An aqueous solution (6 ml) of Ba(SDT) · $3H_2O$ (1.49 mmol) was treated with a stoichiometric amount of Na_2CO_3 (1.50 mmol), resulting in the formation of a white precipitate ($BaCO_3$) that was filtered off. The solution thus obtained was cooled and dropwise treated with an aqueous solution (2 ml) of $KAuCl_4$ or $KAuBr_4$ (0.49 mmol) at 0 °C (and not dropwise added to the gold(III) salt solution, in order to avoid the formation of the 1:2 metal-to-ligand corresponding derivatives). The solution was subsequently treated with a stoichiometric amount of 0.2 mol L^{-1} solution of HCl or HBr, respectively (7.42 ml ≅ 1.49 mmol), yielding a dark brown precipitate that was filtered off and washed with water and diethyl ether. The dark brown solid was finally dried in a desiccator with P_4O_{10}, the final yield being 81%.

3. Results and discussion

N-Methylglycinedithiocarbamate has been synthesized as the barium salt as described elsewhere [24,32]. The gold(III) complexes here reported (Fig. 3) have been prepared by adding the dithiocarbamate ligand to an aqueous solution of $KAuX_4$ (X = Cl, Br) in the appropriate molar ratio.

The analytical data and the conductivity measurements for the ligand and the complexes are reported in Table 1. The compounds are stable at room temperature, insensitive to atmospheric oxygen and moisture and soluble in dimethylsulfoxide (DMSO) only. Conductance measurements are indicative of 1:1 electrolytes for compounds **3** and **5**, while compounds **2**, **4** and **6** are non-conducting in the same solvent [33–35].

3.1. FT-IR spectroscopy

The most significant bands recorded in the FT-IR spectra of the ligand and the complexes have been reported in Table 2.

$$^{-}OOCCH_2N(CH_3)H_2^{+} + CS_{2(l)} + Ba(OH)_2 \xrightarrow[\text{r.t./0 °C}]{H_2O/(CH_3)_2CO} (OOCCH_2N(CH_3)CSS)Ba_{(s)} + 2H_2O$$

Fig. 1. Synthesis of Ba(SDT) · $3H_2O$ (**1**).

$$(OOCCH_2N(CH_3)CSS)Ba + Na_2CO_3 \xrightarrow[\text{r.t.}]{H_2O} (OOCCH_2N(CH_3)CSS)Na_2 + BaCO_{3(s)}$$

$$(OOCCH_2N(CH_3)CSS)Na_2 + KAuX_4 + HX \xrightarrow[0\ ^{\circ}C]{H_2O} [(HOOCCH_2N(CH_3)CSS)AuX_2]_{(s)} + KX + 2NaX$$

The dithiocarbamate compounds exhibit a characteristic band in the range (1450–1580) cm^{-1} assignable to the N–CSS stretching mode [36–38]; this band defines a carbon–nitrogen bond order intermediate between a single bond ($\Delta\tilde{\nu} = (1250–1350)$ cm^{-1}) and a double bond ($\Delta\tilde{\nu} = (1640–1690)$ cm^{-1}) [39]. The presence of a band in the above mentioned range indicates that, of the four possible resonance structures (Fig. 4), in our case we are dealing with a considerable contribution of structure **I**, characterized by a strong delocalization of electrons in the dithiocarbamate moiety.

On passing from the dithiocarbamate barium salt to the complexes, the ν(N–CSS) mode is shifted to higher energies, showing an increase of the carbon–nitrogen double bond character [21,24–26,36]. As regards the halo-derivatives, the ν(N–CSS) band is shifted to higher frequency following the order

$$[(HSDT)_2Au]X < [(HSDT)AuX_2]\ (X = Cl, Br)$$

due to the increase of electron withdrawing effects on increasing the number of halide atoms in the complexes, thus promoting an higher positive charge on the nitrogen atom. Thus we can conclude that the contribution of the structure **IV** (Fig. 4) is greater in the bishalo-derivatives and decreases on passing to the monohalo-derivatives, in which the halide atom is just a counter-ion [20].

The most informative bands due to the carboxylic group are recorded between 1200 and 1730 cm^{-1} both for the ligand and the complexes. For the free dithiocarbamate ligand (**1**) two bands are recorded, one for the antisymmetric mode ($\nu_a(COO^-)$) at 1570 cm^{-1} and another at 1387 cm^{-1} due to the symmetric mode ($\nu_s(COO^-)$), while the spectra of the complexes show two bands at ~1720 and ~1210 cm^{-1} due to ν(C=O) and ν(C–O), respectively. Dithiocarbamates of α-amino acids exhibit bidentate behavior, potentially acting both as *S*,*S*′- and *O*,*O*′-donors; however, the results discussed above undoubtedly demonstrate that the coordination of the ligand does not take place through the carboxylic group, which maintains its acidic form. This is also confirmed by the presence of a strong broad band at around 3400 cm^{-1}, recorded for all the here investigated complexes, assignable to carboxylic O–H stretching vibrations [40].

The bands due to the –CSS moiety are usually coupled to other vibrations and are very sensitive to the environment of this group, allowing us to distinguish between monodentate and bidentate dithiocarbamate coordination. The presence of only one band in the egion (940–1060) cm^{-1} is assumed by Bonati and Ugo [41] to indicate a completely symmetrical bonding of the dithiocarbamate ligand, acting in a bidentate mode (Fig. 5(a)). Conversely, a split band indicates an asymmetrically-bound bidentate ligand ($\Delta\tilde{\nu} < 20$ cm^{-1}, Fig. 5(b)) or a monodentate bound ligand ($\Delta\tilde{\nu} > 20$ cm^{-1}, Fig. 5(c)). In the complexes here reported, the presence of only one band in the investigated region,

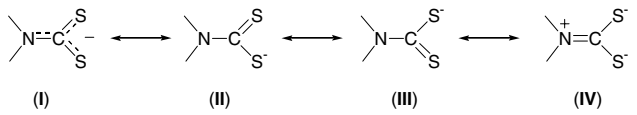

Fig. 4. Resonant forms of the dithiocarbamic –NCSS$^-$ moiety.

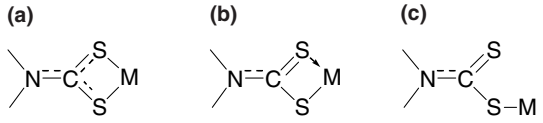

Fig. 5. Different ways of metal–sulfur binding in dithiocarbamate complexes: symmetrical bidentate (a), asymmetrical bidentate (b) and monodentate (c).

commonly attributed to the ν_a(SCS) vibrational mode, suggests a bidentate symmetrical behavior of the dithiocarbamate moiety, ruling out the coordination schemes 5(b) and (c).

For compound [$(HSDT)_3Au$] (**6**) a separate discussion is required. As reported in the literature, gold(III) dithiocarbamate derivatives in a 1:3 metal-to-ligand stoichiometry are generally tetracoordinate in a square-planar geometry with the simultaneous presence of one bidentate and two monodentate dithiocarbamate groups [20]. This case should imply the presence of two well defined N–CSS stretching bands at ~1560 and ~1450 cm^{-1} due to the bidentate and the monodentate ligands, respectively. In addition, as previously discussed, a split band in the range (940–1060) cm^{-1}, assignable to the ν_a(SCS), should be recorded, indicating that dithiocarbamate moieties are linked to the central metal ion in different ways [20]. Surprisingly, for compound **6** only one band was observed for both ν(N–CSS) and ν_a(SCS) at 1567 and 1004 cm^{-1}, respectively, indicating the presence of symmetrically bound dithiocarbamate ligands only, acting in a bidentate mode. This experimental evidence led us to hypothesize the possible existence of an hexacoordinate complex, as previously reported for other gold(III) complexes of tris-dithiocarbamate derivatives of α-amino acids [21].

The two bands recorded in the range (350–380) cm^{-1} are ascribed to $\nu_{a,s}$(SAuS), in agreement with analogous data reported by other authors for similar compounds [37,42].

The bands attributed to the $\nu_{a,s}$(XAuX) (X = Cl, Br) modes are ascribed to the Au–X stretching frequencies for terminal halides [20,42,43]. The above mentioned metal–halide modes have not been found in the spectra of [$(HSDT)_2Au$]X-type complexes, in agreement with the 1:1 electrolyte character of these compounds. It is worth observing that in the far FT-IR spectra of compound **4** the bands assignable to the ν(Au–Cl) vibrations are doubled because of isotopic splitting ν(Au–$^{35/37}$Cl); the existence of only one stable isotope of gold (^{197}Au) helps to make Au–Cl isotopic splitting more easily observable than in the case of chlorides of elements consisting of a mixture of stable isotopes [42].

3.2. ^1H and ^{13}C NMR spectroscopy

The main features of the ^{1}H and ^{13}C NMR spectra of the ligand and the synthesized complexes have been summarized in Table 3.

All the investigated gold(III) complexes have been proved to be stable in DMSO over 48 h. With regards to the alkyl groups bound to the dithiocarbamate moiety, the ^{1}H signals are very close for the free dithiocarbamate ligand (**1**) and the corresponding complexes. A general shift towards larger δ values is observed from the free dithiocarbamate precursor to its gold(III)

Table 3

[b] Due to the $-COO^-$ group.

derivatives, probably due to the lower electron density in the complexes, in which the –NCSS moiety is neutral compared to the free ligand in which such a dithiocarbamic group is anionic [26]. Conversely, for the carbon atoms a significant shielding of the ^{13}C signals, with respect to the free dithiocarbamate ligand, is recorded, in agreement with data reported in the literature for similar compounds [24–26]. The main differences are observable for the ^{13}C signals of the dithiocarbamic carbon atoms. The $\delta(N^{13}CSS)$ values, falling in the range 190–195 ppm, are strongly dependent on both the type of dithiocarbamate–metal bonding and the oxidation state of the metal center [44]. For gold(III) dithiocarbamate derivatives the $\delta(N^{13}CSS)$ values, are usually found in the range 193–201 ppm [45].

There is an appreciable empirical correlation between $\delta(N^{13}CSS)$ values and the carbon–nitrogen stretching vibrations in the infrared spectra: higher ν(N–CSS) values indicate an increased carbon–nitrogen double bond character, which well correlates with lower $\delta(N^{13}CSS)$ values because of a greater electron density on the –NCSS moiety. For the free dithiocarbamate ligand (**1**), there is no charge compensation on the sulfur atoms by coordinated atoms, resulting in extremely low ν(N–CSS) values, correlated with $-N^{13}CSS$ signals located in the upper limit of δ values. All these considerations are fully consistent with data reported in Table 3 for $-N^{13}CSS$ carbon signals.

As concerns compound **6**, it is worth noting that all the $^{1}H/^{13}C$ resonance peaks are doubled; if the hypothesis of an hexacoordinate complex in solid state was correct, these experimental data would suggest that, in solution, a rapid conversion from hexacoordinate to square-planar geometries could exist (Fig. 6) [21].

The downfield $^{1}H/^{13}C$ signals would be then attributed to the bidentate dithiocarbamate ligand, whereas the upfield ones would be ascribed to the monodentate asymmetrically bound HSDT molecules, as coordination through a single sulfur atom would increase the electron density on the –NCSS moiety [44].

Finally, the signals due to the carboxylate/carboxylic carbon atoms are generally shifted by ~9 ppm to lower values with respect to the free ligand (**1**), confirming the complete protonation of the carboxylic group, thus leading to an higher electron density on the carboxylic carbon atom [21].

3.3. Thermal studies

The thermal behavior of the free ligand and the synthesized complexes has been studied by thermogravimetry (TG) and differential scanning calorimetry (DSC) techniques in air flow, in order to establish the different decomposition processes and to confirm the proposed stoichiometries. Experimental data agree to a good extent with the ones obtained by the other spectroscopic techniques, and the results of such analysis, summarized in Table 4, indicate a good correlation between calculated and found weight loss values for all the investigated compounds.

As concerns the free dithiocarbamate ligand (**1**), pyrolysis processes take place in two well-defined steps. The first weight loss at around 100 °C coincides with the endothermic DSC peak and corresponds to the loss of three crystallization water molecules. A second weight loss is recorded at higher temperatures (>200 °C), the pyrolysis process leading to the total conversion to the corresponding metallic sulfate ($BaSO_4$). Several changes in the slope of the TG curve are observed during this second decomposition step, and can be related to the evolution of the hydrocarbon chain as well as to decarboxylation processes [46].

For all the gold(III) dithiocarbamate derivatives **2**–**6**, the thermal degradation occurs in two successive well-defined steps; in Fig. 7 the thermogram of complex **6** is reported as an example. The first TG step corresponds to pyrolysis, decarboxylation and reductive elimination Au(III) → Au(I), thus leading to [Au(SCN)] as a residual, a well known intermediate in the thermal decomposition of metal dithiocarbamates [46,47]. A very intense effect is recorded at higher temperature, that corresponds to removal of the remaining ligand atoms, complete degradation leading to metallic gold [21,25,26]. The formation of metallic gold as the final residual is confirmed by the presence of an endothermic DSC peak at 1066 °C due to the metallic gold melting.

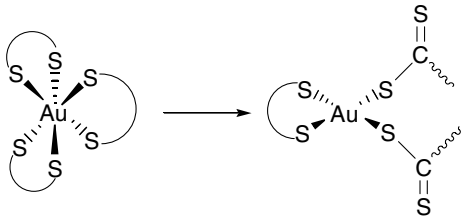

Fig. 6. Hypothesized structural conversion of compound **6** in solution.

3.4. Density functional calculations

Aiming to get useful information about the geometrical structures of the compounds here discussed and their harmonic frequencies, we have chosen as a structural starting point of our theoretical investigation the X-ray study of a palladium(II) analogue compound, [(ESDT)Pd($PrNH_2$)Cl] (ESDT = ethylsarcosinedithiocarbamate), which presents similar ligands and coordination structure around the metallic center [48].

A ball and stick representation of the optimized complex **2** are reported in Fig. 8(a) and (b). The molecular scheme of Fig. 8(b) allows us to observe that almost all the molecule lies on the plane pertaining to the square-planar coordination around the metallic center, with the exception of the –COOH moiety. The optimized geometrical parameters and the corresponding literature experimental values of analogue gold(III) complexes [33] are collected in Table 5. Inspection of this table clearly indicates the good agreement between theoretical and available experimental data.

A further point to take into account is the comparison between the calculated harmonic frequencies pertaining to the optimized system and the IR data collected for

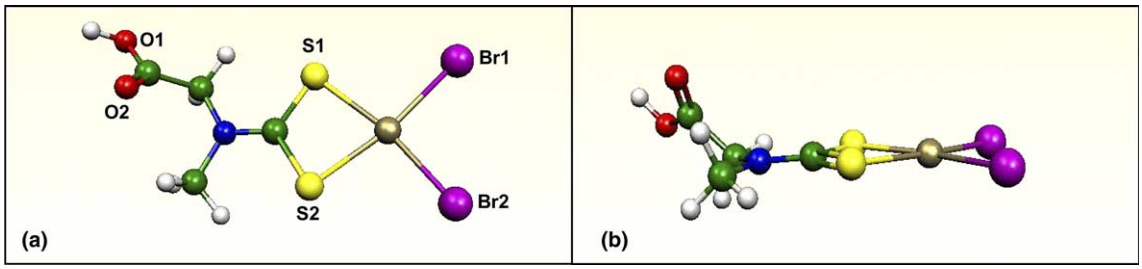

Fig. 8. Ball and stick representation of compound **2** optimized structure: top view (a) and side view (b).

ν(N–CSS)	1426	1571
ν(C=O)	1746	1721

[(HSDT)$AuBr_2$]; in Table 6 are reported both numerical and experimental vibrational outcomes. The analysis of these data allows us to observe that almost all the calculated frequencies result in good agreement with the experimental ones. We note only one strong discrepancy regarding the values pertaining to –NCSS vibrational modes. This molecular region is probably significantly influenced by the crystal packing in the solid, which was not considered in the theoretical simulation, where we take into account only the full molecular geometry optimization. Consequently, the stretching modes result to be influenced in a different way by the two environments.

Finally, we could get useful information from the values of the Hirshfeld charges collected in Table 7.

The analysis of these data indicates that the gold centre maintains a partial positive charge, while the dithiocarbamic C, N and S atoms result almost neutral; this fact suggests that the π-conjugate electron system on the dithiocarbamate moiety drains charge away from the metallic center.

3.5. Mass spectrometry

The ESI-MS spectrum of complex **6** has been performed in order to clarify its chemical composition. Interpretation of the fragmentation scheme has been a very difficult task. The signal corresponding to the molecular ion was not recorded; the largest *m*/*z* value recorded was 525, corresponding to a 1:2 metal-to-ligand fragment. In Fig. 9, a selection of the recorded fragments is reported. One branch of such a scheme represents a series of fragment, all of them including a gold atom, corresponding to successive loss of parts of the ligands, similarly to data reported in the literature [49,50], the last ion recorded having *m*/*z* = 289, that can tentatively correspond to $[AuS_2CNH_2]^+$. The other branch corresponds to withdrawal of a ligand that loses a sulfur atom and, finally, produces a species with *m*/*z* = 87 that should correspond to $[SCN–C(O)H]^+$.

3.6. X-ray photoelectron spectroscopy

XPS measurements were carried out on complex **6** in order to obtain a better insight into its chemical composition. The obtained data for the sample agree

Table 7

Au $4f_{7/2}$	83.8 (Au(I))	2.0
	86.1 (Au(III))	2.0
S $2p_{3/2}$	162.1	2.8
N 1s	400.0	2.5
O 1s	531.3	3.1

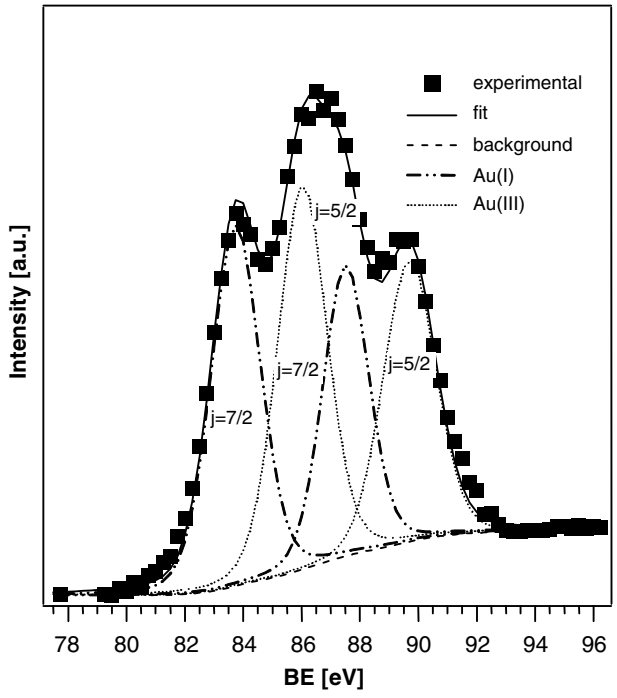

Fig. 10. Deconvolution of the Au(4f) photoelectron peak for compound **6**.

The $Au(4f_{7/2})$ peak analysis required greater attention. The recorder photoelectron signal, together with the bands resulting from the least-squares fitting, is reported in Fig. 10. As a matter of fact, such a signal can be decomposed by means of two distinct doublets, whose $Au(4f_{7/2})$ components are located at BE = 83.8 eV (FWHM = 2.0 eV) and BE = 86.1 eV (FWHM = 2.0 eV). These bands can be ascribed to the presence of gold(I) and gold(III), respectively [53], the former resulting from a partial reduction of gold(III) species in the spectrometer chamber due to the XPS analysis conditions [54–56].

The fact that only one S(2p) signal is recorded could support the hexacoordinate geometry, against a square-planar geometry reported in the literature for some other gold(III) dithiocarbamate derivatives with a 1:3 metal-to-ligand stoichiometry [20]. For square-planar 1:3 complexes, one of the ligands would act as bidentate and the other two as monodentate, coordinating the gold(III) center through one sulfur atom. In such a case, three different signals due to S(2p) orbitals would be expected (that is, one due to sulfur atoms implied in the bidentate coordination, one due to coordinating sulfur atoms belonging to monodentate ligands, and another due to the free sulfur atoms of the monodentate ligand). Indeed, only one single S(2p) signal is recorded in our case. Anyway, at variance with the report by Criado et al. [21], we do not believe that these data alone can support the presence of an hexacoordinate gold(III) geometry in the analyzed complex $[(HSDT)_3Au]$. This claim would be also disproved by the results of density functional calculations.

4. Conclusions

In this paper we report on the synthesis and characterization of five gold(III) dithiocarbamate derivatives of the type $[(HSDT)AuX_2]$, $[(HSDT)_2Au]X$ and $[(HSDT)_3Au]$ (X = Cl, Br; HSDT = *N*-methylglycinedithiocarbamate).

Although none of the complexes here reported has been obtained in the crystalline state, and thus the structure cannot be undoubtedly proposed, the other results suggest that coordination of the 1:1 and 1:2 metal-to-ligand dithiocarbamate derivatives takes place in a near square-planar geometry through the sulfur donating atoms, the –NCSS moiety coordinating the metal atom in a bidentate symmetrical mode and lying in the same plane, as reported in the literature for analogous gold (III) complexes.

A particular case is that of compound $[(HSDT)_3Au]$ whose structure has not been undoubtedly accomplished. Experimental results seem to support the hypothesis of an hexacoordinate tris-dithiocarbamate gold(III) derivative, against a square-planar geometry generally proposed for gold(III) complexes in a 1:3 metal-to-ligand stoichiometry.

Received 24 August 2004; accepted 14 December 2004

Abstract

Four new potential bidentate ligands – oximes of ferrocenyl ketones containing sulfur in their side chains [(*E*)-, and (*Z*)-(η^5-C_5H_5)Fe(η^5-C_5H_4)–C(=NOH)–$(CH_2)_n$–SCH_3, $n = 1$ or 2] were synthesised and characterized by IR, ^1H and ^{13}C NMR spectral data. Single crystal X-ray structure determinations of these compounds are also reported.

1. Introduction

Ferrocene derivatives containing one or more heteroatoms have acquired an important position in organic synthesis, since they are suitable ligands capable of coordinating transition metal ions giving complexes with potential applications as catalysts for different synthetic reactions [1]. Recently, selective hydrogenation of multifunctional molecules using homogeneous catalysts which contain bidentate ligands with chiral ferrocene-based backbones has been reviewed [2]. Other reviews have discussed the Ir-catalysed hydroamination and the Pd-catalysed hydrosilylation of alkenes using bidentate ferrocenyl ligands [3]. A number of transition metal complexes with ferrocenylcarbaldehyde acylhydrazones as bidentate ligands have been described [4]. Ligands usually contain nitrogen, oxygen or phosphorus functionalities, but there are only a few sulfur-containing ligands. Bidentate ligands containing nitrogen or sulfur, such as ferrocenylcarbaldehyde thiosemicarbazones [5] or ferrocenoylthioureas [6], are of particular interest considering that these two elements form functionalities known as good electron-donating groups. Such ligands would provide additional possibilities to design complexes of many transition metals. Hence, synthesis of such a type of ferrocene derivatives arouse our interest. Recently, we reported the synthesis of several acylferrocenes including sulfur in their structures [7]. In continuation of these investigations, we synthesised 1-ferrocenyl-1-hydroxyiminothialkanes (isomeric oximes of 1-ferrocenyl-3-thiabutan-1-one, **1a** and 1-ferrocenyl-4-thiapentan-1-one, **1b**; Scheme 1), potential ligands containing

nitrogen and sulfur in their side chains in such positions which enable formation of five- and six-membered chelate rings, respectively. Although many oximes containing ferrocene moieties are known [8], commonly derived from formyl and acetylferrocenes, to the best of our knowledge the compounds mentioned above have not been described before. The present paper deals with the details of their synthesis, as well as spectral characterisation including X-ray crystal structures of the (*E*)- and (*Z*)-isomers. It has been previously noted that oxime isomers exhibit different capabilities to form metal complexes [9].

2. Experimental

2.1. Materials and instruments

All chemicals used were commercially available and were used as received. Solvents were purified by distillation. IR spectra were measured with a Perkin–Elmer 457 grating FT instrument. NMR spectra were recorded on a Varian Gemini 200 spectrometer, using $CDCl_3$ as the solvent. Chemical shifts are expressed in ppm using TMS as an internal standard. Melting points were determined by a Kofler hot-plate apparatus. Diffraction intensity data of single crystals were collected by means of a Nonius Kappa CCD with graphite-monochromated Mo Kα radiation via ϕ and ω scans. The structures were solved with direct methods (SHELXS-86) and full-matrix least-squares refined against F^2 (SHELXL-97).

2.2. Preparation of 1-ferrocenyl-1-hydroxyiminothialkanes *2a,2b* and *3a,b*

2.2.1. General procedure

A solution of hydroxylamine hydrochloride (10 mmol) and sodium acetate (10 mmol) in water (6 mL) was added to the respective ketone (**1a**,**b**; 1 mmol). The suspension was stirred vigorously, and methanol was added slowly until the mixture became clear (12–15 mL). This solution was refluxed with stirring overnight. Methanol was distilled off, the remaining suspension was neutralised with saturated sodium bicarbonate and extracted with three 20 mL portions of diethyl ether. The combined organic layers were washed with water and brine, and then dried over anhydrous sodium sulfate. After evaporation of the solvent, the crude product was separated by column chromatography (20 g SiO_2) using toluene as eluent. The first red band was a trace of the corresponding substrate, and the following orange bands were (*E*)-, then (*Z*)-isomeric oximes. Single crystals were obtained by slow evaporation of solutions in dichloromethane.

2.2.2. (*E*)-1-Ferrocenyl-1-hydroxyimino-3-thiabutane (*2a*)

Yield: 66%; m.p. 109–111 °C; IR (KBr): ν_{max} = 3221, 2926, 1641, 1426, 1379, 1299, 1105, 1028, 991, 943, 879, 828, 519, 505, 490 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$): δ = 2.22 (3H, s), 3.72 (2H, s), 4.20 (5H, s), 4.35 (2H, t, J = 2.0 Hz), 4.64 (2H, t, J = 2.0 Hz), 9.44 (1H, br s); ^{13}C NMR ($CDCl_3$) δ = 16.3, 26.9, 66.9, 69.4, 69.7, 79.2, 155.9.

2.2.3. (*Z*)-1-Ferrocenyl-1-hydroxyimino-3-thiabutane (*3a*)

Yield: 12%; m.p. 85–87 °C; IR (KBr): ν_{max} = 3415, 3210, 3098, 2915, 1637, 1411, 1885, 1106, 1000, 984, 894, 818, 502, 488, 473 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$): δ = 2.15 (3H, s), 3.53 (2H, s), 4.19 (5H, s), 4.39 (2H, t, J = 2.0 Hz), 4.99 (2H, t, J = 2.0 Hz), 9.71 (1H, br s); ^{13}C NMR ($CDCl_3$) δ = 15.6, 36.7, 69.5, 70.1, 71.0, 72.6, 153.0.

2.2.4. (*E*)-1-Ferrocenyl-1-hydroxyimino-4-thiabutane (*2b*)

Yield: 71%; m.p. 99–101 °C; IR (KBr): ν_{max} = 3552, 3414, 3226, 2916, 1735, 1636, 1618, 1436, 1410, 1379, 1318, 1297, 1151, 1106, 1035, 1025, 1001, 935, 883,

827, 749, 706, 586, 518, 507 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$): δ = 2.23 (3H, s), 2.89 (4H, m), 4.19 (5H, s), 4.34 (2H, t, J = 2.0 Hz), 4.55 (2H, t, J = 2.0 Hz), 9.64 (1H, br s); ^{13}C NMR ($CDCl_3$) δ = 15.6, 28.2, 31.0, 66.6, 69.3, 69.8, 80.2, 158.0.

2.2.5. (*Z*)-1-Ferrocenyl-1-hydroxyimino-3-thiabutane (**3b**)

Yield: 10%; m.p. 91–93 °C; IR (KBr): ν_{max} = 3414, 2909, 1618, 1412, 1390, 1283, 1260, 1190, 1002, 982, 967, 896, 825, 629, 605, 549, 498, 481 cm^{-1}; ^1H NMR (200 MHz, $CDCl_3$): δ = 2.19 (3H, s), 2.83 (4H, m), 4.19 (5H, s), 4.38 (2H, t, J = 2.0 Hz), 4.90 (2H, t, J = 2.0 Hz), 9.15 (1H, br s); ^{13}C NMR ($CDCl_3$) δ = 15.7, 32.3, 34.2, 69.5, 69.9, 70.1, 70.7, 155.5.

3. Results and discussion

3.1. Synthesis of 1-ferrocenyl-1-(hydroxyimino)thialkanes **2a,b** and **3a,b**

Overnight treatment of ketones **1a** and **1b,** obtained by a previously described procedure [2], with hydroxylamine hydrochloride and sodium acetate in a boiling mixture of methanol and water gave a mixture of the (*E*)/(*Z*)-oxime isomers. After removal of the solvent and extraction, the obtained solid was analyzed by thin layer chromatography on silica, using toluene as eluent and repeating elution three times. In both cases, two products with very close R_f values (accompanied with trace amounts of the starting substrate) were observed. These were separated by careful column chromatography (SiO_2/toluene) giving yellow-orange crystals of (*E*)- and (*Z*)-1-ferrocenyl-1-hydroxyimino-3-thiabutane (**2a** and **3a**) in 78% and (*E*)- and (*Z*)-1-ferrocenyl-1-hydroxyimino-4-thiapentane (**2b** and **3b**) in 81% overall yield, respectively (Scheme 1). The ratio of isomers was estimated on the basis of ^1H NMR data of the unseparated mixture and was found to be **2a/3a** = 85:15 and **2b/3b** = 88:12 in $CDCl_3$, respectively. However, they interconvert on prolonged standing in solution. The (*Z*)-isomers are much less stable, so we were not able to obtain ^1H and ^{13}C NMR spectra of pure compounds **3a** and **3b.**

3.2. Spectral characterisation of 1-ferrocenyl-1-hydroxyiminothialkanes **2a,b** and **3a,b**

IR spectra of the products showed a broad band between 3600 and 2800 (OH) and a strong absorption in the range 1640–1615 cm^{-1} (C=N), characteristic for oximes. This, together with the absence of the C=O absorption, confirmed the transformation of the ketones to the corresponding oximes. In the ^1H NMR spectra of both **2a** and **3a**, three singlets were observed and attributed to the methyl and methylene groups and unsubstituted cyclopentadienide (Cp) rings. The positions of the two expected triplets of the substituted ferrocene rings were significantly different in the (*E*)- and (*Z*)-isomers (δ 4.35 and 4.64 ppm for **2a**, δ 4.40 and 4.99 ppm for **3a**). Similarly, in the ^1H NMR spectra of **2b** and **3b** two singlets and a multiplet were observed as expected, whereas the protons of the substituted Cp rings were positioned at δ 4.34 and 4.56 (for **2b**), and 4.38 and 4.91 ppm (for **3b**). ^{13}C NMR data were also in accordance with the proposed structures. Further proof was provided by X-ray crystal structure determinations of these oximes.

3.3. Crystal structures of 1-ferrocenyl-1-hydroxyiminothialkanes **2a,b** and **3a,b**

In the crystal structures of the title compounds, the Cp rings adopt nearly eclipsed conformations, with average torsion angles of 6° in **3b**, 3° in **2a**, and less than that in **2b** and **3a**. Angles N(1)–C(11)–C(12) are larger in the (*E*)-isomers (124.6° in **2a**, 123.7° in **2b**) than in the (*Z*)-isomers (116.1° and 113.4° in **3a**, and 115.3° in **3b**). The C=N bonds are twisted out of the

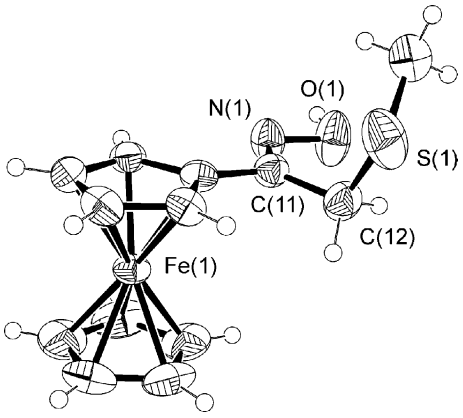

Fig. 1. Molecular structure of **2a** with 50% displacement ellipsoids.

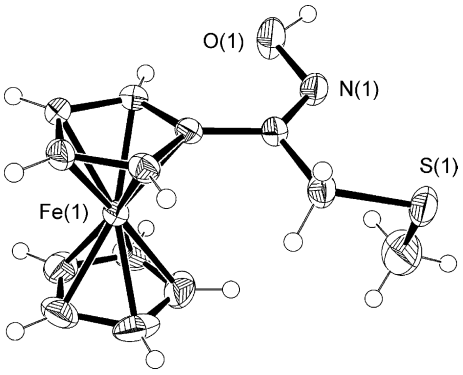

Fig. 2. Molecular structure of **3a** with 50% displacement ellipsoids.

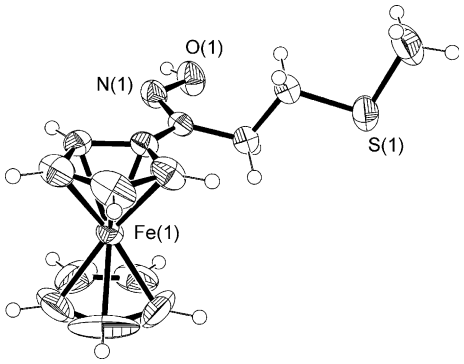

Fig. 3. Molecular structure of **2b** with 50% displacement ellipsoids.

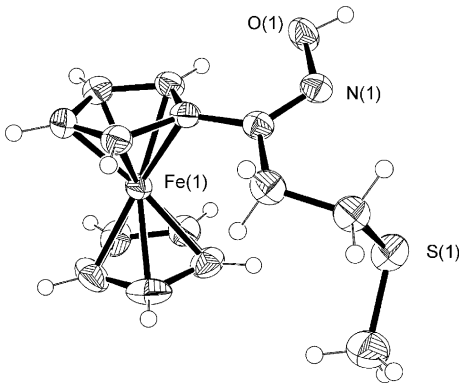

Fig. 4. Molecular structure of **3b** with 50% displacement ellipsoids.

Cp ring plane by dihedral angles of 7.8° in **2a**, 13.0° in **2b**, 16.6° in **3a** and 24.8° in **3b**. In crystals of **3a**, two molecules were found in the asymmetric unit, one of them with the sulfur atom showing a 0.85:0.15 disorder. It is noteworthy that in the latter molecule the C=N bond is rotated inside the Cp ring plane by −9.8°. The oximes form dimers in the crystal by hydrogen bonding between OH and N′, with N′–O distances of 2.775 Å in **2a**, 2.797 Å in **2b**, 2.777, 2.793 Å in **3a** and 2.801 Å in **3b**. There is no evidence for interconversion of the (*E*)/(*Z*)-isomers in the lattice. The molecular structures are shown in Figs. 1–4, and crystal data and structure refinement details are summarised in Table 1.

4. Conclusion

In this work, the synthesis and structural characterisation of (*E*)/(*Z*)-isomeric oximes of 1-ferrocenyl-3-thiabutan-1-one and 1-ferrocenyl-4-thiapentan-1-one are described. These compounds are bidentate ligands containing a thioether group which can be used to design new transition metal complexes. On prolonged standing in solution, an equilibrium is formed between the energetically preferred (*E*)- and less stable (*Z*)-isomers.

Abstract

The reactions of *N*,*N*′-di(2-methoxyphenyl)formamidine (*o*-HDMophF) with transition metal halide complexes afforded $CuCl_2 \cdot$(*o*-HDMophF), **1**, $[CoX_4][o\text{-}H_2DMophF]_2$ (X = Cl, **2**; Br, **3**) and MCl_2(*o*-HDMophF)$_2$ (M = Cd, **4**; Ni, **5**; Mn, **6**; Pd, **7**). These complexes were characterized by single-crystal X-ray diffraction and elemental analyses. The neutral *o*-HDMophF ligands in complexes **4**–**6** and **7** are coordinated to the metal centers in new bidentate and monodentate fashions, respectively. In the crystal structures of **1**–**7**, C–H···X and/or N–H···X (X = Cl, Br) interactions are found to link the metal units to the *o*-HDMophF ligand or its protonated cation ($o\text{-}H_2DMophF^+$). The neutral *o*-HDMophF compound in **1** adopts the *s-trans-anti-s-trans*-conformation, while those in complexes **4**–**6** and **7** adopt the *s-trans-anti-s-trans*- and *s-cis-anti-s-trans*-conformations, respectively. The $o\text{-}H_2DMophF^+$ cations of complexes **2** and **3** adopt the *s-cis-syn-anti-s-trans* and *s-trans-anti-anti-s-trans* conformations.

1. Introduction

The anion of the compound *N*,*N*′-di(2-methoxyphenyl)formamidine, *o*-DMophF$^-$, has been subjected to several studies of its coordination ability to metal centers. Tetradentate, tridentate and bidentate coordination modes **I**–**III** (Scheme 1) have been seen for this anion. In the tetradentate mode of coordination, **I**, two nitrogen atoms and two oxygen atoms are chelating and bridging to the metal centres. Such coordination was found in the dinuclear complex Ag_2(*o*-DMophF)$_2$ [1]. The coordination mode, **II**, which features chelation by one nitrogen atom and one oxygen atom together with the formation of a bridge through the two nitrogen atoms, was found in the dinuclear complex *trans*-$Ru_2(O_2CCH_3)_2$(*o*-DMophF)(*o*-DMophF′) (*o*-DMophF′ = (*o*-methoxyphenyl)(*o*-oxyphenyl)formamidine anion) [2]. The nitrogen atoms of the *o*-DMophF$^-$ ligands in the quadruply bonded complexes, *cis*-$Cr_2(O_2CCH_3)_2$(*o*-DMophF)$_2$ and *trans*-$Mo_2(O_2CCH_3)_2$(*o*-DMophF)$_2$ [3], are bridged to the metal centers, while the oxygen atoms are not coordinated, **III**. No complex containing the neutral *o*-HDMophF ligand or its protonated form $o\text{-}H_2DMophF^+$ has been reported. We report herein several mononuclear complexes of *o*-HDMophF ligands that coordinate to the metal centers in new bidentate and monodentate fashions, **IV** and **V**, respectively. The

synthesis and structures of $CuCl_2 \cdot$(*o*-HDMophF), $[CoX_4][o\text{-}H_2DMophF]_2$ (X = Cl and Br) and MCl_2 (*o*-HDMophF)$_2$ (M = Cd, Ni, Mn and Pd) and the conformations of the neutral *o*-HDMophF and its protonated cation *o*-H_2DMophF$^+$ form the subject of this report.

2. Experimental

2.1. General procedures

All manipulations were carried out under dry, oxygen-free nitrogen by using Schlenk techniques, unless otherwise noted. Solvents were dried and deoxygenated by refluxing over the appropriate reagents before use. *n*-Hexane and diethyl ether were purified by distillation from sodium/benzophenone, dichloromethane from P_2O_5 and acetonitrile from CaH_2. The visible absorption spectra were recorded on a Hitachi U-2000 spectrophotometer. IR spectra were obtained from a Jasco FT/IR-460 plus spectrometer. Elemental analyses were obtained from a PE 2400 series II CHNS/O analyzer.

2.2. Materials

$CoCl_2 \cdot 6H_2O$, $CoBr_2$, $MnCl_2$, $NiCl_2$ and $PdCl_2$ were purchased from Strem Chemical Co. $CuCl_2 \cdot 2H_2O$ and $CdCl_2 \cdot H_2O$ were purchased from MERCK Co. The ligand *N*,*N*′-di(2-methoxyphenyl)formamidine (*o*-HDMophF) was prepared according to a previously reported procedure [1].

2.3. Preparations

2.3.1. $CuCl_2 \cdot$(*o*-HDMophF)

$CuCl_2 \cdot 2H_2O$ (0.17 g, 0.99 mmol) was added to a solution of *N*,*N*-di(2-methoxy-phenyl)formamidine (*o*-HDMophF) (0.25 g, 0.98 mmol) in 20 ml CH_2Cl_2. The mixture was refluxed for 24 h and then allowed to cool down to room temperature to afford a brown solution and a dark brown solid. The solid was filtered out and *n*-hexane was added to induce precipitation. The precipitate was filtered and washed by ether (3×10 ml) and then dried under reduced pressure to give the dark brown product. Yield: 0.24 g (56%). UV–vis (CH_2Cl_2): 546 nm. *Anal*. Calc. for $C_{15}H_{16}CuCl_2N_2O_2$ (MW = 390.74), C, 46.11; H, 4.13; N, 7.17. Found: C, 46.13; H, 4.16; N, 7.23%. FT-IR (cm^{-1}) (KBr disk): 3197(b), 2963(s), 2345(w), 1685(s), 1638(s), 1594(s), 1524(m), 1508(w), 1459(s), 1340(m), 1286(w), 1259(s), 1175(w), 1113(s), 1021(s), 803(s), 750(s), 457(w), 419(w).

2.3.2. $[CoCl_4][o\text{-}H_2DMophF]_2$

$CoCl_2 \cdot 6H_2O$ (0.24 g, 1.01 mmol) was added to a solution containing *o*-HDMophF (0.51 g, 1.99 mmol) in 20 ml CH_2Cl_2. The mixture was then refluxed for 24 h and allowed to cool down to room temperature to afford a blue solution and a light blue solid. The solid was filtered out and then *n*-hexane was added to induce precipitation. The precipitate was filtered and washed by ether (3×10 ml) and then dried under vacuum to give the light blue product. Yield: 0.44 g (78.4%). UV–vis (CH_2Cl_2): 644 nm. *Anal*. Calc. for $C_{30}H_{34}CoCl_4N_4O_4$ (MW = 715.34), C, 50.37; H, 4.79; N, 7.83. Found: C, 49.93; H, 4.96; N, 7.70%. FT-IR (cm^{-1}) (KBr disk): 3447(b), 1718(w), 1685(s), 1655(s), 1637(w), 1560(m), 1541(s), 1524(w), 1508(m), 1459(s), 1259(s), 1113(m), 1023(s), 799(m), 750(s).

2.3.3. $[CoBr_4][o\text{-}H_2DMophF]_2$

Procedures for **3** were similar to those for **2**. Yield: 0.36 g (40%). UV–vis (THF): 675 nm. *Anal*. Calc. for $C_{30}H_{34}Br_4CoN_4O_4$ (MW = 893.18), C, 40.34; H, 3.84; N, 6.27. Found: C, 40.47; H, 4.04; N, 5.86%. FT-IR (cm^{-1}) (KBr disk): 3448(b), 1716(w), 1685(s), 1654(s), 1633(w), 1562(m), 1541(s), 1520(w), 1509(m), 1458(s), 1257(s), 1116(m), 1025(s), 794(m), 753(s).

2.3.4. $CdCl_2$(*o*-HDMophF)$_2$

Procedures for **4** were similar to those for **2**. Yield: 0.41 g (60%). *Anal*. Calc. for $C_{30}H_{32}CdCl_2N_4O_4$ (MW = 695.92), C, 51.78; H, 4.62; N, 8.05. Found: C, 51.73; H, 4.68; N, 7.88%. UV–vis (CH_2Cl_2): 348 nm. FT-IR (cm^{-1}) (KBr disk): 3189(w), 2938(m), 1735(w), 1685(w), 1649(s), 1591(s), 1514(s), 1459(s), 1433(m), 1396(w), 1333(m), 1288(w), 1258(m), 1245(s), 1183(s), 1157(m), 1118(s), 1048(m), 1026(s), 790(w), 755(s), 669(w), 585(w), 485(w), 418(w).

Procedures for **7** were similar to those for **2**. Yield: 0.46 g (77%). UV–vis (CH_2Cl_2): 502 nm. *Anal*. Calc. for $C_{30}H_{32}PdCl_2N_4O_4$ (MW = 689.93), C, 52.23; H, 4.67; N, 8.12. Found: C, 52.40; H, 4.66; N, 8.07%. FT-IR (cm^{-1}) (KBr disk): 3448(b), 3357(s), 3233(m), 2838(w), 1655(s), 1598(s), 1514(m), 1494(s), 1458(m), 1420(w), 1389(w), 1371(m), 1328(w), 1309(w), 1297(m), 1277(m), 1246(s), 1208(w), 1185(w), 1157(m), 1115(s), 1048(m), 1023(s), 955(m), 844(w), 789(w), 757(s), 598(m), 538(w), 507(w), 490(w), 467(w), 440(w).

2.4. X-ray crystallography

Single crystal X-ray diffraction data were collected at 22 °C using either a Bruker AXS P4 (complexes **1**, **2** and **6**) or a Siemens CCD diffractometer (complexes **2**, **4** and **5**), which were equipped with graphite-monochromated Mo Kα (0.71073 Å) radiation. Data reduction was carried by standard methods with the use of well-established computational procedures [4].

A light yellow crystal of **1** was mounted on the top of a glass fiber with epoxy cement. Cell constants were derived from least-squares refinement of 40 reflections having $10.1 < 2\theta < 24.8$. The ω-scan data collection method was used to collect the data points at $3.84° < 2\theta < 50.00°$. The structure factors were obtained after Lorentz and polarization correction. An empirical absorption correction based on a series of ψ-scans was applied to the data. The positions of some of the heavier atoms, including the copper atom, were located by direct methods. The remaining atoms were found in a series of alternating difference Fourier maps and least-square refinements [5]. The final residuals of the final refinement were $R_1 = 0.0459$, $wR_2 = 0.1233$. The crystallographic procedures for **2**, **6** and **7** were similar to those for **1**.

A yellow crystal of **3** was mounted on the top of a glass fiber with epoxy cement. The hemisphere data collection method was used to scan the data points at $4.24° < 2\theta < 50.0°$. The structure factors were obtained after Lorentz and polarization correction. An empirical absorption correction based on 'multi-scan' was applied to the data. The positions of some of the heavier atoms, including the Co atom, were located by direct methods. The remaining atoms were found in a series of alternating difference Fourier maps and least-square refinements [5]. The final residuals of the final refinement were $R_1 = 0.0351$, $wR_2 = 0.0673$. The crystallographic procedures for **4** and **5** were similar to those for **3**. For complex **4**, no solution can be obtained if *C*2/*c* was used to solve the structure. The space group *Cc* was then selected to get the final structure.

For complexes **1**, **5**, **6** and **7**, all the hydrogen atoms, except the methyl hydrogen atom, H30A, H30B and H30C in **5**, were located in the difference electron density map and refined isotropically. The hydrogen atoms of complexes **2**, **3** and **4** and H30A, H30B and H30C in **5** were placed in geometrically calculated positions using the HADD program and refined using a riding model. Basic information pertaining to crystal parameters and structure refinement is summarized in Table 1.

3. Results and discussion

3.1. Synthesis

The reactions of *N*,*N*′-di(2-methoxyphenyl)formamidine (*o*-HDMophF) with $CuCl_2 \cdot 2H_2O$, $CoCl_2 \cdot 6H_2O$, $CoBr_2$, $CdCl_2 \cdot H_2O$, $MnCl_2$, $NiCl_2$ and $PdCl_2$ in refluxing CH_2Cl_2 afforded the complexes $CuCl_2 \cdot (o\text{-}HDMophF)$, **1**, $[CoX_4][o\text{-}H_2DMophF]_2$ (X = Cl, **2**; Br, **3**) and $MCl_2(o\text{-}HDMophF)_2$ (M = Cd, **4**; Ni, **5**; Mn, **6**; Pd, **7**), respectively. It is noted that although similar reaction conditions were used to prepare **1**–**7**, different types of products were obtained, presumably due to the different reactivity of the metal centers to *o*-HDMophF.

3.2. Structure of *1*

Yellow complex **1** was solved in the space group $P2_1/c$. Fig. 1 shows the ORTEP drawing of **1**, and the correct formulation for this complex is $CuCl_2 \cdot (o\text{-}HDMophF)$. Selected bond distances and angles are listed in Table 2. The copper atom is bonded to two chlorine atoms to form a linear geometry. The two Cu–Cl distances are 2.1873(15) and 2.1752(15) Å and the Cl–Cu–Cl angle is 178.71(4)°. The packing diagram of complex **1** shows

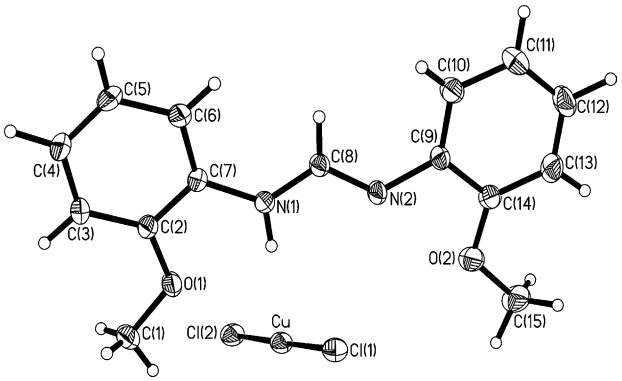

Fig. 1. An ORTEP diagram of complex **1**.

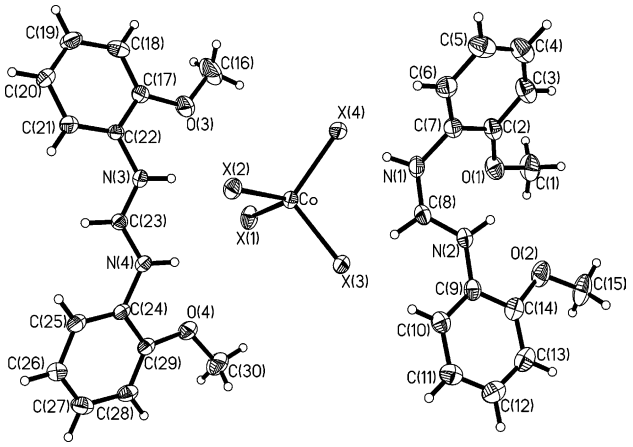

Fig. 2. A representative ORTEP drawing of complexes **2** (X = Cl) and **3** (X = Br).

that the metal units and *o*-HDMophF are interlinked through extensive N–H···Cl and C–H···Cl hydrogen bonds (H···Cl = 2.467–3.204 Å). Some weak Cu···O interactions (3.157 Å) are also found.

3.3. Structures of **2** and **3**

The structures of complexes **2** and **3** were solved in the space group $P2_12_12_1$, and a representative ORTEP drawing is shown in Fig. 2. Selected bond distances and angles are listed in Table 2. The Co atoms in **2** and **3** are bonded to four halide atoms, forming a distorted tetrahedral geometry. The Co–Cl lengths are in the range from 2.2560(12) to 2.2923(12) Å with the Cl–Co–Cl angles varying within the range from 106.34(5)° to 113.23(5)°, while the Co–Br lengths are in the range from 2.3980(9) to 2.4171(9) Å with the Br–Co–Br angles varying within the range from 106.45(3)° to 113.06(4)°. It is noted that two different conformations are observed for the *o*-H_2DMophF$^+$ cations for each complex (vide infra).

The packing diagram of complex **2** and **3** shows that the molecules pack into layers of discrete CoX_4^{2-} (X = Cl, **2** and Br, **3**) anions which are separated by layers of the *o*-H_2DMophF$^+$ cations. The ions interact through extensive N–H···X and C–H···X hydrogen bonds (H···Cl = 2.521–2.903 Å, ∠N–H···Cl and ∠C–H···Cl = 147.5–175.3°; H···Br = 2.527–3.037 Å,

∠C–H···Br and ∠N–H···Br = 122.0–171.2°). The distance of the π–π stacking interactions is 4.002 Å.

3.4. Structures of **4**–**6**

Pale crystals of **4** conform to the space group *Cc* with twenty molecules in a unit cell. Five independent $CdCl_2$(*o*-HDMophF)$_2$ molecules were found in each asymmetric unit of **4**. Light yellow crystals of **5** and colorless crystals of **6** all conform to the space group $P2_1/c$ with four molecules in a unit cell. Fig. 3 shows the representative ORTEP drawing for the complexes **4**–**6**. Selected bond lengths and angles for **4**–**6** are listed in Tables 3 and 4, respectively. It is seen from Fig. 3 that the metal atoms are bonded to two *cis* chloride atoms, two *trans* amine nitrogen atoms and two *cis* methoxy oxygen atoms. The *o*-HDMophF ligands chelate the center metal atoms through the amine nitrogen atom and the methoxy oxygen atom to form five-membered rings. The neutral *o*-HDMophF ligands in complexes **4**–**6** are thus coordinated to the metal centers in a new bidentate bonding mode, as shown in **IV**, Scheme 1. The metal centers, which adopt a distorted octahedral coordination geometry, have bond angles that significantly deviate from 90° or 180°, presumably due the chelation of the bidentate *o*-HDMophF ligands. The bis-chelate complexes are all chiral, showing either Δ or Λ configuration, and have approximate C_2 symmetries. As seen in Table 3, the five independent molecules show subtle differences in the bond distances and angles. It is also noted that in complexes **4**–**6** the M-O distances are all significantly longer than the M-N distances. The molecules interact through extensive C–H···Cl hydrogen bonds by means of interactions among the chloride atoms and the C–H hydrogen atoms of the bidentate *o*-HDMophF ligand. The C–H···Cl distances are in the range from 2.705 to 2.879 Å.

3.5. Structure of **7**

Yellow crystals of **7** conform to the space group $P2_1/c$ with two molecules in the unit cell. Fig. 4 shows the

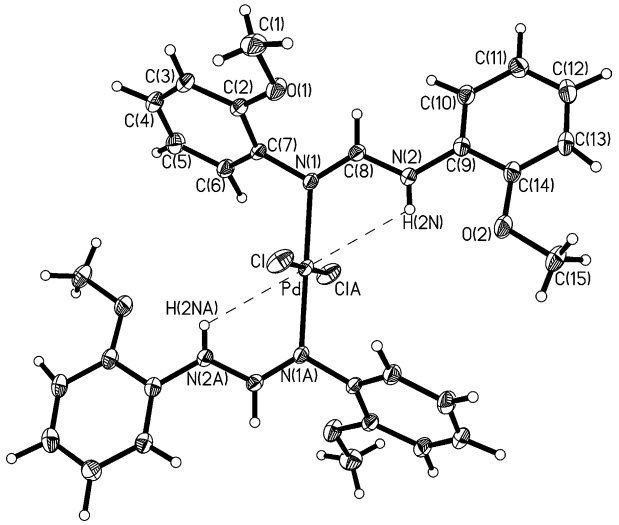

Fig. 4. An ORTEP drawing of complex **7**.

ORTEP drawing for complex **7** and some selected bond distances and angles of interest are given in Table 4. The palladium atom which adopts a distorted square planar coordination geometry is bonded to two *trans* chloride atoms (Pd–Cl = 2.2986(10) Å) and two *trans* amine nitrogen atoms (Pd–N(1) = 2.019(3) Å). In marked contrast to the bonding mode adopted in complexes **4**–**6**, the neutral *o*-HDMophF ligands are coordinated to the Pd atom through only one of the two nitrogen atoms. The oxygen atoms are not coordinated. The neutral *o*-HDMophF ligands in complex **7** are thus coordinated to the metal centers in a new monodentate bonding mode, as shown in **V**, Scheme 1. It is also noted that two short N–H···Pd distances (Pd···H = 2.794 Å, ∠Pd···H–N = 116.0°) which are *trans* to each other are observed.

The molecules interact through extensive C–H···Cl hydrogen bonds by means of interactions among the chloride atoms and the C–H hydrogen atoms of the monodentedate *o*-HDMophF ligand. The C–H···Cl distance is 2.794 Å and the C–H···Cl angle is 160.9°.

3.5.1. Conformation of the neutral *o*-HDMophF and the cation *o*-H_2DMophF$^+$

The neutral *o*-HDMophF or *o*-H_2DMophF$^+$ cation in each complex is not flat, but twisted around the C–N bonds. Table 5 lists the dihedral angles between the two phenyl rings of the neutral *o*-HDMophF or *o*-H_2DMophF$^+$ cation in each complex, as well as the torsional angles used to define their conformations (vide infra, Table 6). It is seen from Table 5 that complex **7** shows the largest dihedral angle. A conformational descriptor for anionic diarylformamidine bearing an *m*-alkoxy substituent has been proposed by Ren and co-authors [6]. Based on their proposition, three stable

conformations exist for diarylformamidine which are defined as (a) *s-cis*,*s-cis*- (*s-cis*-/*s-trans*- are defined between N–C (methine) bond and the ring C–C bond prioritized by the OR group), (b) *s-cis-s-trans*-, and (c) *s-trans-s-trans*-, respectively. To describe the conformations for the neutral *N*,*N*′-di(2-pyridyl)formamidine (HDpyF) and *N*,*N*′-di(6-methyl-2-pyridyl)formamidine (HDMepyF) ligands, where the amine hydrogen atoms are retained, we have modified this descriptor and show eight possible conformations for the neutral dipyridylformamidine ligands [7]. These eight conformations are: (a) *s-trans-anti-s-trans*, (b) *s-trans-anti-s-cis*, (c) *s-cis-anti-s-trans*, (d) *s-cis-anti-s-cis*, (e) *s-trans-syn-s-trans*, (f) *s-trans-syn-s-cis*, (g) *s-cis-syn-s-trans*, and (h) *s-cis-syn-s-cis*, where *syn* and *anti* indicate the relative positions of the methine and amine hydrogen atoms, respectively. Based on this descriptor, the conformations of the neutral *o*-HDMophF in complexes **1**, **4**, **5** and **6** are assigned as *s-trans-anti-s-trans* while that in complex **7** is *s-cis-anti-s-trans*.

Scheme 2. Possible conformation for the cationic *o*-H_2DMophF$^+$ ligands. (a) *s-trans-anti-anti-s-trans*; (b) *s-trans-syn-syn-s-trans*; (c) *s-cis-anti-anti-s-cis*; (d) *s-cis-syn-syn-s-cis*; (e) *s-trans-anti-anti-s-cis*; (f) *s-trans-syn-syn-s-cis*; (g) *s-trans-trans-syn-s-trans*; (h) *s-cis-anti-syn-s-cis*; (i) *s-trans-anti-syn-s-cis*; and (j) *s-cis-anti-syn-trans*.

To describe the conformation for the *o*-H_2DMophF$^+$ cations in complexes **2** and **3** which contains two amine hydrogen atoms, one more *syn* or *anti* should be added to describe the relative position of the amine hydrogen atoms. As shown in Scheme 2, 10 possible conformations can be drawn for the *o*-H_2DMophF$^+$ cation. Based on this new descriptor, the conformations of the two *o*-H_2DMophF$^+$ cations in complexes **2** and **3** are assigned as *s-cis-syn-anti-s-trans* and *s-trans-anti-anti-s-trans*. Table 6 lists the conformations of the neutral *o*-HDMophF, anionic *o*-DMophF$^-$ and cationic *o*-H_2DMophF$^+$ adopted in the metal complexes reported so far. For comparison, it is noted that the conformation of the cationic H_2DMepyF$^+$ ligands in the complexes *trans*-[$Mo_2(H_2DMepyF)_2(CH_3CN)_4$](ax-$CH_3CN)_2(BF_4)_6 \cdot 2CH_3CN$ and *trans*-[$Mo_2(H_2DMepyF)_2(CH_3CN)_4$](ax-$BF_4)_2(BF_4)_4 \cdot 2CH_3CN$ are similar to those in the anionic diarylformamidine ligands since the amine hydrogen atoms have been removed and these cationic ligands were assigned the *s-cis*, *s-cis* conformation [8].

4. Conclusions

The synthesis and structures of seven complexes containing neutral *o*-HDMophF or its cation *o*-H_2DMophF$^+$ have been successfully accomplished. The *o*-HDMophF ligands in complexes **4**–**6** and **7** are coordinated to the metal centers in new bidentate and monodentate bonding modes, respectively. All of them show supramolecular structures in the solid state by various types of weak interactions, including C–H···X and N–H···X (X = Cl or Br) hydrogen bondings and π–π stacking interactions.

The neutral *o*-HDMophF ligands in complexes **1**, **4**, **5** and **6** adopt the *s-trans-anti-s-trans* conformation while that in complex **7** adopts the *s-cis-anti-s-trans* conformation. The *o*-H_2DMophF$^+$ cations in **2** and **3** adopt the new *s-cis-syn-anti-s-trans*- and *s-trans-anti-anti-s-trans*-conformations.

Abstract

The complexation behaviour of the bidentate ligand tetrakis(*O-iso*propyl)methylenediphosphonate (L = $(i\text{PrO})_2\text{P(O)CH}_2\text{-P(O)(O}i\text{Pr)}_2$) with lanthanide ions has been studied by using triflates Ln(OTf)_3 (Ln = La, Pr, Nd) as sources of the Ln^{3+} cations. At the 2:1 L:Ln stoichiometric ratio, adducts of composition $[\text{Ln(OTf)}_3\text{(L)}_2\text{(OH}_2)_2]$ were isolated (Ln = La, Pr, Nd). In the X-ray structure of the cationic $[\text{Nd(OTf)}_2\text{(L)}_2\text{(OH}_2)_2]\text{(OTf)}$, the two coordinated triflates are monodentate. Finally, at higher L/Ln ratios, complexes were difficult to isolate because of a high degree of solvation, but, in one instance, with Ln = La, by using inert atmosphere techniques, the tripositive complex $[\text{La(L)}_4]\text{(OTf)}_3\text{(CH}_3\text{CN)}_3$ has been obtained and characterised by X-ray. By contrast, in the crystal structures of $[\text{Ln(NO}_3)_3\text{(L)}_2]\text{(CH}_3\text{CN)}_2$, (Ln = Ce, Pr, Nd), all three nitrates are bidentate.

1. Introduction

There is currently much interest with respect to the application of lanthanide molecular compounds in organic synthesis, with a particular emphasis in the field of enantioselective catalysis by lanthanide coordination complexes [1]. In this area, complexes with both anionic and neutral ligands have been successfully employed. Since the lanthanide cations are very oxophilic, they are expected to interact strongly with highly polarised oxygen-bearing functional groups: for instance, complexes in which a phosphoryl (P═O) group is coordinated to a lanthanide element are well known [2]. However, structurally characterised complexes in which two phosphoryl moieties have been incorporated in an organic ligand chelated to a lanthanide ion are less common: the additional rigidity conferred to the complex by this type of ligands may have a positive effect for further synthetic and/or catalytic applications. In such complexes, the two phosphoryl groups have been linked to a pyridine N-oxide [3–7], an aromatic residue [8–10], a macrocyclic moiety [11], or to a simple one-carbon unit spacer, like in diphenylphosphinomethane dioxide [12–14] or hydroxydiphosphonates such as $(\text{MeO})_2\text{P(O)-CR(OH)-P(O)(OMe)}_2$ (R = Me, *t*Bu, Ph) [15,16]; in this latter case, the hydroxyl group may induce instability, and an interesting rearrangement can occur in the coordination sphere of the complexed lanthanide.

Some complexes of lanthanide nitrates with tetra-*iso*propyl- [17,18] and tetramethyl methylenediphosphonate [19] have been very recently described and some of them have been structurally characterised [18,19]. This type of ligand is attracting because methylenediphosphonates are very easily accessible in a single step by the Arbuzov reaction of an alkyl phosphite with dibromomethane [20]. Another described route to these compounds involves the reaction of the easily available methylenebis(phosphonic dichloride) with diverse

doi:10.1016/j.poly.2005.01.001

alcohols [21–23]. A great variety of methylenediphosphonate ligands can thus be anticipated, including optically active compounds if the alcohols used derive from the chiral pool.

It therefore seemed to us desirable to structurally characterise lanthanide triflate complexes with the tetra-*iso*propylmethylenediphosphonate: $(i\mathrm{PrO})_2\mathrm{P(O)}\text{-}\mathrm{CH_2P(O)}(\mathrm{O}i\mathrm{Pr})_2$ = L as chelating ligand, because, since the triflates are labile ligands, different complexes than that obtained with the nitrates should be expected with these precursors. We describe hereafter the isolation and crystal structures of complexes of lanthanide triflates with ligand L. We have also obtained crystal structures of cerium, neodymium and praseodymium nitrate complexes with the L ligand that have a slightly different composition and solid-state conformation than that those previously described with lanthanum and praseodymium [18], and we wish to report on them as well.

2. Results and discussion

Lanthanide nitrates have been previously used as precursors in the synthesis of complexes with chelating phosphonates [15–19] and diphosphine oxides [14], whilst the more labile lanthanide triflates have only been engaged in complexation with diphosphine oxides [13]. The reaction of the ligand L and lanthanide nitrates in the 2:1 stoechiometric ratio afforded complexes of which the composition $[\mathrm{Ln(NO_3)_3(L)_2}]$ (Ln = Ce, Pr, Nd, Dy, Y) is consistent with their elemental analysis. They were further characterised by proton NMR (except for Ln = Dy), ^{31}P NMR, and IR spectroscopy. The compounds with Ln = Ce, Nd [17], Pr [17,18] have already been described, but, with Ln = Dy, the compound prepared was assigned the composition $[\mathrm{L_3Dy_2(NO_3)_6}]$ [17]. In our case, we find that with Ln = Dy (and also Y, which is similar in size), the general formula $[\mathrm{Ln(NO_3)_3(L)_2}]$ is better suited. It should be noted that, as previously observed [15,16], acceptable ^{31}P spectra were obtained even with the strongly paramagnetic dysprosium complex, the signal having a linewidth of about 2 kHz. Since the ^{31}P spectrum of $[\mathrm{Y(NO_3)_3(L)_2}]$ was already broad at room temperature ($w1/2$ = ca. 30 Hz), and we suspected this was due to a dynamic process, we undertook a low temperature ^{31}P NMR study. The resulting very complex spectra indicate that several exchange processes with coalescence temperatures between −40 °C and below −100 °C are operative in this compound. This is not too surprising, if one takes into consideration the number of possible isomers in a 10-coordinated complex. For instance, no less than 8 enantiomeric pairs and 3 meso isomers are possible for 5 identical and symmetrical bidentate ligands around a sphenocorona, and many more are to be expected in our case.

A very recent report [18] presented the X-ray structures of $[\mathrm{Ln(NO_3)_3(L)_2}]$ (L = La, Pr) that were obtained by crystallisation of the complexes from dichloromethane–hexane. In this report, Mehring et al. obtained viscous oils obtained by evaporation of their acetonitrile solutions. We found that, on standing, the oils resulting from slow evaporation of acetonitrile solutions of $[\mathrm{Ln(NO_3)_3(L)_2}]$ (Ln = Ce, Pr and Nd) eventually deposited crystals of these complexes containing acetonitrile in the lattice, that we were able to analyse by X-ray. We feel that these structures are of interest because the lanthanide coordination sphere is significantly different in our solvates than in the already described unsolvated complexes [18] (see later for a discussion).

With the triflates, the new isolated products are water solvates of composition $[\mathrm{Ln(OTf)_3(L)_2(OH_2)_2}]$ (Ln = La, Pr, Nd). They were characterised by elemental analysis, ^{1}H and ^{31}P NMR, and X-ray structure with Ln = Nd. When the L:Ln ratio was increased to 4:1, solids were also obtained but they were deliquescent and only in the case of lanthanum could we obtain a few crystals of a compound for which the X-ray analysis revealed that the composition was $[\mathrm{La(OTf)_3(L)_4(CH_3CN)_3}]$. Table 1 presents the X-ray experimental details of all analysed compounds: $[\mathrm{Ln(NO_3)_3(L)_2}](\mathrm{CH_3CN})_2$ (Ln = Ce (**A**), Pr (**B**), Nd (**C**)), $[\mathrm{Nd(OTf)_2(L)_2(OH_2)_2}](\mathrm{OTf})$ (**D**) and $[\mathrm{La(L)_4}]\text{-}\mathrm{OTf})_3(\mathrm{CH_3CN})_3$ (**E**).

2.1. Solid state structures of the nitrates

X-ray quality crystals of **A**, **B** and **C** were obtained from acetonitrile. These three compounds are isomorphous and isostructural.

The structure of **A** is displayed in Fig. 1, and selected bond lengths and distances are presented in Table 2.

We describe in detail the structure of **B**, as a representative example, because its structure can be accurately compared with that of three previously described praseodymium phosphonate complexes: unsolvated $[\mathrm{Pr(NO_3)_2(L)_2}]$ [18]: $\mathbf{B}^0$, $[\mathrm{Pr(NO_3)_2(L^1)_2}]$ [16]: $\mathbf{B}^1$ ($\mathrm{L^1}$ = $[(\mathrm{MeO})_2\mathrm{P(O)}]_2\mathrm{C(OH)Me}$), and $[\mathrm{Pr(NO_3)_2(L^2)_2}]$ [15]: $\mathbf{B}^2$ ($\mathrm{L^2}$ = $[(\mathrm{MeO})_2\mathrm{P(O)}]_2\mathrm{C(OH)Ph}$), The structure of **B** consists of discrete molecules without any apparent intermolecular contacts. Likewise, there are no noticeable short contacts involving the nitrogen atom belonging to the acetonitrile solvent. Like in $\mathbf{B}^0$, $\mathbf{B}^1$ and $\mathbf{B}^2$, the 10-coordinated praseodymium atom in **B** is chelated by the nitrate anions and by the phosphoryl groups of the two phosphonate ligands. In these complexes, one can define an equatorial plane (Pl1) containing the praseodymium atom, one nitrate ligand (nitrogen N1) and the nitrogen atoms (N2 and N1_2) of the other two nitrate ligands. The chelating phosphonates are located on either parts of this plane. The conformation of the two

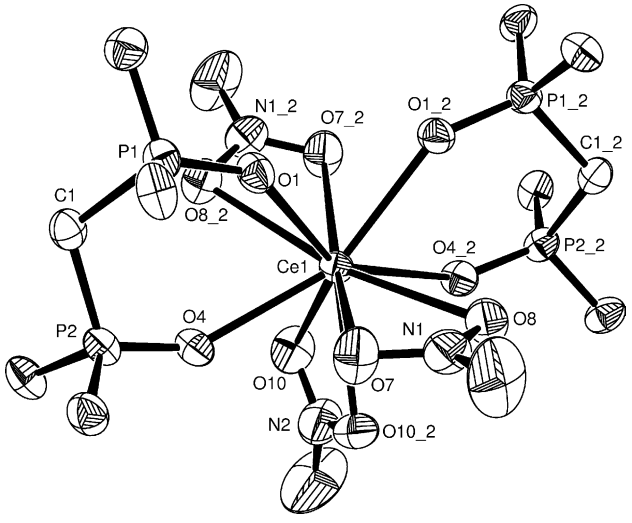

Fig. 1. An ORTEP plot of one molecule of **A** (50% ellipsoids). The *iso*propyl groups, methylene hydrogens, and the acetonitrile solvent molecules have been omitted for clarity.

6-membered rings consisting of the chelated phosphonates and the praseodymium atom is that of a flattened chair, the five heteroatoms (Pr and the two P═O groups) of these two rings being quasi-coplanar (planes Pl2 and Pl3 respectively). Likewise, the ''bite'' angle of the chelating diphosphonate in **B**: 73.26(6)° is similar to that found in $\mathbf{B}^0$: 74.95(6)° and 73.98(6)°, $\mathbf{B}^1$: 72.34(9)°, and $\mathbf{B}^2$: 73.6(3)° and 72.1(3)°. The other praseodymium-centred bonds and distances show no particular or unusual features.

There are, however, noticeable differences between the geometry of **B** and that of $\mathbf{B}^0$, $\mathbf{B}^1$ and $\mathbf{B}^2$, which are very similar to one another. In **B**, two nitrate ligands are almost perpendicular to the equatorial plane Pl1, the dihedral angles being equal to 88°; on the other hand, in $\mathbf{B}^1$ and $\mathbf{B}^2$, the nitrates are more slanted, this angle varyng from 61° to 72°. Even in $\mathbf{B}^0$, which has the same ligands around Pr than **B**, these angles are 57° and 69°. Likewise, the coordination of the diphosphonate ligands is less skewed in **B** than in $\mathbf{B}^0$, $\mathbf{B}^1$ or $\mathbf{B}^2$, as indicated by the value of the dihedral angles Pl2/Pl3 (**B**: 3°, $\mathbf{B}^0$: 24.5°, $\mathbf{B}^1$ and $\mathbf{B}^2$: 25°). Theses differences in geometry have the consequence that the coordination polyhedron around praseodymium in **B**, if one takes into consideration the O…O non bonding distances, is best described as a sphenocorona rather than a bicapped square antiprism in $\mathbf{B}^0$, $\mathbf{B}^1$ and $\mathbf{B}^2$ (Fig. 2). **B** and $\mathbf{B}^0$ can thus be considered as conformational isomers in the solid state.

This type of polyhedron has been observed in other lanthanide complexes [24].

The structures of **A** and **C** do not differ significantly from that of **B** except, of course, for the overall shortening of the Ln–O bonds from **A** to **C** due to the lanthanide contraction.

As a final remark, the configuration of **A**, **B**, $\mathbf{B}^0$, $\mathbf{B}^1$, $\mathbf{B}^2$ and **C** is notably different from that of a related cerium complex with the bis(diphosphino)methane dioxide ligand: $[Ce(NO_3)_3(Ph_2P(O)CH_2P(O)Ph_2)_2]$ [14]. In this latter complex, there is no equatorial plane containing the cerium atom, and the dihedral angle between the ligand planes is 92°.

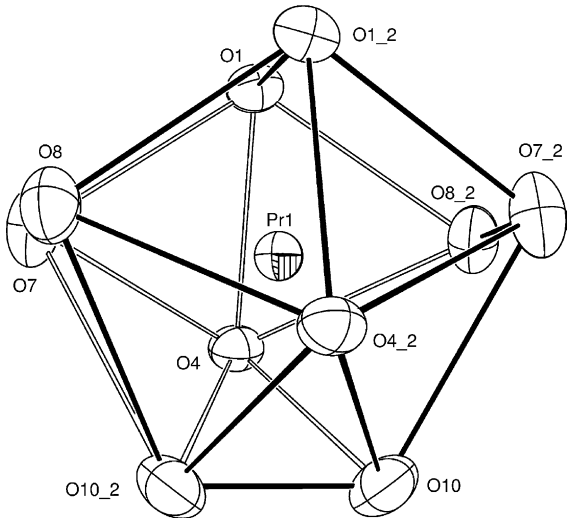

Fig. 2. Coodination polyhedron around praseodymium in **B**.

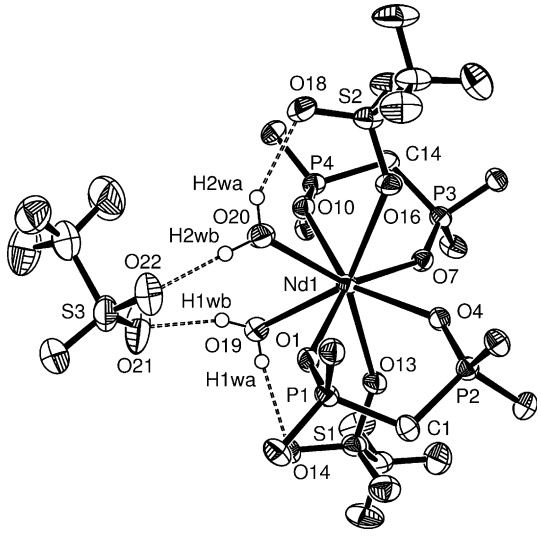

Fig. 3. An ORTEP plot of one molecule of **D** (50% ellipsoids). The *iso* propyl groups and the methylene hydrogens have been omitted for clarity.

2.2. Solid state structures of the triflates

X-ray quality crystals of $[Nd(OTf)_3(L)_2(OH_2)_2]$ (**D**) were also obtained from acetonitrile. The structure of **D** is displayed in Fig. 3, and selected bond lengths and distances are presented in Table 3.

This original structure consists of discrete ion pairs $[Nd(L)_2(OTf)_2(OH_2)_2](OTf)$ without any apparent intermolecular contacts. The 8-coordinated, monocationic neodymium atom is chelated by the phosphoryl groups of the two phosphonate ligands, bonded to two water molecules and to two monodentate triflates; the last triflate is not bonded to neodymium. The data were of sufficient quality that the coordinated water protons could be located and their positions refined. An interesting feature of this structure is that each of these protons interacts via hydrogen bonding with one oxygen atom of either the coordinated or the uncoordinated triflates. The distances span from 1.84 and 1.89 Å (hydrogen bonds to the "loose" triflate) to 2.06 and 2.08 Å (bonds to the coordinated triflates). These type of hydrogen bonds are also present in a few other lanthanide triflate hydrate complexes with chelating ligands [25–27]. The Nd–O (phosphoryl) bonds are quite similar to that found in the analogue of **C**: $[Nd(NO_3)_2(L^1)_2]$ [16], the Nd–O (monodentate triflate) bonds can be compared to that in $[Nd(OTf)_3(OPPh_3)_4]$ [28] and the Nd–O (water) bonds have no noteworthy features. Finally,

Fig. 3 shows the square antiprismatic coordination of the neodymium atom.

At the 4:1 ligand to Ln ratio, we were able to isolate a defined product **E** in the case of lanthanum, by working under strict exclusion of air and moisture. The crude crystals that were obtained at low temperature were covered with oil and quickly transferred to the diffractometer: any attempt to dry them resulted in the formation of amorphous product. The composition of **E** was shown by X-ray to be $[La(L)_4](OTf)_3(CH_3CN)_3$ (Fig. 4).

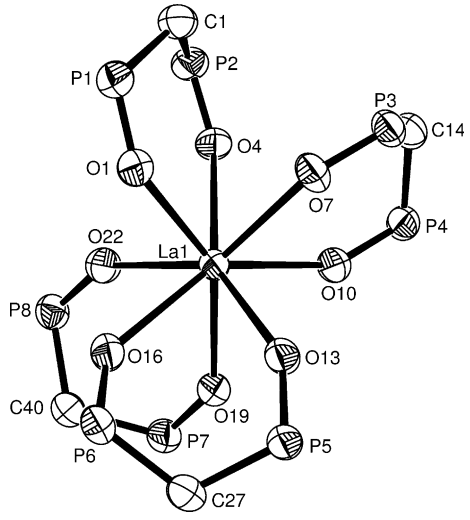

Fig. 4. An ORTEP plot of one molecule of **E** (50% ellipsoids). The *iso*propoxy groups, methylene hydrogens, uncoordinated triflates and acetonitrile solvent molecules have been omitted for clarity.

Selected bond lengths and distances are presented in Table 4.

Here, the 8-coordinated, tricationic lanthanum atom is only chelated by the phosphoryl groups of the four phosphonate ligands and has no interaction with either the lattice acetonitriles or the triflate anions, which have

thus been expelled from the coordination sphere of lanthanum. Two related complexes with bis(diphosphino)methane dioxide as chelating ligand have been described in the literature: $[Eu(Ph_2P(O)CH_2P(O)Ph_2)_4](H_2O)_2(ClO_4)_3$ [12], and $[La(Ph_2P(O)CH_2P(O)Ph_2)_4](OTf)_3(H_2O)_{1.5}$ [13], in which the coordination of the ligands can be compared to that of **E**. In particular, the La–O and P=O bonds are similar in this latter lanthanum complex and **E**. The coordination geometry of the lanthanum atom in **E** can be described as square antiprismatic.

3. Conclusion and perspectives

We have been able to structurally characterise for the first time methylenediphosphonate complexes of lanthanide triflates, and to extend the range of characterised methylenediphosphonate complexes of lanthanide nitrates. As expected, the triflate ligand is more labile: the lanthanide nitrate bis(methylenediphosphonate) complexes, prepared from the commercial hydrated nitrates, retain all three nitrate ions bonded to the lanthanide metal and no water is coordinated, whilst the lanthanide triflates, bis(methylenediphosphonate) complexes have water in the coordination sphere and one uncoordinated triflate. We have also shown that when used in the 4:1 L:Ln ratio, methylenediphosphonates are able to completely displace the triflates. Our next step will be to use other diphosphonate ligands bearing chiral alcohols at the phosphorus atom. Work in this direction is already in progress.

4. Experimental

4.1. General

All reactions were performed in air with commercially available starting materials and solvents, except for the preparation of **E** which was performed in a Braun Labmaster 130 drybox under argon. ^{1}H NMR spectra were measured at 300.13 MHz, and ^{31}P NMR spectra at 122 MHz (t = 20 °C). Elemental analyses were obtained at the Service de microanalyse du CNRS, Gif-sur-Yvette, France.

4.2. Syntheses

The 2:1 complexes were prepared by mixing together lanthanide nitrates or triflates (0.73 mmol) and $(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2$ (0.50 g, 1.45 mmol) in acetonitrile (5 ml). The complexes that precipitated on concentrating the acetonitrile solution were washed in ether and dried in vacuo. The 4:1 complex was prepared as described below.

4.2.1. Bis(methylenediphosphonate) lanthanide nitrate complexes

$[Ce(NO_3)_3\{(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2\}_2]$: colourless powder. Yield 0.31 g (77%). *Anal.* Calc. for $C_{26}H_{60}CeN_3O_{21}P_4$: C, 30.77; H, 5.96; N, 4.14. Found: C, 30.65; H, 5.91; N, 3.96%. IR (KBr): $\nu(NO_3^-)$: 1482, 1453, 1315, 1298 cm^{-1}, ν(P=O) 1215 cm^{-1}. ^{1}H NMR (CD_3CN) δ 1.52 (br, $w_{1/2}$ = 15 Hz, 48H, CH_3), 5.63 (br, $w_{1/2}$ = 25 Hz, 8H, CH), 6.68 (br, $w_{1/2}$ = 60 Hz, 4H, CH_2). ^{31}P NMR (CH_3CN): δ 43.2 ($w_{1/2}$ = 25 Hz).

$[Pr(NO_3)_3\{(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2\}_2]$: pale yellowish-green powder Yield 0.34 g (84%). *Anal.* Calc. for $C_{26}H_{60}N_3O_{21}P_4Pr$: C, 30.75; H, 5.95; N, 4.14. Found: C, 30.53; H, 5.92; N, 3.87%. NMR and IR data identical to those previously described [18].

$[Nd(NO_3)_3\{(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2\}_2]$: pale purple powder. Yield 0.35 g (78%). *Anal.* Calc. for $C_{26}H_{60}N_3NdO_{21}P_4$: C, 30.65; H, 5.94; N, 4.12. Found: C, 30.35; H, 5.88; N, 3.93%. IR (KBr): $\nu(NO_3^-)$: 1483, 1453, 1319, 1301 cm^{-1}, ν(P=O) 1218 cm^{-1}. ^{1}H NMR (CD_3CN) δ 1.45 (br, $w_{1/2}$ = 10 Hz, 24H, CH_3), 1.49 (br, $w_{1/2}$ = 10 Hz, 24H, CH_3), 5.36 (br, $w_{1/2}$ = 30 Hz, 8H, CH), 5.67 (br, $w_{1/2}$ = 80 Hz, 4H, CH_2). ^{31}P NMR (CH_3CN): 82 ($w_{1/2}$ = 180 Hz).

$[Dy(NO_3)_3\{(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2\}_2]$: colourless powder. Yield 0.33 g (80%). *Anal.* Calc. for $C_{26}H_{60}DyN_3O_{21}P_4$: C, 30.11; H, 5.83; N, 4.05. Found: C, 29.77; H, 5.71; N, 3.96%. IR (KBr): $\nu(NO_3^-)$: 1504, 1323 cm^{-1}, ν(P=O) 1208 cm^{-1}. ^{31}P NMR (CH_3CN): −64 ($w_{1/2}$ = 2 kHz).

$[Y(NO_3)_3\{(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2\}_2]$: colourless powder. Yield 0.31 g (86%). *Anal.* Calc. for $C_{26}H_{60}N_3O_{21}P_4Y$: C, 32.41; H, 6.28; N, 4.36. Found: C, 32.12; H, 6.32; N, 4.01%. IR (KBr): $\nu(NO_3^-)$: 1505, 1326 cm^{-1}, ν(P=O) 1209 cm^{-1}. ^{1}H NMR (CD_3CN): δ 1.35 (d, J_{HH} = 6 Hz, 24H, CH_3), 1.36 (d, J_{HH} = 6 Hz, 24H, CH_3), 2.65 (t, J_{PH} = 21 Hz, 4H, CH_2), 4.78 (m, 8H, CH). ^{31}P NMR (CH_3CN): 17.6.

4.2.2. Bis(methylenediphosphonate) lanthanide triflate complexes

$[La(SO_3CF_3)_3\{(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2\}_2(H_2O)_2]$: colourless powder. Yield 0.40 g (86%). *Anal.* Calc. for $C_{29}H_{64}F_9LaO_{23}P_4S_3$: C, 26.57; H, 4.92; N, 0.0. Found: C, 26.08; H, 4.91; N, 0.0%. IR (KBr): ν(O–H) 3278 cm^{-1}, [ν(S–O), ν(C–F)]: 1300, 1234 cm^{-1}, ν(P=O) 1212 cm^{-1}, ν(C–S) 634 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ 1.34 (d, J_{HH} = 6 Hz, 24H, CH_3), 1.35 (d, J_{HH} = 6 Hz, 24H, CH_3), 2.69 (t, J_{PH} = 21 Hz, 4H, CH_2), 3.85 (br, H_2O), 4.94 (m, 8H, CH). ^{31}P NMR ($CDCl_3$): δ 19.7.

$[Pr(SO_3CF_3)_3\{(i\text{PrO})_2P(O)CH_2P(O)(O i\text{Pr})_2\}_2(H_2O)_2]$: pale yellowish-green powder Yield 0.35 g (78%). *Anal.* Calc. for $C_{29}H_{64}F_9O_{23}P_4PrS_3$: C, 26.53; H, 4.90; N, 0.0. Found: C, 26.09; H, 4.86; N, 0.0%. IR (KBr): ν(O–H) 3304 cm^{-1}, [ν(S–O), ν(C–F)]: 1300, 1233 cm^{-1}, ν(P=O) 1199 cm^{-1}, ν(C–S) 635 cm^{-1}. ^{1}H NMR

($CDCl_3$): δ −21.1 (br, $w_{1/2}$ = 60 Hz, 4H, H_2O) 1.12 (br, $w_{1/2}$ = 15 Hz, 24H, CH_3), 3.62 (br, $w_{1/2}$ = 20 Hz, 24H, CH_3), 8.99 (br, $w_{1/2}$ = 35 Hz, 8H, CH), 21.04 (br, $w_{1/2}$ = 60 Hz, 4H, CH_2). ^{31}P NMR ($CDCl_3$): δ 107 ($w_{1/2}$ = 40 Hz).

$[Nd(SO_3CF_3)_3\{(iPrO)_2P(O)CH_2P(O)(OiPr)_2\}_2(H_2O)_2]$: pale purple powder Yield 0.35 g (78%). *Anal*. Calc. for $C_{29}H_{64}F_9NdO_{23}P_4S_3$: C, 26.47; H, 4.90; N, 0.0. Found: C, 26.35; H, 4.82; N, 0.0%. IR (KBr): ν(O–H) 3278 cm^{-1}, [ν(S–O), ν(C–F)]: 1300, 1235 cm^{-1}, ν(P=O) 1214 cm^{-1}, ν(C–S) 635 cm^{-1}. ^{1}H NMR ($CDCl_3$): δ −5.0 (br, $w_{1/2}$ = 100 Hz, 4H, H_2O) 0.90 (br, $w_{1/2}$ = 20 Hz, 24H, CH_3), 2.64 (br, $w_{1/2}$ = 20 Hz, 24H, CH_3), 6.61 (br, $w_{1/2}$ = 35 Hz, 8H, CH), 12.04 (br, $w_{1/2}$ = 60 Hz, 4H, CH_2). ^{31}P NMR ($CDCl_3$): δ 103 ($w_{1/2}$ = 60 Hz).

4.2.3. Tetrakis(methylenediphosphonate) lanthanum triflate complex

Crystals of $[La\{(iPrO)_2P(O)CH_2P(O)(OiPr)_2\}_2(OTf)_3(CH_3CN)_3]$ (**E**) were obtained as follows: Dry lanthanum triflate (0.18 g, 0.36 mmol) and $(iPrO)_2P(O)CH_2P(O)(OiPr)_2$ (0.50 g, 1.45 mmol) were mixed together in acetonitrile (5 ml). The solution volume was reduced to 1 ml and transferred into a glass tube of 5 mm internal diameter. About 2 ml of diethyl ether was carefully layered on top of this solution which was kept at 4 °C. Colourless, transparent crystals appeared after about 48 h. They were immersed in Paratone 8277 oil and quickly mounted on the diffractometer.

4.3. X-ray crystallography

Suitable single crystals of **A**, **B**, **C** and **D** were obtained from concentrated acetonitrile solutions at room temperature, and of **E** as described in Section 4.2.3. X-ray intensities were measured with a Nonius KappaCCD diffractometer at 150(1) K using Mo Kα radiation (λ = 0.71073 Å) and a graphite monochromator. A summary of the crystal structure determinations is presented in Table 1.

5. Supplementary material

CCDC 255823–255827 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; E-mail: deposit@ccdc.cam.ac.uk].

Abstract

Reaction of sodium azide with manganese(II) and 4-amino-1,2,4-triazol or 3-chloropyridine leads to the 1D systems $[Mn(N_3)_2(4\text{-amtr})_2]_n$ (**1**) or $\{[Mn(N_3)_2(3\text{-Clpy})_2]\cdot 1/2(3\text{-Clpy})\}_n$ (**2**), respectively. Compound **1** crystallises in the *C*2/*m* (monoclinic) group and consists of chains of Mn(II) cations bridged by double $\mu_{1,3}$-azido bridges in trans arrangement. Compound **2** crystallises in the *I*2/*a* (monoclinic) group and in this case the 1D system shows alternating double $\mu_{1,1}$ and $\mu_{1,3}$ bridges. Magnetic properties follow the expected antiferromagnetic (compound **1**) and alternating ferro-antiferromagnetic (compound **2**) behaviour.

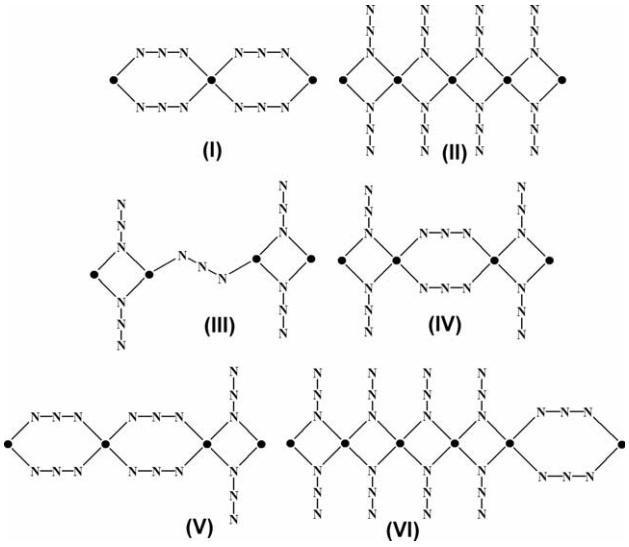
1. Introduction



Compounds with general formula $[Mn(N_3)_2(R\text{-py})_2]_n$ in which R-py is a pyridinic ligand with a R group in *meta* or *para*-position, provides a series of 1D derivatives in which the alternance of end-to-end ($\mu_{1,3}$-N_3, EE mode) and end-on ($\mu_{1,1}$-N_3, EO mode) azide bridges results in a complete graduation of magnetic responses [1].

This series of compounds, Scheme 1, goes from compounds containing only EE bridges [2,3a] to compounds containing only EO bridges [3] with antiferromagnetic or ferromagnetic response, respectively (I, II), trough systems in which the ratio of EE:EO bridges is 2:1 (V), [4] 1:1 (III, IV) [1,2a,5] or 1:4 (VI) [4a]. This gradual change of AF/F interactions provides an interesting material to study unusual magnetic properties as the topological ferrimagnetic response of compounds type V, [4] the EPR of chains with a gradual change of the superexchange and dipolar interactions [2a] or to develop theoretical studies to explain the new properties [2a,3b,4b].

As a consequence, study of the coordination chemistry and magnetic properties of azido-bridged systems has deserved the attention of magnetochemists in recent years due to the large number of the well characterised uncommon topologies and magnetic responses. The ability of the azido bridge to give different coordination modes as the EE, generally associated to antiferromagnetic coupling, or EO, generally associated to ferromagnetic coupling, [1] is the key of the versatility of this ligand. Moreover, in some limited cases, more exotic coordination modes as the $\mu_{1,1,1}$, $\mu_{1,1,3}$ or even $\mu_{1,1,1,1}$ and $\mu_{1,1,3,3}$ have been obtained with several cations [6]. In addition to molecular compounds with a wide range

Scheme 1. Characterised 1D motifs for Mn(II)-azido chains.

of nuclearity, [1,7] azido ligand easily tends to give extended systems up to 3D dimensionality, containing in the most of the cases EE and EO azido bridges simultaneously, which often gives long range order at moderately low temperatures [1,8].

Following our research on the Mn^{II}/azide/pyridine systems, we have structurally characterized two new systems, using L = 4-amino-1,2,4-triazol (4-amtr) and 3-chloropyridine (3-Clpy) to obtain the 1D systems $[Mn(N_3)_2(4\text{-amtr})_2]_n$ (**1**) and $\{[Mn(N_3)_2(3\text{-Clpy})_2]\cdot 1/2(3\text{-Clpy})\}_n$ (**2**). The two compounds consist of chains in which the manganese atoms are bridged by two azido ligands. For **1** the bridges are exclusively end-to-end, type I, showing the expected antiferromagnetic coupling whereas for **2** there are a regular alternance between the end-to-end and end-on coordination modes, type IV, giving an alternating ferro-antiferromagnetic system. The antiferromagnetic interactions have been correlated with the bond parameters of the bridging fragment on basis on the previously reported coupling model.

2. Experimental

2.1. General and physical measurements

Infrared spectra were recorded on a Bruker IFS-125 model FT-IR spectrophotometer as KBr pellets. Magnetic susceptibility measurements were carried out on polycrystalline samples at the Servei de Magnetoquímica of the University of Barcelona, with a DSM8 pendulum susceptometer working in the range 4–300 K under magnetic fields of approximately 1 T. Diamagnetic corrections were estimated from Pascal Tables.

2.2. Compounds preparation

WARNING! The reported azido complexes are potentially explosive. Only a small amount of material should be prepared and it should be handled with care.

2.2.1. $[Mn(N_3)_2(4\text{-amtr})_2]_n$ (*1*)

Irregular shaped crystals of 1 were separated from a clear aqueous solution (15 mL) containing $Mn(NO_3)_2\cdot 4H_2O$ (0.50 g, 2 mmol), NaN_3 (0.32 g, 5 mmol) and 4-amino-1,2,4-triazol (0.67 g, 8 mmol) after one day at room temperature. Yield: 0.18 g, 60%. $\nu_{as}(N_3)$ 2091 (vs) cm^{-1}. *Anal.* calc. for $C_4H_8MnN_{14}$: C, 15.6; H, 2.6; N, 63.8; Mn, 17.9. Found: C, 15.4; H, 2.5; N, 64.0; Mn, 18.1%.

2.2.2. $\{[Mn(N_3)_2(3\text{-Clpy})_2]\cdot 1/2\ (3\text{-Clpy})\}_n$ (*2*)

An aqueous solution (5 mL) of NaN_3 (0.32 g, 5 mmol) was added drop by drop to a methanolic solution (40 mL) of $Mn(NO_3)_2\cdot 4H_2O$ (0.50 g, 2 mmol) and 3-chloropyridine (0.68 g, 6 mmol). The resulting solution was filtered off and the filtrate was allowed to stand for several days at room temperature to deposit yellow-green crystals. Yield: 0.55 g, 65%. $\nu_{as}(N_3)$ 2135,(vs) and 2064 (vs) cm^{-1}. *Anal.* calc. for $C_{50}H_{40}Cl_{10}Mn_4N_{34}$: C, 35.5; H, 2.4; N, 28.2; Mn, 13.0. Found: C, 35.3; H, 2.2; N, 28.4; Mn, 13.2%.

2.2.3. X-ray data collection for compounds *1* and *2*

The X-ray single-crystal data for **1** [2] were collected on a modified STOE four circle diffractometer at 90(2)[88(2)] K. Crystal size: $0.40\times 0.22\times 0.14$ mm [$0.26\times 0.23\times 0.18$ mm]. The crystallographic data, conditions retained for the intensity data collection, and

[b] $wR(F_o)^2=\{\sum[w((F_o)^2-(F_c)^2)^2]/\sum[w(F_o)^4]\}^{1/2}$.

some features of the structure refinement are listed in Table 1.

Graphite-monochromatized MoKα radiation ($\lambda = 0.71069$ Å) with the ω-scan technique was used to collect the data sets. The accurate unit cell parameters were determined from automatic centring of 28 [35] reflections ($10.2° < \theta < 15.4°$) [$8.8° < \theta < 15.4°$] and refined by least-squares methods. 1262 [4746] reflections, 872 [4053] independent reflections, R_{int} 0.030 [0.021] were collected in the range ($3.3° < \theta < 30.0°$) [$2.9° < \theta < 29.0°$]. Intensity decay of 5% [4%] for control reflections (0 0; 1; 0 −2 0; −1 −1 0) [0 6 0; 3 1 0; 1 1 4], measured after every set of 100 reflections, was observed during data collection. Corrections were applied for Lorentz-polarization effects, intensity decay and for absorption in case of **1**, using the DIFABS [9] computer program. The structures were solved by direct methods using the SHELXS-86 [10] program and refined by full-matrix least-squares methods on F^2, using the SHELXL-93 [11] program incorporated in the SHELXTL/PC V 5.03 [12] program library and the PLATON [13] program. Anisotropic displacement parameters were applied to all non-hydrogen atoms. The hydrogen atoms were assigned with isotropic displacement factors and included in the final refinement cycles by use of geometrical restraints. In case of **2**, split occupancy of 0.5 and geometrical restraints were applied to atoms of disordered 3-Clpy lattice molecule located on the special position with site symmetry 2 (diad). Final $R[I > 2\sigma(I)]$ and wR factor for all observed reflections: 0.0421 and 0.1157 [0.0362 and 0. 0864]; number of refined parameters: 65 [247]. Maximum and minimum peaks in the final difference Fourier synthesis: 0.79 and −1.03 e Å^{-3} [0.48 and −0.37 e Å^{-3}]. Selected bond parameters are given in Tables 2 and 3, respectively.

3. Results and discussion

3.1. Crystal structure of $[Mn(N_3)_2(4\text{-amtr})_2]_n$ (1)

The labelled diagram for **1** is shown in Fig. 1. The basic structure consist of octahedrically coordinated manganese atoms in which the coordination sites are occupied by two 4-amino-1,2,4-triazol ligands in *trans* arrangement and four azido ligands. The azido ligands link the manganese atoms in the $\mu_{1,3}$ (EE) coordination mode, giving a 1D system with double azido bridges along the [0 0 1] direction. Bond parameters around Mn^{II} atoms are quite regular with all the bond lengths practically equal, around 2.222 Å and all the Mn–N–N bond angles of 129.6(2)°. Intrachain Mn···Mn distance is 5.362(2) Å.

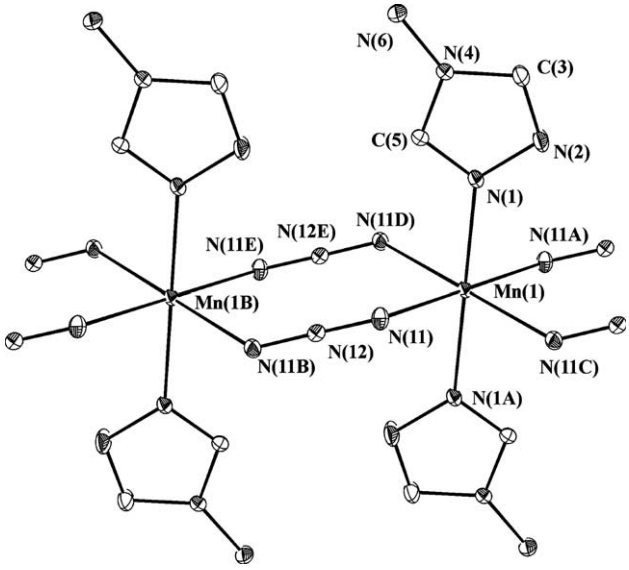

Fig. 1. ORTEP view (50% ellipsoids) of $[Mn(N_3)_2(4\text{-amtr})_2]_n$ (**1**). The chains are oriented along the *c*-axis of the unit cell. *Symmetry codes*: (A) $-x, -y, -z$; (B) $-x, y, -z-1$; (C) $-x, y, -z$; (D) $x, -y, z$.

The Mn–$(\mu_{1,3})_2$–Mn unit shows a chair distortion with a dihedral angle of 22.6(1)° between the azido plane and the plane determined by N(11)–Mn(1)–N(11D), Fig. 2(a).

The H-atoms of the $-NH_2$ group promotes a 3D network on basis of the N(6)–H···N(11) interactions, Fig. 3. N(6)···N(11) distances, 3.098(3) Å corresponds to a strong H-bond.

3.2. Crystal structure of $\{[Mn(N_3)_2(3\text{-}Clpy)_2]\cdot 1/2(3\text{-}Clpy)\}_n$ (2)

The labelled diagram for **2** is shown in Fig. 4. The basic structure consists of manganese atoms in octahedral environment with the coordination sites occupied by two *trans* 3-chloropyridines and four azido ligands. The manganese atoms are linked by double azido bridges, giving a 1D system along [0 0 1] direction, in which the azido ligands show a regular alternance between the $\mu_{1,1}$ and the $\mu_{1,3}$ coordination modes resulting an alternating system.

Mn–N bond lengths to pyridinic ligands (2.267–2.274 Å) are slightly larger than the Mn–N bond lengths to azido ligands (around 2.200 Å). The Mn–$(\mu_{1,1})_2$–Mn unit forms a planar centrosymmetric Mn_2N_2 ring with a Mn(1)–N(11)–Mn(1A) bond angle of 100.48(7)° and a Mn···Mn distance of 3.408(2) Å. The Mn–$(\mu_{1,3})_2$–Mn unit is not fully planar, showing a dihedral angle between the mean azido plane and N(21)–Mn(1)–N(23) plane of 9.77(9)°, with the Mn atoms 0.240(1) Å out the azido plane. In this case, the free 3-Clpy molecule intercalated between the coordinated 3-Clpy ligands forces to increase asymmetrically the interligand distance and produces a very unusual boat-distortion, Fig. 2(b). Mn···Mn distance of 5.287(2) Å. The intercalated 3-Clpy molecule forms mean dihedral angles of 5.5(1)° and 8.2(1)° with the neighbouring coordinated 3-Clpy ligands. The forces that determine the intercalation of neutral ligands in the structure should be attributed to π–π stacking, from the mean distance between the coordinated and intercalated 3-Clpy ligands (around 3.5 Å).

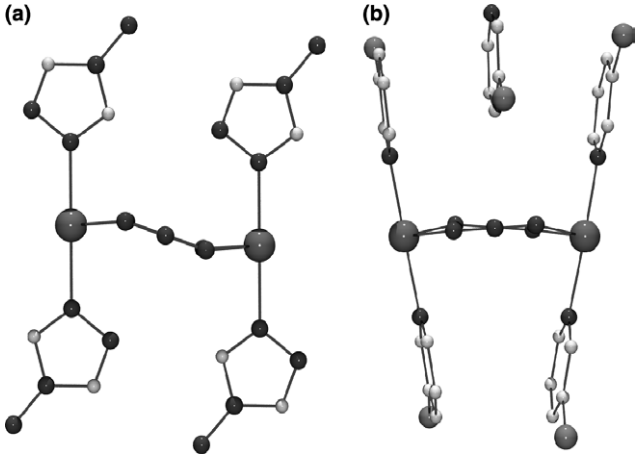

Fig. 2. Chair and boat conformation for the Mn–$(\mu_{1,3})_2$–Mn fragments for compounds **1** (a) and **2** (b).

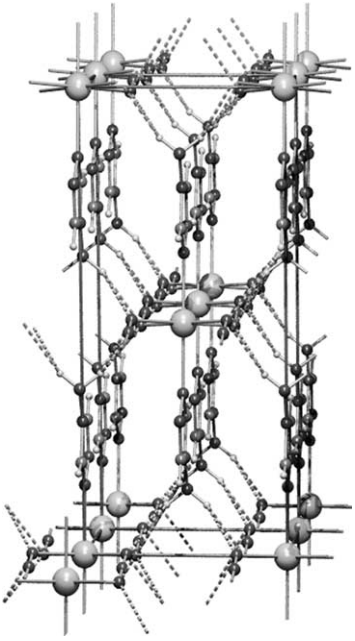

Fig. 3. 3D H-bond network built from the N(6)–H(6)···N(11) contacts for compound **1**.

3.3. Susceptibility measurements and coupling constants evaluation

The $\chi_M T$ product and the molar magnetic susceptibility versus temperature for $[Mn(N_3)_2(4\text{-amtr})_2]_n$ (**1**) and $\{[Mn(N_3)_2(3\text{-Clpy})_2]\cdot 1/2(3\text{-Clpy})\}_n$ (**2**) in the 300–4 K range are plotted in Fig. 5.

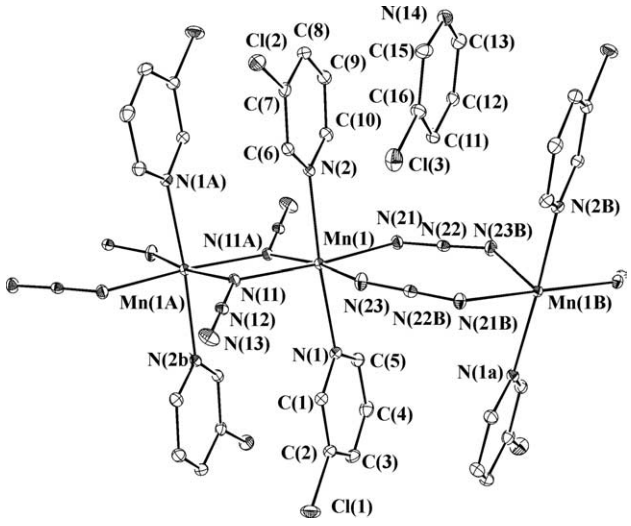

Fig. 4. ORTEP view (50% ellipsoids) with atom labelling scheme of $\{[Mn(N_3)_2(3\text{-}Clpy)_2]\cdot 1/2(3\text{-}Clpy)\}_n$ (**2**). The chains are oriented along the *c*-axis of the unit cell. *Symmetry codes*: (A) $-x+1/2, -y+1/2, -z+1/2$; (B) $-x+1/2, y, -z+1$.

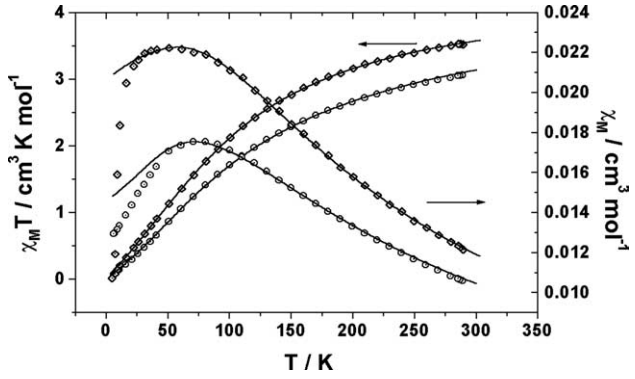

Fig. 5. Plot of χ_M and $\chi_M T$ product for compounds **1** (dot centred circles) and **2** (dot centred squares). Solid lines correspond to the best calculated fit (see text).

As can be expected from the structural data of **1**, this system show antiferromagnetic response: $\chi_M T$ at room temperature takes a 3.06-cm^3 K mol^{-1} value, decreasing continuously on cooling and tends to zero at low temperature, showing a maximum of susceptibility around 75 K. Fit for the experimental data was performed with the analytical expression derived by Fisher [14] for a infinite chain of classical spins, based in the Hamiltonian $H = -J\Sigma S_i \cdot S_{i+1}$ and local spin $S = 5/2$. Best fit parameters for the experimental data in the 50–300 K range were $J = -11.9(6)$ cm^{-1} and $g = 2.00(1)$. Introducing a zJ' parameter in the equation in order to take into account the possible interchain interactions derived from the H-bond network, which involves N(11)-atoms of the azido ligands, the best fit parameters in the 20–300 K range of temperature were $J = -11.1(2)$ cm^{-1}, $zJ' = -3.7(1)$ cm^{-1} and $g = 1.98(1)$. This second fit confirms that main J value is slightly greater than -11 cm^{-1}.

Magnetic response for **2** shows an overall antiferromagnetic behaviour. $\chi_M T$ at room temperature takes a 3.52-cm^3 K mol^{-1} value and decreases continuously on cooling and tends to zero at low temperature, showing a broad maximum of susceptibility at 50 K. Fit for the experimental data was performed with the analytical expression for an alternating system proposed by Drillon and co-workers [15] on basis on the Hamiltonian $H = -J_1\Sigma S_{2i} \cdot S_{2i+1} - J_2\Sigma S_{2i} \cdot S_{2i+2}$. Best fit calculated parameters for the experimental data in the 25–300 K range were $J_1 = -16.7(4)$ cm^{-1}, $J_2 = 6.0(2)$ cm^{-1} and $g = 1.992(4)$.

3.4. Coupling constants correlation

End-to-end coordination mode for the azido ligand has been studied previously from the structure-magnetic behaviour point of view for different electronic configurations [1,3b]. In the Mn^{II} case (d5), was shown that the antiferromagnetic components of the interaction should decrease for larger dihedral angles (δ between the main azido plane and the N–Mn–N plane), indicating that the loss of overlap due to the increase in the torsion angles becomes the driving force that controls the antiferromagnetic coupling. Due to the residual overlap of the t_{2g} orbitals with the non-bonding π MOs of the azido mediator, even for large dihedral δ angles there is always an AF dominant interaction. In the case of double EE azido bridges, the AF coupling was related directly with the degree of chair/boat distortion of the $Mn(\mu_{1,3}\text{-}N_3)_2$–Mn fragment.

In our case, compound **1** is clearly chair distorted with a δ angle of 22.6° whereas **2** exhibits a more planar $Mn(\mu_{1,3}\text{-}N_3)_2$–Mn boat-distorted unit (δ is only 9.77°). These structural parameters are in good qualitative agreement with the lower J_1 value of -11.9 cm^{-1} for **1** in comparison with the J value found of -16.7 cm^{-1} calculated for **2**. On the other hand, the coupling due to the EO bridges for **2**, give the normal ferromagnetic behaviour characteristic of Mn–N–Mn bond angles slightly greater than 100°.

Synthesis, characterisation and magnetic properties of cobalt (II) complexes with 3-hydroxypicolinic acid (HpicOH): $[Co(picOH)_2(H_2O)_2]$ and *mer*-$[N(CH_3)_4][Co(picOH)_3] \cdot H_2O$

Abstract

Two complexes with Co^{2+} and 3-hydroxypicolinic acid, $[Co(picOH)_2(H_2O)_2]$ (**I**) and *mer*-$[N(CH_3)_4][Co(picOH)_3] \cdot H_2O$ (**II**), have been synthesised and characterised using single-crystal X-ray diffraction, elemental analysis, infrared spectroscopy, and thermoanalytical measurements. The 3-hydroxypicolinate ligands are coordinated to the Co^{2+} centres via its typical N,O-chelating coordination fashion. While in **I** the presence of two coordinated water molecules leads to the formation of a neutral $[Co(picOH)_2(H_2O)_2]$ complex which is strongly hydrogen bonded to another four neighbouring complexes, in **II** the inclusion of a third $picOH^-$ ligand leads to an anionic octahedral complex, $[Co(picOH)_3]^-$, in which all the N- and O-atoms are occupying *mer* positions. The properties of these two compounds were further investigated by measuring their magnetic behaviour.

1. Introduction

3-Hydroxypicolinic acid (HpicOH) is a relatively simple organic molecule, which can act as a versatile ligand with distinct coordination fashions. For example, deprotonation of the carboxylic acid and hydroxyl groups makes O,O-chelation possible with the consequent formation of a typical six-membered chelate ring [1–3]. The mono-deprotonated ligand ($picOH^-$) can also form five-membered chelate rings through the pyridinic nitrogen atom and the carboxylate group (N,O-chelation) with this coordination fashion being the most commonly found in the literature [1–9]. Interestingly, there is only one report for single coordination through the pyridinic nitrogen atom [6], and no examples are known of single coordination via the (de)protonated hydroxyl group.

We have exploited the versatile chelating properties of HpicOH to synthesise a series of lanthanide complexes and investigate the role of this ligand in the photoluminescence of the materials [1]. However, HpicOH is more commonly used with second- and third-row transition metal centres [5–8], and only a handful of structures containing first-row transition cations are found in the literature [2–4,9]. Other derivatives of picolinic acid are also known to form complexes with several metal centres [10,11], particularly those of 2-hydroxynicotinic acid which are of special interest [12,13]. Following our interest in exploring the coordination chemistry of HpicOH, we report on the synthesis, structural characterisation and magnetic behaviour of two novel Co^{2+}

complexes with this ligand: $[Co(picOH)_2(H_2O)_2]$ and *mer*-$[N(CH_3)_4][Co(picOH)_3] \cdot H_2O$.

2. Experimental

2.1. Syntheses

Chemicals were readily available from commercial sources and were used as received without further purification. Syntheses were carried out in PTFE-lined stainless steel reaction vessels (ca. 40 cm^3), under autogeneous pressure and static conditions in a preheated oven at 150 °C. Reactions took place over a period of 48 h after which time the vessels were cooled slowly to ambient temperature before opening.

In a typical synthesis, an aqueous solution of $CoCl_2 \cdot 6H_2O$ (0.5 mmol) was added dropwise to an aqueous solution containing 3-hydroxypicolinic acid (2 mmol) and $[(CH_3)_4N]OH$ (2 mmol) and then the final pH was adjusted to ca. 7 with 1 M CH_3COOH. This mixture was treated under hydrothermal conditions as described above and then transferred into a covered beaker. A pale orange powder of $[Co(picOH)_2(H_2O)_2]$ was obtained (yield: 15.7%) and orange single-crystals of the same compound were grown after 10 days from the supernatant solution (m.p. 160 °C). Red crystals of *mer*-$[N(CH_3)_4][Co(picOH)_3] \cdot H_2O$ could be obtained from the same mother solution after ca. 2 months (m.p. 228 °C).

2.2. Single-crystal X-ray diffraction

Suitable single-crystals of $[Co(picOH)_2(H_2O)_2]$ (**I**) and *mer*-$[N(CH_3)_4][Co(picOH)_3] \cdot H_2O$ (**II**) were mounted on a glass fibre using perfluoropolyether oil [14]. Data for **I** were collected at 180(2) K on a Nonius Kappa charge coupled device (CCD) area-detector diffractometer (Mo Kα graphite-monochromated radiation, $\lambda = 0.7107$ Å), equipped with an Oxford Cryosystems cryostream and controlled by the COLLECT software package [15]. Images were processed using the software packages of Denzo and Scalepack [16] and the data were corrected for absorption by using the empirical method employed in Sortav [17,18]. Data for **II** were collected at ambient temperature (at the Unidade de Raios-X, RIAIDT, University of Santiago de Compostela, Spain) on a Bruker SMART 1000 charge coupled device (CCD) area-detector diffractometer (Mo Kα graphite-monochromated radiation, $\lambda = 0.7107$ Å), controlled by the SMART software package [19]. Images were processed using the SAINTPlus software package [20] and data were corrected for absorption by using the semi-empirical method of SADABS [21]. The two structures were solved by the direct methods of SHELXS-97 [22] and refined by full-matrix least squares on F^2 using SHELXL-97 [23]. Non-hydrogen atoms were directly located from difference Fourier maps and refined with anisotropic displacement parameters. The last difference Fourier map synthesis showed, for **I**, the highest peak (0.354 e $Å^{-3}$) located at 1.14 Å from O(2), and the deepest hole (−0.614 e $Å^{-3}$) located at 0.70 Å from Co(1); for **II**, the highest peak (0.389 e $Å^{-3}$) located at 0.84 Å from O(4), and the deepest hole (−0.490 e $Å^{-3}$) located at 0.67 Å from Co(1).

Hydrogen atoms bound to carbon were placed in calculated positions and refined using a riding model with an isotropic displacement parameter fixed at x times U_{eq} for the atom to which they are attached ($x = 1.5$ for –CH_3 and –OH groups, $x = 1.2$ for the remaining hydrogen atoms). Hydrogen atoms from water molecules were directly located from successive difference Fourier maps and refined with the O–H and H···H distances restrained to 0.95(1) and 1.55(1) Å (for **I**), and 0.85(1) and 1.39(1) Å (for **II**), respectively (in order to ensure a chemically reasonable geometry for these molecules), and using a riding model with an isotropic displacement parameter fixed at 1.5 times U_{eq} of the atom to which they are attached. Hydrogen atoms associated with the –OH groups could also be directly located in successive difference Fourier maps, but their position was instead placed geometrically using HFIX instructions in SHELXL.

2.3. Instrumentation

FT-IR spectra were measured from KBr disks (Aldrich, 99%+, FT-IR grade) on a Matson 700 FTIR spectrometer. Elemental analyses for C, H and N were performed in the Microanalysis Laboratory of the University of Aveiro. Thermogravimetric analyses (TGA) were carried out using a Shimadzu TGA-50, with a heating rate of 10 °C/min. Magnetic measurements were performed using a Quantum Design SQUID (Superconducting Quantum Interference Device) magnetometer MPMS at the University of Lisbon (Portugal).

3. Results and discussion

3.1. Crystal structure of $[Co(picOH)_2(H_2O)_2]$ (*I*)

The reaction under aqueous media between Co^{2+} and 3-hydroxypicolinic acid led to the formation of a highly crystalline, air- and light-stable product which was formulated as $[Co(picOH)_2(H_2O)_2]$ (**I**) on the basis of single-crystal X-ray diffraction (Table 1) and elemental analysis. This structure shares striking similarities with those recently reported by Jin and co-workers [4], $[Zn(picOH)_2(H_2O)_2]$ and $[Mn(picOH)_2(H_2O)_2]$, also containing first-row transition metal cations.

Compound **I** is formed by neutral centrosymmetric $[Co(picOH)_2(H_2O)_2]$ complexes (Fig. 1), in which the Co^{2+} centre is located at an inversion centre and six-coordinated to two N,O-chelating $picOH^-$ anionic ligands [bite angle of 78.23(5)°] plus two water molecules, $\{CoN_2O_4\}$, with the coordination geometry resembling a slightly distorted octahedron (Fig. 1 and Table 2). As found in the structures containing Zn^{2+} and Mn^{2+} [4], the water molecules are *trans*-coordinated (Fig. 1) with the O_{water}–Co–O_{water} vector not being exactly perpendicular to the $\{N_2O_2\}$ plane of the octahedron formed by the two $picOH^-$ anionic ligands (Table 2). The vector is indeed tilted by a combination of ca.

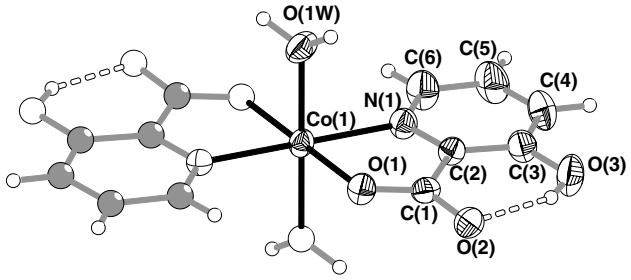

Fig. 1. Schematic representation of the neutral complex $[Co(picOH)_2(H_2O)_2]$ of **I**, emphasising the slightly distorted octahedral coordination environment for the Co^{2+} metal centre. Non-hydrogen atoms belonging to the asymmetric unit are represented with thermal ellipsoids drawn at the 70% probability level. For selected bond lengths (in Å) and angles (in °) see Table 2. For details on the hydrogen-bonding geometry, see Table 4.

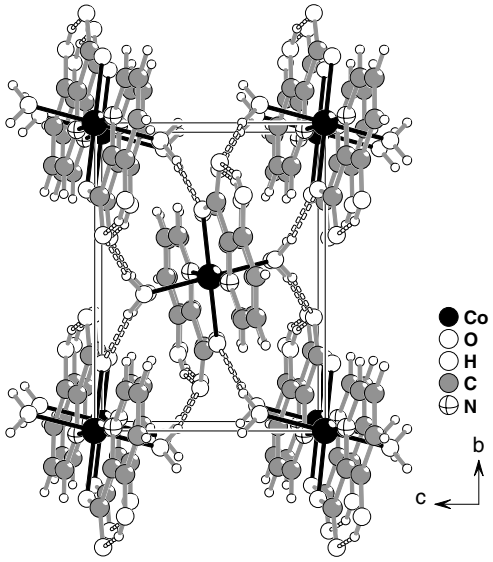

Fig. 2. Crystal packing of **I** viewed in perspective along the *a* direction, showing how the O–H···O hydrogen bond interactions (represented as dashed white-filled bonds) establish physical links between neighbouring $[Co(picOH)_2(H_2O)_2]$ complexes. For details on the hydrogen-bonding geometry, see Table 4.

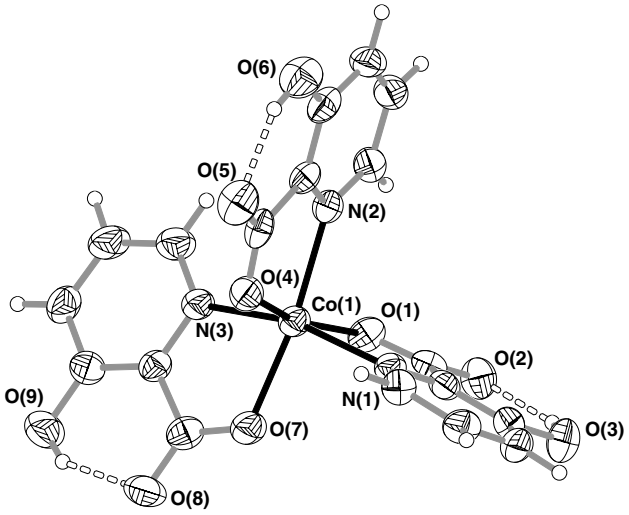

Fig. 3. Schematic representation of the anionic *mer*-$[Co(picOH)_3]^-$ complex in **II**, showing the slightly distorted octahedral coordination environment for the Co^{2+} metal centre and the labelling scheme for selected atoms. Non-hydrogen atoms are represented with thermal ellipsoids drawn at the 70% probability level. For selected bond lengths (in Å) and angles (in °) see Table 3. For details on the hydrogen-bonding geometry, see Table 5.

3.1° and 0.9° in both directions of the $\{N_2O_2\}$ plane, values comparable with those registered for $[Zn(picOH)_2(H_2O)_2]$ and $[Mn(picOH)_2(H_2O)_2]$ (ca. 2.9/0.8 and 2.5/1.2, respectively) [4]. Interestingly, this distortion seems to be driven by the presence of extensive hydrogen-bonding networks in the crystal structures of these structures. In fact, apart from the homonuclear, intra-molecular and strong O–H···O hydrogen bond between the hydroxyl and the carboxylate groups (Fig. 1 and Table 4), each $[Co(picOH)_2(H_2O)_2]$ moiety is further strongly hydrogen-bonded via the coordinated water molecules to another four neighbouring complexes, leading to a recurring $R_2^2(10)$ graph set motif [24] which expands the dimensionality of the structure into the two dimensions (see Fig. 2).

3.2. Crystal structure of *mer*-$[N(CH_3)_4][Co(picOH)_3]\cdot H_2O$ (**II**)

The substitution of the coordinated water molecules from the coordination sphere of **I** by a third 3-hydroxypicolinate ligand leads to the formation of an intriguing *mer*-isomer $[Co(picOH)_3]^-$ complex anion (Fig. 3) which co-exists in the asymmetric unit of **II** with a tetramethylammonium cation plus a water molecule of crystallisation (not shown), corresponding to the empirical formula *mer*-$N(CH_3)_4][Co(picOH)_3]\cdot H_2O$ (**II**).

As in the previous structure, the crystallographically unique Co^{2+} centre appears six-coordinated, $\{CoN_3O_3\}$ (Fig. 3), with a geometry resembling a distorted octahedron due to the geometrical constraints of the $picOH^-$ ligand: on the one hand, the chelating nature of 3-hydroxypicolinate leads to an average bite angle of ca. 78.7° which, although comparable with the analogous value for **I** [78.23(5)°], imposes some strain in the octahedral geometry; on the other, the presence of three large substituent ligands within the first coordination sphere leads to an inherent steric hindrance directly affecting the global geometry of the complex. In fact, these distortions are reflected in the ranges of the *cis* and *trans* angles of the octahedron which can be found within the 78.45(8)°–98.22(9)° and 163.84(9)°–171.45(9)° ranges, respectively (Table 3). The average Co–O and Co–N distances are almost identical (ca. 2.07 and 2.14 Å, respectively) and comparable with those found in related compounds [25,26].

The hydrogen-bonding network present in the crystal structure of **II** is not so extensive as that described for **I**. However, physical bridges via homonuclear and relatively strong O–H···O hydrogen bonds between neighbouring *mer*-$[Co(picOH)_3]^-$ complex anions are assured by the water molecules of crystallisation (Table 5 and Fig. 4) which, along with interactions of the intra-molecular nature, lead to the formation of supramolecular hydrated $\{mer\text{-}[Co(picOH)_3]\cdot H_2O\}^-$ anionic tapes running along the *a* direction (Fig. 4, perpendicular to the plane of the representation). This supramolecular arrangement is constructed from a recurring $C_3^2(7)$ graph set motif [24].

3.3. Magnetic measurements

Magnetisation (M) measurements were performed in the 2–270 K temperature (T) range and in a constant magnetic field of $H = 100$ Oe. No thermal irreversibility

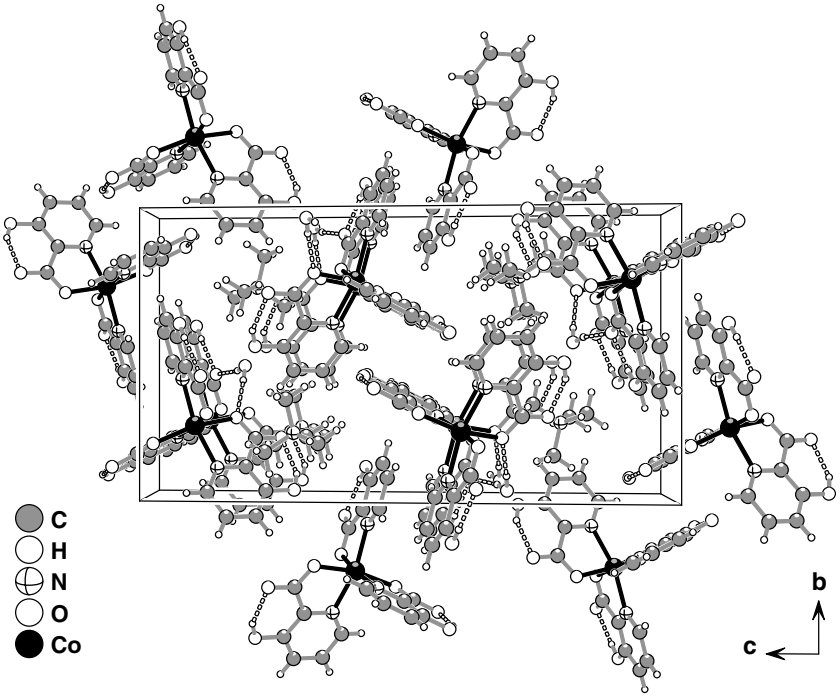

Fig. 4. Crystal packing of **II** viewed in perspective along the *a* direction, with the O–H···O hydrogen-bonding interactions represented as dashed white-filled bonds. The crystallisation water molecule establishes a physical link between neighbouring anionic *mer*-$[Co(picOH)_3]^-$ complexes, leading to the formation of supramolecular hydrated $\{mer\text{-}[Co(picOH)_3]\cdot H_2O\}^-$ anionic tapes running along the *a* direction. For details on the hydrogen-bonding geometry, see Table 5.

was observed since measurements taken with decreasing temperature gave identical results, either after cooling from ambient temperature to 2 K in zero applied magnetic field (zero field cooling), or after cooling under the measurement field.

Fig. 5 represents the magnetic susceptibility multiplied by the temperature (χT, with χ = M/H) for compounds **I** and **II**. The temperature dependence indicates deviation from simple paramagnetic (Curie-like) ion behaviour. Such is ascribed to the influence

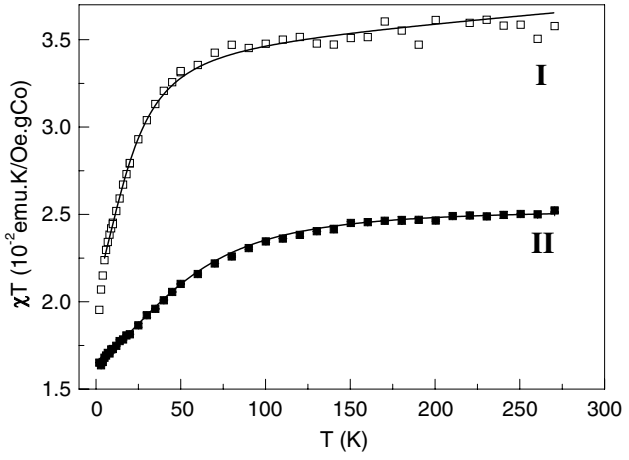

Fig. 5. Temperature dependence of the magnetic susceptibility multiplied by temperature (χT vs. T)for compounds **I** and **II**. Solid lines are fits to Eq. (1) (considering the influence of crystal field).

of crystal field of **I** and **II**, just like it is also observed in several mononuclear systems containing high-spin Co^{2+} ions in an octahedral coordination geometry [27]. The lowest energy levels of the Co^{2+} cations are Γ_6 and Γ_7 doublets, and in a first approximation one can consider that only these two are thermally populated. Hence the total susceptibility, can be described by [27]:

$$\chi = A\frac{g_z^2\chi_z + 8g_x^2\chi_x}{4T} + \chi_0, \quad \text{with}$$
$$\chi_z = \frac{1+9e^{-(2D/T)}}{1+e^{-(2D/T)}} \quad \text{and} \quad \chi_x = \frac{1+\frac{3T}{4D}\left(1-e^{-(2D/T)}\right)}{1+e^{-(2D/T)}}, \tag{1}$$

where $A = N\mu_B^2/3k$, g_z and g_x are the Landé factors associated with z and x directions, respectively, D is the crystal field splitting and χ_0 is the residual temperature independent which accounts for diamagnetic contributions. Within this approximation, D includes the Γ_6 and Γ_7 energy gap and the influence of the orbital momentum [27]. Fitting the data to Eq. (1) (lines in Fig. 5) we obtain $D = 24$ and $65\ cm^{-1}$ for samples **I** and **II**, respectively, in good agreement with the values expected for Co^{2+} cations (Ref. [27] and references therein). From the fitting, it is also feasible to calculate $g_x = 2.1$, $g_z = 2.3$ and $g_x = 1.8$, $g_z = 1.7$. Small variations of these parameters are not critical for the quality of the fit and are subject to absolute errors of the order of 0.1. Although at present we do not have a plausible

Table 6
Analytical and spectroscopic data for 3-hydroxypicolinic acid and compounds **I** and **II**

Compound	Elemental composition (%)[a]			Vibrational data (in cm^{-1})[b]			
	C	N	H	$\nu_{asym}(-CO_2^-)$	ν(C–N)	$\nu_{sym}(-CO_2^-)$	$\nu(C-O)_h$

I	38.05 (38.83)	7.38 (7.55)	3.55 (3.26)	1644s	1602s	1343s	1268s
II	46.31 (46.73)	9.93 (9.91)	4.83 (4.63)	1631s	1602s	1333s	1248s

[a] Calculated values are in parentheses.
[b] s: strong.

explanation for the difference between these values for the two compounds, the ratio g_z/g_x is ca. 1.1, in good agreement with the values reported for similar compounds (1.06) [27]. The differences registered for the crystal field splitting can be attributed to the influence of the donor atoms present in the Co^{2+} first coordination shell. In fact, compound **II** has one more pyridinic ring bound to the metal, which increases the crystal field splitting, in agreement with the spectrochemical series.

3.4. Vibrational spectroscopy

Selected and diagnostic FT-IR data for compounds **I** and **II** are given in Table 6 (only bands of 3-hydroxypicolinic acid sensitive to metal coordination are reported). Infrared spectroscopy confirms the coordination of $picOH^-$ to the metal centres via the carboxylate group, with the asymmetric stretching $\nu_{asym}(-CO_2^-)$ mode showing shifts up to 70 cm^{-1} to lower wavenumbers when compared with the values registered for the free ligand. Furthermore, the measured values of $\Delta[\nu_{asym}(-CO_2^-) - \nu_{sym}(-CO_2^-)]$ for **I** (301 cm^{-1}) and **II** (298 cm^{-1}) are clear evidence of the presence of carboxylate groups coordinated to the Co^{2+} centres in unidentate fashion [28], in agreement with the N,O-chelation described by the crystal structures (Figs. 1 and 3). The $\nu(C-O)_h$ mode for **I** and **II** shows shifts up to ca. 14 and 34 cm^{-1}, respectively, possibly due to hydrogen-bonding involving the carboxylate groups and the water molecules (Tables 4 and 5). The typical stretching ν(C–N) vibrational mode of substituted pyridines appears for the uncoordinated ligand at 1609 cm^{-1} and shows small shifts (up to 7 cm^{-1}) for the two compounds (Table 6), in good agreement with N,O-chelation involving the nitrogen atom of $picOH^-$.

3.5. Thermal analysis

Thermal decomposition of compound **I** occurs in a multi-step process between ambient temperature and ca. 500 °C leading to the formation of the stoichiometric amount of CoO (total weight loss of 78.1%, calculated 79.8%). The first weight loss (ca. 9.5%) occurs in the 80–180 °C temperature range (DTG peak at 150 °C) and is attributed to the release of the two coordinated water molecules (calculated weight loss of 9.7%). Between 180 and 500 °C, a total weight loss of ca. 68.6% (DTG peaks at 353, 409, 418 and 432 °C) corresponds to the release of the organic component.

The thermal decomposition of **II** between ambient temperature and ca. 550 °C is slightly more complex than that of **I** with more overlapping decomposition steps corresponding to the oxidation of the organic molecules. However, as for **I**, at ca. 550 °C only the stoichiometric CoO residue remains with a total weight loss of ca. 88.6% (calculated 86.7%).

Received 30 September 2004; accepted 7 December 2004

Abstract

Three new Mn(II) diphosphonates have been synthesized by hydrothermal reactions, namely, $Mn(H_2L^1)$ (**1**), $Mn(H_3L^1)_2$ (**2**) ($H_4L^1 = C_6H_5CH_2N(CH_2PO_3H_2)_2$) and $Mn_2(H_2L^2)_2(H_2O)$ (**3**), (H_4L^2 = 4-CH_3–$C_6H_4CH_2N(CH_2PO_3H_2)_2$). The structure of compound **1** features $\langle 0\,0\,1\rangle$ and $\langle 0\,0\,2\rangle$ manganese(II) phosphonate layers, in which the Mn(II) ion is five-coordinated by five oxygens from five diphosphonate ligands in a distorted square pyramidal geometry. The Mn(II) ion in compound **2** is octahedrally coordinated by six phosphonate oxygens from six ligands. Neighboring MnO_6 octahedra are interlinked by bridging diphosphonate ligands into a polymeric double chain along the *c*-axis. Such chains are interlinked by strong hydrogen bonds between non-coordinated phosphonate oxygens into a 2D layer. Compound **3** is composed of $\langle 0\,0\,1\rangle$ and $\langle 0\,0\,2\rangle$ manganese(II) phosphonate layers, in which each metal ion is octahedrally coordinated by five phosphonate oxygens from four ligands and an aqua ligand. In all three compounds, the amine group of the ligand is protonated and the phenyl group is orientated toward the interlayer space.

1. Introduction

During the past two decades, considerable research efforts have been devoted to the synthesis of metal phosphonates with open-framework or microporous structures due to their interesting optical, ion-exchange, catalytic and sensing properties [1]. The strategy of attaching functional groups such as crown ether, amine, hydroxyl and carboxylate groups to the phosphonic acid has proven to be effective for the isolation of a variety of metal phosphonates with open-framework and microporous structures [1–10]. Results of metal compounds with aminodiphosphonic acids, $RN(CH_2PO_3H_2)_2$. have shown that the organic substituent on the amine group plays a subtle role on the structures of the metal phosphonates formed [11]. For instance, $Cd(H_3L)_2$ ($H_4L = C_6H_5CH_2N(CH_2PO_3H_2)_2$) features double chains that are further interlinked by hydrogen bonds. With one more CH_2-group between the phenyl and the amine group, $Cd(H_3L')_2$ ($H_4L' = C_6H_5CH_2CH_2N(CH_2PO_3H_2)_2$) has a layered structure [11a]. Recently, a number of divalent metal compounds of substituted aminodiphosphonic acids, $RN(CH_2PO_3H_2)_2$ have been reported [12]. A copper compound with ethylamine-bis(methylphosphonate) was reported by Makaranets et al. [12a], cobalt(II) and lead(II) complexes with $NH(CH_2PO_3H_2)_2$ were recently reported [12b,12c]. Several layered zirconium fluoride alkylamino-*N*,*N*-bis(methylenephosphonate) complexes have been isolated by Vivani et al. [12d]. To further our studies on metal compounds with substituted aminodiphosphonic

doi:10.1016/j.poly.2004.12.018

acids, two derivatives of $HN(CH_2PO_3H_2)_2$ were synthesized, namely, $C_6H_5CH_2N(CH_2PO_3H_2)_2$ (H_4L^1) and 4-CH_3-$C_6H_4CH_2N(CH_2PO_3H_2)_2$ (H_4L^2). Hydrothermal reactions of the above two diphosphonic acids and manganese(II) acetate resulted in three new Mn(II) diphosphonates, namely, $Mn(H_2L^1)$ (**1**), $Mn(H_3L^1)_2$ (**2**) and $Mn_2(H_2L^2)_2(H_2O)$ (**3**). Compounds **1** and **3** are layered with different architectures, whereas compound **2** features double chains of the manganese(II) diphosphonate that are hydrogen bonded. Herein, we report their syntheses, crystal structures and characterizations.

2. Experimental

2.1. Materials and methods

The two aminodiphosphonic acids, $C_6H_5CH_2N(CH_2PO_3H_2)_2$ (H_4L^1) and 4-CH_3-$C_6H_4CH_2N(CH_2PO_3H_2)_2$ (H_4L^2), were prepared by a Mannich type reaction according to the procedures previously described [11,13]. All other chemicals were of reagent grade quality from commercial sources and used without further purification. Elemental analyses were performed on a German Elementary Vario EL III instrument. IR spectra were recorded on a Perkin Elmer Spectrum One FT-IR spectrometer on KBr pellets in the range 4000–400 cm^{-1}. TGA analyses were carried out with a TGA/STA449C unit, at a heating rate of 15 °C/min under a nitrogen atmosphere. Magnetic susceptibility measurements on polycrystalline samples of compounds **1** and **3** were performed with a Quantum Design SQUID magnetometer at a field of 1.0 T in the range of 6–300 K. Raw data were corrected for the susceptibility of the container and the diamagnetic contributions of the samples using Pascal's constants. X-ray powder diffraction data were collected on a Rigaku Dmax 2500 diffractometer using Cu Kα radiation (λ = 1.5406 Å) in the 2θ range of 3°–80° with a step size of 0.05° and a counting time of 0.6 s per step.

2.2. Synthesis of $Mn(H_2L^1)$ (*1*)

About 0.5 mmol of $Mn(ac)_2 \cdot 4H_2O$, 0.5 mmol of H_4L^1 and 10 ml of de-ionized water were mixed and the solution's pH value was adjusted to 5.0 by the addition of tetrabutylammonium hydroxide solution (10%). The resultant solution was sealed into a 25-ml Telflon-lined stainless steel autoclave and heated at 160 °C for 5 days (the final pH value is 6.0). Light pink crystals of compound **1** were recovered in 48% yield based on Mn. The measured X-ray powder diffraction pattern matches with the one simulated from its single crystal structure data, thus compound **1** was obtained as a monophase. Elemental *Anal.* for **1**, $C_9H_{13}NO_6P_2Mn$: calc. (found) C 31.06 (31.33), H 3.76 (3.52), N 4.02 (3.88), IR (KBr, cm^{-1}): 3032 m, 2980 m, 2946 br, 2769 w, 2358 w, 1492 m, 1417 m, 1222 m, 1187 s, 1159 s, 998 m, 756 m, 713 m, 561 s, 485 m.

2.3. Synthesis of $Mn(H_3L^1)_2$ (*2*)

A mixture of 0.5 mmol of $Mn(ac)_2 \cdot 4H_2O$, 1.0 mmol of H_4L^1, 10 ml of deionized water and 3.0 ml of tetramethylammonium chloride solution (40%) was sealed into a 25-ml Telflon-lined stainless steel autoclave and heated at 180 °C for 5 days (the initial and final pH values were around 2.0). Small needle-like light pink crystals of compound **2** were collected in a 54% yield based on Mn. Its purity was confirmed by X-ray powder diffraction measurements. Elemental *Anal.* for **2**, $C_{18}H_{28}N_2O_{12}P_4Mn$: calc. (found) C 33.61 (33.38), H 4.39 (4.18), N 4.49 (4.72), IR (KBr, cm^{-1}): 2985 br, 2576 br, 1498 w, 1456 s, 1435 m, 1333 m, 1227 s, 1252 s, 1111 s, 1037 s, 920 s, 891 s, 739 m, 706 m, 552 s, 482 s.

2.4. Synthesis of $Mn_2(H_2L^2)_2(H_2O)$ (*3*)

Compound **3** was synthesized by a similar method used for compound **1**. About 0.5 mmol of $Mn(ac)_2 \cdot 4H_2O$, 0.5 mmol of H_4L^2 and 10 ml of de-ionized water were mixed and the solution's pH value was adjusted to 5.0 by the addition of tetrabutylammonium hydroxide solution (10%). The resultant solution was sealed into a 25-ml Telflon-lined stainless steel autoclave and heated at 160 °C for 5 days (the final pH value is 5.0). Plate-shaped pink crystals of compound **3** were recovered in a 64% yield based on Mn. Its purity was confirmed by X-ray powder diffraction measurements. Elemental *Anal.* for **3**, $C_{20}H_{32}N_2O_{13}P_4Mn_2$: calc. (found) C 32.36 (32.25), H 4.34 (4.52), N 3.77 (3.58), IR (KBr, cm^{-1}): 3280 br, 2978 m, 2940 m, 2834 w, 2310 w, 1616 w, 1459 m, 1419 m, 1295 m, 1193 s, 1122 s, 983 s, 796 m, 761 s, 738 s, 568 s, 489 s, 439 m.

2.5. Crystal structure determinations of compounds *1–3*

Single crystals of compounds **1**–**3** were mounted on a Siemens Smart CCD diffractometer equipped with graphite-monochromated Mo-Kα radiation (λ = 0.71069 Å). Intensity data were collected by the narrow frame method at 293 K. The data sets were corrected for Lorentz and polarization as well as for absorption by the SADABS program [14]. All three structures were solved by direct methods and refined by full-matrix least-squares fitting on F^2 by SHELX-97 [15]. All non-hydrogen atoms were refined with anisotropic thermal parameters and all hydrogen atoms were located at geometrically calculated positions. The hydrogen atoms for the water molecules in compound **3** were not included in the refinement. Crystallographic data and structural refine-

3. Results and discussion

The structure of compound **1** features ⟨0 0 1⟩ and ⟨0 0 2⟩ manganese(II) phosphonate layers. The Mn(II) ion is five-coordinated by five phosphonate oxygens of five diphosphonate anions in a distorted square pyramidal geometry. The Mn–O distances range from 2.062(4) to 2.308(4) Å (Table 2), which are comparable to those reported in other Mn(II) phosphonates [2b,9,10]. Each pair of Mn(II) ions are bridged by two diphosphonate groups, forming eight-membered rings (Mn–(O–P–O)$_2$–Mn). The diphosphonate ligand acts as a pentadentate ligand and bridges with five manganese(II) ions. The Mn–O(13) distance of 2.660(4) Å indicates that it is a very weak bond if any. Based on charge balance, the P–O distances as well as its coordination mode, the diphosphonate anion is 2− in charge and the amine group as well as O(13) remain protonated.

The interconnection of Mn(II) by bridging diphosphonate anions lead to ⟨0 0 1⟩ and ⟨0 0 2⟩ layers of Mn(II) phosphonate (Fig. 1). The phenyl groups are orientated

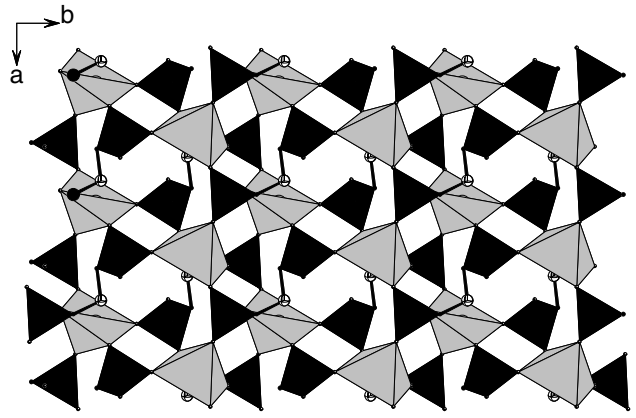

Fig. 1. A ⟨002⟩ manganese(II) phosphonate layer in compound **1**. MnO_5 polyhedra and C–PO_3 tetrahedra are shaded in light and dark grey, respectively. N atoms are drawn as octand circles. The $C_6H_5CH_2$-groups have been omitted for clarity.

toward the interlayer space (Fig. 2). The interlayer distance is about 12.6 Å.

Compound **2** has a *M*/*L* molar ratio of 1:2. It is isostructural with $Cd(H_3L^1)_2$ previously reported [11a]. The Mn(II) ion lies on a position with a twofold symmetry. It is octahedrally coordinated by six oxygens from six phosphonate ligands. The Mn–O distances are in the range of 2.158(1) to 2.216(1) Å (Table 2), which are comparable to those in compound **1** and those reported in other Mn(II) phosphonates [2b,9,10], but are slightly shorter than the Cd–O distances reported in the isomorphous Cd compound [11a]. Unlike that in compound **1**, the diphosphonate ligand in compound **2** is tridentate and bridges with three Mn(II) ions. One phosphonate group (P1) is monodentate, whereas the other phosphonate group (P2) is bidentate. Similar to that in $Cd(H_3L^1)_2$ [11a], the amine group and the two phosphonate groups of the ligand are 1H-protonated. O(13) and O(23) atoms are 1H-protonated based on the P–O distances.

The MnO_6 octahedra are bridged by tridentate diphosphonate ligands to form a one-dimensional double chain along the *c*-axis. These double chains are interlinked via hydrogen bonds formed between non-coordinated phosphonate oxygens into ⟨100⟩ and ⟨200⟩ layers (Figs. 3 and 4). The O(13) ··· O(12) and O(13)–H(13a) ··· O(12) bond length and angle are 2.642(2) Å and 167.6°, respectively. Similarly, the O(23) ··· O(22) and O(23)–H(23a) ··· O(22) bond length and angle are 2.597(2) Å and 162.2°, respectively (Table 2). The protonated nitrogen atom also forms a hydrogen bond with the non-coordinated oxygen (O12). The N(1) ··· O(12) and N(1)–H(0a) ··· O(12) bond length

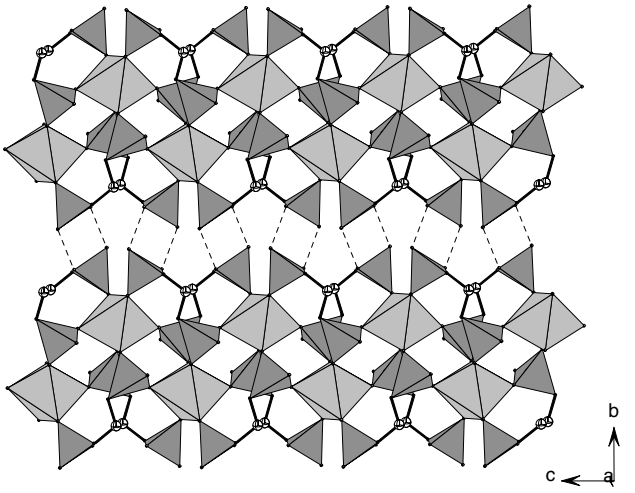

Fig. 3. A ⟨200⟩ manganese(II) phosphonate layer in compound **2**. MnO_6 octahedra and C–PO_3 tetrahedra are shaded in light and dark grey, respectively. N atoms are drawn as octand circles. The $C_6H_5CH_2$-groups have been omitted for clarity. Hydrogen bonds are represented by dotted lines.

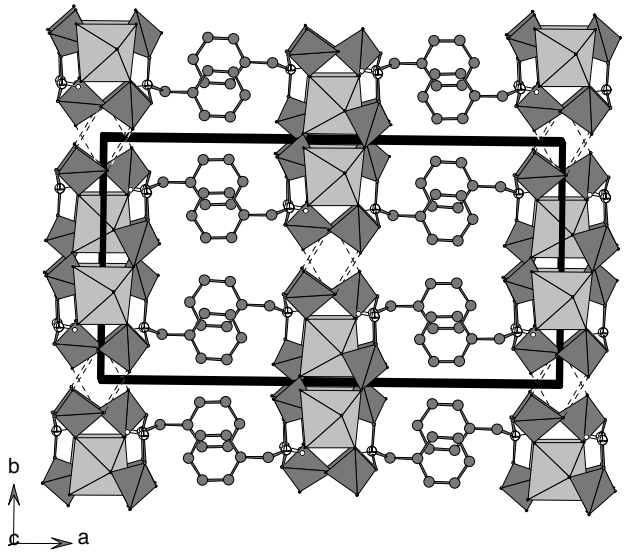

Fig. 4. View of the structure of compound **2** down the *a*-axis. MnO_6 octahedra and C–PO_3 tetrahedra are shaded in light and dark grey, respectively. N and C atoms are drawn as octand and black circles, respectively.

and angle are 2.642(2) Å and 151.2°, respectively (Table 2). The phenyl groups of the diphosphonate ligands are oriented toward the interlayer space (Fig. 6). The interlayer distance of 12.1 Å is slightly smaller than that of the isomorphos Cd compound [11a].

Unlike $Cd(H_3L^2)_2$, with a double chain structure and a *M*/*L* molar ratio of 1:2, $Mn_2(H_2L^2)_2(H_2O)$ (**3**) has a new type of layered structure and a *M*/*L* molar ratio of 1:1. The Mn(II) ion is octahedrally coordinated by five oxygens from four diphosphonate ligands and an aqua ligand. One diphosphonate anion forms an eight-membered chelating ring with Mn(1) (Mn1–O13–P1–C8–N1–C9–P2–O23). The Mn–O distances range from 2.127(3) to 2.325(3) Å (Table 2), which are comparable to those in compounds **1** and **2**. The diphosphonate anion is pentadentate, it chelates with a Mn(II) ion bidentately (O13 and O23) and is also connected to three other Mn(II) ions. O21 and O12 remain non-coordinated and O13 is a bidentate metal linker. This type of coordination mode is different from that of the H_2L^1 anion in compound **1** which is also pentadentate. Two Mn(II) ions are bridged by a pair of O(13) atoms to form a Mn_2O_2 unit. The aqua ligand is also bidentate and bridges with two Mn(II) ions. One oxygen atom (O21) is 1H-protonated, as is the nitrogen atom, based on charge balance, the coordination mode of the ligand as well as P–O distances.

The cross-linkage of Mn(II) ions by bridging aqua and phosphonate ligands results in ⟨001⟩ and ⟨002⟩ manganese(II) phosphonate layers (Fig. 5). Within the 2D layer, each pair of MnO_6 octahedra forms a dimeric unit via edge-sharing (O(13)–O(13)) and such dimeric units are interconnected via corner sharing (the aqua ligand) to form a 1D zigzag chain along the *a*-axis. These 1D chains are further bridged by phosphonate ligands into ⟨001⟩ and ⟨002⟩ layers. This type of layered structure has not been reported in other transition metal aminodiphosphonates. The interlayer distance of 16.28 Å is much larger than those of compounds **1** and **2**, mainly due to the additional methyl group on the phenyl ring (Fig. 6).

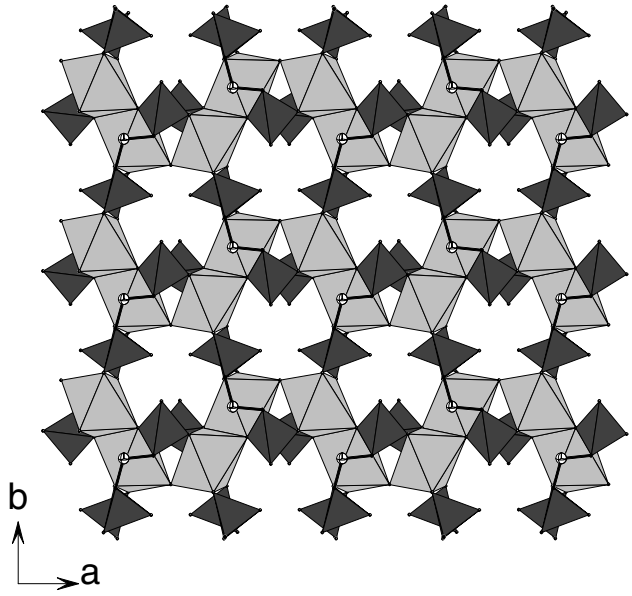

Fig. 5. A ⟨002⟩ manganese(II) phosphonate layer in compound **3**. MnO_6 octahedra and C–PO_3 tetrahedra are shaded in light and dark grey, respectively. N atoms are drawn as octand circles. The 4-Me–$C_6H_4CH_2$-groups have been omitted for clarity.

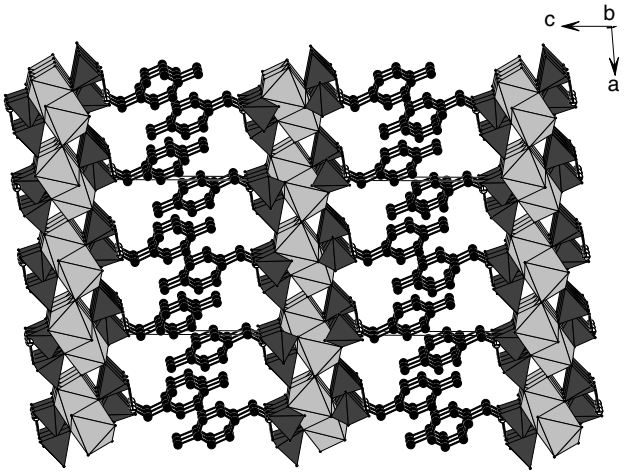

Fig. 6. View of the structure of compound **3** down the *b*-axis. MnO_6 octahedra and C–PO_3 tetrahedra are shaded in light and dark grey, respectively. N and C atoms are drawn as octand and black circles, respectively.

The synthetic conditions for the above three compounds merit further discussions. The neutral aminodiphosphonate ligands occur in zwitterionic forms, that is one proton of one phosphonate group being transferred to the amine group. Upon their complexion with metal ions, the coordination modes adopted and the structures of the metal phosphonates are mainly governed by the pH value of the solution and the *M*/*L* molar ratio used. When the *M*/*L* molar ratio is 1:2 and the reaction media is acidic, metal compounds with a formula of $M(H_3L)_2$ are usually isolated. When a *M*/*L* molar ratio of 1:1 was applied and the reaction was carried out under a weakly acidic condition, an additional proton of the diphosphonate ligand can be deprotoned and $M(H_2L)$ can be obtained. The removal of the remaining two protons requires a higher pH value and higher *M*/*L* molar ratios such as 3:2 and 2:1 [2b]. The different coordination modes of H_2L^1 and H_2L^2 are probably related to the different substituents on the amine group. However more studies are needed to further understand the subtle role which the substituents play.

The broad band centered at 3280 cm^{-1} for compound **3** is due to the H–OH stretching vibration of the water molecule. The sharp bands at 2980 cm^{-1} for **1**, 2985 cm^{-1} for **2**, 2978 cm^{-1} for **3** can be assigned to

the CH_2 stretching vibrations. The broad bands around 2900 cm^{-1} for all three compounds originate from the N–H and O–H stretching vibrations. The bands in the region of 2750 and 2790 cm^{-1} are ν(P–OH), which are characteristic of hydrogen phosphonate groups. The weak band at 1616 cm^{-1} in compound **3** is due to the δ(H–OH) vibration. The set of bands between 1200 and 900 cm^{-1} is due to the stretching vibrations of the tetrahedra C–PO_3 groups.

Compound **1** was stable up to 320 °C. Above this temperature, there was a sharp weight loss continued up to 550 °C, corresponding to the pyrolysis of organic groups. The total weight loss at 1000 °C is 38.4%, which is in good agreement with the calculated one of 38.8% if the final product is assumed to be $Mn(PO_3)_2$. Compound **2** was stable up to 290 °C. Then a continuous weight loss was observed up to 1000 °C, during which two processes occurred: the release of the water molecules formed by the condensation of hydrogen phosphonate groups and the burnt of organic groups. The total weight loss is 54.5%, which is much less than the calculated value of 67%, if the final product is assumed to be $Mn(PO_3)_2$. As a result, the decomposing process was not complete at 1000 °C. The TGA diagrams of compound **3** exhibit two main steps of weight losses. The first step started at 280 °C and ended at 670 °C, during which the aqua ligand was released and the organic groups were burnt. The second weight loss occurred above 820 °C, corresponding to further decomposition of the compound. The final product is $Mn(PO_3)_2$ based on XRD powder studies.

Magnetic properties of compounds **1** and **3** have been measured. At room temperature, the effective magnetic moment (μ_{eff}) for compound **1** is calculated to be 5.83μ_B, which is slightly smaller than the theoretical one (5.93μ_B) for a high spin Mn^{2+} ($S = 5/2$) ion. At low temperatures, the μ_{eff} value decreases with cooling, and reaches 4.22μ_B at 6 K (Fig. 7). Thus. there is an antiferromagnetic interaction between Mn(II) centers at low temperature. Linear fitting of χ^{-1} data with temperature according to Curies–Weiss law in the temperature range of 50–300 K gave the Curie constant of 4.306 emu K mol^{-1} and the Weiss constant (θ) of −2.70 K, indicating a weak antiferromagnetic exchange between the magnetic centers bridged by phosphonate groups (Mn ⋯ Mn 5.027 Å) within the 2D layer. The magnetic interaction between neighboring layers is negligible due to a large interlayer separation. For compound **3**, the μ_{eff} value of 8.22μ_B at 300 K corresponds to two high spin Mn^{2+} ($S = 5/2$) ions. At low temperatures, μ_{eff} decreases with cooling, and reaches 3.31μ_B at 6 K (Fig. 7). Thus there is a significant antiferromagnetic interaction between Mn(II) centers at low temperature. The Curie constant C is 8.86 emu K mol^{-1} and θ is −14.5 K, calculated by fitting of the magnetic data in the temperature range 100–300 K. The stronger antiferromagnetic interaction in compound **3** is due to much shorter Mn ⋯ Mn contacts between two neighboring Mn(II) centers bridged by an aqua ligand (Mn ⋯ Mn 4.014(1) Å) or a pair of phosphonate oxygen atoms (O13) (Mn ⋯ Mn 3.358(1) Å).

Received 30 July 2004; accepted 15 December 2004

Abstract

The aqueous system Zn(II)-*tn*-$[Ni(CN)_4]^{2-}$ in contact with air captured carbon dioxide in the form of a carbonato ligand yielded the compound $Zn_2(tn)_2(CO_3)Ni(CN)_4 \cdot H_2O$ by crystallization, which was characterized by elemental analyses, IR spectroscopy and single crystal structure analysis. Its crystal structure is polymeric and is built up of a positively charged framework $[Zn_4(tn)_4(CO_3)_2Ni(CN)_4]_n^{2n+}$, free tetracyanonickellate anions with a nickel atom on the inversion centre and water molecules of crystallization. Two crystallographically different zinc atoms exhibit tetrahedral and penta-coordinations. The zinc atoms are interconnected by two crystallographically independent bridging *tn* ligands, μ_3-CO_3^{2-} carbonato ligand and one centrosymmetric tetracyanonickellate anion acting as *trans*-[-NC-Ni(CN)$_2$-CN-] ligand. The carbonato ligand coordinates three zinc atoms by an unusual mode, two by an unidentate and one by a bidentate fashion with one oxygen donor atom forming two Zn–O coordination bonds.

1. Introduction

Cyanocomplexes exhibit high structural variability due to both terminal and bridging functions of the cyano ligand. This was explored previously in the syntheses of various types of host–guest and mineralominetic systems [1,2]. Recently, coordination oligomers and polymers based on cyanocomplexes have become popular among both chemists and physicists due to their interesting magnetic properties [3–6]. Their synthetic design follows the idea of linking suitable building blocks (''brick and mortar'' method [7]) by bridging cyano ligands. Suitable *N*-donor ligands like *en*, *bipy*, etc. (*en* = 1,2-diaminoethane; *bpy* = 2,2′-bipyridine) coordinated to the cationic central atom act as blocking ligands leaving thus the remaining coordination sites free for the polymerization process and, in such a way, the connectivity of the cationic building block (''brick'') can be tuned. We have used this approach in the preparation of several cyanocomplexes exhibiting mainly low-dimensional character and their magneto-structural correlations were studied [8–10]. The use of 1,3-diaminopropane (*tn*) as blocking ligand and the square $[Ni(CN)_4]^{2-}$ anion as ''mortar'' led to the formation of the complexes $Ni(tn)_2Ni(CN)_4 \cdot H_2O$ [11], $[Cu(tn)_2Ni(CN)_4]_2 \cdot 4H_2O$ [12], two polymorphs of $Cu(tn)Ni(CN)_4$ [13] and $Cd(tn)_2Ni(CN)_4$ [14]. Our initial aim was, for the sake of comparison, to prepare and characterize the zinc analogue of the above mentioned compounds $M(tn)_2Ni(CN)_4 \cdot nH_2O$. From the

aqueous system Zn(II)-*tn*-$[Ni(CN)_4]^{2-}$ large single crystals of the title compound crystallized which unexpectedly contained a μ_3-CO_3^{2-} carbonato ligand. Here, we report its synthesis, characterization and crystal structure.

2. Experimental

2.1. Materials and measurements

1,3-Diaminopropane was purchased commercially from Aldrich and was used as obtained. $K_2[Ni(CN)_4] \cdot H_2O$ was prepared from KCN and $Ni(NO_3)_2 \cdot 6H_2O$ according to the literature [15] and recrystallized from water. KCN, $Ni(NO_3)_2 \cdot 6H_2O$ and $Zn(NO_3)_2$ were of analytical grade (Lachema Brno). Elemental analysis for C, H and N was performed on a Perkin–Elmer 2400 Analyser, contents of metallic elements were determined gravimetrically (Ni) and complexometrically (Zn). IR spectra were taken on a Thermo Nicolet AVATAR FT-IR spectrophotometer in KBr discs (4000–400 cm^{-1}).

2.2. Preparation of $Zn_2(tn)_2(CO_3)Ni(CN)_4 \cdot H_2O$

20 ml of 0.1 M aqueous solution of $K_2[Ni(CN)_4]$ (2 mmol) and 20 ml of 0.1 M aqueous solution of $Zn(NO_3)_2$ (2 mmol) were successively added to 0.67–1.00 ml of *tn* (8–12 mmol) in 10 ml of water. The eventually formed turbidity was removed by filtration. Yellow crystals of the product appeared within two weeks of crystallisation at laboratory temperature. The crystals were filtered off, washed with a small quantity of cold water and ethanol, and dried in air. Yield: 31%.

Anal. Calc. for $C_{11}H_{22}N_8NiO_4Zn_2$ (M_r = 519.81): C, 25.42; H, 4.27; N, 21.56; Ni, 11.29; Zn, 25.16. Found: C, 25.47; H, 4.27; N, 21.23; Ni, 11.85; Zn, 24.78%.

IR spectrum (in cm^{-1}; s = strong, m = medium, w = weak, v = very, sh = shoulder): ν(OH): 3616s, 3424s, $\nu(NH_2)$: 3320vs, 3256vs; $\nu(CH_2)$: 2952s, 2928m, 2904m, 2864m; ν(CN): 2168vs, 2128vs; $\delta(OH_2)$: 1650w; $\delta(NH_2)$: 1612s; $\nu(CO_3)$: 1504vs; $\rho(NH_2)$: 632m, 596w, 560w;ν(Ni–C): 544w δ(Ni–CN): 416m.

2.3. Single crystal X-ray experiment

Cell parameters and data collection were done on a KUMA KM-4κ-axis diffractometer equipped with a CCD area detector (graphite monochromatized Mo Kα radiation, λ = 0.71073 Å) at 150 K on a prismatic single crystal with dimensions 0.15 × 0.15 × 0.10 mm. The relevant crystal data are: monoclinic, a = 10.581(2), b = 17.872(3), c = 9.801(1) Å, β = 95.73(1)°, V = 1844.1(5) $Å^3$, $P2_1/c$, Z = 4, μ = 3.626 mm^{-1}, ρ_c = 1.872 g cm^{-3}.

A total of 928 frames were registered, from these 10478 reflections were collected (the θ range was 3.09°–26.68° and Miller indices limits were $-12 \leqslant h \leqslant 12$, $-21\ k \leqslant 21\ -6 \leqslant l \leqslant 12$). After data reduction and limiting the 2θ range to 50°, 3128 independent reflections were obtained (R_{int} = 0.0330), of these 2806 were observed ($I > 2\sigma(I)$). The completeness of the data was 0.932. An empirical absorption correction based on ψ-scan was used (SHELXTL V5.1 system [16]) with minimum and maximum transmission factors of 0.037 and 0.081. The structure was solved by the heavy atom method using

the SHELXS 86 program [17]. Refinement based on intensities was performed using the SHELXL 97 program [18]. All but the hydrogen atoms were refined anisotropically. Hydrogen atoms of the water molecule were found in the difference map and their positions were refined using a common isotropic thermal parameter; the remaining hydrogen atoms from the *tn* ligand were placed in calculated positions and their common group isotropic thermal parameters were refined (totally 248 parameters). The final parameters were: $R_1 = 0.0229$, $S = 1.081$, $wR_2 = 0.0472$ (all data), $R_1 = 0.0197$, $wR_2 = 0.0465$ (observed). The final difference map was featureless and the maximum peak and hole were 0.27(7) and $-0.32(7)$ e Å^{-3}. Selected geometric parameters and possible hydrogen bonds are gathered in Tables 1 and 2, respectively. For geometric calculations (hydrogen bond geometry) the program PARST 95 was used [19]. The figures were drawn with the DIAMOND program [20].

3. Results and discussion

3.1. Synthesis

Our initial intention was to prepare a coordination polymer containing as building blocks the $[Zn(tn)_2]^{2+}$ cation and the $[Ni(CN)_4]^{2-}$ anion. An analogous approach when using *en* instead of *tn* led to the formation of $Zn(en)_2Ni(CN)_4$ with a chelate bonded *en* ligand [21] while from the Cd(II)–*tn*–$[Ni(CN)_4]^{2-}$ system the $Cd(tn)_2Ni(CN)_4$ complex was isolated, in which *tn* ligands exhibit bridging character [14]. From the aqueous system Zn(II)–*tn*–$[Ni(CN)_4]^{2-}$, which was in contact with air, crystallized the title compound $Zn_2(tn)_2(CO_3)Ni(CN)_4 \cdot H_2O$ (ZTNC). The fixation of atmospheric CO_2 is not an uncommon phenomenon; it exhibits special interest with regard to the greenhouse effect [22,23]. It has been described that carbon dioxide is captured by amines [24,25]. Several complexes were formed by an insertion of CO_2, either in the form of the carbonato ligand or in another form. Examples that can be mentioned are $[\mu\text{-}CO_3\{Zn(pmap)\}_2](ClO_4)_2$ (*pmap* = bis[2-(2-pyridyl)ethyl]-(2-pyridyl)-methylamine) [26], $[Cu_3(bpy)_6(\mu_3\text{-}CO_3)]_2(ClO_4)_8 \cdot H_2O$ [27] and $\{[tren]Zn(OCO_2Me)\}(BPh_4) \cdot 2MeOH$ (*tren* = tris(2-aminoethyl)amine) [28]. As the initial mother liqueur did not contain a carbonato anion, this presumably was formed by an uptake of carbon dioxide from air. The presence of the diamine *tn* could be helpful for this process. To our knowledge ZTNC is the first example of a cyanocomplex which fixes CO_2. Our attempts to prepare this compound by addition of sodium carbonate to the initial mother liqueur were not successful.

3.2. IR spectra

The IR spectrum of ZTNC is rich and the most important peaks are gathered in the experimental part. Very characteristic are the absorption bands at 2168 and 2128 cm^{-1}, which can be assigned to the stretching vibrations of the cyano groups $\nu(C{\equiv}N)$ [29]; the peak observed at the higher wavenumber can be assigned to bridging cyano groups and the one placed at a lower wavenumber to terminal cyano groups. The presence of the Ni–CN entity is manifested by a strong δ(Ni–CN) vibration observed at 416 cm^{-1}. The *tn* ligands causes many absorption bands; those that are easily identifiable arise from $\nu(NH_2)$ (3320, 3256 cm^{-1}) and $\nu(CH_2)$ (2952s, 2928, 2904, 2864 cm^{-1}) stretching and $\delta(NH_2)$ (1612 cm^{-1}) deformation vibrations. The presence of the water molecule in the structure can be seen from the observation of absorption bands at 3616 and 3424 cm^{-1}, identified as asymmetric and symmetric ν(OH) stretching vibrations. The positions of all these observed absorption bands are very close to those found in the IR spectrum of $Zn(en)_2Ni(CN)_4 \cdot 2H_2O$ [30].

The free carbonato anion has two vibrational modes, E′ and A. Upon coordination the E′ mode is split and the A mode become IR active; the bands corresponding to the E′ mode occur in the 1600–1200 cm^{-1} region [31]. In the IR spectrum of ZTNC in this region several absorption bands at 1612s, 1504vs, 1472vs, 1416vs, 1320m and 1236m cm^{-1} were observed. In $[Cu_3(bpy)_6(\mu_3\text{-}CO_3)]_2(ClO_4)_8 \cdot H_2O$ the absorption bands due to stretching modes arising from the carbonato ligand were observed at 1474 and 1445 cm^{-1} [27]. In the

IR spectrum of the similar $Zn(en)_2Ni(CN)_4$ compound several absorption bands (1608s, 1590vs, 1580vs, 1460w, 1446w, 1384w, 1328m and 1278m cm^{-1}) due to various vibration modes in the amine ligand *en* were observed in this region [30]. Taking into account the intensities and positions of the observed absorption bands in ZTNC and the literature data it is possible to assign the band observed at 1504 cm^{-1} in the spectrum of ZTNC to the C–O stretching mode, but the assignment of the other observed bands to the respective vibration modes is not unambiguous as some overlap may also exist.

3.3. Crystal structure

The crystal structure of ZTNC (Fig. 1) is polymeric. As can be seen from Fig. 2, the zinc atoms which are approximately placed within sheets parallel to the (0 1 0) plane are linked by bridging *tn* and carbonato ligands forming two types of cavities. One type of these cavities is occupied by bridging tetracyanonickellate anions which thus participate in the formation of the positively charged framework $[Zn_4(tn)_4(CO_3)_2Ni(CN)_4]_n^{2n+}$. The second type of cavity contains free tetracyanonickellate anions and water molecules of crystallization. As a consequence, the formed structure can be viewed as a host–guest system in which the host framework accommodates as guests $[Ni(CN)_4]^{2-}$ anions and water molecules. An analogous host–guest system was formed by $[Zn_2(en)_3Ni(CN)_4][Ni(CN)_4] \cdot 3H_2O$ [32].

In the framework, there are two crystallographically and stereochemically different zinc atoms which are catenated by two crystallographically different bridging *tn* molecules. Moreover, two crystallographically equivalent Zn2 atoms are linked by a centrosymmetric bridging tetracyanonickellate anion (Ni1 atom is on the inversion centre) with bridging cyano groups placed in *trans* positions. The Zn1 atom is deformed tetrahedrally coordinated by two oxygen atoms from carbonato anions and two nitrogen atoms from *tn* ligands, the angles being in the range 102.26°–116.86° (Table 1, Fig. 1). At a distance of 2.7750(19) Å from this atom is situated the water molecule O4, the observed distance is too long to be considered as a coordination bond, but there may exist a weak interaction as deduced from the hydrogen bond geometry around the O4 atom (see below).

The Zn2 atom exhibits pentacoordination in the ZnO_2N_2N form; the oxygen atoms arise from the chelate bonded carbonato ligand and the nitrogen atoms from two diamine molecules and one bridging cyano group.

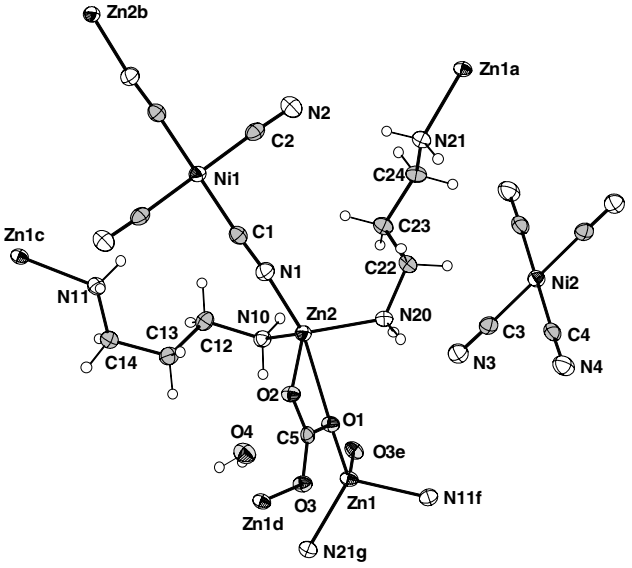

Fig. 1. Thermal ellipsoid drawing of ZTNC along with atom numbering scheme. The symmetry codes are: (a) $1 + x$, y, z; (b) $3 - x$, $1 - y$, $1 - z$; (c) $2 - x$, $0.5 + y$, $0.5 - z$; (d) x, $0.5 - y$, $0.5 + z$; (e) x, $0.5 - y$, $z - 0.5$; (f) $2 - x$, $y - 0.5$, $0.5 - z$; (g) $x - 1$, y, z.

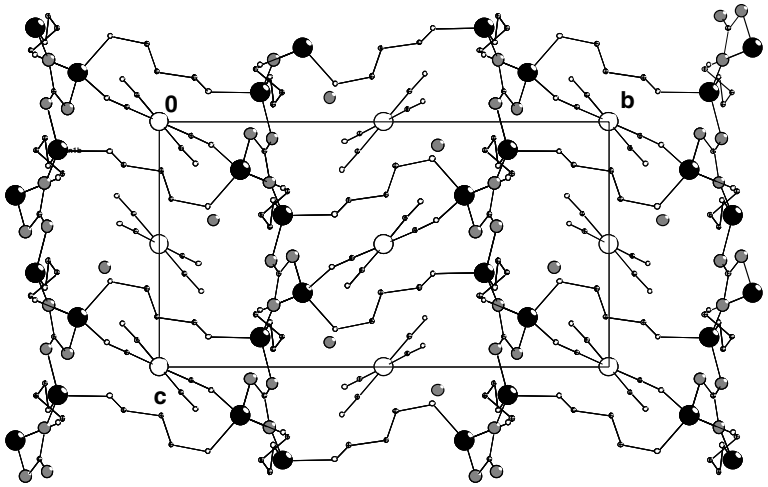

Fig. 2. View of the polymeric character of the structure of ZTNC.

Among the Zn2–X (X is nitrogen or oxygen) bond distances four Zn2–X ones are from the narrow range 2.0104–2.0347 Å and the fifth coordination bond (Zn2–O1) is considerably longer (2.3906(15) Å) (Table 1). The problem of the shape of coordination polyhedra in pentacoordinated complexes was extensively studied, especially for Cu(II) complexes, and various criteria for describing them were derived [33–36]. The calculated τ parameter [33] (0.728) suggests that the shape of the ZnO_2N_2N coordination polyhedron is closer to trigonal bipyramidal, in line with the results of the methods of the sum of angle deviations [34], which give a better *R* factor (0.126) for a trigonal bipyramidal shape than for the square pyramidal (0.152) and tetragonal pyramidal shapes (0.212).

The free tetracyanonickellate anion (Ni2) is placed on the inversion centre. Both Ni1 and Ni2 nickel atoms exhibit square coordination by four cyano ligands. The observed geometric parameters are within the usual values found for such complexes [1].

The μ_3-carbonato ligand forms four coordination bonds to three zinc atoms ($2 \times$ Zn1, Zn2) and thus exhibits bridging as well as chelate character (Fig. 2c). A search in the CCSD [37] has shown that, up until now, this coordination mode (not mentioned in the paper of Huang et al. [27]) was found only in $Cs_2[Pr_2(CO_3)_4]$ [38]. The Zn–O bonds in ZTNC are in the range 1.9475–2.3906 Å which is somewhat more spread than the observed range of 2.028–2.304 Å in $[((benpa)Zn)_2(\mu_2\text{-}CO_3)](ClO_4)_2$ (*benpa* = *N*,*N*-bis-2-(ethylthio)ethyl-*N*-((6-neopentylamino-2-pyridyl)methyl)-amine) with a *bis* (bidentate) binding of the carbonato ligand [39]. The observed C–O bonds are normal [27,39].

Aliphatic diamine ligand *tn* prefers a chelate type of bonding to transition metals ions but in the case of d^{10} elements it is not characteristic; there are only few examples of a chelate bonded *tn* ligand, e.g., in [-Zn(*tn*)-(μ_2-*tn*)-Zn(*tn*)-(μ_2-*tn*)]Cl_4 [40]. More often bridging bonding occurs. As an example one can mention $Cd(tn)_2Ni(CN)_4$ in which the Cd–*tn*–Cd catenation is made up of bridging *tn* ligands with the *tn* skeleton in a *trans–gauche–trans–trans* conformation [14]. In the title compound ZTNC both bridging *tn* ligands are in *gauche–trans–gauche–trans* conformation.

The water molecules are placed in the formed cavities of the structure (Fig. 2). The water molecules form two hydrogen bonds of the O–H···N type with the nitrogen atoms (N2, N4) from the terminal cyano ligands and function as an acceptor for the N10–H10B···O4 hydrogen bond with the amine group from *tn* (Fig. 3). In the direction of the assumed fourth position, corresponding to the tetrahedral orientation of the electron lobes around the O4 oxygen atom, is placed the Zn1 atom at a long distance of 2.7750(19) Å. The observed X···O···Y angles around the O4 atom (X and Y are N2, N4, N10 and Zn1 atoms) exhibit values of 110°, 114°, 103°, 129°, 104° and 90°, and may suggest a weak interaction between O4 and Zn1 atoms. All remaining hydrogen atoms from the *tn* amine groups are involved in weak hydrogen bonds of the N–H···N type with nitrogen atoms of the terminal cyano ligands and N–H···O type with oxygen atom of the carbonato ligand (Fig. 3, Table 2).

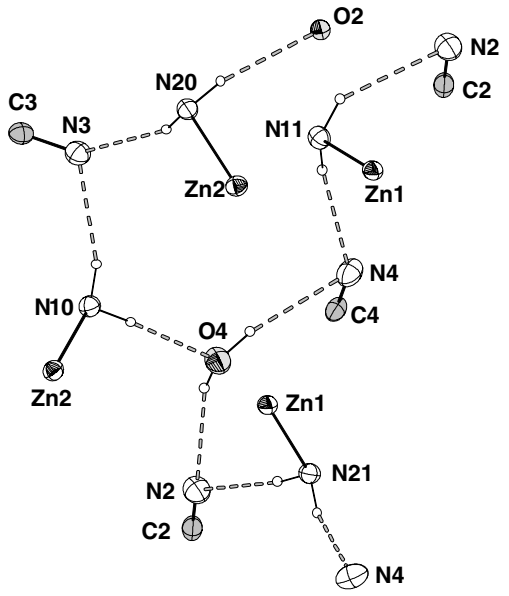

Fig. 3. Possible hydrogen bonds (dashed grey lines) in ZTNC.

4. Supplementary material

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC 246271. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: int. code +44 1223 336 033; E-mail: deposit@ccdc.cam.ac.uk; http://www.ccdc.cam.ac.uk].

Syntheses and characterizations of Co(II) and Ni(II) complexes of dihydrobis(thioxotetrazolyl)borato with Co[S_4] and Ni[S_4H_2] cores

Yu-Ling Wang, Rong Cao *, Wen-Hua Bi

State Key Laboratory of Structural Chemistry, Fujian Institute of Research on the Structure of Matter, Chinese Academy of Sciences, Graduate School of the Chinese Academy of Sciences, Yangqiao West Road 155, Fuzhou, Fujian 350002, People's Republic of China

Received 23 November 2004; accepted 17 December 2004

Abstract

The sodium salt of the dihydrobis(1-methyl-5-thiotetrazolyl)borato anion $[Btt^{Me}]^-$ has been synthesized by the reaction of $NaBH_4$ with 1-methyl-5-thiotetrazole. Treatment of $Na[Btt^{Me}]$ with anhydrous $CoCl_2$ and $NiCl_2 \cdot 6H_2O$, respectively, gives the complexes $Co(Btt^{Me})_2$ (**1**) and $Ni(Btt^{Me})_2$ (**2**), which have been characterized by IR, ^1H NMR, ESI-MS, UV–Vis spectroscopy as well as X-ray crystallography. Compound **1** contains a central [CoS_4] core and exhibits a slightly distorted trigonal-bipyramidal coordination geometry with a very weak apical Co···H–B interaction, whereas **2** features a central [NiS_4H_2] core in a distorted octahedral coordination geometry and exhibits relatively strong Ni···H–B interactions. These results indicate that the ligand can act in the bidentate (k^2-S,S) or tridentate (k^3-S,S,BH) mode. The electrochemical behavior of **1** and **2** has also been investigated by cyclic voltammetry.

1. Introduction

The soft tripodal ligands Tm and Tt (Tm = hydrotris(thioxoimidazolyl)borato, Tt = hydrotris(thioxotriazolyl)borato) play an important role in coordination chemistry, and their complexes with transition metals have been extensively investigated in recent years as sulfur-rich metalloenzyme models in bioinorganic chemistry [1,2]. Recently, a great deal of attention has focused on the bis-substitution products Bm and Bt (Bm = dihydrobis(thioxoimidazolyl)borato; Bt = dihydrobis(thioxotriazolyl)borato) (Scheme 1) and their metal complexes [3,4]. The soft donor Bm or Bt ligands have also been employed in bioinorganic chemistry to study the structure and reactivity of the active sites of metalloenzymes such as liver alcohol dehydrogenase (LADH) and [NiFe] hydrogenases [3] and in biomedical fields for labelling biomolecules with ^{99m}Tc or $^{186/188}Re$ [4]. To date, the notable examples of this family are $Ni(Bm^{Me})_2$, possessing a central [NiS_4H_2] core, $M(Bm^{Me})_2(CO)_3$ (M = Re or Tc), containing a fac-$[M(CO)_3]^+$ moiety, and $M(Bm^R)_2$ (M = Zn, Cd, Hg), with a central [MS_4] core [3,4]. As previously reported, Bm and Bt can formally act as bidentate ligands through the S atoms. Furthermore, they display agonistic M···H–B interactions toward most transition-metal ions, and this interaction may be influenced by many factors such as the electronic configuration of the metal ions, the substituents of the ligands, the flexibility and conformation of the chelating rings and the nature of the ligating atoms (N or S) [5].

In contrast to the extensively studied Bm and Bt ligands, there is no information on the Btt (Btt = dihydrobis(thioxotetrazolyl)borato) ligand (Scheme 1) and its related metal complexes. In this paper, we report the

syntheses, crystal structures and properties of two complexes, **1** and **2**, of the novel Btt^{Me} (Btt^{Me} = dihydrobis(1-methyl-5-thiotetrazolyl)borato) ligand, which may render models for studying various metalloenzymes derivatives such as Co-LADH [6].

2. Experimental

2.1. Materials and physical measurements

All reagents were commercial reagent grade and used without further purification unless otherwise noted. The solvents CH_3CN and THF were purified and degassed by standard procedures. The synthesis of $Na(Btt^{Me})$ was carried out under N_2 and other reactions were performed in air. The IR spectra were recorded on a Magna750 FT-IR spectrophotometer using KBr pellets from 4000 to 400 cm^{-1}. ^1H NMR spectra were recorded on a Varian UNITY-500 spectrometer (500 MHz). The UV–Vis spectra in CH_3CN solution were measured on a Perkin–Elmer Lambda 900 UV–Vis spectrometer. The electrospray mass spectra (ESI-MS) were run on a Finngan LCQ mass spectrometer using acetonitrile as the mobile phase. Electrochemical experiments were carried out on an Epsilon electrochemical analyzer. Cyclic voltametry (CV) was performed using a conventional three-electrode single compartment cell supplied by BAS Inc. The working electrode was a glassy carbon disc (GCE). The auxiliary electrode was a Pt wire. The reference electrode comprised an Ag wire immersed in acetonitrile solution containing 0.1 M $(Bu_4N)PF_6$ as supporting electrolyte. At the beginning of each experiment a cyclic voltammogram of the solution containing only the supporting electrolyte was measured under nitrogen atmosphere. Then the complexes were added and the resulting complex concentration was ~1 mM. The CV was recorded at a scan rate of 200 mV/s. Formal redox potentials are given vs. the reference system Cp_2Fe/Cp_2Fe^+ in volts.

2.2. Synthesis of the sodium salt of dihydrobis(1-methyl-5-thiotetrazolyl)borato

Under a nitrogen atmosphere 2.32 g of 1-methyl-5-thiotetrazole (20 mmol) and 0.378 g of $NaBH_4$ (10 mmol) were mixed in 30 ml degassed THF solution. The solution was refluxed overnight and the resulting cloudy solution was allowed to cool to room temperature and filtered. The filtrate was concentrated under reduced pressure to 3 ml and the white precipitate formed was washed with CH_2Cl_2 and ether, and then dried in vacuo for 2 h. Yield: 75%. IR data (cm^{-1}): 3070 (w), 2954 (w), 2497 (m), 2480 (m), 1645 (m), 1618 (m), 1510 (m), 1458 (m), 1439 (m), 1392 (s), 1336 (s), 1275 (s), 1196 (s), 1151 (m), 1105 (s), 999 (w), 972 (w), 860 (m), 758 (m), 742 (m), 710 (m), 617 (m), 465 (w). ^1H NMR data: δ 3.72 (s, CH_3). *Anal.* Calc. for $Na(Btt^{Me})$: C, 17.98; H, 3.00; N, 41.95. Found: C, 17.45; H, 2.36; N, 41.69%. UV–Vis (λ/nm ε/$mol^{-1}\,cm^{-1}$): 246 nm (73 900). MS (*m*/*z*, I%): 244, 100 $[Btt^{Me}]^-$.

2.3. Synthesis of $Co(Btt^{Me})_2$ (**1**)

$Na(Btt^{Me})$ 0.11 g (0.4 mmol) and anhydrous $CoCl_2$ 0.026 g (0.2 mmol) were stirred in CH_3OH overnight. The resulting blue precipitate was dissolved in CH_2Cl_2, and hexane was carefully layered over the CH_2Cl_2 solution. After one week blue crystals suitable for X-ray diffraction were obtained. Yield: 53%. IR data (cm^{-1}): 2951 (w), 2472 (m), 2378 (w), 2318 (w), 2291 (w), 1645 (w), 1470 (s), 1425 (s), 1398 (s), 1367 (m), 1364 (s), 1275 (s), 1198 (s), 1147 (m), 1092(m), 1080(m), 1005 (w), 968 (w), 854 (w), 758 (m), 744 (m), 521 (w), 465 (m). *Anal.* Calc. for $C_8H_{16}B_2CoN_{16}S_4$: C, 17.61; H, 2.93; N, 41.09. Found: C, 17.35; H, 2.52; N, 40.71%. ^1H NMR data: δ 3.708 (s, CH_3). UV–Vis (λ/nm ε/$mol^{-1}\,cm^{-1}$): 240 (66 750), 376 (11 120), 565 (750). MS (*m*/*z*, I%): 380, 10, $[Co_2(L)Na]^{4+}$; 545, 12, $[Co(L)_2]^+$; 720, 100, $[Co_3(L)_2(CH_3OH)_2]^{4+}$; 847, 68, $[Co_2(L)_3]^+$.

2.4. Synthesis of $Ni(Bt^{Me})_2$ (**2**)

$Na(Btt^{Me})$ 0.11 g (0.4 mmol) and $NiCl_2 \cdot 6H_2O$ 0.047 g (0.2 mmol) were dissolved in methanol and stirred overnight, and a yellow precipitate was obtained. The product was dissolved in CH_3CN and the resulting solution slowly evaporated in air to give yellow crystals. Yield: 47%. IR data (cm^{-1}): 2951 (w), 2503 (s), 2384 (m), 2276 (s), 2245 (s), 2198 (m), 2017 (w), 1618 (w), 1471 (s), 1419 (s), 1362 (s), 1348 (s), 1277 (s), 1130 (m), 1093 (m), 1068 (m), 1001 (m), 943 (m), 845 (m), 756 (s), 615 (w), 530 (w), 486 (w). *Anal.* Calc. for $C_8H_{16}B_2N_{16}NiS_4$: 17.62; H, 2.94; N, 41.10. Found: C, 17.38; H, 2.63; N, 40.83%. ^1H NMR data: δ 3.715 (s, CH_3). UV–Vis

(λ/nm ε/mol^{-1} cm^{-1}): 246 (60 950); 403 (2490). MS (*m*/*z*, I%): 380, 94, $[Ni_2(L)Na]^{4+}$; 545, 30, $[Ni(L)_2]^{+}$; 567, 58, $[Ni(L)_2Na]^{+}$; 719, 100, $[Ni_3(L)_2(CH_3OH)_2]^{4+}$; 845, 65, $[Ni_2(L)_3]^{+}$.

2.5. X-ray structure determination

X-ray diffraction data were collected on a Bruker P4 diffractometer with a Mercury CCD area detector (Mo Kα; λ = 0.71073 Å) for **1** and on a Siemens Smart CCD area-detector diffractometer (MoKα; λ = 0.71073 Å) for **2**. Empirical absorption correction was applied using the program SADABS [7]. The structures were solved using direct methods and refined by full-matrix least-squares on F^2 with SHELXTL (version 5.10) [8]. Non-hydrogen atoms were refined anisotropically. The hydrogen atoms were placed at their calculated positions except for hydrogen atoms on boron, which were located and refined isotropically for both complexes. The absolute structure of **1** was determined with a Flack parameter of 0.018(10) [9]. Additional information about crystal data collection and refinement parameters for **1** and **2** is presented in Table 1, while selected bond distances and angles are listed in Tables 2 and 3, respectively.

3. Results and discussion

The procedure of preparing the sodium salt of the dihydrobis(1-methyl-5-thiotetrazolyl)borato anion $[Btt^{Me}]^-$ is similar to that of preparing $Na(Bm^{Me})$ (Bm^{Me} = dihydrobis(thioxoimidazolyl)borato) (Scheme 2) [3a]. Reaction of $Na(Btt^{Me})$ with anhydrous $CoCl_2$ and $Ni(NO_3)_2 \cdot 6H_2O$ (molar ratio 2:1) affords two novel mononuclear complexes $Co(Btt^{Me})_2$ (**1**) and $Ni(Btt^{Me})_2$ (**2**), respectively. Both complexes are soluble in dimethylsulfoxide, acetonitrile and dichloromethane, but insoluble in methanol.

3.1. Crystal structures

X-ray diffraction shows the molecular structures in Figs. 1 and 2. Interestingly, two crystallographically independent molecules are found in the asymmetric unit of **1** and **2**, which are similar in their configuration.

The geometrical parameters of the two independent molecules in the asymmetric unit of **1** are somewhat different from each other (Table 2). The Co–S bond lengths vary from 2.3175(10) to 2.3773(9) Å (Co1) (av. 2.3458 Å) and 2.3204(9) to 2.4186(9) Å (Co2) (av. 2.3525 Å), and the S–Co–S bond angles range from 91.72(3)° to 140.20(4)° (Co1) and 95.39(3)° to 130.41(4)° (Co2). It is noteworthy that **1** has a larger range of S–Co–S bond angles compared with that in previously reported $M(Bm)_2$ complexes (M = Zn, Cd, Hg) (85°–124°), whose coordination geometry around the metal center are slightly distorted tetrahedral [3a]. At a first glance, **1** exhibits a severely distorted tetrahedral geometry in the solid state with a central $[CoS_4]$ core in which the cobalt atom is bound by two Btt^{Me} ligands through four S atoms. The Co1–S2 bond length (2.3773(9) Å) is much longer compared with the other Co–S distances, and the bond angles S2–Co1–S3, S2–Co1–S4 and S2–Co1–S1 are 91.72(3)°, 96.22(3)° and 107.36(4)°, respectively, which are close to 90°. In addition, the S2–Co1–H2A angle

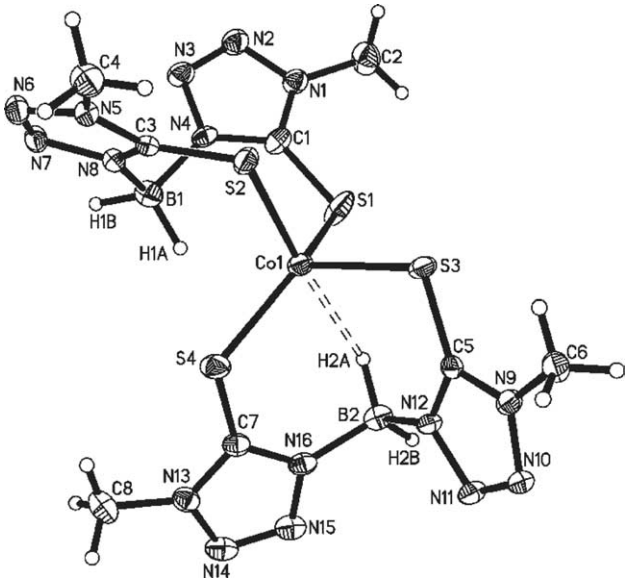

Fig. 1. The ORTEP drawing of molecule I of $Co(Btt^{Me})_2$ with 60% thermal ellipsoids.

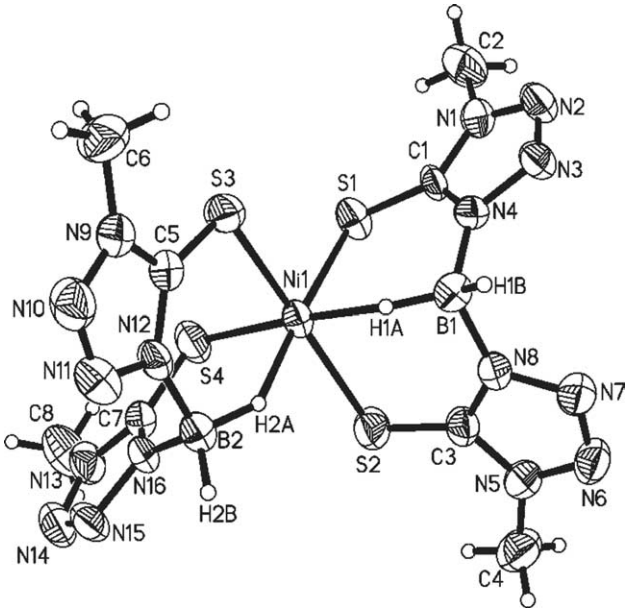

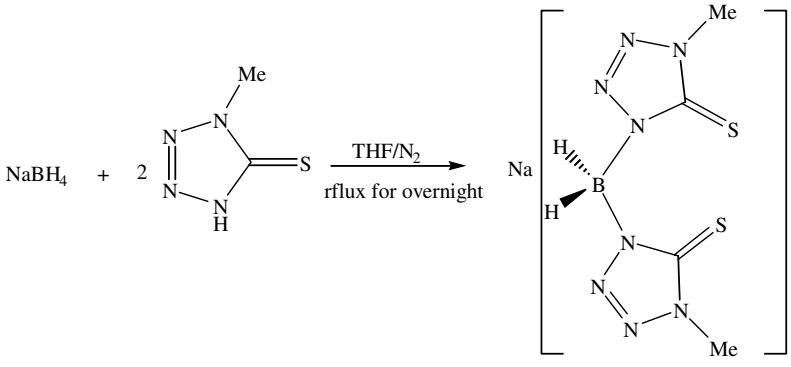

Fig. 2. The ORTEP drawing of molecule I of $Ni(Btt^{Me})_2$ with 50% thermal ellipsoids.

Scheme 2.

(172.0°) is close to the theoretical value of 180° for a trigonal bipyramid. These parameters indicate that the overall geometry around the Co1 atom should be best considered as a distorted trigonal bipyramid, if the very weak Co1···H2A–B2 interaction is taken into account. Interestingly, if the other weaker Co1···H1A–B1 interaction is further considered, the coordination geometry around Co1 can also be described as highly distorted octahedral. The coordination geometry around the Co2 atom is somewhat similar to that around the Co1 atom, however, the long distance of Co2–H4A (2.99(4) Å) indicates no interaction between Co2 and H4A. Hence, only a trigonal-bipyramidal coordination geometry of Co2 should be considered, with the axial bond angle S8–Co2–H3A being 173.6°, and the bond angles S8–Co2–S5, S8–Co2–S6 and S8–Co2–S7 being 91.58(3)°, 95.39(3)° and 106.54(3)°, respectively. The Co–H distances are 2.57(4) (Co1–H1), 2.32(4) (Co1–H2), 2.13(3) (Co2–H3) and 2.99(4) (Co2–H4) Å, respectively, which are much longer than that found in other borohydrido Co derivatives such as $Co(Tm^{Ph})_2$ [Co–H = 2.11(3) Å], $Co(pzBm^{Me})_2$ [(Co–H) = 1.95 Å] and $Co(Bp^{But,Pri})_2$ [(Co–H) = 1.95 Å] (Bp = dihydrobis(pyrazoly)borato) [10–12].

In the crystal structure of complex **2**, the geometrical parameters of the two independent molecules in the asymmetric unit are almost identical within experimental error. The most notable feature of **2** is that it contains a central $[NiS_4H_2]$ core, and the coordination geometry around the Ni atom is described as distorted octahedral, surrounded by four S atoms and two H atoms from two Btt^{Me} ligands with two relatively strong Ni···H–B interactions in which the two borohydrido groups are in a *cis* arrangement. From this viewpoint, the Btt^{Me} ligand acts as an S, S, H tripod. The structure of **2** is similar to that of the closely related nickel complexes $Ni(Bm)_2$ and $Ni(Bt)_2$ [3b,5]. The Ni–H distances are 1.98(10) (Ni1–H1), 1.89(10) (Ni1–H2), 1.87(9) (Ni2–H3) and 1.93(6) (Ni2–H4) Å, which are somewhat longer than that found in $Ni(Bm)_2$ (Ni–H = 1.863 Å) and $Ni(Bt)_2$ (av. Ni–H = 1.86 Å) [3b,5]. The Ni–S bond lengths are slightly different from each other, with those *trans* to the borohydrido groups being slightly shorter than the axial ones.

These different Ni···H and Co···H interactions result that the Btt^{Me} ligands in **1** adopt a 'boat-like' eight-membered ring configuration and in **2** the Btt^{Me} ligands adopt a 'twist' eight-membered ring configuration.

3.2. Infrared spectroscopy

In the IR spectra of the ligand, two medium absorptions at 2497 and 2480 cm^{-1} show the typical B–H stretching vibrations. For complex **1**, the medium absorption at 2472 cm^{-1} can be assigned to a terminal B–H stretching vibration and two weak absorptions at 2378 and 2318 cm^{-1} are indicative of a weak Co···H–B interaction. In the infrared spectrum of **2**, the corresponding bands are at 2550–2350 and 2300–2200 cm^{-1}, respectively. Compared with **1**, the absorption intensity of the B–H bond at low frequency is much greater than that of the corresponding one in **1**, and the result is attributable to the relatively strong Ni···H–B interaction. These are in good agreement with the crystal analytical results.

3.3. Electra spectra

In the UV–Vis spectra of **1** and **2** in CH_3CN solution, the absorptions [λ/nm ε/mol^{-1} cm^{-1}] at 240 (66 750) for **1** and 246 (60 950) for **2** display π–π^* transitions for the coordinated Btt^{Me} ligands, based on the absorption at 246 (73 900) in the spectra of the uncoordinated ligands. The absorption observed at 376 (11 120) in the UV–Vis spectrum of **1** can be assigned to the charge transfer from the ligands to the Co(II) center [6] and the absorption at 565 (750) to a d–d transition [13]. The position of the 376 nm absorption is higher in energy than the band of similar intensity found in $Co(PhTt)_2$ (380 (7400)) (PhTt = phenyltris(methylthio)methylborate) [14]. For **2**, the absorption at 403 (2490) may be associated with the d–d transition [$^3A_{2g}(F) \rightarrow {}^3T_{1g}(P)$] in an octahedral field for a d^8 ion [5], with an energy which is comparable with that observed in the related complex $Ni(Bt)_2$ (417 (1120)) [5].

3.4. Electrochemistry

Electrochemical data of $Na(Btt^{Me})$ and complexes **1** and **2** are summarized in Table 4. The cyclic voltammogram of $Na(Btt^{Me})$ in acetonitrile revealed one irreversible oxidation peak at +0.47 V and one irreversible reduction peak at –1.83 V (vs. Cp_2Fe/Cp_2Fe^+). Figs. 3 and 4 display the cyclic voltammograms of **1** and **2**, respectively. As shown in Fig. 3, a scan initiated in the negative direction reveals an irreversible reduction at

Table 4
Electrochemical data

Complex	E^f (V)	ΔE_p (mV)	$I_{p,ox}/I_{p,red}$	
$Na(Btt^{Me})$	+ 0.47			irrev
	−1.83			irrev
$Co(Btt^{Me})_2$	−1.56			Irrev
	−0.23			irrev
	+0.45			irrev
	0.78	142	1.1	quasi-rev
$Ni(Btt^{Me})_2$	−1.11			irrev
	+0.45			irrev
	+0.75	131	0.73	quasi-rev

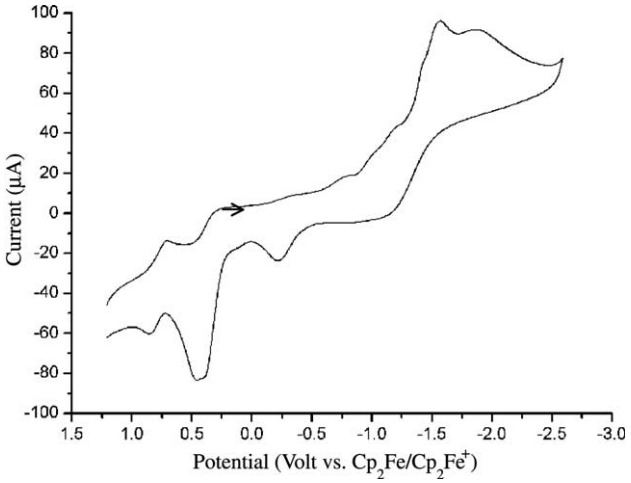

Fig. 3. Cyclic voltammogram of $Co(Btt^{Me})_2$ in 0.1 M TBAP-CH_3CN at a glassy-carbon electrode with a scan rate of 200 mV/s.

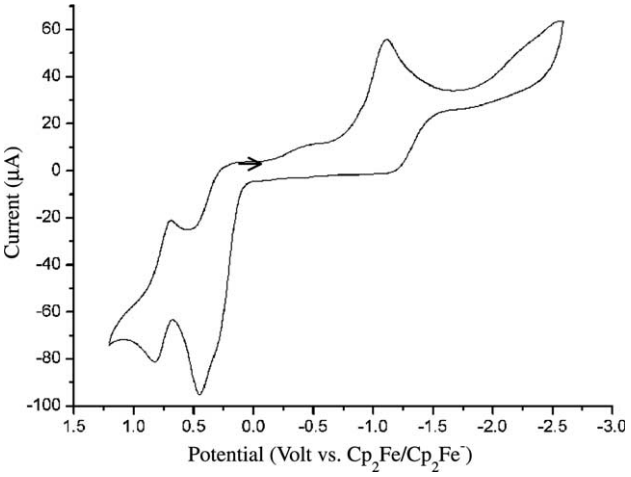

Fig. 4. Cyclic voltammogram of $Ni(Btt^{Me})_2$ in 0.1 M TBAP-CH_3CN at a glassy-carbon electrode with a scan rate of 200 mV/s.

−1.56 V of **1**. Then, an irreversible oxidation at −0.23 V of the reductive product of **1** is observed. It is noted that the irreversible oxidation at 0.45 V should be assigned to the oxidation of the coordinated Btt^{Me} ligands, for the oxidation potentials in **1** and the free ligand are nearly identical. Finally, a quasi-reversible redox process at +0.78 V is observed, which should be contributed to a metal-based quasi-reversible redox process.

Compared with **1**, complex **2** displays similar cyclic electrochemical behavior. An irreversible reduction of **2** at −1.11 V is observed. The irreversible oxidation of the coordinated ligands at +0.48 V is also indicative of the oxidation of the coordinated Btt^{Me} ligands. A metal-based quasi-reversible redox process at +0.75 V is also observed. However, the related complex $Ni(Bm)_2$ exhibits irreversible oxidation [2b].

4. Supplementary materials

Crystallographic data for the structures are available from the Cambridge Crystallographic Data Centre (CCDC Nos. 248456 and 248278 for compounds $Co(Btt^{Me})_2$ and $Ni(Btt^{Me})_2$, respectively). These data can be obtained free of charge via www.ccdc.cam.ac.uk/data_request/cif, by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033.

Abstract

Chelation of the tetradentate pyridyl di-Schiff-base ligands, *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-propane-1,3-diamine (L^1) or *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-ethane-1,2-diamine (L^2) to a cadmium(II) centre reveals interesting structural deviations from regular octahedral geometry in the resulting hexacoordinated complexes $[Cd(L^1)(NCS)_2]$ (**1**) and $[Cd(L^2)(NCS)_2]$ (**2**), respectively. The two tetradentate ligands L^1 and L^2 differ only in the polymethylene chain – $(CH_2)_3$ and $(CH_2)_2$, respectively, which connects the two halves of the symmetric ligands. Complex **1** assumes a trigonal prismatic (TP) geometry. The structure of **2** reveals a severely distorted octahedral geometry. The structural differences between $[Cd(L^1)(NCS)_2]$ (**1**) and $[Cd(L^2)(NCS)_2]$ (**2**) can be traced to the length of the polymethylene spacers and the formation of a six- versus a five-membered metal-chelate ring together with the pyramidal $Cd(L^1)$ and planar $Cd(L^2)$ arrangement.

1. Introduction

Octahedral coordination geometries are ubiquitous as the fundamental geometries of transition metal hexacoordinated complexes. Non-octahedral structures can be realized by considering a trigonal twist about the threefold axis of the octahedron (twist angle $\phi = 60°$) with a trigonal prismatic (TP) stereochemistry at $\phi = 0°$ (cf. Scheme 1). TP coordination was first observed [1] for the layer lattices of heavy metal sulphides (MoS_2 and WS_2) but could only be rationalized as peculiarities of the solid state. Structural authentication of a TP geometry in a discrete molecule was first available in the year 1965 and the concerned work of Eisenberg and Ibers [2] merits paramount importance from a chemical point of view. The breakthrough was then followed by a good number of structurally characterized TP complexes in cases of various 3d, 4d and 5d transition metals under differing ligand environments. Scrutiny of the underlying aspects in favour of TP coordination with much regard to electronic and steric influences of metals and ligands had started earlier [3–12]. Later on, theoretical analyses, i.e., ab initio calculations at the DFT level [13–17], ligand field-based models [18] and continuous symmetry measures [19] efficiently correlated the experimental findings and, of course, provided a sophisticated perspective of optimized structure–energy relationships.

doi:10.1016/j.poly.2005.01.005

The trigonal prismatic geometry for a metal ion with a d^{10} electronic configuration is not unexpected as there is no crystal field stabilization energy. In Zn(II) complexes, the TP geometry has been previously established [20,21]. A perfectly prismatic structure of Cd(II) was found in the potassium salt of the tris(acetylacetonato) complex [22], and distorted trigonal prisms were observed with other ligands such as nitrates, carboxylates, triamines, oxalato and a derivative of triazacyclononane [23,24]. However, to the best of our knowledge no TP geometry with a neutral, tetradentate Schiff-base ligand has been reported up to date. Herein we describe a neutral trigonal prismatic cadmium complex of the formula $[Cd(L^1)(NCS)_2]$ incorporating the tetradentate ligand *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-*propane*-1,3-diamine (L^1). Use of the closely related ligand *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-*ethane*-1,2-diamine (L^2) in the complex $[Cd(L^2)(NCS)_2]$ resulted in a severely distorted octahedral geometry. The structural differences are investigated in terms of conformational requirements of the ligands.

2. Results and discussion

2.1. Synthesis of the ligands and complexes

Facile condensation of 2-acetylpyridine with 1,3-diaminopropane or 1,2-diaminoethane in a 2:1 molar ratio furnished the two neutral tetradentate ligands *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-propane-1,3-diamine (L^1) and *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-ethane-1,2-diamine (L^2), respectively.

x = 3, L = L^1
x = 2, L = L^2

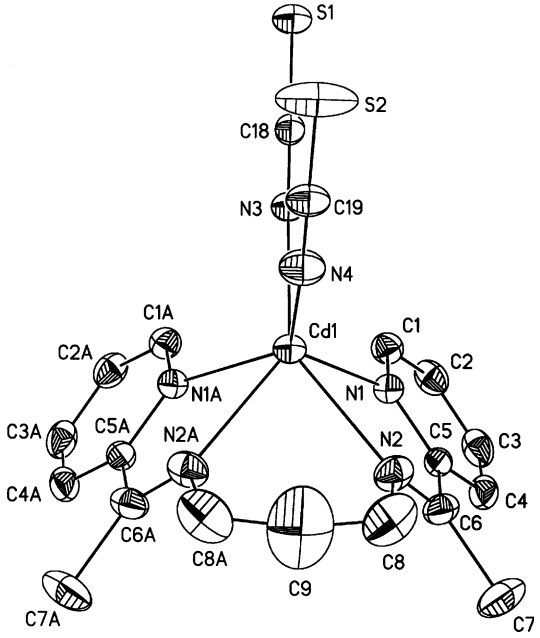
$$Cd(OAc)_2\cdot 2H_2O + L + 2NH_4SCN \xrightarrow[\text{magnetic stirring}]{\text{dry methanol}} [Cd(L)(NCS_2)]\downarrow + 2NH_4OAc + 2H_2O \quad (1)$$

L=L^1, **1**
L=L^2, **2**

At ambient temperature, reaction of L with $Cd(OAc)_2\cdot 2H_2O$ in dry methanol in the presence of NH_4SCN yielded two neutral cadmium complexes, **1** and **2** (Eq. (1)). The products were insoluble in the reaction medium and were isolated in the pure form via filtration.

2.2. Bonding and geometrical features

Compound **1** is a molecular complex with the tetradentate chelating *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-propane-1,3-diamine ligand and two terminal (N-bound) isothiocyanato groups around the cadmium centre. Thus each cadmium atom is coordinated by six nitrogen donors, two from the *cis*-arranged NCS groups and four from the organic ligand. A molecular view and selected bond parameters of **1** are displayed in Fig. 1 and Table 1, respectively. A mirror plane passes through the molecule which contains Cd1, C9 and the two NCS groups and relates the two halves of the organic ligand. Significant distortion from classical octahedral towards TP geometry is clearly revealed in the molecular structure. An idealized octahedron is made up with two exactly parallel, staggered equilateral triangles of side *s* with an inter-triangular distance *h* (Scheme 1). Evaluation



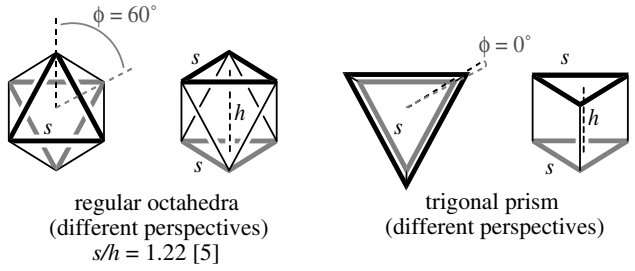


Fig. 1. Perspective view and atom labelling scheme of **1**. All the non-hydrogen atoms are represented by 20% thermal probability ellipsoids.

Table 1
Selected bond distances (Å) and angles (°) for compound $[Cd(L^1)(NCS)_2]$ (**1**)

Distances			
Cd(1)–N(1)	2.358(2)	Cd(1)–N(4)	2.255(4)
Cd(1)–N(2)	2.393(2)	Cd(1)–N(1A)	2.358(2)
Cd(1)–N(3)	2.316(3)	Cd(1)–N(2A)	2.393(2)
Angles			
N(4)–Cd(1)–N(3)	84.97(13)	N(3)–Cd(1)–N(1)	86.63(8)
N(1)–Cd(1)–N(2)	68.45(8)	N(3)–Cd(1)–N(2)	142.46(7)

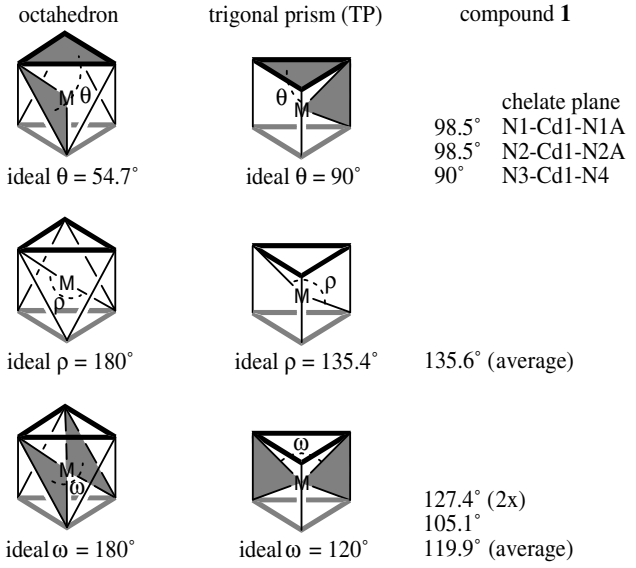
N(4)–Cd(1)–N(1)	134.92(5)	N(1)–Cd(1)–N(1A)	88.47(10)



Scheme 1. Octahedron and trigonal prism with enhanced triangular faces and relevant parameters for the assessment of their relationship and distortion. ϕ is the twist angle between the enhanced triangles around the C_3 axis.

of the *s*/*h* ratio and twist angle (ϕ) value for the hexacoordinated complexes provides a measure of trigonal distortion [5].

The CdN_6 coordination sphere in **1** can be described as being constituted of two triangles (N3, N1, N1A and N4, N2, N2A) with an average side (*s*) of 3.228 Å. These two N_3 triangles are slightly tilted with a dihedral angle of 8.8° and an inter-triangular separation between the centroids of 2.802 Å (*h*). A view of the $Cd1N_6$ motif showing the twist angles ϕ is represented in Fig. 2. The torsion angles N–C_n–C_n'–N′ (C_n, C_n' = centroids of the two N_3 triangles; N, N′ = near eclipsed pair of donor atoms) of 0°, 6° and 6° are fairly close to the twist angle of a regular TP geometry (ϕ = 0°). The average twist angle of 4° in **1** is similar to the trigonal prismatic complex Zn[(py)$_3$tach] [20]. The *s*/*h* ratio in **1** is 1.15 indicating an elongation relative to an ideal trigonal prism with square faces (*s* = *h*, *s*/*h* = 1.00). Consideration of the angular parameters θ, ρ and ω (Scheme 2) in the comparison between octahedral and trigonal prismatic limiting structures clearly indicates that compound **1** can be regarded as a trigonal prism (see parameters for **1** in Scheme 2).

A molecular view of [Cd(L^2)(NCS)$_2$] (**2**) with the tetradentate ligand *N*,*N*′-bis-(1-pyridin-2-yl-ethylidene)-ethane-1,2-diamine (L^2) (with a shorter dimethylene spacer in place of L^1) is depicted in Fig. 3 and selected

Scheme 2. Angular parameters involved in the comparison between the octahedral and trigonal prismatic limiting structures. θ = angle between the mean plane of the two N_3 triangles and the chelate planes defined by the metal and each pair of near eclipsed N vertices. ρ = angle between the metal and *trans* N-donor sites. ω = angle between the triangular faces defined by the metal and near eclipsed N atoms.

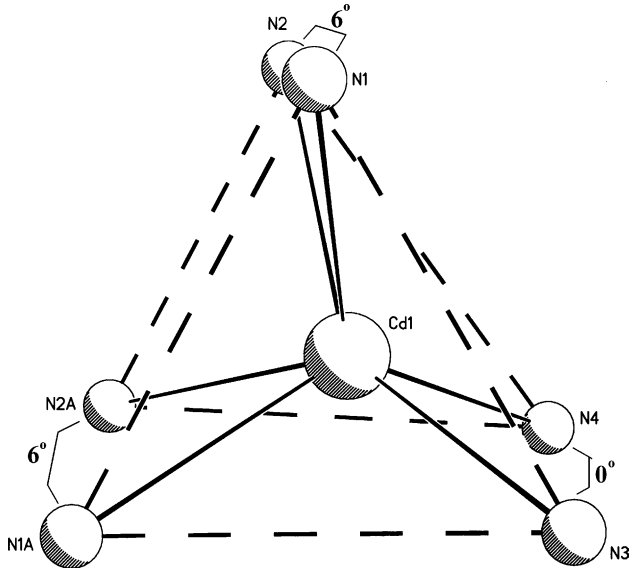


Fig. 2. ORTEP view of the CdN6 coordination sphere of **1** showing all the individual twist angles. Non-bonded N···N distances (Å): N1···N1A···N3 triangle N1/N1A···N3 3.206, N1···N1A 3.290; N2···N2A···N4 triangle N2/N2A···N4 3.376, N1···N1A 2.915.

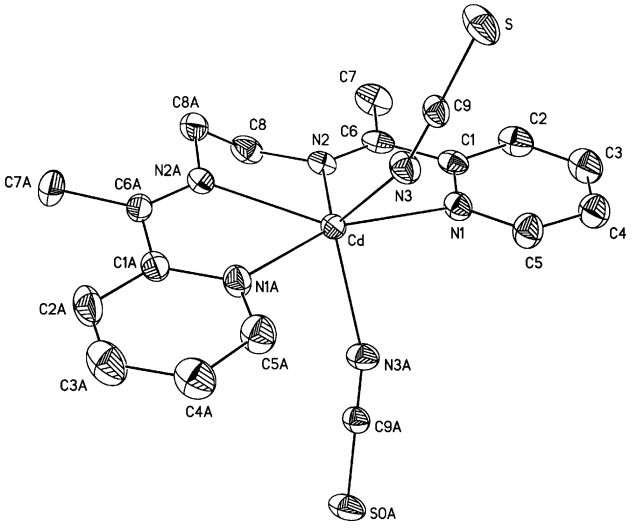

Fig. 3. Perspective view and atom labelling scheme of **2**. All the non-hydrogen atoms are represented by 20% thermal probability ellipsoids.

bond parameters are listed in Table 2. The CdN_6 coordination sphere is strongly distorted from an octahedron with a crystallographic twofold symmetry axis passing through the metal atom and the midpoint of the C8–C8A bond of L^2. The six nitrogen atoms in **2** at an average distance of 2.356 Å define a polyhedron that is neither close to the octahedral nor the TP geometry. The structure may be imagined to consist of two symmetry related N_3 triangles (N1, N2, N3 and N1A, N2A, N3A) with an average side (s) of 3.246 Å and separated by a distance (h) of 2.786 Å. Then the s/h ratio of ~1.17 (<1.22) indicates an elongated octahedral structure. The triangular twist angle ϕ measured at the donor atoms N1, N3A or N1A, N3 is only 8.3° with the imaginary C_3 axis passing through the centroids of the imagined triangles. Such a small angle would be close to the prismatic limit ($\phi = 0°$, Scheme 1). Yet, the third donor set N2, N2A is twisted by 41.3° about the threefold axis towards the octahedral extreme (60°). The average *trans* angles ∠N1–Cd–N1A and ∠N3–Cd–N3A at ~133° are also close to the prismatic limit ($\rho = 135.4°$, Scheme 2). The deviation in **2** mimics the benzenedithiolato-chelated d^0–Ta(V) ion [25] where an average twist angle ϕ of 19.3° also indicated a significant departure from a regular octahedral coordination. In **2** the average dihedral angle θ of 59.8° is closer to an octahedral than to a TP geometry. Dihedral angles ω between the individual CdN_2 planes are averaged at only 60.3°, consistent with severe distortion.

2.3. Comparison of ligand binding in *1* and *2*

In the following the structural divergence in the cadmium complexes **1** and **2** will be comparatively discussed on the basis of the geometrical selectivity and bonding aspects of the concerned ligands.

(i) The Cd(L^1) moiety in **1** defines a square pyramidal geometry. The metal atom is displaced upward by ~1.2 Å from the plane comprised of the L^1 donor atoms N1, N2, N2A and N1A. This does not allow the coordination polyhedron to be completed to an octahedron via the $(NCS)_2$ coordination. In **2** the metal atom along with the L^2 donor atoms N1, N2, N2A and N1A constitutes a planar arrangement (mean deviation = 0.09 Å) and would welcome the two NCS groups to complete a close to octahedral geometry. The two Cd(L) situations are portrayed by space-filling models represented in Fig. 4. It is well known that chelate ligands giving rise to a five-membered chelate ring (e.g. an N–C–C–N ligand moiety) are better suited for larger metal ions whereas a chelate ligand yielding a six-membered chelate ring (e.g. an N–C–C–C–N ligand moiety) is better for smaller metal ions [26]. This assumes the metal ion at the intersection of the N lone-pairs and the chelate ring near its energy minimum. Thus, the N–C–C–C–N ligand moiety simply cannot accommodate the large Cd ion within its plane. The N lone-pairs and with it the pyridylimine moieties are tilted out of the N–C–C–C–N plane, so that the TP structure results (Fig. 4). On the other hand, the N–CH_2–CH_2–N ligand moiety in compound **2** is much better suited for accommodating the large Cd ion in the plane of a five-membered chelate ring. Therefore, the tetradentate ligand in compound **2**, with its five-membered chelate rings could span the equatorial plane in a distorted octahedral geometry.

(ii) The ratio of the ligand bite (b = distance between the donor atoms) to the average Cd1–N distance (a) in **1** is not compatible with the chelate being able to span the edge of the octahedron ($b/a = 1.41$ for the ideal octahedron). In **1** the bite

Table 2
Selected bond distances (Å) and angles (°) for compound $[Cd(L^2)(NCS)_2]$ (**2**)

Distances			
Cd–N(1)	2.460(3)	Cd–N(2)	2.372(3)
Cd–N(3)	2.236(3)		
Angles			
N(3)–Cd–N(3A)	109.83(18)	N(1)–Cd–N(1A)	156.01(17)
N(3)–Cd–N(2)	120.99(12)	N(2)–Cd–N(2A)	70.99(16)
N(3)–Cd–N(2A)	114.90(11)	N(3)–Cd–N(1A)	85.02(11)
N(3)–Cd–N(1)	81.25(11)	N(2)–Cd–N(1A)	137.03(12)
N(2)–Cd–N(1)	66.84(12)		

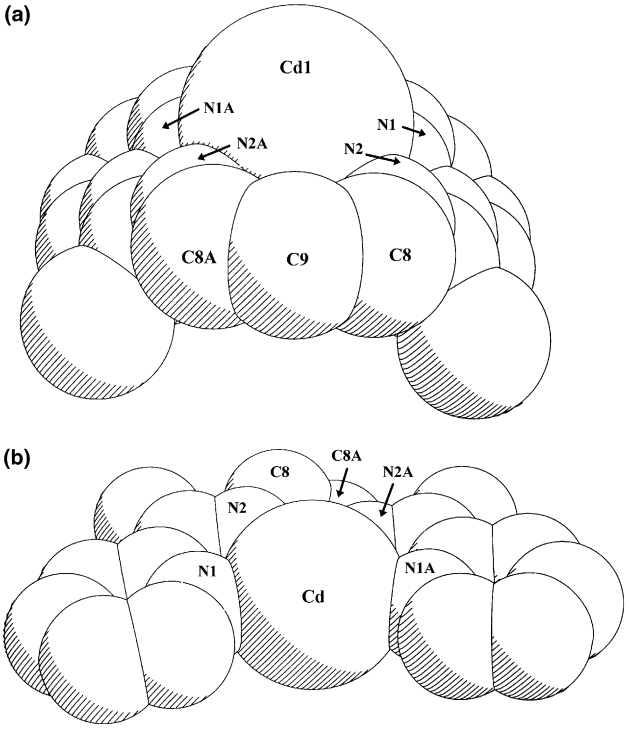

Fig. 4. Space-filling model of metal–L moiety for **1** (a) and **2** (b).

is quite short (b/a = 1.24) and L^1 encapsulates the metal atom in a TP fashion (b/a = 1.31 for ideal TP). In **2** the ratio (b/a = 1.37) is much closer to the octahedral limit.

(iii) In complex **1** the intermolecular packing along the crystallographic *b*-direction is controlled by π-stacking interactions [27] between the pyridyl planes (Figs. 5(a) and (b)). The overlapping ring planes are related by a center of inversion, thus, are exactly parallel. The ring slippage has a slip angle of 24.6° and a vertical displacement between the ring centroids of 1.58 Å (centroid separation 3.796 Å, interplanar distance 3.45 Å). [27,28]. The shortest overlapping carbon contact C5-C1[3] is 3.45 Å. Therefore, the π-stacking in **1** corresponds closely to strong π-interactions which are classified by centroid–centroid contacts <3.8 Å, slip angles <25° and vertical displacements <1.5 Å [27]. On the other hand, the intermolecular packing in **2** exhibits only very weak π-stacking interactions between the pyridyl planes deduced by rather long centroid–centroid distances (>4.2 Å), large interplanar distances (>3.65 Å) together with large slip angles (=30°) and vertical displacements (>2.1 Å) between the ring centroids [27].

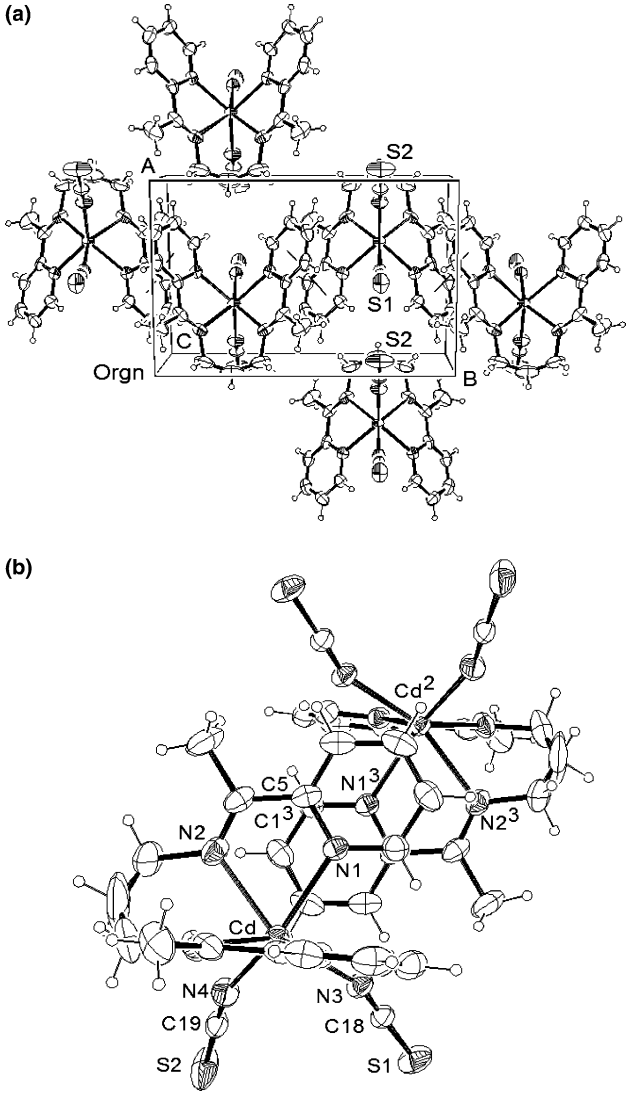

Fig. 5. (a) Intermolecular π-stacking (thin lines) along *b* in **1**. (b) Perpendicular view of the π-overlap between two molecules to show the typical ring slippage; symmetry transformation [2] = 1 − *x*, y − 1/2, 1 − *z*; [3] = 1 − *x*, 1 − *y*, 1 − *z*.

