and becomes unfavourable at an axial position. The distortion is thus manifested by elongation of the Co–N(5) distance (2.73(2) Å) and smaller chelate bite angle (N(2)–Co–N(5), 65.8(5)°). However, the sum of the van der Waals radii of Co(II) and azo-N are greater than the Co–N(5) bond length and warrants a covalent interaction [28]. The Co–N(9) bond length (N(9) is an azo-N) is shorter ($\Delta d \sim 0.2$ Å) than Co–N(5) and supports stronger covalency. The six Co–N bond lengths are expectedly unequal for a distorted octahedral geometry. The shortest length is observed for Co–N(NCS) (Co–N(10), 1.976(3); Co–N(1), 2.000(3) Å) and the longest one are exhibited by Co–N(azo) (Co–N(9), 2.487(3); Co–N(5), 2.732(1) Å). The Co–N(imidazole) distances lie in between them: Co–N(2), 2.073(3) Å and Co–N(6), 2.020(3) Å. The distortion in chelate plane-2 (vide supra) may be the reason for the elongation of the Co–N(2) bond length. The shortening of the Co–N(imidazole) bond distances (Co–N(2/6)) relative to Co–N(azo) (Co–N(5/9)) suggest preferential binding of N(imidazole) to Co(II). The N=N distances are longer than the free ligand values [22,23]. The elongation may be due to the combined effect of the steric requirement of the chelated azoimine group as well as d(Co) → π*(azo) charge transference.

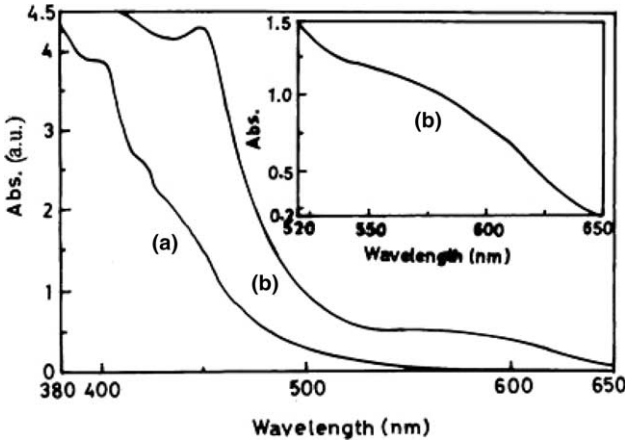

Fig. 3. UV–Vis spectra of (a) $[Co(MeaaiMe)_4](ClO_4)_2 \cdot H_2O$ (**3b**) [0.21×10^{-3} M] and (b) $[Co(HaaiMe)_2(NCS)_2]$ (**6a**) [2.1×10^{-3} M] in MeCN solvent.

2.3. Spectra and magnetism

The IR stretchings of the complexes are assigned on comparing with the free ligand data [6,24]. Not all the bands have been assigned and some significant vibrations are compared. The broad band appearing at 3414–3416 cm^{-1} is due to $\nu(H_2O)$. The strong band at 1085–1093 cm^{-1} with a weak stretch at 624–627 cm^{-1} are due to $\nu(ClO_4)$ for complexes **3** and **4**. The complexes upon exposure to heat treatment in a thermostatic oven at 80° for 10 min do not show $\nu(H_2O)$ (~3415 cm^{-1}). This shows water loss during the thermal program. The complexes absorb water reversibly on cooling in air, which is evident from the reappearance of $\nu(H_2O)$ in the IR spectra. However, we could not study the complete thermal behaviour because of explosive ClO_4^- in the complexes. The strong sharp band at 2076–2079 cm^{-1} is due to ν(CN) of –NCS for complex **6**. Moderately intense stretchings at 1583–1600 and 1438–1452 cm^{-1} are due to ν(C=N) and ν(N=N), respectively, for all the complexes [8–10].

Solution electronic spectra (Fig. 3) of the complexes were recorded in acetonitrile solution in the UV/Vis region (250–900 nm). The data are listed in Table 3. The complexes **3** and **4** show intense bands at >400 nm which may be due to MLCT transitions. The electronic spectra support the tetrahedral structure of the complexes [29]. For the complexes **6** and **7**, three transitions in the range 470–640 nm are observed. The intensity

[a] Solvent: MeCN.
[b] Solvent: dry MeCN; Pt-disk working electrode, Pt-wire auxiliary and SCE, TBAP as supporting electrolyte, scan rate 50 mV s^{-1}, potential $E_{1/2} = (E_{pa} + E_{pc})/2$ in V, $\Delta E_p = |E_{pa} - E_{pc}|$ in mV.
[c] E_{pc} in V.

pattern of the bands are different; the transition at 450–455 nm is of high intensity ($\varepsilon \sim 10^4$ M^{-1} cm^{-1}) and sharp while the other two transitions, 520–575 and 605–620 nm, are weak ($\varepsilon \sim 10^2$–10^3 M^{-1} cm^{-1}) and broad. Based on the low intensity and low energy nature the bands are considered to be d–d transitions. The high intense transition at 450–455 nm may be assigned to MLCT transitions. The spectral pattern and the intensity support tetrahedral-Co in **3**, **4** and octahedral-Co in **6**, **7** [29].

Bulk magnetic moment (μ) measurements of both $[Co(RaaiR')_4](ClO_4)_2 \cdot H_2O$ (**3**, **4**) and $[Co(RaaiR')_2(X)_2]$ (X = N_3 (**5**), NCS (**6**/**7**)) complexes at room temperature (300 K) suggest high spin mononuclear ones (Table 3). $[Co(RaaiR')_4](ClO_4)_2 \cdot H_2O$ exhibit μ in the range 4.5–4.8 BM and $[Co(RaaiR')_2(NCS)_2]$ exhibit μ in the range 4.3–4.4 BM, slightly greater than the spin only value [30].

2.4. Electrochemistry

Redox properties of the complexes were examined by cyclic voltammetry in MeCN solution in the potential range ±1.6 V versus a SCE electrode. A representative voltammogram is shown in Fig. 4 and data are given in Table 3. $Co(RaaiR')_4(ClO_4)_2$ exhibit a couple on scanning in the positive direction ($0.0 \rightarrow -1.6$ V) at 0.9–1.2 V and peak-to-peak separation $\Delta E_P > 80$ mV, which shows quasireversibility of the voltammogram. On scanning in the negative direction ($0.0 \rightarrow -1.6$ V) three redox responses were observed at −0.2 to −0.3; −0.5 to −0.6 and −1.0 to −1.2 V. These three couples are quasireversible ($\Delta E_P \geqslant 100$ mV). The current height of the third couple is about double that of the first or second couple. Redox response at positive to reference is oxidative in nature and may be assigned to a Co(III)/Co(II) type. Redox couples at negative to SCE are reductive responses. There are four dangling azo groups in the imidazole-N coordinated RaaiR′ and may show, in principle, four azo reductions [–N=N–] $\rightarrow$ [–N^{-}–N–]$^{-}$. This is indeed observed. The third and fourth reductions may overlap at high negative potential. However, the potential is very close to the free ligand redox data [6].

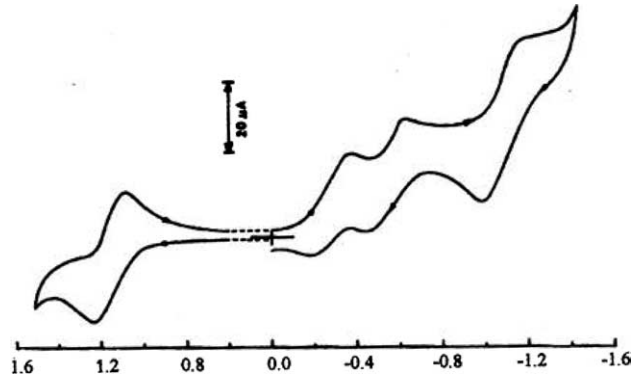

Fig. 4. Cyclic voltammogram of $[Co(MeaaiMe)_4](ClO_4)_2 \cdot 2H_2O$ (**3b**) in MeCN solvent.

Cyclic voltammograms of $Co(RaaiR')_2(NCS)_2$ also record similar observations. The Co(III)/Co(II) couple appears at 0.8–0.9 V and four reductive responses at −0.2 to −0.3, −0.5 to −0.6, −1.2 to −1.3, −1.5 to −1.6 V. Reductions refer to accommodation of electrons into the LUMOs dominated by the azo groups. Ligand reductions appear at less negative values for $Co(RaaiR')_2(NCS)_2$ compared to $[Co(RaaiR')_4](ClO_4)_2$ which may be due to better stability of the chelated azoimine fragment in the former. The higher Co(III)/Co(II) redox potential for $Co(RaaiR')_4^{2+}$ compared to $Co(RaaiR')_2(NCS)_2$ suggests fairly stable Co(II) in the Td geometry compared to that of the Oh geometry. The electrostatic effects in the tetrahedral compounds, which are already in +2 state $(Co(RaaiR')_4^{2+}$, means they are hard to oxidize, where as oxidation of the octahedral complexes $Co(RaaiR')_2(NCS)_2$ is easier because they are neutral.[1]

3. Conclusion

We have synthesized cobalt(II) complexes of 1-alkyl-2-(arylazo)imidazole (RaaiR′) and one of the complexes has been structurally characterized as tetrahedral tetrakis $[Co(RaaiR')_4](ClO_4)_2 \cdot H_2O$. The structure shows that RaaiR′ act as monodentate imidazole-N donor ligands. The reaction of N_3^- or SCN^- with $[Co(RaaiR')_4](ClO_4)_2 \cdot H_2O$ has synthesized $Co(RaaiR')_2(X)_2$ ($X = N_3^-, SCN^-$). The structural characterization shows pseudooctahedral *cis*-N(azo), N(azo); *cis*-N(imidazole), N(imidazole) and *cis*-X,X configuration. Their spectral, magnetic and electrochemical study confirms the structure of the complexes.

4. Experimental

4.1. Materials

$Co(ClO_4)_2 \cdot 6H_2O$ was prepared by treatment of cobalt carbonate (E. Merck, India) with perchloric acid (E. Merck, India) followed by slow evaporation on a steam bath, filtration through a fine glass-frit and preservation in a desiccator containing concentrated sulfuric acid for subsequent use. 1-Alkyl-2-(arylazo)imdazoles (RaaiR′) were prepared following the literature procedures [24]. All other chemicals and solvents are reagent grade. Solvents are used after drying.

[1] Explanation is thankfully received from one of the referees.

4.2. Physical measurements

Microanalyses (C, H, N) were performed using a Perkin–Elmer 2400 CHNO/S elemental analyzer. Spectroscopic measurements were carried out using the following instruments: UV–Vis spectra, reflectance spectra, JASCO UV–Vis/NIR model V-570; IR spectra (KBr disk, 4000–200 cm^{-1}), JASCO FT-IR model 420. Room temperature magnetic moments were measured using a vibrating sample 155 magnetometer at 298 K. Molar conductances (Λ_M) were measured in a Systronics conductivity meter 304 model using ca. 10^{-3} M solutions in MeOH. Electrochemical measurements were carried out with the use of a computer controlled EG&G PARC VersaStat model 250 electrochemical instrument using a Pt-disk working electrode and Pt-wire auxiliary electrode. The reported results are referenced to SCE in acetonitrile and are uncorrected for junction potential. Cyclic voltammograms of the complexes were drawn within the potential range +1.6 to −1.6 versus SCE. Estimation of cobalt and manganese were carried out by the complexometric titration method [31].

4.3. Preparation of $[Co(MeaaiMe)_4](ClO_4)_2 \cdot H_2O$ (**3b**)

4.3.1. Direct reaction

1-Methyl-2-(*p*-tolylazo)imidazole (MeaaiMe) (0.1 g, 0.50 mmol) in MeOH (10 ml) was added dropwise to a stirred solution of $Co(ClO_4)_2 \cdot 6H_2O$ (0.045 g, 0.125 mmol) in MeOH (10 ml) at 298 K. The red-orange solution was stirred for 15 min, filtered and left undisturbed for two weeks. Bright red-orange crystals were obtained. They were washed with a cold water–methanol mixture and ether. Finally, they were dried in vacuo. The yield was 0.10 g (75%). The microanalytical data of the complex is as follows, $[Co(MeaaiMe)_4](ClO_4)_2 \cdot H_2O$ (**3b**): *Anal*. Calc. for $C_{44}H_{50}N_{16}Cl_2O_9Co$: C, 49.07; H, 4.64; N, 20.82; Co, 5.48. Found: C, 49.15; H, 4.58; N, 20.91; Co, 5.43%. IR (KBr disk) (cm^{-1}): $\nu(H_2O)$ 3416 (m); $\nu(ClO_4^-)$ 1085(s), 624(w); ν(C=N) 1597(m), ν(N=N) 1445(m).

All the other complexes were prepared by the same procedure. In all cases, crystalline products were obtained. The yield varied from 75% to 80% and microanalytical and IR data of the complexes are as follows. $[Co(HaaiMe)_4](ClO_4)_2 \cdot H_2O$ (**3a**): *Anal*. Calc. for $C_{40}H_{42}N_{16}Cl_2O_9Co$: C, 47.06; H, 4.12; N, 21.96; Co, 5.78. Found: C, 47.18; H, 4.03; N, 21.82; Co, 5.58%. IR (KBr disk) (cm^{-1}) $\nu(H_2O)$ 3416 (m); $\nu(ClO_4^-)$ 1085(s), 624(w); ν(C=N) 1587(m); ν(N=N) 1444(m). $[Co(HaaiEt)_4]_4(ClO_4)_2 \cdot H_2O$ (**4a**) *Anal*. Calc. for $C_{44}H_{50}N_{16}Cl_2O_9Co$: C, 49.07; H, 4.64; N, 20.82; Co, 5.48. Found: C, 49.17; H, 4.59; N, 20.87; Co, 5.45%. IR (KBr disk) (cm^{-1}) $\nu(H_2O)$ 3414 (m); $\nu(ClO_4^-)$ 1089(s), 626(w); ν(C=N) 1598(m); ν(N=N) 1446(m). $[Co(MeaaiEt)_4](ClO_4)_2 \cdot H_2O$ (**4b**): *Anal*. Calc. for $C_{48}H_{58}N_{16}Cl_2O_9Co$: C, 50.88; H, 5.12; N, 19.79; Co, 5.21. Found: C, 50.79; H, 5.21; N, 19.70; Co, 5.19%. IR (KBr disk) (cm^{-1}) $\nu(H_2O)$ 3416 (m); $\nu(ClO_4^-)$ 1089(s), 627(w); ν(C=N) 1598(m); ν(N=N) 1446(m).

Reactions under identical conditions with $Co(ClO_4)_2 \cdot 6H_2O$ and MeaaiMe in different mole proportions, 1:2, 1:3, 1:6, have isolated complexes of same composition.

4.3.2. Transmetallation reaction

To a solution of $[Zn(MeaaiMe)(H_2O)Cl_2]$ (0.18 g, 0.50 mmol) in methanol $Co(ClO_4)_2 \cdot 6H_2O$ (0.1 g, 0.25 mmol) was added in the same solvent and stirred for 1 h. The solution was slowly evaporated in air from which bright orange-red crystals were separated. They were then filtered, washed with cold methanol and dried over $CaCl_2$.

4.4. Reaction of NCS^- with $[Co(HaaiMe)_4](ClO_4)_2 \cdot H_2O$

4.4.1. Method I

To a methanolic suspension of $[Co(HaaiMe)_4](ClO_4)_2 \cdot H_2O$ (0.25 g, 0.25 mmol), NH_4SCN (0.07 g, 1 mmol) was added and refluxed. Within a few minutes the suspension became clear orange-red and the refluxing was continued for 2 h. Bright brown crystals were deposited on slow cooling and collected by filtration. They were then dried in a $CaCl_2$ dessicator and the yield was 0.09 g. The composition of the complex has been supported by microanlytical, spectral and magnetic data. $Co(HaaiMe)_2(NCS)_2$ (**7a**). *Anal*. Calc. for $C_{22}H_{20}N_{10}S_2Co$: C, 48.26; H, 3.65; N, 25.60. Found: C, 48.39; H, 3.71; N, 25.56%. IR (KBr disk) (cm^{-1}) ν(C=N) 1595(m); ν(N=N) 1436(m); ν(SCN) 2076(s).

Similarly, the reaction of NaN_3 with $[Co(HaaiMe)_4](ClO_4)_2 \cdot H_2O$ in a 4:1 mole ratio in MeOH under identical reaction conditions has isolated $Co(HaaiMe)_2(N_3)_2$ (**5a**). *Anal*. Calc. for $C_{20}H_{20}N_{14}Co$: C, 46.60; H, 3.88; N, 38.06. Found: C, 46.72; H, 3.93; N, 37.95; Co, 11.04%. IR (KBr disk) (cm^{-1}) ν(C=N) 1589(m); ν(N=N) 1434(m); $\nu(N_3)$ 2044(s).

4.4.2. Method II

1-Methyl-2-(phenylazo)imidazole (HaaiMe) (0.09 g, 0.5 mmol) in MeOH (15 ml) was added dropwise to a stirred solution of $Co(ClO_4)_2 \cdot 6H_2O$ (0.25 g, 0.25 mmol) in the same solvent (10 ml) at 298 K. The brown solution was stirred for 15 min followed by the addition of NH_4SCN (0.04 g, 0.5 mmol) in MeOH (10 ml). The solution colour intensified. It was then filtered and left undisturbed for a week. A dark brown

crystal was obtained. It was washed with water and then by methanol. Finally, it was dried in vacuum. Yield was 65%.

4.5. Synthesis of $Co(HaaiMe)_2X_2$ [X = N_3 (5), NCS (6/7)]

These complexes were prepared by a common procedure and the reaction conditions had been settled following the synthesis of $Co(MeaaiMe)_2(N_3)_2$ [24].

To a methanolic solution (20 ml) of $CoCl_2 \cdot 6H_2O$ (0.06 g, 0.25 mmol), HaaiMe (0.09 g, 0.50 mmol) in the same solvent was added dropwise and stirred under ambient conditions for 4 h. The solution was evaporated slowly in air to half of the original volume and an excess of NaN_3 (0.06 g, 1 mmol) in MeOH was added. The solution was kept in a freezer. Crystals were deposited then separated by filtration, washed with cold methanol and dried over $CaCl_2$ in a dessicator. Yield: 35%.

Other products were also prepared following a similar procedure by adding NH_4SCN in place of NaN_3. The yield was 60%. The microanalytical data of the complexes are as follows: $Co(HaaiMe)_2(NCS)_2$ (**6a**). *Anal.* Calc. for $C_{22}H_{20}N_{10}S_2Co$: C, 48.26; H, 3.65; N, 25.60. Found: C, 48.34; H, 3.74; N, 25.52%. IR (KBr disk) (cm^{-1}) ν(C=N) 1587(m); ν(N=N) 1436(m); ν(NCS) 2076(s). $Co(MeaaiMe)_2(NCS)_2$ (**6b**). *Anal.* Calc. for $C_{24}H_{24}N_{10}S_2Co$: C, 50.09; H, 4.17; N, 24.35, Co, 10.24%. Found: C, 50.01; H, 4.20; N, 24.21; Co, 10.22%. IR (KBr disk) (cm^{-1}) ν(C=N) 1589(m); ν(N=N) 1434(m); ν(NCS) 2078(s). $Co(HaaiEt)_2(NCS)_2$ (**7a**). *Anal.* Calc. for $C_{24}H_{24}N_{10}S_2Co$: C, 50.09; H, 4.17; N, 24.35; Co, 10.24. Found: C, 50.00; H, 4.22; N, 24.24; Co, 10.21%. IR (KBr disk) (cm^{-1}) ν(C=N) 1587(m); ν(N=N) 1436(m); ν(NCS) 2079(s). $Co(HaaiEt)_2(NCS)_2$ (**7b**). *Anal.* Calc. for $C_{26}H_{28}N_{10}S_2Co$: C, 51.74; H, 4.64; N, 23.21; Co, 9.77. 4.6. X-ray crystal structure analysis

Suitable single crystals of complexes **3b** and **6a** were mounted on a Siemens CCD diffractometer equipped with graphite monochromated Mo Kα (λ = 0.711073 Å) radiation at 293 K for **3b** and 294 K for **6a**. The crystallographic data are listed in Table 4. Unit cell parameters were determined from least squares refinements of setting angles of 6372 reflections for **3b** and 2875 for **6a** with 2θ in the range $3.06° \leqslant 2\theta \leqslant 58.84°$ and $3.4° \leqslant 2\theta \leqslant 56.6°$, respectively. The intensity data were corrected for Lorentz and polarisation effects and an empirical absorption correction was also employed using the SAINT program for complexes. A total of 17268 [unique data, 6372] and 5909 [unique data, 2875] reflections were measured for complexes **3b** and **6a**, respectively. All these structures were solved by direct methods and followed by successive Fourier and difference Fourier syntheses. Full-matrix least-squares refinements on F_o^2 were carried out using SHELXL-97 with anisotropic displacement parameters for all non-hydrogen atoms. Hydrogen atoms were constrained to ride on the respective carbon or nitrogen atoms with isotropic displacement parameters equal to 1.2 times the equivalent isotropic displacement of their parent atom in all cases. All calculations were carried out using SHELXS-97, SHELXL-97, PLATON-99 and ORTEP-3 programs.

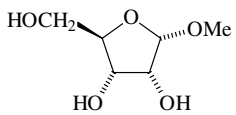
AMP



CMP

Adenosine

β-Rib1Me

α-Rib1Me

2. Experimental

2.1. Materials

Adenosine 5′-monophosphate (sodium salt, Sigma, >99%), cytidine 5′-monophosphate (sodium salt, Sigma, >98%), adenosine (Sigma, 99%), methyl α- and β-D-ribofuranoside (Sigma, 100%), L-cysteine (Cys, Sigma, 98%), sodium chromate (Merck), were used without further purification. $Na[CrO(ehba)_2]\cdot H_2O$ was synthesized from 2-ethyl-2-hydroxybutanoic acid (ehba, Aldrich, 99%), and sodium dichromate (Merck) in acetone (Merck, AR grade) according to the literature method [17]. Water was deionized and doubly distilled from $KMnO_4$. 4-(2-Hydroxyethyl)-1-piperazineethanesulfonic acid (HEPES, Research Organics) was added to adjust the pH value of the solution to 7.5. Acetate buffer (made from Merck, AR, reagents) was used for experiments at pH 5.5.

Warning: Cr^{VI} and Cr^{V} compounds are toxic and carcinogens [18].

2.2. EPR Measurements

EPR Spectra were obtained on a Bruker EMX spectrometer. The microwave frequency was generated with a Bruker 04 ER (9-10 GHz) and measured with a Bruker EMX 048T frequency meter. The magnetic field was measured with a Bruker EMX 035M NMR-probe gaussmeter. Reactions were carried out by addition of $Na[Cr^{V}O(ehba)_2]$ (1.0 mM), or Na_2CrO_4 (1.0 mM) and Cys (1.0 mM), to solutions of nucleotide, nucleoside or riboside, (2.00 to 150 mM) in Ar-saturated HEPES buffer (100 mM, pH 7.5 ± 0.1) at 20 ± 1 °C. Stock solutions were: $Na[Cr^{V}O(ehba)_2]$ (100 mM) in DMF; Na_2CrO_4 (100 mM) in H_2O; and Cys (100 mM) in H_2O (kept under Ar). EPR Spectra were simulated with the program PEST WINSIM [19], using 100% Lorentzian lineshapes. The spectral parameters for each Cr^{V} species were consistent within all simulations, with maximum deviations in the g_{iso} values being ±0.0001 units. In the simulations, values for ^{1}H a_{iso} were included only where the ^{1}H a_{iso} value is greater than the line width (LW) of the Cr^{V} species, since the signal is not significantly affected where the ^{1}H a_{iso} value is $\leqslant$LW.

3. Results

The one-electron reduction of Cr^{VI} by Cys at pH 7.5 generates Cr^{V}, which rapidly disproportionates [20]. When this reaction is performed in the presence of excess ribonucleotide, Cr^{V} can be stabilized by formation of Cr^{V}/nucleotide complexes. These Cr^{V} species can be followed by EPR spectroscopy, where strong isotropic signals are observed at room temperature in the X-band spectra. In HEPES (pH 7.5) buffer, the reaction of chromate with Cys (1:1 ratio) in the presence of 100-times excess of AMP or CMP, gives the Cr^{V} EPR spectra shown in Fig. 1(a) and (b). The best fit of the spectra affords one quintet at $g_{iso} = 1.9803$ and one quartet at $g_{iso} = 1.9798/7$ (signals were deconvoluted by fitting the spectra to Lorentzian derivatives, correlation $R > 0.99$), with four ^{53}Cr (9.55% abundance, $I = 3/2$) hyperfine peaks at 16.2×10^{-4} cm^{-1} spacing (Table 1).

The reaction of 20 mM adenosine, 1 mM Cr^{VI} and 1 mM Cys at pH 7.4 gives the spectrum shown in Fig. 1(c). Deconvolution of the EPR signal affords one quintet at $g_{iso} = 1.9803$ and one quartet at $g_{iso} = 1.9798$ with hyperfine coupling constants listed in Table 1. This signal had been previously proposed to consist of only one component with Cr^{V} coupled to four equivalent carbin-

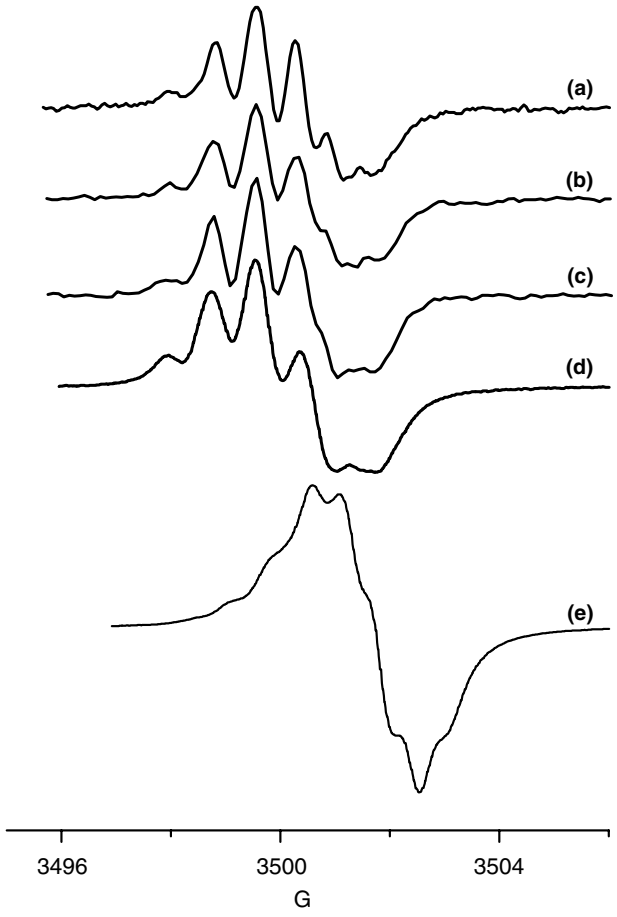


Fig. 1. X-band EPR spectra of mixtures 1 mM Cys + 1 mM Cr^{VI} and: (a) 100 mM AMP, pH 7.5, t = 7 min; (b) 100 mM CMP, pH 7.5, t = 7 min; (c) 20 mM adenosine, pH 7.4, t = 2 h; (d) 150 mM β-Rib1Me, pH 7.5, t = 24 h; (e) 100 mM α-Rib1Me, pH 5.5, t = 24 h. Frequency = 9.7 GHz, mod. ampl. = 0.2 G.

olic protons [21], however, such a model does not reproduce the signal pattern. The mixture of β-Rib1Me, Cr^{VI} and Cys (150:1:1) at pH 7.5 (or pH 5.5) also affords EPR spectra composed of one quintet at 1.9803 and one quartet at 1.9798 (Fig. 1(d)), while the Cr^{V} EPR spectra generated by reaction of 100 mM α-Rib1Me, 1 mM Cr^{VI} and 1 mM Cys in acetate buffer (pH 5.5) consist of two quintets at g_{iso} = 1.9793 and 1.9791 (Fig. 1(e), Table 1).

Alternatively, Cr^{V}/nucleotide complexes were obtained by the ligand-exchange reaction of $[Cr^{V}O(ehba)_2]^-$. At pH 7.5 and room temperature, $[Cr^{V}O(ehba)_2]^-$ is not stable [22], but in the presence of excess ribonucleotide rapid ehba substitution takes place and the ligand-exchange products can be easily observed by EPR spectroscopy. The EPR spectra of ribonucleotide/$[Cr^{V}O(ehba)_2]^-$ mixtures show a quintet at g_{iso} = 1.9803, a quartet at g_{iso} = 1.9798/7 and two triplets at g_{iso} = 1.9792 and 1.9788, besides the singlet of the starting Cr^{V} complex at g_{iso} = 1.9783. The relative intensity of these signals depends on the nucleotide to Cr^{V} mole ratio and the reaction time. Spectra taken 5 min after mixing AMP or CMP with $[Cr^{V}O(ehba)_2]^-$ in 2-5:1 mole ratio are dominated by the signal at g_{iso} = 1.9783 (>50%) (Figs. 2(b), (c) and 3(a)) while for ribonucleotide:Cr^{V} mole ratio $\geqslant$20:1, only the signals of the ehba-exchanged products are observed (Figs. 2(d) and 3(b)). When a 100:1 mole ratio is used, the Cr^{V} signals at g_{iso} = 1.9803 and 1.9798/7 are the dominant EPR features in the spectra (Figs. 2(e) and 3(c)). The final spectra of these ligand-exchange reactions are superimposable to those of the AMP (or CMP), Cr^{VI} and Cys (100:1:1) mixtures, although they are 200-times more intense than the latter ones.

Table 1

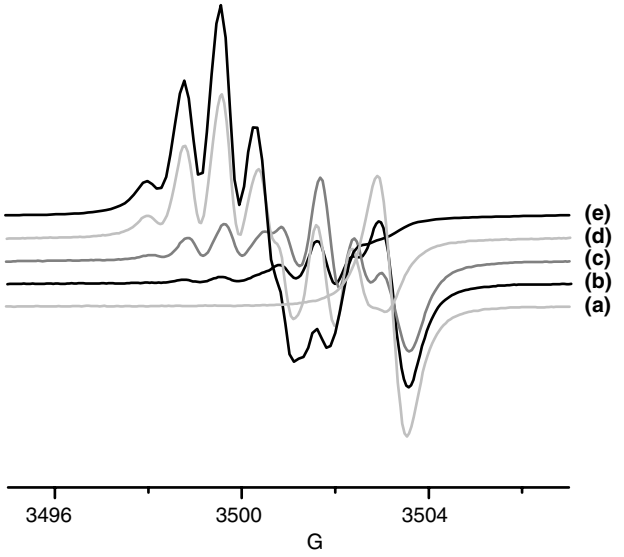

Fig. 2. X-band EPR spectra of (a) $[Cr^{V}O(ehba)_2]^-$; and mixtures of 1 mM $[Cr^{V}O(ehba)_2]^-$ with: (b) 2 mM AMP, $t = 4$ min; (c) 5 mM AMP, $t = 4$ min; (d) 20 mM AMP, $t = 19$ min; (e) 100 mM AMP, $t = 10$ min. Frequency = 9.7 GHz, pH 7.5, mod. ampl. = 0.2 G.

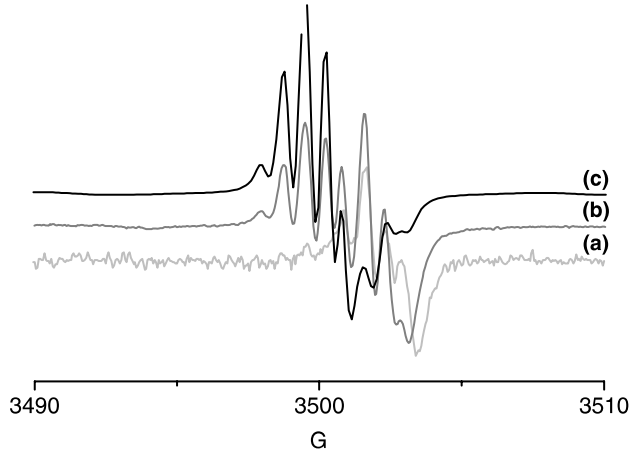

Fig. 3. X-band EPR spectra from mixtures of 1 mM $[Cr^{V}O(ehba)_2]^-$ and: (a) 2 mM CMP, $t = 19$ min; (b) 20 mM CMP, $t = 19$ min; (c) 100 mM CMP, $t = 12$ min. Frequency = 9.7 GHz, pH 7.5, mod. ampl. = 0.2 G.

Reactions of 20 mM of the following nucleotides, nucleosides and nucleic bases: 2′-deoxyadenosine, adenine, 2′-deoxythymidine 5′-monophosphate (dTMP), 2′-deoxythymidine, thymine, guanine, 2′-deoxyguanosine, 3′,5′-CMP, 3′,5′-dTMP, 3′,5′-AMP, guanosine 3′,5′-monophosphate, with 1.0 mM Cr^{VI} and 1.0 mM Cys in Ar-saturated 200 mM HEPES buffer (pH 7.4 ± 0.1) at 20 °C, for 1.5–2 h, gave no EPR signal.

4. Discussion

The most common means of characterizing Cr^{V} complexes in solution is EPR spectroscopy. The EPR spectral parameters, g_{iso} and A_{iso} values, together with the proton shf coupling, are useful in determining the binding modes of ligands to the Cr^{V} centre [8,16]. An empirical relationship between the nature and number of donor groups and the EPR spectral parameters of Cr^{V} complexes has been established [16,23]. Thus, we used the isotropic EPR parameters (g_{iso} and A_{iso} values) and the shf pattern of the signal to characterize the Cr^{V}/AMP and Cr^{V}/CMP species formed in the reaction of AMP (or CMP) with either Cr^{VI} and Cys or $[Cr^{V}O(ehba)_2]^-$.

The two EPR signals at $g_{iso} = 1.9803$ (quintet) and 1.9798/7 (quartet) (A_{iso} (16.2×10^{-4} cm^{-1})) observed in the Cr^{VI}/Cys reaction performed in the presence of excess AMP or CMP, at pH 7.5, have g_{iso} and A_{iso} values consistent with those calculated for five-coordinate oxo-Cr^{V} complexes with four alcoholato donors ($g_{calc} = 1.9800$, $A_{calc} = 16.5 \times 10^{-4}$ cm^{-1}) [8,23]. The simulation of the shf pattern indicates that the EPR signal is a composite of two oxo-Cr^{V}-ribonucleotide$_2$ species with four (two from each chelate ring) and three carbinolic protons coupled to the Cr^{V} electronic spin, respectively (Table 1, Figs. 4(a) and 5(a)). This shf pattern is consis-

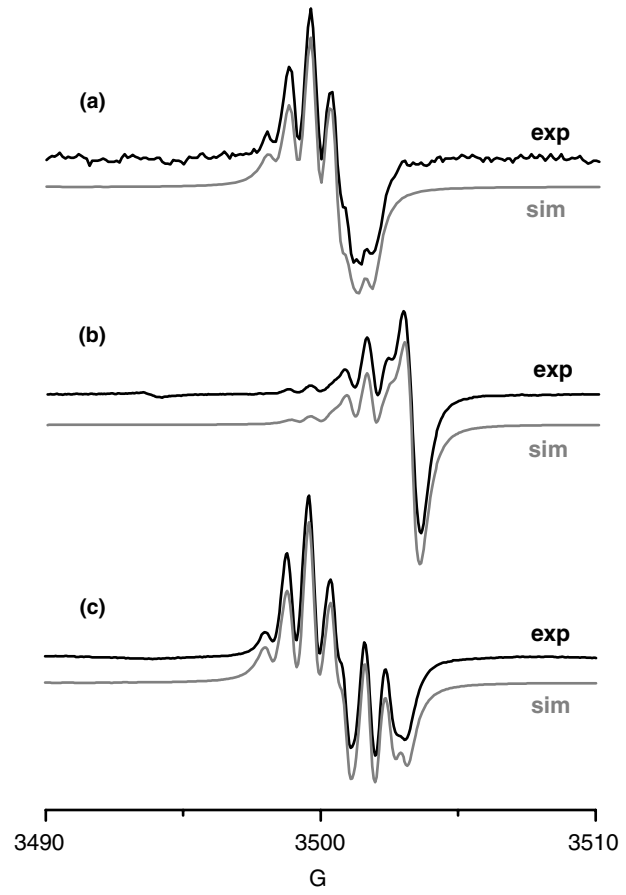

Fig. 4. Experimental and simulated X-band EPR spectra from mixtures of: (a) AMP + Cr^{VI} + Cys (100:1:1); (b) AMP + $[Cr^{V}O(ehba)_2]^-$ (2:1), $t = 4$ min; (c) AMP + $[Cr^{V}O(ehba)_2]^-$ (20:1), $t = 19$ min. LW = 0.35 G.

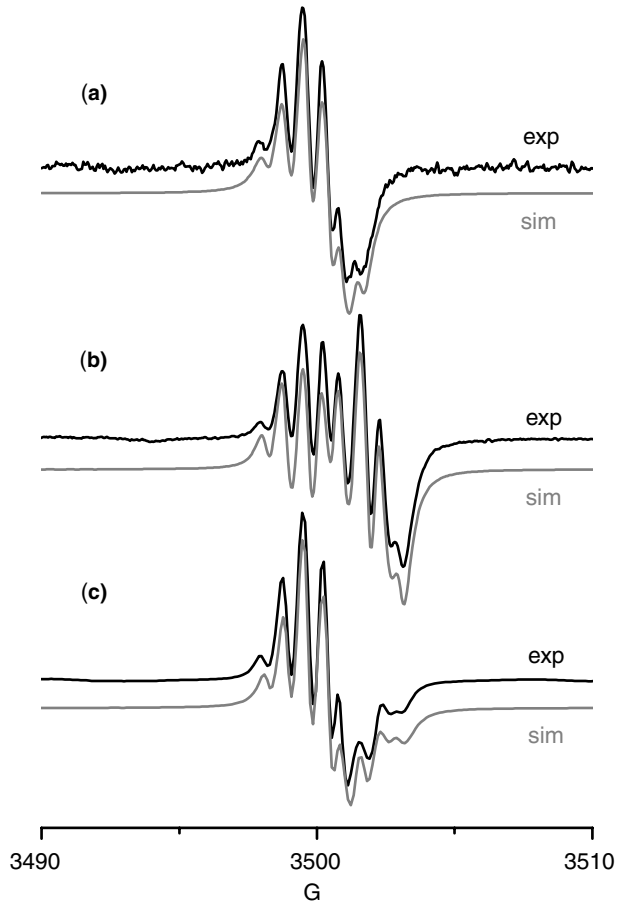

Fig. 5. Experimental and simulated X-band EPR spectra from mixtures of: (a) CMP + Cr^{VI} + Cys (100:1:1); (b) CMP + $[Cr^{V}O(ehba)_2]^-$ (20:1), $t = 20$ min; (c) CMP + $[Cr^{V}O(ehba)_2]^-$ (100:1), $t = 12$ min. LW = 0.35 G.

tent with that previously observed for oxo-Cr^{V} bischelates formed with 1,2-cyclopentanediol [24].

The values of the shf coupling constants (^1H a_{iso}) are maximal when the carbinolic protons lay near the Cr^{V}-ligand plane ($a_{Heq} \sim 1 \times 10^{-4}$ cm^{-1}), and decrease as the carbinolic protons move away this plane to reach the minimal values at the largest angles ($a_{Hax} \sim 0.35 \times 10^{-4}$ cm^{-1}) [24–26]. The EPR spectra of the Cr^{V} species formed with both AMP and CMP show two Cr^{V} components split by non equivalent carbinolic protons coupled to the Cr^{V} electronic spin: one Cr^{V} component with four protons disposed at angles in between the "pseudo-axial/equatorial" orientations, and a second Cr^{V} species with two "pseudo-axial" protons (^1H a_{iso} 0.41×10^{-4} cm^{-1}, <LW (AMP) and 0.40×10^{-4} cm^{-1}, <LW (CMP)), and two protons protruding at intermediate angles. This EPR pattern is very close to that found for the average conformations of the two geometric isomers of $[Cr^{V}(O)(1,2\text{-cyclopentanediolato})_2]^-$ [24]. So that, in the present case, the two Cr^{V} components can be attributed to the two geometric isomers of $[Cr^{V}(O)$–$O^{2\prime},O^{3\prime}$-ribonucleotide$_2]^-$ (**I** and **II** in Fig. 6). The fact that the shf coupling constants obtained for $[CrO(O^{2\prime},O^{3\prime}$-AMP$)_2]^-$ and $[CrO(O^{2\prime},O^{3\prime}$-CMP$)_2]^-$ are only slightly different (Table 1), indicates that the Cr^{V} complexes formed with the two nucleotides adopt a similar conformation.

The ligand-exchange reactions of $[Cr^{V}O(ehba)_2]^-$ with AMP or CMP result in five Cr^{V} EPR signals with $g_{iso} = 1.9803$ (quintet), 1.9798/7 (quartet), 1.9792 (triplet), 1.9788 (triplet) and 1.9783 (singlet) (Figs. 4(b), (c) and 5(b), (c)). The quintet and quartet correspond to the two geometric isomers of $[CrO(O^{2\prime},O^{3\prime}$-ribonucleotide$)_2]^-$ as discussed above for the nucleotide/Cys/Cr^{VI} system. The g_{iso} values and the multiplicity of the signals at $g_{iso} = 1.9792$ and 1.9788 are consistent with those expected for the two geometric isomers of $[Cr^{V}O(ehba)$-$(O^{2\prime},O^{3\prime}$-ribonucleotide$)]^-$ (**III**–**IV** in Fig. 6) [9]. The singlet at $g_{iso} = 1.9783$ is due to $[Cr^{V}O(ehba)_2]^-$ and is observed at low nucleotide:Cr^{V} mole ratios (Fig. 4(b)) or very short reaction times. When more than 20-times

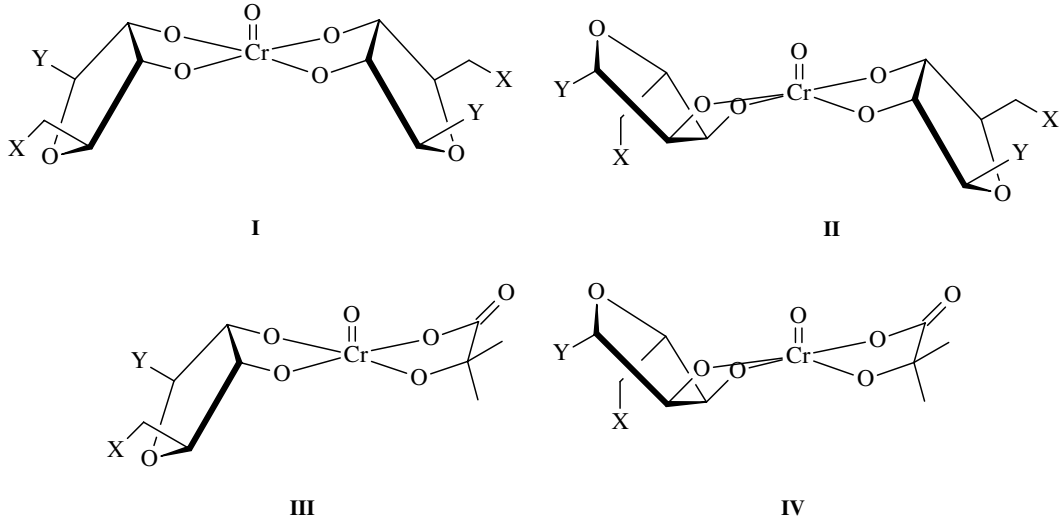

Fig. 6. Structures of Cr^{V} complexes of β-ribose derivatives (X = OPO_3 or OH; Y = nucleic base or OMe).

excess of nucleotide over Cr^V is used, the oxo-Cr^V-$O^{2'},O^{3'}$-ribonucleotide$_2$ isomers dominate the EPR spectra (Fig. 5(c)).

The reaction of adenosine with Cr^{VI}/Cys (20:1:1) at pH 7.5 affords EPR spectra analogous to those of the AMP/Cr^{VI}/Cys mixtures. The kinetic profiles for the formation of these Cr^V species in both reactions are essentially the same, and the EPR spectra are superimposable at any time. This reveals that the 5′-O-monophosphate functionality has no influence on either the chelating properties of the nucleotide or the structure of the resulting Cr^V bischelate.

The reaction of β-Rib1Me with Cr^{VI}/Cys gives EPR spectra with the same pattern as observed for the Cr^V/nucleotide and Cr^V/nucleoside systems: a quintet at g_{iso} 1.9803 and a quartet at g_{iso}1.9798. The ^1H a_{iso} values of $[CrO(O^2,O^3\text{-Rib1Me})_2]^-$ are only slightly different from those of $[CrO(O^{2'},O^{3'}\text{-ribonucleotide})_2]^-$, giving EPR signals with the same spectral features. This means that the Cr^V species formed with the β-1-substituted D-ribose derivatives have very close conformations, with a similar spatial orientation of the coupled carbinolic protons. Unlike β-Rib1Me, α-Rib1Me affords differently featured EPR spectra (Fig. 1(e), Table 1): g_{iso} values lower than observed for Cr^V species formed with the β-derivatives, and a different shf splitting of the signal that reveals a substantial modification of the Cr^V-bischelate conformation.

Other modifications in the ribose moiety, such as replacement of the 2′-hydroxyl by hydrogen or esterification of the 3′-hydroxyl with phosphate groups, suppress completely the chelating properties of the nucleotide. These results reveal that OH groups in both the 2′ and 3′ positions of the ribose ring are required for stabilization of Cr^V.

5. Conclusions

The common EPR spectral pattern found for Cr^V complexes of adenosine, AMP, CMP and β-Rib1Me reveals that the shape of the Cr^V EPR signal is not affected by groups oriented *anti* to the 2,3-diolato moiety of the ribofuranosic ring. Small differences in the ^1H a_{iso} coupling constants of the Cr^V bischelates formed with these ligands reflect the adoption of very similar conformations for the four β-ribose derivatives under study. The shf pattern of these Cr^V bischelates differs from that of the Cr^V species formed with α-Rib1Me – in which the methoxy group is *syn* to the 2,3-diolato donor site. This observation indicates that the α- and β-derivatives of ribose afford Cr^V-bischelates with different geometries, and thus, different spatial orientations of the carbinolic protons in the chelate ring. Another important difference concerns the g_{iso} values: α-Rib1Me affords Cr^V complexes with g_{iso} values lower than the β-isomer, revealing that the spatial orientation of the 1-substituent influences the strength of the diolato-Cr^V linkage. Therefore, EPR spectra can be used as an easy means to distinguish between Cr^V complexes formed with α- and β-1-subtituted-D-ribose derivatives bound to Cr^V through the 2,3-diolato group.

the geometry at the metal centres. In addition, the presence of other ligands in the same coordination sphere also plays an important role in the resulting structure. Particularly, different supramolecular assemblies involving stacking interactions as well coordination and/or hydrogen bond motifs can be observed when pyrazoles and pseudohalides (e.g. azide and thiocyanate) are combined with transition metal ions. For instance, coordination bonds are responsible for the formation of a 1-D linear chain structure in $[Ni(\mu_2\text{-}1,3\text{-}N_3)(5\text{-}HmPz)_4]_n(ClO_4)_n$ [14] (5-HmPz = 5-methylpyrazole) whereas intermolecular hydrogen bonds between pyrazoles and pseudohalides result in supramolecular species composed by monomers of the type $[MX_2(HPz^*)_4]$ (M = Mn(II), Ni(II); $X = N_3^-$, SCN^-; HPz* = pyrazole, 3-substituted pyrazole [15–17]) or $[Pd(SCN)_2(HdmPz)_2]$ (HdmPz = 3,5-dimethylpyrazole) [18].

An interesting situation arises when azide anion and pyrazolate group act simultaneously as bridges, yielding the $M(\mu\text{-}1,1\text{-}N_3)(\mu\text{-pyrazolato})M$ core (M = d^8 electronic systems). The crystal packing of $[(CO)_2Rh(\mu_2\text{-}1,1\text{-}N_3)(\mu\text{-pyrazolato})Pd(\eta^3\text{-}C_3H_5)]$ shows a 1-D columnar stacking arrangement of heterobimetallic units with extended Rh–Rh interactions [19].

This work was developed on the basis of our earlier studies on the spontaneous formation of a coordination polymer from the reaction among $[PdCl_2(MeCN)_2]$, pyrazole (HPz), and azide group [20]. This prompted us to initiate a research program based on the supramolecular pyrazole-pseudohalide systems. In this paper we wish to report the syntheses and spectroscopic studies of a new class of coordination polymer having a backbone composed of palladium atoms bridged simultaneously by pyrazolato and azido groups: $[(N_3)(HL)Pd\{Pd_3(\mu\text{-}N_3)(\mu\text{-}L)_5\}_{10}(\mu\text{-}L)_2Pd(L)(HL)]$ {L = Pz^- (**1**); mPz^- (**2**), IPz^- (**3**)} and $[(N_3)(HPz)Pd\{Pd_6(\mu\text{-}N_3)_2(\mu\text{-}Pz)_5(\mu\text{-}L)_5\}_{10}(\mu\text{-}L)_2Pd(Pz)(HPz)]$ {L = mPz^- (**4**), $dmPz^-$ (**5**); IPz^- (**6**) {L = pyrazolate (Pz^-), 4-methylpyrazolate (mPz^-), 4-iodopyrazolate (IPz^-), 3,5-dimethylpyrazolate ($dmPz^-$)}.

2. Experimental

2.1. General comments

The materials used in the syntheses were all commercially available and were used without purification. All solvents were dried and kept over molecular sieves prior to use. Literature procedures were followed for the synthesis of $[PdCl_2(MeCN)_2]$ [21].

2.2. Synthesis of *1–3*

To a deep orange solution of $[PdCl_2(MeCN)_2]$ (0.39 mmol) in 10 mL of MeOH, the appropriate pyrazolyl ligand (0.81 mmol) dissolved in 2 mL of methanol was added dropwise. After stirring the resulting mixture for 5 min, NaN_3 (0.81 mmol) dissolved in 2 mL of water was added dropwise yielding a yellow suspension, which was filtered off and the obtained solid was washed with methanol and dried under vacuum. Yield 75%.

2.3. Synthesis of *4–6*

Pyrazole (0.43 mmol) and the corresponding substituted pyrazolyl ligand (0.43 mmol), dissolved in 2 mL of methanol, were added dropwise to a deep orange solution of $[PdCl_2(MeCN)_2]$ (0.39 mmol) in 10 mL of MeOH. After stirring the resulting mixture for 5 min, NaN_3 (0.81 mmol) dissolved in 2 mL of water was added affording a yellow suspension, which was filtered off and the obtained solid was washed with methanol and dried under vacuum. Yield 70%.

2.4. Instrumentation

The C, H and N analyses were carried out with a CE Instruments EA1110 CHNS-O microanalyzer. The molecular weight determinations were performed by vapor phase osmometry, using chloroform as solvent, in the Analytische Laboratorien Gmbh, Malissa und Reuter, D-51789 Lindlar Germany. Infrared spectra were

recorded as KBr pellets or $CHCl_3$ solution in KBr window on a Nicolet FTIR-Impact 400 spectrophotometer (range 4000–400 cm^{-1}). ^{1}H and $^{13}C\{^1H\}$ NMR spectra were recorded in $CDCl_3$ solutions at room temperature on a Brucker AC-200 spectrophotometer working at 200 MHz for hydrogen and 50 MHz for carbon, using $SiMe_4$ as internal standard. Electronic absorption spectra were obtained in chloroform solution with a Perkin–Elmer Lambda 14 P spectrometer.

3. Results and discussion

During our investigations on some mononuclear pyrazolyl complexes of Pd(II) containing pseudohalides [18,22–24], we have obtained physical, analytical and spectroscopic evidences of the formation of an unusual coordination polymer when azide and pyrazole were employed in the reaction (compound **1**) [20]. Elemental analysis results together with osmometry data of samples obtained from repeated syntheses were consistent with a $C_{165}H_{167}N_{143}Pd_{32}$ formulation. Compound **1** was obtained as an air stable amorphous powder, soluble in chloroform and toluene, giving rise to non-conducting solutions. The solution behavior of **1** closely parallels those of some organic polymers, showing two stages of dissolution. First, it is observed a swollen and solvated mass which broke up, in a second stage, affording a solution. In addition, thin molecular films can be obtained by slow solvent evaporation. Encouraged by these observations, we synthesized a series of analogous compounds employing 4-methylpyrazole (**2**) and 4-iodopyrazole (**3**) as well mixed species with two distinct pyrazole ligands (**4**, **5**, and **6**). The analytical data obtained for the compounds are listed in Table 1. The aim was to search for trends in the spectroscopic and structural aspects as a function of pyrazole ligand. In this way, compounds **4**–**6** were successfully synthesized under identical experimental conditions used for **1**. It is important to point out that these mixed polymers are structurally similar to **1**–**3** (see Scheme 3), but have random distributions of pyrazole ligands. The obtained

Scheme 3. Syntheses of **1**–**3**.

solids are thermally stable up to 250 °C, air stable and, with exception of **3** and **6**, are soluble in chloroform.

Crystallographic studies on the polymers via X-ray diffraction of single crystals or Rietveld method were not performed due to their amorphous nature. For this reason the challenging task of this work was to present a consistent structural proposal for these systems based on physical, analytical and spectroscopic evidences.

3.1. Infrared spectroscopy

The most important bands observed in the IR spectra of the complexes along with their tentative assignments are presented in Table 2. It has been shown that the coordination mode of pyrazole-type ligands can be inferred on basis of IR data [25]. In principle the absence of an intense and broad νNH band (ca. 3300 cm^{-1}) cannot distinguish unambiguously between the anionic monodentate (C_s) and exobidentate (C_{2v}) coordination modes. However, the presence of exobidentate pyrazolato groups, clearly detected in the spectra of **1**–**6**, could be inferred by other IR evidences. Firstly it was observed the shift to lower frequency (1491–1558 cm^{-1}) of the band attributed to the ring breathing mode when compared with the free ligand (1533–1596 cm^{-1}) (see Table 2). The number of bands assigned to γCH vibrational modes can be also used as diagnosis for pyrazole coordination. The appearance of the expected two γCH bands at 870 and 742 cm^{-1} for **1** strongly supports the exobidentate character of pyrazole instead of three ones for monodentate pyrazole complexes [25]. Concerning the 4-substituted-pyrazolyl derivatives two γCH bands are expected for monodentate mode. In this work the presence of only one absorption in the spectra of **2** and **3** (819–827 cm^{-1} region) reveals exobidentate coordination. With regard to the mixed species **4**–**6** the simultaneous coordination of two distinct bridging pyrazolates was confirmed by IR spectra.

A strong $\nu_{as}N_3$ band appeared in the 2081–2087 cm^{-1} region in all IR spectra, shifted about 40 cm^{-1} to higher frequencies with respect to Pd(II) compounds containing terminal azido groups [18,20,22–24], being therefore consistent of bridging azide [26]. The ν_sN_3 mode occurs as a medium-weak band in the range 1250–1360 cm^{-1} and is only IR active when azido group acts in a terminal or asymmetrical bridging (*end-on*) fashion [27]. For this reason the presence of the ν_sN_3 band in the IR spectra of **1**–**6** in the 1248–1253 cm^{-1} region strongly suggests the existence of azido group coordinated in an *end-on* fashion. It is worth mentioning that IR spectra of the soluble polymers were also obtained in chloroform solution and exhibited the same pattern of those registered in solid state. Therefore it seems plausible suggest that the structures of the polymers in the solid state are retained in solution.

3.2. Molecular weight determinations

Osmometry data obtained for the soluble polynuclear complexes (see Table 1) revealed a value of $n = 10$ ($\overline{M_w} = 7600$ g mol^{-1}, **1**; $\overline{M_w} = 8600$ g mol^{-1}, **2**; $\overline{M_w} = 15400$ g mol^{-1}, **4**; $\overline{M_w} = 16200$ g mol^{-1}, **5**), indicating a low degree of polymerization. It is important to point out that additional IR results showed a good agreement with these molecular weight data since end-group bands associated to terminal azide (2035–2040 cm^{-1}, $\nu_{as}N_3$) and neutral monodentate pyrazole (ca. 3300 cm^{-1}, νNH) are also indicative of the formation of low-weight polymers.

3.3. NMR spectroscopy

NMR experiments carried out for compounds **1**, **2**, **4**, and **5** exhibited a series of broad signals being consistent with their oligomeric or polymeric structures. The spectra displayed characteristic resonances corresponding to

hydrogen and carbon pyrazolate atoms of the inner-chain repeating units of the polymers and low-intensity signals originated from pyrazolyl end-groups (Table 3).

Therefore, it becomes evident from NMR the formation of low-molecular weight coordination polymers in agreement with osmometry and IR spectroscopy. Moreover, the ^{1}H NMR spectra display two distinct pyrazolate environments in a 2:1 ratio, which we attributed to the six-membered ring Pd(μ-L)$_2$Pd and the Pd(μ-N$_3$)(μ-L)Pd metallocycle, respectively. Such assumption is also supported by $^{13}C\{^{1}H\}$ NMR spectra. For instance, the spectrum of **1** clearly shows the typical ^{13}C signals of the Pd(μ-Pz)$_2$Pd moiety [28] centered at 140.55 ppm (C$_3$/C$_5$), 107.12 and 106.25 ppm (C$_4$) whereas the Pd(μ-N$_3$)(μ-Pz)Pd core is associated to the resonances at 139.05 (C$_3$/C$_5$) and 104.81 ppm (C$_4$) (see Scheme 4).

3,5-dimethylpyrazolate (dmPz$^-$)	Me	H	Me

Scheme 4. Numbering scheme of pyrazolate groups.

3.4. Structural propositions

Although proposals for the structures of compounds **1**–**6** on the basis of elemental analyses, molecular weight determinations and spectroscopic data are not a trivial matter, some models are suggested in this work from comparisons with structurally characterized compounds containing the boat-shaped M(μ-Pz)$_2$M [28] and M(μ-Pz)(μ-N$_3$)M frameworks (M = d^8 electronic systems; Pz = pyrazolate). According to earlier reports [19,29–31] the five-membered M(μ-Pz)(μ-X)M core (X = OH$^-$, Cl$^-$, N$_3^-$) adopts a nearly planar conformation which is suitable to columnar stacking, giving rise to 1-D polymeric structures. Therefore one of our assumptions involves the existence of such arrangement along the polymeric backbones of this series, in which the bidentate (Pz)$_2$Pd(Pz)$_2$ fragment acts as U-shaped spacer-chelator groups keeping the Pd(μ-Pz)(μ-N$_3$)Pd rings stacked above one another, along a given axis, yielding a polymeric structure with sinusoidal conformation. Another structural possibility take into account that the (Pz)$_2$Pd(Pz)$_2$ fragment adopts an inverted configuration compared to the U-shaped one, giving rise to a linear polymeric chain. In order to illustrate the suggested structural models, we choose compound **1** to represent the isostructural series, as can be seen in Fig. 2.

It is worth mentioning that other alternative structures are possible depending on the sequence of Pd(μ-L)(μ-N$_3$)Pd units (e.g. alternate "up and down") in the polymeric chain as well the ligands disposition in the (L)$_2$Pd(L′)$_2$ unit of the mixed-species. Thus, all these coordination polymers are likely to be correctly formulated as random copolymers.

3.5. UV–Vis spectroscopy

The UV–Vis results (Table 4) agree with the proposed structural models for the complexes. The most striking feature of electronic spectra was the presence of low-intensity absorptions at ca. 410–460 and 733–759 nm which do not appear in the spectra of the mononuclear complexes [Pd(N$_3$)$_2$(L)$_2$] (L = 1-phenyl-3-methylpyrazole, 3,5-dimethylpyrazole), being suggestive of the polynuclear nature of these compounds. These bands can be assigned to 4dz^2 (a_{1g}) → 5pz (a_{2u}) transitions whose energies strongly depend on intrachain metal–metal separation: on decreasing Pd–Pd distance there is an enhancement of the 4dz^2 → 5pz interaction causing a red-shift in this transition [32]. Many authors have ascribed the dz^2–pz transition as evidence of columnar stacking of square-planar d^8 complexes via metal–metal interactions in the solid state [33–35]. In addition it was also observed in the electronic spectra intense UV bands in the spectral range of 258–291 nm attributed to d–d transitions ($^{1}A_{1g} \rightarrow {}^{1}E_g$), which are typical of d^8 square-planar systems [36]. In **1** it can also be observed

a $^1A_{1g} \rightarrow {}^1A_{2g}$ band near 307 nm. A LMCT transition, assigned to $\pi_{N3} \rightarrow b_{1g}Pd$ excitation, is also found in the 354–364 nm range [37,38].

4. Final remarks

We show in this article the synthetic, analytical and spectroscopic investigations of coordination polymers comprising palladium(II), unsubstituted and substituted pyrazolates and azido group. Some key points of this exciting chemistry deserve further comments. First, the polymerization reactions are extremely dependent on the pseudohalide group as well on the R groups of the pyrazolate ring. In fact, our previous results showed that, under identical experimental conditions, the use of thiocyanate, instead of azide, gave rise to the mononuclear *trans*-$[Pd(SCN)_2(HPz)_2]$ [22–24] whereas replacement of pyrazole by 3,5-dimethylpyrazole yielded the H-bonded polymer *trans*-$[Pd(N_3)_2(HdmPz)_2]$ [18]. Therefore we concluded that the self-assembly reaction via coordinative bonds only takes place combining palladium(II), pyrazole or 4-substituted pyrazoles and azide ion. Another point of interest is the spontaneous deprotonation of the pyrazole molecule to the pyrazolate without the need of any base. Such behavior has already been reported in the presence of soft metals (e.g. Ag^+) [39]. A hypothesis could be postulated taking into account the strength of azide as a Brönsted-Lowry base ($pK_b = 9.08$) [40], which could deprotonate pyrazole directly or by means of a hydrolysis. Further studies on the properties of these systems, e.g. host–guest chemistry and manufacturing of thin molecular films, as well the synthesis involving self-assembly reactions among pyrazoles, azide, and another transition metals are also underway in our laboratory.

roles in the structures of the zinc amides. Zinc amides with less-sterically demanding amido ligands are prone to yield bridging dimers in the solid state, as demonstrated by $\{Zn[N(SiMe_3)Ph]_2\}_2$ [11], $[Zn(NPh_2)]_2$ [12] and $\{ZnN[Si(CH_3)_2CH_2CH_2Si(CH_3)_2]_2\}_2$ [15]. Zinc amides derived from significantly more sterically bulky amido ligands, however, are generally found as monomers in the solid state, as exemplified by $Zn[N(SiMe_3)(2,6\text{-}Me_2C_6H_3)]_2$, $Zn[N(SiMe_3)(2,6\text{-}{}^iPr_2C_6H_3)]_2$, $Zn[N(SiMe_3)(2,5\text{-}{}^tBu_2C_6H_3)]_2$ and $Zn[N(SiMePh_2)_2]_2$ [11,13]. However, mercury amides always appear to be monomeric in the solid state, no matter whether bulky amido ligands are used or not. A search of the Cambridge Structural Database maintained by the Cambridge Crystallographic Database Centre (CCDC) indicates that the N–Hg–N angle in two-coordinate R_2N–Hg–NR_2 compounds range from ca. 172° to 180°. We also note that the use of silylamides as supporting ligands in these structurally characterized two coordinate Hg compounds is extremely limited [15]. This does not mean that all Hg amides are linear or only two coordinate. Supporting donor or solvent ligands can also be present to create three- or higher coordinate Hg complexes, which causes obvious deviations from the nearly linear geometry seen in the two coordinate Hg compounds. An additional strategy used in keeping the two coordinate Hg species monomeric is the presence of highly electronegative groups, either in the σ- (e.g., CF_3, TeF_5 and SF_5) and/or π-sense (e.g., $SiMe_3$), which are bonded to the nitrogen atom to reduce the electron donation of the amido ligands [18]. In our laboratory, we have synthesized and begun to report numerous main group metal (bis)amides based on various bulky silylamido ligands of the formula [N($SiMe_3$)(R)] [9,19]. This survey of preparative main group chemistry has led us to our current interest in the bulky silylamides of Zn and Hg.

In this report, we continue looking at the synthesis and structural characterization of main group bis(amides) by preparing new zinc and mercury complexes containing the bulky silyamido ligands – [N($SiMe_3$)(R)], where R is either –$SiPh_2{}^tBu$ or adamantyl (Ad). These compounds have been characterized by X-ray diffraction and have been shown to be monomeric in the solid state, containing approximately linear N–M–N bonds. Additionally, we have reacted solutions of these two coordinate Zn and Hg monomers with gaseous CO_2 and have begun to determine the reaction products obtained.

2. Experimental

2.1. General considerations

All manipulations were carried out in an Ar-filled glovebox or by using standard Schlenk techniques [20]. Anhydrous solvents were purchased from Aldrich or Fisher Scientific Company, after which they were stored in the glovebox over 4 Å molecular sieves. Anhydrous $ZnCl_2$, $HgBr_2$, Me_3SiNCO, $Me_3SiN{=}C{=}NSiMe_3$ and ^{n}BuLi (2.5 M in hexanes) were purchased from Aldrich. The ligands (Me_3Si)(R)NH (R = –$SiPh_2{}^tBu$ and Ad) were synthesized by the literature procedures [21]. ^{1}H and ^{13}C NMR spectra were obtained on a Bruker AMX 250 spectrometer using C_6D_6 or $CDCl_3$ as a solvent. GC/MS data of the organic products after reactions with CO_2 were obtained on a Hewlett–Packard Model 5890 GC equipped with an HP Model 5972 mass selective detector. Elemental analyses for carbon, hydrogen and nitrogen content were measured in sealed volatile sample pans using a Perkin–Elmer series II CHNS/O 2400 analyzer, or performed commercially by Desert Analytics, Tucson, Arizona.

2.2. $Zn[N(SiMe_3)(SiPh_2{}^tBu)]_2$ (**1**)

In a glovebox, a solution of ^{n}BuLi (3.1 ml, 7.7 mmol) was added slowly to (Me_3Si)($^tBuPh_2Si$)NH (2.50 g, 7.6 mmol) in 50 ml diethyl ether at room temperature, and the reaction mixture was stirred for 3 h. Anhydrous $ZnCl_2$ (0.52 g, 3.8 mmol) was added in small portions via a solid addition funnel. The mixture was stirred overnight and then the solvents removed. The residue was held in vacuo for 2 h and was then extracted with 60 ml hexanes, and filtered through Celite filter aid. Hexane was removed under reduced pressure to yield **1** as a white solid (2.11 g, 77%). An analytical sample was obtained by recrystallization from a saturated hexane solution at −20 °C to afford **1** as colorless crystals. ^{1}H NMR (C_6D_6): δ 0.12 (s, 18H, –SiMe_3), 1.07 (s, 18H, –Si(CMe_3)), 7.15 (m, 16H, C_6H_5), 7.62 (m, 4H, C_6H_5). ^{13}C NMR (C_6D_6): δ 6.09 (–SiMe_3), 20.18 (–Si(CMe$_3$)), 29.13 (–Si(CMe_3)), 128.21 (C_6H_5), 129.62 (C_6H_5), 136.06 (C_6H_5), 139.63 (C_6H_5). *Anal.* Calc. for $C_{38}H_{56}N_2Si_4Zn$: C, 63.52; H, 7.86; N, 3.99. Found: C, 63.55; H, 7.32; N, 4.48%.

2.3. $Hg[N(SiMe_3)(SiPh_2{}^tBu)]_2$ (**2**)

Similarly to the preparation of **1**, [(Me_3Si)($^tBuPh_2$-Si)N]Li was generated in situ from the reaction of (Me_3Si)($^tBuPh_2Si$)NH (2.00 g, 6.1 mmol) and ^{n}BuLi (2.5 ml, 6.2 mmol) in 50 ml of diethyl ether at room temperature. The Li salt was treated with anhydrous $HgBr_2$ (1.10 g, 3.1 mmol) over a 24-h period to form a white precipitate, which after extraction and removal of solvent led to **2** (2.14 g, 82%) as a white solid. Recrystallization from a saturated hexane solution at −20 °C afforded **2** as colorless crystals. ^{1}H NMR (C_6D_6): δ 0.05 (s, 18H, –SiMe_3), 1.14 (s, 18H, –Si(CMe_3)), 7.15 (m, 16H, C_6H_5), 7.77 (m, 4H, C_6H_5). ^{13}C NMR (C_6D_6): δ 5.95 (–SiMe_3), 19.73 (–Si(CMe$_3$)), 29.19 (–Si(CMe_3)),

128.39 (C_6H_5), 129.51 (C_6H_5), 136.18 (C_6H_5), 139.63 (C_6H_5). *Anal.* Calc. for $C_{38}H_{56}N_2Si_4Hg$: C, 53.46; H, 6.61; N, 3.28. Found: C, 52.44; H, 6.51; N, 3.22%.

2.4. Zn[N(SiMe$_3$)(Ad)]$_2$ (3)

Analogously to the preparation of **1**, [(Me_3Si)(Ad)N]-Li was generated in situ from (Me_3Si)(Ad)NH (2.23 g, 10.0 mmol) and ^{n}BuLi (4.0 ml, 10.0 mmol) in 50 ml diethyl ether at room temperature. $ZnCl_2$ (0.68 g, 5.0 mmol) was added via solid addition funnel and allowed to react overnight. The precipitate was extracted and filtered to give **3** (1.88 g, 74%) as a white solid. An analytically pure sample of **3** was obtained by recrystallization from saturated hexane solution at −20 °C as colorless crystals. ^{1}H NMR (C_6D_6): δ 0.29 (s, 18H, –SiMe_3), 1.51 (m, 12H, –CH_2–), 1.79 (m, 12H, –CH_2–), 1.96 (m, 6H, –CH–). ^{13}C NMR (C_6D_6): δ 5.87 (–SiMe_3), 31.05 (–CH$_2$–), 36.58 (–CH$_2$–), 51.98 (–CH–), 53.40 (–CN). *Anal.* Calc. for $C_{26}H_{48}N_2Si_2Zn$: C, 61.20; H, 9.48; N, 5.49. Found: C, 61.13; H, 9.52; N, 5.49%.

2.5. Hg[N(SiMe$_3$)(Ad)]$_2$ (4)

As in **3**, [(Me_3Si)(Ad)N]Li, generated in situ from (Me_3Si)(Ad)NH (2.50 g, 11.2 mmol) and ^{n}BuLi (4.5 ml, 11.2 mmol), was treated with $HgBr_2$ (2.02 g, 5.6 mmol) in 50 ml diethyl ether at room temperature. After reacting for 24 h, workup of the reaction as above yielded **4** as a white solid (2.89 g, 80%). An analytically pure sample was obtained by recrystallization from saturated hexane solution at −20 °C to afford **4** as colorless crystals. ^{1}H NMR (C_6D_6): δ 0.33 (s, 18H, –SiMe_3), 1.50 (m, 12H, –CH_2–), 1.86 (m, 12H, –CH_2–), 1.99 (m, 6H, –CH–). ^{13}C NMR (C_6D_6): δ 6.26 (–SiMe_3), 31.01 (–CH$_2$–), 36.54 (–CH$_2$–), 52.10 (–CH–), 54.96 (–CN). *Anal.* Calc. for $C_{26}H_{48}N_2Si_2Hg$: C, 48.38; H, 7.50; N, 4.34. Found: C, 48.58; H, 7.54; N, 4.39%.

2.6. Reactions with CO_2

Two different procedures were used in the treatment of **1**–**4** with gaseous CO_2. In the first route, a hexane solution of the metal amide was placed in a flask under inert atmosphere, and CO_2 was simply bubbled through the solution for approximately an hour. The reaction contents were heated to ca. 60 °C and held for additional time if no reaction was apparent at room temperature. Any organic products were identified by GC/MS. In a second procedure, more forcing conditions were used. A closed, glass Fischer–Porter (F–P) bottle reactor system was used in order to hold the contents under pressure (60 psig) and temperature (60 °C) [22]. Again, the metal amide was added as a hexane solution into the F–P bottle, and CO_2 was added to a pressure of 60 psig and then allowed to react at 60 °C for an hour. Careful depressurization of the F–P reactor in a hood was followed by analysis of the organic solution by GC–MS. Identification and quantification of the Me_3Si–NCO and/or $Me_3SiN{=}C{=}NSiMe_3$, if formed, was possible by comparison to authentic purchased samples.

2.7. X-ray crystallography

Crystallographic data and details of X-ray studies for **1**–**4** are given in Table 1. As all of the compounds are extremely air-sensitive the crystals were always handled under an inert atmosphere, covered with oil and immediately transferred to the N_2 stream of the diffractometer. Data were collected at low temperatures on a Bruker P4/CCD diffractometer using λ (Mo Kα) = 0.71073 Å radiation. The structures were solved using the direct methods, completed by subsequent difference Fourier syntheses, and refined by full matrix least-squares procedures on F^2. SADABS absorption corrections were applied to all data. All non-hydrogen atoms were refined with anisotropic displacement coefficients. All H atoms in **1** and the H atoms of Me groups in **4** were found on the residual densities and refined with isotropic thermal parameters. Other H atoms in **4** and all H atoms in **2** and **3** were treated as idealized contributions. Both Ad groups in the crystal structure of **3** and one Ad group in **4** are disordered over two positions (in ratios 76/24, 63/37 and 68/32, respectively) related by rotation around the N–C bond by ca. 60°. The Flack parameters for **1** and **2** are 0.003(8) and 0.082(8), respectively. All software and sources of scattering factors are contained in the SHELXTL (6.10) program package (G. Sheldrick, Bruker XRD, Madison, WI) [23,24].

3. Results and discussion

Compounds **1**–**4** were directly synthesized via metathesis reactions of two equivalents of the lithium amides [(Me_3Si)(^{t}BuPh_2Si)]NLi or [(Me_3Si)(Ad)]NLi with one equivalent of $ZnCl_2$ or $HgBr_2$. While the $ZnCl_2$ reactions occurred immediately as shown by the production of LiCl, the reactions of $HgBr_2$ with lithium amides were more sluggish, requiring longer times for the reaction to reach completion. Colorless crystals of **1**–**4** suitable for X-ray diffraction analysis were obtained via recrystallization of a saturated hexane solution at −20 °C.

3.1. Complexes containing the –[N(SiMe$_3$)(SiPh$_2$^{t}Bu)] ligand

X-ray diffraction analysis reveals that in the solid-state Zn[N($SiMe_3$)($SiPh_2$^{t}Bu)]$_2$ (**1**) is monomeric with a two coordinate Zn center (Fig. 1). The sp hybridized Zn atom is bonded to two nitrogen atoms in an

approximate linear arrangement. We presume that owing to the increased steric hindrance presented by the –[N(SiMe$_3$)(SiPh$_2$^{t}Bu)] ligands, the N–Zn–N angle (167.87(10)°) is forced to be significantly deviated from linearity. This is in stark contrast to the strictly linear structures found in Zn[N(SiMe$_3$)(2,6-Me$_2$C$_6$H$_3$)]$_2$, Zn[N(SiMe$_3$)(2,5-^{t}Bu$_2$C$_6$H$_3$)]$_2$ and Zn[N(SiMe$_3$)(2,6-^{i}Pr$_2$-C$_6$H$_3$)]$_2$ (N–Zn–N angles are 177.18°, 179.56° and 180°, respectively) [11]. The Zn–N bond distances in **1** (1.853(2) and 1.858(2) Å) are slightly longer than those found in Zn[N(SiMe$_3$)(^{t}Bu)]$_2$ (1.82 Å) and Zn[N(SiMe$_3$)$_2$]$_2$ (1.82 Å, by gas-phase electron diffraction) [14,17], but equivalent to that found in Zn[N(SiMePh$_2$)]$_2$ (1.85 Å) [13]. Compared to the N(1)–Si(2) distance of 1.718(2) Å, a relatively longer N(1)–Si(1) bond length of 1.732(2) Å is observed; both are comparable to the N–Si bond lengths found in Zn[N(SiMe$_3$)-(2,6-^{i}Pr$_2$C$_6$H$_3$)]$_2$ (1.728(14) Å) and Zn[N(SiMe$_3$)(2,5-^{t}Bu$_2$C$_6$H$_3$)]$_2$ (1.731(4) Å) [11]. Interestingly, the Si(2)–N(1)–Zn(1) angle of 116.06(11)° is significantly larger than the Si(4)–N(2)–Zn(1) angle of 111.46(11)°, while the Si(2)–N(1)–Si(1) angle of 129.77(12)° is substantially smaller than the Si(4)–N(2)–Si(3) angle of 132.97(13)°. Both ligand nitrogen atoms are located in nearly ideal trigonal–planar environments, within the $ZnSi_2$ planes. Important bond distances and angles for **1** and **2** are shown in Table 2.

Compound **2** (Fig. 2) features similar structural characteristics. The complex is again monomeric with the Hg atom attached to two ligand nitrogen atoms. No solvent ligands are coordinated to the Hg atom. Compared to the N–Zn–N arrangement in **1**, the N–Hg–N angle found in **2** (176.1(3)°) is much closer to linearity, likely due to the larger size of the Hg atom relative to Zn. The N–Hg–N angle in the related structures Hg[N(Si-Me$_3$)(2,6-^{i}Pr$_2$C$_6$H$_3$)]$_2$ and {HgN[Si(CH$_3$)$_2$CH$_2$CH$_2$Si-(CH$_3$)$_2$]$_2$}$_2$ show no deviation from linearity (180°) [11,15]. The Hg–N distances found in **2** (2.034(7), 2.015(7) and 2.026(7), 2.034(7) Å for two independent molecules) are close to those seen in bis[2,3,4,5-tetrakis(trifluoromethylthio)pyrrolyl]mercury {Hg[N(CSC-F$_3$)$_4$]$_2$} (2.02 Å) [25], but slightly shorter than in Hg(N=SF$_2$)$_2$ (2.05 Å) [26], Hg[N(SO$_2$CH$_3$)$_2$]$_2$ (2.07 Å) [27], Hg[PhC(NSiMe$_3$)$_2$]$_2$ (2.07 Å) [28] or Hg[N(SiMe$_3$)-C(Ph)NC(Ph)=C(SiMe$_3$)$_2$]$_2$ (2.065 Å) [29]. The larger Hg atom in **2** also leads to substantially longer Hg–N

Table 2

[a] The values for two symmetrically independent molecules are given.

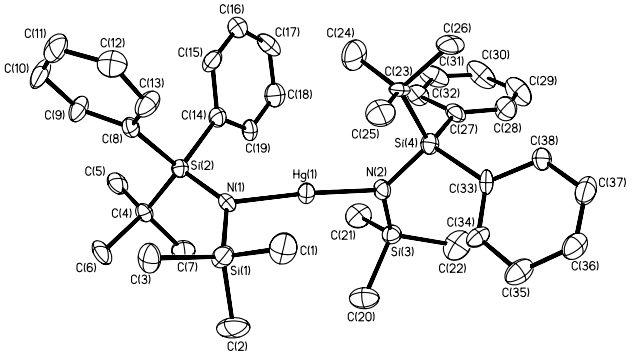

Fig. 2. Molecular structure of **2** (30% ellipsoids). Only one of two symmetrically independent molecules is shown. The H atoms are omitted for clarity.

bonds relative to the Zn–N bonds in **1** (increase of 0.17 Å) and thus to a less-crowded molecule. An interesting feature present in the structure of **2** is that the Si–N–Si angles found in the two –N[(SiMe$_3$)(SiPh$_2$^{t}Bu)] groups attached to Hg are significantly different – the Si(2)–N(1)–Si(1) angle of 134.0(5)° (133.6(5)°) is opened up considerably relative to its counterpart Si(4)–N(2)–Si(3) angle of 126.1(5)° (127.3(5)°) in both independent molecules. This naturally causes the other angles around N(1) to diminish in order to maintain a trigonal planar geometry at the nitrogen atom. This indicates that the two –N[(SiMe$_3$)(SiPh$_2$^{t}Bu)] ligands are attached to the Hg atom with different arrangements. We find no apparent close interactions in the crystal structure between Hg and the ligand periphery that might contribute to the opening up of one Si–N–Si angle relative to the other.

3.2. Complexes containing the –[N(SiMe$_3$)(Ad)] ligand

We have also prepared Zn (**3**) and Hg (**4**) complexes utilizing the somewhat less sterically hindered ligand –[N(SiMe$_3$)(Ad)]. The structure of **3** is shown in Fig. 3, while the structure of **4** appears in Fig. 4. Pertinent bond

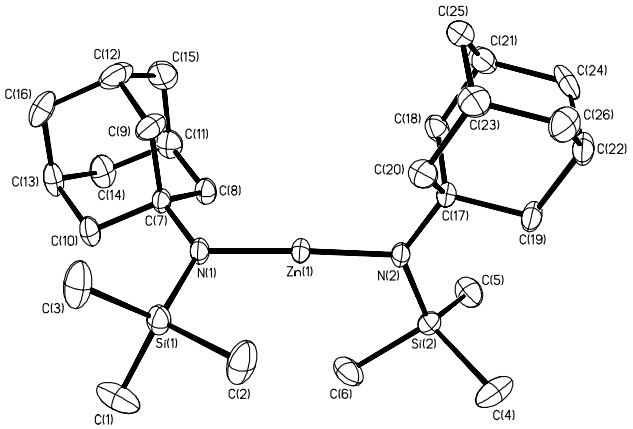

Fig. 3. Molecular structure of **3** (30% ellipsoids). For clarity, the H atoms are omitted and only one of two possible positions for both disordered Ad groups is shown.

lengths and angles are given in Table 3. Both Ad groups in the crystal structure of **3** and one Ad group in **4** are disordered over two positions related by rotation around the N–C bond by an angle of ca. 60°. Only one position for these Ad groups is shown in Fig. 3 and 4. The use of this ligand allows the N–Zn–N angle (177.46(6)°) in **3** to be much closer to the idealized linear arrangement. Similar to **1**, the zinc atom is coordinated to two ligand nitrogen atoms in a solvent-free, monomeric structure. Quite interestingly, the crystal structure indicates that the two adamantyl groups located on the two amido ligands are *syn* to each other, that is they lie on the same side of the N–Zn–N line. Looking down the N–Zn–N coordinate (Fig. 5) it can be seen that the N–C(Ad) bonds of the two ligands (N(1)–C(7) and N(2)–C(17)) have a torsion N(1)–C(7)···N(2)–C(17) angle of 77.6°. Obviously, with the adamantyl groups being arranged in a *syn*-like geometry, this causes the two –SiMe$_3$ groups bound to N also to be roughly

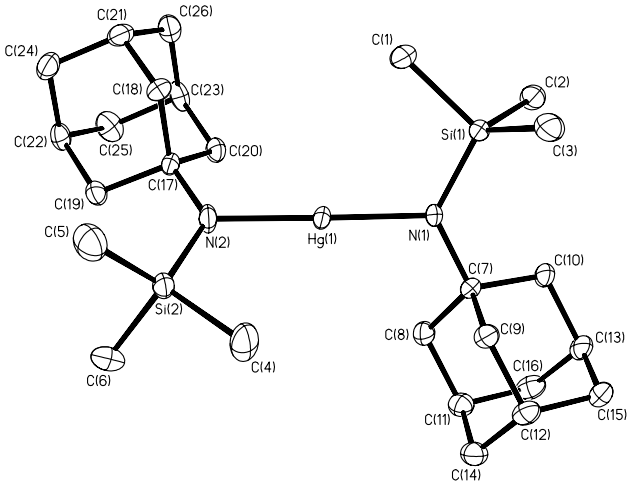

Fig. 4. Molecular structure of **4** (25% ellipsoids). For clarity, the H atoms are omitted and only one of two possible positions for the disordered Ad group is shown.

Table 3

C(7)–N(1)–M(1)	118.05(12)	116.32(19)
C(17)–N(2)–Si(2)	127.49(11)	126.9(2)
C(17)–N(2)–M(1)	116.95(11)	116.4(2)

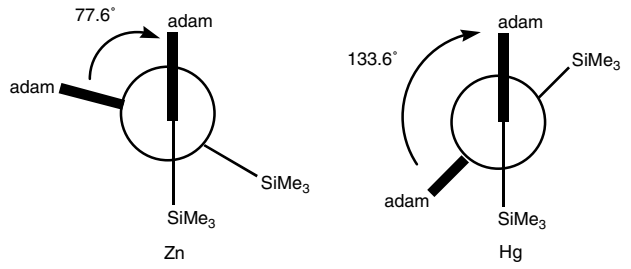

Fig. 5. View down the N–M–N axis for **3** (M = Zn) and **4** (M = Hg) showing the difference in location of the adamantyl groups on the amido ligands.

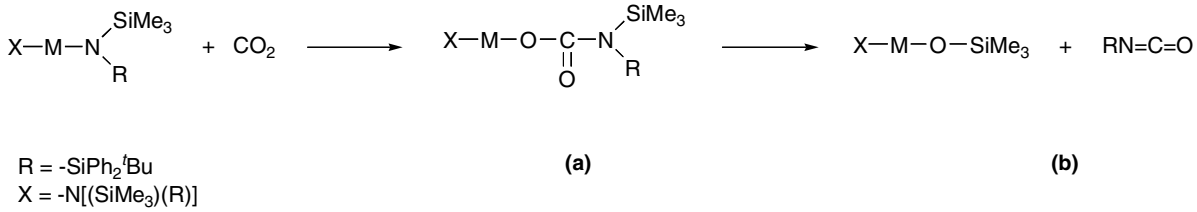

syn. The torsion angle N(1)–Si(1)···N(2)–Si(2) between the –N–$SiMe_3$ groups is 75.1°. Both Zn–N distances of 1.827(15) and 1.828(14) Å are found to be identical and marginally shorter than those observed in **1** (ave. 1.856(4) Å). Although not imposed by crystallography, this suggests that the two ligands reside symmetrically on both sides of the zinc atom. This is confirmed by the negligible differences seen in the Si(1)–N(1)–Zn(1) (114.75(9)°) and Si(2)–N(2)–Zn(1) (115.51(8)°) angles, as well as the C(7)–N(1)–Si(1) (127.11(12)°) and C(17)–N(2)–Si(2) (127.49(11)°) angles.

Compound **4**, containing the same –[$N(SiMe_3)$(Ad)] ligand, also adopts an almost linear structure with a N–Hg–N bond angle of 178.80(10)°. Despite being prepared in diethyl ether, again no coordinated solvent is present. In contrast to the arrangement of the ligands in **3**, the crystal structure reveals that the adamantyl and –$SiMe_3$ groups of each –[$N(SiMe_3)$(Ad)] ligand reside in a configuration that is an *anti* arrangement, rather than the *syn* geometry seen in **3**. The torsion angle C(7)–N(1)···N(2)–C(17) for the two N–C(Ad) bonds is 133.6° (a perfect *anti* configuration would be 180°) and the torsion angle Si(1)–N(1)···N(2)–Si(2) for the two N–$Si(Me_3)$ bonds is 120.6°. An *anti*-like arrangement similar to this has been seen previously in the structure of the mercury amide $Hg[N(CF_3)TeF_5]_2$, where the –TeF_5 groups have opposite locations relative to the N–Hg–N coordinate [18]. The two Hg–N bond lengths in **4** (2.004(3) and 2.009(3) Å) are close each other, but slightly shorter than those in **2** (ave. 2.027(9) Å). The N–Si bond lengths in **4** (1.715(2) and 1.713(2) Å) are comparable to the corresponding lengths found in **2**. As in **3**, although not rigorously imposed by crystallography, the essentially identical angles between the pairs Si(1)–N(1)–Hg(1) (116.22(14)°) and Si(2)–N(2)–Hg(1) (116.64(16)°), C(7)–N(1)–Si(1) (126.1(2)°) and C(17)–N(2)–Si(2) (126.9(2)°), and C(7)–N(1)–Hg(1) (116.32(19)°) and C(17)–N(2)–Hg(1) (116.4(2)°), indicate that the two –$N(SiMe_3)$(Ad) ligands are symmetrically coordinated to the Hg atom. Neither of the two ligand nitrogen atoms shows any deviation from trigonal planar geometry.

3.3. Attempted reactions of *1–4* with CO_2

One of our primary interests in these complexes involves their possible interactions with carbon dioxide. More specifically, we are interested in determining under what conditions bis(silylamido) species of the *s* and *p* block elements either (a) directly insert CO_2 (and stop) to yield isolable metal carbamates as final products, or (b) after insertion, in a subsequent reaction produce silyl-isocyanates via elimination from these metal carbamato intermediates (Scheme 1) [30]. The driving force for the elimination reaction is believed to be the formation of a strong Si–O bond as shown. With **1**–**4** it is not possible to predict beforehand whether CO_2 will react with the complexes to form species of type (a) or (b) above, or even react at all.

Complexes **1**, **2** and **4** were all unreactive towards gaseous CO_2 under a variety of conditions. Initial experiments simply bubbling CO_2 through solutions of the

Scheme 1. Possible route to either (a) metal carbamates, or (b) isocyanates, from a metal bis(silylamide).

metal bis(amides) at atmospheric pressure indicated no reaction, and so more severe conditions were used. Using the Fisher–Porter bottle and raising the reaction temperature to 60 °C and the CO_2 pressure to 60 psig also did not cause any reaction as evidenced by CO_2 uptake (monitored by loss of CO_2 pressure) or precipitation of any solids. GC/MS analysis of the solution did not indicate the presence of any new organic species. The ^1H and ^{13}C NMR spectra of the final solutions were consistent with the presence of unreacted starting bis(amides).

Compound **3**, however, appeared to react with CO_2 under mild conditions. Upon bubbling CO_2 through the hexane solution of **3** an immediate reaction was seen to occur as evidenced by a slight evolution of heat as well as the formation of a white precipitate A. GC/MS analysis of the hexane solution indicated that neither Me_3SiNCO nor $Me_3SiN{=}C{=}NSiMe_3$ had formed. As well, (Ad)NCO was not seen in the GC/MS analysis. However, removal of the hexane solvent afforded a white solid B that could be conclusively identified as (Ad)N=C=N(Ad) by high resolution mass spectroscopy and ^1H NMR. By inference, this indicates that the initial white precipitate A formed upon CO_2 addition and isocyanate/carbodiimide elimination could possibly be (a) $[Zn(OSiMe_3)_2]_2$, an expected by-product from the formation of (Ad)N=C=N(Ad), (b) $\{Zn[N(Ad)(SiMe_3)](OSiMe_3)\}_x$, also expected if the reaction is not complete, or a mixture of the two compounds. The white solid A is only sparingly soluble in a variety of solvents. The ^1H NMR spectrum obtained in $CDCl_3$ is consistent with the presence of both adamantyl and trimethylsilyl groups, but in a variety of environments, indicating an oligomeric structure and/or a mixture of products. The ^{13}C NMR spectrum does not provide more definitive information – particularly telling is that no low-field carbamato type peak is seen; however, this peak can be difficult to observe even when the metal carbamate is extremely soluble. It is not surprising that the product remaining from the Zn/CO_2 reaction may be oligomeric as we have shown earlier that alkyl Zn amides can insert CO_2 to give either tetrameric or dimeric products [19b]. Sita has reported in a similar case that the reaction product of $Pb[N(SiMe_3)_2]_2$ and CO_2 gives a white product with similar difficulties with characterization, and it is indicated that the compound is likely oligomeric [31]. We speculate that the lack of reaction of **1** or **2** with CO_2 can be attributed to the sterically crowded nature of the metal–N[$(SiMe_3)(SiPh_2{}^tBu)$] moiety. This lack of reactivity is similar to the situation seen earlier by Sita when he treated $Sn[N(SiMe_3)(2,6\text{-}{}^iPr_2C_6H_3)]_2$ with CO_2 [32]. While the metal–nitrogen bonds in **3** and **4** are less sterically constrained than in **1** or **2**, the lack of reactivity of **4** versus **3** may be attributed to the lower oxophilicity of Hg relative to its more oxophilic congener Zn, which readily undergoes insertion of CO_2 [3,19b].

4. Summary

The utilization of sterically demanding ligands, [N-$(SiMe_3)(R)$] (R = –$SiPh_2{}^tBu$ and adamantyl), can stabilize two coordinate complexes of zinc and mercury. No coordinating solvents are found in any of these species. Compounds **1**–**4** have been synthesized and their solid-state geometry established by X-ray diffraction analyses. The crystal structures for **1**–**4** indicate that zinc and mercury bis(silylamides) form monomeric, two coordinate compounds of roughly linear N–M–N arrangement, with $Zn[N(SiMe_3)(SiPh_2{}^tBu)]_2$ (**1**) deviating most significantly from linearity. A quite unusual feature seen is the difference in solid-state structures shown by **3** and **4**. While in the solid state $Zn[N(SiMe_3)(Ad)]_2$ (**3**) is found with a *syn* arrangement of the adamantyl ligands, the Hg analog **4** adopts an arrangement that is *anti*. **1**, **2** and **4** do not react with CO_2, even at 60 °C and 60 psig pressure, while **3** reacts readily with CO_2 to give (Ad)N=C=N(Ad).

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 256302–256305 for the compounds **1**–**4**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44-1223-336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

isolated, their stability was low in the reaction medium. The copper(II) nitrate–TMEDA 1:1 complex became turbid in aqueous solution due to disproportionation reaction and form a more stable 1:2 complex. Previously, it has been shown that dimers of the chelate complexes tend to show negligible catalytic activity [11]. In order to better define the coordination chemistry of substituted diamines with copper(II), mixed ligand complexes of oxalate and diamines have been synthesized and discussed.

2. Experimental

$CuSO_4$, $K_2(C_2O_4)$ and diamines were used as purchased from Aldrich company Limited. $Cu(C_2O_4)\cdot 1/2H_2O$ was prepared according to the reported method [12].

2.1. Preparation of Cu(TMEDA)oxalate·4H$_2$O (1)

To a stirred solution of TMEDA (0.48 ml, 3.2 mmol) in water (2 ml), finely powdered $Cu(C_2O_4)\cdot 1/2H_2O$ (0.25 g, 1.6 mmol) was added. Unreacted copper oxalate was removed by filtration. Ethanol (2 ml) was added to the filtrate and the solution was allowed to stand. After several days, a mixture of colourless and blue crystals formed. The blue crystals of **1** were separated for analysis; m.p. 232 °C; yield, 79%. *Microanal*. Calc. for $CuC_8H_{22}O_8N_2$: C, 28.3, H, 7.1, N, 8.2. Found: C, 28.3, H, 7.3, N, 8.1%. IR bands: 3407 (s), 2926 (m), 1673 (s), 1046 (m), 520 (m). UV/Vis bands: $\lambda_{max} = 15.0 \times 10^3$ cm^{-1} with a shoulder at 9.8×10^3 cm^{-1}.

2.2. Preparation of Cu(TriMPDA)oxalate (2)

To a stirred solution of *N*,*N*,*N*′-trimethyl-1,3-propanediamine (0.37 ml, 1.6 mmol) in water (4 ml) was added $Cu(C_2O_4)\cdot 1/2H_2O$ (0.25 g, 6.4 mmol). The excess copper oxalate was removed by filtration. The addition of ethanol immediately precipitated a blue solid which was dissolved in water (2 ml) and allowed to stand for crystallization. After several days blue crystals of **2** were formed which were separated by filtration, dried, m.p. 240 °C; yield, 68%. *Microanal*. Calc. for $CuC_8H_{16}O_4N_2$: C, 35.9, H, 6.0, N, 10.5. Found: C, 35.8, H, 5.8, N, 10.6%. IR bands: 3443 (m), 2930 (m), 1619 (s), 1044 (m), 495 (m). UV/Vis bands: $\lambda_{max} = 13.6 \times 10^3$ cm^{-1} with a shoulder at 9.6×10^3 cm^{-1}.

2.3. Preparation of Cu(TriMEDA)oxalate (3)

To a stirred solution of $Cu(C_2O_4)\cdot 1/2H_2O$ (0.5 g, 3.2 mmol) in ethanol (5 ml) and water (5 ml), was added *N*,*N*,*N*′-trimethylethylenediamine (0.81 ml, 6.4 mmol). The resulting solution was allowed to stand. Blue/violet crystals of **3** were grown after a few days; m.p. >240 °C; yield, 77%. *Microanal*. Calc. for $CuC_7H_{14}O_4N_2$: C, 33.1, H, 5.5, N, 11.0. Found: C, 33.2, H, 5.4, N, 11.4%. IR bands: 3424 (m), 2927 (m), 1619 (s), 1055 (m), 790 (s), 490 (m). UV bands: $\lambda_{max} = 18.4 \times 10^3$ cm^{-1}.

2.4. Physical measurements

Infrared spectra were recorded on a Perkin–Elmer FT-IR 1720X spectrometer in the range 4000–200 cm^{-1}. Samples were examined as nujol mulls between caesium iodide plates or as potassium bromide discs. Melting points were determined using a Gallenkamp melting-point apparatus. A Philips PU 8710 spectrophotometer was used to carry out the optical measurements, the samples were placed in silica cuvettes (1 cm path length). Elemental analyses were obtained from the microanalytical laboratory at University College London. Single-crystal X-ray diffraction data for the compounds were collected with a CAD-4 diffractometer and Mo Kα radiation ($\lambda = 0.71069$ Å) using ω–2θ scan. The unit cell parameters were determined by least-squares refinement on diffractometer angles ($9.99° \leqslant \theta \leqslant 12.51°$) for 25 automatically centered reflections. The structures were solved by heavy-atom method using DIRDIF-99 programs, refined anisotropically (non-hydrogen atoms) by full-matrix least-squares on F^2 using SHELXL-97 program [13]. Crystallographic details and selected interatomic distances and angles are given in Tables 1–4.

3. Results and discussion

The compounds have been characterized by IR, UV, elemental analysis and X-ray single crystallography. All three compounds have ratios of 1:1:1 for the copper, oxalate and diamine ligand but the common structure of compounds **1**, **2** is not shared by compound **3**.

Both compounds **1** and **2** have a six coordinate $CuN_2O_2O'_2$ chromophore with an elongated, rhombic, octahedral structure. The neutral Cu(L)ox units where L = diamine and ox = oxalate, involve bridging oxalate anions which gives a zig-zag polymeric chain structure. In **1**, the water molecules are not coordinated to the copper atom but are present as lattice water (Fig. 1). The water molecules are hydrogen bonded to each other and to oxygen atoms, O(2) and O(4), of the oxalate groups (Fig. 2). In the IR spectrum of compound **1**, ν(OH) has a single broad band at 3407 cm^{-1}, indicating hydrogen bonding to other water molecules and to the oxygen of the bridging oxalate group [14]. In **2**, hydrogen bonding between H(1) of the secondary amine group and the oxygen O(4) of the oxalate group within the chain, at a distance of 2.323 Å, has been suggested. Compound **2** contains no water. Generally, the diamine

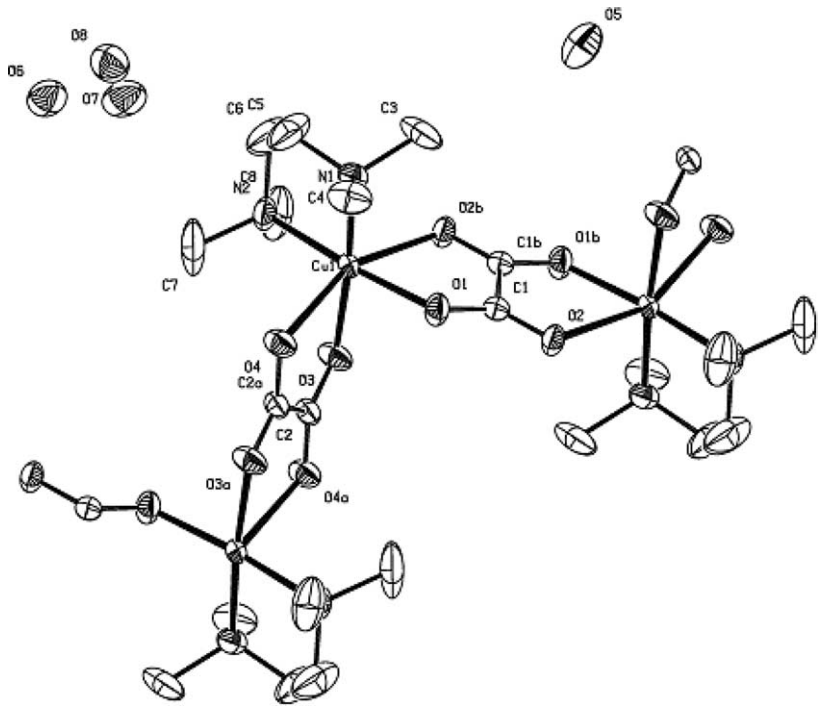

Fig. 1. X-ray single crystal structure of compound **1**.

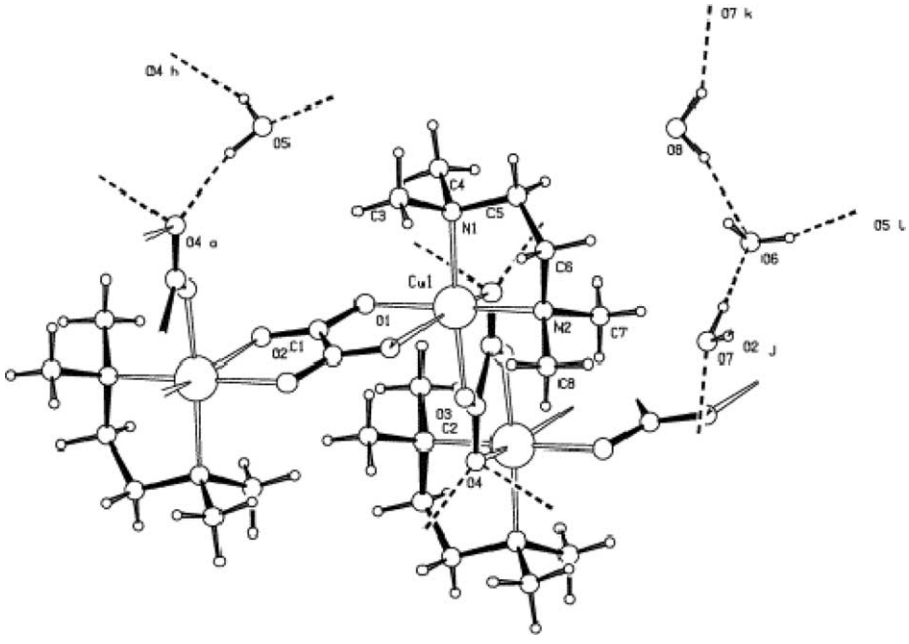

Fig. 2. Hydrogen bonding within complex **1**.

ligand is coordinated to the metal and the two oxalate ligands are asymmetrically coordinated with one long Cu–O bond and one short Cu–O bond (Fig. 3).

Table 2 shows selected bond lengths and angles in compound **1**. Compound **1** has a symmetrically coordinated TMEDA (mean Cu–N 2.052 Å) and two asymmetrically coordinated bridging oxalate (Cu–O (1.999–2.383 Å)) that are centrosymmetric (Fig. 1). Cu–O bond lengths are comparable to those reported (1.940–2.345 Å) for $[Cu(DMEDA)ox(H_2O)]_2$ $[Cu(DMEDA)_2](ClO_4)_2$ [15]. Compound **2** has an asymmetrically coordinated TriMPDA (Cu–N(1) 2.048 Å and Cu–N(2) 2.093 Å), the shorter bond being to the least substituted nitrogen N(1) and two asymmetrically coordinated

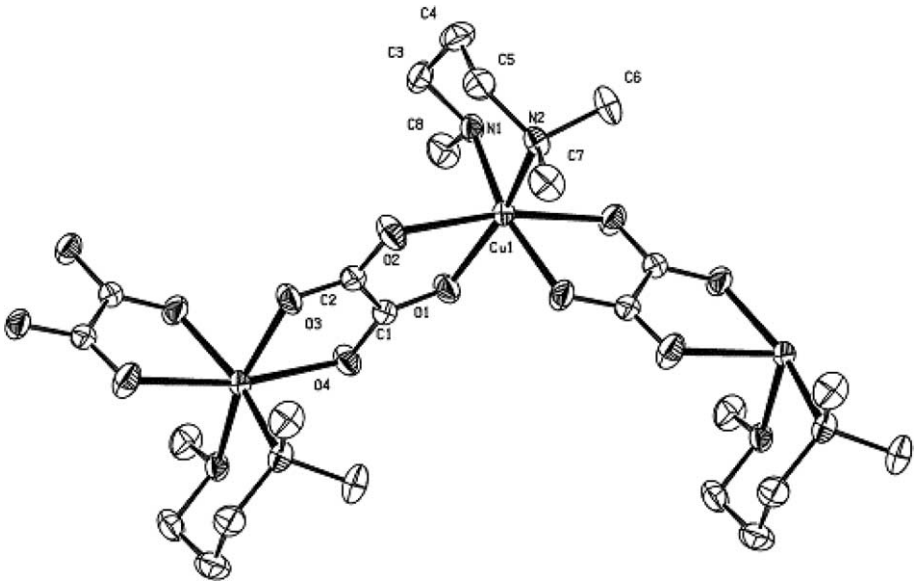

Fig. 3. X-ray single crystal structure of compound **2**.

bridging oxalate groups (shorter bonds Cu–O(1) 2.017 Å, Cu–O(3) 1.978 Å and longer bonds Cu–O(2) 2.379 Å, Cu–O (4) 2.396 Å) (Fig. 3). The oxalate groups are involved in an asymmetric bridging role between copper atoms. Selected bond lengths and angles of compound **2** are shown in Table 3.

The mean O–C–O angles within the oxalate in complex **1** is 125.8° and in complex **2** 125.9° [16–18]. Similarly, the bond lengths and angles associated with TMEDA are normal for such complexes [19]. In complex **2**, the six-membered ring Cu–N(1)–C(3)–C(4)–C(5)–N(2)– is in a chair conformation. The mean C–N bond length, (1.49 Å) in complex **2** is noticeably longer than the average C–N bond length of (1.47 Å). The mean C–N bond length of complex **1** is 1.481 Å. This difference is attributed to the increase in the size of ring from five- in **1** to six-membered in **2** [20].

The bite angle of TMEDA at copper is 86.1° which compares well with that observed in $(Cu(TMEDA)Cl_2)_2$, where the angle is 85.3° [19]. The bite angles of the two oxalate groups in compound **1** are 75.48° and 76.66°, which are significantly different to each other. These angles compare well with those observed in **2** and in $Cu(bipy)ox\cdot 2H_2O$, where the oxalate bite angles are 77.4° and 77.9° [12]. The bite angle of TriMPDA at the copper center is 91.33° and those of the oxalate groups in compound **2** are 74.67° and 76.05° which are similar to those reported elsewhere [21].

In compound **1**, the N(1), N(2), O(1), O(2) atoms are distorted from a planar arrangement. The O(2)–Cu–O(4) angle of 156.90° is significantly reduced from 180°. Previously, this distortion has been attributed to the small bite angle of the oxalate groups [12]. In compound **2**, the N(1), N(2), O(1), O(3) atoms are again distorted from a planar arrangement. The O(2)–Cu–O(4) angle of 168.05° is reduced from 180° but not to the same extent as in **1**.

In compound **3**, the copper is described as square planar with two nitrogen atoms from the diamine and two oxygen atoms from the oxalate (Fig. 4). Table 4 shows selected bond lengths and angles of compound **3**. The copper deviates slightly out of the O(2), O(3), N(1), N(2) plane by ca. 0.031 Å. The TriMEDA is almost symmetrically coordinated with the bond lengths for Cu–N(1) and Cu–N(2) being 2.001 and 1.952 Å and the bite angle is 86.95°. This compares well with the reported bite angle of 86.4° for the diamine ligand in oxalato(*N*,*N*′-dimethylethylenediamine)copper(II) monohydrate [22]. This shortening of the bond to the least substituted nitrogen has been noted previously [23,24]. The C(4)–N(1)–Cu(1) angle of 105.3° and C(3)–N(2)–Cu(1) of 109.5°,

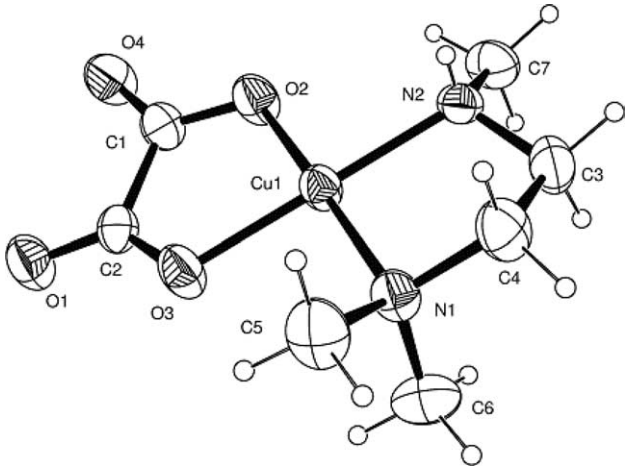

Fig. 4. X-ray single crystal structure of compound **3**.

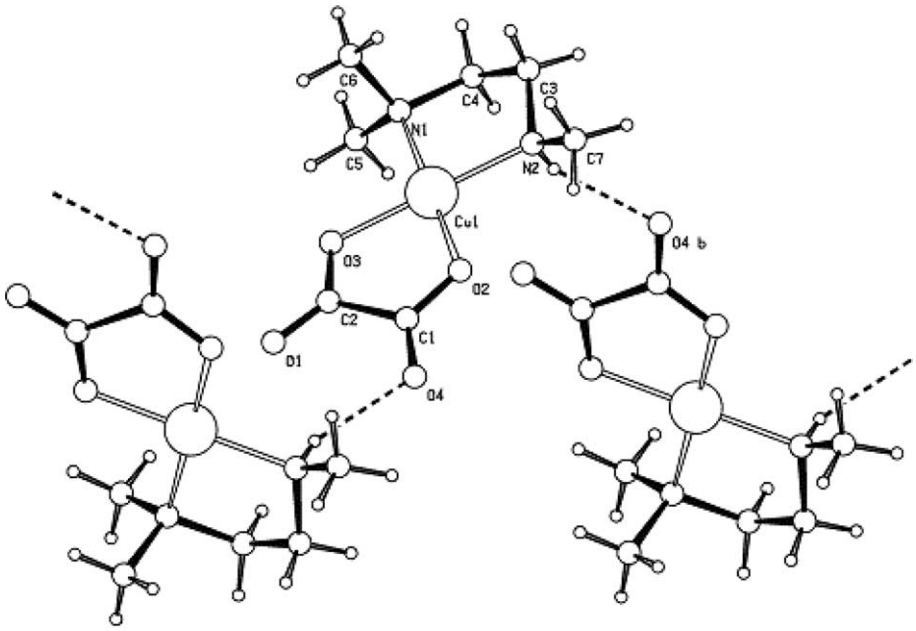

Fig. 5. Hydrogen bonding within complex **3**.

reflect the substitution on the nitrogen, with the largest angle at the least substituted nitrogen. The oxalate group is almost symmetrically coordinated to the copper through two oxygen atoms with Cu–O bond lengths of 1.922 and 1.948 Å in 1,2-*cis*-conformation. This contrasts with the asymmetry of the oxalate groups observed in compounds **1** and **2**. Within the oxalate group, the C–C bond length of 1.555 Å and the average C–O bond length of 1.247 Å are in accord with those previously reported [21]. Two long and two short bond lengths have been observed. This reflects the difference between those that are chelating (mean C–O length 1.274 Å) and those that are terminal (mean C–O 1.218 Å). The O–C–O angles are unequal. The O(1)–C(2)–O(3) moiety, where only one of the oxygen interacts with a copper, has an angle of 127.0°. This agrees well with the value of 126–128° observed in the free ion and oxalic acid [16–18]. In the O(4)–C(2)–O(1) moiety, the angle is reduced to 124.0°. Both oxygen atoms are involved in interactions, O(2) with Cu and O(4) in hydrogen bonding. The bite angle of the oxalate group is 84.53°. This compares well with the value of 84.2°, reported for oxalate(*N*,*N*′-dimethylethylenediamine)copper(II) [23]. The Cu(L)(C_2O_4) units are linked together by hydrogen bonding between the hydrogen H(1) bonded to N(1) and an oxygen, O(4), of an oxalate group in a neighbouring unit to from winding chains (Fig. 5).

4. Electronic properties

The diffuse reflectance spectra of complexes **1**, **2** and **3** were recorded between 8000 and 50 000 cm^{-1}. The compounds **1** and **2** have a main band with a shoulder and compound **3** have a single broad band.

The reflectance spectra of **1** had previously been reported [25]. Fukuda et al. recorded the spectra between 10 000 and 29 400 cm^{-1}. They reported a band at λ_{max} = 14 030 cm^{-1}. However, they failed to report a shoulder at this main band at lower frequency because their scan range was to too narrow.

Complex **1** has a main band at $\lambda_{max} = 15 \times 10^3$ cm^{-1} with a shoulder at 9.8×10^3 cm^{-1}. Similarly, the spectrum of complex **2** has a main band at $\lambda_{max} = 13.6 \times 10^3$ cm^{-1} with a shoulder at 9.6×10^3 cm^{-1}. These two-band spectra are common to the compounds that are isostructural. The spectrum of complex **3** has a single broad absorption at 18.4×10^3 cm^{-1}.

This sensitivity of the electronic spectra to the two modes of coordination has been previously reported in compounds of type Cu(L)(C_2O_4)·xH_2O where L = bipy and 1,10-phen [12,26,27]. The first modes contains an axially elongated N_2O_4 chromophore consisting of one bipy and two *catena* bridging oxalates which is comparable to complex **1** containing TMEDA and complex **2** containing TriMPDA. The second mode has an N_2O_2 chromophore of an oxalate and one bipy in a square plane at copper(II) which is comparable to complex **3** with TriMEDA. It can be concluded that the observation of two bands is consistent with the elongated tetragonal distortion seen in complexes **1** and **2**. The electronic broad band for complex **3** is consistent with an N_2O_2, ca. square planar chromophore.

The electronic reflectance spectra of complexes **1** and **2** are clearly different from complex **3**. This difference is associated with the local molecular structure of the

Table 5
ESR values for compounds **1**–**3**

Complex	ESR Spectra		
	g_1	g_2	g_3
Cu(TMEDA)oxalate·$4H_2O$ (**1**)	2.080	2.224	2.334
Cu(TriMPDA)oxalate (**2**)	2.108	2.232	2.315
Cu(TriMEDA)oxalate (**3**)	2.119		

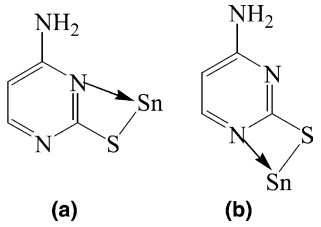
complex. This local structure is shared by complexes **1** and **2** but not complex **3** and is best seen by the presence of the low energy shoulder in **1** and **2**.

The compounds were also analyzed by electron spinning resonance (ESR) and observed g values for the crystalline samples lie in the range 2.08–2.34, with no absorptions at high or low fields (Table 5). The ESR spectra for both complexes **1** and **2** are clearly axial but a small rhombic component is indicated. This suggests a non-square planar geometry for complexes **1** and **2** as shown by the crystal structures obtained. The lowest observed g values for the complexes are greater than 2.08 and this is consistent with a $d_{x^2-y^2}$ or d_{xy} ground state.

5. Conclusion

Three new copper complexes have been synthesized and characterized by spectroscopic and X-ray single crystallographic methods. The structures of compound **1** and **2** are based on polymers where oxalato ligand is chelating and bridging between the metal centers. Both compounds share a common zig-zag structure with copper in a distorted octahedral configuration. Compound **3** is a monomer where oxalate is chelating only mode and the geometry around copper can be described as distorted square planar. Difference between the monomeric and polymeric structures was also shown by diffuse reflectance spectroscopy and ESR spectroscopy.

6. Supplementary material



Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 262838 for compound **1**, 262839 for compound **2** and 262840 for compound **3**. Copies of this information may be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Scheme 1. Two possible coordination modes of HSapym.

2. Experimental

2.1. Materials and measurements

All reagents and solvents were purchased commercially and used without further purification unless otherwise noted. The melting points were obtained on a Kofler micro melting point apparatus and are uncorrected. ^{1}H NMR spectra were obtained on a Varian Mercury Plus 400 MHz NMR spectrometer. Chemical shifts are given in ppm relative to Me_4Si in $CDCl_3$ as solvent. Elemental analyses were performed with a PE-2400 II elemental analyser.

2.2. Syntheses of the compounds *1–6*

2.2.1. *[Me_2SnCl(Spym)] (1)*

Under a dry nitrogen atmosphere, 2-mercaptopyrimidine (0.112 g, 1 mmol) and sodium ethoxide (0.068 g, 1 mmol) were added in benzene (20 ml) to a Schlenk flask and stirred for about 10 min. Then dimethyltin dichloride (0.220 g, 1 mmol) was added to the flask, and stirring was continued for 14 h at 40 °C. After filtration, the filtrate was gradually evaporated until a solid product was obtained. The solid was recrystallized from diethylether–petroleum ether. Transparent colourless crystals of compound **1** were formed. Yield: 79%; m.p. > 200 °C (dec.). *Anal*. Calc. for $C_6H_9ClN_2SSn$: C, 24.40; H, 3.07; N, 9.49. Found: C, 24.24; H, 3.18; N, 9.61%. ^{1}H NMR ($CDCl_3$): 8.44–7.18 (m, 3H, aromatic-H); 1.12 (s, 6H).

2.2.2. *[Bu_2SnCl(Spym)] (2)*

The procedure was the same as that of compound **1** and the crystalline compound **2** was formed in diethylether–petroleum ether. Yield: 82%; m.p. 120–125 °C. *Anal*. Calc. for $C_{12}H_{21}ClN_2SSn$: C, 37.97; H, 5.58; N, 7.38. Found: C, 37.86; H, 5.54; N, 7.56%. ^{1}H NMR ($CDCl_3$): 7.06–8.38 (m, 3H), 0.79–0.90 (s, 18H). ^{1}H NMR ($CDCl_3$): 7.34–7.90 (m, 3H, aromatic-H); 0.92–1.10, 1.05–1.28 (m, 18H).

2.2.3. *[Ph_2ClSn(Sapym)] · EtOH (3)*

The procedure was the same as that of compound **1** and crystalline compound **3** was formed in ethanol. Yield: 83%; m.p. 112–114 °C. *Anal*. Calc. for $C_{18}H_{20}ClN_3OSSn$: C, 44.98; H, 4.19; N, 8.74. Found: C, 43.16; H, 4.32; N, 8.59%. ^{1}H NMR ($CDCl_3$): 6.94–8.07 (m, 12H, aromatic-H); 6.02 (s, 2H); 4.65 (s,1H); 3.51 (q, 2H); 0.92 (t, 3H).

2.2.4. *[($PhCH_2$)$_2$Sn(Spym)$_2$] (4)*

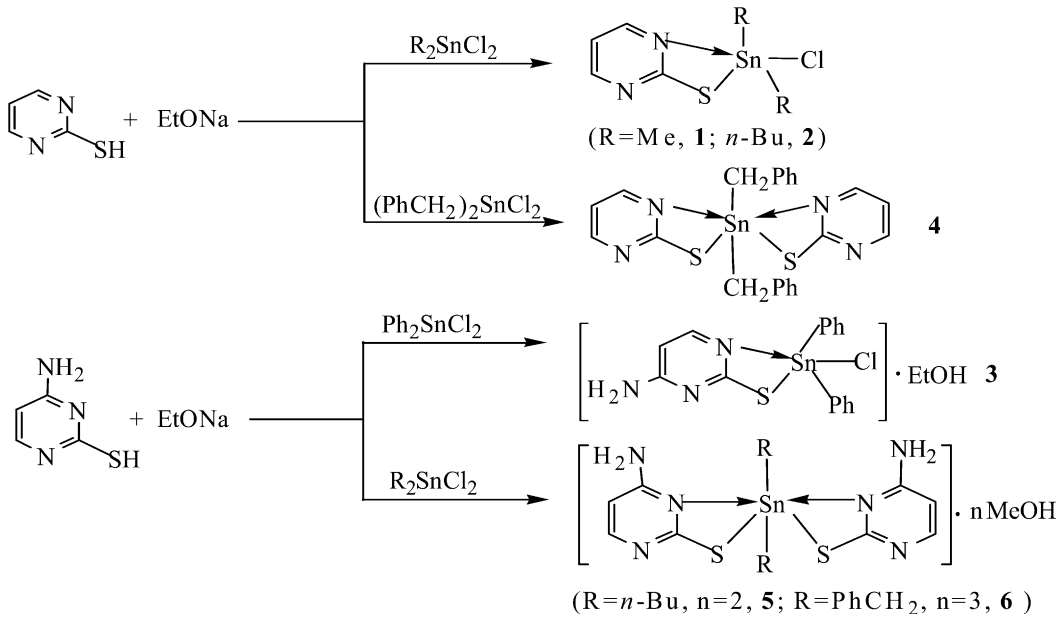
Under a dry nitrogen atmosphere, 2-mercaptopyrimidine (0.224 g, 2 mmol) and sodium ethoxide (0.136 g, 2 mmol) were added in benzene (20 ml) to a Schlenk flask and stirred for about 10 min. Then dibenzyltin dichloride (0.371 g, 1 mmol) was added to the flask, and stirring was continued for 14 h at 40 °C. After filtration, the filtrate was gradually evaporated until a solid product was obtained. The solid was recrystallized from diethylether–petroleum ether. Yield: 84%; m.p. 164–166 °C. *Anal*. Calc. for $C_{22}H_{20}N_4S_2Sn$: C, 50.49; H, 3.85; N, 10.71. Found: C, 50.56; H, 3.78; N, 10.62%. ^{1}H NMR ($CDCl_3$): 6.86–8.42 (m, 18H, aromatic-H); 3.20 (s, 4H).

2.2.5. *[Bu_2Sn(Sapym)$_2$] · 2MeOH (5)*

The procedure was the same as that of compound **4** and in methyl alcohol crystals of compound **5** were obtained. Yield: 84%; m.p. 170 °C. *Anal*. Calc. for $C_{18}H_{34}N_6O_2S_2Sn$: C, 39.35; H, 6.24; N, 15.30. Found: C, 39.29; H, 6.31; N, 15.38%. ^{1}H NMR ($CDCl_3$): 6.42–7.96 (m, 12H, aromatic-H); 6.02 (s, 2H); 4.50 (s, 1H); 3.39 (s, 3H); 0.92–1.10, 1.05–1.28 (m, 18H).

2.2.6. *[($PhCH_2$)$_2$Sn(Sapym)$_2$] · 3MeOH (6)*

The procedure was the same as that of compound **4** and in methyl alcohol crystals of compound **6** were obtained. Yield: 84%; m.p. 95–97 °C. *Anal*. Calc. for $C_{25}H_{54}N_6O_3S_2Sn$: C, 44.84; H, 8.13; N, 12.55. Found: C, 44.76; H, 8.18; N, 12.62%. ^{1}H NMR ($CDCl_3$): 6.34–7.89 (m, 18H, aromatic-H); 6.02 (s, 2H); 4.50 (s, 1H); 3.39 (s, 3H); 3.26 (s, 4H).



2.3. X-ray crystallographic studies of compounds *1–6*

All X-ray crystallographic data were collected with graphite-monochromated Mo Kα radiation (λ = 0.71073 Å) at 298(2) K on a Bruker SMART CCD 1000 diffractometer. The structures were solved by direct methods and refined by a full-matrix least squares procedure based on F^2 using the SHELXL-97 program system. The positions of hydrogen atoms were calculated, and their contributions were included in structural factor calculations.

3. Results and discussion

3.1. Syntheses of the compounds *1–6*

The synthesis procedure was as in Scheme 2.

Scheme 2.

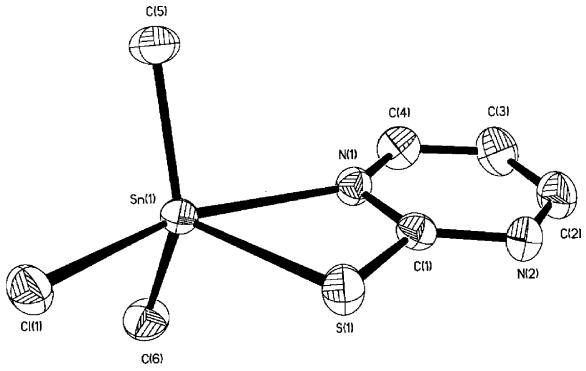


Fig. 1. Molecular structure of compound **1**.

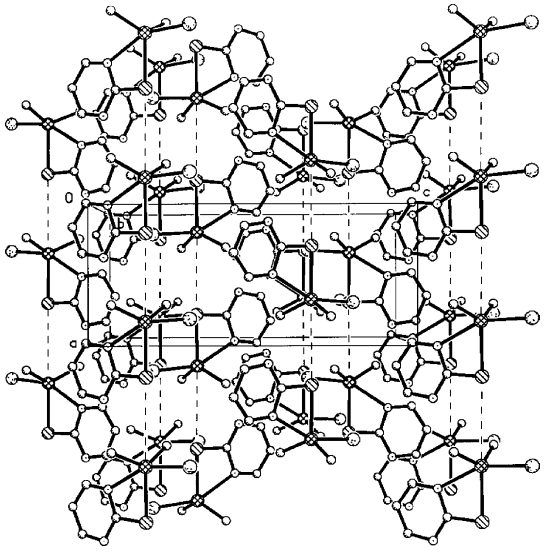

Fig. 2. Cell packing of compound **1**.

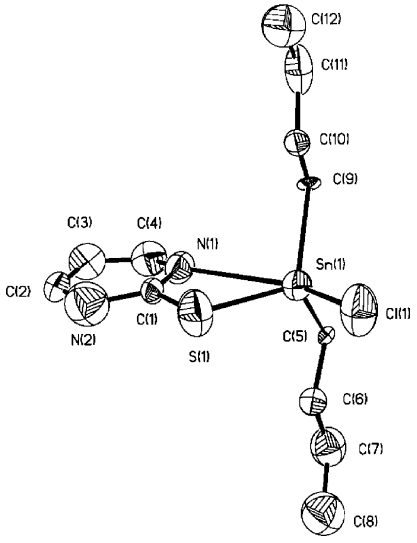

Fig. 3. Molecular structure of compound **2**.

3.2. ^1H NMR data of the compounds 1–6

^1H NMR data showed that the signal of the –SH proton in the spectrum of the ligand is absent in compounds **1**–**6**, indicating the removal of the –SH proton and the formation of Sn–S bonds. Moreover, the signal (4.65 ppm for compound **3**, 4.50 ppm for both **5** and **6**) further prove the existence of different solvent molecules in these compounds.

3.3. Crystal structures of compounds 1–6

The crystal structures and crystal packing of compounds **1**–**6** are shown in Figs. 1–9. All H atoms have

been omitted for clarity. Table 1 lists the crystal data and structure refinement parameters for compounds **1**–**6**, and their selected bond lengths and angles are shown in Tables 2–7, respectively. In general, each of compounds **1**–**3** has a penta-coordinated tin atom (Scheme 3a) and for compound **3**, the ligand HSapym

coordinates to the Sn atom in coordination mode **b**. However, for compounds **4**–**6**, the tin environment is six-coordinated (Scheme 3b), and for compounds **5** and **6**, the ligand HSapym chelates the Sn atom in coordination mode **a**. The detailed description is as follows.

*3.3.1. Structures of compounds **1**, **2** and **3***

The structures of compounds **1**–**3** are all penta-coordinated with R_2ClSn chelated by the thiol S and heterocyclic N atoms of the same ligand. The structure for each complex is distorted *cis*-trigonal bipyramidal with the Cl and N atoms in axial sites and two C atoms and one S atom occupying the equatorial plane. The Cl–Sn–N angles are 156.8(1)°, 149.4(4)° and 157.0(3)° for compounds **1**, **2** and **3**, respectively.

3a **3b**

(R=Me, *n*-Bu, Ph or $PhCH_2$; R'=H or NH_2)

Scheme 3.

The Sn–S bond lengths (2.473(2) Å for compound **1**, 2.39(1) Å for compound **2** and 2.452(3) Å for compound **3**), approaching the sum of the covalent radii of Sn and S atoms (2.42 Å) [14], indicate typical Sn–S covalent bonds. Concerning the Sn–N bond lengths, there exists some obvious differences. For compounds **1** and **2**, derived from HSpym, the Sn–N bond lengths are 2.450(3) and 2.90(2) Å, respectively, indicating the different bulkiness of the alkyl groups. In contrast, for compound **3**, the diphenyltin(IV) derivative of HSapym, the Sn–N bond length (2.39(1) Å) is much shorter than those in compounds **1** and **2**, which evidences the influence of the amino group to strengthen the coordination bond of N to Sn.

Especially, there exists a weak intermolecular Sn···S non-bonded interaction in crystals of compound **1**, stabilizing its infinite 1D chain structure. The Sn···S distance is 3.95 Å, similar to that of $Ph_3Sn(MNBT)$ (3.97 Å) and $Ph_2Sn(SCH_2CH_2S)$ (3.89 Å) but shorter than that in tribenzyl(2-thiolatopyridine-*N*-oxide)tin(IV) (4.15 Å) [12,14–16]. For compound **3**, there is an intermolecular N···H hydrogen bonding between the amino group and the heterocyclic N that does not coordinate to Sn, leading to the formation of a dimer. The N···H distance is 2.15 Å.

*3.3.2. Structures of compounds **4**, **5** and **6***

The three compounds are all six-coordinated with the R_2Sn moiety coordinated by two thiol S and two heterocyclic N atoms from two deprotonated ligands. The nitrogen atoms occupy *trans* positions with the N–Sn–N angle ranging from 146.59(9)° to 149.4(2)°. The sulfur atoms occupy *cis* positions with S–Sn–S angles ranging from 89.86(8)° to 91.75(4)°. Thus the structure for each is distorted trapezoidal bipyramid with two C atoms in bent axial positions, the trapezoidal plane being defined by the two Sn–S covalent bonds and two Sn–N secondary interactions. On each side of the central tin atom, the sulfur and nitrogen equatorial ligating atoms belong to the same moiety, so their positions are fixed and the S–Sn–N angles can only admit very little deformation. The sum of the angles between the tin atom and the equatorial ligating atoms (i.e., two N and two S in each case) is 360.14° for **4**, 360.03° for **5** and 359.93° for **6**, indicating that the five atoms almost lie in the same plane.

The Sn–S bond lengths are similar, ranging from 2.475(1) to 2.5053(4) Å, shorter than those in $R_2Sn(MNBT)_2$ (2.49–2.54 Å) [13]. The Sn–N bond lengths, 2.596(6) and 2.673(7) Å for compound **5** and 2.566(3) and 2.655(3) Å for compound **6**, are all shorter than those in compound **4** (2.627(4) and 2.799(4) Å), evidencing the influence of the amino group to strengthen the coordination trend of N to Sn.

It is worth noting that it is by the N(3) atom that the deprotonated HSapym coordinates to the central Sn atom in compounds **5** and **6**. The fact suggests that under the influence of the amino group, the coordination ability of N(3) to Sn is larger than that of N(1). However, in the case of compound **3**, due to the greater steric bulk of the phenyl group, Sn–N coordination occurs between the N(1) and Sn atoms.

4. Conclusions

A series of organotin complexes of derivatives of 2-mercaptopyrimidine and 4-amino-2-mercaptopyrimidine have been synthesized and characterized. Detailed studies on the structures and spectra of these compounds indicate that the structures of mono-chelated diorganotin(IV) chlorides have a distorted trigonal bipyramidal geometry and *cis*-chelated complexes have distorted skew-trapezoidal bipyramid geometry. Besides, both the substituent from the ligand and the stereoconstraints from the R groups of the R_2Sn moiety were found to have great influence on the final coordination mode. The influence of different substituents shows that the coordination capability from N to Sn in HSapym is larger than that in HSpym. Especially for HSapym, the coordination ability of N(3) is greater than N(1).

5. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 233178, 227958, 233183, 235029, 238965 and 238960 for compounds **1**–**6**, respectively. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

[21,22]. These peripheral units are particularly noteworthy as they allow for cation selectivity and complex stability to be enhanced through changing the numbers and types of macrocycle donors [23,24]. The usual purification methods such as crystallization and chromatographic separation cannot be used in most phthalocyanines due to their extreme insolubility [25]. The solubility of phthalocyanines can be enhanced by adding various groups such as a crown ether [26–29], mixed donor macrocycle [30–35] or macropolycycle [36,37] to the benzene rings.

We have described, for the first time, the synthesis and characterization of metal-free phthalocyanine peripherally fused to four spherical or cylindrical macrotricyclic moieties [38]. These compounds may allow new functionalized materials to be prepared, which is of importance for analytical chemistry as a new type of Cs^+ and NH_4^+ extraction agent. On the other hand, the importance of this new type of phthalocyanine may be regarded as an important step in that it may be a viable sensor and molecular material [39].

2. Experimental

2.1. Material

4-(2-{2-[2-(1,7-Dioxa-4,10-diazacyclododecane)ethoxy]ethoxy}ethyl)-1,7-dioxa-4,10-diazacyclododecane [40], 4,10,16,22,27,30-hexaoxa-1,7,13,19-tetraazabicyclo[11.11.8]dotriacontane [41] and 1,2-bis(2-tosyloxyethylmercapto)-4,5-dicyanobenzene [42] were prepared according to the literature procedures. Reagent grade chemicals were used as received. Solvents were purified according to standard methods [43] before use. Silica gel (70–230 mesh) was used for chromatographic separations.

2.2. Measurements

Melting points were determined with an electrothermal apparatus and were uncorrected. The ^1H, ^{13}C NMR and IR spectra were recorded on a Varian XL-200 spectrometer and on a Perkin–Elmer Spectrum One spectrometer with the samples in KBr pellets, respectively. Optical spectra in the UV–Vis region were recorded with a Unicam UV2-100 spectrophotometer, using 1 cm pathlength cuvettes at room temperature. Fast atom bombardment mass spectra were recorded on a Varian MAT 711 and VG Zap-Spec spectrometers using *m*-nitrobenzyl alcohol as the matrix. The elemental analysis and the metal contents of the compounds were determined on a Hewlett-Packard 185 CHN analyzer and on a Unicam 929 AA spectrophotometer.

2.3. Synthesis

2.3.1. 2,3,5,6,8,9,11,12,14,15,17,18,20,21,23,24,26,27-Octadecahydro-4,10:19,25-di(ethanooxyethano)-1,4,7,10,13,16,19,22,25,28-[2′,3′-dicyanobenzo]tetraoxadithiatetraazacyclotriacontine (**4**) or 25,26-(2′,3′-dicyanobenzo)-4,10,13,19,31,36-hexaoxa-24,27-dithia-1,7,16,22-tetraazatricyclo[14. 12.5.5^{7,22}]-octatriacontane (**5**)

A three-necked flask containing dry acetonitrile or propionitrile (200 ml) and fitted with a condenser was evacuated, refilled three times with argon, and connected to a vacuum line. Under argon, the flask was charged with **1** (1.84 g, 4 mmol) and finely ground anhydrous Na_2CO_3 (10.6 g, 100 mmol) and the mixture was stirred at 40 °C for 45 min. Compounds **2** or **3** (3.52 g, 5.2 mmol) were added to this mixture under argon atmosphere and the reaction mixture was heated and stirred at 125 °C for 7 days. The reaction was monitored by thin layer chromatography [silica gel (chloroform:petroleum ether:methanol) (6:3:1) (**4**) or (chloroform:petroleum ether:methanol) (7:2:1) (**5**)]. At the end of this period, the mixture was cooled to room temperature and filtered using Celite as the filtering agent and washed with dichloromethane (50 ml). The major liquor and washing solvents were combined and evaporated to dryness under reduced pressure. The residue was purified in a silica gel column using chloroform/petroleum ether:methanol (6:3:1) (**4**) or chloroform:petroleum ether:methanol (7:2:1) (**5**) as eluents. The appropriate fraction was evaporated, 100 ml of dichloromethane was added, and the mixture was filtered off and washed with methylene chloride. After evaporation of the solvent, the products were obtained as a solid or an oil.

Compound **4** or **5** (0.57 g, 0.8 mmol) was dissolved under an argon atmosphere in dry and degassed methanol (50 ml) on a vacuum line. Dry sodium methoxide (72 mg, 1.33 mmol) in dry methanol (10 ml) was added to the solution at room temperature and then anhydrous ammonia was bubbled through the reaction mixture for 8 h at reflux temperature, after which time the reaction was complete as shown by thin layer chromatography [silica gel (chloroform:methanol (9.5:0.5)]. The ammonia inlet was stopped and the volume of the solution reduced to 10 ml under reduced pressure and then the residue was placed in a refrigerator at −18 °C overnight. The pale green amorphous solid was separated by filtration and dried in vacuo.

*2.3.3. Metal-free phthalocyanines (**8**–**9**)*

Compound **6** or **7** (0.36 g, 0.5 mmol) and dry 2-(dimethylamino)ethanol (1 ml) were placed under an argon atmosphere in a standard Schlenk tube and degassed several times. The reaction mixture was refluxed and stirred under argon for 24 h (**8**) or 26 h (**9**). After cooling to room temperature, the solvent was evaporated to dryness under reduced pressure. The residue was solidified by treating with a mixture of diethyl ether:methanol (1:1), filtered off, and then chromatographed on silica gel with chloroform:methanol (9:1) (**8**) or chloroform:petroleum ether:methanol (7:2:1) (**9**) as eluents.

*Compound **8***: Yield: 0.17 g (48%); m.p. >300 °C. *Anal.* Calc. for $C_{136}H_{218}N_{24}O_{24}S_8$: C, 57.74; H, 7.71; N, 11.88. Found: C, 57.55; H, 7.59; N, 12.03%. *2.3.4. Nickel(II) phthalocyanines (**10**–**11**)*

A mixture of **4** or **5** (0.71 g, 1 mmol), anhydrous $NiCl_2$ (0.13 g, 1 mmol), dry *n*-pentanol (1.5 ml) and 5 drops of DBU was placed in a well-stoppered Schlenk tube under an argon atmosphere. Then the mixture was heated and stirred gently to 150 °C. The mixture was refluxed at this temperature for 24 h. The crude product was cooled to room temperature and diethyl ether was added dropwise to this mixture until precipitation occurred. The resulting dark green precipitate was filtered off, washed with water and ethanol, and then dried. The solid product was purified by column chromatography [silica gel (methanol:chloroform) (9.5:0.5)] (**10**) or [silica gel (chloroform:petroleum ether:methanol) (8:2:1)] (**11**).

Compound ***10***: Yield: 0.23 g (32%); m.p. >300 °C. *Anal*. Calc. for $C_{136}H_{216}N_{24}O_{24}S_8Ni$: C, 56.61; H, 7.49; N, 11.65; Ni, 2.03. Found: C, 56.77; H, 7.35; N, 11.80; Ni, 2.24%. 3. Results and discussion

The synthesis of the cylindrical or spherical macrotricyclic compounds **4**–**5** was performed by starting with 4-(2-{-2[2-(1,7-dioxa-4,10-diazacyclododecane)ethoxy]-ethoxy}ethyl)-1,7-dioxa-4,10-diazacyclododecane **2** [40] or 4,10,16,22,27,30-hexaoxa-1,7,13,19-tetraazabicyclo [11.11.8]dotriacontane **3** [41] and 1,2-bis(2-tosyloxyethylmercapto)-4,5-dicyanobenzene **1** [42] in acetonitrile or propionitrile, respectively, in the presence of Na_2CO_3 for a period of 7 days, affording the asymmetrical cylindrical or spherical macrotricycles **4** or **5**, respectively (Scheme 1). The template effect of sodium cations accounts for the high yield obtained in the desired ring closure. Final purification of the supercryptands by chromatography [silica gel, chloroform:petroleum ether:methanol (6:3:1)] (**5**) or [silica gel, chloroform: petroleum ether:methanol (7:2:1)] afforded **4** in 40% and **5** in 30% yields, for which elemental analyses and FAB mass spectral data were satisfactory: 706.2 $[M]^+$ and 706 $[M]^+$, respectively. ^{1}H NMR spectra of **4** and **5** showed new signals due to aromatic and SCH_2 protons at δ = 7.42–7.32 and 2.69–2.62 ppm, respectively, as expected. The proton-decoupled ^{13}C NMR spectra of the same compounds clearly indicate the presence of nitrile carbon atoms with peaks at δ = 115.47 and 115.69 ppm, respectively. The disappearance of N–H and presence of C≡N stretching vibrations which occur as strong absorptions at 2228 (**4**) and 2229 cm^{-1} (**5**), seen in the IR spectra of these compounds, also confirm the formation of **4** and **5**.

The transformation of the cylindrical and spherical substituted macrotricycle phthalonitriles **4** and **5** into the isoiminoindoline derivatives **6** and **7** was performed by bubbling dry ammonia through a solution of **4** and **5** in dry CH_3OH in the presence of catalytic amounts of CH_3ONa over a period of 8 h [44,45]. In the preparation of metal-free phthalocyanine, the isoiminoindoline route is more convenient than the phthalonitrile route since the reaction conditions employing **8** and **9** are mild in comparison to those employing **4** and **5** [46,47]. In the ^{1}H NMR spectra of **6** and **7**, there are broad signals at δ = 8.35 (**6**) and 8.49 ppm (**7**) due to the imino groups, which can be identified easily owing to deuterium-exchangeable characteristics of these NH protons. In the ^{13}C NMR spectra of **6** and **7**, the disappearance of the C≡N signals, along with the appearance of new peaks at δ = 159.67 (**6**) and 164.13 ppm (**7**) concerning C=NH groups, is in agreement with the proposed structure. In the IR spectra of these compounds, the C≡N stretching vibrations disappeared after conversion of **4** and **5** to isoiminoindolines (**6**,**7**) which show absorptions at 3355 and 3329 cm^{-1} for the N–H groups, respectively, which also suggests the formation of **6** and **7**. In the FAB mass spectra of these compounds, the presence of the characteristic molecular ion peaks at *m*/*z* = 723.1 (**6**) and 723.3 $[M]^+$ (**7**) confirmed the proposed structure.

The first example of a metal-free phthalocyanine containing cylindrical or spherical macrotricyclic moieties was synthesized in good yield according to the previously reported procedure [48–50]. Condensation of four molecules of the isoiminoindoline derivative **6** and **7** into the metal-free phthalocyanine **8** and **9** was carried out in a Schlenk system in 2-(dimethylamino)ethanol at reflux temperature for 22 and 26 h, respectively. In the ^{1}H NMR spectrum of **8**, the typical shielding of inner core protons was seen as a broad signal at around δ = −1.42 ppm which could be attributed to the NH resonances as confirmed by deuterium exchange. However, similar chemical shifts could not be observed in the ^{1}H NMR spectrum of **9**. The signals related to aromatic and aliphatic protons in the cylindrical and spherical macrotricyclic moieties and phthalocyanine skeleton gave significant absorbances characteristic of the proposed structures. This spectrum closely resembles that of the precursor compound (**6**) as expected. A distinct difference encountered in the ^{1}H NMR spectra of phthalocyanines when compared with previously obtained macrocycle substituted derivatives is the sharp signals, which indicates a lower tendency to aggregate even at the concentration used for NMR measurements [51–53]. The IR spectrum of **8** is very similar to that of **6**

Scheme 1. The synthesis of the metal-free and metallophthalocyanines.

and contains the characteristic stretching peaks of aromatic and supercryptand groups. The resonances at 3407–3390 and 1602–1603 cm^{-1}, belonging to N–H stretching and bending vibrations of metal-free phthalocyanines (**8**,**9**), also support the proposed structure. In addition to the results of elemental analysis, the mass

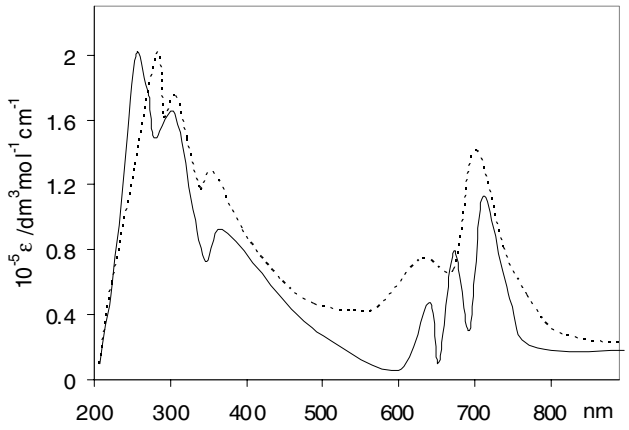

Fig. 1. UV–Vis spectra of **8** (solid line) and **10** (dotted line).

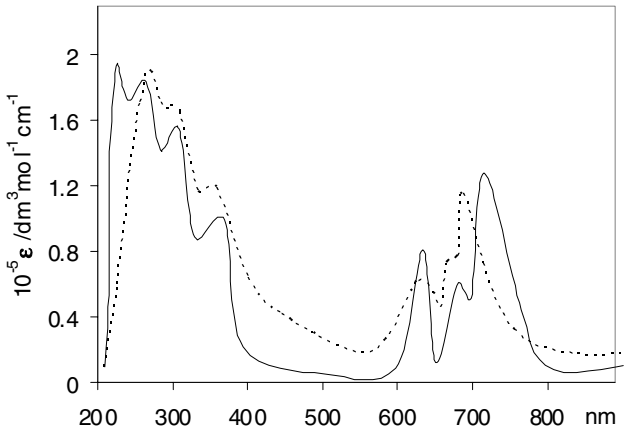

Fig. 2. UV–Vis spectra of **9** (solid line) and **11** (dotted line).

spectra were determined. The molecular ion peaks at $m/z = 2826.3$ $[M]^+$ (**8**) and 2827.2 $[M + 1]^+$ (**9**) were found by the FAB technique (matrix *m*-nitrobenzyl alcohol) for the metal-free phthalocyanines, together with some reasonable ion fragments.

The preparation of metallophthalocyanines (**10**,**11**) from dicyano compounds can be carried out under different reaction conditions [54]. The reactions in the presence of a strong organic base such as 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) in dry *n*-pentanol at reflux temperature are the most efficient ones in comparison to the other route [55,56]. The metal content of the metallophthalocyanines are in accord with their calculated results. This is also supported by the presence of the characteristic molecular ion peaks in the mass spectrum of **10** at $m/z = 2882.3$ $[M]^+$ and **11** at $m/z = 2883.5$ $[M + 1]^+$. The ^{1}H NMR spectra of these compounds are almost identical with those of the metal-free phthalocyanines, with the absence of the NH protons belonging to the cavity of the phthalocyanine core. Also, it should be mentioned that the peaks of the ^{1}H NMR spectra are broad as encountered in some other soluble phthalocyanines. The aromatic protons are shifted to lower field because of the π-electron ring current of the phthalocyanine core, even after complexation with Ni(II). A common feature of the ^{1}H NMR spectra of the Ni(II) phthalocyanines (**10**,**11**) is the broad absorption when compared with that of the precursor dicyano compounds. In the IR spectra of **10** and **11**, the disappearance of the strong C≡N stretching vibrations of precursors **4** and **5** can be taken as clear evidence for metallophthalocyanine formation. Also, the characteristic vibrations in the IR spectra of **10** and **11** are very similar to those of the metal-free phthalocyanines (**8**,**9**) with the exception of the N–H resonances of the phthalocyanine core. They are in agreement with the structural information.

The UV–Vis absorption spectra of **8** and **9** in a chloroform solution (ca. 1×10^{-5} M) at room temperature are shown in Figs. 1 and 2. In general, phthalocyanines show typical electronic spectra with two strong absorption regions, one in the UV region at about 300–350 nm related to the B band and the other in the visible region at 600–700 nm related to the Q band. The split Q bands in **8** and **9**, which are characteristic for metal-free phthalocyanines, were observed at $\lambda_{max} = 714$, 681, 635 and 711, 673, 640 nm, respectively. These intense Q bands indicate monomeric species, as species with D_{2h} symmetry show two intense absorptions around 700 nm [57–61]. Such split Q band absorptions are due to the $\pi \Rightarrow \pi^*$ transition from the HOMO to the LUMO of the phthalocyanine ring related to the fully conjugated 18π electron system. The presence of strong absorption bands in **8** and **9** in the near UV region at λ_{max} 353, 298, 271 and 367, 306, 275 nm also shows Soret region B bands which have been ascribed to the deeper $\pi \Rightarrow \pi^*$ levels of LUMO transitions [62–64].

UV–Vis absorption spectra of the metallophthalocyanines **10** and **11** in pyridine show intense Q absorptions at 701 and 695 nm (Figs. 1 and 2), with weaker absorptions at 630 and 628 nm, respectively. The single Q bands in metallo derivatives and the split form in their metal-free counterparts are characteristic [65]. These absorptions are generally observed in the case of metallophthalocyanines, indicating the presence of aggregated species together with monomeric ones. Figs. 1 and 2 show that the Q band region is considerably different from **10** and **11**. The observed peaks, as mentioned above, indicate that the symmetry of the molecules have been changed. This result is typical of metal complexes of substituted and unsubstituted *Pc* with D_{4h} symmetry [66,67]. When Ni(II) metal ions are included in the phthalocyanine core of **8** and **9**, the average position of the Q-bands of the resulting metallophthalocyanines (**10**,**11**) is slightly shifted to the blue with respect to the parent metal-free phthalocyanines. B band absorptions of the nickel(II) phthalocyanines (**10**–**11**) were observed at 348, 302, 285 and 363, 302, 275 nm as expected, respectively.

4. Conclusion

We have described for the first time, the synthesis of metal-free and metallophthalocyanines containing cylindrical or spherical subunits. 1,2-Bis(2-tosyloxy-ethyl-mercapto)-4,5-dicyanobenzene (**1**) reacts with macrobicyclic aza-crown moieties (**2**–**3**) in actonitrile or propionitrile under basic conditions to yield the dicyano compounds (**4**–**5**) containing cylindrical or spherical polymacrocyclic units. Compound **1** is a good target for preparing dicyano derivatives. On the other hands, the presence of nitrogen atoms bearing localized electron pairs make compounds **2** and **3** interesting targets for preparing dicyanobenzo units containing cylindrical or spherical macrotricycles. The exhaustive study of the synthesis of the corresponding isoiminoindoline derivative precursor of the metal-free phthalocyanines has been carried out from the dicyano compounds by bubbling through dry ammonia in dry methanol in the presence of CH_3ONa. Starting from **4** and **5**, nickel(II) phthalocyanines (**10**–**11**) were prepared. Unfortunately, all attempts made to grow crystals suitable for X-ray crystallographic studies were unsuccessful. However, ^1H, ^{13}C NMR, IR, elemental analysis, mass spectral data and UV–Vis measurements of the metal-free and the metallophthalocyanines are fully consistent with their identity.

Acknowledgements

This study was supported by the Research Fund of Karadeniz Technical University, Project No. 2002.111.8 (Trabzon/Turkey). We are indebted to Dr. Ayhan Çelik (University of Edinburgh/England) for assistance with some spectral data.

at low concentrations, although the basis for its toxicity it not clearly understood. The concern arises because it accumulates in particular food species, with potential consequences for human health (renal tubular dysfunction, hypertensive disorders, respiratory problems and others). According to the literature, one general mechanism for cadmium detoxification is the chelation of the metal [10,13,14,16].

We have been working for the last year on the synthesis and coordination capability of compounds containing thiazoline rings [15,16] due to their interesting biological properties. Moreover, these compounds are able to form complexes with cadmium [15,17] and could play an important role in its detoxification.

For all these reasons, in this paper, we report the synthesis and the characterization by single crystal X-ray diffraction, elemental analysis and spectroscopic measurement of a novel hydrazone derivative ligand, 2-acetyl-2-thiazoline hydrazone (ATH), and its complex with Cd(II).

2. Experimental

2.1. General procedures

All chemicals were of reagent grade and used without any further purification. 2-Acetyl-2-thiazoline was synthetized according to the method described by Doornbos and Peer [18]. Chemical analyses of carbon, hydrogen, nitrogen and sulfur were performed by microanalytical methods using a Leco CHNS-932 microanalyser. IR spectra were recorded on a Perkin–Elmer FT-IR 1720 spectrophotometer, from KBr pellets in the 4000–370 cm^{-1} range and on a Perkin–Elmer FT-IR 1700X spectrophotometer, from polyethylene pellets in the 500–150 cm^{-1} range. Electronic spectra were measured on a Shimadzu UV-3101 PC using a 10 mm quartz cell. ^1H and ^{13}C NMR spectra were obtained with a Bruker AM 400 instrument at 400 and 100 MHz, respectively. The NMR study has been carried out in D_2O for the complex and $DCCl_3$ for ATH. In addition, the NMR study of ATH has also been carried out in D_2O to be able to compare NMR spectra of both compounds.

2.2. Synthesis of 2-acetyl-2-thiazoline hydrazone (ATH)

A solution of 0.977 g (7 mmol) of 2-acetyl-2-thiazoline and 0.350 g (7 mmol) of hydrazine hydrate in 30 ml ethanol was heated to reflux for 3 h. The solvent was then removed under reduced pressure to obtain a brown oil. 2 ml of absolute ethanol was added and a yellow solid appeared (0.825 g, 76.2%). This solid was recrystallized from water, yielding prismatic crystals of considerable size (ca. 0.4 mm), suitable for X-ray diffraction.

^1H NMR (deuteriochloroform): δ 5.76 (s, 2H, NH_2), 4.38 (t, $J = 8.3$ Hz, 2H, CH_2–N), 3.24 (t, $J = 8.3$ Hz, 2H, CH_2–S), 2.08 (s, 3H, CH_3); ^{13}C NMR (deuteriochloroform): δ 169.90 C(1), 142.45 C(4), 64.87 C(2), 32.07 C(3), 10.39 C(5). Elemental Analysis, Found: C, 42.06; H, 6.35; N, 29.67; S, 22.19%. Calc. for $C_5H_9N_3S$: C, 41.94; H, 6.34; N, 29.33; S, 22.39%. UV–Vis (EtOH): λ_{max}, nm; (ε, L mol^{-1} cm^{-1}) 261 (5859).

2.3. Synthesis of $[Cd(NO_3)_2(ATH)_2]$

This complex was isolated from an 80% ethanol solution (2 mL) of $Cd(NO_3)_2 \cdot 4H_2O$ (216 mg, 0.7 mmol) that was added to an 80% ethanol solution (15 mL) of ATH (100 mg, 0.7 mmol). The resulting solution was allowed to evaporate slowly at room temperature. After a few days, yellow prismatic crystals of considerable size (ca. 0.6 mm) were isolated from the solution (104 mg, 57.0%). The crystals were separated by filtration, washed with cold ether and air-dried. ^1H-NMR (D_2O): 4.31 (t, $J = 8.6$ Hz, 2H, CH_2–N), 3.45 (t, $J = 8.6$ Hz, 2H, CH_2–S), 2.10 (s, 3H, CH_3); ^{13}C-NMR (D_2O): δ 175.22 C(1), 142.71 C(4), 63.64 C(2), 33.69 C(3), 13.48 C(5). Elemental Analysis, Found: C, 23.12; H, 3.41; N, 21.33; S, 11.87%. Calc. for $C_{10}H_{18}CdN_8O_6S_2$: C, 22.97; H, 3.47; N, 21.42; S, 12.27%.

2.4. Crystal structure determinations

X-ray diffraction measurements were performed using a Bruker SMART CCD diffractometer for ATH and a Siemens P4 diffractometer for the complex.

Crystal data, data collection and structure analysis parameters are given in Table 1. For ATH, the first 50 frames were recollected at the end of the data collection to monitor for decay, whereas in the case of complex, the examination of three standard reflections, monitored after 97 scans, showed only a slight change during data collection.

Data reduction was made using the SAINTPLUS program [19] for ATH and the XSCANS program [20] for the complex. Data were corrected for absorption effects using an empirical method based on azimuthal scan data in the case of the ligand. In the same way, absorption corrections were applied using the SADABS program [21] for the complex. The structures were solved by direct methods and subsequent Fourier differences using the SHELXS 97 program [22] included in the WINGX package [23], and refined by full-matrix least-squares analysis with SHELXL 97 [22]. H atoms attached to C and N atoms were positioned geometrically, with U_{iso} values derived from U_{eq} values of the corresponding C and N atoms. In the structure of the complex, one of the two ATH ligands were disordered and were modelled using two sets of positions. For this procedure, the occupancy of the two alternate orientations were constrained to unity

[a] $R = \sum||F_o| - |F_c||/\sum|F_o|$.
[b] $R = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$.
[c] GOF = $\{\sum[w(F_o^2 - F_c^2)^2]/(N_{reflections} - N_{params})\}^{1/2}$.

and soft constraints (with EADP) were applied to the disordered ATH. The refined occupancy was 0.53(1) for the orientation named A and 0.47(1) for the orientation named B. The non-hydrogen atoms were refined with anisotropic displacement parameters excepting atoms involved in disorder which were refined with isotropic displacement parameters. The Flack parameters of ATH and the complex indicate that the crystals did not contain inversion-twins. Diagrams were generated using ORTEP3 for Windows [24].

3. Results and discussion

3.1. Description of the crystal structures

The molecular structure of ATH with the atomic labelling is shown in Fig. 1. Selected bond lengths, angles and hydrogen-bond parameters are given in Table 2.

In the S–C(1)–N(1)–C(2)–C(3) ring, the short endocyclic C=N bond [C(1)–N(1) = 1.270(2) Å] is accompanied

Table 2
Selected bond lengths (Å), angles (°) and hydrogen-bond parameters for ATH

S–C(1)	1.773(2)	S–C(3)		1.803(2)
C(1)–N(1)	1.270(2)	C(1)–C(4)		1.465(2)
C(4)–N(2)	1.295(2)	C(4)–C(5)		1.493(3)
N(2)–N(3)	1.361(2)	N(1)–C(2)		1.467(3)

N(3)–H(3B)···N(1)	$-x, y, z-0.5$	0.860(2)	3.093(3)	149.2(2)

by a high N–C–S angle [N(1)–C(1)–S = 117.4(1)°] and a relatively long S^{II}–C(sp^2) bond [S–C(1) = 1.773(2) Å], which is characteristic of a thiazoline ring [25]. It is known that the imino tautomers can exist as two geometrical isomers, *syn* (*Z*) and *anti* (*E*), but in this crystal, only *E* isomers have been observed.

The thiazoline ring is essentially planar, with maximum mean-plane deviation from C(3) (0.031 Å).

The molecular packing is determinated by a hydrogen-bond network N(1)···H(3B)–N(3) of the intermolecular type. A diagram showing this network is given in Fig. 2.

A diagram of the molecular structure of the Cd(II) complex, showing the higher occupancy molecule for simplicity, is shown in Fig. 3. Selected bond lengths, angles and hydrogen bond parameters are given in Table 3.

The structure consists of discrete neutral monomeric units in which the environment around the cadmium(II) atom may be described as a very distorted octahedral geometry. The ligand–metal–ligand bite angles differ from the ideal value of 90°, varying between 65.1(6)° [N(4)–Cd–N(5)] and 136.1(4)° [N(1A)–Cd–O(4)]. The metallic atom is coordinated by two monodentate nitrate oxygen atoms, [Cd–O(1) = 2.334(12) Å; Cd–O(4) = 2.383(12) Å], two thiazolinic nitrogen atoms [Cd–N(1A) = 2.230(12) Å; Cd–N(4) = 2.384(12) Å] and two iminic nitrogen atoms [Cd–N(2A) = 2.414(10) Å; Cd–N(5) = 2.427(14) Å].

The crystal structure of the complex exhibits a positional disorder due to the existence of two quite different orientations from the ATH, numbering C(1)···C(5). In this ligand, the C(1) atom is common in both orientations. A representation of this disorder is shown in Fig. 4, with only the Cd atom and the disordered ligand displayed for simplicity.

The Cd–O distances of the monodentate nitrate groups are comparable with the calculated average value [2.418(82) Å] for 58 six-coordinate cadmium(II) complexes obtained with CONQUEST software [26] from the Cambridge Structural Database (CSD) [27]. Likewise, the Cd–N_{imino} distances are slightly higher than the mean value calculated for 47 six-coordinate cadmium(II) complexes using the data of 47 crystal structures obtained from the CSD: 2.347(87) Å. Moreover, the Cd–$N_{thiazoline}$ bond distances are comparable to

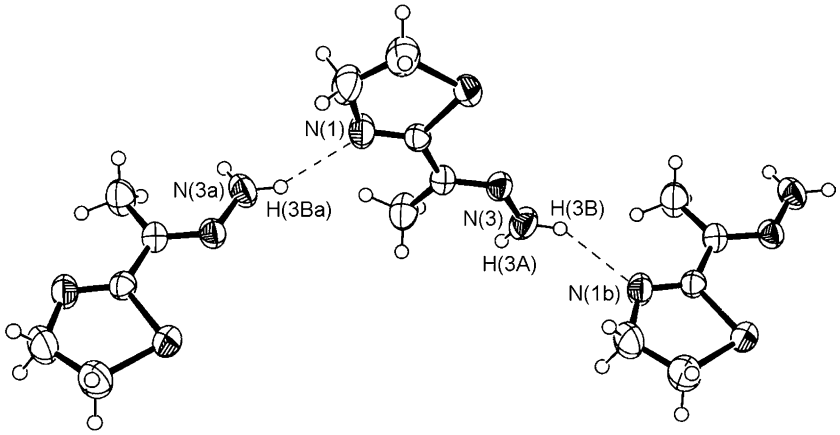

Fig. 2. View of the hydrogen bond network of ATH. Symmetry codes: (a) $-x, y, z+0.5$; (b) $-x, y, z-0.5$.

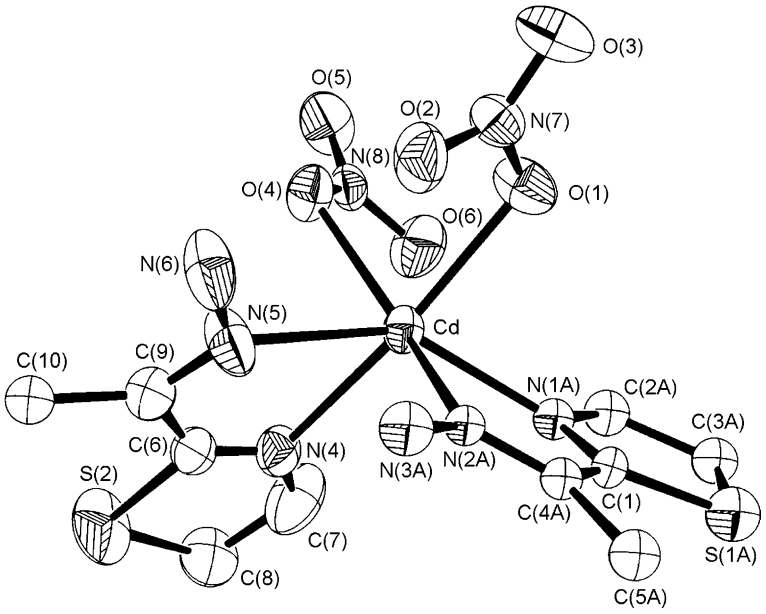

Fig. 3. Molecular structure of $[Cd(NO_3)_2(ATH)_2]$ showing the atom-numbering scheme. The thermal ellipsoids are drawn at the 40% probability level.

those found for $[CdCl_2(HzTz)] \cdot H_2O$ [HzTz = (2-thiazolin-2-yl)hydrazine] [2.241(2) Å] [17], $[Cd(NO_3)_2(PyTT)(H_2O)]$ [2.351(2) Å] and $[CdCl\{(\mu\text{-}Cl)_2CdCl(\mu\text{-}Cl)(\mu\text{-}PyTT)Cd\}_2]_n$ [2.271(2) Å] [16].

The five-membered chelate ring Cd–N(1A)–C(1)–C(4A)–N(2A) is essentially planar with the maximum deviation, in relation to the corresponding mean plane, from C(1) [0.079 Å]. On the contrary, the puckering parameters calculated for the chelate ring Cd–N(4)–C(6)–C(9)–N(5) [$q = 0.135$ Å; $\phi = 173.4°$], according to Cremer and Pople [28], indicate a conformation near to envelope with the Cd atom deviating 0.330 Å from the plane formed by N(4), C(6), C(9) and N(5) [maximum mean-plane deviation from C(6) = 0.019 Å].

The main difference of the organic moiety with respect to the structure of ATH is due to the different degree of rotation of the thiazoline rings around the C(1)–C(4A) and C(6)–C(9) bonds, which does permit the coordination through N(1A) and N(4) [torsion angles S(1A)–C(1)–C(4A)–N(2A) = 175.8° and S(2)–C(6)–C(9)–N(5) = 177.9° in the complex, respectively, 9.7° in ATH].

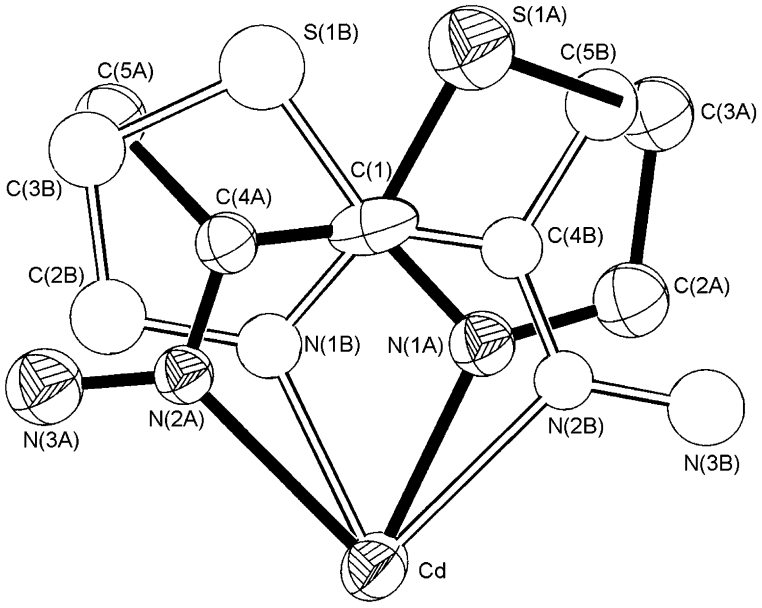

Fig. 4. A drawing demonstrating the disordering of the ATH ligand in the complex.

The thiazoline ring S(1A)–C(1)–N(1A)–C(2A)–C(3A) is essentially planar with maximum mean-plane deviation from S(1A) (0.042 Å). However, the thiazoline ring S(2)–C(6)–N(4)–C(7)–C(8) shows a conformation near to envelope with the apex at C(7). This atom is 0.202 Å out of the plane formed by N(4), C(6), S(2) and C(8) [maximum mean-plane deviation from C(6) = 0.010 Å]. This geometry is proved by the puckering parameters $q = 0.133$ Å and $\phi = 113.7°$ [28].

Focusing our attention on the N(7)–O(1)–Cd and N(8)–O(4)–Cd angles, we see that their values differ significantly from linearity, amounting to 110.1(9)° and 107.2(9)°, respectively. Likewise, the mean plane formed by the atoms O(1), O(2), O(3) and N(7) of one monodentate nitrate ligand forms an angle of 97.0° with the plane constituted by N(2A)–Cd–N(5). In the same way, in the other monodentate nitrate ligand there is an angle of 94.5° between the mean plane formed by O(4), O(5), O(6) and N(8) and the plane N(1A)–Cd–N(4). Both facts may possibly be explained in terms of crystal packaging effects, but as they facilitate the approach from O(2) and O(6) to the central ion, it cannot be excluded that they are conditioned by the existence of weak interactions O(2)–Cd [2.801(15) Å] and O(6)–Cd [2.766(15) Å].

The crystal packing is stabilized by a complicated hydrogen-bond network in which O(1) and O(2) act as hydrogen acceptors, hydrazinic nitrogen N(3A) acts as hydrogen donor and hydrazinic nitrogen N(6) acts on both forms. A diagram showing this network is given in Fig. 5.

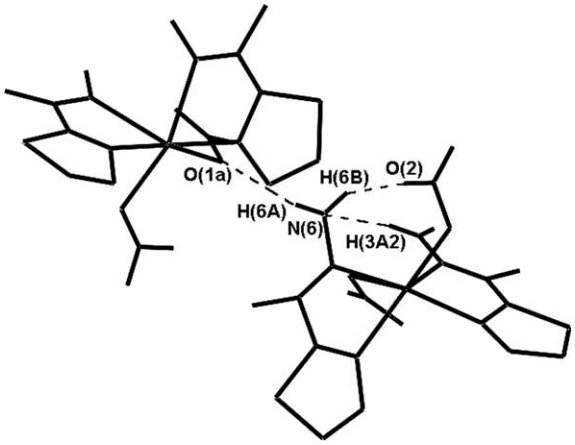

Fig. 5. View of the hydrogen network of $[Cd(NO_3)_2(ATH)_2]$.

3.2. Spectroscopic studies

The IR spectrum of ATH in the 4000–370 cm^{-1} region shows the presence of bands due to thiazoline ring at 1593 (W_1), 1003 (W_2), 915 (W_3), 714 (W_4), 675 (W_5), 657 (W_6), 619 (W_8), 549 (W_7) and 421 (Γ_1) cm^{-1} [29–31].

Moreover, the bands of NH_2 vibrations are detected at 3352, 3317, 3195 [$\nu(NH_2)$], 1567 [$\delta(NH_2)$], 1346 [$\omega(NH_2)$] and 1031 [$r(NH_2)$] cm^{-1} [30,32–34].

Other relevant bands are registered at 1653 cm^{-1} [ν(C=N)] and at 943 cm^{-1} [ν(N–N)] [30,35].

In the IR spectrum of the complex two bands can be observed in the 4000–370 cm^{-1} region at 1641 and 952 cm^{-1}, assigned to ν(C=N) and ν(N–N) vibrations, respectively. Moreover, other bands due to organic moiety vibrations are detected as is shown in Table 4. Bands

Table 4
Infrared bands (cm^{-1}) assigned to organic moiety vibrations of ATH and $[Cd(NO_3)_2(ATH)_2]$

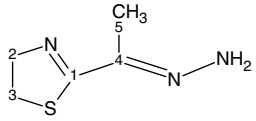
	ν(N–N)	943 (w)	952 (m)

Abbreviations: s, strong; m, medium; w, weak; v, very.

due to nitrate ligands are registered at 734, 709 and 602 cm^{-1} (ν_4), 818 cm^{-1} (ν_2), 1145 and 1030 cm^{-1} (ν_1) and 1446, 1430 and 1299 cm^{-1} (ν_3) [36].

In addition, in the 1700–1800 cm^{-1} region, the IR spectrum of the complex shows four combination bands due to nitrate groups. Methods to discriminate between bidentate and monodentate bonded nitrate groups have been reported and have been proved reliable. Some of them are based on the pattern or the splitting of the ($\nu_1 + \nu_4$) combination bands [37–40]. The bands registered at 1767 and 1744 cm^{-1} are assigned to ($\nu_1 + \nu_4$) combination bands. The value of the splitting ($\Delta = 23$ cm^{-1}) reveals the presence of one monodentate nitrate group, in agreement with Lever's criteria [38]. In the same way, the bands registered at 1748 and 1733 cm^{-1} ($\Delta = 15$ cm^{-1}) can be assigned to the other monodentate nitrate group.

Four bands assignable to Cd-ligand stretching vibrations are observed in the low frequency range. The band at 185 cm^{-1} is tentatively assigned to the (Cd–ONO_2) vibration due to monodentate nitrate ligands, in accord with the literature data for this type of bond [16,36].



The bands at 221 and 234 cm^{-1} can be assigned to the ν(Cd–$N_{thiazoline}$) vibration [16,30], whereas the band at 302 cm^{-1} is assigned to the ν(Cd–N_{imino}) vibration, according to the literature [16,41].

As usual [42], the coordination to the d^{10} Cd(II) ion shifts the ^{1}H NMR signals of the complexes downfield from those of the free ligand ($\Delta\delta \approx 0.0$–0.2 ppm). A comparison of the chemical shift data for ATH and the complex in Table 5 confirms this statement. The small shift is due to the weak Lewis acidity of this ion. The trends in the ^{13}C NMR shifts are similar. The signals of the carbon atoms 1, 3 and 5 show a slight downfield shift to those of the free ligand ($\Delta \approx 1.1$–3.2 ppm), whereas the C(2) and C(4) suffer an upfield shift ($\Delta\delta \approx -1.4$ and -2.9 ppm, respectively). The chemical shift differences are due to two superimposing effects: the negative inductive effect of the coordinated metal ion leads to a downfield shift and, on the other hand, the interaction of the paired metal d electrons with the organic ligand induces an upfield shift.

4. Supplementary material

CCDC 258903, corresponding to ATH, and CCDC 258904, to $[Cd(NO_3)_2(ATH)_2]$, contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union

Table 5
NMR spectral data for ATH and its Cd complex in D_2O solvent

Compound	^{1}H NMR			^{13}CNMR				
	CH_3	CH_2–S	CH_2–N	C5	C3	C2	C4	C1
ATH	1.99	3.24	4.27	11.89	32.63	65.01	145.64	172.98

complexes [24]. In this paper, we report the spectral characteristics of four copper(II) complexes derived from di-2-pyridyl ketone *N*(4)-methyl-*N*(4)-phenylthiosemicarbazone (Hdptsc) (Fig. 1). The crystal structures of two complexes formulated as $[Cu(dptsc)Br]_2$ (**2**) and $[Cu(dptsc)(\mu\text{-}N_3)]_2$ (**3**) are also described.

2. Experimental

2.1. Materials

Di-2-pyridyl ketone (Fluka) was used as received. $CuCl_2 \cdot 2H_2O$, $CuBr_2$, $Cu(OAc)_2 \cdot H_2O$, $Cu(NO_3)_2 \cdot 2.5H_2O$ and NaN_3 were commercial products of higher grade (Merck) and solvents were purified according to standard procedures. Elemental analyses were carried out using a Heraeus Elemental Analyzer and the molar conductance measurements of the complexes were carried out in DMF solvent at 28 ± 2 °C on a Century CC-601 digital conductivity meter with dip type cell and platinum electrode. Approximately 10^{-3} M solutions were used. The magnetic susceptibility measurements were made using a simple Gouy balance at room temperature using mercury tetrathiocyanatocobaltate(II), $Hg[Co(NCS)_4]$ as calibrant. Infrared spectral measurements were done on a Shimadzu DR 8001 series FTIR instrument using KBr pellets for spectra in the region 4000–400 cm^{-1}, and far IR spectra were recorded using polyethylene pellets in the 500–100 cm^{-1} region on a Nicolet Magna 550 FTIR instrument. An Ocean Optics SD 2000 Fiber Optic Spectrometer was used to measure solid-state reflectance spectra in the range 200–900 nm. ^1H NMR spectra were recorded using AMX 400 MHz FT-NMR Spectrometer with $CDCl_3$ as solvent and TMS as the internal standard. EPR spectral measurements were carried out on a Varian E-112 X-band spectrometer using TCNE as standard.

2.2. Synthesis of ligand

The ligand, Hdptsc was synthesized as reported earlier [24]. A solution of di-2-pyridyl ketone (1.84 g, 10 mmol) in 5 ml methanol was treated with *N*(4)-methyl, *N*(4)-phenylthiosemicarbazide (1.81 g, 10 mmol) in 25 ml methanol and refluxed for 2 h. On slow evaporation at room temperature, bright yellow crystals of Hdptsc separated out. These crystals were collected, washed with methanol and dried over P_4O_{10} in vacuo.

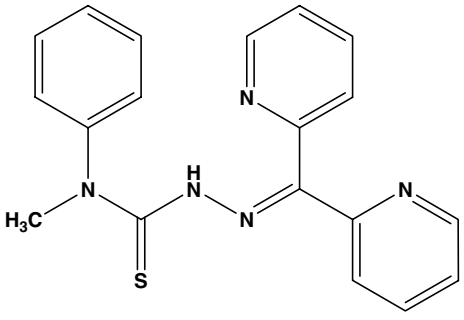

Fig. 1. Structure of Hdptsc.

2.3. Synthesis of $Cu(dptsc)Cl]_2 \cdot 3H_2O$ (**1**)

Methanolic solutions of Hdptsc (0.347 g, 1 mmol) and $CuCl_2 \cdot 2H_2O$ (0.171 g, 1 mmol) were mixed and heated under reflux for 2 h. Dark blue-green crystals of complex **1** were obtained, which were separated, washed with methanol followed by ether and dried over P_4O_{10} in vacuo. Yield: 0.25 g (52%).

2.4. Synthesis of $[Cu(dptsc)Br]_2$ (**2**)

Hdptsc (0.347 g, 1 mmol) was dissolved in methanol (15 ml) and refluxed with a solution of $CuBr_2$ (0.223 g, 1 mmol) in 1:1 methanol–chloroform mixture. Blue crystals separated out, which were filtered, washed with methanol followed by ether and dried in vacuo. Colourless single crystals suitable for X-ray diffraction were grown by slow evaporation of a 1:1:1 solution of methanol, chloroform and dichloromethane of the complex. Yield: 0.175 g (33%).

2.5. Synthesis of $[Cu(dptsc)(\mu\text{-}N_3)]_2$ (**3**)

$Cu(OAc)_2 \cdot H_2O$ (0.199 g, 1 mmol) dissolved in methanol (15 ml) was added to Hdptsc (0.347 g, 1 mmol) and refluxed. NaN_3 (0.0651 g, 1 mmol) was then added to the solution and further refluxed for 3 h. Dark blue crystals of **3** separated out, which were collected and dried in vacuo. Single crystals for X-ray diffraction were grown by slow evaporation of a 1:1:1 solution of methanol, chloroform and dichloromethane of the complex. Yield: 0.35 g (56%).

2.6. Synthesis of $[Cu(dptsc)(NO_3)]_2 \cdot H_2O$ (**4**)

A solution of $Cu(NO_3)_2 \cdot 2.5H_2O$ (0.233 g, 1 mmol) in a methanol–chloroform mixture (20 ml, v/v) was added to Hdptsc (0.347 g, 1 mmol) and refluxed for 2 h. The resulting crystals were washed with methanol, followed by ether and dried in vacuo. Yield: 0.35 g (65%).

2.7. X-ray crystallography

Single crystal X-ray diffraction measurements were carried out on a Bruker Smart Apex CCD diffractometer equipped with a fine-focused sealed tube. The unit cell parameters were determined and the data collections were performed using graphite-monochromated Mo Kα

Table 1
Elemental analyses, colours and molar conductivities of the Cu(II) complexes

Compound	Colour	Composition % (Found/Calc.)			λ_M[a]	μ_{eff}[b] (BM)
		Carbon	Hydrogen	Nitrogen		
$[Cu(dptsc)Cl]_2 \cdot 3H_2O$ (**1**)	Blue	48.54 (48.30)	3.65 (4.05)	14.71 (14.82)	32	1.63
$[Cu(dptsc)Br]_2$ (**2**)	Blue	46.63 (46.58)	3.32 (3.29)	14.35 (14.30)	27	2.24
$[Cu(dptsc)(\mu\text{-}N_3)]_2$ (**3**)	Blue	50.53 (50.49)	3.62 (3.57)	24.82 (24.79)	27	1.98
$[Cu(dptsc)(NO_3)]_2 \cdot H_2O$ (**4**)	Blue	46.67 (47.44)	3.45 (3.56)	17.98 (17.47)	24	2.56

[b] Magnetic susceptibility.

($\lambda = 0.71073$ Å) radiation. Both the crystals were found to be monoclinic with a $P2_1/c$ space group. Least square refinements of 17855 and 17083 reflections were done for compounds **2** and **3**, respectively. The data collected were reduced using the SAINT program [25]. The trial structures were obtained by direct methods [26] using SHELXS-86, which revealed the position of all non-hydrogen atoms and refined by full-matrix least squares on F^2 (SHELXL-97) [27] and the graphic tool was DIAMOND for windows [28]. All non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were treated with a mixture of independent and constrained refinements.

3. Results and discussion

3.1. Synthesis of complexes

Compounds **1**, **2** and **4** were prepared by direct reaction between the ligand and the corresponding metal salts, while compound **3** was prepared by the displacement of the acetate in $Cu(OAc)_2 \cdot H_2O$ by the azide ion. The complexes are mostly blue or blue-green coloured, as expected with thiosemicarbazone coordination, resulting from the ligand to copper charge transfer bands [29]. Elemental analyses (C, H, N) data (Table 1) of the complexes are consistent with the 1:1:1 ratio of metal:thiosemicarbazone:gegenion and also reveals that compounds **1** and **4** are hydrated. Conductivity measurements in DMF solution (10^{-3} M) indicate that all the complexes are non-electrolytes suggesting anionic coordination to the metal centre.

3.2. Crystal structures of $[Cu(dptsc)Br]_2$ and $[Cu(dptsc)(\mu\text{-}N_3)]_2$

Structural studies of compound **2** reveal a three-dimensional copper-thiosemicarbazone network consisting of two units of [Cudptsc] with a distorted square pyramidal geometry around Cu(II), with the basal plane

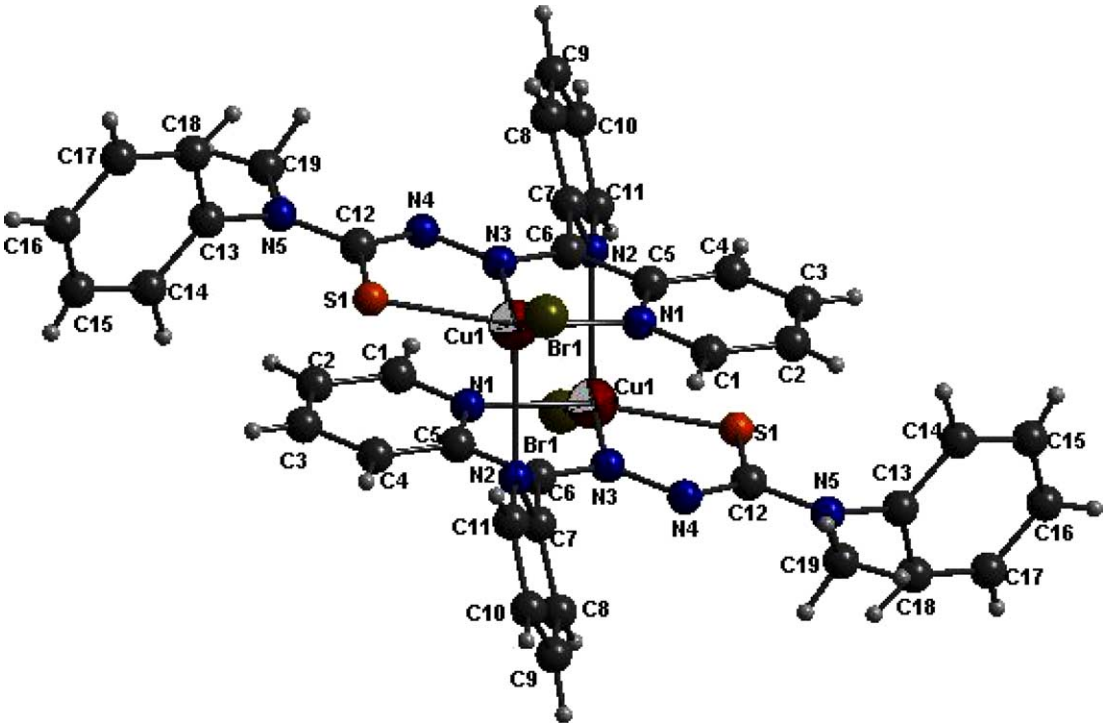

Fig. 2. Molecular structure of complex **2**.

consisting of one of the pyridyl nitrogens, azomethine nitrogen, thiolate sulfur and the bromine atom, while the pyridyl nitrogen of the second ligand unit occupies the apical position. A labelled representation of **2** is depicted in Fig. 2 along with the structural data refinements (Table 2) and selected bond distances and angles (Table 3). The bite angles N(1)–Cu(1)–N(3) (80.05°), Br(1)–Cu(1)–N(1) (96.81°), Br(1)–Cu(1)–S(1) (95.22°) and S(1)–Cu(1)–N(3) (83.60°) also support the distortion from square pyramidal geometry. The basal plane consisting of N(1), N(3), Br(1), S(1) and Cu(1) shows a maximum mean deviation of −0.3411 Å at N3. The Cu(II) atom is deviated at a distance of 0.3002 Å out of the mean plane towards the apical position. The thiosemicarbazone moiety comprising of N(5), C(12), S(1), N(4) and N(3) atoms and the pyridyl ring, Cg(3), make dihedral angles of 18.73° and 18.58°, respectively, with the metal chelate CuN_2BrS square plane. The loss of the proton bound to N(4) in Hdptsc produces a negative charge, which is delocalized on the thiosemicarbazone moiety. Delocalization of electron density over the entire thiosemicarbazone moiety is evidenced by the little marginal change in the C(6)–N(3) and N(3)–N(4) bond distances in **2**, compared to that of the uncomplexed thiosemicarbazone [30]. The bond distance S(1)–C(12) is longer and C(12)–N(4) is shorter than the corresponding values in the free ligand, which support thiolate formation in the ligand on complexation [31].

The structural pattern of the discrete binuclear complex, $[Cu(dptsc)(\mu\text{-}N_3)]_2$ (**3**) is best viewed as two end-on $\mu_{1,1}$-azido bridged quasi-square pyramids. Each *Hdptsc* unit acts as a tridentate chelate, coordinating through one of the pyridyl nitrogens, azomethine nitrogen and the thiolate sulfur to a single Cu(II) center which is involved in a $\mu_{1,1}$-azido bridging to an identical coordination network, thus materializing a penta-coordinated environment (Fig. 3). The base of each distorted square pyramidal unit is occupied by N(1), N(3), N(6) and S(1) atoms, with the apical position occupied by the N(6) atom of the second azido group. Each azido ligand functions as an electron donor to the coordination network through an end-on azido bridging mode. The centrosymmetric nature of the structure is revealed by an inversion center with the two azido-bridged angles, Cu–N–Cu (92.94°) and N–Cu–N (87.06°), being the same in both the units. The intramolecular Cu–Cu distance is found to be 3.303 Å and the axial Cu(1)–N(6)

N(3)–Cu(1)–N(6)a			89.29
N(6)–Cu(1)–N(7)			19.40
N(6)–Cu(1)–N(6)a			87.06
N(7)–Cu(1)–N(6)a			95.25
Cu(1)–N(6)–Cu(1)a			92.94

distance is found to be 2.5628 Å. The nitrogen atoms N(3) and N(6) are closer to the Cu(II) center with bond distances Cu(1)–N(3) (1.964 Å) and Cu(1)–N(6) (1.956 Å) compared to Cu(1)–N(1) (2.027 Å) and Cu(1)–S(1) (2.2603 Å). A maximum deviation of 0.1649 Å at N(1) is revealed at the base of the square pyramid with the central Cu(II) atom positioned 0.0689 Å above the mean plane. The pyridyl ring Cg(1) is less deviated from the basal plane (the dihedral angle between the two least square planes is 3.00°), when compared to the thiosemicarbazone moiety, which deviates more, at a dihedral angle of 13.51° from the basal CuN_3S plane. The dimer is located on an inversion centre and the bridging Cu_2N_2 network is perfectly planar. Similar to **2** above, the C(6)–N(3) and N(3)–N(4) bond distances in **3** reveal extensive delocalization over the entire binuclear coordination framework.

The diverse π–π stacking, C–H---π and ring–metal interactions give rise to polymeric chains in the unit cells of **2** and **3** (Figs. 4 and 5). The shortest π–π interactions are perceived at 3.3631 Å for $Cg(2)–Cg(2)^{i}$ [i = $1-x$, $1-y$, $1-z$] in **2**. Ring–metal interactions $Cg(2)---Cu(1)^{iii}$ [iii = x, $1/2-y$, $1/2+z$] are observed in **3** at a distance of 3.774 Å. Two C–H---π interactions each are shown in the unit cells of **2** and **3**. They are $C(8)–H(8)---Cg(1)^{iv}$ [d_{H---Cg} = 3.0853 Å; iv = $-1+x$, y, z] and $C(10)–H(10)---Cg(5)^{v}$ [d_{H---Cg} = 2.6471 Å; v = $-1+x$, $1/2-y$, $-1/2+z$] for **2** and $C(10)–H(10)---Cg(3)^{vi}$ [d_{H---Cg} = 2.9888 Å; vi = $1-x$, $-y$, $1-z$] and $C(15)–H(15)---Cg(2)^{vii}$ [d_{H---Cg} = 2.9537 Å; v = $1-x$, $-1/2+y$, $1/2-z$] for compound **3**.

3.3. Spectrochemical studies

The ν_a(N–H) vibrations of the imino group are observed at ca. 3428 cm^{-1} in the IR spectrum of Hdptsc. In the ^1H NMR spectrum, the N(4)H resonance, at a downfield value of 14.68 ppm, is consistent with the intramolecular N(4)–H---N(2) hydrogen bonding revealed by its crystal structure [30]. A strong band at 1580 cm^{-1} in the IR spectrum of Hdptsc corresponds to ν(N3–C6) stretching, which suffers a positive shift on complexation due to a change in bond order [31,32] (Table 4). The absence of a ν(S–H) band around 2565 cm^{-1} supports the predominant thione form of the ligand in the solid state, while the lack of an (N–H) stretching in the spectra of the complexes endorses the ligand coordination to Cu(II) ion in the deprotonated thiolate form. A medium band around 644 cm^{-1} indicates out-of-plane pyridyl ring vibrations ρ(py) of Hdptsc, which suffers a positive shift in all complexes. The IR bands observed at 1360 and 793 cm^{-1} in the ligand have significant contributions from C=S stretching and bending vibrations, and are shifted to lower wavenumbers on complexation [33]. Solid state reflectance spectrum of the ligand shows an absorption maximum in the region 37000 cm^{-1} attributed to intra-ligand $\pi^* \leftarrow \pi$ transitions of the pyridyl ring and imine function of the thiosemicarbazone moiety (Table 5). The peaks at ca. 27 000 and 30 030 cm^{-1} indicate $\pi^* \leftarrow$ n transitions of the thioamide function, which are shifted to higher energy values upon complexation. As expected, the Cu(II) ← S charge transfer transitions [34] are observed at ca. 23 000 cm^{-1}. For all the compounds, the peaks observed at ca. 17 000 and 14 000 cm^{-1} are assigned to d_{xz}, $d_{yz} \leftarrow d_{x^2-y^2}$ and $d_z^2 \leftarrow d_{x^2-y^2}$ transitions in an elongated square based pyramidal geometry [35,36]. Magnetic moment values for the bromo (**2**) and nitrato (**4**) complexes are greater than the spin only value for a dimeric system, since a larger Cu–Cu distance, revealed by the crystal structure in **2**, render the electron spins parallel resulting

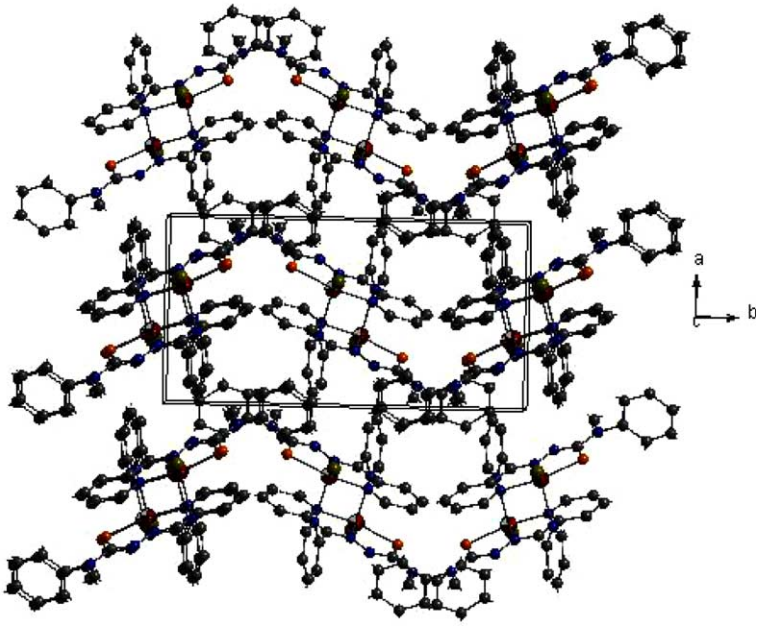

Fig. 4. Molecular packing diagram of **2** viewed down the '*c*' axis.

in a high magnetic moment. The azido (**3**) and the chloro complex (**1**) show magnetic moment values close to the spin only value per copper for a dimer, suggesting the absence of spin–orbit coupling and anti-ferromagnetic interactions. A medium band at 245 cm^{-1} in the IR spectrum of **2** is indicative of the coordinated bromine.

Compound **3** exhibits strong bands at 2041 and 1310 cm^{-1} corresponding to the ν_a and ν_s of the coordinating azido group [37]. The prominent bands at 699 cm^{-1} and a weak band at 444 cm^{-1}, assigned to δ(NNN) and ν(Cu–N), suggest a non-linear Cu–N–N–N bond [34]. Bands corresponding to ν_1, ν_2, ν_4 at 1010, 1284 and 1385 cm^{-1}, respectively, are observed in **4** whereas a $\nu_1 + \nu_4$ combination band at ca. 1750 cm^{-1} indicates monocoordinated nitrato group [37]. Magnetic moment measurement of **4** supports its potential dimeric disposition where the magnetic susceptibility value is found to be higher than that of a coupled Cu(II) ion pair, which is presumed with the association of small amounts of paramagnetic impurities in the compounds [38].

3.4. Electron paramagnetic resonance spectra

EPR spectra of the samples with 100-kHz field modulation at room temperature were recorded in the X-band. An isotropic spectrum with a broad signal is obtained for **3** and the remaining complexes gave axial spectra in the solid state at room temperature. The copper(II) ion, with a d^9 configuration, has an effective spin of $S = 1/2$ and is associated with a spin angular momentum $m_s = \pm 1/2$, leading to a doubly degenerate spin state in the absence of a magnetic field. In a magnetic field the degeneracy is lifted between these states and the energy difference between them is given by $E = h\nu = g\beta H$, where h is Planck's constant, ν is the frequency, g is the Lande's splitting factor (equal to 2.0023 for a free electron), β is the Bohr magneton and H is the magnetic field. For the case of a $3d^9$ copper(II) ion, the appropriate spin Hamiltonian assuming a B_{1g} ground state [36] is given by:

$$\hat{H} = \beta[g_{\parallel}H_zS_z + g_{\perp}(H_xS_x + H_yS_y)] + A_{\parallel}I_zS_z + A_{\perp}(I_xS_x + I_yS_y)$$

The EPR spectra of the compounds **1**, **2** and **4** in the polycrystalline state at 298 K show typical axial spectra with slightly different $g_{\parallel}$ and $g_{\perp}$ features. The variations in g values indicate that the geometry of the compound is affected by the nature of the coordinating gegenions (Table 6). The spectrum of compound **3** in the polycrystalline state (298 K) shows a broad signal indicating only one g value, 2.0638, due to dipolar broadening and enhanced spin lattice relaxation.

The geometric parameter G calculated as $G = (g_{\parallel} - 2.003)/(g_{\perp} - 2.003)$ is a measure of the exchange interaction between copper centers in the polycrystalline compound. It is perceived that, if $G > 4$, the exchange interaction is negligible and vice versa in the complexes. All complexes with $g_{\parallel} > g_{\perp} > 2.003$ and G values falling within the range of 2–4 are consistent with a $d_{x^2-y^2}$ ground state in a square planar or square pyramidal geometry. The g values are found to be lower than those reported for copper(II) complexes prepared from a substituted 2-benzoylpyridine thiosemicarbazone [39], indicating a stronger metal-ligand bonding. Absence of half field signals for the compounds reinforces the assumption of very weak super exchange interactions.

The solution spectra of complexes **1** and **4** were recorded in DMF at 298 K. They are isotropic in nature with well-resolved four hyperfine lines. The hyperfine splitting is due to the interaction of the electron spin with the copper nuclear spin (^{65}Cu, $I = 3/2$). There are indications of nitrogen superhyperfine splitting in the high field component in some spectra. The A_{iso} and g_{iso} values show variations in **1** and **4**, their values indicating dissimilarity in bonding in the complexes.

The spectra of complexes **1**, **3** and **4** in DMF at 77 K show rhombic features with three g values g_1, g_2, and g_3 where $g_3 > g_2 > g_1$. It is observed that the g values for complexes in the solid state at 298 K and in DMF at 77 K are not much different from each other, hence the geometry around the copper(II) ion is unaffected on cooling the solution to liquid nitrogen temperature. In the low field region, the chloro and nitrato complexes show six hyperfine lines that are moderately resolved and perpendicular features overlapping with seventh one suggesting a dimeric state with two copper centers. The g_3 values of the complexes are less than 2.3 and they assign considerable covalent character to the M–L bonds [40]. For the compounds **1**, **3** and **4**, the lowest g value (g_1) is less than 2.04 indicating a compressed rhombic symmetry with all axes aligned parallel and is consistent with distorted trigonal bipyramidal stereochemistry or a compressed axial symmetry or rhombic symmetry with slight misalignment of the axes. In the spectra with $g_3 > g_2 > g_1$, rhombic spectral values $R = (g_2 - g_1)/(g_3 - g_2)$ may be significant. If $R > 1$, a predominant d_{z^2} ground state is present. If $R < 1$, a predominant $d_{x^2-y^2}$ ground state is present and when $R = 1$, then the ground state is approximately an equal mixture of d_{z^2} and $d_{x^2-y^2}$, the structure is intermediate between square planar and trigonal bipyramidal geometries. All the present complexes have values $R < 1$ suggesting a distorted square based pyramidal geometry with a $d_{x^2-y^2}$ ground state. These observations are consistent with g values of the corresponding complexes in the polycrystalline state at 298 K and further supports the distorted square pyramidal geometry around copper(II) ion in these complexes.

Spin Hamiltonian parameters are calculated from the frozen state EPR and electronic spectra (Table 7). The

Table 7
Spin Hamiltonian and orbital reduction parameters of the complexes **1** and **4**

Compound	$[Cu(dptsc)Cl]_2 \cdot 3H_2O$ (**1**)	$[Cu(dptsc)(NO_3)]_2 \cdot H_2O$ (**4**)
$g_{\|/gzz}(g_3)$	2.2224	2.1816
$g_{yy}(g_2)$	2.0597	2.0341
$g_{xx}(g_1)$	1.9808	1.9723
$g_{av\ (77k)}$	2.0876	2.0627
g_{av} (solid)	2.0858	2.0750
R[a]	0.404	0.98
$K_{\|}$	0.6686	0.6357
$K_{\perp}$	0.6534	0.6030

[a] $R = (g_2 - g_1)/(g_3 - g_2)$.

orbital reduction factors were estimated using the following expressions [41].

$$K_{\|}^2 = (g_{\|} - 2.0023)\Delta E(d_{xy} - d_{x^2-y^2})/8\lambda_0,$$

$$K_{\perp}^2 = (g_{\perp} - 2.0023)\Delta E(d_{xz,yz} - d_{x^2-y^2})/2\lambda_0,$$

where λ_0 is the spin–orbit coupling constant and has a value of $-828\ cm^{-1}$ for Cu(II) d^9 systems.

According to Hathaway [42], $K_{\|} = K_{\perp} = 0.77$ for pure σ bonding and $K_{\|} < K_{\perp}$ for in-plane bonding, while for out-of-plane bonding $K_{\|} > K_{\perp}$. It is seen that for complexes **1** and **4** $K_{\|} > K_{\perp}$, indicating stronger out-of-plane π bonding.

4. Supplementary data

Crystallographic data for structural analysis has been deposited with the Cambridge Crystallographic Data center, CCDC 231110 for compound $[Cu_2(dptsc)_2Br_2]$ (**2**) and CCDC 231109 for compound $[Cu_2(dptsc)_2(N_3)_2]$ (**3**). Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 IEZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

esterification that causes uncontrolled reactivity, forming larger clusters [5–7]. To circumvent this, we have investigated alternative polydentate alcohol ligands [8].

From the commercially available ligands of interest, we have begun an investigation of the bidentate catechol (cat-H_2, Eq. (1)). Catechol is of interest since it has a number of applications ranging from biology, electrochemistry and catalytic investigations. In addition, it is reported that transition metal species that utilize the cat ligand favor chelation over a bridging mode of bonding. This will allow us to selectively reduce the more easily hydrolyzable monodentate ligands and thus garner control over the condensation process of these very reactive species. The metal cations we are interested in involve Group 4 and 5 cations due to their wide spread use in materials production.

(1)

We undertook the synthesis and characterization of Group 4 and 5 metal alkoxides derivatized with cat-H_2 (see Eq. (1)). Since, literature reports indicate that the fully substituted species could not be isolated [9–11], we chose to investigate the highest degree of substitution we could invoke. Therefore, two equivalents of cat-H_2 were reacted with the following alkoxides [Ti(μ-ONep)-(ONep)$_3$]$_2$ [12] (ONep = OCH_2CMe_3), [Zr(μ-OPr^i)(ONep)$_3$ · HONep]$_2$ [13] (OPr^i = $OCHMe_2$), $Hf(OEt)_4$ (OEt = OCH_2Me), and three equivalents with $M(OEt)_5$ (M = Nb or Ta). The resulting modified precursors were structurally identified as $Ti_3(\mu_3\text{-}O)(\mu\text{-cat})_3(cat)(cat\text{-}H)_2$ (**1**), $Zr_4(\mu_4\text{-}O)(\mu\text{-cat})_6(\mu\text{-cat-}H)_2(py)_4$ (**2**), $Hf_4(\mu_4\text{-}O)$-$(\mu\text{-cat})_6(\mu\text{-cat-}H)_2(py)_4$ (**3**), $M(cat)_2(cat\text{-}H)(py)$ (M = Nb (**4**); Ta (**5**)). The synthesis and characterization of these compounds in relationship to existing catechol derivatives is presented in the following discussion. In addition, the utility of these precursors as potential nanoparticle precursors to Group 4 and 5 ceramic materials was undertaken using **1**–**5**. Details of the process to synthesize these materials are also presented.

2. Experimental

All reactions were performed under a dry, inert atmosphere using standard Schlenk line and glovebox techniques. The following chemicals were purchased from Aldrich and used without further purification: cat-H_2, HONep, Ti(OPr^i)$_4$, Zr(OPr^i)$_4$ · HOPr^i, $Hf(OEt)_4$, $M(OEt)_5$ (M = Nb, Ta). All solvents used were used as received as anhydrous solvents (sure-sealed). [Ti(μ-ONep)-(ONep)$_3$]$_2$ [12] and [Zr(μ-OPr$_i$)(ONep)$_3$(HONep)]$_2$ [13] were synthesized according to literature routes wherein Ti(OPr^i)$_4$ or Zr(OPr^i)$_4$(HOPr^i) complex were reacted with HONep.

FT-IR spectral data were obtained on a Bruker Vector 22 spectrometer using KBr pellets pressed and handled under an atmosphere of flowing nitrogen. Elemental analysis was performed on a Perkin–Elmer 2400 CHN-S/O elemental analyzer. Thermal gravimetric analysis/Differential thermal analysis (TGA/DTA) data were performed on a Universal V3.0G TA Instrument by heating from room temperature to 650 °C at a ramp rate of 5°/min under an argon atmosphere. Solution NMR spectra were obtained on a Bruker DRX400 using a 5 mm broadband solution probe: ^1H (399.8 MHz) and $^{13}C\{^1H\}$ (100.6 MHz). Chemical shifts were referenced to the residual proton signal from the solvent in the ^1H NMR spectra or to the deuterated solvent resonance in the ^{13}C NMR spectra. Solid-state ^{13}C CPMAS NMR data were collected on a Bruker Avance400 using standard experimental conditions with a 4mm magic angle spinning (MAS) NMR probe and two pulse phase modulated (TPPM) high power ^1H decoupling. Typical acquisition conditions included 2 ms contact time, 1024 or 2048 scans, 10 kHz MAS spinning speed and 5 s recycle delay. The chemical shift was referenced to the carbonyl resonance (δ = 176 ppm) of the standard glycine with respect to TMS (δ = 0 ppm). For NMR analysis the rotors were packed with crystalline material under an atmosphere of argon.

2.1. $Ti_3(O)(cat)_4(cat\text{-}H)_2$ (*1*)

In a vial, cat-H_2 (0.171 g, 1.55 mmol) was added to a stirring solution of $Ti(ONep)_4$ (0.311 g, 0.777 mmol) dissolved in THF (~2 mL) and heated (~65 °C) for 5 min. After the reaction cooled to room temperature, the volatile material was removed by rotary evaporation, forming an off red powder. This powder was redissolved in pyridine and then set aside to slowly evaporate until crystals formed. Yield: 52% (0.328 g). FT-IR (KBr, cm^{-1}): 3132(s), 3062(m), 3019(s), 2958(s), 2928(s), 2857(s), 1654(s), 1635(s), 1607(s), 1534(s), 1508(s), 1484(w), 1326(m), 1245(w), 1205(m), 1099(m), 1016(m), 885(m), 863(m), 823(w), 808(w), 744(w), 678(w), 666(w), 648(w), 623(w), 605(w), 582(m), 562(s), 545(m), 536(m), 507(w). Elemental *Anal*. Calc. for $C_{50}H_{45}N_2O_{14}Ti_3$: C, 74.58; H, 5.5; N, 3.45. Found: C, 66.05; H, 4.89; N, 9.69%.

2.1.1. General synthesis

Due to the similarity of the synthesis of **2**–**5**, a general description will be provided. The appropriate amount of cat-H_2 dissolved in pyridine was added via pipette to a stirring solution of $M(OR)_x$ in py. After 1 h, if the

reaction mixture was not homogeneous, it was warmed slightly until a clear solution was obtained. The reactions were then set aside to slowly evaporate over an extended period of time.

2.2. $Zr_4(O)(cat)_6(cat\text{-}H)_2(py)_4$ (**2**)

Used $[Zr(\mu\text{-}OPr_i)(ONep)_3(HONep)]_2$ (0.439 g, 0.467 mmol), cat-H_2 (0.205 g, 1.862 mmol). Yield: 16% (0.118 g). FT-IR (KBr, cm^{-1}): 3052(m), 3019(s), 2959(s), 2927(s), 2869(s), 1635(s), 1606(s), 1580(m), 1544(s), 1486(w), 1448(w), 1438(m), 1328(m), 1315(m), 1253(w), 1215(m), 1192(m), 1100(m), 1023(m), 876(m), 809(w), 741(w), 701(m), 683(m), 607(w), 580(m), 503(m). Elemental *Anal.* Calc. for $C_{68}H_{52}N_4O_{17}Zr_4$: C, 52.49; H, 3.34; N, 3.57. Found: C, 54.07; H, 4.21; N, 3.76%.

2.3. $Hf_4(O)(cat)_6(cat\text{-}H)_2(py)_4$ (**3**)

Used $Hf(OEt)_4$ (0.101 g, 0.282 mmol), cat-H_2 (0.062 g, 0.563 mmol). Yield: 31% (0.162 g). FT-IR (KBr, cm^{-1}): 3053(m), 3021(s), 2960(s), 2927(s), 2871(s), 1635(s), 1608(s), 1580(m), 1543(s), 1488(w), 1449(w), 1329(m), 1270(w), 1252(w), 1215(m), 1193(m), 1149(s), 1100(m), 1069(s), 1042(s), 1024(m), 878(m), 810(w), 740(w), 696(m), 683(s), 609(w), 527(s), 508(s). Elemental *Anal*. Calc. for $C_{68}H_{52}N_4O_{17}Hf_4$: C, 42.93; H, 2.73; N, 2.92. Found: C, 48.96; H, 3.47; N, 4.84%.

