$): 1.7br (H_2O), 1.9(d) $^2J_{PH}=13$ Hz, 2.03(d) $^2J_{PH}=13$ Hz, 2.5(d) $^2J_{PH}=13$ Hz, 7.3–7.9(m). ^{45}Sc NMR (CH_2Cl_2) 123 ($[ScCl_3(Ph_2MePO)_3]$), 80(w) ($[ScCl_2(Ph_2MePO)_4]^+$). $^{31}P\{^1H\}$ NMR (CH_2Cl_2) 29.0 (Ph_2MePO), 40.5 [P], 42.5 [2P] $[ScCl_3(Ph_2MePO)_3]$], 42.4 $[ScCl_2(Ph_2MePO)_4)]^+$. Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 8 Ω^{-1} cm^2 mol^{-1}, +XS Ph_2MePO 23.

4.14. $[ScBr_2(Ph_2MePO)_4]Br$

To a solution of Ph_2MePO (0.22 g, 1.0 mmol) in ice-cold acetone (10 cm^3) was added a solution of $ScBr_3\cdot 6H_2O$ (0.09 g, 0.25 mmol) in acetone (5 cm^3). After stirring for 1 h, the solution was concentrated to approximately 5 cm^3 and refrigerated overnight. The white precipitate was filtered off and dried in vacuo. Yield 0.14 g, 49%. (Found: C, 55.3; H, 4.8. Calc. for $C_{52}H_{52}Br_3O_4P_4Sc$: C, 54.3; H, 4.6%). IR (cm^{-1}) (CsI disc): 3420br, 3050w, 2908w, 1638m, 1486m, 1438s, 1363w, 1138s (PO), 1094m, 1073w, 1028m, 998w, 894s, 787m, 746s, 719m, 695s, 515s. ^1H NMR ($CDCl_3$): 1.92(d) $^2J_{PH}=13$ Hz, 7.3–7.9(m). ^{45}Sc NMR (CH_2Cl_2) 100, $w_{1/2}=5000$ Hz. $^{31}P\{^1H\}$ NMR (CH_2Cl_2) 41.0, 40.3(w). Λ_M (10^{-3} mol dm^{-3} CH_2Cl_2) = 22 Ω^{-1} cm^2 mol^{-1}.

4.15. X-ray crystallographic studies

Crystallographic details together with data collection and refinement parameters are given in Table 5. Crystals were obtained by vapour diffusion from $MeNO_2$–Et_2O systems (with excess Me_3AsO added for that complex), or from CH_2Cl_2–Et_2O. Data were recorded from small, modest quality crystals at low temperature using a Nonius Kappa CCD diffractometer. The structure solutions and refinements (on F or F^2 (Cl compound)) were carried out using standard methods [14–17] except for $[ScCl_2(Ph_3AsO)_4]Cl$ which was initially solved and refined in the triclinic space group $P\bar{1}$ (no. 2) (with $Z=4$). The value of Z caused concern [18]; subsequent re-examination of the data showed systematic absences consistent with a monoclinic space group and the structure was re-solved and refined in this higher symmetry space group. Anisotropic refinement of