2.4. ^1H NMR spectra

The ^1H NMR spectrum of diamagnetic $[Cd(L^1)(NCS)_2]$ (**1**), in DMSO–d_6 at room temperature exhibits sharp singlets at δ = 3.92 and 2.36 ppm due to six methylene protons which is fully consistent with the crystallographically imposed mirror symmetry. The eight pyridyl proton signals do not exhibit spin structure and appear as broad singlets at 8.95, 8.29 and 7.83 ppm with the relative intensities 1:2:1. The methyl resonance is observed at 2.46 ppm as a sharp singlet as expected.

The ^1H NMR spectrum of $[Cd(L^2)(NCS)_2]$ (**2**), in DMSO–d_6 at room temperature revealed well resolved spin-spin structures for the pyridyl protons in the domain of 8.82–7.43 ppm. The methylene proton resonance appeared as a singlet at 3.84 ppm, in agreement with the presence of a twofold axis bisecting the C–C bond of the dimethylene moiety of the ligand. Like **1**, the methyl resonance was observed as a sharp singlet at 2.42 ppm.

3. Experimental

3.1. Materials and measurements

$Cd(OAc)_2 \cdot 2H_2O$, 2-acetylpyridine and 1,3-diaminopropane were purchased from Fluka AG (Switzerland). Ammonium thiocyanate and 1,2-diaminoethane were obtained from S.D. Fine Chemicals (India). Reagent grade solvents were distilled and dried by standard methods and were used for all reactions. Spectral measurements were carried out using the following equipment: IR (KBr disc), Perkin–Elmer RXI FT-IR spectrometer; ^1H NMR (DMSO–d_6, s = singlet, d = doublet, t = triplet), Bruker 300 MHz FT NMR, FAB Mass spectra JEOL JMS 600 spectrometer. A Perkin–Elmer 2400 Series II elemental analyzer was used for microanalysis (C, H, N).

3.2. Preparations

3.2.1. Ligands

L^1: 1,3-Diaminopropane (1.11 g, 15 mmol) and 2-acetylpyridine (3.63 g, 30 mmol) were refluxed in 30 mL of dry methanol for 8 h. The resulting solution

was evaporated under reduced pressure to obtain a yellowish-brown semi-solid mass. The mass was then extracted thrice (3 × 10 mL) with *n*-hexane, which on slow evaporation afforded deep yellow needles. The product was finally dried under vacuum over fused $CaCl_2$. Yield: 2.77 g (65%). *Anal.* Calc. (%) for $C_{17}N_4H_{20}$: C, 72.83; H, 7.19; N, 19.98. Found: C, 72.91; H, 7.13; N, 19.93. IR (ν/cm^{-1}): 1680 ($\nu_{C=N}$). FAB Mass spectrum: *m*/*z* 281 $(L^1 + 1)^+$. ^{1}H NMR {δ(*J*/Hz), DMSO–d_6}: Pyridyl protons, 8.52 (d, *J* = 7.0, 2H), 7.96 (d, *J* = 7.8, 2H), 7.80 (t, *J* = 7.4, 2H), 7.37 (t, *J* = 6.8, 2H); methylene protons, 3.82 (s, 4H), 3.48 (s, 2H); methyl protons, 2.34 (s, 6H).

L^2: The ligand was prepared by a procedure similar as that for L^1, by starting with 1,2-diaminoethane (0.9 g, 15 mmol) and 2-acetylpyridine (3.63 g, 30 mmol) to obtain a yellow semi-solid mass, which on recrystallization from *n*-hexane gave pale yellow product. Yield: 2.44 g (61%). *Anal.* Calc. (%) for $C_{16}N_4H_{18}$: C, 72.22; H, 6.75; N, 21.09. Found: C, 72.15; H, 6.81; N, 21.04. IR (ν/cm^{-1}): 1681 ($\nu_{C=N}$). FAB Mass spectrum: *m*/*z* 267 $(L^2 + 1)^+$. ^{1}H NMR {δ(*J*/Hz), DMSO–d_6}: Pyridyl protons, 8.56 (d, *J* = 7.0, 2H), 7.98 (d, *J* = 8.2, 2H), 7.79 (t, *J* = 7.8, 2H), 7.32 (d, *J* = 7.8, 2H); methylene protons, 3.75 (s, 4H); methyl protons, 2.32 (s, 6H).

3.2.2. Complexes

*[Cd(L^1)(NCS)$_2$] (**1**)*. To a solution of $Cd(OAc)_2 \cdot 2H_2O$ (0.133 g, 0.5 mmol) in 15 mL dry methanol was added (0.006 g, 1 mmol) of NH_4SCN. To the resulting solution (0.140 g, 0.5 mmol) of L^1 dissolved in 10 mL dry methanol was added in one go. The solution gradually became turbid and to ensure complete reaction magnetic stirring was continued for 3 h, and the reaction was left overnight at room temperature for complete precipitation. The solid was then collected by filtration, thoroughly washed with cold methanol and finally dried under vacuum over fused $CaCl_2$. Yield: 234 mg (92% with respect to L^1). *Anal.* Calc. (%) for $C_{19}N_6H_{20}S_2Cd$: C, 44.84; H, 3.96; N, 16.51. Found: C, 44.88; H, 3.89; N, 16.57. IR (ν/cm^{-1}): 2072 (ν_{NCS}). FAB Mass spectrum: *m*/*z* 510 $(\mathbf{1} + 1)^+$. ^{1}H NMR {δ(*J*/Hz), DMSO–d_6}: Pyridyl protons, 8.95 (s, 2H) 8.29 (s, 4H), 7.83 (s, 2H); methylene protons, 3.92 (s, 4H of C8 and C8A atoms); 2.36 (s, 2H of C9 atom); methyl protons, 2.46 (s, 6H).

[Cd(L^2)(NCS)$_2$] (**2**). The complex was prepared by a similar procedure. Yield: 222 mg (90% with respect to L^2). *Anal.* Calc. (%) for $C_{18}N_6H_{18}S_2Cd$: C, 43.68; H, 3.67; N, 16.98. Found: C, 43.73; H, 3.61; N, 17.04. IR (ν/cm^{-1}): 2070 (ν_{NCS}). FAB Mass spectrum: *m*/*z* 496 $(\mathbf{2} + 1)^+$. ^{1}H NMR {δ(*J*/Hz), DMSO–d_6}: Pyridyl protons, 8.82 (d, *J* = 6.8, 2H), 8.12 (t, *J* = 7.5, 2H), 7.87 (t, *J* = 7.2, 2H), 7.43 (d, *J* = 8.0, 2H); methylene protons, 3.84 (s, 4H); methyl protons, 2.42 (s, 6H).

3.3. Crystal structure determination

Crystals of **1** and **2** were grown by slow evaporation of solvent from DMSO solution. Data collection were performed by the ω-scan method within the limits $2.19° \leqslant \theta \leqslant 28.66°$ and $2.54° \leqslant \theta \leqslant 28.87°$ for **1** and **2**, respectively, on a Bruker AXS CCD diffactometer with graphite monochromated Mo Kα radiation (λ = 0.71073 Å) radiation. Data collection and cell refinement were carried out with SMART [29], data reduction with SAINT [29], and experimental absorption correction with SADABS [30].

Structure analysis and refinement. The structure was solved by direct methods (SHELXS-97) [31]; refinement was done by full-matrix least squares on F^2 using the SHELXL-97 program suite [31]. All non-hydrogen positions were found and refined with anisotropic temperature factors. The hydrogen atoms were calculated with appropriate riding models (AFIX 43 for aromatic hydrogens on pyridine, AFIX 23 for CH_2 and AFIX 33 for CH_3) and U_{eq}(H) = 1.2 U_{eq}(C) for CH and CH_2 and U_{eq}(H) = 1.5 U_{eq}(C) for CH_3. Significant crystal data are listed in Table 3. Graphics were obtained with ORTEP 3 for Windows [32–34]. Supramolecular interactions (π-contacts) were calculated with PLATON for Windows [35–37].

4. Conclusion

The effect of variation of the polymethylene spacer length in the pyridyl Schiff-base ligands L^1 (spacer

–$(CH_2)_3$–) and L^2 (spacer –$(CH_2)_2$–) was studied in the case of neutral hexacoordinated structures with the $Cd(NCS)_2$ fragment. The molecular structures of the resulting complexes strongly deviate from the classical octahedron, with $[Cd(L^1)(NCS)_2]$ showing a trigonal prismatic coordination polyhedron around cadmium. This and the structural differences between $[Cd(L^1)(NCS)_2]$ (**1**) and $[Cd(L^2)(NCS)_2]$ (**2**) can be traced to the length of the methylene spacers and the formation of a six- versus a five-membered metal-chelate ring together with the pyramidal $Cd(L^1)$ and planar $Cd(L^2)$ arrangement.

Abstract

Reaction of tridentate ONS donor ligands H_2L^1, H_2L^2 and H_2L^3 (H_2L^1 = 2-hydroxyacetophenone hexamethyleneimine-3-thiosemicarbazone; H_2L^2 = 2-hydroxyacetophenone morpholine-3-thiosemicarbazone; H_2L^3 = 2-hydroxyacetophenone *N*(4)-methyl, phenyl thiosemicarbazone) with $Mn(OAc)_2 \cdot 4H_2O$ afforded manganese(IV) complexes of the type $[MnL_2]$ in an ethanol–methanol mixture under air. The crystal structure of $Mn(L^2)_2 \cdot 0.25H_2O$ reveals an octahedral geometry with the ligand coordinated in a meridional fashion. The molecule is packed in the crystal lattice with extended hydrogen bonding networks. EPR spectra of the complexes in frozen solution at 77 K show a weak signal at $g \approx 4$ and a strong sextet at $g \approx 2$ consistent with manganese(IV) in an octahedral environment. Cyclic voltammetry in DMSO/ dichloromethane show quasi-reversible peaks corresponding to the Mn(IV)/ Mn(III) redox couple.

1. Introduction

The coordination chemistry of manganese has continued to attract attention in recent years due to its presence in several biological systems [1]. A mononuclear Mn(III) centre was found in the active site of some enzymes that display superoxide dismutase activity [2]. In addition, manganese plays an important role in the oxygen-evolving complex (OEC) of photosystem-II [3]. Detailed investigations indicate that the photosystem II (PS II) has an oxo-bridged tetramanganese cluster (Mn_4) as its key structural feature [4]. However the possibility of a mononuclear manganese(IV) center in the S_2 state of PS II cannot be ruled out [5]. Since the manganese is believed to be in its +2 to +4 oxidation state a number of different OEC model complexes were synthesized and their properties investigated [6]. Besides, the use of mononuclear manganese(IV) complexes in catalytic oxidation of organic compounds [7] makes the investigation of mononuclear manganese(IV) complexes more important. Synthetic monomanganese(IV) species in

doi:10.1016/j.poly.2005.01.004

biomimetic O, N coordination are also of vital importance in the above perspective. Over the past two decades quite a few manganese(IV) complexes have been isolated and characterised [8,9].

Manganese(IV) is considered as an enigmatic oxidation state; it is usually attained in oxidizing conditions or in the presence of strong bases, except in cases where the presence of phenolato or alcoholato groups in the ligands may bring about the oxidation of Mn(II) into the Mn(III) or even the Mn(IV) oxidation state in aerobic conditions [10]. However the reaction conditions, nature of the ligands or the ligand donor set that yield a stable manganese complex in its +2, +3 or +4 state are yet not clear [11,12]. While a monoprotic ligand with an NNS donor set is likely to give a manganese(II) complex [13], a diprotic ligand with an ONS donor set is most likely to give a manganese(III) or (IV) complex under aerobic condition. It has been reported previously that manganese(II) compounds react with primary hydroxamic acids in aerobic condition, producing Mn(IV) hydroximato complexes with a conjugated metal–ligand ring [14]. In contrast, secondary hydroxamic acids that cannot form conjugated ring systems yield only Mn(II) complexes, while bidentate thiohydroxamic acids yield Mn(IV) complexes from Mn(III) precursors in the presence of oxidizing species [15]. It has also been observed that diprotic ONS donor ligands derived from salicylaldehyde derivatives – (*o*-OH)$RC_6H_3CH{=}N{-}NHC(=S)$-R′ – that can form conjugated metal–ligand ring systems yield manganese(IV) complexes when R′ is NH_2 or NHPh [16]. As part of our efforts to optimise the factors that determine the spontaneous oxidation of manganese(II) to manganese(IV) in the presence of air, we prepared three manganese complexes of 2-hydroxyacetophenone *N*(4) disubstituted thiosemicarbazones (H_2L) (Fig. 1). While Mukhopadhyay et al. [12] have reported formation and characterization of manganese(IV) complexes of *N*(4)-monosubstituted salicylaldehyde thiosemicarbazones, it was not supported by X-ray crystal structure data. Very recently, an optically active manganese(IV) complex was reported whose structure was confirmed by X-ray crystallography [17]. Herein, we report the serendipitous formation of three Mn(IV) complexes of 2-hydroxyacetophenone *N*(4)-disubstituted thiosemicarbazones, discuss their spectral properties, redox behavior and the X-ray crystal structure of one of them (compound **2**).

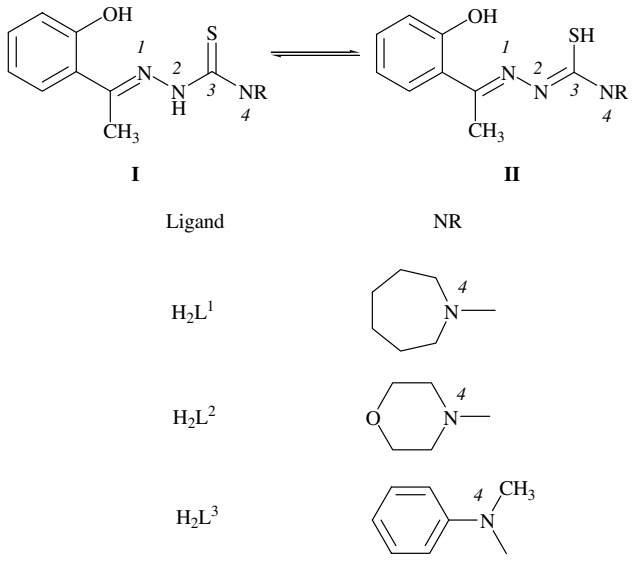

Fig. 1. Schematic diagram of the ligands used for preparation of the complexes.

2. Experimental

2.1. Materials and methods

The thiosemicarbazones H_2L^1, H_2L^2 and H_2L^3 were prepared as reported previously [18]. All the ligands were purified by recrystallisation, manganese(II) acetate tetrahydrate (Reagent grade, E. Merck) was purified by standard methods and solvents were purified by standard procedures before use.

2.2. Preparation of the complexes

2.2.1. $[Mn(L^1)_2]$ (**1**)

To a hot ethanol solution (25 mL) of the thiosemicarbazone, H_2L^1 (0.291 g, 1.0 mmol), was added 10 mL of a methanolic solution of manganese(II) acetate tetrahydrate (0.122 g, 0.5 mmol) with stirring. The yellow solution changed slowly into a coffee brown color on continued stirring. A deep brown residue appeared within 10 min. Stirring was continued for another 20 min. The deep brown precipitate was washed with ethanol followed by ether. It was then dried over P_4O_{10} in vacuo: Yield 0.21 g (67%). *Anal.* Calc. for $C_{30}H_{38}MnN_6O_2S_2$ (633.73): C, 56.77; H, 6.19; N, 13.24; Mn, 8.66. Found: C, 57.26; H, 6.09; N, 13.42; Mn, 8.82%.

2.2.2. $[Mn(L^2)_2]\cdot H_2O$ (**2**)

To a hot ethanol solution (20 mL) of the thiosemicarbazone, H_2L^2 (0.28 g, 1.0 mmol), was added 10 mL of a methanolic solution of manganese(II) acetate tetrahydrate (0.122 g, 0.5 mmol) with stirring. The yellow solution changed into a deep greenish black color in barely a minute. Black powdery material began to form within 3 min. Stirring was continued for an hour, the product formed was allowed to settle, it was filtered, washed with ethanol and ether in succession and then dried over

P_4O_{10} in vacuo. Yield 0.26 g (83%). MS (FAB): m/z = 627 $[Mn(L^2)_2 \cdot H_2O]^+$ (15), 609 $[Mn(L^2)_2]^+$ (100). *Anal*. Calc. for $C_{26}H_{30}MnN_6O_4S_2.H_2O$ (627.63): C, 49.76; H, 5.14; N, 13.39; Mn, 8.75. Found: C, 50.05; H, 5.22; N, 12.94; Mn, 8.83%. X-ray quality crystals were obtained over a period of 13 days by diffusion of ethanol into a dichloromethane solution.

2.2.3. $[Mn(L^3)_2]$ (**3**)

To a hot ethanol solution (20 mL) of the thiosemicarbazone, H_2L^3 (0.30 g, 1.0 mmol), was added 10 mL of methanolic solution of manganese(II) acetate tetrahydrate (0.122 g, 0.5 mmol) with stirring. The yellow solution changed into a deep brown color in a few minutes. Brownish black microcrystals settled within 5 min. The solution was set aside undisturbed for complete crystallization, which was then filtered after 2 h, the product was washed with ethanol and ether. It was then dried over P_4O_{10} in vacuo. Yield 0.25 g, (76%). *Anal*. Calc. for $C_{32}H_{30}MnN_6O_2S_2$ (649.69): C, 59.16; H, 4.65; N, 12.94; Mn, 8.46. Found: C, 59.32; H, 4.74; N, 13.05; Mn, 8.47%.

2.3. Physical measurements

Elemental analyses were performed on a Heraeus Elemental Analyzer at CDRI, Lucknow. The metal contents were determined in a Perkin–Elmer AAnalyst 700 Atomic Absorption Spectrometer, after decomposing the compounds by standard methods. Magnetic measurements were performed in the polycrystalline state on a Gouy magnetic balance using $Hg[Co(SCN)_4]$ as a calibrant. Diamagnetic corrections for various atoms and structural units were computed from Pascal's constants. The effective magnetic moments were calculated from the corrected molar susceptibilities of the complexes using Curie's relation. The FT-IR spectra were recorded on a Shimadzu DR 8001 series FTIR spectrometer as KBr pellets and the electronic spectra were recorded on a Shimadzu 160A UV–Vis spectrophotometer in dichloromethane solvent. Diffuse reflectance spectra were recorded on Ocean Optics, Inc. SD200 Fiber Optic Spectrometer in a magnesium oxide matrix. The EPR spectra were recorded on a Varian E-112 Spectrometer using TCNE as the standard marker, with 100 kHz modulation frequency and 0.2 mT modulation amplitude. The cyclic voltammetric measurements were performed on a BAS CW-50 electrochemical measurement unit. The cyclic voltammetric (CV) measurements were done after degassing (N_2 bubbling for 15 min.) dichloromethane (DCM)/dimethylsulfoxide (DMSO) solutions (10^{-3} M) containing 0.1 M tetrabutylammoniumperchlorate (TBAP) as the supporting electrolyte. The three-electrode system consisted of platinum foil (counter), glassy carbon (working) and silver–silver chloride (reference) electrodes.

2.4. X-ray crystallography

Data for complex **2** was collected at 213(2) K on a Siemens SMART PLATFORM diffractometer equipped with a CCD area detector and a graphite monochromator utilizing MoKα radiation (λ = 0.71073 Å). Data collection parameters are listed in Table 1. Cell refinement and data reduction for the compound were performed using the SAINT program [19]. A total of 16 741 reflections were collected resulting in 6818 unique reflections. The intensities were corrected for Lorentz and polarization effects. The structure was solved by a direct method procedure, as implemented in the SHELXTL program [20]. The positions of all the non-hydrogen atoms were included in the full-matrix least-squares refinement, using the SHELXTL program. The positions of all the H-atoms were geometrically fixed at calculated positions, and they were allowed to ride on the corresponding non-hydrogen atoms. The final R-factor converged to 0.054 (wR_2 = 0.1083); the maximum and minimum values of electron densities in the final electron density maps were 0.785 and −0.971 e Å^{-3}, respectively.

3. Results and discussion

3.1. Preparation of the compounds

The thiosemicarbazones act as dibasic tridentate ONS donor ligands and deep brown colored manganese complexes were formed from the reaction mixture. Elemental analysis and the FAB mass spectra of the prepared complexes indicated that the complexes have a stoichiometry $M^{IV}L_2$. The magnetic moment values of the compounds were in the range 3.9–4.1 BM, which indicate that the manganese could be in a d^3 high spin electronic configuration. While formation of Mn^{4+} complexes occur under oxidizing conditions [21], we were able to obtain manganese(IV) complexes in a simple and straightforward reaction using 2-hydroxyacetphenone *N*(4)-disubstituted thiosemicarbazone. Although we were not able to pursue the reaction kinetics leading to the formation of such a system, we could assign a notable difference in the behavior of different thiosemicarbazone ligands towards stabilizing the different oxidation states of manganese.

3.2. X-ray structural properties

An X-ray quality single crystal of compound **2** $[Mn(L^2)_2 \cdot 0.25H_2O]$ of $0.44 \times 0.26 \times 0.16$ mm dimension was grown by slow diffusion of ethanol into a dichloromethane solution of the compound over period of 13 days. The ORTEP diagram of compound **2** is shown in Fig. 2. Each thiosemicarbazone acts as a dibasic tridentate chelating agent. Bond lengths and bond angles are presented in Table 2. The ligands with their donor atoms are arranged around the manganese ion in a meridional fashion. However unlike in many other complexes where the thiosemicarbazone moiety is planar

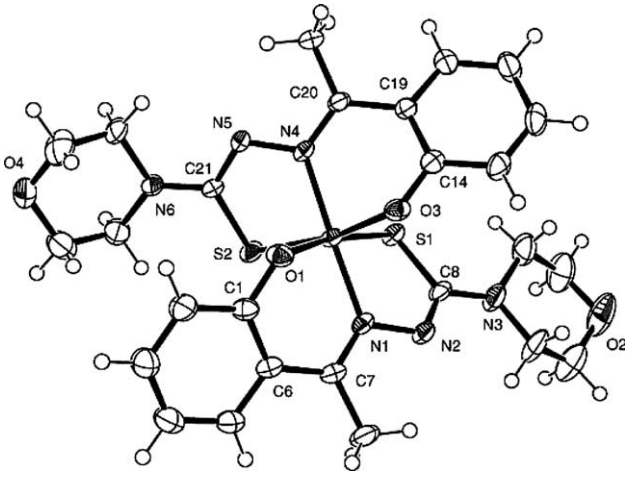

Fig. 2. ORTEP diagram of compound **2** showing 50% probability ellipsoids. Hydrogen atoms are shown as small spheres of arbitrary radii. The water molecule is omitted for clarity.

[17,22], in compound **2** it has undergone considerable distortion from planarity. The distortion of the thiosemicarbazone moiety deprives itself of the electron delocalization possible in its conjugated backbone. While O1, O3, S1 and S2 lie in the equatorial plane, N1 and N4 occupy the axial positions of the distorted octahedron. The length of Mn–N and Mn–O bonds are in good agreement with the corresponding bonds in the complex bis(salicylato)(bipyridine) manganese(IV) [23]. There is a marked decrease in metal ligand bond lengths when Mn(II) complexes of Schiff bases are compared to those of Mn(IV): {Mn(IV)–O(phenolate) = 1.906 Mn(II)–O(phenolate) = 2.054 Mn(IV)–N(imine) 2.005 Mn(II)–N(imine) 2.258 [21]. Manganese(II) and manganese(IV) complexes (high spin d^5 and d^3, respectively) adopt octahedral coordination geometries [24] compared to manganese(III) complexes (high spin d^4) that undergo Jahn–Teller distortion. The coordination geometry around manganese resembles that of an $Mn^{IV}N_4O_2$ manganese(IV) amide species [9c] having an acyclic amine function. The *cis* and *trans* angles are in the ranges 81°.48–99.16° and 169°.43–177.54°. The MnO_2S_2 fragment is distorted from the mean plane by 0.18 Å. Each thiosemicarbazone fragment is subtending an angle of 170.18° and 169.43° at the Mn center, which is smaller than 180° that is expected for an ideal octahedron. The planes containing Mn, O1, N1, S1, N4 and Mn, O3, N1, S2, N4 are deviated from the mean plane by 0.02 Å and 0.01 Å (Mn), respectively. The inter-planar angles lie in the interval of 85–89°. The Mn–N distance is longer than the average Mn–O distance by more than 0.1 Å and is longer than other $Mn–N_{(azomethine)}$ bond lengths reported previously, which indicate a marginal axial distortion along the N–Mn–N axis. A similar

structure is suggested for the other complexes, **1** and **3**, based on other spectral measurements.

The Mn ion is displaced from the plane of the hydroxyacetophenone-imine fragment O1, C1, C6, C7, N1 by 0.73 Å. Therefore, the phenol-imine chelate ring can be considered as folded along the O1, N1 line, which is referred to as a ''step-forming distortion'' observed in chelates of salicylaldehydes [25]. The manganese ion is displaced by 0.88 Å from the plane formed by N1, N2, C8 and S1. This leads to an envelop like conformation for the chelate ring consisting of Mn, N1, N2, C8 and S1, whose folding occurs along the N1, S1 line. This distortion causes a skewed arrangement of the ligand moiety around the metal, leading to a ''butterfly'' type structure for the molecule about the metal centre. Compound **2** is associated with a molecule of water with partial occupancy in its crystal lattice. There is extensive hydrogen bonding and C–H...π interactions in the crystal lattice as a consequence of packing. The C–H...π and classical and non-classical hydrogen bonding interactions are listed in Table 3.

3.3. IR and electronic properties

The infrared spectral data are given in Table 4. A new band at ca. 1591 cm^{-1} is due to the newly formed C=N bond as a result of the enolisation. It is further supported by the absence of a band due to the NH group in the 3100–3300 cm^{-1} region in all the complexes that was present in the thiosemicarbazone ligands. Coordination of the azomethine nitrogen with manganese is evidenced by a shift of the band at ca. 1600 to ca. 1560 cm^{-1}. The details of the electronic spectra recorded in dichloromethane solution are given in Table 5. All the compounds are found to be stable in dichloromethane and chloroform. The spectra in the visible region is typical of $Mn^{IV}O_2N_2S_2$ complexes reported previously [11,12]. While bands at ca. 450 and 620 nm are broad and intense as CT bands, others are shoulders or buried under these high intensity bands. The unusually intense peaks in the visible region ($\log\varepsilon \approx 3$) are attributed to the ''intensity stealing'' influence of the sulfur/oxygen containing ligands, whereby the intensity of the bands in the visible region are enhanced. The bands at ca. 720, 620 and 510 nm (Table 5) of compounds **1**–**3** can be attributed to $^4A_{2g} \rightarrow {}^4T_{2g}$, $^4A_{2g} \rightarrow {}^4T_{1g}$, $^4A_{2g} \rightarrow {}^4T_{1g}$ (P) transitions [9b,21,26] and the intense band at ca. 450 nm to the $S(p_\pi) \rightarrow Mn(d_\pi)$ LMCT transition, [12,15] while the broad high intensity peak at ca. 360 nm can be assigned to the phenolate → Mn charge transfer band which is identical to octahedral Mn^{4+} complexes of Schiff base ligands containing phenolate/hydroxylate donor groups [9a,27]. The solution in DMF also gives a similar spectrum. However, bands in the visible region appear at lower wavelength with lower intensity when a solution in DMF is allowed to

stand for a day. This could be due to the coordination of DMF with the manganese metal center and a probable change in oxidation state. The solid-state diffuse reflectance spectra of the complexes show a broad band extending from 480 to 800 nm with peak ca. 550 nm corresponding to octahedral manganese d^3 systems.

3.4. EPR spectra

The EPR spectra of compounds **1**–**3** in the polycrystalline state at 298 K and in DMF solution at 77 K (Fig. 3) are comparable to the spectral features of previously reported Mn(IV) complexes. The EPR spectral parameters are presented in Table 5. The Mn(IV) ion is a d^3 system and hence can be treated theoretically similar to Cr(III) compounds. In a crystal field of strict octahedral symmetry a d^3 ion has a $^4A_{2g}$ ground state leading to an isotropic $g \approx 2$ resonance [28]. Distortion and spin orbit coupling split the quartet ground state into two Kramer's doublets separated by $2(D^2 + 3E^2)^{1/2}$, where D and E are, respectively, axial and rhombic zero-field-splitting parameters. The nature of the polycrystalline or glassy state EPR spectra varies widely depending on values of D, E and microwave quantum value hv [29]. The spectrum becomes simple under limiting conditions. The two limiting cases are when the zero-field splitting parameter $2D$, is either much larger or much smaller than hv. In the first case the feature at low field ($g \approx 4$) is predicted to be strong while the $g \approx 2$ component is weak as reported previously [11,30]. When D is small the $g \approx 2$ signal should dominate with a weaker signal in the low-field region as observed for tris(thiohydroxamato) manganese(IV) [15], tris(dithiocarbamato) manganese(IV) [31], manganese(IV) amide [9c] and salicylaldehyde thiosemicarbazone and dithiocarbazate manganese(IV) complexes [12,14]. In the case of the present complexes $g_{eff} \approx 4$ varies between 4.5 and 3.4 in the solid state at 298 K and between 4.1 and 3.8 in DMF at 77 K. This might be due to marginal changes in the geometry of the molecule upon dissolution. In compounds **1** and **3** the $g \approx 4$ signal is asymmetric, broad and weak without any resolved ^{55}Mn hyperfine splitting, while the $g \approx 2$ signal is moderately strong with well-resolved ^{55}Mn hyperfine splitting ($I = 5/2$). All the three compounds have an A value ranging from 250 to 270 MHz (91–97 G), this is comparable with values reported for $Mn^{IV}O_3S_3$ ($A \approx 100$ G) [15] and $Mn^{IV}S_6$ ($A \approx 95$ G) [32] systems having $2D \ll hv$. In all the three cases, weak signals corresponding to forbidden transitions ($\Delta M_S = \pm 1$, $\Delta M_I = \pm 1$) were observed between the hyperfine sextet lines in the $g \approx 2$ signal. The spectrum in DMF at 77 K is devoid of any significant feature at $g \approx 4$. This is an extreme case when the value of D is negligible compared to hv, i.e., the complex is nearly an ideal octahedron. However, none of the manganese complexes in DMF solution at room temperature give any spectra. In distorted manganese(IV) complexes, i.e., one lacking cubic symmetry, the zero-field splitting may be quite significant. Its magnitude depends on the relative orientation of the molecular axis and the magnetic field direction, molecular tumbling will modulate this interaction and the line broadening will be so large as to cause the EPR signal often to go undetected [32].

3.5. Cyclic voltammetry

The redox properties of the complexes were investigated by cyclic voltammetry at a glassy carbon working electrode in DMSO and dichloromethane solvents using a silver–silver chloride reference electrode. The cyclic voltammograms are shown in Fig. 4 and redox potentials are listed in Table 6. Both the cyclic responses are single electron redox processes. The response at more positive potential can be due to the $Mn^{IV}L_2$–$Mn^{III}L_2^-$ redox couple, while the one at more negative potential can be assigned to the $Mn^{III}L_2^-$–$Mn^{II}L_2^{2-}$ couple [33]. The $Mn^{IV}L_2$–$Mn^{III}L_2^-$ redox couple of compound **2** is observed at ~0.1 V more positive a value than those of the other two.

The electrode reactions occur at different potentials in DMSO and dichloromethane solvents. Both Mn^{IV}/Mn^{III} and Mn^{III}/Mn^{II} potentials lie at more positive values (~0.2 V) in DMSO compared to those in dichloromethane, indicating that the Mn(IV) compounds are

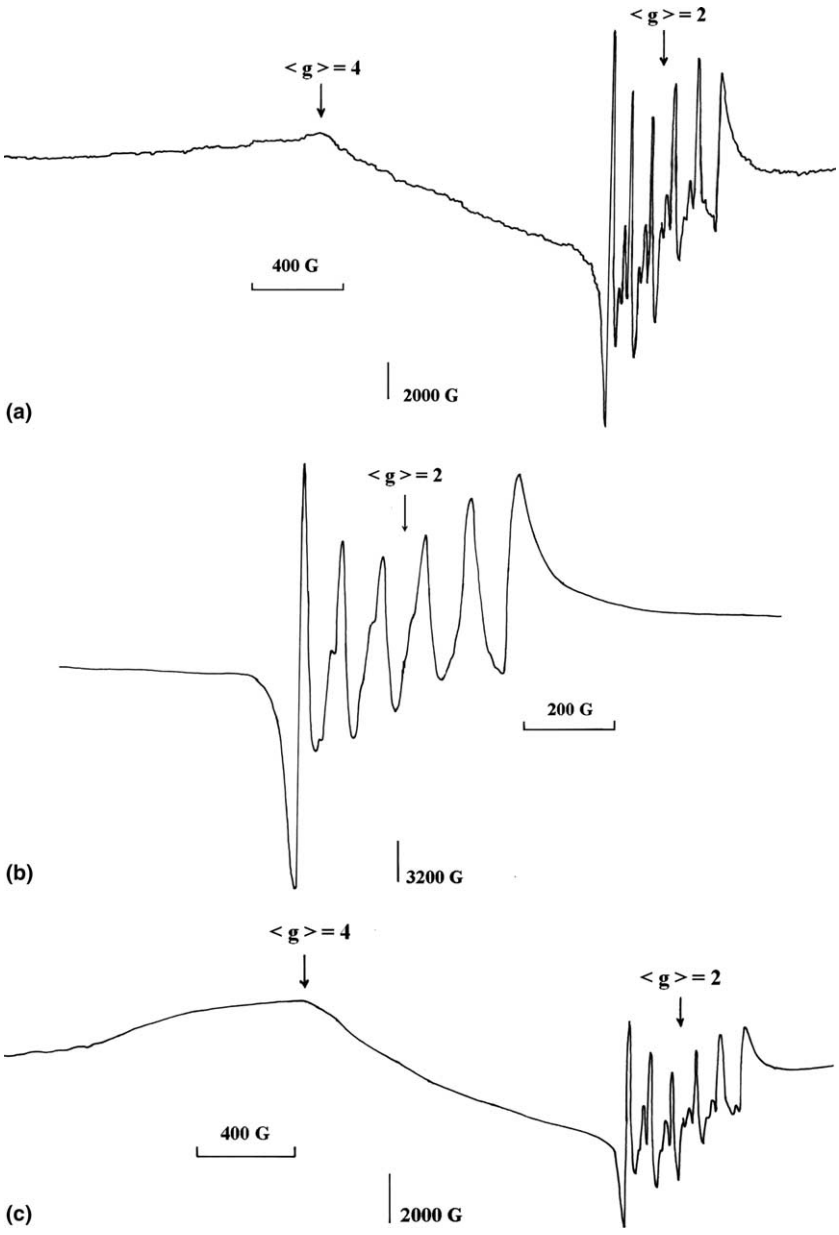

Fig. 3. EPR spectra of (a) $Mn(L^1)_2$ (**1**), (b) $Mn(L^2)_2 \cdot H_2O$ (**2**) and (c) $Mn(L^3)_2$ (**3**) at 77 K in DMF.

relatively stable in the latter solvent. The lower reduction potential (∼−0.1 V) may be the reason why complexes tend to fade color on standing in DMSO. The ligands in complexes **1**–**3** differ only in the nature of *N*(4) substituents. In complex **1** the *N*(4) substituent can be considered as an aliphatic group, in compound **2** the oxygen containing six membered ring is more electron withdrawing, while in compound **3** the presence of a electron releasing methyl group and electron withdrawing phenyl group compensate for each other and overall have an effect similar to that of the hexamethylene imine group in complex **1**. As a consequence the potentials of complexes **1** and **3** are very close in either solvent while that of complex **2** is more positive. This indicates that the ease of formation of the Mn(IV) complex is less spontaneous for compound **2** than for compounds **1** and **3**.

The Mn^{IV}/Mn^{III} redox couple is quasi-reversible (ΔE_p = 90–190 mV) in both DMSO and dichloromethane, while Mn^{III}/Mn^{II} is irreversible in all cases except for compound **2** in dichloromethane where the couple shows quasi-reversible nature. Absence of an anodic peak in both solvents (irreversible) corresponding to a Mn^{III}/Mn^{II} couple suggests MnL_2^{2-} is unstable in either solvent. A comparison of Mn^{IV}/Mn^{III} reduction potentials reported previously versus SCE, for a salicylate-pyridine complex lie well on the positive side (+0.44 V versus SCE) [23] while the trend is similar for MnO_4N_2

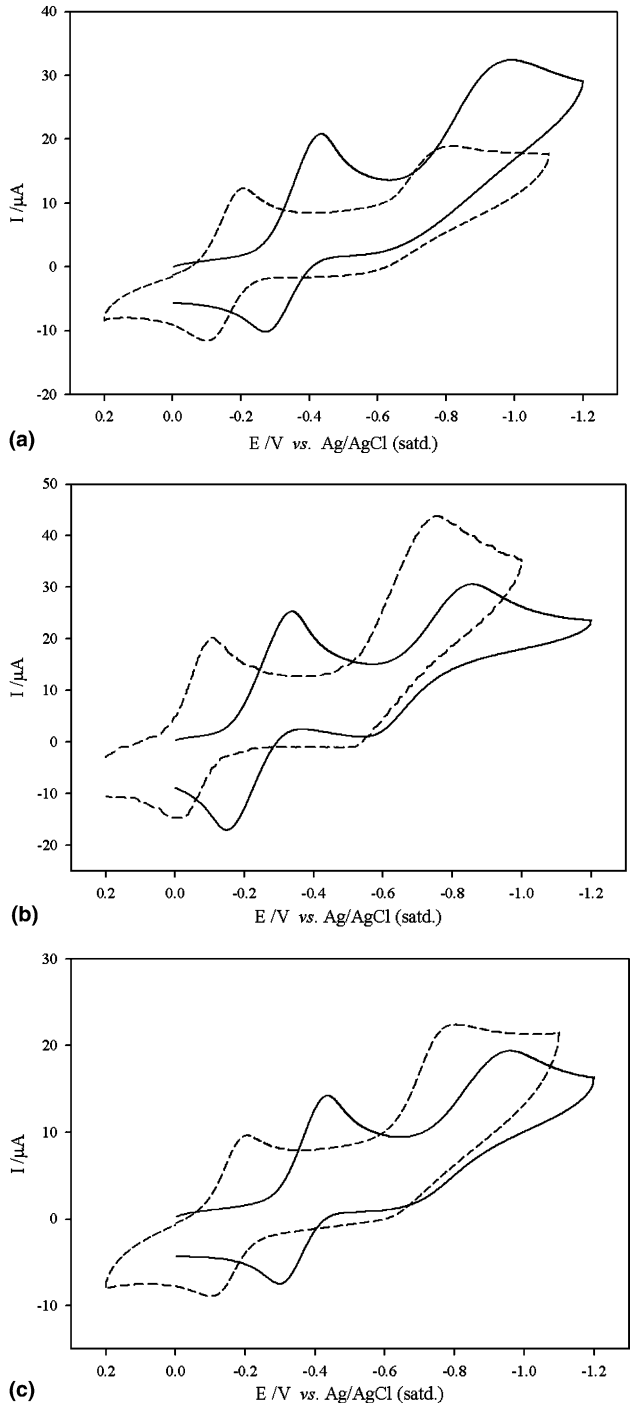

Fig. 4. Cyclic voltammogram of (a) $Mn(L^1)_2$ (**1**), (b) $Mn(L^2)_2 \cdot H_2O$ (**2**), (c) $Mn(L^3)_2$ (**3**) at a scan rate of 100 mV/s in dichloromethane (solid line) and DMSO (dashed line) solvents.

complexes for carboxylato coordinated MnL_2 than those in salicylaldimine complexes involving alkoxide coordination [21]. In the case of 2-hydroxy-2′-carboxy-5-methylazobenzene manganese complex, $Mn(azc)_2$, the Mn^{IV}/Mn^{III} couple lies more positive than the corresponding phenolate derivative – 2,2′-dihydroxyazobenzene manganese complex – $Mn(azp)_2$ [10]. The more positive Mn^{IV}/Mn^{III} cathodic reduction potential is due to the lower pK value of the carboxylic donor atoms compared to phenolate donor atoms [10,11,21]. Compounds **1**–**3** in this work show comparatively lower potentials in either solvent than the corresponding phenolate donor set ligands. The borderline nature of the thiolate group of the thiosemicarbazone could explain the spontaneous formation from the Mn(II) precursor and stabilization of the manganese(IV) complexes in the present case.

Table 6
Electrochemical data[a] of compounds **1**–**3**

[a] Supporting electrolyte is TBAP (0.1 M); working electrode glassy carbon; reference electrode is Ag/AgCl (satd.).
[b] E^0_{298} is calculated as the average of anodic (E_{pa}) and cathodic (E_{pc}) peak potentials; $\Delta E_p = E_{pa} - E_{pc}$.
[c] Cathodic peak potential.

4. Conclusion

Based on our observation in this study, we contradict the suggestion that electron delocalisation along the ligand moiety can be one factor that may promote ambient oxidation of manganese(II) to manganese(IV). However it may be true that electron releasing groups in the ligand moiety or in the ring structure can facilitate the formation of manganese(IV) complexes. In a previous report salicylaldehyde thiosemicarbazone having methyl or Br substituents on the aromatic ring system has yielded Mn(IV) complexes [12], while the presence of a methyl group on the thiosemicarbazone moiety, as observed in our case, has facilitated its formation rather easily. Besides, substitution at the N(4) position can be said to have negligible influence on Mn(II)–Mn(IV) oxidation as thiosemicarbazones that have mono, di or no substituent(s) were found to give manganese(IV) complexes. Semicarbazones of hydroxyaldehydes/ketones were found to give only Mn(II) complexes despite the fact that they differ in having an oxygen donor atom instead of sulfur [34]. This indicates that a soft donor atom, such as sulfur, plays an important role in accomplishing the Mn(II) to Mn(IV) conversion and stabilizing the later. However further efforts are needed to optimise the factors that determine the facile conversion of Mn(II) to Mn(IV) by proper variation of the substituents on the thiosemi-

carbazone moiety to control the electronic factors. In short, we have accomplished the facile synthesis of three manganese(IV) complexes of *N*(4)-disubstituted thiosemicarbazones of 2-hydroxyacetophenone and characterized them by IR, UV–Vis and EPR spectroscopic methods. The structure of one of them, compound **2**, was established by X-ray crystallography and was found to have an octahedral geometry with the ligands coordinated in a meridional fashion. The reduction potential of the manganese(IV)–manganese(III) couple was found to be low and is predicted to be due to a higher p*K* value of the donor atoms.

5. Supplementary information

Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic Data center, CCDC 229814 for compound $Mn(L^2)_2 \cdot H_2O$ reported in this paper. Copies of this information may be obtained free of charge from the Director, The Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk/data_request/cif).

Abstract

The interaction between silver(I) ions with 3,5-di(*tert*-butyl)-1,2-benzenediol (**I**) and sulfur-containing derivatives of sterically hindered diphenols: 4,6-di(*tert*-butyl)-3-(2-hydroxyethylsulfanyl)-1,2-benzenediol (**II**), 2-(2,5-dihydroxyphenylsulfanyl)acetic acid (**III**), 2-(2,5-dihydroxy-3,4,6-trimethylphenylsulfanyl)acetic acid (**IV**), 2-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]acetic acid (**V**), 5,7-di(*tert*-butyl)-8-hydroxy-2,3-dihydro-1,4-benzoxathiin-2-one (**VI**), 3-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]-2-methyl-carboxyamidopropanoic acid (**VII**) was studied. A competition of redox process and complexation is possible when these organic compounds interact with silver(I) ions. **I**–**IV**, **VI** and **VII** were found to reduce Ag(I) to Ag(0), silver sol formation being possible under certain conditions. The sols were examined by TEM and optical spectroscopy methods. The interaction of **V** with silver(I) ions is not accompanied by a redox reaction, the latter being hindered by complexation. The complexation was studied by potentiometric titration, and the complex of **V** with Ag(I) was characterized by the means of X-ray powder diffraction, elemental analysis, TG/DTA and IR spectroscopy. The antimicrobial activities of **V** and its Ag(I) complex, evaluated by minimum inhibitory concentration (MIC), were also tested.

Keywords: Silver(I) complex; Sterically hindered diphenols; Silver sol; Antimicrobial activities; Electronic spectra

1. Introduction

Silver and its compounds are widely known as effective catalysts, elements of optical and electronic devices, pharmaceuticals and medical materials [1–8]. Ag(I) complexes have shown a variety of noteworthy antimicrobial activities, although the mechanisms of action are not yet entirely clarified. Of particular note is the fact that essentially all types of Ag(I) pharmaceuticals do not give rise to microorganisms' resistance, in contrast to many antibiotics. Other biological effects have also been observed, such as antifungal and antitubercular activities [9]. At the same time a few Ag(I) complexes have been investigated in this connection. The main aims of that research were the synthesis of pharmacologically active Ag(I) complexes with Ag(I)–O, Ag(I)–N, Ag(I)–S and Ag(I)–P bond, and the establishment of structural relationships of such complexes with bioactivities [10–26]. However, in some cases the elucidation of this problem is complicated by the fact that many Ag(I) complexes are hard to crystallize

doi:10.1016/j.poly.2005.01.007

and some are believed to be polymeric [10–12,27,28]. One of the key factors determining the antimicrobial effects of Ag(I) complexes is reported to be the nature of the atom coordinated to Ag(I) and its bonding properties, rather than the solubility, charge, chirality or degree of polymerization of the complexes [12,15,17–19,21,22,24]. Moreover, it has been found that most Ag(I) complexes with the same or similar core structures consisting of the same coordinating donor atoms have shown very similar spectra of the antimicrobial activities, in particular Ag(I) complexes with the dimeric Ag_2O_4-core molecular structure [14,16,18,19,21]. The broader spectrum of the antimicrobial activities exhibited by these Ag(I)–oxygen bonding complexes is attributed to a direct interaction or complexation of the silver(I) ion with biological ligands [24]. These ligands contain the potential target sites for the inhibition of bacterial and yeast growth by these Ag(I) complexes that reportedly might be the sulfur-containing residues of proteins. It has been presumed that one of the key factors leading to a broad spectrum of antimicrobial activities is the ease of ligand-exchange between Ag–O cores and Ag–S (biological ligand) bonds, caused by the weak Ag(I)–O bond strengths [24,29].

In this connection it is of interest to study various aspects of silver chemistry, specifically the peculiarities of silver(I) ion interactions with organic compounds incorporating the O-donor atoms coordinated to the Ag(I) center. The structure–activity correlation in the antimicrobial and antifungal activities by Ag(I)–oxygen bonded complexes with organic ligands of that kind is also of interest. It should be noted that many of these organic compounds are biologically active themselves. Studying the interaction and complexation of bioactive organic ligands with metal ions is a topical line of investigation on the chemistry of complexes, because metal ions can change the magnitude and directionality of the pharmacological effects of organic ligands as pharmaceuticals [9], while coordinated metals are often more active and less toxic as opposed to the respective metal ions [30,31]. In addition, the coordinated ligands are supposed to play the role of a carrier of the metal ions to the biological systems.

In the present work we have studied the interactions of silver(I) ions with 3,5-di(*tert*-butyl)-1,2-benzenediol (**I**) and sulfur-containing derivatives of sterically hindered diphenols (SHD): 4,6-di(*tert*-butyl)-3-(2-hydroxyethylsulfanyl)-1,2-benzenediol (**II**), 2-(2,5-dihydroxy- phenylsulfanyl)acetic acid (**III**), 2-(2,5-dihydroxy-3,4,6-trimethylphenyl-sulfanyl)acetic acid (**IV**), 2-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]acetic acid (**V**), 5,7-di(*tert*-butyl)-8-hydroxy-2,3-dihydro-1,4-benzoxathiin-2-one (**VI**), 3-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenyl-sulfanyl]-2-methyl-carboxyamidopropanoic acid (**VII**).

IV –R= CH_3

Many of the derivatives of SHD were found to be universal inhibitors of free-radical processes, effectively retarding both oxidation processes and free-radical reactions of fragmentation of biomolecules (lipids, peptides, carbohydrates, vitamins, etc.) [32,33]. Activation of that sort of processes may cause a wide variety of diseases in man, including cardiovascular, neurodegenerative, oncological, hemorragic and other diseases [34]. Studying bioactivities of synthesized multipurpose inhibitors of free-radical reactions in experiments with animals and with model systems lends support to their use in medicine being promising. Thus, an effective bioantioxidant has been found among them, which is distinguished by pronounced antihypoxic and anti-inflammatory properties [35]. A sulfur-containing derivative thereof exhibits high antiviral, neurotropic and nootropic activity, and is superior to piracetam [36–38].

Derivatives of SDH can participate in complexation as ligands due to electron-donor atoms of their functional groups and to peculiarities of their structure, but some of them are known to be active as reductants (especially in alkali medium) [39]. That is why both their complexation with Ag(I) ions and redox interaction were studied here.

Among the derivatives of SHD investigated in our work it was only 2-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]acetic acid that did not reduce Ag(I) ions in solution, but formed a complex therewith. The complexation in solution was studied by potentiometric titration. The solid complex that we have first obtained was tolerant of heat and light, and it was characterized by means of elemental analysis, thermogravimetric and differential thermal analysis (TG/DTA), FT-IR and X-ray diffraction. However, a full structural analysis could not be performed because no crystals suitable for single-crystal X-ray analysis were obtained. A special investigation showed that most of the metal complexes formed with the SHD derivatives containing one or two *tert*-butyl groups were hard to crystallize. A similarly hindered crystallization was found also for many metal complexes with hinokitiol ligand that is the 4-isopropyl-substituted compound of tropolone [24]. Their structure can be revealed by Rietveld analysis using X-ray powder diffraction data. Unfortunately, X-ray diffraction analysis of

the Ag(I) complex powder sample we had synthesized showed that it had decomposed while the X-ray diffraction pattern was registered, and that lack of tolerance to X-rays became the "fatal" circumstance which prevented us from using the above mentioned method to elucidate the structure of the complex either with a powder or with a monocrystalline sample. Therefore our notion of the coordination core of the Ag(I) complex was formed on the basis of findings provided by other physico-chemical methods and reported here.

We also estimated the antimicrobial and antifungal activities of the Ag(I) complex as compared with those of the free ligand.

If the interaction of SHD derivatives with silver(I) ions resulted in the latter being reduced, those systems were used to produce stable silver sols without any special stabilizers added. The sols were examined by transmission electron microscopy (TEM) and UV spectroscopy methods.

2. Experimental

2.1. Materials and methods

Chemicals were purchased from commercial sources and were used without further purification. The SHD derivatives were prepared according to [36,40,41]. The purity of these compounds was checked by thin-layer chromatography, and their structures were characterized by ^{1}H and ^{13}C NMR measurements and IR spectra. The preparation of the Ag(I) complex is described later.

Potentiometric titration was carried out in water–ethanol (1/1, v/v) solution as the SHD derivatives are generally hardly soluble in water. These solutions were prepared with twice-distilled water before every experiment and used immediately. A digital pH/mV-meter I-130 was used to monitor the e.m.f. variations of electrochemical cells opposing a silver-wire electrode to a silver chloride reference electrode. The silver chloride electrode was connected to the solution to be titrated by a salt bridge filled with KNO_3 solution (0.1 mol dm^{-3}). All measurements were carried out at 25 ± 0.1 °C and at a constant ionic strength of 0.1 mol dm^{-3} KNO_3. The titrations were carried out with continuous magnetic stirring by adding portions of $AgNO_3$ solution to that of the ligand. Argon was bubbled through the solutions during the titrations to ensure the absence of oxygen. To determine the composition and stability constants of the Ag(I) complexes formed on Ag(I) interaction with **V**, $AgNO_3$ solutions (2×10^{-5} and 4×10^{-5} mol dm^{-3}) were titrated with 10^{-2} mol dm^{-3} ligand solution. The set of ln β_n values were obtained by mathematical analysis of the ln ($[Ag(I)]_{total}/[Ag(I)]_{free}$) versus [L] relationships [42]. To determine the conditions of Ag(I) interaction with the ligand **V**, which favor the production of only one complex with Ag(I):ligand = 1:2, ligand solutions (2×10^{-3} and 4×10^{-3} mol dm^{-3}) were titrated with 0.1 mol dm^{-3} $AgNO_3$ solution.

Infrared spectra of the solids (the ligand **V** and the synthesized Ag(I) complex) were recorded by a Spectrum 1000 spectrophotometer in the wavelength range 4000–400 cm^{-1} at room temperature, using nujol mulls of the ligand and its complex and polyethylene windows.

Thermogravimetric (TG) and differential thermal analyses (DTA) were performed with an OD103 instrument. TG/DTA measurements were run under air between 20 and 900 °C (10 °C min^{-1}).

CHN elemental analyses were carried out according to the standard methods by the Microanalytical Laboratory, Bioorganic Chemistry Institute, National Academy of Sciences, Belarus. Silver and sulfur determinations were carried out using an atomic emission spectrometer with an inductively coupled plasma excitation source (Spectroflame Modula). A sample of the Ag(I) complex was decomposed under treatment with $HNO_3 + H_2O_2$ using a Milestone mls 1200 mega microwave digestion system. After the complex had been decomposed, the contents of silver and sulfur in the resulting solution was determined.

X-ray powder diffraction patterns of the free ligand **V** and its Ag(I) complex sample were measured at room temperature with an X-ray diffractometer DRON–3.0 (Co Kα radiation, MnO_2-filter, 1°/min, in the range of 2θ from 5° to 70°). As the complex tended to decompose while the X-ray diffraction pattern was registered, for each successive angle range of 10° a new portion of the sample was used.

Optical absorbance spectra of sols were registered in the wavelength range from 300 to 700 nm using the two-beam spectrophotometer "SPECORD M40 UV-VIS". The spectra were interpreted with regard to the spectral characteristics of the water–ethanol solutions of the SHD derivatives at pH 6 or 9. To determine the size and shape of the particles by TEM method, an EM-125 K instrument was used.

2.2. Synthesis of the Ag(I) complex with 2-[4,6-di-(tert-butyl)-2,3-dihydroxyphenylsulfanyl]acetic acid (V)

1.6 ml of $AgNO_3$ solution in water (0.1 mol dm^{-3}) was added dropwise to a clear solution of 0.32 mmol of ligand **V** in water–ethanol (1/1, v/v) mixture, the reaction vessel being shielded from light. A white precipitate formed instantaneously. After 1 h stirring, it was collected on a membrane filter (JG 0.2 μm), washed with ethanol (100 ml) and water (100 ml), and dried in vacuo (yield >98%). The relatively photostable compound was soluble in dimethylformamide (DMF), dimethylsulfoxide (DMSO), acetonitrile, sparingly soluble in ethanol, *i*-propanol, *n*-butanol, but insoluble in water, diethyl

ether and chloroform. When the complex was dissolved in the media with high donor numbers, it decomposed with time to yield silver particles [43]. *Anal*. Calc. for $C_{32}H_{47}O_8S_2Ag$: C, 52.53; H, 6.43; O, 17.51; S, 8.76; Ag, 14.77. Found: C, 52.37; H, 6.40; O, 17.90; S, 8.67; Ag, 14.63%.

2.3. Synthesis of the silver sols

Silver sols were produced by slowly (drop by drop) adding a solution of the organic reductant (compounds **I**–**VII**) to a water–ethanol $AgNO_3$ solution under permanent stirring, at pH 6 or 9. Silver(I) stock solutions were standardized by means of potentiometric titrations. Sodium tetraborate buffer was used to provide the basic medium. The silver concentration in the sols was 1×10^{-4} mol dm^{-3}. The sols were stored in closed, light-tight vessels.

2.4. Antimicrobial activities

Antimicrobial activities of free ligand **V** and its silver(I) complex were estimated by a minimum inhibitory concentration (MIC, μg/ml) as usual. The evaluation of their inhibitory effect on the bacterial and fungal growth was carried out by the twofold serial dilution method [44]. The following test microorganisms were used: *Escherichia coli* (ATCC 25922), *Pseudomonas aeruginosa* (ATCC 9027), *Candida albicans* (ATCC 855-653), *Bacillus subtilis* (ATCC 6633), *Staphylococcus aureus* (209–P), *Proteus vulgaris* (collection of Medical Postgraduate Education Academy of Belarus). The compounds were dissolved in DMSO and tested at concentrations ranging from 62.5 to 10^3 μg ml^{-1} (for the ligand) and from 31.2 to 500 μg ml^{-1} (for the complex). Test inoculum of 25×10^4 bacteria ml^{-1} and 25×10^4 yeasts ml^{-1} were applied. The absence of microbial growth after an incubation period of 24 h at 37 °C for bacteria or of 48 h at 30 °C for fungi was taken to be a criterion of effectiveness. In every case MIC was determined as the lowest concentration of the compound under study, which inhibits the bacterial and fungal growth, compared with the control system in which the bacteria and fungi were grown in the absence of any test compound. The amount of DMSO in the medium was 1% and did not affect the growth of the tested microorganisms. There were three replicates for each dilution. Results were always verified in three separate experiments.

3. Results and discussion

It has been found that silver(I) ions are reduced to give the metal when they interact with compounds **I**–**VII** at pH 6 or 9, except for compound **V** which does not reduce silver(I) ions at pH 6.

When **I** was used to produce Ag sols at different pH, the absorbance maxima characteristic of colloidal silver appeared in the UV–Visible spectra of the sols: at 412 nm (pH 9) and at 405 nm (pH 6) (Fig. 1(a), 1).

No sol was produced when $AgNO_3$ reacted with **II**, but a silver mirror was formed on the bottom and walls of the reaction vessel at pH 6 and 9, suggesting the autocatalytic nature of the reaction [45]. No absorbance maxima of colloidal silver were observed in the UV–Visible spectra in that case.

The sol produced by Ag(I) reduction with **III** at pH 9 was orange–brown, with a maximum at 410 nm present in its absorbance spectrum (Fig. 1(a), 2). A yellow–orange sol was formed at pH 6, which became light-green upon aging. The absorbance spectrum is characterized by a maximum at 309 nm, which, according to [46], can be evidence for large aggregates of silver particles present in the sol, which is shown to be the case by TEM (Fig. 2).

A pink sol was formed when Ag(I) was reduced with **IV** in alkali medium. The as-prepared sol had an absorbance maximum at 430 nm (Fig. 1(a), 3). The sol produced at pH 6 was yellow, with an absorbance maximum at 420 nm.

No colloidal silver was formed by reacting Ag(I) with **V** at pH 6, as evidenced by the characteristic absorbance maximum being absent in that case. Yet **V** does reduce Ag(I) in alkali medium. An absorbance maximum is observed at 360 nm, which, according to [47], may be assigned to subcolloidal silver (Fig. 1(b), 1). The system is unstable: a grey coarse-dispersion precipitate of metallic silver is formed overnight.

An absorbance maximum at 420 nm characteristic of Ag colloids over 2 nm in size was observed in the as-prepared sol when Ag(I) was reduced with **VI** at pH 9 (Fig. 1(b), 2). The reduction of Ag(I) at pH 6 yields a brown–grey sol, with a rather broad absorbance maximum about 512 nm, characteristic of silver colloids 25–60 nm in size (the aforesaid refers to the as-prepared sol).

The absorbance spectrum for the system produced by Ag(I) interacting with **VII** demonstrates a strong narrow maximum at 430 nm (Fig. 1(b), 3). According to [48], it is evidence of silver colloids 5–10 nm in size. A pale-pink sol was produced at pH 6, which demonstrated a very broad (from 404 to 700 nm) maximum in the absorbance spectrum, with a small shoulder at 309 nm, disappearing on aging.

Thus, according to the spectral data, silver sols are formed most effectively when silver(I) ions are reduced with the compound **III**, its structure lacking *tert*-butyl substituents in the benzene ring. The methyl substituents appearing in the structure of **IV** markedly decrease the capacity of this compound for reduction of silver(I) ions, esulting in the sol production. The diphenol with just *tert*-butyl substitutors in the benzene ring (**I**) proved

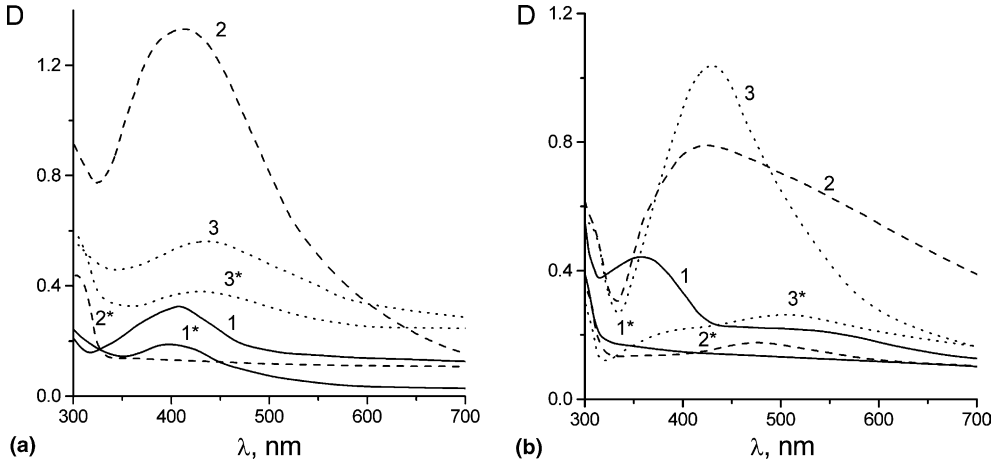

Fig. 1. Absorbance spectra of as-prepared silver sols produced using the compounds: (a) 1 – **I**, 2 – **III**, 3 – **IV**; (b) 1 – **V**, 2 – **VI**, 3 – **VII** (* is for the spectra of the silver sols produced at pH 6).

to be even less efficient at producing the silver sol. But the introduction of sulfur-containing substituents, as in the structures of **II**, **VI**, **VII**, results in the sol forming somewhat more actively.

TEM investigation showed that silver colloids and their aggregates in the sols are surrounded by a layer presumably formed by organic reductant compounds and their oxidation products (Fig. 2). That layer may make the sols stable. Particle sizes of silver colloids vary from 10 to 35 nm.

Ag(I) reduction with **V** at pH 6 was found to be hindered by a competing process yielding an insoluble compound. As the most likely product here is a complex, the direct potentiometric titration method was chosen to characterize it. When $AgNO_3$ interacts with **V**, complexation occurs according to: $Ag(I) + L \leftrightarrow AgL$ and $Ag(I) + 2L \leftrightarrow AgL_2$. Using the potentiometric study results the constants $\beta_1 = 2.5 \times 10^3$ и $\beta_2 = 2.5 \times 10^6$ were calculated. Based on that data, synthetic conditions were created to purposefully provide the preferential formation of the complex with $Ag(I):L = 1:2:AgNO_3$ solution was added in small portions to the ligand solution under continuous stirring, so that the complexation always took place with an excess of ligand present. The fact that it was only one, AgL_2, complex thus was formed under those conditions was confirmed by the results of titration of the ligand solution with that of $AgNO_3$. The titration curve was S-shaped and had only one inflection. The results of the titration allowed us to determine the molar ratio of Ag(I) to the ligand, which was found to be 1:2. The complex is characterized by an X-ray pattern of its own, differing significantly from that of **V**.

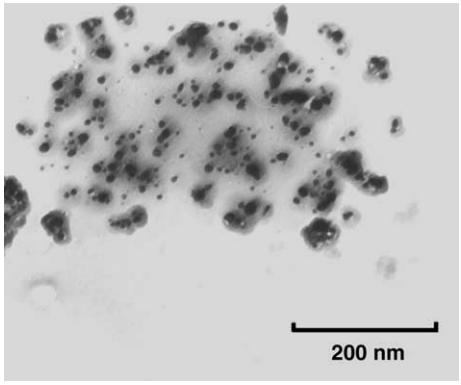

Fig. 2. TEM image of silver nanoparticles and their aggregates surrounded by a layer presumably formed by organic reductant compounds and their oxidation products.

Thermal analyses in flowing air with identification of the end products by X-ray powder diffraction has shown the complex to be anhydrous and unsolvated, because the DTA curve lacks any endothermic peaks over a wide range from 60 to 150 °C. The Ag(I) complex decomposes over the thermal range 180–540 °C to give silver metal. The agreement between the experimental (85.10%) and theoretical (85.24%) weight losses for the above process confirms the formula of the Ag(I) complex. The DTA curve shows a complicated process with exothermic peaks at 150, 260, 380, 420 °C. The first exothermic peak observed at 150 °C may be due to the thermal polymerization of the complex without any noticeable weight loss [49]. The second exothermic peak observed at 260 °C corresponds to the maximal weight loss due to the thermal destruction of an organic ligand [50]. The third peak observed at 380 °C corresponds to a small weight loss and, according to [51], is most likely due to decarboxylation of coordinated (deprotonated) carboxylic groups. Above 400 °C pyrolitic decomposition of the ligand takes place, as usual.

In the IR spectrum of the ligand **V** there is a strong band at 1695 cm^{-1} and a weaker one at 1775 cm^{-1} which can be assigned to the stretching C=O vibrations of the COOH group (Fig. 3(a)). The former band

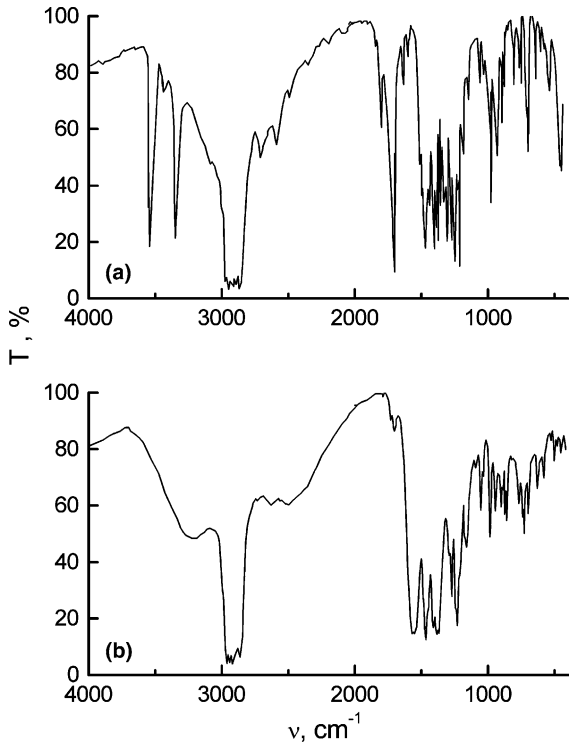

Fig. 3. Solid FT-IR spectra of **V** (a) and its Ag(I) complex (b).

becomes quite weak, and the latter virtually disappears in the spectrum of the complex (Fig. 3(b)), while a new band at 1556 cm^{-1} appears, which can be assigned to a COO^- antisymmetric stretching vibration.

Thus, we may suggest that the ligand molecules are coordinated via the carboxylic group. The simultaneous presence of a band corresponding to the stretching vibrations of C=O in a COOH group at 1697 cm^{-1} and the band at 1556 cm^{-1}, corresponding to COO^-, allows us to suggest that Ag(I) substitutes the hydrogen atom of COOH only in one of the coordinated ligand molecules. Narrow bands at 3550–3350 cm^{-1} are present in the ligand spectrum, which are assigned to stretching O–H vibrations. According to [52], bulky substituents in a ligand molecule may hinder intermolecular association. In the spectrum of the Ag(I) complex, instead, the respective bands are broadened and virtually merged into one band at 3300 cm^{-1}, suggesting that OH groups are coordinated to the metal ion or form hydrogen bonds. A polymeric Ag(I) complex also can be formed with **V**, as that type of structure, according to [16,18,19], is not uncommon with Ag(I) complexes.

Antimicrobial activities of the Ag(I) complex, which is (according to IR data) an Ag(I)–O bonding compound, together with those of the ligand **V** are listed in Table 1, as estimated by the MIC (μg ml^{-1}). It should be emphasized that antimicrobial tests of these compounds were first performed here. The metal-free ligand **V**, 2-[4,6-di-(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]acetic acid, has shown moderate activities (125 and 62.5 μg ml^{-1}) against Gram-positive bacteria (*B. subtilis*, *St. aureus*) and no activity (>1000 μg ml^{-1}) against Gram-negative bacteria (*E. coli*, *Ps. aeruginosa*, *Pr. vulgaris*) and yeast (*C. albicans*). The Ag(I) complex, on the contrary, was found to be considerably more active against a wide spectrum of Gram-negative and -positive bacteria and much better at inhibiting the growth of *C. albicans* than the free ligand **V** (Table 1).

Table 1
Antimicrobial activities of the free 2-[4,6-di(*tert*-butyl)-2,3-dihydroxyphenylsulfanyl]acetic acid (ligand **V**) and its Ag(I) complex evaluated by minimum inhibitory concentration (MIC, μg ml^{-1})

Microbe	Ligand **V**	Ag(ligand **V**)$_2$
Escherichia coli	>1000	62.5
Proteus vulgaris	>1000	62.5
Pseudomonas aeruginosa	1000	<31.2
Staphylococcus aureus	125	62.5
Bacillus subtilis	62.5	<31.2
Candida albicans	>1000	31.2

Hence, the complexation of Ag(I) with the ligand **V** leads to appreciably enhancing the activities, a substantial effect being found with some of the cultures. Of particular note is the activity against *C. albicans* in connection with the currently central investigations into the synthesis and in vitro testing of new metal-based anti-fungal drugs [22–26]. Similar broad spectra were also obtained in the case of previously investigated Ag(I) complexes with other organic ligands formed by Ag(I)–N and/or Ag(I)–O bonding [12,24], and literature findings are mostly consistent with those presented here. Yet another important experimental fact is that for the above mentioned complexes the antimicrobial activity spectra were broader than those observed in the Ag(I)–S and Ag(I)–P bonding compounds [11,13–15,20], allowing us to argue for the previous suggestion about the same or similar antimicrobial mechanism and mode of action for the complexes of that type, in which the crucial factors are the kind of atom (O, N) coordinated to Ag(I) and its moderate bonding strength as well as the ease of ligand-exchange reactions with some biological ligands, such as proteins, which comprise a donor S-atom [24]. It must be also emphasized that our findings concerning the Ag(I) complex activity cannot be interpreted unambiguously, because the Ag(I) complex under study is unlikely to remain intact throughout the screening protocol, with the result that the MIC values reflect the combined effect of the action of the Ag(I) complex, Ag(I) ions and, probably, silver colloids, which might be generated in the test media.

4. Conclusion

When SPH derivatives under study interact with silver(I) ions, two competitive processes are possible: redox process and complexation. The compounds **I**–**IV**,

VI and **VII** are found to reduce silver(I) to silver(0), silver sol formation being possible under certain conditions. Raising the pH up to 9 favors the sol formation, while the effectiveness of this process is lower at the lower pH value of 6, and sometimes the silver reduction arrests itself. The properties of the sols (dispersion, coloration, stability) largely depend on the nature of the organic reductant used.

Thus, among the sulfur-containing SPH derivatives studied we have found **V** to stand out as the compound which is distinguished by its interaction with Ag(I) being unaccompanied by a redox reaction, the latter being hindered by a competitive complexation. The data of the spectral investigation are evidence for the formation of a coordination core of the complex where two ligands are bound to Ag(I) by oxygen atoms of COOH and OH functional groups. However, if just a carboxylic group and a hydroxyl in the ortho-position are present in the organic compound, it is not enough for a stable complex to be formed, as conformed by the lack of a complex with **I**. In contrast to the free ligand **V**, the Ag(I) complex shows a broad spectra of antimicrobial activities. These facts may be of interest in the design of new effective metal-based drugs. In this paper we did not set ourselves the task of testing the antimicrobial activity of the sols synthesized, because the high lability and difficulties of preparation of liophobic sols is known to drastically decrease the possibilities of their use as medicines.

Received 12 July 2004; accepted 4 January 2005

Abstract

Quantitative Raman spectra of molten $PbCl_2$–ACl (A = K, Cs) mixtures have been measured at different compositions and at temperatures up to 680 °C. Spectral changes upon melting the Cs_4PbCl_6, $CsPbCl_3$, KPb_2Cl_5 and $PbCl_2$ solids have been also measured. All spectra of melts are mainly characterized by an isotropic (polarized) ν_P and an anisotropic (depolarized) ν_D band. The intensity and position of the ν_P ($\sim 237 \pm 2\ cm^{-1}$) and ν_D ($\sim 113 \pm 3\ cm^{-1}$) bands remain practically constant at $X_{PbCl_2} \leqslant 0.5$ indicating that the structure is predominated by coordination polyhedra of the type $Pb_nCl_{3n}^{n-}$ ($n \leqslant 4$). With increasing $PbCl_2$ mole fraction the ν_P and ν_D bands shift to the "red" and the "blue", respectively, reaching the corresponding values of 215 and 132 cm^{-1} in pure molten $PbCl_2$. Furthermore, the intensity ratio of the anisotropic to isotropic spectra increases indicating contributions to the scattering intensity arising from dipole–induced-dipole interactions in these melts.

1. Introduction

Molten lead (II) chloride and its mixtures with alkali metal halides have been the subject of a series of physicochemical investigations in the early days of molten salt research [1]. The structure of these melts has been also studied by Raman [2] and X-ray diffraction [3] spectroscopies. Solid $PbCl_2$ and the solid binary compounds with alkali metal chlorides exhibit solid phase transformations and have been extensively studied [4]. Furthermore, a series of glasses involving $PbCl_2$ have been prepared and appear to have rather interesting optical properties [5].

The present work concerns the Raman spectra of molten $PbCl_2$–KCl and $PbCl_2$–CsCl systems. Composition dependent measurements are correlated to the melt structure. The changes of vibrational modes on melting the compounds $PbCl_2$, KPb_2Cl_5, $CsPbCl_3$ and Cs_4PbCl_6 have been also measured. The purpose of this work is to contribute to the understanding of the melt structure as well as of the structure of the amorphous materials involving lead (II) chloride.

2. Experimental

The source of all chemicals used was Alfa Chemical Co. (99% purity). The $PbCl_2$ was further purified by sublimation in sealed fused silica containers. The KCl and CsCl were recrystallized from the melt in special vacuum of argon filled furnaces. Details for the purification of different metal chlorides can be found elsewhere [6]. The congruently melting binary compounds ($A_nPb_mCl_{n+2m}$; A = K, Cs) were prepared by mixing and melting the appropriate amounts of the $PbCl_2$ and ACl salts in fused silica containers and then rapid cooling to room temperature. All operations were carried out in either

sealed fused silica containers and/or in a nitrogen filled glove box with less than 1 ppm H_2O.

Details for the Raman systems and techniques used for measuring spectra at elevated temperatures can be found elsewhere [6]. The molten binary mixtures $PbCl_2$–KCl and $PbCl_2$–CsCl have a yellowish coloration which becomes deeper with increasing $PbCl_2$ mole fraction and/or temperature. So, the melts partially absorb the Ar-ion laser lines and thus no semi-quantitative intensity measurements are possible. At temperatures up to 700 °C, there is no significant absorption of the 647.1 nm Kr-ion laser line and thus spectra excited with this line permitted relative intensity measurements and a comparison of intensities from cells containing different $PbCl_2$ compositions. For these quantitative measurements the optical geometry, the scattering volume and the spectral conditions were kept the same [6b] and thus the relative per mole of $PbCl_2$ intensities could be calculated. The measured Raman bands were rather broad and their frequencies were determined within 1–2 cm^{-1}. The reduced isotropic and anisotropic spectra were calculated by methods described elsewhere [7].

3. Results and discussion

3.1. Melting the binary compounds

The Raman spectra of the four solids listed in Table 1 have been measured from LN_2 temperature up to a few degrees above their melting points. Apart from band broadening and slight frequency shifts the spectra of the solids remained unchanged at all temperatures and no solid phase transitions were detected. The spectra of the solids at room temperature and of the melts are shown in Fig. 1. The crystal structures of these compounds show that the coordination of lead (II) can vary from 9 to 6 (Table 1). In the case of Cs_4PbCl_6 independent octahedral $PbCl_6^{4-}$ species with D_{3d} distortions are formed. The $\nu_t = 201$ cm^{-1} frequency, measured in the solid, corresponds to the terminal Pb–Cl stretching frequency (A_{1g}) of the "octahedra". For the same compound, the pair of the bands above 50 cm^{-1} are assigned to two modes arising from the splitting of the

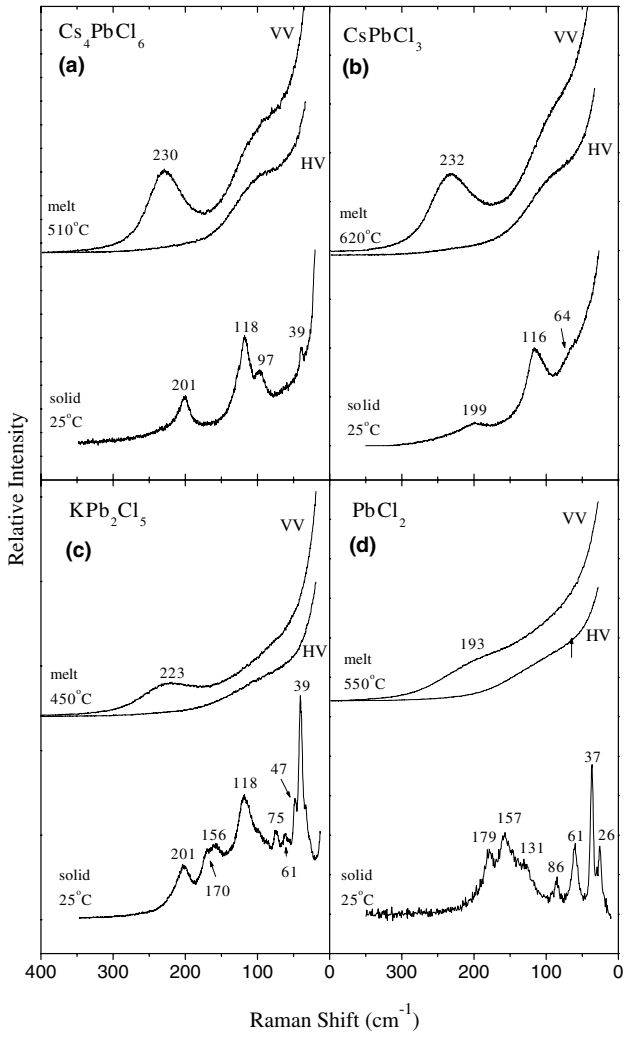

Fig. 1. Changes of vibrational modes upon melting the polycrystalline compounds Cs_4PbCl_6, $CsPbCl_3$, KPb_2Cl_5 and $PbCl_2$. Spectral conditions: $\lambda_0 = 647.1$ nm, laser power 150 mw, spectral slit width 2.5 cm^{-1}, scan rate 1 cm^{-1} s^{-1}.

[f] Number in parenthesis are frequencies calculated from the reduced isotropic spectra.

T_{2g} octahedral mode in the D_{3h} symmetry of the $PbCl_6^{4-}$ (i.e., $T_{2g} \rightarrow A_{1g} + E_g$). In all other compounds the lead (II) polyhedra share their chlorides with neighboring lead (II) cations and thus the anticipated Pb–Cl frequencies are expected to be near but lower relative to the terminal ν_t frequencies. As noted in Table 1 some of these compounds have been studied as single crystals by Raman spectroscopy and certain assignments of the measured bands have been made.

Upon melting $PbCl_2$ (Fig. 1) the spectra are dominated by a weak polarized and a weak depolarized band over a relatively intense and extended liquid wing. The melt spectra of all other compounds have more defined bands, but all of them are mainly characterized by one polarized and one depolarized band. All measured bands are "blue" shifted relative to the "octahedral" ν_t frequency. As shown in Table 1, the polarized frequency of the melt, for all these compounds, do not differ much, especially if the temperature/liquid wing correction is applied by using the reduced [7] representation of the spectra (see also Figs. 2 and 3). Thus, the polarized band in these melts lays in the range ~215 to ~237 cm^{-1} and shows no obvious correlation to the solid frequencies. It is also noteworthy that these frequencies are above the octahedral Pb–Cl stretching frequency ($\nu_t \approx 201$ cm^{-1}), which implies that the Pb(II) coordination polyhedra in the melt are more likely to have a coordination number less than six.

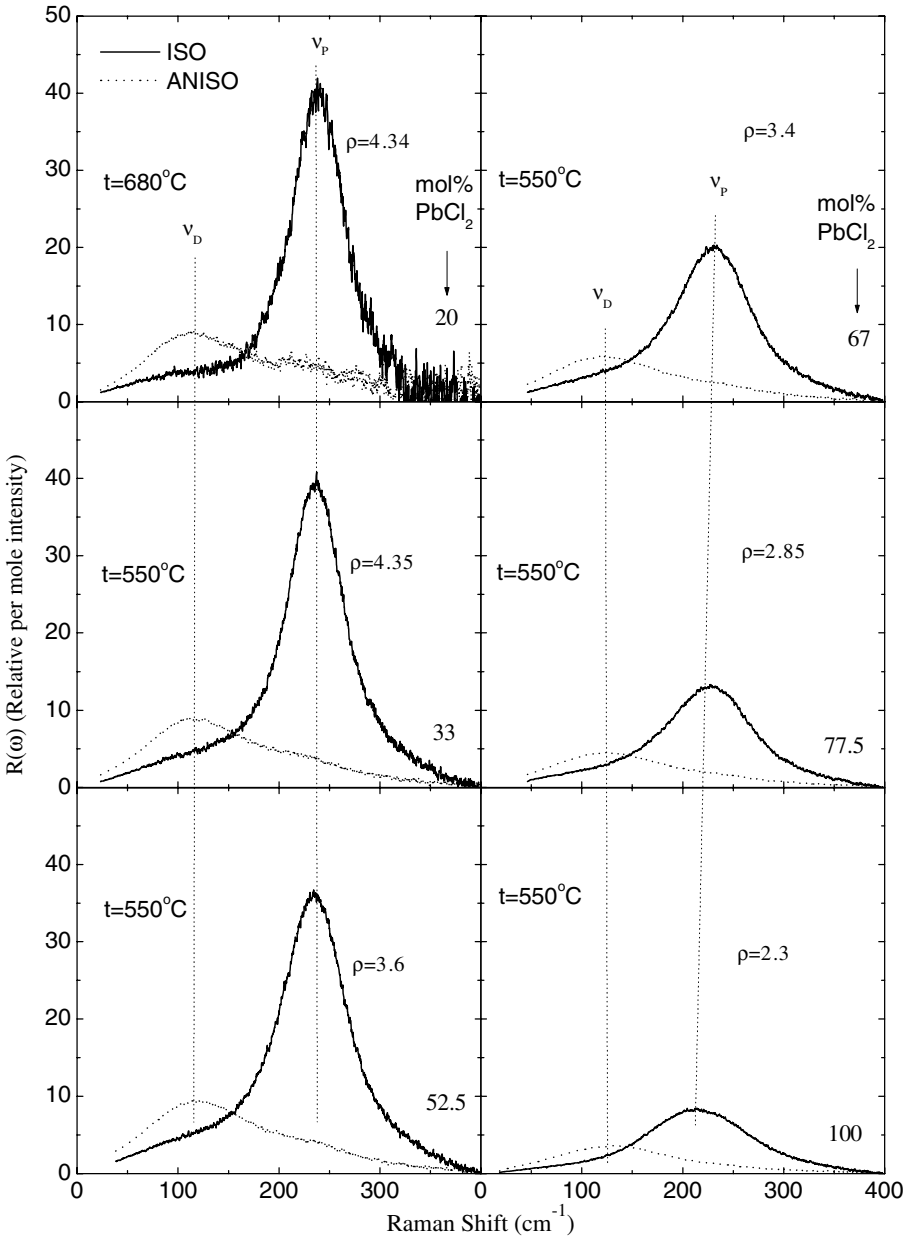

Fig. 2. Relative reduced per mole isotropic and anisotropic spectra of $PbCl_2$–KCl melt mixtures at different compositions. Spectral conditions as in Fig. 1 ρ gives the intensity ratio of the ν_D to ν_P peak intensities in the reduced ISO and ANISO spectra.

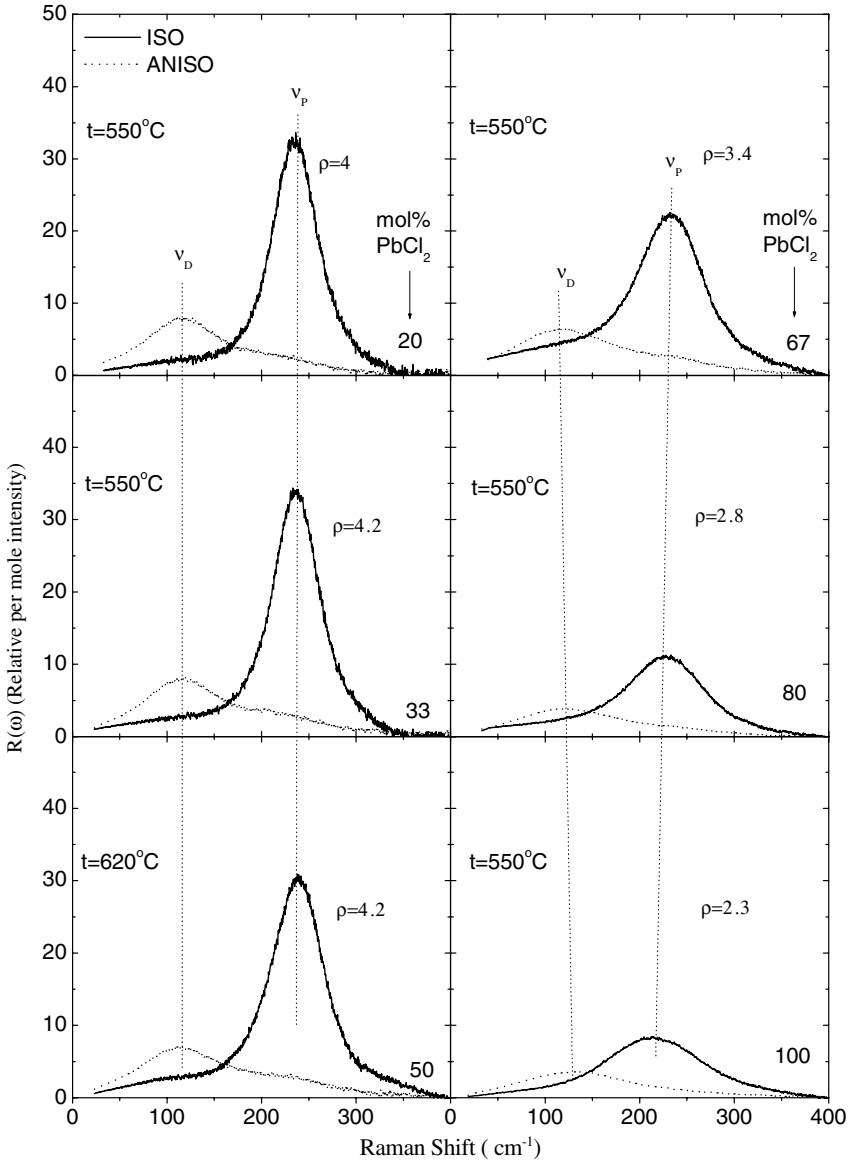

Fig. 3. Relative reduced per mole isotropic and anisotropic spectra of $PbCl_2$–CsCl mixtures at different compositions. Spectral conditions as in Fig. 1, ρ as in Fig. 2.

3.2. Isotropic and anisotropic spectra of mixtures and predominant vibrational modes

For both the $PbCl_2$–KCl and $PbCl_2$–CsCl molten systems, Raman spectra were measured at different compositions and in most cases at 550 °C. For two compositions (90 mol% KCl and 50 mol% CsCl) the spectra were measured at a temperature a few degrees above the liquidus. Following the procedures of our earlier work [7], we have calculated the reduced isotropic and anisotropic contributions to the Raman scattering and the results are shown in Figs. 2 and 3. The units on the $R(\omega)$ abscissa represent the relative per mole of $PbCl_2$ intensity. Two main bands marked as ν_P and ν_D predominate the isotropic and anisotropic spectra, respectively.

It should be noted here that for an isotropic ionic medium, the mechanism for light scattering is related to the fluctuations of the polarizability tensor $\Delta\Pi$ which is expressed [9] in terms of the anisotropic (ANISO) and isotropic (ISO) contributions:

$$\Delta\Pi_{\mathrm{ISO}} = \Pi^{\mathrm{Sr}}_{\mathrm{ISO}} + \Pi^{\gamma}_{\mathrm{ISO}} \tag{1}$$

$$\Delta\Pi_{\mathrm{ANISO}} = \Pi^{\mathrm{DID}}_{\mathrm{ANISO}} + \Pi^{\mathrm{B}}_{\mathrm{ANISO}} + \Pi^{\mathrm{SR}}_{\mathrm{ANISO}} + \Pi^{\gamma}_{\mathrm{ANISO}} \tag{2}$$

The different terms are: Π^{SR} refers to a short range term which describes the effect of near neighbor interactions of the ionic charge clouds; Π^{DID} is the dipole–induced-dipole (DID) interactions of an ion with the neighboring ions (including first and second coordination shears); Π^{B} and Π^{γ} give the change in polarizability induced on a given ion by the Coulomb field gradient

and the Coulomb field, respectively. All four terms contribute to the light scattering spectra but in certain cases due to cross correlation a degree of mutual cancellation may occur [9].

Simulations of light scattering intensities [9c] have shown that the isotropic SR term (Eq. (1)) arises mainly from the stretching frequencies of the coordination polyhedra involved in the melt structure. Thus, the main isotropic band (ν_P) in the region ~215–237 cm^{-1} (Figs. 2 and 3) is attributed to Pb–Cl stretching frequencies of the lead (II) coordination polyhedra predominating the structure. As pointed out before, the frequency region of the isotropic band imposed indirectly an average coordination of less than six. The quantitative Raman measurements permitted the evaluation of the relative per mole intensities on going from pure $PbCl_2$ to the dilute solutions; it appears that the dilute solutions have a much higher per mole scattering intensity than the mixtures rich in $PbCl_2$. Furthermore, the ratios $\rho = D_P/D_D$ of the peak intensity of the reduced ν_P band relative to the ν_D band are also calculated and marked in the figures. It appears that:

obs.: (1a) in dilute solutions and up to 50 mol% $PbCl_2$ the frequency of the isotropic (ν_p) band and the ratio ρ do not change much.
obs.: (1b) in the same mole fraction region the anisotropic band (ν_D) also shows the same characteristics, i.e., about constant frequency and constant per mole intensity.

These observations are best interpreted to indicate that the same coordination polyhedra predominate the melt structure and contribute to the average stretching frequency in the region $X_{PbCl_2} \leqslant 0.5$. The maximum mole fraction of 0.5 implies a molar stoichiometry for these species with an average of 1 $PbCl_2$:1 ACl or in other words a general species of the type $Pb_nCl_{3n}{}^{n-}$. Examples of structures with such a stoichiometry are given in Fig. 4. With the exception of the trigonal (or pyramidal) $PbCl_3{}^-$ species, the other structures are dominated by lead (II) tetrahedra bridged by edges or corners. For $PbCl_3{}^-$ in aqueous solution a stretching frequency of ~249 cm^{-1} has been reported [10], while by comparing the terminal frequency of $CdCl_6{}^{4-}$ and $CdCl_4{}^{2-}$ [11] to that of $PbCl_6{}^{4-}$ a terminal tetrahedral frequency of $PbCl_4{}^{2-}$ can be scaled to be 232 cm^{-1}. In other words, the observed value ν_P = 230 cm^{-1} ($X_{PbCl_2} \leqslant 0.5$) is compatible with all these structures (n = 2,3,4) with the Pb–Cl stretching frequency arising from the tetrahedra participating in the structures. Furthermore, the $PbCl_3{}^-$ species in C_{3v} symmetry cannot be definitely excluded since a proper pyramidal angle may shift the Pb–Cl frequency close to the 230 cm^{-1} value. On the other hand, structures with $n \geqslant 5$ are unlikely to be present since they correspond to highly charged species which are not commonly found in melts.

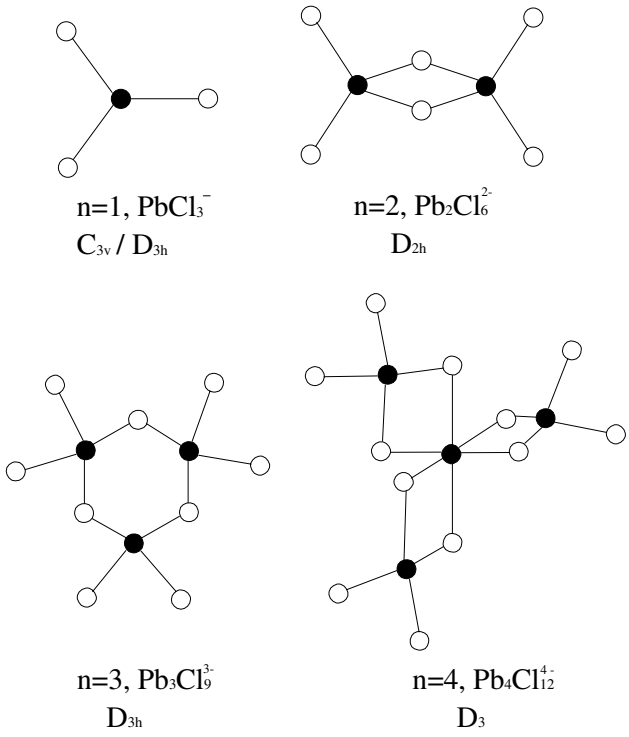

Fig. 4. Molecular models of $Pb_nCl_{3n}{}^{n-}$ anionic species. n = 1 corresponds to a trigonal planar (D_{3h} point symmetry) or a pyramidal (C_{3v}) molecule. n = 2 and n = 3 are the dimer-four atom ring molecule (D_{2h}) and the trimer-six atom ring molecule (D_{3h}), respectively, composed of bridged tetrahedra. n = 4 corresponds to two possible structures, one is an extension of the trimer structure, the tetramer with four bridged tetrahedra forming an eight atom ring (D_{4h}), the other shown here is a tetramer composed by an octahedra edge bridged with three tetrahedra (D_3).

The enthalpy of mixing data for the $PbCl_2$–CsCl system [12] show that the enthalpy interaction parameter exhibits a shallow minimum between 25 and 35 mol% $PbCl_2$. This points out towards the existence of species that stabilize thermodynamically the mixture with $PbCl_2$–CsCl stoichiometries of 1:2, 1:3 and 1:4 while species with 1:1 ratios are difficult to reconcile. Thus, the interpretation of the thermodynamic and spectroscopic data appear to be at odds. This discrepancy may be bridged if it is assumed that at $X_{PbCl_2} \leqslant 0.5$ a continuous multi-species equilibrium takes place involving all the 1:1 species (Fig. 4) as well as species with different stoichiometries (e.g., $PbCl_4{}^{2-}$, $PbCl_6{}^{4-}$). The average stretching frequency of all the species involved is centered at ~230 cm^{-1} which is close to the Pb–Cl tetrahedral frequency. In conclusion the Raman data support the formation of anionic coordination polyhedra in melts with $X_{PbCl_2} \leqslant 0.5$ but do not point out a definite predominant lead (II) species in these melts.

3.3. Anisotropic spectra and DID interactions

As the $PbCl_2$ mole fraction increases from above 0.5 to 1.0 the following spectral changes are observed:

obs.: (2a) the frequency of the isotropic ν_P band shifts progressively from $\sim$235 cm^{-1} in the 50/50 mixture to $\sim$215 in pure molten $PbCl_2$.
obs.: (2b) a similar shift occurs for the anisotropic ν_D band.
obs.: (2c) in the same composition range the per mole ($PbCl_2$) isotropic intensity decreases by a factor of four
obs.: (2d) the anisotropic band ν_D gains intensity relative to the isotropic ν_D band, reaching a ratio $\rho = 2.3$ in molten $PbCl_2$.

The ν_P red shift (obs.: 2a) presumably implies that the average coordination increases with increasing $PbCl_2$ content. X-ray diffraction data of molten $PbCl_2$ suggest a coordination number of either 8 [3a], 7 [3b] or 6 [3c]. The latest value of six [3c] arises from corrections of previous data [3b] and appears to be more accurate. For the same melt $\nu_P = 215\ cm^{-1}$ is below the average tetrahedral frequency ($\sim$235 cm^{-1}) and is closer to an octahedral frequency ($\sim$205 cm^{-1}). Thus, the suggested value of six, by the recent X-ray data, is somehow compatible with the observed Raman frequency. However, the decreasing per mole intensity (obs.: 2c) implies that the contribution of the SR term (Eq. (1)) is diminishing and that the cation–anion nearest neighbor interactions are weakened. An account of this could be given by examining the competition between cations for a common anion. In melts rich in ACl the second nearest neighbors to the Pb^{2+} are the A^+ cations. With increasing $PbCl_2$ the A^+ cations are replaced by the doubly charged, highly polarizable Pb^{2+} cations which attract more efficiently the chlorides of the lead (II) polyhedra. This in turn weakens the Pb–Cl interactions within the polyhedra and red shifts the corresponding frequency.

The increasing anisotropic intensity (obs.: 2d) is a phenomenon observed previously in the spectra of other molten salt systems involving large and highly polarizable cations and is related to the DID interactions between neighboring cations [7,13]. The studies of alkali metal chlorides and fluorides show that for highly polarizable cations (e.g., Cs^+) the anisotropic intensity is even higher than that of the isotropic intensity [7]. The DID term (Eq. (2)) becomes rather important for such systems overcoming the other interactions. In a similar way the spectra of rare earth fluoride (LnF_3) systems with alkali fluorides show that with increasing LnF_3 mole fraction and/or Ln^{+3} ionic size the anisotropic intensity of the bending modes increases and in certain cases (e.g., LaF_3–KF) approaches the isotropic intensity. This effect was attributed to the diminishing shielding of the Ln^{3+} cations by the coordinating fluorides which enhanced the DID interaction between nearest neighbor cations (Ln–Ln) [13].

The ionic radius of Pb^{2+} is $\sim$1.19 Å and thus the shielding by the chloride anions in the coordination polyhedra is not very effective. Even in pure molten $PbCl_2$, with an anticipated (see above) coordination number of six, the shielding of the Pb^{2+} by the chloride is not complete and this allows the neighboring Pb^{2+} cations to interact. Due to Pb^{2+} high polarizability ($\alpha \approx 2.65$ $Å^3$) [14] the "pure" DID interactions between lead (II) ions are enhanced and give rise to strong anisotropic scattering (like in the cases of CsCl [7c] and CsF [7b] melts) which is superimposed on the bending modes of the coordination polyhedra. The result in the reduced spectra is a rather strong anisotropic band with a maximum arising from a superposition of the bending modes band(s) and the reduced anisotropic band of the "pure" DID scattering. When molten $PbCl_2$ is diluted with alkali chlorides, the neighboring cations change gradually and the Pb–Pb, DID interactions diminish; this alters the relative contributions of the DID and bending modes to the ν_D band and thus its maximum may shift with composition (obs.: 2b). Finally, it should be noted that the shielding of the central Pb^{2+} cation by the chlorides changes during the vibrational motion of the coordination polyhedra. For a breathing symmetric vibration (i.e., isotropic) the chlorides move towards and against the neighboring cations and a rather symmetric average shielding is imposed. On the other hand, the bending modes change locally the shielding in certain directions which in turn influences the cation–cation DID interactions asymmetrically along the same direction. In other words, the enhanced anisotropic scattering indicates that there should be coupling between the polyhedra bending modes and the DID interaction between neighboring cations.

Abstract

Reactions of Zn(II), Cd(II) and Co(II) ions with 4-methylimidazole-5-carbaldehyde (4-Me-5-CHOIm) afforded four novel complexes $[Zn(4\text{-Me-5-CHOIm})_4](NO_3)_2$ (**1**), $[Cd(4\text{-Me-5-CHOIm})_4](NO_3)_2(H_2O)$ (**2**), $[Co(4\text{-Me-5-CHOIm})_2(H_2O)_2](NO_3)_2$ (**3**) and $[Co(4\text{-Me-5-CHOIm})_2(NO_3)_2]$ (**4**). Compounds **1**–**3** were characterized by X-ray diffraction, establishing tetrahedral ($I\bar{4}$), distorted dodecahedral ($C2/c$) and octahedral ($P\bar{1}$) coordinating geometries of the metal ions, respectively. The crystal structure of **3** includes in the unit cell two symmetry-independent cations: $[Co(1)L_2(H_2O)_2]^{2+}$ and $[Co(2)L_2(H_2O)_2]^{2+}$which differ slightly in bond lengths and valence angles. In solution, NMR and potentiometric methods have confirmed the preference of the central ions not only to adopt a specific coordination number and geometry of coordination polyhedra, but also the function of the ligands which can be either monodentate (ZnN_4) or bidentate (CdN_4O_4 and CoN_2O_4).

1. Introduction

Zinc is the second most prominent trace metal in the human body and is involved in a large number of enzymatic functions, fulfilling both structural (Zn-finger family protein) [1–6] and catalytic roles [1,7–9]. There are a number of zinc enzymes in the cytoplasm in which the metal ion coordinates only N, O donor ligands [10,11]. For example: superoxide dismutase with the ZnN_4 chromophore at the active center, carbonic anhydrase (ZnN_3, H_2O) or leucine, amine-peptidase (ZnO_4). The role of metal ions in such active centers is fundamental and the structural characterization of the local metal coordination sites is essential in understanding their function. Removal of the zinc from the holoenzyme or the replacement of Zn(II) by the chemically similar Cd(II) ion, generally results in apoprotein having no catalytic activity [12,13]. Additionally, cadmium has been designated as a human carcinogen by the International Agency for Research on Cancer and the US National Toxicology Program [14,15]. Therefore, an especially important question in current coordination chemistry is how a protein selects a specific metal, e.g., Zn^{II} but not Cd^{II}, from the mixture of ions present in a cell or in another environment [16]. All of the above mentioned zinc metalloproteins contain one or more imidazole ligands of the amino acid residue histidine. For this reason, simple imidazole heterocycles [17] are generally used in model studies of local metal coordination sites.

Basically, this study had the following four main goals: (1) the synthesis, crystal structure and spectroscopic studies of some low molecular weight complexes of zinc(II) and cadmium(II) with 4-methylimidazole-5-carbaldehyde (4-Me-5-CHOIm), (2) to present the coordination chemistry of Co(II)-4-Me-5-CHOIm complexes taking into account that Co(II)-compounds have been shown to be important tools in the study of the zinc(II) chromophore in the active centre of metalloenzymes [18], (3) to compare the stability constants of some imidazole complexes with a number of alkyl substituted imidazoles with Co(II), Zn(II) and Cd(II) in aqueous solution based on results obtained from potentiometric measurements, (4) to determine how well conventional structural data for examining complexes correlate with NMR and potentiometric studies in aqueous solution.

2. Experimental

2.1. Investigation in the solid state

2.1.1. Reagents and physical measurement

$Cd(NO_3)_2 \cdot 4H_2O$, $Zn(NO_3)_2 \cdot 6H_2O$ and $Co(NO_3)_2 \cdot 6H_2O$ were purchased from Merck Chemical Company and 4-Me-5-CHOIm (Aldrich 99%) were used as received. Elemental analyses were run on a Model 240 Perkin–Elmer CHN Analyzer. Infrared spectra (Perkin–Elmer 180 spectrophotometer; 4000–400 cm^{-1}) were recorded in KBr and FIR spectra (400–30 cm^{-1}) in Nujol with specimens applied as a suspension of the complexes in Nujol onto a polyethylene window. Raman spectra were performed at room temperature with a Bio-Rad spectrometer, resolution 4 cm^{-1}. The incident radiation (λ = 1064 nm) was provided by a Neodymium laser YAG (Spectra-Physics). The electronic spectra (Cary 5 UV–Vis–NIR spectrophotometer; 5000–30 000 cm^{-1}) were recorded in Nujol mulls. Magnetic measurements were carried out on a magnetic susceptibility balance (Sherwood Scientific) at room temperature by Guoy's method using $Hg[Co(NCS)_4]$ as the calibrant.

2.1.2. Preparation of the complexes

*2.1.2.1. $[ZnL_4](NO_3)_2$ (**1**).* A sample of 4-Me-5-CHOIm (3 mmol, 0.330 g) dissolved in mixture of analytically pure MeOH (12 mL) and redistilled water (12 mL) was added to the same solvents (24 mL) containing 0.5 mmol (0.149 g) of $Zn(NO_3)_2 \cdot 6H_2O$. The molar ratio M:L was 1:6. The solution was stirred for 7 h and left to crystallize at room temperature. After two weeks colourless crystals of the complex suitable for X-ray investigation were obtained. The product was filtered and dried under vacuum. The colourless crystals were collected in 39% yield. *Anal.* Calc. for $C_{24}H_{20}N_{10}O_{10}Zn$: C, 45.8; H, 3.2; N, 22.2. Found: C, 45.4; H, 3.0; N, 22.1%.

Selected vibrations (FT-IR and FT-Raman in italics; cm^{-1}): ν(NH) 3164vb *(3164)*; ν(C=O) 1669vs *(1668)*; interaction between ν(C=C) and ν(C–N) 1524vs *(1528)*; $\nu(NO_3)$ 1381vb *(1382)*.

*2.1.2.2. $[CdL_4](NO_3)_2(H_2O)$ (**2**).* 4-Me-5-CHOIm (2.0 mmol, 0.220 g) dissolved in 20 mL of analytically pure EtOH was stirred with 0.5 mmol (0.154 g) of $Cd(NO_3)_2 \cdot 4H_2O$ dissolved in 20 mL of the same solvent. The molar ratio M:L was 1:4. The solution was left to crystallize at room temperature. After three weeks colourless crystals of a compound suitable for X-ray investigation were obtained. The precipitate was separated by filtration and washed with 30 mL of 2-propanol, before being dried under vacuum. The colourless crystals were collected in 74% yield. *Anal.* Calc. for $C_{20}H_{26}N_{10}O_{11}Cd$: C, 34.6; H, 3.8; N, 20.2. Found: C, 34.5; H, 3.5; N, 20.0%.

Selected vibrations (FT-IR and FT-Raman in italics; cm^{-1}): ν(OH, lattice water) 3608s; ν(NH) 3144vb *(3133)*; ν(C=O) 1656vs *(1656)*; interaction between ν(C=C) and ν(C–N) 1512vs *(1512)*; $\nu(NO_3)$ 1360vb *(1364)*.

*2.1.2.3. $[CoL_2(H_2O)_2](NO_3)_2$ (**3**).* A mixture of $Co(NO_3)_2 \cdot 6H_2O$ (0.073 g, 0.25 mmol) in propan-2-ol (20 mL) and 4-Me-5-CHOIm (0.111 g, 1.0 mmol) in propan-2-ol (20 mL) was stirred at room temperature for 1 h. The molar ratio Co:L was 1:4. After evaporation of half the solution (5 days), orange-pink crystals of $[CoL_2(H_2O)_2](NO_3)_2$, suitable for X-ray analysis, were collected by vacuum filtration and dried in a vacuum box. In addition, a small amount of a violet precipitate of $[CoL_2](NO_3)_2$ was obtained from the residual filtrate. The crystals were collected in 33% yield. *Anal.* Calc. for $C_{10}H_{16}N_6O_{10}Co$: C, 27.3; N, 19.1; H, 3.7. Found: C, 27.6; N, 18.9; H, 3.7%.

Selected vibrational bands (FT-IR and FT-Raman in italics; cm^{-1}): ν(OH, coordinated water) 3407vb; ν(C=O) 1614vs *(1613)*; interaction between ν(C=C) and ν(C–N) 1525vs *(1528)*; $\nu(NO_3)$ 1481s.

*2.1.2.4. $[CoL_2](NO_3)_2$ (**4**).* A solution of $Co(NO_3)_2 \cdot 6H_2O$ (0.145 g, 0.5 mmol) in a mixture of propan-2-ol (15 mL) and trimethyl orthoformate (5 mL) was slowly added to a solution of 4-Me-5-CHOIm (0.111 g, 1.0 mmol) in propan-2-ol (20 mL). The molar ratio Co:L was 1:2. The mixture was stirred for 30 min, and then left standing at room temperature. Passive evaporation of ca. half the volume resulted in a violet precipitate. The precipitate was collected by vacuum filtration and dried in a vacuum box. Unfortunately, the violet crystals of definite stoichiometry were not suitable for X-ray investigation. The crystals were collected in 43% yield. *Anal.* Calc. for $C_{10}H_{12}N_6O_8Co$: C, 29.8; N, 20.8; H, 3.0. Found: C, 30.0; N, 20.6; H, 2.9%.

Selected vibrational bands (FT-IR and FT-Raman in italics; cm^{-1}): ν(NH) 3140vb *(3138)*; ν(C=O) 15620vs *(1620)*; interaction between ν(C=C) and ν(C–N) 1524vs *(1528)*; $\nu(NO_3)$ 1360vb *(1358)*.

2.1.3. X-ray crystal structure analysis

Diffraction intensity data for single crystals of the Cd(II), Zn(II) and Co(II) complexes were collected at room temperature on a KappaCCD (Nonius) diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Corrections for Lorentz, polarization and absorption effects [19] were applied. The structures were solved by direct methods using the program package SIR-92 [20] and refined using a full-matrix least square procedure on F^2 using SHELXL-97 [21]. Anisotropic displacement parameters for all non-hydrogen atoms and isotropic temperature factors for hydrogen atoms were introduced. Further details of the structures analysis are given in Table 1 and in the supplementary material.

2.2. Solution studies

2.2.1. Potentiometric measurements

The stability constants of the proton and metal(II) complexes were determined by pH-metric titration of 5 cm^3 samples in aqueous solutions. The ligand concentration was 1.0×10^{-1} or 5×10^{-2} mol dm^{-3} and the metal ion:HL^+ ratios were 1:4, 1:6, 1:8. The ionic strength was adjusted to $I = 0.5$ mol dm^{-3} with KNO_3 in each case. The titration was performed over the range pH 2.5–8.7 or 2.5–5.6 for aldehydes. All titration solutions were thermostated at 25 ± 0.1 °C using the constant-temperature water-bath. The pH was measured using PHM-84 pH-meter (Radiometer) and a GK 2400C combination electrode. The electrode system was calibrated by periodic titration of HCl of known titre with a NaOH solution according to [23]. The dissociation constants of the conjugate acid and the stability constants, β_n of the complexes were refined by the SUPERQUAD program [24].

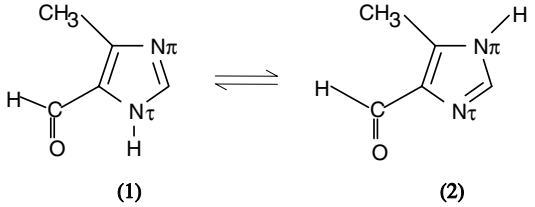
2.2.2. NMR measurements

NMR spectra of the D_2O solutions (294 K) of the Cd(II) and Zn(II) complexes were taken on a Mercury-400BB spectrometer and were recorded at 400.09 MHz. The chemical shifts were referenced to the proton signals of 1,4-dioxane (3.75 ppm) as an internal standard. An aqueous solution (D_2O) of cadmium(II) or zinc(II)-4-Me-5-CHOIm in 1:4 molar ratio was prepared using 1 cm^3 solution of $Cd(NO_3)_2 \cdot 4H_2O$ (0.925 g, 0.3 mmol) or $Zn(NO_3)_2 \cdot 6H_2O$ (0.0892 g, 0.3 mmol) dissolved in 2 cm^3 D_2O and 2 cm^3 of the stock solution of the ligand (0.16517 g, 1.5 mmol 4-Me-5-CHOIm dissolved in 5 cm^3 D_2O).

4-Me-5-CHOIm: ^{1}H NMR (D_2O) δ: 9.63 (s, 1H, C*H*O), 7.74 (s, 1H, C*H*), 4.85 (s, N*H*, H_2 (residual water from D_2O)), 2.47 (s, 3H, CH_3) ppm.

Cd(II)-4-Me-5-CHOIm: ^{1}H NMR (D_2O) δ: 9.78 (s, 1H, C*H*O), 7.89 (s, 1H, C*H*), 4.82 (s, N*H*, H_2 ($Cd(NO_3)_2 \cdot 4H_2O$), H_2 (residual water from D_2O)), 2.60 (s, 3H, CH_3) ppm.

Zn(II)-4-Me-5-CHOIm: ^{1}H NMR (D_2O) δ: 9.71 (s, 1H, C*H*O), 8.00 (s, 1H, C*H*), 4.84 (s, N*H*, H_2 ($Zn(NO_3)_2 \cdot 6H_2O$), H_2 (residual water from D_2O)), 2.59 (s, 3H, CH_3) ppm.



2.2.3. Spectroscopic measurements

The visible-range absorption spectra of the Co(II) complexes in aqueous solution were recorded on a Specord M-500 (Carl Zeiss, Jena) spectrophotometer. Solutions for these measurements were prepared using the initial metal concentration 2×10^{-2} mol dm^{-3} and the concentration ratio of metal–ligand was 1:6. The highest concentration of the protonated ligand was 0.12 mmol dm^{-3}. The absorption spectra were recorded after pH adjustment by NaOH or HNO_3 at constant ionic strength (I = 0.5 M).

3. Results and discussion

3.1. Single crystal X-ray diffraction studies

The two nitrogen atoms present at positions 4 and 5 in the unsaturated imidazole ring induce the tautomerism shown in Scheme 1.

Scheme 1. The tautomeric equilibrium between 4-Me-5-CHOIm (**1**) and 4-CHO-5-MeIm (**2**).

Our previous investigation of Cu(II) complexes [25] revealed stabilization of tautomer (2) as the only one able to form a chelate ring with the central atom. Hence it was interesting to investigate the preference of the central ion to adopt a specific coordination number and the geometry of coordination polyhedra. An important second goal was to understand the influence of the nature of the donor atoms and the function of the optionally monodentate or bidentate ligands. The X-ray diffraction method proved to be indispensable in this part of the investigations.

*3.1.1. Molecular structure of the Zn(II) complex **1***

The molecular structure of the $[Zn(4\text{-CHO-}5\text{-MeIm})_4]^{2+}$ ion is presented in Fig. 1. Selected geometrical data are given in Table 2. Compound (**1**) crystallizes in a tetragonal system. The central zinc atom occupies the special position ($2\,c\,\bar{4}$) and the other atoms are in the general position (8 g 1) of the space group $I\bar{4}$ (ITC No. 82). In the coordination sphere of the central ion there are four 4-CHO-5-MeIm (tautomer 2) moieties. Each molecule acts as a monodentate ligand [26] coordinated to the zinc ion through the unprotonated nitrogen atom (Nτ) of the heterocyclic ring (chromophore ZnN_4). The four identical zinc–nitrogen bond lengths [2.022(3) Å] as well as the values of the nitrogen–zinc–nitrogen angles [111.8(1)° and 105.0(1)°] indicate that tetrahedral coordination is a good approximation for the zinc(II) central ion. The

aldehyde groups of the azole molecules are oriented in such a way that their O atoms do not interact directly with the zinc atom [the Zn–O distance of 3.065 Å is rather long]. Similar phenomena were observed by Vahrenkamp and co-workers [27] who examined Zn(II) complexes with *N*-methylimidazole-2-carbaldehyde and thiolate donors. However, aldehydes derived from pyridine act as bidentate ligands and form five membered N,O chelate rings with the zinc cation. The geometric parameters for some representative Zn(II) complexes are compared in Table 2. The charge of the cationic complexes is balanced by two nitrate anions which are involved in hydrogen bonds of the N–H···O type with the imidazole ligands. The geometry of these hydrogen bonds is presented in Table 5. Oxygen atoms of the nitrate groups are disordered equally between two sites [site occupancy factor 0.5]. The packing in the crystal structure of (**1**) is shown in Fig. 2.

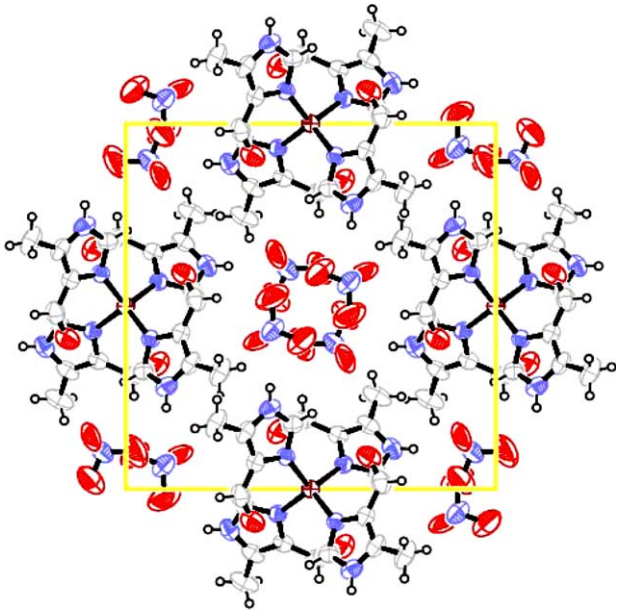

Fig. 2. Packing in the crystal structure of $[Zn(4\text{-CHO-5-MeIm})_4](NO_3)_2$ (**1**) viewed along *c*-axis of the unit cell.

3.1.2. Molecular structure of the Cd(II) complex 2

The cadmium complex crystallizes in the monoclinic system (space group *C*2/*c*, ITC No. 15). The $[Cd(4\text{-CHO-5-MeIm})_4]^{2+}$ cation has C_2 symmetry coinciding with the crystallographic symmetry. The four 4-CHO-5-MeIm (tautomer 2) molecules act as N,O bidentate ligands. The Cd atom is eight-coordinated with four 'pyridinic' nitrogen atoms of the imidazole rings and four oxygen atoms of the aldehyde groups (Fig. 3(a)). Selected geometrical data for (**2**) are given in Table 3. The shape of the coordination polyhedron can be described as a distorted dodecahedron of C_2 symmetry (Fig. 3(b)). The most interesting feature of the dodecahedron is that the oxygen atoms occupy the vertices with four neighbours and the nitrogen atoms are in the vertices with five neighbours. Cadmium–nitrogen bond distances of 2.292(1) and 2.298(1) Å are similar to those observed for other eight-coordinated N,O Cd(II) complexes and cadmium–oxygen distances of 2.745(1) and 2.700(1) Å are, in general, slightly longer than those found in the literature [28]. It is noteworthy that the complex cation $[Zn(4\text{-CHO-5-MeIm})_4]^{2+}$ obtained by us is a rare example of a dodecahedron composed of N,O donors present in small-molecule ligands. In the crystal structure, N–H groups of the ligands form bifurcated hydrogen bonds to the oxygen atoms of the nitrate groups. The geometry of the hydrogen bonds is given in Table 5.

3.1.3. Molecular structure of the Co(II) complex 3

The crystal structure of (**3**) includes in the unit cell two symmetry-independent cations: $[Co(1)L_2(H_2O)_2]^{2+}$ and $[Co(2)L_2(H_2O)_2]^{2+}$ which differ slightly in bond lengths and valence angles, (a phenomenon which is reflected in the IR spectra-vide infra). The coordination spheres of Co(1) and Co(2) are presented in Fig. 4(a),(b) together with the atom numbering scheme. Selected bond distances and valence angles are listed in Table 4. In both six-coordinate cobalt(II) complexes two molecules of 4-CHO-5-MeIm (L-tautomer 2) and two water molecules are coordinated to the central ion forming a chromophore of the CoN_2O_4 type. The

Symmetry transformations used to generate equivalent atoms: (a) $-x+1, y, -z+1/2$.

4-CHO-5-MeIm molecules act as bidentate N,O ligands, coordinating through the 'pyridinic' nitrogen atom of the imidazole ring (Nτ) and the oxygen atom of the aldehyde group. The shape of Co(1) and Co(2) coordination polyhedra is that of a distorted octahedron of symmetry $\bar{1}$, with the equatorial plane defined by the 4-CHO-5-MeIm bidentate ligands and two water molecules occupying axial positions (i.e. in a *trans* position to each other). This example of a Co(II) complex could be considered as a geometric *trans*-isomer of an analogous Co(II) complex with imidazole-4-acetate, the crystal structure of which has been recently reported [29]. In the imidazole-4-acetate Co(II) complex there are two

bidentate azole molecules as N,O ligands and two water molecules (in *cis* positions to each other). The bond lengths [Co–N = 2.071(1), 2.092(1) and Co–O = 2.128(1), 2.135(1) Å] are slightly shorter than those observed by us for (**3**). The crystal structure of the *cis*-Co(II) isomer is stabilized by hydrogen bonds of the O–H···O type to the coordinated oxygen atom of a water molecule and to the third molecule of water, which is outside the coordination sphere. Similar features were also observed for *cis*-Co(II) complexes with 1-benzyl-2-hydroxymethylimidazole [30]. The charge of the cationic complexes of (**3**) is balanced by two nitrate anions which interact as acceptors with water molecules and N–H groups of imidazole ligands via hydrogen bonds, the geometry of which is given in Table 5.

3.2. The IR and Raman spectra

The Zn(II) and Cd(II) complexes are insoluble in most common solvents except DMSO. The NMR spectra – almost identical to that of the free parent aldehyde – gave no further information. This observation however, does not exclude the possibility that donor solvent replaces 4-Me-5-CHOIm in the zinc and cadmium complexes upon dissolution. Therefore, we only use in solution NMR as a tool for examining the coordination affinity of 4-Me-5-CHOIm towards Cd^{II} and Zn^{II} (vide infra). The characteristic IR (Raman) bands and relevant crystallographic data are listed in Table 6. Upon coordination of 4-CHO-5-MeIm with transition metals, the aldehyde ν(C=O) band, except for the Zn-complex, is shifted to lower wavenumber compared to the free ligand, thus proving the expected M–O coordination. There is some correlation between this shift and the lengths of the M–O bond. The longer the metal–oxygen distance, the smaller the value of $\Delta\nu$. The position and appearance of a prominent doublet at 1614 and 1586 cm^{-1} in the ν(CO) region of the spectrum of **3** correlate with the X-ray data and indicate the presence two independent cations in the unit (Fig. 5). Additionally, the structure of the Co(II)-complex shows that the two molecules of 4-CHO-5-MeIm are in the *xy* plane and the ν(C=O) band is shifted by about 50 cm^{-1}. These are typical for the values of transition metal complexes with planar aldehydes [27,31]. Therefore, the similar value of the ν(C=O) shift ($\Delta\nu$ = 47 cm^{-1}) probably indicates the same arrangement of the aldehyde ligands in complex **4**. Interestingly, only the IR spectra of this complex show an additional strong band at 1481 cm^{-1} indicating a bidentate coordination of one nitrate group to Co(II) ion [32,33] which give as a final result, the CoN_2O_4 chromophore.

3.3. The d–d electronic spectra and magnetic properties

Ligand-field spectra of the $[CoL_2(H_2O)_2](NO_3)_2$ (**3**) complex were recorded in the solid state as well as in solution (methanol). The spectrum of complex **3** in the

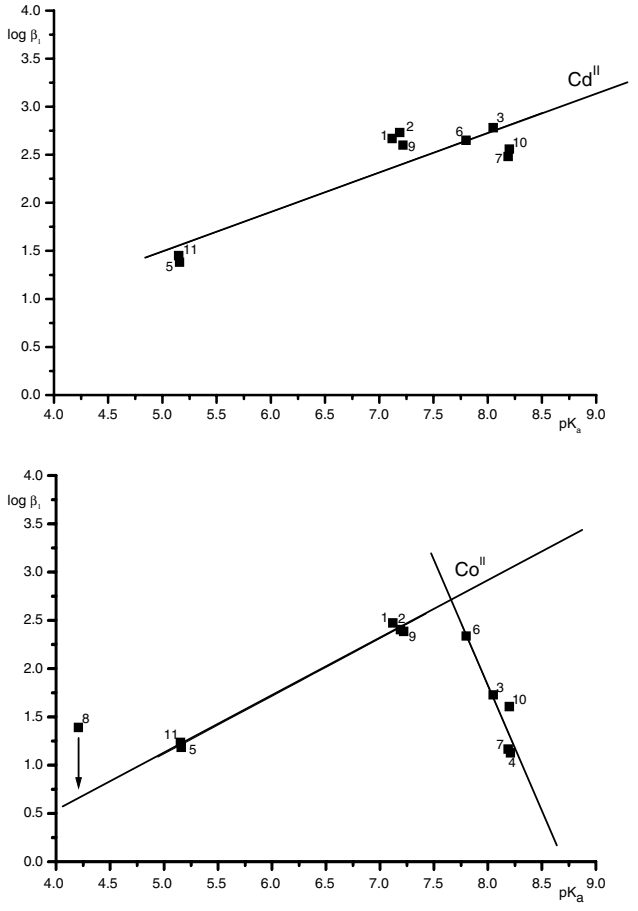

Fig. 5. The dependence of $\log\beta_1 = f(pK_a)$ for the complexes of Cd^{II} and Co^{II} with imidazole derivatives **1**–**11** (Table 7).

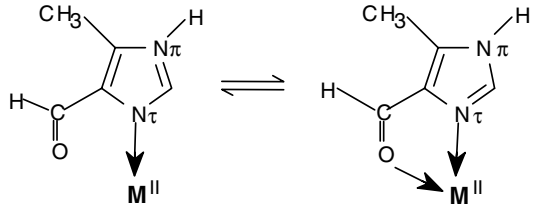
solid state (diffuse reflectance) is characterized by two d–d strong bands and one band of weaker intensity, which are consistent with an octahedral geometry [34]. The first band (ν_1 = 1103 nm) is assigned to the transition $^4T_{2g} \rightarrow {}^4T_{1g}(F)$, while the second ($\nu_2$ = 593 nm), a weak band, is assigned to the transition $^4A_{2g} \rightarrow {}^4T_{1g}(F)$. The third band ($\nu_3$ = 492 nm) assigned to the transition $^4T_{1g}(P) \rightarrow {}^4T_{1g}(F)$ is diffuse and asymmetric, indicating overlap of several bands. The positions of individual bands for the complexes, assuming a Gauss distribution, are: 433 and 518 nm. However, the calculated Racah parameter (B) value is not reliable considering the mixture of two complexes and distortion of the coordinate polyhedron due to the unsymmetrical Co–N and Co–O bonds forming the chelate ring. When the spectrum of complex **3** in methanol solution is recorded, the position of the d–d transition band shifts only slightly to 513 nm 'red shift' (ε = 17.6 M^{-1} cm^{-1}). These results suggest that the coordination sphere around the cobalt(II) ions in solution is the same as in the solid state.

The electronic spectrum of the solid complex **4** shows two strong d–d bands at 1234 and 530 nm (523, 474-Gauss distribution) and a very weak one at 589 nm. The presence of the three chelate rings strongly suggests an even greater distortion from regular octahedral geometry to that observed in complex **3**. The position of the d–d band in the spectrum of complex **4** in methanol solution (ε = 17.7 M^{-1} cm^{-1}) is the same as the position of the analogous one in complex **3**. We regard this as additional evidence for the presence of a species similar in structure to complex **3**. However, when the spectrum of complex **4** is taken in methanol solution, the position of the d–d bands shifts towards the UV region (from 530 to 513 nm) (a partial exchange of the nitrate anion with the methanol molecules).

The effective magnetic moments of the cobalt(II) complexes at room temperature are 4.53 and 4.55 μ_B for (**3**) and (**4**), respectively. These values are consistent with high-spin six-coordinate complexes.

3.4. Investigation in aqueous solution



In order to understand why different elements are found in association with some different organic groups, we have compared the data obtained for the model complexes in the solid state to those in aqueous solution. The acid dissociation constants of protonated imidazolecarbaldehydes and some imidazole derivatives as reference compounds, as well as the equilibrium stability constants of their complexes with Co(II), Zn(II) and Cd(II) determined by the pH potentiometric technique at 298 K are given in Table 7. The data show that the basicity of ligands depends on the side group of the imidazole ring. The basicities of carbaldehyde derivatives are about three orders of magnitude smaller, due to the withdrawing effect of the CHO group, which changes the electron density of the pyridine type nitrogen atom. In order to generalize the conclusion following from the potentiometric investigation of the imidazole complexes, Fig. 5 presents an exemplary correlation between the values of the logarithms of the stability complex of the first complexes of Co(II) and Cd(II) and the ligand basicity. The result indicates that the stability of cadmium(II) complexes, contrary to those of zinc(II) [44] and cobalt(II) do not depend on the steric hindrance to complexation presented by some ligands. All of the experimental points for Cd(II) complexes are found on one line. For Co(II) (Fig. 5(b)) complexes the points corresponding to $\log\beta_1 = f(pK_a)$ for the chosen imidazole derivatives lie about two intersecting lines which were plotted according to linear approximation coefficients, calculated by the least-squares method. The points corresponding to derivatives containing an alkyl substituent situated in position 2 or 4, which present steric hindrance to complexation, are found on the line with negative slope. From our earlier studies [37,38,40,41,43,44] it follows that such ligands, in reaction with the Co(II) and Zn(II) ions, decrease the coordination number of the central ion from six to four. This results in a configuration equilibrium of the octahe-

dron ↔ tetrahedron type. For cobalt(II) complexes this is supported by the position of the absorption maximum and by a high value of the mean molar absorption (ε) coefficient [37,38,40,41,43,44]. The points corresponding to the other Co(II) complexes are found on the line with positive slope. A CHO group situated at position 2 or 4, contrary to CH_3, does not present a steric hindrance to complexation and suggests that an additional interaction of the oxygen atom with the metal ion exists which results in the formation of a weak, five membered chelate. It leads to the establishment a new configurational equilibrium for Co(II) and Cd(II) complexes (Scheme 2).

For example: $[M(H_2O)_5L]^{2+} \leftrightarrow [M(H_2O)_4L]^{2+} + H_2O$ ($M = Co^{II}$, Cd^{II}). Such additional interaction of Co(II) with an O donor atom from the CHO group of 4-Me-5-CHOIm is reflected in an increased complex stability (Fig. 5(b)). According to Siegel [45] a positive value of the differences ($\log\Delta_{M/L} = \log\beta_{1\,exp} - \log\beta_{1\,calc} = 0.64$) between the experimentally measured stability constants ($\log\beta_{1\,exp} = 1.38$) and those expected on the basis of the

Scheme 2. The intramolecular configurational equilibrium for Co(II) and Cd(II) complexes with 4-CHO-5-MeIm.

acid–base properties of the ligand ($\log\beta_{1\,calc} = 0.66$) reflects the extent of the formation of the chelate complex in equilibrium.

The possibility of equilibrium (1) for Cd(II) complexes in aqueous solution (D_2O) is supported by NMR data. The NMR spectra allow coordinated and uncoordinated CHO groups in Cd(II) and Zn(II) complexes to be distinguished. The extent of Zn–O and Cd–O interaction with the aldehyde oxygen can be

estimated by taking into account the $\Delta\delta$ values. These are twofold higher for Cd-4-Me-5-CHOIm compounds ($\Delta\delta = 0.15$ ppm). Than for zinc(II) complexes ($\Delta\delta = 0.08$ ppm.). The role 4-Me-5-CHOIm plays towards the Cd(II) ion (bidentate N,O donor ligand) or as a *N*-monodentate when coordinated to Zn(II), still remains to be elucidated. Both possibilities agree well with the X-ray data (Figs. 1, 3(a)) of Zn(II) and Cd(II) complexes in the solid state (vide supra).

The visible-range absorption spectra of the Co(II) complexes with 4-Me-5-CHOIm in aqueous solutions suggests that complexation in this system involves replacing water molecules in the hydration sphere of the central ion by the ligand molecules with retention of the pseudo-octahedral structure (pH 4.4, $\lambda = 514$ nm, $\varepsilon = 18\ M^{-1}cm^{-1}$).

3.5. Conclusion

In the present study, new complexes of Zn^{II}, Cd^{II} and Co^{II} with 4-Me-5-CHOIm have been prepared and structurally characterized. The structures of all the compounds are very different from each other. In Zn(II) complexes the most common structural motif is one in which a tetrahedral zinc center is attached to four molecules of the ligand. The cobalt derivatives exhibit an octahedral structure in which two imidazoles coordinate to cobalt in a bidentate fashion, while the cadmium complex exhibits an unusual eight-coordinate structure (CdN_4O_4). This comparison clearly emphasizes that zinc has a greater preference for tetrahedral ZnN_4 coordination than do either cobalt or cadmium, an observation that is in accord with the prevalent role of zinc in the structural sites of enzymes. Moreover, the fact that the zinc complexes exhibit different structures to those of cobalt and cadmium should be taken into consideration while using these metals as spectroscopic probes for studying zinc enzymes. The structural data obtained correlate well with studies of these complexes in aqueous solution. The NMR and potentiometric studies have confirmed different modes of coordination of 4-CHO-5-MeIm in the zinc(II) ions (monodentate) in comparison to cobalt(II) and cadmium(II) ions in which the pyridine-like nitrogen atom of the imidazole ring and the oxygen atom of CHO group participate in formation of the coordination bonds. This results in the formulation of a five-membered chelate ring. Furthermore, we have observed some differences in the strength of donor capacity between the Nτ and Nπ nitrogen atoms of the imidazole ring. Coordination by Nτ atoms gives shorter bonds (Table 2.) and more stable complexes in solution (higher value of β_n). Both structural and potentiometric data suggest 4-Me-5-CHOIm as a potentially good chelator for the removal of toxic cadmium from the body.

4. Supplementary material

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication numbers: CCDC 247515–247517 (for **1**–**3**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; (fax: +44 1223 336 033, e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.com.ac.uk).

Received 24 November 2004; accepted 5 January 2005

Abstract

Laser ablation synthesis of heteroatomic Se_mS_n molecules from selenium, selenium–sulfur mixtures and selenium disulfide alone or mixed with selenium and sulfur was studied using common MALDI–TOF (matrix assisted laser desorption-ionization–time of flight) mass spectrometric instrumentation. From elemental gray and red selenium, the formation of Se_m^+ ($m = 2$–9) and Se_m^- ($m = 1$–7) was achieved. Composite Se_mS_n species were obtained when laser pulses were applied onto a selenium–sulfur mixture or to solid selenium disulfide (SeS_2). For the first time, nine-membered Se_mS_n compounds are observed. Likewise, it was observed that positively charged mixed substances formed were of higher molecular weight than the negatively charged ones. Ions $Se_mS_n^-$ with $m + n = 3$ or 4 and $Se_mS_n^+$ with $m + n = 5$ or 8 dominate in the mass spectra of SeS_2. At least 12 new selenium sulfides not described in the literature were identified from the mass spectra, while most of them were generated from selenium disulfide and detected in the positive mode. Their stoichiometry was confirmed using isotopic pattern modelling.

Keywords: Selenium; Sulfur; Selenium disulfide; Laser ablation synthesis; TOF mass spectrometry

1. Introduction

Interaction of laser radiation with solid materials results in several processes. Laser pulses in some cases initialize formation of various species. Mass spectrometry was found to be a powerful tool for studying species formed during laser ablation processes [1].

For preparation of semiconductive nanocrystalline selenium films, beside sublimation of selenium grains and annealing of the amorphous selenium film [2], pulsed laser ablation is becoming the most prospective method. The TOF mass spectrometric identification of charged homopolyatomic species after laser ablation of selenium powder has firstly been reported by Giardini Guidoni et al. [3]. This process has also been studied by Hearley et al. [4], who observed formation of Se_m^+ ($m = 1$–5) and Se_m^- ($m = 1$–6) ions. The cyclic structure of the Se_m ($m = 3$–8) species has been calculated ab initio using the Hartree–Fock method [5]. First-principles local-density-functional calculations of Se_m ($m = 3$–8) have revealed the fact that Se_6 and Se_8 are the most stable species, which is in agreement with two selenium forms identified in crystalline structures [6]. The nature of selenium films created by pulsed laser deposition strongly depends on experimental conditions, such as laser energy density, the number of laser pulses and the nature of the substrate [7].

Sulfur and selenium atoms can be connected together in many ways, often forming heterocyclic compounds

doi:10.1016/j.poly.2005.01.012

that usually possess from six to eight atoms. The procedures for their preparation can be found elsewhere [8, 9 and references therein] . Twelve-membered rings 1,2-Se_2S_{10}, 1,7-Se_2S_{10} and 1,2,3,4,5-Se_5S_7 have also been prepared [10]. According to ab initio MO calculations possible stability of 10-membered Se_5S_5 rings has also been proposed [11]. Smaller Se_mS_n compounds with $n + m \leqslant 6$, Se_4S_4, Se_5S_2, Se_5S_3 and Se_6S positively charged and with $n + m \leqslant 4$ negatively charged were identified from mass spectra produced via laser ablation synthesis from selenium–sulfur melt [4].

The most powerful method for the determination of the structure of Se_mS_n compounds is evidently ^{77}Se NMR [12,13]. Enrichment of the samples by ^{77}Se increases the quality of NMR spectra [14,15]. The ^{77}Se NMR chemical shifts of Se_mS_n were found to be in good agreement with the theoretical values calculated from ab initio molecular orbital and density functional techniques involving Stuttgart relativistic large core effective core potential approximation [16]. Complex mixtures of selenium sulfides can effectively be separated by HPLC [17]. Selenium sulfides undergo interconversion reactions with unknown mechanisms, where formation of intermediates containing hypervalent sulfur atoms is estimated [18], however, unambiguous experimental elucidation of this process is still missing.

Mixed SeS_n ($n = 1$–7) species have been identified by mass spectrometry in sulfur–quartz ores from the Southern Urals [19]. Composite Se_mS_n ($m + n \leqslant 8$) species were identified in mass spectra after electron impact ionization of a selenium–sulfur mixture previously heated and extracted from CCl_4 [20]. Selenium monosulfide was found to be carcinogenic to livers of male and female rats and livers and lungs of female mice [21]. Selenium disulfide has been patented as an antidandruff agent for shampoos [22,23]. Toxicological studies of selenium disulfide have, for example, determined its LD 50 orally for rats as 138 mg/kg [24].

Chalcogen-based thin solid films of composition, s, $SrS_{1-x}Se_x$ or $ZnS_{1-x}Se_x$ possess interesting opto-electronic properties with highly perspective technological applications [25]. Also selenium–sulfur film doped by paraffins and prepared via pulsed laser deposition performs optical memory properties [26].

Laser ablation synthesis from sulfur, selenium and sulfur–selenium mixture was described by Hearley et al. [4]. However, in that work the resolution of the mass spectrometer was too low to allow monitoring of isotopic patterns of the peaks. Therefore, the charge of the observed species could not be determined from the spectra, as, e.g., signals of Se_3^- and Se_6^{2-} were not distinguishable. Moreover, in the case of mixed selenium–sulfur species, the signals of Se_mS_n were equal to $Se_{m+2}S_{n-5}$, because the mass of two atoms of the isotope ^{80}Se (159.83304 Da) is close to five atoms of the isotope ^{32}S (159.86035). Because such pairs of compounds have significantly different isotopic patterns, mass spectrometer with resolution over 500 is needed to distinguish them. In this work, we have therefore re-examined the selenium–sulfur system.

2. Experimental

2.1. Chemicals and reagents

Elemental gray selenium, selenium disulfide, guanosine-5′-monophosphate bradykinin, α-cyano-4-hydroxycinnamic acid and harmane were obtained from Sigma–Aldrich (Steinheim, Germany), red selenium from Charles Druce Ltd. (London, United Kingdom) and elemental sulfur from Spolek pro chemickou a hutní výrobu (Ústí nad Labem, Czech Republic). Benzene was purchased from Lachema a.s. (Brno, Czech Republic). The purity of bradykinin and selenium disulfide was 98%, all other chemicals were of analytical or higher grade purity.

2.2. Apparatus

Mass spectra measurements were performed on an AXIMA CFR (Kratos Analytical, Manchester, United Kingdom) mass spectrometer with nitrogen laser (337 nm) from Laser Science Inc. (Franklin, MA, USA). Molecular ions $[M + H]^+$ of α-cyano-4-hydroxycinnamic acid and bradykinin were applied for external calibration in the positive mode. For the negative mode, molecular $[M - H]^-$ ions of harmane and guanosine-5′-monophosphate were used. Each mass spectrum was accumulated from at least 100 laser shots. The ultrasound bath UC 006 DM1 was obtained from Tesla (Rožnov pod Radhoštěm, Czech Republic).

2.3. Procedure of synthesis

The approach used for laser ablation synthesis in this work is the same as that described in our previous works [27,28]. A suspension containing 1 mg ml^{-1} of fine powdered elements, selenium disulfide or their mixtures in benzene in volume of 1 μl was pipetted onto a sample plate and dried in an air stream at room temperature. Laser pulses initiated the synthesis and products formed were analyzed with pulsed extraction in negative and positive modes, and in linear or reflectron arrangements.

3. Results and discussion

3.1. Se_m and S_n homopolyatomics

In the first stage, powdered elements were applied on the sample probe using a simple procedure described in

the experimental part. When a laser power of 2.0 mW is exceeded, formation of homopolyatomic selenium species is seen both in the positive and negative modes. Positively charged Se_m^+ ($m = 2$–9) and negatively charged Se_m^- ($m = 1$–7) species are detected from powdered red or gray selenium and no different results were observed between these allotropic modifications of selenium. An example of mass spectra obtained from gray selenium in the linear negative mode is shown in Fig. 1. In contrast to previous observations [4], the resolution of Axima-CFR allows us to monitor isotopic patterns of the ions. The detailed view on the Se_5^- anion in Fig. 2 shows an excellent agreement with the model calculated from natural abundance of selenium isotopes. Moreover, the presence of multiply charged selenium species can unambiguously be excluded. The stability of all observed selenium species was examined with the Post-source Decay (PSD) technique. Even with the highest laser power that is possible to be applied with the instrumentation (6 mW), no fragments of Se_m parent ions were observed. It is therefore possible to conclude that the species are relatively stable, more than similar sulfur compounds, which yield intense S_{n-1} and S_{n-2} fragments [27]. Detailed information about formation and behavior of S_n species produced by laser ablation synthesis from the powdered element can be found elsewhere [27,28].

3.2. Mixture of the elements

Several ways of generating mixed Se_mS_n compounds have been examined. Similarly to the phosphorus–sulfur system described before [27], laser ablation synthesis from a simple elemental mixture has been done and the results were compared with those when the selenium–sulfur mixture was previously treated with ultrasound. Moreover, laser ablation of selenium disulfide and also mixtures with elements eventually sonicated have also been studied.

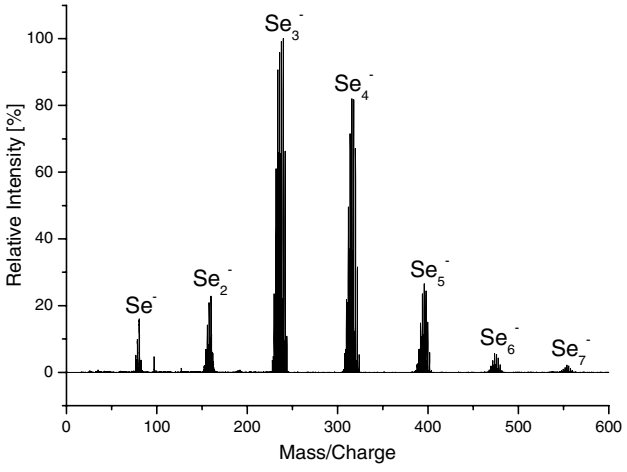

Fig. 1. Mass spectra of negatively charged selenium species produced during laser ablation of gray selenium powder. Linear negative mode with pulsed extraction, laser power of 2.67 mW.

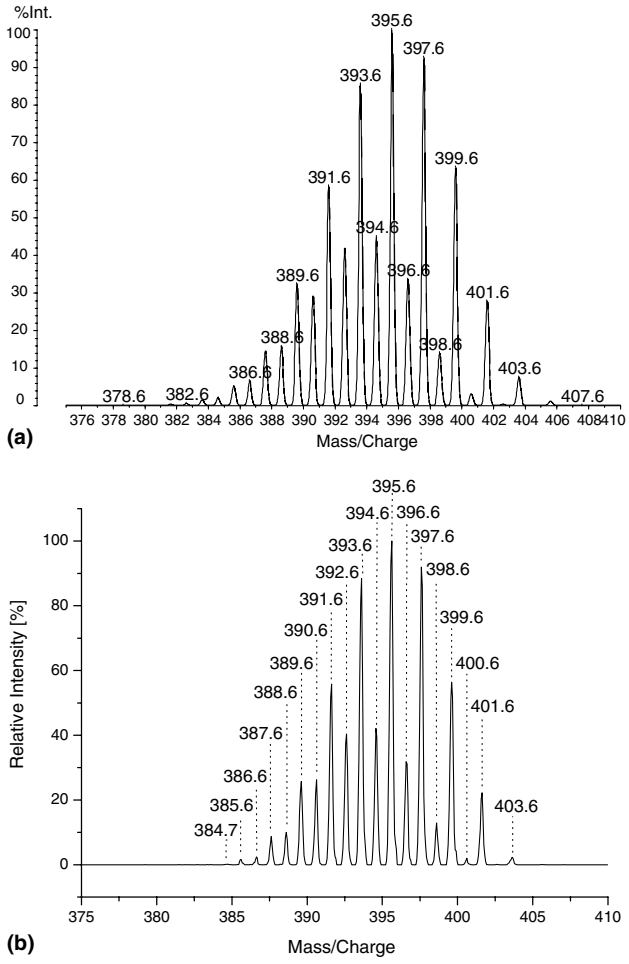

Fig. 2. Theoretical isotopic distribution of the Se_5 ion (a) in comparison with the detailed view on the experimental Se_5^- mass spectra (b).

When laser pulses are aimed at the area where selenium and sulfur are in contact, generation of singly charged heteroatomic ions is achieved. The stoichiometry of the species identified in the mass spectra both in the positive and negative modes is shown in Tables 1 and 2. A difference between theoretical and experimental peak intensities exceeding 5% was considered as an indication of two isotopic patterns overlapping. Compounds with nearly all possible atom combinations for $n + m \leqslant 5$ are formed. Moreover, some additional signals corresponding to a higher number of selenium atoms in these compounds were detected in the negative mode. On the other hand, positively charged species with relatively high selenium–sulfur ratio are also generated. We suggest that the predominance of selenium atoms in the mixed species allows them to be charged negatively and, on the other hand, more sulfur atoms in the species facilitate the possession of the positive

charge. Applying ultrasound for homogenization of the mixture and consecutive laser ablation did not bring any increase in the number of mixed compounds and no sono-synthesis was observed. It is interesting to note that ultrasound had significant influence on the number of species ionized after treatment of the phosphorus–sulfur mixture [28].

These results are only in partial agreement with the findings of Hearley et al. [4]. Our results suggest in addition to previously identified ions, negatively charged Se_mS_n compounds with $n + m = 5$. The authors also observed different peaks that correspond to positively charged eight-membered molecules. However, this difference may be a result of the sample preparation where the mixture of selenium and sulfur was prepared by co-melting of the elements.

3.3. Selenium disulfide

Mass spectra resulting from laser ablation of selenium disulfide are shown in Figs. 3 and 4. The stoichiometry of the selenium sulfides is summarized in Tables 3 and 4. A significant difference between abundance of ions obtained in positive and negative modes was observed. In the negative mode, mixed compounds Se_mS_n with $n + m = 3$ or 4 dominate in the spectra. Population of heavier species is lower and does not exceed the molecular weight of 500 Da. On the contrary, in the positive mode, the species with $n + m = 5$ or 8 dominate in mass spectra and species with low molecular weight almost cannot be observed.

Twenty-five either positively or negatively charged highly abundant species generated from selenium–sulfur mixture or selenium disulfide were studied using the Post-source Decay technique. Besides examining the stability of the ions, the aim of the experiments was to find out whether the species with the same stoichiometry but different origin yield equal fragments under the same conditions. In this way, we wanted to estimate whether their structure is the same or not (isomers).

The experiments revealed that most of the selenium sulfides generated have behavior similar to sulfur homopolyatomics, losing one sulfur atom when laser power of 4.0 mW is exceeded [27]. The behavior of species with the same stoichiometry and different source (e.g., negatively charged ions with $m/z = 269$ Da) was found to be the same, as they lose equally one sulfur atom after exceeding the same threshold laser power. That means that no difference in the properties of these species was observed. Therefore, it is possible to suggest that they possess the same structure. The only exception in the behavior was found in the case of positively charged eight-membered species generated from SeS_2. These compounds undergo interesting fragmentation paths, including the loss of polyatomic neutral species. The compounds $Se_4S_4^+$ and $Se_5S_3^+$ yield a S_3 fragment, $Se_6S_2^+$ loses particles S_2 and SeS_2. In addition, Se_7S^+ ionization with high laser power results in the loss of neutral atoms S, Se and the particle SeS.

It was found that mixing selenium disulfide with selenium or sulfur does not increase the number of species formed. Conversely, in the equimolar mixture of selenium and selenium disulfide, formation of compounds with higher numbers of sulfur atoms, such as SeS_9^+, $Se_2S_n^+$ ($n = 5, 7$), $Se_3S_9^+$ and $Se_mS_5^-$ ($m = 1$–2), is suppressed. Also here, all mixtures were homogenized by ultrasound without any increase in the number of Se_mS_n molecules observed.

An overview of all known compounds together with new compounds synthesized in this work is given in Table 5. In total, 12 new heteroatomic species were identified. However, atoms in all these compounds can be arranged into numerous isomeric forms and therefore, the total number of new species formed can be much higher.

It follows from a comparison of the results summarized in Tables 1 and 3 or in Tables 2 and 4 that the number and the nature of the species formed from laser ablation of the elemental mixture and from selenium disulfide is significantly different. It seems that some of the Se–S bonds in selenium disulfide are not broken during the LA process and therefore, species with higher

molecular weight can be formed. Most of the newly observed species correspond to Se_mS_n compounds with $n + m = 9$. Nine-membered heteroatomic selenium–sulfur species have not yet been reported. Hypervalence of some of the atoms previously supposed in relation to interconversion reactions of selenium sulfides [18] is possible. Eventually, during the LA process some interconversion reactions between Se_mS_n molecules take place and the fast analytical procedure applied in this work allows them to be detected.

4. Conclusions

Twelve compounds of stoichiometry SeS_n ($n = 8$, 9), Se_2S_7, Se_3S_n ($n = 6$, 7, 9), Se_4S_n ($n = 5$, 6, 8), Se_5S_4, Se_6S_3 and Se_7S_2 have been newly identified. Most of them were obtained via laser ablation synthesis of selenium disulfide powder in the positive mode. Laser ablation of selenium, sulfur and their mixtures has also been examined and the mass spectra were interpreted including isotopic pattern modelling. Compounds with the same stoichiometry but different origin (SeS_2 or Se–S mixture) were found to perform identical Post-source Decay behavior, losing one sulfur atom when high laser power is applied for their generation. Selenium species Se_m^- ($m = 1$–7) and Se_m^+ ($m = 2$–9) have unambiguously been identified. The effect of ultrasound homogenization was found to have no influence on the ionization process when selenium–sulfur mixtures were subsequently ablated. The same was observed for mixtures arising from selenium disulfide. The advantage of laser ablation synthesis as a tool for generation and TOF mass spectrometric identification of new compounds in Se–S systems has been proved in this work.

Abstract

Treatment of $Ba(N(SiMe_3)_2)_2(THF)_2$ with tetraglyme or triglyme (1 equiv) followed by 3,5-di-*tert*-butylpyrazole (2 equiv) in toluene afforded bis(3,5-di-*tert*-butylpyrazolato)(tetraglyme)barium (68%) and bis(3,5-di-*tert*-butylpyrazolato)(triglyme)barium (32%) as colorless solids after crystallization from hexane. Similar treatment of $Sr(N(SiMe_3)_2)_2(THF)_2$ with tetraglyme, triglyme or *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDETA) (1 equiv) followed by 3,5-di-*tert*-butylpyrazole (2 equiv) in toluene afforded bis(3,5-di-*tert*-butylpyrazolato)(tetraglyme)strontium (50%), bis(3,5-di-*tert*-butylpyrazolato)(triglyme)strontium (73%) and bis(3,5-di-*tert*-butylpyrazolato)(PMDETA)strontium(II) (64%), respectively, as colorless solids. The X-ray crystal structures of these complexes revealed monomeric molecules in which each metal coordination sphere is capped by one neutral polydentate ligand and two terminal η^2-pyrazolato ligands. Volatility studies showed that these complexes fail to sublime, and rather decompose under sublimation conditions with neutral ligand loss for the barium complexes and loss of the neutral ligands and 3,5-di-*tert*-butylpyrazole for the strontium complexes.

1. Introduction

There is considerable interest in organometallic complexes of the heavier group 2 elements (Ca, Sr, Ba) that can serve efficiently as precursors in chemical vapor deposition (CVD) film growth processes [1–3]. Desirable properties of CVD precursors include high thermal stability, acceptable volatility below the decomposition temperature, lack of elements that might contaminate the thin film material, as well as efficient film growth chemistry. These restrictions are particularly challenging in the heavier alkaline earth metals because of the large ion sizes and low charge/radius ratios, which lead to polymeric complexes, weak ligand–metal interactions and generally low thermal stability [4]. Therefore, careful selection of ligands is a central issue in the design of CVD precursors for the heavier group 2 elements. To date, cyclopentadienyl, β-diketonato and β-ketoiminato ligands have been the most widely employed in group 2 CVD precursors, since these ligands can provide monomeric structures with sufficient thermal stability to allow vapor transport [1–3]. However, many problems have been encountered in film growth with these existing precursors, including low vapor pressure, erratic vapor transport, unacceptably high carbon incorporation in the thin film materials and premature precursor decomposition by loss of neutral ligands. To overcome some of these problems, fluorinated β-diketonato ligands have been employed to increase the Lewis acidity of the group

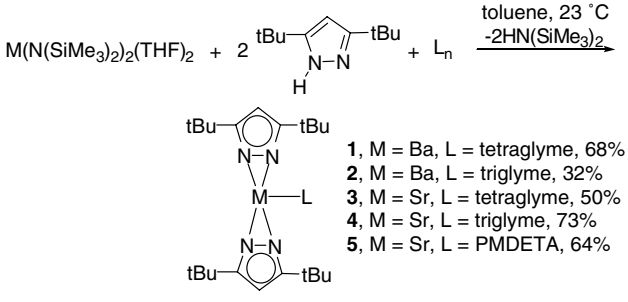
doi:10.1016/j.poly.2005.01.011

2 metal centers and thus enhance thermal stability, and polydentate donor ligands have been used to saturate the coordination spheres of the metal ions [1,3d,3e]. In addition, alternative film growth procedures have been employed to minimize problems with thermal precursor decomposition. These have included aerosol-assisted CVD [5], spray pyrolysis [6], spray MOCVD [7], supercritical fluid transport CVD [8], atomic layer deposition [9] and liquid delivery MOCVD [10].



Recently, we have reported the synthesis and characterization of several magnesium [11] and calcium [12] complexes that contain various nitrogen donor ligands. The majority of our efforts in this area have been aimed at preparing volatile pyrazolato complexes that might be used as CVD precursors, since the pyrazolato ligand bears some similarity to the widely used cyclopentadienyl and β-diketiminato ligands. The pyrazolato ligand is a versatile nitrogen donor ligand, and has been employed with metals across the periodic table [13]. Very few pyrazolato complexes of strontium and barium have been reported [14]. In related work, neutral 3,5-dimethylpyrazole was used as a capping ligand in several volatile barium and strontium β-diketonato complexes [15]. While heavier group 2 CVD precursors with nitrogen donor ligands remain poorly developed, $Ba(tmhd)_2(hmtt)$ (tmhd = tetramethylheptanedionate; hmtt = 1,1,4,7,10,10-hexamethyltriethylenetetramine) binds hmtt selectively over tetraglyme and exhibits enhanced vapor transport relative to $Ba(tmhd)_2$(tetraglyme) [16]. $Ba(tmhd)_2(tetraen)_2$ (tetraen = triethylenetetramine) has been evaluated as a precursor to YBCO films, and is claimed to be substantially more volatile and thermally stable than related $Ba(tmhd)_2$ sources [17]. Marks and colleagues [3e] have reported a series of thermally stable precursors of the formula $Ba(hfac)_2$(polyether) (hfac = 1,1,1,5,5,5-hexafluoro-2,4-pentanedionato), and a key to their thermal stability is the electron-withdrawing character of the hfac ligand. Based upon these precedents, exploration of group 2 compounds containing electron-withdrawing nitrogen donor ligands such as pyrazolato might provide new leads for group 2 CVD source compounds.

Within the above context, we report the synthesis and structural characterization of several monomeric strontium and barium complexes that contain pyrazolato ligands along with neutral polydentate nitrogen and oxygen donor ligands. Solid state structural determinations reveal monomeric complexes with terminal η^2-pyrazolato ligands. The polydentate donor ligands saturate the remaining coordination sites and thus ensure the formation of monomeric complexes. The complexes described herein are not volatile, and instead decompose upon heating with loss of the neutral donor ligands. Thus, the bis(pyrazolato)metal fragment does not possess sufficient Lewis acidity to impart the thermal stability that is required for use in a CVD precursor.

2. Results and discussion

2.1. Synthesis and properties of new complexes

Even though we have employed salt metathesis routes to prepare many magnesium [11i] and calcium [12] pyrazolato complexes, this method was not successful for the synthesis of the strontium and barium pyrazolato complexes described herein. Instead, salt methathesis routes afforded complex reaction mixtures from which pure products could not be isolated. Previous workers with barium and strontium have emphasized that the larger ionic size and the reduced electronegativity of strontium and barium tend to lead to polymeric insoluble species, which are often charged "ate" complexes [18]. An alternative route to complexes of the heavier alkaline earth metals is through protonation reactions involving silylamido precursors [14c,19]. Thus, we examined the reactions of 3,5-di-*tert*-butylpyrazole (tBu$_2$pzH) with silylamido complexes of strontium and barium. Treatment of $Ba(N(SiMe_3)_2)_2(THF)_2$ [20] with 2 equivalents of tBu$_2$pzH in the presence of tetraglyme or triglyme (1 equiv) afforded Ba(tBu$_2$pz)$_2$(tetraglyme) (**1**, 68%) and Ba(tBu$_2$pz)$_2$(triglyme) (**2**, 32%) as colorless crystals after workup (Eq. (1)). Analogous treatment of $Sr(N(SiMe_3)_2)_2(THF)_2$ [21] with tBu$_2$pzH in the presence of tetraglyme, triglyme or *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (PMDETA) afforded Sr(tBu$_2$pz)$_2$(tetraglyme) (**3**, 50%), Sr(tBu$_2$pz)$_2$(triglyme) (**4**, 73%) and Sr(tBu$_2$pz)$_2$(PMDETA) (**5**, 64%) as colorless crystalline solids.

(1)

The formulations and structures of **1**–**5** were established by spectral and analytical methods and by X-ray crystallography. As described below, the solid state structures of **1**–**5** consist of monomeric complexes containing terminal η^2-tBu$_2$pz ligands and the neutral donor ligand L with its maximum number of Lewis basic sites coordinated to the metal centers. The NMR spectra of **1**–**5** are simple and consist of well-resolved, sharp signals for both the proton and the carbon atoms. In the ^{1}H NMR spectra of **1**–**4**, the signals for the *tert*-butyl groups and the pyrazolato ligand core methine fragment appear in a narrow range of δ = 1.61–1.64 and δ = 6.41–6.29 ppm, respectively. A small difference was observed

for the *tert*-butyl group ^{1}H NMR resonance in **5**, which appears slightly upfield at $\delta = 1.55$ ppm. In the $^{13}C\{^1H\}$ NMR of **1–5**, the signals for the carbon atoms of the pyrazolato ligand core methine fragment appear between $\delta = 96.05$ and 97.67 ppm.

To assess the potential use of **1–5** as precursors in CVD applications, preparative sublimation experiments were carried out in a horizontal sublimation apparatus. Samples of **1–5** (~0.5 g) were loaded in the sublimation apparatus under argon and then were heated gradually at 0.05 torr. Complexes **1** and **2** did not sublime, but decomposed at about 130–150 °C to afford the neutral ligands at the cold end of the sublimation tube and nonvolatile white residues at the hot end of the sublimation tube. The nonvolatile residues were insoluble in toluene and were not analyzed further. Presumably, these complexes are of the formula $[Ba(tBu_2pz)_2]_n$. Thermal decomposition was also observed for **3–5**, however, both the neutral ligands and some of the tBu_2pzH sublimed between 130 and 150 °C. Again, the nonvolatile residues were insoluble in toluene, and were not analyzed further.

2.2. X-ray crystal structures of *1–3*

The X-ray crystal structures of **1–5** were determined in order to establish the molecular geometry about the metal center and the binding modes of the pyrazolato ligands. The diffraction experiments for **4** and **5** yielded poor results and are not discussed herein. However, the molecular structures of **4** and **5** were unambiguously established from these analyses. Experimental crystallographic data for **1–3** are summarized in Table 1, selected bond lengths and angles are given in Tables 2–4 and perspective views are presented in Figs. 1–3.

[a] The designator #1 indicates a symmetry related position $1/2 - x$, $1/2 - y$, z.

Complex **1** crystallizes from hexane as nine-coordinate, monomeric molecules (Fig. 1). Each barium center is bonded to two η^2-tBu_2pz ligands and one η^5-tetraglyme ligand. The overall geometry about the barium ions is distorted pentagonal bipyramidal if the centers of the nitrogen–nitrogen bonds of the pyrazolato ligands are considered to be monodentate donors. The tetraglyme ligand is situated in the equatorial plane, with the barium atom and five tetraglyme oxygen atoms being approximately coplanar. The η^2-tBu_2pz ligands occupy the axial sites. The barium–nitrogen bond distances range between 2.702(5) and 2.763(5) Å. The longer barium–nitrogen bond lengths are associated with the

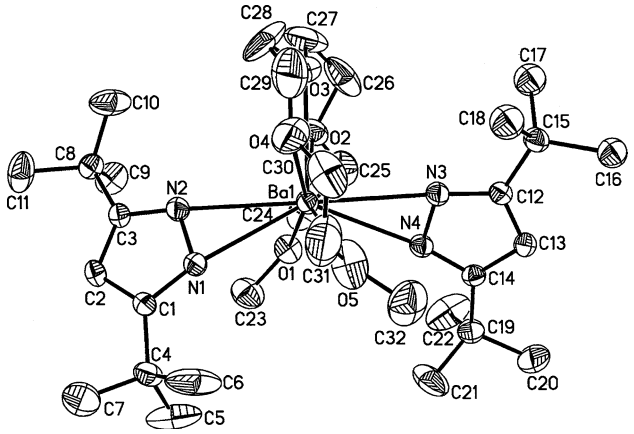

Fig. 1. Perspective view of **1** with probability ellipsoids at the 20% level.

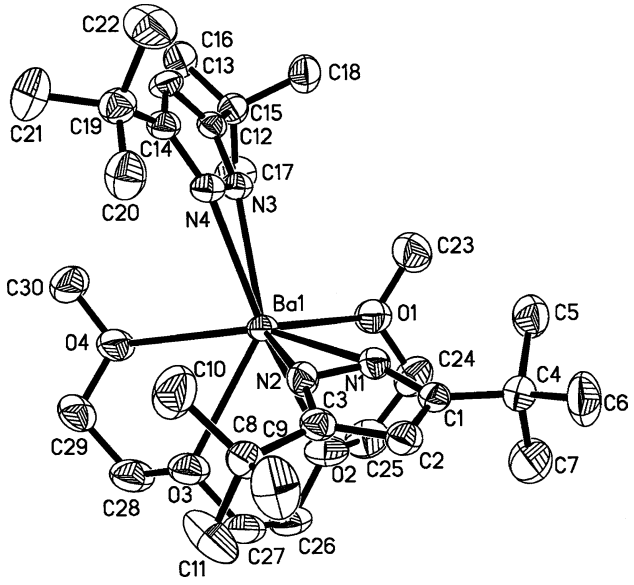

Fig. 2. Perspective view of **2** with probability ellipsoids at the 50% level.

nitrogen atoms (N(2), N(3)) that are farther from the open mouth of the tetraglyme ligand, and it is highly likely that this slight lengthening is due to steric interactions between the tetraglyme carbon atom backbone and the *tert*-butyl groups containing C(8) and C(15). However, the differences between the short and long barium–nitrogen bonds are small ($\Delta_{Ba-N} = 0.047$, 0.054 Å), and are consistent with η^2-bonding of the tBu$_2$pz ligand. The nitrogen–barium–nitrogen bite angles are 29.17(14)° and 29.25(13)°. The planes of the C_3N_2 cores of the tBu$_2$pz ligands are twisted from each other by 57.3(3)°. The tetraglyme ligand wraps around the barium center with barium–oxygen bond lengths of 2.797(7)–2.899(8) Å.

Complex **2** exists as an eight-coordinate monomeric molecule in which the barium center is bonded to two η^2-pyrazolato ligands and one η^4-triglyme ligand (Fig. 2). The triglyme ligand oxygen atoms are approximately

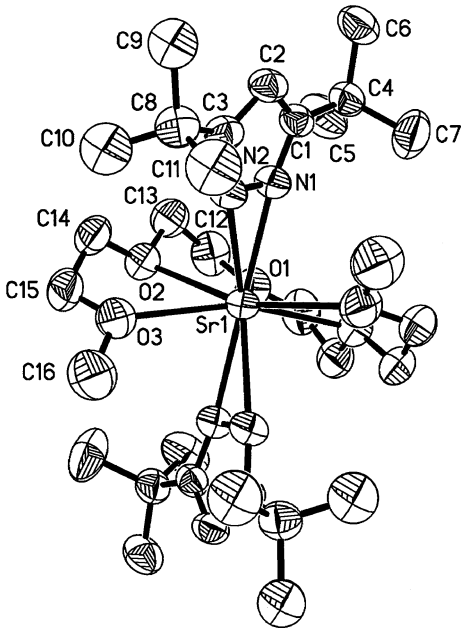

Fig. 3. Perspective view of **3** with probability ellipsoids at the 50% level.

coplanar with the barium center, while the pyrazolato ligands are *trans* to each other with a bent arrangement towards the open side of the triglyme ligand. Therefore, the geometry about the barium center is distorted octahedral if the centers of the nitrogen–nitrogen bonds of the pyrazolato ligands are considered to be monodentate donors. The barium–nitrogen bond distances range between 2.678(2) and 2.723(2) Å. This range is slightly shorter than that of **1**, which is most likely due to the lower coordination number of the barium atom of **2**, compared to that of **1**. Within each tBu$_2$pz ligand, the differences in the barium–nitrogen bond lengths ($\Delta_{Ba-N} = 0.031$ Å) are at the edge of experimental uncertainty. Thus, the tBu$_2$pz ligand exhibits idealized η^2-bonding. The bite angles of the pyrazolato ligands about the barium atom are 29.76(6)°. The C_3N_2 cores of the tBu$_2$pz ligands are twisted from each other by 49.16(8)°. The twisting of the pyrazolato ligand cores may result from steric interactions between the *tert*-butyl groups containing C(8) and C(19). The triglyme ligand is bonded to the barium center through four approximately coplanar oxygen atoms with barium–oxygen bond lengths of 2.812(2)–2.861(2) Å.

Complex **3** crystallizes from hexane as a 9-coordinate monomer (Fig. 3). The molecule is located on a twofold rotation axis that passes through both the strontium center and O(1). The strontium ion is coordinated to two η^2-pyrazolato ligands and one η^5-tetraglyme ligand, with an overall geometry that is similar to that of **1**. The strontium–nitrogen bond lengths are 2.563(2) and 2.578(2) Å, and are consistent with idealized η^2-bonding of the tBu$_2$pz ligand. The bite angle of the pyrazolato

ligand is 31.36(7)°, which is slightly larger than the related values in **1** and **2** due to the shorter strontium–nitrogen bond lengths in **3**. The C_3N_2 cores of the tBu$_2$pz ligands are twisted from each other by 66.43(8)°. The twisting of the pyrazolato ligand cores may result from steric interactions between the *tert*-butyl groups containing C(8) and C(8′). The strontium–oxygen bond distances range between 2.631(3) and 2.752(2) Å.

2.3. Comments on the synthetic route to *1*–*5*

As noted above, protonation reactions between M(N(SiMe$_3$)$_2$)$_2$(THF)$_2$ (M = Sr, Ba) and tBu$_2$pzH in the presence of the neutral polydentate ligand L provide **1**–**5** in moderate to good crystallized yields. A recent report on pyrazolato complexes of calcium, strontium and barium has summarized the synthetic approaches reported to date [14c]. Treatment of M(N(SiMe$_3$)$_2$)$_2$(THF)$_2$ (M = Ca, Sr, Ba) with 3,5-dimethylpyrazole (Me$_2$pzH) afforded low and variable yields of M(Me$_2$pz)$_2$(Me$_2$pzH)$_4$. With the correct stoichiometry of 1:6, free Me$_2$pzH was obtained in the product mixture and M(Me$_2$pz)$_2$(Me$_2$pzH)$_4$ could not be isolated as pure materials. This result contrasts with the efficient preparations of **1**–**5** described herein. It is possible that the liberated HN(SiMe$_3$)$_2$ competes with Me$_2$pzH for coordination to the metal centers, which could result in a mixture of products. In the preparation of **1**–**5**, the neutral donor ligands L should bind with higher formation constants than monodentate ligands such as HN(SiMe$_3$)$_2$ or tBu$_2$pzH. Thus, the success or failure of protonation reactions involving M(N(SiMe$_3$)$_2$)$_2$(THF)$_2$ may be dependent upon the relative donor properties of the new ligands versus the parent pyrazoles and HN(SiMe$_3$)$_2$. Other side reactions of group 2 amido complexes have been reported during protonation reactions [22].

2.4. Comparison of the solid state structures of *1*–*3* with those of previously reported group 2 pyrazolato complexes

Until recently, structurally characterized pyrazolato complexes of strontium and barium were limited to [Ba{(Me$_2$pz)$_3$Ge}$_2$] · (dioxane)$_{0.5}$ [14a] and [Ba$_6$(Me$_2$pz)$_8$(THF)$_6${(OSiMe$_2$)$_2$O}$_2$] [14b]. [Ba{(Me$_2$pz)$_3$Ge}$_2$] · (dioxane)$_{0.5}$ has barium–nitrogen distances of 2.779(4)–2.967(4) Å, which are longer than those in **1** and **2** because the pyrazolato ligands in [Ba{(Me$_2$pz)$_3$Ge}$_2$] · (dioxane)$_{0.5}$ are bridging while those in **1** and **2** are terminal. [Ba$_6$(Me$_2$pz)$_8$(THF)$_6${(OSiMe$_2$)$_2$O}$_2$] has barium–nitrogen distances of 2.665(9)–2.694(8) Å for the terminal η^2-Me$_2$pz ligands and 2.792(7)–3.007(8) Å for the bridging $\mu,\eta^2{:}\eta^5$-Me$_2$pz ligands. The barium–nitrogen distances in the terminal η^2-Me$_2$pz ligands are similar to the values found in **1** (2.702(5)–2.763(5) Å) and **2** (2.678(2)–2.723(2) Å). [Ba$_6$(Me$_2$pz)$_8$(THF)$_6${(OSiMe$_2$)$_2$O}$_2$] contains terminal η^2-pyrazolato ligands, like **1** and **2**, but it also contains $\mu,\eta^2{:}\eta^5$-pyrazolato ligands.

A recent report by Deacon and Ruhlandt-Senge described the synthesis and structural characterization of a series of group 2 pyrazolato complexes that included M(Ph$_2$pz)$_2$(THF)$_4$ (M = Ca, Sr, Ba), M(Ph$_2$pz)$_2$(DME)$_n$ (M = Ca, Sr, n = 2; M = Ba, n = 3) and M(Me$_2$pz)$_2$(Me$_2$pzH)$_4$ (M = Ca, Sr) [14c]. This study provides the first examples of strontium pyrazolato complexes, and greatly increases the amount of structural data that is available for complexes of the heavier group 2 metal containing pyrazolato ligands. In eight-coordinate M(Ph$_2$pz)$_2$(THF)$_4$, the strontium–nitrogen and barium–nitrogen distances range between 2.539(3)–2.639(3) and 2.736(5)–2.813(5) Å, respectively. For nine-coordinate **3**, the strontium–nitrogen distances (2.563(2), 2.578(2) Å) are similar to those in Sr(Ph$_2$pz)$_2$(THF)$_4$, in spite of the difference in coordination numbers at the metal center. For nine-coordinate **1** and eight-coordinate **2**, the barium–nitrogen distances (**1**, 2.702(5)–2.763(5) Å; **2**, 2.678(2)–2.723(2) Å) are similar to slightly shorter than the analogous values in Ba(Ph$_2$pz)$_2$(THF)$_4$. It is possible that the polydentate ether ligands in **1**–**3** are less bulky than four monodentate tetrahydrofuran ligands, which allows closer approach of the tBu$_2$pz ligands. In eight-coordinate Sr(Ph$_2$pz)$_2$(DME)$_2$, the strontium–nitrogen bond lengths range between 2.539(3) and 2.566(3) Å, whereas the barium–nitrogen distances in ten-coordinate Ba(Ph$_2$pz)$_2$(DME)$_3$ lie between 2.735(4) and 2.796(4) Å. Again, these values overlap with those of **1**–**3**. The strontium–nitrogen bond length for the pyrazolato ligands in six-coordinate Sr(Me$_2$pz)$_2$(Me$_2$pzH)$_4$ is 2.622(2) Å, which is within the same range as those observed in **3**. Thus, the metal–nitrogen bond lengths in **1**–**3**, M(Ph$_2$pz)$_2$(THF)$_4$, M(Ph$_2$pz)$_2$(DME)$_n$ and M(Me$_2$pz)$_2$(Me$_2$pzH)$_4$ are not particularly sensitive to the coordination number at the metal center. Instead, variations in the metal–nitrogen distances may originate from intramolecular and intermolecular steric interactions between the pyrazolato ligand carbon atom substituents and the carbon backbones of the neutral donor ligands. Since the bonding in complexes of the heavier group 2 elements is predominantly ionic [1a,1d], small variations in the metal–nitrogen bond lengths are unlikely to be high in energy and can be balanced by crystal packing interactions.

The results described herein, coupled with previous reports of group 2 pyrazolato complexes [11i,12,14], demonstrate that η^2-pyrazolato ligand bonding is strongly preferred. Until recently, the η^2-pyrazolato ligand coordination mode was rare and was limited to a few lanthanide and actinide complexes [13]. However, work in the past few years has greatly expanded the number of crystallographically characterized complexes with η^2-pyrazolato ligands [23], and there is a good

precedent for this coordination mode. Since the bonding in group 2 complexes is predominantly ionic, it is very likely that η^2-pyrazolato ligand bonding is preferred because it entails maximum charge contact between the filled nitrogen-based orbitals and the positively charged metal ions.

2.5. Comments on CVD precursor design for the group 2 elements

Marks and coworkers have described the synthesis of barium CVD precursors of the formula $Ba(hfac)_2$(polyether) [3e], and have demonstrated that these precursors are thermally stable and can be delivered steadily in the gas phase using thermal evaporation. However, the presence of fluorine in these precursors is a liability, since fluorine can degrade the properties of many thin film materials. It was our original thought that replacement of the hfac ligand by a pyrazolato ligand might lead to complexes that retain high thermal stability, since the electronegative nitrogen atoms might impart electron withdrawing properties similar to those of the hfac ligand. In our previous report on calcium pyrazolato complexes of the formula $Ca(t\text{Bu}_2\text{pz})_2(L)$ [12], we noted that only $Ca(t\text{Bu}_2\text{pz})_2$(triglyme) was volatile and proposed that the volatility in these complexes was related to the steric fit of the neutral polydentate ligand about the calcium center. Thus, it was possible that analogous complexes of the larger ions strontium and barium would be thermally stable and volatile due to decreased intramolecular steric interactions between the pyrazolato and L ligands. This prediction was the motivation for the present study. However, the results of this study have demonstrated that **1**–**5** lack sufficient thermal stability to serve as CVD precursors, and instead decompose upon heating in the solid state to afford the neutral ligand and $t\text{Bu}_2\text{pzH}$. The lower charge/radius ratios of strontium and barium ions make them weaker Lewis acids than the calcium ion. Thus, the metal centers in **1**–**5** are not sufficiently strong Lewis acids to retain the neutral Lewis bases at temperatures required for vapor transport. Potential approaches to increase the Lewis acidity of strontium and barium complexes include the use of more electron-withdrawing fluorinated pyrazolato ligands or to use more nitrogen-rich electron withdrawing heterocyclic ligands such as 1,2,4-triazolate or tetrazolate. These and other objectives are being currently pursued in our laboratory.

2.6. Conclusions

We have prepared and structurally characterized a series of monomeric strontium and barium complexes that contain $t\text{Bu}_2\text{pz}$ ligands and neutral polyether or polyamine donor ligands. The $t\text{Bu}_2\text{pz}$ ligands bond to the metal centers with the terminal η^2-coordination mode, and the neutral polydentate ligands then saturate the remaining coordination sites. These complexes fail to sublime and are therefore not of potential utility in CVD applications that employ thermal precursor delivery. However, the results described herein complexes provide further insight into the coordination of pyrazolato ligands to group 2 metal centers, and offer new directions in the design of volatile precursors for film growth.

3. Experimental

3.1. General considerations

All reactions were performed under an inert atmosphere of argon using either glovebox or Schlenk line techniques. Toluene and hexane were distilled from sodium. PMDETA, triglyme and tetraglyme were purchased from Aldrich Chemical Company and were dried by distillation from sodium prior to use. $Ba(N(SiMe_3)_2)_2(THF)_2$ [20] and $Sr(N(SiMe_3)_2)_2(THF)_2$ [21] were prepared according to literature methods. 3,5-Di-*tert*-butylpyrazole was synthesized according to a literature method [24]. ^1H and $^{13}C\{^1H\}$ NMR spectra were obtained at 300 or 75 MHz in benzene-d_6. Infrared spectra were obtained using Nujol as the medium. Elemental analyses were performed by Midwest Microlab, Indianapolis, IN. Melting points were obtained on a Haake-Buchler HBI digital melting point apparatus and are uncorrected.

3.2. Preparation of bis(3,5-di-tert-butylpyrazolato)(tetraglyme)barium (*1*)

A 100 ml Schlenk flask was charged with $Ba(N(SiMe_3)_2)_2(THF)_2$ (0.251 g, 0.416 mmol), tetraglyme (0.092 ml, 0.416 mmol) and toluene (30 ml). The resultant mixture was stirred at ambient temperature for 0.25 h. To this solution was added $t\text{Bu}_2\text{pzH}$ (0.150 g, 0.832 mmol) and the resultant mixture was stirred for an additional 3 h. The volatile components were removed under reduced pressure to afford a colorless crystalline solid. This solid was redissolved in hexane (40 ml) and was stored at −25 °C for 24 h to afford **1** as colorless crystals (0.200 g, 67%): m.p. 250–260 °C (dec, loses tetraglyme); IR (Nujol, cm^{-1}) 3096 (m), 1504 (s), 1353 (s), 1313 (m), 1218 (m), 1097 (s), 1022 (m), 1006 (s), 994 (s), 948 (s), 869 (w), 851 (s), 831 (w), 764 (s); ^1H NMR (benzene-d_6, 23 °C, δ) 6.36 (s, 2H, pyrazolato ring C–***H***), 3.18 (m, 4H, CH_3–O–CH_2CH_2–O–$CH_2C\boldsymbol{H}_2$), 3.15 (m, 4H, CH_3–O–CH_2CH_2–O–$C\boldsymbol{H}_2CH_2$), 2.97 (m, 4H, CH_3–O–$CH_2C\boldsymbol{H}_2$–O–CH_2CH_2), 2.92 (m, 4H, CH_3–O–$C\boldsymbol{H}_2CH_2$O–CH_2CH_2), 2.71 (s, 6H, O–$C\boldsymbol{H}_3$), 1.64 (s, 32H, $C(C\boldsymbol{H}_3)_3$); $^{13}C\{^1H\}$ NMR (benzene-d_6, 23 °C, ppm) 158.26 (s, pyrazolato ring ***C***–$C(CH_3)_3$),

96.09 (s, pyrazolato ring ***C***–H), 70.51 (s, CH_3–O–***C***H_2CH_2–O–CH_2CH_2), 70.32 (s, CH_3–O–CH_2***C***H_2–O–CH_2CH_2), 68.99 (s, CH_3–O–CH_2CH_2–O–***C***H_2CH_2), 68.82 (s, CH_3–O–CH_2CH_2O–CH_2***C***H_2), 58.29 (s, O–***C***H_3), 32.54 (s, pyrazolato ***C***$(CH_3)_3$), 32.32 (s, pyrazolato C(***C***$H_3)_3$).

Anal. Calc. for $C_{32}H_{60}BaN_4O_5$: C, 53.52; H, 8.42; N, 7.80. Found: C, 53.24; H, 8.35; N, 7.93%.

3.3. Preparation of bis(3,5-di-tert-butylpyrazolato)(triglyme)barium (2)

In a fashion similar to the preparation of **1**, treatment of $Ba(N(SiMe_3)_2)_2(THF)_2$ (0.251 g, 0.416 mmol) with triglyme (0.800 ml, 0.416 mmol) and *t*Bu_2pzH (0.150 g, 0.832 mmol) in toluene (30 ml) afforded **2** as colorless crystals (0.090 g, 32%): m.p. 210 °C (dec); IR (Nujol, cm^{-1}) 1507 (s), 1402 (m), 1355 (s), 1314 (m), 1247 (s), 1220 (m), 1202 (s), 1091 (s), 1069 (s), 1020 (w), 1008 (s), 994 (s), 943 (s), 864 (m), 842 (s), 825 (w), 766 (s); ^{1}H NMR (benzene-d_6, 23 °C, δ) 6.41 (s, 2H, pyrazolato ring C–***H***), 3.03 (s, 4H, C***H***$_2$–O–CH_2CH_2), 2.96 (s, 8H, CH_2–O–C***H***$_2$C***H***$_2$), 2.78 (s, 6H, O–C***H***$_3$), 1.63 (s, 32H, C(C***H***$_3)_3$); ^{13}C{^{1}H} NMR (benzene-d_6, 23 °C, ppm) 158.59 (s, pyrazolato ring ***C***–C$(CH_3)_3$), 96.95 (s, pyrazolato ring ***C***–H), 70.69 (s, ***C***H_2–O–CH_2CH_2), 69.86 (s, CH_2–O–***C***H_2CH_2), 69.76 (s, CH_2–O–CH_2***C***H_2), 58.29 (s, O–***C***H_3), 32.25 (s, pyrazolato ***C***$(CH_3)_3$), 32.32 (s, pyrazolato C(***C***$H_3)_3$).

Anal. Calc. for $C_{30}H_{56}BaN_4O_4$: C, 53.45; H, 8.37; N, 8.31. Found: C, 53.36; H, 8.03; N, 8.06%.

3.4. Preparation of bis(3,5-di-tert-butylpyrazolato)(tetraglyme)strontium (3)

In a fashion similar to the preparation of **1**, treatment of $Sr(N(SiMe_3)_2)_2(THF)_2$ (0.230 g, 0.416 mmol) with tetraglyme (0.092 ml, 0.416 mmol) and *t*Bu_2pzH (0.150 g, 0.832 mmol) in toluene (30 ml) afforded **3** as colorless crystals (0.140 g, 50%): m.p. 180–185 °C; IR (Nujol, cm^{-1}) 3096 (m), 1504 (s), 1423 (s), 1400 (s), 1377 (vs), 1317 (s), 1283 (w), 1266 (w), 1245 (vs), 1202 (s), 1117 (vs), 1096 (vs), 1067 (vs), 1025 (vs), 1006 (s), 997 (m), 951 (s), 875 (w), 854 (vs), 834 (w), 801 (w), 766 (vs); ^{1}H NMR (benzene-d_6, 23 °C, δ) 6.29 (s, 2H, pyrazolato ring C–***H***), 3.23 (m, 8H, CH_3–O–CH_2CH_2–O–C***H***$_2$C***H***$_2$), 3.04 (m, 4H, CH_3–O–CH_2C***H***$_2$–O), 2.98 (m, 4H, CH_3–O–C***H***$_2CH_2$–O), 2.66 (s, 6H, O–C***H***$_3$), 1.61 (s, 32H, C(C***H***$_3)_3$); ^{13}C{^{1}H} NMR (benzene-d_6, 23 °C, ppm) 158.50 (s, pyrazolato ring ***C***–C$(CH_3)_3$), 96.05 (s, pyrazolato ring ***C***–H), 70.83 (s, CH_3–O–***C***H_2CH_2–O–CH_2CH_2), 69.86 (s, CH_3–O–CH_2***C***H_2–O–CH_2CH_2), 68.99 (s, CH_3–O–CH_2CH_2–O–***C***H_2CH_2), 68.61 (s, CH_3–O–CH_2CH_2O–CH_2***C***H_2), 58.42 (s, O–***C***H_3), 32.46 (s, pyrazolato ***C***$(CH_3)_3$), 32.28 (s, pyrazolato C(***C***$H_3)_3$).

Anal. Calc. for $C_{32}H_{60}N_4O_5Sr$: C, 57.50; H, 9.05; N, 8.38. Found: C, 57.42; H, 8.86; N, 8.35%.

3.5. Preparation of bis(3,5-di-tert-butylpyrazolato)(triglyme)strontium (4)

In a fashion similar to the preparation of **1**, treatment of $Sr(N(SiMe_3)_2)_2(THF)_2$ (0.230 g, 0.416 mmol) with triglyme (0.080 ml, 0.416 mmol) and *t*Bu_2pzH (0.150 g, 0.832 mmol) in toluene (30 ml) afforded **4** as colorless crystals (0.190 g, 73%): m.p. 173–175 °C; IR (Nujol, cm^{-1}) 1508 (s), 1318 (w), 1248 (s), 1221 (w), 1203 (m), 1118 (w), 1093 (m), 1069 (m), 1022 (s), 1000 (s), 995 (s), 937 (s), 868 (s), 844 (s), 828 (w), 765 (s), 668 (w); ^{1}H NMR (benzene-d_6, 23 °C, δ) 6.35 (s, 2H, pyrazolato ring C–***H***), 3.15 (s, 4H, C***H***$_2$–O–CH_2CH_2), 2.97–2.91 (m, 8H, CH_2–O–CH_2C***H***$_2$), 2.79 (s, 6H, O–C***H***$_3$), 1.64 (s, 32H, C(C***H***$_3)_3$); ^{13}C{^{1}H} NMR (benzene-d_6, 23 °C, ppm) 158.71 (s, ***C***–C$(CH_3)_3$), 96.62 (s, pyrazolato ring ***C***–H), 70.34 (s, ***C***H_2–O–CH_2CH_2), 69.53 (s, CH_2–O–***C***H_2CH_2), 68.75 (s, CH_2–O–CH_2***C***H_2), 58.89 (s, O–***C***H_3), 32.46 (s, pyrazolato ***C***$(CH_3)_3$), 32.38 (s, pyrazolato C(***C***$H_3)_3$).

Anal. Calc. for $C_{30}H_{56}N_4O_4Sr$: C, 57.71; H, 9.04; N, 8.97. Found: C, 56.65; H, 8.88; N, 9.01%.

3.6. Preparation of bis(3,5-di-tert-butylpyrazolato)-(PMDETA)strontium (5)

In a fashion similar to the preparation of **1**, treatment of $Sr(N(SiMe_3)_2)_2(THF)_2$ (0.230 g, 0.416 mmol) with PMDETA (0.087 ml, 0.416 mmol) and *t*Bu_2pzH (0.150 g, 0.832 mmol) in toluene (30 ml) afforded **5** as colorless crystals (0.165 g, 64%): m.p. 138–140 °C; IR (Nujol, cm^{-1}) 1511 (w), 1305 (w), 1247 (s), 1220 (w), 1150 (w), 1105 (w), 1012 (s), 993 (w), 774 (s); ^{1}H NMR (benzene-d_6, 23 °C, δ) 6.34 (s, 2H, pyrazolato ring C–***H***), 2.19 (m, 8H, C***H***$_2$C***H***$_2$), 2.08 (s, 12H, NC***H***$_3$), 1.77 (s, 3H, CH_2N(C***H***$_3$)CH_2), 1.55 (s, 32H, C(C***H***$_3)_3$); ^{13}C{^{1}H} NMR (benzene-d_6, 23 °C, ppm) 159.12 (s, pyrazolato ring ***C***–C$(CH_3)_3$), 96.62 (s, pyrazolato ring ***C***–H), 57.02 (s, N–***C***H_2CH_2), 55.51 (s, N–CH_2***C***H_2), 45.25 (s, N–(***C***$H_3)_2$), 42.13 (s, N–***C***H_3), 32.33 (s, overlapped pyrazolato ***C***$(CH_3)_3$) and pyrazolato C(***C***$H_3)_3$.

Anal. Calc. for $C_{31}H_{61}N_7Sr$: C, 60.10; H, 9.93; N, 14.14. Found: C, 59.72; H, 9.31; N, 15.41%.

3.7. X-ray structure determinations of 1–5

Crystalline samples of **1**–**5** were mounted in sealed thin wall capillaries under nitrogen atmosphere for X-ray data collection. All crystal structures were collected on a Bruker P4/CCD diffractometer equipped with Mo radiation. For each collection, a full sphere of data was collected at 10 s/frame with 0.2° between each frame. The frame data were indexed and integrated with

the manufacturer's SMART and SAINT software. Absorption corrections were applied with Sheldrick's SADABS program and the structure was solved and refined using the programs of SHELX-97. All reported crystal structures consist of monomeric neutral complexes with no associated solvent or ions. The crystal structures of **4** and **5** had considerable disorder and were solved only to the point of positive structural identifications. Data for **1**–**3** are contained in Tables 1–4 and Figs. 1–3.

Complex **1** crystallized as colorless rhomboids. Data collection proceeded at room temperature. Hydrogen atoms were placed in calculated positions. Substantial disorder is evident in both the *tert*-butyl substituents and in the tetraglyme ethylene linkages, and is reflected in large thermal ellipsoids. Alternate and partial occupancy positions were defined for one disordered *tert*-butyl group (C(16)–C(18)) and the partial atoms were kept isotropic.

Complex **2** crystallized as colorless rods. Diffraction data were collected at −80 °C. Hydrogen atoms were placed in calculated positions for the *tert*-butyl groups, and in observed refined positions for all others.

Complex **3** crystallized as colorless mounds that were cut for data collection at room temperature. Hydrogen atoms were placed in calculated positions and were held riding. Alternate and partial occupancy positions were defined for one disordered *tert*-butyl group (C(9)–C(11)) and the partial atoms were kept isotropic. All other nonhydrogen atoms were refined anisotropically. The strontium atom is located on a crystallographic twofold axis.

4. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, quoting No. 246332 for **1**, No. 246333 for **2** and No. 246334 for **3**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1233-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

The effect of various substituents on the structural parameters of the $P(O)[N(CH_3)(CH_2C_6H_5)]_2$ moiety. Syntheses and spectroscopic characterization of some new phosphoramidates, crystal structures of $P(O)(X)[N(CH_3)(CH_2C_6H_5)]_2$, $X = C_6H_5C(O)NH$, Cl and $CCl_3C(O)NH$

Abstract

Some new phosphoramidates with the general formula $P(O)(X)[N(CH_3)(CH_2C_6H_5)]_2$, $X = C_6H_5C(O)NH$ (**1**), Cl (**2**), $CCl_3C(O)NH$ (**3**), $N(CH_3)_2$ (**4**) and 4-NO_2–C_6H_4NH (**5**) were prepared and characterized by IR, ^1H, ^{13}C, ^{31}P NMR spectroscopy and elemental analysis. The structures have been determined for compounds **1**–**3**. Compounds **1** and **3** were obtained in the form of centrosymmetric dimers which were produced by intermolecular –P=O···H–N– hydrogen bonds. In molecules **1**–**5**, containing carbon atoms with two bond distances from the phosphorus atoms, $^2J(P,CH_2) > {}^2J(P,CH_3)$.

Keywords: X-ray crystallography; NMR spectra; Phosphoramidate; Hydrogen bond

1. Introduction

Phosphoramidates are attractive to study owing to their extensive applications in biochemistry [1,2]. Although many compounds of this series have been reported [3–6], only a few crystal structures, of the formula $P(O)[N(H)R]X_2$ [7], $P(O)[N(H)R]_3$ [8,9], $RC(O)N(H)P(O)X_2$ [10] and $RC(O)N(H)P(O)[NR^1R^2]_2$ [11–13], are currently known. These compounds were used as O-donor ligands in the reaction with small and hard metal ions [14] and the lithiations of them were discussed [8]. The P–N bond characteristics and its influence on ^{31}P NMR chemical shifts were considered [15] and also P–C and P–H coupling constants were discussed in order to obtain assignments, conformational and configurational analysis [16,17].

In this study, we report the structures of three new phosphoramidates: *N*-benzoyl, *N*′,*N*″-bis(*N*-benzylmethyl)phosphoric triamide **1**, *N*,*N*′-bis(*N*-benzylmethyl), phosphoramidic chloride **2**, and *N*-trichloroacetyl, *N*′,*N*″-bis(*N*-benzylmethyl)phosphoric triamide **3**. We also considered the structural parameters of several previous reported structures [18–23]. Furthermore, we synthesized two other phosphoramidates: *N*,*N*-dimethyl, *N*′,*N*″-bis(*N*-benzylmethyl)phosphoric triamide **4** and *N*-4-nitrophenyl, *N*′,*N*″-bis(*N*-benzylmethyl)phosphoric triamide **5**. Two bond distance coupling constants, $^2J(P,C)_{benzylic}$ of these molecules were compared to $^2J(P,C)_{methyl}$.

2. Experimental

2.1. Materials

Dimethylamine solution (40% in water), 4-nitroaniline (⩾99%), phosphorus pentachloride (⩾98%), formic acid (98%), phosphorus oxychloride (⩾98%) (Fluka) and *N*-benzylmethylamine (⩾98%), benzamide (>98%), 2,2,2-trichloroacetamide (>98%) (Merck) were used as supplied. In all reactions, low temperature conditions were used.

2.2. X-ray measurements

X-ray data were collected on an Enraf Nonius CAD4 for compound **1** and a Bruker SMART 1000 CCD single crystal diffractometer for compounds **2** and **3** with graphite monochromated Mo Kα radiation (λ = 0.71073 Å). The structures were refined with SHELXL-97 [24] by full matrix least squares on F^2. The positions of hydrogen atoms were obtained from the difference Fourier map. Routine Lorentz and polarization corrections were applied and an absorption correction was performed for compounds **2** and **3** using the SADABS program [25].

2.3. Spectroscopic measurements

^{1}H, ^{13}C and ^{31}P NMR spectra were recorded on a Bruker Avance DRS 500 spectrometer. ^{1}H and ^{13}C chemical shifts were determined relative to internal TMS, ^{31}P chemical shifts relative to 85% H_3PO_4 as external standard. Infrared (IR) spectra were recorded on a Shimadzu model IR-60 spectrometer. Elemental analysis was performed using a Heraeus CHN-O-RAPID apparatus.

2.4. Syntheses

$C_6H_5C(O)NHP(O)Cl_2$ and $CCl_3C(O)NHP(O)Cl_2$ were prepared similar to the procedure by Kirsanov et al. [26,27] and $Me_2NP(O)Cl_2$ and 4-NO_2–$C_6H_4NHP(O)Cl_2$ were prepared similar to the procedure by Keat and Shaw [28] and Johnson et al. [29], respectively.

2.4.1. *N*-benzoyl, *N*′,*N*″-bis(*N*-benzylmethyl)phosphoric triamide (**1**)

N-benzylmethyl amine (1.21 g, 10 mmol) was added to a solution of *N*-benzoyl phosphoramidic dichloride (0.595 g, 2.5 mmol) in chloroform (40 ml) and stirred at −5 °C. After 4 h, the solvent was removed and the residue that formed was stirred in H_2O. The product was filtered and washed with H_2O and recrystallized from chloroform/*n*-heptane; m.p. 141 °C. *Anal.* Calc. for $C_{23}H_{26}N_3O_2P$: C, 67.80; H, 6.43; N, 10.31. Found: C, 67.83; H, 6.40; N, 10.30%. ^{31}P NMR ($CDCl_3$): δ 16.65 (m). ^{13}C NMR ($CDCl_3$): δ 168.95 (s, C═O), 138.04 (d, ^3J(P,C) = 4.2 Hz), 133.49 (d, ^3J(P,C) = 8.7 Hz), 132.38 (s), 128.64 (s), 128.46 (s), 128.27 (s), 128.12 (s), 127.23 (s), 53.10 (d, ^2J(P,C) = 5.3 Hz), 33.82 (d, ^2J(P,C) = 5.0 Hz). ^{1}H NMR ($CDCl_3$): δ 2.72 (d, ^3J(PNCH) = 10.3 Hz, 6H, $2CH_3$), 4.22 (dd, ^3J-(PNCH) = 9.3 Hz, ^2J(H,H) = 15.0 Hz, 2H, $2CH_{benzylic}$), 4.37 (dd, ^3J(PNCH) = 9.3 Hz, ^2J(H,H) = 15.0 Hz, 2H, $2CH_{benzylic}$), 7.22–7.44 (m, 12 Ar–H), 7.50 (t, ^3J(H,H) = 7.2 Hz, 1Ar–H), 8.16 (d, ^3J(H,H) = 7.7 Hz, 2Ar–H), 9.64 (s, NH, 1H). ^{1}H{^{31}P} NMR ($CDCl_3$): δ 2.72 (s), 4.22 (d, ^2J(H,H) = 15.0 Hz), 4.37 (d, ^2J(H,H) = 15.0 Hz), 7.21–7.53 (m), 9.64 (s). 2.4.2. *N*,*N*′-bis(*N*-benzylmethyl)phosphoramidic chloride (**2**)

N-benzylmethyl amine (2.41 g, 20 mmol) was added to a solution of phosphoryl chloride (0.76 g, 5 mmol) in acetonitrile (25 ml) and stirred at −5 °C. After 8 h, the precipitate was filtered and the product was obtained from solution by column chromatography [silica gel; hexane:ethyl acetate (4:1)]; m.p. 120 °C. *Anal.* Calc. for $C_{16}H_{20}ClN_2OP$: C, 59.54; H, 6.25; N, 8.68. Found: C, 59.51; H, 6.21; N, 8.66%. ^{31}P NMR ($CDCl_3$): δ 34.18 (m). ^{13}C NMR ($CDCl_3$): δ 138.11 (d, ^3J(P,C) = 5.5 Hz), 129.34 (s), 129.14 (s), 128.34 (s), 53.54 (d, ^2J(P,C) = 4.0 Hz), 34.11 (d, ^2J(P,C) = 3.5 Hz). ^{1}H NMR ($CDCl_3$): δ 2.63 (d, ^3J(PNCH) = 12.6 Hz, 6H, $2CH_3$), 4.33 (m, 4H, $2CH_2$), 7.29–7.44 (m, 10Ar–H). ^{1}H{^{31}P}NMR ($CDCl_3$): δ 2.63 (s), 4.33 (m), 7.29–7.44 (m). IR (KBr, cm^{-1}): 3015, 1484, 1442, 1334, 1219, 1190 (νP═O), 1126, 1064, 949, 910, 786 (νPN), 699, 631, 530 (νPCl), 446.

2.4.3. *N*-trichloroacetyl, *N*′,*N*″-bis(*N*-benzylmethyl)-phosphoric triamide (**3**)

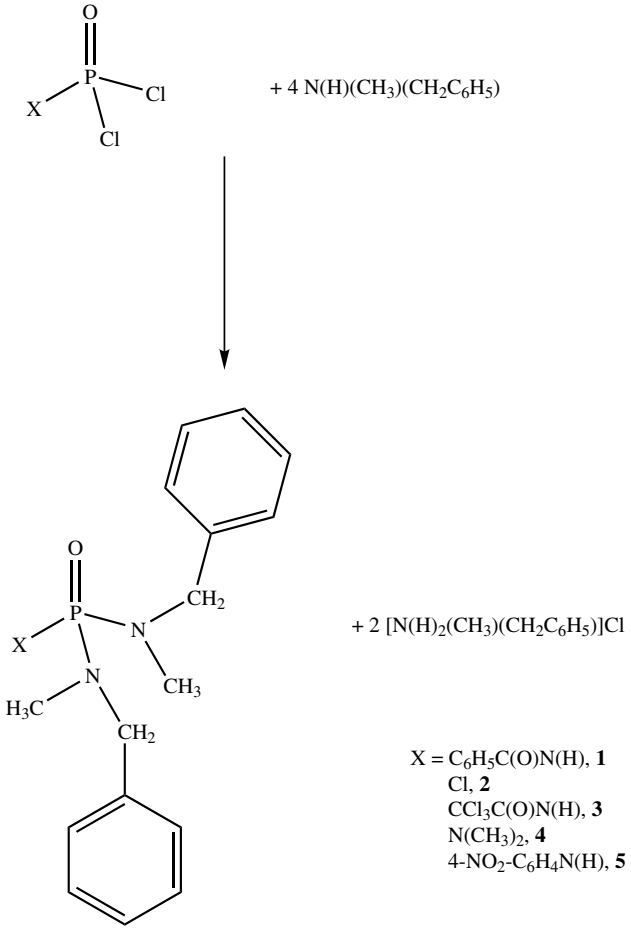
N-benzylmethyl amine (0.97 g, 8 mmol) was added to a solution of trichloroacetyl phosphoramidic dichloride (0.56 g, 2 mmol) in acetonitrile (40 ml) and stirred at −5 °C. After 4 h, the solvent was removed and the residue that formed was stirred in H_2O. The product was filtered and washed with H_2O and recrystallized from chloroform/*n*-heptane; m.p. 153 °C. *Anal.* Calc. for $C_{18}H_{21}Cl_3N_3O_2P$: C, 48.18; H, 4.72; N, 9.36. Found: C, 48.16; H, 4.70; N, 9.37%. ^{31}P NMR (d_6-DMSO): δ 13.86 (m). ^{13}C NMR (d_6-DMSO): δ 163.50 (s, C═O), 139.27 (d, ^3J(P,C) = 4.8 Hz), 129.81 (s), 129.48 (s), 128.63 (s), 93.08 (d, ^3J(P,C) = 9.6 Hz, CCl_3), 59.63 (s), 51.82 (d, ^2J(P,C) = 4.9 Hz), 33.23 (d, ^2J(P,C) = 4.6 Hz). ^{1}H NMR (d_6-DMSO): δ = 2.49 (d, ^3J(PNCH) = 10.2 Hz, 6H, $2CH_3$), 4.16 (d, ^3J(PNCH) = 9.1 Hz, 4H, $2CH_2$), 7.26–7.39 (m, 10Ar–H), 10.34 (b, 1H, NH). ^{1}H{^{31}P}NMR (d_6-DMSO):

δ 2.49 (s), 4.16 (s), 7.26–7.39 (m), 10.34 (b). IR (KBr, cm^{-1}): 3405 (νNH), 3020, 2915, 2760, 1712 (νC=O), 1452, 1348, 1230, 1198 (νP=O), 1145, 1008, 948, 876 (νPN), 834, 794 (νPN), 695, 669 (νCCl), 588, 491, 453.

2.4.4. N,N-dimethyl, N′,N″-bis(N-benzylmethyl)-phosphoric triamide (4)

N-benzylmethyl amine (0.81 g, 5 mmol) was added to a solution of *N*,*N*-dimethylphosphoramidic dichloride (2.42 g, 20 mmol) in acetonitrile (30 ml) and stirred at −5 °C. After 8 h, the precipitate was filtered and the product was obtained from solution by column chromatography [silica gel; hexane:ethyl acetate (8:1)]. *Anal.* Calc. for $C_{18}H_{26}N_3OP$: C, 65.24; H, 7.91; N, 12.61. Found: C, 65.23; H, 7.89; N, 12.63%. ^{31}P NMR ($CDCl_3$): δ 25.48 (m). ^{13}C NMR ($CDCl_3$): δ 138.44 (d, ^3J(P,C) = 4.5 Hz), 130.24 (s), 128.23 (s), 127.13 (s), 53.18 (d, ^2J(P,C) = 4.6 Hz), 37.03 (d, ^2J(P,C) = 4.0 Hz), 33.92(d, ^2J(P,C) = 3.7 Hz). ^1H NMR ($CDCl_3$): δ 2.54 (d, ^3J(PNCH) = 9.1 Hz, 6 H, $N(CH_3)_2$), 2.69 (d, ^3J(PNCH) = 9.6 Hz, 6H, $2CH_3$), 4.10 (dd, ^3J-(PNCH) = 8.3 Hz, ^2J(H,H) = 14.8 Hz, 2H, $2CH_{benzylic}$), 4.20 (dd, ^3J(PNCH) = 8.3 Hz, ^2J(H,H) = 14.8 Hz, 2H, $2CH_{benzylic}$), 7.23–7.36 (m, 10Ar–H). $^1H\{^{31}P\}$NMR ($CDCl_3$): δ 2.54 (s), 2.69 (s), 4.10 (d, ^2J(H,H) = 14.8 Hz), 4.20 (d, ^2J(H,H) = 14.8 Hz), 7.23–7.36 (m). IR (KBr, cm^{-1}): 3415, 2920, 2765, 2420, 1724, 1443, 1296, 1204 (νP=O), 998, 946, 778 (νPN), 731 (νPN), 694, 592, 472.

2.4.5. N-4-nitrophenyl, N′,N″-bis(N-benzylmethyl)-phosphoric triamide (5)



N-benzylmethyl amine (0.97 g, 8 mmol) was added to a mixture of *N*-4-nitrophenyl phosphoramidic dichloride (0.51 g, 2 mmol) in carbon tetrachloride (30 ml) and stirred at −5 °C. After 6 h, the solvent was removed and the residue that formed was stirred in H_2O. The product was filtered and washed with H_2O; m.p. 115 °C. *Anal.* Calc. for $C_{22}H_{25}N_4O_3P$: C, 62.26; H, 5.94; N, 13.20. 3. Results and discussion

The reaction of *N*-benzylmethylamine with *N*-benzoyl phosphoramidic dichloride, trichloroacetyl phosphoramidic dichloride, phosphoryl chloride, *N*,*N*-dimethyl phosphoramidic dichloride and *N*-4-nitrophenyl phosphoramidic dichloride leads to the corresponding phosphoramidates, Scheme 1. The general synthetic methods involve the reactions between the halogen–phosphorus compounds with an amine either alone (in excess) or in the presence of another HCl scavenger (such as triethylamine). The main challenge in these reactions is the separation of the phosphoramidate from the alkylammonium chloride byproduct.

3.1. NMR Study

The molecules **1**–**5** indicate two various ^2J(P,C) coupling constants for the CH_3 and CH_2 groups in the

Scheme 1. Preparation of compounds **1**–**5**.

Table 1
$^2J(P,C)_{aliphatic}$ and $^2J(P,C)_{benzylic}$, Hz in some phosphoramidates

No.	Compound	$^2J(P,C)_{aliphatic}$	$^2J(P,C)_{benzylic}$	Reference

[a] This work.

benzylmethylamine moiety, furthermore, compound **4** shows a $^2J(P,C)$ coupling constant for the CH_3 in the $N(CH_3)_2$ group. $^2J(P,C)$ coupling constants in these compounds are in the range of 3.5–5.3 Hz and for each compound $^2J(P,CH_2) > {}^2J(P,CH_3)$, Table 1. The presence of phenyl groups linked to CH_2 causes the deshielding of the CH_2 carbon atoms relative to the CH_3 carbon atoms. Methylene and methyl carbon atoms in compounds **1**–**5** appear in the range of 51.82–53.54 and 33.23–34.11 ppm in ^{13}C NMR spectra, respectively. The deshielding of the methylene groups leads to a greater interaction with the corresponding phosphorus atoms. Also, in compounds with the $P(O)[N(CH_2CH_3)(CH_2C_6H_5)]$ moiety [21], Table 1, $^2J[P,(CH_2)_{benzylic}] > {}^2J[P,(CH_2)_{aliphatic}]$.

The *ipso*-carbon atoms of the phenyl rings related to the amine groups are split into doublet signals by their phosphorus atoms, $^3J(P,C)$ coupling constant, also molecules **1** and **3** show a $^3J(P,C)$ coupling constant for the benzoyl and trichloroacetyl groups of 8.7 and 9.6 Hz, respectively. NH signals of compounds **1** and **3** do not show two bond distance couplings with the P atom, $^2J(PNH)$, but in molecule **5**, a doublet signal is obtained for NH with $^2J(PNH) = 9.2$ Hz. The protons of methyl and methylene groups in these compounds indicate $^3J(PNCH)$ coupling constants. Fig. 1 indicates the multiplet structure in the ^{31}P NMR spectrum of compound **5** which is produced by the couplings with H atoms of two $N(CH_3)(CH_2C_6H_5)$ groups, the measured $^3J(PNCH)$ from the ^1H NMR spectrum for this compound are 10 and 7.1 Hz (for the methyl and methylene protons of the $P\text{–}N(CH_3)(CH_2C_6H_5)$ moiety). The two benzylic protons are diastereotopic and usually appear with different chemical shifts, but when the rotational energy barrier around the P–N bond is low, these appear with equal chemical shifts on the NMR timescale. Each of

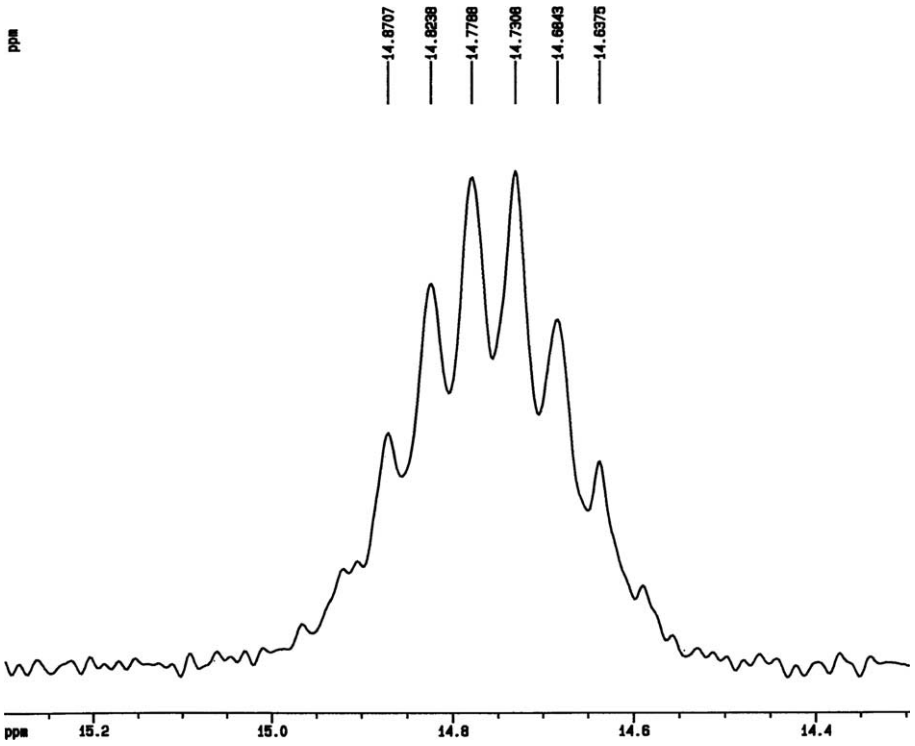

Fig. 1. ^{31}P NMR spectrum of compound **5**.

the benzylic protons (of compounds **1**, **2**, **4** and **5**) represents the splitting by the phosphorus atom, ^3J(PNCH), followed by ^2J(H,H) splitting. Compound **3** shows only a doublet signal produced by a ^3J(PNCH) coupling constant (the benzylic protons do not have different chemical shifts at 298 K). A similar result was obtained for the benzylic protons of $(CH_3)(C_6H_5CH_2)$ NP(O)(Cl)(4-$OC_6H_4CH_3$) [30] (a doublet peak at 4.26 ppm) which on lowering the temperature, the protons appear with different chemical shifts.

3.2. X-ray crystallography investigation

Single crystals of compounds **1**–**3** were obtained from a solution of chloroform and 1-heptane after slow evaporation at room temperature. The crystal data and the details of the X-ray analysis are given in Table 2, selected bond lengths and angles are given in Table 3. Molecular structures of compounds **1**–**3** are shown in Figs. 2–4.

Both compounds **1** and **3** contain one amidic hydrogen atom and form centrosymmetric dimers, see Fig. 5 for compound **3**, that are produced by two equivalent intermolecular –P═O···H–N– hydrogen bonds (Table 4). The earlier studied *N*-benzoyl, phosphoric triamides exist either in the form of dimeric aggregates [31] or as polymeric chains [32].

In molecules **1** and **3**, the phosphoryl and the carbonyl groups are anti, Figs. 2 and 4. The phosphorus atoms in the structures **1**–**3** have a slightly distorted tetrahedral configuration. The bond angles around the P(1) atoms in these compounds are in the range of 118.9°–102.53°, for the angles O(1)–P(1)–N(2) and N(2)–P(1)–Cl(1) in structure **2**. For both compounds **1** and **3**, the highest values of the bond angles around phosphorus atoms were obtained for the angles O(1)–P(1)–N(2) and N(2)–P(1)–N(1). The angles O(1)–P(1)–N(1) in compounds **1** and **3**, 105.55(12)° and 104.81(8)°, are lower than the angles O(1)–P(1)–N(2) and O(1)–P(1)–N(3) (118.26(13)°, 109.80(13)° for **1** and 117.53(9)°, 112.05(9)° for **3**).

P(1)–N(2) and P(1)–N(3) bond lengths are 1.630(3) and 1.629(2) Å in compound **1** and 1.6312(17) and 1.6271(17) Å in compound **3**. Also, in compound **2** P(1)–N(1) and P(1)–N(2) are 1.610(4) and 1.634(4) Å, respectively. They are significantly shorter than the typical P–N single bond length (1.77 Å) [33]. The shortening of PN bond lengths is likely related to an electrostatic effect (polar bond) which overlaps with P–N σ bond [34]. In compounds **1** and **3**, the P(1)–N(1)

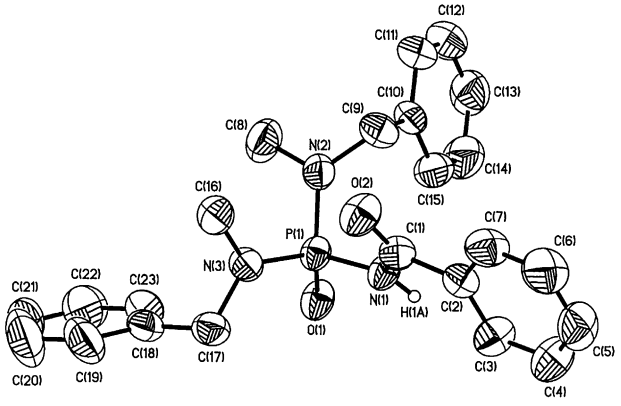

Fig. 2. Molecular structure and atom-labelling scheme for $P(O)(C_6H_5\text{-}C(O)NH)[N(CH_3)(CH_2C_6H_5)]_2$, compound **1** (50% probability ellipsoids).

bond lengths (1.676(2) and 1.7037(16) Å, respectively) are longer than the P(1)–N(2) and P(1)–N(3) bond lengths due to the resonance interaction with the C=O system that causes a partial multiple-bond character in N(1)–C(1) (compare N(1)–C(1) in compound **1** and

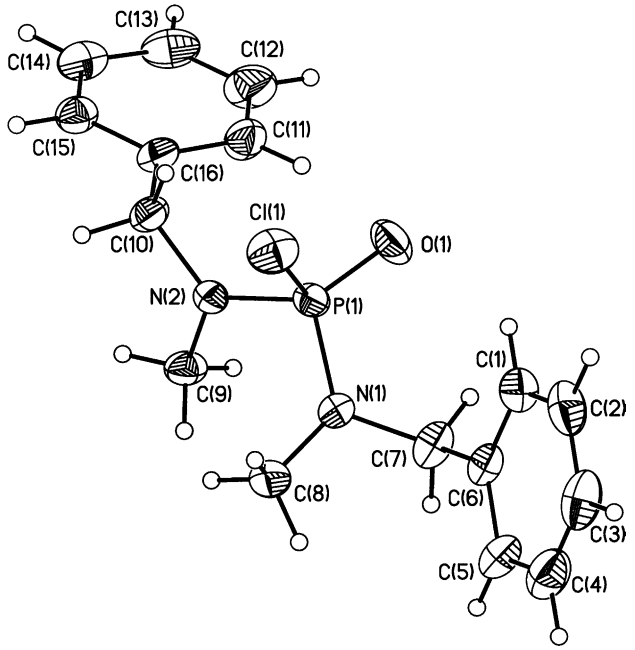

Fig. 3. Molecular structure and atom-labelling scheme for $P(O)(Cl)[N(CH_3)(CH_2C_6H_5)]_2$, compound **2** (50% probability ellipsoids).

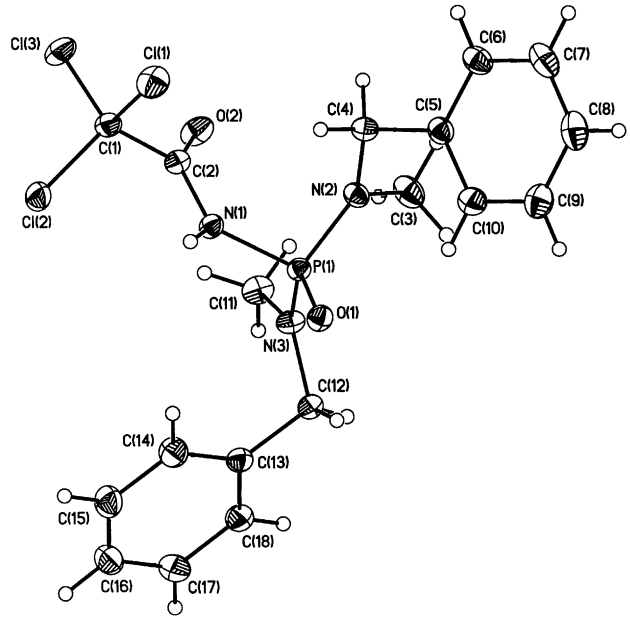

Fig. 4. Molecular structure and atom-labelling scheme for $P(O)(CCl_3C(O)NH)[N(CH_3)(CH_2C_6H_5)]_2$, compound **3** (50% probability ellipsoids).

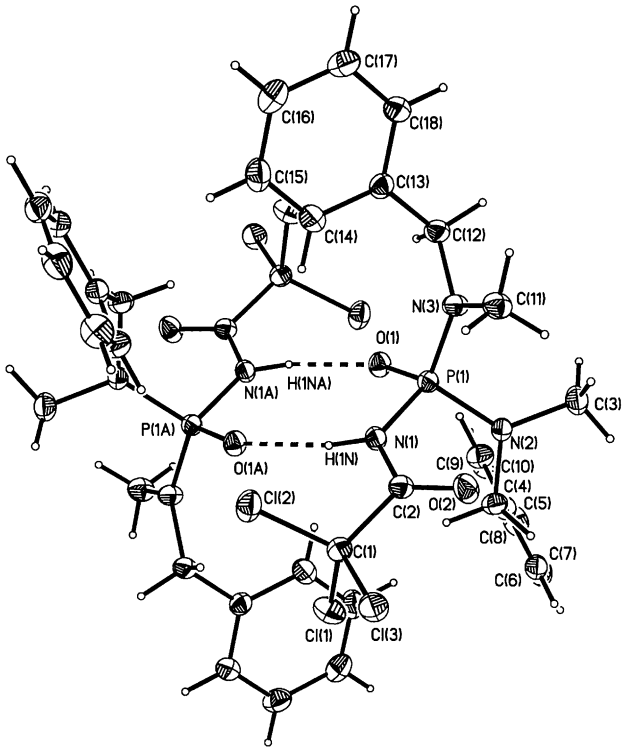

Fig. 5. Centrosymmetric dimer of compound **3**, produced by hydrogen bonds.

N(1)–C(2) in compound **3** with other N–C bond lengths, Table 3). In the previous reported structures, we obtained the P–N bond lengths of (O)P–N(H)–C(O) and $P–NR^1R^2$ moieties in the range of 1.678(2)–1.718(3) Å and 1.6032(17)–1.642(2) Å, respectively (Table 5).

The environment of the nitrogen atoms is practically planar. In compound **1**, the angles C(8)–N(2)–C(9), C(8)–N(2)–P(1) and C(9)–N(2)–P(1) are 113.6(3)°, 118.2(2)° and 125.5(2)°, respectively, with average 119.1°. Similar results were obtained for the bond angles around N(3) atom (average 120°). Also, the sum of the surrounding angles for N(1), N(2) in compound **2** and N(2), N(3) in compound **3** are 359°, 358.9° and 359.7°, 359.9°, respectively. Furthermore, the angles C(1)–N(1)–P(1) in compound **1** and C(2)–N(1)–P(1) in compound **3** are 127.6(2)° and 127.13(13)°. These results confirm the sp^2 hybridization for the nitrogen atoms,

[a] This work.
[b] These compounds appear as two crystallographically independent molecules.
[c] The data are related to P–N of the (O)P–N(H)–C(O) moiety.

although due to repulsion and steric interactions, some angles are greater and others are smaller than 120°.

The P=O bond lengths in molecules **1**–**3** are 1.476(2), 1.459(4) and 1.478(2) Å, which are larger than the normal P=O bond length (1.45 Å) [33]. The P=O bond lengths in our previously reported structures are in the range of 1.455(1)–1.487(3) Å (Table 5).

4. Supplementary data

Crystallographic data for the structures in this paper have been deposited with Cambridge Crystallographic Data Center as Supplementary Publication Nos. CCDC 240844 ($C_{23}H_{26}N_3O_2P$), 240845 ($C_{16}H_{20}Cl_1N_2OP$) and 240846 ($C_{18}H_{21}Cl_3N_3O_2P$). Copies of the data may be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336033; E-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Abstract

Multinuclear titanium(IV) oxo carboxylates of the general formula $[Ti_8O_8(OOCR)_{16}]$ (where R = Bu^t (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**)) have been synthesized in a reaction of titanium isopropoxide with the appropriate organic acids in a molar ratio of 1:2. The composition and structure of these compounds were identified by elemental analysis, IR, NMR and X-ray single-crystal diffraction. The crystal structure of **1** was solved in the orthorhombic space group *Pbca*. Titanium atoms form oligomeric $[Ti_8(\mu_2\text{-}O)_8]$ rings, where each Ti cation is surrounded by six oxygen atoms (two μ_2-oxo and four μ-carboxylato bridges). Within the ring the Ti–Ti distances between neighboring titanium ions range from 3.333(1) to 3.366(1) Å and the mean value of the Ti–Ti–Ti angle is 134.2(1.3)°. Results of IR, NMR and MS studies proved that in the structures of **2** and **3**, multinuclear $[Ti_8(\mu_2\text{-}O)_8]$ clusters stabilized by carboxylate bridges are also formed. TGA/DTG, MS and variable temperature IR + (VT-IR) studies have been carried out in order to determine the thermal stability and thermal decomposition mechanism of the Ti(IV) carboxylates mentioned above.

1. Introduction

The study of the synthesis of titanium(IV) oxo carboxylates, structural characteristics and pyrolysis pathway are motivated by their potential applications as sol–gel or chemical vapor deposition (CVD) precursors. According to the literature reports, two methods are used in preparation of Ti(IV) oxo carboxylate derivatives. Complexes of the general formula $O[Ti(OOCR)_3]_2$ were the main products of a multistage reaction of titanium tetrachlorine with organic acids [1,2]. During the process mentioned above, $[TiCl_{4-x}(OOCR)_x]$ (x = 1–4) derivatives have also been isolated [3–5]. Barrow et al. [6,7] showed that titanium(IV) oxo chloro-carboxylates $O[TiCl_2(OOCBu^t)(Bu^tCOOH)]_2$ and $O[TiCl(OOCBu^t)_2]_2$ were the main products of the reaction between $TiCl_4$ and trimethylacetic acid in a 1:2.5 molar ratio. The crystal structure of $[\{TiCl_2(OOCBu^t)(Bu^t\text{-}COOH)\}_2O]$ is formed of dimers, composed of Ti atoms octahedrally surrounded by oxygen atoms of one oxygen bridge (μ_2-O) and two bifurcated carboxylates (μ-O) of the *syn–syn* type. The Ti–O distances were 1.77 Å for Ti-(μ_2-O) and 1.99–2.09 Å for Ti-(μ-O) [7].

The stoichiometric reaction of titanium alkoxides ($Ti(OR')_4$; R′ = Et, Pr^i) with carboxylic acids is the next method of synthesizing titanium oxo carboxylates [8,9]. Titanium oxo carboxylato alkoxides were crystallized from 1:1–4 molar ratio mixtures of $Ti(OR')_4$/HOOCR. X-ray diffraction studies exhibited that the following four types of complexes may be formed: (a) $[Ti_6O_4(OR)_{12}(O_2CR')_4]$, (b) $[Ti_6O_4(OR)_8(O_2CR')_8]$, (c) $[Ti_4O_4(OR)_4(O_2CR')_4]$ and (d) $[Ti_6O_6(OR)_6(O_2CR')_6]$ (R = Et, Pr^i, R′ = Me, Np (neopentyl), Bu^t, Ph) [10–16].

doi:10.1016/j.poly.2005.01.014

The main factor influencing the formation of these types of multinuclear Ti(IV) clusters is the nature of the alkoxide and carboxylate ligands [13]. Ammala et al. [17] report that $[Ti_6O_6(OCH_2Bu^t)_6(O_2CPh)_6]$ and $[Ti_6O_4(OPr^n)_8(O_2CPh)_8]$ were also synthesized in the reaction of $[Fe_4(\mu_3\text{-}O)_2(O_2CPh)_8(py)_2]$ with $Ti(OPr^n)_4$ in toluene. The application of the large excess of organic acid leads to the formation of Ti(IV) oxo carboxylato derivatives (e.g., polymeric chains of $[TiO(OAc)_2]_n$ were obtained for the ratio 1:10) [8,9].

In the reported work we have focused on structural studies and spectral characteristics of multinuclear Ti(IV) carboxylato derivatives, synthesized from titanium isopropoxide and HOOCR, R = Bu^t, CH_2Bu^t, $C(CH_3)_2Et$. Analysis of the thermogravimetric (TGA), MS-EI, and variable temperature IR spectroscopy have been used in order to study the thermal stability of the synthesized compounds and their thermal decomposition pathway.

2. Experimental

The studied compounds were synthesized under argon atmosphere, using standard Schlenk line and glovebox techniques. $Ti(OPr^i)_4$ (prepared from $TiCl_4$ (Aldrich) and 2-propanol (Aldrich) in the presence of trimethylamine) was freshly vacuum distilled prior to use, whereas Bu^tCOOH, Bu^tCH_2COOH and $Et(Me)_2CCOOH$, (Aldrich) were used as received.

Infrared (IR) spectra were recorded on a Perkin–Elmer Spectrum 2000 spectrometer within the range 160–4000 cm^{-1} with a medium slit width and a peak resolution of 2.0 cm^{-1}. The crystals were studied as a powder dispersed in a KBr pellet (400–4000 cm^{-1}) and as a Nujol suspension between CsI plates (160–700 cm^{-1}). The low temperature IR spectra (liquid nitrogen temperature (LNT)) have been recorded using a SPECAC variable temperature cell. Solution ^1H and ^{13}C NMR spectra ([D_8]toluene) were recorded using a 5-mm solution probe on a Varian Gemini 200. Solid state ^{13}C NMR spectra were registered on a Bruker AMX 300. Thermogravimetric analysis (TGA) was carried out using the SDT 2960 TA Instrument, in nitrogen atmosphere from 25 to 500 °C at a ramp rate of 3° min^{-1}. Mass spectra were recorded with a MS AMD-604 spectrometer, using the EI method, at 70 eV, in the range 150–350 °C.

2.1. Preparation of $[Ti_8O_8(OOCR)_{16}]$

$Ti(OPr^i)_4$ (1.00 g, 3.52 mmol) was added dropwise to a solution of organic acid (7.04 mmol, 0.72 g of Bu^tCOOH, 6.90 mmol, 0.80 g of Bu^tCH_2COOH or 0.80 g of $Et(CH_3)_2CCOOH$) in toluene (3.00 cm^3), and stirred for 12 h. Crystals were grown by slow evaporation of the reaction mixture under argon atmosphere (glovebox). The colorless crystals were obtained after 2–3 days.

2.1.1. $Ti_8O_8(OOCBu^t)_{16}$ (1)

Yield: 0.56 g (55.0%). The % Ti was gravimetrically determined as TiO_2, according to the Meth-Cohn et al. method [13]. *Anal.* Calc. for $C_{80}H_{144}O_{40}Ti_8 \times C_7H_8$: C, 47.03; H, 6.85; Ti, 17.30. Found: C, 47.33; H, 7.03; Ti, 17.46%. IR (KBr, cm^{-1}) 1545 (s, COO), 1512 (m, COO), 1429 (s, COO), 1417 (m, COO), 1229 (m, C–Me_3), 750 (m, Ti–O), 611 (m, Ti–O), 504 (m, Ti–O). ^{13}C NMR (solid, δ, ppm) 26.5 (CH_3), 38.7 (C–(CH_3)$_3$), 188.2, 186.7 (COO).

2.1.2. $Ti_8O_8(OOCCH_2Bu^t)_{16}$ (2)

Yield: 0.25 g (24.2%). *Anal.* Calc. for $C_{81}H_{146}O_{40}Ti_8$: C, 48.99; H, 7.47; Ti, 16.30. Found: C, 47.66; H, 7.45; Ti, 16.80%. U_{eq} is defined as one third of the trace of the orthogonalized *U*ij tensor.