2.4. $Nb(cat)_2(cat\text{-}H)(py)$ (**4**)

Used $Nb(OEt)_4$ (0.308 g, 0.968 mmol), cat-H_2 (0.320 g, 2.91 mmol). Yield: 95% (0.450 g). FT-IR (KBr, cm^{-1}): 3134(s), 3065(m), 3015(s), 2962(s), 1599(s), 1577(s), 1545(s), 1508(s), 1473(w), 1452(m), 1437(m), 1333(m), 1248(w), 1205(m), 1096(m), 1064(m), 1014(m), 869(m), 836(m), 806(w), 766(w), 741(w), 703(s), 678(m), 637(w), 620(w), 604(w), 515(w). ^1H NMR (399.8 Hz, py-d_5) δ 6.78 (br s, $O_2C_6H_4$). ^{13}C NMR (100.6 MHz, py-d_5) δ 159.9, 119.9, 113.9 ($O_2C_6H_3$). Elemental *Anal*. Calc. for $C_{23}H_{17}N_1O_6Nb$: C, 55.86; H, 3.43; N, 2.80. Found: C, 53.69; H, 3.44; N, 4.64%.

2.5. $Ta(cat)_2(cat\text{-}H)(py)$ (**5**)

Used $Ta(OEt)_4$ (0.508 g, 1.25 mmol), cat-H_2 (0.413 g, 3.751 mmol). Yield: 91.4% (0.758 g). FT-IR (KBr, cm^{-1}): 3131(s), 3067(m), 3050(m), 3023(m), 2965(s), 1636(s), 1609(m), 1580(s), 1541(s), 1482(w), 1449(w), 1420(s), 1337(m), 1317(s), 1293(m), 1252(w), 1211(m), 1197(m), 1155(s), 1100(m), 1070(m), 1044(s), 1016(m), 872(m), 812(w), 744(w), 692(m), 675(m), 630(w), 606(w), 529(w). ^1H NMR (399.8 Hz, py-d_5) δ 6.82 (br s, $O_2C_6H_4$), 6.74 (br s, $O_2C_6H_4$). ^{13}C NMR (100.6 MHz, py-d_5) δ 159.9, 119.8, 114.9 ($O_2C_6H_3$). Elemental *Anal*. Calc. for $C_{28}H_{22}N_2O_6Ta$: C, 57.80; H, 3.78; N, 4.77. Found: C, 62.71; H, 4.48; N, 6.22%.

2.5.1. General X-ray crystal structure information[1]

Each crystal was mounted onto a thin glass fiber from a pool of Fluorolube™ and immediately placed under a liquid N_2 stream, on a Bruker AXS diffractometer. The radiation used was graphite monochromatized Mo Kα radiation ($\lambda = 0.7107$ Å). The lattice parameters were optimized from a least-squares calculation on carefully centered reflections. Lattice determination and data collection were carried out using SMART Version 5.054 software. Data reduction was performed using SAINT Version 6.01 software. The structure refinement was performed using XSHELL 3.0 software. The data were corrected for absorption using the SADABS program within the SAINT software package.

Each structure was solved using direct methods. This procedure yielded the heavy atoms, along with a number of the C, N and O atoms. Subsequent Fourier synthesis yielded the remaining atom positions. The hydrogen atoms were fixed in positions of ideal geometry and refined within the XSHELL software. These idealized hydrogen atoms had their isotropic temperature factors fixed at 1.2 or 1.5 times the equivalent isotropic U value of the C atoms to which they were bonded. The final refinement of each compound included anisotropic thermal parameters on all non-hydrogen atoms. Additional information concerning the data collection and final structural solutions of **1**–**5** can be found in the supplemental information. Any variations from standard structural solution associated with the representative compounds are discussed below. All CIF files were checked for errors using the free on-line Checkcif service provided by the International Union of Crystallography (available on the Web at http://www.iucr.org/acs/checkcif.html).

3. Results and discussion

Since cat-H_2 is commercially available, inexpensive, stable and can act as a chelating ligand, it is an attractive ligand for a variety of applications and has lead to extensive reports of transition metal complexes. As mentioned previously, we are interested in the Group 4 and 5 cations for materials synthesis; however, for our systems, non-oxygen anions (i.e., halides, sulfides, etc.) can have deleterious effects on the properties of the materials of interest and therefore are avoided.

Several cationic species where the Group 4 cations use the cat ligand without the afore-mentioned anions

[1] The listed Versions of SAINT, SMART, XSHELL, and SADABS Software from Bruker Analytical X-ray Systems Inc., 6300 Enterprise Lane, Madison, WI 53719 were used in analysis.

have been reported, including the following for Ti species: $[Et_3NH]_2[Ti(cat)_3]$ [14], $K_4[TiO(cat)_2]\cdot 9H_2O$ [14], along with several neutral species including $[Ti_6O_4(OPr^i)_4(cat)_4\{(CO)_9Co_3CCO_2\}_4]$ and $[Ti_6O_4(OBu^n)_{10}(O_2CCH_3)_8]$ (note several reports indicate that species with molar ratios of catechol:Ti greater than 1 were unsuccessful) [9–11]. Zirconium cat adducts have also been reported including: $[Zr_3(acac)_4(cat)_4(MeOH)_2]$, $[Zr(acac)_2(DBcat)]_2$ (H_2DBcat = 3,5-di-*tert*-butylcatechol) and $[Zr_4(\mu_4\text{-}O)(acac)_4(DBcat)_3(OMe)_4(MeOH)]$ [15]. Only one Hf derivative, $Na[Hf(cat)_4]\cdot H_2O$ [16,17], has been reported.

For Group 5 a similar set of cationic and neutral species have been isolated for vanadium, including: $[V(cat)_3][Z]\cdot solv$, where $Z\cdot solv = NHEt_3\cdot MeN$; $K\cdot H_2O$, $K[V(O)(cat)]\cdot(H_2O)(EtOH)$ [18], V(O)(DBcat)(DBBQ) (where DBBQ = 3,5-di-*t*-butyl-1,2-benoquinone) [19], $[Na(\mu\text{-}cat)_2V(cat)(MeOH)_2]_2\cdot MeOH$ [20,21], V(O)(cat)(SEI) where SEI = (4-(2-(salicylideniimino)ethyl)imidazole) [22,23], $[V(O)_2(DBcat)][NHEt_3]$ [24], $[(MeOH)Na(\mu\text{-}DBcat)_2V(\mu\text{-}DBcat\text{-}H)(\mu_3\text{-}OMe)\text{-}V(MeOH)_2]_2\cdot MeOH$ [25], V(O)(cat-H)(SDC), V(O)(DBcat-H)(SDC) and V(O)(DBcat)(SDC) where SDC = *N*-salicylideneglycinato-*N*,*O*,*O*′) [26], $V(DBcat)_2(bipy)\cdot$ toluene [27]. However, surprisingly, there are no species reported for Nb or Ta metals with the cat ligand. It is of note that there are numerous structurally characterized species that possess both cat and halide ligands, and as previously mentioned, the latter anions can be a derisive contamination in the materials we have interest in.

From the above collection of structures, no fully substituted catecholate complexes for Group 4 or 5 compounds have been reported. Therefore, we chose to synthesize and characterize this family of compounds. While the $OCHMe_2$ (OPr^i) derivatives are commercially available, the ONep derivatives have several characteristics that make them more attractive than the OPr^i derivatives. Initially, we used $[Ti(\mu\text{-}ONep)(ONep)_3]_2$ [12] and $[Zr(\mu\text{-}OPr^i)(ONep)_3\cdot HONep]_2$ [13] to study the fully substituted cat-H_2 Group 4 species. As we observed the full exchange was accessible, we proceeded to use the commercially available ethoxide derivatives for the Hf, V and Ta catechol derivatives. The synthesis and characterization of **1**–**5** are discussed below.

3.1. Synthesis

The simple alcoholysis reactions were investigated according to Eq. (1) to generate fully cat-substituted Group 4 species. The reaction was undertaken using pyridine (py) as the solvent to maintain solubility of the final products. For the Ti system, after heating to solubilize the reaction mixture, the color changed from clear to red and a small precipitate formed that was removed by centrifugation. Additional investigations with other alkoxides showed the same product was isolated independent of the pendant alkoxy chain. Therefore, we used commercially available alkoxide species for the remainder of experiments where applicable. For the Zr and Hf reactions the colors changed from clear to yellow but did not require any heating. The Hf reaction was similar to the Zr reaction, turning from clear to yellow with no precipitate and no heating required. For Group 5 species, the appropriate amount of cat-H_2 dissolved in pyridine was added via pipette to a stirring solution of $M(OEt)_5$ OET = ethoxidein pyridine in pyridine. Color changes were noticeable for the clear solutions of niobium and tantalum, going to deep red and yellow, respectively. Again, py proved to be the best solvent for generating the cleanest products. For each reaction, X-ray quality crystals were grown by slow evaporation. The resulting modified precursors were structurally identified as **1**–**5** shown in Figs. 1–5, respectively, and show that full substitution of the alkoxide for cat ligands had occurred for each reaction.

3.1.1. Crystal structure

For **1**, the species isolated was trinuclear using a μ_3-O to bind the three Ti metal centers together in a corner missing cube arrangement (see Fig. 1). Each metal center is octahedrally coordinated using one cat ligand as a chelating ligand and one as a bridging chelating ligand. While py molecules are present in the lattice, none were found bound to the metal centers. Based on charge balance, two of the cat ligands can have one hydroxide (cat-H) present; however, the protons could not be located and are assumed to be disordered over the entire molecule for all of the following molecules discussed.

An alternative location of the H atom may be in that a pyridimium molecule is formed, generating $[py\text{-}H]^{+-}[Ti(cat)_3]$. The FTIR spectrum indicates the presence of an OH but due to overlapping stretches it is difficult to identify the presence of pyridimium ion [28]. A search of the structurally characterized pyridimium ions

with Group 4 cations necessarily contain halide anions.[2] Attempts to observe the pyridium ion using high speed ^{1}H solid state NMR investigations revealed cat resonances but no resonance could be conclusively assigned to a pyridimium ion and there are no transition metal pyridimium ion chemical shift reports available in the literature; however, organic pyridimium ions have been reported at 7–8 ppm [29] which overlap with the solid state cat resonances observed. Based on these data, we feel the more traditional disordered OH for metal alkoxides [1–3] is the actual structure and have used this notation throughout this work; however, the pyridimium ion cannot be fully ruled out at this point.

Both **2** and **3** possess similar central cores to each other, best described as a tetrahedral arrangement of four Zr or Hf atoms around a μ_4-O (see Figs. 2 and 3, respectively). Each metal is eight coordinated adopting a distorted bicapped trigonal prismatic structure through the additional binding of two chelating bridging cat ligands and a terminal py solvent molecule. Two of the cat ligands must be cat-H in order to balance the charge of the molecule, but again the protons were not located in the structural solution.

In contrast, the Group 5 species (**4** and **5** shown in Figs. 4 and 5, respectively) adopted mononuclear species. Similar complexes are formed, independent of the cation. Each metal has three cat ligands binding in a chelating manner, but based on charge balance one of the cat ligands must possess a hydroxy group. This H atom was not located in the final structure and must be disordered over several sites. Each Group 5 metal finishes its 7-coordination by binding a py molecule to formally form what appears to be a capped octahedral geometry. Bond distances and angles are in agreement with literature values [9–11,14–27].

3.1.2. Bulk characterization

The FTIR spectra show the stretches of **1**–**5** are consistent with the cat ligand as would be expected for the full substitution. The alkyl stretches and bends associated with the OEt, OPr^i and/or ONep ligands are absent,

[2] A search of the Cambridge Data Crystal Data Base (Version 1.6 – Feb 21, 2005 update) reveals 10 references that contain a pyridiumium ion with a Group 4 metal center, but all possess halide ligands.

indicating complete exchange, but there are some sharp stretches observed around 3000 cm^{-1} that are consistent with the residual OH groups present for each sample. As expected from their similar crystal structures, the spectra of **2** and **3** are nearly indistinguishable from each other, as are the spectra of **4**–**5**. For **1**, the FTIR spectrum looks similar to **2** and **3** with the notable additional stretches around 600 cm^{-1} that are consistent with the Ti–O stretches [1–3].

Elemental analyses of the bulk powders of **1**–**5** do not agree with the crystal structures obtained. The variations are often attributed to "trapped" and bound solvent that is often labile enough to cause variations and thus make meaningful data impossible to collect [30–32]. Therefore, alternative methods were necessary to prove the identify of the bulk powder.

TGA/DTA data was collected for **1**–**5** under an argon atmosphere. For compound **2**, there are two weight step losses but only one exothermal event. This occurs at ~350 °C. The first weight loss can be associated with loss of the py and the subsequent thermal events with the cat ligands. Surprisingly, the thermal decomposition of the Hf analog **3** is different in comparison to **2**. For **2** there is a steady weight with a very broad but small exothermal thermal event (<400 °C) across the weight loss process. For **4**, there is an endotherm associated with a slight weight loss that is consistent with loss of py. At higher temperatures an exotherm starting around 400 °C is associated with the largest weight loss consistent with the loss of catechol ligands. Similar TGA/DTA data are recorded for **5**. The calculations for weight loss of the bulk powders for Group 4 species **1** (21.1%), **2** (27.9%), **3** (32.6%) are consistent with the observed values of 21.0%, 26.0%, 31.8%, respectively, indicating that the bulk powders are in general agreement with the single crystal structures. For the Group 5 species, the experimental weight loss for **4** (24.5%) and **5** (35.5%) were substantially more than what was calculated at 18.0% and 33.2%, respectively. This again may be a reflection of the amount of solvent located in the lattice (Tables 1 and 2).

Solid-state ^{13}C NMR spectra were collected on the crystalline materials of **1**–**5** to further investigate the identity of the bulk powder. Fig. 6 shows the solid state NMR spectra for **1**–**5** and Table 3 metrically lists this data. The resulting solid-state ^{13}C NMR spectra of **1** reveals numerous aromatic peaks with no alkoxide resonances. For the crystal structure of **1**, two types of cat ligands are present (chelating and unidentate bridging) which should lead to 12 types of carbon resonances. There are numerous overlapping ^{13}C resonances observed between δ 170 and 110 ppm, with the overlap

most likely resulting from crystal packing inequivalancies. However, these data would indicate that the sample investigated is fully substituted with cat ligands and that the simplicity of the aromatic region argues for the bulk of the material to be consistent with the solid state structure.

For **2** and **3**, the solid-state spectra are consistent with each other. The resonances observed fall within the same range observed for **1** but are broader and less defined in comparison to **1**. This is most likely due to the more complex nature of the final structure, wherein, there are three types of cat ligands present (two unidentate bridging and one chelating). Additionally, the bound and trapped py molecules will contribute additional complexity to this region. For **2**, there are some resonances associated with alkoxide ligands, indicating a

5	157.2, 153.9, 148.9, 141.0, 139.1, 136.9, 123.9, 119.7, 117.0, 113.0

minor impurity. Some of these have been identified in the spectrum (Fig. 6(b)). This contaminant would be another aspect of the elemental analyses data that is not consistent with the bulk powder. Multiple crystallizations did not remove this impurity.

For **4**–**5**, the ^{13}C MAS NMR spectra are nearly identical. The six carbons of the catechol rings are observed between 165 and 110 ppm but these resonances are split. This splitting is associated with packing inequivalencies and the asymmetry of the rings induced by the presence of the proton. For **4** (Fig. 6(d)), several minor alkoxy peaks have also been noted, as observed for **2**.

3.1.3. Solution state NMR

It is of interest to know the solution behavior of these compounds prior to use as nanoparticle precursors since the nuclearity of the solution compound may play a big role in the nanoparticle formation. Crystalline material of each sample was dissolved in py-d_5 and sealed under vacuum. Compounds **1**–**3** were not soluble enough to obtain meaningful NMR spectra, even at elevated temperatures. Therefore, these have been omitted from the experimental section. Compounds **4** and **5** possess increased solubility in comparison to the Group 4 derivatives. The ^{1}H NMR spectrum for compound **4** displayed one resonance associated with cat (δ 6.78 ppm); however, there was a shoulder present on the broad resonance. For **5**, two ^{1}H NMR resonances were noted at δ 6.82 and 6.74 ppm. The $^{13}C\{^{1}H\}$ NMR spectra show three resonances with slight variations in the chemical shifts of the two species. Based on these data it appears the monomer molecular species are retained in solution.

3.1.4. Materials synthesis

Due to the reduction of clustering wrought by the cat ligand for some of these compounds, it was of interest to determine their utility as MOCVD and/or nanoparticle precursors. It has been previously noted that similar properties of the precursor are desired for both MOCVD and nanoparticle production [33]. Based on the high decomposition temperatures observed in the TGA/DTA data of **2**–**6**, these compounds were eliminated for consideration of further investigation. For **1**, the thermal decomposition temperature was at the upper limit of utility. The compound did not sublime which prevented further investigations using MOCVD techniques. Nanoparticle synthesis was attempted following Stucky et al. [34] methodology. In general, **1** was added to benzyl alcohol and heated to 250 °C for 24 h. After this time, the reaction was allowed to cool to room temperature, and hexanes were added to precipitate the resultant material. The mother liquor was removed by centrifugation and the orange precipitate was washed several times with hexanes. The powder was redispersed in hexanes and a drop of the slurry was placed onto a TEM grid. The TEM image is shown in Fig. 7. While the particles are clustered together, the material consists of polydispersed nanocrystalline ceramic material.

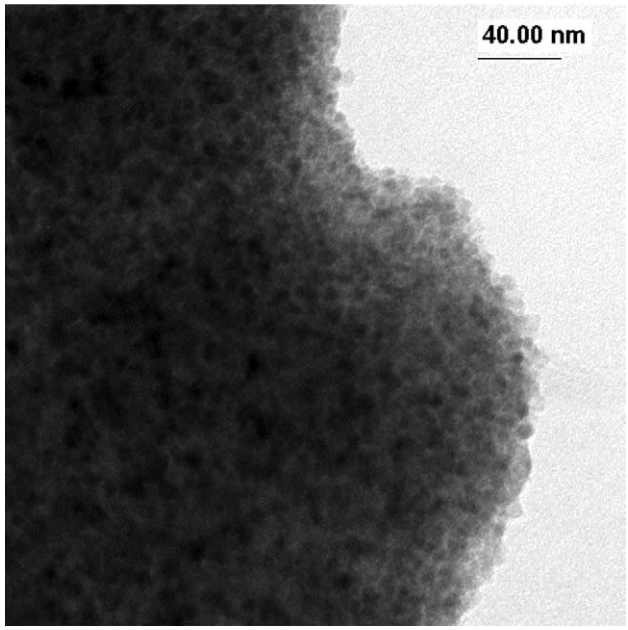

Fig. 7. TEM figures of nanoparticles of **1**.

4. Conclusion

In contrast to initial reports [9–11], we have successfully isolated the first fully substituted catechol derivatives of Group 4 and 5 species. For the Group 4 family of compounds, an oxide formed to link the metals together, the Ti complex being trinuclear and the heavier congeners Zr and Hf being tetranuclear. For the Group 5 species only monomers were isolated. For each compound, due to charge balance, the catechol ligands must have –OH present which was disordered over the entire molecule. The majority of the molecules synthesized and characterized did not display the expected thermal decomposition necessary for MOCVD or nanoparticle synthesis. However, we were successfully in the production of TiO_2 nanoparticles using compound **1**.

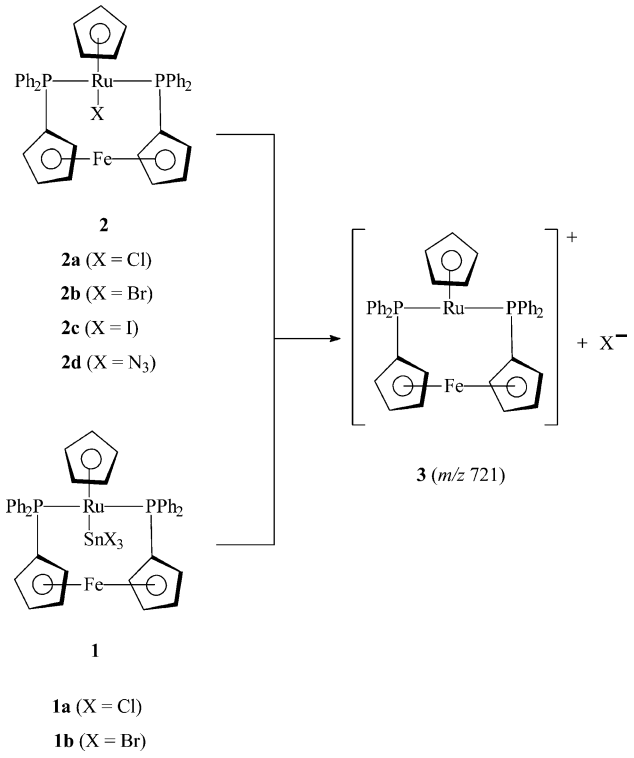
cooperative effects of the metal centers in their chemical interaction with external substrates. Furthermore, this kind of transition metal derivative possesses uncommon catalytic properties, as for instance in the cross-coupling of Grignard reagents of organic bromides and allylic alcohols [14].

Although ESI-MS and ESI-MS^2 have been increasingly used as powerful techniques for structural characterization of organometallic and coordination compounds [2,5,15–24], no similar studies on the characterization of heteropolymetallic complexes, especially those containing a Ru–Sn bond, have been reported. Therefore, the main purpose of this paper is to characterize the novel heterotrimetallic RuCp(dppf)SnX_3 complexes (**1**) as well as their heterobimetallic RuCp(dppf)X precursors (**2**) by ESI-MS and ESI-MS^2.



2. Experimental

Complexes **1** [25] and **2** [26] were synthesized following previously described procedures. Acetonitrile solutions of **1** and **2** were prepared in a concentration of 2×10^{-5} mol L^{-1}. All experiments were performed using a commercial LCQ Advantage ion trap mass spectrometer (ThermoElectron, San Jose, CA) equipped with an ESI source and operated in the positive ion mode. The spectra shown represent the average of about 50 scans (0.2 s/scan). Samples were infused into the ESI source with a syringe pump at a flow rate of 3–5 μL min^{-1}. Typical ESI conditions were as follows: capillary temperature, 150 °C; sheath gas (N_2) flow rate, 20 units (roughly 0.50 L min^{-1}); spray voltage 4.5 kV; capillary voltage 25 V; tube lens offset voltage, 25 V. In the MS^n operation mode, the parent ion of interest was first isolated by applying an appropriate waveform across the end cap electrodes of the ion trap to eject all trapped ions by resonance, except those with the *m/z* ratio of interest. The isolated ions were then subjected to a supplementary ac signal for excitation by resonance and collision-induced dissociation (CID). The collision energy was set to a value at which product ions were produced in measurable amounts, i.e. ca. 10%. The isolation width used in the MS^n experiments was 2 units.

3. Results and discussion

Compounds **1** [25] and **2** [26] (Scheme 1) have already been fully characterized both in the solid state and in solution, which facilitates the comparison of their structural solution NMR patterns with ESI-MS and ESI-MS^2.

Fig. 1 shows the ESI(+) mass spectrum of complex **2a** in acetonitrile solution. Very similar ESI(+) mass spectra were obtained for the analogous complexes **2b** and

Scheme 1.

2c (not shown). Through ESI, the cationic species $[Ru(C_5H_5)(dppf)]^+$ (**3**) (Scheme 1) is transferred from solution to the gas phase and detected by mass spectrometry. It is likely that the solution contains mainly neutral **2a**, which is in equilibrium with **3** and Cl^-. Because ruthenium displays seven abundant isotopes, [^{104}Ru (18.6%), ^{102}Ru (31.6%), ^{101}Ru (17.1%), ^{100}Ru (12.6%), ^{99}Ru (12.7%), ^{98}Ru (1.86%)], ^{96}Ru (5.54%)] and iron possesses four isotopes [^{58}Fe (0.28%), ^{57}Fe (2.1%), ^{56}Fe (91.72%) ^{54}Fe (5.9%)] [27], cation **3** is detected by MS as an isotopomeric cluster of singly charged ions centered at *m/z* 721 (for ^{102}Ru and ^{56}Fe), and with an isotopic pattern that matches well to that calculated [28] for $C_{39}H_{33}P_2RuFe$ (Fig. 1). In solution, **3** associates with acetonitrile forming $[\mathbf{3} + CH_3CN]^+$, which is transferred to the gas phase by ESI and detected by MS as a solvent adduct ion centered at *m/z* 762 (Fig. 1).

Fig. 2 shows the positive-ion ESI tandem mass spectrum at *m/z* 721, which is the highest abundance isotope of structure **3**. Upon CID, prominent fragments of *m/z* 657 ($[\mathbf{3} - C_5H_4]^+$), 644 ($[\mathbf{3} - C_6H_5]^+$), 580 ($[\mathbf{3} - C_6H_5{-}C_5H_4]^+$), 536 ($[\mathbf{3} - P(C_6H_5)_2]^+$) and 305 ($[Fe(C_5H_4)P(C_6H_5)_2]^+$) were observed, which is consistent with the structure proposed for **3** (Scheme 1).

The spectrum of **2d** (Fig. 3) obtained under the same electrospray conditions displays two major cations: **3** and $[Ru(C_5H_5)(dppf)N]^+$ (**4**). The latter was detected by MS as an isotopomeric cluster of singly charged ions centered at *m/z* 735 (for ^{102}Ru and ^{56}Fe), and with an

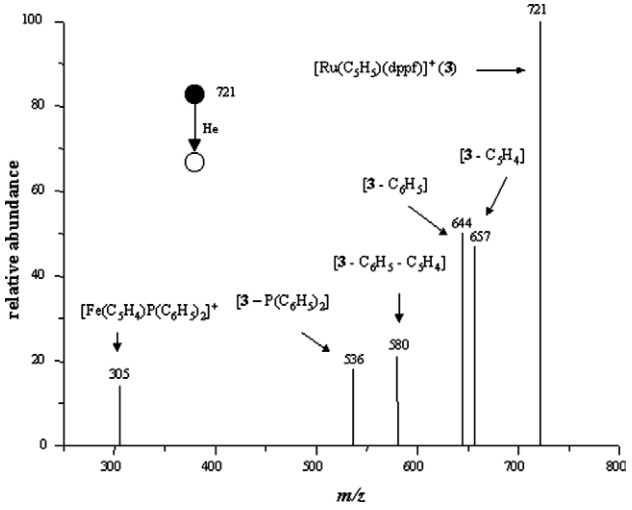

Fig. 2. Positive-ion ESI mass spectrum of mass-selected cation **3** (ionic cluster centered at *m/z* 721). For more details on the ''empty and filled circle'' notation, see [49].

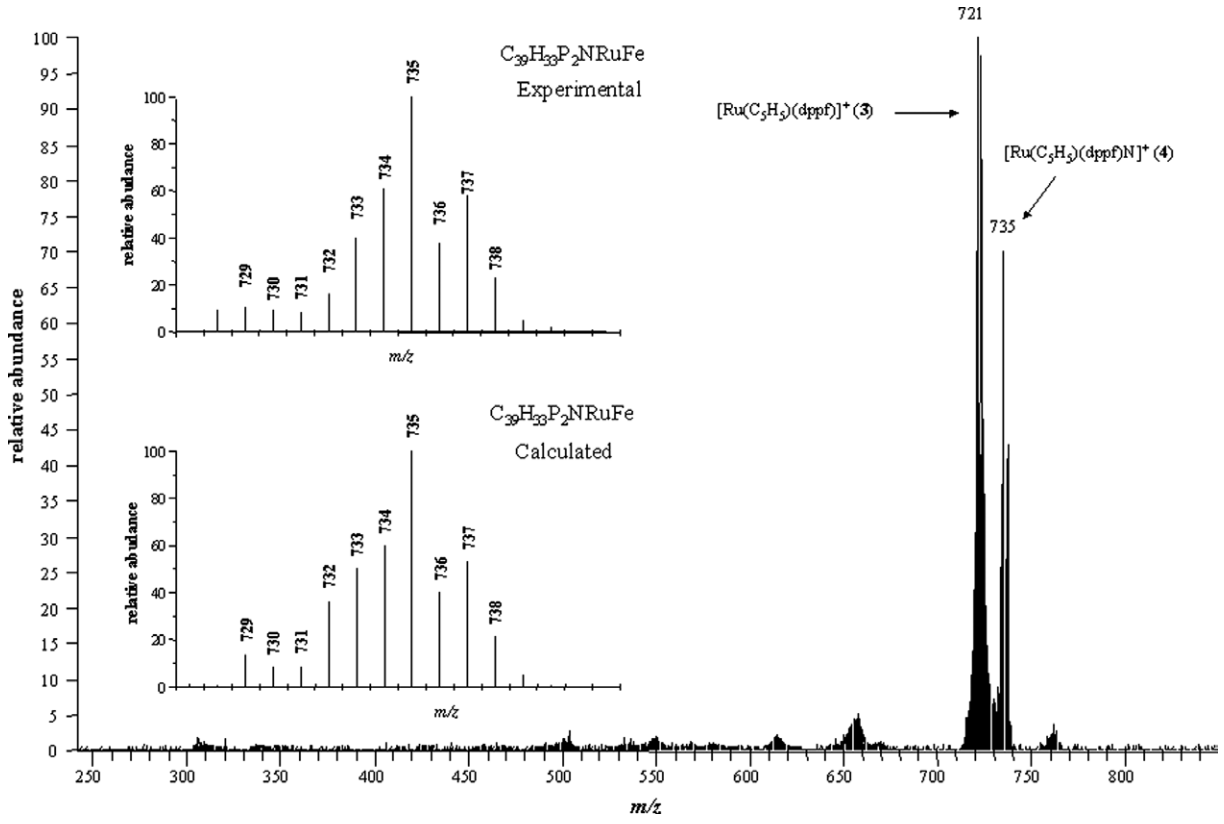
isotopic pattern that fits well to that calculated for $C_{39}H_{33}P_2NRuFe$ [28]. In the positive-ion ESI tandem mass spectrum of the mass-selected ion **4** (not shown), the following most intense fragments are observed: [**4** – C_5H_4] (*m/z* 671), [**4** – C_6H_5] (*m/z* 658), [**4** – FeC_5H_4] (*m/z* 615) and [**4** – $(C_6H_5)_3$] (*m/z* 504).

The formation of ion **4** is suggested to occur in the electrospray ion source via an initial oxidation of the ruthenium atom of **2d** ($Ru^{II} \rightarrow Ru^{III}$) followed by the release of a nitrogen molecule (Scheme 2). We assume that this initial oxidation contributes to the weakening of the N–N bond in the azide moiety, which ultimately causes the formation of cation **4**. In this cation, the remaining nitrogen stays connected to the ruthenium atom, likely via a double Ru–N bond (Scheme 1). This occurs because the filled ruthenium d_{yz} orbital is available to interact with the empty p_z nitrogen orbital, thus allowing the formation of a π Ru → N bond. Moreover, the extra empty orbital in this N atom and its proximity with the Fe atom could suggest a Ru–N–Fe interaction, as represented in Scheme 2. However, additional studies are required to confirm this hypothesis.

Oxidation processes in electrospray ion sources are well known and can occur under certain experimental conditions [29–33]. Similar oxidation processes were also verified to take place for the analogous bimetallic ruthenocenyl ruthenium complex $[Ru(C=CHPh)(\eta^5\text{-}C_5H_5)(dppr)]Cl$ (dppr = $[Ru(\eta^5\text{-}C_5H_4PPh_2)_2]$). In its positive-ion ESI mass spectrum, beside an intense fragment related to the singly charged cation $[Ru(C=CHPh)(\eta^5\text{-}C_5H_5)(dppr)]^+$, a doubly charged cation was also detected at low cone voltages. However, its formation was attributed to the oxidation of the dppr-ruthenium moiety, giving rise to a complex with Ru present in two different oxidation states (Ru^{II} and Ru^{III}) [19]. Based on this example, we can also consider the



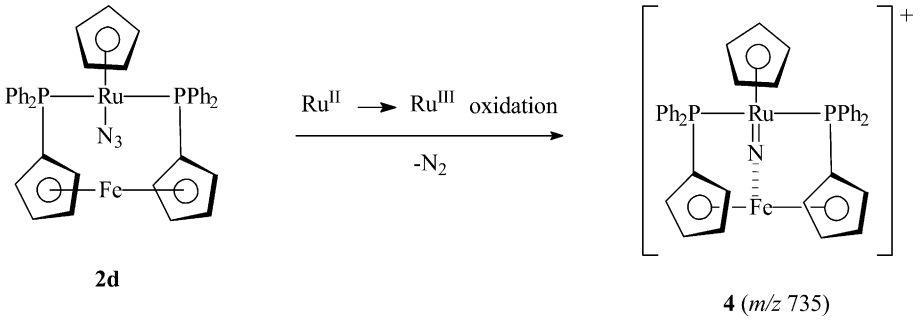


Fig. 3. Positive-ion ESI mass spectrum of the acetonitrile solution of complex $[Ru(C_5H_5)(dppf)]N_3$ (**2d**). Insets show the ion intensities and the *m*/*z* distributions (experimental and calculated [28]) of cation **4** ($C_{39}H_{33}P_2NRuFe$).

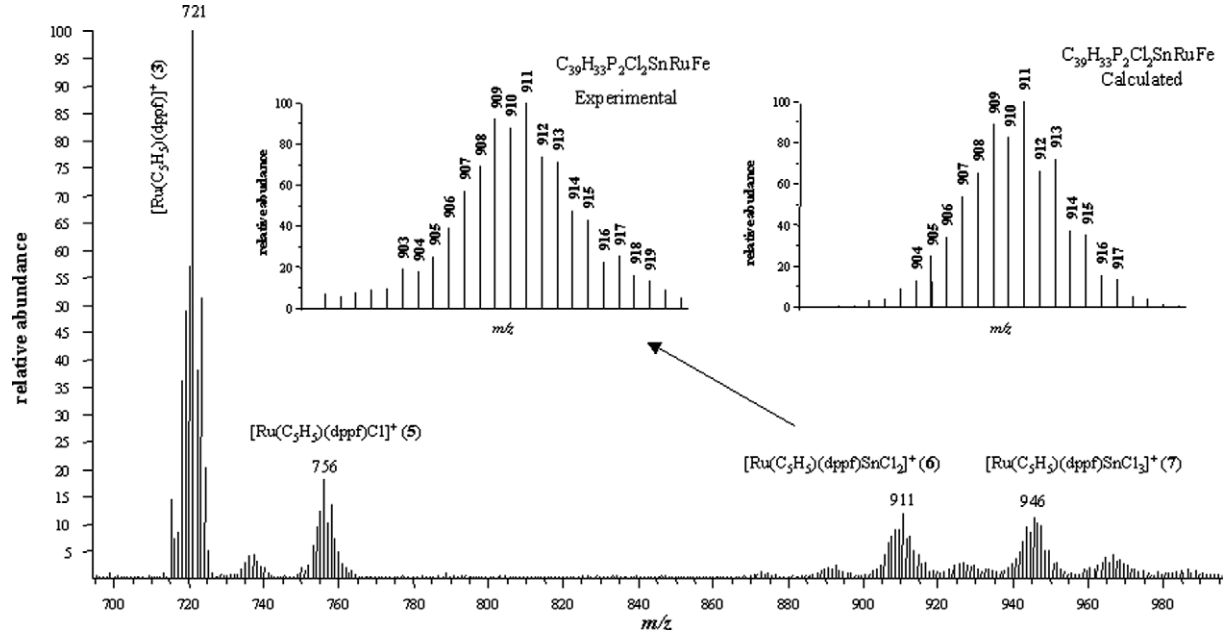
2d **4** (*m*/*z* 735)

Scheme 2.

alternative oxidation of the ferrocene centre in **2d** ($Fe^{2+} \rightarrow Fe^{3+}$), a well known and facile process, to yield the cation of *m*/*z* 735 after the release of N_2. Although it is difficult to distinguish between both oxidation processes, i.e. $Ru^{2+} \rightarrow Ru^{3+}$ or $Fe^{2+} \rightarrow Fe^{3+}$, by using only mass spectrometry, electrochemical measurements could elucidate this issue. In fact, cyclic voltammetry experiments are underway in our laboratory and will be the subject of a future publication.

Fig. 4 shows the positive-ion ESI mass spectrum of complex **1a** in acetonitrile solution (a similar mass spectrum was obtained for the analogous complex **1b**). As previously verified for complex **2a**, cation **3** (*m*/*z* 721) is by far the predominant species. Thus, it is likely that in acetonitrile solution, **1a** is in equilibrium with **3** and its negative counterpart $SnCl_3^-$. This is an unexpected result since the presence of electronegative substituents (such as Cl, Br) connected to Sn, which promote the formation of a π RuSn bond and contribute to increase the order of this bond, should impede, or at least strongly inhibit, such a dissociation. Other minor clusters centered at *m*/*z* 756, $[Ru(C_5H_5)(dppf)Cl]^+$ (**5**), *m*/*z* 911, $[Ru(C_5H_5)(dppf)SnCl_2]^+$ (**6**) and *m*/*z* 946, $[Ru(C_5H_5)(dppf)SnCl_3]^+$ (**7**) are also observed in this spectrum. The formation of these cations is tentatively explained in Scheme 3. For instance, cation **5** is likely formed via the previously described $Ru^{II} \rightarrow Ru^{III}$ oxidation followed by the loss of a neutral $SnCl_2$ molecule. On the



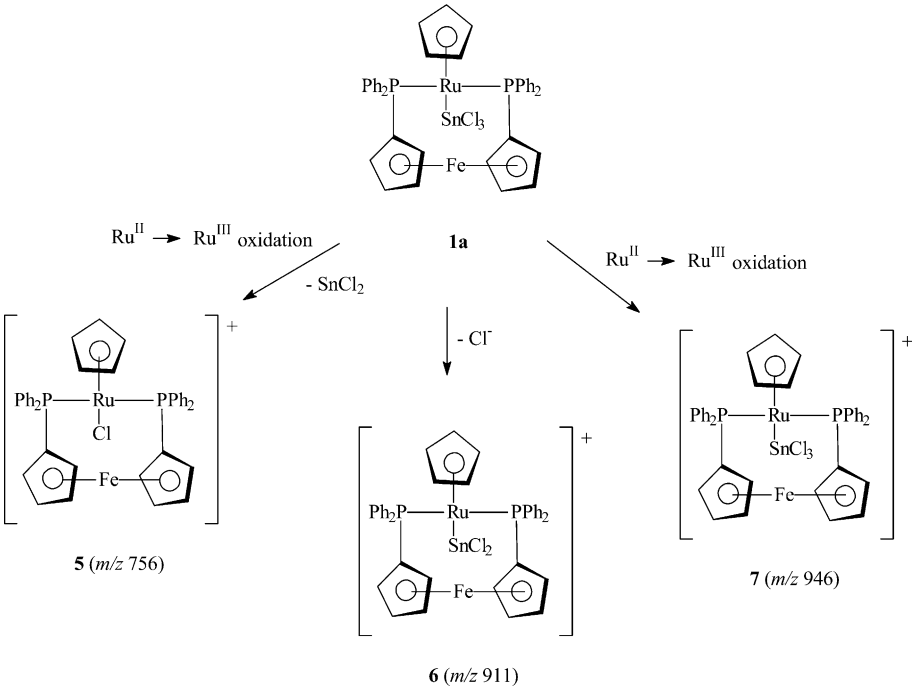


Fig. 4. Positive-ion ESI mass spectrum of the acetonitrile solution of complex $[Ru(C_5H_5)(dppf)]SnCl_3$ (**1a**). Insets show the ion intensities and the *m*/*z* distributions (experimental and calculated [28]) of cation **6** ($C_{39}H_{33}P_2Cl_2$ SnRuFe).

other hand, cation **6** is produced via a simple release of Cl^- from **1a**, whereas cation **7** corresponds to the singly charged intact complex **1a**, likely formed upon $Ru^{II} \rightarrow Ru^{III}$ oxidation. The experimental isotopic patterns of these cations fit well to those calculated for $C_{39}H_{33}P_2ClRuFe$ (**5**), $C_{39}H_{33}P_2Cl_2SnRuFe$ (**6**) (Fig. 4) and $C_{39}H_{33}P_2Cl_3SnRuFe$ (**7**) [28]. The mass-selection and CID of **5** characteristically display the loss of a chlorine atom, giving rise to the fragment of *m*/*z* 721 as cation **3** (spectrum not shown). The positive-ion ESI tandem mass spectrum of the mass-selected ion **6** (not shown) furnishes exclusively cation **3** (*m*/*z* 721) via the release of a neutral $SnCl_2$ molecule. Finally, the mass selection and fragmentation of ion **7** also yields exclu-

Scheme 3.

sively the *m*/*z* 721 fragment via the $SnCl_3$ radical loss (spectrum not shown).

3.1. Detection of catalytically active species

It has been verified that complexes **2** and **1** [34] as well as similar heterotrimetallic Ru(II)–Sn(II) complexes [35,36] and $RuCl_3$–SnX_2 composite systems [37] are effective catalysts in the conversion of methanol to acetic acid [38]. The mechanism of this reaction has been studied [35,37,39,40] but is not yet fully understood. Thus, taking into account that ESI is able to transfer ions from solution to the gas phase [6,8,41–44], and most importantly, the composition of ESI-generated ions often closely reflects that of the solution [5,16,17,41,45,46], we hypothesize that cation **3**, undoubtedly detected in acetonitrile solutions of complexes **2** and **1** (Scheme 1), could be the catalytically active species in this conversion. This hypothesis is based on several studies [47,48] describing the use of ESI-MS to detect cationic species likely to be involved in catalytic processes. For instance, Dyson and coworkers [48] verified that in the electrospray ionization mass spectrum of $[Ru_4\ (\eta^6\text{-}C_6H_6)_4\text{-}(OH)_4]^{4+}$, the main species present in aqueous solution are the intact cubane tetramer and the dimer $[Ru_2\text{-}(\eta^6\text{-}C_6H_6)_2(OH)_2]^{2+}$ and proposed that the latter is an active benzene hydrogenation catalyst.

4. Conclusion

ESI proved to be a suitable and efficient technique for the characterization of heterotrimetallic $Ru(\eta^5\text{-}C_5H_5)(dppf)SnX_3$ (**1**) complexes, containing a Ru–Sn bond, and their heterobimetallic $Ru(\eta^5\text{-}C_5H_5)(dppf)X$ (**2**) precursors. The formation of cation **3**, likely the catalytically active species in the single step conversion of methanol to acetic acid, from **2** and **1** seems to be a general tendency for these ruthenium complexes.

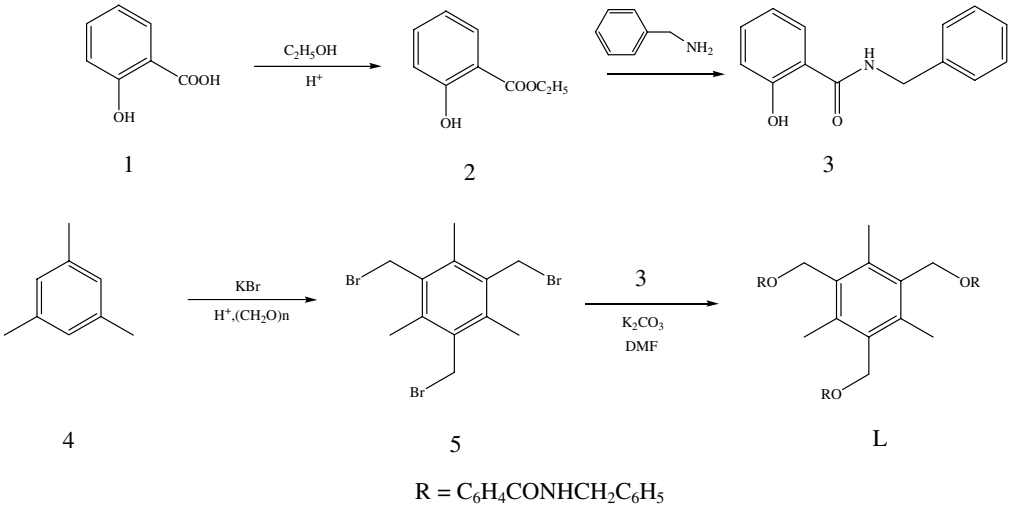
L **L_1**

Scheme 1. The chemical formula of the ligands **L** and $\mathbf{L}_1$.

arms, the solid complex is still highly luminescent. In order to study the influence of the skeleton of the amide type tripodal ligand on the structure and luminescence properties of rare earth complexes, recently we prepared another new amide type tripodal ligand, 1,3,5-trimethyl-2,4,6-tris{[(2′-benzylaminoformyl)phenoxyl]methyl}-benzene (**L**) (Scheme 1), and investigated the reaction of **L** with rare earth nitrates. Interestedly, the crystal structure of $[Sm(NO_3)_3\mathbf{L}]_n$ demonstrates a (10,3)-a net type coordination polymeric structure. To our best knowledge, it is the first example of a (10,3)-a net directed by rare earth ions. Although there are some examples found in coordination polymers of (10,3)-a nets, a unique type of three-connected 3-D net [6,7], nearly all of them are directed by transition metal ions with nitrogen-donor ligands [8]. This is partly due to the tendency of transition metals to have a relatively low coordination number.

As a part of our systematic studies, in this paper we report the preparation, properties and structure of complexes of rare earth nitrates with 1,3,5-trimethyl-2,4,6-tris{[(2′-benzylaminoformyl)phenoxyl]methyl}benzene (**L**).



2. Experimental

2.1. Materials

N-Benzylsalicylamide (**3**) [9] and 1,3,5-tribromomethyl-2,4,6-trimethylbezene (**5**) [10] were prepared according to the literature methods. Other chemicals were obtained from commercial sources and used without further purification.

2.2. Preparation of tripodal ligand *L*

The synthetic route for the tripodal ligand is shown in Scheme 2. *N*-Benzylsalicylamide (0.58 g, 2.57 mmol), potassium carbonate (0.5 g, 3.6 mmol) and DMF (10 cm^3) were warmed to ca 80 °C and 1,3,5-tribromomethyl-2,4,6-trimethylbenzene (0.5 g, 0.85 mmol) was

R = $C_6H_4CONHCH_2C_6H_5$

Scheme 2. The synthetic route for the tripodal ligand **L**.

added. The reaction mixture was stirred at 80–90 °C for 5 h. After cooling down, the mixture was poured into water (100 cm^3). The resulted solid was treated by column chromatography on silica gel [petroleum ether:-ethyl acetate (3:1)] to get tripodal ligand **L**, yield 65%; m.p. 74–76 °C; ^1H NMR ($CDCl_3$, 300 MHz) δ: 2.17 (s, 9H), 4.34 (d, $J = 6$ Hz, 6H), 4.94 (s, 6H), 6.90–8.31 (m, 27H), $H_{(N-H)}$ not detected; IR (KBr) ν: 3390, 1652, 1530, 1478, 1293, 1217, 754 cm^{-1} ; *Anal*. Calc. for $C_{54}H_{51}N_3O_6$: C, 76.33; H, 6.01; N, 4.95. Found: C, 76.19; H, 5.92; N, 4.94%.

2.3. Preparation of the complexes

A solution of 0.1 mmol **L** in 10 cm^3 of ethyl acetate was added dropwise to a solution of 0.1 mmol rare earth nitrates (RE = La, Pr, Nd, Sm, Eu, Gd, Tb, Ho, Y) in 10 cm^3 of ethyl acetate. The mixture was stirred at room temperature for 4 h. The precipitated solid complex was filtered, washed with ethyl acetate and dried in vacuo over P_4O_{10} for 48 h and submitted for elemental analysis, yield 60%. Analytical data and molar conductance values of the complexes are given in Table 1. Slow diffusion of diethyl ether into the DMF solution of the samarium complex afforded colorless rhombic crystals.

2.4. Chemical and physical measurements

The RE(III) ion was determined by EDTA titration using xylenol-orange as an indicator. Carbon, nitrogen and hydrogen were determined using an Elementar Vario EL (see Table 1). The IR spectra were recorded in the 4000–400 cm^{-1} region using KBr pellets and a Nicolet Nexus 670 FTIR spectrometer (see Table 4). Thermal analyses (TG and DTA) were performed on a Beijing WCT-2A thermobalance using about 10 mg powder sample and working at a heating rate of 5 °C min^{-1} in static air. ^1H NMR spectra were measured on a Varian Mercury 300 spectrometer in $CDCl_3$ solutions, with TMS as an internal standard. Luminescence spectra were obtained on a Hitachi M-850 fluorescence spectrophotometer.

2.5. Crystal structure determination

For the samarium complex, X-ray measurements were performed on a Siemens P4 four-circle diffractometer with graphite-monochromatized Mo Kα radiation ($\lambda = 0.71073$ Å) at 295 ± 2 K. The structure was solved by full-matrix least-squares techniques with anisotropic thermal factors for all non-hydrogen atoms. Theoretical models fixed the hydrogen atoms of the compound. All calculations were performed using the program package SHELXTL-97.

3. Results and discussion

The analytical data for the newly synthesized complexes, listed in Table 1, indicate that the nine complexes conform to a 1:1 metal-to-ligand stoichiometry. All the complexes are soluble in DMSO and DMF and are sparingly soluble in ordinary organic solvents such as methanol, ethanol, acetonitrile, acetone, chloroform, benzene and cyclohexane.

3.1. Crystal structure of $[Sm(NO_3)_3\mathbf{L}]_n$

A summary of the crystallographic data and details of the structure refinements are listed in Table 2. Selected bond lengths and bond angles are given in Table 3.

The single-crystal X-ray analysis of the complex $[Sm(NO_3)_3\mathbf{L}]_n$ reveals that each Sm atom is coordinated with nine oxygen donor atoms, six of which belong to three bidentate nitrate groups and the remaining three to carbonyl groups from three tripodal ligands (Fig. 1). The coordination polyhedron around Sm is a distorted monocapped square antiprism. At the same time, each ligand binds to three Sm(III) ions using its three oxygen atoms of the amide groups (Fig. 2(a)). So the whole structure consists of an infinite array of trigonal Sm(III) ions bridged by tridentate ligands and a (10,3)-a net is formed. A schematic view of this 3-D net is shown in Fig. 2(b). Characteristic features of a

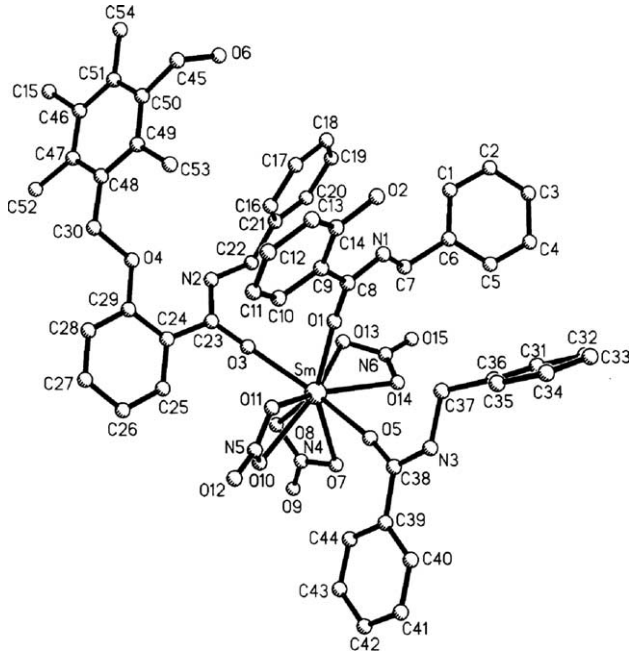

Fig. 1. Coordinated environment of the Sm atoms in $[Sm(NO_3)_3L]_n$.

single (10,3)-a net are 4_1 helices [6,7], all of the same handedness, running parallel to the cubic cell edges. In contrast to its prototypal frame, this complex contains two types of alternating centers, so that the original interconnected 4_1 helical chains become 2_1–Sm–L–Sm–L–helixes, which happen to be left handed. In addition, all the counter ions, NO_3^-, do not fill the formed channels, but bind to the Sm(III) ions. So the whole frame is a completely neutral network.

The conformation of the ligand in the complex is interesting. The three arms are so long that their terminal groups can "fold back". Through intra-molecular π–π interactions, two benzyl groups wrap around the central benzene ring, one above and the other below, forming the "folding-shape" of the ligand. The three parallel phenyl rings are separated by 3.699 Å (a and b) and 3.746 Å (a and c) (Fig. 3). The dihedral angle between (a) and (b) is 13.6°, and 15.7° between (a) and (c). Two oxygen atoms of the carbonyl groups in the ligand, namely, O1 and O5, are located in the outer part of the whole ligand molecule (Fig. 3). This conformation is necessary for the ligand to bind three Sm(III) ions simultaneously.

In general, a net of the (10,3)-a type exhibits large channels of octagonal section, and their dimension is related to the length of the rods connecting the centers [8]. The large channels are usually filled by the counter ions, such as Sr^{2+} in $SrSi_2$ (rod length 2.39 Å), PF_6^- in [Ag(hmt)] $PF_6 \cdot H_2O$ (rod length 3.85 Å) [8b] and SbF_6^- in $[Ag_2(2,3\text{-}Me_2pyz)_3][SbF_6]_2$ (rod length 7.16–7.58 Å) [8d]. Some of the nets exhibit interpenetration, in the same handedness or the opposite handedness. In fact,

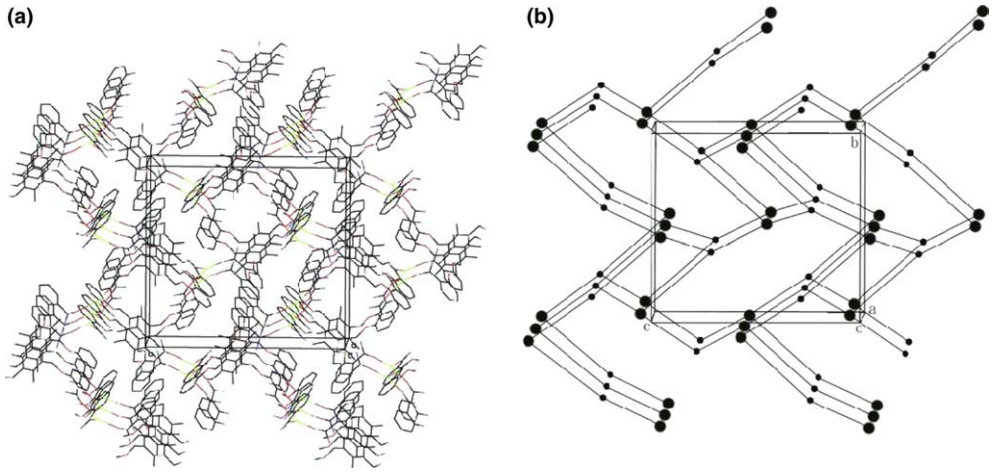

Fig. 2. (a) Structure view of $[Sm(NO_3)_3L]_n$ down the *a* axis. All the nitrates and the benzyl groups are omitted for clarity. (b) Schematic view of the framework in $[Sm(NO_3)_3L]_n$ (small balls, Sm ions; large balls, centers of the central benzene rings of the ligands).

the main problem encountered in constructing molecular-based microporous materials is the obstruction formed by self-interpenetration of networks. So interpenetration should be avoided in preparing the porous materials. It is noteworthy that although the rods are long (length 9.15–9.49 Å), no interpenetration is observed in this complex. But unfortunately, the ligands fill the channels themselves with their "thick" rods and large terminal groups (Fig. 4). It seems like a contradiction. So there is much to do to find well-designed molecular materials with large channels or holes, especially in (10,3)-a nets, which have chiral channels [11].

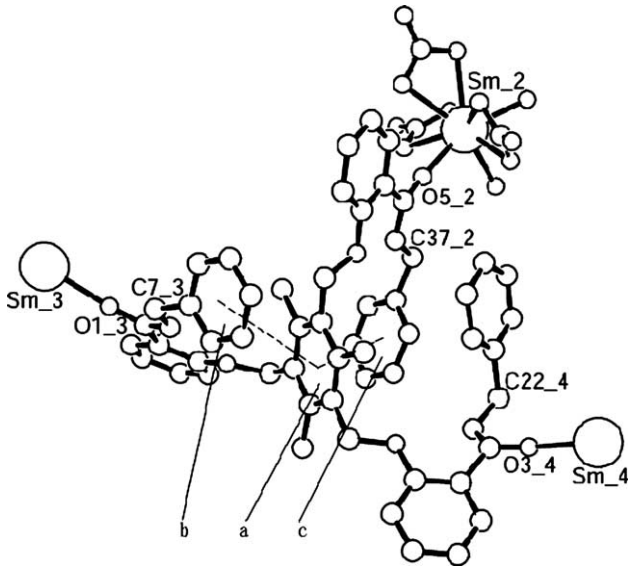

Fig. 3. The intra-molecular π–π interaction (indicated by dashed lines).

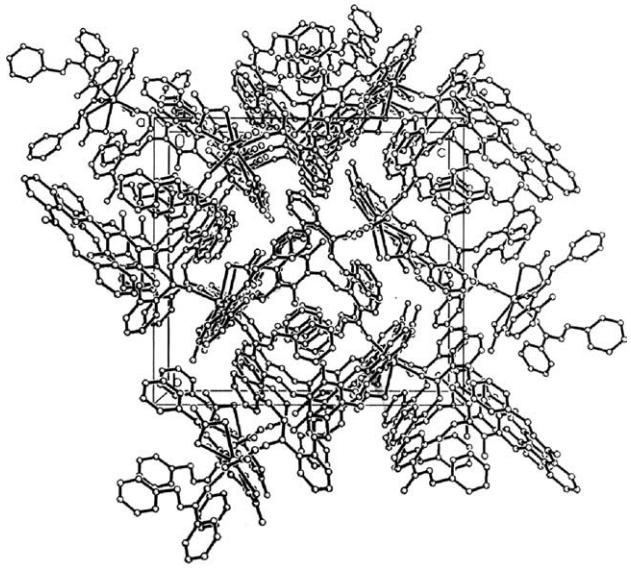

Fig. 4. The molecular packing arrangement.

3.2. Infrared spectra

The most important IR peaks of the ligand and the complexes are reported in Table 4.

The "free" ligand **L** exhibit two absorption bands at 1652 and 1217 cm^{-1} which are assigned to ν(C=O) and ν(C–O–C), respectively. In the complexes, the low-energy band remains unchanged, but the high-energy band red shifts to about 1610 cm^{-1} ($\Delta\nu = 42\ cm^{-1}$) as compared to its counterpart for the "free" ligand, indicating that only the oxygen atom of C=O takes part in coordination to the metal ions.

The characteristic frequencies of the coordinating nitrate groups (C_{2v}) appear at ca 1500 (ν_1), 1300 (ν_4), 1030 (ν_2) and 815 (ν_3) cm^{-1} [12], and the

Table 4
The IR spectra data (cm^{-1})

Compound	ν(C=O)	ν(C–O–C)	$\nu(NO_3^-)$				
			ν_1	ν_4	ν_2	ν_5	$\nu_1 - \nu_4$
L	1652s	1217s					
$[La(NO_3)_3\mathbf{L}]\cdot 2H_2O$	1611s	1219s	1480s	1283s	1026	817w	197
$[Sm(NO_3)_3\mathbf{L}]\cdot 2H_2O$	1611s	1225s	1484s	1301s	1028	816w	183
$[Eu(NO_3)_3\mathbf{L}]\cdot 2H_2O$	1611s	1225s	1483s	1302s	1028	815w	181
$[Tb(NO_3)_3\mathbf{L}]\cdot 2H_2O$	1612s	1224s	1482s	1302s	1028	815w	180
$[Y(NO_3)_3\mathbf{L}]\cdot 2H_2O$	1613s	1223s	1490s	1305s	1030	816w	185

difference between two strongest absorptions (ν_1 and ν_4) of the nitrate groups is about 190 cm^{-1}, clearly establishing that the NO_3^- groups in the solid complexes coordinate to the rare earth ion as bidentate ligands [13]. Additionally, no bands at 1380, 820 and 720 cm^{-1} in the spectra of complexes indicates that free nitrate groups (D_{3h}) are absent. This is in agreement with the results of the structural analyses discussed above.

In the IR spectra of the complexes, broad bands at 3450 cm^{-1} occur from the O–H stretching vibrations of water and the absence of a band for $\rho_r(H_2O)$ at ca 590 cm^{-1} shows that the water molecules in the complexes are not coordinated water [13]. This inference is verified by the result of TG-DTA analysis.

3.3. Thermal analysis

The TG and DTA curves for the Y complex show that the complex has no melting point and the water molecules contained in the complex are all crystallized water molecules, because only one endothermic peak appears at ca 104 °C and the percent of water is consistent with the result of the elemental analysis. The complex is stable up to ca 218 °C and then decomposes in the temperature range 218–800 °C, producing three exothermic peaks.

3.4. Luminescence properties of the complexes

Ligand-based excitations cause structural emission of rare earth complexes and the ligand luminescence is quenched showing that ligand-to-metal energy transfer occurs [14]. The ability to transfer energy from being ligand-centered to metal-centered is important in the design of rare earth(III) supramolecular photonic devices [15]. The luminescence spectra of the ligand and the Eu^{3+} and Tb^{3+} complexes in the solid state were recorded at room temperature. The emission spectra of the complexes are shown in Fig. 5.

On excited by the absorption band at 320 nm, the "free" ligand exhibits broad emission bands (λ_{max} = 450 nm). It is shown in Fig. 5 that the complexes show the characteristic emissions of Eu^{3+} or Tb^{3+}. This indicates that the tripodal ligand **L** is a good organic chelator to absorb energy and transfer it to the metal ions. In the spectrum of the Eu^{3+} complex, the relative intensity of $^5D_0 \rightarrow {}^7F_2$ is more intense than that of $^5D_0 \rightarrow {}^7F_1$ showing that the Eu(III) ion does not lie in a centrosymmetric coordination site [16], in agreement with the crystal structure analysis. In addition, the emission bands at ca 450 nm in the complexes are still visible, indicating that the energy transfer in these complexes is not so effective. An intramolecular energy transfer from the triplet state of the ligand to the resonance level of the

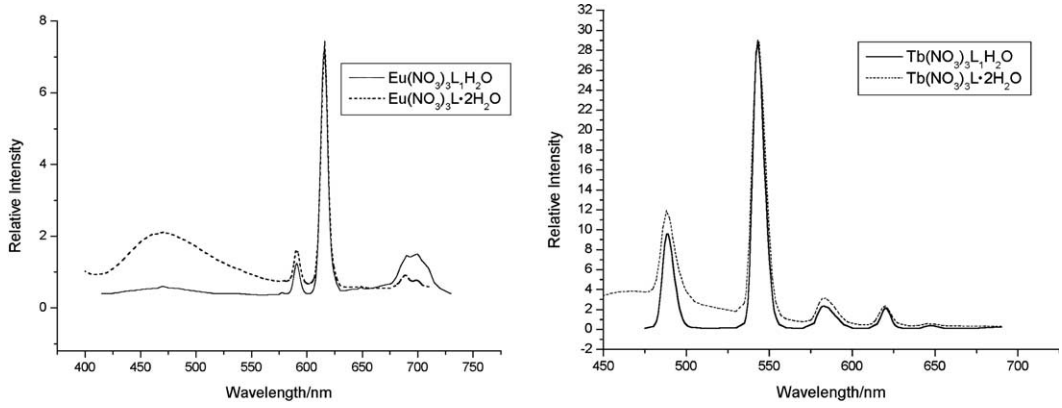

Fig. 5. Emission spectra of complexes in the solid state (excited at 320 nm).

RE(III) ion is one of the most important processes having influence on the RE(III) luminescence quantum yields of RE(III) chelates [17]. So considering the emission spectra of the complexes, we can conclude that the triplet energy of **L** is not at a very appropriate level.

4. Conclusions

In this paper, we report the preparation, properties and crystal structure of the complexes of rare earth nitrates with 1,3,5-trimethyl-2,4,6-tris{[(2′-benzylaminoformyl)phenoxyl]methyl}benzene (**L**). The complex $[Sm(NO_3)_3\mathbf{L}]_n$ is the first example determined by X-ray structure analysis, showing a (10,3)-a net constructed by RE(III) ions and a flexible tripodal ligand. We deduce that there may be two reasons for this interesting result. Firstly, NO_3^-, as a suitable counter ion was chosen. The coordination number provided by the ligand is only three, which is not sufficient for high coordinated rare earth ions. An additional three bidentate nitrates make the total coordinated number nine, satisfying the need of high coordination number. The other reason is the "folding-shaped" conformation of the ligand in the structure, which makes it easy for the oxygen atom to coordinate with the rare earth ions. This is one of the key triggers for the construction of the backbone of the 3-C, 3-D network. In addition, this structure is very different from the structure of the rare earth complex of 1,1,1-tris{[(2′-benzylaminoformyl)phenoxyl]methyl}propane ($\mathbf{L}_1$) [5], which is a 1-D coordination polymer with a H-bonded 3-D network. Comparing the luminescence spectra of the complex $[Eu(NO_3)_3\mathbf{L}]\cdot 2H_2O$ with the complex of europium(III) nitrate with $\mathbf{L}_1$, we found that the tripodal ligand $\mathbf{L}_1$ is more effective in energy-transfer than **L**. The complexes of ligand $\mathbf{L}_1$ show no emission bands from the ligand at ca 450 nm, but the emission bands in the complexes of ligand **L** are still visible (Fig. 5). This may be due to the suitable lowest triplet energy of $\mathbf{L}_1$ in its rare earth nitrate complexes. So the skeleton of the tripodal ligand is very essential in determining the structure and luminescent properties of the rare earth complexes.

is inert to the oxidation of glycine. Two electrons within the complex are transferred to Au(III) from glycine to form a Au(I)-imine intermediate, which being unstable undergoes hydrolysis to NH_4^+ and glyoxylic acid. An excess of $[AuCl_4]^-$ oxidizes glyoxylic acid to CO_2 and Au(o) through the intermediate formation of formic acid. Since the rate law was not given (dependence of the rate on [glycine], $[H^+]$ and $[Cl^-]$), it was of interest to study the kinetics of the oxidation of histidine, another amino acid.

2. Experimental

2.1. Chemicals and solutions

The solutions of $AuCl_4^-$ (Johnson and Matthey) were freshly prepared in perchloric acid (E. Merck, GR), though such solutions are stable over 24 h. The concentrations were determined from the optical density measured at 310 nm on a HP 8452A diode array spectrophotometer using carefully determined $\varepsilon = 4.82 \times 10^3\ dm^3\ mol^{-1}\ cm^{-1}$, which compared well with the lit. value [19–21] $4.86 \times 10^3\ dm^3\ mol^{-1}\ cm^{-1}$. The solutions of L-histidine (BioChemika Micro Select, Fluka) and D-histidine (Puriss, Fluka) were freshly prepared by weighing the samples. $LiClO_4$ solution for adjusting the ionic strength (μ) was prepared and standardised as described earlier [22]. All other chemicals were used as received. The solutions were prepared in water, distilled twice, and purged by nitrogen.

2.2. Reaction products

At the end of the reaction, the metal ion from the reaction mixture was removed using an ion exchange method. A portion of the filtrate was treated with a saturated solution of 2,4-dinitrophenylhydrazine and the same was left overnight in a refrigerator. The precipitated 2,4-dinitrophenylhydrazone was separated by filtration and recrystallised from a mixture of ethyl acetate and light petroleum. The melting point of the precipitated hydrazone, 190 ± 0.5 °C, was characteristic of β-imidazolyl pyruvic acid, indicating that the seat of the reaction is not the imidazole ring since it remained intact. Another portion of the eluent on treatment with Nessler's reagent confirmed the presence of the NH_4^+ ion.

2.3. Stoichiometry

Several reaction mixtures having excess of $AuCl_4^-$ over known histidine concentrations were prepared. The optical density of the reaction mixtures was measured at 310 nm at room temperature until a constant value was recorded. The mean of several such estimates yielded $\Delta[AuCl_4^-]/\Delta[\text{Histidine}] = 1.07 \pm 0.10$. Hence, in view of the characterised products and the stoichiometry ratio, the equation of the reaction is expressible by Eq. (1).

$$H_2O + C_3H_3N_2CH_2CH(NH_2)COOH + AuCl_4^- \rightarrow C_3H_3N_2CH_2COCOOH + AuCl_4^{3-} + NH_4^+ + H^+ \quad (1)$$

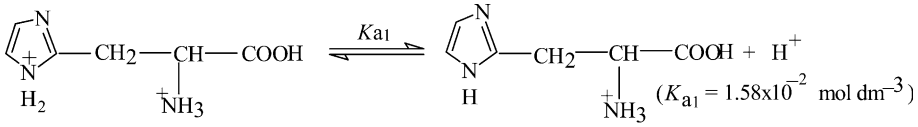
2.4. Kinetics

The reaction mixtures were prepared so as to conform to the pseudo-first-order conditions (excess of histidine over Au(III) ion) for studying the rate of the reaction that was followed at 360 nm (Beer's law was obeyed) with a Spectrochem MK II colorimeter fitted with a thermostated reaction cell. The pseudo first order rate constants k_{obs} were calculated from the slopes of the plots between $\log(A_t - A_\infty)$ against time "t", which were linear for more than two half-lives (80–90%) where A_t and A_∞ are the optical densities of the reaction mixture at any time "t" and infinite time, respectively. These linear plots indicated the monophasic character of the reaction and that the products did not interfere with the rate profile of the reaction. There was no trace of metallic gold in the reaction mixture at the time of measuring A_∞ after several half-lives. The EXCEL program was used for plotting the $\log(A_t - A_\infty)$-time data and evaluating the least square values of the slopes and intercepts of the linear plots. The pseudo first order rate constants, k_{obs} were generally reproducible within 5%.

The repetitive spectra of the reaction mixtures for several concentrations of histidine, recorded on a HP8451A spectrophotometer, had not shown any change from the spectral characteristics of the control solution of $AuCl_4^-$. The absorbance of the spectra decreased with time and no isosbestic points appeared, indicating that the spectra of the products of the reaction do not overlap with that of the $AuCl_4$ solution. The absence of any transient absorbance peaks in the spectra over a period of time, therefore, suggests that the intermediates, if formed, are weak or only weak bridged complexes are formed.

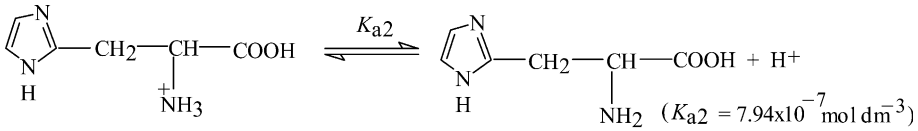
2.5. Test for free radical

The addition of acrylonitrile (6% v/v) to the reaction mixture, degassed with nitrogen, produced cloudiness due to the formation of polyacrylonitrile, indicating the formation of free radicals. A similar solution of acrylonitrile when added to similarly degassed blank solutions of $AuCl_4$ and histidine did not produce any cloudiness.



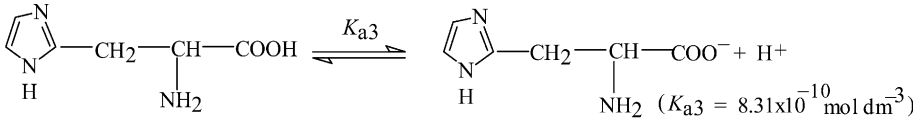
3. Results

k_{obs} increased proportionately with [Histidine] at constant [H^+], [Cl^-] and ionic strength (Table 1). The plot of k_{obs} against [Histidine]$_0$ was linear and passed through the origin, suggesting a first order dependence in histidine. The decreasing k_{obs} with increasing [Cl^-] and [H^+], at constant concentrations of the other, is reported in Tables 1 and 2, respectively. The correlations between k_{obs} and [H^+] or [Cl^-] at constant concentration of the other, are shown in Figs. 1 and 2, respectively. These plots indicate the absence of a linear correlation between k_{obs} and the respective concentrations of H^+ and Cl^- ions. A later analysis of the respective data indicated that a linear correlation between k_{obs} and [H^+] or [Cl^-] is consistent with the empirical rate law, Eq. (2), where $k_2 = k_{obs}$/[Histidine] and X is a constant. These results suggested the presence of an equilibria between species that differ by a single proton and a [Cl^-] ion



$$k_2 \cdot X = a + b[H^+]^{-1}[Cl^-]^{-1}. \quad (2)$$

k_{obs} decreased with an increase in the ionic strength, Table 3, and the plot, in accordance with Eq. (3) [23,24], is linear with a negative slope, Fig. 5, suggesting the reactive species have opposite charges



$$\log k_{obs} = \log k_0 + 1.02 Z_a Z_b \left(\frac{\sqrt{\mu}}{1+\sqrt{\mu}} - 0.05\mu \right). \quad (3)$$

(4)

(5)

(6)

4. Mechanism and discussion

The following equilibria between various histidine species, A^{2+}, B^+, C and D^- (the charge shown is the net total charge on that species), and the respective equilibrium constants [25] are known. The retarding effect of the H^+ ion could be due to any one or all the equilibria shown in Eqs. (4)–(6). However, these equilibria have no bearing on the retarding effect of the Cl^- ion. For an initial [Histidine] = 0.002 and [H^+] = 0.02 mol dm^{-3}, the calculated [B^+] is 8.5×10^{-4} mol dm^{-3} using the given K_{a1} value The concentrations of C and D^-, using the respective K_{a2} and K_{a3} values, can be shown to be negligibly small compared to [B^+]. The equilibria (7)–(9), involving Au(III) species [19,26,27], can also explain the retarding effect of both H^+ and Cl^- ions.

$$AuCl_4^- + H_2O \overset{K_{hy}}{\rightleftharpoons} AuCl_3H_2O + Cl^- \quad (7)$$

$$AuCl_3H_2O \overset{K_a}{\rightleftharpoons} AuCl_3OH^- + H^+ \quad (8)$$

$$AuCl_3(OH)^- + H_2O \overset{K_{aq}}{\rightleftharpoons} AuCl_2(H_2O)(OH) + Cl^- \quad (9)$$

The equilibrium (9) is excluded from consideration because the calculated [$AuCl_2(H_2O)(OH)$] is negligibly small. The equilibria (7) and (8) can be combined to a single equilibrium (10). A consequence of equilibrium (10) is that the likely reactive Au(III) species are $AuCl_4^-$ and $AuCl_3OH^-$ ions. The equilibrium constant K ($=K_{hy}K_a$) can be calculated from the known K_{hy} and K_a values. The rate constants tend to limiting values at the higher end of the [H^+] (Fig. 1) and [Cl^-] (Fig. 2) because the equilibrium constant K has a very small value. The reactivity of $AuCl_4^-$ and $AuCl_3OH^-$ ions is consistent with the analysis of the rate data that indicated two parallel reactions. The reactivity of $AuCl_3OH^-$ is $\approx 10^3$ times the reactivity of $AuCl_4^-$(aq) (Table 4). The

participation of a hydroxo species, $AuCl_3OH^-$, is consistent with the inverse dependence of the rate on $[H^+]$, that is suggestive of an inner-sphere mechanism [28].

$$AuCl_4^-(aq) + H_2O \overset{K}{\rightleftharpoons} AuCl_3OH^- + Cl^- + H^+ \quad (10)$$

$$AuCl_4^- + R\text{-}CH_2CH(N^+H_3)COOH \xrightarrow{k} \underset{\mathbf{C}}{[AuCl_4^-R\text{-}CH_2CH(NH_2)COOH]^{\ddagger}} + H^+ \quad (11)$$

$$AuCl_3OH^- + R\text{-}CH_2CH(N^+H_3)COOH \xrightarrow{k_1} \underset{\mathbf{C_1}}{[AuCl_3R\text{-}CH_2CH(NH_2)COOH]^{\ddagger}} + H_2O \quad (12)$$

$$[AuCl_4^-R\text{-}CH_2CH(NH_2)COOH]^{\ddagger} \xrightarrow{fast} R\text{-}CH_2C^{\bullet}(NH_2)COOH + AuCl_4^{2-} + H^+ \quad (13)$$

Though the formation of intermediates between Au(III) and histidine is not indicated by the spectral study of the reaction mixture in the UV region, their formation in the proposed mechanism would be reasonable in view of the NMR studies on glycine [1a], glycylglycyl-L-histidine [17]. The observation that the imidazole ring is not the seat of reaction because it is present in the final oxidation product of the reaction is consistent with the view that the binding of a proton or a metal ion is very unfavourable at the pyrrole nitrogen of histidine [17].

The results of the spectral studies would not be in contradiction to the assumption of the formation of transient intermediates in the rate-determining step. The mechanism in Scheme 1 is based on this assumption.

The probable free radical is R-$CH_2C^{\cdot}(NH_2)$COOH where R is the imidazole ring. The presence of a free radical is indicative of the one electron reduction of Au(III) in the rate determining step. Transient Au(II) is reported in several redox reactions [29–35]. The unstable Au(II) can oxidise the free radical instantaneously to the imine (15). Imines with a proton on N are seldom stable and undergo fast hydrolysis to the NH_4^+ ion and the final product (17).

Alternately, Au(II) may disproportionate to Au(III) and Au(I) instantaneously, reaction (17), because the rate of disproportionation [36], 1.67×10^8 dm^3 mol^{-1} s^{-1}, is very near to the rate of diffusion. Au(II) is, therefore, very likely removed through disproportionation that makes the reactions (15) most unlikely. The rate law, deduced from reactions (10)–(17), is expressible by Eq. (18) which changes to Eq. (21) on substituting the proper values of $[AuCl_4^-]$ and $[\mathbf{B}^+]$ (R–$CH_2CH(N^+H_3)$COOH), given by Eqs. (19) and (20), respectively, and applying the inequality $K \ll [H^+][Cl^-]$ in view of $[H^+]$and $[Cl^-]$ used where $k_2 = k_{obs}/[\text{Histidine}]_0$

$$\frac{-\mathrm{d}[\mathrm{Au(III)}]}{\mathrm{d}t} = \left(k + \frac{k_1 K}{[H^+][Cl^-]}\right)[AuCl_4^-][\mathbf{B}^+], \tag{18}$$

$$[AuCl_4^-] = \frac{[\mathrm{Au(III)}][H^+][Cl^-]}{K + [H^+][Cl^-]}, \tag{19}$$

$$[\mathbf{B}^+] = \frac{K_{a1}[\text{Histidine}]_0}{K_{a1} + [H^+]}, \tag{20}$$

$$\frac{k_2(K_{a1} + [H^+])}{K_{a1}} = \left(k + \frac{k_1 K}{[H^+][Cl^-]}\right). \tag{21}$$

The reactivity of the species $\mathbf{B}^+$ in outer-sphere oxidation with $[Co(III)W]^{5-}$ ($E^0 = 1.01$ V [37],) and $[Mncdta]^-$ ($E^0 = 0.81$ V [38],) ions [39] is of the same order as are the respective E^0 values of these ions, and so is the reactivity of the species $\mathbf{D}^-$ with $[Mncdta]^-$ and $Fe(CN)_6^{3-}$ ($E^0 = 0.36$ V) ions [40]. Though E^0 (=0.95 V [41],) for the $AuCl_4^-/AuCl_2$ couple is between the E^0 values of $[Co(III)W]^{5-}$ and $[Mncdta(OH_2)]^-$ ions, the reactivity of the species $\mathbf{B}^+$ with the Au(III) ion is greater than that with the $[Co(III)W]^{5-}$ ion. This is probably because the present reaction is inner-sphere.

The slope value, −0.3, of the plot in Fig. 5 is less than the expected slope of −1 considering that the reactive histidine species B^+ has a net single positive charge and the reactive Au(III) species have a single negative charge. The deviation from the expected value could be due to the spreading of the net single positive charge over the entire histidine molecule.

The Eq. (21) is consistent with the linear plots of the left hand side against $[H^+]^{-1}$ at constant $[Cl^-]$ (Fig. 3), and $[Cl^-]^{-1}$ at constant $[H^+]$ (Fig. 4) with intercepts on the rate axis. The values of k (0.120 dm^3 mol^{-1} s^{-1}) and k_1 (139 dm^3 mol^{-1} s^{-1}) obtained from the plot in Fig. 4 are in close agreement with those (k = 0.114 dm^3 mol^{-1} s^{-1}; k_1 = 15.6 dm^3 mol^{-1} s^{-1}) obtained from the plot in Fig. 3 at 31 °C. This close agreement

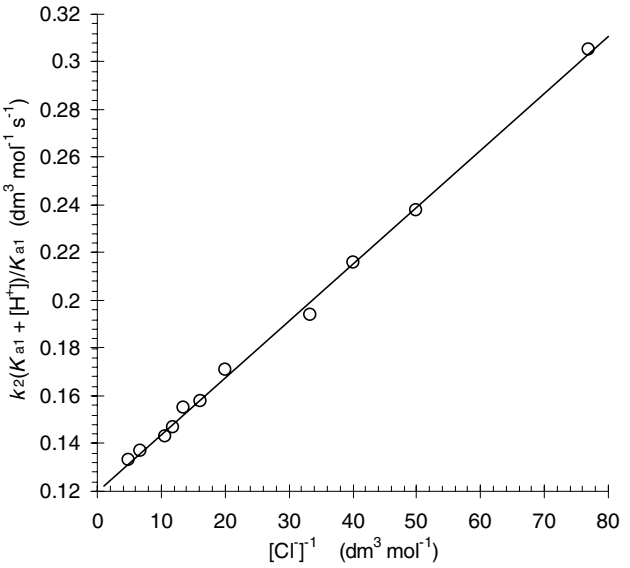

Fig. 4. The linear plot of $k_2(K_a + [H^+])K_a^{-1}$ against $[Cl^-]^{-1}$ at constant $[H^+]$, consistent with the Eq. (21), at 31 °C.

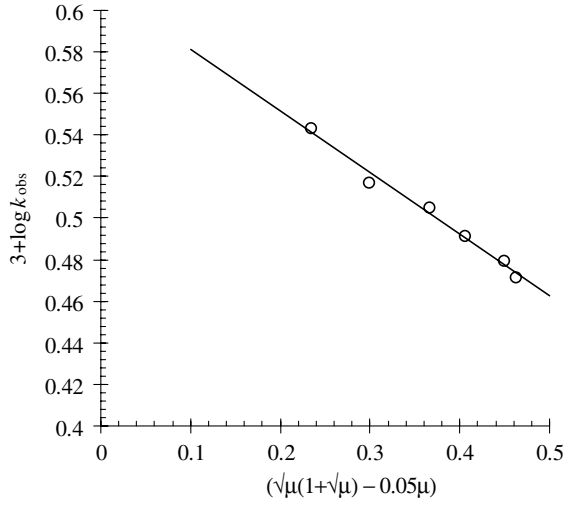

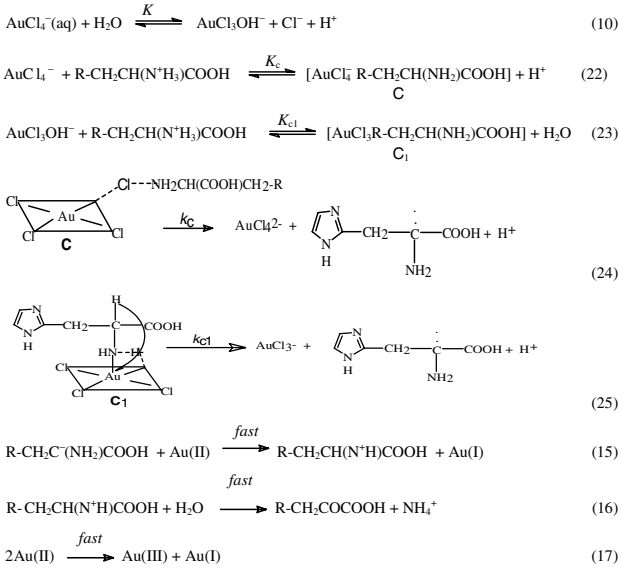

Fig. 5. The linear plot of log k_{obs} against $\{\mu/(1 + \sqrt{\mu}) - 0.05\mu\}$ has an intercept of −0.3. The ionic strength is varied using $LiClO_4$.

between the values of k and k_1 obtained from two different plots, not only support the validity of the rate law but that of the proposed mechanism too. The values of k and k_1 at different temperatures are in Table 4. The values of K_{a1} [25], and K [20] (Table 4) at different temperatures, were estimated from the published data. The large difference in the values of k and k_1 ($k_1 \approx 10^3 k$) reflect the ease of formation of the respective transient species.

The two intermediates are formed by equatorial coordination of histidine with the respective Au^{3+} species. The rate of formation of the intermediate formed by elimination of a water molecule is obviously faster than that formed through a chloride bridge. This mechanism is unlikely to show any difference in the rates of oxidation of H^1-histidine and H^2-histidine (deuteriated molecule). Since an authentic sample of H^2-histidine was

Scheme 2.

unprocurable from a reliable source, the rates of H^2-histidine were not measurable. However, the most disturbing aspect of the mechanism is the value of k_1 (110 dm^3 mol^{-1} s^{-1} at 27 °C) which is inadmissible for a process in which a water molecule is eliminated because of the reaction between H^+ and OH^- ions. The rate of such a process is diffusion controlled. This indicated the presence of some other factor with k_1 and thus a modification in the mechanism is required.

The alternate mechanism presumes the formation of the intermediates in equilibrium steps rather than in the rate-limiting steps. The intermediates so formed could be of a transitory nature defying spectrometric detection if the rates of the formation and decomposition of the intermediates to the products approach the rate of the backward reaction of the equilibrium, so that there is no accumulation of the intermediates over a period of time. Yet another reason for the intermediates defying spectrometric detection could be that the molar absorptivity coefficient of the transition complexes might not be very different from that of tetrachloroaurate(III) solution. The mechanism so modified is considered in Scheme 2 in which the reaction (15A) is eliminated for the reasons given earlier.

The rate law, based on Scheme 2, is in Eq. (26). The transformed form of (26) is Eq. (27) which is identical with Eq. (21) where $k = k_c K_c$ and $k_1 = k_{c1} K_{c1}$

$$\frac{-\mathrm{d}[\mathrm{Au(III)}]}{\mathrm{d}t} = \left(k_c K_c + \frac{k_{c1} K_{c1} K}{[H^+][Cl^-]}\right)[AuCl_4^- -][B^+], \tag{26}$$

$$\frac{k_2(K_{a1} + [H^+])}{K_{a1}} = \left(k_c K_c + \frac{k_{c1} K_{c1} K}{[H^+][Cl^-]}\right) = \left(k + \frac{k_1 K}{[H^+][Cl^-]}\right). \tag{27}$$

The square planar $AuCl_4^-$ is isoelectronic with the square planar $[Ag(OH)_4]^-$ ion. The latter is reported to form intermediates with the $H_2PO_2^-$ ion [42] and several others [43–50] in which the ligand is axially coordinated. The high rates of S(IV) oxidation with the $AuCl_4^-$ ion is attributed to the axially coordinated SO_2^{2-} and HSO_4^- ions in the intermediates [1e]. Therefore histidine can coordinate with Au(III) either axially (**C1**) or equatorially (**C**). In the equatorial coordination, the amide nitrogen can coordinate with $AuCl_4^-$ through a chloride bridge [1e] though glycine substitutes for one of the chlorines. It may be mentioned that it is not clear if glycine had two simultaneous paths of oxidation as observed presently. Since the nature of coordination in the two intermediates is different, their rate of decomposition are obviously expected to be different and there is no direct removal of OH^- by a proton as in Scheme 1.

In conclusion, histidine forms transitory intermediates with $AuCl_4^-$ and $AuCl_3OH^-$, preferring an equatorial coordination with the $AuCl_4^-$ ion, and the substitution is likely to be through a chloride bridge whereas an axial coordination is preferred with the $AuCl_3OH^-$ ion despite the sterically hindered large histidine molecule. Since this coordinated species may be under strain it obviously has an overall high rate of decomposition compared to strain free equatorially coordinated species. The intermediates defy spectrometric detection either because the total rates of formation and decomposition to the products have approached the rate of the backwards reaction of the equilibrium step so that there is no accumulation of the intermediates over a period of time or the molar absorptivity coefficient of the transition complexes is not very different from that of the tetrachloroaurate(III) solution.

is adjacent to the oximic α-carbon. Far now, this particular oxime and their complexes with copper(II) and nickel(II) ions have been studied in solution (potentiometric, UV–Vis, EPR studies) only [8]. It is known that this class of oximes predominantly coordinates to metals via the nitrogen atom (mainly transition metal ions) or via the oxygen atom (s-, p-metal ions). Additionally, deprotonation of the **1a** oximic group allows formation of dimeric species where the nitrogen and oxygen atoms act as metal donors [8–11].

In the present work, the focus is on elucidating molecular structures of mentioned-above **1a** complexes in solid state based on molecular spectroscopy methods (IR, RA and EPR). To give detailed assignment of vibrational spectra and consequently to solve molecular structures we applied quantum-mechanical calculations at the DFT level of theory. Additionally, we performed potential energy distribution calculations (PED) to show a detailed description of vibrational modes and atomic charge distribution to give an explanation of the **1a** anionic nature (the APT population analysis).

2. Experimental

2.1. Preparation

2.1.1. Na–*1a*

The sodium salt of 2-cyano-2-(hydroxyimino)acetic acid was synthesized by the reported procedure [7]. Elemental analysis (C, H, N) was conducted at the Faculty of Pharmacy of Jagiellonian University according to standard microanalytical procedures (*Anal.* Calc. for $Na_2C_3H_{0.7}N_2O_{3.35}$: C, 21.9; H, 0.4; N, 17.0. Found: C, 22.2; H, 0.7; N, 16.7%). In the microcrystalline sample, the sodium-to-**1a** molar ratio (2:1) was confirmed by a standard analytical procedure (AAS).

2.1.2. Cu–*1a* and Ni–*1a*

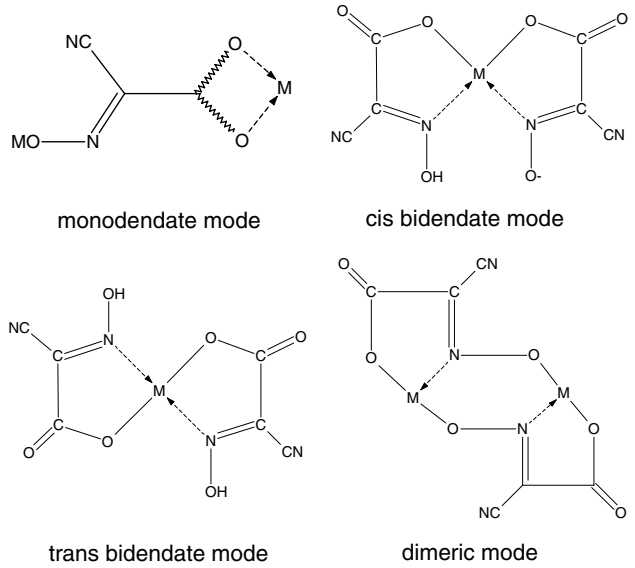
The complexes were prepared as described below using 1:2 molar ratio of metal ions to **1a**. An aqueous solutions of $Cu(NO_3)_2 \cdot 2.5H_2O$ and $NiCl_2 \cdot 6H_2O$ (21.9 and 21.4 mg in 5 ml H_2O, respectively) were added to Na–**1a** (25 mg) dissolved in water (5 ml). In case of the Cu–**1a** complex the clear dark green solution was stirred (20 min) with heating (~35 °C) and treated dropwise with 0.5 M HNO_3 (to pH 2). The resulting green solution was still heated and stirred (1 h) then filtered and concentrated by evaporation at room temperature. Dark green microcrystalline precipitate began to form within a week. The procedure for the Ni–**1a** complex was analogues. The $NiCl_2 \cdot 6H_2O$–**1a** mixture was clear straw-colored and after treating with 1 M KOH (to pH 8) the solution became dark red. Finally, after a few days dark red microcrystalline powder was obtained. Despite of co-precipitation of the synthesized complexes with nitrate and chloride ions, respectively, elemental analyses indicated clearly that the metal-to-**1a** molar ratio is about (1:2).

2.2. Spectroscopy

For FT-Raman measurements, a few milligrams of the compound was placed in capillary tube and measured directly; 512 and 3000 scans were collected (with a resolution of 4 cm^{-1}) for the sodium and the transition metal ions compounds, respectively. Fourier transform mid-infrared (FT-MIR, 256 scans) and Fourier transform far-infrared (FT-FIR, 512 scans) spectra were run in KBr and low molecular weight polyethylene discs, respectively. Resolution was set at 4 cm^{-1} (MIR) and 2 cm^{-1} (FIR). Sodium–**1a** salt FT-Raman spectrum was recorded on a Bio-Rad step-scan spectrometer (FTS 6000) combined with a Bio-Rad Raman Accessory (FTS 40). Excitation at 1064 nm was made by a Spectra-Physics Topaz T10-106c cw Nd:YAG laser. Raman spectra of the copper and nickel complexes were collected on a Jobin Yvon spectrometer model T6400 equipped with an argon ion laser (excitation at 514.5 nm) and a CCD camera as a detector (Princeton Instruments). FT-IR spectra were measured on Bruker (IFS 48) and Bio-Rad (FTS 60V) spectrometers in the mid and far IR regions, respectively. The accuracy of the readings was ±1 cm^{-1}.

EPR spectrum of the Cu–**1a** complex (the microcrystalline powder sample) was recorded on a Bruker spectrometer ELEX SYS X500 [X-band (9.5 GHz)] at 298 K.

3. Computational details



B3LYP [12,13] calculations with 6-311++G(d,p) and LanL2DZ [14,15] basis sets (for the sodium salt and the transition metals complexes, respectively) were carried out using the quantum-mechanical GAUSSIAN-98 set of programs [16]. Optimum geometries and harmonic frequencies were determined by using SGI 2800 computer in the Academic Computer Center "Cyfronet" in Krakow and on a Cray SV1ex-1-32 computer in Interdisciplinary Center for Mathematical and Computational Modeling in Warsaw. No symmetry constraints were imposed during the optimization process. At the B3LYP/6-311++G(d,p) level a scaling factor of 0.983 was applied to the most harmonic frequencies [except to ν(OH) modes (0.953)] in order to yield the best fit to the experimental data, as suggested by Michalska and co-workers [17]. Raman intensities were determined by RAINT program [18] using values of Raman scattering activities obtained from the Gaussian outputs. The potential energy distributions (PED) were obtained from the Veda program [19], while atomic charge

calculations were performed using APT population analysis (GAPT, Generalized Atomic Polar Tensor) [20]. For the latter, the optimized geometries at the B3LYP/LanL2DZ level of theory were used.

4. Results and discussion

The **1a** complexes can exist as variety of geometrical isomers, where a metal ion is chelated by the ligand in the bidentate mode via the carboxylic oxygen and oximic nitrogen atoms or in the monodentate fashion via either the carboxylate ion or the oximato fragment (Scheme 1). Potentiometric and UV–Vis studies have suggested that the copper complex exists as $[CuHL_2]^-$ species at pH 2, while the nickel complex is present in the $[NiL_2]^{2-}$ form at pH range of 6–10. In these complexes, two ligand molecules are located to each other in the *trans* configuration. However, crystallographic data of Cu(II) complex showed the dimeric structure [8]. All discussed above molecular structures of **1a** complexes are presented in Scheme 1.

In order to identify the molecular structures of the **1a** complexes obtained in this work we used theoretical simulation of their vibrational spectra. It should be emphasized that this method allows to predict a general coordination pattern only but it is very valuable in the case of the lack of crystallographic data. However, this is more than enough to distinguish between *cis* and *trans* conformation of the metallocomplex with information whether coordinated ligands are protonated or not. Thus, for the purpose of this work, we considered as models bis-chelate square planar molecules with different conformation of the ligand (*cis* $[MHL_2]^-$ and *trans* with the protonated $[MH_2L_2]$ as well as deprotonated oximic group $[ML_2]^{2-}$). However, for the sodium complex we assumed that sodium ions can be coordinated to either oximate or carboxylate moieties [MHL] or to both of them simultaneously $[M_2L]$ (see Scheme 1).

Scheme 1.

In case of the nickel–**1a** complex, frequency calculations at equilibrium geometries yield only real values; hence all models correspond to local minima. The comparison of theoretical and experimental IR spectra in the range of 1000–1800 cm^{-1} showed (Fig. 1) that $[NiL_2]^{2-}$ model reproduces the best obtained experimental data, where Ni(II) coordinates to deprotonated **1a** ligands in *trans* configuration (Fig. 2). The deprotonation of both ligand molecules is confirmed by the detailed analysis of the oximic vibrations as it is discussed below. It is clear that there has to be a counter cation for the dianionic form of 2-cyano-2-(hydroxyimino)acetic acid in this structure. It is known, from our previous works [22,24], that the type as well as the binding site of a counterion do not effect significantly experimental and theoretical vibrational spectra. Hence, in our models the presence of the counterion is neglected.

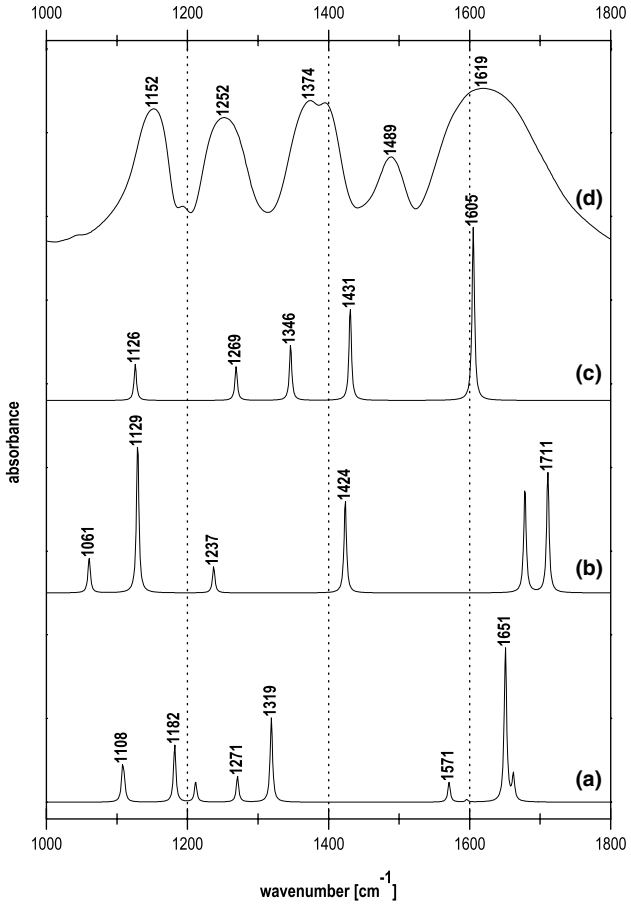


Fig. 1. Comparison of theoretical and experimental IR spectra (1000–1800 cm^{-1}) of the **1a** nickel complex: (a) *cis* $[NiHL_2]^-$, (b) *trans* $[NiH_2L_2]$, (c) *trans* $[NiL_2]^{2-}$ and (d) experimental spectrum.

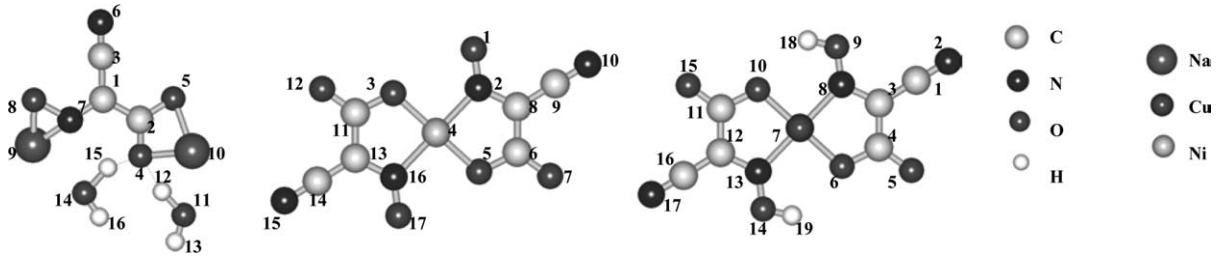

Fig. 2. Model structures of **1a** complexes with the atom numbering used in calculations.

The same procedure was applied to determinate the structure of the **1a** complex with Cu(II) ions. The dimeric species can be ruled out based on the EPR spectrum typical for a complex with orthorhombic symmetry ($g_1 = 2.249$, $g_2 = 2.188$ and $g_3 = 2.051$; cf. Fig. 3). Frequency analysis of *trans* $[CuL_2]^{2-}$ showed one imaginary value what indicated this model to be a transition state and excluded it finally from further studies. Moreover, the differences in experimental IR and Raman spectra of the nickel and copper complexes evidently indicates that these compounds are not isostructural. Additionally, the comparison of the calculated vibrational spectra of the other copper complex models with experimental IR and Raman clearly indicates that *trans* $[CuH_2L_2]$ form exists in solid state (see Figs. 2 and 4). Also, the presence of the protonated oximic groups has been established by their positions in the vibrational spectra (Section 4.3).

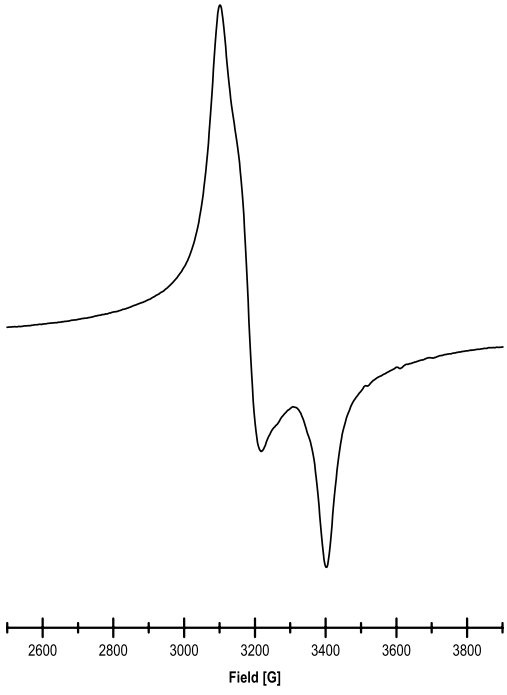

Fig. 3. Microcrystalline EPR spectra of the **1a** copper complex at the X band frequency at 298 K.

In case of the sodium–**1a**, several structures with different binding of this metal ion to the carboxylic and/or oximic groups were taken into consideration. As mention in Section 2 two sodium atoms are present in this complex of **1a**. Furthermore, despite of the elemental analysis results (water-to-Na–**1a** molar ratio is 1:3), two water molecules were added to the model structure to mimic H-bond presented in experimental IR spectrum (see Fig. 5). Finally, the comparison of experimental and simulated vibrational spectra showed that both NOH and COOH have to be deprotonated to allow coordination of two sodium ions ($[Na_2L] \cdot 2H_2O$; cf. Fig. 2).

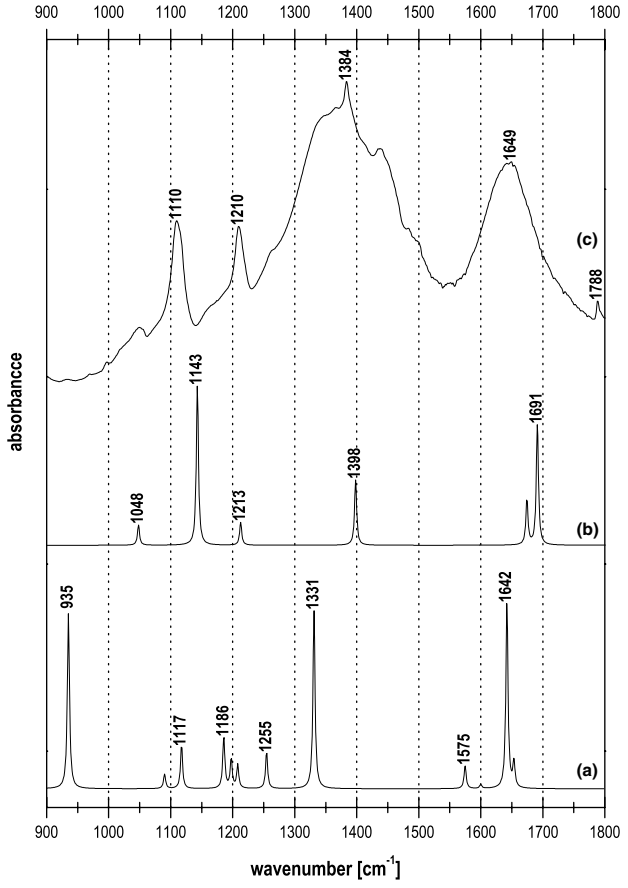

Fig. 4. Comparison of theoretical and experimental IR spectra (900–1800 cm^{-1}) of the **1a** copper complex: (a) *cis* $[CuHL_2]^-$, (b) *trans* $[CuH_2L_2]$ and (c) experimental spectrum.

Geometrical parameters, charge distribution and vibrational spectra for assigned molecular structures of **1a** complexes are discussed below.

4.1. Geometry

Computed bond lengths obtained for structures of E-isomer [H_2L] of **1a** and its complexes with metal ions present here are shown in Table 1. The comparison between bond length values in all studied complexes with the uncoordinated protonated **1a** molecule shows differences mainly in "functional" groups coordinating to the metal ions. The carbonyl bonds in the complexes lengthen considerably (0.04–0.06 Å) after the coordination, whereas the C—O bond involved in metal ion binding shorten slightly in the transition metal complexes (~0.01 Å) and over 0.05 Å in the sodium salt. This results probably from the bidentate coordination of the sodium ion by carboxylate group. The observed trend of changes in bond lengths for this group is typical for many oxocarboxylic acid oximic complexes [3,7,21,23,24].

The oximic NO and CN bonds in the sodium and nickel compounds are close to those reported for the N-coordinated deprotonated oxime group [3–5,23]. This indicates that the CNO^- moiety exists in the nitroso-form (C—N=O). The lengths of the oximic bonds in the protonated copper complex are longer than those in the **1a** molecule, contrary to the deprotonated complexes, where the C=N bond is elongated and the N—O bond is shortened upon coordination. The latter effect was observed for the *cis* complex of 2-hydroxyiminopropanoic acid [H_3C—C(COOH)=NOH, hpa] with Cu(II) ion regardless of the ligand protonation state [22]. Besides, in the **1a** copper complex the elongation of the oximic bonds supports the *trans* configuration of the investigated compound like it was found for the *trans* nickel hpa complex.

M—N		2.236	1.935	1.962

Functional groups are denoted as: ox – oximic, car – carboxylic, cya – cyano groups and M as metal ion. Upper symbols are denoted as: $[H_2L]$ – the fully protonated ligand; $[CuH_2L_2]$, $[Na_2L]\cdot 2H_2O$, $[NiL_2]^{2-}$ – applied models of complexes.
[a] The oximic oxygen atom.
[b] The carboxylic oxygens.

Regarding the cyano group, its bond lengthens upon the complexation with all metal ions studied here. Interestingly, coordination of the alkali ion causes a slight change of the C≡N length (0.003 Å), whereas for transition metal ions the elongation is rather significant (~0.03 Å). Besides, the deprotonation of the oximic group causes the decrease of the electron density of the cyano bond, and consequently, its lengthening. The B3LYP/LanL2DZ method predicted this bond to be too long (cf. Table 1), but it is still close enough to those observed in related cyanoxime complexes (1.13–1.15 Å) [3–5,7].

The metal–ligand bond distances were calculated in the range comparable to other complexes. For sodium salt of **1a**, the distances between sodium and carboxylic oxygen atoms were calculated at 2.20 and 2.44 Å. These values are consistent with the range of 2.01–2.59 Å found for other oximic complexes with alkali metal ions. Similarly, the Na–N_{oximic} bond length is 2.24 Å, while its typical value is observed in the 2.22–2.54 Å range [21,25,26]. However, the comparison of calculated

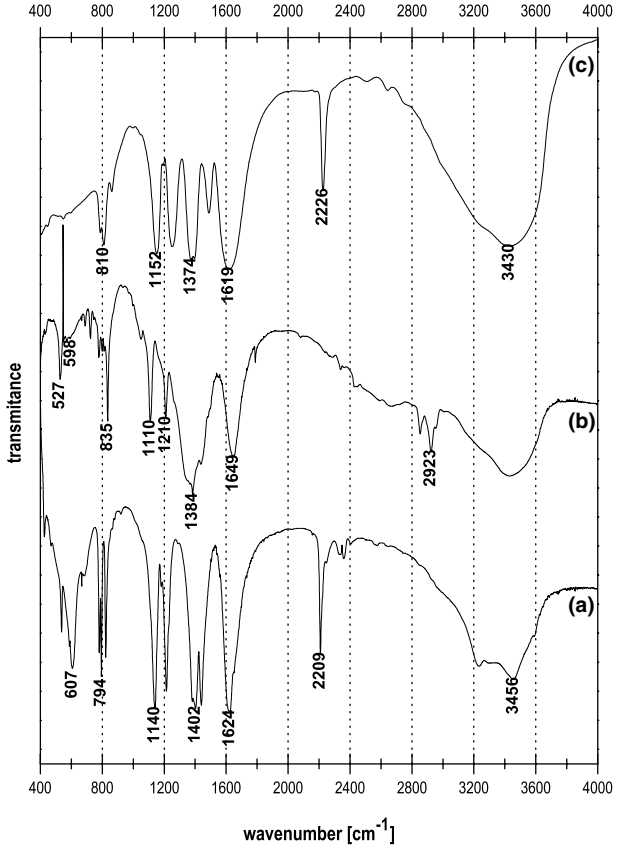

Fig. 5. Mid-IR spectra (400–4000 cm^{-1}) of (a) the **1a** sodium complex, (b) the **1a** copper complex and (c) the **1a** nickel complex.

metal–ligand bond lengths for proposed structures (*trans* $[NiL_2]^{2-}$ and $[CuH_2L_2]$) indicates the stronger binding of Ni(II) than Cu(II) ion to **1a**. It seems that the transition metal ion rather than the deprotonation state of the oximic group is responsible for this effect. As calculated for *trans* $[NiH_2L_2]$ isomer, the metal–nitrogen bond lengths (Ni—N = 1.855 Å, Ni—O = 1.851 Å) are still shorter than respective bonds in $[CuH_2L_2]$. All calculated metal–ligand bond lengths are in the range of the oximic complexes studied so far [3–5,7,22–26].

4.2. Atomic charges

The atomic charges at all atoms in **1a** at the different protonation stages and its complexes studied here are given in Table 2. The effective charges at the metal ions are reduced up on binding ligand and are +1.06 [(Cu(II)], +0.91 and +0.86 [Na(I), for the ion bonded to the carboxylate and oximato groups, respectively], +0.72 a.u. [Ni(II)]. The smallest change of the charge value in the sodium ion is consistent with the weakest metal–ligand interaction.

As expected, the electron density on the oxygen atoms in the deprotonated carboxylic group of **1a** (denoted in Table 2 as $[HL]^-$) is almost equal on both oxygens. The further deprotonation of the oximic group (see data for $[L]^{2-}$) causes only a charge increase at the carboxylic oxygens by ~ -0.1 a.u. Upon coordination of the copper ion, the withdrawal of electronic charge towards O-atom bonded to the metal ion is expected and observed. The similar distribution of the electron density on the carboxylic group is found for the sodium salt. The difference between charges on the O-atoms for the sodium compound is lower than for $[CuH_2L_2]$. It results from the fact that Na(I) ion coordinates to both oxygen atoms. Interestingly, a reverse trend is observed for the nickel complex. It appears that the deprotonation of the oximic group reduces the electron density at the carboxylic O-atom and shifts it towards the Ni-atom.

In the oximic group, the electron density is systematically shifted toward the oxygen atom. The deprotonation of the carboxylic proton causes an increase of negative charge at the NOH moiety (see data for $[HL]^-$ form of **1a**). After coordination of Cu(II), the negative charge density is accumulated on the N-atom and partially moved towards the metal ion. Upon the removal of the oximic proton the distribution of electron density changes significantly. The C and O atoms become strongly negative, whereas positive charge is accumulated on the N atom. This affects the C=N and N—O bond lengths as discussed above. These changes of the charge distribution follow the coordination of the sodium and nickel ions to the fully deprotonated ligand. Again, the largest withdrawal of the electronic charge from the N-atom towards the metal ion is observed in $[NiL_2]^{2-}$.

It is worth to look at the charge distribution of the cyano group. Upon the deprotonation of the carboxylic proton, the negative charge of the N-atom increases by 0.18 a.u. whereas a charge at the C-atom decreases by 0.13 a.u., due to the withdrawing electron character of C≡N. After coordination of Cu(II), the electron density flows from the N-atom through the cyano carbon towards the remaining fragment of the ligand. However, the deprotonation of the oximic proton causes more ionic character of the cyano bond than in the $[HL]^-$ form. This group behaves as an electron donating substituent in coordination of sodium and nickel ions. Regardless the coordination mode and the type of a metal ion, the same effective charge (−0.08 a.u.) is shifted from C≡N towards the adjacent oximic C-atom. Furthermore, the difference between the effective charges at the carbon and nitrogen atoms in C≡N follows the trend: $[CuH_2L_2]$ (0.03 a.u.), $[Na_2L]\cdot 2H_2O$ (0.55 a.u.) and $[NiL_2]^{2-}$ (0.99 a.u.). It worth to note that this differ-

[a] Geometry by B3LYP/LanL2DZ for all models.

ence for models $[CuL_2]^{2-}$ and $[NiH_2L_2]$ are 0.97 and 0.01 a.u., respectively. It clearly indicates that polarization of the cyano group strongly depends on the deprotonation of the oximic group only. That can be traced in vibrational properties of this group as will be shown below.

4.3. Vibrational spectra

The calculated and experimental vibrational frequencies and assignments of the characteristic modes for all investigated complexes are summarized in Table 3 (full description of the internal coordinates and vibrational spectra are given in the Supplementary Material, Tables I–VI). Experimental (IR and Raman) spectra of the complexes are shown in Figs. 5–7. It should be emphasized that the simulated spectra refer to the isolated molecule at 0 K, whereas the assignments are made for the vibrational spectra of the solid state. Thus, some differences in the calculated versus experimental frequencies or intensities are most probably caused by intermolecular interactions (crystal packing) or by anharmonicity of vibrations. Vibrational modes which are of great importance in the determination of discussed molecular structures are shown below.

4.3.1. $\nu(OH)$ and $\delta(OH)$

The IR spectra of all compounds exhibit broad absorption bands with maxima at 3456 and 3234 [Na–**1a**], 3450 [Cu–**1a**] and 3430 cm^{-1} [Ni–**1a**] (cf. Fig. 5). These are assigned to the stretch vibration of the oximic OH (in the copper complex) as well as free or weakly H-bonded hydrated water molecules in the other complexes. Calculations for the applied models predict the presence of those vibrations at 3720, 3719, 3265 and 2983 cm^{-1} [$\nu(OH)_{H_2O}$] for the sodium salt (cf. Fig. 2) and at 3496 and 3499 cm^{-1} [$\nu(OH)_{ox}$] for the copper complex. Additionally, calculations of vibrational spectra for Ni and Cu complexes with hydrated waters showed that $\nu(OH)_{H_2O}$ should appear in the mentioned-above experimental range (data not shown). Moreover, bands at ~1620 cm^{-1} are characterized by significant values of FWHM resulting from the presence of bending modes of H_2O [$\delta(OH)$]. Hence, we can conclude that water molecules are not directly coordinated to the complex structures. Furthermore, the absence of IR absorptions characteristic for water molecules located in the first coordination sphere of a complex confirms this assumption (at ~900 and ~770 cm^{-1}, the rocking and the wagging vibrations of the OH group, respectively).

4.3.2. $\nu(C{\equiv}N)$

The stretches modes of cyano bond in the IR and Raman spectra of the **1a** complexes (cf. Table 3) definitely indicate the shortening of this bond in the following order: Na–**1a**, Ni–**1a** and Cu–**1a**. The mode frequencies of the sodium and nickel compounds are typical for their coordination motifs [3,5]. However, a participation of the C≡N group in the metal binding may be suggested by the high-shift of the C≡N stretch (2242 cm^{-1}, Raman spectrum, see Fig. 7(b)) for the cooper complex comparing to the latter. Surprisingly, IR and Raman intensities for this complex are very low, in the contrary to the other complexes. That is due to the electron density distribution. As showed above, the smallest polarization of the cyano bond is observed for $[CuH_2L_2]$.

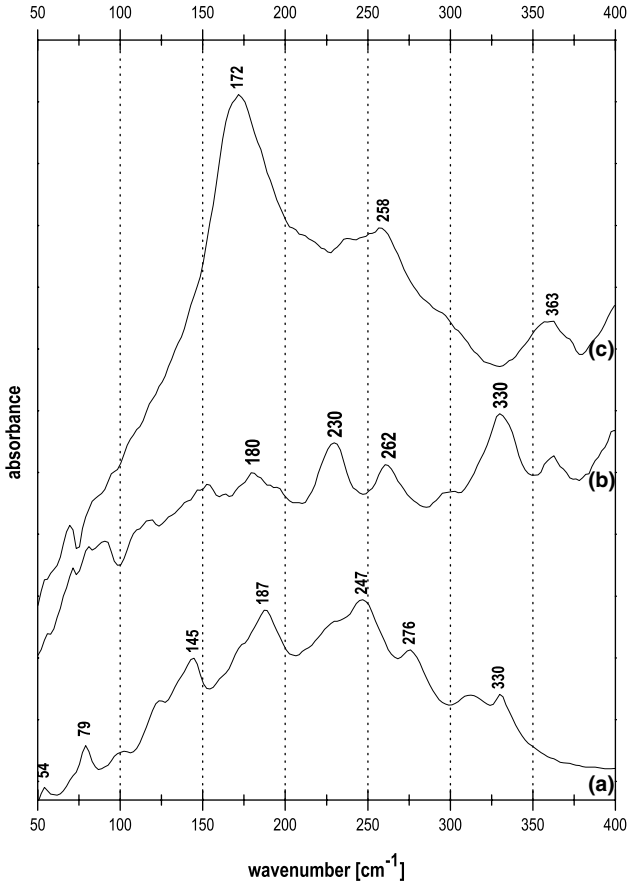

Fig. 6. Far-IR spectra (50–400 cm^{-1}) of (a) the **1a** sodium complex, (b) the **1a** copper complex and (c) the **1a** nickel complex.

4.3.3. $\nu_{as}(COO)$ and $\nu_s(COO)$

A characteristic features of the vibrational spectra of the **1a** complexes is the lowering of frequencies of the asymmetric carboxylate stretching [ν_{as}(COO)] down to ~1610 cm^{-1}. Thus, the change in these mode frequencies can be attributed to the deprotonation of the carboxylic group as well as the ability to bind the metal centers. The position of this band in the sodium complex is typical for the alkali complexes of hpa [21]. That clearly indicates the absence of a significant influence of the withdrawing electron cyano group on the coordination fashion by the carboxylate anion. Furthermore, a

smaller low-frequency shifts of this vibration for 3-d metal ions complexes support bidentate coordination of the 2-cyano-2-(hydroxyimino)acetate anion to metal center. Similar behavior has been found previously for other transition metals oximates [22]. Additionally, the vibrational spectra of those complexes exhibit the splitting of the COO stretching vibration. The in-counter-phase modes are observed in IR whereas the in-phase counterparts are present in the Raman spectrum. That is consistent with the proposed model where two ligands in *trans* configuration coordinate to the metal ion (see Table 3). Moreover, the deprotonation of the oximic group but not a metal ion [Cu(II) versus Ni(II)] seems to be responsible for the lower shift-frequency of the ν_{as}(COO) in the nickel complex. The IR frequency of the latter is almost the same as for the sodium salt with the deprotonated C=NO.

According to the DFT results, the symmetric stretching mode [ν_s(COO)] appears mainly in the range of 1165–1110 cm^{-1} with its relatively small contribution in the normal mode (22–60% PED). Merely, the spectra of Na–**1a** exhibit additional bands in the typical frequency range for ν_s(COO), at ~1381 cm^{-1} with 36% participation of this vibration.

4.3.4. ν(C=N) and ν(N—O)

The positions of the ν(C=N) and ν(NO) vibrations in IR and Raman spectra are dependent to a great extend on the oxime or nitroso character of this group in a particular compound and are reflected by the coordination mode. The vibrational spectra of the sodium and nickel complexes exhibit a significant shift of ν(C=N) to lower frequencies, at ~1440 and ~1490 cm^{-1}, for Na–**1a** and Ni–**1a**, respectively. That clearly indicates that **1a** appears in these complexes as a nitroso-containing anion. The lower shift of the band of the sodium salt results primarily from a participation in coordination of the oximic oxygen atom. DFT fully confirms this assignment (1454 cm^{-1}, 69% PED). The ν(C=N) of the nickel complex is found in our experiment in the similar range as for the Ir(III) and Ru(II) complexes of other α-hydroxyiminocarboxylic acids with the deprotonated oximic group (1515–1495 cm^{-1}) [23]. On the other hand, the C=N stretch vibration of the copper complex is assigned to the band at 1650 cm^{-1} in the Raman spectrum [1678 cm^{-1} (66% PED) calculated]. This frequency indicates that oximic not nitroso group takes part in Cu(II) coordination.

The high-frequency shift of the ν(NO) modes in the vibrational spectra of Na(I) and Ni(II) compounds confirms additionally that these metal ions are bonded to the ligand by the nitrogen atom of the nitroso group (cf. Table 3). B3LYP predicts positions of this mode very well, with an error less than 4.0%. Additionally, the simulated spectra of the nickel complex exhibit the different position of the mode in IR (1269 cm^{-1}) and Raman (1275 cm^{-1}) spectra, respectively. The same has been observed in the experimental spectra and results from the *trans* ligand conformation. The difference is equal to 9 cm^{-1}. The most pronounced feature of vibrational spectra of the copper complex is in their very low frequencies of the ν(NO) vibrations (1050 and 1045 cm^{-1} in IR and Raman, respectively) comparing to Na–**1a** and Ni–**1a**. Thus, the positions of these bands are consistent with the protonated *trans* structure.

4.3.5. Metal–ligand vibrations

The frequency region below 500 cm^{-1} provides information on the metal–ligand stretch vibrations. The far IR and Raman spectra of the complexes present here in this particular range are shown in Figs. 6 and 7. The IR absorptions at 307, 330 and 357 cm^{-1} are assigned to the metal–nitrogen stretching vibration of Na, Cu(II) and Ni(II) complexes, respectively. The contribution of this vibration to the normal modes is less than 50%, as predicted by calculated PEDs (cf. Table 3). As expected, the coordination by the oximic nitrogen atom of the s-type metal ions is considerably weaker. Similar observation has been found for the metal-carboxylic oxygen stretch modes. Moreover, the comparison of frequencies of Na–O_{oximic} with Na–$O_{carboxylic}$ indicates the stronger coordination this alkali ion by the nitroso moiety than by the carboxylate anion.

5. Conclusions

The experimental IR and Raman spectra of solid state supported by the DFT calculations have shown that the transition metal complexes of 2-cyano-2-(hydroxyimino)acetic acid have *trans* bidendate square-planar geometry with the different protonation state of the oximic group. This is similar to their structures in solution determined previously by our potentiometric and spectroscopic studies [8]. However, two sodium ions are bonded to the carboxylate as well as oximate moieties. Vibrational analysis has clearly indicated the binding nature of the oximic and carboxylic oxygen atoms and the oximic nitrogen atom. It also shows the presence of the nitroso form of the oximic group in Ni–**1a** and Na–**1a**. Furthermore, the latter effects the coordination strength in all complexes presented. Namely, this causes the increase of the stability of the nickel complex comparing to the copper one and the binding ability of the oximic group comparing to the carboxylic one in Na–**1a**. The magnitude of all stretch vibrations has been shown to be well correlated with the atomic charge distribution. The calculations of atomic charges have suggested that the deprotonation of the carboxylic group does not change significantly the electronic distribution in the **1a** molecule, whereas the removal of the oximic proton causes the accumulation of the positive charge on the oximic nitrogen. Moreover, the electron density is shifted from the metal ion towards the carboxylic oxygens in the copper and sodium complexes in reverse to Ni–**1a**. And in the oximic group, the N-atom is an electron donor for metal ions.

species was observed. Adducts such as $Cu_2(TFA)_4L_2$ [L = MeCN [7a], quinoline [7b], 2-hydroxypyridine (2-pyOH)] and $Cu(TFA)_2L_4$ [L = H_2O] [7a], 3-hydroxypyridine (3-PyOH) [7c] or mixed-ligand species such as $Cu(TFA)_2(3\text{-pyOH})_2(THF)_2$ were also reported. A number of $Ba(TFA)_2$ complexes with O- and N-donor polydentate ligands have been described [8,9]. The complex with 15-crown-5 has been used for $MTiO_3$ films (M = Ba, Sr) [8,9].

We wish to report herein the synthesis and characterization in the solid state as well as in solution of various adducts of copper(II) and barium(II) fluorinated carboxylates. Indications about their stability and reactivity are given as well.

2. Experimental

All manipulations were routinely performed under nitrogen using Schlenk tubes and vacuum line techniques. Solvents were purified by standard methods. Trifluoroacetic (TFAH), perfluorobutyric (PFBH) and difluoroacetic acids (Aldrich) were stored over molecular sieves. $[Cu(OMe)_2]_\infty$ was prepared by anodic dissolution of the metal [10]. FT-IR spectra were recorded as Nujol mulls on an IR-FTS 45 Perkin–Elmer spectrometer. Elemental analyses were done at the Centre de Microanalyses du CNRS. FT-IR data and general characteristics are collected in Table 1. ESR spectra (X-band), were obtained at rt on powders with a Bruker spectrometer (microwave power of 10 mW, modulation frequency of 100 kHz). DPPH (diphenylpicrylhydrazyl) was used as reference (g = 2.0036).

2.1. Syntheses

2.1.1. $[Cu_2(TFA)_4(THF)_2]$ (1) and $Cu(O_2CCHF_2)_2(THF)$ (2)

TFAH (1.6 ml, 20.6 mmol) was added to a THF/toluene (1:3, 40 ml) suspension of $[Cu(OMe)_2]_\infty$ (1.30 g, 10.3 mmol). The dark green solution obtained after stirring overnight and filtration, concentration yielded green crystals of **1** at −20 °C (2.20 g, 59%). *Anal.* Calc. for $C_8H_8F_6O_5Cu$: C, 26.57; H, 2.23. Found: C, 26.14; H, 2.16%. Additional crops of crystals were contaminated with $Cu_2(TFA)_4(MeOH)_2$ (IR and analytical evidence).

The same procedure applied to CHF_2CO_2H (0.46 ml, 7.27 mmol), $[Cu(OMe)_2]_\infty$ (0.458 g, 3.63 mmol) and THF (30 ml) gave green crystals of **2** at −20 °C (0.65 g, 55%) by addition of toluene. *Anal.* Calc. for $C_8H_{10}O_5F_4Cu$: C, 29.50; H, 3.09. Found: C, 29.45; H, 2.92%.

2.1.2. $[Cu(TFA)(OAc)]_m(THF)_{0.25m}$ and $Cu_2(PFB)_4(THF)_2$ (3)

TFAH (0.25 ml, 3.30 mmol) was added to a suspension of $Cu(OAc)_2$ (0.30 g, 1.65 mmol) in THF (15 ml). After 3 h, the green solution was concentrated. Addition of toluene gave a green-blue solid at −20 °C (0.32 g, 76%). *Anal.* Calc. for $C_5H_5F_3O_{4.25}Cu$: C, 23.68; H, 1.99. Found: C, 23.97; H, 1.58%.

The same procedure applied to perfluorobutyric acid (0.45 ml, 3.43 mmol), $Cu(OAc)_2$ (0.284 g, 1.56 mmol) in THF (20 ml) gave green crystals of **3** (0.57 g, 65%). *Anal.* Calc. for $C_{12}H_8F_{14}O_5Cu$: C, 25.66; H, 1.44. Found: C, 25.75; H, 1.53%. Sublimation at 190 °C/2×10^{-4} Torr gave the very hygroscopic $[Cu(PFB)_2]_m$.

2.1.3. $Cu_2(TFA)_4(^iPrOC_2H_4OH)_2$ (4)

2-Isopropoxyethanol (1.1 ml, 9.35 mmol) was added to **1** (0.678 g, 2.08 mmol) in toluene (20 ml). After stirring for 12 h at rt, concentration afforded green crystals (0.66 g, 81%). *Anal.* Calc. for $C_9H_{12}F_6O_4Cu$: C, 27.46; H, 3.06. Found: C, 27.65; H, 3.36%. ESR: $\langle g \rangle$ = 2.0834.

2.1.4. $Cu(TFA)_2(Me_2NC_2H_4NMeC_2H_4NMe_2)$ (5)

$Me_2NC_2H_4NMeC_2H_4NMe_2$ (1.0 ml, 4.80 mmol) was added to **1** (0.690 g, 2.12 mmol) in toluene (15 ml). The solution was stirred at rt overnight and evaporated. Recrystallization in THF gave blue crystals (0.90 g, 92%). *Anal.* Calc. for $C_{13}H_{23}F_6N_3O_4Cu$: C, 33.73; H, 5.01; N, 9.08. Found: C, 33.26; H, 5.15; N, 8.81%. ESR: $\langle g \rangle$ = 2.1039.

2.1.5. $[Cu(TFA)(OC_2H_4NMe_2)]_4$ (6)

N,*N*′-Dimethylaminoethanol (0.84 ml, 8.4 mmol) was added to $Cu(TFA)_2(MeOH)$ (0.81 g, 2.8 mmol) in toluene (15 ml). Afer stirring at rt overnight, evaporation to dryness, recrystallization in THF gave blue crystals (1.12 g, 85%). *Anal.* Calc. for $C_{24}H_{40}F_{12}N_4O_{12}Cu_4$: C, 27.23; H, 3.81; N, 5.29. Found: C, 27.35; H, 3.86; N, 5.32%. ESR: $\langle g \rangle$ = 2.090. The monocrystals displayed 0.25 lattice THF molecules per tetramer.

2.1.6. $Cu_2(PFB)_4(^iPrOC_2H_4OH)_2$ (7)

2-Isopropoxyethanol (0.31 ml, 2.7 mmol) was added to **2** (0.500 g, 0.90 mmol) in THF (10 ml). Stirring at rt overnight, evaporation to dryness and recrystallization in toluene yielded green crystals (0.40 g, 75%). *Anal.* Calc. for $C_{13}H_{12}F_{14}O_6Cu$: C, 26.53; H, 2.02. Found: C, 26.30; H, 2.04%.

2.1.7. $Ba(O_2CCHF_2)_2 \cdot 0.5MeOH$ (8)

CHF_2CO_2H (0.72 ml, 11.4 mmol) was added to a suspension of BaH_2 (0.794 g, 5.71 mmol) in THF (30 ml) at −40 °C. After stirring overnight at rt, the suspension was evaporated to dryness. Recrystallization in MeOH gave **8** at −20 °C (1.30 g, 61%). *Anal.* Calc. for $C_{5.5}H_7F_4O_{5.5}Ba$: C, 15.74; H, 1.17. Found: C, 15.76;

Table 1
FT-IR data (cm^{-1}) of the Cu(II) and Ba fluorinated carboxylate adducts

Compound	$\nu(CO_2)$		ν(M–O)	ν(OH)	Observation[a]
	$\nu_{as}(CO_2)$	$\nu_s(CO_2)$

$Cu(O_2CCHF_2)_2(THF)$ (**2**)	1674 s	1460 m	629 w, 604 w, 526 w, 489 w		green; very hygroscopic. THF s, toluene ss, hexane in
$Cu_2(PFB)_4(THF)_2$ (**3**)	1684 s	1418 m	529 br m[b]		green; air-stable for a few hours
$Cu_2(TFA)_4(^iPrOC_2H_4OH)_2$ (**4**)	1706 s	1464 m	628 w, 538 w, 528 w, 505 w	3176 br	air-stable for some hours; toluene, s; EtOH, ss; hexane, H_2O, in
$Cu(TFA)_2(Me_2NC_2H_4NMeC_2H_4NMe_2)$ (**5**)	1704 s	1424 m	606 w, 585 w, 520 w, 501 w, 480 w, 461 w		blue, turn purple in air; THF, H_2O, EtOH, s; toluene, in
$[Cu(TFA)(OC_2H_4NMe_2)]_4$ (**6**)	1691 s	1420 m	637 w, 614 w, 523 w, 496 w, 472 w		air-stable for some hours; toluene, THF, s; EtOH, ss; Et_2O, hexane, in
$Cu_2(PFB)_4(^iPrOC_2H_4OH)_2$ (**7**)	1698 s	1437 m	656 w, 601 w, 530 w, 494 w, 455 w	3166 br	air-stable for some hours; toluene, s; EtOH, ss; hexane, H_2O, in
$Ba(O_2CCHF_2)_2 \cdot 0.5MeOH$ (**8**)	1652 s	1460 m	599 m, 525 m	3333 br, 3196 br	hygroscopic, THF, ss; MeOH, s
$Ba(TFA)_2\{MeN(C_2H_4OH)_2\}_3$ (**9**)	1677 s	1463 w	600 w, 564 w, 542 w, 518 w	3317 br, 3184 br	air-stable for some hours, THF, s; MeOH, s; $CHCl_3$, s
$Ba(TFA)_2(N(C_2H_4OH)_3)_2$ (**10**)	1682 s	1434 m	599 w, 567 w, 521 w	3354 br	Air stable for some hours; THF, s; MeOH, s; $CHCl_3$, s

[a] s, soluble; ss, slightly soluble; in, insoluble.
[b] IR spectra on NaCl (products react with KBr).

H, 1.23%. ^{1}H NMR (CD_3OD): 5.96 t (J_{H-F} = 53.10 Hz, 2H, CH), 3.5 s (Me, 1.5H).

2.1.8. $Ba(TFA)_2\{MeN(C_2H_4OH)_2\}_3$ (9)

N-Methyldiethanolamine (0.7 ml, 6.04 mmol) was added to a solution of $Ba(TFA)_2$ (0.549 g, 1.51 mmol) in THF (20 ml). After stirring overnight at rt and concentration, colorless needles were obtained (0.475 g, 44%). *Anal*. Calc. for $C_{19}H_{39}F_6N_3O_{10}Ba$: C, 31.66; H, 5.45; N, 5.83. Found: C, 31.53; H, 5.45; N, 5.79%. ^{1}H NMR ($CDCl_3$): 5.10 br (6H, OH), 3.70 (J = 4.4 Hz, 12H, OCH_2), 2.5 t (J = 4.4 Hz, 12H, NCH_2), 2.22 s (9H, NMe).

2.1.9. $Ba(TFA)_2\{N(C_2H_4OH)_3\}_2$ (10)

Same procedure as for **9** applied to triethanolamine (0.4 ml, 3.10 mmol) and $Ba(TFA)_2$ (0.564 g, 1.55 mmol) gave **10** (0.89 g, 87%). *Anal*. Calc. for $C_{14}H_{30}F_6O_{10}Ba$: C, 26.37; H, 4.74; N, 4.39. Found: C, 26.55; H, 4.86; N, 4.45%. ^{1}H NMR ($CDCl_3$): 3.4 t (J = 4.4 Hz, 24H, OCH_2), 2.72 t (J = 4.4 Hz, 24H, NCH_2), 4.9 br (6H, OH).

All Cu compounds were soluble in THF. Complexes **4** and **7** were more soluble in toluene than in ethanol. The Ba–TFA complexes with polyols were soluble in solvents such as $CHCl_3$.

2.1.10. Crystallography of 3, 4, 6 and 9

Suitable crystals of **3** and **9** were grown directly from the reaction medium, those of **4** and **6** were obtained by recrystallization in toluene/hexane and in THF, respectively. X-ray single-crystal diffraction data were collected at low temperature (160 K) with a Nonius Kappa CCD diffractometer equipped with a normal monochromatized focus X-ray tube having a molybdenum target. The data were collected using the COLLECT software [11a] then were processed through the DENZO reduction software [11b]. The structures were solved and refined on F^2 using the SHELXTL software [12]. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were included in the final refinement model in calculated positions with isotropic thermal parameters. Crystal structure and refinement data are summarized in Table 2. For compound **3** the quality of the crystal did not allow a high resolution and a high data to parameters ratio required for full unrestrained anisotropic refinement. Therefore the C–F and C–C bond length were restrained to acceptable values and all non-hydrogen anisotropic displacement parameters (ADP) were restrained so that their Uij approximate to isotropic behaviour. For **6**, some CF_3 groups were disordered over two positions and lattice THF molecules were found and refined with 0.25 occupation. For compound **9**, one of the fluorine

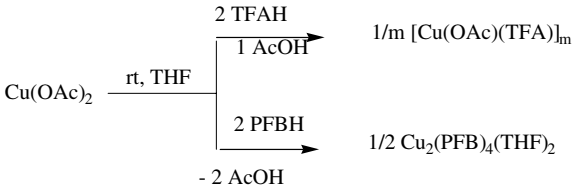
atoms of one CF_3 group was splitted over two positions with half occupancies factors.

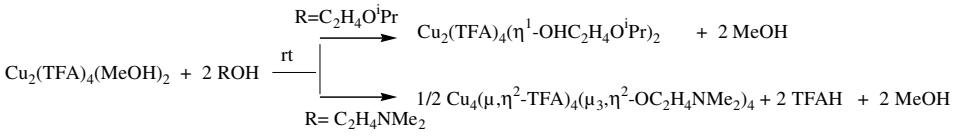
3. Results and discussion



Synthetic routes and reactivity, namely stabilisation by Lewis bases of Cu(II) and Ba trifluoroacetates were investigated. The various compounds were isolated in high yields and were characterized by elemental analysis, FT-IR, ^{1}H NMR or ESR and for $Cu_2(PFB)_4(THF)_2$ **3**, $Cu_2(TFA)_4(OHC_2H_4O^iPr)_2$ **4**, $Cu_4(TFA)_4(OC_2H_4N\text{-}Me_2)_4$ **6** and $Ba(mdeaH_2)_3(TFA)_2$ **9**, by single crystal X-Ray diffraction.

3.1. Synthesis and characterization

3.1.1. Copper(II) fluorocarboxylates



The synthesis of anhydrous of Cu(II) trifluoroacetate, $[Cu(TFA)_2]_m$, was reported by reacting the acid with Cu_2O in the presence of dioxygen, trifluoroacetic anhydride being added to remove the by-product, water [13]. Ligand exchange between $Cu(TFA)_2(H_2O)_x$ and acetone, followed by heating (135–145 °C) under reduced pressure was reported as another way to ligand free $Cu(TFA)_2$, characterized as $[Cu_2(TFA)_4]_\infty$ [6].

We have investigated various alternative routes to anhydrous Cu(II) trifluoroacetate. The reaction between copper(II) methoxide $[Cu(OMe)_2]_\infty$ and TFAH in THF afforded the $Cu_2(TFA)_4(THF)_2$ (**1**) adduct. If the reaction was conducted in methanol, a $Cu(TFA)_2$ methanol adduct was obtained, the methanol ligands could not be exchanged by THF at rt. The difluoroacetate $Cu(O_2CCHF_2)_2(THF)$ (**2**) could be prepared from $[Cu(OMe)_2]_\infty$ and CHF_2CO_2H in THF. Its lower Lewis acidity, as compared to that of the trifluoroacetate **1**, precluded contamination by methanol as ligand which was observed for the last crops in the synthesis of **1**. Attempts to prepare $Cu(TFA)_2$ from $Cu(OAc)_2$ at rt afforded an heteroleptic derivative, $[Cu(TFA)(OAc)]_m(THF)_{0.25m}$. In contrast, the homoleptic perfluorobutyrate $Cu_2(PFB)_4(THF)_2$ (**3**) was easily obtained, in similar conditions, from anhydrous $Cu(OAc)_2$ and perfluorobutyric acid (PFBH = $CF_3C_2F_4CO_2H$) (Eq. (1)).

(1)

Ligand exchange reactions at rt applied to **1** and **3** with isopropoxyethanol afforded $Cu_2(TFA)_4(^iPrO\text{-}C_2H_4OH)_2$ (**4**) and $Cu_2(PFB)_4(^iPrOC_2H_4OH)_2$ (**7**), respectively. $Cu(TFA)_2(Me_2NC_2H_4NMeC_2H_4NMe_2)$ (**5**) was obtained from **1** in the presence of *N*,*N*,*N*′,*N*″,*N*″-pentamethyldiethyltriamine. The TFA ligands of **1** or $Cu(TFA)_2(MeOH)$ appeared labile, even at rt, in the presence of dimethylaminoethanol and a tetranuclear carboxylatoaminoalkoxide $[Cu(TFA)(OC_2H_4\text{-}NMe_2)]_4$ (**6**) was obtained in high yield (characterized by X-ray – see below – with lattice THF molecules) (Eq. (2)).

(2)

Compounds **1**, **2**, and **3** are hygroscopic. Compound **1** either as solid or in solution gave hydroxide species (ν(OH) = 3641, 3595, 3336, 3191 cm^{-1}) after several weeks in air. The same species was obtained by reacting $Cu(OH)_2$ and one equivalent of TFAH in THF. However, no single crystals could be obtained so far by either route. Cu(II) carboxylatohydroxides $Cu_2(OH)_3(O_2CR)$ (R = C_mH_{2m+1}, m = 5–10) have been reported as 2D-magnetic materials [14].

3.1.2. Barium fluorinated carboxylates

The reaction between BaH_2 and CF_3CO_2H in THF was reported as a clean route to anhydrous, ligand free $[Ba(TFA)_2]_m$, the driving force being the elimination of dihydrogen [8,9]. We have investigated its reactivity toward various ligands mostly functional alcohols which might be used as media for the MOD deposition of high Tc superconductors.

No reaction was observed even on refluxing for 5 h in THF between $[Ba(TFA)_2]_m$ and excess (>4 equivalents) of bidentate ligands such as TMEDA or functional alcohols such as $Me_2NC_2H_4OH$ or $^iPrOC_2H_4OH$. In contrast, polyols such as *N*-methyldiethanolamine $MeN(C_2H_4OH)_2$ ($mdeaH_2$) and triethanolamine $N(C_2H_4OH)_3$ ($teaH_3$) were able to achieve depolymerization of $[Ba(TFA)_2]_m$ in THF even at rt giving, respectively,

$Ba(TFA)_2\{MeN(C_2H_4OH)_2\}_3$ (**9**) and $Ba(TFA)_2\{N(C_2H_4OH)_3\}_2$ (**10**). These adducts were more soluble than $[Ba(TFA)_2]_m$ in methanol. The difluorinated acetate $[Ba(O_2CCHF_2)_2]_m$ was prepared from BaH_2 and CHF_2CO_2H. Its solubility in THF is lower than that of the trifluoroacetate oligomer but comparable in methanol. As observed for $[Ba(TFA)_2]_m$ [8,9] and expected for the less acidic difluoroacetate, no adduct was formed with MeOH. Its recrystallization in methanol yielded $[Ba(O_2CCHF_2)_2]_m \cdot 0.5mMeOH$ (**8**) but the methanol molecules were in the lattice as evidenced by the absence of shift in the FT-IR with respect to the free ligand.

3.2. Spectroscopic characterization and physicochemical properties

The FT-IR spectra of the various compounds (Table 1) display very intense broad absorption bands around 1290–1100 cm^{-1} corresponding to the C–F vibrations. Additional sharp bands due to the coordinated Lewis base are present as well, they are shifted to lower frequencies with respect to those of the free ligand. The absorption bands characteristic of the carboxylate ligands appear generally around 1704–1674 cm^{-1} for the asymmetric $\nu_{as}(CO_2)$ vibration and around 1464–1420 cm^{-1} for the symmetric ones. The values of the difference $\Delta = \nu_{as}(CO_2) - \nu_s(CO_2)$ around 240 cm^{-1} suggest that the TFA ligands are bridging in the copper(II) species [15]. FT-IR spectra of $Ba(TFA)_2\{MeN(C_2H_4OH)_2\}_3$ (**9**) and $Ba(TFA)_2\{N(C_2H_4OH)_3\}_2$ (**10**) display comparable features but their $\nu_{as}(CO_2)$ absorption bands are observed at lower frequencies than those of the Cu(II) fluorocarboxylates. The value of Δ is 214 cm^{-1} for **9** where the trifluoroacetates are identified as non-coordinated anions by X-Ray diffraction (see below). Its $\nu_{as}(CO_2)$ vibration occurs at 1677 cm^{-1} while a frequency of 1694 cm^{-1} (Δ = 212 cm^{-1}) is recorded for $Ba(\eta^1\text{-}TFA)_2(mdeaH_2)_2$ [15] making it difficult to rely on the IR data for deciding about the coordination behavior of TFA on barium centers. The ν(OH) absorption bands of the copper species **4** and **7** correspond to alcohol ligands while those of **8** account for lattice alcohol molecules. In contrast, the absence of ν(OH) absorption bands for **6** supports a trifluoroacetatoalkoxide formula. The strong, broad bands at 3317, 3184 cm^{-1} of **9** and 3354 cm^{-1} of **10** account for the absence of deprotonation of the polyols. ^1H NMR spectra of the Ba derivatives in $CDCl_3$ are rather uninformative although they confirmed the presence of the polyols in the metal coordination sphere. The ESR data of the Cu(II) species are in agreement with the literature body [17].

The high Lewis acidity of fluorinated carboxylates makes them extremely prone to hydration. In general, the compounds are more stable in the solid state than in solution (THF or MeOH media). The Cu adducts with O-donor ligands are also more stable toward ambient atmosphere than those based on N-donor Lewis bases. Indeed, **5**, the $Cu(TFA)_2$ adduct with pentamethyldiethylenetriamine (pmedta) turns rapidly into a purple species in air. The barium species are hygroscopic, they appear less soluble in organic media than the copper(II) ones but more than the Y trifluoroacetate derivatives [18].

Symmetry transformations used to generate equivalent atoms: #1: $-x$, $-y$, $-z$; #2: $-x$, $-y+1$, $-z+1$.

The coordination of the copper(II) fluorocarboxylates by organic ligands provides solubility in solvents such as THF or even toluene. Compounds **4** and **7** are more soluble in toluene than in ethanol. The order of solubility in methanol, the solvent the most used for the deposition of high Tc superconductors, is in the favour of the perfluorobutyrate, the order being $Cu_2(PFB)_4(THF)_2 \gg Cu_2(O_2CCF_3)_4(THF)_2 \approx Cu_2(O_2CCHF_2)_4(THF)_2$. Compound **6** is the least soluble Cu species in methanol among those reported here.

The various copper trifluoroacetate derivatives as well as $Cu_2(O_2CCHF_2)_4(THF)_2$ have poor volatility. Only ~10% sublimation is observed for $Cu_2(TFA)_4(THF)_2$ (250 °C/2×10^{-4} Torr) for instance whereas no sublimation occurs at all for $Cu_2(O_2CCHF_2)_4(THF)_2$ or $Cu_2(TFA)_4(MeOH)_2$. In contrast, **3** sublimes completely at 190 °C/2×10^{-4} Torr as a ligand free, extremely hygroscopic $[Cu(PFB)_2]_m$ species. Thermogravimetric analysis (N_2, 1 atm) of **3** shows the loss of THF between 170 and 240 °C whereas decomposition of the carboxylate ligands occurs at 240–310 °C. The amount of residue (10%) is lower than the value expected for copper(II) oxide (14%) due to partial volatility under the TGA conditions [2].

The TFA ligands of some copper derivatives are extremely labile. Complexes **1**, **3** and $[Cu(OAc)(TFA)]_m$, react with the KBr plates for the IR spectra (as Nujoll mulls) giving dark green–brown Cu(II) bromide derivatives. In contrast, FT-IR spectra could be obtained with NaCl plates. The exchange between TFA ligands with aminoethanol giving **6** provides a rare example of a high yield synthesis of a metal alkoxide starting from a carboxylate. The reaction between the monofluoroacetate adduct $Cu_2(O_2CCFH_2)_4(H_2O)_2$ and 2-diethylaminoethanol was reported to afford the $[Cu_2(\mu,\eta^2\text{-}O_2CCFH_2)_4(\eta^1\text{-}O_2CCFH_2)_2]^{2-}$ anion, the counter-ion, protonated aminoethanol $Et_2NHC_2H_4OH$, interacts via H-bonding [19]. This illustrates the versatility of the behaviour of fluorinated carboxylates in the presence of nitrogen donor ligands [16,18].

3.3. Molecular structures of Cu(II) and Ba fluorocarboxylates

The copper TFA or PFB adducts **4** and **3** are discrete dinuclear species in the solid displaying the typical paddle-wheel structures found for other carboxylate adducts with four bridging carboxylates having syn-syn conformation [7]. The Lewis bases occupy the axial position of a distorted tetragonal pyramid of the five-coordinate metal centres. Their structures are depicted in Figs. 1

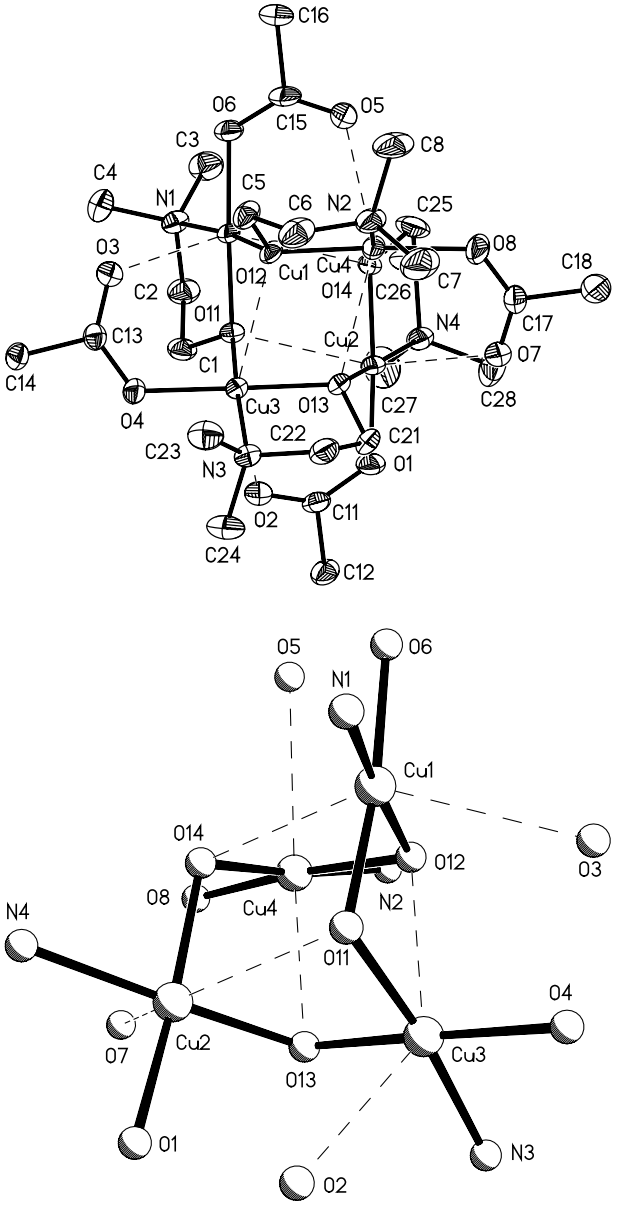

Fig. 3. (a) Molecular structure of **6** showing the atom numbering scheme (thermal ellipsoids at 30% probability). The fluorine atoms on C14, C16 and C18 are disordered over two positions. The dotted lines indicate the long axial Cu–O bonds, (b) drawing of the copper–oxygen core showing the long Cu–O interactions (>2.69 Å).

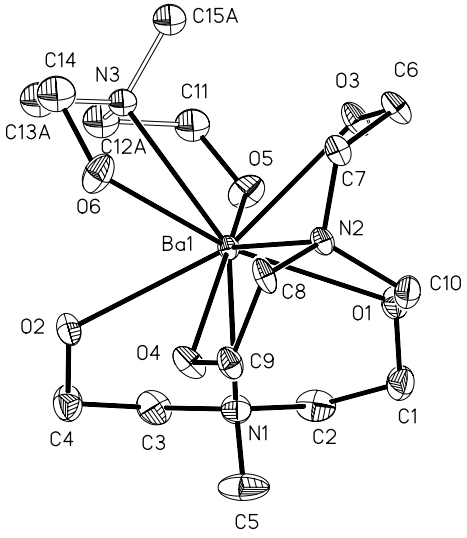

Fig. 4. Molecular structure of the $[Ba(mdeaH_2)_3]^{2+}$ cation of compound **9** showing the atom numbering scheme. (thermal ellipsoids at 30% probability).

and 2, respectively, selected bond lengths and bond angles being collected in Tables 3 and 4. The overall structure of **4** is similar to that of the other structurally characterized $Cu_2(TFA)_4L_2$ adducts (L = quinoline, acetonitrile) [7], the functional alcohol being only monodentate in contrast to its behaviour in $Y_2(TFA)_6$-(η^2-$OHC_2H_4O^iPr)_2$ [16]. Two independent molecules **3a** and **3b** are found in the asymmetric unit cell for $Cu_2(O_2CCF_2CF_2CF_3)_4(THF)_2$. Their basal Cu–O bonds have comparable lengths [1.956(8)–1.980(7) Å] as also observed for $Cu_2(TFA)_4(\eta^1$-$OHC_2H_4O^iPr)_2$, (1.973(2)–1.984(2) Å). As expected, the coordination bonds, Cu–O(THF) or Cu–O(OHR), are longer with values of 2.093(6)–2.093(7) Å in agreement with the literature body [20]. The Cu···Cu distances 2.706(2) and 2.713(2) Å in the perfluorobutyrate **3** are shorter than for the analogous trifluoroacetate adduct **4** or for $Cu_2(TFA)_4(MeCN)_2$ 2.766(1) Å or $[Cu_2(TFA)_4]_\infty$ 3.086(2) Å. The Cu···Cu distance has been reported to be very sensitive to the nature of the R substituent of the carboxylate as well as to that of the apical, neutral ligand [6,7]. The Cu···Cu distance increases with the electron-withdrawing ability of the R group of either terminal or bridging carboxylates whereas axial coordination tends to shorten it. The Cu···F distances are larger than 4.50 Å for **3** and **4** excluding thus any interaction in the solid.

Compound **6** corresponds to a copper(II) trifluoroacetatoaminoalkoxide with lattice THF molecules. The structure of the tetranuclear unit was previously reported without any other characterization or yield of the compound [21]. In this structure, the CF_3 groups and three of the aminoethoxide ligands were disordered. Our results are based on a low temperature [163(2) K] versus rt data collection and more reflections were taken into account (9235 versus 3584). The disorder is thus limited to three CF_3 groups and the metric parameters are more precise, especially for the Cu–N bond distances [2.039(3)–2.048(2) versus 2.052(12)–2.062(13) Å]. Its molecular structure corresponds to a tetranuclear $[Cu(\mu,\eta^2$-TFA$)(\mu_3,\eta^2$-$OC_2H_4NMe_2)]_4 \cdot 0.25THF$ species (Fig. 3). The four metal form an eight-membered ring folded into a boat like configuration as observed for $Cu_4(teaH)_4 \cdot 2teaH_3$ [22]. The copper atoms are square planar coordinated with three oxygens and one nitrogen

with a deviation of the atom from the CuO_3N mean plane less than 0.3 Å. The Cu–O and Cu–N bond lengths spread over the range 1.927(1)–1.956(2) and 2.039(3)–2.052(2) Å, respectively (Table 5). Moreover, for each copper atom, two longer Cu···O contacts are found in apical positions with distances comprised in the range 2.690(2)–2.741(2) Å and involving one of the oxygens of a TFA ligand as well as that of the aminoethoxide. The copper stereochemistry may thus be described as an elongated octahedron. This is probably the result of the Jahn-Teller effect and folding of the Cu_4 ring [16]. It results in an important distorsion for the axial ligation (∠O–Cu–O ∼ 148°) as well as to a highly dissymmetrical Cu–μ,η^2-TFA coordination (1.952 av. versus 2.721 av. Å). In contrast, the Cu-μOR bridges are only slightly dissymmetrical. The Cu···Cu distances of 3.172 Å av. are quite long as compared to the paddle-wheel type compounds probably as a result of the bridging aminoethoxide ligand. No short Cu···F or N···F distances were found in the solid state. A number of copper(II) carboxylatoalkoxides have been structurally characterized [20]. They are mostly based on tetranuclear units associated into polymers. Typical examples are $[Cu_4(OAc)_6(bdmap)(H_2O)_6]_\infty$ (bdmapH=1,3-bis(dimethylamino)propanol) or $[Cu_4(\mu,\eta^2\text{-}OAc)_4(O\text{-}Me)_4]_\infty$ associated rerspectively by H-bonding involving the H_2O molecules [23], or via acetate ligands [24] or $[Cu_4(\mu,\eta^2\text{-}OAc)_4\{MeN(C_2H_4O)(C_2H_4OH)\}_4]_\infty$ in which the four copper are linked in an anti-tricyclo[4.2.0.$0^{2,5}$]octane-like fashion [25].

Compound **9** $[Ba(mdeaH_2)_3](TFA)_2$ (Fig. 4) obtained by reaction between $Ba(TFA)_2$ and *N*-methyldiethanolamine at rt is ionic (Eq. (3)). The Ba···O(TFA) distances are larger than 4.83 Å and the trifluoroacetates act thus as counter-ions. The Ba^{2+} cation is surrounded by three tridendate *N*-methyldiaminoethanol ligands and is thus nine-coordinate, as often observed for that metal. Complex **9** represents, to the best of our knowledge, the first example of an anionic Ba trifluoroacetate. The transanular Ba–N coordination bonds [2.899(7)–2.954(8) Å] are longer than the Ba–O(H) ones [2.740(6)–2.836(6) Å] (Table 6). By contrast to fluorinated alkoxides or fluorinated β-diketonates which form neutral adducts [26–28], no short Ba···F distances are observed. The structure of $Ba(\eta^1\text{-}TFA)_2\{MeN(C_2H_4OH)_2\}_2$ (**11**) has

been recently reported by us [16]. It cocrystallizes in the asymmetric unit cell with $[Cu\{MeN(C_2H_4O)(C_2H_4OH)\}_2]$ in a reaction aimed to provide heterometallic Ba–Cu trifluoroacetate derivatives. The Ba species **11** is actually an intermediate to the formation of the ionic Ba–TFA derivatives **9**. Oxidation of copper and partial deprotonation of *N*-methyldiethanolamine appears to preclude the formation of this species.

(3)

Although various heterometallic fluorocarboxylates are known [29], no reaction is observed by mixing the $Cu(TFA)_2$ adducts with THF or isopropoxyethanol and barium trifluoroacetate at rt in THF, methanol or isopropoxyethanol media. In contrast, heterometallic Ba–Cu(II) species could easily be obtained by mixing barium trifluoroacetate and copper(II) alkoxides [16].

4. Conclusions

A number of adducts of copper(II) and barium fluorocarboxylates have been prepared as possible precursors for MOD of high Tc superconductors and characterized. O-donors are better able to stabilize copper(II) fluorocarboxylates toward ambient atmosphere than N-donor Lewis bases. In contrast to alcohols such as methanol or isopropoxyethanol, polyols such as *N*-methyldiethanolamine and triethanolamine could form stable adducts of $Ba(TFA)_2$ by depolymerization of the oligomer. These derivatives are ionic but remain soluble in organic media.

5. Supplementary material

Tables of coordinates, of thermal parameters, of bond lengths and angles have been deposited at the Cambridge Crystallographic Data Base Centre. CCDC reference numbers for **3**, **4**, **6** and **9** are 227439, 227442, 227443 and 227446, respectively.

$R_1 = R_2 = H$; 2,2'-Biimidazole (H_2bim)

$R_1 = Me$, $R_2 = H$; N-Methyl-2,2'-biimidazole (MeHbim)

$R_1 = -EtOH$; $R_2 = H$; N-hydroxyethyl-2,2´-biimidazole (HOEtHbim)

$R_1 = R_2 = Me$; N,N'-Dimethyl-2,2'-biimidazole (Me_2bim)

Scheme 1.

2. Experimental

2.1. Materials and instrumentation

Ammonia (30%, from Normasolv), glyoxal (40%, from Merck), activated carbon (from Panreac), sodium hydride (60% dispersion in mineral oil, from Aldrich), methyl iodide (98%, from Aldrich), dimethyl sulfate (99%, from Probus) and sodium hexachloroplatinate(IV) hexahydrate (98%, from ABCR) were used as supplied. Solvents were reagent grade.

Elemental chemical analyses were performed on a Fisons EA1108CHNS-O microanalyser. Melting points (m.p.) were determined using a Büchi apparatus. The IR spectra of samples included in KBr discs (4000–400 cm^{-1}) or in Nujol mulls between polythene sheets (400–100 cm^{-1}) were recorded on a Bruker IFS66V FT-IR spectrometer, and Raman spectra of polycrystalline samples were recorded on the same spectrometer using an FRA-106 accessory (IR and Raman bands are reported using the following abbreviations: s: strong, m: medium, w: weak, sh: shoulder, v: very). ^1H and ^{13}C NMR spectra (see Scheme 1 for numbering scheme) were obtained in DMF-d_7 at room temperature (293 K) on a Bruker AMX 300 spectrometer and referred to $SiMe_4$, and ^{195}Pt NMR spectra were obtained in the same solvent at room temperature on a Bruker AMX 500 spectrometer and referred to a 1 M solution of Na_2PtCl_6. NOE experiments and ^1H–^{13}C HMBC and HMQC experiments were run at 293 K, and 223 K for MeHbim, on a Bruker AMX 500 apparatus. All physical measurements reported were made by the RIAIDT services of the University of Santiago de Compostela (http://www.ti.usc.es/riaidt/index.htm).

2.2. Synthesis of the ligands

In an attempt to improve the yields of previously published methods for the preparation and purification of some of the ligands [8], these methods were modified slightly as follows.

2.2.1. H_2bim

Glyoxal (98 mL, 0.86 mol) and ammonia (100 mL, 1.56 mol) were reacted for 22 h at 4 °C. The brown solid recovered by filtration was extracted with DMF in a soxhlet apparatus, and the extract was decoloured with activated carbon and then concentrated to dryness, affording a beige solid. Yield: 15%. M.p. >300 °C. *Anal.* Calc. for $C_6H_6N_4$: C, 53.7; H, 4.5; N, 41.8. Found: C, 53.9; H, 4.4; N, 41.8%. ^1H NMR (ppm): 12.67 (s,vb, N–H); 7.22 (s,b, H5/H5′) and 7.02 (s,b, H4/H4′).

2.2.2. MeHbim

A solution of NaH (29.8 mmol) in dry DMF (50 mL) was added under argon to a suspension of H_2bim (4.0 g, 29.8 mmol) in 50 mL of the same solvent. After 7 h reaction at room temperature, followed by a further hour at 100 °C, MeI (1.86 mL, 29.8 mmol) was added and reaction was continued for a further 24 h at room temperature. The reaction mixture was filtered. The filtrate was concentrated and the solid was work-up as in [8]. Yellow solid. Yield: 20%. M.p. 146–147 °C. *Anal.* Calc. for $C_7H_8N_4$: C, 56.7; H, 5.4; N, 37.8. Found: C, 56.8; H, 5.3; N, 37.9%. ^1H NMR (ppm), $T = 293$ K: 12.77 (s,vb, N–H), 7.24 (s, H5), 7.18. (s,b, H5′/H4′), 6.98 (s, H4), 4.11 (s, N–CH_3); $T = 223$ K: 13.27 (s, N–H), 7.39 (s, H5′); 7.34 (s, H5), 7.11 (s, H4′), 7.00 (s, H4), 4.07 (s, N–CH_3). ^{13}C NMR (ppm), $T = 293$ K: 140.3 (C2′), 139.5 (C2), 128.0 (C4), 123.6 (C5), 35.0 (N–CH_3); $T = 223$ K: 140.1 (C2′), 139.1 (C2), 129.2 (C4′), 127.9 (C4), 123.8 (C5), 118.0 (C5′), 35.0 (N–CH_3).

2.2.3. HOEtHbim

A solution of H_2bim (4.0 g, 29.8 mmol) in a mixture of 96% EtOH (30 mL), 20% NaOH (7.5 mL) and 2-chloroethanol (0.52 mL, 7.8 mmol) was refluxed for 6 h, allowed to cool to room temperature and neutralized with 37% HCl, and the solid recovered by filtration of the reaction mixture was washed with hot ethanol. Recrystallization from water afforded a yellow solid. Yield: 13%. M.p. 134–136 °C. *Anal.* Calc. for $C_8H_{10}N_4O$: C, 53.9; H, 5.7; N, 31.4. Found: C, 53.3; H, 5.5; N, 31.2%. ^1H NMR (ppm): 12.70 (s,vb, N–H), 7.30 (d, H5), 7.26 (s,b, H5′), 7.07 (s,b, H4′), 6.98 (d, H4), 4.68 and 3.86 (t, N–CH_2–CH_2–OH). ^{13}C NMR (ppm): 138.7 (C2′), 137.2 (C2), 125.5 (C4′), 124.2 (C4), 122.8 (C5), 120.8 (C5′), 63.3 and 50.5 (N–CH_2–CH_2–OH).

2.2.4. Me_2bim

Prepared by methylation of H_2bim with Me_2SO_4 [8]. Yellow solid. Yield: 74%. M.p. 113-114 °C. *Anal.* Calc. for $C_8H_{10}N_4$: C, 59.2; H, 6.2; N, 34.6. Found: C, 59.1;

H, 6.2; N, 34.5%. ^{1}H NMR (ppm): 7.28 (d, H5/H5′), 7.03 (d, H4/H4′), 4.02 (s, N–CH_3). ^{13}C NMR (ppm): 139.2 (C2/C2′), 127.8 (C4/4′), 123.6, (C5/5′), 35.3 (N–CH_3).

2.3. Synthesis of the complexes

2.3.1. [$PtCl_4(H_2bim)$]

A solution of H_2bim (0.120 g, 0.89 mmol) in water (35 mL) was added to a solution of $Na_2PtCl_6 \cdot 6H_2O$ (0.500 g, 0.89 mmol) in 25 mL of the same solvent. After stirring for 72 h at 70 °C, the mixture was filtered and the filtrate concentrated to dryness, leaving a yellow solid that was washed with water and dried under reduced pressure. Yield: 48%. *Anal.* Calc. for $C_6H_6N_4Cl_4Pt$: C, 15.3; H, 1.3; N, 11.9. Found: C, 15.3; H, 1.3; N, 11.6%. IR (Raman) data (cm^{-1}): 356sh (356m), 346s (346m), 332sh (330vs), 309m (309m), *ν*(Pt–Cl); 232w (231w), 218w (219w), *ν*(Pt–N). ^{1}H NMR (ppm): 7.89 (d, H5/H5′, $^4J_{Pt-H}$ = 8.2 Hz), 7.69 (d, H4/H4′, $^3J_{Pt-H}$ = 10.5 Hz). ^{13}C NMR (ppm): 138.1 (C2/C2′, $^2J_{Pt-C}$ = 27.7 Hz), 125.0 (C4/C4′, $^2J_{Pt-C}$ = 26.9 Hz), 121.7 (C5/C5′, $^3J_{Pt-C}$ = 24.7 Hz); ^{195}Pt NMR (ppm): $\delta = -171$.

2.3.2. [$PtCl_4(MeHbim)] \cdot H_2O$

Preparation as for [$PtCl_4(H_2bim)$], but using 0.132 g (0.89 mmol) of MeHbim in 20 mL of water, 0.500 g (0.89 mmol) of $Na_2PtCl_6 \cdot 6H_2O$ in 25 mL of water, and 17 h stirring at 70 °C. Yellow solid. Yield: 20%. *Anal.* Calc. for $C_7H_{10}N_4OCl_4Pt$: C, 16.7; H, 2.0; N, 11.1. Found: C, 16.6; H, 2.1; N, 10.7%. IR (Raman) data (cm^{-1}): 344s (346s), 328m (330s), 303w, 285m (279w), *ν*(Pt–Cl); 254sh (257m), *ν*(Pt–N). ^{1}H NMR (ppm): 7.96 (d, H5′, $^4J_{Pt-H}$ = 8.0 Hz), 7.92 (d, H5, $^4J_{Pt-H}$ = 8.6 Hz), 7.71 (d, H4′, $^3J_{Pt-H}$ = 10.9 Hz), 7,64 (d, H4, $^3J_{Pt-H}$ = 11.6 Hz), 4.43 (s, CH_3). ^{13}C NMR (ppm): 138.8 (C2′), 137.4 (C2, $^2J_{Pt-C}$ = 28.3 Hz), 125.4 (C4′, $^2J_{Pt-C}$ = 23.2 Hz), 124.7 (C4, $^2J_{Pt-C}$ = 26.1 Hz), 124.5 (C5, $^3J_{Pt-C}$ = 26.1 Hz), 122.2 (C5′, $^3J_{Pt-C}$ = 25.4 Hz), 36.3 (N–CH_3); ^{195}Pt NMR (ppm): $\delta = -171$.

2.3.3. [$PtCl_4(HOEtHbim)$]

Preparation as for [$PtCl_4(H_2bim)$], but using 0.100 g (0.56 mmol) of HOEtHbim in 15 mL of water, 0.300 g (0.53 mmol) of $Na_2PtCl_6 \cdot 6H_2O$ in 10 mL of water, and 24 h stirring at room temperature. Work-up included a final wash of the yellow solid product with ethanol. Yield: 38%. *Anal.* Calc. for $C_8H_{10}N_4OCl_4Pt$: C, 18.7; H, 2.0; N, 10.9. Found: C, 19.2; H, 2.1; N, 11.0%. IR (Raman) data (cm^{-1}): 343vs (343s), 325sh (330vs), 300sh (283w), *ν*(Pt–Cl); 254w (253w), *ν*(Pt–N).

2.3.4. [$PtCl_4(Me_2bim)$]

Preparation as for [$PtCl_4(H_2bim)$], but using 0.072 g (0.44 mmol) of Me_2bim in 10 mL of water, 0.250 g (0.44 mmol) of $Na_2PtCl_6 \cdot 6H_2O$ in 10 mL of water, and 48 h stirring at room temperature. Concentration of the filtered reaction mixture to dryness under vacuum at 65 °C afforded an oil that was washed with chloroform and mixed with water, upon which a yellow solid precipitated out. Yield: 31%. *Anal.* Calc. for $C_8H_{10}N_4Cl_4Pt$: C, 19.2; H, 2.0; N, 11.2. Found: C, 19.1; H, 2.2; N, 10.9%. IR (Raman) data (cm^{-1}): 350sh (354sh), 342m (344m), 324s (326s), 290w (295w), *ν*(Pt–Cl); 262w (263w), 254w, *ν*(Pt–N). ^{1}H NMR (ppm): 7.97 (d, H5/H5′), 7.69 (d, H4/H4′, $^4J_{Pt-H}$ = 13.4 Hz), 4.61 (s, N–CH_3). ^{13}C NMR (ppm): 138.5 (C2/C2′), 127.0 (C4/C4′, $^2J_{Pt-C}$ = 23.5), 124.7 (C5/C5′, $^3J_{Pt-C}$ = 21.9), 38.9 (N–CH_3); ^{195}Pt NMR (ppm): $\delta = -224$. Crystallization from DMF afforded crystals suitable for single-crystal X-ray crystallography.

2.4. Crystallography

2.4.1. X-ray data collection and reduction

Data were collected from a prismatic crystal of [$PtCl_4(Me_2bim)$] mounted on a glass fibre in an Enraf Nonius MACH3 automatic diffractometer [9]. Cell constants and an orientation matrix for data collection were obtained by least-squares refinement of the data for 25 reflections in the range $11.093° < \theta < 21.182°$. Data were collected at 293(2) K using Mo K_α radiation (λ = 0.71073 Å) and the ω-scan technique, and were corrected for Lorentz and polarization effects [10]. A semi-empirical absorption correction (ψ scan) was also made [11].

2.4.2. Structure solution and refinement

The structure was solved by the Patterson method [12] and subsequent difference Fourier maps, and was refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters [13], with all hydrogen atoms riding at calculated positions (C–H = 0.93–0.97 Å). The Flack x parameter (absolute structure parameter) was calculated to be 0.00(2) for the present structure and 0.98(2) for the inverted structure, thus providing strong evidence that the absolute structure has been assigned correctly [14]. Atomic scattering factors were taken from International Tables for Crystallography [15]. Molecular graphics were drawn using PLATON [16]. The crystal data, experimental details and refinement results are summarized in Table 1.

2.5. In vitro cytotoxicity studies

2.5.1. Cell lines and growth conditions

The human ovarian cancer cell line A2780 and its cisplatin-resistant mutant A2780cis (both from the European Collection of Cell Cultures through Sigma–Aldrich) were grown at 37 °C under humidified 5:95 CO_2/air in RPMI 1640 medium (Sigma–RBI, Spain) supplemented with 10% fetal bovine serum (FBS,

Sigma–RBI, Spain) and 2 mM L-glutamine (Sigma–RBI, Spain).

2.5.2. In vitro chemosensitivity assay

Cells were seeded into 96-well plates (Beckton–Dickinson, Spain) in volumes of 100 μL (containing 4000 cells/well), and after incubation for 24 h were treated with the platinum complexes dissolved in TE–NaCl buffer (pH 7.5) containing 10 mM tris(hydroxymethylamino)methane hydrochloride (Tris–HCl), 0.1 mM disodium ethylenediaminetetraacetate (EDTA) and 50 mM NaCl. After a further 96 h incubation the cells were fixed by 15 min treatment with 10 μL of 11% glutaraldehyde per well, the fixative was removed, the cells were washed four times with deionized water, and cell biomass was determined by staining with crystal violet [17], and measuring the optical density at 595 nm, for which a Tecan Ultra Evolution microplate reader was used. IC_{50} (the drug concentration that inhibits cell growth by 50% with respect to controls) was determined graphically using Prism 2.01 (GraphPad Software Inc.).

For comparison, the cytotoxicity of cisplatin was evaluated under the same experimental conditions. All compounds were tested in two independent experiments with quadruplicate points. These experiments were performed in the Screening Unit of the Institute for Industrial Pharmacy, University of Santiago de Compostela.

3. Results and discussion

3.1. Synthesis

Our modifications of previously published methods for the preparation of H_2bim, MeHbim and HOEtbim failed to achieve significant improvements in yield. The yield of the dimethylation reaction was more satisfactory, 74%. Those of the complexation reactions ranged from 20% to 50%. Only in the case of the MeHbim derivative did the complex contain water of crystallization.

3.2. Solid state structure of [$PtCl_4(Me_2bim)$]

Crystals of [$PtCl_4(Me_2bim)$] consist of discrete molecules, the structure of which is shown in Fig. 1 together with the atomic numbering scheme used. The Pt atom is coordinated to the two unmethylated N atoms of the biimidazole ligand and to four Cl atoms in a distorted octahedral environment, the main distortion of which is the N(1)–Pt–N(3) bite angle, 79.0(3)°. The Pt atom lies only 0.0162 Å from the Cl(1)N(1)N(3)Cl(2) plane. The two rings of the Me_2bim ligand are both planar, and make a dihedral angle of 10.0(5)° with each other, and dihedral angles of 5.4(4)° [the N(1) ring] and 11.5(4)° [the N(3) ring] with the Cl(1)N(1)N(3)Cl(2) plane.

The Pt–N bond lengths (Table 2) are similar to those found in other complexes in which Pt(IV) forms a PtN_2C_2 ring with an *N*,*N*′-bidentate ligand. In particular, the geometry around the Pt atom is close to those found in [$PtCl_4$(bipy)] [18] (bipy = 2,2′-bipyridyl) and [$PtCl_4$(bpym)] · MeOH [19] (bpym = 2,2′-bipyrimidine), in which the bite angles are 81.3° and 80.3°, respectively. Among these three complexes, the angle opposite the bite [Cl(1)–Pt–Cl(2)] widens as the bite angle narrows,

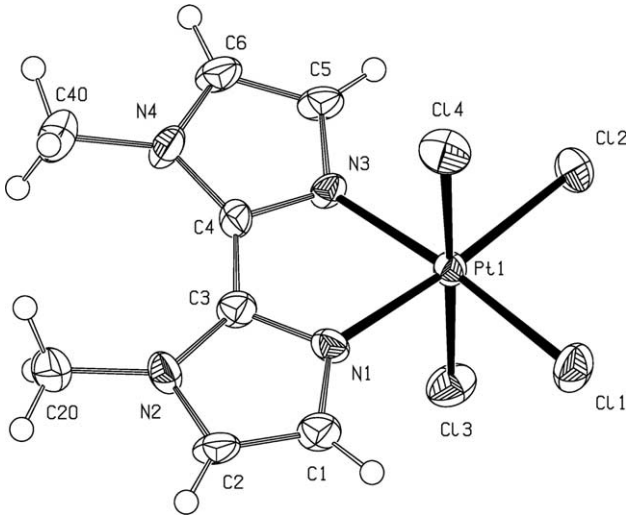

Fig. 1. ORTEP representation of the molecular structure of [$PtCl_4(Me_2bim)$], showing the numbering scheme. Thermal ellipsoids are drawn at the 50% probability.

Table 2
Selected bond lengths (Å) and angles (°) in [$PtCl_4(Me_2bim)$]

Bond lengths (Å)	
Pt(1)–N(1)	2.018(8)
Pt(1)–N(3)	2.030(7)
Pt(1)–Cl(2)	2.306(2)
Pt(1)–Cl(1)	2.311(2)
Pt(1)–Cl(4)	2.311(2)
Pt(1)–Cl(3)	2.324(2)
Bond angles (°)	
N(1)–Pt(1)–N(3)	79.0(3)
N(1)–Pt(1)–Cl(2)	174.0(2)
N(3)–Pt(1)–Cl(2)	95.0(2)
N(1)–Pt(1)–Cl(1)	93.7(2)
N(3)–Pt(1)–Cl(1)	172.6(2)
Cl(2)–Pt(1)–Cl(1)	92.28(10)
N(1)–Pt(1)–Cl(4)	89.2(2)
N(3)–Pt(1)–Cl(4)	87.1(2)
Cl(2)–Pt(1)–Cl(4)	90.31(10)
Cl(1)–Pt(1)–Cl(4)	91.42(10)
N(1)–Pt(1)–Cl(3)	90.3(2)
N(3)–Pt(1)–Cl(3)	91.5(2)
Cl(2)–Pt(1)–Cl(3)	90.07(10)
Cl(1)–Pt(1)–Cl(3)	89.97(10)
Cl(4)–Pt(1)–Cl(3)	178.53(10)

being 89.1°, 90.18° and 92.28° for the bipy, bpym and Me_2bim derivatives, respectively. The Cl–Pt–Cl angle involving the Cl atoms *cis* to the N atoms is 178.3° in [$PtCl_4(bipy)$], 177.6° in [$PtCl_4(bpym)$] and 178.53° in [$PtCl_4(Me_2bim)$].

In the bipy and bpym complexes the influence of the N atoms makes the *trans*-Pt–Cl bonds shorter than the *cis*-Pt–Cl bonds [2.301(2)–2.307(3) Å as against 2.316(3)–2.335(2) Å]. This structural *trans* influence is not so strong in the Me_2bim derivative, in which one of the *cis*-Pt–Cl bonds is the same length as one of the *trans*-Pt–Cl bond distances, 2.311(2) Å, a situation similar to that found in [$PtCl_4(dpk)$] (dpk = di-2-pyridyl ketone) [20] (in which there are *trans*- and *cis*-Pt–Cl distances of 2.301 and 2.302 Å, respectively) and close to that found in Pt(IV) complexes in which two N-coordinated monodentate imidazole rings occupy *cis* positions [21].

Comparison of the PtN_2C_2 ring of [$PtCl_4(Me_2bim)$] with those of the two Pt-complexes of biimidazole derivatives for which structures have been described previously, [$PtCl_2(MeHbim)] \cdot Et_4NCl$ [22] and [PtI_2-(Me_2bim)] [23] shows no significant differences. In particular, the Pt–N distances are practically indifferent to the redox state of the metal atom.

3.3. Spectral characteristics

The IR and Raman bands of the biimidazole ligands undergo small shifts upon coordination. With regard to those of the ring stretching vibrations (1600–1300 cm^{-1}) the four complexes are similar to each other and to those previously described complexes of these ligands [7,24], which suggest that these ligands have similar coordination modes in all these compounds.

For [$PtCl_4(LL)$] compounds with an ideal C_{2v} $PtCl_4N_2$ framework four ν(Pt–Cl) bands are expected in their IR and Raman spectra: two A_1, B_1 and B_2. In general these bands are found in the spectra of the new complexes at positions close to those reported for similar compounds [25], suggesting that all have the same $PtCl_4N_2$ structure. As in the case of [$MCl_2(LL)$] compounds (LL = 2,2′-biimidazole or *N*,*N*′-dimethyl-2,2′-biimidazole) [7], the ligand bands hinder a rigorous identification of the expected two ν(Pt–N) bands.

3.4. Studies in solution

The ligands and complexes were characterized by NMR spectroscopy in DMF-d_7. When necessary, assignments were corroborated by NOE and two-dimensional NMR experiments.

The ^{1}H NMR spectrum of H_2bim shows two broad singlets for the ring protons at nearly the same positions as those of two doublets that appear in the spectrum of the *N*,*N*′-dimethyl derivative. By contrast, the spectrum of MeHbim at room temperature (293 K) shows two signals for the protons of the methylated ring but, probably owing to the fast exchange of the iminic proton, only one broad signal for H5′ and H4′. At 223 K this latter signal splits into two singlets. In the ^{13}C NMR spectra the C4′ and C5′ signals are not observable at 293 K but are present at 223 K. No such room temperature tautomerism is observed in the ^{1}H and ^{13}C NMR spectra of HOEtbim, the signals of which were identified on the basis of the MeHbim spectra obtained at 223 K.

The low solubility of [$PtCl_4(HOEtHbim)$] in DMF led to a poor quality ^{1}H NMR spectrum which makes identification of its signals impossible. In the NMR spectra of the other platinum complexes, all the ^{1}H signals are shifted to lower field than in the spectrum of the free ligand, and the ^{13}C signals show that coordination to Pt(IV) deshielded C5/5′ and N–CH_3 carbons, and shielded C2/2′ and C4/4′ carbons. For example, the ^{1}H spectrum of [$PtCl_4(H_2bim)$] shows two doublets that are both 0.67 ppm downfield of their positions in the spectrum of the free ligand. As in the Pt(II) complex of this ligand [7] the value of $^3J_{HH}$ is approximately 1.5 Hz. The poor solubility of free H_2bim makes it impossible to obtain its ^{13}C NMR spectrum in DMF, but the above-noted shifts in carbon signals may be deduced from its ^{13}C CP/MAS spectrum, which shows signals at 139.1, 129.1, 126.8, 120.8 and 118.6 ppm for carbons 2, 2′, 4, 4′, 5 and 5′ (the splitting of the signals being due to the asymmetrically hydrogen bonded structure of solid H_2bim [26]).

The above data and the observation of platinum-hydrogen and platinum-carbon couplings and of δ

Table 3
Cytotoxicity (IC_{50}) of the the prepared compounds and cisplatin against human ovarian cancer cell lines

Compound	IC_{50} (μM)		RF[a]
	A2780	A2780cis	
$[PtCl_4(H_2bim)]$	16.7 ± 0.5	25.6 ± 0.4	1.5
$[PtCl_4(MeHbim)] \cdot H_2O$	11.4 ± 0.3	16.8 ± 0.5	1.5
$[PtCl_4(HOEtHbim)]$	20.6 ± 0.4	67.9 ± 0.6	3.3
$[PtCl_4(Me_2bim)]$	30 ± 4	16 ± 5	0.5
Cisplatin	0.38 ± 0.4	3.5 ± 0.5	9.2

[a] The resistance factor: RF = IC_{50}(A2780cis)/IC_{50}(A2780).

(^{195}Pt) values similar to those found for other compounds with a *cis*-$PtCl_4N_2$ kernel [27], confirm the persistence of this kernel in DMF solution.

3.5. Cytotoxicity

Table 3 lists the results of testing the new compounds and cisplatin for cytotoxicity against the human ovarian cancer cell line A2780 and the cisplatin-resistant line A2780cis. Against A2780 the new compounds had IC_{50} values in the low micromolar range but were in general less active than other Pt(IV) [28–30] or dinuclear Pt(II) [31] complexes that have recently been described and were far less active than cisplatin.

The cisplatin resistance of A2780cis line is known to be multifactorial, a combination of decreased accumulation, enhanced DNA repair tolerance and elevated glutathione levels [28]. The ability of all the new compounds except the HOEtHbim derivative to circumvent cisplatin-induced resistance is suggested by their having values <2 for the resistance factor RF (the ratio of the values of IC_{50} against the resistant and parent lines) [28]. The RF value of $[PtCl_4(Me_2bim)]$, 0.5, seems particularly promising.

4. Supplementary data

Crystallographic data have been deposited with The Director, CCDC, 12 Union Road, Cambridge CB21EZ, UK (fax: +44 1223 366033; e-mail: deposit@ccdc.cam.ac.uk or http:www.ccdc.cam.ac.uk) and are available on request, quoting the deposition number 252712.

one-electron oxidation with PbO_2 was especially very interesting for us [6a,6d,6e,6f,6g]. While upon oxidation they are easily generate relatively stable M(II)-phenoxyl radical complexes [6], the proceeding unexpected oxidative C–C coupling in bis-salicylaldimine Cu^{II} complexes [6b] and reduction via radical intermediates of Cu^{II} and Pd^{II} bis-salicylaldiminates upon treatment with PPh_3 were also observed [6d,6e,6f,6g].

In this context recently, we have described some bulky *N*-aryl-3,5-di-*t*-butylated salicylaldimine metal(II) chelates, which *t*-butyl groups are introduced into salicylic moiety [7]. Our preliminary studies revealed that while the above ligands easily coordinate with Cu(II), Co(II) and Pd(II) ions, the preparation of Ni^{II}, Mn^{II}, Zn^{II}, VO^{IV} metal ions complexes with above ligands were unsuccessful [7].

In the present paper, we report the synthesis, spectroscopic and redox behaviors of a new series of bis[*N*-alkyl-3,5-Bu^t_2-salicylideneiminato]copper(II) complexes, CuL^x_2, derived from 3,5-DTBS and alkylamines RNH_2 R = CH_3(L^1H), C_2H_5 (L^2H), *n*-C_3H_7(L^3H), *n*-C_4H_9-(L^4H), *iso*-C_4H_9(L^5H), *t*-C_4H_9(L^6H), C_5H_{11}(L^7H), *neo*-C_5H_{11}(L^8H), *n*-C_6H_{13}(L^9H), *cyclo*-C_6H_{11}(L^{10}H). The copper(II) complexes are abbreviated as **1**, **2**, **3**, **4**, **5**, **6**, **7**, **8**, **9** and **10**, correspondingly.

2. Experimental

2.1. Measurements

C, H and N analyses were performed with a LECO CHNS 932 elemental analyzer. Electronic absorption spectra were recorded on a Shimadzu 1601 UV–Vis spectrophotometer in the range 1100–200 nm. IR spectra were recorded on a Perkin–Elmer FTIR spectrometer using KBr disks. The room temperature (r.t.) magnetic susceptibility measurements were performed by the Gouy balance using a tube calibrated with Hg[Co(NCS)$_4$]. Diamagnetic corrections were made using Pascal's constant. ESR spectra were taken on a Varian E109 C X-band spectrometer. The field and frequency calibration were made using DPPH (g = 2.0037) powder. Errors for g- and A-parameters of the complexes and g-factor of radicals are ±0.001, ±0.5G and ±0.0002, respectively.

Electrochemical measurements were recorded on a PC-controlled Eco Chemie-Autolab-12 potentiostat/galvanostat in nitrogen degassed acetonitrile (MeCN) solutions of ca. 10^{-3}–10^{-4} M **X** containing 0.05 M Et_4NBF_4 as the supporting electrolyte. The three-electrode cell contained a platinum working and counter electrodes and an Ag/AgCl reference electrode. The potentials are referred to Ag/AgCl in the potential range +2.0 to −1.5 V. All solutions were purged with N_2 for about 5 min prior to each set of experiment.

2.2. Materials

All the chemicals and solvents were of analytical grade and were used without further purification. Cu$(AcO)_2 \cdot H_2O$, 2,4-di-*tert*-butylphenol, all alkylmines ($CH_3NH_2 \cdot HCl$, $C_2H_5NH_2 \cdot HCl$, *n*-$C_3H_7NH_2$, *n*-$C_4H_9NH_2$, *iso*-$C_4H_9NH_2$, *t*-$C_4H_9NH_2$, *n*-$C_5H_{11}NH_2$, *neo*-$C_5H_{11}NH_2$, *n*-$C_6H_{13}NH_2$, *cyclo*-$C_6H_{11}NH_2$) and $(NH_4)_2Ce(NO_3)_6$ abbreviated as ACN, were obtained from Aldrich Chemical Co. 3,5-di-*t*-butylsalicylaldehyde was prepared by standard methods [8].

2.3. Preparation of ligands

All salicylaldimines, L^xH, were prepared in high yields (80–96%) via condensation of the 3,5-di-*t*-butylsalicylaldehyde with the corresponding alkyl amines (1:1 molar ratio) in methanol/ethanol at reflux for 5–6 h in the presence of 3–5 drops of formic acid and recrystallized from methanol or hexane. Except *t*-butyl-, *neo*-pentyl- and *cyclo*-hexylamines, all other amine Schiff bases were obtained as yellow viscous oils and used without further purification for the preparation of the complexes. The crude oil samples were purified using a column chromatography technique (SiO_2 column, eluent hexane–MeOH (5:1)).

2.4. Synthesis of the complexes

The **X** complexes were prepared by following general procedure. To a solution of 1 mmol of the appropriate ligand in MeOH (80–90 ml) was added, with stirring at 50–60 °C, 100 mg (0.5 mmol) Cu$(AcO)_2 \cdot H_2O$ in MeOH (10–15 ml) solution and the mixture was refluxed on a water bath for 1.5–2.0 h. Then the solution volume evaporated to 15–20 ml and left to cool to room temperature. The precipitated product was filtered and washed with cold MeOH, *n*-hexane and dried in air. Recrystallization from $CHCl_3$–methanol yielded **X** as microcrystalline powder (76–91%). Analytical, and spectroscopic data for the **X** are given in the Tables 1, 4, 5 and 6.

3. Results and discussion

All of the *N*-alkyl-3,5-Bu^t_2-salicylaldimines studied were prepared in high yields as a yellow oils or crystalline solids (L^6H, L^8H, L^{10}H) by the condensation of 3,5-DTBS with the appropriate alkyl amine in refluxing methanol and in the presence of a catalytic amount of formic acid. Satisfactory elemental analyses were obtained for all of L^xH ligands and **X** chelates (Table 1). We also tried to prepare Ni^{II}, Co^{II}, Mn^{II}, VO^{IV} and Zn^{II} complexes with L^xH by using the method similar to that for preparation of Cu^{II}. But in spite of all our repeated

Table 1

attempts, we have not succeeded in preparing their complexes under above conditions.

3.1. Infrared spectra

The spectra of viscous oil L^xH samples unlike polycrystallic L^6H, L^8H and $L^{10}H$ ligands together with bands in the 1626–1648 cm^{-1} region due to ν(C=N) stretch, also display a stronger bands at 1728–1731 cm^{-1} assignable to ν(C=O), which clearly indicates that the oil samples the ligands consist of enol-imine and keto-amine tautomer forms (Table 2). While the spectra of polycrystallic L^6H, L^8H and $L^{10}H$ samples according their IR spectra predominantly of enol-imine tautomer (Table 2), their $CHCl_3$ solution spectra together with imine bands (1625–1630 cm^{-1}) also exhibit a band at 1728–1731 cm^{-1}, supporting that in solution these ligands are exist in both enol-imine and keto-amine tautomer forms. The IR spectra of the complexes show the ν(C=N) stretching shifted to 1610–1626 cm^{-1}, while the ν(OH) stretching (2600–2800 cm^{-1} due to intramolecularly H-bonded OH in L^xH) and ν(C=O) disappears in all the complexes, indicating that the ligands are coordinated in their phenol-imine tautomer form. New bands, which are absent in the spectra of all the free lignds, were observed at 1530 and 1547 cm^{-1}, attributable to the coordinated ν(C–O) mode [10], and in the 450–660 cm^{-1} region assigned to the M–O and M–N bonds.

3.2. Electronic spectra

The electronic spectral data of L^xH in ethanol are collected in Table 2. The absorption bands appeared in the UV region and at around 408–420 nm can be assigned to intraligand $\pi \rightarrow \pi^*$ and $n \rightarrow \pi^*$ transitions in L^xH, and $n \rightarrow \pi^*$ transitions in dipolar zwitterionic or keto-amine tautomer structures, respectively [11]. All **X** complexes in chloroform solution along with nearly identical intraligand bands in the 273–387 nm region, also exhibit an intense band at ca. 460–500 assigned to Cu(II) (dπ)-to-(equatorial) phenolate (pπ) MLCT transition and low intense band appeared as a shoulder at 630–790 nm (Table 3), originated from $d_{xy} \rightarrow d_{x^2-y^2}$ transition in a distorted planar geometry of Cu^{II} compounds, respectively [11,12].

[a] Shoulder.
[b] A very weak shoulder.

3.3. Magnetic measurements

The r.t. μ_{eff} values of **X** except **1**, **8** and **10** are lie in the range 1.74–1.78 BM (Table 3). Despite the fact that the presented chelates are more bulky than their planar non-di-*tert*-butylated *N*-alkyl-salicylaldiminato copper(II) analogs [9a], the μ_{eff} values of the former are significantly lower than those reported for the latter (1.86–1.92 BM) [13]. The reason of this probably associated with the existence of complexes in the magnetically diluted state due to bulkiness salicylic moiety. As reported by Hathaway in the magnetically dilute copper(II) complexes, when the copper ions are well separated from each other (>5 Å), then the μ_{eff} may be given by the spin-only vale of 1.73 BM [15a].

3.4. ESR investigation

3.4.1. Solid-state spectra

The solid state and solution spin Hamiltonian parameters of **X** complexes estimated from ESR spectra are listed in Table 4. The ESR spectra of powder samples of all **X** were obtained at 300 K. No half-field $\Delta M_s = \pm 2$ lines typical for binuclear triplet-state species [14a,14b] were observed. The polycrystalline ESR spectra of **X** are typical of monomeric distorted tetragonal copper(II) complexes with a $d_{x^2-y^2}$ ground state ($g_\parallel > g_\perp > g_e$) [15]. Selected spectra are shown in Fig. 1. The polycrystalline ESR spectra of the complexes **1**, **3** and **5** exhibit only one an exchange-averaged broad signal (Fig. 1(a) and (b)), which is attributable to dipolar interaction between crystallographycally non-equivalent Cu^{II} centers in the solid [15]. The ESR spectrum of powder samples all of other **X** complexes display three copper hyperfine lines in the parallel region ($g_\parallel$ = 2.159–2.229, $A_\parallel^{Cu}$ = 128–168 *G*) (Table 4, Fig. 1(c) and (d)). This fact indicates that the complexes are monomeric in the polycrystalline state with $|J| \leqslant 0.2\ cm^{-1}$ [14c]. It is interesting that the spectrum of *N*-cyclohexyl substituted **10**, besides three resolved $g_\parallel$ components also exhibits low intensity lines at the low-field (g = 2.559) and high-field (g = 1.915) sides of the monomeric signal (Fig. 1(d) and (e)), indicating the presence of the exchange-coupled binuclear species in polycrystalline state for this complex [15]. The exchange-coupling term G, estimated from the $G = (g_\parallel - 2.0023)/$

[a] The values of copper hyperfine constants (A) are given in *G*.

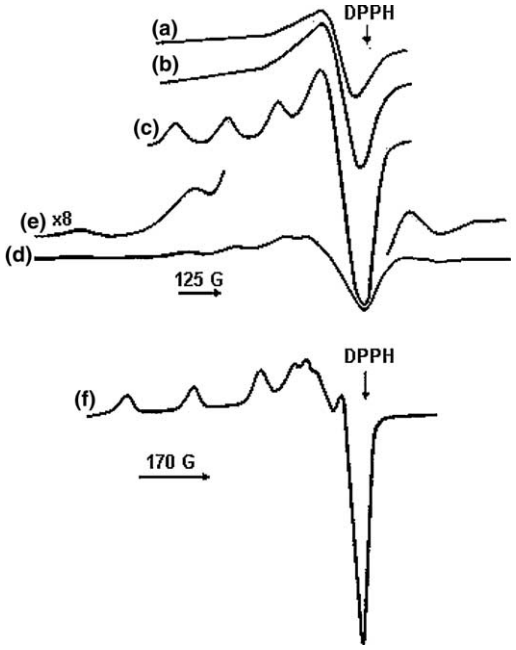

Fig. 1. Powder ESR spectra (X-band, r.t.); (a) **1**, (b) **3**, (c) **4** and (d) **10**; (f) $CHCl_3$ glass spectrum of **3** at 153 K.

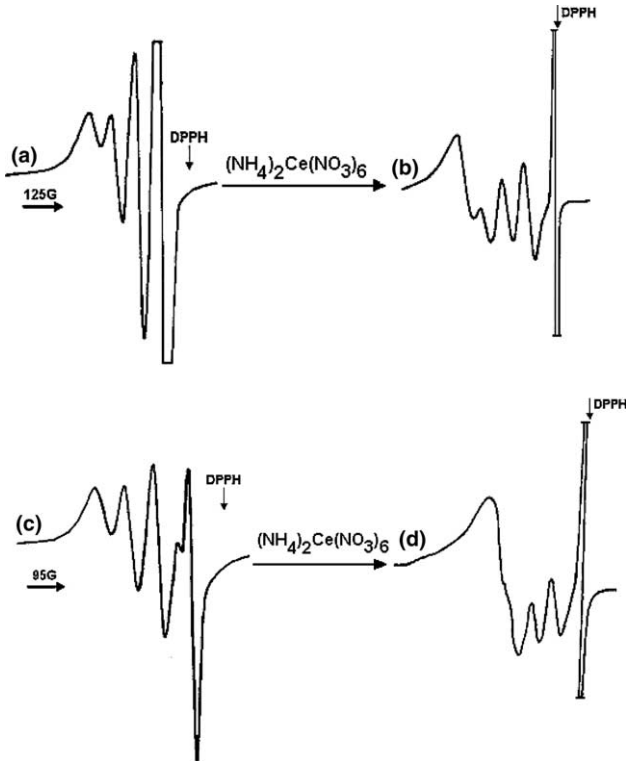

Fig. 2. ESR spectra of **5** (a) and **6** (c) complexes in $CHCl_3$ at r.t. and for systems obtained by the oxidation of **5** (b) and **6** (d) with 8-fold excess of $(NH_4)_2Ce(NO_3)_6$.

($g_\perp - 2.0023$), lying within 2.63–3.78 < 4 suggests the presence of a exchange coupling between Cu^{II} centers and the misalignment is appreciable [15] except **4** and **9** for all **X** complexes, respectively. The **4** and **9** complexes which have $G > 4$, (4.48 for **4** and 4.38 for **9**), suggest that the local tetragonal axes are aligned parallel and the exchange coupling effects are not operative for theses complexes [15].

3.4.2. Solution ESR spectra

The room temperature ESR spectra of **X** exhibit in toluene/$CHCl_3$ solutions in generally show well resolved four-line hyperfine patterns without ^{14}N-shfs resolutions on the high-field copper components (Fig. 2(a) and (c)). The frozen-solution ESR spectra at 153 K (Fig. 1(f)) are indicative of a $d_{x^2-y^2}$ ground state ($g_\parallel > g_\perp > 2.03$) (Table 4) and thus suggest a dominantly tetragonal component in the solution stereochemistry [12,14,15]. As it is expected for **6**, the lowest $A_\parallel$ (132 G) and highest $g_\parallel$ (2.265) values, due to tetrahedral distortion of Cu(II) geometry as a result of steric hindrance between bulky *N*-Bu^t and salicylic Bu^t groups, were observed. An increased distortion from a planar geometry to distorted tetrahedral with increasing in bulkiness of R is also reflected in the large $g_\parallel/A_\parallel$ values; $g_\parallel/A_\parallel = 150$, 168 and 185 cm were observed for **8**, **10** and **6**, respectively (Table 4) [16]. It is interesting that with increasing of tetrahedral distortion in Cu(II) geometry the gradually decreasing in the value of in-plane σ-bonding parameter, α^2(0.66–0.72), evaluated using the expression $\alpha^2 = |A|/0.036 + (g_\parallel - 2.0023) + 3/7(g_\perp - 2.0023) + 0.04$ [17], indicate that there is a substantial in the in-plane σ-bonding in these complexes. The values of the exchange-coupling parameters, *G*, of 3.41–3.63 estimated from frozen glass ESR spectra of **X,** except **6** and **10**, were <4.0 (Table 4), suggesting the presence of an exchange interaction in these complexes at frozen-glass state [15a,15b].

3.5. Chemical oxidation of X with $(NH_4)_2$ $Ce(NO_3)_6$

The present investigation of the oxidative behavior of **X** complexes, revealed that when they are treated with the "mild" oxidant $(NH_4)_2Ce(NO_3)_6$(ACN) in $CHCl_3$ at r.t., along with significantly decreasing signal of intensity of **X**, the generation of radical signals with $g = 2.0048 - 2.0086$ and the appearance of a new broad singlet centered at $g = 2.116 - 2.194$ were also observed (Fig. 2(b) and (d)). Note that very poor solubility of ACN in $CHCl_3$, the reaction mixture periodically was stirred for 4–5 s before of each scanning. Upon addition of 8–10-fold excess ACN to $CHCl_3$ solutions of **5**, **6**, **7**, **8** and **10** and stirring a color simultaneously turned from dark brown to green. In the ESR spectra of these oxidized complexes besides significantly decreasing in the intensity of the initial spectra, the appearance of strong radical signals ($g = 2.0071 - 2.0086$) and a new broad signal centered at $g = 2.116$, 2.182, 2.185, 2.194 and 2.172, respectively, were observed. The observed *g*

values are slightly greater than that observed free phenoxyl radicals (2.004–2.005). It is more likely that there is contribution of metal orbitals to the molecular orbital that contain the unpaired electron. Under similar conditions the oxidation of **1**, **2**, **3**, **4** was rather difficult than that for **5**, **6**, **7**, **8** and **10** complexes. Although the broad line near $g = 2.18$, observed in the spectra of oxidized **X**, may be originate from aggregated Cu(II) intermediates, a detailed explanation of the observed spectral changes is not possible at present. It is noteworthy that when oxidation of **5**, **6**, **7**, **8** and **10** complexes was carried out with a twofold excess ACN while the decreasing in the intensity of the initial spectra and generation of a strong radical signal were appeared, but no new signal assignable to Cu(II) species was detected (Fig. 3). The detection of radical signals for **X** + ACN systems undoubtedly supports the generation of the coordinated phenoxyl radical because of one electron oxidation of the coordinated phenolate oxygen atoms in **X**. The decreasing in the ESR signal intensity of the oxidized **X** probably results from an antiferromagnetic coupling between unpaired d^9 copper electron and coordinated radical center in Cu^{II}–PhO$^{\cdot}$ radical species. It is necessary to note that radical species generated from free L^8H and $L^{10}H$ are too unstable and their spectra can be detected only at 130 K as unresolved singlets at $g = 2.0049$ and 2.0053, respectively. Note that the generation of coordinated radical species recently were observed in the oxidation of bis(*N*-aryl-3,5-Bu^t_2-salicylaldiminato)copper(II) complexes [7a]. It is interesting in the oxidation of bis(*N*-aryl-3,5-Bu^t_2-salicylaldiminato)palladium(II) along with coordinated Pd^{II}–phenoxyl radical species the generation of nitroxide radical species also were detected [7b]. In addition, our unpublished complexes with similar ligands bis(*N*-cyclohexyl-3,5-But_2-salicylaldiminato) cobalt(II) and bis(*N*-3,5-Bu^t_2-phenyl-3,5-But_2-salicylaldiminato)cobalt(II) in the chemical oxidation under above conditions also affords generation of radical species, in which ESR spectra exhibit octets of doublets with $g = 2.0027$, $A^{Co} = 9.25G$, $A^{H} = 3.65G$ and $g = 2.0037$, $A^{Co} = 9.0G$, $A^{H} = 3.75G$, respectively, clearly indicating the presence of a coordinated phenoxyl radical of Co(III). We take this as good evidence that the chemical oxidation of above complexes yields phenoxyl or semiquinone coordinated Co(III) species.

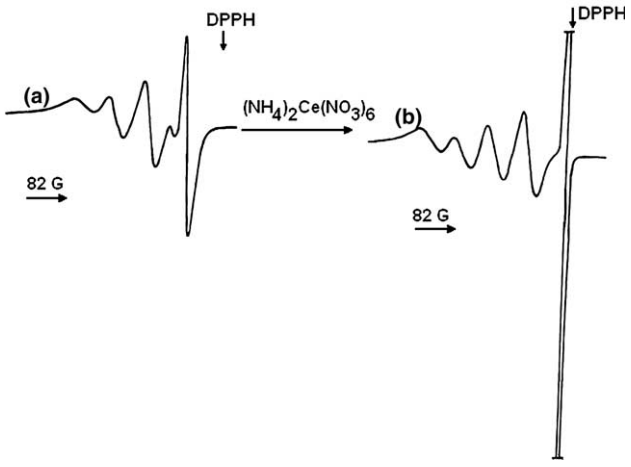

Fig. 3. ESR spectra of **8** (a) in $CHCl_3$ and oxidized **8** (b) generated by twofold excess of ACN.

The spectral changes for **X** + ACN systems was monitored by UV–Vis spectroscopy during the progress of the oxidation of **X** complexes with ACN in $CHCl_3$. When 8–10-fold excess ACN is added to the solution of **X** in $CHCl_3$, the dark brown solution turns to green or light green with the decreasing in the absorbance of a d–d shoulder bands of **X** and the appearance of new absorption maxima at 630–709 nm and a very weak shoulders at 800–830 nm for some of them were observed (Tables 3 and 5). Changes in the values of the absorbances and wavelengths of the d–d bands detected during oxidation processes of **X** are summarized in Table 5. As can be seen from Table 5, after each stirring of the heterogeneous reaction mixtures increase in the wavelength and in the absorbance values of the absorption maxima takes place. The green color and absorbance of the oxidized *n*-alkyl substituted **X** practically did not change during 40–50 min. At the same time, upon oxidation of **X** complexes bearing R = *t*-butyl, *t*-amyl and cyclohexyl groups, the color simultaneously turned to dark green and a red shift in λ_{max} was detected (Table 5). The green color of these systems after about 1 h gradually converted to light yellow with the disappearing of d–d bands in the electronic spectra. It is thought that the appearance of new maximums at about 640–800 nm and their red shifts during oxidation may be related with the changes in the coordination sphere around the Cu(II) in the oxidized **X**. Although a new appeared bands are similar to the d–d bands of Cu^{II} ions [14,17], the similar visible absorptions also have been identified in many M^{II}–phenoxyl radical complexes, which has been attributed to MLCT or LMCT transitions involving the phenoxyl radical [18].