2.2. X-ray crystallography

The diffraction data were collected at 100(2) K for a $0.30 \times 0.25 \times 0.20$ mm single crystal using Kuma CCD diffractometer, Mo Kα radiation $\lambda = 0.71073$ Å. The 181753 reflections were measured with the $\omega - 2\theta$ method. A shape-based absorption correction was applied for **1** (RED167 package of programs, Oxford Diffraction, 2000) with the maximum and minimum transmissions of 0.9037 and 0.8603. The structure was solved by direct methods and refined with a full-matrix least-squares procedure on F^2 using the SHELX-97 program package [18]. Details of the data collection and structure refinement are presented in Table 1.

3. Results and discussion

3.1. Synthesis

$Ti(OPr^i)_4$ was added to a stirred solution of HOOCR (R = Bu^t, CH_2Bu^t, $C(CH_3)_2Et$) in toluene, (molar ratio alkoxide/acid = 1:2, Ar atmosphere, room temperature (RT)). At the beginning, the reaction mixture became turbid but after 2 h, a clear solution was formed. Colorless crystals were grown by slow evaporation (glovebox) of the solvent over 2–3 days. Based on the results of elemental analysis, the general formula of the synthesized complexes was determined as $[Ti_8O_8(OOCR)_{16}]$, where R = Bu^t (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**). However microanalysis data suggest the presence of solvent molecules (toluene) in the crystal lattice of **1**. Single crystals, suitable for crystallographic studies were obtained only for compound **1**, but their stability was very low, and they were destroyed in air (RT), with the formation of a white crystalline powder. During the crystallization of **2** and **3** only crystalline powder was formed. Compounds **1**–**3** were insoluble in aliphatic and sparingly soluble in aromatic solvents.

3.2. Crystal structure

Due to the low stability of **1** in the air at RT, the X-ray measurements were carried out at low temperature (~100 K). The poor quality of crystals obtained for **2** and **3** made their crystallographic studies impossible. The chemical unit of **1**, with the atom-numbering scheme, is shown in Fig. 1. Crystal data and atomic coordinates are listed in Tables 1 and 2. The selected bond distances and angles are presented in Table 3.

The ring molecule of the reported complex is composed of eight distorted $[TiO_6]$ octahedra linked by two μ_2-O (*cis*) and four μ-O (carboxylate) bridges (Fig. 1, Table 3). The $[Ti_8(\mu_2\text{-}O)_8]$ ring is not planar. The Ti_8 ring conformation with alternating positive and negative values of Ti–Ti–Ti–Ti torsion angles resembles the cyclohexane chair conformation, but their absolute values vary from 5.11(7)° for Ti1–Ti2–Ti3–Ti4 to 37.14(7)°

for Ti6–Ti7–Ti8–Ti1. The *rms* deviation of Ti ions from the Ti_8 best plane is 0.2073 Å.

Eight of the bridging carboxylates are positioned approximately in the ring plane (Fig. 1), the dihedral angles between the Ti_2COO planes and the best plane of the Ti_8 ring range from 8.88(5)° to 21.85(3)°, with the mean value being 16.5(4)°. The remaining eight carboxylates form the bridges between the Ti ions alternating between the two sides of the ring plane and are approximately perpendicular to that plane. The dihedral angles between the Ti_8 best plane and the Ti_2COO planes vary from 72.81(7)° to 81.29(6)°, with a mean value of 77.8(3)°.

The bridging oxygen atoms in the $[Ti_8(\mu_2\text{-}O)_8]$ rings form alternating longer and shorter Ti–O bonds, the average Ti–O distances and *esd* in the series being 1.904(8) and 1.735(7) Å for the longer and shorter bonds, respectively. The angles in that ring vary from 133.15(1)°–134.67(1)° to 132.42(1)°–136.28(1)° for Ti–O–Ti and Ti–Ti–Ti, respectively (Table 3). Also the oxo bridges form alternating shorter 1.997(3)–2.031(3) Å and longer 2.114(3)–2.156(3) Å Ti–O bonds. In the octahedral environment of each Ti ion, they occupy the *trans* positions relative to the shorter and longer carboxylate Ti–O bonds mentioned above. The other two *trans* trimethyl acetate bridges are positioned outside the $[Ti_8(\mu_2\text{-}O)_8]$ rings, and the corresponding Ti–O(carboxylate) distances vary in the range 2.002(3)–2.013(3) and 2.013(3)–2.031(3) Å.

Kickelbick and Scubert [16] reported an oligomeric ring structure of the general formula $[Ti_9O_8(OPr^i)_4(OOCC(Me){=}CH_2)_{16}]$ (monoclinic, space group *Ia*). That complex consisted of a ring of nine $[TiO_6]$ octahedra linked by six μ_2-O, two μ_3-O and 16 μ_2-O(OOC) bridges. Also in that case, the non-equivalent Ti–O bonds of μ_2-oxo bridges (1.90–1.93 and 1.72–1.74 Å) were compensated by asymmetric Ti–O distances of *trans* carboxylate groups (1.97–2.11 and 2.09–2.16 Å). Analysis of the literature reports exhibited that in another type of $[Ti_x(\mu_n\text{-}O)_y]$ (n = 2, 3) cluster the Ti–O distances were shorter, e.g., in the structure of $([Ti_6O_6(OPr^i)_6(O_2CBu^t)_6]$, Ti-($\mu_3$-O) = 1.878(4), 1.890(2) and 2.142(3) Å [14], and in $[Ti_6O_4(Opr^n)_8(O_2CR)_8]$ (R = CH_3, Ph), Ti-($_2$-O) = 1.724(6)–1.768(2) and 1.900(6)–1.942(2) Å, and Ti-(μ_3-O) = 1.911(2), 1.941(2) and 2.082(2) Å [9,16].

The low temperature experiment for the reported complex **1** allowed building a satisfactory model for the majority of the $OOCBu^t$ moieties. Only for two Bu^t groups the rotational disorder was accounted for in the final model. Both these groups do not participate in intermolecular interactions between the adjacent rings. The complex molecules of **1** form some hydrophobic interactions with the adjacent molecules via their Bu^t groups on the side surfaces and around the ring. However, the important component of the packing interactions is due to the toluene molecules found in the structure. Two of them are positioned near the ring center, between the $OOCBu^t$ moieties perpendicular to the molecule ring plane. Another two toluene molecules participate in the packing interactions involving the carboxylate ligands positioned in the ring plane.

3.3. Analysis of NMR data

The ^{13}C NMR spectroscopy in the solid state have been used to study the structural similarities between **1**, **2** and **3**. Also, ^1H and ^{13}C NMR spectra of $[D_8]$toluene solutions of these compounds were registered in

Table 4
The solid-state and solution NMR studies of $[Ti_8O_8(OOCR)_{16}]$ (R = Bu^t (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**))

Compound	Method	δ [ppm]

		J_{H-H} = 4.0 Hz	J_{H-H} = 4.0 Hz						

The solid-state ^{13}C NMR spectra were registered on a Bruker AMX 300, solution ^1H, ^{13}C NMR spectra ($[D_8]$ toluene) were recorded using a 5-mm solution probe on a Varian Gemini 200 spectrometer.

order to determine the structural changes of the investigated compounds after their solubilization. The observed chemical shifts are listed in Table 4.

The signals due to the carbon atoms of coordinated carboxylate groups are located between 180.3 and 188.2 ppm in the solid-state ^{13}C NMR spectra of **1**–**3**. In spectra of **1** and **3**, the carbon atoms show two lines of equal intensity at 186.6 and 188.1 ppm, whereas a wide single signal at 180.5 ppm is found in the spectrum of **2** (Table 4). However, a detailed analysis of the C(COO) peak in the spectrum of this compound revealed that it also consists of two components, with $\delta = 180.3$ and 180.7 ppm. Considering crystallographic data, the above phenomenon can be explained by the presence of two different types of carboxylate groups in the structures of **1**–**3**. Crystallographic data showed that the COO groups formed the bridges in the plane of the $[Ti_8(\mu_2\text{-}O)_8]$ ring, exhibiting asymmetry of the C–O bond lengths, 1.237(6)–1.250(5) (shorter) and 1.263(6)–1.299(6) Å (longer). Differences in the length of bonds formed by the carboxylate group bridges outside of the ring plane were smaller (1.258(6)–1.276(5) and 1.261(5)–1.275(6) Å). The ^{13}C NMR studies suggest that **1** and **3** form a similar type of carboxylate group interaction in $[Ti_8O_8(OOCR)_{16}]$ molecules. Undetected splitting of the C(COO) signal, observed in the ^{13}C NMR spectrum of **2**, can be interpreted as a result of the smaller differences between the length of the C–O bonds formed by COO groups outside compared to within the $[Ti_8(\mu_2\text{-}O)_8]$ ring plane.

Analysis of ^{13}C NMR spectra of **1**–**3** $[D_8]$toluene solutions shows clear similarities in the chemical shift and splitting of the resonance signals with their analogs in the solid state spectra (Table 4). The NMR data reveal the presence of two types of carboxylate groups in the structure of the studied compounds, which is consistent with the X-ray structure of **1**. In ^1H NMR spectra of **1**–**3** $[D_8]$toluene solutions, only the signals attributed to appropriate hydrocarbon groups were detected.

3.4. Infrared spectra studies

IR spectra of the studied carboxylates were registered at liquid nitrogen temperature (LNT), in conditions analogous to the single crystal X-ray measurements. In order to study similarities between the structures of **1**–**3**, a detailed analysis of IR spectra in the following ranges (a) 1350–1600 cm^{-1} and (b) 400–900 cm^{-1} have been carried out. The wavenumbers of absorption bands registered in the above regions are listed in Table 5.

3.4.1. Stretching frequencies of carboxylate ligands

The split bands attributed to $\nu_{as}(COO)$ and $\nu_s(COO)$ vibrations were found in the ranges 1500–1575 and 1400–1440 cm^{-1} (Table 5). Values of the $\Delta[\nu_{as}(COO) - \nu_s(COO)]$ parameter, calculated for the suitable band components were 116 and 94 cm^{-1}, 116 and 107 cm^{-1} for **1** and **3**, as well as 131 and 103 cm^{-1} for **2**. Comparison of the above results with the literature data [19–22] indicate that the detected $\nu_{as}(COO)$ frequencies and Δ parameter values correspond to bidendate carboxylate groups, participating in *syn–syn* bridges. The different interactions of COO ligands in the structure of the studied compounds are the main factor that causes splitting of the stretching band. That conclusion is consistent with the structural and NMR data presented in this paper.

Table 5
Wavenumbers [cm^{-1}] for the vibrations of acetate ions and oxo bridges (M–O–M) in LNT spectra of $[Ti_8O_8(OOCR)_{16}]$ (where R = Bu^t (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**))

3.4.2. Absorption bands between 400 and 900 cm^{-1}

The bands due to vibrations of carboxylate ligands and M–O–M titanium-oxide bridges of $[Ti_8(\mu_2\text{-}O)_8]$ rings have been found in the range 400–900 cm^{-1} (Table 5). According to the literature data [19,22], their frequencies can be assigned to COO bending ($\delta_s(O\text{-}CO)$ = 551–641 cm^{-1}) and rocking ($\rho(COO)$ = 419–507 cm^{-1}) modes.

The band for Ti–O–Ti stretching modes ($\nu_a(Ti\text{–}O\text{–}Ti)$) was found in the range 714–758 cm^{-1} (Table 5). According to Nakamoto's report on vibrational spectra of complexes containing M-(μ_2-O) bridges in their structure [19], the bands assigned to M–O–M asymmetric vibrations appear in the IR spectrum, while symmetric ones appear in the Raman spectrum. The frequency for the bands mentioned above depends on the type of oxygen bridge and the number of concomitant carboxylate bridges. For the linear M-(μ_2-O) monobridges $\nu_a(M\text{–}O\text{–}M) \cong 843\text{–}885\ cm^{-1}$, and for non-linear one,

ν_a(M–O–M) ≅ 827 cm^{-1}. Presence of the oxygen bridge in the vicinity of carboxylate bridges causes the frequency shift of the ν_a(M–O–M) vibrations towards 749–772 cm^{-1} [19]. In IR spectra of **2** and **3**, the appearance of ν_a(TiOTi) bands at 714, 754 cm^{-1} (**2**), and at 722, 758 cm^{-1} (**3**) was observed. That confirms the formation of non-linear Ti–O–Ti bridges near the Ti-carboxylate ones in the structure of these compounds, similar to those found in the structure of **1**.

The possible low temperature phase transition and thermal stability of Ti–O bonds in [Ti$_8$(μ_2-O)$_8$] clusters have been investigated by means of variable temperature IR spectroscopy (VT-IR). Analysis of the dependence between the frequency of Ti–O–Ti motions (ν_a(TiOTi)) and the temperature exhibited only insignificant shifts (6–7 cm^{-1}) of this band towards higher wavenumbers in the spectra of **2** and **3**. These results suggest that the stability of [Ti$_8$(μ_2-O)$_8$] rings is very high and a temperature phase transition does not occur. The temperature evolution of the ν_a(TiOTi) frequency, observed in VT-IR spectra of **1**, was significantly higher (15–16 cm^{-1}). Moreover only for this compound, clear changes in the diagram slopes between 0 and 60 °C were observed (Fig. 2). Considering crystallographic and TGA data, the latter effect can be explained by the loss of solvent molecules from the crystal lattice of **1**.

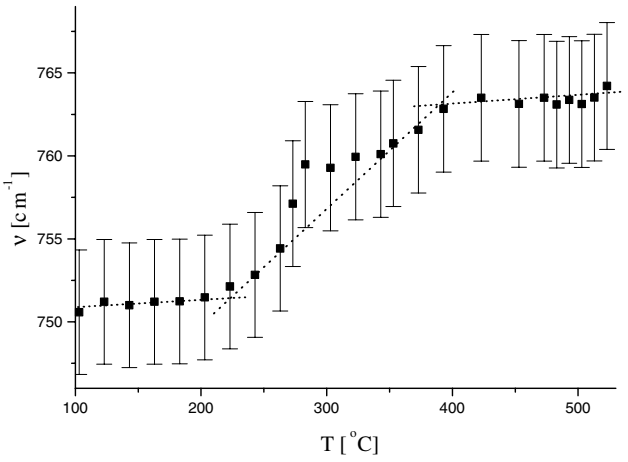

Fig. 2. Temperature evolution of the ν_a(TiOTi) band in the VT-IR spectra of [Ti$_8$O$_8$(O$_2$CBu^t)$_{16}$] (SPECTRUM 2000, KBr, −175 to 250 °C).

3.5. Thermal characterization

The thermal decomposition mechanism of Ti(IV) ring carboxylates was studied using thermogravimetric and differential thermal analysis (TG/DTA) methods over the temperature range 25–550 °C with a heating rate of 3 °C min^{-1} under a nitrogen atmosphere. The TGA/DTA data of **1** show that the decomposition proceeded in four endothermic stages, with maxima at 63, 260, 370 and 421 °C, with a weight loss of 73.4%. A multistep thermal decomposition was also observed for **2** and **3**; the maxima of endothermic stages were found at 108, 311, 381, 417 °C (weight loss: 70.1%) for **2**, and 300, 340, 393, 410 °C (weight loss: 71.2%) for **3**. Thermogravimetric analysis exhibited that the pyrolysis of **1**–**3** proceed with their complete conversion to TiO$_2$. Moreover, one endothermic peak near 63 °C is observed for **1**, which can be explained by the loss of solvent molecules from the crystal lattice of this compound.

Table 6
The mass spectra of [Ti$_8$O$_8$(OOCR)$_{16}$], where R = Bu^t (**1**), CH$_2$Bu^t (**2**), C(Me)$_2$Et (**3**), registered between 150 and 350 °C (MS-EI 70 eV)

	[Ti$_8$O$_8$(O$_2$CCMe$_2$Et)$_{14}$(O$_2$CCH$_3$)$_2$]$^+$	2240		4.7	**100**	**100**	**100**	**100**	**100**	**100**

Analysis of MS-EI spectra, registered in the temperature range 150–350 °C confirms the formation of the [Ti-(μ_2-O)]$_8$ rings stabilized by carboxylate bridges in the structures of all the studied compounds. Results of MS-EI experiments are presented in Table 6. Multinuclear titanium species were detected below 200 °C, which indicates partial decomposition of these compounds at lower temperatures. The characteristic peaks at $m/z = 2027$ ($[Ti_8O_8(OOCBu^t)_{15}]^+$), $m/z = 1811$ ($[Ti_8O_8(OOCCH_2Bu^t)_{10}(OOCCH_3)(OOCH)_2]^+$) and $m/z = 2240$ ($[Ti_8O_8(OOCC(Me)_2Et)_{14}(OOCCH_3)_2]^+$) with 100% intensity appear above 240 °C. Also TG/DTA data show the beginning of the mass detachment of samples **1**–**3** at this temperature. Simultaneously, the presence of multinuclear fragmentation ions above 240 °C indicates their thermal stability, which may be useful for their transport in the gas phase. That factor may be important for application of these compounds as precursors in the chemical vapor deposition methods. Comparison of **1**–**3** MS data showed that the thermal stability of multinuclear Ti(IV) fragmentation ions increases in the row $Bu^t < CH_2Bu^t < C(Me)_2Et$.

4. Conclusions

New titanium multinuclear Ti(IV) oxo carboxylates, with the general formula $[Ti_8O_8(OOCR)_{16}]$, where R = Bu^t (**1**), CH_2Bu^t (**2**), $C(CH_3)_2Et$ (**3**), have been synthesized in a reaction of titanium isopropoxide ($Ti(OPr^i)_4$) with suitable organic acids, in the molar ratio 1:2. X-ray studies of **1** revealed that the structure of this compound is formed by rings, composed of eight distorted [TiO_6] octahedra connected by two μ_2-O and four μ_2-O (carboxylate) bridges. Structural data exhibited the presence of solvent molecules (toluene) in the crystal lattice of **1**. The thermogravimetric and IR studies proved that solvent molecules are removed from the structure of this compound between 0 and 60 °C. The obtained results prove that the low stability of the crystals of **1** is caused by the presence of solvent molecules in the crystal lattice and their loss at room temperature. Spectral analysis of **1**–**3** powders showed that these compounds form a ring structure of the general formula $[Ti_8O_8(OOCR)_{16}]$. Variable temperature IR studies indicate the high thermal stability of the studied multinuclear Ti(IV) oxo carboxylates. Analysis of MS-EI data suggests that during the thermal decomposition of **1**–**3**, volatile multinuclear Ti-oxide species are formed above 240 °C. The stability of these species changes in the row $Bu^t < CH_2Bu^t < C(Me)_2Et$.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 256553. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1233-336-033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

A new extended tetrathiafulvalene (TTF) dithiolate ligand, benzotetrathiafulvalenedithiolate ($btdt^{2-}$), together with mercury complexes based on it, have been synthesized and characterized by cyclic voltammetry, ESR, IR and magnetic susceptibility measurements. The crystal structure of $(Me_4N)_2[Hg(btdt)_2] \cdot 4/3H_2O \cdot 2/3C_4H_9O$ (**4**) is determined, in which the central Hg atom is in an approximately tetrahedral coordination environment. Both ESR and cyclic voltammetry studies show that there is very little conjugating interaction between the two extended TTF dithiolate ligands. The neutral complex $Hg(btdt)_2$ (**5**) is prepared from **4** by oxidation with iodine. The electrical conductivity of **5** was measured as compressed pellets and the room temperature conductivity is 0.0015 S cm^{-1}. Magnetic susceptibility measurements reveal that complex **5** is a radical antiferromagnet.

1. Introduction

Metal complexes of 1,2-dithiolene ligands have been intensively studied as materials for molecular conductors and superconductors [1]. The crystal structure of these complexes reveal that intermolecular interaction through the sulfur–sulfur interatomic contact is the basic requirement for high conductivity. The incorporation of more heteroatoms, such as S or Se, into the periphery of the structure stabilizes the interactions via direct S···S or Se···Se overlap on the adjacent inter- and intra-stack ions. Recently metal complexes with extended tetrathiafulvalenedithiolene ligands have been of great interest because of their possible extended π-conjugation system and their better electrical conduction properties [2–14]. A few highly conducting molecule crystals of nickel, copper and gold complexes with extended TTF ligands have been reported [4–6]. Since the basic idea on the design of a molecular conductor is to reduce the HOMO–LUMO energy gap in the molecule by extending the π conjugated system and improving the planarity [12], the synthesis of highly conjugated and planar ligands becomes the main target. However, in these metal complexes with extended TTF dithiolate ligands, the side groups on the TTF framework all are alkyl groups. As we know, the length and type of the side alkyl group on the TTF framework have great effect on the conducting properties of the resulted complexes [3,10]. Bulky alkyl groups on the TTF framework will lead to molecules with non-compact packing, which decrease the intermolecular reaction. In order to eliminate the alkyl group effect on the TTF framework and increase the planarity and π-conjugation of the extended TTF dithiolate, we report herein the synthesis of a new extended TTF dithiolate ligand, benzotetrathiafulvalenedithiolate, together with mercury complexes based on this ligand.

2. Experimental

2.1. General procedures

Reagent-grade tetrahydrofuran (THF) was purified and distilled with standard methods. Other solvents and chemicals were purchased from commercial sources and used as received. Schlenk techniques were used in carrying out manipulation under nitrogen atmosphere. Elemental analyses for C, H and N were performed on a Perkin–Elmer 240C analyzer. The ESR spectra were measured using a Bruker ER 200-D-SRC spectrometer. The IR spectra were taken on a Vector22 Bruker Spectrophotometer (400–4000 cm^{-1}) with KBr pellets. NMR spectra were measured on a Bruker AM 500 spectrometer. Cyclic voltammetry data were recorded by an EG&G PAR Model 273 electrochemical analytical instrument. The magnetic susceptibility was measured using a Quantum Design MPMS-XL7 SQUID magnetometer at temperatures ranging from 1.8 to 300 K. The temperature dependence of the resistivity was measured by the conventional four-probe method using a copper wire attached with indium in the temperature range of 80–293 K. The $btdt^{2-}$ ligand and the related complexes were synthesized as shown in Scheme 1.

2.2. Preparation of 2,3-bis(2-cyanoethylthio)-benzotetrathiafulvalene (3)

2-Thioxo-1,3-benzodithiol (**1**) [15,16] and 5-bis-(2-cyanoethylthio)-1,3-dithiole-2-one (**2**) [9] were synthesized as described in the literature. Under a nitrogen atmosphere, to the mixture of **1** (0.92 g, 5 mmol) and **2** (0.86 g, 3 mmol) was added 25 ml of freshly distilled $P(OC_2H_5)_3$. The reaction mixture was heated at 110 °C for 1 h and then allowed to cool to room temperature. After 25 ml of methanol was added to the above suspension, on filtering an orange-red precipitate was collected and washed with methanol, which was then chromatographed on a silica gel column using dichloromethane as the eluent. Orange-yellow powder **3** was obtained. Yield: 0.72 g (56%, based on **2**). *Anal.* Calc. for $C_{16}H_{12}N_2S_6$: C, 45.28; H, 2.83; N, 6.60; S, 45.28. Scheme 1.

2.3. Preparation of $(Me_4N)_2[Hg(btdt)_2] \cdot 4/3H_2O \cdot 2/3C_4H_9O$ (4)

Under a nitrogen atmosphere, a methanol solution of Me_4NOH (0.45 ml, 25% (w/w), 1 mmol) was added to **3** (212 mg, 0.5 mmol) in 20 ml of THF at −5 °C. A red-orange precipitate was observed immediately and the reaction mixture was left stirring at the same temperature for 30 min. THF was removed in vacuo at 10 °C and the resulting pink solid was dissolved in 20 ml of methanol. Then $Hg(OAc)_2$ (80 mg, 0.25 mmol) in 10 ml of methanol was added and a gold-yellow precipitate was observed immediately, the reaction mixture was left to stir at 0 °C for 12 h. The gold-yellow precipitate was filtered off, washed with methanol and ether, and dried in vacuo. Yield: 210 mg (86%). *Anal.* Calc. for $C_{28}H_{32}N_2S_{12}Hg$: C, 34.26; H, 3.26; N, 2.86; S, 39.16. Found: C, 34.16; H, 3.28; N, 3.02; S, 39.42%. IR (KBr cm^{-1}): *v* 3442(w), 3018(w), 1598(m), 1566(m), 1479(s), 1445(s), 1433(m), 1118(w), 1022(w), 947(s), 864(m), 746(m), 674(w), 467(w). Air-stable gold-yellow plate-shaped crystals of $(Me_4N)_2[Hg(btdt)_2] \cdot 4/3H_2O \cdot 2/3C_4H_9O$ were obtained by slow diffusion of diethyl ether into a solution of the product in acetonitrile.

2.4. Preparation of $[Hg(btdt)_2]$ (5)

Microcrystalline complex **5** was obtained by slow diffusion of iodine vapor into a DMF solution of complex **4** under nitrogen. The microcrystalline precipitate was filtered off, washed with DMF, acetonitrile, methanol and ether, and then dried in vacuo. *Anal.* Calc. for $C_{20}H_8S_{12}Hg$: C, 28.83; H, 0.96; S, 46.12; N, 0. Found: C, 29.10; H, 0.91; S, 46.23; N, 0%. IR (KBr cm^{-1}): *v* 1564(m), 1467(s), 1444(s), 1431(s), 1282(s), 1257(m), 1197(s), 1117(s), 1026(m), 959(m), 886(w), 770(m), 733(s), 674(m), 469(w).

3. X-ray crystallography

The structure of complex **4**, $(Me_4N)_2[Hg(btdt)_2] \cdot 4/3H_2O \cdot 2/3C_4H_9O$, was determined. The crystal was mounted in Infineum oil and placed in a dinitrogen cold stream on a Siemens (Bruker) SMART CCD-based diffractometer. Cell parameters were retrieved using SMART software and refined using SAINT on all observed reflections. Data were collected using the following strategy: 606 frames of 0.3° in with $\phi = 0°$, 435 frames of 0.3° in ω with $\phi = 90°$, and 235 frames of 0.3° in ω with $\phi = 180°$. An additional 50 frames of 0.3° in ω with $\phi = 0°$ were collected to allow for decay correction. The highly redundant data sets were reduced using SAINT and corrected for Lorentz and polarization effects. Absorption corrections were applied using SADABS supplied by Bruker. Structures were solved by direct methods using the program SHELXL-97. The positions of the metal atoms and their first coordination spheres were located from direct-methods *E*-maps; other non-hydrogen atoms were found in alternating difference Fourier syntheses and least-squares refinement cycles and, during the final cycles, refined anisotropically. Hydrogen atoms were placed in calculated positions and refined as riding atoms with a uniform value of U_{iso}. Crystallographic parameters and agreement factors are contained in Table 1.

4. Result and discussion

4.1. Synthesis

The benzotetrathiafulvalenedithiolene was prepared similar to the literature method [9]. The synthetic procedure is shown in Scheme 1. Cyanoethyl was used as the protecting group in the cross-coupling reaction to synthesize the unsymmetrical TTF derivative. By silica gel column chromatography, using CH_2Cl_2 as eluent, 2, 3-bis(2-cyanoethylthio)-5,6-benzotetrathiafulvalene was obtained in high yield (56%). Under nitrogen atmosphere, the cyanoethyl group was removed by using Me_4NOH as the base in THF at −5 °C, which generated the dithiolate. Then the dithiolate ligand reacted further

with mercury(II) ions and resulted the isolation of the metal complex. The analytically pure neutral complex **5** was obtained by slow diffusion of iodine vapor into a DMF solution of complex **4** under nitrogen. The yielded microcrystalline powder sample of complex **5** is insoluble in common solvents.

4.2. Crystal structure of *4*

There are one and half molecules of complex **4** in each asymmetric unit. The atom labeling scheme of one anion part of the solvated complex, $(Me_4N)_2[Hg(btdt)_2]\cdot 4/3H_2O\cdot 2/3C_4H_9O$, is shown in Fig. 1. The selected bond lengths and angles are listed in Table 2. The mercury atom is in an approximately tetrahedral geometry. The dihedral angle between the planes [S1, S2, S3, S4, C10, C11] and [S7, S8, S9, S10, C20 C21] is 90.3°. In the five-membered ring containing the mercury atom, the average Hg–S and C=C bond lengths are 2.532(2) and 1.352(9) Å, respectively. The S–C bond distance of the dithiolate are 1.732(6)–1.755(6) Å, which are somewhat shorter than the S–C bond distance of the two TTF units (1.745(7)–1.780(7) Å). The bond angles of S(1)–Hg–S(2) and S(7)–Hg–S(8) are 89.02(5)° and 88.74(5)°, respectively, which are smaller than the idealized tetrahedral value. The dihedral angle between the planes [S7, S8, S9, S10, C20. C21, C22] and [S11, S12, C23–C29] is 132.1°, and the angle between the planes [S1, S2, S3, S4, C10, C11, C12] and [S5, S6, C13–C19] is 132.8°. The two TTF units in complex deviate from planarity due to the non-planar coordination of the central atom Hg and the packing effects of intermolecular adjacent TTF units. The packing diagram for complex **4** is shown in Fig. 2, the short intermolecular S···S distances in crystal are 3.868 Å ($S(5)\cdots S(12)^a$, symmetry operations: $x, 1-y, 1.5+z$), 3.949 Å ($S(3)\cdots S(12)^a$) and 3.956 Å ($S(5)\cdots S(10)^a$), which are somewhat shorter than that of the similar mercury complex with an extended TTF ligand [3].

Symmetry operations a: $x, 1-y, 1.5+z$.

4.3. Cyclic voltammetry

Cyclic voltammetry of the ligand **3** and complex **4** were carried out on a Macroscopic platinum-disc electrode in DMF solution, and the reference electrode was Ag/AgCl (using 0.1 mol dm^{-3} $(Bu_4N)ClO_4$ as supporting electrolyte, 100 mV S^{-1}). The ligand **3** shows a single electron oxidation peak at 0.8 V. Similar to the mercury complex with TTF ligand [3], a single oxidation peak at 0.48 V was observed for complex **4**, indicating that the two TTF units in complex **4** were completely absent of interaction and independently oxidized to remove one electron with equal potential in DMF solvent. This is the reason that the monoanionic species of **4** is difficult to isolate.

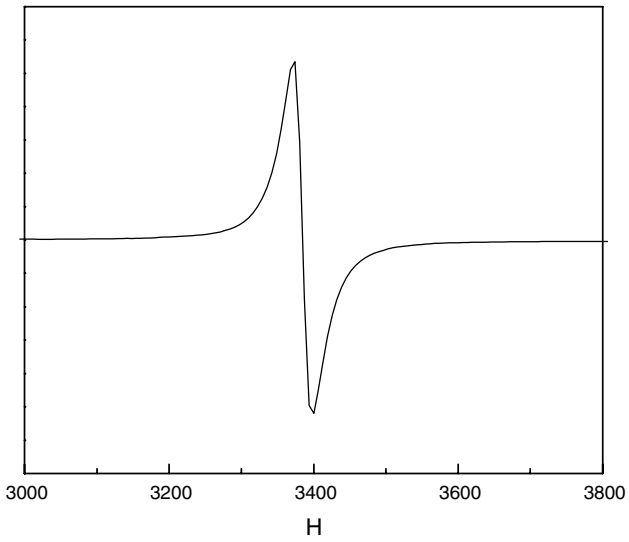

Fig. 3. ESR spectrum of complex $Hg(btdt)_2$ (**5**) at 110 K.

4.4. ESR spectra

The ESR spectrum of the neutral complex **5** was measured in the solid state at 110 K. Complex **5** contained a singlet with a g value of 2.003 (Fig. 3). There is little conjugation interaction between the two linked TTF dithiolate units in this molecule since complex **5** has approximately tetrahedral coordination around the Hg atom, as shown in structural analyses. Each extended TTF dithiolate unit has an independent single electron radical, which accounts for the singlet observed in the ESR spectrum. The result is in accord with other neutral mercury complexes with a TTF-based ligand [3].

4.5. Magnetic properties

Magnetic susceptibility measurements for complex **5** were performed on a Quantum Design MPMS-XL7 SQUID magnetometer at temperatures ranging from 1.8 to 300 K. For complex **5**, at the room temperature, $\chi_M T$ is 0.042 emu K mol^{-1}, much smaller than the value (0.75) of two electrons radicals in a molecule sheet. As the temperature is lowered, the $\chi_M T$ value decreases al-

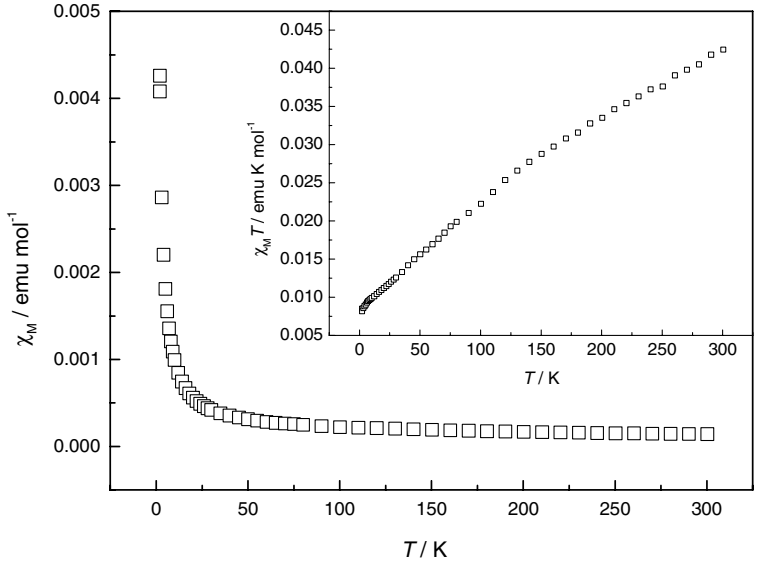

Fig. 4. Temperature dependence of the χ_M and $\chi_M T$ (inset) for complex $Hg(btdt)_2$ (**5**).

most linearly to reach 0.008 emu K mol^{-1} at 2 K (Fig. 4), implying that an antiferromagnetic interaction dominates the magnetic properties of this complex over the whole temperature range. Since the absence of a conjugation interaction between the two TTF dithiolate groups of the intramolecule, due to the tetrahedral coordination around the central Hg atom, each TTF dithiolate group is viewed as an independent radical cation. This was confirmed by the ESR spectrum of complex **5** which contained a singlet with a g value of 2.003. Thus, the intramolecular spin coupling between the radicals is not the source leading to the strong antiferromagnetic properties of complex **5**. It is suggested that the strong antiferromagnetic coupling results from intermolecular exchange, since the spin widely delocalizes in the individual TTF-dithiolate group and further leads to the effective intermolecular interaction. It is consistent with the ESR result exhibiting no coupling radical cation in the molecule. Using the mean-field expression of the Curie–Weiss temperature $\theta = 2zj'S(S+1)/3k_B$ [17], the magnetic interaction $zj'k_B$ between the radicals can be estimated to be ca. -465.3 K (-322.9 cm^{-1}) with $S = 1/2$, which supports the results mentioned above.

4.6. Electrical conductivities

The electrical conductivities of neutral complex **5** were measured as compressed pellets over the range 80–293 K (Fig. 5), the room temperature conductivity is 0.0015 S cm^{-1} and the activation energy is 0.24 eV. Since the Hg atom is in an approximately tetrahedral environment, with two non-planar coordinating dithiolate ligands, only a very weak conjugation interaction between the two extended TTF dithiolate units exists in complex which together with the molecule's non-compact packing lead to lower conductivity. From room temperature to 125 K, the change in the value of resistivity (ρ) is very small. Below 125 K the value of ρ increases rapidly on lowering the temperature, indicating that complex **5** is a semiconductor.

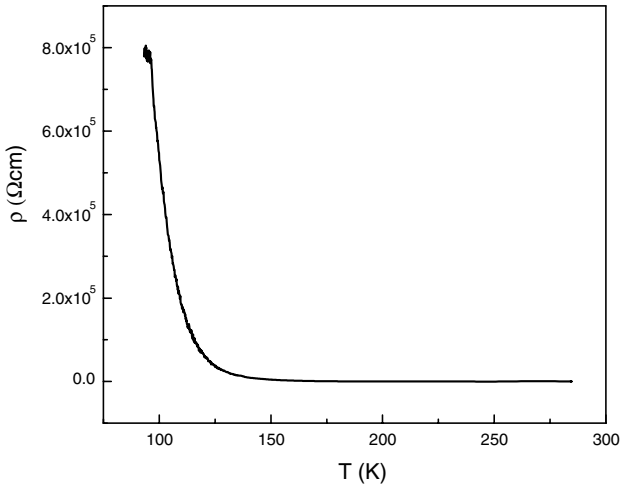

Fig. 5. Temperature dependence of the electrical resistivity of $Hg(btdt)_2$ (**5**).

The work on the nickel analogs of this new tetrathiafulvalene 4,5-dithiolate ligand, and experiments aimed at highly conducting metal complexes and multi-functional materials are current under way in our laboratory.

Studies on cobalt(II), nickel(II) and copper(II) derivatives of some new *meso*-aryl substituted octabromoporphyrins

Regimol G. George, M. Padmanabhan *

School of Chemical Sciences, Mahatma Gandhi University, Priyadarshini Hills, Kottayam 686560, Kerala, India

Received 13 November 2003; accepted 24 January 2005

Abstract

A series of Co(II), Ni(II) and Cu(II) derivatives of a variety of porphyrins with tolyl (H_2TxTP) and naphthyl (H_2NxTP) moieties as *meso*-substituents are synthesised and characterised. H_2TxTP has the tolyl functions bonded to *meso*-carbons at the *o*-, *m*- or *p*-positions of the tolyl moieties while H_2NxTP has naphthyl groups bonded through their α- or β-positions. Their octabromo derivatives (MTxOBP and MNxOBP) were also synthesised by electrophilic substitution at the β-pyrrole positions. Optical spectra showed that the Q bands remain almost unaltered for both tolyl and naphthyl derivatives of the nonbrominated porphyrins while the B bands of their naphthyl derivatives are seen to be more red-shifted than their tolyl analogues. Even though a similar trend based on the *meso*-substituents is observed among all MTxOBP and MNxOBP derivatives, a substantial red-shift is seen for all the bromoderivatives compared to their nonbrominated species MTxTP and MNxTP. The energy difference $\Delta\bar{\nu}$ associated with this red-shift of the Soret band is seen to be in the range 1700–2050 cm^{-1} for Co(II) and Ni(II) derivatives, the naphthyl derivatives always having higher values. Energy level reordering due to electron-withdrawing Br-substituents, distortion bringing about non-planarity in the π-framework resulting in HOMO–LUMO level changes and the mesomeric effect due to *meso*-aryl moieties can be considered to be the reasons for the observed spectral changes. The EPR spectra of the Cu(II) derivatives of bromoporphyrins have lower $A_{\parallel}^{Cu}$ and $A_{\perp}^{Cu}$ hyperfine values compared to their nonbrominated analogues, indicating enhanced delocalisation of electron spin to the octabromoporphyrinato moiety. An enhanced Cu–N σ-covalency is seen in the Cu(II)–bromoporphyrins, as evident from their lower α^2 values.

1. Introduction

Synthesis of varyingly substituted porphyrins and their metalloderivatives continues to be an active area of research owing to their wide applications as versatile catalysts, enzyme mimics, nonlinear optical materials and as candidates for photodynamic therapy [1–6]. The fact that there are twelve substitutional sites on the periphery and a highly tunable π framework which can act as an electron sink makes electronic and redox modulation of the porphyrin macrocycle an interesting and fruitful exercise leading to products of varying chemical, optical and photophysical properties [7–12]. We have been interested in developing electronically and structurally modified porphyrins, especially on solid polymer matrices, and have demonstrated their ability to carry out a few enzyme mimetic reactions efficiently [13–18]. Knowing the ability of Br substitution to bring

doi:10.1016/j.poly.2005.01.008

about interesting electronic, redox and structural modification of aryl porphyrins, we have synthesised and studied some of the interesting properties of a series of octabromoporphyrins and also their Fe(III) and Mn(III) derivatives [19–21]. The studies on such perbrominated porphyrins are of great relevance in the context of growing interest on nonplanar porphyrins which are generated either by substitution of the β-pyrrole positions by bulky/electron withdrawing substituents or by incorporating bulky groups at the *meso*-positions. Realising the biological significance of such distorted porphyrins is one of the major concerns of experimental and theoretical chemists alike with regard to tracing the origin of their red-shifts [22–25]. In this work we report the synthesis and characterisation of Co(II), Ni(II) and Cu(II) derivatives of some *meso*-tolyl and *meso*-naphthyl porphyrins and also their octabromo derivatives and discuss salient features of their spectral properties.

2. Experimental

Pyrrole (Fluka) was distilled over KOH pellets, under reduced pressure before use. The α-naphthaldehyde and β-naphthaldehyde (E. Merck) were used as such. All the solvents employed in the present study were of spectral grade and were distilled before use. Liquid bromine procured from Ranbaxy and basic alumina obtained from Acmes were used as received. The metal salts (E. Merck) were also used without further purification. The UV–Vis spectral measurements were carried out with a Shimadzu 160A UV–Vis spectrophotometer. Elemental analyses were done using a Perkin–Elmer CHN analyzer. The EPR Spectra were measured on a Varian E-109 X-band spectrometer with the micropower set at 5 mW and with a modulation frequency of 100 K. The solution of copper(II) porphyrins was made in a toluene–methanol mixture with a concentration ca. 10^{-4} M. The 'g' marker employed was TCNE radical.

2.1. Preparation

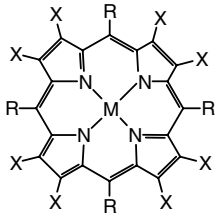
2.1.1. Free-base porphyrins H_2TxTP, H_2NxTP, H_2TxOBP and H_2NxOBP

The free-bases of tetratolyl (H_2TxTP) and tetranaphthyl porphyrins (H_2NxTP) including those reported earlier [19] were synthesised by Adler's method involving the condensation between pyrrole and the respective aldehydes in propionic acid medium [26]. Their brominated free-bases, tolyl (H_2TxOBP) and naphthyl porphyrins (H_2NxOBP), were prepared by brominating the Cu(II) derivatives of the respective porphyrins H_2TxTP and H_2NxTP, based on the reported procedure [19,27]. The yields of the bromoderivatives were in the range 75–80%.

2.1.2. Cobalt(II), nickel(II) and copper(II) complexes of H_2TxTP and H_2NxTP

The metallation of the nonbrominated porphyrins H_2TxTP and H_2NxTP was carried out by a known procedure. The free-base tolylporphyrins H_2TxTP (0.5 g, 0.74 mmol) or free-base naphthylporphyrins H_2NxTP (0.5 g, 0.61 mmol) were dissolved in a suitable solvent mixture ($CHCl_3$:CH_3OH, 40 mL, 1:1, v/v). To this, the metal carrier $CoCl_2 \cdot 6H_2O$ (1.6 g, 7 mmol), $Cu(CH_3COO)_2 \cdot 4H_2O$ (1.4 g, 7 mmol) or $NiCl_2 \cdot 6H_2O$ (1.7 g, 7 mmol) dissolved in glacial CH_3COOH (1.5 mL) was added for the synthesis of the respective metalloderivatives. NaOAc was employed as a base. On refluxing the reaction mixture on a water bath, the metallation gets initiated as evident from the UV–Vis spectral measurements. The metallation usually gets completed within 4 h for Co(II) derivatives, 6–8 h for Ni(II) derivatives and 2 h for Cu(II) derivatives. The reaction mixture was washed repeatedly with water to remove the unreacted metal salts and the metalloporphyrins formed were purified by column chromatography on basic alumina using $CHCl_3$ as eluent and were further purified by recrystallisation using hexane/$CHCl_3$ mixture. Metallation was confirmed by UV–Vis spectroscopy. Yields were in the range of 80–85% for Co(II), 70–75% for Ni(II) and 85–90% for Cu(II) complexes.

2.1.3. Cobalt(II), nickel(II) and copper(II) complexes of H_2TxOBP and H_2NxOBP

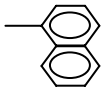


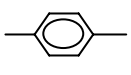
The metallation of all the bromoporphyrins could be carried out at room temperature. To a solution of the metal carrier of $CoCl_2 \cdot 6H_2O$ (2 g, 8.75 mmol), $NiCl_2 \cdot 6H_2O$ (2.12 g, 8.75 mmol) or $Cu(CH_3COO)_2 \cdot 4H_2O$ (1.75 g, 8.75 mmol) in $CHCl_3$:MeOH mixture (60 mL, 2:1, v/v) was added H_2TxOBP (0.60 g, 0.46 mmol) or H_2NxOBP (0.66 g, 0.46 mmol), 2 mL of glacial $MeCO_2H$ and 1 g of powdered NaOAc. The reaction mixture was stirred either at room temperature or on a water bath for about 1–2 h. The completion of the metallation reaction was monitored by electronic spectroscopy. The mixture was then taken in a separating funnel, washed repeatedly with water after which the organic phase was separated and dried over anhydrous Na_2SO_4. The compound was purified by column chromatography (basic Al_2O_3, $CHCl_3$ eluent) to obtain the metalloderivative and then by recrystallisation using hexane/$CHCl_3$ mixture (yield 95%).

3. Results and discussion

The free-base porphyrins, which are purified by careful column chromatography, are characterised by chemical analysis, electronic and ^1H NMR studies [19–21]. All the free-base porphyrins gave reasonably good ^1H NMR signals as reported by us earlier [19]. The effect

due to various aryl groups at the *meso*-positions and also due to the Br substitution at the eight β-pyrrole positions on the optical absorption, fluorescence emission and redox potential of the free-base porphyrins has been reported by us recently [19,20].





As mentioned in the preparatory section all the metalloporphyrins were purified by column chromatography. The compounds were characterised by electronic and EPR studies. The various Co(II), Ni(II) and Cu(II) derivatives of both the nonbrominated and brominated porphyrins prepared are summarised in Table 1, wherein the substituents indicated in (*1*) are specified.

(*1*)

It is seen that among the nonbrominated porphyrins, the naphthyl derivatives undergo easier metallation than the tolyl derivatives. This could be attributed to the possible distortional change brought about on the porphyrin ring in H_2NxTP by the bulkier *meso*-naphthyl groups as compared to the tolyl porphyrins. The metallation of all the bromoporphyrins are also found to be very facile as it could be carried out at room temperature. It is known that all perbrominated porphyrins tend to exist in a highly distorted form because of the presence of bulky Br atoms at the eight β-pyrrole positions [27,28]. Since the mechanism of metallation involved has been proposed to be following a "sitting atop mechanism," such a distortion also can be expected to facilitate metallation processes. Further, the electron withdrawing effect due to the eight Br-atoms at the β-pyrrole positions can be expected to help substantially the deprotonation step of the –NH protons, augmenting the metallation. Compared to cobalt(II) and nickel(II) derivatives, the copper(II) metalloporphyrins are seen to be easily formed.

[a] Calculated values are given in parentheses.

3.1. Electronic spectra

The electronic spectra of the metal complexes were recorded in $CHCl_3$ at 298 K. The data are presented in Table 2. Some of the salient features associated with the electronic spectra are given below.

The Co(II), Ni(II) and Cu(II) porphyrins of the nonbrominated forms of the tetratolyl and tetranaphthyl porphyrins show characteristic absorption peaks of typical *meso*-aryl derivatives. We see that the B band of the naphthyl derivatives in all their metalloderivatives have absorptions at higher wavelength compared to their tolyl derivatives. However, we do not observe any perceptible difference in the absorption maxima for both B and Q bands among the various tolyl derivatives and also within the naphthyl species.

The cobalt(II) complexes of the brominated porphyrins manifest significant changes compared to their nonbrominated species. Both B and Q bands for the complexes are seen to be red-shifted compared to their nonbrominated derivatives. The red-shift $\Delta\bar{\nu}$ was calculated as the energy difference of the Soret band in wavenumbers between the complexes of brominated and nonbrominated porphyrins. The energy difference $\Delta\bar{\nu}$ for them is seen to be in the range 1915–2130 cm^{-1}, the naphthyl species having larger differences than the tolyl derivatives. As in the case of cobalt(II) derivatives, the nickel(II) species of all the brominated porphyrins also show red-shifted B and Q bands, which is evident from Table 2. The $\Delta\bar{\nu}$ for the B band for these complexes was found to be between 1770 and 1940 cm^{-1} which is comparatively lower than that for their Co(II) derivatives.

In the case of Cu(II) bromoporphyrins, the expected red-shifts are also seen for both B and Q bands, but the significant feature, however, is the appearance of two overlapping peaks centered ca. 445 and 470 nm for the B band of the Cu(II) complexes of brominated porphyrins compared to their nonbrominated species. This phenomenon is not manifested by their analogous Ni(II) and Co(II) derivatives. In all the three metal derivatives, $\Delta\bar{\nu}$ is seen to be the lowest for the *ortho*-tolyl porphyrins and the highest for their naphthyl derivatives. The underlying factors involved in the above spectral features could be summarised as below.

The fact that the naphthyl porphyrins have a greater red-shifted Soret band as compared to the tolyl derivatives in all their Co(II), Cu(II) and Ni(II) complexes

[a] Molar extinction coefficient ε in $10^{-4}/dm^3\ mol^{-1}\ cm^{-1}$.
[b] $\Delta\bar{\nu} = \bar{\nu}_2 - \bar{\nu}_1$, where $\bar{\nu}_1$ is the energy of the B band for brominated porphyrin and $\bar{\nu}_2$ that for the corresponding nonbrominated porphyrin.

for both brominated and nonbrominated forms could be attributed to the higher mesomeric participation of the naphthyl moieties with the macrocyclic π-framework by adjusting the porphyrin-aryl dihedral angle. Because of a less extended π-system, the tolyl groups will have lesser conjugative participation with the porphyrin π-framework than their naphthyl analogues. The fact that all the metalloderivatives of *o*-tolyl porphyrins in their brominated and nonbrominated forms have their B and Q bands absorbing at lower wavelength could be attributed to the inability of the *o*-tolyl groups to tilt in order to reduce the dihedral angle for better conjugative interaction because of higher steric strain caused by $-CH_3$ groups at the *ortho*-position of the *meso*-tolyl moieties.

The pronounced red-shift observed for the Co(II), Ni(II) and Cu(II) derivatives of all the brominated porphyrins compared to their nonbrominated derivatives can be explained in terms of the electronic change caused by the electron-withdrawing Br-groups coupled with distortion of the porphyrin framework brought about by the bulky Br-atoms at the eight pyrrole β-positions [19,27,28]. The trend in the red-shift of B band observed for tolyl and naphthyl derivatives of the Br-substituted porphyrins is similar for their Co(II), Ni(II) and Cu(II) complexes and could be explained by considering the various factors which influence the energies of both the HOMO and LUMOs of the metalloporphyrins. It is evident that the eight Br substituents at the β-pyrrole positions would drain out electron density from the porphyrin – framework making the macrocycle more susceptible to reduction [19,27]. The concerted action by the electronegative Br atoms would also make the system resistant to oxidation. These would result in lowering of both LUMOs and the HOMO levels. One of the major factors for the red-shift of the porphyrins (in both B and Q) is essentially this electronic effect. Coupled with this electronic modulation there is also a significant effect due to a steric factor. The bulky Br-atoms at the eight pyrrole β-positions would bring about major structural distortion within the porphyrin framework to ease steric strain. Such a distortion would cause a significant perturbation in conjugation, the effect of which would be significant alteration of π-energy levels including destabilisation of the HOMO and some lowering of the LUMOs. INDO level calculation has testified such a reordering in the energy levels of the frontier orbitals on distortion [29]. Because of the lowered symmetry the degenerate e_g^* orbitals (LUMOs) can be expected to be split, lowering the energy of one component. A substantial reduction in the HOMO–LUMO gap is, therefore, expected because of such a geometry variation. The major red-shift observed on bromination can be attributed essentially to these factors.

It is known that while Co(II) and Ni(II) porphyrins show affinity to Lewis-bases and ligating solvents and coordinate them at the axial positions of the metal centre, while Cu(II) porphyrins exhibit no such tendency and remain unligated. We have verified this with Lewis-bases like pyridine and imidazole for all the MTxTP and MNxTP of nonbrominated porphyrins. We were, however, interested in knowing whether Cu(II) derivatives of bromoporphyrins would have any affinity towards Lewis-bases because of the strong electron accepting ability of the bromoporphyrinato framework (compared to the nonbrominated porphyrins). While Co(II) and Ni(II) derivatives of the bromoporphyrins were found to show enhanced affinity towards Lewis-bases, their Cu(II) derivatives were still resistant to any adduct formation, as evident from practically no change seen in the electronic spectra even in an excess of base.

3.2. EPR spectra

The EPR spectra of all the Cu(II) porphyrins were measured at the X-band frequency to understand both the electronic and bonding features between the paramagnetic Cu(II) and the porphyrinato moiety. The spectra were recorded in a toluene–methanol mixture at liquid nitrogen temperature. While two hyperfine peaks of the parallel components of the anisotropic spectra are clearly discernible in the low field, the other two are seen overlapped in the perpendicular component. The spin

[a] Not resolvable.

Hamiltonian parameters for the copper(II) compounds were extracted from the spectra by a known procedure [30], by considering the axial symmetry of the metalloporphyrins. The value of α^2 (σ-covalency factor) was also evaluated from the EPR parameters using the Kivelson and Neiman equation [31], $\alpha^2 = (A^{\parallel}/P + (g_{\parallel} - 2.0023) + 3/7(g_{\perp} - 2.0023) + 0.04)$, where P is the spin–orbit coupling factor. It is known that metalloporphyrins are sensitive to the molecular environment around them. This has been well demonstrated by the difference in electronic spectra observed for these complexes. The EPR data also yield similar results, as exemplified by the variations in the spin Hamiltonian parameters for Cu(II) in different molecular environments. The various parameters evaluated for the Cu(II)-porphyrins are presented in Table 3.

The $g_{\parallel}$ and $g_{\perp}$ values, along with other parameters, are in conformity with a square planar geometry for all the brominated and nonbrominated copper(II) porphyrins studied [32,33]. The nature of the *meso*-aryl substituents is not seen to be affecting these parameters significantly. However, the hyperfine constants $A_{\parallel}^{Cu}$ and $A_{\perp}^{Cu}$ are found to be altered considerably in copper(II) bromoporphyrins compared to their nonbrominated porphyrins. All the brominated porphyrins have $A_{\parallel}^{Cu}$ around 19 mT which is less than their nonbrominated porphyrins ($A_{\parallel}^{Cu}$ ca. 20 mT). Similarly the $A_{\perp}^{Cu}$ are found to be lowered from ca. 3.5 mT to ca. 3 mT on bromination. The lower Cu-hyperfine values seen for the copper(II) bromoporphyrins can be understood from the fact that the porphyrinato moiety, being depleted in electron density by the eight peripheral Br atoms, would withdraw electron density from the metal $d_{x^2-y^2}$ orbital thus delocalising the free electron significantly onto the ligand moiety compared to the Cu(II)-nonbrominated porphyrins. The higher Cu-hyperfine constants found for the metal derivatives of nonbrominated porphyrins implies more delocalisation of the unpaired Cu electron.

The α^2 value evaluated from the spin Hamiltonian parameters represents the bonding coefficient of the b_1 molecular orbital (which is a linear combination of metal $d_{x^2-y^2}$ and four in plane sp^2 hybridised orbitals of the porphyrinato moiety, one on each of the N atoms) and gives a qualitative idea about the measure of σ-covalency of the Cu–N bond. The stronger the in-plane σ-bond interaction between Cu^{2+} and N's, the higher is the energy of the b_1 molecular orbital because of its antibonding character. The α^2 values evaluated for all the Cu(II)-nonbrominated porphyrins are in the range 0.555–0.564, showing that the *meso*-substituents have little influence on the nature of the M–N covalent bonding. However, in the case of the brominated species, the α^2 values are lowered to 0.528 indicating more σ-covalency between copper and nitrogen facilitated by the electron-withdrawing Br substituents, which are in direct interaction with the porphyrin π-system.

Received 12 November 2004; accepted 25 January 2005

Abstract

The in situ measurements of infrared spectra and the Ag K-edge EXAFS spectra of the fully Ag^+ exchanged zeolite X (Ag_{86}–X) were carried out from room temperature to 300 °C under vacuum. By evacuation at room temperature the O–H stretch vibration (ν(O–H)) mode around 3 μm disappears and the coordination number of oxygen around Ag, N_{Ag-O}, decreases due to removal of water molecules. The T–O asymmetric stretch (ν_{as}(T–O)) mode associated with zeolite framework oxygen appears around 10 μm. These infrared spectra are fitted by summing up Gaussian peaks. The positions of the main two peaks are 1000 and 1100 cm^{-1} at room temperature. At 100 °C, a third infrared peak appears at around 955 cm^{-1}, the total N_{Ag-O} becomes small and the coordination number of Ag around Ag, N_{Ag-Ag}, is 0.5. These results suggest that Ag atoms change sites in the zeolite and play an important role as a precursor of the Ag clusters. At 300 °C, the peaks around 1000 and 1100 cm^{-1} shift to 1050 and 1140 cm^{-1}, respectively, and N_{Ag-Ag} becomes 2.9, which indicates that the Ag clusters attached to the zeolite framework are stabilized at high temperature. When the zeolite with Ag clusters is exposed to atmosphere, it is found that: (1) the ν(O–H) mode around 3 μm appears again, (2) there are two main peaks (1000 and 1100 cm^{-1}) and a small peak around 856 cm^{-1} and (3) the local structure of the Ag clusters formed at 300 °C never reverses.

1. Introduction

Zeolites are crystalline aluminosilicates showing unique properties due to the presence of channels and cages in the structure. There are a number of applications as molecular sieves and catalysts [1]. Zeolite frameworks are made of SiO_4 and AlO_4 tetrahedra connected by corners. The negatively charged Al sites are neutralized by the charge-balancing framework cations, such as the Na^+ ion. There are 86 Na^+ ions in a unit cell of zeolite X. The Na^+ ions are exchanged by Ag^+ ions when the zeolites are put in a solution containing Ag^+ ions. In the fully Ag^+-exchanged zeolite X (Ag_{86}–X), 86 Ag^+ ions are located: (i) at site I (the center of the hexagonal prism), (ii) at site II (single six-ring in the large cage) and at site III (sequence of four-rings in the large cavity) [2]. When the hydrated Ag_{86}–X, with a white color, is heated under vacuum, the color changes into yellow and the silver ions are reduced to Ag atoms which form silver clusters consisting of the reduced Ag atoms and Ag^+ ions [3,4]. The silver clusters are stabilized by the silicate matrix, that is, the zeolite framework.

Measurements of the infrared vibrational spectra [5–8] give information on the dynamics of the zeolite framework and the cations. Extended X-ray absorption fine structure (EXAFS) measurements are suitable for observations of the local structure around Ag^+ ions or Ag atoms which are attached to the framework in the

zeolite. For example, silver-almina catalysis are investigated by in situ infrared spectroscopy and EXAFS [9]. It is interesting to study the effect of the formation of Ag clusters on the zeolite framework of Ag_{86}–X by means of infrared and EXAFS measurements which enable us to prepare complementary information.

In this paper, we report the results obtained by the in situ infrared and XAFS measurements for Ag_{86}–X heated from room temperature (RT) to 300 °C under vacuum. The effect of the formation of Ag clusters on the zeolite framework is discussed.

2. Experimental

Ag_{86}–X powder samples were prepared by immersing Na_{86}–X ($Na_{86}[(AlO_2)_{86}(SiO_2)_{106}]_{46} \cdot 2H_2O$) zeolite in 0.1 M $AgNO_3$ solution for 12 h at 25 °C. The solution was stirred every hour. After careful filtration the Ag^+-exchanged X zeolite powder was dried at room temperature in the darkroom. The amounts of the exchanged Ag^+ ions in the X zeolite were determined by means of electron probe microanalyzer (EPMA, JX A-8800L, JEOL) [10,11]. The Ag_{86}–X zeolite was set into the in situ infrared and EXAFS measurement vacuum cell (RVX-I) in which the sample can be heated up to 300 °C and cooled down to liquid nitrogen temperature under vacuum. Ag_{86}–X and Na_{86}–X samples were used for infrared measurements and Ag_{86}–X was used for the EXAFS measurements. NaCl single crystal windows were used for infrared measurements and Kapton® films were used for EXAFS measurements. A high-purity Si single-crystal wafer was used as the substrate for the infrared measurements. Zeolite powder was deposited on the wafer, then blown off an excessive specimen with a hand blower. A small quantity of zeolite was stuck electrostatically. For EXAFS measurement, the sample was filled in the space of a glass filter sandwiched by two cover glasses. The glass filter was suitable for removing H_2O vapor from the zeolite. These glass parts were set in the copper holder. The sample thickness was about 3 mm for obtaining a reasonable edge jump (more than 1.0) of the Ag K-absorption edge.

The infrared light absorption spectra were obtained at normal incidence of radiation. The infrared measurements were performed on a BOMEN MB-100 spectrometer equipped with a liquid nitrogen-cooled HgCdTe detector at 4 cm^{-1} resolution with 128 interferometric scans. The sample was held at one temperature for more than 2 h in the heating operation and then cooled down to room temperature where the infrared spectra were obtained. Ag K-edge (25.5 keV) EXAFS spectra were measured at BL-10B of Photon Factory in KEK using the Si (3 1 1) channel-cut monochrometer. The energy and current of the storage ring were 3.0 GeV and 250–300 mA, respectively. The EXAFS spectra for the sample heated in a vacuum were obtained at liquid nitrogen temperatures in order to reduce the Debye–Waller effect. The EXAFS measurement for the sample under atmospheric pressure was carried out at 300 K. The analyses of the EXAFS data were performed by XANADU code [12] and FEFF6.01 code [13].

3. Results

3.1. Infrared absorption spectra

Fig. 1 shows the infrared spectra of hydrated Na_{86}–X and Ag_{86}–X under air at room temperature. In the hydrated state Na_{86}–X and Ag_{86}–X give very similar spectra. There are some absorption bands at the 3 and 10 μm regions. The strongest vibration bands at 10 μm region are assigned to a T–O asymmetric stretch (ν_{as}(T–O)) involving a motion primarily associated with oxygen atoms [14].

3.1.1. Ag_{86}–X

Fig. 2(A) shows the change of infrared spectra for Ag_{86}-(ν_{as}(T–O)) at room temperature as a function of evacuation time. The absorption bands around 3 μm vanish after ca. 5 min evacuation. These bands are assigned to the O–H stretching vibration (ν(O–H)) of water and/or OH group adsorbed in zeolite. Since water molecules confined in the zeolite framework are present up to 350 °C [4], it is difficult to understand why the IR spectra of the O–H stretches due to the water molecules vanish in ca. 5 min evacuation at room temperature. A further IR study on the O–H stretches is now planned.

The ν_{as}(T–O) bands at 10 μm region change drastically on evacuation. The intensity of the shoulder near 1100 cm^{-1} increases and the shoulder grows into peak

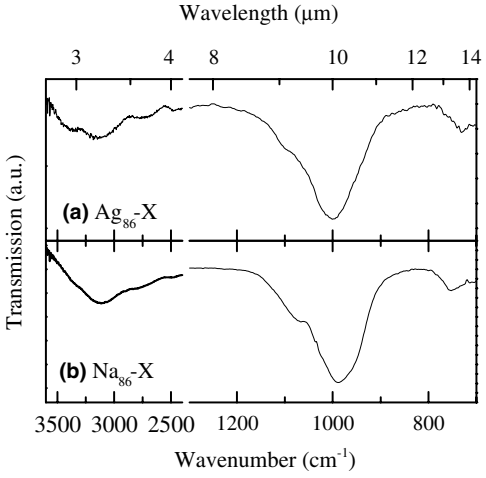

Fig. 1. Infrared absorption spectra of zeolite-X in air at RT. (a) Ag_{86}–X, (b) Na_{86}–X.

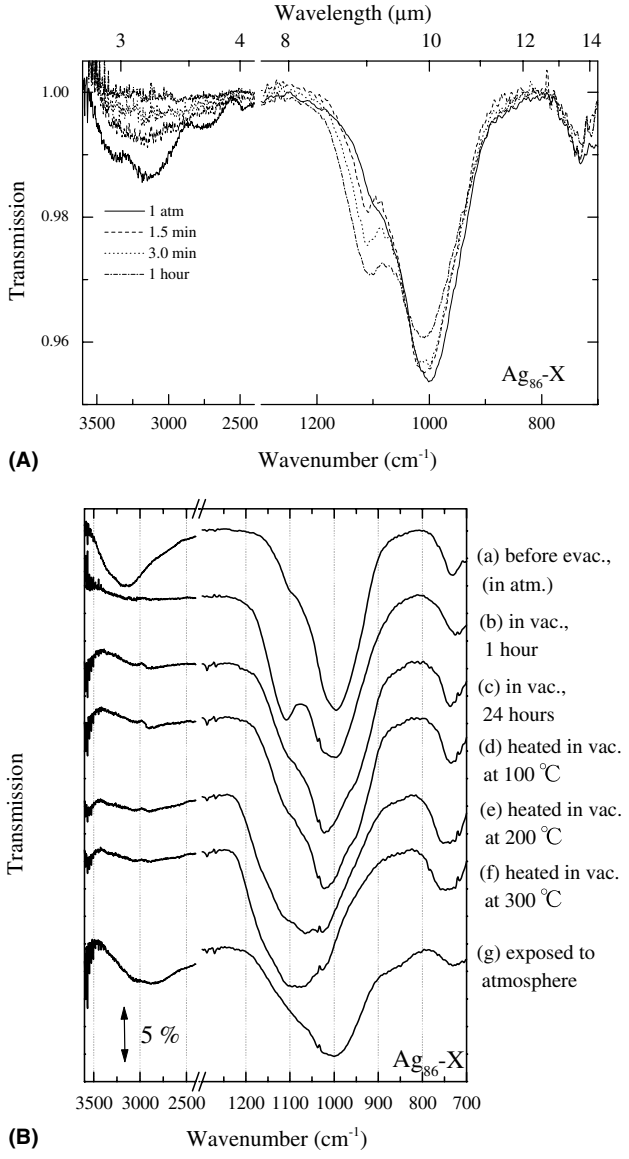

Fig. 2. Infrared absorption spectra of zeolite Ag_{86}–X. (A) Time-variations of infrared spectra under evacuation. (B) Infrared absorption spectra under different conditions. (a) Before evacuation (in atm), (b) in vacuum, 1 h, (c) in vacuum, 24 h, (d) heated in vacuum at 100 °C, (e) heated in vacuum at 200 °C, (f) heated in vacuum at 300 °C, (g) sample was exposed to air after heating and evacuating. All spectra are measured at room temperature.

after 1 h evacuation. These spectral changes on evacuation are considered to arise from the field balance in the zeolite framework due to a change in the position of Ag^+ ions caused by desorption of water from the zeolite cage.

The infrared spectral changes in the process of the formation of silver clusters in Ag_{86}–X heated at various temperatures under vacuum are shown in Fig. 2(B). After evacuating for 24 h (c) at RT, the bands around 10 μm change considerably. The intensity of the band near 1100 cm^{-1} slightly decreases and a new shoulder is observed around 950 cm^{-1}. It is noted that there is little difference between the spectrum heated at 100 °C (d) after evacuation for 1 h and the spectrum evacuated for 24 h at RT (c). After the sample was heated at 200 °C (e), the absorption spectrum changes drastically. A lower wavenumber shoulder of the main peak at 1000 cm^{-1}, which was observed in 24 h (c) and 100 °C (d), vanishes and the higher wavenumber shoulder becomes ambiguous. From (c) stage to (e) stage, some Ag^+ ions are reduced to Ag atoms which play as a precursor for the formation of silver clusters. At 300 °C (f), the absorption spectrum is almost similar to (e) in shape, but the peak shifts to higher wavenumber. These spectral changes arise from the changes of ν_{as}(T–O) in the zeolite framework by growth of the silver clusters.

When the sample was cooled down to RT from 300 °C and exposed to air, the absorption band around 3 μm appears again ((g) in Fig. 2(B)) as seen in stage (a) in Fig. 2(B). This suggests that the framework structure of the hydrated zeolite does reverse. On the other hand, the IR bands assigned to ν_{as}(T–O) do not return by absorbing moisture. A trailing edge around 850 cm^{-1} grows in addition to the 10 μm region band.

On the other hand, for the samples that were exposed to air after 24 h evacuation at RT and/or heated at 100 °C, the IR spectra do completely return to the spectra before evacuation.

3.1.2. Na_{86}–X

Fig. 3(A) shows the change of infrared spectra for Na_{86}–X at RT as a function of evacuation time. As shown for Ag_{86}–X, the absorption bands in the 3 μm region vanish after evacuation (b). At the absorption bands around 10 μm, there appear shoulders at the low wavenumber side. These spectral changes finish after ca. 5 min. After the 24 h evacuation at RT ((c) in Fig. 3(B)), the intensity of the shoulder at lower wavenumber decreases. The spectrum at 100 °C ((d) in Fig. 3(B)) is the same as that for the 24 h evacuation. It is noted that the spectra for Na_{86}–X do not change further as the temperature rises to 200 (e) and 300 °C (f) under evacuation, which is totally different behavior from Ag_{86}–X. When Na_{86}–X is exposed to air after heating up to 300 °C ((f) in Fig. 3(B)), the spectrum (g) is found to be the same as that before evacuation.

From these results, it is pointed out that the zeolite framework in Na_{86}–X has not changed on heating up to 300 °C. Moreover, it is quite apparent that the Ag atoms give influence to the framework by heating and the effect of Ag on the framework is entirely different from that of Na.

3.2. EXAFS

Figs. 4 and 5 show the EXAFS $k\chi(k)$ spectra and their Fourier transforms for Ag_{86}–X measured at 100 K after heating to various temperatures, respectively. There are two peaks in Fourier transform ((b) in Fig. 5): peak A

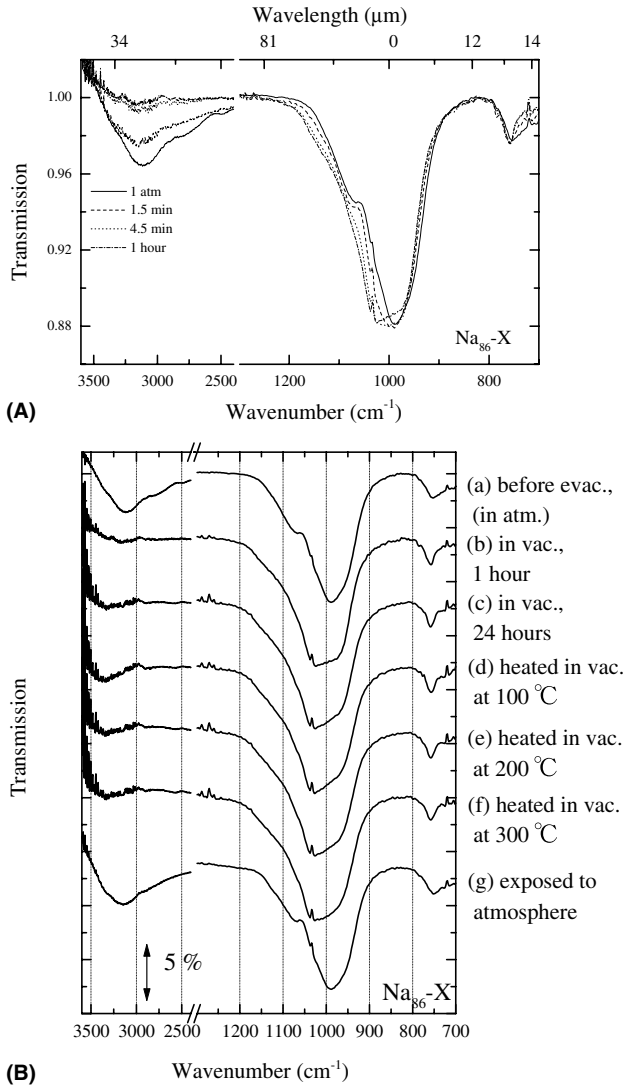

Fig. 3. Infrared absorption spectra of zeolite Na_{86}–X. (A) Time-variations of infrared spectra under evacuation. (B) Infrared absorption spectra at different conditions. (a) Before evacuation (in atm), (b) in vacuum, 1 h, (c) in vacuum, 24 h, (d) heated in vacuum at 100 °C, (e) heated in vacuum at 200 °C, (f) heated in vacuum at 300 °C, (g) sample was exposed to atmosphere after heating and evacuating. All spectra are measured at room temperature.

around 2 Å and peak B around 3 Å. Peak A is considered to come from Ag–O contributions (H_2O and oxygens in the framework) and peak B is from longer Ag–O and Ag–Ag contributions, as reported for the silver clusters in Ag–A zeolite [10]. A similar double peak was obtained in the Fourier transform for the Ag/Al_2O_3 (Ag; 0.6 wt%) system [9]. The behavior of peak B is interesting: the intensity of peak B slightly decreases after the sample was heated to 100 °C and increases again after being heated to 200 °C, though the changes are small. On the other hand, the intensity of peak B increases outstandingly after heating to 300 °C. This large change can be found clearly in the $k\chi(k)$ spectra ((e) in Fig. 4).

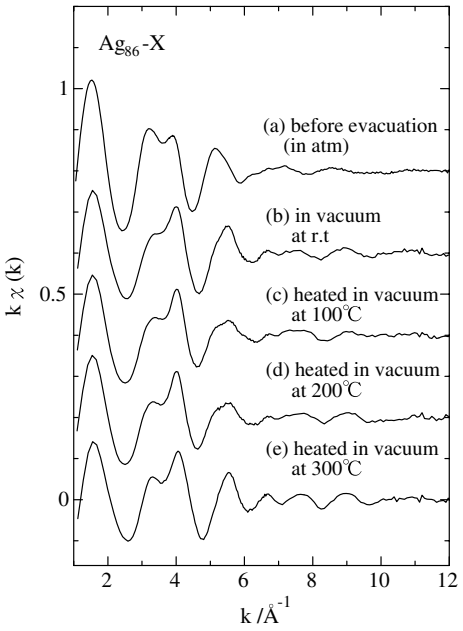

Fig. 4. EXAFS $k\chi(k)$ spectra of the Ag K-edge for Ag_{86}–X under different conditions. (a) Before evacuation (in atm), (b) in vacuum at RT, (c) heated in vacuum at 100 °C, (d) heated in vacuum at 200 °C, (e) heated in vacuum at 300 °C. The spectrum of (a) was measured at RT, and the spectra from (b) to (e) were measured at 100 K.

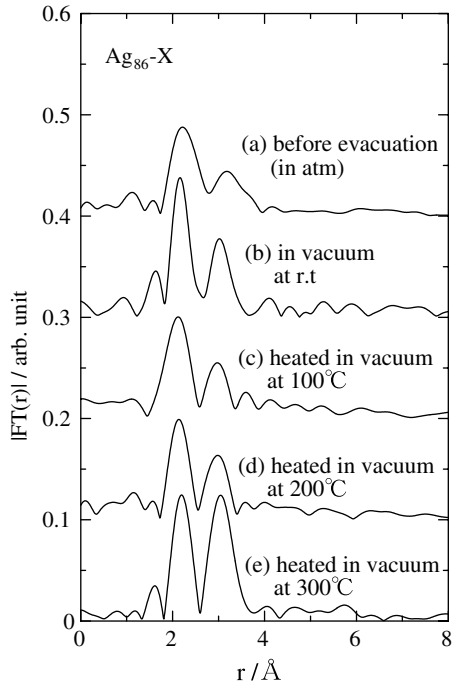

Fig. 5. Fourier transforms for the corresponding EXAFS spectra shown in Fig. 4.

In order to discuss quantitatively the change of local structure around Ag in the Ag_{86}–X zeolite, we perform non-linear least-square fitting (curve-fitting) to the EXAFS spectra using the following equation:

$$\chi(k) = \sum_j \frac{S_0^2 N_j}{kr_j^2} f_j(k, r_j) \exp(-2\sigma_j^2 k^2) \times \exp(-2r_j/\lambda(k)) \sin[2kr_j + \varphi_j(k)], \quad (1)$$

where r_j is the interatomic distance between X-ray absorbing and photoelectron scattering atoms in jth shell, N_j is the coordination number of the jth shell. $f_j(k, r_j)$ and $\phi_j(k)$ are the backscattering amplitude and phase shift functions, which were calculated by FEFF 6.01 code [12]. The k-range used in a curve-fitting method is from about 3.0–11.5 $Å^{-1}$ for the Ag K-edge. $\lambda(k)$ is the photoelectron mean free path obtained by the FEFF 6.01 calculation [12]. As in the case for Ag–A zeolite [9], we applied the three-shell fitting method to Ag_{86}–X. The three-shell model consists of two Ag–O (short and long contact distances) and one Ag–Ag contact. The Ag–O contact with a short distance is represented by Ag–O(1) and the contact with long distance by Ag–O(2).

The structural parameters obtained from the curve-fitting are compiled in Table 1. An example of the curve-fitting for Ag_{86}–X heated up to 300 °C is shown in Fig. 6. The quality of the fitting is fairly good. During the evacuation at RT, the contact distance of Ag–O(1) decreases from 2.38 ± 0.02 to 2.29 ± 0.02 Å and $N_{Ag–O(1)}$ decreases from 4.1 ± 0.2 to 2.1 ± 0.2, which indicates that some H_2O molecules attached to Ag^+ ions and the zeolite framework are removed. By removal of water, the contact distances of Ag–O(2) and Ag–Ag decrease, while the coordination numbers of $N_{Ag–O(2)}$ increase but those of $N_{Ag–Ag}$ decrease.

By heating Ag_{86}–X from RT to 100 °C under vacuum it is found for the Ag–O(1) contact, the distance decreases from 2.29 to 2.27 Å and $N_{Ag–O(1)}$ remains at 2.1. For Ag–O(2), the contact distance increases from 2.96 to 3.01 Å but $N_{Ag–O(2)}$ decreases from 3.8 to 2.9. It is noted that $N_{Ag–Ag}$ decreases from 1.2 to 0.6 and the Ag–Ag contact distance decreases from 2.88 to 2.78 Å. These changes suggest that Ag^+ ions are reduced to Ag atoms by further removal of water. Between 100 and 200 °C, the coordination number of Ag–Ag is found to be small; that is, 0.6 at 100 °C and 0.5 at 200 °C. This small coordination number suggests that the Ag atoms change sites in the zeolite. By heating from 200 to 300 °C, the Ag–O(1) and Ag–O(2) contacts show little changes in the contact distances and in the coordination number, respectively. On the other hand, $N_{Ag–Ag}$ increases dominantly from 0.5 to 2.9, which is much larger than $N_{Ag–Ag}$ at RT. This increase of $N_{Ag–Ag}$ at 300 °C suggests the formation of an Ag cluster consisting of Ag atoms and Ag^+ ions in Ag_{86}–X.

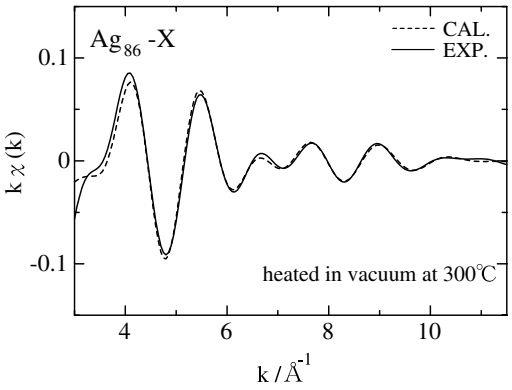

Fig. 6. Comparison between experimental $k\chi(k)$ spectra and the corresponding calculated curve for Ag_{86}–X measured after the sample was heated at 300 °C.

When air was introduced into the sample chamber after the clusters had been formed in Ag_{86}–X at 300 °C, it is found the local structure around Ag does not reverse to the state before evacuation. This indicates that the Ag clusters in Ag_{86}–X are stable due to presence of moisture.

4. Discussion

Now we discuss the effect of the formation of Ag clusters on the zeolite framework in the Ag_{86}–X zeolite during heating under vacuum. As shown in Fig. 2(A), the changes in ν_{as}(T–O) due to the contribution from the zeolite framework are observed by the infrared measurements in the wavenumber region between 800 and 1200 cm^{-1}. Such changes are shown in Fig. 7. The curves in Fig. 7 are derived from the data shown in Fig. 2(B). These spectra are fitted by summing up two or three

Table 1
Structural parameters (r, contact distance; N, coordination number; and σ, root mean square displacement) obtained from the EXAFS curve-fitting method measured at 100 K for Ag_{86}–X

	Ag–O(1)			Ag–O(2)			Ag–Ag		
	r (Å)	N	σ (Å)	r (Å)	N	σ (Å)	r (Å)	N	σ (Å)
(a) RT (atm)[a]	2.38	4.1	0.14	3.05	2.3	0.13	2.99	2.0	0.14
(b) After RT (vacuum)	2.29	2.1	0.08	2.96	3.8	0.12	2.88	1.2	0.13
(c) After 100 °C	2.27	2.1	0.10	3.01	2.9	0.12	2.78	0.6	0.13
(d) After 200 °C	2.27	1.6	0.09	2.99	3.7	0.12	2.80	0.5	0.13
(e) After 300 °C	2.28	1.9	0.09	2.94	3.6	0.13	2.84	2.9	0.13

Error in r is ±0.02 Å, in N is ±0.2 and in σ is ±0.03 Å.
[a] Measured at room temperature in atmosphere.

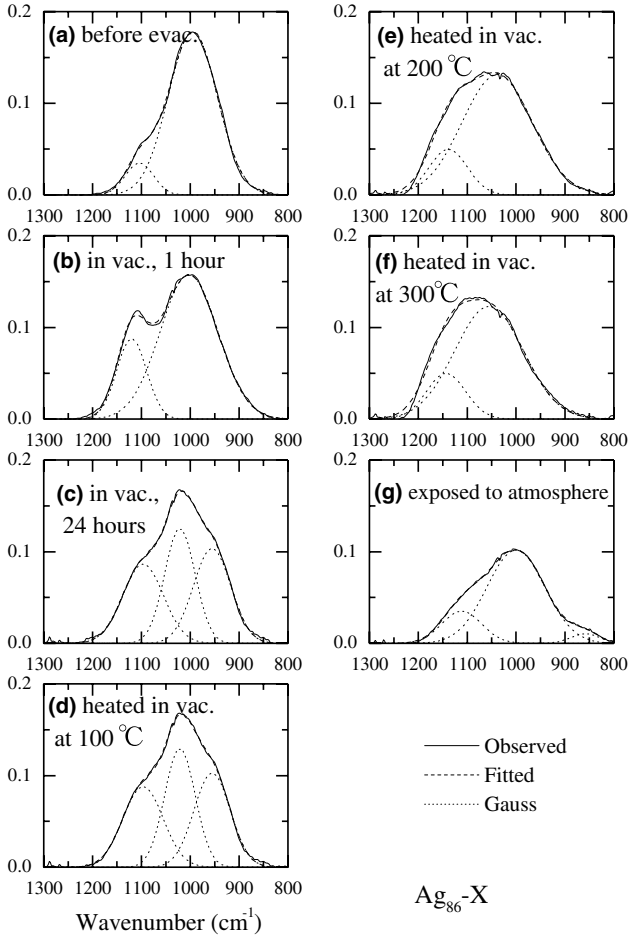

Fig. 7. Gaussian peak fitting of the infrared absorption spectra for Ag_{86}–X. (a) Before evacuation (in atm), (b) in vacuum, 1 h, (c) in vacuum, 24 h, (d) heated in vacuum at 100 °C, (e) heated in vacuum at 200 °C, (f) heated in vacuum at 300 °C, (g) sample was exposed to air after heating up to 300 °C in vacuum.

Gaussian peaks represented as dotted curves in Fig. 7. The quality of the fitting is fairly good.

In the change from (a) to (b), the disappearance of the ν(O–H) mode around 3 μm is observed. As shown in Fig. 7, the position of the main peak remains around 1000 cm^{-1}, but the intensity of a side peak around 1100 cm^{-1} increases and shifts to higher wavenumber (from 1104 to 1120 cm^{-1}). In this stage the infrared spectra are fitted by two Gaussian peaks. The information on the coordination numbers and the contact distances of Ag–O(1) and Ag–O(2), respectively, derived from the EXAFS analysis are related to the interaction between Ag^+ ions (or Ag atoms) and the zeolite framework. The coordination number $N_{Ag–O(1)}$ decreases from 4.1 to 2.1 and the distances of the Ag–O and Ag–Ag contacts decrease in this stage. Before evacuation (that is, in the hydrated state), Ag^+ ions exist on the basis of the balance of fields by the zeolite framework and water molecules. As the vacuum-dehydration of Ag_{86}–X proceeds, the water molecules are removed. This results in the decrease of the contribution to the zeolite framework from water molecules and the increase in the attraction between Ag^+ ion and the zeolite framework.

A drastic change is observed in the cases of (c) and (d). In these stages the infrared spectra are fitted by three Gaussian peaks, which is completely different from the stages (a) and (b) at RT and the stages (e) and (f) at high temperatures. The intensity of the main peak around 1000 cm^{-1} decreases remarkably and shifts slightly to a larger wavenumber (from 1002 to 1020 cm^{-1}). Additionally, a new peak appears at a lower wavenumber around 955 cm^{-1}. As seen from Table 1, the total coordination number of oxygen (the sum of $N_{Ag–O(1)}$ and $N_{Ag–O(2)}$) decreases from 5.9 at RT to 5.0 at 100 °C. In the same temperature range, the Ag–Ag contact distance decreases from 2.88 to 2.78 Å and $N_{Ag–Ag}$ from 1.2 to 0.6. As the dehydration proceeds, the repulsion between Ag^+ ions becomes weak because Ag atoms are produced by the removal of water and the potential barriers related to the Ag^+ ions and zeolite framework become comparatively low. The mobility of Ag atoms is expected to increase by raising temperature. The appearance of the peak around 955 cm^{-1} may relate to the alteration of the positions of Ag atoms in the zeolite.

As the temperature is raised to 200 °C (e), the peak in the low wavenumber (around 955 cm^{-1}) disappears and the infrared spectrum is fitted by two peaks. The broad main peak appears at 1039 cm^{-1} and a small peak at 1150 cm^{-1}. As seen from Table 1, the distance for the Ag–Ag contact increases from 2.78 Å at 100 °C to 2.84 Å at 200 °C. The total coordination number of oxygens around Ag at 200 °C is 5.3 and larger than that at 100 °C is 5.0. From these results, it is expected that at 200 °C some Ag atoms move into sites I and I′ in the zeolite [2] and may play as a precursor of Ag clusters. In the spectrum at 300 °C (f) the IR spectrum is fitted by two peaks. The main peak appears at 1055 cm^{-1} and a small peak at 1150 cm^{-1}. It is important to point that there is little change in the spectra between 200 and 300 °C. With increasing temperature from 200 to 300 °C, $N_{Ag–Ag}$ changes from 0.5 to 2.9. This indicates that Ag clusters are formed at sites I and I′ where a great portion of Ag contributes to cluster formation with the total coordination number of oxygens around Ag being 5.5.

When the zeolite, heated up to 300 °C, is cooled down to room temperature and exposed to atmosphere, the ν(O–H) mode around 3 μm appears again. Around the 10 μm region there appear two peaks whose positions are the same as those observed before evacuation (a) and a small peak at low wavenumber (856 cm^{-1}) (g). This suggests that the framework structure of the zeolite does reverse to the state before evacuation. From the EXAFS results it is found that the local structure of the Ag clusters formed at 300 °C does not reverse when the zeolite is cooled down to room temperature and

exposed to atmosphere. From these results it is concluded that the Ag clusters are stable and the framework structure of the zeolite does reverse considerably on exposure to atmosphere after heating up to 300 °C.

From the EXAFS parameters compiled in Table 1, it is expected that the framework O(1) interacts with Ag^+ ions, since the contact distance remains to be around 2.27 Å in the temperature range between 100 and 300 °C. The framework O(2) may interact with Ag atoms above 100 °C, judging from the decrease in the contact distances, due to the reduced amount of positive charges of the Ag^+ ions, from 3.01 Å at 100 °C to 2.94 Å at 300 °C.

5. Summary

The in situ infrared and EXAFS measurements were carried out for Ag_{86}–X heated up to 300 °C under vacuum. By evacuation at room temperature, the ν(O–H) mode around 3 μm disappears and the coordination number of oxygen around Ag decreases due to removal of water molecules. The T–O asymmetric stretch, (ν_{as} (T–O)) mode associated with zeolite framework oxygen, appears around the 10 μm region. These IR spectra are fitted by two or three Gaussian peaks. The positions of the main peaks are 1000 and 1100 cm^{-1} at room temperature. At 100 °C a new peak appears around 955 cm^{-1}, the total $N_{Ag–O}$ becomes small and $N_{Ag–Ag}$ is 0.5, which suggests that the Ag atoms change sites in the zeolite and play an important role as a precursor of the Ag clusters. At 300 °C, the corresponding peak positions shift to 1050 and 1140cm^{-1} and $N_{Ag–Ag}$ becomes 2.9, which indicates that the size of the Ag clusters attached to the zeolite framework becomes large at high temperature. It is suggested that there is a transition region from the state consisting mainly of Ag^+ ions to the state containing Ag clusters formed by Ag atoms and Ag^+ ions in the temperature range between 100 and 200 °C. When the zeolite with Ag clusters is exposed to atmosphere, it is found that: (1) the ν(O–H) mode around 3 μm appears again, (2) there appear two peaks (1000 and 1100 cm^{-1}) and a small peak around 856 cm^{-1} and (3) the local structure of the Ag clusters formed at 300 °C does not reverse.

Acknowledgements

We thank Mr. S. Matsuda for his support on the EXAFS measurements and Mr. R. Kakizaki for his support on the Infrared measurements. This work was performed under the approval of Proposal Nos. 2000G272 and 2002G279 of Photon Factory (KEK). This work was partially supported by the Research Grants of Hirosaki University.

Received 20 December 2004; accepted 31 January 2005

Abstract

Two new (saccharinato)silver (I) complexes, $[Ag_2(sac)_2(pyet)_2]$ and $[Ag_4(sac)_4(pypr)_2]$ (sac = saccharinate, pyet = 2-pyridineethanol and pypr = 2-pyridinepropanol), have been prepared and characterized by elemental analyses, IR, thermal analysis and single crystal X-ray diffraction. Both complexes crystallize in triclinic space group of $P\bar{1}$. In $[Ag_2(sac)_2(pyet)_2]$, two monomeric $[Ag(sac)_2(pyet)]$ units are doubly bridged by the sulfonyl oxygen atoms of the sac ligands, forming an $[Ag_2(sac)_2(pyet)_2]$ dimer, in which each silver (I) centre is three coordinate with a T-shaped coordination and the Ag···Ag separation is 5.205 Å. The dimeric units are connected by strong O–H···$O_{sulfonyl}$ intermolecular hydrogen bonds into a one-dimensional chain running parallel to *b*. The one-dimensional hydrogen bonded chains are further linked by π(sac)–π(pyet) stacking interactions. The tetranuclear complex, $[Ag_4(sac)_4(pypr)_2]$, is achieved by bridging of $[Ag_2(sac)_2]$ with two [Ag(sac)(pypr)] units through the sulfonyl oxygen atoms of the sac ligands. The two silver (I) ions in the centre with a short Ag–Ag bond distance of 2.8480(13) Å exhibit a T-shaped geometry with three sac ligands, while the two terminal silver (I) ions are coordinated by a sac ligand and a pypr ligand in a near linear geometry. The tetranuclear units are held together by O–H···O and C–H···O hydrogen bonds.

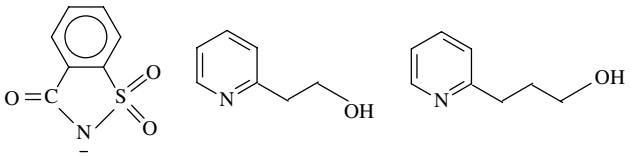
Keywords: Saccharinate; 2-Pyridineethanol; 2-Pyridinepropanol; Dinuclear and tetranuclear silver (I)

1. Introduction



Saccharin, alternatively named 1,2-benzisothiazoline-3-(*2H*)one 1,1-dioxide or *o*-sulphobenzimide in the form of its water soluble sodium salt, is widely used as a non-caloric sweetener and food additive [1]. The coordination chemistry of saccharin is interesting. Although no metal complexes of neutral saccharin are known, the corresponding, deprotonated, saccharinate anion (sac) acts as a polyfunctional ligand due to the presence of the negatively charged imino nitrogen, carbonyl oxygen and sulfonyl oxygen atoms. The most common coordination mode of sac is ligation through the nitrogen atom, usually observed in the aquabis(saccharinato) complexes of divalent transition metals [2–6] and coordination via the carbonyl or sulfonyl oxygen is less common.

In recent years, we have investigated the synthesis, spectroscopic, thermal and structural properties of transition metal complexes of sac with substituted pyridine

doi:10.1016/j.poly.2005.01.006

ligands, especially those containing additional donor groups such as alkylhydroxyl and alkylamine. We have recently focused our investigations into the complexation of sac with silver (I), since these species are very rare and only two silver (I) complex of sac, [Ag(sac)] [7] and $[Ag(sac)(PPh_3)_2]$ [8] have appeared previously in the literature. Recently, we reported the two new silver (I)-saccharinato complexes Na[Ag(sac)] [9] and $[Ag_2(\mu\text{-sac})_2(\mu\text{- hep})_2]_n$, where hep is *N*-(2-hydroxyethyl)piperazine [10]. In this study, we report the synthesis, spectroscopic and thermal characterizations and crystal structures of two new (saccharinato)silver (I) complexes with 2-pyridineethanol (pyet) and 2-pyridinepropanol (pypr), namely $[Ag_2(sac)_2(pyet)_2]$ and $[Ag_4(sac)_4(pypr)_2]$.

sac *pyet* *pypr*

2. Experimental

2.1. Materials

$AgNO_3$, $Na(sac)\cdot 2H_2O$, pyet and pypr were purchased commercially and used as received.

2.2. Preparation of the silver (I) complexes

Pyet (0.12 g, 1 mmol) was added to an aqueous solution (20 ml) of $AgNO_3$ (0.17 g, 1 mmol) and the resulting solution was mixed with an aqueous solution (20 ml) of $Na(sac)\cdot 2H_2O$ (0.24 g, 1 mmol) at room temperature. The resulting solution was kept in darkness at room temperature and colorless single crystals of $[Ag_2(sac)_2(pyet)_2]$ were obtained after two days. Yield: 82%. d.p. 127 °C. *Anal.* Calc. for $C_{28}H_{26}N_4O_8S_2Ag_2$: C, 40.7; H, 3.2; N, 6.8; S, 7.8. Found: C, 40.5; H, 3.3; N, 6.10; S, 7.5%.

The following method was used for the preparation of $[Ag_4(sac)_4(pypr)_2]$. Solid $Na(sac)\cdot 2H_2O$ (0.24 g, 1 mmol) was added to a solution (40 ml) of $AgNO_3$ (0.17 g, 1 mmol) in a water and isopropanol mixture (1:1, v:v) and this resulted in the formation of a white precipitate, which was dissolved by the addition of pypr (0.14g, 1 mmol) to the reaction medium. After a week at room temperature, colourless crystals of $[Ag_4(sac)_4(pypr)_2]$ were formed. Yield: 25%. d.p. 132 °C. *Anal.* Calc. for $C_{44}H_{38}N_6O_{14}S_4Ag_4$: C, 36.8; H, 2.7; N, 5.9; S, 8.9. Found: C, 36.5; H, 2.8; N, 5.8; S, 9.0%.

2.3. Physical measurements

IR spectra were recorded a Jasco FT-IR-430 spectrophotometer as KBr pellets in the frequency range 4000–300 cm^{-1}. The elemental analyses (C, H, N and S contents) were determined on a Vario EL Elemental Analyser. Thermal analysis curves (TG and DTA) were obtained using a Rigaku TG8110 thermal analyzer in a static air atmosphere. A sample of 5–10 mg was used.

2.4. X-ray structure determination

Intensity data for $[Ag_2(sac)_2(pyet)_2]$ and $[Ag_4(sac)_4(pypr)_2]$ were collected using Bruker SMART1000 CCD and Enraf Nonius KappaCCD area diffractometers with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 133(2) and 120(2) K, respectively. The structures were solved with SHELXS 97 and refined using SHELX 97 [11]. All the non-hydrogen atoms were refined anisotropically. All the hydrogen atoms, except the hydroxyl H atoms in $[Ag_2(sac)_2(pyet)_2]$, were placed in idealised locations and refined by riding on their carrier atoms, whereas the hydroxyl hydrogen atoms of

$[Ag_2(sac)_2(pyet)_2]$ were refined freely. The molecular plots were prepared by using ORTEPIII [12]. The details of data collection, refinement and crystallographic parameters are summarized in Table 1.

3. Results and discussion

3.1. Synthesis

The mixed-ligand silver (I) complexes of sac with pyet and pypr were prepared by the direct reaction of silver (I), sac and pyet or pypr in solution. The composition of the complexes was determined by elemental and TG analyses. The binuclear complex was obtained in a high yield over 80%, whereas the yield of the tetranuclear complex was relatively low (25%). Although no other complex was isolated from the same reaction solution of the tetranuclear complex, the low yield of the complex may be due to the presence of other species with very high solubility. The elemental analyses were consistent with their proposed formulae. Both complexes are insoluble in warm H_2O and common alcohols such as methanol or ethanol, but soluble in warm H_2O–alcohol mixtures. Both complexes are non-hygroscopic and light-stable at room temperature. $[Ag_2(sac)_2(pyet)_2]$ does not melt, but decomposes at 127 °C, whereas $[Ag_4(sac)_4(pypr)_2]$ melts with decomposition at 132 °C.

3.2. IR spectra

The most significant absorption bands in the IR spectra of the title complexes together with their assignments are given in Table 2. The position of the bands in the spectra of both complexes is similar. The strong and broad bands in the 3330–3350 cm^{-1} range are attributed to the ν(OH) vibrations of the pyet and pypr ligands. The relatively weak bands at 2900–3070 cm^{-1} are due to the ν(CH) vibrations. The absorption band of the carbonyl group of sac in $[Ag_2(sac)_2(pyet)_2]$ appears at ca. 1649 cm^{-1} as a very strong, single band. The frequency of the carbonyl group is characteristic of *N*-coordinated sac ligands as reported for Na[Ag(sac)] [9] and Na(sac) · $2H_2O$ [13]. However, the C=O bands in $[Ag_4(sac)_4(pypr)_2]$ are observed at 1651 and 1626 cm^{-1} as two distinct and strong bands, indicating the different interactions of the sac ligands. The higher absorption band is due to an *N*-bonded sac in which its carbonyl group remains uncoordinated, whereas the band at lower frequency shows the coordination of the sac ligand through the carbonyl group, shifting by ca. 25 cm^{-1} compared to the higher band. This shift is in agreement with the participation of the carbonyl oxygen in metal bonding as also observed in the IR spectrum of [Ag(sac)] [14]. The absorption bands at ca. 1580 and 1460 cm^{-1} correspond to the ring ν(CC) vibrations. The stretching vibrations of $\nu_{asym.}(SO_2)$ and $\nu_{sym.}(SO_2)$ occur characteristically at ca. 1290 and 1150 cm^{-1}, respectively. In both complexes, the asymmetric stretching band at around 1280 cm^{-1} are found to split into two or three bands, although the S–O distances in both complexes are almost identical. Additional peaks at ca. 1330 and 970 cm^{-1} are attributed to the symmetric and asymmetric stretching modes of the CNS moiety of the sac ligands, respectively. The *N*-coordination of the py ligands is confirmed by the absorption bands at around 675 cm^{-1} due to γ(py) [15].

3.3. Thermal behaviour

The thermal decomposition pathways of the title complexes were followed up to 600 °C in a static atmosphere of air. $[Ag_2(sac)_2(pyet)_2]$ is stable up to 127 °C and then begins to decompose in three stages. Elimination of the pyet ligand occurs in the first stage of decomposition between 127 and 240 °C with three endothermic effects at 150, 189 and 213 °C. The experimental mass loss of 29.5% agrees well with the calculated mass loss of 29.8%. The decomposition of the sac moiety occurs in the second and third stages in the temperature range 250–517 °C with two violently exothermic DTA peaks at 370 and 464 °C (mass loss: found 44.5%, calcd. 44.1%). As well as microanalyses, the mass loss calculations suggest that the residue left as a final decomposition product is metallic silver. Total mass loss is 74.0% and the final residue consisting mainly of silver forms 26.0% of the total mass (calcd. 26.1%).

$[Ag_4(sac)_4(pypr)_2]$ follows a different decomposition path compared to that of the dimeric complex. It begins to decompose with melting at 132 °C. The first decomposition stage between 132 and 231 °C corresponds to the endothermic removal of two pypr ligands with a mass loss of 19.4% (calcd. 19.1%). In the next stages, the exothermic degradation of four sac ligands occurs

in the 235–528 °C range with a small and two sharp exothermic DTA peaks at 256, 435 and 489 °C, and results in the formation of silver metal as the end product. The experimental total mass loss value of 70.5% is consistent with the calculated value 69.9%.

3.4. Description of the crystal structure of $[Ag_2(sac)_2(pyet)_2]$

A molecular view of $[Ag_2(sac)_2(pyet)_2]$ with the atom numbering scheme is shown in Fig. 1. The selected bond lengths and angles together with the hydrogen bonding geometry are given in Table 3. The complex crystallizes in the triclinic space group $P\bar{1}$. The structure consists of individual molecules of dinuclear $[Ag_2(sac)_2(pyet)_2]$ units formed from doubly bridged monomeric [Ag-$(sac)_2$(pyet)] units joined through the sulfonyl oxygen atoms of the sac ligands (Fig. 1). Each silver (I) centre is three coordinated by an *N*-bonded sac ligand, an *N*-bonded pyet ligand and the bridging sulfonyl oxygen atom of sac in the adjacent $[Ag(sac)_2(pyet)]$ unit, exhibiting a distorted T-shaped AgN_2O coordination environment. In the dimeric unit, there is an eight-membered chelate ring with an Ag···Ag separation of 5.205 Å, indicating the absence of any interaction between two silver centres. We have previously observed that the pyet ligand behaves as a bidentate donor via the N and hydroxyl O atoms to other divalent transition metals [16–18]. Here, it acts a monodentate ligand through the N atom and the hydroxyl O atom remains uncoordinated.

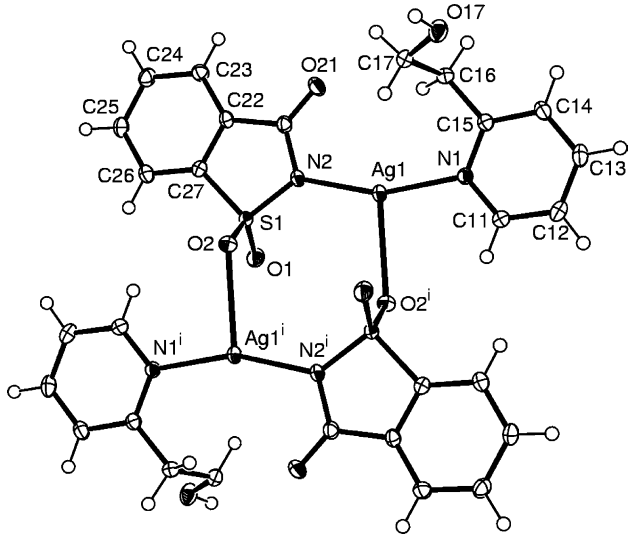

Fig. 1. Dimeric molecular unit in $[Ag_2(sac)_2(pyet)_2]$ with the atom labelling scheme and 50% thermal ellipsoids (arbitrary spheres for the H atoms). Symmetry code: (i) = $-x$, $2-y$, $-z$.

Table 3
Selected geometrical data for $[Ag_2(sac)_2(pyet)_2]$[a]

Bond lengths (Å) and angles (°)			
Ag1–N1	2.1753(11)	N1–Ag1–N2	159.14(4)
Ag1–N2	2.1444(12)	N1–Ag1–$O2^i$	96.11(4)
Ag1–$O2^i$	2.6454(10)	N2–Ag1–$O2^i$	104.75(4)

D–H···A	*d*(D–H)	*d*(H···A)	*d*(D···A)	∠(DHA)
Hydrogen bonds				
O17–H17···$O1^{ii}$	0.82(2)	2.02(3)	2.8083(17)	163(2)
C12–H12···$O17^{ii}$	0.95	2.55	3.4133(19)	150
C16– H16B···$O21^{iii}$	0.99	2.43	3.4124(16)	172

[a] Symmetry operations: (i) $-x$, $2-y$, $-z$; (ii) x, $y-1$, z; (ii) $1-x$,

The Ag–N_{sac} and Ag–N_{pyet} bond distances are similar, being 2.1753(11) and 2.1444(12) Å, respectively. The Ag–N_{sac} bond distance is similar to the corresponding values found in [Ag(sac)] [2.16 Å] [7], Na[Ag(sac)] [2.1405(11)] and 2.1570(11) Å] [9], but differs from the bond values reported for $[Ag(sac)(PPh_3)_2]$ [2.285(8) Å] [8] and $[Ag_2(\mu\text{-sac})_2(\mu\text{-hep})_2]_n$ [2.084(2) Å] [10]. The bridging Ag–$O_{sulfonyl}$ bond distance of 2.6454(10) Å is comparable to that of Na[Ag(sac)] [2.6390(10) Å] [9], but significantly longer than the corresponding bond in [Ag(sac)] (2.45 Å) [7].

The sac ligand is essentially planar with a root-mean-square (rms) deviation of the non-hydrogen atoms (excluding the sulfonyl O atoms) from the best least-squares plane of 0.03 Å and the pyet ligand is also planar with an rms deviation of 0.004 Å, but C17 and O17 atoms deviate by 1.375(2) and 2.241(2) Å, respectively, from the best pyet plane. The sac and pyet ligands coordinate to silver (I) in an approximately linear fashion with an N–Ag–N angle of 159.14(5)°. The dihedral angle between the planes of sac and pyet is 5.65(6)°, showing the approximately coplanar arrangement of their ring systems.

The individual $[Ag_2(sac)_2(pyet)_2]$ molecules are linked by strong hydrogen bonds between the hydrogen of the hydroxyl group and the uncoordinated sulfonyl O atom of the sac ligands in the neighbouring units, forming a one-dimensional chain running parallel to the *b*-axis (see Fig. 2(a)). The one-dimensional hydrogen bonded chains are further linked by non-conventional intermolecular C–H···O hydrogen bonds and π(sac)–π(pyet) stacking interactions [Cg···Cg = 3.75(7) Å] as shown in Fig. 2(b).

3.5. Description of the crystal structure of $[Ag_4(sac)_4(pypr)_2]$

The molecular structure of the tetranuclear silver (I) complex $[Ag_4(sac)_4(pypr)_2]$ with the atom labelling is shown in Fig. 3. The selected bond lengths and angles are given in Table 4. The compound crystallizes in the triclinic space group $P\bar{1}$ and has two tetrameric molecules in its asymmetric unit with a similar conformation. The structure consists of isolated molecules of [Ag_4 $(sac)_4(pypr)_2$], which are built up from the bridging of

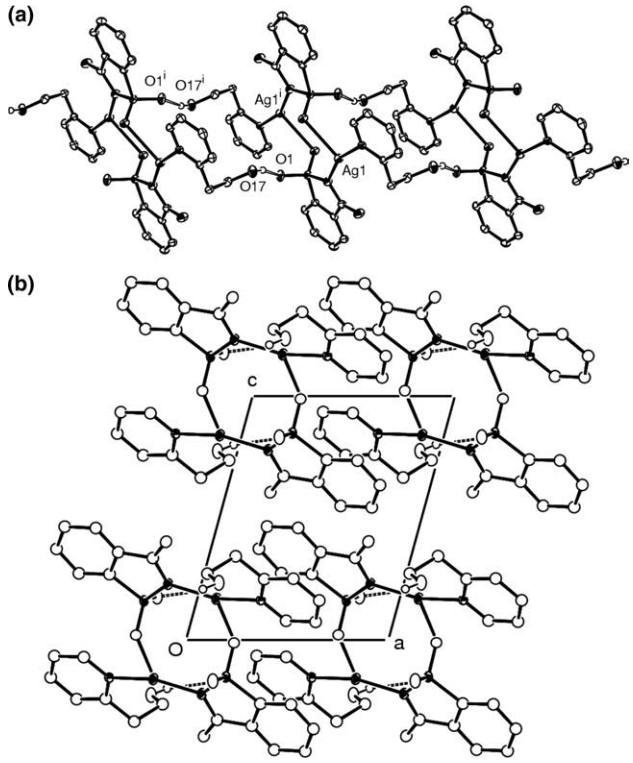

Fig. 2. (a) A fragment of the hydrogen bonded one-dimensional chain of $[Ag_2(sac)_2(pyet)_2]$. Symmetry code: i = –*x*, –*y*, –*z*. (b) Projection of the structure of $[Ag_2(sac)_2(pyet)_2]$ on the *ac* plane, showing π(sac)–π (pyet) interactions. The phenyl and ethylene H atoms are removed for clarity.

the central $[Ag_2(sac)_2]$ unit with two [Ag(sac)(pypr)] units through the sulfonyl oxygen atoms of the sac ligands. $[Ag_4(sac)_4(pypr)_2]$ exhibits two different silver centres. The two silver (I) ions (Ag1 and its symmetry-equivalent partner $Ag1^i$) in the centre exhibit a T-shaped planar $AgNO_2$ geometry with three sac ligands, while the two outer silver (I) ions (Ag2 and $Ag2^i$) are coordinated by a sac ligand and a pypr ligand in a near linear AgN_2 geometry [N2–Ag2–N3 = 168.6(4)°]. The sac ligands in the central $[Ag_2(sac)_2]$ unit act as a bidentate chelating ligands via the N and carbonyl O atoms forming an roughly planar eight-membered chelate ring. The central Ag1 pair of silver atoms appear to be interacting based on the Ag–Ag^i (i = 1 – *x*, 1 – *y*, –z) distance of 2.8480(13) Å, while Ag2 has no metal neighbours within 5 Å. The separation of the two central Ag3 atoms in the second asymmetric molecule of $[Ag_4(sac)_4(pypr)_2]$ is 2.8590(13) Å. These silver–silver contacts are some 0.60 Å shorter than twice the van der Waals radius of silver (3.44 Å) and clearly indicate a strong bonding interaction between the Ag1 and the Ag3 centres in the tetranuclear complex. The Ag–Ag distances found in $[Ag_4(sac)_4(pypr)_2]$ are also much shorter than those reported for other tetranuclear silver units $[Ag_4(SPh)_4(PPh_3)_4]$ [3.1300(3) Å] [19] and $[Ag_4(tren(mim)_3)_2]^{4+}$ [2.929(1) and 3.1313(9) Å] [20], where SPh and tren(mim)$_3$ are thiolate and tris {2-2(1-methyl)imidazolyl]methyliminoethyl} amine, respectively. The significance of short silver–silver distances has been debated: Jansen reported a value of 3.30 Å as the upper limit for an Ag···Ag contact in coordination compounds [21], whereas Dance et al. [22] stated that since the linear geometry at silver (I) indicates the fulfilment of its coordination requirements, there is no bonding interaction between silver (I) centres as close to each other as 2.886 Å in $[Ag(SCMeEt)_2]_n$. However, we argue that there is a significant bonding interaction between the silver centres at the short distances in the present $[Ag_4(sac)_4(pypr)_2]$ complex.

The Ag–N_{sac} bond distances in $[Ag_4(sac)_4(pypr)_2]$ are similar to those reported for the related silver (I)-saccharinato complexes [7,9–11], but the terminal Ag–N_{sac}

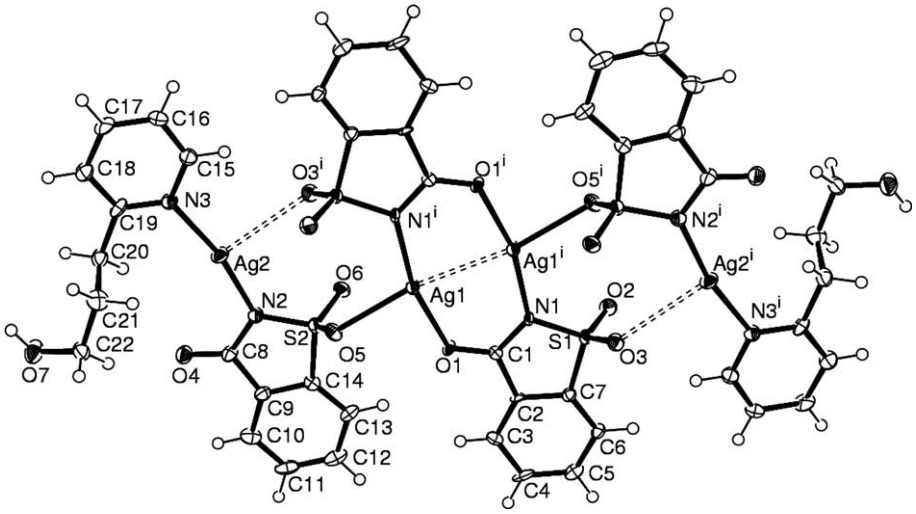

Fig. 3. View of tetrameric unit in $[Ag_4(sac)_4(pypr)_2]$ with the atom labelling scheme and 50% thermal ellipsoids (arbitrary spheres for the H atoms). Symmetry code (i) = 1 – *x*, 1 – *y*, –*z*. The asymmetric unit of the complex contains two molecules and one of them was removed for clarity.

C40–H40···O2^{i}	0.95	2.38	3.289(17)	161

[a] Symmetry operations: (i) $1-x, 1-y, -z$; (ii) $1-x, 1-y, 1-z$; (iii) $1+x, y, z$; and (iv) $1+x, y-1, z$.
[b] O10, O17 and C38 and C40 atoms belongs to the second molecule in the asymmetric unit of the compound.

bond distances are noticeably longer than the corresponding bonds and the Ag–O_{sac} bonds in the central unit. The Ag–$O_{carbonyl}$ bond distance of 2.230(8) Å is almost identical to that observed in [Ag(sac)] [2.22 Å] [7], but slightly shorter than those found in $[Ag_2(\mu\text{-sac})_2(\mu\text{-hep})_2]_n$ [2.2535(11) and 2.3010(14) Å] [10]. The bridging Ag–$O_{sulfonyl}$ bond distance of 2.431(9) Å is similar to the equivalent value observed in [Ag(sac)] (2.45 Å) [7], but is significantly shorter than the 2.6390(10) Å found in Na[Ag(sac)] [9]. Furthermore, there is a weaker interaction between the sulfonyl O atoms of the sac ligands in the central unit and the silver (I) centres at the terminal units, yielding a Ag–$O_{sulfonyl}$ bond distance of 2.960(9) Å and probably suggesting the "semi-coordination" of the sulfonyl group of sac to silver (I). The Ag–N_{pypr} bond distance is 2.140(10) Å. Similarly, the hydroxyl group of pypr is uncoordinated in $[Ag_4(sac)_4(pypr)_2]$ in contrast to the bidentate coordination behaviour in the presence of divalent transition metals [23–25]. This may be explained in terms of hard and soft acids and bases. As a soft acid, silver (I) will not prefer a hard base OH for coordination.

The ring systems of sac and pypr are planar. The rms deviations from the best planes of the sac1 with N1, sac2 with N2 and pypr species are 0.010, 0.016 and 0.012 Å, respectively. The displacement of the silver (I) ions from the corresponding planes is as follows: Ag1 from sac1 = 0.356(11) Å, Ag2 from sac2 = 0.212(9) Å and Ag2 from pypr = 0.0429(19) Å. The planes of sac and pypr coordinated the terminal Ag2 atoms are roughly coplanar with a dihedral angle of 10.7(6)°.

The unit-cell packing of the molecules of $[Ag_4(sac)_4(pypr)_2]$ is shown in Fig. 4. Relevant hydrogen bonds are listed in Table 4. The packing of the tetramers forms

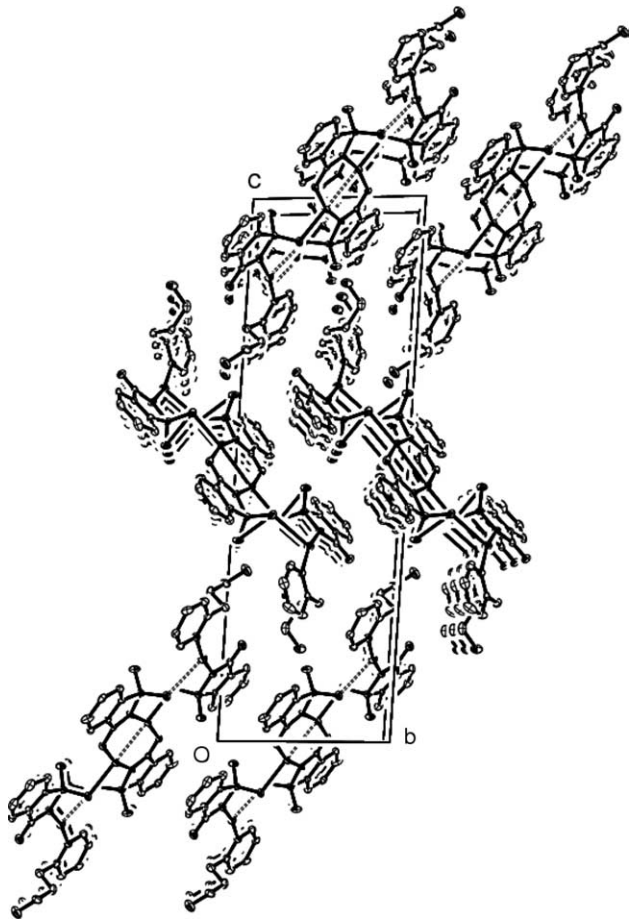

Fig. 4. A view of the unit cell of $[Ag_4(sac)_4(pypr)_2]$ viewed along the *a* axis. It shows the packing of the tetramers to form a herringbone motif. The phenyl and ethylene H atoms are removed for clarity.

a herring-bone motif. The two molecules in the asymmetric unit of the structure are connected by strong intermolecular O–H···O bonds (H···O = 1.89 Å), involving the hydroxyl H of pypr and sulfonyl O of sac. The O10, O17 and C38 and C40 atoms belongs to the second molecule in the asymmetric unit of the compound. The strong hydrogen bonds form hydrogen bonded dimers, which are further linked by C–H···O interactions, resulting in a layered structure. The C38–H38···O7^{iv} bond has an exceptionally short H···O contact of 2.20 Å, but this may arise from unmodelled disorder of some of the carbon atoms in the py ring containing C38.

4. Supplementary material

Crystallographic data for the structures reported in the paper have been deposited at the CCDC as supplementary data, CCDC Nos. 253479 and 253480 for $[Ag_2(sac)_2(pyet)_2]$ and $[Ag_4(sac)_4(pypr)_2]$, respectively. Copies of the data can be obtained on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK

(Fax: +44 1223 336033; E-mail: deposit@ccdc.cam.ac.uk; http://www.ccdc.cam.ac.uk).

Abstract

X-ray structure of the $[ReCl_3(bipy)(PPh_3)]$ complex has been determined and its geometric parameters have been examined using the density-functional theory method. The UV–Vis spectrum of the complex has been discussed on the basis of the electronic transitions of $[ReCl_3(bipy)(PPh_3)]$ calculated with the time-dependent DFT method.

Keywords: Rhenium(III) complexes; Bipyridine ligand; X-ray structure; DFT calculations

1. Introduction

Design of biological labels for various therapeutic, diagnostic and mechanistic applications is currently in the centre of scientific research. Transition metal complexes can be covalently linked to different biomolecules in electron-transfer studies and other analytical applications [1–3]. In this context, rhenium polypyridine complexes show a great potential to be developed in bioanalytical applications in view of their photophysical and photochemical properties. A wide of diimine rhenium complexes have been recently synthesized and studied in detail [4–12].

The $[ReCl_3(MeCN)(PPh_3)]$ complex has proven to be useful precursor in the synthesis of other Re(III) compounds [13,14]. Rouschias and Wilkinson [15] reported the synthesis of $[ReCl_3(MeCN)(PPh_3)]$ in 1967, along with its reactions with pyridyl ligands that led to the formation of $[ReCl_3(py)_3]$, $[ReCl_3(py)_2(PPh_3)]$ and $[ReCl_3(bipy)(PPh_3)]$. However, the crystal and molecular structure of the $[ReCl_3(bipy)(PPh_3)]$ complex has not been determined, and reports of rhenium (III) complexes with 2,2′-bipirydyl ligand are sparse. The only structurally characterised rhenium (III) bipirydyl complexes appear to be $[ReBr_3(CO)_2(bipy)]$ [16], $[ReCl_2(bipy)_2][PF_6]$ [17] $[Re(p\text{-}CH_3C_6H_4S)\{SCH_2CH(NHCOCH_3)COO\}(bipy)]$ [18] and $[ReCl(bipy)(Tp)][OTf]$ (Tp = hydridotris(pyrazolyl)borate) [19].

Here, we present X-ray and electronic structure of the $[ReCl_3(bipy)(PPh_3)]$ complex. The electronic structure of $[ReCl_3(bipy)(PPh_3)]$ has been determined basing on the results of the density-functional theory (DFT) calculations. The spin-allowed triplet–triplet electronic transitions of $[ReCl_3(bipy)(PPh_3)]$ have been calculated with the time-dependent DFT method (TDDFT) and the UV–Vis spectrum of the title complex has been discussed on this basis.

The recent calculations with the TDDFT method for open- and closed-shell of 5d-metal complexes (including rhenium complexes) have supported the TDDFT

doi:10.1016/j.poly.2005.02.001

method to be applicable for such systems giving good assignment of experimental spectra [20–26].

2. Experimental

2.1. General procedure

All solvents were of reagent grade and were used as received. Ammonium perrhenate, Ph_3P and bipyridine (bipy) were purchased from Aldrich and used as received. The $[ReCl_3(bipy)(PPh_3)]$ complex was prepared according to the literature method [15].

IR spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–VIS 8500 in the range 800–220 nm in deoxygenated dichloromethane solution. Magnetic susceptibilities were measured at 296 K by the Faraday method. Elemental analyses (C, H, N) were performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Crystal structures determination and refinement

The X-ray intensity data of $[ReCl_3(bipy)(PPh_3)]$ were collected on a KM-4-CCD automatic diffractometer equipped with CCD detector with 44 s exposure time was used and a quarter of Ewald sphere was collected. The unit cell parameters were determined from least-squares refinement of the setting angles of 3697 strongest reflections. Details concerning crystal data and refinement are given in Table 1. Lorentz, polarization and numerical absorption corrections [27] were applied. The structure was solved by means of the Patterson method and subsequently completed by the difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using full-matrix, least-squares technique. The hydrogen atoms of the phenyl rings were treated as ''riding'' on their parent carbon atoms [*d*(C–H) = 0.96 Å] and assigned isotropic temperature factors equal 1.2 times the value of equivalent temperature factor of the parent carbon atom. SHELXS97 [28], SHELXL97 [29] and SHELXTL [30] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.3. Computational details

GAUSSIAN 03 program [31] was used in the calculations. The geometry optimization was carried out with the DFT method with the use of B3LYP functional [32,33] and different basis set on the rhenium atom: LANL2DZ, LANL2DZ with additional d ($\alpha = 1.0$) and f ($\alpha = 1.0$) functions [34] and SDD with effective core potential [35]. 6-31G(d) basis set was used for the chlorine, nitrogen, phosphorous and carbon atoms and 6-31G on the hydrogen atoms The electronic spectrum was calculated with the TDDFT method [36]. The nature of the intramolecular hydrogen bonds was studied by means of the Bader theory of atoms in molecules (AIM) [37]. The AIM method was extended and implemented within GAUSSIAN program and Ahlrichs DFT Coulomb Fitting Basis Set was used on the rhenium atom in the AIM calculations [38,39].

Crystal data and structure refinement for $[ReCl_3(bipy)(PPh_3)]$

Empirical formula	$C_{28}H_{23}Cl_3N_2PRe$
Formula weight	711.00
Temperature (K)	291(2)
Wavelength (Å)	0.71073
Crystal system	monoclinic
Space group	$P2_1/n$
Unit cell dimensions	
a (Å)	10.204(2)
b (Å)	24.381(5)
c (Å)	11.005(2)
β (°)	106.77(3)
Volume (Å^3)	2621.4(9)
Z	4
Density (calculated) (Mg/m^3)	1.802
Absorption coefficient (mm^{-1})	5.023
$F(0\,0\,0)$	1384
Crystal size (mm)	$0.14 \times 0.14 \times 0.03$
θ Range for data collection (°)	3.47–25.11
Index ranges	$-12 \leqslant h \leqslant 11$, $0 \leqslant k \leqslant 29$, $0 \leqslant l \leqslant 13$
Reflections collected/independent	4654/4654
Completeness to $2\theta = 50.2°$ (%)	97.2
Maximum and minimum transmission	0.8721 and 0.5419
Data/restraints/parameters	4654/0/316
Goodness-of-fit on F^2	1.090
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0586$
	$wR_2 = 0.1512$
R indices (all data)	$R_1 = 0.0725$
	$wR_2 = 0.1633$
Largest difference peak and hole (e/Å^3)	2.850 and −2.088

3. Results and discussion

The $[ReCl_3(bipy)(PPh_3)]$ complex was obtained in the reaction of $[ReCl_3(MeCN)(PPh_3)_2]$ with bipyridine according to the literature method [15]. The elemental analysis of the complex is in good agreement with its formulation. The characteristic band corresponding to the ν(CN), ν(C=C) modes of the bipy ligand appears at 1604 cm^{-1} in the IR spectrum of $[ReCl_3(bipy)(PPh_3)]$. The $[ReCl_3(bipy)(PPh_3)]$ complex shows room temperature magnetic moment of 1.7 BM. This value is typical of mononuclear complexes with low-spin rhenium (III) (d^4) ions in O_h field [40], and arises because of the large spin–orbit coupling ($\xi = 2500$ cm^{-1}) [41]. A similar deviation from the expected value (2.8 BM) has been found for $[ReX_2(pymS)(PPh_3)]$ (X = Cl, Br, I) [42,43],

$[ReCl_3(NCR)(PPh_3)_2]$ (R = Me, Et, Ph), $[ReCl_3$ (NCR)-$(P(p\text{-tol})_3)]$ (R = Me, Et) [44] and $[ReCl_3(\eta^3\text{-}N,N,P\text{-}N\{CH_2CH_2PPh_2\}CH_2CH_2P(O)Ph_2\})]$ [45].

3.1. Crystal structure

The $[ReCl_3(bipy)(PPh_3)]$ complex crystallises in the monoclinic space group $P2_1/n$ and its crystal structure is composed of the molecules located in general positions linked via weak intermolecular C(19)–H(19)···Cl(3)(1#: $-x$, $-y$, $-z+1$) hydrogen bonds [46–48] (D···A distance 3.442(11) Å and D–H···A angle 135.9°).

Fig. 1 depicts the perspective drawing of $[ReCl_3(bipy)(PPh_3)]$ with atomic numbering. The structure shows a distorted octahedral geometry about Re with the three bromine ligands arranged in a facial fashion. The N–Re–N bond angle of 75.9(3)° is less than 90°, as required by the bite distance exerted by the steric demand of the chelating bipyridine ligand. The intramolecular hydrogen bond [42–44] linking C(6)–H(6)···Cl(3) (D···A distance 3.520(14) Å and D–H···A angle 154.0°), C(19)–H(19)···Cl(3) (D···A distance 3.304(11) Å and D–H···A angle 124.8°), C(18)–H(18)···Cl(3) (D···A distance 3.765(11) Å and D–H···A angle 152.3°), C(6)–H(6)···Cl(2) (D···A distance 3.604(12) Å and D–H···A angle 102.8°) and C(28)–H(28)···Cl(2) (D···A distance 3.342(11) Å and D–H···A angle 125.4°) provide additional stabilisation of the $[ReCl_3(bipy)(PPh_3)]$ complex. The presence of the intramolecular hydrogen bonds in the structure of $[ReCl_3(bipy)(PPh_3)]$ was confirmed by the AIM calculations. The selected geometrical and topological parameters of the hydrogen bonds are summarised in Table 2. If H-bonds exist, the ranges of ρ_{BCP} and $\nabla^2\rho_{BCPv}$ (BCP = bond critical point) are 0.002–0.035e/a_0^3 and 0.024–0.139e/a_0^5, respectively [49]. The calculated ρ and $\nabla^2\rho$ values for $[ReCl_3(bipy)(PPh_3)]$ are in good agreement with the criteria of the charge density and the Laplacian of the charge density at the bond critical points.

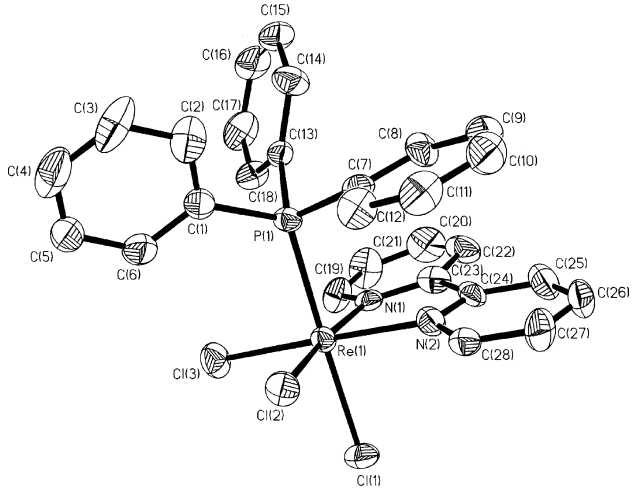

Fig. 1. Thermal ellipsoid plot of $[ReCl_3(bipy)(PPh_3)]$ showing the atom numbering scheme (50% probability ellipsoids). The hydrogen atoms are omitted for clarity.

Table 2
The selected geometrical (C···Cl distance) and topological parameters (electronic densities – $\rho_{H\cdots Cl}$ (in e/a_3^0)) and Laplacians of electronic densities – $\nabla^2\rho_{H\cdots Cl}$ (in e/a_5^0) for the bond critical points of H···Cl bonds for $[ReCl_3(bipy)(PPh_3)]$

Hydrogen bond	C···Cl (Å)	$\rho_{H\cdots Cl}$	$\nabla^2\rho_{H\cdots Cl}$

Exp. stands for experimental; LANL2DZ* – LANL2DZ basis set with additional d ($\alpha = 1.0$) and f ($\alpha = 1.0$) functions.

The most important experimental bond lengths and angles of $[ReCl_3(bipy)(PPh_3)]$ are reported in Table 3. The Re–N bond lengths (2.099(8) and 2.094(8) Å) of the title complex are similar to those found for the other rhenium (III) polypyridyl compounds: in $[ReCl_2(bipy)_2]PF_6$ – 2.094(5) and 2.096(5) Å [17] and in the $[ReL(terpy)_2]^{2+}$ (L = Cl, OH, NCS) complexes – about 2.10 Å [50]. These values are significantly shorter than comparable distances for saturated amine complexes, where metal-to-ligand π-back bonding is not possible, for instance, the Re–NH_2 distance in the $[Re(N_2)(ampy)(tbpy)(PPh_3)]PF_6$ compound is 2.197(7) [51]. A lengthening of the Re–N_{bipy} distances in Re(V) complexes [52–56], consistent with the notion of the greatest M–L back bonding occurring when the metal is most electron-rich, also confirms a significant π-back bonding between the rhenium and bipy ligand of $[ReCl_3(bipy)(PPh_3)]$. The Re–Cl(1) distance (2.434(2) Å) is affected by *trans* influence of the triphenylphosphine and is therefore longer than the Re–Cl(2) (2.372(3) Å) and Re–Cl(3) (2.364(3) Å) bond lengths located in *trans* positions to the bipy ligand.

The bond valences (v_{ij}) were computed as $v_{ij} = \exp[(R_{ij} - d_{ij})/B]$ [57–59], where d_{ij} is the observed bond length and R_{ij} is the bond-valence parameter (in the formal sense R_{ij} is the single-bond length between i and j atoms [60]). The R_{Re-N}, R_{Re-P}, R_{Re-Cl}, were taken as 2.06, 2.46 and 2.23 [57], respectively, and the value of B was taken as 0.37 [53]. The computed bond valences of the rhenium are $v_{Re-N} = 0.90$, 0.91 $v_{Re-P} = 1.03$ and $v_{Re(1)-Cl} = 0.58$, 0.68, 0.70 v.u. [valence units], thus PPh_3 moiety is strongest bonded to the rhenium and chloride substituents are bonded weakest.

Table 4
The Mulliken atomic charges and spin densities of $[ReCl_3(bipy)(PPh_3)]$

the B3LYP functional. The energy of the singlet state is of 15.8 kcal higher. The optimized geometric parameters (with different basis sets on the rhenium atom) of the triplet state are gathered in Table 3. The optimised geometries are in good agreement with the experimental one, the largest differences are found for the Re–Cl and Re–P bond distances. The similar elongation of rhenium–halogene and rhenium–phosphorous bond lengths in the B3LYP has been found in other rhenium complexes [14,61]. The differences of the calculated and experimental Re–Cl(2,3) bonds lengths can be explained by strong hydrogen bond involving Cl(2) and Cl(3) atoms. The formation of the hydrogen bond causes local deficiency of electron density on the chloride ions and consequently the Cl(2) and Cl(3) ligands are closer to the rhenium atom in the experimental structure.

Table 4 presents the Mulliken atomic charges and spin densities for $[ReCl_3(bipy)(PPh_3)]$. The calculated charge on the rhenium atom is considerable lower than the formal charge +3. It results from a charge donation from the chloride ions and triphenylphosphine ligand, which act as σ-donors. There is large positive charge on the P atom and the charges on the chloride ligands are significantly smaller than −1. The bipy ligand of $[ReCl_3(bipy)(PPh_3)]$ acts as an electron acceptor, the charges on the bipyridine nitrogen atoms bonded with the rhenium atom are negative.

In the title complex, there is positive spin density of about 2 on the rhenium atom and small negative or positive spin densities on the donor atoms of the other ligands (Table 4). It confirms the presence of two unpaired electrons on the rhenium atom.

3.3. Molecular orbitals

The energies and characters of several highest occupied and lowest unoccupied molecular orbitals of $[ReCl_3(bipy)(PPh_3)]$ are presented in Table 5. The selected HOMO and LUMO orbitals of $[ReCl_3(bipy)(PPh_3)]$ with α spin are depicted in Fig. 2. Most of the MOs of the title complex has complicated character. The percent participation of atomic orbitals in the selected HOMO

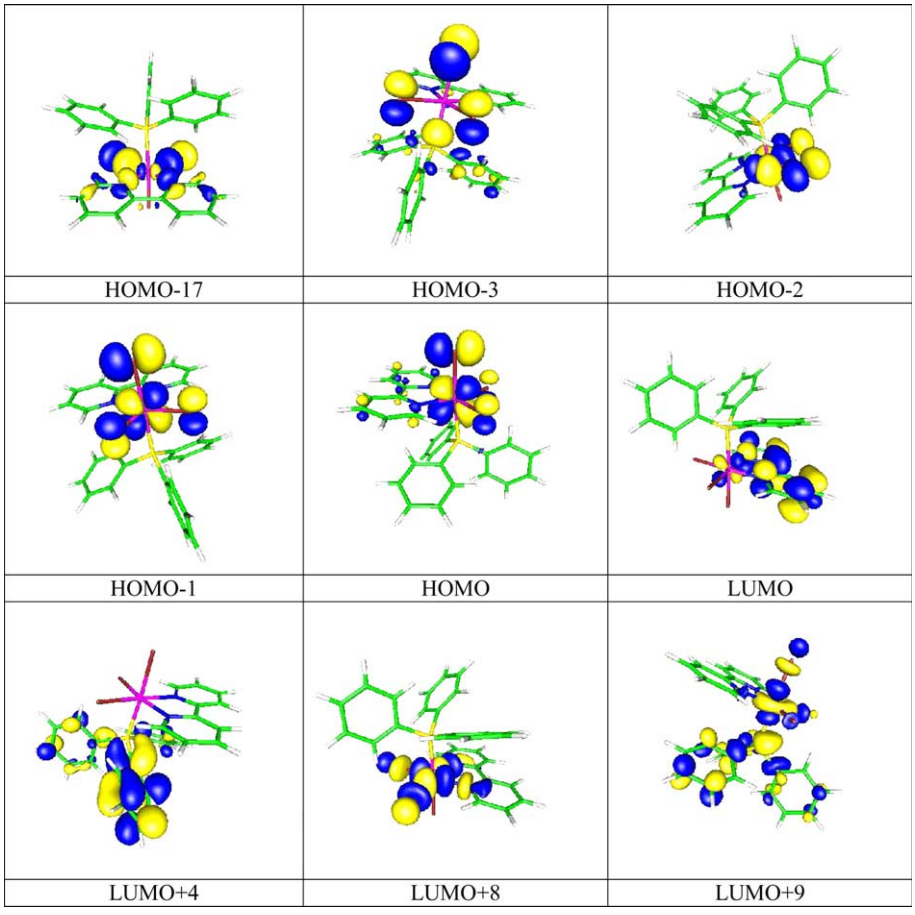

Fig. 2. The selected HOMO and LUMO orbitals with α spin for $[ReCl_3(bipy)(PPh_3)]$. Positive values of the orbital contour are represented in blue (0.04 au) and negative values – in yellow (−0.04 au). (For interpretation of the references to color in this figure legend, the reader is referred to the web version of this article.)

and LUMO orbitals for [$ReCl_3$(bipy)(PPh_3) are shown in Table 6. The MO compositions was determined on the basis of Mulliken analysis.

Among the highest occupied MOs of [$ReCl_3$(bipy)(PPh_3)], the largest numbers constitute π orbitals of the bipyridine and phenyl rings with a contribution from the Cl atoms. The rhenium d_π atomic orbital (d_{xz}, d_{yz} and d_{xy}) and π orbitals of the chlorine ligands, but in anti-bonding arrangement, make main contributions into the HOMO − 2, HOMO − 1 and HOMO with α-spin and HOMO, LUMO and LUMO + 1 with β-spin. The d_z^2 rhenium orbital with an antibonding admixture of the chlorine and phosphorus lone pairs orbitals constitute the LUMO + 9 with α-spin and LUMO + 5 with β-spin orbitals. The largest participation of the $d_{x^2-y^2}$ rhenium orbital is visible in the LUMO + 8 with α-spin and the LUMO + 13 with β-spin. The LUMO, LUMO + 1 and LUMO + 2 with α-spin and LUMO + 1 and LUMO + 2 with α-spin have predominantly π*(bipy) character. The triphenylphosphine ligand participates in the higher LUMO orbitals. The HOMO − 3 with α-spin and HOMO − 2 with β-spin are π orbitals of the chloride ligands and phenyl groups with a substantial contribution from the free electron pairs on the phosphorus atom. The LUMO + 3, LUMO + 4, LUMO + 5 with α-spin and the LUMO + 5, LUMO + 6, LUMO + 7 with β-spin present π interaction of the phosphorous orbitals with π* orbitals of the phenyl groups.

3.4. Electronic spectrum

The experimental and calculated electronic spectra of [$ReCl_3$(bipy)(PPh_3)] are presented in Fig. 3. Each calculated transition in Fig. 3(b) was represented by a Gaussian function with the height equal to the oscillator strength and width equal to 0.04.

Table 7 shows the spin-allowed triplet–triplet electronic transitions calculated with the TDDFT method and the assignments of the calculated transitions to the experimental absorption bands for [$ReCl_3$(bipy)(PPh_3)].

The investigated complex is of large size, the number of basis functions is equal 560. Eighty electron transitions calculated by the TDDFT method do not comprise all the experimental absorption bands. The UV–Vis spectrum of [$ReCl_3$(bipy)(PPh_3)] was calculated only to 290 nm, so the shortest wavelength

experimental band (at 228.8 nm) cannot be assigned to the calculated transitions, and the assignments of the band at 301.0 nm may be incomplete. Considering that the solution spectra of PPh_3 and bipy exhibit intense absorption bands in 260–200 nm region, some additional intraligand and interligand transitions are expected to be found at higher energies in the calculation.

The calculations result in many transitions. Some of them have very small oscillator strengths. Except for the electronic transitions of d → d character and the low energy part of the spectrum, only transitions with oscillator strengths larger than 0.0050 are listed in Table 7.

The assignment of the calculated transitions to the experimental bands is based on the criterion of the energy and oscillator strength of the calculated transitions. In the description of the electronic transitions the main components of the molecular orbital are used. The HOMO − 2, HOMO − 1, HOMO and LUMO + 8 with α-spin and HOMO, LUMO and LUMO + 1 with β-spin. orbitals are treated as d orbitals.

The broad and intense (Fig. 3) longest wavelength experimental band of $[ReCl_3(bipy)(PPh_3)]$ with maximum at 636.8 nm is mainly attributed to two transition of $d \rightarrow \pi^*_{bipy}$ character with large oscillator strength calculated at 834.6 nm.

The experimental band at 436.6 nm is assigned to the transitions of MLCT ($d \rightarrow \pi^*_{bipy}$) and LMCT ($\pi_{Cl} \rightarrow d$ and $\pi_{Ph} \rightarrow d$) type, calculated in the range 540–433 nm.

The transitions calculated between 400 and 350 nm are ascribed to the experimental band at 401 nm. These transitions are of MLCT ($d \rightarrow \pi^*_{bipy}$) and LLCT ($\pi_{Cl} \rightarrow \pi^*_{bipy}$ and $\pi_{Ph} \rightarrow \pi^*_{bipy}$) character.

The experimental absorption band at 301 nm is assigned to the transition calculated in the range 340–290 nm. Among these electronic transitions are transitions of d → d, LMCT ($\pi_{Cl} \rightarrow d$, and $\pi_{Ph} \rightarrow d$ and $\pi_{bipy} \rightarrow d$), MLLCT ($d \rightarrow \pi^*_{bipy}$, $d \rightarrow \pi^*_{Ph}$) and LLCT ($\pi_{Cl} \rightarrow \pi^*_{bipy}$, $\pi_{Ph} \rightarrow \pi^*_{bipy}$ and $\pi_{Ph} \rightarrow \pi^*_{Ph}$) origin. The transitions of d → d have small oscillator strengths and they do not contribute significantly to the overall shape of the spectrum. They are hidden under the more intense transitions of CT type.

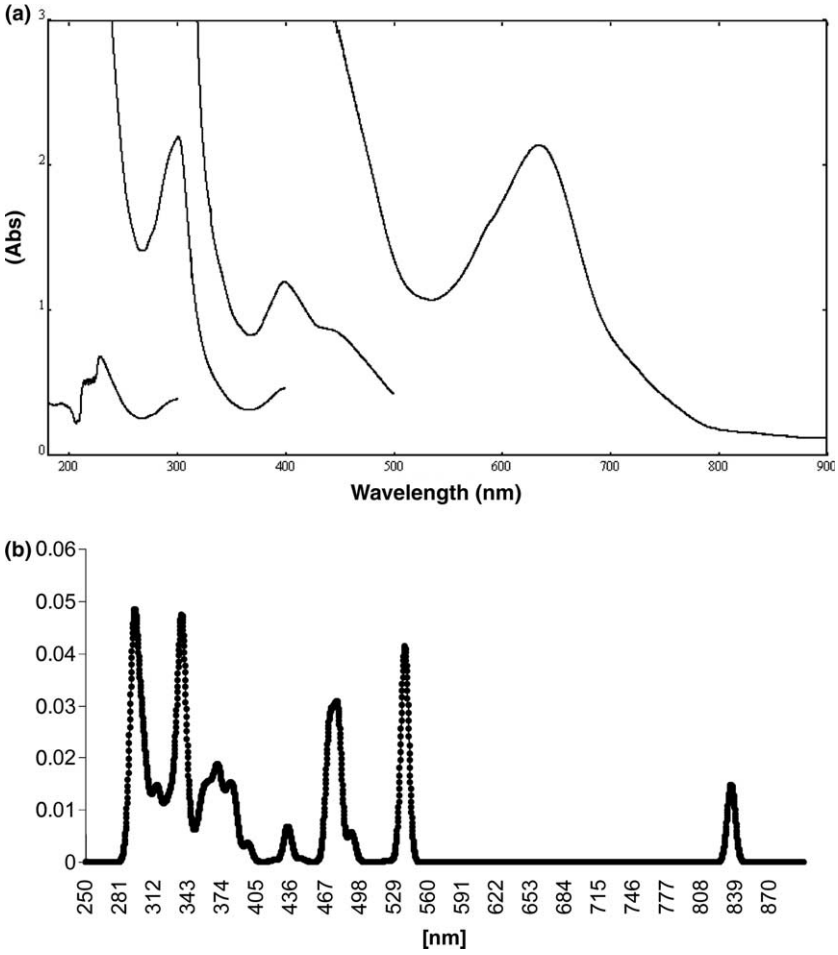

Fig. 3. The experimental (a) and calculated (b) electronic absorption spectrum of $[ReCl_3(bipy)(PPh_3)]$.

Received 20 January 2005; accepted 11 February 2005

Abstract

Two new neutral trinuclear oxo-centered complexes, $[Fe_3(\mu_3\text{-}O)(O_2CPh)_5(salox)L_1L_2]$ [$L_1 = L_2 = MeOH$ (**1**), $L_1 = EtOH$, $L_2 = H_2O$ (**2**)] are reported. In both complexes, the central oxygen atom is bridging the three iron(III) ions, which form a triangle with an average edge of ~3.3 Å. The central $[Fe_3(\mu_3\text{-}O)]^{7+}$ core is planar. The benzoato ligands are coordinated through the usual *syn*,*syn* μ_2:η^1:η^1 mode and the salicylaldoximato ligand shows the common μ_2:η^1:η^1:η^1 coordination mode. Two of the iron(III) ions have an O_6 coordination environment while the third has an O_5N one. The two crystallographically independent trimers in the structure of **1** (**a** and **b**, respectively) through intermolecular interactions form polymeric chains of the . . .a–a–b–b. . . type, along the *ac* diagonal of the unit cell. In **2**, again through intermolecular interactions, the trimers form layers lying parallel to the [1 0 1] plane. Mössbauer spectra at room temperature from polycrystalline samples of **1** and **2** give rise to two well-resolved doublets with an average isomer shift consistent with high spin iron(III) ions. The two doublets, at 2:1 ratio, are characterized by different quadrupole splitting and are assigned to the nonequivalent iron(III) ions of the clusters. Magnetic measurements of **1** and **2** in the 2–z300 K temperature range show antiferromagnetic interactions between the iron(III) ions in the trimers stabilizing a $S = 1/2$ ground state. The derived values for the exchange interaction constants fall in the range usually found in $[Fe_3(\mu_3\text{-}O)]^{7+}$ clusters. Solid state X-band EPR spectra of **1** and **2** at liquid helium temperatures give rise to broad lines extending several hundred Gauss, indicating weak intermolecular interactions. EPR spectra from **1** and **2** in an acetone glass at 4.2 K exhibit a strong symmetric signal at $g \sim 2.0$ which is attributed to the $S = 1/2$ ground state of the clusters.

1. Introduction

Our interest in the coordination chemistry of phenolic oximes is related to our continuing effort to synthesize polynuclear 3d metal clusters in a quest for new molecule-based magnetic materials. 'Metal-oximates' have been attracting the interest of inorganic chemists, since they can be used as 'building blocks' for the designed synthesis of polynuclear clusters [1]. According to this synthetic route, the ligands already bound to one metal have free coordination sites and can bind to a second metal of the same or different kind. The major advantages of this method are, the better control of the reaction and of the products formed, factors that cannot be controlled by following the self-assembly route. By using the strategy of 'metal oximates' as building blocks, various homo- and hetero-metal complexes have been synthesized [2–8]. The propensity of phenolic oximes to form polynuclear complexes by using both the oxime

and phenolate groups as chelating and/or bridging units, along with their ability to act in their mono- or di-anionic form, make them interesting candidates for the exploration of their metal coordination chemistry [9].

In their mono-anionic form, phenolic oximes usually act as chelating agents through their oximate nitrogen and phenolate oxygen atoms (mode A in the following scheme) in a variety of mono- and poly-nuclear metal complexes [10–14]. A more interesting coordination mode, includes the use of the phenolate oxygen atom as both chelating and bridging agent (mode B) [10,15].

In their di-anionic form, phenolic oximes usually use their phenolate oxygen and oximate nitrogen atoms to chelate to one metal ion and their oximate oxygen as bridging unit to bind a second metal (mode C). A variety of di- [16–18], tri- [14,19] and tetranuclear [20–22] metal complexes presenting the μ_2:η^1:η^1:η^1 coordination mode have been reported. The oximate oxygen atom can also bind two metal ions, presenting the μ_3:η^1:η^2:η^1 coordination mode (mode D) giving rise to higher nuclearity complexes, such as hexanuclear [23,24], although this coordination mode is also observed in trinuclear [25] and tetranuclear [11] complexes. There is also one example [10] where the dianion of phenolic oximes can act as chelating tridentate ligand according to mode E.

Further restricting our discussion to polynuclear iron(III) complexes with the simplest member of the phenolic oximes, 2-hydroxy-benzaldehyde (salicylaldoxime, H_2salox), only a few examples have been reported. As far as we know, the only example of iron(III) salicylaldoximato complex is the tetranuclear [11] cluster [{Fe(Hsalox)(salox)}$_4$], in which the four Hsalox$^-$ act as chelating agents through their phenolate oxygen and oximate nitrogen atoms (mode A), whilst the four salox^{2-} further use their oximate oxygen atom to bind to two additional metal centers (mode D). In the remaining examples, coligands have been used to complete the coordination spheres of iron(III) centers in polynuclear complexes. In the dinuclear compound [(Me_3tacn)Fe(III)(salox)$_3$Fe(III)] [16], as well as in the tetranuclear compound [(Me_3tacn)$_2$Fe$_4$(salox)$_2$(μ_3-O)$_2$(μ_2-CH_3CO_2)$_3$](ClO_4) [20] (where Me_3tacn = 1,4,7-trimethyl-1,4,7-triazacyclononane) the dianion of salicylaldoxime adopts the μ_2:η^1:η^1:η^1 coordination mode. The only trinuclear iron(III) salicylaldoximato complex known so far is [(C_2H_5)$_3$NH][Fe_3O(Hsalox)(salox)$_2$ (salmp)] [19] (salmp = 2-(bis(salicylideneamino)-methyl) phenol, a new ligand formed during the reaction process), where the Hsalox$^-$ ligands act as chelating units and the salox^{2-} ligands adopt the μ_2:η^1:η^1:η^1 coordination mode.

The aim of our project is to explore the use of salicylaldoxime in iron(III) carboxylate chemistry, encouraged by our previous results on manganese(III) [24]. Herein, we report the first results of our project, in particular the synthesis, X-ray crystal structure, spectroscopic (solid state and frozen solutions EPR, Mössbauer) characterization and magnetic behavior of two neutral trinuclear oxo-centered iron(III) complexes, [Fe_3 (μ_3-O)-(O_2CPh)$_5$(salox)L_1L_2] (L_1 = L_2 = MeOH (**1**), L_1 = EtOH, L_2 = H_2O (**2**)). The reported complexes are the first examples of trinuclear carboxylato iron(III) complexes with salicylaldoxime, and can be considered as precursors for the synthesis of higher nuclearity complexes, based on the principle of using 'metal oximates' as 'building blocks' for polynuclear clusters. In both compounds, the salox^{2-} ligands adopt the μ_2:η^1:η^1:η^1 coordination mode (mode C) thus, the possibility of further using the oximate oxygen atom, under certain reaction conditions, to bind to a second metal is left open.

2. Experimental

2.1. Compound preparations

All manipulations were performed under aerobic conditions using materials as received (Aldrich Co). All chemicals and solvents were of reagent grade.

2.1.1. [Fe_3(μ_3-O)(O_2CPh)$_5$(salox)(MeOH)$_2$] · 1.25MeOH · 1.05H_2O (**1**)

A methanolic solution of H_2salox (0.069 g, 0.50 mmol) was stirred under reflux, until sodium benzoate (0.216 g, 1.50 mmol) was added. The reflux continued for 30 min and then $Fe(NO_3)_3 \cdot 9H_2O$

(0.202 g, 0.50 mmol) was added. The color of the solution immediately turned to deep brown. After 24 h of reflux, small amounts of a brown-red solid were filtered, washed with MeOH and identified as compound **1** by FT-IR spectroscopy. The brown filtrate was sealed and after a period of one week X-ray quality brownish-red crystals of **1** were formed (Yield: 0.34 g, ~70%). The crystals of **1** were collected by filtration, washed with cold MeOH and dried in vacuo. The resulting powder analyzed as solvent-free. *Anal.* Calc. for (**1**) ($C_{44}H_{38}NO_{15}Fe_3$): C, 53.47; H, 3.88; N, 1.42. Found: C, 53.45; H, 3.86; N, 1.40%.

2.1.2. $[Fe_3(\mu_3\text{-}O)(O_2CPh)_5(salox)(EtOH)(H_2O)]\cdot EtOH$ (**2**)

The procedure followed was the same as described above, but $FeCl_3\cdot 6(H_2O)$ and ethanol were used instead (Yield: 0.35 g, ~70%). The powder of **2** analyzed as solvent-free. *Anal.* Calc. for (**2**) ($C_{44}H_{38}NO_{15}Fe_3$): C, 53.47; H, 3.88; N, 1.42. Found: C, 53.45; H, 3.87; N, 1.39%.

2.2. General and physical measurements

Elemental analysis for carbon, hydrogen, and nitrogen was performed on a Perkin Elmer 2400/*II* automatic analyzer. Infrared spectra were recorded as KBr pellets in the range 4000–500 cm^{-1} on a Bruker Equinox 55/S FT-IR spectrophotometer. EPR spectra were recorded on a Bruker ER 200D-SRC X-band spectrometer equipped with an Oxford ESR 9 cryostat in 4.2–300 K temperature range. Variable temperature magnetic susceptibility measurements were carried out on polycrystalline samples of **1** and **2** in the 2.0–300 K temperature range using a Quantum Design MPMS SQUID susceptometer under a magnetic field of 1000 G. Magnetization measurements were carried out at 2.5 K over the 0–5 T magnetic field range. Diamagnetic corrections for the complexes were estimated from Pascal's constants. Mössbauer spectra were taken with a constant acceleration spectrometer using a ^{57}Co (Rh) source at RT and a variable temperature Oxford cryostat.

2.2.1. X-ray crystallography and solution of structures

Brownish-red prismatic crystals of **1** ($0.05\times0.25\times0.75$ mm) and **2** ($0.05\times0.15\times0.25$ mm) were mounted in capillary with drops of mother liquid. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite monochromated Mo radiation. Important crystal data and parameters for data collection for **1** are reported in Table 1. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11° < 2\theta < 23°$. Intensity data were recorded using a θ–2θ scan. Three standard reflections, monitored every 97 reflections showed less than 3% intensity fluctuation and no decay. Lorentz, polarization and ψ-scan absorption corrections were applied using Crystal Logic software. The structures were solved by direct methods using SHELXS-86 [26] and refined by full matrix least-squares techniques on F^2 with SHELXL-97 [27]. Further experimental crystallographic details for **1**: $2\theta_{max} = 40°$, scan speed 1.2°/min; scan range 1.7 + $\alpha_1\alpha_2$ separation; reflections collected/unique/used, 7740/7452 [R_{int} = 0.0332]/7452; 779 parameters refined; $(\Delta/\sigma)_{max} = 0.014$; $(\Delta\rho)_{max}/(\Delta\rho)_{min} = 0.725/-0.579$ e/Å^3; R/R_w (for all data), 0.1223/0.2282. The crystals of **1** were of poor diffraction ability, despite their sufficient size, so the data collection stopped at $2\theta = 40°$ because over half of the reflections collected were unobserved. Nevertheless, the quality of the data is adequate to establish the structure. Due to the lack of sufficient number of data only the metal ions and the coordinated atoms as well as the $salox^{2-}$ ligands were refined anisotropically. The phenyl rings of the benzoates were refined isotropically and fixed to the geometry of a regular hexagon. Hydrogen atoms on the phenyl rings and on the methyl groups of the coordinated methanols were introduced at calculated positions as riding on bonded atoms. Further experimental crystallographic details for **2**: $C_{46}H_{44}NO_{16}Fe_3$, fw = 1033.93, a = 15.12(2) Å, b = 15.61(2) Å, c = 20.15(2) Å, β = 95.26(3)°, V = 4736(2) Å^3, $Z = 4$, space group $P2_1/n$, $2\theta_{max} = 35°$ (data collected between 35° and 40° was more than 70% unobserved and it was not used), scan speed 1.2°/min; scan range 1.7 + $\alpha_1\alpha_2$ separation; reflections collected/unique/used, 3125/2971 [R_{int} = 0.0401]/2971; 208 parameters refined; $(\Delta/\sigma)_{max} = 0.013$; $(\Delta\rho)_{max}/(\Delta\rho)_{min} = 0.96/-0.91$ e/Å^3; R/R_w (for 1797 refs with $I > 2\sigma(I)$), 0.2486/0.5077; R/R_w (for all data), 0.3458/0.5897. The crystals of **2** were very small in size

$R_1 = \sum(|F_o| - |F_c|)/\sum(|F_o|)$ and $wR_2 = \{\sum[w(F_o^2 - F_o^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$ for 5082 reflections with $I > 2\sigma(I)$.

[a] $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$ and $P = ((\max F_o^2, 0) + 2F_c^2)/3$; a = 0.1046, b = 86.0886.

and of very poor diffraction quality. Repeated efforts to grow larger crystals proved unsuccessful. We continued with data collection in order to establish the gross structure of the complex. Since the structure of **2** proved quite similar to that of **1**, we felt that complete structural characterization was not crucial. Thus, the refinement was done with anisotropic thermal parameters for the iron(III) ions only, whilst all the rest atoms were refined isotropically. No H-atoms were included in the refinement. The phenyl rings of the salox^{2-} and benzoate ligands were fitted to the geometry of a regular hexagon. The crystallographic analysis revealed the presence of one ethanol of crystallization per trimeric complex.

3. Results and discussion

3.1. Syntheses

As mentioned earlier, our aim was to investigate the use of salicylaldehyde oxime (H_2salox) to the iron(III) carboxylate chemistry, extending our previous experience on manganese [24]. The 1:1 molar ratio reaction of $Mn(O_2CR)_2$ (R = Me, Ph) and H_2salox in EtOH led to the hexanuclear complexes $[Mn_6O_2(O_2CR)_2(salox)_6(EtOH)_4]$ (R = Me, Ph). These complexes contain the novel $[Mn_6^{III}(\mu_3\text{-}O)_2\ (\mu_2\text{-}OR)_2]^{12+}$ core, whose topology consists of six Mn ions arranged as two $\{Mn_3(\mu_3\text{-}O)\}$ subunits bridged by two oximato oxygen atoms. Both compounds proved to behave as single molecule magnets (SMM) and are the first members of a new class of manganese-based SMMs containing exclusively Mn^{III} ions with blocking temperature greater than 2 K. In order to investigate the possibility of synthesizing the corresponding polynuclear iron(III) complexes and to study their magnetic properties, we have designed the 1:3:1 molar ratio reaction of $Fe^{3+}/PhCO_2^-/H_2$salox in alcoholic media. The 1:3:1 molar ratio has been chosen so that the M/carboxylate/H_2salox ratio remains the same in going from manganese(II) to iron(III) ions. But it turned out that in the iron(III) case, the amount of the carboxylate ions was very high, and the trinuclear oxo-centered complexes **1** and **2** were formed. The salox^{2-} ions are coordinated through the usual μ_2:η^1:η^1:η^1 mode while the possibility of further use of the oximato oxygen atom to bridge a second metal and to increase the nuclearity of the derived complex has failed. Nevertheless, we still consider compounds **1** and **2** as useful staring materials for polynuclear iron(III) complexes, under different reaction conditions.

The synthesis of **1** and **2** can be summarized in Eqs. (1) and (2), respectively, based on the reasonable assumption that H_2O from the starting materials and/or the solvent is the source of the O^{2-} ion.

$$3Fe(NO_3)_3\cdot 9H_2O + 5PhCO_2Na + H_2salox + 2MeOH \xrightarrow{MeOH} [Fe_3O(O_2CPh)_5(salox)(MeOH)_2] + 5NaNO_3 + 4HNO_3 + 26H_2O \quad (1)$$

$$3FeCl_3\cdot 6H_2O + 5PhCO_2Na + H_2salox + EtOH \xrightarrow{EtOH} [Fe_3O(O_2CPh)_5(salox)(EtOH)(H_2O)] + 5NaCl + 4HCl + 16H_2O \quad (2)$$

3.2. IR spectroscopy

In the IR spectrum of both **1** and **2**, medium-intensity bands at 3451, 3063, 2924 cm^{-1} (for **1**) and 3414, 3063, 2980 cm^{-1} (for **2**), are assigned to the $\nu(OH)_{H_2O}$, $\nu(CH)_{aromatic}$, $\nu(CH_3)$, respectively. Strong intensity bands at 1598 cm^{-1} and medium intensity bands at 1286 cm^{-1} observed in the spectrum of both complexes are assigned to the ν(C=N) and ν(N–Oox) of the salicylaldoximato ligand [28]. The frequencies of the $\nu_s(CO_2)$ bands of $PhCO_2^-$ coincide in the spectra of **1** (1406 cm^{-1}), and **2** (1405 cm^{-1}). The bands at 1557 cm^{-1} in **1** and **2**, respectively, are assigned to the $\nu_{as}(CO_2)$ of the benzoato ligands. The difference Δ ($\Delta = \nu_{as}(CO_2) - \nu_s(CO_2)$) for **1** is 151 cm^{-1} and for **2** is 152 cm^{-1}, less than that for NaO_2CPh (184 cm^{-1}), as expected for the bridging modes of benzoate ligation [29]. A strong intensity band at 480 cm^{-1} in the spectra of **1** and at 478 cm^{-1} in the spectra of **2** is characteristic of the presence of the $[Fe_3O]$ moiety in the structures of **1** and **2**.

3.3. Structural description of $[Fe_3(\mu_3\text{-}O)(O_2CPh)_5(salox)(MeOH)_2]\cdot 1.25MeOH\cdot 1.05H_2O$ (1)

Compound **1** crystallizes in the monoclinic space group $P2_1/c$ with two crystallographically independent trinuclear complexes in the asymmetric unit (further reported as molecules **1a** and **1b**). The structure of the molecule **1a** is given in Fig. 1. Selected bond distances and angles for both **1a** and **1b** are listed in Table 2. The structure of **1** consists of a trinuclear iron(III) oxo-centered complex. The three Fe^{III} ions in **1a** form an isosceles triangle whilst in **1b** the triangle is best described as scalene (see Table 2). The Fe–O_{oxo} bond distances are in the range 1.86–1.94 Å in both molecules **1a** and **1b**, and the central $[Fe_3(\mu_3\text{-}O)]^{7+}$ moiety is planar. Ions Fe(2) and Fe(3) in molecule **1a** and the corresponding ions Fe(5) and Fe(6) in molecule **1b** have an octahedral oxygen rich coordination environment, while ions Fe(1) and Fe(4) in molecules **1a** and **1b**, respectively, have a distorted octahedral O_5N coordination geometry. The angles within the tetragonal plane of the octahedron range from 82.2° to 97.5° for **1a** and from 78.5° to 99.1° for **1b**. The angles involving the axial positions of the

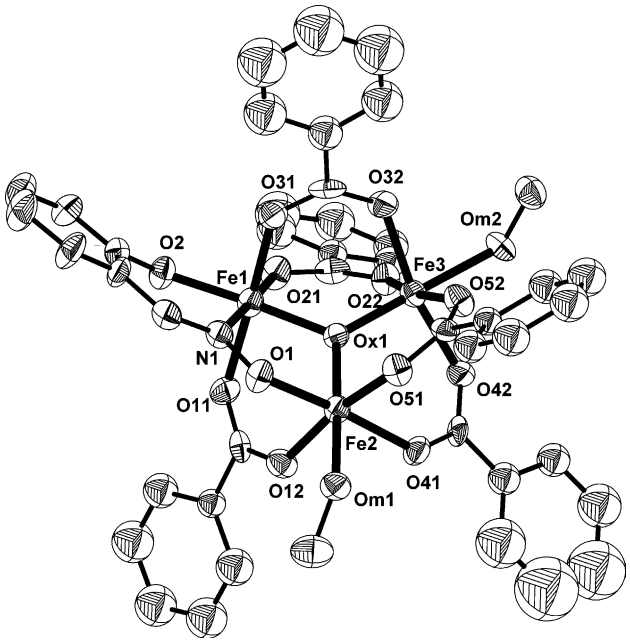

Fig. 1. The molecular structure of the molecule **1a** with the atomic labelling (40% thermal probability ellipsoids).

octahedron range from 168.5° to 178.5° and from 163.9° to 178.1° in **1a** and **1b**, respectively.

The salicylaldoximato ligand shows the common μ_2:η^1:η^1:η^1 coordination mode with the N–O oximato group and the phenolate oxygen atom lying above and below the $[Fe_3(\mu_3\text{-}O)]^{7+}$ plane, respectively. The Fe–$O_{oximato}$ bond distances are 1.982 Å in both molecules **1a** and **1b**, the Fe–$O_{phenoxy}$ are 1.914 and 1.930 Å in molecules **1a** and **1b**, respectively. The Fe–$N_{oximato}$ bond lengths are 2.133 and 2.145 Å in molecules **1a** and **1b**, respectively. The whole salicylaldoximato ligand is planar and makes an angle of 51.1° and 65.3° with the $[Fe_3(\mu_3\text{-}O)]^{7+}$ plane in molecules **1a** and **1b**, respectively.

The benzoato ligands are coordinated in the common *syn*,*syn* μ_2:η^1:η^1 mode. The Fe–$O_{carboxylato}$ bond distances are in the range 1.977–2.029 and 1.990–2.052 Å in molecules **1a** and **1b**, respectively.

The polymeric lattice structure of **1**, shown in Fig. 2, arises from the strong intermolecular interactions between the isolated trimers. More specifically, the oximato oxygen atom O(1) in molecule **1a** is strongly interacting (most likely through hydrogen bonding interactions) to a coordinated methanolic oxygen atom Om(1) belonging to a centrosymmetrically related molecule **1a** [O(1)...Om(1′) = 2.574 Å (1 − *x*, −*y*, 1 − *z*)]. Thus, a dimer of trimers of the a–a type, is formed though two intermolecular interactions across a center of symmetry. The closest Fe···Fe interatomic distance in the a–a dimer is Fe(2)···Fe(2′) = 5.067 Å. The same feature is observed in the case of molecule **1b**, where the oximato oxygen atom O(61) is strongly interacting (most likely through H-bonding interactions) to a coordinated methanol Om(3) from a centrosymmetrically related molecule **1b** [O(61)...Om(3″) = 2.666 Å (2 − *x*, −*y*, 2 − *z*)]. Thus, a dimer of trimers of the b–b type, is formed due to the double interactions described above. The closest Fe···Fe interatomic distance in the b–b dimer is Fe(5)···Fe(5″) = 5.207 Å. Apart from the formation of dimers, another feature is also observed in the lattice structure of **1**. The phenoxy oxygen atom O(62) of molecule **1b** is

strongly interacting (most likely through H-bond) to the second coordinated methanolic oxygen Om(2) of molecule **1a** [O(62)···Om(2″) = 2.693 Å (2 − *x*, −*y*, 2 − *z*)]. Thus, polymeric chains of alternative dimers of the …a–a–b–b… are formed along the *ac* diagonal of the unit cell. The closest Fe···Fe interatomic distance in the a–b part of the chain is Fe(3)···Fe(4″) = 5.518 Å.

3.4. Structural description of $[Fe_3(\mu_3\text{-}O)(O_2CPh)_5(salox)(EtOH)(H_2O)]\cdot EtOH$ (2)

The structure of **2** (Figure S1) is analogous to that of compound **1**, the only difference being in the monodendate ligands completing the octahedral coordination around the iron(III) ions (one ethanol and one water molecules instead of two methanols in **1**). The three Fe^{III} ions form a scalene triangle with edges 3.207, 3.277 and 3.306 Å. The Fe–O_{oxo} bond distances are in the range 1.835–1.923 Å and the central $[Fe_3(\mu_3\text{-}O)]^{7+}$ moiety is planar. Ions Fe(2) and Fe(3) have an octahedral oxygen rich coordination environment, while Fe(1) has a distorted octahedral O_5N coordination geometry.

Despite its similarities in the molecular structure with that of **1**, compound **2** presents a different lattice structure originated by the existence of intermolecular interactions between the isolated trimers. Strong intermolecular interactions (possibly through H-bonds) between the oximato oxygen atom O(1) and the coordinated ethanolic oxygen atom Oe(1) of a centrosymmetrically related trimer [O(1)…Oe(1′) = 2.674 Å (−*x*, −*y*, 1 − *z*)], and between the phenolate oxygen atom O(2) and the coordinated water molecule Ow(1) of a neighboring trimer [O(2)…Ow(1″) = 2.967 Å (0.5 − *x*, −0.5 + *y*, 0.5 − *z*)], are responsible for the 2D polymeric network (parallel to the [1 0 1] crystallographic plane) in **2** (Figure S2). The closest Fe…Fe interatomic distances due to the H-bonding interactions are Fe(2)…Fe(2′) = 5.075 Å, and Fe(1)…Fe(3″) = 5.913 Å.

Compounds **1** and **2** can be considered as part of the large 'basic carboxylates' family of trivalent oxo-centered trinuclear compounds with the general formula $[M_3(\mu_3\text{-}O)(O_2CR)_6L_3]$ (L = terminal monodentate ligand). The only difference between the 'basic carboxylates' and compounds **1** and **2** is that, one of the carboxylates and one of the terminal ligands have been replaced by the oximato and phenoxy group of the salicylaldoxime, respectively. In that sense, bond distances and angles in the coordination sphere are in the ranges found for several iron(III) 'basic carboxylates' [30–37].

3.5. Mössbauer spectra

Fig. 3 shows Mössbauer spectra from powder samples of **1** and **2** recorded at room temperature in the absence of an external magnetic field. The spectra for both compounds consist of two well resolved doublets. Solid lines above the spectra are theoretical simulations assuming two iron sites at 2:1 ratio with the parameters quoted in Table 3. For both compounds the isomer shifts for sites I and II are typical for high spin Fe^{III} in an octahedral environment comprising O/N atoms.

From the crystal structure of complex **1**, site I which represents the majority species is readily assigned to the iron sites with O_6 environment whereas site II, the minority species, is assigned to the iron site with O_5N coordination. Site II is characterized by a significantly larger ΔE_Q relatively to site I. The ΔE_Q parameter reflects the degree of asymmetry around the Fe ion. This can be asymmetry of Fe–L bond lengths and coordination geometry, or asymmetry in the nature of donor atoms (N or O). In terms of coordination geometry, significant *trans* effects are experienced by Fe(2), Fe(3) in

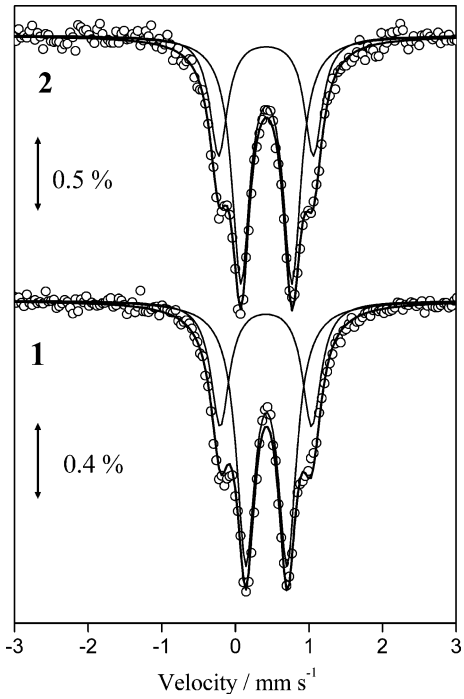

Fig. 3. Room temperature Mössbauer spectra from solid powder samples of **1** and **2**. Solid lines are theoretical spectra assuming two different iron sites with the parameters quoted in Table 3.

Table 3
Mössbauer parameters for **1** and **2**

Complex	Site	Temperature (K)	δ[a,b,c]	ΔE_Q[a,c]	$\Gamma/2$[a,d]	Area (%)[d]
1	I	300	0.42(1)	0.56(1)	0.15	67
		4.2	0.54(1)	0.61(1)	0.19	
	II	300	0.41(1)	1.24(1)	0.15	33

[d] Fixed.

molecule **1a**, and by Fe(5), Fe(6) in molecule **1b**, with the shortest bond being the Fe–(μ_3-O^{2-}) in each case. The corresponding *trans* effect experienced by atoms Fe(1) and Fe(4) is insignificant (see Table 2). In terms of donor atoms, there are two iron atoms with asymmetric O_5N chromophores [Fe(1) and Fe(4)] and four atoms with more symmetric O_6 chromophores [Fe(2), Fe(3), Fe(5) and Fe(6)]. The Mössbauer spectra, therefore, indicate that the O_5N coordination should be considered responsible for the larger ΔE_Q value of site II.

The resolution of the spectrum of complex **1** does not allow us to distinguish the two crystallographically different molecules **1a** and **1b**. We observe however that the spectrum exhibits fairly narrow lines suggesting that the iron sites in molecules **1a** and **1b** are characterized by similar Mössbauer parameters and especially ΔE_Q. The situation for complex **2** is similar and the O_5N coordinated iron atom [Fe(1)] with a larger ΔE_Q is assigned to site II, despite its more symmetric octahedral coordination geometry.

At 4.2 K and in the absence of external magnetic fields a slight broadening of the doublets for both complexes is observed (Fig. S3). No magnetic ordering is evidenced at 4.2 K. The broadening can be attributed to the onset of magnetic relaxation effects. Alternatively, structural changes may occur leading to three distinct sites. Although the deconvolution of the spectra is not unique both can be simulated assuming two sites at 2:1 ratio as in the room temperature case with the parameters quoted in Table 3 (Fig. S3). The average isomer shift for both compounds at 4.2 K is 0.54 mm s^{-1} and the difference in the isomer shifts with the room temperature spectra is due to the second order Doppler effect [38].

3.6. Magnetic behaviour

For complex **1**, the $\chi_M T$ product at 300 K is 3.94 cm^3 mol^{-1} K (Fig. 4), significantly lower than the theoretically expected value for three non-interacting $S = 5/2$ spins (13.14 cm^3 mol^{-1} K), suggesting antiferromagnetic interactions. Upon cooling, the $\chi_M T$ product decreases to 0.31 cm^3 mol^{-1} K at 2 K, without extrapolating to zero as the temperatures tends to zero, which agrees with the interplay of antiferromagnetic interactions, and a magnetic ground state.

As analyzed in the description of the structures, complex **1** actually consists of two independent molecules (**1a** and **1b**), with two rather different geometries; isosceles (for **1a**) and scalene (for **1b**, see description of structures). Due to the different geometries it is expected that

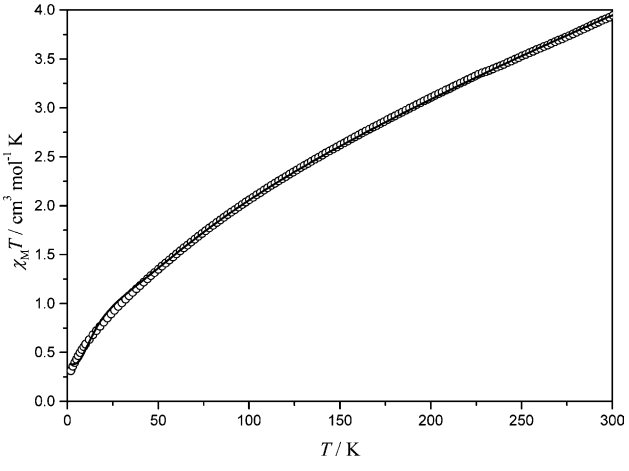

Fig. 4. $\chi_M T$ vs. T experimental data for complex **1**, and theoretical curves based on the Hamiltonian of Eq. (3), using the parameters of solution **A**.

1a and **1b** have different magnetic properties. However, consideration of two different magnetic entities for the analysis of the bulk magnetic susceptibility data would lead to a large number of parameters with a small degree of reliability. Therefore, we have analyzed the data assuming one single trinuclear species.

Initial attempts to simulate the magnetic properties of the complex by considering a single exchange constant, J did not yield satisfactory results. It was, therefore, concluded that a model taking into account a second exchange constant, J', should be considered. The Hamiltonian used was

$$\hat{H} = -2J(\hat{S}_1\hat{S}_3 + \hat{S}_2\hat{S}_3) - 2J'\hat{S}_1\hat{S}_2. \quad (3)$$

The fitting process yielded two solutions of comparable quality (with g fixed to 2.0), as is usually the case for complexes containing the $[Fe_3O]^{7+}$ core, with a $S = 1/2$ ground state [39,40]. The best-fit parameters were, **A**: $J = -27.3\ cm^{-1}$, $J' = -42.7\ cm^{-1}$, $g = 2.0$ ($R = 1.2 \times 10^{-3}$) and **B**: $J = -34.7\ cm^{-1}$, $J' = -24.6\ cm^{-1}$, $g = 2.0$ ($R = 1.7 \times 10^{-3}$). This is better depicted by an error surface plot of J versus J', which reveals the existence of two minima (Figure S4). Both these solutions imply a $S = 1/2$ ground state.

In order to verify the validity of these results, a simulation of the M versus H curve at 2.5 K was carried out with the MAGPACK program package [41,42], using the best-fit parameters of solutions **A** and **B**. These reproduced the experimental curves very nicely, producing practically superimposable curves, without the use of a paramagnetic impurity fraction (Fig. 5).

The situation is similar in the case of complex **2**, with the $\chi_M T$ product decreasing smoothly from 3.65 $cm^3\ mol^{-1}\ K$ at 300 K down to 0.28 $cm^3\ mol^{-1}\ K$ at 2 K, without extrapolating to zero (Fig. 6). For the analysis of the data we assumed the same model as above. The fit shown in Fig. 6 was carried out over the 8–300 K temperature region. Two solutions of comparable quality were determined, their parameters being, **A**: $J = -35.9\ cm^{-1}$, $J' = -29.8\ cm^{-1}$, $g = 2.0$ ($R = 3.7 \times 10^{-4}$) and **B**: $J = -31.3\ cm^{-1}$, $J' = -41.2\ cm^{-1}$, $g = 2.0$ ($R = 4.3 \times 10^{-4}$). Fitting over the 2–300 K temperature range yielded small discrepancies at low temperatures. These discrepancies are attributed to the presence of weak intermolecular interactions.

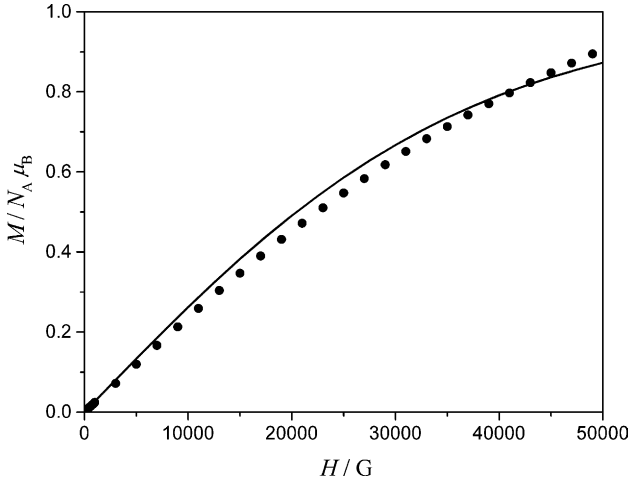

Fig. 5. Variation of the magnetization M vs. the applied field H at 2.5 K for complex **1**. The curves calculated according to the parameters of solutions **A** or **B** are superimposable.

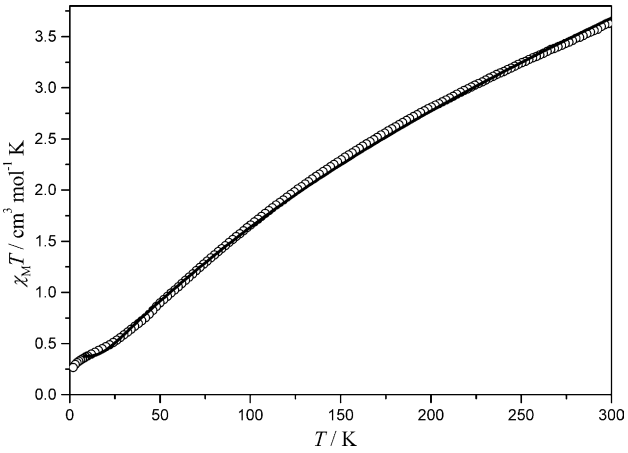

Fig. 6. $\chi_M T$ vs. T experimental data for complex **2**, and the theoretical curve based on the Hamiltonian of Eq. (3) (solution **B**).

The existence of two minima in the fitting procedure of the magnetic susceptibility data is an inherent property of trinuclear complexes [40]. It would be reasonable to correlate the value of the exchange coupling constants with the metric characteristics of the complexes. This approach however may not be realistic in the present case. First, complex **1** consists of two different molecules and the unambiguous determination of the individual magnetic properties is not feasible from the present bulk magnetic susceptibility measurements. Second, even in the simpler case of equilateral complexes the necessity of at least two different exchange coupling constants for the reproduction of the magnetic susceptibility measurements indicate that magnetostructural correlations are not straightforward and other factors have to be taken into account. We observe however that on average, the derived values for the exchange constants for solutions **A** and **B** for both complexes fall well within the range of values usually found in trinuclear complexes [43–47].

3.7. EPR spectroscopy

EPR spectra from powder samples for both complexes at 4.2 K are shown in Fig. 7. For compound **1** the spectra reveal a feature at $g \sim 2.0$ accompanied by broad features at lower magnetic fields. For compound **2** an additional broad feature is observed at higher magnetic fields. The magnetic susceptibility data indicate that the clusters are characterized by a $S = 1/2$ ground state, however the EPR signals cannot be attributed to

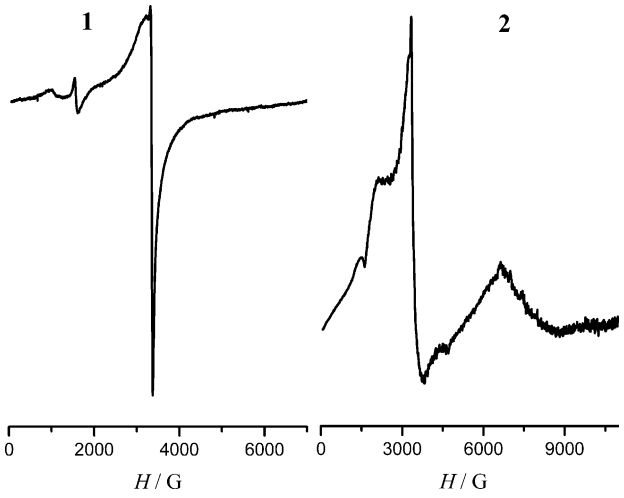

Fig. 7. EPR spectrum from a solid powder sample of **1** and **2** at 4.2 K. EPR conditions: microwave frequency, 9.41 GHz; microwave power, 50 mW; modulation amplitude 10 G_{pp}.

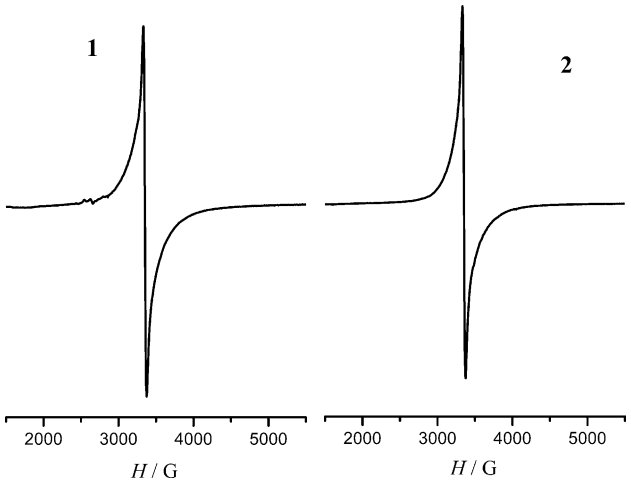

Fig. 8. EPR spectrum from **1** and **2** in acetone glass at 4.2 K. EPR conditions: microwave frequency, 9.41 GHz; microwave power, 2 mW; modulation amplitude 10 G_{pp}.

isolated $S = 1/2$ systems. We attribute this behaviour to intermolecular interactions present in the solid state. This is supported by the crystal structure revealing intermolecular interactions between neighbouring trimers. We note that the low temperature magnetic susceptibility data for complex **2** cannot be reproduced with isolated trimers and the EPR spectra support weak intermolecular interactions. For compound **1** the intermolecular interactions appear to be weak enough, so they do not affect the magnetic susceptibility data. However, weak dipolar interactions may substantially affect the EPR spectra. For instance a weak dipolar interaction between two $S = 1/2$ systems of the order of $\sim 0.05\ cm^{-1}$ can be hardly discernible in bulk magnetic susceptibility measurements, but it will critically affect the EPR measurements leading to spectra extending in a large magnetic field region.

In order to eliminate the solid-state effects, we studied by EPR both compounds in an acetone glass, a weakly coordinating solvent. The 4.2 K spectra are shown in Fig. 8. A strong signal is observed at $g \sim 2.0$ for both compounds. The signal is characterized by a symmetric derivative feature with a line-shape which is better described by a Lorenztian curve. The temperature dependence of this signal indicates that it arises from a ground state. The dependence of the signal on microwave power and the line-shape argues against a free radical species. Further, it is improbable that this signal arises from monomeric Fe^{III} ($S = 5/2$) species resulting from decomposition of the compound upon solvation in acetone. Usually such species gives rise to signals at higher g-values (for instance at $g \sim 4.3$) as a result of zero-field splitting effects. No such signals are observed in the present case. A monomeric Fe^{III} ($S = 1/2$) low spin species can be also excluded because in this case fairly anisotropic signals are expected.

On the other hand, it is reasonable to assume that the EPR signals of Fig. 8 arise from the $S = 1/2$ ground state of isolated trimers in both compounds. The symmetric line-shape of the signals suggests an isotropic system. This is indeed expected from a trimer comprising Fe^{III} ($S = 5/2$) sites antiferromagnetically coupled with the isotropic Heisenberg–Dirac–van Vleck Hamiltonian as the main interaction. Although symmetric EPR lines are expected this is rarely met in trinuclear complexes of Fe^{III} ($S = 5/2$) or Cr^{III} ($S = 3/2$) [39,48–53]. Usually, in such systems, non-Heisenberg interactions such as antisymmetric exchange and/or single-ion zero-field splitting terms result in an anisotropic $S = 1/2$ ground state. Due to the anisotropy, broad EPR signals are observed extending to high field values with $g \ll 2.0$. In the present case the signal is symmetric and confined at the $g \sim 2.0$ region indicating that the contribution of these terms is negligible. From this point of view compounds **1** and **2** are rare cases of triferric complexes where the anticipated $S = 1/2$ EPR signals are indeed observed.

4. Conclusions

As part of our continuing efforts to synthesize polynuclear iron(III) complexes with novel magnetic properties, we have reacted H_2salox with iron(III) in the presence of carboxylates. The two new neutral iron(III) complexes, $[Fe_3(\mu_3\text{-}O)(O_2CPh)_5(salox)L_1L_2]$ ($L_1 = L_2 =$ MeOH (**1**), $L_1 =$ EtOH, $L_2 = H_2O$ (**2**)) derived, contain the $[Fe_3O]^{7+}$ core found in 'basic iron carboxylates'. In complexes **1** and **2** however two iron atoms are in an O_6 coordination environment whereas the third is found in an O_5N one. A detailed characterization of complexes **1** and **2** including spectroscopic and magnetic studies has been carried out. The nonequivalence of the

iron(III) ions is depicted in the Mössbauer spectra. The magnetic properties are interpreted within the context of a trimer with exchange constants typical for complexes with the $[Fe_3(\mu_3\text{-}O)]^{7+}$ core and a $S = 1/2$ ground state. The crystal structure analysis of **1** reveals intermolecular interactions between the trimers forming 1D polymeric chains. In **2** the intermolecular interactions lead to the formation of a 2D network. These interactions give rise to broad EPR spectra in the solid state. The $salox^{2-}$ ligand adopts the usual $\mu_2{:}\eta^1{:}\eta^1{:}\eta^1$ coordination mode, while the possibility of further use of the oximate oxygen atom to bridge to a second metal is left open. In that sense, compounds **1** and **2** can be considered as important starting materials for the synthesis of higher nuclearity clusters under certain reaction conditions.

Abstract

The mixed ligand complex $[La(hfa)_3(Phen)_2]$ (**I**) was obtained by the interaction of $La(hfa)_3$ and Phen; its composition does not depend on the stoichiometry of the reagents. According to the X-ray single crystal analysis data, complex **I** crystallizes in the monoclinic space group $P2_1/n$, with $a = 13.583(3)$ Å, $b = 16.959(3)$ Å, $c = 18.860(4)$ Å, $\beta = 94.71(3)°$ and $Z = 4$. The structure of **I** consists of isolated mononuclear molecules, the coordination number of La being 10. Thermal behaviour and composition of the vapor phase have been studied for **I** by thermal analysis and mass-spectrometry using a Knudsen cell. The mixed ligand complex **I** was found to sublime congruently in the temperature range 370–460 K: $[La(hfa)_3(Phen)_2]_{(s)} = [La(hfa)_3(Phen)]_{(g)} + Phen_{(g)}$, $\Delta_r H^0(T) = 316.2 \pm 1.8$ kJ/mol.

Keywords: Mixed ligand complexes; Ten-coordinated lanthanum complexes; Crystal structures; Thermal behaviors; Mass-spectrometry studies

1. Introduction

The interest in coordination chemistry of lanthanide β-diketonates, $Ln(dik)_3$, is based on the possibility of their use as NMR shift reagents [1], luminescent materials [2,3] and as volatile precursors in the chemical vapor deposition of thin films with electrical and magnetic properties [4,5]. One of the most important features of lanthanide β-diketonates is the possibility to coordinate additional neutral donor ligands (Q) and to form mixed ligand complexes $[Ln(dik)_3(Q)_n]$. The formation of such complexes is based on coordinative unsaturation of the metal in $Ln(dik)_3$ and depends on the Lewis acidity–basicity of both $Ln(dik)_3$ and Q, and on sterical hindrances [6]. The combination of $Ln(dik)_3$ with Q into one molecule of $[Ln(dik)_3(Q)_n]$ offers wide possibilities for modifying the functional properties of lanthanide β-diketonates.

Over the last four decades an extensive literature, dedicated to the synthesis, structure and properties of mixed ligand lanthanide β-diketonates, has evolved. The mixed ligand complexes of $Ln(dik)_3$ with N-donor ligands Phen and Bipy are of a special interest since the insertion of these ligands into the coordination sphere of $Ln(dik)_3$ has significantly influences on the luminescent properties and volatility of lanthanide β-diketonates [7,8]. Mixed ligand complexes of the common composition $[Ln(dik)_3(Q)]$ (Q = Phen, Bipy) were prepared for practically all the lanthanides, and for many β-diketonate ligands – acetylacetonate (acac), dipivaloylmethanate (thd), dibenzoylmethanate (dbm),

pivaloylacetonate (pta) [9–11]. The analysis of the X-ray structure data shows the central lanthanide ion in these mixed ligand complexes to be eight coordinated and to form four chelate rings – three with β-diketonate ligands and one with Phen or Bipy. However, among the $[Ln(dik)_3(Q)]$ (Q = Phen, Bipy) complexes published to date, there is no data about hfa complexes, where hfa – hexafluoroacetylacetonate. Meanwhile, the synthesis, structure and properties of such mixed ligand complexes are indubitably of especial interest because the hfa ligand contains two electron-withdrawing CF_3 groups that increase the Lewis acidity of $Ln(hfa)_3$, contrary to other non-fluorinated lanthanide β-diketonates. One would expect $Ln(hfa)_3$ to be the most active for the addition of neutral ligands. In reality, in 2001 [12] it was found that the early lanthanide elements, which have larger ionic radii, form 10-coordinated complexes of the type $[Ln(hfa)_3(Q)_2]$ (Q = Phen, Bipy, Ln = La, Ce, Pr, Nd, Sm), whereas the elements at the end of the lanthanide series form eight coordinated complexes $[Ln(hfa)_3(Q)]$ (Q = Phen, Bipy, Ln = Dy, Tb, Ho, Yb). The X-ray crystal structure of $[Ln(hfa)_3(Bipy)_2]$ was determined and coordination of two Bipy ligands was confirmed. In our opinion, the complexes $[Ln(hfa)_3(Q)_2]$ (Q = Phen, Bipy) are very interesting objects not only in respect of their structural features, but due to their volatility and thermal dissociation stability:

$$[Ln(dik)_3(Q)_n] \rightarrow Ln(dik)_3 + nQ$$

So, in [11] it was found that $[Ce(pta)_3(Phen)]$ sublimes congruently. The thermal stability of $[Ln(hfa)_3(Q)_2]$ was not studied in [12]. Here we report the synthesis of $[La(hfa)_3(Phen)_2]$ by a different method from that published in [12], the crystal structure of this complex, the results of thermal analysis and mass-spectrometry data as well as the sublimation of $La(hfa)_3$.

2. Experimental

2.1. General

Analytically pure reagents $La_2(CO_3)_3 \cdot 8H_2O$, Hhfa, KOH and $Phen \cdot H_2O$ from Merck were used. Dry Phen was obtained by dehydration of $Phen \cdot H_2O$ at 140 °C (0.01 Torr).

The C, H and N contents were determined by conventional elemental analysis. The lanthanum content was determined titrimetrically.

IR spectra were recorded on a Perkin–Elmer 1600 FTIR spectrometer as Nujol and hexachlorobutadiene mulls between KBr plates in the region 4000–400 cm^{-1}.

^1H NMR spectra were recorded on a Bruker AC-600P spectrometer in $CDCl_3$/TMS.

Thermogravimetric analysis was carried out under argon on a Perkin–Elmer Pyris Diamond thermal analyzer at a heating rate of 10 °C min^{-1}. Isothermal vacuum sublimation experiments were done with 100 mg samples in a glass test tube for 30 min at 0.01 Torr. Weight losses were determined gravimetrically and controlled by titrimetric analyses of the sublimates.

2.2. Synthesis

The starting complex $La(hfa)_3$ was prepared according to the procedure described in [13].

A solution of 0.18 mg (1 mmol) Phen in 25 ml of EtOH was mixed with a hot solution of 0.56 mg (0.5 mmol) $La(hfa)_3$ in 25 ml of EtOH. The mixture was refluxed under stirring for 2 h, resulting in a clear colorless solution. The volume of the solution was reduced to a half under slow evaporation of the solvent at room temperature, and yielded a microcrystalline precipitate after one day. Yield: ~80%. *Anal.* Calc.: C, 41.79; H, 1.69; N, 5.00; La, 12.4. Found: C, 41.67; H, 1.87; N, 4.99; La, 12.4%. IR (cm^{-1}): 1652 (C–O), 1525 (C–C), 1254, 1204, 1146 (C–F), 1592, 1580, 880, 730 (Phen). ^1H NMR (δ, ppm): 9.13 (d, 4H, $^3J = 6$ Hz), 7.95 (d, 4H, $^3J = 8$ Hz), 7.85 (t, 4H, $^3J = 8$ Hz), 7.38 (t, 4H, $^3J = 6$ Hz), 5.65 (s, 3H).

By using $Phen \cdot H_2O$ instead of anhydrous Phen and by changing the molar ratio of $[La(hfa)_3]$:[Phen] from 1:2 to 1:1, the same product $[La(hfa)_3(Phen)_2]$ was obtained with a yield of about 80–85%, calculated with respect to Phen.

2.3. Crystal structure determination

Suitable single crystals of $[La(hfa)_3Phen_2]$ (**I**) were grown by recrystallization of the crude product from EtOH solution.

The diffraction data were collected on an Enraf-Nonius CAD-4 automatic diffractometer (Mo Kα radiation, $\lambda = 0.71073\,E$, $2\theta/\omega$-scanning, θ-max = 28.0°, graphite monochromator). The crystallographic data along with some details of data collection and structure refinement are given in Table 1. On data processing, Lorenz and polarization factors were introduced.

The structure was determined by direct methods (SHELXS-86 [14]) and refined using the full-matrix least-squares method (SHELXL-97 [15]). The structure refinements were carried out anisotropically for all non-hydrogen atoms. Hydrogen atoms were placed in their calculated positions (C–H $0.93\,E$) and refined isotropically in the riding mode. Some of the CF_3 groups were disordered with occupancies in the range of 0.47–0.53. The most important bond distances are given in Table 2.

2.4. Mass-spectrometry and study of the vapor phase

The mass spectra of $[La(hfa)_3]$ and $[La(hfa)_3(Phen)_2]$ were recorded on a MS 1301 spectrometer having a

50–1500 amu mass range, and using 80, 60 and 14 eV ionizing electrons. The complexes were vaporized from a Knudsen effusion cell. The ratio of surface of evaporation to surface of the effusion hole was about 600. The cell temperature was measured with a Pt/Pt(Rh) thermocouple (±1°). The experiments were carried out in the range of 339–393 K for $[La(hfa)_3]$ and 370–460 K for $[La(hfa)_3(Phen)_2]$. The main ion peaks in mass spectra of $[La(hfa)_3]$ at 364 K and $[La(hfa)_3(Phen)_2]$ at 440 K are given in Table 3.

Vapor pressure versus temperature was determined by means of isothermal vaporization experiments and the use of the Herz-Knudsen equation. The enthalpy of sublimation was calculated from the temperature dependences of ion current intensities by using the Clausius–Clapeyron equation and a least-squares method.

3. Results and discussions

3.1. Synthesis and structure description

$[La(hfa)_3(Phen)_2]$ was obtained by the interaction of the lanthanide β-diketonate with the neutral donor ligand in ethanol. It was found that a change of the reagents molar ratio $[La(hfa)_3]$:[Phen] = 1:1, 1:2 and the use of hydrated reagents instead anhydrous ones does not result in a change of the complex composition, giving the same product with the stoichiometry $[La(hfa)_3(Phen)_2]$. A similar situation was described in [12], where for the synthesis of $[La(hfa)_3(Q)_2]$ (Q = Bipy, Phen), the single-step reaction between $La(CF_3SO_3)_3$, Hhfa, CsOH and either Bipy or Phen in a molar ratio 1:3:3:1 in MeOH was used. In [12] the yield of $[La(hfa)_3(Phen)_2]$, calculated with respect to Phen, was about 10%. In our method of synthesis, the yield achieved was 80%. The IR and ^{1}H NMR spectroscopy data confirm the formation of $[La(hfa)_3(Phen)_2]$.

The structure of $[La(hfa)_3(Phen)_2]$ (**I**) consists of isolated mononuclear molecules, with the coordination number of the central lanthanum atom being ten (Fig. 1). The ten donor atoms (four nitrogen atoms from Phen and six oxygen atoms from hfa ligands) are situated in a coordination sphere of the central lanthanum atom, forming a sphenocrown as the coordination polyhedron (Fig. 2).

After $[La(hfa)_3(Bipy)_2]$ (**II**) [12], the structure of **I** is the second example of a structurally characterized ten-coordinated tris-β-diketonate lanthanide complex. The structures of **I** and **II** are similar – three hfa ligands and two neutral ligands (Phen or Bipy) are coordinated by the La atom. It should be noted that some differences are caused by the replacement of Bipy ligands by Phen ligands. So, the structure **II** possesses a C_2 rotation axis through the γ-carbon atom of one hfa ligand and the La

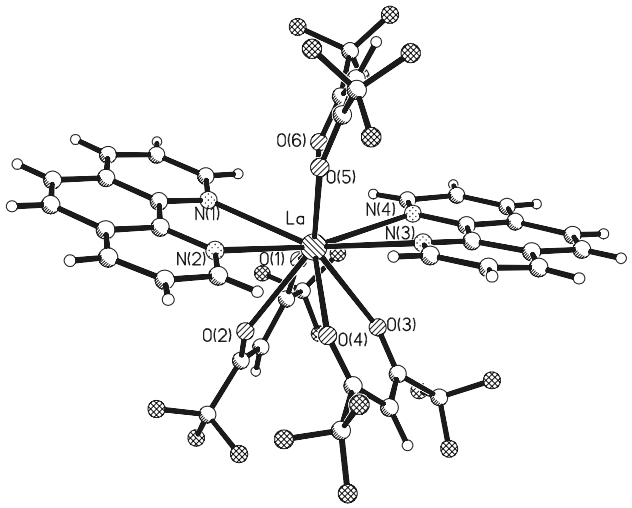

Fig. 1. Molecular structure of $[La(hfa)_3Phen_2]$. For statistical disordered atoms of F, one position is shown.

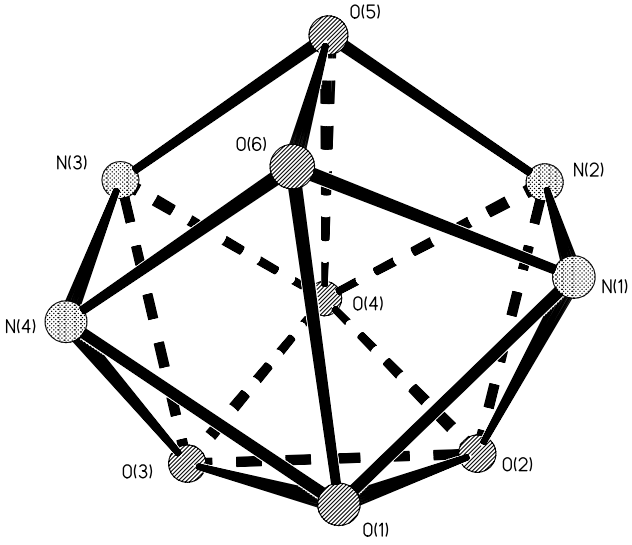

Fig. 2. Coordination polyhedron of La in the structure of $[La(hfa)_3Phen_2]$ – distorted sphenocrown.

atom. In a molecule of **I**, the symmetry axis is absent and the La–O distances vary with a wider range than in **II** (Table 2). However, the average value of La–O bond lengths is the same in **I** and **II** and is equal to 2.548(7) Å. A similar picture is observed with the La–N distances: in **I** the values of La–N bonds vary in the range 2.748(9)–2.799(9) Å and in **II** two the La–N distances are 2.773(3) and 2.771(3) Å, so in **I** the average distance La–N is practically the same (2.773 Å) as in the case of **II**. The similarity of structures **I** and **II** to one another would be expected as both ligands Bipy and Phen have a very similar donor and geometrical characteristics.

The analysis of the packing mode of **I** is of especial interest because in some structures of β-diketonate complexes with Phen ligands an intermolecular π–π stacking interaction between Phen ligands of neighboring molecules occurs. For example, in the crystal structure of barium β-diketonates with two Phen ligands $[Ba(dik)_2(Phen)_2]$ (Hdik = Hthd [16], Hpta [17] and Hhfa [18]), $[Ba(dik)_2(Phen)_2]$ molecules are stacked in the crystal structure forming infinite chains. In the crystal structure of $[La(thd)_3(Phen)]$ [19], the intermolecular π–π stacking interaction results in the formation of dimers. In the case of **I**, the crystal structure consists of centro-symmetrical pairs of $[La(hfa)_3(Phen)_2]$ molecules too (Fig. 3). The phenanthroline ligands from two centrosymmetrically situated neighboring molecules are parallel and the distance between their planes is equal to 3.35 Å. However, π–π interactions between these Phen ligands do not occur because their planes are not overlapped (Fig. 3).

3.2. Thermal behavior of *I*

Upon heating under argon, complex **I** melts at 223 °C and then undergoes two major stages of weight loss (Fig. 4). The first weight loss occurs over 210–310 °C. The DTA and DTG curves show only one narrow endothermic peak in this temperature range at 294 °C. The value of the weight loss at this stage (68%) significantly exceeds the value calculated for the removal of two Phen molecules (32%). On the basis of these facts, it is believed that partial sublimation of $[La(hfa)_3(Phen)_2]$ can take place in this temperature range. The second, smooth stage follows in the temperature range of 310–580 °C, corresponding to about 11% of the total weight loss (79%). This stage corresponds to the thermal decomposition of **I** under argon.

Upon heating in a glass reactor under low pressure (0.01 Torr), the total sublimation of **I** occurs over the temperature range of 200–220 °C, and only one fraction of sublimate was collected in the colder part of the reactor. The elemental analysis and ^1H NMR spectroscopy data showed that the solid sublimate was identical to the starting material.

In order to determine whether $[La(hfa)_3(Phen)_2]$ exists in the vapor phase, or if the solid dissociates into gaseous $La(hfa)_3$ and Phen which recombine in the cold part of the reactor, mass-spectrometry experiments were carried out, not only for the mixed ligand complex but also for the parent complex $La(hfa)_3$.

3.3. Mass-spectrometry study

La(hfa)$_3$. The mass spectrum of $La(hfa)_3$ shows that the major species correspond to mono- and di-lanthanum-containing ions with *m/z* of 553 ($[La(hfa)_2]^+$), 761 ($[La_2(hfa)_3\text{-}2CF_3]^+$), 918 ($[La_2(hfa)_3F]^+$) and 346 amu ($[La(hfa)]^+$). Therefore, the saturated vapor over anhydrous $La(hfa)_3$ consists mainly of monomeric and

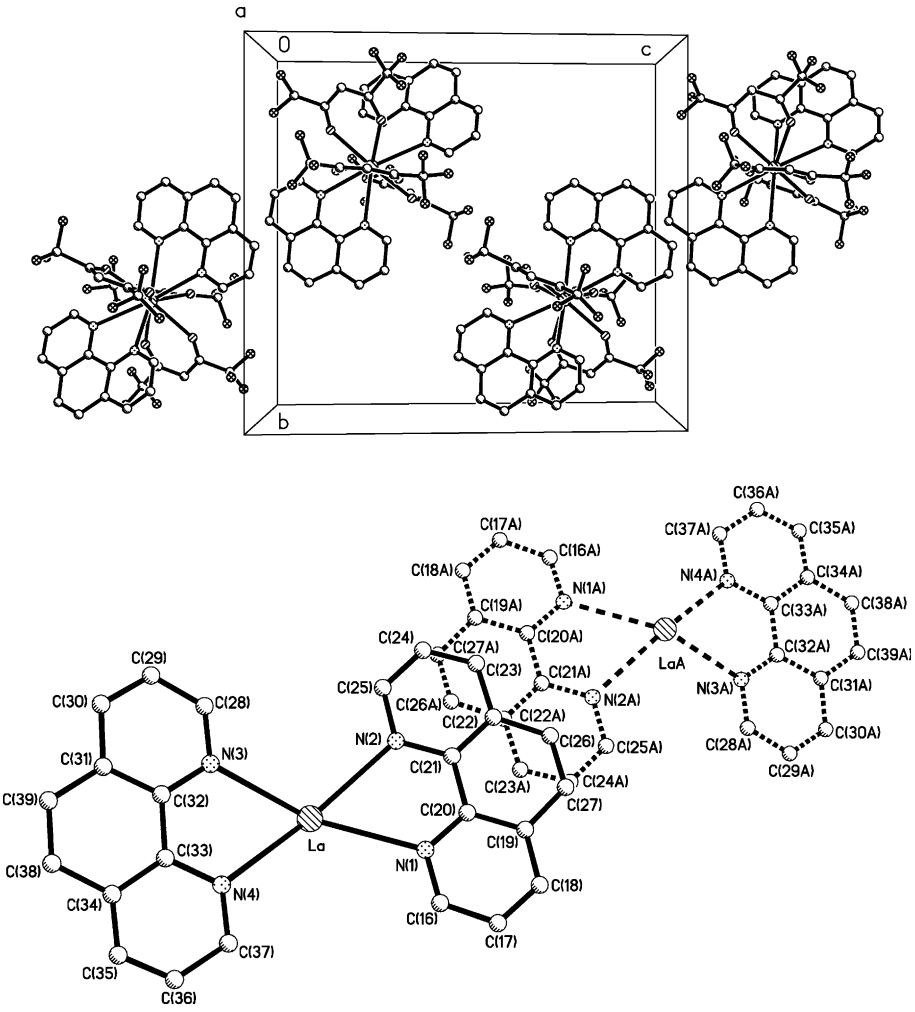

Fig. 3. The crystal packing of $[La(hfa)_3Phen_2]$ (along the *a* axes) and overlap scheme of centrosymmetrically related Phen entities.

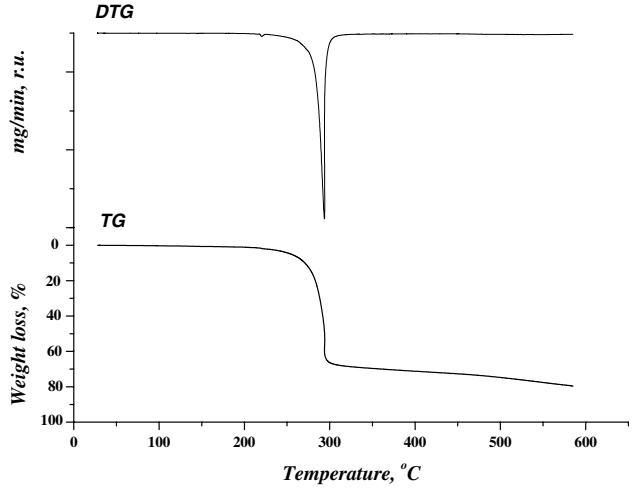

Fig. 4. TG and DTG curves for $[La(hfa)_3Phen_2]$.

dimeric molecules. The sublimation of $La(hfa)_3$ can be described by two parallel processes:

$$[La(hfa)_3]_{(s)} = [La(hfa)_3]_{(g)}$$

$$2[La(hfa)_3]_{(s)} = [La(hfa)_3]_{2(g)}$$

At 364 K, the respective saturated vapor pressures are 6.5×10^{-6} atm for $La(hfa)_3$, and 1.6×10^{-5} atm for $[La(hfa)_3]_2$. The enthalpies of sublimation of the monomeric and dimeric molecules were calculated in the temperature 339–393 K:

$$\Delta_s H^0([La(hfa)_3], k, T) = 102 \pm 7 \text{ kJ/mol}$$

$$\Delta_s H^0([La(hfa)_3]_2, k, T) = 117 \pm 8 \text{ kJ/mol}$$

Most probably, the complicated composition of the saturated vapor over $[La(hfa)_3]$ is the result of the oligomeric structure of this anhydrous complex. The crystal structure of anhydrous $[La(hfa)_3]$ is unknown (and for other anhydrous lanthanide hexafluoroacetylacetonates too), because these complexes, formed by vacuum sublimation, are glassy and only form crystalline products by coordination of additional ligands – H_2O or other neutral organic molecules. A similar vapor composition (monomeric and dimeric species) was found for $[Y(hfa)_3]$ [20], however, in the case of $[Y(hfa)_3]$ the vapor

phase consisted mainly of monomeric molecules $Y(hfa)_3$. The complex $[Y(hfa)_3]$ is more volatile than $[La(hfa)_3]$, which is in good agreement with the tendency to increase lanthanide β-diketonate volatility with a decrease of the ionic radii of these elements [21].

[La(hfa)$_3$(Phen)$_2$]. In contrast to $[La(hfa)_3]$, ions including two lanthanum atoms were not found in the mass spectra of **I**. Peaks assigned to the undissociated form of the mixed ligand complex do not appear (Table 3) even when the ionizing electron energy is lowered to 14 eV. The major species are $[La(hfa)]^+$, $[La(hfa)_2(Phen)]^+$, $[Phen]^+$, $[La(hfa)_2\text{-}F]^+$ (Table 3).

To determine a mechanism of $[La(hfa)_3(Phen)_2]$ sublimation and vapor phase composition, the curves of ionization efficiency for the main species were studied and experiments of full isothermal evaporation of samples were carried out. The analysis of the curves of ionization efficiency, obtained for the main species, show that the vapor phase over $[La(hfa)_3(Phen)_2]$ consisted of $[La(hfa)_3(Phen)]$ and Phen. From the results of full isothermal evaporation experiments it was found that the intensities of the main ion currents were constant during evaporation and the mixed ligand complex $[La(hfa)_3(Phen)_2]$ sublimed quantitatively (without formation of a nonvolatile residue in the Knudsen cell). On the basis of these data, there are grounds for believing that the mixed ligand complex $[La(hfa)_3(Phen)_2]$ sublimes congruently in the selected temperature range:

$$[La(hfa)_3(Phen)_2]_{(s)} = [La(hfa)_3(Phen)]_{(g)} + Phen_{(g)} \quad (1)$$

At 381 K in the vapor over $[La(hfa)_3(Phen)_2]$, the vapor pressure of $[La(hfa)_3(Phen)]$ is equal to 2.3×10^{-7}atm. The temperature dependencies of $[Phen]^+$, $[La(hfa)_2(Phen)]^+$, $[La(hfa)_3(Phen)\text{-}3F]^+$ and $[La(hfa)]^+$ ion current intensities were studied in the temperature range of 370–460 K, and the values of coefficient a in these linear dependencies ($I=aT+b$) were calculated (Table 4). For these four main ions the values of the coefficient a obtained are in close agreement, confirming that the vapor phase over **I** consists of two species – Phen and $[La(hfa)_3(Phen)]$ only and that this complex sublimed congruently according to Eq. 1. Using these data, the standard enthalpy of reaction 1 was calculated:

$$\Delta_r H^0(T) = 316.2 \pm 1.8 \text{ kJ/mol}.$$

So, the conversion of $[La(hfa)_3]$ into the mixed ligand complex $[La(hfa)_3(Phen)_2]$ leads to a decrease of volatility in spite of the mononuclear structure of the latter and the absence of strong intermolecular interactions in the structure of **I**. It can be explained taking into consideration the increase of the molecular mass during formation of the mixed ligand complex. The molecules $[La(hfa)_3(Phen)_2]$ do not exist in the vapor phase, although in the crystal structure both the Phen ligands are equal to each other (Table 2). The stability of $[La(hfa)_3(Phen)]$ in the vapor was expected as similar species were found in the mass spectrum of $[Ce(pta)_3(Phen)]$ [11]. However, for mixed ligand complexes $[Ln(dik)_3(Phen)]$, where Hdik represents the non-fluorinated β-diketones Hacac or Hthd, the molecular ions were not fixed in the vapor phase by mass-spectrometry [8]: under heating these complexes dissociate into $[Ln(dik)_3]$ and Phen. The difference in the sublimation schemes of these mixed ligand complexes depends on the Lewis acidity of the lanthanide β-diketonates, which is the strongest in the case of complexes with hfa ligands. The thermal behavior of $[La(hfa)_3(Phen)_2]$ can be compared to the data obtained for the barium complex, containing two Phen molecules too [19]. According to the mass-spectrometry data, $[Ba(hfa)_2(Phen)_2]$ sublimes incongruently in two stages – evolution of one Phen molecule followed by sublimation of $[Ba(hfa)_2(Phen)]$. The fact that the sublimation schemes are different for **I** and $[Ba(hfa)_2(Phen)_2]$, demonstrate the same influence of the Lewis acidity of metal β-diketonates on the stability of their mixed ligand complexes in respect to evolution of Phen under heating.

Abstract

The $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ complex, in which bpy = 2,2′-bipyridine, BPE = *trans*-1,2-*bis*(4-pyridyl)ethylene and py = pyridine, provides an interesting case of a heptanuclear mixed compound containing two triangular $[Ru_3O]$ clusters attached to a ruthenium polypyridine center. The composition and structural properties of this doubly bridged complex were investigated by means of electrospray mass (ESI-MS) and tandem mass (ESI-MS/MS) spectrometric experiments and NMR spectroscopy (^1H and ^{13}C). The characteristic multi-isotopic distribution, 1/4 *m*/*z* peak separation and dissociation chemistry of the isotopologue $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2]^{4+}$ cation provided detailed and unequivocal MS characterization of the complex. In the electronic spectra of the heptanuclear complex broad bands were observed at 427 and 696 nm, and ascribed, respectively, to $[Ru(bpy)_2(BPE)_2]$ metal-to-ligand charge-transfer and to $[Ru_3O]$ internal cluster transitions. The characteristic waves associated with the $[Ru_3O]^{1-/0/1+/2+/3+}$ redox couples were found at −1.02, 0.16, 1.20, 2.11 V (versus SHE) in the cyclic voltammograms. Another broad wave was observed at −1.22 V, involving superimposed $bpy^{0/-}$ and $BPE^{0/1-}$ redox processes, and a peculiar wave at 1.48 V, exhibiting only a half of the relative intensity, was assigned to the central $Ru^{3+/2+}$ redox pair. Despite the two conjugated BPE bridges, the electrochemical and spectroelectrochemical data indicated only a weak coupling through the π-system in the heptanuclear complex.

1. Introduction

Trinuclear complexes of the general formula $[M_3O(CH_3COO)_6(L)_3]^n$ (M = transition metal, L = solvent or *N*-heterocyclic ligands) feature a triangular structure in which the metal ions are held together by μ-oxo and carboxylate bridges [1–3]. In the particular case of triruthenium compounds, the electronic interaction among the ruthenium ions is usually so strong that the central core $[Ru_3O]^+$ is totally delocalized, behaving as a single metal center [1–4]. From an electrochemical viewpoint, it constitutes an appealing electroactive moiety, since the $[Ru_3O]$ unit displays up to five reversible redox processes in the −1.5 to 2.5 V (versus SHE) range and the choice of terminal and bridging ligand modulates its electrochemical behavior [5,6]. Moreover, each monoelectronic process is accompanied by drastic

chromatic changes [7,8] providing a suitable combination of electronic stimuli and spectroscopic response.

More recently, these trinuclear ruthenium complexes have been increasingly used in the assembly of supramolecular structures [9–11] and to study intramolecular electron transfer reactions in symmetric dimers [12]. The binding of these species to ruthenium polypyridines complexes, simulating $[Ru(bpy)_3]^{2+}$ [13–16], would provide interesting prototypes to study photoinduced energy or electron transfer reactions.

The *trans*-1,2-*bis*(4-pyridyl)ethylene bridge (BPE) is also of interest as such a species belongs to a class of organic ligands bearing C=C double bonds capable of undergoing reversible *trans* → *cis* photoisomerization [17–19]. This type of functionality is being currently exploited for storage and processing information at the molecular level. The isomerization driven by light can actually lead to selective changes in the molecular conformation, modifying the spectroscopic behavior of the system in a controllable fashion [20,21] and promoting, in some cases, molecular motion [22].

This work deals with the chemistry of the BPE doubly bridged heptanuclear complex $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ (Fig. 1). We report herein a unique assembly of polymetallic species that combines the rich redox characteristics of the cluster species and the remarkable chemical and photophysical properties of ruthenium(II) polypyridine complexes. Special emphasis is given to its structural characterization by means of NMR spectroscopy (^1H and ^{13}C), and electrospray mass (ESI-MS) and tandem mass (ESI-MS/MS) spectrometric experiments. The MS experiments, in particular, confirms the characteristic multi-isotopic distribution and dissociation chemistry expected for a $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2]^{4+}$ quadruply charged gaseous cation providing detailed and unequivocal MS characterization of this heptanuclear doubly bridged ruthenium complex.

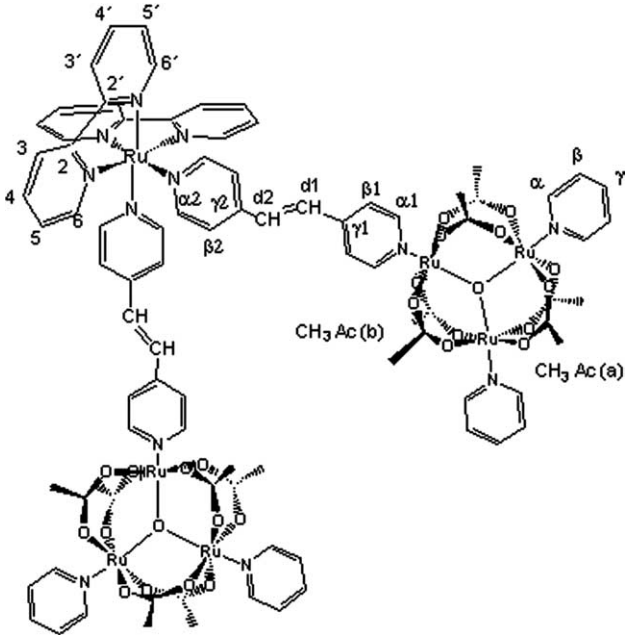

Fig. 1. Structural representation of the heptanuclear complex $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2]^{4+}$ in which the numbering scheme for the assignment of the corresponding NMR spectra is also indicated.

2. Experimental

2.1. Synthesis

The $[Ru(bpy)(BPE)_2](PF_6)_2$ and $[Ru_3O(CH_3COO)_6(py)_2(CH_3OH)]PF_6$ complexes were synthesized according to reported procedures [10,23].

2.1.1. $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$

$[Ru(bpy)_2(BPE)_2](PF_6)_2 \cdot 2H_2O$ (60 mg, 0.056 mmol) was dissolved in CH_2Cl_2 (20 ml) and allowed to react with $[Ru_3O(CH_3COO)_6(py)_2(CH_3OH)]PF_6$ (113 mg, 0.112 mmol) for 72 h, at room temperature, in the dark. The solution was filtered and the liquid was treated with diethyl ether, giving a greenish brown solid. This material was collected on a filter, dissolved in CH_2Cl_2 and purified by chromatography using a neutral alumina column. The product was eluted with a mixture of 50% CH_3CN:CH_2Cl_2 (v/v) and the corresponding solution was evaporated to dryness. After dissolving in a minimum volume of CH_2Cl_2, the solution was filtered onto stirring diethyl ether, giving a dark solid, which was collected on a filter and washed with diethyl ether (50 mg, 30%). Required for $C_{88}H_{92}N_{12}O_{26}Ru_7P_4F_{24} \cdot 3(C_4H_{10}O)$: C, 37.0; H, 3.8; N, 5.2. Found: C, 37.4; H, 4.1; N, 5.6%.

2.2. Physical measurements

Electrospray ionization mass and tandem mass spectra were recorded on a Q-Tof (Micromass) mass spectrometer with quadrupole (Qq) and high resolution orthogonal time of flight (o-TOF) hybrid configuration operated under conditions described in detail elsewhere [24]. The sample introduction was performed using a syringe pump (Harvard Apparatus, Pump 11) set to 10 μl/min pumped through an uncoated fused-silica capillary. All samples were dissolved in pure methanol. The ESI mass spectrum was acquired using an ESI capillary voltage of 3 kV and a cone voltage of 10 V. For the ESI tandem mass spectrum, the mass-selected ions were dissociated using 20 eV collisions with argon.

One dimensional ^1H NMR spectra and two dimensional COSY and HETCOR spectra were recorded on a Varian 300 MHz, model INOVA 1 spectrometer, employing 2×10^{-2} mol l CD_3CN solutions, at room

temperature. UV–Vis spectra were recorded on a Hewlett-Packard model 8453 diode array spectrophotometer, using 10^{-5} mol l solutions.

Cyclic voltammetry was carried out with a Princeton Applied Research model 283 potentiostat. A platinum disk electrode was employed for the measurements, using the conventional Luggin capillary arrangement with an $Ag/AgNO_3$ (0.010 mol l) reference electrode in CH_3CN containing 0.100 mol l tetraethylammonium perchlorate (TEAP). A platinum wire was used as the auxiliary electrode. All the $E_{1/2}$ values presented here were converted to SHE by adding 0.503 V to the observed values. A three electrode system was used for the spectroelectrochemical measurements, arranged in a rectangular quartz cell of 0.025 cm internal optical path length. A gold minigrid was used as transprecursor working electrode, in the presence of the above mentioned auxiliary and reference electrodes.

Steady-state emission spectra were recorded on a LS-100 Photon Technology International Inc. spectrophotometer, at room temperature and 77 K. Photoisomerization measurements were carried out with a 150 W Xenon Arc Lamp and a f/3.4 Monochromator (Applied Photophysics), by irradiating 10% CH_3CN:H_2O samples of the BPE ligand at 313 nm and of the heptanuclear species at 297 nm.

3. Results and discussion

3.1. ^1H and ^{13}C NMR spectra

The ^1H and ^{13}C NMR spectra of the $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ complex are complicated by the large number of signals. Preliminary analysis indicated five non-magnetically equivalent types of aromatic rings: the pyridine rings, two peripheral bpy rings (labelled as **2**, **3**, **4**, **5**, **6** and **2′**, **3′**, **4′**, **5′**, **6′**) and two different rings corresponding to the bridging ligand, one bound to the $[Ru_3O]$ core and the other bound to the $[Ru(bpy)_2]$ center. The assignment was made based on careful evaluation of the 2D correlation NMR spectra, guided by a comparison with data for the complex $[Ru_3O(CH_3COO)_6(py)_2(BPE)]PF_6$ and with the literature data [25,26].

As one can see in Table 1, the δ values of the $[Ru(bpy)_2]$ protons follow the same trends observed for the $[Ru(bpy)_3]^{2+}$ complex [25,27]; the same behavior is observed for the ^{13}C signals in comparison with the free bpy ligand. Owing to coordination to the ruthenium ion, free rotation of the bpy rings is not possible; hence protons **3** and **3′** are sterically strained in such a way that the Van der Waals interaction between them causes a deshielding effect, shifting their signals to lower field in relation to other protons of that ligand. As expected, protons **4**, **5** and **5′** appear as triplets with values of δ varying between 7.2 and 8.1 ppm due to the non-equivalence of the bpy rings. Protons **4′** are superimposed with protons **6′**.

[a] Data from Ref. [30].
[b] H signals d_2 and β_2 are superimposed.

Protons **6′** are subjected to the so called *ring current* effects. These protons are located in the shielding region of the pyridinic aromatic rings and, therefore, have their signals shifted to higher field in relation to the free ligand. However, protons **6** appear downfield shifted; this shift could be addressed assuming that the BPE rings are not co-planar to each other, being otherwise inclined in such a way that subjects protons **6** to the deshielding region.

For the $[Ru_3O(CH_3COO)_6(py)_2]$ moiety, the δ values (Table 1) follow the pattern dictated by the paramagnetic anisotropy of the $[Ru_3O]$ core [1].

In the heptanuclear complex, two signals assigned to the acetate protons are observed (consistent with the presence of two magnetically non-equivalent acetate sites; i.e., four *vicinal* and two in opposite positions with respect to the bridging ligand). For the BPE bridging ligand, a splitting in the proton (and carbon) signals (Table 1) is observed, attributed to the double bond, which constitute a singlet in the free ligand. This split-

ting reflects a decrease in the symmetry of the ligand owing to the bridging coordination mode between two different metallic units. Note that the J coupling constant of the d_1 proton is equal to 16.5 Hz, a value that is typical for the *trans*-isomer [28]. This signal is shifted to higher field, showing that it is sensitive to the paramagnetic anisotropy of the [Ru_3O] unit. This effect is also expressed in the δ values observed for the α_1 and β_1 protons attached to the BPE ring directly bound to the paramagnetic center and for the pyridinic rings, whose corresponding protons appear shifted to higher fields in relation to free pyridine. The magnitude of this effect diminishes with the distance from the [Ru_3O] core and this pattern can be explained considering both dipolar and contact mechanisms for the paramagnetic interactions in the molecule [29]. These interactions are also responsible for the fact that the signals for the acetate methyl protons are shifted in the opposite direction as those of pyridine, whereas inverse trends for protons and carbon shifts are observed for the acetate signals.

3.2. Mass spectrometric structural characterization

ESI-MS and ESI-MS/MS experiments are being increasingly used in the structural characterization of organometallic and metallorganic species, as well as of loosely bonded cationic and ionic coordination species participating as key reaction intermediates [31,32]. In our case, ESI provided an efficient technique for "fishing" directly from solution to the gas phase, both ionic components of the supramolecular complex [Ru(bpy)$_2$(BPE)$_2${Ru$_3$O(CH$_3$COO)$_6$(py)$_2$}$_2$](PF$_6$)$_4$, i.e., either the quadruply charged cationic species [Ru(bpy)$_2$(BPE)$_2${Ru$_3$O(CH$_3$COO)$_6$(py)$_2$}$_2$]$^{4+}$ or the singly charged anionic species PF_6^-, allowing their corresponding mass detection, and isotopic and structural characterization.

The ESI mass spectrum in the positive ion mode of a methanolic solution of the complex detected a prominent cluster of isotopologue cations (*m*/*z* 610 for the most abundant) separated by 1/4 *m*/*z* units, which matched perfectly the features expected for Ru(bpy)$_2$(BPE)$_2${Ru$_3$O(CH$_3$COO)$_6$(py)$_2$}$_2$]$^{4+}$. The characteristic, multi-component isotopic pattern resulting from the presence of seven multi-isotope ruthenium atoms also matched perfectly that calculated for this cation. The ESI mass spectrum in the negative ion mode detected a prominent single and monoisotopic anion of *m*/*z* 145 (144.96) corresponding to PF_6^-.

For structural characterization, the entire cluster of the many quadruply charged isotopologue ions [Ru(bpy)$_2$(BPE)$_2${Ru$_3$O(CH$_3$COO)$_6$(py)$_2$}$_2$]$^{4+}$ (*m*/*z* 610) were mass-selected and subjected to 15 eV collision-induced dissociation (Fig. 2). Dissociation was observed to occur mainly by successive breaking of the BPE–ruthenium bonds, showing this bond to be the weakest for the complex. As summarized in Fig. 3, the quadruply

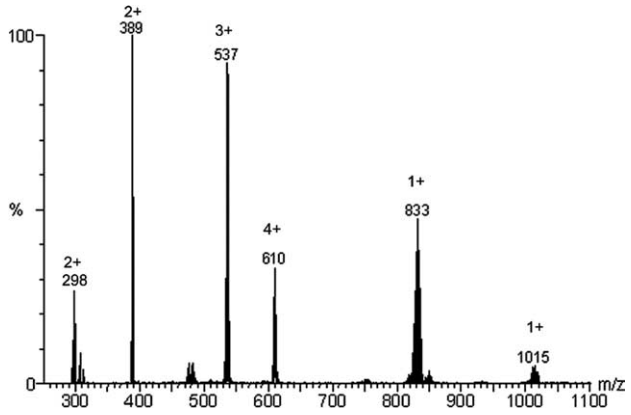

Fig. 2. ESI tandem mass spectrum for 15 eV collision-induced dissociation of [Ru(bpy)$_2$(BPE)$_2${Ru$_3$O(CH$_3$COO)$_6$(py)$_2$}$_2$]$^{4+}$ ions (*m*/*z* 610). The charge states for the ions are indicated.

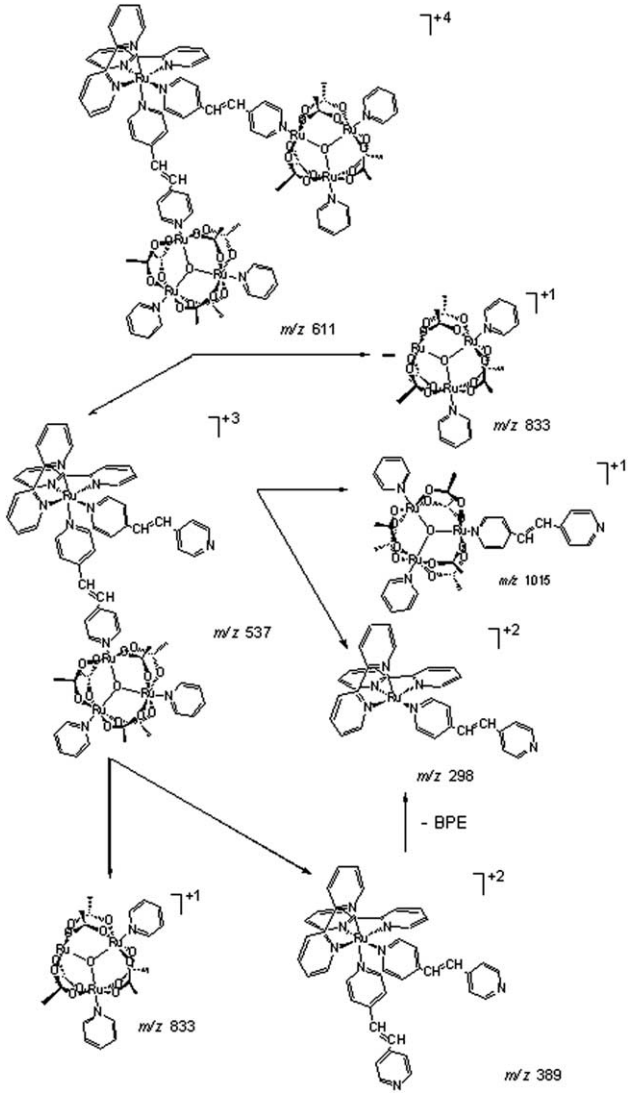

Fig. 3. Dissociation routes for the 15 eV collision-induced dissociation of gaseous [Ru(bpy)$_2$(BPE)$_2${Ru$_3$O(CH$_3$COO)$_6$(py)$_2$}$_2$]$^{4+}$ ions.

charged Ru_7-precursor ions (*m*/*z* 610) dissociate by charge partitioning, with BPE–Ru bond breaking, to form both a triply charged cluster of Ru_4-isotopologue fragment ions (*m*/*z* 537) separated by 1/3 *m*/*z* units and a singly charged cluster of Ru_3-isotopologue ions (*m*/*z* 833) separated by one *m*/*z* unit. The triply charged Ru_4-isotopologue ions (*m*/*z* 537) dissociate in turn via two competitive pathways that give either (i) a doubly charged cluster of Ru_1-isotopologue fragment ions (*m*/*z* 389) separated by 1/2 *m*/*z* units and a singly charged cluster of Ru_3-isotopologue fragment ions (*m*/*z* 833) or (ii) a singly charged cluster of Ru_3-isotopologue fragment ions (*m*/*z* 1015) and doubly charged cluster of Ru_1-isotopologue fragment ions (*m*/*z* 298) separated by 1/2 *m*/*z* units. These ions can also be formed from the doubly charged Ru_1-isotopologue fragment ions (*m*/*z* 389) via the loss of a neutral molecule of BPE. Note in Fig. 3, the characteristic isotopic distribution of both the Ru_7-precursor ion and of all of its Ru_n-fragment ions as well as the charge-diagnostic *m*/*z* separation within each cluster, matching perfectly those expected for the proposed structures.

3.3. Absorption spectra

In Fig. 4 one can see the absorption spectra of the $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ complex. The spectra can be readily interpreted by comparing with the reported data for the model compounds $[Ru(bpy)_2(BPE)_2](PF_6)_2$ and $[Ru_3O(CH_3COO)_6(py)_2(BPE)]PF_6$ [33–35]. The intense bands in the ultra-violet region, i.e., 291 nm ($\varepsilon = 11.7 \times 10^4\ mol^{-1}\ l\ cm^{-1}$) can be assigned to the pyridinic ligand $\pi \rightarrow \pi^*$ transitions; in the visible region one can observe the MLCT bands of the $[Ru(bpy)_2]$ unit at 427 nm ($3.89 \times 10^4\ mol^{-1}\ l\ cm^{-1}$), as confirmed by spectroelectrochemical measurements. Finally, the near infra-red broad band at 696 nm ($1.29 \times 10^4\ mol^{-1}\ l\ cm^{-1}$) is consistent with the typical IC (intra-cluster) transitions, which occurs within an energy level manifold, generated by the combination of the ruthenium and central oxygen orbitals in the $[Ru_3O(CH_3COO)_6]$ fragment [35].

It is worth noting that the bridging coordination of the $[Ru_3O]$ cores does not affect significantly the energy of the MLCT bands, in comparison to the mononuclear precursors $[Ru(bpy)_2(BPE)_2]^{2+}$ ($\lambda_{max} = 430$ nm); the same is valid for the IC transition, in comparison with the $[Ru_3O(CH_3COO)_6(py)_2(BPE)]PF_6$ complex ($\lambda_{max} = 693$ nm) [33–35].

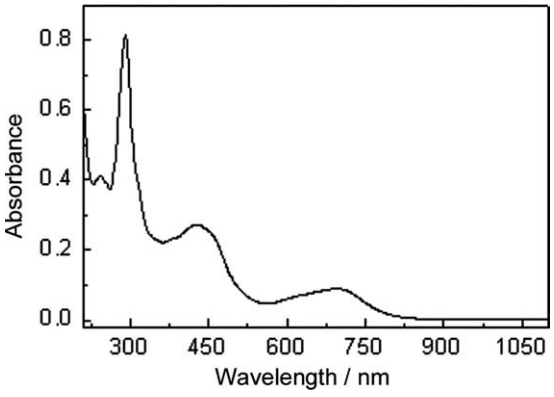

Fig. 4. Absorption spectrum of the $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ complex, in acetonitrile solution.

3.4. Electrochemical measurements

The profile of the voltammograms shown in Fig. 5 consists of four reversible, two electron waves at −1.02, 0.16, 1.20, 2.11 V (versus SHE), ascribed to the $[Ru_3O]^{1-/0/1+/2+/3+}$ redox processes, one mono-electronic wave at 1.48 V, ascribed to the $Ru^{2+/3+}$ pair and finally a wave corresponding to the reduction of the pyridinic ligands. The peak current relation observed for the $[Ru_3O]^{1+/2+}$ and $Ru^{2+/3+}$ pairs have an approximated value of 2:1, being consistent with the proposed coordination of one $[Ru(bpy)_2]$ moiety to two $[Ru_3O]$ cores. The occurrence of only one wave associated with the redox processes in the two $[Ru_3O]$ units demonstrates that electronic coupling between them is not enough to promote detectable splittings in the cyclic voltammograms.

In Fig. 6 one can see the results of the spectroelectrochemical measurements. The observed behavior is consistent with that of monomeric trinuclear complexes [1], as well as with that of analogous polynuclear systems [36,37]. The first reduction process (Fig. 6(a)) implies in a destabilization of the $[Ru_3O]$ energy levels, owing to the increase of electron population, causing bathochromic shifts of both IC (696–915 nm) and

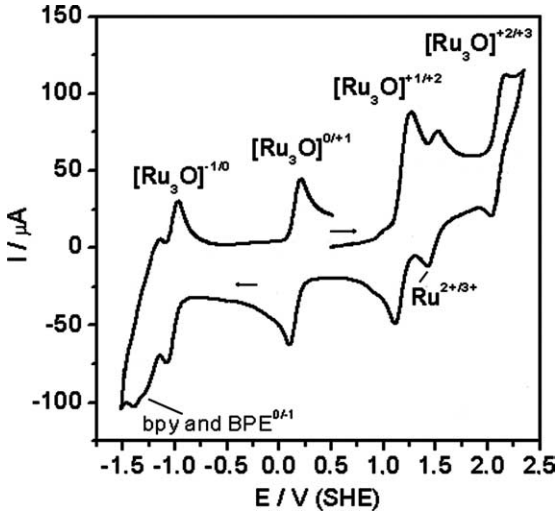

Fig. 5. Cyclic voltammogram of the $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ complex in 3×10^{-3} mol l acetonitrile solutions, 0.1 mol l TEAP, room temperature, scan rate = 200 mV s^{-1}.

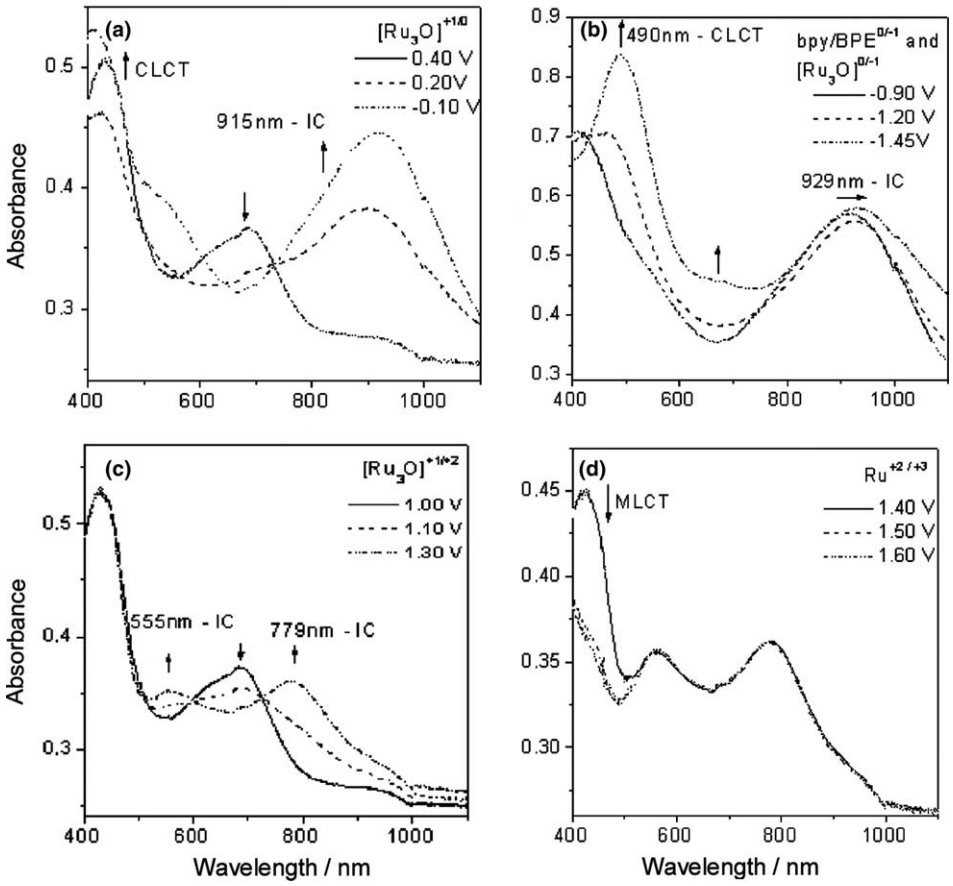

Fig. 6. Spectroelectrochemical behavior of $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ in 3×10^{-3} mol l acetonitrile solutions, 0.1 mol l TEAP, as a function of the applied potentials.

CLCT bands (intensification of the shoulder observed between 400 and 500 nm). In the second reduction process (Fig. 6(b)), besides an additional destabilization of the $[Ru_3O]$ levels due to the addition of a second electron to each unit, an increase in intensity around 680 nm is observed, ascribed to a CLCT transition to the BPE bridge; this behavior is in agreement with that observed earlier for trinuclear complexes bridged by π-conjugated ligands [10,36,38].

The oxidation of the $[Ru_3O]$ center (Fig. 6(c)) is accompanied by the splitting of the IC band at 696 nm into two components at 555 and 779 nm. Finally, the oxidation of the $[Ru(bpy)_2]$ moiety, centered in the metal, leads to the decay of the MLCT band (Fig. 6(d)), once the electron involved in this transition is removed.

Under the experimental conditions of the spectroelectrochemical measurements, it was not possible to reach the positive potential corresponding to the last oxidation wave observed in the cyclic voltammetry.

3.5. Photophysical assays

Many attempts to detect luminescence emission for the complex were made in this work. In general, degassed solutions of the compound, in acetonitrile, ethanol (room temperature), and in ethanol glasses (77 K), were excited at the MLCT wavelength, but in no case the typical MLCT[3] luminescence of the $[Ru(bpy)_n]$ chromophore [13] could be detected. Also, the expected photoisomerization of the coordinated BPE ligand was not observed, in contrast to the free BPE ligand, which exhibited a *cis–trans* isomerization quantum yield of $\phi = 0.24$ in 10% acetonitrile:water solution, in agreement with the literature data [39].

For a series of $[Ru(bpy)_2(Cl)B]^{2+}$ compounds, in which B = pyrazine, 4-4′-bipyridine, 1,2-*bis*(4-pyridyl)ethane or *trans*-1,2-*bis*(4-pyridyl)ethylene (BPE), it has been observed that the emission quantum yield (ϕ_{em}) is extremely low, owing to d–d states [40]. Nevertheless, for the compound containing the bridging BPE ligand, the value of ϕ_{em} is even lower, indicating an additional pathway for energy loss, such as an energy transfer from the ^{3}MLCT to the BPE triplet state involved in photoisomerization. For the $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ complex, this particular BPE excited state can undergo further energy (or electron) transfer to the $[Ru_3O]$ low lying IC states, which would finally decay by a non-radiative mechanism, thus, explaining the quenching of the *trans* → *cis*

photoisomerization. Actually, it has been shown that both energy and electron transfer can provide possible quenching pathways of ^{3}MCLT states (and probably of the bridge low lying triplet state), depending on the oxidation state of the $[Ru_3O]$ core [37].

4. Final remarks

A novel heptanuclear doubly bridged complex $[Ru(bpy)_2(BPE)_2\{Ru_3O(CH_3COO)_6(py)_2\}_2](PF_6)_4$ has been described. Detailed structural characterization of this supramolecular complex by ESI-MS(/MS) and NMR spectroscopy is fully consistent with the binding of two $[Ru_3O]$ units to the $[Ru(bpy)_2]$ center. The observed absorption profile, as well as its electrochemical behavior, are in agreement with a doubly bridged structure involving weakly interacting metallic units. Such weak electronic interaction, however, is strong enough to quench its photophysical properties, so that the emission from the $[Ru(bpy)_2]$ center has not been observed, either at room temperature or at 77 K, also preventing the characteristic *trans* → *cis* photoisomerization of the BPE bridging ligand.

Abstract

Pyridine and imidazole are connected by an azo group (—N=N—) to synthesize 2-[(3′-pyridyl)azo]imidazole (3′-PyaiH) and this has been confirmed by X-ray structure determination. The N(1)-alkylation gives 1-alkyl-2-[(3′-pyridyl)azo]imidazole (3′-PyaiR′) (R′ = Me (**2a**), Et (**2b**), Bz (**2c**)). The reaction between $Mn(ClO_4)_2 \cdot 6H_2O$ and 3′-PyaiR′ in methanol has synthesized $[Mn(3'\text{-PyaiR}')_4](ClO_4)_2$ (**3**). The structure has been confirmed by single crystal X-ray diffraction study in one case, in addition to other spectral characterization. The structure reveals a tetrahedral orientation of four ligands coordinating through imidazole-N only. Cyclic voltammetry exhibits a Mn(III)/Mn(II) couple at >1.1 V along with azo reductions. However, the reaction of $MnCl_2 \cdot 4H_2O$ + 3′-PyaiR′ in the presence of NaN_3 or NH_4CNS (1:2:2 mole proportion) has synthesized $Mn(3'\text{-PyaiR}')_2(X)_2$ (X = N_3 (**4**), NCS (**5**)).

Keywords: Pyridyl-azo-imidazoles; Manganese(II) tetrahedral; X-ray; Electrochemistry

1. Introduction

For the last decade we have been engaged in the design of several types of heterocyclic azo compounds and studies on their complexes [1–3]. This type of molecule has several advantages. To quote a few, the azo group is photochromic, redox responsive, pH-sensitive; stabilizes low valent metal oxidation states due to the presence of a low-lying azo-centred π*-molecular orbital, serves as a molecular switch, is used as a metal ion indicator in complexometric titration, dyes and pigments in textile industry [4–8]. Bi-heterocyclic azo ligands are of current interest [5,7,9] because of their photoswitching property, non-linear optical property, etc. The majority of biheterocyclic azo compounds are symmetric systems in which two identical heterocyclic units are linked by the —N=N— group. Unsymmetric biheterocyclic azo compounds are scarce. A report of thiazole —N=N— imidazole has been appeared in the literature [10]. We have reported a second example of unsymmetric bi-hetetero-cyclic azo compounds, pyridyl-azo-imidazoles (**1**) and their Cd(II) and Ag(I) complexes [11]. The ligands belong to a special case of multimodal systems [12].

In this work, we report on the manganese(II) complexes of 1-alkyl-2-[(3′-pyridyl)azo]imidazoles (3′-PyaiR′, **2**) and their derivatives. Manganese is chosen

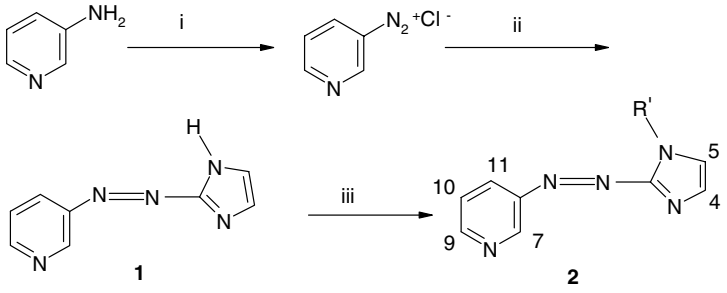
because of its essential structural and catalytic role in many proteins [13]. The active site involves the binding of imidazoles-N from histidine residues to Mn(II). Besides, the high local spin value of Mn(II) (d^5) enable this metal ion in the exploration of magnetic materials [14,15]. The pseudohalides, especially azide (N_3^-) and thiocyanate (SCN^-) are versatile bridging ligands [14–16] in the synthesis of transition metal complexes for improving the magnetic exchange phenomenon. This work also characterizes manganese(II)-azido/thiocyanato complexes of the pyridyl-azo-imidazole system. The X-ray structures of the free ligand, 2-(3′-pyridylazo)imidazole and tetrakis-{1-ethyl-2-(3′-pyridylazo)imidazole} manganese(II) perchlorate (**3**) are also reported herein. However, reaction of $MnCl_2$, 3′-PyaiR′ and NaN_3/NH_4CNS give $Mn(3'\text{-PyaiR}')_2(X)_2$ (X = N_3(**4**), NCS (**5**)) which have been characterized by spectroscopic techniques.

2. Experimental

2.1. Materials

Published methods [11] were used to prepare 1-alkyl-2-(3′-pyridylazo)imidazoles (3′-PyaiR′ where R′ = Me (**2a**), Et (**2b**), Bz (**2c**)) (Scheme 1). $Mn(ClO_4)_2.6H_2O$ was prepared by adding $MnCO_3$ to a warm $HClO_4$ solution (1:1, v/v) and then recrystallizing from water in the presence of a few drops of $HClO_4$. All other chemicals and organic solvents used for the preparation work were of reagent grade, received from SRL, India. Purification of MeCN and preparation of [*n*-Bu_4N][ClO_4] were done following the literature method [3].



2.2. Physical measurements

Microanalyses (C, H, N) were performed using a Perkin–Elmer 2400 CHNO/S elemental analyzer. Spectroscopic measurements were carried out using the following instruments: UV–Vis spectra, reflectance spectra, JASCO UV–Vis/NIR model V-570; IR spectra (KBr disk, 4000–200 cm^{-1}), JASCO FT-IR model 420. Molar conductances were measured by a Systronics conductivity meter, solute concentration ($\sim10^{-3}$ M) in MeCN. Estimation of manganese was carried out by microwave digestion followed by potassium periodate oxidation to pink permanganate, which was determined by a spectrophotometric process [17]. Electrochemistry was carried out with a PAR electrochemistry system 250 potentiostat/versastat and 270 software package. In the cyclic voltametry the following conditions were used: solvent, dry MeCN; supporting electrolyte, [*n*Bu_4N][ClO_4] ($\sim$0.1 M); solute concentration ($\sim10^{-3}$ M); working electrode, Pt-disk mili electrode; reference electrode, SCE; auxiliary electrode, Pt-wire; scan rate, 50 mV s^{-1}; formal potential, $E^0 = 0.5(Ep_a + Ep_c)$, where Ep_a and Ep_c are anodic and cathodic peak potentials, respectively; ΔEp ($|Ep_a - Ep_c|$) is the peak-to-peak separation. All experiments were done under a dry N_2 atmosphere at 295(2) K. EPR spectra were measured in MeCN solution at room temperature (298 K) and liquid nitrogen temperature (77 K) using a Bruker ESR spectrometer model EMX 10/12, X-band ER 4119 HS cylindrical resonator.

2.2.1. Preparation of tetrakis 1-methyl-2-[(3′-pyridyl)azo]imidazole manganese(II) percholate, $[Mn(3'\text{-PyaiMe})_4](ClO_4)_2$ (**3a**)

A methanolic solution (15 ml) of 1-methyl-2-[(3′-pyridyl)azo]imidazole (3′-PyaiMe, 0.3 g, 1.60 mmol) was added dropwise to $Mn(ClO_4)_2 \cdot 6H_2O$ (0.2 g, 0.56 mmol) in the same solvent (20 ml) at room temperature (298 K). The mixture was stirred for 15 min and a small portion of yellow mass was filtered and rejected. The filtrate was kept undisturbed for a few days. A bright orange-red crystalline compound was filtered and washed with cold water and methanol. Finally it was dried in vacuo. The isolated yield was 0.25 g (61%).

All other complexes were prepared by the same procedure and yields varied from 60% to 70%. Microanalytical data of the complexes are as follows: $[Mn(3'\text{-PyaiMe})_4](ClO_4)_2$ (**3a**): *Anal.* Calc. for $C_{36}H_{36}N_{20}O_8Cl_2Mn$: C, 43.11; H, 3.59; N, 27.94; Mn, 5.49. Found: C, 43.25; H, 3.65; N, 27.80; Mn, 5.65%. IR (KBr disk)

2.2.2. Preparation of bis-{1-methyl-2-[(3′-pyridyl)azo] imidazole}-bis-azido-manganese(II), $Mn(3'\text{-PyaiMe})_2(N_3)_2$ (**4a**)

To an aqueous solution (10 ml) of $MnCl_2 \cdot 4H_2O$ (0.2 g, 0.77 mmol), NaN_3 (0.1 g, 1.54 mmol) was added and stirred for 15 min. 3′-PyaiMe (0.29 g, 1.55 mmol) in MeOH (15 ml) was added in dropwise and stirred for another 15 min. A brown precipitate appeared, which was then filtered. The filtrate was kept undisturbed and allowed to evaporate slowly for a week. A brown crystalline product was isolated by filtration, washed with water and cold methanol. It was then dried over a $CaCl_2$ dessicator. Yield: 0.186 g (47%). $[Mn(3'\text{-PyaiEt})_2(N_3)_2]$ (**4b**) was prepared by the same procedure. Microanalytical data are as follows: $[Mn(3'\text{-PyaiMe})_2(N_3)_2]$ (**4a**): *Anal.* Calc. for $C_{18}H_{18}N_{16}Mn$: C, 42.11; H, 3.51; N, 43.66; Mn, 10.72. UV–Vis spectral data (in MeOH) (λ_{max}/nm) ($10^{-3}\,\varepsilon\,M^{-1}\,cm^{-1}$): 448 (7.53), 374 (21.54). Magnetic data: μ, 5.0 BM. EPR data (77 K) $g = 2.01$, $A = 128$ G. $[Mn(3'\text{-PyaiEt})_2(N_3)_2]$ (**4b**): *Anal*. Calc. for $C_{20}H_{22}N_{16}Mn$: C, 44.36; H, 4.07; N, 41.40; Mn, 10.17. Found: C, 44.27; H, 4.00; N, 41.48; Mn, 10.30%. IR (KBr disk) (cm^{-1}); $\nu(N_3)$, 2077 (s); ν(C=N), 1622 (m); ν(N=N), 1405 (m). UV–Vis spectral data (in MeOH) (λ_{max}/nm) ($10^{-3}\,\varepsilon\,M^{-1}\,cm^{-1}$): 450 (8.13), 376 (19.15). Magnetic data: μ, 5.2 BM. EPR data (77 K) $g = 2.03$, $A = 130$ G.

2.2.3. Preparation of bis-{1-methyl-2-[(3′-pyridyl)azo] imidazole}-bis-(thiocyanato)-manganese(II), $Mn(3'\text{-PyaiMe})_2(NCS)_2$ (**5a**)

To an aqueous solution (10 ml) of $MnCl_2.4H_2O$ (0.2 g, 0.77 mmol), NH_4NCS (0.12 g, 1.58 mmol) was added and stirred for 15 min. 3′-PyaiMe (0.31 g, 1.54 mmol) in MeOH (15 ml) was added in dropwise and stirred for another 15 min. A brown red precipitate was separated and then filtered. The filtrate was evaporated slowly in air and crystals were separated, washed with water and cold methanol. These were then dried over $CaCl_2$. Yield: 0.2 g (48%). $Mn(3'\text{-PyaiEt})_2(NCS)_2$ (**5b**) was prepared by the same procedure. Microanalytical data are as follows: $Mn(3'\text{-PyaiMe})_2(NCS)_2$, (**5a**). *Anal.* Calc. for $C_{20}H_{18}N_{12}S_2Mn$: C, 44.04; H, 3.30; N, 30.83; Mn, 10.09. Found: C, 44.16; H, 3.22; N, 30.92; Mn, 9.75%. IR (KBr disk) (cm^{-1}); ν(NCS), 2095 (s); ν(C=N), 1600 (m); ν(N=N), 1400 (m); ν(C=S), 770 (m). UV–Vis spectral data (in MeOH) (λ_{max}/nm) ($10^{-3}\,\varepsilon\,M^{-1}\,cm^{-1}$): 448 (3.26), 372 (12.79). Magnetic data: μ, 5.2 BM. EPR data (77 K) $g = 2.00$, $A = 110$ G. $Mn(3'\text{-PyaiEt})_2(NCS)_2$ (**5b**): *Anal*. Calc. for, $C_{22}H_{22}N_{12}S_2Mn$: C, 46.07; H, 3.84; N, 29.32; Mn, 9.60. Found: C, 46.00; H, 3.90; N, 28.94; Mn, 9.48%. IR (KBr disk) (cm^{-1}); ν(NCS), 2098 (s); ν(C=N), 1597 (m); ν(N=N), 1402 (m); ν(C=S), 773 (m). UV–Vis spectral data (in MeOH) (λ_{max}/nm) ($10^{-3}\,\varepsilon\,M^{-1}\,cm^{-1}$): 450 (5.42), 374 (16.18). Magnetic data: μ, 5.1 BM. EPR data (77 K) $g = 2.01$, $A = 118$ G.

2.3. X-ray crystal structure analysis of 3′-PyaiH (**1**) and $[Mn(3'\text{-PyaiEt})_4](ClO_4)_2$ (**3b**)

Suitable X-ray quality crystals of the compounds were obtained by slow evaporation of ethanolic solutions of the compounds. Data were collected with a Siemens SMART CCD diffractometer using graphite-monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å). The data are set out in Table 1. Unit cell parameters were determined from least-squares refinement of setting angles with 2θ in the range $4.16° \leqslant 2\theta \leqslant 56.48°$ for **1** and $2.1° \leqslant 2\theta \leqslant 56.74°$ for **3b**. The total data collected are 1952 and 26073 out of which unique data are 1090 and 4262 for **1** and **3b**, respectively. The hkl range are $-13 \leqslant h \leqslant 6$, $-12 \leqslant k \leqslant 11$, $-10 \leqslant l \leqslant 11$ for **1** and $-25 \leqslant h \leqslant 26$, $-16 \leqslant k \leqslant 16$, $-26 \leqslant l \leqslant 25$ for **3b**. Reflection data were recorded using the ω scan technique. Data were corrected for Lorentz polarization effects and for linear decay. Semi-empirical absorption corrections based on ψ-scans were applied. The structures were solved by heavy atom methods using SHELXS-97 and successive difference Fourier syntheses. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were fixed geometrically and refined using the riding model. In the final difference Fourier map the residual minima and maxima were [−0.259, 0.182 (e/Å^3) for **1** and −0.318, 0.297 (e/Å^3) for **3b**] carried out using SHELXL-97.

[b] $R_1 = \sum||F_o|-|F_c||/\sum|F_o|$.
[c] $wR_2=[\sum w(F_o^2-F_c^2)^2/\sum w(F_o^2)^2]^{1/2}$, $w=1/[\sigma^2(F_o^2)+(0.0445P)^2+0.0000P]$ for 3′-PyaiH (**1**), and $w=1/[\sigma^2(F_o^2)+(0.0100P)^2+0.0000P]$ for **3b**, where $P=(F_o^2+2F_c^2)/3$.
[d] Goodness-of-fit is defined as $[\sum w(F_o^2-F_c^2)^2/(n_o-n_v)]^{1/2}$, where n_o and n_v denote the number of data and variables.

3. Results and discussion

3.1. Ligands

1-Alkyl-2-[(3′-pyridyl)azo]imidazoles (3′-PyaiMe, **2a**; 3′-PyaiEt, **2b**; 3′-PyaiBz, **2c**) were synthesized by alkylation of 3′-PyaiH using alkyl halide (R′X) in dry THF in the presence of NaH. Spectral characterization of ligands have been reported elsewhere [11]. X-ray quality crystals of 3′-PyaiH have been isolated from an ethanolic solution of the compound.

3.2. Molecular structure

A view of 3′-PyaiH with the atom numbering scheme is shown in Fig. 1 and selected bond parameters are listed in Table 2. Both imidazole and pyridyl fragments are planar and the azo group is virtually coplanar with these groups. The dihedral angle between the two least squares planes is only 6.9(2)°. The N=N bond length is 1.268(2) Å. The distance is close to the reported data (1.267(3) Å) for 1-ethyl-2-(naphthyl-α-azo)imidazolium hexafluorophosphate but longer than the N–N distance of [HaaiMeH$^+$](ClO$_4$). The bonding strength between azo-N(1) and 3-pyridyl-[C(1)–N(1), 1.422(9) Å] is weaker than that of azo-N(2) and imidazole-C(6) [C(6)–N(2), 1.395(6) Å]. This suggests that the intramolecular interaction between azo and imidazole wave functions is stronger than that of pyridyl orbitals. The imidazole N(5)–H is intermolecularly hydrogen bonded with a second imidazole N(4) [N(5)–H$\cdots$N(4); distances: N(5)–H, 0.86; N(4)$\cdots$H, 2.020(6); N(5)$\cdots$N(4), 2.840(2) Å; angle, ∠N(5)–H$\cdots$N(4), 158.8(9)°] and forms a 1D-chain. The 3′-pyridyl group of the molecule is arranged alternately about the 1D-chain (Fig. 2).

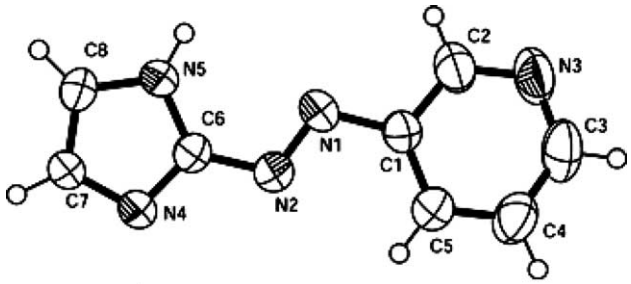

Fig. 1. A view of 3′-PyaiH with the atom numbering scheme.

Table 2
Selected bond lengths (Å) and bond angles (°) for 3′-PyaiH

Bond length (Å)		Bond angle (°)	
N(1)–N(2)	1.2682(19)	N(2)–N(1)–C(1)	112.76(14)
N(1)–C(1)	1.423(2)	N(1)–N(2)–C(6)	113.48(14)
N(2)–C(6)	1.396(2)	N(2)–C(6)–N(5)	127.10(14)
N(4)–C(6)	1.317(2)	N(2)–C(6)–N(4)	121.16(14)
N(5)–C(6)	1.348(2)	N(4)–C(6)–N(5)	111.74(14)
N(3)–C(2)	1.333(2)		
N(3)–C(3)	1.322(3)		

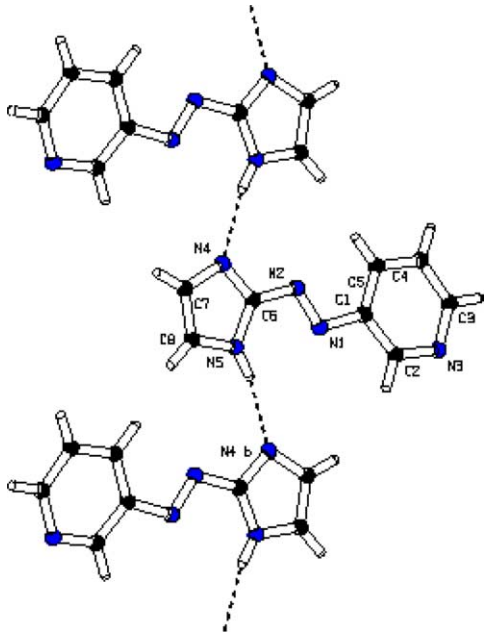

Fig. 2. A 1D chain of 3′-PyaiH.

3.3. The complexes

The reaction of a methanolic solution of 3′-PyaiR′ with $Mn(ClO_4)_2 \cdot 6H_2O$ in a 3:1 stoichiometry of ligand:-metal, aiming to prepare trischelated manganese(II) complexes, has isolated tetrahedral $[Mn(3'\text{-PyaiR}')_4](ClO_4)_2$ (**3**). The composition of the complexes has been determined by microanalytical and spectroscopic data. The molar conductances in MeCN suggest they are 1:2 electrolytic in nature. A single crystal X-ray structure determination confirms the structure of the complexes.

3.4. Spectral and magnetic studies

Infrared spectra show a very strong unstructured transmission centered at 1090–1093 cm^{-1} with a weak stretch at 625 cm^{-1}, which is referred to $\nu(ClO_4)$. Moderately intense stretching at 1580–1590 and 1440–1445 cm^{-1} are due to ν(C=N) and ν(N=N), respectively. A significant observation is the blue shifting of the N=N stretch by 20–25 cm^{-1} in the complexes relative to the free ligand values [11]. In the complexes of the chelated azoimine function $\overline{\text{Mn-N=N-C-N-}}$ π-back donation (dπ(M) → π*(azo)) usually reduces ν(N=N) [1–4]. An increase in ν(N=N) has concluded a no-bond impression between azo-N and Mn(II). The coordination of imidazole-N with Mn(II) may reduce the probability of charge population at π*(azo). This may be the reason for the blue shift of the azo stretch in the complexes.

Solution electronic spectra of the complexes show an intense transition <400 nm which are assigned to ligand centered transitions. Two weak ($\varepsilon \sim 10^3$ dm^3 mol^{-1} cm^{-1}) transitions observed at >440 nm may be referred to the combination of MLCT and d–d transitions. The spectral profile nature is in support of a Td–Mn(II) stereochemistry [17].

The magnetic moment, μ_{eff}, is av. 5.7 BM at 300 K (Table 2) as expected for an isolated $S = 5/2$ Mn(II) monomer. The EPR spectra of a solution in MeCN at 77 K display $g \approx 2$, $m_s = +1/2$ to $-1/2$ fine structure transition split into six hyperfine lines, as expected for a ^{55}Mn(II) complex ($I = 5/2$). A notable feature of the spectra is the relatively low value of the hyperfine coupling constant A, 80–90 G. A low hyperfine coupling constant (A) and high spin magnetic moment data are secondary evidences for tetrahedral Mn(II) stereochemistry [18]. However, the EPR profile cannot distinguish imidazole-N/azo-N coordination. IR spectral data and X-ray structural characterization of one of the complexes (vide infra) suggest imidazole-N coordination to Mn(II).

3.5. Molecular structure

3.5.1. $[Mn(3'\text{-PyaiEt})_4](ClO_4)_2$ (**3b**)

Fig. 3 shows the molecular structure of the complex $[Mn(3'\text{-PyaiEt})_4](ClO_4)_2$ (**3b**) along with the atomic numbering scheme used. Selected bond distances and angles are listed in Table 3. The cationic complex consists of a central manganese atom surrounded by four 3′-PyaiEt ligands. The Mn atom is sitting at the center of inversion of a tetrahedron and one half of the molecule is symmetry generated. Imidazole, azo and phenyl groups are coplanar with a small mean deviation (<0.04 Å). 3′-PyaiEt acts as a monodentate ligand and binds through imidazole-N. The coordination environment about Mn is compressed along the crystallographic c axis in such a way that two of the N–Mn–N angles are greater than the tetrahedral angle, with values N(1)–Mn(1)–N(1*), 132.2(2)° and N(5)–Mn(1)–N(5*), 136.1(2)°. The remaining N–Mn–N angles are less than 109.5° (Table 3). Bond length and bond angles data support a distorted tetrahedral geometry. The Mn–N bond lengths are 2.215(6) and 2.157(6) Å. The N=N bond distance is av. 1.273(7) Å

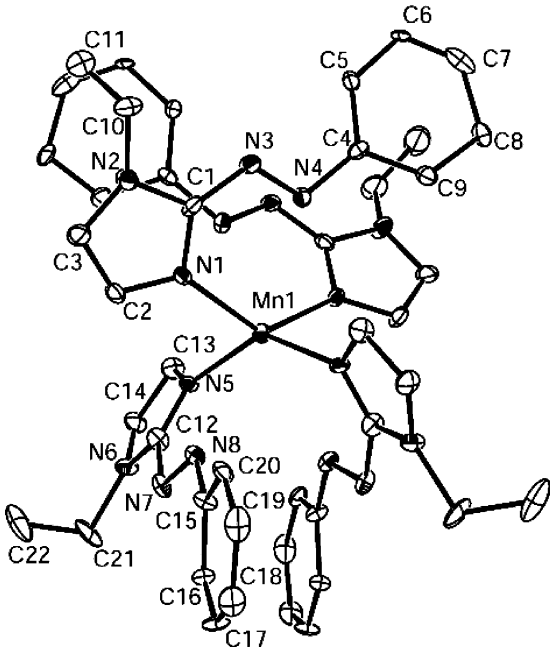

Fig. 3. ORTEP plot of the $[Mn(3'\text{-PyaiEt})_4]^{2+}$ unit.

Table 3
Selected bond distances and bond angles of $[Mn(3'\text{-PyaiEt})_4](ClO_4)_2$ (**3b**)

Bond length (Å)		Bond angle (°)	
Mn(1)–N(1)	2.215(6)	N(1)– Mn(1)–N(5)	96.4(2)
Mn(1)–N(5)	2.157(6)	N(1)–Mn(1)–N(1*)	132.2(2)
N(3)–N(4)	1.247(7)	N(1)–Mn(1)–N(5*)	101.0(2)
N(7)–N(8)	1.299(8)	N(5)–Mn(1)–N(5*)	136.1(2)
Cl(1)–O(1)	1.392(5)	O(3)–Cl(1)–O(1)	114.1(5)
Cl(1)–O(2)	1.362(6)	O(1)–Cl(1)–O(2)	104.7(4)
Cl(1)–O(3)	1.335(6)	O(1)–Cl(1)–O(4)	107.7(4)
Cl(1)–O(4)	1.358(5)	O(3)–Cl(1)–O(2)	116.3(6)
		O(3)–Cl(1)–O(4)	106.5(5)
		O(2)–Cl(1)–O(4)	107.2(5)

(the free ligand value is 1.268(2) Å (vide supra)). The pendant azopyridyl group is oriented in such a way to reduce steric and electronic repulsions. Two ClO_4^- anions balance the charge of the complex and they do not show any non-covalent interactions with the rest of the molecule (see Table 4).

3.6. *Mn(3′-PyaiR′)$_2$(X)$_2$ (X = N$_3$ (**4**), NCS (**5**))*

Upon reaction of a methanolic solution of $Mn(OAc)_2 \cdot 4H_2O$, 3′-PyaiR′ and NaN_3 or NH_4SCN in a 1:2:2 mole proportion, brown red crystalline products of composition Mn(3′-PyaiR′)$_2$(X)$_2$ (X = N_3 (**4**), NCS (**5**)) have been isolated. Microanalytical data support the composition (vide experimental section). The complexes are non-electrolytes. We have failed to grow X-ray quality crystals of the complexes. The structural identification has been carried out by spectroscopic data.

The IR spectra of Mn(3′-PyaiR′)$_2$(N$_3$)$_2$ (**4**) exhibit a strong sharp stretch corresponding to $\nu_{as}(N_3)$ at 2065–2080 cm^{-1}. A similar observation for Mn(3′-PyaiR′)$_2$-(NCS)$_2$ (**5**) at 2090–2100 cm^{-1} along with a medium strong band at 770–775 cm^{-1} refers to ν(CN) and ν(CS) of a coordinated NCS group [16]. We have not attempted to assign all the bands appearing in the IR spectra. However, on comparing with free ligand spectra, the medium strong stretches at 1585–1605 and 1430–1440 cm^{-1} have been assigned to ν(C=N) and ν(N=N), respectively.

The complexes are sparingly soluble in common organic solvents ($CHCl_3$, CH_2Cl_2, CH_3CN, CH_3OH, etc.), but they are soluble in DMF and DMSO. The solution electronic spectra of the complexes in DMF show weak spin forbidden d–d bands at 510–530 (sh) and 450–470 nm, corresponding to an octahedral symmetry, [17] along with a high intense intraligand charge-transfer transition <400 nm. The diffused reflectance spectra of the complexes in the solid state also exhibit similar transitions and this supports structural stability of the complexes in solution.

The magnetic moment μ_{eff} is av. 5.1 BM at 300 K which is as expected for d^5 (S = 5/2) Mn(II) monomeric complexes. The EPR spectra of the polycrystalline powders and solutions (DMF) of the complexes have been recorded at room temperature (298 K) and at liquid N_2 temperature (77 K). The low resolution of the polycrystalline spectra is usual where the metal centres are relatively close together, the hyperfine splittings are poor due to paramagnetic exchange narrowing. The solution spectra show better resolution, therefore these spectra (77 K) were used to determine the EPR parameters. The spectra show the usual six line (I = 5/2) hyperfine splitting, centred at $g \approx 2.0$ which is usual for Mn(II) complexes. Each hyperfine line in the spectra splits into three super-hyperfine lines. The peak-to-peak band width is larger (110–130 G) than the separation observed in case of tetrahedral $Mn(RaaiR')_4^{2+}$ (80–90 G). This supports the interaction of imidazole-N/azo-N with Mn(II).

3.7. Cyclic voltammetry

Redox properties of the manganese complexes have been studied by cyclic voltammetry (CV) using a platinum working electrode. Voltammogram data are collected in Table 2 and a representative voltammogram is shown in Fig. 4. A couple appearing at >1.0 V versus SCE is referred to the Mn(III)/Mn(II) redox process [19]. The quasireversibility of the process is examined from the peak-to-peak separation, ΔEp > 100 mV. The one electron nature of the redox process has been compared with the current height data of $Fe(CN)_6^{3-}$/$Fe(CN)_6^{4-}$. Ligand reductions are irreversible in nature and the Ep_c values are near to the free ligand values. The reduction corresponds to electron accommodation in the azo dominated orbitals. Electrochemical data reveal that tetrahedral Mn(II), $Mn(3'\text{-PyaiR}')_4^{2+}$ and Mn(3′-PyaiR′)$_2$(N$_3$)$_2$ compounds have similar redox efficiency. Mn(3′-PyaiR′)$_2$(NCS)$_2$ show a relatively low Mn(III)/Mn(II) potential. In terms of stabilization of the Mn(II)

Table 4

state, the potential data suggest that imidazole-N and azido-N have almost the same efficiency, and the structural change from Td (in $Mn(3'\text{-PyaiR}')_4^{2+}$) to Oh (in $Mn(3'\text{-PyaiR}')_2(N_3)_2$) has insignificant effect on the energy of the redox levels. It may be due to weak the interaction between Mn(II) and N(azo) (3′-PyaiR′).

3.8. EHMO calculation

To account for the spectral and electrochemical properties of the compounds a theoretical calculation has been carried out with the framework of Huckel formalism (EHMO) using X-ray crystallographic coordinates. Orbital composition of 3′-PyaiH determines that the HOMO is dominated by the azo group (88%) and the LUMO is composed of the azoimidazole function (azo, 60%; imidazole, 25%). Thus, the intraligand charge transfer may be ascribed to $\pi(\text{azo}) \rightarrow \pi^*(\text{azoimidazole})$. In the complex both HOMO and LUMO are constituted by Mn and azo-N wave functions. It is interesting to note that the two coordinated ligands in the asymmetric unit (which upon growing gives four tetrahedrally oriented ligands) have different contributions to the MOs. The two coordinated ligands contribute separately to the constitute HOMO and LUMO. Imidazole contributes only a little amount (4%) to the MOs. The LUMO has a share of 55% azo from one ligand while the HOMO contains 43% azo-N from the other ligand. Mn contributes to both the molecular orbitals: HOMO, 32% and LUMO, 26%. Thus, the electronic transition HOMO → LUMO may be ascribed as a combination of d–d, MLCT and interligand charge transfer transitions.

The no bond situation between Mn(II) and azo-N has prevented the π-back bonding from dπ [Mn(II)] to π* (azo), however, the charge delocalization is associated with the imidazole group and is transmitted to the azo group by extended conjugation, —N=N—imidazole—N—Mn—N—imidazole—N=N—. The process does not reduce the effective π-charge density on the azo function. This in turn has little influence on the bond length and IR frequency of the —N=N— group.

4. Conclusion

We have synthesized tetrahedral Mn(II) complexes of 1-alkyl-2-(3′-pyridylazo)imidazoles. The ligands serve as monodentate imidazole-N donors to synthesize high spin $[Mn(3'\text{-PyaiR}')_4](ClO_4)_2$ complexes. Redox properties show a high potential Mn(III)/Mn(II) couple. The pendant pyridylazo group with N(py) and N(azo) donor centres remain free in the molecule and may serve as a metal seeking agent. The metallo-ligand property of the molecules is under investigation. $Mn(3'\text{-PyaiR}')_2(X)_2$ (X = N_3, NCS) are also reported.

5. Supplementary material

Crystallographic data for the structures have been deposited with the Cambridge Crystallographic data center, CCDC No. 250732 for 3′-PyaiH (**1**) and 250733 for $[Mn(3'\text{-PyaiEt})_4](ClO_4)_2$ (**3b**). Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (Fax: +44 1223 336033, e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgments

Financial support was received from the Council of Scientific and Industrial Research (CSIR), New Delhi. One of us (U.S.R.) is thankful to the University Grants Commission New Delhi, for a fellowship. Our sincere thanks to Dr. G. Mostafa, Department of Physics, Jadavpur University for his help with the crystallography.

Abstract

Four complexes of the type $[Mn(dpa)_2(X)_2]\cdot H_2O$ (dpa = 2,2′-dipyridylamine; $X = N_3^-$, **1**; $X = NCO^-$, **2**) and $[Mn(dpa)_2(X)(OH_2)]ClO_4$ ($X = N_3^-$, **3**; $X = NCO^-$, **4**) have been synthesized using single-pot reactions of manganese(II) salt, dpa and X in 1:2:2 and 1:2:1 molar ratios, respectively. The compounds have been characterized by microanalytical, physicochemical, spectroscopic and magnetic results. Room temperature magnetic moments (μ_{eff}) are in the range 5.88–5.97 BM and are typical of high-spin manganese(II) complexes (t_{2g}^5 idealized, $S = 5/2$). The complexes display a Mn(III)–Mn(II) couple at ~0.6 V versus SCE in DMF solutions. X-ray structure determinations show that in **1**–**4** the manganese(II) centres are in a distorted octahedral environment. Compounds **1** and **2** contain the MnN_6 chromophore, completed by two bidentate dpa units and two terminal azido groups in **1** or *N*-coordinated cyanato ligands in **2**, along with a water of crystallization. In **3** and **4**, one water molecule acts as a coordinating ligand replacing one of the terminal pseudohalides in **1** and **2**, respectively, resulting in a MnN_5O chromophore. The amine H, terminal azido N or cyanato O, O and H's of the water molecule are engaged in extensive hydrogen bonding of the type N–H···N, O–H···N and N–H···O in **1** and **2**. Additionally O–H···O bonding is observed in **3** and **4**. Supramolecular 2D sheet structures are obtained arising from such weak intermolecular forces. All the complexes display high-energy intraligand $^1(\pi–\pi^*)$ fluroscence and intraligand $^3(\pi–\pi^*)$ phosphorescence in glassy solutions (DMF at 77 K).

1. Introduction

The designed construction [1,2] of metallosupramolecular assemblies [3,4] derived from appropriate combinations of metal ions and organic ligands is a rapidly developing area of current research towards the preparation of functional materials [5–8]. The controlled reactions in appropriate ratios of donor and acceptor building blocks held together by covalent [9] as well as non-covalent forces [10] results in variable molecular and crystalline architectures [11]. Recently, we have established the composition of tailored superstructures of zinc(II)azides containing 2,2′-dipyridylamine (dpa) with active amine (–NH–) hydrogen [12]. In continuation, we aim to investigate the binding of this tailored diimine to paramagnetic manganese(II). Dpa may

doi:10.1016/j.poly.2005.01.021

behave as a versatile ligand ranging from monodentate, chelating bi-dentate to bridging tri-dentate [12–17]. However, harnessing hydrogen bonded networks through its active amine (–NH–) hydrogen as a proton donor that may lead to supramolecular architectures is very scarce [16]. Manganese is widespread in biology [18,19] because of its availability in different oxidation states controlling the active site of structures, physico-chemical properties and functions of enzymes. Weak interactions via non-covalent forces are found in several metalloenzymes and metalloproteins affecting a number of biologically important processes [20–22].

In search of a metallosupramolecule based on manganese(II) centres we have successfully synthesized and X-ray crystallographically characterized four mononuclear complexes of types $[Mn(dpa)_2(X)_2]\cdot H_2O$ (in **1** and **2**) and $[Mn(dpa)_2(X)(OH_2)]ClO_4$ (in **3** and **4**) ($X = N_3^-$, NCO^-) through the one-pot reactions of manganese(II) chloride (**1** and **2**) and manganese(II) perchlorate (**3** and **4**) with dpa and X in the molar ratios 1:2:2 and 1:2:1, respectively. The presence of N–H···O, O–H···N, O–H···O and N–H···N types of intermolecular forces are responsible for the formation of supramolecular two-dimensional (2D) sheet structures from the individual zero-dimensional (0D) units. It is of note that a cursory report on the Mn(II)–dpa polymer in combination with azide is reported [17] but such weak interactions among the polymers are not cited. The details of synthesis, structure and physico-chemical characterization of these supramers are cited below.

2. Experimental

2.1. Materials

High-purity 2,2′-dipyridylamine (Fluka, Germany), manganese(II) chloride tetrahydrate (E. Merck, India), sodium azide (E. Merck, India) and sodium cyanate (E. Merck, India) were purchased from the respective concerns and used as received. Manganese(II) perchlorate hexahydrate was prepared by treatment of manganese(II) carbonate (E. Merck, India) with perchloric acid (E. Merck, India) followed by slow evaporation on a steam-bath, filtration through a fine glass frit and preservation in a desiccator containing concentrated sulfuric acid for subsequent use. All other chemicals and solvents were AR grade and were used as received. Purification of solvent (DMF) and preparation of supporting electrolyte ($[Et_4N][ClO_4]$) for electrochemical work were executed following published procedures [23].

Caution! Azido compounds and perchlorate salts of metal ions are potentially explosive. Only a small amount of material should be prepared and handled with care.

2.2. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed on a Perkin–Elmer 2400 CHNS/O elemental analyzer. IR spectra (KBr discs, 4000–300 cm^{-1}) were recorded using a Jasco FT-IR Model 420 spectrometer. Molar conductances were measured using a Systronics conductivity meter where the cell constant was calibrated with 0.01 M KCl solution and dry DMF was used as solvent. Ground state absorption and steady state fluorescence measurements were made with a Jasco Model V-530 UV–vis spectrophotometer and Hitachi Model F-4010 spectrofluorometer, respectively. Time resolved fluorescence measurements were carried out using a time correlated single photon counting (TCSPC) spectrometer from Edinburgh Instruments, Model 199; a hydrogen filled coaxial flash lamp with a pulse width of 1.2 ns at FWHM and a Philips XP-2020Q photomultiplier tube were, respectively, used as the excitation source and the fluorescence detector. Magnetic susceptibilities were measured with a PAR 155 vibrating sample magnetometer with $Hg[Co(SCN)_4]$ as the reference. Electrochemical measurements were carried out with the use of computer controlled EG&G PARC Verastat Model 270 electrochemical instrument using a platinum disk working electrode as described elsewhere [23]. The solutions were IR compensated and the results were collected at 298 K. The following parameters and relations were used: scan rate (v), 50 mV s^{-1}; formal potential $E^\circ = 0.5(E_{pa} + E_{pc})$ where E_{pa} and E_{pc} are anodic and cathodic peak potentials, respectively; ΔE_p is the peak-to-peak separation. The potentials are referenced to a saturated calomel electrode (SCE) and are uncorrected for the junction contributions.

2.3. Preparation of complexes

Mononuclear **1** and **2** were prepared from chloride and perchlorate salts of manganese(II) using the same (1:2:2) mole ratio of the metal ion, dpa and azide/cyanate. Compounds **3** and **4** were prepared using a 1:2:1 ratio of manganese(II) perchlorate, dpa and azide/cyanate; the corresponding ratio with chloride resulted in **1** and **2**, but with very low yield. The typical syntheses are described below.

2.3.1. $[Mn(dpa)_2(N_3)_2]\cdot H_2O$ (**1**)

Dpa (0.11 g, 0.648 mmol) in acetonitrile (5 cm^3) was added slowly to a $MnCl_2\cdot 4H_2O$ (0.641 g, 0.324 mmol) solution (10 cm^3) in the same solvent. NaN_3 (0.042 g, 0.648 mmol) in water (5 cm^3) was added dropwise to it. After filtration through a fine glass frit, the supernatant colourless solution was kept in a dark place at room temperature (298 K) for slow evaporation. Light yellow crystals of **1** were deposited within a week, which were

separated by filtration, washed several times with ether and dried in vacuo over silica gel indicator. The yield was 0.030 g (75%). *Anal*. Calc. for $C_{20}H_{20}N_{12}OMn$ (**1**): C, 48.10; H, 4.04; N, 33.66. Found: C, 48.20; H, 4.09; N, 32.98%. IR (KBr, cm^{-1}): $\nu(N_3)$ 2070, 2048; ν(N–H) 3343. Λ_M (DMF, $\Omega^{-1}\,cm^2\,mol^{-1}$): 5. UV–vis ($\lambda$, nm): 315.

2.3.2. $[Mn(dpa)_2(NCO)_2]\cdot H_2O$ (2)

Complex **2** was synthesized similarly as in **1** except that NaNCO (0.042 g, 0.648 mmol) was added instead of NaN_3. The reaction solution was processed as above. The yield of the colourless crystals was found to be 0.029 g (72%). *Anal*. Calc. for $C_{22}H_{20}N_8O_3Mn$ (**2**): C, 52.91; H, 4.04; N, 22.44. Found: C, 52.26; H, 4.07; N, 22.39%. IR (KBr, cm^{-1}): ν(NCO) 2200, 2181; ν(N–H) 3347. Λ_M (DMF, $\Omega^{-1}\,cm^2\,mol^{-1}$): 8. UV–vis ($\lambda$, nm): 312.

2.3.3. $[Mn(dpa)_2(N_3)(OH_2)]ClO4$ (3)

The synthesis of **3** was carried out by slowly adding NaN_3 (0.021 g, 0.324 mmol) in H_2O (5 cm^3) to a mixture containing dpa (0.11 g, 0.648 mmol) and manganese(II) perchlorate (0.362 g, 0.324 mmol) in acetonitrile (15 cm^3). The colourless solution was filtered through a fine glass frit and kept in a dark place for slow evaporation. Square shaped colourless crystals of **3** suitable for X-ray crystallography were obtained within 10 days. The product was collected by filtration, washed with ether and dried in vacuo over silica gel indicator; yield, 0.046 g (70%). *Anal*. Calc. for $C_{20}H_{20}N_9O_5ClMn$ (**3**): C, 43.14; H, 3.62; N, 22.64. Found: C, 43.24; H, 3.74; N, 22.59%. IR (KBr, cm^{-1}): $\nu(N_3)$ 2053; ν(N–H) 3352; ν(OH), 3419; $\nu(ClO_4)$ 1084, 623. Λ_M (DMF, Ω^{-1} cm^2 mol^{-1}): 120. UV–vis (λ, nm): 317.

2.3.4. $[Mn(dpa)_2(NCO)(OH_2)]ClO_4$ (4)

A similar procedure as in **3** was followed for complex **4** except that NaNCO (0.021 g, 0.324 mmol) was added instead of NaN_3. Yield, 0.047 g (72%). *Anal*. Calc. for $C_{21}H_{20}N_7O_6ClMn$ (**4**): C, 45.30; H, 3.62; N, 17.61. Found: C, 45.39; H, 3.68; N, 17.70%. IR (KBr, cm^{-1}): ν(NCO) 2196; ν(N–H) 3341; ν(OH), 3421; $\nu(ClO_4)$ 1083, 634. Λ_M (DMF, Ω^{-1} cm^2 mol^{-1}): 130. UV–vis (λ, nm): 315.

2.4. X-ray crystallography

A summary of the key crystallographic information of complexes **1**–**4** is given in Tables 1 and 2. Data were

collected on a SMART CCD diffractometer using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) with a detector distance of 4 cm and swing angle of −35°. A hemisphere of the reciprocal space was covered by a combination of three sets of exposures; each set had a different ϕ angle (0°, 88°, 180°) and each exposure of 30 s covered 0.30 in ω. The data collected were reduced using the program SAINT [24] and an empirical absorption correction was carried out using the SADABS [25] program. Reflections with $2\theta \leqslant 55°$ were used for further processing. The structures of all the complexes were solved using direct methods and refined using the full-matrix least-squares method on F^2_{abs} using the SHELXTL [26] software package. All non-hydrogen atoms were anisotropically refined. The water hydrogens were first located from the difference maps and then were constrained to ride on the carrier oxygen atom with U_{iso} values also constrained to 1.5 U_{eq} of the carrier atom for refinement. The molecular graphics were created using SHELXTL. Atomic scattering factors and anomalous dispersion corrections were taken from the International Tables for X-ray Crystallography [27].

3. Results and discussion

3.1. Synthesis and formulation

Dipseudohalide complexes $[Mn(dpa)_2(N_3)_2] \cdot H_2O$ (**1**) and $[Mn(dpa)_2(NCO)_2] \cdot H_2O$ (**2**) were prepared as crystalline products through the one-pot reactions of 1:2:2 mole ratios of manganese(II) chloride, dpa and the pseudohalides (N_3^-/NCO^-), respectively, in aqueous acetonitrile solutions (1:3). Attempts to prepare compounds of the type polynuclear $[Mn(dpa)_2(X)]_nY_n$ or dinuclear $[Mn(dpa)_2(X)]_2Y_2$ [$X = N_3^-$ or NCO^-; $Y = ClO_4$] with a 1:2:1 ratio of $Mn(ClO_4)_2 \cdot 6H_2O$, dpa and N_3^-/NCO^- produced $[Mn(dpa)_2(N_3)(OH_2)]ClO_4$ (**3**) and $[Mn(dpa)_2(NCO)(OH_2)]ClO_4$ (**4**). With the metal chloride, a 1:2:1 ratio resulted in the formation of **1** and **2** with very low yields. However, addition of perchlorate ions in the reaction medium leads to **3** and **4**. This shows the presence of perchlorate ions are needed to isolate **3** and **4**, but its absence, leads to formation of compounds **1** and **2**.

Microanalytical (C, H and N) results and spectroscopic data are useful in this regard to formulate the products. The air-stable moisture-insensitive complexes **1**–**4** are insoluble in common solvents like methanol, ethanol, dichloromethane and acetonitrile, but are soluble in warm dimethylformamide and dimethylsulfoxide. Room temperature solid phase magnetic susceptibility measurements show that the manganese(II) complexes have moments close to their spin only value ($S = 5/2$): 5.88 BM (**1**); 5.89 BM (**2**); 5.93 BM (**3**) and 5.97 BM (**4**). In dimethylformamide **1** and **2** behave as non-electrolytes but a 1:1 electrolytic nature is realized in **3** and **4** [28] as evident from their conductivity values. A point of interest in the IR spectra are the bands [29] due to azide in **1** and **3** and cyanate in **2** and **4**. The asymmetric stretch ν_{asym} (N_3) appears as strong bands at 2070 and 2048 cm^{-1} in **1** and a single band at 2053 cm^{-1} in **3**. Stretches due to the cyanato group are seen at 2200 and 2181 cm^{-1} in **2**, and at 2196 cm^{-1} in **4**. Observation of the two such stretches in **1** and **2** are in line with the *cis* orientation of the pseudohalides. A distinguishable band could be expected for the azide symmetric (ν_{sym}) stretching mode in **1** and **3**, but only a weak signal at about ∼1324 cm^{-1} is observed. A signal corresponding to the azide and cyanate bending vibration, δ, can also be observed at about 638 cm^{-1} (**1** and **3**) and 640 cm^{-1} (**2** and **4**). In the region 420 and 366 cm^{-1}, two medium-to-weak bands are assignable to the ν(M–NCO) stretch, similar to other metal cyanato complexes with M–NCO bonds [30]. The ν(M–O)(H_2O) absorption bands [30] appear in the range 560–480 cm^{-1} for complexes **3** and **4**. Presence of $\nu(ClO_4)$ bands at ∼1080 and ∼620 cm^{-1} in **3** and **4** are noticed. The mild splitting in the perchlorate stretch indicates its involvement in some kind of secondary interactions. Furthermore, the IR spectra of **1**–**4** feature [17] the bands characteristic of the dpa molecule, seen in the stretching and bending modes of C–C and C–N bonds in the ranges between 1645–1390 and 1270–750 cm^{-1}. The –NH– and the –OH– bonds are noticeable at ∼3350 and ∼3430 cm^{-1}, respectively, and are in the higher wavelength region than the ideal value.

Complexes **1**–**4** show intense absorption bands at [31] around 315 nm, which are assigned to intraligand π–π* transitions, as these are similar to that of the free ligand (315 nm) [12]. The six-coordinated high-spin manganese(II) belongs to the $3d^5$ system. There is no excited state with the spin multiplicity six and all the electronic transitions in these complexes are doubly forbidden, (Laporte as well as spin). No bands in the visible region are detected, as expected for an octahedral manganese(II) complex. Reflectance spectra and electronic spectra in DMF solutions are akin in all complexes, reflecting gross structure and electronic structure in the solid state and solution.

3.2. Structure

The structural analyses show that complexes **1** and **2** consist of mononuclear units which are further engaged in hydrogen bonding among themselves and with water of crystallization or counter ions to give supramolecular 2D sheet structures. The ORTEP diagram of the individual unit, the perspective view of the hydrogen bonded sheets and the three dimensional orientation of the

sheets of these complexes are shown in Figs. 1–6 for **1** and **2** and Figs. 7–9 for **3** and **4**.

3.2.1. $[Mn(dpa)_2(N_3)_2]\cdot H_2O$ (**1**) and $[Mn(dpa)_2(NCO)_2]\cdot H_2O$ (**2**)

ORTEP diagrams with the atom labelling scheme of the mononuclear units of **1** and **2** are shown in Figs. 1 and 2. The coordination polyhedron around manganese(II) in both the complexes are best described as distorted octahedron with a MnN_6 chromophore. The coordination includes two chelated tailored diimines (—N=C–NH–C=N–) ligated by four pyridine N atoms [N(1), N(3), N(4), N(6)] and two terminal azide/cyanate N atoms. Three pyridine nitrogens of two different dpa units and one nitrogen of the pendant azido/cyanato group define the equatorial plane around the manganese(II) centres. The deviation of each nitrogen atom from the basal plane in **1** are −0.087, 0.075, 0.091, and −0.079 Å for N(3), N(10), N(1), N(4), and in **2** are 0.004, 0.004, −0.004, and −0.004 Å for N(8), N(4), N(1), N(6), respectively. In **1**, the deviation of manganese(II) from the mean plane is 0.177 Å while that in **2** is −0.195 Å.

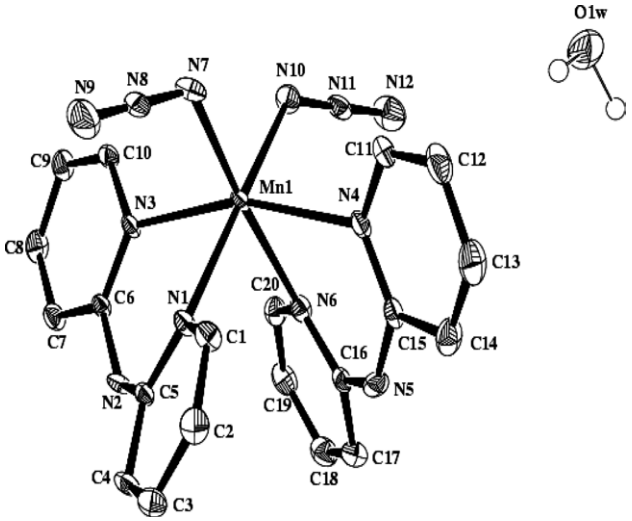

Fig. 1. ORTEP representation of the monomeric $[Mn(dpa)_2(N_3)_2]\cdot H_2O$ (**1**) with the atom numbering scheme and 40% probability ellipsoids for all non-hydrogen atoms.

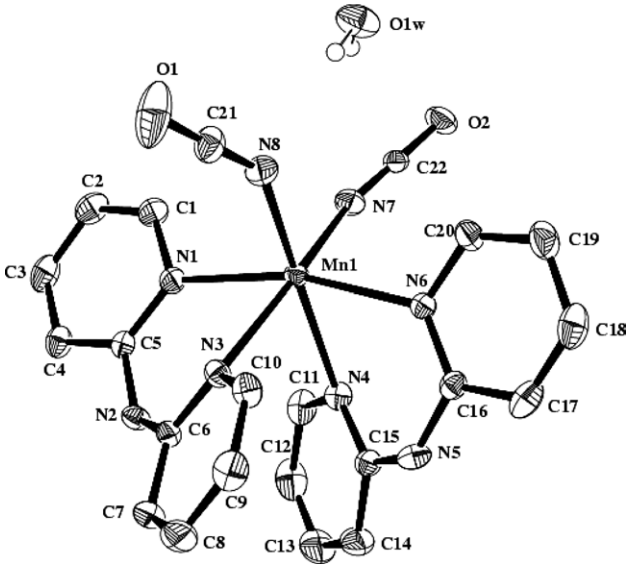

Fig. 2. ORTEP diagram of the monomeric $[Mn(dpa)_2(NCO)_2]\cdot H_2O$ (**2**) with the atom numbering scheme and 40% probability ellipsoids for all non+hydrogen atoms.

The Mn(1)–N distances are significantly greater than the sum of the covalent radii (1.96 Å) but show sufficient coherency with complexes containing pyridine nitrogens bonded to manganese(II) [32,33]. The two dpa ligands chelate the manganese atom with Mn(1)–N distances within a similar range: 2.234(3)–2.318(3) Å in **1** and 2.267(2)–2.324(2) Å in **2**. These distances are greater than Mn(1)–N(N_3/NCO) distances which are in the range, 2.139(2)–2.190(3) Å. Distortion from ideal octahedral coordination is very significant from the ranges of *cisoid* and the *transoid* angles which show sufficient deviation from ideality (Tables 3 and 4). The angles subtended by the dpa units in **2** [76.74(8)°–76.88(8)°] are close to those in compound **1** [77.70(10)°–78.81(10)°]. The angle between the two chelate planes in **1** is 55.39(12)° and in **2** is 47.93(10)°. The dpa ligands are not planar as the dihedral angles between planar pyridine rings (N1, C1 → C5 and N3, C6 → C10; N4, C11 → C15 and N6, C16 → C20) are 21.84(13)° and 14.01(14)° for **1**, and 26.23(12)° and 19.67(12)° for **2**, respectively. Two azides/cyanates are in a *cis* orientation with an angle of 92.24(12)°/97.21(10)°. The N(7)–N(8) [1.176(4) Å] and N(10)–N(11) [1.178(4) Å] distances are greater than N(8)–N(9) [1.155(5) Å] and N(11)–N(12) [1.169(5) Å] distances, respectively, as expected, and the values are very similar to different transition metal azido complexes [32]. Both the azide as well as the cyanate ligands have the expected linear geometry, with N–N–N angles of 178.3(4)°, 178.6(4)°, respectively, for N(9), N(12) and N–C–O angles of 178.4(4)°, 177.7(3)°, respectively, for O(1), O(2). The N(8)–N(7)–Mn(1) and N(11)–N(10)–Mn(1) angles are 122.7(2)° and 128.3(3)°, respectively, which reflects the bending coordination nature of the azides. Similar bending coordination is also observed in the cyanato ligands in **2** with C(21)–N(8)–Mn(1) and C(22)–N(7)–Mn(1) angles of 144.8(2)° and 158.1(2)°. The Mn···Mn separation between the nearest neighbours in each 1D chain in **1** is 7.829 Å, and that within the sheets in **2** is 8.439 Å.

The packing diagram of **1** in the *bc* plane exhibits a hydrogen bonded 1D supramolecular chain. The water of crystallization, unbound nitrogen of the terminal azide and the amine (–NH–) hydrogen play a vital role in the formation of this type of architecture (Table 5). The end nitrogen atom [N(12)] of one terminal azide

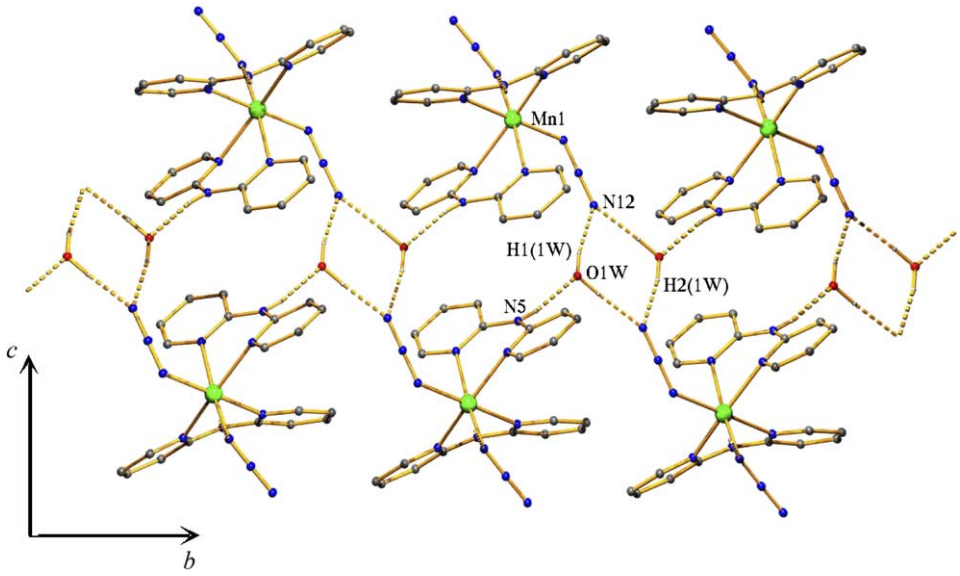

Fig. 3. Hydrogen bonded 1D chains formed by the lattice water in **1**.

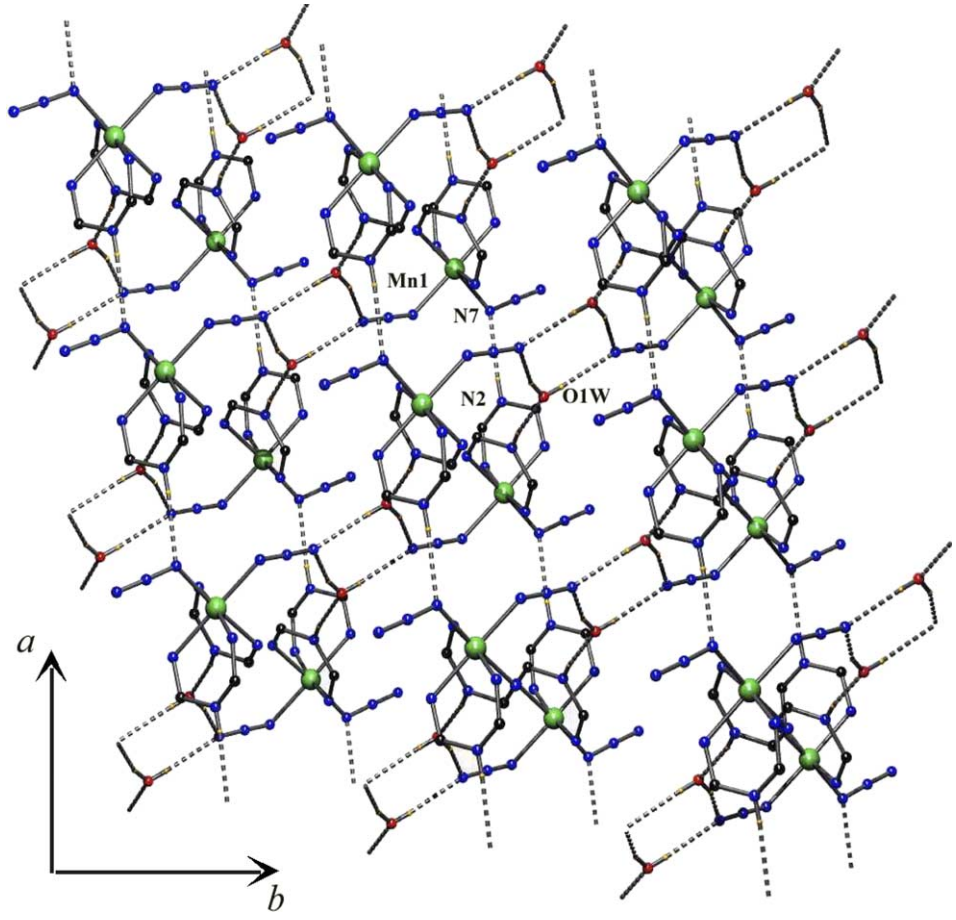

Fig. 4. A perspective view of the supramolecular 2D sheet formed by the N–H···N H-bonding in **1**.

of a mononuclear unit is hydrogen bonded to two hydrogens [H(1W1) and H(2W1)] of two different water molecules by bifurcated hydrogen bonding [H(1W1)···N(12) 1.9571 Å; ∠O(1W)–H(1W1)···N(12), 176.07°]. Another unit placed diagonally is similarly hydrogen bonded to a second water molecule. The oxygen atoms

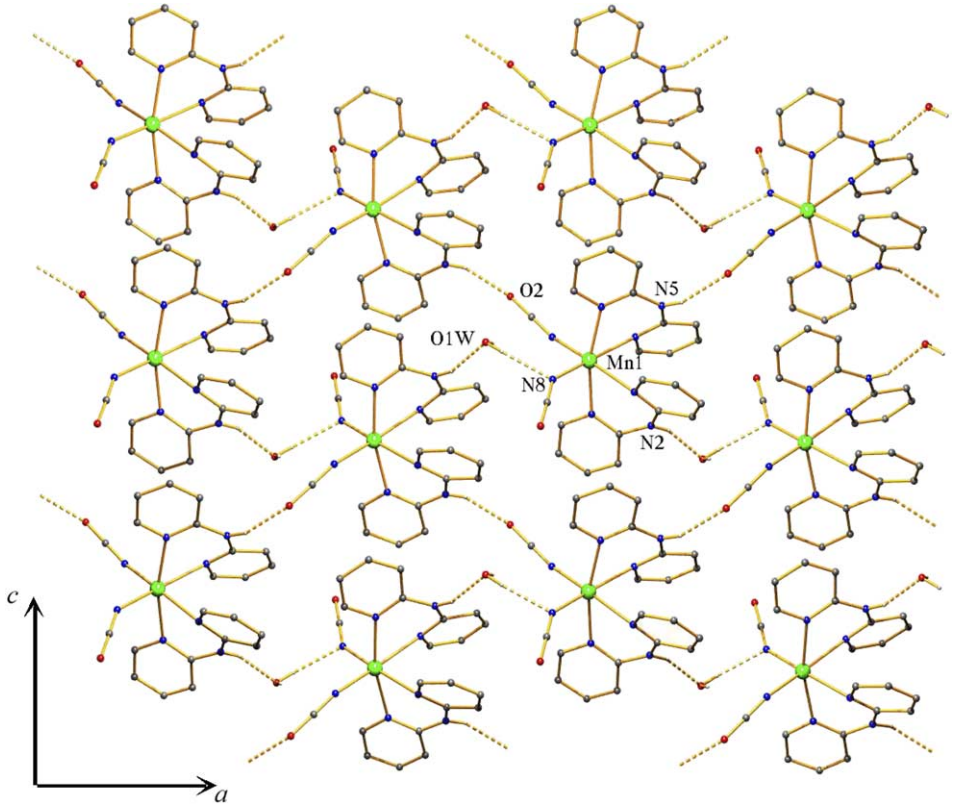

Fig. 5. Hydrogen bonded 2D supramolecular sheets formed by the lattice water in **2**.

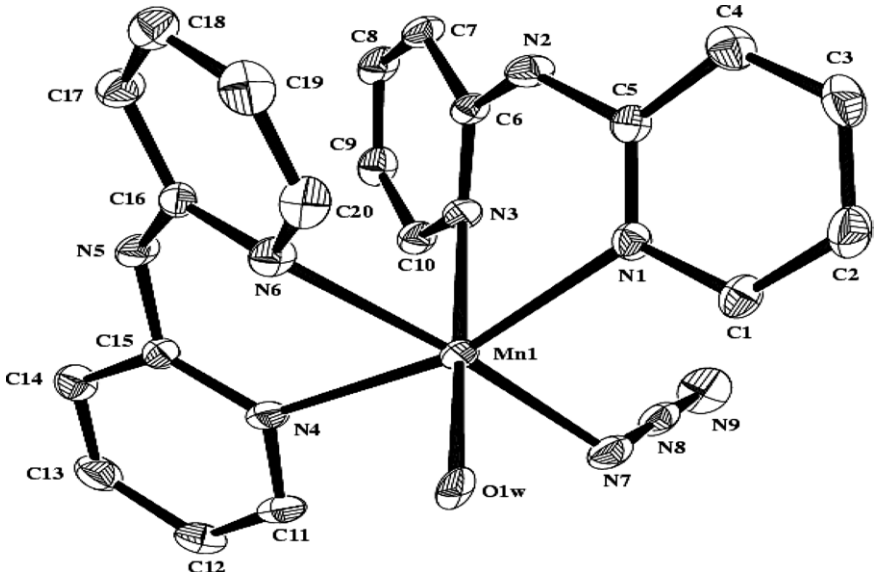

Fig. 6. ORTEP diagram of $[Mn(dpa)_2(N_3)(OH_2)]^+$ (**3**) with the atom numbering scheme and 40% probability ellipsoids for all non-hydrogen atoms.

[O(1W) and O(2W)] of these water of crystallizations are further hydrogen bonded to the amine hydrogens [N(5)] of two other mononuclear units [H(5A)···O(1W), 2.0068 Å; ∠N(5)–H(5A)···O(1W), 165.37°]. Thus four neighbouring mononuclear units are held together through such bifurcated H-bonding interactions to two donor water molecules (Table 5) to form a cyclic motif, $R_2^4(8)$ in Etter's graph notation [34]. These motifs in turn result in one dimensional chains (Fig. 3). These 1D chains are further connected through N–H···N hydrogen bonding between amine nitrogen [N(2)] donors and [N(7)] of bound azido nitrogen acceptors.

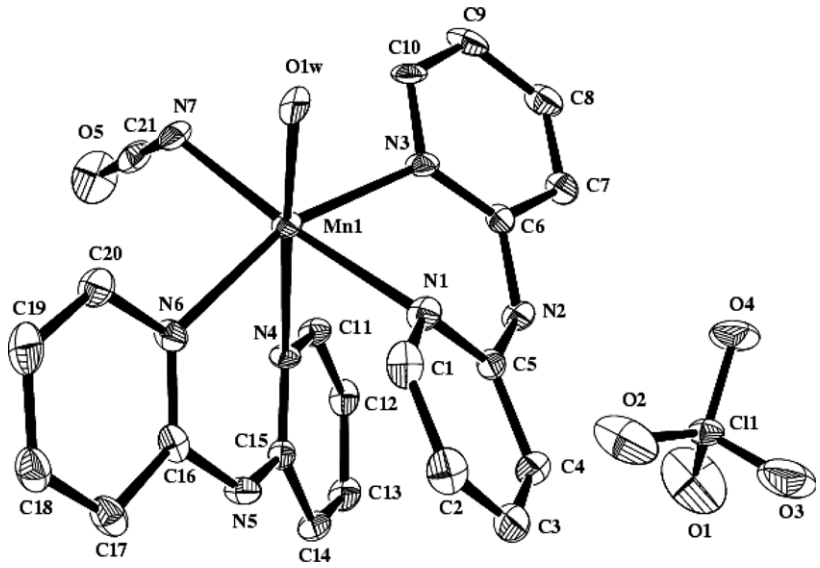

Fig. 7. ORTEP representation of $[Mn(dpa)_2(NCO)(OH_2)]ClO_4$ (**4**) with the atom numbering scheme and 40% probability ellipsoids for all non-hydrogen atoms.

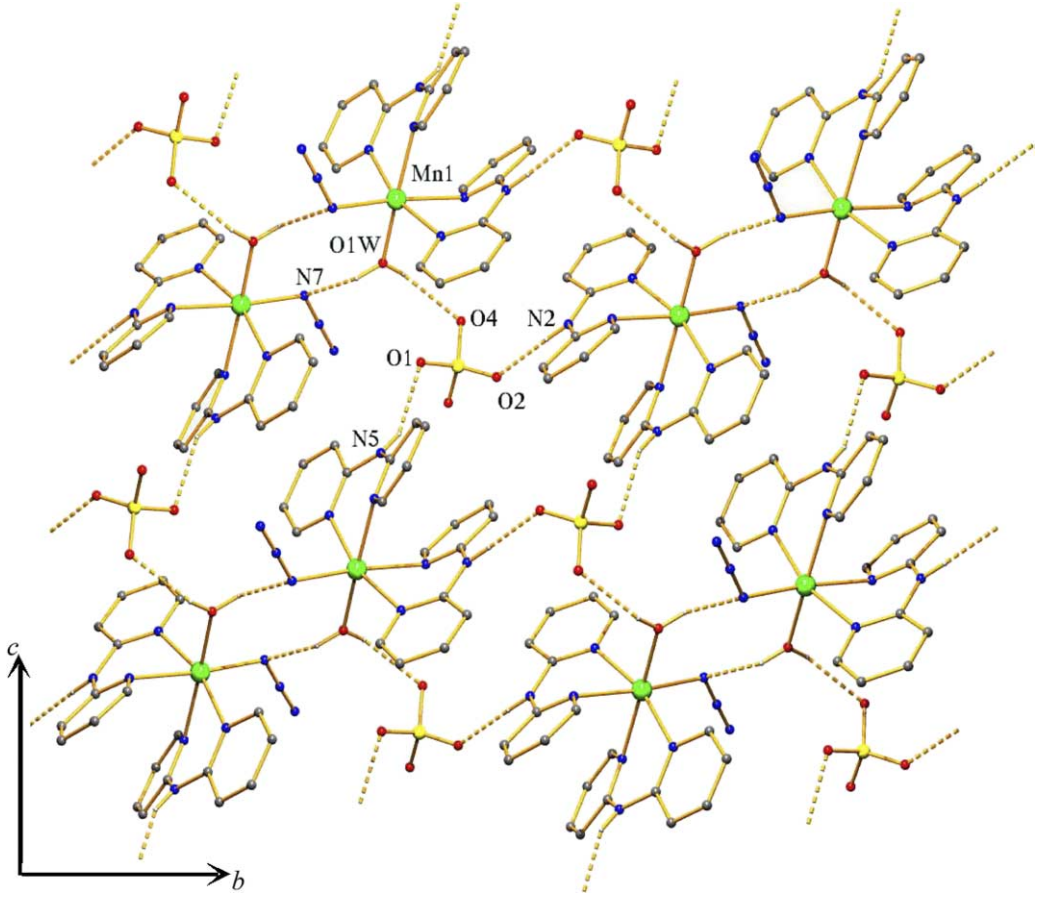

Fig. 8. A Perspective view of 2D supramolecular sheets formed by H-bonding in **3** and **4**.

These two hydrogen bonding systems are interwoven and facilitates a 2D supramolecular sheet in the *ab* plane (Fig. 4).

In **2** the packing diagram is very different from that seen in **1**. Fig. 5 shows the hydrogen bonded 2D sheet structure of the complex in the *ac* plane. Each unit is

Symmetry codes: a x, $1+y$, z; b $1-x$, $-y$, $1-z$; c $-1+x$, y, z; d $1/2-x$, $1-y$, $1/2+z$; e $3/2-x$, $1-y$, $1/2+z$.

hydrogen bonded to four neighbouring units; directly to two units and to two other units via a water molecule each (Table 5). The bound nitrogen [N(8)] of a terminal cyanate of each unit participates in an O–H···N type of bonding with a nearby water molecule, having a H(2W)···N(8) distance of 2.0590 Å and ∠O(1W)–H(2W)···N(8), 171.72°. The pendant oxygen atom [O(2)] of another cyanate of the same unit hydrogen bonds to an amine hydrogen of another unit with H(5A)···O(2), 0.8601 Å and ∠N(5)–H(5A)···O(2), 157.73°. Two amine hydrogens from the two dpa ligands of this same unit further hydrogen bond to a water molecule [N–H···O(W)] and an oxygen atom of a cyanate [N–H···O] of a different unit. Thus each water molecule is hydrogen bonded to two mononuclear units.

3.2.2. $[Mn(dpa)_2(N_3)(OH_2)]ClO_4$ (**3**) and $[Mn(dpa)_2(NCO)(OH_2)]ClO_4$ (**4**)

Both the complexes consist of mononuclear units containing a $[Mn(dpa)_2(X)(OH_2)]^+$ cation and a ClO_4^- anion each, which are further engaged in hydrogen bonding among themselves to give a supramolecular 2D sheet structure. No coordination of the anions is observed.

Figs. 7 and 8 depict the ORTEP drawing with the atom numbering scheme of the mononuclear units of **3** and **4**, respectively. The complex cations possess a six-coordinated environment with a $Mn^{II}N_5O$ chromophore, namely each of the manganese atoms is coordinated by four nitrogen atoms [N(1), N(3), N(4), N(6)] from two bidentate dpa ligands, one nitrogen from the terminal azide/cyanate [N(7)] and an oxygen atom [O(1W)] of the coordinated aquo ligand. The equatorial plane in **3** is made up of N1, N3, N4 and O1W, from two dpa ligands and an aquo moiety, where the corresponding deviations are −0.064, 0.065, −0.086 and 0.057 Å, respectively. The manganese atom deviates 0.16 Å from the plane. In **4**, the deviations are −0.055, 0.062, −0.060 and 0.054 Å, for N3, N4, N6 and O1W, with a deviation of 0.206 Å of the manganese(II) centre out of the equatorial N_3O plane.

The manganese(II)–N distances are characteristic of typical high-spin manganese(II) complexes. The Mn(1)–N bond lengths and the N–Mn(1)–N bite angles are comparable to those in dpa–manganese(II) structures. The shortest distance (Tables 6 and 7) within the cation is the bond between Mn(II) and oxygen atom of the aqua ligand, followed by Mn(II)–$N_{azide/cyanate}$ and Mn(II)–N_{dpa} distances. Mn–O (H_2O) distances of both complexes are within the ranges found for other Mn(II)-aquo complxes. In **3** and **4** the angle between the two chelate planes is 51.44(16)° and 51.50(2)°. The dpa ligands are not planar as the dihedral angles between the planar pyridine rings (N1, C1 → C5 and N3, C6 → C10; N4, C11 → C15 and N6, C16 → C20) are 21.61(19)°, 17.0(2)° in **3** and 18.0(3)°, 20.7(2)° in **4**. The azide ligand in **3** has the expected linear geometry, with N–N–N angles of 178.6(5)° for N(9). The N(8)–N(7)–Mn(1) angle is 123.0(3)° which reflects the highly bending coordination nature of the azide. In **4** the cyanate ligand also has the expected linear geometry, with the N–C–O angle of 178.9(7)° for O(5). The C(21)–N(7)–Mn(1) angle is 129.1(5)° which reflects the highly bent nature of the cyanate.

The packing diagrams of **3** and **4** are exactly the same and are represented by Fig. 9. The most interesting feature in **3** and **4** is that the interionic hydrogen bonds play an important role in the crystal packing and the stability of the complexes. Adjacent units are cross-linked by three types (N–H···O, O–H···O and O–H···N) of intermolecular hydrogen bonds, which stabilize the conformation. Through the interionic hydrogen bonds, the cations are linked into supramolecular 2D layers. The coordinated water molecules and the perchlorate anions are involved in the hydrogen bonded network. The hydrogen bonding parameters are shown in Table 8 for **3** and **4**. The sheets in **3** and **4** propagate in the *bc* plane as shown in Fig. 9.

A cyclic motif $R_2^2(8)$ in Etter's graphs notation [34] between the two mononuclear cationic units is formed by hydrogen bonding involving a hydrogen of the aquo ligand of one unit and a bound nitrogen of the terminal pseudohalide of the second unit and vice versa. This results in the formation of supramolecular dinuclear species held together solely by hydrogen bonds [O(1W)–H(2W)···N(7); H(2W)···N(7), 2.0800 Å (**3**) and 2.1265 Å (**4**), ∠O(1W)–H(2W)···N(7), 136.13° (**3**), 135.74° (**4**)]. The Mn···Mn separation forming the loop within the sheet is 5.669 Å (**3**) and 5.642 Å (**4**). Each such dimers are further hydrogen bonded separately to six perchlorate anions. Thus each perchlorate anion is hydrogen bonded to three different mononuclear cationic units. Two of the three hydrogen bonded oxygens are involved in a N–H···O type of interaction with the active amine (N2 and N5) hydrogens of dpa ligands of two different units [N–H···O: H(2B)···O(2), 2.1963 Å; ∠N(2)–H(2B)···O(2), 151.30°; H(5A)···O(1), 2.0765 Å; ∠N(5)–H(5A)···O(1), 177.15° (**3**) and H(2B)···O(2), 2.0757 Å; ∠N(2)–H(2B)···O(2), 178.07°; H(5A)···O(3), 2.1973 Å; ∠N(5)–H(5A)···O(3) 151.76°; (**4**)]. The third oxygen hydrogen bonds to hydrogen [H(1W)] of the bound aquo ligand [O(1W)–H(1W)···O(4); H(1W)···O(4), 2.2551 Å (**3**), 2.2483 Å (**4**); ∠O(1W)–H(1W)···O(4), 151.44° (**3**), 152.79° (**4**)]. From Fig. 9 it is clearly

Table 8
Hydrogen bond distances (Å) and angles (°) for **3** and **4**

D–H···A	D–H	H···A	D···A	D–H···A
*Compound **3***

O(1W)–H(2W)···N(7)[a]	0.9005	2.0800	2.800(6)	136.13
N(2)–H(2B)···O(2)[b]	0.8603	2.1963	2.980(7)	151.30
N(5)–H(5A)···O(1)[c]	0.8607	2.0765	2.936(8)	177.15
*Compound **4***				
O(1W)–H(1W)···O(4)[c]	0.8996	2.2483	3.076(8)	152.79
N(2)–H(2B)···O(2)	0.8607	2.0757	2.936(11)	178.07
O(1W)–H(2W)···N(7)[a]	0.9005	2.1265	2.842(7)	135.74
N(5)–H(5A)···O(3)[d]	0.8611	2.1973	2.984(9)	151.76

Symmetry codes: a $1-x, 1-y, 1-z$; b $x, 1+y, z$; c $1-x, 1-y, -z$; d $1-x, 2-y, -z$.

seen that the pendant atoms of the terminal pseudohalides are oriented in such a manner that they lie very close to one of the pyridine rings. This orientation thus facilitates the C–H···O(5)/N(9) type of hydrogen bonding. Also due to the close disposition of the fourth oxygen of the perchlorate ions to a pyridine ring of dpa, a weak C–H···O type of hydrogen bonding is also possible in both complexes. These weak bondings add to the stability of the crystal lattice.

3.3. Electrochemical studies

Cyclic voltammetry of the complexes was recorded in DMF solutions using platinum as the working electrode. A quasi-reversible oxidation response is observed at 0.60 V (**1**), 0.62 V (**2**), 0.65 V (**3**), 0.68 V (**4**), presumably due to the electrode reactions as shown in the following equations:

$$[Mn^{III}(dpa)_2(X)_2]^{1+} \underset{-e}{\overset{+e}{\rightleftharpoons}} [Mn^{II}(dpa)_2(X)_2] \quad (1)$$

$$[Mn^{III}(dpa)_2(X)(OH_2)]^{2+} \underset{-e}{\overset{+e}{\rightleftharpoons}} [Mn^{II}(dpa)_2(X)(OH_2)]^{1+} \quad (2)$$

Presence of a neutral water molecule in **3** and **4** in place of an anionic pseudohalide in **1** and **2** leads to an increase of the potential. The one-electron stoichiometry of couple 1 and 2 was confirmed by comparison of the current height with that of the manganese(II)–manganese(III) couple of other complexes [35].

3.4. Luminescence spectra

The spectroscopic data of all four complexes are listed in Table 9. Complexes with dpa, feature two intense absorptions at 315 nm, which is assignable to the intraligand π–π* transitions. The emission energy of complexes **1**–**4** in DMF solutions at 298 K are almost of similar value ($\lambda_{max} \sim 350$ nm) and are assignable to the intraligand fluorescence. The lifetimes of the fluorescence are within the range of 2.83–2.87 ns. In glassy solution (DMF at 77 K), $^3(\pi–\pi^*)$ phosphorescence has been observed at ~425 nm (Fig. 9) in all the complexes.

Table 9
Photophysical data for **1** to **4**

Sample	Absorption (λ/nm)	Emission (λ/nm)		Lifetime (ns)
		Fluorescence[a]	Phosphorescence[b]	
1	315	355	425	2.87
2	312	353	422	2.83
3	317	354	425	2.83
4	315	354	425	2.85

[a] DMF at room temperature (298 K).
[b] DMF at 77 K.

4. Conclusion

We have reported a homologous series based on manganese complexes of dpa ligand that contains aqua molecules either as a coordinating ligand or as water of crystallization, displaying strong hydrogen bonded networks. This study also shows the use of the N–H group of dpa as a strategy to harness hydrogen bonding with adjacent metal centres with potential proton acceptor site(s), resulting in different crystalline architectures. Difference in the disposition of the aqua ligand (within the coordination sphere or outside it) leads to different supramolecular networks [36]. The metal ions play a vital role in strengthening the hydrogen bonds by influencing the hydrogen bonding properties of donors and acceptors. So this work based on a $3d^5$ metal provokes us to further study new systems with different metal ions, dpa or dpa-like ligands and pseudohalides or other related units.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 209024 (**1**), 209026 (**2**), 209023 (**3**) and 209025 (**4**). Copies of this information can be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 IEZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www.ccdc.cam.ac.uk).

Abstract

The new mixed metal carbonyl clusters (μ_3-FcCHC)$FeCo_2(CO)_7$dppm (Fc = $C_5H_5FeC_5H_4$, ferrocenyl; dppm = $Ph_2PCH_2PPh_2$) (**1**), (μ_3-FcCHC)$FeCo_2(CO)_8$L [L = PPh_3 (**2**); $AsPh_3$ (**3**)] and (μ-FcC≡CH)$Co_2(CO)_5PPh_3$ (**4**) have been synthesized by facile substituted reactions. The crystal and molecular structures of **1**, **2** and **3** have been determined by single crystal X-ray analysis; the ligand dppm replaces two equatorial carbonyls from two $Co(CO)_3$ groups in the $FeCo_2$ core, and the ligands PPh_3 and $AsPh_3$ replace one equatorial carbonyl from a $Co(CO)_3$ group. The new compounds were characterized by IR, ^1H, ^{13}C, ^{31}P (for **1**, **2**) NMR and MS. The electrochemical properties for **1**, **2**, **3** and **5** were investigated and the results show that the replacement of CO alters the electron density on the cluster core $FeCo_2$ leading to a variety of interactions between $FeCo_2$ and the apical FcCHC, and making the Fe of the ligand FcCHC in clusters **1**, **2** and **3** turn into a redox center.

Keywords: Mixed metal cluster; Substituted reaction; Molecular structure; Ferrocenylacetylide

1. Introduction

The site-selective substitution reactions of mixed-metal carbonyl clusters have attracted a great deal of interest since the 1970s [1–3]. Previous studies have shown that the carbonyls bound to cobalt centers are more prone to nucleophilic substitution by two electron donor ligands than the carbonyls bound to the metals Fe and Ru [4,5]. Alkyne and alkynyl species bearing a C≡C functional group belong to a class of surface species which may play a pivotal role in various catalytic reactions such as CO hydrogenation [6,7]. Metal carbonyl clusters bearing ferrocenylacetylide have been demonstrated to possess interesting redox properties [8] and electrocommunication [9]. The incorporation of the ferrocenyl group into clusters through an organic conjugated bridge would lead to some interesting electrochemical properties because both the ferrocenyl group and the transition-metal clusters can function as redox centers of electron transfer entities [10]. The parent cluster (μ_3-FcCHC)$FeCo_2(CO)_9$ (**5**) was obtained by the reaction of (μ-FcC≡CH)$Co_2(CO)_6$ with $Fe_2(CO)_9$ [11]. Although the syntheses and structures of ferrocenylacetylenic cluster compounds have been studied in some detail [12–14], there is as yet no report on the substitution reactions of the parent cluster **5**.

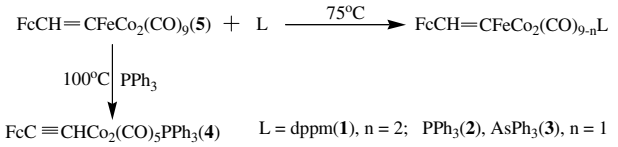
We describe here the preparation and structural characterizations of four new substituted derivatives of **5**. The crystal and molecular structures of **1**, **2** and **3** were determined by X-ray diffraction, and their electrochemical properties investigated by cyclic voltammetry.



2. Experimental

All reactions and manipulations were carried out using standard Schlenk techniques under an atmosphere of pure nitrogen. Solvents were purified, dried and distilled under a nitrogen atmosphere prior to use. Reactions were monitored by TLC. Chromatographic separations and purification were performed on 200–300 mesh silica gel. Dppm, PPh_3 and $AsPh_3$ were purchased from Fluka. The starting material (μ_3-FcCHC)$FeCo_2(CO)_9$ (**5**) was prepared according to the literature method [11]. The new mixed metal carbonyl clusters **1**, **2**, **3** and **4** have been synthesized by facile substituted reactions (see Scheme 1).

IR spectra were recorded on a Nicolet FT-IR spectrometer with KBr discs. Elemental analyses were carried out on an Elementar var III-type analyzer. $^1H(^{13}C)$ NMR spectra in $CDCl_3$ were recorded on a Jeol-Jnm-Al 300FT-MHz spectrometer. ^{31}P NMR spectra in CH_2Cl_2 were recorded on a Bruker AC-500 NMR spectrometer. The mass spectra were determined using a Micromass LCT instrument. The electrochemical properties were determined using a BAS 100A-type analyzer. Melting points were determined with a XT-4 melting point apparatus.

2.1. Synthesis of (μ_3-FcCHC)$FeCo_2(CO)_7$dppm (**1**)

A toluene solution of (μ_3-FcCHC)$FeCo_2(CO)_9$ (100 mg, 0.156 mmol), dppm (60 mg, 0.156 mmol) and 11 mg Me_3NO was stirred for 24 h at 75 °C. The solvent of the resulting dark-green mixture was removed under vacuum. The residue was dissolved in a minimal amount of chloroform and was subjected to chromatographic separation on a silica gel column (2.0 × 40 cm). Elution with a mixture of hexane–benzene (1:1, v/v) afforded a dark-green brand (**1**). Crystals of **1** were obtained by recrystallization from hexane–CH_2Cl_2 at −20 °C. Yield: 31%, m.p.: 225 °C (decomposed). *Anal.* Calc. for $C_{44}H_{32}Co_2Fe_2O_7P_2 \cdot CH_2Cl_2$: C, 51.47; H, 3.24. Found: C, 51.35; H, 3.07%. IR (KBr disk): *ν*(CO) 2040s, 1995s, 1979vs, 1961s, 1929s cm^{-1}. ^1H NMR ($DCCl_3$, *δ*): 7.18–7.40 (m, 20H, C_6H_5), 6.68 (s, 1H, ≡CH), 3.83–4.24 (m, 9H, C_5H_5, C_5H_4), 2.17 (s, 2H, CH_2). ^{13}C NMR ($DCCl_3$, *δ*): 189.0, 176.6 (CO); 129.0, 130.1, 131.7 (C_6H_5); 104.3 (–C≡C–); 69.0 (C_5H_5, C_5H_4); 44.4 (–CH_2–). ^{31}P NMR (CH_2Cl_2, *δ*): 52.45, 45.90 (br, dppm). MS (ESI) 937 (M^+–CO).

Scheme 1.

2.2. Synthesis of (μ_3-FcCHC)$FeCo_2(CO)_8PPh_3$ (**2**)

A toluene solution of (μ_3-FcCHC)$FeCo_2(CO)_9$ (100 mg, 0.156 mmol), PPh_3 (41 mg, 0.156 mmol) and 11 mg Me_3NO was stirred for 12 h at 75 °C. The solvent of the resulting dark-green mixture was removed under vacuum. The residue was dissolved in a minimal amount of chloroform and was subjected to chromatographic separation on a silica gel column (2.0 × 40 cm). Elution with a mixture of hexane–benzene (1:1, v/v) afforded a dark-green brand. The crystals of **2** were obtained by recrystallization from hexane–CH_2Cl_2 at −20 °C. Yield: 38%, m.p.: 155 °C. *Anal.* Calc. for $C_{38}H_{25}Co_2Fe_2O_8P$: C, 52.41; H, 2.87. Found: C, 52.67; H, 2.96%. IR (KBr disk): *ν*(CO) 2041s, 1996vs, 1985s, 1977vs, 1946s, 1911w cm^{-1}. ^1H NMR ($DCCl_3$, *δ*): 7.15–7.48 (m, 15H, C_6H_5), 6.77 (s, 1H, ≡CH), 4.03–4.28 (m, 9H, C_5H_5, C_5H_4). ^{13}C NMR ($DCCl_3$, *δ*): 128.7, 130.0, 130.5, 133.2 (C_6H_5); 101.9 (–C≡C–), 69.2, 69.5 (C_5H_5, C_5H_4). ^{31}P NMR (CH_2Cl_2, *δ*): 49.78 (br, PPh_3). MS (ESI) 870 (M^+).

2.3. Synthesis of (μ_3-FcCHC)$FeCo_2(CO)_8AsPh_3$ (**3**)

A toluene solution of (μ_3-FcCHC)$FeCo_2(CO)_9$ (100 mg, 0.156 mmol), $AsPh_3$ (48 mg, 0.156 mmol) and 11 mg Me_3NO was stirred for 16 h at 75 °C. The solvent of the resulting dark-green mixture was removed under vacuum. The residue was dissolved in a minimal amount of chloroform and was subjected to chromatographic separation on a silica gel column (2.0 × 40 cm). Elution with a mixture of hexane–benzene (1:1, v/v) afforded a dark-green brand (**3**). Crystals of **3** were obtained by recrystallization in hexane–CH_2Cl_2 at −20 °C. Yield: 38%, m.p.: 154 °C. *Anal.* Calc. for $C_{38}H_{25}Co_2Fe_2O_8As$: C, 49.91; H, 2.74. Found: C, 50.26; H, 2.98%. IR (KBr disk): *ν*(CO) 2065s, 2020vs, 2003s, 1985s, 1972s, 1959s cm^{-1}. ^1H NMR ($DCCl_3$, *δ*): 7.26–7.48 (m, 15H, C_6H_5), 6.84 (s, 1H, ≡CH), 4.19–4.26 (m, 9H, C_5H_5, C_5H_4). ^{13}C NMR ($DCCl_3$, *δ*): 209.5 (CO); 129.0, 130.3, 132.8 (C_6H_5); 101.7 (–C≡C–); 69.3 (C_5H_5, C_5H_4). MS (ESI) 914 (M^+).

2.4. Synthesis of (μ-FcCCH)$Co_2(CO)_5PPh_3$ (**4**)

Synthesis of **4** follows the procedure described for **2**, with the exception of at 100 °C for 6 h instead of 75 °C for 12 h.Compound **4**: Yield: 14%, m.p.: 131 °C. *Anal.*

Calc. for $C_{35}H_{25}Co_2FeO_5P$: C, 57.55; H, 3.42. Found: C, 57.24; H, 3.91%. IR (KBr disk): ν(CO) 2057m, 2001vs, 1963s cm^{-1}. ^1H NMR ($DCCl_3$, δ): 7.14–7.29 (m, 15H, C_6H_5), 5.40 (s, 1H, ≡CH), 3.33–4.48 (m, 9H, C_5H_5, C_5H_4). ^{13}C NMR ($DCCl_3$, δ): 128.5, 128.7, 132.1, 133.7 (C_6H_5); 101.6 (–C≡C–), 69.2, 69.9 (C_5H_5, C_5H_4). MS (ESI) 730 (M^+).

2.5. X-ray crystallography of the new clusters 1, 2 and 3

Crystal data were measured at 20 °C on a Bruker SMART 1000 CCD for **1** and on a Bruker SMART APEX CCD for **2** and **3** with graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. The cell refinement, data collection and reduction were done by Bruker SAINT and SMART [15]. An absorption correction based on SADABS was applied [16]. All structures were solved by direct methods [17]. All non-hydrogen atoms were refined by full matrix least-squares on F^2. Hydrogen atoms were located and refined by the geometry method. The structure solution and refinement were performed by SHELXSL97 [18]. The crystal data and details of measurements are summarized in Table 1.

3. Results and discussion

3.1. Synthesis and characterization of the new clusters

The reactions of the parent cluster **5** with dppm, PPh_3 and $AsPh_3$ ligands in toluene at 75 °C in the presence of trimethylamine oxide (Me_3NO) give the substituted derivatives (μ_3-FcCHC)$FeCo_2(CO)_7$dppm (**1**) and (μ_3-FcCHC)$FeCo_2(CO)_8L$ [L = PPh_3 (**2**); $AsPh_3$ (**3**)], respectively. The cluster (μ-FcC≡CH)$Co_2(CO)_5PPh_3$ (**4**) was obtained when the reaction temperature was accidentally increased up to 100 °C, and the same compound had been obtained by the replacement reaction of (μ-FcC≡CH)$Co_2(CO)_6$ with PPh_3 [19]. Trimethylamine oxide plays the role of an oxygen transfer agent and

accelerates the substitution reaction [20]. The IR spectra of **1–4** indicate characteristic absorption of the terminal carbonyl ligand in the region 2065–1929 cm^{-1}. In comparison with the IR spectrum of the parent cluster **5** (2095, 2056, 2042, 2023, 2001, 1973 cm^{-1}), the CO absorption of the new clusters shift to lower frequencies and this is consistent with the fact that dppm and L ligands are stronger σ-electron donors and weaker π-electron acceptors than CO. The ^{1}H, ^{13}C, ^{31}P NMR reflect there are FcC≡CH, PPh_3, $AsPh_3$ and dppm ligands in new clusters, respectively. The clusters **1**, **2** and **3** more easily dissolve in polar solvents such as THF, chloroform and toluene than in non-polar solvents, and the cluster **4** is soluble in both non-polar solvents such as hexane and in polar solvents.

3.2. Electrochemical properties of the clusters *1, 2, 3 and 5*

The electrochemical properties of the clusters **1**, **2**, **3** and **5** have been studied by cyclic voltammetry at 298 K in a standard three-electrode system with NEt_4ClO_4 in CHCN solution as the supporting electrolyte. The results are given in Table 2.

The i_{pa}/i_{pc} and ΔE data of Table 2 show the clusters **1**, **2** and **3** undergo a quasi-reversible one-electron oxidation at 0.66, 0.63 and 0.65 V, respectively, which is slightly less than that of their parent cluster **5**. The smaller $E_{1/2}$ values for **1**, **2** and **3** relative to that of their parent cluster **5** suggests that the ligands dppm, PPh_3 and $AsPh_3$ are stronger σ-electron donors than CO. The ΔE and $E_{1/2}$ data for the parent cluster **5** and ligand FcC≡CH indicate that in **5** the first peak at 0.52 V corresponds to an irreversible one-electron oxidation on the cluster core $FeCo_2$ [3] and the second peak at 0.69 V to a quasi-reversible one-electron oxidation on Fe of the ligand FcCHC (see Scheme 2).

The electrochemical data show that the reduction–oxidation on Fe of the ligand FcCHC becomes easier with the replacement of CO by PPh_3, $AsPh_3$ or dppm. The replacement of CO alters the electron density on the $FeCo_2$ cluster core, leading to an interaction between $FeCo_2$ and FcCHC, turning Fe of the latter into a reduction–oxidation center.

Scheme 2.

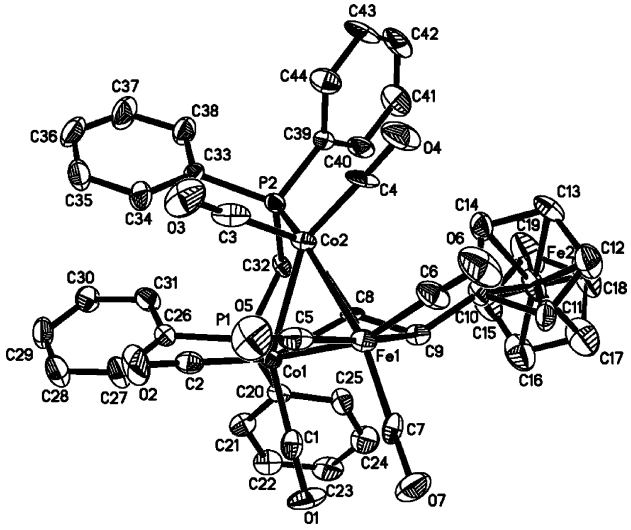

Fig. 1. Molecular structure of **1**.

3.3. Molecular structures of the clusters *1, 2 and 3*

Compounds **2** and **3** are isomorphous. The molecular structures of **1**, **2** and **3** were determined by X-ray single crystal analysis. Crystal data and relevant structural parameters are enumerated in Table 1. The structures, with the atom numbering scheme, of **1** and **3** are shown in Figs. 1 and 2, and selected bond lengths and angles are listed in Tables 3 and 4.

The molecular structures of **1** and **3** are similar to that of the parent cluster **5** [11], that is based on a ferrocenylacetylenic unit $FcC_BH{=}C_A$ and a $FeCo_2$ cluster core. The replacement of CO leads to a variety of interactions between the $FeCo_2$ cluster core and the ferrocenylacety-

lenic unit in which the C_A–Co bond and C_B–Fe bond are slightly shorter than that of the parent cluster **5**. The pair of Co–Fe bonds and a Co–Co bond constitute an isosceles triangle. The C_A–Co(1) and C_A–Co(2) bond lengths (1.871 and 1.880 Å for **1**; 1.873 and 1.869 Å for **2**; 1.878 and 1.867 Å for **3**) are nearly equal, which is different from those of the parent cluster **5** (1.86 and 1.91 Å). The triangle C_ACo(1)Co(2) is also an isosceles triangle. The Fe–C_A and Fe–C_B (1.975 and 2.274 Å for **1**; 1.969 and 2.260 Å for **2**; 1.966 and 2.251 Å for **3**) bond lengths show that the apical $FcC_BH{=}C_A$ group is attached to the $FeCo_2$ core in coordination mode **A** rather than **B** or **C** (see Scheme 3). In **4** the coordination of the ferrocenylacetylenic unit $FcC_B{\equiv}C_AH$ with Co-Co adopts the **D** mode [19]. The C_A–C_B bond lengths of the apical $FcC_BH{=}C_A$ group in **1** (1.373 Å), **2** (1.376 Å) and **3** (1.362 Å), that is close to a C=C double bond, are longer than that in the parent cluster **5** (1.35 Å), which indicates the reinforcing interaction between Fe and the $C_A{=}C_B$ group. The Co(2)–As bond length (2.3324 Å) in **3** is longer than the average Co–P bond length (2.2208 Å) in **1** and **2** as expected from the different covalent radii of arsenic (1.21 Å) and phosphorus (1.10 Å). The new clusters **1**, **2** and **3** each have 48 cluster valence electrons in accordance with Lauher's rule.

Abstract

Two hydrogen-bonded palladium(II) and platinum(II) complexes, [Pd(Hida)$_2$] (**1**) and [Pt(Hida)$_2$] (**2**) (Hida$^-$ = iminodiacetate), have been synthesized and characterized by single crystal X-ray diffraction analyses. Hida$^-$ serves as a bidentate ligand coordinating to both Pd(II) and Pt(II) through its nitrogen and oxygen atom, exhibiting a square planar geometry with a *trans* configuration. The uncoordinated carboxylic group and the imino group of the ligand are involved in strong intermolecular hydrogen bonding to form a two dimensional layered network in both the complexes. The network is propagated along the *ac*-plane and stacks orthogonally to the *b*-axis. The thermogravimetric analyses for complexes **1** and **2** reveal stepwise decomposition processes indicating the probable decarboxylation of the free and bonded carboxylates. As there are two types of hydrogen bonding (N–H···O, O–H···O) present in both the complexes, two endothermic peaks regarding heat change are evident from their DSC diagrams.

1. Introduction

In the context of supramolecular assembly and crystal engineering, various types of interaction are being exploited to build up multi-dimensional networks [1–3]. Such compounds attain a special place due to their potential applications in the field of catalysis [4], non-linear optics [5,6], electrical conductivity [7], biological recognition [8] and molecular sieves [9]. A wide variety of extended networks can, however, be obtained by connecting metal complexes via non-covalent forces, e.g., strong (O–H···O, N–H···O) and weak (C–H···O) conventional H-bonds [10]. Infinite complexes involving acyclic and macrocyclic frameworks are often assembled through metal coordination of suitable bridging ligands [11]. The assembly process of these frameworks is highly influenced by a number of factors, e.g., the coordination nature of metal ions, the structural and functional characterization of organic ligands, the nature of the solvent, temperature and pH of the medium, the metal–ligand ratio, template and counter ions [12–14]. A subtle alteration in any of these factors might result in new complexes with different structural topologies and functions.

Smith and Sawyer [15,16] have reported several 1:1 and 1:2 complexes of iminodiacetic acid (H_2ida) with Pd(II) and Pt(II). In the 1:1 complexes, H_2ida functions as a tridentate (N,O,O′) ligand with a chloride ion occupying the remaining site of the square-planar Pd(II) and Pt(II) centers. The 1:2 complexes are assigned the *trans* configuration, with each ligand forming one acetate ring. The results of a detailed study of their proton NMR spectra in D_2O as a function of pH and temperature have been summarized. Infrared spectra of the complexes have been measured to characterize their structures further. These complexes have not, however, been crystallographically characterized. Considering that carboxylic group ligands might adopt various coordination modes, and the proton in the carboxylic acid might be controlled by minor variation in reaction conditions, we have extended the study of complex formation of Pd(II) and Pt(II) with iminodiacetic acid which might assume supramolecular structures via both coordinate covalent bonds and hydrogen bonds as the building blocks. The successful synthesis and crystal structure elucidation of the complexes [Pd(Hida)$_2$] (**1**) and [Pt(Hida)$_2$] (**2**) have been achieved by us following a different route. The thermal behavior of the complexes has been studied by TG–DSC techniques that further support the extended layer structures formed through intermolecular hydrogen bonding interactions in the complexes.

2. Experimental

2.1. Materials

Palladium chloride ($PdCl_2$) and potassium tetrachloroplatinate(II) used in the palladium and platinum complexes were obtained from Arora-Matthey Limited (India). Potassium chloride and sodium hydroxide were purchased from Merck. Potassium tetrachloropalladate(II) was prepared by the reaction of $PdCl_2$ and KCl. Iminodiacetic acid was a Sigma product. Double distilled water was used throughout.

2.2. Physical measurements

Elemental analyses were carried out in a 2400 Series-II CHN analyzer, Perkin–Elmer, USA. IR spectra were recorded in a Nicolate Magna IR 750 Series-II IR spectrophotometer. The ^{1}H NMR spectra were recorded on a 300 MHz Bruker Avance DPX 300 machine, Switzerland in D_2O solvent with TMS as the internal standard. The TGA was done by a Mettler Toledo TGA/SDTA 851^e system. DSC was recorded on a Perkin–Elmer DSC 7 instrument. FAB mass spectra were recorded on a Fisons VG Autospec mass spectrometer with 3-nitrobenzyl alcohol as the matrix.

2.3. Synthesis of the compounds

2.3.1. Preparation of the monosodium salt of iminodiacetic acid, NaHida

Iminodiacetic acid (0.9 g, 7 mmol) was suspended in a minimum volume of water. To this mixture, NaOH (0.3 g, 7 mmol) was added and dissolved in 10 cm^3 water. The mixture was stirred magnetically for 30 min at 50 °C. The solution was then filtered to remove any suspended material. To the filtrate dehydrated ethanol was added slowly, thereby yielding the white crystalline monosodium salt of iminodiacetic acid, NaHida. It was filtered off and dried in air. Yield 80% (0.87 g). *Anal.* Calc. for $C_4H_6NO_4Na$: C, 30.9; H, 4.0; N, 9.0. Found: C, 30.8; H, 4.1; N, 9.2%.

2.3.2. Synthesis of trans-[Pd(Hida)$_2$] (*1*)

K_2PdCl_4 (0.1 g, 0.3 mmol) was dissolved in 15 cm^3 double distilled water to give a brown solution. To this solution, NaHida (0.05 g, 0.3 mmol) was added and dissolved in 10 cm^3 of double distilled water. The color changed from deep brown to yellow. The solution was stirred for 30 min, filtered to remove any suspended material and kept at room temperature for 5 days to produce pale yellow crystals of complex **1**. The crystals were filtered off, washed with water and then dried in air. The yield was 40% (0.013 g) based on Pd. *Anal.* Calc. for $C_8H_{12}N_2O_8Pd$: C, 25.9; H, 3.2; N, 7.6. Found: C, 25.8; H, 3.3; N, 7.3%.

2.3.3. Synthesis of trans-[Pt(Hida)$_2$] (*2*)

K_2PtCl_4 (0.1 g, 0.25 mmol) was dissolved in 15 cm^3 double distilled water to give a red solution. To this solution, NaHida (0.04 g, 0.25 mmol) was added and dissolved in 10 cm^3 of double distilled water. The color changed from red to light yellow. The solution was stirred for 30 min, filtered to remove any suspended material and kept at room temperature for 3 days to produce yellowish white crystals of complex **2**. The crystals were filtered off, washed with water and then dried in air. The yield was 50% (0.024 g) based on Pt. *Anal.* Calc. for $C_8H_{12}N_2O_8Pt$: C, 20.9; H, 2.6; N, 6.0. Found: C, 20.8; H, 2.7; N, 6.1%.

2.4. Crystal structure determination and structural refinement of complexes *1* and *2*

Single crystals of both **1** and **2** were grown from water. These were then mounted on, respectively, a Siemens P4 4-circle-diffractometer and an Oxford Diffraction Sapphire 2-CCD, both of which were equipped with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Unit cell dimensions and intensity data were measured at 293 K for both **1** and **2**. The structures were solved by direct methods and refined by full-matrix least-squares based on F^2 with anisotropic

thermal parameters for non-hydrogen atoms using SHELXS-97 [17] (structure solution) and SHELXL-97 [18] (structure refinement). The hydrogen atoms were included in structure factor calculations at their idealized positions. Information concerning crystallographic data collection and refinement of the structures is summarized in Table 1.

3. Results and discussion

3.1. Synthesis and spectroscopic characterization of the complexes

It is worthy to note that the present methods of synthesis for both complexes are significantly different from those adopted by Smith and Sawyer [15,16] for the 1:2 complexes of palladium(II) and platinum(II) with iminodiacetate. The starting material for the palladium complex was palladium(II) nitrate, which was reacted with a twofold excess of iminodiacetic acid by warming briefly on a steam bath. The preparation of the corresponding platinum(II) complex involves heating an aqueous solution of K_2PtCl_4 with a fourfold excess of the ligand for several hours (>5).

Significant IR bands (KBr): 1586 sb (ν_{COO^-}) and 1734 sb (ν_{COOH}) cm^{-1} for **1**; 1598 sb and (ν_{COO^-}) 1734 sb (ν_{COOH}) cm^{-1} for **2**.

The ^{1}H NMR spectrum of NaHida in D_2O exhibits two singlets at 2.14 and 3.56 ppm. These correspond to N–H and the four protons of two $-CH_2$ groups, respectively. The ^{1}H NMR spectra of **1** and **2** were recorded in D_2O with TMS as an internal standard at 24 °C. The spectrum of **1** consists of two equally intense peaks with an AB pattern at 3.52 and 3.58 ppm (J_{AB} = 18.0 Hz) and a singlet at 3.22 ppm. The AB pattern, for the two types of acetate proton, and the singlet are assigned to the ring and free acetate protons, respectively, of the *trans* isomer.

The proton NMR spectrum of **2** also exhibits an AB pattern (δ_A = 3.99 ppm, δ_B = 3.97 ppm, J_{AB} = 6.8 Hz) for the ring acetate protons (J_{Pt-HA} = 7.05 Hz, J_{Pt-HB} = 6.78 Hz) and a singlet at 3.22 ppm for the free acetate protons. It may be noted that in neither of the spectra for **1** and **2**, could a N–H resonance or H–N–C–H coupling be noted owing to rapid N–H proton exchange.

The FAB mass spectra show single peak for each of the compounds. The one for the palladium(II) complex exhibits a mass peak centerd at *m*/*z* 371 (100%) $[M + H]^+$; this corresponds to a monomeric formulation based on ^{106}Pd. In the same way, the platinum(II) complex displays a peak at *m*/*z* 460 (100%) $[M + H]^+$ corresponding to a monomer based on the ^{195}Pt isotope.

3.2. Description of the structures of trans-[Pd(Hida)$_2$] and trans-[Pt(Hida)$_2$]

The crystal structure and atomic numbering scheme of *trans*-[Pd(Hida)$_2$] are shown in Fig. 1. Selected bond lengths and angles are given in the tables. As the data show, these molecules are mononuclear complexes with

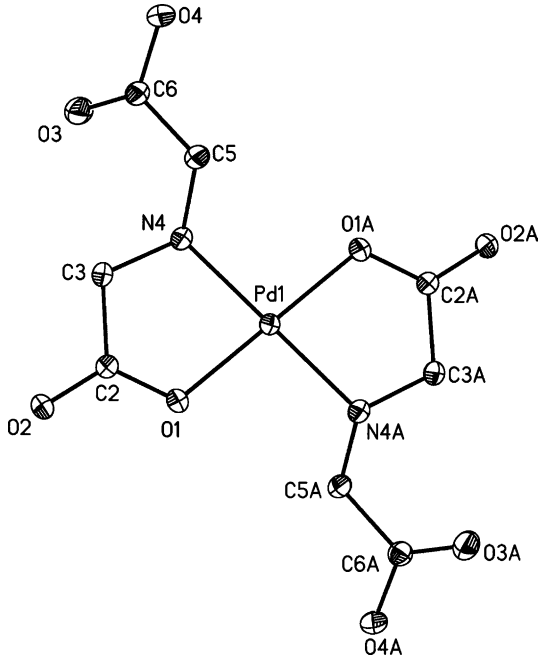

Fig. 1. ORTEP view of *trans*-[Pd(Hida)$_2$] (**1**), showing 30% probability thermal ellipsoids and the numbering scheme. H atoms are omitted for clarity.

a square planar coordination geometry around the Pd/Pt atom. The metal atom is located in the plane of two nitrogen (*trans*-N,N) and two oxygen atoms (*trans*-O,O) of the ligand molecules. The average Pd–N bond length in **1** is 2.061(4) Å, which is considerably larger than the value usually noted [19–21]. A comparable value of 2.059 Å is reported for the Pd(II) macrocycle having the 2-imino-4-thiobiuret [22] ligand, and the deviation might be attributed to the fact that the imino function is involved in hydrogen bonding. On the other hand, normal Pt–NH_2R bonds are in the range 2.03–2.06 Å [23–25] and match well with that observed here. The Pd–O and Pt–O distances (1.988(4) and 2.014(9) Å) are close to the literature values [21,26,27]. The O1–Pd1–O1a (a = $1-x$, $-y$, $-z$) and N4–Pd1–N4a bond angles are strictly 180°. The O1–Pd1–N4 bond angles of 84.1(2)° (83.6(3)° for **2**) within the chelate rings are normal compared to reported values [26,27]. It may be noted that in either of the complexes, the metal–nitrogen bond length is longer than that of the metal–oxygen, reflecting the greater *trans* influence of the N-atom compared to the O-atom of the ligand.

Fig. 2 shows the molecular packing for complex **1**, comprising of an infinite 2D chain in which the molecules in the crystal are held together by a system of hydrogen bonding. This packing is clearly affected by the intermolecular hydrogen bonding occurring between O4–H4···O2k (k = $1+x$, $1/2-y$, $-1/2+z$) and N4–H41···O2c (c = $1-x$, $-1/2+y$, $-1/2-z$) which is responsible for the conformation and stability of the layered network. This network lies in the *ac*-plane and stacks orthogonally to the *b*-axis. To achieve internal charge balance, the non-coordinated oxygen atoms O4 of each carboxylate group must be protonated (hydrogen atoms H4). The O2 atoms of the iminodiacetate groups of both **1** and **2** provide a hydrogen bond acceptor site for the hydrogen atoms H4 and H41 (from N4) from a neighboring formula unit. Other weak intermolecular hydrogen bonds C3–H31···O1h (h = x, $1/2-y$, $-1/2+z$), C3–H32···O3e (e = x, $1/2-y$, $1/2+z$) and C5–H51···O1a occur in complexes **1** and **2**. These are listed in Tables 2 and 3, with the widely accepted criteria that hydrogen bonds should be less than the sum of van der Waals radii of H and the acceptor atom. The values are comparable with those in other palladium and platinum complexes [20]. The shortest distance between two

Pd(II) centers lying in two adjacent sheets is 6.82 Å while that for the Pt(II) analogue is similar. The double layers of the complexes are held together by weak van der Waals' forces.

3.3. Thermal studies

The TGA diagram (Fig. 3) of complex **1** clearly shows three weight loss steps. The first mass loss in the region 220–260 °C corresponds to the loss of two CO_2 molecules from the free carboxylic acid groups of the complex. The observed weight loss of 23.76% is in agreement with the calculated one (23.74%). The second step (260–325 °C) is a composite one corresponding to the decarboxylation of the bound carboxylate and the –NH– groups. The third step (325–380 °C) involves complete decomposition of the complex. The final product is PdO. The total weight loss of 68.2% matches fairly with the calculated one (67.0%). The TGA curve of complex **2** indicates two main weight losses. The first one from 180 to 310 °C corresponds to the decarboxylation of the complex along with some organic decomposition indicating an observed weight loss of 29.4%. The second weight loss from 310 to 340 °C corresponds to the burning of the organic groups with a weight loss of 30.9%. The total weight loss of 60.4% matches with the calculated one (60.0%) if the final product is assumed to be undecomposed *trans*-[Pt(Hida)$_2$]. It is evident from this fact that the decomposition process is not complete.

The DSC thermogram of **1** at ambient pressure has been shown in Fig. 4. The thermogram clearly shows two endothermic peaks, which may indicate the presence of two types of intermolecular hydrogen bond in the complex. In the temperature range 83–116 °C, the peak temperature is 95.5 °C with $\Delta H = -0.56$ J g^{-1}. The other peak shows a heat change ($\Delta H = -0.58$ J g^{-1}) at the peak temperature 156.1 °C in the range 133–182 °C. It is obvious that the first heat change at the lower temperature corresponds to the dislodging of hydrogen bonds of the N4–H41···O2c linkage (H41···O2c = 2.29/2.30 Å) and the second one of the O4–H4···O2k linkage (H4···O2k = 1.84/1.85 Å). In the DSC diagram of complex **2** there are also two endothermic peaks, one with $\Delta H = -0.54$ J g^{-1} at the peak temperature 87.4 °C, and the other having $\Delta H = -0.87$ J g^{-1} at 160.5 °C. Due to the decrease of cell volume, the high-temperature molecular framework of both crystals is more compact, making the transition irreversible. This implies that the non-covalent (H-bonding) interaction plays a significant role in the formation of the 2D infinite sheet-like structure of the complexes.

Abstract

The synthesis and characterisation by solid-state ^{111}Cd NMR of Cd(2,3-), Cd(2,4-), Cd(2,5-) and Cd(2,6-pyridinedicarboxylato)$\cdot x H_2O$ is reported. Results indicate that the ^{111}Cd NMR signal is very sensitive to the relative position of both carboxylates. Similar shifts (at 54.0 and 55.4 ppm) are found for the 2,4- and the 2,6-isomers where the carboxylates groups are *meta* to each other. For the 2,3- and 2,5-derivatives (carboxylates in *ortho* and *para* positions), the signals are detected at 119.6 and 84.2 ppm. The crystal and molecular structure of the seven-coordinated cadmium complex, $[Cd(2,4\text{-pyridinedicarboxylato})(H_2O)_3]\cdot 1/2H_2O$ is also reported. This data allows a correlation between Cd–O and Cd–N coordination and geometry with ^{111}Cd chemical shifts. Additional coupling between ^{111}Cd and ^{14}N in 2,3- (also found in 2,4-pydc) suggests only one N is coordinated to Cd. The anisotropy magnitude, $\Delta\sigma$, and the asymmetry parameter, η, are also analysed.

1. Introduction

Metal pyridinedicarboxylates have interesting properties in biological systems [1–4], and their presence seems to be related with metal-transport and cell membrane protection in some microorganisms [5,6]. These compounds are derived from pyridinedicarboxylic acids (H_2pydc) that form a series that includes the 2,3-, 2,4-, 2,5- and 2,6-pyridinedicarboxylic isomers. Cadmium forms 1:1 complexes with all four isomers and it may exhibit various coordination modes, depending on the relative position of the donor sites: the oxygen atoms from the two carboxylic groups and the nitrogen atom from the pyridinic ring. Because of the donor sites and the variety in relative positions, metal pyridinedicarboxylates may provide excellent models for less characterised samples of biological interest.

^{111}Cd NMR (more commonly ^{113}Cd NMR) spectroscopy is a sensitive probe of the Cd environment as the number and type of coordinating groups and the geometry around the metal ion can be correlated with the ^{111}Cd chemical shift. This signal is highly sensitive to oxygen

doi:10.1016/j.poly.2005.02.007

and nitrogen atom coordination, and the technique is particularly useful in the study of biological compounds of different complexity. Furthermore, Cd(II) may be exchanged for other divalent metals, such as Zn(II), Ca(II), Cu(II) or Mg(II) in several biological compounds and thus this spectroscopic method provides a route for the study of a large variety of ligand–metal environments [7]. Also, some groups have been using ^{113}Cd NMR as a ''spin spy'' in Zn containing proteins, where the strategy is to replace Zn with Cd and use NMR to explore the metal environment in the protein [7,8].

When NMR spectroscopy data is collected in solution, the correlation between cadmium chemical shifts and the coordination number is pH and concentration dependent. On the contrary, solid-state NMR data overcomes the problems associated with the dynamics of fluid systems [9] and adds the advantage of providing the three principal components of the shielding tensor [10,11], rather than the average value normally obtained in solution. Thus, the chemical shift tensor obtained in the solid state is highly sensitive to the local environment of Cd atoms. The technique may be applied to insoluble compounds and the measured data may be correlated with crystallographic information, and structural predictions can be made for compounds of unknown structural characteristics.

In the present work, as a part of a general study of metal(II) pyridinedicarboxylates, we present the synthesis and the determination of the ^{111}Cd chemical shift by CP-MAS NMR under isotropic conditions of the insoluble 1:1 cadmium derivatives of the 2,3-; 2,4-; 2,5 and 2,6-pyridinedicarboxylic acids. We also report the main components of the ^{111}Cd chemical shift tensors using ^{111}Cd CP NMR under static rotor conditions. The crystal structure of [Cd(2,4-pyridinecarboxylato)-$(H_2O)_3$]·1/2H_2O is also presented, thus providing a good example for correlating Cd–O and Cd–N distances and geometry with ^{111}Cd chemical shift.

2. Experimental

2.1. Materials and characterisation of the solids

The ligands 2,3-; 2,4-; 2,5- and 2,6-pyridinedicarboxylic acid (Fluka Products) as well as all the other reagents (analytical-grade purity) were used as provided. Water was purified by a Millipore Milli-Q system yielding 18 MΩ cm. Elemental analyses (C, H, N) was performed on a Carlo Erba EA 1108 microanalyser. Water content in the samples was obtained from thermogravimetric analyses obtained using Shimadzu TGA-51H equipment with powdered samples of about 25 mg under an inert (N_2) atmosphere (temperature range 25–650 °C). Powder XRD data were collected on a Siemens D5000 diffractometer using graphite monochromated Cu Kα radiation.

All the compounds were prepared by adding 4 mL of a NaOH solution (1 M) and 2 mL of a $CdCl_2$ solution (1 M) to a suspension of each pyridinedicarboxylic acid (2.0×10^{-3} mol) in 100 mL of bidistilled water. The solids were obtained by slow evaporation of the solutions at 298 K; the colourless crystals formed were collected by filtration and washed with bidistilled water. Only crystals of the 2,4-pydc derivative were suitable for crystal structure determination.

Compound **1** *(Cd(2,3-pydc)·3H_2O)*. Calc. for $Cd(C_7H_3NO_4)\cdot 3H_2O$: C, 25.34; H, 2.71, N, 4.22; H_2O, 16.29. Found: C, 25.42; H, 2.85; N, 4.29; H_2O, 16.53%.

Compound **2** *(Cd(2,4-pydc)·3.5H_2O)*. Calc. for $Cd(C_7H_3NO_4)\cdot 3.5H_2O$: C, 24.67; H, 2.94, N, 4.11; H_2O, 18.51. Found: C, 24.84; H, 3.07; N, 4.30; H_2O, 19.30%.

Compound **3** *(Cd(2,5-pydc)·2H_2O)*. Calc. for $Cd(C_7H_3NO_4)\cdot 2H_2O$: C, 26.80; H, 2.23, N, 4.46; H_2O, 11.48. Found: C, 27.23; H, 2.36; N, 4.73; H_2O, 11.76%.

Compound **4** *(Cd(2,6-pydc)·1.5H_2O)*. Calc. for $Cd(C_7H_3NO_4)\cdot 1.5H_2O$: C, 27.59; H, 1.97, N, 4.59; H_2O, 8.86. Found: C, 27.66; H, 2.15; N, 4.73; H_2O, 8.81%.

3. Crystallography

X-ray measurements were made at 293(2) K on an Enraf-Nonius CAD-4 diffractometer with graphite-monochromated Mo Kα radiation (λ: 0.71073 Å) operating in a ω–2θ scanning mode, 3107 reflections were collected. Accurate unit cell parameters were determined from least-squares refinement of the $[(\sin\theta/\lambda)]^2$ values of 25 reflections in the 2θ range 22.08–35.38° (scan width $0.8 + 0.35\tan\theta$). Corrections for Lorentz-polarisation factors were applied to the intensity values. Absorption corrections were applied (maximum and minimum transmission factors of 0.867 and 0.708) [12]. The structure was solved by Patterson and Fourier methods and the final molecular model obtained by anisotropic full-matrix least-squares refinement of non-hydrogen atoms. Data reduction and correction structure solution and refinement programs used were SDP [13], SHELX-76 [14], SHELX-86 [15] and SHELX-93 [16]. The refinement method was full-matrix least-squares on F^2. The samples were colourless thin crystal plates, of about $0.08 \times 0.16 \times 0.20$ mm^3 that diffracted poorly. Only about 48% of the X-ray intensity data up to 0.76 Å resolution were above two standard deviations of measurement errors. All the H-atoms in the aromatic ring and four H-atoms of the bonded-to-Cd water hydrogen atoms were located in a difference Fourier map. However, only the pyridinic hydrogen atoms were included in the final model positioned on a stereochemical basis. They were refined with the riding model employing a common iso-

Supplementary material available: table of atomic coordinates, anisotropic thermal parameters, bond lengths and angles, hydrogen atom positions and H-bond distances and calculated and observed structure factor amplitude. Crystallographic data and processing parameters are summarised in Table 1.

4. Cadmium-111 NMR spectroscopy

The ^{111}Cd solid-state NMR spectra of compounds **1**–**4** were recorded on a VARIAN Unity-plus 300 MHz spectrometer using cross-polarisation (CP), magic-angle spinning (MAS) and high power dipolar decoupling. $Cd(CO_3)$, (−30 ppm) was used as a reference [17]. The sample was inserted into a 7 mm silicon nitride rotor. In a typical collection of the isotropic spectra, the relevant parameters employed were: spin rate 5000 Hz, contact time of 2.0 ms, delay time of 4 s, between 258 and 1032 scans were recorded. 7.8 μS of pulse width (90° pulse). For static measurements, the number of scans were increased to a minimum of 6000. All other parameters were kept as previously described.

5. Results and discussion

5.1. Crystallographic structural results

The solid is polymeric and crystallises in the centrosymmetric space group *Pbna*. Selected bond lengths and angles are grouped in Table 2. Fig. 1 is an ORTEP [18] drawing of the complex showing the labelling of the non-hydrogen atoms and their displacement ellipsoids. To complete the environment around Cd(II) and to show the connectivity of the polymeric structure in the unit cell, a symmetry related $[Cd(II)(2,4\text{-pydc})(H_2O)_3]$ molecule through the glide plane operation $x - 1/2$, y, $1/2 - z$ has been included in the plot.

The Cd(II) ion is seven-coordinated by two 2,4-pyridinedicarboxylate groups and three water molecules; an interstitial H_2O molecule, O(4W) is not bounded to Cd. The coordination polyhedron exhibits a geometry that can be described as a distorted pentagonal bipyramid. The equatorial plane is formed by a nitrogen atom and one oxygen (O(4)) from the 2-carboxylate group of the aromatic ring, two oxygen atoms (O(3)′ and O (4)′) both from a neighbouring 2-carboxylate group and an oxygen (O(3W)) from a water molecule. Two H_2O li-

Symmetry transformations used to generate equivalent atoms: (#1) $x - 1/2$, y, $-z + 1/2$; (#2) $x + 1/2$, y, $-z + 1/2$.

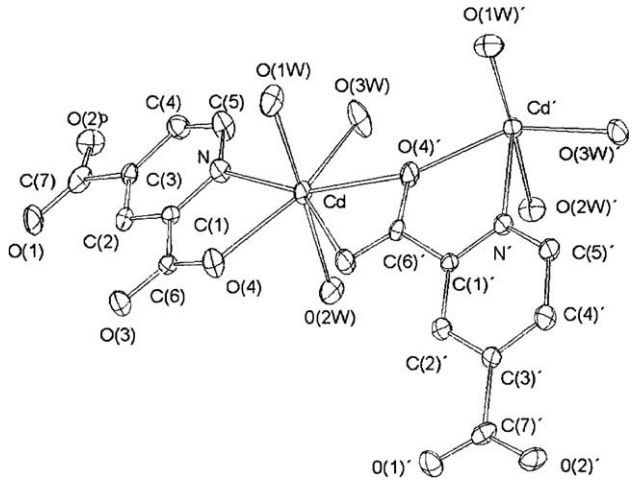

Fig. 1. ORTEP drawing of $[Cd(2,4\text{-pydc})(H_2O)_3]\cdot 0.5H_2O$ showing the non-H atoms labelling and their displacement ellipsoids at 30% probability. The crystallisation water molecule is not included in the plot.

gands, O(1W) and O(2W), are found in the axial positions. The equatorial plane around Cd presents an elongation in the Cd–O(4) direction as shown by the distances Cd–O(3W) = 2.305(5) Å, Cd–N = 2.366(6) Å, Cd–O(3′) = 2.364(5) Å and Cd–O(4) = 2.567(5) Å.

Although several other polymeric hepta-coordinated cadmium(II) carboxylate complexes have been reported, the more striking feature of this compound is that neither of the two oxygen atoms from the 4-carboxylate group are bonded to the metal ion, forming a pendant $-RCOO^-$ group. This fact is perhaps responsible for the formation of zigzag chains of –Cd(II)–O(4)–Cd(II)– in which the Cd(II) ions are bonded through its equatorial planes (see Fig. 2), thus determining a polymeric structure where the chains run approximately in the crystallographic *a*-direction (angle Cd–O(4)–Cd#2 = 151.1(2)°). Similar Cd–O–Cd links have been found in some parts of the structures of the three-dimensional polymeric compounds cadmium(II) malonate monohydrate [19], cadmium diacetate [20] and cadmium maleate [21,22].

The pyridinic ring and the carboxylate groups in the 2- and 4-positions are almost coplanar (angle O(2)–C(7)–C(3)–C(4) = 6.7° and angle O(4)–C(6)–C(1)–N = 6.4°), the organic moieties are arranged in layers, which are parallel to the (*ac*)-crystallographic plane. The C–O bond lengths in the 2-carboxylate are shorter than in the pendant 4-carboxylate, compare distances C(6)–O(3) = 1.235(8) Å and C(6)–O(4) = 1.240(8) Å with distances C(7)–O(1) = 1.243(7) Å and C(7)–O(2) = 1.254(8) Å, respectively; angles are also smaller, angle in 2-carboxylate O(3)–C(6)–O(4) = 123.9(6)° and angle in 4-carboxylate O(1)–C(7)–O(2) = 126.8(7)°, this may be attributable to the fact that the carboxylate in the 4-position is not coordinated to Cd thus it is supporting a larger electronic density.

Interaction between layers is mainly through hydrogen bonds provided by the interstitial O(4W) water molecule that bridges the O(1) from one layer to the O(3W) from a layer below. The O(4W) is on a two fold rotation axis, distances and angle in the bridge are, O(4W)–O(3W) = 2.826(6) Å, O(4W)–O(1) = 2.735(7) Å and O(3W)–O(4W)–O(1) = 105.7(2)°. Hydrogen bonding among layers is completed through O(3W) interaction with O(3) and O(4W) and O(1) and O(2) with axial groups O(W1) and O(W2).

5.2. Cadmium-111 NMR spectroscopy

The CP MAS ^{111}Cd NMR spectra of the powdered samples are shown in Fig. 3. The resonance signals for the compounds Cd(2,3-), Cd(2,4-), Cd(2,5-) and Cd(2,6-pydc)·$x$$H_2O$, are detected at 119.6, 54.0, 84.2 and 55.4 ppm, respectively. Similar shifts at lower frequencies, 54.0 and 55.4 ppm, are measured for the 2,4- and the 2,6-isomers (the carboxylates groups are *meta* to each other); whereas shifts measured at 119.6 and 84.2 ppm, differ considerably for the 2,3- and 2,5-derivatives (the carboxylates groups are *ortho*- and *para*-, respectively). Also, a splitting of the signal is detected for the 2,3- and 2,4-pydc derivatives. This fact is due to a quadrupolar interaction and scalar coupling between ^{111}Cd and ^{14}N (I(^{111}Cd) = 1/2 and I(^{14}N) = 1) that are not completely removed by magic-angle spinning.

According to Olivieri et al. [23], the signal resulting from ^{111}Cd quadrupolar coupled to ^{14}N with MAS is a doublet with a splitting of

$$S_1 = \frac{9\chi D}{20Z}\left(3\cos^2\beta_{CdN} - 1 + \eta\sin^2\beta_{CdN}\cos 2\alpha_{CdN}\right),$$

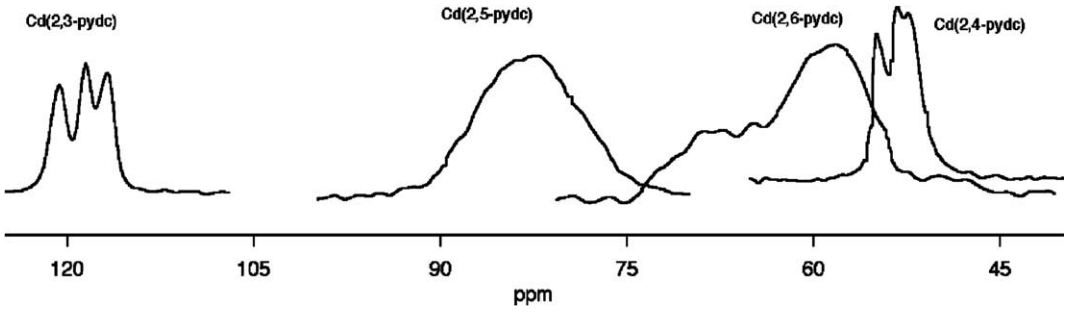

Fig. 3. CP-MAS ^{111}Cd NMR spectra of the cadmium complexes with the different 2,*x*-pyridinedicarboxylates. The splitting due to residual dipolar and the J coupling between ^{111}Cd and ^{14}N is observed in the 2,3-pydc and 2,4-pydc complexes.

where $D = \gamma_{Cd}\gamma_N h/4\pi^2 r^3$ is the dipolar coupling between ^{111}Cd and ^{14}N, Z is the Zeeman energy of ^{14}N, χ is the quadrupole coupling constant, η is the asymmetry in the quadruple coupling tensor, and α and β are the polar and azimuthal angles that define the orientation of the Cd–N bond with respect to the principal axis of the electric field gradient tensor. The magnitude of the splitting is strongly dependent on the internuclear Cd–N distance.

When, in addition to the dipolar (and quadrupolar) interaction, the z-direction of the J tensor and the internuclear direction of Cd–N are coincident, a new contribution from the anisotropy of the J tensor (called J-coupling) is also detected, and an additional ΔJ term must be included in the previous equation [24]:

$$S = \frac{9\chi(D - \Delta J/3)}{20Z}\left(3\cos^2\beta_{CdN} - 1 + \eta\sin^2\beta_{CdN}\cos 2\alpha_{CdN}\right).$$

Thus, if a nitrogen atom is coordinated to only one cadmium atom, a splitting into three signals with separations of $J + S$ and $J - S$ may be observed. The observation of this splitting of the signal gives an immediate determination of the number of bonded nitrogen atoms.

The triplets detected in the 2,4-pydc and 2,3-pydc derivatives confirm that both compounds present the Cd atom coordinated to only one N. This result agrees with the crystal structure resolution of [Cd(2,4-pydc)-$(H_2O)_3$]·1/2H_2O (this paper), where the Cd atom is hepta-coordinated (vide supra) and with preliminary structural studies on Cd(2,3-pydc)·3H_2O [25] that show the Cd ion is hexa-coordinated in a trigonal antiprismatic geometry, surrounded by one N, two O (from different carboxylate groups) and three water molecules.

The measured J-coupling between ^{111}Cd and ^{14}N are J_{Cd-N} = 87.8 Hz, S = 22.8 Hz and J_{Cd-N} = 123.5 Hz, S = 19.5 Hz for the 2,4-pydc and 2,3-pydc, respectively. These data indicate a stronger coupling in the 2,3-derivative and consequently a shorter Cd–N distance (calculated Cd–N distances in 2,3- and 2,4- are 2.311 and 2.366(6) Å respectively).

The static CP NMR spectra present only a broad signal for all the compounds. The detected broadening of the signals is mainly due to the anisotropy of the chemical shift. All the broadening that normally comes from the proton-cadmium dipolar coupling is almost completely removed in CP-experiments (by the high power decoupling). Considering that the broadening effect is mainly due to the anisotropy in the chemical shift, the measured signals can be decomposed into three Lorentzians curves from which the diagonal components of the anisotropy tensor, σ_{11}, σ_{22} and σ_{33}, can be obtained. Fig. 4 shows the spectrum and the deconvoluted signals for Cd(2,5-pydc). The anisotropy magnitude, $\Delta\sigma$, and the asymmetry parameter, η, were also calculated for all compounds.

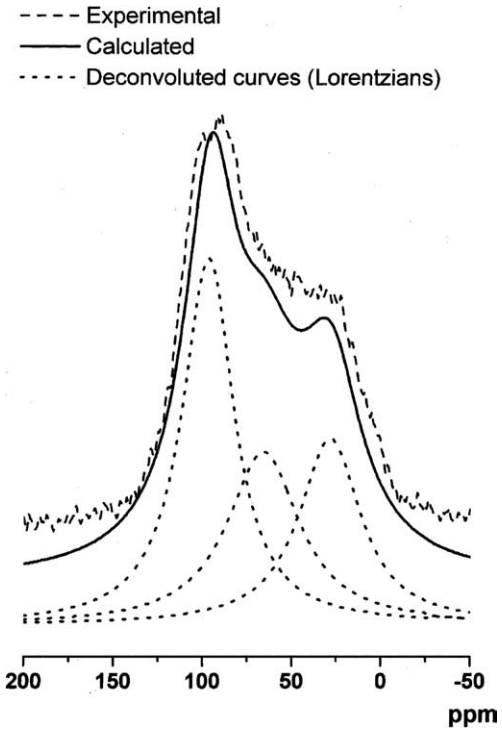

Fig. 4. Experimental and calculated spectrum of Cd(2,5-pydc) obtained from the sum of three deconvoluted Lorentzian components. Each of those components is assigned to the components of the chemical shift anisotropy tensor (see Table 3).

Summarised in Table 3 are the isotropic chemical shifts obtained by CP-MAS as well as those obtained from the equation $\delta_{iso(calc)} = \sigma_{11} + \sigma_{22} + \sigma_{33}$, the principal components of the shielding tensors, the chemical shift anisotropy ($\Delta\sigma$) and the asymmetry parameters, η, of the four 2,x-pydc derivatives studied here. A nice agreement between the experimental δ_{iso} and the calculated value is observed. The absolute differences are Cd(2,3-pydc): 1.98 ppm, Cd(2,4-pydc): 1.11 ppm, Cd(2,5-pydc): 7.8 ppm and Cd(2,6-pydc): 1.98 ppm, but even for the biggest difference the simulated spectrum is in good agreement with the experimental spectrum as can be seen in Fig. 4. These line shape analyses of the powder patterns, indicate differences in the shielding anisotropy of these pyridine-dicarboxylates, however information about the orientation of the tensor in a molecule fixed axis system cannot be determined. This can be done using single crystal NMR, which has also the advantage of having about 5 times more sensitivity than the powder technique [26]. Unfortunately, in this study, the size of the crystals was good for X-ray studies but still too small for a good NMR study.

The anisotropy magnitude $\Delta\sigma$ follow the order: Cd(2,3-pydc) (antiprism) > Cd(2,6-pydc) > Cd(2,5-pydc) > Cd(2,4-pydc) (hepta-coordinated), indicating that the 2,3-derivative shows the larger distortion around the

Table 3

[b] $\Delta\sigma$ is the anisotropy magnitude: $\Delta\sigma = -\delta_{33} + 0.5(\delta_{11} + \delta_{22})$.
[c] η or η_{csa} is the asymmetry parameter.
[*] Calculated [26] as $\eta = 1 - |(\delta_{33} - 2\delta_{22} + \delta_{11})/(\delta_{33} - \delta_{11})|$.
[#] Calculated [25] as $\eta_{csa} = (\delta_{11} - \delta_{22})/((\delta_{11} + \delta_{22} + \delta_{33})/3 - \delta_{33})$.

cadmium ion. The same compound shows $\sigma_{11} = \sigma_{22}$ and therefore $\eta = 1$, which means that the tensor, and consequently Cd(2,3-pydc), present an axial symmetry [27]. Other authors employ different expressions where $\eta = 0$ has the same meaning (see footnote on Table 3) [28]. The magnitude of $\Delta\sigma$ (178 ppm) also indicates a very elongated complex as found in the structural resolution. On the contrary, Cd(2,4-pydc) shows a smaller η value (0.64), this fact also agrees with the structures of both compounds.

The ^{111}Cd chemical shifts differ for the various Cd(2,*x*-pydc) compounds. The δ_{iso} values encountered for the 2,6-pydc and the seven-coordinated 2,4-pydc derivatives suggest that the derivatives with carboxylates groups *meta* to each other cause similar chemical shifts. The η value of the former complex indicates that the complex has a higher symmetry than the 2,4-pydc derivative, which is a more rhombic distorted. The magnitude of the anisotropy, on the other hand, is bigger for the 2,6-pydc compound and predicts that some of the bonds in the complex should be very elongated. The 2,3-pydc isomer (two carboxylates in an *ortho*-position) show the highest δ_{iso} values (119.6 ppm). Although published data [7] indicate that δ_{iso} is shifted to higher fields when the coordination number is increased, the crystal structure of Cd(2,3-pydc) rules out this trend and the increase in δ_{iso} can only be explained by the relative position of the two carboxylate groups.

Also, the intermediate value of δ_{iso} encountered for 2,5-pydc (84.20 ppm) cannot be ascribed to a difference in coordination number, and it may be only related to the *para*-position of the carboxylate groups. The η value (0.9) of 2,5-pydc indicates axial symmetry.

6. Conclusions

Solid-state ^{111}Cd is a sensitive probe in insoluble cadmium pyridinedicarboxylates and the signals are related to the position of the second carboxylate group. The technique provides information on the chemical shifts anisotropy and ^{14}N coupling that may reveal the cadmium environment. The smallest values for δ_{iso} are found for the 2,4- and 2,6-isomers (carboxylates in *meta*-positions to each other), and highest value is found in the 2,3-isomer (carboxylates in the *ortho*-position). The calculated $\Delta\sigma$ values follow the trend Cd(2,3-pydc) > Cd(2,6-pydc) > Cd(2,5-pydc) > Cd(2,4-pydc), indicating that the 2,3-derivative shows the larger distortion around the cadmium ion. However, a study of single crystals of this family could help to better understand the relationship between magnetic and geometric anisotropy.

7. Supplementary material

Crystallographic data have been deposited with the CCDC. Synthesis and characterization of a versatile bis(pyridylether) ligand and its complexes with Ag(I), Cu(II) and Co(II)

Christiana Siaw-Lattey, Hongming Zhang, David Y. Son *

Department of Chemistry, Southern Methodist University, P.O. Box 750314, Dallas, TX 75275-0314, USA

Received 1 October 2004; accepted 2 February 2005

Abstract

A new bis(pyridylether) ligand **L** was synthesized in 46% yield from the reaction of two equivalents of 2-pyridylethanol with α,α′-dibromo-*o*-xylene in the presence of sodium hydroxide. Ligand **L** possesses structural features that allow it to react either intermolecularly or in a chelating fashion with transition metal ions. With $AgNO_3$, ligand **L** forms a helical metallopolymer. Ligand **L**, in combination with 2-pyridylethanol, reacts with $Cu(ClO_4)_2$ to form a bridged dinuclear complex. With $Co(NCS)_2$, ligand **L** behaves as a chelating ligand to give a monomeric octahedral complex.

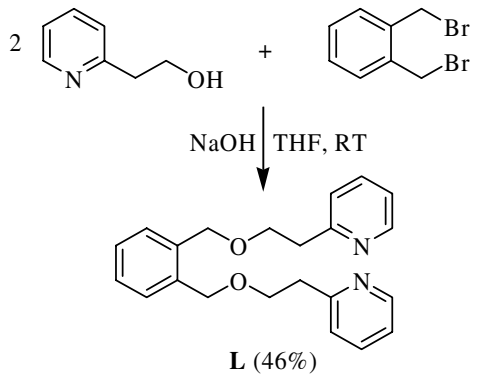
1. Introduction

The interaction of organic multidentate ligands with transition metal ions can lead to a variety of molecular architectures, including macrocycles, polyhedra and linear and helical polymers [1–3]. As might be expected, ligand structure plays a critical role in the type of structure formed. Flexible ligands favor the formation of chelates or macrocycles, while stiff ligands often result in polymeric complexes. In recent research, we have focused on the synthesis of new bis(pyridyl) ligands in which the pyridyl groups are separated by spacer groups of varying flexibility. Depending on the spacer group, we found these ligands interact with silver(I) salts to form either chelated complexes [4] or helical polymers [5].



Supramolecular structure is also affected by the choice of metal ion. For a given ligand, the resulting complex structure is governed by the geometric preferences of the ion. As a part of our fundamental investigations in the synthesis of new multidentate heterocyclic ligands [4–6], we have sought to synthesize ligands that are flexible enough to accommodate a variety of geometric configurations, depending on the coordinated metal ion. In this report, we describe the synthesis of one such bis(pyridyl) ligand and its coordination preferences with Ag(I), Cu(II) and Co(II), metal ions that are known to exhibit a variety of coordination geometries with pyridyl ligands. This ligand reacts with Ag(I) to give a polymeric structure but reacts with Cu(II) and Co(II) to give monomeric complexes in which it is either a bridging or chelating ligand.

2. Results and discussion

The new bis(pyridylether) ligand **L** was synthesized in 46% yield from the reaction of 2-pyridylethanol with α,α′-dibromo-*o*-xylene in THF, in the presence of sodium hydroxide (Scheme 1). This reaction was not as straightforward as it may seem, as other common bases

Scheme 1.

such as triethylamine, diisopropylethylamine, potassium carbonate, potassium hydroxide and lithium hydroxide were ineffective as proton acceptors. Furthermore, this reaction was unsuccessful with α,α′-dichloro-*o*-xylene as the starting material. Ligand **L**, isolated as a yellow oil, is stable under normal room conditions but hygroscopic. As can be seen from the structure of **L**, the ortho substitution pattern and the position of the pyridine nitrogen atoms suggest that this ligand can be chelating. However, the length and flexibility of the arms also allows the possibility of intermolecular complexation. Furthermore, the oxygen atoms present in the pyridyl arms may serve as additional donor atoms [7].

When an aqueous solution of silver nitrate was added to an acetone solution of **L** (1:1 ratio), a cloudy solution resulted which cleared within seconds. The solution was stored in the refrigerator and fine needle-like crystals formed in approximately 3 days.[1] After redissolving the crystals in methanol and adding water, orange block crystals (**Ag**–**L**) formed in 58% yield from the refrigerated solution after approximately one week. The ^{1}H NMR spectrum of **Ag**–**L**, which itself dissolved slowly into acetone-D_6, showed the pyridine proton signals to be spread out and shifted downfield compared to the spectrum of ligand **L**, suggesting Ag–L complexation in solution (Fig. 1). X-Ray crystal analysis of **Ag**–**L** revealed that **L** reacted intermolecularly with Ag(I) to give a one-dimensional helical polymer (Fig. 2). Structurally related bis(pyridylether) ligands such as 1,4-bis(2-pyridyloxymethyl)benzene and 1,4-bis(2-pyridylmethoxy)benzene have been reported to give π–π stabilized zigzag metallopolymers on interaction with $AgNO_3$ [8]. Each helical repeat unit of **Ag**–**L** consists of two ligands and two silver ions. The N–Ag–N bond angle of 160.49(14)° is distorted from linearity due to additional coordination of a nitrate ion oxygen atom (Ag–O(1) 2.591(4) Å), and weaker coordinations from two oxygen atoms of two separate ligands (Ag–O(12) 3.343(3) Å; Ag–O(22A) 2.748(3) Å). We observed no evidence for π–π interactions within each helical strand, as the stacked aryl rings are separated by 8.508(1) Å.

[1] We did not obtain X-ray quality crystals from reactions of **L** with silver triflate or silver tetrafluoroborate.

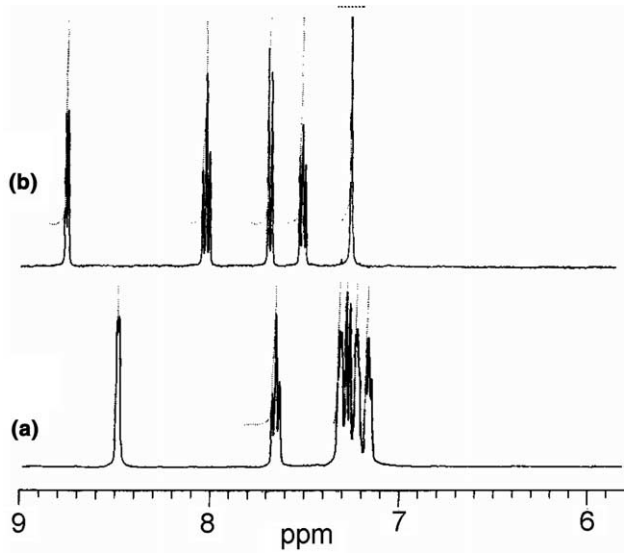

Fig. 1. ^{1}H NMR spectra (aromatic region) in [D_6]acetone of (a) **L**, and (b) **Ag**–**L**.

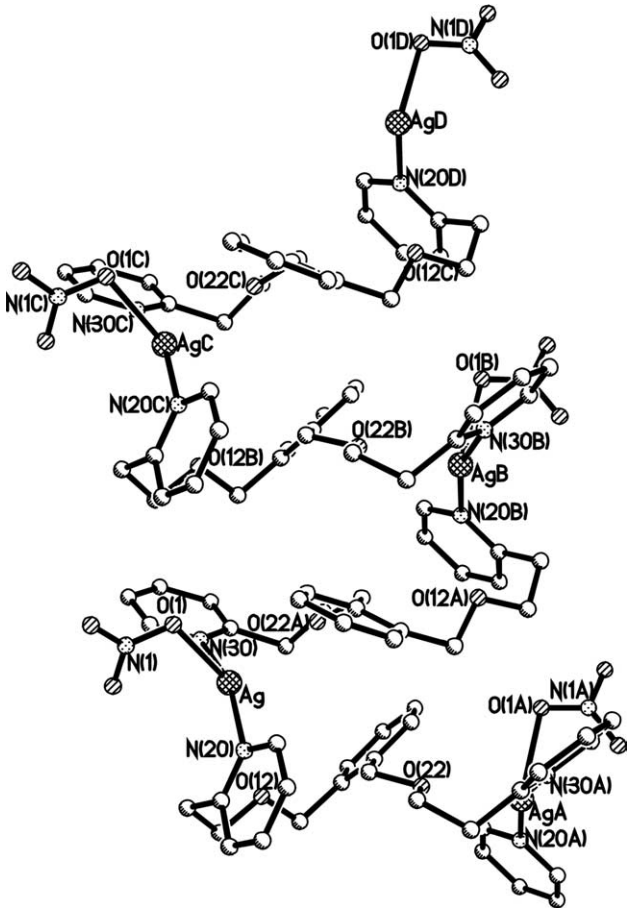

Fig. 2. Subsection of **Ag**–**L** (hydrogen atoms omitted for clarity).

Additionally, there is very little overlap between pyridine rings on adjacent strands. The asymmetric unit of **Ag–L** also included a noncoordinating molecule of water and disordered acetone. Elemental analysis data reflected the loss of the acetone on removal of the crystals from solution.

In various experiments involving the reaction of ligand **L** with copper(II) perchlorate, ($Cu(ClO_4)_2$), we isolated green powders from which X-ray quality crystals could not be grown. In a subsequent experiment, we accidentally utilized a sample of **L** that also contained 2-pyridylethanol in an approximate 5.6/1 mole ratio (**L**/2-pyridylethanol). Reaction of this impure sample with $Cu(ClO_4)_2$ in methanol/dichloromethane resulted in the formation of dark green crystals intermixed with a green powder after several days in a refrigerator. Careful examination revealed the crystals to be blue plates (**Cu–L**) of X-ray quality. Crystallographic analysis revealed a dinuclear structure in which the two Cu ions are pentacoordinate (Fig. 3). The asymmetric unit consists of one molecule of **L**, two deprotonated molecules of 2-pyridylethanol, two noncoordinating perchlorate anions and two molecules of dichloromethane. Elemental analysis data indicated that the dichloromethane molecules were lost on removal of the crystals from solution. Ligand **L** bridges the two copper ions through the pyridine nitrogen atoms (Cu(1)–N(20) 2.006(3) Å; Cu(2)–N(30) 2.007(2) Å) and in a weaker fashion through the oxygen atoms in the arms (Cu(1)–O(12) 2.341(2) Å; Cu(2)–O(22) 2.362(2) Å). Each of the two deprotonated 2-pyridylethanol molecules coordinates to separate copper ions through the pyridine nitrogens (Cu(1)–N(31) 1.997(3) Å; Cu(2)–N(41) 2.009(2) Å). Furthermore, the oxygen atoms of the 2-pyridylethanol molecules form bridges [9–12] between the two copper ions to give a distorted square (Cu(1)–O(1)–Cu(2) 100.31(9)°; Cu(1)–O(2)–Cu(2) 100.92(9)°) with a slight pucker (Cu(1)–O(1)–Cu(2)–O(2) torsion angle −6.2°).

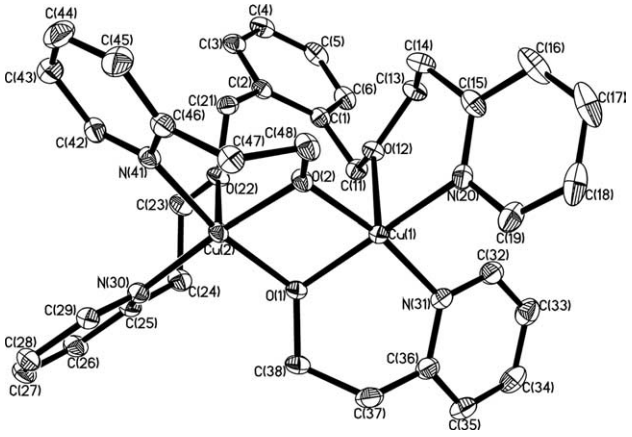

Fig. 3. ORTEP plot of **Cu–L** (50% probability, hydrogen atoms omitted for clarity).

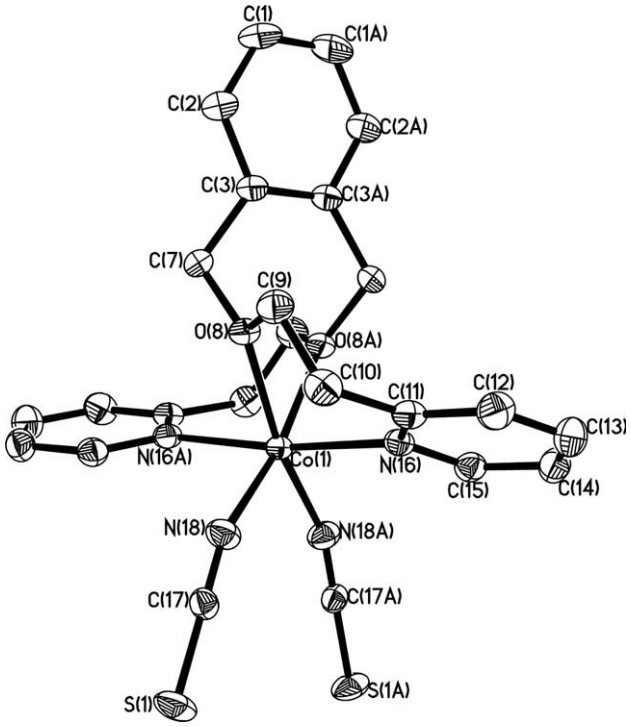

Fig. 4. ORTEP plot of **Co–L** (50% probability, hydrogen atoms omitted for clarity).

A Cu–Cu interatomic distance of 2.9752(5) Å in **Cu–L** is similar to that found in certain bridged Cu_2 complexes such as $(PPh_3)_2Cu_2(\mu\text{-}Cl)_2(\mu\text{-}4,4'\text{-bipy})$ (2.997(1) Å) [13] and the oxygen-bridged $[Cu_2(bis(1\text{-methyl-2-benzimidazolyl})ethane)_2(CH_3O)_2](ClO_4)_2$ complex (2.9872(16) Å) [9]. As might be expected from the stoichiometry of **Cu–L**, we found that the yield of the complex could be increased by increasing the amount of 2-pyridylethanol in the ligand mixture. However, we have still been unable to isolate X-ray quality crystals from the reaction of $Cu(ClO_4)_2$ with pure **L**.[2]

When **L** was mixed with $Co(NCS)_2$ in methanol, an intense blue-green colored solution formed in addition to some blue precipitate. A layer of hexane was added and the mixture was kept in a refrigerator for several weeks, resulting in the formation of purple solid clumps. The purple clumps were redissolved in acetone and layered with hexane, resulting in the formation of purple rodlike crystals in 64% yield (**Co–L**) after several days.[3] No crystals could be grown from the original blue precipitate. X-Ray crystallographic analysis revealed **Co–L** to be a monomeric octahedral complex, with **L** as a chelating ligand (Fig. 4). In **Co–L**, the two arms of **L**

[2] We were unsuccessful in obtaining crystalline products from the reaction of pure **L** with copper(II) chloride, copper(II) nitrate, copper(II) tetrafluoroborate or copper(II) iodide.

[3] Other cobalt(II) salts we examined included cobalt chloride, cobalt bromide and cobalt nitrate.

twist over each other resulting in the two pyridine rings being *trans*, with Co–N bond lengths of 2.1646(16) Å. The N(16)–Co–N(16A) bond angle is slightly deviated from linearity (172.95(8)°). As in the cases of **Ag–L** and **Cu–L**, we observe interactions between the oxygen atoms in the arms of **L** and the metal. In **Co–L**, the two oxygen atoms occupy *cis* positions with Co–O bond distances of 2.2136(13) Å. The coordination sphere is completed with two $(NCS)^-$ anions. The asymmetric unit also includes a molecule of disordered acetone, which elemental analysis data indicate is lost on removal of the crystals from solution.

3. Conclusion

We have synthesized a versatile bis(pyridylether) ligand **L** by a process involving readily available starting materials. By virtue of its structure, **L** can accommodate a variety of geometric conformations in metal complexes, depending on the preference of the transition metal ion. With silver(I), a helical metallopolymer is formed while reactions with Cu(II) and Co(II) result in the formation of a dinuclear and mononuclear complex, respectively. These results suggest that **L** is a good candidate for the formation of well-defined complexes with other transition metal ions. Continued investigations in our laboratory will focus on these studies and the design of other new multidentate ligands.

4. Experimental

General remarks: All reactions were performed under an atmosphere of nitrogen unless stated otherwise. Tetrahydrofuran (THF) was dried over activated 4 Å molecular sieves before use. The following chemicals were obtained from Fisher Scientific, Acros, or Sigma-Aldrich: tetrahydrofuran (THF), dichloromethane (CH_2Cl_2), sodium hydroxide powder (NaOH), anhydrous magnesium sulfate ($MgSO_4$), 2-pyridylethanol and α,α′-dibromo-*o*-xylene. NMR spectra were obtained using a 400 MHz Bruker Avance DRX multinuclear NMR spectrometer. IR spectra were recorded on a Nicolet Magna-IR 560 Spectrometer ESP.

4.1. Ligand *L*

A 100-mL round-bottomed flask equipped with a magnetic stir bar and rubber septum was charged with NaOH (3.03 g, 75.6 mmol) and 2-pyridylethanol (4.3 mL, 37.8 mmol). THF (50 mL) was added and after stirring at room temperature for 30 min, α,α′-dibromo-*o*-xylene (5.0 g, 18.9 mmol) was added. The resulting tan suspension was stirred overnight at room temperature. The suspension was filtered to remove salts and excess NaOH. CH_2Cl_2 (70 mL) was added to the dark yellow filtrate and the organic layer was washed twice with saturated aqueous NH_4Cl, twice with deionized H_2O and dried over anhydrous $MgSO_4$. Solvent removal via rotary evaporation yielded a dark yellow oil that was purified by filtration through a 5-cm silica gel column, using 1:1 ethyl acetate/hexane to remove any unreacted xylene reagent. The product was flushed out using 100% acetone as eluent. The clear light yellow oil obtained after solvent removal was redissolved in CH_2Cl_2 (20 mL) and washed with deionized H_2O to remove all traces of the pyridine starting material. Drying the organic layer over $MgSO_4$ and concentration afforded **L** as a yellow oil in 46% yield (3.04 g). *Anal*. Calc. for $C_{22}H_{24}N_2O_2$: C, 75.83; H, 6.94; N, 8.04. Found: C, 75.59; H, 7.20; N, 7.97%. ^{1}H NMR (400 MHz, [D$_6$]acetone): δ 3.0 (t, $^3J = 6.6$ Hz, –CH_2CH_2Pyr, 4H), 3.8 (t, $^3J = 6.6$ Hz, –OCH_2CH_2, 4H), 4.50 (s, –OCH_2Ph, 4H), 7.23–8.5 (m, aromatic H, 12H). ^{13}C NMR (100.62 MHz, [D$_6$]acetone): δ 38.8 (–CH_2CH_2Pyr), 69.9 (–CH_2CH_2Pyr), 70.4 (–OCH_2Ph), 121.0, 123.7, 127.5, 128.5, 136.3, 137.3, 147.5, 159.8. 4.2. Complex *Ag–L*

To a 10-mL screw-capped vial was added pure **L** (0.10 g, 0.29 mmol). Approximately 3 mL of acetone was added to dissolve the ligand. In a separate vial, $AgNO_3$ (0.049 g, 0.30 mmol) was dissolved in 1 mL of deionized H_2O. The solution of $AgNO_3$ was added to the solution of **L** with a pipette by gently dripping off the side of the vial, without agitation. The resulting cloudiness dissipated within seconds, and the vial was stored in a refrigerator. Fine needle-like crystals formed in about 3 days. The supernatant was decanted and approximately 3 mL of methanol was added to dissolve the crystals. An additional 1 mL of water was also added. The solution was placed in the refrigerator and yellow-orange crystals formed in about one week. Yield: 0.089 g (58%); m.p.: 75–80 °C. *Anal*. Calc. for $C_{22}H_{24}N_3O_5Ag \cdot H_2O$: C, 49.27; H, 4.89; N, 7.83. Found: C, 49.27; H, 4.61; N, 7.93%. ^{1}H NMR (400 MHz, [D$_6$]acetone): δ 3.3 (t, $^3J = 6.6$ Hz, –CH_2CH_2Pyr, 4H), 3.8 (t, $^3J = 6.6$ Hz, –OCH_2CH_2, 4H), 4.5 (s, –OCH_2Ph, 4H), 7.2 (S, Ph, 4H), 7.4 (td, Pyr, 2H), 7.6 (d, Pyr, 2H), 7.9 (td, Pyr, 2H), 8.7 (d, Pyr, 2H). IR (KBr): ν(cm^{-1}) 1436–1384 (N=O, s).

4.3. Complex *Cu–L*

To a 10-mL screw-capped vial was added **L** (0.10 g, 0.29 mmol), consisting of 0.0941 g **L** and 0.0059 g 2-pyridylethanol. About 3 mL of methanol was added. $Cu(ClO_4)_2 \cdot 6H_2O$ (0.11 g, 0.29 mmol) was added and

the reactants mixed, resulting in the formation of an intense green solution. A 1 mL layer of dichloromethane was added to the resulting green solution after which the reaction was stored in a refrigerator. Dark green crystals and some green powder formed in about 4 days. Because the crystalline solid could not be quantitatively separated from the powdery precipitate, a yield could not be determined. M.p.: 167–168 °C. *Anal*. Calc. for $C_{36}H_{40}N_4O_4Cu_2(ClO_4)_2$: C, 47.06; H, 4.39; N, 6.10. Found: C, 47.09; H, 4.37; N, 6.00%. IR (KBr): $\nu(cm^{-1})$ 1086 (Cl–O, s).

4.4. Complex *Co–L*

To a 10-mL screw-capped vial was added pure **L** (0.10 g, 0.29 mmol). Methanol (approximately 3 mL) and $Co(NCS)_2$ (0.50 g, 0.29 mmol) was added and the vial swirled to dissolve and mix the reactants, resulting in the formation of an intense blue-green color and some blue precipitate. A purple color was observed when light was shone through the solution. After layering with 1 mL of hexane, the vial was stored in a refrigerator (in a subsequent experiment we found that the hexane layer was unnecessary). Clumps of purple solid formed in a few weeks. These were manually isolated and redissolved in acetone (3 mL) to form a clear blue solution. A layer of hexane was added and the mixture placed in a refrigerator. The blue precipitate was dissolved in methanol and layered with hexane and cooled in the freezer but no crystals formed. Crystals from the purple solid formed in about 3 days. Yield: 64% (0.10 g); m.p.: 94–96 °C. *Anal*. Calc. for $C_{22}H_{24}N_2O_2Co(SCN)_2 \cdot H_2O$: C, 53.23; H, 4.84; N, 10.35. Found: C, 53.11; H, 4.79; N, 9.83%. IR (KBr): $\nu(cm^{-1})$ 2071 (C═N, s).

5. X-Ray crystallographic study

All data were collected on a Bruker APEX diffractometer equipped with a CCD detector. The structures were solved by direct-methods and subsequent difference Fourier syntheses using the SHELXTL program package (G.M. Sheldrick, SHELXTL, Bruker Analytical X-Ray Systems, Inc., 1990). Abstract

Tetrakis(13,17-dioxa nonacosane-15-sulphanyl) phthalocyaninato zinc(II), ZnPc(SCH($CH_2OR)_2)_4$, where R = $C_{12}H_{25}$, was synthesised and its electrochemical and spectroelectrochemical properties were investigated in dichloromethane. The neutral complex undergoes two quasi-reversible one-electron oxidations and two quasi-reversible one-electron reductions in CH_2Cl_2 containing 0.1 M tetra-*n*-butylammonium perchlorate (TBAP). The half-wave potentials for oxidation of the complex are located at $E_{1/2}$ = 0.61 and 1.38 V, while the two reductions are located at $E_{1/2} = -0.87$ and -1.11 V versus SCE. These potentials show little or no difference compared to those of unsubstituted ZnPc and other SR substituted phthalocyanines under the same experimental conditions, thus suggesting weak electron-donating effects of the peripheral alkylthio substituents on the phthalocyanine rings. The well-defined UV–Vis spectra of electro-reduced and electro-oxidised species, $[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-$, $[ZnPc(-4)(SCH(CH_2OR)_2)_4]^{2-}$ and $[ZnPc(-1)(SCH(CH_2OR)_2)_4]^+$, were obtained by applied potentials ($E_{app} = -1.04$ V, $E_{app} = -1.62$ V, and $E_{app} = 1.20$ V, respectively) in a thin-layer cell. The first and second reduction products showed characteristic spectral changes corresponding to mono- and di-anionic species of zinc phthalocyanines, and the first oxidation showed spectral changes corresponding to the formation of a mono-cationic dimer.

1. Introduction

The importance of phthalocyanines in many fields, such as molecular electronics [1–3], non-linear optics [4–6], liquid crystals [7–10], gas sensors [11–13], photosensitisers [14–16], catalysts [17–20], semiconductive materials [21,22], photovoltaic cells [23–25], and electrochromic displays [26–29], is increasing rapidly as a result of novel compounds with functional groups on the phthalocyanine core or different types of metal in the centre. An important shortcoming of phthalocyanines is their low solubility in common organic solvents, which hinders their wider application. The introduction of alkoxy [30,31] or alkylthio [32–34] substituents to the phthalocyanine cores provides the desired solubility and has turned out to be powerful means of modifying the chemical and physical properties of phthalocyanines. Electron-donating or electron-withdrawing groups on phthalocyanine macrocycle strongly affect not only the position of the longwave absorption bands in the electronic spectra but also the electrode potentials of their

doi:10.1016/j.poly.2005.02.018

reduced or oxidised species in electrochemical reactions [30,35–37]. Phthalocyanines with alkylthio substituents tend to shift the absorption bands to longer wavelengths in the near-IR compared with unsubstituted ones, thereby making an important contribution in semiconductor laser applications [38].

In most applications of phthalocyanine complexes, a good understanding of the redox properties of these complexes is important. Spectroelectrochemical studies of phthalocyanines facilitate understanding of the nature of the redox processes that may take place at either the central metal atom or the phthalocyanine ring, and usually cannot be distinguished by electrochemistry only. Spectroelectrochemical studies of phthalocyanines are also important with regard to their possible use as electrochromic materials, where several colours are displayed depending on the potential applied to the electrode surface [39–42].

Our laboratories have recently reported the synthesis, and electrochemical and spectroelectrochemical properties of double-decker lutetium(III) phthalocyanines and tetrathia macrocycle-bridged metal phthalocyanines substituted with long-alkylthio chains in aqueous and non-aqueous media [39–42]. In this work, the synthesis, and electrochemical and spectroelectrochemical characterisation of tetrakis(13,17-dioxa nonacosane-15-sulphanyl) phthalocyaninato zinc(II), $ZnPc(SCH(CH_2OR)_2)_4$, where $R = C_{12}H_{25}$ (Fig. 1), are reported. Long-alkyl chains introduced into the peripheral position of the phthalocyanine unit provide high solubility in non-coordinating solvents (e.g., dichloromethane, chloroform, diethylether, *n*-hexane), which has been observed for long-alkyl chains or bulky-groups introduced into mono, unsymmetrical, double-decker phthalocyanines, and quinoxaline or some oxime complexes [43–48].

$ZnPc[SCH(CH_2OR)_2]_4$

where $R = C_{12}H_{25}$

Fig. 1. Tetrakis(13,17-dioxa nonacosane-15-sulphanyl) phthalocyaninato zinc(II).

The electrochemistry and spectroelectrochemistry of $ZnPc(SCH(CH_2OR)_2)_4$ were determined in CH_2Cl_2 containing 0.1 M TBAP. Thus, detailed information is provided on several electrochemically generated redox species, such as $[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-$, $[ZnPc(-4)(SCH(CH_2OR)_2)_4]^{2-}$ and $[ZnPc(-1)(SCH(CH_2OR)_2)_4]^+$, which remain stable and keep their colour changes throughout the thin-layer spectroelectrochemical timescale. The first and second reduction products formed with the applied potentials ($E_{app} = -1.04$ V and $E_{app} = -1.62$ V) in a thin-layer cell showed characteristic spectral changes corresponding to mono- and dianionic species of zinc phthalocyanines. On the other hand, the appearance of the first oxidation product with the applied potential ($E_{app} = 1.20$ V) in the thin-layer cell showed characteristic spectral changes corresponding to dimeric formation of mono-cationic species in CH_2Cl_2.

2. Experimental

2.1. Chemicals and reagents

Dichloromethane (CH_2Cl_2) was treated with H_2SO_4 three times and distilled over P_2O_5 and CaH_2 prior to use. Dimethylsulfoxide (DMSO) was freshly distilled after drying over alumina. Tetra-*n*-butylammonium perchlorate (TBAP, Fluka Chemical Co.) was recrystallised from ethyl alcohol and dried in a vacuum oven at 40 °C for at least 1 week prior to use. Ferrocene was recrystallised from ethyl alcohol before using. 4-(13,17-Dioxa nonacosane-15-sulphanyl) phthalonitrile was prepared according to the procedure available in the literature [49].

2.2. Instrumention

^1H and ^{13}C NMR spectra were recorded on a Bruker 200 MHz spectrometer. Infrared (IR) spectra were recorded as KBr pellets on a Perkin–Elmer 983 spectrophtometer. Fast atom bombardment (FAB) mass spectrum was obtained on a VG-ZAB-SPEC spectrometer using *m*-nitrobenzyl alcohol as matrix. Elemental analyses were carried out in Marmara Research Center. Cyclic voltammograms (CV) were carried out using CV measurements with Princeton Applied Research Model 273 potentiostat controlled by an external PC. A three electrode system was used for CV measurements in CH_2Cl_2 and consisted of a glassy carbon working electrode, a platinum wire counter electrode, and a saturated calomel reference electrode (SCE). The reference electrode was separated from the bulk solution by a fritted-glass bridge filled with the

solvent/supporting electrolyte mixture. The ferrocene/ferrocenium couple (Fc/Fc^+) was used as an internal standard but all potentials in the paper are referenced to the SCE. Solutions containing ZnPc(SCH-$(CH_2OR)_2)_4$ were deoxygenated by a stream of high purity nitrogen for at least 5 min. before running the experiment and the solution was protected from air by a blanket of nitrogen during the experiment. Controlled potential electrolysis (CPE) was performed with Princeton Applied Research Model 273 potentiostat/Galvanostat. An ''H'' type cell with a fritted glass to separate the cathodic and anodic portions of the cell was used for bulk electrolysis. The working and counter electrodes were platinum and the reference electrode was a SCE. The sample and solvent were transferred into the electrolysis cell under nitrogen. UV–Vis spectroelectrochemical experiments were performed with a home-built thin-layer cell that utilised a light transparent platinum gauze working electrode. Potentials were applied and monitored with an Princeton Applied Research Model 273 potentiostat. Time-resolved UV–Vis spectra and spectrophotometric titration experiment were recorded Hewlett–Packart Model 8453 diode array spectrophotometer.

2.3. Synthesis of tetrakis(13,17-dioxa nonacosane-15-sulfanyl) phthalocyaninato zinc(II)

A mixture of 4-(13,17-dioxa nonacosane-15-sulfanyl) phthalonitrile (0.717 g, 1.26 mmol), anhydrous zinc acetate (0.059 g, 0.32 mmol) and quinoline (1 ml) was heated and stirred at 195–200 °C for 24 h under argon. After cooling to room temperature, the mixture was treated with ethanol (10 ml) and the waxy precipitate was separated. The dark green metallo-phthalocyanine was isolated by column chromatography (Silica gel, CH_2Cl_2:*n*-hexane/1:1). This compound was soluble in common organic solvents. Yield: 0.220 g (30%). *Anal*. Calc. for $C_{140}H_{232}N_8O_8S_4Zn$: C, 70.95; H, 10.30; N, 4.48. Found: C, 71.58; H, 9.95; N, 4.77%. IR [(KBr)ν_{max}/cm^{-1}]: 2920–2855 (CH_2), 1600, 1465, 1380, 1305, 1260, 1105 (C–O–C), 910, 815, 740. ^1H NMR ($CDCl_3$): δ ppm = 0.83 (t, 24H, CH_3), 1.15 (m, 144H, CH_2), 1.71 (m, 16H, OC–CH_2), 3.65 (t, 16H, OCH_2), 4.02 (br, 20H, CH and OCH_2), 7.85–8.05 (m, 4H, ArH), 8.45–8.87 (m, 8H, ArH). ^{13}C NMR (APT) ($CDCl_3$): δ ppm = 14.1 (CH_3), 22.7 (CH_2), 26.4 (CH_2), 29.3–29.8 (CH_2), 31.9 (CH_2), 48.6 (CH), 70.5 (OCH_2), 71.8 (OCH_2–CHS), 122.0 (Ar CH), 122.5 (Ar CH), 123.6 (Ar CH), 131.3 (Ar CH), 133. 9 (Ar C), 136.5 (Ar C), 138.1 (Ar C), 144. 2 (Ar C). 3. Results and discussion

3.1. Synthesis and spectral characterisation

Formation of tetrakis(13,17-dioxa nonacosane-15-sulphanyl) phthalocyaninato zinc(II), ZnPc(SCH $(CH_2OR)_2)_4$ was achieved in a good yield by cyclotetramerisation reaction of 4-(13,17-dioxa nonacosane-15-sulphanyl) phthalonitrile [49] with anhydrous zinc acetate in a high-boiling solvent such as quinoline. Column chromatography with silica gel was employed to obtain pure product.

The desired compound, which had four long-alkylthio ($SCH(CH_2OR)_2$) groups on the periphery of phthalocyanine macrocycle, was isolated as a mixture of isomers, electrochemical properties of which appear to be the same. This is not a surprise. Similar electrochemical behaviour of the isomers were reported earlier for some tetra-substituted phthalocyanine complexes [39,50]. The dark green waxy product was readily soluble in common organic solvents such as chloroform, tetrahydrofuran, benzene, and toluene. This is clearly due to the introduction of long-alkylthio chains on the peripheral position of phthalocyanine core. Thus, $ZnPc(SCH(CH_2OR)_2)_4$ could be thoroughly characterised by ^1H and ^{13}C NMR and UV–Vis spectroscopy, in addition to elemental analysis. Mass spectrum of $ZnPc(SCH(CH_2OR)_2)_4$ by the FAB technique also showed relatively intense molecular ion peak with the clear apperance of the fragmentation peaks corresponding to the stepwise loss of alkoxy ($OC_{12}H_{25}$) groups (Fig. 2).

In the IR spectrum, characteristic vibration peaks corresponding to the ether groups (C–O–C) at 1105 cm^{-1} and CH_2 stretching at 2920–2855 cm^{-1} are common for such groups on the phthalocyanine cores. The sharp peak belong to the C≡N vibrations in phthalonitrile derivative disappeared after phthalocyanine formation. In the ^1H NMR analysis of the compound in deuteriated chloroform, $ZnPc(SCH(CH_2OR)_2)_4$ showed characteristic chemical shift at 7.85–8.05 and 8.45–8.87 ppm belong to deshielded aromatic protons, along with the peaks from CH, CH_2, and CH_3 protons between 0.83 and 4.02 ppm for the peripherally substituted groups on the phthalocyanine cores.

The high solubility of $ZnPc(SCH(CH_2OR)_2)_4$ has enabled us to obtain the ^{13}C NMR spectrum. The attached proton test (APT) indicates the presence of three tertiary carbons of phthalocyanine core in the aromatic region, 122.0, 122.5, and 131.3 and the signals for aliphatic carbon atoms appeared between 14.1 and 71.8 ppm, as expected.

A close investigation of the mass spectrum of $ZnPc(SCH(CH_2OR)_2)_4$ confirmed the proposed structure. The mass spectrum of $ZnPc(SCH(CH_2OR)_2)_4$ was obtained by the FAB technique using a *m*-nitro

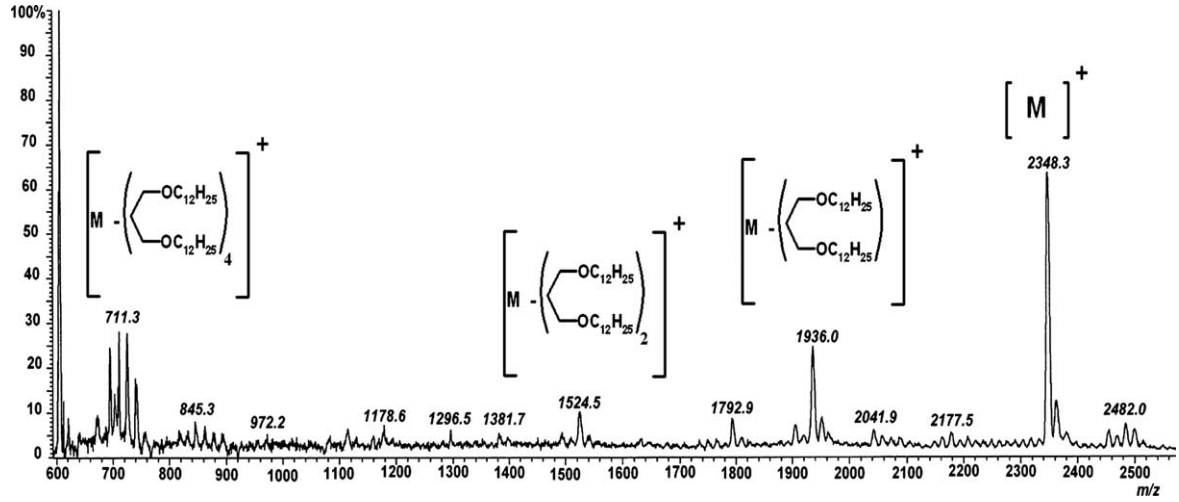

Fig. 2. The mass spectrum of $ZnPc(SCH(CH_2OR)_2)_4$.

benzyl alcohol (MNBA) as matrix. In addition to the $[M]^+$ peak, fragments were observed at 1936.0 (25) $[M - CH(CH_2OC_{12}H_{25})_2]^+$, 1792.9 (9), 1524.5 (10) $[M - 2(CH(CH_2OC_{12}H_{25})_2)]^+$, 1296.5 (6), 1178.6 (8), 705.3 (29) $[M - 4(CH(CH_2OC_{12}H_{25})_2)]^+$, 588.3 (100).

3.2. Electrochemistry

Oxidation and reduction reactions of ZnPc in solution or film states are expected to occur at the phthalocyanine ring only, since Zn metal is electroinactive [50]. Fig. 3 shows a typical cyclic voltammogram of

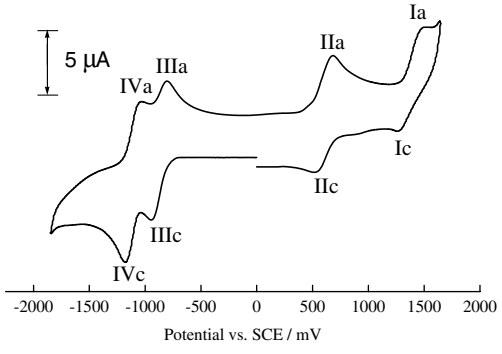

Fig. 3. Cyclic voltammograms of $ZnPc(SCH(CH_2OR)_2)_4$ in CH_2Cl_2 solution containing 0.1 M TBAP. Scan rate = 0.1 V/s.

$ZnPc(SCH(CH_2OR)_2)_4$, which undergoes two quasi-reversible one-electron oxidations and two quasi-reversible one-electron reductions with the corresponding cathodic and anodic peaks in CH_2Cl_2 containing 0.1 M TBAP. The half-wave potentials for reduction of $ZnPc(SCH(CH_2OR)_2)_4$ in CH_2Cl_2, 0.1 M TBAP are located at $E_{1/2} = -0.87$ and -1.11 V, while the two oxidations are located at $E_{1/2} = 0.61$ and 1.38V versus SCE. The half-wave potentials of $ZnPc(SCH(CH_2OR)_2)_4$ and some unsubstituted and alkylthio substituted zinc phthalocyanines from the literature are given in Table 1. The difference between the half-wave potentials of the first reduction and first oxidation processes for $ZnPc(SCH(CH_2OR)_2)_4$, which resembles the energy difference between highest occupied and lowest unoccupied molecular orbitals (HOMO and LUMO), is 1.48 V. This value is in accord with those of unsubstituted and substituted zinc phthalocyanines in Table 1. The potential difference between the first and second reduction processes of the $ZnPc(SCH(CH_2OR)_2)_4$ is 0.24 V, which compares to an average separation for the first and second reduction processes of alkylthio-substituted zinc phthalocyanines at the Pc ring system. Thus, these two couples are assigned to successive ring reduction processes, namely $[ZnPc(-2)(SCH(CH_2OR)_2)_4]/[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-$ and $[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-/[ZnPc(-4)(SCH(CH_2OR)_2)_4]^{2-}$, respectively. Only a few re-

Table 1
Half-wave potentials of $(SCH(CH_2OR)_2)_4$ ZnPc and selected zinc phthalocyanines

Solvent/condition	Compound	Supporting electrolyte	Ox2 (I)	Ox1 (II)	Red1 (III)	Red2 (IV)	Reference
CH2Cl2	$ZnPc(SCH(CH_2OR)_2)_4$	TBAP	1.38 (0.19)	0.61 (0.11)	−0.87 (0.10)	−1.11 (0.11)	tw
DMF	ZnPc	TBAP		0.67	−0.86	−1.30	[30,35]
DMSO	$ZnPc(SC_2H_4OH)_8$	TBAP		0.60	−0.74	−1.11	[51]
CH2Cl2	$ZnPc(SC_6H13)_8$	TBAP		0.64	−0.79	−1.10	[52]

Values of ΔE_p ($=E_{pa} - E_{pc}$) for $ZnPc(SCH(CH_2OR)_2)4$ are given in parenthesis; tw: this work.

ports have given a potential value for the second-step ring oxidation of zinc phthalocyanines, where the potential difference between first oxidation and second oxidation reactions was reported to be about 0.7 V, which is consistent with what was observed for ZnPc(SCH $(CH_2OR)_2)_4$ in this work. Thus, the first and second oxidation processes are based on ring-centred oxidation reactions, namely [ZnPc(-2)$(SCH(CH_2OR)_2)_4$]/[ZnPc(-1) $(SCH(CH_2OR)_2)_4]^+$ and [ZnPc(-1)$(SCH(CH_2OR)_2)_4]^+$/ [ZnPc(0)$(SCH(CH_2OR)_2)_4]^{2+}$, respectively.

The introduction of electron-donating groups to the phthalocyanine cores is expected to lead to an increase in the electron density of the central metal atom, thereby making the MPc complex easier to oxidise and harder to reduce [30,35]. This effect was clearly demonstrated by the fact that the half-wave potentials of $ZnPc(OC_4H_9)_8$ are negatively shifted compared to those of ZnPc [30,35]. Similar behaviour for alkylthio-substituted phthalocyanines could be expected. However, the compound synthesised here and reports on alkylthio-substituted zinc phthalocyanines show little or no difference in their first reduction potentials compared to those of unsubstituted ZnPc [30,35]. For example, the first reduction potential ($E_{1/2}$) for the ZnPc in dimethylformamide is −0.86 V versus SCE, while they are −0.87, −0.74 and −0.79 V versus SCE for ZnPc(SCH(CH_2- $OR)_2)_4$, $ZnPc(SC_2H_4OH)_8$ [51] and $ZnPc(SC_6H_{13})_8$ [52] in CH_2Cl_2 and DMSO, respectively. These data indicate the weak electron-donating influence of the alkylthio-groups on the average electron density of the metal phthalocyanines. A similar weak electron-donating influence of the alkylthio-groups was observed for the complexes investigated before under the same experimental conditions, $[(C_6H_{13}S)_8Pc]_2Lu$ [40,41], $[(C_{12}H_{25}$- $S)_4Pc]_2Lu$ [39] and $[(RS)_6CoPc]_2CR$ [42]. The behaviour of the substituent effect for the oxidation potential of ZnPc(SCH$(CH_2OR)_2)_4$ has been observed to be similar to that of ZnPc. The redox processes of ZnPc(SCH $(CH_2OR)_2)_4$ were examined as a function of potential scan rate in order to ascertain the mode of mass transport. The cathodic and anodic currents for the oxidation and reduction couples in CH_2Cl_2 each increased in direct proportion to the square root of scan rate between 0.02 and 0.25 V/s, thus suggesting that the redox reactions in solution are controlled by diffusion [53]. The peak cathodic and peak anodic current ratio, i_{pc}/i_{pa} for wave I, II, III and IV approached unity, which indicated that these electrochemical reactions were not accompanied by any other physical or chemical processes. The reversibility and stability of the electrogenerated oxidised and reduced species were examined spectroelectrochemically. The controlled potential coulometric (CPC) study indicated that the number of electrons transferred for electrochemical reactions of the complex is one for each oxidation and reduction process.

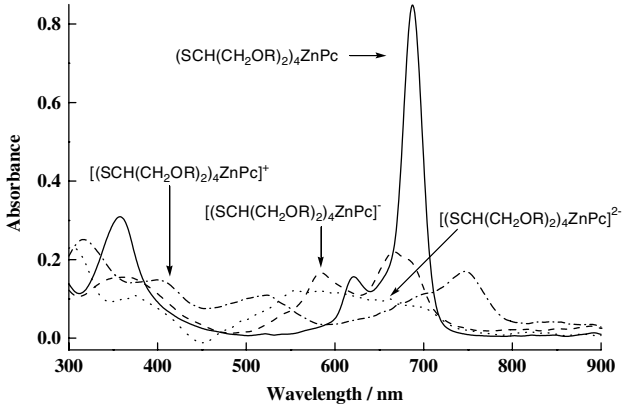

Fig. 4. UV–Vis spectra of $ZnPc(SCH(CH_2OR)_2)_4$ (solid line), $[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-$ (dashed line), $[ZnPc(-4)(SCH(CH_2OR)_2)_4]^{2-}$ (dot line), and $[ZnPc(-1)(SCH(CH_2OR)_2)_4]^+$ (dashed dot line) in CH_2Cl_2 containing 0.2 M TBAP.

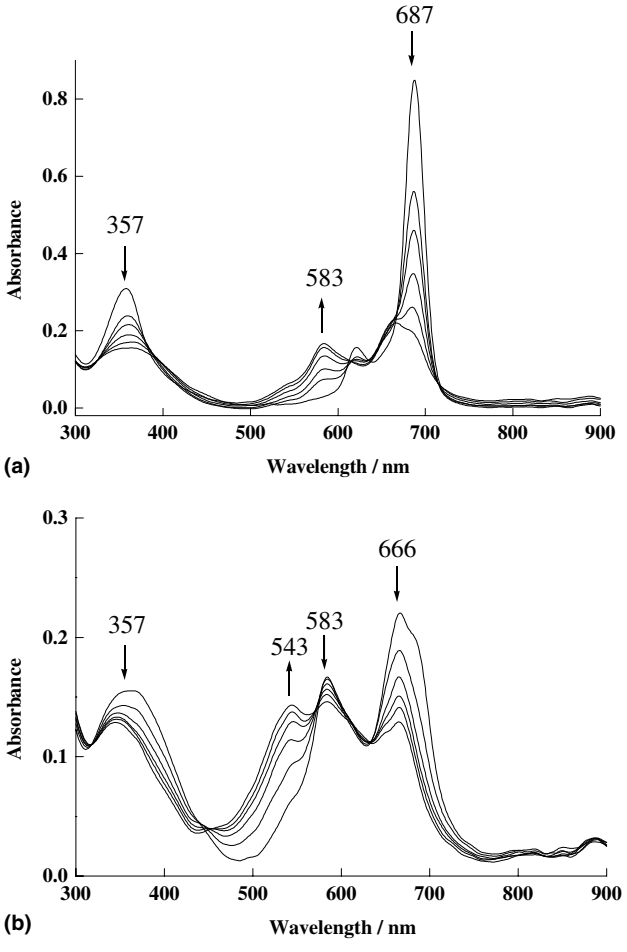

Fig. 5. Time-resolved UV–Vis spectral changes of ZnPc(SCH-$(CH_2OR)_2)_4$ (a) during the first reduction at E_{app} = −1.04V (b) during the second reduction at E_{app} = −1.62 V.

3.3. UV–Vis spectra of electro-oxidised and electro-reduced complexes

Typical absorption spectra for the neutral ZnPc (SCH $(CH_2OR)_2)_4$ and its electrochemically generated

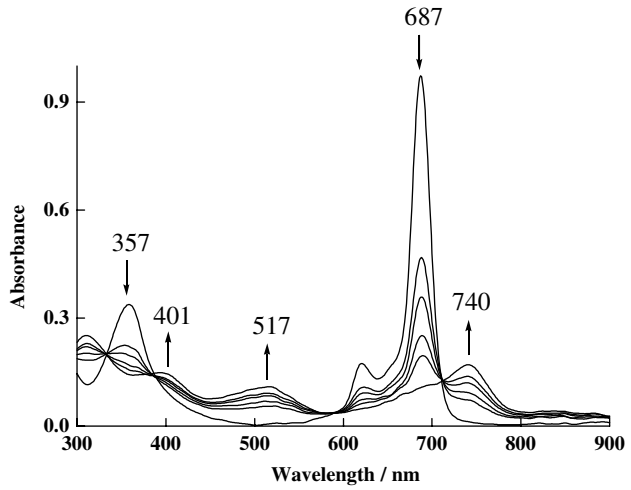

Fig. 6. Time-resolved UV–Vis spectral changes of $ZnPc(SCH(CH_2OR)_2)_4$ during the first oxidation at $E_{app} = 1.20$ V in CH_2Cl_2 solution containing 0.2 M TBAP.

species, $[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-$, $[ZnPc(-4)(SCH(CH_2OR)_2)_4]^{2-}$, $[ZnPc(1)(SCH(CH_2OR)_2)_4]^+$ and $ZnPc(0)(SCH(CH_2OR)_2)_4]^{2+}$, are shown in Fig. 4, Fig. 5(a) and (b), and Fig. 6. The spectroscopic data for neutral and electrochemically generated species are also given in Table 2. The typical UV–Vis spectra of neutral $ZnPc(SCH(CH_2\ OR)_2)_4$ exhibited characteristic Q and B bands. The Q-band observed at 687 nm in the visible region could be attributed to the $\pi \rightarrow \pi^*$ transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the Pc(-2) ring, while the B-band observed at 357 nm in the UV region could be ascribed to deeper π-levels $\rightarrow$ LUMO transition. Both B and Q bands of $ZnPc(SCH(CH_2OR)_2)_4$ are slightly shifted to longer wavelengths compared to unsubstituted ZnPc, but are centred at higher energy compared to hexylthio-substituted zinc phthalocyanines. Such a red shift is an indication that the energy gap between the highest occupied molecular orbital (HOMO) and lowest unoccupied molecular orbital (LUMO) of the complex are narrower than those of the ZnPc, thereby increasing the electroconductivity of the molecule [40].

Spectroelectrochemical studies of metal phthalocyanines provide detailed information on the electron-transfer reaction, the colour changes and the number of electrons for each redox process on the electrode surface [39–41]. However, some spectroelectrochemical characterisations of phthalocyanines could be difficult because of the aggregation behaviour of phthalocyanine molecules in solution. The spectroelectrochemical measurements in this work provide well-defined UV–Vis spectra of electrogenerated species of $ZnPc(SCH(CH_2OR)_2)_4$ due to the lack of aggregation properties of the complex, thereby allowing a good evaluation of spectral changes corresponding to the reduced and oxidised species of $ZnPc(SCH(CH_2OR)_2)_4$ in solution. $ZnPc(SCH(CH_2OR)_2)_4$ was stepwise oxidised or reduced in a thin-layer cell with the applied potentials and the resulting UV–Vis spectra were measured as a function of time. Examples of the time-resolved spectra are shown in Fig. 5(a) and (b) and Fig. 6 and a summary of the spectroscopic data is given in Table 2.

The UV–Vis spectral changes upon the first reduction of $ZnPc(SCH(CH_2OR)_2)_4]$ with applied potential ($E_{app} = -1.04$ V) in a thin-layer cell containing 0.2 M TBAP in $CH_2\ Cl_2$ are shown in Fig. 5(a) and Fig. 4 (dashed line) for the final spectrum of $[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-$. This reduction is accompanied with a change of colour from green to blue-green. Isosbestic points are observed at 385, 614, 665, and 717 nm. The spectrum is typical of a ZnPc(-3) species, characterised by the appearance of new bands at 583 and 666 nm with a blue shift and a decrease in intensity of the Q-band centred at 687 nm [54,55]. The spectrum also shows a broadness and a decrease in the intensity of the B-band. The spectroscopic changes that appeared with the formation of the new bands for the first reduced product are similar to those for the previously observed ZnPc [54,55]. The electron-transfer reaction was reversible on the spectroelectrochemical timescale and the original spectrum (and colour) of the neutral compound was obtained upon re-oxidation. It could be concluded that the reduced phthalocyanine remained fully stable throughout the experiment. The well-defined UV–Vis spectral changes during the second reduction of $ZnPc(SCH(CH_2OR)_2)_4$ with applied potential ($E_{app} = -1.62$ V) in the thin-layer cell are shown in Fig. 5(b) and Fig. 4 (dot line) for the final spectrum of $[ZnPc(-4)(SCH(CH_2OR)_2)_4]^{2-}$. The reduction product results in a colour change from blue-green to purple. Isosbestic points are observed at 318, 445, 572, and 631 nm. A decrease in intensity of the Q and B bands and the appearance of a new band at 543 nm are observed. Re-oxidation at a positive potential of ring-reduced species

Table 2
UV–Vis spectral data of $[ZnPc(SCH(CH_2OR)_2)_4]^n$ in CH_2Cl_2 containing 0.2 M TBAP

Charge, n	species	λ, nm (log ε)			
0	$ZnPc(SCH(CH_2OR)_2)_4$	357 (4.01)		620 (4.01)	687 (4.80)
+1	$[ZnPc(-1)(SCH(CH_2OR)_2)_4]^+$	322 (4.21)	401 (3.99)	517 (3.85)	740 (4.05)
−1	$[ZnPc(-3)(SCH(CH_2OR)_2)_4]^-$	357 (4.00)		583 (4.04)	666 (4.15)
−2	$[ZnPc(-4)(SCH(CH_2OR)_2)_4]^{2-}$	345 (3.89)	543 (3.97)	583 (3.98)	666(3.92)

generates the starting material with the same Q-band intensity.

UV–Vis spectral changes upon the first oxidation of $ZnPc(SCH(CH_2OR)_2)_4]$ with applied potential (E_{app} = 1.20 V) CH_2Cl_2 are shown in Fig. 6 and Fig. 4 (dashed dot line) for the final spectrum of $[ZnPc(-1)(SCH(CH_2OR)_2)_4]^+$. Isosbestic points are observed at 332, 338, 590, and 711 nm. The Q band shifts to high energy due to differential spin-pairing energy, which is centred at 517 nm as a broad band. The new band at low intensity also appears at 740 nm. It could be attributed to the presence of a hole in $1a_{1u}$ which permits transition from eg(π) levels lying below the $1a_{1u}$. B bands with a small blue shift are also observed. The broad and low-intensity spectrum is very similar to those reported for the ring oxidations of phthalocyanines [56–58] and metalloporphyrins [59], which form phthalocyanine and porphyrin cation radical species. The characteristic band centred at 822 nm describes the monomeric form of mono-cationic species of unsubstituted zinc phthalocyanines. The new band centred at 740 nm and the lack of a new band in the range 800 and 1000 nm for $[ZnPc(-1)(SCH(CH_2OR)_2)_4]^+$ could be assigned to the dimeric formation of the mono-cationic species. This behaviour is similar to what was observed for the dimeric formation of the mono-cationic species of ZnPc in solution. Re-reduction at a negative potential of ring-oxidised species generates the starting material with the same Q-band intensity, which means the oxidised product remains stable during the spectroelectrochemical process.

Abstract

Copper(II) complexes of the histidine analogues: β-(2-pyridyl)-DL-alanine, β-(2-thienyl)-DL-alanine, β-(1,2,4-triazol-1-yl)-DL-alanine, β-(2-thiazolyl)-DL-alanine ligands, and for comparison α-(2-thienyl)glycine and 2-(2-aminoethyl)pyridine, were studied by potentiometric, UV–VIS, EPR and thermogravimetric techniques. The amino acid residues of the ligands were described as the main binding sites forming mono- and bis-(ligand) complexes, but the interaction between aromatic triazolyl and pyridyl nitrogen atoms and the copper(II) ion also was detected in the case of β-(1,2,4-triazol-1-yl)-DL-alanine and β-(2-pyridyl)-DL-alanine. The presence of heteroaromatic rings in the amino acid analogues influences the amino acid like coordination mode in the order imidazole > pyridyl ∼ triazolyl > thiazolyl ∼ thienyl rings.

1. Introduction

The growing interest in the synthesis and studies of non-proteinogenic α-amino acids is due to their biological and toxicological properties. The substitution of naturally occurring amino acids in peptides with their structural analogues can produce dramatic changes in biological activity of peptides. For example, the presence of pyridyl-α-alanine or ring substituted derivatives instead of histidine in angiotensin II significantly decreases its substantial pressor acitivity [1]. The histidine decarboxylase enzyme is highly specific for L-histidine, but its structural analogues – β-pyridyl-2-alanine, β-thiazole-2-alanine and β-(1,2,4-triazole-3-alanine) – serve as poor substrates or enzyme inhibitors [2,3]. Moreover, as free α-amino acids they have been found to possess anti-inflammatory [4] and antitumor-antibiotic activities [2,3]. In recent years numerous non-proteinogenic α-amino acids analogues to histidine, phenylalanine, tyrosine have been synthesised and studied [5], but these studies were performed mainly from biological aspects. The imidazole group of histidine is, however, essential for metal binding activity of metalloenzymes. Its substitution with structural analogues in the enzyme could significantly change the metal binding ability too. The interactions between metal ions and different histidine analogue compounds have not been widely investigated yet. There are some literature data about the stereoselectivity of copper(II), nickel(II), cobalt(II) and zinc(II) complexes of the β-pyridyl-2-alanine ligand [6]; proton and 3d metal complexes of compounds containing heterocyclic rings (pyridyl, thiazolyl, pyrazol, thienyl) and amino [7–9] or carboxylate groups [10].

We report the results of the solution equilibrium studies of copper(II) complexes of histidine analogues:

Scheme 1.

β-(2-pyridyl)-DL-alanine (Pyr-Ala), β-(2-thienyl)-DL-alanine (Thien-Ala), β-(1,2,4-triazol-1-yl)-DL-alanine (Triaz-Ala) and β-(2-thiazolyl)-DL-alanine (Thiaz-Ala) ligands, and for comparison α-(2-thienyl)glycine (Thien-Gly) and 2-(2-aminoethyl)pyridine (Amet-Pyr) (see Scheme 1).

2. Experimental

2.1. Materials

The amino acid analogues : β-(2-pyridyl)-DL-alanine, β-(2-thienyl)-DL-alanine, β-(1,2,4-triazol-1-yl)-DL-alanine, β-(2-thiazolyl)-DL-alanine, α-(2-thienyl)glycine and 2-(2-aminoethyl)pyridine were purchased from Bachem and their purities were checked by TLC and HPLC methods. Concentrations of the ligand stock solutions were determined by potentiometric titrations. A stock solution of copper(II) was prepared from analytical grade reagents and the concentration was checked gravimetrically via the precipitation of oximates.

2.2. Potentiometric measurements

The pH-potentiometric titrations in the pH range 2.0–11.0 were performed on 3–4 cm^3 samples in the concentration range 2×10^{-3}–8×10^{-3} mol dm^{-3} at metal ion to ligand ratios ranging between 1:5 and 1:1. Argon was bubbled through the samples to ensure the absence of oxygen and to stir the solutions. Measurements were carried out at 298 K and at a constant ionic strength of 0.2 mol dm^{-3} KCl with a Radiometer pHM84 pH-meter equipped with a 6.0234.100 combined glass electrode (Metrohm) and a Dosimat 715 automatic burette (Metrohm) containing carbonate-free potassium hydroxide in known concentration. The number of experimental points reached around 50–70 data (cm^3 – pH) for each titration curve. The pH readings were converted into hydrogen ion concentration as described earlier [11].

Protonation constants of the ligands and the overall stability constants (log β_{pqr}) of the systems were calculated by means of general computational programs, PSEQUAD [12] and SUPERQUAD [13] using Eqs. (1) and (2).

$$pM + qH + rL \rightleftharpoons M_pH_qL_r, \tag{1}$$

$$\beta_{pqr} = \frac{[M_pH_qL_r]}{[M]^p\cdot[H]^q\cdot[L]^r}. \tag{2}$$

2.3. Spectroscopic measurements

UV–VIS spectra of the copper(II) complexes were recorded on a Hewlett Packard HP 8453 or JASCO UVI-DEC-610 spectrophotometer in the same concentration range as used for the potentiometry. Anisotropic X-band EPR spectra (9.15 GHz) of frozen solutions were recorded at 120 K, using a Varian E-9 spectrometer after addition of 10% ethylene glycol to ensure good glass formation in frozen solutions. The copper(II) stock solutions for EPR measurements were prepared from $CuSO_4\cdot5H_2O$ enriched with ^{63}Cu to get better resolution of the EPR spectra. For this purposes metallic copper (99.3% ^{63}Cu and 0.7% ^{65}Cu) was purchased from JV Isoflex, Moscow, Russia and converted to the sulfate.

2.4. Synthesis of the solid complex of β-(2-thienyl)-DL-alanine

The solid complex was obtained by dissolving in 50 ml of water, 0.5 mmol of Thien-Ala (85.6 mg) and 0.25 mmol of natural $CuSO_4\cdot5H_2O$ (^{63}Cu plus ^{65}Cu) (62.4 mg). NaOH was added to the solution under stirring until pH ~5. The reaction was performed at room temperature. A sky-blue polycrystalline precipitate was separated off after ca. 1 h. It was filtered off, washed with cool water and Et_2O dried at room temperature. Thermogravimetric data were obtained with a Perkin–Elmer TGS-2 apparatus under a nitrogen flow. Elemental analysis (C, H, N) was carried out with a Perkin–Elmer 240 B elemental analyser. IR spectra were recorded with a FT Bruker IFS-66 interferometer using KBr disks in the range 4000–500 cm^{-1}.

Anal. Calc. for $C_{14}H_{16}N_2O_4S_2Cu$ (403.96 g/mol): C, 41.63; H, 3.99; N, 6.93; CuO, 19.7. Found: C, 41.51; H, 3.77; N, 6.87%; CuO, 19.0%.

IR (KBr, cm^{-1}): 3265(s), 3147(s), 2952(w), 1633(vs), 1439(m), 1374(s), 1355(s), 1296(m), 1136(m), 1106(s), 973(w), 870(w), 845(m), 812(w), 710(s), 699(s).

3. Results and discussion

3.1. Protonation constants

The amino acid analogues (Thien-Gly, Thien-Ala, Thiaz-Ala, Triaz-Ala and Pyr-Ala) have principally three dissociable protons: the carboxyl group, the protonated amino group and the protonated aromatic group, which may take part in proton equilibrium pro-

Table 1
Protonation constants of the ligands ($T = 298$ K, $I = 0.2$ mol dm^{-3}; standard deviations are in parentheses)

	HL	H_2L	pK (COOH)	pK (Ar)	pK (NH_2)
Thien-Gly	8.38(1)	10.02(3)	1.64		8.38
Thien-Ala	8.82(1)	10.81(2)	1.99		8.82
Thiaz-Ala	8.38(1)	10.49(1)	2.11		8.38
Triaz-Ala	7.63(1)	9.42(1)	1.79		7.63
Pyr-Ala	8.86(1)	12.82(2)	<1	3.96	8.86
Amet-Pyr	9.63(2)	13.64(2)		4.01	9.63
2-Picolyl-amine [9]	8.69	10.83		2.04	8.79
His [18]	9.09	15.11	1.7	6.02	9.09
Histamine [19]	9.89	16.06		6.17	9.89
Phe [20]	9.11	11.33	2.22		9.11
Ala [14]	9.68	12.03	2.35		9.68

cesses. In the case of aliphatic amino acids the deprotonation of carboxylic and ammonium groups occur around pH 2 and 9, respectively (Gly:pK(COOH) = 2.36, p$K(NH_3^+) = 9.55$ [14] and see Table 1). The heteroaromatic compounds connected as side chains in our ligands themselves are also weak bases (pK values for pyridine: 5.26 [15], 1,2,4-triazole: 2.50 [16], thiazole: 2.68 [17]).

The protonation constants of the studied ligands and some others for comparison are collected in Table 1.

It is clear from these data that the highest pK values belong to the deprotonation of the ammonium group. However, only one more protonation process can be detected by potentiometric titration. For Pyr-Ala it can correspond to the pK value of the pyridine ring, and this is in good agreement with that detected for Amet-Pyr. In the case of the other four amino acid analogues (Triaz-Ala, Thiaz-Ala, Thien-Ala, Thien-Gly) the carboxylate group is a stronger base than the aromatic nitrogen donor atoms and this means that the pK values are characteristic for the proton equilibrium of the carboxylate group.

It can be concluded from an examination of Table 1 that the presence of an aromatic ring, due to its electron withdrawing effect, similarly decreases the pK values of both the ammonium and carboxylic group to Phe [20] and His [18]. Because of the decreasing basicity of the carboxylate group of Pyr-Ala, it was not possible to determine its pK value by potentiometry. On the other hand, the amino acid moiety decreases significantly the proton acceptor ability of the aromatic rings too. These processes take place only below pH 1.5, in agreement with literature data and similar effects were observed earlier for β-(2-pyridyl)-L-alanine, β-(2-pyridyl)-DL-alanine (pK(Ar) = 3.89, $pK(NH_3^+) = 8.95$) [6] and for 4,2′-aminoethylthiazole (pK(Ar) = 1.68, $pK(NH_3^+) = 9.53$) [7].

3.2. Copper(II) complexes of Thien-Gly, Thien-Ala and Thiaz-Ala

The stability constants of the copper(II) complexes are collected in Table 2.

It seems from the stoichiometry of the complexes that three amino acid analogues, Thien-Gly, Thien-Ala and Thiaz-Ala, form mono- and bis(ligand) complexes, $[CuL]^+$ and $[CuL_2]$. The ligands are coordinated to the metal centre in these complexes via (COO^-, NH_2) donor groups, similarly to the simple amino acids. This coordination mode is supported by the VIS and EPR parameters of the $[CuL]^+$ and $[CuL_2]$ complexes (see Table 3) which are in good agreement with those of Ala [22]. The log(K_1/K_2) values, which characterise the binding of the second ligand to the copper(II) ion, are similar to each other and to that of Phe [20].

These values, however, are lower than that of Ala [14] suggesting a favourable stacking interaction between the aromatic side chains in the bis(ligand) complexes [18,23]. The stability constants and spectroscopic parameters of the copper(II) complexes of Thien-Gly and Thien-Ala are similar. The fact that the aromatic thienyl ring, independently from the distance between the aromatic ring and amino acid moiety in the molecule, does not influence the complex formation processes also establishes the amino acid like coordination in both cases.

Table 2
Stability constants (logβ) of copper(II) complexes ($T = 298$ K, $I = 0.2$ mol dm^{-3}; standard deviations are in parentheses)

	Thien-Gly	Thien-Ala	Thiaz-Ala	Triaz-Ala	Pyr-Ala	Amet-Pyr	2-Picolyl-amine [9]	Phe [20]	Ala [14]	His [21]	Histamine [19]

Table 3
UV-VIS and EPR spectral parameters of the copper(II) complexes

		Thien-Gly	Thien-Ala	Thiaz-Ala	Ala [22]
ML	Coordination mode	(COO^-, NH_2)	(COO^-, NH_2)	(COO^-, NH_2)	(COO^-, NH_2)
	λ_{max} [nm] (ε [dm^3 mol^{-1} cm^{-1}])	700 (34)	690 (35)	709 (45)	
	$A_\parallel$ [10^{-4} cm^{-1}]; $g_\parallel$		164.0; 2.312	164.2; 2.296	165.2; 2.308
ML_2	Coordination mode	$2\times$(COO^-, NH_2)	$2\times$(COO^-, NH_2)	$2\times$(COO^-, NH_2)	$2\times$(COO^-, NH_2)
	λ_{max} [nm] (ε [dm^3 mol^{-1} cm^{-1}])	628 (68)	620 (61)	639 (94)	620 (60)
	$A_\parallel$ [10^{-4} cm^{-1}]; $g_\parallel$		179.7; 2.253	180.5; 2.239	179.6; 2.251
	$g_\parallel/A_\parallel$		125	124	125

In the case of Thien-Ala, the complex formation process was investigated in the solid state too. The stoichiometry of the complex isolated from a solution containing copper(II) and ligand in a 1:2 ratio was determined by means of elemental and thermogravimetric analysis and the results confirm the Cu:L = 1:2 stoichiometry and the lack of water in the solid complex. The electronic spectra of the powder show two neighbouring absorptions centred at 540 and 580 nm, which is consistent with the literature data on the electronic spectrum of the [Cu(L-Ala)$_2$] solid complex [24]. A definitive indication of the coordination mode of the ligand in this complex has been obtained by dissolving the solid compound in a non-coordinating solvent. It is slightly or not soluble in methanol, ethylene glycol, DMSO and CH_3CN, but it is partially soluble in DMF. The EPR parameters obtained from the spectrum of the filtrate are $g_\parallel = 2.244$, $A_\parallel = 184\times10^{-4}$ cm^{-1}. These data are similar to those of the bis chelated complex formed by natural Cu(II) with L-Ala in aqueous solution ($g_\parallel = 2.250$, $A\|\ = 185\times10^{-4}$ cm^{-1}) [25] indicating the $2\times$(COO^-, NH_2) coordination mode in the solid complex.

3.3. Copper(II) complexes of Triaz-Ala, Pyr-Ala and Amet-Pyr

The speciation of Cu(II)–Triaz-Ala and –Pyr-Ala systems are different from that of the other ligands. The complex formation processes start in more acidic pH values than in the case of simple amino acids (Fig. 1) and the formation of protonated complexes can be supposed.

It was not possible to calculate the stability constants of the protonated bis(ligand) complexes probably because of the low amount of the species, but the EPR spectra indicate its formation in low concentration (Fig. 2(c)). The $[CuHL]^{2+}$ complex, however, predominates around pH 2 both in equimolar solution and with an excess of ligand (Fig. 2(b)).

In both complexes, the copper(II) ions are bound to one or two ligands via the aromatic nitrogen and the amino group is protonated. The EPR parameters of $[CuHL]^{2+}$ and $[CuH_2L_2]^{2+}$ (see Table 4) are comparable with those, recorded with natural $CuSO_4\cdot5H_2O$, of [Cu(imidazole)]$^{2+}$ ($g_\parallel = 2.359$, $A_\parallel = 145\times10^{-4}$ cm^{-1}) and [Cu(imidazole)$_2$]$^{2+}$ ($g_\parallel = 2.314$, $A_\parallel = 160\times10^{-4}$ cm^{-1}) [22], respectively. The difference can be attributed to the presence of ^{65}Cu in the imidazole complexes, which increases the $A_\parallel$ and decreases the $g_\parallel$ values.

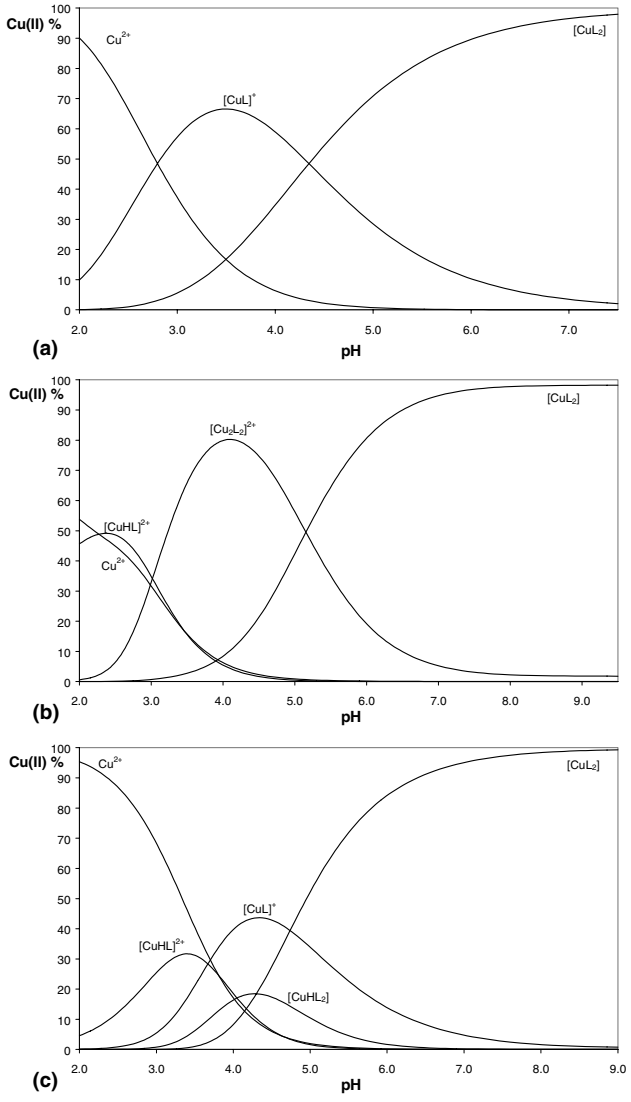

Fig. 1. Species distribution of the complexes formed in the copper(II)-ligand systems ($c_L = 4\times10^{-3}$ mol dm^{-3}, $c_{Cu(II)} = 2\times10^{-3}$ mol dm^{-3}) (a) L = Thiaz-Ala, (b) L = Triaz-Ala, (c) L = Pyr-Ala.