3.6. Cyclic voltammetry

The redox behavior of some **X** complexes has been examined by cyclic voltammetry (CV) under nitrogen in acetonitrile solution in the potential range +1.85 to −2.0 V versus Ag/AgCl reference, and the results are summarized in Table 6. CV of *N*-cyclohexyl-3,5-Bu^t_2-salicylaldimine ligand exhibits a quasi-reversible anodic processes ($E_{1/2} = 0.985$ V) attributable to the phenolate/phenoxyl radical couple. Cathodic scans of this sample in the region of 0.0 to −1.5 V exhibit an irreversible reduction wave at −1.173 V associated with reduction of the imine group [19] and a reversal anodic

[a] Secondary processes means the process related with oxidation of radical species or other decomposition products.

oxidation at −0.626 V probably originated from of the reduction products. The CV of some X complexes recorded in the potential range of 0.0–1.85 V show one or two quasireversible oxidation waves (Fig. 4(b) and (c)). In generally, the oxidation potentials [$E_{1/2} = 1/2 (E_{pa} + E_{pc})$] of the **X** complexes are less sensitive to the involved change in alkyl groups directly attached to the imine nitrogen (Table 6), suggesting that the anodic oxidation processes are associated with the phenolic moieties of the ligands and can be assigned to a quasi-reversible Cu(II)–phenoxide/Cu(II)–phenoxyl couples. At the same time, the values of the first and second reduction potentials ($E_{1/2}$) of an irreversible Cu^{II}/Cu^{I} and Cu^{I}/Cu^{0} redox couples, scanned at a negative potentials in the range 0.0 to −2.0 V versus Ag/AgCl, are very sensitive to the bulkiness of alkyl groups and shifts towards anodically from CH_3 to Bu^t (Table 6) (Fig. 4), i.e., in order of an increase of the tetrahedral distortion around copper(II). Practically all of studied complexes except **10** exhibit virtually identical anodic stripping wave at $-0.213 \div 0.226$ V. First anodic and first cathodic waves are ill-defined. The reason of these probably originates from unstability of the reduction products i.e. the presence of decomposition or disproportion reactions. The cathodic CV of **1** and **2** displays two reduction peaks with $E_{1/2}$, of −1.008, −0.336 and −1.024, −0.323 V versus Ag/AgCl, respectively (Fig. 4(a)). In the reverse anodic scan one anodic stripping peak at $E_{pa} = -0.213$ V for **1** and $E_{pa} = -0.224$ V for **2** due to Cu(0)/Cu(II) oxidation couple, is observed. Complexes **6** and **8** having bulky *t*-butyl and *t*-amyl groups on the imines nitrogen, exhibit only a single quasi-reversible reduction for Cu(II)/Cu(I) couple with $E_{1/2}$ of −0.465 and −0.596 V, respectively. As can be seen from Table 6, the oxidation potentials $E_{1/2}$ of the complexes are not appreciable affected by the distortion of the coordination geometry of Cu(II) ion. The absence of the reduction peaks of imine groups in the complexes during cathodic scans probably indicates that the reduction potentials of the monoanionic ligands have been shifted beyond the lower limit of the potential interval considered in the experimental measurements [20].

Thus, the present work demonstrates that the sterically bulky *N*-alkyl-3,5-di-*tert*-butylsalicylaldimine ligands unlike Ni^{II}, Zn^{II}, Mn^{II}, VO^{IV} and Co^{II} metal ions are readily complexing with Cu^{II}. The stereochemistry and redox behavior of copper(II) complexes have been characterized using ESR, UV–Vis and electrochemical methods. Their ligand centered oxidation potentials are less sensitive to bulkiness of alkyl groups. Chemical oxidation of some complexes leads to the

formation of the directly coordinated Cu(II)–phenoxyl radical species.

been described for the intramolecular addition of carboxylic acid to alkynes to afford enol lactones, by activation of the alkyne [7].

Theoretical studies on these cuboidal heterobimetallic systems suggest a crucial dependence of the reactivity at the heterometal site from the coordination environment around the molybdenum atoms [8]. It is well known that phosphanes occupy a unique role in the design and development of transition metal catalysts. These facts have prompted us to investigate the synthesis, structure, redox properties and reactivity of phosphane substituted $[M_3NiS_4]$ (M = Mo, W) cluster complexes.

2. Experimental

2.1. General remarks

All reactions were carried out under nitrogen atmosphere using standard Schlenk techniques. The solids $\{Mo_3S_7Cl_4\}_n$, $\{Mo_3S_7Br_4\}_n$ and $\{W_3S_7Br_4\}_n$, as well as the homometallic clusters $[Mo_3S_4Cl_3(dmpe)_3]PF_6$, $[Mo_3S_4Br_3(dmpe)_3]PF_6$, $[W_3S_4Br_3(dmpe)_3]PF_6$ and $[Mo_3S_4Cl_3(dppe)_3]PF_6$ (dmpe = 1,2-bis(dimethylphosphanyl)ethane) were obtained according to literature methods [9]. $[Ni(cod)_2]$ (cod = 1,5-cyclooctadiene) was purchased from Strem Chemicals. Solvents for synthesis and electrochemical measurements were dried and degassed by standard methods before use. Chromatographic work was performed on silica gel 60 Å.

Elemental analyses were performed on an EA 1108 CHNS microanalyzer at the Universidad de La Laguna. $^{31}P\{^1H\}$ NMR spectra were recorded with a reference of 85% H_3PO_4 on a Varian 300 MHz. IR spectra were recorded on a Perkin–Elmer System 2000 FT-IR using KBr pellets. Electronic absorption spectra were obtained on a Perkin–Elmer Lambda-19 spectrophotometer. Electrospray mass spectra (ESI-MS) were recorded with a Micromass Quattro LC instrument. Nitrogen was employed as a drying and nebulizing gas. Cone voltage was typically varied from 20 to 100 V in order to investigate the effect of higher voltages on the fragmentation pathways of the parent ions. Isotope experimental patterns were compared with theoretical patterns obtained using the MassLynx 3.5 program. Cyclic voltammetry experiments were performed with an Echochemie Pgstat 20 electrochemical analyzer. All measurements were carried out at room temperature with a conventional three-electrode configuration consisting of platinum working and auxiliary electrodes and an Ag/AgCl reference electrode containing aqueous 3 M KCl. Dichloromethane was used in all experiments and dried and degassed by standard methods. The supporting electrolyte was 0.1 M tetrabutylammonium hexafluorophosphate. $E_{1/2}$ values were determined as 1/2 ($E_a + E_c$), where E_a and E_c are the anodic and cathodic peak potentials, respectively. All potentials reported are not corrected for the junction potential.

2.2. Syntheses

2.2.1. $[Mo_3NiS_4Cl_3(dmpe)_3(CH_3CN)]PF_6$ ([1]PF_6)

To a green solution of $[Mo_3S_4Cl_3(dmpe)_3]PF_6$ (0.4 g, 0.36 mmol) in CH_3CN (40 mL) was added an excess of $[Ni(cod)_2]$ (0.153 g, 0.56 mmol) under nitrogen without any apparent colour change. After stirring for 48 h, the resulting solution was taken to dryness and the solid was redissolved in CH_2Cl_2 and adsorbed in a silica gel column. After washing the column with CH_2Cl_2, elution with acetone/CH_2Cl_2 (1/3) afforded a very concentrated green solution. Finally, the resulting solution was taken to dryness to give an air stable green solid characterized as $[Mo_3NiS_4Cl_3(dmpe)_3(CH_3CN)]PF_6$ [**1**]PF_6 (0.346 g, 79%). *Anal.* Calc. for $C_{20}H_{51}Cl_3F_6Mo_3NNiP_7S_4$: requires C, 19.73; H, 4.22; N, 1.15; S, 10.53. Found: C, 19.79; H, 4.17; N, 0.76; S, 11.03%; λ_{max}/nm (CH_2Cl_2) 650, 463, 330 (sh), 260 (sh) and 237; δ_P(CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), 17.74 (3P, dd) and 25.26 (3P, dd); *m*/*z* (CH_2Cl_2): 1074 (M^+), 1033 ($M^+ - CH_3CN$) and 882 ($M^+ - CH_3CN$ − dmpe).

2.2.2. $[Mo_3NiS_4Br_3(dmpe)_3(CH_3CN)]PF_6$ ([2]PF_6)

This compound was prepared following the general procedure described for [**1**]PF_6, except that $[Mo_3S_4Br_3(dmpe)_3]PF_6$ (0.300 g, 0.24 mmol) was used instead of $[Mo_3S_4Cl_3(dmpe)_3]PF_6$. This compound was reacted with an excess of $[Ni(cod)_2]$ (0.101 g, 0.37 mmol). The air stable green product obtained was characterized as $[Mo_3NiS_4Br_3(dmpe)_3(CH_3CN)]PF_6$ [**2**]PF_6 (0.120 g, 31%). *Anal.* Calc. for $C_{20}H_{51}Br_3F_6Mo_3NNiP_7S_4$: requires C, 17.78; H, 3.81; N, 1.04; S, 9.49. Found: C, 17.89; H, 3.72; N, 0.75; S, 9.06%; λ_{max}/nm (CH_2Cl_2): 656, 470 (sh), 270 (sh) and 240; δ_P (CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), 10.95 (3P, dd) and 22.90 (3P, dd); *m*/*z* (CH_2Cl_2): 1207 (M^+), 1166 ($M^+ - CH_3CN$) and 1016 ($M^+ - CH_3CN$ − dmpe).

2.2.3. $[Mo_3NiS_4Cl_3(dppe)_3(CH_3CN)]PF_6$ ([3]PF_6)

This compound was prepared following the general procedure described for [**1**]PF_6 except that $[Mo_3S_4Cl_3(dppe)_3]PF_6$ (0.500 g, 0.27 mmol) was used instead of $[Mo_3S_4Cl_3(dmpe)_3]PF_6$. This compound was reacted with an excess of $[Ni(cod)_2]$ (0.110 g, 0.40 mmol) during 4 h. The air stable green product obtained was characterized as $[Mo_3NiS_4Cl_3(dppe)_3(CH_3CN)]PF_6$ [**3**]PF_6 (0.078 g, 15%). *Anal.* Calc. for $C_{80}H_{75}Cl_3F_6Mo_3NNiP_7S_4$ requires C, 48.96; H, 3.85; N, 0.71; S, 6.54. Found: C, 49.09; H, 4.10; N, 1.20; S, 6.07%; λ_{max}/nm (CH_2Cl_2): 646, 500 (sh) and 240; δ_P (CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), 26.59 (3P, t, ^3J(P–P_{trans}) 9.1 Hz) and 33.74 (3P, t, ^3J(P–P_{trans}) 10.0 Hz); *m*/*z* (CH_2Cl_2): 1818 (M^+), 1777 ($M^+ - CH_3CN$) and 1379 ($M^+ - CH_3CN$ − dppe).

*2.2.4. [$Mo_3NiS_4Cl_3(dmpe)_3(NC_5H_5)$]$PF_6$ ([**4**]PF_6)*

Compound [**1**]PF_6 (0.075 g, 0.06 mmol) was dissolved in 30 mL of CH_2Cl_2. Excess of pyridine (2 mL, 24.50 mmol) was added with fast stirring for 24 h. The resulting solution was adsorbed in a silica gel column and excess of pyridine was eluted with CH_2Cl_2. Elution with acetone/CH_2Cl_2 (1/3) afforded a very concentrated green solution of the product which was taken to dryness to give an air stable deep green solid characterized as [$Mo_3NiS_4Cl_3(dmpe)_3(NC_5H_5)$]$PF_6$ [**4**]PF_6 (0.070 g, 91%). *Anal.* Calc. for $C_{23}H_{53}Cl_3F_6Mo_3NNiP_7S_4$ requires C, 22.00; H, 4.25; N, 1.12; S, 10.21. Found: C, 22.01; H, 4.10; N, 1.54; S, 9.77. λ_{max}/nm (CH_2Cl_2): 680, 480, 341, 305, 270 (sh) and 239; δ_P (CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), 18.98 (3P, dd) and 24.80 (3P, dd); *m*/*z* (CH_2Cl_2): 1112 (M^+), 1033 ($M^+ - NC_5H_5$) and 882 ($M^+ - NC_5H_5$ − dmpe).

*2.2.5. [$Mo_3NiS_4Cl_3(dmpe)_3(SC_4H_8)$]$PF_6$ ([**5**]PF_6)*

This compound was synthesized following the same procedure as used for compound [**4**]PF_6, taking 0.075 g (0.06 mmol) of cluster [**1**]PF_6 and using an excess of tetrahydrothiophene (15 mL, 168.40 mmol) instead of pyridine. The air stable deep green product obtained was identified as compound [$Mo_3NiS_4Cl_3(dmpe)_3(SC_4H_8)$]$PF_6$ [**5**]PF_6. (0.065 g, 83%). *Anal.* Calc. for $C_{22}H_{56}Cl_3F_6Mo_3NiP_7S_5$ requires C, 20.89; H, 4.46; S, 12.68. Found: C, 20.98; H, 4.18; S, 12.20%; λ_{max}/nm (CH_2Cl_2): 650, 524, 470, 330 (sh), 290 (sh) and 241; δ_P (CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), 18.34 (3P, dd) and 24.44 (3P, dd); *m*/*z* (CH_2Cl_2): 1121 (M^+), 1033 ($M^+ - SC_4H_8$) and 882 ($M^+ - SC_4H_8$ − dmpe).

*2.2.6. [$Mo_3NiS_4Cl_3(dmpe)_3(CO)$]$PF_6$ ([**6**]PF_6)*

Compound [**1**]PF_6 (0.075 g, 0.06 mmol) was dissolved in 10 mL of CH_2Cl_2 adding 1 mL of MeOH. CO was bubbled through the solution for 60 min. The solution was kept in a CO atmosphere for one day. The resulting brown solution was taken to dryness giving a compound characterized as [$Mo_3NiS_4Cl_3(dmpe)_3(CO)$]$PF_6$ [**6**]PF_6 (0.074 g, 100%). *Anal.* Calc. for $C_{19}H_{48}Cl_3F_6Mo_3NiOP_7S_4$ requires C, 18.95; H, 4.02; S, 10.65. Found: C, 19.40; H, 4.11; S, 10.14%; ν_{CO}/cm^{-1} (KBr): 2038; λ_{max}/nm (CH_2Cl_2): 520 (sh), 390 (sh), 312, 260 (sh) and 236; δ_P (CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), 17.74 (3P, dd) and 23.72 (3P, dd); *m*/*z* (CH_2Cl_2): 1061 (M^+), 1033 ($M^+ - CO$) and 882 ($M^+ - CO$ − dmpe).

*2.2.7. [$W_3NiS_4Br_3(dmpe)_3(CH_3CN)$]$PF_6$ ([**7**]PF_6)*

This compound was prepared following the general procedure described for [**1**]PF_6 except that [$W_3S_4Br_3(dmpe)_3$]PF_6 (0.350 g, 0.23 mmol) was used instead of [$Mo_3S_4Cl_3(dmpe)_3$]PF_6. The complex was reacted with an excess of [Ni(cod)$_2$] (0.103 g, 0.37 mmol). The air stable green product obtained was characterized as [$W_3NiS_4Br_3(dmpe)_3(CH_3CN)$]$PF_6$ [**7**]PF_6 (0.227 g, 61%). *Anal.* Calc. for $C_{20}H_{51}Br_3F_6NNiP_7S_4W_3$ requires C, 14.88; H, 3.18; N, 0.87; S, 7.94. Found: C, 14.90; H, 3.03; N, 0.81; S, 7.51%; λ_{max}/nm (CH_2Cl_2): 604, 410 (sh), 310 (sh), 275, 245 and 236; δ_P (CH_2Cl_2): −145.00 (1 P, sept, ^1J(P–F) 704.0 Hz), −10.55 (3P, s, ^1J(P–W) 191.8 Hz) and −8.55 (3P, s, ^1J(P–W) 170.5 Hz); *m*/*z* (CH_2Cl_2): 1471 (M^+), 1430 ($M^+ - CH_3CN$), 1280 ($M^+ - CH_3CN$ − dmpe).

*2.2.8. [$W_3NiS_4Br_3(dmpe)_3(NC_5H_5)$]$PF_6$ ([**8**]PF_6)*

Compound [**7**]PF_6 (0.075 g, 0.05 mmol) was dissolved in 30 mL of CH_2Cl_2. Excess of pyridine (8 mL, 98.10 mmol) was added with fast stirring for 24 h. The resulting solution was adsorbed in a silica gel column and excess of pyridine was eluted with CH_2Cl_2. Elution with acetone/CH_2Cl_2 (1/3) afforded a very concentrated green solution of the product which was taken to dryness to give an air stable deep green solid characterized as [$W_3NiS_4Br_3(dmpe)_3(NC_5H_5)$]$PF_6$ [**8**]PF_6 (0.068 g, 88%). *Anal.* Calc. for $C_{23}H_{53}Br_3F_6NNiP_7S_4W_3$ requires C, 16.71; H, 3.23; N, 0.85; S, 7.76. Found: C, 16.93; H, 3.16; N, 0.79; S, 7.40%; λ_{max}/nm (CH_2Cl_2): 631, 480 (sh), 370 (sh), 284, 253 and 231; δ_P (CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), −9.06 (3P, s, ^1J(P–W) 190.1 Hz) and −8.51 (3P, s, ^1J(P–W) 190.1 Hz); *m*/*z* (CH_2Cl_2): 1509 (M^+), 1430 ($M^+ - NC_5H_5$) and 1280 ($M^+ - NC_5H_5$ − dmpe).

*2.2.9. [$W_3NiS_4Br_3(dmpe)_3(SC_4H_8)$]$PF_6$ ([**9**]PF_6)*

This compound was synthetized following the same procedure as used for compound [**8**]PF_6, taking 0.100 g (0.06 mmol) of cluster [**7**]PF_6 and using an excess of tetrahydrothiophene (15 mL, 168.40 mmol) instead of pyridine. The air stable deep green product obtained was identified as compound [$W_3NiS_4Br_3(dmpe)_3(SC_4H_8)$]$PF_6$ [**9**]PF_6 (0.080 g, 78%). *Anal.* Calc. for $C_{22}H_{56}Br_3F_6NiP_7S_5W_3$ requires C, 15.90; H, 3.40; S, 9.65. Found: C, 15.94; H, 3.31; S, 9.17%; λ_{max}/nm (CH_2Cl_2): 592, 473, 405 (sh), 305 (sh), 285, 253 and 235; δ_P (CH_2Cl_2): −145.00 (1 P, sept, ^1J(P–F) 704.0 Hz), −10.01 (3 P, s, ^1J(P–W) 195.0 Hz) and −8.69 (3 P, s, ^1J(P–W) 160.4 Hz); *m*/*z* (CH_2Cl_2): 1518 (M^+), 1430 ($M^+ - SC_4H_8$) and 1280 ($M^+ - SC_4H_8$ − dmpe).

*2.2.10. [$W_3NiS_4Br_3(dmpe)_3(CO)$]PF_6 ([**10**]PF_6)*

Compound [**7**]PF_6 (0.075 g, 0.05 mmol) was dissolved in 10 mL of CH_2Cl_2 adding 1 mL of MeOH. CO is bubbled through the solution for 30 min. The colour changes from green to brown within 5 min. The solution was kept in a CO atmosphere for one day and was taken to dryness giving a compound characterized as [$W_3NiS_4Br_3(dmpe)_3(CO)$]PF_6 [**10**]PF_6 (0.074 g, 100%). *Anal.* Calc. for

$C_{19}H_{48}Br_3F_6NiOP_7S_4W_3$ requires C, 14.25; H, 3.02; S, 8.01. Found: C, 14.27; H, 2.95; S, 7.75%; ν_{CO}/cm^{-1} (KBr): 2017; λ_{max}/nm (CH_2Cl_2): 570 (sh), 442, 309 and 234; δ_P (CH_2Cl_2): −145.00 (1P, sept, ^1J(P–F) 704.0 Hz), −10.67 (3P, s, ^1J(P–W) 200.0 Hz) and −9.21 (3P, s, ^1J(P–W) 142.9 Hz); *m/z* (CH_2Cl_2): 1458 (M^+), 1430 ($M^+ - CO$) and 1280 ($M^+ - CO - dmpe$).

2.2.11. X-ray crystallography

Suitable crystals for X-ray diffraction characterization of the tetraphenylborate salt of $[\mathbf{1}]^+$ were grown by slow diffusion of MeOH into a CH_2Cl_2 solution. Replacement of the PF_6^- anion in [**1**]PF_6 was done by addition of an excess of $NaBPh_4$ to a methanol solution of [**1**]PF_6 that precipitates the desired tetraphenylborate salt of the tetranuclear cation $[\mathbf{1}]^+$. Suitable crystals of compound [**10**]PF_6 were grown by slow evaporation of a CH_2Cl_2 solution. The air stable crystals were mounted on a glass fibre with the use of epoxy cement. X-ray diffraction experiments were carried out on a Bruker SMART CCD diffractometer using Mo Kα radiation (λ = 0.71073 Å). The data were collected with a frame width of 0.3° in Ω and a counting time of 20 s for [**1**]BPh_4 and 15 s for [**10**]PF_6 per frame at a crystal to detector distance of 4 cm. The software SAINT [10] was used for integration of intensity reflections and scaling and SADABS [11] for absorption correction. Final cell parameters were obtained by global refinement of reflections obtained from integration of all the frame data. The crystal parameters and basic information relating data collection and structure refinement for compounds [**1**]BPh_4 and [**10**]PF_6 are summarized in Table 1. The structures were solved by direct methods and refined by full-matrix methods based on F^2 using the SHELXTL software package [12].

The compounds [**1**]BPh_4 and [**10**]PF_6 crystallized in centro-symmetric space groups *P*2(1)/*c* and P2(1)/*n*, respectively. Their structures are formed by racemic mixtures of the chiral cluster cations $[\mathbf{1}]^+$ and $[\mathbf{10}]^+$. In both cases the non-hydrogen atoms of the cationic clusters were refined anisotropically; the positions of all hydrogen atoms were generated geometrically, assigned isotropic thermal parameters and allowed to ride on their respective parent carbon atoms. The PF_6^- anion in the structure of [**10**]PF_6 was refined as a rigid group with the phosphorus as pivot atom. The fluorine atoms rotate about the phosphorus atom and the same translational shifts are applied to all atoms. Anisotropic thermal parameters were assigned to phosphorus and isotropic to fluorine atoms.

2.2.12. Catalytic test

A typical experimental procedure for the hydrodesulfurization reaction of 1-octanethiol is described. The cluster compound (20 mg) was dissolved in 15 mL of methanol for [**1**]PF_6 or acetone for [**2**]PF_6, [**3**]PF_6 and [**7**]PF_6, and 10 mg of 1-octanethiol was added. The reactions were carried out in an autoclave at 160–180 °C under a hydrogen pressure of 25 bar at 20 °C (≈42 bar at reaction temperature) for 16 h. The resulting products were identified by GC-MS (Agilent Technologies 5973 Mass Selective Detector) and analysed with a chromatograph (Agilent Technologies 6890 Plus) equipped with a HP Ultra-1 capillary column (25 m × 200 μm × 0.33 μm film thickness).

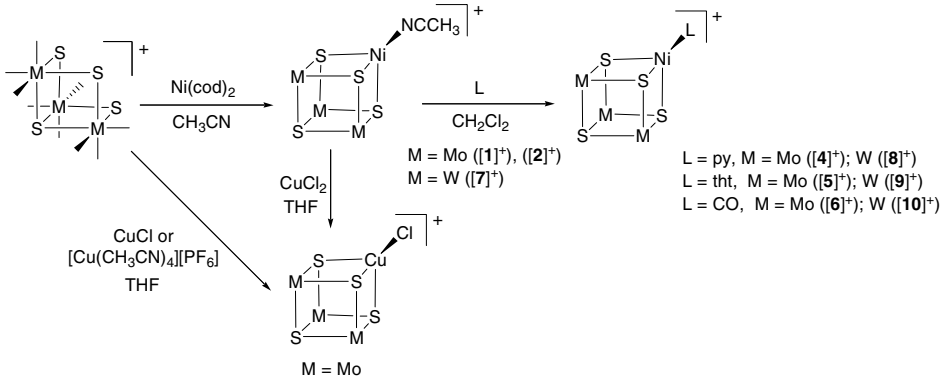
3. Results and discussion

3.1. Synthesis

Clusters with $[M_3NiS_4]^{4+}$ cores (M = Mo, W) have been prepared with various ligands on the group 6 metal (aqua, nta, dppe, Cp derivatives) and on the nickel atom (CO, PPh_3, organic sulfides, phenylsulfinate) [13–15]. Most synthesis strategies started from the aqua clusters $[M_3S_4(H_2O)_9]^{4+}$, which are reacted with Ni metal in acidic media or with divalent nickel salts under reducing conditions to give rise to the heterobimetallic $[Mo_3NiS_4]$ core. Ligand substitutions on the group 6 metal or the nickel atom afford various cluster complexes. Another strategy begins with substitution of the aqua ligands of the trinuclear $[Mo_3S_4(H_2O)_9]^{4+}$ cluster by Cp or Cp′ (Cp′ = Me-Cp) that in a second step incorporates the nickel atom from a Ni^0 complex in an organic solution.

We have shown that $[M_3S_4X_3(diphos)_3]^+$ cluster cations, which are synthesized by scission of polymeric $\{M_3S_7X_4\}_n$ solids with dmpe or dppe, are versatile building blocks for the synthesis of heterobimetallic thiocubane clusters by incorporation of copper or cobalt atoms in organic media [16,17]. The reaction of $[M_3S_4X_3(diphos)_3]^+$ with an excess of $[Ni(cod)_2]$ in acetonitrile affords the $[M_3NiS_4X_3(diphos)_3(CH_3CN)]^+$ clusters as their PF_6^- salts in yields that range from 15% to 79% for molybdenum complexes and 61% yield for $[W_3NiS_4Br_3(dmpe)_3(CH_3CN)]PF_6$, as shown in Scheme 1 [18].



The compounds [**1**]PF_6 and [**7**]PF_6 exchange almost quantitatively the acetonitrile ligand on the nickel atoms by addition of pyridine, tetrahydrothiophene or carbon monoxide in CH_2Cl_2 solutions at room temperature. This substitution did not take place with less nucleophilic ligands such as water, methanol, benzenethiol, furane or pyrrol. Fragmentation of the tetranuclear cluster is observed when [**1**]PF_6 is treated with an excess of triphenylphosphine or dmpe. Reaction of $[Mo_3NiS_4Cl_3(dmpe)_3(CH_3CN)]PF_6$ with divalent $CuCl_2$ in THF affords $[Mo_3CuS_4Cl_3(dmpe)_3Cl]PF_6$ by replacement of a $Ni(CH_3CN)$ cluster fragment by CuCl [18]. This transmetallation reaction does not take place with Cu(I) salts such as CuCl or $[Cu(CH_3CN)_4]PF_6$. The compound $[Mo_3CuS_4Cl_3(dmpe)_3Cl]PF_6$ has been also prepared by reaction of the trimetallic cluster $[Mo_3S_4Cl_3(dmpe)_3]PF_6$ with Cu^I salts, but no reaction has been observed between the triangular cluster and divalent copper salts [16]. These facts are in agreement with the following reaction scheme proposed by Sykes et al. for transmetallation of the aqua cluster $[Mo_3FeS_4(H_2O)_{10}]^{4+}$ (see Scheme 2) [19].

$$[Mo_3FeS_4(H_2O)_{10}]^{4+} + 2\,Cu^{2+} \longrightarrow [Mo_3S_4(H_2O)_9]^{4+} + Fe^{2+} + 2\,Cu^{+}$$

$$[Mo_3S_4(H_2O)_9]^{4+} + Cu^{+} \longrightarrow [Mo_3CuS_4(H_2O)_{10}]^{5+}$$

Scheme 2.

The $^{31}P\{^1H\}$ NMR spectra of $[M_3S_4NiX_3(diphos)_3L]PF_6$ (M = Mo, W; X = Cl, Br; diphos = dmpe, dppe; L = NC_5H_5, SC_4H_8, CO) ([**1**]PF_6–[**10**]PF_6) show two signals corresponding to the three phosphorus atoms above and below the trimetallic plane. In the molybdenum dmpe series, the phosphorus signals are displayed at 11–19 and 23–25 ppm with a doublet of doublets pattern characteristic of an AA′A″BB′B″ second order system. For the dppe derivatives, the signals are triplets and are displayed at lower fields (27 and 34 ppm) than the dmpe derivatives. The singlet signals in the tungsten derivatives are displayed at ca. −9 and −10 ppm, with the characteristic satellites of ^{31}P–^{183}W coupling (^{183}W has 14.4% natural abundance). Incorporation of a nickel atom causes a high field shift of the signals of ca. 8 ppm, but the lineshape of the spectra remains unaltered. This fact has been described previously for the copper cluster cations $[M_3S_4CuX_3(diphos)_3X]^+$ [16]. The averaged 25 ppm high field shift for the resonances of the tungsten clusters in comparison with the analogous molybdenum clusters indicate an increase of

Scheme 1.

electron density at the phosphorus atom caused by a higher electron density of tungsten atoms.

The UV/Vis spectra of reported compounds show a blue-shift of all bands going from Mo ([**1**]PF_6, [**4**]PF_6, [**5**]PF_6) to W ([**7**]PF_6–[**9**]PF_6) of 45–60 nm for the band of lowest energy. A similar hypsochromic shift to Mo/W containing cluster was previously reported for heterobimetallic cluster anions $[\{(OC)_3Re\}_3S_4M(S)]^-$ (M = Mo, W) and was ascribed to the stronger electron accepting ability of the molybdenum compared to tungsten [20]. The substitution of acetonitrile for pyridine or tetrahydrothiophene does not cause any colour change, but upon coordination of CO to clusters [**1**]PF_6 and [**7**]PF_6, a colour change is observed from green to brown. The same effect has been described for the aqua cluster $[M_3NiS_4(H_2O)_9]^{4+}$, (M = Mo, W) [21], and a bathochromic shift of 50 nm of the band at lowest energy is observed going from [**6**]PF_6 to [**10**]PF_6.

The IR carbonyl stretching frequencies in the reported $[M_3NiS_4]$ aqua clusters (2060 cm^{-1} for $[Mo_3NiS_4(H_2O)_9(CO)]^{4+}$ [22] and 2045 cm^{-1} for $[W_3NiS_4(H_2O)_9(CO)]^{4+}$ [21]) have been interpreted based on the Ni^{2+} metal oxidation state which implies an oxidation of the heterometal upon incorporation on the trinuclear molybdenum or tungsten cluster. However, these high frequency values are explained based on Fenske–Hall MO calculations through a competition between the M–Ni^0 bond formation and and the π-backbonding to the CO ligand [8]. The IR spectra of [**6**]PF_6 and [**10**]PF_6 show carbonyl bands at 2038 and 2017 cm^{-1}, respectively, which ranges between those of the aqua and Cp compounds (2020 cm^{-1} for $[Mo_3NiS_4Cp_3(CO)]^+$ and 2032 cm^{-1} for $[Mo_3NiS_4Cp_3'(CO)]^+$). This fact is explained by the electron donating ability of the diphosphine ligand, which is better than that of the aqua ligand, but worse than that of the Cp ligands [23,24,22].

3.2. Structure

The crystal structure analyses of [**1**]BPh_4 and [**10**]PF_6 confirm the presence of cubane-like $[M_3NiS_4]^{4+}$ cluster cores whose innermost part is formed by a tetrahedral arrangement of three molybdenum or tungsten atoms and one nickel atom. Each tetrahedral face is capped by a μ_3-coordinated sulfido ligand, thus generating the cubane-like structure (Fig. 1).

The group 6 metals have an octahedral configuration (if metal–metal bonds are neglected), formed by three sulphur atoms, two phosphorus atoms from the dmpe ligand and one halogen atom. The M–M average bond distances are 2.795 Å for $[\mathbf{1}]^+$ and 2.784 Å for $[\mathbf{10}]^+$. The M–Ni bond distances of 2.672 and 2.735 Å for $[\mathbf{1}]^+$ and $[\mathbf{10}]^+$, respectively, are consistent with the presence of metal–metal single bonds. Selected bond lengths of the cubane complexes and of their trinuclear precursors are listed in Table 2 and selected bonds lengths of previously reported $[M_3NiS_4]$ clusters are listed in Table 3 for comparison.

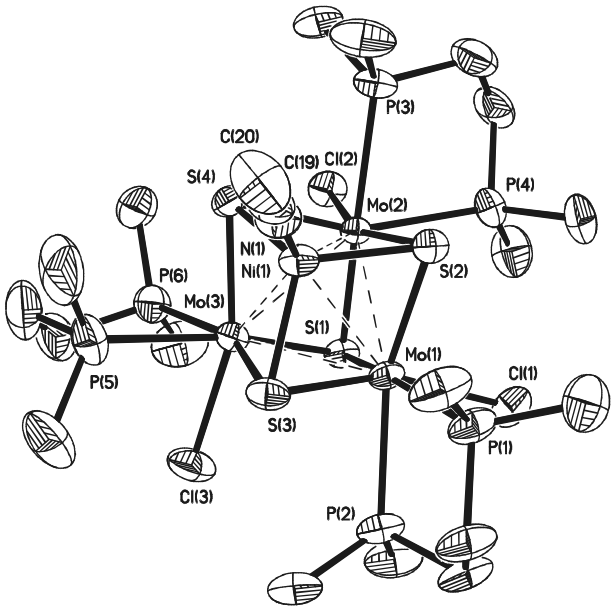


Fig. 1. ORTEP diagram of the cation $[\mathbf{1}]^+$ with 50% thermal ellipsoids and atom numbering scheme. Hydrogen atoms have been removed for clarity.

The molybdenum–molybdenum and tungsten–tungsten bond lengths are very similar to the corresponding distances in $[M_3NiS_4Cp_3']^+$ (M = Mo, W) clusters and slightly longer than the distances in $[M_3NiS_4]^{4+}$ aqua complexes. The molybdenum–nickel bond lengths follow a different tendency which is similar to that reported for aqua complexes and slightly shorter than those reported for $[Mo_3NiS_4Cp_3']^+$ clusters. These differences can be explained based on the electron-accepting properties of the ligands. The fact that diphosphine ligands are better electron-accepting ligands than aqua ligands can cause a weakening of the metal–metal bond. On the other hand, acetonitrile is a poorer electron-accepting ligand than 4,4′-bipy or PPh_3 and, consequently, it decreases the Mo–Ni distance. Owing to the differences in the bond distances between M–M and M–Ni, the cubane-like cluster framework is distorted with respect to the Ni vertex of the cluster cube. This fact is apparent by the size of the S–M–S angles, which lie in a range of 99.5–106.9° for $[\mathbf{1}]^+$ and $[\mathbf{10}]^+$, and of the S–Ni–S angles, which are around 109.5° for $[\mathbf{1}]^+$ and 107° for $[\mathbf{10}]^+$. This difference in the S–Ni–S angles reflects the smaller difference between metal bond distances in $[\mathbf{10}]^+$ as compared to $[\mathbf{1}]^+$. The stability of the M_3NiS_4 cluster core is evidenced by mass spectroscopy. The base peak in the mass spectra of [**1**]PF_6–[**10**]PF_6 are the molecular cations, followed by the loss of the ligand on the nickel atom. In the analogous copper clusters, the M–Cu bond is larger

than the M–M bond and in MS spectra, fragments without the Cu atom have been detected [16].

Among the bond distances between the molybdenum or tungsten atoms and the μ_3-S ligands capping the M_2Ni faces, those at the *trans* position to the M–P bond are by 0.02–0.03 Å longer than the other M–S distances. This may be attributed to the *trans* influence of the phosphane ligand being stronger than the one of the halogen ligands.

The nickel atom is, in all cases, tetrahedrally bonded to three μ_3-sulfur atoms and one ligand (acetonitrile or CO in $[\mathbf{1}]^+$ and $[\mathbf{10}]^+$, respectively). In the structure of [**10**]PF_6, a very regular tetrahedron around Ni is observed. In the structure of [**1**]PF_6, a distortion of the Ni environment is observed due to a bending of the CH_3CN away from the threefold axis through the cluster core, the S–Ni–C angle varying between 104.9(1)° and 114.9(1)°.

3.3. Electrochemical properties of $[Mo_3NiS_4]$

The electrochemical behaviour of compounds [**1**]PF_6–[**10**]PF_6 have been studied by cyclic voltammetry, the results from which are collected in Table 4 together with the previously reported data of triangular precursors [9]. The cyclic voltammogram of [**1**]PF_6–[**10**]PF_6 complexes are broadly similar, with two quasi-reversible oxidation waves and three or two irreversible reduction processes for molybdenum or tungsten derivatives, respectively. On the basis of the relative heights and by comparison with $[M_3NiS_4Cp_3'PPh_3]^+$ [24] and the aqua complexes $[M_3NiS_4(H_2O)_{10}]^{4+}$ [25], all processes seem to be one-electron processes. Compared to the W analogues the Mo clusters are more difficult to oxidize (ca. 0.20 V) and more easily reducible.

The incomplete cubane precursor $[M_3S_4X_3(diphos)_3]^+$ undergoes a chemically quasi-irreversible two electrons reduction ($M_3^{IV} \rightarrow M^{IV}M_2^{III}$) followed by an irreversible one-electron reduction ($M^{IV}M_2^{III} \rightarrow M_3^{III}$) (Fig. 2) [9]. The addition of a Ni–L fragment exerts an important electronic effect, the detection of two oxidation waves and the split into two irreversible processes of the quasi-reversible two-electrons reduction (Fig. 3). Nickel incorporation seems to produce an electronic communication inside the heterocubane core. This fact may complicate the assignment of oxidation states for the metal atoms [8,13,25,26] Similar effects have been described for platinum and copper incorporation to incomplete cuboidal clusters [16], whereas palladium insertion does not cause the split of the reduction wave [24]. Recent calculations based on topological AIM theories show that the incorporation of nickel or copper in the trinuclear $[Mo_3S_4X_3(PH_3)_6]^+$ complex does not produce changes in molybdenum charges.

The electronic structure of the 16 metal electron $[M_3M'S_4]$ (M = transition metal) cubane clusters is characterized by three bonding M–M′ orbitals, three weakly antibonding M–M′ orbitals and two non-bonding orbitals primarily located at the transition metal [8]. The first oxidation process of [**1**]PF_6–[**10**]PF_6 appears at

Table 4

[a] $E_{1/2}$ (ferrocene/ferrocene$^+$) = 0.44 V (ΔE = 66 mV).
[b] Electrochemical data in acetonitrile.

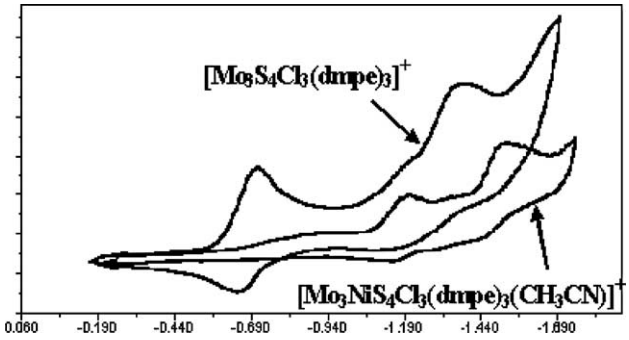

Fig. 2. Cyclic voltammogram (reduction region) for the compound [**1**]PF_6 and the precursor complex $[Mo_3S_4Cl_3(dmpe)_3]PF_6$ (scan rate 100 mV s^{-1}).

the same potential, ca. 0.44 or 0.23 V for Mo or W derivatives, respectively, and it is unaffected by the nature of the ligands (diphosphanes, halogens) or the ligands on the nickel atoms. However, the second oxidation potentials are mainly affected by the nature of the ligand on the nickel atom. A previous study on the electrochemical properties of $[Mo_3PtS_4(dppe)_3Cl_4]$ and $[Mo_3NiS_4(dppe)_3Cl_4]$ only reports one reversible oxidation wave at ca. 0.65 V (vs. SCE) [26]. Consequently, the substitution of CH_3CN in [**3**]PF_6 by the Cl^- ligand does not substantially change the oxidation capability of these clusters.

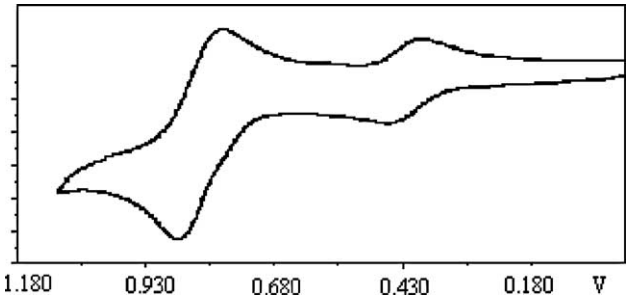

Fig. 3. Cyclic voltammogram (oxidation region) for the compound [**5**]PF_6 (scan rate of 100 mV s^{-1}).

3.4. Catalysis

Cuboidal heterobimetallic clusters have been used as model systems for the active sites of the industrial HDS catalysts. However, their application in catalysis for other organic reactions is largely unexplored, an exception being $[Mo_3PdS_4]$ and $[Mo_3S_4Ni]$-based systems which catalyse the addition of methanol or carboxylic acids to electron deficient alkynes [7].

The CO adsorbtion capacity has often taken as a measure of the HDS activity of a heterogeneous catalyst. In our case, 16 electron clusters [**1**]PF_6 and [**7**]PF_6 react with CO to afford [**6**]PF_6 and [**10**]PF_6, respectively. These clusters also react with organosulfur and -nitrogen molecules in CH_2Cl_2. The ability of the heterometal atom to bind CO in the $[M_3M'Q_4]^{n+}$ (Q = S, Se) depends strongly of the number of electrons, but also the coordination environment around the group 6 atoms. The clusters [**1**]PF_6–[**3**]PF_6 and [**7**]PF_6 have been tested as catalyst in the desulfuration of 1-octanethiol in experimental conditions at which a commercial heterogeneous Ni–MoS_2 catalyst desulfurizes 1-octanethiol completely. Experiments afforded in all cases a brown precipitate originating from partial decomposition of the cluster and a considerable amount of dioctyldisulfide, but no homogeneous HDS activity was detected. When acetone was taken as solvent, a great amount of aldol condensation products of acetone were obtained. However, it was shown in a blind experiment without the cluster that

aldol condensation of acetone was thermally induced and not related to the presence of the cluster.

No catalytic activity was detected in the addition of methanol to methyl propiolate taking $[Mo_3NiS_4Cl_3(dmpe)_3(CH_3CN)]PF_6$ as catalyst, in the conditions described previously by Hidai et al. for the addition of alcohols to alkynic acid esters catalysed by $[Mo_3PdS_4(tacn)_3Cl]PF_6$ (tacn = 1,4,7-triazacyclononane) [27].

4. Supplementary material

CCDC reference numbers 251825 and 251826 contains the supplementary crystallographic data for this paper. These data can be obtained free of charge via the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033, e-mail deposit@ccdc.cam.ac.uk or on the web http://www.ccdc.cam.ac.uk.

in the study of *N*,*N*,*N*′,*N*′-tetraalkylpyridine-2,6-dicarboxamide ligands has been twofold: firstly, to study the effect of steric congestion brought by employing isopropyl or phenyl groups at the terminal carboxamide side arms, i.e., R = $-CH(CH_3)_2$ or $-C_6H_5$ and secondly to investigate the effect of change in the donor set of atoms in the two side arms on the coordination geometry adopted by the complexes. In our recent studies, it has been shown that substitution of the donor atoms by atoms of different size and electronegativity is reflected by major changes in the coordination geometries and solid state structures adopted by the corresponding complexes [7]. Crystal structures of Cu_2Cl_4(S-dept) and $CuCl_2$(O-deap) have shown important differences between the two complexes. Cu_2Cl_4(S-dept) is a tetranuclear copper(II) complex, formed by a cationic $[Cu_2Cl_2\{\mu\text{-(S-dept)}\}_2]^{2+}$ and an anionic dinuclear complex $[Cu_2Cl_4(\mu\text{-}Cl)_2]^{2-}$ [7c]. On the other hand, $CuCl_2$(O-deap) is a five coordinated trigonally distorted rectangular pyramidal complex [7a]. Similarly, complexes of $CoCl_2$ with S-dept and O-deap have revealed different structures [7b]. This paper describes the comparative X-ray diffraction, IR and visible spectra and magnetic properties of the nickel(II) thiocyanate complexes of tridentate *SNS* and *ONO* donor ligands S-dept and O-deap. Stabilization of the metal–ligand complexes of O-deap in the solid state critically depends upon the solvent used for crystallization. The role of coordinating solvents like acetonitrile and ethanol in the lattice stabilization of the complex is discussed in the paper. It was also of interest to investigate the different thiocyanate bonding modes present in these complexes.

X=S; R= Et (S-dept)
X=O; R= Et (O-deap)

2. Experimental

2.1. Materials

All reactions were carried out in anhydrous solvents. Solvents were dried using standard techniques. Absolute ethanol (AR quality, Hayman Ltd.) and pyridine-2,6-dicarboxylic acid (Fluka) were used as supplied. Anhydrous $NiCl_2$ was prepared by boiling the hydrated salt under reflux with freshly distilled $SOCl_2$ for about 4 h. The anhydrous $NiCl_2$ was filtered, washed with dry benzene and dried in vacuo.

2.2. Preparation of *N*,*N*,*N*′,*N*′-tetraethylpyridine-2,6-dicarboxamide (O-deap) and *N*,*N*,*N*′,*N*′-tetraethylpyridine-2,6-dithiocarboxamide (S-dept)

O-deap was prepared as described earlier [5]. S-dept was obtained by refluxing a mixture of O-deap (8.26 g, 0.03 mol) and P_2S_5 (4.13 g, 0.018 mol) in benzene (50 mL) for 8 h. The reaction mixture was filtered to remove unreacted P_2S_5. Crude sample of S-dept was recovered by removal of the solvent under vacuum. Pure product was obtained as shinning yellow crystals on crystallization from hot ethanol (yield: 7.37 g, 80%). M.p. 130 °C. *Anal*. Calc. for $C_{15}H_{23}N_3S_2$: C, 58.25; H, 7.44; N, 13.59. Found: C, 58.10; H, 7.56; N, 13.48%.

2.3. Ni(S-dept)(NCS)$_2$ (**1**)

A solution of 3 mmol of anhydrous $NiCl_2$ in 20 mL of ethanol was added to a solution of 6 mmol of KSCN in 20 mL of ethanol. The filtrate after removal of quantitative amount of KCl was refluxed with 3 mmol of S-dept for 4 h. Dark brown precipitates of **1** separated out at room temperature. Recrystallization from ethanol gave dark-brown crystals. Yield: 1.26 g (87%); m.p. 226 °C. *Anal*. Calc. for $C_{34}H_{46}N_{10}S_8Ni_2$: C, 42.17; H, 4.75; N, 14.47; S, 26.5; Ni, 12.1. Found: C, 41.76; H, 5.03; N, 14.26; S, 26.1; Ni, 12.0%. Molar conductance [Λ_M, Ω cm^2 mol^{-1}]: 12.0 (CH_3CN) (expected range for 1:1 electrolytes: 120–160 Ω cm^2 mol^{-1}). IR (KBr pellet, cm^{-1}): 2087, 2007, 1602, 1581, 1518, 1469, 1450, 1388, 1360, 1316, 1282, 1260, 1186, 1145, 1094, 1017, 811, 722, 625, 474. Visible spectral data [λ_{max}, nm (ε, M^{-1} cm^{-1})] in methanol: 406 (265), 661 (8.1), 727 sh (6.5), 1092 (7.6). FAB mass [(*m*-nitrobenzyl alcohol): (M^+, 966)], *m*/*z*: 734 [Ni_2(S-dept)$_2$], 676 [Ni(S-dept)$_2$]$^+$, 425 [Ni_2(S-dept)]$^+$, 367 [Ni(S-dept)]$^+$ (base peak), 338 [Ni(S-dept)-C_2H_5]$^+$, 310 [Ni(S-dept)-C_2H_5-C_2H_4]$^+$, 278 [Ni(S-dept)-C_2H_5-C_2H_4-S]$^+$.

2.4. [Ni(NCS)$_2$(O-deap)(CH_3CN)] · CH_3CN (**2**)

This was prepared by the procedure adopted for **1**, except CH_3CN was used as the medium and O-deap as ligand. Recrystallization from acetonitrile gave green crystals. Yield: 1.47 g (91%); m.p. 220 °C. *Anal*. Calc. for $C_{21}H_{29}N_7O_2S_2Ni$: C, 47.19; H, 5.43; N, 18.35; S, 12.0; Ni, 11.0. Found: C, 47.58; H, 5.87; N, 17.97; S, 11.7; Ni, 10.7%. Molar conductance [Λ_M, Ω cm^2 mol^{-1}]: 18 (CH_3CN). IR (KBr pellet, cm^{-1}): 2315, 2287, 2092, 1600, 1561, 1315, 1270, 1198, 1098, 1069, 1046, 1030, 947, 829, 758, 723, 698, 656, 511, 447. Visible spectral data [λ_{max}, nm (ε, M^{-1} cm^{-1})] in methanol: 390 (13.1), 670 (1.7), 742 (1.9), 1071 (1.4).

2.5. [Ni(NCS)$_2$(O-deap)(C$_2$H$_5$OH)] (3)

This complex was prepared by the same procedure but anhydrous ethanol was used as the reaction medium. Yield: 1.20 g (90%); m.p. 200 °C. *Anal.* Calc. for $C_{19}H_{29}N_5O_3S_2Ni$: C, 45.78; H, 5.82; N, 14.05; S, 12.8; Ni, 11.8. Found: C, 45.24; H, 5.64; N, 14.02; S, 12.4; Ni, 11.3%. Molar conductance [Λ_M, Ω cm^2 mol^{-1}]: 6.0 (C_2H_5OH) (expected range for 1:1 electrolytes: 30–45 Ω cm^2 mol^{-1}). IR (KBr pellet, cm^{-1}): 3196, 2100, 1600, 1562, 1316, 1272, 1198, 1098, 1070, 1049, 1030, 947, 830, 762, 722, 705, 657, 510, 442. Visible spectral data [λ_{max}, nm (ε, M^{-1} cm^{-1})] in ethanol: 370 sh (14.2), 664 (4.4), 728 (4.5), 1080 (4.8).

2.6. Physical methods

Elemental analysis (C, H, N) were performed on a Perkin–Elmer Model 2400 CHN analyzer at RSIC, Panjab university, Chandigarh. IR spectra were recorded as Nujol/hcb mulls on KBr plates on a Perkin–Elmer RX-1 FTIR spectrophotometer. The UV–Vis spectra were recorded on a JASCO V-530 UV–Vis spectrophotometer. Reflectance spectra were recorded on an integrating sphere Hitachi model 330 using $MgCO_3$. The FAB mass spectra were recorded on a JEOL SX 102/DA-6000 Mass Spectrometer/Data System using Argon/Xenon (6 kV, 10 mA) as the FAB gas. *m*-Nitrobenzyl alcohol (NBA) was used as the matrix. Variable temperature (34–300 K)[1] solid state magnetic susceptibility measurements were done using a locally built Faraday balance [2].

2.7. X-ray crystallography

The crystals of complexes **1** and **3** were grown from ethanol and **2** from acetonitrile by a method of slow evaporation at room temperature. The data were collected on a Siemens P4 single crystal diffractometer using graphite monochromatized Mo Kα radiation (0.71073 Å). Table 1 shows the unit cell parameters and data measurement details. Data collection and cell refinement were done with XSCANS [10]. Data were corrected for Lorentz and polarization effects but no absorption correction was performed for **1**. Structure was solved by direct methods and refined anisotropically by full matrix least squares methods. All the hydrogens were fixed geometrically as riding atoms with a displacement parameter equal to 1.2 (CH, CH_2) or 1.5 (CH_3) times that of the parent atoms. Data reduction, structure solutions, refinement and molecular graphics were performed using SHELXLTL-PC [11]. During refinement the terminal ethyl groups of the dithioamide ligand showed disorder in terms of abnormal bond lengths and high thermal parameters. The disorder could be resolved successfully for C8, C10, C13, C15 methyl and C9, C12 methylene carbon atoms. Each of their atomic positions was split into two peaks with a total site occupancy of 1.000. These atoms were refined isotropically with restraints using fixed C–C (1.510 Å) and C–N (1.456 Å) distances. All other atoms were refined anisotropically. Torsion angles and least squares planes were calculated by using PARST [12]. The data collection procedure,structure solution and refinement for **2** and **3** were as follows, **2**: 40 reflections ($9.685° < 2\theta < 29.236°$) for accurate cell parameter determination, a total of 26.56 h of X-ray exposure time, $R = 0.0307$, $wR = 0.0780$, $a = 0.0471$ and $b = 0.22$ [in the weighting scheme]. **3**: 40 reflections ($10.207° < 2\theta < 29.936°$) for accurate cell parameter determination, a total of 39.65 h of X-ray exposure time, $R = 0.0465$, $wR = 0.1178$, $a = 0.0627$ and $b = 7.53$ [in the weighting scheme]. CCDC numbers for the complexes **1**, **2** and **3** are 261983, 261984 and 261985, respectively.

3. Results and discussion

Complexes **1**–**3** were obtained in good yield by refluxing $Ni(NCS)_2$ and the S-dept or O-deap ligand. These complexes are air and moisture stable and readily dissolved in common organic solvents. Conductance values in CH_3CN and C_2H_5OH did not show dissociation into ionic species [13]. No molecular ion peak corresponding to the dinuclear nickel species [{Ni(S-dept)(SCN)$_2$}$_2$] (*m*/*z*, 966) was observed in the FAB mass spectrum of **1**. However, some structurally important nickel containing ions were observed (see Section 2). Instability of M^+ ion may be attributed to the facile loss of 2 moles of $(NCS)_2$; the driving force for the formation of [Ni$_2$(S-dept)$_2$] may be the formation of Ni–Ni bond. Thermal analysis (TGA) of complex **1** in air shows that the weight loss of 27.0% between 230 and 320 °C corresponds to the removal of $(SCN)_2$ and ethylene. On heating above 320 °C, it loses the entire organic mass to yield NiO. TGA of **2** did not show the formation of any stable intermediates. The complex on heating above 60 °C loses all the organic components to yield a stable residue of NiO at 680 °C. The μ_{eff} values at 300 K for **1, 2** and **3** (per Ni atom) are 2.98, 2.82 and 2.88 μ_B, respectively. The magnetic moment of **1** was measured over the temperature range 300–34 K[1] (Fig. 1). The $\chi_M T$ value is almost constant (2.205 cm^3 mol^{-1} K) in the range 300–200 K. Below this temperature, $\chi_M T$ decreases slowly to 2.006 cm^3 mol^{-1} K upto 100 K. Between 100 and 34 K, it decreases to 1.326 cm^3 mol^{-1} K. This behaviour suggests the presence of weak antiferromagnetic interactions. The equations for dimers with two $S = 1$ metal ions (as is the case for dinuclear Ni compounds) is

[1] Due to lack of facilities measurements could not be extended below 34 K.

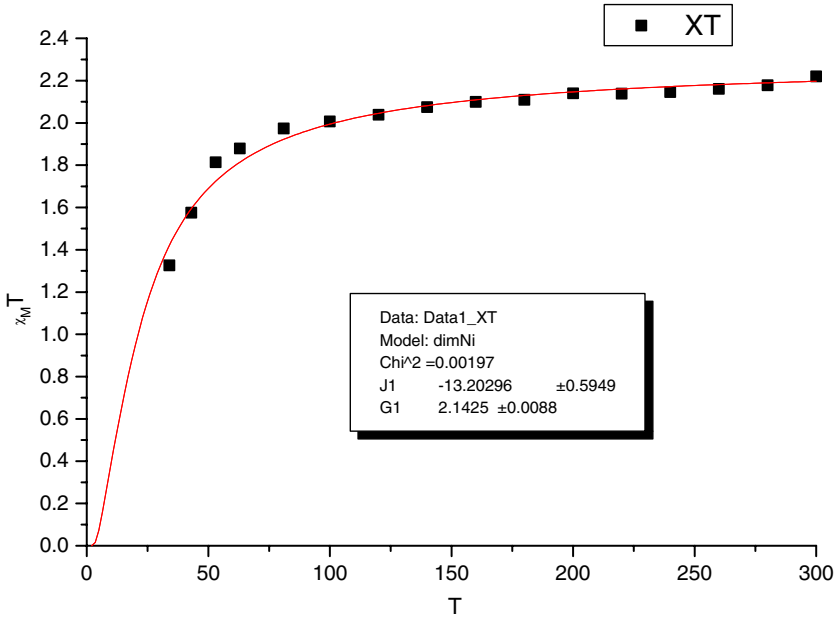

Fig. 1. Showing the variation of $\chi_M T$ with T for complex **1**.

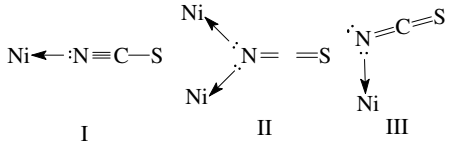
derived from Van Vleck's equation and, by using the spin hamiltonian, $H = -JS_1 \times S_2$, it takes the following form: $\chi T = (Ng^2\beta^2/k)[(2\exp(x) + 10 \times \exp(3x))/(1 + 3\exp(x) + 5\exp(3x))]$, where $x = J/kT$, k being the Boltzman's constant, and J the magnetic coupling constant (in cm^{-1}). The results of the best fit, shown

as the solid line in Fig. 1, were $J = -13.203 \pm 0.595$ cm^{-1}, $g = 2.142 \pm 0.009$.

3.1. Spectroscopic properties

3.1.1. IR spectra

Complex **1** shows two distinct ν(CN) modes for the NCS^- group, at 2087 and 2007 cm^{-1}. The higher frequency band is assigned to the N-bonded terminal thiocyanate group [14], and the lower frequency band at 2007 cm^{-1} strongly indicates the presence of N-bridging thiocyanate ligand joining the two nickel centres. This unusual bridging mode of thiocyanate ligand has been observed for a very limited number of complexes which are listed in Table 3 [15–19]. The position of the C–S stretching frequency in the region 860–690 cm^{-1} is usually employed for differentiating S-bonded from N-bonded terminal thiocyanates [14,20]. However, the ν(CS) modes are obscured by ligand bands in this region which made assignment of the C–S stretches quite uncertain. The peaks attributed to ν(CN) are not perturbed in its solution spectrum thus suggesting that the solid state structure is retained in $CHCl_3$ solution. Complexes 2 and 3 show a single band in the ν(CN) region, at 2092 and 2100 cm^{-1}, respectively, which are assigned to the N-bonded terminal NCS ligands. The carbonyl stretching frequency which appears at 1625 cm^{-1} in the free ligand is shifted to 1600 cm^{-1} suggesting carbonyl coordination to metal centre.



3.1.2. Visible spectra

Complexes **1**–**3** show a close resemblance between absorption in methanol and their reflectance spectra suggesting that the same geometry is retained by the metal ion on dissolution. Complex **1** exhibits three distinct absorption bands at 406, 661 and 1090 with a shoulder band at 738 nm. Similar spectra are observed for **2** and **3**with bands at 390, 670 (sh), 742 and 1080 and 370 (sh), 664, 728 and 1080 nm, respectively. Assuming Oh symmetry for the Ni ions in these compounds, the bands may be assigned to the spin allowed d-d transitions $^3T_{1g}(P) \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ and $^3T_{2g} \leftarrow {}^3A_{2g}$, respectively. The band at about 730 nm may be a consequence of the transition to the ^1E_g level gaining intensity through configurational interaction with the $^3T_{1g}(F)$ level.

3.2. Crystal structures of complexes *1*–*3*

3.2.1. Complex *1*

Crystallization of **1** from ethanol or acetonitrile by slow evaporation of its saturated solution at room temperature afforded good single crystals of $[Ni_2(\mu\text{-}NCS)_2(S\text{-}dept)_2(NCS)_2]$. The bond lengths and angles are listed in Table 2. The complex is a centrosymmetric dimer (Fig. 2). It consists of two distorted octahedrons, one about each Ni^{2+}, which share an edge, formed by the N atoms of the bridging NCS ions. The remaining sites are occupied by two S and one N atoms from the tridentate chelating ligand and from a N atom of the terminally bonded thiocyanate ion. The bond angles around Ni^{2+} are close to that of an ion in an octahedral environment. Both Ni–S bonds are equal and trans to each other. The three M–N bonds in the xy plane are equal with an average M–N distance of 2.028(7) Å. The four nitrogens N1 N4 N5 and $N4^i$ (where i = $-x$, $-y$, $-z + 1$) are almost planar with a deviation of 0.016 Å from a least square plane. The M–N bond lengths for the bridging NCS ligands are Ni–N4 2.022(7) and Ni–$N4^i$ 2.396(8) Å, respectively. This shows that NCS is behaving as an unsymmetrical bridging bidentate ligand through N. The bridging NCS ligands are perpendicular to Ni–Ni^i axis with Ni–N–Ni^i angle of 96.9° (**3**). Ni–Ni distance is 3.316(8) Å, which indicates the absence of any metal–metal bond. Both bridging and terminal NCS ligands are almost linear with small differences in their respective bond distances and angles. The bonding parameters of the terminal NCS ligand fall well within the range generally observed in the literature [15–19,21]. The short N–C distance [N(5)–C(17), 1.151(12) Å] corresponds with structure **I**. The C–S bond distance [C(17)–S(4), 1.631(12) Å] is shorter than the C–S(sp^3) bond distance (1.81 Å) but is close to C=S bond distance (1.61 Å) as given by Pauling [22]. However, it falls well within the range 1.588(13)–1.689(13) Å found for terminally bonded covalent NCS group. The terminal M–NCS linkages in this complex are bent with M–N–C angle 170.8° (8) which fall in the range (141–174°) found for Ni^{2+} having bent terminally bonded NCS anions [6b]. Ni–N5–C17–S4 torsion angle is 15.1°. This non-linearity has been attributed to the steric effects [23] and indicates more electron density localization on N so that **II** becomes the major contributing resonance structure for NCS anion [24].

The C–S bond length [C(16)–S(3), 1.606(10) Å] of the bridging NCS ion is more closer to C=S and is in conformity with structure **II**. As already known [14] this also accounts for the two lone pairs on N atoms directed at the metal ion and the linearity of the group, however, N–C bond [N(4)–C(16), 1.145(10) Å] remains too short to be a double bond. This short N–C bond may be due to inductive effect, which results due to greater flow of electron density from the C–S bond through the C–N bond towards metal ion, as shown in **III**. Bridging through N requires M–NCS linkages to be essentially

had two equal Re–N bonds with Re–Re bond (Table 3). However, Cd^{II} complex contained slightly different M–N bond lengthsand no M–M bond [16]. In the case of Ni^{2+} this type of bonding has been reported for five complexes [17–19] all of them showed bidentate bridging through N of the NCS anion with Ni–Ni distance ranging between 2.993(1) and 3.39(1) Å. In the present complex, the two M–N bond lengths are significantly different from each other and the shorter Ni–N4 distance is comparable to Ni–N5 distance of the terminally bonded NCS anion. Thus the present complex becomes the first example to show maximum asymmetry in bidentate bridging through N atom of the NCS anion. No M–M bonding has been found in the case of any of the Ni^{2+} complexes yet the M–M distance seems to be dependent upon M–N–M (Table 3).

3.2.2. Complex *2*

Crystallization of $[Ni(NCS)_2(O\text{-}deap)(CH_3CN)]\cdot CH_3CN$ by slow evaporation of its saturated solution in acetonitrile at room temperature yields good single crystals. Fig. 3 displays the ORTEP diagram of **2** which crystallizes in $P2_1$ space group with 2 molecules per unit cell. The coordination around the Ni atom can be best described as octahedral as can be ascertained from the bond lengths and angles (Table 2). However, contrary to the expected value in an octahedral geometry, one of the *trans* ligand–metal–ligand angle is not 180° but deviated to a value of 154.3° (O1–Ni1–O2). This apparent deviation from the ideal value may be attributed to the geometrical constraints of O-deap acting as a tridentate meridonal ligand. The two thiocyanate ligands show a marked difference of approach towards the metal coordination polyhedra. While one of the SCN moiety (i.e., S1–C18–N5, Fig. 3) that is placed parallel to O-deap, approaches the metal almost in a nearly linear arrangement (C18–N5–Ni1 = 178°), the other thiocyanate ligand (i.e., S2–C19–N6, Fig. 3) which is approaching orthogonal to the former is substantially deviated from linearity, the C19–N6–Ni1 angle being 162.7°. Nevertheless, their coordinating strengths are almost same as reflected from their almost equal Ni–N bond lengths of 1.995 and 2.043 Å. It is also noteworthy that this type of subtle deviations can modify the geometry around the metal centre. For example, the two five membered rings formed out of the two carbonyl to the metal centre (⩾C=O1···Ni1 and ⩾C=O2···Ni1, Fig. 3) are not placed parallel, but have taken a wedge shape with a wedge angle of 3.7° (angle between the least square planes of these two five membered rings). Similarly, the planar pyridyl moiety is also bent with respect to these rings, the angle between the planes of aromatic pyridyl moiety and the five membered ring involving O1 (i.e., N1, Ni1, O1, C6 and C1) is 11.6° and that with the other ring containing O2 (i.e., N1, Ni1, O2, C11 and C5) is 14.2°. These type of variations, most probably are not only controlled by electronic effects alone, but also

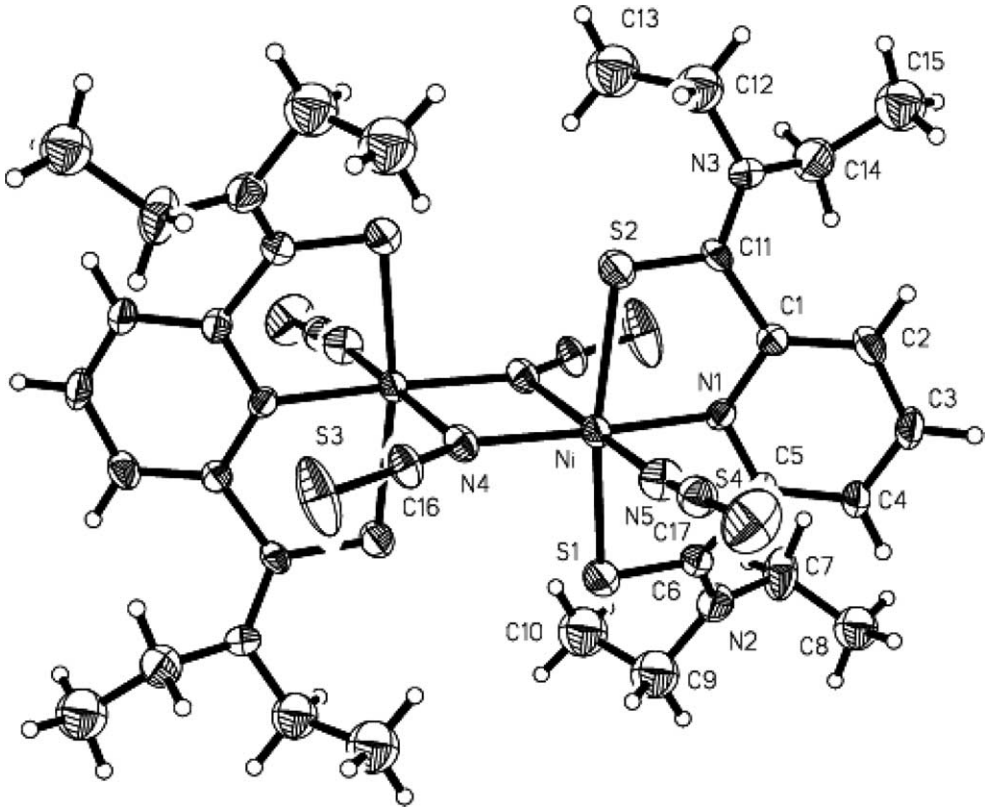

Fig. 2. A perspective view of complex **1** with the atom numbering scheme (thermal ellipsoids are at 50% probability level).

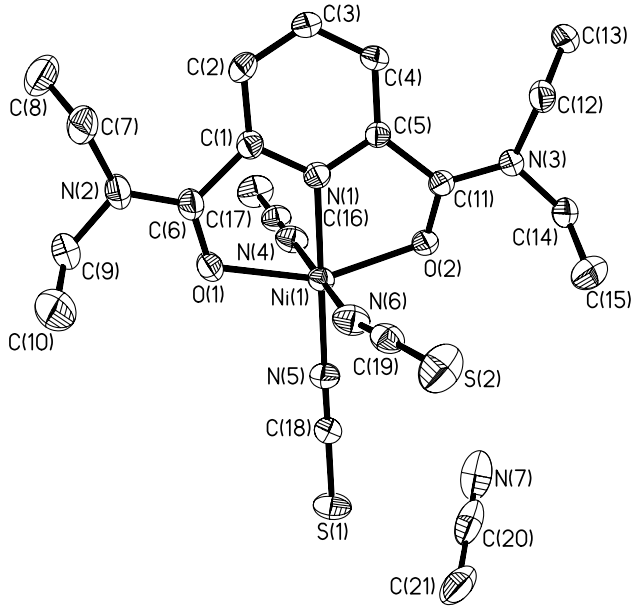

Fig. 3. A perspective view of complex **2** with the atom numbering scheme (thermal ellipsoids are at 50% probability level).

by the subtle steric requirements that are needed for a stable lattice. Such effects which minimize the overall steric congestion are reflected even in the 'coordinating arms' of the ligand. The symmetrically positioned ethyl part of the arms on both sides are placed one 'up' and one 'down' with respect to the meridonal plane of the ligand as evidenced from Fig. 3. The two terminal methyl groups (C10 and C15) that are closer to the coordinating oxygen atoms are 'up' while the other two (C8 and C13) which are away from these oxygen atoms are 'down' (the sense of up and down is with respect to the planar meridonal ligand plane when viewed parallel to Ni(1)–N(1) vector). The sixth coordination of the octahedral geometry is completed by the solvent of crystallization (CH_3CN) itself and its reduced Lewis basicity compared with SCN^- (and hence the weaker coordinating ability) is clear from the higher Ni–N bond length of 2.141 Å. However, the approach towards the metal centre is almost linear, the Ni1–N4–C16 angle being 177.5°.

The role of solvent used for crystallization is twofold in stabilizing the metal ligand complex. Firstly, it completes the coordination around the metal center and imparts stability and secondly, during the packing of molecules in the lattice, the voids generated are filled by these solvent molecules again providing overall stability to the three-dimensional lattice. Packing of this acetonitrile lattice inclusion complex is shown in Fig. 4. Two 'arms' of the neighbouring ligand molecules and the methyl group of the coordinating CH_3CN together generates a cavity and the CH_3CN molecules are occupied in these centres. The stability to this inclusion is imparted through two weak C–H···N interactions of the nitrogen atom of CH_3CN (N7···H12A–

Cl2 = 2.704 and N7···H17C–Cl7 = 2.798 Å) and the other is through a C–H···S interaction of the methyl group of CH_3CN (S1···H21A–C21 = 3.152 Å) and sulphur atom of the thiocyanate moiety. In effect a linear CH_3CN molecule is anchored from both of its terminal ends to the center of the cavity through C–H···N and C–H···S interactions involving the solvent and metal ligand complex. In addition there are three lattice stabilizing C–H···S interactions (involving sulphur atoms of SCN^- moiety) observed in the lattice, S2···H9A–C9 = 2.885, S2···H7A–C7 = 2.922 and S1···H13A–C13 = 3.080 Å.

3.2.3. Complex 3

The structure of **3** obtained after recrystallization in ethanol, is presented in Fig. 5. The coordination around the Ni atom in **3** is also distorted octahedral (Table 2). The difference of 4.3° in the O–Ni–O angle in **2** (154.3°) from **3** (150.0°) shows that O-deap ligand can adopt to subtle geometrical requirements during the complex formation. However, to meet the steric demands, the pyridyl part of O-deap has to undergo a substantial bend from the mean plane of the two five membered rings formed out of the coordination to Ni atom (Fig. 5), the angle being 21.8°. It is interesting that the same deviation in **2** is only 12.7 showing that change in the coordination from acetonitrile to ethanol can have profound influence in the overall topology of the metal ligand complex. As in **2**, the two five membered rings are also wedge shaped, infact the wedge angle has increased to 5.5°. The approach of the two thiocyanate ligands is very similar to that of **2**, the one in the plane of the ligand is linearly placed with respect to the metal (C16–N4–Ni1 = 174.2°), whereas the other orthogonally placed one makes an angle of 163.2° (C17–N5–Ni1). The coordinating arms of the ligand have a very similar up and down conformation as in **2**.

Participation of the amide nitrogen in the coordination process through amide resonance is evident from the very planar nature of N atoms of both **2** and **3** (sum of the angles around nitrogen is 359.8° (**2**) and 359.6° (**3**), respectively). This type of resonance would facilitate more charge on the carbonyl oxygens for better participation in metal–ligand coordination. It is noteworthy that the major difference in the octahedral coordination of Ni in **2** and **3** is that the acetonitrile in **2** is replaced by an ethanol molecule in **3**. Out of the six octahedral metal–ligand bonds in **2**, it is the Ni–N(acetonitrile) that is the longest (2.141 Å, Table 2). However, since enhanced Lewis basicity can be expected for the oxygen atom of ethanol (than that of the nitrogen atom of CH_3CN), the Ni–O(ethanol) is no longer the highest and is reduced to 2.078 Å. In fact it is the shortest among the three Ni–O bonds in **3** (Table 2).

We hypothesised that the sixth coordination of compound **2** can be replaced, if a solvent of similar size (but with equal or higher Lewis basicity) can be used for crystallization. Another motivation was to examine the role

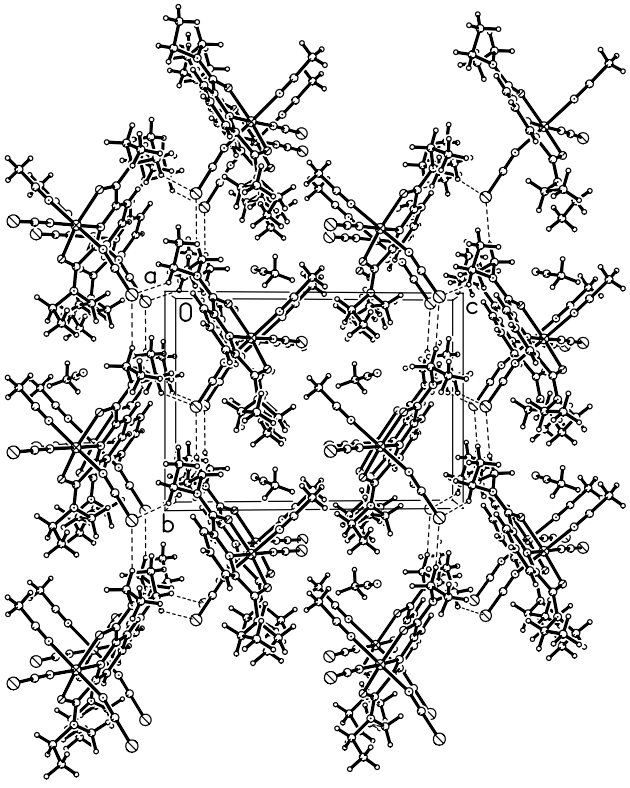

Fig. 4. Packing of complex **2** viewed perpendicular to the *bc* plane.Note the occpancy of solvent acetonitrile (right to the middle of unit cell) in the cavity formed from the arms of the ligand and the methyl group of coordinated CH_3CN. The lattice stabilizing C–H···S interactions are shown by dotted lines.

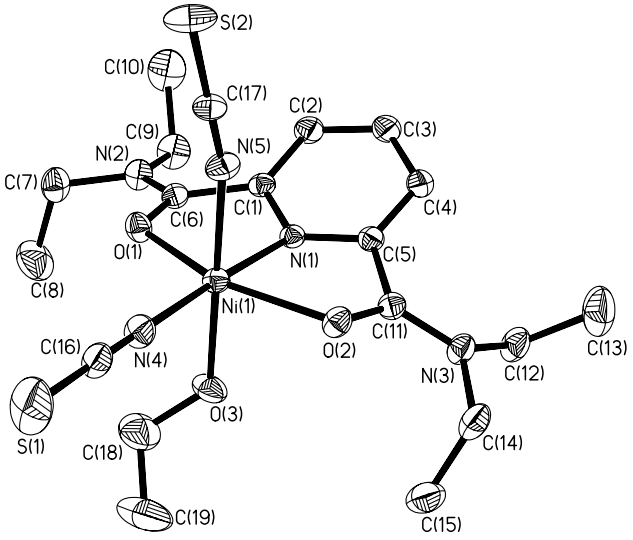

Fig. 5. A perspective view of complex **3** with the atom numbering scheme (thermal ellipsoids are at 50% probability level).

of solvent in stabilizing the three-dimensional lattice, after all, does the solvent play a deciding role in the lattice formation? If so, the compound would display polymorphism, which is of contemporary interest [25]. Ethanol was conceived as appropriate solvent as it satisfies both the condition of size and Lewis basicity. Gratifyingly, compound **3** was successfully crystallized from absolute ethanol with an ethanol occupying the sixth position in the octahedral coordination. But interestingly no solvent of crystallization was included in the lattice and the molecular packing is significantly different from that of **2**. A packing diagram viewed down the *ab* plane is shown in Fig. 6.

In the lattice, one of the thiocyanate groups (i.e., S1–C16–N4) is involved in a lattice stabilizing C–H···S interaction (C10–H10A···S1 = 2.835 Å) whereas the other one (i.e., S2–C17–N5) is hydrogen bonded to the hydrogen atom of the coordinated ethanol (O3–H3A···S2 = 2.431 Å) through a O–H···S hydrogen bond. Thus, as in **2** both the thiocyanate groups are involved in S–H···O/C interactions. In addition, the hydrogen atom at the para position of the pyridyl moiety also takes part in a C–H···O hydrogen bond with one of the carbonyl oxygen atoms (C3–H3B···O2 = 2.448 Å). Thus, our initial hypothesis of obtaining a complex in which the replacement of an acetonitrile with ethanol was realized, but the lack of inclusion of ethanol as a solvent of crystallization amply displays the complex interplay of weak interactions in stabilizing the three-dimensional lattice of these molecules. These observations show that, at molecular level certain predictability can be realized, but the nature of molecular packing is still a complex process to comprehend and indeed it is one of the challenges in crystal engineering [26].

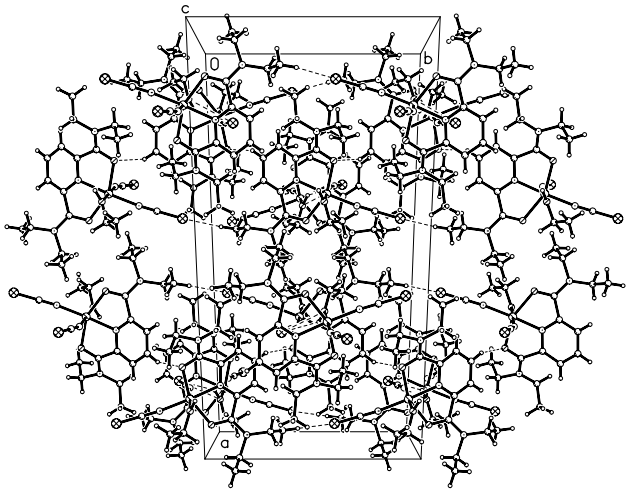

Fig. 6. Packing of complex **3** viewed perpendicular to the *ab* plane. The lattice stabilizing C–H···S interactions are shown by dotted lines.

Acknowledgements

We sincerely thank Professor Rabindranath Mukherjee for his kind help with low temperature magnetic susceptibility measurements on complex **1**. A.K. is grateful to CSIR, New Delhi, India for senior research fellowship.

Foreword

Polyhedron Symposia-in-Print, number 27 *Ansa* metallocenes and related compounds

It is well known that the incorporation of substituents on cyclopentadienyl rings may have a profound effect on the reactivity of metallocene compounds by varying both the electronic nature and steric environment of a metal center. In particular, an important class of ring-substituents is one that links the two cyclopentadienyl groups together. Such complexes are called *ansa* metallocenes, a term that is derived from the Latin word *ansa*, meaning "bent handle, attached at both ends". The interest in *ansa* metallocenes stems from the ability of the bridge to displace the cyclopentadienyl rings from their natural positions and thereby provide an additional influence on reactivity. Closely related to *ansa* metallocenes are "half-sandwich" counterparts in which the bridge is between a cylopentadienyl ring and another donor group. Certain molecules in this class have been dubbed "constrained geometry catalysts" because of their excellent ability to catalyze olefin polymerization. The purpose of this Symposium-in-Print is to highlight recent advances pertaining to these *ansa* metallocene and "constrained geometry" systems.

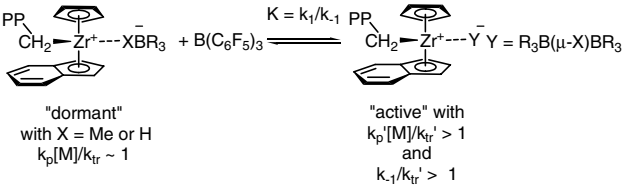
apolar media in which typical polymerization reactions are conducted.



As activity is correlated with the weakness of this interaction, the search for less coordinating anions has focused on dinuclear anions in which two group 13 atoms are linked via an anionic bridge [5]. Some of these dinuclear activators give rise to extremely active catalysts where polymer tacticity is subtly affected by the nature of the counter-anion [5a]. It is therefore interesting to consider the possible role of such species in olefin polymerization using mononuclear activators [5a] particularly when in situ alkylation using aluminum alkyls and activation with such compounds is employed [6]. It is known that aluminum alkyl scavenging agents degrade activators such as $B(C_6F_5)_3$ and $[Ph_3C][B(C_6F_5)_4]$ [7], and it is therefore not always clear as to the nature of the active species produced under these conditions, depending on activation protocol [8].

Recent studies on 1-hexene polymerization using [*rac*-en(Ind)$_2$ZrMe][MeB$(C_6F_5)_3$] in the absence of additives such as alkyl aluminum compounds indicate that excess $B(C_6F_5)_3$ activator has no effect on the kinetics of initiation and propagation [2h]. However, when using $Al(C_6F_5)_3$, pronounced effects on catalyst activity were noted when using two versus one equivalent and various metallocene or constrained geometry catalysts [9]. This was attributed to "double-activation" of the catalyst precursor, based on the X-ray structure of $[Me_2Si(Ind)_2Zr][MeAl(C_6F_5)_3]_2$, although an alternative explanation based on transient formation of $[Me_2Si(Ind)_2ZrMe][(C_6F_5)_3Al(\mu\text{-Me})Al(C_6F_5)_3]$ [9] featuring this more weakly coordinating di-aluminate counter-ion [10] was not excluded. It should be noted in this regard that a related dicationic complex, $[(^tBu_3P{=}N)_2Ti][MeB(C_6F_5)_3]_2$, is *inactive* in olefin polymerization at least in polar media [11]. More recently, the use of excess $[Ph_3C][B(C_6F_5)_4]$ has been reported to significantly increase the rate of a number of metallocene-catalyzed propene polymerizations; only a portion of this activation has been attributed to an increase in active site concentration [12].

(1)

During the course of some mechanistic work involving the activation of $Me_2X(Cp)IndMMe_2$ (**1**; X = C or Si, M = Zr, Eq. (1)) using $B(C_6F_5)_3$ [3c] we had encountered poor reproducibility in propene polymerizations initiated by the ion-pairs that were *pre-formed* using a B:Zr ratio of 1.0–1.2:1 in the presence of the weakly interacting scavenger $MeAl(BHT)_2$ [5e]. Subsequent work has revealed that the steady-state rate of polymerization and rate of initial monomer insertion of these sterically open, metallocene catalysts is very sensitive to the B:Zr stoichiometry used to form these ion-pairs [13]. The enhanced rates of initiation were interpreted as involving double-activation [9] of the ion-pairs **2a**–**b** [3c] formed from **1a** and $B(C_6F_5)_3$, whereas the effect of excess borane on propagation rates were postulated as arising from two forms of the catalyst differing significantly in their polymerization activity, in equilibrium with one another in the presence of excess borane (e.g., Eq. (2)).

(2)

In this paper, we report that the nature of the Zr-containing by-products formed following consumption of monomer is also sensitive to the initial B:Zr stoichiometry used to form these ion-pairs, and possible interpretations of enhanced propagation rates in the presence of excess borane.

2. Results and discussion

2.1. Propene polymerization and reaction of ion-pairs *2a–b* with propene

As shown in Fig. 1(a), the rate of initial propene uptake using catalyst **1a** (X = C, M = Zr) is strongly increased in the presence of excess borane. Moreover, the steady-state rate of propene consumption is also affected in a similar manner. Thus, an excess of borane appears to increase *both* initiation and propagation rates in a qualitatively similar manner. Additional experiments revealed that this effect is observed on addition of excess borane to a catalyst producing polymer after initiation has occurred. Similar behavior is also observed for catalyst **1c** (X = Si) or for C_s-symmetric catalyst $Me_2C(Cp)FluZrMe_2$ [13].

These polymerizations involved pre-contacting the dialkyl with the borane in a small volume of toluene prior to introduction into the reactor saturated with monomer and containing an excess of the scavenging agent $MeAl(BHT)_2$ and small quantities of $AlMe_3$. While it is tempting to attribute this unexpected behavior to the conditions employed, control studies have shown that there is no reaction between the catalyst components (or the derived ion-pairs) and this scavenging agent [3c] nor its degradation product BHT [14] at least on the time scale of these polymerization

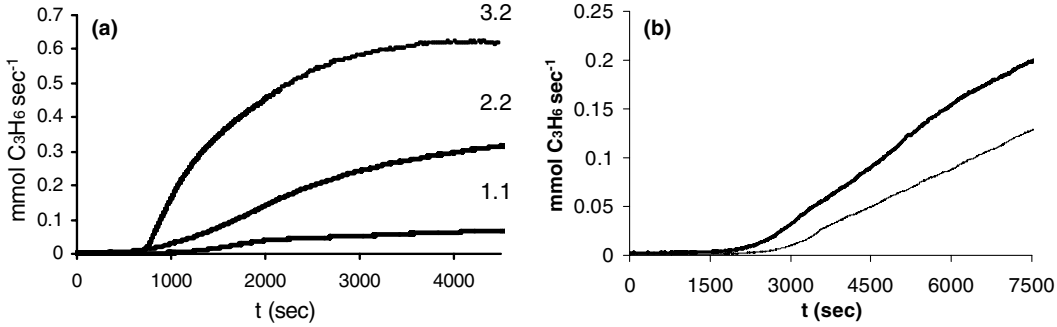


Fig. 1. (a) Propene consumption vs. time for zirconocene **1a** (40 μM) activated by 1.1–3.2 equiv. of $B(C_6F_5)_3$. The induction period observed prior to monomer uptake corresponds to the consumption of dissolved propene so as to produce a pressure drop across the mass flowmeter. (b) Initial rate of monomer uptake using hafnocene **1b** (40 μM) and 3.0 vs. 1.1 equiv. of $B(C_6F_5)_3$.

experiments. Moreover, the activity of Hf analogue **1b** is less affected in the presence of excess borane (Fig. 1(b)), supporting our contention that the observed behavior is intrinsic (i.e., correlated with M–C versus B–C bond strengths), rather than an artifact of the experimental conditions.

With complex **1a**, the microstructure of the PP formed was insensitive to changes in B:Zr stoichiometry over the range studied (1.1:1–70:1), while the MW of the oligomers formed, as judged by the intensity of signals due to vinylidene end groups, increased in the presence of excess borane. The former finding tends to suggest that the nature of the species that is producing polymer is unaffected in the presence of excess borane – there is simply "more" of it.

The change in MW could be consistent with this hypothesis provided excess borane indirectly affects the relative rates of chain-transfer (via β-H elimination with first order rate constant k_{tr}) to propagation (with second order rate constant k_p) as suggested in Eq. (2) [13]. It is easy to show that if the k_p/k_{tr} characteristics of each catalyst state are sufficiently different, and that the rate of isomerization from the more active to the less active state is faster than the rate of chain transfer from the

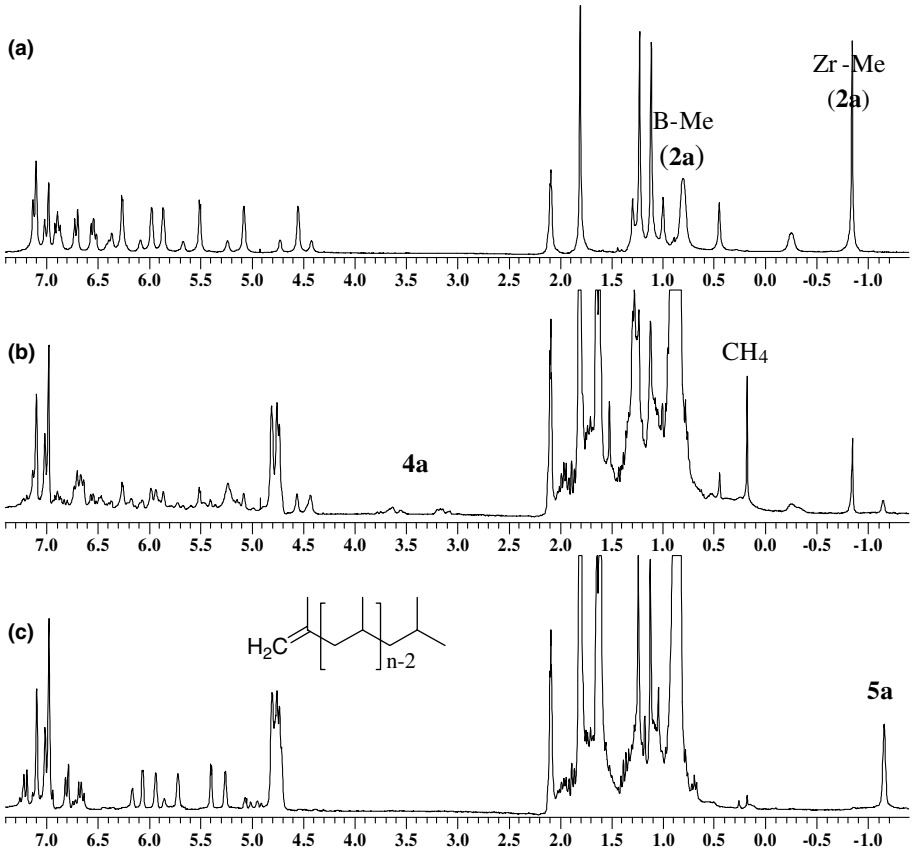

Fig. 2. ^1H NMR spectra (300 MHz, toluene-d_8) of (a) ion-pairs **2a**–**b**, and following the addition of 10.0 equiv. of propene in the presence of (b) 0.0 and (c) 0.2 equiv. of excess $B(C_6F_5)_3$.

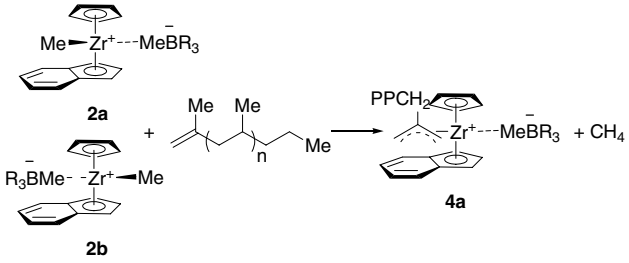


former, the MW of the polymer formed will be dictated by the k_p/k_{tr} characteristics of the less productive state when present in significant quantities at equilibrium [15].

As expected, saturation behavior is observed on the steady-state rate of polymerization as a function of excess borane using both this catalyst and $Me_2C(Cp)FluZrMe_2$ [13] but the interpretation of this observation is rendered difficult in that the chemical nature of both the dormant and active states during propagation is actually unknown as suggested in Eq. (1). In addition, it is not known whether the active state reverts to the dormant state following each insertion; certainly the value of K that was estimated by assuming it *remains* in the active state is sufficiently large (10^4 M^{-1}) so as to suggest to former scenario is likely.

We also examined the reaction of ion-pairs **2a**–**b** (M = Zr, Eq. (1)) and **3a**–**b** (M = Hf) prepared at ratios of 1.0 and 1.2 B:M with fixed amounts of propene using both ^1H and ^{19}F NMR spectroscopy in C_6D_6 at 25 °C. As shown in Fig. 2, it is evident that the isomeric ion-pairs formed from **1a** and 1.2 equiv. $B(C_6F_5)_3$ (Fig. 2(a)) are consumed on addition of 10.0 equiv. of propene (Fig. 2(c)) whereas they are still present in significant amounts when 1.0 equiv. of borane is used (Fig. 2(b)). While mass-transfer effects are undoubtedly important in these NMR experiments, it is clear that there are detectable differences given this limitation.

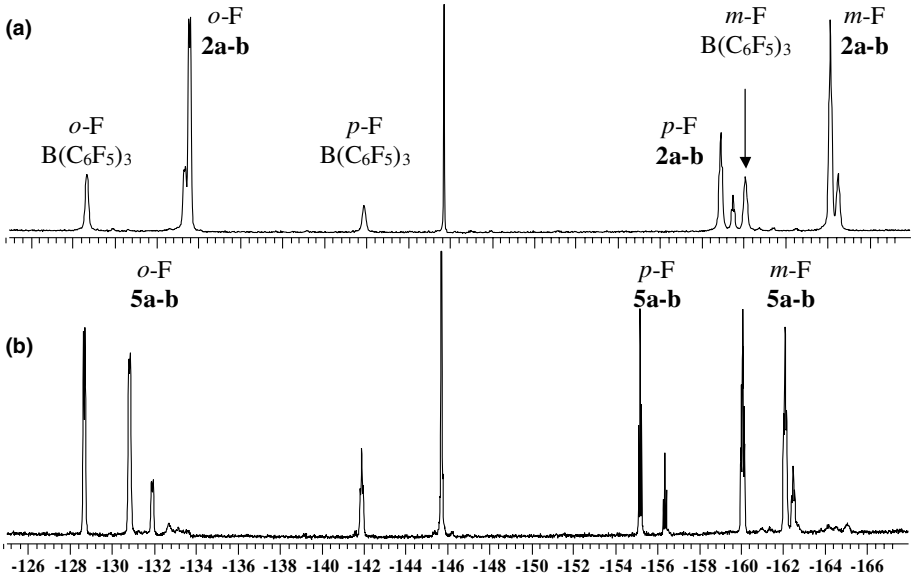
It is also evident from Fig. 2 that the nature of the by-products formed following consumption of monomer is also sensitive to B:Zr stoichiometry. In particular at a 1:1 stoichiometry, significant quantities of methane are produced and multiple signals appear in the region between 3 and 4 ppm (Fig. 2(b)). On monitoring this mixture for extended periods of time at room temperature, it became evident that methane was being produced as ion-pairs **2a**–**b** were being consumed by reaction with the unsaturated (and soluble) oligomers that form under these conditions.

The nature of the complexes formed was not immediately evident from the spectroscopic data, but given extensive literature precedent for allylic C–H activation of olefins to form stable or transient π-allyl complexes [16], it seemed likely that oligomeric π-allyl complexes **4a** were being produced (Eq. (3)). We will demonstrate that this is indeed the case (vide infra).

(3)

2.2. Formation of borohydride complexes 5 and 6 in the presence of excess borane

In the presence of excess borane, very little methane is detected while two complexes **5a**–**b** are produced (Eq. (4)). The major isomer **5a** features a broadened Zr–Me resonance at −1.2 ppm (Fig. 2(c)), while two sets of resonances are observed in the ^{19}F NMR spectrum of the mixture (Fig. 3). Although the reaction is relatively clean, attempted isolation of these complexes invariably resulted in their decomposition. In concentrated solu-



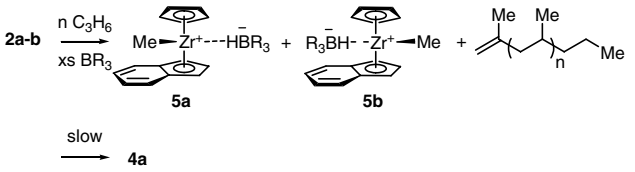


Fig. 3. ^{19}F NMR spectra (282 MHz, toluene-d_8) of (a) ion-pairs **2a**–**b** and 0.2 equiv. of excess $B(C_6F_5)_3$ and (b) following the addition of 10.0 equiv. of propene. All of the signals in (a) are line-broadened due to borane-mediated exchange of isomers **2a** and **2b** [3c,13].

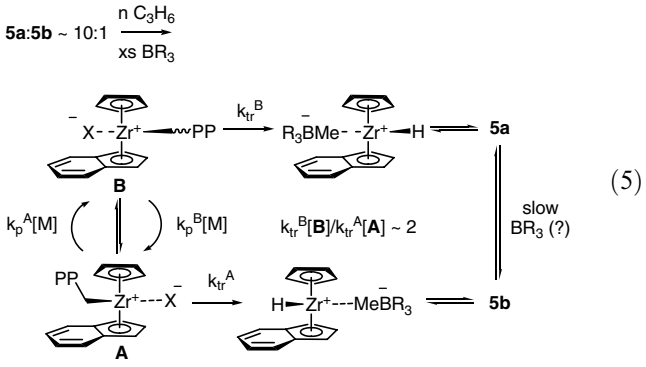

tion these complexes are also reactive towards the unsaturated oligomers present in these mixtures and the products are analogous to those formed from **2a**–**b** (vide infra).

(4)

Depending on how much propene was initially added, and the Zr:B stoichiometry, the relative amounts of these two complexes varied. The minor complex **5b** tended to form in lower amounts when adding small quantities of propene at lower ratios of B:Zr but not in a manner that was easily explained due to the presence of unreacted ion-pairs **2a**–**b** under these conditions. We have since discovered that if sufficient propene is added initially so as to consume all of **2a** and **2b**, that the equilibrium ratio of **5a**:**5b** (ca. 10:1) changes to about 2:1 on addition of more monomer while added oligomer is produced (Fig. 4). In the absence of monomer, this ratio then reverts slowly to the equilibrium ratio by a mechanism which must involve ion-pair reorganization [1b], possibly assisted by excess borane [3c].

In essence, as suggested in Eq. (5), the processes of re-initiation involving **5a**–**b**, subsequent chain growth and chain transfer must afford the (unobserved) cationic hydrides in a 2:1 ratio, presumably via kinetically controlled β-H elimination from the isomeric, propagating ion-pairs **A** and **B**. These then rapidly isomerize (vide infra) to the borohydride complexes which eventually interconvert through an independent mechanism in the absence of monomer.

(5)

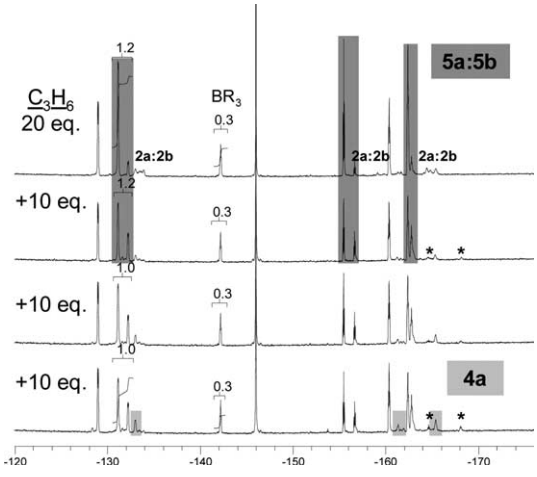

Fig. 4. ^{19}F NMR spectra (282 MHz, toluene-d_8) of ion-pairs **2a**–**b** and 0.2 equiv. of excess $B(C_6F_5)_3$ following the addition of 20 equiv. of propene, and then after three consecutive additions of 10 equiv. of propene. Signals due to borohydride complexes **5a**–**b** are highlighted in dark gray while those due to oligo-π-allyl complexes **4a** are highlighted in light gray. Faint signals marked with an asterisk are due to a weakly coordinating anion with $\delta\Delta \sim 3$ ppm. Tetrafluoro-*p*-xylene added as an internal standard.

The Hf analogues **3a**–**b** were also studied and qualitatively similar behavior was observed. Here, however, consumption of propene was considerably slower under otherwise identical conditions [see Fig. 5(a) (1)–(3)] and as would be expected the oligomers produced were of higher molecular weight. It is interesting to note that a complex **6** analogous to **5a** is present *during* monomer consumption [Fig. 5(a) (2)] and is the sole product present following completion of monomer consumption under these conditions [Fig. 5(a) (3) and Fig. 5(b) (3)]. Unlike its Zr counter-part, complex **6** could be isolated and purified as it was less reactive towards the oligomers produced. We do not know if this differential behavior is intrinsic or simply results from the lower end-group concentrations present [compare Fig. 5(a) (3) versus Fig. 2(c)].

Crystals of complex **6** could be grown from a mixture of hexane and benzene and the molecular structure of this complex is shown in Fig. 6, while crystallographic and refinement data, atomic coordinates and isotropic thermal parameters, and selected bond lengths and angles appear in Tables 1–3, respectively.[1] Complex **6** is an *ansa*-metallocenium ion partnered with a $(C_6F_5)_3BH$ counter-anion where the latter is interacting with the Hf through bridging H and F atoms. We believe this is the first structurally characterized example of this type of complex where the borohydride counter-anion is bridging rather than terminal.

The B–H distance at 1.24(4) Å is somewhat longer than that observed (1.06–1.21 Å) in other structures involving this counter-anion [17] while the Hf–H distance of 2.05(4) Å is only 14% longer than the sum of the single bond covalent radii. The characteristics of the Hf–H–B bridge are consistent with strong, directional bonding where the angle at H is close to linearity

[1] CCDC-257963 contains the supplementary crystallographic data for this structure. These data can be obtained free of charge via www.ccdc.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; or deposit@ccdc.cam.ac.uk).

Tetrafluoro-*p*-xylene added as an internal standard.

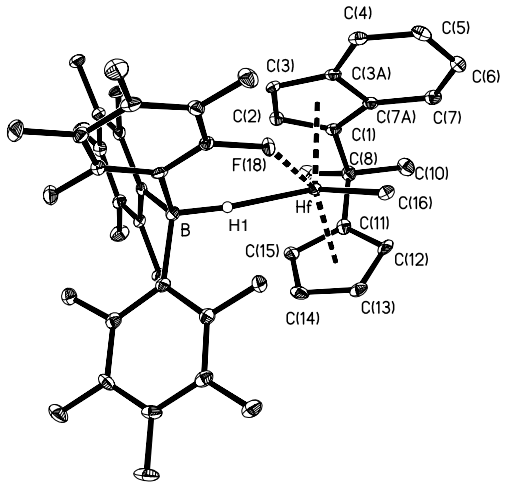

Fig. 6. Molecular structure of borohydride complex **6** with 30% thermal ellipsoids and H-1 depicted.

at 175(3)°. In contrast, the Hf–F interaction is relatively weak at 2.686(2) Å which is about 14% longer than *intramolecular* Zr–F contacts in zwitterionic structures featuring such interactions [2.237(4)–2.423(3) Å] [18], and is even longer than the *intermolecular* Zr–F contacts in $[Cp^*_2ZrH][HB(C_6F_5)_3]$ of 2.416(3) and 2.534(3) Å [17c].

In solution, both of these interactions are maintained. The bridging H atom resonates at δ 0.44 as deduced from the $^1H\{^{11}B\}$ spectrum, in agreement with NMR data reported by Sadow and Tilley [19] for $CpCp^*HfH(\mu\text{-}H)B(C_6F_5)_3$, whereas terminal B–H typically appear at 3–4 ppm in $(C_6F_5)_3BH$ complexes [17]. Furthermore, the Hf–Me signal appears as a line broadened septet at room temperature (J_{HF} = 2.2 Hz) consistent with a time-averaged structure in which all six *o*-F atoms of the counter-anion undergo rapid exchange between terminal and bridging positions. It was not possible to freeze out this process at lower T as has been observed with other complexes [18], consistent with the weakness of the Hf–F interaction observed in the solid state.

It should be noted that complex **6**, once formed, is relatively unreactive towards further insertion of propene. Complexes **5a**–**b** are also much less reactive towards monomer insertion than **2a**–**b** and thus formation of such species is a potential deactivation pathway, at least for complexes where this counter-anion can adopt a bridging mode as is documented here. A similar borohydride complex of unknown structure is produced following 1-hexene or 1-propene polymerization using $[rac\text{-en(Ind)}_2ZrMe][MeB(C_6F_5)_3]$ – it was reactive towards further insertion of propene or 2-methylpentene [2f].

2.3. Reaction of ion-pairs *2a*–*b* with isoalkenes

As mentioned previously, very little of complexes **5** form in the absence of excess borane. The reaction of unreacted ion-pairs **2a**–**b** with the unsaturated oligomers that form is considerably slower and requires about 120 min for completion under the conditions summarized in Fig. 2(b) with [Zr] = 0.025 M and $[C_3H_6]_o \sim 0.25$ M.[2]

[2] The initial end-group concentration is approximately 0.034 M based on integration of the vinylidene signals at δ 4.8 with respect to the Me group of **5a** at δ −1.2 in Fig. 2(c). A similar value can be assumed for the experiment in Fig. 2(b).

We chose to confirm the formation of π-allyl complexes **4a** through the synthesis of discrete complexes of this type using model alkenes. The reaction of ion-pairs **2a**–**b** with both isobutene and 2,4,4-trimethylpentene (TMP) were examined and in each case clean formation of allyl complexes **4b**–**c** was observed.

As illustrated in Scheme 1, complex **4b** is formed via two competing routes, one involving direct C–H activation and the other consisting of a single insertion of isobutene followed by C–H activation to produce neopentane and **4b** [16c]. As neopentane was formed in ca. 3× greater amounts than methane, we conclude that the second pathway is more favorable. With the more sterically hindered TMP only methane production was noted along with the chemoselective formation of **4c** arising from C–H activation at the 2-Me group of TMP.

In the case of complex **4b**, single crystals of this material were obtained by recrystallization from hexane–CH_2Cl_2 and the molecular structure of this compound appears in Fig. 7.[3] This structure features a distorted π-allyl ligand with Zr–C(18), Zr–C(17) and Zr–C(16) distances of 2.372(2), 2.552(2) and 2.598(2) Å, respectively, and a long Zr–C(19) contact of 2.800(4) Å to the counter-anion. The metrical parameters associated with the distorted π-allyl ligand are intermediate between those [2.356(3), 2.580(2), 2.651(2) Å] in the zwitterionic allyl complex [$Cp_2Zr(\eta^3$-2-Me-C_4H_5)–$B(C_6F_5)_3$] [18b], which features a strong Zr–F interaction [2.402(1) Å] in the solid state, and the methallyl complex $Cp^*[\eta^5$-$C_5H_4CMe_2CH_2B(C_6F_5)_3]Zr(\eta^3$-$C_4H_7)$ [16d] [2.412(10), 2.593(8) and 2.513(9)] which features a very long Zr–CH_2–B contact of 3.307(10) Å. Evidently, the interaction of the $MeB(C_6F_5)_3$ anion with the metal center in the present structure, although weak, is of comparable importance to the Zr–F interaction exhibited in the former structure in terms of the extent of distortion of the π-allyl ligand. In agreement with this interpretation, the ^{19}F NMR spectra of **4b** and **4c** in benzene-d_6 are characterized by a smaller separation between the *p*- and *m*-F resonances ($\Delta\delta_{p,m} = 4.5$ ppm) compared with ion-pairs **2a**–**b** ($\Delta\delta_{p,m} = 5.2$–5.4 ppm) but these values are much larger when compared with free $MeB(C_6F_5)_3$ anion ($\Delta\delta_{p,m} = 2.7$ ppm) [20].

The ^{1}H NMR spectra of these π-allyl complexes reveals three signals between 2 and 4 ppm and a single

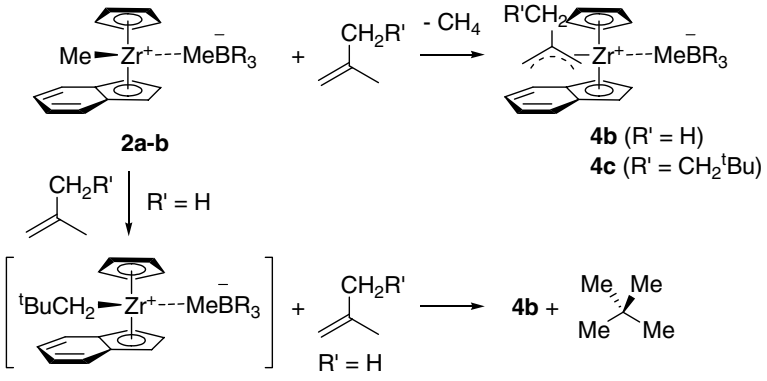
[a] Cp is the centroid of the cyclopentadienyl ligand in each structure.
[b] Ind is the centroid of five-membered ring of the indenyl ligand.

tons through a combination of 2D COSY, and NOESY spectra. These and other chemical shift assignments are summarized in Section 4. The high field signal is due to the allyl proton closest to the indenyl ring in complexes **4b**–**c**. It can be seen by comparing the spectrum of complexes **4a** and **4b** in bromobenzene-d_5 (Fig. 8) that there is a 1:1 correspondence between the ^{1}H signals of the latter with the former mixture of complexes. Multiple signals appear in the spectrum of the former, presumably due to a combination of stereoisomers (the oligomers are basically atactic and regio-irregular) and different chain-lengths being present.

Thus, there is little question that complexes **4a** possess the indicated structure and given the chemoselectivity observed in the formation of **4c** it seems likely that this C–H activation reaction also occurs predominantly at the Me carbon of the vinylidene end-group.



As mentioned previously, borohydride complexes **5a** and **5b** also (slowly) react with unsaturated oligomers in concentrated solution to produce π-allyl complexes **4a** and surprisingly, the counter-anion formed is not $HB(C_6F_5)_3$ but $MeB(C_6F_5)_3$ (i.e., the products are *identical*). This suggests that **5a**–**b** are in equilibrium with the corresponding cationic hydride complexes (Eq. (5) and Scheme 2) and the latter complexes are also reactive towards C–H activation.

By analogy to the reaction of **2a**–**b** with isobutene, it seems probable in this case that this process involves (reversible) insertion into Zr–H by one molecule of oligomer [2f] followed by C–H activation of a second molecule. However, we cannot exclude direct formation of **4a** with elimination of H_2 (this was not detected but could have been obscured by the Me resonances of the oligomers which form) as has been proposed to occur in propene polymerization using other metallocene catalysts [21,22].

3. Conclusions

As summarized above, in the presence of excess borane, initiation involving ion-pairs **2a**–**b** is efficient and the principal by-products are borohydride complexes **5** (or **6** in the case of Hf-analog **3a**–**b**). In the absence of excess borane, and with fixed quantities of propene, any unreacted ion-pairs undergo slow C–H activation to form π-allyl complexes **4**. Thus, the principal effect of having excess borane present is that initiation is increased relative to propagation [13] resulting in more efficient conversion of the starting ion-pairs to **5** and polymer or oligomer.

We do not view the C–H activation reaction of ion-pairs **2a**–**b** (or for that matter **5** which are less reactive – Scheme 2) with the oligomers produced as being very relevant to catalysis as this reaction is quite slow even at high catalyst concentrations (i.e., 120 min at 25 mM [Zr] and 34 mM $H_2C{=}CR_2$ groups for complete conversion of **2a**–**b**). One can estimate from this data that under conditions summarized in Fig. 1, even at $[H_2C{=}CR_2] = 0.2$ M (corresponds to about 50 g of 500 M_n polymer dissolved in 0.5 L of toluene), that this reaction would be ca. 100× slower (i.e., ~8 days for completion at 25 °C!).

Scheme 1.

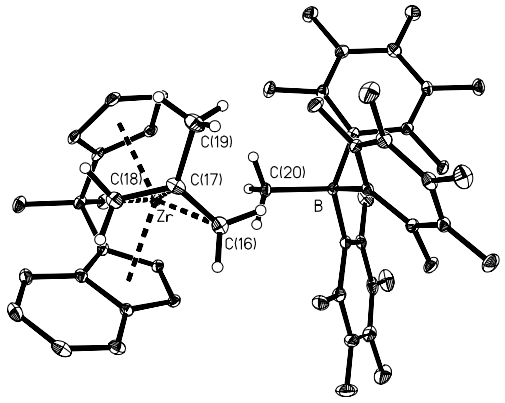


Fig. 7. Molecular structure of π-methallyl complex **4b** with 30% thermal ellipsoids and selected H-atoms depicted. The numbering scheme for the C-atoms of the *ansa*-ligand is the same as shown in Fig. 5.

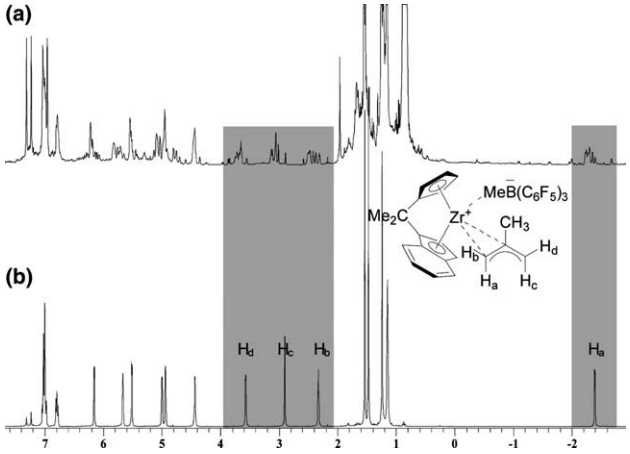

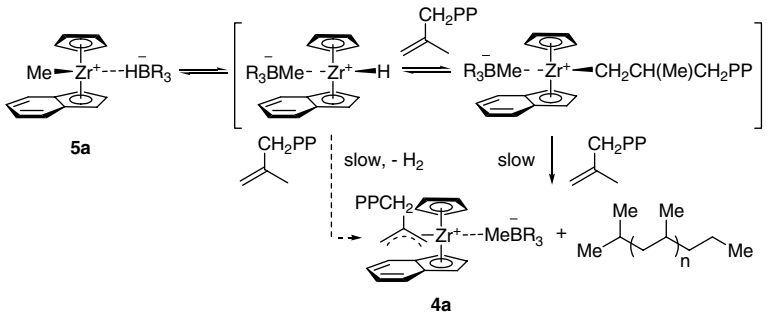

Fig. 8. ^{1}H NMR Spectra (400 MHz, C_6D_5Br) of (a) oligo-π-allyl complexes **4a** formed from ion-pairs **2a**–**b** and propene oligomers and (b) π-methallyl complex **4b** with selected ^{1}H assignments shown and highlighted in gray.

On the other hand, there is indirect evidence of this process occurring in propene polymerization using other metallocene catalysts [21,22] and it is known from model studies [16b] that these π-allyl complexes will undergo further insertion, although sluggishly compared with alkyls. Thus, it is possible that following chain transfer to metal (or to coordinated monomer) that this C–H activation reaction will be more competitive, as the unsaturated oligomer would be coordinated to the metal center [21,22] and direct C–H activation would furnish **4a** and either H_2 (or *n*-propane) as by-products.

It is difficult to reconcile this hypothesis with the observed product distribution here, as in both the presence and absence of excess borane, **5** is the principle product formed following chain transfer and the only volatile product detected is methane. Perhaps, in systems with more weakly coordinating counter-ions, or in sterically hindered metallocenes where formation of **5** is less favorable, this C–H activation reaction is more competitive.

Complex **6** and **5** are the products of chain transfer followed by isomerization (Eq. (5)). This intramolecular isomerization process has been examined theoretically using DFT and QM/MM techniques in a [bis(pyrrolide-imine)TiH][$MeB(C_6F_5)_3$] complex [23] and has a low barrier of 10 kcal mol^{-1} [24]. As we have suggested, and others have indicated with [$en(Ind)_2ZrMe$][$HB(C_6F_5)_3$] [2f], the process appears reversible with metallocene complexes. However, in the present case the equilibrium must be quite unfavorable (perhaps due to strong interaction of the counter-anion with the metal in **5** and **6**) since complexes **5**–**6** are relatively unreactive towards monomer insertion, and thus the formation of these complexes represents a reversible deactivation process. It is likely, following *initial* chain transfer in a reactor continuously supplied with monomer, that complexes **5** (or **6**) thus represent dormant states and that the function of excess borane in polymerizations involving **1** (or other catalysts of this type) is to reactivate species analogous to **5** towards insertion.

This could involve irreversible formation of [Me_2C(Cp)$IndZr(CH_2CHMe)_nR$][$MeB(C_6F_5)_3$], by analogy to the chemistry depicted in Scheme 2, where the $MeB(C_6F_5)_3$ anion is rendered less coordinating as a result of the high-

Scheme 2.

er alkyl group on the metal [2f]. Alternately, the species $[Me_2C(Cp)IndZrR][(C_6F_5)_3B(\mu\text{-}H)B(C_6F_5)_3]$, featuring a more weakly coordinating dinuclear anion [5] could form in situ as suggested in Eq. (2).

The latter counter-anion has not been reported before but does appear to form in situ from $[Bu_4N][(C_6F_5)_3BH]$ [25] and $B(C_6F_5)_3$.[4] A species with an ^{19}F NMR signature very similar to this anion is also present in trace quantities during consumption of propene by borohydride complexes **5a**–**b** (Fig. 4). However, the chemical shifts are also close to those of $[Bu_4N][(C_6F_5)_3BMe]$[4] in which the $MeB(C_6F_5)_3$ anion is non-coordinating [20]. Future work will concentrate on exploring the validity of these hypotheses.

4. Experimental

All manipulations of air- and moisture-sensitive materials were undertaken using standard vacuum and Schlenk techniques or in a glovebox under an atmosphere of nitrogen. Unless otherwise noted, all reagents were obtained from commercial sources and purified as required. All synthetic reactions were carried out in glassware under N_2 using Schlenk techniques or in a glove-box. Tetrahydrofuran, diethyl ether, hexane, toluene and dichloromethane were dried and deoxygenated by passage through columns of A-2 alumina (12×32 mesh) and Engelhard CU-0226s (Q-5) deoxo catalyst under N_2 prior to use, as described in the literature [26]. $MeAl(BHT)_2$ (MAD, [27]), $B(C_6F_5)_3$ [28], the ligands $Me_2X(IndH)CpH$ (X = C, Si) [29], $M(NMe_2)_4$ (M = Zr, Hf) [30], $Me_2X(Ind)CpMMe_2$ complexes (X = C, Si; M = Zr, Hf) [3c,31] and $Me_2C(Cp)FluZrMe_2$ [32] were prepared via the literature procedures.

Routine ^1H, ^{13}C or ^{19}F NMR spectra were obtained on either Varian Mercury or Gemini 300 MHz instruments. All ^1H NMR spectra were referenced with respect to residual protonated solvent while ^{13}C NMR spectra were referenced with respect to deuterated solvent. ^{19}F NMR spectra were referenced with respect to tetrafluoro-*p*-xylene (δ −145.69 toluene-d_8) or external $CFCl_3$. Benzene-d_6 and toluene-d_8 were dried by distillation from potassium and benzophenone under N_2 (g) and stored over activated 4 Å molecular sieves. Variable temperature ^1H, ^{13}C and ^{19}F NMR spectra were recorded on Varian Inova 400 or Unity+ 750 MHz instruments, the thermocouples of which had been calibrated to within 5% of the actual temperature using a methanol standard [33].

4.1. Polymerization procedure

Propylene polymerizations were conducted in either a 1 L Autoclave Engineers Zipperclave reactor. The temperature of the reactor was controlled using a Neslab RTE-110 constant temperature bath by circulation of coolant (50:50 v/v ethylene glycol:water) through an external jacket. The consumption of monomer (propylene) during the course of polymerization was monitored using a calibrated Matheson mass flow meter, which was controlled by a Matheson Dynablender Model 8219 power supply/readout device. The progress of polymerization was monitored using Labtech Acquire data acquisition software, which converted the digital input reading to the desired value (mmol/s of monomer) using appropriate conversion factors.

Prior to each polymerization, the reactor was conditioned by evacuation for ~4 h at 100 °C, and then cooled under nitrogen after three refill-evacuation cycles. About 480 mg of MAD (1 mmol) were dissolved in 25 mL of a stock solution of Me_3Al in toluene (0.4 mM) and the solution was transferred to the reactor via sampling bomb using a known amount of toluene (225 mL) to flush the contents of the sample bomb into the reactor (final concentration of [MAD] = 4 mM and

[4] S. Collins, A. Al-Humydi, R. Gonzales, unpublished results. $[Bu_4N][(C_6F_5)_3B(\mu\text{-}H)B(C_6F_5)_3]$: ^{19}F NMR (282 MHz, C_6D_6) −133.8 (br d, *o*-F) −164.9 (br t, *p*-F) −167.9 (m, *m*-F). $[Bu_4N][MeB(C_6F_5)_3]$: ^{19}F NMR (282 MHz, C_6D_6) −133.4 (br d, *o*-F) −165.6 (br t, *p*-F) −168.3 (m, *m*-F).

[Me_3Al] = 40 μM). The solvent was allowed to saturate with monomer at the 30 psi g and 30 °C while stirring. This procedure has been found to reduce the length of time needed for effective scavenging while effectively sequestering any residual Me_3Al to extremely low levels, through (quasi-irreversible) formation of Me_2AlBHT [27,34].

Stock solutions were prepared in the glove box by dissolving 20 mg of the metallocene complex **1** (0.058 mmol) in 25 mL toluene (2.3 mM) and 300 mg borane (0.598 mmol) in 25 mL toluene (23 mM). A stock solution of the ion-pair and excess borane was then prepared by adding a known volume of the former to the latter solution at 25 °C. Polymerizations were initiated by adding a known volume of the resulting stock solution of the ion-pair to the reactor via gas-tight syringe through a septum port. Temperature control was generally ±1 °C following catalyst introduction and catalyst concentrations were chosen so as to avoid exothermic conditions. Polymerization reactions were typically conducted for periods of time corresponding to attainment of steady state as revealed by a stable mass flow profile and then for an additional period = the length of time required to reach steady state in most cases.

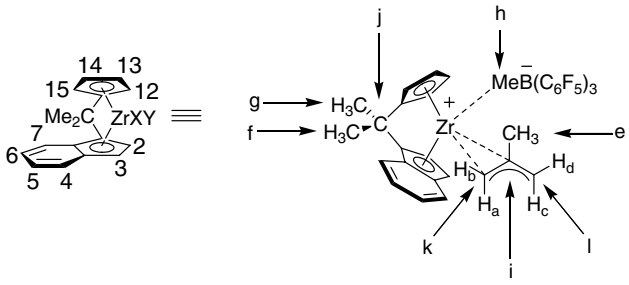

Fig. 1 depicts typical flow profiles observed under various conditions summarized in the text. The lag period observed prior to detectable uptake corresponds to consumption of dissolved propene so as to produce a small pressure drop across the mass flow meter – the length of this period is thus sensitive to catalyst activity (and absolute [Met]) as well as the extent of saturation of the solution with propene prior to catalyst introduction.

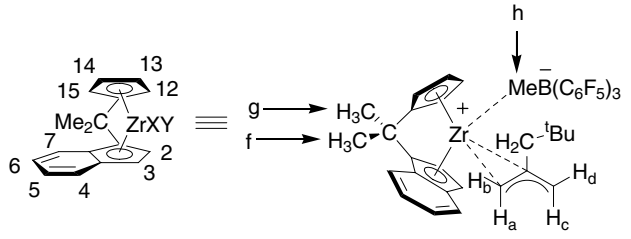
Reactions were halted by venting the monomer and emptying the reactor contents into methanol. Solvent was partially evaporated to dryness in vacuo and then the syrup was transferred to an aluminum pie plate. Solvent was allowed to further evaporate at room temperature in a hood and then at 60 °C in a vacuum oven (~1 mmHg). Polymer characterization procedures have been reported in detail elsewhere [35].

4.2. Formation of ion-pairs **2a**–**b** from complex **1a** and $B(C_6F_5)_3$ in toluene-d_8

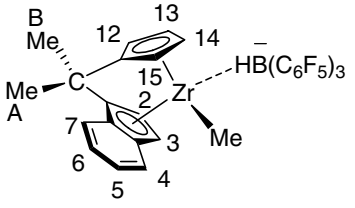
Stock solutions of $Me_2C(Ind)CpZrMe_2$ (0.10 M) and $B(C_6F_5)_3$ (0.10 M) in toluene-d_8 were mixed in a 1:1 ratio at 25 °C in a glove box. Upon adding the metallocene to the $B(C_6F_5)_3$ solution, an immediate color change from colorless to orange red indicated a rapid reaction at this temperature. The ^1H and ^{19}F NMR spectra of the resulting solution show two sets of signals in a roughly 1:3.5 at ambient temperature due to different stereoisomers. ^1H and ^{19}F NMR spectra are depicted in Figs. 2 and 3, respectively.

4.3. [$Me_2C(Cp)IndZr(\eta^3$-$C_4H_7)$][$MeB(C_6F_5)_3$] (**4b**)



Inside the glove box, to a 25 mL round bottom flask, was added 86 mg (0.168 mmol) of $B(C_6F_5)_3$, dissolved in 1 mL of benzene-d_6. A solution of *ansa*-zirconocene complex **1a** (50 mg, 0.146 mmol) in 1 mL of benzene-d_6 was added to the $B(C_6F_5)_3$ solution at 25 °C to form an orange-red solution of the *ansa*-zirconocenium ion-pair **2a**–**b**. Outside the glove box, isobutene was bubbled into the ion-pair solution while stirring the reaction mixture for ~30 min. To ensure complete consumption of ion-pair, the reaction mixture was monitored by ^1H or ^{19}F NMR spectroscopy. At complete consumption of the ion-pair, the ^1H and ^{19}F NMR spectra indicated that the reaction was very clean and the product was stable at 25 °C. After completion of reaction, the reaction mixture was then pumped down in vacuo to dryness. The allyl complex produced was washed with hexane and crystals were obtained by redissolving the solid in minimal dichloromethane and then layering it with hexane (in 1:1 mixture) and placing this mixture in a −30 °C freezer in the dry box, overnight. The product was isolated as a yellow-orange crystals (114 mg, 91% yield). ^1H NMR (bromobenzene-d_5, 400 MHz, 25 °C): δ 6.99 (m, 3H, H_4, H_6, and H_7), 6.79 (ddd, J = 8.8, 6.2, 1.6, 1H, H_5), 6.15 (dd, J = 3.5, 1.1 Hz, 1H, H_3), 5.66 (dm, J = 3.7 Hz, 1H, H_{13}), 5.51 (d, J = 3.7 Hz, 1H, H_2), 4.99 (dm, J = 3.7 Hz, 1H, H_{14}), 4.94 (m, 1H, H_{12}), 4.44 (dd, J = 4.8, 2.7 Hz, 1H, H_{15}), 3.57 (dm, J = 4.5 Hz, 1H, H_a), 2.90 (t, J = 1.1 Hz, 1H, H_c), 2.33 (t, J = 4.0 Hz, 1H, H_b), 1.54 (s, 3H, Me_f), 1.47 (s, 3H, Me_e), 1.24 (s, 3H, Me_g), 1.14 (b, 3H, Me_h), −2.39 (dt, J = 3.7, 1.1 Hz, H, H_d). ^{13}C NMR (bromobenzene-d_5, 100 MHz, 25 °C): δ 153.3 (C_i), 148.9 (dm, J_{C-F} = 236.6 Hz, *o*-C, $B(C_6F_5)_3$), 137.8 (dm, J_{C-F} = 244.0 Hz, *p*-C, $B(C_6F_5)_3$), 136.8 (dm, J_{C-F} = 246.9 Hz, *m*-C, $B(C_6F_5)_3$), not observed $B(C_6F_5)_3$ (*ipso*-C), 128.5, 128.3, 126.7, 126.0, 122.6, 120.0, 118.5, 113.4, 110.7, 108.1, 103.1, 99.5, 97.6, 97.1 (Cp and indenyl), 89.3 (C_l), 69.0 (C_k), 38.0 (C_j), 26.5 (C_e), 25.0 (C_g), 24.0 (C_f), 11.2 (C_h). ^{19}F NMR (bromobenzene-d_5, 282 MHz, standard: tetrafluoro-*p*-xylene, −145.71 ppm): δ −133.1 (br d, J = 24.4 Hz, *o*-*F*), −160.7 (t, J = 21.4 Hz, *p*-*F*), −165.2 (m, *m*-*F*). IR (Nujol, KBr plates, cm^{-1}): 1642 (w), 1514 (w), 1088 (w), 970 (w), 910 (w), 820 (w). Elec-

trospray ionization mass spectrometry: positive-ion at *m/z* 365.1 (M^+, Zr^{90}), negative-ion at *m/z* 526.8 (M^-, B^{11}). Elemental *Anal*. Calc. for $C_{40}H_{26}BF_{15}Zr$: C, 53.76; H, 2.93. Found: C, 53.18; H, 2.93%.



A crystal of dimensions $0.35 \times 0.25 \times 0.10$ mm was coated with Paratone oil and mounted on Cryoloops™ and placed on the goniometer head of a Bruker Apex CCD diffractometer. The reflections were collected at 100(2) K using ψ and ω scans. The diffraction source was graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Unit cell determination was achieved by using reflections from three different orientations. Data integration was accomplished using SAINT. An empirical absorption correction and other corrections were done using multi-scan SADABS. Structure solution, refinement and modeling were accomplished using the Bruker SHELXTL package. The structure was obtained by full-matrix least-squares refinement of F^2 and the selection of the appropriate atoms from the generated difference map. Hydrogen atoms of the borate anion were found from the difference map, U_{iso}(H) values fixed according to a riding model, and their positions refined. All other hydrogen positions were calculated and their U_{iso}(H) values fixed according to a riding model.

4.4. [$Me_2C(Cp)IndZr(\eta^3$-2-($CH_2{}^tBu)C_4H_4$)][$MeB(C_6F_5)_3$] (**4c**)

Inside the glove box, to a 25 mL round bottom flask, was added 82 mg (0.160 mmol) of $B(C_6F_5)_3$ dissolved in 1 mL of benzene-d_6. A solution of *ansa*-zirconocene complex **1a** (50 mg, 0.146 mmol) in 1 mL of benzene-d_6 was added to the borane solution at 25 °C to form an orange-red solution of the *ansa*-zirconocenium ion-pair **2a**–**b**. Outside the glove box, excess 2,4,4-trimethyl-1-pentene (140 μL, 0.883 mmol) was added via microsyringe to the ion-pair solution with magnetic stirring, and the reaction mixture stirred for ~1 h to ensure complete consumption of ion-pair, as monitored by NMR spectroscopy. At complete consumption of ion-pair, the ^{1}H and ^{19}F NMR spectra indicated that the reaction was clean and the product was stable at 25 °C. After completion of reaction, the reaction mixture was then pumped down. The allyl complex produced was washed with hexane (2×5 mL) and the orange-red solid further dried in vacuo to dryness (109 mg, 81% yield). ^{1}H NMR (benzene-d_6, 300 MHz, 25 °C): δ 6.64 (m, 3H, H_4, H_6, and H_7), 6.40 (ddd, $J = 9.1$, 4.9, 2.8 Hz, 1H, H_5), 6.18 (dd, $J = 3.3$, 0.6 Hz, 1H, H_3), 5.93 (d, $J = 3.3$ Hz, 1H, H_2), 5.36 (dd, $J = 5.2$, 2.7 Hz, 1H, H_{13}), 5.19 (dd, $J = 5.2$, 2.7 Hz, 1H, H_{14}), 5.15 (dd, $J = 5.2$, 2.7 Hz, 1H, H_{12}), 4.34 (dd, $J = 5.2$, 2.7 Hz, 1H, H_{15}), 3.54 (dm, $J = 3.85$ Hz, 1H, H_a), 3.17 (s, 1H, H_c), 1.85 (t, $J = 4.39$ Hz, 1H, H_b), 1.24 (s, 3H, Me_f), 1.23 (s, 2H, CH_2), 1.22 (s, 3H, Me_g), 0.79 (s, 9H, ^{t}Bu), −0.24 (b, 3H, Me_h), −2.53 (dt, $J = 3.5$, 1.1 Hz, H, H_d). ^{19}F NMR (benzene-d_6, 282 MHz): δ −133.0 (br d, $J = 18.3$ Hz, *o-F*), −160.9 (t, $J = 21.4$ Hz, *p-F*), −165.1 (m, *m-F*). IR (Nujol, KBr plates, cm^{-1}): 1642 (w), 1512 (m), 1273 (w), 1089 (m), 970 (m), 803 (w). Electrospray ionization mass spectrometry: positive-ion at *m/z* 421.2 (M^+, Zr^{90}), negative-ion at *m/z* 526.9 (M^-, B^{11}).

4.5. Reaction of propylene with zirconocenium ion-pairs **2a**–**b**; formation of borohydride complexes **5a**–**b**

The reaction was conducted in screw cap NMR tubes. Stock solutions of $Me_2C(Ind)CpZrMe_2$ (0.05 M) and $B(C_6F_5)_3$ (0.05 M) in toluene-d_8 were mixed in a 1:1.2 or 1:1 ratio at 25 °C in a glove box. There was an immediate color change from colorless to orange red. Outside the glove box, 10 equiv. of propylene was added to the ion-pair solution in each NMR tube using a vortex mixer. The ^{1}H and ^{19}F NMR spectra obtained are summarized in Figs. 2 and 3. ^{1}H NMR of the major isomer **5a** (benzene-d_6, 300 MHz): δ 7.23 (d, $J = 8.5$ Hz 1H,H_4), 6.96 (m, 1H, H_5), 6.78 (dm, $J = 9.1$ Hz, 1H, H_7), 6.65 (m, 1H, H_6), 6.09 (d, $J = 3.0$ Hz, 1H, H_3), 5.91 (dd, $J = 5.5$, 3.3 Hz, 1H, H_{14}), 5.73 (dd, $J = 4.4$, 2.2 Hz, 1H, H_{13}), 5.42 (d, $J = 3.3$ Hz, 1H, H_2), 5.28 (dd, $J = 5.5$, 2.7 Hz, 1H, H_{12}), 4.75 (dd, $J = 5.5$, 2.7 Hz, 1H, H_{15}), 1.20 (s, 3H, Me_A), 1.09 (s, 3H, Me_B), −1.10 (septet, $^3J_{H-F} = 2.2$ Hz, 3H, Me–Zr).^{19}F NMR (benzene-d_6, 282 MHz): δ −131.0 (br d, $J = 18.3$ Hz, *o-F*), −155.0 (t, $J = 21.4$ Hz, *p-F*), −162.0 (m, *m-F*). ^{1}H NMR spectrum of the minor isomer **5b** (benzene-d_6, 300 MHz): δ 0.27 (s, 3H, Me–Zr) other signals due to this isomer could not be assigned and/or overlapped with those of **5a**.^{19}F NMR (benzene-d_6, 282 MHz): δ −132.2 (br d, $J = 18.3$ Hz, *o-F*), −156.5 (t, $J = 21.4$ Hz, *p-F*), −162.8 (m, *m-F*).

4.6. $Me_2C(Cp)IndHfMe(\mu\text{-}H)B(C_6F_5)_3$ (**6**)

Inside the glove box, to a 25 mL round bottom flask, was added 180 mg (0.351 mmol) of $B(C_6F_5)_3$, dissolved in 2 mL toluene. A solution of *ansa*-hafnocene complex **1b** (100 mg, 0.233 mmol) in 2 mL of toluene was added to the solution of $B(C_6F_5)_3$ at 25 °C, and a bright yellow solution of the *ansa*-hafnocenium ion-pair was formed. Outside the glove box, propylene was bubbled into the ion-pair solution with magnetic stirring. The solution became orange and the reaction mixture was stirred for ~30 min. To ensure complete consumption of the starting ion-pair, the reaction mixture was monitored by ^1H or ^{19}F NMR spectroscopy, and if needed, additional propylene was added. At complete consumption of the ion-pair, the ^1H and ^{19}F NMR spectra indicated that the reaction was very clean (Fig. 5) and the product was stable at 25 °C for more than one day. After completion of the reaction, the reaction mixture was then pumped down in vacuo and the mixture was dissolved in 2 mL of hexane and recrystallized at −30 °C to form yellow crystals (192 mg, 89% yield). ^1H NMR (benzene-d_6, 300 MHz): δ 7.28 (d, J = 8.8 Hz, 1H, H_4), 6.97 (dm, J = 6.6 Hz, 1H, H_5), 6.82 (ddd, J = 9.1, 1.7, 0.9 Hz, 1H, H_7), 6.60 (dm, J = 6.6 Hz, 1H, H_6), 5.99 (d, J = 3.3 Hz, 1H, H_3), 5.95 (dd, J = 5.2, 3.3 Hz, 1H, H_{14}), 5.65 (dd, J = 5.2, 2.7 Hz, 1H, H_{13}), 5.45 (d, J = 3.3 Hz, 1H, H_2), 5.20 (dd, J = 5.2, 2.7 Hz, 1H, H_{12}), 4.60 (dd, J = 5.2, 2.7 Hz, 1H, H_{15}), 1.19 (s, 3H, Me_A), 1.11 (s, 3H, Me_B), −1.10 (septet, $^3J_{H-F}$ = 2.2 Hz, 3H, Me–Hf). In the $^1H\{^{19}F\}$ NMR spectrum (benzene-d_6, 750 MHz) the signal at δ −1.10 collapsed to a singlet. In the $^1H\{^{11}B\}$ NMR spectrum (benzene-d_6, 400 MHz) the signal associated with μ-H appeared at δ 0.44. ^{13}C NMR (bromobenzene-d_5, 100 MHz, 25 °C): δ 148.9 (dm, J_{C-F} = 240 Hz, *o*-C, $B(C_6F_5)_3$), 141.3 (dm, J_{C-F} = 241 Hz, *p*-C, $B(C_6F_5)_3$), 138.1 (dm, J_{C-F} = 244 Hz, *m*-C, $B(C_6F_5)_3$), not observed $B(C_6F_5)_3$ (*ipso*-C), 128.0, 127.6, 127.5, 126.3, 122.6, 120.2, 118.2, 115.0, 114.0, 110.0, 107.4, 104.0, 99.9, 96.3 (Cp and indenyl), 40.9 (C-bridged), 38.6 (Hf–Me), 26.1 and 24.2 (2C, Me_A, Me_B). ^{19}F NMR (benzene-d_6, 282 MHz) δ −130.7 (d, J = 24.4 Hz, *o-F*), −155.0 (t, J = 21.4 Hz, *p-F*), −162.2 (m, *m-F*). IR (Nujol, KBr plates, cm^{-1}): 2095 (br), 1646 (m), 1516 (s), 1287 (m), 1112 (m), 964 (m), 910 (w), 818 (w), 789 (w), 728 (w). Electrospray ionization mass spectrometry: positive-ion at *m*/*z* 415.2 (M^+, Hf^{180}), negative-ion at *m*/*z* 512.8 (M^-, B^{11}). Elemental *Anal*. Calc. for $C_{36}H_{20}BF_{15}Hf \cdot 1/2C_6H_{14}$: C, 48.30; H, 2.81. Found: C, 50.46; H, 2.89%.

A crystal of dimensions $0.50 \times 0.30 \times 0.30$ mm was coated with Paratone oil and mounted on Cryoloops™ and placed on the goniometer head of a Bruker Apex CCD diffractometer. The reflections were collected at 100(2) K using ψ and ω scans. The diffraction source was graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). Unit cell determination was achieved by using reflections from three different orientations. Data integration was accomplished using SAINT. An empirical absorption correction and other corrections were done using multi-scan SADABS. Structure solution, refinement and modeling were accomplished using the Bruker SHELXTL package. The structure was solved by direct methods and refined by full-matrix least-squares refinement of F^2 and the selection of the appropriate atoms from the generated difference map. Hydrogen atoms of the borate anion were found from the difference map, U_{iso}(H) values fixed according to a riding model, and their positions refined. All other hydrogen positions were calculated and their U_{iso}(H) values fixed according to a riding model.

4.7. Reaction of propylene with borohydride complexes **5a–b**

The reaction was conducted in a 5 mm screw cap NMR tube equipped with a septum. Stock solutions of $Me_2C(Ind)CpZrMe_2$ (167 μL, 0.025 M) and $B(C_6F_5)_3$ (200 μL, 0.025 M) in toluene-d_8 were mixed in a 1:1.2 ratio at 25 °C in a glove box in the NMR tube, while a stock solution of propene in toluene-d_8 (ca. 0.5 M) was prepared outside the box by bubbling propene through toluene-d_8 at 25 °C and 1 atm. Outside the box, ~20 equiv. (ca. 170 μL) of propylene was added to the ion-pair solution via syringe and then the tube mixed using a vortex mixer and then was transported to the NMR laboratory (5–10 min) and spectra recorded. The ^1H and ^{19}F NMR spectra revealed the nearly complete consumption of ion-pairs **2a–b** and formation borohydride complexes **5a–b** in about a 10:1 ratio. Three more additions of 85 μL each of the propene stock solution were conducted and spectra recorded after each addition. The ^{19}F NMR spectra appear in Fig. 4 while the ^1H NMR spectra are available from the authors on request.

Acknowledgments

3,4,5-trimethoxybenzaldehyde were obtained commercially from Aldrich Chemical Co. THF and toluene were dried over and distilled from Na/benzophenone prior to use. Cyclopentadiene was collected under an atmosphere of nitrogen from freshly cracked dicyclopentadiene and pyrrolidine was distilled under argon prior to use. Manipulation of air and moisture sensitive compounds was carried out using standard Schlenk techniques under an argon atmosphere. NMR spectra were measured on a Varian 300 MHz spectrometer. Chemical shifts are reported in ppm and are referenced to TMS. IR spectra were recorded on a Perkin–Elmer Paragon 1000 FT-IR Spectrometer employing a KBr disk.

The GCMS spectrum for fulvene **1** was measured on a FINNIGAN TRACE GCMS 2000 Series (70 eV) and 1×10^{-5} M solutions in ethyl acetate were used.

For mass spectrometric analysis of titanocene **2**, a stock solution of the sample was prepared by dissolving the compound in 0.5 ml dichloromethane. A 10-fold dilution of these solutions was made in acetonitrile and electrospray mass spectrometry was performed on a quadrupole tandem mass spectrometer (Quattro Micro, Micromass/Waters Corp., USA) in a negative ion mode.

With a view to elucidate the structures, spectroscopic data, bonding properties and energies of formation, the application of theoretical methods is advantageous. For this purpose, the GAUSSIAN 98 Revision A11 [24] running under Red Hat Linux was used. DFT calculations were performed at the B3LYP level using the 6-31G* basis set for the species of interest.

2.1. 6-(3′,4′,5′-Trimethoxyphenyl)fulvene (*1*)

The synthesis of fulvene **1** was carried out under argon as outlined in reference [25]. Pyrrolidine (2.5 ml, 30.0 mmol) was added to a solution of 3,4,5-trimethoxybenzaldehyde (3.9 g, 20.0 mmol) and cyclopentadiene (4.1 ml, 60.0 mmol) in 30 ml of methanol. After this addition the solution turned from colourless to deep red. When TLC analysis (silica/dichloromethane) showed only one product band after 2 h, acetic acid (1.8 ml, 32.0 mmol) was added. The reaction mixture was partitioned between 20 ml of ether and 40 ml water and extracted with a total of 3×20 ml ether. The combined organic extracts were washed with a saturated aqueous NaCl solution. The organic solution was dried over magnesium sulfate and the solvent removed under reduced pressure. The crude product was triturated with pentane. After solvent removal under reduced pressure a deep red/orange product was obtained. 3.8 g (85% yield wrt 3,4,5-trimethoxybenzaldehyde); m.p. 41.0–43.0 °C.

^{1}H NMR (δppm $CDCl_3$): 6.75, 6.65, 6.40 (C_5H_4, 4H m); 6.95 (C_6H_2, 2H s); 3.95 (*p*-OCH_3 and *o*-OCH_3, 9H s); 7.20 (Ph-C*H*-Cp, 1H s).

^{13}C NMR (δppm $CDCl_3$): 153.3, 144.7, 139.4, 138.3, 135.5, 132.3, 130.6, 127.3, 120.0, 108.0 (C_5H_4 and C_6H_2); 61.0 (*o*-OCH_3); 56.2 (*m*-OCH_3).

IR absorptions (cm^{-1} KBr): 3001 (m), 2937 (m), 1576 (s), 1503 (m), 1417 (m), 1329 (s), 1242 (m).

GCMS: 244.2 (M^+ 70%), 229.1 ($M^+ - CH_3$ 50%), 213.1 ($M^+ - OCH_3$ 40%), 201.2 ($M^+ - COCH_3$ 13%), 155.1($M^+ - CCH(C_5H_4)$ 17%), 115.1 ($M^+ - COCH_3)_3$ 100%).

Anal. Calc. for $C_{15}H_{16}O_3$: C, 73.75; H, 6.60; Found: C, 72.31; H, 6.50%.

2.2. [1,2-Di(cyclopentadienyl)-1,2-di(3′-4′-5′-trimethoxyphenyl)-ethanediyl] titanium dichloride [1,2-(3′,4′,5′-(MeO)$_3$-C_6H_2)$_2$$C_2H_2${$\eta^5$-$C_5H_4$}$_2$]$TiCl_2$ (*2*)

$TiCl_4$ (6.25 mmol, 1 M in toluene) was added to 90 ml of dry toluene and 10 ml dry THF. The solution turned immediately from colourless to pale yellow. The solution was stirred and cooled down to −78 °C, and then was treated dropwise with *n*BuLi (7.8 ml, 12.5 mmol). The solution turned from yellow to brown during the addition. After this addition, the mixture was allowed to warm up slowly to r.t. and the solution finally turned black. After 20 h stirring, a solution of **1** (3.05 g, 12.5 mmol) in dry toluene was added to the solution of $TiCl_2 \cdot 2THF$ at r.t. under argon. It was then stirred under reflux for another 16 h. The solvent was removed under vacuum. The resulting black solid was extracted with 3×20 ml of chloroform and filtered on celite. The solvent was removed under vacuum and the residue dissolved in 8 ml of chloroform and filtered twice through Whatman No. 1 filter paper. The solvent was removed again under vacuum and the residue triturated with a total of 40 ml pentane to give 2.5 g (66% yield) black solid. The ratio of *trans* and *cis* isomers was 58–42%. The mixture cannot be purified or separated by column chromatography or crystallisation; therefore the elemental analysis shows some discrepancy between measured and calculated values and an X-ray crystal structure is not available.

^{1}H NMR (δppm $CDCl_3$): 6.36 (*cis*-C_6H_2, 4H s); 6.33 (*trans*-C_6H_2, 4H s); 7.23–6.00 (C_5H_4, 8H m); 5.34 (*trans*-PhC*H* Cp, 2H s); 4.63 (*cis*-PhC HCp, 2H); 3.80 (*cis-m*-CH_3, 6H s); 3.78 (*cis-m*-CH_3, 12H s); 3.74 (*trans-p*-CH_3, 6H s); 3.67 (*trans-m*-CH_3, 12H s).

^{13}C NMR (δppm $CDCl_3$): 153.3, 153.1, 152.8, 137.5, 137.0, 136.5, 135.8, 133.9, 129.0, 126.6, 120.3, 117.4, 116.5, 115.4, 109.7, 106.5, 105.9, 105.2 (*cis* and *trans*-C_6H_3 and C_5H_4); 60.9, 60.8 (*cis* and *trans-o*-O(CH_3)$_2$), 56.3, 56.2 (*cis* and *trans-m*-O(CH_3)$_2$); 54.4, 52.2 (*cis* and *trans*-PhCHCp).

IR absorptions (cm^{-1} KBr): 3104 (m), 2991 (s), 2976 (m), 2965 (s), 1583 (m), 1461 (m), 1412 (m), 1120 (m), 1000 (m), 821 (m).

MS: 641.0 ($M + Cl^-$).

Anal. Calc. for $C_{30}H_{32}Cl_2O_6Ti$: C, 58.94; H, 5.31; Found: C, 57.74; H, 5.19%.

2.3. MTT-based cytotoxicity tests

The pig kidney carcinoma cell line, LLC-PK, was obtained from the American Tissue Culture Collection.

The cytotoxic activity of titanocene **2** was determined using an MTT-based assay. In more detail, cells were seeded into a 96-well plate (5000 cells/well) and allowed to attach for 24 h. Subsequently, the cells were treated with various concentrations of the cytotoxic agents. In order to prepare drug solutions, **2** was first dissolved in DMSO, followed by dilution with medium to the required maximum concentration of 1.5×10^{-3} M, with a final concentration of DMSO not exceeding 0.7%. From this stock solution, solutions with lower concentrations were prepared by further dilution with medium. Care was taken that the drug solutions were applied within 1 h on the cells to avoid interference with already hydrolysed compounds. After 48 h, the relevant drug was removed, the cells were washed twice with PBS and fresh medium was added for another 24 h for recovery. Viability of cells was determined by treatment with MTT in medium (5 mg/11 ml) for 3 h. The purple formazan crystals formed were dissolved in DMSO and absorbance measured at 540 nm using a VICTOR^2 multilabel plate reader (Wallac). IC_{50} (inhibitory concentration 50%) values were determined from the drug concentrations that induced a 50% reduction in light absorbance.

3. Results and discussion

3.1. Synthesis

Fulvene **1** (Scheme 1) was synthesised according to reference [23], by reacting the corresponding benzaldehyde with cyclopentadiene in the presence of pyrrolidine as a base. Afterwards titanocene **2** (Fig. 2) could be obtained by a reductive dimerisation of fulvene **1** with titanium dichloride (Scheme 1). $TiCl_2$ was synthesised by reduction of $TiCl_4$ with *n*BuLi as described in the literature [17,18] (Scheme 1). The determined *cis–trans* ratio at the bridge is 58:42 for **2**.

3.2. Theoretical studies

Density functional theory calculations were carried out for fulvene **1** and titanocene **2** at the B3LYP level using the 6-31G** basis set.

Selected bond lengths of the optimised structure of fulvene **1** (Fig. 2, for the atom numbering scheme see

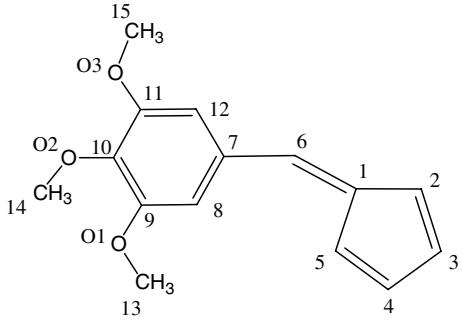

Fig. 1. Structure of fulvene **1**.

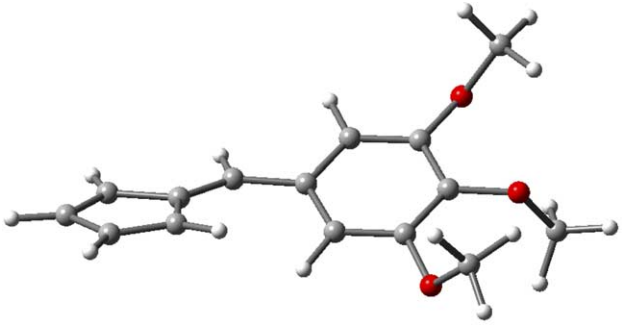

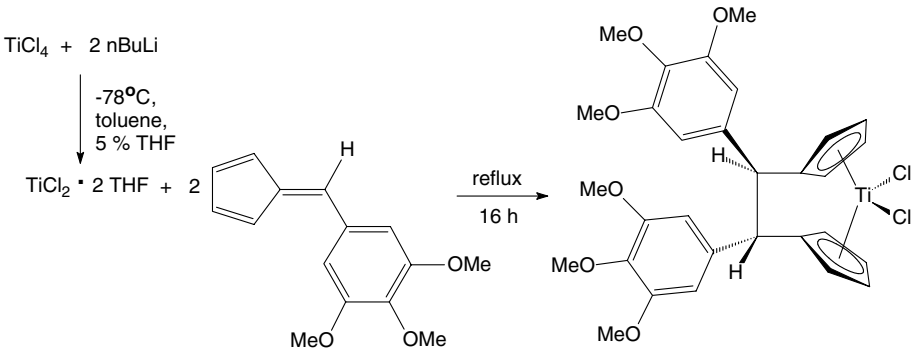

Fig. 2. Gaussview plot of the optimised structure of fulvene **1**.

Scheme 1. Synthesis of titanocene **2**.

Table 1
Selected bond lengths of the DFT-calculated structure of **1**

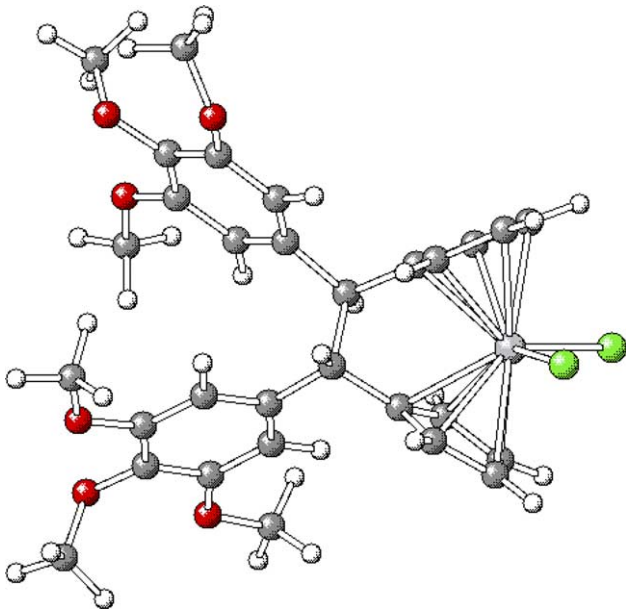
	1: Bond length [pm]
C(1)–C(2)	148.1
C(2)–C(3)	136.4
C(3)–C(4)	147.5
C(1)–C(6)	136.4
C(6)–C(7)	146.4
C(7)–C(8)	141.2
C(8)–C(9)	139.6
C(9)–C(10)	140.8
C(9)–O(1)	139.9
C(10)–O(2)	140.0
O(1)–C(13)	147.5
O(2)–C(14)	148.0

Fig. 1) can be found in Table 1. As expected, the carbon–carbon bond lengths in the cyclopentadiene system of this fulvene vary significantly, demonstrating the flexibility of the resonance system within the five-membered ring. This is confirmed by the length of the regular exocyclic double bond C(1)–C(6), calculated as 136.4 pm, and the single bond carrying the aryl substituent C(6)–C(7) is calculated as 146.4 pm (Table 1). For fulvene **1**, a distortion from planarity is seen with a dihedral angle between the phenyl ring and the five-membered dienyl ring of 25.5°. In the calculated structure of **1**, the three methyl groups are oriented alternating up and down relative to the plane of the phenyl ring.

Optimised structures were also calculated for titanocene **2** (Fig. 3, for the atom numbering scheme see Scheme 2) at the B3LYP level using the 6-31G** basis set. Selected bond lengths of this structure are listed in Table 2.

The length of the bonds between the metal centre and the carbon atoms of the cyclopentadienyl rings bound to the metal ion vary between 236.4 and 245.3 pm and are in the range of bond lengths found in previous calculations for comparable *ansa*-titanocenes (236.4–245.4 pm) [20–23]. The carbon–carbon bonds of the cyclopentadienyl rings have values of 140.3–143.0 pm. These values suggest that the titanocene has no plane of symmetry bisecting the Cl–Ti–Cl plane and that the calculated structures exhibit C_2 symmetry. The titanium–chlorine bond length is 234.5 pm. These values are in agreement with the corresponding values calculated previously for (1,2-diphenyl-1,2-dicyclopentadienyl)ethanediyl} titanium dichloride [20]. The bridge length [C(6)–C(6′)] is 157.1 pm and is slightly elongated in comparison to (1,2-diphenyl-1,2-dicyclopentadienyl)-ethanediyl} titanium dichloride (153.6 pm) [20]. The steric bulk of the subsituted phenyl rings attached to the bridging carbon centres causes a lengthening of the bond, in order to relieve the resultant steric strain.

The $TiCl_2$ angle was calculated for **2** to be 97.7°. The dihedral angle between the aryl rings was calculated as



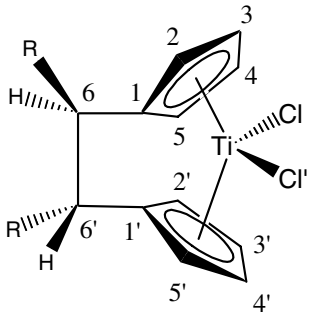


Fig. 3. Gaussview plot of the optimised structure of titanocene **2**.

Scheme 2. Numbering scheme for structural discussion of titanocenes **2**.

58.1°, whereas the dihedral angle between the cyclopentadienyl rings is −46.4°. The angle formed by the bonds between C(1), C(6) and C(6′) takes a value of 107.4°, between C(7), C(6), and C(6′) a value of 113.6°, and between C(7), C(6) and C(1) a value of 114.5°. All these angles are in agreement with the corresponding values calculated previously for comparable *ansa*-titanocenes prepared by our group [20–23].

3.3. Cytotoxicity studies

The in vitro cytotoxicity of compound **2** was determined by an MTT-based assay [26] involving a 48 h drug exposure period, followed by 24 h of recovery time. The compound was tested for its activity on pig kidney carcinoma (LLC-PK) cells. The IC_{50} value found for **2** is 9.0×10^{-4} M [Fig. 4] and this is slightly worse with respect to the inhibition value found previously for [1,2-di(cyclopentadienyl)-1,2-di(4-*N*,*N*-dimethylaminophe-

Table 2
Selected bond lengths from the DFT-calculated structure of complex **2**

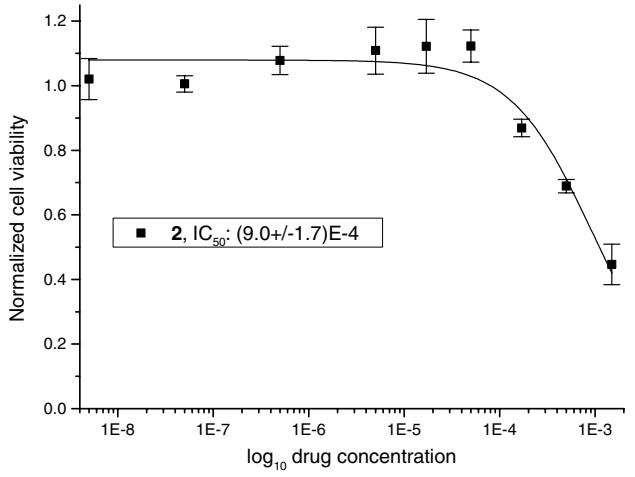

Fig. 4. Cytotoxicity curve from typical MTT assays showing the effect of compound **2** on the viability of pig kidney carcinoma (LLC-PK) cells.

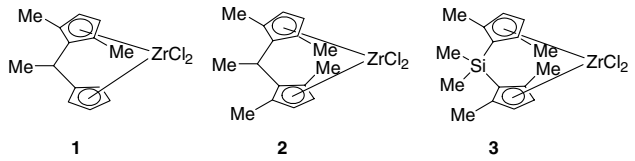
nyl)ethanediyl] titanium dichloride, which has an IC_{50} value of 2.7×10^{-4} M [21]. Under identical conditions, *cis*-platin showed an IC_{50} value of 3.3×10^{-6} M, whereas Cp_2TiCl_2 is found at 2.0×10^{-3} M [21].

4. Conclusion and outlook

Compound **2** has an IC_{50} value against LLC-PK cells in the upper 10^{-4} M range, which is slightly more cytotoxic than unsubstituted titanocene dichloride, for which Phase I/II clinical trials have been performed. The use of three methoxy substituents has improved the water solubility quite well, but the observed cytotoxicity is not impressing. It is intended to perform further in vitro cellular tests with the compound to evaluate its potential for testing in animal models and additionally to search for differently substituted titanocenes also derived from fulvenes.



Acknowledgements

The authors thank the Higher Education Authority (HEA) and the Centre for Synthesis and Chemical Biology (CSCB) for funding through the HEA PRTLI cycle 3. In addition funding from Science Foundation Ireland (SFI/04/BRG/C0682) and COST D20 (WG 0001) was granted.

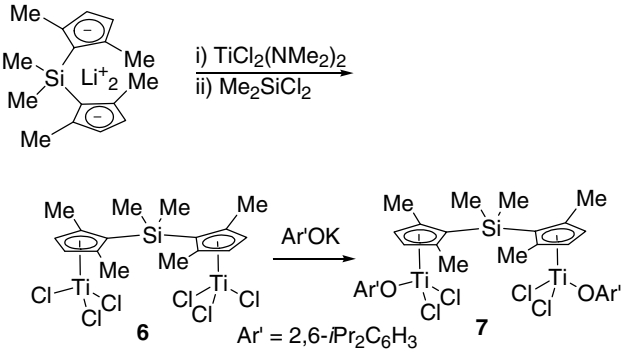
2. Results and discussion



2.1. Syntheses and characterizations

The C1-bridged *ansa*-titanocene complex [Me(H)C(η^5-C_5H_4)(η^5-2,5-$Me_2C_5H_2$)]$TiCl_2$ (**4**) was prepared using the ligand of *ansa*-zirconocene complex **1** [3]. Thus, the reaction of the dilithium salt with $TiCl_2(NMe)_2$ in pyridine afforded the desired bis(dimethylamido)titanium complex which was transformed to the dichloride complex **4** by treatment with Me_2SiCl_2 (Eq. (1)). The overall yield from the dilithium salt was rather low (28%). The ^1H and ^{13}C NMR spectra are in agreement with the structure. Two doublet signals are observed for Me_2Cp–H protons at 6.67 and 6.64 ppm (J = 3.6 Hz) and four Cp–H signals are observed at 6.67, 6.83, 5.45 and 5.18 ppm in the ^1H NMR spectrum. The bridge-CH signal is observed at 3.90 ppm as a quartet. The complex is sparingly soluble in benzene or toluene. Complex [($CH_3CH_2CH_2$)(H)-C(η^5-C_5H_4)(η^5-2,5-$Me_2C_5H_2$)]$TiCl_2$ (**5**) was synthesized by almost the same method and conditions applied for the synthesis of **4**. The overall yield from the dilithium salt was 50%. The complex is freely soluble in toluene. The Cp–H and Me_2Cp–H signal pattern is identical to that observed for **4** and the bridge-CH signal is observed at 3.60 ppm as a triplet.

(1)

Attempts to prepare the *ansa*-titanocene complex using the ligand of **3** were unsuccessful. The major product is a dinuclear complex when equimolar amount of the dilithium salt and $TiCl_2(NMe_2)_2$ are reacted even under fairly dilute conditions (Eq. (2)). Only four singlet signals are observed at 5.80 (Cp–H), 3.11 (NCH_3), 2.01 (CH_3) and 1.03 ($SiCH_3$) ppm with an integration ratio of 2:12:6:3 in the ^1H NMR spectrum. The integration ratio strongly supports the formation of a dinuclear complex. The same kind of dinuclear titanium complex was obtained when the dilithium salt of methylene-bridged 2,5-dimethylcyclopentadienyl indenyl ligand was reacted with an equimolar amount of $TiCl_2(NMe_2)_2$ [5]. Because unbridged cyclopentadienyl phenoxy titanium dichloride complexes have been reported to serve effectively as catalysts for olefin polymerizations [7], the dinuclear Me_2Si[(η^5-2,5-$Me_2C_5H_2$)Ti{O(2,6-*i*$Pr_2C_6H_3$)}Cl_2]$_2$ (**7**) has been prepared (Eq. (2)). Recently, dinuclear CGC-type complexes have drawn extensive attention because of their enhanced reactivity compared to the mononuclear counterparts [8]. Thus, addition of two equivalents of $TiCl_2(NMe_2)_2$ to the dilithium salt provides cleanly the desired dinuclear complex, Me_2-Si[(η^5-2,5-$Me_2C_5H_2$)Ti(NMe_2)$_2$Cl]$_2$, which is cleanly transformed to the trichloride complex by treatment with Me_2SiCl_2 (overall yield from the dilithium salt, 75%). Addition of 2,6-diisopropylphenoxypotassium to the trichloride complex affords the desired complex **7** in 86% yield. The ^1H and ^{13}C NMR spectra and the elemental analysis data are in agreement with the structure.

(2)

Attempts to prepare the *ansa*-titanocene complex using the ligand of **2** were unsuccessful. The main product of the reaction between the ligand and $TiCl_2(NMe_2)_2$ was a dinuclear bis(dimethylamido)(chloro)titanium complex, as observed for the ligand of **3**. This failure might be attributed to the repulsion between the methyls attached on each cyclopentadienyl ring. The repulsion between the methyls was observed even in the solid structure of zirconium complex **2** [3]. Because the titanocene complexes have smaller metal–Cp distances, more severe repulsion is expected for the desired *ansa*-titanocene complex, which may hamper the formation of the *ansa*-complex. In the case of *ansa*-titanocene complexes **4** and **5**, that kind of repulsion does not exist due to the presence of methyl groups on only one cyclopentadienyl ligand, consequently allowing formation of the desired *ansa*-complexes.

Single crystals of **4** suitable for Xray crystallography were deposited in the reaction pot when the bis(dimethylamido) titanium complex was reacted with Me_2SiCl_2 in the absence of stirring and its structure was confirmed by X-ray crystallographic studies. The ORTEP drawing with selected bond distances and angles are shown in Fig. 1. It shows a characteristic strained *ansa*-metallocene structure: small angle of Cp(c)–Ti–Cp(c) (Cp(c), centroid of Cp), deviation of C_b–C–C_b (C_b, bridgehead carbon on Cp) angle from the ideal tetrahedral value

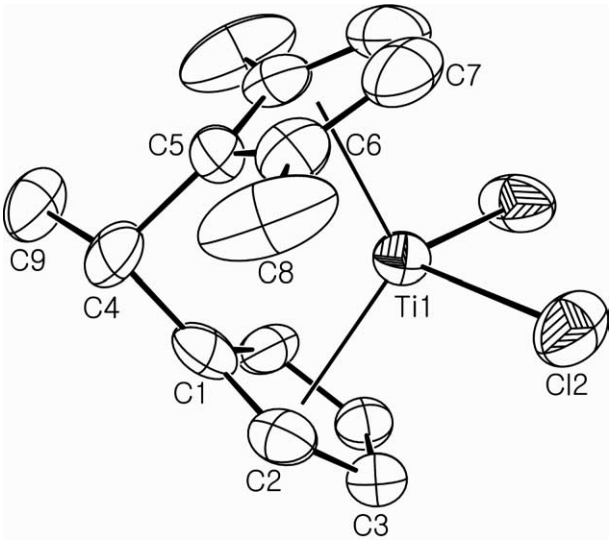


Fig. 1. Thermal ellipsoid plot (30% probability level) of the structure of **4**. Selected bond distances (Å) and angles (°): Ti–C(1), 2.355(18); Ti–C(2), 2.336(11); Ti–C(3), 2.408(13); Ti–C(5), 2.323(17); Ti–C(6), 2.371(13); Ti–C(7), 2.411(15); Ti–Cl, 2.343(4); Cp(c)–Ti, 2.043; Me_2Cp(c)–Ti, 2.060; Cl–C–Cl, 98.7(2); Me_2Cp(c)–Ti–Cp(c), 120.4; C(1)–C(4)–C(5), 95.5(12).

of 109.5°, increase of C–Ti bond distances on going from bridgehead carbon to peripheral carbons. The Cp(c)–Ti and Me_2Cp–Ti distances (2.043 and 2.060 Å, respectively) are smaller than those observed for the corresponding zirconium complex **1** (2.188 and 2.186 Å, respectively) [3]. The Me_2Cp(c)–Ti–Cp(c) angle, which measures how far the metal is displaced from the cyclopentadienyl ligand, is smaller (120.4°) in **4** than the corresponding angle in **1**, indicating that the titanium atom is displaced more closely to the mouth of the cyclopentadienyl ligands and that, consequently, the reaction site is opened less in **4**. The Cl–Ti–Cl angle is smaller (98.2(7)°) than that observed for **1** (102.11(7)°). The C_b–C(bridge)–C_b angle (95.5(12)°) is more strained in **4** than the corresponding angle is in **1** (100.7(4)°). The methyl group attached on the cyclopentadienyl is out of the cyclopentadienyl plane as much as the methyl is in **1** (the H_3C–C–Cp(c) angle for **1** and **4**, 175.5° and 176.0°, respectively).

Table 1
Ethylene polymerization results of **1**–**7** and CGC[a]

Complex	Time (min)	Temperature (°C)[b]	Activity (10^{-6} g/mol h)	M_w	M_w/M_n
1	10	80	15	183 000	12

[b] Final temperature.

2.2. Polymerization studies

The complexes **1**–**7** were studied for ethylene polymerization after activation with MAO (Table 1). The C1-bridged zirconocene complexes **1** and **2** show similar activities to [Me_2Si(Me_4C_5)(N*t*Bu)]$TiCl_2$ (CGC), but the titanocene complexes **4** and **5** show much higher activities than CGC. The Me_2Si-bridged complex **3** shows extremely high activity for ethylene polymerization. The activity is 15 times higher than that observed for CGC under the same conditions. The dinuclear complexes **6** and **7** show negligible activity under the same conditions. Interestingly, the molecular weights of the polymers obtained by the titanocene complexes **4** and **5** are significantly higher (M_w, ~800 000) than those of

Table 2
Ethylene/1-hexene copolymerization results of **3**, **5** and **CGC**[a]

Entry	Complex	1-Hexene (mol/L)	Time (min)	Temperature (°C)[b]	T_m (°C)	Activity (10^{-6} g/mol h)	M_w	M_w/M_n
1	**3**	0.10	5	93	117	132	210 000	3.0

[e] 14 mol% of 1-hexene content by the ^{13}C NMR analysis.

polymers obtained by the zirconocene complexes **1**, **2** and CGC.

The ethylene/1-hexene copolymerization reactivities were investigated for the highly active complexes **3** and **5** (Table 2). Complex **3** shows still higher activity than CGC but in the case of the titanocene complex **5**, the activity reduces to the level of CGC by the addition of 1-hexene. The 1-hexene incorporation ability of **3** and **5** is inferior to that of CGC. Polymers containing 3 and 4 mol% of 1-hexene are obtained by **3** and **5**, respectively, but CGC gives a polymer containing 14 mol% of 1-hexene under the same conditions (entries 3, 8 and 11) [9]. The T_m value is correlated with the 1-hexene incorporation. With the initial increase of the 1-hexene feeding amount, the T_m value decreases but a plateau is observed above 0.3 M of 1-hexene feeding for both **3** and **5**, which implies that the 1-hexene incorporation is limited to some extent and that it cannot be easily increased above that value merely by increasing the 1-hexene feed amount. The molecular weight is reduced not only by the addition of 1-hexene but also with the increase of the 1-hexene feeding for complex **5**, implying 1-hexene acts as a chain transfer agent in this catalyst system.

3. Conclusion

C1-bridged 2,5-dimethylcyclopentadienyl *ansa*-titanocene complexes, [Me(H)C(η^5-C_5H_4)(η^5-2,5-$Me_2C_5H_2$)]-$TiCl_2$ (**4**) and [($CH_3CH_2CH_2$)(H)C(η^5-C_5H_4) (η^5-2,5-$Me_2C_5H_2$)]$TiCl_2$ (**5**) show much higher activity for ethylene polymerization than the corresponding *ansa*-zirconocene complex [Me(H)C(η^5-C_5H_4)(η^5-2,5-$Me_2C_5H_2$)]-$ZrCl_2$ (**1**) and the molecular weights of the obtained polymers are significantly higher (M_w, ~800 000) than those of polymers obtained with the zirconocene complex **1**. The Me_2Si-bridged complex [Me_2Si(η^5-2,5-$Me_2C_5H_2$)$_2$]$ZrCl_2$ (**3**) shows extremely high activity for ethylene polymerization and the activity is 15 times higher than that of [$Me_2Si(Me_4C_5)$(N*t*Bu)]$TiCl_2$ (CGC). However, Complexes **3** and **5** are inferior to CGC in terms of comonomer incorporation ability in ethylene/1-hexene copolymerization.

4. Experimental

4.1. General considerations

All manipulations were performed under an inert atmosphere using standard glove box and Schlenk techniques. Toluene, pentane, THF and C_6D_6 were distilled from benzophenone ketyl. Pyridine was dried over CaH_2. Toluene used for polymerization reactions was purchased from Aldrich (anhydrous grade) and purified further over Na/K alloy. Ethylene was purchased from Conley Gas (99.9%) and purified by contact with molecular sieves and copper overnight under a pressure of 150 psig. Methylaluminoxane (MAO) was purchased as a solution in toluene from Akzo (7.6 wt% of Al, MMAO type 4). $TiCl_2(NMe_2)_2$ was prepared according to the literature method [10]. NMR spectra were recorded on a Varian Mercury plus 400 or Bruker spectrometer. Elemental analyses were carried out at the Inter-University Center Natural Science Facilities, Seoul National University. Gel permeation chromatograms (GPC) were obtained at 140 °C in trichlorobenzene using Waters Model 150-C+ GPC and the data were analyzed using a polystyrene analyzing curve. Differential scanning calorimetry (DSC) was performed on a Thermal Analysis 3100.

4.2. Synthesis of [Me(H)C(η^5-C_5H_4)(η^5-2,5-$Me_2C_5H_2$)]$TiCl_2$ (**4**)

$TiCl_2(NMe_2)_2$ (0.209 g, 1.01 mmol) and the dilithium salt [Me(H)C(C_5H_4)(2,5-$Me_2C_5H_2$)]Li_2 (0.200 g, 1.01 mmol) were weighed in a vial inside a glove box. Cold pyridine (2.5 mL, −20 °C) was added and the resulting mixture was stirred for 3 min at room temperature. The solvent was removed to give a residue which was dissolved in benzene. The solution was filtered and the solvent was removed by vacuum to give a red oily residue which was used for the next reaction without further purification. ^{1}H NMR (pyridine-d_5): δ 6.44 (quartet, J = 2.0 Hz, 1H, Cp–H), 6.37 (quartet, J = 2.0 Hz, 1H, Cp–H), 6.18 (d, J = 3.2 Hz, 1H, Me_2Cp–H), 6.12 (d, J = 3.2 Hz, 1H, Me_2Cp–H), 5.48 (quartet, J = 2.0 Hz, 1H, Cp–H), 5.17 (quartet, J = 2.0 Hz, 1H, Cp–H), 3.86 (quartet, J = 7.2 Hz, 1H, C*H*CH_3), 2.98 (s, 6 H, NCH_3), 2.97 (s, 6H, NCH_3), 2.07 (s, 3H, CH_3), 1.95 (s, 3H, CH_3), 1.61 (d, J = 7.2 Hz, 3H, CHCH_3) ppm. The bis(dimethylamido)titanium complex was dissolved in benzene (1.5 mL) and Me_2SiCl_2 (0.39 mL, 3.0 mmol) was added. The solution was stirred for 1 h to give dark brown precipitates, which were collected by filtration. The solid was pure by analysis of the ^{1}H and ^{13}C NMR spectra (0.085 g; overall yield, 28%). Single crystals suitable for X-ray crystallography were deposited when the bis(dimethylamido) complex was reacted with Me_2SiCl_2 in the absence of stirring. ^{1}H NMR (C_6D_6:pyridine-d_5, 10:1): δ 6.76 (quartet, J = 2.8 Hz, 1H, Cp–H), 6.83 (quartet, J = 2.8 Hz, 1H, Cp–H), 6.67 (d, J = 3.6 Hz, 1H, Me_2Cp–H), 6.64 (d, J = 3.6 Hz, 1H, Me_2Cp–H), 5.45 (dd, J = 3.6, 2.8 Hz, 1H, Cp–H), 5.18 (dd, J = 3.6, 2.8 Hz, 1H, Cp–H), 3.90 (quartet, J = 7.2 Hz, 1H, C*H*CH_3), 1.83 (s, 3H, CH_3), 1.67 (s, 3H, CH_3), 1.40 (d, J = 7.2 Hz, 1H, CHCH_3) ppm. ^{13}C NMR (C_6D_6:pyridine-d_5, 10:1): δ 133.88, 132.32, 131.58, 129.95, 126.70, 124.89, 111.91, 111.36, 109.28, 102.59, 32.43, 18.78,

16.22, 15.87 ppm. *Anal.* Calc. for $C_{14}H_{16}Cl_2Ti$: C, 55.48; H, 5.33. Found: C, 55.11; H, 5.53%.

4.3. Synthesis of [(CH$_3$CH$_2$CH$_2$)(H)C(η^5-C$_5$H$_4$)-(η^5-2,5-Me$_2$C$_5$H$_2$)]TiCl$_2$ (5)

$TiCl_2(NMe_2)_2$ (1.80 g, 8.70 mmol) was dissolved in toluene (10 mL) and the dilithium salt [$(CH_3CH_2CH_2)$-$HC(C_5H_4)(2,5\text{-}Me_2C_5H_2)$]$Li_2(THF)_{2.25}$ (3.38 g, 8.70 mmol) was dissolved in a cosolvent of toluene (25 mL) and pyridine (7 mL). After the two solutions were cooled in a refrigerator (−20 °C), they were rapidly combined. The combined solution was stirred for 20 min at room temperature and the solvent was removed by vacuum. The bis(dimethylamido) complex was extracted with pentane. Removal of the solvent gave a red residue which was pure by analysis of the ^{1}H NMR spectrum. The residue was used for the next reaction without further purification. ^{1}H NMR (C_6D_6): δ 6.38 (s, 1H, Cp–H), 6.32 (s, 1H, Cp–H), 6.13 (d, J = 2.8 Hz, 1H, Me_2Cp–H), 6.08 (d, J = 2.8 Hz, 1H, Me_2Cp–H), 5.22 (s, 1H, Cp–H), 5.03 (s, 1H, Cp–H), 3.61 (t, J = 7.8 Hz, 1H, bridge-CH), 3.01 (s, 6H, NCH_3), 2.98 (s, 6H, NCH_3), 2.05–1.93 (m, 2H, $CH_2CH_2CH_3$), 1.95 (s, 3H, CH_3), 1.82 (s, 3H, CH_3), 1.46 (dq, J = 14.4, 7.2 Hz, 2H, $CHCH_2CH_2$), 0.97 (t, J = 7.6 Hz, 3H, CH_2CH_3). The residue was dissolved in pentane (35 mL) and Me_2SiCl_2 (2.25 g, 17.3 mmol) was added. The solution was stirred for 30 min. The solvent was decanted and product was dissolved in toluene. Some impurities were deposited from the solution when the solution was stored at room temperature for 1 day. The precipitates were removed by filtration over Celite. Removal of solvent gave a brown solid (1.44 g, overall 50%). ^{1}H NMR (C_6D_6): δ 6.73 (quartet, J = 2.8 Hz, 1H, Cp–H), 6.65 (quartet, J = 2.8 Hz, 1H, Cp–H), 6.63 (d, J = 4.0 Hz, 1H, Me_2Cp–H), 6.60 (d, J = 4.0 Hz, 1H, Me_2Cp–H), 5.15 (dd, J = 5.2, 3.2 Hz, 1H, Cp–H), 4.99 (dd, J = 4.8, 2.4 Hz, 1H, Cp–H), 3.59 (t, J = 8.4 Hz, 1H, bridge-CH), 1.75–1.60 (m, 2 H, CH_2CH_3), 1.70 (s, 3H, CH_3), 1.55 (s, 3H, CH_3), 1.22 (dq, J = 14.4, 7.2 Hz, 2H, $CHCH_2CH_2$), 0.83 (t, J = 7.6 Hz, 3H, CH_2CH_3). ^{13}C NMR (C_6D_6): δ 133.99, 132.36, 131.90, 129.84, 127.10, 124.52, 111.69, 111.38, 109.25, 102.03, 38.48, 32.09, 21.13, 18.63, 16.11, 14.19 ppm. *Anal.* Calc. for $C_{16}H_{20}Cl_2Ti$: C, 58.04; H, 6.11. Found: C, 57.67; H, 6.20%.

4.4. Synthesis of Me$_2$Si[(η^5-2,5-Me$_2$C$_5$H$_2$)TiCl$_3$]$_2$ (6)

$TiCl_2(NMe_2)_2$ (0.341 g, 1.65 mmol) was dissolved in toluene (14 mL) and the dilithium salt $Me_2Si[(2,5\text{-}Me_2\text{-}C_5H_2)]Li_2 \cdot (THF)_2$ (0.300 g, 0.820 mmol) was dissolved in a cosolvent of toluene (2 mL) and pyridine (2 mL). After the two solutions were cooled in a refrigerator (−20 °C), they were rapidly combined. The combined solution was stirred for 3 h at room temperature and solvent was removed by vacuum. Toluene (10 mL) was added and the solution was filtered over Celite. Removal of solvent gave a red residue which was triturated in pentane. The obtained solid was pure by the analysis of the ^{1}H and ^{13}C NMR spectra. ^{1}H NMR (C_6D_6): δ 5.80 (s, 4H, Cp–H), 3.11 (s, 24H, NCH_3), 2.01 (s, 12H, CH_3), 1.03 (s, 6H, $SiCH_3$). ^{13}C NMR (C_6D_6): δ 134.68, 123.33, 116.47, 48.60, 17.23, 3.50. The residue was dissolved in toluene (10 mL) and excess Me_2SiCl_2 (~2 mL) was added. The solution was stirred for 3 h. The solvent was removed by vacuum to give a red residue which was triturated in pentane (0.340 g, 75%). ^{1}H NMR (C_6D_6:pyridine-d_5, 10:1): δ 6.45 (s, 4H, Cp–H), 2.05 (s, 12H, CH_3), 0.79 (s, 6H, $SiCH_3$). ^{13}C NMR (C_6D_6:pyridine-d_5, 10:1): δ 147.63, 135.44, 128.80, 19.95, 1.76. *Anal.* Calc. for $C_{16}H_{22}Cl_6Ti_2Si$: C, 34.88; H, 4.03. Found: C, 34.52; H, 4.22%.

4.5. Synthesis of Me$_2$Si[(η^5-2,5-Me$_2$C$_5$H$_2$)Ti{O(2,6-iPr$_2$C$_6$H$_3$)}Cl$_2$]$_2$ (7)

To a flask containing **6** (0.247 g, 0.448 mmol) and cold toluene (5 mL, −20 °C) was added KO(2,6-iPr$_2$C$_6$H$_3$) (0.165 g, 0.896 mmol), which was prepared by treatment of KH with the corresponding alcohol in THF. The solution was stirred for 2 h and filtered over Celite. The solvent was removed by vacuum to give a yellow residue which was triturated in pentane. The yield was 0.320 g (86%). ^{1}H NMR (C_6D_6): δ 7.10–6.98 (m, 6H), 5.66 (s, 4H, Cp–H), 3.48 (septet, J = 6.4 Hz, 4H, CH), 2.22 (s, 12H, CH_3), 1.28 (d, J = 6.4 Hz, 24H, $CH(CH_3)$), 1.19 (s, 6H, $SiCH_3$). ^{13}C NMR (C_6D_6): δ 164.49, 145.20, 138.51, 131.21, 124.90, 123.80, 122.94, 27.45, 24.08, 19.74, 2.16. *Anal.* Calc. for $C_{40}H_{56}Cl_4O_2SiTi_2$: C, 57.57; H, 6.76. Found: C, 57.25; H, 6.58%.

4.6. Crystallographic studies

A crystal of **4**, coated with grease (Apiezon N), was mounted inside a thin glass tube with epoxy glue and placed on an Enraf-Nonius CCD single crystal X-ray diffractometer. The structures were solved by direct methods (SHELXL-97) [11] and refined against all F^2 data (SHELXL-97). All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were treated as idealized contributions. Detailed structural data are given in the supplementary information. *Crystal data for* **4:** $C_{14}H_{16}Cl_2$ Ti, M = 303.07, a = 10.962(4) Å, b = 13.744(5) Å, c = 9.000(3) Å, Z = 4, d = 1.485 g/cm^3, orthorhombic, space group *Pnma*, crystal size 0.20 × 0.15 × 0.15 mm, T = 293(2) K, $2.71 \leqslant \Theta \leqslant 25.44$, $-12 \leqslant h \leqslant 13$, $-16 \leqslant k \leqslant 15$, $-10 \leqslant l \leqslant 10$, 4914 measured reflections, 1281 independent reflections (R_{int} = 0.2039), μ = 0.999 mm^{-1}, R_1 [$F^2 > 2\sigma(F^2)$] = 0.1142, ωR_2 = 0.2456.

4.7. Polymerization

In a dry box, to a dried 70 mL glass reactor was added 30 mL of toluene or 1-hexene solution in toluene. The reactor was assembled and brought out from the dry box. The reactor was heated to a given temperature by mantle. After an activated catalyst, prepared by mixing 0.25 μmol of catalyst and MAO (Akzo, MMAO type 4, 6.4 wt% of Al, 0.63 g (Al/Zr, 6000) or 0.84 g (Al/Zr, 8000)), was added via a syringe, ethylene (100 psig) was fed immediately. After polymerization had been conducted for a given time, the ethylene was vented and acetone was added to the reactor to give white precipitates which were collected by filtration and dried under vacuum.

Chart 1.

certain extent, but isospecificity and regioselectivity of the catalyst becomes poorer [12]. Much of the literature deal with modifying the structure of the metallocene itself, because this is the most effective way to regulate polymerization behavior and polymer structure [2,13,14].

Keeping in view these factors, we report in this paper another member of *ansa*-zirconocene catalysts, namely *rac*-dimethylsilyl-bis(2,4,6-trimethyl-1-indenyl)zirconium dichloride (**1**) (see Chart 1). The influence of polymerization temperature (T_p) on polypropylene microstructure has been studied and the results are compared with the *rac*-dimethylsilylbis(indenyl)zirconium dichloride (**2**) congener under identical conditions.

2. Results and discussion

2.1. Polymerization kinetics

The results of propylene polymerization by catalyst **1** are shown in Table 1. As can be seen from the table, the activity of catalyst **1** was strongly affected by T_p. Low catalytic activity was observed at low T_p, which increased to a maximum at 70 °C and then decreased. A similar behavior has been observed with most Ziegler–Natta catalysts. This was interpreted as slow chain propagation at low temperature and rapid catalyst deactivation at elevated temperatures [15]. Catalyst **2** showed a different activity behavior. A sharp decrease in activity was observed with increase in T_p and the maximum activity was observed at 40 °C. Compared to **2**, catalyst **1** shows better stability at high temperature.

The influence of T_p on the kinetic profiles of propylene polymerization was also investigated (Fig. 1). As can be seen from the figure, all polymerizations performed by **1** have a short induction period followed by rate decay after the maximum rate is reached. It can also be seen that the extent of rate decay increases with increasing T_p. At 50 °C the rate decayed to about 1/3 of the maximum rate after 60 min of polymerization, while the rate decayed to only about 1/5 of the maximum value when T_p was 90 °C. This means that deactivation of the catalyst was accelerated at higher temperature.

The molecular weight of the produced isotactic polypropylene (PP) was also affected by T_p. It can be seen from Table 1 that for catalyst **1**, increasing T_p from 30 to 90 °C caused a drop in M_η from 63 300 to 5930. The same trend was observed for complex **2** but the molecular weight was lower than in the case of **1**. In general, a decrease in molecular weight of polypropylene with T_p is a typical phenomenon found in the propylene polymerization by metallocene/MAO catalysts. Usually, the activation energies of chain termination by β-H elimination (the most frequent chain termination reaction in

metallocene complexes) or other chain transfer reactions are higher than that of propagation. The high polymer molecular weight produced by **1** compared to **2** can be explained by the presence of 2-methyl in the former system, which suppresses chain termination by β-H elimination reaction [1].

2.2. Polymer microstructure

The microstructure of the polypropylene produced by **1** at different T_p was analyzed by ^{13}C NMR spectroscopy. The ^{13}C NMR spectra of PP by **1** are shown in Fig. 2, and the measured methyl pentad intensities at

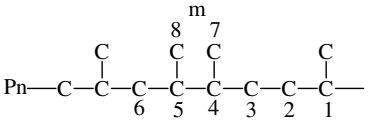
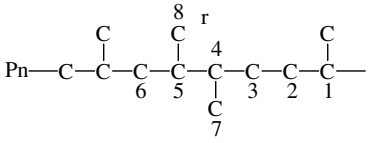
Polymerization conditions are the same as in Table 1.

different T_p are summarized in Table 2. Under similar polymerization conditions, the isotacticity of PP produced by **1** is higher than that of **2**, and it is very sensitive to T_p. For catalyst **1**, the [mmmm] pentad percentage dropped from 92% to 51% and the melting temperature from 149 to 84 °C as the T_p increased from 30 to 90 °C. Comparing the two metallocenes **1** and **2** at the same T_p, it is clear that introducing the methyl groups in the former greatly improves the isotacticity and melting temperature. At T_p = 50 °C, **1** gives PP with [mmmm] = 92% and T_m = 146 °C, while catalyst **2** displays [mmmm] of 82% and T_m of 134 °C under the same conditions.



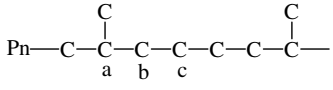
The increase of stereoirregular pentads [mmmr], [mmrr] and [mrrm] with T_p can be explained by the acceleration of chain epimerization at high temperature [2]. Low propylene concentration at high T_p is also a factor favoring epimerization. It can be seen in Table 2 that there are also strong increases of the pentads [mmrm]+[rmrr], [mrrr] and [rrrr] with T_p. These pentads are formed when successive mis-insertion happens. So it means that the active site control over the chain propagation is partly lost when T_p increases, and chain-end control begins to play an important role. Therefore, possible change of the catalyst's configuration from racemic to mesomeric at elevated temperature may also play an important role in influencing the stereochemical structure of PP. An evidence for this change is the loss of the catalyst's stability at high temperature.

2.3. Regioselectivity



The dominating mechanism in isospecific polymerization is 1,2-insertion (also called primary insertion). But polypropylene produced by isospecific zirconocenes shows incomplete regioregularity [16,17] caused by occasional insertions of isolated secondary (2,1 meso and racemic) units.

^{13}C NMR is a powerful tool for studying regioregularity in polypropylene, and the amount of regioerrors in the PP chain can be calculated from the relative intensities of the peaks arising from the regioirregular structures. In Fig. 2 a series of ^{13}C NMR signals were assigned to various regioirregular structures, including the structures formed by 2,1-insertion and 1,3-insertion (see Chart 2). According to the literature, the 1,3-enchainment is formed by the transformation of a part of the 2,1-insertion through β-hydrogen exchange [16]. The amount of regioirregular structures in PP obtained by **1** at different T_p is listed in Table 3. It is seen that the total number of regioirregular insertions increases with increase in T_p. Table 3 also shows that for catalyst **1**, only 2,1-insertion in the *m*-configuration is observed and no 2,1-insertion in the *r*-configuration is found, while catalyst **2** produces PP with 2,1-insertions both in the *m*-configuration and the *r*-configuration. The total amount of regioirregular structures is higher in catalyst system **2**/MAO than in **1**/MAO. The higher regiospecificity of catalyst **1** than **2** can possibly be attributed to the substitution pattern of the indenyl ligand in the former system. On the other hand, **1** shows higher stereospecificity when a 2,1-insertion happens, namely, **1** does not produce any 2,1-*r*-insertion.



It has been reported in the literature that 2,1-insertion units will reduce the molecular weight, because the rate of β-hydrogen transfer, after a secondary insertion, is higher than after a primary insertion [18]. The slightly higher molecular weight of PP by **1**/MAO than **2**/MAO may also be explained based on lower 2,1-insertion

2,1-*m*-insertion

2,1-*r*-insertion

1,3-insertion

Chart 2. Regioirregular structures.

Table 3
Regioerrors in isotactic polypropylene prepared at different T_p

Run no.	T_p (°C)	Catalyst	2,1 m-in (%)	2,1 r-in (%)	1,3-in (%)	Total (%)
1	30	**1**	0.37	0.00	0.00	0.37
2	50	**1**	0.42	0.00	0.16	0.58
3	70	**1**	0.10	0.00	0.52	0.62

6	50	**2**	0.44	0.10	0.19	0.73

Polymerization conditions are the same as in Table 1.

and 1,3-insertion rates in the former. However, it is still unclear if there are direct connections between the low rate of β-hydrogen transfer (high molecular weight) and low rate of mis-insertions (high regioregularity) when we try to explain the effect of changing the ligand structure in *ansa*-zirconocenes. On the other hand, the proportion of 1,3-insertion in iPP produced by **1** increases rapidly with increasing T_p. This phenomenon means that the β-hydrogen transfer becomes faster at higher temperature. Usually, 1,3-insertion can help to overcome the hindrance to chain growth caused by a 2,1-insertion via a β-hydride shift initiated transformation of the Zr-chain bond. The higher activity of **1**/MAO than **2**/MAO at 70 °C and higher temperatures might be partly the result of this effect.

2.4. End group analysis

As can be seen from Table 1, the molecular weight of PP decreases with increasing T_p. By ^{13}C NMR analysis (Fig. 2), the changes of chain end groups and thus the chain transfer reactions with T_p can be clearly seen. Three types of chain end groups, namely isopropyl, *n*-propyl and vinylidene groups were observed in PP synthesized by **1**/MAO at T_p values from 30 to 90 °C (see Chart 3).

As shown in Fig. 2(A), in PP produced by **1**/MAO at 50 °C, only isopropyl end groups (represented by the signals d, e and f) can be found. This kind of end group should be produced when the polymer chain was transferred to $AlMe_3$ in MAO. This chain transfer in propylene polymerization will produce the isopropyl end group either from Al–polymer connection or by the insertion of a propylene unit into the metal–methyl group. Therefore, isopropyl end groups are formed either at the initiated or the terminated polymer chains through the chain transfer reaction by MAO.

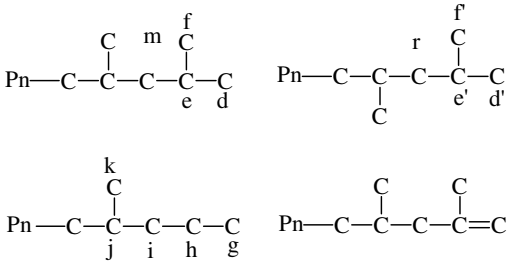

Chart 3. Chain-end structures.

The ^{13}C NMR spectra of PP obtained at 70 and 90 °C (Fig. 2B and C) still display strong peaks of the isopropyl end groups, meanwhile weak signals of the *n*-propyl end group (the peaks g, h, i, j and k) and the vinylidene group (peaks at 111.0 and 136.5 ppm, not shown in Fig. 2) are also detected. These end groups are formed by either β-H transfer or chain transfer to the monomer. Because the molar ratio of the (isopropyl end groups)/(*n*-propyl end groups) is high at all temperatures, the main chain transfer reaction is still by the cocatalyst in the **1**/MAO catalyst system.

It is worth noting that in the ^{13}C NMR spectra of PP obtained at 90 °C, an isopropyl end group with a racemic configuration between the last and the second last monomer units is also detected, which are represented by the signals d′ and f′. This is consistent with the low stereospecificity of the polymerization at such a high temperature.

In conclusion, the influences of T_p on activity and molecular weight in the **1**/MAO catalyzed propylene polymerization are similar to those observed by Kaminsky et al. [9] in *rac*-dimethylsilylbis(2,4,7-trimethyl-1-indenyl)zirconium dichloride. Under our experimental conditions, catalyst **1**/MAO shows better stereochemical and regiochemical control than $Me_2Si(2,4,7\text{-}Me_3Ind)_2ZrCl_2$ and gives PP with higher stereospecificity. The reason might be the steric hindrance caused by 7-methyl in $Me_2Si(2,4,7\text{-}Me_3Ind)_2ZrCl_2$. This methyl is moved to position 6 in **1**, which is quite far from the bridge and opposite the indenyl and thus causes less hindrance. As compared to **2**, which is less reactive and produces low molecular weight polypropylene, catalyst **1** polymerizes propylene with high activity to afford PP with higher molecular weight, higher isotacticity and higher regioregularity. Another beneficial feature of catalyst **1** is its higher stability at elevated temperature. Because the main chain transfer reaction in the **1**/MAO catalyst system is by the cocatalyst, it is foreseeable that the molecular weight of polymer can be further increased when higher monomer concentration is applied.

An important feature relating to catalyst **1** is its easy preparation in terms of starting material and reaction route (the main starting substances for preparing

2,4,6-trimethylindene are *m*-xylene and methacrylic acid [19]), and at the same time its relatively good performance for synthesizing isotactic polypropylene, in many aspects similar to the already industrialized *rac*-Me_2Si(2-Me-4,5-Benz[e]Ind)$_2ZrCl_2$ [20].

3. Experimental

All manipulations were carried out under a dry argon atmosphere using standard Schlenk techniques. Toluene was purified by refluxing over Na-benzophenone ketyl under argon atmosphere and distilled prior to use. Methylaluminoxane (MAO, 10% w/w toluene solution, Albemarle Co.) was used as obtained.

3.1. Synthesis of the ligand and catalyst

2,4,6-trimethylindene was prepared according to an established method [19]. The yield of 2,4,6-trimethylindene was 47%. It is an oil of light yellow color.

For the preparation of dimethylsilylbis(2,4,6-trimethylindene), 15.8 g (0.1 mol) of 2,4,6-trimethylindene was dissolved in 250 ml of tetrahydrofuran in a three-neck flask equipped with magnetic stirrer, a dropping funnel and a condenser. The mixture was cooled to −15 °C and 47.4 ml (2.11 M) of *n* -butyllithium solution in n-hexane was slowly added through dropping funnel. The reaction mixture was stirred for 4 h, then the temperature of the lithium salt was lowered to −78 °C and 6.1 ml (0.05 mol) of dichlorodimethyl silane [$(CH_3)_2SiCl_2$] was added. After this the reaction mixture was slowly warmed to room temperature and stirred for 24 h. Then the mixture was quenched with water, and the organic layer was separated. The aqueous layer was extracted three times with diethyl ether. The combined organic layer was dried over Na_2SO_4, the solvent was removed and the residue was crystallized from methanol:diethyl ether (2:1) to collect 3.7 g of product [21].[1]

For the synthesis of Me_2Si(2,4,6-Me_3Ind)$_2ZrCl_2$, in a three-neck flask 2.82 g (7.5 mmol) of dimethylsilylbis(2,4,6-trimethylindene) was dissolved in 250 ml of dry *n*-hexane at 30 °C and reacted with 8.2 ml (1.84 M) of *n*-butyllithium. After 4 h, the solvent was removed and the lithium salt was dried under vacuum. Then this salt was added to 1.75 g (7.5 mmol) of $ZrCl_4$ in 100 ml of CH_2Cl_2 at −78 °C. The reaction mixture was stirred for 12 h and the solvent was removed. The residue was extracted with hot toluene (100 °C) and 0.35 g of the pure racemic isomer of Me_2Si(2,4,6-Me_3Ind)$_2ZrCl_2$ was obtained by fractional crystallization at −20 °C [21].[2]

3.2. Polymerization procedure

Polymerization was carried out in toluene in a 250 ml glass reactor equipped with a propylene inlet and a magnetic stirrer. Polymerization grade propylene was further purified by passing over activated 4 Å molecular sieves. Toluene (100 ml) was introduced into the reactor and was saturated with propylene of 0.98 atm pressure. Calculated amounts of MAO and metallocene in toluene were added, respectively. After one hour, polymerization was stopped by adding acidified ethanol and the product was poured into an excess of ethanol. The resulting polymer was separated by filtration, washed and dried in vacuum at 60 °C to constant weight.

3.3. Polymer analysis

The intrinsic viscosity [η] of the polymer sample was measured with an Ubbelhode type viscometer using decahydronaphthalene as solvent at 135 ± 0.1 °C. M_η of the polymer was calculated according to the equation: $[\eta] = KM_\eta^\alpha$ ($K = 1.10 \times 10^{-4}$, $\alpha = 0.80$) [22]. ^{13}C NMR spectra of the polymers were recorded on a Bruker Avance 500 spectrometer at 120 °C in *o*-dichlorobenzene-D_4. Hexamethyldisiloxane (HMDS) was added as internal standard. Differential scan calorimetry (DSC) analysis of the polymer sample was performed in a Perkin–Elmer DSC-7 instrument to determine the melting temperature and heat of fusion of the polymer.

control properties such as density of polyethylene [10], AO was used in a ternary system with ethylene/norbornene/AO only for enhancement of norbornene insertion [11] or alternatively as a chain transfer agent to introduce terminal vinyl groups [12].

Recently, we reported the novel *ansa*-zirconocene catalyst, [methylenebis(2,5-dimethylcyclopentadienyl)]zirconium dichloride $[H_2C(Me_2C_5H_2)_2]ZrCl_2$ (**1**), which demonstrated excellent ENC activity. Thus, the careful catalyst design with permethylation adjacent to the *ansa*-bridge lowered the steric hindrance while retaining electronic properties [13]. We have performed preliminary studies on copolymerization of norbornene with AO, revealing that catalyst **1** has adequate activity despite substrate bulkiness. More importantly, this was the first time the AO content in the AO/norbornene copolymer, was calculated using the extended calculation method for ENC [14].

2. Experimental

2.1. Materials

Catalyst **1** was prepared according to the literature procedure [13a]. The cocatalyst methylaluminoxane (MAO) was purchased from Akzo as 8.2 wt% solution in toluene. The monomers, ethylene, propylene, norbornene (bicyclo[2,2,1]hept-2-ene), 1-hexene and 1-octene, were purchased commercially and purified over molecular sieves, CuO and Al_2O_3.

2.2. Polymerization

2.2.1. Copolymerization of ethylene/norbornene or propylene/norbornene

All manipulations were performed in an inert atmosphere using standard Schlenk techniques in conjunction with a VAC dry-box. The copolymerization was carried out using a 500 mL jacketed stainless steel reactor, equipped with a mechanical stirrer. Norbornene was dissolved in toluene to obtain 150 mL solution with the desired mol%. The solution was passed through a purification column and injected into the reactor. After the reactor temperature was stabilized at 70 °C, the MAO toluene solution (Al/Zr = 2000, 6.0 mL, 12.0 mmol, 8.2 wt% in toluene) was injected into the reactor and the reaction mixture was stirred for 15 min. The catalyst (**1**) in toluene (6×10^{-6} mol/L) was added to the reactor and polymerization began as gaseous ethylene or propylene was added to the reactor at a constant pressure. The polymerization time was measured from the moment stirring began. After polymerization occurred, the reactor was vented and the reaction mixture was added into ca. 2 L of acetone. The precipitated white polymer was filtered, washed with acetone several times and dried in a vacuum oven at 80 °C.

2.2.2. Copolymerization of 1-hexene or 1-octene AO/norbornene

All polymerization runs were performed with a 250 mL Schlenk flask immersed in an oil thermostat at 70 °C since the AO is a liquid. With vigorous stirring with a magnetic stirrer, the norbornene and appropriate amount of 1-hexene or 1-octene was dissolved in toluene to obtain 150 mL of a desired mol% solution and then the MAO toluene solution (Al/Zr = 2000, 5.0 mL, 10.0 mmol, 8.2 wt% in toluene) was added to the flask. After ca. 30 min of mixing, polymerization was initiated by addition of the catalyst **1** in toluene (5×10^{-6} mol/L). After polymerization occurred, the reaction mixture was quantitatively transferred into 2 L of acetone. The precipitated white polymer was filtered, washed with smaller quantities of acetone several times and finally dried in a vacuum oven at high temperature.

2.3. Characterization of copolymers

The glass transition temperatures (T_g) were measured with a TA DSC 2010 instrument. The sample was first heated to 300 °C, then cooled to 30 °C at a rate of 20 °C/min, and reheated to 250 °C at a rate of 20 °C/min. The data used in this work was taken from the second heating. The average molecular weights (M_w) and the molecular weight distributions were determined by a Waters/Wyatt GPC-MALLS system at

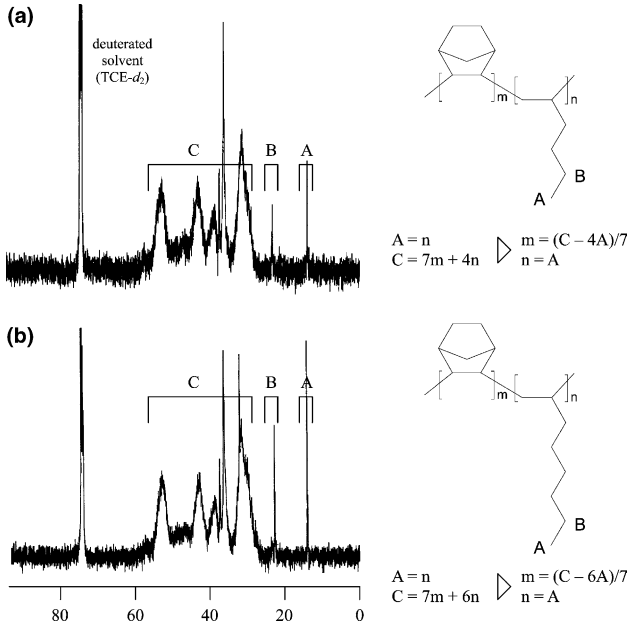

Fig. 1. Representative ^{13}C NMR spectra of (a) 1-hexene/norbornene copolymer (entry 7) and (b) 1-octene/norbornene copolymer (entry 10). Calculation of each monomer incorporation ratio, *m* and *n*, from the peak integration is presented to the right. TCE = 1,1,2,2-tetrachloroethane.

40 °C with chloroform as an eluent. These values were used without further correction. The ^{13}C NMR spectra were recorded by a Bruker Advance 400 FT NMR spectrometer in 1,1,2,2-tetrachloroethane-d_2, at 100 °C, in a 5 mm NMR tube, using inverse gated proton decoupling. Chemical shifts were referenced using the internal solvent resonance which was set to δ 74.0. The AO's content in the copolymers was calculated by ^{13}C NMR spectroscopy as illustrated in Fig. 1.

3. Results and discussion

Monomer composition, thermal property and molecular weight of the resulting polymers were investigated by altering the AO/norbornene feed ratio. The copolymerization results are summarized in Table 1 along with previous copolymerization results involving ethylene/norbornene and propylene/norbornene [13c]. The polymerization activity decreases as the accompanying norbornene monomer goes from ethylene to the bulkier 1-octene. However, within 1-hexene or 1-octene α-olefins, the activity change was not differentiated by the [*N*]/[AO] feed ratio. It ranged from 0.9 to 1.1 kg (polymer)/mmol(Zr) h. On the contrary, Tritto and co-workers [8b] reported the activity for the copolymerization of propylene/norbornene under another *ansa*-metallocene, *rac*-Et(indenyl)$ZrCl_2$/MAO, was decreased as the [*N*]/[*P*] feed ratio was increased. The polymer's glass transition temperature (T_g) is greatly dependent on the AO feed ratio and hence on its mole fraction in the polymer. Use of 1-hexene feed compositions of 39% and 75% result in polymer T_g's of 223.9 and 98.2 °C, respectively. In the case of 1-octene, uses of 30% and 51% result in T_g's of 207.8 and 166.8 °C, respectively.

The monomer composition of the polymer was determined by using ^{13}C NMR spectroscopy in 1,2-dideutero-1,1,2,2-tetrachloroethane with a pulse sequence of inversely gated proton decoupling for correct integration in order to achieve the relationship between polymer T_g and comonomer content. Fig. 1 shows representative ^{13}C NMR spectra of each AO/norbornene copolymer, demonstrating that AO's are incorporated in the polymer. The terminal CH_3 and its adjacent CH_2 carbon peaks for pendant alkyls of each AO are observed at ca. δ 14 and δ 23 (integrations A and B), respectively. The other peaks ranging from δ 26–60 (integration C) are assigned to the remaining carbon atoms. So the AO content in the polymers can be calculated from measuring peak integrations and equations illustrated to the right side of each spectrum in Fig. 1. This calculation method has been used to determine the norbornene content in ENC and to elucidate the microstructure of the copolymer in the literature. In addition it is demonstrated that the experimental calculation and theoretical prediction are very closely matched [15]. However, it should be mentioned that the composition percentage of norbornene calculated by ^1H NMR spectroscopy gives a lower value for AO content than that of ^{13}C NMR, with approximately a 10% difference.

There is an approximate linear relationship between the polymer T_g at °C (T_g) and norbornene content in mol% of the polymer (NB) (Fig. 2), described in Eq. (1).

$$NB = T_g/5 + 47. \quad (1)$$

The relationship is adopted for both the copolymers of 1-hexene and 1-octene, ignoring effects of molecular weights or polymer non-uniformity induced by long polymerization time. According to the experimental data, reduction of the norbornene mole fraction (or, increase of the AO mole fraction) by 1% lowers the T_g of the polymer by 5 °C. This is distinguished from a relationship, $NB = T_g/4 + 14$, applied for the ENC copolymer produced by other *ansa*-metallocenes, rac-ethylene(indenyl)$ZrCl_2$,[15b] and a relationship for propylene/norbornene copolymer, $NB = T_g/2.7 + 5$, derived from the work of Henschke et al. [8].