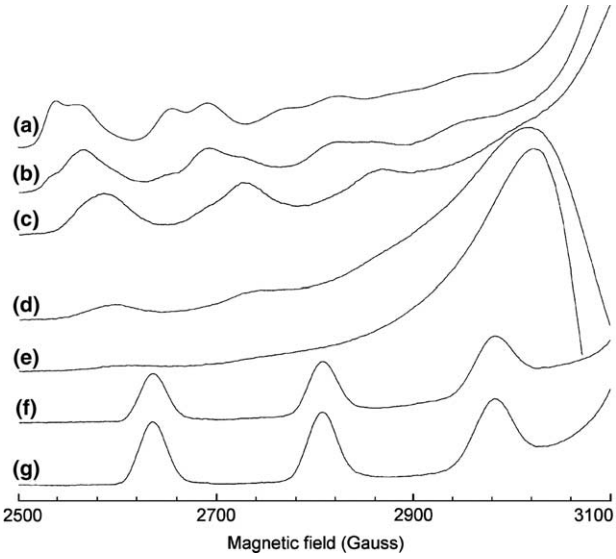

Fig. 2. Low-field parallel region of the X-band anisotropic EPR spectra recorded on the ^{63}Cu(II)–Triaz-Ala system at 140 K at different copper(II)-to-ligand molar ratios and pH values. Copper(II) concentration was 5×10^{-3} mol dm^{-3}. (a) Cu(II):L = 1:1, pH 1.42; (b) Cu(II):L = 1:2, pH 2.24; (c) Cu(II):L = 1:2, pH 3.03; (d) Cu(II):L = 1:2, pH 3.25; (e) Cu(II):L = 1:2, pH 4.00; (f) Cu(II):L = 1:2, pH 6.40; (g) Cu(II):L = 1:2, pH 10.27.

The deprotonation of the amino group is accompanied by a significant change of EPR spectra (Fig. 2). The spectra detected in the equimolar solution ($c_{Cu(II)} = 5 \times 10^{-3}$ mol dm^{-3}, pH of 3–8; $c_{Cu(II)} = 5 \times 10^{-2}$ mol dm^{-3}, pH of 2–8) and at excess of ligand (Cu:L = 1:2, pH of 3–6) show a broad, unresolved and isotropic band centred at $g \sim 2.130$ (Figs. 2(d) and (e)). A weak resonance can be simultaneously observed at 1560 G in the $\Delta M = \pm 2$ region. It reveals that di- or polynuclear species with dipolar coupling of the copper(II) ions are formed (the fitting of potentiometric data was made by the assumption of the formation of a dinuclear $[Cu_2L_2]^{2+}$ complex). In these species the ligands are bound both via amino acid like coordination and via an aromatic nitrogen donor, resulting in a ligand bridged structure. A water molecule completes the equatorial plane of the metal ion. The presence of di- or polynuclear species confirms that in the case of Triaz-Ala, the nitrogen donor atom of the aromatic ring in position 4 is not in a chelatable position with the terminal amino group and the involvement of all three donor groups of the molecule in the binding of the metal ions can take place only in a polynuclear structure. It means, however, that the tridentate coordination of Triaz-Ala can neither be supposed in $[CuL_2]$ species. The spectroscopic data obtained for $[CuL_2]$ are similar to those of bis(ligand) complexes of Thien-Ala and Ala and different from those of Pyr-Ala or His, supporting the amino acid like coordination in the $[CuL_2]$ species.

The complex formation processes of Pyr-Ala are also different from Thien-Gly, Thien-Ala and Thiaz-Ala. Similarly to Triaz-Ala, protonated mono- and bis-(ligand) complexes are present in a small amount around pH 3.5 (Fig. 1(c)). The coexistence of $[CuHL]^+$ species with the aqua ion is indicated by the shoulder high-field of the parallel hyperfine resonance of the spectrum detected in equimolar solution at pH 3.09 and at excess of ligand (1:2 ratio) at pH 3.52 (Fig. 3(a)).

Only approximated EPR parameters can be extracted (Table 4), because the formation of carboxylate complexes does not affect the EPR parameters very significantly in comparison to the aqua ion ($g_\parallel = 2.406$, $A_\parallel = 134 \times 10^{-4}$ cm^{-1}) [22]. In the $[CuHL]^{2+}$ species the ligand may bind monodentately via the pyridine nitrogen donor or carboxylate group or bidentately via amino acid like coordination. The spectroscopic parameters are, however, significantly different from those of amino acid like coordinated copper(II) complexes. It means that in the $[CuHL]^{2+}$ complex the amino group is protonated.

Table 4

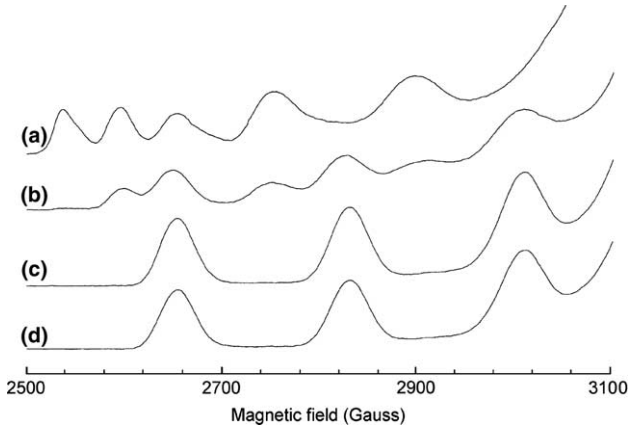

Fig. 3. Low-field parallel region of the X-band anisotropic EPR spectra recorded on the ^{63}Cu(II)–Pyr-Ala system at 140 K at different pH values. Copper(II)-to-ligand molar ratio was 1:2 and copper(II) concentration was 5×10^{-3} mol dm^{-3}, pH: (a) 3.52; (b) 3.97; (c) 7.84; (d) 10.12.

Information about the interaction between the copper(II) ion and the monodentately coordinated ligand can be obtained from value log $\beta([CuHL]^{2+})$ – log $\beta([HL]) = 11.91 - 8.86 = 3.05$. From the comparison of this data with stability constants of $[CuL]^{2+}$ formed in copper(II)–pyridine (log $\beta_1 = 2.49$ [15]) and copper(II)–acetic acid (log $\beta_1 = 1.81$ [15]) systems, the coordination of the aromatic pyridine nitrogen of the ligand can be concluded. This coordination mode is supported by UV–VIS parameters (Table 4), which corresponds to one nitrogen donor coordinated copper(II) complex. (The calculated λ_{max} for coordination of one aromatic nitrogen on the basis of Billo's empirical formulae [27] is 760 nm). On the other hand, the EPR parameters are close to those reported for the Cu(II)–COO^- interaction that exists in the copper(II)–lactobionic acid system ($g_\parallel = 2.369$, $A_\parallel = 138 \times 10^{-4}$ cm^{-1}) [28], so the protonated complex with carboxylate coordination cannot be excluded. $[CuHL]^{2+}$ is followed by the formation of a minor species, $[CuHL_2]^+$, not detectable by EPR spectroscopy.

The deprotonation processes of $[CuHL]^{2+}$ and $[CuHL_2]^+$ belong to the deprotonation of the amino group. The pK values of these processes (Table 2) are much lower than p$K(NH_3^+)$ values, due to the coordination of the amino group and formation of chelates in $[CuL]^+$ and $[CuL_2]$ complexes. The comparison of EPR parameters with those of the monochelated complex of L-Ala [22] (Table 3) and Amet-Pyr (Table 4) reveals the coordination of the (NH_2, Pyr N) donor set with the possible weak interaction of a carboxylate group in the axial position. The EPR parameters of $[CuL_2]$ are different with respect to those of the bis(ligand) complex of L-Ala (Table 3) and Amet-Pyr (Table 4). Particularly, the $g_\parallel$ value is intermediate between the two species: the $g_\parallel$ value of the bis(ligand) complex formed by Amet-Pyr is sensibly lower and substantiates coordination of four nitrogen donor atoms, whilst the $[CuL_2]$ complex of L-Ala is bound only by two nitrogen donor atoms. These data, however, are in good agreement with the parameters measured for the mixed complex formed by Amet-Pyr and Gly ($g_\parallel = 2.236$ and $A_\parallel = 187 \times 10^{-4}$ cm^{-1}), with coordination of the (NH_2, Pyr N; COO^-, NH_2) set, [22] revealing the same type of donor set in $[CuL_2]$ species of Pyr-Ala. The EPR parameters are comparable also with those reported by Micera et al. for the mixed complex [Cu(His)(Ala)], ($g_\parallel = 2.239$ and $A_\parallel = 192 \times 10^{-4}$ cm^{-1}) and for [Cu(His)-(Val)], ($g_\parallel = 2.239$ and $A_\parallel = 190 \times 10^{-4}$ cm^{-1}) [29]. In these cases a mixed CuN_3O coordination mode has been proposed with a (COO^-, NH_2) donor set of the aliphatic amino acid and with the (NH_2, Im N) set of histidine. This conclusion is supported by the electronic absorption data for CuL_2 (612 nm), which are very similar to those of complex $[Cu(Amet\text{-}Pyr))(Gly)]^+$ ($\lambda_{max} = 614$ nm and $\varepsilon_{max} = 71$ M^{-1} cm^{-1}) [22] and [Cu(His)(Ala)] (610 nm) and [Cu(His)(Val)] (610 nm) [29]. The weak coordination of a carboxylate group of one ligand and of an aromatic nitrogen atom of the second one in the two axial positions cannot be excluded on the basis of our measurement.

The $g_\parallel/A_\parallel$ values (see the last rows of Tables 3 and 4) of Pyr-Ala and Amet-Pyr are similar to each other (118 and 117, respectively) and are different from that of Ala (125), indicating a marked planarity of the $[CuL_2]$ complexes, greater than that of L-Ala. In the case of Amet-Pyr, however, the log(K_1/K_2) value is much higher than that of Pyr-Ala. In the bis(ligand) complex of Amet-Pyr, two amino and two aromatic nitrogen donors are bound in the equatorial plane of the copper(II) centre. As it was published earlier [21], the coordination of mixed aromatic N, amino N and O donor atoms are much more preferable than the binding of $2 \times (NH_2$, Ar N) donor groups. For Pyr-Ala, EPR measurements were performed in a more concentrated equimolar solution ($c_{Cu(II)} = c_L = 5 \times 10^{-2}$ mol dm^{-3}) too. In this case a polynuclear $[(CuL)_n]$ species is the major complex in the pH range 4–6. In this species each Cu(II) ion should be surrounded by amino- and pyridine nitrogens and an oxygen atom of a carboxylate group in the equatorial region, and each ligand acts as a bridge between two Cu(II) ions. The arrangement is comparable to that of the analogous species formed by Triaz-Ala. In the spectrum recorded at pH 4.62 the presence in the $\Delta M = \pm 1$ region of an unresolved broad and isotropic resonance centred at $g = 2.098$ can be observed, by which the resonances of the monomers are superimposed (Fig. 4). This indicates a magnetic interaction of two or more $S = 1/2$ ions, even if the lack of fine and hyperfine resolution hinders the advance of a hypothesis about the particular structure of the complex. The presence of a signal in $\Delta M = \pm 2$ region at $H = 1540$ G substantiates our

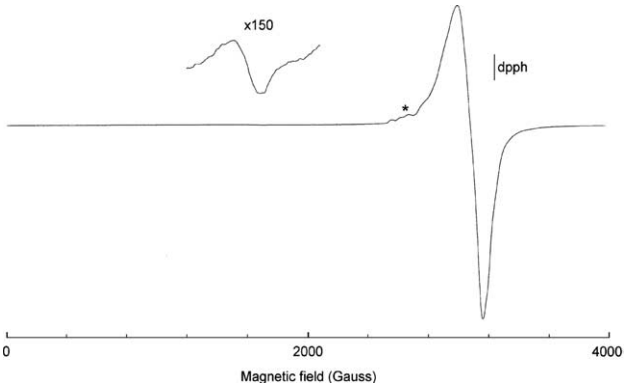

Fig. 4. X-band anisotropic EPR spectrum recorded at 140 K on the ^{63}Cu(II)–Pyr-Ala system at pH 4.62 and metal concentration 5×10^{-2} M. The signals attributable to monomeric species are denoted with an asterisk. The $\Delta M = \pm 2$ transition has been amplified 150-fold.

hypothesis. The approximated λ_{max} value is 672 nm ($\varepsilon_{max} = 33\ M^{-1}\ cm^{-1}$), which corresponds a polynuclear species with the set (NH_2, Pyr N, COO^-, H_2O) coordinated to the copper(II) ions. This value is slightly higher than that of the mixed species [Cu(2-(2-aminoethyl)pyridine)(oxalato)], characterised by a (NH_2, Pyr N, COO^-, COO^-) donor set ($\lambda_{max} = 647$ nm) [22]. The presence of a water molecule instead of a carboxylate ion in the coordination sphere of copper(II) would increase the λ_{max} value by about 20 nm [27].

4. Conclusion

The complex forming properties of five non-proteinogenic histidine analogues were studied and the results of their copper(II) complexes are summarised in this paper. The main binding sites of all five amino acid ligands are the amino acid moiety and in all cases amino acid like coordinated complexes are present in almost the whole pH range studied. Depending on the type of aromatic ring, however, the complex formation processes and/or stability of complexes are affected more or less compared to those of simple amino acids.

For three ligands, Thien-Gly, Thien-Ala and Thiaz-Ala, the coordination of aromatic donor groups was not detected in any species, but similarly to Phe the stability of bis(ligand) complexes is enhanced due to the stacking effect of aromatic rings.

The interaction between aromatic triazolyl or pyridyl nitrogen atoms and copper(II) ion was assumed in the case of Triaz-Ala and Pyr-Ala. It results in the formation of protonated mono- and bis-(ligand) complexes in strong acidic media with monodentate binding of the ligands. Following the deprotonation of the amino group, the binding of all donor groups (amino, carboxylate and aromatic nitrogen) can be supposed. In the case of Triaz-Ala, because of the steric effect, it could exist only as a polynuclear structure with ligand bridging, while tridentate coordination of Pyr-Ala was detected in the mononuclear complexes formed in diluted solution ($c_L = 5 \times 10^{-3}$ mol dm^{-3}). The polynuclear structure, however, also can be formed in the copper(II)–Pyr-Ala system, but with a more concentrated solution ($c_L = 5 \times 10^{-2}$ mol dm^{-3}) than in the case of Triaz-Ala.

As a conclusion, we can state that the presence of heteroaromatic rings in an amino acid analogue can influence the amino acid like coordination mode. Their effects decrease in order imidazole > pyridyl ~ triazolyl > thiazolyl ~ thienyl rings.

Abstract

Polyfunctional ligands derived from condensation reactions in which small molecules, e.g., water, an alcohol, etc., are eliminated can suffer the ravages of hydrolytic attack on reaction with transition metal ions in aqueous based solvents, or solvents containing small amounts of water. A series of such reactions is described involving hydrazone based ligands, in which hydrolyzed ligand fragments, and their resulting coordination complexes, are produced. Structures are reported to identify these products, which reveal some unexpected ligand rearrangements. Variable temperature magnetic data are discussed for some dinuclear complexes, and a DFT study is presented to rationalize an unusual ligand transformation.

1. Introduction

Ligands derived from condensation reactions, which involve elimination of small molecules, e.g., water, or an alcohol, are at risk of hydrolytic attack in solvents that contain water, when reacted with transition metal salts. Such reactions can be promoted or catalyzed by the presence of the transition metal ion, whose high ionic potential can in many cases exert a significant polarizing effect on the hydrolytically vulnerable bonds. In some cases the complexes which are formed contain 'expected' hydrolysis products, but in other cases some surprising results can occur.

In a recent report the ligand L1 was shown to be hydrolytically unstable in the presence of $CuBr_2$ in aqueous acetonitrile, and a mixed oxidation state $Cu(II)_4Cu(I)_2$ complex of the ligand picolinamide hydrazone (PAH) was produced (Scheme 1) [1]. The reduction of copper(II) was associated with the presence of acetonitrile and the reducing capacity of salicylaldehyde, detected during the reaction. The symmetrical open chain diazine ligands PAHAP and PZHPZ (Chart 1) react with Fe(III) nitrate in aqueous solution to spontaneously form the reduced dinuclear $[Fe(II)_2(L)_3]^{4+}$ (L = PAHAP, PZHPZ) complex ions in low yield, suggesting the formation of hydrazine based fragments, presumably resulting from hydrolysis of an imine group, which act as metal ion reductants. In the case of PAHAP, reaction with Fe(III) nitrate also produces the complex ion $[Fe(III)(POAP-H)(H_2O)_2(NO_3)]^{2+}$ (POAP, Chart 1) as a minor product, indicating the imine group as an initial point of hydrolytic

attack in the formation of the analogous acyl ligand, presumably promoted by the coordination of the highly polarizing Fe(III) center [2].

The present report discusses transition metal complexes derived from a group of extended polyfunctional diazine ligands L2–L6 (Chart 1), in which metal ion based ligand hydrolysis has occurred at a 'vulnerable' ligand C=N site, with the formation of complexes containing rearranged ligands and ligand fragments. The ligand L3 has been reported elsewhere, along with a number of coordination complexes, but there is no evidence for ligand hydrolysis [3]. The ligand L4 undergoes hydrolysis in the presence of Co(II) in air, and with Cu(II) salts, but remains intact on reaction with Ni(II) carbonate. Structures are reported for some iron, nickel and copper complexes, and the magnetic properties of some polynuclear copper and iron products are discussed. DFT studies are highlighted in one nickel case where an unusual ligand transformation takes place.

2. Experimental

2.1. Physical measurements

Infrared spectra were recorded as Nujol mulls using a Mattson Polaris FTIR instrument. Mass spectra were obtained using a VG Micromass 7070HS spectrometer and an Agilent 1100 series LC/MSD spectrometer. C, H, N analyses on dried samples were carried out by the Canadian Microanalytical Service, Delta, B.C., Canada. Variable temperature magnetic data (2–300 K) were obtained with a Quantum Design MPMS5S Squid magnetometer operating at 0.1–5.0 T. Calibrations were carried out with a palladium standard cylinder, and the normal diamagnetic corrections were applied.

2.2. Syntheses

2.2.1. L2

2-Acetyl pyridine (3.70 g, 0.0300 mol) was dissolved in methanol (100 mL). Oxalic acid dihydrazide (1.77 g, 0.0150 mol) was added and the mixture refluxed for 12 h. A white precipitate formed, which was separated by filtration, washed with methanol and ether and dried under vacuum (Yield 4.4 g, 91%); m.p. dec. >260 °C. Mass spectrum (*m*/*z*) 189, 162, 134, 106, 78 (molecular ion not observed). IR (ν cm^{-1}) 1681 (C=O), 1012 (pyr). *Anal*. Calc. for $C_{16}H_{16}N_6O_2$: C, 59.25; H, 4.97; N, 25.91. Found: C, 58.67; H, 4.94; N, 25.72%.

2.2.2. L3

Butanedione monoxime (5.04 g, 0.0498 mol) was dissolved in absolute ethanol (40 mL). Picolinic acid hydrazide (3.32 g, 0.0242 mol) was added and the mixture refluxed for several hours with the formation of a white suspended solid. The fine white precipitate was filtered off and washed with methanol (Yield 4.86 g, 91%). Recrystallization from acetonitrile produced colorless crystals, but crystals suitable for structural determination were obtained from the reaction of $Gd(NO_3)_3$ and L3 in a MeCN, MeOH, H_2O mixture, in which there appeared to be no Gd complex formation. Mass spectrum (*m*/*z*) 221 (MH^+), 203, 182, 124, 108, 79. IR (ν cm^{-1}) 3343 (OH), 1677 (C=O), 995 (pyr). *Anal*. Calc. for $C_{10}H_{12}N_4O_2$: C, 54.55; H, 5.45; N, 25.45. Found: C, 54.55; H, 5.58; N, 25.41%.

2.2.3. L4

2-Benzoylpyridine (7.44 g, 41 mmol) was dissolved in $CHCl_3$ (220 mL). 4-Chloro-2,6-pyridine carboxylic acid hydrazide (2.30 g, 10 mmol) was added, along with dry methanol (30 mL), and the mixture was refluxed for 72 h. The volume of the resulting solution was reduced by about 50%, and methanol (30 mL) was added and heating continued until a white precipitate formed. The precipitate was collected by suction filtration, and washed with methanol and diethyl ether (Yield 3.6 g, 65%); m.p. 288–294 °C. Mass spectrum (*m*/*z*) 560 (M), 542 ($M - H_2O$). IR (ν, cm^{-1}) 1697 (C=O), 1574 (C=N), 997 (py). *Anal*. Calc. for $C_{31}H_{22}N_7O_2Cl\cdot 0.5H_2O$: C, 65.49; H, 4.05; N, 17.25. Found: C, 65.25; H, 3.95; N, 17.33%.

2.2.4. L6

2,6-Pyridine carboxylic acid hydrazide (0.93 g, 5.0 mmol) was added to a solution of dipyridyl ketone (1.84 g, 10 mmol) in absolute ethanol (50 mL), and the mixture was refluxed for 10 h. The product formed as a white solid during the reaction, and was filtered off, washed with ethanol and dried in air (Yield 1.7 g, 90%). *Anal*. Calc. for $C_{18}H_{15}N_7O_2(C_{29}H_{21}N_9O_2)_{0.22}$; C, 61.34; H, 4.14; N, 26.35. Found: C, 61.31; H, 4.09; N, 26.19%. The reaction appears to have produced a mixture of mono and disubstituted ligands, with about 20% disubstituted. Separation could not be effected cleanly, and so the mixture was used in the reaction with $Cu(NO_3)_2$ (vide infra).

*2.2.5. $[Cu_2(L7)_2(C_2O_4)(H_2O)_2(NO_3)_2]$ (**1**), $[Cu_2(L7)_2(C_2O_4)](ClO_4)_2$ (**2**)*

L2 (0.324 g, 1.00 mmol) was added to a warm solution of $Cu(NO_3)_2\cdot 3H_2O$ (0.483 g, 2.00 mmol) in $MeOH/H_2O$ (10/5 mL), forming a green solution. Dark green crystals, suitable for a structural analysis, were obtained on standing the solution at room temperature over several days (Yield 0.37 g, 45%). *Anal*. Calc. for $[(C_7H_9N_3)_2Cu_2(C_2O_4)(H_2O)_2(NO_3)_2]$: C, 29.78; H, 3.44; N, 17.36. Found: C, 29.79; H, 3.33; N, 17.67%. **2** was produced under similar conditions using copper(II) perchlorate (Yield 50%). *Anal*. Calc. for $[(C_7H_9N_3)_2Cu_2(C_2O_4)](ClO_4)_2$: C, 28.08; H, 2.65; N, 12.28. Found: C, 28.37; H, 2.63; N, 12.24%.

*2.2.6. $[Ni(L8)]Br\cdot CHCl_3$ (**3**)*

$NiBr_2$ (0.24 g, 1.0 mmol) was suspended in 50/50 $CH_3CN/MeOH$ (20 mL). L3 (0.20 g, 0.90 mmol) was added and the mixture was heated with stirring. A clear orange solution formed, which was filtered and allowed to stand, forming a red orange powder (Yield 55%). Recrystallization from $CHCl_3$ gave red block shaped crystals suitable for structural determination. A similar reaction with $Ni(ClO_4)_2\cdot 6H_2O$ and $Ni(NO_3)_2\cdot 6H_2O$ gave $[Ni(L8)](ClO_4)\cdot H_2O$ and $[Ni(L8)](NO_3)\cdot 2H_2O$, respectively, as red powders (Yield 60–70%). *Anal*. Calc. for $[(C_{16}H_{15}N_6O_2)Ni](ClO_4)\cdot H_2O$: C, 38.55; H, 3.41; N, 16.86. Found: C, 38.27; H, 3.30; N, 16.73%. *Anal*. Calc. for $[(C_{16}H_{15}N_6O_2)Ni](NO_3)\cdot 2H_2O$: C, 40.08; H, 3.97; N, 20.46. Found: C, 39.56; H, 3.29; N, 20.37%. Similar infrared spectral bands associated with the ligand L8 are observed in all three compounds.

*2.2.7. $[Cu_2(L9)(L10)]\cdot 2H_2O\cdot CH_3OH\cdot L11$ (**4**)*

L4 (0.10 g, 0.18 mmol) was added to a solution of copper acetate (0.18 g, 0.45 mmol) in methanol (20 mL), forming a clear brown solution. Red brown crystals of **4**, suitable for a structural determination, were obtained in low yield (35 mg) after allowing the solution to evaporate to a small volume. *Anal*. Calc. for $[(C_{19}H_{11}N_4O_3Cl)(C_7H_2NO_4Cl)Cu_2](C_{12}H_9N_3)\cdot 7H_2O$: C, 44.53; H, 3.52; N, 10.94. Found: C, 44.47; H, 2.67; N, 11.08%. The dried analytical sample contains no methanol.

*2.2.8. $[Fe_2(PZHPZ)_3](ClO_4)_4\cdot 2CH_3CN$ (**5**)*

L5 [4] (0.070 g, 0.16 mmol) was added to a degassed solution of $Fe(ClO_4)_2\cdot 6H_2O$ (0.122 g, 0.48 mmol) in CH_3CN (10 mL) under an Ar atmosphere. The mixture was heated to reflux for 10 min., and then left at room temperature. Purple crystals formed after several days in the Ar atmosphere (Yield 50 mg), which were kept under the mother liquor prior to structural analysis. Solvent loss occurred on exposure of the bulk sample to air. *Anal*. Calc. for $[(C_{10}H_{10}N_8)_3Fe_2](ClO_4)_4\cdot 7H_2O$: C, 26.45; H, 3.26; N, 24.68. Found: C, 26.40; H, 2.69; N, 24.93% (air dried sample).

*2.2.9. $[Cu_2(L12\text{-}2H)](NO_3)_2\cdot 1.5H_2O$ (**6**)*

L6 (0.25 g, 0.50 mmol) was added to a solution of $Cu(NO_3)_2\cdot 3H_2O$ (0.72 g, 3.0 mmol) in $MeOH/H_2O$ (20/10 mL) and the mixture was warmed. Green crystals were obtained from the resulting green solution on standing at room temperature (Yield 0.21 g, 68%). *Anal*.

Calc. for $(C_{18}H_{11}N_5O_3)Cu_2(NO_3)_2\cdot 1.5H_2O$. C, 34.68; H, 2.26; N, 15.73. Found: C, 34.50; H, 2.12; N, 16.10%.

2.2.10. [Ni(L4-2H)] (7)

$NiCO_3$ (0.18 g, 1.5 mmol) was suspended in 1:1 MeCN/EtOH (20 mL). L4 (0.10 g, 018 mmol) was added and the mixture was heated. Water (5 mL) was added and heating continued for 15 min. with the formation of a red solution. The solution was filtered to remove excess nickel carbonate, and allowed to stand at room temperature. Red crystals suitable for structural analysis formed after two days (Yield 60 mg, 55%).

2.3. X-ray crystallography

The diffraction intensities of a green prismatic crystal of **1** were collected with graphite-monochromatized Mo Kα X-radiation (rotating anode generator) using a Bruker P4/CCD diffractometer at 193(1) K to a maximum 2θ value of 52.8°. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods [5,6]. All atoms except hydrogen atoms were refined anisotropically. Hydrogen atoms were placed in calculated positions with isotropic thermal parameters set to 20% greater than their bonded partners, and were not refined. Neutral atom scattering factors [7] and anomalous-dispersion terms [8,9] were taken from the usual sources. All other calculations were performed with the teXsan [10] crystallographic software package.

Diffraction data were collected for **3**–**5** in a similar manner. Abbreviated structural data for **1**, **3**–**5** are reported in Table 1.

The diffraction intensities of a colourless single crystal of L3 were collected with graphite-monochromated Cu Kα X-radiation using a Rigaku AFC6S diffractometer at 299(1) K and the ω–2θ scan technique to a 2θ value of 120.1°. The data were corrected for Lorentz and polarization effects. The structure was solved by direct methods [5,6]. All atoms except hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced with isotropic thermal parameters set 20% greater than those of their bonded partners at the time of their inclusion. They were optimized by positional refinement. Neutral atom scattering factors [7] and anomalous-dispersion terms [8,9] were taken from the usual sources. All calculations were performed with the teXsan [10] crystallographic software package. Diffraction data for **7** (red prism) were collected in a similar manner. Abbreviated structural details for L3 and **7** are listed in Table 1.

Diffraction data for a single crystal of **6** (green prism, $0.30\times0.40\times0.20$ mm) were collected using a Bruker SMART CCD diffractometer, equipped with an Oxford Cryostream N_2 cooling device [11], with graphite monochromatized Mo Kα radiation. Cell parameters were determined and refined using the SMART software [12a], raw frame data were integrated using the SAINT program [12b] and the structure was solved using direct methods and refined by full-matrix least squares on F^2 using SHELXTL [13]. Non-hydrogen atoms were refined with anisotropic atomic displacement parameters (adps). Hydrogen atoms bound to carbon atoms were placed in geometrically calculated positions with isotropic adps 1.2 times that of the parent atom.

2.4. Computational details

All calculations were carried out using GAUSSIAN-03 [14]. Ligand and complex structures were optimized using Becke's hybrid B3LYP functional [15]. The split-valence with polarization (SVP) basis set of Ahlrichs and coworkers [16] was felt to provide a good compromise between computational accuracy and efficiency, and was used for all calculations, except where noted. For all geometry optimizations, frequencies were also calculated to ensure that the structures were genuine minima on the potential energy hypersurface (no imaginary frequencies were found).

3. Results and discussion

3.1. Structures

3.1.1. $[Cu_2(L7)_2(C_2O_4)(H_2O)_2(NO_3)_2]$ (1)

The molecular structure of **1** is comprised of three similar dinuclear fragments, all involving the bidentate ligand 2-acetylpyridine hydrazone (L7), and a bridging oxalate. In combination they are represented by the averaged formula above. Relevant bond distances and angles are listed in Table 2. Two fragments are shown in Fig. 1(a). The Cu(3) fragment has four distant nitrates bound to a 'flat' dinuclear center, with long Cu–O contacts (Cu(3)–O(12) 2.524(4) Å, Cu(3)–O(14) 2.468(4) Å). Cu–L in plane distances fall in the range 1.973–1.985 Å, and the Cu–Cu distance is 5.149(3) Å. The bridging oxalate has a typical geometry. The Cu(3) dinuclear subunit is hydrogen bonded to the Cu(4) subunit (Fig. 1(a); O(15)–O(9) 2.795(5) Å, O(9)–O(13) 2.786(6) Å). Subunit Cu(4) has a similar geometry with five-coordinate square pyramidal copper centers, and with each metal having an axially bound water molecule (Cu(4)–O(9) 2.273(4) Å). The third dinuclear subunit (Fig. 1(b)) has a similar structure with square pyramidal copper centers, and axial contacts to oxygen atoms from a disordered combination of a water molecule and a nitrate (Cu(1)–O(21) 2.345(5) Å, Cu(2)–O(20) 2.365(5) Å). Other dimensions within this dinuclear subunit are similar to those involving Cu(3) and Cu(4).

3.1.2. L3

The structure of the ligand (L3) is shown in Fig. 2, and relevant bond distances and angles are listed in Table 3. The good refinement shows that a proton resides on N(2) and that the C–O bond has predominantly double bond character (C(6)–O(1) 1.230(5) Å). The N(2)–N(3) distance (1.389(5) Å) indicates this bond to have mostly single bond character. One interesting structural feature that bears on the reactivity of this ligand surrounds the *anti* (*trans*) conformation of the ligand as a whole, and in particular with respect to the two methyl groups, as indicated by the torsional angles C(10)–C(8)–C(7)–C(9) and C(7)–N(3)–N(2)–C(6) (177.4°, 178.1°, respectively), which are both very large. DFT calculations on L3, which utilize the B3LYP functional and 6-31G(d) basis set, indicate that the *anti* form

is more stable than the *eclipsed* form, with an energy difference of ~25 kJ/mol.

3.1.3. [Ni(L8)]Br·CHCl$_3$ (3)

The molecular structure of **3** is shown in Fig. 3(a), and relevant bond distances and angles are given in Table 4. The obvious first point of discussion is the fact that the starting ligand (L3) is not present, but a new Schiff base ligand L8 is formed, based on a central butane-dione fragment. L8 acts in a tetradentate fashion coordinating to the nickel ion via two diazine nitrogen atoms, a pyridine nitrogen and an oxygen atom, creating quite a strong in plane crystal field. This is strong enough to cause the Ni(II) ion to be low spin (vide infra). The NiN_3O subunit is essentially planar (O(1)–Ni–N(5) 179.8(2)°, N(3)–Ni–N(6) 178.9(2)°), with very short Ni-ligand contacts (1.828–1.887 Å). Both C–O bonds have predominantly double bond character (C(6)–O(1) 1.285(6) Å, C(11)–O(2) 1.222(6) Å), and since the ligand has lost one proton, nitrogen atoms N(3) and N(5) bear a formal negative charge, consistent with the short Ni–N distances. The second proton (H(1)) resides on pyridine nitrogen N(1) (difference map), thus giving the complex ion a formal charge of 1+. The bromide ion (Br(1)) balances the charge, and is hydrogen bonded to H(1) and also to a chloroform molecule (Br(1)–H(16) 2.692(6) Å, Br(1)–H(1) 2.467(6) Å).

The flat nature of the Ni(II) ion, generated by the strong in plane crystal field, predisposes the whole ligand to adopt a fairly flat overall conformation, with the methyl groups in an unexpected *cis*-conformation (see structure of L3). The molecules are arranged in a stacked, alternating, *trans*-conformation in the lattice, with pairs of molecules related by an inversion centre. There are many relatively short (<4 Å) intermolecular contacts between individual molecules, e.g., N(4) and O(1) (3.304 Å) (highlighted in Fig. 3(b)), with the Ni–Ni distances between molecules in the stack alternating as 3.663(3), and 4.743(4) Å. Any axial contacts to the nickel centres between molecules are considered too weak to be of bonding significance. However, the intermolecular contacts are clearly instrumental in the parallel arrangement of the molecules of **3**. The complexes

$[Ni(L8)](ClO_4)\cdot H_2O$ and $[Ni(L8)](NO_3)\cdot 2H_2O$ are assumed to have similar overall structures.

Of note is the fact that the DFT structure (Fig. 3(c)) and X-ray structure (Fig. 3(a)) of [Ni(L8)]Br are in excellent agreement. For the square-planar nickel coordination sphere, the average deviation in bond lengths between the two structures was 0.02 Å. The average deviation in bond angles was 0.6°. This is comparable to results reported by Jang et al. [17] for the structures of iron carbonyls, where differences between B3LYP (double-ζ plus polarization basis set) and X-ray crystal structures were on the order of 0.02 Å and 0.5° for bond lengths and angles, respectively. For a medium-sized transition metal complex such as **3** (41 atoms, with 467 basis functions), such agreement is quite reasonable. This indicates the theory and basis set used are likely sufficient for the obtainment of good quality results.

3.1.4. $[Cu_2(L9)(L10)]\cdot 2H_2O\cdot CH_3OH\cdot L11$ (**4**)

The structure of the asymmetric unit in **4** is shown in Fig. 4, and relevant bond distances and angles are listed in Table 5. The original ligand L4 is clearly absent, and instead the complex contains three different ligand fragments derived from L4; the mono-acid ligand (L9), 4-chloro-2,6-pyridinedicarboxylate (L10) and 3-phenyltriazolo[1,5-a]pyridine (L11). Cu(1) and Cu(2) are bridged by the N–N diazine group in L9. A pyridine nitrogen (N(4)) and a carboxylate oxygen (O(2)) and the other pyridine nitrogen (N(1)) complete coordination to Cu(1). Cu(2) is bonded to the hydrazone oxygen O(1) from L9, and three donors (N(5), O(4), O(7)) from the dicarboxylate ligand L10. Cu(1) has four short in plane contacts (1.903–2.006 Å), but in the extended structure a fifth axial contact (Cu(1)–O(3) 2.632(3) Å) indicates that the geometry is axially elongated square-pyramidal (vide infra) (N(3)–Cu(1)–O(2) 162.2°, N(4)–Cu(1)–N(1) 173.4°). Cu(2) has a distorted square pyramidal coordination geometry within the asymmetric unit, with short in plane distances (1.903–2.033 Å), and a longer axial contact (N(2)–Cu(2) 2.368(3) Å). However, in the extended structure (vide infra) a sixth contact (Cu(2)–O(6) 2.375(2) Å) shows that the geometry is actually axially elongated octahedral. There are no anions in the structure indicating that both ligands have

lost two protons. This is consistent with the in plane Cu–O and Cu–N distances. The torsional angle Cu(1)–N(3)–N(2)–Cu(2) (178°) indicates an almost *trans* disposition of the copper atoms about the N–N single bond; however, this is an orthogonal magnetic connection (vide infra). The copper equatorial planes are also connected by a longer N–C–O pathway through N(3) and O(1).

A remarkable feature of the structure is the presence of the 'uncoordinated', fused triazole molecule L11. Fig. 4 shows that the phenyl triazole is held in place above three rings associated with the coordinated ligand L9. The pyridine ring is positioned above the N(1) pyridine ring in L9, the phenyl ring above the chloro-pyridine ring in L9 and the triazole ring above the chelate ring involving O(2) in L9. Distances between these rings subunits are relatively short (e.g., 3.3–4.0 Å) indicating that there are significant π-stacking interactions at play, which help to stabilize the location of the triazole molecule. The shortest distance (3.386 Å) is between N(7) and O(2). This is quite remarkable, possibly unprecedented in normal coordination chemistry, and highlights the importance of π stacking forces as a means of 'holding' a molecule in close proximity to a metal ion site. One is reminded of the unusual stabilization of a tryptophan moiety close to the active site in galactose oxidase, with a possibly similar interaction with a tyrosine ligand [18]. Also the phenyl ring of L9 is positioned above the pyridine ring (N(5)) in L11, with short contacts between ring atoms (3.45–3.77 Å) highlighting the nice fit of the aromatic rings in this complex.

The overall structure of **4** reveals some further surprises. The dinuclear subunit shown in Fig. 4 actually forms a dimer through a carboxylate bridge (O(6)) linking Cu(2) with its symmetry related counterpart. Also, the tetranuclear subunits are cross-linked to form a zig-zag chain, via symmetry related O(6) atoms (Fig. 5), and finally the zig-zag chains are cross-linked into a 2D grid by long axial O(3)–Cu(1) contacts (2.632(3) Å) shown in Fig. 6. The global direct connectivity between the copper atoms in all cases links the metal ions orthogonally, thus predisposing the system

to the absence of significant antiferromagnetic exchange (vide infra).

3.1.5. $[Fe_2(PZHPZ)_3](ClO_4)_4\cdot 2CH_3CN$ (**5**)

The molecular structure of **5** is shown in Fig. 7, and relevant bond distances and angles are listed in Table 6. L5 is clearly absent and the simple pyrazine amidrazone ligand is involved in coordination to Fe(II). Three ligands are wrapped around the two iron(II) centers in a spiral fashion, with three single N–N bonds connecting the metal ions. The dinuclear complex cation is essentially identical to that reported previously for the complex $[Fe_2(PZHPZ)_3](NO_3)_4\cdot 5H_2O$ [2], obtained from the reaction of $Fe(NO_3)_3$ with PZHPZ (Chart 1), with slight differences in internal dimensions. Fe–N distances

in **5** are slightly longer (1.961–1.970 Å) in keeping with a slightly larger Fe–Fe separation (3.621(3) Å). Torsional angles (Fe–N–N–Fe) are very small (43.8°) indicating an acute arrangement of Fe–N bonds about the N–N single bonds (N–N 1.411–1.413 Å). The generally short Fe–N distances are indicative of a strong ligand field for Fe(II), consistent with the low spin nature of this compound (vide infra).

3.1.6. $[Cu_2(L12\text{-}2\,H)](NO_3)_2\cdot 1.5H_2O$ (**6**)

The structure of **6** is shown in Fig. 8, and relevant bond distances and angles are listed in Table 7. The structure reveals that the starting ligand (L6) has been hydrolysed at the hydrazide function during the reaction

with copper nitrate in aqueous methanol to form the corresponding acid. The individual carboxylate ligands result in the formation of a 1D chain, with dinuclear subunits. Each ligand coordinates in a heptadentate fashion binding to Cu(1) via two pyridine nitrogen atoms, one diazine nitrogen atom and a carboxylate oxygen, and to Cu(2) via pyridine and diazine nitrogen atoms, and a terminal hydrazone oxygen. The square-pyramidal Cu(2) coordination sphere is completed by an axial water molecule (Cu(2)–O(6) 2.177(2) Å), and two axial water molecules complete the Jahn–Teller distorted six-coordinate Cu(1) (Cu(1)–O(4) 2.408(1) Å; Cu(1)–O(5) 2.480(1) Å). The chain is propagated by *syn–anti* carboxylate bridging between the dinuclear subunits through oxygen O(2), which binds equatorially to both Cu(1) and Cu(2). The Cu(1)′–N(2)′–N(4)–Cu(2) torsional angle (164.7°) indicates an almost *trans* disposition of the copper basal planes relative to the N–N bridge (Cu(1)–Cu(2)′ 4.683(2) Å). The *syn–anti* carboxylate bridge leads to a much larger metal ion separation (Cu(1)–Cu(2) 5.336(2) Å).

The presence of two nitrate anions per dinuclear subunit indicates that the ligand has lost two protons. The carboxylate is clearly one site of deprotonation. Establishing the other site of deprotonation depends on a clear identification of the bond order within the C(6)–N(2)–N(4)′–C(13)′–O(1) framework (bond distances 1.301, 1.346, 1.354, 1.249 Å, respectively). This is difficult, and is complicated by very short Cu(1)–N(2) and Cu(2)′–N(4)′ distances (1.941(2), 1.943(1) Å, respectively). One could safely conclude that the charge is delocalized within this bridging ligand framework.

3.1.7. [Ni(L4-2H)] (7)

The molecular structure of **7** is shown in Fig. 9, and important distances and angles are listed in Table 8. The complex consists of one full ligand (L4) bonded to a single four coordinate Ni(II) center, via pyridine nitrogen atoms N(1) and N(4), and diazine nitrogen atoms N(3) and N(5). The Ni–N distances are very short (1.82–1.91 Å), typical of square planar Ni(II), but the nickel geometry has a slight tetrahedral distortion (N(3)–Ni(1)–N(5) 164°, N(1)–Ni(1)–N(4) 159°). No anions are present and so the ligand bears a 2− charge. C–O distances are very short (C(13)–O(1) 1.232(7) Å, C(19)–O(2) 1.222(7) Å), indicating them to have double bond character. The sites of deprotonation are, therefore, reasonably assigned to N(3) and N(5). There are no close contacts of significance between individual molecules in the lattice.

3.2. Ligand decomposition reactions

L2 was prepared by the reaction of diethyl oxalate with hydrazine, followed by the reaction of the dihydrazide with 2-acetylpyridine. The production of 2-acetylpyridine hydrazone (L7) and oxalate on reaction with $Cu(NO_3)_2$ in aqueous methanol indicates ligand hydrolysis at the oxalate imine sites rather than the acetyl imine sites. Pre-coordination of two copper(II) ions to the ligand (e.g., as in Scheme 2) would lead to Lewis acid promoted nucleophilic attack by water at the oxalate C=N sites, thus producing oxalate, which could then simply bridge the two copper centers. The 2-acetylpyridine hydrazone could then pivot about the pyridine–copper bond to assume its coordination role as indicated in the structure of **1**. A similar hydrolytic decomposition appears to have occurred for **2**. It is of interest to note that this ligand forms a stable tetranuclear Ni(II) complex $[Ni_4(L2)_4](BF_4)_4 \cdot 6H_2O$, with no evidence of ligand decomposition [19].

The ligand in **3** (L8), produced from the reaction of L3 with $NiBr_2$, would be expected as the product from the direct reaction of butane-2,3-dione and 2-picolinic acid hydrazide. However, ligand L3 was derived from butanedione monoxime, and was characterized by

Scheme 2.

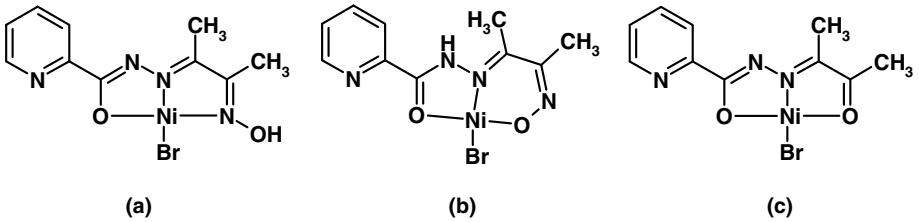
X-ray crystallography so leaving little doubt as to its identity (Scheme 2). In our hands L3 was found to be fairly unreactive to transition metal salts in general, and this was attributed in part to the *anti* conformation of the ligand itself (Fig. 2), which would probably impede the simultaneous coordination of the pyridine and oxime ends of the ligand.

In order for L3 to bind to a metal ion in a chelating fashion a significant energy expenditure (vide supra) would be required to bring suitable donor groups into an appropriate chelating conformation. Two reasonable chelation isomers are possible on reaction with nickel bromide (Fig. 10(a) and (b); Br is proposed as a co-ligand), of which the oxime N-bonded example (a) is the more stable than (b) by 86 kJ mol^{-1}. With this isomer, polarization of both C=N bonds in L3 would occur, and so would provide a hydrolytic mechanism by which both picolinic hydrazide and the methyl ketone shown in Fig. 10 (c) could be released prior to reaction to form L8. It is of interest to note that reaction of L3 with other Ni(II) salts also produced red diamagnetic complexes of L8 (e.g., $[Ni(L8)](ClO_4)\cdot H_2O$ and $[Ni(L8)](NO_3)\cdot 2H_2O$), and it is reasonable to assume that they are all produced by the same hydrolytic process. The square planar Ni(II) complex (**3**) was calculated to be 30 kJ mol^{-1} more stable than the initially proposed [Ni(L3)Br] chelate (Fig. 10(a)). Since the same ligand rearrangement was observed with several nickel salts, it suggests that this might be the overall driving force for the hydrolytic process.

A recent report indicates that complexes of L3 with Cr(III), Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Cd(II) and UO_2^{2+} can be produced by refluxing the ligand with the appropriate metal salt in ethanol. No evidence for ligand decomposition was presented, and no structures were reported. It is of interest to note that a diamagnetic orange nickel(II) complex, [Ni(L3-H)Cl], was discussed [3].

L4 is part of a growing group of tritopic ligands based on a central 2,6-picolinic dihydrazide framework, which form predominantly $[M_9(\mu\text{-}O)_{12}]$ $[3\times3]$ grid structures [20–26]. A similar ligand (L4′) (Chart 1, L4; R = H) appears to be quite stable in its reaction with Mn(II) salts, and the complex $[Mn_9(L4')_6](NO_3)_6\cdot 12H_2O$ has been produced in a reasonable yield, and shown to have a $[Mn_9(\mu\text{-}O)_{12}]$ $[3\times3]$ grid structure by single crystal X-ray diffraction [26]. However, reaction of L4 with copper acetate in methanol in the presence of air produces as the main product complex **4**. The formation of the mono-carboxylate ligand L9, and the dicarboxylate ligand L10 clearly results from a 'reverse hydrolysis' reaction in which the full hydrazone ligand L4 has undergone nucleophilic attack by water at the 2,6-pyridine dicarboxylic acid sites, rather than at the Schiff base imine positions (Scheme 3). This is presumably encouraged by the pre-coordination of L4 to Cu(II), at least in the central pyridine cavity, although it is highly likely that the pre-coordination involves a trinuclear copper(II) complex, similar to other linear $Cu(II)_3$ complexes observed with this class of ligand [25,27].

Perhaps the most surprising result is the formation of the triazole derivative 3-phenyl-triazolo[1,5-a]pyridine (L11). It is of interest to note that the 2-pyridyl analogue 3-(2-pyridyl)-triazolo[1,5-a]pyridine is produced by the reaction of di-2-pyridyl ketone and hydrazine hydrate in methanol–water (1:1) in the presence of air [28], or by the oxidation of di-2-pyridyl ketone hydrazone with nickel(II) peroxide in benzene [29]. It also appears to have resulted from a reaction between a di-2-pyridyl



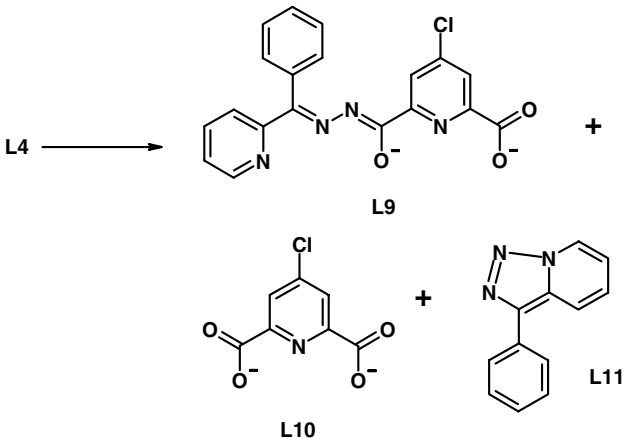


Fig. 10. Chelation isomers for L3 (a,b) and proposed hydrolysis product (c).

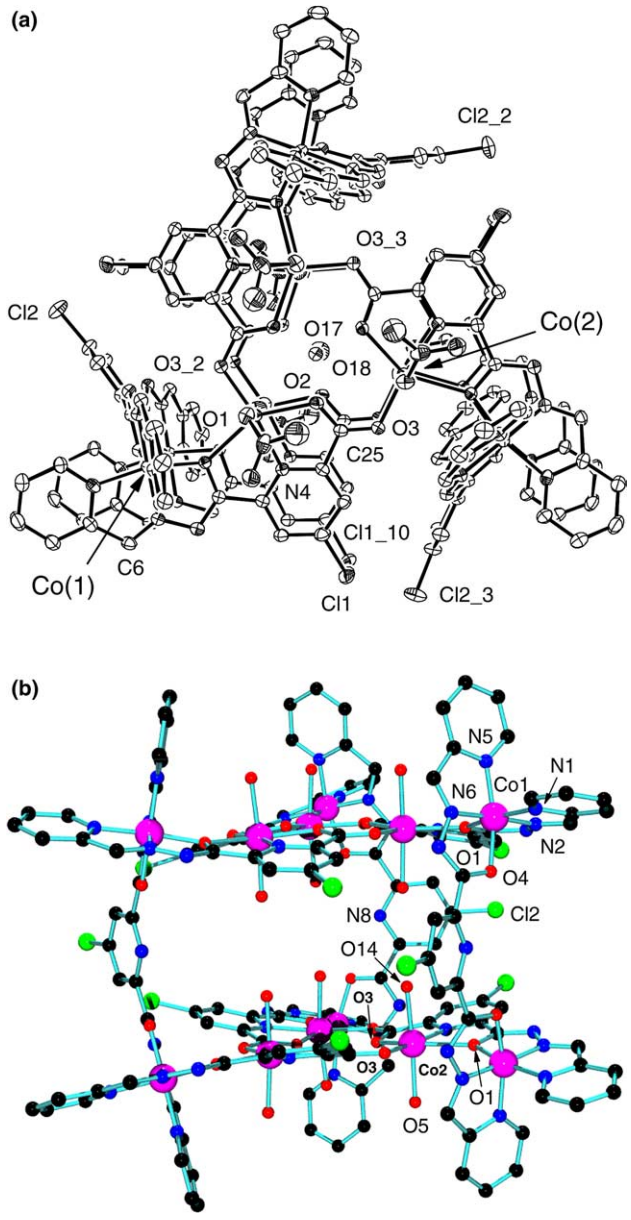
Scheme 3.

ketone hydrazone and copper nitrate in air via an oxidative cyclization, producing the copper(II) complex of the triazole [28]. The hydrazone of 2-benzoyl pyridine can also be oxidatively cyclized to the corresponding triazole 3-phenyl-triazolo[1,5-a]pyridine, by reaction with silver oxide [30]. The simultaneous formation of the mono- and di-acid ligands (L9, L10) suggests that phenyl-2-pyridyl ketone hydrazone is formed first, which then oxidatively cyclizes under mild conditions in the presence of air to produce L11. This process may be catalyzed by the presence of Cu(II) ions.

L4 reacts with cobalt(II) nitrate in CH_3CN/CH_3OH in air to form the complex $[(L4)_3(L9)_6Co(III)_6Co(II)_6(H_2O)_6(NO_3)_6]$ $[Co(H_2O)_6](NO_3)_8(CH_3CN)_3(H_2O)_6$ (**8**), which contains both L4 and L9, and has been reported previously [31]. Two views are shown in Figs. 11(a) and (b) looking down the trigonal axis of the molecule, and from a side view, respectively. The mono-carboxylate ligand L9 binds six metal ions on each trigonal face, with three Co(2) (Co(II)) atoms bridged by *syn–anti* carboxylates in an inner triangular array, with hydrazone oxygen atoms bridging each of them to the outer Co(1) (Co(III)) centers. The Co(1) centers are linked by the two end N_2O pockets of the tritopic ligands L4 to form the dodecanuclear array. The thirteenth cobalt(II) ion appears in the lattice in part to balance the overall charge. There is no evidence to suggest the formation of the di-acid (L10) or the triazole (L11), but again this reaction serves to illustrate the hydrolytic instability of the hydrazone function in this class of ligand.

The formation of the carboxylate ligand L9 from L4 on reaction with $Co(NO_3)_2$ underlines the hydrolytic instability of the hydrazone linkages and the fact that Co(II) is capable of mediating nucleophilic attack at the imine site. The presence of Co(II) at the carboxylate site is a surprise since Co(III) would be expected to be more highly polarizing and to prefer the oxygen rich environment generated in the internal trigonal core. In



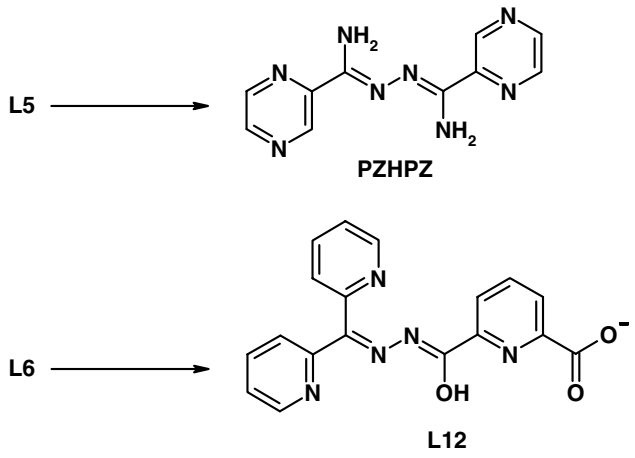


Fig. 11. (a) Structural representation of **8** viewed down the threefold symmetry axis (4% probability thermal ellipsoids), with phenyl rings removed for clarity. (b) Structural representation of **8** viewed at 90° to the threefold symmetry axis (POVRAY ©image).

view of the fact that no ligand decomposition occurs in the reaction between $NiCO_3$ and L4, this suggests that Co(III) is instrumental in the formation of L9.

The formation of the Fe(II) complex **5** containing the bis-bidentate ligand PZHPZ (Chart 1) from L5 (Scheme 4) is somewhat surprising, and indicates a different ligand decomposition mechanism. In this case any water involved in the hydrolysis must have arisen mostly from the hydrated metal salt itself, since CH_3CN was used as the solvent. This type of ligand contains amidrazone fragments at the ends, which are produced by reaction of, e.g., a picolinic-dihydrazide with the

Scheme 4.

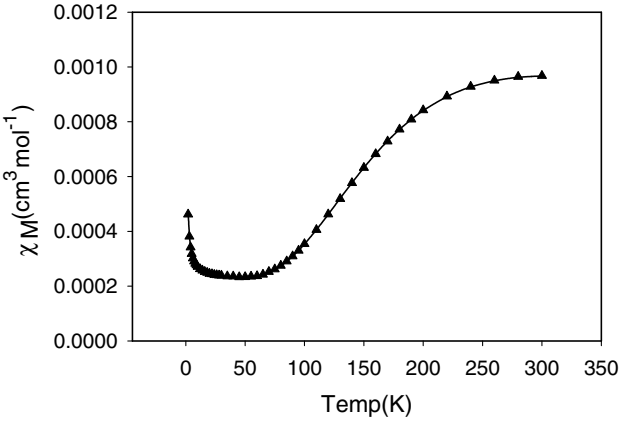

Fig. 12. Variable temperature magnetic data for **1**. The solid line represents the best fit result to Eq. (1) (see text for fitted parameters).

methylimidate ester derived from 2-cyanopyridine or 2-cyanopyrazine. Direct synthesis of PZHPZ can be achieved in high yield by the reaction of 2-pyrazinamide hydrazone with 2-pyrazine methylimidate [2]. It seems reasonable to assume that a reverse hydrolytic step has occurred in the reaction of L5 with a metal ion, in which the appropriate amidrazone is produced as one product by hydrolysis of the imine linkage adjacent to the central pyridine ring. It seems highly unlikely that the appropriate imidate would be produced as well, raising the question as to how PZHPZ is produced. The elimination of a hydrazine molecule between two condensing amidrazone moieties seems unlikely, but perhaps the formation of an amide by metal ion promoted hydrolysis at the peripheral imine C=N group could lead to a more simple metal ion facilitated condensation to produce PZHPZ.

L6 undergoes a simple hydrolysis reaction at the hydrazide carbonyl group on reaction with Cu(II) in aqueous methanol to produce the corresponding carboxylic acid (Scheme 4). This presumably is effected by pre-coordination of the Cu(II) ion to the hydrazide group first, which would polarize the carbonyl group and enhance electrophilic attack by water at the carbon atom.

3.3. Magnetic properties

The variable temperature magnetic properties of **1** show a rise in susceptibility with increasing temperature to a maximum around 300 K (Fig. 12), indicating significant intramolecular antiferromagnetic exchange. The low temperature increase corresponds to the presence of paramagnetic impurity. Given the structure of **1**, with essentially isolated oxalate bridged dinuclear copper(II) species, the data were fitted to a simple exchange expression for two interacting $S = 1/2$ centres ($H_{ex} = -2J\{S_1 \cdot S_2\}$) adapted for a paramagnetic impurity fraction (ρ), Weiss-like temperature correction (θ) and temperature independent paramagnetism ($N\alpha$) (Eq. (1)). A good fit gave $g = 2.21(1)$, $J = -171.5(4)$ cm^{-1}, $\rho = 0.0011$, $\theta = 0$ K, $N\alpha = 200 \times 10^{-6}$ cm^3 mol^{-1}

$$\chi_M = \frac{2Ng^2\beta^2}{k(T-\theta)}\left[\frac{1}{(3+\exp(-2J/kT))}\right](1-\rho) + \left(\frac{Ng^2\beta^2}{4kT}\right)\rho + N\alpha \quad (1)$$

($10^2R = 0.41$; $R = [\sum(\chi_{obs.} - \chi_{calc.})^2 / \sum \chi^2_{obs.}]^{1/2}$). The solid line in Fig. 12 was calculated with these parameters. The large singlet–triplet splitting (343 cm^{-1}) in this case is typical for oxalate bridged di-copper(II) complexes [32]. Compound **2** gave an essentially identical profile of susceptibility as a function of temperature, and fitting of the data to Eq. (1) gave $g = 2.24(4)$, $J = -172(8)$ cm^{-1}, $\rho = 0.0075$, $\theta = -0.2$ K, $N\alpha = 134 \times 10^{-6}$ cm^3 mol^{-1} ($10^2R = 1.7$). This clearly indicates the structural similarity between **1** and **2**, and oxalate bridging.

Complex **3** is diamagnetic, consistent with the square planar structure and the strong in plane ligand field. The corresponding nitrate and perchlorate complexes are also diamagnetic. Complex **7** is also diamagnetic, consistent with its square-planar structure. The variable temperature magnetic properties of **4** show that the magnetic moment is essentially constant between 2 and 300 K (2.9–3.2 μ_B/mol), indicative of essentially isolated spin centers. This is consistent with the structure, which shows a strictly orthogonal connection between Cu(1) and Cu(2) through the diazine (N–N) bridge. The long equatorial, non-orthogonal connection between Cu(1) and Cu(2) via N(3) and O(1) clearly does not lead to any significant spin exchange.

Complex **5** is essentially diamagnetic from 2 to 300 K, indicative of a low spin Fe(II) system, and identical to the behaviour of the iso-structural complex $[Fe_2(PZHPZ)_3](NO_3)_4$ [2]. The chain structure of **6** creates an alternating bridging arrangement between

the copper ions with N–N and *syn–anti* carboxylates connecting the copper magnetic orbitals directly. The presence of a direct *trans* diazine bridge with a large Cu–N–N–Cu torsional angle (164.7°) would suggest quite strong antiferromagnetic exchange [33], while the *syn–anti* carboxylate bridge would not be expected to generate significant exchange [34,35]. Variable temperature magnetic data (Fig. 13) show molar susceptibility reaching a maximum at ~200 K, indicating quite strong antiferromagnetic exchange coupling between the copper centres. Given the likely dominance of the diazine bridge in the exchange process, the data were fitted to Eq. (1), giving $g = 2.20(3)$, $2J = -234(2)\ \mathrm{cm}^{-1}$, $\theta = 1.4\ \mathrm{K}$, $\rho = 0.027$, $N\alpha = 120 \times 10^{-6}\ \mathrm{cm}^3\ \mathrm{mol}^{-1}$ ($10^2R = 3.3$; $R = [\sum(\chi_{\mathrm{obs.}} - \chi_{\mathrm{calc.}})^2/\sum\chi_{\mathrm{obs.}}{}^2]^{1/2}$). The solid line in Fig. 13 is calculated with these fitted parameters. This result is entirely consistent with *trans* N–N bridge connecting Cu(1) and Cu(2) [33]. The small positive θ correction might be considered to arise from the *syn–anti* carboxylate bridge, since the chains are well separated in the extended structure.

The dodecanuclear cobalt complex **8** actually contains thirteen cobalt ions ($Co(III)_6Co(II)_7$), with the $[Co(II)(H_2O)_6]^{2+}$ ion residing in the lattice. The variable temperature magnetic data show a slight variation in moment from 11.0 μ_B at 300 K to 10.2 μ_B at 100 K, followed by a smooth decrease to 8.5 μ_B at 2 K. The gradual drop in moment is indicative of possible weak intra-molecular antiferromagnetic exchange, but because of the complexities involved with fitting magnetic data for Co(II) systems in general no attempt has been made to evaluate an exchange integral. The *syn–anti* carboxylate triangular bridging arrangement of the Co(II) centres would not be expected to lead to significant coupling, which is consistent with the observed data [34,35]. This arises from a mismatch of the metal orbitals in the case of copper, which would be expected to have a similar effect in the present situation, in addition to the long distances of separation of the Co(II) centres (5.180 Å).

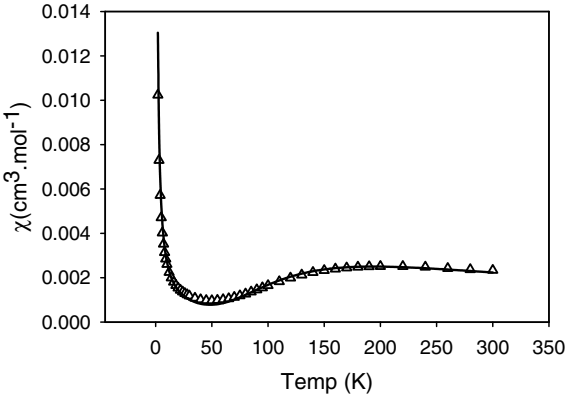

Fig. 13. Variable temperature magnetic data for **6**. The solid line represents the best fit result to Eq. (1) (see text for fitted parameters).

4. Conclusions

Seemingly innocent ligands, based on condensed hydrazone derivatives, have been shown to undergo some unexpected hydrolytic decomposition reactions in the presence of transition metal ions, with some fragments re-arranging to new ligands and some being incorporated into novel complex structures. In one most unusual case oxidatively cyclized 3-phenyl-triazolo [1,5a]-pyridine (L11) is trapped in a complex structure via extensive aromatic π interactions only, but is not coordinated. In another case a novel dodecanuclear Co(II)/Co(III) cluster is produced by the fortuitous combination of a hydrolyzed mono-carboxylate ligand with a complete dihydrazone ligand. In most cases the products can only be successfully characterized by an X-ray structural determination.

5. Supplementary data

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC reference numbers 237242–237247, 254194 for **1**, **3**–**7**, L3, respectively. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

Three new polynuclear lanthanide coordination polymers $[Ln_5(\mu_3\text{-}OH)(oba)_7(H_2O)_2]_n \cdot 0.5nH_2O$ (Ln = Eu (**1**), Ho (**2**)) and $[Yb_6(oba)_9(H_2O)]_n$ (**3**) (H_2oba = 4,4′-oxybis(benzoic acid)), were prepared by hydrothermal reactions. **1** and **2** are isomorphous and exhibit complicated three-dimensional structures based on $[Ln_5(\mu_3\text{-}OH)(oba)_7(H_2O)_2]$ building blocks. In the asymmetric unit, there are five different coordination environments of Ln(III) ions, including a trinuclear hydroxo core. Complex **3** is a three-dimensional coordination polymer built up from a hexanuclear building block. In **3**, Yb(III) ions have six different chemical environments and are in a regular arrangement, resulting in pseudohexagonal prisms along the *a*-axis. The luminescent property of **1** and magnetic behaviors of **2** and **3** have also been studied.

1. Introduction

Coordination polymers have been extensively studied recently due to their interesting structures coupled with their promising applications in ion and solvent molecule exchanges [1–5], gas sorption [6–10], luminescence [11,12], magnetism [13,14] and catalytic behavior [15–17]. While much current research has focused on transition metal coordination polymers [18–27], lanthanide coordination polymers, particularly polynuclear systems, have received less attention owing to the high coordination number and the variable coordination environments of the lanthanides. However, the introduction of polynuclear lanthanide species into the skeleton may create unusual architectures, and polynuclear lanthanide complexes may also exhibit promising magnetic and luminescence properties as a consequence of the unique spectroscopic and electronic characteristics associated with their $4f^n$ electronic configuration. Only a few examples of polynuclear lanthanide coordination polymers have been prepared by lanthanide hydrolysis controlled by different supporting ligands [28–31]. The cubane-like tetranuclear $[Ln_4(\mu_3\text{-}OH)_4]^{8+}$ unit is a common structural motif in these complexes [29–31]. Here, we report pentanuclear lanthanide coordination polymers $[Ln_5(\mu_3\text{-}OH)(oba)_7(H_2O)_2]_n \cdot 0.5nH_2O$ (Ln = Eu (**1**), Ho (**2**)), in which both hydroxyl and carboxyl groups link the lanthanide (III) ions into building

blocks, and a hexanuclear ytterbium coordination polymer $[Yb_6(oba)_9(H_2O)]_n$ (**3**).

2. Experimental

2.1. Chemicals and measurements

$EuCl_3 \cdot 6H_2O$, $HoCl_3 \cdot 6H_2O$ and $YbCl_3 \cdot 6H_2O$ were prepared by dissolving their oxides in concentrated hydrochloric acid, respectively, and the solvents were evaporated to dryness. The lanthanide and water contents of the lanthanide chloride hydrates were determined by EDTA titration. All the other reagents were commercially available and used without further purification. Elemental analyses were performed on an Elementar Vario EL analyzer. The IR spectra were recorded with a Nicolet Avatar 360 FT-IR spectrometer using the KBr pellet technique. The luminescence spectra were recorded at 77 K using a YAG:Nd laser with an excitation wavelength of 355 nm and a SPEX 1403 double grating monochromator. The temperature dependence of magnetic susceptibility for crystalline samples was recorded on an Oxford MagLab 2000 magnetometer in the temperature range of 2–300 K.

2.2. Synthesis

*$[Eu_5(oba)_7(OH)(H_2O)_2]_n \cdot 0.5n(H_2O)$ (**1**)*. A mixture of $EuCl_3 \cdot 6H_2O$ (0.037 g, 0.1 mmol), H_2oba (0.039 g, 0.15 mmol), H_2O (10 ml) and 0.65 M NaOH aqueous solution (0.31 ml, 0.20 mmol) was sealed in a 23-ml stainless-steel reactor with a Teflon liner and heated at 200 °C for 72 h, then slowly cooled to room temperature. Colorless crystals of **1** were obtained. Yield: 0.02 g (38.4%). *Anal*. Calc. for $C_{98}H_{62}Eu_5O_{38.50}$: C, 45.00; H, 2.37; Found: C, 44.89; H, 2.32%. IR (KBr, cm^{-1}): 3447m, 1598s, 1524s, 1400s, 1253s, 1233s, 1160s, 1012w, 881m, 784s, 656w.

*$[Ho_5(oba)_7(OH)(H_2O)_2]_n \cdot 0.5nH_2O$ (**2**)*. Light yellow crystals of **2** were prepared in the same manner as above. Yield: 0.017 g (31.9%). *Anal*. Calc. for $C_{98}H_{62}Ho_5O_{38.50}$: C, 43.91; H, 2.11; Found: C, 44.05; H, 2.30%. IR (KBr, cm^{-1}): 3459m, 1599s, 1526s, 1414s, 1254s, 1235s, 1161s, 1012w, 882m, 784s, 658m.

*$[Yb_6(oba)_9(H_2O)]_n$ (**3**)*. Colorless crystals of **3** were obtained in the same manner. Yield: 0.048 g (43.5%). *Anal*. Calc. for $C_{126}H_{74}O_{46}Yb_6$: C, 45.01; H, 2.16; Found: C, 44.99; H, 2.24%. IR (KBr, cm^{-1}): 3439m, 1599s, 1533s, 1417s, 1305m, 1252s, 1161s, 1097m, 1012w, 881m, 783s, 656w.

2.3. X-ray diffraction determination

The X-ray single crystal data collections for complexes **1**–**3** were performed on a Bruker Smart 1000 CCD diffractometer, using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Semi-empirical absorption corrections were applied using the SADABS program. The structures were solved by direct methods and refined by full-matrix least square on F^2 using the SHELXTL-97 program [32]. All non-hydrogen atoms were refined anisotropically. The hydrogen atoms were generated geometrically and treated by a mixture of independent and constrained refinement. The crystallographic data for complexes **1**–**3** are listed in Table 1, and selected bond lengths (Å) in Table 2.

3. Results and discussion

3.1. Description of the structures

In complexes **1**–**3**, the carboxyl groups of the H_2oba ligands are all deprotonated and adopt four kinds of coordination modes (see Scheme 1). **1** and **2** are isomorphous and thus only the structures of **1** and **3** will be discussed here.

*$[Eu_5(oba)_7(OH)(H_2O)_2]_n \cdot 0.5nH_2O$ (**1**)*. Complex **1** is a three-dimensional polymer containing rugby-like channels. Three types of coordination modes of oba^{2-} ligands are present in the structure: (a) one carboxylate group of the oba^{2-} ligand adopts a bridging bidentate

Scheme 1. The coordination modes of oba^{2-} ligands in **1**–**3**.

mode, while the other adopts a chelating-bridging tridentate mode, connecting four Eu(III) ions ($^{a}oba^{2-}$, Scheme 1(a)); (b) one carboxylate group of the oba^{2-} ligand adopts a bridging bidentate mode, while the other adopts a chelating-bridging tetradentate mode, connecting five Eu(III) ions ($^{b}oba^{2-}$, Scheme 1(b)); (c) each carboxylate group of the oba^{2-} ligand adopts a bridging bidentate mode, connecting four Eu(III) ions ($^{c}oba^{2-}$, Scheme 1(c)). The asymmetric unit of **1** consists of five Eu(III) ions, seven oba^{2-} ligands, one hydroxyl group, two coordinated water molecules and half a lattice water molecule. The coordination environments of five Eu(III) ions are shown in Fig. 1(a) and the details are listed in Table 3. For clarity, we may divide the coordination environments into two parts (Fig. 1(b) and (c)), which are connected by one $^{a}oba^{2-}$ and two $^{b}oba^{2-}$ ligands. In Fig. 1(b), Eu1, Eu2 and Eu3 are linked together by one μ_3-OH, and therefore a distorted tetrahedron is formed by three Eu^{3+} ions and one oxygen atom of μ_3-OH, where the distance of the oxygen atom of

CN, coordination number; No, number.

μ_3-OH to the triangular metal face is 0.639Å. In the europium hydroxo core, the separations of Eu1···Eu2, Eu2···Eu3 and Eu1···Eu3 are 3.898, 3.977 and 4.119 Å, respectively, and a pair of adjacent Eu^{3+} ions are bridged by two carboxylate groups of two oba^{2-} ligands through bridging bidentate and chelating-bridging tridentate fashion. Thus the europium hydroxo core is surrounded by the six carboxyl groups and a cage-like structure is produced. In the trinuclear core, the average distances of Eu1–O(COO^-), Eu2–O(COO^-), Eu3–O(COO^-) and Eu–O(OH^-) are 2.470, 2.416, 2.347 and 2.400 Å, respectively, which are in accord with the values in $[Eu_{15}(\mu_3\text{-}OH)_{20}(\mu_5\text{-}X)]^{24+}$ [33]. The other two Eu^{3+} ions (Fig. 1(c)), Eu4 and Eu5, are bridged by three carboxyl groups of three oba^{2-} ligands through bridging bidentate and chelating-bridging tridentate coordination modes. The average distances of Eu4–O(COO^-) and Eu5–O(COO^-) are 2.430 and 2.418 Å, which are in agreement with the common distances of Eu–O(COO^-), and the distance of Eu4···Eu5 is 4.281 Å. The Eu(III) ions along the *a*-axis are bridged by $^{a}oba^{2-}$ and $^{b}oba^{2-}$ ligands into one-dimensional double-chains with rugby-like micropores. These chains are further cross-linked by oba^{2-} ligands, resulting in the formation of a three-dimensional network, as shown in Fig. 2. There are small rugby-like channels along the *c*-axis.

*$[Yb_6(oba)_9(H_2O)]_n$ (**3**)*. Complex **3** is a three-dimensional polymer. The hexanuclear species $[Yb_6(oba)_9(H_2O)]$ may be viewed as the building block. There are three types of coordination modes of oba^{2-} ligands in **3**: (a) one carboxylate group of the oba^{2-} ligand adopts a bridging bidentate mode, while the other adopts a chelating-bridging tridentate mode, connecting four Yb(III) ions ($^{a}oba^{2-}$, Scheme 1(a)); (b) each carboxylate group of the oba^{2-} ligand adopts a bridging bidentate mode, connecting four Yb(III) ions ($^{c}oba^{2-}$, Scheme 1(c)); (c) one carboxylate group of the oba^{2-} ligand adopts a bridging bidentate mode, while the other adopts a chelating bidentate mode, connecting three Yb(III) ions ($^{d}oba^{2-}$, Scheme 1(d)). In the asymmetrical unit of **3**, there are six Yb(III) ions, nine oba^{2-} ligands and one aqua ligand. The coordination environment of Yb(III) ions is shown in Fig. 3 and the details are listed in Table 4. For clarity we can also divide the Yb(III) ions into two parts: part 1 consists of Yb1, Yb5 and Yb6; while part 2 consists of Yb2, Yb3 and Yb4. The two parts are linked by two $^{a}oba^{2-}$ ligands. In part 1, Yb5 and Yb6 are connected by two bridging bidentate carboxyl groups of two oba^{2-} ligands; while Yb5 and Yb1 are connected by two bridging bidentate carboxylate groups and one chelating-bridging tridentate carboxyl group of three oba^{2-} ligands. In part 2, Yb3 is connected to Yb4 by three bridging bidentate carboxyl groups of three oba^{2-} ligands, and connected to Yb2 by two chelating-bridging tridentate carboxyl groups and one bridging bidentate carboxylate group of three oba^{2-} ligands. The average distances of Yb–O(COO^-)

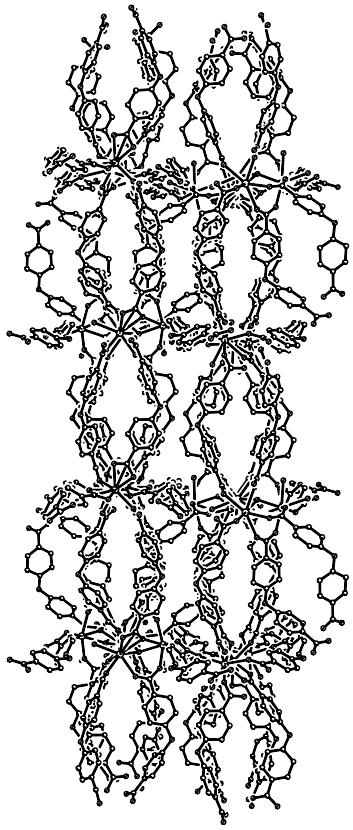

Fig. 2. The three-dimensional network of **1** viewed along the *c*-axis.

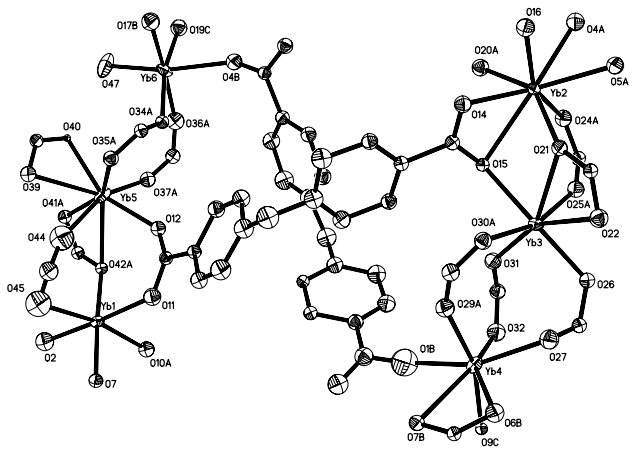

Fig. 3. The coordination environment of Yb^{3+} ions in **3** with thermal ellipsoids at 20% probability. All hydrogen atoms are omitted for clarity.

Table 4
The coordination environment of Yb^{3+} in **3**

	CN	No. of carboxyl oxygen atoms			No. of coordinated H_2O
		$^{a}oba^{2-}$	$^{c}oba^{2-}$	$^{d}oba^{2-}$	
Yb1	6	6			
Yb2	8	6	2		
Yb3	7	4	3		
Yb4	7	4	3		
Yb5	8	4	1	3	
Yb6	6	1	3	1	1

CN, coordination number; No, number.

(from Yb1 to Yb6) are 2.249, 2.356, 2.280, 2.290, 2.330 and 2.231 Å, respectively, and the separations of Yb1···Yb5, Yb5···Yb6, Yb2···Yb3 and Yb3···Yb4 are 4.002, 4.510, 3.823 and 4.330 Å, respectively.

In each asymmetrical unit of **3**, six Yb(III) ions are arranged in the form of a non-planar six-member ring. And along the *a*-axis, two adjacent six-member rings are parallel to each other. As shown in Fig. 4, for instance, a six-member ring constructed by Yb2J, Yb3J, Yb4J, Yb1J, Yb5J and Yb6J is parallel to an adjacent six-member ring formed by Yb2M, Yb3M, Yb4M, Yb1M Yb5M and Yb6M. These two rings are pillared by oba^{2-} ligands along the *a*-axis to yield a pseudohexagonal prism, which is the first example of such an array of lanthanide (III) ions. These pseudoprisms are cross-linked by oba^{2-} ligands, resulting in the formation of a three-dimensional network.

Comparing the structures of **1**–**3**, it can be seen that oba^{2-} ligands display different coordination modes. In **1** and **2**, there are three kinds of oba^{2-} ligands: $^{a}oba^{2-}$, $^{b}oba^{2-}$ and $^{c}oba^{2-}$; while in **3**, the three kinds of oba^{2-} ligands are $^{a}oba^{2-}$, $^{c}oba^{2-}$ and $^{d}oba^{2-}$. The different coordination modes of oba^{2-} ligands lead to the different structures.

Although the "O" atoms between two benzene rings in each oba^{2-} ligand do not participate in the coordination to Ln(III) ions, however, they are important in the structure. With the presence of these "O" atoms, oba^{2-} ligands act as V-shaped, not linear ligands. It is the V-shaped configuration of oba^{2-} ligands, which facilitates the benzene rings and carboxylate groups to adjust their steric configurations more freely and allow the oba^{2-} ligands to display a variety of coordination modes.

3.2. Photophysical properties of complex *1*

The room temperature spectra of powders for **1** are less developed, we comment about low temperature spectra only. The high-resolution emission spectrum of **1** corresponding to $^{5}D_0 \rightarrow {}^{7}F_J$ ($J = 0$–4) transitions excited by 355 nm at 77 K is shown in Fig. 5. The most intensive transition is $^{5}D_0 \rightarrow {}^{7}F_2$, which implies red emission light of **1**. The number of components of the $^{5}D_0 \rightarrow {}^{7}F_1$ transition indicates the presence of more than one chemically different Eu(III) ions site [34]. The intensity of the $^{5}D_0 \rightarrow {}^{7}F_0$ transition is relatively weak and the emission band is broad (see the inserted spectrum in Fig. 5). The inhomogeneous broadening of the $^{5}D_0 \rightarrow {}^{7}F_0$ emission band arises from the site to site variation of the local field acting on the ions, and has consequently been studied by selective excitation techniques.

Setting the analyzing wavenumber to 16233 cm^{-1} and scanning in the range of 578.72–580.4 nm ($^{7}F_0 \rightarrow {}^{5}D_0$), the excitation spectrum (Fig. 6) was obtained. There are two obvious groups of peaks located at about 579.4 and 580.0 nm. The negative charges on the ligands around Eu1, Eu2, Eu3, Eu4 and Eu5 are approximately 3.4, 2.5, 2.6, 3.3 and 3.2, respectively. They can be divided into two groups. One group (3.4, 3.3 and 3.2) contains Eu1, Eu4 and Eu5. The other group (2.5 and 2.6) contains Eu2 and Eu3. As is known, the peak position of $^{7}F_0 \rightarrow {}^{5}D_0$ will shift to lower energy with increasing negative charge on the ligands [35]. So the left peak denoted as A in Fig. 6 can be ascribed to the contribution of $^{5}D_0$ levels of Eu2 and Eu3, and the right peak denoted as B in Fig. 6 can be ascribed to the contribution of $^{5}D_0$ levels of Eu1, Eu4 and Eu5.

3.3. Magnetic properties

The temperature dependence of the magnetic susceptibility of **2** was measured in the temperature range 2–300 K (Fig. 7). The magnetic susceptibility above 50 K obeys the Curie–Weiss law [$\chi = C/(T - \theta)$] with $C = 71.43$ cm^3 mol^{-1} K and $\theta = -10.79$ K. The C value is close to the expected value of 70.35 cm^3 mol^{-1} K for five non-interacting Ho^{3+} free ions. The continuous

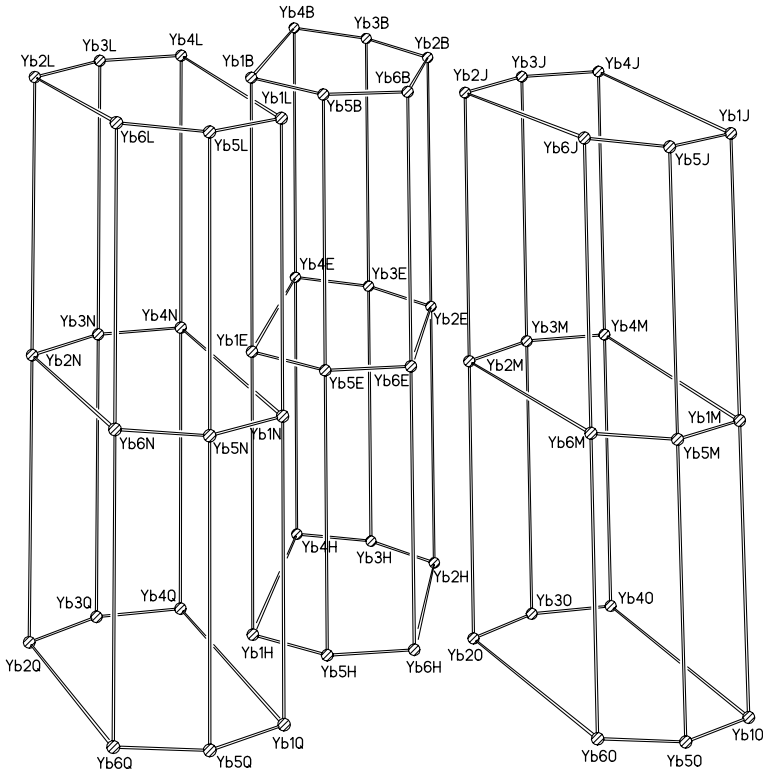

Fig. 4. The hexagonal pseudoprism distribution of Yb(III) ions in **3**.

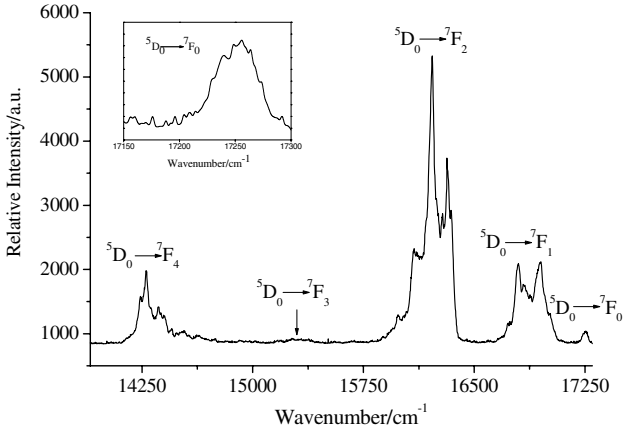

Fig. 5. Emission spectrum of **1** corresponding to $^5D_0 \rightarrow {}^7F_J$ (J = 0–4) transitions at 77 K, λ_{exc} = 355 nm.

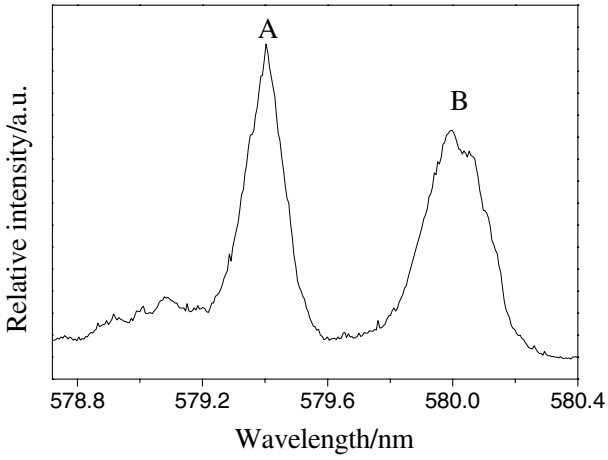

Fig. 6. $^7F_0 \rightarrow {}^5D_0$ excitatation spectrum of powders for **1** recorded at 77 K, λ_m = 616 nm.

decrease in $\chi_M T$ upon cooling should be mainly attributed to the crystal field splitting of a single Ho^{3+} ion together with the possible contribution of the weak interaction through oxygen atoms of hydroxyl and carboxylate bridge with 3.910–4.043 Å Ho···Ho distances.

The variable-temperature magnetic susceptibility of **3** is displayed in Fig. 8, where χ_M is the corrected molar magnetic susceptibility per [Yb_6] unit. At room temperature, the value of $\chi_M T$ is 13.41 $cm^3\,mol^{-1}\,K$, which is approximately close to the calculated value for six Yb free ions (15.42 $cm^3\,mol^{-1}\,K$). Upon cooling, $\chi_M T$ decreases steadily and fast at low temperatures. These results primarily arise from the splitting of the ligand field of the Yb(III) ion together with the possible contribution of the weak antiferromagnetic coupling between Yb(III) ions, considering a possible interaction through two carboxylate bridges with 3.823–4.510 Å Yb···Yb distances. The magnetic susceptibility above 100 K obeys the Curie–Weiss law with the Weiss constant $\theta = -42.61$ K and the Curie constant $C = 15.43$ $cm^3\,mol^{-1}\,K$.

Abstract

A series of tetranuclear heterothiometallic clusters $[Et_4N]_2[(MS_4)_2Au_2(dppe)]$ (**1**: M = Mo; **2**: M = W), $[PPh_4]_2[(MoOS_3)_2Au_2(dppe)]$ (**3**), $[Et_4N]_2[(WOS_3)_2Au_2(dppe)]$ (**4**) (dppe = 1,2-bis(diphenylphosphino)ethane), $[Et_4N]_2[(MS_4)_2Au_2(dppf)]$ (**5**: M = Mo; **6**: M = W) and $[Et_4N]_2[(MOS_3)_2Au_2(dppf)]$ (**7**: M = Mo; **8**: M = W) (dppf = 1,1′-bis(diphenylphosphino)ferrocene) have been synthesized from the reactions of thiometalates $[MXS_3]^{2-}$ (M = Mo or W, X = O or S), $AuCl(SC_4H_8)$ and dppe or dppf. The crystal structures of the complexes **2**, **4** and **6** have been determined by single-crystal X-ray diffraction studies. In the molecular structures of these complexes, the two linear M/Au/S units are linked via bidentate phosphines dppe or dppf. The complexes have been fully characterized by IR, UV–vis as well as elemental analyses. These clusters all exhibit room-temperature luminescence in the solid state.

1. Introduction

The synthetic and structural chemistry of heterothiometallic clusters, especially the Mo(W)/Cu(Ag)/S cluster compounds, has developed rapidly in recent years due to their fascinating biochemical interests [1–3] and potential applications such as catalysis [4] and optical limiting materials [5]. In contrast with the almost well-established Mo(W)/Cu(Ag)/S system [6], the study of Mo(W)/Au/S cluster compounds is still young. To our knowledge, only a few cluster complexes of this system have been synthesized till now [7–11]. Examples include cluster complexes with unidentate ligands PPh_3 or $AsPh_3$, etc., such as $[MS_4Au_2(PPh_3)_2]$ [12,13], $[MS_4Au_2(AsPh_3)_2]$ [14,15] (M = Mo or W), $[WS_4Au_2(Ph_2PCH_3)_2]$ [16] and $[MoS_4Au_2(PCy_3)_2]$ [17]. However, the complexes with bidentate phosphines have not been seen before. In this paper, we succeeded in co-opting the bidentate dppe and dppf as bridging ligands into the Mo(W)/Au/S system leading to the formation of eight new cluster compounds, namely, $[Et_4N]_2[(MS_4)_2Au_2(dppe)]$ (**1**: M = Mo; **2**: M = W), $[PPh_4]_2[(MoOS_3)_2Au_2(dppe)]$ (**3**), $[Et_4N]_2[(WOS_3)_2Au_2(dppe)]$ (**4**), $[Et_4N]_2[(MS_4)_2Au_2(dppf)]$ (**5**: M = Mo; **6**: M = W) and $[Et_4N]_2[(MOS_3)_2Au_2(dppf)]$ (**7**: M = Mo; **8**: M = W).

In contrast to many Au(I) compounds whose photoluminescent properties have been extensively studied [18–20], the photoluminescent properties of heterometallic Mo(W)/Au(I)/S complexes remain essentially

unexplored. Recently, clusters $[Cu_3(dppm)_3(WS_4)]ClO_4$ [21] and $[Cu_4(dcpm)_4(MS_4)](ClO_4)_2$ (M = Mo or W) [17] have been observed to be photoluminescent. In our study, we found that the title complexes also showed photoluminescent properties.

2. Experimental

2.1. General procedures

Experiments were carried out in air. $[Et_4N]_2[MS_4]$ (M = Mo or W), $[Et_4N]_2[WOS_3]$ and K_2MoOS_3 were prepared according to the literature methods [22]. Other chemicals were obtained from commercial sources and were used as received.

2.2. Physical measurements

FT-IR spectra in the 400–4000 cm^{-1} range were recorded on a Perkin–Elmer FT-IR spectrometer using KBr pellets. UV–vis spectra were measured on a Perkin–Elmer instrument Lambda 35 UV/VIS spectrometer. The C, H and N analyses were carried out on an Elemental Vario EL III analyzer. Room-temperature fluorescence spectra were measured on a FLS920P spectrometer with a laser at 397 nm as the excitation light.

2.3. Preparation of the Mo(W)/Au/S compounds

In a typical reaction, a mixture of $[AuCl(SC_4H_8)]$ (0.125 mmol, 0.0800 g) and dppe (0.125 mmol, 0.0498 g) in CH_2Cl_2 (5 mL) was stirred for 20 min and then added to a solution of $[Et_4N]_2[MoS_4]$ (0.25 mmol, 0.1212 g) in CH_2Cl_2 (5 mL). The mixture was stirred for 1 h and filtered. The red precipitate was dissolved in DMF (3 mL). Slow diffusion of *i*PrOH into the solution gave air stable red crystals of **1**. Other compounds were prepared in a similar way as described above. A summary of the characterization data for compounds **1**–**8** is listed in Table 1.

2.4. X-ray crystallography

The data for **2** was collected at 293.15 K on a Siemens SMART CCD diffractometer and the data for **4** and **6**

were collected at 130.15 K on a RIGAKU MERCURY CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structures were solved by direct methods and refined on F^2 by full-matrix least-squares procedures using the SHELXTL software suite [23]. All non-hydrogen atoms were refined anisotropically except for those with disordered positions. All H atoms were located theoretically and not refined, except that H atoms belonging to the disordered atoms were not located. The occupancies of these disordered components were assumed to be 0.50 for each disordered atom. For cluster **2** and **6**, due to the disordered C atoms of $[Et_4N]^+$, some non-bond C···C distance were abnormal at these positions. Nevertheless, the C–C bond lengths involving the disordered C atoms were all reasonable. For cluster **4**, a solvent molecule EtOH is disordered. EtOH was used during the preparation of the starting materials and some may have been left behind. So it is comprehensible that a EtOH molecule is in the structure. A summary of the crystallographic data of **2**, **4** and **6** is presented in Table 2.

3. Results and discussion

3.1. Syntheses

Treatment of $[AuCl(SC_4H_8)]$ with dppe or dppf in CH_2Cl_2 followed by the addition of one equiv. of $[Et_4N]_2[MXS_3]$ (M = Mo or W, X = O or S) resulted in the precipitation of complexes **1**, **2**, **4**, **5**, **6** and **8**. Crystals of **2**, **4** and **6** could be obtained via slowly diffusion of *i*PrOH to their DMF solutions. Similar reactions with half equiv. of $[Et_4N]_2[MXS_3]$ gave polymeric compounds which would not dissolve in any solvent and were not further identified. Complexes **3** and **7** were synthesized by reacting K_2MoOS_3 with [AuCl(dppe)] or [AuCl(dppf)] in DMF and were isolated as the PPh_4^+ and Et_4N^+ salts, respectively.

3.2. Infrared and UV–vis spectroscopic studies

As shown in Table 1, the IR spectra of these complexes show typical absorptions around 520 cm^{-1} due to the Au–P bonds. Other bands at ca. 500 cm^{-1} can be assigned to the vibrations *v*(M═S) according to the literature data and those at lower frequencies are attributed to bridging sulfur atoms [6]. As expected, the vibrations *v*(M═O) are observed at ca. 900 cm^{-1}. The electronic spectra of the compounds derived from MS_4^{2-} (M = Mo or W) have similar patterns to those of the starting materials except that several new bands appear. In addition, for the compounds derived from MOS_3^{2-} (M = Mo or W), the UV–vis spectra are shifted in the direction of shorter wavelengths owing to the coordination of Au atoms to the central MOS_3^{2-} cores [6].

3.3. Crystal structures of 2, 4 and 6

The molecular structure of compound **2** was confirmed by a single-crystal X-ray diffraction study. The structure of the anion of **2** is shown in Fig. 1 and selected bond lengths and angles are listed in Table 3. The skeleton of the cluster core contains one W, two bridging S, two terminal S and one Au atom. Two cluster cores, orientated in opposite directions, are linked via a dppe bridging ligand to form a Z-like

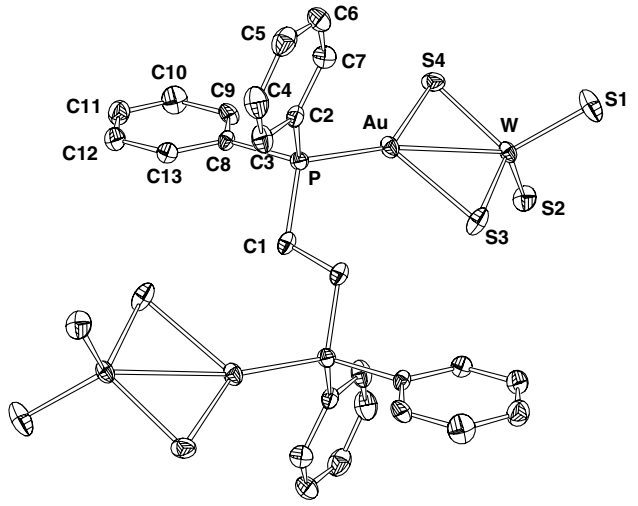

Fig. 1. Structure and labelling of the $[(WS_4)_2Au_2(dppe)]^{2-}$ anion of **2**. Thermal ellipsoids are drawn at the 20% probability level. All H atoms are omitted for clarity.

Symmetry transformations used to generate equivalent atoms: [a]For **2**: #1: $-x+1$, y, $-z+1/2$; #2: $-x+1/2$, $-y+1/2$, $-z$. [b]For **4**: #1: $-x+2$, $-y$, $-z$; #2: $-x+1$, $-y$, $-z$. [c]For **6**: #1: $-x+1$, $-y+1$, $-z+1$.

structure. A crystallographic inversion center overlaps the symmetry of the molecule. In each S_2WS_2Au fragment, the WS_4^{2-} dianion acts as a bidentate ligand coordinating one Au atom through two bridging S atoms leaving the other two S atoms uncoordinated. The tungsten atom has a distorted tetrahedral coordination geometry with S–W–S angles in the range of 107.9(1)–110.4(1)°. The mean bond length of W=S_t is 2.148(2) Å, which is characteristic of a pure double bond and consistent with the values reported for the starting material $(NH_4)_2WS_4$ [24]. The two W–S_{br} bond lengths, 2.259(2)–2.260(2) Å, are within the normal range for the W–μ-S bonds observed for other W/Au/S clusters and are considered to be single bonds. The gold center shows a trigonal planar geometry with the total of the angles around the gold being about 360.0°. The gold–tungsten distance is 2.859(1) Å, which is slightly greater than those in the complexes $[WS_4Au_2(PPh_3)_2]$ [13] at 2.823(1) Å, $[WS_4Au_2(AsPh_3)_2]$ [15] at 2.803(1) Å and $[WS_4Au_2(Ph_2PCH_3)_2]$ [16] at 2.839(1) Å. The narrow W–S–Au angles [74.1(1)° and 75.9(1)°], which are comparable to other related terminal phosphine ligand derivatives, also reflect the existence of a relatively strong metal–metal bond. Finally, the Au–P bond length is 2.254(2) Å which is a little greater than that found in $[WS_4Au_2(PPh_3)_2]$ [13].

The molecular structure of **4** is shown in Fig. 2 and important bond lengths and angles are given in Table 3. The structure resembles that of **2** except that a W=S bond in **2** is replaced by a W=O bond in **4**. The compound shows crystallographic inversion symmetry as in complex **2**. The tungsten atom also shows a tetrahedral geometry with the angles ranging from 108.1(2)°

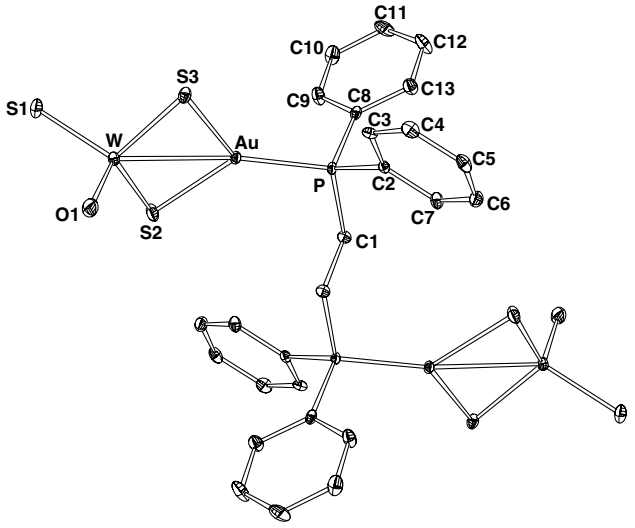

Fig. 2. Structure and labelling of the $[(WOS_3)_2Au_2(dppe)]^{2-}$ anion of **4**. Thermal ellipsoids are drawn at the 20% probability level. All H atoms are omitted for clarity.

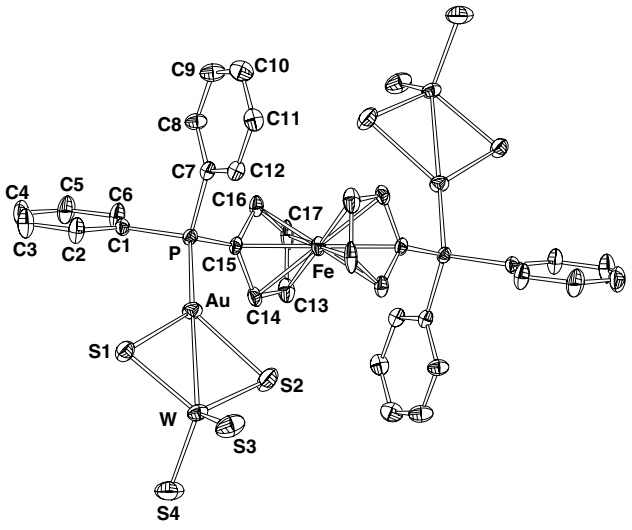

Fig. 3. Structure and labelling of the $[(WS_4)_2Au_2(dppf)]^{2-}$ anion of **6**. Thermal ellipsoids are drawn at the 20% probability level. All H atoms are omitted for clarity.

to 110.6(1)°, while the Au atom has a trigonal planar geometry with the sum of the angles being about 360.0°. The W–Au distance is 2.827(1) Å, which is comparable to that of $[WS_4Au_2(PPh_3)_2]$ [13] [2.823(1) Å] but significantly smaller than that of **2** [2.859(1) Å]. As expected, the mean W–S–Au angle [74.2(1)°] of **4** is smaller than that of **2** [75.0(1)°].

The crystal structure of **6** was determined by a single-crystal X-ray diffraction study. An ORTEP diagram of the anion is shown in Fig. 3 and selected bond lengths and angles are given in Table 3. As found in the structures of **2** and **4**, a crystallographic center of symmetry is located at the center of the anion of **6**. The structure of the anion of **6** is closely related to that of **2** except that the two linear W/Au/S fragments are interconnected through a dppf ligand rather than a dppe ligand. The W–Au distance is 2.837(1) Å, an intermediate value between those for **2** and **4**. The bond lengths and angles within the W/Au/S fragment are typical and those for the dppf ligand are all normal.

3.4. Luminescent properties

The luminescent data for clusters **1**–**8** are listed in Table 4. Fig. 4 depicts the emission spectra of clusters **1**–**4** in the solid state at 298 K.

The emission observed for clusters **1**–**4** range from 564 to 662 nm, which are much higher than that of the free ligand dppe (434 nm). Therefore, we tentatively assign the origin of the emission as the ligand-to-metal charge transfer (LMCT) transition. For the series of clusters **5**–**8** with dppf as the ligand, it is likely that the emissions at 570–664 nm are due to the intraligand (IL) transition ($\pi \rightarrow \pi^*$) localized on the dppf moieties.

Table 4
Luminescent data for **1**–**8**

Compound	Emission λ_{max} (nm)
$[Et_4N]_2[(MoS_4)_2Au_2(dppe)]$ (**1**)	622
$[Et_4N]_2[(WS_4)_2Au_2(dppe)]$ (**2**)	564

Study of the interaction between oxovanadium(IV) and hydroxamic acids

Péter Buglyó *, Norbert Pótári

University of Debrecen, Department of Inorganic and Analytical Chemistry, P.O. Box 21, H-4010 Debrecen, Hungary

Received 7 February 2005; accepted 9 March 2005
Available online 14 April 2005

Abstract

The interaction between oxovanadium(IV) and primary hydroxamic acids (aceto- (HAha), benzohydroxamic acid (HBha) or *N*-hydroxy-*N*′-[3-(*N*-hydroxy-carbamoyl)-propyl]-heptane-1,7-dicarboxamide (H_2Diha)) as well as the corresponding *N*-methyl substituted hydroxamic acids (HMeAha, HMeBha, H_2MeDiha) was studied by pH-potentiometric and pH-stat methods in aqueous solution. Stoichiometry and stability constants of the VO(IV) complexes formed in the pH range 2.0–5.0 were determined and the effect of the substituents on the C or N atoms of the hydroxamic group is discussed. The dihydroxamic acids are more effective oxovanadium(IV) binders than the monohydroxamic ones. Above pH = 4.5–5.0 (depending upon ligand excess), slow redox reaction was found in all the systems studied. During this process, beside the oxidation of VO(IV) to the appropriate V(V)–hydroxamate complex, formation of amides as reduction products was detected under anaerobic conditions. The same reaction can also take place when stirring sparingly soluble VOA_2 type complexes (A: Bha or MeBha) in water in the absence of oxygen. The exact stoichiometry of the redox reaction was determined by pH-stat measurements and found to be $2VO(R_1CON(R_2)O)_2 + R_1CON(R_2)OH + H_2O = 2[VO_2(R_1CON(R_2)O)_2]^- + 2H^+ + R_1CON(R_2)H$ (R_1: CH_3, C_6H_5; R_2: H, CH_3) for the monohydroxamates. The *N*-methyl hydroxamic acids tend to oxidise VO^{2+} significantly slower than the corresponding primary ones.

Keywords: Hydroxamic acids; Oxovanadium(IV) complexes; Stability constants; pH-potentiometry; Amide formation; Vanadium(V)

1. Introduction

Hydroxamic acids form stable, five-membered [O,O] chelates with many metal ions [1]. Based on this interaction numerous microorganisms developed hydroxamate type metal sequestering siderophores for the uptake, storage and transport of metal ions with biological relevance [2]. Especially hard metals and their higher oxidation states are capable to form the most stable hydroxamate complexes. Although the interaction of vanadium(V) with numerous monohydroxamic acids is well documented in the literature [3–6], it is much less known about the corresponding oxovanadium(IV) complexes. Furthermore, the effect of the substituents at the C or N atoms of the hydroxamic group on the stability of the oxovanadium(IV) hydroxamate chelates has not been investigated yet.

Some of the results in the literature obtained for VO(IV)–hydroxamate systems are contradictory. Dessì et al. [7] have studied the interaction between VO(IV) and aceto-, benzo- or *N*-phenyl-benzohydroxamic acids by EPR. It was found that primary monohydroxamic acids can undergo two deprotonation processes and thus act as either hydroxamato(1-) or hydroximato(2-) ligands forming 1:1 or 1:2 complexes with different protonation degrees. Recently, the VO(IV)–acetohydroxamate system was investigated at high excess of ligand

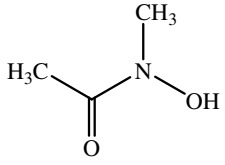
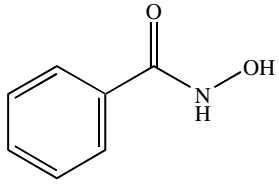
(1:6 or higher) by da Silva Santos et al. [8] using pH-potentiometry and spectrophotometry. The same complexation pattern was found as by Dessì et al.



On the contrary, a study by Brown et al. [9] on the interaction of VO(IV) with *N*-substituted mono- or dihydroxamic acids at anaerobic conditions revealed that the ligands undergo oxygen abstraction on reaction with the metal ion to form V(V) hydroxamates and the corresponding amides. During the redox reaction the metal ion is oxidized directly by the hydroxamic acid. Slow irreversible reaction was also found when studying the complex formation reactions between oxovanadium(IV) and aceto-, propio- or alaninehydroxamic acids by pH-potentiometry [10]. It was found that in the pH-range 4.0–5.0 the usual waiting time was not enough to reach pH equilibrium. Re-acidification of the titrated samples indicated the formation of V(V) by change in colour from the initial pale blue to yellow [10].

Similar irreversible reaction was also found between U(IV) and *N*-phenyl-benzohydroxamic acid, where beside U(VI), the formation of the reduction product of the ligand, *N*-phenyl-benzamide, was detected [11]. Other studies on the interaction of Fe(II) with natural tris hydroxamic acids, desferrioxamine B (H_4DFB^+) or desferricoprogen (DFC), also revealed that these ligands are capable to oxidize the metal ion directly under anaerobic conditions with the formation of the corresponding highly stable Fe(III) complexes and DFB- or DFC-monoamide [12,13].



The goal of this work was to study the interaction between oxovanadium(IV) and a set of mono- and dihydroxamic acids (see Scheme 1) in aqueous solution using pH-potentiometry and, to compare the effect of the substituents at the C or N atoms of the hydroxamic group on the stability of the metal chelates. We also present our results on the slow redox reaction observed above

pH = 5.0 in these systems yielding V(V) and the appropriate amide under anaerobic conditions.

2. Experimental

2.1. Reagents

Acetohydroxamic acid (HAha), benzohydroxamic acid (HBha), vanadyl sulphate hydrate and sodium vanadate were Aldrich or BDH products of puriss. quality and were used as received. Syntheses of the dihydroxamic acids was published previously [14]. *N*-methyl-acetohydroxamic (HMeAha) and *N*-methylbenzohydroxamic (HMeBha) acids were prepared according to the literature methods [15] by reacting *N*-methylhydroxylamine with acetylchloride or benzoylchloride in basic methanol at 0 °C. The crude products were purified with vacuum distillation to afford colourless oils. HMeAha: ^{1}H NMR (360 MHz, D_2O) δ = 2.11 (3H, s, CH_3–CO), 3.22 (3H, s, N–CH_3); ESI-MS *m*/*z*: 90 (M + 1). HMeBha: ^{1}H NMR (300 MHz, D_2O) δ = 3.33 (3H, s, N–CH_3), 7.49 (5H, br, Ar); ESI-MS *m*/*z*: 152 (M + 1).

For all the ligands the purities were also checked from the prepared stock solutions by pH-potentiometric titrations and the equivalent weights were determined by the Gran method [16]. A VO(IV) stock solution was prepared according to Nagypál and Fábián [17] and standardised for metal ion concentration by permanganate titration, VIS spectrophotometry or ICP-AES and for hydrogen ion concentration by pH-potentiometry, using the appropriate Gran function [16].

2.2. Potentiometric measurements

The stability constants of the proton and VO(IV) complexes of the ligands were determined by pH-potentiometric titration of 10.0 ml samples. The ionic strength was adjusted to 0.20 M KCl in each solution studied. In all cases, the temperature was 25.0 ± 0.1 °C. The ligand concentration was in the range 2–10 mM and the molar ratios in the VO(IV)–ligand systems were in the range 1:1 to 1:20. All the titrations were performed over the range pH 2–11 or until precipitation occurred with a carbonate- and oxygen free KOH solution of known concentration (~0.2 mol dm^{-3}), under a purified argon atmosphere. After adding VO(IV) to the ligand solution at pH ~ 2.0, the sample to be titrated was completely deoxygenated by bubbling argon through it. The titrations were carried out in a special glass vessel with an NS joint for the electrode and for adding the KOH solution to ensure strictly anaerobic conditions. As usual, a maximum change in pH of 0.002 within 30 s was allowed in each titration point to reach pH equilibrium, however, more than 10 min was never allowed to wait after adding an aliquot of base. At least two parallel titrations were carried out. The reproducibility of the titration points included in the evaluation was within 0.005 pH unit throughout the whole pH range. Titration points with 10 min waiting time were omitted from the calculations. The average number of points per system used in the calculations was 60.

pH was measured with a Radiometer pHM 84 instrument equipped with a Metrohm combined electrode with NS joint (type 6.0233.100), calibrated for hydrogen ion concentration according to Irving et al. [18]. A pK_w value of 13.76 ± 0.01 was determined and used for the calculations. Protonation constants of the ligands (K_i = [H$_i$A]/[H][H$_{i-1}$A]) were determined using Superquad computer program [19]. The concentration stability constants β_{pqr} = [M$_p$H$_q$A$_r$]/[M]^p[H]^q[A]^r for the metal complexes were calculated with the aid of the PSEQUAD program [20]. The uncertainties (σ values) in the stability constants are given in parenthesis in the Table 1.

During the calculations the following VO(IV)–hydroxo complexes were assumed: [VO(OH)]$^+$ (log β_{1-10} = −5.94) and [{VO(OH)}$_2$]$^{2+}$ (log β_{2-20} = −6.95) calculated from the data published by Henry et al. [21], the Davies equation being used to take into consideration the different ionic strengths, [VO(OH)$_3$]$^-$ (log β_{1-30} =

−18.0) and $[(VO)_2(OH)_5]^-$ (log β_{2-50} = −22.5) with data taken from [22].

2.3. pH-stat measurements

In order to measure the amount of the protons liberated during the redox process at anaerobic conditions and thus to determine the stoichiometry of the redox reaction between the metal ion and the ligands, pH-stat measurements were carried out in the VO(IV)–HAha, VO(IV)–HMeAha, VO(IV)–H_2Diha or VO(IV)–H_2MeDiha systems using a Radiometer TTT 60 titrator. At 1:7–1:8 or 1:4 (H_2Diha, H_2MeDiha) metal-to-ligand ratio where the ligand concentration was 2.0–4.0 mM, the added amount of base was monitored in the function of time to keep constant the initial pH of 5.5 in the samples during the measurements.

2.4. Study of the oxidation of VO(IV) in the solid complexes

IR spectra were measured as a KBr disk on a Perkin Elmer FTIR spectrometer. ESI mass spectra were recorded on a Bruker BIOTOF II ESI-TOF instrument equipped with a Cole Palmer 74900 Series pump. Microanalyses were performed at the University of Szeged, Hungary.

$V^{IV}O(Bha)_2$, and for comparative purposes $K[V^{V}O_2(Bha)_2]$ were prepared under argon from aqueous solutions with the reaction of two equivalents of the respective ligand and one equivalent of metal ion at pH = 3 according to the literature procedures [3,23] and the poorly soluble microcrystalline solids obtained were characterised by IR, ESI-MS or micro analytical methods giving satisfactory results. Elemental analysis: *Anal*. Calc. for $V^{IV}O(Bha)_2$: C, 49.57; N, 8.26. Found C, 49.20; N, 8.04%. *Anal.* Calc. for $K[V^{V}O_2(Bha)_2]$: C, 42.64; N, 7.10. Found: C, 42.68; N, 6.81%. IR (cm^{-1}) for $VO(Bha)_2$ 993 (V=O); for $K[VO_2(Bha)_2]$ 946 (V=O).

In order to monitor the redox reaction in the VO(IV)–HBha system, in a few experiments the non-isolated solid, $VO(Bha)_2$, was further stirred in aqueous solution under an argon atmosphere. After 24 h the complex was filtered off, washed with water, dried and checked for composition by IR (993 and 932 cm^{-1} (V=O)) and microanalysis (Found: C, 45.67; N, 7.45%). The untreated mother liquors were also analysed for benzamide by ESI-MS.

3. Results and discussion

3.1. Protonation processes of the ligands

Protonation processes of the hydroxamic acids were re-examined and the protonation constants (log K_i) calculated are summarised in Table 1. The log K_i values are in good agreement (less than 0.04 log units) with published data obtained at the same experimental conditions [14,24]. The protonation constant determined in this work for HMeBha (8.30) fits also in the general trend of log K_i values for monohydroxamates with different substituents. The differences in acidity of the ligands have already been discussed [24].

3.2. VO^{2+} complexes of the hydroxamic acids

With HBha and HMeBha purple microcrystalline precipitation occurred in the presence of the metal ion at 4 mM concentration (vide infra) therefore the titrations were carried out at a ligand concentration of 2 mM. In all systems, slow base consumption processes were observed in solution starting at pH 4.2–5.0 and 10 min was not enough to reach pH equilibrium at these titration points. Repeated titration of the samples after decreasing the pH down to 2.0 revealed that irreversible, redox processes took place even in the absence of oxygen. This is illustrated in the Fig. 1, where, as a representative example, the different shape of the titration curves of the VO(IV)–H_2Diha system is shown at 1:2 ratio. The yellow colour of the re-acidified samples at pH = 2.0 also indicated the formation of VO_2^+(V) during the titration. This result, which has already been found in VO^{2+}–monohydroxamate systems [10,25], is in contradiction with recently published solution equilibrium study, where no indication for any redox reaction was found at higher ligand excess [8].

Due to the irreversible process outlined above the titration curves were evaluated in the pH range 2.0–5.0 only. For all the monohydroxamic acid systems the formation of $[VOA]^+$ and $[VOA_2]$ as major species was detected with the involvement of one or two (O,O) hydroxamate chelates, respectively. The same binding mode was found previously by EPR [7]. The assumption of $[VOH_{-1}A]$ improved the fit significantly. The calculated stability constants are summarised in Table 1, while a representative speciation of the VO(IV)–HBha system is shown in Fig. 2. The log β values obtained for the complexes in the VO(IV)–HAha system (Table 1) are in reasonable agreement with published data ($[VOA]^+$: 8.58, $[VOA_2]$: 16.21) [8].

In order to compare the effect of the substituents at the C (Me versus Ar) or N (H versus Me) atoms of the hydroxamic group of the ligands (see Scheme 1) on VO^{2+} binding, the proton displacement equilibrium constants were calculated (last row in Table 1). These derived constants (monohydroxamic acids: log K = log K_{VOA} − log K_1; dihydroxamic acids: log K = log K_{VOA} − log K_1 − log K_2) refer to the following equilibria: $VO^{2+} + HA \rightleftharpoons [VOA]^+ + H^+$ or $VO^{2+} + H_2A \rightleftharpoons [VOA] + 2H^+$, respectively. Higher value of log K indicates stronger metal–ligand interaction. Comparison between

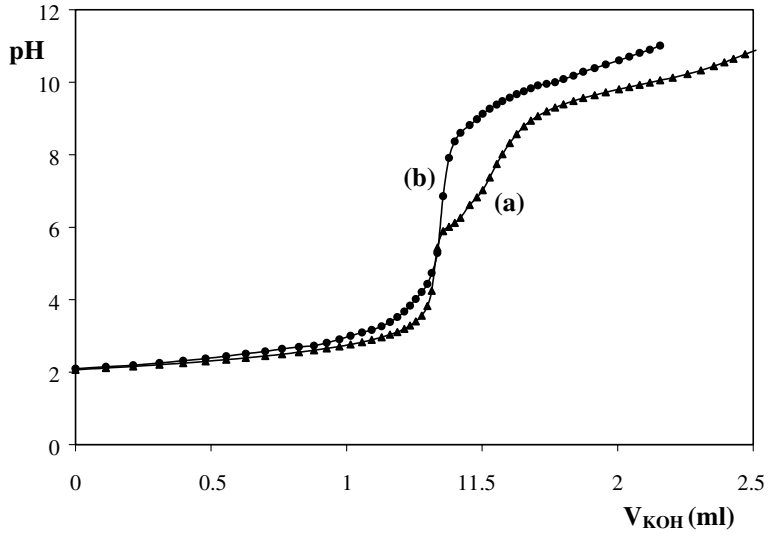

Fig. 1. Titration curve of the oxovanadium(IV)–H_2Diha system at 1:2 ratio (a) and repeated titration after acidifying (b), $c_{VO(IV)}$ = 2 mM, I = 0.2 M (KCl), T = 25.0 °C.

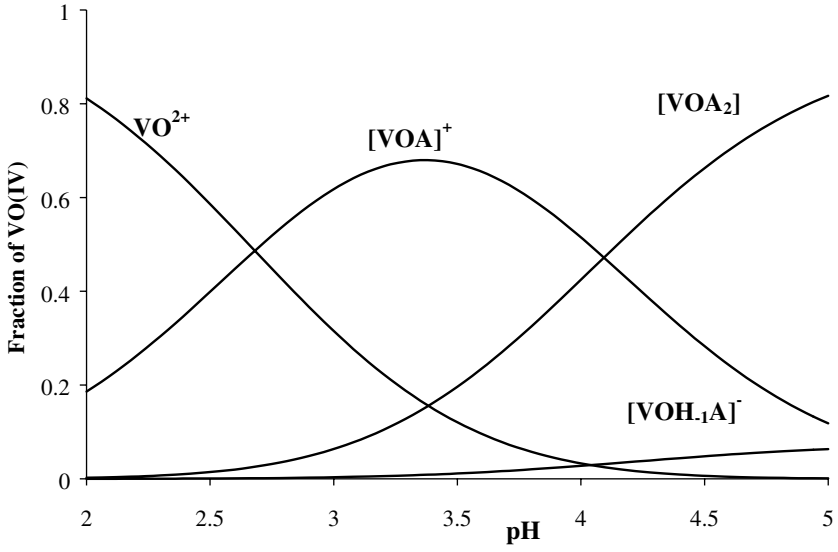

Fig. 2. Speciation curves of the complexes formed in the VO(IV)–HBha system at 1:4 ratio, c_{HBha} = 4 mM, I = 0.2 M (KCl), T = 25.0 °C.

the corresponding derived constants (last row in Table 1) reveals that the N–Me ligands form 0.7–0.8 log unit more stable [VOA] complexes than the corresponding primary hydroxamates. The stability difference between the metal chelates of the C substituted (Me versus Ar) pairs is only 0.3–0.4 log unit in favour of the aromatic ligands. Similar trends were previously also found for Fe(III) or Cu(II) systems [26,12] and originate from the more pronounced effect of N substitution compared to C substitution on the delocalisation of the lone pair of N into the C–N bond. Delocalisation increases the electron density on the carbonyl oxygen thus yielding higher stability for the metal chelate. On the other hand, due to the lower effect of C substitution and favoured charge distribution in the presence of π-electrons, the electron withdrawing effect of the phenyl group does not appear in the stability of the complexes [24].

For the dihydroxamic systems (VO(IV)–H_2Diha or VO(IV)–H_2MeDiha) the useful parts of the titration curves (below pH 5.0) could be fitted well with the assumption of the formation of $[VOHA]^+$ and [VOA]. $[VOHA]^+$ may contain one (O,O) chelate while the other functional group is protonated. On increasing pH deprotonation and coordination of the second hydroxamic group to the metal ion takes place. This binding mode is supported by previous results on the VO^{2+}-desferrioxamine B (H_4DFB^+) system [25], in which the species $[VOH_2DFB]^+$ was found to have two (O,O) chelates around the metal ion. The H_4DFB^+ model compound, H_2MeDiha, with the same length and structure

of the connecting chain of H_4DFB^+, is therefore co-ordinated most probably in the same manner. Comparison of the proton displacement equilibrium constants calculated for $[VOH_2DFB]^+$ ($\log\beta_{VOH_2DFB} - \log\beta_{H_4DFB} = 37.09–37.59 = -0.50$) [25] with that of [VOA] formed in the H_2MeDiha system ($\log\beta_{VOA} - \log\beta_{H_2A} = 17.30–17.75 = -0.45$) (Table 1) also indicates identical binding modes.

Direct comparison of the metal binding strength of HAha (a monohydroxamate) with that of H_2Diha (a dihydroxamate) via derived equilibrium constants is difficult due to the different stoichiometry of the complexes with the same donor atom environment around the metal ion. Therefore pVO ($-\log[VO^{2+}]_{free}$) values were calculated at pH = 4.0 where bis chelated complexes are the major species in both systems but neither slow redox processes nor hydrolysis of the free VO^{2+} took place. pVO values at pH = 4.0 (c_{VO} = 2 mM; c_{HAha} = 4 mM or c_{H_2Diha} = 2 mM) for the HAha (3.50) and for the H_2Diha (4.67) systems indicate that H_2Diha is stronger metal binder. This difference suggests the effect of polychelate formation with the dihydroxamic acid.

3.3. Monitoring the redox reaction in solution

The slow base consumption processes observed above pH 4.2–5.0 were studied in detail in the VO(IV)–HAha, VO(IV)–HMeAha, VO(IV)–H_2Diha and VO(IV)–H_2MeDiha systems. It was found that to the 1:1 ratio corresponded the widest pH range where 10 min waiting time was not enough to reach pH equilibrium. With increasing ligand excess the oxidation of VO^{2+} started at higher pH and the non-equilibrium pH range became narrower. The irreversible process took place, however, to a certain degree even at twenty fold ligand excess. The hindrance of this slow reaction applying increasing ligand excess may suggest the involvement of a 1:1 species rather than bis chelated complex in the redox process.

Our finding is in contradiction with earlier results, in which the speciation of the VO(IV)–HAha system is determined in the range pH = 2–11 without any indication for the redox process [7,8]. The formation of the EPR silent side product, VO_2^+(V), on one hand [7], and the large ligand excess used in the solution equilibrium work [8], which is found in this study to suppress the redox reaction, on the other hand, may explain the contradictory results. Due to the disturbing redox reaction the stability constants published by da Silva Santos et al. [8] can only be considered as tentative values. Nevertheless, the speciation model provided by them is supported by EPR [7] which confirms the presence of the hydroximato type complexes, $[VOH_{-1}(Aha)_2]^-$ and $[VOH_{-2}(Aha)_2]^{2-}$, above pH = 7.

A brief comparison of the rate of the oxidation of VO(IV) at anaerobic conditions in the presence of primary or secondary hydroxamic acids revealed that with any of the *N*-methyl derivatives, this process is significantly slower than with the corresponding primary ligands. This is illustrated in Fig. 3, where beside the titration curves of the VO(IV)–H_2Diha or VO(IV)–H_2MeDiha systems at 1:1 ratio the pH-ranges are also depicted where 10 min waiting time was not enough to reach pH equilibrium. As it is seen in Fig. 3, at identical titration parameters, with Diha (a) the base consumption is significantly larger and the non-equilibrium pH-range during the titration is wider than with MeDiha (b) indicating faster process (liberation of protons) in the former system.

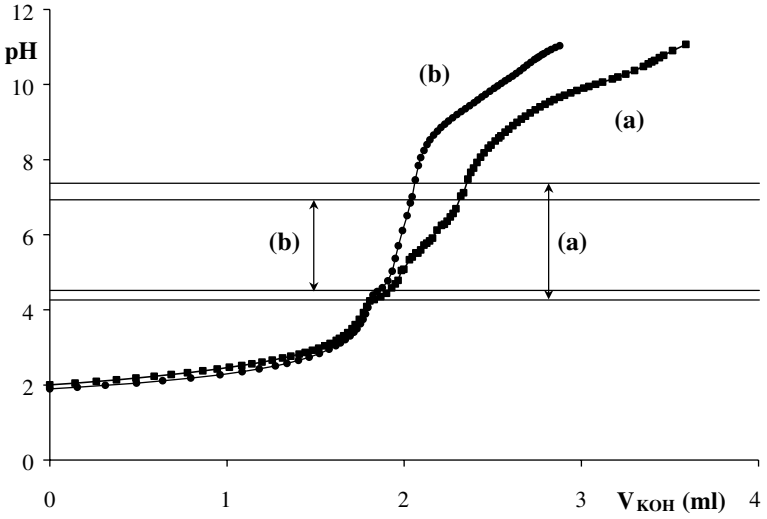

Fig. 3. Titration curves and pH-ranges where 10 min waiting time was not enough to reach pH equilibrium in the VO(IV)–H_2Diha (a) or VO(IV)–H_2MeDiha (b) system at 1:1 ratio, $c_{VO(IV)}$ = 4 mM, I = 0.2 M (KCl), T = 25.0 °C.

3.4. Study of the redox process in heterogeneous system

Previous work has already demonstrated that different *N*-substituted mono- and dihydroxamic acids are capable to oxidize VO(IV) to V(V) in solvent mixture with the parallel formation of the corresponding amides [9]. In this study freshly prepared, sparingly soluble complex obtained from VO(IV)–HBha solution was characterised as $VO(Bha)_2$. For comparison, the corresponding V(V) complex was also synthesized and characterised by microanalysis and IR (see Section 2). In another experiment, VO(IV) was again reacted with HBha and the purple microcrystalline solid obtained was further stirred in solution under argon for 24 h. An almost black solid was isolated, dried and analyzed for composition. Decrease in the carbon and nitrogen content (see Section 2) compared to that of $VO(Bha)_2$ is consistent with the partial oxidation of VO(IV) to V(V) in the solid complex. The practically unchanged C/N ratio in the VO(IV)-(6.12), V(V)-(6.27) complex and in the solid (6.13) isolated after 24 h also supports the sole oxidation of the metal ion, if it is still partial, and the lack of any decomposition of the coordinated ligand. After 24 h and after filtering the solid, analysis of the mother liquor by ESI-MS also proved the presence of the reduction product of benzohydroxamic acid, benzamide (m/z = 122 (M + 1)), in solution (Fig. 4).

3.5. Determination of the stoichiometry of the redox reaction

Due to the difficult separation and extensive purification of the products, earlier study with secondary hydroxamic acids was not successful in determining the accurate stoichiometry of the reaction between the hydroxamic acids and VO(IV) [9]. In this work therefore, pH-stat measurements were carried out in solution in order to determine the amount of the protons liberated during the process. Using high ligand excess, at pH = 5.5, where the bis complex is exclusively formed, the deprotonation of the uncomplexed ligand does not occur and the redox process is found to proceed, the base consumption of samples was monitored as a function of time under anaerobic conditions. Typical time dependence curves in the VO(IV)–HAha and VO(IV)–HMeAha systems are shown in Fig. 5. It should be mentioned that due to the slightly different analytical concentrations of the components in the two samples the volume of the base solution which was necessary to keep the pH at 5.5 is also different. As it is shown in Fig. 5 secondary ligands were found to react much more slowly than the primary ones in agreement with the potentiometric studies. While more than 10 h in the VO(IV)–HAha system, about 30 h in the VO(IV)–HMeAha system was necessary for the reaction to be completed. Further stirring showed no proton liberation

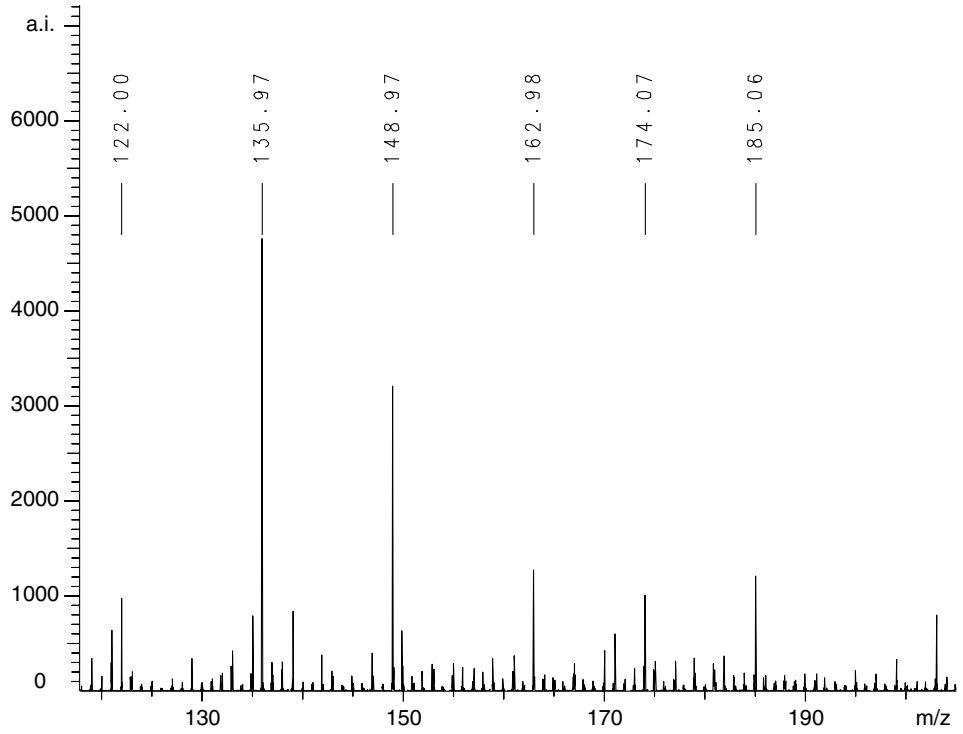

Fig. 4. ESI-MS spectrum of the mother liquor after filtering the solid complex formed in the VO(IV)–HBha system after 24 h stirring under argon. M/z = 122.0 indicates the formation of benzamide.

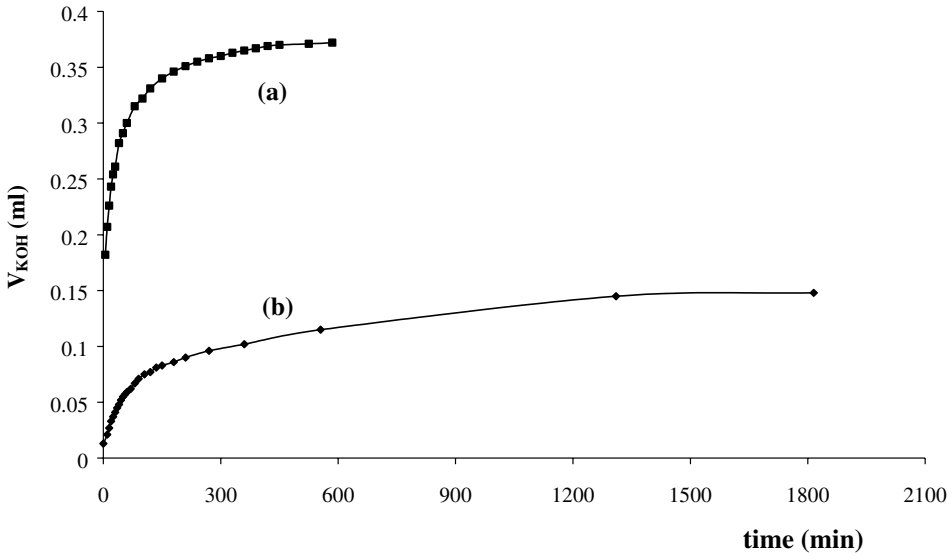

Fig. 5. pH-stat curves recorded at pH = 5.5 in the VO(IV)–HAha (a) or VO(IV)–HMeAha (b) system at 1:8 ratio, $c_{VO(IV)}$ = 2.56 mM (a) or 2.10 mM (b), I = 0.2 M (KCl), T = 25.0 °C.

or any other change in the samples. Preliminary experiments indicated the liberation of one equivalent of proton pro metal ion in the HAha system, according to Eq. (1).

$$2VO(Aha)_2 + HAha + H_2O = 2[VO_2(Aha)_2]^- + 2H^+ + CH_3CONH_2 \quad (1)$$

pH-stat measurements carried out with HAha, HMeAha, H_2Diha or H_2MeDiha proved the stoichiometry given by Eq. (1), where one mole of hydroxamic group oxidises two moles of VO(IV) with the formation of two protons and one mole of amide. With all the four ligands the difference in the amounts of the consumed and calculated base necessary for neutralising the protons was found to be less than 4%.

4. Conclusion

Both mono- and dihydroxamic acids form stable VO(IV) complexes in the pH range 2.0–5.0. The effect of the substituents at the nitrogen of the hydroxamic group on stability of the VO(IV) chelate was found higher than that at carbon in agreement with earlier results for Fe(III) or Cu(II) systems [12] due to the more pronounced effect of N substitution compared to C substitution on the delocalisation of the lone pair of N into the C–N bond. H_2Diha or H_2MeDiha showed increased VO(IV) binding capability in the complexes where the denticity of the ligands was higher than that of monohydroxamates.

Depending upon ligand excess, above pH = 4.5–5.0 slow redox reaction was found in all the aqueous systems studied under anaerobic conditions. During this reaction the ligands were capable to oxidise VO(IV) to the V(V)–hydroxamate complex with the parallel formation of the corresponding amide. pH-stat measurements were used to determine the exact stoichiometry of this process. Both primary and *N*-methyl monohydroxamic acids react with two equivalents of VO^{2+} in aqueous solution. For the secondary hydroxamic acids the rate of redox reaction with VO^{2+} is significantly slower than for the corresponding primary ones.

Further studies are in progress to characterise the active species involved in the redox process and to explore the differences in rate of the reaction for the primary and secondary ligands.

Abstract

The cadmium(II)-substituted tungstoarsenate $[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{12-}$ (**1**) has been synthesized and characterized in the solid state by XRD, IR, elemental analysis and in solution by ^{183}W and ^{111}Cd NMR. Single crystal X-ray analysis was carried out on $Cs_4K_3Na_5[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]\cdot 20H_2O$. Polyanion **1** consists of two lacunary $[B\text{-}\alpha\text{-}AsW_9O_{34}]^{9-}$ Keggin moieties linked via a rhomblike ($Cd_4O_{14}Cl_2$) group leading to a sandwich-type structure. Interestingly, the two external Cd atoms have a terminal Cl ligand, but the derivative with terminal water ligands, $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{10-}$ (**2**), can also be prepared as shown by ^{183}W and ^{111}Cd solution NMR.

1. Introduction

Polyoxometalates (POMs) have been known for almost 200 years and a century later the first structural details were revealed [1]. POMs constitute a rapidly growing class of molecular metal–oxygen clusters with an enormous diversity of structures [2–8]. The significant interest in POM chemistry is driven by potential applications in many areas including catalysis, medicine, material science, and nano/biotechnology [4–8].

Amongst all known transition metal substituted polyoxometalates (TMSPs), the sandwich-type species are probably the largest subfamily [9]. In 1973 Weakley et al. [10a] described the first sandwich-type polyoxoanion, $[Co_4(H_2O)_2(B\text{-}\alpha\text{-}PW_9O_{34})_2]^{10-}$. Since then, several other derivatives of this structural type have been reported. To date, the class of Weakley-type sandwich species consists of the Keggin derivatives $[M_4(H_2O)_2(B\text{-}\alpha\text{-}XW_9O_{34})_2]^{n-}$ ($n = 12$, X = Ge^{IV}, Si^{IV}, M = Mn^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}; $n = 10$, X = P^V, As^V, M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}; $n = 6$, X = P^V, As^V, M = Fe^{3+}; $n = 16$, X = M = Cu^{2+}; $n = 10$, X = M = Fe^{3+}) and the Wells-Dawson derivatives $[M_4(X_2W_{15}O_{56})_2]^{n-}$ (X = P^V, As^V, $n = 16$, M = Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}, $n = 12$, M = Fe^{3+}) [10].

Other types of sandwich-type POMs are also known and include species based on two lone-pair containing α-Keggin fragments, e.g., $[\alpha\text{-}As^{III}W_9O_{33}]^{9-}$. The first member of this class ($[Cu_3(H_2O)_2(\alpha\text{-}AsW_9O_{33})_2]^{12-}$) was reported by Hervé and coworkers in 1982 [11a]. Since then several isostructural derivatives have been characterized [11b–h,12f]. Another class of sandwich-type POMs is based on two lone-pair containing, β-Keggin fragments, e.g., $[\beta\text{-}Sb^{III}W_9O_{33}]^{9-}$. The first members of this class, $[M_2(H_2O)_6(WO_2)_2(\beta\text{-}SbW_9O_{33})_2]^{(14-2n)-}$

doi:10.1016/j.poly.2005.03.010

(M^{n+} = Fe^{3+}, Co^{2+}, Mn^{2+}, Ni^{2+}), were reported by Krebs and coworkers in 1997 [12a]. Since then many more isostructural derivatives have been reported [12b–f]. The last class of sandwich-type POMs is based on two *A*-α-Keggin fragments, e.g., $[A\text{-}\alpha\text{-}PW_9O_{34}]^{9-}$. The first member of this class, $[Co_3(H_2O)_3(A\text{-}\alpha\text{-}PW_9O_{34})_2]^{12-}$, was reported by Knoth et al. in 1985 [13a]. Since then some isostructural derivatives have been identified [13b–f].

Surprisingly little work on cadmium-substituted polyoxotungstates has been reported to date, especially regarding structurally characterized species. Nevertheless, the diamagnetic nature of Cd-containing POMs has prompted some NMR studies. Twenty years ago Contant [14] reported for the first time on cadmium-containing Keggin and Wells-Dawson species. In 1995 Kirby and Baker [15] reported on a NMR study of the first sandwich-type polyoxometalate including Cd^{2+} ions. More recently, Bi et al. [10p,q] prepared Cd-substituted, sandwich type polyanions based on the tungstoarsenate fragments $[As_2W_{15}O_{56}]^{12-}$ and $[AsW_9O_{34}]^{9-}$, respectively. Very recently, Alizadeh et al. [16] synthesized and structurally characterized the tetra-cadmium containing $[Cd_4(H_2O)_2(PW_9O_{34})_2]^{10-}$.

Here we report on interaction of Cd^{2+} ions with the trilacunary Keggin derivative $[A\text{-}HAsW_9O_{34}]^{8-}$ in aqueous solution.

2. Experimental

2.1. Materials and methods

All chemicals were of reagent grade and used as purchased. The IR spectra were recorded on a Nicolet Avatar FTIR spectrophotometer as KBr pellets. Elemental analysis was performed by Kanti Labs Ltd. in Mississauga, Canada.

2.2. Synthesis of lacunary polyanion precursor $Na_8[A\text{-}HAsW_9O_{34}] \cdot 11H_2O$

A 30 g (91 mmol) sample of $Na_2WO_4 \cdot 2H_2O$ and 1.18 g (5.1 mmol) As_2O_5 were dissolved in 40 mL of water. Subsequently, the pH was adjusted to 8.4 using glacial acetic acid. After a few seconds the solution became cloudy and after about 2 min a white precipitate started to form. The solution was stirred for another 30 min and then the solid was isolated on a sintered funnel. The product was washed three times with ethanol and air-dried with aspiration. IR: 937(m), 884(m), 851(m), 765(s), 672(m), 518(w), 472(w), 444(w) cm^{-1}. This procedure is different from that reported previously by one of us, which involves using H_3AsO_4 instead of As_2O_5 [10q].

2.3. Synthesis of $Cs_4K_3Na_5[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2] \cdot 20H_2O$ (**1a**)

A 0.33 g (1.66 mmol) sample of $CdCl_2 \cdot H_2O$ was dissolved with stirring in 20 mL of 0.5 M NaAc buffer (pH 4.8). Then 2.00 g (0.75 mmol) of $Na_8[A\text{-}HAsW_9O_{34}] \cdot 11H_2O$ was added. The solution was heated to 80 °C for about 1 h and filtered after it had cooled. Then 0.5 mL of 1.0 M CsCl and 0.5 mL of 1.0 M KCl solutions were added to the filtrate. Slow evaporation at room temperature led to 1.8 g (yield 78%) of a white crystalline product after about one week. IR: 951(s), 882(s), 835(s), 784(s), 746(sh), 724(s), 480(w), 442(w) cm^{-1}. *Anal.* Calc. for **1a**: Cs, 8.6; K, 1.9; Na, 1.9; W, 53.4; Cd, 7.3; As, 2.4; Cl, 1.2. Found: Cs, 8.3; K, 2.1; Na, 1.9; W, 53.9; Cd, 7.1; As, 2.4; Cl, 1.3%.

2.4. ^{183}W and ^{111}Cd NMR spectroscopy

All NMR spectra were recorded on a 400 MHz JEOL ECX instrument at room temperature using D_2O as a solvent. The ^{183}W NMR measurements were performed at 16.656 MHz in 10 mm tubes and the ^{111}Cd measurements were performed at 84.757 MHz in 5 mm tubes. As references (external standards) we used aqueous solutions of 1 M Na_2WO_4 and 0.1 M $Cd(ClO_4)_2$, respectively.

2.5. X-ray diffraction analysis

A colorless crystal with dimensions $0.26 \times 0.12 \times 0.08$ mm was selected and mounted on a glass fiber for indexing and intensity data collection at 167 K on a Bruker D8 SMART APEX CCD single-crystal diffractometer using Mo Kα radiation (λ = 0.71073 Å). Direct methods were used to solve the structure and to locate the heavy

atoms (SHELXS97). Then the remaining atoms were found from successive difference maps (SHELXL97). Routine Lorentz and polarization corrections were applied and an absorption correction was performed using the SADABS program [17]. Crystallographic data are summarized in Table 1.

3. Results and discussion

3.1. Synthesis and structure

We have synthesized the dimeric tungstoarsenate(V) $[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{12-}$ (**1**) as a mixed cesium–potassium–sodium salt. The title polyanion consists of two trilacunary $[B\text{-}\alpha\text{-}AsW_9O_{34}]^{9-}$ Keggin units linked via a rhomblike $Cd_4O_{14}Cl_2$ group resulting in a sandwich-type structure with idealized C_{2h} symmetry (see Fig. 1). Polyanion **1** was synthesized by interaction of Cd^{2+} ions with the trilacunary precursor $[A\text{-}HAsW_9O_{34}]^{8-}$ in aqueous acidic medium upon heating to 80 °C. This indicates that the Keggin precursor has undergone isomerization from $A\text{-}AsW_9 \rightarrow B\text{-}AsW_9$ during the course of the reaction. However, this transformation is well known and has been observed in solution and in the solid state [10q].

Bond valence sum (BVS) calculations confirm that there are no protonation sites on **1**, indicating that the charge of the title polyanion must be −12 [18]. Crystallographically we could identify only 4 Cs^+, 3 K^+ and 3 Na^+ counterions, but elemental analysis indicated that indeed 5 Na^+ ions were present in **1a**. Therefore the charge of −12 for **1** is fully balanced in the solid state by an appropriate number of counterions. Disorder of some alkali ions (in particular sodium) is a common problem in polyanion chemistry.

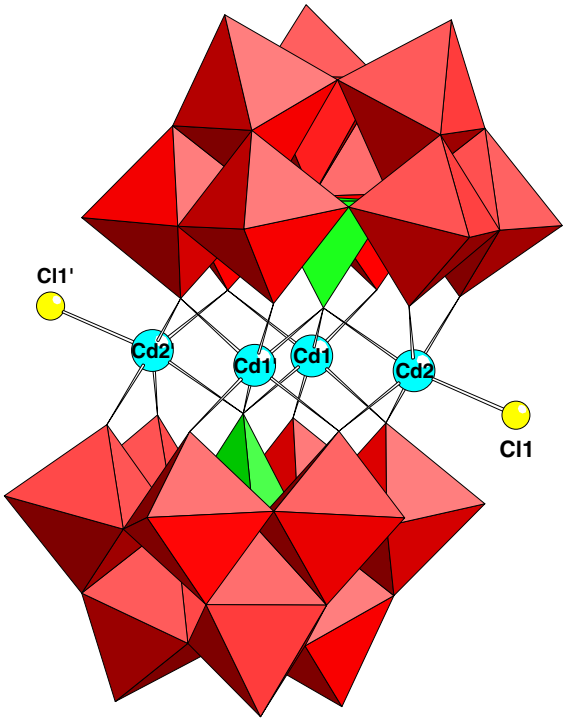

Fig. 1. Combined polyhedral/ball and stick representation of $[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{12-}$ (**1**).

The structural type of **1** had first been described in 1973 by Weakley et al. [10a] for $[Co_4(H_2O)_2(PW_9O_{34})_2]^{10-}$. To date this Keggin-based structure is known for most first-row transition metals (including mixed-metal derivatives) and it has also been possible to substitute the tetrahedral phosphorus(V) heteroatom by arsenic(V), silicon(IV), germanium(IV), iron(III), and copper(II) [10]. Therefore, this structural type represents one of the largest TMSP families.

The Weakley-type structures have in common that the two external transition metal ions in the central rhombus have one terminal ligand each, whereas the two internal metal ions do not have any terminal ligands. In all of the above known derivatives with the Weakley structure, the terminal ligand on the external transition metal ions is a water molecule. However, in **1** the two external cadmium ions have a chloro ligand instead of a water molecule. Clearly, the chloride ions originate from the cadmium source ($CdCl_2 \cdot H_2O$) which we used for the synthesis of **1**. Nevertheless, it must be remembered that synthesis of **1** is carried out in aqueous solution, so that the number of water molecules dominates by far the chloride ions. Therefore, the external cadmium ions incorporated in **1** have a strong preference for chloro rather than aqua ligands.

Recently one of us reported on the aqua derivative of **1** which was formulated as $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{10-}$ based on IR [10q]. Very recently Alizadeh et al. [16] reported on $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}PW_9O_{34})_2]^{10-}$ which represents the phosphorus derivative of **1**. They prepared this polyanion by reaction of $Cd(NO_3)_2 \cdot 4H_2O$ with $Na_8[A\text{-}\beta\text{-}HPW_9O_{34}] \cdot 24\text{-}H_2O$ in aqueous acidic medium (pH 6). These authors characterized their product in solution by ^{31}P and ^{113}Cd NMR. Very recently our group has synthesized the germanium(IV) derivative $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$ by reaction of $CdCl_2$, GeO_2, and $Na_2WO_4 \cdot 2H_2O$ in 0.5 M sodium acetate buffer (pH 4.8) [10u]. Interestingly, the external cadmium ions in the product polyanion contain aqua rather than chloro ligands. It is possible that the higher affinity of Cd^{2+} for chloro ions is overcompensated by charge density considerations of the germanium(IV) based polyanion. Specifically, the hypothetical dichloro derivative $[Cd_4Cl_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{14-}$ would have a charge of 14−, which is apparently less stable than the diaqua derivative $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$ with a charge of 12−. Interestingly, our $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$ and

the $[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{12-}$ reported here have both the same charge of −12.

It is of interest to evaluate in detail the bond lengths and angles of the cadmium centers in **1** and to compare these with the isostructural derivatives $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}PW_9O_{34})_2]^{10-}$ and $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$. In general, as Cd^{2+} is a d^{10} ion no Jahn–Teller distortion is expected. In fact, the two inner Cd centers of **1** exhibit a fairly regular coordination sphere and the Cd(1)-O distances range from 2.19 to 2.34(1) Å. On the other hand, the coordination sphere of the external Cd(2) shows a Jahn–Teller distortion, which is most likely due to the presence of the terminal chloro ligand. The equatorial Cd(2)–O distances range from 2.24 to 2.29(1) Å, whereas the axial Cd(2)–O and Cd(2)–Cl distances are 2.47(1) and 2.475(4) Å, respectively. The bond angles in the central $Cd_4Cl_2O_{14}$ fragment can be classified according to the type of bridging ligand. The Cd–O–Cd angles involving the μ_4-oxo ligand O1As are: Cd1–O1As–Cd1′ 101.2(4)°, Cd1–O1As–Cd2 93.3(3)° and Cd1–O1As–Cd2 94.6(3)°, respectively. On the other hand, the angles around the μ_3-oxo ligands O8C2 and O9Cd are: Cd1–O8C2–Cd2 98.9(4)° and Cd1–O9Cd–Cd2 100.4(4)°. The Cd···Cd separations in **1** are as follows: Cd1···Cd2 3.533(2) Å, Cd1···Cd2′ 3.494(2) Å and Cd1···Cd1′ 3.614(2) Å, respectively.

Comparison of these parameters for **1** with those of the structurally closely related $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$ [10u] and $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}PW_9O_{34})_2]^{10-}$ [16] allows to draw the following conclusions: the terminal chloro ligands in **1** result in a significantly longer terminal cadmium bond (Cd–Cl 2.475(5) Å) compared to those in the two aqua compounds (2.260(14) and 2.309(8) Å). This is the reason for the more pronounced Jahn–Teller distortion of the external Cd centers in **1**, which in turn results in larger Cd1···Cd2 distances (e.g., 3.494(2) Å, 3.533(2) Å in **1** versus 3.357(2) Å, 3.404(2) Å in $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$).

We were also able to synthesize the aqua derivative of **1** with the proposed formula $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{10-}$ (**2**) as based on IR and multinuclear NMR (see below). Polyanion **2** was prepared by an analogous procedure as **1**, but $Cd(NO_3)_2 \cdot 4H_2O$ was used instead of $CdCl_2 \cdot H_2O$ to ascertain the absence of chloride ions.

3.2. NMR Studies

Tungsten-183 NMR is a very powerful solution technique in polyanion chemistry to obtain structural information. The fact that polyanions **1** and **2** are diamagnetic makes them ideal candidates for NMR studies. In addition both species contain cadmium ions and therefore we decided to perform a detailed ^{183}W and ^{111}Cd NMR study on **1** and **2**. If the dimeric, sandwich-type polyanion structure with C_{2h} symmetry is preserved in solution, then five peaks (intensity ratio 2:2:2:2:1) are expected in ^{183}W NMR and two peaks (1:1) are expected for ^{111}Cd NMR. In fact, this is exactly what we observed. The room-temperature ^{183}W NMR spectrum of **1** exhibits five peaks at −75.9, −92.0, −94.2, −109.8, −121.8 ppm with intensity ratios 1:2:2:2:2 (see Fig. 2, top). For **2** we obtained an almost identical spectrum with five peaks at −75.9, −92.6, −94.3, −107.9, −119.9 ppm and the anticipated intensity ratios (see Fig. 2, bottom). As expected, a change of the terminal ligand on the external cadmium centers in **1** and **2** does not affect the chemical shifts of the tungsten centers significantly. In fact, only four of the six belt tungsten atoms in each Keggin unit should be affected, as they are only 3 bonds from the terminal chloro ligands in **1** or aqua ligands in **2** (see Fig. 1). Therefore we suggest that the two upfield signals in the ^{183}W NMR spectra of **1** and **2** (see Fig. 2) correspond most likely to those tungsten atoms in question. All other tungsten centers are further away from the terminal cadmium ligands in **1** and **2**. Of course, the unique cap tungsten atom corresponds to the smallest, most downfield signal. The ^{183}W NMR spectra of **1** and **2** correspond also very nicely to our results on the isostructural germanium derivatives $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$ and $[Zn_4(H_2O)_2(B\text{-}\alpha\text{-}GeW_9O_{34})_2]^{12-}$ [10u].

The ^{111}Cd NMR spectrum of **1** shows two singlet peaks at 55.3 and 14.7 ppm, respectively (see Fig. 3, top). The upfield signal is very broad which is probably due to the quadrupolar moment of the chloro ligand. Therefore, we can assign this signal to the external cadmium ions in **1** whereas the other, sharp signal corre-

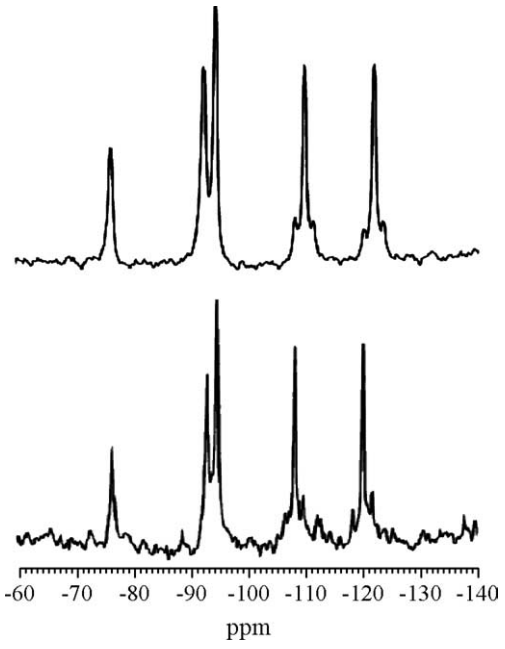

Fig. 2. Tungsten-183 NMR spectra of $[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{12-}$ (**1**), top, and $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{10-}$ (**2**), bottom.

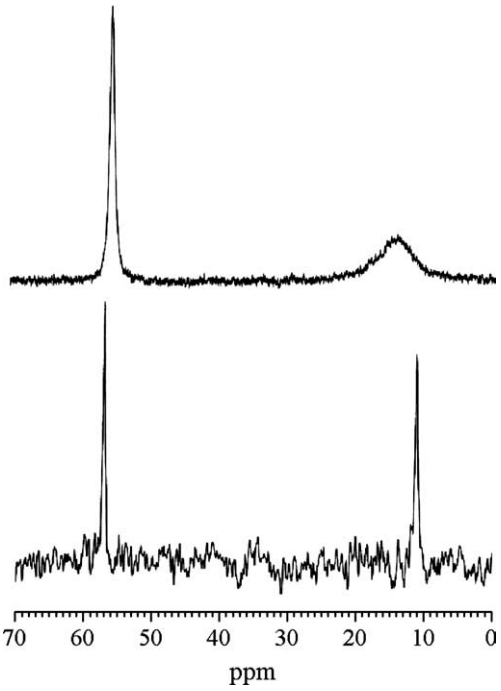

Fig. 3. Cadmium-111 NMR spectra of $[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{12-}$ (**1**), top, and $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{10-}$ (**2**), bottom.

sponds to the internal cadmium centers. The ^{111}Cd NMR spectrum of **2** exhibits two sharp peaks at 57.0 and 11.1 ppm, respectively, with equal intensities (see Fig. 3, bottom). This is fully consistent with water molecules as terminal ligands on the external cadmium ions. In analogy to **1** we assign the upfield signal at 11.1 ppm to the external cadmium ions and the downfield signal at 57.0 ppm to the internal cadmium ions of **2**. These results are also in good agreement with Alizadeh et al. [16], who performed ^{113}Cd NMR studies on $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}PW_9O_{34})_2]^{10-}$. They observed a very similar chemical shift for the internal cadmium ions (52.76 ppm), but the signal for the outer cadmium centers is significantly more downfield (26.25 ppm). This difference in ^{111}Cd NMR behavior must be due to the different hetero atoms X (X = As, P), as all other parameters are the same for both polyanions (e.g., structure, charge). Our work shows that this 'hetero atom effect' is more pronounced for the external than the internal cadmium ions. The nuclear shielding of the outer cadmium centers is a much better sensor for the type of hetero atom present than that of the internal cadmiums, in spite of the fact that the Cd–O bond lengths and Cd–O–X angles are very similar in both cases.

4. Conclusion

The dimeric, cadmium-substituted tungstoarsenate $[Cd_4Cl_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{12-}$ (**1**) has been synthesized by reaction of Cd^{2+} ions with $[A\text{-}HAsW_9O_{34}]^{8-}$ in aqueous, acidic medium. Polyanion **1** has a sandwich-type structure based on two $[B\text{-}\alpha\text{-}AsW_9O_{34}]^{9-}$ Keggin moieties encapsulating four cadmium centers in a rhomblike ($Cd_4O_{14}Cl_2$) group. Therefore, **1** represents only the second structurally characterized, Cd-containing polyanion and it is the first structurally characterized, Cd-containing tungstoarsenate(V). An interesting aspect of **1** is the fact that the external cadmium centers have terminal chloro ligands. Nevertheless we were also able to synthesize the aqua derivative $[Cd_4(H_2O)_2(B\text{-}\alpha\text{-}AsW_9O_{34})_2]^{10-}$ (**2**). Both species were investigated by ^{183}W and ^{111}Cd NMR in solution and we have shown that the former is an ideal method to establish the purity and to confirm the overall polyanion structure of **1** and **2**. On the other hand, the latter is an ideal technique to study the local coordination environment of the cadmium ions and it also allows to clearly distinguish **1** and **2** due to peak broadening caused by the quadrupolar chloride ions. Furthermore, this effect allows to assign the two Cd NMR peaks to the two types of cadmium ions in **1** and **2** and it also allows to indirectly assign some of the ^{183}W NMR peaks of the title polyanions.

In conclusion, synthesis of diamagnetic derivatives (e.g., Cd^{2+}, Zn^{2+}) of TMSPs is very attractive, as it allows to perform multinuclear NMR studies in solution involving addenda atoms (e.g., ^{183}W, ^{111}Cd). Although single crystal X-ray analysis is the most powerful technique to establish novel polyanion structures, multinuclear NMR is a very important, complementary tool to establish the structural integrity of polyanions in solution. Considering that polyanions have a multitude of potential applications in solution (e.g., medicine, catalysis) such diamagnetic complexes can be considered as model compounds to help understand structure-activity relationships of entire families of polyanions.

5. Supplementary material

One X-ray crystallographic file in CIF format. This material can be obtained from the Fachinformationszentrum Karlsruhe, Abt. PROKA, 76344 Eggenstein-Leopoldshafen, Germany (fax: +49 7247 808 666; e-mail: crysdata@fiz-karlsruhe.de) on quoting the depository number CSD – 415053.

Abstract

Reaction of silver(I) nitrate with equimolar amounts of the rigid diphos ligand *trans*-1,2-bis(diphenylphosphino)ethene (*trans*-dppen) and some heterocyclic thiones (L) in acetonitrile/methanol solvent gave rise to triply-bridged coordination cages $[Ag_2(\mu_2\text{-}trans\text{-dppen})_3L_2](NO_3)_2$. On the other hand, the complexes produced when using the flexible 1,5-bis(diphenylphosphino)pentane (dpppent) turned out to be diphosphine-bridged polymers of the type $[Ag(\mu_2\text{-dpppent})(L)(ONO_2)]_n$ with the diphosphine ligand acting as bridge between two pseudo-tetrahedraly coordinated metal centres. The structures of one representative for each of the two aforementioned series of complex compounds, namely, $[Ag_2(\mu_2\text{-}trans\text{-dppen})_3(pymtH)_2](NO_3)_2$ (pymtH = pyrimidine-2-thione) and $[Ag(\mu_2\text{-dpppent})(tHpymtH)\ (ONO_2)]_n$ (tHpymtH = tetrahydropyrimidine-2-thione) have been established by single-crystal X-ray diffraction.

1. Introduction

Sulfur donors are known to be good ligands for monovalent group-11 cations [1], and the research field concerning silver(I) in sulfur-dominated coordination spheres is vast and ever expanding. Among the frequently used S-donors, the extended family of heterocyclic thioamides, are of particular interest since their metal complexes are known to have relevance to biological systems [2–4]. The coordination mode of the neutral thioamides, also known as ''thiones'', towards soft acids is virtually limited to the thione-S monodentate and bidentate (μ_2-S) types, thus the majority of the Ag(I) complexes bearing simple neutral ligands such as pyridine-2-thione or pyrimidine-2-thione are monomeric or dimeric exhibiting the common trigonal planar or tetrahedral coordination around the metal centre [5]. Our previous approach to this area involved the employment of neutral thioamide ligands in heteroleptic phosphane derivatives of Ag(I) halides or Ag(I) nitrate, whereby some examples of monomers [6,7] or symmetric dimers [8], with pseudo-tetrahedraly coordinated silver(I) have been structurally characterized. On the other hand, oligomeric or polymeric Ag(I) species can be obtained [9–11] for thioamide ligands in their thionate anionic form, generated by deprotonation. It

should be noted, however, that a few silver-thione polymers of neutral pyridine-2-thione constructed on the basis of μ_2-S or μ_3-bridges, are also known [12,13].

Bidentate phosphines exhibit excellent ligating properties towards almost all transition metals [14–16] and diphosphine containing silver(I) complexes have attracted widespread attention [17]. Taking into account that the double bridging coordination mode of both diphosphines and heterocyclic thiones is quite common for univalent group-11 metal complexes, we recently introduced a series of oligomethylene-backboned diphosphines $Ph_2P(CH_2)_nPPh_2$ as a second soft donor with the aim of provoking some variability in the nuclearity of silver-thione complexes. The role of the flexibility of the bridging phosphine in controlling product selectivity in the formation of a multisilver complex is already recognized. Thus, while with long-chained flexible diphosphines, silver(I) salts with oxo-anions selectively form dinuclear (2:2) macrocycles, the rigid bis(diphenylphosphino) acetylene (dppa) gives stable cationic disilver complexes with triply-bridging diphosphine units [18,19]. On the other hand, by proper selection of thiolato ligands, novel oligonuclear structures can be constructed for Ag(I) complexes containing short bite diphosphines like bis(diphenylphosphino)methane [20]. In this context, our related work was initially devoted to silver(I) nitrate derivatives of some heterocyclic thiones containing bridging 1,2-bis(diphenylphosphino) ethane (dppe) and 1,4-bis(diphenylphosphino)butane (dppb). Interestingly, the only common feature of the two types of structures was the presence of pseudo-tetrahedraly coordinated metal centres exhibiting the same P_2S_2 donor set, since the complexes bearing the longer chained diphosphine (dppb) were found to be quadroubly bridged dimers build by a perfect combination of two kinds of bridges, whereas polymerization occurred in the case of dppe [21]. To prove the role of chain length, bulkines and flexibility of the bidentate phosphine and to gain more information concerning the effect of polymerization, we decided to include further potentially bidentate/bridging diphosphines in our studies. In this paper, we present our results on the use of the long chained 1,5-bis(diphenylphosphino)pentane (dppp) and the rigid *trans*-1,2-bis(diphenylphosphino)ethene (*trans*-dppen).

2. Experimental

2.1. Materials and instruments

Commercially available silver nitrate, *trans*-1,2-bis(diphenylphosphino)ethene (*trans*-dppen) and 1,5-bis(diphenylphosphino)pentane (dpppent) were used as received while the thiones (Merck or Aldrich) were recrystallized from hot ethanol prior to their use. All the solvents were purified by respective suitable methods and allowed to stand over molecular sieves. Infra-red spectra, molar conductivities in 10^{-3} M solutions in acetonitrile, magnetic susceptibility measurements and elemental analyses for carbon, nitrogen and hydrogen were performed as described previously [22]. Thermogravimetric analyses were performed on a SETSYS-1200 machine with DTG facility in dry nitrogen atmosphere. Sample sizes were in the range 8–10 mg and open Pt crucibles were used. The heating rate was 10°/min.

2.2. X-ray crystallographic study

Single crystals of **3** and **10** suitable for X-ray crystallographic study were grown by slow concentration of acentonitrile/methanol solutions of the compounds over several days at ambient temperature. X-ray diffraction data were collected on an Enraf-Nonius Kappa CCD area-detector diffractometer. The programs DENZO [23] and COLLECT [24] were used in data collection and cell refinement. Details of crystal and structure refinement are shown in Table 1. The structures were solved using program SIR97 [25] and refined with program SHELX-97 [26]. Molecular plots were obtained with program ORTEP-3 [27].

2.3. Synthesis of complexes *1–14*

The complexes were prepared according to the following general procedure. A suspension of silver nitrate (0.5 mmol) and 1,5-bis(diphenylphosphino)pentane or *trans*-1,2-bis(diphenylphosphino)ethene (0.5 mmol) in 20 cm^3 acetonitrile was stirred at 50 °C until a white precipitation was formed. A solution of the appropriate thione (0.5 mmol) in methanol was then added and the new suspension was stirred to clearness. The resulting solution was filtered off and the clear solution was kept at room temperature. Slow evaporation of the solvent at room temperature gave the microcrystalline solid, which was filtered off and dried in vacuo.

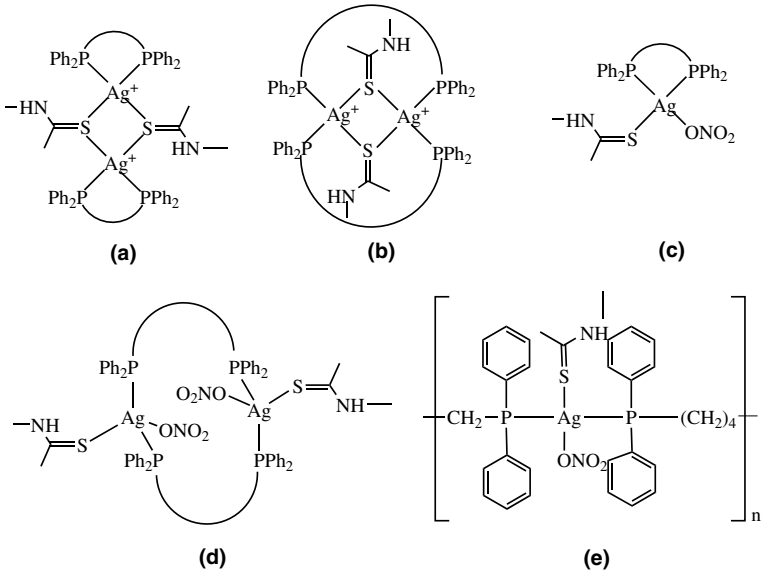
3. Results and discussion

3.1. Preparative considerations

Before discussing the experimental results, we should point out that both, 1,5-bis(diphenylphosphino)pentane (dpppent) and *trans*-1,2-bis(diphenylphosphino)ethene (*trans*-dppen) showed a marked preference for the formation of macrocycles in their reactions with Cu(I), in the presence of heterocyclic thione ligands [28–30], whereas *cis*-1,2-bis(diphenylphosphino)ethene yielded predominantly chelated monomeric species [31].

The reaction between equimolar quantities of silver(I) nitrate and 1,5-bis(diphenylphosphino) pentane (dpppent) followed by the addition of one equivalent of the apropriate thione (L) [L = pyridine-2-thione (py2SH), pyrimidine-2-thione (pymtH), tetrahydropyrimidine–thione (tHpytH), 5-methyl-1,3,4-thiadiazole-2-thione



(mtdztH), benz-1,3-oxazoline-2-thione (bzoxtH), 5-methyl-benz-1,3-imidazole-2-thione (mbzimtH_2), 4-methyl-5-trifluoromethyl-4H-1,2,4-triazoline-3(2H)-thione (mftztH), and 6-mercaptopurine (pur6SH) in dry acetonitrile/methanol solution at 30 °C afforded microcrystalline solids which, on analysis were found to be of composition [$AgNO_3$(dpppent)L] (compounds **1**–**8**).

According to our previous experience with thione/phosphine complexes of Ag(I) nitrate, Ag^+ tends to adopt a tetrahedral coordination whith the counterion kept outside the coordination sphere, despide its strong coordination ability. Within the meaning of this criterion, two structures (structures **a** and **b**, Scheme 1) come into question that reproduce the above given stoichiometry.

On the other hand, if the coordination of the nitrate anion is weak, the formation of a monomeric, dimeric or polymeric complex (structures **c**–**e**, respectively), could be possible, but formation of **c** is unlikely as it is less compatible with the stereochemical characteristics of the long-chained diphosphine applied. Indeed, the structure determination of the tetrahydropyrimidine-2-thione complex (compound **3**) by X-ray diffraction confirmed compounds **1**–**8** to be coordination polymers of type [Ag(μ-dpppent)(L)(ONO_2)]$_n$.

In general, diphosphines bearing a long-chained flexible backbone, are expected to bridge metal centres forming dimeric macrocycles of type [M(diphos)$_2$M] rather than polymeric adducts, the later being continuously favoured upon decreasing the diphosphine chain length. Indeed, the ability of 1,5-bis(diphenylphosphino)pentane to serve as a bridge between two metal centres in monovalent coinage metal complexes is well documented, among others in a recent publication of Pettinari and co-workers [32], where the flexible diphosphine was shown to predominantly form dimers of type [M(μ-dpppent)(μ-X)]$_2$ (M = Cu, Ag and X = Br, I). Likewise, treating an acetonitrile solution of Cu(I) chloride with stoichiometric amounts of dpppent and a heterocyclic thione ligand, the complexes formed were of the formula [CuCl(dpppent)L], whereby the thione-free dimer [Cu(μ-dpppent)(μ-Br)]$_2$ was found to be the only product of the analogous reactions when copper(I) bromide was used [30]. Consequently, the formation of the polymers under investigation was considered as unpredictable with respect to the geometrical features of the diphos ligand applied. Moreover, it contrasted, regarding the stoichiometric composition of the products formed, with the findings of our recent work on analogous $AgNO_3$ compounds, where the use of 1,2-bis(diphenylphosphino)ethane (dppe) afforded polymers of general formula [Ag(dppe)(L)$_2$]$_n$(NO_3)$_n$ [21], with the latter containing ionic outer-sphere nitrate groups. Thus, following the same procedure, we repeated the reactions using the apropriate thione in a twofold excess, aiming to attain cationic complexes, but we obtained once more compounds **1**–**8**. Likewise, we treated compounds **1**–**8** with two equivalents of an apropriate thione per formula unit, however the products isolated in all the cases turned out to be once more the polymeric complexes initially used as starting materials.

The second series of mixed ligand complexes obtained on treating silver(I) nitrate with equimolar quantities of *trans*-1,2-bis(diphenylphosphino)ethene (*trans*-dppen) and the same set of heterocyclic thiones was of the composition [($AgNO_3$)$_2$(*trans*-dppen)$_3$(L)$_2$]. On the basis of the above composition it was presumed that these compounds could be phosphine-bridged dinuclear cages. This was indeed found for six of the thiones applied (compounds **9**–**14**), but not for mbzimtH_2 or

Scheme 1.

pur6SH, where the reaction, carried out under the same experimental conditions as usual, gave in both cases a powder of uncertain stoichiometry.

Complexes **1**–**14** are diamagnetic, air stable, microcrystalline solids, only slightly soluble in common organic solvents. In accordance with their polymeric nature, the molar conductivities of complexes containing dpppent (compounds **1**–**8)** in dry acetonitrile solutions are somewhat lower than those of the dinuclear compounds **9**–**14**, but still fairly high to suggest complete ionization in solution.

3.2. Spectroscopic characterization

The solid state FT-IR spectra of complexes **1**–**14**, recorded in the range 4000–250 cm^{-1} provide useful information regarding the mode of thione ligand coordination. They show the disappearance of the S–H stretching band around 2560 cm^{-1} due to the "free" ligands and the presence of the ν(NH) band in the 3190–3230 cm^{-1} region, suggesting M–S bond formation. Moreover, they contain all of the bands required by the presence of heterocyclic thioamides occurring in their thione form, with shifts indicating the exclusive S-coordination mode of these ligands. Further, they show all the expected strong phosphine bands, which remain practically unshifted upon coordination. The asymmetric N–O stretching mode (ν_1) of the NO_3 anion appears as a band of medium intensity in the 1375–1285 cm^{-1} range, in some cases not recognizable because of overlapping with strong absorptions due to the thione and phosphine ligands. Unfortunately, nothing certain can be stated about the coordination mode of the nitrate ion since the thione ligands strongly absorb in the regions where the bands associated with coordinated nitrate occur.

The electronic absorption spectra of the complexes in chloroform solutions appear to be mainly of intraligand character, consisting of two intense sharp bands in the 250–260 and 282–307 nm regions, as well as an additional rather broad band with maximum at 335–370 nm. The first two bands can be attributed to intraligand $\pi^* \leftarrow \pi$ transitions on the phenyl group of the phosphine ligands, since the uncoordinated 1,5-bis(diphenylphosphino)pentane and *trans*-1,2-bis(diphenylphosphino) ethene both reveal two strong absorptions at 259 and 287.5 nm and 258.5 and 296 nm, respectively, which are known to undergo small shifts upon coordination to Ag(I). The lower energy band lies in the region where the free thiones absorb, expressing a small red shift as a consequence of the coordination to Ag(I) and should be, therefore, considered as a thione-originating intraligand transition which possess some MLCT character [33,34] (Fig. 1).

3.3. Thermal decomposition

Thermal analysis in nitrogen atmosphere shows the complexes **1**–**8** decompose in three or four stages. Fig. 2 illustrates TG and DTA data curves for the polymeric $[Ag(NO_3)(dpppent)(tHpymtH)]_n$ (compound **3**). The three low temperature initial stages involve a weak endothermic and a very strong exothermic effect in the temperature range 240–360 °C and are connected with an overall weight loss of ~16% which is consistent with gradually thermal breakdown of the tetrahydropyrimidine-2-thione ligand. Note that the very strong exothermic effect is an attribute of the decomposition of complexes bearing non-aromatic thione ligands, whereby the corresponding DTA courve in the case of aromatic thione compounds allways show endothermic events instead.

The observed mass loss (~67%) in the final, slightly endothermic stage, show excellent agreement for simultaneous loss of the diphosphine molecule and conversion of the resultant silver nitrate to Ag_2O under NO_2 evolution. However no clear distinction between these

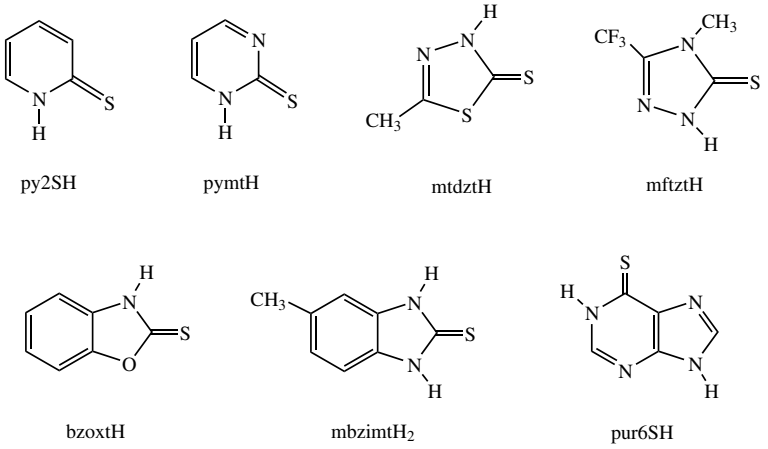


Fig. 1. The heterocyclic thione ligands used with their abbreviations.

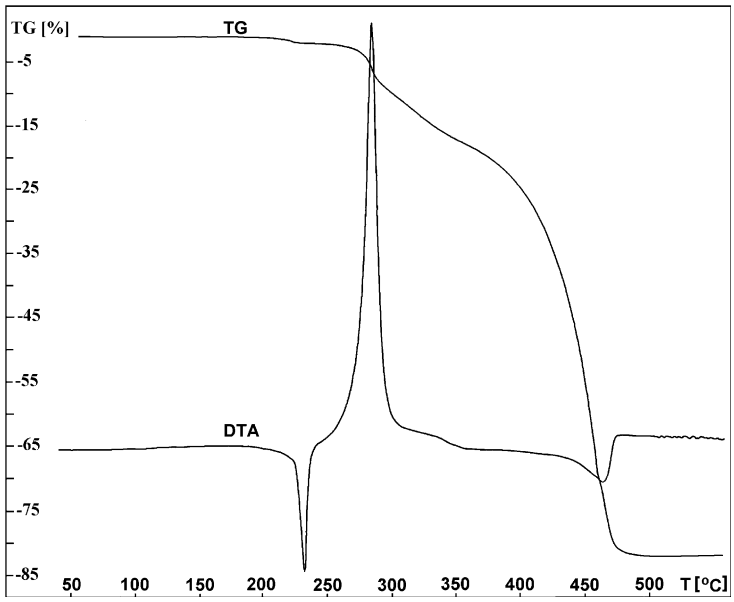

Fig. 2. TG and DTG curves for compound **3**.

two processes can be made, thus this stage must be somewhat complicated in character.

Complexes **9**–**14** show an analogous decomposition patern but they are in general thermally less stable, decomposition being usually completed at 450 °C. Noticeable is the particular short final stage, that extends over a temperature range of only 60 °C. In the majority of the cases solvent retention occurs at the temperature of 190 °C indicated by a strong exothermic effect connected with a weight loss corresponding to one molecule of CH_3CN per formula unit.

3.4. Crystal structures

Colorless crystals of **3** suitable for X-ray were obtained by slow evaporation of a CH_3CN/CH_3OH solution of the compound. The complex crystallizes in the monoclinic space group *C*2/*c*, with eight monomer units in the unit cell. Details regarding the crystal data collection and refinement for the complex are reported in Table 1. Bond lengths and angles around the Ag(I) are listed in Table 2. Fig. 3 shows the monomeric unit of the complex with the labelling of the atoms, and Fig. 4 the resultant polymer. The structure is substantially disordered, with each of the individual components of the monomeric entity being affected in some degree. Four of the five carbon atoms (C5–C8) in the pentane chain are disordered over two sites, whereas disorder in the thione ligand involves three carbons (C3–C5). Similarly the three oxygen atoms in the NO_3 ion are highly disordered. Moreover, there are high displacement parameters associated with an aryl group attached to P2, which had to be restricted to a hexagon with ideal bond lengths and angles.

Complex **3** is a coordination polymer consisting of Ag(I) cations linked through the phosphorous atoms of the 1,5-bis(diphenylphosphino)pentane ligand. Each silver nucleus completes the familiar tetrahedral coordination environment considering the S-atom from the tetrahydropyrimidine-2-thione ligand, one O-atom from the weakly coordinated nitrate anion and the two bridging P-atoms belonging to two different diphosphine units. The repeating unit extends into an infinite one-dimensional chain formed by linking Ag and P1 atoms by unit cell translations along the *b* axis, in which the tetrahydropyrimidine-thione units are ordered in a *syn* configuration.

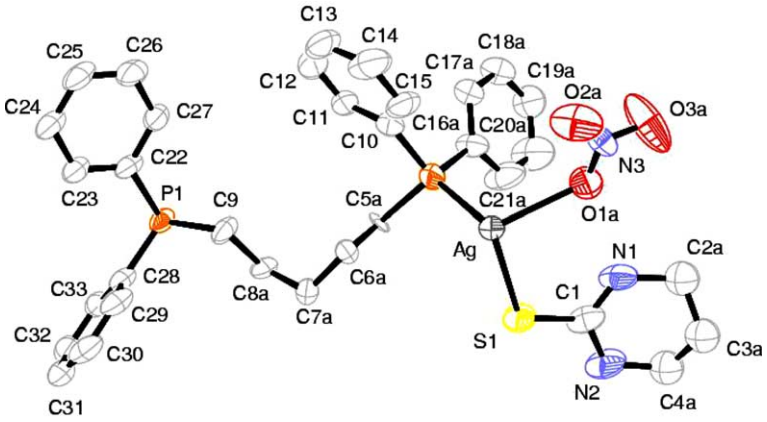

Fig. 3. The monomeric unit [Ag(μ-dpppent)(tHpymtH)(ONO_2)] of **3** with atom labels (disorder removed). Displacement ellipsoids are shown in the 50% probability level.

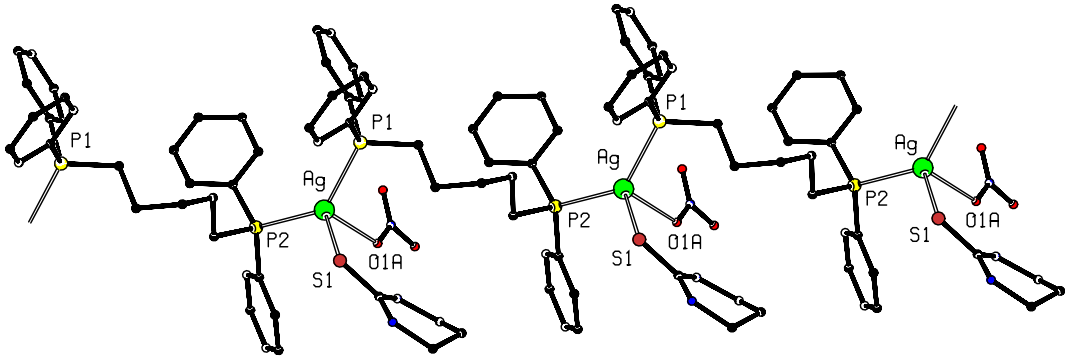

Fig. 4. A view of the polymeric chain [Ag(dpppent)(tHpymtH)(NO_3)]$_n$ with hydrogen atoms removed for clarity. Displacement ellipsoids are shown at the 50% probability level.

Considering the angles involving the central metal atom, there are considerable distortions from the ideal tetrahedral geometry, the most remarkable being the P(1)#−Ag–P(2) angle, with a large value of 132.75(5)° which can be partly accounted for the steric hindrance induced by the bulky phenyl-rings of the two phosphine units, but probably also for the presence of the weakly coordinated nitrate. Namely, the weak anion-cation interaction, indicated by the large Ag–O distance of 2.535(8) Å, is associated with angles involving the coordinated nitrate oxygen-atom that are less than the ideal tetrahedral value of 109.4°, thus allowing an appropriate opening up of the angle between the sterically demanding groups. Another remarkable feature in the structure of **3** is the quite large Ag–S–C angle of 113.92(19)°, which may be attributed to the presence of a strong hydrogen N–H···O bridge (Table 2).

The Ag–S bond distance of 2.5623(15) Å, coincident with the sum of the corresponding atomic radii, is typical for this bonding arrangement. Likewise, the two Ag–P distances lie within the limits of 2.426–2.504 Å found for a number of complexes containing tetracoordinated silver atoms bonded to two phosphorus atoms [35,36] and vary little [Ag(1)–P(1) = 2.4501(5), [Ag(1)– P(2) = 2.4658(5) Å]. Finally, the geometrical characteristics of the tetrahydropyrimidine-thione ligand, where the sex-membered ring adopts an envelope conformation, are not altered noticeable upon coordination.

Compound **10** crystallizes in the orthorhombic space group *Pna2*$_1$, with 4 discrete molecules in the unit cell as well as four lattice CH_3CN molecules. Main bond lengths and angles are given in Table 3 and a perspective drawing showing the atom numbering is shown in Fig. 5.

The crystal structure of **10** is built by dinuclear units in which the two tetrahedral silver centres are linked by three bridging diphosphine units, whereby the fourth position of each tetrahedron is occupied by the S-atom of a thione unit. Interestingly, the two thione rings are almost parallel to each other adopting a relative *cis* orientation. Each of the two nitrate anions is placed near to a thione unit and is adjusted to its nitrogen-bound hydrogen atom via hydrogen bonding interactions (see Table 3). Furthermore, each of these counterions is close

to a lattice CH_3CN molecule, which will not be further discussed as there is no evidence of any specific interaction involving this latter solvent molecule. One of the nitrate ions is hydrogen bonded to both thione units (Fig. 6). As well as the N–H···O bonds (Fig. 6, Table 3) there is also evidence of N–H···N interactions.

trans-1,2-Bis(diphenylphosphino)ethene (*trans*-dppen) is well known to serve as a phosphorus(σ) donor bridge between metal centres in coordination compounds [28,29,37,38]. However, in view of the rigidity of the diphosphine backbone, the formation of the three-fold bridging motif realized in the complex under discussion should be considered as quite strained, the more so as this rigidity is accompanied with a remarkable accumulation of stericaly demanding Ph_2PCH_2-units around the metal centres. Nevertheless, some related triply bridged $[M_2L_3]$ complexes with rigid bridging diphosphines such as $Ph_2P{-}C{\equiv}C{-}PPh_2$ [39] and $Ph_2P{-}C{\equiv}C{-}C{\equiv}C{-}PPh_2$ [40] have been characterised in the solid state. Among the Ag(I) complexes, this cage structure is known to exist, with no terminal ligands and thus with trigonal coordination of the two metal atoms, in the triply-bridged disilver helical complexes $[Ag_2(\mu_2\text{-dppa})_3]^{2+}$

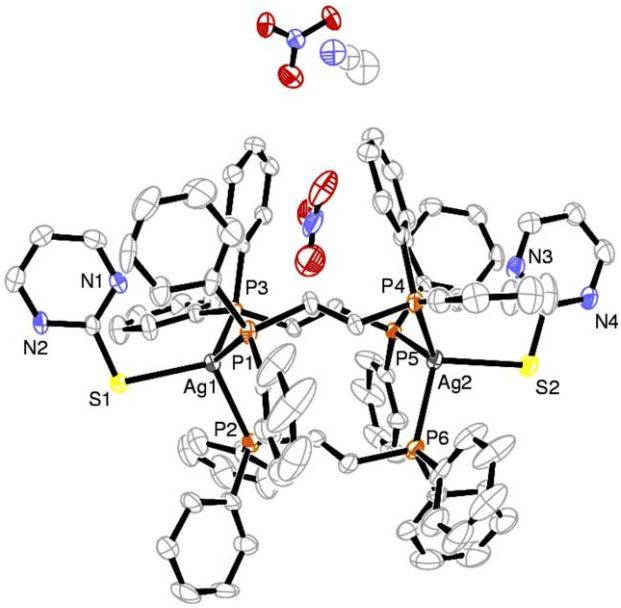

Fig. 5. A view of $[Ag_2(\textit{trans}\text{-dppen})_3(tHpymtH)_2](NO_3)_2 \cdot CH_3CN$ (**10**) with hydrogen atoms and disorder removed for clarity. Displacement ellipsoids are shown at the 50% probability level.

bearing the rigid bis-(diphenylphosphino)acetylene (dppa) [19]. Some examples of such cages with more or less strong anion–cation interactions, thus exhibiting tetrahedrally coordinated Ag(I) centres have been also reported recently [41]. Further related $[Ag_2L_3]$ complexes involve 2,6-bis(diphenylphosphino)pyridine [42], 3,6-bis(diphenylphosphino)pyridazine [42] and 2,9-bis(diphenylphosphino)-1,8-naphthyridine [43]. With *trans*-dppen, evidence for the formation of discrete $[Ag_2L_3]$ cages was found in solution, although, on crystallization, only the corresponding ring-opened polymeric structures could be obtained [41].

The geometrical characteristics of the structure under investigation generally refer to those of other silver(I) complexes tetrahedrally coordinated by phosphine and thione ligands. There are six different Ag–P bond distances around the two Ag(I) centres, each of them within the limits expected for a complex containing a tetracoordinated silver atom bearing phosphorus and sulfur donor ligands [44]. Likewise the two Ag–S distances [2.5660(10) and 2.5923(10) Å] are typical for this type of ligation. Interestingtly, the formation of the $Ag(PP)_3Ag$ cage does not require significant conformational rearrangements on the part of the diphosphine ligands; upon coordination the two P atoms of each diphosphine unit twist about the ethene bridge altering the dihedral angle through the four atoms by about 8°, taken as the average of the torsion angles P(1)–C(9)–C(10)–P(4), P(3)–C(11)–C(12)–P(5) and P(2)–C(13)–C(14)–P(6), with respect to the corresponding value (176.6°) in the free *trans*-dppen [45], thus only moderately modifying the bite size of the diphosphine.

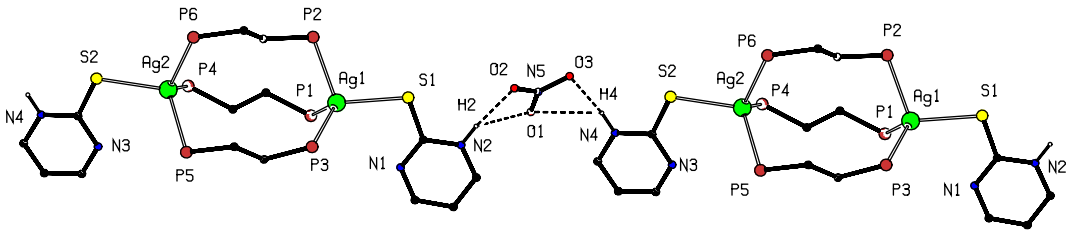

Fig. 6. Plot showing the N–H···O hydrogen bonds linking a nitrate ion to two thione units. Phenyl rings and hydrogen atoms are removed for clarity.

4. Conclusion

Two series of heterocyclic thione ligated silver(I) nitrate complexes in which Ag(I) centres are bridged either by 1,5-bis(diphenylphosphino)pentane or *trans*-1,2-bis(diphenylphosphino)ethene have been prepared and spectroscopically characterised. The complexes bearing the former long chained dpppent contain weakly coordinated nitrate groups and are polymeric. This contrast with the hitherto observed coordination behaviour of this flexible diphos ligand, since the majority of its univalent group I_B metal complexes are dinuclear macrocycles. Likewise as non-predictable should be considered the behaviour of the rigid bridging ligand *trans*-dppen, which is known to preferably form dinuclear macrocycles, as it favours in the present case the selective formation of triply bridged disilver derivatives, indepentend from the metal-to-ligand ratio applied. These results clearly demonstrate that factors other than the chain length, flexibility or stereochemical constrains between bulky groups on the part of the bridging ligand additionally play an important role in determining the structure being formed in each case. In this context, at least the effect of polymerization observed seems to be of particular interest and will be, therefore, object of more extensive studies.

5. Supplementary material

CCDC- 263254 (**3**) and CCDC-263255 (**10**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html [or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44-1223/336-033; e-mail: deposit@ccdc.cam.ac.uk].

Abstract

Under varying conditions the reaction of cysteamine hydrochloride ($SHCH_2CH_2NH_3$)Cl with stoichiometric amounts of Cd and Pb salts in water gave $[Cd_{2.5}Cl_5(SCH_2CH_2NH_3)]$ (**1**), $[Cd(SCH_2CH_2NH_2)_2]$ (**2**), $[Pb_2Cl(SCH_2CH_2NH_2)_3]$ (**3**) and $[Pb_2(SCH_2CH_2NH_2)_3](NO_3)_{0.67}(Cl)_{0.33}$ (**4**). Compound **1** is a molecular solid, one that contains a solid state-like core, but is nevertheless soluble in common organic solvents. The geometry around the Cd atoms in **1** are octahedral with varying numbers of sulfur and chlorine atoms. In contrast the pentacoordinate Cd atoms in **2** possess distorted square pyramidal geometry comprised of cysteamine sulfur and nitrogen atoms. Compounds **3** and **4** are structurally similar despite the presence and involvement of the anion in **4**. The Pb atoms in **3** possess both distorted square pyramidal and octahedral geometry, while in **4** the geometry around the Pb atoms is distorted square pyramidal. The NO_3 and Cl anions in **4** participate in more extensive hydrogen bonding by comparison to **3**, which has a Cl anion only. The hydrogen bonding in these compounds is not confined to the presence or absence of anions, as it is also observed between the amine of cysteamine with adjacent sulfur and nitrogen atoms. Full characterization of the compounds was achieved using IR, ^{1}H NMR, ^{13}C NMR, EA, Mass Spectrometry and X-ray crystallography.

Keywords: Cadmium; Lead; 2-Aminoethanethiolate; Intermolecular hydrogen-bonding

1. Introduction

Cysteamine (2-aminoethanethiol, $SHCH_2CH_2NH_2$) may be considered a derivative of either cysteine ($HSCH_2CH(NH_2)COOH$) or Penicillamine ($SH(CH_3)_2CCH(NH_2)COOH$) and its chemistry with transition metals has been studied extensively. The compounds may be used as alkylating agents and as a radiation protectant [1]. Mononuclear and polynuclear complexes of Ni(II) with cysteamine were the first reported examples [2]. Since then a wide range of metal complexes with various stoichiometries have been reported [3,4]. These are of the formula: M_xL_y ($x = 3$–6, $y = 4$–12, L = cysteamine and M = Au^+, $Cu^{1+/2+}$, Cd^{2+}, Co^{3+}, Fe^{3+}, Hg^{2+}, Ir^{3+}, $Mo^{3+/4+}$, Ni^{2+}, Os^{3+}, Pb^{2+}, Pd^{2+}, Pt^{2+}, Re^{3+}, Rh^{3+}, Ru^{3+}, Zn^{2+}) [1,3–7] and ML_2 for the alkaline earth metals and Bi^{3+}, $Ag^{1+/2+}$, Pd^{2+}, Zn^{2+}, ReO^{5+} and Ni^{2+} [8–10]. The study of mercaptide ions as donors, especially 2-aminoethanethiol, of mL_2 stoichiometry have not been subjected to detailed study as the complexes obtained are extremely insoluble, bridged and/or even polymeric in nature, making structural studies prohibitively difficult [3]. Recently, Bi^{3+} and ReO^{5+} cysteamine complexes of ML_2 stoichiometry have been characterized by X-ray structures [10,11]. In recently reported Pb-cysteamine complexes ($PbCl_2 \cdot (SCH_2CH_2NH_3)$, $Pb(SCH_2CH_2NH_2)_2 \cdot 2PbCl(SCH_2CH_2NH_2)$ and $Pb(SCH_2CH_2NH_2)_2$), the molecules are held together through intermolecular Pb–S bonds, unlike **3**

and **4** reported here [12]. This clearly implies that the reaction conditions affect the structural chemistry.

Our continued interest in aqueous chemistry of heavy metal-thiolates led us to study Cd and Pb-aminoethanethiolates [13,14]. In a previous study with cysteamine [15], we have shown that binding to Hg in water results in a linear S–Hg–S linkage (bond angle 168.53°). This follows the precedent found in other monodentate thiolate ligands such as cysteine [16,17]. There were also some S–H hydrogen bonding, something that has not been observed for Hg containing metalloproteins such as MerR and MerP [18,19]. Here, we describe the cysteamine complexes of Cd(II) and Pb(II) which, in addition to forming unique structures, also possess extensive hydrogen-bonding involving something that has not been reported previously for similar dinuclear complexes.

2. Experimental

All the reactions were carried out at room temperature in deionized water. The reagents $CdCl_2$, $CdCO_3$, $Pb(Ac)_2 \cdot 3H_2O$ and $PbNO_3$ (J.T. Baker) and cysteamine hydrochloride (TCI America) were used as received. NMR (^1H and ^{13}C) data were obtained with JEOL-GSX-400 and 270 instruments operating at 199.17 and 399.78 MHz using d^6-DMSO and D_2O as solvents, with tetramethylsilane as the reference. IR data were recorded as KBr pellets on a Matheson Instrument 2020 Galaxy Series spectrometer and are reported in cm^{-1}. X-ray data for **1**–**4** were collected on a Nonius Kappa-CCD unit using Mo Kα radiation and crystallographic data are summarized in Table 1. For bond lengths and bond angles see Tables 3–6. A summary of the IR spectra for compounds **1**–**4** in tabular form is included in the supplementary information.

2.1. Preparation of $[Cd_{2.5}Cl_5(SCH_2CH_2NH_3)]$ (**1**)

Cadmium (II) chloride (0.94 g, 5 mmol) was added to a stirring solution of cysteamine hydrochloride (1.14 g, 10 mmol) in deionized water (20 mL) and the resulting mixture was stirred over 3 days. The solution was then filtered to remove a white precipitate and the filtrate was allowed to stand for 4 weeks in the refrigerator (4 °C), during which colorless crystals were formed. Crystalline yield: 0.29 g (10%), m.p. 222–224 °C (dec). ^1H NMR (d^6-DMSO, 200 MHz, ppm): δ 2.69 (t, 4H, CH_2N), 3.14 (t, 4H, CH_2S), 7.75 (s, 6H, NH_3). ^{13}C NMR (d^6-DMSO, 200 MHz, ppm): δ 33.9 (CH_2S), 43.1 (CH_2N). IR (KBr, ν/cm^{-1}): 657 (C–S), 1230 (C–N, stretching), 1258, 1320, 1376, 1427 (S–CH_2), 1491, 1561, 1583 (–NH_2 and N–H, bending), 2361, 2938, 3130 (NH_3^+), 3450 (R–NH_2, stretching). MS (EI, positive): m/z 247 $(M + 2)^+$, 171 $(M - SCH_2CH_2NH_2)^+$, 92 $(M - 2(SCH_2CH_2NH_2))^+$, 76 $(SCH_2CH_2NH_2)^+$. *Anal.* Calc. for $C_4H_{14}N_2S_2Cl_5Cd_{2.5}$: C, 7.84; H, 2.30; N, 4.57; S, 10.47. Found: C, 7.65; H, 2.20; N, 4.55; S, 10.43%.

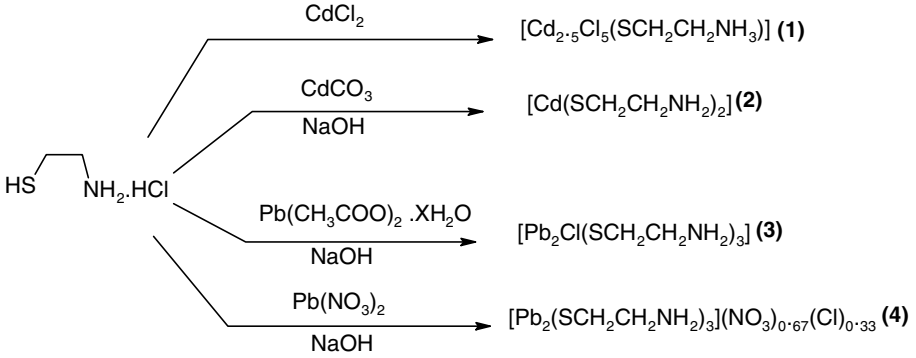
2.2. Preparation of $[Cd(SCH_2CH_2NH_2)_2]$ (2)

To a stirring solution of cysteamine hydrochloride (1.14 g, 10 mmol) in deionized water (20 mL) sodium hydroxide (0.80 g, 20 mmol) was added followed by addition of cadmium carbonate (0.86 g, 5 mmol). The mixture was stirred over one day and then solution was filtered to isolate a white precipitate. The filtrate was allowed to stand for 3 days in the refrigerator (4 °C), during which colorless crystals formed in near quantitative yield. Crystalline yield: 0.62 g (47%), m.p. 172–174 °C. ^{1}H NMR (D_2O, 200 MHz, ppm): δ 2.73 (t, 4H, CH_2N), 3.01 (t, 4H, CH_2S). ^{13}C NMR (D_2O, 200 MHz, ppm): δ 28.29 (CH_2S), 44.02 (CH_2N). IR (KBr, ν/cm^{-1}): 622–661 (C–S), 1051, 1064, 1120, 1214, 1228 (C–N, stretching), 1423 (S–CH_2), 1580 (–NH_2 and N–H, bending), 3551 (R–NH_2, stretching). MS (EI, positive): m/z 266 $(M + 2)^+$, 190 $(M - SCH_2CH_2NH_2)^+$, 114 $(M - 2(SCH_2CH_2NH_2))^+$, 76 $(SCH_2CH_2NH_2)^+$. *Anal.* Calc. for $C_4H_{12}N_2S_2Cd$: C, 18.15; H, 4.57; N, 10.58; S, 24.23. Found: C, 18.00; H, 4.62; N, 10.51; S, 24.05%.

2.3. Preparation of $[Pb_2Cl(SCH_2CH_2NH_2)_3]$ (3)

To a stirring solution of cysteamine hydrochloride (1.14 g, 10 mmol) in deionized water (20 mL) sodium hydroxide (0.80 g, 20 mmol) was added followed by addition of lead acetate trihydrate (1.90 g, 5 mmol) and the mixture was stirred over one day. The solution was then filtered to remove a yellow precipitate and the filtrate was allowed to stand for 3 days in the refrigerator (4 °C), during which pale yellow crystals formed. Crystalline yield: 0.64 g (19%), m.p.: 120–122 °C. ^{1}H NMR (D_2O, 200 MHz, ppm): δ 2.852 (t, 6H, CH_2N), 3.028 (t, 6H, CH_2S). ^{13}C NMR (D_2O, 200 MHz, ppm): δ 29.1 (CH_2S), 48.5 (CH_2N). IR (KBr, ν/cm^{-1}): 668–657 (C–S), 1032, 1065, 1105, 1219 (C–N, stretching), 1417 (S–CH_2), 1596 (–NH_2 and N–H, bending), 3463 (R–NH_2, stretching). MS (EI, positive): 359 $(Pb(SCH_2CH_2NH_2)_2)^+$, 282 $(Pb(SCH_2CH_2NH_2))^+$, 76 $(SCH_2CH_2NH_2)^+$. *Anal.* Calc. for $C_6H_{18}N_3S_3ClPb_2$: C, 10.63; H, 2.67; N, 6.20; S, 14.18. Found: C, 10.24; H, 2.48; N, 5.87; S, 13.37%.



2.4. Preparation of $[Pb_2(SCH_2CH_2NH_2)_3](NO_3)_{0.67}(Cl)_{0.33}$ (4)

Sodium hydroxide (0.80 g, 20 mmol) was added to a stirring solution of cysteamine hydrochloride (1.14 g, 10 mmol) in deionized water (20 mL) followed by addition lead nitrate (1.66 g, 5 mmol) and the mixture was stirred over a day. The solution was then filtered to remove a white precipitate, and the filtrate was allowed to stand for 10 days in the refrigerator (4 °C), during which colorless crystals formed. Crystalline yield: 0.41 g (24%), m.p. 132–134 °C. ^{1}H NMR (d^6-DMSO, 200 MHz, ppm): δ 2.746 (m, 4H, CH_2N), 3.204 (t, 4H CH_2S). ^{13}C NMR (d^6-DMSO, 200 MHz, ppm): δ 30.0 (CH_2S), 49.3 (CH_2N). IR (KBr, ν/cm^{-1}): 628–706 (C–S), 1046-1221 (C–N, stretching), 1430 (S–CH_2), 1593 (–NH_2 and N–H, bending), 3448 (R–NH_2, stretching). MS (EI, positive): 359 $(Pb(SCH_2CH_2NH_2)_2)^+$, 282 $(Pb(SCH_2CH_2NH_2))^+$, 76 $(SCH_2CH_2NH_2)^+$. *Anal.* Calc. for $C_6H_{18}N_{3.67}S_3O_{2.02}Cl_{0.33}Pb_2$: C, 10.35; H, 2.61; N, 7.38; S, 13.82. Found: C, 10.36; H, 2.57; N, 7.36; S, 13.55%.

3. Result and discussion

3.1. Synthesis and characterization

Cysteamine hydrochloride and various metal salts were combined in a 1:1 ratio in deionized water to produce compounds **1**–**4** (Scheme 1). Compounds **1**, **2** and **4** gave white precipitates, while **3** was isolated as a yellow precipitate. The compounds were isolated by filtration in high yields (60–90%) and the supernatants were used to grow X-ray quality crystals at 4 °C. The characterization data (IR, NMR, EA, Mass Spectrometry) were matched for both the precipitates and the crystals. The

Scheme 1. Synthesis of compounds **1**–**4**.

Table 2
NMR data for cysteamine hydrochloride and compounds **1**–**4**

^{1}H and ^{13}C NMR/ compounds (in ppm)	Cysteamine hydrochloride	**1**	**2**	**3**	**4**
^{1}H NCH_2	2.69	2.69	2.73	2.85	2.74
^{1}H SCH_2	2.99	3.14	3.01	3.02	3.20
^{13}C NCH_2	42.8	43.1	44.0	48.5	49.3
^{13}C SCH_2	22.2	33.9	28.2	29.1	30.0

compounds are soluble in hot water but not in common organic solvents.

In the ^{1}H NMR for **1**–**4** (Table 2), single peaks were observed for the CH_2N and CH_2S groups, which is consistent with symmetrical structures in solution. When bound to the metal ion the ligand hydrogen atoms become more deshielded compared to the free ligand, cysteamine hydrochloride. However, in **1** no change in the chemical shift for CH_2N confirms the presence of a free amine. The significant shifts in CH_2S peaks in the ^{1}H and ^{13}C spectra for compounds **1**–**4** indicate a strong metal–sulfur interaction.

In the IR spectra for **1**–**4** the C–S and S–CH_2 stretches are shifted to lower frequencies when compared to free cysteamine hydrochloride. This implies coordination of the metal to the thiols. The ammonium bands at 2938–3130, 1561–1583 cm^{-1} and no change in the C–N stretching in **1** indicate free amine. For **2**–**4** the NH_2 stretching and bending modes are observed at higher frequencies compared to the free ligand, indicating the presence of a metal–nitrogen contact. In the mass spectrum for **2** the parent peak is observed at 266 (*m*/*z*) while the successive loss of two cysteamine units is observed for all the complexes.

4. Description of structures

Compound $[Cd_{2.5}Cl_5(SCH_2CH_2NH_3)]$ (**1**) has three-dimensional connectivity indicative of a solid-state material but it is nevertheless soluble in common solvents. This qualifies **1** as a "molecular solid" [20]. The structure contains layers of $(Cd(Cl)SR)_x$ perpendicular to one another (Fig. 1). The structure is comprised of alternate opposite open cores of hexacoordinate Cd with Cl and S present at the corners. Similar polymeric chains with hexacoordinate Cd atoms are also observed in $[Cd_2(5\text{-}CF_3\text{–}pyS)_4(DMF)]_n$, where the coordination is completed by S, N of the ligand and solvent, DMF [21]. This is not observed for **1**, where the coordination is completed by S and Cl to achieve octahedral geometry. The repeating pattern observed in the unit is Cd1(2S,4Cl)–Cd2(S,5Cl)–Cd1(2S,4Cl) and so on. Cd1 and Cd3 are coordinated to two sulfurs and four chlorines with two chlorides involved in bridging with another unit, whereas Cd2 is bonded to one sulfur, one terminal chlorine and four core bonded chlorine atoms.

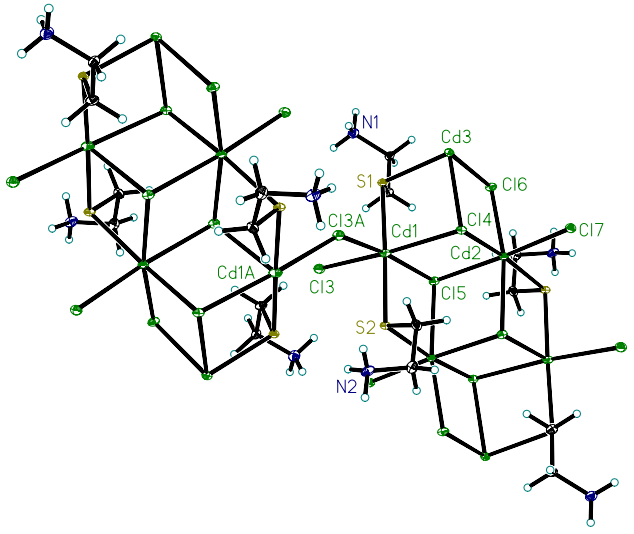


Fig. 1. View of the unique repeating unit of compound **1** at 50% thermal ellipsoids value.

Selected bond lengths and angles are given in Table 3. The Cd–S bond length varies in different cores. For Cd1 and Cd3, the distances are nearly the same (average 2.498 Å) while for Cd2, the bond distance is comparatively higher (2.601 Å). By comparison, $[CdBr_2(C_5H_{13}NS)]$, which also contains polymeric Cd–S chains has Cd–S distances ranging from 2.515 to 2.520 Å [22].

Variation in the Cd–Cl bond lengths is also observed for different chlorides (terminal, core bonded and bridging) as well as for different Cd atoms. For Cd(1), the distance between Cd and the core bonded chlorine is shorter (average 2.808 Å), compared to the bridging chlorine (2.920 Å). The bond lengths of chloride present in the core are nearly the same with an average distance of 2.790 Å. For Cd(2), Cd–Cl bond distances for core bonded and terminal chloride are nearly the same.

However a shorter Cd–Cl distance with a terminal chlorine, compared to bridged is observed in the complex $[Cd_2Cl_4(C_{14}H_{23}N_4OPS)_2]$ [23], where the bridging Cd–Cl distance is 2.644 Å, compared to terminal Cd–Cl, 2.387 Å. The S–Cd–S angle in **1** is almost linear (178.2° and 180.0°) due to the presence of a regular structure, when compared to the similar complex $[CdBr_2(C_5H_{13}NS)]$ (126.9°) [22]. The linear Cl–Cd–Cl angle (range 167–180°) and average angle of 90° signify octahedral geometry around the metal ion, whereas in $[Cd_2Cl_4(C_{14}H_{23}N_4OPS)_2]$ [23] a distorted tetrahedral geometry around Cd is indicated by Cl–Cd–Cl angles, ranging from 89° to 112°. The terminal amine is oriented away from the core with a N1–C2–C1 angle of 111.9° to reduce steric interactions. There are no signs of intramolecular hydrogen-bonding observed within a unit. However, intermolecular hydrogen-bonding involving chlorine with amines on adjacent units is observed. Similar hydrogen-bonding has been observed in $[CdBr_2(C_5H_{13}NS)]$ [22], where bromine is involved in inter-chain hydrogen-bonding with adjacent ammonium groups.

Compound (**2**) consists of discrete $[Cd(SCH_2CH_2NH_2)_2]$ molecules (Fig. 2) that are linked through intermolecular hydrogen bonds (Fig. 3). Selected bond lengths and angles are shown in Table 4. Cd is pentacoordinate, bonded to three sulfur and two nitrogen atoms in a distorted square pyramidal geometry. In the dimeric structure the two cadmium atoms are related by a center of inversion situated at the mid-point of the line between the two metal centers. One of the ligands acts as a terminal chelating unit (S, N) while the other behaves as both a chelate and a bridge through the sulfur. The Cd_2S_2 core is nearly planar with average internal angles close to 90°, with two different fused five-membered cysteamine rings (axial, terminal cysteamine unit and equatorial, cysteamine unit attached to the core). The Cd–S

N(1)–Cd–N(2)	85.54 (7)	N(1)–Cd–S(2)	137.38 (5)
N(2)–Cd–S(2)	81.66 (5)	N(1)–Cd–S(1)	78.22 (5)
N(2)–Cd–S(1)	161.82 (6)	S(2)–Cd–S(1)	104.85 (2)
S(1)′–Cd–S(1)	93.54 (2)	Cd′–S(1)–Cd	86.46 (2)
N(1)–Cd–S(1)′	101.85 (5)	N(2)–Cd–S(1)′	97.79 (6)

bond distances vary from 2.492 to 2.735 Å in axial, equatorial and the central core but are comparable to related sulfur-bridged compounds (2.537–2.713 Å) as well as those containing S/N ligands (2.466–2.673 Å) [22–24]. The Cd–N bond distances are also different in both four- (2.308 Å) and five-membered fused rings (2.436 Å) but comparable to Cd–N bond distances in similar complexes [23–27].

The Cd–S1 distance is larger than Cd–S2 and Cd–N1 is smaller than Cd–N2 implying a stronger Cd–S bond in the axial position. The Cd–S and Cd–N bond distances show an opposite trend, similarly observed for distorted octahedral $[Cd(3\text{-}CF_3\text{–}pyS)_2(DMF)_2]$ [21]. The cysteamine units in axial and equatorial positions are neither perpendicular nor parallel to each other (N(1)–Cd–S(1)′, 101.8° and C(1)–S(1)–Cd(1)′, 102.9°). The deformity is due to the interaction of the sulfur and nitrogen with the amine hydrogen of the equatorial cysteamine molecule of another unit. The presence of the M_2S_2 core and intermolecular hydrogen-bonding (N–H–S, N–H 0.92 Å and H–S 2.95 Å) results in the distortion of planarity of the axial cysteamine ring. The equatorial and the axial cysteamine have torsion angles

Cd–S(2)–C(3)–C(4) 48.9° and Cd–S(1)–C(1)–C(2) 28.6°, that minimize strain energy.

In the structure of $[Pb_2Cl(SCH_2CH_2NH_2)_3]$ (**3**), four- and five-coordinate Pb, are observed (Fig. 4). The Pb atoms possess stereochemically active lone pairs giving four-coordinate Pb a distorted square pyramidal geometry and five-coordinate Pb an octahedral geometry. The five-coordinate Pb atoms form a planar four-membered M_2S_2 ring with average internal angles of nearly 90°.

The Pb–S distance in the pentacoordinate Pb is larger than the Pb–S distance of tetracoordinate Pb (Table 5). The bridging Pb–S distance (2.897 Å) between tetra and pentacoordinate Pb is in agreement with other related lead–thiolate complexes (2.671–2.960 Å) [28,29]. The Pb–N distance in pentacoordinate Pb is smaller compared to Pb–N in tetracoordinate Pb. These distances are comparable to [Pbc[15]crown-5](SCN)$_2$ [30], where the Pb–N distances range from 2.436 to 2.532 Å. The Pb–S and Pb–N bond distances in different units are opposite with a stronger Pb–S bond in the axial position. This trend is also observed in **2**. When compared to a similar complex $Pb(SCH_2CH_2NH_2)_2$ the Pb–S and Pb–N distances are in agreement [12].

Pb(1)–N(1)	2.629 (6)	Pb(1)–N(2)	2.613 (7)
Pb(1)–S(1)	2.713 (2)	Pb(1)–S(2)	2.673 (2)
Pb(2)–S(2)	2.897 (2)	Pb(2)–N(3)	2.394 (7)
Pb(2)–S(3)	2.7377 (19)	Pb(2)–S(3)′	3.053 (2)
Pb(2)–Cl(1)	3.082 (2)		
N(1)–Pb(1)–S(1)	73.17 (15)	N(1)–Pb(1)–S(2)	86.41 (16)
N(2)–Pb(1)–S(1)	81.08 (16)	N(2)–Pb(1)–S(2)	73.51 (16)
N(3)–Pb(2)–S(2)	83.89 (18)	N(3)–Pb(2)–S(3)	73.61 (17)
S(2)–Pb(1)–S(1)	99.56 (6)	S(3)–Pb(2)–S(2)	83.81 (6)
S(2)–Pb(2)–S(3)′	165.09 (5)	S(3)–Pb(2)–S(3)′	84.35 (6)

The tetra-coordinate Pb unit is linked to the M_2S_2 core Pb through one of its sulfur atoms, which is nearly linear (165.0°), very much comparable to the polymer sheet $Pb(SCH_2CH_2OH)(NO_3)$ (162.7°) [31] and $Pb(SPh)_2$ (158.9°) [29]. The bond angles around the tetracoordinate Pb are nearly equal within the ring (73°) and between two cysteamine units (83° and 86°). The chloride bonded to the central Pb forms a hydrogen-bond with the $-NH_2$ group of the tetracoordinate Pb of another unit (Fig. 4). The NH of the cysteamine attached to the core form a hydrogen-bond with the sulfur of the tetracoordinate Pb of a second unit. Hence the intermolecular hydrogen-bonding is responsible for the stacking of the molecules and making the Pb_2S_2 cores parallel to each other. Such stacking is also observed in $Pb(SPh)_2$ [29]. The whole molecule is symmetrical with an axis going through the plane of the four membered Pb_2S_2 ring.

The crystal structure of $[Pb_2(SCH_2CH_2NH_2)_3](NO_3)_{0.67}(Cl)_{0.33}$ (**4**) reveals two types of Pb, both in a four coordinate geometry (Fig. 5). The M_2S_2 core, fused five membered cysteamine above and below the core plane and four coordinate metal linked to the core with sulfur as in **4**, is also observed in **3**. The axial Pb–S bond lengths (average 2.697 Å) are shorter than the Pb–S bond lengths of the core (average 2.989 Å). The bridging Pb–S distance (2.893 Å) connecting the core and the axial unit is nearly the same as the bridging Pb–S bond of **3** (2.987 Å). Like compounds **2** and **3**, Pb–S and Pb–N distances also show opposite trends in axial and the core units. Except for the presence of chloride attached to central Pb in **3**, compounds **3** and **4** are nearly identical and have similar lattice parameters (Table 1). Bond lengths and bond angles for **4** are given in Table 6. The presence of extensive hydrogen-bonding in **4** might explain the higher thermal stability compared to **3**. This

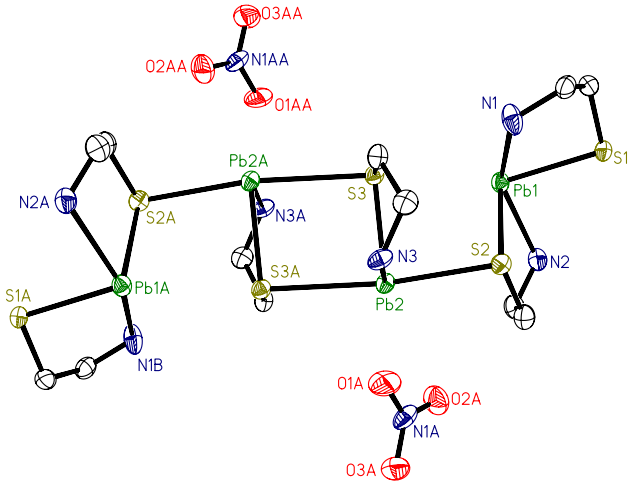

Fig. 5. Molecular structure of compound **4.** The counter anions are 2/3rd NO_3^- and 1/3rd Cl^- (sitting at the same position). For the sake of clarity, only NO_3^- are shown.

Table 6

Pb(1)–S(2)–Pb(2)	96.11 (6)	Pb(2)–S(3)–Pb(2)′	95.65 (6)

is due to the presence of NO_3^- anions, which supplies more hydrogen bonding contacts than single chloride anions. The amine hydrogens are also weakly hydrogen bonded to sulfur and chlorine atoms as observed in **2** and **3**.

5. Conclusion

In the present manuscript we have described the Cd(II) and Pb(II) compounds of 2-aminoethanethiol with the help of crystal structures. As the reactions were carried out following the same general procedure the products were similar. Compounds **2**, **3** and **4** show structural similarities involving bridging sulfurs to form a four-membered M_2S_2 core. Beside the central core, fused five-membered axial (with tetracoordinate metal) and equatorial (with pentacoordinate metal) cysteamine units are also observed in in **2**, **3** and **4**. It is important to note that the reaction conditions affect the structural chemistry as in **3** and **4** there is no Pb–Pb interaction observed, compared to a similar $Pb(SCH_2CH_2NH_2)_2$ complex [12]. A common feature of all the four compounds is intermolecular hydrogen-bonding involving nitrogen/sulfur and the counter anions.

Abstract

Treatment of $[Ru_3(CO)_{10}(\mu\text{-}dppm)]$ (**1**) with $PPh_3{=}S$ at ambient temperature in THF gave the known compound $[Ru_3(CO)_7(\mu_3\text{-}CO)(\mu_3\text{-}S)(\mu\text{-}dppm)]$ (**2**) and the new compound $[Ru_3(CO)_6(\mu_3\text{-}CO)(\mu_3\text{-}S)(PPh_3)(\mu\text{-}dppm)]$ (**3**). Compound **3** can also be prepared by the room temperature reaction of **2** with PPh_3 in the presence of Me_3NO. A similar reaction of $[Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-}dppm)]$ (**4**) with PPh_3 afforded (**3**), $[Ru_3(CO)_6(\mu_3\text{-}S)_2(PPh_3)(\mu\text{-}dppm)]$ (**5**) together with the previously reported compound $[(\mu\text{-}H)_2Ru_3(CO)_7(\mu_3\text{-}S)(\mu\text{-}dppm)]$ (**6**). In contrast, a similar treatment of the sulfur-selenium compound $[Ru_3(CO)_7(\mu_3\text{-}S)(\mu_3\text{-}Se)(\mu\text{-}dppm)]$ (**7**) with PPh_3 afforded only $[Ru_3(CO)_6(\mu_3\text{-}S)(\mu_3\text{-}Se)(PPh_3)(\mu\text{-}dppm)]$ (**8**). Both compounds **5** and **8** exist as two isomers in solution, arising from the reversible migration of a metal–metal bond, induced by the dppm ligand. The reaction of **6** with PPh_3 under the same conditions gave $[(\mu\text{-}H)_2Ru_3(CO)_6(\mu_3\text{-}S)(PPh_3)(\mu\text{-}dppm)]$ (**9**). Protonation of **4** and **7** by trifluoroacetic acid gave the mono-protonated species $[(\mu\text{-}H)Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-}dppm)]^+$ (**10**) and $[(\mu\text{-}H)Ru_3(CO)_7(\mu_3\text{-}Se)(\mu_3\text{-}S)(\mu\text{-}dppm)]^+$ (**11**), respectively, isolated as their PF_6 salts. All the compounds have been characterized by spectroscopic data together with single crystal X-ray diffraction studies for **3** and **5**.

1. Introduction

Transition metal carbonyl clusters containing sulfido ligands have received considerable attention due to their application in cluster aggregation reactions and in generating new coordination modes and geometries [1–3]. Sulfido ligands are valuable agents for the synthesis and stabilization of metal cluster complexes [4]. Several synthetic routes are available for the preparation of sulfido or selenido transition-metal clusters, among these, those that involve the oxidative addition of $Ph_3P{=}E$ (E = S or Se) to zero-valent metal centers appear to be the most effective [5]. This method, takes advantage of the frailty of the $Ph_3P{=}E$ bond and has been successfully used by the Tiripicchio group to synthesize tertiary phosphine substituted iron and ruthenium clusters containing capping chalcogenido ligands [6,7]. This method is effective in producing monophosphine as well as diphosphine-substituted sulfido and selenido clusters, but the monophosphine derivatives of iron and ruthenium clusters containing capping sulfido ligands are

doi:10.1016/j.poly.2005.02.006

generally large in numbers in compare to the diphosphine derivatives [2,6]. Recently, we became interested in the synthesis of capping chalcogenido trimetallic clusters from the oxidative addition reactions of dppm=E or PPh_3=E (E = S or Se) with osmium and ruthenium carbonyl clusters [2,8,9]. We have very recently reported the synthesis of the capping sulfido triruthenium clusters $[Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-dppm})]$, $[(\mu\text{-}H)_2Ru_3(CO)_7(\mu_3\text{-}S)(\mu\text{-dppm})]$, $[Ru_3(CO)_7(\mu_3\text{-}CO)(\mu_3\text{-}S)(\mu\text{-dppm})]$ and $[Ru_3(CO)_6(\mu_3\text{-}CO)(\mu_3\text{-}S)\{\eta^1\text{-}C(NMe_2)_2\}(\mu\text{-dppm})]$ from the reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with tetramethylthiourea [10]. The reaction of the corresponding osmium analog $[Os_3(CO)_{10}(\mu\text{-dppm})]$ with tetramethylthiou rea afforded the capping sulfido cluster $[Os_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-dppm})]$ [11]. Furthermore, we have also reported [8] that the reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with dppmS provides a number of sulfido complexes $[Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-dppm})]$, $[Ru_3(CO)_7(\mu_3\text{-}CO)(\mu_3\text{-}S)(\mu\text{-dppm})]$, $[Ru_3(CO)_5(\mu_3\text{-}CO)(\mu_3\text{-}S)(\mu\text{-dppm})]$ and $[Ru_3(CO)_6(\mu_3\text{-}CO)(\mu_3\text{-}S)(\mu\text{-dppm})(\eta^1\text{-}Ph_2PCH_2P(=O)Ph_2)]$. As a continuation of our previous work, we have now investigated the reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (**1**) with Ph_3P=S. We have also investigated the reactions of $[Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-dppm})]$ (**4**), $[Ru_3(CO)_7(\mu_3\text{-}S)(\mu_3\text{-}Se)(\mu\text{-dppm})]$ (**7**) and some related compounds with PPh_3 in the presence of Me_3NO and the results are described in the present paper.

2. Experimental

All the reactions were performed under a nitrogen atmosphere using standard Schlenk techniques. Solvents were dried and distilled prior to use by standard methods (CH_2Cl_2 over CaH_2 and THF from sodium benzophenone). The starting clusters $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (**1**) [12], $[Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-dppm})]$ (**4**) [10] and $[Ru_3(CO)_7(\mu_3\text{-}S)(\mu_3\text{-}Se)(\mu\text{-dppm})]$ (**7**) [10] were prepared according to the known procedures. Infrared spectra were recorded on a Shimadzu FT-IR 8101 spectrophotometer. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker DPX 400 spectrometer. Mass spectra were recorded on a Varian Mat 312 mass spectrometer.

2.1. Reaction of 1 with PPh_3S

A THF solution (30 mL) of **1** (0.100 g, 0.103 mmol) and PPh_3S (0.033 g, 0.112 mmol) was stirred at room temperature for 1.5 h. The solvent was removed under reduced pressure and the residue was chromatographed by TLC on silica gel. Elution with cyclohexane/CH_2Cl_2 (3:2, v/v) developed three bands. The first band was too small for complete characterization. The second band gave the known compound $[Ru_3(CO)_7(\mu_3\text{-}CO)(\mu_3\text{-}S)(\mu\text{-dppm})]$ (**2**) (0.028 g, 29%) while the third band gave $[Ru_3(CO)_6(\mu_3\text{-}CO)(\mu_3\text{-}S)(PPh_3)(\mu\text{-dppm})]$ (**3**) (0.026 g, 24%) as orange crystals from hexane/CH_2Cl_2 at −4 °C. *Anal.* Calc. for $C_{50}H_{37}O_7P_3Ru_3S$: C, 50.97; H, 3.17. Found: C, 51.25; H, 3.33%. IR (νCO, CH_2Cl_2): 2029sh, 2008vs, 1992s, 1960s cm^{-1}; IR(νCO, KBr): 1744w cm^{-1}; ^1H NMR (CD_2Cl_2): δ 7.34 (m, 35H), 3.92 (m, 1H), 3.49 (m, 1H); $^{31}P\{^1H\}$ NMR(CD_2Cl_2): δ 50.4 (s, 1P), 28.3 (s, 2P); Mass spectrum: *m/z* 1177 (M^+).

2.2. Reaction of 4 with PPh_3

A methanolic solution (1 mL) of Me_3NO (0.010 g, 0.112 mmol) was added dropwise to a dichloromethane solution (35 mL) of **4** (0.100 g, 0.105 mmol) and triphenylphosphine (0.035 g, 0.120 mmol) over about 10 min. The resulting reaction mixture was stirred at room temperature for 45 min. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with cyclohexane/CH_2Cl_2(7:3, v/v) developed four bands. The first band afforded $[(\mu\text{-}H)_2Ru_3(CO)_7(\mu_3\text{-}S)(\mu\text{-dppm})]$ (**6**) (0.007 g, 8%) while the second band was unreacted **4** (0.005 g). The third band yielded $[Ru_3(CO)_6(\mu_3\text{-}S)_2(PPh_3)(\mu\text{-dppm})]$ (**5**) (0.033 g, 35%) as red crystals from heptane/CH_2Cl_2 at −4 °C. *Anal.* Calc. for $C_{49}H_{37}O_6P_3Ru_3S_2$: C, 49.78; H, 3.16. Found: C, 49.98; H, 3.35%. IR (νCO, CH_2Cl_2): 2019s, 2000vs, 1964m, 1944m cm^{-1}; ^1H NMR (CD_2Cl_2): δ 7.33 (m, 35H), 4.10 (m, 1H), 3.94 (m, 1H), 3.07 (t, 2H, J = 11.8 Hz); $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 69.7 (s, 2P), 56.4 (s, 1P), 47.3 (s, 1P), 26.4 (d, 1P, J = 29.0 Hz), 16.8 (d, 1P, J = 29.0 Hz); Mass spectrum: *m/z* 1181 (M^+). The fourth band gave **3** (0.010 g, 11%) as orange crystals from heptane/CH_2Cl_2 at −4 °C.

2.3. Reaction of 7 with PPh_3

A similar reaction of **7** (0.030 g, 0.032 mmol) with PPh_3 (0.010 g, 0.120 mmol) in the presence of Me_3NO (0.006 g, 0.067 mmol) at room temperature afforded $[Ru_3(CO)_6(\mu_3\text{-}S)(\mu_3\text{-}Se)(PPh_3)(\mu\text{-dppm})]$ (**8**) (0.018 g, 55%) as red crystals from hexane/CH_2Cl_2 at −4 °C. *Anal.* Calc. for $C_{49}H_{37}O_6P_3Ru_3SSe$: C, 49.64; H, 3.12. Found: C, 50.12; H, 3.27%. IR (νCO, CH_2Cl_2): 2019s, 1998vs, 1964s, 1944m cm^{-1}; ^1H NMR (CD_2Cl_2): δ 7.38 (m, 35H), 4.20 (m, 1H), 3.98 (m, 1H), 3.19 (t, 2H, J = 10.8 Hz); $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 59.7 (s, 2P), 54.5 (s, 1P), 48.0 (s, 1P), 22.9 (d, 1P, J = 25.8 Hz), 13.5 (d, 1P, J = 25.8 Hz); Mass spectrum: *m/z* 1228 (M^+).

2.4. Reaction of 6 with PPh_3

A similar reaction of **6** (0.030 g, 0.032 mmol) with PPh_3 (0.010 g, 0.120 mmol) and Me_3NO (0.005 g, 0.056 mmol) followed by similar chromatographic separation gave $[(\mu\text{-}H)_2Ru_3(CO)_6(\mu_3\text{-}S)(PPh_3)(\mu\text{-dppm})]$ (**9**) (0.018 g, 55%) as orange crystals from hexane/CH_2Cl_2 at −4 °C. *Anal.* Calc. for $C_{49}H_{39}O_6P_3Ru_3S$: C, 51.08;

H, 3.41. Found: C, 51.62; H, 3.52%. IR (νCO, CH_2Cl_2): 2047vs, 1991s, 1973s cm^{-1}; ^1H NMR (CD_2Cl_2): δ 7.25 (m, 35H), 3.90 (m, 1H), 3.66 (m, 1H), −18.08 (dt, 1H, J = 12.8, 39.2 Hz), −18.85 (dd, 1H, J = 12.0, 30.0 Hz); $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 38.1 (s, 1P), 25.0 (d, 1P, J = 45.5 Hz), 24.3 (d, 1P J = 45.5 Hz); Mass spectrum: m/z 1151 (M^+).

2.5. Reaction of **2** with PPh_3

A similar reaction to that above of **2** (0.040 g, 0.042 mmol), PPh_3 (0.015 g, 0.057 mmol) and Me_3NO (0.007 g, 0.078 mmol) followed by a similar chromatographic separation gave **3** (0.017 g, 40%).

2.6. Protonation of **4**

An excess of CF_3COOH (one drop from a Pasteur pipette) was added to a CD_2Cl_2 solution (0.5 mL) of **4** (0.025 g, 0.011 mmol) in an NMR tube. After recording ^1H and $^{31}P\{^1H\}$ NMR spectra, the volatiles were removed under vacuum, and the residue was dissolved in methanol (5 mL). Addition of a methanolic solution of ammonium hexafluorophosphate (0.022 g) followed by a few drops of water gave a yellow precipitate which was recrystallized from CH_2Cl_2/Et_2O to give [(μ-H)-$Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-dppm})$][$PF_6$] (**10**) (0.016 g, 64%) as yellow crystals. IR (νCO, CH_2Cl_2): 2105s, 2054vs, 2014vs, 1985m cm^{-1}; ^1H NMR (CD_2Cl_2): δ 7.35 (m, 20H), 3.85 (t, 2H, J = 10.0 Hz), −10.25 (dd, J = 8.0, J = 18.4 Hz); $^{31}P\{^1H\}$ NMR (CD_2Cl_2): δ 68.2 (d, 1P, J = 87.0 Hz), 41.8 (d, 1P, J = 87.0 Hz).

2.7. Protonation of **7**

A similar protonation of **7** followed by similar work-up gave [$Ru_3(CO)_7(\mu_3\text{-}S)(\mu_3\text{-}Se)(\mu\text{-dppm})$][$PF_6$] **(11)**. IR ($\nu$CO, CH_2Cl_2): 2106s, 2052vs, 2014vs, 1985m cm^{-1}; ^1H NMR ($CDCl_3$): δ 7.39 (m, 20H), 3.91 (m, 2H), −10.17 (dd, J = 8 Hz, J = 18.4 Hz); $^{31}P\{^1H\}$ NMR ($CDCl_3$): 67.9 (t, J = 24.9 Hz), 41.2 (t, J = 19.9 Hz).

2.8. X-ray crystallography

Crystals of **3** and **5** suitable for X-ray diffraction studies were grown by an interlayer diffusion technique from CH_2Cl_2/heptane at −4 °C. Crystallographic data were collected using a FAST area detector diffractometer

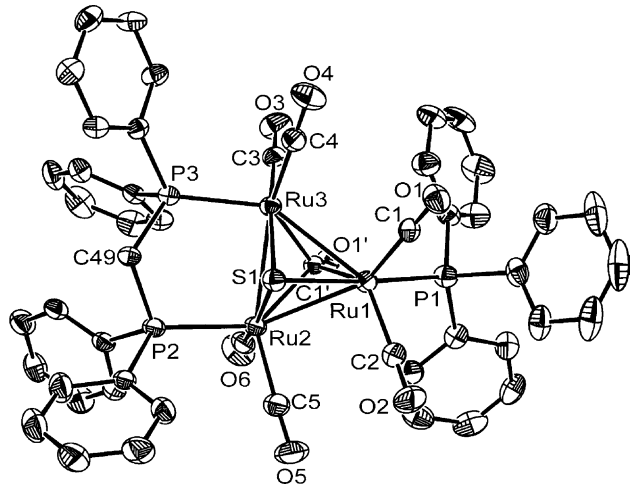
Details in common: X-ray radiation, Mo Kα (λ = 0.71073 Å), temperature (K) 150(2), refinement method: full-matrix least-squares on F^2.

and Mo Kα radiation ($\lambda = 0.71073$ Å) by following a previously described procedure [13]. The unit cell parameters were determined by the least-square refinement of the diffractometer angles for 250 reflections and the data were corrected for absorption using DIFABS [14]. The structures were solved by direct methods (SHELXS-97) [15] and refined on F^2 by full-matrix least-squares (SHELXL-97) [16] using all unique data. All non-hydrogen atoms were anisotropic. The hydrogen atoms were included in calculated positions (riding model). The crystal data and refinement details are summarized in Table 1.

3. Results and discussion

The reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (**1**) with $PPh_3{=}S$ at ambient temperature gave the previously reported compound $[Ru_3(CO)_7(\mu_3\text{-CO})(\mu_3\text{-S})(\mu\text{-dppm})]$ (**2**) and the new compound $[Ru_3(CO)_6(\mu_3\text{-CO})(\mu_3\text{-S})(PPh_3)(\mu\text{-dppm})]$ (**3**) in 29% and 24% yields, respectively (Scheme 1). Compound **3** can also be prepared in 40% yield by the room temperature reaction of **2** with PPh_3 in the presence of Me_3NO. We have recently synthesized **2** from the reaction between **1** and tetramethylthiourea, and it has been characterized by a solid-state structure determination [10]. Compound **3** has been characterized by a combination of spectroscopic data and single crystal X-ray diffraction studies.

The molecular structure of **3** is depicted in Fig. 1, crystal data are collected in Table 1 and selected bond distances and angles are given in Table 2. This molecule has a well-known bicapped triangular structure, composed of three ruthenium atoms, one triply bridging sulfido, one triply bridging carbonyl ligand, a bridging dppm, a PPh_3 and six terminal carbonyl groups. The three Ru–Ru bond distances {Ru(1)–Ru(3) = 2.8008(5), Ru(1)–Ru(2) = 2.8318(5) and Ru(2)–Ru(3) = 2.8206(5) Å} are almost equal in magnitude. The three acute angles [Ru(1)–Ru(3)–Ru(2) = 60.496(14), Ru(2)–Ru(1)–Ru(3) = 60.098(14), and Ru(1)–Ru(2)–Ru(3) = 59.405(13)°] are also almost equal thus providing an equilateral triangle, which is nearly symmetrically capped by the sulfur atom {Ru(1)–S(1) = 2.3585(12), Ru(3)–S(1) = 2.3826(12) and Ru(2)–S(1) = 2.3686(11) Å}, but asymmetrically capped by the carbonyl group with three different Ru–C distances {Ru(2)–C(1) = 2.163(4), Ru(1)–C(1) = 2.201(4) and Ru(3)–C(1) = 2.151(4) Å}. It has also a mirror



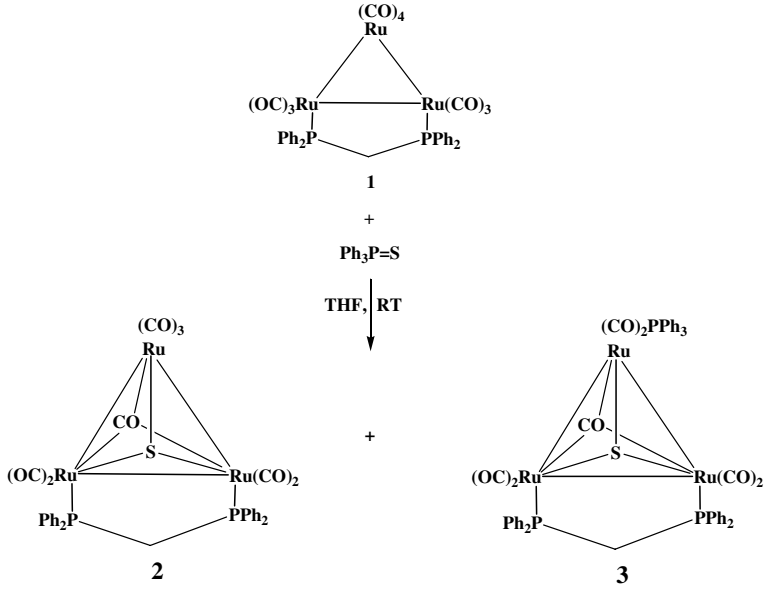


Fig. 1. ORTEP drawing of $[Ru_3(CO)_6(\mu_3\text{-CO})(\mu_3\text{-S})(PPh_3)(\mu\text{-dppm})]$ (**3**). Thermal ellipsoids are drawn at the 50% probability level.

plane passing through the Ru(1) atom and bisecting the Ru(2)–Ru(3) bond and the methylene carbon, C(49), of the dppm ligand. Each of the Ru atoms is ligated by the two terminal carbonyl groups. The PPh_3 ligand is coordinated to the Ru(1) atom in an axial position and lies on the mirror plane. The structure of **3** may be deduced from **2** [10] by the replacement of one axially positioned CO by a PPh_3 ligand. The Ru(1)–P(1) bond distance of 2.3530(13) Å, involving the terminal PPh_3 ligand, is comparable to those found in $[Ru_4(CO)_{12}(\mu\text{-}CO)(\mu_4\text{-}Se)_2(PPh_3)_2]$ {average 2.351(4) Å} [17]. The Ru–P bond distances involving the bridging dppm ligand {Ru(2)–P(2) = 2.3491(13) and Ru(3)–P(3) = 2.3054(13) Å} are comparable to the corresponding distances in **1** {2.322(2) and 2.334(2) Å} [12] and **2** {2.334(2) and 2.366(2) Å} [10]. The dppm ligand is coplanar with three Ru atoms. The compound contains 48 valence electrons, as expected for an electron precise trinuclear cluster containing three metal–metal bonds and each metal atom can achieve an 18-electron configuration.

The spectroscopic data of **3** are in accord with the solid-state structure. The mass spectrum shows the molecular ion peak at *m*/*z* 1177 and ion multiplets corresponding to the successive loss of six carbonyl groups. In addition to the *ν*(CO) stretching vibration bands due to the terminal carbonyl ligands between 2029s and 1960m cm^{-1}, the infrared spectrum of **3** exhibits a low energy absorption band at 1744 cm^{-1} due to the triply bridging carbonyl ligand. The $^{31}P\{^1H\}$ NMR spectrum exhibited two singlets at δ 50.4 and 28.3 with a relative intensity of 1:2. The singlet at δ 28.3 is due to the equivalent phosphorus atoms of the dppm ligand and that at δ 50.4 is assigned to the PPh_3 ligand. In addition to the usual resonances for the phenyl protons of dppm and PPh_3 ligands, the ^1H NMR spectrum shows two multiplets at δ 3.92 and 3.49 for the two diastereotopic methylene protons of the dppm ligand.

The reaction of $[Ru_3(CO)_7(\mu_3\text{-}S)_2(\mu\text{-}dppm)]$ (**4**) with PPh_3 in the presence of Me_3NO at room temperature gave **3** and $[Ru_3(CO)_6(\mu_3\text{-}S)_2(PPh_3)(\mu\text{-}dppm)]$ (**5**) in addition to the known compound $[(\mu\text{-}H)_2Ru_3(CO)_7(\mu_3\text{-}S)(\mu\text{-}dppm)]$ (**6**) in 11%, 35% and 8% yields, respectively (Scheme 2). A similar reaction of $[Ru_3(CO)_7(\mu_3\text{-}S)(\mu_3\text{-}Se)(\mu\text{-}dppm)]$ (**7**) with PPh_3 afforded only $[Ru_3(CO)_6(\mu_3\text{-}S)(\mu_3\text{-}Se)(PPh_3)(\mu\text{-}dppm)]$ (**8**). The dihydrido compound **6** is supposed to be formed by the displacement of a triply bridging sulfido ligand in **4** by two bridging hydride ligands. We have previously

Scheme 2.

reported **6** as a by product derived from the reaction of **1** with tetramethylthiourea [10]. Compounds **5** and **8** have been characterized by a combination of elemental analysis, infrared, ^{1}H NMR, $^{31}P\{^{1}H\}$ NMR and mass spectroscopic data together with single crystal X-ray diffraction studies for **5**.

The crystal of **5** contains two crystallographically independent molecules in its asymmetric unit. Both molecules are structurally similar, and an ORTEP diagram of the molecular structure of one of these molecules is shown in Fig. 2. The crystal data are given in Table 1 and the selected bond distances and angles are collected in Table 3. The molecule consists of an open cluster of three ruthenium atoms with two metal–metal bonds {Ru(1)–Ru(2) = 2.8106(6), Ru(1)–Ru(3) = 2.8280(5) Å} and a non-bonded separation of 3.569(5) Å, along the Ru(2)–Ru(3) edges, six terminal carbonyl ligands, a triphenylphosphine, two triply bridging sulfido ligands and a bridging dppm ligand. Both the metal–metal bonds are nearly equal in magnitude and the average value {2.8196 (5) Å} is comparable to the average Ru–Ru bond distances in $[Ru_3(CO)_7(\mu_3\text{-}Se)_2(\mu\text{-}dppe)]$ {2.806(2) Å} [18]. The dppm ligand spans the non-bonded metal–metal edge through the two phosphorus atoms occupying axial sites of the two basal metal atoms. The Ru–P distances involving the dppm ligand {Ru(2)–P(2) = 2.3031(13) and Ru(3)–P(3) = 2.2889(13) (Å)} are slightly shorter than those found in **1** [12]. The two P atoms of the dppm ligand are essentially coplanar with the three Ru atoms and the methylene carbon atom (C49) is seen to lie on the off-plane. The P(2)–C(49)–P(3) angle of 120.7(3)° is significantly larger than the theoretical one (113°) [6a], an indication of the strain for the dppm molecule. Each of Ru(1), Ru(2) and Ru(3) are ligated by the two equatorially bound carbonyl ligands. The PPh_3 ligand is axially coordinated to the apical Ru(1) atom. The Ru–S distances to the central seven-coordinate ruthenium atom Ru(1), {Ru(1)–S(1) = 2.3931(12) and Ru(1)–S(2) = 2.4131(13) Å} are slightly longer than those found to the external six-coordinate ruthenium atoms {2.3596(12)–2.4024(13) Å}. The structure is similar to that of **4** with the exception of the presence of a PPh_3 ligand coordinated to the apical Ru(1) and it occupies an axial site. The Ru(1)–P(1) bond distance of 2.3262(13) Å involving the terminal PPh_3 ligand is comparable to that found in **3**. The PPh_3 ligand is lying in the mirror plane of the molecule passing through the Ru(1), S(1), S(2) and C(49) atoms. The Ru–P bond distances involving the bridging dppm ligand {Ru(2)–P(2) = 2.3031(13) and Ru(3)–P(3) = 2.2889(13) Å} are comparable to the corresponding distances in **1** [12], **2** [10] and **3**. As usual, the triply bridging sulfido ligand acts as a four-electron donor and the dppm donates four electrons to the cluster which results in a total of 50 valence electrons and the observation of two formal Ru–Ru bonds present

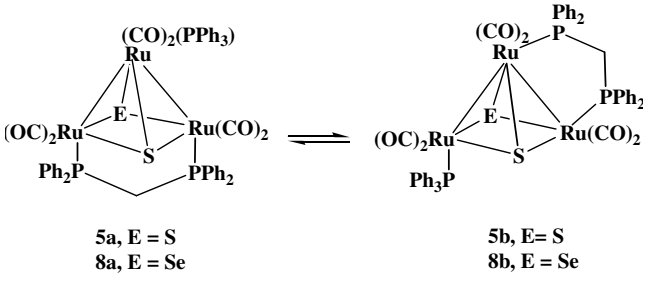
in the trinuclear framework is consistent with the electron count.

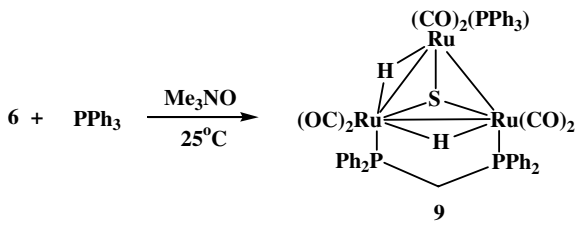


The infrared spectra of **5** and **8** are very similar indicating that they are structurally similar. The ^{1}H and $^{31}P\{^{1}H\}$ NMR data of both **5** and **8** indicate that they exist as a mixture of two isomers in solution. In addition to the usual phenyl resonances in the aromatic region, the aliphatic region of the ^{1}H NMR spectra contains two multiplets and a triplet. For **5**, the multiplets at δ 4.10 and 3.94 are due to the methylene protons of the minor isomer **5b** while the triplet at δ 3.07 is due to the major isomer **5a**. Similarly for **8,** the multiplets at δ 4.20 and 3.98 are due to the methylene protons of the minor isomer **8b** and the triplet at 3.19 is assigned to the major isomer **8a**. Consistent with this, the $^{31}P\{^{1}H\}$ NMR spectrum of each of **5** and **8** exhibits three singlets and two doublets. For **5**, the singlets at δ 69.7 and 47.3 are due to the ^{31}P nuclei of the dppm and triphenylphosphine ligands, respectively, of the major isomer **5a** whereas the doublets at δ 26.4 and 16.8 (J = 29.0 Hz) are due to the ^{31}P nuclei of the dppm and the singlet at δ 56.4 is due to PPh_3 ligand of the minor isomer **5b**. Similarly for **8**, the doublets at δ 22.9 and 13.5 (J = 25.8 Hz) and the singlet at δ 48.0 have been assigned to the ^{31}P nuclei of the minor isomer **8b** whereas the singlets at δ 59.7 and 54.5 are due to the major isomer **8a**. The $^{31}P\{^{1}H\}$ NMR spectrum thus indicates that the phosphorus nuclei of dppm ligand are equivalent in the major isomer, but they are non-equivalent in the minor isomer. In the major isomer, the dppm ligand bridges the two non-bonded ruthenium atoms whereas in the minor isomer, it spans one of the metal–metal edges. The short-bite dppm ligand pushes the basal Ru atoms to approach in such a way that a fluxional motion takes place in solution consisting of the reversible migration of a metal–metal bond from a side of the open triangle to the basal plane as shown in Scheme 3. This fluxional behavior of **5** and **8** is similar to that exhibited by $[Ru_3(CO)_7(\mu_3\text{-}Se)_2(\mu\text{-dppm})]$ in which the reversible migration of a Ru–Ru bond from a side of the open triangle to the basal plane induced by the dppm ligand has been reported [6b]. Thus compound **8** is structurally similar to **5**, but it contains a triply bridging Se atom in place of one of the triply bridging S atoms.

Treatment of **6** with PPh_3 in the presence of Me_3NO at room temperature afforded the PPh_3 substituted compound $[(\mu\text{-H})_2Ru_3(CO)_6(\mu_3\text{-S})(PPh_3)(\mu\text{-dppm})]$ (**9**) (Scheme 4) in 55% yield. Unfortunately, we were unable to grow crystals for X-ray quality of **9,** therefore, the characterization is made on the spectroscopic data.

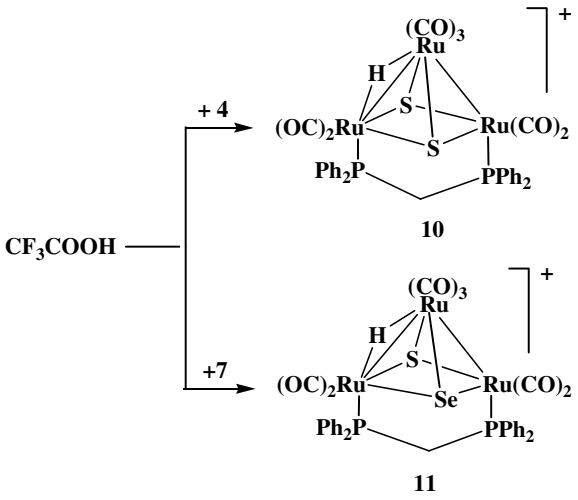
The IR spectrum of **9** indicates that all the carbonyl groups are of a terminal type. In addition to the usual phenyl resonances, the ^{1}H NMR spectrum in the aliphatic region exhibits two multiplets at δ 3.90 and 3.66 due to methylene protons of the dppm ligand. The hydride region of the ^{1}H NMR spectrum contains a doublet of triplets at δ −18.08 (J = 12.8, J = 32.0 Hz) and a doublet of doublets at δ −18.85 (J = 12.0, J = 39.2 Hz), indicating the presence of two bridging hydride ligands. The $^{31}P\{^{1}H\}$ NMR spectrum shows three equal intensity signals, two doublets at δ 25.0 and 24.3 due to the nonequivalent ^{31}P nuclei of the dppm ligand and a singlet at δ 38.1 due to the PPh_3 ligand. The FAB mass spectrum shows the molecular ion peak at m/z 1151, consistent with the formulation of $[(\mu\text{-H})_2Ru_3(CO)_6(\mu_3\text{-S})(PPh_3)(\mu\text{-dppm})]$, and fragmentation peaks due to the sequential loss of six carbonyl ligands. Thus the spectroscopic data of **9** are quite consistent with a structure where the PPh_3 ligand is coordinated to the rear ruthenium atom and one hydride ligand bridges the same Ru–Ru edge as the dppm and the other hydride bridges one of the remaining Ru–Ru edges as seen in the precursor **6**. It is interesting to note that compound **6** is dynamic at room temperature owing to the edge hopping of the hydride ligands [19], but the displacement of a CO by a PPh_3 suppresses such a dynamic behavior in **9**.

In order to compare the protonation of **4** and **7** with that of **1** we have reacted these compounds with CF_3COOH. As expected treatment of **4** and **7** with an excess of trifluoroacetic acid afforded the cationic hydrido derivatives $[(\mu\text{-H})Ru_3(CO)_7(\mu_3\text{-S})_2(\mu\text{-dppm})]^+$ (**10**) and $[(\mu\text{-H})Ru_3(CO)_7(\mu_3\text{-Se})(\mu_3\text{-S})(\mu\text{-dppm})]^+$ (**11**), respectively (Scheme 5), isolated as their PF_6 salts.



Unfortunately, suitable single crystals could not be grown for any of the protonated species for X-ray analysis. So, their characterization was done on the basis of spectroscopic data. The ν(CO) stretching frequencies of **10** and **11** are shifted to higher wave numbers than those

5a, E = S
8a, E = Se



5b, E= S
8b, E = Se

Scheme 3.

9

Scheme 4.

Scheme 5.

of their respective parent compounds. This increase in CO stretching frequencies for the protonated species is due to the decrease in electron density at the metal centers. The π back donation to π* CO orbitals is decreased, which in turn, increases the CO bond order and, concomitantly, the CO stretching frequencies [20]. The ^{1}H NMR spectra of the protonated species in the hydride region contain a doublet of doublets {δ −10.25 (J = 8.0, J = 18.4 Hz) for **10** and −10.25 (J = 8.0 Hz, J = 18.4 Hz) for **11**} in agreement with the assumption that the hydride is bridging one of the bonded ruthenium–ruthenium edges not bridged by the dppm ligand. The $^{31}P\{^{1}H\}$ NMR spectra of **10** and **11** exhibit two doublets {δ 67.9 and 41.2 (J = 19.92 Hz) for **10**; δ 68.2 and 41.8 (J = 87.0 Hz) for **11**} indicating that the ^{31}P nuclei of the dppm ligand are non-equivalent.

4. Conclusions

We have found that the reaction of **1** with PPh_3=S at ambient temperature afforded the known compound **2** and the new compound **3** (Scheme 1). The reaction of **4** with PPh_3 in the presence of Me_3NO at ambient temperature furnished two new compounds **3** and **5**, in addition to the previously reported compound **6** (Scheme 2). In contrast, a similar reaction of **7** with PPh_3 afforded exclusively **8**. The X-ray crystallographic analysis unambiguously reveals that **3** contain a Ru_3S core with a triply bridging carbonyl ligand on one face of the ruthenium triangle and the triply bridging sulfido ligand on the opposite face. On the other hand, **5** is a bi-capped "open" cluster having the basic Ru_3S_2 skeleton to which the dppm ligand bridges the open Ru–Ru edge. The PPh_3 ligand in both complexes **3** and **5** occupies the axial position of the apical ruthenium atom. Both compounds **5** and **8** exist as two isomers in solution arising from the reversible migration of a metal–metal bond induced by the dppm ligand.

Abstract

The syntheses, characterisations, photophysical properties and their applications in organic light emitting devices of a series of 2-phenylbenzothiazolato (bt)/substituted 2-phenylbenzothiazolato (X-bt) platinum(II) based square-planar complexes [(X-bt)Pt(acac); acac = acetylacetonate; X = unsubstituted (**1**), F (**2**), OMe (**3**) and CF_3 (**4**)] are discussed. Reaction of K_2PtCl_4 with btH/X-btH in glacial acetic acid for a few days results in the dinuclear chloro-bridged Pt(II) complex, (bt/X-bt)Pt(μ-Cl)Pt(bt/X-bt) which is cleaved with acetylacetone to give the corresponding mononuclear (bt/X-bt)Pt(acac) complex. The (MeO-bt)Pt(acac) complex has been characterized by X-ray single crystal structure analysis. The packing diagram shows the Pt–Pt distances and the intermolecular spacings are 3.369 and 3.360 Å, respectively, which is consistent with excimer formation. It has also been supported by time-resolved photoluminescence (PL) measurements. The nature of the lowest emitting states are the triplet MLCT as well as triplet π–π* states and it has been tuned according to the electronic properties of the substituents. The electroluminescent (EL) devices were fabricated by doping platinum complexes **1** and **2** (the corresponding devices denoted as D-1 and D-2, respectively) into the host CBP (4,4′-(*N*,*N*′-dicarbazole)biphenyl), in the emitting zone with a doping content of 5%, 7% and 9%. The EL performances for these devices are exceptionally high (14.3 and 16.0 cd A^{-1} @2 mA cm^{-2} and luminances 10 550 and 11 320 cd m^{-2} @100 mA cm^{-2} for D-1 and D-2, respectively).

1. Introduction

The development of organometallic based optoelectronics, such as light-emitting devices, chemosensors and photovoltaic dye-sensitized devices [1] is one of the exciting applications of transition metal complexes. Extensive work on cyclometallating or oligopyridine complexes of Ru(II) [2], Os(II) [3], Re(I) [4] and Ir(III) [5] have been studied for their long triplet excited-state lifetimes, high emission quantum yields and tunable emission wavelengths in the above mentioned areas. Recently, significant research has been focused on the syntheses of cyclometallated complexes of iridium(III) and particularly in light emitting diodes [5]. Platinum(II) complexes have also been used as luminescent centres in organic light-emitting diodes (OLEDs) [6]. Only few of the reported platinum(II) complexes are emissive at room temperature in solution. Pt(II) species chelated with aromatic ligands, such as bipyridine, phenanthroline, 2-phenylpyridine or similar derivatives, emit in solution from excited states localized on the aromatic systems. These Pt(II) complexes benefit from having relatively high metal-centred (MC) states when compared to their palladium analogues [7]. If the emitting states (MLCT or intraligand) and MC states lie too close in energy, they can thermally equilibrate, thereby quenching

doi:10.1016/j.poly.2005.02.009

the emission through fast radiationless decay through the MC states [8]. Moreover, the open coordination centres of the square planar platinum(II) complex can allow for other deactivating pathways to occur through metal interactions with the environment [9]. These facts are responsible for not so encouraging photoluminescence (PL) and electroluminescence (EL) performances of platinum based complexes. Recently, Che et al. reported new orange-yellow emitting schiff-base complexes of platinum(II) [10] showing modest results. The present work reports the syntheses and characterization of some strong orange-emitting cyclometallated platinum(II) complexes, (bt)Pt(acac) (**1**)/(X-bt)Pt(acac) (X = F (**2**), OMe (**3**), CF_3 (**4**); bt = 2-phenylbenzothiazolato; acac = acetylacetonate), study of their photophysical properties, X-ray single crystal structure analysis of (MeO-bt)Pt-(acac) and their applications in OLEDs.

2. Experimental

2.1. Materials

Potassium tetrachloroplatinate(II) was purchased from Alfa Aesar, USA, 2,4-pentanedione from Lanscaster, 2-ethoxyethanol and glacial acetic acid from Tedia Company, Ins. and the rest of the chemicals and solvents (AR grade) from Tokyo Kasei Kogyo Co. Ltd., Japan, and they were used as received.

2.2. Instrumentation

The ultraviolet–visible (UV–Vis) spectra of the phosphorescent Ir(III) complexes were measured on an UV–Vis spectrophotometer (Agilent model 8453) and corrected for background due to solvent absorption. Photoluminescence (PL) spectra were carried out with a spectrofluorometer (Jobin-Yvon Spex, model Fluorolog-3). The photo-physical measurements of these complexes have been carried out in aerated dichloromethane. NMR spectra were recorded on a Varian 300 MHz. MS spectrometer (EI and FAB) were taken by micromass TRIO–2000. Elemental analyses have been carried out by using a Heraeus CHN-O-RAPID analyzer. TG–DTA analysis was carried out by using a thermal analyzer (SEIKO 1TG/DTA 200). Emission lifetimes were obtained by exponential fitting of emission decay curves recorded on a Continuum NY61 spectrofluorometer.

2.3. Crystallography

Single crystal diffraction data for Pt(MeO-bt)(acac) were collected on a Bruker Smart-CCD diffractometer equipped with a normal focus, 3kW sealed-tube X-ray source (λ = 0.71073 Å). The intensity data were collected in the ω scan mode (width of 0.3/° frame) and corrected for *Lp* and absorption effects using the SAINT [11] program. Cell refinement and data reduction were carried out using the program Bruker SHELXTL [12]. The structure was solved by direct methods using the SHELXTL [12] version 5.1 software packages. The structure was further refined by full-matrix least-squares methods based on F^2 using SHELXTL version 5.1 [12]. Non-hydrogen atom positions were refined anisotropically, whereas the hydrogen positions were not refined.

2.4. Syntheses

bt/X-bt (X = –F, –OMe, $–CF_3$): The detailed synthetic procedure of these ligands has been described in the literature [13].

(bt/X-bt)Pt(μ-Cl)$_2$Pt(bt/X-bt) [14]: The ligands (2 mmol) were added to a suspension of potassium tetrachloroplatinate (1 mmol) in glacial acetic acid (300 ml) and the reaction mixture was stirred for several days (3–5 days) whilst maintaining the temperature at ~80 °C, which resulted in a yellow coloured product that was distinctly discernable from the red platinum(II) salt. The product was isolated through filtration and washed with water, acetone and ether 5–6 times to remove almost all the excess starting materials.

(bt)Pt(μ-Cl)$_2$Pt(bt). Yield: 45%. *Anal*. Calc. for $C_{26}H_{16}N_2Cl_2S_2Pt_2$: C, 35.4; H, 1.8; N, 3.2. Found: C, 35.2; H, 1.8; N, 3.1%.

(F-bt)Pt(μ-Cl)$_2$Pt(F-bt). Yield: 48%. *Anal*. Calc. for $C_{26}H_{14}N_2F_2Cl_2S_2Pt_2$: C, 34.0; H, 1.5; N, 3.1. Found: C, 33.7; H, 1.7; N, 3.1%.

(MeO-bt)Pt(μ-Cl)$_2$Pt(MeO-bt). Yield: 50%. ^{1}H NMR (300 MHz, $CDCl_3$): 9.92 (d, 1H, J = 8.7 Hz), 9.93 (d, 1H, J = 7.5 Hz), 8.40 (d, 2H, J = 8.6 Hz), 7.92 (d, 1H, J = 6.3 Hz), 7.78 (d, 1H, J = 6.7 Hz), 7.52 (m, 2H), 7.35 (m, 2H), 6.96 (d, 2H, J = 8.2 Hz), 6.53 (d, 1H, J = 7.2 Hz), 5.56 (s, 1H), 3.81 (s, 3H), 3.51 (s, 3H). *Anal*. Calc. for $C_{28}H_{20}N_2O_2Cl_2S_2Pt_2$: C, 35.4; H, 1.8; N, 3.2. Found: C, 35.2; H, 1.8; N, 3.1%.

(bt/X-bt)Pt(acac) [15]: The dinuclear complexes (1 mmol) were dissociated into the mononuclear platinum(II) complexes by reacting with acetylacetone (2.5 mmol) in the presence of sodium carbonate (8 mmol) and 2-ethoxyethanol (10 ml) as solvent under refluxing conditions for 12 h. These complexes show better solubility in common organic solvents with respect to their corresponding dinuclear complexes. These complexes were recrystallised from a mixture of dichloromethane and methanol (1:1).

2.5. OLED fabrication and testing

Organic layers were fabricated by high-vacuum thermal evaporation onto a glass substrate precoated with an indium–tin-oxide (ITO) layer with a sheet resistance of 20 Ω. Prior to use, the ITO surface was ultrasonicated in a detergent solution followed by rinsing with deionized (DI) water, dipped into acetone, trichloroethylene and 2-propanol, and then degreased with a vapor of 2-propanol. After degreasing, the substrate was oxidized and cleaned in a UV-ozone chamber before it was loaded into an evaporator. In a vacuum chamber at a pressure of 10^{-6} torr, 500 Å of NPB (*N*,*N*′-di-1-napthyl-*N*,*N*′-diphenylbenzidine) as the hole transporting layer; 200 Å the complex doped (7%) CBP as the emitting layer; 100 Å of BCP (2,9-dimethyl-4,7-diphenyl-1,10-phenanthroline) as a hole and exciton blocking layer (HBL); 650 Å of Alq_3 (*tris*(8-quinolinato)aluminium) as electron transport layer; and a cathode composed of 10 Å lithium fluoride and 2000 Å aluminum were sequentially deposited onto the substrate to give the device structure. Fig. 1(a) and (b) show the multilayer structure of the device and the chemical structures of the molecules used in fabricating the EL device, respectively. The current–voltage (*I–V*) profiles and light intensity characteristics for the above-fabricated devices were measured in a vacuum chamber of 10^{-6} torr at ambient temperature using a Keithley 2400 Source Meter/2000 Multimeter coupled to a PR 650 Optical Meter.

3. Results and discussion

3.1. Syntheses and characterizations

The synthetic routes for the platinum(II) complexes described here involves two steps. In the first step, K_2PtCl_4 is reacted with an excess of bt/substituted bt to produce a chloride-bridged dinuclear complex (Fig. 2, inset), i.e. (bt/X-bt)Pt(μ-Cl)$_2$Pt(bt/X-bt). All these complexes, except (MeO-bt)Pt(μ-Cl)$_2$Pt(MeO-bt), are almost insoluble in common organic solvents which makes them impossible for solution phase characterization. The polar methoxy substituent is assumed to be responsible for making the corresponding dinuclear platinum(II) complex have a better solubility in more or less polar organic solvents. The ^{1}H NMR spectrum

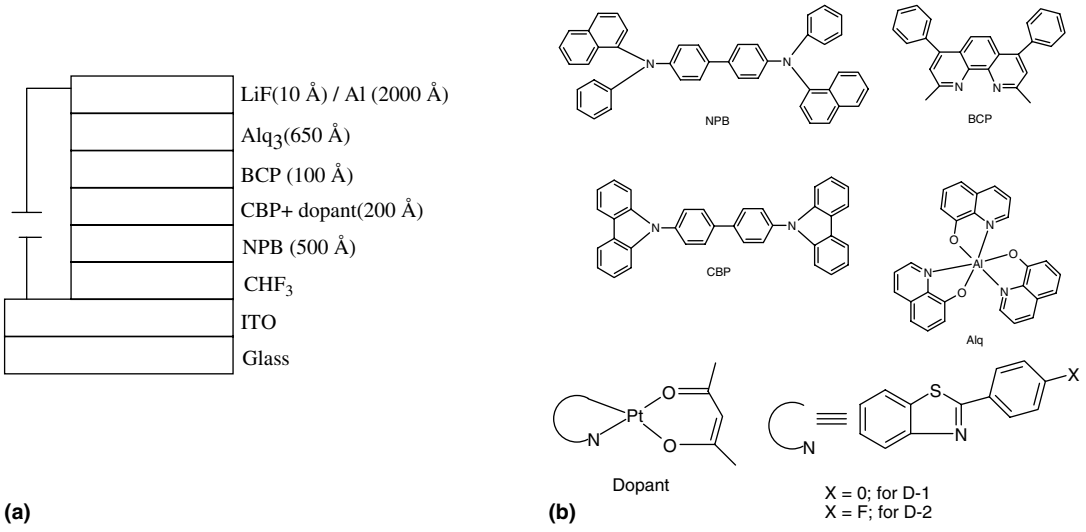

Fig. 1. (a) Multilayer device structure. (b) The chemical structures of the molecules used in this device.

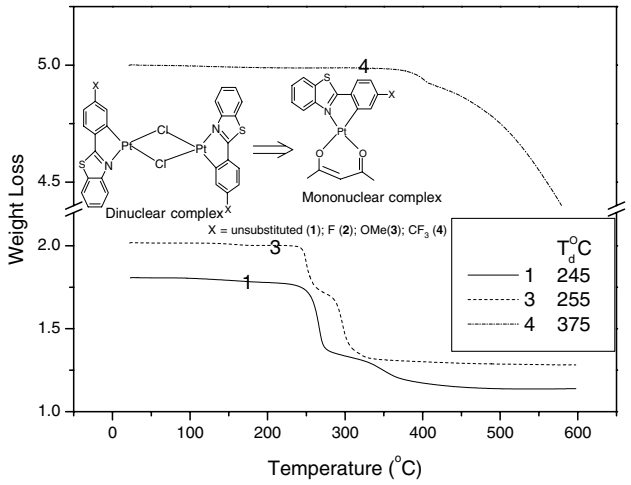

Fig. 2. TGA thermograms of the platinum(II) complexes **1**, **3** and **4**, T_d represents decomposition temperature (inset: the chemical structures of the complexes investigated).

of (MeO-bt)Pt(μ-Cl)$_2$Pt(MeO-bt) (deposited) shows the splitting of the methyl proton in the methoxy substituent of the dinuclear complex, suggesting that the two non-equivalent methoxy protons exist in the two separate ligands of that complex. It is the result from different interactions with the solvent molecules. The chloride-bridged dinuclear complexes can be readily dissociated to emissive, mononuclear complexes by replacing the bridging chlorides with monoanionic 2,4-pentanedionate (Fig. 2, inset). These mononuclear complexes were characterised by ^{1}H NMR spectra and elemental analyses, but ^{13}C NMR spectra were not recorded due to not having the required level of solubility in deuterated solvents. Thermogravitometric analysis (TGA) shows the stability of these complexes in the range of 245–375 °C (Fig. 2) and they can be easily sublimed at low pressure (10^{-3} mmHg).

3.2. Crystal structures

X-ray single crystal structure analysis was carried out for one of the platinum complexes **3**, which authenticates the square planar geometry (discrepancy factor ~5%; Fig. 3(a)). X-ray quality single crystals of the complex were grown by slow diffusion of methanol into a dichloromethane solution of **3**. The bond length of Pt1–N1 (2.02 Å) is slightly larger compared to that of common Pt–N bonds, as this N is opposite to the acetylacetonate oxygen atom, having a weak *trans* influence. The bond length of Pt1–O2 (2.085 Å) is higher compared to that of Pt1–O1 (1.994 Å), as O2 is *trans* to carbon which has a strong *trans*-influence. The bond length of Pt1–C9 (1.967 Å) is consistent with other reported cyclometallated complexes [6d,16]. The Pt(1)–O(1) (1.994 Å) and Pt(1)–O(2) (2.085 Å) bond lengths are also consistent with other reported cyclometallated–diketonato derivatives [17]. The C(9)–Pt(1)–O(1), 90.65(16)°; C(9)–Pt(1)–N(1), 80.48(17)°; O(1)–Pt(1)–N(1), 171.11(15)°; C(9)–Pt(1)–O(2), 176.82(15)°; O(1)–Pt(1)–O(2), 91.23(13)°; N(1)–Pt(1)–O(2), 97.62(14)° bond angles are typical for cyclometallates and –diketonate derivatives of Pt [16,17]. There is very little distortion away from the square plane. The molecular packing diagram of Pt(MeObt)(acac) (Fig. 3(b)) shows the molecules pack as head-to-tail dimers; each molecule of the dimer is related to the other by a center of inversion. The short inter plane and metal–metal distances (Pt1···Pt1 = 3.369; Pt2···Pt2 = 3.369; Plane–Plane = 3.360 Å;

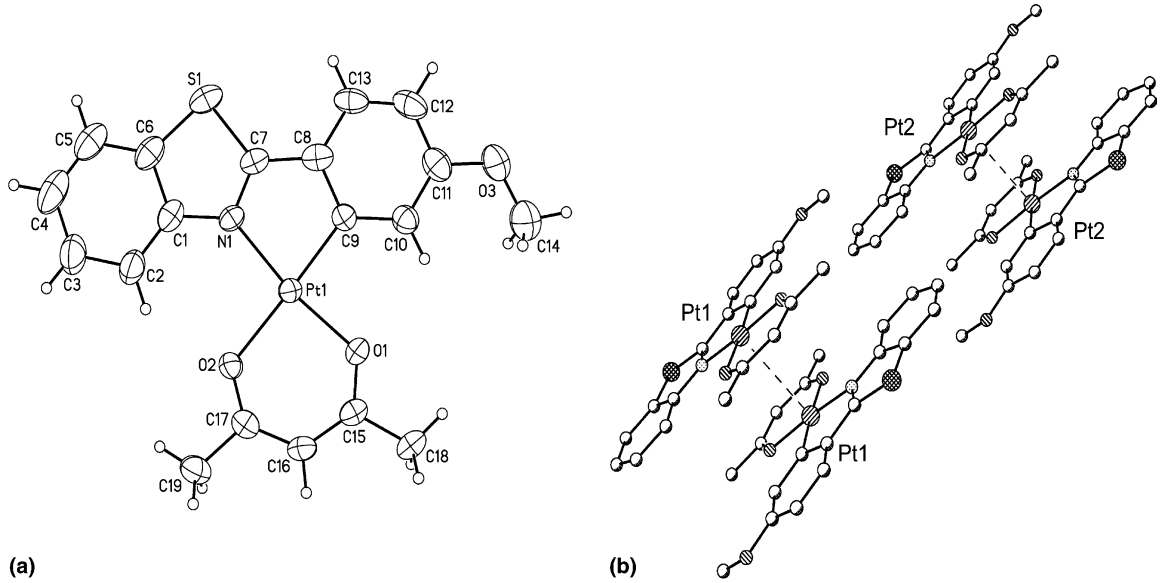

Fig. 3. (a) Molecular structure of complex **3** (shows 50% thermal probability); (b) molecular packing diagram showing the π stacking of complex **3**.

centre of symmetry is formed between the acac and the five membered ring) suggest that there exist extensive π–π and metal–metal interactions [6d] which support the excimer formation.

3.3. Photophysical behavior

The absorption spectra of all the complexes in dichloromethane were recorded at room temperature, and show intense higher energy transitions $^1\pi$–π^* (280–350 nm; $\varepsilon \sim 5 \times 10^3$ dm^3 mol^{-1} cm^{-1}) as well as comparatively lower energy, broad triplet state transitions (350–475 nm; $\varepsilon \sim 2 \times 10^3$ dm^3 mol^{-1} cm^{-1}), as shown in Fig. 4. These broad MLCT states exhibit solvatochromic effects. The complexes emit orange light in the solid state as well as in solution. Highly structured PL emission and sharp vibronic progressions of ~2185 cm^{-1} were observed (Fig. 5). These observations helped us to identify the nature of the lowest-emitting states of both triplet π–π* and MLCT character. In general, the electron-donating substituent raises the highest occupied molecular orbitals (HOMO) and the lowest unoccupied molecular orbitals (LUMO) and the reverse is truth for an electron-withdrawing substituent [18,19]. The complex **4** which contains electron-withdrawing substituted (–CF_3) benzothiazolate shows a bathochromic shifted emission, while those contain electron-releasing substituted (–F (**2**), –MeO (**3**)) benzothiazolates undergo *ipso*-chromic shifted emission with respect to the unsubstituted complex, **1**, as shown in Fig. 5. Hence it can be inferred that the position occupied by the substituents in (2-phenyl)-benzothiazolate of the iridium(III) complexes are dominated by LUMO character. The maximum absorbance and emission of all the complexes are listed in Table 1. The excimer formation was evidenced through the time resolved photoluminescence measurements [20]. The emission kinetic trace for one of the complexes **4** produced by excitation at 378 nm and monitored near the lower energy shoulder emission (e.g., 656 nm; Fig. 5) shows monoexponential decay behavior. The reciprocal of the lifetimes (known as emission decay rate constant, k_{obs}) obtained are shown in Fig. 6 as a function of concentration. The lifetime was found to decrease steadily with increasing concentration, indicative of excimer formation. The emission lifetime of the monomer of complex **4** at infinite dilution, τ_0 (0.58 μs), and the apparent rate constant of self-quenching, k_Q, were determined by using Eq. (1) (0.58 μs; 7×10^8 M^{-1} s^{-1}) from the linear variation of the observed emission decay constant, k_{obs}, as a function of the concentration of the complex, [Pt]. The high value of k_Q indicates extensive excimer formation. It should also be true for the other platinum(II) complexes.

3.4. Electroluminescence

All these complexes are thermally stable up to 245–375 °C and they can be easily sublimed at low pressure (10^{-3} mmHg) and emit tunable bright yellow-orange light at room temperature. All these features make them good emitters in highly efficient EL devices. The platinum complexes, **1** and **2** (the corresponding devices denoted as D-1 and D-2, respectively) were doped into the host material, CBP (4,4′-(*N*,*N*′-dicarbazole)biphenyl), in the emitting zone with doping contents of 5%, 7% and 9%. The observed device performances were found to vary marginally throughout the doping concentration range (Table 2). Current-density, voltage and luminance characteristics (*I*–*V*–*L*) for devices D-1 and D-2 with 5% doping level are shown in Fig. 7(a) and (b), respectively. Comparison of device performances for the devices D-1 and D-2 at 5% doping level are also summarized in Table 3, which show the maximum luminance yields of 14.3 and 16.0 cd A^{-1} @2 mA cm^{-2} for D-1 and D-2, respectively. The maximum emission wavelength (λ_{em}^{max}) for D-2 shows apparent *ipso*-chromic shift with respect to that of device D-1 (Fig. 8), as observed in PL emission spectra. The maximum emission wavelengths in the EL spectra are found to be independent of the applied voltage (for current density up to 100 mA cm^{-2}), but show bathochromically shifted emission with increasing doping concentration. The EL intensity of the shoulder peak

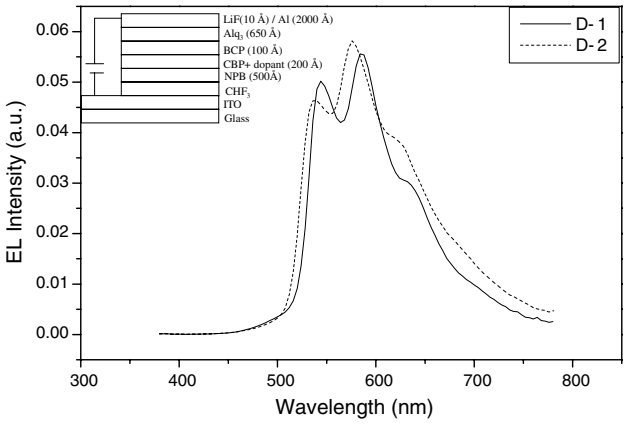

Fig. 8. EL spectra for the platinum(II) complexes **1** and **2** (inset: multilayer EL device configuration).

(~625–630 nm) has been observed to increase with increasing doping concentration, whereas that of the other two major peaks was found to decrease (~540 and ~584 nm). These observations support that the emission from the shoulder peak is generated from the excimer and it is also consistent with the results obtained from the molecular packing diagram (Fig. 3(b)) and concentration dependent luminescence decay measurements discussed before. It is to be noted that at 100 mA cm^{-2} current density, the luminances are found to be 10550 and 11320 cd m^{-2}, obtained for D-1 and D-2, respectively, and under similar conditions there have not been significant changes of luminance yields (i.e., 10.6 and 11.3 cd A^{-1}, for D-1 and D-2, respectively).

4. Conclusion

The syntheses and characterizations of a series of platinum(II) complex dopants have been performed. The EL performances of OLEDs employing these platinum(II) dopants are found to be substantially superior to those previously reported for OLEDs based on cyclometallated platinum(II) complexes [6]. These EL results were even far better than those previously reported [21] where a similar type of cyclometallated iridium(III) dopants were used in the same device structure. It should be mentioned that the device containing fluoro-substituted dopant shows relatively better EL performances with respect to that using the unsubstituted benzothiazolato Pt(II) complex.

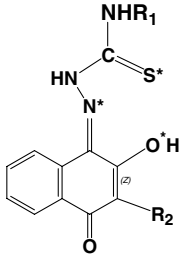
at 600 nm, an axially elongated electronic environment ($g_{\parallel} \gg g_{\perp} > 2.0$) appropriate for a $d_{x^2-y^2}$ ground state [5] and positive redox potentials of the Cu(II)/Cu(I) couple [6], ranging from +0.150 to +0.80 V. However, it has been suggested that copper(II)–thiolato/thionato complexes are usually unstable with respect to intramolecular redox reorganizations thus forming Cu(I), disulfide and other thiolato derived oxidation products [7]. The thermodynamics of these reactions could be disfavored if the reduction potential of the Cu(II)/Cu(I) couple is suppressed by (a) imposing the appropriate stereochemistry [8] that favors copper(II); (b) introducing multiple bond character at the sulfur donor site [9]; (c) use of bulky substituents on ligands [10] or (d) the sulfur center should be electronically constrained by the adjacent redox active part of the ligating systems [2].



One such attempt is explored in the present work by incorporating the redox active quinone/semiquinone redox couple [11] in close proximity of thione or thiol sulfur center which probably could control the electronic as well as electrochemical behavior of their copper(II) complexes. The tridentate ONS ligating system of thiosemicarbazones can provide a thione/thiolato sulfur center while the naphthoquinone segment may complement the other aspect of constraining this center necessary for the stability of Cu(II) species.

Thiosemicarbazones are unique amongst the sulfur family of ligating systems not only because they possess a wide range of biological properties [12] but also due to the fact that their complexes exhibit various structural, electronic as well as biological potentialities [13]. The coupled chromophore of quinone–thiosemicarbazones probably may increase the covalent character in copper–ligand bonding thus disfavoring thiol oxidation and may enhance the stability of copper(II)–thiolato/thionato complexes. This work is an extension of our recent efforts in understanding the structural, electrochemical and biological properties of transition metal thiosemicarbazones complexes [14]. The present communication describes the detailed EPR analysis and redox behavior of pseudo-square-planar copper(II)–quinone thiosemicarbazones complexes possessing either thione or thiol sulfur centers. The copper(II) complexes described herein have been synthesized using ligands as presented in Fig. 1.

2. Experimental

2.1. Materials

Copper chloride dihydrate, 2-hydroxy-1,4-naphthoquinone, thiosemicarbazide and N^4-methyl-thiosemicarbazide were purchased from Fluka A.G. and were used without further purification. Solvents were purified by the literature methods [15] prior to their use. Ligands are synthesized according to the procedures described earlier by Miller and co-workers [16].

2.2. Preparation of the ligands

2.2.1. Preparation of L_1–L_3

To a suspension of 0.01 mol of quinone (2-hydroxy-1,4-naphthoquinone; 3-methyl-2-hydroxy-1,4-naphthoquinone and 3-chloro-2-hydroxy-1,4-naphthoquinone) in water, 10 ml of 0.1 N NaOH was added so as to obtain a dark red solution. An aqueous-methanolic (50%) solution of thiosemicarbazide (0.01 mol) was then added dropwise to the above solution with constant stirring. The mixture was further stirred for about 3 h at the end of which the solution was neutralized with 10% HCl, until precipitation. The crude product was recrystallized from aqueous methanol and dried under vacuum over $CaCl_2$ yielding a reddish yellow crystalline product (L_1–L_3, respectively). The analyses (%) for the ligands are as follows:

L_1: Calc. for $C_{11}H_9N_3O_2S$: C, 53.48; H; 3.67; N; 16.99; S, 12.97. Observed: C, 53.81; H, 3.51; N, 17.38; S, 12.68. L_2: Calc. for $C_{12}H_{11}N_3O_2S$: C, 55.17; H, 4.21; N, 16.08; S, 12.32. Observed: C, 54.93; H, 4.07; N, 16.64; S, 12.68. L_3: Calc. for $C_{11}H_9N_3O_2SCl$: C,

46.90; H, 2.68; N, 14.91; S, 12.32. Observed: C, 46.17; H, 2.91; N, 15.47; S, 12.03. IR (KBr, cm^{-1}): 3410 ν(–OH); 3350, 3270 ν(–NH); 1620 ν(C=N); 1160, 820 ν(C=S).

2.2.2. Preparation of L_4

This was synthesized according to a similar procedure outlined earlier except instead of thiosemicarbazide, its N^4-methyl derivative was reacted with 2-hydroxy-1,4-naphthoquinone. L_4: Calc. for $C_{12}H_{11}N_3O_2S$: C, 55.17; H, 4.21; N, 16.08; S, 12.32. Observed: C, 55.02; H, 4.18; N, 16.83; S, 12.65.

IR (KBr, cm^{-1}): 3410 ν(–OH); 3370, 3280 ν(–NH); 1620 ν(C=N); 1160, 820 ν(C=S).

2.2.3. Preparation of L_5 and L_6

To a methanolic suspension of 2-hydroxy-1,4-naphthoquinone (0.01 mol), 10 mL of glacial acetic acid was added so as to adjust the pH to ca. 4.5 and the mixture was warmed to get a clear solution. An aqueous-methanolic (50%) solution of thiosemicarbazide or N^4-methyl thiosemicarbazide (0.01 mol) was then added dropwise to the above solution with constant stirring. The mixture was further stirred for about 3 h at the end of which a dark red colored solid started precipitating after 30 min. The crude product thus obtained was recrystallized from aqueous methanol and dried under vacuum over $CaCl_2$ yielding reddish yellow crystalline products (L_5 and L_6, respectively). The analyses (%) are as follows:

L_5: Calc. for $C_{11}H_9N_3O_2S$: C, 53.48; H, 3.67; N, 16.99; S, 12.97. Observed: C, 53.40; H, 3.24; N, 17.22; S, 12.60. L_6: Calc. for $C_{12}H_{11}N_3O_2S$: C, 55.17; H, 4.24; N, 16.08; S, 12.26. Observed: C, 54.79; H, 4.00; N, 16.48; S, 12.43.

IR (KBr, cm^{-1}): 3390, 3270 ν(–NH); 1680 ν (^{4}C=O); 1610 ν(^{1}C=O); 1162, 820 ν(C=S).

2.3. Preparation of copper(II)–thiosemicarbazone complexes

A general procedure adopted for the synthesis of the copper(II) complexes of L_1–L_6 was as follows:

Equimolar quantities (0.002 M) of the ligands (L_1–L_6) and copper(II) chloride dihydrate were dissolved in 20 mL of methanol separately and these solutions were degassed with N_2 for 5 min. The copper solution was added dropwise to ligand solution under N_2 atmosphere in a Schlenk assembly with constant stirring. After the complete addition of the copper solution, the pH of the reaction mixture was adjusted to 6–7 using alcoholic ammonia solution (6% v/v). The precipitated complexes were filtered, washed with acetone, recrystallized from methanol and dried under vacuum over $CaCl_2$. These complexes hereafter are referred as Cu_1–Cu_6, corresponding to ligands L_1–L_6.

2.4. Physical measurements

Elemental analyses were carried out using a Hosli-Holland C, H, and N analyzer. The magnetic susceptibility was measured at room temperature on a Faraday type magnetic balance with a permanent magnetic field of 7000 G and the instrument was calibrated with $Hg[Co(SCN)_4]$. The IR spectra were recorded on a Perkin–Elmer FTIR spectrometer using KBr discs while UV–Vis spectral measurements of DMSO solutions were made on a Shimadzu UV-300 spectrophotometer. The X-band ESR spectra at 298 and 77 K were recorded on a Varian ESR spectrometer with 100 kHz field modulation frequency and the instrument was calibrated with DPPH as the standard. Cyclic voltammetric experiments were performed on a BAS CV-27 assembly equipped with an X–Y recorder. Measurements were made on degassed 10 mM DMSO solutions of the complexes (N_2 bubbled for 15 min prior to measurements) containing 0.1 M tetraethyl ammonium perchlorate as a supporting electrolyte. The working system consisted of Pt-inlay (working), Pt-disc (auxiliary) and Ag/AgCl (reference) electrodes. The Ag/AgCl reference electrode was calibrated with the ferricinium/ferrocene redox couple, located at $E_{1/2}$ = +0.40 V (ΔE_p = 0.06 V).

3. Results and discussion

The interaction of L_1–L_6 with copper(II) chloride yields mono-ligand complexes with [CuLCl] composition (Table 1). All the complexes are non-electrolytic in nature indicating the coordination of the chloride ion to the metal center. The room temperature magnetic moments for these complexes (1.74–1.95 BM) correspond to the values normally observed for square-planar copper(II) compounds [17]. Slight deviation from the 'spin-only' value probably originates from mixing-in effects due to effective low symmetry.

3.1. Infrared spectra

The significant IR bands with their assignments of the copper(II) complexes in the region 4000–200 cm^{-1} are presented in Table 2. The IR spectra of L_1–L_4 exhibit an intermolecularly hydrogen bonded ν(–OH) vibration at ~3400 cm^{-1} [18], which disappears after complexation with the copper ions. It is further corroborated with the downfield shift of 50–80 cm^{-1} for ν(C–O) as well as an appearance of a band at 500 cm^{-1} due to a ν(Cu–O) stretch in the spectra of the copper complexes [19]. An azomethine nitrogen ν(C=N) band around 1620 cm^{-1} in the uncomplexed thiosemicarbazones undergoes a shift towards the lower energy side by ~40 cm^{-1} in the spectra of Cu_1–Cu_4. The bonding of the imine nitrogen as one of the coordinating sites is

further confirmed with the presence of a band in the range 435–480 cm^{-1} assigned to a ν(Cu–N) vibration for these complexes [14f]. The increase for the ν(N–N) frequency in the spectra of the complexes is probably due to enhanced double bond character through chelation, thus offsetting the loss of electron density via donation to the metal ion, and is supportive of azomethine nitrogen coordination. The thiocarbonyl absorption around 820 cm^{-1} is found to be shifted towards lower wavenumbers by ~40–60 cm^{-1} and is indicative of thionato sulfur coordination [20]. The ν(Cu–S) vibration in the range 340–365 cm^{-1} further corroborates the sulfur bonding.

Copper complexes of $\mathbf{L}_5$ and $\mathbf{L}_6$ exhibit different absorption characteristics as compared to complexes of $\mathbf{L}_1$–$\mathbf{L}_4$. The quinone carbonyl stretch is observed at two different frequencies. The free $\nu(^4C{=}O)$ band at 1650 cm^{-1} for the free ligands does not exhibit any change after complexation while the chelated carbonyl $\nu(^1C{=}O)$ absorption undergoes a substantial decrease by ~50 cm^{-1} in the spectra of Cu_5 and Cu_6 [18]. It implies that the ^{1}C-quinone carbonyl is one of the coordinating centers, which is further confirmed by a new band at 510 cm^{-1} due to ν(Cu–O) vibration. A downward shift of 50 cm^{-1} for the $\nu(C{-}N^1)$ spectral band of the thiosemicarbazide linkage along with a characteristic ν(Cu–N) stretch at 480 cm^{-1} is indicative of hydrazinic nitrogen coordination [21]. On the other hand, the $\nu(^2N{-}H)$ vibration from the same linkage disappears in the complexes, suggesting the deprotonation of the ^{2}N–H proton thus forming a thiolato sulfur center. It means that this center is involved in coordination as evidenced from the decrease in the frequency (by ~60 cm^{-1}) of the thioamide band, which is partly ν(C=S) and found at 820 cm^{-1} in the uncomplexed thiosemicarbazone ligands. In addition, a new band appears at 1590 cm^{-1} due to the formation of the —C=N chromophore as a consequence of thiol formation, along with the emergence of a ν(Cu–S) band at 370 cm^{-1}, thus corroborating the thiol formation [22].

Although ligands $\mathbf{L}_1$–$\mathbf{L}_6$ possess identical donor sets (ONS), there exists a slight difference in the type of donor atom bonded to the copper(II) ion. Thus, $\mathbf{L}_1$–$\mathbf{L}_4$ have imine nitrogen, phenolic oxygen and thione sulfur as potential bonding sites while $\mathbf{L}_5$ and $\mathbf{L}_6$ coordinates through hydrazinic nitrogen, quinone carbonyl and thiol sulfur (atoms marked as * in Fig. 1 represent the point of attachments for $\mathbf{L}_1$–$\mathbf{L}_6$).

All the complexes exhibit a sharp band at 340 cm^{-1} originating from a ν(Cu–Cl) vibration indicating the presence of chloride coordination thus completing the

square-planar geometry for the present series of complexes [23].

3.2. Electronic spectra

The significant absorption peaks for all the complexes in DMSO are depicted in Table 3. The ligands exhibit two broad signals in the region 39400 and 30240 cm^{-1}, presumably arising from $n \rightarrow \pi^*$ and $\pi \rightarrow \pi^*$ transitions [24] which remain unaffected in the spectra of Cu_1–Cu_4. However, for Cu_5 and Cu_6, the later absorption shows a slight shift (~5 nm) to the higher energy side indicating the enolization of the thiocarbonyl group. Such an effect is observed for thiosemicarbazone complexes containing thiolato binding [13].

The electronic spectra of the complexes in DMSO solution exhibit characteristic absorption curves corresponding to the square-planar geometry. For square-planar complexes with a $d_{x^2-y^2}$ ground state, three spin-allowed transitions are expected [25], viz., $^2B_{1g} \rightarrow {}^2A_{2g}$ ($d_{x^2-y^2} \rightarrow d_{z^2}$), $^2B_{1g} \rightarrow {}^2B_{2g}$ ($d_{x^2-y^2} \rightarrow d_{xy}$) and $^2B_{1g} \rightarrow {}^2E_g$ ($d_{x^2-y^2} \rightarrow d_{xz,yz}$). It is rather difficult to resolve these bands because they are very close in energy and individual transfers cannot be distinguished. In our case, the first transition appears as a shoulder ($\Delta_\parallel$) in the region 14000–16000 cm^{-1} (Table 3) while the broad absorption around 21000 cm^{-1} is assigned to the second ($\Delta_\perp$) transition. The third peak, however, may have been obscured by an intense LMCT charge transfer band, a characteristic feature usually found to be associated with metal–thiosemicarbazone complexes [13]. These bands are utilized for evaluating the covalency parameters from ESR studies.

3.3. ESR studies

All the magnetically non-diluted polycrystalline powdered complexes (Cu_1–Cu_6) exhibit asymmetrical EPR spectra from which the approximate $g_\parallel$ and $g_\perp$ values were determined. However, these spectra are not self-explanatory with regard to the hyperfine structure, which indicate the existence of a strong dipolar interaction between the central metal ion and the bound strong field ligands as a consequence of enhanced spin lattice relaxation. EPR spectra of DMSO solutions at 298 K (Fig. 2) exhibit four fairly resolved components originating from −3/2, −1/2, 1/2 and 3/2 transitions ($\Delta M_s = \pm 1$). The signal corresponding to $M_I = -3/2$ splits clearly into three peaks because of super-hyperfine structure (shf) due to an imine or hydrazinic nitrogen atom of the bound ligand molecules. The analysis of this hyperfine structure results in three components with a splitting of about 15 G and an intensity ratio very close to 1:2:1. From this spectrum, the isotropic spectrochemical splitting factor (g_0), isotropic hyperfine splitting constant ($^{Cu}A_0$) and isotropic ligand super-hyperfine constant ($^{N}A_0$) are calculated and those are subsequently used in the evaluation of other spectral parameters.

The effective spin-Hamiltonian describing the EPR spectra of copper(II) complexes in a tetragonal (D_{4h}) crystal field [26] can be written as:

$$H = \beta[g_\parallel H_z S_z + g_\perp (H_x S_x + H_y S_y)] + {}^{Cu}A_\parallel S_z I_z(\mathrm{Cu}) + {}^{Cu}A_\perp [S_x I_x(\mathrm{Cu}) + S_y I_y(\mathrm{Cu})] + [{}^{N}A_\parallel S_z I_z(\mathrm{N}) + {}^{N}A_\perp \{S_x I_x(\mathrm{N}) + S_y I_y(\mathrm{N})\}],$$

where the terms involved have their usual meanings.

The low temperature (77 K) DMSO frozen glass EPR spectra (Fig. 3) of these complexes display four line copper hyperfine lines, characteristic of monomeric copper(II) complexes with $g_\perp$ component having super-hyperfine interactions. Since the super-hyperfine structure is well resolved, it seems that the quinone–thiosemicarbazone ligating system (ONS) appears to be coplanar with the two chelate rings, thus corroborating the nearly planar geometry ($g_\parallel > g_\perp$). Kivelson and Nieman [27] have pointed out that compounds having $g_\parallel \geqslant 2.3$ are ionic in nature while those with $g < 2.3$ are covalent in character. The $g_\parallel$ values for the present series of complexes (Table 3) reveal the appreciable covalency with $d_{x^2-y^2}$ as the ground state.

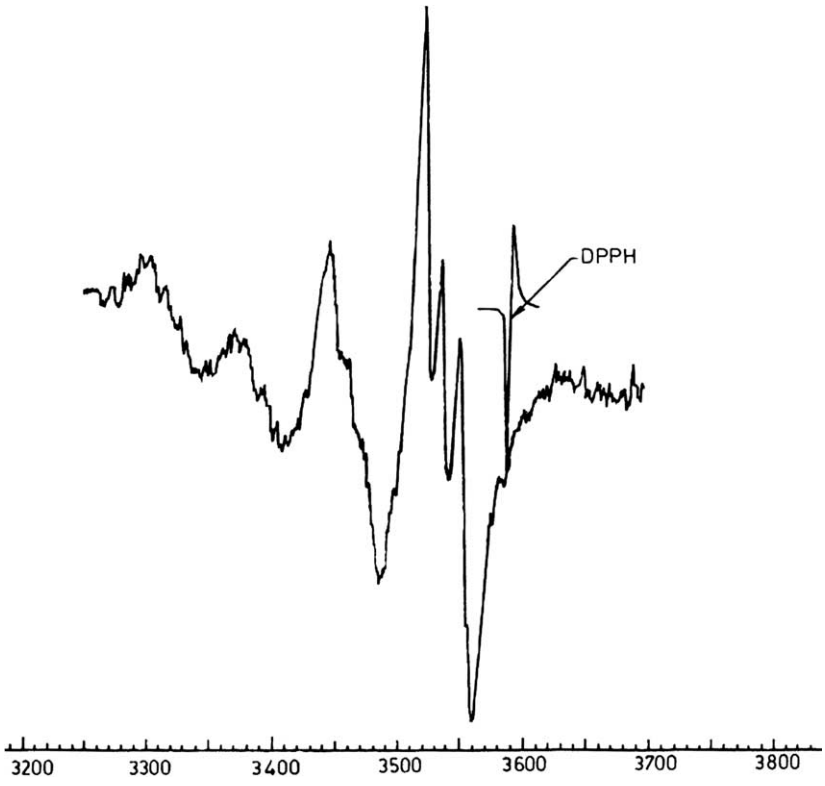

Fig. 2. EPR spectrum of Cu_2 in DMSO at 298 K.

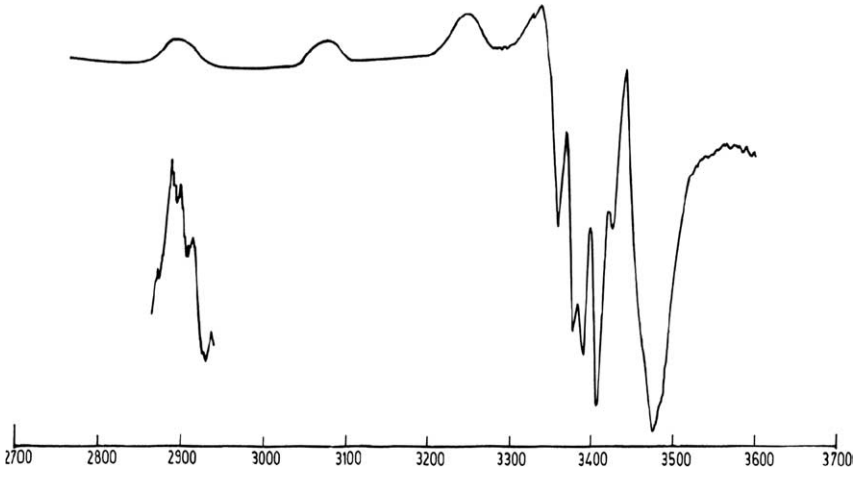

Fig. 3. EPR spectrum of Cu_2 in DMSO at 77 K.

Considering the pattern of the EPR spectra and the square-planar geometry from the electronic absorption spectra, it is quite logical to assume a tetragonal environment for the present series of copper(II) complexes. The unpaired spin is placed in an antibonding B_{1g} orbital. The ground state wave functions for this as well as for other antibonding orbitals in the LCAO-MO model are [26]:

$$\Psi A_{1g} = \gamma(d_z^2) - 1/2(1-\gamma'^2)^{1/2}[\sigma_x^{(1)} + \sigma_y^{(2)} - \sigma_x^{(3)} - \sigma_y^{(4)}],$$

$$\Psi B_{1g} = \alpha(d_{x^2-y^2}) - \alpha'\{[-\sigma_x^{(1)} + \sigma_y^{(2)} + \sigma_x^{(3)} - \sigma_y^{(4)}]/2\},$$

$$\Psi B_{2g} = \beta d_{xy} - \beta'\{[P_y^{(1)} + P_x^{(2)} - P_y^{(3)} - P_x^{(4)}]/2\},$$

$$\Psi E_{1g} = \gamma d_{xy} - \gamma'\{[P_z^{(1)} - P_z^{(3)}]/2^{1/2}\},$$

where α, α', β, β', γ and γ' represent in plane σ-bonding, in plane π-bonding and out of plane π-bonding

coefficients from metal and ligand orbitals, respectively. The ligand orbital involved in the in plane σ-bonding are considered to have sp^2 hybrid orbitals [29]. Overlap is included for the function describing in plane σ-bonding as $\alpha^2 - 2\alpha' S + \alpha'^2 = 1$, where $S = 0.093$ is the overlap integral between the copper $d_{x^2-y^2}$ orbital and the ligand orbital. These coefficients are evaluated from the following expressions [28] as:

$$g_{\parallel} - 2.0023 = (-8\lambda_0\alpha^2\beta^2/\Delta_{\parallel})[1 - (2\alpha'/\alpha)S - (\alpha'/2\alpha\beta)(1-\beta^2)^{1/2}\tau(n)],$$

$$g_{\perp} - 2.0023 = (-2\lambda_0\alpha^2\gamma^2/\Delta_{\perp})[1 - (2'/\alpha)\mathrm{S} - (\alpha'/2\alpha)(1-\gamma^2)^{1/2}\tau(n)],$$

$$^{\mathrm{Cu}}A_{\parallel} = P[\{-\alpha^2(4/7 + K_0) - 2\lambda\alpha^2\{(4\beta^2/\Delta_{\parallel}) + (3\gamma^2/7\Delta_{\perp})\},$$

$$^{\mathrm{Cu}}A_{\perp} = P[\alpha^2(2/7 - K_0) + 22/14(\lambda\alpha^2\gamma^2/\Delta_{\perp})],$$

$$^{\mathrm{N}}A_{\parallel} = (\alpha'^2/4)g_{\mathrm{N}}\beta_{\mathrm{N}}[(8\pi/9)|\Psi_0^2|_{2\mathrm{s}} + (8/15)\langle r^{-3}\rangle_{2\mathrm{p}}],$$

$$^{\mathrm{N}}A_{\perp} = (\alpha'^2/4)g_{\mathrm{N}}\beta_{\mathrm{N}}[(8\pi/9)|\Psi_0^2|_{2\mathrm{s}} - (8/15)\langle r^{-3}\rangle_{2\mathrm{p}}]\},$$

where λ_0 is the spin–orbit coupling constant for the copper(II) ion ($-828\ \mathrm{cm}^{-1}$), K_0 is the Fermi contact term (0.43), P is the free ion dipole term ($-0.036\ \mathrm{cm}^{-1}$), $\tau(n)$ is the integral over the ligand function (0.333), S is the overlap integral between $d_{x^2-y^2}$ and normalized nitrogen orbitals (0.093), $|\Psi_0^2|_{2\mathrm{s}}$ measures the 2s electron density at the ^{14}N nucleus ($32.4 \times 10^{24}\ \mathrm{cm}^{-3}$) and $\langle r^{-3}\rangle_{2\mathrm{p}}$ is the average value of r^{-3} for nitrogen 2p orbitals ($20.9 \times 10^{24}\ \mathrm{cm}^{-3}$).

For copper(II) complexes with a $^2B_{1g}$ ground state in D_{4h} symmetry ($g_{\parallel} > g_{\perp}$), the '$g$' values may be expressed [30] as:

$$K_{\parallel}^2 = (g_{\parallel} - 2.0023)\Delta_{\parallel}/8\lambda_0,$$

$$K_{\perp}^2 = (g_{\perp} - 2.0023)\Delta_{\perp}/2\lambda_0,$$

where $K_{\parallel}$ and $K_{\perp}$ are the parallel and perpendicular components of the orbital reduction factor (K). According to Hathaway [31], for pure σ-bonding $K_{\parallel} \approx K_{\perp} \approx 0.77$, for in plane π-bonding $K_{\parallel} < K_{\perp}$ whereas $K_{\parallel} > K_{\perp}$ implies strong out of plane π-bonding. The lower K values and $K_{\parallel} < K_{\perp}$ for copper(II)–thiosemicarbazones are indicative of covalent nature and strong in plane π-bonding. For these complexes, the G values are greater than or equal to 4 suggesting that there is negligible interaction between two copper(II) centers [32] as well as appreciable ligand field strength of quinone–thiosemicarbazones.

The in plane σ-covalency parameter (α^2) was calculated following the simplified equation suggested by Kivelson and Nieman [27] as:

$$\alpha^2 = -A_{\parallel}/ - 0.036 + (g_{\parallel} - 2.0023) + (3/7)(g_{\perp} - 2.0023) + 0.04.$$

The α^2 values (0.67–0.69) accounts for the fraction of the unpaired electron density located on the copper(II) ion (Table 4). These values are comparable to the one obtained for copper complexes of thiosemicarbazones [21,32–35] indicating the presence of appreciable covalency in the σ-bond. The other parameter α'^2 was obtained from the normalization condition of the B_{1g} orbital, $\alpha^2 - 2\alpha\alpha' S + \alpha'^2 = 1$. It represents the fraction of electron density donated from the nitrogen for σ-bond formation.

In-plane and out-of plane π-bonding parameters are evaluated from the following relations as:

$$\alpha^2\beta^2 = [(g_{\parallel} - 2.0023)\Delta_{\parallel}]/8\lambda_0,$$

$$\alpha^2\gamma^2 = [(g_{\perp} - 2.0023)\Delta_{\perp}]/2\lambda_0,$$

$$\beta^2 = 2\beta'^2 - 1,$$

$$\gamma^2 = 2\gamma'^2 - 1.$$

The β'^2 value (0.42–0.45) accounts for electron density on the ligand through the nitrogen atom, which indicates that the unpaired electron is largely delocalized along the quinone–thiosemicarbazone linkage. Such a pronounced feature may be attributed to the synergistic effect of the sulfur center having a vacant π-orbital as well as the charge accumulating property of the quinone moiety [11]. β'^2 values also approximately represent the % of electron delocalization on the nitrogen site and consequently reveal that it spends ≈42–44% of its time

Table 4
Simulated LCAO−MO coefficients and bonding parameters from EPR data for Cu_1–Cu_6

Parameter	Cu_1	Cu_2	Cu_3	Cu_4	Cu_5	Cu_6
G	4.1	4.2	3.9	4.2	4.1	4.0

γ^2	0.8178	0.8015	0.8246	0.8059	0.8163	0.8307
γ'^2	0.6428	0.6937	0.6216	0.6265	0.6406	0.6273

on quinone thiosemicarbazone ligands. Similarly, the other π-bonding parameter γ'^2, also significantly contribute for substantial delocalization of electron density within the sulfur-nitrogen-quinone ligating centers. Such a pronounced effect results in the formation of stable chelate rings of copper–thiosemicarbazone bonds, thus conferring nearly planar geometry around the copper center.

EPR parameters also reflect the degree of tetrahedral distortion of square-planar copper(II) complexes. From structurally well-characterized copper complexes of thiosemicarbazones [13], it has been observed that increase in $g_{\|}$ values with concomitant decrease in $^{Cu}A_{\|}$ components lead to an increase in the tetrahedral distortion. The degree of distortion $f(\alpha)$ $(=g_{\|}/A_{\|})$ is regarded as an index of deviation from idealized geometry. Values of 110–120 are typical for planar complexes, while the range of 130–150 is characteristic of slight to moderate distortion and 180–250 cm^{-1} indicate considerable distortion [36,37]. Values from 127 to 141 cm^{-1} for the present series of complexes suggest a small to moderately distorted geometry. Fig. 4 depicts the correlationship between $g_{\|}$, $A_{\|}$ and $f(\alpha)$ for Cu_1–Cu_6. Inspection of this diagram [38] suggests that the '$g_{\|}$' values linearly varies with $f(\alpha)$, as a consequence of the destabilization of the square planar geometry. Moreover, this tetrahedral distortion influences the copper hyperfine structure, suggesting that the unpaired electron is asymmetrically delocalized along the chelate rings. Thione sulfur binding for Cu_1–Cu_4 probably induces more structural deformations leading to substantial departure from the planar geometry. On the other hand, the thiol sulfur present in Cu_5 and Cu_6 enforces the structure to remain in a nearly square-planar geometry. Such a difference may originate from the fact that thiolato sulfur binding incorporates greater covalency in the metal–ligand bonding through delocalized dπ–pπ in-plane π–bonding as evidenced from the higher β'^2 values.

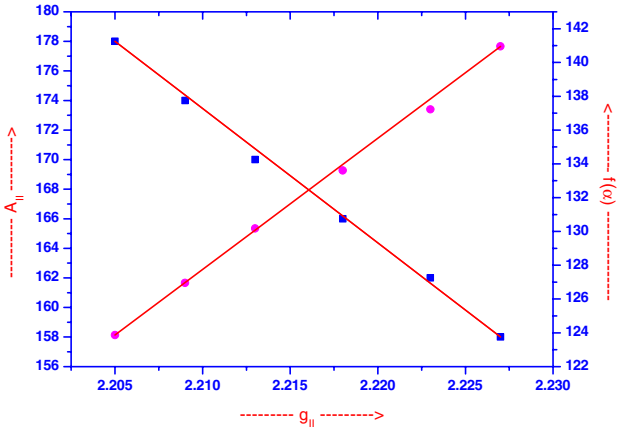

Fig. 4. Variation of $g_{\|}$ with $A_{\|}$ (■) and degree of tetrahedral distortion (●). The straight lines represents the best-fit curve.

4. Electrochemistry

The redox behavior of the copper(II) complexes have been investigated by cyclic voltammetry at a platinum electrode in the range from +1.0 to −2.0 V. In the positive range, the oxidation process Cu(II)/Cu(III) can be observed while scanning between 0 and −2.0 V is found to be associated with copper and quinone reduction steps.

Fig. 5 depicts the cyclic voltammetric response exhibited by Cu_2 in DMSO. In the scan between 0 and −2.0 V, the reduction process occurring at A is directly associated with reoxidation peak at E in the reverse scan, suggesting one electron redox change (Table 5) originating from the chemically reversible [Cu($\mathbf{L}_2$)Cl] → [Cu($\mathbf{L}_2$)Cl]$^-$ but electrochemically quasi-reversible Cu(II)/Cu(I) redox couple [39]. The other subsequent reduction peak B is ill shaped with its counterpart D at a more −ve potential ($E_c > -1.4$ V) and this possibly proceeds via two e^- transfer changes for quinone to catechol [11].

Analysis of the cyclic voltammetric response of peak A/E (Fig. 5) for these complexes indicates that the ratio of i_{pa}/i_{pc} is approximately equal to unity and the peak-to-peak separation (ΔE_p) is in the range of 0.70–0.110 V. In the absence of either uncompensated solution resistance or anomalous electrode surface effects, the marked departure of ΔE_p from 0.059 V can be qualitatively assumed as an index of occurrence of significant geometrical reorganizations accompanying the redox changes [40]. It is expected that the Cu(II)/Cu(I) couple experiences some structural reorganization

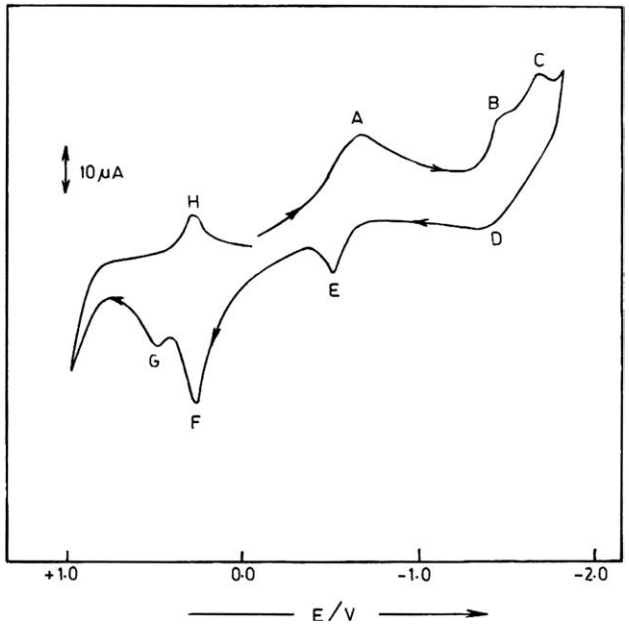

Fig. 5. Cyclic voltammetric response of Cu_2 in DMSO at a scan rate of 100 mV s^{-1}.

Table 5
Cyclic voltammetric data for Cu_1–Cu_6

Parameter	Cu_1	Cu_2	Cu_3	Cu_4	Cu_5	Cu_6
E_{pc} (V)	−0.56	−0.63	−0.59	−0.68	−0.475	−0.530

ΔE_p (V)	0.170	0.140	0.180	0.130	0.110	0.110
% i_{pc}/i_{pa}	83	88	87	88	87	87

barrier in view of the likely rearrangement from square planar Cu(II) to pseudo-tetrahedral Cu(I). However, cyclic voltammetric tests performed either on any copper(II) complex in the presence of a saturated DMSO solution of TEAP exhibited no variations in the diagnostic electrochemical features. It, therefore, could be originating from the chemical equilibrium between square-planar to tetrahedral (or pseudo-tetrahedral) geometries with concomitant departure from pure electrochemical reversibility for the Cu(II)/Cu(I) couple as measured by mean ΔE_p values of ~0.090 V at 0.01 V s^{-1} for the present series of complexes.

The often interrelated factors which raises the $E_{1/2}$ value of the Cu(II)/Cu(I) couple may be considered to be: (i) those which stabilize Cu(II) species by reducing its crystal field stabilization energy (CFSE) either by decreasing the ligand σ-donor ability or by constraining the geometry of the copper center favoring Cu(I) and (ii) the presence of π-acceptor ligands which favors the formation of Cu(I) species [41]. Patterson and Holm [42] have shown that softer ligands tend to favor more positive $E_{1/2}$ values while hard acids give rise to more negative values. As mentioned earlier, the effects of stereo-chemical changes on redox potentials are directly correlated to conversion of square-planar copper(II) species to tetrahedral Cu(I) products, the redox potentials observed for the present series of complexes indicate a moderate strength for quinone–thiosemicarbazones. It implies that greater deformation in the chelate rings of a coordinated thiosemicarbazone ligand induces substantial departure from square planar geometry with more difficulty in stabilizing the Cu(I) state, an observation in concurrence with the earlier speculation from EPR spectral studies. The influence of geometrical distortions on the redox properties can be asserted by the plot (Fig. 6) of $f(\alpha)$ versus $E_{1/2}$ wherein it is observed that the increase in tetrahedral distortion leads to more negative values of Cu(II)/Cu(I) reduction potentials [42]. The linear relationship observed for these complexes may originate from thione/thiol sulfur coordination, position of methyl substitution as well as charge accumulation tendency of the quinonoidal structure. As expected,

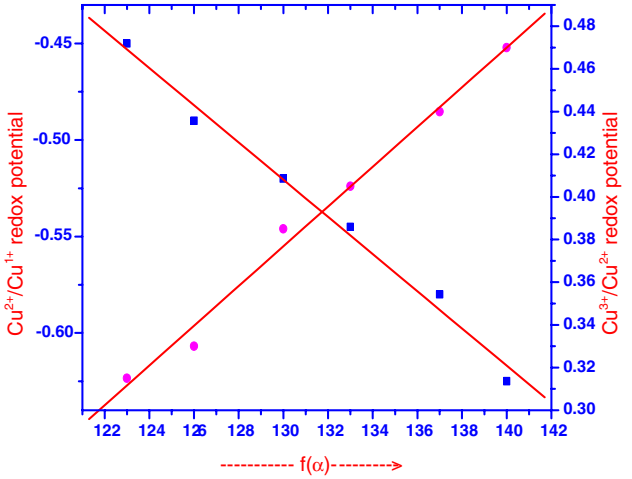

Fig. 6. Correlation of degree of tetrahedral distortion $f(\alpha)$ against Cu^{2+}/Cu^{1+} (■) and Cu^{3+}/Cu^{2+} (●) redox potentials. The straight lines represent the best-fit curve.

methyl substitution on the thiosemicarbazone side chain ($\mathbf{L_4}$) exerts more distortion in the structure of the Cu_4 complex. A similar correlation has also emerged from ESR studies. Finally, it should be mentioned here that the potentials of the Cu(II)/Cu(I) couple of the present series of complexes are notably more positive than those reported for thiosemicarbazone complexes [21,33,43]. Beyond any doubt, the negative shift is obviously due to the difference in the chemical environment and the chromophore around the Cu(II) ions. Nevertheless, it is likely attributable not only to inductive electronic factors but also because of columbic effects such as formation of charged or neutral sulfur donor sites.

The cyclic voltammetric behavior of Cu_1–Cu_6 between +1.0 and 0 V exhibit cathodic response (peak H) in the range 0.275–0.405 V with its counterpart (peak G) in the range 0.370–0.535 V. This feature corresponds to a quasi-reversible Cu(III)/Cu(II) redox process as indicated by ΔE_p values as well as non-equivalent current intensities of cathodic and anodic peaks (% i_{pc}/i_{pa}). The redox process associated with oxidation of Cu(II) to Cu(III) for all the complexes [43] may probably

originate due to the presence of a thione/thiol sulfur center and redox active quinone moiety. Since the quinone ring is planar and the thiosemicarbazide side chain is flexible, the ligand can adopt different conformations so as to fit the smaller sized Cu(III) ion, thus favoring the oxidation process. Moreover, this oxidation step results in the formation of a low-spin d^8 Cu(III) state with a preference for a square-planar geometry [44]. It is quite likely that this process does not proceed via a change in the geometry of the complex in DMSO solution. This fact is clearly reflected in Table 5, indicating that the Cu(III) state can be stabilized at relatively lower oxidation potential. Interestingly enough, the observed redox potentials for the present series are significantly lower than those reported earlier for thiosemicarbazone complexes [33,45,46], thus reflecting the influence of the electronic features of the redox active quinone moiety. The extent of electrochemical stability may be assessed from the correlation (Fig. 6) between the $E_{1/2}$ values for the Cu(III)/Cu(II) redox process with that of the degree of tetrahedral distortion $f(\alpha)$. Inspection of this figure indicates a linear relationship, revealing that departure from a square-planar structure of the complex leads to destabilization of the copper(III) species formed in the solution. Also, the type of bound sulfur center and quinone segment of the ligand seems to modulate the redox behavior of these complexes.

The other peaks (C and F) are related either to quinone redox forms or coupled chemical reactions at the electrode surface. Some of them loose intensity on repetitive and reverse scanning.

5. Conclusions

EPR spectral properties of the copper(II)–quinone thiosemicarbazones revealed appreciable covalency in the metal–ligand bonding, presumably arising out of copper(II)–thione/thiol coordination. The fraction of electron density (~42–45%) from the copper center is distributed over the entire chelate rings of the ligand molecules suggesting that there is extensive delocalization through in-plane π-bonding as well as σ-bonding interactions. Moreover, these complexes possess a significant amount of tetrahedral distortion as a consequence of deviation from square-planar to tetrahedral geometry leading to increased $g_{\|}$ values with a concomitant decrease in the $A_{\|}$ parameter. It implies that the planarity of the [CuONSCl] chromophore is disturbed due to the presence of the π-acceptor sulfur center along with the substituents on the ligands. Redox properties of these complexes indicate that the Cu(II)/Cu(I) redox couple is associated with structural reorganizations from square-planar to tetrahedral geometry. The linear relationship between degree of tetrahedral distortion and $E_{1/2}$ values suggest that the thiol complexes (Cu_5 and Cu_6) are electrochemically more versatile for electron transfer reactions as compared to the thione complexes (Cu_1–Cu_4). Such a difference stems from the fact that the thiolato complexes contain the redox active quinone form, which may be controlling the electronic structure of the complex through intramolecular reorganizations leading to enhanced thermodynamic stability. Moreover, Cu(III)/Cu(II) redox changes are also found to be present at fairly higher potentials for the thione complexes, implying that the thiol complexes are both structurally and electrochemically more stable. Thus, Cu_5 and Cu_6 complexes represent better structural mimics of blue copper proteins. The present study highlights that the spectroscopic parameters together with the redox behavior may be regarded as an index for constructing potentially feasible structural models of copper containing metallo-enzymes. Also, it is possible to modulate the copper–sulfur interactions by incorporating an appropriate ligating system which may modulate the electronic and stereochemical features that are necessary for stabilizing the copper(II) center.

2. Experimental

2.1. Materials

4-Methylphenol, 4-chlorophenol, *N*,*N*-diethylamino-1,3-propandiamine, morpholine, cyclohexylamine and DMF were obtained commercially and used without purification. Tetrabutylammoniumperchlorate (TBAP) was recrystallised from methanol (*Caution*: Although no problems were encountered, suitable care and precautions should be taken when handling the perchlorate salts, as these are potentially explosive). Analytical grade copper perchlorate, copper acetate, copper chloride and other reagents were used as such without further purification.

2.2. Physical measurements

Elemental analysis was carried out with a Heraeus-CHN-Rapid Analyzer. ^{1}H NMR spectra were recorded using a 90 MHz spectrometer, (model EM 390) and IR spectra were recorded on a Shimadzu IR-408 spectrometer using KBr discs. Electronic spectra were recorded on a Hitachi-320 spectrophotometer. The FAB mass spectra were recorded on a Jeol SX 102/DA-6000 Mass spectrometer. Variable temperature (77–300 K) magnetic susceptibility measurements were performed on the Princeton Applied Research Model-155 vibrating sample Magnetometer operating at 5000 G and calibrated with metallic nickel supplied with the instrument. The cyclic voltammograms were obtained in an apparatus comprising a PAR model-175 universal programmer, Model-173 Potentiostat/Galvanostat, Model-176 current follower and Model-179 coulomb/ampere hour meter (EG&G Ltd.) and Hitachi (057) Perkin–Elmer X–Y recorder. Platinum foils (1 cm^2) were used as the working electrode, as well as counter electrodes, and Ag/AgCl as the reference electrode. The ferrocenium/ferrocene (1+) couple was used as an internal standard. The potentials reported are relative to the Ag/AgCl electrode and $E_{1/2}$ of the ferrocenium/ferrocene (Fe^+/Fe) couple, which under the experimental conditions is 470 mV in DMF and ΔE_p for Fe^+/Fe is 70 mV. Electrochemical measurements were carried out under a N_2 atmosphere. TBAP was used as the supporting electrolyte (0.1 M) and all the complex solutions were around 10^{-3} M concentration.

2.3. Synthesis of the precursor compounds

2.3.1. N,N-Bis(2-hydroxy-5-methylbenzyl)-N′,N′-diethyl-1,3-propane diamine P.C.-1

N,*N*-Diethyl-1,3-propanediamine (6.5 g, 0.05 mol) was added with cooling to a solution prepared by dissolving paraformaldehyde (3 g, 0.1 mol) in methanol (60 ml) containing KOH (0.05 g). To this, 4-methylphenol (10.8 g, 0.1 mol) in methanol (60 ml) was added. The solution was then heated to reflux for 6 h and the solvent was removed under vacuo. The product obtained as yellow oil was recrystallised from cold methanol.

Yield: 12 g (65%). *Anal*. Calc. for $C_{23}H_{34}N_2O_2$: C, 74.55; H, 9.25; N, 7.56. Found: C, 74.51; H, 9.21; N, 7.60%. ^{1}H NMR ($CDCl_3$, δ ppm): 6.7–6.8 (m, aromatic CH), 3.65 (d, 4H, benzyl CH_2), 2.6–2.7 (m, 8H, NCH_2), 2.25 (s, 6H, aromatic CH_3), 1.8 (s, 2H, alkyl CH_2), 1.1 (m, 6H, alkyl CH_3). Selected IR data (KBr, υ cm^{-1}): 3400, 1470.

2.3.2. N,N-Bis(2-hydroxy-5-chlorobenzyl)-N′,N′-diethyl-1,3-propane diamine P.C.-2

Synthesis of this precursor compound, using 4-chlorophenol in the place of 4-methylphenol, was carried out following the same procedure as above. The yellow oil P.C.-2 was recrystallised from cold methanol.

Yield: 15 g (73%). *Anal*. Calc. for $C_{21}H_{28}O_2N_2Cl_2$: C, 61.31; H, 6.86; N, 6.81. Found: C, 61.30; H, 6.86; N, 6.83%. Selected IR data (KBr, υ cm^{-1}): 3350, 1470.

2.3.3. N,N-Bis(2-hydroxy-5-methylbenzyl)-cyclohexylamine P.C.-3

Cyclohexylamine (5 g, 0.05 mol) was added to a cold methanolic solution (60 ml) containing paraformaldehyde (3 g, 0.1 mol) and 0.025 g of KOH. To this solution, 4-methylphenol (10.8 g, 0.1 mol) in methanol (60 ml) was added. After gently refluxing the reaction mixture for 6 h, the solvent was removed by slow evaporation at room temperature. The white solid was washed with cold methanol, filtered and recrystallised from hot methanol.

Yield: 11.6 g (57%), m.p: 180 °C. *Anal*. Calc. for $C_{22}H_{29}NO_2$: C, 77.84; H, 8.61; N, 4.13. Found: C, 77.83; H, 8.63; N, 4.15%. ^{1}H NMR ($CDCl_3$, δ ppm): 6.7–6.9 (m, aromatic CH), 3.5–3.8 (d, 4H, benzyl CH_2), 2.4–2.7 (m, 2H, cyclohexyl N–CH), 2.25 (s, 6H, aromatic CH_3), 1.2–1.8 (m, 11H, ring CH_3). Selected IR data (KBr, υ cm^{-1}): 3450, 1475.

2.4. Synthesis of ligands

2.4.1. N,N-Bis{2-hydroxy-5-methyl-3-(morpholin-1-ylmethyl)benzyl}-N′,N′-diethyl-1,3-propanediamine (L^1H_2)

The precursor compound P.C.-1 (3.7 g, 0.01 mol) in ethanol (100 ml) was mixed with an excess of morpholine (2 g, 0.023 mol), and formaldehyde (35%, 2.5 ml, 0.025 mol) was added slowly with stirring. The solution was then heated to reflux for 24 h with the addition of 2 ml formalin at approximately 8 h intervals. The resulting mixture was evaporated under vacuo. The yellow oil obtained was washed with saturated sodium carbonate solution (20 ml) and then extracted with chloroform. The product L^1H_2 was obtained as yellow oil on

evaporation of the chloroform layer. The crude L^1H_2 was then recrystallised from ethanol.

Yield: 3.1 g (55%). *Anal*. Calc. for $C_{33}H_{52}N_4O_4$: C, 69.68; H, 9.21; N, 9.85. Found: C, 69.69; H; 9.20; N, 9.82%. ^{1}H NMR ($CDCl_3$, δ, ppm): 6.8 (d, 4H, aromatic CH); 3.5–3.8 (t, 16 H, benzyl CH_2, morpholine OCH_2), 2.5 (d, 12H, NCH_2), 2.3 (s, 6H, aromatic CH_3), 1–1.8 (m, 2H, alkyl CH_2), 0.8–1 (m, 6H, alkyl CH_3). Selected IR data (KBr, υ cm^{-1}): 3450, 1470.

2.4.2. N,N-Bis{2-hydroxy-5-chloro-3-(morpholin-1-ylmethyl)benzyl}N′,N′-diethyl-1,3-propanediamine (L^2H_2)

Synthesis of the ligand L^2H_2 was carried out following the above procedure using P.C.-2 (4.11 g, 0.01 mol) in the place of the P.C.-1. The ligand was recrystallised from ethanol.

Yield: 4.5 g (74%). *Anal*. Calc. for $C_{31}H_{46}N_4O_4Cl_2$: C, 61.08; H, 7.61; N, 9.19. Found: C, 61.10; H, 7.61; N, 9.21%. ^{1}H NMR ($CDCl_3$, δ, ppm): 6.68–7.06 (d, 4H, aromatic CH), 3.68 (s, 8H, benzyl CH_2, 4H, morpholine OCH_2), 2.25 (s, NCH_2), 1.6 (m, 2H, alkyl CH_2), 1.2–1.4 (m, 6H, alkyl CH_3). Selected IR data (KBr, υ cm^{-1}): 3450, 1480.

2.4.3. N,N-Bis{2-hydroxy-5-methyl-(3-piperidin-1-ylmethyl)benzyl} cyclohexylamine (L^3H_2)

P.C.-3 (6.76 g, 0.02 mol) in methanol was mixed with piperidine (1.87 g, 0.22 mol). Then formaldehyde (35%, 2 ml, 0.02 mol) was added dropwise with stirring under cooling. This mixture was stirred for 24 h at room temperature and then heated gently under reflux for 8 h. The alcohol was removed under vacuo and a yellow oil was extracted with dichloromethane and recrystallised from ethanol.

Yield: Yellow oil, 6 g (69%). *Anal*. Calc. for $C_{34}H_{51}N_3O_2$: C, 76.50; H, 9.63; N, 7.87. Found: C,76.54; H, 9.65; N, 7.84%. ^{1}H NMR ($CDCl_3$, δ, ppm): 7.18–6.76 (m, 5H, aromatic CH), 3.56 (s, 6H, benzyl CH_2), 2.5 (d, 1H, cyclohexyl NCH_2), 2.2 (s, aromatic CH_3), 1.2–1.5 (m, 16H, ring CH_2). Selected IR data (KBr, υ cm^{-1}): 3450, 1470. Mass spectrum: *m*/*z* 436.

2.5. Synthesis of the copper complexes

2.5.1. Synthesis of $[Cu_2L^1(ClO_4)_2]\cdot 2CH_3OH\cdot 2H_2O$ (**1a**)

The ligand L^1H_2 (1.86 g, 3.3 mmol) and lithium hydroxide (0.28 g, 6.6 mmol) in methanol were boiled and copper(II) perchlorate (2.44 g, 6.6 mmol) in hot methanol was added and heated to reflux for several hours. The solution was filtered when hot and the volume was reduced to one third and kept at room temperature. A dark green coloured compound was filtered and dried in vacuo. The complex was recrystallised from methanol.

Yield: 2 g (61%). *Anal*. Calc. for $C_{35}H_{62}Cu_2N_4O_{16}Cl_2$: C, 42.36; H, 6.30; N, 5.65; Cu, 12.81. Found: C, 42.40; H, 6.31; N, 5.66; Cu, 12.84%. Selected IR data (KBr, υ cm^{-1}): 3320, 1460,1100, 625 (perchlorate) [27] 480, 280. UV–Vis: λ_{max} (nm) (ε, M^{-1} cm^{-1}) (DMF): 690(232), 410(sh), 340(sh), 287(14626). μ_{eff}: 1.51 BM.

The following complexes were also prepared by carrying out the same procedure but varying the ligand (L^1H_2 and L^2H_2) and/or copper(II) salt, and the products were recrystallised from methanol.

2.5.2. $[Cu_2L^1Cl_2]\cdot 2CH_3OH$ (**1b**)

The complex $[Cu_2L^1Cl_2]\cdot 2CH_3OH$ was synthesized by following the previously described procedure for complex **1a**, using copper(II) chloride salt instead of copper(II) perchlorate. Colour: Green. Yield: 2.2 g (81%). *Anal*. Calc. for $C_{35}H_{58}Cu_2N_4O_6Cl_2$: C, 50.72; H, 7.05; N, 6.76; Cu, 15.33. Found: C, 50.71; H, 7.02; N, 6.80; Cu, 15.37%. Selected IR data (KBr, υ cm^{-1}): 3300, 1480, 480, 310–325, 280. UV–Vis: λ_{max} (nm) (ε, M^{-1} cm^{-1}) (DMF): 720(259), 405(sh), 325(sh), 290(11419). μ_{eff}: 1.63 BM.

2.5.3. $[Cu_2L^1Br_2]\cdot 2CH_3OH$ (**1c**)

The complex $[Cu_2L^1Br_2]\cdot 2CH_3OH$ was synthesized by following the previously described procedure for the complex **1a**, using copper(II) bromide salt instead of copper(II) perchlorate. Colour: Green. Yield: 2.25 g (75%). *Anal*. Calc. for $C_{35}H_{58}Cu_2N_4O_6Br_2$: C, 45.80; H, 6.37; N, 6.10; Cu, 13.85. Found: C, 45.79; H, 6.35; N, 6.15; Cu, 13.90%. Selected IR data (KBr, υ cm^{-1}): 3250, 1480, 480, 280, 270. UV–Vis: λ_{max} (nm) (ε, M^{-1} cm^{-1}) (DMF): 730(278), 410(sh), 320(sh), 287(12208). μ_{eff}: 1.64 BM.

2.5.4. $[Cu_2L^2(ClO_4)_2]\cdot 2CH_3OH\cdot 2H_2O$ (**2a**)

The complex $[Cu_2L^2(ClO_4)_2]\cdot 2CH_3OH\cdot 2H_2O$ was synthesized by following the previously described procedure for the complex **1a**, using L^2H_2 instead of L^1H_2. Colour: Dark green. Yield: 2.5 g (73%). *Anal*. Calc. for $C_{33}H_{56}Cu_2N_4O_{16}Cl_4$: C, 38.34; H, 5.46; N, 5.42; Cu, 12.29. Found: C, 38.30; H, 5.48; N, 5.46; Cu, 12.30%. Selected IR data (KBr, υ cm^{-1}): 3300, 1460, 1100,625, 480, 280. UV–Vis: λ_{max} (nm) (ε, M^{-1} cm^{-1}) (DMF): 680(281), 400(sh), 320(sh), 290(12850). FAB-MS *m*/*z* (% intensity): $[Cu_2L^2]^{2+}\cdot 2H_2O$, 770(5). μ_{eff}: 1.68 BM.

2.5.5. $[Cu_2L^2Cl_2]\cdot 2CH_3OH$ (**2b**)

The complex $[Cu_2L^2Cl_2]\cdot 2CH_3OH$ was synthesized by following the previously described procedure for the complex **1a**, using L^2H_2 instead of L^1H_2 and copper chloride in place of copper perchlorate. Colour: Green. Yield: 2.3 g (78%). *Anal*. Calc. for $C_{33}H_{52}Cu_2N_4O_6Cl_4$: C, 45.57; H, 6.03; N, 6.44; Cu, 14.61. Found: C, 45.55; H, 6.01; N, 6.40; Cu, 14.59%. Selected IR data (KBr, υ cm^{-1}): 3250, 1460, 470, 320, 285. UV–Vis: λ_{max} (nm)

(ε, $M^{-1}\,cm^{-1}$) (DMF): 720(236), 390(sh), 360(sh), 290(13222). μ_{eff}: 1.69 BM.

2.5.6. $[Cu_2L^2Br_2]\cdot 2CH_3OH$ (**2c**)

The complex $[Cu_2L^2Br_2]\cdot 2CH_3OH$ was synthesized by following the previously described procedure for the complex **1a**, using L^2H_2 instead of L^1H_2 and copper bromide in place of copper perchlorate. Colour: Green. Yield: 2.6 g (79%). *Anal.* Calc. for $C_{33}H_{52}Cu_2N_4O_6Cl_2Br_2$: C, 41.35; H, 5.47; N, 5.84; Cu, 13.26. Found: C, 41.31; H, 5.43; N, 5.85; Cu, 13.22%. Selected IR data (KBr, υ cm^{-1}): 3250 1470, 470 (Cu–N); 310 (Cu–Br); 285 (Cu–O). UV–Vis: λ_{max} (nm) (ε, $M^{-1}\,cm^{-1}$) (DMF): 730(259), 390(sh), 340(sh), 290(14192). μ_{eff}: 1.68 BM.

2.5.7. $[Cu_2L^3(OAc)_2]\cdot 2H_2O$ (**3a**)

The ligand L^3H_2 (1.44 g, 3.3 mmol) and lithium hydroxide (0.16 g, 6.6 mmol) in methanol were boiled and copper(II) acetate (1.43 g, 6.6 mmol) in hot methanol was mixed and refluxed for several hours. The solution was filtered when hot and the volume was reduced to one third and kept at room temperature. The dark green colour compound was filtered and dried in vacuo. The complex was recrystallised from methanol. The other complexes were also prepared by carrying out the same procedure but varying the copper(II) salt.

Yield: 1.9 g (77%). *Anal.* Calc. for $C_{38}H_{59}Cu_2N_3O_8$: C, 56.14; H, 7.31; N, 5.17; Cu, 15.63. Found: C, 56.10; H, 7.27; N, 5.16; Cu, 15.60%. Selected IR data (KBr, υ cm^{-1}): 3350, 1600 (terminal acetate), 1590 (bridged acetate) [28,29], 485 (Cu–N), 280 (Cu–O). UV–Vis: λ_{max} (nm) (ε, $M^{-1}\,cm^{-1}$) (DMF): 690(277), 430(sh), 340(sh), 285(11142). μ_{eff}: 1.61 BM.

The other complexes derived from this ligand (L^3H_2) are given below.

2.5.8. $[Cu_2L^3Cl_2].CH_3OH\cdot 2H_2O$ (**3b**)

The complex $[Cu_2L^3Cl_2]\cdot CH_3OH\cdot 2H_2O$ was synthesized by following the previously described procedure for the complex **3a**, using copper chloride in the place of copper acetate. Colour: Green. Yield: 1.5 g (65%). *Anal.* Calc. for $C_{35}H_{57}Cu_2N_3O_5Cl_2$: C, 52.69; H, 7.20; N, 5.27; Cu, 15.93. Found: C, 52.70; H, 7.17; N, 5.28; Cu, 15.91%. Selected IR data (KBr, υ cm^{-1}): 3350, 1470, 470 (Cu–N), 325 (Cu–Cl), 280 (Cu–O). UV–Vis λ_{max} (nm) (ε, $M^{-1}\,cm^{-1}$) (DMF): 700(230), 433(sh), 330(sh), 292(13714). μ_{eff}: 1.63 BM.

2.5.9. $[Cu_2L^3Br_2]\cdot CH_3OH\cdot 2H_2O$ (**3c**)

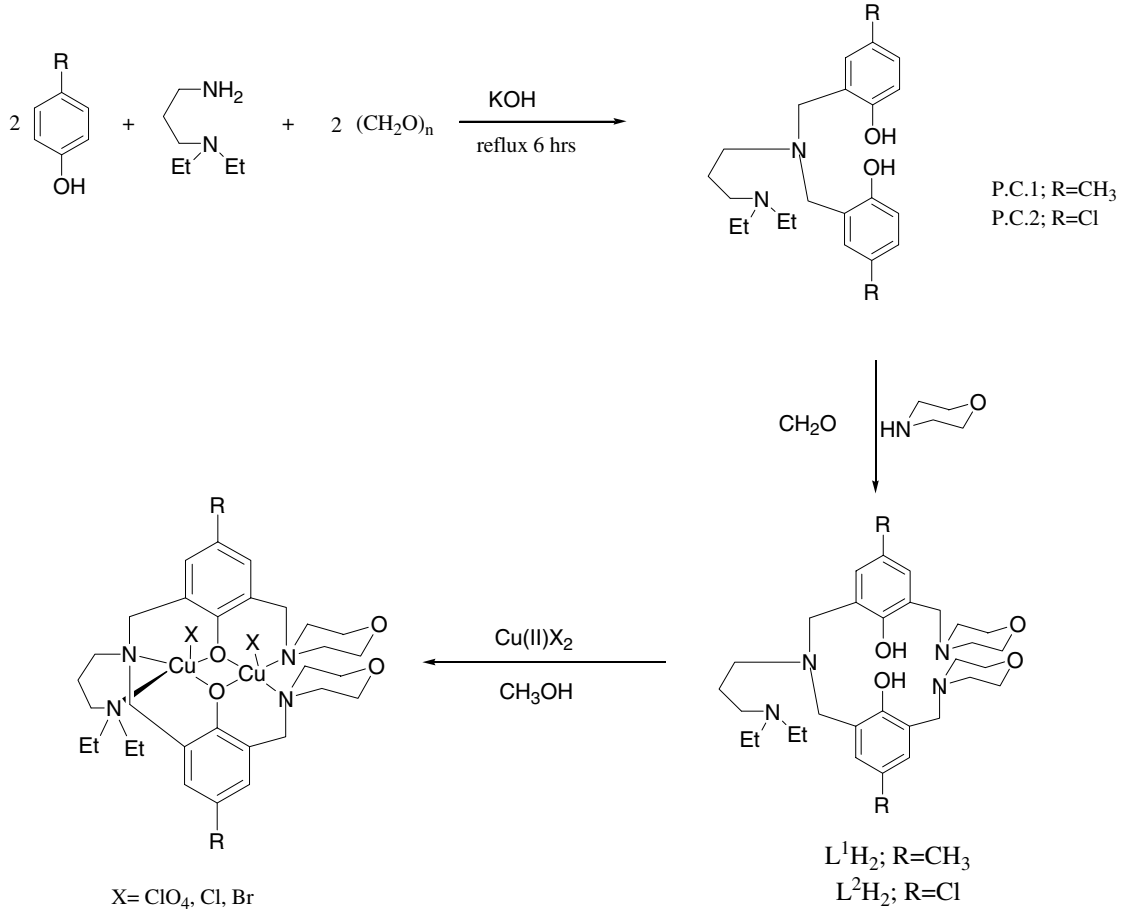
The complex $[Cu_2L^3Br_2]\cdot CH_3OH\cdot 2H_2O$ was synthesized by following the previously described procedure for the complex **3a**, using copper bromide in the place of copper acetate. Colour: Green. Yield: 1.75 g (67%). *Anal.* Calc. for $C_{35}H_{57}Cu_2N_3O_5Br_2$: C, 47.41; H, 6.48; N, 4.74; Cu, 14.33. Found: C, 47.38; H, 6.47; N, 4.72; Cu, 14.31%. FAB-MS. *m/z* (% intensity): $[Cu_2L^3Br]^+$, 641(10). μ_{eff}: 1.65 BM.

3. Results and discussion

The precursor compounds were synthesised using the literature method [30]. The yield of the precursor compounds was as follows. P.C.-1: 65%, P.C.-2: 73% and P.C.-3: 57%. All the precursor compounds were recrystallised using cold methanol. Binucleating hexadentate (L^1H_2 and L^2H_2) and pentadentate (L^3H_2) ligands were prepared by the mannich base reaction of the respective precursor compound, substituted amine and formaldehyde in a 1:1:1 molar ratio. The yield of the ligands was found to be in the range 55–74%. The ligands were recrystallised from ethanol and used for the complex syntheses. Schemes 1 and 2 show the syntheses of the ligands and their complexes. The yields of the complexes fall in the range 61–81%. The recrystallised samples of the complexes were used for the analyses. Attempts to recrystallise the complexes with different solvents using various methods, like slow evaporation, diffusion etc, resulted in microcrystalline compounds not suitable for X-ray diffraction study.

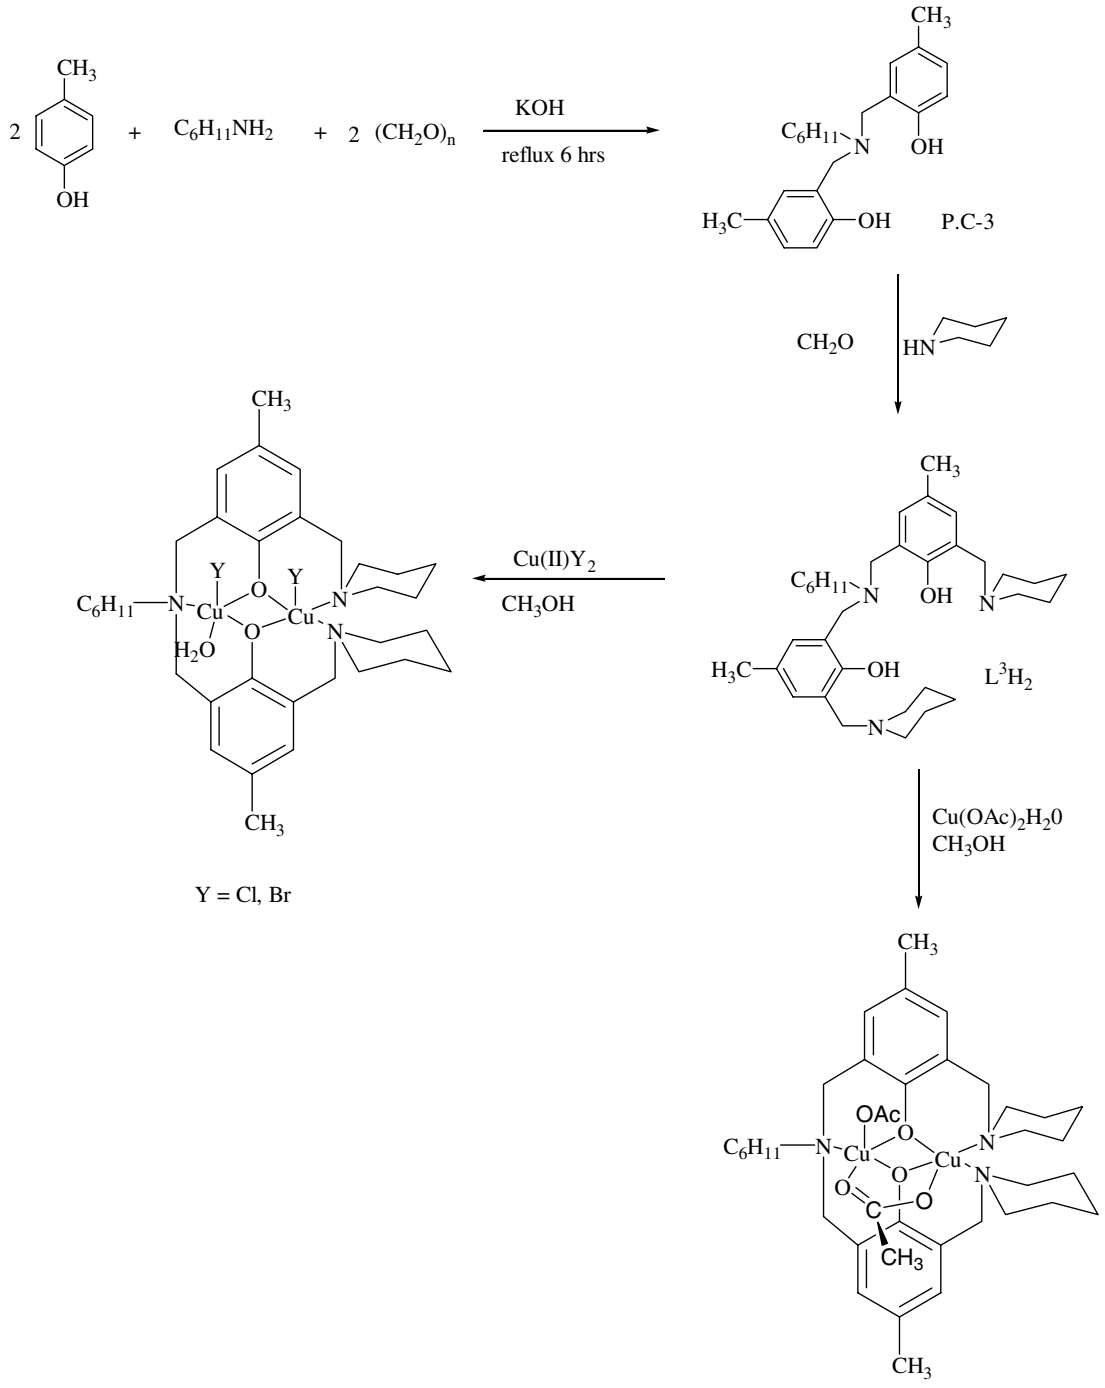
The electronic spectra of the complexes are recorded in DMF solvent. All the complexes exhibit a band around 680–730 nm due to a d–d transition [31,32]. The peak in the region 320–360 nm is due to a ligand to metal charge transfer (LMCT) transition [26,33,34]. In addition to the above said two bands, all the complexes show considerably greater intensity around 245–290 nm. This is due to an intraligand transition [34–36]. The higher λ_{max} value for all these complexes (d–d transition) are characteristic for a trigonal bipyramid geometry of the Cu(II) ion [24,31,36–40].

3.1. Magnetic properties of the complexes



The values of the magnetic moments observed at room temperature for the binuclear copper(II) complexes were found to be 1.51–1.69 BM, smaller than the spin only value. This clearly indicates the occurrence of an antiferromagnetic exchange interaction within the molecule. Variable temperature magnetic susceptibility measurements were performed on a powdered sample in the temperature range 77–300 K. The results are displayed in Fig. 1. The best fit values of $-2J$, g and P are given in the Table 1. The data for the various complexes are fitted to a modified Bleaney–Bowers equation [41] to evaluate the singlet–triplet energy separation ($-2J$):

$$\chi_m = Ng^2(\beta^2/3kT)[3 + \exp(-2J/kT)]^{-1}(1 - P) + (0.45P/T) + N_\alpha,$$



where χ_m is the paramagnetic susceptibility per metal atom after the correction for diamagnetism. N is Avagadro's number, β is the Boltzman constant, g is the average gyromagnetic ratio and P is the fraction of monomeric copper(II) impurities. $-2J$ is the singlet–triplet energy separation. N_α is the temperature independent, usually assumed to be 120×10^{-6} cgs units for copper(II) compounds. The value of the exchange integral $-2J$ for the complexes varies from 45 to 178 cm^{-1}, indicative of weak antiferromagnetic coupling between the copper(II) ions. The observed singlet–triplet energy separation ($-2J$) of complexes **1a** and **1c** are 112 and 116 cm^{-1}, respectively, and for the complexes **2a** and **2c** the observed $-2J$ values are 45 and 52 cm^{-1}, respectively. The observed low value may be due to more flexible nature of the propylene linkage [42]. The complex **3a**, exhibits a higher $-2J$ value of 178 cm^{-1}. This higher value shows that one of the acetate anions may form an additional bridge between the copper(II) ions [42–44], apart from the phenolate bridge. The exchange integral value for **3c** is 106 cm^{-1}. The very close $-2J$ values observed for complexes **1a**, **1c** and **3c** indicate the presence of only only phenolate bridge between the copper(II) ions.

Copper complexes with distorted square planar geometry generally show higher exchange integral values [20] and they exhibit λ_{max} values between 520 and 630 nm. The observed λ_{max} value (680–730 nm) indicates a deviation from planar geometry to trigonal bipyramidal geometry around the Cu(II) ions [42]. This deviation in the geometry leads to a smaller exchange integral value.

A higher $-2J$ value is observed for complexes of L^1H_2 when compared to complexes of L^2H_2.This higher $-2J$ value may be due to the geometry around Cu(II) ions and also due to the substitution effect in the ligand. Complexes **1a** (L^1Cu_2) and **2a** (L^2Cu_2) show λ_{max} around 680 and 690 nm, respectively. This 10 nm difference does not have much influence on the structure of the complexes which may have more or less the same geometry. So the change in the magnetic exchange interaction is more influenced by substitution in the ring than the geometry. Presence of an electron withdrawing group at the para position of the bridging phenoxide ion in L^2H_2 will decreases the electron density around the Cu(II) centers [42,45–51] when compared to the methyl group

Scheme 1. Synthesis of ligand L^1H_2 and L^2H_2 and their complexes.

Scheme 2. Synthesis of ligand L^3H_2 and its complexes.

Table 1
Magnetic exchange parameters for the complexes

Complexes	$-2J$ (cm^{-1})	g	P
1a	112	1.839	0.001
1c	116	1.896	0.015
2a	45	1.940	0.015
2b	52	1.830	0.001
3a	178	2.016	0.001
3c	106	2.06	0.001

present in L^1H_2. Reduction in the electron density weakens the Cu–O bond and reduces the spin exchange interaction.

3.2. ESR spectral analysis

ESR spectra of the complexes were recorded in DME solvent at liquid nitrogen temperature (77 K). The absorption signal for both complexes **2c** and **3a** consists

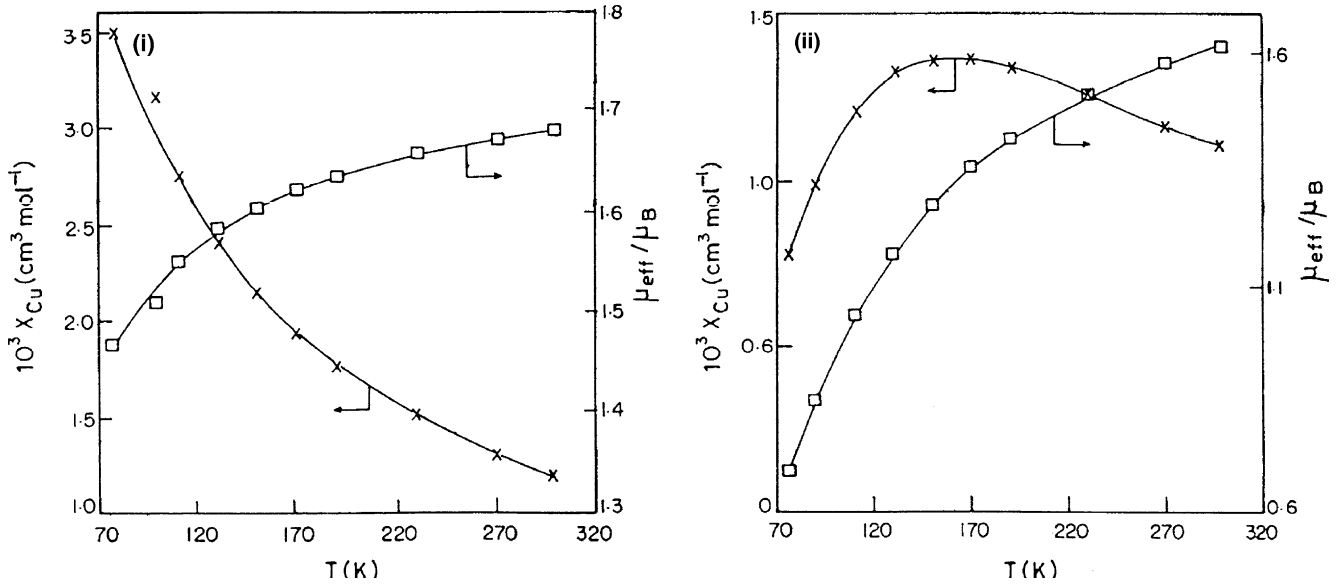


Fig. 1. Temperature variations of magnetic susceptibility (×) and effective magnetic moment (□) for the complexes (i) $[Cu_2L^2(ClO_4)_2]\cdot 2CH_3OH\cdot 2H_2O$ **2a**, (ii) $[Cu_2L^3(OAc)_2]\cdot 2H_2O$ **3a**.

of a broad band centered at about $g = 2$. Hyperfine splitting due to the spin of the copper nucleus was not detected because of the broadness of signal. These observations confirm the occurrence of super exchange coupling between the copper(II) ions in the binuclear complexes.

3.3. Electrochemistry

Conductivity measurements [52] of binuclear copper(II) complexes in DMF solvent resulted in Λ_m values in the range 10–15 Λ_m/S/cm^2/M^{-1}, indicating the complexes are neutral. The cyclic voltammograms of the complexes are recorded in DMF solvent and are reproduced in Fig. 2 (scan rate 50 mV/s). The electrochemical data of the complexes are presented in Table 2. It has been observed for all the complexes (i) the E_{pc} and E_{pa} values change with scan rate (ii) ΔE_p values increase with increasing scan rate, and were found to be more than 60 mV and (iii) the cathodic peak currents (I_c) are greater than the anodic (I_a) peak currents. These observations indicate that the nature of the electron transfer processes is quasi-reversible.

The first reduction potential for all the complexes was observed in the potential range −0.48 to −0.8 V (E^1_{pc}) and the second reduction potential was observed in the potential range −0.76 to −1.4 V (E^2_{pc}). Coulometric experiments conducted at 100 mV higher than the first reduction potential show the consumption of one electron per molecule ($n = 0.95$). The same experiments conducted at 100 mV slightly higher than the second reduction potential confirms the consumption of two electrons per molecule ($n = 1.92$). The redox process may involve the following steps.

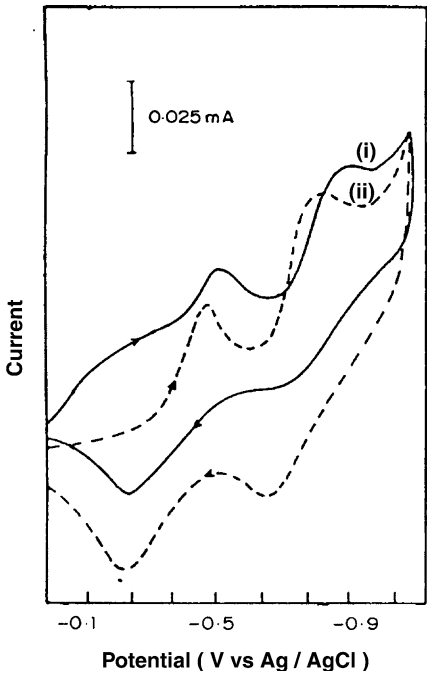

Fig. 2. Cyclic voltammogram of (i) $[Cu_2L^1Br_2]\cdot 2CH_3OH$ **1c** (——). (ii) $[Cu_2L^2Br_2]\cdot 2CH_3OH$ **2c** (-----) in DMF solvent at 25 °C (scan rate 50 mV/s).

$$Cu^{II}Cu^{II} \overset{E^1_{pc}}{\rightleftharpoons} Cu^{II}Cu^{I} \overset{E^2_{pc}}{\rightleftharpoons} Cu^{I}Cu^{I}$$

The first reduction potential for the perchlorate complex **1a** was observed at −0.62 V which is a more negative potential than the corresponding halo complexes **1b** and **1c**. Upon halide ion coordination the geometry around the copper may be distorted from planarity. The distortion in the geometry is observed from the red shift in the

λ_{max} values of the halo complexes. It is known that more distortion in the coordination geometry around the metal will favour electrochemical reduction and hence the anodic shift in the first reduction potential occurs [31,38]. A similar trend had been observed among other series of complexes.

The first reduction potential of complex **3a** was observed at −0.8 V, which is more negative than other complexes **3b** and **3c**. In addition to a phenolate bridge, the presence of an acetate bridge enhances the complex to show a greater negative potential as evidenced from a higher exchange integral value (178 cm^{-1}).

The reduction potential is also affected by the substituents at the para position of the phenoxide of the phenyl rings. Replacement of a methyl group with a relatively electron withdrawing chloride shifts the first as well as the second reduction to more anodic potentials. The electron withdrawing substituent decreases the electron density around the metal ion and favours easy reduction [47,48].

The higher $E^1_{1/2}$ and $E^2_{1/2}$ values for the chloro complexes compared to the bromo complexes indicate that the addition of an electron to the chloro complex is more difficult than the bromo complex. This may be due to higher basicity of the chloride ion when compared to the bromide ion.

4. Conclusion

This paper describes binuclear copper(II) complexes of two ligand systems. In the first system (L^1H_2 and L^2H_2) only substitution in the ligand is varied. In the second system (L^3H_2), the external bridging system is varied. The magnetic exchange interaction and electrochemical properties of binuclear copper(II) complexes within the first system does not vary when compared to second system. The substitution in the ligand has much less influence than the bridging ligands between the metal centers in the complexes. This may be due to a change in the geometry around the copper ions in the complexes.

In continuation of such studies, our investigations on dichloro-mono (1-phenylamidino-*O*-alkylurea)copper (II) (alkyl = methyl, ethyl, *n*-propyl, *n*-butyl, *n*-amyl) have shown that in these complexes, copper(II) ions exist as monomers having square planar geometry. Evidence was also obtained for the magnetic field induced "molecular alignment" in some of these complexes cooled in a magnetic field (10 KG) to 77 K [2]. Recently, we have synthesized and reported two types of copper complexes, viz., [Cu(II)(1-phenylamidino-*O*-*n*-butylurea)en$(H_2O)]_2^{2+}$ and [Cu(II) sulfato-mono(1-phenylamidino-*O*-methylurea)]$_2$ [3]. Fine structure characteristics of the $S = 1$ system, were obtained in both complexes with zero field splitting (ZFS) of 0.0525 and 0.0225 cm^{-1}, respectively, suggesting the formation of binuclear complexes in the solid state. The presence of a half-field signal ($\Delta M_s = \pm 2$) in the complex [Cu(II)(1-phenylamidino-*O*-*n*-butylurea)en$(H_2O)]_2^{2+}$ further confirmed the formation of a binuclear complex. On dissolution in dimethyl formamide (DMF) and methanol (MeOH), breaking of the binuclear complex into a mononuclear complex takes place, in addition to change in ligation to an axial position. This is reflected in the electronic spectra of the complex in solution. An important finding of our previous study is that among the different alcohols used in forming mixed complexes with en, only [Cu(II)(1-phenylamidino-*O*-*n*-butylurea)en$(H_2O)]_2^{2+}$, prepared from dichloro 1-phenylamidino-*O*-*n*-butylurea copper(II), is ferromagnetic in nature. It is our interest to synthesize a number of copper(II) complexes with *n*-butyl substituted dicyandiamide in different alcohols and to study their spectroscopic properties in order to investigate the nature of the complexes in the solid and solution states. In the EPR spectra of frozen complexes in DMF, the interaction of Cu^{2+}–Cu^{2+} pairs ($S = 1$) were detected. The formation of the binuclear complex was confirmed by the presence of a half-field transition ($\Delta M_s = \pm 2$) at ca. 1600 G.

It has been reported that coordinated amidino-*O*-alkylurea acts as a versatile hydrogen-bonding ligand [4–7] and hydrogen-bonding interactions are of great importance in biological systems [8–11]. Recently, Suksangpanya et al. [12] studied the interaction of transition metal complexes containing this type of ligand having versatile hydrogen-bonding capacity with DNA bases. In view of the above points, we have also extended our investigations to biological activities in terms of the antibacterial and antifungal properties of bis(1-*n*-butylamidino-*O*-alkylurea) copper(II) complexes. The complexes show growth inhibitory activity against pathogenic fungi, viz., *Ceratocystis paradoxa*, *Aspergillus niger*, *Trichoderma koningii*, and pathogenic bacteria, viz., *Bacillus* sps(1), *Bacillus* sps(3). Investigations on these complexes are presented in this paper.

2. Experiment

2.1. Materials and instrumentation

All the chemicals used were of reagent grade. Sodium dicyanoamide was purchased from Fluka and *n*-butyldicyandiamide was prepared by an earlier reported method [13].

2.2. Preparation of bis(1-n-butylamidino-O-alkylurea)copper(II)chloride complexes

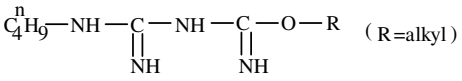
The complexes were prepared by refluxing cupric chloride dihydrate (0.01 mol) and *n*-butyldicyandiamide (0.02 mol) on a water bath for 1–3 h in the appropriate alcohols. The pink or purple complexes so obtained were washed repeatedly with the appropriate alcohols and acetone. They were dried in air. The analytical, magnetic susceptibility and electronic data are presented in Table 1.

2.3. Physical measurements

Infrared (IR) spectra of pellets were recorded on a Bruker IFS-66V spectrometer and far IR spectra using polyethylene pellets in the range 500–50 cm^{-1}. Photoacoustic spectra (PAS) on solid samples were recorded using a home-made spectrophotometer in the 350–800 nm range using a tungsten halogen lamp as the source [14], whereas absorption spectra in solution were recorded on a Beckman DU640 spectrophotometer. A Philips PR-9500 bridge was used for conductivity measurements. Magnetic susceptibility measurements were carried out with a PAR 155 Vibrating Sample Magnetometer. EPR spectra were recorded using a Bruker ESP 300 spectrometer operating at X-band (9.5 GHz) with 100 KHz field modulation. The g values were calculated relative to a 2,2 diphenyl-1 picrylhydrazil (DPPH) standard with $g = 2.0036$. Temperature was varied in the range 100–350 K using a Bruker Variable temperature accessory B VT-2000. Elemental analysis was carried out on a Perkin–Elmer 240C and the amount of copper was determined by decomposing the complexes with a mixture of HNO_3 and H_2SO_4 and finally by performing an iodometric titration.

3. Results and discussions

3.1. IR spectra



n-Butyldicyandiamide(Bu^{n}dcda) has a strong nitrile(C$\equiv$N) band at 2176 cm^{-1}. In the IR spectra of bis(ligand)copper(II) complexes, there is the absence of a band around 2176 cm^{-1} and also there is no C=O stretching band around 1740 cm^{-1} indicating that the

Bu^nAMeUH = 1-*n*-butylamidino-*O*-methylurea; Bu^nAEtUH = 1-*n*-butylamidino-*O*-ethylurea; Bu^nAPr^nUH = 1-*n*-butylamidino-*O*-*n*-propylurea; Bu^nAPr^iUH = 1-*n*-butylamidino-*O*-*i*-propylurea; Bu^nABu^nUH = 1-*n*-butylamidino-*O*-*n*-butylurea; Bu^nABu^iUH = 1-*n*-butylamidino-*O*-*i*-butylurea.

complexing ligand is not *n*-butyl substituted guanylurea. Instead all bis(ligand) complexes have a very strong ν_a (C–O–C) stretch at ca. 1190–1220 cm^{-1} and ν_s(C–O–C) at ca. 960 cm^{-1} [15] to support 1-*n*-butylamidino-*O*-alkylurea(I). Further the IR spectra of Bu^ndcda showed a band at ca. 1615 cm^{-1} for the butylamidine (azomethine) C=N stretching, this had a downward shift (ν 20–34 cm^{-1}) in all the bis(ligand) complexes showing that the azomethine nitrogen is coordinated to the metal ion. This downward shift is further supported by the lowering of ν(C–N) [16,3]. The increase in value of ν (C=N) to ca. 1656 cm^{-1} in all the complexes is presumably due to a change in the C=N bond order, on coordination through the nitrogen atom, facilitated by the transfer of electron density from the C–O–C moiety. The electron density on the N=C–O–C fragment of 1-*n*-butylamidino-*O*-alkylurea is delocalized in the complexes and the =C–O– bond order is raised [2,3,17]. The presence of new bands at ca. 475 cm^{-1} is due to (Cu–N) in all the complexes.

(I)

3.2. Electronic spectra

The electronic spectra of $Cu(1\text{-}Bu^nAAUH)_2]Cl_2$ complexes in MeOH showed a typical broad absorption band in the range 17 936–18 310 cm^{-1} (Table 1). The photoacoustic signals of bis(1-*n*-butylamidino-*O*-methyl urea)copper(II) chloride in the solid state showed a broad band ca. 18 980 cm^{-1}. The observed spectra are consistent with a distorted octahedral geometry around copper(II), having 1-*n*-butylamidino-*O*-alkylurea as ligands. Compared to the solid state spectra, the solution spectra were shifted to lower energy, probably as a result of axial ligation. Also the shift in the absorption band was strongly dependent on the nature of the solvent. For $[Cu(Bu^nAEtUH)]_2Cl_2 \cdot 2H_2O$, the following bands were observed (Absorption bands in cm^{-1}): 15 873 (Py), 16 520 (DMSO), 17 093 (DMF) and 18 240 (MeOH). The room temperature magnetic susceptibility of the complexes was found to be in the range 1.82–2.00 BM. These values are close to the spin-only value of 1.73 BM for a d^9 configuration. The conductivity measurements of the complexes in MeOH suggest that the complexes are 1:2 electrolytes [18].

3.3. EPR studies

EPR spectra of polycrystalline samples of $Cu(1\text{-}Bu^nAAUH)_2]Cl_2$ (1-Bu^nAAUH = 1-*n*-butylamidino-

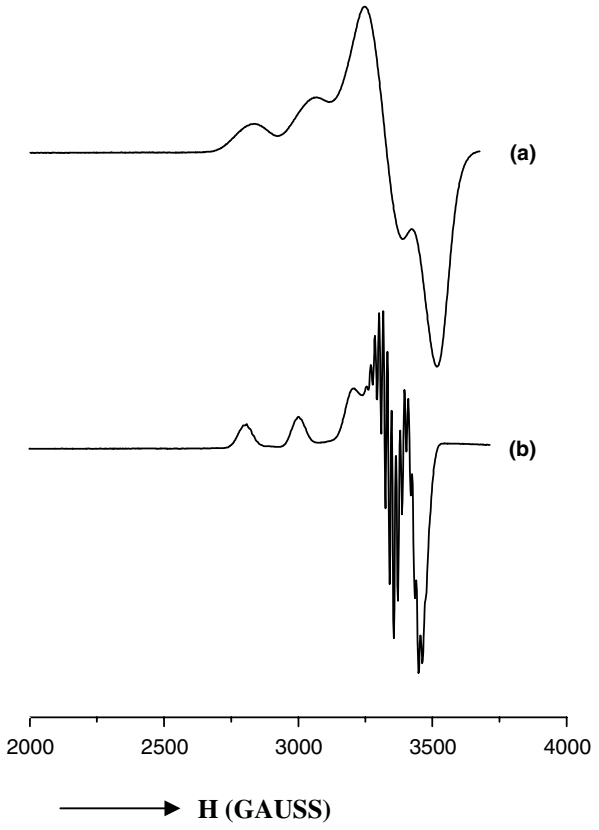

Fig. 1. EPR spectra of complex **3** (a) in solid at 300 K and (b) in methanol at 100 K.

O-alkylurea and alkyl = methyl, ethyl, *n*-propyl, *i*-propyl, *n*-butyl and *i*-butyl) showed the copper(II) signal having axial symmetry. In addition, a relatively weak $\Delta M_s = \pm 2$ transition was observed at 1550 G (g ca. 4.00). A typical room temperature spectrum for the complex bis(1-*n*-butylamidino-*O*-*n*-propylurea)copper (II) chloride is shown in Fig. 1(a). In order to establish the extent of covalency in the metal-ligand interaction and to reduce the broadening due to spin–spin interactions in solids, the EPR spectra of the copper(II) complexes in MeOH and DMF were recorded at 300 and 100 K.

3.4. Solution studies

In MeOH, a quartet hyperfine structure with m_I dependent linewidths was seen at 100 K. The EPR parameters $g_\parallel$, $g_\perp$, $A_\parallel{}^{Cu}$ and $A_\perp{}^{Cu}$ were measured from the anisotropic spectra (Fig. 1(b)) of magnetically diluted copper complexes in frozen MeOH solutions at 100 K (Table 2(a)), which showed that the complexes exist as mononuclear species in MeOH.

The EPR parameters and d–d transition energies were used to evaluate the bonding parameters α^2, β^2 and γ^2, which may be regarded as measures of the covalency of the in-plane σ-bonds and the in-plane and out-of-plane π-bonds, respectively. The in-plane σ-bonding parameter α^2 was calculated using the expression of Kivelson and Neiman [19]

$$\alpha^2 = -\left(\frac{A_\parallel}{0.036}\right) + \left(g_\parallel - 2.0023\right) + \frac{3}{7}(g_\perp - 2.0023) + 0.04.$$

The orbital reduction factors $K_\parallel$ and $K_\perp$ were estimated from the expressions [20,21].

$$K_\parallel^2 = (g_\parallel - 2.0023)E_{d\text{–}d}/8\lambda_0,$$
$$K_\perp^2 = (g_\perp - 2.0023)E_{d\text{–}d}/2\lambda_0,$$

[a] $A_\perp$ for monomers is estimated by using equation $A_{iso} = (A_\parallel + 2A_\perp)/3$ from RT spectra, $A^N \approx 15$–17 G.

where $K_{\|} = \alpha^2\beta^2$, $K_{\perp} = \alpha^2\gamma^2$, and λ_0 represents the one electron spin–orbit coupling constant for the free ion, equal to $-828\ \mathrm{cm}^{-1}$. Significant information about the nature of bonding in the copper(II) complex can be derived from the magnitude of $K_{\|}$ and $K_{\perp}$. In case of a pure σ-bonding $K_{\|} \approx K_{\perp}$ ca. 0.77, whereas $K_{\|} < K_{\perp}$ implies considerable in-plane π-bonding, while for out of plane π-bonding $K_{\|} > K_{\perp}$. Furthermore, α^2, β^2 and γ^2 have values much less than 1 (the value for 100% ionic bonding, this value decreasing with increasing covalent bonding). In all the complexes it is observed that $K_{\|} < K_{\perp}$, indicating the presence of significant in plane π-bonding.

The effect of different alkyl groups on the ligand in the formation of binuclear complexes was studied by recording the EPR spectra of these complexes in frozen solutions of DMF at 100 K. This is shown in Fig. 2. At lower temperatures, the EPR spectrum of bis(1-*n*-butylamidino-*O*-methylurea)copper(II)chloride consisted of an axially symmetric spectrum ($g_{\|} = 2.1990$, $g_{\perp} = 2.0580$) having a weak quartet hyperfine structure on the parallel components arising from the interaction of an unpaired electron with a single copper nucleus ($I = 3/2$) (Fig. 2(a)). This signal is typical of a copper mononuclear complex ($S = 1/2$). Apart from this, a weak signal at half the resonance field ($\Delta M_s = \pm 2$) was observed. The origin of this signal is discussed in the next section. It may be mentioned that Wasson and Trapp [1] investigated copper(II) complexes with *O*-alkyl-1 amidinourea (alkyl = methyl, ethyl, *n*-propyl) using EPR spectroscopy. However, all the complexes were reported to be mononuclear complexes ($S = 1/2$) having a square planar structure CuN_4^{2-}.

The higher analogs of bis(1-*n*-butylamidino-*O*-alkylurea)copper(II) chloride (alkyl = *n*-butyl and *i*-butyl) (Fig. 2(e) and (f)) showed well resolved spectra showing several features associated with the triplet state ($S = 1$) of the binuclear complex. The half-field resonance ($\Delta M_s = \pm 2$) exhibited a well resolved seven line hyperfine structure with an average hyperfine splitting of $A = 95$ G. This was in agreement with reported exchange coupled copper(II) binuclear complexes [3]. With regard to the allowed $\Delta M_s = \pm 1$ transitions, the lowest field resonance (parallel components) observed at 2975 G showed a seven line hyperfine structure similar to that of the $\Delta M_s = \pm 2$ transition, whereas, at higher fields only a few lines could be seen. In addition to this, an intense pair of bands at ca. 3270 and 3435 G, due to the perpendicular component of the triplet state, were observed in the EPR spectra. The hyperfine coupling constant observed on the parallel components of the binuclear complex ($A_{\|} = 95$ G) is nearly half of that observed for the corresponding mononuclear complexes ($A_{\|} = 200$ G) which further confirms the formation of binuclear complex from its monomers. Within the series, the formation of binuclear species went on increasing from bis(1-*n*-butylamidino-*O*-methylurea)copper(II)-chloride to bis(1-*n*-butylamidino-*O*-*n*-butyl/*i*-butylurea) copper(II) chloride. The most accurate values of $g_{\|}$, $g_{\perp}$, $A_{\perp}^{Cu}$ and D for the binuclear complexes were deduced by computer simulation assuming axial symmetry. Fig. 3(a) and (b) show the EPR spectra of the bis(1-*n*-butylamidino-*O*-*n*-butylurea)copper(II)chloride complex in second harmonic and first harmonic presentation respectively. The simulated spectrum (Fig. 3(c)) was obtained by adjusting the relative amounts of the binuclear and mononuclear complexes. The best fit of the simulated spectrum with the experimental one was obtained by using a binuclear to mononuclear complex weight ratio of 0.85:0.15. The spin Hamiltonian parameters used

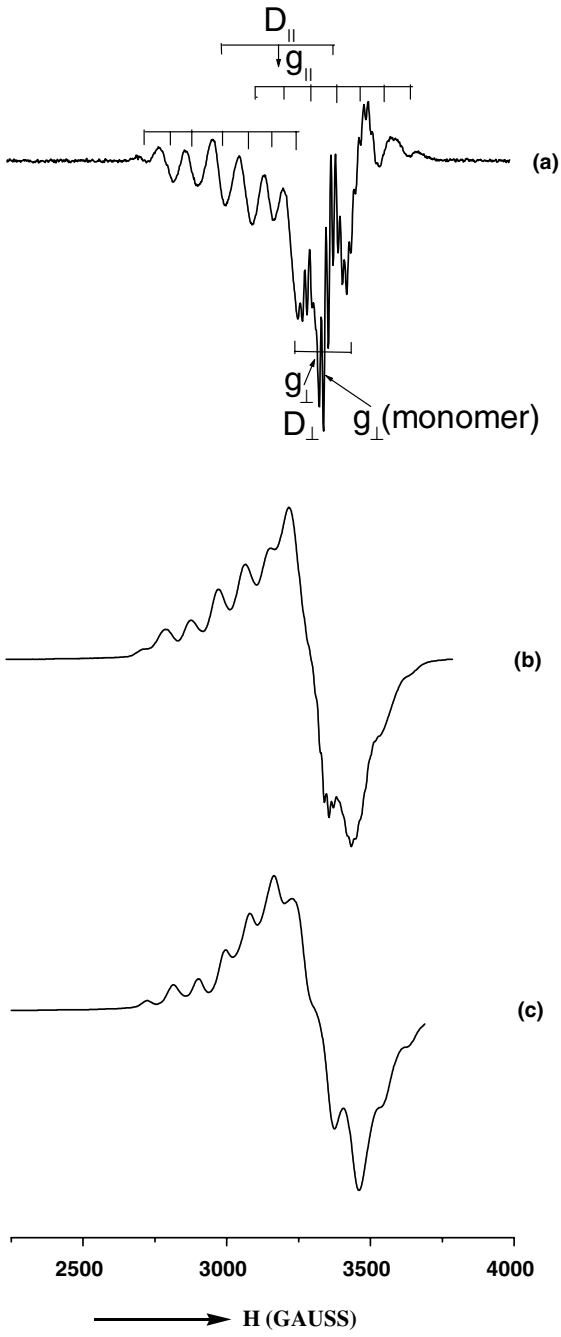

Fig. 3. EPR spectra of complex **5** in DMF at 100 K (a) second harmonic spectrum, (b) first harmonic spectrum and (c) simulated spectrum for complex generated by adjusting the relative amounts of binuclear to mononuclear complex in the weight ratio 0.85:0.15.

for the simulation of binuclear and mononuclear complexes are given in Table 2(a) and (b). The observed g values for the copper complexes were close to those reported for copper complexes having a nearly square planar geometry. The trend in g value ($g_{\|} > g_{\perp} > 2.00$) suggested that the unpaired electron in the copper(II) ion is in the $d_{x_2-y_2}$ orbital. The average distance between two interacting copper ions in the binuclear complexes was calculated from the zero field splitting (D term) by using the equation $D = 3g^2\beta^2/2r^3 = 1.39 \times 10^4\ (g/r^3)$ and was estimated to be nearly 5.5 Å.

Similar triplet state spectra have been reported in a μ-oxalato binuclear copper(II) complex, [(mpym)$(H_2O)(NO_3)Cu(C_2O_4)Cu$ $(NO_3)(H_2O)$ (mpym)] · $2H_2O$ [mpym = 4-methoxy-2-(5-methoxy-3-methyl-1H-pyrazole-1-yl)-6-methylpyrimidine] [22]. The discrete binuclear species consists of a copper ion in a strongly elongated octahedral environment coordinated by two nitrogen atoms and two oxygen atoms of the bridging oxalato group in the equatorial plane, and the water molecule and nitrate ion in axial positions. The presence of nine line super hyperfine structure ($^{14}A^{N} \sim 15$ G) on the lowest field parallel component of the bis(1-*n*-butylamidino-

O-methylurea)copper(II)chloride complex in the frozen state and in solution at room temperature clearly suggests that, in all the complexes, the copper ion is bound to four nitrogens in the equatorial plane.

The temperature dependence of the EPR spectra of the bis(1-*n*-butylamidino-*O*-*n*-butylurea)copper(II)chloride complex in DMF is shown in Fig. 4. The EPR spectrum changed drastically as the sample was heated from 100 to 200 K. The low temperature spectrum consists of predominantly binuclear species. The relative intensity of the binuclear species decreased while the signal due to mononuclear species grew in intensity as the complex was heated between 100 and 175 K. On further heating above this temperature the EPR spectra only showed the presence of mononuclear species. Similar changes were observed for the other complexes. The nature of the changes detected in the EPR spectra at different temperatures suggests that in bis(1-*n*-butylamidino-*O*-alkylurea)copper(II)chloride complexes, there is a monomer-binuclear complex equilibrium in DMF.

3.5. Biological activities

Biological activities in terms of the antibacterial and antifungal properties of bis(1-*n*-butylamidino-*O*-alkylurea)copper(II) complexes were determined by the standard 'disc diffusion' method [23]. The bacteria and fungi were grown in nutrient agar and potato dextrose agar (PDA) plates respectively. The compounds to be tested were dissolved in DMF to a final concentration of 1% and soaked in filter paper discs of 5 mm diameter and 1 mm thickness. These filter papers were found to hold a quantity of 0.01 cm^3 solution. These discs were placed on the already seeded plates (of 0.1 ml of test organisms with an approximate density of 1×10^6 CFU/ml) and incubated at 28 ± 1 °C for 24 to 48 h. A clearing zone around the disc indicated the inhibitory activity of the compound on the organism.

The results of antibacterial and antifungal studies are given in Table 3. The majority of the complexes were found to be active against test organisms. Bis(1-*n*-butylamidino-*O*-methylurea)copper(II)chloride was found to have the highest activity against bacteria and fungi whereas the other complexes were moderate and less active. The studied complexes were found to be inactive against some organisms.

4. Conclusions

We have synthesized copper(II) complexes of the type $[Cu\ (1\text{-}Bu^nAAUH)_2]Cl_2$ ($1\text{-}Bu^nAAUH$ = 1-*n*-butylamidino-*O*-alkylurea and alkyl = methyl, ethyl, *n*-propyl, *i*-propyl, *n*-butyl, *i*-butyl). These complexes were characterized by elemental analyses, magnetic moments, conductivity measurements, electronic, IR and EPR studies. The important conclusion of the present investigations is the formation of binuclear species from its monomers in frozen DMF solutions as the complexes were cooled below 200 K. The presence of half-field signals $\Delta M_s = \pm 2$ with seven line hyperfine structure in the frozen solutions confirms the existence of the binuclear complex. Within the series, the formation of binuclear species increased from bis(1-*n*-butylamidino-*O*-methylurea)copper(II)chloride to bis(1-*n*-butylamidino-*O*-*n*-butyl/*i*-butylurea)copper(II)chloride. However, all the complexes were present as mononuclear species in MeOH. The trend in *g* value ($g_\parallel > g_\perp > 2.00$) suggested that the unpaired electron in the copper(II) ion is in the $d_{x^2-y^2}$ orbital. The optical and EPR studies indicated a nearly square planar geometry around the copper ion. The interionic distance r was estimated to be nearly 5.5 Å. Most of the complexes exhibited antibacterial and antifungal activity, however, bis(1-*n*-butylamidino-*O*-methyl urea)copper(II)chloride was found to be highly active.

Acknowledgments

The authors express their gratitude to Dr. V.K. Manchanda, Head, Radiochemistry Division for his

keen interest in this work. The authors thank Dr. A.R. Dhobale for recording photoacoustic spectra in the solid state. One of the authors (R.K. Hemakumar Singh) is grateful to Manipur University, Imphal for a leave grant.

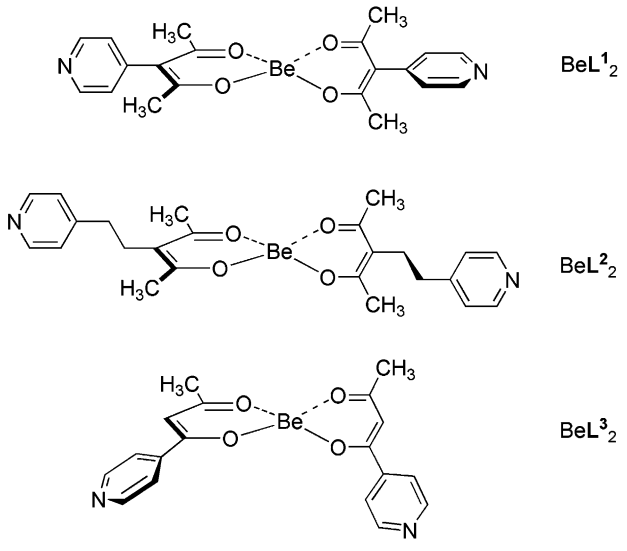
Fe(III) [12] metal ions by means of acetylacetonate chelation leading to neutral linear (BeL^1_2, CuL^1_2) or triangular (AlL^1_3, FeL^1_3) molecular complexes. The pyridyl termini of the building blocks could be easily involved in the formation of extended coordination frameworks with a variety of metal ions, such as Cu(I,II), Co(II) and Cd(II) [11,12]. Further modification of the tecton functionality is feasible by extension of the organic portion as well as varying the position of the pyridyl pendant on the diketonate frame, which may afford either linear or angular M–N binding directions (Scheme 1). In this paper, we report on the synthesis and structures of pyridyl functionalized beryllium diketonates and cadmium (zinc) heterometallic coordination polymers thereafter.



2. Results and discussion

Pyridyl functionalized beryllium diketonates exist as molecular complexes. Crystal structures $[BeL^1_2]_2 \cdot H_2O \cdot CH_3OH$ (**1**), BeL^2_2 (**2**) and BeL^3_2 (**3**) reveal the expected tetrahedral [BeO_4] environment of the central atom, with typical coordination geometry: the Be–O separations and ∠O–Be–O angles are uniform and lie within the ranges of 1.60–1.62 Å and 105–113°, respectively (Fig. 1). The solvated structure $[BeL^1_2]_2 \cdot H_2O \cdot CH_3OH$ (**1**) comprises of a finite supramolecular ensemble, in which association of two molecular [BeL^1_2] moieties occurs via hydrogen bonding, N···HOH···N between pyridyl–N sites and a water molecule (N(4)···O(9) 2.87, N(1)···O(9) 2.92 Å, Fig. 1(a)). The latter forms additional a relatively strong hydrogen bond with the methanol molecule (O(9)···O(10) 2.79 Å). All the molecular beryllium species retain the pyridyl–N donor functions that were not employed in the coordination and thus these compounds may be considered as potential "metalloligands" for the preparation of mixed-metal complexes. Actually linear molecules BeL^1_2 and BeL^2_2 involve side nitrogen atoms situated at 14 and 18 Å, respectively, and hence in combination with transition metal ions the pyridyl N-donors BeL^1_2 and BeL^2_2 could serve as monodentate or exobidentate ligands, bridging pairs of metal atoms at distances of ca. 18 and 23 Å, respectively. In view of the metalloligand geometry, tecton BeL^1_2 is relatively rigid rod-like linker, while evident geometric flexibility of the BeL^2_2 tecton is imposed by two ethylene "spacers" connecting the diketonate and pyridyl fragments. In the structure of BeL^2_2 (**2**), the latter both prefer to adopt an *anti*- conformation to each other (looking straight down the C–C bond of the aliphatic ethylene spacer), with a corresponding torsion angle C(3)–C(6)–C(7)–C(10) of −175° (Fig. 1(b)). Unlike these cases, the BeL^3_2 tecton adopts a geometrically rigid structure and orthogonal orientation of the two chelates at the tetrahedral Be^{2+} matrix dictates a nearly angular situation of the pyridyl groups, with a bite angle of ca. 110° (Fig. 1(c)). This angular configuration of the side pyridyl functions within the metalloligand BeL^3_2 is especially well suited for designing heterometallic squares or rhomboids, in combination with octahedral metal ions.

In the structure $[Cd\{BeL^1_2\}_2Cl_2] \cdot H_2O$ (**4**), the cadmium atom adopts a nearly tetrahedral coordination geometry with two chlorides and two N-coordinated beryllium tectons in the coordination sphere (Fig. 2, Table 1). The terminal uncoordinated pyridyl groups are involved in hydrogen bonding with the water molecule, N···HOH···N (N(2)···O(5) 2.92 Å, ∠O–H---N 158°), that provides a bridge between two molecular complexes, and the overall structure exists as a coordination/hydrogen bonded zig-zag polymer. The hydrogen bonding association is quite similar to that observed in the structure $[BeL^1_2]_2 \cdot H_2O \cdot CH_3OH$ (**1**).

The crystal structures of compounds **5**–**8** have several common features, presumably associated with a complementary shape form of BeL^1_2 tectons and their ability to afford tight antiparallel packing. The closest alignment of the extended organic molecules predetermines the simplicity of the resulting coordination patterns that exist in the form of linear chains and hence the cadmium (zinc) ion coordinates only two pyridyl nitrogen atoms, in *trans*-positions. Recently, we have discussed other examples of the intrinsic role of ligand–ligand packings for coordination geometries [11,13,14].

Thus, in structure $[Cd\{BeL^1_2\}(MeOH)(NO_3)_2] \cdot CHCl_3 0.5MeOH$ (**5**) the heptacoordinated Cd(II) ions are bridged axially by the bidentate linear BeL^1_2 tectons, leading to infinite 1D $[Cd\{BeL^1_2\}]_\infty$ chains. The other coordination sites of the cadmium are filled by oxygen

Scheme 1.

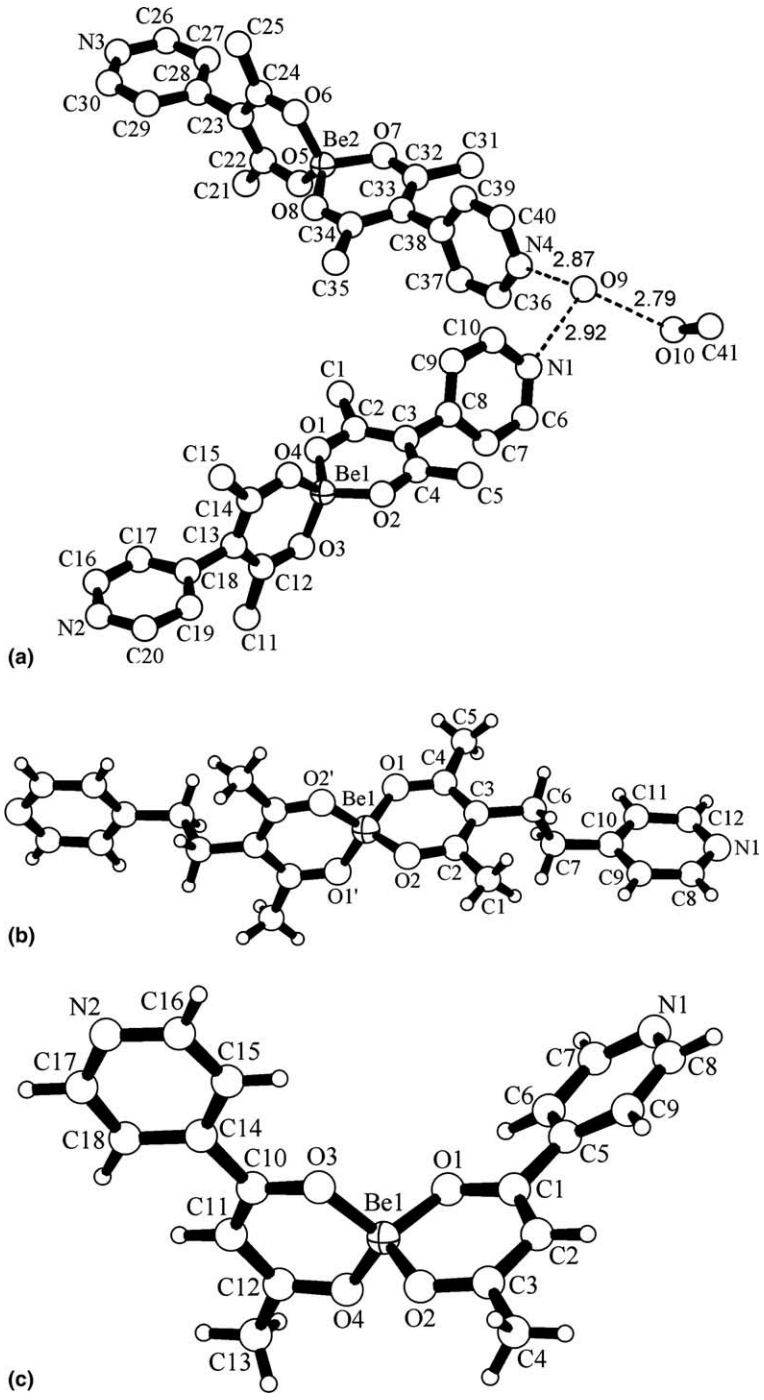


Fig. 1. Molecular structures of berillium diketonates: (a) three-component hydrogen bonded associate $[Be\mathbf{L}^{1}{}_{2}]_2 \cdot H_2O \cdot CH_3OH$ (**1**) (hydrogens are omitted for clarity); (b) $Be\mathbf{L}^{2}{}_{2}$ complex **2**; (c) $Be\mathbf{L}^{3}{}_{2}$ complex **3**.

atoms of two bidentate nitrates, bound in an almost symmetrical fashion, and a coordinated methanol molecule. Two neighbouring $[Cd\{Be\mathbf{L}^{1}{}_{2}\}]_\infty$ chains are held together, as double-chains, by means of hydrogen bondings between the coordinated methanol molecule and nitrate OH---O 1.93 Å; ∠OH---O 160°, Fig. 3(a). The two components consisting of the double-chain are packed tightly and the shortest separation between cadmium atoms of neighbouring chains is 6.07 Å. Such a close situation of the metal ions in the space effects the ease of their further interconnection by a suitable bridging anion, instead of the terminal nitrate in **5**.

This possibility for increasing the dimensionality of the structure was demonstrated by a cadmium thiocyanate complex $[Cd\{Be\mathbf{L}^{1}{}_{2}\}(NCS)_2] \cdot 0.5MeOH$ (**6**), a 2D layered structure which is supported by the bridging

function of the $Be\mathbf{L}^{1}_{2}$ tecton and typical *N*,*S*-thiocyanate bridges (Fig. 3(b)). Packing of successive $[Cd\{Be\mathbf{L}^{1}_{2}\}]_\infty$ chains is antiparallel with perfect complementary shape, while a pair of thiocyanate ions bridge the cadmium atoms of neigbouring chains. The octahedral environment of the cadmium atoms consists of two sulfur (2.76 Å) and four nitrogen atoms, the pyridyl–N donors are in *trans*-positions.

For two isostructural compounds $[M(H_2O)_4\{Be\mathbf{L}^{1}_{2}\}](ClO_4)_2$ (M = Zn **7**, Cd **8**) the higher dimensionality (3D) has been realized by means of hydrogen bonding involving coordinated water molecules of the linear $[M(H_2O)_4\{Be\mathbf{L}^{1}_{2}\}]_\infty$ chains and uncoordinated ClO_4^- anions (for **7**, OH---O 2.78 and 2.98 Å, ∠OH---O 155° and 172°, respectively, Fig. 4). The cadmium (zinc) ions coordinate two pyridyl–N donors in *trans*-positions and

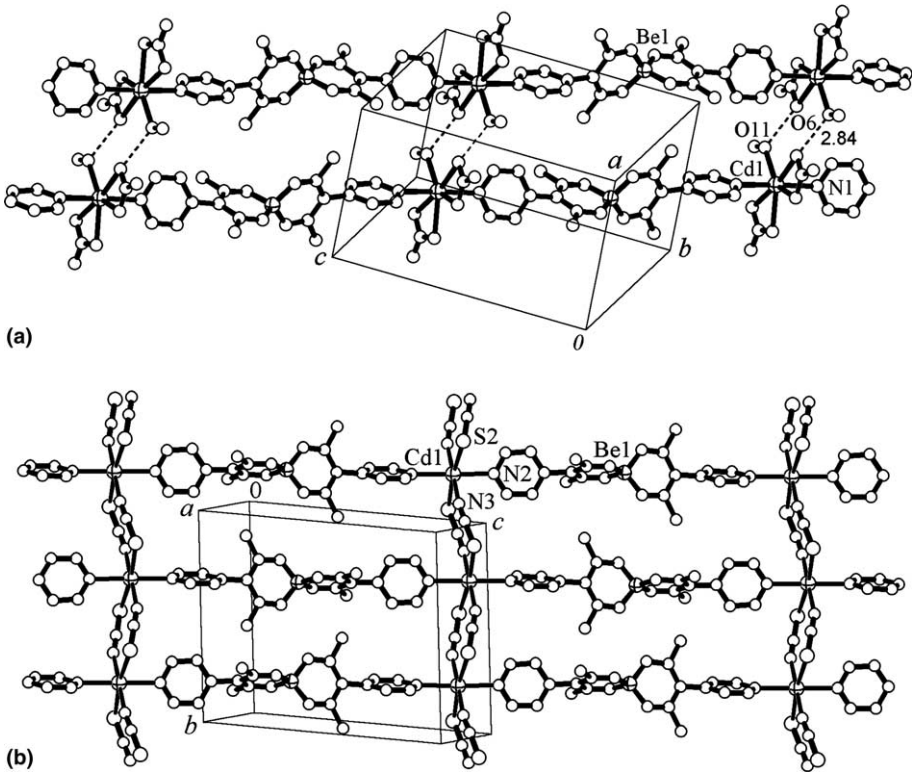

Fig. 3. (a) 1D coordination/H-bonded double-chain polymer $[Cd\{BeL^1_2\}(MeOH)(NO_3)_2]\cdot CHCl_3\cdot 0.5MeOH$ (**5**) involving heptacoordinated Cd(II) ions bridged axially by the bidentate linear BeL^1_2 tectons; two neighbouring chains are linked together by means of hydrogen bonding between a coordinated methanol molecule and nitrate; (b) View of the 2D layered structure $[Cd\{BeL^1_2\}(NCS)_2]\cdot 0.5MeOH$ (**6**) supported by the bridging function of the BeL^1_2 tecton and *N*,*S*-thiocyanate bridges.

four equatorial coordination sites are occupied by water molecules. Each perchlorate anion provides hydrogen bond bridging of two closely situated coordination chains (Fig. 4(b)). The result of this bonding is a simple 3D octahedral six-connected framework, in which a third of the links are BeL^1_2 coordination bridges and two thirds of the links are hydrogen bonded ClO_4^- ions. Two identical frameworks interpenetrate [15] without significant bonding interactions.

The structure of the heterobimetallic complex $[Cd_2\{BeL^2_2\}_3(MeOH)(NO_3)_3](NO_3)\cdot 4.5MeOH$ (**9**) is even more complicated (Table 2). Each cadmium ion coordinates three pyridyl–N groups adopting a typical T-shape CdN_3 geometry. Within the $Cd/\{BeL^2_2\}$ portion, total interconnection of these T-shape blocks results in the generation of a 2D "bilayer" architecture (Fig. 5). The latter is one of seven known supramolecular isomers of $[M_2L_3]$ polymers involving bitopic bridging ligands [16–20] and has also been reported for related systems with 1,2-bis(4-pyridyl)ethane [21]. One of the two unique cadmium atoms shows characteristic seven-fold coordination completed with two bidentate nitrate ligands [16,22,23] while coordination of Cd(1) is slightly unusual and involves the methanol molecule and two bridging nitrate groups (Fig. 5(a) and (b)). This situation is remarkable: extended BeL^2_2 tectons bridge pairs of cadmium atoms at large distances of 23 Å and alignment of the Cd–$\{BeL^1_2\}$–Cd fragments is dominated by the demands of the shape-complementary packing of the organic portion, similarly to the above systems. Thus, the close situation of the Cd(1) centers, at 5.12 Å, is a prerequisite effecting unusual double nitrate bridging. These bridges connect the $[Cd_2\{BeL^2_2\}_3]$ bilayers pairwise in a fashion shown in Fig. 5, yielding a double bilayer supporting large interval voids. The overall 3D supramolecular structure is generated by interpenetration of successive double bilayers in the crystal.

The metalloligand BeL^3_2 has a rigid molecular structure supporting angular binding directions of pyridyl–N donors and offers a synthetic strategy for construction of supramolecular squares in combination either with octahedral or tetrahedral metal centers. The cadmium ion in $[Cd\{BeL^3_2\}_2I_2]\cdot 2CHCl_3$ (**10**) adopts a nearly octahedral coordination polyhedron including four pyridyl nitrogen atoms in the equatorial plane and two iodides in axial positions. This affords formation of 1D chains of heterometallic sharing Cd-vertices. Each square provides an internal cage of about 3.6×3.0 Å size, well suited for housing a guest chloroform molecule. The latter is situated exactly inside the square and disordered over two overlapping positions related by inversion (Fig. 6).

An additional set of guest molecules is located between the coordination chains.

3. Conclusion

The work demonstrates the potential of pyridyl functionalized diketonate ligands for construction of heterobimetallic coordination polymers. Molecular beryllium diketonate species provide an easy access to the family of extended N-donor bridges with tuneable effective length and geometry. Increasing the structure's dimensionality could be provided by bridging counteranions (SCN^-) or by partial hydrogen bonding. The crystal packing patterns observed for the complexes are essentially influenced by shape complementarity of the molec-

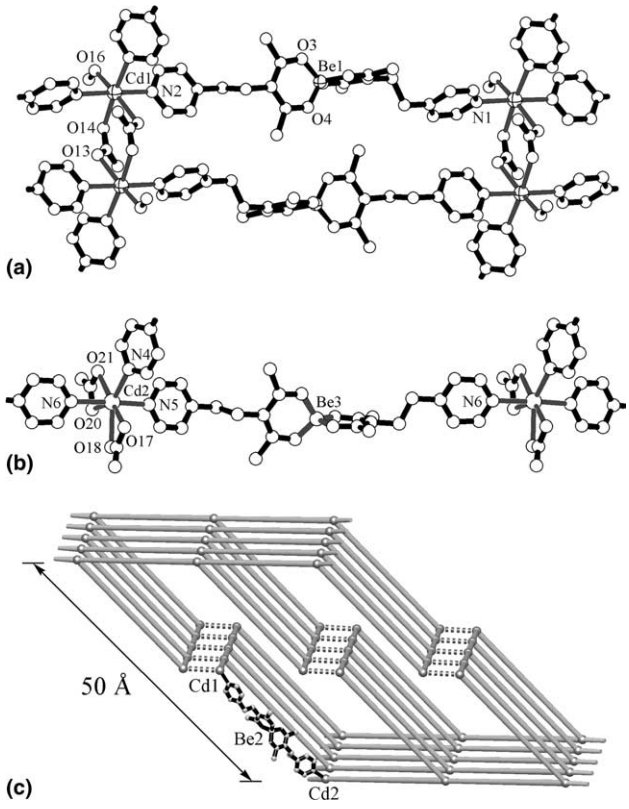

Fig. 5. Two types of coordination environment of cadmium atoms in structure $[Cd_2\{BeL^2_2\}_3(MeOH)(NO_3)_3](NO_3)\cdot 4.5MeOH$ (**9**) involving the characteristic T-shape CdN_3 motif: (a) pairs of bridging nitrate groups connect Cd/Be coordination topologies. Note the closest situation of shape-complementary BeL^2_2 tectons; (b) heptacoordination of Cd(2) ions completed with two bidentate nitrate groups; (c) overall 2D "double bilayer" topology of the coordination network in **9**; broken lines represent double nitrate bridging that connects two separate Cd/Be bilayers.

ular beryllium diketonate blocks. Beryllium diketonate supporting angular orientation of pyridyl–N functions offers a potential for the generation of metal-organic squares and their integration into polymeric superstructures.

4. Experimental

4.1. Reagents and general procedures

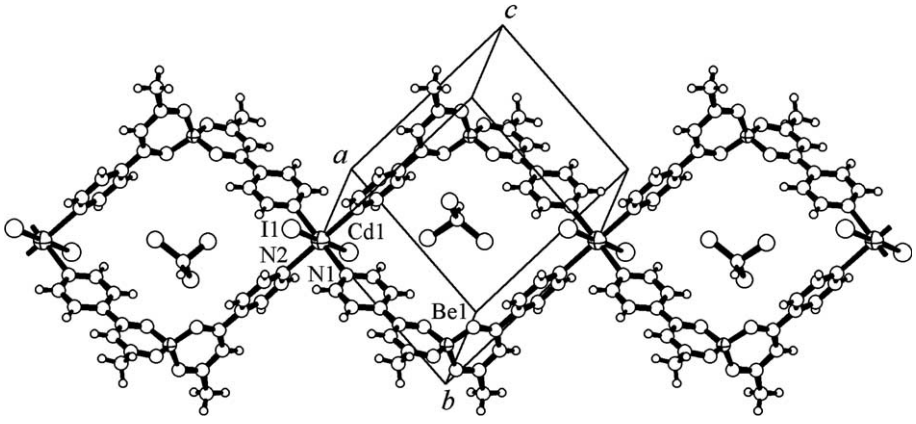
Compounds HL^1 [24], HL^3 [25] and BeL^1_2 [11] were prepared according to the literature procedures. All chemicals used were of reagent grade. Absolute ethanol was freshly distilled from Mg ethoxide.

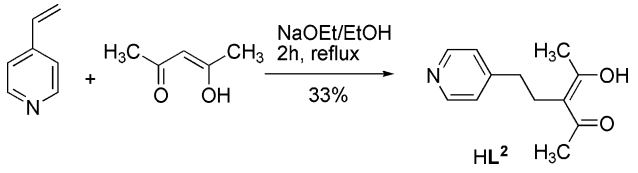
The IR spectra were recorded on a UR-10 (Carl Zeiss, Jena) spectrometer in the range 4000–400 cm^{-1}. Samples were prepared as KBr pellets. ^1H NMR (400 MHz) spectra were recorded in $CDCl_3$.

4.2. Synthesis of β-diketones, beryllium and heterobimetallic complexes

The synthetic methods for the preparation of pyridyl functionalized β-diketones HL^1, HL^2 and HL^3 are diverse. HL^1 has been prepared by acylation of 4-picoline [24], while HL^3 has been synthesized by means of the Claisen condensation [25]. Compound HL^2 has been described in a patent [26]. Insertion of the 4-pyridylethylene group into an acetylacetone fragment was achieved by the Michael addition. Treatment of Hacac, 4-vinylpyridine (taken in excess) in the presence of NaOEt at reflux for 2 h followed by a work-up procedure afforded the product HL^2 in 33% yield (Scheme 2).

The target molecular beryllium diketonates were readily prepared in moderate yields of up to 62% according to Scheme 3. The compounds are colorless crystalline solids, which are well soluble in common organic solvents such as methanol, $CHCl_3$, CH_2Cl_2 and poorly soluble in water. Single crystals of $[BeL^1_2]_2\cdot H_2O\cdot CH_3OH$, BeL^2_2 and BeL^3_2 suitable for





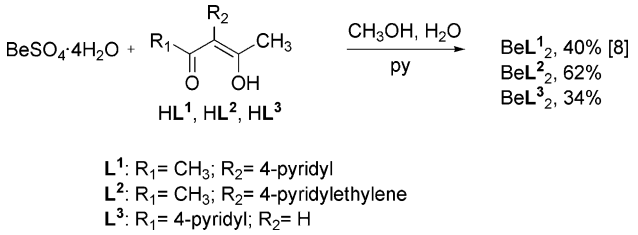


Fig. 6. 1D chain of supramolecular squares sharing Cd-vertices in the structure of $[Cd\{BeL^3_2\}_2I_2]\cdot 2CHCl_3$ (**10**), supported by octahedral cadmium centers and angular N-donor BeL^3_2 bridges. Each rectangular cavity has inner dimensions of 3.6×3.0 Å and is populated with a guest chloroform molecule.

Scheme 2.

Scheme 3.

X-ray analysis were obtained by slow evaporation of methanolic solutions.

4.2.1. 3-(4-Pyridylethylene)-2,4-pentanedione, HL^2

Following a general procedure [27], acetylacetone (28.5 g, 0.285 mol) was added to a solution of NaOEt (1.09 g [0.047 mol] Na in 19 mL of absolute ethanol) leading to the formation of a white precipitate. The mixture was heated to reflux (oil bath temperature ~115 °C). To the boiling solution freshly distilled 4-vinylpyridine (15.0 g, 0.142 mol) in 5 mL of absolute ethanol was added over 15 min. The slightly yellow solution was stirred under reflux for 2 h. Ethanol was removed in vacuum and the residue was acidified with diluted HCl to pH 7–8, leading to precipitation. The resultant mixture was kept in a refrigerator overnight (−10 °C) and then water (300 mL) was added. The aqueous solution was extracted with $CHCl_3$ (3 × 100 mL). The organic layer was dried over Na_2SO_4 and the solvent was removed. The residue was distilled in a vacuum, yielding 9.63 g (33%) of a yellowish oil, which was solidified in a refrigerator (b.p. 153–168 °C/1 mm). ^1H NMR ($CDCl_3$) is complicated due to keto-enol tautomerism of the compound: δ, 2.07 (s), 2.18–2.20 (bs), 2.40–2.75 (bm), 3.61–3.65 (m), 7.12–7.16 (m), 7.19–7.22 (m), 8.48–8.52 (m), 16.81 (s).

4.2.2. Bis-[3-(4-pyridylethylene)-2,4-pentanedione]-beryllium, BeL^2_2

A solution of $BeSO_4 \cdot 4H_2O$ (0.886 g, 5.00 mmol) in 6.5 mL H_2O was slowly added to a solution of HL^2 (2.28 g, 11.1 mmol) and pyridine (810 μL) in CH_3OH/H_2O (11.5 mL, 10.5:1) over 5 min. The resultant solution was stirred at r.t. for 10 min and then 15 mL water was added dropwise. A colorless precipitate of the complex was formed spontaneously after 10–15 min stirring. The solid was filtered off, washed with cold CH_3OH/H_2O (5 mL, 1:3) and dried. The yield was 1.30 g (62%). IR (cm^{-1}) 3080w, 3000w, 2980w, 2935w, 1585s, 1480s, 1430m, 1380s, 1315m, 1290w, 1280w, 1230w, 1190m, 1160w, 1025m, 990m, 915w, 870s, 850s, 805m, 775w, 750w, 720w, 665w, 570w, 520m, 465w; ^1H NMR ($CDCl_3$) δ 2.19 (s, 12H), 2.57–2.63 (m, 4H), 2.73–2.79 (m, 4H), 7.21 (d, J = 6.0 Hz, 4H), 8.55 (d, J = 6.0 Hz, 4H).

4.2.3. Bis-[1-(4-pyridyl)-1,3-butanedione]beryllium, BeL^3_2

A solution of $BeSO_4 \cdot 4H_2O$ (3.30 g, 18.6 mmol) in 10 mL H_2O was slowly added to a solution of HL^3 (6.10 g, 37.4 mmol) and pyridine (1.5 mL) in CH_3OH (20 mL) over 30 min. The precipitate was filtered off and washed with water (3 × 30 mL). The solid was recrystallized with 2-propanol/$CHCl_3$, affording the crystalline product (2.10 g, 34%). IR (cm^{-1}) 3050w, 2920w, 1590s, 1555s, 1540s, 1520s, 1495s, 1420s, 1395s, 1370s, 1325s, 1230w, 1215m, 1120m, 1030s, 995w, 980m, 870w, 850m, 825s, 795m, 780m, 760m, 710w, 690w, 670w, 615w, 585w, 545m, 525w, 515w, 465w, 445w; ^1H NMR ($CDCl_3$) δ 2.32 (s, 6H), 6.40 (s, 2H), 7.83 (d, J = 6.0 Hz, 4H), 8.75 (d, J = 6.0 Hz, 4H).

Coordination compounds $[Cd\{BeL^1_2\}_2Cl_2] \cdot H_2O$ (**4**), $[Cd\{BeL^1_2\}(NCS)_2] \cdot 0.5MeOH$ (**6**) and $[Cd\{BeL^3_2\}_2I_2] \cdot 2CHCl_3$ (**10**) were obtained by using a layering technique, in yields up to 20%, 73% and 68%, respectively. In a typical synthesis, a solution of the metal salt (0.10 mmol) in MeOH (or MeOH/H_2O for **4**) was layered over a solution of BeL^1_2(BeL^3_2) (0.10 mmol) in $CHCl_3$/MeOH. Slow interdiffusion of the layers within ca. two weeks afforded crystallization of the heterobimetallic complex.

Crystals of **5**, **7**–**10** suitable for single crystal X-ray structural analysis were grown by the partial evaporation of the solvent from a solution of the compounds in a mixture of chloroform and methanol at r.t. over a 5–7 day period.

4.2.4. $[Cd\{BeL^1_2\}(MeOH)(NO_3)_2] \cdot CHCl_3 \cdot 0.5MeOH$ (5)

Solutions of BeL^1_2 (36 mg, 0.10 mmol) in $CHCl_3$/MeOH (1 mL, 4:1) and $Cd(NO_3)_2 \cdot 4H_2O$ (30 mg, 0.097 mmol) in 1 mL MeOH were combined. The resulting mixture was filtered off and the filtrate was left for 2 days to afford colorless crystals of the compound (49 mg, 66%). $[Cd_2\{BeL^2_2\}_3(MeOH)(NO_3)_3](NO_3) \cdot 4.5MeOH$ (**9**) was obtained similarly in 44% yield.

4.2.5. $[Zn\{BeL^1_2\}(H_2O)_4](ClO_4)_2$ (7)

Solutions of BeL^1_2 (36 mg, 0.10 mmol) in $CHCl_3$/MeOH (2 mL, 4:1) and $Zn(ClO_4)_2 \cdot 6H_2O$ (37 mg, 0.099 mmol) in 2 mL MeOH were combined and the mixture was left for 7 days to afford colorless platelets of the complex (28 mg, 40%). $[Cd\{BeL^1_2\}(H_2O)_4](ClO_4)_2$ (**8**) was prepared in a similar fashion in 50% yield.

Most of the heterobimetallic coordination polymers readily lose the incorporated guest molecules of the solvents (MeOH, $CHCl_3$) in air within minutes, with loss of crystallinity and disintegration of the structure. Pyridylacetylacetone coordination polymers **4**–**8** also slowly decompose under mother solutions.

4.3. Crystal structure determination

Crystallographic measurements for compounds **1**–**10** were made using a Siemens SMART CCD area-detector three-circle diffractometer (Graphite monochromated Mo Kα radiation, $\lambda = 0.71073$ Å, exposure time was 30–40 s per frame). The data frames were integrated using SAINT and empirical absorption corrections (SADABS) were employed. The structures were solved by direct methods and refined by full-matrix least-squares techniques in anisotropic approximations using SHELXS-86 and SHELXL-97 [28,29]. In structures **2**–**4** and **7**, the hydrogen atoms were located from the difference-Fourier syntheses and refined isotropically. In the other cases the positions of the hydrogen atoms were idealized and included in the calculations with their isotropic U values set invariant at 0.08 Å^2 (**1**, **8**) or at 1.2 times the level with respect to the U_{eq} values of the corresponding carbon atom. Hydrogen atoms of non-coordinated solvate methanol molecules were not added. In **7**, the perchlorate anions are disordered over two closely situated positions with partial contributions of 0.82 and 0.18; structures **5** and **6** shows equal disordering of solvate methanol molecules and in structure **10** both unique chloroform molecules are equally disordered over two overlapping positions related by inversion. The refinement proceeded smoothly and therefore it was possible to refine the atoms of disordered groups anisotropically. In structure **9** one of the solvate methanol molecules lies at a center of inversion and thus both carbon and oxygen atoms, which are related by symmetry, were refined as carbon atoms. Crystal data are given in Table 3.

Abstract

In the presence of air, the interaction of $AgSO_3CF_3$ with phosphorus–nitrogen π-electron-rich compounds $ArC(=NPPh_2)[N(SiMe_3)_2]$ (Ar = phenyl, *p*-tolyl, 4-pyridyl, 3-pyridyl and 2-pyridyl) and $1,4\text{-}C_6H_4\{C(=NPPh_2)[N(SiMe_3)_2]\}_2$ in acetonitrile led to the formation of metallic silver and the oxidative cleavage product $\{[ArC(NH_2)_2](Ph_2PO_2)\}_n$ (Ar = phenyl, **1**; *p*-tolyl, **2**; 4-pyridyl, **3**; 3-pyridyl, **4**; 2-pyridyl, **5**) and $[\{1,4\text{-}C_6H_4[C(NH_2)_2]_2\}(Ph_2PO_2)_2]_n$ (**6**), respectively. Structural analyses of compounds **1**–**6** revealed that these ionic salts are held together by charge-assisted hydrogen bonds forming 1D, 2D and 3D polymeric networks.

1. Introduction

The construction of polymeric networks is an intensive research area within the realm of supramolecular chemistry because of their potential uses in materials science [1]. The molecular design, synthesis and structure of supramolecular polymeric networks depend strongly on the properties of the building blocks and the strength and directional characteristics of the interactions among these components. The proper disposition of connections leads to the formation of infinite assemblies in the solid state. Generally, the types of construction blocks for supramolecular polymers can be divided into three main groups, the first one involving their components being held together by hydrogen bonds, the second by coordination bonds, and the third by electrostatic forces. Hydrogen bonds that are cooperative with electrostatic forces are known as charge-assisted hydrogen bonds. Many examples of self-assembled coordination polymers which contain a nanotube [2], cage [3], core [4], cyclic ring [5] or helix [3,6,7] in their networks and of multiple hydrogen-bonded complexes [7–9] have been reported.

There are fewer examples in which the components are held together by charge-assisted hydrogen bonds. The use of the diprotonated 4,4′-bipyridine as a hydrogen bond donor unit and $[MCl_n]^{m-}$ (M = Pd, Pt, Zn, Mn, Os, Fe) as an acceptor to form several polymeric molecular networks has been designed and reported by Orpen [10]. A similar strategy has also been applied to the formation of infinite networks using $PtCl_4^{2-}$ and 4,4′-bis(piperidinium) derivatives [11]. Brammer reported a similar design to produce polymeric supramolecular networks by various platinum chloride and 1,4-diazabicyclooctane [12]. Burrows used guanidinium and sulfonated phosphane to form a charge-assisted hydrogen-bonded layer structure [13]. Hosseini and coworkers have successfully employed the bis(amidinium) dication in the construction of 1D charge-assisted

doi:10.1016/j.poly.2005.02.020

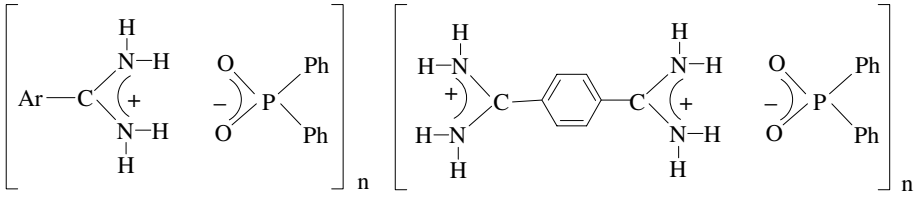
polymeric chains and some of them are connected by hydrogen bonds to form 2D networks [14]. They also used a dication and a metal-containing anion to build 1D, 2D and 3D metal-containing electrostatic supramolecular polymers [15].

We are interested in the preparation and structure of organic supramolecular polymers in which the components are linked together strongly by charge-assisted hydrogen bonds. The strategy to the design of these organic crystals was based on the iterative assembly processes between complementary units that are held together simultaneously by strong but less directional electrostatic forces along with weak but directional hydrogen bonds. Much research work by Hosseini's group [14] has shown that the diprotonated bis(amidinium) dication provides four acidic N–H protons pointing outwards and the dicarbonylate dianion provides four oxygens for the hydrogen bonding. Since every two protons are fixed on the same side of the skeleton, the cation is capable of forming a di-hapto mode of interaction, which results in a 1D arrangement with the anions.

In order to develop 2D and 3D organic molecular networks, tri- or multi-hapto modes of hydrogen bonding interaction is the key factor. Arylamidinium cations of compounds **1**–**5** that can provide four acidic N–H protons pointing outwards and are thus capable of producing four hydrogen bonds in a tetra-hapto mode of interaction seemed to be an appropriate candidate of choice. Moreover, the diprotonated dication of compound **6** contributes eight N–H hydrogen bonds in an octa-hapto mode of interaction (Chart 1). The anion of compounds **1**–**6**, diphenylphosphinate, can offer oxygen atoms as acceptors to form hydrogen bonds with three cations among **1**–**6**.

2. Experimental

2.1. General procedures



Unless otherwise stated, the reactions were carried out under nitrogen atmosphere in flamed Schlenk-type glassware on a dual manifold Schlenk line. Solvents were pre-dried. All chemicals used were of reagent grade, obtained from Aldrich or Fisher Scientific Chemical Company. NMR spectra were measured in appropriate solvents on a Varian INOVA 400 MHz FT-NMR spectrometer. Fast atom bombardment (FAB) mass spectra were recorded on a Finnigan MAT SSQ710 mass spectrometer and electrospray ionization high-resolution mass spectra (ESI-HRMS) were performed on a quadrupole-time of flight (Q-TOF) mass spectrometer equipped with a turbo ionspray source (PE SCIEX API QSTAR Pulsar i, Applied Biosystem). The IR spectra were recorded using KBr pellets on Perkin–Elmer Paragon 1000PC or Nicolet Nagan-IR 550 Series II FTIR spectrometers, and excitation and fluorescence spectra on a Photon Technology International (PTI) Alphascan spectrofluorimeter. Elemental analyses were performed by the Shanghai Organic Institute of the Chinese Academy of Sciences and Shanxi University.

2.2. Preparation of phenylamidinium diphenylphosphinate (*1*)

$AgSO_3CF_3$ (0.26 g, 1.00 mmol) in acetonitrile (30 ml) was added to a solution of $PhC(=NPPh_2)[N(SiMe_3)_2]$ (0.45 g, 1.00 mmol) in THF (10 ml). Upon stirring the solution in air at room temperature for 2 h, black metallic silver was observed. The reaction mixture was then filtered. The filtrate was allowed to evaporate slowly in air at room temperature to give colorless crystals of **1**. Yield: 0.23 g, 69%, m.p. 266–267 °C. ESI-HRMS (in methanol, positive mode): *m/z* positive mode, 121.0768 ($[PhC(NH_2)_2]^+$, $C_7H_9N_2$ requires 121.0765); negative mode, 217.0422 ($[Ph_2PO_2]^-$, $C_{12}H_{10}O_2P$ requires 217.0418). ^{31}P-{^1H} NMR (DMSO-d_6): δ 16.8 (s). ^1H NMR (DMSO-d_6): δ 7.30 (m, 6H, Ph), 7.56–7.78 (m, 9H, Ph), 9.01 (br m, 2H, NH_2), 11.12 (br m, 2H, NH_2).

2.3. Preparation of p-tolylamidinium diphenylphosphinate (*2*)

Compound **2** was produced using the same reaction conditions and procedures as for **1**. $AgSO_3CF_3$ (0.21 g, 0.82 mmol) and $(4\text{-}MeC_6H_4)C(=NPPh_2)[N(SiMe_3)_2]$ (0.38 g, 0.82 mmol) were used. Yield: 0.24 g, 83%, m.p. 284–285 °C. ^1H NMR (DMSO-d_6): δ 2.38 (s, 3H, CH_3), 7.29–7.31 (m, 6H, Ar), 7.38 (d, J = 8.0 Hz, 2H, Ar),

ESI-HRMS (in methanol): *m/z* positive mode, 135.0913 ($[(4\text{-}MeC_6H_4)C(NH_2)_2]^+$, $C_8H_{11}N_2$ requires 135.0922); negative mode, 217.0399 ($[Ph_2PO_2]^-$, $C_{12}H_{10}O_2P$ requires 217.0418). IR (cm^{-1}, in KBr): 3147bs, 2921bs, 1705m, 1614m, 1593m, 1559m, 1488m, 1437m, 1131s, 1070w, 1038s, 1018s, 999m, 822m, 720s, 698m, 555s.

2.4. Preparation of 4-pyridylamidinium diphenylphosphinate (3)

The synthesis of compound **3** followed the same procedures as for **1**. $AgSO_3CF_3$ (0.26 g, 1.00 mmol) and $(4\text{-}NC_5H_4)C(=NPPh_2)[N(SiMe_3)_2]$ (0.45 g, 1.00 mmol) were used. Yield: 0.25 g, 75%, m.p. 241–242 °C. *Anal.* Calc. for $C_{18}H_{18}N_3O_2P \cdot 0.25H_2O$: C, 62.88; H, 5.38; N, 12.23. Found: C, 62.83; H, 5.50; N, 8.55%. ESI-HRMS (in methanol): *m/z* positive mode, 122.0714 ($[4\text{-}NC_5H_4C(NH_2)_2]^+$, $C_6H_8N_3$ requires 122.0718); negative mode, 217.0422 ($[Ph_2PO_2]^-$, $C_{12}H_{10}O_2P$ requires 217.0418). ^{31}P-{^1H} NMR (DMSO-d_6): δ 17.2 (s). ^1H NMR (DMSO-d_6): δ 7.35 (m, 5H, Ar), 7.66–7.73 (m, 7H, Ar), 8.84 (m, 2H, Ar), 9.38 (br m, 2H, NH_2), 10.34 (br m, 2H, NH_2). 2.5. Preparation of 3-pyridylamidinium diphenylphosphinate (4)

Compound **4** was prepared similarly. $AgSO_3CF_3$ (0.26 g, 1.00 mmol) and $(3\text{-}NC_5H_4)C(=NPPh_2)[N(SiMe_3)_2]$ (0.45 g, 1.00 mmol) were used. Yield: 0.26 g, 76.7%, m.p. 249–250 °C. ESI-HRMS (in methanol): *m/z* positive mode, 122.0725 ($[3\text{-}NC_5H_4C(NH_2)_2]^+$, $C_6H_8N_3$ requires 122.0718); negative mode, 217.0427 ($[Ph_2PO_2]^-$, $C_{12}H_{10}O_2P$ requires 217.0418). ^{31}P-{^1H} NMR (DMSO-d_6): δ 17.0 (s). ^1H NMR (DMSO-d_6): δ 7.31 (d, $J = 1.2$ Hz, 6H, Ar), 7.59–7.63 (m, 1H, Ar), 7.65–7.69 (m, 4H, Ar), 8.16 (d, $J = 8$ Hz, 1H, Ar), 8.82–8.84 (m, 1H, Ar), 8.93 (d, $J = 1.2$ Hz, 1H, Ar), 9.16 (br, m, NH_2), 11.22 (br, m, NH_2). ^{13}C NMR (DMSO-d_6): δ 123.8, 125.8, 127.6, 127.7 129.2, 131.0, 131.1, 136.0, 141.2, 142.5, 148.5, 153.7, 164.3. IR (cm^{-1}, in KBr): 3140bs, 2923bs, 1711m, 1597m, 1529w, 1472m, 1436m, 1420m, 1130vs, 1037s, 1016s, 866m, 825m, 757m, 721s, 700s, 561s.

2.6. Preparation of 2-pyridylamidinium diphenylphosphinate (5)

Compound **5** was also prepared in a similar manner. $AgSO_3CF_3$ (0.23 g, 0.89 mmol) and $(2\text{-}NC_5H_4)C(=NPPh_2)[N(SiMe_3)_2]$ (0.40 g, 0.89 mmol) were used. Yield: 0.22 g, 73%, m.p. 246–247 °C. ESI-HRMS (in methanol): *m/z* positive mode, 122.0712 ($[2\text{-}NC_5H_4C(NH_2)_2]^+$, $C_6H_8N_3$ requires 122.0718); negative mode, 217.0410 ($[Ph_2PO_2]^-$, $C_{12}H_{10}O_2P$ requires 217.0418). ^{31}P-{^1H} NMR (DMSO-d_6): δ 17.0 (s). ^1H NMR (DMSO-d_6): δ 7.29–7.31 (m, 6H, Ar), 7.66–7.71 (m, 4H, Ar), 7.73–7.77 (m, 1H, Ar), 8.09–8.13 (m, 1H, Ar), 8.20–8.22 (m, 1H, Ar), 8.79–8.81 (m, 1H, Ar), 9.30 (br m, NH_2), 11.10 (br m, NH_2). ^{13}C NMR (DMSO-d_6): δ 123.0, 127.6, 127.8, 128.3, 129.3, 129.3, 131.0 131.1, 138.4, 141.1, 142.3, 144.8, 149.9, 162.2. IR (cm^{-1}, in KBr): 3182bs, 2948bs, 1711m, 1591w, 1571w, 1529w, 1462m, 1436m, 1177s, 1130vs, 1042s, 1022s, 1001s, 861w, 809w, 721s, 706m, 555s.

2.7. Preparation of 1,4-phenylenediamidinium diphenylphosphinate (6)

Compound **6** was similarly prepared. $AgSO_3CF_3$ (0.26 g, 1.00 mmol) and $1,4\text{-}C_6H_4\{C(=NPPh_2)[N(SiMe_3)_2]\}_2$ (0.41 g, 0.50 mmol) were used. Yield: 0.23 g, 77%, m.p. 289–290 °C. ESI-HRMS (in methanol): *m/z* positive mode, 82.0522 ($\{1,4\text{-}C_6H_4[C(NH_2)_2]_2\}^{2+}$, half of $C_8H_{12}N_4$ requires 82.0525); negative mode, 217.0422 ($[Ph_2PO_2]^-$, $C_{12}H_{10}O_2P$ requires 217.0418). ^{31}P-{^1H} NMR (DMSO-d_6): δ 16.8 (s). ^1H NMR (DMSO-d_6): δ 7.31 (m, 11H, Ar), 7.65–7.70 (m, 9H, Ar), 7.93 (m, 4H, Ar), 9.18 (br m, 2H, NH_2), 11.46 (br m, 2H, NH_2). IR (cm^{-1}, in KBr): 3347bs, 3171bs, 2964m, 1674s, 1550s, 1441s, 1405m, 1265s, 1089bs, 845s, 700s, 545s.

2.8. X-ray crystallography

Crystals of **1**, **2**, $\mathbf{3} \cdot CH_3CN$, $\mathbf{4} \cdot 0.5THF$, **5** and $\mathbf{6} \cdot 2H_2O$ suitable for X-ray diffraction were grown by slow evaporation of each respective solution of these compounds in air. The intensity data were collected with a Bruker AXS SMART 1000 CCD area-detector diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 293 K. The collected frames were processed with the proprietary software SAINT [16] and an absorption correction was applied (SADABS [17]) to the collected reflections. The structures of these molecules were solved by direct methods and expanded by standard difference Fourier syntheses using the software SHELXTL [18]. Structure refinements were made on F^2 using the full-matrix least-squares technique. All non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were placed in their idealized positions and allowed to ride on the respective carbon atoms. Pertinent crystallographic data and other experimental details are summarized in Table 1.

3. Results and discussion

3.1. Synthesis and structural characterization

Phosphorus–nitrogen compounds are π-electron-rich compounds and potential precursors for inorganic polymers with unusual properties. This led to considerable interest in the syntheses of phosphorus–nitrogen compounds and their coordination chemistry towards transition metals. We have synthesized a series of phosphorus–nitrogen ligands (**L**^{1}–**L**^{6} in Scheme 1) and studied their coordination chemistry towards transition metals of Group VI, VII, VIII and X. We also intended to further explore their coordination chemistry towards Group XI metals. However, in the presence of air, the interaction of $AgSO_3CF_3$ with phosphorus–nitrogen π-electron-rich compounds [19] $ArC(=NPPh_2)[N(SiMe_3)_2]$ (Ar = phenyl, *p*-tolyl, 4-pyridyl, 3-pyridyl and 2-pyridyl) and 1,4-$C_6H_4\{C(=NPPh_2)[N(SiMe_3)_2]\}_2$ in acetonitrile led to the formation of metallic silver and the oxidative cleavage product $\{[ArC(NH_2)_2](Ph_2PO_2)\}_n$ (Ar = phenyl, **1**; *p*-tolyl, **2**; 4-pyridyl, **3**; 3-pyridyl, **4**; 2-pyridyl, **5**) and $[\{1,4\text{-}C_6H_4[C(NH_2)_2]_2\}(Ph_2PO_2)_2]_n$ **6**, respectively (Scheme 1). To elucidate the mechanism of the oxidative cleavage process, the reaction of Ag(I) with ligand **L**^{3} was monitored by ^{31}P NMR spectroscopy. Under oxygen free conditions, upon the addition of excess $AgSO_3CF_3$ to a solution of **L**^{3} in CH_2Cl_2, the ^{31}P NMR

resonance of $\mathbf{L^3}$ at δ 36.5 disappeared completely within 10 min and a new broad singlet appeared at δ 46.1, which was the only ^{31}P signal observable in the reaction mixture. This downfield shift of the ^{31}P resonance of the ligand indicated the formation of a Ag(I) phosphine complex. The new resonance at δ 46.1 persisted in solution and no new resonance was observed even after 5 h. However, as soon as a solution of the Ag(I) phosphine complex was exposed to air, metallic silver was precipitated out from the solution, and a resonance at δ 16.8 corresponding to $(Ph_2PO_2)^-$ anion appeared in the resultant ^{31}P NMR spectrum. Oxidative cleavage of the N–P bond of $ArC(=NPPh_2)[N(SiMe_3)_2]$ to $(Ph_2PO_2)^-$ by a transition metal complex has been observed previously [20]. In fact, the P–N ligands, when dissolved in solution, would slowly be oxidized by air to give the corresponding ionic salt via oxidative cleavage. For instance, when a solution of $\mathbf{L^1}$ in CH_2Cl_2 was exposed to air, the ^{31}P NMR spectrum showed that

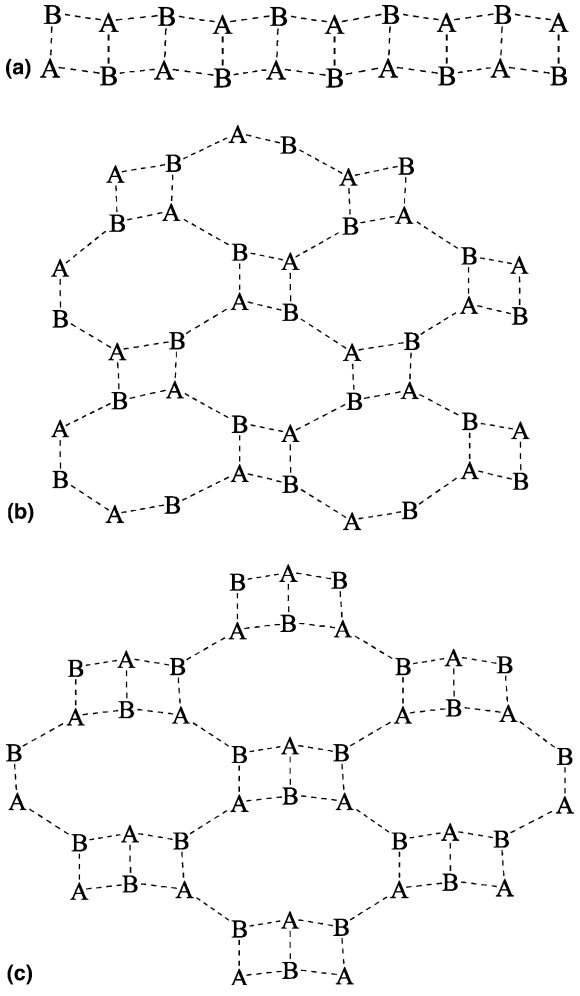

Fig. 1. Schematic diagrams showing the arrangements of cations and anions for (a) **1** and **2**, (b) **3** and **4**, and (c) **5**, where **A** is the cation and **B** the anion.

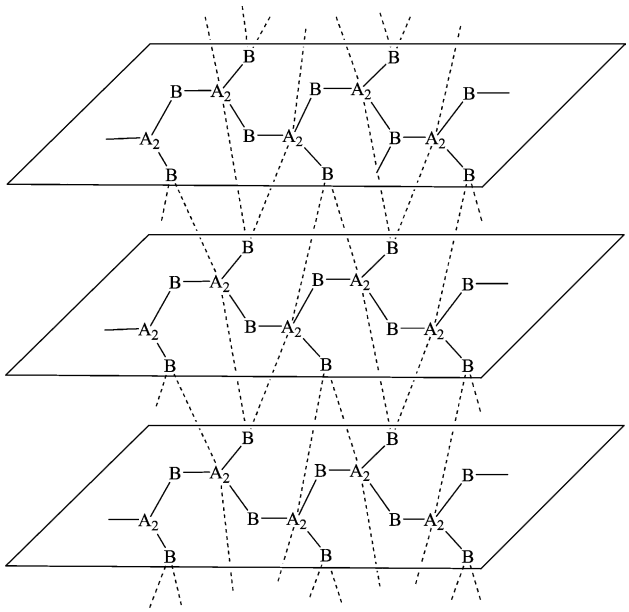

Fig. 2. Schematic diagram showing the arrangement of cations and anions for **6**, where $\mathbf{A_2}$ is the dication and **B** the anion.

a peak corresponding to the $(Ph_2PO_2)^-$ anion slowly appeared in about 24 h with the formation of a white precipitate, which was confirmed to be compound **1** by NMR (^1H and ^{31}P), MS (FAB, both positive and negative modes) and X-ray crystallography. The oxidative cleavage of $\mathbf{L^1}$ to **1** by air was very slow and took more than a week to complete. This suggested that Ag(I) assisted and accelerated the oxidative cleavage process and a Ag(I) phosphine complex intermediate was involved in the process. Attempts to isolate and characterize the Ag(I) intermediate are as yet unsuccessful. Furthermore, we found that the metathesis of benzamidine hydrochloride monohydrate (BHC) with sodium diphenylphosphinate (SDPP) did not give **1**. When the two salts were dissolved in a solvent mixture of 1:1 tetrahydrofuran and acetonitrile at room temperature

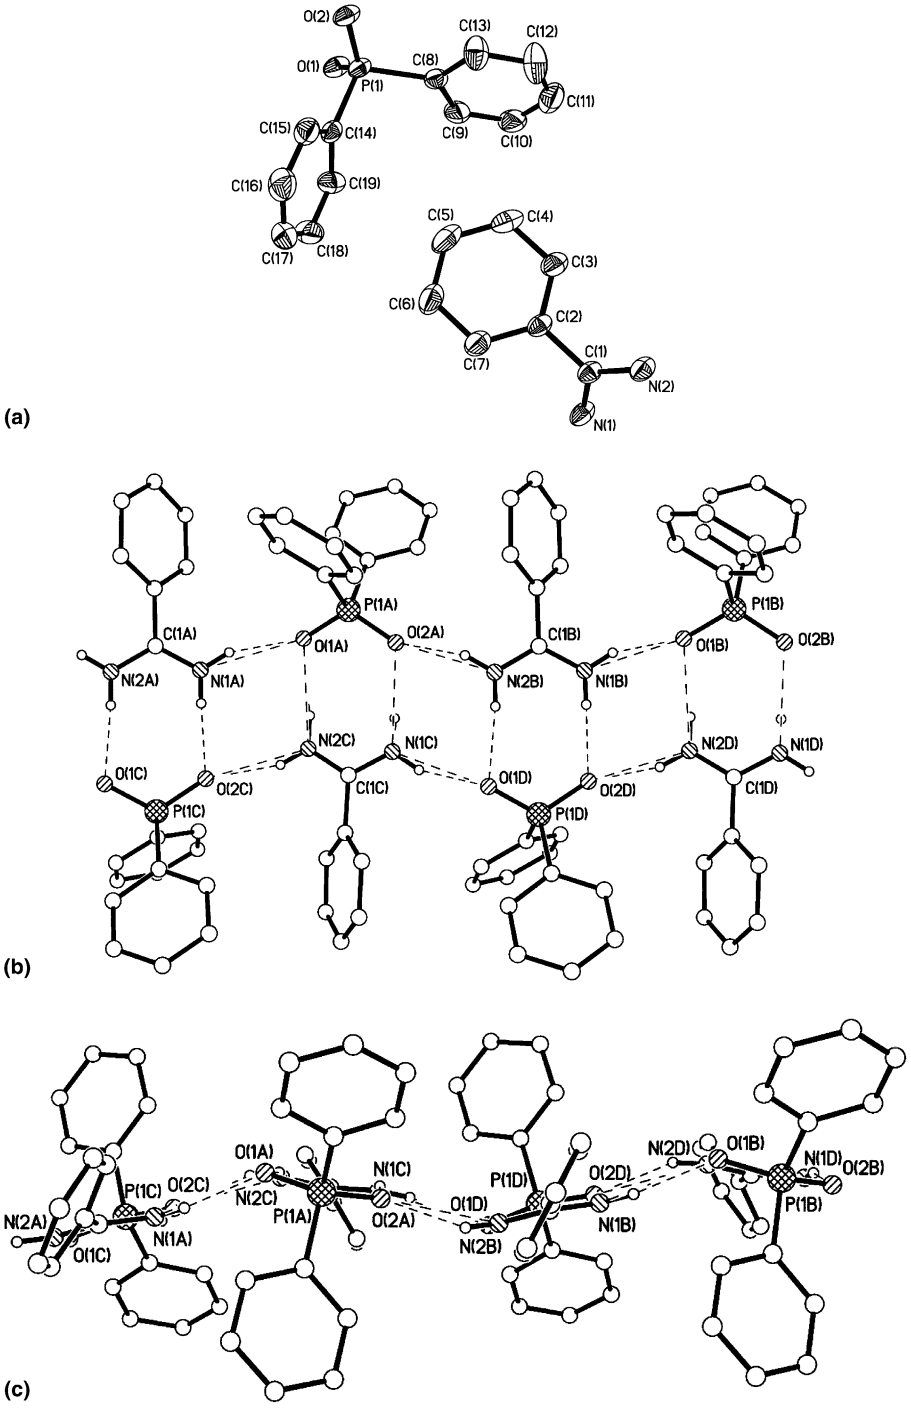

Fig. 3. (a) ORTEP drawing of **1**. (b) Crystal packing diagram for **1** with the hydrogen bonds between cations and anions indicated by the dashed lines. (c) Side-view of the molecular packing showing the 1D polymeric skeleton.

and stirred for 24 h, colorless crystals of benzamidine and diphenylphosphinic acid were isolated by slow evaporation of the solvents at room temperature.

The structures of compounds **1**–**6** were ascertained by X-ray crystallography. Selected bond lengths and bond angles are given in Table 2. Structural analyses revealed that these ionic salts are held together by the electrostatic forces between the cation and the anion, and strengthened by hydrogen bonds to form, depending on the nature of the aryl groups, a 1D, 2D or 3D polymeric network (Figs. 1 and 2). The C–N and P–O distances of **1**–**6** are very similar and the major difference among **1**–**6** lies in their spatial arrangements. Within the NCN fragment of the arylamidinium cations of **1**–**6**, the C–N distances are in the range of 1.297(3)–1.315(3) Å, and the NCN angles in the range of 119.6(2)–123.1(3)°. These values are comparable to those of the cyclic bis(amidinium) dication (C–N distances, 1.29–1.32 Å ; NCN angle, 112.5°) [15e]. Within the OPO fragment of the diphenylphosphinate anion, the P–O distances fall in the range of 1.4873(17)–1.5213(16) Å. The C–N and P–O distances indicate that the charge of the amidinium cation $[ArC(NH_2)_2]^+$ (**A**) or dication $[(NH_2)_2CC_6H_4C(NH_2)_2]^{2+}$ ($\mathbf{A_2}$) and the diphenylphosphinate anion $[Ph_2PO_2]^-$ (**B**) is delocalized over the N–C–N and O–P–O frameworks, respectively.

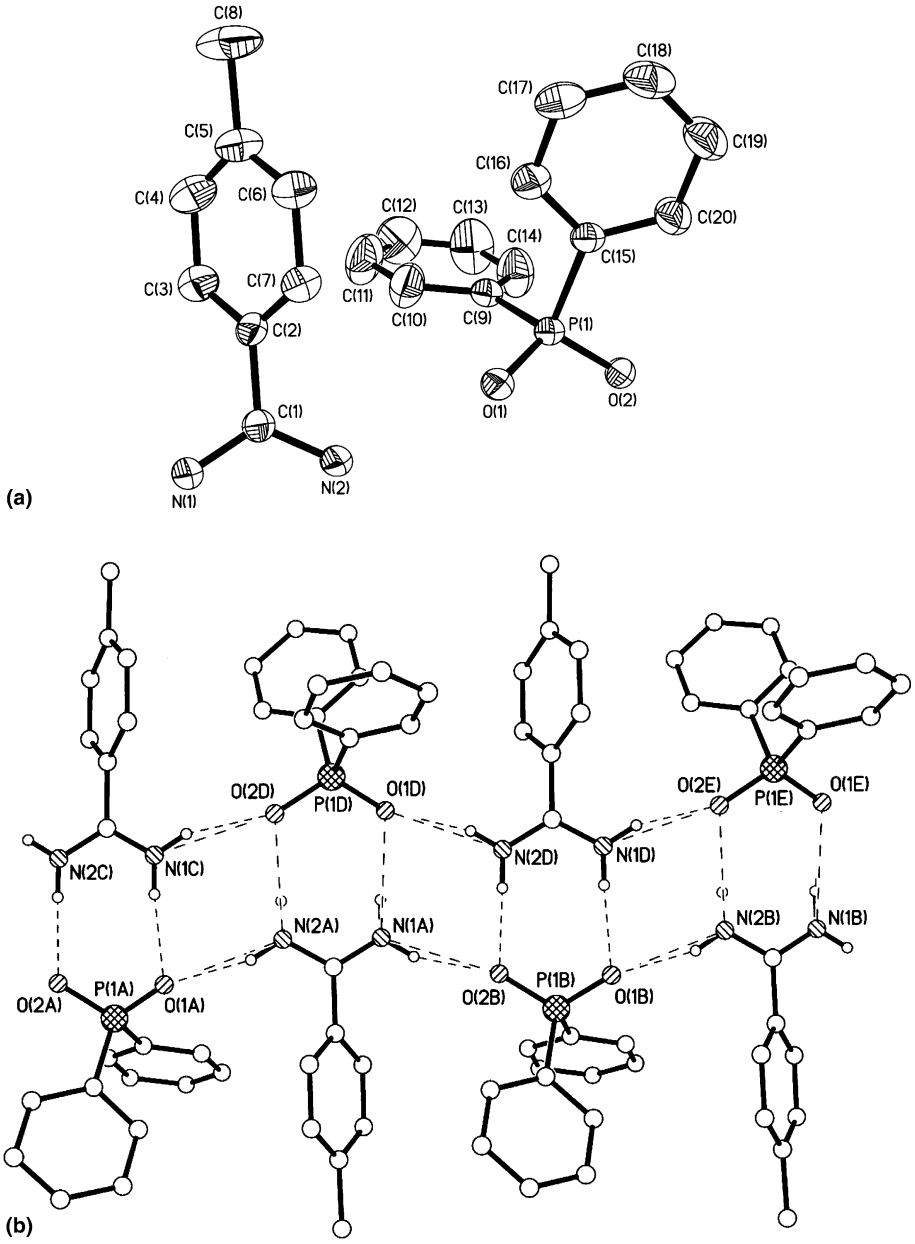

Fig. 4. (a) ORTEP drawing of **2**. (b) Crystal packing diagram for **2** with the hydrogen bonds between cations and anions indicated by the dashed lines.

Fig. 3(a) shows a perspective drawing of **1**. For the amidinium cation, the dihedral angle formed between the NCN plane and the phenyl ring plane is 51.1°. Fig. 3(b) shows four subunits in the crystal lattice. The distance between N(1A) and O(2C) is 2.791 Å, N(2A) and O(1C) is 2.855 Å, and that between O(2C) and N(2C) is 2.762 Å, N(1A) and O(1A) is 2.812 Å. It means that the electrostatic force between **A** and its neighboring unit **B** is approximately the same in all directions. Moreover, the distance between the oxygen atoms of **B** and the hydrogen atoms of the NH_2 groups is around 1.98 (±0.03) Å, indicating the presence of N–H···O hydrogen bonds. By the association of electrostatic forces and hydrogen bonds, **A** and **B** are gathered rationally and regularly to form a 1D polymeric network. The molecular packing for **1** can be best represented

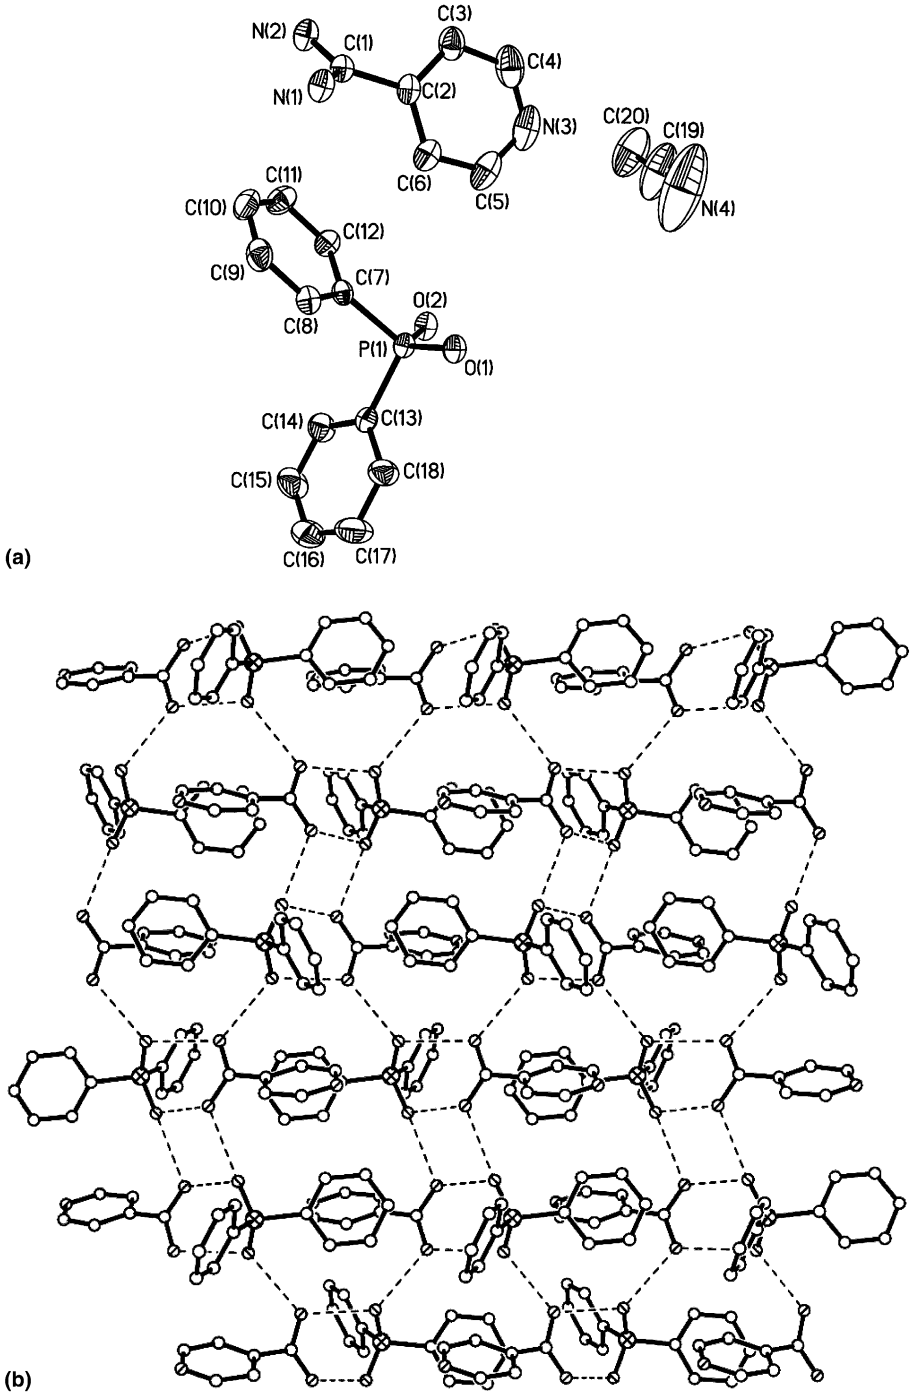

Fig. 5. (a) ORTEP drawing of **3**. (b) Crystal packing diagram for **3** with the hydrogen bonds between cations and anions indicated by the dashed lines.

by Fig. 1(a). The crystal structure of **2** is very similar to that of **1** where cations and anions are gathered rationally and regularly to form a 1D zig-zag polymeric structure (Fig. 4). Within the conjugated cation $[(p\text{-}CH_3C_6H_4)C(NH_2)_2]^+$ (**A**), the tolyl plane forms a dihedral angle of 46.6° with the [N(1)C(1)N(2)] plane.

The molecular structure of **3** is shown in Fig. 5(a) and bears a close resemblance to that of **1** and **2**. The dihedral angle formed between the conjugated NCN plane and the pyridyl ring plane is 56.1°. Likewise, every cation interacts with three anions and vice versa. The distance between every nitrogen atom and the nearest oxygen atom is ca. 2.86 (±0.08) Å. The distance between oxygen atoms and hydrogen atoms in N–H···O bonds is ca. 2.04 (±0.04) Å. However, the network structure of **3** is very different from that of **1** and **2**. Fig. 5(b) shows the molecular packing diagram of **3**. The cations and anions gathered to form a 2D planar polymeric motif. A simplified diagram of the lattice of **3** is shown in Fig. 1(b).

The molecular structure (Fig. 6(a)) of **4** is very similar to that of **3**. The dihedral angle formed between the conjugated NCN plane and the pyridyl ring plane is 50.7°. As in **3**, every cation interacts with three anions and vice versa. The distance between every nitrogen atom and the nearest oxygen atom is ca. 2.87 (±0.07) Å. The distance between oxygen atoms and hydrogen atoms in N–H···O bonds is ca. 2.04 (±0.04) Å. Fig. 6(b) shows the packing diagram of **4** in which the cations and

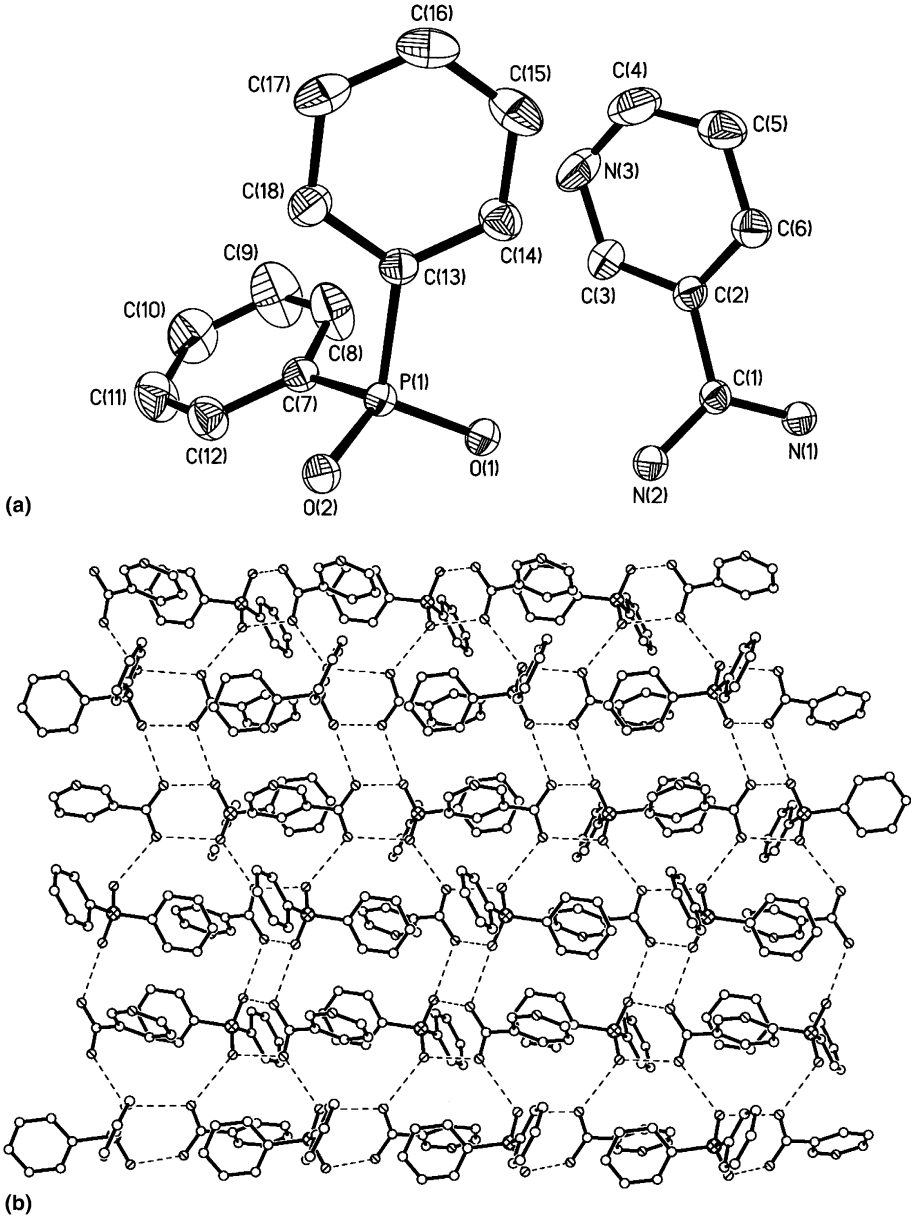

Fig. 6. (a) ORTEP drawing of **4**. (b) Crystal packing diagram for **4** with the hydrogen bonds between cations and anions indicated by the dashed lines.

anions are arranged in a 2D planar polymeric structure (Fig. 1(b)).