The polymer T_g decreases along with the polymerization time, as observed in entries 7 and 9 for 1-hexene, and in entries 10 and 11 for 1-octene (Table 1). The 1-octene content in the polymer increases from 21% to 34% upon extension of the polymerization time from 1 to 12 h (entries 11 and 12). The corresponding result for 1-hexene appears in entries 7 (39% AO feed, 1 h) and 8 (43% AO feed, 13.5 h) in which the AO contents are greatly changed in spite of small differences in its initial feed ratio. These results indicate that norbornene inserts more rapidly than the AO, causing a comonomer composition drift to higher concentration of α-olefin, and consequently a polymer of high AO content with an extension of polymerization time.

The molecular weight, determined by multi-angle laser light scattering (MALLS), was dependent on α-olefin monomer feed ratio, but not on the kind of α-olefin monomer. On increasing the 1-hexene feed from 39% to 75%, the M_w decreased from 15800 to 5500 g/mol. Additionally, increase of 1-octene feed from 34% to 51% diminished the M_w from 17500 to 6700 g/mol. According to these observations, coordination of AO to the active site of the catalyst seems to render the growing polymer chain susceptible to chain transfer reaction.

We are currently investigating methods to increase the copolymer molecular weight and to effect terpolymerization of ethylene/AO/norbornene with catalyst **1**.

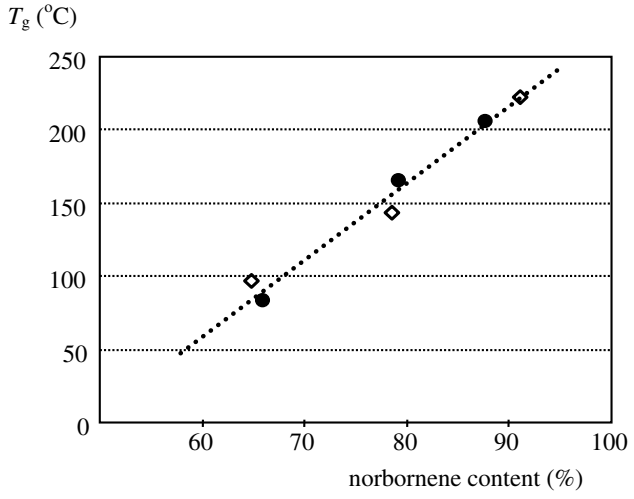

Fig. 2. Relationship between T_g's of AO/norbornene copolymers and norbornene content for AO = 1-hexene (◇) and AO = 1-octene (●).

4. Conclusions

We have found that the methylene bridged *ansa*-metallocene $[H_2C(Me_2C_5H_2)_2]ZrCl_2$ is a very effective catalyst especially for the copolymerization of 1-hexene/norbornene or 1-octene/norbornene. The α-olefin content in the copolymer, characterized and calculated by ^{13}C NMR spectroscopy and reported for the first time, greatly affected the glass transition temperature in such a way that increase of AO mole fraction by 1% lowers the polymer T_g by ca. 5 °C. The molecular weight of the copolymer was drastically decreased upon increase of AO feed.

Acknowledgements

We gratefully thank Ms. Sunyoung Park for the GPC-MALLS analysis and LG Chem./Research Park for the financial support. Prof. David G. Churchill of KAIST (Daejeon, Republic of Korea) has been very helpful in the written preparation of this manuscript.

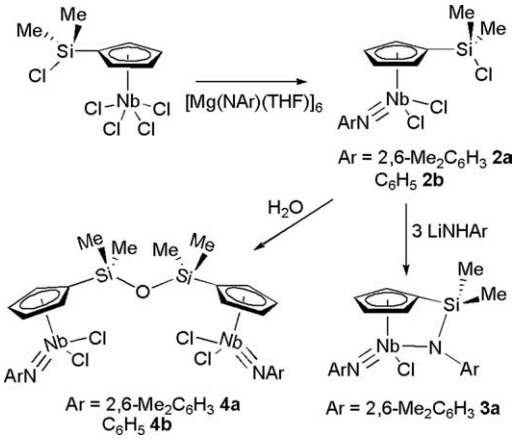
of $[Nb(C_5H_4SiMe_2Cl)Cl_2(N^tBu)]$ with $LiNH^tBu$ [11]. Finally, Chen and co-workers [25] observed that the imido compound $[Ta(C_5Me_4H)Cl_2(N^tBu)]$ was obtained on treating $TaCl_5$ with the aminosilyl-cyclopentadiene $C_5Me_4H(SiMe_2NH^tBu)$. From these results, it is clear that the thermodynamic stability of the M-imido bond is much higher than that of the bridging cyclopentadienyl-silyl-η-amido-M system (M = group 5 metal).



Most of these group 5 metal compounds containing the cyclopentadienyl-silyl-η-amido ligand were isolated as oily products. It has been suggested that aryl-imido ligands provide more crystalline solids [26]. Consequently, we decided to extend our research on Si–Cl functionalized monocyclopentadienyl niobium complexes [11,27,28] to isolate new aryl-imido derivatives using the organomagnesium compounds $[Mg(NAr)(THF)]_6$ (Ar = 2,6-$Me_2C_6H_3$, **1a**; Ph, **1b**) as imido transfer reagents. This method was first published by Power and co-workers [29] to obtain titanium and zirconium imido compounds. The main advantage of the organomagnesium compounds is their lower tendency to promote reduction of the metal centre than their lithium analogues. The reactivity of the Si–Cl bond of these imido complexes and the first X-ray structure of a group 5 metal silyl-η-amido complex is reported.

2. Results and discussion

The magnesium imide compound $[Mg(NAr)(THF)]_6$ (Ar = 2,6-$Me_2C_6H_3$, **1a**) was synthesized following the method reported [29] for the analogous phenyl derivative $[Mg(NPh)(THF)]_6$ (**1b**). Hence, reaction of $[MgBu_2]$ with 1 equivalent of the corresponding aniline $ArNH_2$ (Ar = 2,6-$Me_2C_6H_3$) in THF at −78 °C gave $[Mg(NAr)(THF)]_6$ (**1a**) as a scarcely soluble white solid in high yield (Eq. (1)). Compound **1a** was identified by ^1H NMR, but its instability prevented suitable elemental analysis being obtained, and the hexameric structure was proposed by analogy with the phenyl derivative **1b**, for which X-ray structure had been determined [29].

$$\underset{\text{Ar=2,6-Me}_2\text{C}_6\text{H}_3}{MgBu_2} + H_2NAr \xrightarrow[-2BuH]{THF} \underset{\mathbf{1a}}{[Mg(NAr)(THF)]_6} \qquad (1)$$

These magnesium imide compounds $[Mg(NAr)(THF)]_6$ (Ar = 2,6-$Me_2C_6H_3$, **1a**; Ph, **1b**) can be used to transfer the imido ligand when reacted with the monocyclopentadienyl niobium complex $[NbCp^{Cl}Cl_4]$ (Cp^{Cl} = $C_5H_4(SiMe_2Cl)$) (Scheme 1). Reaction of the niobium complex with 1 equivalent of the magnesium imides gave the new imido compounds $[NbCp^{Cl}Cl_2(NAr)]$ (Ar = 2,6-$Me_2C_6H_3$, **2a**; Ph, **2b**) as red oils after 3 h in diethylether at room temperature. Compared with the analogous reaction with the alkaline amide compound LiNHAr, this procedure prevents the formation of the corresponding amine NH_2Ar as a by-product,

Scheme 1.

which is difficult to eliminate because its solubility is close to that of compounds **2**, although the same compounds can also be obtained using the lithium amide LiNHAr (Ar = 2,6-$Me_2C_6H_3$, Ph). Also, this procedure seems to be a faster way to isolate the imido compounds and demonstrates the remarkable stability of the Nb-imido bond, formation of which is preferred to a bridging silyl-η-amido system between the cyclopentadienyl ring and the niobium centre.

The presence of a silicon–chlorine bond in compounds **2** moved us to try the synthesis of the silyl-η-amido complexes using the same magnesium imide to transfer the [NAr] moiety, but unfortunately decomposition was observed. However, reaction of **2a** with excess LiNHAr (Ar = 2,6-$Me_2C_6H_3$) in diethylether afforded the desired compound $[Nb(\eta^5\text{-}C_5H_4SiMe_2\text{-}\eta^1\text{-}NAr)Cl(NAr)]$ (**3a**) in moderate yield, whereas the same reaction for Ar = Ph was unsuccessful. We have observed that using more than two equivalents of the lithium amide compound is required although we have never detected the substitution of the remaining chlorine atom by another amido group, probably due to the steric hindrance of the [2,6-$Me_2C_6H_3$] substituent. However, the related diamido compound $[NbCp(NAr)(NHAr)_2]$ (Ar = 2,6-$Me_2C_6H_3$) was obtained through an analagous procedure [26]. This is the same method reported previously for introducing a bridging amido group between the metal atom and the silylcyclopentadienyl ligand in similar niobium complexes [11].

The dinuclear Si–O–Si bridged compounds $[\{NbCl_2(NAr)\}_2\{(\eta^5\text{-}C_5H_4SiMe_2)_2(\mu\text{-}O)\}]$ (Ar = 2,6-$Me_2C_6H_3$, **4a**; Ph, **4b**) were obtained in low yields upon addition of a stoichiometric amount of H_2O to toluene solutions of compounds **2a** and **2b**, respectively. The selective hydrolysis of the Si–Cl bond with formation of a Si–O–Si bridge was the expected behaviour for this type of niobium compound [11,27]. In contrast, it was observed [6,30–33] that the hydrolysis reactions of related monocyclopentadienyl group 4 metal complexes with

the chloro-silylcyclopentadienyl ligand afforded Si–O–M bridges. Attempts to produce further hydrolysis of Nb–Cl bonds failed and led to decomposition products with elimination of the corresponding amine.

The molecular structure of compound **3a** was determined by X-ray diffraction studies on a single crystal. Fig. 1 shows a view of the molecular structure of complex **3a** and Table 1 summarizes selected bond distances and angles. The coordination around the niobium centre is typical of half-sandwich imido complexes and could be described as a pseudo-tetrahedral structure with the centroid of the cyclopentadienyl ring, the chloro ligand, the imido nitrogen and the nitrogen of the bridging silyl-η-amido system occupying the four coordination sites.

The most remarkable feature of this structure is the distorted geometry due to the presence of this silyl-η-amido group bridging the cyclopentadienyl ring and the niobium atom. The Cg–Nb–N(1) (amido-silyl) bond angle (Cg = centroid of the Cp ring) of 100.76° for compound **3a** is the closest angle reported for amido ligands, which showed values in the range 106.60° and 116.67°

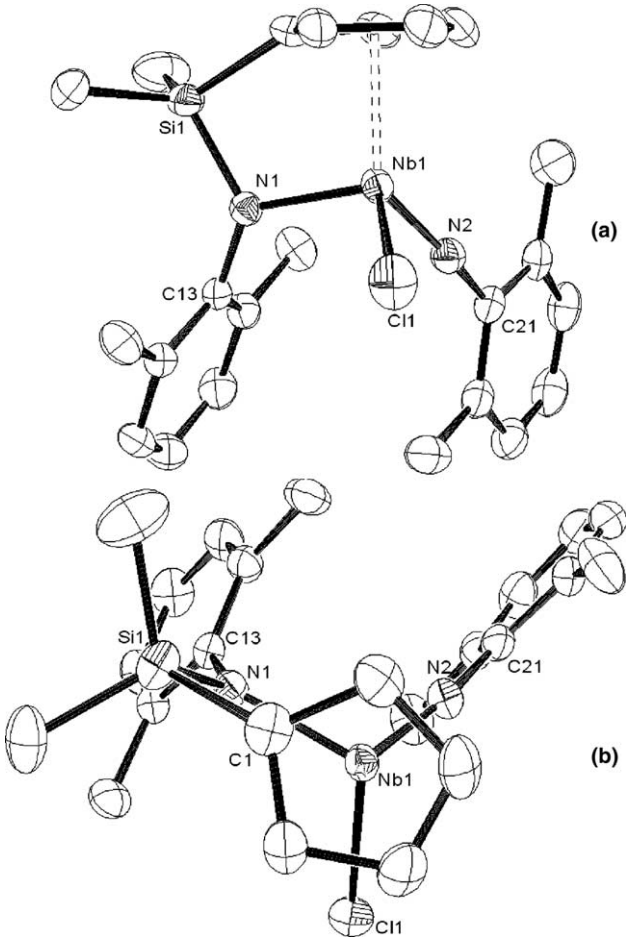


Fig. 1. Molecular structure of compound **3a**. (a) ORTEP ellipsoids are drawn at the 50% probability level and hydrogen atoms are omitted for clarity. (b) View perpendicular to the cyclopentadienyl ring plane.

Bond angles (°)	
Cg–Nb–Cl	112.85
Cg–Nb–N(1)	100.76
Cg–Nb–N(2)	130.20
N(2)–Nb–N(1)	102.3(1)
N(2)–Nb–Cl	101.05(8)
N(1)–Nb–Cl	107.83(7)
N(1)–Si–C(1)	91.9(1)
Si–N(1)–Nb	108.9(1)
C(13)–N(1)–Si	126.6(2)
C(13)–N(1)–Nb	124.7(8)
C(21)–N(2)–Nb	172.8(2)

Cg is the centroid of the cyclopentadienyl ring.

for unbridged ligands [11,21,26,34,35], and in addition is smaller than those reported for constrained silyl-η-amido group 4 metal complexes (105–108°) [7,36]. Moreover, the Cg–Nb–N(2) (imido ligand) bond angle of 130.20° is the most open observed for half-sandwich imido complexes [11,21,26,34,35], for which the expected value is in the range 119.24–124.15°, whereas the Cg–Nb–Cl bond angle of 112.85° and the angles formed by the three N(1), N(2) and Cl substituents about the niobium atom are in the usual range found for this type of half-sandwich imido compound.

As a consequence of the constrained bridging situation, the silicon atom presents a distorted tetrahedral environment (C(1)–Si–N(1) = 91.9(1)°) and the N(1) a distorted planar environment (Si–N(1)–Nb = 108.2(1)°). Furthermore, the N(1)–Nb and N(1)–Si bond distances of 2.016(2) and 1.754(2) Å are, respectively, slightly longer than the related Nb–N(amide) and Si–N(amide) bonds found in monoamide complexes of the type $[NbCp^RCl(NHR)(NR)]$ [26,37] and in the non-bridged aminosilyl compound $[NbCp^RCl_2(N^tBu)]$ ($Cp^R = C_5H_4(SiMe_2NH^tBu)$, Si–N = 1.719(9) Å) [11]. This is an indication of the lower N–Nb and N–Si π-bonding contribution. These data together with the co-planarity of the Nb, N(1), C(13) and Si atoms are consistent with the behaviour known for group 4 metal constrained geometry cyclopentadienylsilyl-η-amido complexes [7,18].

Regarding the cyclopentadienyl ring, the C–C bond distances are in the range 1.401–1.432 Å, indicating a preference for η^5-coordination in contrast to other half-sandwich group 5 metal imido and group 4 metal constrained geometry complexes, for which significant contribution of a η^3-allyl-η^2-olefin structure is proposed [7,21]. On the other hand, the Nb–C bond lengths, 2.382–2.519 Å, show two bonds clearly longer,

Nb–C(4) and Nb–C(5), corresponding to the C–C bond opposite to the imido ligand, as typically found for imido complexes [21,35]. Also, the Nb–C(1) bond supporting the bridge is not the shortest one as found in group 4 metal constrained geometry complexes [7,38]. This could be related with the location of the C(1) atom with respect to the imido ligand.

Another notable feature found in the structure of complex **3a** is that the imido-aryl group is almost perpendicular to the Cp ring, whereas in the other 2,6-disubstituted aryl-imido half-sandwich complexes the aromatic ring is almost coplanar with the cyclopentadienyl ligand, regardless of the nature of the other ligands present [21,26,35,37,39]. Moreover, the silyl group does not occupy the *trans* position with respect to the imido ligand as in the silylcyclopentadienyl imido compounds [$NbCp^RCl_2(NR)$] ($Cp^R = C_5H_4(SiMe_2NH^t$-Bu) [11], $C_5H_4(SiMe_3)$ [34]). Finally, the Nb–N(2) bond distance of 1.786(2) Å and the almost linear Nb–N(2)–C(21) bond angle of 172.8 (2)° of the imido ligand correspond to a typical triple bond of a 4-electron-donor ligand [23].

3. Experimental

All manipulations were performed under argon atmosphere, using standard Schlenk techniques or a glovebox. Solvents used were previously dried and freshly distilled under argon: diethylether and tetrahydrofuran from sodium benzophenone, ketyl and hexane from sodium–potassium amalgam. Deuterated solvents from Scharlau were degassed and stored over molecular sieves. NMR spectra were recorded on a Varian Unity FT-300 and chemical shifts are given in ppm (δ). C, H and N microanalyses were performed on a Perkin–Elmer 240B microanalyzer. Unless otherwise stated, reagents were obtained from commercial sources and used as received. $ArNH_2$ (Ar = 2,6-$Me_2C_6H_3$, Ph) (Aldrich) were distilled before use and stored under argon. LiNHAr was prepared in tetrahydrofuran in almost quantitative yield from $ArNH_2$ and ^{n}BuLi (Aldrich, 1.6 M in hexane) and the resulting product was washed with hexane (2 × 10 mL). $[Mg(NPh)(THF)]_6$ (**1b**) [29] and $[Nb[\eta^5\text{-}C_5H_4(SiClMe_2)]Cl_4]$ [27] were prepared according to the literature procedures.

3.1. [Mg(NAr)(THF)]$_6$ (Ar = 2,6-$Me_2C_6H_3$, **1a**)

Compound **1a** was isolated as a white solid following the procedure reported for $[Mg(NPh)(THF)]_6$ (**1b**) [29], from $ArNH_2$ (5.00 g, 41.25 mmol) and $[MgBu_2]$ (41.25 mmol) in THF (8.45 g, 95% yield). Data for **1a**: ^{1}H NMR: 6.71 (d, J = 7.6 Hz, 2H, $Me_2C_6H_3$), 6.62 (t, J = 7.6 Hz, 1H, $Me_2C_6H_3$), 3.55 (m, 4H, OCH_2), 2.34 (s, 6H, $Me_2C_6H_3$), 1.40 (m, 4H, CH_2).

3.2. [Nb{η^5-$C_5H_4(SiMe_2Cl)$}Cl_2(NAr)] (Ar = 2,6-$Me_2C_6H_3$, **2a**)

Diethylether (50 mL) was added to a solid mixture of $[Nb\{\eta^5\text{-}C_5H_4(SiMe_2Cl)\}Cl_4]$ (1.00 g, 2.54 mmol) and $[Mg(NAr)(THF)]_6$ (**1a**) (0.54 g, 0.42 mmol) at room temperature and the reaction mixture was stirred for 3 h. Over this time the mixture became dark red and the solvent was removed to half volume under reduced pressure. Hexane (20 mL) was added and the solution was filtered. The volatiles were completely removed to give a dark red oil which was characterized as **2a** (1.11 g, 90%). Data for **2a**: ^{1}H NMR: 6.78 (d, J = 7.1 Hz, 2H, $Me_2C_6H_3$), 6.67 (t, J = 7.1 Hz, 1H, $Me_2C_6H_3$), 6.25 (m, 2H, C_5H_4), 5.81 (m, 2H, C_5H_4), 2.34 (s, 6H, $Me_2C_6H_3$), 0.53 (s, 6H, $SiMe_2$). ^{13}C NMR: 154.1 (C_i, $Me_2C_6H_3$), 135.1 ($Me_2C_6H_3$), 129.8 ($Me_2C_6H_3$), 126.1 ($Me_2C_6H_3$), 123.1 (C_5H_4), 122.0 (C_i, C_5H_4), 113.3 (C_5H_4), 19.3 ($Me_2C_6H_3$), 2.3 ($SiMe_2$). *Anal.* Calc. for $C_{15}H_{19}Cl_3NNbSi$: C, 40.88; H, 4.35; N, 3.18. Found: C, 41.09; H, 4.45; N, 3.12%.

3.3. [Nb{η^5-$C_5H_4(SiMe_2Cl)$}Cl_2(NAr)] (Ar = C_6H_5, **2b**)

Compound **2b** was prepared from $[Nb\{\eta^5\text{-}C_5H_4(SiMe_2Cl)\}Cl_4]$ (1.00 g, 2.54 mmol) and $[Mg(NAr)(THF)]_6$ (**1b**) (0.47 g, 0.42 mmol) following the method given for **2a** and was obtained as a red oil (0.94 g, 90% yield). Data for **2a**: ^{1}H NMR: 7.02–6.80 (m, 5H, C_6H_5), 6.28 (m, 2H, C_5H_4), 5.86 (m, 2H, C_5H_4), 0.49 (s, 6H, $SiMe_2$). ^{13}C NMR: 156.0 (C_i, C_6H_5), 129.6 (C_6H_5), 128.7 (C_6H_5), 126.5 (C_6H_5), 124.5 (C_5H_4), 122.2 (C_i, C_5H_4), 114.4 (C_5H_4), 2.5 ($SiMe_2$). *Anal.* Calc. for $C_{13}H_{15}Cl_3NNbSi$: C, 37.84; H, 3.66; N, 3.39. Found: C, 37.12; H, 3.49; N, 3.46%.

3.4. [Nb(η^5-$C_5H_4SiMe_2$-η^1-NAr)Cl(NAr)] (Ar = 2,6-$Me_2C_6H_3$, **3a**)

A solution of **2a** (1.06 g, 2.40 mmol) in diethylether (30 mL) was treated dropwise with a solution of LiNHAr (Ar = 2,6-$Me_2C_6H_3$) (0.91 g, 7.21 mmol) in diethylether (30 mL) and the mixture was stirred for 16 h at room temperature. After addition of hexane (30 mL), the solution was filtered and the solvents were removed under vacuum to ca. 30 mL. The remaining solution was cooled to −38 °C to give complex **3a** as a yellow crystalline solid (0.70 g, 60% yield). Data for **3a**: ^{1}H NMR: 6.96–6.69 (m, 6H, $Me_2C_6H_3$), 6.46 (m, 2H, C_5H_4), 6.33 (m, 1H, C_5H_4), 6.23 (m, 1H, C_5H_4), 2.23 (s, 3H, $Me_2C_6H_3$), 2.12 (s, 6H, $Me_2C_6H_3$), 1.94 (s, 3H, $Me_2C_6H_3$), 0.28 (s, 3H, $SiMe_2$), 0.07 (s, 3H, $SiMe_2$). ^{13}C NMR: 132.1, 130.1, 124.3, 121.1, 118.2, 112.3, 112.0 and 109.5 ($Me_2C_6H_3$ and C_5H_4, C_{ipso} not observed), 19.4 ($Me_2C_6H_3$), 19.3 ($Me_2C_6H_3$), 17.5

($Me_2C_6H_3$), 0.2 (SiMe_2), −1.3 (SiMe_2). *Anal.* Calc. for $C_{23}H_{28}ClN_2NbSi$: C, 56.50; H, 5.77; N, 5.73. Found: C, 55.90; H, 5.43; N, 5.59%.

3.5. [{$NbCl_2(NAr)$}$_2${(η^5-C_5H_4)$_2$($Me_2SiOSiMe_2$)}] (Ar = 2,6-$Me_2C_6H_3$, **4a**)

Distilled water (0.02 mL, 1.20 mmol) was added to a mixture of **2a** (1.06 g, 2.40 mmol) and NEt_3 (0.33 mL, 2.40 mmol) in toluene (60 mL). After stirring for 24 h at room temperature, the solution was filtered and the volatiles removed under vacuum to give **4a** as a brown solid (0.40 g, 40% yield). Data for **4a**: ^{1}H NMR: 6.78 (m, 4H, $Me_2C_6H_3$), 6.73 (m, 2H, $Me_2C_6H_3$), 6.35 (m, 4H, C_5H_4) 5.91 (m, 4H, C_5H_4), 2.39 (s, 12H, $Me_2C_6H_3$), 0.37 (s, 12H, SiMe_2). *Anal.* Calc. for $C_{30}H_{38}Cl_4N_2Nb_2OSi_2$: C, 43.60; H, 4.63; N, 3.39. Found: C, 42.91; H, 4.29; N, 3.05%.

3.6. [{$NbCl_2(NAr)$}$_2${(η^5-C_5H_4)$_2$($Me_2SiOSiMe_2$)}] (Ar = C_6H_5, **4b**)

This compound was prepared as above from **2b** (1.00 g, 2.42 mmol), NEt_3 (0.34 mL, 2.42 mmol) and distilled water (0.02 mL, 1.21 mmol) to yield **4b** (0.37 g, 40%). Data for **4b**: ^{1}H NMR: 6.92–6.70 (m, 10H, C_6H_5), 6.40 (m, 4H, C_5H_4) 5.96 (m, 4H, C_5H_4), 0.33 (s, 12H, SiMe_2). *Anal.* Calc. for $C_{26}H_{30}Cl_4N_2Nb_2OSi_2$: C, 40.54; H, 3.93; N, 3.64. Found: C, 39.88; H, 3.81; N, 3.47%.

3.7. X-ray crystallographic study of **3a**

Suitable single crystals for the X-ray diffraction study were grown by standard techniques from a saturated solution of **3a** ($C_{23}H_{28}ClN_2NbSi$) in diethylether. A light yellow crystal, $0.31 \times 0.30 \times 0.16$ mm, monoclinic, space group $P2_1/n$ was used. Data collection were performed at 200 K on a Kappa-CCD area detecting diffraction system using a Mo Kα radiation. The unit cell dimensions were determined from 110 reflections between $\theta = 3.102°$ and 21.448°. Unit cell parameters were $a = 8.3381(5)$ Å, $b = 21.597(2)$ Å, $c = 12.751(1)$ Å, $\beta = 92.549(7)°$, $V = 2294.0(3)$ Å^3, $Z = 4$. X-ray data were collected within the θ-range of $3.01° < \theta < 27.51°$ to a completeness of 0.998. An empirical absorption correction was applied, and symmetry equivalent and multiple measured reflections were averaged with the program SORTAV [40]. A total of 19118 reflections were collected and merged ($R_{int} = 0.0688$) to give 5271 unique reflections of which 3884 were observed with $I > 2\sigma(I)$. The crystal structure was solved by direct methods and refined using full-matrix least squares on F^2 [41]. All non-hydrogen atoms were anisotropically refined. Hydrogen atoms were geometrically placed and left riding on their parent atoms. The final cycle of full-matrix least-squares refinement based on 5271 reflections and 253 parameters converged to final values of $R_1(F^2 > 2\sigma(F^2)) = 0.0388$, $wR_2(F^2 > 2\sigma(F^2)) = 0.0927$, $R_1(F^2) = 0.0668$, $wR_2(F^2) = 0.1014$ and goodness-of-fit = 1.011. Final difference Fourier maps showed no peaks higher than 0.513 nor deeper than −0.453 e Å^{-3}. Geometrical calculations were made with PLATON [42]. The crystallographic plots were made with ORTEP-3. All calculations were made at the University of Alcalá.

4. Supplementary material

Crystallographic data for the structural analysis for **3a** have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 259073. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 366 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

2. Experimental

2.1. General methods

^{1}H, $^{11}B\{^{1}H\}$, and $^{13}C\{^{1}H\}$ NMR spectra were recorded on Varian INOVA-400 or 500 MHz spectrometers. The solvents used were chloroform-d_1 ($CDCl_3$), benzene-d_6 (C_6D_6), or tetrahydrofuran-d_8 (THF-d_8) as indicated. Chemical shifts (δ) are reported in parts per million (ppm). Proton and carbon chemical shifts are relative to respective solvent internal standards: 7.27 (for proton), 77.23 (for carbon) ($CDCl_3$): 7.16, 128.39 (C_6D_6): 3.58, 67.40 (THF-d_8). Boron-11 chemical shifts are relative to prospective external reference: δ 0.00 (BF_3/Et_2O 1.0 M LiCl in D_2O). The coupling constants (J) are reported in Hz. The following abbreviations are used to describe peak patterns: "s" for singlet, "d" for doublet, "t" for triplet. "q" for quartet, "m" for multiplet, and "br" for broad peak. Data are presented as follows: chemical shift (multiplicity, integrated intensity, coupling constant, and assignment). High-resolution mass spectra (HRMS) were recorded on a VG-250S spectrometer with electron-impact spectra at 70 eV. Elemental analyses were conducted on a Perkin–Elmer 240 CHN analyzer by the analytical service in the Department of Chemistry at the University of Michigan, Ann Arbor. Melting points were recorded on a Laboratory Devices MEL_TEMP melting point apparatus with an uncorrected thermometer.

Solvents were freshly distilled prior to use. THF and diethyl ether were distilled from sodium and benzophenone ketyl under N_2. Pentane and hexane were distilled from sodium. All reagents were purchased from the commercial vendors and were used as received or distilled if necessary. All reactions were conducted under an inert atmosphere of argon or in the glovebox under nitrogen unless otherwise specified.

2.2. Syntheses

2.2.1. (*N*-allyl-*N*-ethylamino)vinylphenylborane (**12**)

A solution of *N*-allyl-*N*-ethylamine (3.61 g, 42.5 mmol) in 10 mL of CH_2Cl_2 was added to a solution of phenylvinylboron chloride [10] (6.4 g, 42.7 mmol) in 20 mL of CH_2Cl_2 at −78 °C with stirring. The mixture was stirred for 1 h. Triethylamine (4.3 g, 42.6 mmol) was then added and a white precipitate formed immediately. The reaction mixture was allowed to warm to 25 °C with stirring for 3 h. The solid was removed by filtration and the solvent was removed in vacuo. Vacuum distillation of the residue gave the product as a clear colorless liquid (84%), bp 67–70 °C at 0.05 torr. The ^{1}H NMR and ^{13}C NMR spectra were consistent with it existing as two B–N

rotomers with a ratio of 1:1. ^{1}H NMR (C_6D_6, 400 MHz): δ 7.42 (d, 4 H, J = 8.0 Hz, ArH), 7.31–7.19 (m, 6H, ArH), 6.64 (dd, 1H, J = 19.0, 13.2 Hz, BCH), 6.57 (dd, 1H, J = 19.0, 13.2 Hz, BCH′), 6.02 (bt, 2H, J = 13.2 Hz, alkene), 5.80–5.50 (m, 4H, alkene), 5.12–4.91 (m, 4H, alkene), 3.68 (dt, 2H, J = 5.2, 1.7 Hz, $=CCH_2$), 3.51 (dt, 2H, J = 5.2, 1.7 Hz, $=CCH'_2$), 3.12 (q, 2H, J = 7.1 Hz, Et), 2.93 (q, 2H, J = 7.1 Hz, Et′), 0.99 (t, 3H, J = 7.1 Hz, Et), 0.81 (t, 3H, J = 7.1 Hz, Et′). ^{13}C NMR (C_6D_6, 100.6 MHz): shows two sets of signals. ^{11}B NMR (C_6D_6, 115.5 MHz): δ 39.4 HRMS (EI, *m*/*z*): calc. for $C_{13}H_{18}{}^{11}BN$ (M^+), 119.1532; found 119.1528. *Anal.* Calc. for $C_{13}H_{18}BN$: C, 78.42; H, 9.11; N, 7.03. Found: C, 78.28; H, 8.59; N, 6.50%.

2.2.2. 1-Ethyl-2,5-dihydro-2-phenyl-1H-1,2-azaborole (*13*)

A solution of **12** (17.2 g, 86.4 mmol) in 20 mL of CH_2Cl_2 was added to a solution of bis (tricyclohexylphosphine)benzylidene ruthenium(IV) dichloride (Grubbs catalyst) (3.55 g, 4.31 mmol) in 40 mL of CH_2Cl_2 at 25 °C. The mixture was stirred at 25 °C for 10 h after which the color had changed from purple-red to dark brown. The solvent was removed in vacuo giving the product (12.6 g, 85%) as a clear colorless liquid, bp 60 °C at 0.05 torr. ^{1}H NMR (C_6D_6, 400 MHz): δ 7.75 (d, 2H, J = 8.0 Hz, ArH), 7.33 (t, 2H, J = 8.0 Hz, ArH), 7.25 (t, 1H, J = 8.0 Hz, ArH), 6.93 (d, 1H, J = 8.1 Hz, vinyl), 6.60 (d, 1H, J = 8.1 Hz, vinyl), 3.51 (m, 2H, $NCH_2CH=$), 3.26 (q, 2H, J = 7.0 Hz, Et), 0.94 (t, 3H, J = 7.0 Hz, Et). ^{13}C NMR (C_6D_6, 100.6 MHz): δ 148.5, 134.1, 132.3, 123.1, 128.9, 128.1, 127.6, 60.3 ($NCH_2C=$), 41.4 (Et), 16.7 (Et). ^{11}B NMR (C_6D_6, 115.5 MHz): δ 39.4. HRMS (EI, *m*/*z*): Calc. for $C_{11}H_{14}{}^{11}BN$ (M^+), 171.1219; found, 171.1224. *Anal.* Calc. for $C_{11}H_{14}BN$: C, 77.24; H, 8.25; N, 8.19. Found: C, 77.83; H, 8.45; N, 7.68%.

2.2.3. Lithium 1-ethyl-2-phenyl-1H-1,2-azaborolide (*14*)

1-Ethyl-2,5-dihydro-2-phenyl-1*H*-1,2-azaborole (5.0 g, 29.2 mmol) was dissolved in 15 mL of ether at −78 °C. To this was added a solution of LDA (3.13 g, 29.2 mmol) in 15 mL of ether. The mixture was stirred at −78 °C for 2 h and at 25 °C for 10 h. After removal of the solvent the residue was washed with 3 × 20 mL of pentane. The residue was dried under vacuum to give the product as a light yellow powder (3.9 g, 77%). ^{1}H NMR (THF-d_8, 400 MHz): δ 7.51 (d, 2H, J = 8.0 Hz, ArH), 7.05 (t, 2H, J = 8.0 Hz, ArH), 6.87 (t, 1H, J = 8.0 Hz, ArH), 5.91 (m, 1H, H_4), 5.86 (m, 1H, H_5), 4.16 (m, 1H, H_3), 3.78 (q, 2H, J = 7.0 Hz, Et), 1.27 (t, 3H, J = 7.0 Hz, Et). ^{13}C NMR (THF-d_8, 100.6 MHz): δ 133.9, 127.2, 123.8, 112.8, 111.9, 86.5 (br), 43.2 (Et), 19.6 (Et). ^{11}B NMR (THF-d_8, 115.5 MHz): δ 29.4.

2.2.4. (η-1-Ethyl-2-phenyl-1H-1,2-azaborolyl)(η-pentamethylcyclopentadienyl)zirconium(IV) dichloride (*8*)

A solution of lithium 1-ethyl-2-phenyl-1*H*-1,2-azaborolide (0.42 g, 2.37 mmol) in 10 mL of ether was added to a suspension of pentamethylcyclopentadienylzirconium trichloride (0.78 g, 2.34 mmol) in 10 mL of ether at −78 °C. Stirring was maintained for 12 h as the mixture was slowly warmed to 25 °C. The solvent was removed in vacuo and the residue was washed with pentane and dried, affording the product (0.54 g, 56%) as a yellow powder. The product could be recrystallized from CH_2Cl_2/pentane to afford yellow crystals. ^{1}H NMR (400 MHz, C_6D_6): δ 7.79 (dd, J = 8.2, 1.4 Hz, 2H, ArH); 7.29 (t, J = 7.3 Hz, 2H, ArH); 7.19 (t, J = 7.4 Hz, 1H, ArH),; 6.24 (t, J = 2.6 Hz, 1H ring CH); 5.33 (dd, J = 4.9, 2.7 Hz, 1H, ring CH); 4.62 (dd, J = 4.9, 2.7 Hz, 1H, ring CH); 4.06 (dq, J = 14.0, 7.0 Hz, 1H, NCH); 3.86 (dq, J = 14.0, 7.0 Hz, 1H, NCH′); 1.77 (s, 15H, CpMe) 0.89 (t, J = 7.3 Hz, 3H, NCH_2CH_3). ^{13}C NMR (100.6 MHz): δ 134.5, 128.5, 127.7, 127.5, 123.5, 114.1, 44.1, 16.8, 12.1. ^{11}B NMR (115.6 MHz, C_6H_6): δ 33.7. HRMS: Calc. for $C_{21}H_{28}{}^{11}B^{35}Cl_2N^{90}Zr$, 465.0740. Found: 465.0740. *Anal.* Calc. for $C_{21}H_{28}BCl_2N^{90}Zr$: C, 53.96; H, 6.05; N, 3.00. Found: C, 52.52; H, 6.41; N, 2.79%.

2.2.5. 1-Ethyl-3-chlorodimethylsilyl-2,3-dihydro-2-phenyl-1H-1,2-azaborole (*15*)

A solution of Me_2SiCl_2 (0.69 mL, 0.73 g, 5.65 mmol) in 15 mL of ether was added dropwise to a solution of lithium 1-ethyl-2-phenyl-1*H*-1,2-azaborolide (1.0 g, 5.65 mmol) in 25 mL of ether at −78 °C. When the addition was complete, the mixture was warmed slowly to 25 °C and stirred for 10 h. The solvent was removed under reduced pressure and the residue was extracted with pentane. The extracts were filtered through celite and the solvent was removed in vacuo leaving the product as an orange oil (1.38 g, 92%). ^{1}H NMR (400 MHz, $CDCl_3$): δ 7.40 (dd, J = 7.7, 1.8 Hz, 2H, ArH), 7.23 (m, 3H, ArH); 6.32 (dd, J = 3.8, 1.3 Hz, 1H, ViH); 5.70 (dd, J = 3.8, 2.4 Hz, 1H, ViH); 3.30 (m, 1H, NCH); 3.12 (m, 1H, NCH′); 2.64 (br s, 1H, BCH); 0.94 (t, J = 7.1 Hz, 3H, CMe), 0.14 (s, 3H, SiMe′), 0.09 (s, 3H, SiMe′). ^{13}C NMR (100.6 MHz, C_6D_6): δ 139.1, 133.5 (Ph), 128.8 (Ph), 127.9 (Ph), 122.2, 41.1 (NCH_2), 39 (br, BCH), 17.3 (CMe), 2.4 (SiMe), 0.2 (SiMe′). ^{11}B NMR (115.5 MHz, C_6D_6): δ 44.6. HRMS: Calc. for $C_{13}H_{19}{}^{11}B^{35}ClNSi$: 263.1068. Found: 263.1078. *Anal.* Calc. for $C_{13}H_{19}BClNSi$: C, 59.21; H, 7.28; N, 5.31. Found: C, 59.04; H, 7.12; N, 5.46%.

2.2.6. 1-Ethyl-3-(cyclopentadienyldimethylsilyl)-2,3-dihydro-2-phenyl-1H-1,2-azaborole (*16*)

A solution of cyclopentadienyl lithium (0.16 g, 2.27 mmol) in 10 mL of THF was added slowly to

a solution of 1-ethyl-3-chlorodimethylsilyl-2-3-dihydro-2-phenyl-1*H*-1,2-azaborole (0.60 g, 2.27 mmol) in 10 mL of THF at −50 °C. The reaction mixture was slowly warmed to 25 °C and stirred for 12 h. The solvent was removed in vacuo and the residue was extracted with pentane. Solvent was removed from the extracts leaving the desired product as a brown oil (0.58 g, 87%). ^{1}H NMR (400 MHz, C_6D_6): δ 7.40 (dd, J = 7.9, 1.2 Hz, 2H, ArH); 7.16 (t, J = 7.0 Hz, 2H, ArH); 7.10 (t, J = 7.0 Hz, 1H, ArH); 6.54 (br s, 2H, Cp); 6.50 (br s, 2H, Cp), 6.28 (dd, J = 4.0, 1.1 Hz, 1H, ViH); 5.54 (dd, J = 3.9, 2.8 Hz, 1H, ViH); 3.30 (m, 1H, NCH); 3.22 (br s, 1H, Cp); 3.10 (m, 1H, N CH′), 2.45 (dd, J = 2.6, 1.1 Hz, 1H, BCH); 0.92 (t, J = 7.1 Hz, 3H, CMe); −0.13 (s, 3H, SiMe); −0.35 (s, 3H, SiMe′). ^{13}C NMR (C_6D_6, 100.6 mHz): δ 137.8, 133.5, 133.0, 130.4, 128.6; 128.0, 127.7, 113.4, 67.5, 41.1, 37.4 (br), 25.6, 17.5, −4.8, −4.9. ^{11}B NMR (115.5 Hz, C_6D_6): δ 45.0. HRMS: Calc. for $C_{18}H_{24}{}^{11}BNSi$: 293.1771. Found: 293.1774.

2.2.7. [(η^5-cyclopentadien-1-yl)(η^5-1-ethyl-2-phenyl-1H-1,2-azaborol-3-yl)dimethylsilane]zirconium dichloride (**9**)

A solution of lithium diisopropylamide (0.66 g, 6.20 mmol) in THF (20 mL) was added to a solution of 1-ethyl-3-[cyclopentadienyldimethylsilyl]-2,3-dihydro-2-phenyl-1*H*-1,2-azaborole (0.91 g, 3.10 mmol) in 20 mL of THF at −78 °C. The mixture was slowly warmed to 25 °C and allowed to stir for 12 h. After removal of the solvent in vacuo the residue was washed with pentane. The solid was dissolved in 20 mL of toluene and added to a suspension of $ZrCl_4$ (0.69 g, 3.00 mmol) in 10 mL of toluene at −50 °C. When the addition was complete, the mixture was allowed to warm to 25 °C with stirring for 12 h. The solvent was removed under reduced pressure and the product was extracted with ether, which was then filtered through celite. Removal of solvent left a yellow solid, which was recrystallized from CH_2Cl_2/pentane to give yellow needles. The yield was 0.80 g (59%). ^{1}H NMR (300 MHz, $CDCl_3$): δ 7.57 (m, 2H, ArH); 7.38 (d, J = 2.5 Hz, 1H, C_3H_2BN), 7.26 (m, 3H, ArH), 6.98 (M, 1H, Cp); 6.87 (m, 1H, Cp); 6.00 (m, 1H, Cp); 5.92 (d, J = 2.5 Hz, 1H, C_3H_2BN); 5.88 (m, 1H, Cp); 4.08 (dq, J = 13.7, 7.1 Hz, 1H, NCH); 3.75 (dq, J = 13.7, 7.1 Hz, NCH); 1.21 (t, J = 7.3 Hz, 3H, CH_3C); 0.62 (s, 3H, SiMe); 0.37 (s, 3H, SiMe′). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ 140.4, 135.6, 129.5, 128.6, 127.3, 120.9, 120.6, 112.5, 110.4, 44.1, 16.8, −2.3, −3.5. ^{11}B NMR (115.6 MHz, $CDCl_3$): δ 34.6. HRMS: Calc. for $C_{18}H_{22}{}^{11}B^{35}Cl_2NSi^{90}Zr$: 451.0039. Found: 451.0016. *Anal.* Calc. for $C_{18}H_{22}B^{35}Cl_2NSi^{90}Zr$: C, 47.68; H, 4.90; N, 3.09. Found: C, 47.92; H, 5.17; N, 3.11%.

2.2.8. Bis(1-ethyl-2,3-dihydro-2-phenyl-1H-1,2-azaborol-3-yl)dimethylsilane (**17**)

The title compound was prepared in the same manner as (**16**) from lithium 1-ethyl-2-phenyl-1*H*-1,2-azaborolide (0.41 g, 2.31 mmol) in 15 mL of THF and 1-ethyl-3-chlorodimethylsilyl-2,3-dihydro-2-phenyl-1*H*-1,2-azaborole (0.01 g, 2.31 mmol) in 15 mL of THF. The product was obtained as a yellow oil (0.85 g, 92%). ^{1}H NMR (400 MHz, C_6D_6): δ 7.41 (dd, J = 8.0, 1.5 Hz, 4H, ArH); 7.18 (t, J = 7.3 Hz, 4H, ArH); 7.12 (t, J = 7.3 Hz, 2H, ArH); 6.29 (dd, J = 4.0, 1.1 Hz, 2H, ViH); 5.58 (dd, J = 3.6, 1.1 Hz, 2H, ViH); 3.26 (m, 2H, NCH); 3.11 (m, 2H, NCH); 2.43 (dd, J = 2.6, 1.1 Hz, 2H, BCH); 0.89 (t, J = 7.0 Hz, 6H, CMe); −0.18 (s, 3H, SiMe); −0.42 (s, 3H, SiMe). ^{13}C NMR (100.6 MHz, $CDCl_3$); δ 137.4, 133.5 (Ph); 128.3 (Ph); 127.7 (Ph), 113.7, 41.2 (NCH_2), 37.2 (br, BCH), 17.9 (CMe), −4.3 (SiMe), −4.4 (SiMe). ^{11}B ($CDCl_3$, 115.5 MHz): δ 45.2. HRMS: Calc. for $C_{24}H_{32}{}^{11}B_2N_2Si$: 398.2520. Found: 398.2516.

2.2.9. Rac-(bis(η^5-1-ethyl-2-phenyl-1H-1,2-azaborol-3-yl)dimethylsilane)zirconium dichloride (**10**)

A solution of lithium diisopropylamide (0.46 g, 4.26 mmol) in 10 mL of THF was added to a solution of bis (1-ethyl-2,3-dihydo-2-phenyl-1*H*-1,2-azaborol-3-yl)dimethylsilane (0.85 g, 2.13 mmol) in 10 mL of THF at −78 °C. The mixture was slowly warmed to 25 °C and stirred for 8 h. The solvent was removed in vacuo and the residue was washed with 3 × 10 mL of pentane. The solid was dissolved in 10 mL of toluene and the resulting solution was added to a suspension of $ZrCl_4$ (0.49 g, 2.143 mmol) in 10 mL of toluene at −50 °C. Stirring was continued for 12 h and the mixture was warmed slowly to 25 °C. The solvent was removed in vacuo and the product was dissolved in ether which was filtered through celite. Removal of the solvent under reduced pressure gave an orange solid which was recrystallized from CH_2Cl_2 to give orange crystals of product (0.80 g, 68%). ^{1}H NMR (300 MHz, C_6D_6): δ 7.70 (dd, J = 8.1, 1.5 Hz, 4H, ArH); 7.25 (t, J = 7.6 Hz, 4H, ArH); 7.15 (t, J = 7.4 Hz, 2H, ArH); 6.83 (d, J = 2.5 Hz, 2H, C_3H_2BN); 5.86 (d, J = 2.5 Hz, 2H, C_3H_2BN); 3.75 (dq, J = 13.4, 6.9 Hz, 2H, NCH); 3.38 (dq, J = 13.4, 6.9 Hz, 2H, NCH′); 0.64 (t, J = 7.2 Hz, 6H, CH_3), 0.32 (s, 6H, SiMe). ^{13}C NMR (100.6 MHz, $CDCl_3$): δ 135.6, 131.4, 128.5, 127.6, 119.7, 44.7, 17.2, −1.0. ^{11}B (115.6 MHz, $CDCl_3$): δ 31.8. HRMS: Calc. for $C_{24}H_{30}{}^{11}B_2{}^{35}Cl_2N_2Si^{90}Zr$: 556.0788. Found: 556.0770. *Anal.* Calc. for $C_{24}H_{30}B_2Cl_2N_2SiZr$: C, 51.62; H, 5.43; N, 5.02. Found: C, 51.32; H, 5.39; N, 5.08%.

2.3. X-ray data collection

X-ray quality crystals of **8**, **9**, and **10** were crystallized from dichloromethane at room temperature. A suitable crystal was mounted on a standard Bruker SMART CCD-based X-ray diffractometer equipped with a normal focus Mo-target X-ray tube ($\lambda = 0.71073$ Å) operated at 2000 W power (50 kV, 40 mA). The X-ray intensities were measured at 158(2) K; the detector was placed at a distance of 4.959 cm from the crystal. Analysis of the data showed negligible decay during data collection; the data were processed with SADABS [11] and corrected for absorption. The structure was solved and refined with the Bruker SHELXTL [12] (version 5.10) software package. All non-hydrogen atoms were refined anisotropically with the hydrogen atoms located on a difference Fourier map and allowed to refine isotropically. Additional details are presented in Table 1 and are given as Supplementary materials as CIF files.

2.4. Polymerization conditions

A 2 L reactor was charged with mixed alkane solvent and 1-octene. Hydrogen was added by differential pressure expansion from a 75 mL addition tank from 2.1 MPa to near 1.9 MPa. The reaction and container were heated to 140 °C and saturated with ethylene at 3.4 MPa. In an inert atmosphere glovebox the appropriate quantities of zirconium complex and MAO (1:1000 m) were combined and this solution was transferred to a catalyst addition tank. The polymerization were initiated by injecting this catalyst solution into the reactor. The polymerization condition were maintained for 15 min with ethylene provided on demand at 3.4 MPa. The polymer solution was removed from the reactor and combined with a hindered phenol antioxidant and isopropanol. Volatile components were removed from the polymer in a vacuum oven set at 140 °C for about 20 h. The dried polymers were weighed and analyzed. Additional details are given in [13].

3. Results and discussion

3.1. Synthesis

The 1,2-azaborolyl ring system has been prepared by several routes [10,14–16]. In our hands a synthesis via a ring closing metathesis from B-vinyl-*N*-allyl-aminoboranes is particularily convenient. The B-phenyl-*N*-ethyl azaborolyl **14** was easily prepared by this route (Scheme 1) which had previously been used to prepare the corresponding B-phenyl-*N*-methyl derivative **14a** [10]. The reaction of phenylvinylboron chloride [11] with allylethylamine in pentane containing triethylamine gave a 84% yield of aminoborane **12**. The ^{1}H and ^{13}C NMR spectra of **12** are complex indicating that it exists as a 1:1 mixture of rotomers about the B–N bond. The appreciable π-bond character of this B–N bond makes the rotation about this bond slow on the NMR time scale [17]. On treatment of **12** with 5 mol% Grubbs catalyst in CH_2Cl_2 at 25 °C for 12 h, cyclization occurred to afford a 74% yield of the ring closed product **13**. The reaction of **13** with LDA in ether gave the lithium 1,2-azaborolide **14** which was isolated as a pale yellow powder in 96% yield. The ^{1}H, ^{11}B, and ^{13}C NMR chemical shift values of the ring atoms of **14** are very similar to those previously reported for corresponding N-methyl derivative **14a** [10] and other 1,2-azaborolides [14]. The reaction of **14** with Cp^*ZrCl_3 in ether gave the expected **8** as yellow crystals in 56% yield.

The dimethylsilyl-bridged mixed 1,2-azaborolyl cyclopentadienyl zirconium complex **9** was prepared by a straightforward route outlined in Scheme 1. Silylation of **14** with an excess of dichlorodimethylsilane afforded the 3-chlorodimethylsilyl isomer **15** as an orange oil in 96% yield. Compound **15** was not detectably contaminated with the possible 5-regio isomer. It seems probable

Scheme 1. Synthesis of lithium 1-ethyl-2-phenyl-1,2-azaborolide (**14**) and its conversion to zirconium complexes **8**, **9**, and **10**.

that C(3) of **14** is more nucleophilic than C(5) due to its larger negative charge density which is indicated by the higher field signal for C(3) in the ^{13}C NMR spectrum [18a]. The sequential reaction of **15** with CpLi followed by LDA and then $ZrCl_4$ gave **9** or yellow crystals in 59% yield.

The reaction of **15** with lithium azaborolide **14** afforded the dimethylsilyl derivative **17** as a yellow oil in 92% yield. As was the case from **16**, it was not detectably contaminated by regioisomers. The reaction of **17** with LDA followed by $ZrCl_4$ gave **10** as a yellow crystalline product in 68% yield. The ^{1}H and ^{13}C NMR spectra of **10** suggested that it was a single diastereomer. A subsequently obtained X-ray crystal structure showed that it is the racemic isomer.

3.2. Structure

The molecular structures of **8**, **9**, and **10** are illustrated in Figs. 1–3, respectively. Selected bond distances and angles are compared in Table 2. These compounds are the first structurally characterized monocyclic 1,2-azaborolyl zirconium complexes although we have previously reported structures for zirconium complexes of fused ring 1,2-azaborolyls [18b]. Prior crystallographic work on both early and late transition metal 1,2-azaborolyl complexes shows that the ligand usually binds in an unsymmetrical η^5-manner [15,19]. Compounds **8**, **9**, and **10** conform to this pattern. In each case the 1,2-azaborolyl ring is largely coplanar. The B–Zr distances (2.68 Å, ave) are somewhat longer than the C–Zr and N–Zr distances (2.44–2.54 Å, range). The longer boron–metal distances are consistent with the larger atomic radius of boron compared to that of carbon and nitrogen. A similar pattern is found in the structures of most metal π-coordinated complexes of boron heterocycles [20].

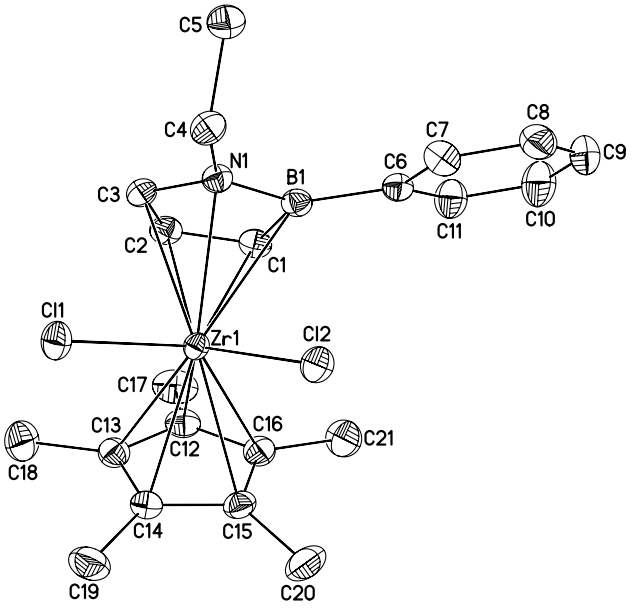

Fig. 1. Molecular structure of **8** (ORTEP). Thermal ellipsoids are at the 50% probability level. Hydrogen atoms have been omitted for clarity.

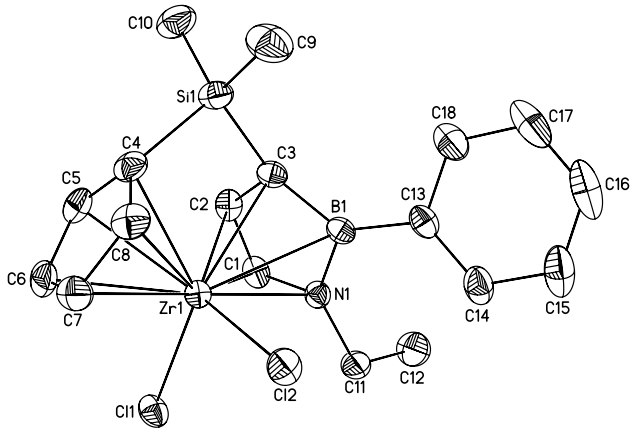

Fig. 2. Molecular structure of **9** (ORTEP). Thermal ellipsoids are at the 50% probability level. Hydrogen atoms have been omitted for clarity.

Comparison of the structures of **8**, **9**, and **10** shows that the corresponding intraring 1,2-azaborolyl distances vary by no more than ±0.02 Å. Similarly the distance of Zr atoms to the corresponding ring atoms vary by no more than ±0.05 Å. Thus the bridges in **9** and **10** exert little perturbation on the structure found for **8**.

The structures of **8**, **9**, and **10** can also be compared with those of similar zirconocene dichlorides. The Cp planes of Cp_2ZrCl_2 intersect an angle of 52° [21]. The mean plane of the 1,2-azaborolyl ring of **8** intersects its Cp* plane at an angle of 52.5(1)°. In the dimethylsilyl bridged **1** the Cp planes intersect at 57° [22]. The corresponding Cp/1,2-azaborolyl planes of **9** intersect at 60.1(1)° and the 1,2-azaborolyl/1,2-azaborolyl planes of **10** intersect at 57.3(1)°. Thus, all three *ansa*-complexes have very similar open wedges to the Zr atoms.

3.3. Polymerization studies

On activation by a 10^3 molar excess of MAO in a hydrocarbon solvent the 1-ethyl-2-phenyl-1,2-azaborolyl zirconium complexes **8**, **9**, **10** form active catalysts for the polymerization of mixtures of ethylene and 1-octene. The results are summarized in Table 3. In all cases, the product was polyethylene with the incorporation of approximately 1% 1-octene. All three 1,2-azaborolyl complexes are significantly better catalysts than 1-diisopropylamino-1-boratabenzene zirconium complexes **2** [5a,6a] and **5** [7] and 1-diisopropylamino-1,2-thiaborolyl zirconium complex **3** [6a] under identical conditions. MAO activated **2** has previously been found to have

approximately the same ethylene polymerization activity as Cp_2ZrCl_2, albeit under somewhat different conditions [5a]. Thus we can safely conclude that **8**, **9**, and **10** are significantly more active than Cp_2ZrCl_2 from the polymerization of ethylene.

Table 3
Comparison of the efficiency of ethylene/1-octene polymerization of **8**, **9**, and **10** with selected other complexes

Complex	Efficiency (g polymer/mol Zr atom)	Reference
8	234×10^4	this work
9	66×10^4	this work
10	126×10^4	this work
2	20.4×10^4	[6c]
3	6.0×10^4	[6a]
5	2.4×10^4	[7]

The η^5-1,2-azaborolyl ligands of **8**, **9**, and **10** are nearly isostructural with the η^5-Cp groups of zirconocene dichlorides. Furthermore, the degree of canting of the rings of **8**, **9**, and **10** is nearly identical to that found in the corresponding zirconocenes. Therefore, it is unlikely that the greater reactivity of the 1,2-azaborolyl zirconium complexes is due to steric efforts. Fu and co-workers [15] found that the 1,2-azaborolyl ligand in Fe(II) complexes is more electron-rich than Cp. Thus, it is likely that electron density at Zr is higher for **8**, **9**, and **10** than it is for the corresponding zirconocenes. It may be that the higher catalytic activity of the 1,2-azaborolyl zirconium complexes is associated with the greater electron density and lower electrophilicity at the active metal center. It has previously been observed that electron withdrawing groups decrease the activity of zirconium-based Ziegler–Natta catalysts [23].

Contrary to our expectations the dimethylsilyl bridging in **9** and **10** led to a small decrease rather than an increase is the polymerization activity relative to **8**. It may be that the lack of conformational mobility enforced by the bridge holds that 1-ethyl and 2-phenyl substituents in positions which interfere with the propagation steps. A similar but larger drop-off in activity was observed between **2** and **5** [7].

4. Conclusion

In summary, we have developed an efficient synthetic route to Me_2Si-bridged and non-bridged (1,2-azaborolyl) zirconium(IV) dichlorides **8**, **9**, and **10**. The 1,2-azaborolyl is an electron rich surrogate for Cp and the structure of its zirconium complexes closely resemble those of the corresponding zirconocenes. On activation by excess MAO, **8**, **9**, and **10** form highly active catalysts for the polymerization of ethylene.

5. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 262648, 262649, and 262650 for compounds **8**, **9**, and **10**, respectively. Copies of this information may be obtained from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1233 336 033; e-mail: deposit@ccdc.cam.ac.uk, or http://www.ccdc.cam.ac.uk).

Acknowledgments

This work was supported by the National Science Foundation and the Dow Chemical Company. We are grateful to the Dow Chemical Company for running the polymerization experiments. We are also grateful to the Boulder Scientific Company from a generous gift of the Grubbs catalyst.

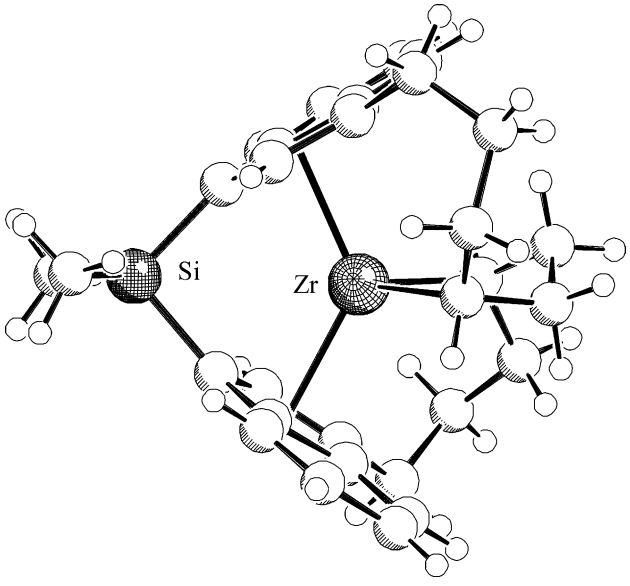
examples will be described and discussed in this account to illustrate such recent developments in *ansa*-metallocene chemistry.

2. Attempts via metallacyclopentane formation

It is well known that the reduced zirconocenes or titanocenes [$Cp_2M(II)$] add two equivalents of alkenes or alkynes to form the respective five-membered metallacycles [6]. It was tempting to try to use a variant of this rather general reaction type in *ansa*-metallocene synthesis. We have made such an attempt by reducing the ω-pentenyl-substituted *rac*-*ansa*-zirconocene dichloride complex **1** with sodium-amalgam in THF. The expected doubly trimethylene-linked zirconacyclopentane derivative **2** was actually formed in high yield (95% isolated) and characterized by X-ray diffraction (see Fig. 1) [7]. We expected that subsequent treatment of **2** with, e.g., HCl would yield the respective doubly bridged *ansa*-zirconocene dichloride by protonolytic cleavage of both Zr–$C(sp^3)$ σ-bonds. However, we obtained the mono-alkenyl system **4** instead, which indicated a much preferred reaction of the reactive η^2-alkene-type complex **3** to take place under our typical reaction conditions (see Scheme 1). K. Mach et al. subsequently showed that *ansa*-metallocene bridges can actually be formed by the metallacyclopentane route, but the reaction is apparently limited to specific cases, where the protonolysis reaction of the five-membered metallacycle is sufficiently preferred over the alternative cleavage pathway via concerted ring opening. In K. Mach's case, the linked titanacyclopentane **6** was formed by Mg-reduction from



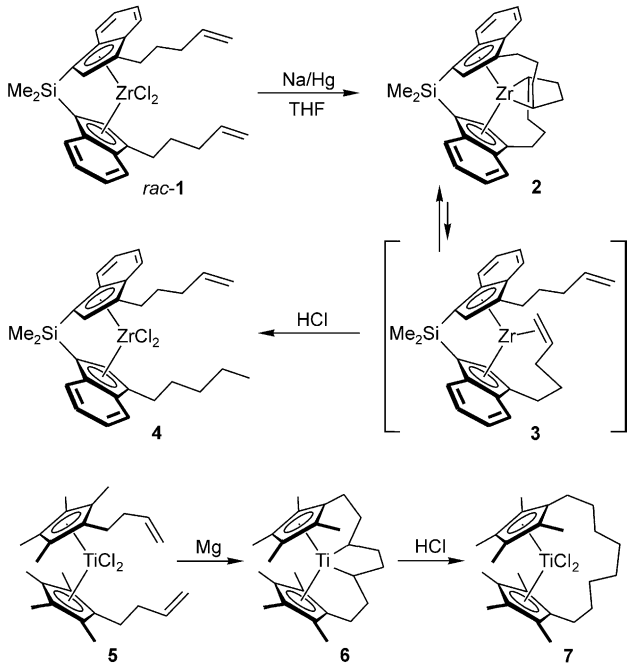


Fig. 1. A view of the molecular structure of the *ansa*-zirconacyclopentane derivative **2**.

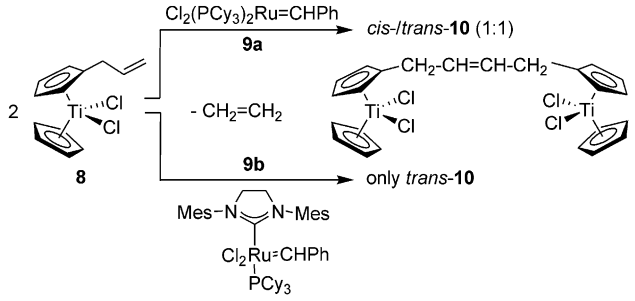
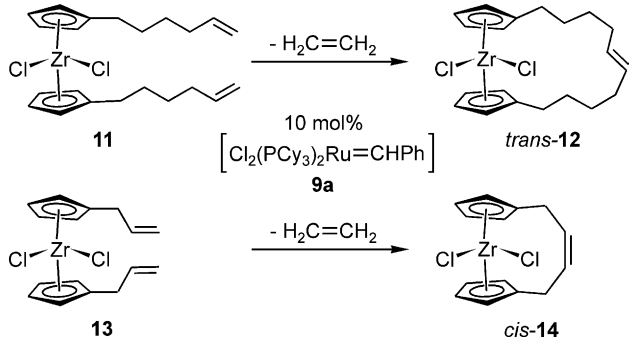
Scheme 1.



5 and subsequently gave the octamethylene-bridged *ansa*-titanocene **7** upon treatment with HCl [8].

3. *ansa*-Metallocene formation by olefin metathesis

The olefin metathesis reaction has found increasing use in organic synthesis in recent years [9]. This is, among other reasons, due to the availability of a variety of metal alkylidene catalysts that allow the metathetical transformation of organic substrates in the presence of a great number of organic functional groups. Therefore, it was tempting to also employ the catalytic olefin metathesis reaction for selective transformations at (suitably substituted) Group 4 bent metallocenes and related systems, hoping that even these otherwise reactive organometallic functionalities would prove stable and largely inert toward the typical metathesis conditions. This actually turned out to be the case for a variety of typical Cp-zirconium and -titanium systems when treated with the typical Ru-based olefin metathesis catalysts.



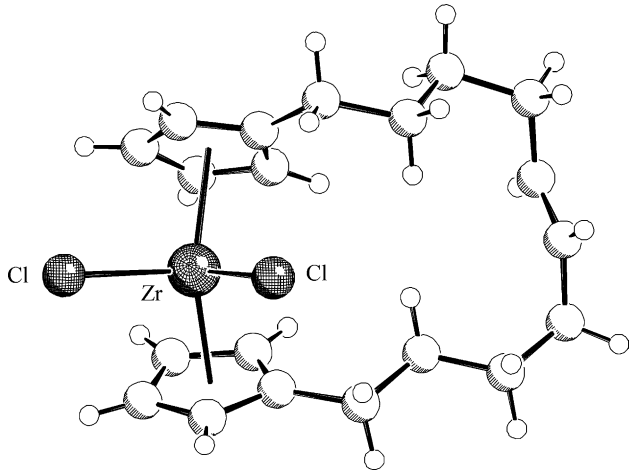
Here is a typical example. The alkyl-Cp-containing titanocene dichloride complex **8** undergoes an intermolecular metathetical coupling reaction in the presence of ca. 3 mol% of $(PCy_3)_2Cl_2Ru{=}CHPh$ (**9a**) to give a ca. 50% isolated yield of a ca. 1:1 mixture of *cis*- and *trans*-**10**. Similar treatment of **8** with the more active second generation Grubbs catalyst (**9b**) gave almost pure *trans*-**10** (see Scheme 2) [10].

We have applied related intramolecular olefin metathesis reactions for the synthesis of *ansa*-metallocenes. Treatment of sodium cyclopentadienide with

Scheme 2.

ω-hexenyl bromide followed by deprotonation (MeLi) and transmetallation gave the bis-hexenyl-functionalized zirconocene dichloride complex **11** (isolated in 38% yield). Its treatment with 10 mol% of $(PCy_3)_2Cl_2$-Ru=CHPh (**9a**) under high dilution conditions using a syringe pump resulted to the formation of a sizeable amount of the corresponding intramolecular olefin metathesis coupling product **12**. Crystallization from a toluene solution furnished this large *ansa*-zirconocene dichloride as the pure *trans*-isomer (*trans*-**12**) in 25% yield (see Scheme 3 and Fig. 2) [11].

Scheme 3.



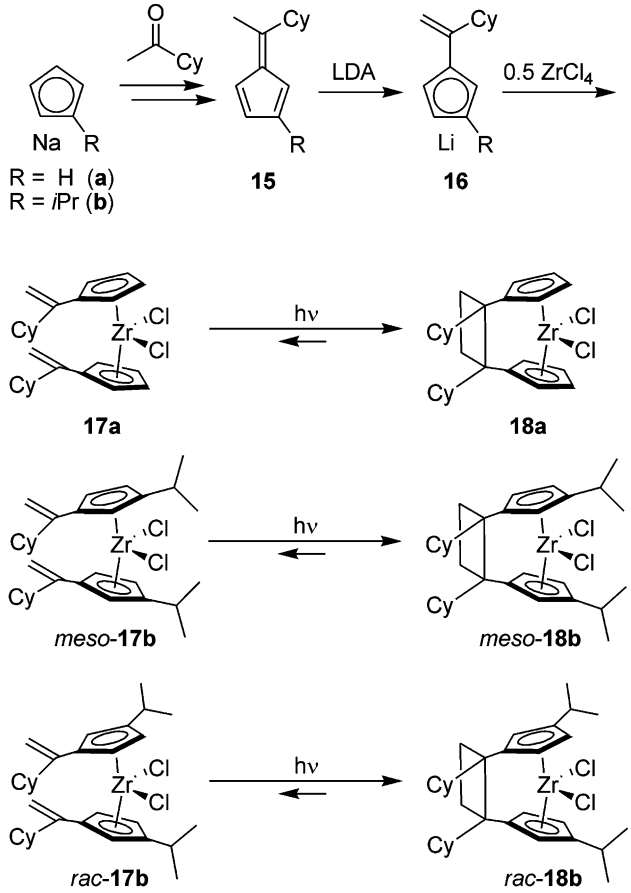


Fig. 2. A view of the large *ansa*-metallocene *trans*-**12**.

Ring closing metathesis of bis(allyl-Cp)zirconium dichloride (**13**), that was prepared by a similar route, occurs readily upon treatment with the Ru-carbene catalyst **9a** under similar conditions, as we [11] and Hayashi and coworkers [12] have found independently. We isolated the product *cis*-**14** in ca. 50% yield from the reaction mixture. The *ansa*-metallocene *cis*-**14** was characterized by X-ray diffraction and its conformational behavior characterized by dynamic NMR spectroscopy [11].

4. Ring closure by intramolecular photochemical [2 + 2]cycloaddition

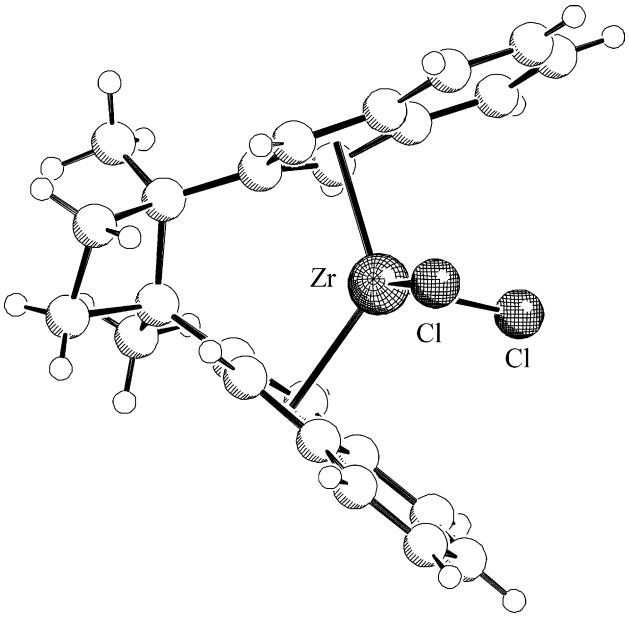
Alkenyl-substituted Cp-ligands can conveniently be prepared by means of fulvene routes. The reaction sequence starting with the condensation reaction between Na-cyclopentadienide with methylcyclohexylketone to yield the fulvene **15a** marks a typical example. Treatment of **15a** with LDA results in a clean selective deprotonation at the fulvene methyl group to yield the alkenyl cyclopentadienide **16a**. Subsequent transmetallation then gave the corresponding zirconocene complex **17a** (see Scheme 4). Irradiation of the metallocene **17a** rapidly resulted in an intramolecular [2 + 2]cycloaddition

Scheme 4.

reaction with formation of the cyclobutylene-bridged *ansa*-zirconocene **18a**. This reaction is wavelength dependent. With 300–350 nm UV-light we observed a photostationary equilibrium of **18a**:**17a** ≈ 70:30, that was reached and maintained after 4 h of irradiation in a Pyrex NMR tube in benzene-d_6 at ambient temperature [13]. Using a 450 nm light source we achieved a rapid (1 h) and almost complete (>98%) conversion of **17a** to **18a** (see Scheme 4).

Similarly, the doubly substituted alkenyl-cyclopentadienide **16b** was obtained by treatment of isopropylcyclopentadienide with methylcyclohexyl-ketone followed by LDA deprotonation. Transmetallation with $ZrCl_4$ in this case gave ca. a 1:1 mixture of the *meso*-**17b** and *rac*-**17b** diastereoisomers, that we were able to separate by fractional crystallization. Each of these diastereoisomeric metallocenes was intramolecularly [2 + 2] coupled by 450 nm irradiation to yield the corresponding *ansa*-metallocenes *meso*-**18b** and *rac*-**18b**, respectively. The [2 + 2]cycloaddition product *meso*-**18b** was characterized by X-ray diffraction [13a]. A number of related examples were investigated using a variety of substituent combinations. The eventually resulting photostationary equilibrium in some cases turned out to be quite sensitive to the specific substituents used [13b]. The [2 + 2]cycloaddition method has increasingly been used in the coupling of "*ansa*-bridges" in more complicated cases [14].

An extension to a series of related alkenyl-functionalized bis(indenyl)zirconium complexes gave an interesting result. For this study the 2-alkenyl indenes (**19**) were synthesized by a Ni-catalyzed cross-coupling reaction of 2-bromoindene with the respective 1-alkenyl-*Grignard* reagents (see Scheme 5), or in the case of **19b** by alkenyl-*Grignard* addition to 2-indanone followed by H^+-catalyzed dehydrogenation. Subsequent deprotonation followed by transmetallation then gave the corresponding bis(2-alkenylindenyl)$ZrCl_2$ complexes **20**. These systems form the respective *ansa*-metallocenes very easily. Thus, irradiation (HPK 125, Pyrex filter) rapidly resulted in the practically complete conversion to the *ansa*-metallocenes **21** that were isolated as crystalline solids from the reaction mixtures in fair yields [15,16]. The complexes **21a** (R = CH_3) and **21b** (R = cyclohexyl) were both characterized by X-ray diffraction which has revealed the remarkable structural features of these systems. As depicted in Fig. 3 the cyclobutylidene bridge in the complexes **21** is located at the narrow back side of the bent metallocene wedge. Consequently the indenyl phenylene subunits are both pointing toward the open front side, thus featuring their aromatic π-systems oriented above and below the σ-ligand system. There is indication that suitable ligands bonded to the metal at the front side of the bent metallocene can potentially interact electronically with this "π-electron box". This was shown for the corresponding (η^4-s-*trans*-butadiene)metallocene complex **22a** that features a butadiene *meso*-H/π-indenyl interaction. In the ^{1}H NMR spectrum of **22a** this leads to a shifting of the ^{1}H NMR H-*meso* resonance to strongly negative δ-values (ca. δ −1.5 in benzene-d_6) [15,16]. This corresponds to an "upfield" shift of Δδ ≈ −2.9 relative to the parent compound (η^4-s-*trans*-butadiene)$ZrCp_2$ [17].



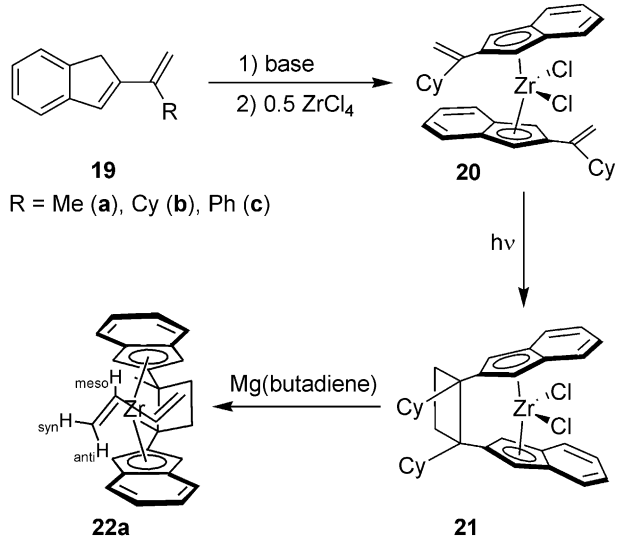


Fig. 3. Molecular structure of complex **21a**.

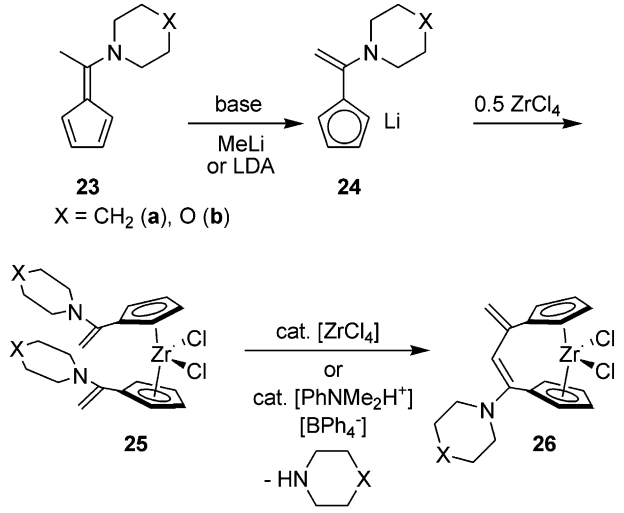
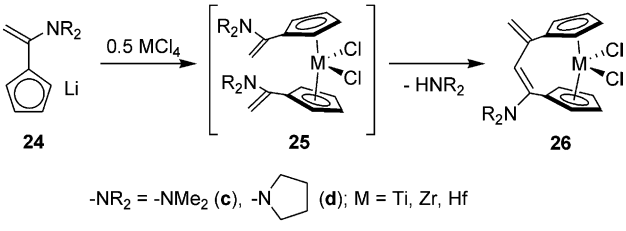
Scheme 5.



5. Intramolecular Mannich coupling at the metallocene framework

The fulvene route has also been used to prepare a variety of Group 4 metallocene complexes bearing



enamino substituents at their Cp-ligands. The synthesis made use of the readily available amino fulvenes (**23**) that were prepared by the method of Hafner et al. [18] by condensation of activated dialkylacetamides with cyclopentadienide. Deprotonation with a suitable base furnished the substituted aminoethenylcyclopentadienides (**24**) [19]. Transmetallation with $ZrCl_4$ gave the bis(enamino-Cp)$ZrCl_2$ complexes that in some cases (e.g., **25a**, **25b**) could be isolated [20] (see Scheme 6).

Treatment of **25a** or **25b** with catalytic amounts of $ZrCl_4$ or a *Brønsted* acid resulted in a rapid intramolecular *Mannich*-type condensation reaction to yield the C_3-bridged *ansa*-zirconocene complexes **26(a,b)** with extrusion of one equivalent of piperidine or morpholine, respectively. It must be assumed that protonation of one of the enamino substituents of the starting material **25** generates a reactive iminium ion that is then intramolecularly attacked by the adjacent enamino-carbon-nucleophile to make the essential new carbon–carbon bond of the *ansa*-bridge. Amine elimination and deprotonation then closes the catalytic cycle to give the observed coupling products (**26**) (see Scheme 7).

In many cases the synthesis of the *ansa*-metallocenes can conveniently be carried out as a one-pot reaction starting from the respective enamino-Cp reagent. This is especially very convenient in the case of the dimethyla-

Scheme 6.

Scheme 7.

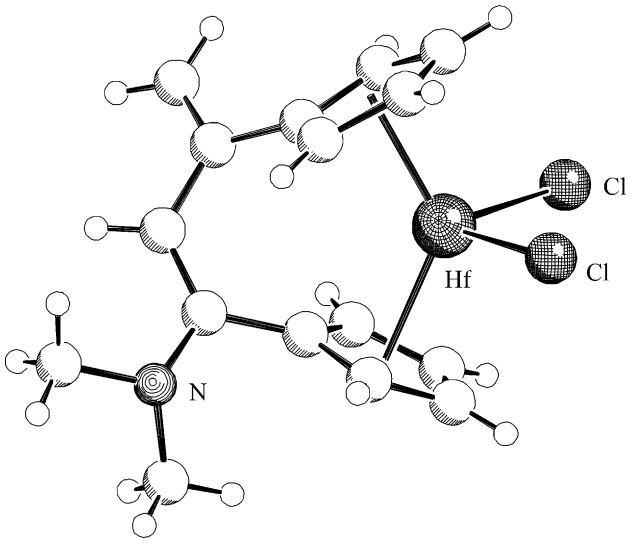


Fig. 4. A projection of the molecular geometry of the *ansa*-hafnocene complex **26c′**.

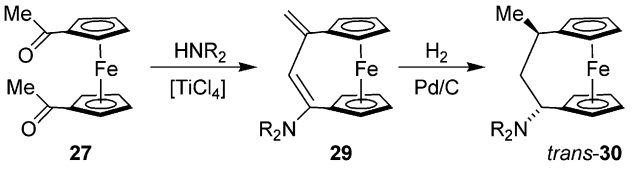
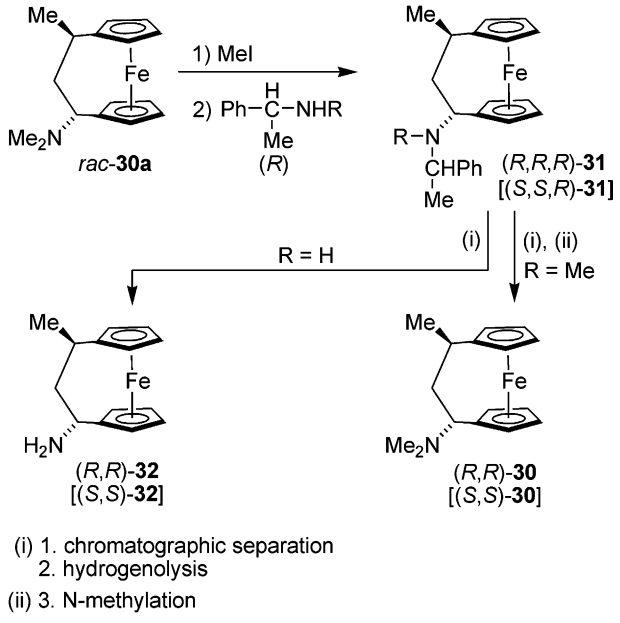
mino-ethenyl systems (**24c**) or their pyrrolidino-ethenyl analogues (**24d**). We must assume that the reaction of these reagents with the respective Group 4 metal halides initially also leads to the formation of the corresponding substituted bis(enamino-Cp) Group 4 metal complexes. With these (small) enamino substituents, however, these intermediates rapidly react further with the *Lewis* acidic metal halide components to enter the catalyzed *Mannich*-type condensation reaction. In many of these cases, the corresponding unsaturated C_3-bridged Group 4 ansa-metallocenes (**26**) were obtained in good yields [21–24]. Many examples were characterized by X-ray diffraction. A typical example (**26c′**, M = Hf) is depicted in Fig. 4. Some of these complexes were used as precursors for the generation of active homogeneous *Ziegler–Natta* olefin polymerization catalysts [21,22].



6. Use of the intramolecular Mannich reaction in [3]ferrocenophane chemistry

A variety of [*n*]ferrocenophanes can readily be prepared by a number of conventional methods [25,26]. Nevertheless, our intramolecular *Mannich*-type coupling reaction turned out to be so convenient that it was adapted and modified for the synthesis of a series of [3]ferrocenophane systems, some of which have turned out to be well suited frameworks for the preparation of some useful chelate ligands [27].



For the synthesis of the unsaturated [3]ferrocenophanes (**29**) it was convenient to start from the readily available 1,1′-diacetylferrocene (**27**). Its treatment with excess dimethylamine in the presence of the *Lewis* acid $TiCl_4$ [28] rapidly resulted in the formation of the intramolecular coupling product **29a** ($-NMe_2$), which was probably formed by a *Mannich*-type condensation

reaction via a bis(enamino)ferrocene intermediate (**28**) [29]. Subsequent catalytic hydrogenation (Pd/C, H_2) gave the saturated [3]ferrocenophane-amines (**30**), that contain two newly formed chiral centers (see Scheme 8). Both the *cis*- and the *trans*-diastereoisomers of the products **30** are formed, but in all cases investigated so far it was the *trans*-**30** product that was formed predominantly, with *trans*-/*cis*-**30** ratios ranging from 5:1 to ca. 7:1. The *trans*-products were obtained pure by crystallization. We have obtained a variety of products with various $–NR_2$ substituents, either introduced directly or by exchange at the amino[3]ferrocenophane stage **30** [29]. In the latter cases, it was shown that the amine exchange reactions proceeded with overall retention of configuration at the α-carbon center, i.e., by a two-step sequence involving the nucleophilic iron center as a very efficient neighboring group [30,31]. The three-carbon bridge fits almost perfectly between the pair of ferrocene Cp-rings, both in the unsaturated systems **29** as well as the saturated [3]ferrocenophane systems **30**, which is illustrated in Fig. 5 for a pair of representative examples ($–NEt_2$, **29b**, **30b**).

The enantiomerically pure *trans*-**30** [3]ferrocenophanylamines were obtained each in ca. 25% yield (from a possible 50%) by treatment of the *trans*-**30a** racemate ($–NMe_2$) with a Ph–CH(Me)–NHMe enantiomer. The

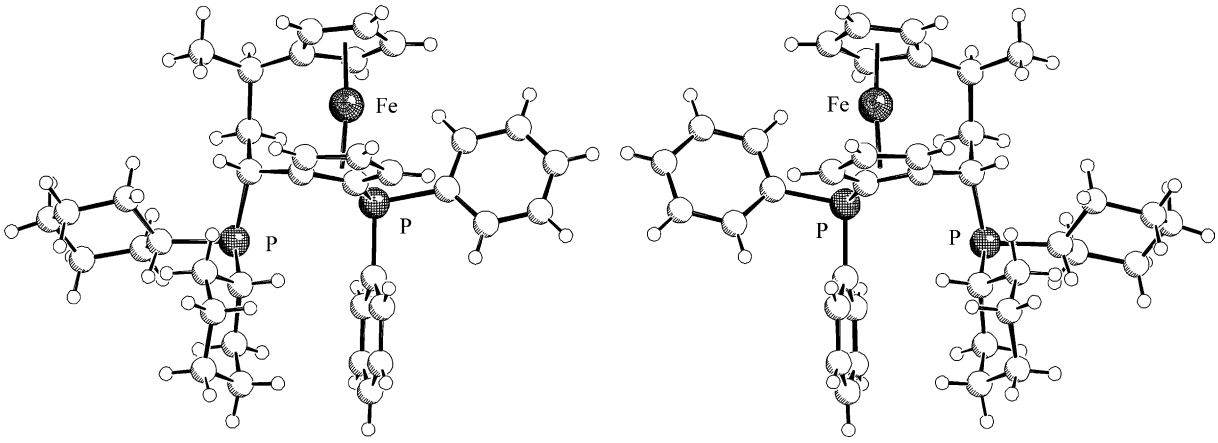

Fig. 6. A view of the molecular structures of the separately prepared enantiomers of **35**.

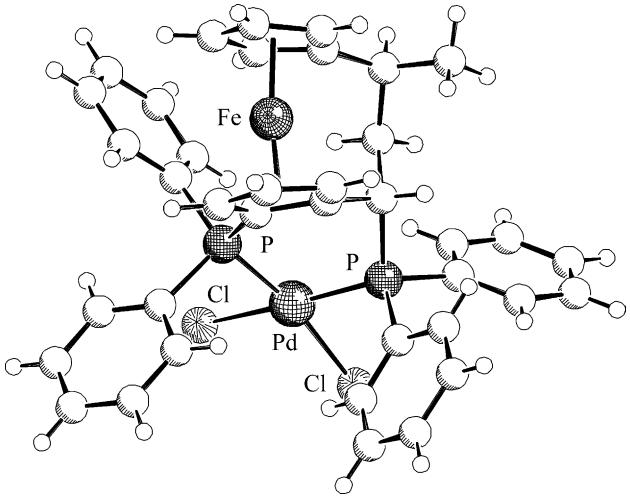
diastereomeric amine-exchange products, e.g., (*R*,*R*,*S*)-**31** and (*S*,*S*,*S*)-**31**, were readily separated by column chromatography and then the chiral auxiliary was selectively removed by catalytic hydrogenation. Subsequently, *N*-methylation eventually yielded the (*R*,*R*)- and (*S*,*S*)-**30** enantiomers (see Scheme 9) [32]. The parent amino[3]ferrocenophane system (**32**), exhibiting a free $-NH_2$ substituent at the α-position of the saturated bridge, was obtained optically pure by means of a variant of this route employing the Ph–CH(Me)–NH_2 enantiomers as the resolving chiral auxiliaries [33].

Treatment of each of the **30a** ($-NMe_2$) enantiomers with butyl lithium followed by $ClPPh_2$ resulted in a directed metallation with subsequent formation of the enantiomerically pure (*P*,*N*)-[3]ferrocenophane chelate systems **33**. Stereospecific exchange of the $-NMe_2$ group by treatment with $HPPh_2$ or $HPCy_2$ furnished the corresponding (*P*,*P*)-[3]ferrocenophane chelates **34** and **35**, respectively [27,34,35] (see Fig. 6). The Pd(II) complex



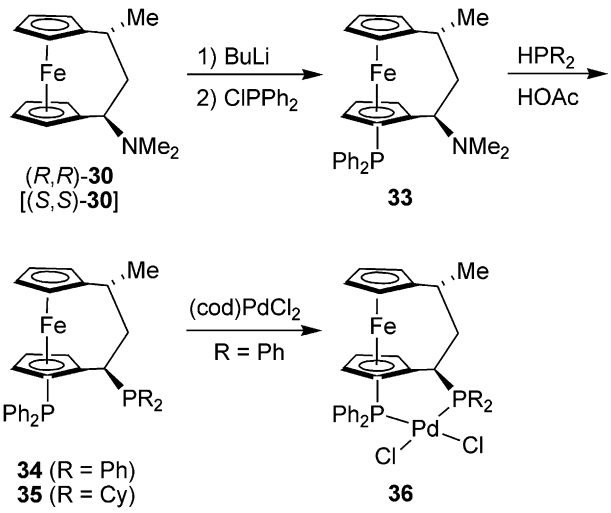


Fig. 7. A view of the molecular structure of the (*P*,*P*)-[3]ferrocenophane chelate–Pd complex **36**.

Scheme 10.

36 (see, e.g. Fig. 7) gave an active catalyst for alternating CO/1-alkene copolymerization after suitable electrophilic activation. The $-PCy_2$-derived chelate ligand (**35**) gave a Pd-catalyst that showed a high asymmetric induction in alternating CO/propene copolymerization and its $-PPh_2$ analogue (**34**) gave an effective Rh-catalyst for asymmetric hydrogenation of dimethylitaconate (95% ee) [27] (see Scheme 10).

7. Some conclusions

Carrying out carbon–carbon coupling reactions at the framework of the sensitive Group 4 bent metallocenes had been notoriously difficult. It took some time until some limited organic functional group chemistry begun to appear in Group 4 metallocene chemistry, other than the well established procedures of introducing various types of substituents via attachment at the free ligand state prior to the final transmetallation step. It seems that useful developments toward carrying out

typical organic functional group transformations at the bent metallocene stage are increasingly emerging from the literature. It has been shown that a number of carbon–carbon coupling reactions can indeed be performed at the Group 4 bent metallocene frameworks by a variety of procedures from the current repertoire of synthetic organic chemistry, if care is taken that these methods are adapted to the specific needs and features of the rather sensitive bent metallocenes of the oxophilic Group 4 transition metals. Many examples originating from my research group as well as from others have demonstrated this, such as the, e.g., formation of ansa-metallocenes via metallacyclopentane formation, by means of intramolecular photochemical alkenyl [2 + 2]cycloaddition or catalyzed intramolecular Mannich-type coupling, or, last but not least, by application of the olefin metathesis reaction catalyzed by ruthenium carbene complexes. Especially, these latter examples nicely demonstrate the increasing importance of catalytic procedures for the preparation of novel organometallic systems. Since these organometallic products are themselves often valuable precursors for the generation of new catalysts, some examples described in this article illustrate an interesting current development to use catalytic pathways to generate new catalysts.

Acknowledgements

G.E. thanks his coworkers and collaborators, whose names are given in the references, for their valuable contributions to this chemistry. He also acknowledges the generous financial support from the Deutsche Forschungsgemeinschaft, the Fonds der Chemischen Industrie, and the Alexander von Humboldt foundation for the investigations that were carried out in his group at the University of Münster.

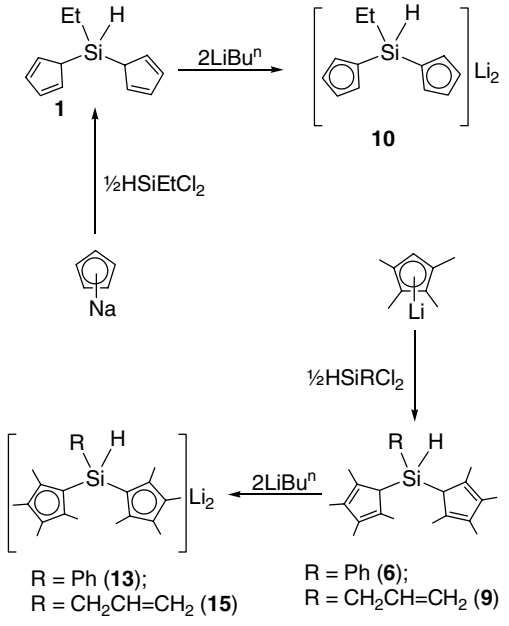
1. Introduction

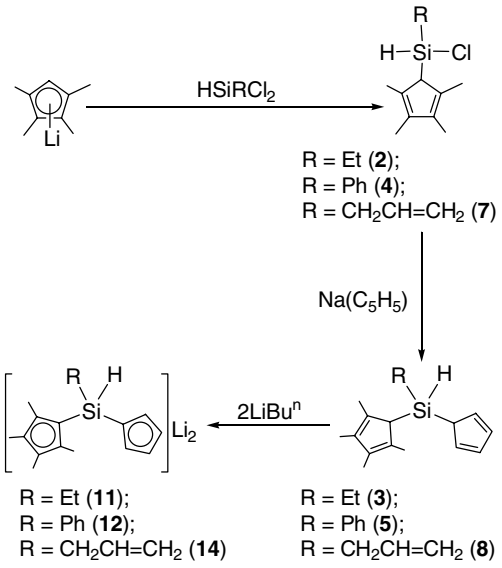
The catalytic activity of group 4 metallocene complexes in the polymerization of olefins has been the principal reason for the dramatic growth in interest towards these compounds [1]. The main focus of this research field is centred on the design of metallocene complexes towards the goal of "made to measure" catalysts that can direct the catalytic reaction in producing polymers with desired physical properties. *ansa*-Cyclopentadienyl systems are now widely recognized to afford better catalytic activity and selectivity in the polymerization of olefins than their non-*ansa* counterparts [2]. Recent studies have demonstrated that the incorporation of the *ansa*-bridge may have a profound influence on the chemical behaviour of these complexes [3].

Industry requirements for the development of supported metallocene polymerization catalysts, that can offer homogeneous single-site selectivity in a heterogeneous medium, is presently of utmost importance. Several studies on immobilized catalysts have recently been published [4]. The immobilization of the catalyst is normally achieved by the introduction of functional groups in the ligand system and their interaction with the surface of an inorganic oxide with the metallocene framework remaining, in most cases, unaltered [5].



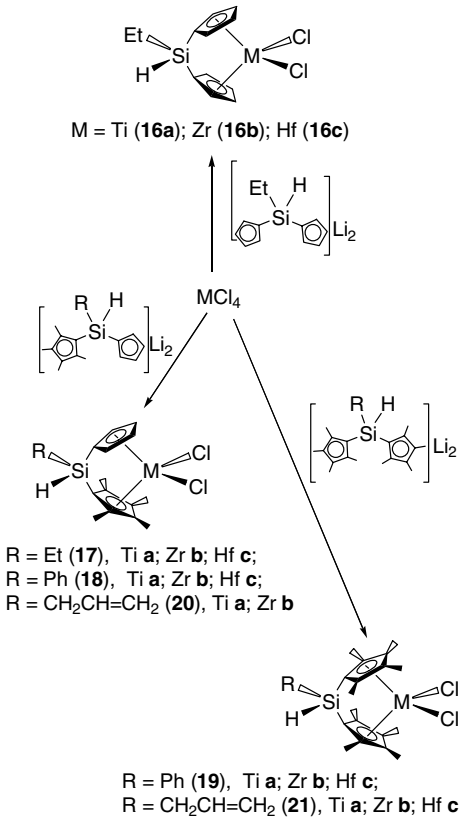
Suzuki et al. [5d] have reported the hydrosilylation of *ansa*-zirconocene complexes with vinyl substituents at the silicon *ansa* bridge to give derivatives which were subsequently supported on silica. In a similar manner O'Hare and co-worker [5e] have reported the immobilization on silica of an *ansa*-bisindenyl complex. Alt et al. [6] have also recently published their work relating to the modification by hydrosilylation of *ansa*-cyclopentadienyl ligands and their subsequent incorporation in group 4 metallocene systems. Collins and co-workers [5a] have reported the anchoring, on modified silica surfaces, of *ansa*-metallocene complexes via hydrosilylation reactions. Seyferth and Wyrwa [7] have also carried out work incorporating group 4 metallocene fragments in organosilicon dendrimers.

As part of our ongoing studies in *ansa*-metallocene complexes [8], we recently published our initial results on the modification of the *ansa*-ligand framework via hydrosilylation reactions [9]. As a continuation of this work we now report the synthesis of new group 4 *ansa*-metallocene complexes and the reactivity of the *ansa*-bridge Si–H bond in the hydrosilylation of unsaturated silane substrates. We also describe the hydrosilylation of vinyl or allyl substituents at the silicon *ansa* bridge of group 4 metallocene complexes. The catalytic activity of the *ansa*-zirconocene complexes in the polymerization of ethylene is included.



2. Results and discussion

The ligand systems, $Et(H)Si(C_5H_5)_2$ (**1**), $Et(H)Si(C_5HMe_4)Cl$ (**2**), $Et(H)Si(C_5HMe_4)(C_5H_5)$ (**3**), $Ph(H)Si(C_5HMe_4)Cl$ (**4**), $Ph(H)Si(C_5HMe_4)(C_5H_5)$ (**5**), $Ph(H)Si(C_5HMe_4)_2$ (**6**), $CH_2{=}CHCH_2(H)Si(C_5HMe_4)$-Cl (**7**), $CH_2{=}CHCH_2(H)Si(C_5HMe_4)(C_5H_5)$ (**8**) and $CH_2{=}CH$-$CH_2(H)Si(C_5HMe_4)_2$ (**9**) were prepared as yellow oils following previously reported synthetic protocols (Schemes 1 and 2) and isolated as mixtures of the double bond position isomers [8,9]. In the preparation of **2** and **4**, an excess of the dichlorosilane reagent was used in order to favour monosubstitution. **1**–**9** were characterized by ^1H NMR spectroscopy and electron impact mass spectrometry (see Section 5). The *ansa*-biscyclopentadiene compounds, **1**, **3**, **5**, **6**, **8** and **9** were lithiated in the traditional manner with *n*-butyllithium, to give the dilithium derivates, $Li_2\{Et(H)Si(C_5H_4)_2\}$ (**10**), $Li_2\{Et(H)Si(C_5Me_4)(C_5H_4)\}$ (**11**), $Li_2\{Ph(H)Si(C_5Me_4)$-$(C_5H_4)\}$ (**12**), $Li_2\{Ph(H)Si(C_5Me_4)_2\}$ (**13**), $Li_2\{CH_2{=}$ $CHCH_2$-$(H)Si(C_5Me_4)(C_5H_4)\}$ (**14**) and $Li_2\{CH_2{=}CH$-$CH_2(H)$-$Si(C_5Me_4)_2\}$ (**15**), in high yields.



The reaction of **10**–**15** with either $[TiCl_4(THF)_2]$, $ZrCl_4$ or $HfCl_4$, yielded the corresponding *ansa*-metallocene (IV) dichloride complexes, $[M\{Et(H)Si(\eta^5$-$C_5H_4)_2\}$-$Cl_2]$ (M = Ti (**16a**), Zr (**16b**), Hf (**16c**)), $[M\{Et(H)Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)\}Cl_2]$ (M = Ti (**17a**), Zr (**17b**), Hf (**17c**)), $[M\{Ph(H)Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)\}Cl_2]$ (M = Ti (**18a**), Zr (**18b**), Hf (**18c**)), $[M\{Ph(H)Si(\eta^5$-$C_5Me_4)_2\}Cl_2]$ (M = Ti (**19a**), Zr (**19b**), Hf (**19c**)), $[M\{CH_2{=}$ $CHCH_2(H)Si(\eta^5$-$C_5Me_4)(\eta^5$-$C_5H_4)\}Cl_2]$ (M = Ti (**20a**), Zr (**20b**)) and $[M\{CH_2{=}$ $CHCH_2(H)Si(\eta^5$-$C_5Me_4)_2\}Cl_2]$ (M = Ti (**21a**), Zr (**21b**), Hf (**21c**)) (Scheme 3).

Scheme 1.

Scheme 2.

Scheme 3.

16–**21** were isolated as crystalline solids and characterized spectroscopically.[1] The ^{1}H NMR spectra for **16** showed the expected signals, namely 4 multiplets in the region δ 6.0–7.2, corresponding to the C_5 ring protons, and two multiplets, at ca. δ 1.1 and 1.4, assigned to the ethyl group. A triplet, at ca. δ 5.1, was observed for the proton bonded directly to the silicon atom. The mixed cyclopentadienyl chiral complexes **17**, **18** and **20** gave eight signals assigned to the four protons of the unsubstituted cyclopentadienyl moiety and to the four methyl groups of the tetramethylcyclopentadienyl fragment. For **17** the α-protons of the ethyl unit are diastereoscopic and give rise to two overlapping multiplet signals (δ 1.4) with a further multiplet being observed for the β-protons (δ 1.5). The Si–H proton resonates (δ 5.2) as a pseudo-triplet due to its coupling with the two inequivalent α-protons of the ethyl group. For **18** three multiplets for the phenyl moiety (δ 7.3, 7.6 and 8.0) and a singlet (δ 5.9) assigned to the Si–H proton were observed. For **20** the α-protons of the allyl unit are again diastereoscopic and were observed as an unresolved multiplet (δ 2.5) arising from both geminal and vicinal couplings. Further multiplets were observed for the central CH (δ 6.1) and terminal olefinic protons (δ 5.2 and 5.3, *cis* and *trans*, respectively, with respect to H_β). As in the case of **17**, the Si–H signal in **20** was observed as a pseudo-triplet (δ 5.2). The C_s symmetric complexes **19** and **21** gave in the ^{1}H NMR spectra, four singlets, in the region δ 1.6–2.2, corresponding to the per-methyl substituted *ansa*-ligand. For **19**, three multiplets for the phenyl moiety (δ 7.3, 7.5 and 8.0) and a singlet for the Si–H proton (δ 6.0) were also observed. For **21**, the ^{1}H NMR spectra were completed with the assignment of four multiplets (δ 2.6, 5.2, 5.3 and 6.1) and a triplet (δ 5.3) to the allyl and Si–H protons, respectively. The $^{13}C\{^{1}H\}$ NMR spectra for **16**–**21** showed the expected signals for the different ligand systems present (see Section 5). Signals for the allyl carbons of **20** and **21** were observed in the ^{13}C NMR spectra at ca. δ 20, 132 and 117 corresponding to the silicon bonded, central and terminal carbons, respectively. The signal due to the *ansa*-bridge silicon atom in **16**–**21** was observed in the ^{29}Si NMR spectra with the nature of this signal depending on the substituents present; **16**, **17**, **20** and **21** a doublet of multiplets and **18** and **19** a doublet. The multiplicity of the signal corresponds to the coupling of the silicon atom with its hydride substituent and the α-protons of the ethyl or allyl group.

The molecular structures of **21b** and **21c** were established by single crystal X-ray diffraction studies. The molecular structures and atomic numbering schemes are shown in Figs. 1 and 2. Selected bond lengths and angles for **21b** and **21c** are given in Table 1. In the case of **21c**, there are two distinct molecules in the asymmetric unit. A disordered toluene molecule was also located in the asymmetric unit.

For **21b** and **21c**, the usual bent metallocene conformation is observed with the geometry around the metal atom being pseudo-tetrahedral. The *ansa* ligand chelates

[1] We were unable to obtain the hafnium derivative of 20 with sufficient purity.

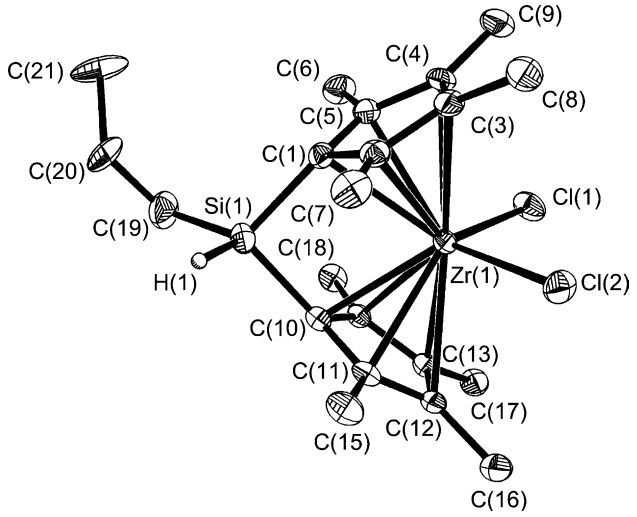


Fig. 1. Molecular structure and atom-labelling scheme for $[Zr\{CH_2{=}CHCH_2(H)Si(\eta^5\text{-}C_5Me_4)_2\}Cl_2]$ (**21b**) with thermal ellipsoids at 30% probability.

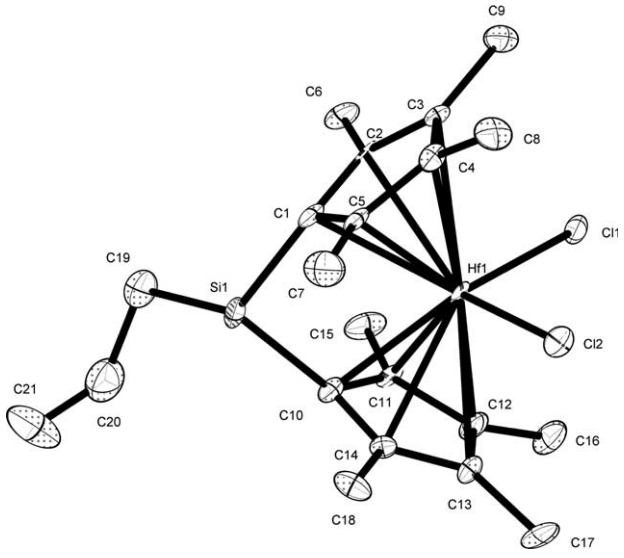

Fig. 2. Molecular structure and atom-labelling scheme for $[Hf\{CH_2{=}CHCH_2(H)Si(\eta^5\text{-}C_5Me_4)_2\}Cl_2]$ (**21c**) with thermal ellipsoids at 50% probability.

the zirconium or hafnium atom and both C_5 rings are bound to the metal in an η^5 mode. The centroids of the tetramethylcyclopentadienyl rings form an angle with the metal atom of 128.5° **21b** and 129.05° and 128.65° **21c**, which is typical for dichloride group 4 *ansa*-metallocene complexes. In **21b** the hydrogen atom (H(1)) bonded to the silicon atom was located in the difference map. The carbon atoms of the allyl moiety in **21b** are disordered, therefore we make no reference to the bond distances and angles of this fragment. However, in **21c** the allyl carbon atoms were clearly resolved and exhibit bond distances of C(19)–C(20) 1.51(1) and 1.53(1) Å and C(20)–C(21) 1.33(1) and 1.26(1) Å which

Cent(1) and Cent(2) are the centroids of C(1)–C(5) and C(10)–C(14), respectively.

[a] Refers to the average bond distance between Zr or Hf and the carbon atoms of the C_5 ring of the corresponding cyclopentadienyl moiety.

are typical for carbon carbon single (C(19)–C(20)) and double bonds (C(20)–C(21)), respectively. The angles Si(1)–C(19)–C(20) 108.7(5)° and 109.4(5)° and C(19)–C(20)–C(21) 124.8(9)° and 126.3(9)° indicate that C(19) and C(20) are sp^3 and sp^2 hybridized, respectively. Selected structural data of **21b** and **21c** can be compared with similar *ansa*-metallocene complexes using Table 2.

We have previously reported the modification of *ansa*-metallocene systems via hydrosilylation processes [9] and in order to gain a better understanding into the possible electronic or steric factors that may influence the outcome of these reactions we have tested **16**–**21** as hydrosilylation reagents. The hydrosilylation of $Si(CH{=}CH_2)_4$ by **16**–**21** in the presence of the Karstedt catalyst (divinyltetramethylsiloxane Pt(0)) was attempted. The per-methyl substituted *ansa*-complexes **19** and **21** did not react, inferring that the Si–H bond is not sufficiently reactive (even at high temperatures) to participate in the hydrosilylation reaction. This may be due to electronic effects caused by the electrodonating nature of the methyl ring substituents which translates to a less reactive Si–H bond [13]. The mixed cyclopentadienyl complexes (with four fewer methyl substituents) **17**, **18** and **20** did react with $Si(CH{=}CH_2)_4$ giving the product formed by the reaction of only one of the double bonds of the silane substrate. Only in the case of **17a** and **17b** were we able to isolate the final product with high purity

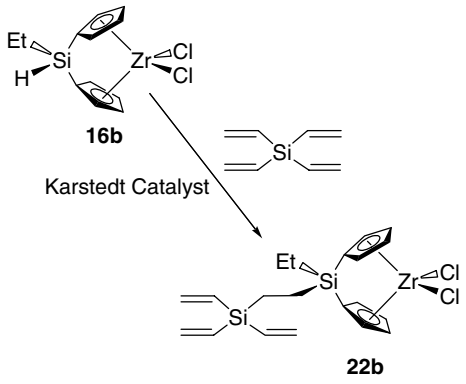
and although the experimental conditions were directed towards the polyhydrosilylation of the silane substrate only the monohydrosilylation derivative, [M{(CH_2=CH)$_3$SiCH_2CH_2(Et)Si(η^5-C_5Me_4)(η^5-C_5H_4)}Cl_2] (M = Ti (**23a**), Zr (**23b**)), was obtained (Scheme 4). This fact may be due to steric hindrance in the hypothetical tetra-substitution of the silane substrate by four metallocene units. However, Alt et al. [6a] have recently prepared tetranuclear complexes via the hydrosilylation of *ansa*-cyclopentadienyl ligands and their subsequent incorporation in group 4 *ansa*-metallocene systems. Our synthetic strategy differs from that used by Alt in that in our case the reactivity takes place at the group 4 *ansa*-metallocene complex and not from previous modification of the organic ligand.

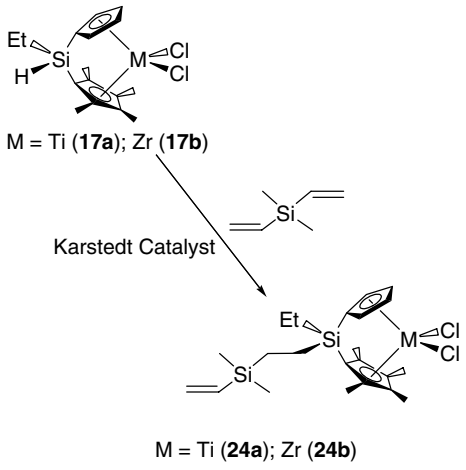


23a and **23b** were isolated as red and yellow oils, respectively, and characterized by NMR spectroscopy. The ^{1}H NMR spectra showed the expected signals for the cyclopentadienyl moieties namely four singlets and four multiplets. The three unreacted vinyl groups of the silane gave an ABX system in the ^{1}H NMR spectra and signals at ca. δ 133 (C_α) and 136 (C_β) in the ^{13}C{^{1}H} NMR spectra. The –CH_2CH_2– fragment, resulting from the hydrosilylation of the vinyl group, gave a complex set of multiplets with geminal and vicinal couplings in the ^{1}H NMR spectra. Two signals were observed in the ^{29}Si{^{1}H} NMR spectra at ca. δ −18 and −9, corresponding to the vinyl substituted and *ansa* bridge silicon atoms, respectively. The hydrosilylation reaction can also give the alternative regioisomer, [M{(CH_2=CH)$_3$Si(CH_3)CH(Et)Si(η^5-C_5Me_4)(η^5-C_5H_4)}Cl_2], via α-addition [14]. This minor product was detected, in quantities of ca. 5–10%, by ^{1}H NMR spectroscopy.

Scheme 4.

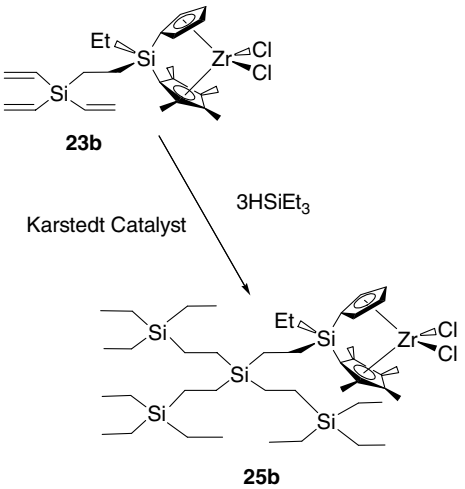
The *ansa*-metallocene complex without ring substituents **16b** was also tested in this reaction. It was hoped that the complete absence of electrodonating ring substituents would aid in the polyhydrosilylation of the tetravinylsilane. However, only the monohydrosilylation product, [Zr{(CH_2=CH)$_3$SiCH_2CH_2(Et)Si(η^5-C_5H_4)$_2$}Cl_2] (**22b**), was detected (Scheme 5). Nevertheless the Si–H bond in **16b** was shown to be more reactive than its methyl substituted counterparts **17**–**21** with the reaction of hydrosilylation being complete after 3 h at room temperature whereas for **23a** and **23b** the experimental conditions required were 100 °C and 40 h reaction time. **22b** was isolated as a yellow oil and characterized by NMR spectroscopy giving data similar to **23a** and **23b** (see Section 5).

Similar reactions have been carried out between **17a** and **17b** and dimethyldivinylsilane and gave the products [M{(CH_2=CH)Me_2SiCH_2CH_2(Et)Si(η^5-C_5Me_4)(η^5-C_5H_4)}Cl_2] (M = Ti (**24a**), Zr (**24b**)), as red and yellow oils, respectively, formed by the hydrosilylation of only one of the double bonds of the silane substrate



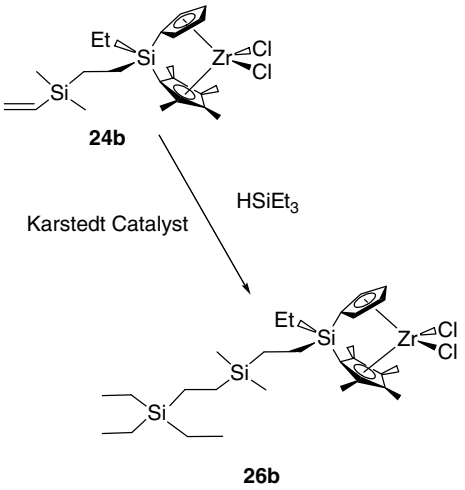
Scheme 5.

(Scheme 6). The NMR spectra of **24a** and **24b** are similar in all aspects to those previously discussed for **22** and **23** and showed in addition the presence of the minor regioisomer produced by α-addition (5–10%).

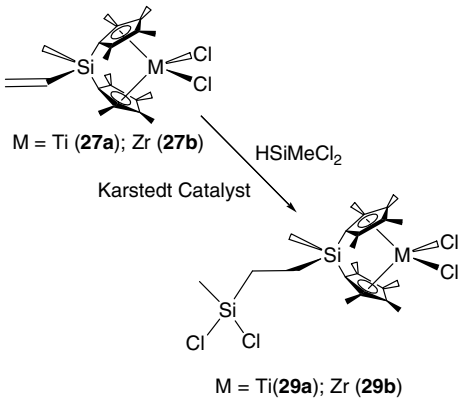


Further hydrosilylation of the vinyl groups of **22**–**24** was not possible when the hydrogen–silicon bond corresponded to the *ansa*-metallocene complexes. It appears that the reaction of one of the vinyl groups with the *ansa*-metallocene complex deactivates the remaining vinyl groups towards hydrosilylation by the Si–H of the *ansa* bridge. This may be attributed to electronic and/or steric effects. However, with triethylsilane, hydrosilylation took place at all the remaining vinyl groups of **23b** and **24b**, to give [Zr{$(Et_3SiCH_2CH_2)_3SiCH_2CH_2$(Et)Si($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_4$)}$Cl_2$] (**25b**) and [Zr{$(Et_3SiCH_2CH_2)Me_2SiCH_2CH_2$(Et)Si($\eta^5$-$C_5Me_4$)($\eta^5$-$C_5H_4$)}$Cl_2$] (**26b**) (Schemes 7 and 8).

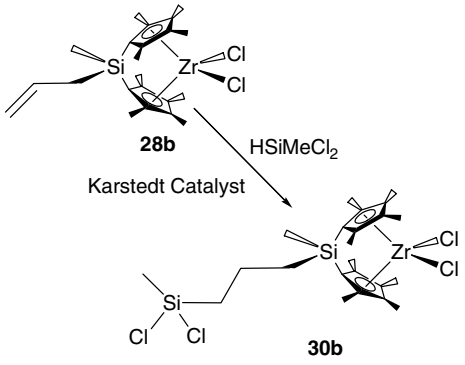
25b and **26b** were isolated as yellow oils and characterized by NMR spectroscopy. The reaction was deemed to have gone to completion by the absence of any signals in ^1H and $^{13}C\{^1H\}$ NMR spectroscopy corresponding to the vinyl groups of the parent complexes. The ^1H NMR spectra showed the expected signals for the C_5H_4 and C_5Me_4 moieties. In addition two multiplets, assigned to the ethyl groups of $SiEt_3$, and a complex set of multiplets, corresponding to the two distinct $-CH_2CH_2-$ fragments, were observed. The presence of the minor α-addition regioisomers was again detected (5–10%). $^{29}Si\{^1H\}$ NMR spectra revealed three signals corresponding to the three distinct silicon atoms present.



The hydrosilylation of the previously reported complexes [M{CH_2=CH(Me)Si(η^5-C_5Me_4)$_2$}Cl_2] (M = Ti (**27a**), Zr (**27b**)) and [Zr{CH_2=$CHCH_2$(Me)Si(η^5-C_5Me_4)$_2$}Cl_2] (**28b**) [8e], by $HSiMeCl_2$ has successfully been carried out. The reaction, in the presence of the Karstedt catalyst, gave after two hours reaction time the β-hydrosilylation products [M{$Cl_2MeSiCH_2CH_2$(Me)Si(η^5-C_5Me_4)$_2$}Cl_2] (M = Ti (**29a**), Zr (**29b**)) and [Zr{$Cl_2MeSiCH_2CH_2CH_2$(Me)Si(η^5-C_5Me_4)$_2$}Cl_2] (**30b**)



Scheme 6.



Scheme 7.

Scheme 8.

Scheme 9.

Scheme 10.

(Schemes 9 and 10). The presence of the minor α-addition regioisomer was also detected (5–10%).

29 and **30** were isolated as yellow solids and characterized by NMR spectroscopy. In the ^{1}H NMR spectra the presence of signals due to the vinyl or allyl protons of the starting products, **27** and **28**, was not observed. In the region of δ 0.5–1.8 multiplet signals were observed, two in the case of **29** (–$SiCH_2CH_2Si$–) and three for **30** (–$SiCH_2CH_2CH_2Si$–). For **29** and **30** a singlet at δ 0.4 was observed corresponding to the methyl protons of the dichloromethylsilyl fragment. Two signals were recorded in the $^{29}Si\{^1H\}$ NMR for **29** and **30** at ca. δ −10 and 32 and assigned to the *ansa* bridge and chloride bonded silicon atoms, respectively. In the $^{29}Si\{^1H\}$ NMR spectra of the vinyl and allyl substituted *ansa*-metallocene precursors of **29** and **30** a unique signal was observed for the *ansa* bridge silicon atom at δ −21.2, −22.7 and −15.6 for **27a**, **27b** and **28b**, respectively [15].

3. Polymerization studies

The polymerization of ethylene using the zirconium derivatives described in this paper as catalysts has been carried out. The polymerization experiments were conducted with a MAO–metal catalyst ratio of 3000:1, at 20 °C and at olefin pressure of 2 bar for 15 min. Polymerization was also carried out with the reference compound $[Zr(\eta^5\text{-}C_5H_5)_2Cl_2]$, under the same experimental conditions. The catalytic activities and polymer molecular weight and distribution values are given in Table 3.

Complex **29b** proved to be the most active catalyst of the series. A slightly lower value was recorded for the reference complex $[Zr(\eta^5\text{-}C_5H_5)_2Cl_2]$. The low catalytic activities observed for **22**, **23b** and **25** may be due to steric factors as proposed previously by De Jesús and co-workers [16] for similar modified metal-

[a] At 20 °C, 2 bar monomer pressure, 200 mL toluene, $[Al] = 9 \times 10^{-2}$ mol L^{-1}, $[Zr] = 3 \times 10^{-5}$ mol L^{-1}, $t_{Pol} = 15$ min.
[b] In kg Pol (mol Zr h)$^{-1}$.

locene systems. In general, but not always, the complexes that contain a carbon carbon double bond substituent give low catalytic activities. This is most probably due to the fact that during the polymerization of ethylene, the vinyl or allyl groups of the *ansa*-ligand co-polymerize with the monomer thus immobilizing the metallocene complex on the polymer chain to give a pseudo-heterogeneous catalyst. This phenomenon with similar *ansa*-metallocene complexes has previously been reported [17].

4. Conclusions

In this paper we have reported the synthesis and catalytic activity of new *ansa*-metallocene complexes containing a Si–H bond which can be exploited in reactions of hydrosilylation to modify the ligand framework. The potential of translating this reactivity to the immobilization of *ansa*-metallocene catalysts on distinct substrates should be of great interest.

5. Experimental

All reactions were performed using standard Schlenk tube techniques in an atmosphere of dry nitrogen. Solvents were distilled from the appropriate drying agents and degassed before use. $C_5H_2Me_4$, $[TiCl_4(THF)_2]$, $ZrCl_4$, $HfCl_4$, $HSiMeCl_2$,$Si(CH{=}CH_2)_4$, $SiMe_2(CH{=}CH_2)_2$ and $HSiEt_3$ were purchased from Aldrich, $HSiEtCl_2$ and $HSiPhCl_2$ from Fluka and $HSi(CH_2CH{=}CH_2)Cl_2$ and the Karstedt catalyst from ABCR. All the commercial reagents were used directly. $Na(C_5H_5)$ [18], **27a**, **27b** and **28b** [8e] were prepared as previously described. IR spectra were recorded on a Thermo Nicolet Avatar 330 FT-IR spectrophotometer. ^1H, ^{13}C and ^{29}Si NMR spectra were recorded on a Varian Mercury FT-400 spectrometer. Microanalyses were carried out with a Perkin–Elmer 2400 or LECO CHNS-932 microanalyser. Mass spectroscopic analyses were preformed on a Hewlett–Packard 5988A (*m/z* 50–1000) instrument. Polymer molecular weights and distribution were determined by GPC (Waters 150C Plus or Alliance GPC-2000) in 1,2,4-trichlorobenzene at 150 °C.

5.1. Synthesis of $Et(H)Si(C_5H_5)_2$ (*1*)

$Et(H)SiCl_2$ (3.66 g, 28.38 mmol) was added to a solution of $Na(C_5H_5)$ (5.00 g, 56.76 mmol) in THF (50 mL) at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred for 15 h. Solvent was removed in vacuo and hexane (150 mL) was added to the resulting orange oil. The mixture was filtered and solvent removed from the filtrate under reduced pressure to yield the title compound as a dark orange oil (4.54 g, 85%). ^1H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ −0.38 (2H), 0.96 (3H) (m, Si*Et*), 3.07 (m, 2H, *H*C_5), 3.47 (m, 1H, Si*H*), 5.52 (2H), 6.00 (2H), 6.64 (2H), 6.97 (2H) (m, C_5H_4). MS electron impact (*m/e* (relative intensity)): 188 (25) $[M^+]$, 159 (19) $[M^+ - Et]$, 123 (62) $[M^+ - C_5H_5]$, 93 (100) $[M^+ - C_5H_5, -Et]$.

The preparation of **2**–**9** was carried out in an identical manner to **1**.

5.2. $Et(H)Si(C_5HMe_4)Cl$ (*2*)

From $Et(H)SiCl_2$ (5.02 g, 39.00 mmol) and $Li(C_5HMe_4)$ (2.50 g, 19.50 mmol). Yield: 3.57 g, 94%. ^1H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ −0.54 (2H), 0.94 (3H) (m, Si*Et*), 1.85 (6H), 1.99 (3H), 2.04 (3H) (s, C_5Me_4), 3.24 (m, 1H, *H*C_5), 4.73 (m, 1H, Si*H*). MS electron impact (*m/e* (relative intensity)): 214 (18) $[M^+]$, 122 (100) $[M^+ - Et(H)SiCl]$, 91 (52) $[M^+ - C_5HMe_4]$.

5.3. $Et(H)Si(C_5HMe_4)(C_5H_5)_2$ (*3*)

From $Et(H)Si(C_5HMe_4)Cl$ (**2**) (2.00 g, 9.31 mmol) and $Na(C_5H_5)$ (0.82 g, 9.31 mmol). Yield: 2.05 g, 90%. ^1H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ −0.48 (2H), 0.95 (3H) (m, Si*Et*), 1.88 (3H), 1.90 (3H), 1.96 (3H), 2.07 (3H) (s, C_5Me_4), 2.90 (1H), 3.01 (1H) (m, *H*C_5), 3.42 (m, 1H, Si*H*), 6.57 (1H), 6.59 (1H), 6.66 (1H), 6.83 (1H) (m, C_5H_4). MS electron impact (*m/e* (relative intensity)): 244 (18) $[M^+]$, 215 (28) $[M^+ - Et]$, 179 (100) $[M^+ - C_5H_5]$, 123 (52) $[M^+ - C_5HMe_4]$, 121 (41) $[M^+ - Et(H)SiC_5H_5]$.

5.4. $Ph(H)Si(C_5HMe_4)Cl$ (*4*)

From $Ph(H)SiCl_2$ (6.92 g, 39.00 mmol) and $Li(C_5HMe_4)$ (2.50 g, 19.50 mmol). Yield: 4.66 g, 91%. ^1H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ 1.63 (3H), 1.68 (3H), 1.96 (3H), 2.02 (3H) (s, C_5Me_4), 3.43 (m, 1H, *H*C_5), 5.14 (m, 1H, Si*H*), 7.30 (2H), 7.38 (2H), 7.74 (1H) (m, Si*Ph*). MS electron impact (*m/e* (relative intensity)): 262 (74) $[M^+]$, 227 (26) $[M^+ - Cl]$, 141 (23) $[M^+ - C_5HMe_4]$, 122 (100) $[M^+ - Ph(H)SiCl]$.

5.5. $Ph(H)Si(C_5HMe_4)(C_5H_5)_2$ (*5*)

From $Ph(H)Si(C_5HMe_4)Cl$ (**4**) (2.00 g, 7.61 mmol) and $Na(C_5H_5)$ (0.67 g, 7.61 mmol). Yield: 1.96 g, 88%. ^1H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ 1.65 (3H), 1.71 (3H), 1.72 (3H), 1.91 (3H) (s, C_5Me_4), 3.06 (1H), 3.13 (1H) (m, *H*C_5), 3.60 (m, 1H,

Si*H*), 6.63 (1H), 6.67 (1H), 6.73 (1H), 6.95 (1H) (m, C_5H_4), 7.29 (2H), 7.33 (2H), 7.46 (1H) (m, Si*Ph*). MS electron impact (*m/e* (relative intensity)): 292 (24) [M^+], 262 (28) [$M^+ - 2\times Me$], 227 (100) [$M^+ - C_5H_5$], 171 (55) [$M^+ - C_5HMe_4$].

5.6. $Ph(H)Si(C_5HMe_4)_2$ (6)

From $Ph(H)SiCl_2$ (1.73 g, 9.75 mmol) and Li(C_5HMe_4) (2.50 g, 19.50 mmol). Yield: 2.05 g, 90%. ^{1}H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ 1.62 (6H), 1.68 (6H), 1.85 (6H), 1.99 (6H) (s, C_5Me_4), 3.27 (m, 2H, HC_5), 4.06 (m, 1H, Si*H*), 7.03 (2H), 7.17 (2H), 7.22 (1H) (m, Si*Ph*). MS electron impact (*m/e* (relative intensity)): 348 (9) [M^+], 227 (100) [$M^+ - C_5HMe_4$], 121 (14) [$M^+ - Ph(H)SiC_5HMe_4$], 105 (17) [$M^+ - 2\times C_5HMe_4$].

5.7. $CH_2{=}CHCH_2(H)Si(C_5HMe_4)Cl$ (7)

From $CH_2{=}CHCH_2(H)SiCl_2$ (2.74 g, 19.50 mmol) and Li(C_5HMe_4) (2.50 g, 19.50 mmol). Yield: 3.57 g, 94%. ^{1}H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ 1.52 (m, 2H, $CH_2CH{=}CH_2$), 1.81 (6H), 1.82 (3H), 1.86 (3H) (s, C_5Me_4), 2.74 (m, 1H, HC_5), 4.77 (m, 1H, Si*H*), 4.93 (m, 2H, $CH_2CH{=}CH_2$), 5.59 (m, 1H, $CH_2CH{=}CH_2$). MS electron impact (*m/e* (relative intensity)): 226 (1) [M^+], 121 (100) [$M^+ - CH_2CH{=}\ CH_2(H)SiCl$], 103 (46) [$M^+ - C_5HMe_4$].

5.8. $CH_2{=}CHCH_2(H)Si(C_5HMe_4)(C_5H_5)$ (8)

From $CH_2{=}CHCH_2(H)Si(C_5HMe_4)Cl$ (**7**) (2.00 g, 8.81 mmol) and Na(C_5H_5) (0.78 g, 8.81 mmol). Yield: 1.78 g, 79%. ^{1}H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ 1.50 (m, 2H, $CH_2CH{=}CH_2$), 1.66 (3H), 1.74 (3H), 1.80 (3H), 1.91 (3H) (s, C_5Me_4), 2.73 (1H), 3.03 (1H) (m, HC_5), 4.64 (m, 1H, Si*H*), 4.94 (m, 2H, $CH_2CH{=}CH_2$), 6.49 (m, 1H, $CH_2CH{=}CH_2$), 5.95 (2H), 6.41 (2H), (m, C_5H_4). MS electron impact (*m/e* (relative intensity)): 256 (5) [M^+], 215 (7) [$M^+ - CH_2CH{=}CH_2$], 191 (19) [$M^+ - C_5H_5$], 149 (100) [$M^+ - CH_2CH{=}CH_2, -C_5H_5, -H$].

5.9. $CH_2{=}CHCH_2(H)Si(C_5HMe_4)_2$ (9)

From $CH_2{=}CHCH_2(H)SiCl_2$ (1.37 g, 9.75 mmol) and Li(C_5HMe_4) (2.50 g, 19.50 mmol). Yield: 2.86 g, 94%. ^{1}H NMR (400 MHz, $CDCl_3$) (for the predominant isomer): δ 1.48 (m, 2H, $CH_2CH{=}CH_2$), 1.83 (12H), 1.92 (6H), 1.97 (6H) (s, C_5Me_4), 2.70 (m, 2H, HC_5), 3.98 (m, 1H, Si*H*), 4.88 (m, 2H, $CH_2CH{=}CH_2$), 5.67 (m, 1H, $CH_2CH{=}CH_2$). MS electron impact (*m/e* (relative intensity)): 312 (21) [M^+], 191 (85) [$M^+ - C_5HMe_4$], 149 (100) [$M^+ - CH_2CH{=}CH_2, -C_5HMe_4$], 121 (98) [$M^+ - CH_2CH{=}CH_2(H)SiC_5HMe_4$].

5.10. Synthesis of $Li_2\{Et(H)Si(C_5H_4)_2\}$ (10)

LiBu^n (1.6 M in hexane) (13.3 mL, 21.24 mmol) was added dropwise to a solution of $Et(H)Si(C_5H_5)_2$ (**1**) (2.00 g, 10.62 mmol) in hexane (100 mL) at −78 °C. The mixture was allowed to warm to 25 °C and stirred for 15 h. Solvent was removed in vacuo to give a white solid which was washed with hexane (2 × 50 mL) and dried under vacuum to yield a free flowing white solid of the title complex (2.06 g, 97%). *Anal.* Calc. for $C_{12}H_{14}Li_2Si$: C, 71.99; H, 7.05. Found: C, 71.58; H, 7.00%.

The preparation of **11**–**15** was carried out in an identical manner to **10**.

5.11. $Li_2\{Et(H)Si(C_5Me_4)(C_5H_4)\}$ (11)

From $Et(H)Si(C_5HMe_4)(C_5H_5)_2$ (**3**) (2.00 g, 8.18 mmol) and LiBu^n (1.6 M in hexane) (10.2 mL, 16.36 mmol). Yield: 1.89 g, 90%. *Anal.* Calc. for $C_{16}H_{22}Li_2Si$: C, 74.98; H, 8.65. Found: C, 74.49; H, 8.60%.

5.12. $Li_2\{Ph(H)Si(C_5Me_4)(C_5H_4)\}$ (12)

From $Ph(H)Si(C_5HMe_4)(C_5H_5)_2$ (**5**) (2.00 g, 6.83 mmol) and LiBu^n (1.6 M in hexane) (8.6 mL, 13.66 mmol). Yield: 1.83 g, 88%. *Anal.* Calc. for $C_{20}H_{22}Li_2Si$: C, 78.93; H, 7.29. Found: C, 78.66; H, 7.27%.

5.13. $Li_2\{Ph(H)Si(C_5Me_4)_2\}$ (13)

From $Ph(H)Si(C_5HMe_4)_2$ (**6**) (2.00 g, 5.73 mmol) and LiBu^n (1.6 M in hexane) (7.2 mL, 11.46 mmol). Yield: 1.69 g, 82%. *Anal.* Calc. for $C_{24}H_{30}Li_2Si$: C, 79.97; H, 8.39. Found: C, 79.45; H, 8.31%.

5.14. $Li_2\{CH_2{=}CHCH_2(H)Si(C_5Me_4)(C_5H_4)\}$ (14)

From $CH_2{=}CHCH_2(H)Si(C_5HMe_4)(C_5H_5)$ (**8**) (2.00 g, 7.80 mmol) and LiBu^n (1.6 M in hexane) (9.8 mL, 15.60 mmol). Yield: 1.73 g, 83%. *Anal.* Calc. for $C_{17}H_{22}Li_2Si$: C, 76.10; H, 8.26. Found: C, 75.89; H, 8.22%.

5.15. $Li_2\{CH_2{=}CHCH_2(H)Si(C_5Me_4)_2\}$ (15)

From $CH_2{=}CHCH_2(H)Si(C_5HMe_4)_2$ (**9**) (2.00 g, 6.40 mmol) and LiBu^n (1.6 M in hexane) (8.0 ml, 12.80 mmol). Yield: 1.70 g, 78%. *Anal.* Calc. for $C_{21}H_{30}Li_2Si$: C, 77.74; H, 9.32. Found: C, 77.44; H, 9.28%.

5.16. Synthesis of [Ti{Et(H)Si(η⁵-C₅H₄)₂}Cl₂] (16a)

THF (50 mL) was added to a solid mixture of $[TiCl_4(THF)_2]$ (1.67 g, 4.99 mmol) and $Li_2\{Et(H)Si(\eta^5\text{-}C_5H_4)_2\}$ (**10**) (1.00 g, 4.99 mmol). The resulting solution was stirred for 15 h. Solvent was removed in vacuo and toluene added (75 mL) to the resulting solid. The mixture was filtered and the filtrate concentrated (10 mL) and cooled to −30 °C to yield crystals of the title complex (0.78 g, 51%). IR (ZnSe): ν_{Si-H} 2187 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 1.11 (3H), 1.37 (2H) (m, Si*Et*), 5.05 (t, 1H, Si*H*) ($^3J(^1H–^1H)$ 3.3 Hz), 6.02 (2H), 6.08 (2H), 7.22 (2H), 7.25 (2H) (m, C_5H_4). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 1.5, 7.3 (Si*Et*), 101.7 (C^{ipso}), 118.2, 120.4, 134.7, 136.2 (C_5H_4). ^{29}Si NMR (79.49 MHz, $CDCl_3$): δ −24.0 (doublet of multiplets) ($^1J(^{29}Si–^1H)$ 214.7 Hz). MS electron impact (*m/e* (relative intensity)): 304 (74) [M^+], 268 (32) [M^+ − Cl], 240 (37) [M^+ − Cl, −Et], 176 (100) [M^+ − Cl, −Et, $-C_5H_4$]. *Anal.* Calc. for $C_{12}H_{14}Cl_2SiTi$: C, 47.24; H, 4.63. Found: C, 47.11; H, 4.59%.

The preparation of **16b**–**32** was carried out in an identical manner to **16a**.

5.17. [Zr{Et(H)Si(η⁵-C₅H₄)₂}Cl₂] (16b)

From $ZrCl_4$ (1.16 g, 4.99 mmol) and $Li_2\{Et(H)Si(C_5H_4)_2\}$ (**10**) (1.00 g, 4.99 mmol). Yield: 0.63 g, 36%. IR (ZnSe): ν_{Si-H} 2177 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 1.17 (3H), 1.37 (2H) (m, Si*Et*), 5.07 (t, 1H, Si*H*) ($^3J(^1H–^1H)$ 3.3 Hz), 6.02 (2H), 6.11 (2H), 6.97 (2H), 7.00 (2H) (m, C_5H_4). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 1.7, 7.3 (Si*Et*), 104.6 (C^{ipso}), 113.7, 116.0, 127.8, 129.3 (C_5H_4). ^{29}Si NMR (79.49 MHz, $CDCl_3$): δ −24.2 (doublet of multiplets) ($^1J(^{29}Si–^1H)$ 213.4 Hz). MS electron impact (*m/e* (relative intensity)): 348 (70) [M^+], 316 (25) [M^+ − Et], 282 (39) [M^+ − Cl, −Et], 253 (45) [M^+ − Et, $-C_5H_4$]. *Anal.* Calc. for $C_{12}H_{14}Cl_2SiZr$: C, 41.36; H, 4.05. Found: C, 41.05; H, 4.04%.

5.18. [Hf{Et(H)Si(η⁵-C₅H₄)₂}Cl₂] (16c)

From $HfCl_4$ (1.60 g, 4.99 mmol) and $Li_2\{Et(H)Si(C_5H_4)_2\}$ (**10**) (1.00 g, 4.99 mmol). Yield: 0.67 g, 31%. IR (ZnSe): ν_{Si-H} 2166 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 1.11 (3H), 1.36 (2H) (m, Si*Et*), 5.06 (t, 1H, Si*H*) ($^3J(^1H–^1H)$ 3.3 Hz), 5.95 (2H), 6.03 (2H), 6.88 (2H), 6.90 (2H) (m, C_5H_4). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 1.8, 7.5 (Si*Et*), 106.1 (C^{ipso}), 111.5, 113.9, 126.4, 127.9 (C_5H_4). ^{29}Si NMR (79.49 MHz, $CDCl_3$): δ −24.9 (doublet of multiplets) ($^1J(^{29}Si–^1H)$ 215.1 Hz). MS electron impact (*m/e* (relative intensity)): 436 (26) [M^+], 407 (16) [M^+ − Et], 250 (65) [M^+ − Et(H)Si(C_5H_4)$_2$]. *Anal.* Calc. for $C_{12}H_{14}Cl_2HfSi$: C, 33.08; H, 3.24. Found: C, 32.99; H, 3.19%.

5.19. [Ti{Et(H)Si(η⁵-C₅Me₄)(η⁵-C₅H₄)}Cl₂] (17a)

From $[TiCl_4(THF)_2]$ (1.30 g, 3.90 mmol) and $Li_2\{Et(H)Si(C_5Me_4)(C_5H_4)\}$ (**11**) (1.00 g, 3.90 mmol). Yield: 0.89 g, 63%. IR (ZnSe): ν_{Si-H} 2172 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 1.38 (3H), 1.48 (2H) (m, Si*Et*), 1.87 (3H), 1.90 (3H), 2.15 (3H), 2.16 (3H) (s, C_5Me_4), 5.21 (dd, 1H, Si*H*) ($^3J(^1H–^1H)$ 4.4 Hz), 5.59 (1H), 5.62 (1H), 7.17 (1H), 7.22 (1H) (m, C_5H_4). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 3.3, 7.8 (Si*Et*), 13.7, 15.7, 15.8 (C_5Me_4), 95.3 (C^{ipso}), 115.2, 117.0, 132.3, 134.3 (C_5H_4), 99.7, 129.8, 131.7, 144.0, 144.5 (C_5Me_4). ^{29}Si NMR (79.49 MHz, $CDCl_3$): δ −25.5 (doublet of multiplets) ($^1J(^{29}Si–^1H)$ 210.6 Hz). MS electron impact (*m/e* (relative intensity)): 360 (48) [M^+], 324 (100) [M^+ − Cl, –H], 288 (91) [M^+ − 2 × Cl, −H]. *Anal.* Calc. for $C_{16}H_{22}Cl_2SiTi$: C, 53.20; H, 6.14. Found: C, 53.01; H, 6.09%.

5.20. [Zr{Et(H)Si(η⁵-C₅Me₄)(η⁵-C₅H₄)}Cl₂] (17b)

From $ZrCl_4$ (0.91 g, 3.90 mmol) and $Li_2\{Et(H)Si(C_5Me_4)(C_5H_4)\}$ (**11**) (1.00 g, 3.90 mmol). Yield: 0.73 g, 46%. IR (ZnSe): ν_{Si-H} 2168 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 1.36 (3H), 1.46 (2H) (m, Si*Et*), 2.03 (3H), 2.07 (3H), 2.08 (6H) (s, C_5Me_4), 5.20 (dd, 1H, Si*H*) ($^3J(^1H–^1H)$ 4.4 Hz), 5.71 (1H), 5.78 (1H), 6.99 (1H), 7.04 (1H) (m, C_5H_4). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 3.6, 7.9 (Si*Et*), 12.3, 12.4, 14.4, 14.9 (C_5Me_4), 95.1 (C^{ipso}), 112.1, 113.9, 126.4, 127.8 (C_5H_4), 102.5, 124.7, 126.0, 135.7, 136.2 (C_5Me_4). ^{29}Si NMR (79.49 MHz, $CDCl_3$): δ −26.7 (doublet of multiplets) ($^1J(^{29}Si–^1H)$ 207.6 Hz). MS electron impact (*m/e* (relative intensity)): 402 (88) [M^+], 366 (100) [M^+ − Cl], 338 (86) [M^+ − Cl, −Et]. *Anal.* Calc. for $C_{16}H_{22}Cl_2SiZr$: C, 47.50; H, 5.48. Found: C, 47.33; H, 5.48%.

5.21. [Hf{Et(H)Si(η⁵-C₅Me₄)(η⁵-C₅H₄)}Cl₂] (17c)

From $HfCl_4$ (1.25 g, 3.90 mmol) and $Li_2\{Et(H)Si(C_5Me_4)(C_5H_4)\}$ (**11**) (1.00 g, 3.90 mmol). Yield: 0.82 g, 43%. IR (ZnSe): ν_{Si-H} 2164 cm^{-1}. ^1H NMR (400 MHz, $CDCl_3$): δ 1.34 (3H), 1.45 (2H) (m, Si*Et*), 2.03 (3H), 2.07 (3H), 2.08 (6H) (s, C_5Me_4), 5.18 (dd, 1H, Si*H*) ($^3J(^1H–^1H)$ 4.4 Hz), 5.67 (1H), 5.73 (1H), 6.91 (1H), 6.97 (1H) (m, C_5H_4). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 3.6, 7.8 (Si*Et*), 12.1, 12.2, 14.0, 14.5 (C_5Me_4), 97.0 (C^{ipso}), 109.5, 111.5, 125.0, 126.9 (C_5H_4), 104.6, 121.5, 123.3, 133.8, 134.3 (C_5Me_4). ^{29}Si NMR (79.49 MHz, $CDCl_3$): δ −27.3 (doublet of multiplets) ($^1J(^{29}Si–^1H)$ 207.2 Hz). MS electron impact (*m/e* (relative intensity)): 492 (85) [M^+], 456 (100) [M^+ − Cl, −H], 428 (19) [M^+ − Cl, −Et]. *Anal.* Calc. for $C_{16}H_{22}Cl_2HfSi$: C, 39.07; H, 4.51. Found: C, 39.00; H, 4.46%.

5.22. [Ti{Ph(H)Si(η^5-C_5Me_4)(η^5-C_5H_4)}Cl_2] (**18a**)

From $[TiCl_4(THF)_2]$ (1.10 g, 3.28 mmol) and $Li_2\{Ph(H)Si(C_5Me_4)(C_5H_4)\}$ (**12**) (1.00 g, 3.28 mmol). Yield: 0.82 g, 61%. MS electron impact (*m*/*e* (relative intensity)): 598 (100) [M^+], 564 (14) [M^+ − Cl], 549 (24) [M^+ − Cl, −Me], 486 (13) [M^+ − $SiMeCl_2$], 445 (23) [M^+ − $CH_2CH_2CH_2SiMeCl_2$]. *Anal.* Calc. for $C_{23}H_{36}Cl_4Si_2Zr$: C, 45.91; H, 6.03. Found: C, 45.44; H, 6.00%.

5.43. Polymerization of ethylene

The zirconocene catalyst (6 μmol), MAO (10% in toluene) (1800 μmol) and toluene (200 mL) were mixed together for 15 min in a 1 L glass autoclave. The N_2 pressure inside the autoclave was reduced by applying a vacuum. Ethylene pressure of 2 bar was then applied and maintained to the autoclave and stirring of the mixture commenced (1000 rpm). After exactly 15 min, stirring was halted and the ethylene pressure released. Excess MAO was then destroyed by adding cautiously a mixture of methanol/HCl (90:10). The polymer was isolated by filtration and washed with ethanol and dried under vacuum at 90 °C for 16 h.

5.44. X-ray structure determination of [Zr{CH_2=CH-$CH_2(H)Si(\eta^5$-$C_5Me_4)_2$}Cl_2] (**21b**)

Data were collected on a Bruker SMART CCD-based diffractometer operating at 50 kV and 30 mA, using ω/2θ scan-technique. Absorption corrections were applied using the SADABS program (maximum and minimum transmission coefficients 0.9608 and 0.7384). The structure was solved using the Bruker SHELXTL-PC software by direct methods and refined by full-matrix least-squares methods on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions (except H(1) which was located in a difference map), and refined in the riding mode. Weights were optimized in the final cycles. Crystallographic data are given in Table 4.

5.45. X-ray structure determination of [Hf{CH_2=CH-$CH_2(H)Si(\eta^5$-$C_5Me_4)_2$}Cl_2] (**21c**)

Data were collected on a Bruker SMART CCD-based diffractometer operating at 50 kV and 100 mA, using ω/2θ scan-technique. The structure was solved using the SHELXS-97 software by direct methods and refined by full-matrix least-squares methods on F^2. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions, and refined in the riding mode. Weights were optimized in the final cycles. Crystallographic data are given in Table 4.

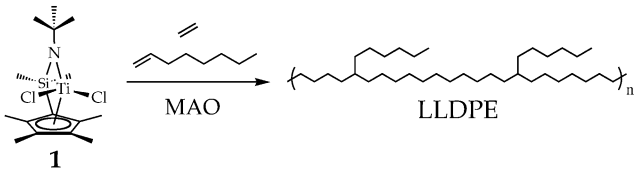

Fig. 1. The titanium *ansa*-tetramethylcyclopentadienyl-amido precatalyst **1**, upon activation with methylaluminoxane (MAO), readily copolymerizes ethylene and α-olefins to form linear low density polyethylene (LLDPE).

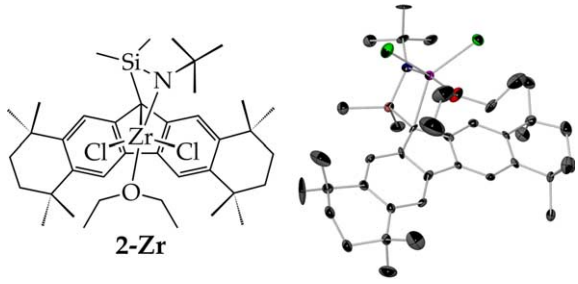

Fig. 2. The first CGC with η^1 ligation to the carbon-based five-membered ring [26]. X-ray structure of **2-Zr** with thermal ellipsoids drawn at 50% probability and hydrogen atoms omitted.

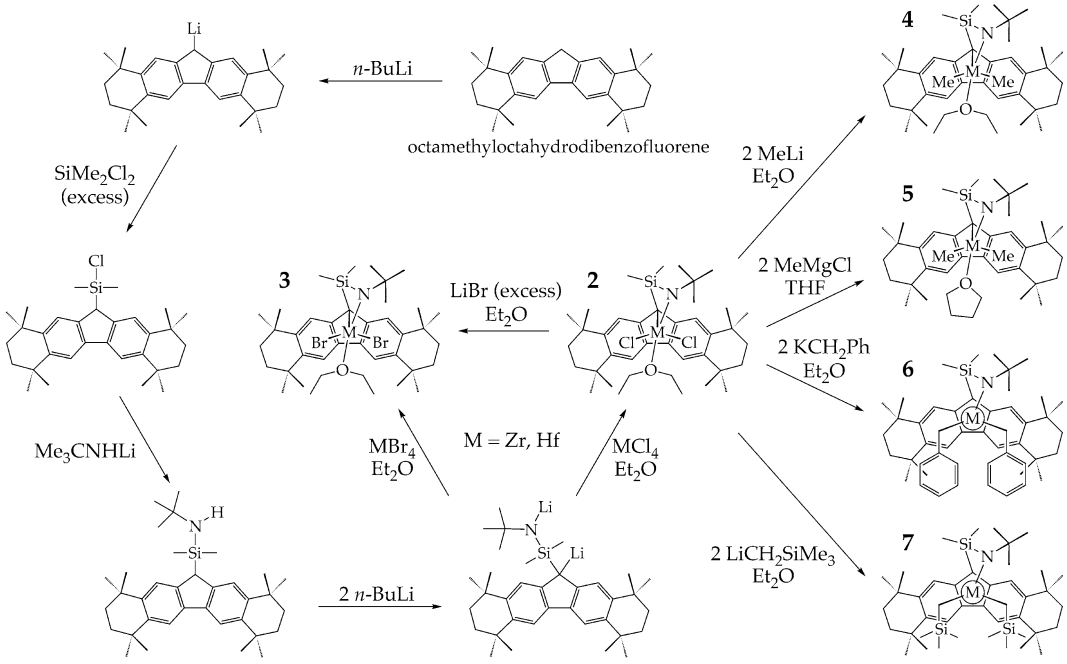

contain the η^1-Oct motif. These structures are compared to alkylated derivates with normal η^5-Oct binding in the context of quantifying and understanding this variable hapticity, which may be related to the unusual preference toward α-olefins over ethylene that **2-Zr**/MAO can exhibit.

2. Results and discussion

2.1. Synthesis of Zr and Hf complexes

The synthesis of zirconium and hafnium Oct-amido complexes (Scheme 1) parallels that of Okuda for the synthesis of zirconium fluorenyl-amido complexes [18]. Octamethyloctahydrodibenzofluorene [27] is deprotonated with *n*-butyllithium [25,28] and transferred into a hexane solution containing excess dimethyldichlorosilane. Subsequent reaction with Me_3CNHLi, followed by double deprotonation with *n*-butyllithium and combination with $ZrCl_4$ or $HfCl_4$ provides **2-Zr** or **2-Hf**. Interestingly, these five steps can be performed in two flasks (OctLi must be added to excess $SiMe_2Cl_2$), without isolation of the intermediates or their separation from salts, to yield 17 g of **2-Zr** as yellow microcrystals in 31.6% overall yield. The dibromide **3-Zr** was obtained from $ZrBr_4$. Additionally, we have shown that **3-Zr** and **3-Hf** can be synthesized from the dichlorides **2-Zr** and **2-Hf** via direct halide exchange with an excess of LiBr in diethyl ether.

2-Zr and **2-Hf** are readily derivatized with alkylating agents. The use of methyllithium with diethyl ether as solvent provides diethyl ether adducts **4-Zr** and **4-Hf**, whereas with methylmagnesium chloride in the presence of tetrahydrofuran, THF adducts **5-Zr** and **5-Hf** are obtained. The use of larger alkylating agents does not afford ethereal adducts. The dibenzyl species **6-Zr** and **6-Hf** are made from benzyl potassium and the bis(trimethylsilylmethyl) species **7-Zr** and **7-Hf** are made from trimethylsilylmethyllithium.

Scheme 1. Synthetic route to zirconium and hafnium *ansa*-Oct-amido complexes **2**–**7**.

2.2. X-ray crystallography of Zr and Hf complexes

Crystals suitable for X-ray crystallography were obtained for complexes **3-Zr**, **3-Hf,** and **5-Zr** by cooling saturated diethyl ether solutions. Crystals of **6-Zr** and **6-Hf** were grown by vapor diffusion of diethyl ether into saturated dichloromethane solutions, while crystals of **7-Zr** were obtained by cooling a saturated pentane solution. Fig. 3 depicts the structural results of the X-ray crystallography.

It is readily apparent that ethereal solvents remain bound to the metal in **3-Zr**, **3-Hf**, and **5-Zr**, resulting in a trigonal bipyramid with oxygen and nitrogen in the apical positions. This trigonal bipyramid structure is unprecedented for fluorenyl-amido complexes; even the remarkably similar $Me_2Si(\eta^5\text{-}2,7\text{-}^tBu_2\text{-}C_{13}H_6)(\eta^1\text{-}N\text{-}^tBu)ZrCl_2$ [29,30] and $Me_2Si(\eta^5\text{-}3,6\text{-}^tBu_2\text{-}C_{13}H_6)(\eta^1\text{-}N\text{-}^tBu)ZrCl_2$ [23,31] adopt the η^5, pseudotetrahedral geometry. Apparently there is an important difference between a 2,3,6,7-*tetra*-substituted fluorenyl ligand (Oct) and a *di*-substituted fluorenyl ligand. **3-Zr** and **3-Hf** are isomorphic, and only **5-Zr** cocrystallizes with solvent, packing one diethyl ether molecule into the cleft of each Oct ligand. In this case, note the selectivity of the metal to bind THF despite the use of diethyl ether as the crystallization solvent.

6-Zr, **6-Hf**, and **7-Zr**, which bear the larger benzyl or trimethylsilylmethyl groups, crystallize as ether-free species with a pseudotetrahedral coordination sphere and η^5 ligation to Oct. **6-Zr** and **6-Hf** are isomorphic and each of these structures contains one benzyl group that is arguably η^2. The M–CH_2Ph bond length is 2.295 Å for **6-Zr** (2.299 Å for **6-Hf**) and the M–(C_{ipso}) distance is 2.793 Å for **6-Zr** (2.871 Å for **6-Hf**). The structure of **7-Zr** is quite similar to that published for the parent fluorenyl-containing compound, $Me_2Si(\eta^5\text{-}C_{13}H_8)(\eta^1\text{-}N\text{-}^tBu)Zr(CH_2SiMe_3)_2$ [18].

Table 1 lists selected bond lengths and angles for **2-Zr** [26], **3-Zr**, **3-Hf**, **5-Zr**, **6-Zr**, **6-Hf**, and **7-Zr**. In the η^1

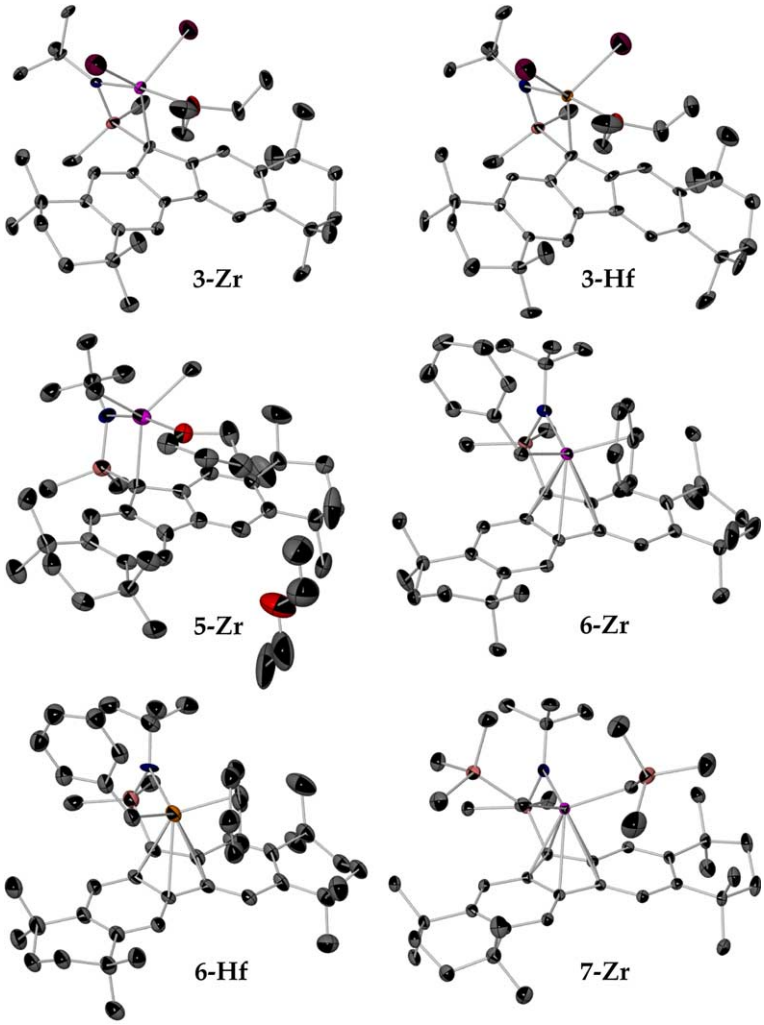

Fig. 3. X-ray structures of **3-Zr**, **3-Hf**, **5-Zr**, **6-Zr**, **6-Hf**, and **7-Zr** with thermal ellipsoids drawn at 50% probability and hydrogen atoms omitted.

[a] *cent* is defined as the centroid of the five-membered ring of the Oct ligand.

trigonal bipyramidal structures, the metal–C(1) bond lengths are consistently shorter (2.281–2.330 Å) than the corresponding bond lengths in the η^5 pseudotetrahedral structures (2.373–2.397 Å). The shortening of the remaining M–C bond upon η^5 to η^1 ring-slip is typical for cyclopentadienyl [32] and indenyl ligands [33]. In *ansa*-metallocenes and cyclopentadienyl-amido complexes, the $C_{5centroid}$–C(1)–Si angle is always less than 180°; examples are *rac*-$Me_2Si(\eta^5\text{-}C_9H_6)_2ZrCl_2$ (163.7°) [34] and $Me_2Si(\eta^5\text{-}C_5Me_4)(\eta^1\text{-}N\text{-}^tBu)TiCl_2$ (152.3°) [35]. For the η^5 complexes in Table 1, this angle is ~156°, a typical value. Strikingly, the $C_{5centroid}$–C(1)–Si angles for the η^1 complexes are considerably larger than 180° and range from 197.9° to 204.9°. Thus, *the silicon atom and the metal are on opposite sides of the Oct ligand.* This results in the most sterically open class of CGCs reported.

2.3. Hapticity analysis of Zr and Hf complexes by X-ray crystallography

While η^5-fluorenyl ligands are the most common [36–40], a number of η^3-fluorenyl examples have also been documented [41–46]. In contrast, η^1-fluorenyl ligands are quite rare. The first definitive examples were found with octahedral mid-transition metal species such as $Mn(\eta^1\text{-}C_{13}H_9)(CO)_3(P(n\text{-}Bu)_3)_2$ [47], $Mn(\eta^1\text{-}C_{13}H_9)(CO)_3(PEt_3)_2$ [48], and $Re(\eta^1\text{-}C_{13}H_9)(CO)_5$ [49,50]. Later, examples were found with early transition metal species such as pseudotetrahedral $(\eta^5\text{-}C_5H_4Me)_2Zr(\eta^1\text{-}C_{13}H_9)Cl$, $(\eta^5\text{-}C_5H_5)_2Zr(\eta^1\text{-}C_{13}H_9)_2$ [51], and pseudotrigonal bipyramidal $Me_2C(\eta^5\text{-}C_5H_4)(\eta^1\text{-}C_{13}H_8)TaMe_3$ [52].

The assignment of hapticity can sometimes be arbitrary [53], but the metrical parameters cataloged in

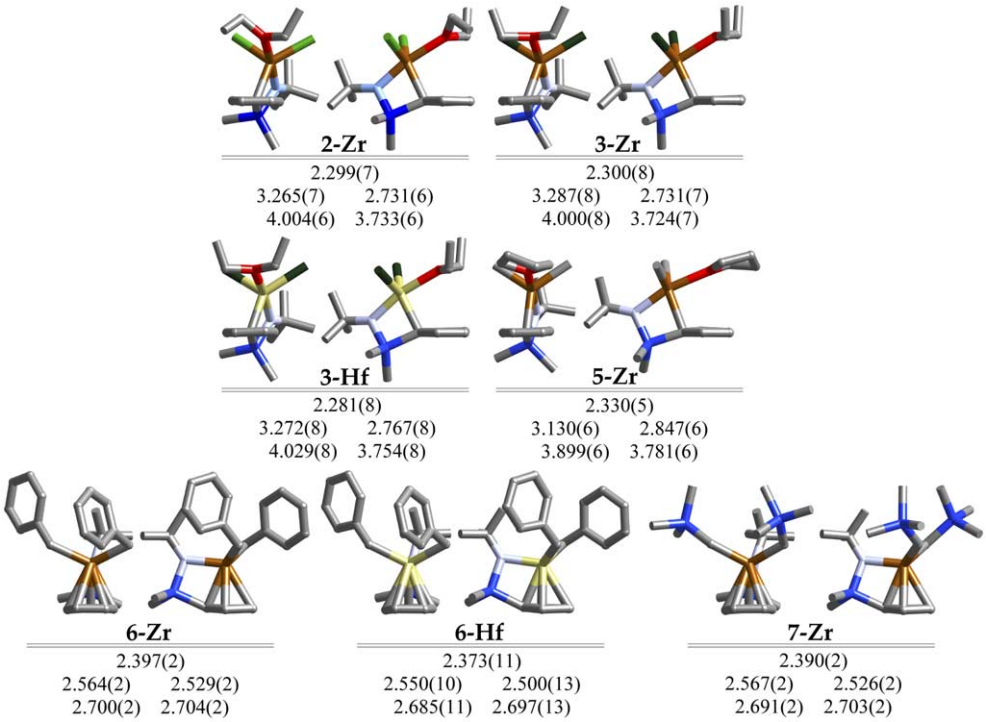

Fig. 4. Structures of **2-Zr**, **3-Zr**, **3-Hf**, **5-Zr**, **6-Zr**, **6-Hf**, and **7-Zr** with the Oct ligand truncated to the five-membered ring. Bond lengths and interatomic distances (Å) correspond to the metal–Oct interaction, moving clockwise from the C(1) carbon.

Fig. 4 largely support the conclusion that **2-Zr**, **3-Zr**, **3-Hf**, and **5-Zr** are η^1, while **6-Zr**, **6-Hf**, and **7-Zr** are η^5. Assignments from the literature place the threshold for zirconium–carbon bonding between 2.65 and 2.81 Å [41,54]. For example, the two "non-bonded" carbons in $(\eta^5\text{-}C_{13}H_9)(\eta^3\text{-}C_{13}H_9)ZrCl_2$ are 2.801 and 2.807 Å from the metal while the remaining eight "bonded" carbons are between 2.395 and 2.645 Å away [42]. In $Re(\eta^1\text{-}C_{13}H_9)(CO)_5$ the bonded carbon is 2.307 Å from rhenium while the four unequivocally non-bonded carbons are between 3.193 and 4.149 Å from the metal [50]. In structures **2-Zr**, **3-Zr**, **3-Hf**, and **5-Zr**, the bonded carbon is between 2.281 and 2.330 Å from the metal. Each structure has one metal–carbon interatomic distance between 2.731 and 2.847 Å, which is at the upper limit of the bonding range. The remaining three distances for each structure are at least 3.130 Å, considerably beyond normal zirconium–carbon or hafnium–carbon bond lengths.

An alternative method for assessing hapticity is by measurement of the carbon–carbon bond lengths of the five-membered ring. In octamethyloctahydrodibenzofluorene, long bonds are found connecting the sp^3 carbon to the aromatic rings (1.515 Å) and short bonds are found as part of the aromatic rings (1.401 Å) [26]. The parameter δ can be defined as the difference between these bond lengths – or average difference for non-symmetrical species – as defined in Fig. 5. Table 2 lists carbon–carbon bond lengths and the calculated parameter δ for a variety of fluorenyl- and Oct-containing compounds. The entries are listed in order of *decreasing* δ, which corresponds to *increasing* hapticity since the carbon–carbon bond lengths are predicted to become more similar as an η^5, aromatic cyclopentadienide core is approached.

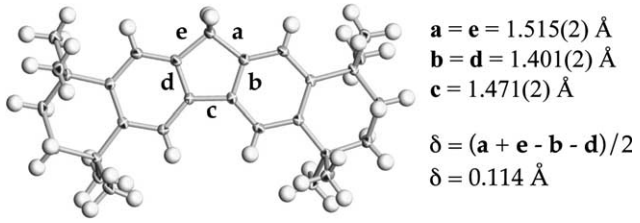

Fig. 5. The bond length difference parameter δ is 0.114 Å for octamethyloctahydrodibenzofluorene and is predicted to decrease with increasing hapticity.

The largest value of δ (0.095 Å) is found for $Re(\eta^1\text{-}C_{13}H_9)(CO)_5$, an electronically ($18e^-$) and coordinatively (octahedral) saturated compound that cannot increase its η^1 hapticity with the fluorenyl ligand. Although $(\eta^5\text{-}C_5H_4Me)_2Zr(\eta^1\text{-}C_{13}H_9)Cl$ and $Me_2C(\eta^5\text{-}C_5H_4)(\eta^1\text{-}C_{13}H_8)TaMe_3$ are not electronically saturated, sterics probably dissuade a greater hapticity, resulting in a high δ value (0.081 for both). The next three species are **3-Hf**, **3-Zr**, and **5-Zr**, which have δ values of 0.069, 0.066, and 0.047 Å, respectively, which still indicate significant carbon–carbon bond length differences. This last value is also found for a complex reported as η^3, $Mo(\eta^3\text{-}C_{13}H_9)(\eta^3\text{-}C_3H_5)_3$. The remaining twelve compounds, including **6-Zr**, **7-Zr**, and **6-Hf**, have δ values of 0.030 Å or less and are predicted to be η^5. Three anomalies exist in this range: $(\eta^5\text{-}C_{13}H_9)(\eta^3\text{-}C_{13}H_9)ZrCl_2$ ($\delta = 0.025$), which is reported as η^3; **2-Zr** ($\delta = 0.021$), which is reported as η^1; and fluorenylLi$(Et_2O)_2$ ($\delta = -0.018$), which is reported as η^2. It

should be noted that δ is an *indirect* measure of hapticity. It only measures carbon–carbon bond length distortions that occur in response to a metal's location and bonding. Thus, δ and hapticity are reasonably correlative, but the exceptions remind us that hapticity is best determined by measuring metal–carbon interatomic distances.

2.4. Hapticity analysis of Zr complexes in solution by NMR

The solution ^{1}H NMR spectra of the diethyl ether complexes (**2-Zr**, **2-Hf**, **3-Zr**, **3-Hf**, **4-Zr**, and **4-Hf**) show sharp resonances for the ethereal protons, a trait usually attributed to unbound ether species. Thus suggests solution species with η^5-Oct ligation. The THF adducts, however, provide somewhat broad resonances for the ethereal protons, indicating that THF coordination and low Oct hapticity are maintained in solution. Careful inspection of the ^{1}H and ^{13}C NMR chemical shifts of compounds **2-Zr** through **7-Zr** indeed reveals unusual chemical shifts for only the THF adduct **5-Zr** (Table 3). The aromatic C–H protons in the 1 and 4 positions of the Oct moiety are the most upfield of this group at 7.82 and 8.15 ppm. The M–C(1) carbon is the most downfield (86.3 ppm) and, of the aromatic carbons, two have comparatively high chemical shifts (133.6 and 137.6 ppm) and four have comparatively low chemical shifts (117.4, 118.5, 139.7 and 141.9 ppm). These unusual chemical shifts for **5-Zr** are mirrored in $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-N-}^t\text{Bu})ZrCl_2 \cdot THF$ and $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-N-}^t\text{Bu})ZrBr_2 \cdot NCMe$ (see Table 3), suggesting that each of these also maintains η^1-Oct ligation in solution.

3. Conclusions

A series of sterically expanded *ansa*-fluorenyl-amido zirconium and hafnium complexes with the general formula $Me_2Si(\eta^n\text{-}C_{29}H_{36})(\eta^1\text{-N-}^t\text{Bu})MX_2 \cdot L_m$ was synthesized and characterized. Incorporation of the octamethyloctahydrodibenzofluorenyl (Oct) ligand effected ethereal binding in the solid-state when the remaining ligands were small (X = Cl, Br, or Me). Ether-free species were observed when larger ligands (X = benzyl or trimethylsilylmethyl) were present. X-ray crystallography established that an unusual trigonal bipyramidal η^1-Oct structure accompanied ethereal binding ($n = 1$, $m = 1$), while the ether-free species adopted the anticipated pseudotetrahedral η^5-Oct structure ($n = 5$, $m = 0$). The hapticity assignments were made largely by analyzing the relevant metal–carbon distances, but a correlation between hapticity and converging carbon–carbon bond lengths of the five-membered ring was also identified.

4. Experimental

4.1. General remarks

All air sensitive procedures were carried out under a purified atmosphere of nitrogen in a glove box equipped with a −35 °C freezer, or by using standard Schlenk line techniques. Solvents were dried and distilled under nitrogen into Straus flasks and stored until needed. Diethyl ether and tetrahydrofuran were distilled from sodium/benzophenone; *n*-heptane and dichloromethane were distilled from calcium hydride; and toluene was distilled from elemental sodium.

The commercially available reagents *n*-butyllithium (Acros, 2.5 M in hexanes or Alfa Aesar, 2.87 M in hexanes), $LiCH_2SiMe_3$ (Aldrich, 1.0 M in pentane), MeLi (Aldrich, 1.6 M in diethyl ether), MeMgCl (Aldrich, 3.0 M in tetrahydrofuran), zirconium tetrachloride (Strem, 99.5+%), hafnium tetrachloride (Strem, 99.9+%), zirconium tetrabromide (Strem, 98%), and lithium bromide (Aldrich, 99.995+%) were used as received, unless otherwise noted. Both KCH_2Ph [58] and the ligand $Me_3CNHSiMe_2(C_{29}H_{37})$ [26] were prepared according to literature procedures.

All NMR chemical shifts are given in ppm and were recorded on a Mercury-300BB spectrometer (^{1}H, 299.91 MHz; ^{13}C {^{1}H}, 75.41 MHz) using the residual

protonated solvent peak as an internal standard ($CDCl_3$: ^1H, 7.27 ppm; ^{13}C, 77.0 ppm. C_6D_6: ^1H, 7.15 ppm; ^{13}C, 128.0 ppm).

4.2. Syntheses

4.2.1. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)ZrCl_2 \cdot OEt_2$ (**2-Zr**)

In the glove box $Me_3CNHSiMe_2(C_{29}H_{37})$ (3.00 g, 6.26 mmol) was charged into a 100 ml pear-shaped round bottom and then attached to a 3 cm swivel frit. The frit was then evacuated and diethyl ether (50 ml) was vacuum transferred in. Next, *n*-butyllithium (5.51 ml, 13.77 mmol, 2.5 M in hexanes) was syringed in. The orange slurry was stirred for 20 h and then the diethyl ether was removed under vacuum. $ZrCl_4$ (1.46 g, 6.26 mmol) was added in the glove box and diethyl ether (40 ml) was vacuum transferred in on the line. After slowly warming to room temperature and stirring the light brown slurry for 48 h, the LiCl was filtered off and the cake was extracted until colorless. The slurry was concentrated to about 10 ml and the precipitated solid was collected by filtration. The cake was washed once to remove a brown oil and then evacuated until dry. This yielded 1.42 g (31.8%) of product as a neon yellow solid. Large rod-shaped crystals can be grown by cooling a saturated diethyl ether solution to −35 °C. ^1H NMR (C_6D_6): δ 0.86 (s, 6H, $(CH_3)_2Si$), 1.10 (t, $^3J_{HH}$ = 7.0 Hz, 6H, ether–CH_3), 1.26 (s, 9H, –$C(CH_3)_3$), 1.28, 1.35, 1.38, 1.39 (s, 24H, Oct–CH_3), 1.62 (m, 8H, Oct–CH_2), 3.25 (q, $^3J_{HH}$ = 7.0 Hz, 4H, ether–CH_2), 8.01, 8.24 (s, 4H, Oct–CH_1). ^{13}C {^1H} NMR (C_6D_6): δ 5.9, 15.5, 32.3, 32.6, 32.8, 32.9, 33.4, 34.95, 35.02, 35.3, 35.4, 56.4, 66.0, 71.9, 121.5, 123.2, 125.3, 134.8, 145.6, 148.9. Elemental analysis: *Anal.* Calc.: C, 62.44; H, 8.13; N, 1.87; Cl, 9.45. Found: C, 61.40; H, 8.24; N, 1.81; Cl, 9.45%.

4.2.2. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)HfCl_2 \cdot OEt_2$ (**2-Hf**)

2-Hf was prepared in a manner analogous to **2-Zr** except that $HfCl_4$ (3.34 g, 10.43 mmol) was utilized yielding 3.30 g (39.5%) of **2-Hf** as a yellow solid. ^1H NMR (C_6D_6): δ 0.84 (s, 6H, $(CH_3)_2Si$), 0.99 (t, $^3J_{HH}$ = 6.0 Hz, 6H, ether–CH_3), 1.31, 1.34, 1.39, 1.42 (s, 24H, Oct–CH_3), 1.37 (s, 9H, –$C(CH_3)_3$), 1.65 (app. s, 8H, Oct–CH_2), 3.19 (q, $^3J_{HH}$ = 6.0 Hz, 4H, ether–CH_2), 7.99, 8.22 (s, 4H, Oct–CH_1).

4.2.3. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)ZrBr_2 \cdot OEt_2$ (**3-Zr**)

3-Zr was prepared in a manner analogous to **2-Zr** except that $ZrBr_4$ (2.57 g, 6.26 mmol) was utilized yielding 1.30 g (24.8%) of **3-Zr** as a bright yellow powder. Large rod-shaped crystals can be grown by cooling a saturated diethyl ether solution to −35 °C. ^1H NMR (C_6D_6): δ 0.86 (s, 6H, $(CH_3)_2Si$), 1.11 (t, $^3J_{HH}$ = 7.0 Hz, 6H, ether–CH_3), 1.27, 1.34, 1.39, 1.41 (s, 24H, Oct–CH_3), 1.31 (s, 9H, –$C(CH_3)_3$), 1.61 (m, 8H, Oct–CH_2), 3.26 (q, $^3J_{HH}$ = 7.0 Hz, 4H, ether–CH_2), 8.01, 8.27 (s, 4H, Oct–CH_1). ^{13}C {^1H} NMR (C_6D_6): δ 5.8, 15.5, 32.1, 32.7, 33.0, 34.98, 35.0, 35.3, 35.4, 56.9, 65.9, 72.0, 122.0, 124.0, 126.0, 134.6, 146.0, 148.8.

4.2.4. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)HfBr_2 \cdot OEt_2$ (**3-Hf**)

In the glove box, **2-Hf** (0.13 g, 0.16 mmol) was charged into a 100 ml pear-shaped round bottom flask followed by the addition of anhydrous LiBr (4.90 g, 56.42 mmol). Next, the flask was attached to a 3 cm swivel frit and brought out to the line where diethyl ether (60 ml) was vacuum transferred in. The slurry was then stirred for 2 days after which time the solvent was removed under vacuum and pentane (30 ml) was vacuum transferred in. All insoluble material was removed via filtration and the cake was extracted until colorless. Concentration of the filtrate to 5 ml followed by filtration yielded 0.07 g (69.0%) of **3-Hf** as an orange-yellow powder. Large rod-shaped crystals can be grown by cooling a saturated diethyl ether solution to −35 °C. X-ray crystallography suggested that complete salt metathesis of the Hf–Cl bonds had been achieved. This was further supported by ^1H NMR via a characteristic shift of the aromatic Oct–CH_1 protons from 8.22 ppm (**2-Hf**) to 8.26 ppm (**3-Hf**). A similar shift is observed between **2-Zr** and **3-Zr**. ^1H NMR (C_6D_6): δ 0.89 (s, 6H, $(CH_3)_2Si$), 1.03 (t, $^3J_{HH}$ = 6.0 Hz, 6H, ether–CH_3), 1.28, 1.31, 1.35, 1.36 (s, 24H, Oct–CH_3), 1.32 (s, 9H, –$C(CH_3)_3$), 1.63 (m, 8H, Oct–CH_2), 3.19 (q, $^3J_{HH}$ = 6.0 Hz, 4H, ether–CH_2), 8.00, 8.26 (s, 4H, Oct–CH_1).

4.2.5. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)ZrMe_2 \cdot OEt_2$ (**4-Zr**)

In the glove box **2-Zr** (0.50 g, 0.67 mmol) was charged into a 100 ml pear-shaped round bottom flask, which was then attached to a 3 cm swivel frit. The frit was evacuated on the vacuum line and diethyl ether (50 ml) was then vacuum transferred in. Next, a LiBr-free diethyl ether solution of CH_3Li (0.83 ml, 1.33 mmol, 1.6 M in diethyl ether) was slowly syringed into the yellow solution while vigorously stirring. The solution began to bleach and acquire a very pale fluorescent yellow color. (Note: Extended exposure to excess CH_3Li leads to a dark brown/black solution and complete decomposition of the product in a matter of hours.) After 2 h the precipitated LiCl was removed via filtration and extracted until colorless. Concentration of the filtrate to 10 ml and collection of the precipitated product on the frit led to 0.42 g (89.0%) of product as a pale yellow solid. ^1H NMR (C_6D_6): δ −0.59 (s, 6H, $Zr(CH_3)_2$), 0.89 (s, 6H, $(CH_3)_2Si$), 1.10 (t, $^3J_{HH}$ = 7.0 Hz, 6H, ether–CH_3), 1.32, 1.37 (s, 24H,

Oct–CH_3), 1.33 (s, 9H, –C(CH_3)$_3$), 1.64 (m, 8H, Oct–CH_2), 3.24 (q, $^3J_{HH}$ = 7.0 Hz, 4H, ether–CH_2), 7.93, 8.23 (s, 4H, Oct–CH_1). ^{13}C {^{1}H} NMR (C_6D_6): δ 6.6, 15.5, 32.6, 32.8, 32.9, 33.2, 34.5, 34.8, 35.2, 35.55, 35.57, 39.4, 55.0, 65.9, 70.8, 120.6, 122.7, 123.7, 135.0, 142.6, 146.7.

4.2.6. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)HfMe_2 \cdot OEt_2$ (**4-Hf**)

4-Hf was prepared in a manner analogous to **4-Zr** except that **2-Hf** (0.40 g, 0.49 mmol) was utilized yielding 0.23 g (60.5%) of **4-Hf** as a pale yellow powder. ^{1}H NMR (C_6D_6): δ −0.16 (s, 6H, Hf(CH_3)$_2$), 0.84 (s, 6H, (CH_3)$_2$Si), 1.02 (t, $^3J_{HH}$ = 6.0 Hz, 6H, ether–CH_3), 1.34, 1.35, 1.36, 1.38 (s, 24H, Oct–CH_3), 1.37 (s, 9H, –C(CH_3)$_3$), 1.66 (app. s, 8H, Oct–CH_2), 3.17 (q, $^3J_{HH}$ = 6.0 Hz, 4H, ether–CH_2), 7.84, 8.21 (s, 4H, Oct–CH_1).

4.2.7. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)ZrMe_2 \cdot THF$ (**5-Zr**)

In the glove box, **2-Zr** (5.00 g, 6.67 mmol) was charged into a 100 ml pear-shaped round bottom flask. The flask was then attached to a 3 cm swivel frit and diethyl ether (80 ml) was vacuum transferred in on the line. Next, while the flask was still cold, MeMgCl (4.44 ml, 13.33 mmol, 3.0 M in THF) was slowly added via syringe. A large quantity of white precipitate immediately formed. The contents of the flask were stirred for 2 h before the precipitated salt was removed by filtration. The cake was extracted until the eluent was colorless. The solvent was then removed under vacuum and the frit was brought into the box where the off-white product was recrystallized by cooling a saturated diethyl ether solution to −35 °C, yielding 2.98 g (63.0%) of product as nearly white crystals which were suitable for X-ray diffraction. ^{1}H NMR (C_6D_6): δ 0.02 (s, 6H, Zr(CH_3)$_2$), 0.77 (s, 6H, (CH_3)$_2$Si), 1.14 (br, 4H, THF–CH_2), 1.34, 1.37, 1.40, 1.43 (s, 24H, Oct–CH_3), 1.52 (s, 9H, –C(CH_3)$_3$), 1.69 (m, 8H, Oct–CH_2), 2.81 (br, 4H, THF–CH_2), 7.82, 8.15 (s, 4H, Oct–CH_1). ^{13}C {^{1}H} NMR (C_6D_6): δ 3.9, 15.5, 32.6, 32.7, 32.9, 33.3, 34.5, 34.8, 35.0, 35.9, 36.0, 39.7, 57.2, 65.8, 86.3, 117.4, 118.5, 133.6, 137.6, 139.7, 141.9.

4.2.8. Synthesis of $Me_2Si(\eta^1\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)HfMe_2 \cdot THF$ (**5-Hf**)

5-Hf was prepared in a manner analogous to **5-Zr** except that **2-Hf** (0.43 g, 0.54 mmol) was utilized yielding 0.43 g of **5-Hf** as an off-white solid (>95% yield, some persistent THF). ^{1}H NMR (C_6D_6): δ 0.29 (s, 6H, Hf(CH_3)$_2$), 0.70 (s, 6H, (CH_3)$_2$Si), 1.01 (br, 4H, THF–CH_2), 1.33, 1.40, 1.45, 1.48 (s, 24H, Oct–CH_3), 1.67 (s, 9H, –C(CH_3)$_3$), 1.73 (m, 8H, Oct–CH_2), 2.41 (br, 4H, THF–CH_2), 7.67, 8.13 (s, 4H, Oct–CH_1). ^{13}C {^{1}H} NMR (C_6D_6): δ 3.8, 15.9, 25.8, 33.0, 33.03, 33.3, 33.7, 34.9, 35.4, 35.5, 36.2, 36.4, 51.4, 66.2, 71.6, 117.5, 118.8, 126.6, 133.8, 137.9, 142.0.

4.2.9. Synthesis of $Me_2Si(\eta^5\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)Zr(CH_2Ph)_2$ (**6-Zr**)

In the glove box, **2-Zr** (4.00 g, 5.33 mmol) was charged into a 100 ml pear-shaped round bottom flask followed by the addition of KCH_2Ph (1.39 g, 10.66 mmol). The flask was then attached to a 3 cm swivel frit and brought out onto the line where diethyl ether (60 ml) was vacuum transferred in. The contents were allowed to slowly warm to room temperature and then stir for 2 h before the salt was removed by filtration and the cake extracted until colorless. Concentration of the slurry to 20 ml, followed by filtration, led to the desired product as a yellow solid (3.21 g, 76.5%). Large block-like crystals were grown by the vapor diffusion of diethyl ether into dichloromethane saturated with **6-Zr**. ^{1}H NMR (C_6D_6): δ −0.48, 0.86 (d, $^2J_{HH}$ = 10.5 Hz, 4H, Zr–CH_2), 0.99 (s, 9H, –C(CH_3)$_3$), 1.01 (s, 6H, (CH_3)$_2$Si), 1.34, 1.38, 1.39, 1.42 (s, 24H, Oct–CH_3), 1.62 (m, 8H, Oct–CH_2), 6.69 (m, 4H, Zr–$CH_2C_6H_5$), 6.89 (m, 2H, Zr–$CH_2C_6H_5$), 7.16 (m, 4H, Zr–$CH_2C_6H_5$), 8.15, 8.16 (s, 4H, Oct–CH_1). ^{13}C {^{1}H} NMR ($CDCl_3$): δ 6.2, 32.4, 32.6, 32.8, 33.0, 33.5, 34.8, 35.06, 35.08, 35.09, 56.9, 61.3, 73.1, 119.8, 121.2, 122.2, 123.1, 127.5, 128.8, 133.4, 143.5, 145.5, 146.8. ^{13}C {^{1}H} NMR (C_6D_6): δ 6.4, 32.57, 32.6, 33.06, 33.1, 33.6, 34.9, 35.2, 35.26, 35.3, 57.2, 61.9, 73.9, 120.1, 122.0, 122.7, 123.6, 128.3, 129.3, 134.1, 143.7, 145.7, 147.0

4.2.10. Synthesis of $Me_2Si(\eta^5\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)Hf(CH_2Ph)_2$ (**6-Hf**)

6-Hf was prepared in a manner analogous to **6-Zr** except that **2-Hf** (1.50 g, 1.87 mmol) was utilized yielding 0.42 g (25.8%) of **6-Hf** as a yellow-orange solid. Large block-like crystals were grown by the vapor diffusion of diethyl ether into dichlormethane saturated with **6-Hf**. ^{1}H NMR (C_6D_6): δ −0.30, 0.66 (d, $^2J_{HH}$ = 7.2 Hz, 4H, Hf–CH_2), 0.95 (s, 6H, (CH_3)$_2$Si), 1.01 (s, 9H, –C(CH_3)$_3$), 1.33, 1.34, 1.35, 1.36 (s, 24H, Oct–CH_3), 1.57 (m, 8H, Oct–CH_2), 6.65 (m, 4H, Hf–$CH_2C_6H_5$), 6.82 (m, 2H, Hf–$CH_2C_6H_5$), 7.12 (m, 4H, Hf–$CH_2C_6H_5$), 8.04, 8.26 (s, 4H, Oct–CH_1). ^{13}C {^{1}H} NMR ($CDCl_3$): δ 6.2, 32.5, 32.6, 33.0, 33.6, 33.7, 34.9, 35.0, 35.08, 35.1, 55.9, 70.4, 71.4, 120.0, 121.1, 122.4, 122.7, 127.5, 128.0, 134.1, 143.5, 146.5, 147.4.

4.2.11. Synthesis of $Me_2Si(\eta^5\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)Zr(CH_2SiMe_3)_2$ (**7-Zr**)

In the glove box, **2-Zr** (0.50 g, 0.67 mmol) was charged into a 100 ml pear-shaped round bottom flask. The flask was then attached to a 3 cm swivel frit and brought out to the vacuum line where pentane (50 ml) was vacuum transferred in. Next, $LiCH_2SiMe_3$ (1.40 ml, 1.40 mmol, 1.0 M in pentane) was slowly

syringed into the still cold solution in the flask. The contents were allowed to stir for 1 h before the LiCl was removed by filtration and the salt was extracted until colorless. The solvent was removed under vacuum yielding a yellow foam. This was brought into the box where 5 ml of pentane was added causing the precipitation of a neon yellow powder. The solvent was decanted and the powder collected and dried under vacuum yielding 0.35 g (67.0%) of **7-Zr**. Pentane (5 ml) was then saturated with **7-Zr** and stored in a −35 °C freezer for one month, resulting in the formation of large block-like crystals. ^{1}H NMR (C_6D_6): δ −1.32, −0.77 (d, $^2J_{HH}$ = 12.3 Hz, 4H, Zr–CH_2), 0.17 (s, 18H, –Si(CH_3)$_3$), 0.89 (s, 6H, (CH_3)$_2$Si), 1.31 (s, 9H, –C(CH_3)$_3$), 1.39, 1.41, 1.41, 1.49 (s, 24H, Oct–CH_3), 1.68 (m, 8H, Oct–CH_2), 7.92, 8.17 (s, 4H, Oct–CH_1). ^{13}C {^{1}H} NMR ($CDCl_3$): δ 3.3, 6.3, 32.2, 32.9, 33.1, 33.3, 34.3, 34.9, 35.08, 35.1, 35.3, 55.0, 55.9, 71.1, 120.1, 122.5, 123.2, 133.9, 142.7, 146.1.

4.2.12. Synthesis of $Me_2Si(\eta^5\text{-}C_{29}H_{36})(\eta^1\text{-}N\text{-}^tBu)Hf(CH_2SiMe_3)_2$ (7-Hf)

7-Hf was prepared in a manner analogous to **7-Zr** except that **2-Hf** (0.40 g, 0.49 mmol) was utilized yielding 0.24 g (54.5%) of **7-Hf** as a yellow powder. ^{1}H NMR ($CDCl_3$): δ −2.09, −1.38 (d, $^2J_{HH}$ = 12.0 Hz, 4H, Hf–CH_2), −0.11 (s, 18H, –Si(CH_3)$_3$), 0.89 (s, 6H, (CH_3)$_2$Si), 1.33, 1.35, 1.46, 1.49 (s, 24H, Oct–CH_3), 1.37 (s, 9H, –C(CH_3)$_3$), 1.79 (app. s, 8H, Oct–CH_2), 7.72, 8.02 (s, 4H, Oct–CH_1).

4.3. Crystallographic studies

Crystals were mounted at room temperature in mineral oil, and affixed to a glass fiber. X-ray crystallographic data were obtained using a Bruker SMART 1000 three-circle diffractometer operating at 50 kV and 40 mA, Mo Kα (λ = 0.71073 Å) with a graphite monochromator and a CCD-PXL-KAF2 detector or a Bruker GADPS instrument operating at 40 kV and 40 mA, Cu Kα (λ = 1.54578 Å) with a graphite monochromator and a CCD-PXL-KAF2 detector. Details of the crystallographic data collection and refinement are summarized in Table 4. The molecular structures were solved by direct methods and were refined employing the SHELXS-97 [59] and SHELXL-97 programs [60].

5. Supplementary material

Crystallographic data for **3-Zr** (CCDC 260056), **3-Hf** (CCDC 260057), **5-Zr** (CCDC 260058), **6-Zr** (CCDC

260055), **6-Hf** (CCDC 260059), and **7-Zr** (CCDC 260060) have been deposited with the Cambridge Crystallographic Data Centre. These data can be obtained free of charge via www.ccdc.cam.ac.uk/data_request/cif, or by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033.

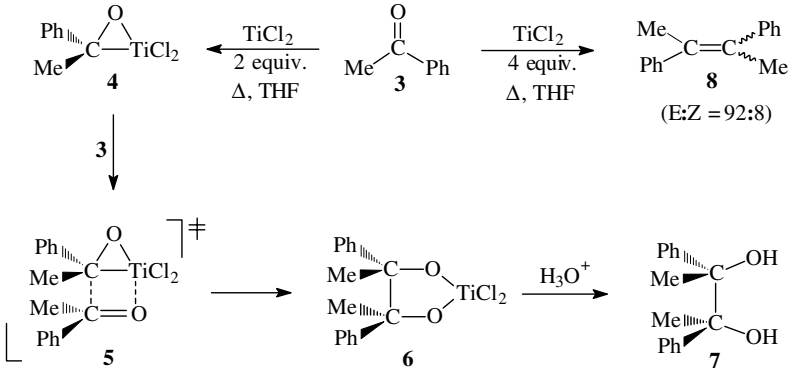
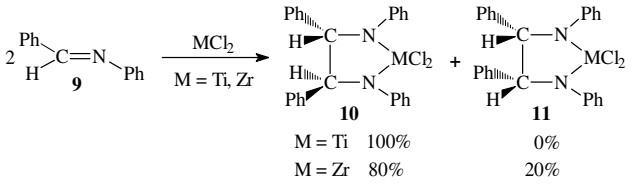
1. Introduction

Over the last decade we have been interested in applying the diverse chemical reactions of subvalent transition metal salts to the methodology of organic synthesis [1–4]. Our attention was especially drawn to the salts of Group 4 metals by the reports of the novel reductive dimerization of carbonyl derivatives to olefins by subvalent titanium reductants of unspecified oxidation state and composition (Eq. (1)).

(1)



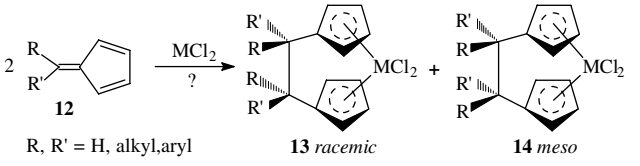
Such reports have issued independently from three different research groups where each utilized an empirical combination of a Ti(III) or Ti(IV) salt with a main-group metal or metal hydride [5–7]. This transformation, which has come to be termed the McMurry coupling after one of its discoverers, has found many valuable applications in organic synthesis [8–10]. But the use of such empirical reductants either in mechanistic studies of the McMurry coupling itself or in the synthesis of transition metal organometallics has up to now proved to be impractical. Hence, the recent discovery of a convenient, low-temperature route to the Group 4 dichlorides, MCl_2, as bis-THF solvates in THF, or as slurries with LiCl in toluene, has proved crucial for a systematic study of reductive dimerizations [2–4]. In a process termed alkylative reduction the MCl_4 is dialkylated with *n*-butyllithium at −78 °C to form intermediate **1**; warming **1** to 25 °C and above causes the reductive elimination of butyl groups (as butane and butene) and the high-yielding production of **2** (Eq. (2)).



(2)

By the use of such reagents as **2** of well-defined valence and stoichiometry, considerable control could be exerted on both the extent and stereochemistry of the reductive coupling of ketones [2]. Acetophenone (**3**), for example, reacts with 2 equiv. of $TiCl_2$ in refluxing THF to give upon hydrolysis 83% of the *racemic*-2,3-diphenyl-2,3-butanediol (**7**) only, while with 4 equiv. of $TiCl_2$ the ketone gives 88% of olefin **8** as a 92:8 mixture of *E* and *Z* isomers. The exclusive formation of *racemic* **7** is consistent with the likely intermediacy of the three-membered ring **4** and the sterically controlled transition state **5** for the insertion of the second ketonic unit to form **6** (Scheme 1) [3,4].

Accordingly, the stereoselective reductive coupling of carbonyl derivatives by $TiCl_2$ depicted in Scheme 1 and the analogous reductive coupling subsequently observed with imines, such as *N*-benzylideneaniline (**9**), as mediated by $TiCl_2$ or $ZrCl_2$ (Scheme 2), have provided excellent model systems with which to assess steric effects in forming C–C bonds in such *ansa*-bridged systems, such as **6** and **10** and **11** (where the bridging O–CH_2–CH_2–O and NPh–CHPh–CHPh–NPh linkages can be envisaged as providing a "handle" (L. *ansa*) on the metal center). In all three systems these intermediate metallocycles can readily be hydrolyzed and the ratio of the resulting *racemic*:*meso* glycols (**7**) or diamines [$(PhCH–NHPh)_2$ from **10** and **11**] can be determined by ^1H NMR spectroscopy. Alternatively, the ratio of the metallocycles **10** and **11** can be estimated directly from their ^1H NMR spectra.



Scheme 1.

Scheme 2.

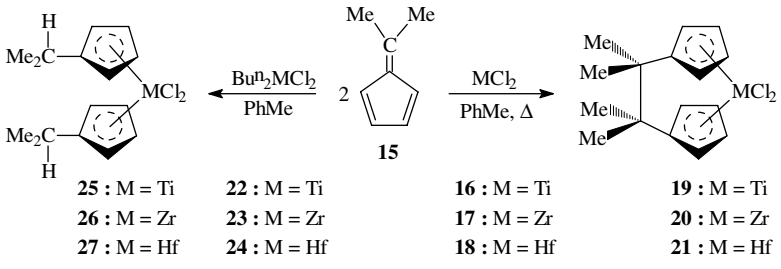
Because of the foregoing success with the efficient and stereoselective reductive dimerizations of both ketones and imines with Group 4 metal dichlorides, we were inspired to attempt a similar dimerization of 6-substituted fulvenes (**12**) with the hope of producing thereby novel *ansa*-metallocenes having some stereochemical preference for the substituents on the *ansa*-bridge (ratio of **13**:**14**) (Eq. (3)) [11,12]. Were such a dimerization to succeed, it would represent a radical departure from established routes to bridged or *ansa*-metallocenes and offer a new approach to stereochemical isomers of such systems as **13** and **14** [12].

(3)

2. Results

2.1. Initial attempts with 6,6-dimethylfulvene (*15*) and Group 4 metal dihalides

The reactions of 6,6-dimethylfulvene (**15**) with the Group 4 metal dichlorides, $TiCl_2$ (**16**), $ZrCl_2$ (**17**) or $HfCl_2$ (**18**), were initially examined in THF, a solvent in which such salts are readily prepared at room temperature according to Eq. (2) (e.g., $TiCl_2 \cdot 2THF$) [11]. Although *ansa*-metallocene formation (**19**–**21**) was observed in refluxing THF, such reductive dimerization was slow (Scheme 3). Accordingly, individual slurries in toluene of **16**, **17** and **18** admixed with LiCl by-product were prepared according to Eq. (2) and allowed to react with 2 equiv. of fulvene **15** at reflux. Although the fulvene was largely consumed and the *ansa*-metallocenes **19**–**21** formed in good to high yield, moderate to fair yields of unbridged substituted metallocenes (**25**–**27**) were also obtained. The source of the unbridged metallocenes **25**–**27** as side-products was traced to the presence of undecomposed Bu_2MCl_2 (**22**–**24**) in the MCl_2 formed in toluene at 25 °C . Clearly Bu_2MCl_2 performed a bis-hydrometallation by transfer of two moles of fulvene **15** [13].



2.2. Preparation of tetramethylethylene-bis(cyclopentadienyl)metal dichlorides *19*, *20* and *21*

In light of this insight complete conversion of any Bu_2MCl_2 remaining in the toluene suspension to MCl_2 could be assured by heating the reagent at reflux for several hours. Then the reaction of such purified MCl_2 gave yields of over 90% for *ansa*-metallocenes **19**–**21**, as well as pure product by Soxhlet extraction or flash column chromatography in 80–85% yield.

2.3. Preparation of bis(isopropylcyclopentadienyl)metal dichlorides *25*, *26* and *27*

The discovery of the interesting bis-hydrozirconation by Bu_2MCl_2 leading to unbridged metallocenes **25**–**27** prompted us to attempt to maximize this course of reaction by generating the individual $Bu^n{}_2MCl_2$ at −78 °C in toluene (Eq. (1)) and immediately thereupon adding the 2 equiv. of 6,6-dimethylfulvene. The resulting reaction was warmed to 25 °C and then heated at 65 °C for several hours. This procedure was most effective in producing 75–85% yields of bis(isopropylcyclopentadienyl)-zirconium dichloride (**26**) and bis(isopropylcyclopentadienyl)hafnium dichloride (**27**), which products were shown to be free of the corresponding *ansa*-derivatives (**20** and **21**, respectively) by NMR criteria [13].

However, in the reaction of $TiCl_4$ with *n*-butyllithium in toluene at −78 °C, minutes after admixing the reagents the solution turned black, which signaled formation of $TiCl_2$. Even though the fulvene **15** was then

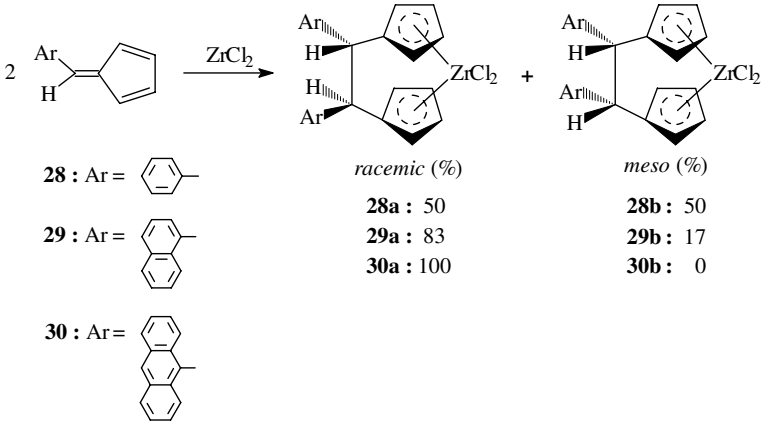
Scheme 3.

added at −78 °C, subsequent warming of the mixture to 25 °C and then to 65 °C led to an inseparable mixture of bis(isopropylcyclopentadienyl)titanium dichloride (**25**) and tetramethylethylene-bis(cyclopentadienyl)titanium dichloride (**19**), formed in approximately equal amounts.

2.4. ansa-Zirconocenes from 6-substituted fulvenes and zirconium dichloride

In order to investigate steric effects on the stereochemistry of *ansa*-bridge formation a trio of 6-arylfulvenes (**28**–**30**), where Ar = phenyl, 1-naphthyl or 9-anthryl, was subjected to reductive coupling by pure $ZrCl_2$ (free of $Bu^n{}_2ZrCl_2$, cf. supra). In each reaction *ansa*-bridge formation occurred in satisfactory yield but with different ratios of *racemic*- and *meso*-isomers (Scheme 4). A random ratio of *racemic*:*meso*-isomers was obtained with Ar equals phenyl (**28a**:**28b** = 50:50), a great preference with Ar equals 1-naphthyl (**29a**:**29b** = 83:17) and an exclusive formation of *racemic*-isomer (**30a**) with Ar = 9-anthryl.

In order to learn whether the covalent radii of Ti (132 pm) and Zr (145 pm) would have any effect on the *racemic–meso*-isomer ratio of *ansa*-bridged product, the reductive dimerization of 6-phenylfulvene (**28**) was also performed with pure $TiCl_2$. In this case, *ansa*-derivative formation also occurred efficiently in 75% yield but again the ratio of *racemic*- and *meso*-isomers obtained was 50:50 (analogous to **28a** and **28b**, with Zr replaced by Ti).



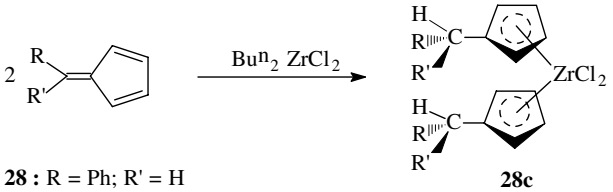
2.5. Structure assignments of the resulting ansa-metallocenes and the unbridged substituted metallocenes

The ultimate structure determination usually is achieved by an XRD analysis of a single crystal of a substance. Although not yet achieved with any of the present metallocenes, partly refined electron-diffraction data however were obtained on the major isomer resulting from the coupling of two units of 6-(1-naphthyl)fulvene by $ZrCl_2$. By plotting such data this 1,2-di(1-naphthyl)ethylene-bis(cyclopentadienyl)zirconium dichloride has been shown unambiguously to be the *racemic*-isomer (**29a**) and that furthermore two chlorine atoms are also bonded to the zirconium center. This structural evidence confirms the assignment made in Section 4.7.4. of the ratio of *racemic*-(**29a**) to *meso*-(**29b**) isomers formed by integration of the methine H singlets at 6.28 and 6.20 ppm in the ^1H NMR spectrum of the isomeric mixture.

To substantiate the presence of the MCl_2 group in these metallocenes, two representative metallocenes, tetramethylethylene-bis(cyclopentadienyl)titanium dichloride (**19**) and tetramethylethylene-bis(cyclopentadienyl)zirconium dichloride (**20**), were subjected to mass spectrometry by the electrospray technique with NaI. Both **19** and **20** yielded mass spectra having prominent peaks for parent ions containing $^{35}Cl_2$, $^{35}Cl^{37}Cl$ and $^{37}Cl_2$ mass contributions, respectively, in the expected intensity ratios. Therefore, based on the XRD of **29a** and the MS data for **19** and **20**, we can be confident that all these metallocenes resulting from the interaction of 2 equiv. of a fulvene with 1 equiv. of either MCl_2 or $Bu^n{}_2MCl_2$ contain the atomic grouping of MCl_2 (details in Sections 4.3, 4.6.1 and 4.7.1).

Further structural specification for the individual metallocenes is completely corroborated by NMR spectroscopic data (cf. Section 4.3): (1) the individual ^1H NMR spectrum has the proper integral ratio of protons, with each proton having the expected chemical shift and proton–proton coupling; and (2) the individual ^{13}C NMR spectrum of the pure metallocene or isomeric mixture displays exactly the proper number of singlets with the expected chemical shifts; moreover, the ^{13}C NMR spectrum in a DEPT experiment shows the expected number of quaternary C and methine C (C–H) centers.

On the basis of the foregoing array of instrumental analyses we judge that the structures assigned to these novel metallocenes are dependably correct.



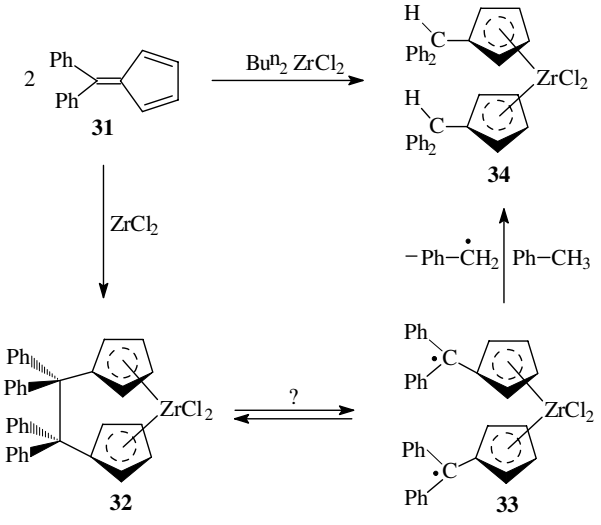
Scheme 4.

2.6. Attempted synthesis of tetraphenylethylene-bis(cyclopentadienyl)zirconium dichloride (32) and the generalized hydrozirconation of fulvenes

Since 6,6-dimethylfulvene (**15**) undergoes efficient reductive dimerization to *ansa*-derivatives **19**, **20** and **21** with the respective metal dichloride, we were curious to determine whether 6,6-diphenylfulvene (**31**) would react similarly (Scheme 5). To an organic chemist, *ansa*-product **32** would have a structure closely similar to the unknown hexaphenylethane, $Ph_3C–CPh_3$, which if fleetingly formed would be expected rapidly to dissociate into stable trityl radicals [14]. When reductive coupling of **31** with $ZrCl_2$ was attempted, no *ansa*-derivative was isolable.

Instead, substituted zirconocene **34** was obtained in 25% yield. Because a number of 6-substituted fulvenes, such as **28**, **29**, **30** and **31**, undergo satisfactory hydrozirconation with $Bu^n{}_2ZrCl$ (Eq. (4)), an authentic sample of **34**, prepared in an unambiguous manner, was available for spectral comparison and positive identification of product **34** resulting from the attempted synthesis of **32**.

28 : R = Ph; R' = H — **28c**



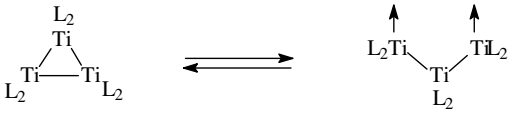
29 : R = 1-Naphthyl; R' = H — **29c**

30 : R = 9-Anthryl; R' = H — **30c**

31 : R = Ph; R' = Ph — **31c = 34**

(4)

Accordingly, it is reasonable to conclude that the F-strain [15] imposed on the *ansa*-C–C bond of **32** by the near eclipsing of neighboring phenyl groups causes dissociation of **32** into stabilized biradical **33**. Eventual H-atom abstraction by **33** from toluene would result in product **34**.



Scheme 5.

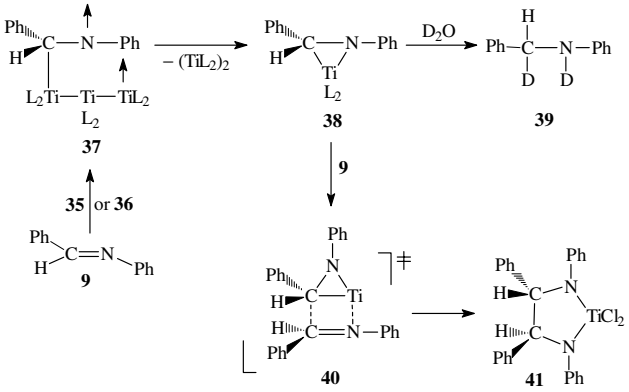
3. Discussion

3.1. Mechanism of the reductive dimerization of the model system, benzylideneaniline (9), with Group 4 metal dichlorides

In considering the reactivity of $TiCl_2$ (**16**), $ZrCl_2$ (**17**) or $HfCl_2$ (**18**) toward a carbonyl (Scheme 1), an imine (Scheme 2) or a fulvene substrate (Eq. (3)), it is important to realize that the monomeric MCl_2 unit delivered must first be detached from a highly associated aggregate $[MCl_2]_x$. For unsolvated MCl_2 generated in toluene such an aggregate could resemble the layer lattice of $TiCl_2$, for example, where infinite layers of Ti atoms are sandwiched between two layers of Cl atoms. But the MCl_2 formed in Eq. (2) clearly can exist in much smaller, oligomeric aggregates. In THF solution the complex $TiCl_2 \cdot 2THF$ (**35**) has been shown to form [2]. Although the degree of association of such a complex is not known, its ready solution in toluene would not be consistent with a polymeric aggregate. Furthermore, such a solution of $TiCl_2$ is diamagnetic and does not show an EPR signal even at low temperatures.

Fortunately, information on the state of aggregation of titanium(II) salts has been obtained from a study of the properties of titanium(II) isopropoxide (**36b**), which can be prepared analogous to $TiCl_2$ (Eq. (2)), by treating $Ti(OPr^i)_4$ with 2 equiv. of *n*-butyllithium. Even when prepared in THF, complex **36b** can be completely freed of THF in vacuo and redissolved in toluene. Such solutions of **36b** exhibit a strong EPR signal indicative of a biradical and hence the presence of two unpaired electrons. The strength of the signal coupling is best in accord with the unpaired electrons being on titanium centers located 1,3 to each other (**36b**), rather than on vicinal or the same Ti center(s) (Eq. (5)) [16,17]. The bulky nature of the isopropoxy ligands may strain the three-membered ring (**36a**) and favor the biradical **36b**. With much smaller chloro ligands the diamagnetic ring in **35a** should be much less strained. There would likely be sufficient room about each Ti atom in **35a** to accommodate two THF units and thereby permit octahedral coordination.

35a : L = Cl — **35b :** L = Cl



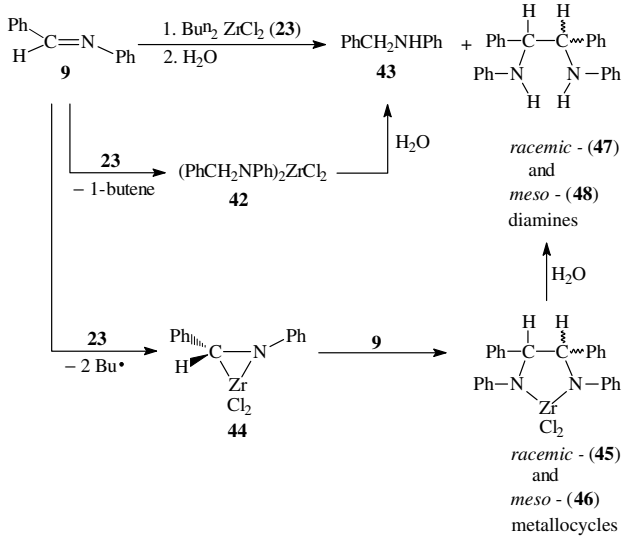
36a : L = OPr^i — **36b :** L = OPr^i

(5)

The process of forming a three-membered ring or epimetallated product, like **4** for carbonyl substrates or **38** for imines such as **9**, could be viewed as in Scheme 6. Attack of **35** (or **36**) on **9** would lead to biradical **37**, which would close the most rapidly to **38** by intramolecular radical displacement [18]. The presence of **38** in such reductive coupling was corroborated by work-up of the reaction mixture with D_2O and finding the *N*-phenylbenzylamine dideuterated (**39**).

The observed stereochemistry of reductive coupling can be readily understood by postulating the insertion of a second **9** into the C–Ti bond of **38** via transition state **40** where the phenyl groups would minimize steric repulsion by forming the *racemic* dimer **41** [19]. With little modification the less stereoselective coupling of **9** by $ZrCl_2$ (*racemic*:*meso* = 80:20) can follow from the longer C–M bond in the Zr intermediate analogous to **38**. The larger covalent radius of Zr over Ti, 145 versus 132 pm, would mean that the two carbon centers would be farther apart in the transition state (similar to **40**) and thus not as sensitive to the steric effects of the phenyl groups.

The only remaining puzzling observation is that made in the attempted transfer-hydrozirconation of **9** by $Bu^n_2ZrCl_2$ (**23**).[1] From our experience with other substrates in hydrozirconation [13], the expected major product should have been *N*-phenylbenzylamine (**43**), formed via **42**. Although **43** was in fact obtained in 49% yield, yet comparable amounts (51%) of an 80:20 mixture of *racemic*- and *meso*-1,2-dianilinoethanes (**47** and **48**) were also formed, products expected to arise from the reductive coupling of **9** by $ZrCl_2$ (cf. supra). However, at the temperature of reaction, 25 °C, $ZrCl_2$ had not yet formed from the decomposition of



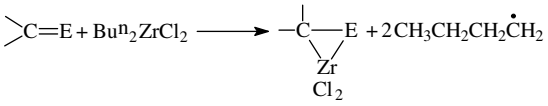
Scheme 6.

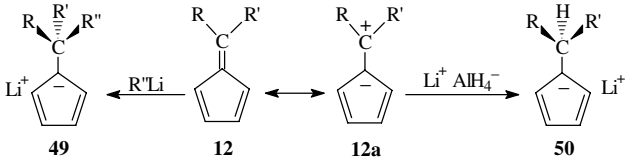
$Bu^n_2ZrCl_2$ in toluene. We are forced to conclude therefore that epimetallated zirconium intermediate **44** has been formed from **23** by the process of the transfer-epimetallation of **9** (Scheme 7).[1] The generation of the *racemic*- and *meso*-metallocycles (**45** and **46**) would ensue as with the titanium analog (**38** → **41**, Scheme 6). Transfer-epititanation of a wide variety of unsaturated substrates by $Bu^n_2TiCl_2$ (**22**) has been amply demonstrated to be an important process in the functionalization of alkenes and alkynes [20,21], in the Kulinkovich cyclopropanol synthesis [22] and in olefin polymerization [23,24].

3.2. Transfer-hydrometallation of fulvenes and the synthesis of unbridged substituted bis(cyclopentadienyl)metal dichlorides

3.2.1. Chemical and physical properties of fulvenes (12)

Fulvenes (**12**) are colored nonaromatic hydrocarbons possessing a dipole moment and a high degree of chemical reactivity by virtue of their uneven π-electron

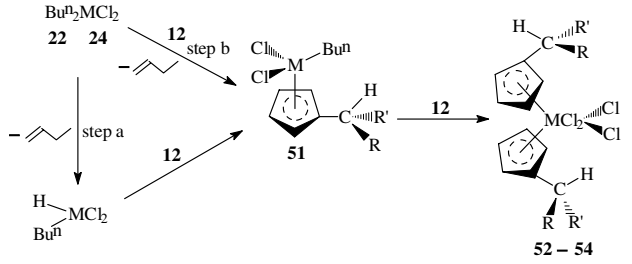




Scheme 7.

[1] The generalized reactions discussed in this section, "transfer-hydrometallation" and "transfer-epimetallation", as well as their metal-specific counterparts, "transfer-epititanation, transfer-epizirconation, transfer-hydrotitanation and transfer-hydrozirconation, are reactions that have been studied and established in previous publications of our research group. Transfer-hydrozirconation as described in [13] refers to the transfer of zirconium dichloride dihydride from di-*n*-butylzirconium dichloride to an unsaturated substrate C = E (carbonyl, imine or fulvene) with release of 1-butene:

Analogously, transfer-epizirconation as described in [20] and [21] refers to the transfer of zirconium dichloride from di-*n*-butylzirconium dichloride to C = E (carbonyl, imine or fulvene) with release of two butyl radicals (or as butane and 1-butene):

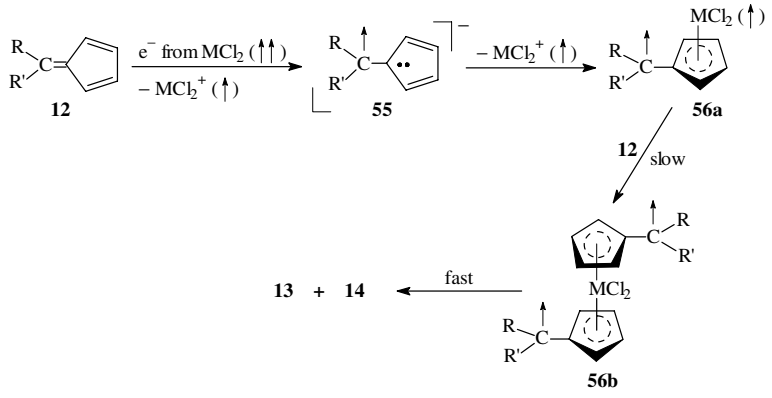


Scheme 8.

distribution (**12a** and its resonance structures). Especially for our present purposes, the long-known addition reactions of fulvenes with organolithium reagents (RLi) [25] and with $LiAlH_4$ [26] are especially relevant (Scheme 8). In the formation of adducts **49** and **50** the regioselectivity is driven by the aromatic stabilization attained with the formation of the cyclopentadienyl anion.

3.2.2. Transfer-hydrometallation of fulvenes

Whether the elimination of 1-butene from $Bu^n{}_2MCl_2$ (**22**–**24**) *precedes* the interaction of $Bu^n{}_2MCl_2$ with the fulvene to produce H_2MCl_2 (step a) or *accompanies* such an interaction with the fulvene (step b) cannot be decided at present (Scheme 9). Either path produces the "open-face sandwich" (**51**). π-Complexation of **51** with a second **12**, so that the RR′HC-groups on the ring are *anti* to each other, would yield the final metallocenes (**52**–**54**) with minimal steric hindrance.



Scheme 9.

3.3. Reductive coupling of fulvenes by union with biradicals

Analogous to the mechanistic insight gained from the reductive dimerization of ketones or of benzylideneaniline by Group 4 metal(II) dichlorides (Schemes 1 and 2), we propose the analogous biradical "open-face sandwich" **56** (Scheme 10), which could be formed via radical-anion **55** by SET from biradical $MCl_2(\uparrow\uparrow)$. Interaction of **56a** with a second fulvene **12** would surely be sensitive to steric factors during the formation of the *ansa*-C–C bond. But if the rate of formation of the final *ansa*-complexes **13** and **14** is determined by the complexation of biradical **56a** with a second fulvene **12** to form **56b**, then the subsequent C–C bonding would be fast and steric hindrance would have only an attenuated effect on the *ansa-racemic*- and *meso*-isomeric ratio. Whether R = phenyl and R′ = H or whether M = Ti or Zr in **56b** would then have no large steric effect. Only when R = 1-naphthyl or 9-anthryl and R′ = H would a steric effect become unavoidable. This effect may have nothing to do with steric bias in the relatively rapid *ansa*-C–C bond formation but rather in the rate of complexation of **56a** with the prochiral π-electron cloud surface of the second fulvene.

3.4. Comparative polymerization of ethylene by ansa-metallocene and unbridged metallocene procatalysts with MAO cocatalysis

A complete survey of all the *ansa*- and unbridged catalysts synthesizable from fulvenes has not yet been made. However, the preliminary results obtained thus far and presented in Table 1 permit us to propose three valuable trends in reactivity: first, *ansa*-metallocenes are much more active polymerization catalysts than their unbridged counterparts: for Ti, consider runs 1, 2 and 3; for Zr, compare runs 4, 5 and 6 as well as runs 7 and 9; second, the normal order of polymerization activity for unbridged metallocenes, Zr > Ti > Hf, is changed

Scheme 10.

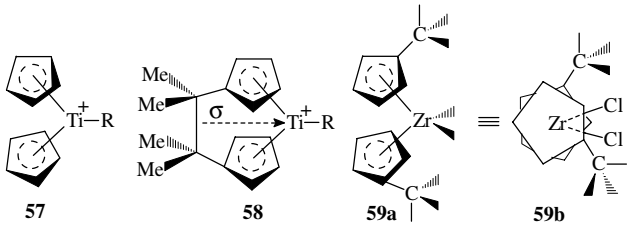


Table 1
Comparative polymerization of ethylene with metallocene procatalysts and MAO cocatalysts

Run	Metallocene	Polymerization activity[a] (g PE/g M h atm)
1	Tetramethylethylene-bis(cyclopentadienyl)titanium dichloride (**19**)	2640
2	Titanocene dichloride	1100
3	*racemic*- and *meso*-1,2-Diphenylethylene-*bis*(cyclopentadienyl)titanium dichloride, 1:1 mixture (titanium analogue of **28a** and **28b**)	3170
4	*racemic*- and *meso*-1,2-(Diphenylethylene-*bis*(cyclopenta-dienyl)zirconium dichloride (**28a** and **28b**), 1:1 mixture	360
5	Bis(benzylcylcopentadienyl)zirconium dichloride (**28c**)	242
6	Bis[(diphenylmethyl)cyclopentadienyl)]zirconium dichloride (**34**)	62
7	Bis[(1-naphthylmethyl)cyclopentadienyl)]zirconium dichloride (**29c**)	126
8	1,2-Di-[(1-naphthylethylene)-cyclopentadienyl]titanium dichloride (titanium analogue of **29a**)	313
9	1,2-Di-[(1-naphthylethylene)-cyclopentadienyl]zirconium dichloride (83:17 mixture of **29a** and **29b**)	52
10	Bis(isopropylcyclopentadienyl)hafnium dichloride	182

[a] All runs were conducted in toluene at ambient temperature with uncontrolled exotherm employing 0.2–1.0 mmol of metallocene and 50 equiv. of MAO. Comparisons of polymerization activity are reported per grams of metal in the catalyst and are measured for polymerizations proceeding under a constant pressure of ethylene, under the spontaneous exotherm of polymerization and in a reaction mixture turning rapidly from homogeneous to heterogeneous. Therefore, this empirical measure of activity, widely used in industry, cannot be expected to rank polymerization rates of catalysts in an absolute and accurate series. But as employed here, such measurements can readily distinguish among catalysts of high activity, intermediate activity and low activity. Finally, it should be noted that the accurate measurement of initial polymerization rates (the only reliable measure of intrinsic catalyst activity) is a most difficult procedure to carry out in a reproducible and reliable manner (cf. Fischer, D. "Untersuchungen zur Propenpolymerisation an Homogenen Zirconocen/Methylaluminoxan Ziegler-Natta Katalysatoren", *Doctoral Dissertation*, Albert-Ludwig University, Freiburg (Breisgau), Germany, 1992.

for *ansa*-metallocenes, where Ti > Zr > Hf; and third, unbridged substituted zirconocenes have depressed activities, as the steric size of the cyclopentadienyl ring substituent increases: note runs 5, 6 and 7.

The usual reason for the lesser polymerization activity of unbridged titanocenes over analogous zirconocenes is the lower kinetic stability of the titanocenium cation **57**, which has been proposed as the active polymerization site [27]. The greater reactivity for *ansa*-titanocenes over *ansa*-zirconocenes or *ansa*-hafnocenes, therefore, may arise from the greater stabilization of cation **58**. A source of such stabilization of the titanium cation in **58** could be the σ-bond hyperconjugation provided to the backside of the empty sp^3-hybridized orbital of the cationic Ti center (**58**).[2] Since such stabilization would be more important in *ansa*-titanocenes than in *ansa*-zirconocenes (better orbital-energy match and shorter distance between the metal center and the σ-electrons of the C–C bond), *ansa*-titanocenes should show a larger increase in polymerization activity than *ansa*-zirconocenes.

Finally, the reduced polymerization activity of bis(substituted cyclopentadienyl)zirconium dichlorides (with substituents of $PhCh_2$-, Ph_2CH- and 1-naphthylmethyl (runs 5, 6 and 7)) can be attributed to the favoring of those conformers where the substituents project out of the wider gap between the tilted rings (**59a** and **59b**). Such substituents thereby impede the interaction of such zirconocenes with the MAO cocatalyst and the approach of the ethylene to the zirconocenium cation in the active site.

4. Experimental

4.1. Starting reagents and solvents

Cyclopentadiene was freshly cracked from commercially available dicyclopentadiene and distilled under an atmosphere of dry argon directly before use. 6,6-Dimethylfulvene, 6,6-diphenylfulvene, 1-naphthaldehyde, 9-anthraldehyde, benzylideneaniline, titanium(IV), zirconium(IV) and hafnium(IV) chlorides and *n*-butyllithium in hexane were obtained from

[2] Such σ-bond hyperconjugation is widely recognized as stabilizing carbenion ions β to silicon as in $R_3Si–CH_2–CH_2+$ (W. Hanstein, H.J. Berwin, T.G. Trayler, J. Am. Chem. Soc. 92 (1970) 829) and in promoting the facile ring-opening of the cyclopropyl carbenium ion to the allyl cation (S.F. Cristol, R.M. Segueira, C.H. DePuy, J. Am. Chem. Soc. 87 (1965) 4007). Since the ansa-C–C bond is closer to the titanium cation, σ-bond hyperconjugation is more likely to be the operative effect than some inductive release of electron density from the *ansa*-carbon centers to the titanium centers but operative through the π-bonding of the rings.

commercial sources in at least 98% purity and were used directly. All solvents employed with organometallic reagents or anhydrous metal salts were dried and distilled from a sodium metal–benzophenone ketyl mixture prior to use [28].

4.2. General procedures

All procedures involving the purification of reaction solvents, the individual preparation of Group 4 metal dialkylmetal dichlorides, Group 4 metal dichlorides and their subsequent reactions leading to metallocenes and their purification were conducted under an atmosphere of anhydrous, oxygen-free argon. The drying and deoxygenation of argon were carried out by means of a purification apparatus previously described [28]. Nonhydrolytic workup of certain reactions to recover the organic ligand was achieved with 3 N aqueous HCl.

4.3. Instrumentation and analysis

After purification the reaction products were routinely subjected to IR and ^{1}H and ^{13}C NMR spectroscopic and, in some cases, mass spectrometric analysis. Since such data served to corroborate the structures assigned to the metallocenes satisfactorily, elemental analyses were considered unnecessary. The IR spectra were recorded with a Perkin–Elmer instrument (model 457) and samples were measured under argon either as mineral oil mulls or as KBr films. The NMR spectra (^{1}H and ^{13}C) were recorded under argon with a Bruker spectrometer (model EM-360) and tetramethylsilane (Me_4Si) was used as the internal standard. The chemical shifts reported are expressed on the δ scale in parts per million (ppm) from the Me_4Si reference signal. No data on J_{HH} coupling constants exhibited in the ^{1}H NMR spectra have been included because such values are in all cases in the expected range and unexceptional. However, it is worth noting that DEPT measurements in the ^{13}C NMR spectra reported here were able to distinguish quaternary carbon centers (C) from methine–carbon (C–H) centers. The latter but not the former carbon signals underwent resonance with inversion of signal. The number of quaternary C signals and methine–carbon signals observed fit the assigned structure in every case.

The gas chromatographic analyses were carried out with a Hewlett–Packard instrument (model 5880) provided with a 2-m OV-101 packed column or with a Hewlett–Packard instrument (model 4890) having a 30 m SE-30 capillary column. Melting points were determined on a Thomas-Hoover Unimelt capillary melting point apparatus and are uncorrected.

The mass spectral measurements were performed at the Mass Spectrometry & Proteomics Facility at the Ohio State University and employed a Micromass ESI-Tof™ mass spectrometer (Micromass, Wythenshawe, UK) equipped with an orthogonal electrospray source (Z spray) operated in a positive ion mode. The samples were prepared in a solution containing acidified methanol and sodium iodide as an internal mass standard.

4.4. Preparation of Group 4 metal dichlorides

4.4.1. Titanium dichloride (*16*)

The preparation of titanium dichloride in THF and its isolation as the LiCl-free and analytically supported complex, $TiCl_2 \cdot 2THF$ (**35**), has been described elsewhere [2]. The complex **35** was analyzed after removal of the THF in vacuo and found to have retained two moles of solvated THF per Ti unit. However, the solvate-free titanium dichloride (**16**), prepared in hydrocarbon slurry with LiCl, has proved more effective in the following reductive dimerizations of fulvenes. A colorless solution of $TiCl_4$ (5.5 mL, 5.5 mmol) in 20 mL of THF was prepared at −78 °C to avoid cleavage of the THF. Then 6.9 mL of *n*-butyllithium 1.6 M in hexane (11 mmol) was added dropwise at −78 °C causing the formation of a red-brown solution. The dark red solution was brought to RT, stirred for 12 h and then heated at reflux for 3 h. After solvent removal in vacuo the dark residue was diluted with 30 mL of toluene to give a black solution of **16** (5.5 mmol) with suspended LiCl.

4.4.2. Zirconium dichloride (*17*)

Zirconium dichloride can likewise be prepared in THF and isolated as the LiCl-free and analytically pure complex, $ZrCl_2 \cdot 2THF$ (**17**). Again, here the complex **17** in toluene slurried with LiCl has proved more effective in *ansa*-metallocene preparations. Thus a clear solution of $ZrCl_4$ (0.20 g, 0.86 mmol), prepared in 20 mL of THF at −78 °C, was treated with 1.1 mL of 1.6 M *n*-butyllithium in hexane (1.72 mmol). The dark red solution was brought to RT, stirred for 12 h and then heated at reflux for 3 h. After solvent removal in vacuo the black residue was treated with 20 mL of toluene to give a black solution of **17** (0.86 mmol) with suspended LiCl.

In a similar manner a suspension of $ZrCl_2$ (5.89 mmol) and LiCl in hexane alone was prepared from 5.89 mmol of $ZrCl_4$ and 11.8 mmol of *n*-butyllithium in a total of 40 mL of hexane.

4.4.3. Hafnium dichloride (*18*)

Hafnium dichloride (**18**) prepared in THF appears to form the solvate, $HfCl_2 \cdot 2THF$, as well but the solvate is not stable upon removal of the THF in vacuo. Thus a clear solution of $HfCl_4$ (3.73 g, 11.6 mmol) in 80 mL of THF at −78 °C was treated with 15 mL of 1.6 M *n*-butyllithium (23.2 mmol). The pale yellow solution was then stirred for 12 h at RT and then heated at reflux for 5 h. The dark brown solution was freed of solvent in

vacuo and the residue of $HfCl_2$ (**18**) and LiCl was suspended in 60 mL of toluene.

4.5. Synthesis of fulvenes

4.5.1. 6-Phenylfulvene (*28*)

To a solution of freshly distilled benzaldehyde (distilled under argon, 0.40 mL, 4.0 mmol) and freshly cracked cyclopentadiene (0.82 mL, 10 mmol) in 4.0 mL of methanol was added 0.5 mL of pyrrolidine. After 15-min stirring a 0.4 mL-portion of acetic acid was added and the solution stirred for a further 15 min. A mixture of ether and water was added and the organic layer separated and dried over solid $MgSO_4$. Ether removal from the organic layer left pure 6-phenylfulvene (**28**), 584 mg (89%) of dark orange crystals, mp. 33–34 °C. The reaction could be run on a 20-fold scale with little decrease in yield. *Anal*. Calc. for $C_{12}H_{10}$: C, 93.46; H, 6.54. Found: C, 93.65; H, 6.49%.

^{1}H NMR ($CDCl_3$): 7.59–9.56 (m, 2H), 7.42–7.30 (m, 3H), 7.20 (s, 1H), 6.71–6.64 (m, 2H), 6.52–6.49 (m, 1H), 6.33–6.31 (m, 1H). ^{13}C NMR ($CDCl_3$): 145.3, 138.2, 136.8, 136.4, 130.8, 130.7, 129.0, 128.6, 127.2, 120.3.

4.5.2. 6-(1-Naphthyl)fulvene (*29*)

To a solution of 1-naphthaldehyde (9.1 g, 58.2 mmol) in 50 mL of methanol was added the fresh cyclopentadiene (12.0 mL, 0.146 mol). After 15-min stirring 7.30 mL of pyrrolidine was introduced, causing the mixture to turn orange during 4 h-stirring at RT. Addition of 5.3 mL of acetic acid, further stirring for 20 min and dilution of the reaction mixture with water and ether yielded a biphasic system. The organic layer was separated, dried over $MgSO_4$ and freed of solvent to provide the crude **29**. Its purification by flash column chromatography on silica gel with a hexane–ethyl acetate eluent gave orange crystals of **29** (9.93 g, 84%), m.p. 52–54 °C.

Anal. Calc. for $C_{16}H_{12}$: C, 93.71; H, 6.29. Found: C, 93.84; H, 6.18%.

^{1}H NMR ($CDCl_3$): 8.11 (d, 1H), 7.90 (t, 3H), 7.76 (d, 1H), 7.53 (t, 3H), 6.69 (d, 2H), 6.56 (s, 1H), 6.50 (s, 1H). ^{13}C NMR ($CDCl_3$): 147.1, 135.7, 134.9, 133.8, 133.4, 132.0, 131.8, 130.0, 129.4, 128.6, 126.6, 126.2, 126.1, 125.4, 124.4, 121.5.

4.5.3. 6-(9-Anthryl)fulvene (*30*)

In a procedure analogous to the foregoing, a solution of 9-anthraldehyde (15.0 g, 82.8 mmol) and cyclopentadiene (15.0 mL, 0.182 mol) in 75 mL of methanol was treated with 9.1 mL of pyrrolidine and worked up with water and ether. The crude **30** was purified by flash column chromatography to give orange crystals of **30** (12.6 g, 68%), m.p. 100–101 °C.

Anal. Calc. for $C_{20}H_{14}$: C, 94.45; H, 5.55. Found: C, 94.22; H, 5.60%.

^{1}H NMR ($CDCl_3$): 8.5 (s, 1H), 8.16–8.13 (m, 2H), 8.06–8.01 (m, 2H), 7.94 (s, 1H), 7.51–7.44 (m, 4H), 6.65–6.60 (m, 2H), 6.52–6.49 (m, 1H), 5.89 (d, 1H). ^{13}C NMR ($CDCl_3$): 150.3, 134.5, 134.3, 132.4, 131.2, 130.6, 130.1, 128.5, 127.7, 126.3, 125.8, 125.4, 125.3, 122.5.

4.6. ansa-Metallocene dichlorides of titanium

4.6.1. From 6,6-dimethylfulvene (*15*)

To a black solution of 10.0 mmol of $TiCl_2 \cdot 2THF$ (**16**) in 30 mL of toluene (cf. Section 4.4.1) were added 20.0 mmol (2.41 mL) of 6,6-dimethylfulvene (**15**) and the resulting mixture heated at reflux for 6 h. Thereupon, the suspension was filtered and the black solid was washed twice with chloroform. The filtrate was freed of volatiles in vacuo to give red-brown **19**, spectrally quite pure, consistently in >90% yield in duplicate runs. Alternatively, the solvent was removed in vacuo, and the solid residue transferred under argon to the thimble of a Soxhlet extraction apparatus. Extraction with hexane over 20 h gave a hexane solution of 1,1,2,2-tetramethylethylene-bis(cyclopentadienyl)titanium dichloride (**19**). By solvent removal, washing with cold pentane and vacuum-drying, product **19** was isolated as a reddish brown solid (2.81 g, 85%). Further purification could be achieved by flash column chromatography with a gradient of hexane–chloroform, starting from pure hexane and ranging to pure chloroform. This metallocene is oxygen- and moisture-sensitive, turning yellowish green in moist air. ^{1}H NMR ($CDCL_3$): 6.90 (t, 4H), 6.25 (t, 4H), 1.45 (s, 12H). ^{13}C NMR ($CDCl_3$): 145.5, 128.5, 112.5, 45.5, 28.0. MS (electrospray in ESI with N_2 gas; capillary voltage 3000 V, source temperature 110 °C, cone voltage 55 V) prominent parent ion + Na peaks (intensity) at 297 (10), 299 (5), 301 (1), corresponding to the theoretical masses and intensities of $C_{12}H_{12}{}^{35}Cl_2TiNa$, $C_{12}C_{12}{}^{35}Cl^{37}ClTiNa$ and $C_{12}C_{12}{}^{37}Cl_2TiNa$, respectively.

4.6.2. From 6-phenylfulvene (*28*)

In a similar manner, a solution of 6-phenylfulvene (**28**, 1.54 g, 10.0 mmol) and a solution slurry of $TiCl_2 \cdot 2THF$ (**16**, 5.0 mmol) with the suspended LiCl in 50 mL of toluene were heated at reflux for 6 h. The reaction suspension was filtered and the black filter cake washed twice with chloroform. Removing volatiles from the filtrate gave >90% of a spectrally pure 1:1 mixture of *meso*- and *racemic*-isomers. Alternatively, analogous Soxhlet extraction and subsequent workup provided 85% of a brown-red 1:1 mixture of the *meso-ansa*- and the *racemic-ansa*-isomers of 1,2-diphenylethylene-bis(cyclopentadienyl)titanium dichloride. The conclusion that both isomers are present in such product is drawn from the ^{13}C NMR spectrum, which displays 18 sp^2-carbon and 2 sp^3-carbon

(methine carbon) signals. The ^{1}H NMR signals also come in signal packets of 10:4:4:1:1, consistent with the presence of both *meso*- and *racemic*-isomers. The equal intensity of the methine singlets at 4.85 and 4.35 ppm confirm the presence of a 1:1 mixture. The signal at 4.35 ppm is assigned to the *racemic*-isomer, since its methine H should be shielded by the π-cloud of the adjacent phenyl group. The *meso*- and *racemic*-isomers could be separated by flash column chromatography with a hexane–chloroform gradient. ^{1}H NMR ($CDCl_3$): 7.16–6.80 (m, 10H), 5.88–5.85 (m, 4H), 5.77–5.76 (m, 4H), 4.85 (s, 1H), 4.35 (s, 1H). ^{13}C NMR ($CDCl_3$): 140.8, 139.2, 137.4, 136.9, 134.0, 130.6, 129.3, 129.1, 128.8, 128.5, 127.8, 127.5, 126.9, 126.9, 117.7, 116.7, 113.2, 109.4, 53.9, 51.1.

The greater thermal lability and reactivity of the other *ansa*-metallocenes made their isolation more difficult, so a more extensive study of *ansa*-metallocenes was undertaken with zirconium analogues.

4.7. ansa-Metallocene dichlorides of zirconium

4.7.1. From 6,6-dimethylfulvene (*15*)

A solution of 6,6-dimethylfulvene (**15**, 1.20 mL, 10 mmol) in 60 mL of toluene was combined with a solution slurry of ZrCl2 (**17**, 5.0 mmol, cf. Section 4.4.2.) and LiCl in 50 mL of toluene and the mixture stirred at reflux for 8 h. Filtration of the reaction mixture and washing of the filtered cake twice with chloroform gave an extract, from which volatiles were removed in vacuo. The off-white **20** was spectrally pure and isolated in >90% yield. Alternatively, nonhydrolytic workup and Soxhlet extraction provided 1.31 g of colorless tetramethylene-bis(cyclopentadienyl)zirconium dichloride (**20**) in 70% yield. ^{1}H NMR ($CDCl_3$): 6.70 (t, 4H), 6.20 (t, 4H), 1.45 (s, 12H). ^{13}C NMR ($CDCl_3$): 143.5, 123.3, 108.8, 45.2, 28.4. MS (electrospray in ESI with N_2 gas; capillary voltage 3000 V, source temperature 110 °C, cone voltage 55 V) the three most prominent parent ion + Na peaks (intensity) at 339 (1.5), 341 (1.5) and 343 (1.0), corresponding to the theoretical intensities of $C_{12}C_{12}{}^{35}Cl_2ZrNa$, $C_{12}C_{12}{}^{35}Cl^{37}ClZrNa$ and $C_{12}C_{12}{}^{37}Cl_2ZrNa$, respectively.

4.7.2. From 6,6-diphenylfulvene (*31*), (attempted)

Heating a suspension of $ZrCl_2$ (**17**, 9.5 mmol) and LiCl with a solution of 6,6-diphenylfulvene (**31**, 2.20 g, 9.5 mmol) in 60 mL of toluene for 18 h gave upon usual nonhydrolytic workup an off-white, air- and moisture-sensitive solid in about 25% yield that proved to be bis(diphenylmethyl(cyclopentadienyl))zirconium dichloride (**34**), rather than the expected *ansa*-metallocene **32**. The presence of a singlet signal for the methine hydrogen at 5.64 ppm provided decisive evidence against the presence of **32**. Moreover, the straightforward hydrozirconative coupling of **31** by dibutylzirconium dichloride (**23**) (Section 4.9.5) provided an authentic sample of **34** for confirming the structure of this reaction product. ^{1}H NMR ($CDCl_3$): 7.28–7.09 (m, 20H), 6.05 (t, 4H), 5.78 (t, 4H), 5.64 (s, 2H). ^{13}C NMR ($CDCl_3$): 143.4, 136.3, 129.0, 128.4, 126.7, 116.0, 115.2, 51.5.

4.7.3. From 6-phenylfulvene (*28*)

A suspension of $ZrCl_2$ (**17**, 10.0 mmol) and LiCl in 30 mL of toluene was heated at reflux with 6-phenylfulvene (3.08 g, 20 mmol) for 8 h. Work-up by filtration gave >90% of essentially pure **28a** and **28b**. Alternatively, nonhydrolytic workup and Soxhlet extraction gave 3.53 g (75%) of a colorless 1:1 mixture of the *meso-ansa*-(**28b**) and *racemic-ansa*-(**28a**) isomers of 1,2-diphenylethylene-bis(cyclopentadienyl)zirconium dichloride. Spectral evidence for such a composition of these isomers and the assignment of the methine H at 4.28 ppm to the *racemic*-isomer follow the arguments given in Section 4.6.2. for the titanium analogue. ^{1}H NMR ($CDCl_3$): 7.16–6.90 (m, 20H), 5.90 (t, 4H), 5.85–5.70 (m, 4H), 4.91 (s, 1H), 4.28 (s, 1H). ^{13}C NMR ($CDCl_3$): 141.6, 139.8, 135.6, 129.5, 129.0, 128.7, 127.8, 127.6, 127.0, 113.5, 113.3, 110.7, 106.1, 54.4, 51.3.

4.7.4. From 6-(1-naphthyl)fulvene (*29*)

In a similar procedure, a solution of 6-(1-naphthyl)fulvene (**29**, 352 mg, 1.72 mmol) in 30 mL of toluene was heated at reflux with $ZrCl_2$ (**17**, 0.86 mmol) for 4 h. The reaction mixture was filtered and the filter cake washed repeatedly with toluene. The solvent was removed from the combined filtrate and washings in vacuo to give 369 mg (75%) of off-white *meso-ansa*-(**29b**) and *racemic-ansa*-(**29a**) isomers. The spectral evidence for the presence of both *meso*- and *racemic*-isomers is: (1) the presence of 30 sp^2-C signals; and (2) the presence of 2 sp^3-C signals and of 2 ^{1}H methine singlets. The ratio of the *meso*:*racemic*-isomers can be obtained by integrating the ^{1}H methine singlets at 6.20 and 6.28 ppm and obtaining a ratio of 6.20:6.28 signals of 17:83. Noting that the *racemic* methine H should be more shielded (Section 4.6.2), we can conclude that the *racemic-ansa*-isomer (**29a**) is the major isomer. Upon recrystallization of mixture **29a** and **29b** from a toluene–hexane pair a colorless product was recovered; its ^{1}H NMR spectrum now lacked the singlet at 6.20 ppm and its ^{13}C NMR spectrum had no signal at 45.5. Hence, the recrystallized product consisted of essentially the *racemic-ansa*-isomer. Crystal samples submitted thus far to Professor A.L. Rheingold (then of the University of Delaware and now of the University of California at San Diego) for single-crystal X-ray determination have led to the unambiguous determination that this isomer has the *racemic* structure (**29a**). However, better crystals will be required, in order to refine the data to attain $R < 10\%$.

^{1}H NMR ($CDCl_3$): 8.56 (d, 4H), 7.99 (d, 2H), 7.79–7.66 (m, 6H), 7.52–7.18 (m, 8H), 6.85 (m, 4H), 6.52

(m, 4H), 6.44 (s, 2H), 6.20–6.28 (2s, total of 2H). ^{13}C NMR ($CDCl_3$): 136.58, 136.12, 134.94, 134.57, 133.87, 131.63, 129.21, 129.13, 128.98, 128.17, 128.05, 127.86, 127.51, 127.21, 126.40, 125.72, 125.64, 125.55, 125.50, 125.25, 124.46, 1223.13, 123.02, 122.16, 121.52, 120.00, 113.43, 113.24, 110.28, 106.66, 48.30, 45.46.

4.7.5. From 6-(9-anthryl)fulvene (30)

A solution of 6-(9anthryl)fulvene (**30**, 2.23 g, 8.8 mmol) in 30 mL of toluene was stirred with a suspension of $ZrCl_2$ (14.4 mol) and LiCl in 20 mL of toluene at RT for 12 h and then at reflux for 6 h. The cooled reaction mixture was filtered and the filtrate cake washed thrice with 20-mL portions of toluene. The combined filtrate and washings were freed of solvent in vacuo to give 1.92 g (65%) of light brown *racemic*-1,2-(di-9-anthryl)ethylene-bis(cyclopentadienyl)zirconium dichloride (**30a**). Recrystallization from a toluene–hexane gave colorless, air- and moisture-sensitive **30a**. ^1H NMR ($CDCl_3$): 7.95 (d, 2H), 7.74 (d, 4H), 7.65 (d, 2H), 7.44–7.15 (m, 10H), 6.81 (m, 4H), 6.47 (m, 2H), 6.40 (s, 2H), 6.16 (s, 2H). ^{13}C NMR ($CDCl_3$): 137.8, 136.1, 134.6, 133.9, 131.7, 129.2, 129.0, 128.2, 128.1, 127.6, 126.4, 125.9, 125.6, 125.3, 124.5, 123.1 spectrum (6.16) and in the ^{13}C spectrum (48.4) are consonant with only one *ansa*-isomer. Steric control decisively supports the *racemic* structure (**30a**) for that single isomer.

4.8. ansa-Metallocene dichlorides of hafnium

4.8.1. From 6,6-dimethylfulvene (15)

A mixture of 6,6-dimethylfulvene (**15**, 1.00 mL, 8.7 mmol) and a suspension of $HfCl_2$ (11.6 mmol) and LiCl in 60 mL of toluene was heated at reflux for 12 h. The cooled reaction mixture was freed of solvent in vacuo and the residue subjected to Soxhlet extraction with 10% chloroform in hexane to yield 1.83 g (90%) of colorless, air- and moisture-sensitive tetramethylene-bis(cyclopentadienyl)hafnium dichloride (**21**). ^1H NMR ($CDCl_3$): 6.57 (t, 4H), 6.02 (t, 4H), 1.46 (s, 12H). ^{13}C NMR ($CDCl_3$): 141.6, 121.7, 106.7, 44.7, 28.5.

4.9. Hydrometallations of fulvenes

4.9.1. Hydrotitanation of 6,6-dimethylfulvene (15), (attempted)

Attempts to generate di-*n*-butyltitanium dichloride (**22**) at −78 °C just before adding 6,6-dimethylfulvene (**15**) to such a reagent failed because of the instability of **22** even at such low temperatures. Thus to a solution of $TiCl_4$ (4.0 mL, 4.0 mmol) in 30 mL of toluene at −78 °C were slowly added 2 equiv. of *n*-butyllithium (5.0 mL of 1.6 M in hexane, 8.0 mmol). During 30 min the progression of a colorless reaction mixture to yellow to green to brown and then to black signaled decomposition of **22** to $TiCl_2$ (**16**). Addition of 2 equiv. of 6,6-dimethylfulvene and warming to RT and finally 65 °C led to the formation of a mixture of tetramethylethylene-bis(cyclopentadienyl)titanium dichloride (**19**) (NMR spectral data in Section 4.6.1) and bis(isopropylcyclopentadienyl)titanium dichloride (**25**), readily identifiable by a 12H doublet at 1.45 and a 2H septet at 3.25 ppm.

4.9.2. Hydrozirconation of 6,6-dimethylfulvene (15)

To a white suspension of $ZiCl_4$ (2.12 g, 9.1 mmol) in 50 mL of toluene at −78 °C were slowly added 2 equiv. of *n*-butyllithium (18.2 mmol, 11.4 mL of 1.6 M), whereupon the solution turned light brown as it was warmed to RT. After 6 h 6,6-dimethylfulvene (**15**, 1.97 g, 18.6 mmol) was added and the reaction continued for 1 h at RT and 6 h at 65 °C. Filtration of the cooled reaction mixture and removal of volatiles in vacuo gave the light-brown bis(isopropylcyclopentadienyl)zirconium dichloride (**26**) consistently in >90% yield. Extraction with hexane in a Soxhlet apparatus over 1 h gave colorless **26** in 75% yield. ^1H NMR ($CDCl_3$): 6.60 (t, 4H), 6.45 (t, 4H), 3.25 (septet, 2H), 1.45 (d, 12H). ^{13}C NMR ($CDCl_3$): 142.0, 114.6, 112.0, 28.3, 23.2.

4.9.3. Hydrozirconation of 6-phenylfulvene (28)

A mixture of 6-phenylfulvene (**28**, 860 mg, 5.6 mmol) and di-*n*-butylzirconium dichloride (**23**, 2.8 mmol, cf. Section 4.9.2) in 40 mL of toluene was allowed to react at RT for 1 h and at reflux for 2 h. Solvent removal in vacuo and the solid washed well with pentane to remove any residual **28**. The residue was slurried again with toluene and the LiCl filtered off. The filtrate was freed of volatiles in vacuo to give 282 mg (95%) of light brown bis(benzylcyclopentadienyl)zirconium dichloride (**28c**). Further purification by Soxhlet extraction gave 75% of colorless **28c**. ^1H NMR (C_6D_6): 715–6.99 (m, 10H), 5.89 (t, 4H), 5.69 (t, 4H), 3.98 (s, 4H). ^{13}C NMR ($CDCl_3$): 140.71, 133.81, 129.59, 129.16, 127.03, 117.51, 112.96, 36.07.

4.9.4. Hydrozirconation of 6-(1-naphthyl)fulvene (29)

A mixture of 6-(1-naphthyl)fulvene (**29**, 1.9 g, 9.2 mmol) and $Bu^n{}_2ZrCl_2$ (**23**, 4.6 mmol) in 40 mL of toluene was allowed to react for 1 h at RT and 3 h at 65 °C. The cooled mixture was filtered to remove the LiCl. The filtrate was freed of solvent in vacuo and the residue was extracted with methylene chloride in a Soxhlet apparatus. In this way a 55% yield of almost colorless bis(1-naphthylmethyl(cyclopentadienyl))zirconium dichloride (**29c**) was obtained. ^1H NMR ($CDCl_3$): 8.05 (m, 3H), 7.88 (m, 4H), 7.76 (m, 3H), 7.44 (m, 4H), 6.21 (m, 4H), 6.16 (m, 4H), 4.52 (s, 4H). ^{13}C NMR ($CDCl_3$): 142.5, 136.0, 133.9, 128.8, 127.4, 127.0, 126.1, 125.9, 125.7, 124.7, 124.0, 117.5, 112.4, 47.7.

4.9.5. Hydrozirconation of 6,6-diphenylfulvene (31)

A mixture of 6,6-diphenylfulvene (**31**, 202 g, 8.84 mmol) and $Bu^n{}_2ZrCl_2$ (**23**, 4.42 mmol) in 40 mL of

toluene was allowed to react for 1 h at RT and 3 h at 65 °C. The cooled reaction mixture was freed of solvent in vacuo and the residue extracted with methylene chloride in a Soxhlet apparatus. The filtrate was freed of volatiles to give a light brown residue of bis(diphenylmethyl(cyclopentadienyl))zirconium dichloride (**31c**) (65% yield). Washing with pentane gave an off-white sample of **31c**, whose ^{1}H and ^{13}C NMR spectra were identical with the product obtained in Section 4.7.2.

*4.9.6. Hydrohafniation of 6,6-dimethylfulvene (**15**)*

A mixture of 6,6-dimethylfulvene (**15**, 1.7 mL, 14.2 mmol) and $Bu^{n}_{2}HfCl_{2}$ (**24**, 7.1 mmol, made analogous to $Bu^{n}_{2}ZrCl_{2}$ from $HfCl_{4}$ and 2 equiv. of *n*-butyllithium) in 40 mL of toluene was allowed to react for at RT for 1 h and at 65–70 °C for 4 h. The toluene was removed from the reaction mixture and the residue extracted with hexane in a Soxhlet apparatus. The hexane yielded 2.44 g (73%) of red-brown bis(isopropylcyclopentadienyl)hafnium dichloride (**27**). ^{1}H NMR ($CDCl_{3}$): 6.30 (t, 3H), 6.12 (t, 4H), 3.14 (septet, 2H), 1.14 (d, 12H). ^{13}C NMR ($CDCl_{3}$): 141.3, 113.1, 110.7, 27.0, 22.6.

4.10. Comparative polymerizations of ethylene with metallocene catalysts

*4.10.1. Typical polymerization run for tetramethylethylene-bis(cyclopentadienyl)titanium dichloride (**19**)*

Polymerizations were conducted in 250 mL resin-coated glass pressure (Fisher-Porter) bottle provided with magnetic stirring and equipped with a metal head (polymer coated on the inside) bearing a pressure gauge, an outlet for gas and reagents by syringe, and a stopcock for evacuation. The metallocene procatalysts, tetramethylethylene-bis(cyclopentadienyl)titanium dichloride (**19**, 0.560 mmol), in 100 mL of predried and deoxygenated toluene was treated with 28 mmol of MAO in toluene (Al:Ti = 50:1) and the bottle purged with anhydrous ethylene to initiate the polymerization. Under an ethylene overpressure of 40 psi the polymerizations are allowed to proceed for 10 min. Usual quench with aqueous HCl and filtration with a methanol-wash allow the polyethylene to be isolated. In this case the polymerization activity (PA) in grams of polyethylene (PE) per gram of Ti, per atmosphere was calculated as 2640. Such polyethylene generally melted over 135 °C.

4.10.2. Analogous polymerization with bis(cyclopentadienyl)titanium dichloride

An analogous polymerization of ethylene using 0.53 mmol of titanocene dichloride and 28 mmol (50 equiv.) of MAO for 10 min gave a PA = 1100 g PE/g Ti h atm.

*4.10.3. Analogous polymerization with bis(isopropylcyclopentadienyl)hafnium dichloride (**27**)*

A parallel polymerization of ethylene using 1.02 mmol of **27** and 50 equiv. of MAO for 30 min gave a PA = 182 g PE/g Hf h atm.

*4.10.4. Analogous polymerization with bis(benzylcyclopentadienyl)zirconium dichloride (**28c**)*

With 0.85 mmol of **28c** and 50 equiv. of MAO for 15 min of ethylene purge, a PA of 242 g PE/g Zr h atm was obtained.

*4.10.5. Analogous polymerization with bis(diphenylmethyl(cyclopentadienyl))zirconium dichloride (**31c**)*

With 0.18 mmol of **31c** and 50 equiv. of MAO for 10 min of ethylene purge, a PA of 62 g PE/g Zr h atm was obtained.

*4.10.6. Analogous polymerization with bis(1-naphthylmethyl(cyclopentadienyl))zirconium dichloride (**29c**)*

With 0.79 mmol of **29c** and 50 equiv. of MAO for 15 min of ethylene purge, a PA of 126 g PE/g Zr h atm was obtained.

4.10.7. Analogous polymerization with 1:1 racemic- and meso-1,2-diphenylethylene-bis(cyclopentadienyl) titanium dichloride

With 0.45 mmol of this metallocene and 50 equiv. of MAO for 10 min of ethylene purge, a PA of 3170 g PE/g Zr h atm was obtained.

4.10.8. Analogous polymerization with racemic- and meso-1,2-di(1-naphthyl)ethylene-bis(cyclopentadienyl)-titanium dichloride

With 0.20 mmol of this catalyst and 50 equiv. of MAO for 10 min of ethylene purge, a PA of 313 g PE/g Zr h atm was obtained.

*4.10.9. Analogous polymerization with 1:1 racemic- and meso-1,2-diphenylethylene-bis(cyclopentadienyl)-zirconium dichloride (**28a** and **28b**)*

With 0.75 mmol of this catalyst and 50 equiv. of MAO for 10 min of ethylene purge, a PA of 360 g PE/g Zr h atm was obtained.

*4.10.10. Analogous polymerization with 83:17 mixture of racemic- and meso-1,2-di(1-naphthyl)ethylene-bis(cyclopentadienyl)zirconium dichloride (**29a** and **29b**)*

With 0.22 mmol of this mixture and 50 equiv. of MAO for 15 min of ethylene purge, a PA of 52 g PE/g Zr h atm was obtained.

*4.11. Reductive dimerizations of N-benzylideneaniline (**9**)*

4.11.1. With titanium dichloride

To 15 mmol of $TiCl_{2}$ (**16**) in 40 mL of toluene (free of $Bu^{n}_{2}TiCl_{2}$, Eq. (2)) but containing the LiCl by-product

was added 5.40 g (30 mmol) of *N*-benzylideneaniline (**9**) at 25 °C. The mixture was heated at reflux for 2 h to form a dark khaki-colored suspension. Hydrolysis with 1 N aqueous HCl and separation of the organic layer, which was dried over $MgSO_4$ and freed of solvent in vacuo, provided 5.10 g (94% recovery) of products, which by ^1H NMR spectroscopy and comparison with spectral data of authentic samples to consist of 15% of *N*-phenylbenzylamine (**39**, but without D atoms) and 85% of *racemic*-1,2-dianilino-1,2-diphenylethane. After exchange with D_2O, the *racemic*-isomer showed a sharp C–H peak at 4.6 ppm. The corresponding CH peak for the *meso*-isomer at 5.0 ppm was absent [29].

When an identical reaction run was worked up with DCl in D_2O, the *N*-phenylbenzylamine (**39**) was monodeuteriated in the methylene group (^1H NMR peak at 4.29 and the N–H peak at 3.97 ppm was absent), the changes of which are consistent with the structure, Ph–CHD–ND–Ph (**39**).

*4.11.2. With zirconium dichloride (**17**)*

Similar to the foregoing, a mixture of *N*-benzylideneaniline (**9**) (6.00 g, 33 mmol) and freshly prepared $ZrCl_2$ (**17**, 16.3 mmol) free of $Bu^n{}_2ZrCl_2$ but containing LiCl was heated to reflux for 4 h. Hydrolytic work-up gave a 90% conversion to a mixture of *N*-phenylbenzylamine (20%) and an 80:20 mixture of *racemic*-1,2-dianilinoethane and *meso*-1,2-dianilinoethane (85%). The proportion of *racemic* to *meso*-isomers was determined by integration of C–H proton peaks at 4.6 and 5.0 ppm.

*4.11.3. With di-n-butylzirconium dichloride (**23**)*

N-Benzylideneaniline (**9**, 2.1 g, 11.4 mmol) and a slurry of $Bu^n{}_2ZrCl_2$ (**23**, 5.7 mmol) and LiCl in 40 mL were mixed at 25 °C to form a dark brown suspension in an exothermic reaction. After being stirred for 1 h at RT the reaction mixture was heated at reflux for 2 h and then subjected to the usual hydrolytic work-up. In 85% recovery, the reaction products consisted of *N*-phenylbenzylaniline (49%) and an 80:20 mixture of *racemic*- and *meso*-1,2-dianilino-1,2-diphenylethane (51%). Although the *N*-phenylbenzylaniline could have resulted either from transfer-hydrozirconation or epizirconation, formation of the *racemic*- and *meso*-1,2-dianilinoethanes require epizirconation, either directly by $ZrCl_2$ or by transfer (cf. discussion in Section 3.1).

*4.11.4. With zirconium dichloride (**17**) and the isolation of the mixture of racemic- and meso-1,1-dichloro-2,3,4,5-tetraphenyl-2,5-diazaazirconacyclopentanes (**10** and **11** with M = Zr)*

The experiment described in Section 4.11.2 but instead of a hydrolytic work-up the reaction mixture was cooled to RT and filtered to remove the LiCl. The filtrate was freed of toluene in vacuo and the dark tan washed repeatedly to give a mixture of *racemic*- and *meso*-isomers **10** and **11**, calculated to be a 70% yield and present in a 80:20 ratio. This product could be recrystallized from a toluene–hexane pair. ^1H NMR (THF-d_8) of **10** and **11**: 7.60–7.00 (m), 6.93–6.88 (m), 6.56–6.46 (m), 4.90 (s, *meso*-CH), 4.55 (s, *racemic*-CH); ^{13}C NMR (THF-d_8): 65.3 (*racemic*-CH), 63.3 (*meso*-CH).

*4.11.5. Polymerization with the mixture of racemic- and meso-1,1-dichloro-2,3,4,5-tetraphenyl-2,5-diazazirconacyclopentanes (**10** and **11** with M = Zr)*

Analogous to the foregoing polymerizations a mixture of **10** and **11** (160 mg, 0.29 mmol) in 100 mL of toluene was treated with 28 mmol (50 equiv.) of MAO was treated with ethylene at 40 psi for 15 min. Usual work-up gave 9.45 g of polyethylene for a PA = 129 PE/g Zr h atm.

Acknowledgments

The authors hereby thank the US National Science Foundation and Akzo Corporate Research America for supporting the initiation of this research, the Solvay Corporation of Brussels, Belgium for its continuation and the Boulder Scientific Company of Mead, Colorado for bringing this project to ultimate fruition. Former group members, Drs. Adetenu A. Adeosun, John N. Gitua and Peter O. Otieno have contributed valuable orienting experiments to the research approach herein described.

[15] In organic chemistry Front or F-Strain can refer to the retardation of the quaternization of tertiary amines by alkyl iodides in S_N2 reactions, where the steric hindrance between substituents in such backside-attack raises the energy of the transition state (below). Also in equilibria of Lewis acid–Lewis base complexation, such as in $R_3'N - BR_3$ adduct formation, greater F-strain between the R and R′ groups promotes complex dissociation. Cf. M.S. (1)

The compounds Li[$(C_5H_4)CMe_2PHR$] (R = Ph, Cy) are always obtained as by-products in ca. 40% yield. We assume that Li_2PR attacks the methyl groups of 6,6-dimethylfulvene to give LiPHR, which then reacts with dimethylfulvene to give the observed by-products. The amount of Li[$(C_5H_4)CMe_2PHR$] was determined by ^{31}P NMR spectroscopy and a corresponding amount of ^{n}BuLi was added followed by 6,6-dimethylfulvene to give **1** in high yield and purity (97%) and **2** as a mixture with the monolithio salt (ca. 70% purity).

Attempts to further purify **2** failed. Therefore, preparation of the [3]ferrocenophane was carried out with the mixture of **2** and Li[$(C_5H_4)CMe_2PHR$], and [3]ferrocenophane **4** was purified by recrystallisation from toluene, while **3** was obtained from pure **1** and $FeCl_2$ in THF (Eq. (2)). The [3]ferrocenophanes are obtained as orange-yellow powders.

(2)

2.2. Spectroscopic properties of $Li_2[\{(C_5H_4)CMe_2\}_2PR]$ [R = Ph (**1**), Cy (**2**)] and of $[Fe\{(C_5H_4)CMe_2\}_2PR]$ [R = Ph (**3**), Cy (**4**)]

Compound **1** was characterised by ^{1}H, ^{13}C, ^{31}P and ^{7}Li NMR spectroscopy, and **2** only by ^{31}P NMR spectroscopy. In the ^{1}H NMR spectrum, the methyl groups of the CMe_2 group in **1** are inequivalent and exhibit different chemical shifts and coupling constants (0.95 ppm, $^{3}J_{P-H}$ = 15.5 Hz and 1.79 ppm, $^{3}J_{P-H}$ = 2.6 Hz). Two multipletts are observed at 5.21 and 5.52 ppm for the expected AA′BB′ coupling pattern of the C_5H_4 rings. In the ^{13}C NMR spectrum, a large P–C coupling constant is observed for the *ipso* carbon atom and two signals for the *ortho* carbon atoms of the phenyl ring. The latter suggest hindered rotation about the P–C(Ph) bond.

In the ^{1}H NMR spectra of **3** and **4**, two doublets with different $^{3}J_{P-H}$ coupling constants [1.09 ppm, $^{3}J_{P-H}$ = 16.8 Hz and 1.65 ppm, $^{3}J_{P-H}$ = 2.8 Hz (**3**); 1.39 ppm, $^{3}J_{P-H}$ = 15.0 Hz and 1.55 ppm, $^{3}J_{P-H}$ = 2.4 Hz (**4**)] are observed for the two inequivalent methyl groups, one of which has a *trans* and the other a *cis* orientation to the lone pair of electrons of the phosphorus atom.

2.3. Molecular structures of $[Fe\{(C_5H_4)CMe_2\}_2PR]$ [R = Ph (**3**), Cy (**4**)]

Yellow needles of **3** and **4** were obtained after recrystallisation from *n*-hexane. Compound **3** (Fig. 1) crystallises in the monoclinic space group $P2_1/n$ with four molecules in the unit cell, and compound **4** (Fig. 2) in the monoclinic space group $C2/c$ with eight molecules in the unit cell. Selected bond lengths and angles are given in Table 1. In both [3]ferrocenophanes, the cyclopentadienyl rings are almost synperiplanar and are nearly parallel [deviation 3.9° (**3**) and 4.6° (**4**)]. The small deviation from being parallel is presumably caused by the phosphanylalkyl bridge. The two methyl groups are inequivalent; one has a *trans* and the other a *cis* orientation to the lone pair of electrons of the phosphorus atom. In **3** the phenyl ring and the cyclopentadienyl rings are almost parallel (deviations: 9.6° and 8.0°).

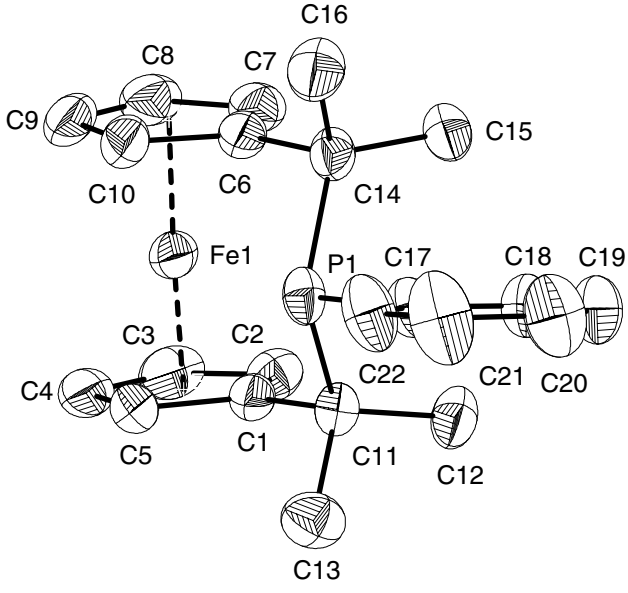

Fig. 1. Molecular structure of [Fe({(η^5-C_5H_4)CMe_2}$_2$PPh)] (**3**) showing the atom-numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP). Hydrogen atoms are omitted for clarity.

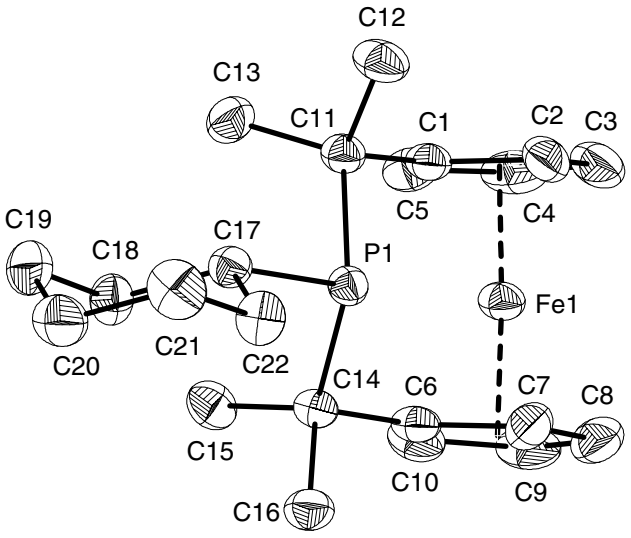

Fig. 2. Molecular structure of [Fe({(η^5-C_5H_4)CMe_2}$_2$PCy)] (**4**) showing the atom-numbering scheme employed (ORTEP plot, 50% probability, SHELXTL PLUS; XP). Hydrogen atoms are omitted for clarity.

2.4. Electrochemistry

Fig. 3 shows the cyclic voltammetric behaviour of [Fe{(η^5-C_5H_4)CMe_2}$_2$PPh] (**3**) in CH_2Cl_2 solution.

As expected for a monoferrocene complex, it undergoes an oxidation process ($E^{o\prime}$ = +0.37 V, versus SCE) with features of chemical reversibility. In fact, analysis of the cyclic voltammetric responses with scan rate increasing from 0.02 to 2.0 V s^{-1} shows that: (i) the current function $i_{pa} \cdot v^{-1/2}$ decreases by about 10% for each 10-fold increase of the scan rate; (ii) the current ratio i_{pc}/i_{pa} remains constantly equal to 1; and (iii) the peak-to-peak separation progressively increases from 76 to 182 mV. These parameters are diagnostic for an electrochemically quasireversible one-electron process which is chemically reversible on the short timescale of cyclic voltammetry [40]. In reality, as deducible from Fig. 3(b)–(d), in the longer timeframe of controlled potential coulometry (E_w = +0.7 V) the process is accompanied by the formation of a new species which in turn undergoes oxidation at higher potential ($E^{o\prime}$ = +0.80 V). On stepwise oxidation, the original yellow solution (λ_{max} = 440 nm) tends to become blue after consumption of 0.7 electrons per molecule (λ_{max} = 690 nm) (Fig. 4); then, after consumption of about 1 electron per molecule, the solution remains blue but the band shows overlap of two close absorptions (λ_{max} = 660 and 690 nm); finally, after consumption of 1.1 electrons per molecule the solution again takes on a yellow colour but absorbs at different wavelengths from the original solution (λ_{max} = 360 nm). On further exhaustive oxidation in correspondence of the second anodic process (E_w = +1.0 V), about two electrons per molecule are consumed. The final solution turns blue again and the spectrum only shows an absorption at λ_{max} = 690 nm.

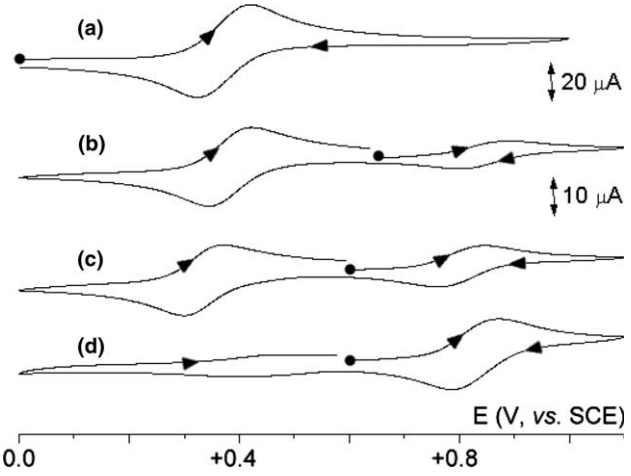

Fig. 3. Cyclic voltammetric responses recorded at a platinum electrode for a CH_2Cl_2 solution of $[Fe\{(\eta^5\text{-}C_5H_4)CMe_2\}_2PPh]$ (**3**) (1.9×10^{-3} mol dm^{-3}) before and after controlled potential coulometry. $[NBu_4][PF_6]$ (0.2 mol dm^{-3}) supporting electrolyte. (a) Original solution; (b) after consumption of 0.7 electrons per molecule; (c) after consumption of 0.9/1.0 electrons per molecule; (d) after consumption of 1.1 electrons per molecule. (●) Starting potential. Scan rate: 0.2 V s^{-1}.

In an attempt to account for such electrochemical behaviour, it is useful to note that the formation of uncharacterised products was also observed in the irreversible oxidation of both the [1]ferrocenophane $[Fe(\eta^5\text{-}C_5H_4)_2PPhMe]^+$ [41] and the [5]ferrocenophane $[Fe\{(\eta^5\text{-}C_5H_4)CH_2CH_2\}_2PPh]$ [13]. In particular, in the latter case, this has been attributed to a dimerisation reaction (with formation of a P–P bond) rather than to formation of the corresponding phosphine oxide $[Fe\{(\eta^5\text{-}C_5H_4)CH_2CH_2\}_2P(O)Ph]$ [13], since the oxidation potential of the by-product arising from the primary process $[Fe\{(\eta^5\text{-}C_5H_4)CH_2CH_2\}_2PPh]^{0/+}$ looks different from that of a crystallographically characterised sample of $[Fe\{(\eta^5\text{-}C_5H_4)CH_2CH_2\}_2P(O)Ph]$. We

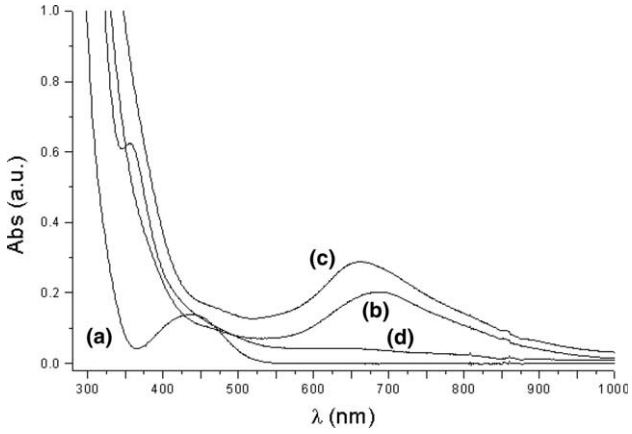

Fig. 4. UV/Vis spectral profiles obtained on stepwise oxidation of $[Fe\{(\eta^5\text{-}C_5H_4)CMe_2\}_2PPh]$ (**3**) (1.9×10^{-3} mol dm^{-3}) in correspondence of the primary anodic process. CH_2Cl_2 solution containing $[NBu_4][PF_6]$ (0.2 mol dm^{-3}) as supporting electrolyte. (a) Original solution; (b) after 0.7 electrons/molecule; (c) after 0.9/1.0 electrons/molecule; (d) after 1.1 electrons/molecule.

note, however, that the comparison of the two oxidation processes was done in different solvents. In our case we are inclined to assign the secondary step as due to the process $[Fe\{(\eta^5\text{-}C_5H_4)CMe_2\}_2P(O)Ph]^{0/+}$, since $[Fe\{(\eta^5\text{-}C_5H_4)CMe_2\}_2PPh]$, even in the solid state, proved to be air-sensitive. This assumption is also supported by the observation that a powdered sample that was not maintained under strictly anaerobic conditions (for about one month) also showed this second oxidation step.

[b] This work.

On this basis, a tentative explanation of the electrochemical data would be that the primarily generated ferrocenium ion $[\mathbf{3}]^+$ reacts with traces of air (or water from the nominally anhydrous solvent) to give $[Fe\{(\eta^5\text{-}C_5H_4)CMe_2\}_2P(O)Ph]^+$, which, because of the inappropriate potential, is reduced to the corresponding ferrocene $[Fe\{(\eta^5\text{-}C_5H_4)CMe_2\}_2P(O)Ph]$; on application of the proper potential, the latter is again oxidised to the corresponding monocation.

Table 3 compiles the redox potentials for the ferrocene/ferrocenium process in a series of phosphaferrocenophanes.

We note that the oxidation of methylated derivatives such as $[Fe\{(C_5H_4)CMe_2\}_2PPh]$, $[Fe(C_5Me_4)_2PPh]$ and $[Fe\{(C_5Me_4)(C_5H_4)\}CH_2PPh]$ occurs at potentials similar to that of unsubstituted ferrocene, and this suggests that the electron-donating ability of the bridging carbon atoms or the cyclopentadienyl methyl groups is attenuated by the electron-withdrawing ability of the PPh group.

3. Experimental

3.1. General

All experiments were carried out under purified dry nitrogen. Solvents were dried and freshly distilled under argon. The NMR spectra were recorded with an AVANCE DRX 400 spectrometer (Bruker), ^{1}H NMR: internal standard TMS; ^{13}C NMR: internal standard TMS; ^{31}P NMR: external standard 85% H_3PO_4. The IR spectra were recorded on an FT-IR spectrometer Perkin–Elmer System 2000 in the range 350–4000 cm^{-1}. MS: MAT 8230 (Finnigan) 70 eV. The melting points were determined in sealed capillaries under nitrogen and are uncorrected (BOETIUS). Materials and apparatus for electrochemistry and spectroelectrochemistry have been described elsewhere [42]. Potential values are referred to the saturated calomel electrode (SCE).

Li_2PR (R = Ph, Cy) were prepared from PH_2R and two equivalents of MeLi. $FeCl_2$ is commercially available.

3.2. Synthesis of dilithiumphenylphosphinobis(dimethylmethylcyclopentadienide), $Li_2[\{(C_5H_4)CMe_2\}_2PPh]$ (**1**)

6,6-Dimethylfulvene (4.33 ml, 36 mmol) was added dropwise to a suspension of Li_2PPh (2.2 g, 18 mmol) in 50 ml of Et_2O and stirred for at least 12 h, during which time the yellow suspension turned colourless. The solid was isolated by filtration, washed 3 times with 30 ml of Et_2O and dried in vacuo. The amount of $Li[(C_5H_4)CMe_2PHPh]$ was determined by ^{31}P NMR spectroscopy. The mixture was dissolved in 30 ml of THF and the appropriate amount of $^{n}BuLi$ (corresponding to the amount of $Li[(C_5H_4)CMe_2PHPh]$) was added. The solvent was evaporated, the residue was suspended in Et_2O and the appropriate amount of 6,6-dimethylfulvene was added. After stirring for 12 h the colourless solid was isolated by filtration, washed with Et_2O and *n*-hexane and dried. Yield: 4.9 g (81.5%) of **1** as a colourless air-sensitive powder. M.p.: 256 °C (decomp.).

^1H NMR (THF-d_8): δ 0.95 (d, $^3J_{P-H}$ = 15.5, 6H, CH_3 in CMe_2), 1.79 (d, $^3J_{P-H}$ = 2.6, 6H, CH_3 in CMe_2), 5.21 (m, 4H, C*H* in C_5H_4), 5.52 (m, 4H, C*H* in C_5H_4), 7.26 (m, 3H, *o*- and *p*-C*H* in Ph), 7.93 (m, 2H, *m*-C*H* in Ph). $^{13}C\{^1H\}$ NMR (THF-d_8): δ 26.20 (d, $^2J_{P-C}$ = 4.1, C–CH_3), 35.50 (d, $^2J_{P-C}$ = 26.5, C–CH_3), 37.40 (d, $^1J_{P-C}$ = 39.4, *C*–CH_3), 102.30 (s, *m*-*C* in C_5H_4), 104.10 (d, $^3J_{P-C}$ = 6.6, *o*-*C* in C_5H_4), 127.58 (d, $^2J_{P-C}$ = 14.1, *ipso*-*C* in C_5H_4), 127.64 (d, $^3J_{P-C}$ = 8.4, *m*-*C* in Ph), 128.50 (s, *p*-*C* in Ph), 136.00 (d, $^2J_{P-C}$ = 14.1, *o*-*C* in Ph), 138 (d, br, $^2J_{P-C}$ = 14.0, *o*-*C* in Ph), 143.80 (d, $^1J_{P-C}$ = 41.9, *ipso*-*C* in Ph). ^{31}P NMR (THF-d_8): δ 42.9, s. ^7Li NMR (THF-d_8): δ = −7.2, s. IR $\tilde{\nu}$ (cm^{-1}): 3074 w (ν(CH) aryl), 2864 m ($\nu(CH_3)$), 1462–1360 m ($\delta(CH_3)$).

3.3. Synthesis of dilithiumcyclohexylphosphinobis-(dimethylmethylcyclopentadienide), $Li_2[\{(C_5H_4)CMe_2\}_2PCy]$ (**2**)

Analogously to the synthesis of **1** from Li_2PCy (1 g, 7.8 mmol) in 50 ml Et_2O and 6,6-dimethylfulvene (1.9 ml, 15.6 mmol). The amount of $Li[(C_5H_4)CMe_2PHCy]$ was determined by ^{31}P NMR spectroscopy. The mixture was dissolved in 30 ml of THF and the appropriate amount of $^{n}BuLi$ (corresponding to the amount of $Li[(C_5H_4)CMe_2PHCy]$) was added. The solvent was evaporated, the residue suspended in Et_2O and the appropriate amount of 6,6-dimethylfulvene added. After stirring for 12 h the colourless solid was isolated by filtration, washed with Et_2O and *n*-hexane and dried. Yield: 2.5 g of **2** (m.p.: 257 °C (decomp.)) as a colourless air-sensitive powder, which contained ca. 30% of $Li[(C_5H_4)CMe_2PHCy]$. Attempts to further purify **2** failed. Therefore the mixture was employed in the synthesis of **4**.

^{31}P NMR (THF-d_8): δ 54.0, s.

3.4. Synthesis of [bis(cyclopentadienyldimethylmethyl)-phenylphosphino]ferrocenophane, $[Fe\{(C_5H_4)CMe_2\}_2PPh]$ (**3**)

Solid **1** (1.2 g, 3.6 mmol) was added in small portions to a suspension of $FeCl_2$ (0.46 g, 3.6 mmol) in 50 ml of THF. The solution turned yellow to brown. After stirring overnight the solvent was evaporated and 50 ml of Et_2O was added to the remaining brown oil, giving a brown solid and an orange solution. The solution was filtered over dry Al_2O_3, and the residue washed repeatedly with Et_2O until the washings were colourless. The Et_2O fractions were combined and the solvent evaporated. Fifty millilitres of hexane was added to the residue, filtered and the hexane evaporated leaving 1.0 g (74%) of **3** as an orange powder. Yellow crystals were obtained from a concentrated solution of **3** in *n*-hexane at −20 °C. M.p.: 143 °C.

^1H NMR ($CDCl_3$): δ 1.09 (d, $^3J_{P-H}$ = 16.8, 6H, CH_3 in CMe_2), 1.65 (d, $^3J_{P-H}$ = 2.8, 6H, CH_3 in CMe_2), 4.05 (s, 2H, C*H* in C_5H_4), 4.16 (s, 2H, C*H* in C_5H_4), 4.19 (s, 2H, C*H* in C_5H_4), 4.41 (s, 2H, C*H* in C_5H_4), 7.42 (m, 3H, *o*- and *p*-C*H* in Ph), 7.86 (m, 2H, *m*-C*H* in Ph). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 24.3 (d, $^2J_{P-C}$ = 5.0, C–CH_3), 31.7 (d, $^2J_{P-C}$ = 33.9, C–CH_3), 32.1 (d, $^1J_{P-C}$ = 22.3, *C*–CH_3), 67.0 (d, $^4J_{P-C}$ = 2.1, *C*H in C_5H_4), 67.2 (d, $^4J_{P-C}$ = 2.5, *C*H in C_5H_4), 68.8 (d, $^3J_{P-C}$ = 6.2, *C*H in C_5H_4), 95.0 (d, $^2J_{P-C}$ = 12.4, *ipso*-*C* in C_5H_4), 127.8 (d, $^3J_{P-C}$ = 8.3, *m*-*C* in Ph), 129.0 (s, *p*-*C* in Ph), 136.7 (d, $^2J_{P-C}$ = 23.9, *o*-*C* in Ph), 137.8 (d, $^1J_{P-C}$ = 34.7, *ipso*-*C* in Ph). ^{31}P NMR ($CDCl_3$): δ = 50.5, s. IR (KBr), $\tilde{\nu}$ (cm^{-1}): 3077 m (ν(CH) aryl), 2969 s ($\nu(CH_3)$), 1431 br, m ($\delta(CH_3)$), 1359 m (ν(CC) in C_5H_4). EI-MS: *m*/*z* = 376 (100%, M^+), 268 (69%, M^+ − PPh), and fragmentation products thereof. *Anal.* Calc. for $C_{22}H_{25}PFe$ (376): C, 70.2; H, 6.7; P, 8.2. Found: C, 70.1; H, 5.1; P, 7.6%.

3.5. Synthesis of [bis(cyclopentadienyldimethylmethyl)-cyclohexylphosphino]ferrocenophane, $[Fe\{(C_5H_4)CMe_2\}_2PCy]$ (**4**)

The mixture containing **2** (0.50 g, 1.47 mmol) and $Li[(C_5H_4)CMe_2PHCy]$ (0.15 g, 0.65 mmol), obtained as described above, was added as a solid in small portions to a suspension of $FeCl_2$ (0.23 g, 1.8 mmol) in 25 ml of THF. The solution turned yellow, then brown and finally almost black. After stirring overnight the solvent was evaporated and 50 ml of Et_2O was added to the remaining black oil giving a brown solid and an orange solution. The solution was filtered over dry Al_2O_3, and the residue washed repeatedly with Et_2O until the washings were colourless. The Et_2O fractions were combined and the solvent evaporated. The residue was recrystallised from 10 ml of *n*-hexane giving 0.27 g (48%) of **4** as yellow crystals. M.p.: 188 °C.

^{1}H NMR ($CDCl_3$): δ 1.2–1.9 (br, m, 11H, C*H* and CH_2 in Cy), 1.39 (d, $^3J_{P-H}$ = 15.0, 6H, CH_3 in CMe_2), 1.55 (d, $^3J_{P-H}$ = 2.4, 6H, CH_3 in CMe_2), 3.99 (s, 2H, C*H* in C_5H_4), 4.04 (s, 2H, C*H* in C_5H_4), 4.09 (s, 2H, C*H* in C_5H_4), 4.27 (s, 2H, C*H* in C_5H_4). $^{13}C\{^1H\}$ NMR ($CDCl_3$): δ 24.92 (d, $^2J_{P-C}$ = 4.2, C–*C*H_3), 26.49 (s, *C*4 in Cy), 28.85 (d, $^3J_{P-C}$ = 9.3, *C*3 in Cy), 32.43 (d, $^2J_{P-C}$ = 31.9, C–*C*H_3), 32.65 (d, *C*–CH_3, $^2J_{P-C}$ = 26.5), 34.40 (d, J_{P-C} = 15.2, *C*2 in Cy), 38.84 (d, $^1J_{P-C}$ = 35.0, *C*1 in Cy), 66.37 (d, $^4J_{P-C}$ = 2.7, *C*H in C_5H_4), 66.86 (d, $^4J_{P-C}$ = 2.0, *C*H in C_5H_4), 68.66 (d, $^3J_{P-C}$ = 8.4, *C*H in C_5H_4), 68.75 (s, *C*H in C_5H_4), 96.2 (d, $^2J_{P-C}$ = 11.3, *ipso-C* in C_5H_4). ^{31}P NMR ($CDCl_3$): δ 67.8, s. IR (KBr), $\tilde{\nu}$ (cm^{-1}): 2970 s ($\nu(CH_3)$), 1444 br, m ($\delta(CH_3)$), 1359 m (ν(CC) in C_5H_4). EI-MS: *m*/*z* = 382 (26%, M^+), 267 (100%, M^+ – PCy), and fragmentation products thereof. *Anal*. Calc. for $C_{22}H_{31}PFe$ (382): C, 69.1; H, 8.2. Found: C, 68.5; H, 7.3%.

3.6. Data collection and structural refinement of **3** and **4**

Data (λ(Mo Kα) = 0.71073 Å) were collected with a Siemens CCD (SMART) diffractometer. All observed reflections were used for refinement (SAINT) of the unit cell parameters. Empirical absorption correction was applied with SADABS [43]. The structures were solved by direct methods (SHELXTL PLUS) [44]. Fe, P and C atoms were refined anisotropically; H atoms were located by difference maps and refined isotropically. Table 2 lists crystallographic details.

4. Supplementary material

CCDC 266919 (**3**) and 266918 (**4**) contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from the Cambridge Crystallographic Data Centre (CCDC), 12 Union Road, Cambridge CB2 1EZ, UK via www.ccdc.cam.ac.uk/data_request/cif, e-mail: deposit@ccdc.cam.ac.uk.

copolymer results in significant increase in viscoelastic, mechanical properties and compatibility of ES copolymers with LLDPE [7]. Additionally, ES copolymers contain syndiotactic styrene dyads, which enhance the thermal properties, as syndiotactic polystyrene is known to have a T_m of 273 °C.

Other discoveries put forth regarding piano-stool catalysts include the effect that substitution of alkyl groups on the cyclopentadienyl ring and of the halides on the titanium catalyst center for various substituents has on the copolymerization of ethylene and α-olefins. Most significant to this work are Nomura's publications on the aryloxy substituted $CpTi(R)_2OAr$ complexes [8–13]. The authors found that by substituting one of the halide groups on the Ti catalyst center with an aryloxy group, polyethylene, poly(ethylene-*co*-1-butene), and poly(ethylene-*co*-styrene) could be obtained with reasonable activity, molecular weight, polydispersity, and comonomer distribution [8–13].

There is a significant commercial drive to combine the inherent advantages of SSC catalysts (high activity, control over monomer reactivity and polymer structure control) with the attributes of supported catalyst technology (morphology and high bulk density control) [14]. With this in mind, piano-stool catalysts have been supported on a variety of substrates including, but not limited to, lightly cross-linked polystyrene beads [15], alumina or $MgCl_2$ [14], butyl ethylmagnesium treated silica [14], mesoporous silica [16], and (4-hydroxystyrene)-styrene (HPS) copolymers [17].

In this work, various piano-stool catalysts were reacted with a (4-hydroxystyrene) styrene copolymer (HPS), in essence creating bulky aryloxy substituents (macroligand). We have previously shown that the presence of the macroligand is vital for the production of butyl branched polyethylene produced during ethylene homopolymerization [18]. More importantly, the support should be regarded as a part of the ligand–metal environment. Hence, chemical and structural changes to the support affect the overall performance of the piano-stool complex bound to the HPS support [18]. In this paper, the use of macroligated catalysts for the copolymerization of ethylene with 1-octene and styrene has been explored. The effect of using the macroligated catalysts with appropriate cocatalysts for ethylene/α-olefin copolymerization on the molecular weight, branch content, melting temperature, degree of crystallinity, and copolymer microstructure has been analyzed in detail.

2. Experimental

2.1. Reagents and general techniques

All reactions were performed under nitrogen in Schlenk glassware or in an inert atmosphere dry box. All solvents used were obtained from a solvent manifold [19]. Titanium tetrachloride, bis(trimethylsilyl)cyclopentadiene, 2,5,5-tris(trimethylsilyl)-1,3-cyclopentadiene, cyclopentadienyltitanium trichloride, pentamethyl-cyclopentadienyltitanium trichloride, styrene, 4-acetoxy styrene, AIBN, tetrahydrofuran, and hydrazine hydrate were obtained from Aldrich. AIBN was recrystallized from acetone, and styrene was distilled over calcium hydride. Methyl aluminoxane (MAO, 30 wt% (4.7 M) in toluene) was generously supplied by Albemarle. The copolymerizations were performed using heavy-walled glass reactors and a polymerization manifold [20]. The styrene-*co*-hydroxy styrene (HPS, macroligand) and the supported aryloxy cyclopentadienyltitanium trichloride complexes were synthesized as previously reported [18].

2.2. Instrumentation

^{13}C NMR spectra of the polyolefins in tetrachloroethylene-d_2 were recorded at 150 MHz on an Avance DPX 600 using a quantitative pulse program for solution NMR at 135 °C. Gel permeation chromatography (GPC) of the polyolefins was performed with a Polymer Laboratories PL-220 high temperature GPC equipped with a Wyatt MiniDawn (620 nm diode laser) high temperature light scattering detector and refractive index detector. Experiments were performed at 135 °C using 1,2,4-trichlorobenzene as solvent, and results were based on calibration with polystyrene standards. The dn/dc value for polyethylene used was −0.11. Thermal analyses were performed using a TA differential scanning calorimeter (DSC) 2910 equipped with liquid nitrogen cooling accessory unit. Experiments were performed under a continuous nitrogen purge (50 mL/min) with a heating and cooling scan rate of 10 °C/min.

3. General procedure for supported catalyst preparation (HPS-Ti-1 to -4)

Synthesis of the support matrix poly(styrene-*r*-4-hydroxystyrene (HPS)) and subsequent assembly of the aryloxy piano stool complex on HPS was carried out in the glovebox using precursor catalysts (**1**–**4**) as previously reported [18,21]. The support contains 0.3 mol% hydroxystyrene, as determined by ^1H NMR. The supported catalysts were analyzed via elemental analysis in order to determine the weight percent of Ti, as well as the ratio of Cl:Ti. For all cases, it was determined that the Cl:Ti ratio was between 1 and 2, meaning that the most prevalent forms of the supported catalysts were Form A and Form B (Fig. 1). Although a Form C (containing three bonds to the macroligand) is not ruled out, the authors believe that this form would be sterically hindered. The reaction of the homogeneous

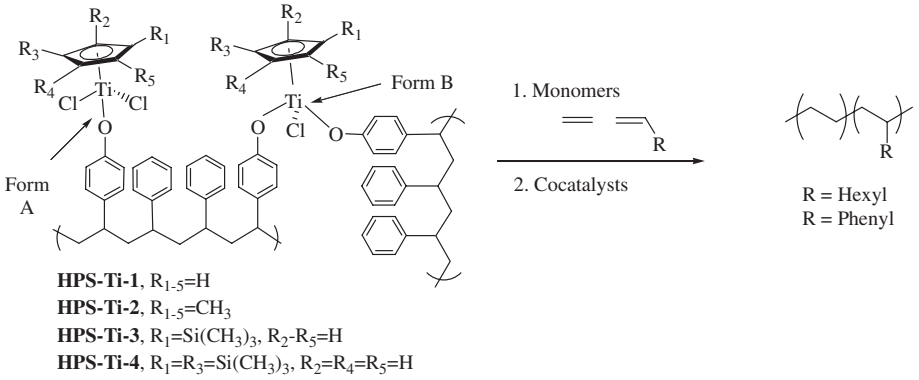

Fig. 1. Synthesis of ethylene/α-olefin random copolymers using supported aryloxy piano stool complexes.

catalysts with the support was observed to form a gel, which further supports the crosslinked structure outlined in Fig. 1. Independent confirmation of the proposed supported structure was obtained via ^{1}H and ^{13}C NMR. The ^{1}H NMR displays a downfield shift for the trimethylsilyl protons from δ 0.2 for the precursor of **HPS-Ti-4** to δ 0.4 ppm for **HPS-Ti-4**. Further confirmation of the presence of Forms A and B was obtained from the ^{13}C NMR of **HPS-Ti-4**, which displays two peaks in the trimethylsilyl region at δ −0.1 (Form A) and δ 1.5 ppm (Form B).

4. Synthesis of mono(phenoxy)(trimethylsilylcyclopentadienyl) titanium(IV) dichloride (5)

To a mixture of 10.0 mL of dichoromethane and (trimethylsilyl)cyclopentadienyltitanium trichloride (**3**, 102 mg, 0.34 mmol), phenol (32 mg, 0.35 mmol) was added slowly with constant stirring, The reaction was allowed to proceed at room temperature for a period of 12 h. The solvent was removed in vacuo, affording an orange solid (110 mg, 82% yield).

^{1}H NMR ($CDCl_3$): 0.4 (s, 9H, $Si(CH_3)_3$), 6.8 (t, 2H), 7.1 (t, 2H), 7.0–7.4 (m, 5H, C_6H_5).

^{13}C NMR ($CDCl_3$, CPD): −0.2, 118.8, 124.6, 123.9, 126.9, 128.6, 129.8, 137.5, 168.3.

5. Synthesis of bis(phenoxy)(trimethylsilyl-(cyclopentadienyl)) titanium(IV) chloride (6)

To a solution of 10.0 mL of toluene and (trimethylsilyl)cyclopentadienyltitanium trichloride (**3**, 102 mg, 0.34 mmol), phenol (75 mg, 0.7 mmol) was added slowly with constant stirring, and the reaction mixture was refluxed for a period of 1 day. The solvent was removed in vacuo, affording a red solid in 90% yield.

^{1}H NMR ($CDCl_3$): 0.3 (s, 9H, $Si(CH_3)_3$), 6.6–7.4 (m,14H, C_6H_5, C_5H_4).

^{13}C NMR ($CDCl_3$, CPD): 0.0, 115.7, 118.9, 121.5, 123.2, 126.3, 130.1, 133.7, 167.6.

6. Copolymerization of ethylene and 1-octene

To a mixture of 10.0 mL of toluene and 1.7 mL of 30 wt% of MAO in toluene in a polymerization reactor, 38.2 mg of **HPS-Ti-1** was added. To this system, 1-octene (5 mL) was added, and ethylene (60 psig) was supplied for 15 min with stirring. The ethylene supply was stopped and the reactor was vented to remove excess ethylene, the reaction mixture was quenched with 10% hydrochloric acid–methanol mixture and the polymer was collected by filtration and dried in vacuo overnight resulting in ethylene/1-octene copolymer (Table 1,

Table 1

entry 1). For copolymerizations catalyzed with an unsupported catalyst, conditions were identical to the supported catalyst systems, however, only 3–5 mg of the catalyst were used (Table 1, entries 5–7).

7. Homopolymerization of styrene

To 50 mL round bottom flasks equipped with magnetic stirbars, 10.5 mL of distilled toluene, 25–30 mg of the supported catalyst, and 1.7 mL of MAO were added. (Al:Ti ratios for **HPS-Ti-1** and **HPS-Ti-2** were 600, while **HPS-Ti-3** was 1000 and **HPS-Ti-4** was 1400. The amount of MAO was increased for **HPS-Ti-3** and **-4**, as we knew that the homogeneous precursors were much less active.) After sealing with septa, the charged flasks were removed from the glovebox and placed on magnetic stirrers. At zero minutes reaction time, 3.0 mL (0.026 mol) of distilled styrene (which had been loaded in syringes in the glovebox) were added to each flask. If gelation did not occur within a few minutes, the reaction was allowed to proceed for 50–60 min. The reaction mixture was quenched with 10% hydrochloric acid–methanol mixture, and the polymer was collected by filtration and dried in vacuo overnight.

8. Copolymerization of ethylene and styrene

To a 12 fluid ounce glass reactor, 75 mL of distilled toluene, 25–30 mg of supported catalyst, and 1.7 mL of MAO were added. (Al:Ti ratios were the same as for the styrene polymerization.) The reactor was then fitted with the mechanical stirring apparatus and reactor head. To a 25 mL side-port on the reactor head, 21.5 mL (0.188 mol) of distilled styrene were added. The entire closed system was then removed from the glove box and attached to a medium pressure line and mechanical stirrer [20]. After flushing the system, the reactor was pressurized to 60 psig with ethylene gas. At this point, the styrene was added by back-pressuring the side port of the reactor with nitrogen. The nitrogen line was then detached from the reactor, and the excess nitrogen in the reactor was vented out of the side port. The reactor was then repressurized with ethylene, and the reaction was allowed to proceed for 1.5 h. The reaction mixture was quenched with 10% hydrochloric acid–methanol mixture and the polymer was collected by filtration and dried in vacuo overnight.

9. Results and discussions

We have designed synthetic schemes to tether pianostool complexes on hydroxy-functionalized polystyrene supports (HPS) in order to study the influence of the support matrix on the catalyst performance and the properties of the resulting polyolefin [18]. Additionally, we studied how the substituents on the cyclopentadienyl ring affect both the amount of comonomer incorporated into the copolymer and also the microstructure of the copolymer. These effects on polymer yield, activity, weight average molecular weight (M_w), polydispersity index (PDI), melting point (T_m), and percent comonomer incorporation are outlined in Tables 1–3.

Table 2
Homopolymerization of styrene

9.1. Ethylene/1-octene copolymers

During ethylene homopolymerizations, the supported aryloxy complexes (**HPS-Ti-1** to **-4**), in conjunction with different cocatalysts (MAO, tris(pentafluorophenyl)borane, dimethylanilinium borate, trityl borate), afford linear or branched polyethylenes from an ethylene only feed. The production of butyl branched polyethylene from an ethylene only feed has been attributed to 1-hexene produced from an ethylene trimerization process triggered by the use of macroligated catalysts [18]. In order to determine the effect of the macroligand on the properties of LLDPE, ethylene and 1-octene copolymerizations were performed using the macroligated catalysts (**HPS-Ti-1**–**4**) and MAO as the cocatalyst. It was

observed that for the ethylene/1-octene copolymers, **HPS-Ti-3** and **HPS-Ti-1** show higher activity than **HPS-Ti-2** and **HPS-Ti-4**. Also, **HPS-Ti-3** affords higher levels of 1-octene incorporation compared to the other three macroligated catalysts. The copolymers synthesized from these supported catalysts are of moderately high molecular weights (Table 1, entries 1–4).

For 1-octene incorporation, the trend followed **HPS-Ti-3** > **HPS-Ti-2** > **HPS-Ti-4**. The trend in the molecular weight of the ethylene/1-octene copolymer was found to be **HPS-Ti-4** > **HPS-Ti-3** > **HPS-Ti-1** > **HPS-Ti-2**. The trends observed in the activity and the molecular weight of the copolymer produced from the macroligated catalysts agree well with the results obtained by Nomura and co-workers. These authors have shown that in the case of non-bridged cyclopentadienyl aryloxy titanium species like ^{t}BuCp, $(CH_3)_5$Cp, and $(^{t}Bu)_2$Cp, the Cp–Ti–O bond angle changes from 117.6°, 120.5° and 119.3° [9,22,23]. For 1-hexene incorporation, the activity of the substituents has been shown to follow the trend: ^{t}Bu Cp > $(CH_3)_5$Cp > $(^{t}Bu)_2$Cp. On the other hand, the molecular weight for the copolymer is highest for $(^{t}Bu)_2$Cp followed by the ^{t}Bu and the $(CH_3)_5$Cp analogues. Nomura and co-workers [9,22,23] have attributed the observed trends in activity and molecular weight of the ethylene/hexene copolymer produced to the rotational flexibility of the subsituents on the cyclopentadienyl ring.

Another interesting feature is that the formation of ethylene/octene-based copolymers using supported aryloxy-based cyclopentadienyl complexes can also be used as additional evidence for the presence of the tethered aryloxy moiety. A previous control polymerization performed with complex **3**, MAO as the cocatalyst, and ethylene and 1-octene in the monomer feed produced HDPE (Table 2, entry 5). On the other hand, the use of small molecular analogues **5** and **6** with MAO resulted in the formation of ethylene/1-octene copolymers (LLDPE) from ethylene and 1-octene copolymerization (Table 1, entries 6 and 7, respectively).

9.2. Copolymer microstructure analysis of ethylene/octene copolymers obtained from macroligated catalysts

In order to determine the copolymer composition of the copolymers synthesized, ^{13}C NMR of the copolymers was performed at 135 °C. The ^{13}C NMR resonances of the copolymer synthesized from complex **HPS-Ti-1** were analyzed. The spectrum is similar to that reported by Cavagna [24,25], and hence low level of octene incorporations were expected. The nomenclature for carbon assignments, monomer sequence distribution and equations relating signal intensity to the sequences as reported by Randall were used to identify the branches in ^{13}C NMR of the polyolefin [25]. The ^{13}C peak resonances were assigned as 14.19 ($1s + 1B_6$, CH_3, EOE + EOO + OOE + OOO), 22.85 ($2s + 2B_6$,

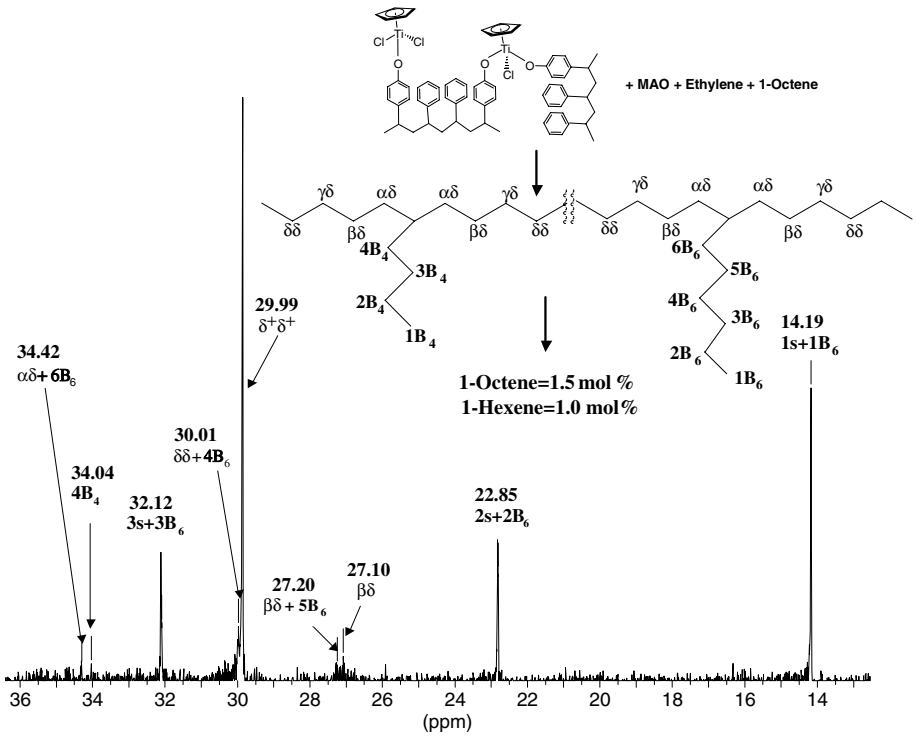

Fig. 2. ^{13}C NMR composite pulse decoupling (CPD) spectrum of ethylene/octene copolymer synthesized from complex **HPS-Ti-1** with MAO as the cocatalyst.

EOE + EOO + OOE + OOO), 27.10 (βδ, OOEE + EEOO), 27.20 (βδ + $5B_6$, EOE), 29.99 (δδ, EEE), 30.01 (δδ + $4B_6$, EEE), 32.12 (3s + $3B_6$, EOE), 34.04 ($4B_4$, EHE), 34.42 (αδ + $6B_6$, EOEE + EEOE), and 38.01 (CH, EOO + OOE, methine), as shown in Fig. 2. A quantitative relationship between signal intensity to monomer sequences was established to quantify the 1-octene incorporated in the copolymer [25]. The 1-octene content, calculated from the ratio of the sum of the octene-centered sequences to that of all the sequences, was determined to be 1.5 mol%. The presence of a $4B_4$ branch (butyl branch) was also observed. This can be attributed to the 1-hexene formed by ethylene trimerization and further incorporation of 1-hexene into the copolymer. The resonances $4B_4$ and (αδ + $6B_6$) were used to quantify the ratio of hexene (1.0 mol%) and octene (1.5 mol%) incorporated into the ethylene chain.

The microstructure of ethylene/octene copolymer obtained from complexes **HPS-Ti-2** and **HPS-Ti-3** were also analyzed and assigned as δ 14.22 (1s + $1B_6$, EOE + EOO + OOE + OOO), 22.87 (2s + $2B_6$, EOE + EOO + OOE + OOO), 26.95 (βδ, OOEE + EEOO), 27.05 (βδ + $5B_6$, EOE), 29.97 (δδ, EEE), 32.21 (3s + $3B_6$, EOE), 34.51 (αδ + $6B_6$, EOEE + EEOE), and 38.04 (CH, methine). The α-olefin incorporation in the copolymers obtained from **HPS-Ti-2** and **HPS-Ti-3** were estimated to be 2.5 and 3.8 mol%, respectively, as established by ^{13}C NMR. These values are corroborated by the observed depression in melting point. The microstructure of ethylene/octene copolymers from the macroligated catalysts (**HPS-Ti-1** to **3**) is similar to the microstructure of copolymers obtained from non-bridged cyclopentadienyl aryloxy complexes [23].

9.3. Ethylene/styrene copolymers

Homopolymerizations of styrene with the supported catalysts **HPS-Ti-1** to **-4** and assorted cocatalysts (MAO, tris(pentafluorophenyl)borane, dimethylanilinium borate, trityl borate) were performed in order to determine any differences between the catalysts and to discern if they would yield syndiotactic polystyrene as do the unsupported analogues. Table 2 shows that these polymerizations did indeed yield syndiotactic polystyrene with varying activities, molecular weights and polydispersities. Overall, polymerizations cocatalyzed with MAO display higher yields than those polymerized with a borane as the cocatalyst. The DSC results show that runs with **HPS-Ti-2**, **-3**, and **-4** contain the expected melting temperature at 270 °C, which is associated with syndiotactic polystyrene. The polystyrene obtained with **HPS-Ti-1**, however, lacks the melting transition around 270 °C. Also, the GPC data indicates significantly lower molecular weight and a multimodal distribution. The data indicate that the polystyrene produced with catalyst **HPS-Ti-1** is neither completely syndiotactic nor does it have uniform molecular weight. This may be due to leaching of the precursor catalyst from the supported catalyst, **HPS-Ti-1**. As the precursor to this supported catalyst ($CpTiCl_3$) is known to produce syndiotactic polystyrene in high yield and purity, the macroligand form of the catalyst displays an obvious and significant effect on the polymer properties.

Xu et al. [17] reported similar styrene polymerization results with $CpTiCl_3$, which had been supported onto a polystyrene terpolymer containing hydroxy and methoxy moieties. While our reaction conditions are comparable, it is apparent that the melting point data that we obtained for entry 8 corresponds to the production of polystyrene with higher syndiotactic content. This further supports our argument that the use of macroligated catalysts is an additional tuning parameter in dictating the characteristics of the resulting polymer.

Additionally, entry 9 displays that the polystyrene produced with **HPS-Ti-2** was obtained with activity that was two to three orders of magnitude lower than the rest of the catalysts. It is widely known and accepted that the precursor, Cp^*TiCl_3, produces syndiotactic polystyrene in high yield and activity. This phenomenon further illustrates the effect that the macroligand imparts on the catalyst's ability to polymerize styrene. Polymerizations with the borane cocatalyst system produced very similar results with respect to catalyst activity, polymer yield, and melting behavior, thereby ensuring this result is neither an anomaly nor dependent upon the cocatalyst system employed.

Polymerization of ethylene and styrene with the supported catalysts **HPS-Ti-1** to **-4** and MAO catalyst system produced very interesting results, Table 3. As with the styrene homopolymerization, very similar results were obtained with the borane cocatalyst system. It is evident that activity shows a marked decrease with the introduction of the ethylene comonomer. Although no trend is evident from yield and activity results with respect to cyclopentyl substituents, it is apparent from the DSC analysis that each supported catalyst produced very different polymers. In entries 12 and 14, the data is consistent with the presence of a reactor blend of polyethylene and syndiotactic polystyrene. Entry 13, however, suggests that only polyethylene is produced. A degree of crystallinity of 13.4% was calculated by dividing the heat of fusion value for the polyethylene melting by the total heat of fusion for a perfect polyethylene crystal (293 J/g) [26]. Finally, data in entry 15 suggest that only syndiotactic polystyrene is produced. This can also be seen in the DSC chromatogram (Fig. 3).

Analysis of the homopolymerizations of ethylene and styrene sheds some light on the polymer composition of entries 13 and 15. For the homopolymerization of styrene, **HPS-Ti-2** is clearly a poor performer, as the activity of this polymerization is two to three orders lower

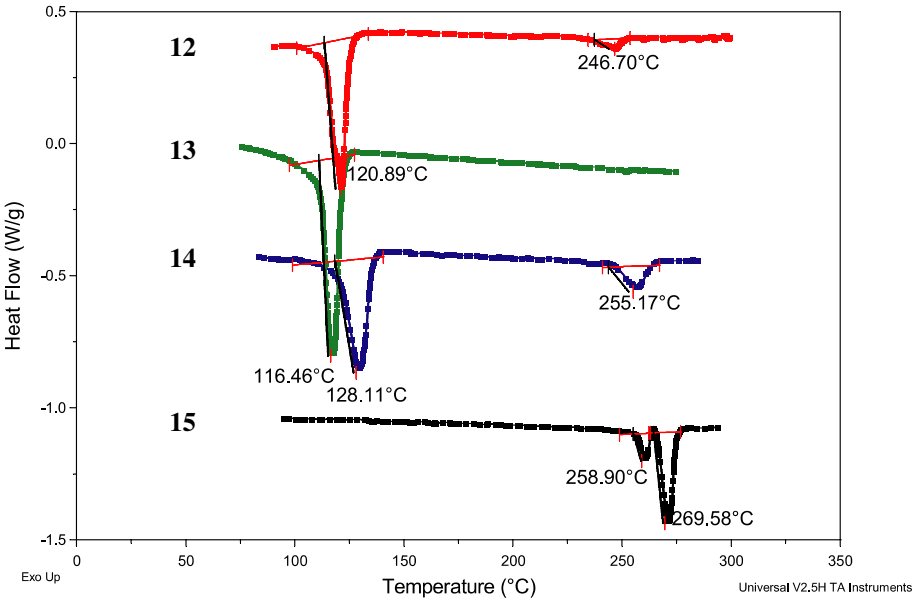

Fig. 3. Differential scanning calorimetry chromatograms of entries 12–15 (before extraction).

than that of the other catalysts employed. For this reason, it is expected that **HPS-Ti-2** would preferentially polymerize ethylene in copolymerization conditions with styrene. Indeed, the DSC chromatogram of the polymer obtained with **HPS-Ti-2** in the presence of ethylene and styrene monomers is consistent with the production of polyethylene.

Similarly, **HPS-Ti-4** displays a remarkably lower activity for the homopolymerization of ethylene than the other catalysts employed in this study [18]. Using this information in conjunction with the styrene homopolymerization results from Table 2, it is possible to predict that **HPS-Ti-4** would only polymerize styrene in copolymerization conditions with ethylene. As predicted, the entry 15 data and the DSC chromatogram display a preferential polymerization of styrene.

HPS-Ti-1 and **HPS-Ti-3** display sufficiently high activities in homopolymerizations of ethylene and styrene, and therefore it is conceivable that they would produce either a copolymer or a reactor blend of two homopolymers. Evidence of such a blend of homopolymers was detected through DSC and NMR analyses.

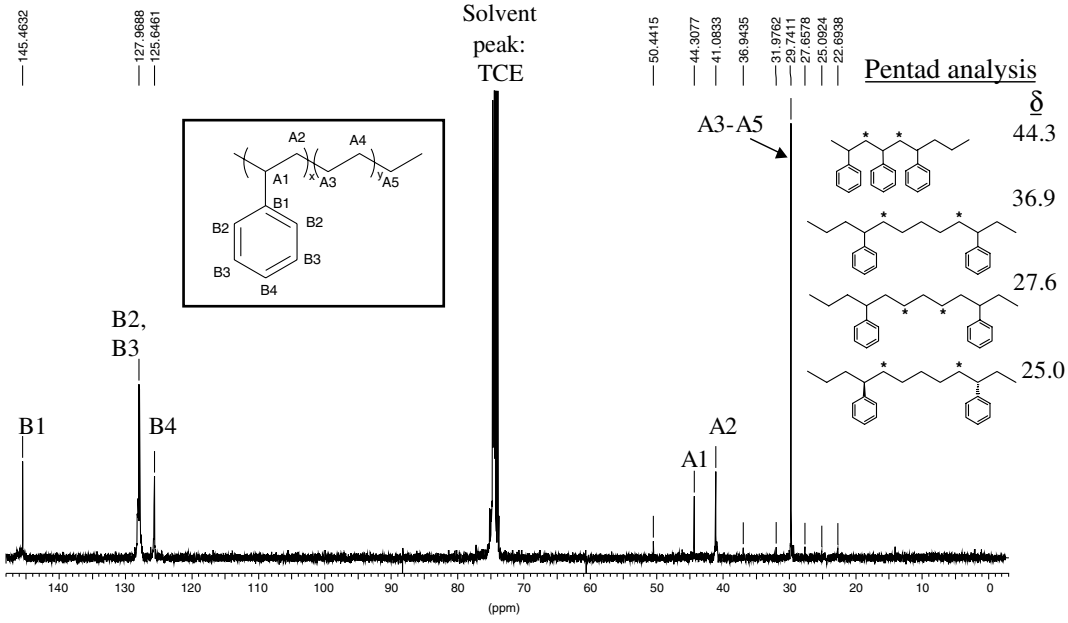

Fig. 4. ^{13}C NMR of entry 14.

Sequential Soxhlet extractions in methyl ethyl ketone (MEK) and tetrahydrofuran (THF) were performed on the entry 12 sample, in order to determine the relative amounts of atactic polystyrene, random ethylene/styrene copolymer, and polyethylene that were present. These results indicate that there is a significant amount of atactic polystyrene (MEK-soluble, >50%), random ES copolymer (THF-soluble, 11%), and polyethylene (THF-insoluble, 32%, $T_m = 132$ °C). Entry 14 was analyzed via ^{13}C NMR, as insufficient yield did not allow for Soxhlet extraction. As shown in Fig. 4, significant resonances in the NMR were consistent with syndiotactic polystyrene and polyethylene. Peaks consistent with the presence of an ES copolymer are of very low intensity, suggesting that an insignificant amount of the sample consists of random ES copolymer. The NMR and DSC data of entry 14 indicate the presence of two homopolymers: syndiotactic polystyrene and polyethylene.

Due to insufficient yield quantities, Soxhlet extractions could not be performed on entries 13 or 15. While DSC results of entry 15 are consistent with syndiotactic polystyrene, DSC results of entry 13 cannot conclusively determine whether or not a significant portion of the sample contains atactic polystyrene.

In summary, there seems to be a notable macroligand effect on the homopolymerization of styrene and the copolymerization of ethylene and styrene. This is clearly demonstrated in the decrease of the melting temperatures for the polystyrene. For the copolymerizations, it is evident that although the variety of substituents on the cyclopentadienyl ring does not have a correlation with the polymer composition, there is clearly another effect that causes these catalysts to produce different copolymer compositions. This effect is demonstrated through the supported catalysts behavior in homopolymerizations of styrene and ethylene. As the results are mirrored with the borane cocatalyst system, we believe that they are true results and not merely anomalies.

10. Conclusions

In order to study the influence of the support matrix on the catalyst performance and the properties of the resulting polyolefin, macroligated aryloxy titanium complexes (**HPS-Ti**) were prepared. In this paper, the effect of the macroligand on ethylene and α-olefin (1-octene or styrene) copolymerization using aryloxycyclopentadienyl macroligated catalysts were studied.

LLDPE has been synthesized from ethylene and 1-octene feed using supported aryloxycyclopentadienyltitanium complexes. The activity of the supported catalysts for copolymerization and the amount of 1-octene incorporated into the copolymer is dependent upon the substituents on the cyclopentadienyl ring. The microstructure of the copolymers was determined using ^{13}C NMR and shows random incorporation of the octene comonomer. The formation of ethylene/1-octene copolymers using supported aryloxy-based cyclopentadienyl complexes can also be used as additional evidence for the presence of the tethered aryloxy moiety, since the precursor piano-stool complex affords HDPE during attempted copolymerization. (Due to the incorporation of the comonomer, the melting points (T_m) and the enthalpy of fusion (ΔH) of the copolymers is depressed as determined by DSC.)

We have also explored the effect of supported single-site catalysts on styrene and ethylene/styrene polymerizations. Polymerizations with each of the supported catalysts, (**HPS-Ti-1** to **-4**) were carried out with MAO and borane cocatalysts. The MAO and borane cocatalyst systems produced very similar results.

DSC analysis displayed that **HPS-Ti-1** produced polystyrene with lower syndiotactic content than the precursor catalyst, indicating the presence of a strong macroligand effect. DSC analysis also showed that polymer composition varies greatly with the specific supported catalyst. Polymerizations of ethylene and styrene via **HPS-Ti-1** and **HPS-Ti-3** display both polyethylene and syndiotactic polystyrene melting behavior, while polymerizations of ethylene and styrene via **HPS-Ti-2** and **HPS-Ti-4** produce melting temperatures consistent with polyethylene or syndiotactic polystyrene, respectively. Based on homopolymerization data with styrene and ethylene, the phenomenon of different catalysts producing vastly different polymer compositions in copolymerization conditions was proscribed to the fact that certain supported catalysts preferentially polymerize ethylene or styrene.

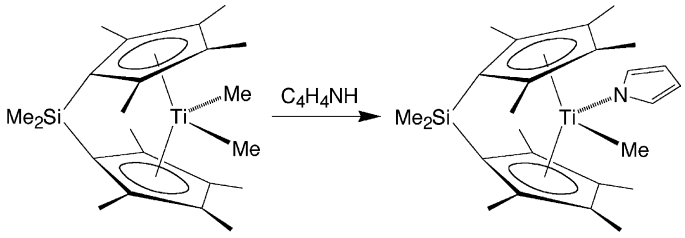
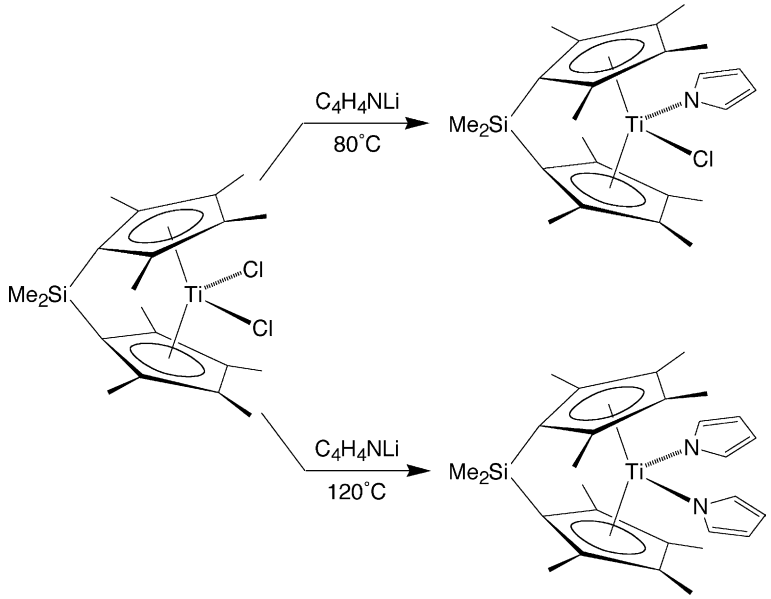


Scheme 1.

$Cp_2Ti(NC_4H_4)_2$ [8] are monodentate because the cyclopentadienyl ligand coordinates more effectively in an η^5-mode than does the pyrrolyl ligand, an observation attributed to the sp^2-lone pair electrons on nitrogen being higher in energy than those involved in the π-system of the pyrrolyl anion [4b,9,10]. In this paper we provide further examples of this uncommon class of molecules that feature the Ti—NC_4H_4 moiety by describing the synthesis, structure and reactivity of a series of *ansa* titanocene complexes, namely $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)X$ (X = H, Me, Cl, NC_4H_4) and $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$.



2. Results and discussion

2.1. Synthesis and structural characterization of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)X$ (X = Me, Cl, NC_4H_4)

As noted above, there is a paucity of well-defined titanium pyrrolyl compounds, with the only structurally characterized Ti—NC_4H_4 compound listed in the Cambridge Structural Database [11] being $Cp_2Ti(NC_4H_4)_2$ [8a]. Access to a series of *ansa* titanocene pyrrolyl compounds is, however, readily provided via two synthetic procedures, namely (i) the reaction of

Scheme 2.

Scheme 3.

the dimethyl compound $[Me_2Si(C_5Me_4)_2]TiMe_2$ [12] with pyrrole, C_4H_4NH (Scheme 2) and (ii) the reaction of the dichloride $[Me_2Si(C_5Me_4)_2]TiCl_2$ [13] with the lithium derivative $LiNC_4H_4$ (Scheme 3). Thus, $[Me_2Si(C_5Me_4)_2]TiMe_2$ reacts with C_4H_4NH at 120 °C to give $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$, while $[Me_2Si(C_5Me_4)_2]TiCl_2$ reacts with $LiNC_4H_4$ to give sequentially $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$ and $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$. The molecular structures of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$, $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$ and $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$ have been determined by X-ray diffraction, as illustrated in Figs. 1–3, respectively. The incorporation of an *ansa* bridge into a metallocene system often facilitates a shift of the cyclopentadienyl rings towards a reduced hapticity [14–16] and thereby provides a possible mechanism for modifying the coordination mode of the ancillary ligand. However, it is evident from the structures of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$, $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$ and $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$ that this perturbation is sufficiently small that it does not promote a shift towards η^5-coordination of the pyrrolyl ligand.

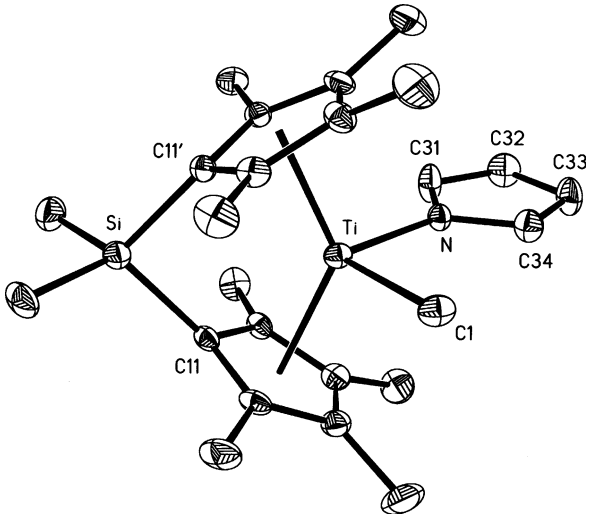


Fig. 1. Molecular structure of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$.

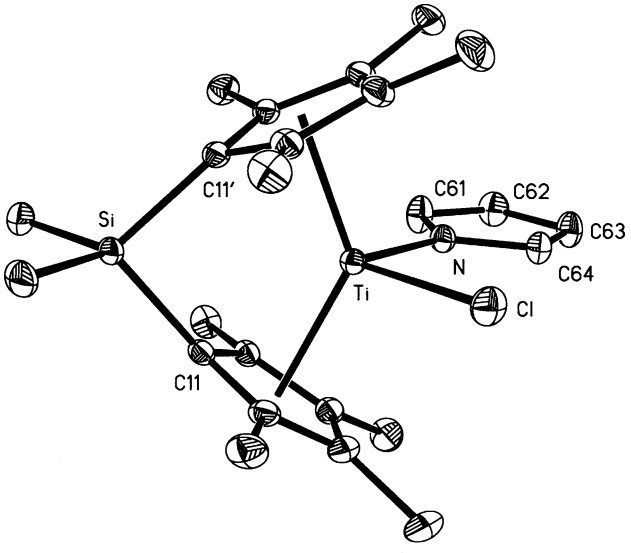

Fig. 2. Molecular structure of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$.

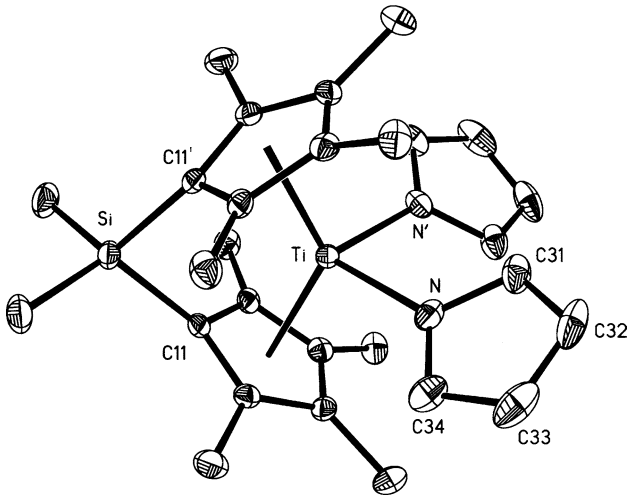

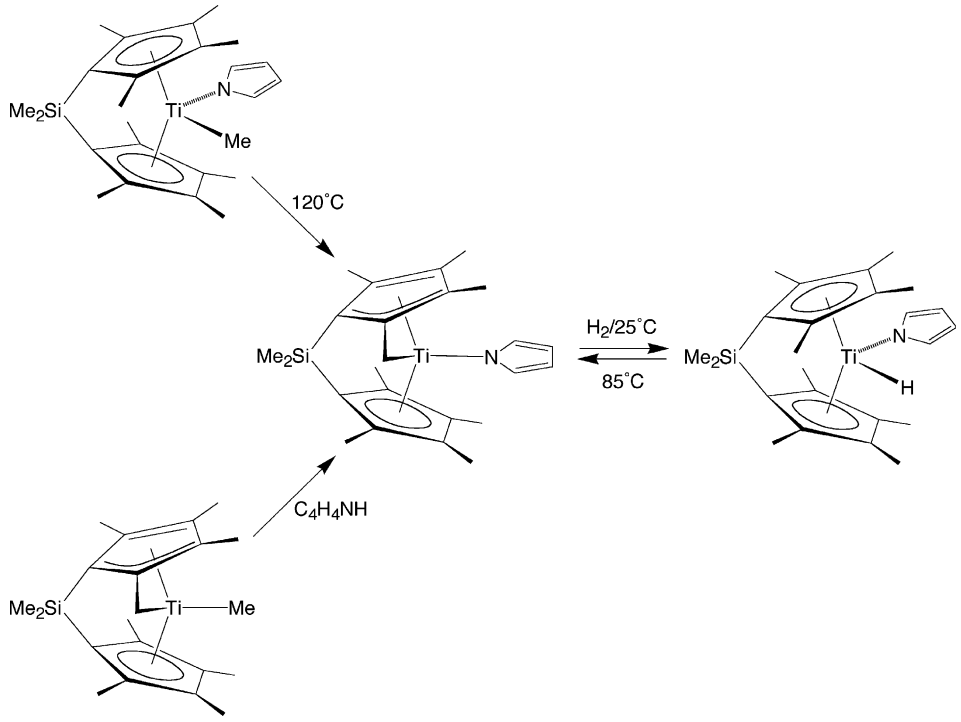

Fig. 3. Molecular structure of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$.

2.2. Synthesis and structural characterization of the fulvene complex $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$

The methyl complex $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$ provides a pathway to two other pyrrolyl compounds, namely the fulvene complex $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ and the hydride derivative $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$ (Scheme 4). Thus, $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$ eliminates methane upon prolonged heating at 120 °C to give a fulvene complex $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ that is derived by formal abstraction of a hydrogen atom from a ring methyl group. Support for the formation of a fulvene ligand is provided by NMR spectroscopy which indicates the presence of a CH_2 group by observation of (i) two doublets at δ 1.89 and 2.83 ($^2J_{HH}$ = 4 Hz) in the ^{1}H NMR spectrum and (ii) a doublet of doublets signal at δ 86.2 ($^1J_{CH}$ = 151 and 154 Hz) in the ^{13}C NMR spectrum. While NMR spectroscopy indicates that one of the methyl groups has been activated and transformed into the methylene group of a fulvene moiety, it does not indicate from which of the methyl groups the hydrogen atom was abstracted. Definitive evidence is, nevertheless, provided by an X-ray diffraction study on $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ (Fig. 4), which demonstrates that it is a ring methyl group adjacent to the $[Me_2Si]$ bridge that is activated; the structure is, therefore, analogous to that of the phenyl counterpart $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]TiPh$ [12]. In this regard, $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ may also be

Scheme 4.

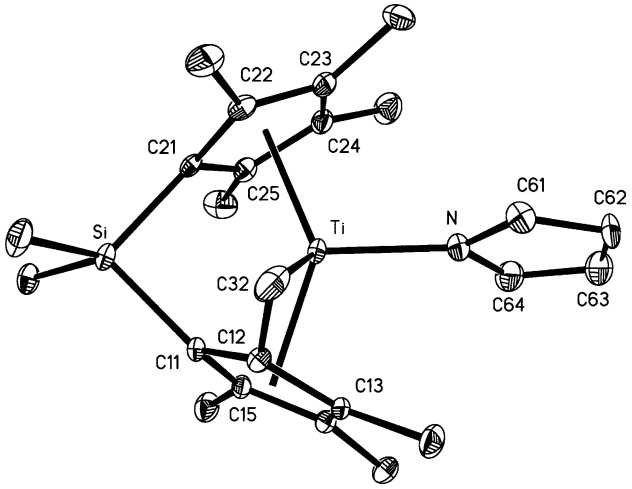

Fig. 4. Molecular structure of $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]$-$Ti(NC_4H_4)$. Selected bond lengths (Å): Ti—C11 2.263(5), Ti—C12 2.162(6), Ti—C13 2.393(5), Ti—C14 2.583(5), Ti—C15 2.503(5), Ti—C32 2.356(7).

obtained by reaction of $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]$-TiMe [12] with C_4H_4NH at 120 °C (Scheme 4). The preferential reactivity of pyrrole with the Ti—Me bond is noteworthy in light of the fact that the Ti—C bond involving the *exo*-methylene group is often more reactive. For example, $Cp^*(C_5Me_4CH_2)ZrPh$ reacts with H_2 and H_2O to give $Cp^*{}_2Zr(Ph)H$ and $Cp^*{}_2Zr$-(Ph)OH, respectively [17].

With respect to the coordination mode of the fulvene moiety [18], the principal interaction is with only four carbon atoms, namely those of the *exo* double bond and the two adjacent atoms, with Ti—C bond lengths in the range 2.16–2.39 Å; the carbon atoms of the *endo* double bond are much further from the titanium center, with bond lengths of 2.502(5) and 2.583(5) Å. As such, the complex may be viewed as a trialkylidenemethane, i.e. $C(CR_2)_3$, derivative supplemented by a weaker titanium–olefin interaction (Fig. 5). In this regard, although fulvene complexes are common, the bonding is typically discussed in terms of whether the interaction is better described as coordination of a neutral η^6-fulvene (i.e. a "diene-olefin") or as that of a dianionic η^1,η^5-ligand (Fig. 5) [18–20]. We first described the trialkylidenemethane coordination mode for $[Me_2Si(C_5Me_4)(C_5Me_3$-$CH_2)]TiPh$ [12] and this mode has now been reported for several other complexes, including $Cp^*[C_4H_4$-$(CHR)]TiCl$ [21] and $[C_5Me_4CH_2]Ta(cb)_2X$ (cb = carbazolyl; X = Cl, CH_2SiMe_3, CH_2Ph) [3a].

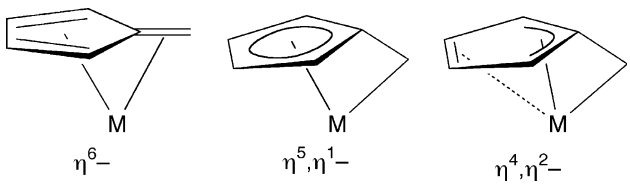

Fig. 5. Coordination modes of fulvene ligands.

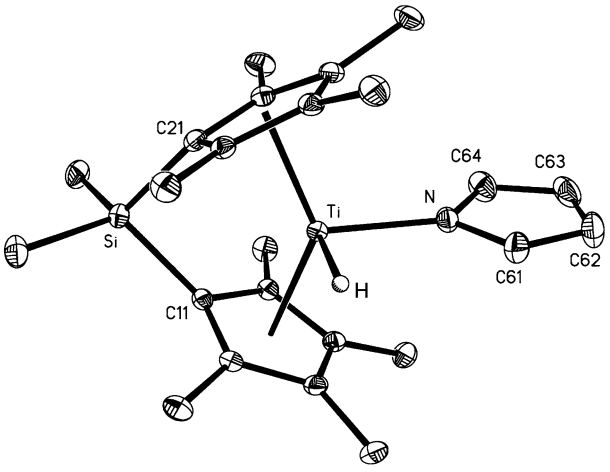

Fig. 6. Molecular structure of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$.

2.3. Synthesis and structural characterization of the hydride complex $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$

The fulvene complex $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]$-$Ti(NC_4H_4)$ serves as a useful precursor for the pyrrolyl–hydride complex $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$ via reaction with H_2 at room temperature (Scheme 4). The molecular structure of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$ has been determined by X-ray diffraction (Fig. 6), while the [Ti—H] moiety is characterized spectroscopically by an absorption at 1601 cm^{-1} in the IR spectrum and a signal at δ 4.62 in the ^1H NMR spectrum. Interestingly, the formation of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$ is reversible, with elimination of H_2 and regeneration of $[Me_2$-$Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ occurring at 85 °C. In accord with this reversibility, treatment of $[Me_2Si(C_5$-$Me_4)_2]Ti(NC_4H_4)H$ with D_2 at 80 °C results in incorporation of deuterium into the hydride and one ring methyl group (δ 1.80) of each cyclopentadienyl ring of the $[Me_2Si(C_5Me_4)_2]$ ligand.

2.4. Nature of the titanium–pyrrolyl interaction in ansa-titanocene complexes

As noted above, the pyrrolyl ligand is considered to be a less effective π-donor ligand than dialkylamido counterparts. Evidence in support of this notion is provided by consideration of the Ti—NC_4H_4 bond lengths in $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)X$ (X = H, Me, Cl, NC_4H_4) and $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$, as summarized in Table 1. Thus, the average Ti—NC_4H_4 bond length of 2.08 Å is approximately 0.2 Å longer than the mean value of 1.89 Å for the Ti—NMe_2 bond length in structurally characterized complexes listed in the Cambridge Structural Database [11]. While this comparison furnishes excellent evidence that the pyrrolyl ligand is a less effective π-donor than is the Me_2N ligand, it provides no indication as to whether there is any π-character associated with the Ti—NC_4H_4 interaction. In this regard, the use of Ti—NC_4H_4 bond lengths to evaluate whether or not there exists any π-character requires knowledge of the hypothetical Ti—NC_4H_4 bond length in the absence of π-donation, and an estimate of this value in this system may be obtained by consideration of the Ti—Ph bond length of $[Me_2Si(C_5Me_4)_2]Ti(Ph)Cl$ (Fig. 7). Thus, since (i) the Ti—Ph bond is expected to possess negligible π-character and (ii) the planar phenyl and pyrrolyl ligands have a comparable size, an estimate of the Ti—NC_4H_4 bond length in the absence of π-donation may be obtained by adjusting the Ti—Ph bond length of $[Me_2Si$-$(C_5Me_4)_2]Ti(Ph)Cl$ [2.172(3) Å] by the difference in covalent radii of carbon (0.77 Å) and nitrogen (0.73 Å) [22,23]. On this basis, a Ti—NC_4H_4 bond length of 2.14 Å would be predicted for $[Me_2Si(C_5Me_4)_2]$-$Ti(NC_4H_4)X$ in the absence of π-donation.

The experimentally observed average Ti—NC_4H_4 bond length of 2.08 Å for the various titanium pyrrolyl compounds is, therefore, intermediate between the values for the hypothetical value in the absence of π-donation (2.14 Å) and the average value for Ti—NMe_2 bond lengths (1.89 Å). However, while it is intermediate, it is evident that the average Ti—NC_4H_4 bond length is much closer to the hypothetical value in the absence of π-donation. In this regard, it is pertinent to note that, because the frontier orbitals of a metallocene reside in

Table 1
Ti—N bond lengths of pyrrolyl complexes

	d (Ti—N) (Å)
$[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$	2.090(3)
$[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$	2.090(7)
$[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$	2.086(3)
$[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$	2.058(2)
$[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$	2.072(4)

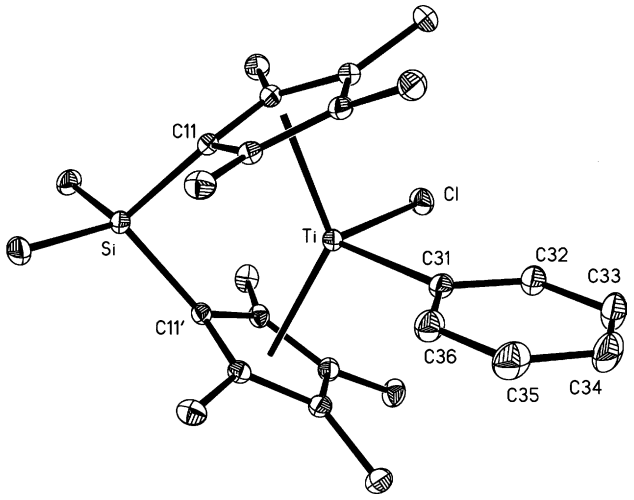

Fig. 7. Molecular structure of $[Me_2Si(C_5Me_4)_2]Ti(Ph)Cl$.

the equatorial plane [24], the pyrrolyl ligand would be required to be orthogonal if it were to act as an effective π-donor ligand.

A further relevant comparison of bond lengths is provided by substituted pyrrolyl compounds. Specifically, the 2,4-diphenylpyrrolyl complex $[pyr^{Ph_2}]Ti(NMe_2)_3$ has been shown by X-ray diffraction to exhibit η^1-coordination of the $[pyr^{Ph_2}]$ ligand, and the two independent Ti—$NC_4Ph_2H_2$ bond lengths [2.052(4) Å and 2.038(4) Å; average = 2.045 Å] are ca. 0.16 Å longer than the Ti—NMe_2 bond lengths [1.881(4)–1.898(4) Å; average = 1.888 Å] [25]. In accord with this observation, the Ti—NC_4H_4 bond length in the hypothetical compound $[\eta^1$-$NC_4H_4]Ti(NMe_2)_3$ (1.99 Å) is calculated to be 0.15 Å longer than the Ti—NMe_2 bond lengths (1.84 Å) [26]. Thus, in all titanium pyrrolyl compounds which exhibit η^1-coordination, the Ti—N bond length indicates that there is little π-character associated with the bond.

A final noteworthy aspect of the series of pyrrolyl compounds $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)X$ (X = H, Me, Cl, NC_4H_4) pertains to rotation of the pyrrolyl ligand about the Ti—N bond. Of these complexes, only the chloride derivative exhibits ^1H and ^{13}C NMR spectra consistent with hindered rotation on the NMR timescale at room temperature (Fig. 8). For example, at 290 K, the pyrrolyl ligand of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$ is characterized by 4 distinct signals (A–D). Upon raising the temperature, however, the signals broaden in a manner that is consistent with rotation about the Ti-pyrrolyl bond, with interconversion of A/D and B/C pairs. The coalescence temperature for the interconversion of B and C is 300 K, from which values of $k = 31\ s^{-1}$ and $\Delta G^{\ddagger} = 15.5$ kcal mol^{-1} may be obtained for the barrier to rotation. This value also serves as an upper limit for the rotation of the pyrrolyl ligand in $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)X$ (X = H, Me, NC_4H_4). With respect to the greater barrier for the chloride derivative, it is pertinent to note that the barrier to rotation about the Zr—Ph bond is also greatest for the chloride derivative in a series of related zirconocene phenyl compounds, namely $[Me_2Si(C_5Me_4)_2]Zr(Ph)X$ (X = Ph, H, Cl) [27].

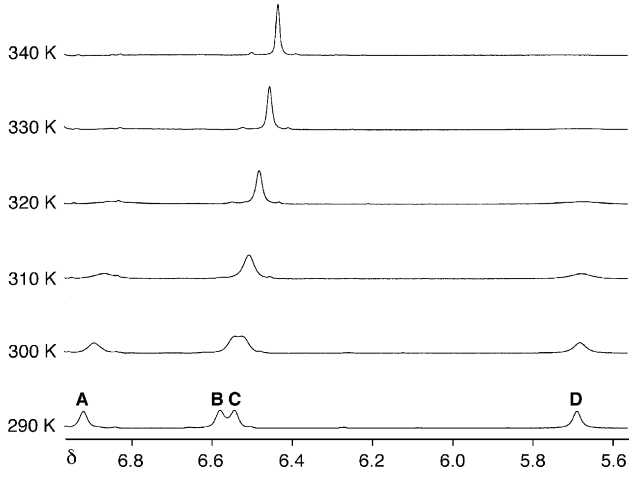

Fig. 8. Variable temperature ^1H NMR spectra of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$ in d^8-toluene, focusing on the four signals of a static pyrrolyl ligand. At 330 K only the B/C pair of protons have coalesced, with the signal for the A/D pair remaining in the base line due to the much greater frequency difference for the A and D signals compared to that for B and C.

3. Conclusions

In summary, a series of titanium–pyrrolyl compounds, namely $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)X$ (X = H, Me, Cl, NC_4H_4) and $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ has been synthesized and structurally characterized by X-ray diffraction. Consideration of the Ti—NC_4H_4 bond lengths indicates that the pyrrolyl ligand does not act as an efficient π-donor in this system, such that the experimentally observed average Ti—NC_4H_4 bond length of 2.08 Å is much closer to the hypothetical value in the absence of π-donation (2.14 Å) than the average value of Ti—NMe_2 bond lengths (1.89 Å).

4. Experimental

4.1. General considerations

All manipulations were performed using a combination of glovebox, high-vacuum and Schlenk techniques under a nitrogen or argon atmosphere. Solvents were purified and degassed by standard procedures. ^1H and ^{13}C NMR spectra were measured on Bruker 300 DRX, Bruker 400 DRX, and Bruker Avance 500 DMX spectrometers. Chemical shifts are reported in ppm relative to $SiMe_4$ ($\delta = 0$) and were referenced internally with respect to the protio solvent impurity (δ 7.15 for C_6D_5H) and ^{13}C resonances (δ 128.0 for C_6D_6). Coupling constants are given in hertz. Infrared spectra were recorded on Perkin–Elmer 1430 and 1600 spectrometers and are reported in cm^{-1}. $LiNC_4H_4$ [8c], $[Me_2Si(C_5Me_4)_2]TiCl_2$ [13], $[Me_2Si(C_5Me_4)_2]TiMe_2$ [12], and $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]TiMe$ [12] were prepared by the literature methods.

4.2. Synthesis of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$

Toluene (15 mL) was added to a mixture of $[Me_2Si(C_5Me_4)_2]TiCl_2$ (0.12 g, 0.29 mmol) and $LiNC_4H_4$ (0.063 g, 0.86 mmol) in an ampoule. The mixture was stirred at 80 °C for ca. 24 h, after which period the volatile components were removed in vacuo. The residue was extracted into pentane (ca. 100 mL), concentrated to ca. 10 mL, and placed at −78 °C giving

$[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$ as a dark green solid, which was isolated by filtration and dried in vacuo (0.05 g, 35%). Anal. Calc. for $C_{24}H_{34}NSiClTi$: C, 64.4; H, 7.6; N, 3.1. Found: C, 64.6; H, 7.6; N, 2.7%. IR Data (KBr pellet, cm^{-1}): 2958 (m), 2905 (s), 2212 (w), 1656 (w), 1441 (s), 1381 (s), 1322 (m), 1252(s), 1206 (w), 1148 (m), 1087 (vs), 1033 (s), 909 (w), 818 (s), 769 (s), 721 (s), 677 (s), 653 (m), 568 (w), 475 (s). ^1H NMR data (C_6D_6): 0.54 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.68 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.27 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.67 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.91 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.16 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 5.73 [br s, 1H of NC_4H_4], 6.66 [s, 2H of NC_4H_4], 7.05 [br s, 1H of NC_4H_4]. ^{13}C NMR data (C_6D_6): 2.6 [q, $^1J_{C-H}$ = 121, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 3.1 [q, $^1J_{C-H}$ = 120, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 10.4 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 13.8 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 15.4 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 16.7 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 95.1 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], obscured by solvent [2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 109.4 [d, $^1J_{C-H}$ = 168, 1CH of NC_4H_4], obscured by solvent [1CH of NC_4H_4], 111.0 [d, $^1J_{C-H}$ = 167, 1CH of NC_4H_4], 121.9 [d, $^1J_{C-H}$ = 175, 1CH of NC_4H_4], 133.9 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 141.2 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 147.6 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$].

4.3. Synthesis of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$

Toluene (20 mL) was added to a mixture of $[Me_2Si(C_5Me_4)_2]TiCl_2$ (0.24 g, 0.58 mmol) and $LiNC_4H_4$ (0.168 g, 2.30 mmol) in an ampoule. The mixture was stirred at 120 °C for ca. 24 h, after which period the volatile components were removed in vacuo. The product was extracted into pentane (ca. 100 mL), concentrated to ca. 10 mL, and placed at −78 °C giving $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$ as a dark green solid, which was isolated by filtration and dried in vacuo (0.14 g, 50%). Anal. Calc. for $C_{28}H_{38}N_2SiTi$: C, 70.3; H, 8.0; N, 5.9. Found: C, 70.2; H, 8.0; N, 5.5%. IR Data (KBr pellet, cm^{-1}): 3110 (w), 2913 (s), 2203 (w), 1543 (w), 1442 (s), 1379 (s), 1326 (m), 1259 (m), 1190 (w), 1147 (m), 1077 (vs), 1025 (vs), 837 (s), 772 (m), 716 (vs), 680 (s), 649 (m), 615 (w), 568 (w), 471 (m). ^1H NMR data (C_6D_6): 0.65 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.45 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.85 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 6.57 ["t", $^3J_{H-H}$ = 2, 4H of 2 NC_4H_4], 6.74 [br s, 4H of 2 NC_4H_4]. ^{13}C NMR data (C_6D_6): 2.7 [q, $^1J_{C-H}$ = 120, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 12.3 [q, $^1J_{C-H}$ = 127, 4Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 16.2 [q, $^1J_{C-H}$ = 127, 4Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 98.6 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 108.4 [d, $^1J_{C-H}$ = 172, 4CH of 2 NC_4H_4], 128.4 [d, $^1J_{C-H}$ = 176, 4CH of 2 NC_4H_4], 130.0 [s, 4C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 145.6 [s, 4C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$].

4.4. Synthesis of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$

A solution of $[Me_2Si(C_5Me_4)_2]TiMe_2$ (0.30 g, 0.80 mmol) in toluene (15 mL) was treated with freshly dried pyrrole (0.21 g, 3.20 mmol). The mixture was stirred at 120 °C for ca. 24 h, after which period the volatile components were removed in vacuo. The residue was extracted into pentane (ca. 10 mL) and placed at −78 °C to deposit $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$ as a red crystalline solid. The crystals were washed with cold pentane (2.3 mL) and dried in vacuo (0.22 g, 64%). Anal. Calc. for $C_{25}H_{37}NSiTi$: C, 70.2; H, 8.7; N, 3.3. Found: C, 70.8; H, 8.6; N, 3.2%. IR Data (KBr pellet, cm^{-1}): 2948 (m), 2901 (m), 2874 (m), 1477 (w), 1460 (w), 1440 (m), 1408 (w), 1379 (s), 1354 (m), 1325 (s), 1249 (s), 1205 (w), 1151 (w), 1129 (w), 1084 (s), 1053 (w), 1035 (s), 1016 (s), 910 (w), 839 (vs), 812 (vs), 766 (s), 716 (vs), 675 (vs), 658 (s), 569 (w), 542 (w), 476 (vs). ^1H NMR data (C_6D_6): 0.43 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.61 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.72 [s, 1Me of $TiCH_3$], 1.36 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.46 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.97 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.04 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 5.94 [br s, 2H of NC_4H_4], 6.61 [t, $^3J_{H-H}$ = 2, 2H of NC_4H_4]. ^{13}C NMR data (C_6D_6): 2.8 [q, $^1J_{C-H}$ = 123, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 3.1 [q, $^1J_{C-H}$ = 121, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 10.3 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 13.0 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$],15.1 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 15.2 [q, $^1J_{C-H}$ = 126, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 60.8 [q, $^1J_{C-H}$ = 124, 1Me of $TiCH_3$], 94.6 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 109.4 [d, $^1J_{C-H}$ = 168, 2CH of NC_4H_4], 123.3 [d, $^1J_{C-H}$ = 176, 2CH of NC_4H_4], 125.7 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 127.1 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 135.5 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 140.9 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$].

4.5. Synthesis of $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$

(a) A solution of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$ (ca. 20 mg) in benzene (ca. 0.8 mL) was heated at 120 °C for 7 days. The quantitative formation of green $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ was demonstrated by ^1H NMR spectroscopy. The solvent was removed by lyophilization to give $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ as a solid. (b) A solution of $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]TiMe$ (ca. 5 mg) in benzene (ca. 0.8 mL) was treated with pyrrole and heated at 120 °C for ca. 24 h. The quantitative formation of $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ was demonstrated by ^1H NMR spectroscopy. Anal. Calc. for $C_{24}H_{33}NSiTi$:

C, 70.1; H, 8.1; N, 3.4. Found: C, 70.1; H, 8.1; N, 3.1%. IR Data (KBr pellet, cm^{-1}): 3086 (w), 2959 (s), 2910 (s), 2865 (s), 1616 (m), 1442 (s), 1380 (s), 1330 (s), 1252 (s), 1201 (w), 1154 (s), 1130 (m), 1070 (s), 1053 (m), 1029 (s), 918 (w), 838 (s), 813 (s), 776 (br s), 656 (s), 626 (m), 570 (w), 497 (w), 459 (w). ^{1}H NMR data (C_6D_6): 0.03 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 0.31 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 1.30 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 1.61 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 1.73 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 1.76 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 1.77 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 1.84 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 1.89 [d, $^2J_{H-H}$ = 4, 1H of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 2.15 [s, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 2.83 [d, $^2J_{H-H}$ = 4, 1H of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 5.65 [br s, 2H of NC_4H_4], 6.46 [t, $^3J_{H-H}$ = 2, 2H of NC_4H_4]. ^{13}C NMR data (C_6D_6): 0.7 [q, $^1J_{C-H}$ = 120, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 3.1 [q, $^1J_{C-H}$ = 120, 1 Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 10.6 [q, $^1J_{C-H}$ = 126, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 12.6 [q, $^1J_{C-H}$ = 126, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 12.86 [q, $^1J_{C-H}$ = 124, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 12.92 [q, $^1J_{C-H}$ = 126, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 13.9 [q, $^1J_{C-H}$ = 126, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 14.3 [q, $^1J_{C-H}$ = 126, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 16.5 [q, $^1J_{C-H}$ = 126, 1Me of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 86.2 [d of d, $^1J_{C-H}$ = 151, 154, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$],95.5 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 104.6 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$],106.5 [d, $^1J_{C-H}$ = 166, 2CH of NC_4H_4], 117.7 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 121.1 [d, $^1J_{C-H}$ = 173, 2CH of NC_4H_4], 128.9 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$],129.5 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 130.7 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$],134.4 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 137.2 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$],139.0 [s, 1 C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$], 142.4 [s, 1C of $(CH_3)_2Si\{C_{10}(CH_3)_7(CH_2)\}$].

4.6. Synthesis of $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$

A solution of $[Me_2Si(C_5Me_4)(C_5Me_3CH_2)]Ti(NC_4H_4)$ (ca. 20 mg) in benzene (ca. 0.8 mL) was treated with H_2 (ca. 1 atm) and stirred at room temperature for 12 h, after which period the quantitative formation of red brown $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$ was demonstrated by ^{1}H NMR spectroscopy. The solvent was removed by lyophilization to give $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$ as a solid. IR Data (KBr pellet, cm^{-1}): 3093 (m), 2911 (s), 2728 (w), 2230 (w), 1703 (w), 1655 (w), 1601 (m), 1441 (s), 1378 (s), 1317 (m), 1252 (s), 1202 (w), 1152 (s), 1130 (m), 1076 (s), 1028 (s), 913 (w), 837 (vs), 768 (s), 719 (vs), 675 (vs), 598 (w), 481 (m). ^{1}H NMR data (C_6D_6): 0.46 [s, 1 Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.57 [s, 1 Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.35 [s, 2 Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.81 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.94 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.19 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 4.62 [s, 1H of Ti*H*], 6.09 [br s, 2H of NC_4H_4], 6.66 [t, $^3J_{H-H}$ = 2, 2H of NC_4H_4]. ^{13}C NMR data (C_6D_6): 3.0 [q, $^1J_{C-H}$ = 121, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 3.1 [q, $^1J_{C-H}$ = 121, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 10.8 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 13.8 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 14.0 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 16.7 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 95.5 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 108.7 [d, $^1J_{C-H}$ = 162, 2CH of NC_4H_4], 118.5 [d, $^1J_{C-H}$ = 180, 2CH of NC_4H_4], 123.6 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], obscured by solvent [2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 133.2 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 139.9 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$].

4.7. Synthesis of $[Me_2Si(C_5Me_4)_2]Ti(Ph)Cl$

A solution of $[Me_2Si(C_5Me_4)_2]TiCl_2$ (0.50 g, 1.2 mmol) in Et_2O (15 mL) was treated with PhMgCl (1.44 mL of 2.0 M in THF; 2.9 mmol) and stirred at room temperature for ca. 16 h. After this period, the volatile components were removed under reduced pressure and the residue was extracted into pentane (ca. 150 mL). The pentane extract was concentrated to ca. 10 mL and placed at −78 °C, giving $[Me_2Si(C_5Me_4)_2]Ti(Ph)Cl$ as a red crystalline solid which was isolated by filtration. The isolated crystals were washed with cold pentane (2.5 mL) and dried in vacuo (0.24 g, 44%). Anal. Calc. for $C_{26}H_{35}SiTiCl$: C, 68.0; H, 7.7. Found: C, 68.0; H, 8.0%. IR Data (KBr pellet, cm^{-1}): 3036 (s), 2988 (s), 2954 (s), 2898 (vs), 1941 (w), 1870 (w), 1813 (w), 1638 (w), 1594 (w), 1562 (m), 1477 (s), 1439 (s), 1410 (s), 1380 (vs), 1321 (s), 1253 (s), 1127 (m), 1018 (s), 840 (vs), 812 (s), 767 (s), 724 (s), 702 (s), 676 (s), 625 (w), 572 (w), 488 (s), 469 (m). ^{1}H NMR data (C_6D_6): 0.58 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.62 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.38 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$],1.75 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.80 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.25 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 6.11 [d, $^3J_{H-H}$ = 8, 1H of C_6H_5], 6.95 [t, $^3J_{H-H}$ = 8, 1H of C_6H_5], 7.06 [t, $^3J_{H-H}$ = 8, 1H of C_6H_5], 7.13 [d, $^3J_{H-H}$ = 8, 1H of C_6H_5 (partially obscured by solvent)], 7.63 [d, $^3J_{H-H}$ = 8, 1H of C_6H_5]. ^{13}C NMR data (C_6D_6): 2.8 [q, $^1J_{C-H}$ = 121, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 3.3 [q, $^1J_{C-H}$ = 121, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 12.7 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 13.9 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 14.9 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 16.7 [q, $^1J_{C-H}$ = 127, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 91.0 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$],124.0 [d of t, $^1J_{C-H}$ = 158, $^2J_{C-H}$ = 7, 1C of of C_6H_5], 125.3 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 126.9 [d of d, $^1J_{C-H}$ = 155,

$^2J_{C-H}$ = 7, 1C of C_6H_5], 128.9 [d of d, $^1J_{C-H}$ = 156, $^2J_{C-H}$ = 7, 1C of C_6H_5], 132.3 [d of t, $^1J_{C-H}$ = 152, $^2J_{C-H}$ = 8, 1C of C_6H_5], 133.1 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 138.3 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 138.9 [d of t, $^1J_{C-H}$ = 159, $^2J_{C-H}$ = 7, 1C of C_6H_5], 140.5 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 204.2 [*ipso*, s, 1C of C_6H_5].

4.8. X-ray structure determinations

X-ray diffraction data were collected on a Bruker P4 diffractometer equipped with either a point detector or a SMART CCD detector and crystal data, data collection and refinement parameters are summarized in Table 2. The structures were solved using direct methods and standard difference map techniques, and were refined by full-matrix least-squares procedures on F^2 with SHELXTL (Version 5.10) [28]. The crystallographic data for $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)H$ (CCDC #262716), $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Me$ (CCDC #262718), $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)Cl$ (CCDC #262719), $[Me_2Si(C_5Me_4)_2]Ti(NC_4H_4)_2$ (CCDC #262717), $[Me_2Si(C_5Me_4)(C_5Me_3\text{-}CH_2)]Ti(NC_4H_4)$ (CCDC #262720), and $[Me_2Si(C_5Me_4)_2]$- Ti(Ph)Cl (CCDC #262721) have

Scheme 1.

compounds of p-block elements have been reported to date, $Me_4C_2(C_5H_4)_2Sn$ and $Me_4C_2(C_5H_4)_2Pb$ [25],[1] which were isolated in only 2% yield and were not characterized crystallographically.

Although cyclopentadienylaluminum compounds containing a tethered amine [26,27] and amide ligand [28] have been reported, no *ansa*-aluminocene compounds containing two bridged cyclopentadienyl rings have yet been described. Our motivation for pursing these compounds is multifold. We anticipated that the interannular ("*ansa*") bridge would slow the haptotropic rearrangements of the cyclopentadienyl–aluminum bonds to the extent that they could be studied on the NMR time scale. We also expect the constraints of the bridge on the coordination geometry of the cyclopentadienyl rings to increase the Lewis acidity of the aluminum in the same way that it increases the Lewis acidity of early transition metals [29–32]. Finally, we plan to develop chiral *ansa*-aluminocene compounds for application as asymmetric catalysts of Lewis acid-promoted reactions.

In this report, we describe the synthesis and characterization of $[Me_4C_2(C_5H_4)_2Al\text{-}\mu\text{-}Cl]_2$ (**2**), and its Lewis base adducts $[\{Me_4C_2(C_5H_4)\}Al(THF)Cl]$ (**3**) and $[\{Me_4C_2(C_5H_4)\}Al(CN\text{-}t\text{-}Bu)Cl]$ (**4**). The molecular structures of all three compounds were determined by single crystal X-ray crystallography. Whereas migration of aluminum over its cyclopentadienyl ring(s) is normally too rapid to be followed on the NMR time scale, the tetramethylethano bridge in compounds **2**–**4** impedes the migration to the extent that it can be studied for the first time using dynamic NMR methods.

2. Results and discussion

2.1. Synthesis and characterization of $[Me_4C_2(C_5H_4)_2Al\text{-}\mu\text{-}Cl]_2$ (2)

Initial efforts to prepare an *ansa*-aluminocene compound by transmetallation of the ligand framework from $[Me_4C_2(\eta^5\text{-}C_5H_4)_2Ca(THF)_x]$ [13] to $AlCl_3$ were unsuccessful. No reaction occurred, even upon heating the mixture to 80 °C in toluene. Since magnesocenes have been used successfully in the synthesis of cyclopentadienylaluminum compounds [33–37], we prepared the corresponding *ansa*-magnesocene compound $[Me_4C_2(\eta^5\text{-}C_5H_4)_2Mg]$ (**1**) in the manner described by Brintzinger and coworkers [14] for related *ansa*-magnesocene compounds. Compound **1** does react with $AlCl_3$ at room temperature in toluene to afford the *ansa*-aluminocene compound $[Me_4C_2(C_5H_4)_2AlCl]_2$ (**2**) (Scheme 1).

The *ansa*-aluminocene compound was isolated in 47% yield as an air-sensitive, off-white powder. Decomposition of the compound after one day at room temperature under an N_2 atmosphere is accompanied by its discoloration to dark blue. The compound is stable for months when stored in a −30 °C freezer. Interestingly, compound **2** is stable in toluene for over a week at room temperature but is not stable in benzene solution, in which its turns dark blue over 24 h. Despite the instability of **2** in benzene, single crystals of the compound that were suitable for an X-ray structure determination were grown by evaporation of benzene from a saturated solution. The molecular structure of the dimer is shown in Fig. 1(a) along with a view down the backbone of the bridge (Fig. 1(b)). Crystallographic data and selected bond lengths and angles are listed in Tables 1 and 2, respectively.

The dimer sits on a center of inversion in the unit cell, so the geometries of each half of the dimer are identical with one σ-coordinated (η^1) and one η^5 cyclopentadienyl ring. The C–C bonds in the η^1 cyclopentadienyl ring are localized, with two double bonds at C(8)–C(12) and C(10)–C(11) and three single bonds at C(9)–C(8), C(9)–C(10), and C(11)–C(12). The aluminum adopts a highly distorted tetrahedral geometry with a narrow Cl(1)–Al(1)–Cl(1A) bond angle of 85.07(3)° and a much wider C(9)–Al(1)-centroid angle of 117.6°. The geometry of the aluminum center is similar to that found in another dimeric cyclopentadienylaluminum chloride compound, $[(EtMe_4C_5)(Ph)Al\text{-}\mu\text{-}Cl]_2$, reported by Roesky and coworkers [38]. The Al-centroid distance of 1.939 Å for the η^5 ring is longer than the corresponding bonds in $[(\eta^5\text{-}C_5H_5)(2,6\text{-}t\text{-}Bu\text{-}4\text{-}Me\text{-}C_6H_2O)_2Al]$ (1.920 Å) [39] and $[(\eta^5\text{-}C_5H_5)\{(2,6\text{-}i\text{-}Pr_2C_6H_3)N\}Al]_2$ (1.886 Å) [40]. The Al–C(9) distance for the η^1 ring is within the 1.976–2.080 range reported for other η^1-cyclopentadienylaluminum(III) compounds

[1] During the publication of this paper, a communication describing the synthesis and structural characterization of a C_2-symmetric *ansa*-stannocene complex appeared in print (C.J. Pilotto, E.P. Roth, G.M. Canfield, J.E.B. Johnson, B.J. Balaich, L.N. Zakharov, A.L. Rheingold, Organometallics 24 (2005) 1806).

[35–37,41–44]. The torsion angle between the bonds connecting the ethano bridge to the cyclopentadienyl rings (C(5)–C(6)–C(7)–C(8), −43.18(15)°) is somewhat larger in magnitude than the corresponding angle in bis-η^5 *ansa*-metallocene complexes (29–32°) containing a similar ligand framework [45,46]. The larger torsion angle allows the methyl substituents on the bridge to be fully staggered.

2.2. NMR spectroscopic characterization of the fluxional properties of 2

The room temperature ^{1}H NMR spectrum of a 50 mM solution of **2** (Fig. 2) in toluene-d_8 exhibited only two resonances for the cyclopentadienyl rings at δ 5.13 and δ 6.16 and only one resonance at δ 1.01 for the methyl groups on the ethano bridge due to a dynamic process that averages the proton environments. As the sample was cooled, the high field cyclopentadienyl resonance broadened and separated into two new signals at δ 6.15 and δ 4.36. The δ 6.15 signal is attributable to protons attached to non-coordinated sp^2-hybridized (olefinic) ring carbons and the 4.36 signal is characteristic of protons attached to sp^3-hybridized (allylic) carbons σ-coordinated to aluminum. The lower field

cyclopentadienyl resonance decoalesced at a lower temperature into two more closely spaced signals at δ 6.40 and δ 6.33. The methyl resonance broadened and shifted downfield by more than 0.1 ppm, but it did not decoalesce by −94 °C, at which point the toluene-d_8 became too viscous to permit recording NMR spectra on further cooling. No further change in the spectrum was observed upon cooling a 50 mM solution of **2** in methylcyclohexane-d_{14} to −124 °C.

Interestingly, for more dilute solutions of **2**, the methyl proton resonances *did* decoalesce (Fig. 3). The separation between the two methyl signals increased with increasing dilution of the sample. The chemical shifts of the downfield pair of cyclopentadienyl proton resonances also varied considerably with the concentration of the sample.

We considered the possibility that this concentration dependence of the coalescence behavior was due to a monomer–dimer equilibrium. Efforts to determine the degree of aggregation of **2** in solution by measuring the colligative properties of the solutions were unsuccessful. The poor thermal stability of **2** over days at room temperature in cyclohexane precluded a molecular weight determination using the Signer ebulliometric method [50], and we were unable to obtain reliable freezing point depression data from a cyclohexane solution of the compound. Variable temperature $^{13}C\{^1H\}$ and ^{27}Al NMR spectra (Supporting Information) offered no additional insight into this behavior.

A −94 °C ROESY experiment (Supporting Information) revealed that the cyclopentadienyl protons resonating at δ 4.36 and δ 6.15 are nearest the bridge and, therefore, on carbons α to the *ipso* ring carbons. A −94 °C COSY experiment (Supporting Information) showed cross peaks between all four cyclopentadienyl ^1H NMR signals, indicating that each resonance corre-

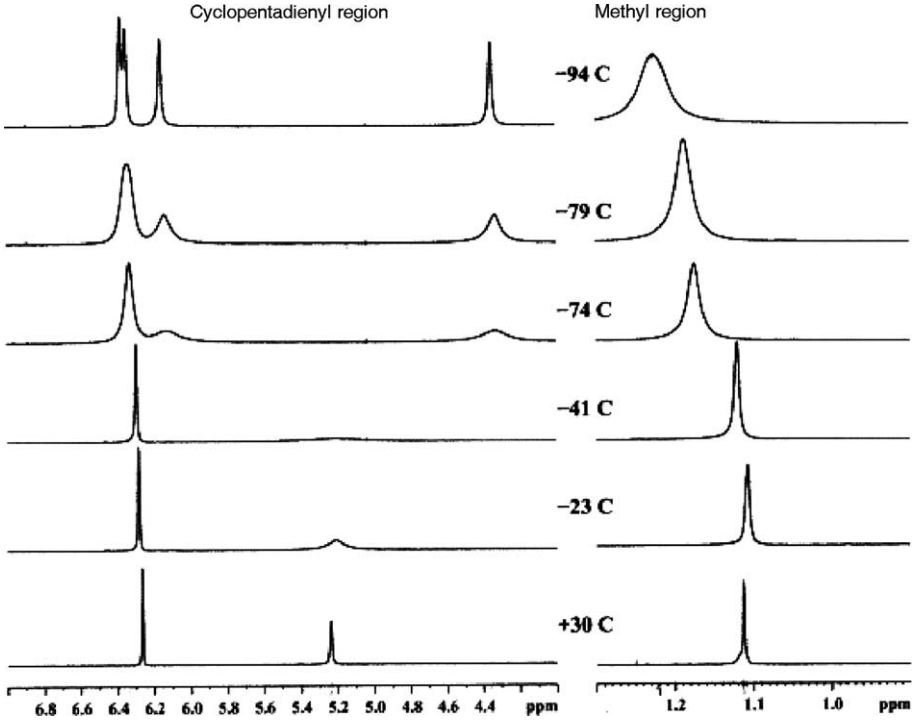

Fig. 2. Variable temperature ^1H NMR spectra of a 50 mM solution of **2** in toluene-d_8.

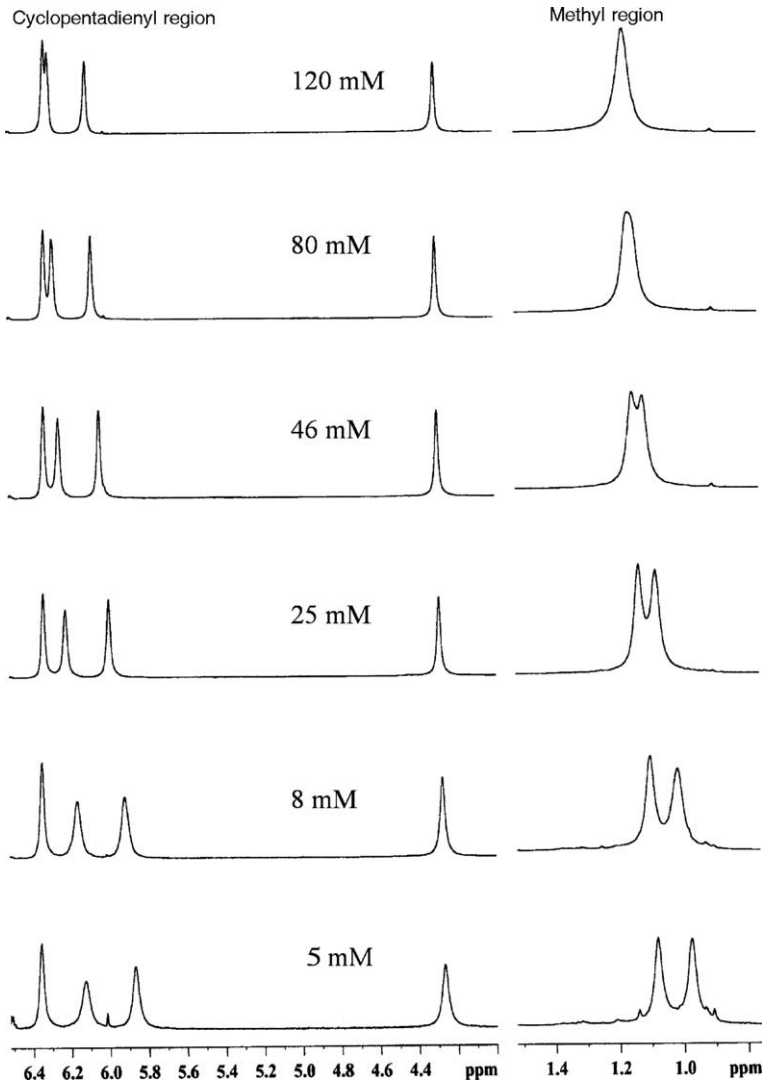

Fig. 3. ^{1}H NMR spectra of samples of **2** at different concentrations in toluene-d_8 at −94 °C.

sponds to two protons at equivalent positions on opposite rings and that the coordination geometries of the rings are equivalent. The presence of only two ^{1}H NMR resonances for the methyl groups, one ^{13}C NMR signal for the two cyclopentadienyl *ipso* carbons, and one ^{13}C NMR signal for the two quarternary carbons of the ethano bridge in the −94 °C ^{1}H and ^{13}C{^{1}H} NMR spectra (Supporting Information) further support this conclusion. The combined NMR data are consistent with η^1 geometries for both cyclopentadienyl rings. Fig. 4 illustrates two possible bonding arrangements of the cyclopentadienyl ligand framework.

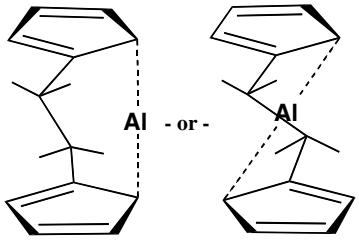

Fig. 4. Possible geometries of the dicyclopentadienyl ligand framework in **2**.

It is not possible to identify with certainty the fluxional pathways responsible for the signal averaging exhibited by **2** from the variable temperature ^{1}H and ^{13}C NMR spectra; however, the chemical shifts and coalescence behavior of the ^{1}H and ^{13}C NMR resonances rule out a circumambulatory type migration of the aluminum about the periphery of its cyclopentadienyl rings through either an $\eta^2 \rightarrow \eta^3 \rightarrow \eta^2$ migration [47] or a series of 1,5 sigmatropic shifts [48] since only the α carbons and their protons exhibit the high field chemical shifts indicative of localized coordination to aluminum. Possible rearrangement pathways include $\eta^1 \leftrightarrow \eta^5$ shifts, $\eta^1 \leftrightarrow \eta^3$ shifts, and 1,3-migration of the aluminum between the two α carbons of the ring. The last alternative is symmetry-forbidden unless it proceeds with stereo-

chemical inversion at aluminum [49]. Our findings with compound **4** (vide infra), suggest that this type of inversion could, in fact, play a role in the rearrangements of these compounds.

^{27}Al NMR spectroscopy is a useful tool for probing the coordination environment of aluminum, and Benn et al. [51–55] have shown that the chemical shifts of inorganic and organo-aluminum compounds can be correlated to the coordination number of the aluminum. In general, the ^{27}Al NMR chemical shifts increase as the coordination number of the aluminum decreases. The room temperature ^{27}Al NMR spectrum of **2** in toluene-d_8 exhibited a single broad signal at δ −2, which broadened into the baseline as the temperature of the sample was reduced to −50 °C (Supporting Information). An ^{27}Al NMR chemical shift of δ −2 is at a considerably higher field than that of other di- and tricyclopentadienylaluminum(III) compounds, which usually appear in the 52–118 ppm range [55]. In fact, it is more characteristic of cyclopentadienylaluminum(III) compounds containing at least one η^5 cyclopentadienyl ring. We believe that the δ −2 chemical shift of **2** reflects the contribution of a bis-η^5 geometry to the average structure of the compound at the fast exchange limit at room temperature. As the dynamic exchange slows, the line broadens into the baseline. Temperature-dependent quadrupole broadening effects undoubtedly contribute to this line broadening.

Rate constants for the dynamic averaging of the ^{1}H and ^{13}C NMR signals for **2** were determined over a >50 °C temperature range by line shape analysis of cyclopentadienyl and methyl signals in the variable temperature ^{1}H and ^{13}C NMR spectra. Both 75 and 5 mM solutions of **2** in toluene-d_8 were examined in order to check for concentration effects on the rate of rearrangement. Eyring plots of the data are shown in Fig. 5. An excellent linear fit of the kinetic data was found for both concentrations. Similar values (within error) for the activation parameters were obtained from the two Eyring plots: 75 mM (5 mM): $\Delta H^{\neq} = 8.7 \pm 0.7$ (7.7 ± 1.1) kcal mol^{-1}, $\Delta S^{\neq} = -3 \pm 5$ (-7.6 ± 3) cal K^{-1} mol^{-1}. Thus, sample concentration has little, if any, effect on the rearrangement process.

2.3. Lewis base adducts of *2*

2.3.1. Synthesis and characterization of *{Me$_4$C$_2$(C$_5$H$_4$)$_2$}AlCl(THF) (3)*

We prepared Lewis base adducts of **2** in order to reduce the symmetry of the complex so that the fate of each individual cyclopentadienyl proton and carbon could be examined in order to elucidate the haptotropic rearrangement(s) of the system.

[{Me$_4$C$_2$(C$_5$H$_4$)$_2$}AlCl(THF)] (**3**) was obtained in 94% yield as a white powder by dissolving **2** in THF and then removing the excess solvent under reduced pressure. Unlike **2**, compound **3** is stable for more than a week in the solid state at room temperature in the absence of air. X-ray quality crystals of **3** were grown from benzene solution by slow evaporation of the solvent. Rear and side views of the molecular structure are shown in Fig. 6. X-ray crystallographic data and selected bond distances and angles are listed in Tables 1 and 3, respectively. As in the structure of **2**, one cyclopentadienyl ring is η^1 coordinated at an α carbon and contains localized single and double C–C bonds with double bonds at C(2)–C(3) and C(4)–C(5) and single bonds at C(1)–C(2), C(3)–C(4) and C(1)–C(5). The second ring is η^3. The η^3 interaction involves both β ring carbons (C(10) and C(11)) and one α ring carbon (C(12)), with C(10) more distant from Al(1) than C(11) and C(12), which are on the same side as the THF moiety. The tighter coordination of C(11)–C(12) is reflected in its bond length, which is significantly longer than the other C–C bonds in the ring. C18 and C19 are disordered in the THF molecule with occupancies of 66% and 33%. The Al(1)–Cl(1) bond distance in **3** (2.1925(8) Å) is shorter than the bonds between aluminum and the bridging chlorides in **2** (2.3221(7) and 2.4078(8) Å), and the O(1)–Al(1)–Cl(1) angle of 96.47(5)° is wider than the Cl(1)–Al–Cl(1A) angle of 85.07(3)° in **2**. The torsion angle (C(5)–C(6)–C(7)–C(8), 46.60(6)°) associated with the conformation of the bridge is larger in magnitude than the corresponding angle in compound **2**.

Cyclopentadienyl and methyl regions of the variable temperature ^{1}H NMR spectra of **3** are shown in Fig. 7. Variable temperature ^{1}H NMR spectra of the THF proton resonances are included in the Supporting Information. As the sample was cooled, the two cyclopentadienyl resonances split into eight resonances (peaks 1–8 in the −99 °C spectrum in Fig. 7). The single resonance for the methyl groups split into four peaks.

The presence of only two cyclopentadienyl proton resonances and one methyl group resonance in the 43 °C ^{1}H NMR spectrum of **3** indicated that the aluminum center was epimerizing. Dynamic exchange between free and bound THF was evident in the VT ^{1}H NMR spectra of a solution of **3** to which excess THF had been added (Supporting Information). This suggests that THF dissociation is responsible for the epimerization of the aluminum, although we cannot rule out intramolecular inversion at aluminum as the cause. It is noteworthy that excess THF did not influence the rate of signal averaging in the VT ^{1}H NMR spectra, contrary to the effect of excess *t*-BuNC on the rate of signal averaging for compound **4** (vide infra).

The COSY (Fig. 8) and ROESY spectra (Figs. 9–11) allowed us to assign the absolute positions of the cyclopentadienyl protons relative to the tetramethylethano bridge and the THF ligand and to assign a solution structure for the compound (Fig. 12) that is similar to the structure found in the solid state, except that one cyclopentadienyl ring is η^2 instead of η^3. The ^{27}Al NMR chemical shift of compound **3** (δ 78) is consistent with this geometry. A complete analysis of the spectra is provided in the Supporting Information.

Although, we were able to identify the structure of **3** in solution from the low-temperature 1-D and 2-D ^{1}H NMR data, it was not possible to elucidate the nature of the cyclopentadienyl ring rearrangements on aluminum from the ^{1}H NMR coalescence pattern due to the involvement of multiple dynamic processes.

*2.3.2. Synthesis and characterization of {Me$_4$C$_2$(C$_5$H$_4$)$_2$}AlCl(CN-t-Bu) (**4**)*

In order to eliminate the NMR signal averaging associated with Lewis base dissociation, and possibly make the NMR coalescence patterns easier to interpret, we prepared compound **4** with the expectation that *t*-butyl isocyanide would coordinate the aluminum irreversibly.

Crystallographic analysis of a single crystal of **4** revealed two unique molecules in the unit cell. Each molecule bears two η^1 cyclopentadienyl rings. Since they are structurally similar, only one of the molecules is shown in Fig. 12. Crystallographic data and selected bond lengths and angles are listed in Tables 1 and 4. Each cyclopentadienyl ring exhibits localized single and double C–C bonds like the η^1 rings of **2** and **3**. Although Al1–C17 (2.1089(16) Å) is slightly longer, C17–N1 (1.143(3) Å) is comparable in length to the corresponding bonds in Cp$_3$Al(CN-*t*-Bu) (2.067(6) and 1.152(7) Å, respectively) [35]. Al(1)–Cl(1) is slightly shorter than the corresponding bond in **3** and significantly shorter than the Al–Cl bonds in **2**. Angle C(17)–Al(1)–Cl(1) is

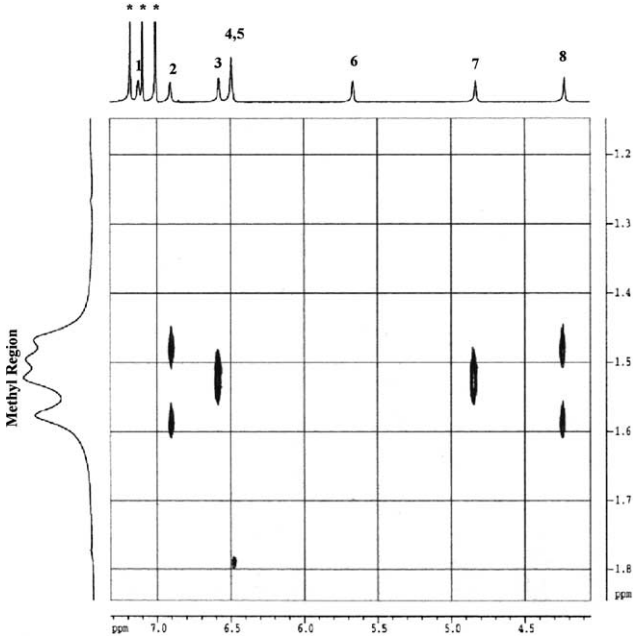

Fig. 10. Partial ROESY spectrum of **3** (−94 °C in toluene-d_8) showing coupling between the cyclopentadienyl and methyl protons (∗ labels solvent peaks).

much wider than Cl(1)–Al(1)–Cl(1A) in **2** and O1–Al(1)–Cl(1) (96.47(5)°) in **3**, which is consistent with the tighter coordination of the chloride and isocyanide ligands. The torsion angle C5–C6–C7–C8 (−45.4(2)°) of the bridge is between that of **2** and **3** in magnitude (see Fig. 13).

Variable temperature ^{1}H NMR spectra of **4** in toluene-d_8 are shown in Fig. 14. The appearance of only two cyclopentadienyl resonances at δ 5.5 and 6.6 and one methyl resonance from the tetramethylethano bridge at δ 1.41 in the 30 °C spectrum indicates that epimerization of the aluminum center occurs in addition to cyclopentadienyl ring rearrangement. By −41 °C, each cyclopentadienyl resonance decoalesced into two signals and the methyl resonance decoalesced into two signals. As the sample was cooled further, these signals broadened again but did not decoalesce by −94 °C.

A ROESY experiment was performed at −40 °C (Fig. 15) since this appeared to be the slow exchange region for one dynamic process. The ROESY spectrum revealed that peaks a and b correspond to the four cyclopentadienyl protons nearest the ethano bridge.

Addition of a small amount of methylcyclohexane-d_{14} (ca. 25% by volume) to a toluene-d_8 solution of **4**

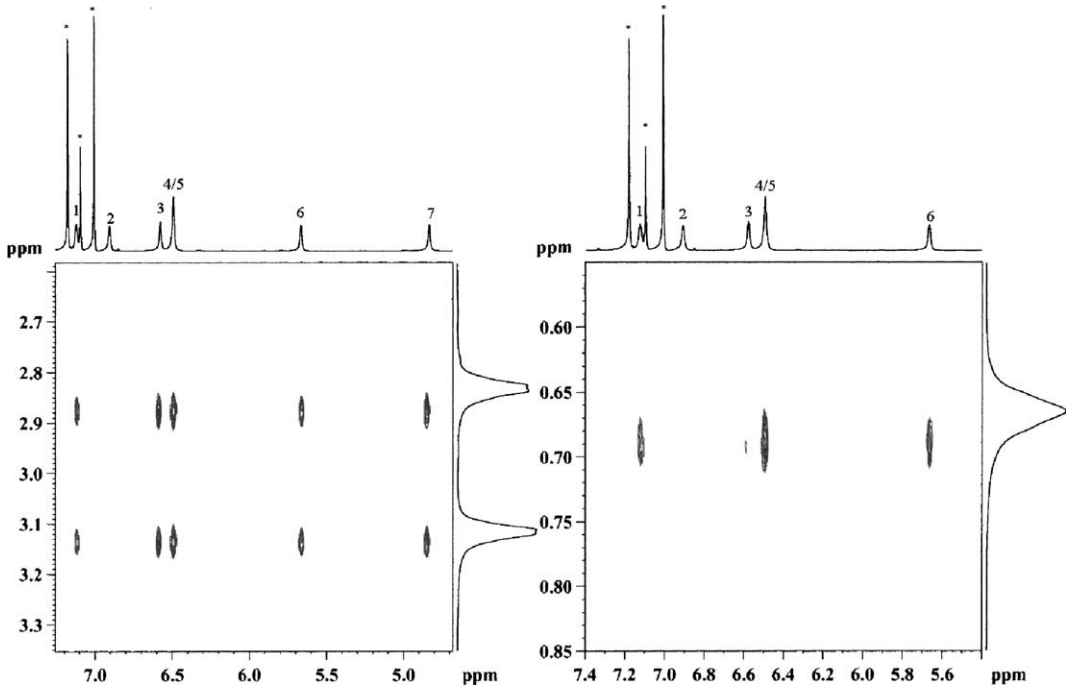

Fig. 11. Partial ROESY spectrum of **3** (−94 °C in toluene-d_8) showing coupling between the cyclopentadienyl and THF protons (∗ labels solvent peaks).

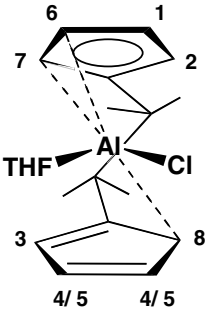

Fig. 12. Proposed solution structure for **3**. Numbering of cyclopentadienyl carbon positions corresponds to numbering of ^{1}H NMR peaks in Fig. 7.

allowed the sample to be cooled to −114 °C so that further decoalescence of the ^{1}H NMR signals could be achieved. Partial −114 °C COSY and ROESY spectra of **4** are shown in Fig. 16. We were surprised to find that the two protons corresponding to "allylic-type" signals (7 and 8) belong to the *same* cyclopentadienyl ring. Cross peaks in the −114 °C ROESY spectrum indicate that signals 1, 2, 7, and 8 correspond to one cyclopentadienyl ring and signals, 3, 4, 5, and 6, belong to the other one. The data are consistent with the solution structure shown in Fig. 17, in which one cyclopentadienyl ring is η^3 and the other is η^5. Curiously, the room temperature ^{27}Al NMR chemical shift of the compound (δ 104) is more consistent with the bis-η^1 geometry of the rings found in the crystal. Perhaps, as suggested for **2**, the average solution structure at room temperature differs from the low temperature structure. We suspect that the solvent may play a role in this behavior. Notably, the ^{1}H NMR chemical shift profile of **4** in pure methylcyclohexane-d_{14} at −114 °C (Supporting Information) is considerably different from that seen in Fig. 15.

At least two different processes are responsible for the dynamic averaging of the ^{1}H NMR signals of **4**. On process exchanges the coordination geometries of the

cyclopentadienyl rings. The other process exchanges the positions of the chloride and isocyanide ligands. Based on the low temperature solution structure of **4**, slippage of the cyclopentadienyl rings between η^3 and η^5 geometries would be the shortest pathway for accomplishing the first process, which appears to be "frozen out" by −41 °C in the variable temperature ^{1}H NMR spectra (Fig. 14). Further cooling leads to a slowing of the second process to the extent that the different chemical shifts for left and right cyclopentadienyl protons on each ring begin to be resolved.

To rule out the involvement of isocyanide ligand dissociation in the second process, we examined the effect of excess *t*-butyl isocyanide on the ^{1}H NMR and ^{13}C{^{1}H} NMR spectra of **4** in toluene-d^8 (Supporting Information). Both revealed separate peaks for free and bound *t*-butyl isocyanide, indicating that *t*-butyl isocyanide dissociation *does not* occur on the timescale of the signal averaging and some other process is responsible for the exchange between chloride and isocyanide ligand positions. Unlike THF (vide infra), excess isocyanide ligand *did* increase the rate of the signal averaging, however, an effect that is dependent on isocyanide ligand concentration. The effect of free *t*-butylisocyanide on the rate of signal averaging suggested an associative process involving a five-coordinate aluminum. The room temperature ^{27}Al NMR spectrum of a solution of **4** in the presence of a 20-fold excess of *t*-butyl isocyanide revealed no change in the chemical shift of the compound, however.

3. Summary and conclusions

Calculations at the ab inito level show that the potential energy surface for the rearrangement of cyclopentadienylaluminum between different haptotropes is extremely shallow with barriers ranging from 1 to 5 kcal mol [14,55]. Due to these low barriers, the actual pathway(s) by which the cyclopentadienylaluminum compounds rearrange have never been established experimentally since the rearrangements have been too rapid to capture on the NMR time scale. We have shown that introduction of an interannular bridge between the cyclopentadienyl rings of a dicyclopentadienylaluminum compound increases the barrier to rearrangement to $\sim$8 kcal mol^{-1}, in the case of compound **2**, making it possible to "freeze-out" the process in the ^{1}H and ^{13}C NMR spectra of the compound at experimentally accessible temperatures.

We suspect that the geometry of the bridge and the hapticity of the cyclopentadienyl rings on aluminum are intimately linked and that the rate of ring rearrangement is limited by the barrier to conformational rearrangement of the bridge. Indeed, in bis-η^5 *ansa*-metallocene complexes [56], fluctuation of the bridge between right and left zig-zag conformations is accompanied by a swiveling of the η^5 cyclic polyene ligands between two different orientations.

While the variable temperature NMR data ruled out a circumambulatory migration pathway for the aluminum in compound **2**, it did not allow us to pinpoint the actual dynamic processes responsible for the signal averaging. Coordination of THF to aluminum complicated the analysis with the competing dynamic process of THF site exchange, which probably occurs via reversible THF dissociation.

A different mechanism, possibly stereochemical inversion at aluminum, is responsible for the rapid exchange between the chloride and *t*-butyl isocyanide coordination sites in compound **4**. Such an inversion has been invoked to explain the enantiomerization of chiral tetrahedral chelate complexes of Be, B, Cd, Zn, and Hg [57]. The "freezing-out" of the epimerization process

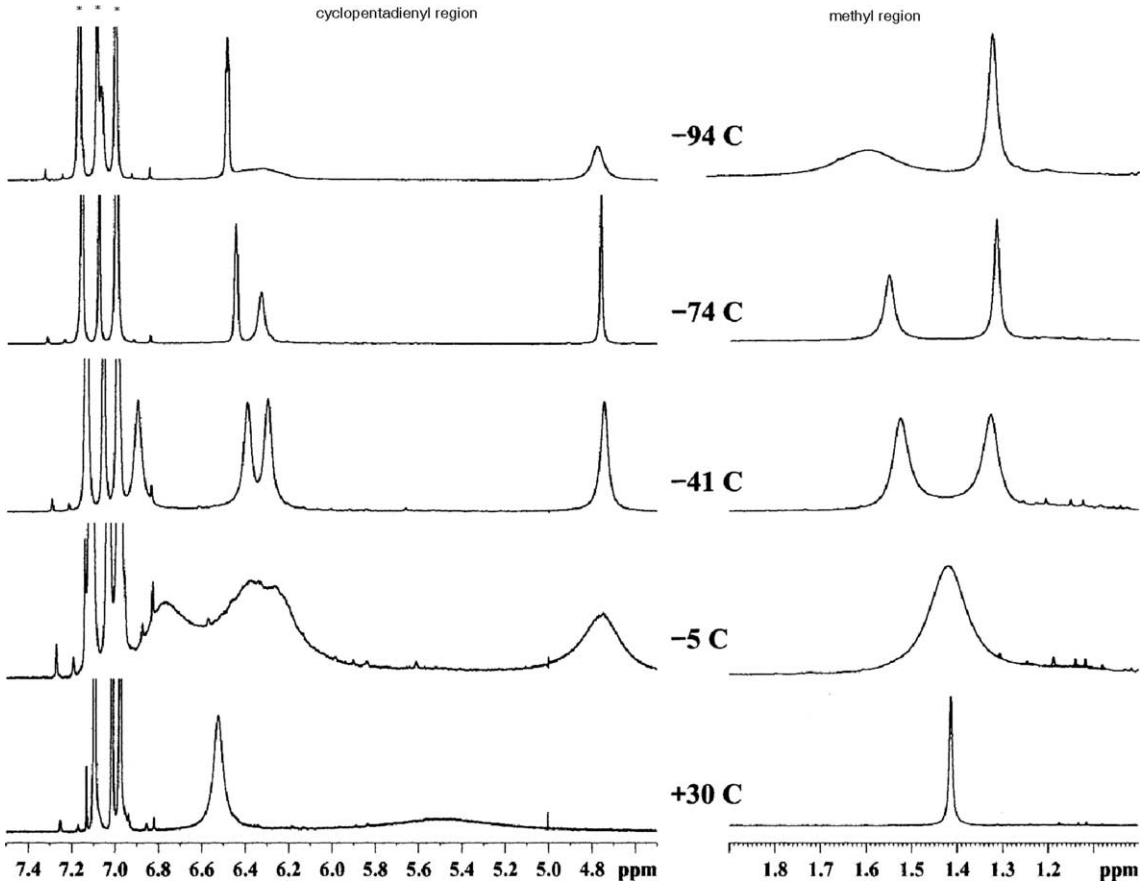

Fig. 14. Variable temperature ^{1}H NMR spectra of **4** in toluene-d_8 (* labels solvent peaks).

in the ^{1}H NMR spectrum of **4** occurs at a lower temperature than the cyclopentadienyl ring rearrangements. Ongoing work includes modeling the variable temperature ^{1}H NMR spectra of this system in order to extract out the kinetic parameters for the two fluxional processes. We will continue to investigate the role of excess *t*-butyl isocyanide in accelerating the dynamic averaging of the cyclopentadienyl ligand environments in **4**. We will also continue to investigate the possible involvement of stereochemical inversion at aluminum in the rearrangement of these pseudo-tetrahedral *ansa*-aluminocene compounds.

4. Experimental

4.1. General considerations

All experiments were performed under inert atmosphere conditions using a combination of glovebox, high vacuum and Schlenk techniques. Non-deuterated solvents were dried over alumina columns and stored in line-pots over sodium/benzophenone. Deuterated solvents were dried over 4A molecular sieves. Argon was purified by passage over an oxytower BASF catalyst (Aldrich) and 4A molecular sieves. NMR spectra were recorded on Bruker Avance 300 MB (300 MHz ^{1}H; 75.4 MHz, ^{13}C; 78 MHz, ^{27}Al) and Bruker Avance 500 (500 MHz, ^{1}H; 125 MHz, ^{13}C; 130 MHz, ^{27}Al) spectrometers. All chemical shifts are reported in ppm and referenced to residual protons in the solvent (^{13}C, ^{1}H) or $Al(OH)_3$ (^{27}Al external reference, 0 ppm). IR spectra were recorded on a Perkin–Elmer-Spectrum 1000 FT-IR Spectrometer. Elemental analyses were determined by Desert Analytics (Tuscon, AZ).

6,6-Dimethylfulvene was prepared according to the literature procedure [58]. Solid $MeAlCl_2$ was obtained by removing the solvent from a 1.0 M hexane solution from Aldrich under vacuum.

4.2. $[(CH_3)_4C_2(C_5H_5)_2]$

This molecule has been described previously [59,60]. The route that we used for its preparation is described below.

To a suspension of activated calcium (5.50 g, 137 mmol) [13] in 250 mL of THF was added 33 mL of 6,6-dimethylfulvene (274 mmol). The solution turned brown while being stirred overnight at room temperature. The solution was transferred slowly via a cannula

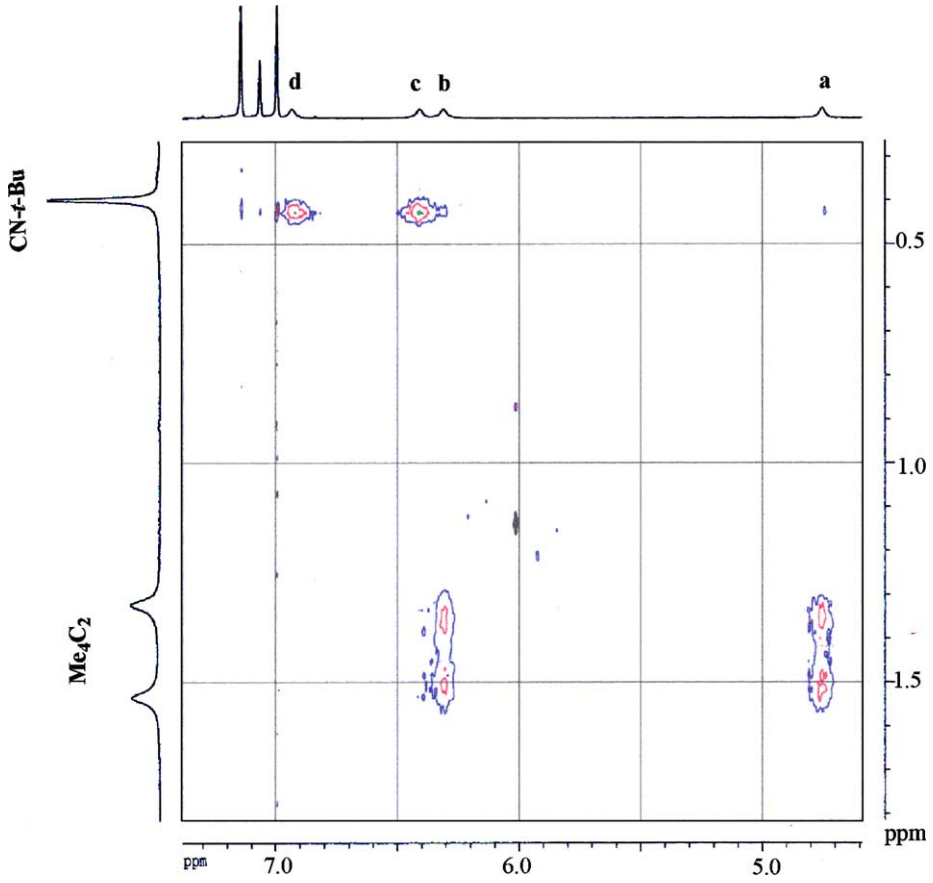

Fig. 15. Partial −40 °C ROESY spectrum of **4** in toluene-d_8.

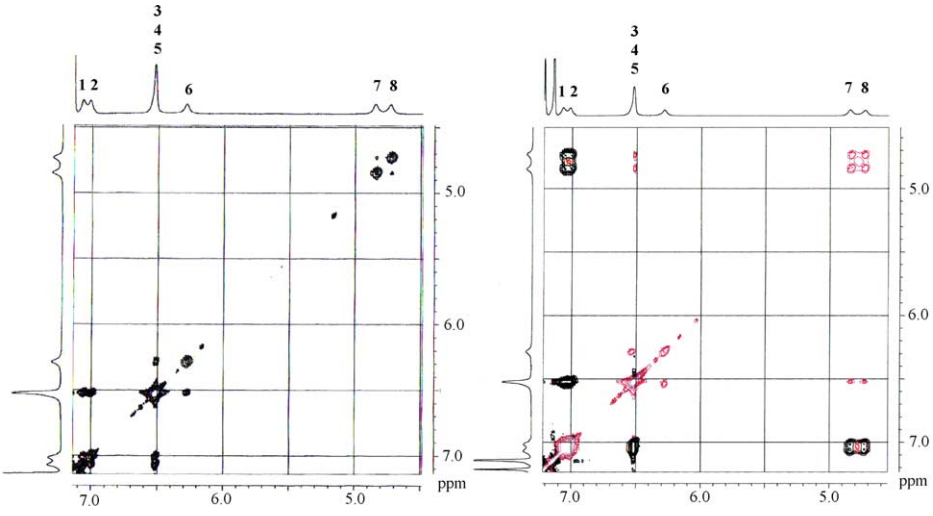

Fig. 16. Partial COSY (left) and partial ROESY (right) spectra of a solution of **4** in ~3:1 toluene-d_8:methyl-cyclohexane-d_{14} at −114 °C. Pink shading of peaks in ROESY spectrum indicates exchange.

to another flask containing 200 mL of distilled water. The resulting bright yellow solution was stirred an additional hour at room temperature. (Workup of the reaction mixture did not involve air free procedures.) The volume of the solution was increased to 600 mL with distilled water, and the solution was acidified with concentrated HCl to a pH of 2 and diluted with ether (200 mL). The aqueous portion was extracted with ether (2×100 mL), and the combined organic phases were washed with water (100 mL) and dried over $MgSO_4$. The solution was concentrated to 100 mL under reduced pressure and stored at −60 °C. Bright yellow crystals

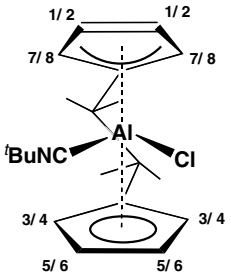

Fig. 17. Proposed solution structure for **4**. Numbering of cyclopentadienyl ring positions corresponds to number of 1H NMR peaks in Fig. 15.

formed after 20 h. The product was separated by filtration and dried under vacuum (6 h, 100 mTorr) to afford 6.67 g (23%) of free ligand.

4.3. [$Me_4C_2(C_5H_4)_2Mg$] (**1**)

16 mL (16.3 mmol) of a 1.0 M heptane solution of dibutylmagnesium was syringed into a solution of [$Me_4C_2(C_5H_5)_2$] (3.4 g, 16.0 mmol) in 50 mL heptane. The mixture was heated to 70 °C and stirred overnight under argon. White solid precipitated from the mixture. The white precipitate was isolated by filtration, washed with petroleum ether, and then dried under vacuum (yield 1.52 g, 40%). ^{1}H NMR (300 MHz, 297 K, THF-d_4): δ 1.08 (s, 12H, (CH_3)$_4$); δ 5.76 (s, 4H, C_5H_4); δ 5.99 (s, 4H, C_5H_4).

4.4. [$Me_4C_2(C_5H_4)_2Al$-μ-$Cl]_2$ (**2**)

Aluminum trichloride (1.15 g, 8.45 mmol) was added from a solid dispenser to a solution of **1** (2.0 g, 8.46 mmol) in 50 mL toluene. The mixture appeared yellow orange color and was stirred overnight at room temperature. The yellow solution was filtered to remove $MgCl_2$. The toluene then was removed from the filtrate under reduced pressure leaving a yellow oil. Addition of 25 mL petroleum ether to the oil precipitated a yellow-tinged white powder that was collected by filtration and dried under vacuum (yield 1.12 g, 48%). ^{1}H NMR (500 MHz, 297 K, toluene-d_8): δ 1.01 (s, 12H, (CH_3)$_4$); δ 5.13 (s, 4H, C_5H_4); δ 6.16 (s, 4H, C_5H_4); ^{13}C{^{1}H} NMR (125 MHz, 297 K, toluene-d_8): δ 24 C_2(CH_3)$_4$; δ 97 (C_5H_4); δ 117 (C_5H_4); δ 148 (quaternary, C_5H_4); ^{27}Al NMR (130 MHz, 297 K, toluene-d_8): δ −2. *Anal.* Calc. for $C_{14}H_{16}AlCl$: C, 69.98; H, 7.28. Found: C, 68.18; H, 7.42%.

4.5. [$Me_4C_2(C_5H_4)_2AlCl(THF)$] (**3**)

THF (10 mL) was condensed onto 0.3 g of **2** $Me_4C_2Cp_2AlCl$ at −78 °C and the mixture was warmed to room temperature. The compound dissolved immediately and the solution was stirred for 30 min. THF was then removed under reduced pressure and the white product was washed with 10 mL pentane and dried under vacuum to afford 0.35 g (94% yield) of **3** as a white powder. ^{1}H NMR (500 MHz, 297 K, toluene-d_8): δ 1.39 (s, 12H, (CH_3)$_3$); δ 1.09 (t, THF); δ 3.4 (t, THF); δ 5.5 (s, 4H, C_5H_4), δ 6.25 (s, 4H, C_5H_4); ^{13}C{^{1}H} NMR (125 MHz, 297 K, toluene-d_8): δ 24.8, 26.2 (CH_3)$_4$; δ 42.8 THF; δ 72 THF; δ 98 C_5H_4; δ 117 C_5H_4; δ 150 (quaternary, C_5H_4); ^{27}Al NMR (130 MHz, 297 K, toluene-d_8): δ 78.

4.6. [$Me_4C_2(C_5H_4)_2AlCl(CN^tBu)$] (**4**)

t-Butylisocyanide (0.5 mL, 1.09 mmol) was syringed into a solution of 0.3 g (1.09 mmol) $Me_4C_2Cp_2AlCl$ in 20 mL benzene at room temperature under argon. The mixture was stirred for 2 h. Volatiles were removed under vacuum to afford a white solid. The solid product was washed with 10 mL pentane and was dried under reduced pressure to yield 0.19 g (53% yield) of **4**. ^{1}H NMR (500 MHz, 297 K, toluene-d_8): δ 0.53 (s, 9H, (CNC(CH_3)$_3$); δ 1.41 (s, 12H, (CH_3)$_4$; δ 5.5 (s, very broad, 4H, C_5H_4); δ 6.6 (s, 4H, C_5H_4); ^{13}C{^{1}H} NMR (125 MHz, 297 K, toluene-d_8): δ 27.3 (CH_3)$_4$; 27.5 (CNC(CH_3)$_4$); δ 42.8 $CH(Me)_2$; δ 122.8 C_5H_4; δ 149.3 (quaternary, C_5H_4); ^{27}Al NMR (130 MHz, 297 K, toluene-d_8) δ 104; IR(Nujol mull/NaCl plates: (ν N≡C) 2258 cm^{-1}.

5. X-ray crystal structure determinations

Crystals were removed from their container and covered with a layer of hydrocarbon oil. A suitable crystal was selected, attached to a glass fiber and placed in the low-temperature nitrogen stream [61]. Data for **2** were collected at 83(2) K, **3** at 85(2) K, **4** at 84(2) K using a Bruker/Siemens SMART APEX instrument (Mo Kα radiation, λ = 0.71073 Å) equipped with a Cryocool NeverIce low temperature device. Data were measured using omega scans of 0.3° per frame for 10 s (**2**) and 5 s (**3**, **4**), and a full sphere of data was collected for each A total of 2132 (**2**) and 2450 (**3**, **4**) frames were collected with a final resolutions of 0.77 Å (**2**, **3**) and 0.84 Å (**4**). The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved using SMART [62] software and refined using SAINTPLUS [63] on all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPLUS software. Absorption corrections were applied using SADABS [64]. Structures were solved by direct methods and refined by least squares method on F^2 using the SHELXTL program package [65]. Structures were solved in the space groups $P2_1/c$ (**2**) and $P\bar{1}$ (**3**, **4**). All non-hydrogen atoms were refined anisotropically. The THF molecule in **3** is disordered

with a majority occupancy of 66% for C18 and C19. A large residual of 1.651 e $Å^{-3}$ remains 0.93 Å from Cl(2) in **4**. This is due to crystal size (cutting led to loss of crystallinity) and absorption problems and could not be modeled or eliminated. No decomposition was observed during data collection. Details of the data collection and refinement are given in Table 1. Further details are provided in the Supporting Information.

Acknowledgments

We are grateful to the donors of The Petroleum Research Fund, administered by the ACS and the Idaho NSF EPSCoR program (EPS-0132626) for support of this research. We thank Professor Richard V. Williams for his helpful advice.

Appendix A. Supplementary data

Additional variable temperature 1-D NMR spectra, COSY and ROESY spectra of compounds **2**–**4** (13 pages). CCDC 262014, 262015, 240803 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/data_request/cif, by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2005.04.014.

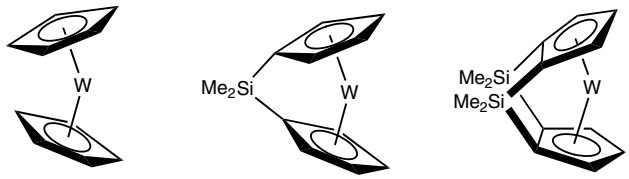
This paper describes computational work on a doubly silicon-bridged *ansa*-metallocene, $[W(\eta^5\text{-}C_5H_3)_2\text{-}(SiMe_2)_2]$, ($a$-$Si_2Cp_2W$), that is shown to have the lowest singlet state of comparable energy to the lowest triplet state.

2. Computational methods

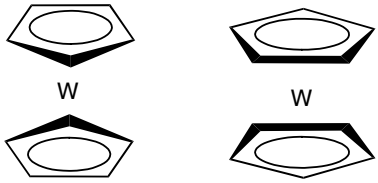
DFT calculations, using the ADF code version 2004 [18], were performed using Vosko, Wilke and Nusair's local functional [19], with the Becke 88 [20,21] and the Perdew 86 [22] non-local exchange and correlation gradient corrections. The basis sets used were uncontracted triple-ζ Slater-type orbitals (STOs). Hydrogen, carbon and silicon were given extra polarization functions (2p on H, 3d on C, and 4d on Si). The cores of atoms were frozen, C up to the 1s level, Si up to 2p, and W up to 4d. Scalar ZORA relativistic corrections [23–26] were used. The calculations used gradient corrections applied after the SCF convergence.



The SCF energy surface for methane addition to **3** and release from **6** was scanned to identify maxima and minima. These were then confirmed as stationary points by frequency calculations. Structures **4** and **5** showed additional imaginary frequencies of -5i and -25i cm^{-1} corresponding to rotation of methyl groups on the bridging Si. These are considered negligible.

Total energies given in Table 1 are referenced with respect to atomic fragments with zero spin as calculated by the ADF program. They represent relative SCF energies and give only this component of the energy surface. Neither zero-point energies nor thermal contributions to enthalpy, or entropy are given here.

Orbital surfaces were calculated using Molekel and represent a surface with value ±0.03.



3. Results

Geometries were optimized for **1**–**3** with the spin set at 0 and 1 and no symmetry constraints.

1 **2** **3**

1 was also optimized with C_{2v} symmetry imposed; two optimizations were carried out under this constraint, where the ring conformation was set to orientations **A** and **B**. In these cases, only a spin of 0 was employed.

A **B**

Total energies and the angle between the ring planes are given in Table 1.

Stationary points for the addition of CH_4 to a-Si_2Cp_2W, **3**, were computed with spin 0. These comprised **3** + CH_4, a methane σ-complex, **4**, the transition state for oxidative addition, **5**, and the methyl hydride product, **6**. SCF energies are given in Table 1. Table 1 also reports the energies of the LUMO, HOMO and HOMO − 1 for **1**–**4** ($S = 0$).

In the case of **1** and **2**, the $S = 1$ optimization gave the lower total SCF energy. For **3**, the SCF energies of both multiplicities were the same within computational error. When **1** was optimized with no symmetry constraints and spin 0 the structure was found to be significantly bent. The minimum SCF energy structure was found to be virtually identical to **1A** where the rings were constrained to have four carbons lie at the back of the

Orbital energies (eV) of the LUMO, HOMO and HOMO − 1 of **1**–**3** with $S = 0$.

metallocene wedge. The total SCF energies of **1A** and **1B** were found to be very close.

Conformations **1A** and **1B** were found to have different HOMOs, that of the former being of b_1-symmetry and that of the latter a_1-symmetry. In line with this result, **2**, which has ring conformation **A**, has a b_1-symmetry type HOMO, while **3** with a **B** type ring conformation has an a_1-symmetry type HOMO. For all compounds, the LUMO is of a_1-symmetry.

Stationary point SCF energies on the pathway to methane addition to **3** are given in Table 1. The methane σ-complex, **4**, is stabilized by 0.38 eV relative to **3** and methane, and no barrier was found to binding on the singlet surface. The methyl hydride **6** was 1.3 eV more stable than the reactants and the SCF energy barrier to oxidative addition from the σ-complex was 0.03 eV.

4. Discussion

Addition of methane to tungstenocenes is overall enthalpically favourable, though entropically unfavourable. The entropy is similar for all tungstenocenes as it is dominated by the gas phase entropy of methane. The thermal decomposition temperature of a tungstenocene methyl hydride is therefore controlled by the size of the enthalpy change. Thus, a study of addition and decomposition should in principle be carried out on a Gibbs free energy surface as a function of temperature. This is not currently possible and current practice is to compute reaction pathways on an SCF energy surface to identify minima, as models for intermediates, and saddle points, as models for transition states. The benefit of this approach is that it illuminates crucial electronic factors that control reactivity.

The Cartesian system assumed for the metallocenes is given in Fig. 1. For a C_{2v} structure, z is the C_2 axis and xz is the metallocene plane in which further ligands may be bound.