The molecular structure of **5** is shown in Fig. 7(a). The dihedral angle formed between the conjugated NCN [N(1)C(1)N(2)] plane and the pyridyl ring is 43.2°. There is another half of the molecule in the same unit cell. A whole molecule can be organized by combining half of the molecule in one unit cell with the other half of the molecule of another unit cell. The dihedral angle formed between the conjugated NCN [N(4)C(19)N(4A)] and the pyridyl ring is 2.7° and is very different from that of the other molecule. Every cation interacts with three anions and vice versa in the crystal packing. The distance between every nitrogen atom and the nearest oxygen atom is ca. 2.80 (±0.04) Å. The distance between oxygen and hydrogen atoms in N–H···O bonds is ca. 2.01 (±0.05) Å. Similar to **3** and **4**, cations and anions tend to form a 2D planar polymer

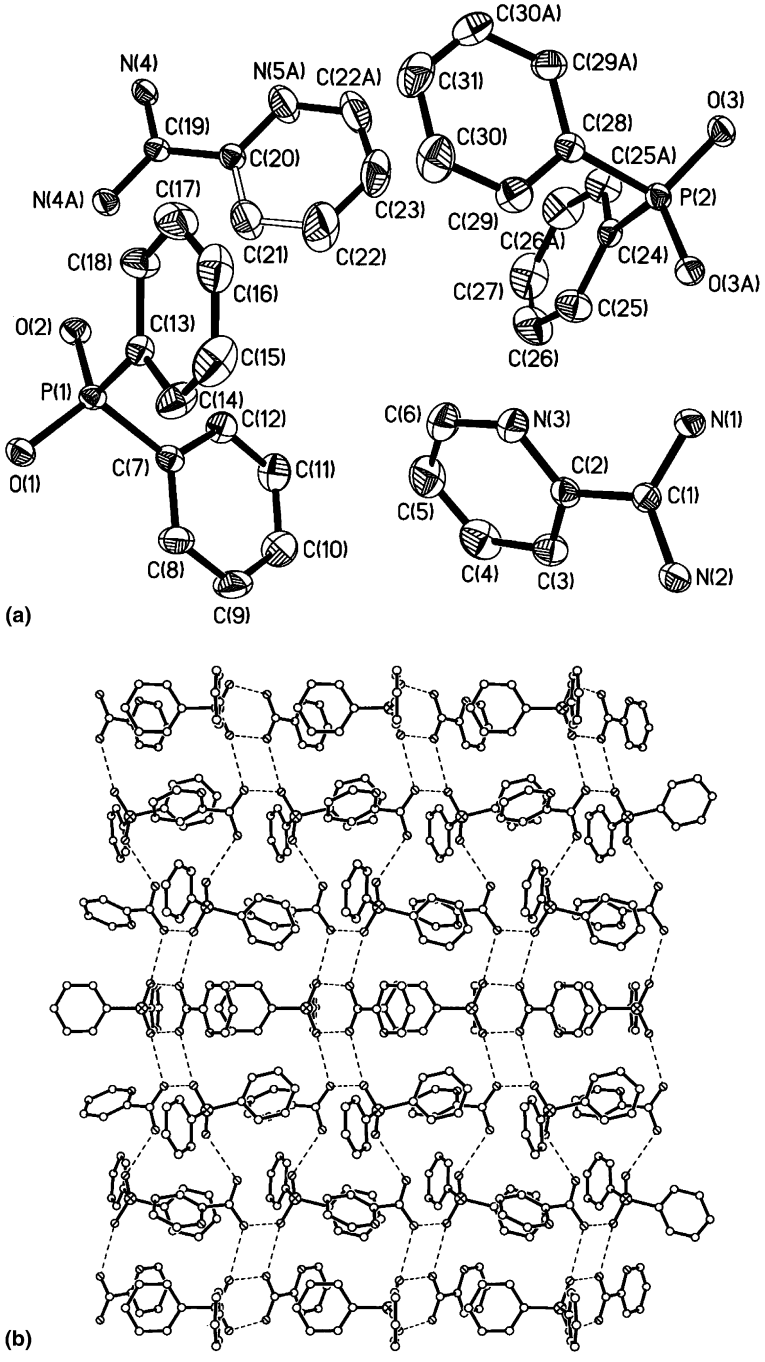

Fig. 7. (a) ORTEP drawing of **5**. (b) Crystal packing diagram for **5** with the hydrogen bonds between cations and anions indicated by the dashed lines.

(Fig. 7(b)). However, three molecules, instead of two as in **3**, are connected together in the lattice of **5** and Fig. 1(c) gives a good representation of this lattice arrangement.

Single-crystal X-ray analysis of **6** revealed that other than having a bis(amidinium) dication, its molecular structure (Fig. 8(a)) is similar to those of **1**–**5**. There are two independent molecules in the unit cell. The C–N and P–O distances are comparable to those of **1**–**5**. For **6**, the dihedral angles formed between the plane of the phenylene ring and the NCN planes are 12.8 [N(1)C(1)N(2)] and 42.8° [N(3)C(8)N(4)], and between the two NCN planes is 30.4°. For the other independent molecule, the corresponding dihedral angles are 35.4°, 3.4° and 33.5°. With the use of a dication, the molecular arrangement in the crystal structure of **6** is more complex than those observed in **1**–**5** and Fig. 8(b) shows a portion of the crystal packing. It is clear from the simple schematic diagram shown in Fig. 2 that compound **6** forms a three-dimensional polymeric network. It looks like a stair, in which every plane is a step. There are two association types of anions in **6**. One is associated with two cations located in the same plane, having O ··· N distances of 2.764 and 2.867 Å. Another is associated with three cations, in which one is located on the same plane and two located on another plane above or below, having O ··· N distances of 2.750, 2.756 and 2.896 Å (or 2.882, 2.788 and 2.832 Å), respectively. The two different sets of distances are due to the two NCN planes of

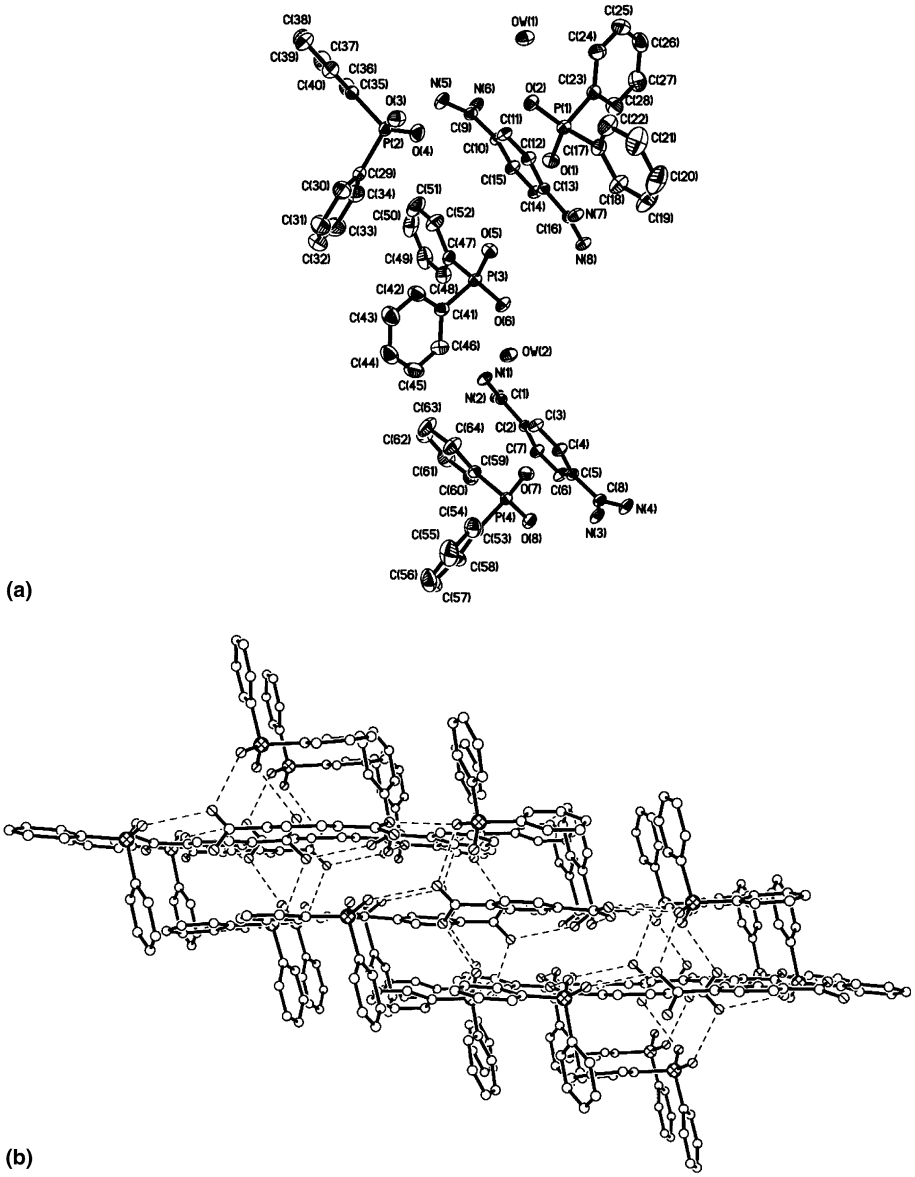

Fig. 8. (a) ORTEP drawing of **6**. (b) Crystal packing diagram for **6** with the hydrogen bonds between cations and anions indicated by the dashed lines.

one dication having different dihedral angles with the phenylene ring.

3.2. Optical and spectroscopic properties

To examine the significance and extent of hydrogen bonding interactions in our compounds, the solid-state fluorescence properties of **1** and **3** have been studied and compared with that of BHC and SDPP. The excitation and emission spectra of **1** and **3** should be similar to that of BHC and SDPP if hydrogen bonding is insignificant. Fig. 9 showed the solid-state fluorescence excitation spectra and emission spectra of compound **1**, BHC and SDPP. Relative to that of BHC and SDPP, the positions of the maximum excitation and emission wavelengths of **1** are remarkably bathochromically shifted. The excitation and emission peaks of **1** appear at 373 and 466 nm, respectively, whereas those of BHC are at 308 and 350 nm, and SDPP at 300 and 324 nm, respectively. The excitation and emission peaks of **3** (Fig. 10) are at 345 and 475 nm, respectively. The substantial red shift in the excitation and emission maxima for **1** and **3** as compared with those of BHC and SDPP suggests that hydrogen bonding interactions in their solid-state structures is significant and extensive. We believe that such hydrogen bonding should be present in all cases.

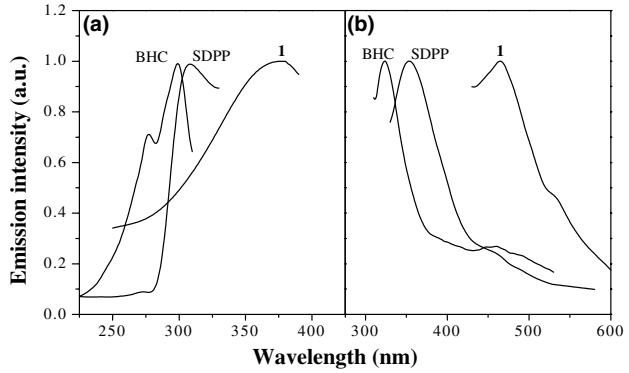

Fig. 9. (a) Excitation and (b) emission spectra of benzamidine hydrochloride (BHC), sodium diphenylphosphinate (SDPP), and **1**.

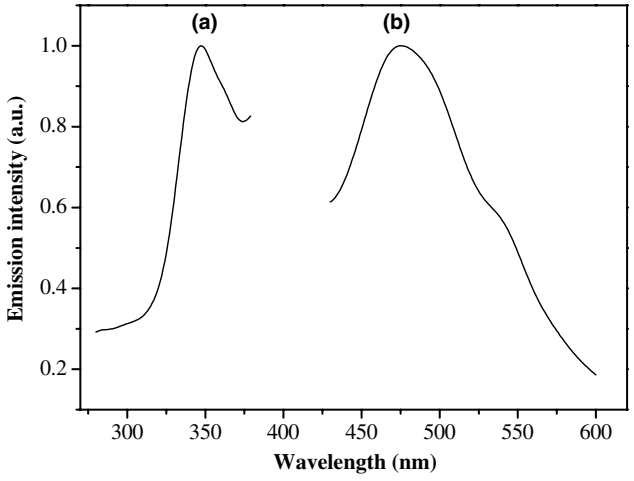

Fig. 10. (a) Excitation and (b) emission spectra of **3**.

Because of the special solid-state structures of **1**–**6**, some typical absorption peaks appeared in their infrared spectra. For the secondary amine salt, vibrations involving anti-symmetric and symmetric NH_2^+ stretchings are characterized by strong multiple IR absorptions located in the 3000–2700 cm^{-1} region [21]. The double strong broad peaks ranging from 3400 to 2700 cm^{-1} indicate the N–H vibration of $[ArC(NH_2)(NH_2)]^+$ group. The characteristic stretching frequencies of the C = N group are in the range from 1605 to 1674 cm^{-1} [21]. The strong peaks around 1710 cm^{-1} are due to the C–N stretching absorption of the $[ArC(NH_2)(NH_2)]^+$ group. Acid salts containing the PO_2^- group have two strong IR bands in the region 1323–1092 cm^{-1} (out-of-phase stretch) and 1164–995 cm^{-1} (in-phase stretch). Acid salts of the type $R_2PO_2^-$ absorb in the lower part of the region. The two peaks around 1130 and 1035 cm^{-1} should be the P–O stretches of $[Ph_2PO_2]^-$. The three typical absorption bands of **1**–**6** are listed in Table 2.

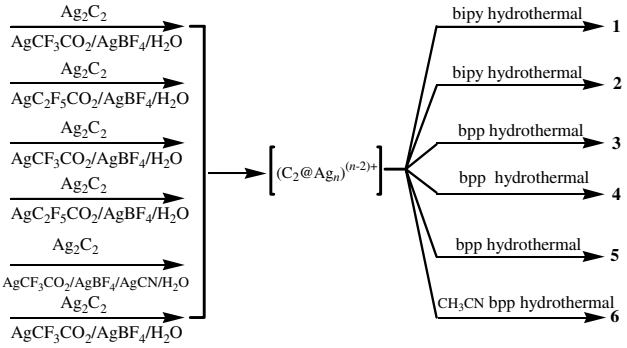
The ^1H, ^{31}P and ^{13}C NMR spectra have been investigated in DMSO-d_6 for **1**–**6**. Since compounds **3** and **6** have very low solubility in DMSO, satisfactory ^{13}C NMR spectra could not be obtained in these two cases. The chemical shift data are listed in Table 3. The ^{31}P chemical shifts of all six compounds are very similar and appear in the range from δ 16–18 ppm. The ^1H

Table 3
IR and NMR data of compounds **1**–**6**

Compound	IR absorption in cm^{-1} (KBr)			NMR data (DMSO-d_6)		
	N–H	C–N	P–O of $Ph_2PO_2^-$	^{31}P	^1H of NH_2	^{13}C of $[-C(NH_2)_2]^+$
1	3140, 2933	1711	1130, 1037	16.8	11.12, 9.01	166.5
2	3147, 2921	1705	1131, 1038	16.9	11.31, 8.88	166.1
3	3369, 3053	1662	1251, 1172	17.2	10.34, 9.38	
4	3140, 2923	1711	1130, 1037	17.0	11.22, 9.16	164.3
5	3182, 2948	1711	1130, 1042	17.0	11.10, 9.30	162.2
6	3347, 3171	1674	1260, 1171	16.8	11.48, 9.18	

chemical shifts of the NH_2 protons are similar too, and appear around δ 11.0 and 9.0 ppm. This indicates that there are two kinds of NH protons in the solution state. The characteristic ^{13}C chemical shifts of $[-C(NH_2)(NH_2)]^+$ appear in the range from δ 162 to 167 ppm.

4. Supplementary material



Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 257438–257443 for compounds **1**–**6**, respectively. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EW, UK (fax: +44 1223 336 033; E-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Scheme 1.

the rigid linear bipy and conformationally flexible bpp ligands for the linkage of labile $C_2@Ag_n$ cages, which are presumed to be formed in situ, in the construction of solid-state architectures. The synthetic procedure shown in Scheme 1 yielded the following six complexes: $[Ag_{13}(C_2)_2(CF_3CO_2)_9(bipy)_4(H_2O)_3]$ (**1**), $[Ag_{18}(C_2)_2(C_2F_5CO_2)_{18}(bipyH)_4]\cdot 3H_2O$ (**2**), $[Ag_6(C_2)(CF_3CO_2)_4(bpp)]$ (**3**), $[Ag_6(C_2)(C_2F_5CO_2)_5(bppH)]_n$ (**4**), $[Ag_6(C_2)(CF_3CO_2)_5(bppH)]_n$ (**5**) and $[Ag_{23}(C_2)_4(CF_3CO_2)_{15}(bpp)_6]\cdot H_2O$ (**6**).

2. Experimental

2.1. Synthesis

All chemicals were purchased from ACROS and Aldrich and used without further purification. Ag_2C_2 was prepared as described previously [4]. *Caution!* Thoroughly dried Ag_2C_2 detonates easily upon mechanical shock, and only a small quantity should be used in any chemical reaction. Excess amount can be disposed of via slow decomposition in an alkaline solution [8]. To ensure safety, we used moist Ag_2C_2 in all preparations.

2.1.1. $[Ag_{13}(C_2)_2(CF_3CO_2)_9(bipy)_4(H_2O)_3]$ (*1*)

Excess moistened Ag_2C_2 (~0.5 g, 2 mmol) was added to 1 mL of a concentrated aqueous solution of $AgCF_3CO_2$ (0.885 g, 4 mmol) and $AgBF_4$ (0.244 g, 1.3 mmol) in a plastic beaker with stirring. The undissolved amount of Ag_2C_2 was filtered off, and then 30 mg bipy was added to the filtrate. The resulted suspension was placed in a 25 mL Teflon-lined stainless steel reaction vessel and subjected to hydrothermal conditions at 108 °C for 40 h, and then cooled to room temperature at 6 °C/h. Colorless rhombus-like crystals of **1** were isolated in ~65% yield. *Anal.* Calc. for $C_{62}H_{38}Ag_{13}F_{27}N_8O_{21}$: C, 23.67; H, 1.22; N, 3.56. Found: C, 23.59; H, 1.16; N, 3.50%.

2.1.2. $[Ag_{18}(C_2)_2(C_2F_5CO_2)_{18}(bipyH)_4]\cdot 3H_2O$ (*2*)

Complex **2** was synthesized in a similar manner to complex **1** using $AgC_2F_5CO_2$ instead of $AgCF_3CO_2$. Colorless block-like crystals were isolated in ~40% yield. *Anal.* Calc. for $C_{98}H_{42}Ag_{18}F_{90}N_8O_{39}$: C, 23.91; H, 0.86; N, 2.28. Found: C, 23.85; H, 0.82; N, 2.31%.

2.1.3. $[Ag_6(C_2)(CF_3CO_2)_4(bpp)]$ (*3*)

Excess moistened Ag_2C_2 (~0.5 g, 2 mmol) was added to 1 mL of a concentrated aqueous solution of $AgCF_3CO_2$ (0.455 g, 2 mmol) and $AgBF_4$ (0.248 g, 1.3 mmol) in a plastic beaker with stirring. The undissolved amount of Ag_2C_2 was filtered off, and then 52 mg (0.26 mmol) of bpp was added to the filtrate. The resulted suspension was placed in a 25 mL Teflon-lined stainless steel reaction vessel and subjected to hydrothermal conditions at 110 °C for 36 h, and then cooled to room temperature at 6 °C/h. Colorless block-like crystals of **3** were isolated in ~57% yield. *Anal.* Calc. for $C_{23}H_{14}Ag_6F_{12}N_2O_8$: C, 20.90; H, 1.07; N, 2.12. Found: C, 20.73; H, 1.01; N, 2.15%.

2.1.4. $[Ag_6(C_2)(C_2F_5CO_2)_5(bppH)]_n$ (*4*)

Complex **4** was synthesized in a similar manner to complex **3** using $AgC_2F_5CO_2$ instead of $AgCF_3CO_2$. Colorless block-like crystals were isolated in ~45% yield. *Anal.* Calc. for $C_{30}H_{15}Ag_6F_{25}N_2O_{10}$: C, 20.09; H, 0.84; N, 1.56. Found: C, 19.93; H, 0.91; N, 1.61%.

2.1.5. $[Ag_6(C_2)(CF_3CO_2)_5(bppH)]_n$ (*5*)

This complex was obtained serendipitously from an attempt to trap CN^- inside the silver cage by introducing AgCN into the reaction system. Excess Ag_2C_2 (~0.5 g, 2 mmol) and AgCN (~0.06 g, ~0.5 mmol) were added to 1 mL of a concentrated aqueous solution of $AgCF_3CO_2$ (0.455 g, 2 mmol) and $AgBF_4$ (0.245 g, 1.26 mmol) in a plastic beaker with stirring until saturated. The undissolved amount of Ag_2C_2 and AgCN was filtered off, and 52 mg (0.26 mmol) bpp was added to the filtrate. The resulted suspension was treated with the hydrothermal method as described above. Colorless block-like crystals were isolated in ~40% yield. *Anal.* Calc. for $C_{25}H_{15}Ag_6F_{15}N_2O_{10}$: C, 19.45; H, 0.98; N, 1.81. Found: C, 19.37; H, 1.02; N, 1.78%.

2.1.6. $[Ag_{23}(C_2)_4(CF_3CO_2)_{15}(bpp)_6]\cdot H_2O$ (*6*)

When the procedure for **1** was repeated with addition of several drops of CH_3CN under hydrothermal reaction condition, colorless block-like crystals of complex **6** were harvested in ~60% yield. *Anal.* Calc. for $C_{116}H_{86}Ag_{23}F_{45}N_{12}O_{31}$: C, 25.43; H, 1.58; N, 3.07. Found: C, 25.50; H, 1.62; N, 2.98%.

2.2. X-ray crystallography

X-ray measurements on single crystals of complexes **1**–**6** were performed on a Bruker SMART 1000 CCD diffractometer using Mo Kα radiation ($\lambda = 0.71073$Å) at 293 K. Data collection and reduction were performed

using SMART and SAINT software [9], with frames of 0.3° oscillation in the θ range $2° < \theta < 28°$. An empirical absorption correction was applied using the SADABS program [10]. The structures were solved by direct method and all non-hydrogen atoms were refined anisotropically by full-matrix least squares on F^2 using the SHELXTL program package [11]. In complex **5**, atom Ag5 is disordered over two positions. The crystal data and details of refinement are summarized in Table 1, and selected bond distances and angles are listed in the legends for figures.

3. Results and discussion

The group 11 (Cu, Ag, Au) acetylenediides exhibit properties that are characteristic of covalent polymeric solids, but their proneness to detonation upon mechanical shock and insolubility in common solvents present serious difficulties in structural characterization. As a working hypothesis, it is presumed that depolymerization of silver acetylenediide occurs upon dissolving in a concentrated aqueous solution of soluble silver salts to afford labile polyhderal $C_2@Ag_n$ cage species. The assembly of such $C_2@Ag_n$ aggregates to form a crystalline solid is a complex process that is influenced by the presence of ancillary ligands, co-existing anions, and solvate molecules.

3.1. $[Ag_{13}(C_2)_2(CF_3CO_2)_9(bipy)_4(H_2O)_3]$ (1)

X-ray structure determination has revealed that complex **1** has a three-dimensional architecture, in which the basic building block is a double cage comprising 13 silver atoms with each single cage encapsulating an acetylenediide dianion. As shown in Fig. 1, the double cage is generated from edge sharing of a distorted pentagonal bipyramid (Ag1 to Ag7 cage **A**) and an irregular bicapped trigonal prism (cage **B**). For cage **A**, the equatorial silver atoms lie with 0.26 Å of their least-squares plane. The enclosed C_2^{2-} dianion is π-coordinated to the two apices (Ag6 and Ag7) with Ag–C bond distances in the range of 2.432(9)–2.627(8) Å. The C_2^{2-} binds to the equatorial silver atoms via four σ- and one π-Ag–C interactions in the range 2.100(9)–2.525(8) Å. As to cage **B**, atom sets Ag5Ag8Ag10a and Ag4Ag9Ag10 constitute two triangular faces making a dihedral angle of 23.9°. Atoms Ag11 and Ag12 cap the faces Ag5Ag8Ag10a and Ag4Ag9Ag10, respectively. The enclosed C_2^{2-} dianion coordinates to its neighboring silver atoms via σ-type Ag–C interactions in the range of 2.098(9)–2.59(1) Å [12]. Two such double cages share an edge Ag10Ag10a to form a centrosymmetric Ag_{24} quadruple cage, whose remaining coordination sits are filled by the trifluoroacetate and aqua ligands.

The $[Ag_{24}(C_2)_4(CF_3CO_2)_{16}(H_2O)_6]$ unit are further connected by independent bipy ligands I and II to form a chain along the $[\bar{1}\,1\,0]$ direction, and such chains are further interlinked by bipy ligands III and IV to span a layer orientated parallel to the $(1\,1\,\bar{1})$ plane. Argentophilic interactions between atoms of the type Ag2–Ag2a (3.244(2) Å) further connects the layers into a three-dimensional architecture [13] (Figs. 2 and 3).

Of the nine independent trifluoroacetate groups in the asymmetric unit, one simply acts as a space-filling anion without coordination to a silver(I) atom. The others adopt monodentate or μ_2-*O*,*O*′ modes around the silver(I) cage.

3.2. $[Ag_{18}(C_2)_2(C_2F_5CO_2)_{18}(bipyH)_4]\cdot 3H_2O$ (2)

In the crystal structure of **2**, the building unit is a quasi-centrosymmetric double cage composed of 16 silver(I) atoms, with each single cage encapsulating an acetylenediide dianion, as shown in Fig. 4. Each single cage takes the shape of a distorted monocapped square antiprism. For the lower cage, atom sets Ag1Ag2Ag3Ag4 and Ag5Ag6Ag7Ag8 are each coplanar within 0.01 and 0.14 Å, respectively, making a dihedral angle of 6.5°. Atom Ag9 caps the Ag5Ag6Ag7Ag8 face. As to the upper cage, atom sets Ag9Ag10Ag11Ag12 and Ag13Ag14Ag15Ag16 are each coplanar within 0.18 and 0.03 Å, respectively, making a dihedral angle of 5.1°. Atom Ag7 caps the Ag9Ag10Ag11Ag12 face. These two single cages share an edge Ag7Ag9 to form the double cage. A C_2^{2-} species is entrapped in each silver polyhedron and stabilized mainly by σ-type interactions. The Ag–C bond lengths range from 2.20(1) to 2.69(1) Å (Fig. 4).

Eighteen independent pentafluoropropionate ligands exhibit three kinds of coordination modes around the $(C_2)_2@Ag_{16}$ double cage, namely one monodentate, one μ_3-*O*,*O*,*O*′ and 16 μ_2-*O*,*O*′.

The four bipy ligands in the asymmetric unit are each protonated at one terminal to satisfy the charge balance. They are pairwise coordinated to the remaining silver(I) atoms, giving rise to two $[Ag(bipyH)_2]^{3+}$ cations with bond lengths Ag17–N2 2.147(9), Ag17–N3 2.14(1), Ag18–N6 2.138(9), Ag18–N7 2.116(9) Å.

Three solvated water molecules in the asymmetric unit serve as acceptors in hydrogen bonding, with the C and N atoms of the bipy ligands acting as donors as shown in Table 2.

Presumably, the existence of the $[Ag(bipyH)_2]^{3+}$ cations promotes the formation of the anionic cluster $[Ag_{16}(C_2)_2(C_2F_5CO_2)_{18}]^{6-}$. The hydrophobic tails of the pentafluoropropionate ligands prevent further linkage between adjacent silver polyhdera, yielding a discrete supermolecule. This is analogous to the case of $[(Ag_2C_2)(AgC_2F_5CO_2)_6(L)_3(H_2O)]\cdot H_2O$ (L = 4-hydroxyquinoline), in which the presence of pentafluoropropionate, 4-hydroxyquinoline and aqua ligands obstruct further linkage between silver polyhedra [14]. Another

Selected bond distances (Å): C1–C2 1.23(1), C3–C4 1.20(1), C1–Ag2 2.458(8), C1–Ag7 2.627(8), C1–Ag3 2.105(8), C1–Ag6 2.589(9), C1–Ag4 2.356(8), C2–Ag2 2.525(8), C2–Ag7 2.432(9), C2–Ag6 2.530(9), C2–Ag1 2.100(9), C2–Ag5 2.366(8), C3–Ag4 2.415(9), C3–Ag10 2.438(9), C3–Ag12 2.109(8), C3–Ag9 2.363(9), C4–Ag5 2.59(1), C4–Ag8 2.321(9), C4–Ag10 2.547(9), C4–Ag11 2.098(9).

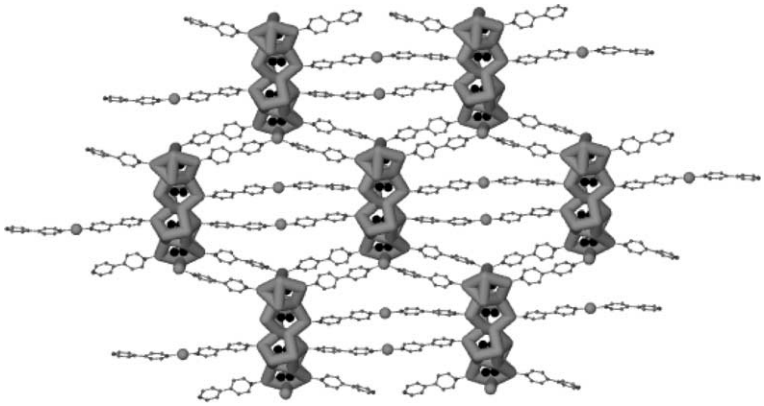

Fig. 2. Layer structure in **1** parallel to the $(1\,1\,\bar{1})$ plane constructed from $[Ag_{24}(C_2)_4(CF_3CO_2)_{16}(H_2O)_6]$ moieties that are interconnected by bipy ligands, as viewed from the [1 1 0] direction. All the aqua ligands have been omitted for clarity.

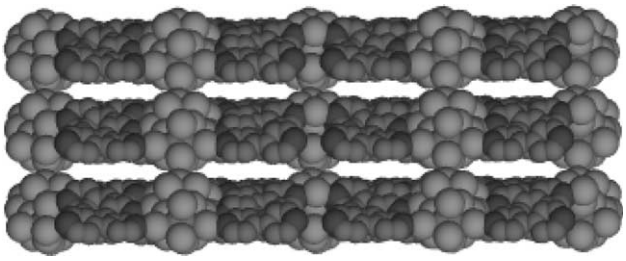

Fig. 3. Three-dimensional architecture of **1** generated from linkage of layers by argentophilic Ag(I)···Ag(I) interactions viewed from [1 1 2] direction.

feature common to **2** and $[(Ag_2C_2)(AgC_2F_5CO_2)_6(L)_3(H_2O)]\cdot H_2O$ is the existence of the $(C_2)_2@Ag_{16}$ double cage of similar geometry.

Judging from the results obtained here and in our previous reports, it can be inferred that whenever ancillary ligands participate in the formation of a higher-dimensional architecture, the $C_2@Ag_n$ cages tend to be highly distorted, whereas the cages in the discrete clusters are much more regular in shape [14,15]. A plausible explanation is that the competition of the ancillary

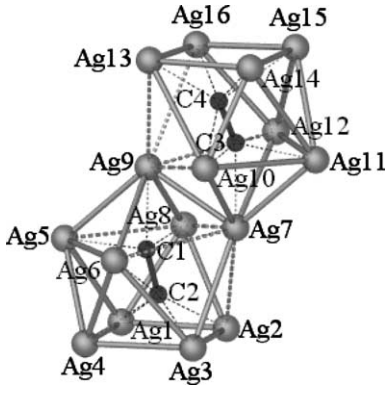

Fig. 4. Double cage unit $(C_2)_2@Ag_{16}$ in **2** generated from two monocapped square antiprisms sharing an edge. The Ag···Ag distances longer than 3.4 Å (twice the van der Waals radius of silver atom) are represented by thick broken lines. The Ag–C bonds are represented by thin broken lines. Selected bond distances (Å): C1–C2 1.22(1), C3–C4 1.18(1), C2–Ag1 2.50(1), C2–Ag2 2.30(1), C2–Ag3 2.24(1), C2–Ag4 2.34(1), C1–Ag5 2.24(1), C–1Ag6 2.42(1), C2–Ag6 2.69(1), C3–Ag7 2.26(1), C1–Ag7 2.67(1), C1–Ag8 2.32(1), C1–Ag9 2.20(1), C3–Ag9 2.63(1), C3–Ag10 2.40(1), C4–Ag10 2.67(1), C3–Ag11 2.36(1), C3–Ag12 2.23(1), C4–Ag13 2.23(1), C4–Ag14 2.46(1), C4–Ag15 2.31(1), C4–Ag16 2.45(1).

ligands with the acetylenediide and perfluorocarboxylate anions for coordination sites around the silver(I) atoms may lead to the distortion of the $C_2@Ag_n$ cages.

3.3. $[Ag_6(C_2)(CF_3CO_2)_4(bpp)]$ (**3**)

X-ray structure determination revealed that complex **3** has a bpp-bridged layer structure. The basic building block is a $C_2@Ag_8$ single cage in the form of a distorted triangulated dodecahedron (Fig. 5). Atom sets Ag1-Ag2Ag6bAg3 and Ag4Ag5Ag6Ag1a are each coplanar within 0.06 and 0.19 Å, respectively, making a dihedral angle of 97.1°. The enclosed C_2^{2-} dianion retains its triple bond character and bonds to the neighboring silver(I) atoms with both σ- and π-type interactions in the range 2.122(5)–2.640(5) Å.

Two single cages share edge Ag1Ag1a to form a centrosymmetric double cage, and such cages are further fused together to form an infinite column via sharing of the edge Ag6Ag6b, together with further connection of the type Ag3Ag3b, as shown in Fig. 5.

Two kinds of coordination modes of the trifluoroacetate ligands are found in **3**, namely μ_3-*O*,*O*,*O*′ and μ_2-*O*,*O*′. The flexible bpp ligands, each with its $-CH_2CH_2CH_2-$ spacer adopting a TG conformation [16], further interlink the infinite silver(I) columns to generate a two-dimensional network in the *bc* plane with Ag5–N1 2.306(5), Ag3–N2 2.208(4) Å (Fig. 6).

3.4. $[Ag_6(C_2)(C_2F_5CO_2)_5(bppH)]_n$ (**4**)

Complex **4** has a branched-tree architecture, in which the basic building block is a $C_2@Ag_7$ single cage in the shape of a distorted monocapped trigonal prism. Triangular faces Ag1Ag2Ag3 and Ag4Ag5Ag6 make a dihedral angle of 14.4°, and atom Ag7 caps the latter face.

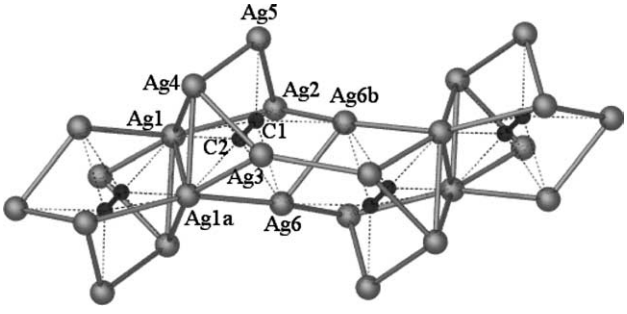

Fig. 5. Portion of an infinite column in **3** generated from edge-sharing of $C_2@Ag_8$ single cages. Symmetry code: (a) $-x+1, -y, -z+1$ (b) $-x+1, y, 0.5-z$. Selected bond lengths (Å): C1–C2 1.217(7), C2–Ag1a 2.268(5), C1–Ag1 2.571(5), C2–Ag1 2.640(5), C1–Ag2 2.122(5), C2–Ag3 2.187(5), C2–Ag4 2.243(5), C1–Ag5 2.368(5), C2–Ag6 2.441(5), C1–Ag6 2.500(5), C1–Ag6b 2.566(5).

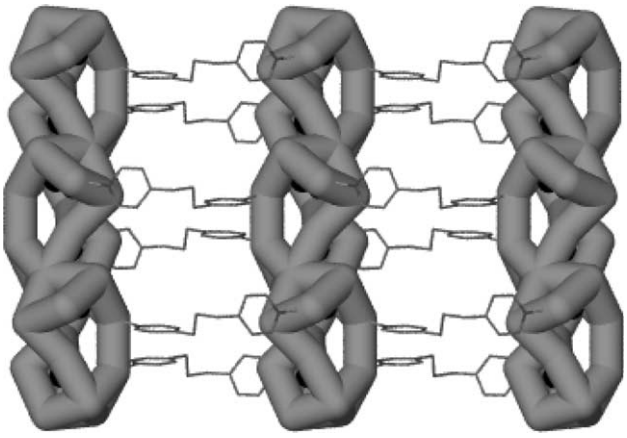

Fig. 6. Two-dimensional network of **3** constructed from bpp bridging of silver(I) columns. Trifluoroacetate ligands have been omitted for clarity.

Two single cages are fused together via sharing of the vertex Ag1, together with further connections of the types Ag3–Ag7a and Ag3a–Ag7, to form a centrosymmetric double cage AA′. An infinite silver column is generated in the sequence AA′AA′··· parallel to the *c* direction via vertex-sharing at Ag5 (Fig. 7).

One terminal of the bpp ligand is protonated and the other coordinated to a silver atom of type Ag7, and such ligation results in the attachment of cationic branches to the silver backbone. As in the case of **3**, the flexible bpp ligands adopt the TG conformation (Fig. 8).

3.5. $[Ag_6(C_2)(CF_3CO_2)_5(bppH)]_n$ (**5**)

Complex **5** is virtually iso-structural to **4**, featuring the same $C_2@Ag_7$ cage and branched-tree architecture. In **5**, atom sets Ag1Ag2Ag3 and Ag4Ag5Ag3a constitute the two trigonal faces of a distorted monocapped trigonal prism, making a dihedral angle of 6.6°, with Ag6 caps the Ag4Ag5Ag3a face. The trapped C_2^{2-} dianion coordinated to the silver(I) vertices with mixed σ/π interaction in the range 2.13(1)–2.64(1) Å.

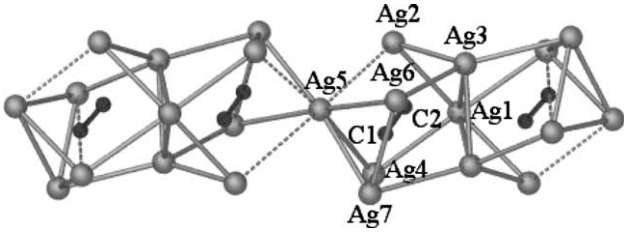

Fig. 7. Portion of an infinite column in **4** generated from vertex- and face-sharing of $C_2@Ag_7$ cages in the shape of a distorted monocapped trigonal prism.

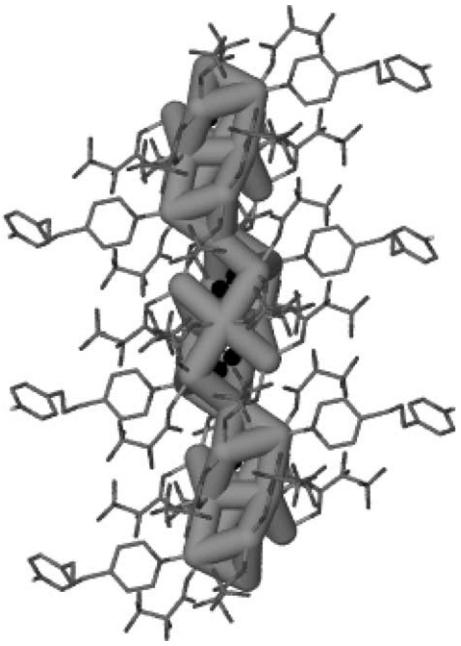

Fig. 8. Infinite branched-tree architecture in **4** generated from the attachment of protonated bpp ligands to the silver(I) backbone.

The silver(I) cages are fused together via sharing of vertex Ag3a, with further connections of Ag1–Ag5a, Ag4–Ag5a and Ag4–Ag6a, to form an infinite column, as shown in Fig. 9.

One terminal of the bpp ligand is protonated and the other is coordinated to a silver atom of type Ag2 (N2–Ag2 2.14(1) Å), and such ligation results in the attachment of cationic branches to the silver backbone, which resembles that found in **4**.

3.6. $[Ag_{23}(C_2)_4(CF_3CO_2)_{15}(bpp)_6]\cdot H_2O$ (**6**)

The basic building block in **6** is an unusual example of a silver(I) column composed of four consecutive

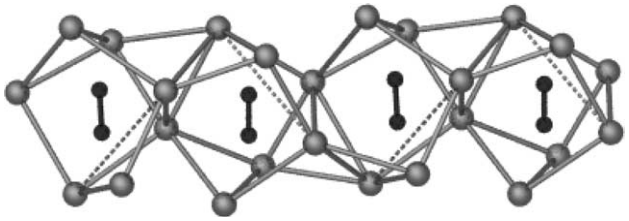

Fig. 9. Portion of an infinite column in **5** generated from edge-sharing of $C_2@Ag_7$ single cages in the shape of a distorted monocapped trigonal prism. Symmetry code: (a) $x, -y + 1/2, z + 1/2$ (b) $x, y, z + 1$.

$C_2@Ag_n$ cages fused in a row. The specific geometries of each polyhedron are shown in Fig. 10. Cage **A** takes the shape of a distorted monocapped trigonal prism, with atom sets Ag3Ag4Ag5 and Ag1Ag2Ag21b constituting the triangular face, making a dihedral angle of 9.2°. The rectangular face Ag3Ag4Ag21bAg1 (mean atomic deviation 0.06 Å) is capped by Ag6 lying about 2.3 Å above it. Cage **D** is best described as an irregular monocapped trigonal antiprism, in which Ag21Ag22Ag23 and Ag17Ag19Ag20 constitute two trigonal faces at a dihedral angle of 14.7°. Atom Ag2a caps the irregular face Ag19Ag20Ag21Ag23. Cages **B** and **C** are essentially distorted triangular dodecahedra. For **B**, atom sets Ag11Ag12Ag13Ag3 and Ag7Ag8Ag9Ag10 are each coplanar within 0.26 and 0.21 Å, respectively, making a dihedral angle of 87.5°. For **C**, atom sets Ag7Ag16Ag17Ag18 and Ag12Ag13Ag14Ag15 are each coplanar within 0.23 and 0.09 Å, respectively, making a dihedral angle of 89.3°. This sequence of four fused polyhedra is repeated by the *c* translation to form an infinite column with embedded C_2^{2-} along its stem. The bpp ligands, which take the TG configuration, all function as μ_2-bridges to connect the silver(I) columns into a two-dimensional architecture, as shown in Fig. 11.

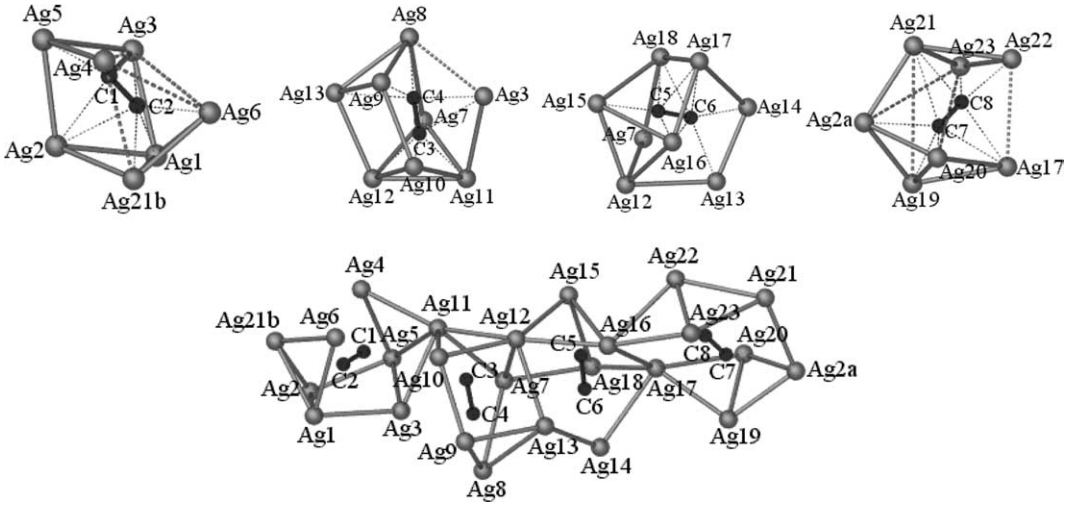

Fig. 10. Cages **A** and **D** (distorted monocapped trigonal prisms), **B** and **C** (distorted triangular dodecaheda), fused to form the building block in **6**.

Fig. 11. Two-dimensional architecture of **6** generated from bpp-bridged silver(I) columns.

4. Conclusion

We have shown that a variety of discrete and higher-dimensional supramolecular structures can be constructed by linking $C_2@Ag_n$ polyhedra with 4,4′-bipyridine or bis(4-pyridyl)propane. The present findings, together with our previous reports [4,5,14,15], provide some insight into the expected geometry of cage motifs in silver(I) double/multiple salts. In general, the generation of a higher-dimensional architecture tends to favor the appearance of distorted polyhedral cages, as exemplified by complexes **1** and **2**. In the presence of ancillary ligands that have significantly lower affinity than the acetylenediide and perfluorocarboxylate anions for coordination to silver(I) atoms, regular cage motifs can often be harvested. This work opens the gate to further investigations of the influence of diverse types of bridging ligands on the assembly of $C_2@Ag_n$ cages.

bioactivity. In this context, a broad array of medicinal applications of metal complexes has been investigated and several recent reviews summarize advances in this field [7–12]. Previous studies have been carried out on the chemotherapeutic and anti-microbial activity of a limited number of metal-coumarin complexes. Kumar et al. [13,14] synthesised a number of hydroxy-substituted coumarin transition metal complexes, which included a series of complexes of hydroxynitrocoumarins, hydroxyaminocoumarins, 4-hydroxy-3-phenylazocoumarin and 8-acetyl-4-methylumbelliferone. The complexes were tested for their antifungal ability using *Rhizoctonia solani* (causative organism for sheath blight in rice plants) and also against the bacterial strain *Escherichia coli*. Their results demonstrated that metal complexes displayed greater inhibition of microbial growth than free ligands and, furthermore, activity was comparable to that of the commercial bactericide, Agrimycin-100. Kostova et al. [15–20] have carried out a series of studies on the cytotoxicity of lanthanide and zirconium complexes of hydroxylated coumarins and reported IC_{50} values of 50–300 μM for the neodymium complexes of bis-coumarins when screened using HL-60, Hl-60/Dox and SKW-3 cell lines. A recent study by Nath et al. [21] has shown that triorganotin(IV) derivatives of 7-hydroxycoumarin, and their adducts with 1,10-phenanthroline (phen), have potent anti-inflammatory activity.

We have previously studied the chemotherapeutic potential of a series of metal-free hydroxynitrocoumarins [22–27]. These compounds were tested against both normal human and neoplastic skin cell lines and were found to be selectively cytotoxic to human skin malignant melanocytes and renal cell carcinoma. An earlier study had found that 7-hydroxy-8-nitrocoumarin was cytotoxic to a panel of cell lines including K562 (human erythroleukemic), HL-60 (human promyelocytic) and CHrC5 (Chinese hamster ovary) [28]. It was thought that the biological activity exhibited by the compounds could be increased by their coordination to a metal centre and a study to investigate this proposal is currently underway. However, a tandem study on the antimicrobial activity of a series of these metal complexes was carried out given the results obtained by Kumar et al. [13,14] on related coumarin complexes.

The present paper details the synthesis of a Cu(II) and a number of Ag(I) hydroxynitrocoumarin complexes and their subsequent in vitro screening against a range of Gram positive and Gram negative bacterial strains and also against a clinical isolate of *Candida albicans*. In addition, a silver(I) complex containing hydroxynitrocoumarin and phen ligands also isolated and its anti-microbial activity was investigated.

2. Experimental

2.1. Chemistry

Chemicals and solvents were purchased from Sigma–Aldrich Co. (Dorset, UK), with the exception of 4-methyl-7-hydroxy-8-nitro-chomen-*2*-one (hmncH) which was obtained from Lancaster (Lancashire, UK) and used without further purification. Infrared spectra of solids (in a KBr matrix) were recorded in the region 4000–400 cm^{-1} on a Nicolet Impact 410 Fourier-Transform Infrared spectrophotometer. A JEOL JNM-LA300 FT-NMR spectrometer was used to record ^1H NMR spectra (−5 to 15 ppm from TMS) and ^{13}C NMR spectra (−33 to 233 ppm from TMS) as solutions in d^6-DMSO. Microanalytical data were provided by the Microanalytical Laboratory, National University of Ireland, Belfield, Dublin 4. Solid state magnetic susceptibility measurements were carried out at room temperature in the Dublin Institute of Technology, Cathal Brugha Street, Dublin 1, using a Johnson Matthey Magnetic Susceptibility Balance with $[HgCo(SCN)_4]$ being used as a reference standard.

2.1.1. $[Cu(hnc)_2(H_2O)_2]\cdot 2H_2O$ (*1*)

A solution of $CuCl_2\cdot 2H_2O$ (0.082 g, 0.48 mmol) in water (10 cm^3) was added to a solution of NaOH (0.04 g, 0.97 mmol) and 4-hydroxy-3-nitro-*2H*-chromen-2-one (hncH) (0.20 g, 0.97 mmol) in water (10 cm^3) and the mixture left to stir for 2 h. After standing for 2 days, a green product precipitated which was filtered off, washed with cold water and methanol and then dried in a vacuum oven at 40 °C. The solid was recrystallised from water. Yield: 0.20 g (81%). The complex was soluble in DMSO, and sparingly soluble in ethanol, methanol and water. *Anal.* Calc. C, 42.24; H, 2.32; N, 5.47; Cu, 12.77. Found: C, 43.04; H, 2.08; N, 5.27; Cu, 12.46%. IR (KBr): 3471, 3447, 2950, 1686, 1671, 1613, 1552, 1467, 1376, 1343, 1281, 1261, 1212 cm^{-1}. μ_{eff} = 2.01 BM.

2.1.2. $[Ag(hnc)]$ (*2*)

A solution of $AgNO_3$ (0.164 g, 0.96 mmol) in water (10 cm^3) was added to a solution of NaOH (0.04 g, 0.97 mmol) and hncH (0.20 g, 0.97 mmol) in water (10 cm^3) and the mixture left to stir for 2 h. Upon standing a yellow precipitate formed, which was filtered off, washed with methanol and cold water and then dried under vacuum at 40 °C. The solid was recrystallised from water. Yield: 0.14 g (46%). The complex was soluble in DMSO, and sparingly soluble in methanol, ethanol and water. *Anal.* Calc. C, 34.42; H, 1.28; N, 4.46%. Found: C, 34.33; H, 1.16; N, 4.28%. ^1H NMR: Ar–H5 (7.88 ppm, 1H, ddd, J = 7.88, 1.83, 0.36 Hz), Ar–H6 (7.22 ppm, 1H, brd, J = 7.53 Hz), Ar–H7 (7.51 ppm,

1H, dt, $J = 8.61$, 7.5, 1.83 Hz) Ar–H8 (7.17 ppm, 1H, ddd, $J = 8.82$, 1.11, 0.36 Hz); ^{13}C NMR: C2, 167.6; C3, 120.47; C4, 152.44; C4a, 122.29; C5, 125.59; C6, 122.89; C7, 132.08; C8, 116.02; C8a, 157.58 ppm. IR (KBr): 1687, 1610, 1584, 1462, 1434, 1347, 1308, 1286 cm^{-1}.

*2.1.3. [Ag(hmnc)] (**3**)*

A solution of $AgNO_3$ (0.169 g, 0.995 mmol) in water (10 cm^3) was added over a period of 10 min to a solution of NaOH (0.04 g, 0.97 mmol) and hmncH (0.20 g, 0.90 mmol) in water (10 cm^3) at room temperature. A brown/red solid immediately precipitated and the resulting suspension was left to stir for 1 h. The solid was filtered off, washed with cold water and dried under vacuum at 40°C. Yield: 0.180 g (61%). The complex was soluble in DMSO and insoluble in all other common solvents. *Anal.* Calc. C, 36.16; H, 1.84; N, 4.27. Found: C, 37.08; H, 1.80; N, 4.15%. ^1H NMR: CH_3 (2.3 ppm, 3H, d, $J = 0.7$ Hz), Vinyl–H, (5.7 ppm, 1H, d, $J = 0.7$ Hz), Ar–H5 (6.3-7.3 ppm, 1H, d, $J = 9.3$ Hz), Ar–H6 (6.33 ppm, 1H, d, $J = 9.3$ Hz) ^{13}C NMR: C2, 166.44; C3, 103.0; C4, 159.81; C4a, 102.38; C5, 125.9; C6, 120.3; C7, 154.48; C8, 130; C8a, 148.21; CH_3, 18 ppm. IR (KBr): 3412, 1719, 1617, 1588, 1541, 1506, 1420, 1369, 1329, 1276 cm^{-1}.

*2.1.4. [Ag(phen)$_2$hnc] (**4**)*

A solution of $AgNO_3$ (0.123 g, 0.72 mmol) in water (10 cm^3) was added to a solution of phen (0.131 g, 0.72 mmol) in ethanol (10 cm^3) giving an immediate yellow precipitate. This suspension was then added to a solution comprising hncH (0.15 g, 0.72 mmol) and NaOH (0.029 g, 0.72 mmol) in water (10 cm^3) over a 10 min period at room temperature. The mixture was then refluxed for 1 h and the resulting yellow solid was filtered off, washed with cold water and dried under vacuum at 40 °C. Yield: 0.180 g (74%). The complex was soluble in DMSO, methanol and ethanol and sparingly soluble in water. *Anal.* Calc. C, 58.7; H, 2.98; N, 10.38. Found: C, 57.7; H, 2.94; N, 9.96%. ^1H NMR: Phen–H H2, (9.17 ppm, 4H, dd, $J = 4.6$, 1.6 Hz), H3, (8.01 ppm, 4H, dd, $J = 4.6$, 8.2 Hz), H4, (8.78 ppm, 4H, dd, $J = 1.6$, 8.3 Hz) H5 (8.22 ppm, 4H, s) hnc protons Ar–H5 (7.86 ppm, 1H, ddd, $J = 7.7$, 1.8, 0.4 Hz) Ar–H6 (7.20 ppm, 1H, dt, $J = 7.7$, 1.11 Hz) Ar–H7 (7.49 ppm, 1H, dt, $J = 8.61$, 1.7 Hz), Ar–H8 (7.47 ppm, 1H, dd, $J = 8.6$, 1.1 Hz) IR (KBr): 3442, 1685, 1619, 1570, 1509, 1462, 1421, 1297, 1208 cm^{-1}.

2.2. Antifungal susceptibility testing

A clinical isolate of *C. albicans* ATCC 10231 was obtained from American Type Culture Collection (Maryland, USA). Antifungal susceptibility testing was performed using broth microdilution assays according to the National Committee for Clinical Laboratory standards (Document M27-A2) protocol with slight modifications. M27-A2 method was altered by substituting Antibiotic Medium 3 (Oxoid Ltd.) for RPMI 1640 medium. Using this method minimum inhibitory concentrations (MICs) were determined by UV spectrophotometer at 405 nm by comparing the turbidity of growth in each well. MIC_{80} is defined as the lowest concentration of drug that inhibits growth by 80%.

2.3. Anti-microbial testing

All bacterial isolates were obtained from clinical samples: *Staphylococcus aureus* (urinary track infection), methicillin-resistant *S. aureus* (wound infection), *Staphylococcus simulans* (facial skin), *Micrococcus luteus* (facial skin) *E. coli* (gastro-intestinal tract), *Bacillus oleronius* (facial skin), *Pantoea agglumerans* (facial skin). The Gram-positive strains used were *S. aureus* (SA), *methycillin-resistant S. aureus* (MRSA), *S. simulans* (S.Sim.) and *M. luteus* (Ml) and the Gram negative strains were *E. coli* (E.Coli), *B. oleronius* (BO) and *P. agglumerans* (PA).

The coumarin complexes were tested against four Gram positive and three Gram negative strains to determine their antibacterial activity. Bacterial strains were grown overnight in nutrient broth medium at 30 °C and 200 rpm in an orbital incubator. The absorbance of these cultures was measured at 660 nm and cultures were diluted to an optical density of 0.1. The cell suspension (100 μl) was added to the wells of a 96 well plate containing novel coumarin derivative dissolved in nutrient broth medium in serial dilutions from 100 to 0.25 μg/ml. Plates were incubated at 30 °C for 24 h and the optical density was measured spectrophotometrically (Dynex Technology) at 660 nm.

3. Results and discussion

3.1. Complex synthesis and spectral characterisation

$[Cu(hnc)_2(H_2O)_2] \cdot 2H_2O$ (**1**) and [Ag(hnc)] (**2**) were prepared in aqueous solution by deprotonating the hydroxy group of hncH with NaOH and then adding copper(II) chloride dihydrate and silver(I) nitrate, respectively. [Ag(hmnc)] (**3**) was synthesised in a similar manner. The mixed-ligand Ag(I) complex [Ag(phen)$_2$hnc] (**4**) was prepared by treating silver(I) nitrate with phen (1:1) and subsequent reaction with a solution containing hncH and NaOH.

The infrared spectra of the complexes and free ligands were recorded in KBr matrix. The most significant changes in absorption frequencies between the

free and coordinated ligands are the $\nu_{asym}(NO_2)$ stretch of the nitro group, the ν(C=O) and ν(C–O) stretches of the lactone (in hncH), and the phenoxy alcohol ν(O–H) stretch (in hmncH). The values for the ν_{asym} nitro for all of the complexes (ca. 1580 cm^{-1}), when compared with that of the free ligand (ca. 1535 cm^{-1}), have all increased, but the effect on ν_{sym} nitro is more difficult to determine as there are many overlapping bands in this region. The ν_{C-O} stretch of the alcohol on both the lactone (in hncH) and the phenoxy (in hmncH) rings also decreased by 80–100 cm^{-1} upon formation of the complexes. Both of these shifts would be consistent with bonding to the metal being through the nitro and hydroxyl/phenoxy oxygen groups, to form a 6-membered chelate ring. There was also a significant shift in the $\nu_{C=O}$ bond, which lowers by ca. 60 cm^{-1} upon complexation for the hncH complexes but hardly at all for the hmncH complex. This is not too surprising,as in the hncH complexes the carbonyl is located on the same lactone ring as the ligand binding site. Such a large shift in $\nu_{C=O}$ in similar complexes has been taken as evidence that complexation occurs through the carbonyl oxygen atom [15–20]. It has recently been shown that, in the case of 7-hydroxy-4-methylcoumarin complexes of Na^+, Cu^+ and H^+, where bonding is through the phenolate anion, coordination to the cation induced polarisation on the lactone ring and resulted in significant shifts in the carbonyl stretching frequency [31]. In the mixed-ligand species **4** distinctive bands for the phen ligand were evident at 1421, 853 and 738 cm^{-1}.

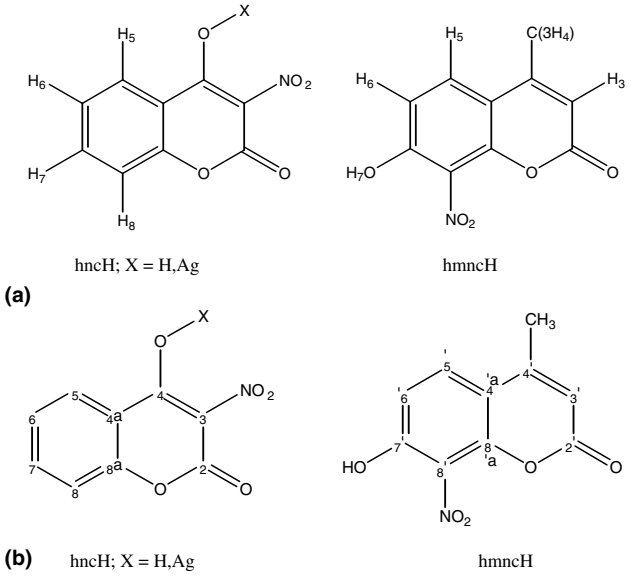

Fig. 1. Structures of the hncH and hmncH ligands used in this study showing atom numbering used in (a) ^{1}H NMR spectral assignments and (b) ^{13}C NMR spectral assignments.

The ^{1}H NMR solution spectra of the Ag(I) complexes show resonance shifts for all of the complexes relative to the uncoordinated ligand (see Fig. 1 for atom numbering). For the hncH complexes, coordination through the nitro and phenoxy oxygen atoms of the lactone ring results in upfield shifts of between 0.03 and 0.06 ppm for the protons on the fused aromatic ring, particularly so for the mixed hncH–phen complex **4**. Also of note is the disappearance of the exchangeable hydrogen peak for the now deprotonated and coordinated hydroxy oxygen atom of the complexed ligands. The ^{13}C NMR spectra show that the carbon atoms on the lactone ring which is attached to the nitro groups experience the most significant downfield shift (ca. 40 ppm) upon coordination of the Ag(I) cation.

The ^{1}H NMR spectrum of the Ag(I) hmncH complex **3** shows significant downfield shifts (ca. 0.15–0.7 ppm) for all protons, particularly those on the aromatic ring, when compared to the metal-free ligand. Similar shifts were noted in the ^{13}C NMR spectrum, with the largest being for the carbon atoms attached to the hydroxy and nitro groups (−15 and +40 ppm, respectively). There was no significant shift observed for the carbonyl carbon atom upon coordination to the metal. The ^{1}H NMR spectrum of the hncH–phen complex **4** has additional signals at 9.18, 8.80, 8.05 and 8.00 ppm corresponding to the presence of the two phen ligands and the integrals confirm the 2:1 phen:coumarin ratio.

3.2. X-ray crystal structure of $[Cu(hnc)_2(H_2O)_2] \cdot 2H_2O$ (1)

The X-ray crystal structure of **1** is shown in Fig. 2. Selected bond lengths and angles are given in Table 2. Although Kumar et al. [14] had previously isolated a Cu(II) complex of hncH, their assignment of the structure isolated is quite different to that reported herein. The metal center in **1** exhibits octahedral geometry, comprising two bidentate hnc^- ligands and two monodentate water ligands. The water molecules are *trans* to one another with Cu–O (water) bond lengths of 1.9557(14) and 1.9957(13) Å to O11 and O12, respectively, and an O12–Cu–O11 bond angle of 177.76(6)°. The hnc^- ligands are coordinated to the metal via the deprotonated hydroxy group and one oxygen of the nitro group. The geometry of the ligands relative to one another is *trans*, as is the geometry of the individual binding sites relative to one another [O5–Cu–O10 179.37(5), O1–Cu–O6 176.96(5)°]. The Cu–O (hnc) bond lengths are unremarkable as they lie in a similar range to previously reported distances [32,33]. The packing structure diagram for **1** (Fig. 3), illustrates the extent of hydrogen-bonding in the gross array, with the lactone

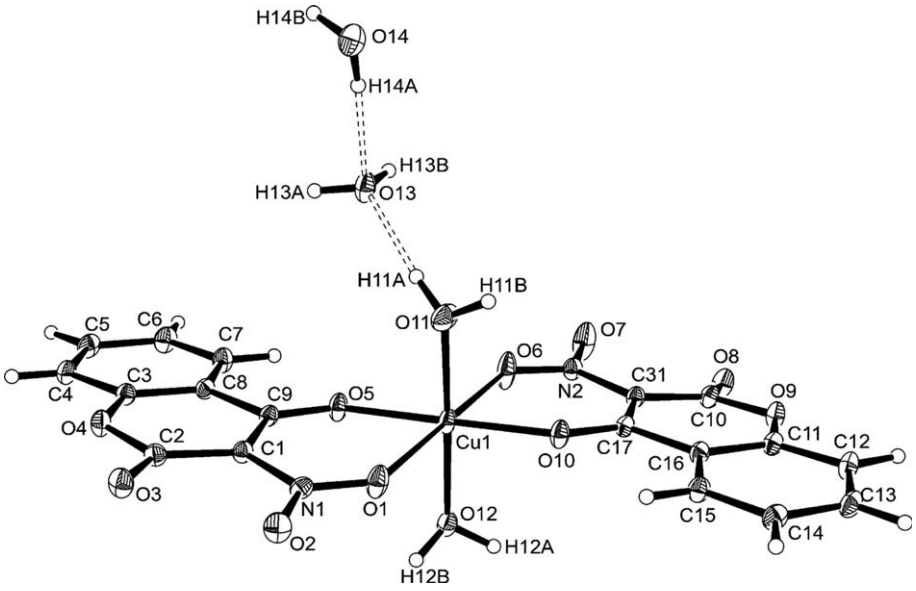

Fig. 2. Crystal structure of $[Cu(hnc)_2(H_2O)_2] \cdot 2H_2O$. Ellipsoids are represented at the 30% probability level.

carbonyl and the nitro group interacting with the lattice water molecules which are, in turn, involved in hydrogen-bonding to the two ligated waters. This extensive H-bonding within the crystal could account for the observed shift in the IR carbonyl stretching frequency.

3.3. X-ray crystal structure of [Ag(4-OH-3-NO$_2$-C)] (**2**)

The X-ray crystal structure of **2** is shown in Fig. 4 and selected geometric data are given in Table 3. The complex is polymeric, with each silver having seven contacts within its coordination sphere and being bonded to four separate coumarin molecules. In particular, within the asymmetric unit there is one axial Ag–O(O1) and one equatorial Ag–O(O5) bond, at 2.5102(17) and 2.3531(16) Å, respectively. Axial metal coordination is completed by an Ag–C6 interaction (2.527(2) Å) to the coumarin moiety generated by the $1 - x$, $1/2 + y$, $1/2 - z$ symmetry operation. While this Ag–C bond is interesting, comparable interactions have been

Table 2

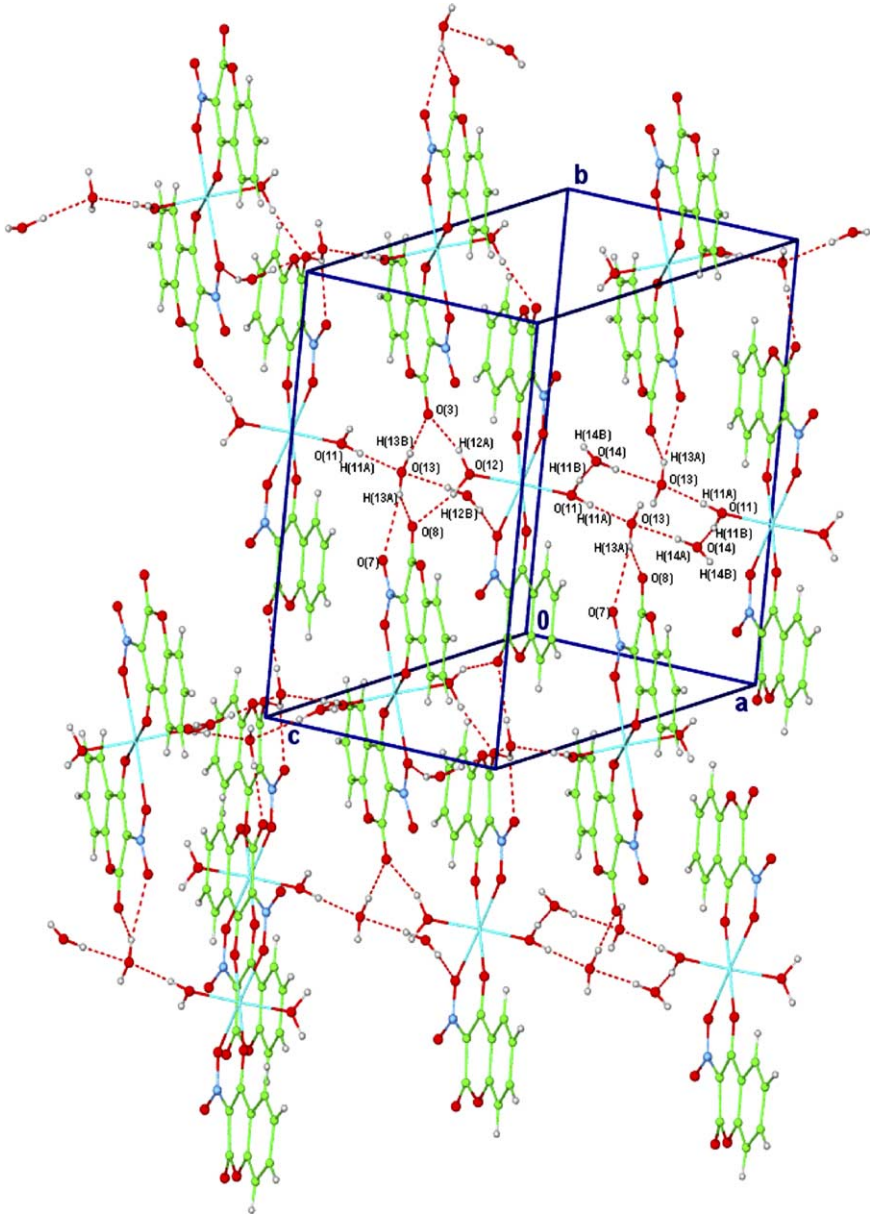

Fig. 3. Crystal packing structure of $[Cu(4\text{-hnc})_2(H_2O)_2] \cdot 2H_2O$.

previously reported for Ag(I) polycyclic aromatic complexes [39]. In the equatorial plane, each silver is also coordinated to two lactone oxygens (O3) from neighbouring molecules in the lattice. [Ag–O3[a] 2.4733(15), Ag–O3[b] 2.4970(16) Å; [a]symmetry operator $-x$, $1/2 + y$, $1/2 - z$, [b]symmetry operator x, $-1/2 - y$, $z - 1/2$]. There are also two potential longer contacts to the metal in the equatorial plane. [Ag–O2[b] 2.6784(17), Ag–O4[c], 2.7841(13) Å; [b]symmetry operator $-x$, $1/2 + y$, $z - 1/2$, [c]symmetry operator x, $-1/2 - y$, $1/2 - z$]. Bond distances for Ag–O_{OH}, Ag–$O_{C=O}$, Ag–O_{NO} and Ag–C are similar to others previously reported [34–36]. The axial bond angles of the C6‴(aryl)–Ag–O1 (nitro) (172.5°), the O5(hydroxy)-Ag–O3′(carbonyl) (72°) and O5(hydroxy)–Ag–O1(nitro) (66.8°), as well as others given in Table 3, suggests that the geometry at the metal centre is best described as a distorted pentagonal bipyramid.

3.4. Antimicrobial results

The metal-free ligands and complexes were screened for their in vitro antimicrobial activities against selected Gram positive bacteria {*S. aureus* (SA), *methicillin-resistant S. aureus* (MRSA), *S. simeoleus* (S.Sim.), *M. luteus* (Ml)} and Gram negative bacteria {*E. coli* (E.Coli), *B. olenius* (BO), *P. agglumerans* (PA)} and also against the pathogenic fungus *C. albicans* (Can). The results are presented in Table 4 as MIC_{80} values (in μM) which is the minimum concentration required to inhibit 80% of the growth of the microbe at 30 °C.

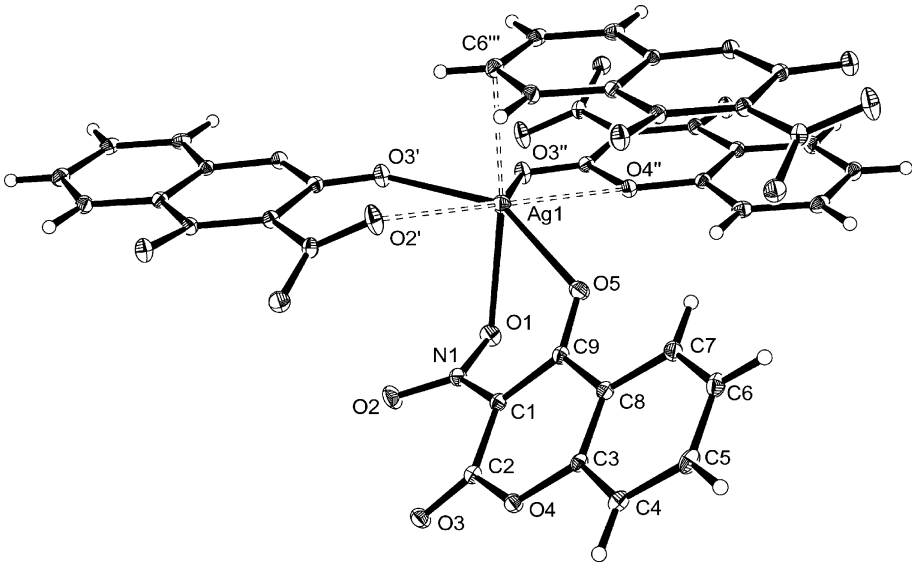

Fig. 4. Crystal structure of [Ag(4hnc)]. Ellipsoids are represented at the 30% probability level. Atoms in asymmetric unit denoted by unprimed labels. Singly, doubly and triply primed atom labels denote atoms generated via the $1 - x$, $1/2 + y$, $1/2 - z$, $-x$, $1/2 + y$, $1/2 - z$ and x, $-1/2 - y$, $-1/2 + z$ symmetry operations.

The metal-free ligands, $[Cu(hnc)_2(H_2O)_2] \cdot 2H_2O$ (**1**) and the simple Cu(II) salt showed no significant antibacterial or antifungal activity. For the silver-containing samples the antimicrobial activity of the simple salt $AgNO_3$ was, almost without exception, superior to that of [Ag(hnc)] (**2**) and [Ag(hmnc)] (**3**) across all of the bacterial and the fungal species studied. However, one interesting exception to that trend was in the activity of complexes **2** and **3** against the clinically important bacterium MRSA. [Ag(hmnc)] (**3**) was approximately four times more active that $AgNO_3$ against MRSA. In general however, the phen-containing complex $[Ag(phen)_2hnc]$ (**4**) displayed the greatest inhibitory effects against all of the microbes studied, with its performances against the bacterium MRSA and the fungal isolate *C. albicans* being the most emphatic. The phen ligand itself also showed considerable activity against test strains, but complex **4** was still six times more active against MRSA and three times more active against *C. albicans*, than phen and was compara-

ble in activity to the commercially available fungicides clortrimazole and ketoconazole (MIC_{80} = 5.5 and 25 μM, respectively). We and others have reported the anti-*Candida* activity of several other phen complexes [37–39]. The activity of phen complexes is believed to be related to the abstraction by the phen ligands of metal ions present in trace amounts in the growth media, and that it is the resulting metal-phen complexes that are responsible for the high anti-*Candida* activity. The present work has shown that while the presence of phen in a complex does indeed increase the anti-*Candida* activity of the resulting complex, it is likely that the coumarin-metal moieties have a role to play as well.

4. Conclusions

The results presented here demonstrate that a number of potent anti-bacterial and antifungal agents have been synthesised. In particular, $[Ag(phen)_2hnc]$ (**4**) shows good activity against methicillin-resistant *S. aureus* (MRSA) but not against the drug susceptible variant *S. aureus*. Complex **4** is also active against *C. albicans* and is more potent than metal-free phen. Since MRSA is frequently associated with superficial infections of wounds and ulcers the ability of **4** to inhibit the growth of MRSA might indicate a possible clinical use for the complex. It is possible that the complex compound could be incorporated into an ointment or cream for topical application to the affected area to retard the development and dissemination of infection. **4** is active against *C. albicans* and compares favourably with some of the conventional anti-fungal agents, such as clortrimazole and ketoconazole. With drug-resistant strains of microbes increasing in importance in the clinical setting, these new compounds may offer alternative candidates to those compounds presently in clinical use. A study is currently under way to elucidate the mechanism of action of the most active compounds.

5. X-ray crystallography

Single crystals of **1** and **2** were analysed at 150 K using a Nonius Kappa CCD diffractometer equipped with graphite monochromated Mo Kα radiation. Details of the data collections, solutions and refinements are given in Table 1. Both structures were solved using SHELXS-97 [29] and refined using full-matrix least-squares in SHELXL-97 [30]. Convergence was uneventful, with the following points of note.

The asymmetric unit in **1** was seen to contain two molecules of water in addition to one full molecule of the copper complex. The water hydrogen atoms were all located and refined at distances of 0.89 Å from the relevant parent atoms. In **2** the asymmetric unit is comprised of one full ligand moiety, bonded in bidentate fashion to a silver atom. Both refinements were implemented using full-matrix least-squares.

Crystallographic data for **1** and **2** have been deposited with the Cambridge Crystallographic Data Centre as supplementary publications CCDC 253929 and 253930, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: (+44) 1223 336033, e-mail: deposit@ccdc.cam.ac.uk].

2. Experimental

2.1. Reagents and general procedures

All manipulations were carried out under argon, using standard Schlenk techniques. Solvents were distilled from drying agents and degassed. The NMR spectra were recorded in C_6D_6 or C_7D_8 at ambient probe temperature using the following Bruker instruments: DRX 400 (^{1}H, 400.32 MHz) or Avance 300 (^{1}H, 300.13; ^{13}C, 75.5 MHz) and referenced internally to residual solvent resonances (chemical shift data in δ). ^{13}C NMR spectra were all proton-decoupled. Elemental analyses were determined by the Institute for Soil, Climate and Water, Pretoria, South Africa. The mass spectrum was recorded on a VG 70 SEQ Micromass. The following abbreviations are used throughout the experimental section: bs = broad singlet, d = doublet, dd = doublet of doublet, m = multiplet, s = singlet, t = triplet. Coupling constants (J) are given in Hz.

2.2. Synthetic procedures

2.2.1. Reaction of $LiCHR_2$ with $C_6H_3(Pr^i{}_2\text{-}2,6)NC$ in hexane

A solution of $C_6H_3(Pr^i{}_2\text{-}2,6)NC$ (0.75 g, 4.03 mmol) in hexane (25 ml) was added dropwise to a suspension of $LiCHR_2$ (0.67 g, 4.03 mmol) in hexane (30 ml) at −80 °C. The reaction mixture was allowed to warm up to room temperature and stirred for 15 h to give an orange reaction mixture. Filtration of the reaction mixture and concentration of the filtrate gave upon cooling to −60 °C orange crystals of compound **2** (0.30 g, 27%). Melting point 135 °C. Elemental *Anal.* Calc. for $C_{34}H_{24}N_2Si_2$ requires: C, 74.64; H, 9.97; N, 5.12. Found: C, 74.41; H, 9.80; N, 5.10%. Mass spectrum [*m*/*z* (%)]: 546 (11 $[M]^+$), 503 (5, $[M - Pr^i]^+$), 473 (60, $[M - SiMe_3]^+$), 385 (22, $[M - C_6H_3Pr^i{}_2]^+$). ^{1}H NMR (C_6D_6): δ 0.18 (s, $SiMe_3$, 18 H), 1.53 [d, $CHMe_2$, $^3J(^1H–^1H)$ = 6.86 Hz, 24H], 2.79 (septet, $CHMe_2$, 4H), 6.72 (s, CH, 2H), 6.94 (s, *p*-H, 2H), 7.34 (s, *m*/*o*-H, 4H). ^{13}C NMR (C_6D_6): δ −1.1 (s, $SiMe_3$), 22.6, 22.8 (s, $CHMe_2$), 28.4, 28.7 (s, $CHMe_2$), 123.2, 124.1 (Ar–C), 133.1 (s, *C*H), 134.9, 149.7 (*ipso* C), 184.9 (s, CN).

2.2.2. Reaction of [LiN(Ar)C(R)CHR] and $SnCl_2$ [Ar = $C_6H_3(Pr^i{}_2\text{-}2,6)$; R = $SiMe_3$]

Solid $SnCl_2$ (0.18 g, 0.95 mmol) was added to a solution of [LiN(Ar)C(R)CHR] (**1a**) (see Section 2.2.3) (0.69 g, 1.96 mmol) in diethyl ether (30 ml) at −30 C. The reaction mixture was allowed to warm to room temperature and stirred for 15 h. Removal of volatiles in vacuo and extraction of the residue with hexane gave orange crystals of **2** (0.30 g, 56%).

2.2.3. Synthesis of [LiN(Ar)C(R)CHR] (**1a**)

$LiCHR_2$ (0.51 g, 3.07 mmol) was dissolved in diethyl ether (30 ml). The solution was cooled to −90 °C and a solution of $C_6H_3(Pr^i{}_2\text{-}2,6)NC$ (0.57 g, 3.07 mmol) in diethyl ether (20 ml) was added drop-wise. The reaction mixture was allowed to warm to room temperature during a period of 3 h, then stirred for further 12 h to give a deep orange solution. After removing the diethyl ether in vacuo and extracting the residue with hexane, the orange solution was concentrated. After cooling the solution for a period of 2 weeks without obtaining crystals, the solvent was removed in vacuo leaving a viscous red oil (0.86 g, 79%). ^{1}H NMR spectroscopic characterisation (all lines very broad) of the oil was consistent with the formation of compound **1a**. ^{1}H NMR (C_6D_6): δ 0.37 and 0.50 (bs, $SiMe_3$, 9H), 1.36 [bs, $CHMe_2$, 12H], 3.53 (bs, $CHMe_2$, 2H), 3.85 (bs, CH, 1H) 7.14 and 7.30 (bs, Ar–H, 3H).

2.2.4. Synthesis of [LiN(Ar)C(R)CHR(thf)$_2$] (**1b**) [Ar = $C_6H_3(Pr^i{}_2\text{-}2,6)$; R = $SiMe_3$]

A solution of $C_6H_3(Pr^i{}_2\text{-}2,6)NC$ (1.07 g, 5.71 mmol) in hexane (15 ml) was added to a solution of $LiCHR_2$ (0.95 g, 5.71 mmol) in thf (20 ml) at −80 °C. The reaction mixture was allowed to warm to room temperature and was stirred for 15 h to give a deep red solution. After removing all the volatiles in vacuo and extracting the residue in hexane (25 ml) the deep red solution was filtered. Concentration and cooling of the filtrate gave red crystals of compound **1b** (1.52 g, 38%). ^{1}H NMR (C_6D_6): δ 0.10 (s, $SiMe_3$, 9H), 0.40 (s, $SiMe_3$, 9H), 1.25 [bs, CH_2(thf) and $CHMe_2$, 14H], 1.39 [d, $CHMe_2$, 6H], 3.41 (bs, OCH_2, 8H), 3.55 (bs, $CHMe_2$, 2H) 4.25 (s, CH, 1H), 7.15 [bs, Ar–H and C_6D_5H]; ^{1}H NMR (C_7D_8, 203 K, 2 isomers): δ 0.42, 0.66, 0.69, 0.75 (s, $SiMe_3$) 1.32 [bs, CH_2(thf)], 1.40 [bs, $CHMe_2$], 1.48 [d, $CHMe_2$], 1.65 [bs, $CHMe_2$], 1.82 [d, $CHMe_2$], 3.41 (bs, OCH_2), 3.76 (bs, $CHMe_2$) 3.92, 3.98 (s, CH), 7.33–7.44 [Ar–H].

2.2.5. Synthesis of [LiN(Ar)C(R)CHPh(tmen)] (**1c**) [Ar = $C_6H_3(Pr^i{}_2\text{-}2,6)$; R = $SiMe_3$]

A solution of $C_6H_3(Pr^i{}_2\text{-}2,6)NC$ (0.40 g, 2.26 mmol) in diethyl ether (15 ml) was added to a solution of LiCH(R)Ph(tmen) (0.60 g, 2.26 mmol) in diethyl ether (20 ml) at −60 °C. The reaction mixture was stirred over night in an acetone cool bath allowing it to warm up to room temperature over a period of 15 h. The solvent was then completely removed in vacuo to give a yellow solid. The product was extracted into hexane, the solution was concentrated and cooled to −20 °C yielding yellow crystals of **1c** (0.50 g, 50%). ^{1}H NMR (C_6D_6): δ 0.19 (s, $SiMe_3$, 9H), 1.28 [d, $CHMe_2$, $^3J(^1H–^1H)$ = 6.83 Hz, 6H], 1.42 [d, $CHMe_2$, $^3J(^1H–^1H)$ = 6.82 Hz, 6H], 1.51 (bs, NCH_2, 4H), 1.65, (bs, NMe_2, 12H), 3.51 (m, $CHMe_2$, 2H) 5.21 (s, CH, 1H), 7.05 [t,

$^3J(^1H–^1H)$ = 7.77 Hz, 1H], Ph hidden under solvent peak, 7.83 [d, $^3J(^1H–^1H)$ = 7.77 Hz, 2H].

2.2.6. Synthesis of [LiN(Ar)C(R)CHPh(tmen)] (1d) [Ar = $C_6H_3(Bu^t_2$-2,5); R = $SiMe_3$]

Compound **1d** was synthesised as described for **1c** from $C_6H_3(Bu^t_2$-2,5)NC (0.41 g, 1.95 mmol) and LiCH(R)Ph(tmen) (0.56 g, 1.95 mmol) in diethyl ether (30 ml) at −70 °C. Red crystals of **1d** (0.46 g, 47%) were obtained after recrystallisation from hexane at −60 °C. ^{1}H NMR (C_6D_6): δ 0.23 (s, $SiMe_3$, 9H), 1.38 (s, Bu^t, 9H), 1.58 (s, very broad, tmen, 16H), 1.76 (s, Bu^t, 9H), 5.29 (s, CH, 1H), 6.68 (s, Ph, 2H), 6.85 (dd, Ph, J = 8.23 Hz, J = 2.21 Hz, 1H), 2H hidden under solvent peak, 7.39 (d, Ph, ^3J = 8.23 Hz, 1H), 8.03 (d, Ph, ^3J = 7.70 Hz, 2H); ^{13}C NMR (C_6D_6): 2.6 (s, $SiMe_3$), 31.9, 32.0 (s, Bu^t), 34.4, 35.8 [s, CMe_3], 44.0 (bs, NMe_2), 56.0 (s, NCH_2), 98.4 (CH), 118.5, 123.0, 126.5, 129.8, 140.9, 144.6, 146.9, 153.3, 158.9, 165.7 (Ar–C), 197.6 (CN).

2.3. Crystal structure determination

Intensity data were collected on a Bruker SMART 1K CCD area detector diffractometer with graphite monochromated Mo Kα radiation (50 kV, 30 mA). The collection method involved ω-scans of width 0.3°. Data reduction was carried out using the program SAINT+ [7].

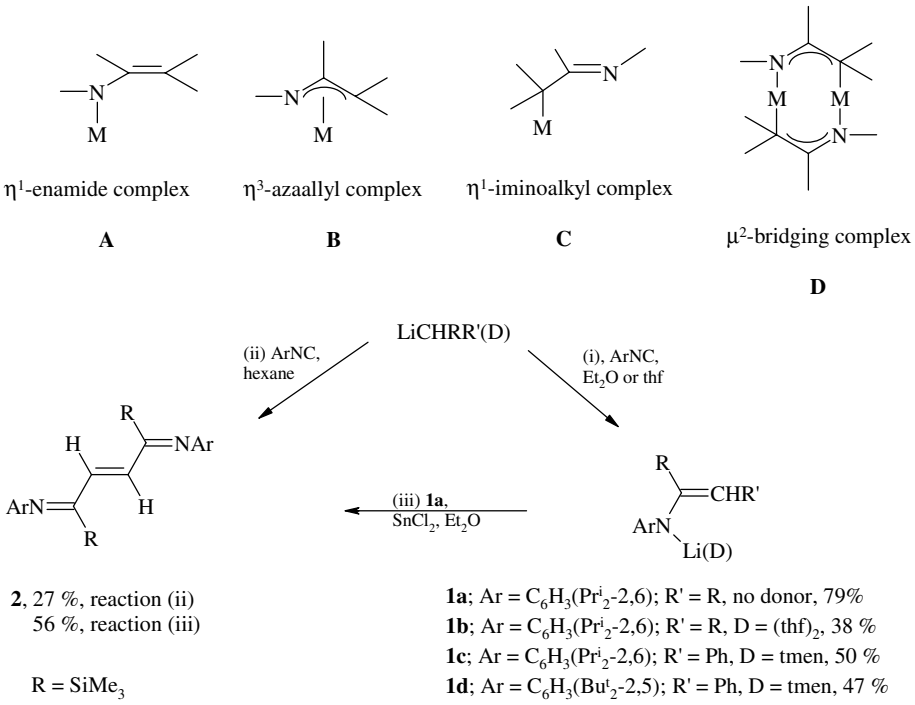
The crystal structures were solved by direct methods using SHELXTL [8]. Non-hydrogen atoms were first refined isotropically followed by anisotropic refinement by full matrix least-squares calculation based on F^2 using SHELXTL. Hydrogen atoms were located from the difference map and then positioned geometrically and allowed to ride on their respective parent atoms. Further crystallographic data are summarised in Table 1. Diagrams and publication materials were generated using SHELXTL [8], PLATON [9] and ORTEP3 [10].

3. Results and discussion

3.1. Synthesis

The lithium-1-azaallyl complexes **1** were obtained in moderate yields from the reaction of $LiCHR_2$ or LiCH(R)Ph(tmen) (R = $SiMe_3$, tmen = *N*,*N*,*N*′,*N*′-tetramethylethylendiamine) with ArNC [Ar = $C_6H_3(Pr^i_2$-2,6) or $C_6H_3(Bu^t_2$-2,5)] in the presence of polar solvents (Et_2O or thf) at low temperatures [(i) in Scheme 1]. In analogy to previous studies it is believed that the formation of the lithium-1-azaallyls involves the insertion of the lithium alkyl into the aryl isocyanide to give a lithioaldimine [ArN=C(Li)CHRR′] intermediate followed by a 1,2 trimethylsilyl shift from C → C [3a]. A variation of the reaction conditions by replacing Et_2O or thf with hexane led in the case of the reaction of $LiCHR_2$ and $C_6H_3(Pr^i_2$-2,6)NC unexpectedly to a mixture of compounds from which the diazahexatriene **2** was isolated in low yield as the only product [(ii) in Scheme 1]. The related compound, ArN=C(R)CH=CHC(R)=NAr, was recently obtained as a side-product of the synthesis of $\overline{[LiN(Ar)C(R)CHC(R)NAr]}$[R = $SiMe_3$, Ar = $C_6H_3(Bu^t_2$-2,5)] from the reaction of $LiCHR_2$ with $C_6H_3(Bu^t_2$-2,5)NC [5]. The formation of diazahexatrienes as a new class of product in the $LiCHR_2$/ArNC system is not fully understood but oxidative coupling of two 1-azaallyl anions $[ArNC(R)CHR]^-$ and the consecutive loss of two trimethylsilyl groups may be implicated. The related coupling of $[LiN(R)C(Bu^t)CHR]_2$ with iodine yielding RN=C(Bu^t) CHR–CHRC(Bu^t)=NR has been described previously [11]. Attempts to use **1a** as a ligand transfer reagent to synthesise a tin derivative of **1a** were not successful and led to the formation of **2** [(iii) in Scheme 1].

The lithium-1-azaallyls are yellow (**1c**) or red solids (**1b**, **1d**) that are highly air sensitive and very soluble in hydrocarbons. The orange diazahexatriene **2** is moderately soluble in hexane and stable in moist air.



The room temperature ^{1}H NMR spectra of **1a** and to a lesser degree **1b** showed broad lines indicating the presence of a mixture of possible isomers (**A**–**C**) and/or rotamers [hindered rotation around the N–C(azaallyl) bond of the ligand]. Variable temperature ^{1}H NMR studies of a solution of **1b** in C_7D_8 demonstrated the existence of two isomers at −70 °C. The room temperature ^{1}H NMR spectra of **1c** and **1d** were in contrast well resolved showing the existence of a single isomer in solution. The characteristic signal for the 1-azaallyl proton (C*H* R) was found at δ 4.3 (**1b**) and δ 5.2 (**1c**, **1d**) indicating solution structures with considerable double bond character in the 1-azaallyl backbone best represented by **A**. Metal-1-azaallyls with solution structures similar to **B** or **C** were found to show C*H*R signals at higher field strength (δ 2.5–3.5) [3e]. The corresponding signal in **2** was found at δ 6.72 as expected for an olefinic proton and close to the previously reported value of δ 6.52 for $C_6H_3(Bu^t_2$-2,5)-N=C(R)CH=CHC(R)=N$C_6H_3(Bu^t_2$ -2,5) [5].

3.2. Structural studies

The lithium-1-azaallyls that have been crystallographically characterised in the last two decades suggest that their structures may be classified in three structural types (I–III) depending on the aggregation state and the presence or absence of additional neutral donors in the form of coordinating solvents or internal donor groups. Type I (e.g., **E**) [12] is found in the absence of donor groups leading invariably to dimeric or in the case of $[LiN(R)C(Bu^t)CH_2]_3$ [13] trimeric structures featuring a central $(LiN)_2$ or $(LiN)_3$ core that is stabilised by

Scheme 1. Reactions of LiCHRR′(D) with isocyanides.

additional interactions between the Li atom and the delocalised π electrons of the 1-azaallyl ligand (η^3-azaallyl, **B**). In the case of the α-picoline derivative $[C_5H_4N(CR_2Li\text{-}2)]_2$ such an arrangement would destroy the aromaticity of the pyridine ring and a bridging iminoalkyl structure (**D**) is consequently favoured [14]. Type II (e.g., **F**) [3a] is observed in the presence of a single monodentate solvent molecule (or internal donor group) giving rise to dimeric or less frequently trimeric structures. The $(LiN)_2$ or $(LiN)_3$ is typically retained but the Li···C interaction between the Li atom and the 1-azaallyl backbone is increasingly supplemented or replaced by coordination of the Li atom to the donor solvent or an internal donor group (η^1-enamide, **A**). In the case of $[LiN(R)C(Bu^t)CHR'(thf)]_2$ [R = SiMe(OMe)$_2$, R′ = SiMe$_3$ or R = R′ = SiMe$_2$OMe] [15] the $(LiN)_2$ ring is replaced by an eight-membered $\overline{LiNSiOLiNSiO}$ macrocycle. A few complexes with bidentate co-ligands also fall into this category. More frequently, however, the presence of a bidentate or two monodentate ligand results in monomeric structures of type IIIa (e.g., **G**) [4e] with strong coordination of the Lewis base (frequently N, O) to the trigonal planar Li atom that may be supplemented by further Li···C interactions to the 1-azaallyl depending on the steric and electronic properties of the substituents and the presence or absence of other groups such as Ph that can compete with the azaallyl for coordination to the Li atom. **H** [16] may serve as an example were additional coordination of the phenyl ring to the Li atom is favoured over coordination to the 1-azaallyl backbone. The unexpected type IIIa structure of $[LiN(R)C(C_6H_4Br\text{-}4)CR_2(thf)]$ (R = SiMe$_3$) [17] having only a single thf ligand is likely to be the result of steric crowding of the complex due to the presence of three bulky trimethylsilyl groups that prevent dimerisation to a type II structure. Type IIIb structures are typically found in compounds with three or more additional donor atoms leading to monomeric structures (η^1-enamide, **A**) with approximately tetrahedral coordination of the lithium atom and little interaction between lithium and the 1-azaallyl backbone. Structurally characterised lithium-1-azaallyl complexes reported in the literature are found in Table 2.

[a] Degree of aggregation.
[b] Neutral donor (solvent or internal group).
[c] Number of additional donor atoms per Li (excluding N of azaallyl).

The preference for *syn*- or *anti*-conformation in lithium-1-azaallyls is of interest. The lithium-1-azaallyls that have been crystallographically characterised so far adopt with few exceptions a *syn*-conformation of the Li atom with respect to the double bond. This is in agreement with theoretical calculations by Armstrong et al. [19] who found that the *syn*-conformation of $[LiN(H)C(Bu^t)CH_2]$ is stabilised by 9.4 kcal/mol compared to the *anti*-conformation. The lithium complex **I** is so far the only example of a lithium-1-azaallyl with a trigonal planar Li atom adopting an *anti*-conformation possibly as a result of **I** being a zwitterion in which the azaallyl backbone is part of a strained four-membered ring [25].

The molecular structures of compounds **1b**–**1d** with the atom numbering scheme are illustrated in Figs. 1–3, selected bond distances and angles are summarised in Table 3. All three complexes are monomeric with

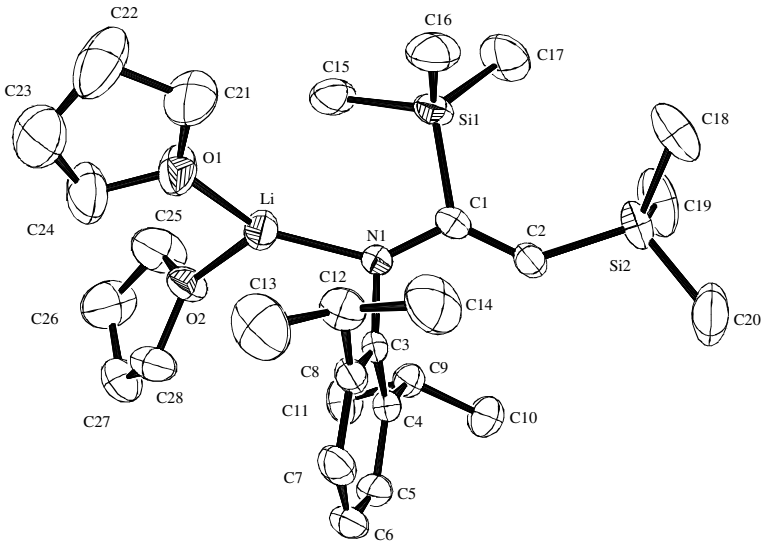

Fig. 1. Molecular structure of **1b**. Thermal ellipsoids are drawn on the 50% probability level. H atoms have been omitted for clarity.

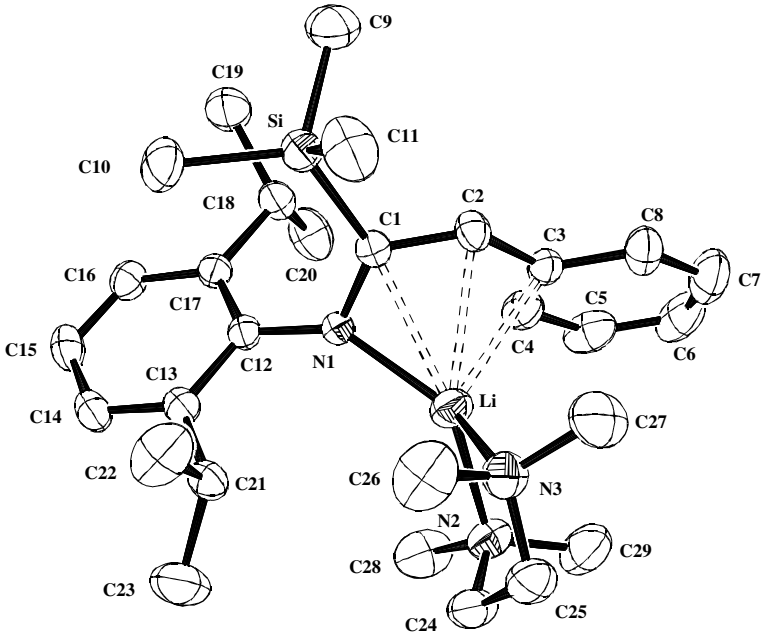

Fig. 2. Molecular structure of **1c**. Thermal ellipsoids are drawn on the 50% probability level. H atoms have been omitted for clarity.

two additional donor atoms and therefore belong to type IIIa with the shortest distance (Li–N1, Table 3) between the Li atom and the negatively charged N atom of the 1-azaallyl ligand and considerably longer contacts to the neutral donor atoms (except O2) of the solvent molecules. The coordination around the Li atom is approximately trigonal planar (Σ°Li, Table 3) in all three complexes with the largest deviation from planarity for complex **1d**. Complexes **1c** and **1d** show additional Li···C contacts to C1–C3 and C4(C8), respectively, in the range of 2.45 to 2.52 Å. The contact distances and geometries are similar to related complexes in category III and may be best compared to [LiN($C_6H_3Me_2$-2,6)C(R)CHR(tmen)] [4e] or [LiN(R)C(Ph)CHPh(tmen)] [3a].

Possibly as a result of steric crowding that is evident from the large angles around the sp^2 hybridised carbons C1 and C2 in the backbone [C2–C1–Si1 126.1(1)°, N1–C1–C2 126.1(2)°, C1–C2–Si2 134.5(2)°], **1b** is exceptional in being the first example of a lithium-1-azaallyl being a *Z* isomer (with regard to the two $SiMe_3$ groups) and adopting an *anti*-conformation

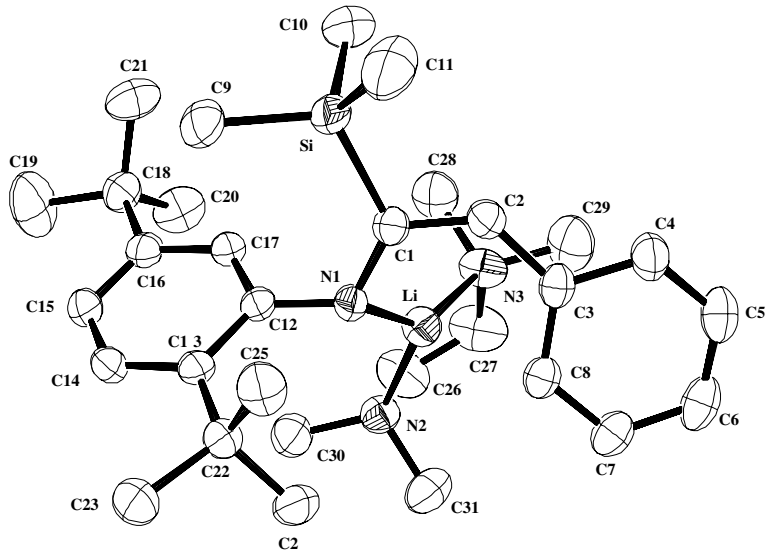

Fig. 3. Molecular structure of **1d**. Thermal ellipsoids are drawn on the 50% probability level. H atoms have been omitted for clarity.

Table 3
Selected bond distances (Å) and angles (°) for compounds **1b**, **1c**, and **1d**

Compound	**1b**	**1c**	**1d**

Li–D2[b]	1.901(4)	2.147(4)	2.069(4)
Li···C1		2.446(4)	[2.614(4)]
Li···C2		2.459(4)	
Li···C(Ar)[c]	[2.636(4)]	2.530(4)	
Li···C8			2.506(4)
N1–C1	1.378(2)	1.362(2)	1.356(2)
C1–C2	1.379(3)	1.393(2)	1.392(2)
C1–Si1/Si	1.883(2)	1.912(2)	1.918(2)
C2–Si2	1.827(2)		
Σ°Li[d]	357.3(2)	357.0(2)	350.7(2)
N1–C1–C2	126.1(2)	120.6(2)	121.7(2)
N1–C1–Si1	107.4(1)	127.8(1)	126.9(1)
C2–C1–Si1	126.1(1)	111.4(1)	111.3(1)

[a] D1 = O1 for **1b**; N1 for **1c** and **1d**.
[b] D2 = O2 **1b**; N2 for **1c** and **1d**.
[c] C(Ar) = C3 (**1b**, *ipso*-C of N-bound Ar ring); C3 (**1c**, *ipso*-C of Ph ring).
[d] Sum of bond angles around Li.

(with regard to lithium). The four atoms Li, N1, C1 and C2 are essentially planar [largest deviation from planarity for N1 0.024(1) Å] with the aryl ring (C3–C8) being approximately perpendicular (74.1°) to this plane. It is also noteworthy that further contacts between Li and one methyl group of Si1 [Li···C15 2.808(4) Å] and the *ipso*-C of the aryl ring [Li···C3 2.636(4) Å] increase the coordination sphere around Li in **1b** from trigonal planar to distorted trigonal bipyramidal. The significantly shorter C2–Si2 bond distance of 1.827(2) Å in **1b** as compared to the C1–Si1 bond distances in **1b**–**1d** may be an indication of a possible stabilisation (Si–C δ*–π interaction) of the partial negative charge on C2 by the adjacent trimethylsilyl group. The ability of Si to stabilise carbanions has previously been well established [34].

In all three complexes there is only limited delocalisation in the backbone of the azaallyl ligand (η^1-enamide, **A**) as evident from the N1–C1 and C1–C2 bond distances (Table 3) that correspond to N–C single and C=C double bonds, respectively.

The molecular structure of compound **2** with the atom numbering scheme is illustrated in Fig. 4, selected bond distances are found in Table 4.

Compound **2** crystallises as a monomer with half a molecule of **2** in the asymmetric unit, the other half being generated by a centre of inversion. Compound **2** is a rare example of a structurally characterised diazahexatriene and has a structural precedence in $C_6H_3(Bu^t_2\text{-}2,5)N{=}C(R)CH{=}CHC(R){=}NC_6H_3(Bu^t_2\text{-}2,5)$ [5] and the related hydrazine and hydroxylamine derivatives R′N=CHC(COPh)=C(COPh)CH=NR′ [R′ = $NHC_6H_3[(NO_2)_2$-2,4]] [35] or HON=C(NH_2)-CH=CHC(NH_2)=NOH [36]. The atoms N1, C13, C14 and their symmetry related equivalents in the backbone of the molecule show little deviation from planarity as evident from their torsion angles [C14′–C14–C13–N1 −175.5(2)°; C14′–C14–C13–Si1 −3.2(2)°; C1–N1–C13–C14 4.5(2)°]. The N=C, C–C and C=C bond distances (Table 4) are similar to those in $C_6H_3(Bu^t_2\text{-}2,5)N{=}C(R)CH{=}CHC(R){=}NC_6H_3$ (Bu^t_2- 2,5) and alternate between single and double bonds with only a limited degree of delocalisation not uncommon in related linear conjugated C=C double bond systems [37].

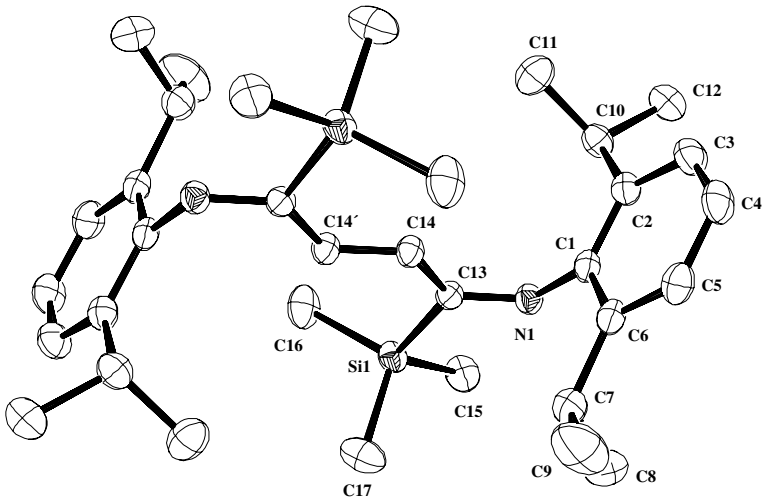

Fig. 4. Molecular structure of **2**. Thermal ellipsoids are drawn on the 50% probability level. H atoms have been omitted for clarity.

Table 4
Selected bond distances (Å) for compounds **2**

N1–C1	1.432(2)	N1–C13	1.295(2)
C13–C14	1.472(2)	C14–C14′	1.339(2)

′ $-x+1, -y, -z+1$.

4. Supplementary data

Full crystallographic data (CCDC 257844 for compound **1b**, 257845 for compound **1c**, 25786 for compound **1d** and 257847 for compound **2**) have been deposited at the Cambridge Crystallographic Database Centre and are available on request from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

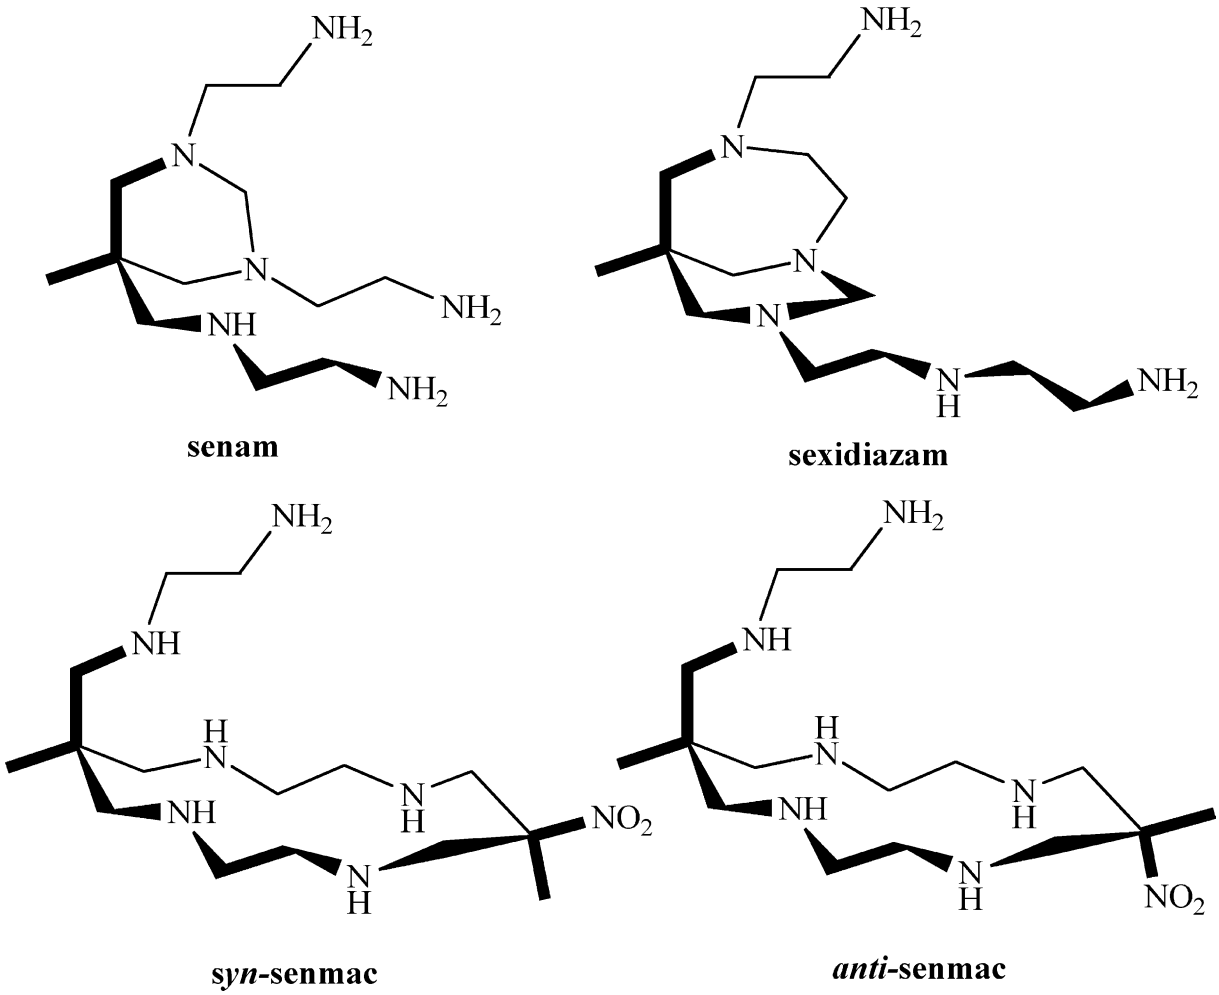

Fig. 1. Some of the possible macrocyclic ligand species derived from "sen".

its definition resulted in characterisation of an aminal derivative of the ligand. The aminal formation may be a consequence of solvent methanol oxidation catalysed by Cu(II), as an aminal is also formed in a synthesis under similar conditions of the Cu(II) complex of another podand hexamine.

2. Experimental

2.1. Synthesis

3,7-diaza-5-(4′-amino-2′-azabutyl)-5-methylnonane-1,9-diamine (sen), as its hexahydrochloride, was prepared from the benzenesulfonate of 2-hydroxymethyl-2-methyl-propane-1,3-diol (1,1,1-tris(benzenesulfonyloxymethyl) ethane) via its reaction with 1,2-ethanediamine following literature procedures [6].

Cu(II) complex of a mono-aminal derivative of sen ("senam"). Methanolic NaOH (1.0 g in 50 mL) was added to a slurry of sen·6HCl (1.9 g) in methanol (50 mL) and the mixture stirred vigorously for 30 min before precipitated NaCl was filtered out. $CuCl_2\cdot 2H_2O$ (1.1 g) in methanol (600 mL) was added to give a violet solution, which was was evaporated to dryness. The violet residue was dissolved in water, excess $NaClO_4$ added and the solution allowed to slowly evaporate at room temperature. A structure determination (see below) on the crystals obtained showed them to be the triperchlorate of the complex of the monoprotonated ligand, $[Cu(senamH)(OClO_3)_2]ClO_4$ (**1**). *Anal.* Calc. for $C_{12}H_{31}Cl_3CuN_6O_{12}$: C, 23.20; H, 5.03; N, 13.53. Found: C, 23.1; H, 4.7; N, 13.2%. Use of $[NH_4][PF_6]$ in place of $NaClO_4$ as the precipitant provided crystals once again of the complex of the monoprotonated ligand, here as its chloride-di-(hexafluorophosphate), $[Cu(senamH)Cl(FPF_5)](PF_6)\cdot 2H_2O$ (**2**), the composition also being deduced from a structure solution. Yield, 2.0 g (75%). *Anal.* Calc. for $C_{12}H_{35}ClCuF_{12}N_6O_2P_2$: C, 21.06; H, 5.15; N, 12.28. Found: C, 21.4; H, 5.3; N, 12.0%.

1-(2″-aminoethyl)-3-(7′amino-2′,4′-diazaheptyl)-3-methyl-cyclo-1,5-diazaheptane, isolated in the form of its

monoaminal derivative, *''sexidiazam''*, *as its Cu(II) complex*. 1,1,1-Tris(benzenesulfonyloxymethyl)ethane (22 g) was dissolved in diethylentriamine (dien, 25 g) and the solution was heated at 120 °C for three days under a nitrogen atmosphere. NaOH (4.9 g) in methanol (200 mL) was added to the cooled mixture, followed by $CuCl_2 \cdot 2H_2O$ (55 g). The methanol was then evaporated off under reduced pressure. The blue-violet residue was dissolved in water (2 L) and subjected (in portions) to chromatography on Na^+-form SP Sephadex using 0.30 mol L^{-1} sodium chloride as eluant. Two major components were separated, the first proving to be simply the Cu(II) complex of dien. The second component eluate was evaporated to dryness and the residue extracted with ethanol to leave the bulk of the NaCl undissolved. The extract was then taken to dryness and the blue residue (8.9 g) redissolved in water. Addition of $NaClO_4$ and slow evaporation of the solution at ambient temperature provided crystals of $[Cu(sexidiazamH)Cl(OClO_3)]ClO_4$ (**3**) suitable for a structure determination. *Anal*. Calc. for $C_{14}H_{33}Cl_3CuN_6O_8$: C, 28.82; H, 5.70; N, 14.41. Found: C, 29.0; H, 5.9; N, 14.3%.

Cu(II) complexes of 6(aminoethylaminomethyl)-6, 13-dimethyl-13-nitro-1,4,8,11-tetra-azacyclotetradec-ane (''senmac''). A methanolic solution containing Cu(II) and sen in the ratio 3:2 was prepared exactly as described above for the synthesis of **1** and **2**, then mixed with nitroethane (1.0 g), aqueous formaldehyde (37%, 4 g), triethylamine (2.0 g) and water (100 mL), filtered to remove some greenish material, and heated at 60 °C for 12 h. After being cooled to room temperature, the solution was acidified with acetic acid (2 mL) and then evaporated to dryness under vacuum. The red-violet residue was dissolved in water and subjected to chromatography on Na^+-form SP Sephadex using 0.15 mol L^{-1} trisodium citrate as eluant. Five components, F1–F5, were thereby separated (as distinct from six, with the ryongamine complex as the leading species, in earlier work [5]), the third being present in too small a quantity to be adequately characterised. After recovery of each complex as its chloride (F1 0.12 g; F2 0.15 g; F4 0.38 g; F5 0.42 g) using Dowex 50W × 2/HCl, attempts were made to obtain crystalline derivatives suitable for structure determinations. In the cases of F2 and F5, these were successful using pyridine-2,6-dicarboxylate (dipicolinate = $dipic^{2-}$, actually found to be present in its monoprotonated form, $Hdipic^-$) plus perchlorate as the counter-anions, giving what proved to be identical species $[Cu(senmacH)(Hdipic\text{-}O)](ClO_4)_2 \cdot 1.5H_2O$ (**4**), whereas for F4, perchlorate alone ultimately proved to be the most useful additional counter-anion, giving $[Cu(senmacH)Cl(OClO_3)](ClO_4)_2 \cdot 3H_2O$ (**5**). No means of satisfactorily crystallising F1 was found. *Anal*. Calc. for $C_{22}H_{43}Cl_2CuN_8O_{15.50} = [Cu(senmacH)(Hdipic\text{-}O)](ClO_4)_2 \cdot 1.5H_2O$: C, 32.94; H, 5.40; N, 13.97. Found:

2.2. Crystallography

The data for the five compounds were collected at 100(2) K on a Nonius Kappa-CCD area detector diffractometer [8] using graphite-monochromated Mo Kα radiation (λ 0.71073 Å). The crystals were introduced in glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from ten frames, then refined on all data. A 180° φ-range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed to 28 mm. The data were processed with DENZO-SMN [9]. The structures were solved by direct methods or Patterson map interpretation with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97 [10]. Absorption effects were corrected empirically with the program DELABS from PLATON [11]. The terminal atom N6 in **4** and the nitro group and one perchlorate anion in **5** were found disordered over two positions each, which were refined with occupancy parameters constrained to sum to unity. All non-hydrogen atoms were refined with anisotropic displacement parameters, with some restraints for some fluorine and water oxygen atoms in **2** and some perchlorate and water oxygen atoms in **4**. The hydrogen atoms bound to nitrogen and oxygen atoms were found on Fourier-difference maps (except those of one water molecule in **2** and those of N6 and the water molecules in **4**). The carbon-bound hydrogen atoms were introduced at calculated positions. All hydrogen atoms were treated as riding atoms with a displacement parameter equal to 1.2 (NH, OH, CH, CH$_2$) or 1.5 (CH$_3$) times that of the parent atom. The absolute configuration in **1** was determined from the value of the Flack parameter [−0.009(11)] [12]. Crystal data and structure refinement parameters are given in Table 1 and selected bond lengths and angles in Table 2. The molecular plots were drawn with SHELXTL [13].

3. Results and discussion

While six-coordination for Cu(II) with N-donor ligands is far from exceptional [14], numerous tetramine complexes in which the metal is essentially square planar, with weak axial ligation, are well known [4,5,15–18]. Thus, there is a basis for expecting that a sexidentate amine like sen could form complexes with Cu(II) having a 3:2 M:L stoichiometry. For a homologue of sen, such a complex has been characterised by elemental analysis [6c] and, for a sen derivative where CH_2OH replaces CH_3, a tetranuclear complex in which four of the N-donors of one ligand molecule are bound to one metal and the remaining two to another, has been structurally characterised [19]. Aqueous reaction mixtures containing CuX_2, with X a variety of different anions, and sen in a 3:2 ratio readily provide solid complexes but, despite numerous efforts, we were unable to obtain any of these in a crystalline form suitable for a structure determination. However, on using a methanolic medium to prepare the complex prior to its crystallisation from water, suitable crystals were obtained by both the addition of $NaClO_4$ or $[NH_4][PF_6]$ to a solution of the chloride. The structure solutions for both crystals show the presence of a very similar complex of the Cu(II) cation with a monoprotonated form of an aminal derivative of sen, ''senam'', (Fig. 2) and it is presumed that the molecule of formaldehyde incorporated to form the aminal must arise from a Cu-catalysed oxidation of methanol during the synthesis. A similar aminal structure is found in a ryongamine though, in this case, the reaction mixture contained deliberately added formaldehyde [5]. Another similarity with the ryongamine structure is that the ligand is present in a form where the pendent arm is monoprotonated (not unexpectedly for the ryongamine, since it was isolated from an acidic solution). This may simply be a consequence of the lack of deliberate pH control during the crystallisation processes but does indicate that binding of Cu(II) (present, initially, in sufficient quantities) to the pendent arm must be relatively weak, at least when one of the donors is an aminal-N.

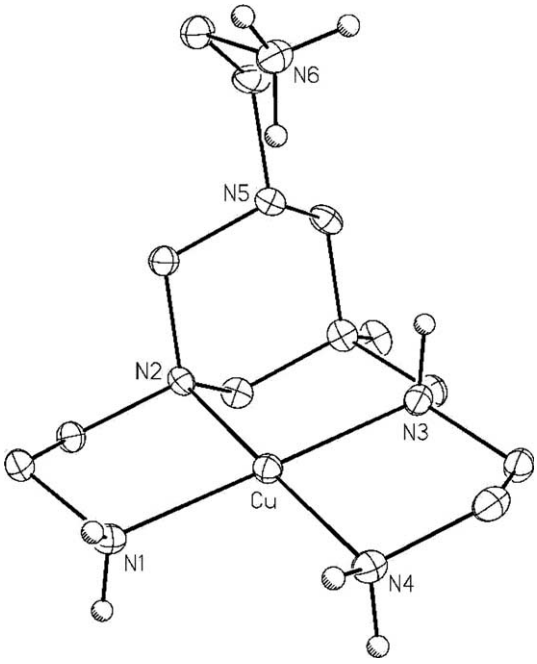

Fig. 2. View of complex **1**. The counter-ions and the carbon-bound hydrogen atoms are omitted for clarity. Displacement ellipsoids are drawn at the 30% probability level.

In $[Cu(senamH)(OClO_3)_2]ClO_4$ (**1**), the Cu atom has close to a square planar environment (Fig. 1, Table 2), but two longer contacts with perchlorate ions complete the coordination sphere to give an axially elongated octahedron, with unequal Cu–O(ClO_3) distances, 2.551(3) and 2.615(3) Å, reflecting the asymmetry of the ligand structure with respect to the CuN_4 plane. The formation of the aminal unit restricts the movement of the pendent arm such that it is turned back over the CuN_4 plane, with the third (uncoordinated) perchlorate anion being involved in H-bonding to the terminal NH_3^+ group of the pendent arm and to both coordinated NH_2 units on an adjacent complex cation. The pendent-arm NH_3^+ group is also H-bonded to the bound oxygen of coordinated perchlorate. The two five-membered chelate rings on Cu are of opposite conformation (δ,λ), the usual situation for a ''232tet'' derivative [17,18] when the central, six-membered ring has a chair form, though the presence of the pendent arm and the aminal unit renders the whole complex chiral and, in accord with the space group $P2_12_12_1$, only one configuration of the complex appears in the lattice, viz., it must crystallise as a ''racemic mixture''. In $[Cu(senamH)Cl(FPF_5)](PF_6)\cdot 2H_2O$ (**2**), distortions of the coordination environment (Fig. 3) due to the aminal bridge and the markedly asymmetric axial contacts (Cu–Cl 2.573(2) Å, Cu–FPF_5 2.937(6) Å) are associated with the five-membered rings being of identical, chiral conformations, despite the retention of an essentially chair conformation for the six-membered link. Paradoxically, this is associated with crystallisation in a centrosymmetric lattice where the complex cations can be regarded as lying in sheets parallel to the *ac* plane, with their chirality alternating from one sheet to the next. The sheets form pairs in that the Cu–Cl vectors of adjacent sheets are oriented either towards or away from one another into the region between the layers. As part of a complicated network of H-bonds, here involving the anions (coordinated and ''free'') as well as water molecules, hexafluorophosphate anions appear to bridge complex cations in a given sheet by quite short contacts (F···N 2.873(10) Å, although N–H···F is only 123.3°) to the pendent-arm NH_3^+ group, The two structures illustrate the subtlety of the factors that may determine the solid state array in a crystalline complex.

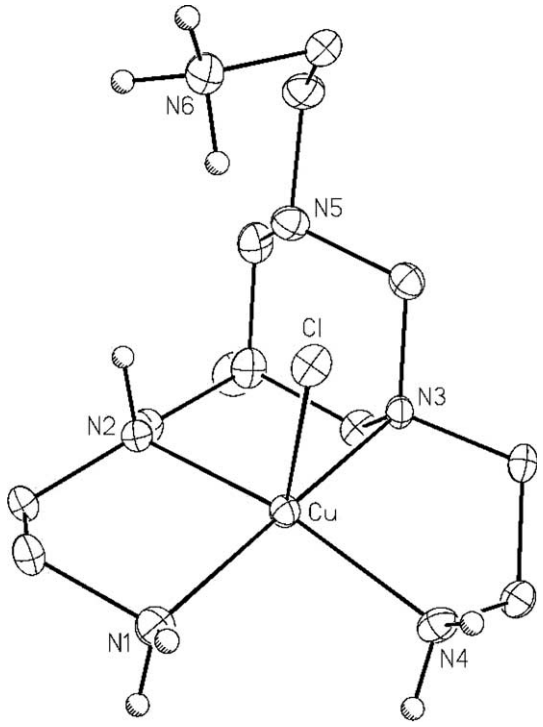

Fig. 3. View of complex **2**. The counter-ions, the solvent molecules and the carbon-bound hydrogen atoms are omitted for clarity. Displacement ellipsoids are drawn at the 20% probability level.

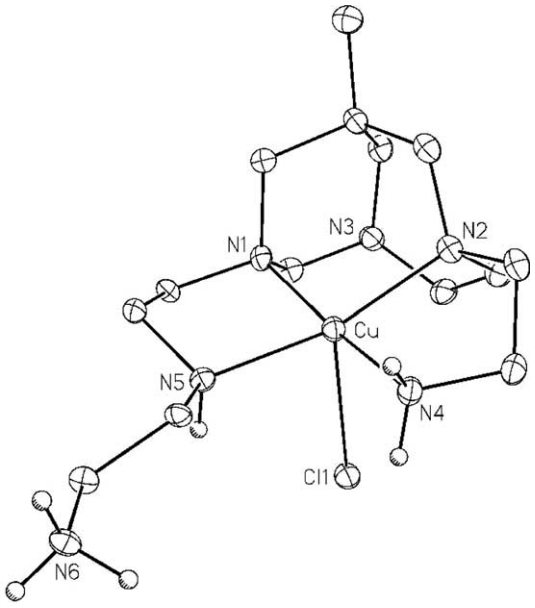

Fig. 4. View of complex **3**. The counter-ions and the carbon-bound hydrogen atoms are omitted for clarity. Displacement ellipsoids are drawn at the 30% probability level.

Confirming the ready formation of aminals in complex ion systems of this and many similar [2] types, and the stability of the six-membered-ring aminal, a closely related complex was isolated during efforts to characterise the Cu(II) complex of the product of the reaction between 1,1,1-tris(benzenesulfonyloxymethyl)ethane and diethylentriamine. The nature of the polyamine ligand (a sexidentate diazepan derivative, hence ''sexidiaz'', being ''sexidiazam'' as its aminal), as is apparent from the structure of the complex, [Cu(sexidiazamH)Cl($OClO_3$)]ClO_4 (**3**) (Fig. 4), shows that what is a minor pathway in the reaction between 1,1,1-tris(benzenesulfonyloxymethyl)ethane and ethane-1,2-diamine [20] has become the major one with 3-azapentane-1,5-diamine (diethylenetriamine), leading to a ligand which is not a simple podand. Once again, the Cu(II) environment is essentially a tetragonally distorted octahedral one (Table 2), with unsymmetrical axial interactions (Cu–Cl 2.563(1) Å, Cu–$OClO_3$ 2.897(4) Å). As in [Cu(senamH)Cl(FPF_5)](PF_6)·$2H_2O$, this unsymmetrical axial coordination is associated with the five-membered chelate rings in a given complex cation having the same conformation and the lattice being centrosymmetric, with cations of one configuration lying in alternating planes. The six-membered ring containing the aminal unit is dimensionally very similar to those in [Cu(senamH)($OClO_3$)$_2$]ClO_4 and [Cu(senamH)Cl(FPF_5)](PF_6)·$2H_2O$, except that the substituent on the uncoordinated aminal-N has an axial, rather than an equatorial orientation, presumably as a consequence of this nitrogen atom now being part also of a seven-membered chelate ring.

It is possible that relatively unstable aminal species are formed in the macrocyclisation reactions of the Cu(II)/sen system, since, despite clear chromatographic separations of five species, after recovery of the complex ions under strongly acidic conditions, crystal structure determinations showed the second and fifth species to be identical. Difficulties encountered in attempting to crystallise the residue from the first fraction may also reflect decomposition resulting in the formation of a mixture, and it may be that the first and fourth components are related in the same way as the second and fifth. In any case, in neither of the two macrocyclic complexes for which the structures were determined was an aminal unit present and, presumably partly in consequence of this, the pendent arms extend directly out from the macrocycles. In [Cu(senmacH)(dipic-O)(OH_2)](ClO_4)$_2$·1.5H_2O (**4**), the species isolated from the second and fifth components, the expected macrocycle is present and in the very commonly encountered ''cyclam *trans*-III'' conformation [15,21], with the methyl substituents on the opposed six-membered chelate rings being *syn*, so that the methyl group at the C–NO_2 centre is equatorial and that at the C(pendent arm) centre is axial (Fig. 5). The pendent arm is therefore an equatorial substituent and extends maximally from the macrocycle periphery, though with the terminal NH_3^+ group being disordered over two orientations. The Cu(II) centre has an axial carboxylate-O ligand [Cu–O(dipic) 2.287(5) Å] and a more remote axial interaction with a water molecule

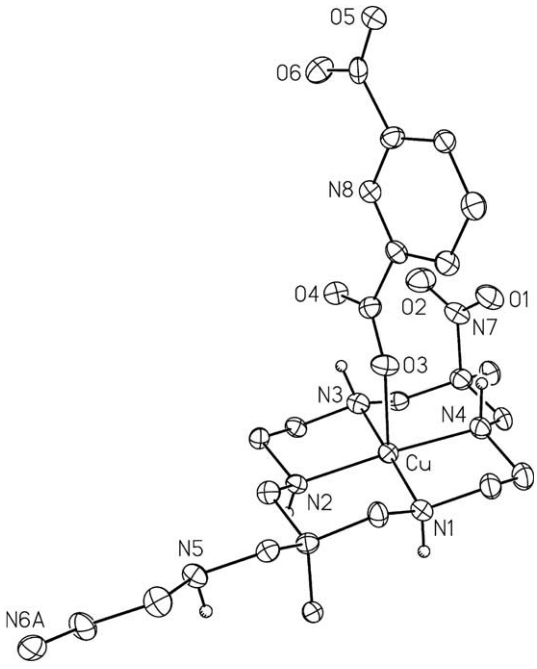

Fig. 5. View of complex **4**. The counter-ions, the solvent molecules and the carbon-bound hydrogen atoms are omitted for clarity. Only one position of the disordered atom N6 is represented. Displacement ellipsoids are drawn at the 30% probability level.

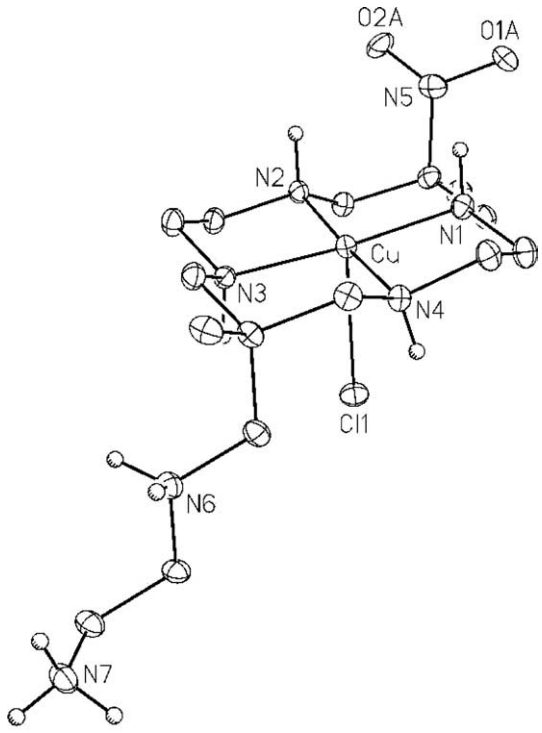

Fig. 6. View of complex **5**. The counter-ions, the solvent molecules and the carbon-bound hydrogen atoms are omitted for clarity. Only one position of the disordered nitro group is represented. Displacement ellipsoids are drawn at the 30% probability level.

[Cu–OH_2 2.585(6) Å], with the former being to the same side of the mean macrocyclic plane as the nitro group and pendent arm substituents. Charge balance requires that the uncoordinated carboxylate group retains its proton, although its exact location was not found in the crystal structure. There are numerous H-bonding interactions throughout the lattice and one of the consequences is that the complex cations form pairs in which there is symmetrical bonding of the uncoordinated dipicolinate carboxylate to NH units of the pendent arm of the adjacent complex. (Extensive H-bonding involving unidentate dipicolinate is also seen in a Mn(III) cyclam complex [22].) The planes of the dipicolinate rings lie parallel throughout the lattice but this does not seem to signify any stacking interactions [23], since little overlap in projection of the rings is apparent and no C···C contact is <3.6 Å. The nitro group planes lie essentially parallel to those of the dipicolinate groups and in fact the only contact which might be regarded as of a stacking kind is that between a nitro-O and the uncoordinated oxygen of the carboxylate group bound to Cu, where O···O = 3.254(6) Å.

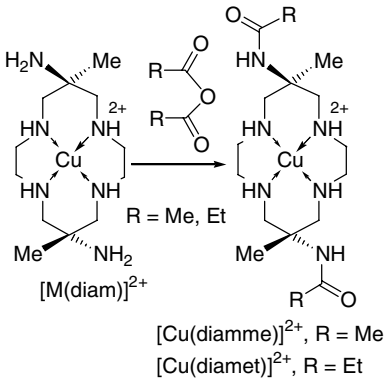
In [Cu(senmacH)Cl($OClO_3$)](ClO_4)$_2\cdot 3H_2O$ (**5**), again the expected macrocycle is present and is in the *trans*-III conformation, though here the substituents are *anti*, with both methyl groups being equatorial, so that the pendent arm, being axial, is less extended laterally from the macrocycle (Fig. 6). The Cu(II) is bound axially to a chloride ion [Cu–Cl 2.700(1) Å] and a slightly closer perchlorate-O [Cu–O(ClO_3) 2.603(4) Å]. The extension of the Cu–Cl bond with respect to that found in comlex **3** is associated with a lattice which has an obvious layer structure, in various ways reminescent of that of [Cu(senamH)Cl(FPF_5)](PF_6)$\cdot 2H_2O$. The cations lie in sheets parallel to *ac*, with separations alternating between ~14 and ~8 Å. All Cu–Cl vectors are oriented into the larger space, which is also occupied by perchlorate anions and water molecules, giving an extended H-bonding array in which each chloride interacts with 3 water molecules [Cl1···O 3.133(4), 3.168(4) and 3.181(4) Å]. The pendent arms form part of the same array, each $-NH_2^+CH_2CH_2NH_3^+$ unit chelating a water molecule. Only nitro groups and perchlorate anions occupy the smaller space and, although there is disorder of both entities, it is appears possible that there may be some attractive O···O interactions [24] between them.

4. Conclusions

The present work demonstrates that it is possible to conduct a very simple and efficient synthesis of quite sophisticated pendent arm macrocycles, providing both *syn* and *anti* isomers of functionalised cyclam-like ligands in comparable yields. The simplicity and rapidity of the method, coupled to the ease with which Cu(II) can be removed from such macrocycles [16], suggest it should be advantageous over methods known for

syntheses of some similar ligands [25]. The aminal formation processes further characterised here and observed in the original work on "ryongamines" [5] are an obvious means of controlling the orientation of pendent arms with respect to the macrocyclic centre which can be added to the employment of a ligand in different isomeric forms to the same end. Note that the detection of comparable amounts of both *syn* and *anti* isomers of unfunctionalised ryongamines under the conditions of synthesis used herein suggest that the *syn* isomer of the functionalised ryongamine could well have been present in the products of the earlier synthesis.

5. Supplementary material



Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 264310–264314. Scheme 1.

3. Structural study

The structure of *di*(perchlorato-κ^1O)-($R^1R^4S^8S^{11}$-*trans*-6,13-bisethylamido-6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane-$\kappa^4N^1N^4N^8N^{11}$)copper(II), [Cu(diamet)$(OClO_3)_2$] was determined by X-ray diffractometry, see Section 4.2 for details. The structure is centrosymmetrical and molecular, with copper in square-planar coordination by the four endocyclic secondary amine nitrogen atoms of the macrocycle and with weaker axial interactions with perchlorate oxygen atoms O2 and O2 ($1-x$, $1-y$, $1-z$), see Fig. 1 and Table 1 for significant dimensions. The macrocycle has a conformation with near symmetrical chair and gauche conformations of the chelate rings, see Table 2 for displacements from CuN_2 planes for the chelate rings. The perchlorate ions are also linked to the cation by hydrogen bonds N1–H1···O2 ($1-x$, $1-y$, $1-z$). The amide groups do not interact with the copper, but form N–H···N and N–H···O intramolecular hydrogen bonds and also N–H···O intermolecular hydrogen bonds between amide groups which link the "molecules" into a chain; see Table 3 for hydrogen bond parameters.

The structure of the cation is similar to that for the nickel(II) compound [1], which has the $[Ni(diamet)]^{2+}$ cation in the same configuration and closely similar conformation, with *trans*-coordinated oxygen atoms of water or hydrogen carbonate, except that the M–N distances are shorter and the M–O distances longer for copper(II). Structures have been reported for *trans*-*RRSS*-[Cu(diam)$(OClO_3)_2$] [2], *trans*-*RRSS*-[Cu(diam)$(H_2O)_2$]$(ClO_4)_2$ [3] and *trans*-*RRSS*-[Cu(diam-H_2)$(OClO_3)_2$]$(ClO_4)_2$ [4], all with similar coordination geometry and macrocycle conformations.

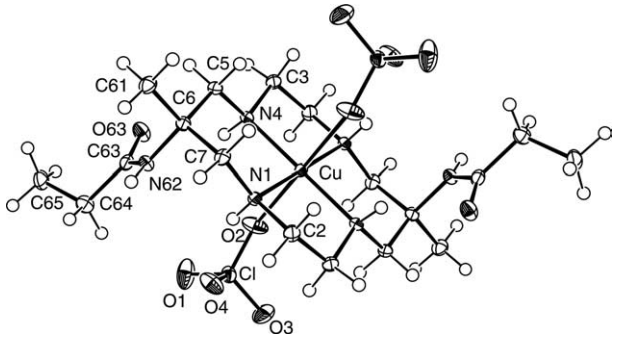

Fig. 1. The "molecule" of *trans*-[Cu(diamet)$(OClO_3)_2$] drawn [6] with displacement ellipsoids at the 50% confidence level, with H-atoms shown as circles of arbitrary radius.

Table 1
Selected dimensions (Å, °) for *trans*-[Cu(diamet)$(OClO_3)_2$]

Atoms	Distance	Atoms	Angle
Cu–N1	2.012(2)	N1–Cu–N4	86.62(8)
Cu–N4	1.996(2)	N1–Cu–N4^i	93.38(8)
Cu–O2	2.528(2)	N1–Cu–O2	93.20(8)
		N4–Cu–O2	81.75(8)

Symmetry codes: $i = 1-x, 1-y, 1-z$.

Table 2
Displacement of atoms (Å) from the CuN_4 plane for *trans*-[Cu(diamet)$(OClO_3)_2$]

Atom	Displacement	Atoms	Displacement
C2	0.337(4)	C3	0.360(4)
C5	0.811(4)	C6	0.494(5)

4. Experimental

The compound [Cu(diam)]$(ClO_4)_2$ [4] was prepared from diam [5] and dried by heating at 100 °C. DMSO can be substituted for DMF in the preparations; commercial anhydrous DMF and DMSO were used; these solvents need not be rigorously dried.

The perchlorate salts described were not observed to be shock sensitive and decomposed non-violently if strongly heated. They should still be treated with the caution due to any perchlorate compound.

4.1. Synthesis of compounds

4.1.1. (trans-6,13-Bis-ethylamido-6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane)copper(II) perchlorate, [Cu(diamet)](ClO$_4$)$_2$

[Cu(diam)](ClO$_4$)$_2$ (1 g) was dissolved in DMF (1 g) by warming. Propionic anhydride (1 g) was added and the solution heated at c. 100 °C for 30 min. Propan-2-ol (20 cm^3) was added and after 1 h. the red crystals were filtered off, yield 90+%. The reaction was faster than the analogous reaction for nickel(II). The *product* crystallizes in two forms, as with the nickel(II) analogue, (a) from DMF/propan-2-ol or rapidly from water and (b) slowly from water as large crystals. *Anal.* Calc. for $C_{18}H_{38}Cl_2N_6NiO_{10}$: C, 34.2; H, 6.1; N, 13.3. Found (a): C, 34.2; H, 6.2; N, 13.3%. (b): C, 34.3; H, 6.1; N, 13.3%. Spectra; infrared {ν_{max} (cm^{-1})} (a): ν(NH) 3342sp, 3234sp, 3069w,br; amide bands 1674, 1547; (b): ν(NH) 3279, 3219, 3093w; amide bands 1649, 1555); visible spectrum in water (same for both forms): {λ_{max} (nm) (ε) (mol dm^{-3} cm^{-1})} 504 (76); in 1 mol dm^{-3} NaOH; 514 (82).

4.1.2. (trans-6,13-Bis-methylamido-6,13-dimethyl-1,4,8,11-tetraazacyclotetradecane)copper(II) perchlorate hemihydrate, [Cu(diamme)](ClO$_4$)$_2$·1/2H$_2$O

The red compound was prepared as for the propionyl homologue by using acetic anhydride. *Anal.* Calc. for $C_{16}H_{35}Cl_2CuN_6O_{10.5}$: C, 31.3; H, 5.7; N, 13.7. Found: C, 31.1; H, 5.7; N, 13.6%. Infrared spectrum {ν_{max} (cm^{-1})}: ν(NH) 3398sp, 3242sp; amide bands 1668, 1527; visible spectrum {λ_{max} (nm) (ε) (mol dm^{-3} cm^{-1})}; in water 512 (43); in 1 mol dm^{-3} NaOH; 512 (88).

4.2. Structural study

4.2.1. Crystal data [7]

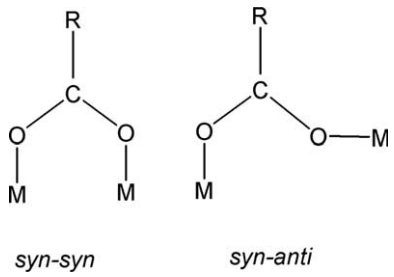
$C_{18}H_{42}Cl_2CuN_6O_{10}$, M_r = 632.98, red block grown from water, 0.75 × 0.38 × 0.24 mm, orthorhombic, space group *Pbca*, a = 9.513(1), b = 14.731(2), c = 18.659(3) Å, Z = 4, cell parameters from 4511 reflections.

4.2.2. Data collection

Bruker SMART 1K CCD area detector diffractomer, ω scans, Mo Kα radiation, T = 118(2) K, multi-scan absorption correction (based on symmetry-related measurements [8]), T_{min} = 0.495, T_{max} = 0.992, 8428 measured reflections. (average R equivalents 0.0450), $h - 9 \rightarrow 11$, $k - 13 \rightarrow 17$, $l - 23 \rightarrow 23$, θ_{min} 2.77°, θ_{max} 26.35°, 2444 independent reflections, 1793 reflections with $I > 2\sigma(I)$.

4.2.3. Refinement [9]

Refinement on F^2, $R[F^2 > 2\sigma(F^2)] = 0.038$, $wR(F^2) = 0.099$ $(w = 1/[\sigma^2(F_o^2) + (0.0553P)^2 + 0.7095P]$ where $P = (F_o^2 + 2F_c^2)/3)$, 183 parameters.



H(N) atoms were located from difference syntheses and their positions refined, H(C) atoms are riding in calculated positions.

Appendix A. Supplementary Data

Scheme 1.

Scheme 1). Specially, the *syn–anti* mode confirmation is very rare and only a limited number of X-ray structures have been reported with this *syn–anti* acetate bridging mode [9,10,12,14–20].

However, to the best of our knowledge, so far only one polymeric Cu(II) structure with an N-containing ligand has been published with acetate as the bridging molecule in a $[–\mu\text{-OAc–Cu–}\mu\text{-OAc–Cu}]_n$ fashion [9].

In this study, we report the synthesis, spectroscopic characterization and magnetic properties of $\{[Cu(dpa)(CH_3COO)](ClO_4)\cdot 0.5THF\}_n$, a new polymeric copper(II) compound with an infinite zig-zag chain structure, having the acetate ligand in a *syn–anti* bridging mode.

2. Experimental

2.1. General remarks and physical measurements

All starting reagents and solvents were purchased from commercial sources and were used as received. C, H, N analyses were performed on a Perkin–Elmer 2400 Series II analyzer. Infrared spectra (4000–300 cm^{-1}) were recorded on a Perkin–Elmer Paragon 1000 FT-IR spectrometer equipped with a Golden Gate ATR device, using the reflectance technique. Ligand field spectra were obtained on a Perkin–Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference. Magnetic susceptibility measurements (5–300 K) were carried out using a Quantum Design MPMS-5 5T SQUID magnetometer. Data were corrected for the magnetization of the sample holder and for diamagnetic contributions, which were estimated from the Pascal constants.

2.2. Synthesis of the compound

To an acetonitrile solution (10 ml) containing $Cu(ClO_4)_2\cdot 6H_2O$ (0.37 g, 1 mmol) and dpa (0.2 g, 1 mmol) was added slowly an acetonitrile (5 ml) solution containing CH_3COOH (0.02 g, 0.33 mmol) and Et_3N (0.03 g, 0.33 mmol). The reaction mixture was stirred for 10 min and was then filtered to remove the impurities. The resulted blue filtrate was diluted with 10 ml of THF and it was allowed to stand at room temperature. After 2 days dark blue crystals were obtained. Yield: 0.31 g (ca. 66%). *Anal.* Calc. for $C_{16}H_{19}ClCuN_3O_{6.5}$: C, 42.1; H, 4.2; N, 9.2. Found: C, 42.7; H, 4.5; N, 8.9%. UV–Vis (λ_{max}/nm): 632, 380, 314, 279.

The positive ion mass spectrum of a fresh solution of the compound in acetonitrile exhibits a prominent signal at $m/z = 320$ (relative intensity $I = 100\%$ in the range $m/z = 100$–500). This signal matches very well with the calculated isotopic distribution for $[Cu(dpa)(CH_3COO)]^+$.

2.3. X-ray crystallography and data collection

Intensity data for a single crystal were collected using Mo Kα radiation ($\lambda = 0.71073$ Å) on a Nonius KappaCCD diffractometer. The structure was solved by automated Patterson methods using DIRDIF-99 [21] and was refined on F^2 by least-squares procedures using SHELXL-97 [22]. A SADABS multiscan correction [23] was applied. The hydrogen atoms of the methyl group were refined as rigid rotors to match maximum electron density in a difference Fourier map. All other hydrogens were placed at calculated positions and were refined riding on the parent atoms. The THF molecule is disordered around a centre of symmetry. A suitable disorder model could be defined in which the THF molecule partly occupies one of the two possible positions and orientations, each having a site occupation factor of 0.5. Geometric calculations and molecular graphics were performed with the PLATON package [24]. Crystallographic data are listed in Table 1.

3. Results and discussions

3.1. Description of the crystal structure of $\{[Cu(dpa)(CH_3COO)](ClO_4)\cdot 0.5THF\}_n$

A plot of the title compound with the atomic labelling scheme is shown in Fig. 1, with selected bond lengths and angles listed in Table 2. The molecular structure of the title compound consists of one-dimensional ladder-like chains in which the CH_3COO^- acts as an asymmetric didentate bridging ligand, ClO_4^- anions and disordered THF molecules. Each copper(II) atom is five-coordinated and adopts a square-pyramidal geometry with a N_3O_2 donor set. The coordination geometry is slightly distorted from square pyramidal, as ascertained by the observed τ value of 0.06 (the structure index is defined as $\tau = (\beta - \alpha)/60$, where β and α are the largest coordination angles, $\tau = 0$ for square pyramidal (SP) and $\tau = 1$ for trigonal bipyramidal (TBP) geometry [25]). One oxygen atom of an acetate bridge and the three nitrogen atoms of the dpa ligand constitute the basal plane of the square pyramid, and the oxygen of a symmetry-related acetate bridge occupies the apical position of the square pyramid. The copper(II) atom lies 0.015(3) Å above the basal plane toward the acetate oxygen atom O(32)b. The largest distortions from the square pyramidal geometry are indicated by the O(31)–Cu(1)–N(3) = 168.98(12)° and N(1)–Cu(1)–N(2) = 165.14(13)° angles. The Cu(II) atoms are connected through single *syn–anti* acetate bridges with a Cu···Cu separation of 4.039 Å, forming is this way a 1D zig-zag polymeric compound (Fig. 2).

Table 2
Selected bond lengths (Å) and bond angles (°) for $\{[Cu(dpa)(CH_3COO)](ClO_4)\cdot 0.5THF\}_n$

Bond lengths (Å)	
Cu(1)–O(31)	1.950(2)
Cu(1)–O(32)b	2.388(3)
Cu(1)–N(1)	1.984(3)
Cu(1)–N(2)	1.998(3)
Cu(1)–N(3)	1.985(3)
Cu(1)–Cu(1)a	4.0399
Bond angles (°)	
O(31)–Cu(1)–N(1)	97.86(12)
O(31)–Cu(1)–N(2)	96.92(12)
O(31)–Cu(1)–N(3)	168.98(12)
O(31)–Cu(1)–O(32)b	102.27(10)

N(1)–Cu(1)–N(3)	83.00(14)
N(1)–Cu(1)–O(32)b	87.12(12)
N(2)–Cu(1)–N(3)	82.20(14)
N(2)–Cu(1)–O(32)b	91.25(12)
N(3)–Cu(1)–O(32)b	88.74(12)

Symmetry codes: a = 1/2 − *x*, −1/2 + *y*, 1/2 − *z*; b = 1/2 − *x*, 1/2 + *y*, 1/2 − *z*.

3.2. Infrared and ligand-field characterisation

The infrared spectra of the title compound exhibits the bands expected for the organic ligands and

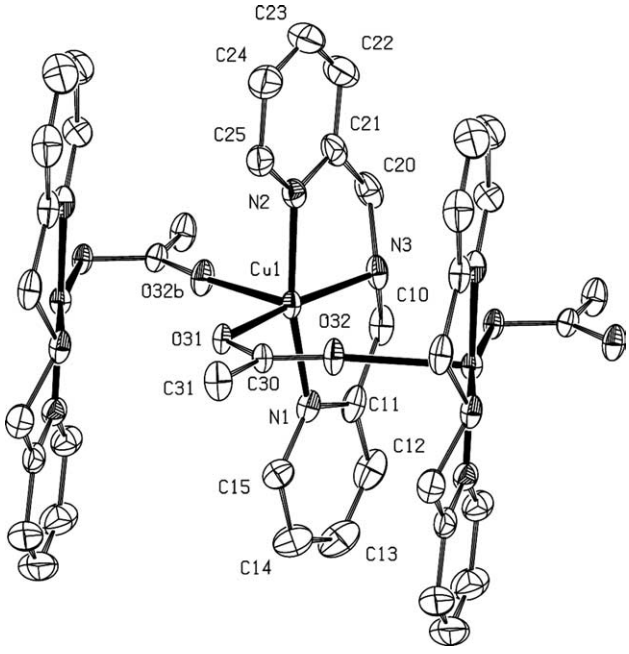

Fig. 1. Thermal ellipsoid plot at 50% probability of $\{[Cu(dpa)(CH_3COO)](ClO_4)\cdot 0.5THF\}_n$ with atom-labelling scheme. Hydrogen atoms, the uncoordinating perchlorate anion and the disordered THF molecule are omitted for clarity. Atoms marked with a "b" are generated by a twofold screw axis.

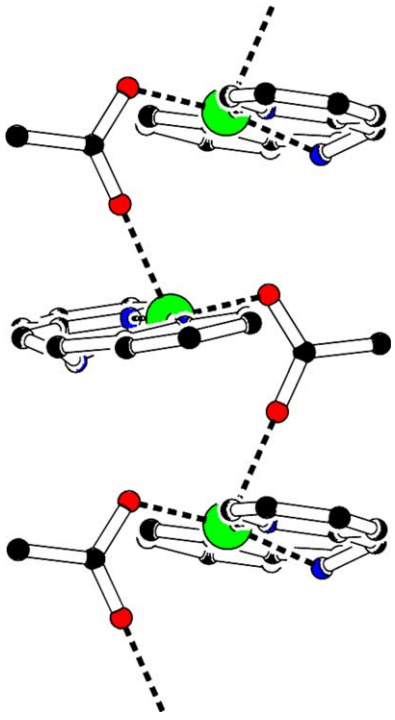

Fig. 2. The zig-zag chain of Cu–OAc units.

counterion. Particularly, the asymmetric stretching vibration ν_{asym}(COO) is observed at 1613 cm^{-1}, while the symmetric stretching vibration ν_{sym}(COO) appears at 1449 cm^{-1}. The difference between ν_{asym}(COO) and ν_{sym}(COO) of about 164 cm^{-1} agrees with a bridging coordination mode for the acetate molecule [9,12,26]. The ligand field spectrum of the compound shows a broad band with a maximum at 15.7×10^{-3} cm^{-1} characteristic of a copper(II) $d_{zx}, d_{yz} \rightarrow d_{x^2-y^2}$ ($^2B_1 \rightarrow {}^2E$) transition [27] in a tetragonal ligand field, in which the copper(II) has a distorted square-pyramidal coordination environment.

3.3. EPR and magnetic properties

The EPR spectrum measured as a powdered solid at RT and 77 K shows an unresolved axial $S = 1/2$ signal with $g_\perp$ of 2.06 and a $g_\parallel$ of 2.24. The EPR spectrum recorded in frozen solution (DMF/MeOH 1:1 mixture) at 77 K shows a resolved spectrum with $g_\perp$ of 2.04, a $g_\parallel$ of 2.26 and an $A_\parallel$ of 17.9 mT, consistent with the planar geometry and the $CuN_3O(O)$ chromophore [28].

The magnetisation of a powdered sample of $\{[Cu(dpa)(CH_3COO)](ClO_4) \cdot 0.5THF\}_n$ was measured from 5 to 300 K in an applied field of 0.1 T. The resulting molar magnetic susceptibility, χ_M, is plotted in Fig. 3. On lowering the temperature from 300 to 5 K, the χ_M value stays almost constant (μ_{eff} around 1.60–1.65 BM, which is slightly below the theoretical value expected for one non-coupled Cu(II) centre with $S = 1/2$). At around 50 K the χ_M value start to increase until it reaches a value of about 0.10 cm^3 mol^{-1} K at 5 K (μ_{eff} around 1.78 BM), a behaviour indicative of a very weak ferromagnetic coupling between Cu centres.

The temperature dependence of χ_m has been fitted using the equation [29] derived from the Heisenberg exchange Hamiltonian for an uniformly spaced chain of spins with $S = 1/2$: $H = -J\sum_{i=1}^{n-1} S_{A_i} \cdot S_{A_i+1}$ (in which A_i are the nearest neighbour Cu(II) ions and the exchange parameter J is positive for ferromagnetic and negative for an antiferromagnetic interaction). A Temperature Independent Paramagnetism (TIP) of 60×10^{-6} cm^3 mol^{-1} per Cu(II) ion has been used. The best fit of the experimental magnetic susceptibility data for a chain (solid line in Fig. 3) was obtained using the magnetic parameters $g = 2.0$, $J = 0.21$ cm^{-1}, p (which is the paramagnetic impurity which is present in the bulk sample) 0.41%, with a final $R = 1.09 \times 10^{-6}$. As the Cu···Cu distance is fairly large (4.039 Å) this very weak ferromagnetic interaction most likely occurs via the Cu–O–C–O–Cu pathway. This is consistent with a few other formato and acetato bridged polymeric compounds, $\{[Cu(di\text{-}2\text{-}pyridylamine)(\mu\text{-}O_2CH)(OH_2)]_n(NO_3)_n\}$ and $\{[Cu(diethylenetriamine)(\mu\text{-}O_2C\text{-}H_3)]_n(ClO_4)_n\}$, which also exhibit a weak ferromagnetic interaction with J values of 0.75 and 0.52 cm^{-1}, respectively [10,30].

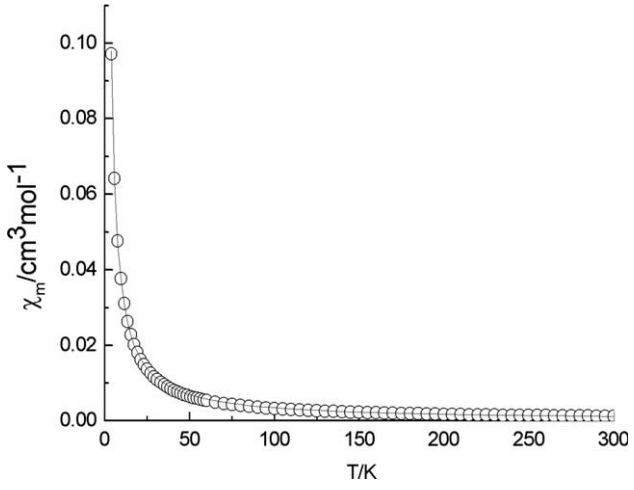

Fig. 3. Temperature dependence of χ_M vs. T per Cu atom. The solid lines is the best fit with $J = 0.21$ cm^{-1} (see text).

4. Conclusions

In this paper, an unusual *syn–anti* acetato-bridged Cu(II) compound is presented, which adopts a 1D zigzag polymeric array. The magnetic interaction is very weak ($J = 0.21$ cm^{-1}), which is not surprising as the Cu–Cu distance is fairly large, and the magnetic orbitals are orthogonal.

5. Supplementary material

Crystallographic data (excluding structure factors) have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication No. CCDC 262052. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http//www.ccdc.cam.ac.uk).

environment mainly from industrial sources, especially oil refineries and power plants using vanadium-rich fuel oil and coal. Such sources can mobilize appreciable amounts of vanadium and increase the natural background level [16,17]. It is highly useful to examine the recovery and removal of vanadium from the viewpoint of exploitation of undeveloped resources and environmental control.

Anion-exchange resins and chelating resins have been used for separation and concentration procedures [18,19], however, there are very few reports about the adsorption mechanism of vanadium. Chitosan which is an amino-polysaccharide extracted from crustacean shells is effective for removing vanadate anions from dilute solutions under acidic conditions. Guzmán et al. [20] had shown, on the basis of the speciation of vanadate in an external acidic solution, that the high adsorbability of chitosan was attributed to the strong ion exchange interaction between the protonated amine sites of chitosan and anionic isopolyvanadate species such as decamer. Considering the optimum pH for the adsorption, however, chitosan would be inadequate for the practical application to separate and concentrate of vanadium in natural water, such as sea water, without pretreatment. The ion exchange adsorption of such highly charged anionic species would also be greatly suppressed by the coexisting high concentration of background electrolytes. Furthermore, isopolyvanadates in the environment are negligible at the quite low concentration of vanadium (μg dm^{-3} levels or less in sea water [21,22]).

ECTEOLA–Cellulose, which has generally been used for separation of biopolymers [23–25], is a reaction product of epichlorohydrin, triethanolamine and cellulose. The concrete chemical structure is not clear, however, it does contain diethanolamine groups as anchor groups (Fig. 1). Because vanadate can react with tri- or tetradentate ethanolamine derivatives to form a pentacoordinated vanadium(V) complex at neutral to weakly basic pH [26–29], it is expected that ECTEOLA–Cellulose can be used as a chelating adsorbent for the separation and concentration of vanadium from a matrix. In the present work, therefore, the interaction of vanadium(V) oxoanions with ECTEOLA–Cellulose was examined by using distribution and ^{51}V NMR measurements. The NMR method for gel suspension samples is an excellent technique for the speciation of adsorbed species in the gel phase [7–10,30,31] and the characterization of the nature of the gel internal solution [32,33]. The complexation of vanadate with ethanolamine derivatives, such as ethanolamine (EA), diethanolamine (DEA), methyldiethanolamine (MDEA) and triethanolamine (TEA), which would be analogues of the functional group of ECTEOLA–Cellulose, was also investigated by ^{51}V NMR spectroscopy. A comparison between the complexation of vanadate with the functional groups of the gel and with the ethanolamine derivatives gave important information about the adsorption of vanadium(V) onto ECTEOLA–Cellulose.

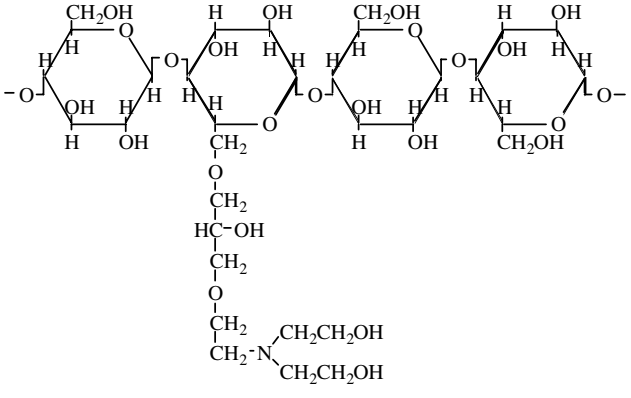

Fig. 1. Expected functional group of ECTEOLA–Cellulose.

2. Experimental

2.1. Materials

All chemicals were of analytical grade and used without further purification. ECTEOLA–Cellulose was obtained from SERVA Electrophoresis (Germany). The nitrogen content of the gel, which corresponds to the amount of functional groups introduced, was 0.40 mmol g^{-1} by an elemental analysis. Stock solutions of sodium vanadate were prepared as described in [34].

2.2. Distribution measurements

The effect of pH in the equilibrated solution on the adsorption of vanadate onto ECTEOLA–Cellulose was examined under acidic conditions as follows: to 20 cm^3 of a 4.0×10^{-6} mol dm^{-3} vanadate solution ($I = 0.01$, CH_3COONa–HCl), in which the pH was adjusted with a little amount of HCl or NaOH solution, 0.1 g of ECTEOLA–Cellulose was added. The mixture was stirred mechanically for 90 min at room temperature and then the pH of the equilibrated solution was measured. The vanadium(V) concentration in the equilibrated solution was determined by ion-exchange phase visible light absorptiometry [22].

We also examined the adsorption behavior under weakly basic conditions as follows: to 20 cm^3 of a 4.0×10^{-4} mol dm^{-3} vanadate solution ($I = 0.1$, NaCl), in which the pH was adjusted with a little amount of HCl or NaOH solution, 0.5 g of ECTEOLA–Cellulose was added. The mixture was stirred mechanically and then the pH of the equilibrated solution was measured in the same way as that for the acidic conditions. The vanadium(V) concentration in the equilibrated

solution was determined spectrophotometrically with 4-(2-pyridylazo)resorcinol (PAR, Dojin, Japan) as a coloring reagent [21]. The gels in equilibrium with the vanadate solutions were also used for ^{51}V NMR measurements.

To evaluate the formation constant of vanadate with ECTEOLA–Cellulose, the variation of the adsorbability for ECTEOLA–Cellulose with the concentration of vanadate in the equilibrated solution ($I = 0.1$) at pH 8.7 was investigated in the same way as mentioned above.

The distribution coefficient K_d is expressed as $K_d = (C_V^{int} - C_V^{eq})v/C_V^{eq}m$, where v is the volume of the solution (20 cm^3), m is the mass of the gel, C_V^{int} is the initial concentration of vanadium(V), and C_V^{eq} is the concentration of vanadium(V) in the equilibrated solution.

2.3. NMR measurements

^{51}V NMR measurements were performed on a JEOL JNM-GSX 500 spectrometer with a 10 mm multinuclear probe at 25 ± 1 °C. The standard NMR parameters were as follows: an observed frequency of 131.5 MHz, the flip angle was approximately 90° (32 μs), the pulse repetition time was 0.5 s and the spectral width was 151.5 kHz. The field frequency lock was achieved with a ^{2}H resonance of D_2O solution in a 2 mm concentric tube. Chemical shifts are reported relative to an external reference of $VOCl_3$ via a second reference of 0.5 mol dm^{-3} vanadate in a 2 mol dm^{-3} NaOH solution which gives the high-field resonance at −541.2 ppm relative to that of $VOCl_3$ [35]. Complexation of vanadate with various ethanolamine derivatives was examined at 1.0×10^{-3} mol dm^{-3} total vanadate concentration and at varying pH. The concentrations of various vanadium(V) species in solutions were determined from the fractions of the total integrated areas observed in ^{51}V NMR spectra. The NMR spectra for ECTEOLA–Cellulose in equilibrium with vanadate solutions were measured in the same way as those for ordinary solution samples.

3. Results and discussion

Vanadate undergoes condensation reactions to form a variety of isopolyvanadates including a dimer, *cyclo*-tetramer, *cyclo*-pentamer and decamer in aqueous solutions [36,37]. The concentrations of monomeric vanadates are dependent on both pH and the total vanadate concentration. In the presence of a ligand, further reactions will occur to give complexes of which characteristics can be deduced from ^{51}V NMR spectroscopy. Because the complexation is observed only in alkaline solution, equilibria examined in this paper are basicaly written with the components, diprotonated vanadate $H_2VO_4^-$ ($pK_{aV} = 8.17$ [38]), non-protonated free ethanolamine derivative and H^+. Protonation constants of ethanolamine derivatives were taken from [26,39].

3.1. EA system

A reversible complexation of vanadate occurs to provide tetrahedrally coordinated esters in the presence of a large amount of ethanol in aqueous media [40]. Despite EA being a simple ligand, such as ethanol, the nature of the complexation with vanadate has not been clarified yet. The concentrations of various vanadate species are dependent on pH, and it is, therefore, expected that the reaction between vanadate and EA is dependent on pH. First, the complexation was examined at a constant concentration ratio of EA to total vanadate as a function of pH. Fig. 2 shows ^{51}V NMR spectra of solutions containing 1.0×10^{-3} mol dm^{-3} vanadate and 0.4 mol dm^{-3} EA at various pH. The large signal, whose chemical shift is dependent on pH, is due to free $H_2VO_4^-/HVO_4^{2-}$ (V_1). The other signals at −570 ∼−576, −579 and −587 ppm are dimer (V_2), *cyclo*-tetramer (V_{4c}) and *cyclo*-pentamer (V_{5c}), respectively. The small and broad signal is ascribed to complexes.

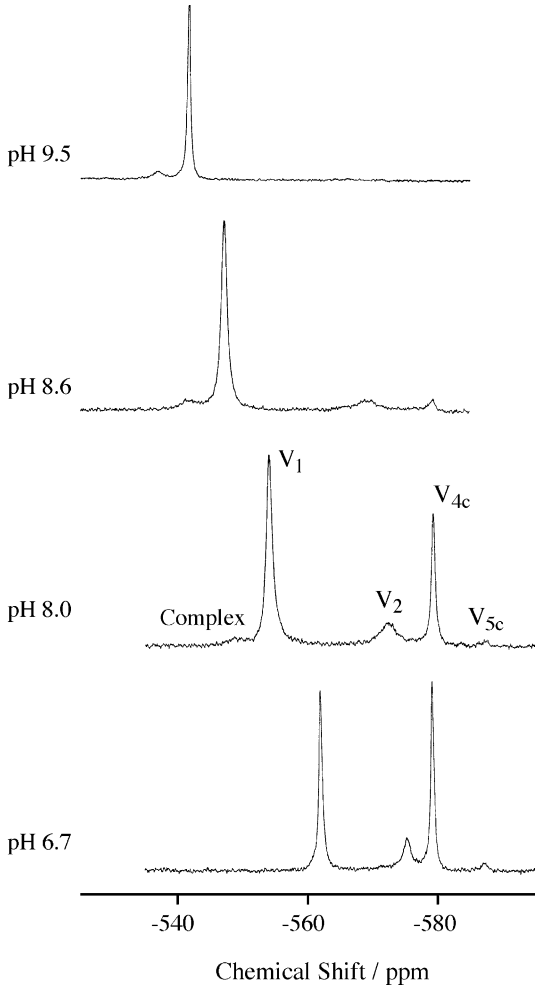

Fig. 2. ^{51}V NMR spectra of solutions containing 1.0×10^{-3} mol dm^{-3} vanadate and 0.4 mol dm^{-3} EA at different pH. V_1: $H_2VO_4^-/HVO_4^{2-}$; V_2: dimer; V_{4c}: *cyclo*-tetramer; V_{5c}: *cyclo*-pentamer.

Since the chemical shift of the signal is dependent on the pH of the solution, protonated and deprotonated complexes should be added to the speciation scheme.

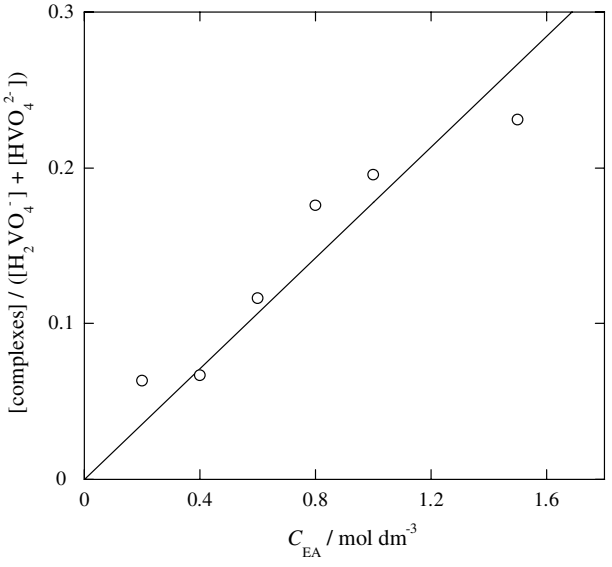
When complexes with low stability and with 1:n stoichiometry are formed, the concentration ratio of the complexes to vanadate ($[\text{complexes}]/([H_2VO_4^-]+[HVO_4^{2-}])$) is proportional to C_{EA}^n under a condition of $C_{EN} \gg C_V$ at a constant pH, where C_{EA} and C_V are the total concentrations of EA and vanadium(V). In order to estimate the stoichiometry of the complexes the quotient $([\text{complexes}]/([H_2VO_4^-]+[HVO_4^{2-}]))$ which is calculated from ^{51}V NMR intensities is plotted against C_{EA} at a constant pH of 10 (where $C_{EA} \gg C_V$). The plot can be fitted on a straight line passing through the origin (Fig. 3), which shows that the stoichiometry of the complexes is 1:1. Possible binding structures for the 1:1 complexes of vanadate with EA are shown in Scheme 1. The following equilibria should be taken into consideration in this system:

$$H_2VO_4^- + H_2NCH_2CH_2OH \rightleftharpoons VL(N,O) + H_2O$$

$$\beta_{VL(N,O)} = \frac{[VL(N,O)]}{[H_2VO_4^-][EA]}. \quad (1)$$

$$H_2VO_4^- + H_2NCH_2CH_2OH \rightleftharpoons VL(O) + H_2O$$

$$\beta_{VL(O)} = \frac{[VL(O)]}{[H_2VO_4^-][EA]}. \quad (2)$$



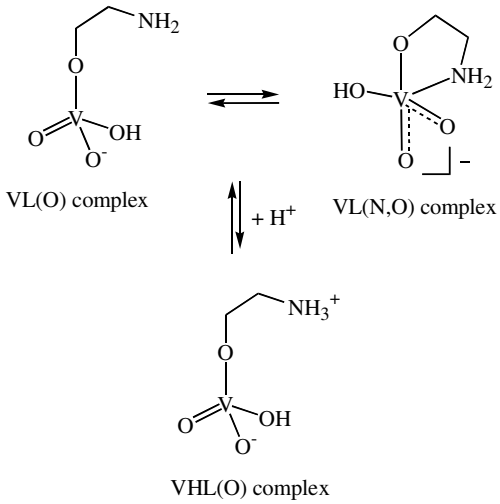


Fig. 3. Determination of the stoichiometry of vanadate complexes with EA at pH 10. The quotient of $[\text{complexes}]/([H_2VO_4^-]+[HVO_4^{2-}])$, which is estimated from ^{51}V NMR intensities, is expressed as a function of total concentration of EA, C_{EA}.

Scheme 1.

$$H_2VO_4^- + H_2NCH_2CH_2OH + H^+ \rightleftharpoons VHL(O) + H_2O$$

$$\beta_{VHL(O)} = \frac{[VHL(O)]}{[H_2VO_4^-][EA][H^+]}. \quad (3)$$

$$VHL(O) \rightleftharpoons VL(N,O) + H^+$$
$$VHL(O) \rightleftharpoons VL(O) + H^+$$

$$K_{aVL} = \frac{([VL(N,O)] + [VL(O)])[H^+]}{[VHL(O)]}. \quad (4)$$

Since only one resonance, whose chemical shift is dependent on pH, is observed for these expected complexes, the observed chemical shift would be expressed by the following equation:

$$\delta_{obs} = \frac{[VL(N,O)]\delta_{(N,O)} + [VL(O)]\delta_{(O)} + [VHL(O)]\delta_{H(O)}}{[VL(N,O)] + [VL(O)] + [VHL(O)]}$$
$$= \frac{\delta_{(N,O),(O)}K_{aVL}/[H^+] + \delta_{H(O)}}{K_{aVL}/[H^+] + 1}, \quad (5)$$

where $\delta_{(N,O)}$, $\delta_{(O)}$ and $\delta_{H(O)}$ represent the individual chemical shifts of VL(N,O), VL(O) and VHL(O), respectively, and $\delta_{(N,O),(O)}$ is an apparent characteristic chemical shift for non-protonated species as follows:

$$\delta_{(N,O),(O)} = \frac{[VL(N,O)]\delta_{(N,O)} + [VL(O)]\delta_{(O)}}{[VL(N,O)] + [VL(O)]}. \quad (6)$$

The acid dissociation constant of the vanadate complexes K_{aVL} and the characteristic chemical shifts $\delta_{(N,O),(O)}$ and $\delta_{H(O)}$ were estimated by a least-square-fitting of the experimental points in Fig. 4 to Eq. (5) and were found to be $pK_{aVL} = 7.8$, $\delta_{(N,O),(O)} = -536$ ppm and $\delta_{H(O)} = -563$ ppm.

One can easily estimate a value of $([VL(N,O)]+[VL(O)]+[VHL(O)])/([H_2VO_4^-][EA])$ from the NMR signal intensity ratio of the complexes to free vanadate, and pK_a values of $H_2VO_4^-$ ($pK_{aV} = 8.17$ [38]) and HEA^+

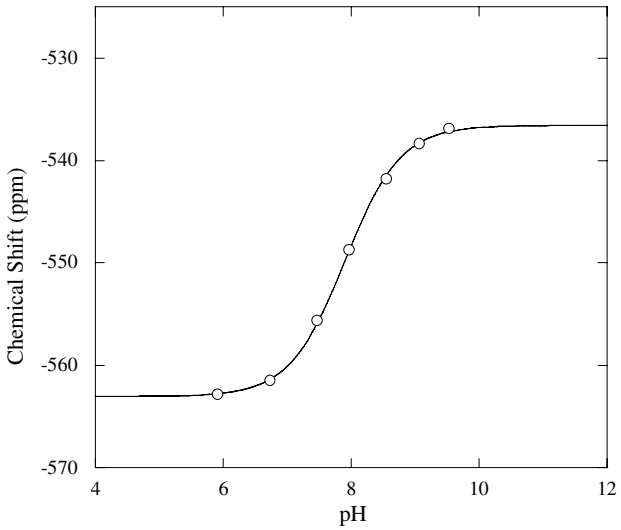

Fig. 4. Change in chemical shift of the V–EA complexes against pH. Solid line is a theoretical curve using the values obtained.

(protonated ethanolamine, $pK_{aL} = 9.5$ [39]). The quotient is expressed as follows:

$$\frac{[VL(N,O)] + [VL(O)] + [VHL(O)]}{[H_2VO_4^-][EA]} = \beta_{VL(N,O)} + \beta_{VL(O)} + \beta_{VHL(O)}[H^+]. \quad (7)$$

As shown in Fig. 5, the plot of the values $([VL(N,O)] + [VL(O)] + [VHL(O)])/([H_2VO_4^-][EA])$ estimated versus the hydrogen ion concentration gave a straight line, and the values of $\log(\beta_{VL(N,O)} + \beta_{VL(O)}) = 1.0$ and $\log\beta_{VHL(O)} = 8.5$ were obtained from the intercept and slope, respectively.

At pH 10, Eq. (7) can be simplified as

$$\frac{[VL(N,O)] + [VL(O)]}{[H_2VO_4^-]} = \left(\beta_{VL(N,O)} + \beta_{VL(O)}\right)[EA]. \quad (8)$$

The plot of the ratio on the left versus the free ligand concentration [EA] can be fitted on a straight line passing through the origin (Fig. 6). From the slope of the line, the value of $\log(\beta_{VL(N,O)} + \beta_{VL(O)}) = 1.2$ was obtained. This value is almost the same as the $\log(\beta_{VL(N,O)} + \beta_{VL(O)})$ value determined by the analysis with Eq. (7) in Fig. 5, and therefore we employed the average value of 1.1.

The combination of Eqs. (1)–(3) with Eq. (4) gives the following equation:

$$K_{aVL} = \frac{\beta_{VL(N,O)} + \beta_{VL(O)}}{\beta_{VHL(O)}}, \quad (9)$$

where $\beta_{VL(N,O)} + \beta_{VL(O)}$ and $\beta_{VHL(O)}$ values evaluated using Figs. 5 and 6 also give $pK_{aVL} = 7.4$, which is almost identical with the value determined from the pH dependence of the chemical shift as shown in Fig. 4. These show that the data are internally consistent. The pK_{aVL} value evaluated is much lower than the pK_a value of HEA^+ ($pK_{aL} = 9.50$ [39]), which means that coordination of the amine nitrogen to pentacoordinated vanadium(V) promotes the deprotonation. That is, the predominant binding structure of the non-protonated 1:1 complex is the (N,O)-bidentate complex VL(N,O), not VL(O).

3.2. DEA, MDEA and TEA systems

DEA, MDEA and TEA can be analogues of the functional group of ECTEOLA–Cellulose. Knowledge on the complexation of vanadate with such ethanolamine

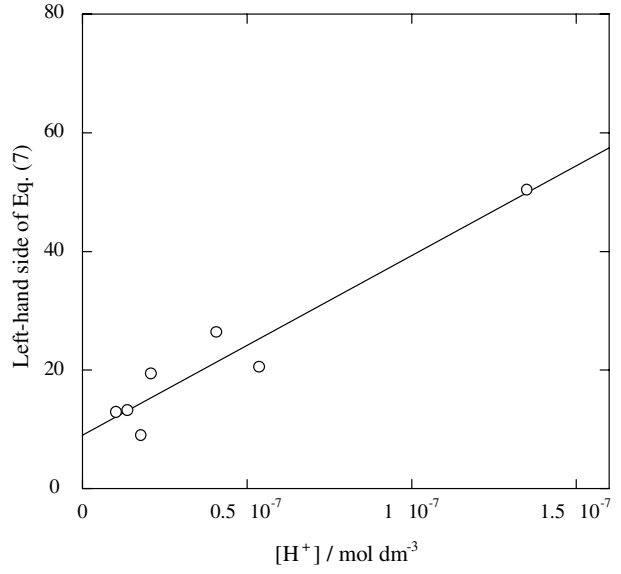

Fig. 5. Determination of formation constants of the 1:1 complexes of vanadate with EA. The quotient on the left of Eq. (7) is plotted as a function of hydrogen ion concentration, $[H^+]$.

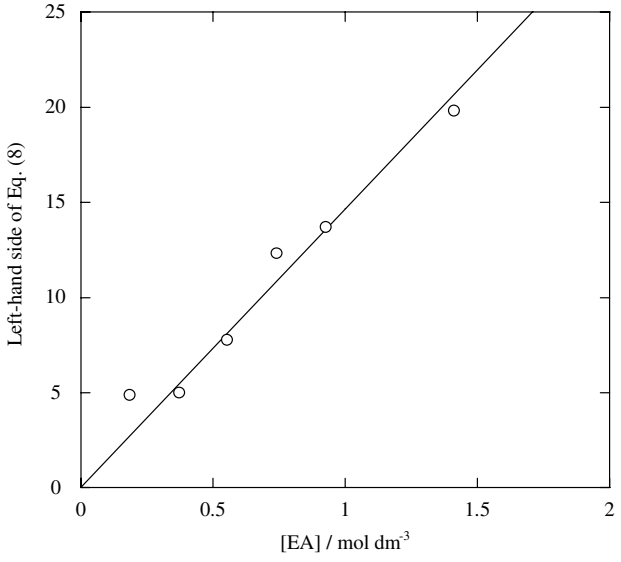

Fig. 6. Determination of formation constants of the 1:1 complexes of vanadate with EA at pH 10. The quotient on the left of Eq. (8) is plotted as a function of free EA concentration, [EA].

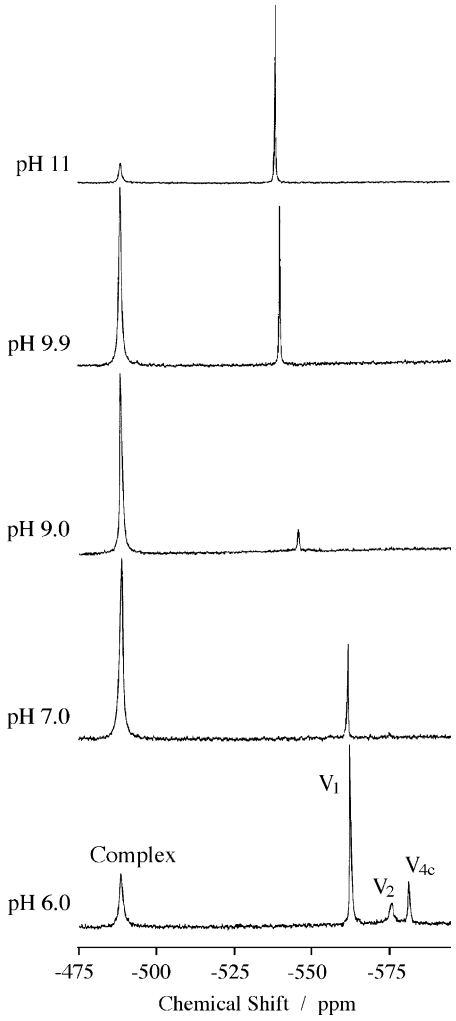

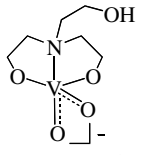

Fig. 7. ^{51}V NMR spectra of solutions containing 1.0×10^{-3} mol dm^{-3} vanadate and 0.1 mol dm^{-3} TEA at different pH. V_1: $H_2VO_4^-/HVO_4^{2-}$; V_2: dimer; V_{4c}: *cyclo*-tetramer.

derivatives should provide important information about the interaction with ECTEOLA–Cellulose. Binding of vanadate with these ethanolamine derivatives occurs spontaneously in aqueous solution to produce a limited number of products. Fig. 7 shows the ^{51}V NMR spectra for solutions containing vanadium(V) and TEA at different pH values. The new signal at −489 ppm, the chemical shift being independent of the pH of the solution, is assigned to a complex. Crans et al. [26,28] concluded by ^{51}V and ^{17}O NMR studies that the stoichiometry of the complex was 1:1, the overall charge of the complex was −1 and the binding structure was as follows:

(N,O,O) complex

The formation constant of the (N,O,O) complex can be written as follows:

$$H_2VO_4^- + TEA \rightleftharpoons VL(N,O,O) + 2H_2O$$

$$\beta_{(N,O,O)} = \frac{[VL(N,O,O)]}{[H_2VO_4^-][TEA]}. \quad (10)$$

We estimated the concentration ratio $[VL(N,O,O)]/[H_2VO_4^-]$ from the corresponding NMR signal intensities and pK_a of $H_2VO_4^-$, and then plotted this ratio against free ligand concentration [TEA] (Fig. 8). We obtained a good straight line passing through the origin and estimated the formation constant from the slope (Table 1). We also got signals due to the same type of (N,O,O) complex for DEA and MDEA systems. The formation constants of $H_2VO_4^-$ with DEA and MDEA were evaluated in the same way as that for TEA and are listed in Table 1 together with their chemical shift values. The formation constants evaluated agree well with the values reported by Crans et al. ($\log\beta_{(N,O,O)} = 3.0$ for DEA [27], 3.0 for MDEA [41] and 3.3 for TEA [26]). EA undergoes a comparatively weak interaction with vanadate compared with DEA, MDEA and TEA. The formation of monodentate and monochelate complexes such as VL(N,O), VL(O) and VHL(O) complexes was ignored in the tridentate and tetradentate ligand systems, since the presence of these less stable complexes would have a minimal effect on any conclusions obtained.

To illustrate the equilibrium conditions, a distribution diagram for the V–TEA system was calculated and plotted using the formation constant determined and oligomerization constants reported in [38]. Fig. 9 shows the distribution diagram for solutions containing 1.0×10^{-3} mol dm^{-3} vanadate and 0.1 mol dm^{-3} TEA (the same conditions as in Fig. 7). The experimental

Table 1
Formation constants and chemical shifts of vanadate complexes with ethanolamine derivatives and ECTEOLA–Cellulose

Ligand		$\log\beta_{(N,O,O)}$	Chemical shift
$HN(CH_2CH_2OH)_2$	DEA	3.3	−495
$H_3CN(CH_2CH_2OH)_2$	MDEA	3.6	−488
$N(CH_2CH_2OH)_3$	TEA	3.2	−489
ECTEOLA–Cellulose		3.6	−490

^{51}V NMR data are indicated by symbols for the respective species. The experimental points could be plotted well on the lines calculated.

3.3. ECTEOLA–Cellulose system

Tracey and Gresser [42] have demonstrated that sugars interact with vanadate to form a variety of complexes. However, the complexibility is quite low compared with the diethanolamine derivatives. In the case of cellulose gels, furthermore, cellulose forms hydrogen bonds to cross-link each other, which would prevent the complexation with vanadate species. In the ECTEOLA–Cellulose system, therefore, the interaction of vanadates with the glucopyranoside residues has been ignored, and the following two mechanisms can participate in the vanadium(V) adosorption: anion exchange under acidic conditions and complex formation under alkaline conditions. Fig. 10 shows the pH dependence of vanadium(V) adsorption onto ECTEOLA–Cellulose under acidic conditions (pH 3.0–6.5). The adsorbability is quite high and the maximum is around pH 5.5. Considering the pK_a values of ethanolamine derivatives (pK_{aL} = 7.8 for $HTEA^+$ [39]), at least a part of the functional groups of ECTEOLA–Cellulose would be protonated at a pH lower than 8, then the gel would function as a weakly basic anion exchanger. The feature of the pH-dependence of K_d values almost agrees well with the distribution of dimer and *cyclo*-tetramer as a function of pH. Although the presence of isopolymer species in the bulk solution can be ignored under the conditions examined, the high adsorbability in the acidic solutions should mainly be ascribed to the strong interaction between the protonated functional groups of ECTEOLA–Cellulose and the anionic isopolyvanadates. This topic will be discussed elsewhere. Anyway, on the contrary to the result for the chitosan system reported by Guzmán et al., the decamer could not be a predominant active species for the adsorption at a quite low initial concentration of vanadium(V) ($C_V = 4.0\times10^{-6}$ mol dm^{-3}).

Taking the practical use of ECTEOLA–Cellulose for the removal and recovery of vanadium from sea water into account, we examined the adsorption mechanism at a pH higher than 6 in detail. ECTEOLA–Cellulose would contain diethanolamine groups as an anchor group, so that vanadate should react with the functional group to form the (N,O,O) complex as in the case of TEA, DEA and MDEA. The combination of distribution and NMR measurements makes it possible to clarify the nature of vanadium(V) adsorption. Fig. 11 shows the pH dependence of vanadium(V) adsorption onto ECTEOLA–Cellulose at higher pH values. Below pH about 9, the vanadium(V) adsorbability of this gel increases with the decrease in pH. In comparison with the result in Fig. 10, the adsorbability at the same pH was greatly reduced due to the higher concentration of the supporting electrolyte. Fig. 12 shows ^{51}V NMR spectra for ECTEOLA–Cellulose in equilibrium with

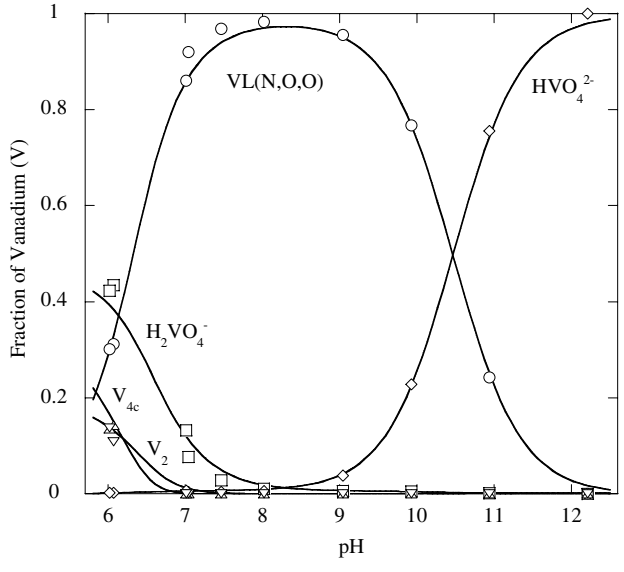

Fig. 9. Distribution diagram for solutions containing 1.0×10^{-3} mol dm^{-3} vanadate and 0.1 mol dm^{-3} TEA. The experimental NMR data points are indicated by symbols, ○: VL(N,O,O) complex; □: $H_2VO_4^-$; ◇: HVO_4^{2-}; △: dimer; ▽: *cyclo*-tetramer.

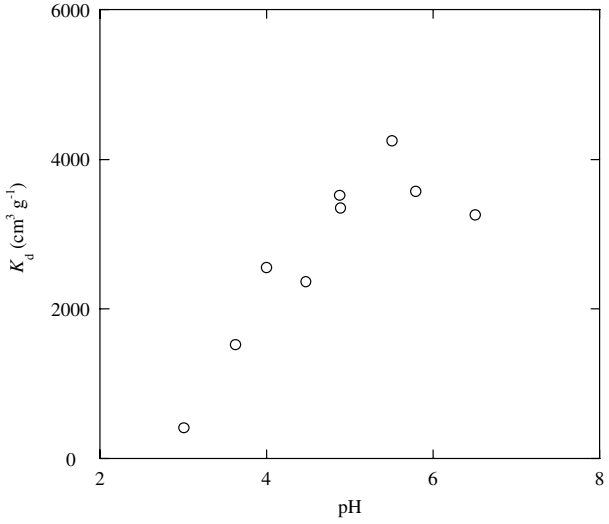

Fig. 10. pH dependence of vanadium(V) adsorption onto ECTEOLA–Cellulose at lower pH. ECTEOLA–Cellulose: 0.1 g; 4.0×10^{-6} mol dm^{-3} vanadate solution (I = 0.01, CH_3COONa–HCl): 20 cm^3.

vanadate solutions, in which the initial concentration of vanadium(V) ($C_V = 4.0 \times 10^{-4}$ mol dm^{-3}) is the same as that of the adsorption experiments in Fig. 11. These NMR spectra for gel suspensions contain signals of vanadium(V) species which exist in both gel and equilibrated solution. At pH 10 the signal at −540 ppm is ascribed to free vanadate in the equilibrated solution and in ECTEOLA–Cellulose. At this pH no adsorption occurs (Fig. 11). At pH lower than 8.7, we can get signals of the dimer and *cyclo*-tetramer for the gel samples. These signals were not observed for the equilibrated solution under the present experimental conditions. This clearly shows that the adsorption is due to the interaction of the dimer and *cyclo*-tetramer with the protonated functional groups, as well as in the case of the acidic conditions. At pH 8.7 a new ^{51}V NMR signal was observed in the gel phase (Fig. 12). This signal could not be observed for the equilibrated solution alone. The chemical shift is around −490 ppm, which is the same as that of the (N,O,O) complex of vanadate with DEA, MDEA or TEA. That is, this is the signal due to the −1 charged (N,O,O)-tridentate complex of pentacoordinate vanadium(V) with the functional group of ECTEOLA–Cellulose. The complexation, which means the fixation of vanadium(V) onto the gel matrix, causes a line broadening. The maximum signal intensity of the (N,O,O) complex is around pH 8 (Fig. 12), and the fraction change agrees well with that of the 1:1 complex with TEA (Fig. 9). These NMR spectra unambiguously show that the adsorption is the consequence of the complexation in addition to the interaction of the isopolyvanadates with the protonated functional groups under weakly basic conditions. The change in the concentration of supporting electrolytes has a small effect on the complexation. It is expected, therefore, that ECTEOLA–Cellulose can be used as a chelating adsorbent for the separation and concentration of a quite low concentration of vanadium from a matrix containing a high concentration of electrolytes under weakly basic conditions.

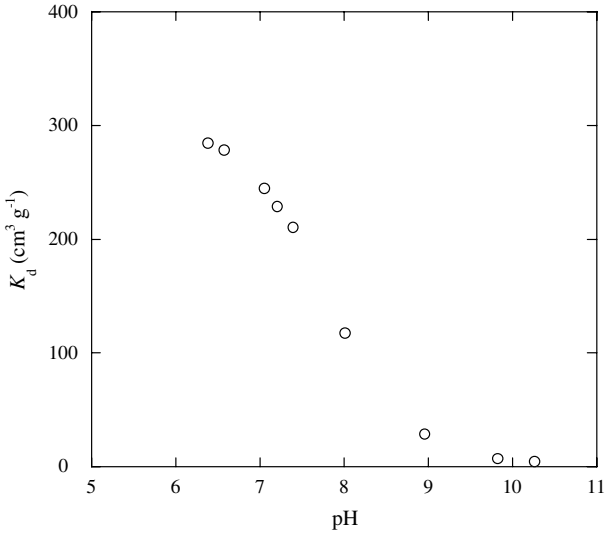

Fig. 11. pH dependence of vanadium(V) adsorption onto ECTEOLA–Cellulose at higher pH. ECTEOLA–Cellulose: 0.5 g; 4.0×10^{-4} mol dm^{-3} vanadate solution ($I = 0.1$, NaCl): 20 cm^3.

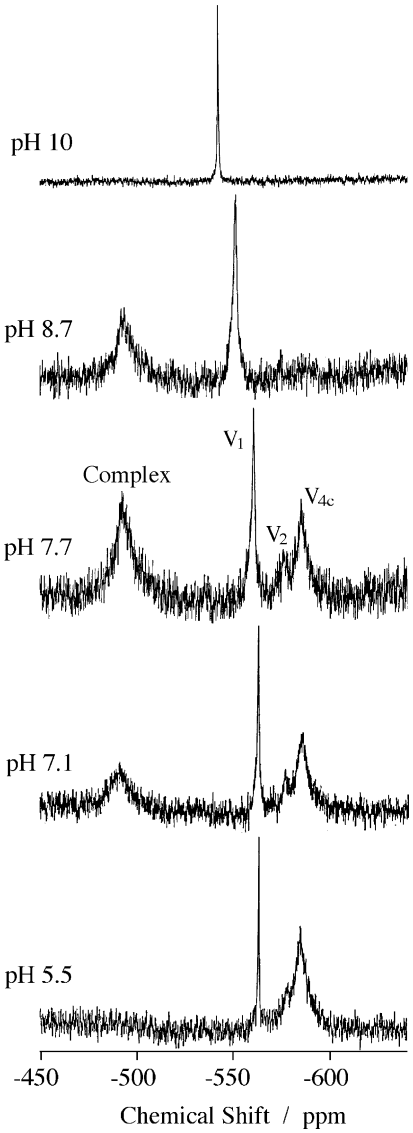

Fig. 12. ^{51}V NMR spectra for ECTEOLA–Cellulose in equilibrium with a solution ($I = 0.1$) containing 4.0×10^{-4} mol dm^{-3} vanadate at various pH. V_1: $H_2VO_4^-/HVO_4^{2-}$; V_2: dimer; V_{4c}: *cyclo*-tetramer.

In order to estimate the formation constant of the (N,O,O) complex of vanadate with the functional group of ECTEOLA–Cellulose, we have carried out a Langmuir analysis. As can be seen from the NMR spectra in Fig. 12, there is no isopolyvanadate in the gel phase at pH 8.7. The adsorption takes place at this pH mainly due to the complexation of vanadate with the functional group inside the gel. This is one piece of important information we can get from ^{51}V NMR spectroscopy. Therefore, the Langmuir analysis was done for the adsorption of vanadate onto ECTEOLA–Cellulose at

pH 8.7. The quotient, $\overline{C}_V/([H_2VO_4^-]\overline{C}_L)$, is given by the following equation:

$$\frac{\overline{C}_V}{[H_2VO_4^-]\overline{C}_L} = \frac{[\overline{H_2VO_4^-}] + [\overline{HVO_4^{2-}}] + [\overline{VL(N,O,O)}]}{[H_2VO_4^-]([\overline{L}] + [\overline{HL}] + [\overline{VL(N,O,O)}])}, \quad (11)$$

where upper bar refers to the gel phase, and C_V and C_L are the total concentrations of vanadium(V) species and the functional group of ECTEOLA–Cellulose, respectively. The adsorbability of vanadium(V) is strong enough to assume $[\overline{H_2VO_4^-}] + [\overline{HVO_4^{2-}}] \ll [\overline{VL(N,O,O)}]$. Considering the p$K_a$ of $HTEA^+$, most of the functional groups might be in the deprotonated form at pH 8.7, that is, $[\overline{L}] \gg [\overline{HL}]$. Since the gel reveals no ion-exchange ability, $[H_2VO_4^-] = [\overline{H_2VO_4^-}]$ can be assumed. Then, we can get the following equation:

$$\frac{[H_2VO_4^-]}{\overline{C}_V} = \frac{1}{\bar{\beta}_{(N,O,O)}\overline{C}_L} + \frac{[H_2VO_4^-]}{\overline{C}_L}, \quad (12)$$

where $\bar{\beta}_{(N,O,O)}$ is the formation constant of the (N,O,O) complex of vanadate with the functional group of ECTEOLA–Cellulose

$$\bar{\beta}_{(N,O,O)} = \frac{[\overline{VL(N,O,O)}]}{[\overline{H_2VO_4^-}][\overline{L}]}. \quad (13)$$

According to Eq. (12), the value on the left was plotted against $[H_2VO_4^-]$. As shown in Fig. 13, a good linear relationship was obtained. From the slope and intercept, we estimated the formation constant of the 1:1 complex with ECTEOLA–Cellulose as $\log \bar{\beta}_{(N,O,O)} = 3.6$, which is almost the same as those with DEA, MDEA and TEA (Table 1).

From the slope of the plot in Fig. 13, we also evaluated the total concentration of functional groups which are available for the complexation as $\overline{C}_L = 0.08$ mmol/g. The $\overline{C}_L$ value evaluated is much smaller than the nitrogen content 0.40 mmol/g in the gel determined by the elemental analysis. This means that only 20% of the functional groups introduced exist as the expected structure shown in Fig. 1. The rest of the functional groups are not suitable for complexation, because of further reactions among cellulose, epichlorophydrin and the functional groups introduced in the course of the sysnthesis of ECTEOLA–Cellulose.

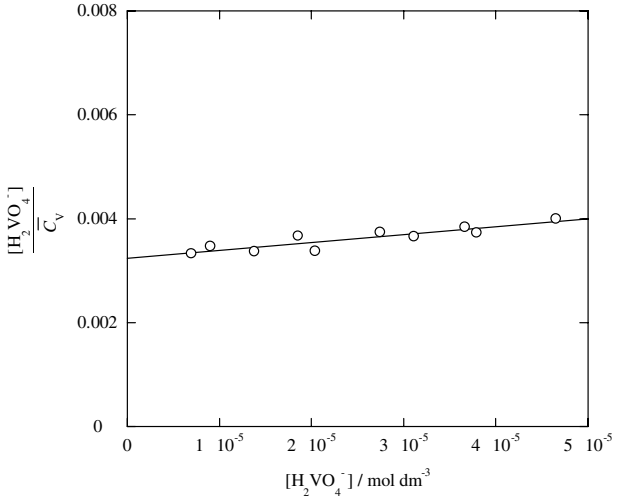

Fig. 13. Langmuir plot for the adsorption of vanadium(V) onto ECTEOLA–Cellulose at pH 8.7.

4. Conclusion

Although anion-exchange resins and chelating resins have been used for separation and concentration procedures, there are very few reports about the adsorption mechanism of vanadium. In the present work, the interaction of vanadium(V) oxoanions with ECTEOLA–Cellulose was examined by using distribution and ^{51}V NMR measurements. The strong adsorbability of vanadium(V) onto ECTEOLA–Cellulose under acidic conditions is ascribed to anion exchange of isopolyvanadate species formed only in the ion exchanger. On the contrary, the vanadium(V) adsorbability in the alkaline region is the consequence of the complexation of vanadate with the functional group to form the −1 charged 1:1 (N,O,O)-tridentate complex. The formation constant of the (N,O,O) complex with ECTEOLA–Cellulose was estimated to be $\log \bar{\beta}_{(N,O,O)} = 3.6$, which was almost the same as those with analogues of the functional group. Since the change in the concentration of supporting electrolytes has a small effect on the complexation, it is expected that ECTEOLA–Cellulose can be used as a chelating adsorbent for the separation and concentration of a quite low concentration of vanadium from a matrix containing a high concentration of electrolytes under weakly basic conditions.

Above all, the present study gave us a guiding principle for the recovery and removal of vanadium, and opened up opportunities to develop an advanced functional gel for further practical application.

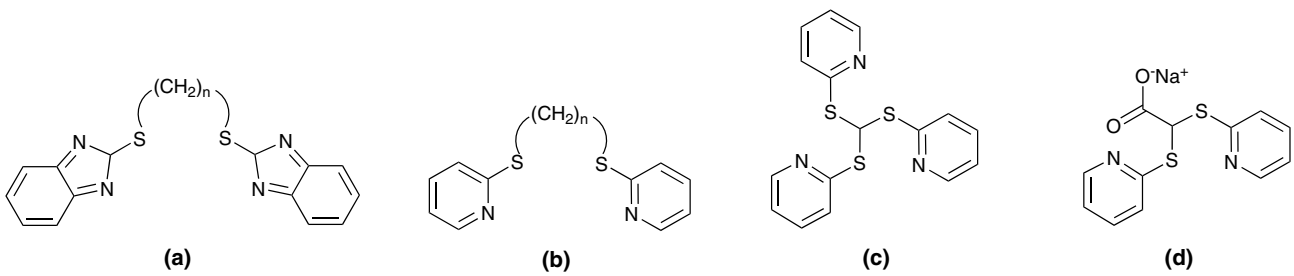
polyurethane foams [12], for room temperature vulcanisation of silicon rubbers [13], for transesterifications [14], for acetylations of alcohols [15] and for dehydrations of alcohols to ethers [16]. The diverse structural motifs known in this family of compounds are primarily attributed to the ambidentate character of the carboxylate ligands and also the tendency of the tin atom to expand its coordination sphere from four to seven. Steric and electronic attributes of organic substituents on tin and/or the carboxylate moiety impart significant influence on the structural characteristics of tin carboxylates. Recently, a number of carboxylate ligands bearing additional strategically placed functional group(s)/donor atom(s) capable of multidentate coordination have been used to derive a structurally interesting class of tin compounds [17].

In recent years a number of authors [18] have synthesized *S*,*N*-ligands of the type $(CH_2)_n(SAz)_2$ (Scheme 1) based on a nitrogenated aromatic ring system such as benzimidazole (Scheme 1(a)) or pyridine (Scheme 1(b)). These ligands are able to coordinate by both S and the neighbouring N atom, and hence to form stable chelate rings of five or more atoms [19–22].

Bearing in mind the above, we have developed a strategy for producing a new class of monoanionic and polyfunctional *N*,*O*,*S*-ligands of considerable co-ordinative flexibility. Toward this end, we report now the synthesis and characterization of some new complexes obtained from the interaction of a number of triorganotin(IV) halides with the novel sodium bis(2-pyridylthio)acetate ligand (Scheme 1(d)).

Crystallisation of the compound $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n$ (**2**), from chloroform/diethyl ether solution, yields the complex $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n \cdot CHCl_3$, which has been characterized by X-ray crystallography.

2. Experimental



2.1. General

All reagents were purchased from Aldrich (Milwaukee) and used as received. All syntheses were carried out under a nitrogen atmosphere. All solvents were distilled and degassed with dry nitrogen prior to use. The samples for microanalysis were dried in vacuo to constant weight (20 °C, ca. 0.1 Torr). Elemental analyses (C, H, N, S) were performed with a Fisons Instruments 1108 CHNS-O Elemental analyser. IR spectra were recorded from 4000 to 100 cm^{-1} with a Perkin–Elmer System 2000 FT-IR instrument. ^1H and ^{119}Sn NMR spectra were recorded on a VXR-300 Varian instrument operating at room temperature (respectively at 300 MHz for ^1H, 75 MHz for ^{13}C and 111.9 MHz for ^{119}Sn). Melting points were taken on an SMP3 Stuart Scientific Instrument. The electrical conductivity measurements (Λ_m, reported as Ω^{-1} cm^2 mol^{-1}) of acetone or dichloromethane solutions were taken with a Crison CDTM 522 conductimeter at room temperature. Electrospray mass spectra (ESIMS) were obtained in positive- or negative-ion mode on a Series 1100 MSD detector HP spectrometer, using an acetone mobile phase. The compounds were added to the reagent grade acetone to give solutions of approximate concentration 0.1 mM. These solutions were injected (1 μl) into the spectrometer via a HPLC HP 1090 Series II fitted with an autosampler. The pump delivered the solutions to the mass spectrometer source at a flow rate of 300 μl min^{-1}, and nitrogen was employed both as a drying and nebulizing gas. Capillary voltages were typically 4000 and 3500 V for the positive- and negative-ion mode, respectively. Confirmation of all major species in this ESIMS study was aided by comparison of the observed and predicted isotope distribution patterns, the latter calculated using the IsoPro computer program [23].

2.2. Synthesis

2.2.1. Synthesis of $[(pyS)_2CHCO_2]Na$ (*1*)

2-Mercaptopyridine (5.508 g, 50.0 mmol) was added to a solution of NaOH (3.600 g, 90.0 mmol) in 40 ml of absolute ethanol. After 1 day stirring, a solution of dichloroacetic acid (3.198 g, 25.0 mmol) in 40 ml of absolute ethanol was added drop wise to the sodium salt so obtained, and this mixture was stirred for 4 days and then heated at gentle reflux for 12 h to give a pale yellow emulsion. The mixture was allowed to cool to r.t. and concentrated and then filtered

Scheme 1.

affording a pale yellow solid. The crude product was recrystallized in ethanol/acetone (1:1) yielding Na-[(pyS)$_2$CHCO$_2$] (**1**) as pale yellow microcrystalline needles. Yield: 76%, m.p. 213–215 °C. ^{1}H NMR (D$_2$O, 293 K): δ 5.78 (s, 1H, C*H*CO$_2$), 7.20 (m, 2H, 5-C*H*), 7.44 (m, 2H, 3-C*H*), 7.67 (m, 2H, 4-C*H*), 8.30 (m, 2H, 6-C*H*). ^{1}H NMR (CD$_3$OD, 293 K): δ 6.08 (s, 1H, C*H*CO$_2$), 7.08 (m, 2H, 5-C*H*), 7.45 (m, 2H, 3-C*H*), 7.62 (m, 2H, 4-C*H*), 8.33 (m, 2H, 6-C*H*). ^{1}H NMR (CDCl$_3$, 293 K): δ 5.60 (s, 1H, C*H*CO$_2$), 7.10 (m, 2H, 5-C*H*), 7.50 (m, 2H, 3-C*H*), 7.65 (m, 2H, 4-C*H*), 8.36 (m, 2H, 6-C*H*). ^{13}C NMR (CD$_3$OD, 293 K): δ 5.44 (*C*HCO$_2$), 121.48 (5-*C*H), 123.93 (3-*C*H), 138.18 (4-*C*H), 150.28 (6-*C*H), 160.40 (2-*C*H). IR (nujol, cm^{-1}): 3046w (CH), 1615s (ν_{asym} C=O), 1581m, 1555m (C=C + C=N), 1411m (ν_{sym} C=O), 1376m, 1132m, 745m. 2.2.2. {[(pyS)$_2$CHCO$_2$]Sn(CH$_3$)$_3$}$_n$ (2)

To a CH$_2$Cl$_2$ solution (50 ml) of Me$_3$SnCl (0.199 g, 1.0 mmol), Na[(pyS)$_2$CHCO$_2$] (0.300 g, 1.0 mmol) was added. The mixture reaction was stirred for 12 h at room temperature, then solvent was removed on a rotary evaporator and chloroform was added (20 ml). The NaCl was removed by filtration and the filtrate reduced to half volume. Then diethyl ether was added (40 ml) and a yellow precipitate afforded, which was filtered off, washed with *n*-hexane (10 ml) and dried to constant weight under reduced pressure. Yield: 58%, m.p. 138–140 °C. ^{1}H NMR (CDCl$_3$, 293 K): δ 0.53 (s, 9H, Sn–C*H*$_3$, ^2J(Sn–^{1}H) = 57.3 Hz), 6.55 (s, 1H, C*H*CO$_2$), 7.00 (m, 2H, 5-C*H*), 7.24 (m, 2H, 3-C*H*), 7.51 (m, 2H, 4-C*H*), 8.43 (m, 2H, 6-C*H*). ^{119}Sn NMR (CDCl$_3$, 293 K): δ 149.2 (s). ^{13}C NMR (CDCl$_3$, 293 K): δ −1.98 (s, Sn-*C*H$_3$, ^1J(^{119}Sn, ^{13}C) = 410 Hz), 48.89 (*C*HCO$_2$), 120.20 (5-*C*H), 122.50 (3-*C*H), 136.34 (4-*C*H), 149.55 (6-*C*H), 157.42 (2-*C*H). IR (nujol, cm^{-1}): 3190w, 3058w (CH), 1616s (ν_{asym} C=O), 1574s, 1558s (C=C + C=N), 1413m (ν_{sym} C=O), 550sbr (Sn–C), 509s, 485sh (Sn–O). ESIMS (major positive-ions, CH$_3$OH), *m/z* (%): 164 (20) [(CH$_3$)$_3$Sn]$^+$, 442 (100) [(CH$_3$)$_3$Sn{(pyS)$_2$CHCO$_2$H}]$^+$, 905 (70) [{(CH$_3$)$_3$-Sn}$_2${(pyS)$_2$CHCO$_2$}$_2$ + Na$^+$]$^+$. ESIMS (major negative-ions, CH$_3$OH), *m/z* (%): 110 (100) [(pyS)]$^-$, 233 (40) [{(pyS)$_2$CHCO$_2$} − CO$_2$]$^-$, 718 (20) [(CH$_3$)$_3$Sn-{(pyS)$_2$CHCO$_2$}$_2$]$^-$. *Anal.* Calc. for C$_{15}$H$_{18}$N$_2$O$_2$S$_2$Sn: C, 40.73; H, 4.10; N, 6.34; S, 14.47. Found: C, 40.35; H, 4.20; N, 6.08; S, 14.08%.

2.2.3. {[(pyS)$_2$CHCO$_2$]Sn(C$_4$H$_9$)$_3$} (3)

Compound **3** was prepared similarly to compound **2**, stirring (C$_4$H$_9$)$_3$SnCl (0.326 g, 1.0 mmol) and Na[(pyS)$_2$-CHCO$_2$] (0.300 g, 1.0 mmol) in dichloromethane solution (30 ml). Re-crystallization from petroleum ether gave complex **3** as a micro-crystalline solid (55% yield), m.p. 66–68 °C. ^{1}H NMR (CDCl$_3$, 293 K): δ 0.83 (t, 9H, C*H*$_3$ of Sn–Bu^n), 1.15–1.35 (m, 12H, C*H*$_2$ of Sn–Bu^n), 1.45–1.65 (m, 6H, C*H*$_2$ of Sn–Bu^n), 6.50 (s, 1H, C*H*CO$_2$), 6.97 (m, 2H, 5-C*H*), 7.23 (m, 2H, 3-C*H*), 7.46 (m, 2H, 4-C*H*), 8.40 (m, 2H, 6-C*H*). ^{119}Sn NMR (CDCl$_3$, 293 K): δ 130.3 (s). IR (nujol, cm^{-1}): 3176w, 3095w (CH), 1614m (ν_{asym} C=O), 1577m, 1557m (C=C + C=N), 1415m (ν_{sym} C=O), 619br, 603sbr (Sn–C), 506sbr, 481sh (Sn–O). ESIMS (major positive-ions, CH$_3$OH), *m/z* (%): 290 (60) [(C$_4$H$_9$)$_3$Sn]$^+$, 323 (30) [{(pyS)$_2$CHCO$_2$} + 2Na$^+$]$^+$, 568 (80) [(C$_4$H$_9$)$_3$Sn{(pyS)$_2$-CHCO$_2$H}]$^+$, 590 (60) [{(C$_4$H$_9$)$_3$Sn}{(pyS)$_2$CHCO$_2$} + Na$^+$]$^+$, 1158 (100) [{(C$_4$H$_9$)$_3$Sn}$_2${(pyS)$_2$CHCO$_2$}$_2$ + Na$^+$]$^+$. ESIMS (major negative-ions, CH$_3$OH), *m/z* (%): 110 (40) [(pyS)]$^-$, 233 (20) [{(pyS)$_2$CHCO$_2$} − CO$_2$]$^-$, 845 (100) [(C$_4$H$_9$)$_3$Sn{(pyS)$_2$CHCO$_2$}$_2$]$^-$. *Anal.* Calc. for C$_{24}$H$_{36}$N$_2$O$_2$S$_2$Sn: C, 50.81; H, 6.40; N, 4.94; S, 11.30. Found: C, 50.75; H, 6.72; N, 4.83; S, 11.22%.

2.2.4. {[(pyS)$_2$CHCO$_2$]Sn(C$_6$H$_{11}$)$_3$} (4)

Compound **4** was prepared similarly to compound **2**, by using (C$_6$H$_{11}$)$_3$SnCl (0.404 g, 1.0 mmol) and Na-[(pyS)$_2$CHCO$_2$] (0.300 g, 1.0 mmol) in dichloromethane solution (30 ml). Re-crystallization from petroleum ether gave complex **4** as a micro-crystalline solid (60% yield), m.p. 104–106 °C. ^{1}H NMR (CDCl$_3$, 293 K): δ 1.06–1.94 (m, 33H, C$_6$*H*$_{11}$), 6.47 (s, 1H, C*H*CO$_2$), 6.97 (m, 2H, 5-C*H*), 7.26 (m, 2H, 3-C*H*), 7.47 (m, 2H, 4-C*H*), 8.40 (m, 2H, 6-C*H*). ^{119}Sn NMR (CDCl$_3$, 293 K): δ 73.2 (s). IR (nujol, cm^{-1}): 3137w, 3038w (CH), 1651m (ν_{asym} C=O), 1574m, 1557m (C=C + C=N), 1414m (ν_{sym} C=O), 552sbr (Sn–C), 491sbr, 483sh (Sn–O). ESIMS (major positive-ions, CH$_3$OH), *m/z* (%): 279 (100) [{(pyS)$_2$CHCO$_2$H} + H$^+$]$^+$, 647 (40) [{(C$_6$H$_{11}$)$_3$Sn}{(pyS)$_2$CHCO$_2$H}]$^+$. ESIMS (major negative-ions, CH$_3$OH), *m/z* (%): 110 (100) [(pyS)]$^-$, 233 (20) [{(pyS)$_2$CHCO$_2$} − CO$_2$]$^-$, 923 (30) [(C$_6$H$_{11}$)$_3$Sn{(pyS)$_2$-CHCO$_2$}$_2$]$^-$. *Anal.* Calc. for C$_{30}$H$_{42}$N$_2$O$_2$S$_2$Sn: C, 55.82; H, 6.56; N, 4.34; S, 9.93. Found: C, 55.35; H, 6.92; N, 4.03; S, 9.30%.

2.2.5. {[(pyS)$_2$CHCO$_2$]Sn(C$_6$H$_5$)$_3$} (5)

Compound **5** was prepared similarly to compound **2**, by using (C$_6$H$_5$)$_3$SnCl (0.386 g, 1.0 mmol) and Na [(pyS)$_2$ CHCO$_2$] (0.300 g, 1.0 mmol) in dichloromethane solution (30 ml). Re-crystallization from petroleum ether gave complex **5** as a micro-crystalline solid (72% yield), m.p. 108–110 °C. ^{1}H NMR (CDCl$_3$, 293 K): δ 6.55 (s, 1H, C*H*CO$_2$), 6.89 (m, 2H, 5-C*H*), 7.17 (m, 2H, 3-C*H*), 7.38–7.85 (m, 17H, C$_6$*H*$_5$ and 4-C*H*),

8.15 (m, 2H, 6-C*H*). ^{119}Sn NMR ($CDCl_3$, 293 K): δ −100.2 (s). IR (nujol, cm^{-1}): 3150w (CH), 1656s (ν_{asym} C=O), 1580m, 1557m (C=C + C=N), 1414m (ν_{sym} C=O), 482mb (Sn–O), 274s (Sn–C). ESIMS (major positive-ions, CH_3OH), *m/z* (%): 383 (80) $[(C_6H_5)_2Sn(pyS)]^+$, 628 (80) $[(C_6H_5)_3Sn\{(pyS)_2CHCO_2H\}]^+$, 717 (100) $[\{(C_6H_5)_3Sn\}O\{(C_6H_5)_3Sn\} + H^+]^+$, 977 (30) $[\{(C_6H_5)_3Sn\}_2\{(pyS)_2CHCO_2\}]^+$, 1278 (60) $[\{(C_6H_5)_3Sn\}_2\{(pyS)_2CHCO_2\}_2 + Na^+]^+$. ESIMS (major negative-ions, CH_3OH), *m/z* (%): 110 (100) $[(pyS)]^-$, 233 (40) $[\{(pyS)_2CHCO_2\} - CO_2]^-$, 627 (10) $[\{(C_6H_5)_3Sn\}\{(pyS)_2CHCO_2\} - H^+]^-$, 905 (60) $[\{(C_6H_5)_3Sn\}\{(pyS)_2CHCO_2\}_2]^-$. *Anal.* Calc. for $C_{30}H_{24}N_2O_2S_2Sn$: C, 57.44; H, 3.86; N, 4.47; S, 10.22. Found: C, 57.13; H, 4.00; N, 4.07; S, 10.08%.

2.3. X-ray crystallography

The crude complex **2** was dissolved in chloroform/diethyl ether solution; a single crystal of $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n \cdot CHCl_3$ suitable for X-ray diffraction analysis was obtained and mounted on a Rigaku AFC5R diffractometer using graphite-monochromatized Cu Kα radiation (1.54178 Å) and a rotating anode generator. The crystals are triclinic, a = 10.132(5) Å, b = 13.845(3) Å, c = 14.783(3) Å, α = 84.39(2)°, β = 77.90(2)°, γ = 88.15(3)°, V = 2018(1) A^3, T = 293 K, space group $P\bar{1}$ (no. 2), Z = 2, μ(Cu Kα) = 14.2 mm^{-1}, 6676 reflections measured, 6375 unique (R_{int} = 0:053), 3489 observed ($I > 3\sigma(I)$) were used in all calculations. The cell parameters were refined by least squares from the angular positions of 14 reflections in the range 68.77° < 2θ < 63.98°. The data were measured at room temperature for 6.1° < 2θ < 124.5° using a θ/2θ scan technique. The data were processed to yield values of I and $\sigma(I)$ corrected for Lorentz, polarisation and absorption effects. The psi scans used for the last correction present severe values (about 15%) of the transmission coefficients. The observed reflections were processed by the direct methods program SIR2004 [24], which provided the complete structure. The successive fourier maps showed the presence of a molecule of chloroform. All non-hydrogen atoms were refined by full-matrix least squares method with anisotropic thermal parameters. The hydrogen atoms were idealised (C–H = 0.96 Å). Each H atom was assigned the equivalent isotropic temperature factor of the parent atom multiplied for 1.3 and allowed to ride on it. At the end of the refinement, a further semi empirical absorption correction was made on the basis of the method of Walker and Stuart [25], using the program written by Ugozzoli [26] and then the structure converged at the final $R(F)$ and $wR(F^2)$ of 0.056 and 0.074, respectively. The final difference Fourier map with a root-mean-square deviation of electron density of 0.2 e $Å^{-3}$ showed no significant features. Calculations were performed using the SIR2004 structure determination package Crystallographic data have been deposited at the CCDC and allocated the deposition number CCDC 264907.

3. Results and discussion

Complexes **2**–**5** have been synthesized by methathetic reaction of $Na[(pyS)_2CHCO_2]$ (**1**) (Scheme 1(d)) with SnR_3Cl acceptors in CH_2Cl_2 solution (Eq. (1)).

$$Na[(pyS)_2CHCO_2] + SnR_3Cl \rightarrow \underset{\mathbf{2\text{–}5}}{[(pyS)_2CHCO_2]SnR_3} + NaCl$$

2 R = CH_3 **3** R = ^{n}Bu
4 R = Cy **5** R = Ph (1)

The derivatives **2**–**5** are stable in air. The complexes are stable in alcohols, acetone, acetonitrile and chlorinated solvents, and they are non-electrolytes in CH_2Cl_2 solution. The identity of these compounds has been established by ESI-MS, IR and multinuclear (^{1}H and ^{119}Sn) NMR spectral studies.

The infrared spectra carried out on the solid samples (nujol mull) showed all the expected bands for the ligand and the tin moieties: weak absorptions near 3100 cm^{-1} are due to the pyridine rings C–H stretching and medium to strong absorptions in the range 1550–1580 cm^{-1} are related to ring "breathing" vibrations.

The presence of the COO moiety is detected by intense absorptions in the range 1614–1656 cm^{-1} and 1413–1415 cm^{-1} due to the asymmetric and symmetric CO_2^- stretching mode, respectively, not significantly shifted with respect to the free ligand (ν_{asym} CO_2^- = 1615 cm^{-1}, ν_{sym} CO_2^- = 1411 cm^{-1}).

In the far-IR region medium to strong absorptions appear upon coordination, due to the stretching modes of Sn–N and Sn–R [27]. The absence of Sn–Cl stretching vibrations in the spectra of **2**–**5** confirms the substitution of the chloride in the complexes formation. In the far-IR spectra the Sn–C stretching frequencies fall as strong or medium broad bands in the range 550–619 cm^{-1} for alkyl derivatives **2**–**4**, and at 274 cm^{-1} for tri(phenyl) complex **5**; these absorptions well agree with the trends previously observed in similar N-donor complexes [28]. In the far-IR spectra of **2**–**5** absorptions assigned to Sn–O have been always detected between 481 and 509 cm^{-1}.

The room temperature ^{1}H NMR spectra of derivatives **2**–**5**, in $CDCl_3$ solution (see Section 2), exhibit only one set of signals for the protons of the pyridyl rings of the $[(pyS)_2CHCO_2]^-$ ligand.

Upon interaction of ligand **1** with organotin(IV) acceptors, for all complexes studied, no significantly large shifts were evident for the proton atoms of pyridyl rings: this implies a lack of direct bond involvement of these rings with the metal. In contrast, in the ^{1}H

NMR spectra of complexes **2**–**5** the signals due to the C*H*COO group exhibit significant downfield shift (from 6.08 ppm in the free ligand to 6.47–6.55 ppm in the complexes): this is suggestive of a strong bonding of the tin atom to the carboxylate group of complexes.

The tin-hydrogen, $^{2}J(^{119}Sn,^{1}H)$, and tin-carbon, $^{1}J(^{119}Sn,^{13}C)$, coupling constants in various cases can be correlated with the percentage of s-character which the Sn atom presents in the Sn–C bond and hence $^{2}J(^{119}Sn,^{1}H)$ and $^{1}J(^{119}Sn,^{13}C)$ may give information about the coordination number of tin [29,30]. In the tri(methyl)tin(IV) derivative **2** the tin-proton coupling constant $^{2}J(^{119}Sn,^{1}H)$ is 57.3 Hz, falling in the range of four-coordinated trimethyltin(IV) species [30]. The tin-carbon coupling constant of compound **2**, $^{1}J(^{119}Sn,^{13}C)$, is 410 Hz; on the basis of Lockarts's equation [29], the Me–Sn–Me angle is estimated to 111°, suggesting a distorted tetrahedral disposition of Me groups.

The ^{119}Sn chemical shifts of triorganotin(IV) derivatives **2**–**5**, at 149.2, 130.3, 73.2 and −100.2 ppm, respectively, are in accordance with those of four-coordinated triorganotin(IV) complexes involving S-, O- or N-donors [31–33].

Electrospray ionization is considered a 'soft' ionization technique and is particularly suitable for study of labile organotin systems in solution. ESI mass spectra, dissolved in methanol solution and detected at fragmentation voltage of 30 V, show molecular ion peaks and structurally important fragment ions. For the ligand **1** significant fragments at *m*/*z* 301 and 579 in the positive- and at *m*/*z* 577 in the negative-ion spectra have been attributable to aggregates of the ligand with Na^{+}; peaks at *m*/*z* 110 and 233, respectively, due to the fragments $[(pyS)]^{-}$ and $[\{(pyS)_2CHCO_2\} - CO_2]^{-}$, are present in the negative-ion spectrum of **1**. Peaks at *m*/*z* 110, 233, 279 and 323, due to the free O-donor ligand or its decomposition fragments, are also present in the spectra of all derivatives **2**–**5**.

Peaks due to the free organotin(IV) acceptors $[R_3Sn]^{+}$ are present in the cationic spectra of derivatives **2** and **3**, due to the instability of these triorganotin derivatives. The instability of triorganotin(IV) derivatives in methanol solutions is also demonstrated by the presence in the positive-ion spectrum of the triphenyl derivative **5** of a fragment at *m*/*z* 383, due to the aggregate $[(C_6H_5)_2Sn(pyS)]^{+}$. In the electrospray spectra of all the triorganotin derivatives **2**–**5**, peaks due to species containing the triorganotin fragments associated to one or two molecules of the ligand have been detected.

Crystallisation of the compound $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n$ (**2**), from chloroform/diethyl ether solution, yields the chloroform complex $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n \cdot CHCl_3$. The identity of **2** has been established by elemental analysis, IR, NMR spectroscopy, and X-ray crystallography. The structure consists of polymeric chains and the molecular structure of two units of the polymer $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n \cdot CHCl_3$ with labelling for the main atoms is shown in Fig. 1. The geometry of $[(pyS)_2CHCO_2]Sn(CH_3)_3$ is similar in the two independent unit and bond lengths and angles are given in Table 1. The tin atom is five-coordinated, being bonded to two oxygen atoms and three methyl groups, respectively. The coordination sphere is essentially distorted trigonal bi-pyramidal with the three equatorial positions being taken up by the methyl substituents and the two axial positions being occupied by oxygens (O–Sn–O = 169.9(3)°, averaged angle). In this mode the tin atom has the least electronegative groups in the equatorial position and the electronegative

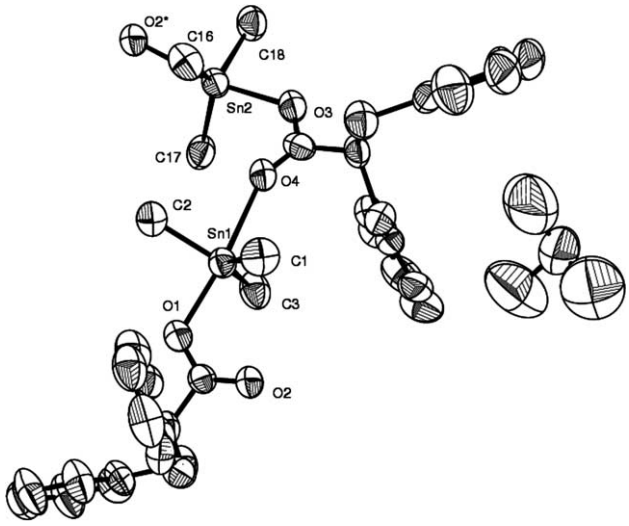

Fig. 1. Molecular structure of two units of the polymer $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n \cdot CHCl_3$, (including the equivalent O2*, $1 + x, y, z$) with 50% displacement ellipsoids and labelling of atoms around the tin atoms.

*Equivalent position: $1 + x, y, z$.

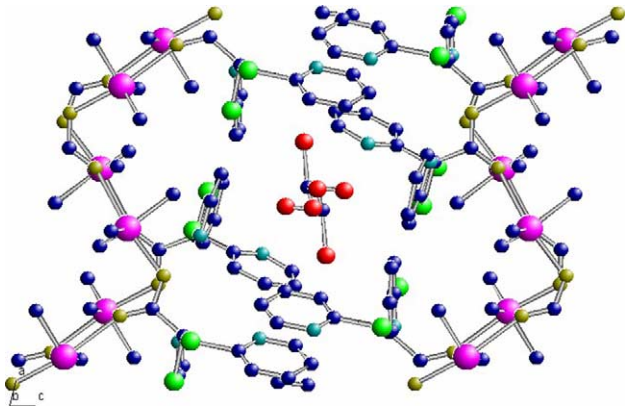

Fig. 2. Projection on the *ac* plane of the polymeric complex $\{[(pyS)_2CHCO_2]Sn(CH_3)_3\}_n \cdot CHCl_3$.

oxygens in the axial position. The Sn–O distances are non-equivalent with the Sn–O (carboxyl) being slightly longer (2.512(8) Å, averaged bond length) than the other (2.182(8) Å, averaged bond length). Thus the R–CO_2 does not function as symmetric bridging ligand. Because of the variation of the bond distances the tin is displaced from the equatorial plane of the three methyl groups towards the covalently bond oxygen by about 0.15(1) Å. The C–Sn–C angles ranging from 110.7(6)° to 128.3(6)°.