For a group 6 metallocene four d electrons are accommodated in the frontier orbitals. The relevant ones are two of a_1-symmetry and one of b_1-symmetry. To concur with an earlier review [15], they are numbered $3a_1$, $2b_1$ and $4a_1$. The calculations indicate that the ground state of **1** is a triplet and has a parallel ring structure as established experimentally [12,13]. The lowest singlet state is bent and is 0.4 eV higher in energy, with a configuration of $3a_1^2 2b_1^2$. The ring orientation makes very little difference to the total energy but does affect the orbital ordering, in that conformation **A** has the $2b_1$ orbital as the HOMO whereas conformation **B** has $3a_1$ as the highest occupied orbital. Both these orbitals have the bonding role of back-donation to a linear combination of the cyclopentadienyl ring e_2 orbitals. The metal lies closest to the carbons at the back of the metallocene wedge, so the overlap with these carbons is crucial to determining the degree of stabilization. The nodal characteristics maximize the stabilization of the $3a_1$ orbital in conformation **A** and the $2b_1$ orbital in conformation **B**. Hence the reversal of orbital ordering between the two conformations. These interactions are illustrated by the orbital surface plots in Fig. 2. The energy separation between the $3a_1$ and $2b_1$ orbitals is greater for conformation **A** than conformation **B**. Also the $3a_1$ orbital in conformation **A** is the lowest energy found for a frontier orbital in either conformation, suggesting that this conformation is favoured by a d^2 metal system, which has been found to be the case [16,27].

The $4a_1$ orbital is significantly destabilized by bending as a result of anti-bonding interaction with the rings. Thus, to achieve a diamagnetic ground state a large

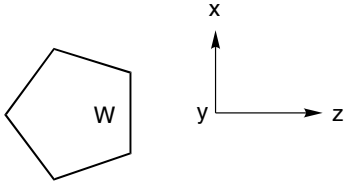

Fig. 1. Coordinate system employed for a bent metallocene unit.

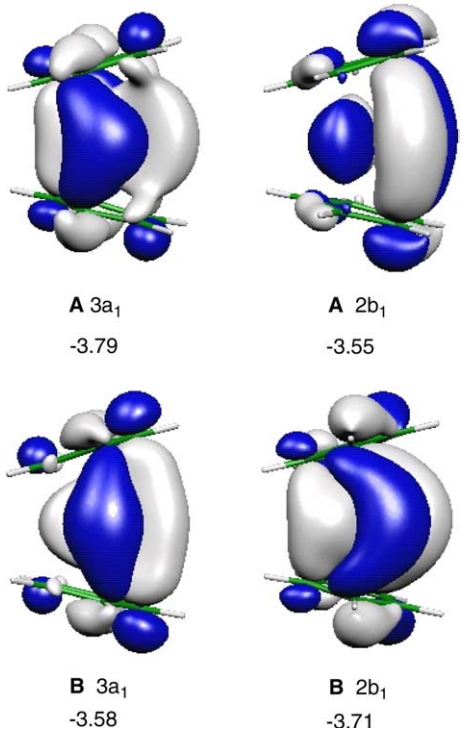

Fig. 2. Isosurfaces and energies (eV) of the $3a_1$ and $2b_1$ MO of **1** with conformations **A** and **B**, showing that for **A** the $3a_1$ orbital maximises interaction with the closest carbons and for **B** the $2b_1$ orbital maximizes interaction with the closest carbons.

inter-ring angle is needed. It is also desirable to maximize the HOMO–LUMO separation. In the unsubstituted case, this is achieved by adopting conformation **B**.

Thus, it seemed a good idea to test whether the doubly Si-bridged metallocene **3** would have a singlet ground state. The inter-ring angle calculated for **3** is 44.4°. This is less than the 60–65° found for tungstenocene structures with a single carbon *ansa*-bridge. For these, the triplet metallocene was found to be 0.14 eV lower in energy than the singlet structure. However, a single bridge holds the rings in the less favourable **A** conformation. For the double Si-bridged compound **3**, the singlet and triplet states are of very similar energy.

For comparison purposes the singlet and triplet energies of **2**, where there is a single Si bridge, were also calculated. In this case, the triplet was 0.37 eV lower in energy. The $3a_1$ and $2b_1$ orbital surfaces of both **2** and **3** are shown in Fig. 3. The stabilization by back donation is greater for the $3a_1$ orbital for **2** and for the $2b_1$ orbital for **3**. As a consequence, the HOMO–LUMO gap is larger for **3** so in this case the cost of going high spin is greater.

In order to establish the likely energy profile for oxidative addition of methane geometries were optimized for the stationary points on the reaction surface. The structure for the methane σ-complex, **4**, the oxidative addition transition state, **5**, and the methyl hydride product, **6**, are shown in Fig. 4. They resemble previously calculated structures for oxidative addition to tungstenocenes [7,9,11]. These stationary points were

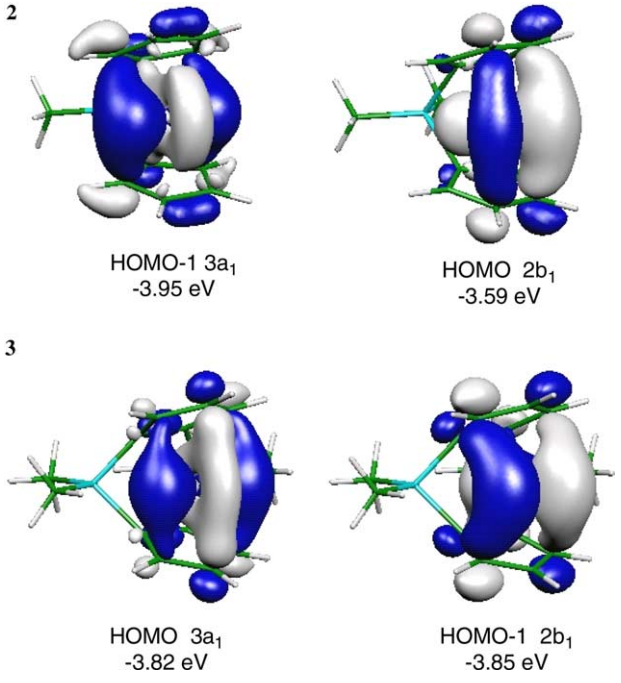

Fig. 3. Isosurfaces and energies (eV) of the $3a_1$ and $2b_1$ orbitals of **2** and **3**.

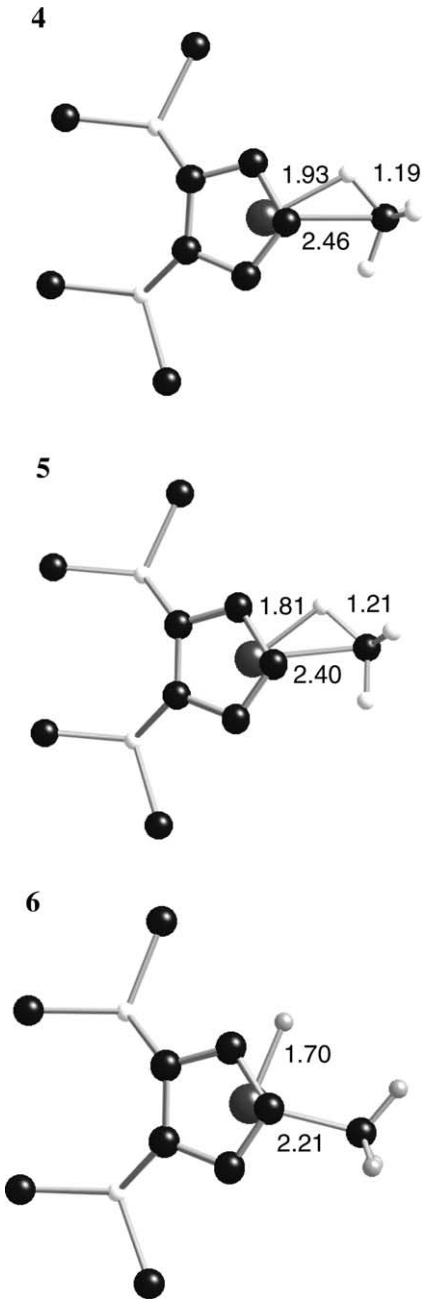

Fig. 4. Calculated structures of stationary points found for methane addition to **3**. (Hydrogens of the metallocene unit have been omitted in the interest of clarity.)

verified by frequency calculations. Transition state **5** had an imaginary vibration of $-352i\ cm^{-1}$ that showed motion of the hydride moving from the metal to the methyl carbon. In addition, both **5** and **6** gave very small imaginary frequencies corresponding to rotation of methyl groups attached to the Si bridges. These are considered to be negligible.

Intermediate **4** shows very little change in the energy of the $3a_1$ and $2b_1$ orbitals when compared with **3** (Table 1). Orbital $4a_1$ is significantly destabilized

and has an anti-bonding interaction with the methane. Search of the energy manifold in the energy region of the methane t_2 orbitals revealed one with a small W contribution at −11.06 eV that was 0.2 and 0.4 eV more stable than the other two. None of these three orbitals were exclusively localized on methane but that was their predominant character, and the most stable corresponds to σ donation from the methane.

One point of interest is a reorientation of the cyclopentadienyl rings during the course of oxidative addition. The structure of **4** shows the rings in orientation **B** with the methane coordinated opposite the pair of bridges. In the transition state **5** there is a slight twist of the rings. When the oxidative addition is complete, the rings have changed to a conformation close to **A**. The bisector of the W–CH_3 and W–H vectors points to only one of the Si bridging atoms. Examination of the rings shows that the carbons connected to this Si have an inter-atomic distance of 2.65 Å while the other two *ipso* carbons are 2.79 Å apart. Fig. 5 shows a rear view of **6**. The methane complex **4** is formally d^4. On oxidative addition two electrons are provided by the metal for bond formation, and the metal configuration changes to d^2. The calculations discussed above demonstrate the superiority of the **A** conformation in stabilizing just two electrons in the $3a_1$ orbital. Thus, the reorientation of the rings facilitates back donation in the oxidized complex. A similar ring reorientation was found between a d^0 Mo complex, $[Mo(\eta^5C_5H_5)_2H_3]^+$, which has conformation **B**, and the d^2 transition state for hydrogen exchange, which has ring conformation **A** [27].

The SCF energetics of the addition are represented graphically in Fig. 6. There was no barrier on the SCF energy surface to methane binding from the singlet state of **3**. The methane σ-complex, **4**, has a binding energy of −37 kJ mol^{-1} and the methyl hydride is exo-energetic by −125 kJ mol^{-1}. The SCF energy barrier found for oxidative addition from **4** was very small as has been calculated to be the case with other tungstenocene systems [9,11].

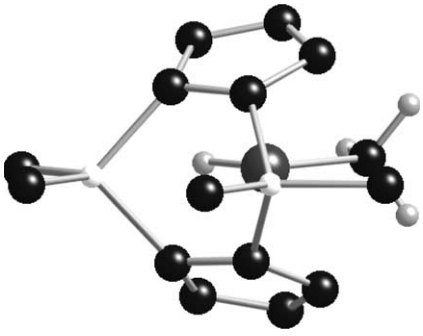

Fig. 5. View of **6** showing **A** type conformation of the rings for the d^2 methyl hydride.

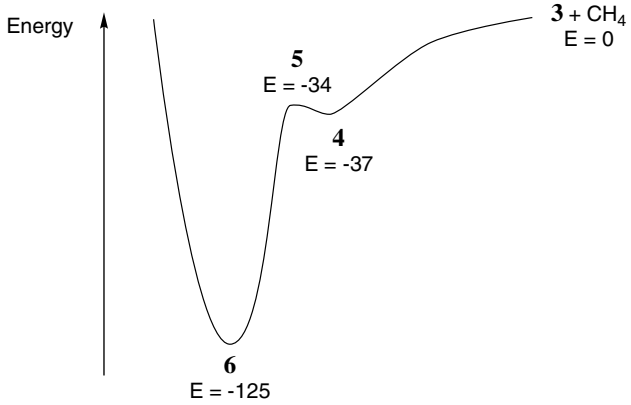

Fig. 6. Energetics of the addition of methane to **3**. Energies are given in kJ mol^{-1}.

5. Conclusions

The orbital energies of metallocene frontier orbitals may be tuned by introduction of *ansa*-bridges. Single *ansa*-bridges favour a ring conformation that stabilizes the $3a_1$ orbital. In contrast double *ansa*-bridges favour a ring conformation that stabilizes the $2b_1$ orbital.

In the latter cases, the $3a_1$ orbital is the HOMO and the gap between this and the $4a_1$ orbital is maximized, leading to an orbital splitting that makes a low spin configuration more competitive for a d^4 configuration. For $[W(\eta^5\text{-}C_5H_3)_2(SiMe_2)_2]$ the singlet and triplet states are of comparable energy with the consequence that binding of methane encounters no barrier on an SCF energy surface.

described [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Cl_2] [1] and the zinc dialkyl compounds [Zn{$(CH_2)_nCH_3$}$_2$] (n = 1, 2 or 3) in toluene at low temperatures [2,3]. In a typical reaction, the mixture was stirred at room temperature for 12 h and then the excess of the dialkylzinc reagent was cautiously hydrolysed by the addition of H_2O, prior to passing the toluene soluble mixture down an alumina column and then eluting with toluene. The compounds **2** and **3** were extracted into pentane and isolated as yellow crystalline solids by cooling the solution to −80 °C. The compound **3** is new and has been characterised by elemental analyis, FAB mass spectrometry and ^{1}H and ^{13}C{^{1}H} NMR spectroscopy. The characterising data for **3** and all the other new compounds described in this work are given in Table 1. In most cases assignments of the ^{1}H NMR spectra were assisted by ^{1}H–^{1}H NMR COSY experiments [6].

Treatment of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Cl_2] with di(*n*-butyl)zinc [Zn{$(CH_2)_3CH_3$}$_2$] in toluene at low temperature affords a mixture of the σ-*n*-butyl compounds [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_3CH_3$}$_2$] (**4**) and [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_3CH_3$}Cl] (**5**). The yellow σ-*n*-butyl compounds **4** and **5** can be separated by fractional recrystallisation from a 1:1 toluene/pentane solution in 16% and 41% yield, respectively. Unexpectedly the NMR data showed the peak due to the hydrogens in the α-CH_2, methylene group relative to the metal is not the highest field resonance of the hydrogens of the *n*-butyl ligand. In the σ-ethyl compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2CH_3$}I] the peak due to the α-CH_2 methylene hydrogens is also found at a lower field relative to the β-methyl hydrogens [2]. The *n*-pentyl-chloride compound [W{(η-C_5H_4)-CMe_2(η-C_5H_4)}{$(CH_2)_4CH_3$}Cl] (**6**) was prepared by the reaction between [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Cl_2] and [Zn{$(CH_2)_4CH_3$}$_2$]. The compound **6** is obtained as a pale orange/red solid in 29% yield following passage in diethyl ether down an alumina column. The corresponding di-*n*-pentyl compound [W{(η-C_5H_4)CMe_2-(ηC_5H_4)}{$(CH_2)_4CH_3$}$_2$] (**7**) was isolated in the same reaction as a very minor product (ca. 1%). It was characterised by ^{1}H NMR spectroscopy only. The di-*n*-hexyl compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_5CH_3$}$_2$] (**8**) was prepared by the reaction between [W{(η-C_5H_4)-CMe_2(η-C_5H_4)}Cl_2] and [Zn{$(CH_2)_5CH_3$}$_2$].

Treatment of the di-*n*-propyl compound [W{(η-C_5H_4)-CMe_2(η-C_5H_4)}{$(CH_2)_2CH_3$}$_2$] (**3**) with NH_4I in THF at 65 °C gave the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_2CH_3$}I] (**9**) as a pale red solid in 47% yield. The compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_2CH_3$}I] (**9**) was treated with [Na{AlH_2(OCH_2O-CH_2CH_3)$_2$}] at low temperature to give, after cautious hydrolysis of excess of [Na{AlH_2($OCH_2CH_2OCH_3$)$_2$}], the *n*-propyl-hydride compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_2CH_3$}H] (**10**) as a yellow crystalline solid in ca. 50% yield.

All IR data are expressed in wave numbers (cm^{-1}).

For the FAB mass spectrometry data, the characteristic isotope patterns were observed.

[a] Microanalytical data given as: element, found(calc.), %.

[b] NMR data are given as chemical shift (δ) [relative intensity, coupling, multiplicity, assignment] at 298 K unless otherwise stated. In C_6D_6 unless otherwise stated. ^{1}H NMR at 500 MHz, $^{13}C\{^1H\}$ at 125 MHz and ^{2}H at 76.75 MHz.

The *n*-butyl-hydride and *n*-pentyl-hydride compounds; [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}H] (*n* = 3, **11**; 4, **12**) were prepared similarly by treatment of the corresponding *n*-alkyl-chloride compounds [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}Cl] (*n* = 3, **5**; 4, **6**) with [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}] as yellow crystalline solids in 42% and 49% yields, respectively.

The isolation and thermal stability at ambient temperatures of the *n*-alkyl-hydrides [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}H] (*n* = 2, **10**; 3, **11**; 4, **12**) in both the solid state and in solution confirmed our expectation the there would be an increased stability of Group 6 *ansa*-metallocene alkyl-hydrides with respect to reductive alkane elimination as a consequence of the presence of the single carbon *ansa*-bridge.

In order to study hydrogen exchange processes between alkyl and hydride ligands in *n*-alkyl hydride species it was necessary to prepare appropriately isotopically labelled compounds, namely [W{(η-C_5H_4)-CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}D], where *n* = 0–4. It had been shown previously that treatment of [W{(η-C_5H_4)-CMe_2(η-C_5H_4)}{CH_2CH_3}I] with [Li{$AlD_2(OCH_2CH_2$-$OCH_3)_2$}] gave a mixture of the desired ethyl-deuteride [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CH_2CH_3)}D] together with the mono-deuterated C_5-ring ethyl-hydride species [W{(η-C_5H_3D)CMe_2(η-C_5H_4)}{CH_2CH_3}H] [2].

A reasonable mechanism for the formation of the mono-deuterated C_5-ring compound has been proposed [7] and is shown in Fig. 1.

When the *n*-alkyl-halide compounds [W{(η-C_5H_4)-CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}X] (X = I and *n* = 2, **9** or X = Cl, *n* = 3, **5**; 4, **6**) were reacted with [Li{AlD_2-$(OCH_2CH_2OCH_3)_2$}] then only the undesired mono-deuterated C_5-ring *n*-alkyl hydride species [W{(η-C_5-H_3D)CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}H] are formed, as shown by ^{1}H and ^{2}H NMR spectroscopy. There was no evidence for the desired tungsten alkyl-deuteride species [W{(η-C_5H_4)CMe_2(η-C_5H_4}{$(CH_2)_n$-CH_3}D]. It seems that as the length and effective bulk of the *n*-alkyl chain is increased from ethyl to *n*-propyl and longer, the direct attack of deuteride at the metal centre is increasingly disfavoured compared to *exo* attack at the cyclopentadienyl rings of the equilibrium dissociated cations (see Fig. 1).

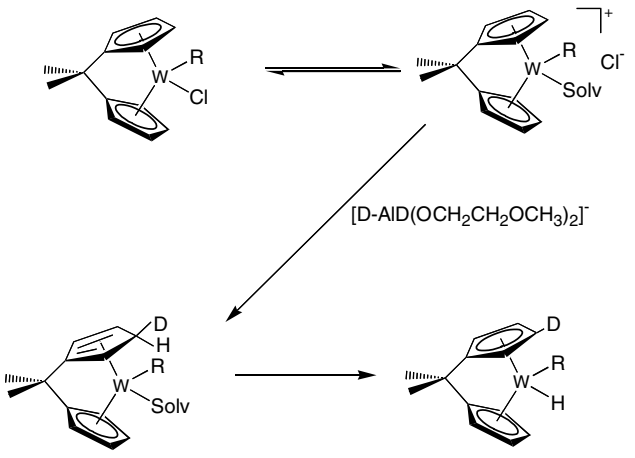

Fig. 1. Mechanism proposed for deuteration of the cyclopentadienyl ring in [W{(η-$C_5H_{4-x}D_x$)CMe_2(η-$C_5H_{4-x}D_x$)}(R)H] [7].

Various alternative routes to the desired compounds [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_nCH_3$}D] (*n* = 2–4) were investigated but none were successful. For example, attempts to deprotonate [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_nCH_3$}H] using KH in the presence of 18-crown-6, followed by quenching of the anticipated salts [K(18-crown-6)][W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_nCH_3$}] [8] with D_2O, gave no tractable products. Alternative deuteride reagents such as $NaBD_4$ or Li-BEt_3D again gave only the ring deuterated *n*-alkyl-hydride compounds. Finally, it was decided to prepare suitable alkyl-deuterides by starting with ring-perdeuterated *ansa*-metallocene alkyl-halides [W{(η-C_5D_4)-$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_nCH_3$}X] (*n* = 1–4; X = Cl or I). Treatment of these with [Li{$AlD_2(OCH_2CH_2OCH_3)_2$}] should result in the *exo* attack of D^- and then the *endo*-deuterium should transfer to the tungsten centre to give the desired W–D group (see Fig. 2).

The perdeuterated *ansa*-ligand [Li_2{$(C_5D_4)C(CD_3)_2$-(C_5D_4)}] and the perdeuterated *ansa*-metallocene dichloride compound [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}Cl_2] (**13d**) (where **d** indicates a perdeuterated ansa ligand system) were prepared by a slightly modified procedure to that used for the analogous protio compounds [9] (see Section 3 and Fig. 3).

The compound **13d** was characterised by ^{2}H NMR spectroscopy and by its subsequent reactions. The extent of deuteration of the metallocene fragment was determined to be >95%.

The deuterated di-*n*-alkyl compounds [W{(η-C_5D_4)-$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_nCH_3$}$_2$] (*n* = 1, **14d**; 2, **3d**; 4, **6d**) and the corresponding *n*-alkyl-halide compounds [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_nCH_3$}X], (X = I, *n* = 1, **15d**; *n* = 2, **9d**; *n* = 4 **7**; X = Cl, *n* = 3, **5d**) were then prepared [2]. Due to the small amount of compound **13d** available these deuterated *ansa*-metallocenes were characterised by ^{1}H and ^{2}H NMR spectroscopy only. The extent of deuteration of the fragment [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}] in all the compounds containing that fragment was shown by NMR data to be 95 ± 2% see Fig. 4.

Addition of [Li{$AlD_2(OCH_2CH_2OCH_3)_2$}] to a solution of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{CH_2CH_3}I] (**15d**) in toluene at low temperature afforded the ethyl-deuteride compound [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}-{CH_2CH_3}D] (**16d**) as a yellow crystalline solid. Compound **16d** was characterised by ^{1}H and ^{2}H NMR spectroscopy. The ^{1}H NMR spectrum of compound **16d** consists of a triplet and a quartet at δ 1.58 and

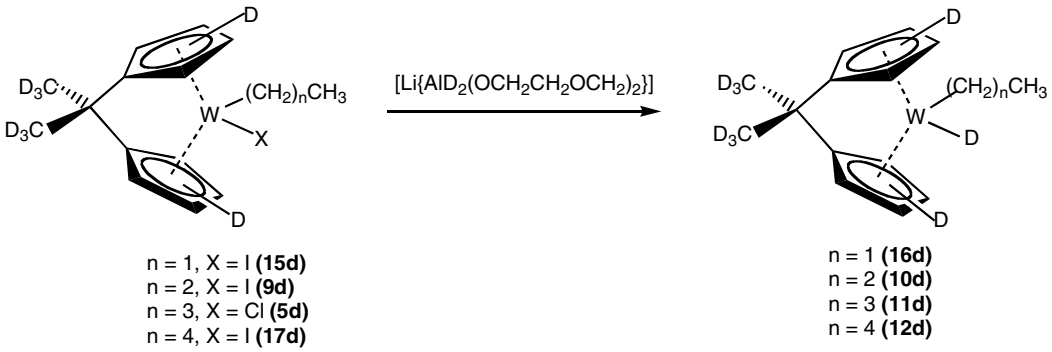

Fig. 2. Proposed route for the synthesis of the tungsten alkyl-deuterides [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_nCH_3$}D] where = 1–4.

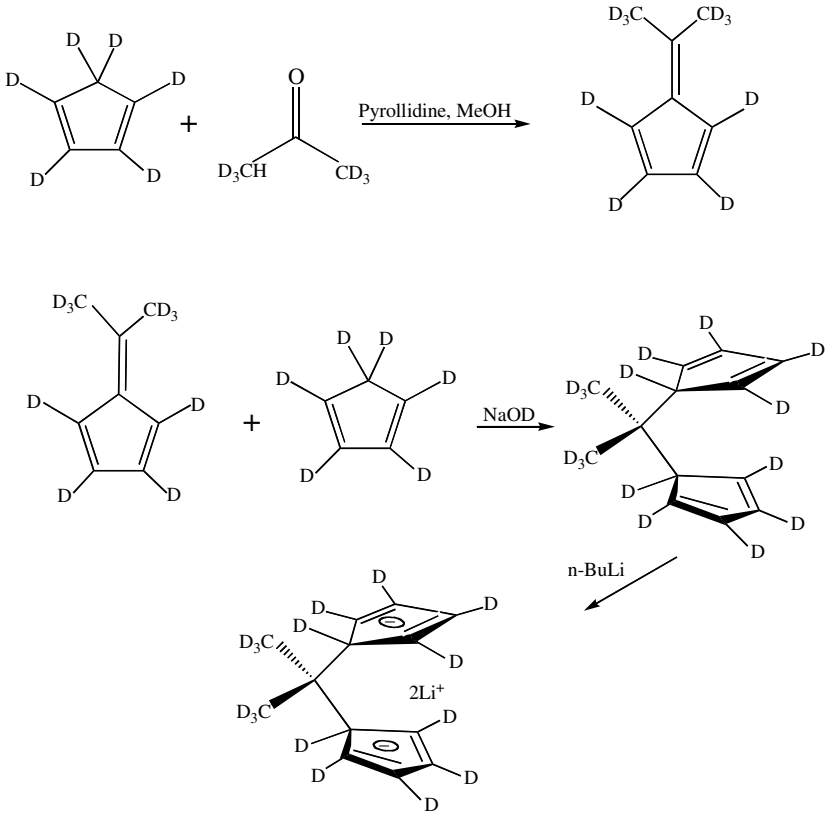

Fig. 3. Synthesis of the perdeuterated ligand precursor {$[Li]_2[(C_5D_4)C(CD_3)_2(C_5D_4)]$}.

1.12 ppm, respectively, corresponding to the protons of the ethyl ligand. Residual cyclopentadienyl proton peaks (5% H) are located at δ 5.12, 4.50, 4.31 and 3.78 ppm. The ^{2}H NMR spectrum of the compound **16d** shows the four deuterium atoms attached to the cyclopentadienyl rings are located at δ 5.08, 4.48 4.28 and 3.75 ppm. Two singlets at δ 0.46 and 0.19 ppm correspond to the deuterium atoms of the $C(CD_3)_2$ bridging unit. A singlet at δ −6.44 ppm is assigned to deuterium attached to the metal. In the ^{1}H NMR spectrum of the corresponding ethyl-hydride compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CH_2CH_3}H] the hydride resonance is found at δ −6.46 ppm [2].

The higher *n*-alkyl-deuteride compounds [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_nCH_3$}D] (n = 2, **10d**; 3, **11d**; 4, **12d**) were prepared by the reaction between [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_nCH_3$}X] (X = I, n = 2, **9d**; 4, **7**; X = Cl, n = 3, **5d**) and [Li{AlD_2(OCH_2-CH_2OCH_3)$_2$}]. Again all compounds were obtained as pale yellow solids and characterised by ^{1}H and ^{2}H NMR spectroscopy. We note that for all the *n*-alkyl-deuterides there was no evidence for intramolecular

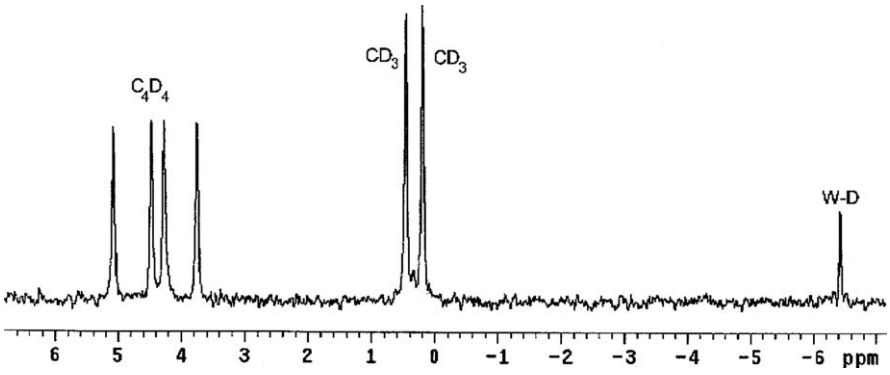

Fig. 4. ^{2}H NMR spectrum of the compound [W{(η-C_5D_4)C(CD_3)$_2$(η-C_5D_4)}{CH_2CH_3}D] (**16d**) in C_6H_6.

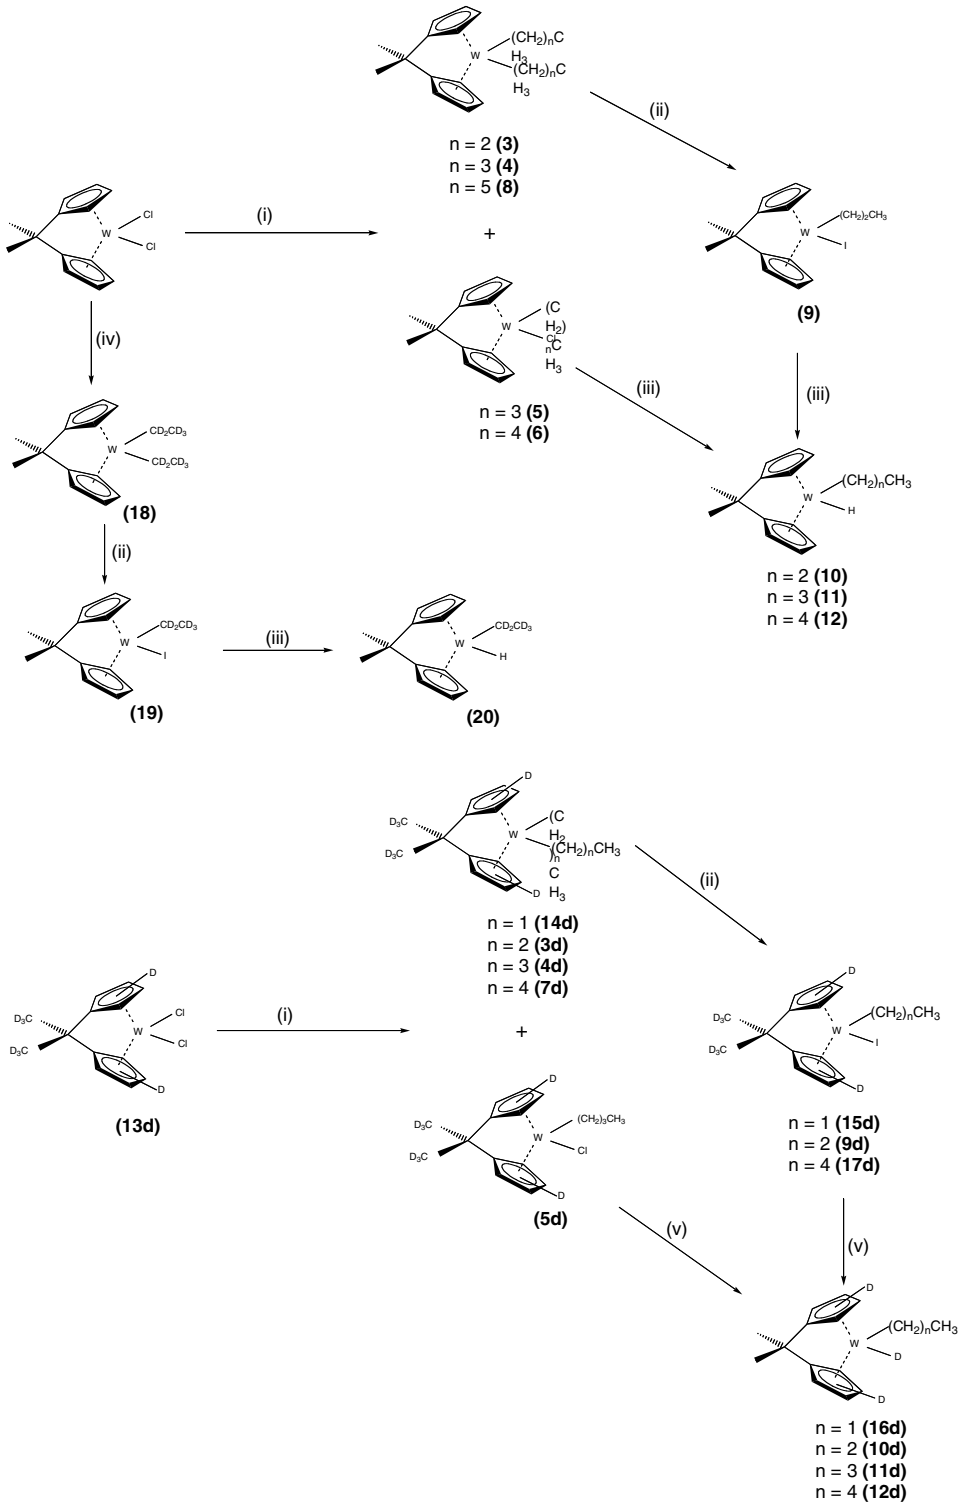
H/D scrambling between alkyl and W–D atoms at room temperature even after prolonged storage.



An alternative approach by which to study H/D scrambling in *ansa*-metallocene *n*-alkyl hydride compounds would be to prepare species in which the *n*-alkyl group was deuterated, as in [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CD_2)_nCD_3$}]. Indeed the H/D scrambling process in [W{(η-C_5H_4)CMe_2(η-C_5H_4)}(CD_3)H] has been described [2]. Perdeuterated diethylzinc [Zn{CD_2CD_3}$_2$] was prepared by the condensation of d^5-iodoethane onto a Zn/Cu couple in a thick walled-glass tube. The tube was sealed under reduced pressure and heated at 140 °C overnight. [Zn{CD_2CD_3}$_2$] was freed from impurity by low pressure distillation and obtained as a pyrophoric colourless liquid. Treatment of a toluene suspension of the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Cl_2] with a 0.4 M solution of [Zn{CD_2CD_3}$_2$] in toluene gave a dark red suspension from which the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CD_2CD_3}$_2$] (**18**) was isolated. The compound **18** was characterised by ^{1}H and ^{2}H NMR spectroscopy. The ^{2}H NMR spectrum shows two peaks at δ 1.60 and 0.62 ppm corresponding to the β-methyl and α-methylene deuterium of the ethyl ligands respectively.

Reaction of the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CD_2CD_3}$_2$] (**18**) with NH_4I in THF at 65 °C gives the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{CD_2CD_3}I] (**19**), as a pale red solid in 47% yield. The compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CD_2CD_3}I] (**19**) was reacted with [Na{$AlH_2(OCH_2OCH_2CH_3)_2$}] at low temperature to give, after cautious hydrolysis of excess [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}], the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CD_2CD_3}H] (**20**) as a yellow crystalline solid (see the Scheme 1).

The compound **20** was characterised by ^{1}H and ^{2}H NMR spectroscopy. In the ^{1}H NMR were four singlets at δ 5.11, 4.48, 4.29 and 3.77 ppm corresponding to the hydrogens of the cyclopentadienyl rings and a pair of singlets at δ 0.53 and 0.29 ppm corresponding to the protons of the CMe_2 bridging unit, the singlet at δ −6.47 ppm is assigned to the hydride proton. Associated with this singlet are the characteristic ^{183}W satellites ($^{1}J_{WH}$ = 31 Hz). The ^{2}H NMR spectrum of the compound **20** shows two peaks at δ 1.58 and 1.13 ppm corresponding to the CD_3 and α-CD_2 groups of the ethyl ligand. The spectroscopic data for the compound **20** are in agreement with that reported for the perprotio compound [W{(η-C_5H_4)CMe_2(η-(C_5H_4)}{CH_2CH_3}H] [2].

The thermolysis of the partially ring deuterated ethyl-deuteride [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CH_2CH_3}D] has been described previously [2] but quantitative kinetic data for the observed intramolecular hydrogen scrambling processes could not be obtained. Therefore, the perdeutero-*ansa*-tungstenocene ethyl-deuteride [W{(η-C_5D_4)C(CD_3)$_2$(η-C_5D_4)}{CH_2CH_3}D] (**16d**) was prepared and H/D scrambling was reinvestigated. A 8 mM solution of the compound **16d** in C_6H_6 and a 6 mM solution of the compound **16** in C_6D_6 were prepared and sealed in separate NMR tubes. ^{1}H and ^{2}H NMR spectra show that at room temperature there had been no observable scrambling between alkyl and deuterium sites. The samples were heated at 65 °C and ^{1}H and ^{2}H NMR spectra were recorded periodically. After ca. 8 h, the ^{2}H NMR spectra showed a peak at δ 1.10 ppm which grew with time (Fig. 5). Simultaneously, the intensity of the W–D peak at δ −6.44 ppm decreased. The ^{1}H NMR spectra shows there is a decrease in intensity of the quartet at δ 1.12 ppm due to the α-methylene hydrogens compared to the triplet at δ 1.58 ppm corresponding to the β-methyl hydrogens of the ethyl ligand.

Additionally a peak at δ −6.45 ppm corresponding to a tungsten-hydrogen group appeared. These NMR data are fully consistent with H/D exchange between the W–D and the α-CH_2 hydrogens of the ethyl group. No evidence for scrambling of deuterium into the β-methyl hydrogens of the compound **16** was observed. Scrambling of deuterium into this position should be indicated by a peak growing in at, or close to, δ 1.58 ppm, by analogy to the ^{1}H NMR spectrum of the compound **16**. No peak in this region ($\delta \pm 0.15$ ppm) was observed. This

Scheme 1. Conditions (i) $[Zn\{(CH_2)_nCH_3\}_2]$ in toluene. (ii) NH_4I in THF, 65 °C. (iii) $[Na\{AlH_2(OCH_2CH_2OCH_3)_2\}]$ in toluene. (iv) $[Zn\{CD_2CD_3\}_2]$ in toluene. (v) $[Li\{AlD_2(OCH_2CH_2OCH_3)_2\}]$ in toluene. When **d** is placed after a compound number this indicates the ansa-bis-cyclopendadienyl ligand is perdeuterated.

conclusion contrasts with that previously reported for studies on $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\{CH_2CH_3\}D]$ where scrambling into the β-position was suggested to occur and further that it occurred at a faster rate than for the α-methylene hydrogens [2]. The quality of the earlier data was significantly worse than for this work and we assume the earlier results were erroneous due to the presence of decomposition products see Fig. 6.

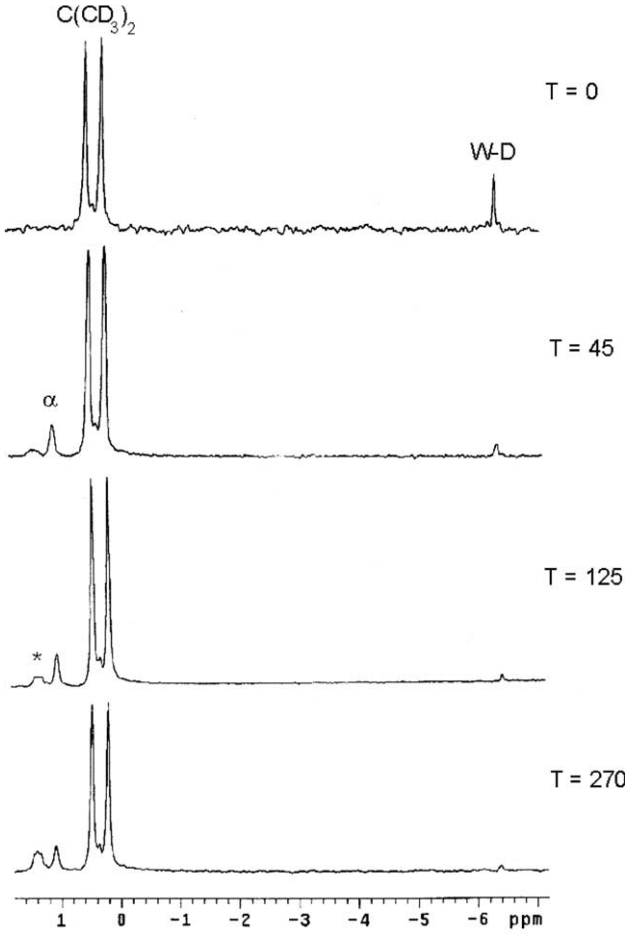


Fig. 5. Partial ^{2}H NMR spectrum of the compound [W{(η-C_5D_4)C$(CD_3)_2$(η-C_5D_4)}{CH_2CH_3}D] (**16d**) in C_6H_6 at 65 °C (*T* in h). The peak marked α corresponds to deuterium in the α-methylene position of the *n*-propyl ligand. * Denotes a decomposition product.

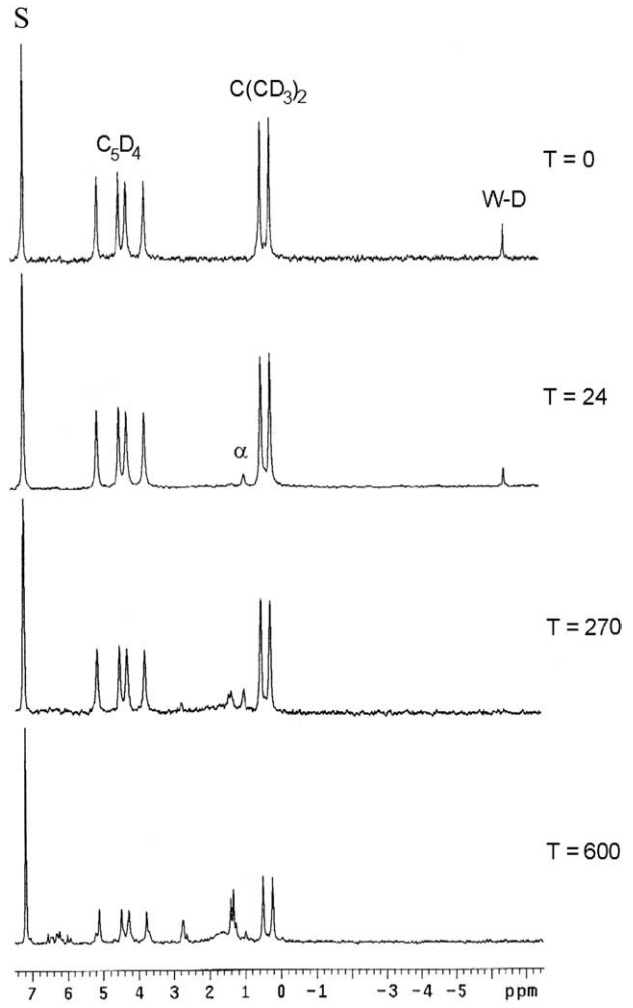

Fig. 6. ^{2}H NMR spectrum of the compound [W{(η-C_5D_4)C$(CD_3)_2$(η-C_5D_4)}{$(CH_2)_2CH_3$}D] (**10d**) in C_6H_6 at 65 °C (*T* in h). The peak marked α corresponds to deuterium in the α-methylene position of the *n*-propyl ligand. S denotes the residual solvent peak.

Apart from the H/D scrambling there is evidence for slow thermal decomposition of the compound **16**. After 45 h; the ^{2}H NMR spectra show new peaks in the cyclopentadienyl region δ 6.65–5.32 ppm and broad peaks at δ 2.71 and 1.38 ppm. These new peaks grow in intensity over time while the intensity of all the peaks of the compound **16d** decrease. The ^{1}H NMR spectra of the partially decomposed compound **16** in C_6D_6 showed no ethane was present. Also, there is no evidence in either the ^{1}H or ^{2}H NMR spectra of the partially decomposed solution of compound **16d** for the formation of new W–D or W–H groups. Attempts to identify the nature the new compounds were unsuccessful due to the very small quantity of alkyl-hydride and -deuteride compounds available.

Further, accurate kinetic data for the scrambling of deuterium from the metal to the α-position of the ethyl group in the compound **16** compared to related alkyl-deuteride species could not be obtained due to the presence of the competing decomposition reactions.

The thermolysis of the d^5-ethyl hydride compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{CD_2CD_3}$_2$H] (**20**) was studied. A 10 mM solution of the compound **20** in C_6D_6 was sealed in a NMR tube and heated at 65 °C for a prolonged period and the ^{1}H NMR spectra were recorded periodically. After 8 h a peak at δ 1.11 ppm appeared corresponding to hydrogen in the α-methylene group. The increase in the intensity of this resonance was accompanied by a decrease in the intensity of the singlet at δ −6.47 ppm corresponding to the tungsten-hydrogen.

After heating the sample of **20** at 65 °C for 77 h a number of new peaks appeared and grew in intensity in the cyclopentadienyl region of the spectrum together with complex peaks in the region δ 2.65–1.35 ppm. We assign these new peaks to one or more decomposition products. There were no peaks at or close to δ 1.58 ppm implying that H/D scrambling into the β-CD_3

group of the d^5-ethyl ligand does not occur, as found for the studies on **16d**.

A 4 mM solution of the *n*-propyl-deuteride [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_2CH_3$}D] (**10d**) in C_6H_6 and a 3 mM solution of the compound **10a** in C_6D_6 were prepared in separate NMR tubes. The ^1H and ^2H NMR spectra showed that at room temperature there had been no observable H/D crambling between *n*-propyl and W–D groups. The samples of **10d** were heated at 65 °C and the ^1H and ^2H NMR spectra recorded periodically. After ca. 12 h the ^2H NMR spectrum showed a new and growing peak at δ 1.02 ppm. We note that the compound **10d** has a peak in the ^1H NMR spectrum of due to the α-CH_2 hydrogens at δ 1.04 ppm. Also, the ^2H NMR spectra showed the peak due to W–D at δ −6.44 ppm decreased. Correspondingly, the relative intensity of the peak due to the α-CH_2 hydrogens in the ^1H NMR spectrum of the compound **10d** decreased compared to the resonance due to the β-CH_2 and γ-CH_3 hydrogens of the *n*-propyl group. Additionally, a peak at δ 6.47 ppm corresponding to a W–H group grew in intensity. These spectra are consistent with scrambling of W–D with only the α-CH_2 hydrogens of the *n*-propyl group. The NMR spectra of the thermolysed solutions of **10d** also showed evidence for one or more new compounds and a relative decrease of intensity of all bands associated with **10d**. The rate of scrambling into the α-position is faster than the rate of formation of decomposition products. Attempts to characterise the decomposition products were unsuccessful. Also, attempts to observe C–D coupling in $^{13}C\{^1H\}$ NMR spectrum of the compound **10d** were thwarted by lack of the of material.

The *n*-butyl-deuteride compound [W{(η-C_5D_4)-$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_3CH_3$}D] (**11d**) also showed H/D scrambling between the W–D and the α-CH_2 hydrogens of the *n*-butyl group. Thus, an 8 mM solution of the compound **11d** in C_6H_6 and a 5 mM solution of the compound **11d** in C_6D_6 were prepared, sealed in NMR tubes were heated at 65 °C. In the ^2H NMR spectra the resonance due to the W–D group at δ −6.45 ppm decreases while a peak at δ 1.01 ppm appears and grows in intensity. In the ^1H NMR spectrum the relative intensity of the peak at δ 1.01 ppm corresponding to the hydrogens of the α-CH_2 of the *n*-butyl compound decreases and a peak at δ −6.46 ppm appears and grows in intensity. Again the rate of this α-hydrogen scrambling process was faster than the decomposition reaction which gives rise to one or more new compounds, the nature of which have not been determined. No evidence of scrambling into other positions of the *n*-butyl group was observed.

Scrambling of deuterium into the α-position of the *n*-pentyl compound [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}-{$(CH_2)_4CH_3$}D] (**12d**) is observed on heating a 6 mM solution in C_6H_6 and a 4 mM solution in C_6D_6 at 65 °C. In both cases a peak at δ 1.04 ppm appeared in the ^2H NMR spectra along with a decrease in the resonance due to the W–D (δ −6.49 ppm). This scrambling process was accompanied by the slow formation of decomposition products. No evidence for scrambling

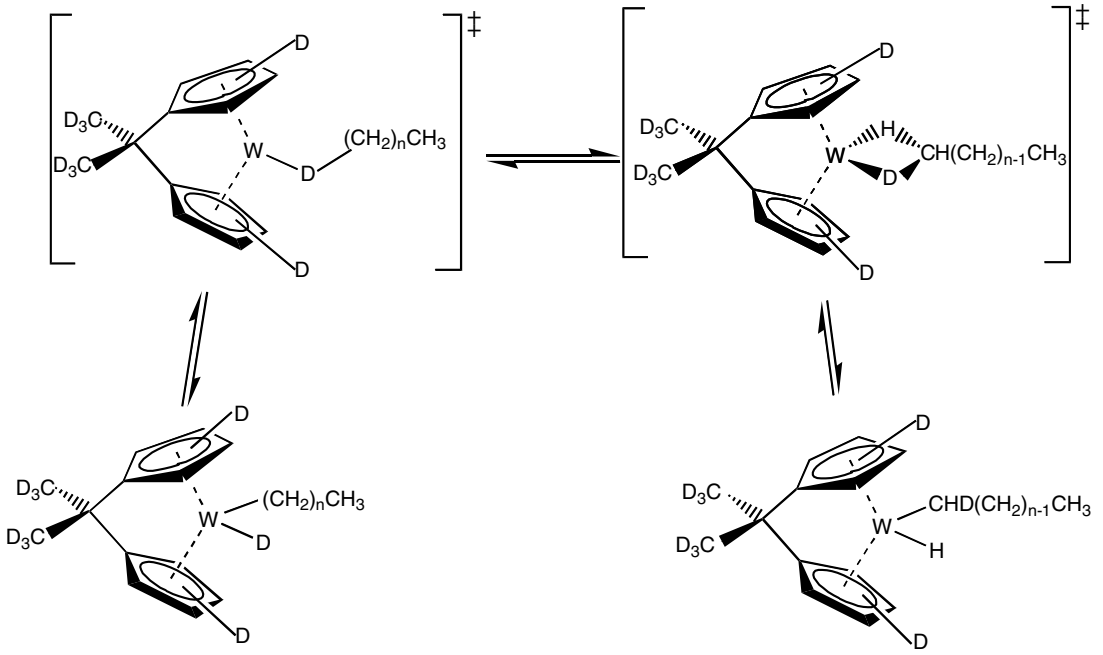

Fig. 7. Intramolecular hydrogen scrambling in the compounds [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_nCH_3$}D] (n = 1–4) via η^1-H and η^2-H,H-σ-complexes.

into other positions of the *n*-pentyl chain was observed by ^1H or ^2H NMR spectroscopy.

In summary, thermolysis of the *n*-alkyl-deuteride compounds $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{(CH_2)_n\text{-}CH_3)_2D\}]$ ($n = 1$–4) and $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\text{-}\{CD_2CD_3)H]\}$ shows intramolecular hydrogen/deuterium exchange between the α-methylene hydrogens of the *n*-alkyl ligand and the W–D group. Exchange into other positions of the *n*-alkyl ligand was not observed for any of the compounds $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{(CH_2)\}_nCH_3)_2D]$ ($n = 1$–4). Similarly, H/D scrambling onto the α-methylene position was also observed by NMR spectroscopy for the d^5-ethyl-hydride compound $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}CD_2CD_3)_2H]$. Whereas the methyl-deuteride compound $[W\{(\eta\text{-}_5H_4)\text{-}CMe_2(\eta\text{-}C_5H_4)\}(CH_3)D]$ is stable at 110 °C, the higher *n*-alkyl-deuteride compounds $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{(CH_2)_nCH_3)_2D]\}$ ($n = 1$–4) decompose slowly above ca. 65 °C.

We propose that the H/D exchange into the α-methylene hydrogens proceeds by an intramolecular mechanism with an intermediate or transition state agostic alkane (see Fig. 7) by analogy with H/D the intermolecular exchange process proposed for the methyl compound $[W\{(\eta\text{-}C_5H_4)C(CH_3)_2(\eta\text{-}C_5H_4)\}\text{-}CH_3D]$ and related studies [2,3,10–26]. Subsequent to this work [6] there have been two reports of migration of transition metal along metal-alkyl chains of the kind hoped for in these studies [27,28]. Also there he been an elegant stdy by Ball et al. [29] in which alkane-σ-transition metal complexes are observed in solution by NMR studies.

3. Experimental

All manipulations of air and/or moisture sensitive materials were performed under an inert atmosphere of dry dinitrogen using standard Schlenk line techniques or in an inert atmosphere dry box containing dinitrogen [30]. Inert gases were purified firstly by passage through columns filled with activated molecular sieves (4 Å) and then either manganese (II) oxide suspended on vermiculite, for the Schlenk line, or BASF catalyst, for the dry box. Celite® filtration aid was purchased from Fluka Chemie and oven-dried at 100 °C prior to use.

Solvents were pre-dried over activated 4 Å molecular sieves and then distilled from Na/K alloy (light petroleum ether (b.p. 40–60 °C), diethyl ether, pentane and DME), from sodium (petroleum ether (b.p. 100–120 °C) and toluene), from potassium (THF) or from calcium hydride (acetonitrile, dichloromethane and TMEDA), under a slow continuous stream of dinitrogen. DMSO and d^1-methanol were used without drying. Deuterated NMR solvents were dried over potassium (benzene, toluene and THF) or calcium hydride (acetone, chloroform, dichloromethane and pyridine), distilled and degassed by the freeze–pump–thaw technique prior to use. $CDFCl_2$ was prepared by the literature method [31]. WCl_6 (99%), $LiAlH_4$ (95%), $LiAlD_4$ (96%), \D Super-Hydride® $LiBEt_3H$ (1.0 M solution in THF), dimethylzinc (2.0 M solution in hexanes), diethylzinc (1.0 M solution in hexanes), ^{t}BuLi (1.7 M solution in pentane), ^{n}BuLi (2.5 M solution in light petroleum ether (b.p. 40–60 °C)), $[Na\{AlH_2(OCH_2\text{-}CH_2OCH_3)_2\}]$ (2.5 M solution in toluene), HCl (1.0 M solution in diethyl ether), HBF_4 (54+ wt% solution in diethyl ether), NH_4I, 1-chloro-*n*-propane, 1-chloro-*n*-butane, 1-chloro-*n*-pentane, 1-chloro-*n*-hexane, d^5-ethanol, pyrrolidine, Me_2SiCl_2 and D_2 were purchased from Aldrich Chemical Company and used without further purification. $ZnCl_2$ was bought from Aldrich Chemical Company and dried in refluxing thionyl chloride for 6 h. Magnesium turnings were preactivated by the addition of a small amount (ca. 2 wt%) of dibromoethane to a suspension in THF and then washed with THF.

The compounds $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}Cl_2]$ [1,2] and $[Li\{AlD_2(OCH_2CH_2OCH_3)_2\}]$ [26], were prepared using standard literature methods. NMR spectra were recorded out on a Varian Unity *Plus* 500 spectrometer (^1H, ^2H, and ^{13}C spectra were recorded at 499.868, 76.750, and 125.703 MHz, respectively). The spectra were referenced internally relative to the residual protio-solvent (^1H), residual deutero-solvent (^2H) and solvent (^{13}C) resonances relative to tetramethylsilane (^1H, ^2H, ^{13}C; $\delta = 0$ ppm). Chemical shifts (δ) are expressed in ppm and coupling constants (J) in Hz. Mass spectra (FAB) were recorded by the EPSRC Mass Spectrometry Service at the University College of Swansea.

IR spectra were recorded on a Mattson Polaris FTIR spectrometer or a Perkin–Elmer 1710 FTIR spectrometer. Samples were prepared as a Nujol mull between NaCl plates. Data are quoted in cm^{-1}.

Elemental analysis data were obtained from the Microanalysis Department of the Inorganic Chemistry Laboratory, Oxford.

3.1. Preparation of $[Zn\{CD_2CD_3\}_2]$

A thick-walled glass tube was charged with a finely ground mixture of zinc powder (7 g, 107.1 mmol) and copper powder (1.7 g, 26.8 mmol). Anti-bumping granules were added and the admixture was dried by heating under reduced pressure at 200 °C for 2 h. d^5-Iodoethane (7.9 g, 49.1 mmol) was transferred to the tube via low pressure distillation and the tube was sealed under reduced pressure, prior to heating overnight at 140 °C. The tube was connected to a Schlenk line, carefully scored and then broken. Volatiles were collected and the compound $[Zn\{CD_2CD_3\}_2]$ obtained as an extremely pyrophoric colourless liquid. Yield of $[Zn\{CD_2\text{-}CD_3)\}_2]$ = 0.55 g, 9%.

3.2. The compounds $[Zn\{(CH_2)_nCH_3\}_2]$

1-Chloro-*n*-propane (19.9 g, 250 mmol) was added dropwise to a suspension 3 of activated magnesium turnings (12 g, 490 mmol) in diethyl ether (150 cm^3) at such a rate to maintain a vigorous reaction. The reaction mixture was stirred for 2 h and a colourless solution was then isolated by filtration. Anhydrous $ZnCl_2$ (17 g, 120 mmol) was added to this ethereal solution via a solid addition tube in a slightly exothermic reaction. The resulting white suspension was stirred overnight and a colourless solution was then separated by filtration. Removal of volatiles under reduced pressure yielded $[Zn\{(CH_2)_2CH_3\}_2]$ as a pyrophoric colourless oil. Yield of $[Zn\{(CH_2)_2CH_3\}_2]$ (based on 1-chloro-*n*-propane) = 5.34 g, 28%. The compounds $[Zn\{(CH_2)_3CH_3\}_2]$ (yield [based on 1-chloro-*n*-butane] = 12.06 g, 42%), $[Zn\{(CH_2)_4CH_3\}_2]$ (yield [based on 1-chloro-*n*-pentane] = 14.32 g, 61%) and $[Zn\{(CH_2)_5CH_3\}_2]$ (yield [based on 1-chloro-*n*-hexane] = 25.05 g, 85%) were prepared via an analogous procedure.

3.3. Preparation of d^6-cyclopentadiene

To a flask containing D_2O (560 cm^3) at 3 °C, elemental sodium (65 g, 2.83 mol) was added in small portions over 2 h. A portion of the resulting solution of NaOD in D_2O (85 cm^3) was transferred to a flask containing DMSO (100 cm^3) and stirred vigorously at 0 °C. Freshly distilled cyclopentadiene monomer (125 cm^3, 1.58 mol) was added to the reaction mixture and stirring continued at 0 °C for 1 h. Cyclopentadiene monomer was transferred from the reaction mixture to a Schlenk tube, at −196 °C, under reduced pressure, allowed to warm to −78 °C and then added to a flask containing fresh NaOD in D_2O (85 cm^3) and DMSO (100 cm^3). This procedure was repeated for a total of 5 exchanges. d^6-Cyclopentadiene was stored at −80 °C. Yield of d^6-cyclopentadiene, 46.1 g, 94% D, 40%.

3.4. Preparation of d^{12}-6,6-dimethylfulvene

To a flask containing d^6-acetone (28.4 cm^3, 386 mmol) in d^1-methanol (100 cm^3) at 0 °C was added freshly distilled d^6-cyclopentadiene monomer (27 g, 94% D, 390 mmol). Pyrrolidine (41.7 cm^3, 500 mmol) was added and the reaction mixture immediately turned deep orange. The reaction mixture was stirred at 0 °C for 0.75 h. Glacial acetic acid (50 cm^3) and D_2O (50 cm^3) were added and the organic layer extracted into pentane (3×40 cm^3). The organic extracts were combined, washed with D_2O (50 cm^3) and dried over anhydrous $MgSO_4$. A pale orange solution was isolated by filtration and volatiles removed under reduced pressure to afford d^{12}-6, 6-dimethylfulvene as dark orange liquid, which was stored at −80 °C. Yield d^{12}-6, 6-dimethylfulvene, 31.6 g, 95% D, 74%.

3.5. Preparation of $[(C_5D_5)C(CD_3)_2(C_5D_5)]$

THF (350 cm^3) was added to a flask charged with NaOD (20 g, 500 mmol), prepared as described above, and the resulting suspension stirred at room temperature for 1 h. Freshly distilled d^6-cyclopentadiene monomer (15.7 g, 94% D, 232 mmol) was added to the reaction mixture which was stirred for 0.5 h to give a pale pink suspension. A solution of d^{12}-6, 6-dimethylfulvene (26.1 g, 95% D, 232 mmol) in THF (40 cm^3) was added dropwise over 0.5 h and the reaction mixture stirred overnight. An orange solution was isolated by filtration, washed with D_2O (50 cm^3) and dried over $MgSO_4$, prior to separation by filtration. Removal of volatiles under reduced pressure afforded the compound $[(C_5D_5)C(CD_3)_2(C_5D_5)]$ as a pale yellow oil. Yield of $[(C_5D_5)C(CD_3)_2(C_5D_5)]$, 22.7 g, 93% D, 55%.

3.6. Preparation of $[Li_2\{(C_5D_4)C(CD_3)_2(C_5D_4)\}]$

A solution of ^{n}BuLi (40 cm^3, 2.5 M, 100 mmol) in light petroleum ether (b.p. 40–60 °C) was added dropwise to a solution of $[(C_5D_5)C(CD_3)_2(C_5D_5)]$ (11.3 g, 94% D, 62.3 mmol) in light petroleum ether (b.p. 40–60 °C) (100 cm^3) at −78 °C. A flocculent white precipitate immediately formed and the reaction mixture was allowed to warm to room temperature and then stirred overnight. A white solid was isolation by filtration, washed with light petroleum ether (b.p. 40–60 °C) (100 cm^3) and diethyl ether (2×50 cm^3) and then dried under reduced pressure. Yield of $[Li_2\{(C_5D_4)C(CD_3)_2(C_5D_4)\}]$,10.8 g, 95% D, 93%.

3.7. Preparation of $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\{(CH_2)_2CH_3\}_2]$ (**3**)

To a suspension of $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}Cl_2]$ (0.6 g, 1.2 mmol) in toluene (40 cm^3) a solution of $[Zn\{(CH_2)_2CH_3\}_2]$ (3.5 cm^3, 1.85 M, 6.5 mmol) in toluene was added slowly at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight. The dark red suspension was hydrolysed via the cautious addition of H_2O (0.6 cm^3) to remove excess $[Zn\{(CH_2)_2CH_3\}_2]$. The reaction mixture was filtered and the filtrate passed down a column containing activated alumina by elution with toluene. The resulting yellow solution was collected and volatiles removed under reduced pressure to give an oily yellow solid. The residue was extracted into pentane (15 cm^3). The solution was cooled to −80 °C to afford $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\{(CH_2)_2CH_3\}_2]$ **3** as a yellow solid. Yield: 0.23 g, 44%.

3.8. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}-{{$(CH_2)_2CH_3$}$_2$]} (**3d**)

The compound [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{{$(CH_2)_2CH_3$}$_2$]} **3d** was prepared by the reaction between the compound **13** (0.44 g, 1.0 mmol) and a solution of [Zn{$(CH)_2CH_3$}$_2$](1 cm^3, 1.1 M, 1.10 mmol) in toluene The compound **3d** was obtained as a yellow solid. Yield: 0. 11 g, 23%.

3.9. Preparation of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_3CH_3$}$_2$] (**4**) and [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_3CH_3$}Cl] (**5**)

To a suspension of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Cl_2] (0.3 g, 0.6 mmol) in toluene (40 cm^3) a solution of [Zn{$(CH_2)_3CH_3$}$_2$] (3.0 cm^3, 1.5 M, 4.5 mmol) in toluene was added slowly at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight. The dark red suspension was hydrolysed via the cautious addition of H_2O (0.5 cm^3) to remove excess [Zn{$(CH_2)_3CH_3$}$_2$]. The reaction mixture was filtered and volatiles removed under reduced pressure. The resulting orange solid was extracted into pentane (15 cm^3) to yield a yellow solution. The residue was extracted into a 1:1 mixture of toluene/pentane (20 cm^3). Cooling of the pentane solution to −80 °C afforded the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_3CH_3$}$_2$] (**4**) as a yellow solid. Yield: 0.045 g, 16%. Cooling of the toluene/pentane solution to −80 °C afforded the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_3CH_3$}Cl] (**5**) as a yellow solid. Yield: 0.11 g, 41%.

3.10. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}-{$(CH_2)_3CH_3$}Cl] (**5d**)

The compound **5d** was prepared by the reaction between the compound **13** (0.24 g, 0.55 mmol) and a solution of [Zn{$(CH_2)_3CH_3$}$_2$] (4 cm^3, 1.5 M, 6 mmol) in toluene in a procedure analogous to that used to prepare the compound **5** and was obtained as an yellow solid. Yield: 0.099 g, 39%.

3.11. Preparation of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_4CH_3$}Cl] (**6**) and [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_4CH_3$}$_2$] (**7**)

To a suspension of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Cl_2] (1.0 g, 2.34 mmol) in toluene (40 cm^3) a solution of [Zn{$(CH_2)_4CH_3$}$_2$] (7.0 cm^3, 1.86 M, 13.0 mmol) in toluene was added slowly at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight. The dark red suspension was hydrolysed via the cautious addition of H_2O (0.6 cm^3) to remove excess [Zn{$(CH_2)_4CH_3$}$_2$]. The reaction mixture was filtered and the filtrate passed down a column containing activated alumina by elution with toluene to give a yellow solution. Further elution with diethyl ether gave an orange solution which was collected separately. Removal of diethyl ether under reduced pressure afforded the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_4CH_3$}Cl] (21) (**6**) as a pale red solid. Yield: 0.31 g, 29%.

Removal of volatiles under reduced pressure from the yellow toluene solution yielded a yellow solid. Extraction into pentane (5 cm^3) prior to cooling to −80 °C afforded a yellow solid in very low yield (ca. 0.01 g, 1%) which was characterised by ^{1}H NMR spectroscopy as [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_4CH_3$}$_2$] (**7**).

3.12. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}-{$(CH_2)_4CH_3$}$_2$] (**6d**)

To a suspension of the compound **13d** (0.27 g, 95% D, 0.58 mmol) in toluene (50 cm^3) a solution of [Zn-{$(CH_2)_4CH_3$}$_2$] (3.0 cm^3, 1.5 M, 4.5 mmol) in toluene was added dropwise at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight. Excess [Zn{$(CH_2)_4CH_3$}$_2$] was hydrolysed by the cautious addition of D_2O (0.4 cm^3). The resulting solid was extracted into pentane (30 cm^3). Cooling of the pentane solution to −80 °C afforded the compound 6a as a yellow crystalline solid. Yield: 0.098 g, 33%.

3.13. Preparation of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_5CH_3$}$_2$] (**8**)

To a suspension of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}Cl_2] (0.33 g, 0.6 mmol) in toluene (40 cm^3) a solution of [Zn{$(CH_2)_5CH_3$}$_2$] (2.0 cm^3, 5.3 M, 10.6 mmol) in toluene was added dropwise at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight. Excess [Zn{$(CH_2)_5CH_3$}$_2$] was hydrolysed via the cautious addition of H_2O (0.5 cm^3). The reaction mixture was filtered and the filtrate passed down a column containing activated alumina by elution with a 1:1 mixture of diethyl ether/toluene. The resulting yellow solution was collected and volatiles removed under reduced pressure to give an orange/yellow solid, prior to extraction into pentane (15 cm^3) to yield a yellow solution. The residue was extracted into a 1:1 mixture of toluene/pentane (20 cm^3). Cooling of the pentane solution to −80 °C afforded the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_5CH_3$}$_2$] (**8**) as a yellow solid. Yield: 0.095 g, 18%. Cooling of the toluene/pentane solution to −78 °C afforded a small amount (ca. 0.025 g, 9%) of a pale red solid characterised by ^{1}H NMR spectroscopy as [W{(η-C_5H_4)CMe_2(η-C_5H_4)}-{$(CH_2)_5CH_3$}Cl].

3.14. Preparation of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_2CH_3$}I] (9)

A mixture of the compound **3**(0.06 g, 0.13 mmol) and NH_4I (0.05 g, 0.34 mmol) in THF (25 cm^3) was heated at 65 °C for seven days in a Rotaflo® ampoule. A gradual colour change from yellow to pale red was observed. The solution was isolated by filtration and volatiles were removed under reduced pressure. The resulting red–orange solid was washed with pentane (20 cm^3) to remove any unreacted compound **3** prior to extraction into a 1:4 mixture of toluene/pentane. Cooling of the red–orange solution to −80 °C afforded the compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_2CH_3$}I] (**9**) as a pale red solid. Yield: 0.032 g, 47%.

3.15. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_2CH_3$}I] (9d)

The compound [W{(η-C_5H_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_2CH_3$}I] (**9d**) was prepared by the reaction between the compound **3d** (0.11 g, 0.24 mmol) and NH_4I (0.07 g, 0.48 mmol) in a procedure analogous to that employed to prepare the compound **9** and was obtained as a pale red solid. Yield: 0.057 g, 44%.

3.16. Preparation of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_2CH_3$}H] (10)

To a solution of the compound **23** (0.03 g, 0.06 mmol) in toluene (20 cm^3) was added a solution of [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}] (0.2 cm^3, 2.5 M, 0.5 mmol) in toluene at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight during which time the colour of the solution changed from orange to pale yellow. Excess [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}] was hydrolysed by the cautious addition of H_2O (0.1 cm^3). Volatiles were removed and the reaction mixture dried under reduced pressure for 2 h. The yellow residue was extracted into pentane (2×20 cm^3) and the volume subsequently reduced to 10 cm^3 prior to cooling to −80 °C. The compound [W{(η-C_5H_4)CMe_2 (η-C_5H_4)}{$(CH_2)_2CH_3$}H] (**10**) was obtained as a yellow crystalline solid. Yield: 0.012 g, 50%.

3.17. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_2CH_3$}D] (10d)

The compound [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_2CH_3$}D] (**10d**) was prepared by the reaction between the compound **9d** (0.020 g, 0.04 mmol) and a solution of [Li{$AlD_2(OCH_2CH_2OCH_3)_2$}] (1 cm^3, 1.5 M, 1.5 mmol) in toluene in a procedure analogous to that used to prepare the compound **16** and was obtained as a yellow solid. Since only a small amount of compound was obtained, and in order to utilise all of the compound prepared, the Yield: **10d** was not calculated.

3.18. Preparation of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_3CH_3$}H] (11)

The compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_3CH_3$}H] (**11**) was prepared by the reaction between the compound **5** (0.1 g, 0.22 mmol) and a solution of [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}] (2 cm^3, 2.5 M, 5 mmol) in toluene in a procedure analogous to that employed to prepare the compound **10** and was obtained as a yellow solid. Yield: 0.038 g, 42%.

3.19. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_3CH_3$}D] (11d)

The compound **11d** was prepared by the reaction between the compound **5d** (0.035 g, 0.08 mmol) and a solution of [Li{$AlD_2(OCH_2CH_2OCH_3)_2$}] (1.5 cm^3, 1.0 M, 1.5 mmol) in toluene in a procedure analogous to that used to prepare the compound **16** and was obtained as a yellow solid. Since only a small amount of compound was obtained, and in order to utilise all of the compound prepared, the Yield: **11d** was not determined.

3.20. Preparation of [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_4CH_3$}H] (12)

The compound [W{(η-C_5H_4)CMe_2(η-C_5H_4)}{$(CH_2)_4CH_3$}H] (**12**) was prepared by the reaction between the chloro compound **6** (0.05 g, 0.11 mmol) and a solution of [Na{$AlH_2(OCH_2CH_2OCH_3)_2$}] (1 cm^3, 2.5 M, 2.5 mmol) in toluene in a procedure analogous to that employed to prepare the compound **11d** and was obtained as a yellow solid. Yield: 0.023 g, 49%.

3.21. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_4CH_3$}D] (12d)

The compound [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}{$(CH_2)_4CH_3$}D] (**12d**) was prepared by the reaction between the iodo compound **17d** (0.022 g, 0.05 mmol) and a solution of [Li{$AlD_2(OCH_2CH_2OCH_3)_2$}] (1.0 cm^3, 1.5 M, 1.5 mmol) in toluene in a procedure analogous to that used to prepare the compound **30** and was obtained as a yellow solid. Since only a small amount of compound was obtained and in order to utilise all of the compound prepared the Yield: **12d** was not calculated.

3.22. Preparation of [W{(η-C_5D_4)$C(CD_3)_2$(η-C_5D_4)}Cl_2] (13d)

The two solids $WCl_4 \cdot DME$ [32] (10.5 g, 25.2 mmol) and [Li_2{$(C_5D_4)C(CD_3)_2(C_5D_4)$}] (5.5 g, 95%, 27.7 mmol) were stirred together in the absence of solvent

to give a good admixture. Diethyl ether (100 cm^3) was added and the resulting brown suspension stirred for two days. The liquid phase was removed by filtration and DME (50 cm^3) was added to the remaining solid. The resulting dark brown suspension was stirred for 0.5 h and a brown solid isolated by filtration. The residue was washed with ethanol (50 cm^3) and then diethyl ether (3×30 cm^3) until the washings were colourless. After drying under reduced pressure, the resulting pale brown solid was extracted into dichloromethane (2×250 cm^3) to give a deep red/brown solution. Removal of volatiles under reduced pressure afforded the compound $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}Cl_2]$ (**13d**) as a purple solid. Yield: 1.25 g, 95% D, 11.3%.

*3.23. Preparation of $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{CH_2CH_3\}_2]$ (**14d**)*

To a suspension of the compound **13d** (0.1 g, 95% D, 0.22 mmol) in toluene (50 cm^3) a solution of $[Zn\{CH_2CH_3\}_2]$ (5.0 cm^3, 1.0 M, 5.0 mmol) in hexanes was added dropwise at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight. Volatiles were removed under reduced pressure and collected in a trap containing propan-2-ol at −196 °C. Excess $[Zn\{CH_2CH_3\}_2]$ can be readily removed in this way. The resulting solid was extracted into pentane (20 cm^3). Cooling of the pentane solution to −80 °C afforded the compound $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{CH_2CH_3\}_2]$ (**14d**) as a yellow crystalline solid. Yield: 0.042 g, 46%. Preparation of $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{CH_2CH_3\}I]$ (**15d**). The compound $[W\{(\eta\text{-}C_5H_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{CH_2CH_3\}I]$ (**15d**) was prepared by the reaction between the compound **14d** (0.03 g. 0.07 mmol) and NH_4I (0.02 g, 0.14 mmol) in a procedure analogous to that employed to prepare the compound **2** and was obtained as a pale red solid. Yield: 0.037 g, 67%.

*3.24. Preparation of $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{CH_2CH_3\}D]$ (**16d**)*

To a solution of the compound **15d** (0.03 g, 0.06 mmol) in toluene (20 cm^3) was added a solution of $[Li\{AlD_2(OCH_2CH_2OCH_3)_2\}]$ (0.5 cm^3, 1.1 M, 0.55 mmol) in toluene at −78 °C. The reaction mixture was allowed to warm to room temperature and stirred overnight during which time the colour of the solution changed from orange to pale yellow. Excess $[Li\{AlD_2(OCH_2CH_2OCH_3)_2\}]$ was hydrolysed by the cautious addition of D_2O (0.35 cm^3). Volatiles were removed, and the reaction mixture dried, under reduced pressure. The yellow residue was extracted into pentane (20 cm^3) and the volume subsequently reduced to 10 cm^3 prior to cooling to −80 °C. The compound **16d** was obtained as a yellow crystalline solid. Since only a small amount of compound was obtained, and in order to utilise all of the compound prepared, the Yield of **16d** was not determined.

*3.25. Preparation of $[W\{(\eta\text{-}C_5D_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{(CH_2)_4CH_3\}I]$ (**17d**)*

The compound $[W\{(\eta\text{-}C_5H_4)C(CD_3)_2(\eta\text{-}C_5D_4)\}\{(CH_2)_4CH_3\}I]$ (**17d**) was prepared by the reaction between the compound **7d** (0.05 g, 0.098 mmol) and NH_4I (0.015 g, 0.11 mmol) in a procedure analogous to that employed to prepare the compound **9** and was obtained as a pale red solid. Yield: 0.026 g, 47%.

*3.26. Preparation of $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\{CD_2CD_3\}_2]$ (**18**)*

The compound **18** was prepared by the reaction between the compound $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}Cl_2]$ (0.47 g, 1.1 mmol) and a solution of $[Zn\{CD_2CD_3\}_2]$ (5 cm^3, 0.4 M, 2 mmol) in toluene in a procedure analogous to that used to prepare the compound **3** and was obtained as a yellow solid. Yield: 0.24 g, 52%.

*3.27. Preparation of $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\{CD_2CD_3\}I]$ (**19**)*

The compound $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\{CD_2CD_3\}I]$ (**19**) was prepared by the reaction between the compound **18** (0.04 g, 0.09 mmol) and NH_4I (0.025 g, 0.17 mmol) in a procedure analogous to that employed to prepare the compound **9** and was obtained as a pale red solid. Yield: 0.032 g, 69%.

*3.28. Preparation of $[W\{(\eta\text{-}C_5H_4)CMe_2(\eta\text{-}C_5H_4)\}\{CD_2CD_3\}H]$ (**20**)*

The compound **20** was prepared by the reaction between the compound **19** (0.027 g, 0.05 mmol) and a solution of $[Na\{AlH_2(OCH_2CH_2OCH_3)_2\}]$ (0.5 cm^3, 2.5 M, 1.25 mmol) in toluene in a procedure analogous to that used to prepare the compound **10**. The compound **20** was obtained as a yellow solid. Yield: 0.012 g, 62%.

Scheme 1.

cane and decaazacyclooctadecane as ligands by the template condensation. In this paper, we report the synthesis, characterization and properties of new copper(II) complexes of (12-methyl-12-nitro-4,7-dioxa-1,10-diazacyclotridecane), $[Cu(L_1)]^{2+}$, and (12,12-dicarboxyethyl-4,7-dioxa-1,10-diazacyclotridecane), $[Cu(L_2)]^{2+}$, with perchlorate, hexafluorophosphate and tetrachlorozincate as counter ions. The mononuclear copper(II) complexes were prepared from the template condensation of (1,8-diamino-3,6-dioxaoctane), formaldehyde with the carbon acids nitroalkane or diethylmalonate in the presence of a metal ion (Scheme 1).

2. Experimental

2.1. Materials and measurements

Safety note. Perchlorate salts of transition metal complexes with organic ligands are often explosive and should be handled with caution. All chemicals and solvents used in the syntheses were of reagent grade and were used without further purification. For the spectroscopic measurements, water was distilled and organic solvents were purified according to the literature method [29]. Electronic absorption spectra were obtained with a Shimadzu UV–Vis scanning spectrophotometer (Model 2101 PC), FTIR (KBr, cm^{-1}) spectra with a Shimadzu Varian 4300 spectrophotometer and conductance measurements with a Metrohm Herisau conductometer E 518. The elemental analysis (carbon, hydrogen and nitrogen) of the complexes was obtained from a Carlo ERBA Model EA 1108 analyser. Magnetic moments were calculated from magnetic susceptibility data obtained using a Johnson Matthey MK-1 magnetic susceptibility balance. Atomic Absorption Spectra (AAS) were recorded on a Perkin–Elmer 4100–1319 spectrophotometer. The electrochemical data were obtained in acetonitrile with 0.1 M $(n\text{-}Bu)_4NClO_4$ as the supporting electrolyte. The working electrode was a platinum disk, the auxiliary electrode was a coiled platinum wire and the reference electrode was $Ag/AgClO_4$ (0.1 M in CH_3CN), which showed +0.24 V versus SCE.

2.2. Preparation of (12-methyl-12-nitro-4, 7-dioxa-1, 10-diazacyclotridecane)copper(II) perchlorate, $[Cu(L_1)](ClO_4)_2$

1,8-Diamino-3,6-dioxaoctane (21.7 mmol, 3.22 g) was added to a solution of $Cu(NO_3)_2 \cdot 2.5H_2O$ (21.9 mmol, 5.19 g) in methanol (150 ml). The resulting blue solution was warmed to ca. 40 °C. Then nitroethane (21.9 mmol, 1.34 g), triethylamine (21.7 mmol, 2.2 g) and excess formaldehyde (12 ml, 36% aqueous, 1.57 mmol) were added. After heating for 60 min, the solution was diluted with a large volume of water, sorbed onto a column of SP-Sephadex C-25 (Na^+ form) resin (25×4 cm) and eluted with 0.2 mol dm^{-3} $NaClO_4$. Only one major purple band was observed and collected, reduced in volume, and the product crystallized by slow evaporation. The complex was isolated as a blue-purple solid, further crystallization was achieved, but with some contamination from the electrolyte. *Anal.* Calc. for $C_{10}H_{21}Cl_2CuN_3O_{12}$: Cu, 12.46; C, 23.56; H, 4.15; N, 8.24%. Found: Cu, 12.34; C, 23.42; H, 4.04; N, 8.30%.

2.3. Preparation of (12-methyl-12-nitro-4,7-dioxa-1, 10-diazacyclotridecane)copper(II) tetrachlorozincate, $[Cu(L_1)][ZnCl_4]$

The perchlorate salt, $[Cu(L_1)](ClO_4)_2$, was dissolved in a small volume of water and an excess of zinc chloride was added, followed by acetone until the solution became turbid. The blue-purple product was collected after 24 h, washed with ethanol, and then recrystallized from hot methanol–propane-2-ol. *Anal.* Calc. for $C_{10}H_{21}Cl_4CuN_3O_4Zn$: Cu, 12.24; Zn, 12.8; C, 23.13; H, 4.05; N, 8.10%. Found: Cu, 12.09; Zn, 12.68; C, 23.02; H, 3.89; N, 8.25%.

2.4. Preparation of (12-methyl-12-nitro-4,7-dioxa-1, 10-diazacyclotridecane)copper(II) hexafluorophosphate, $[Cu(L_1)](PF_6)_2$

To an acetonitrile (50 ml) suspension of $[Cu(L_1)](ClO_4)_2$ (0.5 g) was added excess NH_4PF_6. $[Cu(L_1)](ClO_4)_2$ went into the solution, and white precipitates

of NH_4ClO_4 were formed. NH_4ClO_4 was filtered off, and the filtrate was concentrated to 25 ml. Water (25 ml) was added to the solution, and the mixture was kept in a refrigerator. A yellow Cu(II) complex was prepared, filtered, washed with a 6:1 mixture of water and acetonitrile, and dried in vacuum. *Anal.* Calc. for $CuC_{10}H_{21}N_3O_4P_2F_{12}$: Cu, 10.58; C, 19.99; H, 3.52; N, 6.99. Found: Cu, 10.41; C, 19.76; H, 3.41; N, 7.12%.

2.5. Preparation of (12,12-dicarboxyethyl-4,7-dioxa-1,10-diazacyclotridecane) copper(II) perchlorate, $[Cu(L_2)](ClO_4)_2$

Tetradentate 1,8-diamino-3,6-dioxaoctane (21.7 mmol, 3.22 g) was added to $Cu(NO_3)_2 \cdot 2.5H_2O$ (21.7 mmol, 5.19 g) in methanol (200 ml). The resulting blue solution was warmed, then diethylmalonate (21.7 mmol, 3.2 g), triethylamine (21.7 mmol, 3 ml) and formaldehyde (13.1 mol, 37% aq, 10 ml) were added. After heating for a further 2 h, the solution was left at room temperature overnight. The solution was diluted with water, sorbed onto SP Sephadex C-25 resin (25×4 cm column) and eluted with 0.25 M $NaClO_4$ adjusted to pH $\sim$ 3. Three significant blue bands were collected. The first failed to crystallize readily, proved to be acid-sensitive and hence non-cyclic (L_3), and was discarded. The third band on concentration and standing gave a blue powder. Rapid and essentially complete loss of colour of a solution of this material on acid addition is indicative of a non-cyclic product; the diester macrocycle does not decolourize readily in aqueous acid. Spectroscopy (IR and UV–Vis) indicated a similarity to the precursor, and the micro-analysis indicated a C:N ratio of 7:2, although an acceptable fit for all elements to presumed structures was not forthcoming. Clearly, this material does not arise from a condensate involving diethylmalonate, and complete identification was not pursued. The second band, on concentration, gave blue-purple solids, which were collected, washed with alcohol and ether, and air-dried to give the diester product. *Anal.* Calc. for $C_{15}H_{28}Cl_2CuN_2O_{14}$: Cu, 10.68; C, 30.28; H, 4.74; N, 4.71%. Found: Cu, 10.52; C, 30.08; H, 4.66; N, 4.89%.

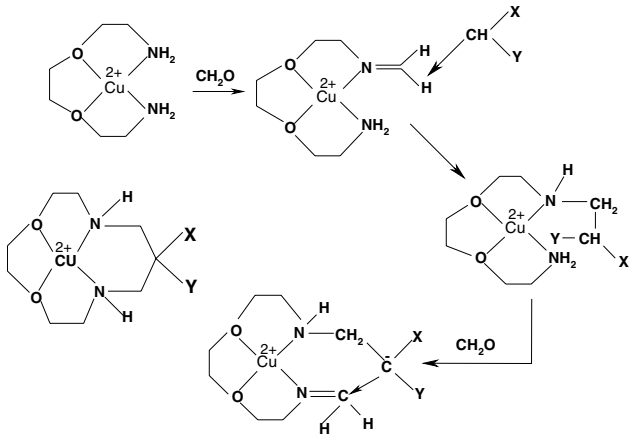
2.6. Preparation of (12,12-dicarboxyethyl-4,7-dioxa-1,10-diazacyclotridecane) copper(II) tetrachlorozincate, $[Cu(L_2)][ZnCl_4]$

The perchlorate salt, $[Cu(L_2)](ClO_4)_2$, was dissolved in a small volume of water and an excess of zinc chloride was added, followed by acetone until the solution became turbid. The blue product was collected after 24 h, washed with ethanol, and then recrystallized from hot methanol-propane-2-ol. *Anal.* Calc. for $C_{15}H_{28}Cl_4CuN_2O_6Zn$; Cu, 10.53; Zn, 10.84; C, 29.86; H, 4.68; N, 4.64%. Found: Cu, 10.45; Zn, 10.68; C, 29.69; H, 4.50; N, 4.78%.

2.7. Preparation of (12,12-dicarboxyethyl-4,7-dioxa-1,10-diazacyclotridecane) copper(II) hexafluorophosphate, $[Cu(L_2)](PF_6)_2$

A solution of 3.1 mmol NH_4PF_6 in 5 ml of H_2O was added to a solution of 1.2 mmol $[Cu(L_2)](ClO_4)_2$ in 10 ml of H_2O. The blue-purple product precipitate was filtered, washed with H_2O, and dried in air. *Anal.* Calc. for $CuC_{15}H_{28}N_2O_6P_2F_{12}$: Cu, 9.26; C, 26.27; H, 4.11; N, 4.08. Found: Cu, 9.11; C, 26.08; H, 3.95; N, 4.23%.

3. Results and discussion



Reaction of copper(II) nitrate, 1,8-diamino-3,6-dioxaoctane, formaldehyde and nitroethane proceeds readily in warm methanol containing triethylamine as a non-coordinating base, with the product macrocycle 12-methyl-12-nitro-4,7-dioxa-1,10-diazacyclotridecane (L_1) actually crystallizing as the copper(II) complex during the reaction without any extensive attempts to refine the conditions, and yields of the isolated solid of 65% have been obtained routinely. Chromatography of a reaction mixture on SP-Sephadex C-25 cation exchange resin indicate that $[Cu(L_1)]^{2+}$ accounts for >84% of copper in the product mixture. The IR spectra of the complexes (Table 1) show a single absorption around 3230 cm^{-1}, which is attributed to ν_{N-H} of the coordinated secondary amines. A much higher ν_{N-H} value (for $[Cu(L_1)](ClO_4)_2$), than that of (6-methyl-6-nitro-1,4,8,

11-tertraazacyclotetradecane)copper(II) perchlorate, (12-methyl-12-nitro-1,4,7,10-tetraazacyclotridecane) copper(II) perchlorate and (10-methyl-10-nitro-1,4,8,12-tetraazacyclopentadecane)copper(II) perchlorate indicates that the Cu–N interaction in the 13-membered diazadioxa is much stronger than in 13-membered tetraaza complexes [16–24]. The products exhibit a characteristic IR vibration for the nitro group, with v_{asym} (NO_2) at 1555 cm^{-1} and v_{sym} (NO_2) at 1355 cm^{-1}. Voltammetry in water defined a Cu(II)–(I) couple at −0.73 V (versus Ag/AgCl) and a multielectron irreversible nitro group reduction at −0.92 V. The product is also extremely resistant to dissociation in aqueous acid. Spectroscopic and electrochemical properties are similar to those reported for other well-characterized analogues [16–24]. The molar conductance values of 245 $\Omega^{-1}\,M^{-1}\,cm^{-2}$, measured in water, correspond to 1:2 electrolytes. The magnetic moments (1.69–1.72 μ_B) of the copper(II) complexes measured in the solid state correspond to a square-planar coordination geometry of the complexes. The electronic spectra (Table 1) of the copper(II) complexes are comparable to those of square-planar copper(II) complexes with other macrocycles, indicating that the 13-membered dioxadiaza ligands of this study do not differ significantly from the tetraaza ligands with respect to the ligand field strength [16–24]. Evidently, the reaction, via Schemes 1 and 2, proceeds to the essential exclusion of other reactions, the formation of the new five-membered ring being favored entropically. We are currently pursuing this type of reaction with a range of nitroalkanes and amine complexes, as well as looking at complexes of the pendant amine ligands resulting from nitro group reduction. It is clear that the experimental method represents a facile and probably general route to a new range of macromonocyclic ligands.

When the identical reaction to that described above was performed with diethylmalonate as the carbon

Scheme 2.

acid, it was not possible to crystallize any product directly. Chromatography on SP-Sephadex C-25 resin indicated that several products were present. The major band, from which a blue solid was crystallized, did not contain a cyclic ligand, decomposing readily in aqueous acid. Spectroscopy and microanalysis best fit a simple structure such as L_3, rather than the required compound L_2. A complex of the latter compound was isolated in low yield from the second band, and despite attempts to vary the outcome by altering the reaction conditions, the result was always similar. The only macrocyclic complex isolated, which amounted to less than 15% of the total copper and was crystallized in no better than 3% yield, proved to contain the macrocycle L_2. The IR spectrum showed a strong band at 1731 cm^{-1} characteristic of an ester. The complex was stable in aqueous acid, indicative of a macrocyclic complex. Voltammetry yielded a well defined reversible copper(II)–(I) couple at a potential of −0.84 V, with an irreversible wave at −1.36 V associated with electron addition to the ester substituents and in a similar position to waves assigned to this process in several macrocyclic complexes with ester substituents [6–15]. The likely reaction of the putative monoimine intermediate (product of the first step in Scheme 1) with hydroxide ion to ultimately form L_3, rather than reaction with the $(EtOOC)_2CH^-$ nucleophile, is not unreasonable since there was no attempt to exclude water form the reaction mixture. The pK_a of diethylmalonate is about 5 units higher than that of nitroethane, strictly limiting the concentration of the anion in the former case. Possibly in stringently anhydrous conditions, reactions involving carbon acids with higher pK_a values may prove more successful. We are pursuing this prospect. Evidently, nitroalkane carbon acids are for more successful reactants than diester alkenes carbon acids under the conditions described. All efforts to obtain the free ligands from the complexes by treating the complexes with excess NaCN, H_2S gas, or strong acid were unsuccessful.

4. Conclusions

Square-planar copper(II) complexes of 13-membered dioxa diaza macrocyclic ligands (12-methyl-12-nitro-4,7-dioxa-1,10-diazacyclotridecane), $[Cu(L_1)]^{2+}$, and (12,-12-dicarboxyethyl-4,7-dioxa-1,10-diazacyclotridecane), $[Cu(L_2)]^{2+}$, with perchlorate, hexafluorophosphate and tetrachlorozincate as counter ions have been prepared by the one-pot template reactions of formaldehyde, 1,8-diamino-3,6-dioxaoctane, with the carbon acids nitroalkane or diethylmalonate in the presence of the copper(II) ion. The spectra of the complexes show that the two nitrogen and two oxygen atoms are coordinated to the copper(II) ion.

H_2L:

2. Experimental

2.1. General methods

Microanalytical (C, H, N) data were obtained with a FLASH EA 1112 Series CHNS Analyzer. A SHIMADZU 3101-PC UV/Vis/NIR spectrophotometer was used to record the electronic spectra. Infrared spectra were recorded on KBr pellets with a JASCO-5300 FT-IR spectrophotometer. ^{1}H spectra of the ligand in $CDCl_3$ solution were recorded on a Bruker 400 MHz spectrometer using $Si(CH_3)_4$ as an internal standard. The room temperature solid-state magnetic susceptibility was measured by using a Sherwood Scientific magnetic susceptibility balance. A CH-Instruments Model 620A electrochemical analyzer was used for cyclic voltammetric experiment on an acetonitrile solution of the complex containing tetrabutylammonium perchlorate (TBAP) as the supporting electrolyte. The three-electrode measurement was carried out at 298 K under a dinitrogen atmosphere with a glassy carbon disc working electrode, a platinum wire auxiliary electrode and a saturated calomel reference electrode (SCE). The CD spectra were measured with a JASCO J-810 spectropolarimeter. EPR spectra were recorded on a JEOL JES-FA200 spectrometer.

2.2. Materials

L-Phenylalaninol [(*S*)-(−)-2-amino-3-phenyl-1-propanol] and salicylaldehyde were purchased from Lancaster and used as received. TBAP, used as the supporting electrolyte in electrochemical measurement, was purchased from Acros, India. Solvents were purified by standard methods. All other chemicals were of analytical grade and were used without further purification.

2.3. Synthesis of ligand H_2L

L-Phenylalaninol [(*S*)-(−)-2-amino-3-phenyl-1-propanol] (0.151g, 1 mmol) and salicylaldehyde (0.122 g, 1 mmol) were stirred together in methanol (15 mL) for 1 h at room temperature. The resulting yellow solution was filtered and the filtrate was kept for 2 days in an open beaker for slow evaporation. The yellow precipitate of H_2L thus obtained was washed with hexane and dried at room temperature. Yield: 0.196 g (77%). Elemental *Anal.* Calc. for $C_{16}H_{17}NO_2$: C, 75.27; H, 6.71; N, 5.49. Found: C, 74.98; H, 6.67; N, 5.65%. IR (KBr, cm^{-1}): 3246.49 (ν_{O-H}), 1631.93 ($\nu_{C=N}$). ^{1}H NMR (400 MHz, $CDCl_3$): δ 2.94 (m, 2H, CH_2–Ph), 3.54 (m, 1H, CH), 3.814 (m, 2H, CH_2–OH), 6.838–7.340 (m, 9H, Ar), 8.1 (s, 1H, HC=N). UV/Vis [CH_3CN; λ_{max}/nm (ε)]: 315 (4689), 255 (13 647), 225 (16 640).

2.4. Synthesis of complex $\mathbf{1}\cdot 2DMF$

To a methanolic solution (15 mL) of ligand H_2L (0.255 g, 1 mmol) was added $Mn(CH_3COO)_2\cdot 4H_2O$ (0.245 g, 1 mmol). The mixture was allowed to stir at room temperature in air for 3 h. The resultant dark brown solution was evaporated to dryness using a rotavapor and a vacuum pump. The solid, thus obtained, was dissolved in dichloromethane, washed twice with water, once with brine solution (using a separating funnel) and dried over anhydrous Na_2SO_4. The resulting dark brown solution, on slow evaporation, gave a brown microcrystalline solid of $[Mn^{IV}L_2]$ (**1**). Yield: 0.381g (68%). This microcrystalline product was recrystallized from DMF–CH_3CN (1:1) to yield single crystals of $\mathbf{1}\cdot 2$DMF, suitable for crystal structure determination. Elemental *Anal.* Calc. for $C_{38}H_{44}N_4O_6Mn$ ($\mathbf{1}\cdot 2$DMF): C, 64.49; H, 6.27; N, 7.92. Found: C, 64.17; H, 6.21; N, 8.01%. IR (KBr, cm^{-1}): 1616.49 ($\nu_{C=N}$). UV/Vis [CH_3CN; λ_{max}/nm (ε)]: 540 (250), 404 (8252), 344 (sh), 294 (sh).

2.5. X-ray crystallography

Data were measured at 298(2) K on a Bruker SMART APEX CCD area detector system [λ(Mo Kα) = 0.71073 Å], graphite monochromator, 1315 frames were recorded with an ω scan width of 0.3°, each for 8 s, crystal-detector distance 60 mm, collimator 0.5 mm. Data reduction was by SAINTPLUS [10], the structure solution used SHELXS-97 [11] and was refined using SHELXL-97 [12]. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were introduced in calculated positions and included in the refinement riding on their respective parent atoms. Additional details of the data collection parameters and refinement are collected in Table 1. The absolute configuration for the compound molecule was successfully determined by refining the Flack parameter (0.03(3)) [13]. The final Fourier difference synthesis showed minimum and maximum peaks of −0.434 and +0.690 e $Å^{-3}$.

Table 1
Crystallographic data for **1** · 2DMF

Chemical formula	$C_{32}H_{30}MnN_2O_4 \cdot 2DMF$
Formula weight	707.71

R_1[a] [$F > 4\sigma(F)$]	0.0668
wR_2[b]	0.1453

[a] $R_1 = \sum||F_o| - |F_c||/\sum|F_o|$.
[b] $wR_2 = [\sum\{(F_o^2 - F_c^2)^2\}/\sum\{w(F_o^2)^2\}]^{1/2}$.

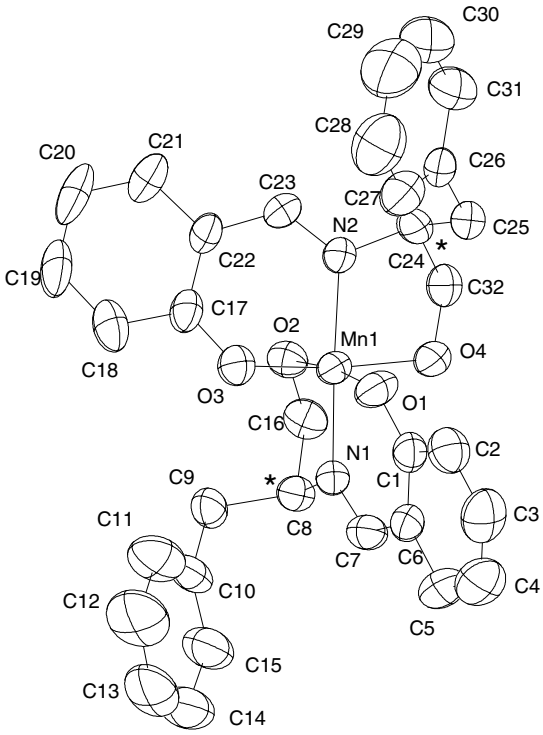
3. Results and discussion

3.1. Synthesis

The ligand H_2L, obtained as a yellow solid by Schiff base condensation (Scheme 1), was reacted with manganese(II) acetate tetrahydrate at room temperature in methanol to afford the mononuclear complex [$Mn^{IV}L_2$] (**1**), in moderate yield. Atmospheric oxygen is the possible oxidizing agent here, which oxidizes the Mn(II) center directly to Mn(IV). This rather easy oxidation is assisted by the fact that the tridentate ligand (L^{2-}), containing phenolate and alkoxide oxygens, effectively stabilizes the +4 oxidation state of manganese. Stabilization of Mn(IV) species by phenolate and alkoxide oxygens is well established [4a,8a].

3.2. Description of the structure

Single crystals of **1** · 2DMF, suitable for X-ray crystallography, were grown by slow evaporation of a 1:1 mixture of dimethyl formamide (DMF) and acetonitrile solution of the compound. Compound **1** · 2DMF crystallizes in the non-centrosymmetric orthorhombic space group $P2_12_12_1$. The asymmetric unit contains one molecule of the complex and two molecules of DMF. The ORTEP drawing of the complex with the atom labelling scheme is shown in Fig. 1. Selected bond lengths and bond angles are listed in Table 2. The geometry around the metal is six coordinated with an N_2O_4 core. The chiral H_2L ligand is dianionic in the complex and acts as a meridional ONO donor using imine nitrogen, phenolate and alkoxide oxygen atoms to bind the metal. The chiral centers are shown by asterisk marks in Fig. 1. The resulting MnN_2O_4 coordination sphere has a nearly planar O_4 equator with respect to which the two N atoms are located in virtually ideal trans positions. The angles at the metal center show deviations from the ideal octahedral values of 90° and 180°, resulting in a distorted octahedral geometry around Mn. The distortion from octahedral geometry is reflected in the acute bite angles between the alkoxide O atom and the imine N atom of the $[ONO]^{2-}$ ligand: [O2–Mn–N1, 82.79(13)° and O4–



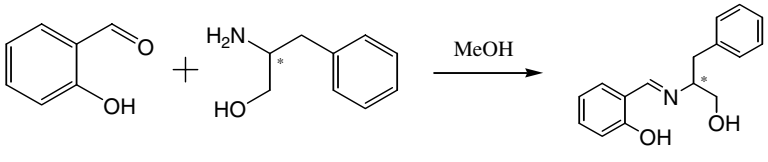


Fig. 1. Thermal ellipsoid plot for complex **1**. Hydrogen atoms are not shown for clarity. The asterisk marks indicate chiral centers.

O(1)–Mn(1)–N(2)	97.19(14)
O(3)–Mn(1)–N(2)	89.66(13)
N(1)–Mn(1)–N(2)	170.22(15)

Mn–N2, 83.89(13)°]. This deviation can be attributed mainly to the rigidity of the Schiff base ligand. Similar distortions from ideal octahedral geometry have been reported by Chakravorty et al. [8h] in Mn(IV) complexes of tridentate ONO donor Schiff base ligands. Thus, the overall geometry around the manganese ion is best described as a distorted meridional octahedron. The average $Mn–O_{phenolate}$, $Mn–O_{alkoxide}$ and Mn–N bond distances of 1.9105(3), 1.884(3) and 1.974(3) Å, respectively, fall in the range of those reported for structurally characterized mononuclear manganese(IV) complexes [8b,8h,8l].

In the crystal structure, there are intermolecular C–H···O hydrogen bonding interactions among $[MnL_2]$ (**1**) complexes resulting in a supramolecular hydrogen bonding network. This consists of hydrogen bonded chain-like arrangements via C(13)–H(13)···O(2) bonds (relevant H-bonding parameters: 0.93, 2.33, 3.195(7), 155.3), that are further interlinked via C(9)–H(9B)···O(4) bonds (relevant H-bonding parameters: 0.97, 2.57, 3.350(5), 137.0) into an intricate hydrogen bonded framework as shown in Fig. 2. Along the chain, each complex MnL_2 is additionally hydrogen bonded to a DMF solvent molecule (not shown in Fig. 2 for clarity). Interestingly, the packing of the chiral complexes in the crystal results in the formation of helical channels, when viewed down the crystallographic *a*-axis (Fig. 3). DMF solvent molecules are accommodated in the alternate channels. We believe that the formation of such helical channels is induced by the chirality of the complex $[MnL_2]$.

3.3. IR spectroscopy

The IR peak due to *ν*(OH), which occurs as a broad feature around 3260 cm^{-1} for the free ligand, is missing in the complex indicating that on complexation the phenol character of the ligand has been lost. The C=N peak of the ligand at 1632 cm^{-1} is shifted to 1616 cm^{-1} in the complex indicating complexation of the imine nitrogen with the metal center.

3.4. Electrochemistry

The cyclic voltammogram of **1** · 2DMF in 0.1 M TBAP/CH_3CN (glassy carbon working electrode, 298 K) shows two reduction responses as shown in Fig. 4. A nearly reversible reduction occurs at $E_{1/2} = -0.47$ V versus SCE ($\Delta E = 0.11$ V), which can be assigned to the $[Mn^{IV}L_2] + e^- \leftrightarrow [Mn^{III}L_2]^{1-}$ couple. Another quasi-reversible reduction is observed at $E_{1/2} = -0.89$ V,

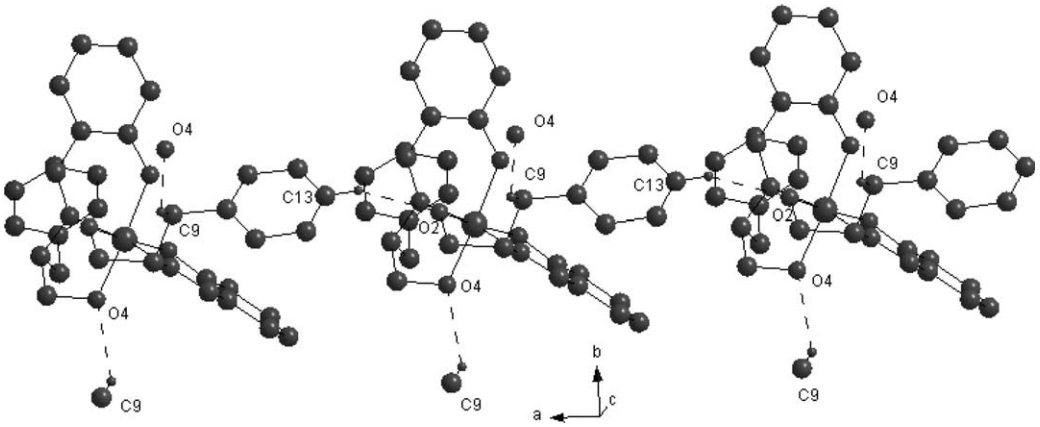

Fig. 2. Inter molecular association via C–H···O type hydrogen bonds into a chain-like structure and its mode of linking to adjacent chains.

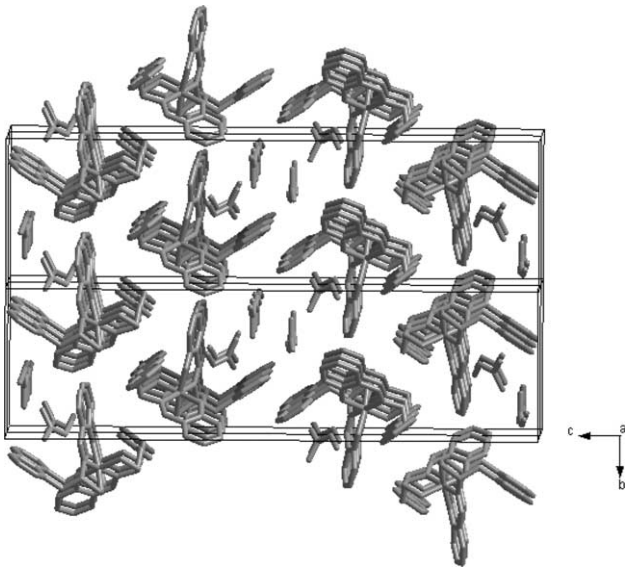

Fig. 3. Packing diagram of **1** · 2DMF showing helical channels when viewed down the crystallographic *a*-axis. The channels are alternatively filled by solvent DMF molecules.

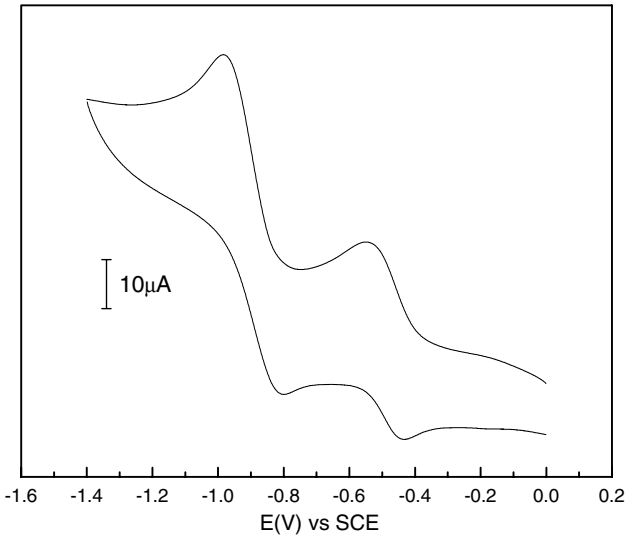

Fig. 4. Cyclic volotammogram of $\sim 10^{-3}$ M acetonitrile solution of **1** · 2DMF at 298 K (0.1 M TBAP, scan rate 100 mV s^{-1}, glassy carbon electrode).

corresponding to the Mn^{III}/Mn^{II} reduction ($\Delta E = 0.18$ V). The rather negative reduction wave at −0.47 V for the Mn^{IV}/Mn^{III} couple indicates a relatively stable Mn(IV) complex which in turn justifies the easy formation of **1** · 2DMF from H_2L and Mn(II) salt in the presence of air at room temperature.

Ligands having alkoxide groups are reported to be efficient in stabilizing the higher oxidation state Mn(IV), thus causing a negative reduction potential for the Mn^{IV}/Mn^{III} couple. For example, Pecoraro et al. [8l] reported quasi-reversible one-electron reductions at $E_{pc} = -0.32$ and −0.46 V (versus Ag/AgCl) in Mn(IV) complexes such as $Mn(SALAHP)_2$ and $Mn(SALA-DHP)_2$, respectively, which are prepared from hydroxyl rich Schiff base ligands.

3.5. Electronic and circular dichroism spectra

The electronic spectrum of the ligand H_2L in acetonitrile is characterized by three intraligand charge transfer transitions, judging from their molar extinction coefficient values [225 nm ($\varepsilon = 16640$ $cm^{-1}M^{-1}$), 255 nm ($\varepsilon = 13647$ $cm^{-1}M^{-1}$), 315 nm ($\varepsilon = 4689$ $cm^{-1}M^{-1}$)] as shown in Fig. 5. The UV visible spectrum of the manganese complex **1** · 2DMF in acetonitrile is dominated by an absorption band at 404 nm ($\varepsilon = 8252$ cm^{-1} M^{-1}) and two shoulders at ∼344 and ∼294 nm (possibly charge transfers in origin). Also a broad absorption band is observed in the visible region around 550 nm, which can be associated with d–d transitions, judging from its intensity.

The circular dichroism spectrum of the ligand H_2L shows two negative bands (ILCT) around 315 and 255 nm as shown in Fig. 5. These peaks correspond to the UV absorption peaks observed around 315 and 255 nm. The CD spectrum of the manganese complex **1** · 2DMF also shows three peaks, but at shifted positions (as negative cotton effects) corresponding to the UV (charge transfer) transitions at 404, 344 and 294 nm. Also the complex shows one broad CD band

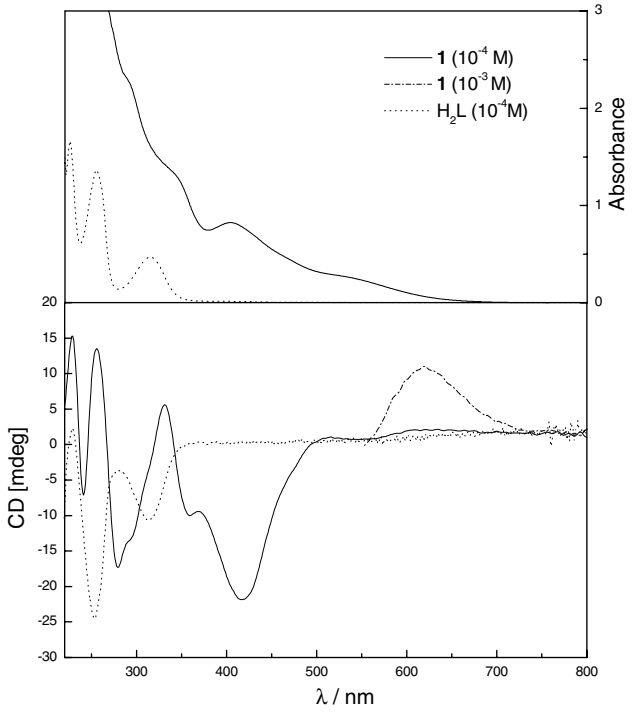

Fig. 5. Electronic (above) and circular dichroism (below) spectra of **1** · 2DMF and ligand H_2L in acetonitrile solution.

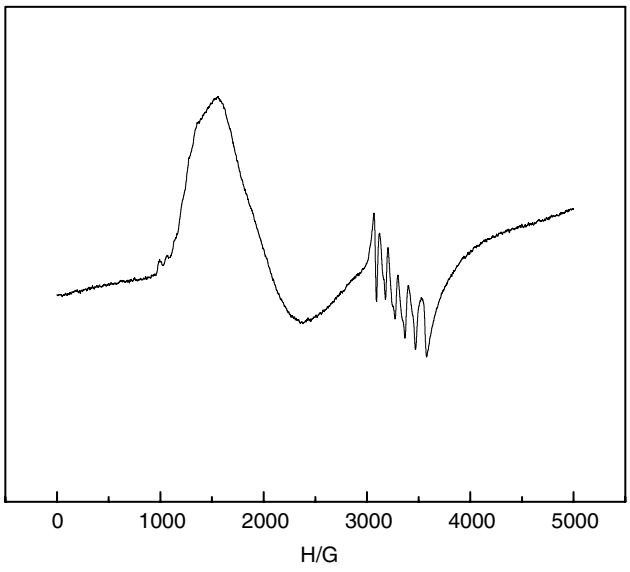

Fig. 6. X-band EPR spectrum of **1** · 2DMF in ethanol solution at liquid nitrogen temperature.

around 600 nm (at a relatively higher concentration, see Fig. 5), which can be assigned as d–d transitions.

3.6. EPR spectroscopy

The EPR measurement of **1** · 2DMF was done at the X-band frequency at liquid nitrogen temperature and the spectrum is shown in Fig. 6. As expected, the spectrum indicates a paramagnetic d^3 system. The EPR features of a d^3 species depend upon the axial (D) and rhombic (E) zero-field splitting parameters. In an axial field ($E/D = 0$), the spectrum is dependent on the magnitude of the zero-field splitting parameters. Two limiting cases are defined when the value of the axial field ($2D$) is either much larger than or much smaller than $h\nu$ (0.31 cm^{-1}). In the first case a strong signal at $g \sim 4$ and a weak signal at $g \sim 2$ are observed. Whereas in the second case a weak signal at $g \sim 4$ and a strong signal at $g \sim 2$ are found [14,8j].

The X-band EPR spectrum of the complex **1** · 2DMF in ethanol solution at liquid nitrogen temperature displays a strong absorption near $g \sim 4$ and a weak but resolved response at $g \sim 2$. This type of spectral profile is characteristic of a d^3 system in which $2D$ is much larger than the microwave frequency, [$2D \gg h\nu$]. The magnitude of the ^{55}Mn hyperfine coupling of 90 G is consistent with that of previous reports for the Mn(IV) complexes [8m,9]. The room temperature magnetic susceptibility of **1** · 2DMF in the solid state is 3.9 BM, which is close to the spin only value (3.87) for a high spin d^3 system. This experimental μ_{eff} value clearly indicates that the complex **1** · 2DMF is a Mn(IV) system, which is in complete agreement with X-ray and EPR results.

4. Conclusions

We have reported here the synthesis, crystal structure and properties of a new mononuclear manganese(IV) chiral complex. In the crystal, the complexes get interlinked into a supramolecular hydrogen bonded network. The chirality of the complex is established by circular dichroism (CD) studies. The complex exhibits two redox waves in the cyclic voltammogram corresponding to Mn^{IV}/Mn^{III} and Mn^{III}/Mn^{II} couples. The EPR spectral feature (an absorption near $g \sim 4$ and a weak but resolved response at $g \sim 2$) is consistent with a Mn(IV) complex.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 262962 for compound **1** · 2DMF. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

method of self-consistent field (SCF) [8]. Thus, the theoretically calculated cluster species reported as being As_2 [9,10], As_3 [11] and As_4 [10,12,13] and also their formation has been proved experimentally.

Subsequently, Bowen et al. [14] determined the electron affinities of several As_n^- ($n = 1–5$) clusters using negative ion photoelectron spectroscopy. The confirmation of the evidence of several other metals' negatively charged cluster species, other than arsenic, was achieved using the pulsed UV laser ablation technique [15].

Lately, electron level theoretical calculations based on DFT and the prediction of infrared and Raman spectra of fullerene-like arsenic cages have been reported [16]. The work of Baruah et al. [16] concluded that clusters of As_n [$n = 4, 8, 20, 28, 32, 36, 60$] would be unstable and would dissociate into As_4 units except for a suggested As_{20} cluster.

Recently, in our laboratory, we have successfully applied commercial MALDI-TOF mass spectrometric instrumentation (MALDI-TOF-MS) for the generation of tellurium, selenium, phosphorus, or sulfur clusters and many new compounds [17–20]. In this work, the possibilities of laser desorption ionization (LDI) and/or laser ablation as a promising approach towards the generation of As_n and As_nS_m clusters are studied.

2. Experimental

2.1. Chemicals and reagents

Elemental gray arsenic of 99.997% purity was purchased from Sigma Aldrich (Steinheim, Germany). Elemental sulfur of 99.98% purity was obtained from Aldrich Chemical Co., Milwaukee, USA. The arsenic sulfides As_2S_2, As_2S_3 and As_2S_5 of 99.99% purity were purchased from Aldrich Chemical Co., Milwaukee, USA, as well. For the calibration of the mass spectrometer 2,5-dihydroxybenzoic acid (gentisic acid, DHBA) of analytical grade purity purchased from Sigma (Steinheim, Germany) was used. The experiments on the generation of As_n clusters with matrix assisted laser desorption/ionisation were done using as matrices *trans*-2-[3-(4-*tert*-butylphenyl)-2-methyl-2-propenylidene]-malononitrile (AnorgPro) from Fluka (Buchs, Switzerland), 2-(4′-hydroxybenzolazo)-benzoic acid (HABA) from Sigma Aldrich (Steinheim, Germany) and α-cyano-4-hydroxycinnamic acid from Sigma Aldrich (Steinheim, Germany). C_{60} fullerene was purchased from Merck (Darmstadt, Germany). All the above mentioned chemicals were used as received without further purification.

2.2. Apparatus

Mass spectrometric measurements were performed on the commercial AXIMA CFR mass spectrometer from Kratos Analytical (Manchester, United Kingdom) equipped with a nitrogen laser emitting on the wavelength of 337 nm. For the calibration of the mass spectrometer in the linear positive and reflectron positive mode, molecular ions $[M + H]^+$ of DHBA were used. In the case of the linear negative and reflectron negative mode, the calibration of the mass spectra was achieved using molecular ions $[M - H]^-$ of DHBA as well. Laser desorption/ionization mass spectra acquired for this work were obtained from at least 400 laser pulses per spectrum and the recorded spectra of all the laser shots were summed.

All the recorded spectra of post-source decay (PSD) measurement were obtained by setting the mass range windows 15 Da at least.

2.3. Sample preparation

Arsenic as well as arsenic sulfides and elemental sulfur are not soluble in any MALDI sample plate 'friendly' solvent. Because of that, the studied samples were placed directly on a spot of the MALDI sample plate and thoroughly milled in a mortar with a glass stick and mixed if necessary. In the case of matrix assisted generation of cluster species, the quick and dirty standard preparation technique was used. Thus, a suspension of arsenic powder in toluene at a concentration of 1 mg ml^{-1} was prepared. The matrices solutions were prepared by dissolving each matrix in toluene and then acidifying by adding 0.1 ml of 0.1% TFA to obtain a concentration of 20 mg ml^{-1} in a vial. A volume of 0.5 μl of both arsenic suspension and matrix were deposited onto a sample plate and air-dried at room temperature.

3. Results and discussion

3.1. The use of MALDI matrices

The investigation on the possibility of using matrices for the generation of homopolyatomic As_n cluster species was considered here. Several different matrices were examined including DHBA, HABA, AnorgPro matrix and C_{60} in order to examine the possibility of the MALDI approach for the cluster(s) production. Such an approach is rare, although recently its application has been described for gold cluster generation [21]. Also, we have tried the generation of cluster species from specially fabricated graphite crucibles as described thoroughly in a previous work [20].

However, it was found that for all the studied matrices, including the AnorgPro matrix especially recommended for inorganic samples by the producer, we were not able to produce arsenic clusters. Moreover, the presence of fragments of matrices in the mass spectra made their evaluation quite difficult and the signals of arsenic species

were suppressed. We have also observed this phenomenon at high laser energies when graphite crucibles were used where, in addition, carbon clusters became co-ablated and were detected in the mass spectra.

3.1.1. Generation of positively charged homopolyatomic As_n^+ clusters via the LDI approach

Because As_n clusters were not generated using MALDI matrices, we have turned to the laser desorption ionisation (LDI) approach.

An example of a mass spectrum of elemental arsenic obtained in the linear positive mode is shown in Fig. 1(a). In the mass spectra the formation of positively charged As_n^+ ($n = 2-7$) clusters has been observed only after applying sufficiently high laser energy, of at least 3 mW, to the solid sample of elemental arsenic. The values of *m/z* corresponding to As_3^+, As_4^+, As_5^+, and As_7^+ clusters clearly indicated their formation (cf. Fig. 1(a), peaks at *m/z* values equal to 224.94, 299.94, 374.73 and 524.48 Da). In the mass spectra the signal corresponding to As_2^+ has also been observed as a peak of relatively low signal intensity (cf. Fig. 1(a), peak at *m/z* value 150.42 Da), while the signal for the As_6^+ cluster was not observed.

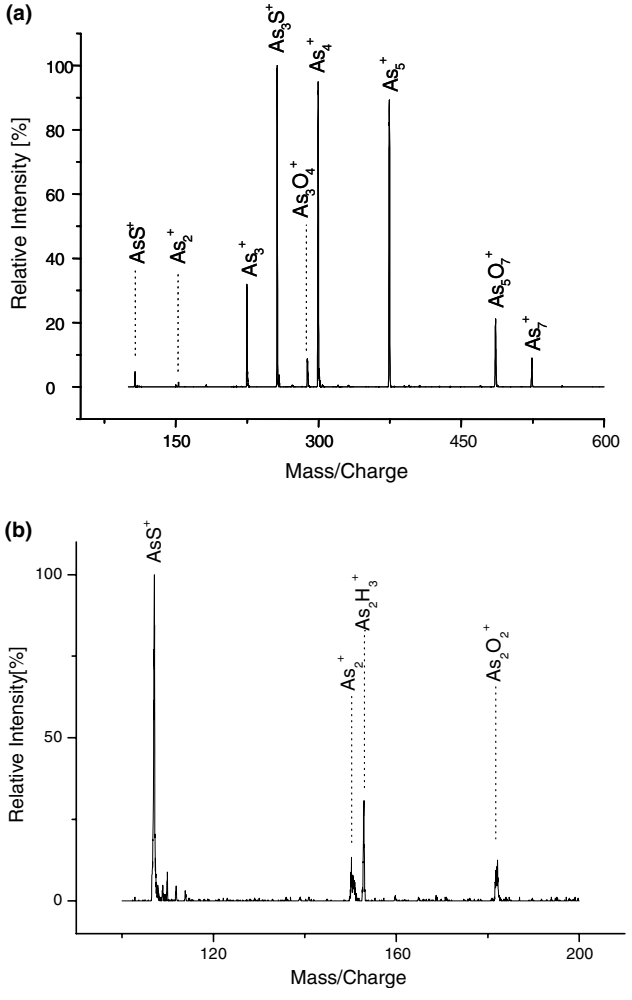

Fig. 1. The positive linear mode mass spectra concerning laser ablation of elemental arsenic. (a) An example of spectra displaying As_n^+ clusters and several other peaks reflecting the evidence of trace impurities contained in highly pure elemental arsenic (purity 99.997%). (b) Detailed view of the range 100–200 *m/z* showing the presence of AsS^+, $As_2^+$and As-hydride $As_2H_3^+$ derived from di-arsan (As_2H_4).

The PSD spectra of detected clusters did not show any signs of decomposition, even at the highest possible laser power (6 mW). In the mass spectra measured in the positive mode, peaks corresponding to AsS^+, As_2^+ and $As_2O_2^+$ are observed (cf. Fig. 1(b), *m/z* values at 107.26, 150.42 and 182.36 Da), while another peak of relatively weak intensity (cf. Fig. 1(b), *m/z* value at 153.14 Da) was assigned to $As_2H_3^+$, according to isotopic pattern modelling. Even if non-dissociative chemisorption of large amounts of H_2 on metal cluster anions has been recently reported [22], we rather suggest that in this case the species was "a chemical compound derived from arsan (AsH_3) or other As-hydrides". We are suggesting that possibly, even in the highly pure arsenic product used in this work, a low but detectable amount of arsan was present and could be detected.

In addition to the peaks of As_n^+ clusters, there were others which were identified using isotopic pattern modelling as arsenic oxides As_nO_m and/or arsenic sulfides As_nS_m, even though elemental gray arsenic of high purity (99.997%) was used. In the case of arsenic sulfides, it can be suggested that the major source of contamination, according to the producer's Certificate of Guarantee, is sulfur, with a content of up to 0.003%. This corresponds to a sulfur molar content of 0.3 mmol kg^{-1} in the pure arsenic used in this work. In reality, such a concentration is very high, as usually in MALDI-TOF-MS a sample concentration of 10^{-5} to 10^{-6} mol l^{-1} is commonly used (by the way, the limit of detection in MALDI is often 10^{-15} mol or even less). Consequently, taking into consideration the previous comments, we have detected and identified the following species: AsS^+ and As_3S^+. Concerning arsenic oxides, it is

Table 1

interesting to note that the presence of As_nO_m species such as As_3O_4, and As_5O_7 (cf. Fig. 1(b), peaks at *m/z* values equal to 288.43, and 486.17 Da) were observed in the mass spectra obtained in the positive linear and reflectron modes as well as in both negative modes, in accordance with the literature [23].

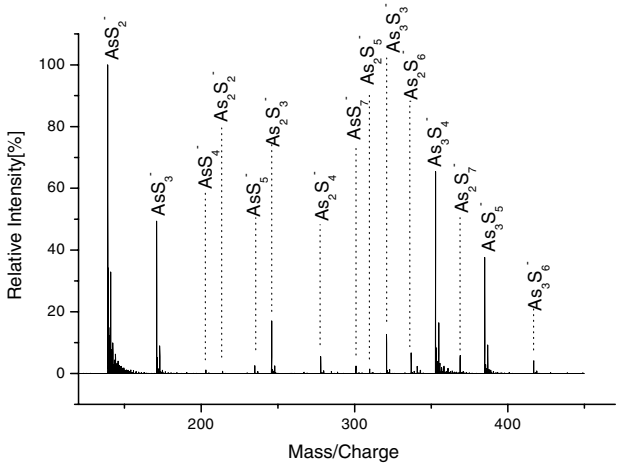

Fig. 2. An example of arsenic sulfide mass spectra recorded in the reflectron negative mode from laser ablation of As_2S_5 powder.

Not only As_2^+, As_3^+, As_4^+, As_5^+ and As_7^+, species of positively charged sulfide clusters, such as AsS^+ and As_3S^+, but also positively charged species such as $As_3O_4^+$, and $As_5O_7^+$ were observed as well. In addition, the $As_2H_3^+$ species derived from di-arsan was detected under the experimental conditions.

3.1.2. Generation of negatively charged As_n^- clusters

The formation of negatively charged As_n^- clusters was suggested theoretically by Zhao et al. [22] and species As^-, As_2^-, As_3^-, As_4^-, As_5^- have already been proved by photoelectron spectroscopy [14]. Therefore, in this chapter we examine the possibility to generate As_n^- clusters by the LDI approach.

The formation of negatively charged As_n^- ($n = 2$–7) clusters has not been observed even when applying a maximal laser power of at least 6 mW to the solid sample of the elemental arsenic. Also, the mass spectra measured in the linear negative and in the reflectron negative mode were represented only by a low number of signals corresponding to $As_nS_m^-$ (S_3^-, AsS^-, AsS_2^-) and/or $As_nO_m^-$ (AsO^-, $As_3O_5^-$, $As_5O_7^-$) species. The stoichiometries were confirmed according to isotopic pattern modelling.

[c] [26].

It is well known that the ionization potential (IP) (first IP of sulfur 10.4 eV and of arsenic 9.8 eV) and electron affinity (EA) (first EA of sulfur 200 kJ mol^{-1} and of arsenic 78 kJ mol^{-1}) are important physico-chemical properties of atoms. This suggests that atoms with high positive values of ionization potential and high positive values of electron affinity would form, in the negative mode, more stable negatively charged species. Therefore, we conclude that the substantially different relative abundance of As_n and/or As_nS_m species in positive and negative modes under the LDI condition is due to preferred formation of As_nS_m species over singly charged As_n^- species as expected.

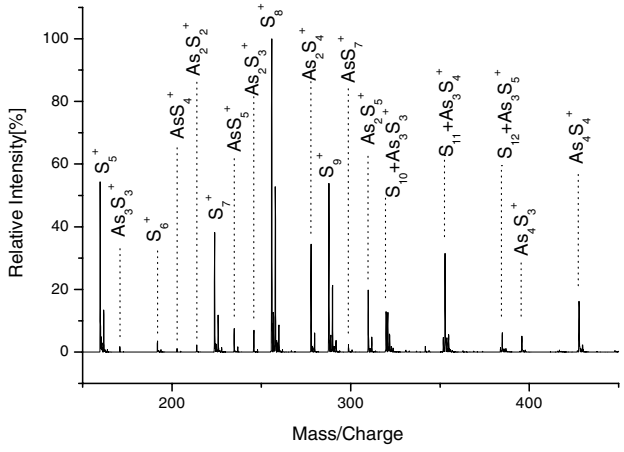

Fig. 3. An example of linear positive mode mass spectra obtained from an As_2S_2 and S_8 mixture used as a precursor for mixed As_nS_m species generation.

The complete summary of both negatively and positively charged arsenic cluster species described and/or identified is given in Table 1.

3.2. Arsenic-sulfur clusters

In the second part of this work we have studied the formation of arsenic sulfide clusters from various precursors. The following possibilities were examined: (i) laser ablation generation from As_2S_2, As_2S_3 and As_2S_5 sulfides, (ii) generation of sulfides from As–S mixtures.

3.2.1. Laser ablation of As_2S_2, As_2S_3 and As_2S_5 sulfides

The generation of As_nS_m species was achieved from thoroughly milled precursors placed directly on the MALDI plate as described elsewhere [17]. The experimental conditions of equal distribution of analysed molecules throughout the spot on the sample plate was strictly abided with the purpose of avoiding the co-ablation of the sample plate surface and formation of unexpected mixed cluster species. The arsenic-sulfur composite clusters were observed both in linear positive, linear negative as well as in the corresponding reflectron modes. Fig. 2 shows an example of a mass spectrum concerning As_nS_m species generated from the arsenic sulfide precursor. The stoichiometries were confirmed using isotopic pattern modelling. The summary of all identified compounds generated from the As_2S_2, As_2S_3 and As_2S_5 sulfides, used as precursors, is given in Tables 2–4, respectively.

Species (both negative and positive) such as AsS_2, AsS_4, AsS_5, AsS_6, AsS_7, As_2S_4, As_2S_6 have been described for the first time and the richest generation of new heteroatomic arsenic-sulfur clusters was observed in the case of As_2S_5 sulfide.

3.2.2. Generation of As_nS_m species from a mixture of the elements

In the previous chapter, we have suggested that the increasing sulfur content in the studied arsenic sulfide precursors leads to a rich laser ablation synthesis of new members of the composite cluster species family.

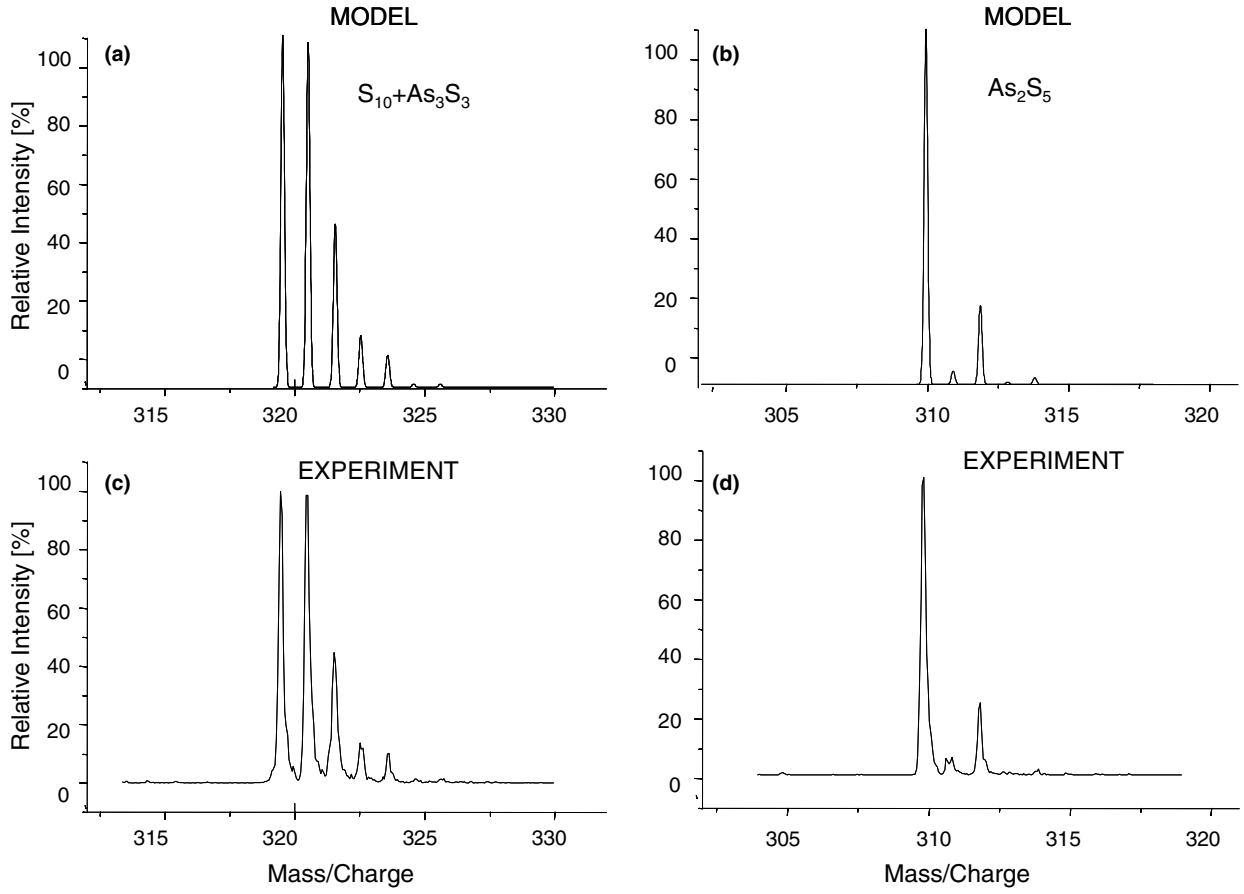

Fig. 4. Comparison of theoretical mass spectra reflecting the isotopic pattern of S_{10} + As_3S_3 and As_2S_5 species (a, b) with experimental spectra (c, d).

Therefore, the effect of sulfur as a possible MALDI matrix for the generation of As_nS_m species was considered and the possibility of different arsenic sulfide cluster generation from mixtures with sulfur was studied.

An example of the measured mass spectra is given in Fig. 3 and the overview of all newly identified stoichiometries generated from the mixture of elemental sulfur and the As_2S_2, As_2S_3 and As_2S_5 sulfides is given in Tables 5–7. All stoichiometries were confirmed according to isotopic pattern modelling and an example of the isotopic pattern confirmation is given in Fig. 4.

The effect of sulfur as a MALDI matrix in the synthesis of mixed arsenic-sulfur clusters was confirmed and, in addition to previous experiments, clusters such as As_4S_3 and As_4S_4 were detected. The richest arsenic-sulfur cluster generation was observed from the mixture of As_2S_2 arsenic sulfide with elemental sulfur. On the other hand, a high excess of sulfur leads to the generation of various sulfur species only.

4. Conclusions

The generation of As_n^+ (n = 2–7) clusters, except As_6^+, has been successfully achieved in the positive mode. The As_6^+ cluster was observed in a few cases only, with an intensity equal to 5 mV, and we confirm here that it is formed in a low abundance and this cluster is most probably unstable. No As_n^- clusters were detected in the negative mode. Clusters with intensity lower or equal than three-times the level of threshold (≈1.2 mV) were considered as non-detected. The stability of arsenic clusters was confirmed in the post-source decay. However, the existence of arsenic fullerene-like cages As_n (n = 20, 28, 32, 36, 60) was not proved. In addition, laser ablation synthesis also leads to the formation of several arsenic oxide ions (AsO, As_3O_4, As_3O_5, As_5O_7) and a positively charged $As_2H_3^+$ arsenic hydride.

New single negatively and positively charged species were generated and identified: AsS_2, AsS_4, AsS_5, AsS_6, AsS_7, AsS_8, As_2S_4, As_2S_6, As_2S_7. All stoichiometries were confirmed using isotopic pattern modelling.

Many new cluster species previously not described in the literature and/or suggested from quantum chemistry calculations were generated via laser ablation synthesis and identified. In pure arsenic, As_nS_m cluster species were detected in the positive mode (AsS and As_3S) and in the negative mode (S_3, AsS, AsS_2). We have also shown that LDI and/or laser ablation mass spectrometry

is a suitable method for the rapid identification of low sulfur impurities in metallic arsenic. Thus, this approach can be used for the detection of super-low impurities found in arsenic for industrial purposes.

due to the possibility of producing attractive novel topologies and intriguing frameworks [1–4]. The major factor for the design of such polymers is in the choice of metal atoms, which allow a wide range of geometries and coordination numbers, ligands, which provide multifunctional abilities, and anions, which can exhibit several possible coordination modes. The fascination of heterometallic compounds is that the presence of two diverse metal centres concurrently can potentially give rise to interesting physical properties and intricate entanglement of coordination networks. Consequently a large number of new and exciting heterometallic structures have been reported to date [5–7]. The introduction of two different anions into mixed-metal systems can also potentially vary the resulting structures, and with a rational selection of anionic pairs, the dimensionality of inorganic solids can be regulated. It is well known that ethylenediamine (en) is a strong coordination agent and has widely been applied in supramolecular design [8–11]. Due to the particularly flexible coordination spheres of copper(II) and cadmium(II), the usage of these dissimilar transition metals conjointly in the preparation of coordination polymers will promote the structural diversity of complexes and their more complicated physico-chemical properties. Moreover, employment of various types of anions, which function as the essential element of the coordination polyhedra, such as carboxylate and halide (or pseudohalide) ligands, may lead to a more gripping series of coordination compounds. The carboxylate group represents a wide variety of binding geometries [12–14], while halide or thiocyanate anions display their rigid nature and can coordinate to the metal centres as terminal or bridging ligands [15–18]. Despite intensive progress in the construction of polymeric solids there is no example of a heterometallic coordination polymer that contains both carboxylate and halide (or pseudohalide) anions.

As we reported earlier, various coordination compounds of unusual stoichiometry and structure can be prepared easily through a "one-pot" reaction using a metal powder or metal oxide as an initial reagent, with a complex-forming agent in non-aqueous solution in air [19]. The synthetic strategy is to construct two kinds of building blocks, by adding en to a first metal atom and attaching anions of different types to a second, which are joined into heterometallic polymeric structures yielded a series of new Cu/M (M = Zn [20], Cd [21]) coordination polymers, revealing zigzag, quasi linear and helical types of chain crystal structures, of the general formula $[Cu(en)_2MX_4]\cdot n$Solv (X = Cl, I, Br, NCS, O_2CMe; Solv = dmf, dmso, CH_3CN, H_2O; n = 0, 0.5, 1). Using this approach, we have also obtained, and structural characterized, 2D polymeric Cu/Cd complexes, which are distinguished by the unique polymeric ladder-like anion $[Cd_2(O_2CMe)_6]_n^{2-}$ [22] and the rather rare $Cd(NCS)_6^{4-}$ fragment with N-bonded thiocyanate groups [21]. An attempt to prepare mixed-anion Cu/Cd heterometallic polymers employing dicyanamide (dca) and thiocyanate bridges has successfully resulted in a 2D Cu/Cd polymer featuring the unique mixed-anion $Cd(dca)_2(SCN)_2^{2-}$ fragment [23]. In the present investigation, we have replaced dca by the acetate ligand and used NCS and halide as the second anions. We also propose an efficient route to influence individual crystal structures and to regulate the dimensionality of the polymeric architectures by using different anion pairs based on the acetate group. In the preparation of mixed-anion heterometallic polymers we used copper powder, cadmium acetate and ammonium halide or thiocyanate as starting materials and investigated the interaction in the following system:

$$Cu^0\text{–}Cd(O_2CMe)_2\text{–}NH_4X\text{–en–Solv} \qquad X = Cl, Br, I, NCS;$$
$$Solv = dmf, dmso, CH_3OH, CH_3CN$$

This paper elucidates the isolation and crystal structures of three novel heterometallic coordination polymers: 1D chain compounds $[Cu(en)_2Cd(\mu\text{-}Cl)(\mu\text{-}O_2CMe)Cl(O_2CMe)]_n$ (**1**) and $[Cu(en)_2CdI_{1.64}(O_2CMe)_{2.36}]_n$ (**2**), and the 2D $[Cu_2(en)_4Cd_2(NCS)_2(NCS)_4(O_2CMe)_2]_n$ (**3**), that have a number of interesting features. To the best of our knowledge this is the first report of heterometallic complexes with mixed-anion $Cd(\mu\text{-}Cl)(\mu\text{-}O_2CMe)Cl(O_2CMe)^{2-}$, $Cd(\mu\text{-}O_2CMe)_2I(O_2CMe)^{2-}$ or $Cd(\mu\text{-}I)(\mu\text{-}O_2CMe)I(O_2CMe)^{2-}$ building blocks and $Cd_2(NCS)_6(O_2CMe)_2^{2-}$ fragments, which are supported by the X-ray structures.

2. Experimental

2.1. General details

Commercial reagents were used without further purification, all experiments were carried out in air. Elemental analyses for metals were performed by atomic absorption spectroscopy and by standard titrimetric methods for anions by the Department of Chemistry, National Taras Shevchenko University of Kyiv and with a Carlo Erba Strumentazion Analyzer (for C, H and N) by the L.V. Pisarzhevskii Institute of Physical Chemistry. Infrared spectra were recorded as KBr discs and in Nujol mulls on a UR-10 spectrophotometer in the 4000–400 cm^{-1} region using conventional techniques. The EPR spectra were recorded on a Bruker ESP 300E (Bruker, Germany) spectrometer operating at X-band and equipped with the Bruker NMR gaussmeter ER 035M and the Hewlett–Packard microwave frequency counter HP 5350B. EPR parameters were calculated by computer simulation of the experimental spectra using Bruker's WIN-EPR SimFonia Software Version 1.25. Magnetic measurements in the temperature range 4.5–300 K were

performed using a Quantum Design SQUID magnetometer (type MPMS XL-5). All susceptibility measurements were made at a field of 5 KGs. The corrections for diamagnetism of the constituent atoms were calculated from the Pascal constants [24].

2.2. Preparations

2.2.1. $[Cu(en)_2Cd(\mu\text{-}Cl)(\mu\text{-}O_2CMe)Cl(O_2CMe)]_n$ (1)

Copper powder (0.16 g, 0.0025 mol), $Cd(O_2CMe)_2$ (0.57 g, 0.0025 mol), NH_4Cl (0.27 g, 0.005 mol), dmso (20 cm^3) and ethylenediamine (0.35 cm^3, 0.005 mol) were heated to 50–60 °C and stirred magnetically until total dissolution of the copper metal was observed (40 min). Dark violet microcrystals of **1** were obtained from the violet reaction mixture in the presence of Pr^iOH after three days. They were collected by filter-suction and dried in vacuo. Yield: 0.36 g, 29.5%. *Anal.* calc. for $C_8H_{22}CuCdCl_2N_4O_4$: Cu, 13.10; Cd, 23.17; Cl, 14.62; C, 19.81; H, 4.57; N, 11.55. Found: Cu, 13.2; Cd, 23.3; Cl, 15.0; C, 19.9; H, 4.6; N, 11.5%. IR (KBr, cm^{-1}): 3300vs ν_{as}(NH), 3170 s ν_s(NH), 1600vs ν_{as}(CO), 1440vs ν_s(CO), 1050vs ν(CN).

2.2.2. $[Cu(en)_2CdI_{1.64}(O_2CMe)_{2.36}]_n$ (2)

Copper powder (0.32 g, 0.005 mol), $Cd(O_2CMe)_2$ (1.73 g, 0.0075 mol), NH_4I (0.72 g, 0.005 mol), dmf (20 cm^3) and ethylenediamine (0.7 cm^3, 0.01 mol) were heated to 50–60 °C and stirred magnetically until total dissolution of the copper metal was observed (40 min). In the course of the reaction a light brown powder, later found to be cadmium(II) oxide, precipitated. The resulting reaction mixture was filtered and dark violet crystals suitable for X-ray crystallography were formed after three days from the violet solution. Yield: 1.15 g, 35%. *Anal.* calc. for $C_{8.73}H_{23.095}CuCdI_{1.635}N_4O_{4.73}$: Cu, 9.86; Cd, 17.45; I, 32.20; C, 16.27; H, 3.62; N, 8.70. Found: Cu, 9.9; Cd, 17.6; I, 32.1; C, 16.3; H, 3.7; N, 8.8%. IR (KBr, cm^{-1}): 3300vs ν_{as}(NH), 3240s ν_s(NH), 1580vs ν_s(CO), 1410s ν_s(CO), 1045vs ν(CN).

2.2.3. $[Cu_2(en)_4Cd_2(NCS)_6(O_2CMe)_2]_n$ (3)

Copper powder (0.32 g, 0.005 mol), $Cd(O_2CMe)_2$ (1.15 g, 0.005 mol), NH_4NCS (1.14 g, 0.015 mol), CH_3OH (20 cm^3) and ethylenediamine (0.7 cm^3, 0.01 mol) were heated to 50–60 °C and stirred magnetically until total dissolution of the copper metal was observed (90 min). After cooling the reaction mixture, white crystals of ammonium acetate precipitated. The solution was filtered, and after successive additions of Pr^iOH into the resulting violet solution, dark violet crystals suitable for X-ray crystallography were deposited over a period of one month. Yield: 1.38 g, 52%. *Anal.* calc. for $C_{18}H_{38}Cu_2Cd_2N_{14}O_4S_6$: Cu, 12.00; Cd, 21.23; C, 20.42; H, 3.62; N, 18.52. Found: Cu, 11.6; Cd, 21.6; C, 20.8; H, 3.7; N, 18.9%. IR (KBr, cm^{-1}): 3320s ν_{as}(NH), 3150m ν_s(NH), 2090vs $\nu(CN_{NCS})$, 1530s ν_{as}(CO), 1430m ν_s(CO), 1040s $\nu(CN_{en})$, 790w ν(CS).

The compounds are sparingly soluble in dmso and dmf and (except for **1**) insoluble in water. All the complexes are indefinitely stable in air.

2.3. X-ray crystallography

Details of the data collection and processing, structure analysis and refinement are summarized in Table 1. Diffraction experiments were performed on a Bruker SMART CCD diffractometer (ω rotation scans with

narrow frames) equipped with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The data were corrected for the effects of absorption using the multi-scan method. The structures were solved by direct methods and refined by full-matrix least-squares methods on F using XTAL 3.7 [25]. The non-hydrogen atoms were refined anisotropically, hydrogen atoms being included at ideal positions but not refined. For **2**, two of the bridging ligand sites were found to be occupied partly by acetate and partly by iodide; the site occupancies being refined to (acetate and iodide) 0.670(3) and $1 - 0.670(3)$ for C(022)C(021)O(021)O(022) and I(2) (group 2) and 0.595(2) and $1 - 0.595(2)$ for C(032)-C(031)O(031)O(032) and I(3) (group 3). The atoms C(021) and C(031) of the acetate groups were refined with isotropic displacement parameters. For **3** the refined absolute structure parameter was 0.04(3).

3. Results and discussion

3.1. Synthesis and spectroscopic characterization

The reaction of copper powder, cadmium acetate and NH_4X (X = Cl, I, NCS) with ethylenediamine in dmso (**1**), dmf (**2**) or CH_3OH (**3**), in open air, using a molar ratio of $Cu:Cd(O_2CMe)_2:NH_4X:en = 1:1:2:2$ (for **1**, X = Cl), 2:3:2:4 (for **2**, X = I) or 1:1:3:2 (for **3**, X = NCS) gave heterometallic compounds which show analytical data accounting for the presence of Cu(II) and Cd(II) in a 1:1 stoichiometry. The title compounds could also be isolated from CH_3OH (in case **1**), dmso (in case **2**) or from dmf and CH_3CN (in case **3**) solutions. Their formation can be understood if one considers the following reaction schemes:

$$Cu^0 + Cd(O_2CMe)_2 + 2NH_4Cl + 2en + 1/2O_2 \rightarrow [Cu(en)_2Cd(\mu\text{-}Cl)(\mu\text{-}O_2CMe)Cl(O_2CMe)] + 2NH_3 + H_2O \quad (1)$$

$$2Cu^0 + 3Cd(O_2CMe)_2 + 2NH_4I + 4en + O_2 \rightarrow 2[Cu(en)_2Cd(\mu\text{-}O_2CMe)_2I(O_2CMe)] + CdO + 2NH_3 + H_2O \quad (2)$$

$$2Cu^0 + 2Cd(O_2CMe)_2 + 6NH_4NCS + 4en + O_2 \rightarrow [Cu_2(en)_4Cd_2(NCS)_6(O_2CMe)_2] + 4NH_3 + 2NH_4O_2CMe + 2H_2O \quad (3)$$

The structural features of these complexes were determined by IR, EPR spectroscopy and single-crystal X-ray diffraction studies.

The IR spectra of all complexes confirmed that ethylenediamine was present. The characteristic ligand peaks: ν(N–H), ν(C–H), ν(C–N) and ν(C–C) in the ranges 3300–3140, 2990–2890, 1050–1040 and 990–980 cm^{-1}, respectively, can be easily identified, although $\delta(NH_2)$ frequencies of en, observed for **3** (1580 cm^{-1}), were obscured by stretching vibrations of the carboxylate group for **1** and **2**. Two strong and broad absorption bands found for acetate groups in **1** and **2** (1600–1580 cm^{-1} and 1440–1410 cm^{-1}) lead to the Δ value [$\nu_{as}(COO) - \nu_s(COO)$] in the range 160–170 cm^{-1}, which can be used as evidence of bridging unidentate or asymmetrical chelating acetate coordination [26]. In the spectrum of **3**, the difference in wavenumbers, $\Delta = 100$ cm^{-1}, between the asymmetric (1530 cm^{-1}) and symmetric (1430 cm^{-1}) COO^- stretching frequencies demonstrate the existence of chelating carboxylate ligands [27], confirmed by the X-ray structure determination. The coordinated thiocyanate groups in **3** are confirmed by the presence of the sharp intense ν(CN) absorption peak at 2090 cm^{-1} and the weak ν(CS) vibration at 790 cm^{-1}.

3.2. Description of the structure of *1*

The structure of compound **1** consists of an infinite 1D helical chain comprised of cationic $Cu(en)_2^{2+}$ and mixed-ligand anionic $Cd(\mu\text{-}Cl)(\mu\text{-}O_2CMe)Cl(O_2CMe)^{2-}$ building blocks, linked together through one bridging chlorine atom and an oxygen atom of the chelating (and also bridging) bidentate acetate ligand (Fig. 1). Selected bond lengths and angles are listed in Table 2. The copper(II) atoms in the $Cu(en)_2^{2+}$ moiety are in a distorted octahedral coordination environment consisting of four nitrogen atoms of ethylenediamine molecules, forming the basal plane (Cu–N distances are in the range 2.010(3)–2.019(3) Å), and with the chlorine atom (Cu–Cl(2) = 2.9902(9) Å) and the oxygen atom of the bridging acetate group (Cu–O(011) = 2.364(2) Å) occupying the apical positions. The bond distances and angles in the chelate rings are similar to those found in the literature [28,29]. The Cd atom is six coordinate; the coordination sphere consisting of two acetate groups, one of which is weakly bidentate [Cd–O(021) = 2.181(2) Å and Cd–O(022) = 2.907(3) Å], the other one being bidentate [through O(011) and O(012)] and bridging unidentate [through O(011)] with Cd–O distances equal to 2.460(3) and 2.356(3) Å. Each of the Cd(II) centres is further coordi-

nated by one terminal and one bridging chlorine atom [Cd–Cl(1) = 2.4711(8) Å and Cd–Cl(2) = 2.4668(8) Å, respectively] to form a CdO_4Cl_2 distorted octahedron. The chains of Cu–Cl(2)–Cd–O(011) atoms reveal a helical shape with angles: Cl(2)–Cd–O(011) = 141.72(5)°, Cl(2)–Cu–O(011) = 165.38(6)°, Cu–Cl(2)–Cd = 111.75(3)°, Cu–O(011)–Cd = 128.18(10)°, Cu–Cd–Cu = 134.71(1)° and Cd–Cu–Cd = 111.97(1)°. The intrachain Cu···Cu and Cd···Cd distances are 8.183(1) Å and 7.350(1) Å, respectively. The chains are additionally strengthened by strong hydrogen bonds [N(11)–H(11aN)···O(021); D–A = 2.940(1) Å, D–H···A = 174(3)°. N(21)–H(21aN)···O(012); D–A = 2.968(1) Å, D–H···A = 164(3)°]. Moreover, two sets of hydrogen bonds assemble the chains, related by crystallographic glide planes, into a

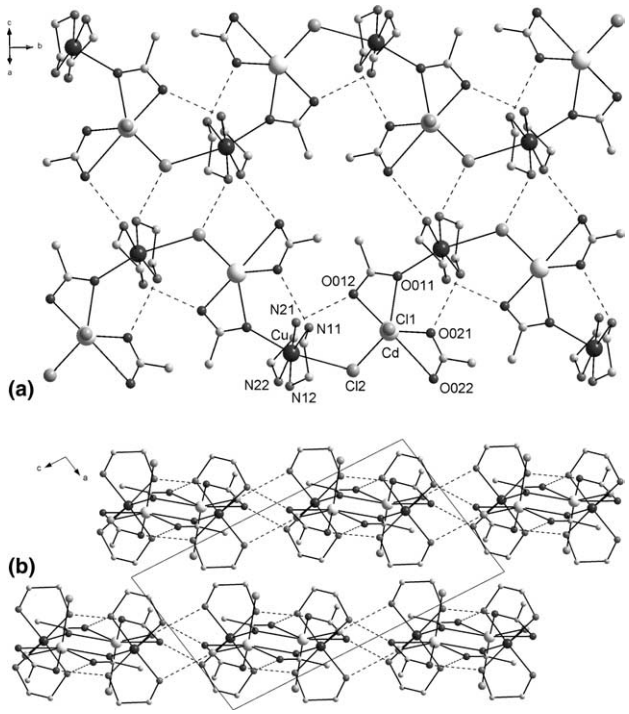

Fig. 2. A fragment of the 2D sheet (a) and a view of the layer arrangement (b) in the structure **1**. The hydrogen atoms are omitted for clarity.

2D structure (Fig. 2). The first set, N(22)–H(22aN)···O(022), involves a hydrogen atom of the NH_2 group of ethylenediamine and an oxygen atom of a weakly chelating bidentate acetate group [D–A = 2.946(1) Å, D–H···A = 160(3)°]. The second set, N(12)–H(12aN)···Cl(2), involves a hydrogen atom of the NH_2 group of ethylenediamine and the bridging chlorine atom [D–A = 3.274(2) Å, D–H···A = 158(4)°]. The nearest interlayer Cu···Cu and Cd···Cd separations are in the range 6.2882(8)–9.696(1) and 8.1307(7)–9.507(1) Å, respectively.

3.3. Description of the structure of **2**

The complex **2** is basically a 1D helical chain structure formed by $Cu(en)_2^{2+}$ and $Cd(\mu\text{-}O_2CMe)_2I(O_2CMe)^{2-}$ building blocks, which are joined through the oxygen atoms from a weakly bidentate chelate acetate ligand and also through the oxygen atoms of the other acetate group which is bridging unidentate and bidentate (Fig. 3). However, both bridging acetate sites are also partially occupied by iodide ions, the site occupancies of the acetate and iodide being refined to 0.670(3) and 1 − 0.670(3) for group 2 and 0.595(2) and 1 − 0.595(2) for group 3. Thus, as well as bridging $Cd(\mu\text{-}O_2CMe)_2I(O_2CMe)^{2-}$ units, there is also a minor component of $[Cu(en)_2Cd(\mu\text{-}I)(\mu\text{-}O_2CMe)I(O_2CMe)]$, there being two possibilities corresponding to the two crystallographically distinct acetate/iodide groups 2 and 3. There may also be some $[Cu(en)_2Cd(\mu\text{-}I)_2$-

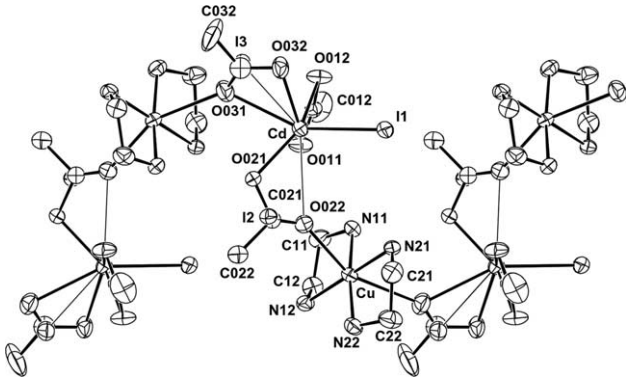

Fig. 3. Perspective view of a helical chain of complex **2** together with the atom numbering. The hydrogen atoms are omitted for clarity.

$I(O_2CMe)$], corresponding the replacement of both bridging acetates. Selected bond lengths and angles for **2** are tabulated in Table 3. For the major component, the environment around the copper(II) atom in the $Cu(en)_2^{2+}$ unit can be best described as a distorted octahedron with four nitrogen atoms of ethylenediamines forming the basal plane [Cu–N distances are in the range 1.994(7)–2.018(6) Å] and with two oxygen atoms of acetate groups [Cu–O(022) = 2.420(9) Å, Cu–O(031) [at $3/2 - x$, $1/2 + y$, $1/2 - z$] = 2.579(10) Å] occupying the apical positions. The cadmium atom in the complex has {6 + 1} coordination and a IO_6 donor set. Each Cd(II) ion is coordinated by one terminal iodine atom [Cd–I(1) = 2.7728(9) Å] and three acetate groups with different coordination modes: one is very asymmetric bidentate and bridging [Cd–O(021) = 2.214(7) Å and Cd–O(022) = 2.948(8) Å], one bidentate [through O(032) and O(031)] and also bridging unidentate [through O(031)] with Cd–O distances equal to 2.288(12) and 2.567(10) Å and the last is bidentate with Cd–O bond lengths equal to 2.263(6) and 2.617(5) Å. The chains of Cu–O(031)–Cd–O(022) atoms present a helical type with angles: O(022)–Cd–O(031) = 118.9(3)°, O(022)–Cu–O(031) = 155.8(3)°, Cu–O(031)–Cd = 126.8(5)°, Cu–O(022)–Cd = 132.9(3)°, Cu–Cd–Cu = 107.16(2)° and Cd–Cu–Cd = 107.52(2)°. The Cu···Cu and Cd···Cd separations within the chains are 7.668(2) and 7.686(1) Å, respectively. Hydrogen bonds also link the chains to form a 2D structure. In **2** only one nitrogen atom from an NH_2 group of en takes part in the intrachain hydrogen bonding with oxygen atoms of the acetate ligands [N(11)–H(11aN)···O(021); D–A = 2.991(9) Å, D–H···A = 152.5(5)°. N(11)–H(11bN)···O(011); D–A = 3.078(9) Å, D–H···A = 148.7(4)°], in contrast with two N_{en} atoms that participated in hydrogen bonding in **1**. Furthermore, only one type of hydrogen bonding interaction, that involves a hydrogen atom of an NH_2 group of en and an oxygen atom of a bidentate acetate group, facilitates the formation of 2D sheets [N(22)–H(22aN)···O(012);

[a] Symmetry transformation used to generate equivalent atoms: $3/2 - x$, $1/2 + y$, $1/2 - z$.

D–A = 3.046(10) Å, D–H···A = 136.3(4)°, N(12)–H(12bN)··· O(012); D–A = 2.878(9) Å, D–H···A = 167.9(5)°, N(22)–H(22bN)···O(032); D–A = 3.12(1) Å, D–H··· A = 140.4(5)°] where all these interactions are related by a cell translation on *a* to the adjacent sheet (Fig. 4). Thus, these hydrogen bonding interactions are to layers where the chains are not translated (Fig. 4).

For the minor component of **2** where the acetate ligands C(022)C(021)O(021)O(022) or C(032)C(031)-O(031)O(032) have been replaced by iodide ions, the building blocks containing the Cd atom now become $Cd(\mu\text{-}I)(\mu\text{-}O_2CMe)I(O_2CMe)^{2-}$. The Cd atom is 6-coordinate and contains an IO_5 donor set. For I(2) and I(3) the distances to the Cd atom are Cd–I(2) = 2.905(1) and Cd–I(3) = 2.743(3) Å with the copper atom now weakly bonded at Cu–I(2) 3.49(1) and Cu–I(3) 3.598(3) Å. The angles at the bridging iodine atoms are Cd–I(2)–Cu = 100.4(3)° and Cd–I(3)–Cu [at $3/2 - x$, $y - 1/2$, $1/2 - z$] = 92.1(1)°. The nearest interlayer metal-metal distances are in the range 7.807(2)–9.784(2) and 8.464(1)–9.784(1) Å for Cu···Cu and Cd···Cd, respectively.

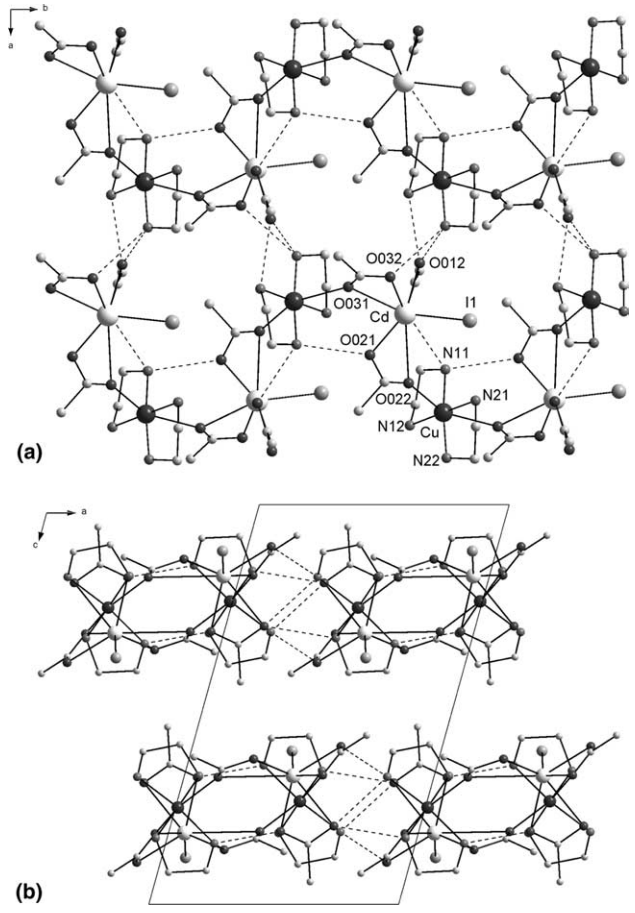

Fig. 4. A view of a fragment of the 2D layer (a) and the packing diagram of the polymeric sheets (b) of major component of complex **2**. The hydrogen atoms are omitted for clarity.

3.4. Description of the structure of *3*

X-ray analysis reveals a 2D wave-like polymeric network for complex **3**, the crystal structure of which consists of 1D anionic chains of $Cd_2(NCS)_6(O_2CMe)_2^{4-}$ and $Cu(en)_2^{2+}$ units. The view of the 1D anionic chain motif together with the atom numbering scheme is presented in Fig. 5, while Fig. 6 shows the perspective view of a 2D sheet. The molecular packing of complex **3**, projected onto the *cb* plane, is represented in Fig. 7.

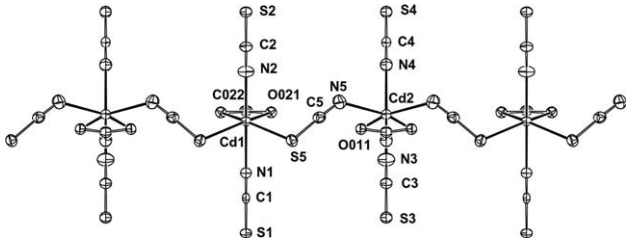

Fig. 5. The view of the 1D anionic chain motif of complex **3** together with the atom numbering scheme. The hydrogen atoms are omitted for clarity.

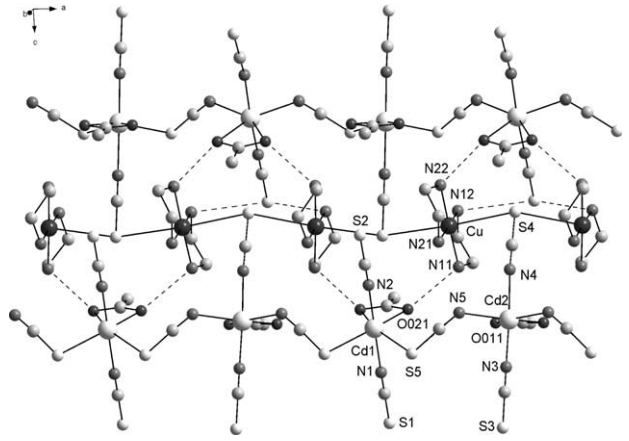

Fig. 6. Perspective view of a sheet in complex **3**. The hydrogen atoms are omitted for clarity.

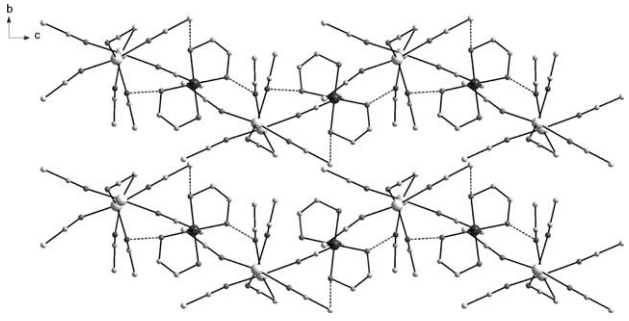

Fig. 7. Molecular packing of complex **3** projected onto the *cb* plane showing the undulating character of the polymeric layers. The hydrogen atoms are omitted for clarity.

Symmetry transformation used to generate equivalent atoms: [a] $1-x$, y, z; [b] $2-x$, y, z; [c] $1-x$, $1-y$, $z-1/2$.

The selected bond lengths and angles are shown in Table 4. Both copper(II) and cadmium(II) atoms are joined through '–Cu–SCN–Cd–' linkages. The copper(II) atom has an elongated octahedral environment with an N_4S_2 donor set; the equatorial positions are occupied by four nitrogen atoms from two ethylenediamine bidentate chelate ligands with Cu–N distances in the range 2.011(9)–2.018(9) Å, with the axial positions occupied by the sulfur atoms from the bridging thiocyanate ligands. The bond distances of Cu–S, 3.1113(12) and 3.1467(14) Å, are shorter than the sum of the van der Waals radii of the Cu and S atoms (3.4 Å) [30] and similar to the values found in other complexes in which the S atoms adopt an axial position in a distorted octahedron around copper(II) [31–33]. The polymers contains two crystallographically independent cadmium atoms, Cd(1) and Cd(2), both of which are six coordinate with $CdS_2N_2O_2$ and CdN_4O_2 distorted octahedral geometries, respectively. Both Cd(II) atoms are coordinated by one chelating bidentate acetate group, one terminal thiocyanate ligand, one $\mu_{1,3}$-NCS group, which connect the copper(II) and cadmium(II) atoms in the 2D layer, and another two $\mu_{1,3}$-NCS groups, which serves to bridge between the metal centres. The Cd(1)–N distances are 2.221(15) and 2.348(12) Å, and Cd(2)–N bond lengths vary between 2.205(16) and 2.333(11) Å. The N(1)–Cd(1)–N(2) angle is 177.7(5)°, while the N–Cd(2)–N bond angles lie in the range 84.8(4)–169.0(6)°. The S–C distances of the thiocyanates are in the range 1.607(15)–1.652(11) Å and the C–N distances vary between 1.157(15) and 1.19(2) Å, which is in accordance with the values observed in other thiocyanato-containing metal complexes [34,35]. The polymeric mixed-anion –NCS–$Cd(NCS)_2(O_2CMe)$–SCN–$Cd(NCS)_2(O_2CMe)$–NCS– chains are almost linear with angles between the three cadmium(II) atoms of 172.01(2)°. The adjacent Cd···Cd distance within the chain is 6.1830(5) Å. The resulting 2D sheets consist of 18-membered [$Cd_3(\mu_{1,3}$-$NCS)_4Cu_2S_{NCS}$] rings folded in a wave-like manner with a dihedral angle of 115.84(2)° between adjacent planes along the c axis. The copper(II) atoms in the layer are located on a straight line as a result of the mirror planes, with the intermetallic Cu···Cu separations through the S_{NCS} atom of 6.165(2) and 6.171(2) Å. The nearest Cu···Cu distances between neighboring –Cu–S–Cu–S– lines are 8.455(2) Å, while the shortest Cu···Cu separation between adjacent 2D sheets is 8.638(2) Å. In addition, a network of intramolecular hydrogen bonds [N(22)–H(22aN)···O(011) [x, $1-y$, $z-1/2$]; D–A = 3.00(1) Å, D–H···A = 151.9(6)°; N(11)–H(11bN)··· O(021), D–A = 2.98(1) Å, D–H···A = 166.1(6)°; N(12)– H(12bN)··· S(3), D–A = 3.629(8) Å, D–H···A = 148.2(5)°] is responsible for the stabilization of the overall 2D architecture.

3.5. Magnetic properties

Magnetic data for **1**–**3** are shown in Fig. 8 as μ_{eff} versus T plots, which indicate that the magnetic behaviour is in general paramagnetic in accordance with the crystal structures of the compounds (the closest intrachain Cu···Cu separations are 8.183(1) Å for **1** and 7.668(2) Å for **2**, and the nearest intralayer Cu···Cu distance is 6.165(2) Å for **3**). The room temperature magnetic moment for each copper atom, ca. 1.8 μ_B, is in the normal range for isolated $S = 1/2$ ions. The drop in the effective magnetic moment below 5 K indicates

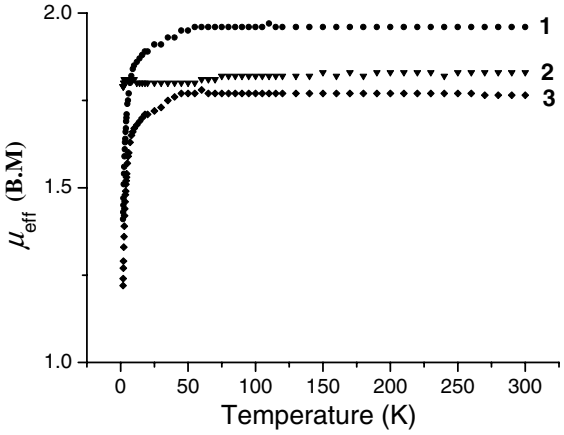

Fig. 8. Plots of the effective magnetic moment vs. temperature for **1**, **2** and **3**.

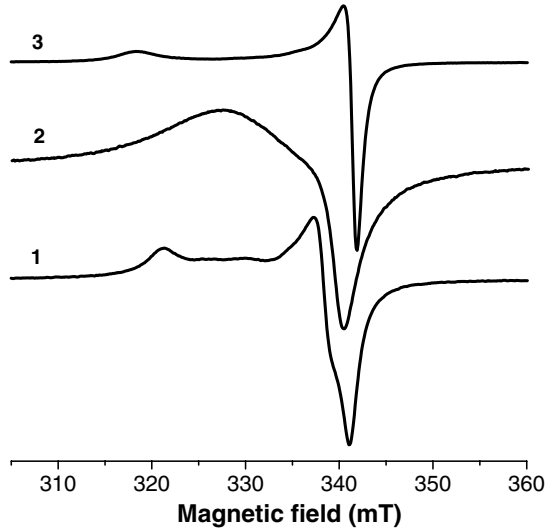

Fig. 9. EPR spectra of polycrystalline complexes **1**–**3** measured at 77 K.

the onset of a weak antiferromagnetic coupling: this is not unexpected for the systems in which hydrogen bond contacts are important. It can be concluded that –Cl–Cd–O– (for **1**), –O–Cd–O– (for **2**) and S_{NCS} (for **3**) bridges effectively prevent any exchange interactions between copper centres.

The EPR spectra of polycrystalline samples exhibit different patterns: axial for **3** (with distinctly resolved g components) and **2**, and rhombic for **1** (Fig. 9). The absence of the signals due to $S = 1$ transitions between 77–295 K support the paramagnetic character of the Cu(II) centres. The spectra remain unchanged upon lowering of the temperature to 77 K. Generally, the EPR spectra of concentrated Cu(II) complexes are affected by interactions between the paramagnetic centres leading, in the case of non-parallel aligned complexes, to the coupling of g tensor components [36]. The crystal g^c values are: $g_1^c = 2.173$, $g_2^c = 2.064$, $g_3^c = 2.045$ for **1**, $g_1^c \sim 2.16$, $g_2^c = g_3^c = 2.058$ for **2** and $g_\parallel^c = 2.193$, $g_\perp^c = 2.046$ for **3**. The $Cu(en)_2^{2+}$ cations immobilized in the matrix of organic polymers exhibits axial g and A. The following EPR spectral parameters, $g_\parallel = 2.210$, $g_\perp = 2.048$, $A_\parallel = 186$ G and $A_\perp = 20$ G [37] are typical for square planar or elongated octahedral geometries for a coordination sphere composed of four nitrogen atoms from two ligands forming aliphatic chelate rings in the Cu(II) plane. Comparison of the molecular EPR parameters with those observed for the complexes present in the studied compounds reveals that the g values of **1** and **2** are greatly modified due to cooperative interactions compared to those for **3**. It is remarkable that diamagnetic Cd(II) complexes are not able to efficiently separate Cu(II) centres, and copper hyperfine splitting is not detected. The observed change of the EPR spectral patterns with cooperative effects should be mainly assigned to the differences in the solid state structures. The studied complexes consist of similar $Cu(en)_2^{2+}$ units with two en ligands coordinated in the Cu(II) plane which are dissimilarly arranged and interact with different donors at the Cu(II) axial positions, although the effect of misalignment of the $Cu(en)_2^{2+}$ units seems to be the more important. The angle between the N_4 planes of two neighboring Cu(II) complexes are 43.84(3)°, 83.3(2)° and 12.5(2)° for **1**, **2** and **3**, respectively. The smallest angle corresponds to the weakest cooperative interactions from the results of the EPR parameters.

4. Conclusions

The reactions of copper powder, cadmium acetate, ethylenediamine and ammonium salts in dmso, dmf and CH_3OH, yield the formation of three novel 1D and 2D polymeric Cu/Cd complexes with unique mixed-anion $Cd(\mu\text{-}Cl)(\mu\text{-}O_2CMe)Cl(O_2CMe)^{2-}$, $Cd(\mu\text{-}O_2CMe)_2I(O_2CMe)^{2-}$, $Cd(\mu\text{-}I)(\mu\text{-}O_2CMe)I(O_2CMe)^{2-}$ and $Cd_2(NCS)_6(O_2CMe)_2^{2-}$ fragments. Evidently for these three systems, a key difference lies in the nature of the X^- anion of NH_4X and our results shows that the type of counterion is of crucial importance in determining the dimensionality and structure of the Cu/Cd polymers formed. Variable-temperature magnetic susceptibility measurements of **1**–**3** show weak antiferromagnetic coupling between the copper centres.

coordination preferences, the ligand can show different coordination behaviour.

Although Zn(II) has a preference for tetrahedral coordination [11], there are many complexes with coordination numbers 5 and 6, which in many cases are induced by conformational requirements of the ligands. The same situation is found in the case of Cd(II), but with a greater preference for high coordination numbers than zinc (II) [10,12]. Pb(II) can adopt many different geometries in its complexes, allowing a degree of tolerance for ligand configuration which is not seen, for example, in d-block elements. Coupled with the ability to bind well both hard and soft donor atoms, these properties make Pb(II) an interesting metal to study, forming as it often does complexes different from those that might be conventionally expected. In the case of Ni(II), square planar complexes with strong field ligands are very stable, although octahedral complexes are also common. When cobalt (II) complexes are synthesised, oxidation to Co(III) is possible, specially in alkali medium in the presence of N-donor ligands. Co(II) complexes can adopt different geometries, while Co(III) complexes are virtually all low-spin and octahedral.

In previous works we have reported the synthesis and characterization of some coordination compounds with ligands derived from benzil and thiosemicarbazide: an open chain thiosemicarbazone, which shows the versatile chelating behaviour of TSC ligands [13], as well as the title ligand with some organotin (IV) derivatives. In this case complexes with 1:1 and 1:2 stoichiometries can be obtained, depending on the counter ion, in which the triazine acts always as a NS chelate. In the 1:2 complexes the ligands occupy the equatorial positions in a distorted octahedral arrangement [14].

In this paper we report the synthesis and characterisation of cadmiun, zinc, lead, cobalt and nickel derivatives of the ligand LH_2OCH_3 (Scheme 1). In these complexes, depending on the preference for a coordinated donor atom and the geometry for the metal ion, the triazine acts as a bidentate ligand and as a bidentate and bridging ligand.

2. Experimental

2.1. Physical measurements

Microanalyses were carried out using a Perkin–Elmer 2400 II CHNS/O Elemental Analyser. IR Spectra in the 4000–400 cm^{-1} range were recorded as KBr pellets on a Jasco FT/IR-410 spectrophotometer. ^1H, ^{13}C and ^{113}Cd NMR spectra were recorded on a Bruker AMX-300 spectrophotometer using $CDCl_3$, DMSO-d_6 and DMF/$CDCl_3$ as solvents and TMS or 0.1 M aqueous $Cd(ClO)_4$ as references. ^{13}C CP/MAS NMR spectra were obtained at 298 K on a Bruker avance-400 spectrometer, using a standard cross-polarisation pulse sequence [15–18]. The external magnetic field was 9.4 T, and the sample was spun at 4–4.5 kHz around an axis inclined 54°44′ with respect to this field. Spectrometer frequencies were set to 100.63 MHz. For the recorded spectra a contact time of 1 ms was used. The number of scans were about 4000. The analysis was done with the WINFIT program. In this program the principal values of the chemical shift anisotropy tensor were determined from the intensity of the sidebands with the Herzfeld and Berger's method [19]. Fast atom bombardment (FAB) mass spectra were recorded on a VG Auto Spec instrument using Cs as the fast atom and *m*-nitrobenzilalcohol (*m*NBA) as the matrix. Matrix assisted laser desorption ionisation-time of flight (MALDI-TOF) mass spectra were recorded using a Bruker Reflex III mass spectrometer equipped with a nitrogen laser emitting at 337 nm, using ditranol as matrix. UV–Vis Spectra in DMF solution were registered on an Ati-Unicam UV2 spectrophotometer and the solid reflectance spectra on a Pye-Unicam SP-8-100. Conductivity data were measured using freshly prepared DMF solutions (ca. 10^{-3} M) at 25 °C with a Metrohm Herisau model E-518 instrument. Electrochemical measurements were performed with a BAS CV 27 voltammograph and a BAS A-4 XY register using glassy carbon (∅ 5 mm) as the working electrode, a platinum wire as the auxiliary electrode, and a double junction with a porous ceramic wick, Ag/AgCl as the reference electrode, standardized for the redox couple ferricinium/ferrocene ($E_{1/2}$ = +0.400 V, ΔE_p = 60 mV). Cyclic voltammetry studies of LH_2OCH_3 and the complexes were carried out on 0.01 M solutions in dimethylformamide containing 0.1 M $[NBu_4][PF_6]$ as the supporting electrolyte. The range of potential studied was between +1.4 and −2.2 V. All solutions were purged with nitrogen steam for 5 min before measurement and the working electrode was polished before each experiment with diamond paste. The procedure was performed at room temperature and a nitrogen atmosphere was maintained over the solution during the measurements. Magnetic susceptibilities of powder samples were

measured in the range 2–293 K with a SQUID magnetometer (MPMS, Quantum Design) in a 1-T external magnetic field.

2.2. Crystallography

A crystal of compound **1a** was mounted on a glass fibre and transferred to a Bruker SMART 6K CCD area-detector three-circle diffractometer with a MAC Science Co., Ltd. Rotating Anode (Cu Kα radiation, $\lambda = 1.54178$ Å) generator equipped with Goebel mirrors at settings of 50 kV and 110 mA. X-ray data were collected at 296 K, with a combination of six runs at different φ and 2θ angles, 3600 frames. The data were collected using 0.3° wide ω scans and a crystal-to-detector distance of 4.0 cm.

The substantial redundancy in data allows empirical absorption corrections (SADABS) [20] to be applied using multiple measurements of symmetry-equivalent reflections (ratio of minimum to maximum apparent transmission: 0.566680). The unit cell parameters were obtained by full-matrix least-squares refinements of 10487 reflections.

The raw intensity data frames were integrated with the SAINT [21] program, which also applied corrections for Lorentz and polarization effects.

The software package SHELXTL [22] version 6.10 was used for space group determination, structure solution and refinement. The space group determination was based on a check of the Laue symmetry and systematic absences and was confirmed using the structure solution. The structure was solved by direct methods (SHELXS-97) [23], completed with difference Fourier syntheses, and refined with full-matrix least squares using SHELXL-97 [24] minimizing $\omega(F_o^2 - F_c^2)^2$. Weighted R factors (R_w) and all goodness of fit (S) are based on F^2; conventional R factors (R) are based on F. All non-hydrogen atoms were refined with anisotropic displacement parameters. All scattering factors and anomalous dispersions factors are contained in the SHELXTL 6.10 program library. The H atoms were introduced in calculated positions with fixed C–H distances. The coordinated DMF molecules were found to be greatly disordered, which was modelled. The occupation factors for each position are 43% for O1 and 57% for O2; 36% for C32A and 64% for C32B; and 36% for C33A and 64% for C33B.

2.3. Syntheses

All reagents and other solvents were obtained from standard commercial sources and were used as received. $Pb(NO_3)_2$ was synthesised from $Pb(SCN)_2$ and nitric acid, according to the procedure described in the literature.

2.4. Methoxy-5,6-diphenyl-4,5-dihydro-2H-[1,2,4]triazine-3-thione, LH_2OCH_3 [25]

Selected spectroscopic data: IR/cm^{-1}: 3184s and 3131s (NH); 1608w (C=N), 1550s (thioamide I), 846w (thioamide IV). ^{1}H NMR (300 MHz, $CDCl_3$, 25 °C): $\delta = 3.1$ (s, 3H, OCH_3), 7.4–7.2 (m, 8H, Ph), 7.5 (m, 2H, Ph), 10.0 (d, 1H, NH), 12.1 (d, 1H, NH). ^{13}C NMR (300 MHz, $CDCl_3$, 25 °C): 83.2 (CR_4), 50.7 (CH_3O), 126.5, 129.3, 133.7, 141.7 (Ph), 142.4 (CN), 169.7 (CS).

2.5. $[Cd(H_2O)L_2]_2$ (**1**)

A mixture of LH_2OCH_3 (0.50 g, 1.70 mmol) and $LiOH \cdot H_2O$ (0.07 g, 1.70 mmol) was dissolved in methanol (25 mL). Then a solution of $Cd(NO_3)_2 \cdot 4H_2O$ (0.52 g, 1.70 mmol) in the same solvent (25 mL) was added. The mixture was stirred for 6 h at room temperature and the yellow solid formed was filtered off, washed with methanol and dried "in vacuo". Yield: 40%; m.p. 200 °C. $[(CdH_2O)L_2]_2$ (1329.4): *Anal.* Calc. C, 54.68; H, 3.34; N, 12.76; S, 9.72. Found: C, 54.92; H, 3.32; N, 13.05; S, 9.53%. Λ_M (DMF, Ω^{-1} cm^2 mL^{-1}): 5. *m/z* (FAB+): 643.0 ($[CdL_2 + 1]^+$, 7%), 752.9 ($[Cd_2L_2 - 1]^+$, 3%), 1017.9 ($[Cd_2L_3]^+$, 15%). Selected spectroscopic data: IR (KBr, cm^{-1}): 1600w, 1573w (C=N), 1490s (NCS), 812w (thioamide IV). ^{1}H NMR (300 MHz, DMSO-d_6, 25 °C): 7.3–7.5 (m, Ph). ^{13}C NMR (300 MHz, DMSO-d_6, 25 °C): 128.3, 128.5, 128.8, 129.0, 129.6, 130.4, 135.6, 135.8 (Ph), 150.8, 155.1 (CN), 180.7 (CS). ^{113}Cd NMR (300 MHz, DMF/$CDCl_3$, 25 °C): 202.0. Yellow crystals of complex **1a**, with the formula $[Cd(DMF)L_2]_2 \cdot 2DMF \cdot 1/4H_2O$, suitable for X-ray analysis, were grown by slow evaporation of a dimethylformamide solution of complex **1**.

2.6. $[Zn(H_2O)L_2]_2$ (**2**)

$Zn(NO_3)_2 \cdot 6H_2O$ (0.25 g, 0.85 mmol) dissolved in methanol (10 mL) was added to a solution of LH_2OCH_3 (0.25 g, 0.85 mmol) and $LiOH \cdot H_2O$ (0.04 g, 0.95 mmol) in methanol (40 mL). The mixture was stirred under reflux during 4 h. Then the yellow solid formed was filtered off, washed with methanol and vacuum dried. Yield: 51%; m.p. >260 °C. $[Zn(H_2O)L_2]_2$ (1228.8): *Anal.* Calc. C, 57.20; H, 3.81; N, 13.35; S, 10.17. Found: C, 56.90; H, 3.44; N, 13.35; S, 10.14%. Λ_M (DMF, Ω^{-1} cm^2 mL^{-1}): 9. *m/z* (MALDI-TOF): 923.7 ($[Zn_2L_3]^+$). Selected spectroscopic data: IR (KBr, cm^{-1}): 1598w, 1578w (C=N), 1495s (NCS), 807w (thioamide IV). ^{13}C CP/MAS NMR: 126.0, 128.5, 130.3, 134.5 (Ph), 151.4, 155.1 (CN), 177.6 (CS).

2.7. $[PbL_2]_2$ (3)

To a solution containing LH_2OCH_3 (0.50 g, 1.68 mmol) and $LiOH \cdot H_2O$ (0.07 g, 1.67 mmol) in methanol (50 mL) was added a solution of $Pb(NO_3)_2$ (0.56 g, 1.69 mmol) in distilled water (5 mL). The mixture was stirred under reflux for 6 h and the brown solid formed was filtered off, washed with methanol, then distilled water and vacuum dried. Yield: 68%; m.p. 222 °C with decomposition. $[PbL_2]_2$ (1470.4): *Anal.* Calc. C, 34.21; H, 2.49; N, 14.97, S, 11.40. Found: C, 34.48; H, 2.55; N, 14.84; S, 11.46%. Λ_M (DMF, $\Omega^{-1}\,cm^2\,mL^{-1}$): 7. *m/z* (FAB+): 472.0 ($[PbL + 1]^+$, 100%), 737.1 ($[PbL_2 + 1]^+$, 4%), 1207.1 ($[Pb_2L_3]^+$, 35%). Selected spectroscopic data: IR (KBr, cm^{-1}): 1599w, 1581w (C=N), 1486s (NCS), 812 (thioamide IV). ^1H NMR (300 MHz, DMSO-d_6, 25 °C): 7.1–7.5 (m, Ph). ^{13}C NMR (300 MHz, DMSO-d_6, 25 °C): 128.4, 129.0, 129.6, 130.1, 136.6 (Ph), 151.9, 154.2 (CN), 178.7 (CS).

2.8. $[CoL_3]$ (4)

A solution of $Co(NO_3)_2 \cdot 6H_2O$ (0.46 g, 1.58 mmol) in methanol (25 mL) was added to a solution of LH_2OCH_3 (0.47 g, 1.58 mmol) and $LiOH \cdot H_2O$ (0.07 g, 1.67 mmol) in methanol (25 mL). The mixture was stirred at room temperature for 6 h. Then the green solid formed was filtered off, washed with methanol and dried "in vacuo". Yield: 33%; m.p. 200 °C. $[CoL_3]$ (850.9): *Anal.* Calc. C, 63.46; H, 3.52; N, 14.80; S, 11.52. Found: C, 63.09; H, 3.38; N, 14.58; S, 11.52%. Λ_M (DMF, $\Omega^{-1}\,cm^2\,mL^{-1}$): 8. *m/z* (FAB+): 587.9 ($[CoL_2 + 1]^+$, 15%), 852.2 ($[CoL_3 + 1]^+$, 25%). Selected spectroscopic data: IR (KBr, cm^{-1}): 1600w, 1579w (C=N), 1480s (NCS), 815w (thioamide IV). ^1H NMR (300 MHz, DMSO-d_6, 25 °C): 7.1–7.6 (m, Ph). ^{13}C NMR (300 MHz, DMSO-d_6, 25 °C): 128.73, 128.78, 128.81, 128.89, 128.95, 129.00, 129.11, 129.51, 129.56, 129.87, 130.01, 130.13, 130.25, 130.34, 130.37, 130.40, 131.31, 131.81, 131.85, 134.81, 134.83, 135.06, 135.13, 135.17, 135.42, 135.46 (Ph), 153.11, 153.25, 154.46, 154.63, 159.91, 160.13, 160.23, 160.36 (CN), 182.57, 183.27, 184.35, 184.70 (CS).

2.9. $[NiL_2]$ (5)

To a solution of LH_2OCH_3 (1.00 g, 3.40 mmol) and $LiOH \cdot H_2O$ (0.07 g, 1.67 mmol) in methanol (130 mL) was added $Ni(NO_3)_2 \cdot 6H_2O$ (0.50 g, 1.70 mmol) dissolved in the same solvent (15 mL). The mixture was stirred at room temperature for 8 h and the brown solid formed was filtered off, washed with methanol and dried "in vacuo". Yield: 39%; m.p. >260 °C. $[NiL_2]$ (586.7): *Anal.* Calc. C, 61.36; H, 3.41; N, 14.32; S, 10.91. Found: C, 61.03; H, 3.52; N, 14.16; S, 10.87%. Λ_M (DMF, $\Omega^{-1}\,cm^2\,mL^{-1}$): 11. *m/z* (MALDI-TOF): 587.0 ($[NiL_2 + 1]^+$. Selected spectroscopic data: IR (KBr, cm^{-1}): 1600w, 1579w (C=N), 1485s (NCS), 817w (thioamide IV).

3. Results and discussion

The complexes were obtained in methanol in the presence of a basic medium, which induces the loss of the methoxy group as a methanol molecule, probably due to an acid–base reaction with the relatively highly acidic N–H bond, yielding LH, according to a mechanism previously published [14].

Analytical data of complexes show 1:2 metal/ligand stoichiometries for all the derivatives, except for complex **4** where the ratio is 1:3, and the absence of nitrate groups. These indicate that in all the complexes the ligand acts as a monoanion L and that in complex **4** the cobalt has been oxidised to Co(III). Oxidation of Co(II) salts in the presence of thiosemicarbazone ligands in ethanol, methanol and chloroform is documented [26–28]. The possibility of oxidation increases with the presence of a basic medium. Measurements of magnetic susceptibility for complex **4** indicate that $\mu_{eff} = 0$ BM, so the complex is diamagnetic, which confirms the oxidation of the metal and the existence of a low-spin octahedral complex. Conductivity measurements in DMF indicate the presence of non-ionic species in this solvent [29]. In the mass spectra of complexes **1**, **2** and **3** (Fig. 1) a peak corresponding to the fragment $[M_2L_3]^+$ can be observed, which indicates the presence of a dinuclear species. Due to the analytical data indicating the absence of nitrate groups, if the complexes contain two metal ions they must contain four ligands to get neutrality, and one of them is lost to form a monopositive ion. The way to get a dinuclear species could be due to the formation of sulfur bridges, as occurs in many thiosemicarbazone complexes [30–32]. Moreover the spectra show peaks corresponding to different fragmentations of the complexes, owing to the loss of L or M. The mass spectrum of complex **4** exhibits a peak corresponding to the fragment $[CoL_3 + 1]^+$ pointing out the presence of a complex containing one cobalt and three deprotonated ligands. Mass spectra of complex **5** shows a peak corresponding to the fragment $[NiL_2 + 1]^+$, which indicates the presence of a species containing one metal ion and two deprotonated ligands. Experimental isotopic distributions show the same patterns as the theoretical ones for all compounds.

The electronic spectrum of complex **4** shows a band centred at ca. 17.241 cm^{-1} and reflectance spectrum shows two bands at 16.667 and 20.000 cm^{-1}, which is consistent with a octahedral low-spin Co(III) complex. The spectrum of complex **5** shows a band at 20.000 cm^{-1}, which agrees with a square-planar environment [33].

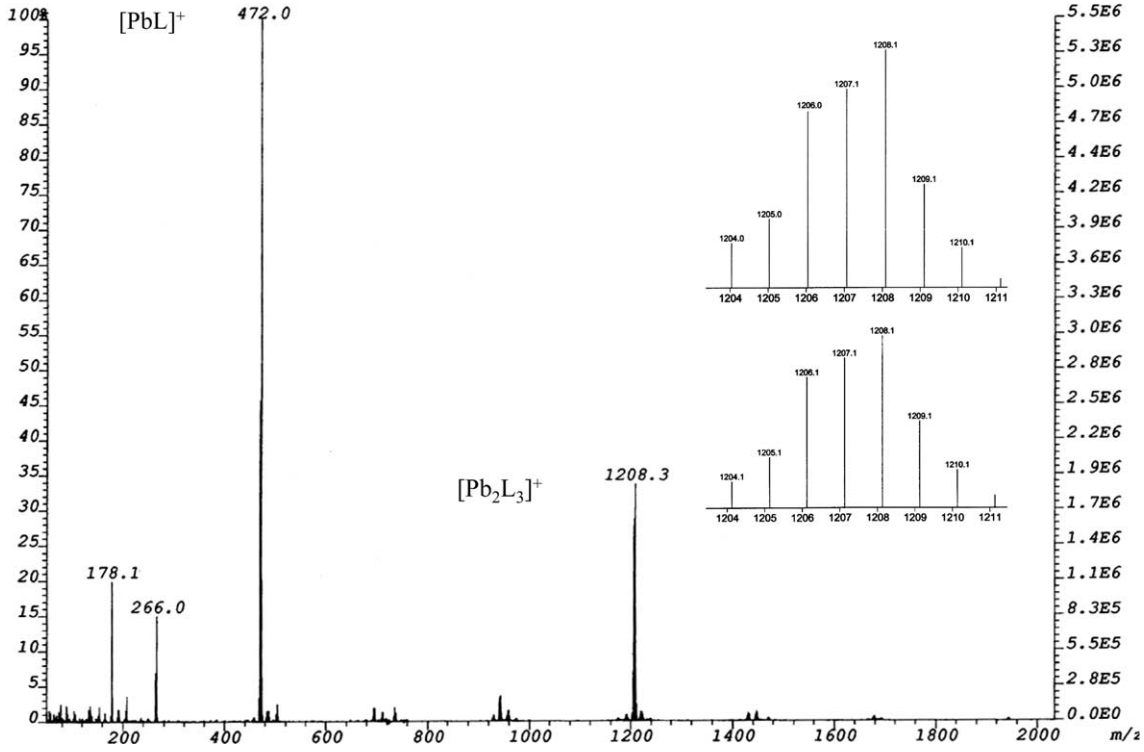

Fig. 1. FAB + spectrum of $[PbL_2]_2$ (**3**).

3.1. Crystal structure of $[Cd(DMF)L_2]_2 \cdot 2DMF \cdot 1/4H_2O$

Crystallographic data of complex **1a** are summarised in Table 1.

The crystal structure of the cadmium complex is formed of discrete $[Cd(DMF)L_2]$ entities linked through one sulfur atom of another thiosemicarbazone ligand, which leads to the dinuclear centrosymmetric $[Cd(DMF)L_2]_2$ species. The molecular structure is shown in Fig. 2 and selected bond distances and angles are summarised in Table 2. In the complex the Cd(II) ion is in a distorted octahedral arrangement formed by two amine nitrogen atoms, three sulfur atoms and the oxygen of a DMF molecule. The two water molecules present in complex **1** have been substituted by solvent molecules, which present great disorder. The coordination mode of the ligand affords four four-member chelate rings. The triazine rings are almost planar with a maximum deviation of 0.0749 Å for C(1) and 0.055 Å for C(16). S(1) is 0.318 Å under this plane and S(2) 0.2487 Å above. So the triazine that contains N(4), N(5) and N(6) is more planar than the one that contains N(1), N(2) and N(3). The aromatic rings form with respect to these planes dihedral angles of 35.75° for C(3)–C(8), 44.77° for C(10)–C(15), 42.55° for C(18)–C(23) and 38.63° for C(25)–C(30). Cd–N bond distances are slightly different (2.322 and 2.306 Å), the one belonging to the ligand that acts as a bridge being shorter. The Cd–S bond distance with the monodentate sulfur atom is shorter than those with the bridging sulfurs, which moreover are quite different (2.6342 and 2.8932 Å).

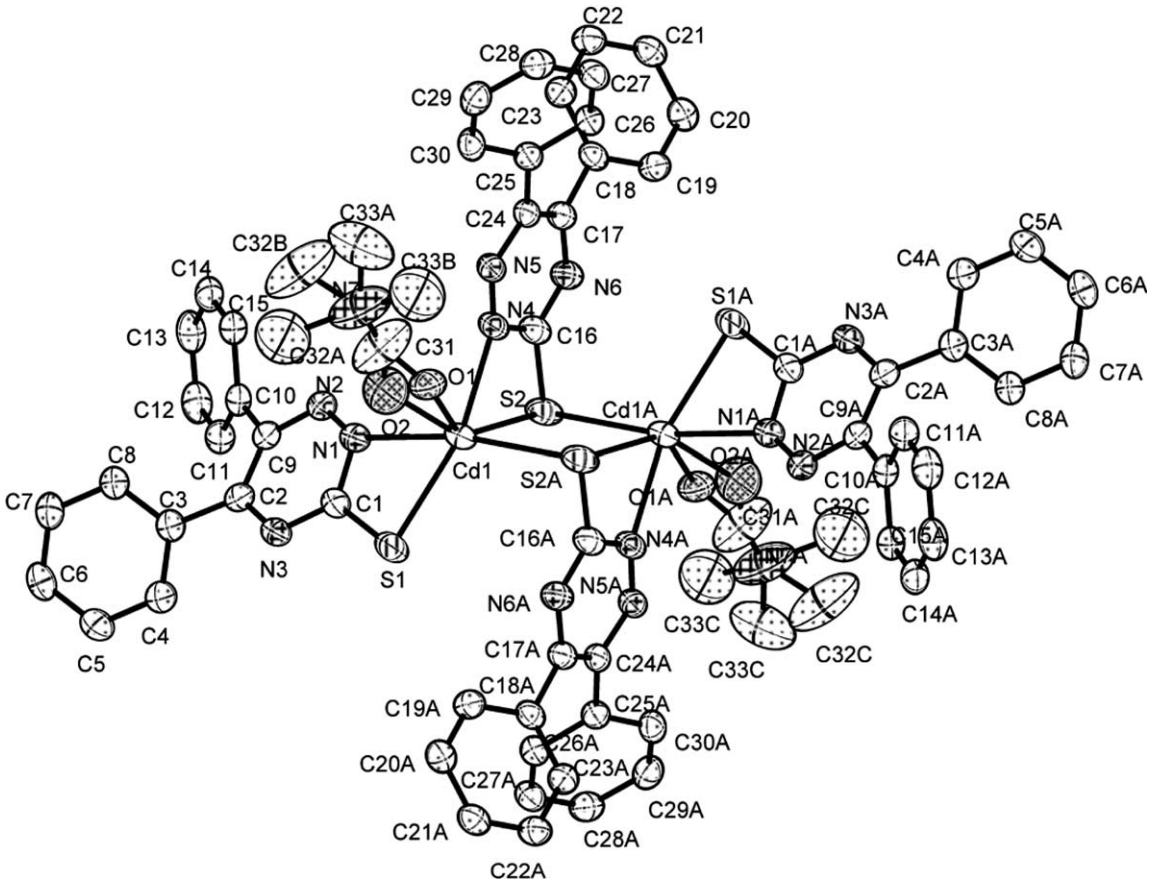

Fig. 2. Molecular structure of $[Cd(DMF)L_2]_2 \cdot 2DMF \cdot 1/4H_2O$ (**1a**). Thermal ellipsoids are shown at 50% probability. Hydrogen atoms are omitted for clarity.

In the complex, owing to the deprotonation, there is a considerable electronic delocalisation through the thiosemicarbazone backbone. As a consequence all the C–N bonds have almost the same length (Table 2), which does not occur in LH_2OCH_3 (1.28–1.459 Å). In the complex the thione bonds are longer than in the precursor ligand (1.628 Å in LH_2OCH_3) and they are intermediate between the theoretical C–S single and double bonds, as is also the case of the N–N bonds [34]. In addition the N(3)–C(2)–C(3) and N(3)–C(8)–C(1) angles are close to 120°, as would be expected for sp^2 hybridisation, while in LH_2OCH_3 the corresponding angle is 108°, corresponding to sp^3 hybridisation.

3.2. IR Spectroscopy

The IR spectrum of LH_2OCH_3 is reported in Section 2. The absence of a band in the 2600 cm^{-1} region in any complex suggests the absence of a thiol tautomer [35]. In the spectra of all complexes there are no bands in the 3000–3300 cm^{-1} region, which indicates the absence of N–H bonds. Moreover bands attributable to the nitrate group are not observed. The absence of these bands confirms that the ligand acts as a monoanion L in all complexes. The band corresponding to the CS moiety is shifted to lower frequencies, indicating coordination of the sulfur to the metal ion. The presence of two bands attributable to C=N bonds could indicates the formation of a new imine group, due to the loss of the methoxy group of the ligand LH_2OCH_3, although the great electronic delocalisation in the ring probably leads to there being only one C=N band and the new band could be due to the hydrazinic CN. These imine nitrogen atoms are not coordinated to the metal ion.

3.3. NMR Spectroscopy

The NMR assignments for LH_2OCH_3 are listed in Section 2. The low solubility of complexes **2** and **5** made it impossible to obtain ^1H and ^{13}C NMR spectra. In addition, the ^{13}C CP/MAS NMR of complex **5** was recorded, but it did not show any clear signal, probably due to a high heterogeneity in the sample. The ^1H NMR spectra of all the complexes only show a multiplet in the aromatic region, corresponding to the phenyl rings of the ligand. The absence of any signal corresponding to amine protons supports the ligand deprotonation. The absence of the singlet attributable to the

Symmetry transformations used to generate equivalent atoms: #1 $-x$, $-y+1$, $-z$.

methoxy group at 3.3 ppm confirms the loss of the inserted methoxy group and the formation of a new C=N bond.

In the ^{13}C NMR spectra the signals corresponding to the methoxy group and the tetrasubstituted carbon atom have disappeared and a new signal corresponding to an imine group is observed. The imine groups are not bonded to the metal ion, as the X-ray diffraction has established for complex **1a**. In addition the signal corresponding to the thione group is deshielded in all complexes, suggesting the presence of metal–sulfur bonds.

The ^{13}C NMR spectrum of complex **4** shows four signals corresponding to CS groups, four to CN and 26 corresponding to aromatic carbon atoms. Two isomers of octahedral complexes with asymmetric chelating ligands are possible. In the *fac* isomer, the A end of each ligand is *trans* to the B end, and the three ligands are equivalent. In the *mer* form, which has a triple statistical probability, two of the A ends are *trans* to each other, and all three ligands are chemically distinct [36]. Thus, if there is an isomer mixture four sets of carbon resonances must be observed, as occurs. So we can establish there is a mixture of *fac* and *mer* isomers.

The ^{113}Cd NMR spectrum of complex **1** in a DMF/$CDCl_3$ solution shows a peak at 202.04 ppm, which indicates a coordination number of six for the cadmium ion. Sulfur ligands are most strongly deshielding, while nitrogen and oxygen donor ligands have a weaker deshielding effect on the Cd(II) ion [37]. Taking this into account and by comparison with the complex $[CdLH_6(NO_3)_2]$ ($\delta = 177.8$ ppm), with the ligand benzilbisthiosemicarbazone LH_6 in which the metal is in a distorted octahedral arrangement with a $N_2S_2O_2$ environment [38], the value of the ^{113}Cd chemical shift is in agreement with a N_2S_3O environment for cadmium ions.

In sight of the data found, and taking into account the results obtained with some organotin derivatives [14], we can assume that the ligand L acts in all complexes as at least as a NS chelate. The structure of complex **2** could consist of a monomer, in which two sulfur and two nitrogen atoms of two ligands occupy the base of a square-base pyramid and with the oxygen of the water molecule in the apex, or a dinuclear one as

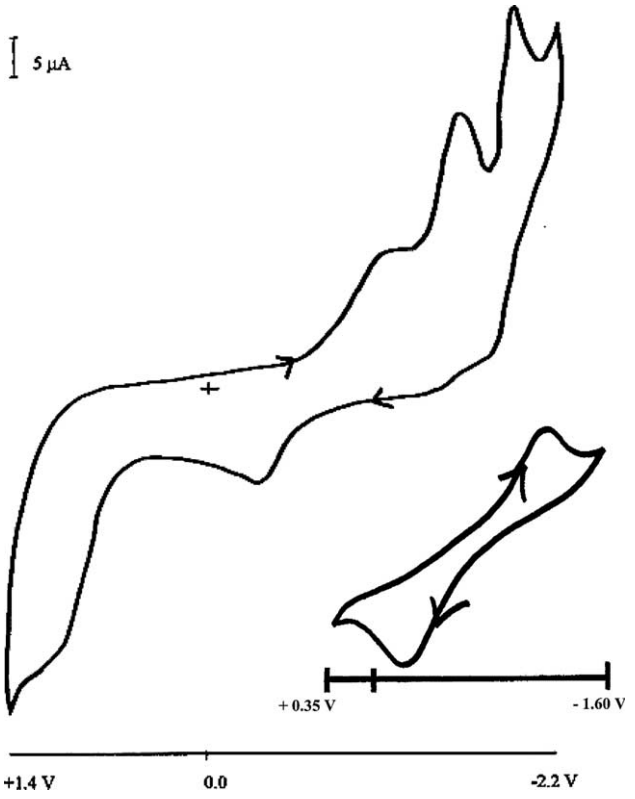

Fig. 3. Cyclic voltammogram of complex $[Cd(H_2O)L_2]_2$ (**1**) in DMF; $v = 100$ mV/s. Inset: the redox couple.

complex **1** shows. Complexes **1a** and **2** show the same spectroscopic characteristics and the same pattern in the mass spectra. In particular, the mass fragment $[Zn_2L_3]^+$ would be difficult to explain without the presence of a dimeric species (molecular association during the experiment would lead to the fragment $[Zn_2L_4 + 1]^+$). Hence the structure of complex **1** could be expected for complex **2**, with Zn(II) in a distorted octahedral arrangement formed by two amine nitrogen atoms, an oxygen of a water molecule and three sulfur atoms, two of them acting as bridge, a structure that has been found in other Zn(II) complexes with N_2S ligands, with a dimeric structure via sulfur bridges [39]. In complex **3** a dimeric structure is also expected, where two of the four ligands act also as bridges, so Pb(II) is in a N_2S_3 environment in a pentacoordinate geometry. However, the structure of complex **3** may be considered as octahedral if the lone pair is considered as "occupying" one position, as is quite common for Pb(II) complexes. Complex **4** presents the expected octahedral geometry for Co(III), with a N_3S_3 environment for the metal ion. In complex **5** the Ni(II) ion is in a square-planar arrangement with the two ligands bonded through the sulfur atom and the amine nitrogen, so the Ni(II) environment is N_2S_2. By comparison with other metal derivatives previously published by us with this ligand [14], we expect the formation of the *cis* isomer.

3.4. Electrochemical behaviour

The cyclic voltammogram of LH_2OCH_3 in DMF only shows an irreversible cathodic wave at −1.897 V, which can be attributed to the reduction of the groups present in the ligand.

The cyclic voltammogram of complex **1** between 1.4 and −2.2 V (Fig. 3) exhibits three cathodic waves at −0.892, −1.482 and −1.847 V and an anodic one at −0.261 V, related to the one at −0.892 V. This redox couple, with $E_{1/2} = -0.576$ V, corresponds to Cd(II)/Cd(I) process. The morphology of the first cathodic peak is similar to that of the Cd(II)/Cd(I) process in $Cd(NO_3)_2 \cdot 4H_2O$ in DMF, although it is shifted to more negative potentials.

On scanning from 1.0 to −2.2 V, the cyclic voltammogram of complex **4** (Fig. 4) shows a redox couple at $E_{1/2} = -0.150$ V, corresponding to a Co(III)/Co(II) process, and two irreversible cathodic peaks corresponding to ligand reduction processes. Analysis of the redox couples of complexes **1** and **4** in the interval 25–800 mV/s shows a linear variation of i_{pc} versus $v^{1/2}$. A small dependence of the potential peak with the scan rate is observed, and the i_{pa}–i_{pc} ratio is close to unity. These

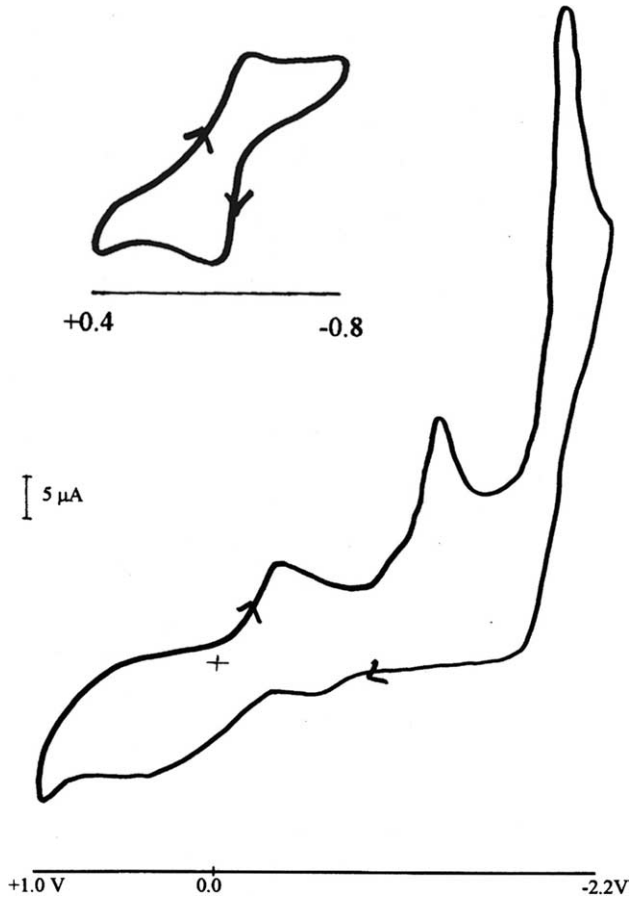

Fig. 4. Cyclic voltammogram of complex $[CoL_3]$ (**4**) in DMF; $v = 100$ mV/s. Inset: the redox couple.

results suggest diffusion controlled quasirreversible processes [40].

4. Conclusions

Reaction of the ligand LH_2OCH_3 with divalent metals leads to the formation of the corresponding coordination compounds, where the ligand has lost the methoxy group and acts as a monoanion. The presence of basic medium is necessary to get all the metal derivatives.

In all the complexes the ligand acts as bidentate and bonds to metal ions through the sulfur atom and the deprotonated amine nitrogen, giving a four-member chelate ring. The structure of the complexes is determined by the structural preferences of the metal ions as well as by the ligand configuration. Complexes **1**, **2** and **3** are dinuclear species, in which the sulfur atom of two thiosemicarbazone ligands acts as a bridge between the metal ions. Complexes **4** and **5** are monomeric compounds.

Preliminary electrochemical results confer good prospects for complex **1** to be a lead compound in the discovery of new sensors for the toxic Cd(II) ion.

The complexes were prepared by adding the appropriate picoline (0.2 ml) to the solution of $[RuCl_2(PPh_3)_3]$ (0.2 g) in methanol (100 ml). The reaction mixture was stirred for 4 h. The solvent was then removed in vacuo and the crude residue was crystallized from methanol. Crystals of $[RuCl_2(\beta\text{-pic})_4]$, suitable for X-ray analysis, were obtained by slow evaporation of the methanolic solution.

2.4. Physical measurements

Infrared spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1} with the samples in the form of KBr pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 800–180 nm in deoxygenated dichloromethane solution. Elemental analyses (C, H, N) were performed on a Perkin–Elmer CHN-2400 analyzer. The ^{1}H NMR spectra were recorded on a Bruker DRX-400 spectrometer in $CDCl_3$ solutions.

2.5. Crystal structure determination and refinement

A rectangular prism crystal was mounted on a KM-4-CCD automatic diffractometer equipped with CCD detector, and used for data collection. X-ray intensity data were collected with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at a temperature of 293.0(2) K, with the ω scan mode. A 12 s exposure time was used and all the Ewald sphere was collected up to $2\theta = 50.22°$. The unit cell parameters were determined from least-squares refinement of the setting angles of 5589 strongest reflections. Details concerning crystal data and refinement are given in Table 1. Examination of 98 reflections on two reference frames monitored after each 20 frames measured showed 2.61% loss of the intensity. During the data reduction, the above decay correction coefficient was taken into account. The orange, transparent crystal used for the data collection did not change its appearance. Lorentz, polarization and numerical absorption [19] corrections were applied. The structure was solved by direct methods and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix, least-squares technique on F^2. All the hydrogen atoms were found from difference Fourier synthesis after four cycles of anisotropic refinement, and refined as ''riding'' on the adjacent carbon atom with an individual isotropic temperature fac-

tor equal to 1.2 times the value of the equivalent temperature factor of the aromatic parent carbon atom and equal to 1.5 times the value of the equivalent temperature factor of the methyl parent carbon atom. The methyl group was allowed to rotate during refinement about its local threefold axis. SHELXS 97 [20], SHELXL 97 [21] and SHELXTL [22] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.6. Computational details

The GAUSSIAN 03 program [23] was used in the calculations. The geometry optimization was carried out with the DFT method with the use of the B3LYP functional [24,25]. The electronic spectrum was calculated with the TDDFT method [26]. Two basis set were used in the calculation. The Lanl2dz basis set [27] was used on the ruthenium atom, 6-31G(d) on the chlorine, nitrogen, oxygen and carbon atoms and 6-31G basis on the hydrogen atoms in the first calculations. The second one was performed using the DZVP basis set [28] with f functions with exponents 1.94722036 and 0.748930908 on the ruthenium atom and polarization and diffuse functions to all other atoms: 6-31+g(2d,p)–chlorine, 6-31+g** – carbon, nitrogen and 6-31g(d,p) on hydrogen atoms. The results obtained from the calculations were compared.

3. Results and discussion

2,3 and 4-Methylpyridine react in methanolic solutions with $[RuCl_2(PPh_3)_3]$ giving complexes of the general formula $[RuCl_2(L)_4]$, where L is the appropriate picoline, with good yields.

Infrared spectra of the complexes exhibit characteristic bands due to picoline ring vibrations. The $\nu_{C=N}$ band in the complexes appears around 1615 (complex with β and γ-picoline) and 1604 cm^{-1} ($[RuCl_2(\alpha\text{-pic})_4]$). The $\nu_{C=C}$ absorption bands are visible at 1435 and 1420 cm^{-1} respectively. The absorption bands at 536 cm^{-1} (complex with α-picolne), 556 cm^{-1} (β-picoline) and 531 (γ-picoline) are due to ν_{Ru-N}. The ^1H NMR spectra of the complexes confirm the presence of picoline molecules in the coordination spheres. The positions of the ^1H NMR signals and their assignments are given in the experimental part of the paper.

The obtained complexes were recrystallized from methanolic solution, but only the complex with β-picoline gave well-shaped crystals suitable for X-ray analysis.

The $[RuCl_2(\beta\text{-pic})_4]$ complex crystallises in the tetragonal space group *P4nc* (no. 104). The molecular structure of the compound is shown in Fig. 1 (a structural drawing of the complex is presented in Fig. 2). Selected bond lengths and angles are listed in Table 2. The asymmetric unit includes a quarter of the molecule. The Ru and Cl atoms lie on fourfold axis (special positions *a* of *P4nc* space group at 0, 0, *z* [29]) and rest of the atoms lie in general positions. The ruthenium atom has an

Table 2
Selected bond lengths (Å) and angles (°) for $[RuCl_2(\beta\text{-pic})_4]$

Bond lengths (Å)	
Ru(1)–N(1)	2.087(3)
Ru(1)–Cl(1)	2.430(6)
Ru(1)–Cl(2)	2.390(5)
Bond angles (°)	
N(1)–Ru(1)–N(1A)	179.5(6)
N(1)–Ru(1)–N(1B)	89.999(1)
N(1)–Ru(1)–N(1C)	90
Cl(1)–Ru(1)–Cl(2)	180.0
N(1)–Ru(1)–Cl(1)	90.2(3)
N(1)–Ru(1)–Cl(2)	89.8(3)

Symmetry transformations used to generate equivalent atoms: A. $1-y,x,z$; B. $1-x,1-y,z$; C. $y,1-x,z$.

octahedral geometry (4 + 2) with *trans* chlorine atoms (Cl(1)–Ru(1)–Cl(2)–180°). The β-picoline ligands are in a square–planar disposition. The angles between N–Ru–Cl are close to 90° (89.8(3)–90.2(3)°), and the N–Ru–N angles are 179.5(6)° and 89.999(1)°. The Ru–ligand distances, such as Ru–Cl 2.430(6), 2.390(5), and Ru–N 2.087(3) Å, are normal and comparable with distances in other ruthenium complexes containing nitrogen heterocyclic ligands [2,30–33]. The bond valences were computed as $v_{ij} = \exp[(R_{ij} - d_{ij})/0.37]$ [34–36], where R_{ij} is the bond-valence parameter (in the formal sense R_{ij} is the single-bond length between i and j atoms) [37]. The R_{Ru-N}, R_{Ru-Cl} values were taken as 1.656 and 1.932 Å [38], respectively. The computed bond valences of the ruthenium complex are $v_{Ru-N(1)} = 0.312$, $v_{Ru-Cl(1)} = 0.260$ and $v_{Ru-Cl(2)} = 0.290$ v.u. (valence units) which means that picoline is the strongest bonded subsituent, and the Ru–Cl(1) bond is the weakest one.

3.1. Geometry and electronic structure

The optimized geometry parameters for the studied complexes are given in Table 3. The calculated bond lengths and angles for $[RuCl_2(\beta\text{-pic})_4]$ agree well with the experiment, the largest difference are found for the ruthenium–chlorine bonds, but the relative differences in these bond lengths are reproduced in the calculations. The geometry calculated by using both basis sets is comparable. The geometries of the complexes with α- and γ-picoline were calculated with the DFT method using the small basis sets (Lanl2dz on the ruthenium atom). The complexes are depicted in Fig. 3. The Ru–N and Ru–Cl distances in the complex with α-picoline are longer than the corresponding bond lengths in complexes with β-and γ-picoline. For the complexes with α- and γ-picoline the frequency calculations were performed and compared with experimental IR spectra. An agreement between the calculated and experimental spectra indicates that the calculated geometry corresponds to the real structure. Several calculated frequencies (experimental values are given in parentheses) of $[RuCl_2(\gamma\text{-pic})_4]$ are 3102 (3049) ν_{CH}, 3047 (3023) ν_{CH}, 1672 (1614) $\nu_{C=N}$, 1545 (1481) ν_{ring}, 1468 (1432) $\nu_{C=C}$, 1374 (1385) ν_{ring}, 1245 (1209) δ_{CH}, 1092 (1088) δ_{CH}, 735 (724) δ_{ring}, 543 (531) ν_{Ru-N} and for $[RuCl_2(\alpha\text{-pic})_4]$ 3068 (3052) ν_{CH}, 3062 (2974) ν_{CH}, 1622 (1604) $\nu_{C=N}$, 1504 (1481) ν_{ring}, 1469 (1435) $\nu_{C=C}$, 1343 (1303) ν_{ring}, 1194 (1187) δ_{CH}, 1098 (1093) δ_{CH}, 737 (696) δ_{ring}, 559

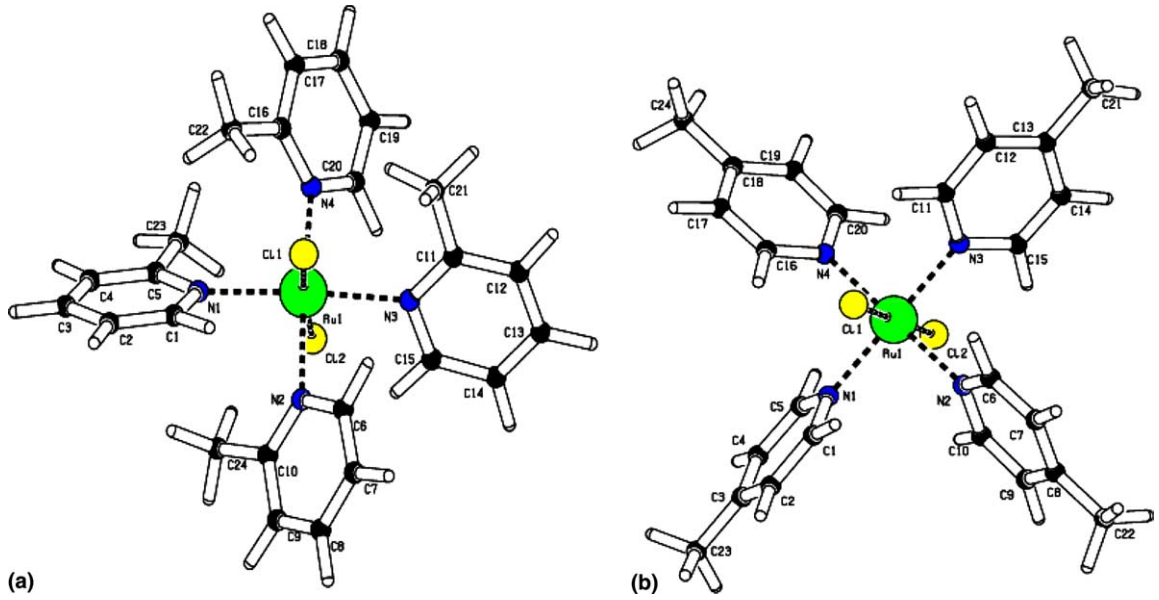

Fig. 3. The idealized geometry of $[RuCl_2(\alpha\text{-pic})_4]$ and $[RuCl_2(\gamma\text{-pic})_4]$.

(536) ν_{Ru-N}. The maximum error between the calculated and experimental values is about 5.7%.

In Table 4 the energies of several HOMO and LUMO orbitals of $[RuCl_2(\beta\text{-pic})_4]$ are gathered. The charge of ruthenium calculated from natural population analysis is smaller than 1 (0.525-Lanl2dz; 0.831-DZVP). This results from charge donation from chloride ions, which act as σ-donors (the charges of Cl ligands are −0.633, −0.627 – Lanl2dz and −0.653, −0.649 – DZVP). The charge on the picoline nitrogen atom bonded with ruthenium is negative (−0.423 Lanl2dz and −0.451 DZVP).

The doubly degenerate HOMO and HOMO − 3 orbitals are d_π (d_{xz}, d_{yz} and d_{yz}, d_{xz}) metal orbital with the admixture of chlorine π orbitals and πC. The HOMO − 1 orbital is created from $d_{x^2-y^2}$ and πC of picoline ligands. The lower lying orbitals are π orbitals of the picoline and chlorine ligands.

The LUMO orbital is composed of β-picoline rings. The d ruthenium orbitals hold small shares in LUMO + 1 (d_{xz}, d_{yz}) and LUMO + 2 ($d_{x^2-y^2}$) molecular orbitals. The LUMO + 5 MO is a combination of d_z^2 and σCl. The LUMO + 7 orbital is d_{xy} with an antibonding

H, HOMO; L, LUMO.

contribution σ (lone pairs) of nitrogen picoline and σ carbon orbitals.

The energy of appropriate HOMO and LUMO orbitals calculated with the DZVP basis set on the ruthenium atom, and diffuse and polarization functions on the other atoms is lower than that obtained from calculation with the Lanl2dz basis on the Ru atom. The HOMO–LUMO gap in both calculations is similar (the difference is 0.25 eV).

The character of the MO orbitals for the complexes with α- and γ-picoline are close to, mentioned above, $[RuCl_2(\beta\text{-pic})_4]$. The d_π metal orbitals (d_{xz}, d_{yz} and d_{yz},

d_{xz}) are visible in the HOMO and HOMO − 2 molecular orbitals of $[RuCl_2(\alpha\text{-pic})_4]$ and $[RuCl_2(\gamma\text{-pic})_4]$. The HOMO − 1 orbital is created from $d_{x^2-y^2}$ and πCl. For the $[RuCl_2(\alpha\text{-pic})_4]$ complex in the LUMO MO, the d ruthenium orbitals hold shares in LUMO + 1 (d_{xz}) LUMO + 2 (d_{yz}) and LUMO+3 ($d_{x^2-y^2}$). The LUMO + 4 MO is a combination of d_z^2 and σCl. The LUMO + 9 orbital is d_{xy} with an antibonding σ contribution (lone pairs) of nitrogen picoline.

The HOMO–LUMO gaps are 3.55, 3.70 and 3.76 eV for $[RuCl_2(\alpha\text{-pic})_4]$, $[RuCl_2(\beta\text{-pic})_4]$ and $[RuCl_2(\gamma\text{-pic})_4]$ complexes, respectively.

3.2. Electronic spectrum

The spin-allowed, singlet transitions were calculated with the TDDFT method. The calculated electronic transitions are gathered in Table 5. The calculated and experimental spectra of $[RuCl_2(pic)_4]$ are depicted in Fig. 4. Each calculated transition in Fig. 4 is represented by a gaussian function with the height equal to the oscillator strength and width equal to 0.05. The spectrum of complex with β-picoline was calculated using the Lanl2dz (dashed line in the Fig. 4) and DZVP basis set (dotted line). Both Lanl2dz and DZVP calculations predict the experimental spectrum of the complex with similar accuracy, but using the DZVP basis set on the ruthenium atom to calculation the UV–Vis spectrum gave better results for the higher energy of transitions than the Lanl2dz basis set.

The experimental spectrum of $[RuCl_2(\beta\text{-pic})_4]$ shows bands at 513.4, 442.0, 381.8, 244.4, 222.2 and 215.8 nm. We ascribe the first experimental bands at 513.4 nm to the calculated transition at 509.0 with small oscillator strengths. This is a d → d transition. The experimental bands at 442.0 nm and 381.8 nm are assigned to the transitions calculated between 430.3 and 377.9 nm. These transitions are of d → π^*_{pic} excitation of MLCT character.

The experimental band at 244.4 nm is ascribed to the transitions calculated between 263.2 and 239.8 nm. The transition is mainly from chlorine ligands orbitals to π^*_{pic} (LLCT character) with the admixture of MLCT transition (H-3 → L) and LMCT (H-2 → L + 5). The calculated transitions between 231.8 and 221.0 are assigned to experimental bands 222.2 and 215.8. They are of LLCT type (interligand transitions) and intraligand ($\pi_{pic} \rightarrow \pi^*_{pic}$ transitions).

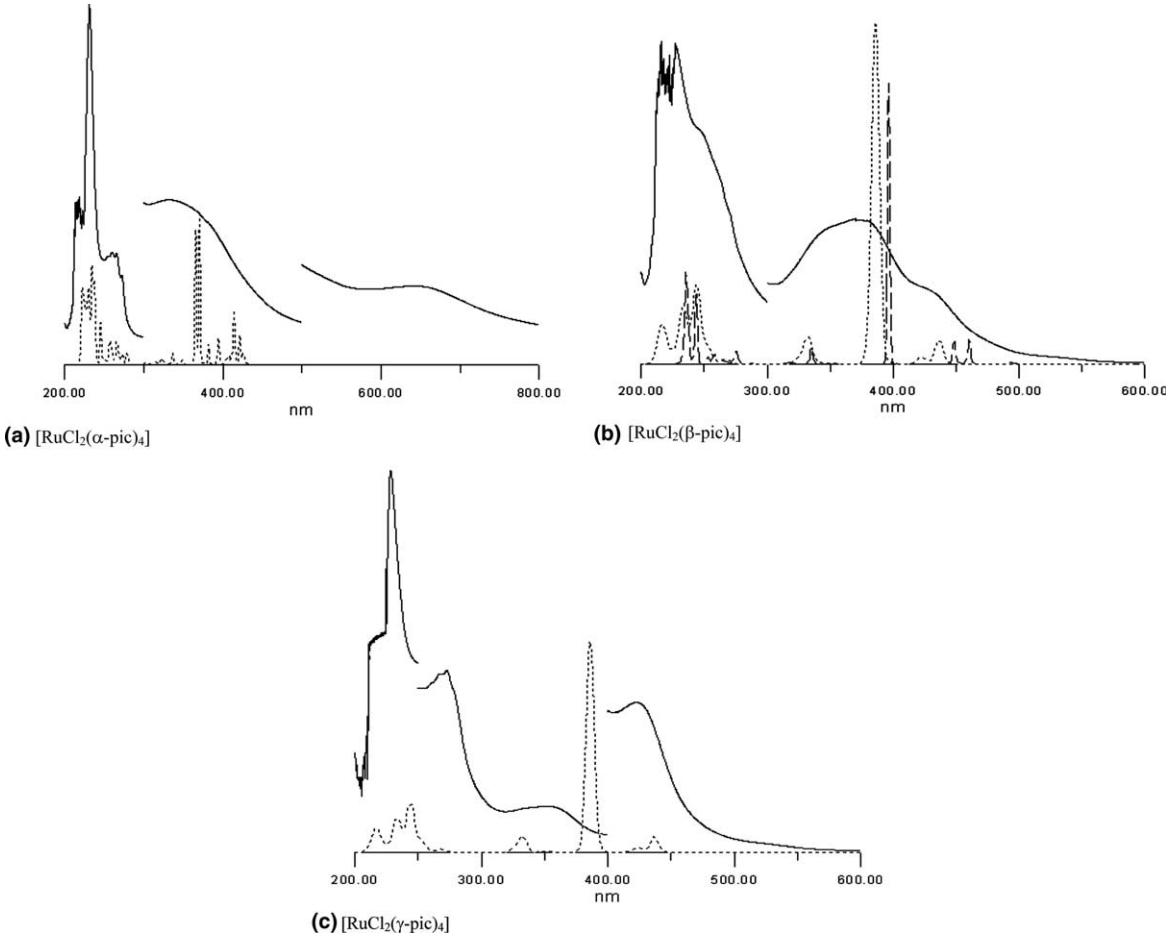

Fig. 4. The calculated and experimental spectra of $[RuCl_2(picoline)_4]$.

The UV–Vis spectrum of $[RuCl_2(\gamma\text{-pic})_4]$ is similar to the electronic spectrum of the β-picoline complex and shows bands at 527.1, 427.0, 352.0, 272.6, 228.2 and 214.6 nm. Based on the calculated geometry of this complex, the spectrum was computed using the DZVP basis set on ruthenium and polarization and diffuse functions on the other atoms. The first experimental band is due to $d \rightarrow d$ transitions and was calculated at 520.0 nm with 0.0006 oscillator strengths. The calculated transitions at 436.61 and 436.50 nm are assigned to the experimental band at 427.0 nm. The transition is of $d \rightarrow \pi^*_{pic}$ (HOMO − 1, HOMO → LUMO) excitation of MLCT character. The next experimental band at 352.0 has the same character and was calculated in the range 386.16 and 332.36 nm.

The experimental band at 272.6 nm is ascribed to the transitions calculated between 268.3 and 240.7 nm. The transition is mainly from chlorine ligands orbitals to π^*_{pic} (LLCT character) with the admixture of MLCT and LMCT transitions. The LLCT type inter- and intraligand transitions ($\pi_{pic} \rightarrow \pi^*_{pic}$) were calculated between 233.4 and 206.9, and are assigned to experimental bands 228.2 and 214.6 nm.

The electronic spectrum of $[RuCl_2(\alpha\text{-pic})_4]$ shows bands at 645.8, 386.0, 265.6, 228.4 and 215.8 nm. The first band, with a small oscillator strength, is of $d \rightarrow d$ type and was calculated at 626.9 nm. The next asymmetric band, with a maximum at 386.0 nm, was calculated in the range 420.8–365.3 nm and is of $d \rightarrow d$ character with an admixture of MLCT transition ($d \rightarrow \pi^*_{pic}$, π^*_{Cl}). The transition from chlorine ligands orbitals to π^*_{pic} (LLCT character) with the admixture of MLCT transitions were calculated between 278.5 and 245.6 nm and are assigned to the band at 265.6 nm. The excitations calculated between 234.4 and 225.2 nm are LLCT type (inter- and intraligand) and are ascribed to the band at 228.4 nm. The experimental band at 215.8 is LLCT and MLCT type and is attributed to the calculated transitions between 223.5 and 219.9 nm.

4. Supplementary data

More details of the crystal structure determination have been deposited with the Cambridge Crystallographic Data Centre with the deposition number: CCDC 248944. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033 or deposit@ccdc.cam.ac.uk or on the www: http://www.ccdc.cam.ac.uk.

C(O)NHCH$_2$C(O)OEt, (CH$_2$)$_3$C(O)OH, (CH$_2$)$_3$C(O)OEt groups are known [6].

This paper presents the syntheses and spectroscopic properties of the [Re(4-NC$_6$H$_4$NH$_2$)X$_3$(PPh$_3$)$_2$] (X = Cl and Br) complexes, obtained in the reaction of [ReOX$_3$(PPh$_3$)$_2$] with 1,4-diaminobenzene. The crystal and molecular structure of [Re(4-NC$_6$H$_4$NH$_2$)Cl$_3$(PPh$_3$)$_2$] has been determined, and its molecular diagram has been calculated with the density functional theory (DFT). Additional information about the binding in the [Re(4-NC$_6$H$_4$NH$_2$)Cl$_3$(PPh$_3$)$_2$] complex has been obtained by NBO analysis. The spin-allowed singlet–singlet electronic transitions of [Re(4-NC$_6$H$_4$NH$_2$)Cl$_3$(PPh$_3$)$_2$] have been calculated with the time-dependent DFT method (TDDFT), and the UV–Vis spectrum has been discussed on this basis.

2. Experimental

2.1. General procedure

All synthetic manipulations were carried out open to the atmosphere. All solvents were of reagent grade and used as received. Ammonium perrhenate, triphenylphosphine and 1,4-diaminobenzene were purchased from Aldrich. The [ReOX$_3$(PPh$_3$)$_2$] complexes were prepared according to the literature methods [16].

Infrared spectra were recorded on a Nicolet Magna 560 spectrophotometer in the spectral range 4000–400 cm^{-1}, with the samples in the form of potassium bromide pellets. Electronic spectra were measured on a spectrophotometer Lab Alliance UV–Vis 8500 in the range 900–200 nm in deoxygenated dichloromethane solution. ^{1}H NMR spectra were obtained in CDCl$_3$ using an INOVA 300 spectrometer. Magnetic susceptibility was measured at 296 K by the Faraday method. Elemental analysis (C, H, N) was performed on a Perkin–Elmer CHN-2400 analyzer.

2.2. Preparation of [Re(4-NC$_6$H$_4$NH$_2$)Cl$_3$(PPh$_3$)$_2$] · PPh$_3$

A mixture of *trans*-[ReOCl$_3$(PPh$_3$)$_2$] (0.83 g, 1 mmol), 1,4-diaminobenzene (0.43, 4 mmol) and acetone (100 ml) was stirred for 2 days, and then 50 ml of acetone was distilled off. [Re(4-NC$_6$H$_4$NH$_2$)Cl$_3$(PPh$_3$)$_2$] was filtered off, washed with ethanol, diethyl ether and dried. Yield: 60%.

IR (KBr, cm^{-1}) 3466 (m), 3360 (s), 3050 (w), 1614 (s), 1588 (s), 1482(m), 1433 (s), 1365 (s), 1327 (m), 1169 (s), 1089 (m), 832 (w), 749 (s), 696 (s), 606 (w), 560 (w), 522 (s), 480 (w).

^{1}H NMR (CDCl$_3$, ppm): δ = 7.26 (s, 2H, NH$_2$); 7.38–7.46 (m, 30H, coordinated PPh$_3$ ligands); 7.77–7.81 (m, 4H of imido ligand and 15H of uncoordinated PPh$_3$).

Anal. Calc. for C$_{60}$H$_{51}$Cl$_3$N$_2$P$_3$Re: C, 60.79; H, 4.34; N, 2.36. Found: C, 60.85; H, 4.40; N, 2.30%.

2.3. Preparation of [Re(4-NC$_6$H$_4$NH$_2$)Br$_3$(PPh$_3$)$_2$]

A procedure similar to that for the chloro analogue was used with *trans*-[ReOBr$_3$(PPh$_3$)$_2$] (0.97 g, 1 mmol) and 1,4-diaminobenzene (0.43, 4 mmol). Yield: 55%.

IR (KBr, cm^{-1}) 3452 (w), 3334 (s), 3047 (w), 1613 (s), 1587 (s), 1483 (m), 1434 (m), 1369 (s), 1327 (m), 1163 (s), 1091 (m), 838 (w), 745 (m), 695 (s), 602 (w), 999 (m), 520 (s), 505 (sh), 480 (w).

^{1}H NMR (CDCl$_3$, ppm): δ = 7.274 (s, 2H, NH$_2$); 7.270–7.254 (m, 4H of imido ligand and 30H of coordinated PPh$_3$ ligands).

Anal. Calc. for C$_{42}$H$_{36}$Br$_3$N$_2$P$_2$Re: C, 47.74; H, 3.43; N, 2.65. Found: C, 47.87; H, 3.55; N, 2.55%.

2.4. Crystal structure determination and refinement

Crystals suitable for X-ray investigation were obtained by recrystallization from acetonitrile. The X-ray intensity data of the title complex were collected on a KM-4-CCD automatic diffractometer equipped with a CCD detector with 40 s exposure time, and all reflections of the Ewald sphere were collected up to θ = 25°. The unit cell parameters were determined from least-squares refinement of the setting angles of the 6795 strongest reflections. Details concerning crystal data and refinement are given in Table 1. Lorentz polarization and numerical absorption corrections [17] were applied. The structure was solved by the Patterson method and subsequently completed by difference Fourier recycling. All the non-hydrogen atoms were refined anisotropically using the full-matrix least-squares technique. All the hydrogen atoms were found from difference Fourier synthesis after four cycles of anisotropic refinement, and refined as ''riding'' on the adjacent atom with an individual isotropic temperature factor equal to 1.2 times the value of the equivalent temperature factor of the parent atom. Carbon-bonded hydrogen atom positions were idealized after each cycle of refinement [d(C–H) = 0.96 Å]. SHELXS-97 [18], SHELXL-97 [19] and SHELXTL [20] programs were used for all the calculations. Atomic scattering factors were those incorporated in the computer programs.

2.5. Computational details

The GAUSSIAN-03 program [21] was used in the calculations. The geometry optimization was carried out with the DFT method with the use of the B3LYP functional [22,23]. The electronic spectrum was calculated with the TDDFT method [24].

In the calculations, the LANL2DZ basis set [25] with additional d (α = 0.3811) and f (α = 0.2033) functions

was used on the rhenium atom, 6-31G(d) on the chlorine, nitrogen, phosphorous and carbon atoms and 6-31G basis on the hydrogen atoms.

Natural bond orbital (NBO) calculations were performed with the NBO code [26] included in GAUSSIAN-03.

3. Results and discussion

3.1. Synthesis

The reaction of *trans*-$[ReOX_3(PPh_3)_2]$ with an excess of 1,4-diaminobenzene in acetone leads to the formation of $[Re(4\text{-}NC_6H_4NH_2)X_3(PPh_3)_2]$ in good yield (Eq. (1)).

$$[ReOX_3(PPh_3)_2] + H_2N\text{–}C_6H_4\text{–}NH_2 \rightarrow [Re(4\text{-}NC_6H_4NH_2)X_3(PPh_3)_2] + H_2O \quad (1)$$

The complexes are air stable. Their solubilities in most polar solvents are low, but they can be crystallized from acetonitrile. Room temperature magnetic susceptibility measurements show the complexes to be diamagnetic. The lack of paramagnetic broadening or shifts of resonances in the ^{1}H NMR spectra of $[Re(4\text{-}NC_6H_4NH_2)X_3(PPh_3)_2]$ also confirms diamagnetism of the complexes. $[Re(4\text{-}NC_6H_4NH_2)X_3(PPh_3)_2]$ are formally rhenium(V) compounds with the arylimido unit as a dianionic NR^{2-} ligand.

3.2. Description of the structure of $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]\cdot PPh_3$

The $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]$ complex crystallizes as the $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]\cdot PPh_3$ adduct in the monoclinic space group $P2_1/n$. The starting oxo complex is synthesized using a large excess of triphenylphosphine, and $[ReOCl_3(PPh_3)_2]$ can be impure with PPh_3. It explains the presence of PPh_3 in the adduct. There are no significant contacts between the uncoordinated triphenylphosphine and the imido complex. Table 1 presents crystal data and structural refinement for $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]\cdot PPh_3$.

A displacement ellipsoids plot of $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]$ is shown in Fig. 1. The rhenium atom of $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]$ is in a distorted octahedral environment with the chloride ions in a *meridional* geometry and two mutually *trans*-triphenylphosphine ligands, and the shortest Re···Re distance is equal to 9.678(1) Å (the second Re atom is obtained by $-x$, $-y$, $-z+1$ symmetry transformation).

The weak intramolecular hydrogen bonds; C(12)–H(12)···Cl(1) [D···A distance = 3.393(2) Å and D–H···A angle = 147.0°], C(24)–H(24)···Cl(2) [D···A distance = 3.548(6) Å and D–H···A angle = 154.0°], C(32)–H(32)···Cl(2) [D···A distance = 3.527(2) Å and D–H···A angle = 134.2°] and C(32)–H(32)···Cl(3) [D···A distance = 3.378(2) Å and D–H···A angle =

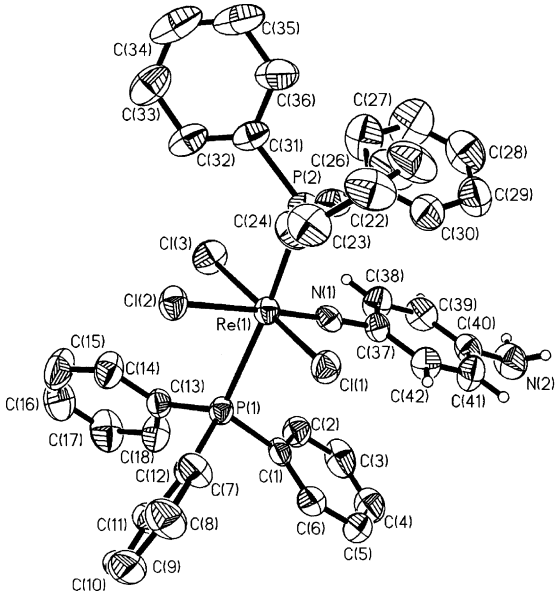

Fig. 1. A displacement ellipsoid plot of $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]$ showing the atom numbering scheme (50% probability ellipsoids). The hydrogen atoms of the phenyl rings are omitted for clarity.

126.1°] provide additional conformational stabilization of the [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$] molecule [27,28].

The most important bond lengths and angles for [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$] are reported in Table 2. The Re(1)–N(1)–C(37) bond angle [177.2(4) Å] agrees with the linear coordination mode of the 4-$NC_6H_4NH_2$ ligand, and the Re–N(1) distance [1.719(4) Å] is typical for Re≡NR of rhenium(V) complexes [6]. Similar to the d^2 complexes *mer*,*trans*-[Re(NR)$Cl_3(PEt_2Ph)_2$] (R = C_6H_4-4-OMe or C_6H_4-4-COMe) [29] and *mer*, *trans*-[Re(NMe)$Cl_3(PEt_2Ph)_2$] [30], no structural *trans* effect of the imido ligand is observed in [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$]. The Re–P bond distances fall within the normal range of Re–P distances observed in six-coordinate tertiary phosphine complexes – 2.45–2.51 Å [31].

The bond valences were computed as $v_{ij} = \exp[(R_{ij} - d_{ij})/b]$ [32–34], where R_{ij} is the bond-valence parameter (in the formal sense the R_{ij} parameter value can be considered as the idealized single-bond length between *i* and *j* atoms). The R_{Re-N}, R_{Re-P}, R_{Re-Cl} were taken as 2.06, 2.46 and 2.23 [34], respectively, and *b* was taken as 0.37 [33]. The computed bond valences of rhenium are $v_{Re-N} = 2.513$; $v_{Re-P} = 0.905$ and 0.915; $v_{Re-Cl} = 0.554$, 0.552 and 0.602 v.u. (valence units), which means that the Re–P bonds are two times stronger than the Re–Cl bonds, the Re–N bond is the strongest one and in a formal sense can be considered as a triple bond.

Table 2
The experimental and optimized bond lengths (Å) and bond angles (°) for [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$]

	Experimental	Optimized

Re(1)–N(1)–C(37)	177.2(4)	179.66

3.3. Optimized geometry and charge distribution

The geometry of the [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$] complex was optimized in a singlet state using the DFT method with the B3LYP functional. The optimized geometric parameters are gathered in Table 2. The calculated bond lengths and angles are in agreement with the values based upon the X-ray crystal structure data, and the general trends observed in the experimental data are well reproduced in the calculations.

Table 3 presents the atomic charges from the natural population analysis (NPA) for [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$]. The calculated charge on the rhenium atom is considerably lower than the formal charge of +5. The populations of the d_{xy}, d_{xz}, d_{yz}, $d_{x^2-y^2}$ and d_{z^2} orbitals of the central atom are 1.300, 1.957, 0.904, 1.145 and 1.042, respectively. This is a result of significant charge donation from the imido ligand, chloride ions and triphenylphosphine molecules. Small differences in values of charges can be noticed between the chloride ion in the *trans* position to the imido group and two mutually *trans* Cl(1) and Cl(3) ligands. The Cl(2) ligand is less negative, which indicates higher electron density delocalization towards the rhenium atom.

3.4. Electronic structure

The rhenium atom of [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$] possesses a d^2 configuration, the highest MO of this compound is of d_{xz} type with antibonding contributions from p_π chloride orbitals. The remaining four d-type orbitals of the rhenium are found among the unoccupied MOs. The d_{yz}, d_{xy}, d_{z^2} and $d_{x^2-y^2}$ orbitals of the central atom constitute mainly the LUMO, LUMO + 1, LUMO + 2 and LUMO + 10, respectively. The d_{yz} and d_{xy} rhenium orbitals bear antibonding character towards the p_π nitrogen orbitals of the imido ligand; the LUMO, LUMO + 1 can be considered as $\pi^*_{Re\equiv NR}$ orbitals.

3.5. NBO analysis

Table 4 presents the occupancies and natural atomic orbital compositions (NAO) of the calculated NBOs

Table 3
Atomic charges from the natural population analysis (NPA) of [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$]

		% Br	64.52	s(26.63%) p(73.20%)

between the rhenium and the donor ligand atoms for [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$]. Some of the Re–L bonds were not detected indicating predominant Coulomb-type interactions between the central ion and the ligands.

The NBO analysis confirms the presence of a triple bond between the rhenium and the imido ligand in [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$]. The Re–N bond orbital of σ-character is strongly polarized towards the nitrogen atom (ca. 74% at N), and the s and p nitrogen orbitals and s and d rhenium orbitals take part in the bond formation. The Re–N bond orbitals of π-character are the result of overlapping of the empty d_{xy} and d_{yz} rhenium orbitals with the occupied p_x and p_z orbitals of the deprotonated nitrogen of the imido ligand.

The NBO analysis also takes into consideration all possible interactions between 'filled' (donor) Lewis-type NBOs and 'empty' (acceptor) non-Lewis NBOs and estimates their energetic importance by second-order perturbation theory. Since these interactions lead to a loss of occupancy from the localized NBOs of the idealized Lewis structure into the empty non-Lewis orbitals, they are referred to as 'delocalization' corrections to the zeroth-order natural Lewis structure. The stabilization energy $E(2)$ associated with delocalization is estimated as

$$E(2) = \Delta E_{ij} = q_i(F(i,j)^2)/(\varepsilon_j - \varepsilon_i),$$

where q_i is the donor orbital occupancy, ε_i, ε_j are diagonal elements (orbital energies) and $F(i,j)$ is the off-diagonal NBO Fock matrix element [35].

Table 5 summarizes the most important delocalizations in [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$] with their stabilization energy $E(2)$ values. Some of them concern the imido ligand. The electron density of the lone pair of the Cl(2) ligand (in the *trans* position to the imido ligand) is delocalized into the $\sigma^*_{Re(1)-N(1)}$ bond orbital. A significant loss of occupancy concerns the p_π orbital of the C(37) atom in the imido group. The electron density of this orbital is delocalized into the $\pi^*_{Re(1)-N(1)}$ bond orbital and π^*_{C-C} bond orbitals of the imido ring.

3.6. Spectroscopic properties

The IR spectra of [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$] and [Re(4-$NC_6H_4NH_2$)$Br_3(PPh_3)_2$] are characterized by strong absorptions at 1169 and 1163 cm^{-1}, respectively, which is within the region (1000–1200 cm^{-1}) expected for a linearly coordinated phenylimido moiety with a triple bond [36]. The absorption bands at ~3400 cm^{-1} correspond to the N–H stretching vibrations and confirm the presence of the uncoordinated NH_2-group.

The experimental and calculated electronic spectra of the chloro complex are represented graphically in Fig. 2. Each calculated transition in Fig. 2 is represented by a

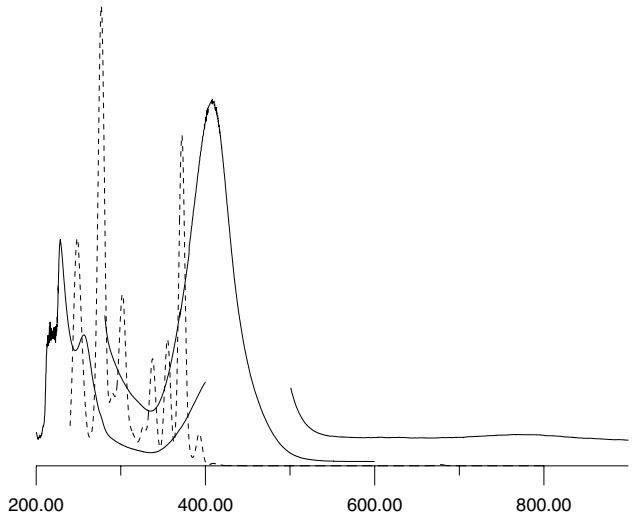

Fig. 2. The experimental (——) and calculated (------) electronic absorption spectrum of [Re(4-$NC_6H_4NH_2$)$Cl_3(PPh_3)_2$].

H, HOMO; L, LUMO.

Gaussian function with the height equal to the oscillator strength and width equal to 0.04. The shape of the UV–Vis spectrum of $[Re(4\text{-}NC_6H_4NH_2)Br_3(PPh_3)_2]$ is the same as for the chloro analogue; the absorption bands of the bromo complex were recorded at 788.0, 421.0, 267.4, 237.0 and 224.8 nm.

Table 6 shows the energy and molar absorption coefficients of the experimental absorption bands of $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]$ and the spin-allowed singlet–singlet electronic transitions calculated with the TDDFT method. Except for the low energy part of the spectrum, only transitions with oscillator strengths larger than 0.01 are listed in Table 6.

The investigated complex is of large size, and the number of basis functions is equal to 812. Eighty electron transitions calculated by the TDDFT method do not comprise all the experimental absorption bands. The UV–Vis spectrum of $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]$ was calculated to ~240 nm, so the shortest wavelength experimental band is not assigned to the calculated transitions, and the assignment of the band at 228.4 nm is probably not complete. Considering that the solution spectra of PPh_3 and 1,4-diaminobenzene exhibit intense absorption bands in 250–200 nm region, some additional intraligand and interligand transitions are expected to be found at higher energies in the calculations for $[Re(4\text{-}NC_6H_4NH_2)Cl_3(PPh_3)_2]$.

The longest wavelength experimental band at 790 nm may be attributed to the transition of d → d character with small oscillator strength, calculated at 678.4 nm.

The absorption band at 419.2 nm corresponds to the LMCT transitions calculated in the range 432–326 nm. These transitions occur from the chloride, imido and phosphine ligand orbitals to the d rhenium orbitals.

The next experimental band at 256.2 nm may be assigned to the transitions calculated between 305 and 249 nm with large oscillator strengths. These are LMCT transitions from the chloride, imido and phosphine ligand orbitals to the d rhenium orbitals and MLCT transitions from the d_{Re} to the acceptor orbitals of PPh_3.

The absorption band at 228.4 nm is attributed to the LLCT transitions with large oscillator strengths. They comprise intra- and interligand transitions.

4. Supplementary data

Supplementary data for $C_{60}H_{51}Cl_3N_2P_3Re$ are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail:

deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk) on request, quoting the deposition number: 263918.

Acknowledgements

The GAUSSIAN-03 calculations were carried out in the Wrocław Centre for Networking and Supercomputing, WCSS, Wrocław, Poland under calculational Grant No. 51/96.

The crystallographic part was financed by funds allocated by the Ministry of Scientific Research and Information Technology to the Institute of General and Ecological Chemistry, Technical University of Łódź.

azobenzene chromophore, 4-[di(biphenyl-4-yl)amino]-azobenzene and 4,4′-bis[bis(4-*tert*-butylbiphenyl-4-yl)-amino]-azobenzene have been used as photochromic amorphous molecular materials [10]. Other azobenzene-based amorphous molecular materials, with a spiro-linked bifluorene, have been synthesized and their photoinduced behavior such as optically induced birefringence, diffraction efficiency and surface relief gratings (SRGs) were investigated in relation to their unique molecular structures [11].

Based on our knowledge, only a few coordination or organometallic compounds have been reported as amorphous molecular materials. Platinum 5-fluorouridine green sulfate is a typical example of an amorphous coordination compound [12]. A polycrystalline sample of titanyl phthalocyanine was vacuum evaporated at ca. 10^{-5} Torr to form an amorphous thin film. Photovoltaic devices consisting of an amorphous thin film of titanyl phthalocyanine and *N*,*N*-dimethyl-3,4:9,10-perylenebis (dicarboximide), sandwiched between ITO and Au electrodes, demonstrated a response to light over the whole visible wavelength region from 400 to 900 nm [13]. Shirota and co-workers [8a] have synthesized copper and titanyl phthalocyanines containing triarylamine moieties. These compounds are soluble in common organic solvents and readily form stable amorphous glasses with high glass transition temperatures. Bazan and co-workers [14] have synthesized Iridium complexes with fluorene-modified phenylpyridine ligands that are resistant to crystallization and can be used in the fabrication of single layer light emitting diodes. It is worth mentioning that the introduction of a metal center into organic systems in order to form coordination or organometallic molecular materials can introduce extra parameters such as color, magnetism and birefringence in amorphous molecular materials. Besides the metal center can improve the electroluminescent properties of coordination molecular materials.

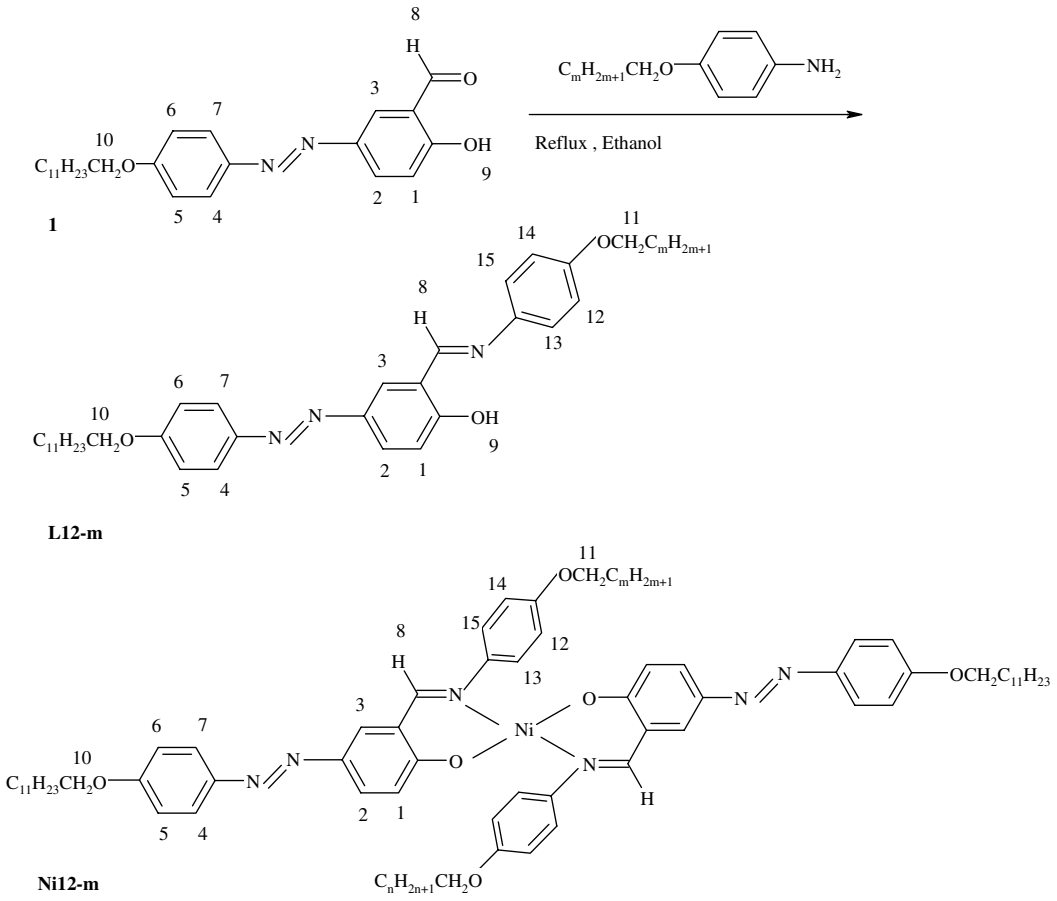
In this work, we report the synthesis and investigation of glass-forming properties of new bis[5-((4-^{n}dodecyloxyphenyl)azo)-*N*-(4-^{n}alkoxyphenyl)-salicylaldiminato]-nickel (II) complex homologues (see Scheme 1).

2. Experimental

2.1. Reagents

All reagents and solvents used were supplied by Merck chemical company and used without further purification. 4-Alkoxynitrobenzene homologues were obtained by reaction between 4-nitrophenol with 1-bromoctan or 1-bromododecane in DMF as solvent and K_2CO_3 as base by refluxing for 3 h [15] and then crude 4-alkoxy nitrobenzene homologues were purified by recrystallization from ethanol. 4-Alkoxyaniline homologues prepared by reduction of the corresponding 4-alkoxynitrobenzene as described in the literature [16].

2.2. Physical measurements



Elemental (C, H and N) analyses were carried out on a Perkin–Elmer automatic equipment model 240B. Electron impact (70 eV) mass spectra were recorded on a Finnigan-mat GC–MS–DS spectrometer model 8430. Infrared spectra were taken with a Bruker FT-IR spectrometer model vector 22, using KBr pellets in the 400–4000 cm^{-1} range. The DSC thermograms of the compounds were obtained on a Mettler–Toledo DSC 822e module, which was calibrated with indium metal ($T = 156.6 \pm 0.3$, $\Delta H = 28.45 \pm 0.6$ J g^{-1}). Samples of 2–5 mg in the solid form were placed in aluminum pans (40 μl) with a pierced lid, and heated or cooled at a scan rate of 10 °C min^{-1} under a nitrogen flow. TGA was carried out on a Mettler–Toledo TGA 851e at a heating rate of 10 °C min^{-1} under a nitrogen atmosphere. X-ray powder diffraction patterns were recorded on a Bruker D8 powder diffractometer (Cu Kα: 1.541 Å). The optical observations were made with a Zeiss polarizing microscope equipped with a Linkam THMSG 600 heating and cooling stage and Linkam THMS 93 programmable temperature-controller. ^{1}H NMR spectra were obtained in deutrated chloroform as solvent on a Bruker FT-NMR AC-400 (400 MHz) spectrometer. All chemical shifts are reported in δ (ppm) relative to tetramethylsilane as an internal standard.

2.3. Materials

*5-(4-Dodecyloxyphenylazo)salicylaldehyde (**1**).* This compound was prepared as described in the literature [17]. Yellow, yield 80%, m.p. 123 °C. MS *m/z* (relative intensity): 411.6 (M + 1,15), 410.6 (M, 45), 242.5 (M − $C_{12}H_{25}$, 25), 121.6 (M − $C_{12}H_{25}OC_6H_4N_2$, 100). *Anal.* Calc. for $C_{25}H_{34}N_2O_3$: C, 73.15; H, 8.35; N, 6.83. Found: C, 72.73; H, 8.14; N, 6.47%. ^{1}H NMR (400 MHz, $CDCl_3$) δ 11.26 (s, H-9), 10.02 (s, H-8), 8.15 (d, $J = 2.8$ Hz, H-3), 8.13 (dd, $J = 2.9$, 8.2 Hz, H-2), 7.89 (dd, $J = 3.0$, 7.9 Hz, H-4, H-7), 7.11 (d, $J = 8.1$ Hz, H-1), 7.01 (dd, $J = 3.2$, 7.9 Hz, H-5, H-6), 4.04 (t, $J = 6.7$ Hz, H-10), 1.84–0.87 (23H, alkyl chain).

3. Syntheses of the ligands

All homologue materials were prepared similarly. Thus, 0.026 mol of the related amine (4-alkoxy aniline) and 0.026 mol of 5-(4-^{n}dodecyloxyphenylazo)salicylaldehyde were dissolved in 100 ml absolute ethanol with a few drops of glacial acetic acid as a catalyst. The

solution was refluxed for 1 h and then left at room temperature. After cooling, the ligands were obtained as yellow micro crystals. The micro crystals were filtered off, washed with 15 ml of cold absolute ethanol and then recrystallized several times in ethanol–chloroform (1:3, v/v).

L12-8. Yellow, yield 85%. MS *m*/*z* (relative intensity): 614.8 (M + 1,15), 613.8 (M, 65), 443.7 (M − $C_{12}H_{25}$, 23), 324.7 (M − $C_{12}H_{25}OC_6H_4N_2$, 100). *Anal.* Calc. for $C_{39}H_{55}N_3O_3$: C, 76.30; H, 9.03; N, 6.85. Found: C, 76.0; H, 8.8; N, 6.6%. ^{1}H NMR (400 MHz, $CDCl_3$) δ 13.99 (s, H-9), 8.72 (s, H-8), 7.97 (dd, J = 3, 6.7 Hz, H-2), 7.95 (d, J = 6.7 Hz, H-3), 7.87 (dd, J = 3, 6.8 Hz, H-4, H-7), 7.30 (dd, J = 3.1, 7.9 Hz, H-5, H-6), 7.10 (d, J = 8.7 Hz, H-1), 6.99 (dd, J = 2, 8.9 Hz, H-13, H-15), 6.95 (dd, 1.9, 8.8 Hz, H-12, H-14), 4.03 (t, J = 6.5 Hz, H-10), 3.98 (t, J = 6.5 Hz, H-11), 1.85–0.86 (38H, alkyl chain).

L12-12. Yellow, yield 87%. MS *m*/*z* (relative intensity): 670.7 (M + 1,13), 669.7 (M, 60), 500.6 (M − $C_{12}H_{25}$, 25), 380.5 (M − $C_{12}H_{25}OC_6H_4N_2$, 100). *Anal.* Calc. for $C_{43}H_{63}N_3O_3$: C, 78.02; H, 9.59; N, 6.35. Found: C, 77.8; H, 9.4; N, 6.2%. ^{1}H NMR (400 MHz, $CDCl_3$) δ 13.99 (s, H-9), 8.73 (s, H-8), 7.97 (dd, J = 3, 6.8 Hz, H-2), 7.95 (d, J = 2.9 Hz, H-3), 7.88 (dd, J = 3, 6.9 Hz, H-4, H-7), 7.31 (dd, J = 3.0, 7.8 Hz, H-5, H-6), 7.11 (d, J = 8.8 Hz, H-1), 7.00 (dd, J = 1.9, 8.9 Hz, H-13, H-15), 6.95 (dd, 1.9, 8.8 Hz, H-12, H-14), 4.04 (t, J = 6.6 Hz, H-10), 3.99 (t, J = 6.5 Hz, H-11), 1.85–0.87 (46H, alkyl chain).

L12-16. Yellow, yield 87%. MS *m*/*z* (relative intensity): 726.8 (M + 1,12), 725.8 (M,63), 556.7 (M − $C_{12}H_{25}$, 26), 433.7 (M − $C_{12}H_{25}OC_6H_4N_2$, 100). *Anal.* Calc. for $C_{47}H_{71}N_3O_3$: C, 78.62; H, 9.97; N, 5.85. Found: C, 77.1; H, 9.5; N, 5.5%. ^{1}H NMR (400 MHz,

$CDCl_3$) δ 13.99 (s, H-9), 8.73 (s, H-8), 7.97 (dd, J = 3, 6.8 Hz, H-2), 7.95 (d, J = 6.8 Hz, H-3), 7.89 (dd, J = 3, 6.8 Hz, H-4, H-7), 7.30 (dd, J = 3.0, 7.6 Hz, H-5, H-6), 7.12 (d, J = 8.8 Hz, H-1), 7.00 (dd, J = 1.9, 8.8 Hz, H-13, H-15), 6.96 (dd, 2.0, 8.7 Hz, H-12, H-14), 4.04 (t, J = 6.6 Hz, H-10), 3.99 (t, J = 6.5 Hz, H-11), 1.85–0.87 (54H, alkyl chain).

Syntheses of the nickel complexes. The nickel complexes were prepared in a similar manner as described by Nejati et al. [17]. Thus, a solution of 4 mmol of $Ni(CH_3COO)_2{\cdot}4H_2O$ in 10 ml of ethanol was added to an ethanol–chloroform (1:1 v/v) solution containing 8 mmol of ligand, and the resulting solution was refluxed for 2 h. The obtained solution was left at room temperature. The nickel complexes were obtained as yellow-green micro crystals. The micro crystals were filtered off, washed with absolute ethanol and then recrystallized in ethanol–chloroform (1:3 v/v).

Ni12-8. Yellow-green, yield 80%. *Anal.* Calc. for $C_{78}H_{108}N_6O_6Ni$: C, 72.94; H, 8.48; N, 6.54. Found: C, 72.4; H, 8.0; N, 6.2%. ^{1}H NMR (400 MHz, $CDCl_3$) δ 8.13 (s, H-8), 7.97 (dd, J = 2.9, 6.9 Hz, H-2), 7.94 (d, J = 6.6 Hz, H-3), 7.84 (dd, J = 3, 6.8 Hz, H-4, H-7), 7.28 (dd, J = 3.1, 7.9 Hz, H-5, H-6), 7.13 (d, J = 8.5 Hz, H-1), 7.00 (dd, J = 2, 8.8 Hz, H-13, H-15), 6.93 (dd, 1.9, 8.7 Hz, H-12, H-14), 4.24 (t, J = 6.1 Hz, H-11), 4.02 (t, J = 6.5 Hz, H-10), 1.81–0.84 (76H, alkyl chain).

4. Results and discussion

4.1. Synthesis

The Schiff base ligands were synthesized in a four-step process, in which the hydroxy group in 4-nitrophenol is first replaced by an alkoxy chain followed by reduction of nitro group to an amine. In the third step, salicylaldehyde is coupled with the diazonium chloride obtained from the 4-dodecyloxyaniline and finally the Schiff base ligands were obtained by reaction of 5-(4-dodecyloxyphenylazo)salicylaldehyde with an appropriate 4-alkoxyaniline (Scheme 1) by refluxing in absolute ethanol, using a few drops of acetic acid as a catalyst. The Schiff-bases, **2a**–**2c**, were purified by repeated crystallization in an ethanol/chloroform mixture. The 5-(4-^{n}dodecyloxyphenylazo)salicylaldehyde and ligand homologues were characterized by IR, ^{1}H NMR, mass spectroscopy and elemental analyses. The Ni complexes were characterized by C, H, N elemental analyses, ^{1}H NMR and IR spectroscopy. Some physical and characterization data for the ligands and the complexes are given in the experimental section and selected IR data are reported in Table 1. The IR spectra of the nickel complexes show that the stretching frequency of the C=N bond was shifted to lower wavenumbers (ca. 15 cm^{-1}) in comparison with the free ligand after coordination. This shift is due to the reduction of the double bond character of the C=N bond, which is caused by the coordination of nitrogen to the metal center and is in agreement with the results obtained from the other similar complexes described previously [17–19]. On the other hand, the disappearance of the OH band of the free ligands in the spectra of the metal complexes indicates that the OH group has been deprotonated and coordinates to the metal ion as $-O^-$. In addition, a comparison of the ^{1}H NMR spectra of the ligands and the Ni complexes indicates that the proton signal corresponding to the OH group of the free ligands has disappeared in the nickel complexes and a large shielding occurrs for the imine proton H-8 ($\Delta\delta = \delta_{ligand} - \delta_{complex} = 0.7$ ppm). Based on these observations and elemental analyses results, we concluded that the Schiff-base ligands are coordinated to the metal center as bidentate (N–O) ligands in a 2:1 ratio.

We recently reported the crystal structure of bis-[5-((4-^{n}propyloxyphenyl)azo)-*N*-(^{n}-pentyl-salicylaldiminato)] Ni(II) [20], which has a similar coordination environment to that of the title complex of this work. In these kinds of complexes, the Schiff base ligands have an approximately *trans*-planar configuration around the Ni central ion and the structure is square planar. Therefore, we propose that the Ni(II) complexes have square planar or nearly square planar coordination geometry.

4.2. Glass formation

The thermal stability of these materials was checked by thermogravimetric analysis (TGA) at first. All other thermal characterizations were then carried out below the decomposition temperature. Glass forming properties of the Schiff base ligands and the related Ni(II) complexes were studied by differential scanning calorimetry, polarizing optical microscopy (POM) observations utilizing a heating–cooling stage and X-ray diffraction (XRD). The transition temperatures of the ligands and the complexes were measured by DSC. Fig. 1(a)–(c)

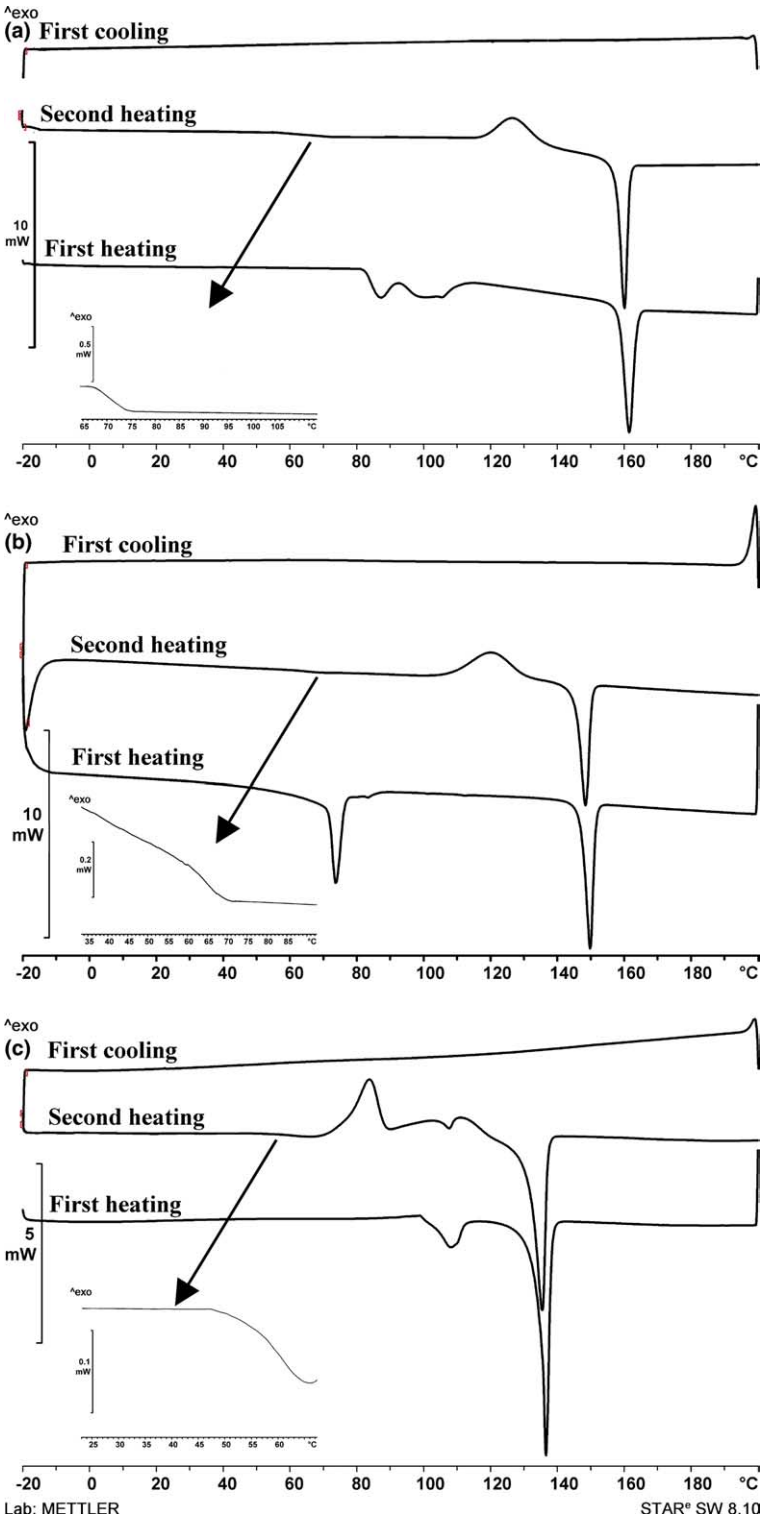

Fig. 2. DSC thermograms of: (a) **Ni12-8**, (b) **Ni12-12** and (c) **Ni12-16**, heating and cooling rate: 10 K min^{-1}.

shows the DSC curves of the ligands. The thermal behaviors of the ligands were similar as it is apparent from the DSC curves; therefore we describe here the behavior of compound **L12-12** as a representative. In the first heating scan, **L12-12** showed four endothermal peaks at 99.1, 102.9, 114.3 and 120.5 °C (Fig. 1(b)). In the second heating scan, four endothermal peaks at 98.1, 101.0, 113.4 and 120.2 °C were observed. When the isotropic melt of **L12-12** was cooled at a cooling rate of 10 K min^{-1}, two exothermal peaks at 108.7, and 99.5 °C were observed (see Fig. 2). The powder XRD patterns of **L12-12** recorded at room temperature prior to heating and after cooling from the isotropic liquid indicated a typical crystalline phase. Therefore, the peaks at 120.5 °C (in the first and second heating scan) are attributed to melting, the peak at 108.7 °C on the cooling step due to crystallization and other peaks may be related to solid–solid phase transitions. The melting peak is narrow and the enthalpy of fusion amounts to 40 kJ mol^{-1}. Such a high value of the enthalpy of fusion is in agreement with the presence of a perfect crystalline state of the compound as found by X-ray analyses [3a]. Melting to the isotropic liquid and crystallization of the isotropic liquid of **L12-12** are confirmed by polarizing optical microscopy and are in agreement with the DSC measurements. On the basis of these observations we can conclude that, due to little difference between melting and crystallization temperatures, the Schiff base ligands do not have a tendency towards supercooling and do not form a glassy state. The tendency of Ni(II) complexes towards glass formation was analyzed using differential scanning calorimetry, POM and XRD. We here again describe the glass-forming behavior of **Ni12-12** as a representative; because the other complexes behave similarly. When a polycrystalline sample of **Ni12-12** obtained by recrystal-

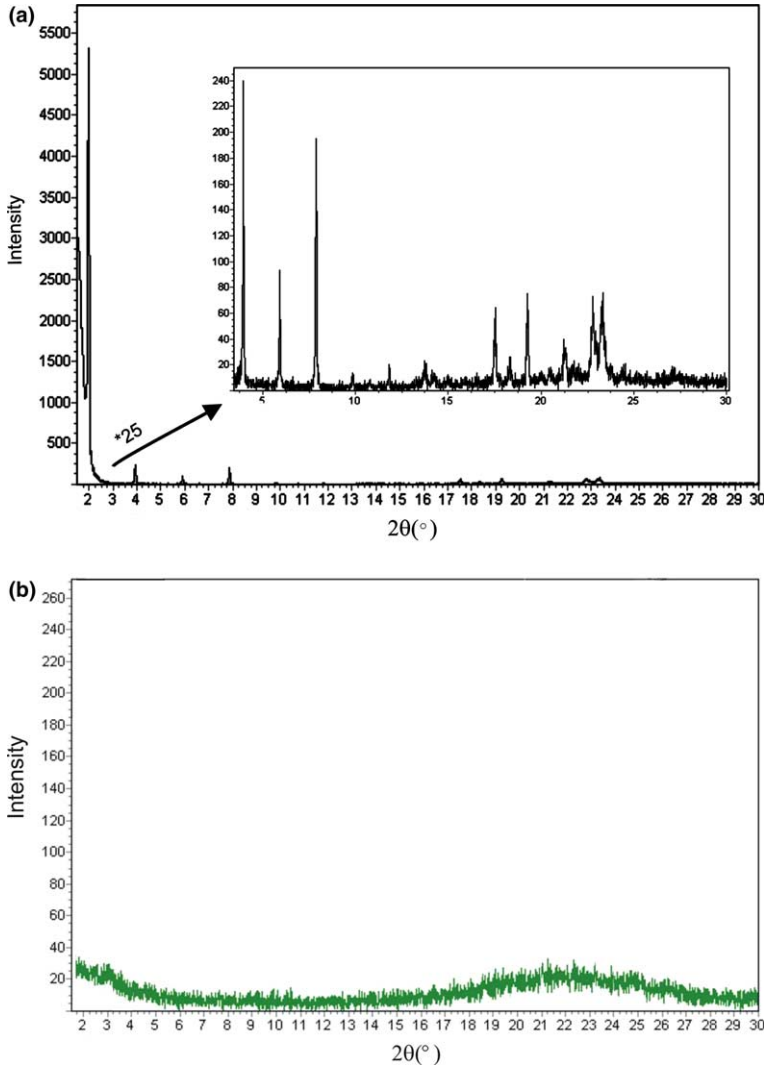

Fig. 3. X-ray diffraction patterns of **Ni12-12**; (a) virgin sample crystallized from ethanol/chloroform, (b) after heating the sample above the melting point and cooling to room temperature.

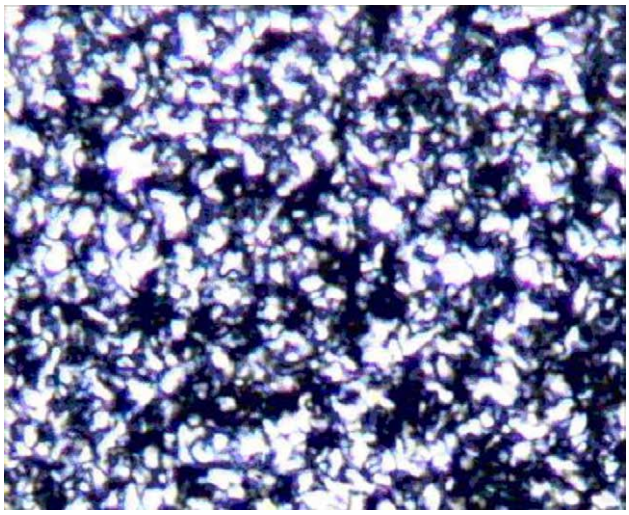

Fig. 4. Optical texture of **Ni12-12** after annealing the isotropic glass phase at room temperature for 7 days between crossed polarizers.

lisation from ethanol/chloroform (1:1 v/v) was heated, two endothermic peaks at 90 and 150 °C due to solid–solid transition and melting were observed. In the cooling cycle no exothermal peaks were observed. When the isotropic liquid was cooled down at the same cooling rate by DSC under polarizing microscopy, a transparent glass was formed via a supercooled liquid. When the amorphous glass sample was again heated, a glass transition phenomenon was observed at 64 °C. On further heating above the glass transition, an exothermic peak was observed at 120 °C due to crystallization producing the same crystals obtained by recrystallization from solution, which melted at 150 °C. Fig. 3 shows the XRD patterns of **Ni12-12**. The powder XRD pattern from virgin crystals of **Ni12-12** (Fig. 3(a)) indicates a crystalline state. In order to determine the amorphous state of **Ni12-12**, the XRD pattern of a sample upon cooling from the isotropic liquid was recorded at room temperature. The XRD pattern of **Ni12-12** after cooling from the isotropic liquid is given in Fig. 3(b). No sharp Bragg peaks were observed in the diffraction pattern of **Ni12-12** and only a broad diffraction hump was observed, indicating an amorphous state. The crystallization process of **Ni12-12** was confirmed by XRD. XRD patterns of **Ni12-12** after annealing the amorphous material at 120 °C for 30 min. and virgin sample are similar, which indicates that the two crystalline phases are identical. Moreover, the high value of the enthalpy of fusion of **Ni12-12** (29.9 kJ mol^{-1}) is in agreement with the presence of a perfect crystalline state of **Ni12-12** as confirmed by the X-ray analyses.

Upon cooling the isotropic liquid of the nickel complexes, only a black field under POM was observed throughout the cooling process even when the temperature reached below −20 °C, which confirms the existence of the amorphous state. However, anisotropic glass phases were found while annealing samples for a long time. When the samples were annealed at room temperature for several days, a schlieren optical texture was formed. Fig. 4 shows the photomicrograph of **Ni12-12** as an example, indicating the formation of a discotic nematic (N_d) mesophase [21]. To further confirm the structure of the mesophase, we carried out XRD experiments. The XRD pattern obtained exhibits only a peak in the small angle area and a broad halo with a wide angle (Fig. 5). On the basis of these observations we can conclude that an anisotropic glass has been formed. Formation of a discotic nematic mesophase in the Ni complexes is in agreement with the discotic structure of the complexes [22]. Thermodynamic data for the Schiff-base ligands and the related Ni complexes are tabulated in Table 2.

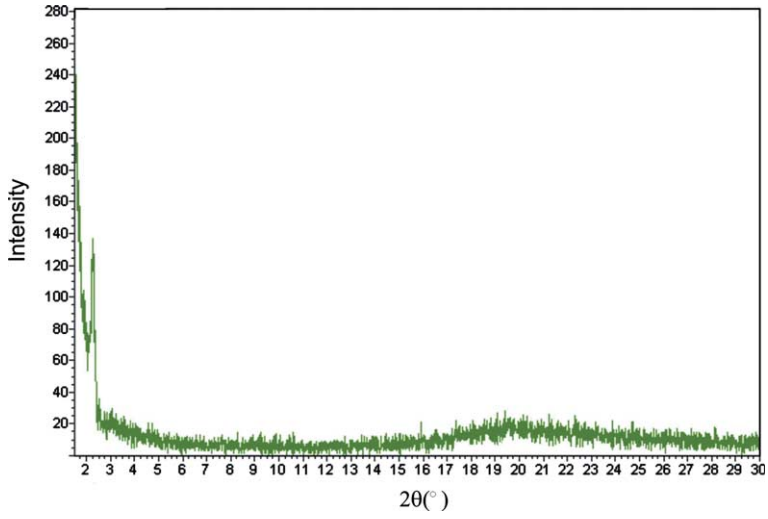

Fig. 5. X-ray diffraction pattern after annealing **Ni12-12** at room temperature for 7 days.

[a] K, crystal; G, glass; I, isotropic.
[b] Overlapped with a previous transition.
[c] Glass transition.

From the above results, it is apparent that the Schiff base ligands do not show any tendency towards glass formation and go to a crystalline phase when cooled from the isotropic liquid, but the related Ni(II) complexes have a great tendency for glass forming and after several days change to an anisotropic glassy state. Some structural requirements such as non-planarity of molecular structure, bulkiness and weight of substitutions and number of conformers of the molecule in the fluid state are responsible for glass formation in organic compounds. Furthermore, the enlargement of molecular size is an important factor for the achievement of the stability of a glassy state [1a]. On the other hand, another requirement is that the molecular system should have a weak tendency towards crystallization despite strong intermolecular attractions [5]. From a structural point of view, the nickel complex is essentially non-planar. It is well known that azobenzene and its *p*,*p*′-substituted derivatives are essentially planar, but the azomethine part of the structure is non-planar. As the X-ray analyses indicates in the crystalline state, in this kind of compound, the two benzene rings (phenylimine and salicylidenic ring) are twisted with respect to the azomethine group plan [23]. The Ni(II) complexes, in comparison with the ligands, have all of the structural requirements to form a glassy state. It is notable that the phenomenon of polymorphism, which is observed for the Ni(II) complexes and suggests the existence of different conformers, is responsible for the formation of the glassy state [1a].

5. Conclusion

In this work, we have prepared a series of nickel complex homologues derived from 5-((4-^{n}alkoxyphenyl)azo)-*N*-(4-^{n}alkoxyphenyl)-salicylaldimine homologues. For the first time, we report the glass forming properties of azo-containing salicylaldimine complexes of nickel. While the Schiff base ligands do not show any glass forming properties, the nickel complexes have a resistance to crystallization and form a glassy state.

$[Os_3Ru(\mu\text{-}H)_2(CO)_{12}(PPh_2H)]$. The reactions of secondary phosphines with $[M_3(CO)_{10}(\mu\text{-dppm})]$ (**1**, M = Ru; **2**, M = Os) have been reported by Azam et al. [14] and Böttcher et al. [15]. The products formed were shown to be dependent on both the metal and steric demands of the phosphines. For example, compound **2** reacts with Ph_2PH in refluxing toluene at 110 °C to give the simple substitution product $[Os_3(CO)_9(\mu\text{-dppm})(Ph_2PH)]$ and the dihydrido–diphosphido compound $[H(\mu\text{-}H)Os_3(CO)_7(\mu\text{-dppm})(\mu\text{-}PPh_2)_2]$ [14], whereas $^tBu_2PH$ gives exclusively the electron deficient compound $[(\mu_3\text{-}H)(\mu\text{-}H)Os_3(CO)_5(\mu\text{-dppm})(\mu\text{-}P^tBu_2)_2]$ [15]. A similar reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ with $^tBu_2PH$ in refluxing heptane gives the corresponding electron deficient compound $[(\mu_3\text{-}H)(\mu\text{-}H)Ru_3(\mu\text{-}CO)(CO)_4(\mu\text{-dppm})(\mu\text{-}P^tBu_2)_2]$ which contains a bridging CO ligand, unlike the homologous osmium isomer [16]. Interestingly, the reaction of **1** with the less bulkyphosphine Cy_2PH leads to the electronically saturated compound $[(\mu\text{-}H)_2Ru_3(CO)_6(\mu\text{-dppm})(\mu\text{-}PCy_2)_2]$ [16]. Recently, we have reported the phosphido and phosphinido clusters $[(\mu\text{-}H)Ru_3(\mu\text{-}PHPh)(CO)_8(\mu\text{-dppm})]$ and $[(\mu\text{-}H)_2Ru_3(\mu_3\text{-}PPh)(CO)_7(\mu\text{-dppm})]$ from the reaction of **1** with $PhPH_2$ in refluxing THF at 66 °C [17]. However, attempts to extend these syntheses to diphenylphosphido bridge complexes did not give the analogous products. We report here that, instead, triruthenium complexes with phosphido, hydrido, CH_2PPh, PPh_2CH_2PPh and PPh ligands were formed via some interesting transformations such as P–C and P–H bonds activations. A part of this work has been described briefly [18].

2. Experimental

All the reactions were performed under a nitrogen atmosphere using standard Schlenk techniques. Solvents were dried and distilled prior to use by standard methods. The starting clusters $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (**1**) [19] and $[Ru_3(CO)_9\{\mu_3\text{-}\eta^2\text{-}Ph_2PCH_2P(C_6H_4)\}]$ (**7**) [8b] were prepared according to known procedures. Infrared spectra were recorded on a Shimadzu FT-IR 8101 spectrophotometer. ^1H and $^{31}P\{^1H\}$ NMR spectra were recorded on a Bruker DPX 400 spectrometer. Chemical shifts for the $^{31}P\{^1H\}$ NMR spectra are relative to 85% H_3PO_4. Fast atom bombardment mass spectra were obtained on a JEOL SX-102 spectrometer using 3-nitrobenzyl alcohol as matrix and CsI as calibrant.

2.1. Reaction of $[Ru_3(CO)_{10}(\mu\text{-dppm})]$ (1) with PPh_2H

To a heptane solution (100 mL) of **1** (0.458 g, 0.473 mmol) was added PPh_2H (0.176 g, 0.945 mmol) and the reaction mixture was refluxed for 1.5 h. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with cyclohexane/CH_2Cl_2 (3:2, v/v) developed four bands. The first band gave $[Ru_3(CO)_6(\mu\text{-}CO)(\mu_3\text{-}CH_2PPh)(\mu\text{-}PPh_2)_2]$ (**3**), (0.094 g, 20%) as pink crystals from hexane/CH_2Cl_2 at −20 °C . IR (ν(CO), CH_2Cl_2): 2052s, 2014s, 2001s, 1964m, 1951m cm^{-1}; $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 47.6 (dd, 1P, J = 19.7, 78.3 Hz), 270.6 (dd, 1P, J = 19.7, 165.9 Hz), 275.9 (dd, 1P, J = 78.3, 165.9 Hz), 19.30 (dd, 1P, J = 25.5, 121.6 Hz). Compound **3** has been characterized by comparing the spectroscopic data with those reported [18]. The second band afforded $[(\mu\text{-}H)Ru_3(CO)_6(\mu_3\text{-}\eta^3\text{-}PPhCH_2PPh_2)(\mu\text{-}PPh_2)_2]$ (**4**) (0.044 g, 8%) as red crystals after recrystallization from hexane/CH_2Cl_2 at −4 °C. *Anal.* Calc. for $C_{49}H_{38}O_6P_4Ru_3$: C, 51.17; H, 3.34. Found: C, 51.29; H, 3.45%. IR (ν(CO), CH_2Cl_2): 2028s, 2000vs, 1967w, 1955m, 1943w cm^{-1}; ^1H NMR ($CDCl_3$): δ 7.24 (m, 35H), 3.04(dd, 2H), −12.25 (virtual dddd, 1H); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 254.5 (ddd, 1P, J = 15.5, 25.3, and 127.5 Hz), 210.10 (dd, 1P, J = 73.7, 127.4 Hz), 51.4 (ddd, 1P, J = 15.7, 73.7, 121.6 Hz), 19.30 (dd, 1P, J = 25.5, 121.6 Hz); FAB MS: m/z 1149 (M^+). The third band gave $[(\mu\text{-}H)_2Ru_3(CO)_5(\mu\text{-dppm})(\mu_3\text{-PPh})(\mu\text{-}PPh_2)_2]$ (**5**) (0.062 g, 10%) as red crystals from hexane/CH_2Cl_2 at −4 °C. *Anal.* Calc. for $C_{60}H_{49}O_5P_5Ru_3$: C, 55.08; H, 3.78. Found: C, 55.31; H, 3.95%. IR (ν(CO), CH_2Cl_2): 2057vs, 2019vs, 2003s, 1961m cm^{-1}; ^1H NMR ($CDCl_3$): δ 7.50–7.12 (m, 40 H), 5.81 (m, 1H), 4.89 (m, 1H), −16.12 (m, 1H), −16.99 (m, 1H); $^{31}P\{^1H\}$ NMR ($CDCl_3$): δ 258.8 (m, 1P), 164.9 (m, 1P), 160.9 (m, 1P), 24.5 (m, 1P), 12.8 (m, 1P); FAB MS: m/z 1307 (M^+). The fourth band gave $[(\mu\text{-}H)_2Ru_3(CO)_6(\mu\text{-dppm})(\mu\text{-}PPh_2)_2]$ (**6**) (0.041 g, 7%) as red crystals from hexane/CH_2Cl_2 at −4 °C. *Anal.* Calc. for $C_{55}H_{44}O_6P_4Ru_3$: C, 53.79; H, 3.62. Found: C, 53.99; H, 3.78%. IR (ν(CO), KBr): 2007vs, 1988s, 1934s, 1934m, 1902m cm^{-1}; ^1H NMR ($CDCl_3$): δ 7.65–7.12 (m, 40H), 4.80 (m, 1H), 4.0 (m, 1H), −16.20 (m, 1H), −17.11 (m, 1H); Mass spectrum: m/z 1227 (M^+).

2.2. Reaction of $[Ru_3(CO)_9\{\mu_3\text{-}\eta^3\text{-}PPhCH_2P(Ph)(C_6H_4)\}]$ (7) with PPh_2H

To a THF solution (35 mL) of **7** (0.150 g, 0.174 mmol) was added PPh_2H (0.0649 g, 0.348 mmol) and dppm (0.1803 g, 0.469 mmol). The reaction mixture was heated to reflux for 1 h. The solvent was removed under reduced pressure and the residue chromatographed by TLC on silica gel. Elution with cyclohexane/CH_2Cl_2 (4:1, v/v) developed several bands. The major band afforded the compound $[(\mu\text{-}H)Ru_3(CO)_6\{\mu_3\text{-}\eta^3\text{-}PPhCH_2PPh_2\}(\mu\text{-}PPh_2)]$ (**4**) (0.070 g, 35%) as red crystals. The minor bands were too small for complete characterization.

2.3. X-ray crystallography

Red crystals of **4** and **5** suitable for diffraction analysis were grown by slow evaporation from a hexane/methylene chloride solution at −4 °C. Crystallographic data were collected at 150 K, using a Bruker-Nonius CCD area detector diffractometer and Mo Kα radiation (λ = 0.71073 Å). The crystal to detector distance was 32 mm, and Ø and Ω scans (1.2° increments, 15 s exposure time) were carried out to fill the Ewald sphere. Data collection and processing were carried out using the program COLLECT [20] and DENZO [21]. Empirical absorption corrections were applied to the data set using multiple and symmetry related data measurements via the program SORTAV [22,23]. The unit cell was indexed on low angle reflections and refined from 25 reflections in a θ range of 12–13°. The structure was solved by direct methods (SHELXS-96) [24] and refined on F^2 by full matrix least squares (SHELXS-97) [25] using all unique data. All non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included in calculated positions (riding model) with U_{iso} set at 1.2 times the U_{eq} of the parent atom. However, due to the poor quality of the crystals of **5**, we are as yet unable to obtain an *R* factor better than 13%. Nevertheless, the connectivities are clearly established and are in agreement with spectroscopic characterization. The crystal data, data collection parameters and refinement results are summarized in Table 1. Selected bond lengths and angles for **4** and **5** are given in Tables 2 and 3, respectively.

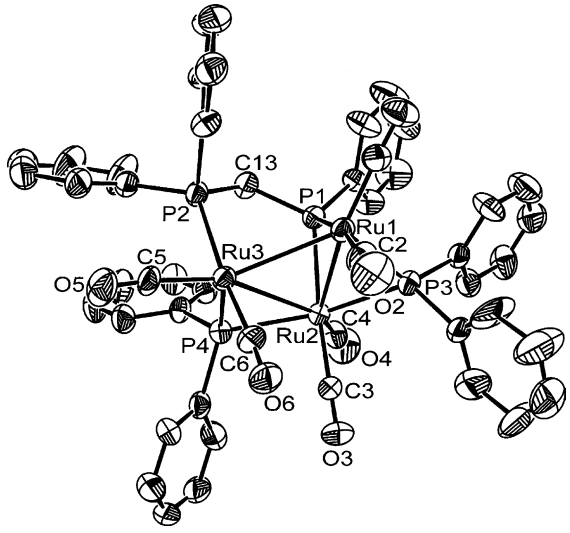
$(\mu_3\text{-CH}_2\text{PPh})(\mu\text{-PPh}_2)_2]$ (**3**), $[(\mu\text{-H})Ru_3(CO)_6(\mu_3\text{-}\eta^2\text{-PPh}_2\text{CH}_2\text{PPh})\text{-}(\mu\text{-PPh}_2)_2]$ (**4**), $[(\mu\text{-H})_2Ru_3(CO)_5\text{-}(\mu\text{-dppm})\text{-}(\mu_3\text{-PPh})(\mu\text{-PPh}_2)_2]$ (**5**) and $[(\mu\text{-H})_2Ru_3(CO)_6\text{-}(\mu\text{-dppm})\text{-}(\mu\text{-PPh}_2)_2]$ (**6**) in 20%, 8%, 10% and 7% yields, respectively (Scheme 1). Compounds **3**–**6** are different from the thermolysis products of **1** which include the triruthenium compound $[Ru_3(CO)_9\{\mu_3\text{-}\eta^2\text{-Ph}_2\text{PCH}_2\text{P-}(C_6H_4)\}]$ (**7**) [8b] and two isomeric binuclear complexes $[Ru_2(CO)_6\{\mu\text{-CH}_2\text{PPh}(C_6H_4)\text{PPh}\}]$ [26] and $[Ru_2(CO)_6\text{-}\{\mu\text{-}(C_6H_4)\text{PPhCH}_2\text{PPh}\}]$ [27].

The new compounds have been characterized by elemental analysis, infrared, ^{1}H NMR, ^{31}P{^{1}H} NMR and mass spectroscopic data together with single crystal X-ray diffraction studies for **4** and **5**. The structure of compound **3**, which contains two bridging PPh_2 groups and a triply bridging $PhPCH_2$ ligand has been discussed previously, and therefore no further comments are needed [18]. The molecular structure of **4** is depicted in

Scheme 1.



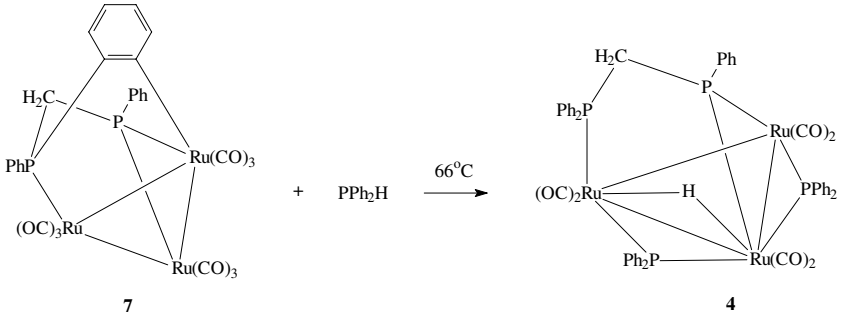


Fig. 1. ORTEP drawing of $[(\mu\text{-H})Ru_3(CO)_6(\mu\text{-PPh}_2)_2\{\mu_3\text{-}\eta^2\text{-PPh}_2\text{CH}_2\text{P(Ph)}\}]$ (**4**). Thermal ellipsoids are drawn at the 50% probability level.

Fig. 1, crystal data are collected in Table 1 and selected bond distances and angles are given in Table 2. The structure consists of a triangular cluster of ruthenium atoms with two elongated metal–metal bonds {Ru(2)–Ru(3) = 2.9862(9) and Ru(1)–Ru(3) = 2.9120(9) Å}, one comparatively shorter metal–metal bond {Ru(1)–Ru(2) = 2.8562(10) Å} and six terminal CO ligands, two bonded to each ruthenium atom. The molecule

contains one triply bridging PPh_2CH_2PPh moiety, two bridging PPh_2 groups and a bridging hydride ligand. The PPh_2CH_2PPh moiety is most probably derived from $PPh_2CH_2PPh_2$ by the cleavage of a P–C bond in **1**, with reductive elimination of a phenyl group as benzene, and the PPh_2 groups are derived from the PPh_2H ligand by P–H bond activation. The longest metal–metal edge is asymmetrically bridged by a PPh_2 ligand, {Ru(2)–P(4) = 2.351(2), Ru(3)–P(4) = 2.302(2) Å}, while the shortest edge is also asymmetrically bridged by the other μ-PPh_2 ligand {Ru(1)–P(3) = 2.276(2), Ru(3)–P(2) = 2.393(2) Å}. The PPh_2 ligands lie on the same plane as the Ru_3 triangle and the Ru–P distances are comparable to those in related phosphido bridged triruthenium clusters [12b,12c,14]. The two Ru–P–Ru angles {Ru(3)–P(4)–Ru(2) = 79.83(7)°, Ru(1)–P(3)–Ru(2) = 75.58(7)°} are nearly the same and comparable to the Ru-P-Ru angles in the phosphido bridged compound $[(\mu\text{-H})_2Ru_3(CO)_8(\mu\text{-}PPh_2)_2]$ [12b]. The bidentate phosphine ligand, PPh_2CH_2PPh sits on the top of the $(\mu\text{-H})Ru_3(CO)_6$ fragment so that the P(2) atom is bonded to the Ru(3) atom while the other P(1) atom bridges Ru(1) and Ru(2) atoms, thus capping one face of the metal framework forming two five-membered Ru(3)–P(2)–C(13)–P(1)–Ru(1) and Ru(3)–P(2)–C(13)–P(1)–Ru(2) metallacycles. A similar bonding mode of the PPh_2CH_2PPh ligand was found in $[(\mu\text{-H})Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}PPh_2CH_2PPh)]$, which was obtained from the thermolysis of **7** in the presence of H_2 at 80 °C [8b]. The Ru–P distances involving the diphosphine ligand {Ru(3)–P(2) = 2.393(2), Ru(1)–P(1) = 2.359(2), Ru(2)–P(1) = 2.373(2), Å} are comparable to the corresponding distances in $[(\mu\text{-H})Ru_3(CO)_9(\mu_3\text{-}\eta^2\text{-}PPh_2CH_2PPh)]$ [8b]. The position of the hydride ligand in **4** could not be reliably located and refined crystallographically but its presence along the longest Ru(2)–Ru(3) edge is on the basis of its bond lengthening effect on the metal triangle [13,28]. This conclusion is further supported by the carbonyl ligands arrangement, in particular the large C(4)–Ru(2)–Ru(3) angle of 145.7(3)° and C(5)–Ru(3)–Ru(2) angle of 157.3(3)° to accommodate the bridging hydride ligand. Compound **4** contains 48 valence electrons, as expected for an electron precise trinuclear cluster containing three metal–metal bonds, and each metal atom can achieve an 18-electron configuration. The formation of compound **4** most probably proceeds via the intermediate formation of the orthometallated compound **7** followed by oxidative addition of two molecules of PPh_2H. To test this hypothesis, we performed the reaction of an authentic sample of **7** (prepared from the thermolysis of **1** by refluxing in cyclohexane at 80 °C [8b]), with PPh_2H in refluxing THF and obtained **4** in 35% yield (Scheme 2).

The spectroscopic data of **4** are in accord with the solid state structure. The mass spectrum shows the molecular ion peak at *m*/*z* 1149. The infrared spectrum shows υ(CO) bands due to the terminal carbonyl ligands. The ^1H NMR spectrum in the hydride region contains a 16 line multiplet at δ −12.25 due to coupling to four non-equivalent ^{31}P nuclei. The $^{31}P\{^1H\}$ NMR spectrum contains four equal intensity signals, two doublet of double doublets at δ 254.5 (J = 15.5, 25.3, 127.5 Hz) and 51.4 (J = 15.7, 73.7, 121.6 Hz) and two doublet of doublets at δ 210.10 (J = 73.7, 127.4 Hz) and 19.30 (J = 25.5, 121.6 Hz) for the four magnetically non-equivalent phosphorus atoms. The strongly deshielded resonances at δ 254.5 and 210.10 are as expected for arylphosphide ligands bridging metal–metal bonds while the resonances at δ 51.4 and 19.30 are consistent with the terminal phosphorus atoms of the PPh_2CH_2PPh ligand [29]. The cross peaks in the ^{31}P–^{31}P COSY spectrum confirms the assignment of the ^{31}P resonances.

The molecular structure of **5** is shown in Fig. 2, crystal data are collected in Table 1 and selected bond distances and angles are given in Table 3. The structure consists of an open cluster of three ruthenium atoms with two metal–metal bonds {Ru(1)–Ru(3) = 3.019(2), Ru(1)–Ru(2) = 2.817(2) Å} and a non-bonded separation of 3.569 Å, along the Ru(2)–Ru(3) edges and five terminal CO ligands distributed as shown in Fig. 2. It contains one μ_3-PPh, two μ-PPh_2, two bridging hydrides and a bridging dppm ligand. The bridging hydrides were not located in the structural analysis but both are believed to bridge the same Ru(1)–Ru(3) vector as the dppm ligand. Thus, the Ru(1)–Ru(3) edge {3.019(2) Å} is significantly longer than the unbridged Ru(1)–Ru(2) edge {2.817(2) Å}. The two phosphorus

7 **4**

Scheme 2.

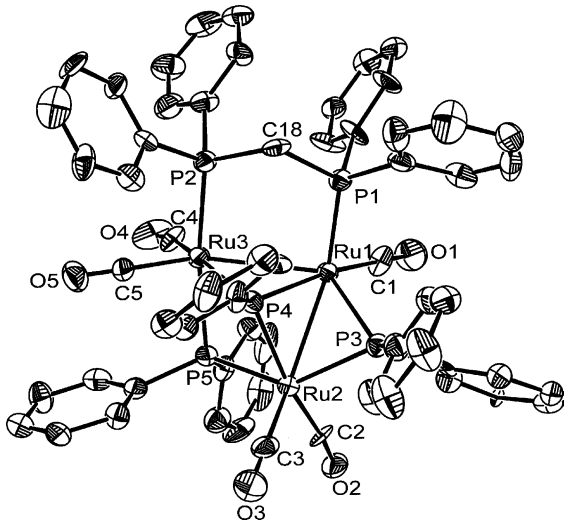

Fig. 2. ORTEP drawing of $[(\mu\text{-H})_2Ru_3(CO)_5(\mu\text{-PPh}_2)_2(\mu\text{-dppm})(\mu_3\text{-PPh})]$ (**5**). Thermal ellipsoids are drawn at the 50% probability level.

atoms, P(1) and P(2), of the dppm ligand are axially bound to Ru(1) and Ru(3) respectively forming a five-membered Ru(1)–Ru(3)–P(2)–C(18)–P(1) metallacycle vertically orientated on the molecular plane. The Ru–P distances involving the dppm ligand {Ru(1)–P(1) = 2.275(5), Ru(2)–P(3) = 2.367(5) Å} are slightly shorter than those found in **1** [30]. Of the two μ-PPh_2 groups, one asymmetrically bridges the closed Ru(1)–Ru(2) edge {Ru(1)–P(3) = 2.341(5), Ru(2)–P(3) = 2.367(5) Å} while the other asymmetrically bridges the open Ru(2)–Ru(3) edge {Ru(2)–P(5) = 2.403(5), Ru(3)–P(5) = 2.436(5) Å}. These values are similar to those found in **4**. As expected the Ru(2)–P(5)–Ru(3) angle of 100.43(19)° is significantly greater than the Ru(1)–P(3)–Ru(2) angle of 73.49(16)° due to metal–metal bonding in the latter. The phosphinidene ligand, PPh, asymmetrically caps the Ru_3 triangle {Ru(1)–P(4) = 2.326(5), Ru(2)–P(4) = 2.376(5), Ru(3)–P(4) = 2.391(5) Å}. As usual, the triply bridging μ_3-PPh ligand acts as a five-electron donor, two μ-PPh_2 ligands donate six electrons and the dppm donates four electrons to the cluster which results in a total of 50 valence electrons. The observation of two formal Ru–Ru bonds present in the trinuclear framework is consistent with the electron count.

The analytical and spectroscopic data of **5** are consistent with the solid-state structure. The IR spectrum of **5** indicates that all the carbonyl groups are terminal. In addition to the usual phenyl resonances, the ^{1}H NMR spectrum in the aliphatic region exhibits two multiplets at δ 5.81 and 4.89 due to methylene protons of the dppm ligand. The hydride region of the ^{1}H NMR spectrum contains two multiplets at δ −16.12 and −16.99 indicating the presence of two bridging hydride ligands. The $^{31}P\{^1H\}$ NMR spectrum shows five multiplets at δ 258.8, 164.9, 160.9, 24.5 and 12.8 due to the five non-equivalent ^{31}P nuclei associated with the cluster. The multiplet at δ 258.8 is assigned to the capping phosphinidene ligand, while the two multiplets at δ 164.9 and 160.9 are due to two μ-PPh_2 ligands and the high field multiplets at δ 24.5 and 12.8 account for the terminal phosphorous atoms of the dppm ligand. The FAB mass spectrum exhibits a molecular ion peak at *m*/*z* 1307 corresponding to the molecular formula of **5**, and fragmentation peaks due to the sequential loss of five carbonyl ligands.

We were unable to obtain X-ray quality crystals of **6** therefore characterization was based on spectroscopic data. The IR spectrum of **6** in KBr indicates that all the carbonyl groups are of a terminal type. In addition to the usual phenyl resonances, the ^{1}H NMR spectrum in the aliphatic region exhibits two multiplets at δ 4.80 and 4.0 due to methylene protons of the dppm ligand. The hydride region of the ^{1}H NMR spectrum contains two equal intensity multiplets at δ −16.20 and −17.11 indicating the presence of two bridging hydride ligands. The spectroscopic data of **6** are very similar to the osmium analogue $[(\mu\text{-H})_2Os_3(CO)_6(\mu\text{-dppm})(\mu\text{-PPh}_2)_2]$ which was obtained from the thermolysis of $[Os_3(CO)_8(\mu\text{-dppm})(PPh_2H)_2]$ and characterized crystallographically [13]. The FAB mass spectrum shows the molecular ion peak at *m*/*z* 1227 consistent with the formulation of **6**, and fragmentation peaks due to the sequential loss of six carbonyl ligands.

4. Conclusion

We have shown that the reaction of **1** with PPh_2H in refluxing heptane afforded the four triruthenium compounds $[Ru_3(CO)_6(\mu\text{-CO})(\mu_3\text{-CH}_2\text{PPh})(\mu\text{-PPh}_2)_2]$ (**3**), $[(\mu\text{-H})Ru_3(CO)_6(\mu_3\text{-}\eta^2\text{-PPh}_2CH_2PPh)(\mu\text{-PPh}_2)_2]$ (**4**), $[(\mu\text{-H})_2Ru_3(CO)_5(\mu\text{-dppm})(\mu_3\text{-PPh})(\mu\text{-PPh}_2)_2]$ (**5**) and $[(\mu\text{-H})_2Ru_3(CO)_6(\mu\text{-dppm})(\mu\text{-PPh}_2)_2]$ (**6**). The X-ray analysis reveals that compound **4** is a closed triangular cluster bearing one bidentate μ_3-η^2-PPh_2CH_2PPh and two μ-PPh_2 ligands whereas compound **5** is an open triangular cluster possessing one μ_3-PPh, two μ-PPh_2 and one dppm ligand. In compound **4**, most probably, the bidentate PPh_2CH_2PPh moiety has been derived from $PPh_2CH_2PPh_2$ by the cleavage of a P–C bond in **1**, and concomitant reductive elimination of benzene via H transfer from a Ph_2PH ligand, simultaneously producing the PPh_2 ligand via oxidative cleavage of the P–H bond. Compound **4** can also be obtained in moderate yield from the reaction of the orthometallated compound **7** with PPh_2H in refluxing THF (66 °C). Compound **5** may be considered as being derived from **1** by the oxidative cleavage of the P–H bond of 3 molecules of PPh_2H to give the three μ-PPh_2 ligands, one of which in turn underwent P–C bond activation to give the μ_3-PPh moiety. The dppm ligand remained intact

during this transformation. Compound **6** is the result of simple oxidative addition of 2 molecules of PPh_2H to **1**.

shown that the similar complexes of first row transition metals are usually six-coordinate [15–19]. The existence of complexes of lanthanides with larger coordination numbers is a natural consequence of their large size, and of the predominantly ionic character of their bonding.

In contrast to tren Schiff bases, there has been less attention to potentially heptadentate Schiff base ligands derived from condensation reactions of other tripodal tetraamines such as tris(3-aminopropyl)amine (tpt or trpn) and corresponding asymmetrical tetraamines with appropriate aldehydes or ketones. We have reported the synthesis and characterization of some complexes of fully condensed potentially heptadentate N_7 and N_4O_3 tripodal Schiff base ligands, derived from template and/or direct condensation reactions of tpt with acetylpyridine and salicylaldehyde, respectively [20–22]. However, herein we report the synthesis and characterization of two new potentially heptadentate Schiff base ligands, H_3L^1 and H_3L^2 (Figs. 1(a) and (c)), together with the synthesis of their gadolinium(III) and samarium(III) complexes (Fig. 3). We report also the synthesis of a gadolinium(III) complex of the previously known ligand H_3L^3 (Fig. 1(e)).

Although, the behavior of the potentially heptadentate N_4O_3 Schiff bases derived from tren as a function of metal ion size has been already investigated by X-ray crystal structure analysis of a series of lanthanide complexes [10–14], the effect of the size of the ligand cavity on encapsulation of a metal ion has been never reported. Therefore, ab initio RHF and density functional B3LYP calculations on La(III) complexes of H_3L^1, H_3L^2 and H_3L^3 ligands as well as their unsubstituted analogues are also reported. In our knowledge, no ab initio or DFT theoretical studies on complexes of potentially heptadentate N_4O_3 ligands have yet been reported.

Fig. 1. Structures of the tripodal heptadentate ligands investigated here.

2. Experimental

2.1. General information

Tris(2-aminoethyl)amine (tren) and the hydrated metal salt were obtained from Aldrich and were used without further purification. The tripodal tetraamine ligands, tris(3-aminopropyl)amine (tpt or trpn) and bis(3-aminopropyl)(2-aminoethyl)amine (ppe), were prepared according to the literature methods [23,24]. 3,5-Di-*tert*-butylsalicylaldehyde (SATBU) [25] and tris-[2-(3,5-di-*tert*-butylsalicylideneimino)-ethyl]amine (H_3L^3) [26] were also prepared as previously described. IR, UV–Vis, and NMR spectra were measured on FT-IR Bomem MB 100, UV-265 FW and Bruker 500 FT-NMR spectrometers, respectively. Conductivity measurements were determined at room temperature in chloroform and toluene solutions (10^{-4} M) on a Metrohm 712 conductometer.

2.2. Theoretical calculations

It is well known that the inclusion of a relativistic effect is essential for heavy-metal complexes, such as second and third row transition metals. Effective core potentials (ECPs) can be used in conventional ab initio methods and in density functional theory, and both methods are most important tools for theoretical calculations of transition metal complexes. Scalar relativistic effects, which replace the chemically inert core electrons by means of a set of parameterized functions that are derived from relativistic calculations, have been included in relativistic ECPs. In addition, the electron-correlation effect is considered in the DFT method itself. In the present work, the geometries of all the Lanthanum complexes were fully optimized at both the restricted Hartree–Fock (RHF) and DFT (B3LYP) [27] levels of theory using the GAUSSIAN 98 program [28] on a Pentium-PC computer with a 2400 MHz processor. At first, all complexes were optimized using the standard LanL2MB basis set [29] and then the resulting structures were used for further calculations using the standard 6-31G* basis set for nitrogen and oxygen donor atoms, 3-21G* basis set for carbon and hydrogen atoms and LanL2DZ for the metal ion [30–32]. Therefore, all complexes were optimized with four different methods. It should be noted that the calculation at a higher level (for example using 6-31G* for all ligand atoms) will be too expensive especially for bulky substituted complexes which consist of 135–144 different atoms.

Vibrational frequency analyses, calculated at the same level of theory, indicate that the optimized structures are at the stationary points corresponding to local minima without any imaginary frequency. A starting molecular

mechanics structure for the ab initio calculations was obtained using the HyperChem 5.02 program [33].

2.3. Ligand synthesis

2.3.1. $\{N[(CH_2)_3N{=}CH(2\text{-}OH\text{-}3,5\text{-}t\text{-}Bu_2C_6H_2)]_3\}\cdot H_2O$ ($H_3L^1\cdot H_2O$)

To a solution of 3,5-di-*tert*-butyl salicylaldehyde (SATBU) (1.4 g, 5.9 mmol) in absolute ethanol (25 ml) was added tpt (0.69 g, 1.98 mmol) in the same solvent (20 ml). The resulting yellow solution was stirred at room temperature for about 45 min. Slow evaporation of the solvent afforded a yellow solid, which was collected by filtration, washed with absolute ethanol and dried in vacuum. Yield: 1.4 g (84%); m.p. 112–114 °C. *Anal*. Calc. for $C_{54}H_{84}N_4O_3(H_2O)$: C, 75.8; H, 10.1; N, 6.5. Found: C, 76.0; H, 10.0; N, 6.6%. IR (cm^{-1}, Nujol): 1633 (s, νC=N).

2.3.2. $\{N[(CH_2)_3N{=}CH(2\text{-}OH\text{-}3,5\text{-}t\text{-}Bu_2C_6H_2)]_2[(CH_2)_2N{=}CH\text{-}(2\text{-}OH\text{-}3,5\text{-}t\text{-}Bu_2C_6H_2)]\}$ (H_3L^2)

A procedure similar to that for H_3L^2 was followed using SATBU (1 g, 4.27 mmol) and ppe (0.52 g, 1.42 mmol). Yield: 1 g (86%); m.p. 139–141 °C. *Anal*. Calc. for $C_{53}H_{82}N_4O_3$: C, 77.3; H, 10.0; N, 6.8. Found: C, 77.0; H, 10.0; N, 6.8%. IR (cm^{-1}, Nujol): 1634 and 1610sh (νC=N).

2.4. Synthesis of the gadolinium complexes

2.4.1. $[Gd(L^1)]$ (**1**)

To a solution of H_3L^1 (0.3 g, 0.358 mmol) in methanol (25 ml) and chloroform (5 ml) was added $Gd(NO_3)_3\cdot 6H_2O$ (0.161 g, 0.358 mmol) in methanol (5 ml). After addition of NaOH (0.058 g, 1.43 mmol) in methanol (5 ml), the solution was refluxed for 6 h. The resulting mixture was filtered to give a yellow powder. This powder was washed with small amounts of methanol and chloroform. Recrystallization in toluene afforded a microcrystalline solid, which was collected by filtration, washed with cold toluene and dried in vacuum. Yield: 0.26 g (70%); m.p. > 200 °C dec. *Anal*. Calc. for $C_{54}H_{81}GdN_4O_3(C_7H_8)_{0.75}$: C, 66.5; H, 8.3; N, 5.3. Found: C, 67.1; H, 7.9; N, 5.0%. IR (cm^{-1}, Nujol): 1615 (s, νC=N).

2.4.2. $[Gd(L^2)]$ (**2**)

This complex was prepared analogously using $Gd(NO_3)_3\cdot 6H_2O$ (0.164 g, 0.364 mmol) and H_3L^2 (0.3 g, 0.364 mmol). The solution was filtered and the filtrate was left standing at room temperature, where slow evaporation yielded a yellow powder. This powder was washed with small amounts of methanol and chloroform. Recrystallization in toluene afforded a microcrystalline solid. Yield: 0.2 g (54.0%); m.p. > 200 °C dec. *Anal*. Calc. for $C_{53}H_{79}GdN_4O_3(C_7H_8)_{0.75}$: C, 66.8; H, 8.2; N, 5.4. Found: C, 66.7; H, 8.2; N, 5.1%. IR (cm^{-1}, Nujol):1616 (s, νC=N).

2.4.3. $[Gd(L^3)]$ (**3**)

This complex was prepared analogously using $Gd(NO_3)_3\cdot 6H_2O$ (0.0835 g, 0.185 mmol) and H_3L^3 (0.147 g, 0.185 mmol). The resulting mixture was filtered to give a yellow powder. This powder was washed with small amounts of methanol and chloroform. Recrystallization in toluene afforded a microcrystalline solid. Yield: 0.19 g (49%); m.p. > 200 °C dec. *Anal*. Calc. for $C_{51}H_{75}GdN_4O_3(C_7H_8)_{0.5}$: C, 65.8; H, 8.0; N, 5.6. Found: C, 65.6; H, 7.9; N, 5.4%. IR (cm^{-1}, Nujol): 1616 (s, νC=N).

2.5. Synthesis of samarium complexes

2.5.1. $[Sm(L^1)]$ (**4**)

To a solution of H_3L^1 (0.3 g, 0.358 mmol) in methanol (25 ml) and chloroform (5 ml) was added $Sm(CH_3COO)_3$ (0.117 g, 0.358 mmol) in DMF (5 ml). After addition of NaOH (0.058 g, 1.43 mmol) in methanol (5 ml), the solution was refluxed for 6 h. The resulting mixture was filtered to give a yellow powder. Recrystallization in toluene afforded a microcrystalline solid, which was collected by filtration, washed with cold toluene and dried in vacuum. Yield: 0.19 g (55%); m.p. > 200 °C dec. *Anal*. Calc. for $C_{54}H_{81}SmN_4O_3(C_7H_8)_{0.5}$: C, 66.7; H, 8.3; N, 5.4. Found: C, 66.5; H, 8.1; N, 5.2%. IR (cm^{-1}, Nujol): 1617 (s, νC=N).

2.5.2. $[Sm(L^2)]$ (**5**)

This complex was prepared analogously using $Sm(CH_3COO)_3$ (0.119 g, 0.364 mmol) and H_3L^2 (0.3 g, 0.364 mmol). The resulting mixture was filtered to give a yellow powder. This powder was washed with small amounts of chloroform and methanol, recrystallized in toluene and dried in vacuum. Yield: 0.16 g (45%); m.p. > 200 °C dec. *Anal*. Calc. for $C_{53}H_{79}SmN_4O_3(C_7H_8)_{0.5}$: C, 66.5; H, 8.2; N, 5.5. Found: C, 66.3; H, 8.1; N, 5.3%. IR (cm^{-1}, Nujol): 1615 (s, νC=N).

3. Results and discussion

3.1. Ligands synthesis

Two new potentially heptadentate tripodal Schiff base ligands H_3L^1 and H_3L^2 have been easily prepared from the reaction of tripodal tetraamine ligands tpt and ppe with 3 equiv. of SATBU. These tribasic lipophilic ligands have two *tert*-butyl groups at the 3- and 5-positions of the salicylidene group and are soluble in slightly polar solvents such as chloroform and methanol, and are insoluble in water. The analytical

s, singlet; d, doublet; t, triplet; m, multiplet; b, broad.

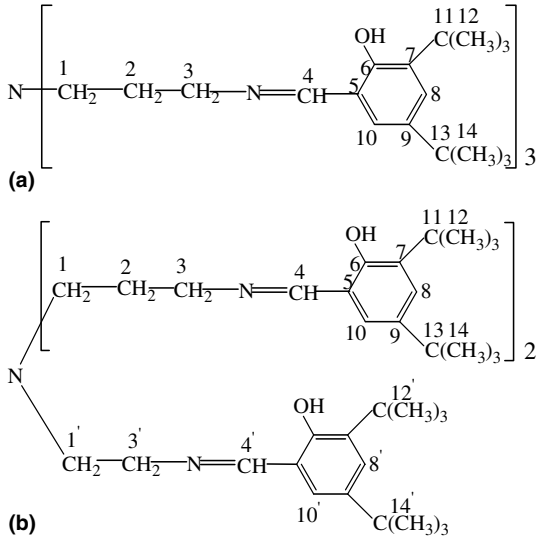

Fig. 2. NMR numbering for (a) H_3L^1 and (b) H_3L^2.

and spectral data are completely consistent with the proposed formulation. The ^{1}H NMR and ^{13}C{^{1}H} NMR spectral assignments for H_3L^1 and H_3L^2 are given in Table 1. The NMR numbering of the atoms is shown in Fig. 2. It should be noted that the H_3L^2 is first example of an asymmetrical tripodal heptadentate N_4O_3 ligand, which is derived from an asymmetrical tripodal tetraamine.

3.2. Gadolinium and samarium complexes

Three new gadolinium(III) complexes, [Gd(L^{1-3})], and two new samarium(III) complexes, [Sm(L^{1-2})], have been synthesized from the reaction of 1 equiv. of each potentially heptadentate tripodal Schiff base ligands with 1 equiv. of the appropriate metal salt in the presence of 4 equiv. of sodium hydroxide. For all resulting complexes, which are insoluble in water, conductivity data in toluene and chloroform show non-ionic behavior, consistent with a neutral product. Furthermore, IR spectra as well as elemental analysis do not show any counter ion or coordinating nitrate anion in any

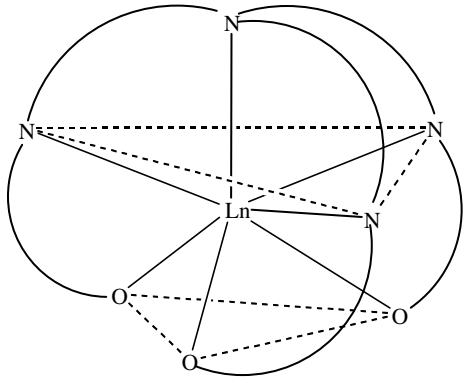

Fig. 3. The simplified proposed structure around the lanthanide ion of [Ln(L^{1-3})] (Ln = Gd or Sm) complexes.

of the complexes and are consistent with the [Ln(L)] formulation. A simplified geometrical structure for these complexes is illustrated in Fig. 3.

3.2.1. IR spectra

The IR spectra of the synthesized complexes contain strong bands characteristic of imine C=N bands, confirming the complexation of the lanthanide ions and absence of ligand hydrolysis. Upon coordination to the metal center, the imine C=N stretch in the IR spectra dropped from 1633, 1634 and 1630 cm^{-1} in the free ligands, H_3L^1, H_3L^2 and H_3L^3, respectively, to 1615, 1616 and 1616 cm^{-1} in the related gadolinium(III) complexes and to 1617 and 1615 cm^{-1} in the related samarium complexes. A similar observation was reported for [Sm(L^3)] and [Nd(L^3)] complexes [11]. Deprotonation of all phenolic functions is confirmed by the lack of O–H stretching bands in the IR region 2500–3500 cm^{-1} for all the complexes. The full IR spectral data (1700–500 cm^{-1}) for complexes **1**, **3** and **4** are compared in Table 2 with those of the previously known complex [Sm(L^3). As can be seen, the IR spectra of the gadolinium complexes are very similar to each other and to those of the corresponding samarium complexes thus indicating that all complexes have the same structure and symmetry.

3.2.2. Electronic spectra

Electronic absorption data for all complexes together with those of the related Schiff base ligands are shown in Table 3. The electronic absorption spectrum of H_3L^3 and the related gadolinium(III) complex are compared in Fig. 4, other compounds described here have similar spectra. As can be seen upon coordination of the ligand to metal, the electronic absorption band of the imine bond (above 300 nm) and even that of the phenolic ring (below 300 nm) are changed in position and intensity. This, in addition to the IR data, confirms the coordination of both latter moieties to the metal ion.

Table 3
Electronic spectroscopy data (nm) for H_3L^{1-3} and related complexes

Compound	λ_{max} (solution, $CHCl_3$–CH_3CN)[a]

3.2.3. X-ray crystal structure of similar complexes

Although the spectral and analytical data show that new neutral lanthanide complexes with the general formula [Ln(L)] are formed, there is this question: is the tertiary nitrogen atom of the new ligands described here normally coordinated to the metal ion?

Essig and co-workers [11] have recently reported the synthesis and X-ray crystal structures of the complexes $[Ln(L^3)](C_7H_8)_{0.5}$ (Ln = Sm, Nd). X-ray diffraction of these complexes shows that the geometry about the metal centers is distorted capped octahedral, and the metal atoms are coordinated by a triply deprotonated N_4O_3 heptadentate ligand. In $[Sm(L^3)]$, Sm–N distances are of two types; an average of 2.556(3) Å to the three imine nitrogen atoms, and a significantly longer interaction of 2.818(4) Å with the apical amine nitrogen. In [Nd(L1)], Nd–N distances are also of two types, an average of 2.586(5) Å to the three imine nitrogens, and a 2.811(5) Å contact with the apical amine nitrogen. Furthermore, X-ray crystal structures of some lanthanide derivatives of a range of similar Schiff base ligands of the type $\{N[CH_2CH_2N{=}CH(2\text{-}OH\text{-}3\text{-}t\text{-}BuC_6H_3)]_3\}$ (H_3L) have also been reported [8–14]. In these neutral 1 + 1 metal–ligand complexes [ML] (M = La, Ce, Sm, Tb, Y, Lu), the apical amine nitrogen–metal distance is in the range of 2.984(4)–2.658(2) Å. Therefore, it is obvious that all reported neutral complexes of lanthanide ions with Schiff bases derived from condensation reactions of tren with various ring substituted salicylaldehydes are seven-coordinate. Thus, it is clear that the structure of $[Gd(L^3)]$ should be similar to $[Sm(L^3)]$ and the above complexes. On the other hand, because of the similar spectroscopic and analytical data for $[Gd(L^{1-3})]$ and $[Sm(L^{1-3})]$ complexes, the structures of $[Ln(L^{1-2})]$ (Ln = Gd, Sm) complexes are probably the same as $[Gd(L^3)]$ and $[Sm(L^3)]$. Therefore, we believe that the gadolinium and samarium atoms in the neutral Schiff base complexes under consideration here, like the above complexes, are completely enclosed by the triply deprotonated N_4O_3 Schiff base ligands and the coordination geometry is probably capped octahedral (or distorted capped trigonal antiprism) (Fig. 3).

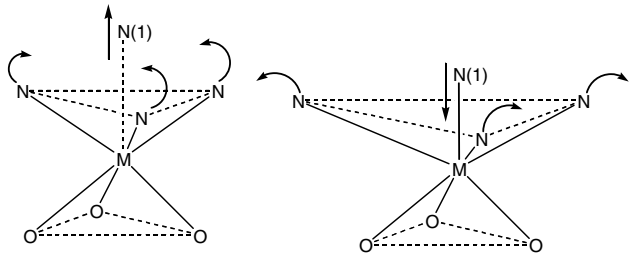

Fig. 5. Illustration of the expansion of the triangular face defined by imine nitrogen atoms, and increasing the sizes of N_{im}–M–N_{im} and N(1)–M–N_{im} bond angles upon coordination of the tertiary nitrogen atom to the metal.

Unfortunately there is only one reported X-ray crystal structure analysis for complexes of potentially heptadentate tripodal Schiff bases derived from tpt [21]. It has been confirmed that in contrast to Schiff base complexes derived from tren, $[M(py_3\ tren)]^{2+}$ (M = Mn, Fe, Co, Ni, Cu, Zn, Cd) which are all six-coordinate [34], $[Cd(py_3\ tpt)]^{2+}$, $[Cd\{N[(CH_2)_3N{=}C(CH_3)\text{-}(C_5H_4N)]_3\}]^{2+}$, is seven-coordinate. The Cd(II)-unique nitrogen distance, 2.486 Å, in the latter complex is about the weighted mean of the other Cd–N distances, 2.425 Å. and is even shorter than one of the Cd–N_{py}

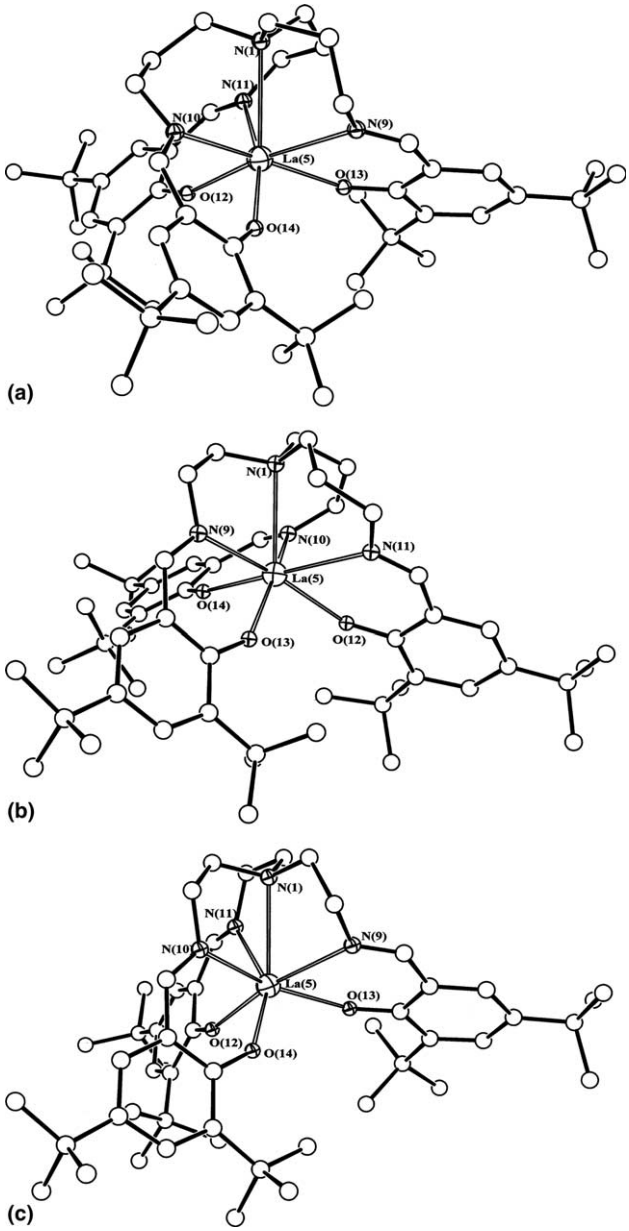

Fig. 6. Calculated molecular structure of (a) $[La(L^1)]$, (b) $[La(L^2)]$ and (c) $[La(L^3)]$ complexes, at the B3LYP level of theory, using the standard 6-31G* basis set for nitrogen and oxygen donor atoms, 3-21G* basis set for carbon and hydrogen atoms and LanL2DZ for the metal ion. Hydrogen atoms are omitted for clarity.

distances, 2.572 Å. This is probably due to the great intrinsic flexibility of propylene chains, in the latter complex. But from this single experimental observation it is not obvious that we will meet similar results in coordination of the tren and trpn Schiff bases to large metals such as lanthanides.

3.3. Ab initio and DFT studies

We were interested to study the relative capability of potentially heptadentate (N_4O_3) ligands, described here to encapsulate lanthanide ions. Unfortunately due to SCF convergence problems we were not able to optimize the gadolinium(III) and samarium(III) complexes synthesized here. This was due to inherent complications, first, to electronic effects, resulting from partially filled f-orbitals, and second, to the size of these bulky molecules. Thus we decided to choose La(III) complexes of H_3L^1, H_3L^2 and H_3L^3 as well as their unsubstituted analogs for ab initio studies. La(III) is an ion with a closed shell configuration and its stereochemistry is similar to Gd(III) and Sm(III) metal ions. On the other hand it is well known that calculations on closed shell configurations are less expensive than that of open shell configurations. Therefore, considering La(III) as the central lanthanide ion, the comparison of the capability of these ligands to encapsulate the lanthanide ion will make less expensive calculations. Although the parameters obtained for the [La($L^{1–3}$)] and [La($L^{1'–3'}$)] complexes at the different levels of theory described here are not identical, all calculations show that the three imine and the unique tertiary nitrogen donor atoms as well as the three phenolate oxygen donor atoms arranged at apices of a distorted capped octahedral (Figs. 6(a)–(c)). Selected bond lengths and bond angles of all complexes calculated with the LanL2MB basis set are compared in Table 4 and those calculated with the standard 6-31G* basis set for nitrogen and oxygen donor atoms, 3-21G* basis set for carbon and hydrogen atoms and LanL2DZ for the metal ion are given in Table 5. As can be seen in Table 4, the considerable difference between the parameters obtained from RHF/LanL2MB calculations relative to those from B3LYP/LanL2MB is in La–N and La–O bond lengths, where La–N bond lengths are slightly longer and La–O bond lengths are always slightly shorter in the former calculation. On the other hand, the significant difference between the parameters obtained from LanL2MB calculations (Table 4) with those derived from calculations at a higher level of theory (Table 5) is only in La–O bond lengths and therefore in calculated values for T_O. The mean of bond lengths and bond angles about the metal center in the substituted and unsubstituted derivatives are almost same, and thus the introduction of bulky *tert*-butyl substituents seems to have essentially no significant effect upon the geometry of the LaN_4O_3 core. In all bulky substituted complexes the La–tertiary nitrogen distance, La–N(1), is usually slightly longer than other bonds. As

The parameters obtained at the HF level are given as plain text, those for the B3LYP level are in bold. T_N and T_O are the sum of the calculated lengths of the sides of the triangle defined by imine nitrogen atoms and oxygen atoms, respectively.

can be expected, the N(1)–La–N(imine) and N(imine)–La–N(imine) bond angles are greater for [La(L^1)] and [La(L^2)] complexes and also their unsubstituted analogs, in which the tertiary nitrogen atom, N(1), is connect to imine nitrogen atoms through propylene chains. On the other hand, in all complexes, the size of the triangle defined by the oxygen atoms is always much smaller than that of imine nitrogen atoms. Obviously, upon coordination of a tertiary nitrogen atom to the metal atom the triangular face defined by the other coordinated nitrogen atoms is expanded and the three N(1)–La–N(imine) bond angles as well as the three N(imine)–La–N(imine) bond angles are increased (Fig. 5). The expansion of this triangular face in these complexes can be readily compared by the sum of the calculated lengths of the sides of the triangle defined by the imine nitrogen atoms, T_N (see Tables 4 and 5). The results show that the latter expansion for [La(L^1)] and [La($L^{1'}$)] is more significant. The mean of the bond lengths and bond angles about the metal center for the calculated structure of [La(L^3)] and the corresponding experimental data for previously known lanthanide complexes, [Sm(L^3)] and [Nd(L^3)] [11], are compared in Table 6. It seems that the results of B3LYP calculations are more reliable than those of RHF calculations. The mean of the bond angles about the central metal atom for La, Nd and Sm complexes is very similar, indicating that the chemical structure of these complexes strongly depends on the structure of these tripodal ligands. The

Table 6

The theoretical data are derived from Table 5 and the experimental values are obtained from [11].

La–N_{im} and La–O bond lengths, as we expect, are considerably greater than similar bond lengths in Sm and Nd complexes. On the other hand there is no significant difference between the Ln–N(1) bond length in these complexes. Note that the Nd–N(1) bond length is even smaller than Sm–N(1) indicating that the comparison of metal–N(1) bond lengths based on the ionic radii of the central metal ions is incorrect. The latter conclusion was supported by the observation that most of the similar complexes of the first row transition metals involve an N_3O_3 donor set of the ligands, with the tertiary nitrogen atom, (N(1)), remaining uncoordinated [15–19].

4. Conclusions

Two new bulky tripodal Schiff base ligands and the related neutral gadolinium(III) and samarium(III) complexes as well as the gadolinium(III) complex of one previously known ligand were synthesized and characterized with various spectroscopic methods. We believe that gadolinium and samarium atoms in these neutral complexes are coordinated by an apical nitrogen atom, three imino groups and three phenolate oxygen donor atoms. The results of this work, as well as previous observations, show that the introduction of bulky *tert*-butyl substituents seems to have essentially no significant effect upon the geometry of the LaN_4O_3 core. The present ab initio study as well as experimental data also confirm that the potentially heptadentate tripodal Schiff bases, derived from a condensation reaction of trpn and ppe with salicylaldehyde derivatives, the same as similar Schiff bases derived from tren, can effectively encapsulate the lanthanide ions and enforce a seven-coordinate geometry. Obviously, the tertiary nitrogen atom of these tripodal ligands will coordinate to the metal atom if the triangular face defined by the other coordinated nitrogen atoms is expanded, and the present data show that by increasing the number of propylene chains, from the complexes of L^3 to L^1 tripodal ligands, this expansion will be more considerable.

for $Ag[Gd(dipic)_2(H_2O)_3] \cdot 3H_2O$ [8], $[M(dipicH_2)(OH_2)_3][Ce(dipic)_3] \cdot nH_2O$ [5b,c] (M = Ca, $n = 5$; M = Sr, $n = 6$), $[Ln(dipic)_3Mn_{1.5}(H_2O)_3] \cdot nH_2O$ [9] (Ln = Pr, $n = 2$; Ln = Gd, $n = 3.5$; Ln = Er, $n = 3$) and $[Yb(dipic)_3Mn_{1.5}(H_2O)_m] \cdot nH_2O$ [10] ($m = 3$, $n = 1.5$; $m = 6$, $n = 6$). Studies involving $dipicH_2$, Ce^{4+} and Ba^{2+} show that different novel chains and networks can be obtained depending on the conditions of crystallization. These are reported in the present paper.

2. Experimental

2.1. Materials

$BaCl_2 \cdot 2H_2O$ and $(NH_4)_2Ce(NO_3)_6$ were purchased from Ranbaxy Chemicals. $DipicH_2$ was purchased from Lancaster Chemicals.

2.2. Preparation of $Ba(dipicH_2)(OH_2)_4Ce(dipic)_3 \cdot 4.6H_2O$ (1)

To a 5 mL aqueous solution of $BaCl_2 \cdot 2H_2O$ (0.245 g, 1.00 mmol) and $(NH_4)_2Ce(NO_3)_6$ (0.549 g, 1.00 mmol), 40 mL methanolic solution of $dipicH_2$ (0.668 g, 4.00 mmol) was added slowly while stirring. As the methanolic solution was being added, the color changed from deep red to orange to pale yellow. After stirring for about 5 min, a small amount of precipitate formed was removed by filtration. The clear filtrate gave yellow crystalline material. Yield: 0.701 g (0.640 mmol, 64%). Recrystallization from hot water yielded pale yellow single crystals of **1** suitable for X-ray data collection. *Anal.* Calc. for $C_{28}H_{31.2}BaCeN_4O_{24.6}$ (MW 1094.83): C, 30.72; H, 2.87; N, 5.12. Found: C, 31.30; H, 1.91; N, 5.44%. IR (KBr disk, cm^{-1}): 3428, 1607, 1568, 1441, 1375, 1275, 1188, 1082, 1018, 916, 727, 682.

[a] Symmetry transformation used to generate equivalent atoms: (#1) $x-1, y-1, z$; (#2) $x+1, y+1, z$.

2.3. Preparation of $Ba(OH_2)_6Ce(dipic)_3$ (**2**)

To a 10 mL aqueous solution of $BaCl_2 \cdot 2H_2O$ (0.499 g, 2.04 mmol) and $(NH_4)_2Ce(NO_3)_6$ (1.109 g, 2.022 mmol), 60 mL methanolic solution of dipicH_2 (1.000 g, 5.983 mmol) was added slowly while stirring. As the methanolic solution was being added, the color changed from deep red to orange to pale yellow. After stirring continuously for 3 h a pale yellow precipitate formed, which was separated by filtration, washed with cold methanol and dried. Yield: 1.165 g (1.322 mmol, 66%). Recrystallization from hot water yielded yellow needles of **2** suitable for X-ray data collection. *Anal.* Calc. for $C_{21}H_{21}BaCeN_3O_{18}$ (MW 880.86): C, 28.63; H, 2.40; N, 4.77. Found: C, 29.14; H, 2.50; N, 4.29%. IR (KBr disk, cm^{-1}): 3437, 1618, 1427, 1338, 1186, 1080, 1024, 920, 770, 731, 667.

2.4. Preparation of $Ba(OH_2)_4Ce(dipic)_3 \cdot 2H_2O$ (**3**)

Compound **2** (0.735 g, 0.834 mmol) was dissolved in 75 mL hot water and filtered. The pH of the solution was adjusted to about 2 by adding a few drops of 0.1 N HNO_3 and it was refluxed at 100 °C for 3 days and concentrated to 25 mL on a water bath. The filtered solution was kept for slow evaporation at room temperature. Yellow prisms of **3** were collected after 5 days.

2.5. X-ray crystallography

X-ray data were collected for compounds **1**, **2** and **3** on an Enraf Nonius CAD-4 diffractometer using graphite monochromated Mo Kα radiation. The data were reduced using XTAL 3.4 [11] and absorption corrections (refdelf [12] or psi-scan [13]) were applied. The structures were solved by a combination of heavy atom and direct methods and refined (over F^2) by least squares techniques using SHELXL-97 [14]. Drawings were made using ORTEP-III [15] and RASMOL 2.6 [16]. One of the four coordinated water molecules in **1** was disordered in two positions, while seven out of eight lattice water sites were refined with occupation factor less than unity. In **3**, two of the four coordinated water molecules were disordered in two positions. The crystal data for the three compounds are presented in Table 1, and selected interatomic distances and angles are in Tables 2–4.

Powder diffractograms were measured using a PW3710 model Philips Analytical X-ray diffractometer.

3. Results and discussion

3.1. Synthesis

The formation of the three compounds **1**, **2** and **3** is controlled by a subtle balance of reaction conditions (solvent, temperature and pH). It was found that the variations in the relative amounts of starting materials used, within reasonable limits, do not play a decisive role in determining the product formed. In order to

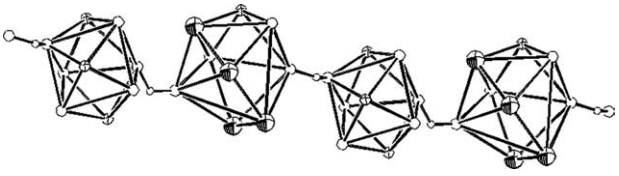

Fig. 2. Perspective view of a segment of the polymeric chain formed by the linking of coordination polyhedra in **1**. Three $dipic^{2-}$ nitrogen atoms (footballs) cap the trigonal prism formed by carboxylate oxygen atoms (large open circles) around Ce. The trigonal prism around Ba is formed by four water molecules (large shaded footballs), one $dipicH_2$ nitrogen atom and four carboxylate oxygen atoms. The alternating $BaNO_8$ and CeN_3O_6 polyhedra are linked by carboxylate groups (C1 and C21, small open circles). The Ba and Ce atoms are not shown.

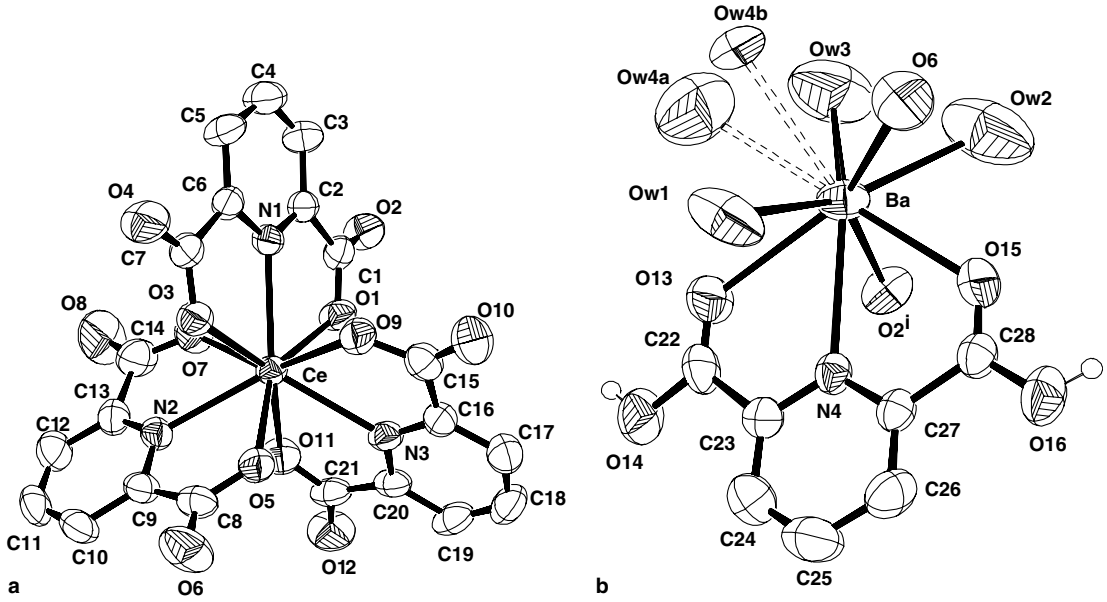

Fig. 1. ORTEP view of the coordination environment of (a) Ce^{4+} and (b) Ba^{2+} in **1**. In this and later ORTEP drawings, atoms are represented as 50% probability ellipsoids and ring and water hydrogens have been omitted for clarity. Symmetry code: (i) $x+1,\ y+1,\ z$. In (b), bonds to disordered atoms are indicated by broken lines.

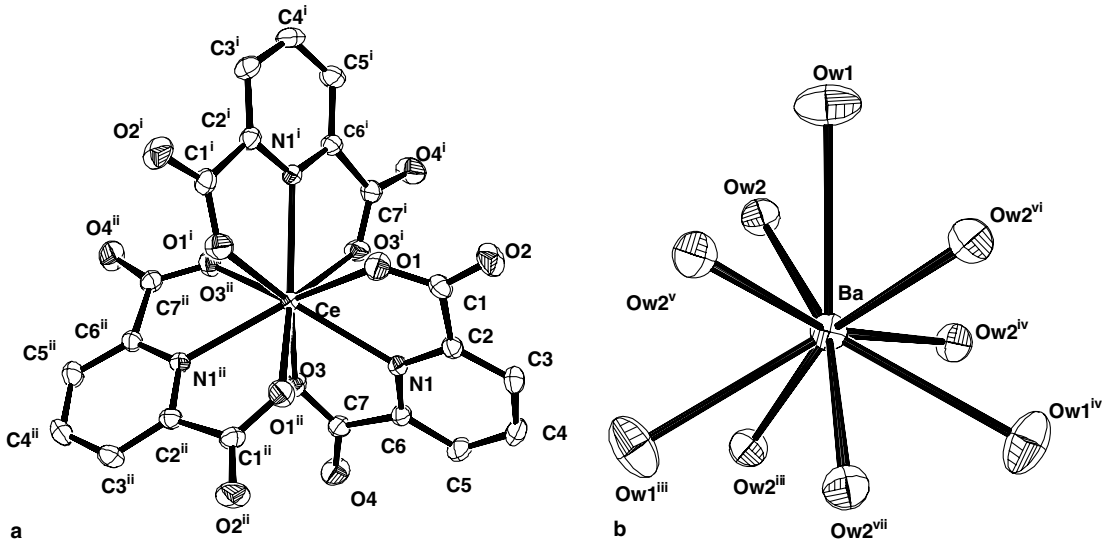

Fig. 3. ORTEP view of the coordination environment of (a) Ce^{4+} and (b) Ba^{2+} in **2**. relate the precipitate obtained to the crystalline compounds as well as to establish that the X-rayed single crystal represents the bulk sample, the experimental powder diffractograms were compared with diffractograms calculated [17] based on the crystal structures.

Prolonged stirring of the initial methanol–water solution produces a precipitate, which is essentially compound **2**. On the other hand, if the methanol–water solution is allowed to evaporate slowly, a pure crystalline form of **1** is obtained in good yield. The precipitate of **2** formed upon stirring the initial preparative solution, can be crystallized from hot water to yield **2** in the pure form. Much of the crystallization in this case is complete by the time the hot aqueous solution cools to room temperature. Compound **3** was obtained as a minor side product from this solution. It crystallizes only after the second crop of **2** is removed, and the solution is reduced to about

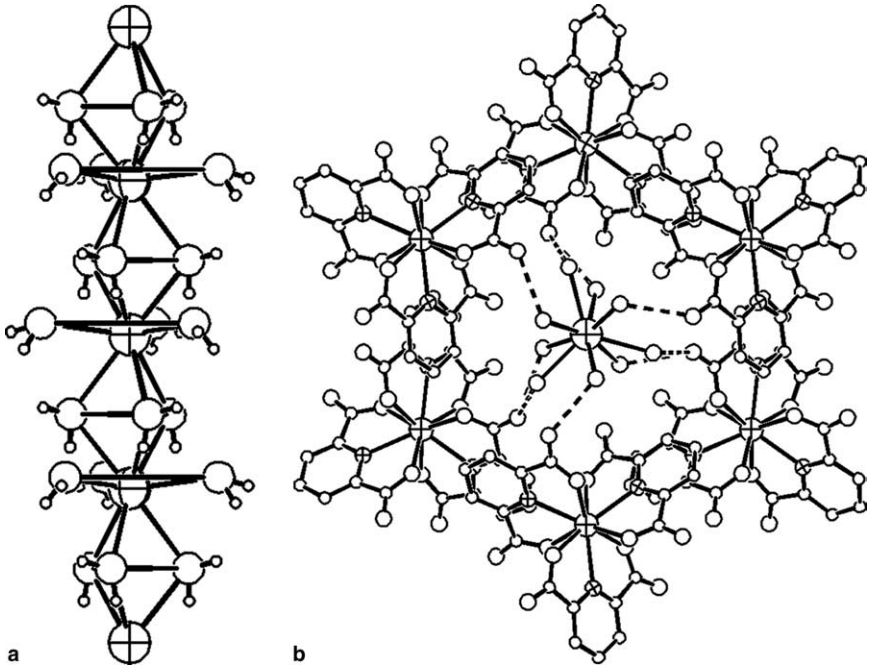

Fig. 4. (a) The polymeric chain of $Ba(OH_2)_6$ units in **2**. Ba atoms are shown as footballs. Water oxygens are represented as open circles. (b) The trigonal arrangement of $Ce(dipic)_3^{2-}$ units. The $Ba(OH_2)_6$ unit is sitting in the trigonal channel. Ba, Ce, and N atoms are shown as footballs in decreasing order of size. C and carboxylate O atoms are shown as open circles. Hydrogen bonds between carboxylate oxygens and water molecules are shown as broken lines.

5% of the initial volume. After several trials it was found that **3** could be obtained in good yield if the pH of the aqueous solution of the initial precipitate of **2** is adjusted to about 2 and the solution is refluxed for several hours, followed by slow evaporation to a small volume at room temperature. Taking into account the loss of material during filtration, the conversion of **2** to **3** is nearly quantitative when done in the above manner. The reverse transformation of **3** to **2** was not observed. Repeated recrystallization of **3** from water even with pH adjustment always produced only crystals of **3**. Crystals of **1** and **3** tend to slowly lose the water of hydration on keeping, this efflorescent nature being mainly responsible for the discrepancy in the elemental analysis values.

3.2. Structure of $Ba(dipicH_2)(OH_2)_4Ce(dipic)_3 \cdot 4.6H_2O$ (1)

The structure of **1** is similar to that observed in the previously reported $Ce(dipic)_3Ca(dipicH_2)(OH_2)_3 \cdot 5H_2O$ [5b] and $Ce(dipic)_3Sr(dipicH_2)(OH_2)_3 \cdot 6H_2O$ [5c]. The coordination around Ce^{4+} and Ba^{2+} is shown in Fig. 1. Both Ce^{4+} and Ba^{2+} are nine-coordinate with distorted tricapped trigonal prismatic coordination geometries. The Ba^{2+} coordination polyhedron is made up of one

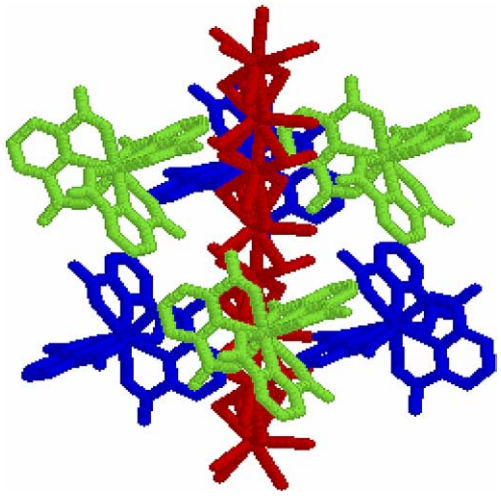

Fig. 5. Stick representation of **2** showing the polymer chain of $Ba(H_2O)_6^{2+}$ passing through the trigonal channels of $Ce(dipic)_3^{2-}$.

$dipicH_2$, four water molecules and two bridging carboxylate oxygen atoms from neighboring Ce^{4+} units. The resulting structure is a one-dimensional chain of alternating nine coordinate Ce^{4+} and nine coordinate Ba^{2+} polyhedra (Fig. 2). Along the chain, the Ce···Ba

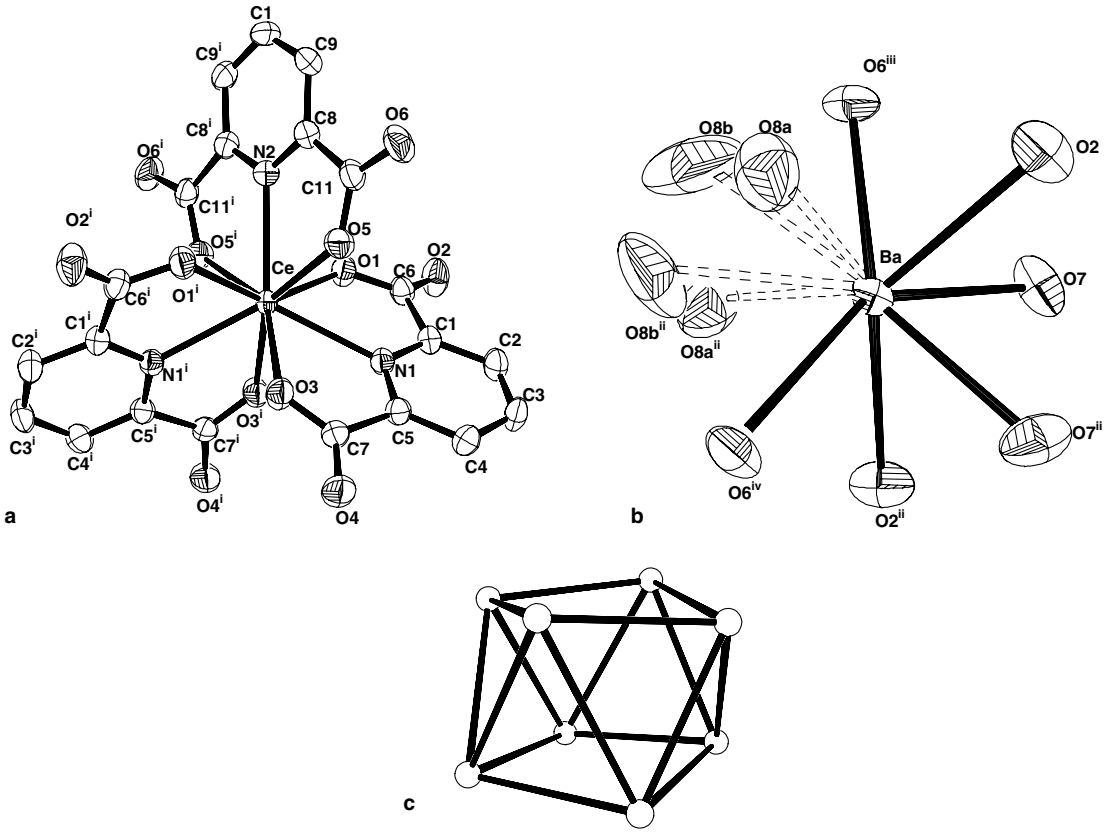

Fig. 6. ORTEP view of the coordination environment of (a) Ce^{4+}, (b) Ba^{2+} and polyhedral drawing (c) showing the distorted square antiprismatic geometry around Ba^{2+} in **3**. In (b), bonds to disordered atoms are indicated by broken lines. In (c), only the major component of the disordered atom (O8) is included. Symmetry code: (i) $-x + 3/2$, y, $-z + 1/2$; (ii) $x - 1/2$, $-y + 1$, $z + 1/2$; (iii) $-x + 2$, $-y + 1$, $-z + 1$; (iv) $-x + 3/2$, y, $-z + 3/2$.

distances alternate between 6.509(3) and 7.027(4) Å. Selected bond lengths and angles are in Table 2.

3.3. Structure of $Ba(OH_2)_6Ce(dipic)_3$ (2)

The structure of **2** is rather different from that of **1**. While the Ce coordination environment (Fig. 3(a)) is the same as that observed in **1**, the Ba coordination environment is made up of water molecules only (Fig. 3(b)). Ce^{4+} is situated on a threefold axis and is coordinated to three symmetry related ligands, resulting in a distorted tricapped trigonal prismatic coordination as observed in **1**. Ba^{2+} is also situated on a threefold axis and coordinated to nine water molecules, again with a tricapped trigonal prismatic geometry. Among the nine water molecules, three lie in the basal plane and the other six are shared with neighboring Ba^{2+} units lying above and below the basal plane, forming a chain (Fig. 4(a)). Ba–O distances (Table 3) are slightly longer (about 0.1 Å) than the distances in **1**. In the crystal, the $Ce(dipic)_3^{2-}$ units pack in a trigonal fashion (Fig. 4(b)). The $Ba(H_2O)_6^{2+}$ polymer chain passes through the trigonal channels created by the anionic units (Fig. 5). Along the chain, the Ba atoms are separated by 9.189(1) Å. The coordinated water molecules are involved in hydrogen bonding with the carboxylate O atoms of the $Ce(dipic)_3^{2-}$ units, with H···O distances in the range 1.7–2.6 Å. The polymer chain of $Ba(H_2O)_6^{2+}$ is similar to the polymer chain structure observed in $SrCl_2 \cdot 6H_2O$ [18]. This type of chain structure is observed in all the hexahydrates of Ca and Sr halides. However, such a hydrate is not known for $BaCl_2$, while $BaI_2 \cdot 6H_2O$ [18a] shows the same structure as the other hexahydrates mentioned above.

3.4. Structure of $Ba(OH_2)_4Ce(dipic)_3 \cdot 2H_2O$ (3)

In **3** also, the coordination of Ce^{4+} is the same as observed in the above two cases. The coordination environments around Ce^{4+} and Ba^{2+} are shown in Fig. 6. As opposed to the above two cases, here Ba^{2+} is eight coordinate. The coordination polyhedron in the present case consists of four water molecules and four carboxylate oxygens from neighboring $Ce(dipic)_3^{2-}$ units, giving a distorted square antiprismatic geometry (Fig. 6(c)). The Ce–O, N and Ba–O distances (Table 4) are similar to those observed in **1** and **2**. If one looks at only the arrangement of Ce and Ba atoms, each Ce is found to be surrounded by four Ba units. All the five atoms are arranged in a square pyramidal geometry with Ce at the apex and the four Ba atoms in the basal plane. The Ce deviates by 2.72 Å from the mean plane defined by its surrounding Ba atoms. Similarly, each Ba is surrounded by four Ce atoms in a distorted tetrahedral fashion. This type of coordination around Ce and Ba units, gives rise to a corrugated sheet structure (Fig. 7). These sheets assemble as layers in the crystal. The water molecules are involved in strong hydrogen bonding with the carboxylate oxygens, the H···O distances lying in the range 1.9–2.5 Å, and connect the layers. Two different

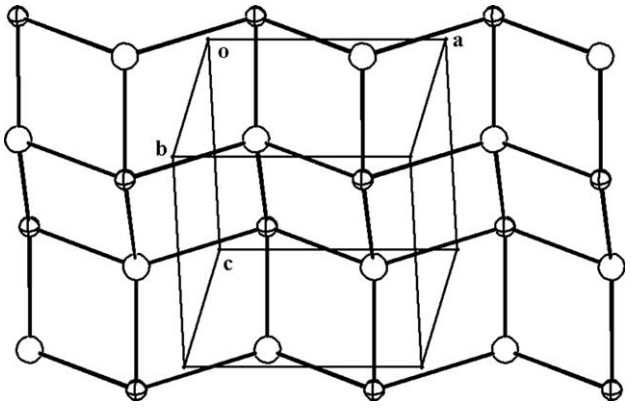

Fig. 7. Corrugated sheet structure made of Ce and Ba atoms in **3**. Footballs represent Ce atoms and open circles Ba atoms.

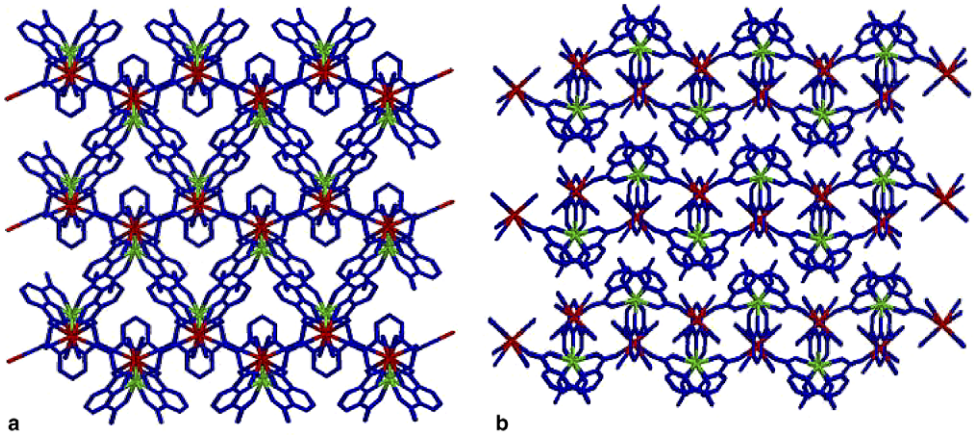

Fig. 8. Different views of the packing in **3**: (a) *ab* plane; (b) *bc* plane.

views of the packing of the cationic and anionic units in the crystal are shown in Fig. 8.

The layer structure observed in the present case may be related to the (4,4) nets of the AX type, seen in the structure of PbO [19]. In the red form of PbO (as well as one polymorph of SnO), the Pb (Sn) atoms are at the apex of a square pyramid with the O atoms forming the base of the pyramid while the O atoms are tetrahedrally surrounded by Pb (Sn) atoms forming AX type layers with A = O and X = Pb (Sn). In the present structure, A and X stand for Ba and Ce coordination polyhedra, respectively.

4. Conclusions

(i) The formation of **1** from methanol–water solution is in keeping with the previous observation with Ce–Ca–dipicH_2 and Ce–Sr–dipicH_2 systems [5b,c]. All the three structures consist of 1-D coordination polymers with alternating Ce and alkaline earth polyhedra. The only difference is that the Ba in **1** is nine-coordinate while Ca and Sr were eight-coordinate. However structures analogous to **2** and **3** were not obtained in the case of Ca and Sr. These differences have to do with the relative size of the cations. Ba^{2+}, being larger than Ce^{4+}, can expand its coordination shell to accommodate 9 or even 10 oxygen ligands.

(ii) The Ce–Ba–dipicH_2 system is delicately balanced with regard to the formation of different polymeric compounds, which are stoichiometrically very similar but structurally very different. The two polymorphs, **2** and **3**, form entirely different network structures.

(iii) Conversion of **2** to **3** is dependent on the pH and thermal aging of the crystallization solution. The fact that the prolonged boiling of the pH adjusted solution of **2** is necessary to crystallize it out as **3** probably means that the oligomeric precursors of the layered structure of **3** are already formed in the boiling solution. It is remarkable that the reverse transformation of **3** to **2** in aqueous solution is not observed.

(iv) **2** and **3** are metal organic analogs of $SrCl_2 \cdot 6H_2O$ and PbO, respectively. This comparison greatly helps in understanding the network in **3**.

(v) Finally, it is to be noted that only a handful of structures are known for alkaline earth–rare earth heteronuclear coordination polymers [5] and clusters [20]. Since alkaline earth ions are optically and magnetically silent, they have the potential to be used as ''binders' for assembling networks of rare earth ions with characteristic solid state properties. The present study shows that multiple networks may be produced from a given set of starting materials by varying the crystallization conditions.

5. Supplementary material

The crystal structure data of complexes **1**, **2** and **3** have been deposited at the Cambridge Crystallographic Data Centre and allocated the deposition numbers CCDC 253800 for **1**, CCDC 253801 for **2** and CCDC 253802 for **3**. Copies of this information can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 IEZ, UK, fax: +44 1223 336 033, e-mail: deposit@ccdc.cam.ac.uk or on the web http://www.ccdc.cam.ac.uk.

Acknowledgments

We thank a referee for helpful comments on the refinement of the structure of compound **3**. We thank the DST (India) for the X-ray diffractometer facility and the UGC (India) for infra-structural support (UPE program). This work was supported by CSIR, India. T.K.P. and S.S. thank the CSIR for award of research fellowships.

obtained on a DuPon TGA 2050. Differential scanning calorimetry (DSC) measurements were carried on a DuPon DSC Q-10.

2.2. Starting materials

The reagents $Cu(OAc)_2\cdot H_2O$ and $CuSO_4\cdot 5H_2O$ were purchased from Merck Co. and used as received. The ligands 1,2-bis(4-pyridyl)ethane (bpa) and *trans*-bis-(4-pyridyl)ethene (bpen) were purchased from Aldrich Chemical Co. and also used as received.

2.3. Preparation of $[Cu_2(OAc)_4(bpa)\cdot 2H_2O]_n$ (**1**)

$Cu(OAc)_2\cdot H_2O$ (0.40 g, 2 mmol) and bpa (0.18 g, 1 mmol) were placed in a flask containing 10 ml CH_3OH. The mixture was stirred at room temperature for 30 min to yield a blue-green precipitate. The blue-green solid was then filtered off and washed with CH_3OH and then dried under vacuum. Yield: 0.47 g (82%). *Anal.* Calc. for $C_{20}H_{28}Cu_2N_2O_{10}$: C, 41.16; H, 4.83; N, 4.80. Found: C, 41.09; H, 4.85; N, 4.76%. IR (KBr disk): 3177(br), 1616(m), 1558(m), 1418(m), 1225(s), 1074(s), 1032(s), 833(s), 682(s), 548(s), 418(s). Crystals suitable for X-ray diffraction were grown by layering a H_2O solution of $Cu(OAc)_2\cdot H_2O$ with bpa in CH_3OH for several weeks.

2.4. Preparation of $[Cu(bpen)(H_2O)_3(SO_4)\cdot 4H_2O]_n$ (**2**)

$CuSO_4\cdot 5H_2O$ (0.25 g, 1 mmol) and bpen (0.18 g, 1 mmol) were placed in a flask containing 10 ml CH_3OH. The mixture was stirred at room temperature for 30 min to yield a blue precipitate. The blue solid was then filtered off and washed with CH_3OH and then dried under vacuum. Yield for **2**: 0.34 g (79%). *Anal.* Calc. for $C_{12}H_{24}CuN_2O_{11}S$: C, 30.80; H, 5.17; N, 5.98. Found: C, 30.51; H, 5.29; N, 5.70%. IR (KBr disk): 3246(br), 1614(m), 1509(m), 1430(m), 1300(s), 1099(m), 1026(m), 981(m), 839(m), 618(m), 560(s). Blue crystals suitable for X-ray diffraction were grown by layering a H_2O solution of $CuSO_4\cdot 5H_2O$ with bpen in CH_3OH for 3 days.

3. X-ray crystallography

The diffraction data for complexes **1** and **2** were collected at 25 °C on a Bruker AXS P4 diffractometer,

which was equipped with graphite-monochromated Mo Kα ($\lambda\alpha$ = 0.71073 Å) radiation. Data reduction was carried out by standard methods with the use of well-established computational procedures [6]. The structure factors were obtained after Lorentz and polarization correction. The positions of some of the heavier atoms, including the copper atom, were located by the direct methods. The remaining atoms were found in a series of alternating difference Fourier maps and least-square refinements [7]. The hydrogen atoms were placed at calculated positions and fixed as riding models during the least-square refinements, and the C–H···π distances were calculated based on the default SHELX C–H bond distances. The final residuals of the final refinement were $R_1 = 0.0765$, $wR_2 = 0.1823$ for **1**. The crystallographic procedures for **2** were similar to those for **1** and the final residuals of the final refinement were $R_1 = 0.0459$, $wR_2 = 0.1321$ for **2**. Basic information pertaining to crystal parameters and structure refinement is summarized in Table 1.

4. Results and discussion

4.1. Synthesis and spectroscopic studies

The complex $[Cu_2(OAc)_4(bpa)\cdot 2H_2O]_n$ (**1**) (bpa = 1,2-bis(4-pyridyl)ethane) was prepared by reaction of $Cu(OAc)_2\cdot H_2O$ with bpa in methanol, while the complex $[Cu(bpen)(H_2O)_3(SO_4)\cdot 4H_2O]_n$ (bpen = *trans*-bis(4-pyridyl)ethene) (**2**) was prepared by reaction of $CuSO_4\cdot 5H_2O$ with bpen in methanol. Their structures have been determined by spectroscopic methods and by X-ray crystallography. The IR spectrum for **1** displays the characteristic bands of the acetate anions at 1616 cm^{-1} for $\nu_{asym(COO)}$, 1418 cm^{-1} for $\nu_{sym(COO)}$ and 682 cm^{-1} for $\delta_{(OCO)}$. The difference between $\nu_{asym(COO)}$ and $\nu_{sym(COO)}$ ($\Delta\nu$) is 198 cm^{-1}, indicating that the acetate groups, which are coordinated to the metal ions in a symmetrical bridging mode (*syn*,*syn*-η^1:η^1:μ_2), are in agreement with the paddle-wheel type structures [8].

4.2. Structure of $[Cu_2(OAc)_4(bpa)\cdot 2H_2O]_n$

The structure of **1** was solved in the space group *C*2/*c*. Fig. 1(a) shows the local coordination of the copper center in **1**. Selected bond distances and angles are listed in Table 2. The copper metal center adopts a slightly distorted square pyramidal coordination geometry with the bond angles only deviating slightly from 90° or 180° (Table 2). The Cu(II) atom is bonded to four oxygen atoms of the bridging carboxylate groups (Cu–O = 1.941(6)–1.960(6) Å) in the basal plane. The Cu(II) atom is also bonded to one bpa ligand (Cu–N = 2.169(6) Å) in the axial position to complete the distorted square-pyramidal coordination geometry.

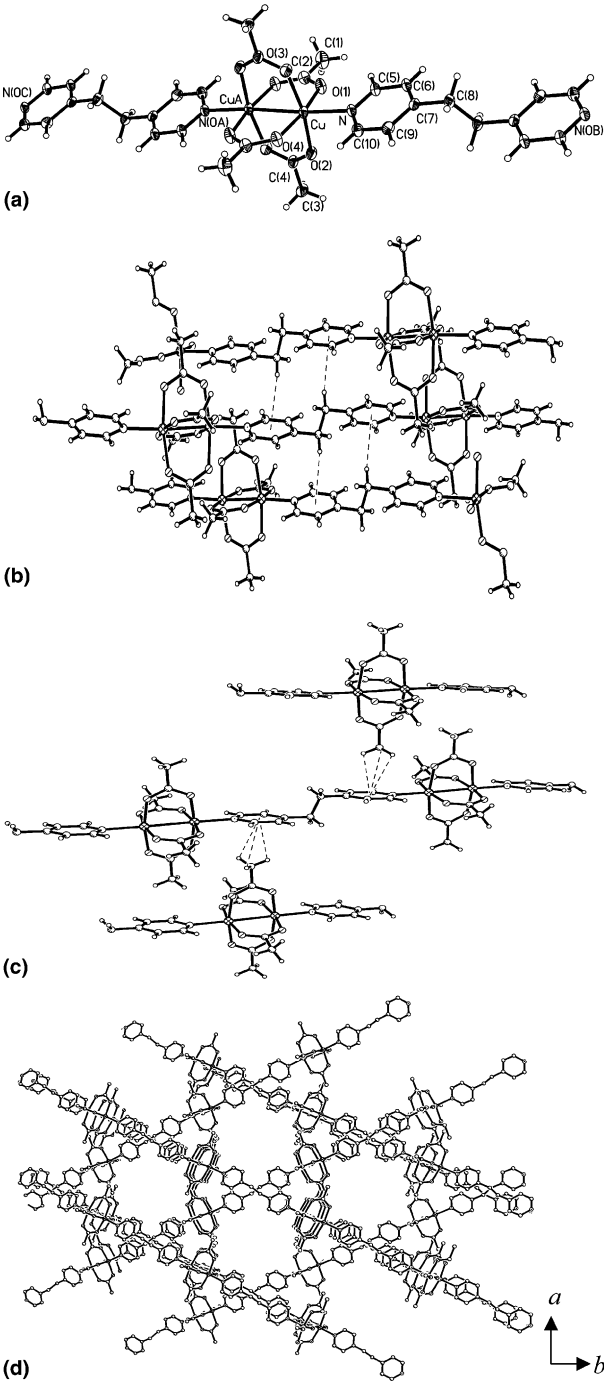

Fig. 1. (a) An ORTEP drawing showing the local coordination of Cu in **1**. (b) An ORTEP drawing showing C–H···π interactions from the methylene hydrogen atoms of the bpa ligand to the center of the pyridyl ring of the other chain. (c) An ORTEP drawing showing C–H···π interactions from the alkyl hydrogen atoms of the acetate ligand to the center of the pyridyl ring of the other chain. (d) An ORTEP drawing showing infinite 1-D chains for **1**, which are interlinked through C–H···π interactions looking down the *c*-axis. Hydrogen atoms are omitted for clarity.

The Cu···Cu separation in the $Cu_2(OAc)_4$ core is 2.605(3) Å while that in the molecular chain separated by the bridging bpa is 13.477 Å. The bpa ligand in

complex **1** adopts an *anti*-conformation with a dihedral angle of −180° (C7–C8–C8B–C7B). Two types of C–H···π interactions were found in the structure. The first one is from the methylene hydrogen atoms of the bpa ligand to the center of the pyridyl ring of the other chain (2.942 Å), Fig. 1(b), while the other is from the methyl hydrogen atoms of the acetate ligands to the center of the pyridyl ring of the other chain (3.025–3.436 Å), Fig. 1(c). It is noted that the C–H···π interactions to the methylene hydrogen atoms appear to link chains that cross each other, whereas those to the methyl hydrogen atoms of the acetate ligands involve parallel chains. The most striking feature in complex **1** is that the molecular chains are interlinked through these C–H···π interactions to form a porous structure, Fig. 1(d). It is seen that the molecular chains are packed in an AB fashion, where the molecular chains in the A layer are positioned over the B layer with an angle of 63.9° to form rhombic channels. The dimensions of the rhombic pores, which are defined as the distances between the midpoints of the ligands, are 13.18 Å for the short and 26.87 Å for the long diagonal lengths. The cavities are occupied by the water molecules.

4.3. Structure of $[Cu(bpen)(H_2O)_3(SO_4)\cdot 4H_2O]_n$

The structure of **2** was solved in the space group $P2_1/c$. Fig. 2(a) shows the local coordination of the copper center in **2**, while Fig. 2(b) shows its infinite 1-D chains consisting of copper(II) ions, bpen ligands and SO_4^{2-} anions. Selected bond distances and angles are listed in Table 2. Fig. 2(b) shows that complex **2** is a coordination polymer of $[Cu(bpen)(H_2O)_3(SO_4)\cdot 4H_2O]_n$, forming a 1-D linear chain. The copper metal center adopts a slightly distorted octahedral coordination geometry with the bond angles only deviating slightly from 90° or 180° (Table 2). The Cu atom is bonded to two *trans* pyridyl nitrogen atoms (Cu–N(1) = 2.028(3) Å and Cu–N(2) = 2.031(3) Å) and two *trans* oxygen atoms of aqua molecules (Cu–O(2) = 1.969(3) Å and Cu–O(3) = 2.005(3) Å) in the equatorial plane. The Cu(II) atom is also bonded to one oxygen atom of an aqua molecule (Cu–O(1) = 2.405(3) Å) and one oxygen atom of the sulfate ligand (Cu–O(6) = 2.471(3) Å) in the axial positions to complete the distorted octahedral coordination geometry. The Cu···Cu distance in the molecular chain separated by the bridging bpen is 13.396 Å. The bidentate ligand bpen

Symmetry transformations used to generate equivalent atoms: (A) $-x + 3/2$, $-y + 1/2$, $-z + 2$ for **1**.

in the structure **2** is flat with a dihedral angle of 0° between the planes of the two pyridyl rings, while the dihedral angle of py–Cu–py is 51.8°.

The most striking feature in complex **2** is that the molecules are interlinked through extensive O–H···O and C–H···O hydrogen bondings and π–π interactions to form a porous structure, as shown in Fig. 2(c). It is seen that the molecular chains are also packed in an AB fashion, where the molecular chains in the A layer are positioned over the B layer with an angle of 51.3°, to form rhombic pores. The cavities are occupied by the water molecules. The dimensions of the rhombic pores, which are defined as the distances between the midpoints of the ligands, are 11.32 Å for the short and 24.15 Å for the long diagonal lengths. The H_2O molecules and SO_4^{2-} anions link the adjacent chains through extensive O–H···O and/or C–H···O hydrogen bondings. The O–H···O distances are in the range from 2.625 to 2.895 Å. The C–H···O distances are in the range from 2.435 to 2.556 Å with C–H···O angles in the range from 124.2° to 134.7°. The distance of the π–π interactions is 3.829 Å.

Complex **2** is in marked contrast to the structure of $[Cu(bpen)(H_2O)(SO_4)]_n$, which was prepared from the reaction mixture of $CuSO_4\cdot 5H_2O$, bpen and H_2O in the mole ratio 1:1:111 at 120 °C. The structure of $[Cu(bpen)(H_2O)(SO_4)]_n$ consists of 1-D $[Cu(bpen)(H_2O)]^{2+}$ cationic chains covalently bonded by the SO_4^{2-} anions to form a 3-D framework [5i].

4.4. Thermal properties

Complexes **1** and **2** are very stable in air at ambient temperature and almost insoluble in common solvents such as water, alcohol, acetonitrile, chloroform, methanol and acetone. Thermal gravimetric analyses (TGA) were carried out to examine the thermal stability of **1** and **2**. The samples were heated in air at 1 atm pressure with a heating rate of 10 °C min^{-1}. The TGA curve shows that **1** is stable up to 114 °C. A total weight loss of 6.4% occurred in the temperature range 114–223 °C, presumably due to the removal of the water molecules per formula unit (calc. 6.2%). A weight loss occurred in the temperature range 223–280 °C, corresponding to the removal of bpa ligands and decomposition of the framework. The TGA curve shows that **2** is stable up to 110 °C. A total weight loss of 47.1% occurred in the temperature range 110–278 °C, mainly corresponding to the removal of the cocrystallized and the bonded H_2O and the sulfate molecules per formula unit (calc. 47.2%). Another weight loss occurred in the temperature range 278–380 °C, consistent with the removal of bpen ligands and decomposition of the framework. Their T_m values have been measured by using differential scanning calorimetry (DSC), which are 247 and 263 °C for complexes **1** and **2**, respectively.

5. Conclusions

The synthesis and structures of two complexes $[Cu_2(OAc)_4(bpa)\cdot 2H_2O]_n$ (**1**) and $[Cu(bpen)(H_2O)_3(SO_4)\cdot 4H_2O]_n$ (**2**) have been successfully accomplished. Complexes **1** and **2** form molecular chains which are packed in AB fashions through C–H···π interactions, π–π interactions and hydrogen bondings, to form porous structures with rhombic channels. Complexes **1** and **2** make interesting comparisons with the complex $\{Cu_2(OAc)_4(bpp)\}_n$ (bpp = 1,3-bis(4-pyridyl)propane) [9]. While bpa and bpp are flexible ligands with two and three backbone carbon atoms, respectively, which can adopt several conformations, and bpen is a rigid ligand, all three ligands adopt the *anti* conformation and the related *trans* (bpen) conformation to show

similar structures with infinite channels. Weak interactions like C–H···π interactions, π–π interactions and hydrogen bondings may play an important role in the self-assembly of these types of structures.

6. Supplementary material

Crystallographic data (CIF files) for the complexes **1** and **2** have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 243076 and 243075. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

cleave DNA in the presence of hydrogen peroxide [10].[1] Extensive literature already reports inert cationic cobalt(III) complexes with intercalating ligands (i.e., planar aromatic ligands such as 1,10-phenanthroline or those with aromatic pendant substituents) having the ability to bind to DNA and having nucleolytic ability upon activation by UV irradiation [11–15]. Although without an overall positive charge or intercalating ligand, neutral chelated amino acid complexes can still bind to DNA via hydrogen bonding and van der Waals' interactions. Here, we report additional characterization of the meridional cobalt(III) complex of β-alanine, *mer*-[Co(β-ala)$_3$], and its nuclease activity.

2. Experimental

2.1. Materials

The β-alanine and 30% aqueous H_2O_2 were purchased from Merck and Baker respectively. Ascorbic acid (H_2A), cobalt(II) chloride hexahydrate and sodium hydroxide were obtained from Fisher Scientific. Linear λ-DNA (in storage buffer: Tris–HCl, NaCl, EDTA) was obtained from Invitrogen. All compounds and reagents were used as supplied.

2.2. Physical measurements

Infrared spectra of all the compounds were recorded as KBr pellets using a Perkin–Elmer 1000 FT-IR spectrometer in the frequency range 4000–450 cm^{-1}. C, H and N microanalysis was carried out with a Perkin–Elmer 2400. The magnetic susceptibility measurement at room temperature was obtained with a Sherwood Magnetic Susceptibility Balance MSB Mk1 which was calibrated with Hg[Co(SCN)$_4$]. UV–Vis spectroscopic measurement of the aqueous solution of the complex was carried out on a Shimadzu UV-160 spectrophotometer. The electrospray ionisation mass spectrum of an aqueous solution of the complex was obtained by using a MAT LCQ bench top quadrupole ion trap mass spectrometer with a spray voltage of 4.5 kV, cone voltage of 15 V and desolvation temperature of 250 °C.

The voltammetric experiments were performed with a BAS (Bioanalytical Systems, West Lafayette, IN, USA): CV-50W electrochemical workstation. A conventional three electrode potentiostat system was used at 25 ± 2 °C with a 3 mm gold working electrode, a platinum wire (1 mm diameter) counter electrode and a Ag/Ag$^+$ reference electrode. The complex was dissolved in TN buffer pH 8.3 (TN is Tris–NaCl; Tris = Tris (hydroxymethyl)aminomethane); the resulting solution was purged with oxygen-free nitrogen gas for 15 min prior to the cyclic voltammetric measurements.

2.3. Synthesis of *mer*-[Co(β-ala)$_3$]

The purple *mer*-[Co(β-ala)$_3$] was prepared by a slight modification of a previously published procedure [16]. Slightly excess fresh cobalt(III) hydroxide was added to an aqueous solution of β-alanine and the resultant mixture was heated in a water-bath at 60 °C with continuous aeration. Unreacted cobalt(III) hydroxide was filtered, and the aeration of the dark red filtrate in the water-bath was continued to concentrate the solution. Cooling this solution initially yielded less soluble pure pink crystals. Repeated aeration with heating in the water-bath and subsequent cooling yielded different batches of products. These included mixtures of varying ratios of pink and violet crystals, and the pure purple crystals. Repeated synthesis of *mer*-[Co(β-ala)$_3$] yielded crystals suitable for X-ray diffraction. *Anal.* Calc. for $C_9H_{18}O_6N_3Co \cdot 2H_2O$: C, 30.09; H, 6.17; N, 11.70. Found: C, 30.65; H, 6.61; N, 11.58%. IR(cm^{-1}): 3398(s), 3254(s), 1609(vs), 1559(vs, doublet), 1468(w), 1409(s), 1378(m), 1319(w), 1279(m), 1214(w), 1179(w), 1147(w), 1078(w), 1031(w), 987(w), 901(m), 768(m), 698(w), 642(m).

2.4. Structure determination

X-ray data on a purple crystal of size 0.40 × 0.18 × 0.10 mm was collected at 295 K with a Bruker AXS SMART APEX area-detector diffractometer using graphite-monochromated Mo Kα radiation (λ = 0.71073 Å). SHELXS-97 and SHELXL-97 were used to solve and refine the structure [17,18]. The refinement converged at $R = 0.0973$ and $wR = 0.2726$ values for 2406 reflections $F_o > 4\sigma(F_o)$. Crystal data, selected bond lengths and angles are tabulated in Tables 1 and 2. Hydrogen bonding distances and angles are given in Table 3.

2.5. DNA cleavage studies

The electrophoresis experiments were performed on a horizontal gel electrophoresis system. Agarose gel electrophoresis experiments were carried out on linearized λ-DNA (viral; 48.5 kb). All samples in TBE buffer pH 8.3 (90 mM Tris–borate, 2.5 mM Na_2H_2EDTA) were incubated at 37 °C for 2 h, and then electrophoresed on 1% agarose gel for 2 h at 80 V. Essentially samples with an increasing concentration of complex with a given concentration of DNA (0.015 or 0.25 μg/μl) for each sample were incubated in the absence or presence of various component(s). The resultant bands for each set of

[1] Preliminary accounts of the cleavage of DNA by copper(II) complexes of glycine, L-threonine, L-proline and *N*,*N*-dimethylglycine were presented at the Malaysian Scientific and Technological Congress (Sept. 2003), Kuala Lumpur, Malaysia.

experiments were photographed under UV light by using a Polaroid camera, GelCam, fixed with an electrophoresis hood.

3. Results and discussion

3.1. Structural characterization and solution properties

The crystal structure of the complex shows that it is the *mer*-isomer of tris(β-alaninato)cobalt(III), *mer*-[Co(β-ala)$_3$] (Fig. 1). One of the two water molecules in the crystal lattice shows disorder. Microanalysis results of the same sample, from which a crystal was used for crystal structure analysis, support the formulation of the complex as $Co(C_3H_6NO_2)_3 \cdot 2H_2O$. Hydrogen bonding links the complex molecules (via use of amino nitrogen protons and carboxylate oxygen atoms) and lattice water molecules into an interlinking network (Table 3). The present complex has some differences with a previously synthesized *mer*-[Co(β-ala)$_3$] which has been shown by crystal structure analysis to be the tetrahydrate [19]. Both structures show that the α-carbon and the carboxylate –COO$^-$ atoms are coplanar and this may allow partial insertion between the base pairs in the major groove of DNA. Unlike the twist-boat conformation of six-member chelate rings in *mer*-[Co(β-ala)$_3$] · 4H$_2$O [19], all the chelate rings in the present complex have a half-chair conformation with the β-carbon atom at the apex of the triangular 'flap' while the other atoms of the ring form an approximately flat seat of the chair.

Magnetic susceptibility determination of this purple needle-shaped complex shows that it is diamagnetic, confirming the starting cobalt(II) has been successfully oxidized to cobalt(III) in the final complex. The pink crystals are paramagnetic and should contain the unoxidized cobalt(II).

The purple *mer*-[Co(β-ala)$_3$] readily dissolves in water. The UV–Vis spectrum shows three bands with absorption maxima values of $\lambda_1 = 575$ nm ($\varepsilon_1 = 97$ M^{-1} cm^{-1}), with a shoulder at 500 nm, $\lambda_2 = 374$ nm ($\varepsilon_2 = 71$ M^{-1} cm^{-1}) attributed to d–d transitions, and $\lambda_3 = 245$ nm ($\varepsilon_3 = 18\,380$ M^{-1} cm^{-1}; UV region) attributed to a LMCT transition. The λ_1 and λ_2 values of the present complex agree well with those of previously synthesized *mer*-[Co(β-ala)$_3$] [λ_{max} (nm)/ε_{max} (M^{-1} cm^{-1}) values are 574/101 and 373/71, respectively [20,21].

In contrast, similar purple *mer*-isomers of [Co(gly)$_3$] (λ_1, 545 nm; λ_2, 373 nm; λ_3, 220 nm) and [Co(L-ala)$_3$] (λ_1, 540 nm; λ_2, 372 nm; λ_3, 221 nm) exhibit shorter λ_1 and λ_3 values [16]. In general, it appears that Co(α-aa)$_3$ complexes of α-amino acid ligands forming five-membered chelate rings have shorter λ_1 values (519–542 nm) than Co(β-ala)$_3$ complexes with six-membered chelate rings [20,21]. This suggests that the β-alaninate ligand interacts less strongly with the cobalt(III) and is therefore a comparatively weaker ligand than α-aminoacidates.

Dissolving the *mer*-[Co(β-ala)$_3$] complex in TN buffer pH 7 and TBE buffer pH 8.3 does not cause any shift in wavelength of the spectral bands (values in TN buffer are $\lambda_1 = 576$, $\varepsilon_1 = 82$; $\lambda_2 = 374$, $\varepsilon_2 = 59$; $\lambda_3 = 245$, $\varepsilon_3 = 16426$ while those in TBE buffer are $\lambda_1 = 576$, $\varepsilon_1 = 86$; $\lambda_2 = 375$, $\varepsilon_2 = 62$; $\lambda_3 = 245$, $\varepsilon_3 = 17483$). This suggests the species in the aqueous and buffer solutions are the same. An aqueous solution of this complex, which is kept over about two weeks, does not show appreciable change in absorbance, and this indicates its high stability in aqueous solution. A strong ESI-MS peak (positive ion mode) of m/z 323.9 (52%) shows the neutral complex species exists in aqueous solution. A full analysis of the ESI-MS spectrum shows presence of a dimer (63%), trimer (94%) and tetramer (34%), besides various β-alanine containing polymetallic complex species (Table 4). These latter species may be due to a combination of hydrogen bonding, bridging by amino acid and an aggregation process.

Analysis of the voltammogram of the complex gives the cathodic reduction peak, E_{pc}, and current, i_{pc}, as

−680 mV and −3.375 μA. The anodic oxidation peak, E_{pa}, and current, i_{pa}, values are −567 mV and 3.375 μA, respectively. The anodic to cathodic peak separation, $\Delta E_p = E_{pa} - E_{pc}$, is 113 mV, and this indicates a quasi-reversible one-electron transfer process [22]. The half-wave potential $E_{1/2}$, taken as $(E_{pc} + E_{pa})/2$, is −624 mV, and this value is lower than those of Co^{III} hexamine complexes which range from −640 to −860 mV [23]. In the latter complexes, the six ligating atoms in the octahedral coordination sphere are nitrogen atoms. The lower reduction potential for *mer*-[Co(β-ala)$_3$] shows that it is more easily reduced. In contrast, a series of Co(III) ternary complexes, [Co(NO$_3$-L$_1$)(NO-L$_2$)], containing NO$_3$-type tripodal tetradentate ligands and NO-type bidentate α-amino acids exhibit irreversible redox waves with ΔE_p of ~1 V and E_{pc} values which ranges from −340 to −1080 mV [24]. These differences are relevant here because some cobalt(III) complexes can be reduced by ascorbic acid while others cannot, and this has been ascribed to differences in their redox potentials [25].

34	1292.6	Co$_4$(β-ala)$_{12}$ (tetramer)	1292.76

3.2. DNA cleavage studies

When *mer*-[Co(β-ala)$_3$] was incubated with λ-DNA in TBE buffer pH 8.3 in the presence of H$_2$O$_2$, there was no apparent degradation of the DNA (Fig. 2, lanes 5–7). However, CoCl$_2$ is a potent nuclease for DNA, cleaving it oxidatively (Fig. 2, lane 4); a recent study has shown that a low concentration of CoCl$_2$ (6 μM) has promoted selective oxidation of Z-DNA at every guanine in

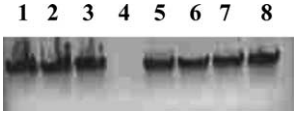

Fig. 2. Results of gel electrophoresis experiment for racemic *mer*-[Co(β-ala)$_3$] and CoCl$_2$ (4 mM) with λ-DNA (0.05 mg/μL) in the presence of 0.5 mM H$_2$O$_2$ in TBE buffer pH 8.3. Lane 1, DNA alone; lane 2, λ-DNA + H$_2$O$_2$; lane 3, λ-DNA + 4 mM complex; lane 4, λ-DNA + 4 mM CoCl$_2$ + H$_2$O$_2$; lanes 5–8, λ-DNA + H$_2$O$_2$ + increasing concentration of complex (200 μM, 2 mM, 3 mM, 4 mM respectively).

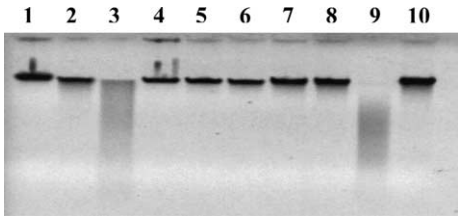

Fig. 3. Agarose gel electrophoresis banding patterns. Reaction of λ-DNA (0.5 μg/μl) with different component(s): Lane 1, λ-DNA + ascorbic acid, AsA (8 mM); lane 2, λ-DNA + H$_2$O$_2$ (2 mM) + H$_2$A (8 mM); lane 3, λ-DNA + complex (4 mM) + H$_2$A (8 mM); lane 4, λ-DNA + CoCl$_2$ (1 mM); and lane 5, λ-DNA + complex (4 mM) + H$_2$O$_2$ (2 mM). λ-DNA (0.5 μg/ml) reacted with same concentration of complex (4 mM) in the presence of 2 mM H$_2$O$_2$, TBE buffer pH 8.3 and various concentration of ascorbic acid: lane 6, H$_2$A (0.1 mM); lane 7, H$_2$A (0.5 mM); lane 8, H$_2$A (1 mM); lane 9, H$_2$A (4 mM); and lane 10, H$_2$A (6 mM).

the presence of the stronger oxidant, KHSO$_5$ [26]. This result for the present complex differs from those of bis(α-aminoacidato)copper(II) complexes, which cleave the DNA in the presence of the weaker oxidant H$_2$O$_2$ in the mM range [10].[1] In addition, it was found that a cationic ternary cobalt(II) complex, [(DOTA)Co(II)-(TPY)](ClO$_4$)2 (DOTA = 1,4,7,10-tetraza-cyclododecane which is an oligopeptide, TPY = 2,2′:6′,2″-terpyridine) binds to DNA strongly and shows anti-tumor properties [27]. In contrast, the neutral, racemic *mer*-[Co(β-ala)$_3$] apparently does not show any nucleolytic property in the absence or presence of H$_2$O$_2$ (Fig. 2, lanes 3 and 5–8) under our experimental conditions.

However when the DNA was reacted with *mer*-[Co-(β-ala)$_3$] in the presence of a reductant, ascorbic acid (H$_2$A), the complex shows high nuclease activity (Fig. 3, lane 3). The combination of this complex with H$_2$O$_2$ and ascorbic acid does not exhibit good nuclease activity except when the H$_2$O$_2$: H$_2$A mole ratio increases to 1:2 (Fig. 3, lane 9); a lower mole ratio or higher mole

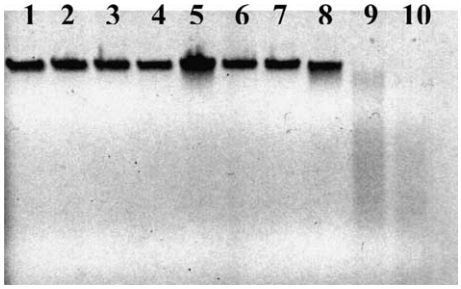

Fig. 4. Agarose gel electrophoresis results. Reactions λ-DNA (0.25 μg/μl) with different component(s) in TBE buffer pH 8.3: lane 1, DNA alone; lane 2, DNA + H$_2$O$_2$ (2 mM); lane 3, DNA + H$_2$A (8 mM); lane 4, DNA + complex (4 mM); lane 5, DNA + CoCl$_2$ (2 mM) + H$_2$A (8 mM); and lane 6, DNA + CoCl$_2$ (2 mM) + H$_2$O$_2$ (2 mM). Reactions of λ-DNA (0.25 μg/μl) with different concentrations of complex in the presence of H$_2$A (8 mM): lane 7, complex (1 mM); lane 8, complex (2 mM); lane 9, complex (3 mM); and lane 10, complex (4 mM).

ratio than this shows reduced cleavage or none. Under our experimental conditions, it is found that the complex alone or ascorbic acid alone cannot cause cleavage of DNA (Fig. 4, lanes 3 and 4). A close parallel may be drawn between this complex and the pro-cancer drugs, platinum(IV) complexes, which are activated by reduction to the platinum(II) analogues by biological reductants such as ascorbic acid and thiols [28,29]. Both the complex and ascorbic acid are required. The effect of the composition of these two reagents has been investigated. It is found that cleavage requires an ascorbic acid: complex mole ratio <4:1 (i.e., the number of moles of ascorbic acid is 2.7× and 2.0× more than that of the complex; Fig. 4, lanes 9 and 10); for mole ratios of 8:1 and 4:1 there is no apparent cleavage (Fig. 4, lanes 7 and 8). Thus, the amount of ascorbic acid required should not be excessively more than the complex, otherwise it can have an inhibitory effect. A similar effect by ascorbic acid has been previously reported where a daily intake of 50 mg afforded a protective effect in cells of people exposed to cobalt chloride [30].

The nucleolytic ability of $[Co(\beta\text{-ala})_3]$ in the presence of ascorbic acid has to result from the reduction of the complex by ascorbic acid. Substituted inert cobalt(III) complexes are known to be easily reduced by ascorbate ions, HA^- and A^{2-} [28]. This reduction can be monitored by UV–Vis spectroscopy as we have found that the absorption maxima decrease without a shift in wavelengths. Previous kinetic and mechanistic studies of the reaction of various cationic and anionic cobalt(III) complexes with ascorbic acid have revealed differences in the reductive ability of its various species, and this reductive order is $H_2A < HA^- < A^{2-}$; the ensuing redox reactions produce ascorbate free radicals [31–33]. As the present investigation involves incubating the complex with ascorbic acid in TBE buffer pH 8.3, the present cobalt(III) complex should be easily reduced by the substantial amount of the more potent ascorbate anion, A^{2-}. Thus, the nucleolytic ability of $[Co(\beta\text{-ala})_3]$ can be attributed to ascorbate free radicals. Such a role of ascorbate radicals as a DNA damaging agent has previously been acknowledged [28]. Although oxidative modification and cleavage of DNA by other free radicals have been widely reported [34,35], this is the first by a neutral cobalt(III) chelated amino acid–ascorbic acid system.

Using an MTT assay, preliminary studies revealed anti-cancer properties of $CoCl_2$ (IC_{50} = 0.06 mM), *mer*-$[Co(\beta\text{-ala})_3]$ (IC_{50} = 2.06 mM) and {*mer*-$[Co(\beta\text{-ala})_3]$ +0.20 mM H_2A system} (IC_{50} = 1.61 mM) towards lung cancer cell line PC9 [36]. The variation in anti-cancer potency parallels their nucleolytic efficiency. The order of nucleolytic efficiency is *mer*-$[Co(\beta\text{-ala})_3]$ < {*mer*-$[Co(\beta\text{-ala})_3] + H_2A$} < $CoCl_2$. These results suggest that a substance or mixture with good nucleolytic ability can be a potential anti-cancer agent.

4. Supplementary data

Full crystallographic data have been deposited with the Cambridge Crystallography Data Center, CCDC No. 248783. Copies of this data can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033, e-mail: deposit@ccdc.cam.ac.uk. or on the www.ccdc.cam.ac.uk/conts/retrieving.html.

complexes [6–14]. A novel aspect is a correlation of the magnetic anisotropy with structural distortion [15].

2. Experimental

2.1. Ligands

All chemicals were of analytical grade. The ligands were prepared according to the literature recipes [16,17]. The starting furan-2-carbaldehydes (**a**) were subjected to the Doebner condensation resulting in the corresponding acids (**b**) (Fig. 1). The acylazides were prepared by treatment of (**b**) with ethyl chloroformate and sodium azide in a one-pot reaction, and then were transformed by thermal cyclization in dowtherm with tributylamine to give the 4,5-dihydropyridines (**c**). Refluxing (**c**) with phosphorus oxychloride and then reduction of the obtained chloro-derivatives yielded furo[3,2-*c*]pyridines (**d**).

2.2. Preparation of the complexes

An ethanol solution of $NiCl_2 \cdot 6H_2O$ (0.04 mol in 100 cm^3) was combined with powdered KNCS (0.08 mol). The precipitated KCl was filtered off and 0.16 mol of the ligand (L^1 = furo[3,2-*c*]pyridine, L^2 = 2-methylfuro[3,2-*c*]pyridine, L^3 = 2,3-dimethylfuro[3,2-*c*]-pyridine, L^4 = benzo[4,5]furo[3,2-*c*]pyridine and L^5 = isoquinoline) was added to the pure solution. Small crystals were formed within 2–3 days at room temperature; these were washed with ethanol and recrystallized

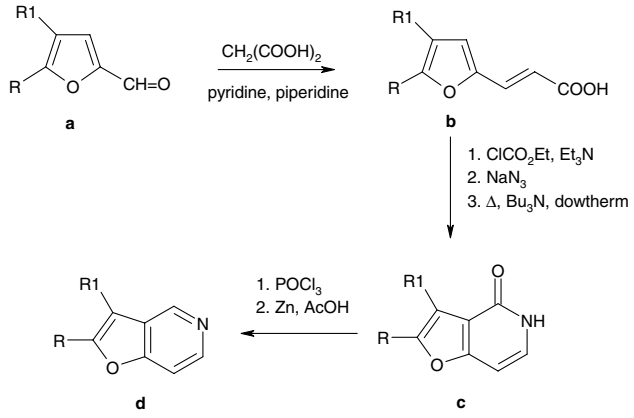

Fig. 1. Preparation of the furo[3,2-*c*]pyridines. L^1, R = R1 = H; L^2, R = CH_3, R1 = H; L^3, R = R1 = CH_3; L^4, R–R1 = CH═CH—CH═CH.

from tetrahydrofuran (THF) (**1**), ethanol (**2**) and CH_2Cl_2/diethylether (**3**–**5**). The composition of the obtained complexes $[Ni(L^1)_4(NCS)_2]\cdot THF$ (**1**), $[Ni(L^2)_4(NCS)_2]\cdot 1.29H_2O$ (**2**), $[Ni(L^3)_4(NCS)_2]\cdot 6.6H_2O$ (**3**), $[Ni(L^4)_4(NCS)_2]\cdot 2H_2O$ (**4**) and $[Ni(L^5)_4(NCS)_2]\cdot CH_2Cl_2$ (**5**) was confirmed by elemental analysis. X-ray structure analysis was performed for compounds **2**, **4** and **5**, since structural data on **1** and **3** can be retrieved from the literature [5].

2.3. Analytical methods and equipment

Elemental C–H–N analysis was carried out with a commercial analyzer (Carlo Erba, 1108). The nickel

content was determined by a complexometric titration on murexide. IR spectra were obtained with a FTIR spectrometer (Philips, PU 9800). Electron spectra were measured in the range 9000–40 000 cm^{-1} (Perkin–Elmer, 450).

Diffraction data were collected on a 3-circle-platform diffractometer (Bruker, SMART 1K CCD). The frame data were acquired with the SMART software at 300 K using Mo Kα radiation ($\lambda = 0.71073$ Å). The structures were solved by direct methods (SHELXS 97) and refined by the least-squares method on F^2 (SHELXL 93, incorporated SHELXTL v5.1). Hydrogen atoms were geometrically positioned and left riding on their parent atoms during structure refinement. The structural data are listed in Table 1.

The magnetic data were collected using the SQUID apparatus (Quantum Design) in the temperature range 2–300 K at the applied field of $B = 0.1$ T. The magnetic susceptibility has been corrected for the underlying diamagnetism using a set of Pascal constants.

3. Results and discussion

3.1. X-ray structure

All five complexes under study possess a molecular structure: they are formed by *trans*-$[NiL_4(NCS)_2]$ units with the solvent molecules embodied in the crystal lattice. The chromophore $\{NiN_4N'_2\}$ is nearly octahedral and approximately forms a compressed tetragonal bipyramid. The ORTEP drawings of the X-ray determinations are in the supporting material.

Compound **2** is non-centrosymmetric so that we are left with six different Ni–N bond lengths. The two Ni–NCS bond lengths, Ni1–N1 2.023(13) and Ni1–N2 2.072(12), average to 2.048 whereas the four equatorial N-donor heterocycles exhibit bond lengths to the metal centre between 2.108 and 2.224 with an average of 2.163 (all distances in Å). The bond angles deviate only slightly from octahedral vertices and can be easily retrieved from the corresponding *cif*-file deposited in the CCDC. The *trans* NCS groups are arranged in a way so that the dihedral angle SC–N...N–CS is −119°. This differs from the previously determined structures for **1** and **3**, where that angle amounts to −14° and 180°, respectively. The planes of the aromatic rings are turned in a way so that their dihedral angle with the Ni1–N2 vector is −35°, −17°, +35°, +2°. The ring arrangement is irregular: three oxygen atoms of the furan ring point to the same side whereas just one is opposite (Fig. 2).

Compound **4** is centrosymmetric and there are three different Ni–N bond lengths. The Ni–NCS bond lengths are Ni1–N1 2.084(4) whereas the equatorial N-donor heterocycles exhibit bond lengths to the metal centre 2.143(3) and 2.146(3) with an average of 2.144. The

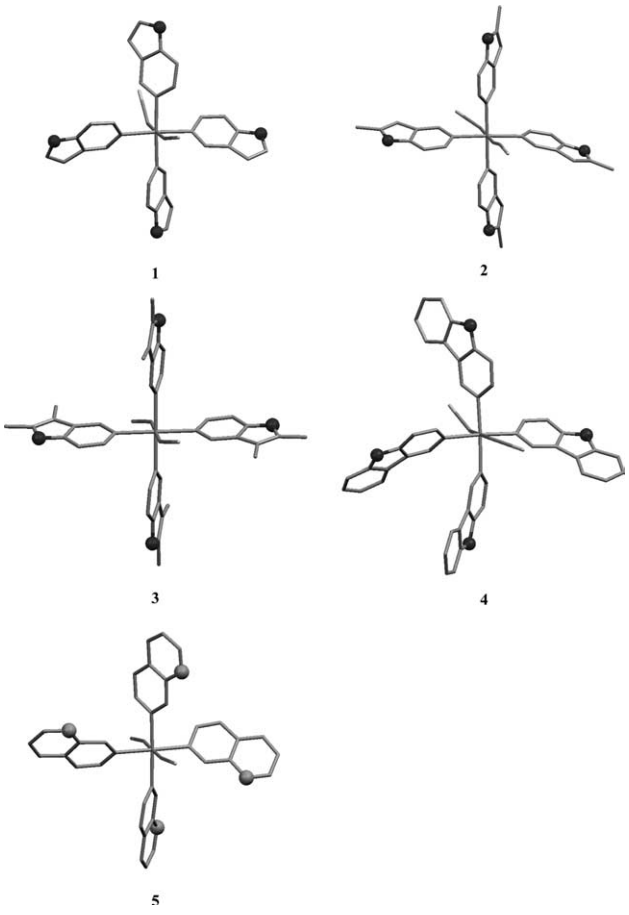

Fig. 2. The molecular structures of compounds **1**–**5**. The oxygen atoms of the furan rings are marked by balls (and the corresponding carbon atom in the isoquinoline complex **5**).

dihedral angle of *trans* NCS, SC–N...N–CS, is −133°. This is nearly the same as for compound **2**. The orientation of the planes of the aromatic rings is described by their dihedral angles relative to the Ni1–N2 vector: +32°, +34°, +41°, +32°. The ring arrangement is regular: opposite oxygen atoms of the furan rings point to different sides. Such an arrangement is not found in the remaining compounds.

Compound **5** is non-centrosymmetric and we can observe six different Ni–N bond lengths. Two Ni–NCS bond lengths, Ni1–N1 2.044(4) and Ni1–N2 2.051(4), average to 2.0475 while four equatorial N-donor heterocycles exhibit bond lengths to the metal centre from 2.133 to 2.160 with an average of 2.143. Dihedral angle of *trans* NCS, SC–N...N–CS, is 162°, which is between angles of compounds **1**, **3** and **2**, **4**. The dihedral angle of the planes of the aromatic rings relative to the Ni1–N2 vector is +35°, +46°, +25°, +49°. The ring arrangement is analogous to compound **2**.

The geometrical distortion has been characterized by two asymmetry parameters using the metal–ligand distances: the axial distortion $D_{str} = d_z - (d_x + d_y)/2$, and the rhombic distortion $E_{str} = (d_x - d_y)/2$. The

Cartesian axes have been chosen with a recipe well-known in magnetochemistry and ESR so that E is positive and $-1/3 < E/D < +1/3$. These data are in Table 2 along with the metal–ligand distances within the chromophore.

3.2. Spectral data

The bands observed in the electronic absorption spectra (Table 3) can be assigned to the three spin allowed transitions $^3T_{2g} \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$ in O_h symmetry. The maxima of the absorption bands for the complexes under study are within the interval usually found for pseudooctahedral nickel(II) complexes [18]. A possible splitting, due to the symmetry lowering to D_{4h} symmetry, is not resolved. It can be concluded that the ligand-field strengths 10 Dq are effectively identical for the furopyridine derivatives and the thiocyanate group.

The mode of coordination of the NCS groups in these complexes has been investigated by means of the infrared absorption spectra. It follows from the literature data [19] that the main criterion of the M–NCS and M–SCN bonding is the band position corresponding to the C–S stretching vibration. The region from 770 to 860 cm^{-1} is assigned to M–NCS bonding, and that between 690 and 730 cm^{-1} to the M–SCN bonding mode. The C–N vibrations of analogous compounds span the region 2080–2110 cm^{-1} and they refer to M–NCS bonding whereas vibrations occurring in the region of 2100–2130 indicate the M–SCN bonding mode. For a bridging thiocyanate group 2130–2180 cm^{-1} values are typical. Thus the NCS groups in the studied complexes are terminally coordinated (ν_{CN} below 2100 cm^{-1}), through the nitrogen donor atom (the absence of ν_{CS} in the region 690–730 cm^{-1}).

3.3. Magnetic data

The magnetic susceptibility of the complexes under study increases monotonously on cooling. The effective magnetic moment keeps almost constant value except at very low temperatures when its decrease reflects a small zero-field splitting (Figs. 3 and 4).

Table 2

4, $[Ni(Bzfupy)_4(NCS)_2]\cdot 2H_2O$	10300, 16600, 27000	2069	796
5, $[Ni(iqu)_4(NCS)_2]\cdot CH_2Cl_2$	10700, 17300		

Restricting ourselves only to the axial zero-field splitting, the spin Hamiltonian becomes

$$\hat{H} = \hbar^{-2} D(\hat{S}_z^2 - \hat{S}^2/3) + \hbar^{-1} B\mu_B g \hat{S}_\alpha \quad (1)$$

($\alpha = x$ and z). The spin-Hamiltonian formalism offers another constraint among the magnetic parameters [14]

$$D = \lambda(g_z - g_x)/2, \quad (2)$$

where λ is the spin–orbit splitting parameter: $\lambda/hc = -315\ \mathrm{cm}^{-1}$. Thus we are left with two free parameters (g_z and g_x), and eventually the temperature-independent paramagnetism (the van Vleck term) α. Since the D value could be small, the closed formulae for the susceptibility are inappropriate so that we are left with the diagonalization of the spin Hamiltonian for a number of reference fields [20]. The susceptibility and magnetization data were treated simultaneously, by minimizing a joint functional

$$F(g_z, g_x, \chi_{TIP}) = w_1 \frac{\sum_{n=1}^{N} |\chi_n^o - \chi_n^c|}{(1/N)\sum_{n=1}^{N} |\chi_n^o|} + w_2 \sum_{m=1}^{M} (M_m^o - M_m^c)^2 \quad (3)$$

(c – calculated, o – observed data, weights $w_1 = w_2 = 0.5$). Such a choice guarantees that the center of the susceptibility data and the highest-field magnetization data are preferentially recovered by the fitting procedure. The calculated magnetic parameters are listed in Table 4.