In the chain structure the carboxylate unit functions as a bridging ligand and connects two different tin centers in a intermolecular manner. The preference for the chain structure seems to be the natural consequence of the principles of five-coordination. In this mode the tin atom is in a trigonal-bipyramidal geometry and has the least electronegative groups in the equatorial position and the electronegative oxygens in the axial position. In solution the polymeric structure breaks down to monomeric structure (even in a non-coordinating solvent such as $CDCl_3$), as evidenced by ^{119}Sn NMR.

The polymeric chains are along the *a* axis and form channels occupied by the solvent molecules, as illustrated in Fig. 2, where the projection on the *ac* plane of the unit cell is shown. The two pyridine rings of the two independent $[(pyS)_2CHCO_2]$ moieties make a dihedral angle of 96.1(5)° and 80.4(5)°, respectively, and form the walls of the channels. Short contact is present between nitrogen atom of a pyridine ring and the carbon atom of the chloroform (N1–C31($x, y, z-1$) = 3.39(3) Å).

and fructose residues, and the torsional angles, ϕ and ψ, O-5(g)–C-1(g)–O-1(g)–C-2(f) and C-1(g)–O-1(g)–C-2(f)–O-5(f), respectively (Fig. 1(a)), and our expectation was that these angles would not change markedly on formation of the complex, as was indicated by the earlier PM3(tm) optimization and is consistent with the higher level computations as shown later.

The geometry of the complex, initially optimized by using semi-empirical PM3(tm) parameters [5a], is similar to that shown in Fig. 1(b), which was obtained by a higher level DFT optimization. The optimized structure of sucrose is shown in Fig. 1(a) for comparison with that of the complex.

The initial PM3(tm) optimization had indicated that the Δ-complex should be strongly preferred over the Λ-complex, but it incorrectly predicted deprotonation of OH-1(f) rather than OH-2(g), as had been shown by ^{1}H NMR spectroscopy [5a]. An additional problem was that the predicted CH-3(g)–OH-3(g) torsional angle in the complex did not fit the evidence of a very low ^{1}H NMR coupling constant in DMSO. There was predicted distortion of both phenanthroline rings from planarity, which appeared to be due to competing interactions between a glucose or fructose residue with the front face of a phenanthroline, and a hydrogen of the other phenanthroline with the other (rear) face [5b]. In the structure shown in Fig. 1(b) the front face of the phenanthroline, designated A, is towards the hydroxyl group, OH-1(f), of the fructose residue and the rear face is towards H-9(B) of the second phenanthroline, designated B. The front face of phenanthroline B is towards the glucose residue, and the rear face is towards H-9(A) of phenanthroline A. The phenanthroline positions are numbered 1-10, and N1-(A) and N-1(B) are trans at Co(III). As in earlier work, phenanthroline A is shown in Fig. 1(b) as being attached to the upper coordination site of Co(III) with the sucrose residue on the left, and ligated glucose to the front, and B is attached to the lower site of Co(III) [5].

The PM3(tm) semi-empirical model has been parameterized to reproduce geometries of transition metal compounds, rather than energies [6–8], which may account for its inability to predict the correct position of deprotonation of sucrose in the dicationic complex. We have therefore carried out ab initio geometrical optimizations, using the following basis sets: HF 3-21(G*) and 6-31(G*), and DFT BP/6-31(G*), and at the higher levels we used LACVP* pseudopotentials at Co(III) [6,7].

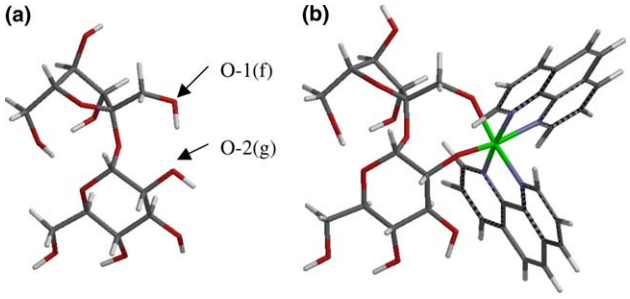

Fig. 1. Structures of sucrose (a) and the complex (b) from DFT optimizations. Phenanthroline ring A is attached to the upper coordination site of Co(III), and B is attached to the lower coordination site and is adjacent to the glucose residue.

2. Methods

Structures were optimized by using Spartan 04 (Wavefunction) starting from the geometrically optimized structures given earlier by using PM3(tm), and heats of formation were initially calculated by using the 3-21(G*) basis set, which provides adequate information under some conditions. Further information was obtained by using HF 6-31(G*) or DFT BP/6-31(G*) basis sets with LACVP* pseudopotentials [6,7]. Heats of formation are given to the nearest kcal mol^{-1}, as in the earlier work [5]. Assignments of all the ^{1}H NMR signals in D_2O and DMSO-d_6 had been made earlier [5], including those of the phenanthrolines, which were based on connectivities and the rules of Ito et al. [9].

3. Results and discussion

An initial comparison of conclusions from the semi-empirical, PM3(tm) and the HF treatments was based on the HF 3-21(G*) basis set which gave the Δ-complex energetically preferred over the Λ-complex by 18 kcal mol^{-1}; the corresponding difference from the PM3(tm) optimization had been 9 kcal mol^{-1} [5a]. There is no physical evidence for the existence of the Λ-complex of sucrose(phen)$_2$, either method of calculation fits this observation, and we did not examine the preference for the Δ-complex over the Λ-complex at higher levels. As noted, the PM3(tm) calculation had incorrectly indicated that deprotonation of OH-1(f) would be preferred over that of OH-2(g) by 3 kcal mol^{-1}, however, calculations at the HF 3-21(G*) and LACVP*/6-31(G*) levels indicate that deprotonation of OH-2(g) is preferred by ca. 5 kcal mol^{-1}, in agreement with experiment [5a]. The inability of the semi-empirical PM3(tm) treatment to predict relative energies for deprotonation is probably due to the reliance on geometrical criteria for parameterization for transition metals [6,7].

To this extent, calculation of energies for the HF optimized structures removes an anomaly in the PM3(tm) treatment [5a], but it introduces an error in the geometry of OH-1(f), which from the ^{1}H NMR spectral evidence in DMSO is pyramidal, in agreement with

the PM3(tm) optimized structure shown as Fig. 2 in [5a]. The ^{1}H signals at OH-1(f) and CH-2(f) had been assigned, and the coupling constants of OH-1(f) with H-1′(f) and H-1(f) in DMSO are 9.5 and 4.0 Hz, respectively, consistent with the predicted torsional angles of 170° and −75°, respectively, at the PM3(tm) level [5a]. The HF optimizations give a near planar OH-1(f), inconsistent with the NMR data [5a], and structures with torsional angles constrained to the values which fit the coupling constants are disfavored by 3 and 2 kcal mol^{-1} in 3-21 (G*) and 6-31 (G*) calculations, respectively. These constrained HF structures relax to the incorrect planar structure on removal of the constraint. Limitations of HF treatments of some pyramidal structures have been noted [6]. The structure re-optimized with the BP/6-31 (G*) basis set and LACVP* pseudopotentials for Co(III) had torsional angles of 176° and −68° between OH-1(f) and H-1′(f) and H-1(f), respectively, in reasonable agreement with the NMR coupling constants in DMSO and the earlier semi-empirical optimization [5a]. This structure from the DFT optimization with the estimated torsional angles is shown in Figs. 1(b) and 2 with H-1′(f) towards and H-1(f) away from the viewer and illustrates the pyramidal geometry at OH-1(f). Except as noted, the HF and DFT structures of the complex are in other respects similar, although only geometries from the latter and PM3(tm) are in Table 1 or the figures.

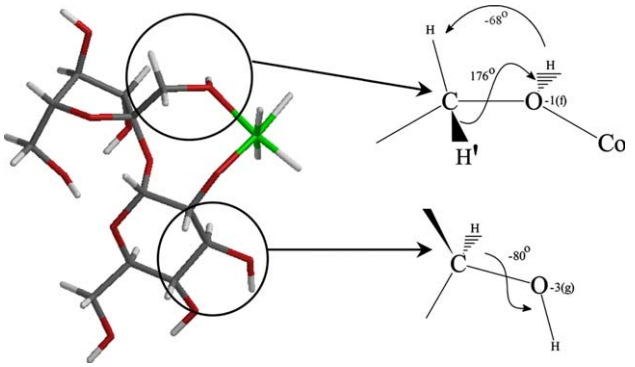

Fig. 2. Structure of the complex with the phenanthroline groups removed for clarity. The insets show the DFT computed torsional angles at CH–OH-1(f) and CH–OH-3(g).

Predicted geometries at Co(III) from the DFT optimization are shown in Table 1, and include comparison with values obtained earlier from the PM3(tm) treatment [5].

As for the parent sugar, the conformation of the sucrose moiety in the complex is defined by the bond angle, C-1(g)–O–C-2(f), between the glucose and fructose residues, and the torsional angles, ϕ and ψ [4], which are shown in Table 1 for the complex. We used DFT to optimize the geometry of sucrose to be consistent with the treatment of the geometry of the Co(III) complex. The structure at the BP/6-31(G*) level shown in Fig. 1(a) is similar to those in the crystal and from other treatments [4,10]. Computed values of the torsional angles ϕ and ψ are 108.6° (107.8°) and −35.6° (−44.8°), respectively, and the C-1(g)–O–C-2(f) bond angle is 117.8° (114.3°), and these are similar to values in the crystal [4], which are in parentheses. These values are similar to those calculated earlier [5,10] and are consistent with the original assumption that complexation does not significantly perturb the sucrose moiety. We note that our computation is for an isolated molecule and does not cover crystal packing or interactions with the environment [10]. However, ^{1}H NMR spectroscopy had shown that the conformation did not change significantly in going from D_2O to DMSO-d_6 [5a].

3.1. Semi-empirical and ab initio geometries

Computed geometries of the Δ-sucrose complex illustrated in Figs. 1 and 2, and Table 1, and given earlier [5],

Table 1
Geometry of Δ-sucrose $Co(phen)_2^{2+}$ [a]

Bonding to sucrose moiety			
Bond/torsional angle (°)			
O-2(g)–Co–O-1(f)	C-1(g)–O–C-2(f)	ϕ	ψ
95.1 (92.8)	117.7 (117.8)	112.0 (114.5)	−36.5 (−51.2)
Bond length/distance (Å)			
Co–O-2(g)	Co–O-1(f)	O-2(g)–O-1(f)	
1.88 (1.89)	2.03 (2.03)	2.89 (2.84)	
Bonding to phenanthroline nitrogens			
Bond angle (°)			
N-10(A)–Co–N-1(A)	N-10(B)–Co–N-1(B)		
81.6 (89.9)	84.6 (89.7)		
Bond length (Å)			
Co–N-1(A)	Co–N-10(A)	Co–N-1(B)	Co–N-10(B)
1.97 (1.93)	2.03 (1.96)	1.97 (1.93)	1.92 (1.92)

[a] Values in parentheses are from the PM3(tm) optimization [5a,5b].

show that PM3(tm) and DFT methods generate similar results, so far as the positions of bonding between sucrose and Co(III)$(phen)_2$ are concerned. However, the PM3(tm) incorrectly predicts the site of protonation in forming the dicationic complex, and indicates that there should be considerable bowing of both phenanthroline groups.

Each phenanthroline is sandwiched between H-9 of the other phenanthroline and either the glucose or fructose moiety. In terms of either semi-empirical (PM3(tm)), or ab initio optimizations using HF or DFT treatments H-9 of one phenanthroline is ca. 2.7 Å from the rear of the other phenanthroline, cf. [9]. The fructose ring is not very close to phenanthroline A, but the glucose ring is close to phenanthroline B, and O-3(g) is ca. 3.1 Å from the center of this ring, from the DFT optimization. Some of these predicted interatomic distances are therefore within the sum of the van der Waals radii and the half-thickness of an arene [11].

Bowing of a phenanthroline depends on the forms of the non-bonding interactions with either the sugar residue or the other phenanthroline, being repulsive or attractive. There is extensive evidence for non-classical –HO hydrogen bonding [12], and Nishio et al. [13] concluded that π-H–C interactions may be modestly attractive. The PM3(tm) optimization had indicated extensive bowing of both phenanthrolines, with phenanthroline A presenting a convex face and a modest tilt towards the sugar residue, and B presenting a concave face towards the sugar and a tilt away from it [5b]. The extent of bowing was given by the dihedrals between the outer rings of the phenanthrolines and the tilt was with respect to the N–Co–N plane, as illustrated in Fig. 2(a) and (b) in [5b] and discussed in detail in that reference. It appeared from this earlier optimization that repulsion from the rear between H-9(B) and phenanthroline A is greater than repulsion of the latter from the front by the fructose residue, but that for phenanthroline B repulsion by the glucose residue is dominant.

Predicted distortions of the phenanthrolines in the DFT optimization are significantly less than from the earlier PM3(tm) optimization [5b]. This is also the situation for the HF optimizations, although these geometries are not shown, because in this respect they are very similar to those in Figs. 1 and 3. The predicted bowing of phenanthroline A is almost zero rather than 15°, and the tilt is <1° rather than 6°, as given earlier, and the new DFT results are illustrated in Fig. 3, where (a) shows phenanthroline ring A viewed in profile with H1 and H2 projecting forward from the plane of the paper. Fig. 3(b) shows phenanthroline ring B viewed in profile with H5 and H6 projecting forward of the plane of the paper. The predicted bowing of phenanthroline B, as given by the sum of the dihedrals, is 16° rather than 19° and the tilt is 3° rather than 6°, estimated as outlined in [5b].

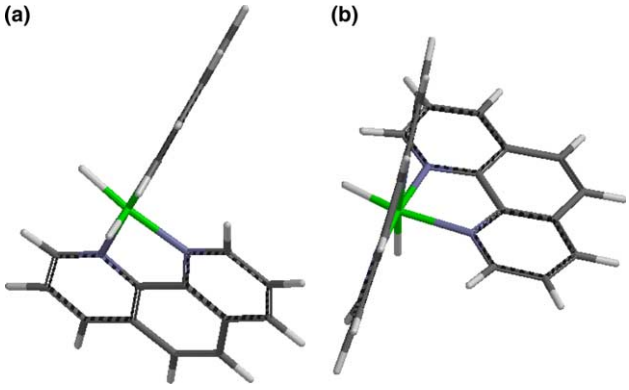

Fig. 3. Bowing of phenanthroline rings, shown in profile, with the sugar residue removed for clarity, and illustrating the predicted near planarity of ring A (a) and bowing of ring B (b).

It appears that in the PM3(tm) optimization the π-HO and π-H–C interactions are treated as repulsive, with consequent distortion of both phenanthrolines, whereas repulsion is less evident in the ab initio optimizations. There is limited direct physical evidence regarding geometries of phenanthroline groups in mixed Co(III) complexes and possible distortions due to interactions with adjacent groups [9]. There is only modest bowing in the mixed carbonato complex, but this third ligand is small and should not interfere with the two phenanthroline groups [18], and Hennig et al. [19] note distortions in some bis-phenanthroline complexes. However, variations in the NMR chemical shifts of the phenanthroline hydrogens [5b] provide evidence on distortions of these groups and indicate that it is less for phenanthroline A than B. The ^{1}H NMR chemical shifts of each phenanthroline group decrease in going from H-2 to H-9 [5b], which, for other Co(III)bis-phenanthroline complexes, was ascribed by Ito et al. [9] to π-shielding by the other phenanthroline group. For phenanthroline A, which is predicted to be near planar (Fig. 3(a)), the approximate decrease is 2.2 ppm, but for B, which is predicted to be bowed (Fig. 3(b)), it is approximately 2.7 ppm [5b], and larger than expected if π-shielding were the only factor controlling the chemical shifts [9]. A deviation from planarity of phenanthroline B should decrease its aromatic character and be reflected in the decrease in the relevant ^{1}H chemical shifts being larger for phenanthroline B than A. Chemical shifts of H-8 and 9 are lower for phenanthroline B than for phenanthroline A, but differences are small for the other positions, excepting H-2, A and B, which are close to the ligating nitrogens and the sucrose residue [5b]. These decreases in chemical shift are in addition to those due to π-shielding by the other phenanthroline as discussed by Ito et al. [9].

As shown in Fig. 1(b), little congestion is predicted between the fructose ring and phenanthroline A, which means that the conformation of the fructose hydroxymethyl group (C-1(f)–OH-1(f)) is not perturbed

and is consistent with the computed torsional angles between OH-1(f) and the hydrogens on C-1(f), as shown in Fig. 2(a), and the ^{1}H coupling constants [5a]. However, congestion between the glucose ring and phenanthroline B should influence the interaction between the latter and OH-3(g). The difference between predicted torsional angles from the semi-empirical and DFT optimizations is consistent with the H-3(g)–OH-3(g) spin–spin coupling constant in DMSO [5a], which depends on the torsional angle between the axial CH-3(g) and OH-3(g), and should be sensitive to the interaction between this OH group and phenanthroline B. The coupling constant must be very low, <2 Hz [5a], much lower than that for a freely rotating CH_2OH group, ca. 6.5 Hz [14], or that expected from the computed torsional angle of −149° from the PM3(tm) optimization which would indicate a significant coupling constant, and was originally ascribed to an apparent π-HO repulsion [5a]. However, the predicted torsional angle of −80° from the DFT optimization (Fig. 2) corresponds to a low coupling constant in accord with experiment and less repulsion between this OH group and phenanthroline B than that predicted earlier from the PM3(tm) optimization [5].

The Co(III)–oxygen bond lengths from the DFT and PM3(tm) optimizations are similar, but DFT generally gives longer Co–N bonds, and therefore lower predicted bond angles (Table 1). Both treatments predict modest deviations from a strictly octahedral symmetry at Co(III), which, as noted earlier [5b], is consistent with assignments of the CD spectra in the d–d region of mixed complexes [3b,5a] and structural evidence on other Co(III) complexes [15,16].

4. Conclusions

Except for differences in bowing of the phenanthroline rings, the predicted deprotonation of OH-2(g), rather than of OH-1(f), and the CH-3(g)–OH-3(g) torsional angle, predicted geometries from the earlier PM3(tm) optimization are not very different to those from the present ab initio treatments, and are better than the HF optimizations as regards the pyramidal geometry of OH-1(f), although DFT does not have this problem. These treatments neglect interactions with solvents, but examination of absorption, circular dichroism and NMR spectroscopy had shown that the structure does not change significantly in going from water to DMSO, despite marked differences between these solvents, especially as regards hydrogen bonding [5a,5b]. The ab initio treatments predict deprotonation of OH-2(g), consistent with the NMR evidence on the structure of the dicationic complex.

Semi-empirical methods and molecular modeling, where appropriate force fields are available [6,7,17,18], are much more economical in time than ab initio methods. This advantage is important in treating geometries, although not necessarily energies, of complex molecules [19]. Computational methods appear to be useful in predicting structures of transition metal complexes with polyol ligands where X-ray crystallography cannot be used, provided that the conclusions are supported by experimental evidence, for example from electronic and NMR spectroscopy.

prepared by reacting phosphorus pentachloride with trichloroacetamide, followed by addition of methanol in accordance with the literature method [8].

Metal salts Na[L] (**1**), Rb[L] (**2**), Tl[L] (**3**) were synthesized in aqueous-alcoholic media.

2.1.1. Na[L] (*1*)

Sodium carbonate (0.106 g, 1 mmol) was added in several portions to a solution of H[L] (0.541 g, 2 mmol) in 10 ml of aqueous 2-propanol (1:3). The solution was stirred with heating until total dissolution of Na_2CO_3 was observed. The solvent was removed in vacuo and the colorless product recrystallized from isopropanol. Yield: 0.573 g, 98%. *Anal*. Calc. for $C_4H_6Cl_3NNaO_4P$: C, 16.43; H, 2.07; N, 4.79. Found: C, 16.47; H, 2.1; N, 4.67%. ^{1}H NMR (D_2O): 3.55 d [6H, $^3J_{PH}$ 11.2 Hz, $PO(OCH_3)_2$]; ^{31}P NMR (D_2O): 16.09 h [$^3J_{PH}$ 11.3 Hz, $PO(OCH_3)_2$]. Na[L-d_6] (**1a**). The compound was obtained as **1**. $NaHCO_3$ and D[L-d_6] were used as starting materials. Yield: 0.585 g, 98%.

2.1.2. Rb[L] (*2*)

Rubidium carbonate (0.231 g, 1 mmol) was added in parts to 10 ml of an aqueous-alcoholic (1:3) solution of [HL] (0.541 g, 2 mmol). A solution of the product was allowed to stand at room temperature in a vacuum desiccator over $CaCl_2$ for 20 days, after which the colorless well-faceted crystals that were deposited were filtered out, washed with few drops of isopropanol and dried over $CaCl_2$. Yield: 0.653 g, 92%. *Anal*. Calc. for $C_4H_6Cl_3NRbO_4P$: C, 13.54; H, 1.70; N, 3.95. Found: C, 13.2; H, 1.76; N, 3.64%. ^{1}H NMR (D_2O): 3.57 d [6H, $^3J_{PH}$ 11.2 Hz, $PO(OCH_3)_2$]; ^{31}P NMR: (D_2O) 16.11 h $^3J_{PH}$ 11.3 Hz, $PO(OCH_3)_2$].

The thallium compound Tl[L] (**3**) was synthesized in a similar fashion by reacting HL (0.584 g, 2 mmol) and Tl_2CO_3 (0.4688 g, 1 mmol) in aqueous 2-propanol. Yield: 0.824 g, 87%. *Anal*. Calc. for $C_4H_6Cl_3NTlO_4P$: C, 10.14; H, 1.28; N, 2.96. Found: C, 10.14; H, 1.42; N, 2.93%. ^{1}H NMR (D_2O): 3.57 d [6H, $^3J_{PH}$ 11.2 Hz, $PO(OCH_3)_2$]; ^{31}P NMR: (D_2O) 16.09 h $^3J_{PH}$ 11.3 Hz, $PO(OCH_3)_2$].

2.1.3. PPh_4[L] (*4*)

To a solution of **1** (0.584 g, 2 mmol) in 10 ml acetonitrile, a solution of 0.838 g PPh_4Br (2 mmol) in 15 ml CH_3CN was added under stirring. Then, the reaction mixture was cooled to room temperature. The white precipitate of NaBr was filtered off, and the solvent was removed in vacuo and the yellow product was recrystallized from isopropanol and hexane. Yield: 1.132 g, 93%. *Anal*. Calc. for $C_{28}H2_6Cl_3NO_4P_2$: C, 55.24; H, 4.30; N, 2.3. Found: C, 55.0; H, 4.15; N, 2.16%. ^{1}H NMR (D_2O): 7.74 m [8H $(PPh_4)^+$ – *ortho*, 7.56 m [12H $(PPh_4)^+$ – *meta* + *para*], 3.55 d [6H, $^3J_{PH}$ = 11.2 Hz, L^-]; ^{31}P NMR: (D_2O) 23.48 m $(PPh_4)^+$, 16.03 [$^3J_{PH}$ 11.3 Hz, $PO(OCH_3)_2$].

2.1.4. $(PPh_4)_2$[L]Br · H_2O (*5*)

To a solution of Na[L], that was prepared as above, PPh_4Br (0.838 g, 2 mmol in 15 ml CH_3CN) was added in the ratio 1:2. The white precipitate of NaBr was filtered off, the solvent was removed in vacuo and the off-white product was recrystallized from an isopropanol–hexane mixture. Yield: 0.941 g, 90%. *Anal*. Calc. for $C_{52}H_{48}BrCl_3NO_5P_3$: C, 59.7; H, 4.63; N, 1.34. Found: C, 60.0; H, 4.63; N, 1.30%. ^{1}H NMR $(CD_3)_2CO$: 7.93 m [20H, $(PPh_4)^+$], 3.25 d [3H, $^3J_{PH}$ = 11.2 Hz, L^-]; ^{31}P NMR: ($(CD_3)_2CO$) 24.05 m $(PPh_4)^+$, 13.05 [$^3J_{PH}$ 11.3 Hz, $PO(OCH_3)_2$].

2.1.5. $(PPh_4)_2$[Na_4L_6] (*6*)

To a solution of 0.8772 g (3 mmol) Na[L], 0.419 g PPh_4Br (1 mmol in 10 ml CH_3CN) was added. The white precipitate of NaBr was filtered off, the solvent was removed in vacuum and the colourless product was recrystallized from isopropanol and hexane. Yield: 1.015 g, 85%. *Anal*. Calc. for $C_{72}H_{76}Cl_{18}N_6Na_4O_{24}P_8$: C, 36.22; H, 3.21; N, 3.52. Found: C, 36.54; H, 3.32; N, 3.41%. ^{1}H NMR ($(CD_3)_2CO$): 7.9 m [10H, $(PPh_4)^+$], 3.53 d [9H, $^3J_{PH}$ 11.2 Hz, $PO(OCH_3)_2$]; ^{31}P NMR ($(CD_3)_2CO$): 22.35 m $(PPh_4)^+$, 12.64 h ($^3J_{PH}$ = 11.2 Hz, $PO(OCH_3)_2$).

All the compounds are soluble in water, DMFA, DMSO, acetone, sparingly soluble in isopropanol, 1,4-dioxane and insoluble in non-polar aprotic solvents.

2.1.6. [$SbPh_4$L] (*7*)

To a solution of Na[L] (0.293 g 1 mmol) in 10 ml acetonitrile was added $SbPh_4Br$ (0.511 g, 1 mmol) in 15 ml acetonitrile. After 15 min, a white precipitate of NaBr was filtered off and the solution was allowed to stand in a vacuum desiccator over $CaCl_2$. After a while colorless crystals of **7** precipitated from the solution, that were recrystallized from isopropanol. The compound is soluble in polar protic solvents, insoluble in water, ethers, benzene and alkanes. Yield: 0.569 g, 85%. *Anal*. Calc. for $C_4H_6Cl_3NTlO_4P$: C, 47.73; H, 4.43; N, 1.99. Found: C, 47.70; H, 4.65; N, 1.74%. ^{1}H NMR ($(CD_3)_2CO$): 7.88 dd [8H, $^3J_{HH}$ = 8.4 Hz, $^4J_{HH}$ = 1.6 Hz, $(SbPh_4)^+$ – *ortho*], 7.61 m [12H, $(SbPh_4)^+$ – *meta* + *para*], 3.25 d [6H, $^3J_{PH}$ = 11.2 Hz, L^-]; ^{31}P NMR ($(CD_3)_2CO$): 12.08 h ($^3J_{PH}$ = 11.2 Hz, L^-).

2.2. Methods

2.2.1. NMR, IR-spectroscopy

IR spectra of the compounds were recorded on an UR-10 spectrometer in the range 400–4000 cm^{-1} (samples as KBr pellets or nujol mulls). ^{1}H and ^{31}P NMR spectra were recorded on a Varian AMX 400 spec-

trometer at room temperature in deuterated water (D_2O) or acetone (acetone d_6) solutions (TMS internal standard).

2.2.2. Crystallography

Details of the data collections and refinements are given in Table 1. Data were collected at room temperature (except **2**, $T = 223$ K) using an Enraf-Nonius CAD-4 for **3**, KUMA KM-4 and Mo-radiation for **6** and Cu-radiation for **1** or with a SMART CCD system for **2**, **4**, **5**, **7**, using Mo-radiation. The structures were solved by the heavy atom method. All non-hydrogen atoms were refined anisotropically. The positions of the hydrogen atoms were idealized. Refinements were by full-matrix least squares based on F^2 and using SHELX-86 and SHELXL-93 [9,10].

3. Results and Discussion

3.1. NMR and IR spectroscopy

The difference in ^{31}P NMR chemical shifts between P═O (12–16 ppm.) is typical and can readily be compared to the related compounds with the formula $CCl_3C(O)NHP(O)R$. The ^1H NMR spectra and CHN analyses were satisfactory for all compounds.

The IR spectra of the compounds have a number of common features (Table 2), that coincide with the literature data [11]. The IR bands in the region 3080 cm^{-1} observed in the spectrum of the neutral ligand, may be ascribed to ν(NH) vibrations of the amide protons. These bands are absent in the spectra of all compounds **1**–**7**, which is evidence for the deprotonated form of the ligand. The spectra for compounds **1**–**7** reveal significantly lower frequencies of ν(PO) compared with HL ($\Delta\nu$(PO) = 40–85 cm^{-1}), reflecting the binding via the phosphoryl oxygen atom [12]. In the case of compound **6** the splitting of the ν(PO) band is caused by the μ^3-dentate function of the phosphoryl oxygen of the "axial" ligand. The ν(CO) values in the spectra of the compounds are shifted to lower frequencies ($\Delta\nu$(CO) = 58–107 cm^{-1}) due to delocalization of π-electron density in the chelate frame under deprotonation or coordination. These facts were observed for a wide range of phosphoramide chelate systems [13,14].

3.2. Description of the structures

The covalence degree of the metal–ligand interaction (in the six-membered chelate metal cycles, e.g., β-diketonates, diphosphinates) directly depends on the nature of the central ion, donor atoms and planarity of the chelate moiety. For the carbacylamidophosphates, the criterion of planarity may be considered to be the value of the torsion angle OPNC ($\angle$PNCO = 0°) [7], which reflects the delocalization degree of π-electron density in the chelate frame as a whole. Thereupon the above-mentioned structures will be studied.

The structures of compounds **1** and **3** are composed of centrosymmetric dimers (Fig. 1(a) and (b)) that are formed by the bridging function of the phosphoryl oxygen atom. The result is a tricyclic system with a central planar four-membered M_2O_2 ring and an overall ladder structure: parameters Na(1) ··· Na(1a) = 3.506(3) Å; $\angle$Na(1)O(1)Na(1a) = 94.28(1)°, $\angle$O(1)Na(1)O(1a) = 85.74(1)° in **1** and parameters Tl(1)–Tl(1a) = 4.111(1) Å, $\angle$Tl(1)O(1)Tl(1a) = 96.2(4)°, $\angle$O(1)Tl(1)O(1a) = 83.8(3)° for **3** (Table 3). A similar type of bonding was observed earlier in $[Na\{(OPPh_2)(SPPh_2)N\}\cdot 2THF]_2$ [15]. The nitrogen atom N(1) and oxygen atoms of methoxy groups of the neighboring dimer moieties are also involved in coordination to each sodium and thallium atom. Thus, polymeric ladder structures for **1** and **3** are realized (Fig. 1(c)).

The unique part of **2** consists of four structurally independent Rb^+ ions (Fig. 2): the closest contact Rb-L exceeds 2.8 Å, so it might be considered as mainly an ionic type of bond. Thus, each L has bridging oxygen atoms of phosphoryl and carbonyl groups. The bridging function of the carbonyl oxygen atom of the amidophosphate ligands was observed for the first time.

The coordination pattern of the amidophosphate ligands (codified here as $\mathbf{L^1}$, $\mathbf{L^2}$, $\mathbf{L^3}$ and $\mathbf{L^4}$ corresponding

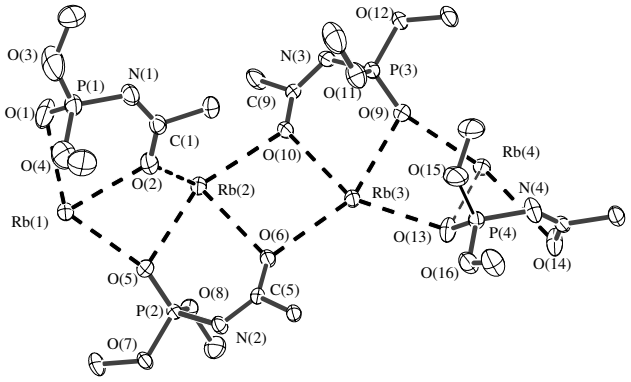
to the oxygen atoms of methoxy groups) is different (schematic representations are depicted in **a** and **b**). The distortion of the chelate frame in the rubidium compound (**a**, **b**) can be explained in terms of the availability of a weak contact Rb–O(CH_3) and has been reflected in the values of the torsion angles (Table 3).



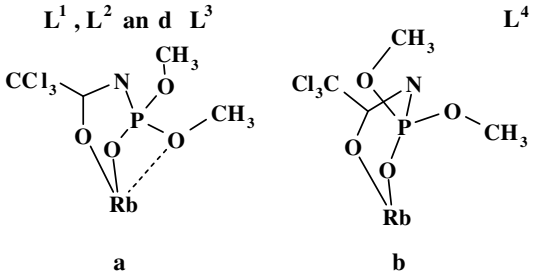


Fig. 2. Structure of RbL. The protons of methyl groups and chlorine atoms are omitted for clarity.

The molecular structures of **1**, **2** and **3** show the ligand's coordination to the metal ion via the oxygen atoms of phosphorylic and carbonylic groups, forming a six-membered chelate ring arrangement in which the ring can be viewed as a heterocycle containing five different atoms. Each chelate cycle is not planar. Table 3 lists the maximum deviation from the mean plane for all compounds. The corresponding bond lengths M–O(P) and M–O(C) in each chelate frame are 2.499(3) and 2.273(3) Å for **1**, 2.94 and 2.96 Å (average) for **2**, 2.610(5) and 2.736(6) Å for **3**; c.f. the sum of ionic radii are $\Sigma_{M^+ + O^{2-}}(Na, O) = 2.36$ Å, $\Sigma_{M^+ + O^{2-}}(Rb, O) = 2.92$ Å, $\Sigma_{M^+ + O^{2-}}(Tl, O) = 2.86$ Å, [16]. There are few previous crystallographic determinations to make comparisons. The most appropriate are $[TlPh_2\{(SPPh_2)_2N\}]$ [11] and $K[(SPPh_2)_2N]$ [17].

In the Na, Rb and Tl salts the C–N–P system is angular (values of the angle C–N–P are shown in Table 3) as it is in the free ligand, but the (O)CNP(O) skeleton has the *syn*-conformation for all compounds. Within the ligand moiety the phosphorous–oxygen and carbon–oxygen distances are significantly longer (Table 3) compared with the free ligand [4]. In contrast, the phosphorous–nitrogen bonds in HL are significantly shorter (0.055 Å (**1**), 0.063 Å (**2**), 0.062 Å (**3**)), suggesting an increase in double bond character as a result of π-delocalization [15]. Taking into consideration that alkali metals are hard Lewis acids, the covalence contribution in the interaction $M^+ - L^-$ is realized. This is also reflected in the values of the torsion angle PNCO (Table 3). The coordination geometry around the sodium, rubidium and thallium atoms in their compounds are irregular (Fig. 3(a) and (b)): C.N. for Na, Rb and Tl atoms in their compounds are 5, 7 and 6, respectively.

The X-ray structures of **4** and **5** reveals that there are no contacts shorter than 2.72 Å between the cation and anion. The tetraphenylphosphonium salt (**4**) contains a non-solvated and deprotonated phosphorylic ligand (Fig. 4(a)). In compound **5** (Fig. 4(b)), two anions L^-(O=P) and Br^- are associated into an ensemble by means of hydrogen bonding with a solvate water molecule [H(2) ··· O(1) 2.017(6) Å, O(5) ··· O(1) 2.840(5) Å, O(5)–H(2) ··· O(1) 167.2(2)°, H(1) ··· Br(1) 2.656(6) Å, O(5) ··· Br(1) 3.365(5) Å, O(5)–H(1) ··· Br(1) 175.3(6)°]. Geometrical parameters of the chelate frame in these structures have some differences from those for the alkali metals and thallium compounds. The mean C=O and P=O distances in **4** are decreased by 0.01 and 0.04 Å, respectively, in contrast with the sodium salt, while the bond CN lengths are almost the same. Such variations in the bond lengths testify that there are no bonding contacts for the carbacylamidophosphate anion in compound **4**. Otherwise there are no significant differences in bond lengths in chelate **5** (deprotonated anionic ligand) compared to that in **1** (Table 3). The presence of the above H-bond evidently stabilizes the structure **5**. These data all agree well with the results of the IR-spectroscopic study (Table 2).

The chelate (O)PNC(O) frame in **4** and **5** are non-planar with maximum deviations of atoms from the mean PNCO plane of 1.241 and 1.162 Å, respectively. This implies an increase in the CNPO torsion angles for both compounds in contrast with those in **1**–**3** (Table 3). Thus, the ionic type of binding realized in compounds **4** and **5** causes the decrease of π-conjugation in the chelate moiety.

The X-ray structure of **6** reveals an unexpected type of coordination moiety $[Na_4L_6]^{2-}$ (Fig. 5); there are no shortened contacts between the cations and anion. Such a type of self-assembly in coordination compounds is realized due to the influence of the PPh_4^+ anion and μ-dentate function of the phosphoryl oxygen atoms.

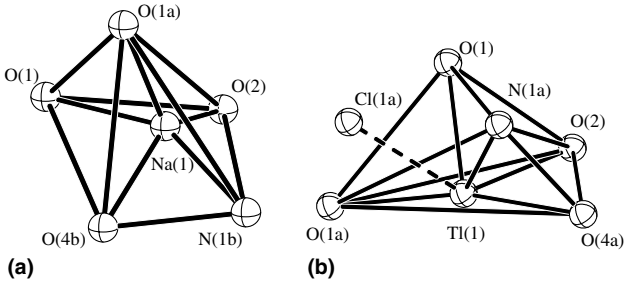

Fig. 3. Coordination polyhedra of NaL (**a**) and TlL (**b**).

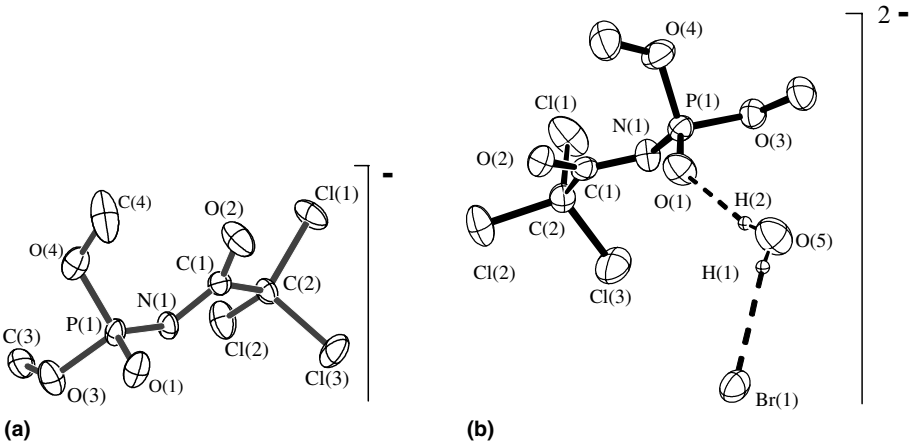

Fig. 4. The anionic moieties in the structure of $PPh_4[L]$ (**a**), $(PPh_4)_2[L]Br \cdot H_2O$ (**b**).

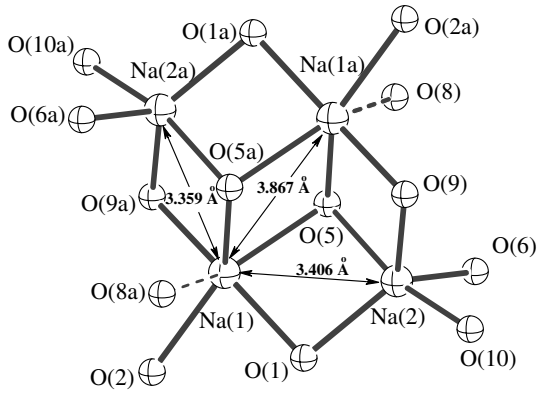

Fig. 5. Na_4-frame geometry and coordination arrangement of Na-atoms.

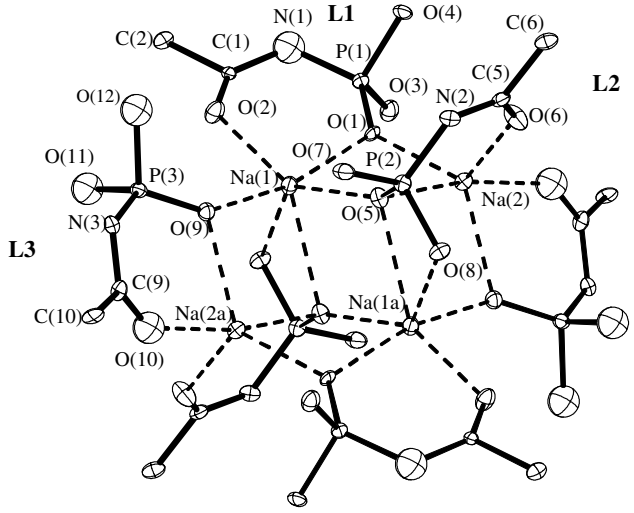

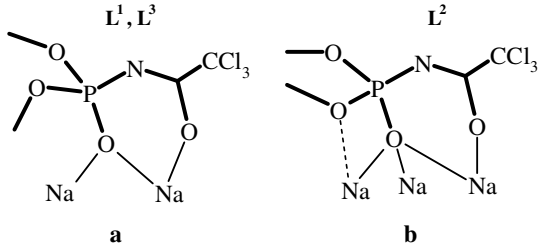

Fig. 6. Structure of the anion $(PPh_4)_2[Na_4L_6]$ (CH_3^-, Cl^- atoms are omitted).

Similarly to the sodium and thallium salts described above, the central ion is coordinated to the ligands in a bidentate-chelate manner. A four-membered planar Na_4 unit has formed (Fig. 5) because of the μ-function of the phosphoryl oxygens, as will be shown later. The corresponding angles Na(1)–Na(2)–Na(1a) and Na(2a)–Na(1)–Na(2) are 69.73(1)° and 110.27(1)°, respectively.

The dihedral angles between the Na_4 plane and the mean planes of the corresponding chelate frames are $\mathbf{L^1}$ – 19.7° – an "equatorial" position, $\mathbf{L^2}$ – 83° – an "axial" position and $\mathbf{L^3}$ – 45.8 – a "meridian" position (the coordination pattern of the carbacylamidophosphate ligands codified here as $\mathbf{L^1}$, $\mathbf{L^2}$ and $\mathbf{L^3}$) (Fig. 6).

Na atoms in the structure of **6** have different environments: C.N. Na(1) = 6 (distorted octahedron with axial axis O(1)–Na(1)–O(9) (∠165.56°)); C.N. Na(2) = 5 (distorted trigonal bipyramid with axial O(10a)–Na(2)–O(5) (∠169.96°)) (Fig. 7).

In contrast to **1**, the phosphoryl oxygen atoms of ligands $\mathbf{L^1}$ (O(1)) and $\mathbf{L^3}$ (O(9)) have a μ^2-bridging function and in $\mathbf{L^2}$ (O(5)) a μ^3-bridging function (schematic representations are depicted in **a** and **b**), as a consequence the acido-ligands in the complex anion are not equivalent. These data all agree well with the results of the IR-spectroscopic study (Table 2). Such dentate differences have an effect on the corresponding NaO(P) contacts: the μ^3-dentate oxygen atom, consisting of an "axial" ligand, forms longer contacts with the three sodium atoms than the μ^2-phosphoryl oxygen (Δ = 0.1–0.3 Å). All these parameters are comparable with those in **1** (Table 3).

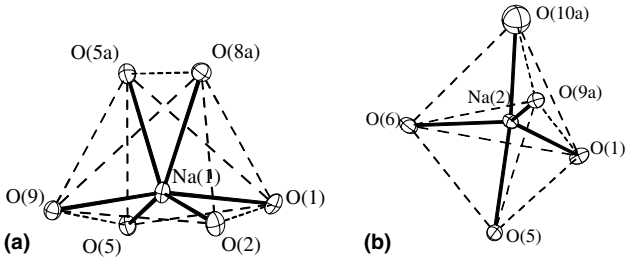

Fig. 7. Coordination polyhedra of sodium atoms in $(PPh_4)_2[Na_4L_6]$: (**a**) Na(1), (**b**) Na(2).

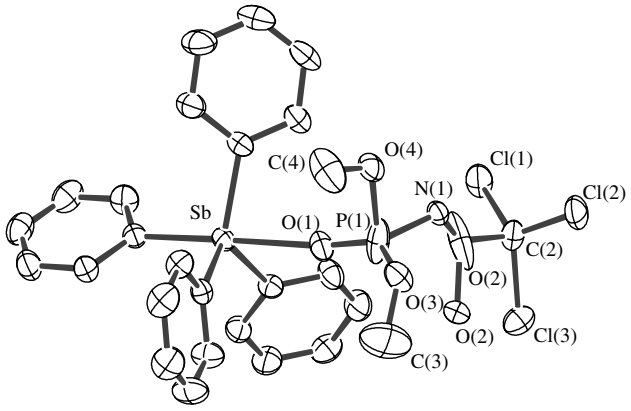

Fig. 8. Molecular structure of $[SbPh_4L]$.

The PNCO torsion angles values for $\mathbf{L^2}$ and $\mathbf{L^3}$ are similar and for $\mathbf{L^1}$ – significantly less than that in NaL (Table 3).

The molecular structure of the antimony complex **7** shows a monodentate coordination of the phosphorylic ligand via the phosphoryl oxygen atom (Fig. 8). The central Sb(1) atom adopts a fivefold coordination with a slightly distorted trigonal bipyramid. One of the phenyl cycles and the O(1) oxygen atom occupy the axial positions (∠[C(40)–Sb(1)–O(1)] = 176.5°). Three equatorial phenyls are non-planar and shifted to the side of $\{L^-\}$, on average by 8°.

The Sb–O bond length is 2.44 Å. The value of the SbOP angle slightly deviates from linearity (172.0°) and is significantly bigger then SbOC in $SbPh_4OCH_3$ (∠SbOC = 126° [18]). The P═O bond length is 1.432(3) Å, which is somewhat less than those in all the above structures, except in **4**. A discussion of all the another parameters in the chelate frame is complicated due to disordering of the trichloroacetamidic part.

The value of the torsion angle OPNC is 79.4° and takes an intermediate position between the same value for **4** (80.1°) and **5** (62.3°), which exhibits a minimum of π-conjugation.

4. Conclusions

The coordination behavior of dimethyl-*N*-trichloracetylamidophosphate towards singly charged cations reveals principal differences from complexes with d- and f-metals studied earlier. The main feature of this ligand is the disposition to form bi- and polymeric structures and associates. It was shown that creation of especial steric conditions (the application of cations with one vacant place for coordination – $SbPh_4^+$) was necessary for the formation of simple systems. Using non-coordinating ions (PPh_4^+) permits the synthesis and to characterize structurally of the ''free'' non-solvated anion. These data could be used for the molecular design of coordination systems based on carbacylamidophosphates.

5. Supplementary data

Crystallographic data have been deposited at the Cambridge Crystallographic Data Center, CCDC Nos: **1** – 237495; **2** – 237497; **3** – 237496; **4** – 237498; **5** – 237499; **6** – 237500; **7** – 237501. metal ion materials containing bio-relevant pyrazolyl thiosemicarbazones and related ligands, the present paper reports the syntheses and spectroscopic identification of new Ni(II) complexes with 5-methyl-3-formylpyrazole-3-piperidinylthiosemicarbazone (HMP_z3Pi), with novel findings from X-ray crystallography of $[Ni(HMP_z3Pi)_2]Cl_2 \cdot 2H_2O$.

2. Experimental

All reagents were of AR/GR grade and were obtained from commercial sources and used without further purification. Spectral and conductance measurements were performed using spectrograde solvents.

2.1. Preparation of 5-methyl-3-formylpyrazole-3-piperidinylthiosemicarbazone (HMP_z3Pi)

The title ligand, HMP_z3Pi (Fig. 1), has been synthesised and thoroughly characterised by physical methods for the first time, as reported in an earlier communication [8g].

2.2. General method of preparation of nickel (II) complexes: $[Ni(HMP_z3Pi)_2]X_2 \cdot 2H_2O$ (X = Cl, Br, ClO_4, BF_4 and NO_3)

The reported Ni(II) complexes have been prepared by refluxing ethanolic solutions of the ligand (1.05 mmol) and the corresponding hydrated Ni(II) salt (0.525 mmol) in a water bath for about 30 min. On slow evaporation of the green solutions, each of the desired Ni(II) complexes crystallised out, was filtered off, washed with cold ethanol and was dried over anhydrous $CaCl_2$; the yield has been recorded to be 75–80%. Diffractable quality dark green crystals of $[Ni(HMP_z3Pi)_2]Cl_2 \cdot 2H_2O$ were obtained on slow crystallisation.

Caution! Extreme care has been taken while treating organic compounds with nickel (II) perchlorate, as potentially explosive mixtures might be formed.

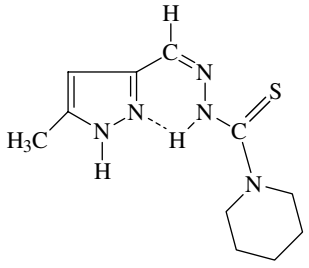

Fig. 1. Structural formulation of 5-methyl-3-formylpyrazole-3-piperidinylthiosemicarbazone (HMP_z3Pi).

2.3. Physical measurements

All physical measurements and analytical procedures adopted for characterisation of the Ni(II) complexes are similar to those described earlier [8e,8h].

2.4. Structure determination

X-ray diffraction data of the ligand (HMP_z3Pi) were collected on a Bruker–Nonius MACH3 diffractometer, while those of the complex $[Ni(HMP_z3Pi)_2]Cl_2 \cdot 2H_2O$ were collected on a CCD diffractometer. The radiation used in either case was Mo Kα and the data were corrected for Lorentz and polarisation effects. The structures were solved by direct methods and refined using the full matrix least squares method based on $|F_{obs}|^2$ [9]. The non-hydrogen atoms were refined anisotropically, while the hydrogen atoms, either located from difference electron density maps or generated using idealised geometry, were used in the structure factor calculations with isotropic thermal parameters using the "riding" model. Neutral atom scattering factors [10] were used and anomalous dispersion effects were included in F_{calc} [11]. The crystallographic data are summarised in Table 3. The final positional and thermal parameters are available as supplementary material.

3. Results and discussion

3.1. Characterisation of 5-methyl-3-formylpyrazole-3-piperidinylthiosemicarbazone (HMP_z3Pi)

The title ligand, HMP_z3Pi, has been characterised by elemental analyses (C, H and N), IR, ^1H NMR and mass spectrum and the results have been reported earlier

[8g]. The proposed structural formulation (Fig. 1) of the ligand, HMP_z3Pi has been established by X-ray crystallography in the present communication.

3.2. Characterisation of the Ni(II) complexes

The reported Ni(II) complexes gave satisfactory C, H, N and metal analyses and conform to the general composition: $[Ni(HMP_z3Pi)_2]X_2 \cdot 2H_2O$ (X = Cl, Br, ClO_4, BF_4 and NO_3). The molar conductance values in MeOH (30 °C) classify them as 1:2 electrolytes [12] (Table 1). All the reported complexes are paramagnetic (μ_{eff} = 3.07–3.26 BM), as expected for a normal spin free d^8 system.

3.2.1. Spectral studies

The solid state electronic spectra (DRS) of all the reported nickel (II) complexes are similar in nature and exhibit three bands in the regions 11 723–11 919 cm^{-1} [$^3A_{2g}$ (F) → $^3T_{2g}$ (F)(ν_1)], 17 241–17 574 cm^{-1} [$^3A_{2g}$ (F) → $^3T_{1g}$ (F)(ν_2)] and 27 248–27 624 cm^{-1} [$^3A_{2g}$ (F) → $^3T_{1g}$ (P)(ν_3)], which correspond to an overall octahedral symmetry.

The MeOH solution spectra of the nickel (II) complexes show two bands in the regions 11 751–11 834 cm^{-1} (ν_1) and 17 212–17 544 cm^{-1} (ν_2), which are very much similar to those in the solid state, thereby suggesting no gross electronic or geometric change of the species on dissolution in the said solvent. The absence of the ν_3 band corresponding to $^3A_{2g}$ (F) → $^3T_{1g}$ (P) transition, in all cases, might lie in the UV region, where it may be obscured by intense internal π → π* transition of the ligand or intense CT absorption bands [8h,13,14]. The characteristic IR bands (4000–200 cm^{-1}) for the free ligand, HMP_z3Pi, when compared with those of its Ni(II) complexes, offer significant indications regarding the bonding sites of the primary ligand molecule (Table 2). A negative shift in the $\nu_{(CH=N)}$ band (1610 cm^{-1}) in the free ligand spectrum to the lower value (1580–1590 cm^{-1}) in its complexes indicate coordination of the azomethine nitrogen to the central metal ion; the IR bands at 470–485 cm^{-1} in the complexes are then assignable to $\nu_{(Ni–N)}$ [8,13–15]. IR bands at 1525 and 630 cm^{-1} in the free ligand spectrum, assignable to $\nu_{(C=N)}$ (pyrazole ring) and the in-plane deformation of the pyrazole ring, respectively, have been found to shift to the higher frequency region, pointing to the participation of the tertiary ring nitrogen atom (^2N) as a potential bonding site [8h,13–16]. The appearance of bands at 280–292 cm^{-1} in the complexes are then assignable to $\nu_{(Ni–N)}$ (pyrazole ring) [8,13–15]. An intense band at 860 cm^{-1} in the spectrum of the free ligand, corresponding to $\nu_{(C=S)}$, has been found to shift to lower frequency regions (785–795 cm^{-1}) in the complexes,

indicating the coordination of the thione sulfur to nickel (II); moreover, the appearance of a new band in the region (365–380 cm^{-1}) in the complexes is assignable to $\nu_{(Ni-S)}$ [8,17,18].

3.3. Crystal structures of HMP_z3Pi (*I*) and $[Ni(HMP_z3Pi)_2]Cl_2 \cdot 2H_2O$ (*II*)

Figs. 2 and 3 show the ORTEP-3 [19] diagrams of the ligand, HMP_z3Pi, and the complex, $[Ni(HMP_z3Pi)_2]Cl_2 \cdot 2H_2O$, respectively, together with the atom numbering schemes. The crystallographic asymmetric unit in the ligand comprises of a single HMP_z3Pi molecular moiety, while that in the complex comprises of a $[Ni(HMP_z3Pi)_2]^{2+}$ cation, two Cl^- counter ions and two molecules of water of crystallisation. Some selected bond distances, bond angles and torsion angles in the two structures are compiled and compared in Table 4.

The nickel (II) ion has a distorted octahedral coordination in the complex. Two molecules (A and B) of the

neutral tridentate ligand, 5-methyl-3-formylpyrazole-3-piperidinylthiosemicarbazone (HMP_z3Pi), coordinate to the Ni(II) ion via the pyrazolyl (tertiary) nitrogens [N(1A), N(1B)], the azomethine nitrogens [N(2A), N(2B)] and the thio-keto sulfurs [S(1A), S(1B)], to form four five-membered chelate rings [Ni–S(1A)–C(6A)–N(3A)–N(2A), Ni–S(1B)–C(6B)–N(3B)–N(2B), Ni–N(1A)–C(4A)–C(5A)–N(2A) and Ni–N(1B)–C(4B)–C(5B)–N(2B)]. The two azomethine nitrogen atoms [N(2A) and N(2B)] coordinate to the Ni(II) ion in a *trans* orientation, while the pyrazolyl ring nitrogen [N(1A) and N(1B)] and the thione sulfur atoms [S(1A) and S(1B)] are in a cis-coordination. This coordination is analogous to that observed in the crystal structures of similar Ni(II) complexes [15,8h].

The slight shortening of the Ni–N(azomethine) [Ni–N(2)] distances compared to the Ni–N(pyrazolyl) [Ni–N(1)] distances (Table 4) may be attributed to the fact that the azomethine nitrogen is a harder base compared to the pyrazolyl nitrogen. A similar effect has also been observed in the structure of $[Ni(HMP_zNBu_2)_2](ClO_4)_2$ [Ni–N(azomethine) 2.037(3), Ni–N(pyrazolyl) 2.112(3)] [8h].

As expected, the S(1)–C(6) double bond distance of 1.668(4) Å in the free ligand is lengthened to 1.689(3) and 1.691(3) Å in ligands A and B, respectively, with a shortening of the N(3)–C(6) bonds, from 1.362(6) Å in the free ligand to 1.346(3) Å [ligand A] and 1.348(4) Å [ligand B] in the complex (Table 4). The significant closing of the C(4)–C(5)–N(2) and N(1)–C(4)–C(5) angles by about 16° and 5°, respectively, as indicated in Table 4, may be attributed to geometrical necessity for coordination.

The two coordinating ligands are more or less planar, with C(3A) and N(3A) in ligand A, and C(2B) and N(3B) in ligand B, having the largest deviations in opposite directions [C(3A): +0.225(3) Å, N(3A): −0.171(2) Å, C(2B): +0.176(4) Å and C(4B): −0.079(3) Å] from the least-squares mean planes through Ni–S(1)–C(6)–N(3)–N(2)–C(5)–C(4)–C(3)–C(2)–N(4)–N(1). The ligands A and B coordinate orthogonally to the metal ion, the dihedral angle between them being 89.69(2)°. The three individual rings in either ligand, namely, the pyrazole and the two five-membered chelate rings, are individually almost planar with small dihedral angles between them. The maximum dihedral angle of 11.31(7)° is between the pyrazole ring N(1A)–N(4A)–C(2A)–C(3A)–C(4A) and the chelate ring Ni–S(1A)–C(6A)–N(3A)–N(2A).

The piperidine rings, both in the free ligand and in the complex, are in chair conformations [20]: in the free ligand, $q_2 = 0.044(6)$ Å, $q_3 = 0.562(6)$ Å, $Q = 0.564(6)$ Å, $\theta = 4.5(6)°$; in the complex, the corresponding parameters are $q_2 = 0.063(4)$ Å, $q_3 = 0.587(4)$ Å, $Q = 0.591(4)$ Å, $\theta = 6.1(4)°$ in ligand A, and $q_2 = 0.050(4)$ Å, $q_3 = 0.569(4)$ Å, $Q = 0.571(4)$ Å, $\theta = 5.0(5)°$ in ligand B [20].

It is known [21] that many thiosemicarbazone ligands exist in solution as two conformers, E and Z. In the present crystallographic study, the Z-form, as indicated by the C(4)–C(5)–N(2)–N(3) torsion angle of −1.8(8)°, was obtained in the solid state for the free ligand. In the complex, $[Ni(HMP_z3Pi)_2]Cl_2 \cdot 2H_2O$, the coordinating ligands exist as E conformers [C(4)–C(5)–N(2)–N(3) torsion angle is 178.5(2)° in ligand A and −178.5(2)° in ligand B], as necessitated by the requirements of coordination. Therefore, Z conformers of the ligand which could be present in solution must be transformed to the E-form before complexation. A possible mechanism for this transformation, leading to an unusual rotation about the azomethine (C=N) double bond, is shown in Fig. 6. The feasibility of this mechanism is due to the electropositive character of the azomethine carbon, C(5), as reported earlier [8b,22].

The intermediate conversion from a double bond to a single bond allows the rotation of the thiosemicarbazone moiety to bring the sulfur atom, S(1), to the *cis*-position with respect to the pyrazolyl nitrogen, N(1), in order to permit complex formation. The C(5)–N(2) bond [1.273(7) Å in the free ligand] resumes its double bond character in the complex [1.275(3) Å in ligand A and 1.279(3) Å in ligand B], once the complexation with Ni(II) is completed.

Table 5 gives the details of the hydrogen bonding and C–H···X contacts. In the free ligand (**I**), an intramolecular hydrogen bond [N(3)–H(3)···N(1)], and two C–H···X contacts [C(11)–H(11B)···S(1) and C(7)–H(7A)···N(3)] stabilise the conformation of the molecule about the C(4)–C(5), N(2)–N(3), N(3)–C(6) and C(6)–N(5) single bonds [Fig. 4]. Each ligand molecule is doubly hydrogen bonded to a symmetry related molecule *via* N(4)–H(4)···S(1) and N(4)–H(4)···N(2) bonds,

Symmetry equivalents: (i) $-1/2 + x$, y, $3/2-z$; (ii) $-x$, $1/2 + y$, $3/2-z$; (iii) $4-x$, $-y$, $1-z$; (iv) x, $1 + y$, z; (v) $4-x$, $-1 - y$, $2-z$.

and also has a C(5)–H(5)···S(1) contact with yet another symmetry related moiety.

The two water molecules play important roles in the crystal structure of the complex (**II**). The water oxygen, O(1W), is the donor in two O–H···Cl bonds with two different chloride ions related by symmetry, and is the acceptor in an O–H···O bond with the second water molecule. The second water oxygen, besides being the donor in the aforesaid O–H···O bond, donates its second hydrogen to a chloride ion, Cl(1), to form a O–H···Cl hydrogen bond. This water oxygen, in its turn, accepts a hydrogen from a hydrazinic nitrogen, N(3A), to form a N–H···O bond; in addition, it is the acceptor of two C–H···O contacts, one from a piperidinyl carbon, C(7A), and the other from a azomethine carbon, C(5A). The chloride ion, Cl(1), accepts two regular hydrogen bonds, one, as mentioned above, from the water oxygen, O(2W), and the other from a hydrazinic nitrogen, N(3B). The two C–H···Cl contacts with this chloride ion are with the azomethine carbon, C(5B), and the piperidinyl carbon, C(7B). The second chloride ion, Cl(2), besides accepting two hydrogen bonds from two different symmetry related water oxygens, O(1W), is also involved in a N–H···Cl hydrogen bond with a pyrazolyl secondary nitrogen atom, N(4B). Both the hydrazinic nitrogen atoms, N(3A) and N(3B), take part in intramolecular C–H···N contacts with neighbouring piperidinyl carbon atoms, C(7A) and C(7B), thereby arresting free rotation of the piperidinyl ring about the C(6)–N(5) single bond. The C(7)–N(5)–C(6)–N(3) torsion angles are 7.3(4)° in ligand A and 2.1(5)° in ligand B. The usual C–H···S contacts reported in similar complexes are also observed in the present structure: C(11A)–H(11B)···S(1A) and C(11B)–H(11D)···S(1B) [8h,15]. There is an additional C(7B)–H(7BB)···S(1A) contact between two symmetry related moieties. Fig. 5 shows the hydrogen bonding and C–H···X contacts observed in the structure of the complex species.

4. Conclusion

The present study shows that the title ligand of the pyrazolyl thiosemicarbazone series, HMP_z3Pi, undergoes complexation with nickel (II) and furnishes bischelates, with two ligands coordinating with nickel (II) orthogonally in a distorted octahedral environment; the azomethine nitrogens are *trans* to each other, while the pyrazolyl tertiary ring nitrogens and the thione sulfurs are in *cis*-positions. X-ray crystallography of both the uncomplexed ligand and its nickel (II) complexes reveals an interesting feature that the thiosemicarbazone moiety of the ligand undergoes an unexpected rotation about the azomethine double bond during complex formation with nickel (II).

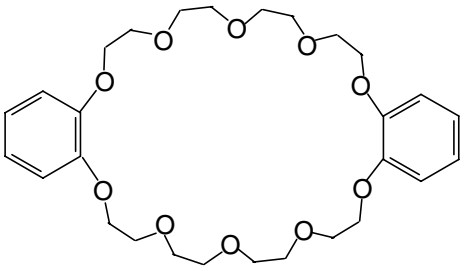

Fig. 1. Structural drawing of dibenzo-30-crown-10 (DB30C10).

pair with the metal complex cation (MCE^+) and a strong ion pair promotes efficient extraction from aqueous solution into a less polar organic phase ($CHCl_3/CH_2Cl_2$) [7]. Recently, competitive binding studies using large crown ethers (crown-18 to crown-24) with picrate, iodide anions and monovalent alkali metal cations (Li^+, Na^+, K^+, Rb^+ and Cs^+) have been reported by Talanova et al. [8]. The picrate anion formed a strong ion pair, which significantly enhanced the extraction process compared to that found with the iodide anion.

The aim of the present study is to investigate the selectivity of large crown ligands towards alkali and alkaline earth metal ions that are present together in solution at high concentrations, e.g., salt bitterns. Bittern, which is a by-product of salt manufacture, is comprised mainly of Na^+, K^+, Mg^{2+}, Ca^{2+}, SO_4^{2-}, and Cl^-, the concentration of Na^+, K^+, Mg^{2+} and Ca^{2+} being 0.5–1.5, 0.5–1.0, 3.0–5.0 and 0.1–0.2 M, respectively. In a previous study we have reported results of K^+/Na^+ selectivity with dibenzo-21-crown-7 and dibenzo-24-crown-8 [9]. Since the K^+ ion has a relatively larger diameter than Na^+, Ca^{2+} and Mg^{2+} cations, we reasoned that the K^+ ion would bind to DB30C10 (Fig. 1) more strongly than the other cations, which could lead to higher selectivity for potash extraction. In fact, we found that the selectivity towards K^+ is higher with DB30C10 compared to DB21C7 and DB24C8. Herein we report the extraction equilibrium constant for K^+ with DB30C10 and the relative selectivities towards Na^+, K^+, Ca^{2+} and Mg^{2+} present either as an equimolar mixture or in a bittern. The crystal structure of [K-DB30C10][picrate] and molecular mechanics calculations to rationalize the observations are also reported.

2. Experimental

2.1. Materials

The compound dibenzo-30-crown-10 (DB30C10) was purchased from Aldrich. KCl, NaCl, $CaCl_2$, $MgCl_2$, KOH and NaOH were of analytical grade and purchased from S.d.Fine Chemicals. Picric acid was procured from Sara fine chemicals. Potassium picrate and sodium picrate were prepared by reacting picric acid with aqueous KOH and NaOH, respectively. Analytical grade dichloromethane was purchased from Ranbaxy and Milli-Q (Millipore Corporation) water was used throughout.

2.2. Physical measurements

The UV–Vis spectra were recorded on a model 8452A Hewlett–Packard diode array spectrophotometer. NMR spectra were recorded on a model DPX 200 Bruker FT-NMR instrument. The cation concentration was measured on a Dionex 500 ion chromatograph.

2.3. Extraction equilibrium constant for potassium (K_e)

2.3.1. Determination of the concentration of picrate (A, Eq. (9)) in the extract (organic phase)

Into 5 cm^3 aqueous solution of KOH (1×10^{-4} M) and picric acid (1×10^{-4} M) was added 5 cm^3 of dichloromethane solution containing 2×10^{-5} M DB30C10. The contents were shaken vigorously in a vortex mixer for 10 min and the dichloromethane layer was separated and passed through anhydrous $MgSO_4$ bed to remove traces of water. The concentration of picrate in this solution – which is expected to be equivalent to the concentration of metal ion extracted since it is present as the counter ion of the complexed ligand – was determined spectrophotometrically (λ_{max}, 376 nm, $\varepsilon = 1.8 \times 10^4$ in dichloromethane). This experiment was carried out at room temperature (25 °C) with different concentrations (0.2×10^{-4}–2.0×10^{-4} M) of crown ether, keeping the metal ion concentration fixed ($c = 1 \times 10^{-4}$ M, ionic strength $I = 1 \times 10^{-4}$). This methodology was followed for four different concentrations of the metal ion (c = 0.0001, 0.001, 0.01 and 0.1 M; I = 0.001, 0.001, 0.01 and 0.1, respectively). Thus 40 different values of A were obtained corresponding to four different concentrations of the metal ion.

2.3.2. Determination of the partition coefficient (P_e, Eq. (9))

The partition coefficient of the crown ether in the biphasic system comprising of dichloromethane and water was determined (25 °C) by equilibration of the two phases, followed by indirect estimation of the ligand in the aqueous layer. In a typical experiment 5 cm^3 water was added to an equal volume of 5×10^{-4} M dichloromethane solution of DB30C10, the two phases were vigorously shaken (10 min) and the aqueous layer was separated. To the aqueous layer were added solid KOH (to make 0.1 M solution), picric acid (to make 5×10^{-3} M solution) and an equal volume of dichloromethane. The ionic strength (I) of the aqueous layer was 0.1. The contents were vigorously shaken to re-extract the crown ether in the K^+-complexed form into the organic layer, with picrate as the counter ion.

Spectrophotometric analysis of picrate in this solution yielded the concentration of DB30C10 in the original aqueous phase. The concentration of the DB30C10 in the original organic layer was also estimated spectrophotometrically, and mass balance was satisfactory. The partition coefficient (P_e) was calculated using the equation: $P_e = [CE]_{aq}/[CE]_{org}$. This experiment was repeated with various concentrations of crown ether in dichloromethane and the average value of P_e was estimated.

2.3.3. Determination of the stability constant of the K^+-complex in the aqueous phase (K_s, Eq. (9))

The stability constant for complex formation in the aqueous phase (K_s) was determined spectrophotometrically following a recently published procedure by Buschmann, which is well suited to ligands with low solubility such as DB30C10 [10]. In a typical experiment, into 5 cm^3 aqueous solutions of KOH of various concentrations ($c = 1\times10^{-3}$, 5×10^{-3}, 1×10^{-2}, 5×10^{-2} and 1×10^{-1} M; $I = 0.001$, 0.005, 0.01, 0.05 and 0.1, respectively) was added 2.7 mg (amount required to make 5 cm^3 1×10^{-3} M solution) of DB30C10 and the reaction mixture was stirred for 24 h at 25 °C. The solutions were then filtered on a 0.2 μm pore size filter paper and the absorbance of the filtrate at 274 nm (λ_{max}) was measured, it gave the combined concentrations (A) of the uncomplexed ligand and metal-complex formed. Likewise, the absorbance due to the ligand under saturated condition (A_0) was estimated as follows: solid DB30C10 (5.4 mg) was suspended in 50 cm^3 of water and stirred. Every 2 h interval about a 5 cm^3 aliquot was taken, filtered through 0.2 μm pore size filter paper, and the concentration of the ligand in the filtrate was determined spectrophotometrically. This was continued until the solution became saturated (14 h), when there was no significant change in the absorbance of the 274 nm band. The average of the three limiting values was considered as the concentration of the ligand in saturated solution. A straight line was obtained by plotting $A/A_0 - 1$ as a function of the initial concentration of the metal ion, the slope of which gave K_s (6.80 ± 0.1).

2.4. Selectivity determination

In a typical experiment, 2.3 mg picric acid (0.01 mmol) was added into 5 cm^3 of an aqueous solution of the equimolar mixture of ions/bittern. Dichloromethane solution (5 cm^3) containing 2×10^{-3} M DB30C10 was added next. The two-phase mixture was vigorously shaken in a vortex mixer for 10 min and the solution was transferred to a separating funnel and allowed to stand for 30 min. The dichloromethane layer was then separated and passed through a bed of anhydrous $MgSO_4$ to remove traces of water, transferred to a crucible, stripped of solvent by gentle heating on a water bath, and then heated in a furnace at 550 °C for 4 h. The residue was dissolved in deionized water (~5 cm^3) and filtered on 0.2 μm filter paper. The relative concentrations of the cations in the filtrate were determined by ion chromatography using Ion Pac CS12 (2 mm) analytical column and 20 mM methylsulfonic acid as eluant with a flow rate of 0.25 cm^3/min. Quantification was made using a standard solution containing a mixture of NaCl, KCl, $MgCl_2$ and $CaCl_2$ (~15 ppm each).

2.5. Preparation of [K-DB30C10][picrate]

A methanolic solution (10 cm^3) of potassium picrate (66.7 mg, 0.25 mmol) was added to DB30C10 (134.2 mg) dissolved in 10 cm^3 of chloroform and the resulting mixture was stirred at room temperature for 6 h. The solution was then evaporated to dryness at room temperature. The yellow solid thus obtained was recrystallized from chloroform–toluene (1:1), which gave needle shaped crystals suitable for single crystal X-ray diffraction studies; ^{1}H NMR ($CDCl_3$): δ 3.67 (s, 16H), 3.74 (d, 8H), 4.01(d, 8H), 6.75 (m, 4H), 6.89 (m, 4H), 8.79 (s, 2H).

2.6. X-ray crystallography

Cell parameters and diffraction intensities for the compound were measured at room temperature on an Enraf-Nonius CAD-4 X-ray diffractometer using graphite monochromatized Mo Kα radiation (0.7107 Å) in the range $\theta = 2$–25° and 25 reflections with θ in the range 9–12° were used for getting accurate cell dimensions. The crystal orientation, refinement of the cell parameters and intensity measurements were carried out using the program CAD-4 PC [11]. The Lorentz polarization corrections and data reduction were carried out using the NRCVAX programme [12]. The structure was solved by direct methods and after the complete convergence of non-hydrogen atoms anisotropically, H-atoms were either fixed stereochemically by the riding model using SHELX-97 or located from the difference Fourier map [13]. The final cycles of least-squares refinements yielded the R-value [$R_1 = 0.0791$ ($wR_2 = 0.2395$)] for the complex.

3. Results and discussion

3.1. Extraction equilibrium of the potassium ion

Two-phase extraction using the picrate anion has been reported earlier for quantitative determination of relative complexing abilities of ligands [14–16]. The picrate anion has an absorption band at 378 nm in dichloromethane, whereas crown ethers do not absorb in this

region. Blank experiments without DB30C10, but otherwise under similar experimental conditions, indicated the absence of picrate in the organic phase, i.e., the picrate independently is unable to extract the metal ion into the organic layer. Therefore, the concentration of the complex can be determined by estimating the concentration of the extracted picrate, as described in the experimental section. Typical UV–Vis spectral changes of the organic phase with increasing concentration of DB30C10 are shown in Fig. 2. When KOH is replaced with NaOH, the concentration of picrate in the organic phase is much lower (Fig. S1, supplementary material).

The extraction equilibrium constant was calculated following the method published by Frensdorff [15]. The two-phase equilibrium for the system containing metal ion (M^+), picrate anion (A^-) and crown ether (CE) can be defined as

$$M^+_{aq} + A^-_{aq} + CE_{org} \overset{K_e}{\rightleftharpoons} MCEA_{org} \quad (1)$$

where $MCEA_{org}$ designates the ion pair. To evaluate K_e, the distributions of all species in both phases have to be considered, which can be accounted by the following equilibria:

$$MCEA_{org} \overset{K_d}{\rightleftharpoons} MCE^+_{org} + A^-_{org} \quad (2)$$

$$CE_{org} \overset{P_e}{\rightleftharpoons} CE_{aq} \quad (3)$$

$$M^+_{aq} + CE_{aq} \overset{K_s}{\rightleftharpoons} MCE^+_{aq} \quad (4)$$

The extraction constant (K_e), dissociation constant of MCEA in the organic phase (K_d), partition coefficient of DB30C10 in water–dichloromethane (P_e) and the stability constant of MCE^+ in the aqueous phase (K_s) can be expressed as

$$K_e = [MCEA]_{org}/[M^+]_{aq}[A^-]_{aq}[CE]_{org}, \quad (5)$$

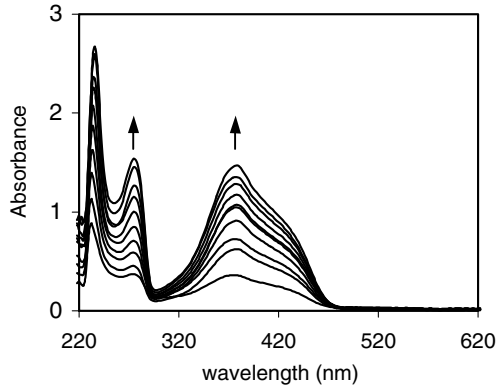

Fig. 2. UV–Vis spectral changes of the extracted organic phase containing [K-DB30C10][picrate] with increasing concentration of the ligand (2×10^{-5} to 2×10^{-4} M); $[K^+] = 0.01$ M and [picrate] = 1×10^{-4} M.

$$K_d = [MCE^+]_{org}[A^-]_{org}/[MCEA]_{org}, \quad (6)$$

$$P_e = [CE]_{aq}/[CE]_{org}, \quad (7)$$

$$K_s = [MCE^+]_{aq}/[M^+]_{aq}[CE]_{aq}. \quad (8)$$

From Eqs. (5)–(8) we can get [15,16],

$$K_e = \frac{[1 + P_e + P_e K_s f(M_0\text{–}A)][2A + K_d - (K_d^2 - 4K_d A)^{1/2}]}{2f[M_0\text{–}A][A_0\text{–}A][CE_0\text{–}A]}, \quad (9)$$

where f is the single ion activity coefficient of the aqueous cation and A is the concentration of the picrate anion in the organic phase; M_0, A_0 and CE_0 are the initial concentrations of the metal ion, picrate and crown, respectively. M_0, A_0 and CE_0 are known for a given system. After incorporating values of P_e, K_s and A obtained experimentally, the two unknowns left in Eq. (9) are K_e and K_d. The value of K_d was optimized by calculating values of K_e from Eq. (9) for a given value of K_d followed by regression analysis.

The partition coefficient P_e was determined by equilibration of DB30C10 in water–dichloromethane phases, followed by its indirect spectrophotometric estimation as described in Section 2. P_e was determined over a range of concentrations of CE and the average value estimated was 1.9×10^{-2}.

The stability constant for complex formation in the aqueous phase (K_s) was estimated using Eq. (10),

$$A/A_0 - 1 = \frac{(\varepsilon_2/\varepsilon_1)K_s}{1 + K_s[CE]_{sat}} C_{salt}, \quad (10)$$

where A is the absorbance due to the ligand and the complex formed (the ligand and the associated complex absorb at the same wavelength), A_0 is the absorbance due to the ligand under saturated condition, ε_1 and ε_2 are molar absorptivities of DB30C10 and its K^+-complex, respectively, $[CE]_{sat}$ is the concentration of the ligand under saturated conditions, and C_{salt} is the initial concentration of the metal ion. A and A_0 were determined experimentally, as described in the Section 2. When $(A/A_0 - 1)$ is plotted against C_{salt}, the slope b can be expressed as

$$b = \frac{(\varepsilon_2/\varepsilon_1)K_s}{1 + K_s[CE]_{sat}}. \quad (11)$$

From Eq. (11) K_s can be written as

$$K_s = \frac{b}{(\varepsilon_2/\varepsilon_1) - b[CE]_{sat}}. \quad (12)$$

Using the value of b and applying the assumptions: (i) $\varepsilon_2/\varepsilon_1 \sim 1$; (ii) $b[CE]_{sat} \ll 1$ (as the solubility of the ligand in water is very low), the value of K_s obtained from Eq. (12) was 6.80 ± 0.1 at 25 °C.

By replacing the experimentally determined values of P_e, K_s and A in Eq. (9) the best fit to the data was

obtained with $K_d = 1.1 \pm 0.6 \times 10^{-6}$, for which the corresponding value of K_e was $2.9 \pm 0.2 \times 10^6$. The accuracy of the regression analysis has been tested by plotting (A/A_0) as a function of [crown]:[picrate] ratio with experimental and calculated data for various metal ion concentrations (Fig. 3). Excellent matching of the experimental and calculated curves indicates good regression analysis for the determination of K_e. The K_e value we obtained for DB30C10 is comparable to that obtained for the A-isomer of dicyclohexyl-18-crown-6 (4×10^6), but significantly higher than that of dibenzo-18-crown-6 (7×10^5) [15]. K_e provides a quantitative idea of the efficiency of extraction of the crown–picrate complex from the aqueous to organic phase. The efficiency of the process reflects not only the strength of the complex formed but also the ability to make an effective ion pair between the cationic and anionic species, as evident from the crystal structure of the complex (vide infra).

It has been reported that Na^+ forms complexes with DB30C10 having 1:1, 2:1 and 3:2 metal:ligand ratios [17]. Similar inconsistent compositions for the Na^+ complex of DB30C10 was also noted by us from ^1H NMR spectral data of the isolated complexes. Because of its low ionic diameter, there is also the possibility for Mg^{2+} and Ca^{2+} to form complexes of inconsistent compositions. Formation of mixed metal complexes comprising these ions (Na^+, Mg^{2+} and Ca^{2+}) also cannot be ruled out. This complicates the determination of K_e for Na^+, Mg^{2+} and Ca^{2+} extraction and such determination was, therefore, not attempted. However, we carried out experimentally the picrate extraction with Na^+ under similar experimental conditions as for K^+ and Fig. 4 shows comparative results for the two metal ions. It can be seen that extraction efficiency of Na^+ is comparatively much poorer.

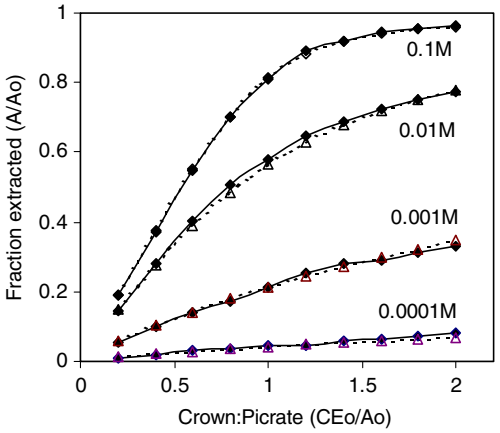

Fig. 3. The fraction of picrate/metal ion extracted is shown as a function of [crown]:[picrate] ratio with different metal ion concentrations. Full curves are from experimental absorbance values and dotted curves are from the calculated absorbance values obtained using the evaluated $K_e = 2.9 \times 10^6\ M^{-2}$ and $K_d = 1.1 \times 10^{-6}$ M.

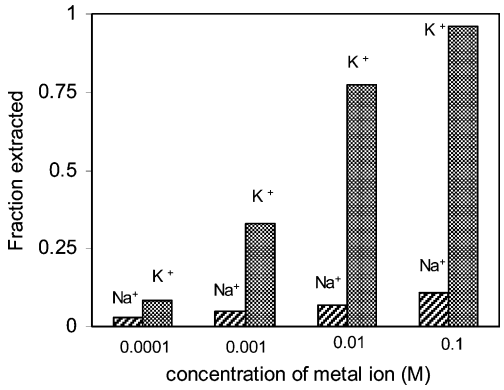

Fig. 4. Bar diagram showing the fraction of Na^+/K^+ extracted with increasing the concentration of metal ions.

3.2. Selectivity

The high extraction equilibrium observed for K^+ in the studies reported above with DB30C10 encouraged us to explore the application of this ligand for selective extraction of the potassium ion from mixtures of ions. Selectivities of the metal ions (Na^+, K^+, Mg^{2+} and Ca^{2+}) were determined by ion chromatographic assay (Fig. S2 shows a typical chromatogram, supplementary material) of the initial aqueous phase and the organic phase following extraction. Experiments were carried out with (i) aqueous solution containing equimolar amounts of Na^+, K^+, Mg^{2+} and Ca^{2+} as chloride salts, and (ii) bittern. Distributions of the metal ions in the original solutions and in the organic extracts, together with values of the observed selectivity ratios, are shown in Table 1. As can be seen from the data for the synthetic mixture, DB30C10 shows high selectivity towards K^+ and the order of selectivity is: $K^+ \gg Na^+ \sim Mg^{2+} > Ca^{2+}$. In the case of bittern, where the absolute concentrations of the ions are higher and their relative concentrations also differ, there are discernible differences in the selectivity ratios. Nevertheless, even in this case, the high selectivity towards K^+ is evident. The results can be rationalized in terms of the crystal structure of the potassium salt of DB30C10 discussed below and the theoretical calculations of conformational geometry and selectivity.

3.3. Crystal structure

The molecular structure of the cation $[K\text{-DB30C10}]^+$ with I^- and SCN^- anions have been established previously by single crystal X-ray studies [18a,18b]. The crystal structure of $[K\text{-DB30C10}]^+$ with the picrate anion was determined in view of the importance of the latter in the extraction process [8]. Crystallographic data for [K-DB30C10](picrate) is given in Table 2. Structures with the picrate counter ion have been reported previously for other crowns, e.g.,15C5, 18C6 with Na^+ and K^+; 21C7, 24C8 with Rb^+ and Cs^+ [8,19].

Table 1
Concentrations of metal ions in the original solutions and potassium selectivity (K^+/M^{n+}) in the extract

Solution	Concentration, M/(%)								Selectivity ratio[a]		
	Original solution				Extract						
	$[Na^+]$	$[K^+]$	$[Mg^{2+}]$	$[Ca^{2+}]$	Na^+	K^+	Mg^{2+}	Ca^{2+}	K^+/Na^+	K^+/Mg^{2+}	K^+/Ca^{2+}
Bittern	0.5(8.2)[b]	0.7(19.2)	4.0(68.9)	0.1(3.7)	(4.9)	(83.4)	(11.1)	(0.6)	7.3	27.0	26.8
Mixture[c]	0.1(18.2)	0.1(30.9)	0.1(19.1)	0.1(31.7)	(4.9)	(88.3)	(5.2)	(1.6)	10.6	10.5	56.6

[a] The ratio is calculated by [% of K^+ in the extract][% of M^{n+} in the original solution]/[% of M^{n+} in the extract][% of K^+ in the original solution].
[b] Distribution in % is given in the parenthesis.
[c] An artificial solution containing equimolar (0.1 M) amount of the cations.

Space group	C_2/c
Radiation used λ (Å)	0.71073
$\rho_{calc.}$ (g cm^{-3})	1.397
Absorption coefficient, μ (cm^{-1})	2.18
Temperature (°C)	23
Final $R(F_o^2)$[a]	0.0791
Weighted $R(F_o^2)$ [b]	0.2395

[a] $R = \sum ||F_o| - F_c|| / \sum |F_o|$.
[b] $R_w = [\sum w(F_o^2 - F_c^2)^2] / \sum [w(F_o^2)^2]^{1/2}$; $w = 1/\sigma(F_o)^2$.

A PLUTO view of [K-DB30C10][picrate] showing the atom-numbering scheme is depicted in Fig. 5. Both cation and anion possess a twofold symmetry. The potassium ion occupies a special position, with the twofold symmetry passing through the C(11)–C(12) atoms of the crown moiety, whereas in the picrate anion the twofold axis bisects the molecule through the N(2), C(18), C(15) and O(6) atoms. The potassium ion is completely covered by the folded ligand, the oxygen atoms of which interact strongly with the cation. The K–O distances vary from 2.867 to 3.056 Å. The C(7)–C(10) carbon atoms of the crown moiety show a high temperature factor, indicating flipping of these atoms leading to a dynamic disorder.

The packing diagram (Fig. S3) shows that two pairs of cations and anions orient in such a way that they are in close proximity to each other. This pairing, which is on account of the π…π, C–H…π and C–H…O interactions, has been well documented in the literature for various supramolecular systems [20]. The terminal phenyl rings of the associated molecular pairs exhibit strong π…π stacking interactions with the picrate anions [Cg(1)…Cg(2) = 3.99 Å, symmetry codes: $1 - x$, $-y$, $1 - z$ and x, $-y$, $-1/2 + z$, where Cg(2) is the centroid

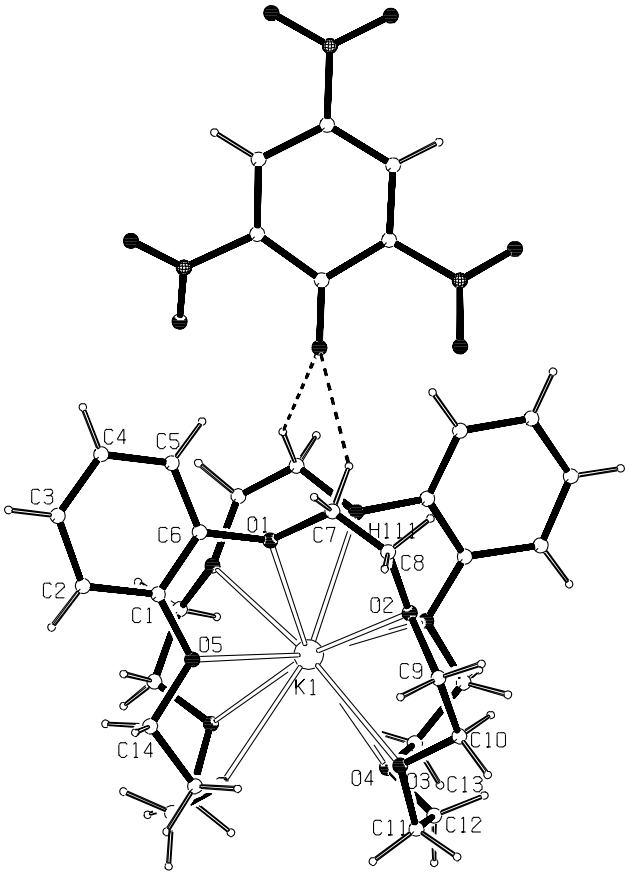

Fig. 5. PLUTO view of the complex [K-DB30C10][picrate] showing the numbering scheme and C–H…O interactions between deprotonated hydroxyl oxygen of picrate and CH_2 of the crown.

of the picrate phenyl ring]. The symmetry related oxygen [O(8)] of the nitro group of the picrate anion from either end is involved in a C–H…O interaction with the CH_2 moiety [H(141)] of the crown ether [H(141)…O(8) = 2.47 Å, C(14)…O(8) = 3.36 Å, ∠C(14)–H(141)…O(8) = 144.0°, symmetry code: $1/2 + x$, $1/2 + y$, z]. The protons associated with C(7) and C(9) also exhibit C–H…π and C–H…O interactions. H(92), attached to the C(9) atom of the crown ring, exhibits a C–H…π interaction with the centroid [Cg(1)] of the phenyl ring consisting of C(1)–C(6) atoms of the associated molecule [H(92)–Cg(1) = 3.14 Å; C9…Cg(1) = 3.824 Å; ∠C(9)–H(92)…

Cg(1) = 128.4°; symmetry = 1/2 + x, 1/2 − y, 1/2 + z]. The deprotonated hydroxyl oxygen [O(6)] of the picrate anion shows a C–H...O interaction with H(72), attached to the C(7) carbon atom of the adjacent cationic moiety [H(72)...O(6) = 2.47 Å, C(7)...O(6) = 3.340 Å, ∠C(7)–H(72)...O(6) = 146.7° symmetry code: −x, y, 1/2 − z]. Since there is evidence of dynamic disorder in C(7) and C(9), there is some uncertainty in the C–H...π and C–H...O interaction parameters involving these two carbon atoms. However, the short distances observed provide evidence of strong ion pair interactions. Similar interactions – albeit weaker than in the solid state – may also exist in solution, leading to effective ion pairing that would facilitate the extraction process.

4. Molecular mechanics study

A number of theoretical studies including molecular mechanics, molecular dynamics, Monte Carlo simulations and quantum chemical calculations have been performed on macrocyclic receptor molecules such as crown ethers, cryptands and hemispherands [21–23]. Among the many crown ethers, 18-crown-6, its complexation with alkali metal ions, and the effect of solvation have been studied in great detail at all levels of theory [21a,21b,21f,21h,21i,21l,21m]. Grootenhuis and Kollman [21b] have performed an elegant MM/MD study of the complexation of DB30C10 with alkali metal ions. Their studies were performed with available solid-state structures and hence no extensive search was performed in the conformational space of the structures of DB30C10 studied using molecular mechanics.

We have employed molecular mechanics (MMFF94) force field using a Monte Carlo conformation search, as implemented in TITAN [24], to examine the conformations of DB30C10 and its complexation with Na^+, K^+, Mg^{2+} and Ca^{2+}. We have not performed any search using solid-state structures since these are not available for the complexes of DB30C10-Mg^{2+}, DB30C10-Ca^{2+} and monomolecular DB30C10-Na^+.

Although many studies have been performed using MMFF94 [25], we undertook some initial force field calculations on 18-crown-6 to assess the reliability of the MM calculations. This ligand has been well studied in the past by other computational methods. MM calculations on *Ci* and *D3d* forms of the crown ether, which are the two lowest energy conformations, suggest that the *Ci* form is 8.3 kcal/mol lower in energy compared to the *D3d* form. This is in fair agreement with earlier molecular mechanics and quantum chemical results [21a,21m]. Having verified the reliability of the technique, a search of uncomplexed DB30C10 conformers was performed next and 4356 trial conformations were generated, of which 100 were retained based on structural dissimilarity and energetic considerations. Finally, nine unique low energy conformations (within a 5 kcal/mol window) were identified (Fig. S4, supplementary material). The ethylene –oxy– units on each side of the benzene ring can rotate and generate the major structural changes found in this set of conformers. These sampled conformers of DB30C10 are found in folded conformations (I, Fig. S4), half-folded conformations (IV, Fig. S4) and unfolded forms (VII, Fig. S4), indicating that there is no significant energetic preference for a particular conformation. The lowest energy conformation identified through the calculations is the folded form, whereas the conformation is unfolded in the crystal structure study carried out by Bush and Truter [18]. The difference may be on account of additional stabilization of the unfolded conformation in the crystal structure as a result of strong intermolecular CH...π and CH...O interactions evident from the structure [18]. We examined the complexation of the K^+ cation with the lowest energy forms of both folded and unfolded conformations of DB30C10. In each calculation, around 5000 structures were sampled and 100 conformers retained. Irrespective of whether one starts with the folded or unfolded ligand conformation, the calculated low energy conformations of the complex indicate that DB30C10 completely wraps around the cation. Fig. 6 shows the lowest energy conformation (I) and also the low energy conformation (II) that is in best agreement with the conformation in the crystal structure observed by others and us. All the eight low energy conformations within the 5 kcal/mol energy window are given in Fig. S5. The calculated distances between the complexed K^+ cation and donor oxygen atoms in Fig. 6(II) range from 2.82 to 3.07 Å in a symmetrical fashion, in close agreement with the distances of 2.87–3.05 Å found experimentally.

In view of the good match of one of the predicted low energy conformations of K^+–DB30C10 with the experimental data, we undertook similar calculations for 1:1 complexes with Na^+, Ca^{2+} and Mg^{2+} (Figs. S6–S9). Some of the sampled low energy complexed conformations of Na^+–DB30C10 [e.g., Fig. S6 (VII)] show an empty pocket where a second Na^+ can be accommodated. Indeed, incorporation of a second Na^+ has been demonstrated from the crystal structure [17c]. We have performed calculations for two sodium ions in DB30C10 crown ether (Fig. S7) and the lowest energy conformation shows that the two sodium ions are 4.4 Å apart, in good agreement with the crystal structure wherein the sodium ions are separated by 4.0 Å [17c]. Even though the diameter of Ca^{2+} (1.98 Å) is close to that of Na^+ (1.90 Å), its complexation behavior is different, with no evidence of the two pockets found with Na^+. The low energy conformations obtained through calculations are shown in Fig. S8. The folded conformation of the ligand is visible, as in the case of K^+. The conformation adopted by Mg^{2+}–DB30C10 is quite different; DB30C10 adopts a twisted conformation around

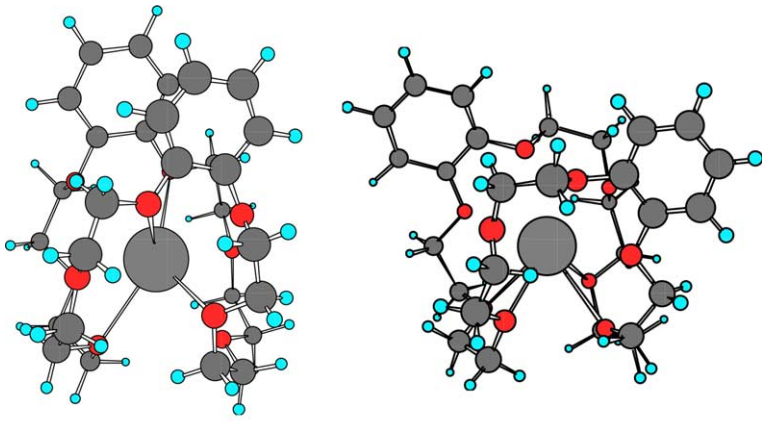

Fig. 6. Two of the eight low energy conformations (energy differences within a 5 kcal/mol window) of [K^+–DB30C10] obtained using MMFF94. (I) is the lowest in energy while (II) is in best agreement with the crystal structure of [K^+–DB30C10].

the Mg^{2+} cation (Fig. S9). The interacting distances between the Mg^{2+} cation and ligand oxygens vary between 2.12 and 3.60 Å: the oxygen atoms on the benzene rings interact weakly as they are located at the larger distance of 3.60 Å while the remaining eight oxygen atoms interact strongly (2.12–2.3 Å) with the Mg^{2+} cation (Fig. S9). Based on higher-level quantum chemical calculations [21o], Glendening and Feller have found a similar conformation with even smaller crowns, such as 18-crown-6, complexed to the Mg^{2+} ion.

To investigate theoretically the hierarchy of selectivity of DB30C10 towards the various cations, we have examined the ionic exchange reaction in Eq. (13),

$$K^+\text{–DB30C10} + M^{+/2+}{}_{(hyd)} \rightarrow K^+{}_{(hyd)} + M^{+/2+}\text{–DB30C10} \quad (13)$$

The exothermicity of this reaction can be considered a measure of the selectivity towards the various cations ($M^{+/2+} = Na^+$, K^+, Mg^{2+}, Ca^{2+}). Wipff et al. [21a,21b] previously reported the selectivity of alkali metal ions for Eq. (13) using a molecular mechanics approach for calculating exothermicity for a hydration sphere of six water molecules around the naked cation. High level quantum chemical calculations have also been performed and the results could qualitatively reproduce the experimental trend [21f,21l,21m,21o]. In the present work we have utilized experimental enthalpies of hydration [26],[1] and have assumed that the water molecules in the free cation are replaced with oxygen atoms of the crown ligand in the complexed state. Table 3 shows the selectivity of DB30C10 crown ether towards the various cations. The calculations suggest the trend: $K^+ > Na^+ > Ca^{2+} > Mg^{2+}$. The calculated results are in agreement with the high selectivity and K_e value for K^+ found experimentally. However, the trends predicted for the other ions are not entirely in agreement with the experimental data. Clearly, other factors such as competitive kinetics of complexation must also be important.

Table 3
Calculated ionic exchange reaction energies with experimental enthalpies of hydration using Eq. (11) (kcal/mol) at MMFF94[a]

	$M^{+/+2}$	$\Delta E^{a,b}$
K^+	Na^+	−10.7
K^+	Ca^{2+}	−157.6
K^+	Mg^{2+}	−205.5

[a] Calculated with use of the lowest energy conformations in each case.
[b] Negative enthalpy differences represent the preference for the K^+ ion.

5. Conclusions

K^+ interacts strongly with DB30C10 in the presence of picrate as a counter ion, leading to a high value ($2.9 \pm 0.2 \times 10^6$) of the extraction equilibrium constant. The crystal structure of [K-DB30C10][picrate] reported herein provides evidence of strong ion pair interactions. Such interactions presumably also exist in the solution state of the complex and facilitate its transport from the aqueous to organic phase. This combination of ligand and counter ion was employed to successfully extract K^+ from bittern and also from an equimolar mixture containing Na^+, K^+, Mg^{2+} and Ca^{2+} ions, with ca. 83% and 88% selectivity, respectively. High selectivity towards K^+ is predicted by molecular mechanics calculations, following the trend: $K^+ > Na^+ > Ca^{2+} > Mg^{2+}$, in reasonable agreement with the observed

[1] A more precise hydration energy for the cations has been used, considering experimental enthalpies of hydration of the cations instead of the cation–water cluster model with four to six water molecules.

results. The trend emanates from a balance between the energetics of crown–cation interaction and cation solvation.

(b) More precise hydration energy for cations have been used-considering experimental enthalpies of hydration of the cations instead of cation–water cluster model with four to six water molecules.

formation of chiral three-dimensional architectures [3d]; the intercalation of $MePh_3P^+$ in the dicyanamide-bridged system leads to a three-dimensional network containing this cation in cavities [4a]. Although there are several examples in the literature illustrating the modification of network topology through simple cation templation, systematic studies concerning the role of the size and the nature of counter ions on the structural organization of coordination polymers have never been investigated.

Numerous bimetallic assemblies based on hexa- [5], hepta- [6] and octa-cyanometallate [7] building blocks form an important family of molecule-based magnets presenting a variety of structures and interesting magnetic and photo-magnetic properties. Among these, coordination polymers based on the $Mn^{2+}/[Mo(CN)_7]^{4-}$ system have recently attracted considerable interest [6,8]. A self-organization of this system leads to formation of two thermodynamically stable pseudo-dimorphic three-dimensional frameworks $Mn_2(H_2O)_5[Mo(CN)_7]\cdot nH_2O$ ($n = 4.00$, 4.75), which order ferrimagnetically below 51 K [9]. The presence of a counter cation in this system changes the topology of supramolecular networks and, as a consequence, their magnetic properties. Firstly, the intercalation of the large flexible counter cation $N(CH_3)_4^+$ leads to the formation of $[N(CH_3)_4]_2[Mn(H_2O)]_3[Mo(CN)_7]_2\cdot 2H_2O$ presenting anisotropic three-dimensional structure which orders ferrimagnetically below 86 K [10]. In this case, the three-dimensional network adopts $N(CH_3)_4^+$ in its cavities. Secondly, the use of the cation K^+ affords the formation of a two-dimensional coordination polymer $K_2[Mn(H_2O)_2]_3[Mo(CN)_7]_2\cdot 6H_2O$ (**1**) having an ordering temperature at 39 K [11]. Its structural organization consists in anionic cyano-bridged {MnMo} double sheets alternated with the counter cation. Thirdly, in a preliminary communication, we showed that the intercalation of NH_4^+ into $Mn^{2+}/[Mo(CN)_7]^{4-}$ leads to the formation of $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2\cdot 4H_2O$ (**2**) presenting a structure similar to **1**, but a three-dimensional [12]. It orders ferrimagnetically below 53 K. Such preliminary results encouraged us to further investigate the role of a counter cation and analyse the different factors which can influence the structural organization of $Mn^{2+}/[Mo(CN)_7]^{4-}$.

In this article, we present two pseudo-dimorphic phases $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2\cdot nH_2O$ ($n = 4$ for **2** and $n = 5$ for **3**) obtained by intercalation of NH_4^+ in the $Mn^{2+}/[Mo(CN)_7]^{4-}$ system and compare their structures with **1**. We analyse the size, the geometry, the polarizability and other characteristics of the counter cations NH_4^+ and K^+ in order to understand their role as structuring agents. In particular, the influence of previously unknown unconventional ionic interactions cation$\cdots\pi(C{\equiv}N)$ (cation = NH_4^+, K^+) on the structural organization of $Mn^{2+}/[Mo(CN)_7]^{4-}$ was established and confirmed by theoretical investigations using binuclear Mn–Mo cyano-bridged models.

2. Experimental

2.1. Synthesis

Unless otherwise noted, all manipulations were performed at ambient temperature using reagents and solvents as received. The precursor $K_4[Mo(CN)_7]\cdot 2H_2O$ was prepared as already described [13].

2.1.1. $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2\cdot nH_2O$ ($n = 4$ for **2** and 5 for **3**)

Compound **2** was obtained by slow diffusion in an H-shaped tube under argon atmosphere of two deoxygenated aqueous solutions containing (0.150 g, 3.1×10^{-4} mol) $K_4[Mo(CN)_7]\cdot 2H_2O$ and (0.183 g, 7.2×10^{-4} mol) $[Mn(H_2O)_6](NO_3)_2$, respectively, in the presence of NH_4NO_3 (0.2 g, 1.88×10^{-3} mol). After a few months, dark green crystals with a parallelepiped shape were formed (Fig. 1S, Supplementary materials). The crystals of compound **3** were detected in the same H-shaped tube beside **2**. Both compounds are stable in air and no any changes were observed in the structures during few weeks. Yield: 0.06 g, 18%.

Anal. Calc. for $C_{14}H_{24}Mn_3Mo_2N_{16}O_8$ (**2**): C, 18.65; H, 2.66; Mn, 18.29; Mo, 21.31; N, 24.87%. *Anal.* Calc. for $C_{14}H_{26}Mn_3Mo_2N_{16}O_9$ (**3**): C, 18.29; H, 2.83; Mn, 17.94; Mo, 20.89; N, 24.38%. Found: C, 18.78; H, 2.89; Mn, 18.35; Mo, 21.26; N, 24.97%.

IR (KBr, cm^{-1}): 3613, 3587(m), 3518(m), 3285(s), 2112(s), 2091(s), 2012(m), 1625(m), 1414(m), 1262(w), 1099(w), 681(m), 579(m), 418(m).

The first dehydrated form $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2$ was obtained by heating of the mixture of **2** and **3** at 80 °C under argon. *Anal.* Calc. for $C_{14}H_{16}Mn_3Mo_2N_{16}O_4$: C, 20.27; H, 1.93; Mn, 19.89; Mo, 23.16; N, 27.03. Found: C, 20.42; H, 2.09; Mn, 20.05; Mo, 23.56; N, 27.57%.

The second dehydrated form $(NH_4)_2Mn_3[Mo(CN)_7]_2$ was obtained by heating of the mixture of **2** and **3** at 160 °C under argon. *Anal.* Calc. for $C_{14}H_8Mn_3Mo_2N_{16}$: C, 22.20; H, 1.05; Mn, 21.78; Mo, 25.36; N, 29.60. Found: C, 22.05; H, 0.05; Mn, 21.45; Mo, 25.56; N, 29.97%.

2.2. X-ray crystallography and structure solution

The crystallographic structure of **1** initially solved in the non-centrosymmetrical space group *C*2/1 (No. 5) [11a] was corrected and re-solved in the centrosymmetrical space group *C*2/*c* (No. 15) [6c,11c]. The crystal structure of **2** was published in a preliminary communication [12]. The crystallographic data for complexes **2** and **3** are listed in Table 1. For both structures data collection were

performed at low temperature ($T = 180$ K) on a IPDS STOEII diffractometer using a graphite-monochromatic Mo Kα radiation ($\lambda = 0.71073$ Å) and equipped with an Oxford Cryosystems Cryostream Cooler Device. The final unit cell parameters have been obtained by means of a least-squares refinement performed on a set of 8000 well-measured reflections, and a crystal decay has been monitored. No significant fluctuations of intensities were observed during the data collection. Structures have been solved by Direct Methods using SHELXS-97 [14], and refined by means of least-squares procedures on a F^2 with the aid of the program SHELXL-97 includes in WinGX version 1.63 [15]. The Atomic Scattering Factors were taken from International tables for X-ray Crystallography. Due to the symmetry operators on which have been located the molecules of H_2O hydrogen atoms have to be disordered, consequently could not be located. Semi-empirical corrections absorption were applied [16] and all non-hydrogen atoms were anisotropically refined, in the last cycles of refinement weighting schemes were used, where weights are calculated from the following formula: $w = 1/[\sigma^2(F_o^2) + (aP)^2 + bP]$, where $P = (F_o^2 + 2F_c^2)/3$.

2.3. Physical measurements

Infrared spectra were recorded as KBr disks or Nujol mulls between NaCl plates on a Nicolet Model 510P spectrophotometer. Thermogravimetry analysis (TGA) were performed using a Netzsch STA 409 instrument under argon atmosphere from 25 to 700 °C at a heating rate of 1 °C min^{-1}; volatiles were determined using a Balzers QMG 421 quadruple mass spectrometer coupled with the ATG equipment. Magnetic susceptibility data were collected with a Quantum Design MPMS-XL SQUID magnetometer on polycrystalline samples. The data were corrected for the sample holder and the diamagnetism contributions calculated from the Pascal's constants [17].

2.4. Computational details

The calculations have been performed with the energy-consistent relativistic effective core potentials (RECPs) derived by the Stuttgart group (called SDD) [18]. For the Mo atom, the core consists of the 1s–3s, 2p–3p, 3d atomic orbitals and the basis set is [8s7p6d]/(6s5p3d). For the Mn atom, the core consists of the 1s–2s and 2p atomic orbitals and the basis set is [8s7p6d1f]/(6s5p3d1f). For the K atom, the core consists of the 1s–2s and 2p atomic orbitals and the basis set is [7s6p]/(5s4p) and for C and N atoms, the 1s orbital is in the core, and the basis set is [4s4p]/(2s2p). H atoms are described by the 6-31G basis set. This basis set will be referred to as BAS1. A more extended basis set, referred to BAS2, has been deduced from BAS1 by augmenting some atomic basis with one diffuse s, one

Table 1
Crystal data and structure refinement for **2** and **3**

Compound	**2**	**3**
Empirical formula	$C_7N_8O_4Mn_{1.5}Mo$	$C_{3.5}N_4O_{2.25}Mn_{0.75}Mo_{0.5}$

Refinement method	full-matrix least-squares on F^2	full-matrix least-squares on F^2
Data/restraints/parameters	3057/0/196	1335/0/118
Absorption corrections	semi-empiricals^{DIFABS} [16]	semi-empiricals^{DIFABS} [16]
T_{min}–T_{max}	0.510–0.848	0.573–0.870
Goodness-of-fit on F^2	1.021	1.089
Scheme of ponderation	weight $= 1/[\sigma^2(F_o^2) + (0.0394P)^2 + 0.4551P]$ where $P = (F_o^2 + 2F_c^2)/3$	weight $= 1/[\sigma^2(F_o^2) + (0.0515P)^2 + 0.4551P]$ where $P = (F_o^2 + 2F_c^2)/3$
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0263$, $wR_2 = 0.0614$	$R_1 = 0.0255$, $wR_2 = 0.0699$
R indices (all data)	$R_1 = 0.0376$, $wR_2 = 0.065$	$R_1 = 0.0307$, $wR_2 = 0.0721$

diffuse p and one polarization d functions. The following exponents have been used: for K, $\zeta_s = \zeta_p = 0.0047$ and $\zeta_d = 0.2$, for N, $\zeta_s = \zeta_p = 0.0639$ and $\zeta_d = 0.8$, for C, $\zeta_s = \zeta_p = 0.0438$ and $\zeta_d = 0.8$. All calculations have been performed with the GAUSSIAN-98 program [19].

In order to calibrate the basis set, a preliminary study has been carried out. The system $NH_4^+ + CN^-$ has been studied with different basis sets (see Table 4) assuming a fixed geometry: a NH bond lies in the medium plane of CN, H pointing towards CN and N being at 3.6 Å from C and N. The CN distance is 1.8 Å. In this table, SDD+sp+d is BAS2. Basis set superposition error (BSSE) corrections are carried out using the counterpoise method of Boys and Bernardi [20]. The addition of diffuse s and p functions to the SDD basis set is crucial as well as the use of augmented basis sets because of the negatively charged ion CN^-. The results obtained with BAS2 agree with those obtained with the much larger basis set aug-cc-pVTZ. In order to mimic the interaction, we are interested in this article, two potassium atoms have been added. In this case, the dependency to the quality of the basis set is not as crucial and the agreement between the basis sets is excellent as long as they have diffuse functions and the effect of the BSSE correction is negligible. Similar conclusions are obtained for the interaction between K^+ and CN^-, where K^+ is constrained to lie at a distance of 3 Å of both C and N: there is a weak dependency to the basis set. The difference between NH_4^+ and K^+ must be due to the higher polarizability of the former, more available to take the electrons from the cyano group when the basis is too small. Finally, both for geometry optimization and interaction energy calculations, the basis set BAS2 has been used to describe K^+, NH_4^+ and the five neighbouring cyano groups in all calculations. The rest of the cluster has been described with BAS1 since it is less involved in the intermolecular interaction. In these three systems, the effect of the method has been checked as well: MP2 and B3LYP give the same interaction energies and the discrepancy with HF is quite small because the main effect of the interaction energies are of electrostatic, exchange and induction nature.

The molybdenum site geometry analysis was performed using Continuous Shape Measures calculation [25].

3. Results and discussion

3.1. Pseudo-dimorphic phases $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2 \cdot nH_2O$ ($n = 4$ for **2** and $n = 5$ for **3**).

3.1.1. Synthesis

The slow diffusion of two aqueous solutions containing $K_4[Mo(CN)_7] \cdot 2H_2O$ [13] and $[Mn(H_2O)_6](NO_3)_2$, respectively, in the presence of NH_4NO_3 in an H-shape tube under argon atmosphere provided dark green crystalline plates of $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2 \cdot 4H_2O$ (**2**) (Fig. 1S, Supplementary materials). Crystals of $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2 \cdot 5H_2O$ (**3**) were also detected in an H-shaped tube beside **2**. Both types of crystals have the same shape and colour and their separation is possible only by crystallographic tests. The examination of numerous randomly chosen crystals of different H-tubes gave around 80% of **2** and 20% of **3** in the mixture.

The infrared stretches (Fig. 2S, Supplementary materials) ν(CN) 2012(m), 2091(s), 2112(s) cm^{-1} for **2** and **3** are shifted toward higher frequencies from those of $K_4[Mo(CN)_7] \cdot 2H_2O$ (2035(w), 2067(s), 2080(m), 2100(w) cm^{-1}) clearly showing the coordination of all the CN^- groups to manganese [26]. In addition, the presence of several sharp peaks indicates crystallographically non-equivalent CN groups in the complexes and the distortion of the Mo site from D_{5h} symmetry. The presence of N–H absorptions (1414(m), 3285(s), 3318(m), 3587(m) cm^{-1}) clearly indicates the presence of NH_4^+ in the network. The X-ray structures (vide infra) are in agreement with these results.

3.1.2. Crystal structures

The crystal structure of **2** has been published in a preliminary communication [12]. The X-ray crystallographic study performed for **2** and **3** at 180 K reveals that both of them crystallize in the monoclinic system with *C*2/*c* (No. 15) space group (Table 1). Both structures possess one Mo site and two Mn sites, namely Mn1 and Mn2. The Mo atoms are surrounded by five –C–N–Mn1 linkages and two –C–N–Mn2 linkages, as can be seen in Fig. 1(a) and (b). The Mo–C bond lengths range from 2.112(3) to 2.166(9) Å (with a mean value of 2.138 Å) for both compounds. All of the Mo–C–N bond angles are close to 180°, ranging from 175.51(26)° to 179.00(27)° for **2** and from 176.26(29)° to 179.87(44)° for **3**. Geometries of the molybdenum sites of **2** and **3** were analysed by using Continuous Shape Measures calculations. Five models were considered: heptagon (D_{7h}), hexagonal pyramid (C_{6v}), pentagonal bipyramid (D_{5h}), capped octahedron (C_{3v}) and capped trigonal prism (C_{2v}). The obtained results clearly show that the molybdenum site geometry in **2** corresponds to the perfect-capped trigonal prism (C_{2v}) while the site geometry in **3** is compatible with the intermediate polyhedron between the trigonal prism and the capped octahedron (Table 1S, Supplementary materials). In both cases, the geometry of $[Mo(CN)_7]^{4-}$ unit is changed from a pentagonal bipyramid (D_{5h}) in the starting compound $K_4[Mo(CN)_7] \cdot 2H_2O$ [13]. Such flexibility of the building block geometry was commonly observed with the compounds presenting phenomena of pseudo-polymorphism [27].

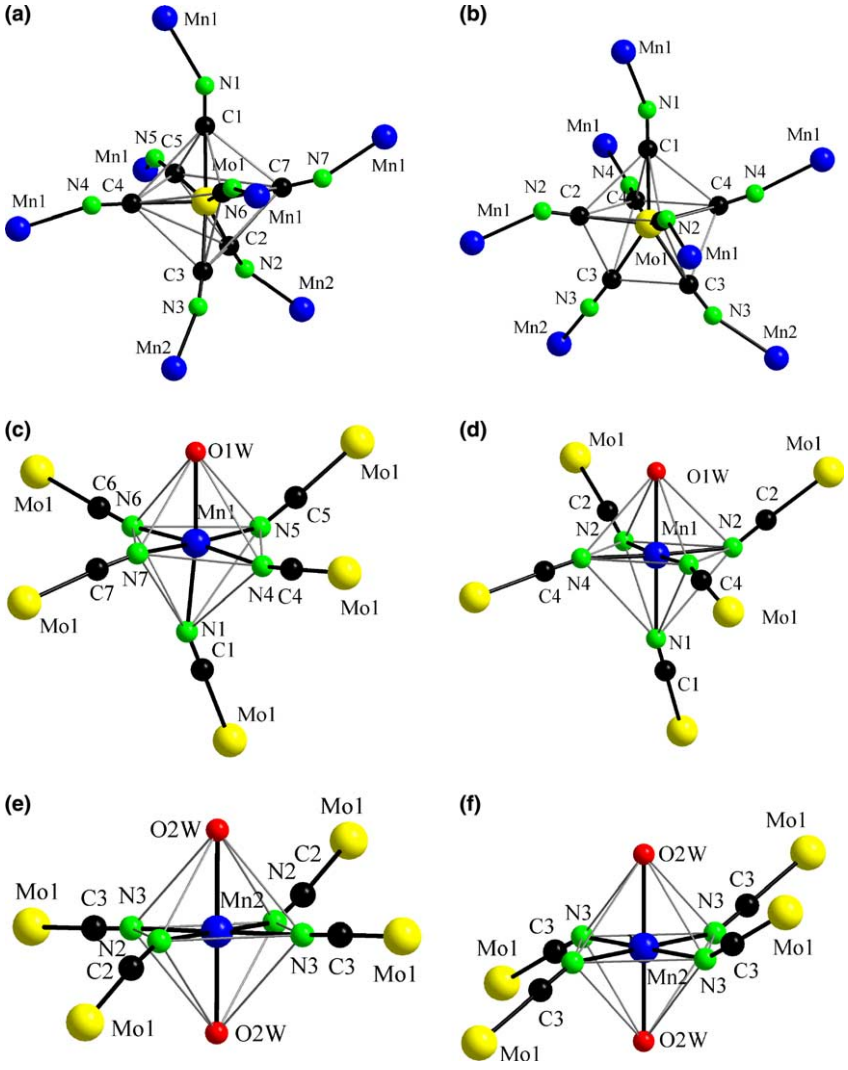

Fig. 1. Local coordination environments of: (a) Mo site for compound **2**; (b) Mo site for compound **3**; (c) Mn 1 site for compound **2**; (d) Mn1 sites for compound **3**; (e) Mn2 site for compound **2**; (f) Mn2 site for compound **3**.

Both structures show six-coordinate Mn1 and Mn2 sites. The Mn1 sites are surrounded by five N–C–Mo linkages and one water molecule forming a distorted octahedral environment (Fig. 1(c) and (d)). The Mn2 ions are surrounded by four N–C–Mo linkages and two water molecules in the *trans* positions leading also to a distorted octahedral environment (Fig. 1(e) and (f)). The Mn–N–C bond angles deviate significantly from 180°, ranging from 142.26(24)° to 167.08(27)° for **2** and from 145.27(43)° to 164.36(29)° for **3**.

Although **3** is not strictly isostructural to **2**, the organization of the three-dimensional structure is similar. The cyano-bridged networks may be described as a corrugated grid-like sheets parallel to the *bc* plane, which are formed by cyano-bridged rhombus motifs, $\{MoC4N4Mn1N2C2\}_2$ in the case of **3** (Fig. 2, Fig. 3S, Supplementary materials). In this plane, the Mo–Mn1 separations across a cyano-bridge range from 5.29 to 5.40 Å. Each two parallel sheets are connected by $Mn2(C3N3)_4$ rhombus running along the *b* axis to form a double sheet parallel to the *bc* plane. These double sheets are also connected to each other by the C1N1 bridge to form the three-dimensional structure (Fig. 3, Fig. 4S, Supplementary materials). The Mo–Mn1 distance through the C1N1 is equal to 5.372 Å for **2** and 5.311 Å for **3**. The NH_4^+ counter cations (N11) are intercalated between the double sheets running along the *bc* plane and are situated in the centres of cubic cavities formed by the anionic networks (Figs. 3 and 4(a)).

It should be noted that a similar structural arrangement was observed for **1** but in this case the double sheets are separated by K^+ and not connected to each other forming a two-dimensional structure (Fig. 4(b)). The shorter inter-double sheet distance for **1** (Mo–Mo) is equal to 7.253 Å.

The three-dimensional arrangement of the crystal structures of **2** and **3** results in channels running along

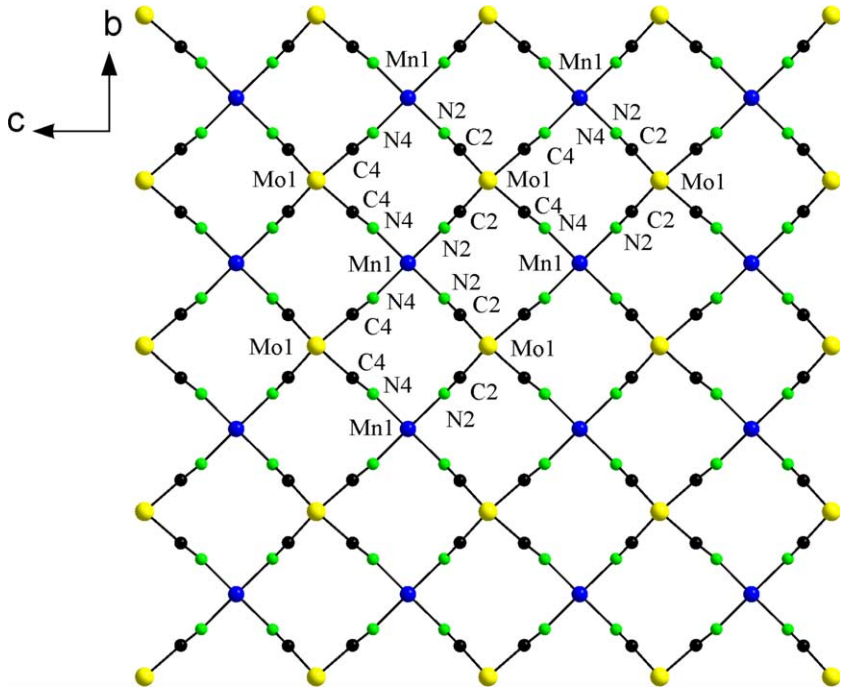

Fig. 2. A view of the structure of **3** in the *bc* plane, showing a corrugated grid-like plan. Mn2 atoms, hydrogen atoms and solvents molecules have been omitted for clarity.

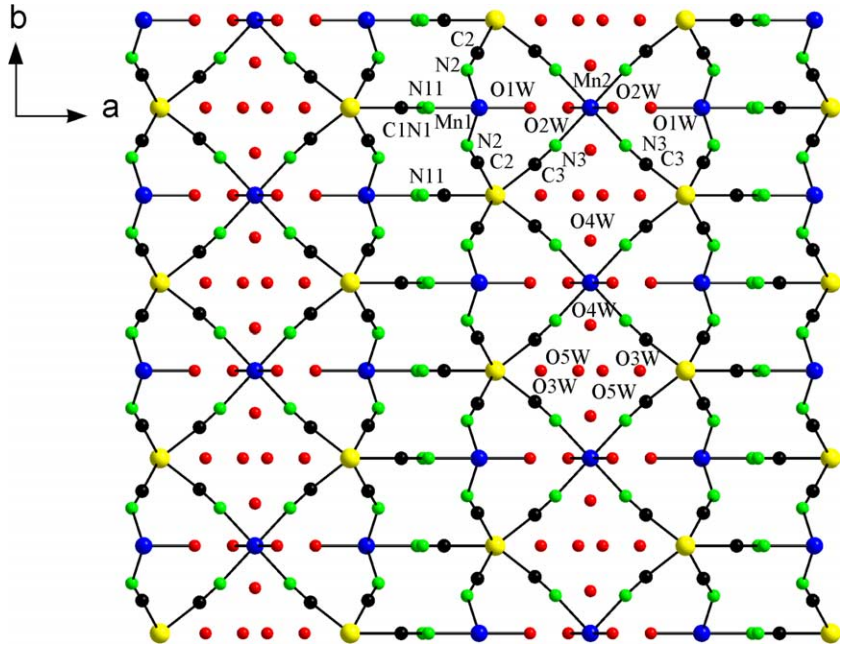

Fig. 3. A view of the structure of **3** in the *ab* plane. Hydrogen atoms have been omitted for clarity.

the *b* axis occupied by coordinated and water of crystallization molecules as shown in a whole view of the structure of **2** viewed in the *ac* plane (Fig. 4(a), Fig. 5S, Supplementary materials). Fig. 5(a)–(d) shows the hydrogen-bonding pathway between water molecules, which are coordinated to manganese atoms and crystallized in the cell for **2** and **3**. In both structures, the four coordinated water molecules situated in the *ac* plane are linked together by means of hydrogen bonds forming a non-centrosymmetrical lozenge $\{O1WO2W\}_2$ in the centre of the channel (Fig. 5(a) and (b)). Four water molecules of crystallization situated in the *ac* plane are also linked by hydrogen bonds and form lozenges {O3WO4W} for **2** and {O3WO5W} for **3**. On the other

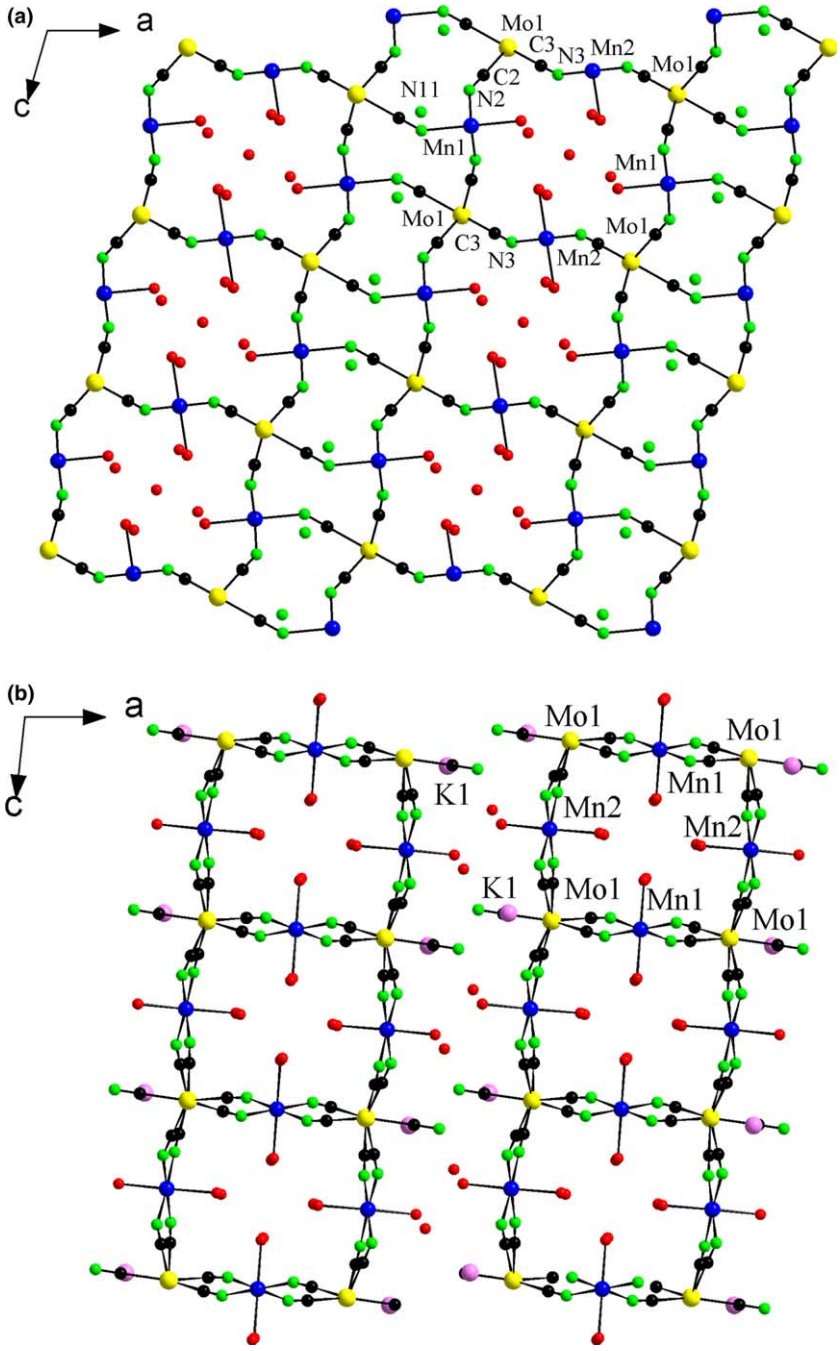

Fig. 4. Global view of the crystal structures in the *ac* plane of (a) **3** and (b) **1**. Hydrogen atoms have been omitted for clarity.

hand, the O2W atoms are linked by hydrogen bonds to the O4W atoms of the water molecules of crystallization and the later are linked to the O3W in **2** or O5W in **3** resulting in columns of water clusters inserted in the channels delimited by the cavities running along the *b* direction (Fig. 5(c) and (d)). The distances implied in hydrogen-bonding pathway (Table 2) are in agreement with the previously reported hydrogen bonds [28]. The cavity size without water molecules may be estimated as (9.123×7.883) Å^2 (or as a cavity volume of 195 Å^3) for **2** and as (9.175×7.776) Å^2 (a cavity volume of 190 Å^3) for **3**. It should be noted that analogous cavities containing hydrogen bonded water clusters were observed in the case of the two-dimensional compound **1** with a cavity size of (9.072×8.104) Å^2 (a cavity volume of 206 Å^3). The cavities found in these three compounds may be used for intercalation of guest molecules having appropriate size and nature.

3.1.3. Thermogravimetric analysis

The thermogravimetric analysis of the mixture of **2** and **3** was performed under argon atmosphere from

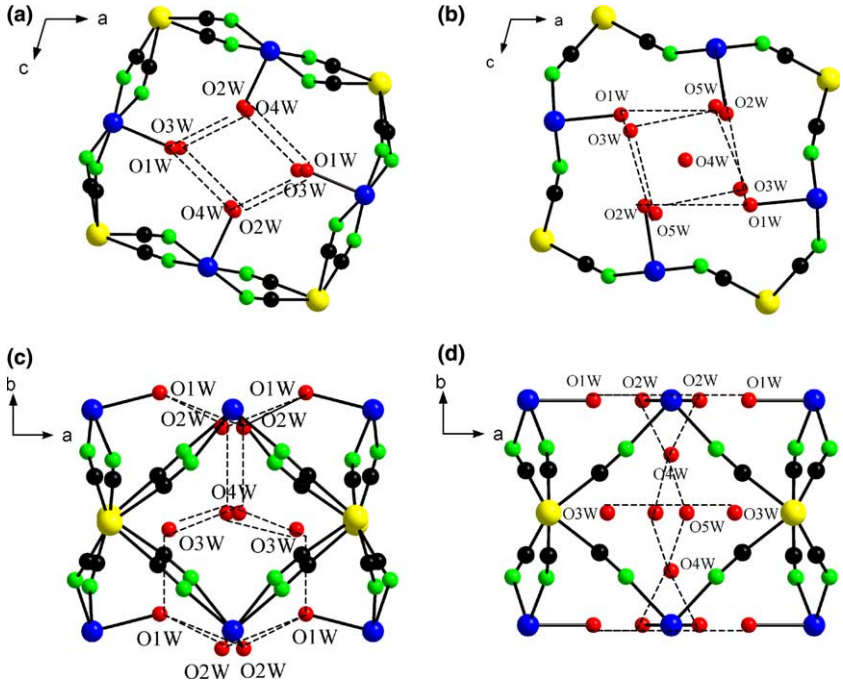

Fig. 5. Fragments of crystal structures showing hydrogen-bonding pathway (dashed line) between coordinated to Mn and crystallized water molecules: (a) for the structure of **2** along the *b* axis; (b) for the structure of **3** along the *b* axis; (c) for the structure of **2** along the *c* axis; (d) for the structure of **3** along the *c* axis.

Table 2
Distances in hydrogen bonding water networks in **2** and **3**

D···A	Distances for **2** (Å)	D···A	Distances for **3** (Å)
O1W···O2W	3.104	O1W···O3W	3.168
	3.329		3.536
O3W···O4W	2.716	O3W···O5W	2.974
	2.784		2.899
O2W···O4W	2.785	O2W···O4W	2.706

		O4W···O5W	2.785
		O4W···O3W	2.803

room temperature up to 700 °C. The curve exhibits four well-pronounced weight losses as the temperature was increased at a heating rate of 1 °C min^{-1}, as shown in Fig. 6(a). The weight loss steps can be determined by the inflection points at 70, 125, 370 and 632 °C, respectively. The first weight loss of 8.4% is in agreement with the loss of the four water molecules of crystallization. This value is slightly higher than the calculated one (8.0%) due to the presence in the mixture of around 20% of the compound **3** containing five water molecules of crystallization. The second weight loss of 8% is consistent with the loss of four coordinated water molecules. The TGA/MASS analysis of the gas evolved during these weight loss steps indicates the presence of water with the ionic current $m/z = 18$ (for H_2O^+). The probable formation of $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2$ at the first step and $(NH_4)_2Mn_3[Mo(CN)_7]_2$ at the second step of dehydration was confirmed by elemental analyses of the samples obtained by heating of the mixture at 80 and 160 °C, respectively. However, the determination of the crystal structures of these dehydrated forms was not successful. The third and fourth weight loss steps of 13.0% and 14.7% correspond to the loss of cyano ligands and ammoniac that induces the decomposition of the compound.

The TGA of compound **1**, having a two-dimensional structure was performed in order to compare the results. The curve shows four weight losses with the inflexion points at 93, 170, 400 and 627 °C (Fig. 6(b)). The first weight loss of 10.7% corresponds to the loss of the six water molecules of crystallization and the formation of $K_2[Mn(H_2O)_2]_3[Mo(CN)_7]_2$. The second loss of 10.6% is in accord with the loss of the six water molecules coordinated to the manganese ion. As in the case of **2** and **3**, the TGA/MASS analysis of the gas evolved during these two weight loss steps indicates the presence of water (ionic current $m/z = 18$ for H_2O^+). Unfortunately, several attempts to determine the crystal structure of **1** after heating of a single crystal at 115 and 215 °C were not successful. The third and fourth weight losses of 8.4% and 14.4%, respectively, correspond to the decomposition of the compound.

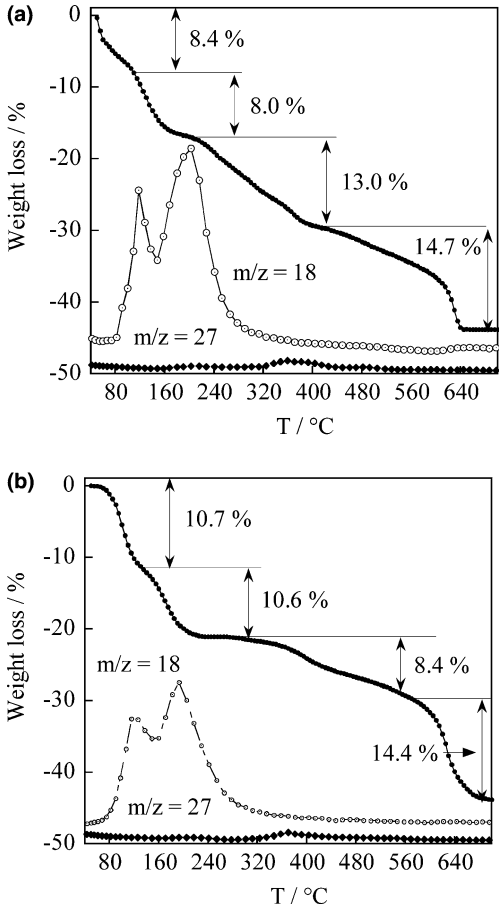

Fig. 6. TGA (•) and TGA/MASS (–○– ionic current $m/z = 18$ for H_2O^+, –♦– ionic current $m/z = 27$ for HCN^+) curves for: (a) a polycrystalline sample containing **2** and **3**; (b) a polycrystalline sample of **1**. Heating rate is 1 °C min^{-1}.

3.2. Role of cations in the structural organization of the $Mn^{2+}/[Mo(CN)_7]^{4-}$ system

3.2.1. K^+ and as templates in $Mn^{2+}/[Mo(CN)_7]^{4-}$

In order to establish the role of the counter cations in the structural organization of the $Mn^{2+}/[Mo(CN)_7]^{4-}$ system, we analyse characteristics of K^+ and NH_4^+ and their behaviour as templates. From the structural point of view, both of them modify the structural organization of $Mn^{2+}/[Mo(CN)_7]^{4-}$ and their intercalation in this system provides the formation of a similar network but with a different dimensionality: in the case of NH_4^+, the structure is three-dimensional and in the case of K^+, the structure is two dimensional. The fragments of the structures of **1**–**3** showing the cavities incorporated counter cations are shown in Fig. 7. In the case of **2** and **3**, NH_4^+ is situated in the centre of the cubic cavity $\{Mn1(CN)_3Mo\}_4$ formed by anionic network, as shown in Fig. 7(a) and (b). The distances between NH_4^+ (N11) and cyano bridges are listed in Table 3. In both cases, three distances N11···N were found shorter than all others indicating the possibility of weak interactions between NH_4^+ and π system of cyano bridges. In the case of the compound **1**, K^+ is situated in the centre of one of the two half-cavities $\{Mn2(O2W)(CN)_3Mo\}_2$ and the opposite side is occupied by a water molecule of crystallization, O6W. Short distances between K^+ and cyano bridges on the one hand and K^+ and the water molecule of crystallization (O6W) on the other hand were found (Table 3) that is indicative of the presence of weak interactions $K^+\cdots\pi(C{\equiv}N)$ and $K^+\cdots$water (Fig. 7(c)).

The factors determined the behaviour of K^+ and NH_4^+ as template as follows: (i) the relative ionic radii of these cations which correspond to 1.51 Å for NH_4^+ and 1.52 Å (CN = 6) or 1.65 Å (CN = 8) for K^+ [29]; (ii) the polarisability which equal to 8.83 a.u. for NH_4^+ and 5.52 a.u. for K^+ [29]; (iii) the geometry of cations: NH_4^+ adopts a tetrahedral geometry while K^+ is a spherical cation; (iv) the hydration energy which equal to 71 kcal mol^{-1} for NH_4^+ and 77 kcal mol^{-1} for K^+ [30]; (v) capacity to create weak interactions with an anionic network: both of them can establish ionic interactions but NH_4^+ is also known as a good donor in hydrogen bonding. It should be noted that the unconventional ionic or hydrogen bonds between the cations such as NH_4^+ and K^+ with the π-system of C_2H_4,

acetylenic groups or an aromatic π-system of benzene and its derivatives are well-known in the literature [31]. However, to the best of our knowledge, this type of interactions where the electron donor is a π-bond of a bridged C≡N ligand have never been investigated.

3.2.2. *Theoretical investigations on cation···π(C≡N) interactions (cation = NH_4^+, K^+)*

In order to inspect the possibility of the formation of unconventional ionic or hydrogen bonds between cations···π-system of cyano ligands (cation = NH_4^+, K^+) and to evaluate their contribution in the structural organization of the $Mn^{2+}/[Mo(CN)_7]^{4-}$ system, we performed a theoretical study using the model consisting in a binuclear cyano-bridged Mo–Mn framework surrounded by its coordination sphere. To model a three-dimensional structure of a molecular cluster, the structure has to be simplified: it appeared that the most satisfying model was to keep the bridging structure of all the cyano groups and to replace the terminal metal atoms by potassium atoms: although a potassium is a crude model for a metal centre, it adequately plays the role of an acceptor with respect to the cyano ligand and consequently accounts for the ligand field on the metal atom opposite with respect to the cyano group. The considered complex is thus $[(KCN)_4\ H_2O\ Mn\ NC\ Mo\ (CNK)_6]^{4+} + K^+$ or NH_4^+. We have only considered the ferromagnetic state although the complex is antiferromagnetic for practical reason and because we were not interested in the magnetic modeling of the molecule. The magnetic state has no influence on the intermolecular distances. Geometry optimization is done assuming the C_s symmetry: no negative frequency was found.

The geometries of the two complexes $[(KCN)_4H_2O\ Mn\ NC\ Mo\ (CNK)_6]^{4+} + NH_4^+$ or K^+ have been optimized; the most important geometrical parameters are summarized in Table 5 and compared to the crystallographic values; the two optimized structures found are plotted in Fig. 8(a) and (b). Almost all the optimized distances match well to the experimental ones, the most important discrepancy arises in the metal–ligand bonds: they tend to be overestimated and a large difference is obtained between the bond with the bridging cyano and the terminal ones. In the case of molybdenum, the bond with the terminal cyano is shorter than the one with the bridging one and vice versa for the manganese. This should be due to the different interaction of the carbon and nitrogen atoms forming the cyano group with the cation: the nitrogen atom is more nucleophilic than the carbon one and tends to be as close as possible to the cation. In the case of Mo, the carbon atom is linked to the metal and in order to approach closer to the cation, the nitrogen atom pushes the cyano group towards the metal. In the Mn coordination sphere, the nitrogen is linked to the metal and tends to move away to be close to the cation. One may consider that this cluster is a satisfactory model of the crystal when noticing that we completely neglect the strain of the three-dimensional structure and the electrostatic interaction with the rest of the crystal. This geometry optimization suggests that there is a cation–π interaction between K^+ or NH_4^+ and the cyano groups. These cations play an active role in determining the geometry of the complex: indeed both

$Mn–N_c–C_c$	155		156	

C_b, N_b belong to the bridge, C_a, N_a form the two equivalent cyano groups linked to Mo and the cation, C_c, N_c the cyano linked to Mn and the cation. Distances are in Å and angles in °. The experimental data are the two extreme ones. The distance to NH_4^+ means the distance to the N atom.

crystals are very distorted, M–CN is far from linearity and there is a large dispersion of the metal–ligand bond distances.

The geometries do not point out a large difference of behaviour between K^+ and NH_4^+: K^+ is slightly closer to the cyano groups by a tenth of angstrom. The calculated interaction energies corrected from the BSSE are -43 kcal mol^{-1} for NH_4^+ and -41 kcal mol^{-1} for K^+ (-41 and -40 kcal mol^{-1} before correction): this difference between the two cations appears negligible. These interactions are repulsive and to analyse the possible existence of a minimum, we have studied the interaction of the two cations with the very simple molecular system $[QCNQ]^{0/2+}$, a cyano group with a CN distance of 1.17 Å, sandwiched by two positive charges: either potassium atoms or punctual charges $Q = 1$ or $Q = 0.5$. The geometry of this system is linear and is kept fixed. Results are summarized in Table 6. The interaction between two positive ions is dissociative but in most of the cases, there is a well corresponding to a cation$-\pi$ interaction. The well is favoured by an atom of K compared to a punctual charge and by more distant charges because the interaction of the cation with the two positive charges is thus reduced. Furthermore, the interaction of K^+ or NH_4^+ with the neutral QCNQ is strongly attractive: in the case of a distance of 2.2 Å, which is a realistic distance for a coordination complex, the cation distance to the nitrogen of the cyano group is 2.9 and 3.0 Å for

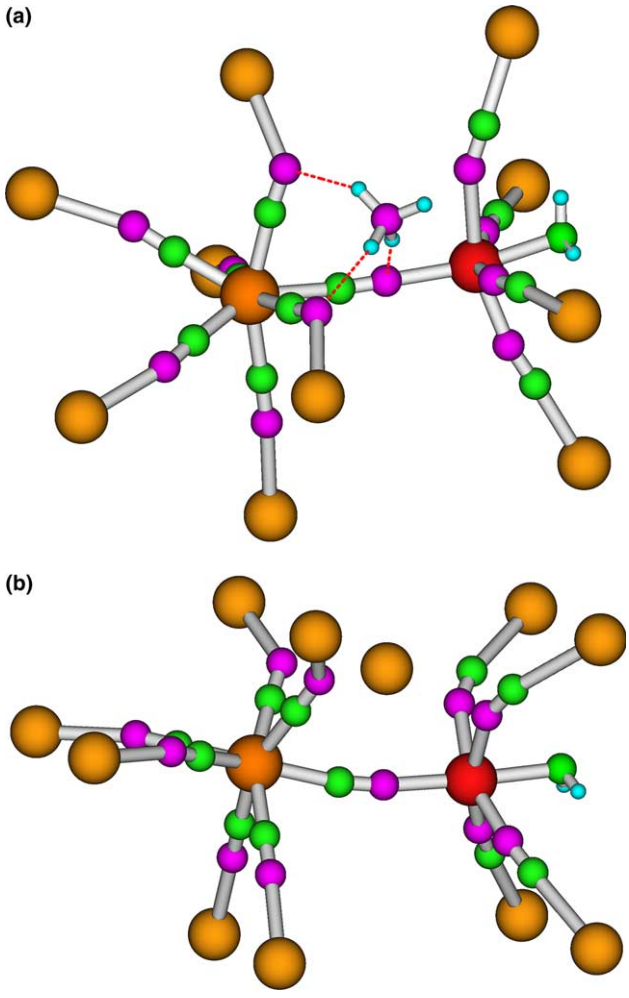

Fig. 8. (a) Optimized geometry for $(KNC)_6$ Mo CN Mn $(NCK)_4$ $OH_2 + NH_4^+$; (b) optimized geometry of $(KNC)_6$ Mo CN Mn $(NCK)_4OH_2 + K^+$.

K^+ and NH_4^+, respectively, and the dissociation energies are 22 and 25 kcal mol^{-1}, respectively. The equilibrium distances match well the distances obtained in the large complex and confirms that there is cation–π interaction in the complex and not only a cation embedded in a cage. The value of the interaction with the QCNQ system is much larger than in the NH_4^+–ethene system: 10 kcal mol^{-1} [32]. This must be due to the higher electron density on the cyano group compared to the ethene because of its negative charge. Furthermore, Kim et al. [32] have compared the interaction of K^+ and NH_4^+ with ethene and have analysed the different contributions to the interaction energy using the SAPT method [33]: as in this study, K^+ lies closer to ethene than ammonium while the interaction is stronger for the latter by 2 kcal mol^{-1}. The contribution of induction is larger than the electrostatic one, which is opposite to the case of cation–water interaction. Because the cation–π distance is slightly larger for ammonium, the induction and

Table 6
Interaction between K^+ or NH_4^+ with QCNQ where Q is either a K atom or a punctual charge

$N–cat_{min}$ and $N–cat_{bar}$ are the N–cation distances at the minimum (no means a dissociative interaction) and at the top of the barrier (if any), ΔE_{bar} is the height of the barrier compared to the minimum energy, ΔE_{diss} is the dissociation energy. Distances are in Å and energies in kcal mol^{-1}.

exchange terms are slightly smaller compared to potassium but this difference is overcompensated with the electrostatic contribution. The conformation of the complex with NH_4^+ allows three N–H bonds out of four to point toward a cyano bridge and to give rise to a hydrogen bond. The three bonds pointing towards a cyano are longer by 0.01 Å, which shows a very small hydrogen bond effect.

4. Conclusion

In summary, pseudo-dimorphic phases $(NH_4)_2Mn_3(H_2O)_4[Mo(CN)_7]_2 \cdot nH_2O$ where $n = 4$ for **2** and $n = 5$ for **3** have been obtained by the introduction of NH_4^+ in the system $Mn^{2+}/[Mo(CN)_7]^{4-}$. The compounds present similar three-dimensional networks of low symmetry and order ferrimagnetically below 53 K. From a structural point of view, we have outlined the difference of behaviours between the guest counter ions NH_4^+ and K^+, which have close size but different nature. The intercalation of both of them modifies the structural organization of the system $Mn^{2+}/[Mo(CN)_7]^{4-}$, however, K^+ motivates the formation of a two-dimensional structure while the introduction of NH_4^+ leads to the formation of a three-dimensional network.

The comparison of the structural organizations of compounds **1**, **2** and **3** shows that in the case of **1**, a water molecule is present together with K^+ in the cavity, which is not the case in **2** and **3**. The hydration energy of K^+ is larger compared to NH_4^+ and K^+ is able to establish ion–dipole interactions with water molecules stronger that NH_4^+. The overall size of $K\cdots H_2O$ is much larger that the size of NH_4^+ which provides the formation of a two-dimensional network in the case of **1**.

Theoretical investigations were performed in order to establish the presence of unconventional ionic or hydrogen bonds between cations and π-system of cyano bridges, which may explain the role of these cations as structural agents. The study shows that: (i) in both cases, there is an important ionic cation–π interaction between K^+ or NH_4^+ and a bridging cyano group between two metals whose effective charge is about 0.5. The distortions showed by the crystallographic structures originate in the interaction between the complex and these cations; (ii) the interactions with the two cations are very similar: the distance $K\cdots CN$ is eventually smaller as anticipated when comparing the ionic radii, but the interaction is slightly larger with ammonium because of the electrostatic contribution being higher due to the larger polarizability of ammonium (8.83 a.u.) compared to K^+ (5.52 a.u.); (iii) NH_4^+ establishes negligible hydrogen bonding with $\pi(C{\equiv}N)$. Consequently, while the ionic bonds cation$\cdots\pi$ play an important role in the structural organization of $Mn^{2+}/[Mo(CN)_7]^{4-}$, but no difference in K^+ and NH_4^+ behaviour was established by theoretical study.

Acknowledgements

The authors thank Mr. Alain Mari for magnetic measurements. The authors thank the CNRS and the Université Montpellier II for financial support and the Norwegian High Performance Computing Consortium (NOTUR) for grants of computing time.

Appendix A. Supplementary materials

Crystallographic data for the structural analysis of **3** have been deposited with the Cambridge Crystallographic Data Centre, CCDC 247302. The crystallographic data of **2** are given in a preliminary communication (CCDC 235836) [12]. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336033, e-mail: deposit@ccdc.cam.ac.uk, http://www.ccdc.cam.ac.uk). Supplementary

data associated with this article can be found, in the online version at doi:10.1016/j.poly.2005.02.003.

Elemental analyses of C, H and N were performed by the MEDAC LTD Vrunel Science Center, United Kingdom. IR spectra were recorded with a Nicolet Impact 420 FT-IR spectrometer using KBr pellets. Magnetic susceptibilities were measured with a Quantum Design SQUID susceptometer.

2.2. Synthesis

2.2.1. Synthesis of $[Fe_3(L1)_2(\mu\text{-}OCH_3)_2Cl_2](FeCl_4)\cdot H_2O$ (2)

About 58 mg of **1** in 2 ml CH_3OH was added slowly into a hot solution of 35 mg $FeCl_3$ in 3 ml CH_3OH at 50 °C. The solution was stirred at 50 °C for another 2 min prior to filtration, and then allowed to stand overnight to give orange-yellow prismatic crystals of **2**. Yield: 29%. *Anal*. Calc. for $Fe_4Cl_6C_{40}H_{42}N_6O_{11}$: C, 39.42; H, 3.47; N, 6.89. Found: C, 39.69; H, 3.47; N, 6.77%. IR (KBr): 3440w, 2935w, 1602m, 1575w, 1439m, 1265m, 1225m, 1163w, 1113m, 1057s, 1024s, 978m, 816m, 769m, 688m, 648w cm^{-1}.

2.2.2. Synthesis of $Fe(L2)Cl_2\cdot H_2O$ (3a)

This complex was obtained as orange-red crystals by the procedure used for complex **2**, except that CH_3OH was substituted by a mixed solvent of CH_3CN and H_2O in 10:1 volume ratio. Yield: 47%. *Anal*. Calc. for $FeCl_2C_{17}H_{12}N_3O_3$: C, 47.15; H, 2.79; N, 9.70. Found: C, 46.93; H, 2.89; N, 9.65%. IR (KBr): 3417m, 3099m, 1685m, 1597m, 1440w, 1325w, 1296w, 1227m, 1169w, 1074w, 1018m, 984w, 839w, 792w, 760m, 663m cm^{-1}.

2.2.3. Synthesis of $Fe(L2)Cl_2\cdot THF$ (3b)

About 35 mg $FeCl_3$ was dissolved in 1 ml CH_3CN and 0.1 ml H_2O at 50 °C, to which 58 mg of **1** in 1 ml CH_3CN was added slowly. After stirring for 5 min, the orange solution was filtered and THF was allowed to diffuse into it. Orange-red crystals of **3b** were obtained after several weeks. Yield: 38%. *Anal*. Calc. for $FeCl_2C_{17}H_{12}N_3O_3$ (THF removed in vacuum): C, 47.15; H, 2.79; N, 9.70. Found: C, 46.74; H, 2.73; N, 9.45. IR (KBr): 3581s, 3513s, 3407brs, 3136brs, 3080s, 2802w, 1685m, 1591s, 1462m, 1321m, 1294m, 1226s, 1180m, 1040s, 1014s, 982w, 930w, 843m, 764s, 713m, 675s cm^{-1}.

2.2.4. Synthesis of $Fe(L3)Cl_2\cdot THF$ (3c)

About 35 mg $FeCl_3$ was dissolved in 1 ml anhydrous CH_3CN and 0.2 ml CH_3OH at 50 °C. To this solution 58 mg of **1** in 1 ml anhydrous CH_3CN was added slowly. After stirring for 5 min, the orange solution was filtered, and anhydrous THF was allowed to diffuse into the solution. Orange-red crystals of **3c** were obtained after several weeks. Yield: 33%. *Anal*. Calc. for $FeCl_2C_{18}H_{14}N_3O_3$ (THF been removed by heating): C, 48.36; H, 3.16; N, 9.40. Found: C, 48.32; H, 3.34; N, 10.90. IR

2.3. X-ray crystallography

Crystals mounted inside Lindemann glass capillaries were used for data collection on a Bruker SMART 1000 CCD diffractometer operating at 50 kV and 30 mA using Mo Kα radiation ($\lambda = 0.71073$ Å) at 293 K. Data collection and reduction were performed using the SMART and SAINT software [24]. An empirical absorption correction was applied using the SADABS program [25]. The structures were solved by direct methods and refined by full-matrix least squares on F^2 using the SHELXTL program package [26]. The THF molecules in **3b** and **3c** were treated using a disordered model, which was refined isotropically in the case of **3b**. In the structures of **2** and **3a**, the water hydrogen atoms could not be located. Crystallographic data of complexes **1a**, **1b**, **2**, **3a**, **3b** and **3c** are listed in Table 1.

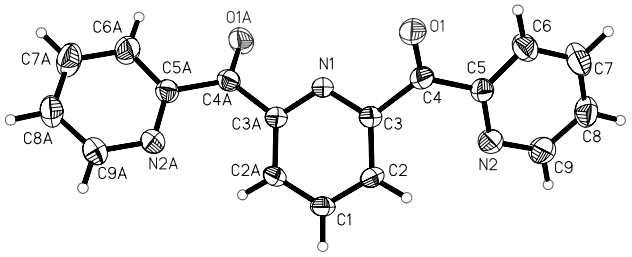

Fig. 1. Molecular structure of compound **1**. Non-hydrogen atoms are shown as 30% probability ellipsoids.

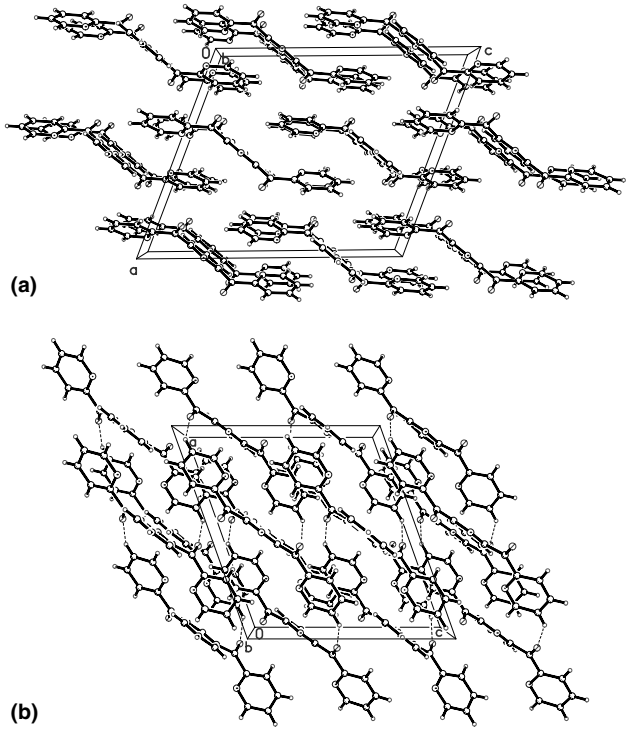

Fig. 2. (a) Packing diagram of **1a** viewed along the *b*-axis. The center-to-center separation between a pair of parallel pyridine rings from adjacent ligands is ca. 3.95 Å. (b) Packing diagram of **1b** viewed along the *b*-axis. The hydrogen-bonded layers (C8–H8A···O1 136°; C8···O1 3.237 Å) match the (0 0 2) planes, and very weak π–π interactions connect them into a three-dimensional network. The center-to-center separation between two parallel pyridine rings from adjacent layers is ca. 4.09 Å.

3. Results and discussion

3.1. Crystal structure of ligand *1*

Two polymorphs of **1** can be crystallized using different solvents: form **1a** from ethyl acetate has a packing featuring very weak π–π interactions (Fig. 1), and form **1b** from water is consolidated by both π–π interactions and intermolecular C–H···O=C hydrogen bonds (Fig. 2). Molecule **1** has site symmetry 2 in both crystalline forms **1a** and **1b**, but the pair of torsion angles along the atom chain N–C–C(carbonylic)–C–N are (−136.3°, −12.5°) and (155.6°, −22.5°), respectively, indicating that different conformations are adopted by **1** in these

two polymorphs. Comparison of the bond lengths and angles of **1a** and **1b** are listed in Table 2. Almost all of the bond lengths in **1b** are a little longer than the corresponding ones in **1a**, except for the similar distances of C2–C3 and the significant longer C=O bond length in **1a** than that in **1b**.

3.2. Hydrolysis/solvolysis of ligand *1* and solvent controlled formation of complexes

As **1** contains two carbonyl groups each flanked by a pair of pyridyl rings, it readily undergoes metal-assisted hydration or alkanol addition under different conditions to give the di-hemiketal $\mathbf{H_2L1}$, the *gem*-diol **HL2** and the hemiketal **HL3** (Scheme 1), the deprotonated forms of which are potential polydentate ligands that can adopt a variety of coordination modes.

Scheme 1. Hydrolysis and solvolysis of ligand **1**.

The reaction of **1** with $FeCl_3$ in hot methanol yielded crystalline complex $[Fe_3(\mathbf{L1})_2(\mu\text{-}OCH_3)_2Cl_2]FeCl_4 \cdot H_2O$ (**2**) with an asymmetric quasi-linear triiron(III) core. In addition, solvated mononuclear complexes $Fe(\mathbf{L2})Cl_2 \cdot H_2O$ (**3a**), $Fe(\mathbf{L2})Cl_2 \cdot THF$ (**3b**) and $Fe(\mathbf{L3})Cl_2 \cdot THF$ (**3c**) were obtained by solvent-dependent reaction between **1** and $FeCl_3$. Using CH_3CN and H_2O as a mixed solvent, **3a** was formed; diffusion of THF into the CH_3CN reaction solution gave **3b**; when THF was diffused into the mixed CH_3CN/CH_3OH reaction solution, product **3c** was generated.

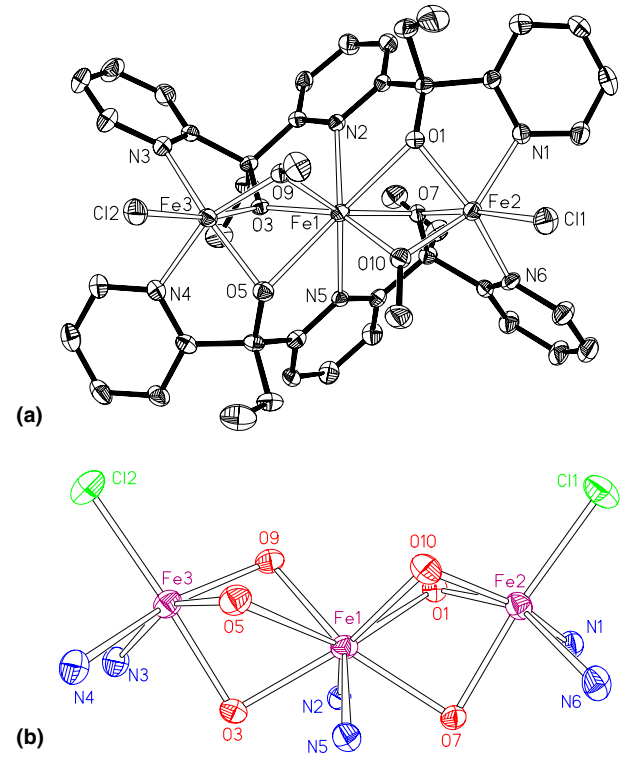

Fig. 3. (a) The quasi-linear asymmetric triiron(III) cation in complex **2**. Hydrogen atoms are omitted for clarity. (b) Saddle-like molecular skeleton composed of fused coordination polyhedra. The atoms are shown as 30% probability ellipsoids.

3.3. Crystal structure of complexes

The cation in compound **2** consists of a quasi-linear array of three iron(III) atoms bridged by two *cis*-related deprotonated di-hemiketals **L1** and two methoxide groups, with a terminal chloro ligand at each end (Fig. 3 and Table 3). All non-cyclic triiron cores reported to date are almost exactly linear [21], whereas in **2**, due to the steric bulk and disposition of the pair of pentadentate ligand **L1**, the Fe2···Fe1···Fe3 angle is 152.63(3)°, and the non-bonding distances between the central to the outer iron(III) atoms are significantly different, being 2.897(1) and 2.916(1) Å [22]. The Fe1 atom is surrounded by two *cis*-related **L1** ligands each employing its central pyridyl N and pair of hemiketal O atoms, as well as a pair of bridging methoxide groups. Owing to the steric effect, the distances between Fe1 and O1/O5 in $[Fe_3(\mathbf{L1})_2(\mu\text{-}OCH_3)_2Cl_2]^+$ are much longer at 2.375(4)/2.463(4) Å as compared to commonly observed iron(III)–oxygen bonds in the range 1.945–2.104 Å. Nevertheless, the central Fe atom can still be considered to be eight-coordinate in a highly distorted FeN_2O_6 dodecahedral coordination environment, in contrast to the distorted octahedral geometry of the outer Fe2 and Fe3 atoms. The Fe–X (X = N or O) bond distances in known eight-coordinate iron complexes are very different: in $Ph_4As[Fe(NO_3)_4]$ reported by Logan and coworkers [27b], the average distance of the Fe–O bonds is 2.13(3) Å; in $Fe(1,8\text{-naphthyridine})_4(ClO_4)_2$ reported by Bernal and coworkers [28,29], the Fe–N distances range from 2.18 to 2.76 Å; in the work of Krüger and coworkers [27a], the Fe–N distances lie in the range of 2.29–2.39 and 2.21–2.33 Å for iron(II) and iron(III) complexes, respectively; and Meier and Rihs [30] have observed a mean Fe–O bond length of 2.40 Å in their iron(II)–crown ether complex. In the present triiron complex **2**, the Fe–X distances range from 1.95 to 2.46 Å. The mean Fe–X distance of the central Fe(III) atom (excluding two unusually long ones) is significantly longer than that of the side Fe(III) atoms, which may be attributed to the difference in their coordination geometries. The trinuclear cation has approximate C_2 molecular symmetry, and its skeletal configuration resembles a saddle (Fig. 3(b)), which has not been observed in reported linear triiron complexes. To our knowledge, only two eight-coordinate Fe(III) complexes have been

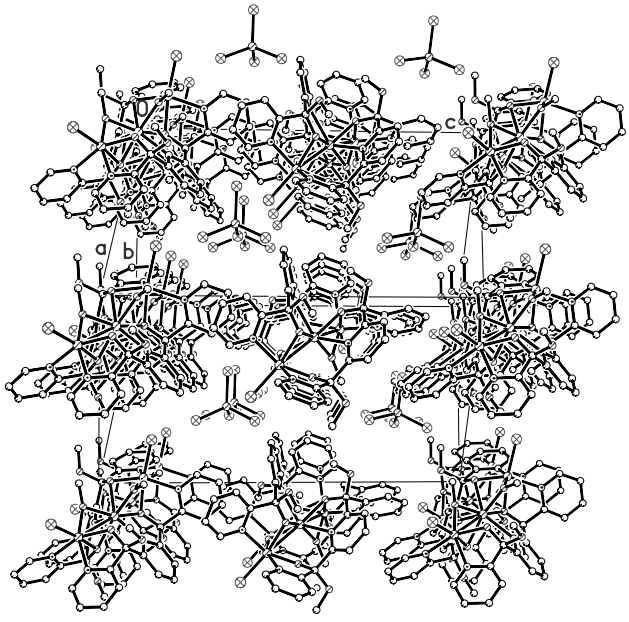

Fig. 4. Packing diagram of compound **2** viewed along $[1\,\bar{1}\,0]$. Hydrogen atoms are omitted for clarity.

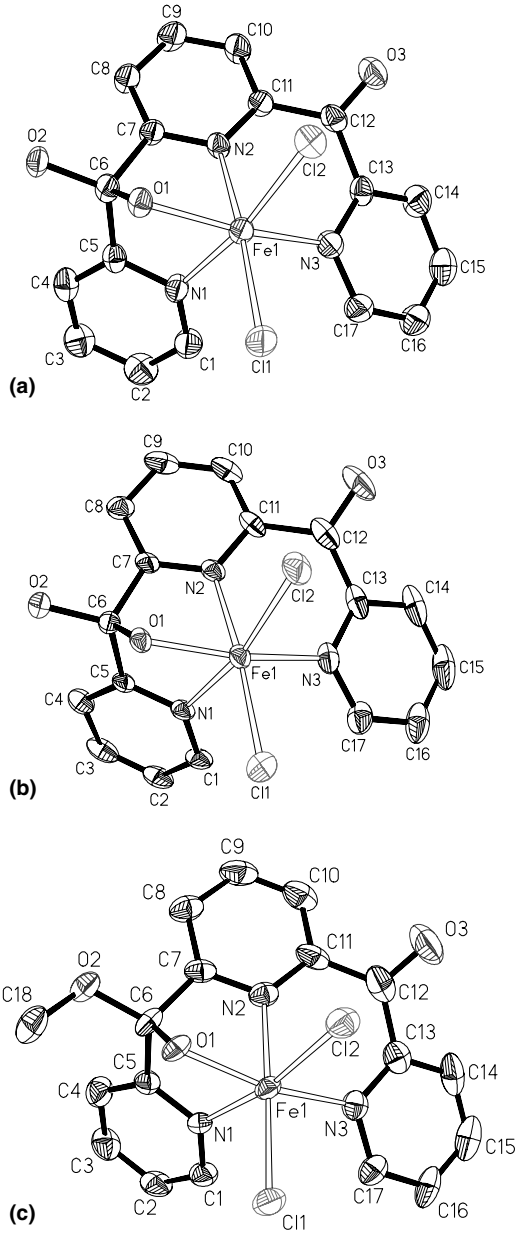

Fig. 5. The cationic monoiron(III) core in **3a** (a), **3b** (b) and **3c** (c). Hydrogen atoms are omitted for clarity. The lattice water molecule in **3a** and THF solvate molecules in **3b** and **3c** are omitted for clarity.

elucidated by X-ray analysis [27] among the few reported examples that commonly bear bidentate, tetradentate or octadentate ligands [27–31].

In the crystal structure of **2**, the trinuclear cations and tetrahedral $FeCl_4^{2-}$ anions are packed in separate columns parallel to the $[1\,\bar{1}\,0]$ direction (Fig. 4). Also present in the crystal are very weak π–π stacking interactions that have a center-to-center separation of ca. 4.00 Å between two almost parallel pyridine rings from adjacent cations that make a dihedral angle of 16.6°.

The neutral complexes **3a**, **3b** and **3c** have similar molecular structures, all containing a six-coordinate Fe(III) center with a pair of *cis*-chloro ligands (Fig. 5). In both hydrated **3a** and THF solvated **3b**, hydrolysis occurs at one carbonyl group of ligand L, whereas in THF solvated **3c** the corresponding carbonyl group undergoes methanolysis. Complexes **3b** and **3c** constitute a nearly isomorphous pair. In the monoiron core, the Fe–O bond length in **3c** (1.905 Å) is significantly longer than those in **3a** (1.952 Å) and **3b** (1.941 Å); consistent with this, the Fe–N bond distances in **3a** are shorter than those in **3b** and **3c**. Selected bond lengths and angles of complexes **3a**, **3b** and **3c** are listed in Table 4 for comparison. Our previous paper has reported the complete solvolysis of ligand **1** in its Cu(II) complex, just like that in complex **2** [23]. However, in the formation of the mononuclear compounds **3a**–**3c**, **1** involves either hydration or methanol addition at only one carbonyl group while the other remains intact. Although the influence of solvent in the formation of coordination complexes is less well understood and systematic studies are few, one can conclude from the preparation of **3a** and **3b** that H_2O is more effective in stabilizing the crystal lattice as compared to THF. When a mixture of CH_3CN, THF and H_2O was used as the solvent, only compound **3a** was deposited.

3.4. Magnetic susceptibility of complex 2

The variable-temperature magnetic susceptibilities of **2** were measured on a polycrystalline sample with a Quantum Design SQUID susceptometer operating at a magnetic field of 0.1 T in the temperature range of 2–300 K. The diamagnetic corrections were evaluated from Pascal's constants for all the constituent atoms. The magnetic behavior of **2** in the form of μ_{eff} versus T plots is illustrated in Fig. 6. At room temperature, the effective moment has a value of 13.62 μ_B; taking the

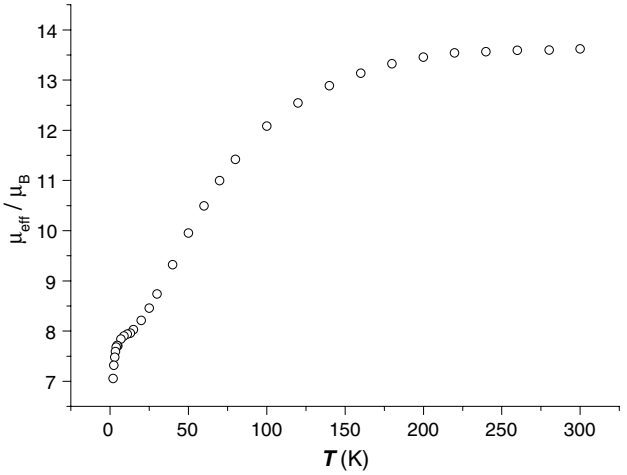

Fig. 6. μ_{eff}–T plot of complex **2**.

structure into account, this is based on the sum of contributions from the trinuclear Fe(III) cation and the isolated $[FeCl_4]^-$ complex anion. Upon cooling, it smoothly decreases to attain a value of 12.88 μ_B at 140 K, and then quickly decreases to 7.05 μ_B at 2 K. These global features indicate a significant antiferromagnetic couple in the Fe(III) complex and the very sharp decrease below 20 K is due to the zero-field splitting effect.

4. Summary

In summary, we have taken advantage of the in situ generation of the *gem*-diol, hemiketal and di-hemiketal forms of **1** under solvent-controlled reaction conditions to obtain mononuclear and quasi-linear trinuclear iron(III) complexes. The doubly deprotonated di-hemiketal form of **1** functions as a pentadentate bridging ligand in **2**, whereas the mono-deprotonated *gem*-diol or hemiketal form of **1** acts as a tetradentate chelating ligand in **3a**, **3b** and **3c**. A significant antiferromagnetic couple in the trinuclear Fe(III) complex **2** was observed.

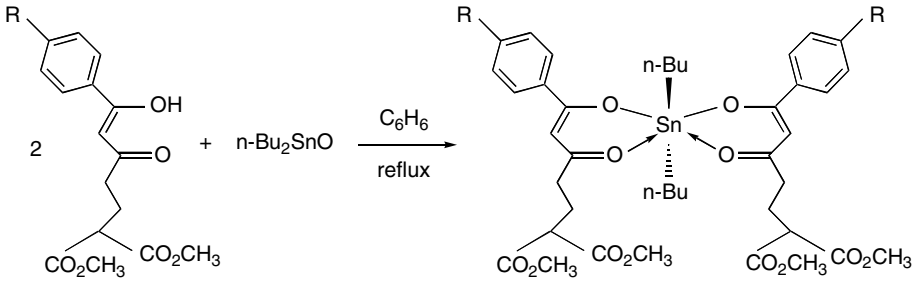

Fig. 1. Synthesis of di-*n*-butyltin(IV) enolates **2a**–**2d**.

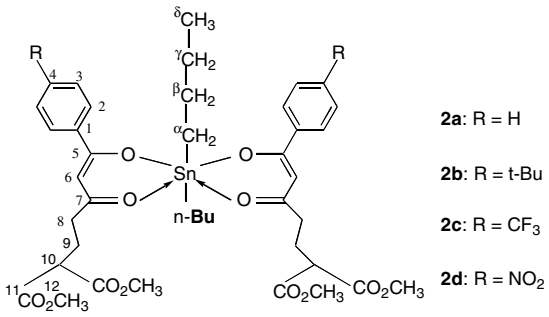
synthesis of new di-*n*-butylhydroxytin(IV)enolates, which exhibit higher states of aggregation in solution at low temperature and their FAB mass spectra showed a dimer structure [27]. Our current interest in the synthesis of organotin(IV) compounds [28–31] prompted us to extend our investigations to the synthesis of new organotin(IV) enolates, which could have biological properties [32]. This paper describes the synthesis of four new di-*n*-butyl[bis{dimethyl-2-(3-oxo-5-phenyl(4-subtituted)penten-5-ato)malonates}]tin(IV) **2a**–**2d** by the reaction of di-*n*-butyl(IV) oxide and 1,3-diketone malonates **1a**–**1d** in a 1:2 molar ratio, in which **1a**–**1d** exist as enolates [33,34] (Fig. 1). All compounds were characterized by ^{1}H, ^{13}C, ^{119}Sn NMR, HMQC, HMBC, infrared spectroscopy and mass spectrometry (FAB). The compound **2d** was also characterized by solid state ^{13}C and ^{119}Sn NMR and its structure was further established by a single crystal X-ray diffraction study at 168 K.



2. Results and discussion

The reaction of 1,3-diketone malonates **1a**–**1d** with di-*n*-butyltin(IV) oxide in a 2:1 ratio, led to di-*n*-butyltin(IV)enolates **2a**–**2d** (Fig. 1). The compounds **2a**–**2c** were obtained as oils, while **2d** was a solid. The ^{1}H NMR spectra in $CDCl_3$ of all the compounds **2a**–**2d** show only one set of signals for each magnetically equivalent H nucleus, thus both $(n\text{-}Bu)_2Sn$ protons and those of the ligands are in a 1:2 ratio, respectively. This can indicate the formation of a unique species or a fast-exchanging equilibrium on the NMR timescale. The H6 and H8 protons appeared as broad signals (0.1 and 0.19 ppm) at higher field with respect to the free ligands (**1a**–**1d**), which suggests a shielding of these protons upon coordination [16], giving evidence for the formation of a Sn–O bonded enolate moiety and a C═O → Sn coordination bond, while the broadening of these signals can suggest a fluxionality between the possible isomers [16,19]. ^{1}H NMR data are summarized in Table 1. The ^{13}C NMR data for compounds **2a**–**2d** are summarized in Table 2. For all compounds the assignment of the *n*-butyl moieties are based on ^{1}H–^{13}C HMQC and ^{1}H–^{13}C HMBC experiments. Thus α and β carbons correlate with the broad signal around 1.5 ppm of Hα and Hβ. The γ-carbon correlates with the signal around 1.27 ppm and δ-carbon correlates with the triplet signal of the methyl group.

The unambiguous assignment of Hβ and Hγ are based on ^{1}H–^{13}C HMBC, where the signal of the γ-carbon correlates with the signal around 1.27 ppm. All these compounds exhibit $^{1}J(^{119}Sn–^{13}C)$, $^{2}J(^{119}Sn–^{13}C)$ and $^{3}J(^{119}Sn–^{13}C)$ coupling constants within the range of *trans* six-coordinated tin compounds [16,17,19–21,26,38]. In particular, $^{1}J(^{119}Sn–^{13}C)$ values for compounds **2a**–**2d** are 872, 879, 866 and 860 Hz, respectively and on the basis of the empirical equation of Holecek and Lycka [39], it was possible to determine θ(C–Sn–C) of these compounds in $CDCl_3$ solution: the calculated values are 160.2° for **2a**, 160.9° for **2b**, 159.7° for **2c** and 159.1° for **2d**, which indicate that the tin atom is in a skewed trapezoidal bipyramidal environment, where the trapezoidal plane is defined by four oxygen atoms derived from two asymmetrically coordinating enolate ligands and the tin-bound organo substituents are orientated over the weakly bound oxygen atoms [17,21]. The value calculated for **2d** agrees well with the angle of 157.1(3)° found in the crystal structure.

The ^{119}Sn NMR spectra of **2a**–**2c** at 19 °C and for **2d** at 25 °C in chloroform show only one peak, which can indicate a unique species or a fast exchanging equilibrium on the NMR time scale (Table 3). Their chemical shifts are within the range of di-*n*-butyltin(IV) hexacoordinated compounds [19,23,35–38]. In order to obtain more information about the structure of these compounds, a variable-temperature NMR study of **2a**–**2d**

was undertaken from 45 to −25 °C for **2a**–**2c** and in the case of **2d** until −45 °C. Thus the spectra at 45 °C exhibit one signal within the range typical of hexacoordinated tin(IV) compounds, the same result was observed upon lowering the temperature to −5 °C for **2a** and **2b**, but not for **2c** and **2d**, which showed two absorptions with slightly different chemical shifts but equal intensity, indicating the presence of both *trans syn*- and *anti*-isomers, in which the alkyl groups must be *trans*, and the isomerism is attributed to a different arrangement of the two ligands as shown in Fig. 2 [19,21]. The same result is found for compound **2d** at 5 °C in which the signals are in ca. 1:4 ratio. All compounds show these two signals at −25 °C, with equal intensity for **2a** and **2b**, while for **2c** and **2d** in ca. 1:1.5 ratio. The spectrum of **2d** at −35 °C showed three signals in a ca. 1:2:4 ratio, the first one at δ −183.54 associated to a five-coordinate species and the other two to the six-coordinate species, this result suggests the existence of an equilibrium between *trans* isomers through a five-coordinate species. Its spectrum at −45 °C exhibited only the signals that belong to the *trans* isomers in ca. 1:2 ratio.

These results show the existence of the mixture of *trans* isomers in solution at low temperature, where chemical shifts of the major isomers for **2c** and **2d** are at lower frequency. The solid state ^{119}Sn NMR spectrum of **2d** (Fig. 3) at room temperature exhibits two signals at −386.07 and −402.10 in a ca. 1:1.5 ratio, as was observed at −25 °C in solution. Its solid state ^{13}C NMR spectrum at room temperature exhibits a set of signals for each magnetically equivalent C nucleus, except for C_5 and C_7, which exhibit two signals each, at δ 200.76, 199.00 and 177.30, 174.40, respectively. The chemical shifts of the major isomer are at a lower frequency than those on the minor isomer, in approximately 0.8:1 ratio (Fig. 4). This result can be attributed again to a different arrangement of the two ligands, giving evidence of the existence of the two *trans*-isomers.

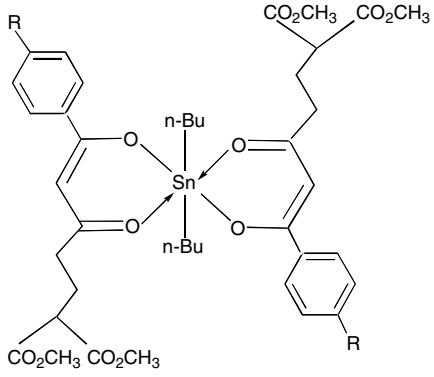
[a] Spectrum obtained at 25 °C [ratio].

The IR data are summarized in Table 4. The spectra exhibit two $\nu_{(C=O)}$ carbonyl oxygen bands, one of them assigned to the CO_2CH_3 groups in the range between 1740 and 1734 cm^{-1} and the other one to the enolate group between 1615 and 1540 cm^{-1}. Also a broad band due to Sn–O is observed between 434 and 302 cm^{-1}.



The FAB mass spectra for **2a**–**2d** exhibit the molecular ion, which by the loss of one *n*-Bu group give the base peaks. Therefore, the fragment ion corresponding to the loss of one ligand from the molecular ion is observed. The spectra show others fragment ions and a possible fragmentation pattern is given in Fig. 5.

Compound **2d** was recrystallized from methanol to provide suitable colourless crystals for X-ray diffraction. Intensity data were collected at 168 K and the crystal structure corresponds to one of the two isomers seen in solution and solid state. An ORTEP view of the compound with the numbering scheme is given in Fig. 6.

Bond distances are listed in Table 5. The tin atom is six-coordinate, showing the metal in skewed trapezoidal bipyramidal arrangement (STB), where four O atoms from two ligands, and two C atoms from the *n*-butyl groups form the coordination polyhedron. This is a distorted octahedron characterized by two different sets of

ν (cm^{-1}), [a] Net liquid, [b] Film.

Sn–O bond. In this context, one ligand has a short bond length Sn_1–O_1 = 2.112(4) Å (primary bond) and a longer one, Sn_1–O_2 = 2.292(5) Å (secondary bond). For the other ligand, the corresponding values are Sn_1–O_3 = 2.115(3) Å and Sn_1–O_4 = 2.349(4) Å. The *n*-Bu groups are *trans* to each other although a strong distortion from 180° is found and the angle is 157.1(3)°. This asymmetry in bond length is a result of the asymmetric nature of the ligand, as well as the presence of the following intermolecular contacts: NO(6)···H(191)$_{arom}$ 2.5827(0.0065), C=O(13)···H(31)$_{arom}$ 2.2576(0.0088), C=O(9)···H(281)$_{methynic}$, 2.5862(0.0101), C=O(15)···H(121)$_{methynic}$ 2.5252(0.0158) and C=O(13)···H(81)$_{vinylic}$ 2.3372(0.0077) Å. Besides the intermolecular contacts,

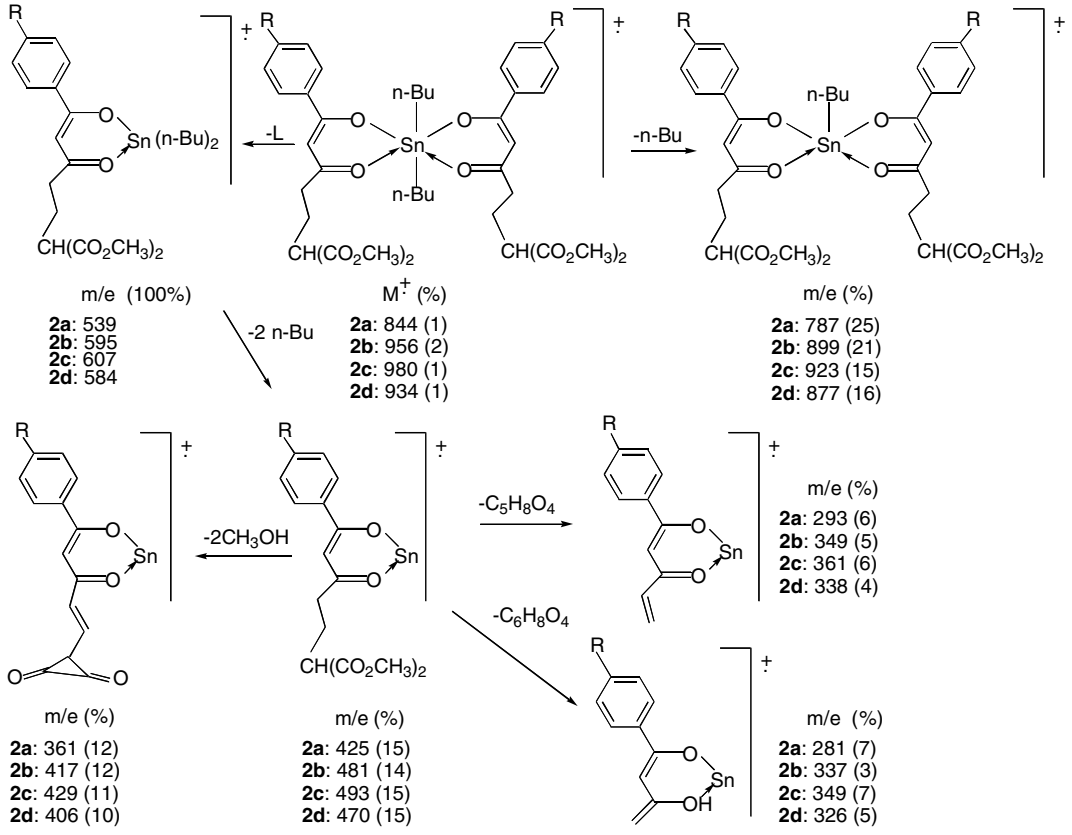

Fig. 5. FAB mass spectra for compounds **2a**–**2d**.

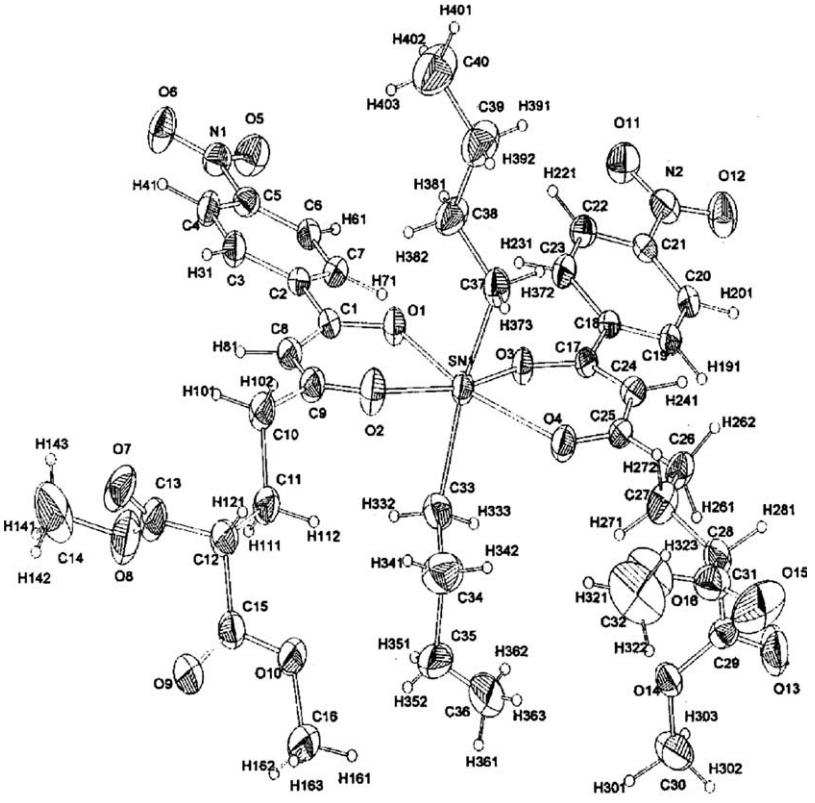

Fig. 6. Molecular structure of $C_{40}H_{50}N_2O_{16}Sn$ and crystallographic numbering scheme.

Table 5
Bond distances selected (Å) for $C_{40}H_{50}N_2O_{16}Sn$ (**2d**)

Sn(1)–O(1)	2.112(4)	C(1)–C(8)	1.387(9)
Sn(1)–O(2)	2.292(5)	C(8)–C(9)	1.396(10)
Sn(1)–O(3)	2.115(4)	C(9)–O(2)	1.261(9)
Sn(1)–O(4)	2.349(4)	O(3)–C(17)	1.289(7)
Sn(1)–C(33)	2.133(9)	C(17)–C(24)	1.380(9)
Sn(1)–C(37)	2.134(8)	C(24)–C(25)	1.416(9)
O(1)–C(1)	1.307(7)	O(4)–C(25)	1.257(8)

there are the following intramolecular contacts: NO(6)···$H(41)_{arom}$ 2.4553(72), NO(5)···$H(61)_{arom}$ 2.3962(72), C–O(7)···$H(121)_{methynic}$ 2.4265(84), NO(11)···$H(221)_{arom}$ 2.4682(65), NO(12)···$H(201)_{arom.}$ 2.4576(74), C=O(15)···$H(281)_{methynic}$ 2.5368(101) and C–O(14)···$H(271)_{methylenic}$ 2.5674(61) Å, which are significantly shorter than the sum of van der Waals radii of oxygen and hydrogen (2.70 Å) [40].

The six-membered ring Sn(1), O(1), C(1), C(8), C(9), O(2) adopts an intermediate between envelope and screw-boat conformation, while the ring Sn(1), O(3), C(17), C(24), C(25), O(4) adopts an intermediate envelop and twist conformation, from their puckering parameters calculated according to Cremer and Pople [41,42], which are: $Q = 0.261$, $\theta = 60.35°$, $\phi = 10.56°$ and $Q = 0.241$, $\theta = 62.06°$, $\phi = 10.64°$, respectively. Therefore the out of-plane displacements calculated for the atoms of each ring are: Sn(1), −0.178(3); O(1), 0.091(6); C(1), 0.034(8); C(8), −0.073(8); C(9), −0.014(9); O(2), 0.139(7) and Sn(1), −0.166(3); O(3), 0.122(6); C(17), −0.001(8); C(24), −0.075(8); C(25), 0.030(8); 0(4), 0.090(6) Å, which give evidence that the six-membered rings do not lie in a plane [43]. In addition, the equatorial plane made by the four O atoms has the oxygen atoms associated with the primary bonds, O(1) and O(3), closer to each other than those associated with the secondary bond, O(2) and O(4), as shown by the corresponding angles O(3)–Sn(1)–O(1) = 79.51(16)° and O(4)–Sn(1)–O(2) = 118.60(17)°, as well as O(1)–O(3) and O(2)–O(4) intramolecular distances of 2.7034(63) and 3.9915(74) Å, respectively. Therefore, bond angle values for C(33)–Sn(1)–O(1), C(33)–Sn(1)–O(3), C(37)–Sn(1)–O(1), C(37)–Sn(1)–O(3) are 99.80(3)°, 97.10(3)°, 99.90(2)° and 97.90(2)°, which are bigger than those of C(33)–Sn(1)–O(2) 85.20(3)°, C(33)–Sn(1)–O(4) 84.50(3)°, C(37)–Sn(1)–O(2) 86.40(3)° and C(37)–Sn(1)–O(4) 80.90(2)°, indicating that the *n*-Bu groups are folded towards the side of the secondary bonds.

3. Conclusion

The new diorganotin(IV) compounds **2a**–**2d** were obtained as enolate derivatives. The tin atom is hexacoordinated in a skewed trapezoidal bipyramidal (STB) geometry according to their spectroscopic data in solution. Their ^{119}Sn variable-temperature NMR studies provide information of the existence of *anti* and *syn* trans isomers, the *syn* isomer being in the major proportion at low temperature. The same result was observed in the solid state ^{13}C and ^{119}Sn NMR for compound **2d**, while its X-ray diffraction study at 168 K shows only the *syn* species, which exhibits interesting intermolecular contacts, NO(6)···$H(191)_{arom.}$, C=O(13)···$H(31)_{arom.}$, C=O(15)···$H(121)_{methynic}$, C=O(9)···$H(281)_{methynic}$ and C=O(13)···$H(81)_{vinylic}$.

The solid state NMR data, as well as low-temperature NMR studies should mirror more closely the structure deduced from the X-ray crystal structure analysis at 168 K where the molecules are effectively locked into place by intermolecular forces, therefore it is possible determine that the major product corresponds to the *trans-syn* isomer and the minor to the *trans-anti* isomer.

4. Experimental

4.1. General procedure and measurements

The reagents were purchased from Aldrich Co. 1,3-Diketone malonates **1a**–**1d** were prepared according to the literature [33,34]. ^{1}H, ^{13}C and ^{119}Sn NMR spectra were recorded on Jeol GLX-270, Jeol Eclipse-400 and Bruker Avance 300-DPX spectrometers, $CDCl_3$ was used as solvent. The solid state ^{119}Sn and ^{13}C CP-MAS NMR spectra for compound **2d** were obtained on a Bruker ASX300 at 10.7 and 10.73 KHz, respectively. High resolution mass spectra (FAB) were obtained with a Jeol JMS-AX 505 mass spectrometer, and infrared spectra were recorded on a Perkin–Elmer 16F PC FT-IR spectrometer. The melting point for compound **2d** was measured in an open capillary tube on a Gallemkamp MFB-595 apparatus and it was uncorrected.

4.2. Preparation of compounds *2a*–*2d*

The procedure outlined below is general for the preparation of compounds **2a**–**2d**.

4.2.1. Synthesis of di-n-butyl[bis{dimethyl-2-(3-oxo-5-phenylpenten-5-ato) malonate}]tin(IV) (*2a*)

A solution of 63.6 mg (0.20 mmol) of **1a** in 10 ml of benzene was placed in a flask equipped with a magnetic stirrer and Dean-Stark trap and 25.7 mg (0.1 mmol) of di-*n*-butyltin(IV) oxide were added. The suspension was refluxed for 8 h. After being cooled to room temperature, the solvent was evaporated under vacuum. The residue was treated with chloroform, the solution was filtered and the solvent was evaporated under

vacuum to yield 41 mg (49%) of compound **2a** as a yellow oil.

4.2.2. Synthesis of di-n-butyl[bis{dimethyl-2-(5-[4-tertbutylphenyl]-3-oxo-penten-5-ato)-malonate}]tin(IV) (2b)

57 mg (0.16 mmol) of compound **1b** and 20.3 mg (0.08 mmol) of di-*n*-butyltin(IV) oxide gave 60 mg (78%) of compound **2b** as a yellow oil.

4.2.3. Synthesis of di-n-butyl[bis{dimethyl-2-(5-[4-trifluoromethylphenyl]-3-oxo-penten-5-ato)-malonate}]tin(IV) (2c)

81.7 mg (0.22 mmol) of compound **1c** and 27.3 mg (0.11 mmol) of di-*n*-butyltin(IV) oxide gave 95 mg (88%) of compound **2c** as a yellow oil.

4.2.4. Synthesis of di-n-buty[bis{dimethyl-2-(5-[4-nitropheny]-3-oxo-penten-5-ato)-malonate}]tin(IV) (2d)

131.2 mg (0.37 mmol) of compound **1d** and 46.6 mg (0.19 mmol) of di-*n*-butyltin(IV) oxide gave a solid, which was recrystallized from methanol to yield 95 mg (54%) of compound **2d**, m.p. 93–94 °C.

4.3. Crystal structure determination of compound 2d

Diffraction data from compound **2d** were collected on an Enraf-Nonius Kappa CCD diffractometer at 168 K. Compound **2d**, $C_{40}H_{50}N_2O_{16}Sn$ (MW 933.53), crystallized in the space group $P\bar{1}$, triclinic, from methanol as yellow light rectangular prisms, size: $0.45 \times 0.33 \times 0.21$ mm^3 with $a = 10.0920(2)$, $b = 13.0880(4)$, $c = 17.3920(2)$ Å, $V = 2142.38(17)$ Å^3, $\alpha = 75.432(10°)$, $\beta = 86.744(15°)$, $\gamma = 74.502(11°)$; $\rho = 1.447$ g/cm^3, $Z = 2$, $\mu = 0.668$ mm^{-1}, $F(0\,0\,0) = 964$. Data collection: a total of 32 417 reflections were measured ($2° > \theta > 26°$), 9831 were independent and of these 3885 were considered observed [$F_o > 4.0\sigma(F_o)$]. Solution and refinement: direct methods, all non hydrogen atoms were refined anisotropically, $R = 0.0606$, $Rw = 0.0570$, $w = 1/\sigma^2$, GoF = 1.1308, largest residual electron density peak/hole in the final difference map: 0.79/−0.50 e Å^{-3}. Atomic scattering factors were taken from the International Tables for X-ray Crystallography [44]. Data reduction were performed by Denzo [45]. All calculations were carried out using the CRYSTALS program package [46] and the molecular graphics by the CAMERON program [47,48].

biphosphine monoxide of metals such as nickel, palladium, rhenium, rhodium and platinum has been extensively described and some species have been found to be efficient catalysts in oligomerization reactions [7,8]. On the other hand various ruthenium complexes with O, P ligands such as keto-phosphine, ether-phosphine, ester-phosphine and *o*-phenylenobis(methyl(phenyl)-phosphine) have been reported, showing the coordination modes P ∼ O: η^1-P and P ∩ O: η^2-O,P [9]. Some of these compounds are regarded as holding interesting properties in catalytic reactions [10].

The present study reports on the synthesis of Ru(II) complexes with the hemilabile biphosphine monoxide ligand $PPh_2(CH)_2P(O)Ph_2$ (dppmO). The behavior of the *tcc*-[$RuCl_2(\eta^2$-dppmO$)_2$] complex – chlorine ions in *trans* positions, phosphorus and oxygen atoms in *cis* positions – towards carbon monoxide was also investigated and proved to be consistent with the predicted hemilabile character of the ligand.

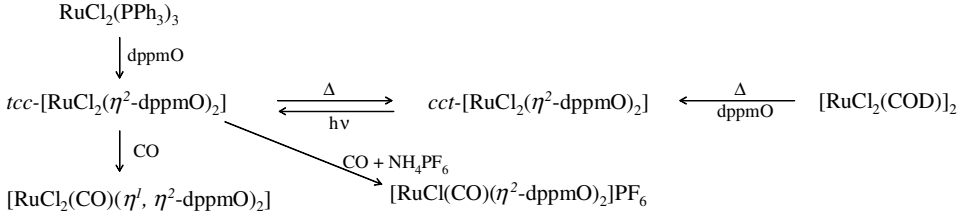
The dppmO ligand presents two chemically different phosphorus atoms and the characterization of the synthesized species through ^{1}H and ^{31}P NMR, reported here, was a very effective tool in disclosing the phosphorus–phosphorus spin coupling systems. The reaction of the biphosphine monoxide ligand with a Ru(III) precursor yielded the *mer*-$RuCl_3(\eta^1,\eta^2$-dppmO$)_2$ complex. The crystallographic structure of the latter was determined by X-ray analysis, identifying a species analogous to the *mer*-$RuCl_3(\eta^1,\eta^2$-$Ph_2PCH_2C(O)Oet)_2$ complex described in the literature [9d].

2. Experimental

All manipulations were performed under an inert atmosphere of purified argon using Schlenk techniques. The solvents were purified according to standard procedures. The $RuCl_2(PPh_3)_3$ [11] and $[RuCl_2(COD)]_2$ [12] complexes as well as the $PPh_2(CH)_2P(O)Ph_2$ [7d] ligand were prepared according to the procedures described in the literature. CO was generated from HCO_2H with H_2SO_4. All the NMR spectra were obtained in a 9.4 T BRUKER DRX400 spectrometer at 298 K, using TMS and H_3PO_4 85% as internal and external references for ^{1}H and ^{31}P (161 MHz), respectively. The IR spectra were recorded as CsI pellets in a Bomen Hartmann and Braun MB Series model spectrometer in the 4000–200 cm^{-1} region. The elemental analysis was performed in a Fison EA 1108 model.

The electrochemical experiments were performed at room temperature in freshly distilled dichloromethane containing 0.1 mol/L TBAP under argon atmosphere (1 atm), using EG/PARC 273A electrochemical equipment. A three-electrode system was used. The working and auxiliary electrodes were a stationary platinum foil and the reference electrode was Ag/AgCl 0.1 mol/L TBAP in CH_2Cl_2, a medium in which ferrocene is oxidized at 0.43 V, with all potentials referred to this electrode.

2.1. *tcc*-[$RuCl_2(\eta^2$-dppmO$)_2$] (t = Cl) (**1**)



$RuCl_2(PPh_3)_3$ (0.050 g, 0.050 mmol) and $PPh_2CH_2P(O)Ph_2$ (0.042 g, 0.10 mmol) were dissolved in acetone (10 mL) and the mixture was stirred for 1 h at room temperature. During this time the color of the solution changed from dark brown to light pink and precipitation of a small amount of solid with the same color occurred. To increase the precipitation ethyl ether was added. The solid was then filtered and washed with ethyl ether. Yield: 0.045 g (94%). *Anal.* Calc. for $C_{50}H_{44}P_4O_2Cl_2Ru$: C, 61.74; H, 4.56. Found: C, 61.69; H, 4.57%. IR (CsI) (RuCl) 317 cm^{-1}; ν(P═O) 1140 cm^{-1}. See Scheme 1.

2.2. *cct*-[$RuCl_2(\eta^2$-dppmO$)_2$] (t = O) (**2**)

$PPh_2CH_2P(O)Ph_2$ (0.23 g, 0.60 mmol) and $[RuCl_2(COD)]_2$ (0.10 g, 0.30 mmol) were added to a solution of dichloromethane/methanol 1:3 (15 mL). The mixture was stirred for 18 h. At the end of this period the solvents were evaporated until only around 3 mL were left and then ethyl ether was added. A light brown solid was obtained, which was then filtered and dried under vacuum. Yield: 0.205 g (70%). *Anal.* Calc. for $C_{50}H_{44}P_4O_2Cl_2Ru$: C, 61.74; H, 4.56. Found: C, 60.85; H, 4.85%. IR (CsI). ν(P═O) 1132 cm^{-1}.

2.3. [$RuCl_2(CO)(\eta^1,\eta^2$-dppmO$)_2$] (**3**)

tcc-[$RuCl_2(\eta^2$-dppmO$)_2$], complex (**1**), was dissolved in 15 mL of dichloromethane and stirred under an atmosphere of CO at room temperature. After 10 min the

Scheme 1. Summary of the reactions for Ru(II) complexes with the dppmO ligand.

light pink color of the solution turned to light yellow. After the removal of around 10 mL of the solvent under vacuum, ethyl ether was added, observing the formation of a pale yellow solid which was then filtered and dried under vacuum. This complex had its structure determined by ^{1}H and ^{31}P NMR. IR (CsI) ν(RuCl) 320 cm^{-1}; $\nu(P_B{=}O)$ 1097 cm^{-1}; $\nu(P_D{=}O)$ 1166 cm^{-1}; ν(CO) 1975 cm^{-1}.

2.4. *[RuCl(CO)(η^2-dppmO)$_2$]PF$_6$ (**4**)*

tcc-[RuCl$_2$(η^2-dppmO)$_2$] (0.015 g, 0.015 mmol) and NH_4PF_6 (0.0244 g, 0.154 mmol) were dissolved in 1:1 methanol/dichloromethane and stirred under a CO atmosphere at room temperature. After 12 h, precipitation of a bright yellow solid occurred. The solid was then washed several times with methanol, filtered and dried under vacuum. Yield: (60%). *Anal*. Calc. for $C_{51}H_{44}P_5O_3F_6ClRu$: C, 55.17; H, 3.99%. Found: C, 54.99; H, 4.19. IR (CsI) ν(RuCl) 320 cm^{-1}; ν(P=O) 1131 cm^{-1}; ν(CO) 1946 cm^1.

2.5. *mer-RuCl$_3$(η^1,η^2-dppmO)$_2$ (**5**)*

$PPh_2CH_2P(O)Ph_2$ (0.13 g, 0.325 mmol) was added to a solution (15 mL) of methanol/dichloromethane (1:3) containing $RuCl_3 \cdot 3H_2O$ (0.04 g, 0.15 mmol). The procedure was conducted under an inert atmosphere to prevent ligand oxidation. After being stirred for 2 h, the mixture was evaporated until a volume of approximately 5 mL remained. A light orange precipitate was obtained with the addition of 15 mL of ether. The compound obtained was then filtered and dried under vacuum. Recrystallization was obtained in a mixture of ethanol/dichloromethane. Yield: 0.083 g (55%). *Anal*. Calc. for $C_{50}H_{44}P_4O_2Cl_3Ru$: C, 58.57; H, 4.33. Found: C, 59.23; H, 4.34%. EPR (experimental) g_y 2.347 and g_z 1.833. EPR (simulated) g_x 2.415, g_y 2.359 and g_z 1.833.

2.6. *X-ray crystallographic analyses of complexes **1** and **5***

Crystals were obtained through slow evaporation of methanol solvent containing the dissolved complexes, at room temperature. A single crystal of approximate dimensions of $0.25 \times 0.2 \times 0.16$ mm^3 for *tcc*-[RuCl$_2$(η^2-dppmO)$_2$] (**1**) and $0.30 \times 0.27 \times 0.20$ mm^3 for *mer*-[RuCl$_3$(η^1,η^2-dppmO)$_2$] (**5**) were used for the data collections and unit cell determinations in an Enraf Nonius CAD-4 diffractometer at room temperature. The data collections were made using the CAD-4 [13] program and the data reductions were performed with the XCAD4 [14] program. The data were corrected for Lorentz, polarization and absorption. The structures were solved using direct methods with SHELXS-97 [15]. The models were refined by full-matrix least-squares procedures on F^2 using SHELXL-97 [16]. The WINGX [17] program was used to analyze and prepare the data for publication. Crystal data, data collection procedures, structure determination

methods and refinement results are summarized in Table 1. Figs. 1 and 2 were prepared using ORTEP-3 for Windows [18]. All non-H atoms were refined anisotropically. Hydrogen atoms were stereochemically positioned and refined using the riding model [21]. The aromatic and methylene H atoms were assigned a thermal parameter 20% greater than that of the equivalent isotropic thermal parameter of the associated C atom. Selected bond lengths and angles are shown in Table 2.

3. Results and discussion

The metal coordination of the *mer*-$[RuCl_3(\eta^1,\eta^2\text{-dppmO})_2]$ species (Fig. 1) may be described as a distorted octahedron with three chlorine atoms in a meridional arrangement, two phosphorus atoms in *trans* positions and the oxygen atom from one of the two phosphine moieties occupying the sixth coordination site. The distortion observed is mainly due to the steric

constraints caused by the chelate ring formed between the phosphine ligand and the metal center. Braunstein and coworkers described the X-ray structure of the *mer*-$[RuCl_3(\eta^1,\eta^2\text{-}(PPh_2CH_2C(O)OEt)_2]$ complex, analogous to the one synthesized here [9d]. In their study the Ru(III)–O distance [2.143(5) Å] is reported to be the shortest one encountered in similar complexes, being just slightly longer than the sum of the two covalent radii. For the *mer*-$[RuCl_3(\eta^1,\eta^2\text{-dppmO})_2]$ species an even shorter Ru(III)–O distance was found [2.076(4) Å]. This fact may be attributed to the greater hard acid character of the oxygen atom, which is directly connected to a phosphorus atom through a double bond system.

The EPR spectrum of *mer*-$RuCl_3(\eta^1,\eta^2\text{-dppmO})_2$ in a dichloromethane frozen solution (at −160 °C) showed a well resolved $g_\perp$ signal of 1.833. The other two g values are very close to each other, with $g_\parallel = 2.388$ and 2.347. This fact indicates the presence of an octahedral configuration with slightly rhombic distortions, consistent with the crystallographic structure shown in Fig. 1.

The structure of the *tcc*-$[RuCl_2(\eta^2\text{-dppmO})_2]$ complex was also determined by single crystal X-ray diffraction, showing both chlorine atoms in *trans* positions and the phosphorus and oxygen atoms of the two ligands in *cis* positions, respectively (Fig. 2). The configuration observed at the metal center is also a distorted octahedron in which the angle between the axial chlorines is smaller than 180°, and the chelate rings show O–Ru–P angles close to 85°. The Ru–Cl distances of ca. 2.4 Å are typical of ruthenium (II) complexes, but the Ru–P bonds are comparatively shorter than those found in simple

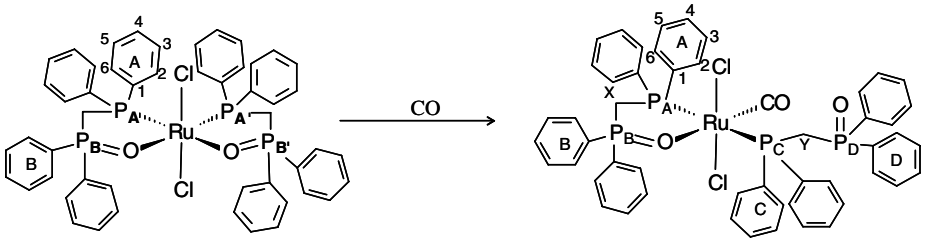
biphosphine ligands probably due to the presence of the oxygen atom, which makes the phosphorus atoms harder [22–29].

The IR spectra of the *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ and *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomers revealed a P=O band dislocated 40–50 cm^{-1} to a region of lower energy, compared to the free ligand [30]. This is indicative of the coordination, through the oxygen atom, of the mono-oxidated ligand to the metal. The Ru–Cl stretching band appears in the region of 310–340 cm^{-1} for these isomeric complexes.

The Ru(II) complexes studied had their structures investigated by NMR, resulting in a very interesting set of data. For this reason, two-dimensional NMR techniques were also applied in order to obtain a deeper understanding of the complexes. The ^1H NMR multiplicity spectral analysis became difficult due to the coupling between ^1H and ^{31}P. In order to eliminate this interaction a $^1H\{^{31}P\}$ spectrum was run, enabling the assignment of the methylene hydrogens between the two phosphorus of the dppmO ligand and the *ortho* hydrogens of the two kinds of aromatic rings (A and B, see Scheme 2). From the integral values it was possible to identify all the other hydrogen chemical shifts. To confirm this assignment a ^1H–^{31}P HMBC was also run using 2 and 8 Hz. In these spectra, it was possible to observe the correlation between the phosphorus and the hydrogen atoms positioned at 2, 3 and 4 bonds, corresponding to *ortho*, *meta* and *para* hydrogens of the phenylic rings A and B. In the $^{13}C\{^1H\}$ spectrum, all the ^{13}C chemical shifts were identified and most of the ^{13}C–^{31}P coupling constants were observed. A ^1H–^{13}C HMCB spectrum enabled the correlation between all the hydrogens and the respective carbons of the phenylic rings. Based on the ^1H–^{31}P HETCOR NMR spectrum, it is possible to conclude that the most deshielded hydrogens pertaining to the phenylic ring correlate to the more shielded phosphorus type (P_A) and not the opposite, as one could expect. These data are presented in the supplemental section.

The ^{31}P chemical shifts and coupling constants of the *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ and *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomers are summarised in Table 3 and the phosphorus nuclei are considered as an AA′XX′ spin system. The values for N and M are actually the sum or difference of the former coupling constants J, where $N = [^2J(P_AP_B) + {}^4J(P_AP_{B'})]$, and $M = [^2J(P_AP_{A'}) + {}^4J(P_BP_{B'})]$. Abraham [31] and Harris [32] consider the $^4J(P_BP_{B'})$ coupling constant to be equal to zero in the simple AA′XX′ systems, which makes the value of the constant M basically the coupling between P_A and $P_{A'}$ corresponding, in our case, to the coupling between the two phosphorus atoms in the *cis* position.

Table 3
$^{31}P\{^1H\}$ NMR of the *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ and *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomers



Complexes	δ	M	N	L
tcc-$RuCl_2(\eta^2\text{-dppmO})_2$	P_A 52.1 P_B 53.8	43.8	17.1	3.6
cct-$RuCl_2(\eta^2\text{-dppmO})_2$	P_A 48.5 P_B 59.2	n.o.	16.0	4.9

n.o., not observable; $N = [^2J(P_AP_B) + {}^4J(P_AP_{B'})]$, in Hz; $M = [^2J(P_AP_{A'}) + {}^4J(P_BP_{B'})]$, in Hz; $L = [^2J(P_AP_B) + {}^3J(P_AP_{B'})]$; δ ppm, in relation to H_3PO_4 85%.

The reaction of *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ with CO generates the $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$ species, which shows a weak band at 320 cm^{-1} related to νRu–Cl, suggesting a *trans* position chlorides, and two strong bands (at 1097 and at 1166 cm^{-1}) attributed to stretching P=O bonds. A very intense band at 1975 cm^{-1} for νC≡O is also observed.

For $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$ (**3**) the $^{31}P\{^1H\}$ NMR spectrum shows four different phosphorus atoms. From ^{31}P–^{31}P COSY (Fig. 3) the deshielded chemical shift was attributed to phosphorus P_B (see Scheme 2) based on the fact that it is coordinated to the metal through oxygen, having a similar chemical environment to the P_B phosphorus in complex **1**. For complex **3**, it was possible to attribute unequivocally all the phosphorus atoms of the molecule (see Table 4). The P_A and P_C signals, with δ 40.8 and 27.2, respectively, are double double doublets due to three possible couplings. Thus, P_A couples with P_C with a coupling constant about 10 times the value of a *cis* coupling, in the 30–40 Hz range [33]. This is characteristic of *trans* position phosphorus atoms and $^2J(P_CP_A)$ = 375.8 Hz.

With the data obtained from ^1H–^{31}P HMBC, using 8 and then 2 Hz for the coupling constants in the NMR experiment, it was possible to finally see the connection

Scheme 2. Structures of *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ and $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$.

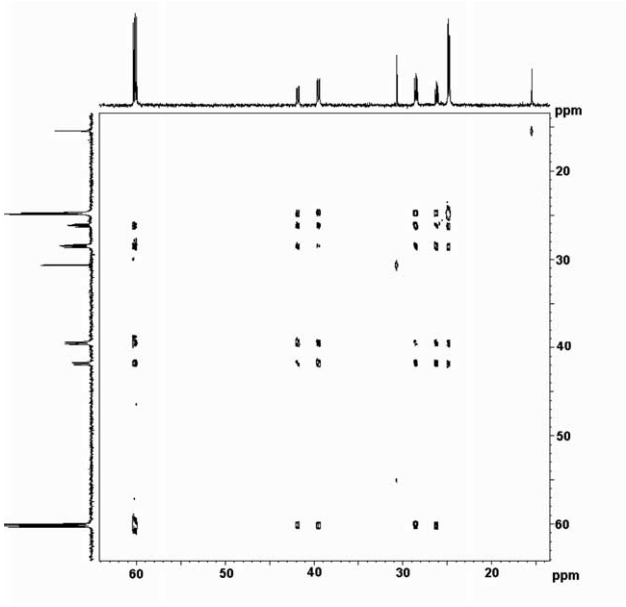


Fig. 3. ^{31}P–^{31}P COSY NMR spectrum in $CDCl_3$ of $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$.

between the *ortho* hydrogen from the phenylic ring, as well as the methylene hydrogen atoms of the ligand, to the corresponding phosphorus atoms (data reported in the supplemental section). In the spectrum where 2 Hz was used, the correlation with hydrogens in *meta* and *para* positions with the respective phosphorus was established. In addition ^1H–^{13}C gHSQC and $^{31}C\{^1H\}$ spectra were also acquired enabling the assignment of all carbon chemical shifts related to the hydrogens of rings A, B, C and D and most of the $J_{13C-31P}$ coupling constants.

A new mono-carbonyl cationic complex was obtained through the reaction of *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ with NH_4PF_6 in the presence of CO. The $[RuCl(CO)(\eta^2\text{-dppmO})_2]PF_6$ complex was also characterized by IR and NMR spectroscopy. The IR spectrum of this new species displays an intense band at 1946 cm^{-1} attributed to $\nu C{\equiv}O$ and a broad band at 1131 cm^{-1} related to the P═O group coordinated to the metal center. A band at 840 cm^{-1} due to the presence of PF_6^- as a counter ion was also observed.

The $^{31}P\{^1H\}$ NMR spectrum of $[RuCl(CO)(\eta^2\text{-dppmO})_2]PF_6$ is very similar to the spectrum of $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$, except that in this case both phosphorus atoms bonded to the oxygen atoms have chemical shifts in the low field region, at 71.3 and 64.1 ppm, respectively (see Table 4). These facts suggest that for this molecule the two P═O groups of the phosphine ligand are coordinated to the metal. The two double double doublets with δ 40.3 and 25.7 were assigned to P_A and P_C, respectively. These two phosphorus atoms are *trans* to one another, therefore they have a coupling constant of ca. 300 Hz.

Cyclic voltammetric measurements of the *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ and *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomers showed reversible processes, attributed to the redox pair RuIII/II. The $E_{1/2}$ value for the *cct* species (Cl atoms in the *cis* position) is more anodic than the value found for the *tcc* complex (Table 5). This fact is due to the *trans* cooperative effect, which describes a rise in the magnitude of the retrodonation metal → ligand in *cis* isomers of $MCl_2(dppm)_2$ (M = Ru and Os) complexes [34,35]. As expected, the carbonyl complexes $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$ and $[RuCl(CO)(\eta^2\text{-dppmO})_2]PF_6$ presented much more anodic $E_{1/2}$ values, even for a reversible $1e^-$ process, as determined by differential pulse voltammetry. It is interesting to observe that when the CO molecule displaces a Cl instead of an O atom of the O,P ligand, as in the case of the cationic species $[RuCl(CO)(\eta^2\text{-dppmO})_2]PF_6$, the redox potential is appreciably increased, as compared to the case in the $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$ complex.

We find that the *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomer can be easily and quantitatively converted into the *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomer by thermolysis (heating at reflux in CH_2Cl_2) and the opposite conversion is reached by photolysis of *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ in CH_2Cl_2

Table 4
^{31}P NMR Chemical Shifts (δ) and J coupling constants (Hz) for $RuCl_2(CO)(\eta^1,\eta^2\text{-dppmO})_2$ and $[RuCl(CO)(\eta^2\text{-dppmO})_2]PF_6$ complexes

solution with white light, resulting in a quantitative conversion to *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$. These processes were followed by cyclic voltammetric and $^{31}P\{^1H\}$ measurements. Similar conversions were observed for the *cis*- and *trans*-$M(dppm)_2Cl_2$ ($M = Os^{II}$, Ru^{II}) complexes [35]. Since the $^{31}P\{^1H\}$ NMR experiments during the isomerization process show free dppmO it is possible to infer that a dissociative mechanism is involved.

As mentioned in the experimental section, the *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomer is light brown while the *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ isomer is pink. Our hypotheses is that the pink color of *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ is due to the MLTC transition at 502 nm of the ruthenium metal to the oxygen atoms of the P=O groups *trans* to phosphorus atoms. In this case, this transition could easily occur (at low energy) since the phosphorus atoms are good π acceptors and could make the oxygen atoms harder and better electron acceptors. It is worth mentioning that complexes such as $RuCl_2(dppm)_2$ (with the absence of an oxygen atom in the ligand) are yellow or light brown and show MLTC transitions below 400 nm [35]. *cct*-$RuCl_2(\eta^2\text{-dppmO})_2$ shows a MLTC transition at 340 nm ($\varepsilon \approx 10^3$ $M^{-1}\,cm^{-1}$). On the other hand *tcc*-$RuCl_2(\eta^2\text{-dppmO})_2$ presents two shoulders (at about 340 and 400 nm) and a well defined band at 502 nm ($\varepsilon \approx 10^2$ $M^{-1}\,cm^{-1}$). Thus the isomerization process can be followed by UV–Vis spectroscopy in CH_2Cl_2.

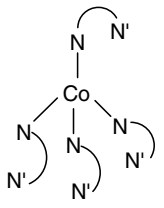
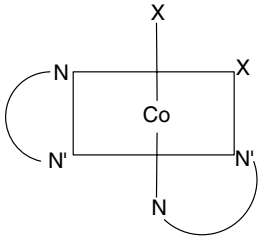
favorable situation with completely filled bonding e-orbitals (Td) versus not yet filled bonding t_{2g}–orbitals for the Oh situation in the high spin Co(II) system. This idea has prompted us to carry out the reaction between $Zn(RaaiR')Cl_2 \cdot H_2O$ and $Co(ClO_4)_2 \cdot 6H_2O$ under ambient conditions. The product characterization by single-crystal X-ray diffraction showed tetrahedral coordination of the complex in which the four imidazole-N from four RaaiR′ ligands coordinates to Co(II). The product isolated from the direct reaction of $Co(ClO_4)_2 \cdot 6H_2O$ and RaaiR′ is chemically and structurally identical with the product obtained from the transmetallation reaction. The reaction of pseudohalide (N_3^- and NCS^-) with $Co(RaaiR')_4^{2+}$ has forced the pendant azo function to chelate Co(II) along with the expulsion of two ligand molecules to synthesise octahedral $Co(RaaiR')_2X_2$. The pseudo-octahedral complexes may exist as five geometrical isomers [6]. In the present case, one isomer has been isolated and characterized by X-ray diffraction.

2. Results and discussion



2.1. Synthesis and formulation

1-Alkyl-2-(arylazo)imidazole [RaaiR′, where R = H (**a**), Me (**b**); R′ = Me (**1**), Et (**2**)], is an unsymmetrical *N*,*N*′-bidentate chelator where *N* and *N*′ refer to N(imidazole) and N(azo) donor centers, respectively. It can also act as a monodentate ligand coordinating through imidazole-N to the metal ion [12–17]. A methanolic solution of $Co(ClO_4)_2 \cdot 6H_2O$ and RaaiR′ (in mole proportions of 1:2, 1:3, 1:4 or 1:6) have isolated brown crystalline products of the same composition, $[Co(RaaiR')_4](ClO_4)_2 \cdot H_2O$ (**3**,**4**). Transmetallation of $[Zn(RaaiR')Cl_2 \cdot H_2O]$ with $Co(ClO_4)_2 \cdot 6H_2O$ in the presence of $NaClO_4$ has also isolated $[Co(RaaiR')_4](ClO_4)_2 \cdot H_2O$ (**3**,**4**). In these complexes, RaaiR′ coordinates through the imidazole-N in a tetrahedral arrangement around Co(II). Microanalytical data support the composition of the complexes and single-crystal X-ray diffraction of one of the complexes has been established as tetrakis 1-methyl-2-(*p*-tolylazo)imidazole cobalt(II) perchlorate (**3b**).



RaaiR′

R = H (**a**), Me (**b**); R′ = Me (**1/3/6**), Et (**2/4/7**)

3, **4**

5 (X = N_3), **6/7** (X = NCS)

The complexes **3** and **4** are 1:2 electrolytes (Λ_M = 160–170 Ω^{-1} cm^2 mol^{-1} in MeCN). In search of the reactivity of $[Co(RaaiR')_4](ClO_4)_2 \cdot H_2O$, we have examined the reaction of N_3^- (NaN_3), NCS^- (NH_4NCS) with a representative compound, $[Co(HaaiMe)_4](ClO_4)_2 \cdot H_2O$ (**3a**), and the products have been characterized as $Co(HaaiMe)_2X_2$ [X = N_3^-(**5**), NCS^-(**6**/**7**)]. A mixture of $Co(ClO_4)_2 \cdot 6H_2O$, NaN_3 (NH_4SCN) and HaaiMe in 1:2:2 mole proportion in methanol solution under stirring conditions in air has also isolated $Co(HaaiMe)_2(X)_2$ (X = N_3, NCS).

2.2. Structure description

2.2.1. *[Co(MeaaiMe)$_4$](ClO$_4$)$_2$ · H$_2$O* (*3b*)

The molecular structure is shown in Fig. 1. Selected bond parameters are given in Table 1. The cationic complex $[Co(MeaaiMe)_4]^{2+}$ consists of a central cobalt atom surrounded by two pairs of MeaaiMe in which each pair is symmetry related as evident from bond lengths and angles. The Co atom sits at the center of a tetrahedron. The ligand, MeaaiMe acts as a monodentate ligand and binds through the imidazole-N donor center. The coordination environment of Co is compressed along the crystallographic *c*-axis in such a way that two of the N–Co–N angles are higher than the tetrahedral angle

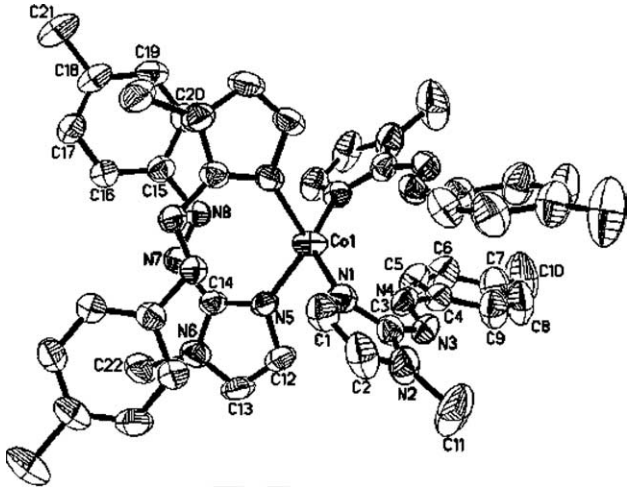


Fig. 1. ORTEP view of $[Co(MeaaiMe)_4]^{2+}$ (**3b**).

Bond distance (Å)		Bond angle (°)	
Co(1)–N(1/1a)	2.045(3)	N(1)–Co(1)–N(1a)	139.51(17)
Co(1)–N(5/5a)	2.079(3)	N(1a)–Co(1)–N(5a)	96.53(11)
N(1)–C(3)	1.329(5)	N(1/1a)–Co(1)–N(5a/5)	102.90(12)
N(3)–N(4)	1.272(4)	N(1)–Co(1)–N(5)	96.53(11)
N(5)–C(14)	1.330(4)	N(5a)–Co(1)–N(5)	121.75(16)
N(7)–N(8)	1.257(4)	N(4)–N(3)–C(3)	112.5(3)
Cl(1)–O(1)	1.315(3)	N(8)–N(7)–C(14)	113.0(3)
Cl(1)–O(2)	1.314(3)	O(2)–Cl(1)–O(3)	109.46(9)
Cl(1)–O(3)	1.314(3)	O(2)–Cl(1)–O(4)	109.41(9)
Cl(1)–O(4)	1.314(3)	O(2)–Cl(1)–O(1)	109.58(9)
N(1)–C(3)	1.329(5)	O(3)–Cl(1)–O(1)	109.51(9)
		O(4)–Cl(1)–O(1)	109.45(9)

with a value of N(1)–Co(1)–N(1a) 139.51(17)° and N(5)–Co(1)–N(5a), 121.75(16)°. Two other N–Co–N angles show a lower value, each of them, N(1)–Co(1)–N(5) and N(1a)–Co(1)–N(5a), being 96.53(11)°. The remaining N–Co–N angles [N(1)–Co(1)–N(5a) or N(1a)–Co(1)–N(5)] are 102.90(12)°. The angular distortion may be due to steric crowding provided by the pendant *p*-tolylazo group. Two types of Co–N bond lengths are Co(1)–N(1), 2.045(3); Co(1)–N(5), 2.079(3) Å. The N=N bond lengths are N(3)–N(4), 1.272(4) and N(7)–N(8), 1.257(4) Å. The free ligand N=N distance is 1.250(1) Å [22,23]. This suggests that one of the N=N groups in the coordinated ligand may participate in a $d\pi(Co) \rightarrow \pi^*$ transition.

2.2.2. [Co(HaaiMe)$_2$(NCS)$_2$] (*6a*)

The single-crystal X-ray structure of Co(HaaiMe)$_2$(NCS)$_2$ (**6a**) is shown in Fig. 2 and bond parameters are set out in Table 2. HaaiMe acts as an unsymmetric bidentate chelator of N-imidazole(N) and N-azo(N′). The other two coordination sites are occupied by two *N*CS groups (underlined atom refers to the donor center). Thus, the molecule shows an octahedral arrangement about Co(II) with *cis*-N(imidazole), N(imidazole); *cis*-N(azo), N(azo) and *cis*-*N*CS, *N*CS donor centers, and has been abbreviated thereafter *cis*–*cis*–*cis*-[Co(HaaiMe)$_2$(NCS)$_2$]. The N–Co–N bond angles subtended by the chelating HaaiMe are N(2)–Co–N(5), 65.8(5)°, N(6)–Co–N(9), 70.42(10)°. The two angles differ widely and deviate significantly from the ideal 90° for a regular octahedral geometry. Observed chelate angles in platinum metal complexes (Ru^{II}, Os^{II}, Pd^{II}, Pt^{II}) of arylazoimidazole [5–11] lie at 76 ± 2° while in the series of 3d transition metal complexes (Mn^{II}, Co^{II}, Ni^{II}, Cu$^{I/II}$) [24–27] the angle is 70 ± 2°. The chelate complexes of Group 12 metals (Zn^{II}, Cd^{II}, Hg^{II}) [12–17] show even lower chelate angles, 65 ± 2°. The chelate angles in the present complex appear in the reported range 65–76°. The *trans* angle values also support the structural distortion [N(2)–Co–N(9), 172.67(10)° while N(6)–Co–N(10), 135.77(11)° and N(1)–Co–N(5) 158.6(6)°], exhibiting severe distortion. The chelate plane consisting of Co, N(2), C(9), N(4), N(5) (plane-1) shows severe distortion from the mean plane while the other chelate plane consisting of Co, N(6), C(14), N(8), N(9) is a good plane (plane-2) (mean deviation ⩽0.02 Å). A closer look to the molecular structure shows that the chelate plane-2 constitutes a part of the molecular plane consisting of Co, N(6), N(9), N(10) and N(2). The pendant phenyl group is no longer planar and makes a dihedral angle of 55–76° with the respective chelate plane. The azo-N(5) is placed at an axial position. Azo-N stereochemically demands larger space

Table 2
Bond distances (Å) and bond angles (°) of [Co(HaaiMe)$_2$(NCS)$_2$] (**6a**)

Bond distance (Å)		Bond angle (°)	
Co–N(1)	2.000(3)	N(1)–Co–N(2)	92.84(11)
Co–N(2)	2.073(3)	N(1)–Co–N(6)	106.97(13)
Co–N(6)	2.020(3)	N(1)–Co–N(9)	84.81(11)
Co–N(9)	2.487(3)	N(1)–Co–N(10)	108.71(13)
Co–N(10)	1.976(3)	N(2)–Co–N(6)	103.79(11)
Co–N(5)	2.73(2)	N(2)–Co–N(9)	172.67(10)
S(1)–C(4)	1.623(4)	N(2)–Co–N(10)	99.71(11)
N(1)–C(4)	1.158(5)	N(6)–Co–N(9)	70.42(10)
N(4)–N(5)	1.259(4)	N(6)–Co–N(10)	135.77(11)
N(8)–N(9)	1.261(4)	N(9)–Co–N(10)	87.63(10)
		Co–N(1)–C(4)	160.6(3)
		Co–N(2)–C(2)	131.5(2)
		Co–N(2)–C(9)	123.0(2)
		Co–N(6)–C(1)	135.1(2)
		Co–N(6)–C(14)	119.0(2)
		Co–N(9)–N(8)	113.23(19)
		Co–N(9)–C(3)	132.6(2)
		N(1)–Co–N(5)	158.6(6)
		N(2)–Co–N(5)	65.8(5)
		N(6)–Co–N(5)	78.6(6)
		N(5)–Co–N(9)	116.1(9)
		N(5)–Co–N(10)	77.6(1)