As expected, the axial zero-field splitting parameter D adopts only small values. Its negative sign means that the ground state $|S, M_S\rangle$ is the Kramers doublet $M_S = \pm 1$. Therefore the effective magnetic moment on extrapolation to the zero temperature approaches a constant value of about $\mu_{eff} \approx 1.7\ \mu_B$ For nearly octahedral complexes the spin-Hamiltonian formalism offers a set of formulae [21]

5, $[Ni(iqu)_4(NCS)_2]\cdot CH_2Cl_2$	2.188	2.178	−1.58	+4.5	0.23	−0.0955	0.95

[a] Conventional discrepancy factor on the magnetic susceptibility. Estimated standard deviation of g-parameters: 0.002.

$$D = 4\lambda^2(\kappa_x^2 - \kappa_z^2)/\Delta_0, \quad (4)$$

$$g_z = g_e - 8\lambda\kappa_z^2/\Delta_0 > g_e, \quad (5)$$

$$g_x = g_e - 8\lambda\kappa_x^2/\Delta_0 > g_e, \quad (6)$$

where $\Delta_0 = 10$ Dq matches the first electronic transition $^3A_{2g} \rightarrow {}^3T_{2g}$. With $D < 0$ the orbital reduction factors are interrelated as $\kappa_x < \kappa_z$ so that the equatorial bond Ni–N is more covalent than the axial bond Ni–NCS (which is more polar). The above formulae yield another relationship

$$\frac{\kappa_x}{\kappa_z} = \left(\frac{g_x - g_e}{g_z - g_e}\right)^{1/2} \quad (7)$$

and these data are involved in Table 4. We tried to correlate the magnetochemical D-values with those from the structural data and the corresponding plot is presented in Fig. 5. One can see that a correlation surely exists.

With the inequivalent equatorial and axial ligands (D_{4h} symmetry) we arrive at a modified spin-Hamiltonian formula [22]

$$D = 4\lambda^2[\kappa_x^2/\Delta_{xy}(^3B_{1g} \rightarrow {}^3E_g) - \kappa_z^2/\Delta_z(^3B_{1g} \rightarrow {}^3B_{2g})], \quad (8)$$

where two close-lying transition energies (experimentally unresolved) occur. This formula, however, contains too many parameters which makes their determination and discussion very complex. On ignoring covalence effects (the orbital reduction factors $\kappa = 1$), a calculation has been performed in the complete space spanned by the d^8 term-functions by involving the electron repulsion, crystal-field and the spin–orbit coupling operators [21,22]. The splitting of the lowest crystal-field multiplets

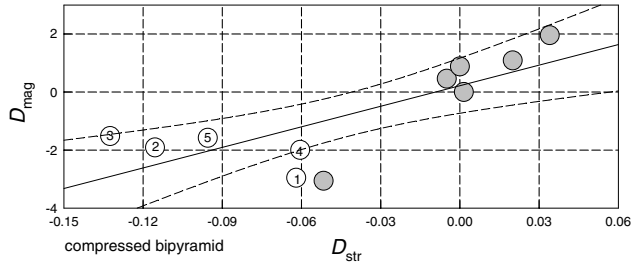

Fig. 5. Correlation of the magnetic D-values with structural D_{str} ones. White points – this work, gray – homoleptic Ni(II) complexes with six imidazole ligands [15]. Dashed – 95% confidence intervals.

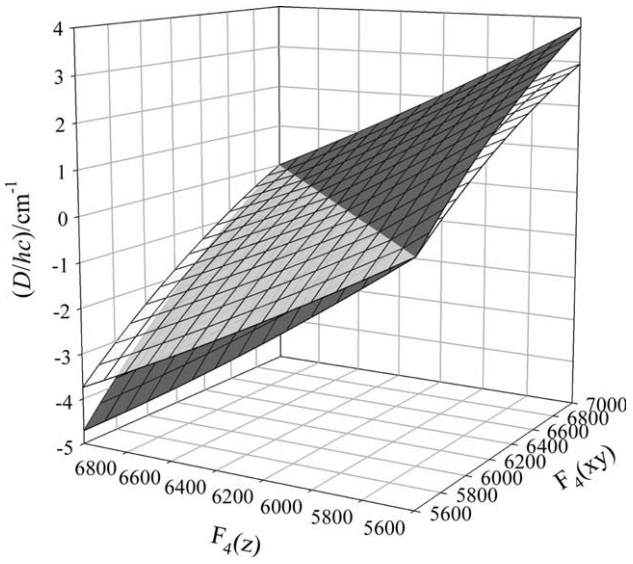

Fig. 6. Calculated D-parameters for Ni(II) systems at different tetragonal crystal fields. Two sets of D-values refer to the spin-Hamiltonian approach (dark) and the exact multiplet splitting (white). The crystal-field quadrupolar integrals are interrelated to the conventional crystal-field parameters through 10 Dq = $(10/6)F_4(xy)$ and $Dt = (2/21)[F_4(xy) - F_4(z)]$.

matches the zero-field splitting parameter $D = E(\Gamma_5) - E(\Gamma_4)$ where the Bethe notation is applied for irreducible representations of the D_4' double group. The modelling in the relevant crystal-field strengths (around 10 Dq = 10 000 cm^{-1} corresponding to $F_4 = 6000$ cm^{-1}) is shown in Fig. 6. It can be concluded that a negative value of the D-parameter is obtained for the compressed tetragonal bipyramid or, more exactly, for the crystal-field quadrupolar integrals obeying a relationship $F_4(xy) < F_4(z)$.

4. Conclusions

In this work, we report on the synthesis, structure, spectral and magnetic properties of five compounds of the formulae $[Ni(fupy)_4(NCS)_2]\cdot THF$, $[Ni(Mefupy)_4(NCS)_2]\cdot 1.29H_2O$, $[Ni(Me_2fupy)_4(NCS)_2]\cdot 6.6H_2O$, $[Ni(Bzfupy)_4(NCS)_2]\cdot 2H_2O$ and $[Ni(iqu)_4(NCS)_2]\cdot CH_2Cl_2$. The chromophore $\{NiN_4N_2'\}$ refers to a slightly compressed tetragonal bipyramid, giving rise to a negative tetragonality parameter D_{str} The electron spectra show

almost identical 10 Dq parameters with unresolved tetragonal splitting. This, however, is evidenced from the magnetic data yielding a negative zero-field splitting parameter D. The greater the (negative) structural distortion, the more negative D-value was observed.

theory [6]. As far as we know, the oxidation of $[Fe(phen)_3]^{2+}$ by $[H_6Co^{III}Mo_6O_{24}]^{3-}$ is the only study reported so far [8]. The standard reduction potential (E^0) and the self-exchange rate constant (k_{22}) for the $[H_6Co^{III}Mo_6O_{24}]^{3-}/[H_6Co^{II}Mo_6O_{24}]^{4-}$ couple in perchloric acid, not having been reported so far, are being reported now. The redox potential is measured directly and the self-exchange rate constant is estimated indirectly in a manner used in some recent studies [9,10], The iodide ion is selected as the substrate to test the Marcus cross-relation since a good number of rates for its oxidation by a number of oxidants are available [11].

2. Experimental

2.1. Materials

$[NH_4]_4[H_6Co^{II}Mo_6O_{24}]\cdot 4H_20$, was prepared by adding 100 ml of a solution of $CoCl_2\cdot 6H_2O$ (4.76 g, 0.02 mol), drop by drop, to 150 ml of a solution of $[NH_4]_6[Mo_7O_{24}]\cdot 4H_2O$ (24.72 g, 0.02 mol) followed by solid NH_4Cl (2 g) to have a pH of 4–4.5. The details of the other procedures were similar to those described [12]. The isolated crystals of $[H_6Co^{II}Mo_6O_{24}]^{4-}$ are stable indefinitely [12]. The Co(III)-complex, $K_3[H_6Co^{III}Mo_6O_{24}]$, was prepared by the oxidation of the corresponding Co(II)-complex ion by $[2KHSO_5\cdot KHSO_4\cdot K_2SO_4]$, oxone [12] (Dupont).

$[H_6Co^{III}Mo_6O_{24}]$ was also prepared by adding a solution of carbonatotetraamminecobalt(III) nitrate (15 g, 500 ml), in small portions, to an equal volume of a boiling solution of $[NH_4]_6Mo_7O_{24}\cdot 4H_2O$ (72 g, 500 ml). The solution was evaporated to about 150 ml and filtered. The addition of NH_4Cl to the hot filtrate produced a precipitate of $[NH_4]_3[H_6Co^{III}Mo_6O_{24}]$ and a small amount of dark olive-green [13] $[NH_4]_3[H_6Co^{III}Mo_5O_{21}]$. Because the olive-green (dimeric) species has a greater solubility, the blue-green monomeric $[NH_4]_3[H_6Co^{III}Mo_6O_{24}]$ was easily separated. The potassium salt, $K_3[H_6Co^{III}Mo_6O_{24}]$, was prepared by adding a saturated KCl (Fluka, Puriss) solution to the $[NH_4]_3[H_6Co^{III}Mo_6O_{24}]$ solution until the potassium salt precipitated. The filtered precipitate was dissolved in a minimum volume of hot distilled water and the decanted solution was allowed to cool at the room temperature when a mixture of blue-green and olive-green crystals separated out. These crystals were air-dried. The stock solution was prepared by dissolving the crystals in a dilute perchloric acid solution. The resulting green solution, believed to contain the monomeric species, $[H_6Co^{III}Mo_6O_{24}]^{3-}$, because the dimeric species, $[H_4(CoMo_5O_{19})_2]^{6-}$, is unstable in acidic solutions, was stable for several weeks [13].

The purity of the prepared Co(III)-hetero ion was checked by recording the UV–Vis spectra of the aqueous solution on a HP 8452A spectrophotometer (bandwidth 2 nm). The solution had λ_{max} at 410 nm (ε, 28.7 $dm^3\ mol^{-1}\ cm^{-1}$) and 602 nm (ε, 19.6 $dm^3\ mol^{-1}\ cm^{-1}$) [8].

Solutions of lithium and sodium perchlorate were prepared as described earlier [14] by neutralising lithium hydroxide (Sigma) and sodium carbonate (E. Merck, GR) by perchloric acid (E. Merck, GR). The solutions of sodium iodide (Puriss, Fluka) were freshly prepared by weighing before the kinetic runs. The other chemicals were of high purity and used as received. Double distilled water, once from an all glass still, was used throughout.

2.2. Repetitive scans of the mixture of $[H_6Co^{III}Mo_6O_{24}]^{3-}$ and H^+

The repetitive scans of an aqueous solution of $[H_6Co^{III}Mo_6O_{24}]^{3-}$ (5×10^{-4} mol dm^{-3}) in 0.05 and 0.5 mol dm^{-3} $HClO_4$ were studied at 410 nm and 8 °C using a Union Giken RA-401 stopped-flow spectrophotometer, dead time of 2 ms, connected to a RA-415 rapid scan attachment. The scans were over 96 nm (selected wavelength ± 48 nm). The reference was an aqueous solution of $[H_6Co^{III}Mo_6O_{24}]^{3-}$ of the same concentration. The gate time was 10 ms (the scan over 96 nm is completed in this time) and the interval time was zero (there is no time lag between the two sequential scans). Thus the first scan was completed between 2 and 12 ms and the second scan was completed between 12 and 22 ms, and so on after the solutions are pushed into the reaction cell. The peaks were blue shifted to 396 nm. The saturation in the absorbance, $[H^+] = 0.05$ mol dm^{-3},[1] was reached between 52 and 62 ms whereas the same absorbance was reached between 32 and 42 ms when $[H^+]$ was 0.5 mol dm^{-3}. Hence, it is rational to assume that the Co(III) and Co(II) species present in acid solution are $H_7Co^{III}Mo_6O_{24}^{2-}$ and $H_7Co^{II}Mo_6^{3-}$, which hereafter are represented as $HCo^{III}Mo_6^{2-}$ and $HCo^{II}Mo_6^{3-}$, respectively.

2.3. Reduction potential of the $HCo^{III}Mo_6^{2-}/HCo^{II}Mo_6^{3-}$ couple

The reduction potential of the cells having different $[HCo^{III}Mo_6^{2-}]/[HCo^{II}Mo_6^{3-}]$ ratios in varying $[H^+]$ (0.01–0.05 mol dm^{-3}) was measured using a platinum electrode against a calomel electrode prepared in saturated KCl solution. The plots of the measured potentials against $\log([HCo^{III}Mo_6^{2-}]/[HCo^{II}Mo_6^{3-}])$ at each $[H^+]$ were linear with intercepts in accordance with the Nernst Eq. (1). The least square values of the intercepts of each plot were calculated using the EXCEL program and the mean value of the intercept was 0.81 V. Hence,

[1] The caption of Fig. 1 of [8] should read correctly $[HClO_4] = 0.05$ mol dm^{-3} in place of 0.5 mol dm^{-3}.

the standard potential (E^0) of the $HCo^{III}Mo_6^{2-}$/$HCo^{II}Mo_6^{3-}$ couple is 1.05 V because the potential of the calomel electrode used was 0.24 V

$$E = E^0 + 0.0591 \log \frac{[HCo^{III}Mo_6^{2-}]}{[HCo^{II}Mo_6^{3-}]}. \quad (1)$$

2.4. Kinetic measurements

The rates were studied under pseudo first-order conditions ($[I^-] \geqslant 10[HCo^{III}Mo_6]^{2-}$) at constant ionic strength ($\mu = 1.0$ mol dm^{-3}, $LiClO_4$) in term of the appearance of the I_3^- ion at 353 nm ($\varepsilon = 2.64 \times 10^4$ dm^3 mol^{-1} cm^{-1} [15],), using a Union-Giken RA-401 stopped-flow spectrophotometer. The other species are transparent at this wavelength. The solutions of desired $[H^+]$, $[LiClO_4]$ and $[HCo^{III}Mo_6^{2-}]$, and $[I^-]$ and $[LiClO_4]$ were stored in separate storage cylinders which, along with the reaction cell, are maintained at the desired temperature (±0.1 °C) by circulating water from a Haake D8G circulatory water bath. The temperature of the solutions in storage cylinders was treated as the temperature of the reaction. The other experimental details were similar to those described earlier [16]. The k_{obs} values, reported in the Tables, are the mean values from at least 8–10 runs and the individual k_{obs} value from each run was reproducible within 5–8% of the mean value. The replacement of $LiClO_4$ by $NaClO_4$ for adjusting the ionic strength did not change the rate constant under identical conditions. However, $LiClO_4$ was used for adjusting the ionic strength.

2.5. Test for free radical

Two milliliters of acrylonitrile was added to the $HCo^{III}Mo_6^{2-}$ solution before adding the iodide solution. Both solutions had been previously purged with nitrogen. A white curdy precipitate of polymeric acrylonitrile appeared in the reaction mixtures, suggesting the formation of a free radical during the reaction. The control solutions of $HCo^{III}Mo_6^{2-}$ and I^-, taken separately, did not induce the polymerisation of the monomer.

2.6. Stoichiometry

The stoichiometry of the reaction was determined under kinetic condition, $[I^-]$ in large excess, by estimating $[I_3^-]$. The I_3^- was extracted with three 10 ml portions of carbon tetrachloride and the concentration was determined at 518 nm ($\varepsilon_{518} = 945$ dm^3 mol^{-1} cm^{-1}) [17]. The results indicated that the mean $\Delta[I_2]/\Delta[HCo^{III}Mo_6^{2-}]$ was 0.502 ± 0.004. Hence the stoichiometry of the reaction is represented by

$$2HCo^{III}Mo_6^{2-} + 2I^- \rightarrow 2HCo^{II}Mo_6^{3-} + I_2 \quad (2)$$

2.7. Characterisation of $HCo^{II}Mo_6^{3-}$

The liberated I_2 from the reaction mixture ($[HCo^{III}Mo_6^{2-}] = [I^-] = 5 \times 10^{-3}$ and $[H^+] = 0.1$ mol dm^{-3}) was removed with several aliquots of CCl_4. A known volume of the remaining solution was heated to remove the traces of iodine and then was treated with a slight excess of oxone ($[2KHSO_5 \cdot KHSO_4 \cdot K_2SO_4]$). The resulting solution was cooled to room temperature and made to the original volume. The estimated concentration of this solution (410 nm, $\varepsilon = 28.7$ dm^3 mol^{-1} cm^{-1}) agreed with that of the starting $HCo^{III}Mo_6^{2-}$ within ±2–3%. Hence, it is concluded that the iodide ion reduces the molybdocobaltate(III) ion to the molybdocobaltate(II) ion.

3. Results

The constancy of the k_{obs} values (1.03 ± 0.02 s^{-1}; $10^2[I^-] = 5.0$, $10^3[H^+] = 5.0$ and $\mu = 1.0$ mol dm^{-3}, 20 °C) at an initial $[HCo^{III}Mo_6^{2-}] = (5.0–50.0) \times 10^{-4}$ mol dm^{-3} indicated a first-order dependence in $HCo^{III}Mo_6^{2-}$. The average $k_{obs}/[I^-]$ is 20.6 ± 0.3 dm^3 mol^{-1} s^{-1} and the passage of the linear plot of the k_{obs} against $[I^-]$ through the origin indicated a first-order dependence in $[I^-]$ ($10^4[Co^{III}Mo_6]^{3-} = 5.0$, $[I^-] = (5.0–100.0) \times 10^{-3}$ mol dm^{-3}, $[H^+] = 0.005$ and $\mu = 1$ mol dm^{-3}). The k_{obs} increased with $[H^+]$, Table 1, and the passing of the linear plots of k_{obs} against $[H^+]$ through the origin, Fig. 1, indicated a first-order dependence in H^+. The k_{obs} (1.03 ± 0.02 s^{-1}) is independent of the initially added $HCo^{II}Mo_6^{3-}$ ($10^4[HCo^{III}Mo_6^{2-}] = 5.0$, $10^4[HCo^{II}Mo_6^{3-}] = (0.2–2.0)$, $10^2[I^-] = 5.0$, $[H^+] = 0.005$, $\mu = 1$ mol dm^3, 20 °C). It indicates that the rate-determining electron-transfer is not a reversible reaction.

4. Mechanism and discussion

There is significant difference in the oxidation of I^- ion by $[Co^{III}W_{12}O_{40}]^{5-}$ and $[H_6Co^{III}Mo_6]^{3-}$ ions. The

$10^4[Co(III)Mo]^{3-} = 2.0$, $10^3[I^-] = 5.0$ and $\mu = 1$ mol dm^{-3}.

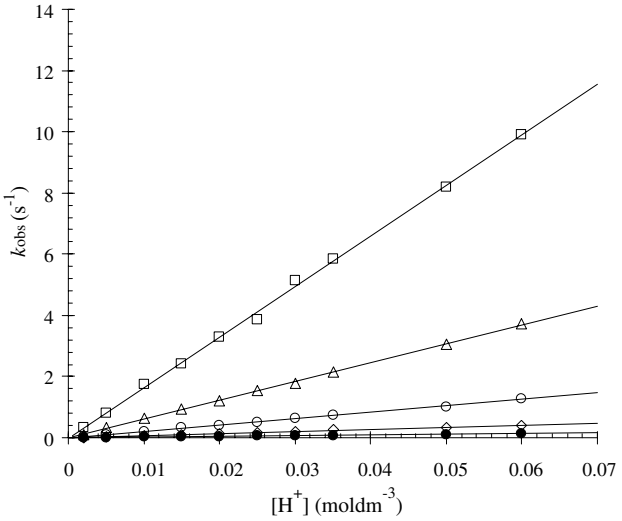

Fig. 1. The linear plots of k_{obs} against [H^+] at temperatures (°C) (10) ●, (15) ◇, (20) ○, (25) △ and (30) □. The linear plots pass through the origin.

k_{obs} in the $[Co^{III}W_{12}O_{40}]^{5-}$ oxidation is independent of [H^+] whereas a first order dependence is observed in the $HCo^{III}Mo_6{}^{2-}$ oxidation. This is due to the fact that the $[Co^{III}W_{12}O_{40}]^{5-}$ ion is not protonated in buffered [18] and perchloric acid solutions [19] whereas $[H_6Co^{III}Mo_6O_{24}]^{3-}$ ion is protonated as evident from the rapid scans of $[H_6Co^{III}Mo_6O_{24}]^{3-}$ and H^+ ion [8], described in the early part of the paper. The proton is probably added to oxygen atoms of low basicity in the shell of the molybdenum octahedra which are exposed to the solution [20] or to the water molecules occupying uncoordinated centres on the shell [21]. The protonated species of $[H_6Co^{III}Mo_6O_{24}]^{3-}$ is $[H_7Co^{III}Mo_6O_{24}]^{2-}$, which is abbreviated as the $[HCo^{III}Mo_6]^{2-}$ ion.

The most likely mechanism of the reaction, in view of the first-order dependence in each of [H^+], [I^-] and $[H_6Co^{III}Mo_6O_{24}]^{3-}$ and the fact that the rate is unaffected by $[H_6Co^{II}Mo_6O_{24}]^{4-}$ ions, is expressed by the most probable reactions (3)–(9)

$$[H_6Co^{III}Mo_6O_{24}]^{3-} + H^+ \overset{K}{\rightleftharpoons} [HH_6Co^{III}Mo_6O_{24}]^{2-} \quad (3)$$

$$[H_6Co^{III}Mo_6O_{24}]^{3-} + I^- \overset{k_4}{\rightarrow} [H_6Co^{II}Mo_6O_{24}]^{4-} + I^{\bullet} \quad (4)$$

$$[HH_6Co^{III}Mo_6O_{24}]^{2-} + I^- \overset{k_5}{\rightarrow} [HH_6Co^{II}Mo_6O_{24}]^{3-} + I^{\bullet} \quad (5)$$

$$I^{\bullet} + I^- \underset{k_{-6}}{\overset{k_6}{\rightleftharpoons}} I_2{}^{-\bullet} \quad (6)$$

$$I^{\bullet} + I^{\bullet} \overset{k_7}{\rightarrow} I_2 \quad (7)$$

$$[HH_6Co^{III}Mo_6O_{24}]^{2-} + I_2{}^{-\bullet} \overset{k_8}{\rightarrow} I_2 + [HH_6Co^{II}Mo_6O_{24}]^{3-} \quad (8)$$

$$I_2 + I^- \underset{k_{-9}}{\overset{k_9}{\rightleftharpoons}} I_3{}^- \quad (9)$$

Reactions (4) and (5) are rate determining. Reactions (6) and (9) are diffusion controlled. Reaction (6) is preferred over (7) for the dissipation of the $I^{\bullet}$ radical because the estimated value [22] of k_6 is 1.3×10^{10} $dm^3\ mol^{-1}\ s^{-1}$ and the equilibrium constant K_6 is [23] 1.1×10^5 $dm^3\ mol^{-1}$. The value [24] of k_9 is $\sim 10^{10}$ $dm^3\ mol^{-1}\ s^{-1}$ and the equilibrium constant K_9 is 720 $dm^3\ mol^{-1}$ [25]. Reactions (6), (8) and (9) are consistent with the observed stoichiometric ratio in Eq. (2).

The rate of disappearance of $[H_6Co^{III}Mo_6O_{24}]_0{}^{3-}$ in view of the reactions (3)–(9) is given by Eq. (10). The passing of the plots of k_{obs} against [H^+] through the origin indicate $1 \gg K\,[H^+]$ and therefore Eq. (10) is reduced to Eq. (11). Further, the species $[H_6Co^{III}Mo_6O_{24}]^{3-}$ are probably inactive or do not react with the iodide ion on the stopped-flow timescale, which is supported by the fact that the plots of k_{obs} against [H^+] have no intercepts combined with the fact that the stopped-flow traces of the reaction are monophasic. Hence, Eq. (11) is reduced to Eq. (12), which is consistent with the plots of k_{obs} against [I^-] and k_{obs} against [H^+] with zero intercepts

$$\frac{d[I_2]}{dt} = \frac{-d[H_6Co^{III}Mo_6O_{24}]_0}{2dt} = \frac{(k_4 + k_5K[H^+])[H_6Co^{III}Mo_6O_{24}][I^-]}{1 + K[H^+]}, \quad (10)$$

$$k_{obs} = 2(k_4 + k_5K[H^+])[I^-], \quad (11)$$

$$k_{obs} = 2k_5K[H^+][I^-]. \quad (12)$$

The activation parameters corresponding to the k_{obs} values at all the [H^+] (Table 1) were calculated by plotting $\ln(k_{obs}/2[I^-])$ against T^{-1}. It was found that the calculated values[2] of ΔE^{I}_{12}, ΔS^{I}_{12} and ΔG^{I}_{12} were independent of the initial [H^+]. Hence, Eq. (12) could be expressed by Eq. (13) where $k_{12} = k_5K[H^+]$. The estimated value of ΔG^{I}_{11} from the use of the ΔG^{I}_{12} value is thus independent of [H^+] and so would be the value of k_{11} deduced from ΔG^{I}_{11}

$$k_{obs} = 2k_{12}[I^-]. \quad (13)$$

The species $[H_2Co^{III}Mo_3O_{12}(HSO_5)]^{3-}$, resulting from the intramolecular electron transfer in the oxidation of $[H_6Co^{II}Mo_6O_{24}]^{4-}$ by the $HSO_5{}^-$ ion [12], has a coordinated $HSO_5{}^{2-}$ radical. A similar coordination complex is unlikely in the oxidation of I^- since the coordination sites in $[HH_6Co^{III}Mo_6O_{24}]^{2-}$ are saturated. However, an outer-sphere precursor complex between I^- and $[HH_6Co^{III}Mo_6O_{24}]^{2-}$ is likely for which K_{os} is the formation constant. The precursor complex is weak because k_{obs} has not shown signs of saturation [26] even

[2] $\Delta H^{\ddagger}_{12} = 151.6 \pm 2.2$ kJ mol^{-1}; $\Delta S^{\ddagger}_{12} = 301 \pm 7$ J K^{-1} mol^{-1} and $\Delta G^{\ddagger}_{12} = 61.7 \pm 2.6$ kJ mol^{-1}.

at high $[I^-]$ and k_{obs} is linearly dependent on $[I^-]$. Hence $k_{obs} = k_{et}K_{os}[I^-]$ where k_{et} is the rate constant for the electron transfer.

K_{os} is expected to be small because species of similar charges are involved. It can be estimated from the extended Fuoss equation [27] (14), where N is the Avagadro's number, $a = r_i + r_j$ (r_i and r_j are the radii of the ions i and j) and w_{ij} is the electric work term required to bring the reactants i and j to a distance a in the precursor complex and is given by Eq. (15). It arises from the Debye–Hückel interionic potential to allow for the effect of ionic strength [27], where z_i and z_j are the charges on the ions i and j, ε_0 and ε are the permittivity in vacuum and the bulk medium and κ is given by the Eq. (16) where k_B is the Boltzmann constant

$$K_{os} = \frac{4}{3}\pi N a^3 \exp(-w_{ij}/RT), \tag{14}$$

$$w_{ij} = \frac{z_i z_j e_0^2 N}{4\pi\varepsilon_0\varepsilon a(1+\kappa a)}, \tag{15}$$

$$\kappa = \sqrt{\frac{2e_0^2 N\mu}{\varepsilon_0\varepsilon k_B T}}. \tag{16}$$

The radius of $[Co^{III}W_{12}O_{40}]^{5-}$ is 0.5 nm and that of $[Ce^{IV}Mo_{12}O_{42}]^{8-}$ is 0.56 nm [28], therefore the radius of $[H_6Co^{III}Mo_6O_{24}]^{3-}$, is likely to be smaller than the radii of both the ions for the ionic radius of Mo^{6+} (0.062 nm) is less than that of W^{6+} (0.068 nm). The assumed value of the radius of $[H_6Co^{III}Mo_6O_{24}]^{3-}$ is 0.40 nm and that of iodide ion is 0.216 nm [29].

4.1. Calculation of k_{et}

The estimated value of κ is 3.28×10^9 m^{-1}, w_{12} is 1.90 kJ and K_{os} is 2.74×10^{-4} dm^3 mol^{-1}. The small value of K_{os} is due to the reaction between similarly charged ions. The calculated value of k_{et}, from the relation $k_{12} = k_{et}K_{os}$, is 1.2×10^3 s^{-1} at $[H^+] = 0.005$ mol dm^{-3} and 1.35×10^4 at $[H^+] = 0.06$ mol dm^{-3} at 25 °C. The corresponding value, calculated for the oxidation by the $[Co^{III}W_{12}O_{40}]^{5-}$ ion [30],[3] is 2.76×10^5 s^{-1} and is independent of $[H^+]$ because k_{12} is independent of $[H^+]$.

4.2. Calculation of exchange rate of $[HCo^{III}Mo_6]^{2-}$–$[HCo^{II}Mo_6]^{3-}$ ions

The unknown self exchange rate of $[HH_6Co^{III}Mo_6O_{24}]^{2-}$/$[HH_6Co^{II}Mo_6O_{24}]^{3-}$ can be calculated using the relations, based on simple Marcus theory [6], given in Eqs. (17)–(20). The method has been used recently to estimate the self-exchange rate of the $[Fe(CN)_5(NO_2)]^{3-}$–$[Fe(CN)_5(NO_2)]^{4-}$ couple [9], and the H_2NCSNH_2–$(H_2N)_2CSSC(NH_2)_2$ couple [10]

$$\Delta G_{12}^{\ddagger} = 0.5(\Delta G_{11}^{\ddagger} + \Delta G_{22}^{\ddagger} + \Delta G_{12}^{0} + \Delta w), \tag{17}$$

$$\Delta G_{12}^{0} = -nF(E_{11}^{0} - E_{22}^{0}), \tag{18}$$

$$\Delta w = w_{12} + w_{21} - w_{11} - w_{22}, \tag{19}$$

$$k_{ij} = K_B T h^{-1} \exp(-G_{ij}^{\ddagger}/RT), \tag{20}$$

where K_B is the Boltzmann constant, h is Planck's constant and T is the Kelvin temperature. ΔG_{12}^0, $\Delta G_{11}^{\ddagger}$, $\Delta G_{22}^{\ddagger}$ are, respectively, the free energy for the cross-reaction and the self exchange reactions of oxidant and reductant couples and $\Delta G_{12}^{\ddagger}$ is the free energy of activation for the cross-reaction.

The experimentally estimated E_{11}^0 for the $[HH_6Co^{III}Mo_6O_{24}]^{2-}$/$[HH_6Co^{II}Mo_6O_{24}]^{3-}$ couple is 1.05 V and is found to be independent of $[H^+]$. The E_{22}^0 value for the $I^{\cdot}/I^-$ couple has been adjusted [31] to 1.33 V from variously reported values [32–34]. This value, used previously in the oxidation by *trans*-$[Ru(tmc)O_2]^{2+}$ (tmc = 1,4,8,11-tetramethyl-1,4,8,11-tetraaza-cyclotetradecane) [35], is used in this paper. The self-exchange rate constant k_{22} for the $I^-/I^{\cdot}$ couple is reported [33,34] to have a value of 7×10^7 dm^3 mol^{-1} s^{-1} and is used presently.

The experimentally determined $\Delta G_{12}^{\ddagger}$ (kJ mol^{-1}) is 61.7 and the estimated ΔG_{12}^0, $\Delta G_{22}^{\ddagger}$ and $\Delta G_{11}^{\ddagger}$ are 27, 28 and 70, respectively, and $w = -1.76$ kJ mol^{-1} ($w_{22} = w_{21} = 0$, $w_{12} = 1.90$ and $w_{11} = 3.66$). $k_{11} = 3.5$ dm^3 mol^{-1} s^{-1} at 25 °C and $\mu = 1.0$ mol dm^{-3} is obtained from the estimated $\Delta G_{11}^{\ddagger}$ and is independent of $[H^+]$ because $\Delta G_{12}^{\ddagger}$ is fortunately independent of $[H^+]$. The k_{11} value for the $[Co^{III}W_{12}O_{40}]^{5-}$/$[Co^{II}W_{12}O_{40}]^{6-}$ couple is 1.7 dm^3 mol^{-1} s^{-1} at the same ionic strength and temperature [36]. Thus the two values are of the same order of magnitude. The small k_{11} value for the $[Co^{III}W_{12}O_{40}]^{5-}$/$[Co^{II}W_{12}O_{40}]^{6-}$ couple [4] is considered to be due to the tungstate environment surrounding the central Co atom. The somewhat higher value for the $[HH_6Co^{III}Mo_6O_{24}]^{2-}$/$[HH_6Co^{II}Mo_6O_{24}]^{3-}$ couple could be due to a more compact environment surrounding the Co atom.

In a recent article Swaddle and co-workers [37] pointed out that the exchange rate of the $[Fe(CN)_6]^{3-}$–$[Fe(CN)_6]^{4-}$ couple reported in the literature is in fact equal to $k'_K[K^+]$ where k'_K ($= k_{ex}/[K^+]_{total}$) is about 60% larger than k_K, the rate constant in the presence of the uncomplexed K^+ ion. k_{ex} is the observed rate constant when $[K^+]$ was controlled with 18-crown-6. Hence, the measured exchange rates in which a cation has a catalytic effect on the rates are larger than the rates predicted by Marcus theory for the reason that the ion pairing by the hydrated cation lowers the anionic–anionic repulsion. The ionic strength as such has only a small effect.

The present reaction is catalysed by the hydrogen ion. It has been shown that the molybdocobaltate species are protonated. Thus the hydrogen ion is not ion pairing with the anionic oxidant and does not act as a bridge between the anionic species. This is supported by the

[3] $\kappa = 3.282\times10^9$ m^{-1}, $w_{12} = 3.694$ kJ, $K_{os} = 6.258\times10^{-4}$ dm^3 mol^{-1} and $k_2 = 172.5$ dm^3 mol^{-1} s^{-1}.

fact that replacement of Li^+ by Na^+ had no perceptible effect on the measured rate. Hence, we are inclined to believe that the estimated exchange rate constant may not be the apparent rate constant. It is to be remembered that the parameters used in the estimation of the self-exchange rate constant were not dependent on $[H^+]$.

The outer-sphere oxidation of I^- by $[HH_6Co^{III}Mo_6O_{24}]^{2-}$ can be supported by estimating the rate constant k_{12} using the simple Marcus cross-relation [6] given by Eqs. (21)–(23)

$$k_{12} = (k_{11}k_{22}K_{12}f_{12})^{0.5}, \tag{21}$$

$$\log f_{12} = \frac{(\log K_{12})^2}{4\log\left(\frac{k_{11}k_{22}}{Z^2}\right)}, \tag{22}$$

$$\log K_{12} = n\Delta E/0.0591. \tag{23}$$

The use of the estimated values of $f_{12} = 0.38$ ($Z^2 = 10^{22}$), $K_{12} = 1.8 \times 10^{-5}$, $k_{11} = 3.54$ and $k_{22} = 7 \times 10^7$ dm^3 mol^{-1} s^{-1} in Eq. (21) leads to a value of $k_{12} = 41.2$ dm^3 mol^{-1} s^{-1} which is in reasonable agreement with the experimental value of 32.6 dm^3 mol^{-1} s^{-1}. Since the f value is dependent on Z^2, a value of $f = 0.29$ is obtained using $Z^2 \approx 10^{19}$ since Z is [38] $\approx 3 \times 10^9$. The value of k_{12} is thus modified to 36 dm^3 mol^{-1} s^{-1} which is in close agreement with the experimental value. Thus the reaction is outer-sphere.

4.3. Application of the modified Marcus' theory

Next the cross-reaction data, Table 2, is considered in terms of a modification [39,40] of the Marcus relationship expressed by the Eqs. (24)–(26) where $Z = 10^{11}$ dm^3 mol^{-1} s^{-1} [31]

$$k_{12} = (k_{11}k_{22}K_{12}f_{12})^{0.5}W_{12}, \tag{24}$$

$$\ln f_{12} = \frac{(\ln K_{12} + \frac{w_{12}-w_{21}}{RT})^2}{4[\ln\left(\frac{k_{11}k_{22}}{Z^2}\right) + \frac{w_{11}+w_{22}}{RT}]}, \tag{25}$$

$$W_{12} = \exp[-(w_{12} + w_{21} - w_{11} - w_{22})/2RT], \tag{26}$$

$$2\ln k_{12} - \ln f_{12} - 2\ln W_{12} - \ln k_{11} = \ln k_{22} + \ln K_{12}. \tag{27}$$

$E^0(I^{\cdot}/I^-)$ [31] = 1.33 V, $r(I^-)$ [29] = 2.16 Å, $r(I^{\cdot})$ [29] = 1.33 Å, k_{22} [33,34] = 7×10^7 dm^3 mol^{-1} s^{-1}.

[a] Symbols used are: A_3, tri-L-alanine; L_3, tri-L-leucine; G_{4a}, tetraglycinamide; G_4, tetraglycine; Aib_3, tri-α-aminoisobutyric acid; DGEN, *N*,*N*′-diglycyl-1,2-diaminoethane.

[b] J.M. Anast, D.W. Margerum, Inorg. Chem. 21 (1982) 3494, have reported a radius of 4.3 Å for Cu(III)-complexes with $H_{-3}Aib_3a$, $H_{-2}Aib_3$ and 4.1 Å for the Cu(III)($H_{-3}A_3G^-$) complex and the corresponding radii for the Cu(II) complexes being 4.7, 4.7 and 4.9 Å. Hence a mean value, 4.5 Å, is obtained for the Cu(III)/Cu(II)$H_{-2}Aib_3$ complex and has been assumed for the other complexes as well.

[c] This work, $[H^+] = 0.005$ mol dm^{-3}.

[d] This work, $[H^+] = 0.06$ mol dm^{-3}.

Eq. (27), the suitably rearranged logarithmic form of the Eq. (24), indicates that a plot of the left hand side ($2\ln k_{12} - \ln f_{12} - 2\ln W_{12} - \ln k_{11}$) against $\ln K_{12}$ should be linear with a predicted unit slope and the intercept must give the best least-square value of the self-exchange rate k_{22} for the $I^{\cdot}/I^-$ couple. The equation was tested for a number of oxidations of the I^- ion by a variety of oxidants (Table 1). The required linear plot is illustrated in Fig. 2.

The least-squares slope, 1.12, of the linear plot is in excellent agreement with the ideal value of 1.0 for an *outer*-sphere mechanism predicted by Eq. (27). The k_{22} value, estimated from the intercept (18.0), is 6.6×10^7 dm^3 mol^{-1} s^{-1} which is also in excellent agreement with the previously reported values [33,34,41].

4.4. Deviations from earlier observations

The points corresponding to $[Cu(H_{-3}G_{4a})]$, $[Cu(H_{-2}Aib_3)]$ and $Cu(H_{-3}G_4)]^-$ are found to show a greater scatter in the plot of log k_{12} versus $\log(f_{12}k_{22}K_{12})$, constructed by Fairbank and McAuley [41], than shown in Fig. 2. The probable reason for this deviation could be the ignoring of the work term and the radii of $I^{\cdot}$ radical, which is significantly different from that of the I^- ion [29]. However, their contention of an outer-sphere mechanism for the reaction between Cu(III)-peptide complexes and iodide ion is correct.

Another observation for the same reason is related to the position of the nickel complexes, (21)–(26) in Table 2. Fairbank and McAuley [41], report that the points for these complexes were above the least square line in their plot. It was stated that another line having an ideal slope of about 0.5 could be drawn through these points but the intercept value of such a line leads to a self-exchange rate $>10^{10}$ dm^3 mol^{-1} s^{-1} for the $I^{\cdot}/I^-$ couple. Therefore, these authors assigned an inner-sphere mechanism for the oxidation of the I^- ion by these Ni(III) complexes.

It is interesting to note that in Fig. 2, the points (21) ($[Ni(9\text{-ane})N_3]^{3+}$) and (24) ($[NiM_r]^{3+}$) are on the line, the points (22) ($[Ni(cyclam)]^{3+}$), (23) ($[NiM_m]^{3+}$) and (25) ($[NiE_m]^{3+}$) are reasonably near the line and the point (26) ($[Ni(tet\text{-}c)]^{3+}$) for which an outer-sphere mechanism is proposed [41] is a little deviated from the line. We are therefore inclined to assign an outer-sphere mechanism to the oxidation of I^- by the named nickel complexes though linear free energy relationships similar to those observed in the outer-sphere processes have been reported for the inner-sphere reactions also [42,43].

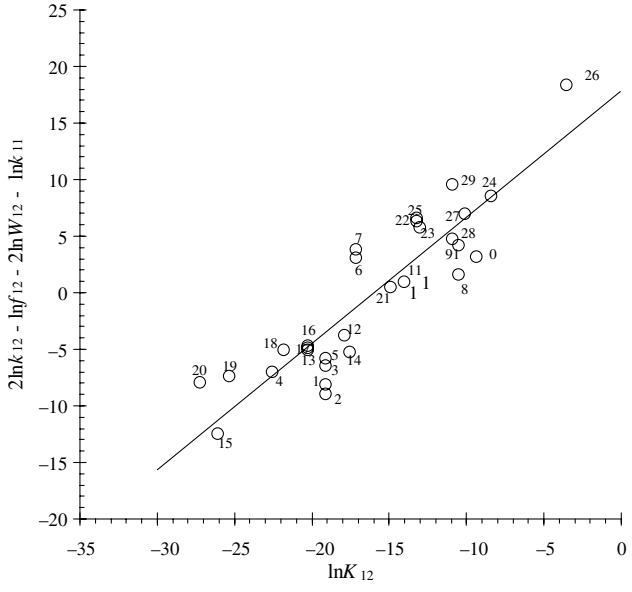

Fig. 2. The linear plot between $2\ln k_{12} - \ln f_{12} - 2\ln W_{12} - \ln k_{11}$ against $\ln K_{12}$ is in agreement with Eq. (27). The points in the plot are labelled according to the numbering of the complexes in Table 2.

4.5. Conclusion

The oxidation of I^- by $[HH_6Co^{III}Mo_6O_{24}]^{2-}$ has a first-order dependence in $[H^+]$ and is therefore different from that of $[Co^{III}W_{12}O_{40}]^{5-}$ oxidation which has zero order dependence in $[H^+]$. The H^+ dependence is caused by the oxidation of I^- by the protonated species $[HH_6Co^{III}Mo_6O_{24}]^{2-}$ whereas the species $[H_6Co^{III}Mo_6O_{24}]^{3-}$ is either inactive or does not react on the time-scale of the stopped flow measurements. The rapid scans of a mixture of H^+ and $[H_6Co^{III}Mo_6O_{24}]^{3-}$ indicated that the protonation equilibrium is attained in a few milliseconds. The measured reduction potential of the $[HH_6Co^{III}Mo_6O_{24}]^{2-}$–$[HH_6Co^{II}Mo_6O_{24}]^{3-}$ couple, 1.05 V, is independent of the initial $[H^+]$. The estimated self exchange rate of the $[HH_6Co^{III}Mo_6O_{24}]^{2-}$–$[HH_6Co^{II}Mo_6O_{24}]^{3-}$ couple is 3.5 dm^3 mol^{-1} s^{-1} since both the Co^{III}–Co^{II} species are likely to exist in the protonated form. The application of the Marcus theory confirms that the reaction is outer-sphere, consistent with the substitution inert nature of the polyoxometalate ions. The application of the Marcus theory, that has taken into consideration the ionic radii of the $I^{\cdot}$ radical and the work term, to the data of the oxidation of the iodide ion by nickel(III) complexes has indicated that these reactions are more likely to be outer-sphere rather than the inner-sphere as suggested in the original study.

complexes with the Schiff bases formed from propane-1, 3-diamine and different pyridine carboxyaldehyde or -ketones [16,17] have prompted us to develop new coordination compounds using azide and thiocyanate ligands. Successfully, we have prepared 12 mononuclear complexes of the type $[Cu(bpap)(N_3/NCS)]ClO_4$ (**1a**–**3b**) and $[Cd(bpap)(N_3/NCS)_2]$ (**4a**–**6b**), characterized on the basis of microanalytical, spectroscopic and other physicochemical properties. X-ray crystallographic studies of $[Cu(bpbp)(N_3)]ClO_4$ (**3a**) and $[Cd(bpbp)(NCS)_2]$ (**6b**) were made to define the coordination sphere. The details of synthesis, structure and luminescence behaviour are described below.

2. Experimental

2.1. Materials

High purity pyridine-2-carboxyaldehyde (Lancaster, UK), 2-acetylpyridine (Lancaster, UK), 2-benzoylpyridine (Lancaster, UK), propane-1,3-diamine (Lancaster, UK), sodium azide (Aldrich, USA), ammoniumthiocyanate (Aldrich, USA) potassium hexafluorophosphate (Fluka, Germany), copper nitrate tetrahydrate (E. Merck, India) and cadmium nitrate tetrahydrate (E. Merck, India) were purchased from their respective concerns and used as received. Copper perchlorate hexahydrate and cadmium perchlorate hexahydrate were prepared by treatment of copper carbonate and cadmium carbonate (E. Merck, India) with perchloric acid (E. Merck, India), respectively, followed by slow evaporation on a steam-bath, filtration through a fine glass-frit, and preservation in a desiccator containing concentrated sulfuric acid (E. Merck, India) for subsequent use. Purification of MeOH (E. Merck, India) and preparation of the supporting electrolyte ($[Et_4N][ClO_4]$) for electrochemical work were executed following a reported method [18]. All other chemicals and solvents were AR grade and were used as received.

Caution! Perchlorate and azido compounds of metal ions are potentially explosive, especially in the presence of organic ligands. Only a small amount of material should be prepared and it should be handled with care.

2.2. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed on a Perkin–Elmer 2400 CHNS/O Elemental Analyzer. IR spectra (KBr discs, 4000–300 cm^{-1}) were recorded using a JASCO FTIR model 420 spectrometer. Molar conductances were measured using a Systronics conductivity meter where the cell constant was calibrated with 0.01(M) KCl solution, and dry MeOH was used as the solvent. Ground state absorption and steady-state fluorescence measurements were made with a Shimadzu model UV-1601PC UV–Vis spectrophotometer and Hitachi model F-4500 spectrofluorimeter equipped with polarization accessory and low temperature unit (77 K). The temperature of the solution was kept to within ±0.1 K by circulating water through a HETO HOLTEN system. Room-temperature solid phase magnetic susceptibilities were measured at 298 K with a PAR 155 vibrating sample magnetometer with $Hg[Co(SCN)_4]$ as the reference. Mass spectra were obtained with a MAT 8200 (electron ionization, EIMS) instrument. Electrochemical measurements (cyclic voltammetry, CV) were carried out with the use of computer controlled EG&G PARC VersaStat model 270 electrochemical instrument using a platinum disk working electrode as described elsewhere [19]. The solutions were IR compensated and the results were collected at 298 K. The following parameters and relations were used: scan rate (v), 50 $mV\,s^{-1}$; formal potential $E^0 = 0.5(E_{pa} + E_{pc})$ where E_{pa} and E_{pc} are anodic and cathodic peak potentials, respectively; ΔE_p is the peak-to-peak separation. The potentials are referenced to a saturated calomel electrode (SCE) and are uncorrected for junction contributions.

2.3. Preparation of the Schiff bases

The Schiff base chelators, bpfp, bpmp and bpbp, were prepared following a reported [16] procedure with little modification. The details for bpfp are described: Pyridine-2-carboxyaldehyde (0.214 g, 2 mmol) was refluxed with propane-1,3-diamine (0.074 g, 1 mmol) in dehydrated alcohol. After 10 h the reaction solution was evaporated under reduced pressure to yield a gummy mass, which was dried and stored in vacuo over $CaCl_2$ for subsequent use [yield, 0.212 g (80%)]. Bpmp and bpbp were prepared similarly by refluxing for with 10 h 2-acetyl pyridine (0.242 g, 2 mmol) and 2-benzoylpyridine (0.366 g, 2 mmol), respectively, instead of pyridine-2-carboxyaldehyde, with propane-1,3-diamine (0.088 g, 1 mmol) in a 2:1 molar ratio. Yield: (78–80%). *Anal.* calc. for $C_{15}H_{16}N_4$ (bpfp): C, 71.40; H, 6.39; N, 27.20. Found: C, 71.41; H, 7.40; N, 27.23%. Mass spectrum (EI): m/z 252 ($M^+ = L^+$). IR (KBr, cm^{-1}): ν(C=N) 1590. UV–Vis (λ, nm): 240, 370. *Anal.* calc. for $C_{17}H_{20}N_4$(bpmp): C, 77.82; H, 7.19; N, 19.98. Found: C, 77.80; H, 7.20; N, 20.00%. 2.4. Preparation of the complexes

Complexes **1a**–**3b** were prepared from the perchlorate salts of copper(II) using the same mole ratio (1:1:1) of

metal, bpfp/bpmp/bpbp and azide/thiocyanate; these were also isolated using the nitrate salt by finally adding one equivalent sodium perchlorate. **4a**–**6b** were prepared from both cadmium(II) nitrate and/or cadmium(II) perchlorate using a mole ratio of 1:1:2 with bpfp/bpmp/bpbp and azide/thiocyanate. Typical syntheses are described below.

2.4.1. Copper(II)azido complexes

Solid bpfp (0.252 g, 1 mmol) was added pinch by pinch to a solution (10 cm^3) of $Cu(ClO_4)_2 \cdot 6H_2O$ (0.37 g; 1 mmol) in MeOH (15 cm^3) followed by NaN_3 (0.065 g, 1 mmol) with constant stirring. After 30 min the green solution mixture was filtered and the supernatant liquid was kept in air for slow evaporation. After 7 days **1a** was separated, washed with toluene and dried in vacuo over silica gel indicator. Yield: 0.86 g (70%). **2a** and **3a** were prepared by the same procedure using bpmp and bpbp, respectively, instead of bpfp. *Anal.* calc. for $C_{15}H_{16}N_7O_4ClCu$ (**1a**): C, 39.39; H, 3.52; N, 21.44. Found: C, 39.40; H, 3.54; N, 21.46%. IR (KBr, cm^{-1}): ν(C=N) 1637, 1592; $\nu(N_3)$ 2073; $\nu(ClO_4)$ 1080, 622. Mass spectrum (FAB): *m*/*z* 357 ($M^+ = [Cu(bpfp)(N_3)]^+$). Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 130; UV–Vis ($\lambda$, nm): 715, 394. *Anal.* calc. for $C_{17}H_{20}N_7O_4ClCu$ (**2a**): C, 42.06; H, 4.15; N, 20.20. Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 120; UV–Vis ($\lambda$, nm): 720, 402.

2.4.2. Copper(II)thiocyanato complexes

To copper(II) nitrate tetrahydrate (0.241 g, 1 mmol) in methanolic solution (10 cm^3), faint yellow bpbp (0.406 g, 1 mmol) was added dropwise. An methanolic solution (5 cm^3) of ammoniumthiocyanate (0.076 g, 1 mmol) was added with constant stirring. To this solution one equivalent of sodium perchlorate was added slowly drop by drop. The final deep green solution was filtered and left for slow evaporation in air. After a few days fine green crystals of **3b** were separated out, which were filtered, washed with methanol and dried in *vacuo* over $CaCl_2$. Yield: 0.125 g (74%). **1b** and **2b** were prepared by the same procedure using bpfp and bpmp respectively instead of bpbp. *Anal.* calc. for $C_{28}H_{24}N_5SO_4ClCu$ (**3b**): C, 53.76; H, 3.86; N, 11.19. Found: C, 53.72; H, 3.88; N, 11.14%. IR (KBr, cm^{-1}): ν(C=N) 1637,1592; ν(NCS) 2100, 2095; $\nu(ClO_4)$ 1080, 622. Anal. Found: C, 43.12; H, 4.01; N, 13.93. Calc. for $C_{18}H_{20}N_5SO_4ClCu$ (**2b**): C, 43.11; H, 4.02; N, 13.96%. IR (KBr, cm^{-1}): ν(C=N) 1637, 1590; ν(NCS) 2098, 2095; $\nu(ClO_4)$ 1080, 622. Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 120; UV–Vis ($\lambda$, nm): 720, 402.

2.4.3. Cadmium(II)azido complexes

A methanolic solution (5 cm^3) of bpfp (0.252 g, 1 mmol) was added dropwise to a solution of $Cd(ClO_4)_2 \cdot 6H_2O$ (0.311 g; 1 mmol) in the same solvent (10 cm^3) followed by NaN_3 (0.13 g, 2 mmol) in warm methanol (5 cm^3). The green solution was filtered and the supernatant liquid was kept in air for slow evaporation. After a few days **4a** was separated, washed with toluene and dried in vacuo over silica gel indicator. Yield: 0.113 g (70%). **5a** and **6a** were prepared by same procedure using bpmp and bpbp, respectively, instead of bpfp. *Anal.* calc. for $C_{15}H_{16}N_{10}Cd$ (**4a**): C, 40.18; H, 3.59; N, 31.24. Found: C, 40.14; H, 3.64; N, 31.26%. IR (KBr, cm^{-1}): ν(C=N) 1637,1592; $\nu(N_3)$ 2073, 2040. Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 5; UV–Vis ($\lambda$, nm): 336. *Anal.* calc. for $C_{27}H_{24}N_{10}Cd$ (**6a**): C, 53.99; H, 4.02; N, 23.32. Found: C, 53.95; H, 4.06; N, 23.35%. IR (KBr, cm^{-1}): ν(C=N) 1637, 1590; $\nu(N_3)$ 2073, 2040. Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 5. UV–Vis ($\lambda$, nm): 335.

2.4.4. Cadmium(II)thiocyanato complexes

A methanolic solution (5 cm^3) of bpbp (0.406 g, 1 mmol) was added dropwise to a solution of $Cd(ClO_4)_2 \cdot 6H_2O$ (0.311 g; 1 mmol) in the same solvent (10 cm^3) followed by NH_4NCS (0.15 g, 2 mmol) in warm methanol (5 cm^3). The green solution was filtered and the supernatant liquid was kept in air for slow evaporation. After a few days **4b** was separated, washed with toluene and dried in vacuo over silica gel indicator. Yield: 0.242 g (72%). **5b** and **6b** were prepared in the same way using bpmp and bpbp. *Anal.* calc. for $C_{17}H_{16}N_6S_2Cd$ (**4b**): C, 42.48; H, 3.35; N, 17.48. Found: C, 42.47; H, 3.39; N, 17.43%. IR (KBr, cm^{-1}): ν(NCS) 2100, 2095; ν(C=N) 1605. Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 5; UV–Vis (MeOH; λ, nm): 330. *Anal.* calc. for $C_{19}H_{20}N_6S_2Cd$ (**5b**): C, 44.88; H, 3.96; N, 16.53. Found: C, 44.76; H, 3.92; N, 16.57%. IR (KBr, cm^{-1}): ν(C=N) 1635, 1592; ν(NCS) 2100, 2095. Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 5; UV–Vis ($\lambda$, nm): 335. *Anal.* calc. for $C_{29}H_{24}N_6Cd$ (**6b**): C, 55.06; H, 3.82; N, 13.28. Found: C, 55.08; H, 3.86; N, 13.31%. IR (KBr, cm^{-1}): ν(C=N) 1637, 1590; ν(NCS) 2100, 2095. Λ_M (MeOH, $\Omega^{-1}\,cm^2\,mol^{-1}$): 5; UV–Vis ($\lambda$, nm): 332.

2.5. Copper(II)–copper(I) interconversion

2.5.1. $[Cu(bpap)(N_3/NCS)]ClO_4 \rightarrow [Cu(bpap)]ClO_4$

To a methanolic suspension (15 cm^3) of the complexes $[Cu(bpap)(N_3)]ClO_4$ (0.14 g, 0.25 mmol), ascorbic acid (0.045 g, 0.25 mmol) in water (5 cm^3) was added with stirring. The brown suspension quickly changed to deep red-brown and stirring was continued for 30 min, and the precipitated mass was filtered, washed with water and cold methanol. The residue was dried over a $CaCl_2$ desiccator and subjected to column chromatography on a silica gel column prepared in $CHCl_3$. A brownish-red band was eluted by $CHCl_3$–MeOH (4:1, v/v) mixture and dried in air. Crystals were obtained by diffusion of a CH_2Cl_2 solution of the complex to a hexane layer. Yield: 54–57%. The microanalytical data of the complexes are as follows: *Anal*. calc. for $[Cu(bpfp)]ClO_4$: C, 43.43; H, 3.88; N, 13.50. Found: C, 43.40; H, 3.85; N, 13.49%. *Anal*. calc. for $[Cu(bpmp)]ClO_4$: C, 46.10; H, 4.55; N, 12.65. Found: C, 46.09; H, 4.54; N, 12.63%. *Anal*. calc. for $[Cu(bpbp)]ClO_4$: C, 45.48; H, 5.38; N, 12.48. Found: C, 45.47; H, 5.37; N, 12.47%.

2.5.2. $[Cu(bpap)]ClO_4 \rightarrow [Cu(bpap)(N_3/NCS)]ClO_4$

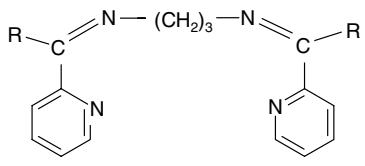
To a methanolic suspension of $[Cu(bpap)]ClO_4$ (0.15 g, 0.25 mmol) an aqueous solution of NaN_3 (0.015 g, 0.25 mmol) was added, air was passed for through the solution for 30 min and from time to time methanol was added to maintain the volume of the solution at 25 ml. The mixture was filtered and kept in a freezer for 4 h. A brown precipitate was filtered and washed with water and cold methanol. The compound was soluble in a mixture of 2-methoxy ethanol and methanol (1:5, v/v) and crystallized by evaporation in air for a week. Yield: 55–60%. The microanalytical data are consistent with complexes **1a**–**3b**.

2.6. X-ray diffraction study

Suitable single crystals of compounds **3a** and **6b** were mounted on a SMART CCD area detector equipped with a graphite monochromotor and Mo Kα(λ = 0.71073) radiation. The intensity data were corrected for Lorentz and polarization effects for all the complexes. Diffraction data for both **3a** and **6b** were measured using the ϕ and ω scan method. The structures were solved by Patterson syntheses using SHELXS-97 [20] and followed by successive Fourier and difference Fourier syntheses. Full-matrix least-squares refinements on F^2 were carried out using SHELXL-97 [21] with anisotropic displacement parameters for all non-hydrogen atoms for the complexes. The hydrogen atoms were fixed geometrically and refined using a riding model. In the final difference Fourier map the residual maxima and minima were 0.395 and −0.262 e $Å^{-3}$ for **3a**, 0.812 and −0.395 e $Å^{-3}$ for **6b**, respectively. All calculations were carried out using PLATON 99 [22] and ORTEP-32 [23]. The crystal data, data collection parameters and the results of analyses of **3a** and **6b** can be found in Table 1.

3. Results and discussion

3.1. Synthesis and formulation



In a one-pot reaction the chelators, the Schiff bases, were prepared by the condensation of one equivalent of propane-1,3-diamine and two equivalents of pyridine-2-carboxyaldehyde/2-acetylpyridine/2-benzoylpyridine in dry alcohol (Scheme 1). The pentacoordinated mononuclear complexes $[Cu(bpap)(N_3/NCS)]ClO_4$ (**1a**–**3b**) initially formed in an MeOH solution containing a 1:1:2 mixture of $Cu(ClO_4)_2 \cdot 6H_2O$, bpap and NaN_3/NH_4NCS; a reactant ratio expected to yield a mononuclear species of the composition $[Cu(pbpa)(N_3/NCS)_2]$. However, microanalyses showed a 1:1:1 ratio of metal, blocking ligand and the pseudohalide, and in the IR spectra the presence of perchlorate bands was noticed. A reactant ratio corresponding to the product stoichiometry afforded better yields of $[Cu(bpap)(N_3/NCS)]ClO_4$ (**1a**–**3b**). In an effort to get $[Cu(bpap)(N_3/NCS)_2]$, the starting material was changed to $Cu(NO_3)_2 \cdot 4H_2O$, and a 1:1:2 molar ratio of nitrate salt, ligand and the pseudohalide produced a gummy mass of indefinite composition. The hexacoordinated mononuclear complexes (**4a**–**6b**) were obtained starting with a 1:1:2 molar ratio of cadmium perchlorate/metal nitrate, bpap and azide/thiocyanate, and conformed in the IR spectra to the absence of perchlorate and/or nitrate bands. The air-stable moisture-insensitive complex salts are highly soluble in common organic solvents like methanol, ethanol, dichloromethane, acetonitrile and dimethylformamide but are insoluble in water. All the complexes were characterized by elemental analysis, electrical conductivity, IR, UV–Vis and reflectance spectra, luminescence behaviour and also magnetic susceptibility, and electrochemistry for the complexes **1a**–**3b**. The results are consistent with the proposed mononuclear formulation. In methanol solutions **1a**–**3b** behave as 1:1 electrolytes [24] as reflected in their Λ_M values (ca. 130 Ω^{-1} cm^2 mol^{-1}) but **4a**–**6b** behave as non-electrolytes as is evident from their low conductivity values (ca. 5 Ω^{-1} cm^2 mol^{-1}). Room-temperature solid-phase magnetic susceptibility measurements show that the copper(II) complexes have magnetic moments close to the spin-only value (S = 1/2), 1.73 BM, as expected from discrete and magnetically non-coupled mononuclear $3d^9$ ions.

3.2. Spectral studies

In the IR spectra, the point of interest is the band due to the azide and thiocyanate in the complexes.

R = H, bpfp; R = Me, bpmp; R = Ph, bpbp

Scheme 1.

The spectra exhibit a very strong and sharp absorption band at 2040–2080 cm^{-1} due to asymmetric stretching vibrations [25] of the terminal azide. The presence of ionic perchlorate bands at 1091 and 621 cm^{-1} is noticed for **1a**–**3b**. The complexes **4a**–**6b** show a characteristic strong transmission at 2098–2105 cm^{-1} along with a weak band at 2090–2093 which correspond to $\nu_{asym}(NCS^-)$. The stretching vibrations of the (C=N) band of the Schiff base are seen at 1629 and 1589 cm^{-1}. All other characteristic ligand vibrations are seen in the range 1600–600 cm^{-1}. The solutions of **1a**–**3b** in MeOH are dark green and exhibit absorptions at ca. 720, 400 nm. The transition >700 nm corresponds to a d–d transition of the copper(II) moiety and the band around 400 nm to intramolecular ($n \rightarrow \pi^*$, $\pi \rightarrow \pi^*$) charge transfer transitions [26]. The solutions of the complexes **4a**–**6b** in MeOH are colourless and exhibit absorptions at ca. 330 nm. Reflectance spectra in nujol and electronic spectra in MeOH solutions are akin in each complex, reflecting similar gross structure and electronic structure in the solid state and in solution.

3.3. Electrochemical studies for the copper(II) complexes

Electroactivity of the complexes was studied in MeOH solutions using cyclic voltammetry and coulometry at platinum working electrodes. A one-electron reductive response is observed, presumably due to the electrode reaction:

$$\left[Cu^{II}(L)(N_3)\right]^{1+} + e \rightleftharpoons \left[Cu^{I}(L)(N_3)\right] \quad (1)$$

The electrode process in the CV is reproducible in the potential range of 0.08 to −0.08 V with no trace of decomposition as reflected in smooth cyclic voltammograms. The one-electron stoichiometry of couple 1 was confirmed by a comparison of the current height with that of a standard [27] copper(II)–copper(I) couple, since attempted coulometry at potentials more cathodic than E_{pc} gave a continuous coulomb count due to some unidentified side reactions [28]. The similar pattern in the electron transfer behaviour of all the complexes at about the same potential once again corroborates a similar structure of the cationic units.

3.4. Luminescence properties

Complexes with bpap shows an intense absorption at ca. 405 nm which is assigned to intraligand π–π* transitions. The emission energy of the complexes in MeOH solutions at 298 K is almost same ($\lambda_{max} \approx 475$ nm) and is assignable to intraligand fluorescence [11]. The lifetimes of the complexes are in range 2.55–2.63 ns. In glassy solutions (MeOH at 77 K) both fluorescence and $^3(\pi–\pi^*)$ phosphorescence is observed at 525 nm. In the solid state they show a distinct emission band at 492 nm, differing from their fluorescence spectra in MeOH (Fig. 3).

3.5. X-ray crystal structure

3.5.1. [Cu(bpbp)(N_3)]ClO_4 (**3a**)

In order to define the coordination sphere, a single-crystal X-ray diffraction study was made in one case, viz **3a**. An ORTEP diagram with the atom numbering scheme of the mononuclear unit in **3a** is shown in Fig. 1. Selected interatomic bond lengths and bond angles are listed in Table 2. The crystal lattice consists of $[Cu(bpbd)(N_3)]^+$ cations and ClO_4^- anions. The coordination polyhedron around the metal centre is best described as distorted trigonal bipyramid (tbp) with a CuN_5 chromophore. The coordination includes a tetradentate Schiff base (bpbp), a chelating blocker ligated by two pyridine nitrogens (N5, N7) and two imine nitrogens (N4, N6), and one terminal azide nitrogen (N1). The equatorial positions are occupied by one imine nitrogen (N6), one pyridine nitrogen (N7) and the azide nitrogen (N1) while the axial positions are occupied by the remaining imine (N5) and pyridine (N4) nitrogen atoms. The distortion from ideal tbp geometry is due to the asymmetric nature of the Schiff base and the deviations of the refine angles (90°/120°) formed at the metal centre. The propylenic part of the Schiff base N4–C27–C26–C25–N6 is to some extent puckered due to sp^3 hybridization of the saturated portion of the chelating ligand and deviation [114.6(6)°] from the ideal bond C27–C26–C25 angle of 109°28′ (Fig. 1). The equatorial Cu–N distances [2.005(5)–2.101(5) Å] as well as the bond angles [93.2(2)–133.98(19)°] show significant variations. The axial Cu–N distances [Cu–N4 1.978(4) Å, Cu1–N5 1.994(5) Å] are however close and these are the smaller bond distances than the three equatorial bond distances [9]. The three bite angles N4–Cu–N7, N4–Cu–N6 and N6–Cu–N5 are 79.83(19)°, 92.14(19)° and 80.3(2)°, respectively. The larger bite in N4–Cu–N6 arises due to a six-membered puckered loop formed from the propylenic arm and the lower value of the non-bite angle N5–Cu–N7 [100.6(2)°]. The axial bond angle, N4–Cu–N5 [170.0(2)°], deviates from the ideal value (180°). The sum (359.88°) of the equatorial angles N6–Cu–N7 [133.98(19)°], N1–Cu–N6 [132.7(2)°] and N1–Cu–N7 [93.20(2)° are very close to 360.00°; so the atoms N1, N6, N7 and Cu are almost the same plane. In the terminal azide ligand the N1–N2 distance [1.170(9) Å] is longer than the N2–N3 length [1.152(10) Å] which indicates that the nitrogen (N1) atom of N_3^- is coordinated to the copper(II) centre. The N_3^- ion is coordinated in a linear fashion as seen from its N1–N2–N3 angle [179.0(8)°] [8,10b].

Table 2
Selected bond distances (Å) and angles (°) for **3a**

Bond distances	
Cu–N(4)	1.978(4)
Cu–N(5)	1.994(5)
Cu–N(7)	2.101(5)

3.5.2. [Cd(bpbp)(NCS)$_2$] (**6b**)

An ORTEP view with the atom numbering scheme of the mononuclear unit in **6b** is shown in Fig. 2. Selected bond lengths and angles relevant to the coordination sphere are listed in Table 3. The metal centre is best described as a distorted octahedron with a CdN_6 chromophore. Distortion from the ideal octahedral geometry is due to the asymmetric nature of the bound tetradentate Schiff base and the deviations of the refine angles (90°/180°) formed at the metal centre (Table 3). The coordination includes the Schiff base ligated by two pyridine nitrogens (N3, N6) and two imine nitrogens (N4, N5), and two nitrogens (N1, N2) of the thiocyanates. The equatorial positions are occupied by the four nitrogen atoms (N3, N4, N5 and N6) of the tetradentate ligand while the nitrogens (N1, N2) of the isothiocyanato groups are placed at the axial positions. The propylenic part of the Schiff base N5–C17–C16–C5–N4 is to some extent puckered due to sp^3 hybridization of the saturated portion of the chelating ligand and deviation [119.1(2)°] from the ideal C15–C16–C17 bond angle of 109°28′. The four N atoms of the ligand creates hardness in the cadmium(II) centre; so it appears to be a major reason to have preferential N-donation of the ambidentate NCS through its electronegative hard centre. The degrees of distortion from an ideal octahedral (90°) geometry are reflected in the *cisoid* [69.42(6)–119.35(8)°] and the *transoid* angles [141.03(7)–160.23(8)°]. Within the equatorial plane the Cd–N distances are in the range [2.271(2)–2.4486(18) Å], comparable to the corresponding values in similar systems [11]. Axial Cd–N distances [2.301(2)–2.4376(19) Å] indicate stronger coordination of the anionic isothiocyanate over the neutral Schiff base [17]. The angles subtended by the ligand around cadmium in the equatorial plane shows a significant variation [69.42(6)–119.35(8)°] from

the ideal 90.00°. The *trans* N2–Cd–N6 angle has a value [160.23(8)°], not close to the ideal value of 180.00°. The angles N1–Cd–N3, N3–Cd–N4 and N4–Cd–N5 in the equatorial plane with values 94.37(8)°, 69.42(6)° and 80.53(6)° are much less than the N1–Cd–N5 angle [119.35(8)°], where N3, N6 belong to the two pyridine ends of the Schiff base. Both the isothiocyanate ligands

are almost linear with exact 179.2(3)° angles. N–C [1.158(3)–1.161(3) Å] and C–S [1.620(3)–1.621(3) Å] bond lengths are as expected for N-coordination [11]. All the other bond lengths and angles on the ligand network are close to the expected values [6a].

4. Conclusion

Twelve new complexes are prepared in combination with tetradentate Schiff bases as blockers. In all cases a chelation mode of the Schiff bases is noticeable. The compounds are new example of luminous materials. We are now investigating the congregation [8] behaviour of related tetradentate N-donor Schiff bases with tailoring on the propylenic arm as well as acidic proton(s) on the ligand network towards the preparation of coordination polymers and supramers of varied molecular and crystalline architectures, which may behave as better luminous materials.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre Nos. 260089 for **3a** and 260090 for **6b**. Copies of this information can be had free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 IEZ, UK (fax: +44 1223 336 033; e-mail: deposit @ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

cationic $[Mo(H_2NO)(H_2O)(NO)(terpy)]^{2+}$ complex and CN^- ions [28,29].

It is noticeable that none of the reported cyanonitrosyl complexes of Mo and W have been obtained either from direct synthesis with nitric oxide or from their cyanocomplexes. Our recent investigations on the reactivity of $[M(CN)_4O(L)]^{n-}$ type complexes have revealed their capability of binding of molecular oxygen [30–32]. These reactions proceed via paramagnetic M^V intermediates with the formation of final peroxo complexes, $[M(CN)_4O(O_2)]^{2-}$. The use of NO (instead of O_2), being known for strong coordination to various metals, could facilitate the isolation of the paramagnetic products since nitric oxide can be reduced only in a one-electron process upon coordination. Based on our previous results, we selected $(PPh_4)_2[M(CN)_4O(pz)]\cdot 3H_2O$ salts for the reaction with NO as they have got the weakest M–L bond of all the characterized salts of that class.

In this work we report for the first time the direct reaction between NO and cyanocomplexes of molybdenum(IV) and tungsten(IV). This process is the first example of oxo ligand substitution in the coordination sphere of $[M(CN)_4O(L)]^{n-}$ type complexes. We also describe the X-ray crystal structure and properties of the molybdenum product.

2. Results and discussion

2.1. Reactions with NO

In order to investigate the reactivity of oxocyanocomplexes of Mo(IV) and W(IV) towards NO we have selected the $[M(CN)_4O(pz)]^{2-}$ anions as they have the weakest M–pz bond of all known complexes of that type [$d_{M-N(pz)}$ = 2.569 Å (Mo) and 2.521 Å (W)] [30,33]. We have observed that bubbling nitric oxide through a dioxygen-free dichloromethane solution of the $[M(CN)_4O(pz)]^{2-}$ complexes results in a colour change from green to yellow. IR liquid spectra measured during that process are presented in Fig. 1 in the case of the molybdenum complex and in Fig. 2 in the case of the tungsten one.

The spectra revealed new intense bands at 1692 cm^{-1} (for Mo) and 1653 cm^{-1} (for W) confirming in both cases the coordination of NO. Their relatively low wavenumbers indicate the nitrosyl ligand to be in the form of the NO^- anion [34–36]. The observed bands change subsequently into one intense band at 1712 cm^{-1}, in both cases. The increase of those bands was also accompanied by a decrease of the characteristic M–O band at 974 cm^{-1} (Mo) or 969 cm^{-1} (W) as well as an increase of two new bands at 1222 cm^{-1} (Mo and W) and 1362 cm^{-1} (Mo) or 1355 cm^{-1} (W) (Figs. 1 and 2). The pair of bands (1712 and 1222 cm^{-1}) appearing in the same positions in the reaction of both molybdenum and tungsten complexes

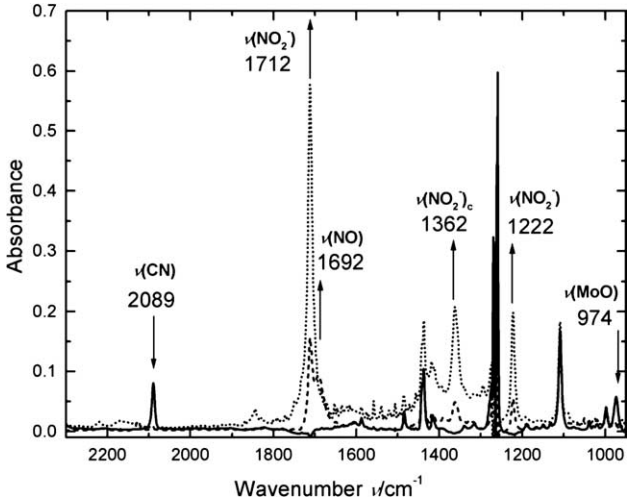

Fig. 1. IR spectra (950–2300 cm^{-1} range) of a deoxygenated dichloromethane solution containing $[Mo(CN)_4O(pz)]^{2-}$ (solid line) after 6 min (dashed line) and 60 min (dotted line) of NO bubbling. Numbers indicate wavenumbers (in cm^{-1}) and the arrows show the direction of the changes.

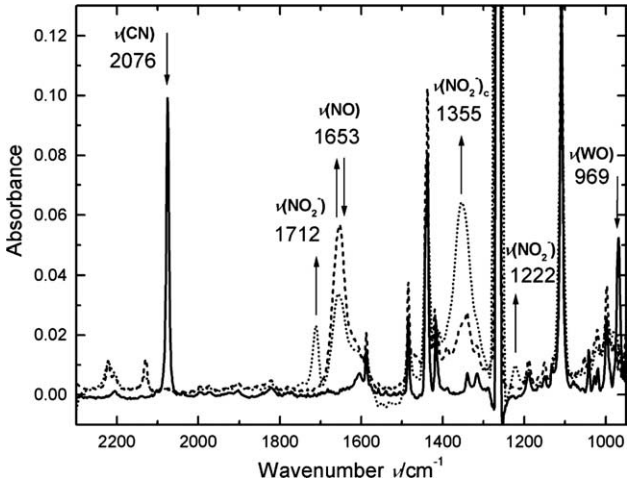

Fig. 2. IR spectra (950–2300 cm^{-1} range) of a deoxygenated dichloromethane solution containing $[W(CN)_4O(pz)]^{2-}$ (solid line) after 8 min (dashed line) and 51 min (dotted line) of NO bubbling. Numbers indicate wavenumbers (in cm^{-1}) and the arrows show the direction of the changes.

was attributed to the stretching vibrations of the NO_2^- group of the uncoordinated nitrites. Such pairs of bands corresponding to stretching N–O vibrations are characteristic of nitrites [4,37]. The formation of NO_2^- anions can be explained by the attack of NO at the oxo ligand in the starting complexes (we observe a decrease of the M–O bands) and subsequent release of a nitrite into solution. After the release of NO_2^-, the resulting complex easily binds other molecules present in solution. In the case of molybdenum at that stage of the reaction the yellow product of the formula $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot C_4H_9OH\cdot CH_2Cl_2$ (**1a**), was isolated from solution. We have observed that the salt is soluble in

methanol and acetonitrile, and insoluble in such solvents as water, ethanol, butane-1-ol, dichloromethane, acetone and diethyl ether. Its recrystallization in the presence of diethyl ether leads to monocrystals of $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot 2C_2H_5OC_2H_5$ (**1b**) that were used for X-ray diffraction measurements.

The described reaction of $(PPh_4)_2[M(CN)_4O(pz)]\cdot 3H_2O$ with NO is not the only one proceeding in solution (Figs. 1 and 2). We have observed that if the complex **1a** is not isolated and further NO is passed through the solution, it results in decay of the nitrosyl complex and the IR band appearing at 1362 cm^{-1} (Mo) or 1355 cm^{-1} (W) was assigned to the N–O stretching vibrations of a coordinated NO_2^- ligand. The reported wavenumbers are typical of nitrito ligands [4]. In the case of Mo we have recorded the IR spectrum of the solution confirming the presence only of free and coordinated nitrites.

2.2. Description of the structure of *1b*

The structure of the **1b** anion is presented in Fig. 3, together with the numbering scheme. The selected bond lengths and angles are gathered in Table 1.

The structure is centrosymmetric and the asymmetric unit contains half of the complex anion. In the anion pyrazine forms a bridge between two molybdenum centres, each of which are surrounded by five equatorial cyano ligands and one axial nitrosyl ligand. The central ion exhibits a distorted pentagonal bipyramidal geometry and is slightly displaced out of the equatorial plane towards the NO ligand (the average N6–Mo1–C angle is 93.5°). Similar deformations have been observed for oxocyano complexes with relevance to the oxo ligand. In salt **1b** the displacement towards the NO ligand is smaller than the ones towards oxo ligands, observed in the oxocyano complexes. The Mo1–N6 and N6–O1 bond lengths [1.775(3) and 1.198(4) Å, respectively] are typical for nitrosyl complexes of molybdenum regardless of the coordination number, other ligands or assignment

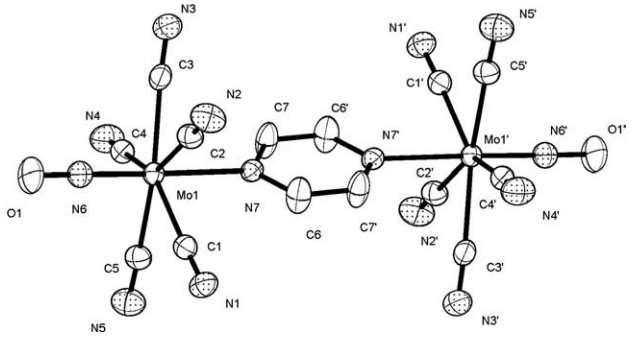

Fig. 3. The structure of the complex anion in $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot 2C_2H_5OC_2H_5$ with the atom labelling scheme and 50% displacement ellipsoids. The ion is located on a centre of symmetry and primed atoms are generated by $0.5 - x$, $1.5 - y$, $-z$.

of the formal oxidation state of molybdenum [18–20,26]. In particular, the Mo–N(nitrosyl) bond in **1b** is slightly shorter than the analogous bond in the [Mo(CN)(HNO)(NO)(terpy)] complex [d_{Mo-N} = 1.802(7) Å] whereas the NO bonds are the same within experimental errors in both complexes {1.198(4) Å in **1b** versus 1.209(9) Å in [Mo(CN)(HNO)(NO)(terpy)]} [29]. The Mo1–N6–O1 group in **1b** is approximately linear [the

angle is 178.2(3)°] and the same geometries have also been observed for Mo(II) complexes ($\{MNO\}^4$ systems in Enemark's notation). It is consistent with general Enemark's considerations for systems with a low number of {MNO} electrons [38]. According to that formalism, the {MNO} group is considered as a discrete entity and the assignment of the formal metal oxidation state is based upon the treatment of the NO ligand as a neutral species. Thus, in our case we should treat **1b** as a compound with Mo(III) ($\{MNO\}^4$) centres. However, the EPR experiments (vide infra) confirms that the salt is diamagnetic. Hence, based on both structural and spectroscopic data (IR and EPR – vide infra) we propose a Mo(IV)–NO^- assignment of the salt. These data [in particular d_{N6-O1} = 1.198(4) Å (**1b**) greater than 1.154 Å in free NO as well as ν(NO) = 1684 cm^{-1} (**1a**) less than 1875 cm^{-1} in free NO] indicate the predominant $d_{Mo} \rightarrow \pi^*_{NO}$ electron density shift and are consistent with such an assignment [2]. The bonding length of Mo1–N7 (2.332 Å) to the pyrazine, is considerably smaller than in the case of the monomeric $[Mo(CN)_4O(pz)]^{2-}$ oxocyano complex ($d_{Mo-N5(pz)}$ = 2.569 Å) which indicates the stronger bonding of diazine as a bridging ligand. The Mo1–C and C–N bond lengths are similar (in average: d_{Mo1-C} = 2.159 Å and d_{C-N} = 1.140 Å) and the Mo1–C–N groups are approximately linear (the average Mo1–C–N angle is 177.3°). These bond lengths are typical for other Mo(IV) cyano complexes [33]. A similar dimeric structure with a bridging pyrazine has recently been published in the case of the cationic porphyrin complex of iron(III), $[\{Fe(oep)(NO)\}_2(\mu\text{-pz})]^+$ [39]. It contains a near linear Fe–N–O group (the Fe–N–O angle is 176.5°) with a slightly shorter NO bond (d_{N-O} = 1.131 Å) in comparison with the structure of **1b**. Moreover, the bridging pyrazine is considerably closer to the central ions ($d_{Fe-N(pz)}$ = 2.039 Å) than in the molybdenum complex ($d_{Mo1-N7(pz)}$ = 2.332 Å).

2.3. IR and EPR spectra of *1a*

The IR spectrum of solid **1a**, presented in Fig. 4, shows an intense band at 1684 cm^{-1}, assigned to the stretching N–O vibrations of the nitrosyl ligand. Its relatively low wavenumber indicates the anionic form of the ligand, NO^- (the analogous wavenumber in free gaseous nitric monoxide is 1875 cm^{-1}) [2]. The IR spectrum also contains several bands characteristic for pyrazine [40] and tetraphenylphosphonium cations as well as solvent molecules outside the coordination sphere [several bands in the range of 2800–3000 cm^{-1}, corresponding to stretching vibrations in CH_3 and CH_2 groups; a band at 1070 cm^{-1} corresponding to conjugated stretching vibrations of C–O of a C–OH group; a band at 1317 cm^{-1} assigned to ν(OH) deformation; one broad band at 3400 cm^{-1} assigned to stretching vibrations of intermolecularly associated OH groups; and a band at

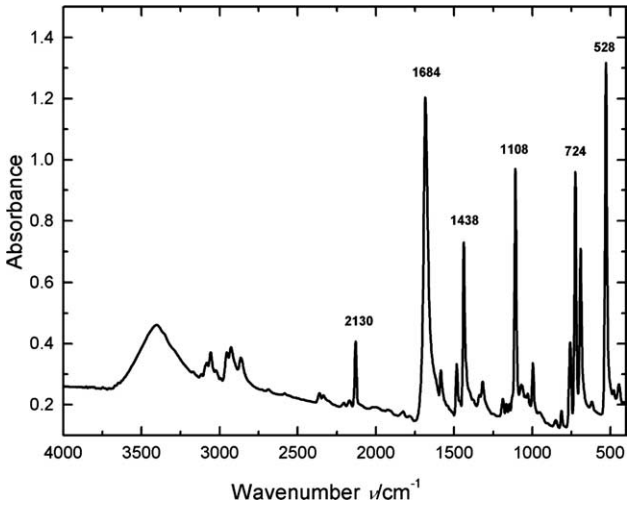

Fig. 4. IR spectrum of $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot C_4H_9OH \cdot CH_2Cl_2$ in KBr. Numbers indicate wavenumbers (in cm^{-1}) of the most intense bands.

724 cm^{-1} assigned to ν(CCl) overlapping with bands of PPh_4^+ origin] [37]. The spectrum does not contain any bands in the 900–990 cm^{-1} region, which indicates the absence of a MoO group in the analyzed compound. In the CN stretching region the bands at 2130, 2169 and 2205 cm^{-1} confirm the presence of cyano ligands.

The EPR spectrum of **1a** confirms the lack of paramagnetic centres both in the solid state and in solution (MeCN). The diamagnetism is consistent with a formal IV oxidation state of molybdenum as well as with a charged NO^- ligand.

2.4. Mass spectrum

Negative ionization reveals the presence of $\{(PPh_4)[Mo(CN)_5(NO)]\}^-$ fragments in the mass spectrum with the characteristic pattern for molybdenum isotopes [^{100}Mo(9.62%); ^{98}Mo(23.75%); ^{97}Mo(9.45%); ^{96}Mo(16.50%); ^{95}Mo(15.70%); ^{94}Mo(9.12%) and ^{92}Mo(15.86%)] at m/z = 591, 593, 594, 595, 596, 597 and 599 (Fig. 5). The positive ionization results in the appearance of two signals at m/z = 339 and 340 confirming the presence of PPh_4^+ cations.

2.5. Electronic absorption spectra

The UV–Vis spectrum (in the range of 300–500 nm) of **1a** in acetonitrile is presented in Fig. 6. It shows an intense band at λ_{max} = 365 nm (ε_{max} = 2800 mol^{-1} dm^3 cm^{-1}) that was assigned to a MLCT type ($d_{Mo} \rightarrow d_{Mo} \rightarrow \pi^*_{NO}$) transition. Analogous bands have been found for other pyrazine complexes, e.g., in the Creutz-Taube ion, $[\{Ru(NH_3)_5\}_2(\mu\text{-pz})]^{n+}$ (n = 4, 5, 6) with a bridging pz [41,42] or in $[Ru(CN)_5(pz)]^{3-}$ with a monodentate pz [43]. We have observed that this band decreases with time

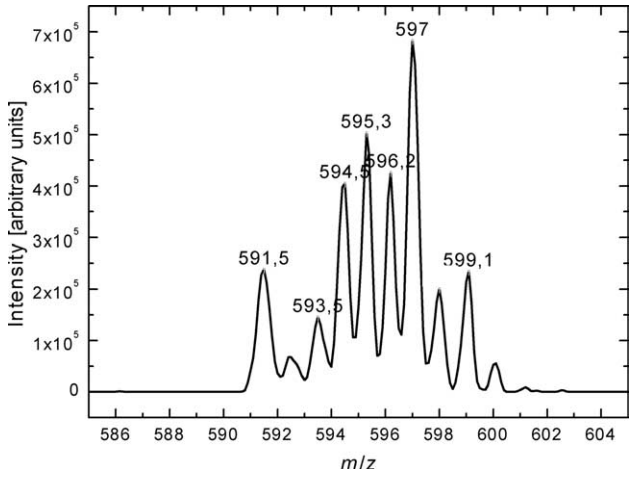

Fig. 5. Mass spectrum of $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot C_4H_9OH\cdot CH_2Cl_2$ (negative ionization). Numbers indicate peak positions corresponding to several molybdenum isotopes. The other signals appear due to the presence of carbon (^{12}C and ^{13}C) and nitrogen (^{14}N and ^{15}N) isotopes.

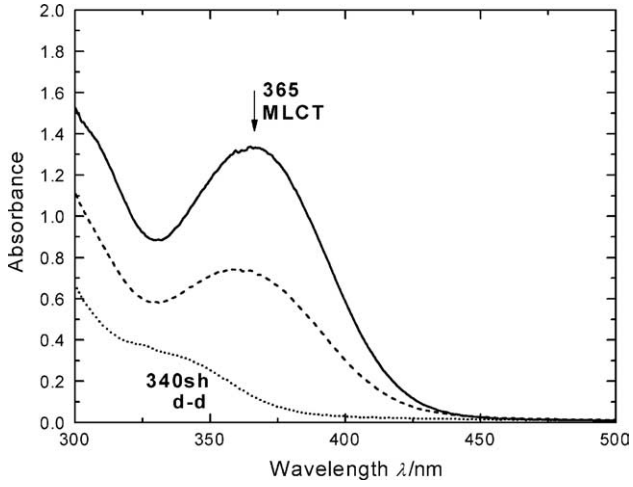

Fig. 6. Electronic absorption spectrum (300–500 nm range) of $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot C_4H_9OH\cdot CH_2Cl_2$ in acetonitrile (solid line, $c = 4.74\times10^{-4}$ M) and the changes observed with time (dotted line corresponds to final spectrum). Numbers indicate band positions (in nm) and the arrow shows the direction of the changes.

(Fig. 6) simultaneously revealing a band at 340 nm (sh) of a very low intensity which was attributed to a d–d transition. The decrease of the band at 365 nm may be the result of pyrazine being released from the coordination sphere. Apart from the bands at 365 and 340 nm in the UV region, one can observe overlapping bands characteristic for pyrazine ($\pi \rightarrow \pi^*$ or $n \rightarrow \pi^*$) and tetraphenylphosphonium cations ($\pi \rightarrow \pi^*$) [44]. The instability of solutions of **1a** in MeCN, detected by a very slow decrease in intensity of the MLCT band in the UV–Vis spectrum, does not affect the interpretation of solution IR and cyclic voltammetry experiments.

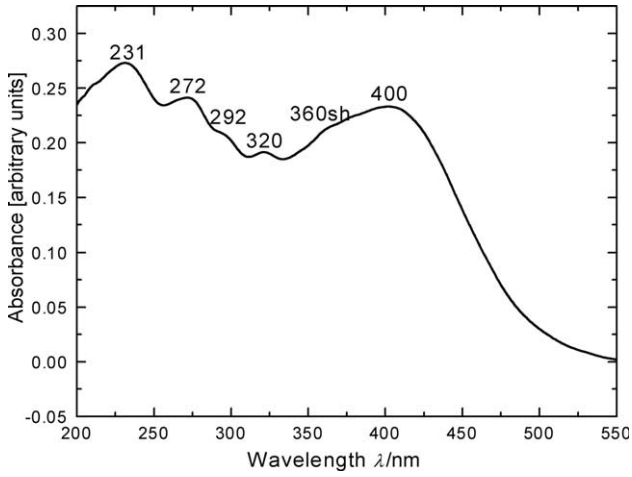

Fig. 7. Diffuse reflectance spectrum of $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot C_4H_9OH\cdot CH_2Cl_2$. Numbers indicate band positions (in nm).

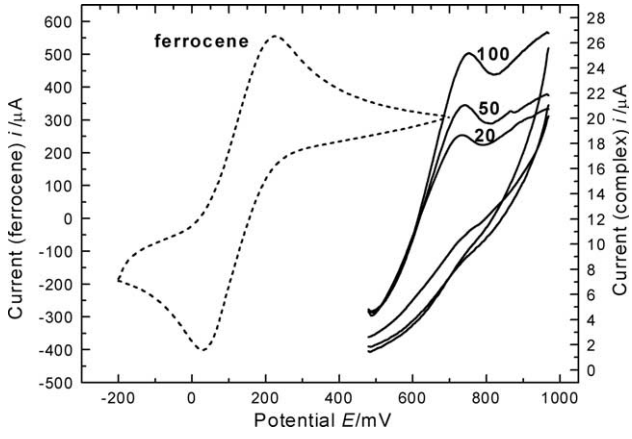

Fig. 8. Cyclic voltammograms of $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]\cdot C_4H_9OH\cdot dot\ CH_2Cl_2$ in acetonitrile (solid lines). Numbers indicate scan speeds (in mV s^{-1}) For comparison the ferrocene curve is given (dashed line).

Similarly to the solution spectrum, the diffuse reflectance spectrum of **1a** exhibits a band at 400 nm (of MLCT character), a shoulder at 360 nm as well as bands of pyrazine and PPh_4^+ origin in the UV region (Fig. 7).

2.6. Cyclic voltammograms

Linear sweep voltammetry measurements revealed that the $[\{Mo(CN)_5(NO)\}_2(\mu\text{-pz})]^{4-}$ complex was irreversibly oxidized at Pt electrodes at $E^0 = 1065$ mV (corresponding to a scan speed of 100 mV s^{-1}) (Fig. 8).

3. Conclusions

We have found that tetraphenylphosphonium salts of oxocyano complexes of molybdenum(IV) and

tungsten(IV), $(PPh_4)_2[M(CN)_4O(pz)]\cdot 3H_2O$ react in anaerobic conditions with NO. The reaction is the first example of direct NO incorporation among cyano complexes of Mo and W and it comprises novel oxo ligand substitution which is released in the form of the NO_2^- anion. It represents a new synthetic route to mixed-ligand cyanonitrosyl complexes of molybdenum(IV) and tungsten(IV), which up until now have been synthesized only in the case of molybdenum in the reaction of hydroxylamine with molybdates(VI) and cyanides.

4. Experimental

4.1. Starting materials and general procedures

Bis(tetraphenylphosphonium) tetracyanooxopyrazine metalates(IV), $(PPh_4)_2[M(CN)_4O(pz)]\cdot 3H_2O$ (M = Mo, W; pz = pyrazine) were synthesized according to the literature method [30]. NO of 99.5% purity was cleaned from trace amounts of higher nitrogen oxides (N_2O_3 and NO_2) by passing through a concentrated KOH solution and an Ascarite II column (NaOH on silica gel, Sigma–Aldrich). Dichloromethane used for the syntheses was purged with argon for 1 h prior to use. All other reagents and solvents were of analytical grade and used without further purification.

Carbon, hydrogen and nitrogen were determined by organic microanalysis on an Euro EA 3000 analyzer. IR spectra of solids were recorded in KBr pellets on a Bruker EQUINOX 55 FT-IR spectrometer whereas the IR spectra of solutions were collected in CaF_2 cuvettes on a Perkin–Elmer 16 PC FT-IR spectrometer. UV–Vis absorption spectra were recorded on a Shimadzu UV 2101PC scanning spectrophotometer. Diffuse reflectance spectra were measured in $BaSO_4$ pellets versus $BaSO_4$ as reference (Shimadzu UV 2101PC equipped with ISR-260 attachment). EPR measurements were carried out on a Bruker ELEXSYS spectrometer operating at X band. The solid samples were examined inside the cavity modulated with a frequency of 100 kHz at −196 °C and room temperature. ESI-MS measurements were performed for acetonitrile solutions on a Bruker ESQUIRE 3000 mass spectrometer using the electrospray negative and positive ionization method. Cyclic voltammetry measurements were carried out in CH_3CN with $[(C_4H_9)_4N]PF_6$ (0.1 M) as the electrolyte using Pt working and counting and Ag/AgCl reference electrodes on a Model EA9 Electrochemical Analyzer. The redox potentials were reported versus ferrocene, which was used as an internal potential standard for measurements in organic solvents to avoid the influence of liquid junction potential. $E_{1/2}$ values were calculated from the average anodic and cathodic peak potentials, $E_{1/2} = 0.5(E_a + E_c)$.

4.2. $(PPh_4)_4[\{Mo(CN)_5(NO)\}_2(\mu\text{-}pz)]\cdot C_4H_9OH\cdot CH_2Cl_2$ (**1a**)

Solid $(PPh_4)_2[Mo(CN)_4O(pz)]\cdot 3H_2O$ (0.30 g, 0.29 mmol) was dissolved in previously deoxygenated dichloromethane (20 cm^3). NO was bubbled through the solution for ca. 7 min until the solution color changed from green to yellow. The volume of obtained solution was reduced to ca. 10 cm^3 by evaporation of the solvent and butane-1-ol was added (12 cm^3). Dichloromethane was then evaporated on a rotary evaporator at 40 °C. The resulting white precipitate was filtered off and the filtrate was left for crystallization at room temperature in air for 5 days. The resulting yellow precipitate was filtered off, washed with a small amount of butane-1-ol and air-dried (yield: 30 mg, 10%). *Anal.* Calc. for $C_{115}Cl_2H_{96}Mo_2N_{14}O_3P_4$: C, 65.50; H, 4.59; N, 9.30. grown within 2 days by slow diffusion of diethyl ether vapor into the saturated solution of **1a** in CH_3CN at 4 °C.

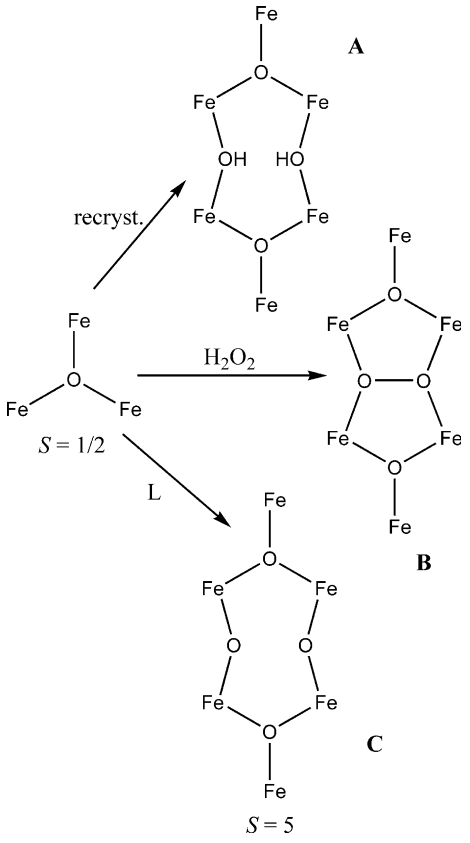
4.3. X-ray structure determination

Crystal data for **1b** were measured on a Bruker SMART diffractometer with a 2K CCD area detector. All data were collected using graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). An empirical absorption correction, based on comparison of Laue equivalents, was applied to the data. The structure was solved by direct methods and refined by full-matrix least squares cycles on F^2 for all data, using SHELXTL [45]. All non-hydrogen atoms were refined with anisotropic displacements parameters. All hydrogen atoms were included in refinement cycles riding on bonded atoms.

5. Supplementary material



Crystal data for **1b**, and a summary of data collection and structure refinement parameters, are given in Table 2. Full crystallographic data may be obtained from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: 44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk). The CCDC reference number is 236366.

described by a $2J$ model (C_{2v} point-group symmetry), assuming the symmetry of an isosceles and not of an equilateral triangle. This has been dubbed the "magnetic Jahn–Teller effect", since the isosceles distortion lifts the 4-fold degeneracy of the $S = 1/2$ ground state in zero field stemming from the equilateral model, and is of theoretical interest. Due to these reasons the physical properties of basic metal carboxylates have been exhaustively studied.

Apart from their interesting physical properties, however, basic metal carboxylates are of special synthetic interest since they can be viewed as building blocks for higher nuclearity molecular species. Focusing further discussion onto iron (III) chemistry, various synthetic routes have been employed to that respect. One such example is the simple recrystallization of the starting material, which has led to the hexanuclear complex $[Fe_6O_2(OH)_2(H_2O)(O_2CPh)_{12}(1,4\text{-dioxane})]$ [6], with an $S = 5$ ground state (Scheme 1, **A**) or to the undecanuclear complex $[Fe_{11}O_6(OH)_6L_{15}]$ [L^- = the anion of 3-(4-methylbenzoyl)-propionic acid] [7]. Reaction with hydrogen peroxide has led to the hexanuclear prismatic anionic complex $[Fe_6(O)_2(O_2)_3(O_2CMe)_9]^-$ presenting an $S = 1$ ground state [8], and to complexes $[Fe_6(O_2)(O)_2(O_2CCMe_3)_{12}L_2]$ (L = Me_3CCO_2H or pyridine) [9], all containing μ_4-peroxo bridges (Scheme 1, **B**).

Scheme 1.

Reactions with various chelating ligands have led to a series of hexanuclear complexes with $S = 5$ ground states (Scheme 1, **C**), and with the general formulae $[Fe_6O_2(OH)_2(O_2CR)_{10}(hep)_2]$ (hep^- = the anion of 2-(2-hydroxyethyl)pyridine and R = Me [10], Ph [11]) or $[Fe_6O_2(OH)_2(O_2CMe)_{10}L_2]$ (L = 1,1-bis(*N*-methyl-imidazol-2-yl)-1-hydroxyethane [12], 2-(*N*-methylimidazol-2-yl)-2-hydroxypropane [10], 6-methyl-(2-hydroxymethyl)pyridine [13]). Such complexes can also be considered as initial steps in the formation process of the mineral core of ferritin.

Ground states higher than $S = 1/2$, which is the rule for basic iron carboxylates, result from competing antiferromagnetic interactions within the cluster, due to its topology.

Azide anions are well known ferromagnetic couplers in their end-on bridging mode. Previous studies [14] have shown that they can replace bridging hydroxides without affecting the total structure of the cluster, but only its magnetic properties. Although end-on azido bridges are extremely rare in iron (III) chemistry [15], we decided to explore the possibility of replacing in situ the hydroxides formed during the recrystallization of a basic iron carboxylate (according to the pathway **A** of Scheme 1) by azides.

Herein, we report the reactivity of basic iron benzoate with azide anions. The reaction product has been characterized structurally, magnetically and spectroscopically (IR, EPR, Mössbauer) and the results of each technique have been correlated to each other. This work can be regarded as the continuation of our research efforts in the cluster chemistry of iron [14c,16].

2. Experimental

2.1. Materials

All reagents and solvents were of analytical grade and used as received, except basic iron (III) benzoate, which was prepared according to a literature procedure [17]. The synthesis was carried out under aerobic conditions. *Warning:* Although no such tendency was observed during the current work, azide salts are potentially explosive and should be handled with caution and in small quantities.

2.2. Synthesis of $[Fe_3O(O_2CPh)_6(EtOH)_2(N_3)]\cdot 2.4EtOH$ (**1**·2.4EtOH)

A paper cone containing solid NaN_3 (0.0162 g, 0.250 mmol) was brought into contact with the surface of a solution of basic iron benzoate (0.262 g, 0.250 mmol) in EtOH (15 mL), in a test tube. After some hours red crystals started to form. The system was left undisturbed and after ca. 1 week dark red prisms of **1**·2.4EtOH were

observed on the test tube walls. These were collected, washed with EtOH and dried in vacuo over silica gel (Yield: 0.15 g, ~50%). The dried sample analysed as **1**·0.7EtOH. *Anal.* Calc. for $C_{47.4}H_{46.2}Fe_3N_3O_{15.7}$: C, 52.88; (52.90), H, 4.33; (4.05), N, 3.90; (4.02). Found: C, 52.90; H, 4.05; N, 4.02% IR bands (KBr, cm^{-1}): 3632 (m), 3400 (m, b), 3064 (m), 2066 (vs), 1602 (vs), 1562 (vs), 1494 (m), 1410 (vs, b), 1178 (m), 1158 (w), 1070 (w), 1026 (m), 840 (w), 820 (w), 718 (vs), 686 (m), 674 (s), 636 (m), 614 (m), 544 (w), 482 (s).

2.3. Physical measurements

Microanalyses were performed by the Microanalytical Laboratory of the Laboratoire de Chimie de Coordination at Toulouse. Infrared spectra (4000–400 cm^{-1}) were recorded as KBr disks on a Perkin–Elmer 16PC spectrometer. Mössbauer measurements were recorded on a constant acceleration conventional spectrometer with a 50-mCi source of ^{57}Co (Rh matrix). The absorber was a powdered sample enclosed in a 20-mm diameter cylindrical, plastic sample-holder, the size of which had been determined to optimize the absorption. Variable-temperature spectra were obtained in the 4.2–300 K range, by using a MD 306 Oxford cryostat, the thermal scanning being monitored by an Oxford ITC4 servocontrol device (±0.1 K accuracy). Recoil [18] programme package or home written routines were used to fit the Mössbauer parameters and determine their standard deviations of statistical origin (given in parentheses). Isomer shift values (δ) are reported relative to iron foil at 300 K. Variable temperature (2–300 K) dc magnetic susceptibility data were collected on powdered microcrystalline solids on a Quantum Design MPMS SQUID susceptometer under a field of 9 kG. Data were corrected with the standard procedure for the contribution of the sample holder and diamagnetism of the sample. Solid state EPR spectra in the 4.2–300 K range were recorded on a Bruker ER 200D-SRC X-band spectrometer equipped with an Oxford ESR 9 cryostat. Simulations of EPR spectra were performed by a program kindly provided to us by Prof. M.P. Hendrich, Department of Chemistry, Carnegie Mellon University [19].

2.4. X-ray crystallography

Crystal data and refinement details for **1**·2.4EtOH are summarized in Table 1.

A crystal of **1**·2.4EtOH, with approximate dimensions of $0.15 \times 0.40 \times 0.50$ mm, was mounted in a capillary, on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo radiation ($\lambda = 0.71073$ Å). Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11° < 2\theta < 23°$. Intensity data were recorded using a θ–2θ scan to $2\theta_{max} = 45.5°$ with scan speed 1.5° min^{-1} and scan range 2.2 plus $\alpha_1\alpha_2$ separation. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization and Ψ-scan absorption corrections were applied using the Crystal Logic software.

The structure was solved by direct methods using SHELXS-97 [20] and refined by full-matrix least-squares on F_o^2 with SHELXL-97 [21] using anisotropic displacement parameters for almost all non-hydrogen atoms. All hydrogen atoms in **1** were introduced at calculated positions as riding on bonded atoms except H(O13) which was located by difference maps. The solvent molecules and the C(62) and C(72) carbon atoms of the coordinated EtOH molecules were refined isotropically with fixed occupation factors.

Scattering factors were taken from [22] The molecular plots were obtained using the ORTEP32 program (see Fig. 1) [23].

CCDC reference number 266618 for **1**.

3. Results and discussion

3.1. Synthesis

Initial investigations of a 1:1 reaction between basic iron benzoate solution and solid NaN_3 in a variety of solvents (MeCN, Me_2CO, EtOH, CH_2Cl_2, and mixtures) under reflux, yielded amorphous yellow solids the IR spectra of which revealed the existence of coordinated azides. The amorphous nature of the solids, however, prevented their characterization by powder

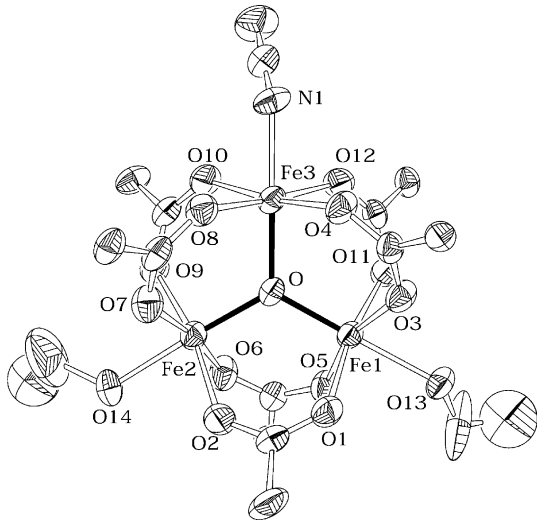

Fig. 1. Partially labelled ORTEP diagram of **1**·2.4EtOH with ellipsoids at the 30% probability level. Hydrogen atoms and phenyl rings have been omitted for clarity.

X-ray diffraction methods, and their very poor solubility in a wide range of solvents hindered our attempts to recrystallize them. Therefore, another crystallization technique was employed for the isolation of X-ray quality single crystals. A paper cone containing the desired amount of solid NaN_3 was inserted into a test tube containing a solution of basic iron benzoate in EtOH. The cone was lowered until its tip touched the free surface of the solution, and then lifted by 1–2 mm, so that only the solvent's meniscus came into contact, without the cone being immersed in the solvent. The low solubility of NaN_3 in EtOH caused a very slow dissolution of the solid, and the slow diffusion led to a very smooth increase of its concentration in solution. This allowed us to obtain X-ray quality crystals of **1**. The reaction that led to this product is summarized by Eq. (1).

$$[Fe_3O(O_2CPh)_6(OH)(H_2O)_2] + NaN_3 + 2EtOH \xrightarrow[20\ ^\circ C]{EtOH} [Fe_3O(O_2CPh)_6(EtOH)_2(N_3)] + NaOH + 2H_2O \quad (1)$$

As confirmed by X-ray crystallography, the reactivity expected was not realized. This can be correlated to the mild conditions employed for the crystallization of the product, with respect to more intense conditions usually employed for other bis-trinuclear complexes [11], and the fact that monatomic bridging modes are very rare for azide anions coordinated to Fe^{III}. However, the presence of a terminal anionic ligand in the trinuclear cluster has serious implications. It leads to a neutral, though non mixed-valent, basic iron carboxylate, a feature that as will be seen affects its solid-state spectroscopic characteristics.

3.2. Description of the structure

The structure of the complex is that of a basic iron benzoate, with six $\eta^1{:}\eta^1{:}\mu_2$-$PhCO_2^-$ ligands and one μ_3 oxide. Two terminal ethanol ligands and a terminal monodentate azido one in the apical positions complete six coordination. The iron atoms are connected by a μ_3-oxide (O), which is coplanar to the Fe_3 plane, with a sum of Fe–O–Fe angles equal to 360.0(3)°. The distances between the Fe^{III} atoms and the donor atoms of the ligands are in the ranges 1.882(5)–2.144(6) Å for Fe1, 1.894(5)–2.116(6) Å for Fe2, and 1.948(5)–2.044(8) Å for Fe3, with the shortest bonds being the Fe–O_{oxo} ones in each case, and the longest being the ones in *trans* respective positions (*trans* effect). The Fe(3)–N_{azido} bond length (2.044(8) Å) is similar with bond lengths found for other six-coordinate iron (III) complexes containing terminal azido ligands (see Table 2) [16e].

Due to the presence of the anionic N_3^- ligand, compound **1** is neutral. Since no counteranions are present, the 3D structure of the complex in the crystal lattice is

primarily defined by intercluster hydrogen-bonding. A hydrogen bond between the hydrogen atom of O(13) (x, y, z) and the N(3′) atom of a neighbouring molecule (′ = x, $-y+1$, $z+1/2$) creates 1D zig-zag chains along the c axis [O(13)···N(3′) = 2.792 Å, O(13)–H(O13) = 0.853 Å, O(13)–H(O13)···N(3′) = 147.28°], see Fig. 2. The closest Fe···Fe separation between two adjacent molecules is 8.061 Å [Fe(1)···Fe(3′)]. This hydrogen-bonding leads to interactions that are too weak to be observed by magnetic susceptibility, but sufficient to influence the spectroscopic properties of the complex in the solid state (see *EPR Spectroscopy*).

Additionally, a series of possible hydrogen bonds between ethanol solvate molecules (OE(3)···OE(1) (x, y, z) 2.881 Å; OE(2)···OE(3) (x, $1-y$, $1/2+z$) 2.518 Å) and between complex and ethanol molecules (OE(1)···N(1) ($1/2-x$, $3/2-y$, $-z$) 2.830 Å; O(14)···OE(2) ($1/2-x$, $-1/2+y$, $1/2-z$) 2.555 Å) form sheets developing parallel to the bc plane (Figure S1).

3.3. IR Spectroscopy

The IR spectrum of dried **1** exhibits two bands characteristic of the antisymmetric and symmetric carboxylate stretching vibrations [ν_{as}(COO) and ν_s(COO)] of the benzoate anions at 1562 and 1410 cm^{-1}, respectively. The difference Δ [$\Delta = \nu_{as}(COO) - \nu_s(COO)$] is 152 cm^{-1}, smaller than that of NaO_2CPh (186 cm^{-1}), as anticipated for a bidentate bridging coordination [24].

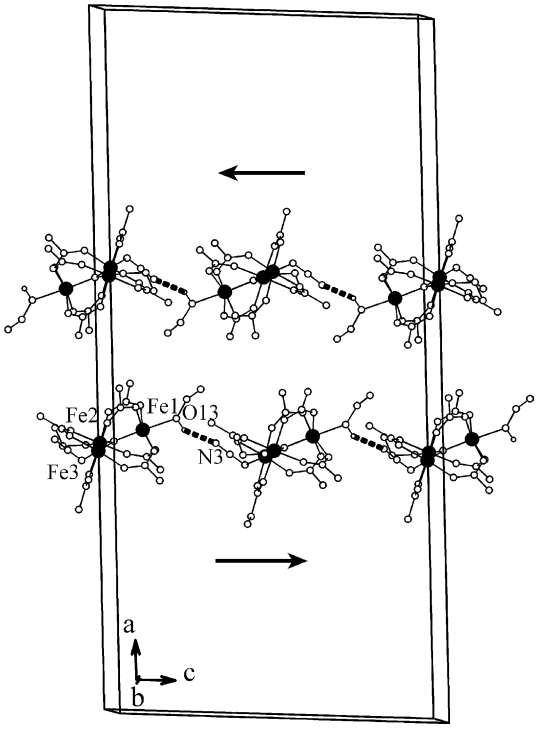

Fig. 2. Crystal packing diagram of **1**, showing the formation of 1D hydrogen-bonded chains along the c axis in opposite directions.

A broad band of medium intensity at 3400 cm^{-1} is attributed to the O–H stretching vibration of the coordinated ethanol molecules. A sharp band at 2066 cm^{-1} is attributed to the antisymmetric stretching vibration [$\nu_{as}(N_3)$] of the terminally bound azide anion. Finally, a strong band at 1602 cm^{-1} is attributed to a ν(C=C) stretching vibration of the aromatic rings, and a medium intensity band at 718 cm^{-1} is attributed to the π(CH) vibration of the aromatic hydrogen atoms.

3.4. Mössbauer spectroscopy

The Mössbauer spectra of complex **1** at six different temperatures between 4.2 and 293 K are shown in Fig. 3. For $T > 80$ K, the spectra consist of an asymmetric composite quadrupole-split doublet, with parameters typical of high-spin iron (III). As described above, the complex contains two iron sites, with FeO_6 [Fe(1) and Fe(2), **A**] and FeO_5N [Fe(3), **B**] chromophores, in a 2:1 ratio. We would expect a higher quadrupole splitting ΔE_Q value for the iron sites with the most distorted octahedral environment. In this case, site **A** has a more homogeneous coordination sphere than **B**, with respect to the type of donor atoms (O_6 versus O_5N environments, respectively), but it presents a higher dispersion of bond lengths [**A**: Fe(1), 1.882(5)–2.144(6) Å and Fe(2), 1.894(5)–2.116(6) Å, **B**: Fe(3), 1.948(5)–2.044(8) Å]. The competition between those two factors is expected to define the relative values of ΔE_{QA} and ΔE_{QB} (see Table 3).

The spectra were fitted with two quadrupole-split doublets. Fitting attempts without any constraint of the variables, yielded for the spectra at 80 and 150 K two doublets in the 2:1 ratio. The higher ratio doublet,

[b] Fitted with one quadrupole-split doublet.

which is attributed to site **A**, presents a smaller quadrupole splitting, suggesting that inhomogeneity of donor atoms plays a more significant role to the increase of the electric field gradient than the dispersion of bond lengths. For the 293 K spectrum, initial attempts without constraint led to solutions with area ratios far from the theoretically expected 2:1 one. Thus, in order to avoid local minima without physical meaning, the area ratio was fixed to 2:1 and the $\gamma_{1/2}$ of site **B** was fixed to 0.2 mm s^{-1}, as determined from the 80 and 150 K spectra. A similar differentiation in quadrupole splittings for two distinct iron sites at a 2:1 ratio was observed in the case of the triferric compounds $[Fe_3(\mu_3\text{-}O)(O_2CPh)_5(salox)L_1L_2$ [$L_1 = L_2 =$ MeOH and $L_1 =$ EtOH, $L_2 = H_2O$] [16g].

The decrease of the isomer shift for $T > 80$ K, for both iron sites, is due to second-order Doppler effect [25]. The quadrupole splitting, as expected for high-spin iron (III), does not present an important temperature dependence.

At liquid helium temperatures we obtain relatively symmetric quadrupole-split doublets. The linewidth of these doublets increases on decreasing temperature and the asymmetry due to the different ligand environments of the three ferric sites vanishes. Therefore, we have fitted the spectra with an average quadrupole-split doublet. The broadening of the Mössbauer lines observed at low-temperatures is attributed to the onset of slow relaxation effects.

3.5. Magnetic properties

The $\chi_M T$ product of complex **1** at 300 K, is 4.23 cm^3 mol^{-1} K, is significantly lower than the theoretically expected value for three non-interacting $S = 5/2$ spins (13.14 cm^3 mol^{-1} K for $g = 2$), suggesting antiferromagnetic interactions. Upon cooling, the $\chi_M T$ product decreases without extrapolating to zero as the temperature tends to zero (Fig. 4), which also agrees with the interplay of antiferromagnetic interactions, and a magnetic ground state.

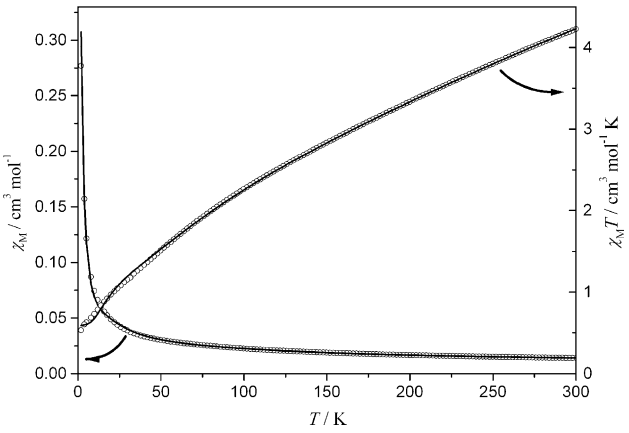

Fig. 4. χ_M vs. T and $\chi_M T$ vs. T experimental data for complex **1**, and theoretical curves based on the Hamiltonian of Eq. (2).

Initial attempts to simulate the magnetic properties of the complex by considering a single J interaction, viewing the complex as an equilateral triangle, did not yield satisfactory results. Inspection of the intermetallic distances, reveals that the Fe–Fe interactions can be grouped into Fe(1)···Fe(3) (3.310 Å) and Fe(2)···Fe(3) (3.334(5) Å) on the one hand, and Fe(1)···Fe(2) (3.270 Å) on the other hand. Thus, the complex is better described by an isosceles triangle, and the exchange parameters can be defined as $J = J_{13} = J_{23}$ and $J' = J_{12}$; the corresponding Hamiltonian is

$$\hat{H} = -2J(\hat{S}_1\hat{S}_3 + \hat{S}_2\hat{S}_3) - 2J'\hat{S}_1\hat{S}_2. \quad (2)$$

The fitting process yielded two solutions of satisfactory quality, with the following sets of parameters **a**: $J = -24.0$ cm^{-1}, $J' = -38.9$ cm^{-1}, $g = 2.0$ ($R = 2.38 \times 10^{-3}$) and **b**: $J = -31.2$ cm^{-1}, $J' = -21.5$ cm^{-1}, $g = 2.0$ ($R = 3.47 \times 10^{-3}$). Small deviations at low temperatures led us to include a paramagnetic impurity (ρ). The best fit parameters were then: **A**: $J = -26.4$ cm^{-1}, $J' = -40.0$ cm^{-1}, $\rho = 1.2\%$, $g = 2.0$ ($R = 2.9 \times 10^{-4}$) and **B**: $J = -33.0$ cm^{-1}, $J' = -24.0$ cm^{-1}, $\rho = 1.2\%$, $g = 2.0$ ($R = 4.2 \times 10^{-4}$). Solution **A** is considered as the most realistic, not only because it presents

the smallest relative error, but also because it is consistent with the structure of the complex. Indeed, Fe(1)–Fe(3) and Fe(2)–Fe(3) pairs present longer intermetallic distances than the Fe(1)–Fe(2) pair, and consequently weaker coupling is expected for them.

Confirmation of the coexistence of two minima was obtained by the calculation of an error surface plot for possible combinations of J and J' values (Fig. 5).

The diagram of energy levels for solution **A** reveals that the first excited $S = 3/2$ state is 25.0 cm^{-1} higher than the ground $S = 1/2$ state, i.e., relatively close to the ground state.

Based on the previously determined parameters, the magnetization M of the complex was calculated as a function of the applied magnetic field. The very good agreement between the calculated values and experimental data confirms the validity of our assumptions (see Fig. 6).

3.6. EPR spectroscopy

The magnetic susceptibility data of powder samples of **1** were well modelled with non-interacting triangular species. Analysis of these data indicates that the complex is characterized by an $S = 1/2$ ground state with an excited state with $S = 3/2$ at 25 cm^{-1}. The EPR spectra of trinuclear transition metal complexes with magnetic properties similar to those of **1** give rise to signals in the $g \sim 2.0$ region. Non-Heisenberg interactions and/or single-ion zero-field splitting result in an anisotropic $S = 1/2$ ground state. Distributions of the magnetic parameters lead to broad features extending to several hundred Gauss at X-band with $g < 2.0$ [26–29].

Fig. 7 shows an EPR spectrum recorded from a powdered sample of 1 at 4.2 K. Broad signals are observed with a prominent feature at $g \sim 2.0$. A weak signal at

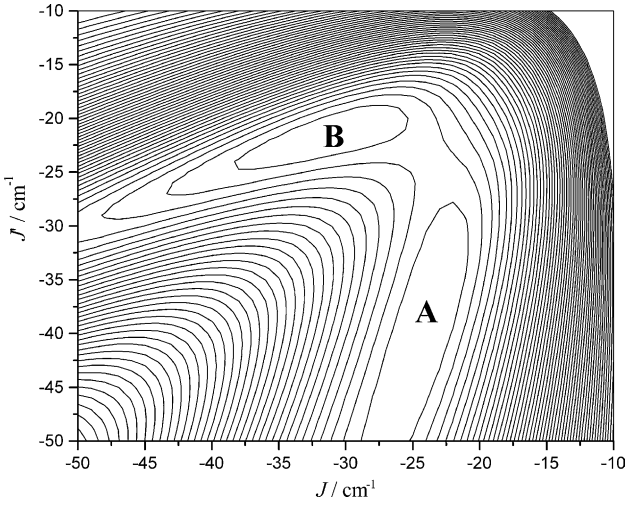

Fig. 5. Surface error plot of J vs. J' (with $g = 2.00$ and $\rho = 1.2\%$) revealing the minima **A** and **B** found by the fitting process.

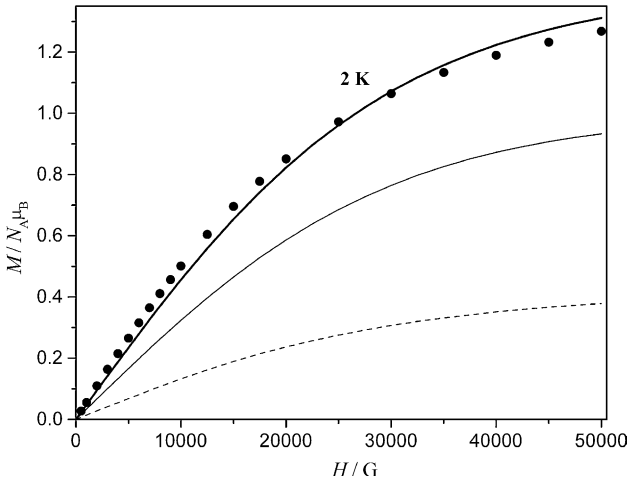

Fig. 6. Variation of the magnetization M vs. the applied field H at 2 K for complex **1**. The dashed, solid and bold lines represent the paramagnetic impurity, the calculated curve according to the parameters of solution **A**, and their sum, respectively.

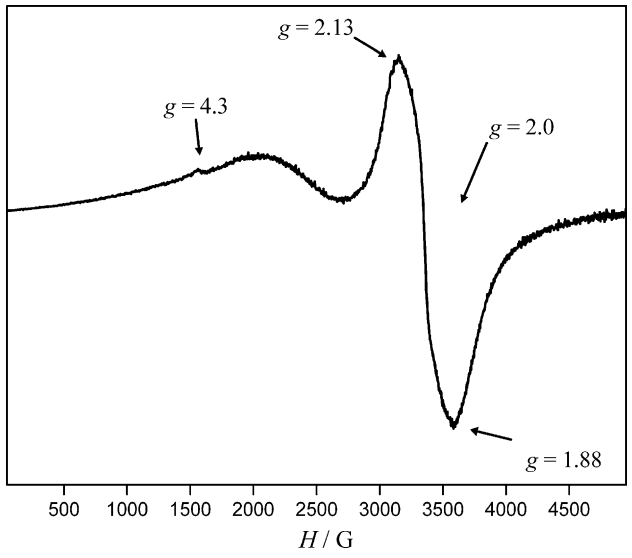

Fig. 7. X-band EPR spectrum of a powder sample of **1** at 4.2 K. EPR conditions: mod. amp. 25 Gpp, microwave power: 36 mW, microwave frequency: 9.41 GHz.

$g \sim 4.3$ is attributed to monomeric Fe^{III} ($S = 5/2$) impurities in agreement with the magnetic susceptibility measurements. The signal at $g \sim 2.0$ consists of an absorption peak at $g \sim 2.13$ a derivative feature at $g \sim 2.0$ and a valley at 1.88. At higher temperatures the intensity of the EPR signals decreases and substantial broadening is observed (not shown) whereas no novel signals attributed to the excited states of the trimer are observed. In the following, we discuss the 4.2 K spectra shown in Fig. 7. These signals cannot be assigned to an isolated $S = 1/2$ species with the assumptions discussed above. Instead, we attribute the observed signals to weak intercluster interactions. This

is supported by the crystal packing depicted in Fig. 2 revealing a one-dimensional arrangement of trimers through hydrogen bonds. We will argue that these interactions are too weak to be discerned in the magnetic susceptibility measurements.

In order to reproduce the main features of the EPR spectrum in the $g \sim 2.0$ region, we assume a weak exchange interaction involving two $S = 1/2$ species with an isotropic g-tensor ($g = 2.0054$) (Eq. (3)),

$$\hat{H}_{\text{inter}} = \hat{S}_1 \tilde{\mathbf{J}}_{\text{inter}} \hat{S}_2 + g\hat{S}_1\mathbf{H} + g\hat{S}_2\mathbf{H}, \quad (3)$$

where $\tilde{\mathbf{J}}_{\text{inter}}$ is a diagonal tensor accounting for the inter-trinuclear interaction. In Eq. (3), $\tilde{\mathbf{J}}_{\text{inter}}$ can be deconvoluted into an isotropic part and a traceless diagonal tensor $\tilde{\mathbf{J}}_{12}$ (Eq. (4)) [30],

$$\tilde{\mathbf{J}}_{\text{inter}} = J_0\mathbf{1} + \tilde{\mathbf{J}}_{12}. \quad (4)$$

In the absence of any inter-trimer interaction, a symmetric derivative is expected from the two $S = 1/2$ species at $g \sim 2.0$ (Fig. 8, thin line). The isotropic part of $\tilde{\mathbf{J}}_{\text{inter}}$ has no effect for such a spectrum. This, however, significantly alters upon involvement of the anisotropic term $\tilde{\mathbf{J}}_{12}$. This interaction induces a splitting of the symmetric line yielding an absorption feature at $g \sim 2.13$, a derivative at $g \sim 2.0$ and a valley at $g \sim 1.88$ for $\mathbf{J}_{12} = [0.03, 0.0, -0.03]$ cm^{-1} (Fig. 8, dashed line). Since the spectra are not sensitive to J_0, this term cannot be determined by EPR. Nevertheless, since the distance between neighbouring trimers is roughly 8 Å in the crystalline sample, J_0 is expected to be small.

The anisotropy of the inter-trimer interaction is mainly of dipolar origin. In the point dipole approximation involving two $S = 1/2$ species, the derived values of $\mathbf{J}_{12}$ correspond to an inter-dipole distance of ~3.4 Å. Also, since isotropic g tensors are involved, an axial $\tilde{\mathbf{J}}_{12}$ tensor is expected [30]. The discrepancy with the experimental results is attributed to the fact that the point-dipole approximation involving two $S = 1/2$ species is an oversimplification of the 1D arrangement of trimers depicted in Fig. 2.

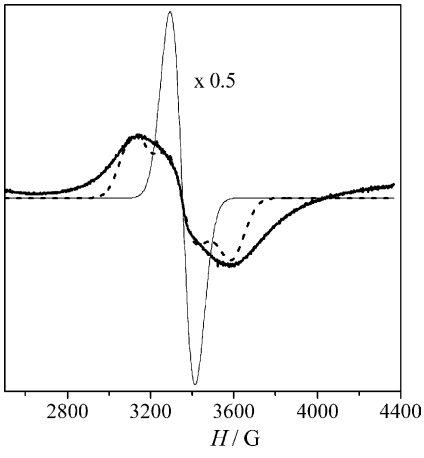

Fig. 8. The experimental EPR spectrum (bold line) of a powder sample of **1** in the $g \sim 2.0$ region and theoretical simulations assuming two non interacting $S = 1/2$ species (thin line) and two $S = 1/2$ species with a weak anisotropic interaction, $\mathbf{J}_{12} = [0.03, 0.0, -0.03]$ cm^{-1} (dashed line). For the simulations, Gaussian line shapes with a 40-G intrinsic line width were considered.

The previous discussion reveals that the EPR spectra of **1** are sensitive to weak inter-trimer interactions. The magnitude of these interactions is too small to be discerned by bulk magnetic susceptibility measurements. We have observed similar behaviour concerning the EPR spectra of powder samples of other trinuclear ferric complexes showing weak 1D or 2D structural interactions [16g].

4. Conclusions

In an attempt to explore the chemistry of iron basic benzoate with sodium azide, we obtained the trinuclear complex **1**, which contains the "iron basic carboxylato" core. From a synthetic viewpoint, it was confirmed that end-on azido bridges are not so easy to obtain in iron (III) carboxylate chemistry, probably due to the increased electrostatic repulsions of Fe^{III}–Fe^{III} pairs, but also due to steric hindrance from the benzoato ligands. Another important factor was the mild conditions used for the crystallization of the product, in contrast to the conditions used to synthesize complexes without azide anion. The terminal azido ligand present in **1** could have future utility as site for facile incorporation of other monoanionic ligands by metathesis. Mössbauer spectroscopy reveals that the inhomogeneity in donor atoms of the environments is more important in influencing the quadrupole-splittings than the geometrical distortions of the ferric sites. The differences in composition of the chromophores for the two types of ferric sites (O_6 and O_5N) are sufficient to distinguish them with Mössbauer spectroscopy. The Mössbauer spectra of complex **1** show asymmetry attributed to the existence of two quadrupole-split doublets, but only well-above liquid helium temperatures. At low temperature the asymmetry vanishes and the quadrupole-split doublets are broadened probably due to slow relaxation effects. Although the magnetic properties of the complex are satisfactorily interpreted with a simple $2J$ model, the 4.2 K EPR spectrum indicates involvement of weak intermolecular interactions. A model involving pair-wise dipolar interactions between neighbouring trimers can reproduce the EPR spectra qualitatively.

$(CH_3OH)_2\}_n$. In this complex, two fluoride atoms link together two Cu(II) metal centres via μ-F bridges. The bimetallic CuF_2Cu moieties are then assembled in an infinite chain via μ_4-SiF_6 anions. The structure is further stabilised by a 3-D network of hydrogen bonds. This compound was obtained by reaction at high temperature (100 °C) in a closed pressure tube from the dipyridylamine ligand and $Cu(BF_4)_2$ in methanol. As reported previously, F^- ions can be formed from gradual ligand-assisted BF_4^- decomposition [23,35] and the hexafluorosilicate ions, by attack of the fluoride ions on the glass surface of the reaction vessel [34]. In the present study, the structure and magnetic properties of a novel SiF_6-bridged polymer are described.

2. Experimental

2.1. Synthesis

All commercially obtained reagents were used without further purification. Copper(II) tetrafluoroborate (20 mg, 0.084 mmol) was added to an equimolar methanolic solution (6 ml) of dipyridylamine. The resulting green limpid solution was allowed to stand at 100 °C for 12 h under autogenous pressure in a sealed tube to form $[Cu_2(\text{dipyridylamine})_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)] \cdot (CH_3OH)_2$ as light green prism-shaped crystals. The crystals were filtered off and washed with MeOH. Yield: 35%. *Anal.* Calc.: C, 37.02; H, 3.64; N, 11.77; Cu, 17.80. Found: C, 33.94; H, 3.70; N, 11.89; Cu, 19.10%. Main IR absorption bands (cm^{-1}): multiplet in 3331–3056, 1651, 1591, 1435, 1018, 703, 418. UV–Vis (reflectance, nm) 336, 690. It should be mentioned that a small amount of side product crystallised and was analysed as $[Cu(\text{dipyridylamine})_2(CH_3OH)](SiF_6)$ (the structure will be described elsewhere). The crystals could be separated manually from the main product.

2.2. Physical measurements

Elemental analyses for C, H and N were performed with a Perkin–Elmer 2400 analyser. The Cu analyses were performed with a Vista MPX ICP analyser. IR spectra were recorded with a Perkin–Elmer Paragon 1000 FTIR spectrophotometer, equipped with a Golden Gate ATR device, using the reflectance technique (4000–300 cm^{-1}). Ligand-field spectra were obtained on a Perkin–Elmer Lambda 900 spectrophotometer using the diffuse reflectance technique, with MgO as a reference, over the range 2000–200 nm at room temperature. X-band powder EPR spectra were recorded on a Jeol electron spin resonance spectrometer using DPPH ($g = 2.0036$) as a standard. Magnetic susceptibility measurements were carried out using a Quantum Design MPMS-5 5T SQUID magnetometer at 1000 Oe in the temperature range 2–300 K. Data were corrected for the diamagnetic contributions estimated from the Pascal constants [36].

Table 1
Crystallographic data and refinement details for $[Cu_2(\text{dipyridylamine})_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)] \cdot (CH_3OH)_2$

Formula	$C_{22}H_{26}Cu_2F_8N_6O_2Si$

Goodness-of-fit on $F^{2\,c}$	1.033

[a] $R = \Sigma\|F_o| - |F_c\|/\Sigma F_o|$.
[b] $wR_2 = \{\Sigma[w(F_o^2 - F_c^2)^2]/\Sigma[w(F_o^2)^2]\}^{1/2}$.
[c] $S = \{\Sigma[(F_o^2 - F_c^2)^2]/(n/p)\}^{1/2}$, where *n* is the number of reflections and *p* is the total number of parameters refined.

2.3. Crystallographic data collection

Crystal data and refinement parameters for the title compound are listed in Table 1. The careful selected crystal was greased on a glass thread. Diffraction data were collected on a Nonius Kappa CCD diffractometer with area detector at 150(2) K. Cryostream Cooler (Oxford Cryosystems) was used for cooling the sample. A graphite monochromated Mo Kα radiation (λ = 0.71073 Å) was employed. The structure was solved by direct methods implemented in SHELXS-97 [37] and refined by a full-matrix least-squares procedure based on F^2 using SHELXL-97 [38]. All non-hydrogen atoms were refined anisotropically, while the hydrogen atoms were included in the model at geometrically calculated positions and refined using a riding model.

3. Results and discussion

The reaction of dipyridylamine and $Cu(BF_4)_2$ in MeOH in Pyrex tube at 100 °C under autogenous pressure, gave a polymeric compound with $[Cu_2(\text{dipyridylamine})_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)] \cdot (CH_3OH)_2$ as repeating unit. Attempts to prepare it under similar conditions, but

using dipyridylamine and $Cu(BF_4)_2$ in CH_3CN or CuF_2 in MeOH, in presence of $Na_2(SiF_6)$, were unsuccessful.

The IR spectrum of the title compound evidences peaks of both the dipyridylamine ligand and the hexafluorosilicate anion. In the 3500–3000 cm^{-1} region, multiple narrow IR absorptions appear. They correspond to the characteristic N–H and C–H vibration bands. Their shape is a proof that hydrogen bonds are present in the material. Below 1650 cm^{-1} several bands can be assigned to the coordinated dipyridylamine ligand, specially the band at 1018 cm^{-1} which is associated with the pyridine ring breathing vibration mode and indicates that all the pyridine rings are coordinated [39]. Below 750 cm^{-1} appear the bands assigned to hexafluorosilicate vibrations. Uncoordinated SiF_6^{2-} is known to have two IR-active vibrations at about 740 and 480 cm^{-1} [40]. These bands, due to the lowering of the anion symmetry upon coordination, are shifted to 703 and 418 cm^{-1} in the present compound. They are assigned to the ν_3 (νSi–F) and ν_4 (δF–Si–F) modes, respectively [41]. On the other hand, not any characteristic signal of the BF_4^- anion are present [23].

4. Structure

An ORTEP view of the repeating unit of the title compound is illustrated in Fig. 1 and selected bond lengths and bond angles are listed in Table 2. This complex is dimeric, consisting of two CuF(dipyridylamine) units related by an inversion centre, these units being connected by two fluoride bridges. In a $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2]$ moiety, the two dipyridylamine ligand planes are at an angle of ~18°. The copper(II) ions are in an octahedral environment with a coordination sphere defined by two nitrogen atoms of the dipyridylamine ligand (Cu–N 1.982 Å) and two fluoride atoms of the μ-F bridges (Cu–F 1.928 Å) in the equatorial plane, and by two fluoride atoms of the SiF_6^{2-} dianion in axial position (Cu–F 2.399–2.368 Å). It should be highlighted that only a few crystal structures were reported so far showing Cu(II)-based complexes with such N,F environment. In those cases, the F atoms (excluded the ones from the bis-μ-F bridge) come from a BF_4 unit [25,28]. The Cu–N bond distances are considered normal for the Cu(II) ion. The Cu–F bond lengths in the CuF_2Cu moiety are in agreement with those previously reported for related Cu(II) complexes [25–28]. Concerning the Cu–F(SiF_6) bond lengths, they are shorter than in the compounds where the BF_4^- anion is weakly coordinated to the CuF_2Cu unit (Cu–F ~2.50–2.69 Å) [25,28] and they are of the same magnitude range as in polymers where SiF_6^{2-} acts as a μ-SiF_6 bridge between two metal centres (Cu–F 2.225–2.335 Å) [32,42]. Interestingly, it is the first time that coordination of the SiF_6^{2-} anion to a CuF_2Cu moiety occurs via two F atoms. The Cu–F–Cu bond angle (99.85°) is of the same magnitude order as for dinuclear F-bridged copper complexes [25]. The F(SiF_6)–Cu–F(SiF_6) angle (167.33°) is comparable to that in the related BF_4^- containing compounds [25,28].

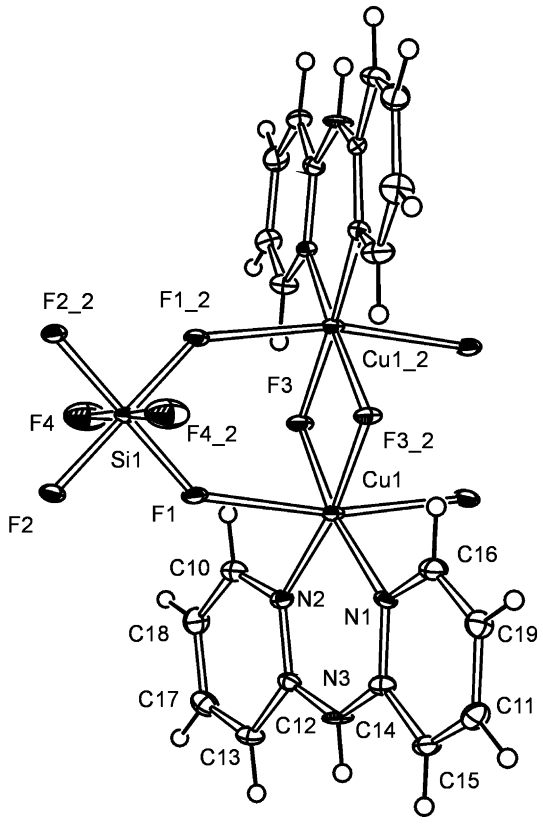

Fig. 1. ORTEP view of the repeating unit of $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)] \cdot (CH_3OH)_2$ with thermal ellipsoids drawn at the 40% probability level. The lattice solvent molecules have been excluded for clarity.

Table 2
Selected bond lengths (Å) and angles (°) for $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)] \cdot (CH_3OH)_2$

Cu1–F1	2.368(2)
Cu1–F2	2.399(2)
Cu1–F3	1.927(2)
Cu1–N1	1.982(3)
Cu1–N2	1.982(3)
Si1–F1	1.693(2)
Si1–F2	1.690(2)
Si1–F4	1.664(2)
Cu1···Cu1_2	2.950
Cu1–F3–Cu1_2	99.85(8)
F3–Cu1–F3_2	80.15(8)
F1–Si1–F1_2	92.06(15)
Si1–F1–Cu1	140.15(11)

As illustrated in Fig. 2, the $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2]$ motif is repeated along the (0 1 0) direction via the SiF_6^{2-} linker, thus forming an infinite chain running

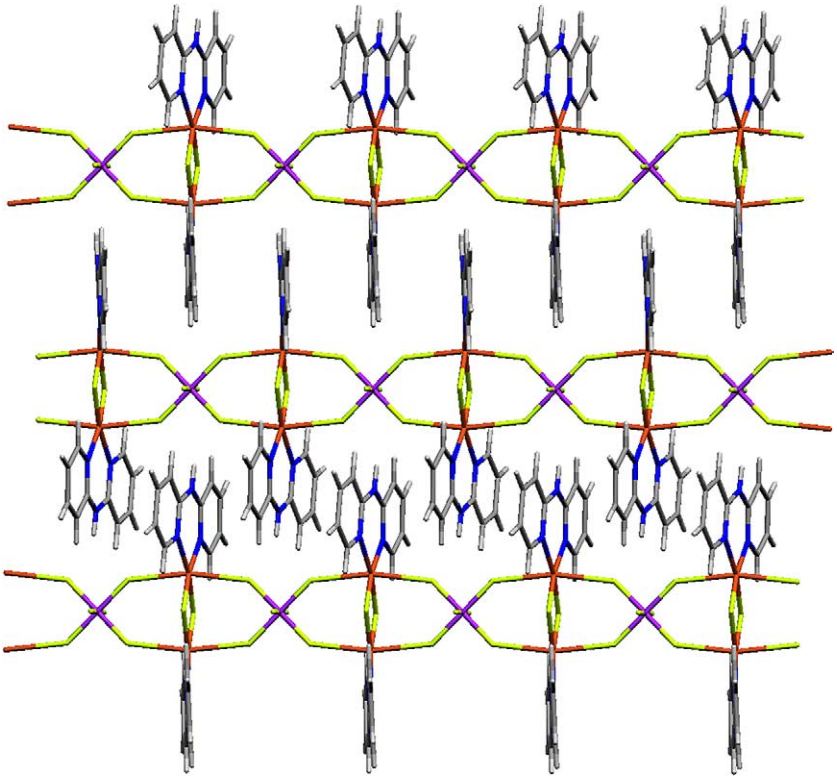

Fig. 2. Stacking diagram of $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)]\cdot(CH_3OH)_2$ along the directions *b* and *c*, evidencing the head-to-tail $\pi\cdots\pi$ interactions between the dipyridylamine ligands (solvent molecules omitted for clarity).

along this direction. These chains are further stacked along the (0 0 1) direction, so that the dipyridylamine ligand planes form interpenetrated columns with $\pi\cdots\pi$ interactions (~3.5–3.8 Å), each dipyridylamine ligand interacting head-to-tail with two dipyridylamine ligands from the adjacent layer. Actually, in view of this stacking, the structure can be best described as inorganic (Cu(II)–Si)-based layers and organic dipyridylamine-based layers, the material thus may be described as a hybrid inorganic/organic material. The structure is stabilised by an important 3-D network of supramolecular contacts, i.e., hydrogen bonds and short contacts. For instance, as illustrated in Fig. 3, the solvent molecules are involved in hydrogen bonding with apical fluoride atoms of hexafluorosilicate anions (O–H$\cdots$F, with O$\cdots$F distances of 2.699 Å). In this scheme are also evidenced interchain interactions between fluoride atoms of hexafluorosilicate anions with amine nitrogen atoms (N–H$\cdots$F, with N$\cdots$F distances in the range of 2.866–2.930 Å).

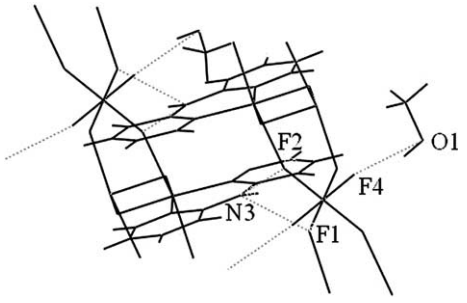

Fig. 3. View of the hydrogen bonds in $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)]\cdot(CH_3OH)_2$ (D$\cdots$A distances: O1$\cdots$ F4 2.699, N3$\cdots$F2 2.866, N3$\cdots$ F1 2.930 Å).

5. Magnetic properties

Fig. 4 shows plots of χ and χT versus T for the title compound where χ is the molar magnetic susceptibility in terms of the repeating unit $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)]\cdot(CH_3OH)_2$. The χT value is 0.621 emu K mol^{-1} at 300 K. This is smaller than the expected value for two uncoupled Cu(II) ions (0.75 emu K mol^{-1}, $g = 2$). Within the temperature range 300–150 K, the χT value is approximately constant, then it decreases reaching a plateau below 20 K. This plateau indicates the presence of a small amount of non-coupled species in the sample, also evidenced by the abrupt increase of the χ at low temperature when cooling. The χT versus temperature behaviour suggests the existence of antiferromagnetic interactions between the metal centres. Given the large separation between the Cu(II) ions imposed by the hexafluorosilicate ion, the non-negligible magnetic pathway arises from the fluoro-bridges in the

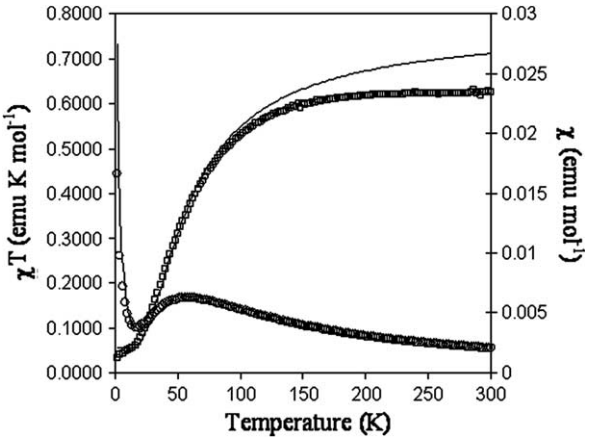

Fig. 4. Temperature dependence of χT (□) and χ(○) for $[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)] \cdot (CH_3OH)_2$. The full lines correspond to the best fit to the experimental data.

CuF_2Cu units. Accordingly, the magnetic data were analysed on the basis of the Bleaney-Bowers expression given for dinuclear Cu(II) compounds, modified by Kahn to take into account some paramagnetic impurity due to the presence of a very small amount of non-coupled species in the sample [36]:

$$\chi = \frac{2Ng^2\beta^2}{kT[3 + e^{-\frac{J}{kT}}]}(1-\rho) + \frac{Ng^2\beta^2}{2kT}\rho,$$

where ρ is the molar fraction of the paramagnetic impurity, the other symbols have their usual meanings.

The best fit of the magnetic susceptibility data yielded $J = -74\ cm^{-1}$, $g = 2.04$, $\rho = 0.07$. The J value indicates that strong antiferromagnetic interactions are dominant in the polymer. Correlation of the structural parameters and the J coupling constant are usually established for bridged metal complexes (e.g., with N_3) however, in the present case, such correlation was not attempted yet due to the lack of sufficient CuF_2Cu examples. It can, however, be noted that the magnetic interactions are slightly less stronger in the present compound than in the relatively similar complex $[Cu(mppzH)_2F]_2(BF_4)_2$ where the Cu–F–Cu angle is of 98.9° and the coupling constant is of $-118\ cm^{-1}$ [25]. The strong antiferromagnetic interactions between the two copper centres in the CuF_2Cu unit are confirmed by a quasi-silent solid-state EPR spectrum at room temperature and 77 K. Only a very broad weak band is observed, attributed to a $S = 1$ system in a crystal lattice with other spins nearby.

6. Concluding remarks

The main interest of the present work lies in the isolation and structural characterisation of a unique polymer combining alternating μ-F and μ_4-SiF_6 bridges $\{[Cu_2(dipyridylamine)_2(\mu\text{-}F)_2(\mu_4\text{-}SiF_6)] \cdot (CH_3OH)_2\}_n$. Its magnetic properties were elucidated using a Bleaney-Bowers model for dinuclear Cu(II) complexes, leading to the extraction of a J parameter of $-74\ cm^{-1}$, indicating strong antiferromagnetic interactions in the polymer.

Pd, Pt, Au, ...) [5]. More recently, cyanide clusters such as $[Re_6Se_8(CN)_6]^{4-}$ [6] or $[Cu_8(i\text{-}mnt)_6]^{4-}$ [7] have also been investigated. Among these anions, the paramagnetic hexacyanometalate $[M(CN)_6]^{3-}$ (M = Fe, Cr) complexes are particularly studied in order to create magnetic interactions between the magnetic moments of the transition metal and the π-electrons of the organic network. Such molecular materials can thus combine both conducting and magnetic properties and lead to multiproperty materials [4,8]. In this prospect, the association of the TTF itself with the hexacyanoferrate anion has been reported [9]. The use of extended molecules such as BEDT-TTF (bis(ethylenedithio)tetrathiafulvalene) [10–14], BET-TTF (bis(ethylenethio) tetrathiafulvalene) [15] or the selenium derivative BEDS-TTF (bis(ethylenediseleno)tetrathiafulvalene) [16], has been also investigated and led to numerous materials. To our knowledge, only two examples with functionalized TTF derivatives have been reported so far. These radical cation salts formulated $(DHET\text{-}DMTTF)_2(Et_4N)[Fe(CN)_6]$ [13a] and $(DHET\text{-}EDTTTF)_2(Et_4N)$ $[Cr(SCN)_6]$ [13b] both incorporate a hydroxyl TTF derivative, either the bis(hydroxyethylenethio)dimethyl-tetrathiafulvalene (DHET-DMTTF) or the bis(hydroxyethylenethio)ethylenedithio-tetrathiafulvalene (DHET-EDTTTF). In these structures, strong hydrogen bonds have been observed between the cyano groups and the hydroxyl groups. Based on this observation, the association of the tetrakis(hydroxymethyl)tetrathiafulvalene ($TTF(CH_2OH)_4$), a TTF derivative bearing four hydroxyl groups, with cyanide anions appeared interesting to investigate.

We report here the synthesis of radical cation salts based on $TTF(CH_2OH)_4$ with either the organic tetrafluorotetracyanoquinodimethane molecule ($TCNQF_4$) or the inorganic paramagnetic $[Fe(CN)_6]^{3-}$ complex (Scheme 1). In order to appreciate the magnetic contribution of the organic part in the resulting salt, the compound incorporating the diamagnetic complex $[Co(CN)_6]^{3-}$ has also been prepared. The synthesis and the crystal structure of the three radical salts formulated $[TTF(CH_2OH)_4][TCNQF_4]$ (**1**) and $[TTF(CH_2OH)_4]_3[18\text{-crown-}6 \subset K][M(CN)_6] \cdot DMF$ with M = Fe (**2a**) and M = Co (**2b**) are reported in this paper, as well as the study of their magnetic properties.

Scheme 1. Molecules studied. The bond labels of the $TTF(CH_2OH)_4$ and $TCNQF_4$ molecules are represented as *a*, *b*, *c* and *d* letters.

2. Experimental

2.1. Synthesis

$TTF(CH_2OH)_4$ was synthesized according to the method described in the literature [17]. The starting compounds $TCNQF_4$, $K_3[Fe(CN)_6]$, $K_3[Co(CN)_6]$ and 18-crown-6 ether were purchased from Aldrich. $TCNQF_4$ was recrystallized twice in acetonitrile prior to use.

Crystals of **1** were obtained by slow diffusion of an acetonitrile (MeCN) solution of 17 mg of $TCNQF_4$ in a dimethylformamide (DMF) solution of 20 mg of $TTF(CH_2OH)_4$ at room temperature. Air-stable dark green crystals were harvested after few days.

Crystals of **2a** and **2b** were grown using the electrocrystallization technique by applying anodic constant current ($I = 0.5$ μA) at platinum wire electrodes ($l =$ 2 cm, $d = 1$ mm) of a two-compartment cell at 25 °C [18]. The supporting electrolyte was a solution of 20 mg of the corresponding potassium hexacyanometalate salt and 50 mg of dried 18-crown-6 ether dissolved in a 5:1 mixture of freshly distilled MeCN and DMF (15 mL). In the anodic compartment 5 mg of $TTF(CH_2OH)_4$ were added. Air-stable black crystals were obtained after 2 weeks.

2.2. X-ray crystallography

Details of data collection and structure refinement are summarized in Table 1. Data were collected at 293 K on a single Φ-axis Stoe-IPDS diffractometer using graphite monochromatized Mo Kα radiation ($\lambda =$ 0.71073 Å). The Stoe software [19] was used for data collection and reduction. No absorption correction was applied due to the low value of the absorption coefficients. Structures were solved by direct-methods and refined by full-matrix least-squares based on F^2, by using the SHELX-97 software package [20].

Hydrogen bonds were detected by the usual but indirect method used for X-ray data, consisting in the observation of short distances between hydrogen bond donor and acceptor [21]. Two types of hydrogen bond, O–H···O and O–H···N are involved in these salts. One singularity of the O–H···O hydrogen bonds lies in the dual hydrogen bond donor and acceptor character of the hydroxyl group. Then even if a hydrogen bond is detected by identifying a short O···O contacts (typically between 2.60 and 2.95 Å) [21,22], the hydrogen atom can be disordered over two positions, each oxygen atom playing alternatively the donor and the acceptor role. Knowing these difficulties, the following process was used for the X-ray structures presented in this paper: (i) identification

Table 1

of short donor (O)–acceptor (O) distances, as indication of the presence of a hydrogen bond, followed by (ii) the introduction of hydrogen atoms using riding model. This method gives a plausible position for the hydrogen atoms, but not necessary the only possible one.

In all structures, all non-hydrogen atoms were refined with anisotropic parameters. For **1**, hydrogen atoms were introduced at calculated positions and were not refined (riding model). For **2a**, O2A and O1E atoms were found disordered over two dependent positions with a 0.6:0.4 refined distribution. Thermal ellipsoids on O3A and O4A were found elongated, but attempts to split them on two positions gave unsatisfactory results. These atoms were then ultimately refined with a full occupancy in one position. Hydrogen atoms were introduced at calculated positions and were not refined (riding model), excepted on the minor position of O2A (O2AB) where no hydrogen atom was introduced. For **2b**, O2A and O1E atoms were found disordered over two dependent positions with a 0.6:0.4 refined distribution. As for **2a**, thermal ellipsoids on O3A and O4A were found elongated, but attempts to split them on two positions gave unsatisfactory results. These atoms were then ultimately refined with a full occupancy in one position. Hydrogen atoms were introduced at calculated positions and were not refined, excepted on the minor position of O2A (O2AB) where no hydrogen atom was introduced.

2.3. Magnetic measurements

Magnetic susceptibility measurements were performed on polycrystalline samples (18.35 mg, 13.93 mg and 19.24 mg for **1**, **2a** and **2b**, respectively) on a Quantum Design MPMS-5 SQUID magnetometer in the temperature range 5–300 K at 5000 G. The data were corrected for the sample holder and for the diamagnetic contribution calculated from Pascal constants.

2.4. Theoretical calculations

The overlap interaction energies ($\beta_{HOMO-HOMO}$) were calculated by the extended Hückel method [23]. A modified Wollsberg–Helmholtz formula was used to calculate the $H_{\mu\nu}$ non-diagonal values [24]. Double-ζ orbitals for carbon, sulfur and oxygen atoms were used.

3. Results

3.1. $[TTF(CH_2OH)_4][TCNQF_4]$ (1)

This salt was obtained by chemical oxidation of $TTF(CH_2OH)_4$ by $TCNQF_4$ in a MeCN/DMF mixture. Single crystals suitable for X-ray diffraction were obtained after few days. From the X-ray analysis, this salt

is formulated [TTF(CH$_2$OH)$_4$][TCNQF$_4$]. It crystallizes in a triclinic setting, space group $P\bar{1}$ (No. 2) with one TTF(CH$_2$OH)$_4$ molecule and one TCNQF$_4$ molecule in general position. The geometry of the TTF(CH$_2$OH)$_4$ molecule is similar to the one already observed in the neutral form and in other radical salts [25,26]. The TTF core and the methylene groups are in the same plane whereas all the oxygen atoms of the hydroxyl group lie slightly upper of this plane but on the same side. TTF(CH$_2$OH)$_4$ molecules are assembled in centrosymmetric dimers with an almost bond-over-bond conformation, associated with a short inter-plane distance (3.388(2) Å) and short S···S contacts (3.3916(15) and 3.4362(16) Å). TCNQF$_4$ molecules crystallize planar with a regular geometry, and are also assembled in centrosymmetric dimers with a short inter-plane contact (3.2198(10) Å, shortest intermolecular C···C distance = 3.284(5) Å).

As in all TTF based molecules, intra-molecular bond lengths in TTF(CH$_2$OH)$_4$ are oxidation state sensitive. C–C double bonds (*a* on Scheme 1) and C–S bonds (*b* and *c* on Scheme 1) are, respectively, longer and shorter when oxidation state increases. A similar trend is known for TCNQF$_4$ molecule; double bonds (*a* and especially *c* on Scheme 1) and single bonds (*b* and *d* on Scheme 1) are, respectively, longer and shorter when reduction state increases. Bond distances in TCNQF$_4$ and TTF(CH$_2$OH)$_4$ in **1** are reported in Tables 2 and 3, respectively, as well as those for the corresponding neutral molecule and for known cation radical salts. Bond lengths examination allows to attribute $a+1$ and $a-1$ oxidation state for the TTF(CH$_2$OH)$_4$ and the TCNQF$_4$ molecules, respectively. This is indeed in accordance with the relative redox potentials of both components. The first and the second oxidation of TTF(CH$_2$OH)$_4$ are reported to occur at 0.39 and 0.65 V versus SCE in DMF [17a,27], and the first reduction potential of TCNQF$_4$ at 0.53 V versus SCE in MeCN [28]. Even if it is not an absolute way to conclude, the high potential difference ($\Delta E = 0.14$ V) is in favor of a full charge transfer salt. This is also confirmed by the geometry of the [TTF(CH$_2$OH)$_4$]$_2$ dimer, a bond-over-bond conformation with a short inter-plane contact (<3.5 Å) is usually associated with fully oxidized $(TTF)_2^{2+}$ dimer [7]. The $\beta_{HOMO-HOMO}$ value calculated by the extended Hückel method for the [TTF(CH$_2$OH)$_4$]$_2$ dimer in **1** is 1.116 eV. This high value is in

The corresponding oxidation state is also reported. *a*, *b*, *c* and *d* bond labels are defined in Scheme 1.

accordance with those calculated for fully oxidized $[TTF(CH_2OH)_4]_2^{2+}$ dimers in the $[TTF(CH_2OH)_4]_x[Re_6S_{8-n}Cl_{6+n}]$ ($n = 0, 1, 2, 3$) cation radical salts series ($\beta_{HOMO-HOMO}$ ranging from 1.006 to 1.176 eV) [26].

The crystal structure of **1** can be described by focusing on the dimeric units. $[TCNQF_4]_2^{2-}$ dimers stack along the *a* axis with their plane almost perpendicular to this direction. As represented Fig. 1(a), $TTF(CH_2OH)_4$ molecules adopt a ladder-like arrangement in the same direction but this time with their plane parallel to the *a* axis. Nevertheless, this structural feature cannot be associated with a magnetic spin ladder behavior because these dimers are indeed electronically isolated one from the other due to the bulkiness of the CH_2OH groups (inter-dimer S···S contacts > 4.65 Å). The cationic and the anionic ribbons define a distorted cubic lattice in the (*b*, *c*) plane (Fig. 1(b)).

A complex hydrogen bond network occurs in **1**. The cohesion of the $[TTF(CH_2OH)_4]_2^{2+}$ dimer is reinforced by three strong and one weaker O–H···O hydrogen bonds between the hydroxyl groups. As represented Fig. 2, O2A–H12A and O4A–H4A groups act as hydrogen bond donors for O3A and O1A, respectively. Corresponding bond distances and angles are summarized in Table 4 and are in the usual range for this kind of interaction [21,22]. The $[TTF(CH_2OH)_4]_2^{2+}$ dimers are connected with each others by O–H···O hydrogen bonds parallel to the ladder direction with O1A–H11A and O3A–H13A acting this time as hydrogen bond donors for O2A and O4A, respectively (Fig. 2). This results in the formation of cyclic $R_4^4(8)$ motifs [30], where all crystallographically independent hydroxyl groups act as both a donor and an acceptor. The cohesion of the cationic ribbon is then ensured by hydrogen bonding. The hydrogen atom involved in the weakest O–H···O hydrogen bonds, namely H13A (O3A···O4A = 3.008(4) Å, O3A–H13A···O4A = 106.5°) is also hydrogen bonded to a nitrogen atom of a $TCNQF_4$ molecule (N3B on Fig. 2) that thus connects adjacent cationic and anionic ribbons (see Table 4 for bond distances and angles).

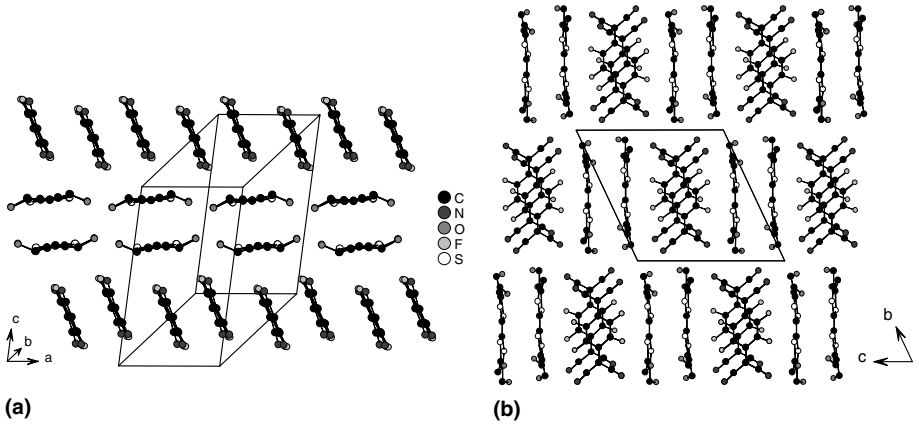

Fig. 1. Crystal structure of **1**. Hydrogen atoms are omitted for clarity. (a) Ribbons of $[TTF(CH_2OH)_4]_2^{2+}$ and $[TCNQF_4]_2^{2-}$ dimers running along the *a* direction, the molecules are viewed along their long axis. (b) Distorted cubic arrangement of the cationic and anionic ribbons in the (*b*,*c*) plane.

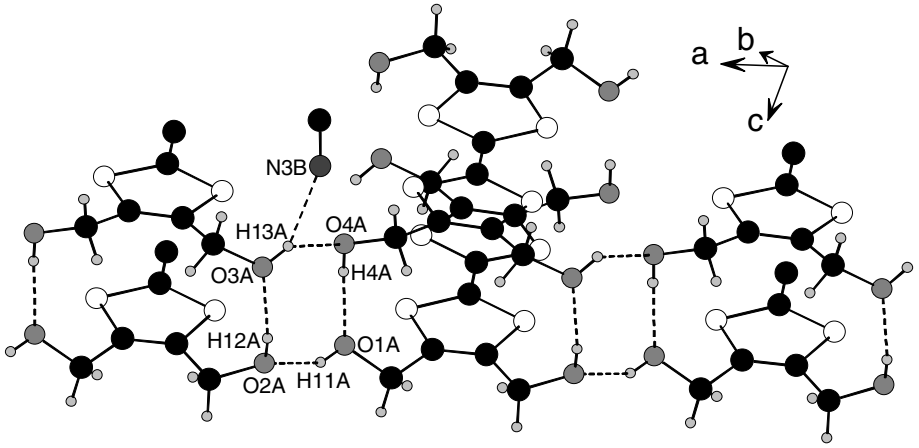

Fig. 2. Hydrogen bond network in **1** represented in dashed lines. Only the central $[TTF(CH_2OH)_4]_2^{2+}$dimer is fully pictured. Only the cyano group of the $TCNQF_4$ molecule involved in the hydrogen bond network is represented.

A and D are the hydrogen bond acceptor and donor, respectively. Values of van der Waals contacts for H···O and H···N are 2.72 and 2.75 Å, respectively.

[a] No hydrogen atom has been introduced on this hydroxyl group during the X-ray elucidation, see Section 2 for details.

The magnetic properties of **1** have been studied by SQUID measurement. The variation of the magnetic susceptibility with the temperature corresponds to a diamagnetic behavior except at low temperature which is attributed to paramagnetic impurities (0.3%). This behavior is in accordance with the presence of fully oxidized, diamagnetic and electronically isolated $[TTF(CH_2OH)_4]_2^{2+}$ and $[TCNQF_4]_2^{2-}$ dimers.

3.2. *[TTF(CH$_2$OH)$_4$]$_3$[18-crown-6 ⊂ K][Fe(CN)$_6$] · DMF (**2a**) and [TTF(CH$_2$OH)$_4$]$_3$[18-crown-6 ⊂ K][Co(CN)$_6$] · DMF (**2b**)*

Electrocrystallization of $TTF(CH_2OH)_4$ with $K_3[Fe(CN)_6]$ or $K_3[Co(CN)_6]$ was performed in a DMF/MeCN mixture. 18-Crown-6 ether was added to the electrolytic solution in order to dissolve the potassium salts. Black air-stable crystals were harvested after 2 weeks. From the X-ray analysis, these salts are isostructural and formulated $[TTF(CH_2OH)_4]_3[18\text{-crown-}6 \subset K][M(CN)_6] \cdot DMF$, with M = Fe (**2a**) or Co (**2b**). They crystallize in a triclinic setting, space group $P\bar{1}$ with one $TTF(CH_2OH)_4$ molecule (**A**) in general position, another molecule (**C**) on an inversion center and one $[M(CN)_6]^{3-}$ anion, one potassium cation, one 6-crown-18-ether molecule and one DMF molecule on inversion centers. The DMF solvent molecule is disordered over two positions.

As represented in Fig. 3, the whole structure can be described as an alternation of cationic and anionic layers stacked in the *c* direction. The anionic layer is composed of hexacyanometalate anions and DMF solvent molecules. In **2a**, $[Fe(CN)_6]^{3-}$ anion adopts a regular octahedral geometry with Fe–C distances and independent C–Fe–C angles ranging from 1.930(5) to 1.947(6) Å and 88.0(2)° to 89.6(2)°, respectively, and C–N distances and Fe–C–N angles ranging from 1.126(7) to 1.145(7) Å and 177.0(6)° to 179.3(5)°, respectively [9–16]. In **2b**, the $[Co(CN)_6]^{3-}$ anion presents also a regular geometry (Co–C = 1.894(5)–1.904(4) Å, C–Co–C = 88.4(2)–89.4(2)°, and C–N = 1.134(5)–1.142(5) Å, Co–C–N = 177.4(4)–178.7(4)°) [10,11].

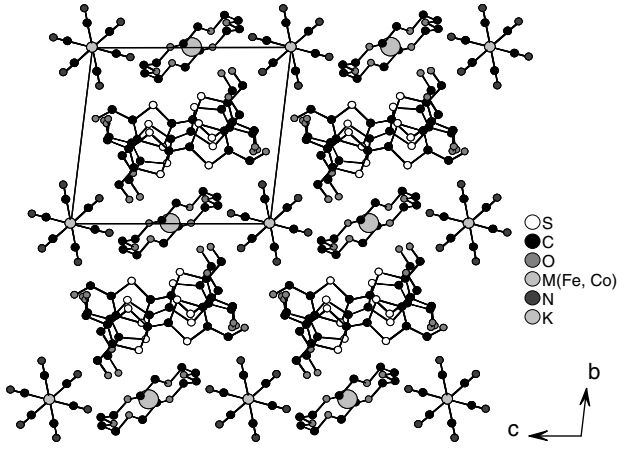

Fig. 3. Crystal structure of **2a** and **2b** viewed along the *a* axis. Hydrogen atoms, DMF solvent molecules and K–O bonds are omitted for clarity.

The cationic layer is built of columns of $TTF(CH_2OH)_4$ molecules (**A** and **C**) developing in the *a* direction, electronically isolated the one to the others by crown-ether-embedded potassium cations (shortest inter-columnar S···S contact > 6.5 Å). The two independent $TTF(CH_2OH)_4$ molecules are planar with the hydroxyl groups pointing slightly outside the TTF plane as already observed in **1**. One of the hydroxyl group (O2A) of the **A** molecule is disordered over two positions with 0.6 : 0.4 refined occupancy. The potassium cation lies in the center of the 18-crown-6 ether molecule with K–O distances ranging from 2.786(4) to 2.819(4) Å in **2a** and from 2.794(3) to 2.815(3) Å in **2b**, as expected for the [18-crown-6 ⊂ K] motif [31]. The coordination sphere of the potassium ion is completed by two oxygen atoms (O2C) of the **C** $TTF(CH_2OH)_4$ molecule (K–O2C = 2.793(4) and 2.804(4) Å in **2a** and **2b**, respectively) defining a 1-D polymeric network along the *b* axis as represented Fig. 4. The potassium cation is thus in a distorted bipyramidal hexagonal coordination environment as commonly observed for alkali cations.

From the salt formulation, namely $[TTF(CH_2OH)_4]_3[18\text{-crown-6} \subset K][M^{III}(CN)_6] \cdot DMF$ (M = Fe, Co), $a + 2/3$ mean oxidation state can be deduced for the $TTF(CH_2OH)_4$ molecules. This charge distribution is in accordance with the geometry of the TTF core. C–S and C=C bond lengths for **A** and **C** molecules (see Table 3) are indeed intermediate between those of the neutral molecule and those of the fully oxidized $[TTF(CH_2OH)_4]^+$ cation. Each column of $TTF(CH_2OH)_4$ molecules is composed of centrosymetric $(\mathbf{ACA})^{2+}$ trimer with a bond-over-bond overlap (shortest S···S contacts are 3.554(2), 3.580(2) and 3.582(2) Å in **2a** and 3.564(2) and 3.592(2) Å in **2b**) and a slight twisting between successive molecules (dihedral angle between the long axis of **A** and **C** molecules is about 10–11°). As shown in Fig. 5, these trimers are packed in a staggered manner with shortest inter-trimer S···S contacts greater than 4 Å (4.060(2) and 4.051(2) Å in **2a** and **2b**, respectively). $\beta_{HOMO-HOMO}$ interactions were calculated by the extended Hückel method and are, respectively, 0.722 and 0.237 eV for the intra- and inter-trimer interactions in **2a**, and 0.746 and 0.239 eV in **2b**. As expected, the HOMO–HOMO overlap in the trimer composed of +2/3 mixed valence $TTF(CH_2OH)_4$ cations is weaker than the one calculated for the fully oxidized $[TTF(CH_2OH)_4]_2^{2+}$ dimer in **1** (0.722 or 0.746 versus 1.116 eV).

As shown in Fig. 5, the cohesion of the $[(TTF(CH_2OH)_4)_3]^{2+}$ trimer is reinforced by O–H···O hydrogen bonds (O2C–H2C···O1A and possibly O1C···O2AA). The corresponding distances and angles are reported in Table 4. Nevertheless, the main interaction occurs between the hydroxyl and the cyano groups of the anions. Each $[Fe(CN)_6]^{3-}$ complex is actually connected to six $TTF(CH_2OH)_4$ molecules by strong O–H···NC hydrogen bonds (O1C–H1C···N1B, O1A–H1A···N2B and O4A–H4A···N3B), as represented in Fig. 6. Geometrical characteristics are summarized in Table 4 and are in the usual range for this kind of interactions [13,32].

On the two remaining hydroxyl groups, one (O2A–H2A) is hydrogen bonded to the carbonyl group of the DMF molecule. This O–H···O hydrogen bond is disordered over two positions (O2AA–H2AA···O1EA

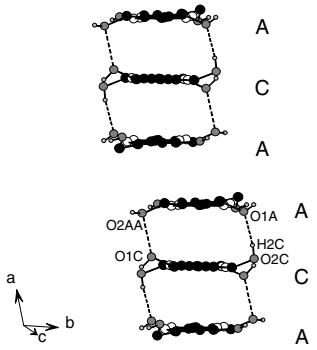

Fig. 5. Stack of $(\mathbf{ACA})^{2+}$ trimers in the *a* direction viewed along the long axis of the $TTF(CH_2OH)_4$ molecules in **2a** and **2b**. Only one of the two disordered position for O2A is pictured. Intra-trimers O–H···O hydrogen bonds are drawn in dashed lines. Hydrogen atoms of CH_2 groups are omitted for clarity.

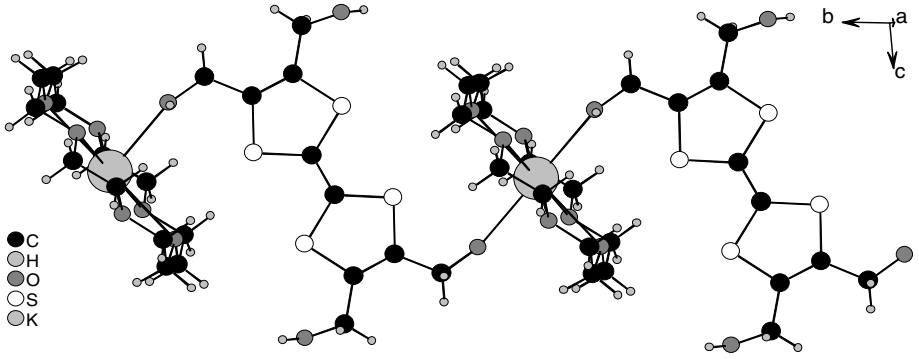

Fig. 4. View of the polymeric chain in **2a** and **2b** composed of $TTF(CH_2OH)_4$ molecules and crown-ether-embedded potassium cations.

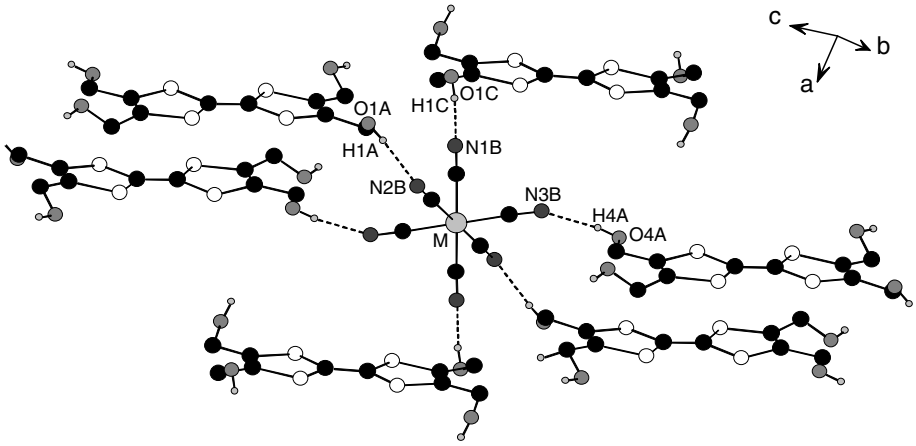

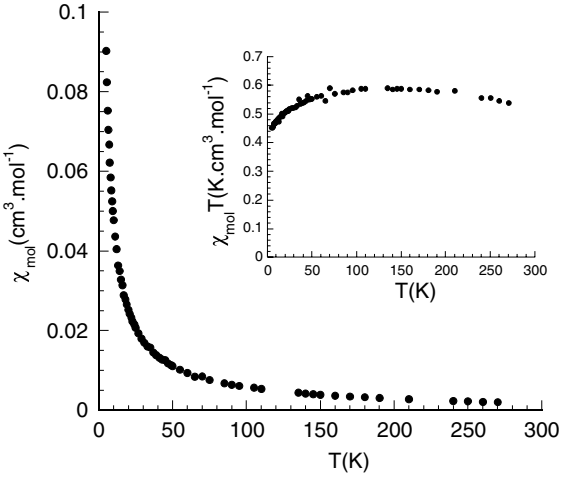

Fig. 6. Hydrogen bonds at the organic-inorganic interface in **2a** and **2b**. $[M(CN)_6]^{3-}$ (M = Fe, Co) anions are involved in six strong O–H···NC hydrogen bonds with $TTF(CH_2OH)_4$ molecules. Only one of the two disordered position for O2A is pictured and hydrogen atoms of CH_2 groups have been omitted for clarity.

and O2AB–H2AB···O1EB) due to the solvent molecule disorder itself. Surprisingly, the latest hydroxyl group (O3A–H3A) does not seem to be involved in any significant hydrogen bond. To summarize, all hydroxyl groups except O3A–H3A act as hydrogen bond donors, either to a cyano group (O1C–H1C, O1A–H1A and O4A–H4A), a hydroxyl group (O2C–H2C) or a carbonyl group (O2A–H2A). This defines a three-dimensional mixed organic-inorganic hydrogen bonded network presenting cavities in which the crown-ether-embedded potassium ions are located.

Magnetic properties have been studied for both salts. Magnetic behavior of **2b** is essentially diamagnetic with a Curie tail at low temperature, certainly due to paramagnetic impurities (4% from fitting with a Curie law). This feature is consistent with the presence of diamagnetic low spin d^6 Co^{III} cation in the complex and diamagnetic $[TTF(CH_2OH)_4]_3^{2+}$ trimers.[2] Compound **2a** being isostructural to **2b**, the same diamagnetic behavior should be observed for the organic part. As shown in Graph 1, the susceptibility curve for **2a** could indeed be fitted by a Curie law ($C = 0.486$ K cm^3 mol^{-1}), which is consistent with isolated paramagnetic $[Fe(CN)_6]^{3-}$ anions with a $S = 1/2$ low spin d^5 state for the Fe^{III} cation (with $g = 2.276$ [33]). Decrease of the susceptibility-temperature product at low temperature may be an indication of weak antiferromagnetic coupling between anions.

4. Discussion

Here are reported three cation radical salts based on $TTF(CH_2OH)_4$, synthesized either by chemical (**1**) or by electrochemical (**2a**–**b**) oxidation. In these salts, the $TTF(CH_2OH)_4$ molecules are associated in diamagnetic dicationic π-oligomer. In **1**, dimers are formed, as already observed in the $[TTF(CH_2OH)_4]_x[Re_6S_{8-n}Cl_{6+n}]$ ($n = 0, 1, 2, 3$) cation radical salts series [26], whereas trimers are observed in **2a–b**. The later case represents the first mixed valence salt based on $TTF(CH_2OH)_4$ donor. No long range electronic delocalization is however observed due to trimerization and then of course no reasonable conducting properties could be expected. Strong HOMO–HOMO interactions evaluated by extended Hückel calculations, lead in both case to diamagnetic isolated entities, as shown by the magnetic measurements.

In **2a** and **2b**, potassium cations from the reactant $K_3[M(CN)_6]$ (M = Co, Fe) as well as crown-ether molecules are incorporated in the structure. The formation of ternary salts incorporating TTF-based cation radicals

[2] The electronic structure of these trimers can be described by four electrons filling two of the three non-degenerated orbitals generated by the three HOMOs.

and both components of the electrolyte has already been observed with alkaline or alkaline earth cations, especially with the $[M(CN)_6]^{n-}$ anions [10,13,15]. Incorporation of crown ether molecule has also already been reported in the proton-conducting metallic cation radical salts series formulated β''-(BEDT-TTF)$_4$[(H_3O)(Cr$(C_2O_4)_3]_2$[$(H_3O)_2$(18-crown-6)] · $5H_2O$ (M = Cr, Ga, Fe), where H_3O^+ ions are located within the 18-crown-6 ether molecule [34]. In our case, the coordination of the potassium cation by oxygen atoms of TTF$(CH_2OH)_4$ molecules lead to the formation of a polymeric chain.

These three salts, **1** and **2a**–**b** are composed of hydrogen bond donor (and acceptor) organic molecules and on hydrogen bond acceptor cyanide anions. These compounds thus represent another example to study the competition of O–H···O and O–H···NC hydrogen bond, where the cyano group can be either organic (**1**) or inorganic (**2a–b**). In **1**, all hydroxyl groups act as hydrogen bond donors, and three of them are involved as acceptor in moderate O–H···O hydrogen bonding (O1A, O2A and O3A). The last donor (O3A–H3A) interacts with a cyano group of the $TCNQF_4$ molecule. Only one of the four cyano groups is then involved in hydrogen bonding. On the other hand, in **2a**–**b**, all the cyano groups of the $[M(CN)_6]^{3-}$ anion are involved in O–H···NC hydrogen bonds, whereas only one hydroxyl group (O1A–H1A) acts as a good acceptor towards another OH group. Furthermore, O···N distance in **1** appears to be longer than O···O ones (2.97 versus 2.77 Å), whereas in **2a**–**b**, O···N distances seems to be slightly shorter than O···O ones (2.75 versus 2.80 Å, see Table 4). The inorganic cyano group then appears to be a better acceptor than the organic hydroxyl group, and the latter appears to be better acceptor than organic nitrile group. In these specific examples, the following hydrogen bond acceptor strength can thus be proposed: $–CN_{inorganic} > –OH_{organic} > –CN_{organic}$. This is of course consistent the shortening of the O–H···N distances when moving from organic cyano group to inorganic one and with electrostatic considerations: cyano groups are more negatively charged in metallic complexes than in organic molecules, and consequently better acceptors.

5. Conclusion

Three new radical cation salts based on the functionalized organic π-donor TTF$(CH_2OH)_4$ and on cyanide anions have been synthesized. Their crystal structures and magnetic properties have been studied. With the hexacyanometallate $[M(CN)_6]^{3-}$ (M = Fe, Co) anions, ternary salts have been obtained incorporating crown-ether-embedded potassium cations. These cations are coordinated by oxygen atoms of TTF$(CH_2OH)_4$ molecules leading to an original polymeric chain. Despite different oxidation states, in all these three salts the organic molecules are combined in electronically isolated and diamagnetic oligomers, as commonly observed in radical cation salts of TTF derivatives bearing hydroxyl groups.

As expected, complex hydrogen bond networks occur in the structures. The organic molecules are connected to each others via hydrogen bonds but the hydroxyl groups interact also with the cyano groups of the anions. The structural analysis of this salts reveals once again that the inorganic cyano groups of the hexacyanometallate $[M(CN)_6]^{3-}$ anions are better hydrogen bond acceptors than the nitrile groups of $TCNQF_4$ molecule.

This study shows that the association of hydrogen bond acceptor anions to hydrogen bond donor functionalized TTFs is a good strategy to produce new molecular materials with original structural organization where the cationic part interact strongly with the anionic one.

6. Supplementary material

Crystallographic data of **1**, **2a** and **2b** have been deposited with the Cambridge Crystallographic Data Centre with CCDC Nos. 264830, 264831 and 264832, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or on the web http://www.ccdc.cam.ac.uk).

Acknowledgments

Financial support from the CNRS and University of Nantes is gratefully acknowledged. We thank P. Batail for discussions about functionalized TTF derivatives. Dr. S. Perruchas thanks Dr. T. Devic and Dr. S. Baudron for help and useful discussions.

2. Experimental

2.1. Synthesis

All manipulations were carried out under dry argon in all-glass reaction and handling vessels that were dried in vacuo. Ammonia (Bayer AG) was made anhydrous by distilling it from sodium and was stored as a sodium–ammonia solution at 195 K. The compound $[Cs_6(PhSb_2)_2]\cdot 11NH_3$ was prepared by placing the starting materials elemental caesium (0.5 g; 3.8×10^{-3} mol) and triphenylantimony (0.268 g, 7.6×10^{-3} mol) into a Schlenk-type reaction tube. Thirty millilitres of ammonia were condensed onto the reaction mixture, which resulted in a blue solution. During three weeks, the colour of the reaction mixture turned brown. After this period, it was possible to isolate dark brown crystals directly from the solution, which were extremely unstable at temperatures above −20 °C or in air.

2.2. Crystallographic analysis

A modification of the method of Kottke and Stalke [16] was used for the isolation, selection and mounting of the crystals. Small amounts of the reaction products were transferred directly from the liquid ammonia into perfluoroether (Galden), which was cooled to 213 K by a stream of cold nitrogen. Single crystals suitable for an X-ray structure analysis were selected with the help of a microscope and collected on the tip of a capillary mounted on a goniometer head. The crystals were then immediately submerged in liquid nitrogen, and transferred to the diffractometer. The structures were solved by direct methods (SHELXS-97) [17] and refined against F^2 (SHELXL-97) [18]. An absorption correction was applied to the data (DELrefABS of the program package PLATON) [19]. The H-atoms were located by difference Fourier synthesis and refined isotropically, all other atoms anisotropically.

Details of the measurement and refinement are given in Table 1. Table 2 contains the resulting atomic parameters. All atoms occupy the general position 2i, except for the nitrogen atom N5, which occupies the special position 1a and is therefore placed on the vertices of the unit cell.

3. Results and discussion

$[Cs_6(PhSb_2)_2]\cdot 11NH_3$ is built from $PhSb_2^{3-}$ anions, Cs^+ cations and ammonia molecules of crystallisation. The approximately planar $PhSb_2^{3-}$ anion (Fig. 1) is an diantimony dumbbell which carries one covalently bound phenyl residue. The threefold negative charge is confirmed by the number of the caesium counter ions per anion in the asymmetric unit. The formal distribution of this charge is easily rationalised by the $(8-N)$ rule [20]: the terminal atom Sb2 has only one covalent bond and is consequently twofold negatively charged, whereas the twofold bound atom Sb1 carries only one formal negative charge. The length of the single Sb–Sb bond in $PhSb_2^{3-}$ is 2.8198(7) Å, which compares well

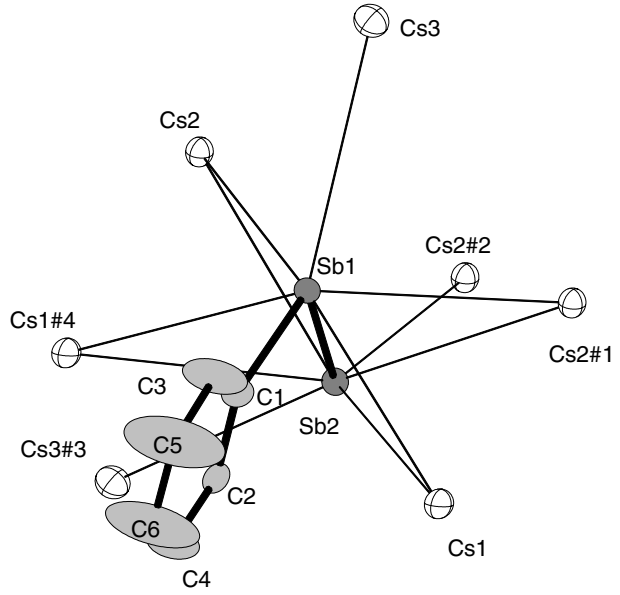

Fig. 1. Caesium coordination sphere of the $PhSb_2^{3-}$-anion in $[Cs_6(PhSb_2)_2] \cdot 11NH_3$. Atomic displacement parameters at 50% probability level. Selected distances (Å) and angles (°): Sb1–Sb2 = 2.8198(7), Sb1–C1 = 2.190(5), C1–C2 = 1.414(8), C2–C4 = 1.392(8), C4–C6 = 1.38(1), C6–C5 = 1.41(1), C5–C3 = 1.39(1), C3–C1 = 1.410(8), Sb1–Cs1 = 3.881(1), Sb2–Cs1 = 4.216(1), Sb1–Cs2#1 = 3.99(1), Sb2–Cs2#1 = 4.0047(8), Sb1–Cs2 = 3.9892(9), Sb2–Cs2 = 4.023(1), Sb1–Cs1#4 = 3.8324(8), Sb2–Cs1#4 = 4.191(1), Sb2–Cs3#3 = 4.210(8), Sb2–Cs2#2 = 4.0466(9), Sb1–Cs3 = 4.154(1); Sb2–Sb1–C1 = 101.1(1), Sb1–C1–C2 = 123.4(4), Sb1–C1–C3 = 120.2(4), C1–C2–C4 = 122.4(5), C2–C4–C6 = 119.2(6), C4–C6–C5 = 120.7(7), C6–C5–C3 = 119.4(7), C5–C3–C1 = 121.5(6). Symmetry operations for the generation of equivalent atoms: #1 = 1 + *x*, *y*, *z*; #2 = 1 − *x*, 1 − *y*, −*z*; #3 = *x*, −1 + *y*, *z*; #4 = − 1 + *x*, *y*, *z*.

to other Sb–Sb single bonds in neutral compounds (i.e., 2.837 Å in Ph_4Sb_2 [21]), but is significantly shorter than the values obtained for Sb_2^{4-}-dumbbells in densely packed ionic solids. In Cs_4Sb_2, the Sb–Sb-distance is 2.923(2) Å [22], in $K_2Ba_3Sb_4$ 2.899(2) Å [23]. This shortening of the single bond in $PhSb_2^{3-}$ may be explained by the lesser charge at the phenyl-substituted Sb atom Sb1, which leads to a reduced repulsion between the Sb atoms. The Sb–Sb bond length of 2.761(1) Å in the $[Sb_3Ph_4]^-$ anion [15] is even shorter.

The Sb atoms of each anion have close contacts to seven surrounding Cs^+ cations, the corresponding Cs–Sb distances range from 3.83(3) to 4.21(3) Å. As can be seen in Fig. 1, four of the Cs^+ cations coordinate to the Sb_2-dumbbell in an η_2-like fashion, which leads to a rectangular arrangement of these cations with the phenyl ring intersecting the larger side of the rectangle. The $PhSb_2^{3-}$ anion is approximately planar, the torsion angle (Sb2–Sb1–C1–C3) is 176.33°.

In the solids Cs_4Sb_2 [22] and $K_2Ba_3Sb_4$ [23], a characteristic trigonal-prismatic environment of the Sb atoms in the Sb_2 dumbbells is observed. If one includes somewhat larger Cs–Sb distances (up to 4.367 Å) into the coordination sphere of Sb, a similar monocapped trigonal prism can be observed for the unsubstituted Sb2 atom in $[Cs_6(PhSb_2)_2] \cdot 11NH_3$ as well (Fig. 2).

Since all three Cs^+ cations in the asymmetric unit of $[Cs_6(PhSb_2)_2] \cdot 11NH_3$ coordinate to two or more Sb atoms of different anions, extended layers parallel to the *ab*-plane are formed (Fig. 3). Between the neutral layers, only Van-der-Waals Contacts via the H atoms of the phenyl rings are observed. Within the layers, the ammonia molecules of crystallisation coordinate to the Cs^+ ions, adding bridging ion-dipole interactions to the ion-pairing interactions comprising the backbone of the layers. Cs–N distances between 3.22 and 3.82 Å were considered for these interactions, the next largest distance being 4.81 Å. The resulting coordination spheres for the Cs^{2+} cations can be deduced from Fig. 3: Cs1 has four contacts to Sb atoms and three contacts to the N atoms of ammonia molecules, one of them serving as a bridging ligand to

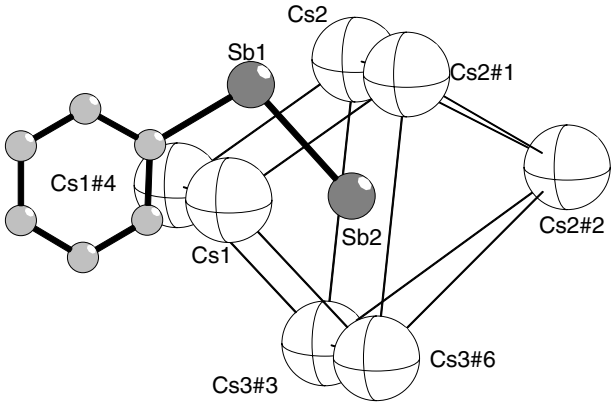

Fig. 2. Monocapped trigonal prismatic environment of Sb2 in $[Cs_6(PhSb_2)_2] \cdot 11NH_3$.

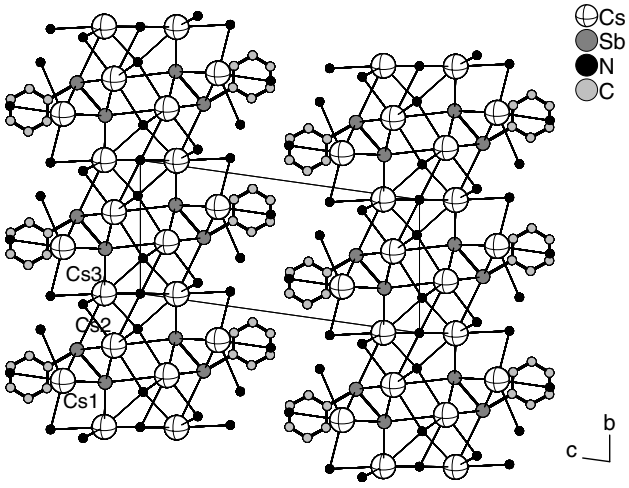

Fig. 3. Projection of the structure of $[Cs_6(PhSb_2)_2] \cdot 11NH_3$ onto the *bc*-plane perpendicular to the layers in the *ab*-direction. H atoms are omitted for clarity.

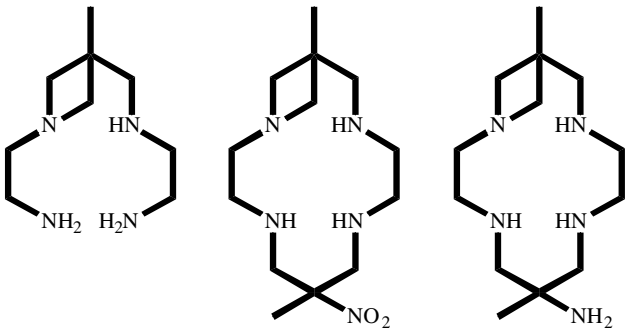
Cs3. Cs2 has five Sb contacts and four ammonia contacts, all of the latters in bridging coordination to several Cs^+ ions. Finally, Cs3 has a total coordination number of nine, which is the sum of three Sb contacts and six contacts to bridging ammonia ligands.



The synthesis of $[Cs_6(PhSb_2)_2] \cdot 11NH_3$ shows that the concept of extending the solution chemistry of Zintl ions by reducing the high charge of the naked ions through the addition of phenyl residues works not only for the tin species already reported but also for antimony. As it is often the case in ammoniates, the stabilisation of the still highly charged anions is further facilitated by extensive ion-pairing.

4. Supplementary data

The crystallographic data have been deposited with the Cambridge Crystallographic Data Centre as Supplementary Publication No. 268483. Copies of the data can be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: int. code +1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or on the web http://www.ccdc.cam.ac.uk).

2. Experimental

2.1. Synthesis

Trans-[Co(**1**)Cl_2]ClO_4 and [Cu(**1**)$OClO_3$]ClO_4 were available from earlier work [10,12]. Details of the ion-exchange chromatographic procedures used for complex ion purification and isolation have also been given earlier [9,10,12]. Other reagents were from commercial sources and used as received.

2.1.1. *[Co(**1**)(R,R-chxn)]$^{3+}$ isomers*

Trans-[Co(**1**)Cl_2]ClO_4 (0.54 g) was dissolved in dmso (20 mL), a large excess (~8-fold) of *trans-(R,R)*-cyclohexane-1,2-diamine (chxn, 0.96 g) added and the mixture heated at 70 °C for 3 h. The final red-orange solution was cooled, diluted with water (2 L) and passed through a column (7 × 120 cm) of Na^+-form SP Sephadex C-25 cation exchange resin to absorb the complex cations. Subsequent elution with 0.12 mol L^{-1} trisodium citrate gave three bands, the first and third minor components proving to be hydrolysed starting material and [Co(*R,R*-chxn)$_3$]$^{3+}$, respectively. (The complexes present in the different bands were characterised after conversion to the chlorides by absorption of the citrate eluates on H^+-form Dowex 50W × 2 cation exchange resin and elution with HCl.) Methyl resonances in both the ^{13}C and ^1H nmr spectra (δ ^{13}C 19.95, 20.44; δ ^1H 1.09, 1.12; D_2O solutions) of the material in the second band indicated the presence of at least two isomers of the product. Overlap with cyclohexane methylene resonances rendered integration of the signals in the ^1H spectrum imprecise but the species giving the higher field resonance appeared to be ~3 times as abundant as the other. Analysis (unrecrystallised chloride): *Anal.* Calc. for $C_{15}H_{36}Cl_3CoN_6O_4 \cdot 2.5H_2O$: C, 35.27; H, 8.09; N, 16.45. Found: C, 35.4; H, 7.8; N, 16.3%. On adding $NaClO_4$ to an aqueous solution of the mixture and allowing slow evaporation at ambient temperature, crystals (0.65 g) of the major species, shown by a structure determination to be Δ-*cis*-β-[Co(**1**)(*R,R*-chxn)]$Cl_2(ClO_4)$, were obtained.

2.1.2. *[Co(**1**)(ala)]$^{2+}$ diastereomers*

One mole per liter NaOH was added carefully to a solution of *trans*-[Co(**1**)Cl_2]ClO_4 (2.0 g) and *R*-alanine (= L-alanine = alaH) (0.5 g) in water (50 mL) until a pH ~ 9 was attained. The resulting red solution was heated at 60 °C for 10 h, then cooled and acidified to pH 2 with 1 mol L^{-1} HCl. Chromatography (SP-Sephadex C-25/0.13 mol L^{-1} sodium citrate) separated four red species, the complexes present being recovered as chlorides via Dowex 50W × 2/HCl treatment and evaporation of the effluents. The first-eluted material proved to be simply hydrolysed starting material. Readily identified alanine methine and methyl, and **1** methyl resonances in the ^1H NMR spectra, as well as methyl and carboxyl carbon resonances in the ^{13}C spectra, indicated that all three of the other fractions were mixtures of at least 3 species in each case. Fractional crystallisation of the second band residue as the chloride led to isolation of one species (^1H δ (azetidine CH_3) 1.01, (alanine CH_3) 1.36, 1.38; ^{13}C δ (methyl) 18.42, 20.75, (carboxyl) 184.7), though the crystals obtained were not suitable for a structure determination. Addition of $[NH_4][PF_6]$ to concentrated solutions of the third and fourth band residues, followed by slow evaporation at room temperature led also to precipitation of single species (Third fraction: ^1H δ (azetidine CH_3) 1.05, (alanine CH_3) 1.38, 1.40; ^{13}C δ (methyl) 18.32, 20.64, (carboxyl) 185.1; Fourth fraction: δ (azetidine CH_3) 0.96, (alanine CH_3) 1.33, 1.35; δ (methyl) 18.00, 20.19, (carboxyl) 185.0). In these two instances, the crystals did prove to be suitable for structural studies, on the basis of which their compositions were established as Λ-*cis*-β_1-[Co(**1**)(*R*-ala)]$(PF_6)_2 \cdot H_2O$ and Λ-*cis*-β_2-[Co(**1**)(*R*-ala)] $(PF_6)_2 \cdot H_2O$, respectively.

2.1.3. *[Co(**3**)Cl]Cl[PF_6] · H_2O, obtained via the Cu complex, [Cu(**2**)]Cl_2*

Aqueous formaldehyde (37%, 10 g), nitroethane (2.4 g) and triethylamine (4.5 g) were added to a solution of [Cu(**1**)$(OClO_3)$]ClO_4 (5.4 g) in methanol (200 mL). The mixture was heated at reflux for 24 h, then cooled, diluted to ~1 L with water and acidified to pH 6 by the addition of acetic acid. SP Sephadex/0.3 mol L^{-1} NaCl chromatography showed the presence of a single red component, the eluate for which was collected and taken to dryness under vacuum. The complex was freed of the bulk of associated NaCl by extraction into methanol and the crude [Cu(**2**)]Cl_2 (6.8 g) obtained by evaporating this extract to dryness was used directly in the following step. Thus, Zn powder (8 g) was added to a solution of [Cu(**2**)]Cl_2 (4.5 g) in water (200 mL). Under vigorous stirring, aqueous HCl (6 mol L^{-1}, 100 mL) was added dropwise to this mixture. Stirring was continued for 2 h after the discharge of the red colour was complete. The protonated ligand present (3.0 g) was

recovered via Dowex 50W × 2/HCl chromatography and evaporation of the eluate to dryness. It was redissolved in water (200 mL) and the solution neutralised by the addition of NaOH (1.2 g) before $CoCl_2 \cdot 6H_2O$ (1.6 g) was dissolved in. After aeration for 12 h, the mixture was subjected to Dowex 50W × 2/HCl chromatography to separate three red components, the first eluted proving to be unreacted Co(II), the second containing the bulk (1.24 g) of the product and the third being a very minor (0.07 g) constituent and presumed to be either the species with the pendent amino group uncoordinated or the complex with CH_3 and NH_2 groups exchanged about their attached quaternary centre [15]. Addition of $[NH_4][PF_6]$ to an aqueous solution of the bulk component provided crystals of [Co(**3**)Cl]Cl-$[PF_6] \cdot H_2O$ suitable for a structure determination.

2.2. Crystallography

The data for the four compounds were collected at 100(2) K on a Nonius Kappa-CCD area detector diffractometer [16] using graphite-monochromated Mo Kα radiation (λ 0.71073 Å). The crystals were introduced in glass capillaries with a protecting "Paratone-N" oil (Hampton Research) coating. The unit cell parameters were determined from 10 frames, then refined on all data. A 180° φ-range was scanned with 2° steps during data collection, with a crystal-to-detector distance fixed to 28 mm. The data were processed with DENZO-SMN [17]. The structures were solved by direct methods with SHELXS-97 and subsequent Fourier-difference synthesis and refined by full-matrix least-squares on F^2 with SHELXL-97 [18]. Absorption effects were corrected empirically with the program DELABS from PLATON [19]. The oxygen atoms of the perchlorate ion in Δ-*cis*-β-[Co(**1**)(*R*,*R*-chxn)]$Cl_2(ClO_4)$ are disordered over two sets of positions which have been refined with occupancy parameters constrained to sum to unity and some restraints on bond lengths and displacement parameters. The C8–C9 bond length in Λ-*cis*-β_1-[Co(**1**)(*R*-ala)]$(PF_6)_2 \cdot H_2O$ had also to be restrained to its ideal value. All non-hydrogen atoms were refined with anisotropic displacement parameters, except the disordered perchlorate oxygen atoms. The hydrogen atoms bound to nitrogen and oxygen atoms were found on Fourier-difference maps (except in the first structure, for which their position was calculated) and all the other hydrogen atoms were introduced at calculated positions; all were treated as riding atoms with a displacement parameter equal to 1.2 (NH, NH_2, OH, CH, CH_2) or 1.5 (CH_3) times that of the parent atom. The first three compounds crystallize in chiral space groups, but only for the last two did the Flack parameter [20] enable the correct enantiomer to be

identified. Crystal data and structure refinement parameters are given in Table 1 and selected bond lengths and angles in Table 2. The molecular plots were drawn with ORTEP3/PovRay [21]. All calculations were performed on a Silicon Graphics R5000 workstation.

3. Results and discussion

Although the present work was undertaken with the objective of exploring the possibility of using ring opening reactions of a coordinated azetidine in synthesis, it soon became apparent that, even under quite forcing reaction conditions, the azetidine ring of **1** remained intact. For none of the various reaction product fractions presently isolated by ion exchange chromatography did the ^{1}H NMR spectra show evidence of loss of the rather distinctive [9–13] azetidine methylene proton resonances in the δ 3.2–4.0 region (nor loss of ring methylene ^{13}C resonances near δ 57 [13].). Thus, what is defined herein concerns the basic coordination properties of **1**. The ligand is in fact a quadridentate amine of uncommon form in that the azetidine unit not only renders the two 1,2-diamine arms inequivalent but restricts their capacity to chelate a metal ion centre. The complete lack of symmetry in complexes of **1** means simple NMR spectroscopy is of limited use in establishing their stereochemistry and is the reason for the focus in the present work on the use of crystal structure determinations.

When **1** is forced by the presence of a bidentate co-ligand to occupy four non-coplanar sites about an octahedral metal ion such as Co(III), there would appear to be fewer isomeric possibilities than for the "parent" 232-tet ligand, as illustrated for the so-called *cis*-β configuration [5,22] (Fig. 1). Indeed, if the known structures of [Co(**1**)Cl$_2$]ClO$_4$ and Δ-*cis*-β-[Co(**1**)en]Cl$_3$[10] (en = ethane-1,2-diamine) are indicative of the necessity for the azetidine-N to be coplanar with its two adjacent *N*-donors, the *cis*-α form may not be possible and only enantiomers possible for the *trans* form. In the case of en as a chelating co-ligand, the ring it forms may adopt chiral conformations but diastereomers associated with the presence of its two enantiomeric forms within a chiral complex are not usually physically separable, except by chance crystallisation in the solid, because of the very rapid conformational interconversion. This is not so when 1*R*,2*R*-*trans*-cyclohexane-1,2-diamine is the chelate, since chelation is only possible for the diequatorial disposition of the amino groups and this fixes the chelate ring conformation as λ [5,23]. By coincidence, in the particular crystal of Δ-*cis*-β[Co(**1**)en]Cl$_3$ chosen for study earlier [10], the en chelate adopts the λ conformation, as does the five-membered chelate ring involving the azetidine-N, while that involving the 'angular' N is δ.

The cation present in the crystalline lattice of Δ-*cis*-β-[Co(**1**)(*R*,*R*-chxn)]Cl$_2$(ClO$_4$) is shown in Fig. 2. The metal atom is hexa-coordinated, the environment being distorted octahedral (Table 2), in an array of *cis*-β configuration and of Δ chirality. In detail, there are very

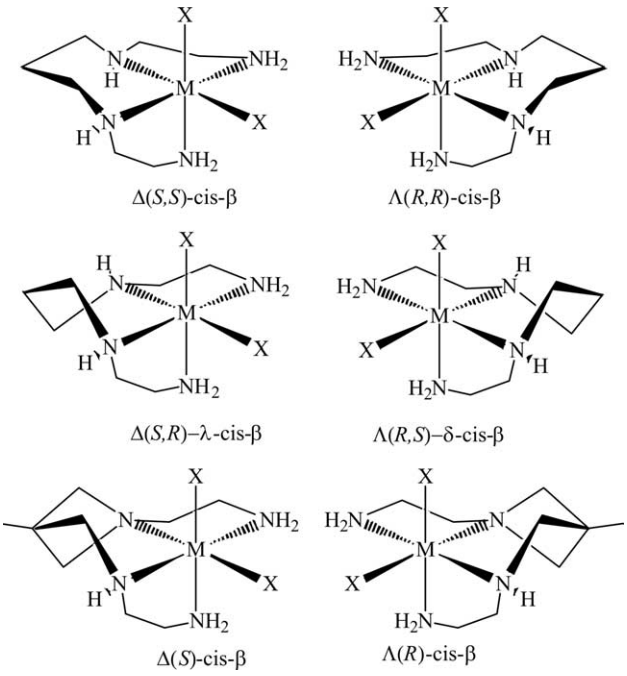

Fig. 1. Binding of a quadridentate amine to an octahedral metal ion – comparison of *cis*-β forms possible for 1,9-diamino-4,7-diazanonane (“232tet”) and **1**, assuming the azetidine-N of the latter cannot occupy an angular site.

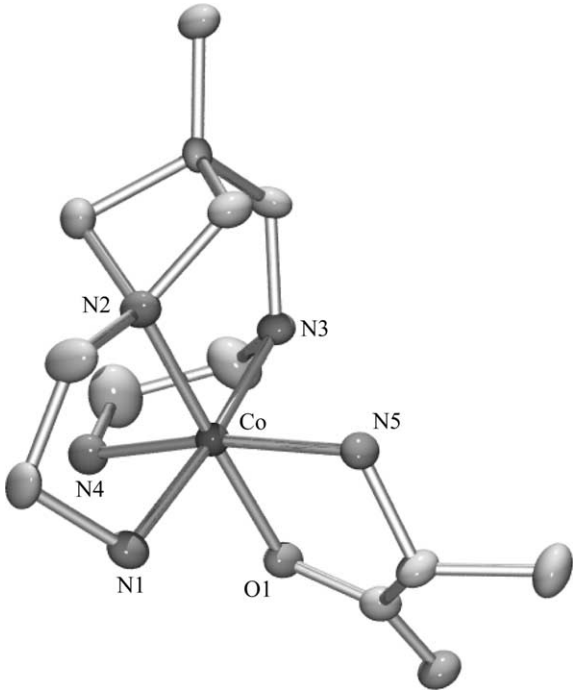

Fig. 3. View of Λ-*cis*-β_1-[Co(**1**)(*R*-ala)]$^{2+}$. Displacement ellipsoids are drawn at the 40% probability level.

close similarities with the structure of Δ-*cis*-β-[Co(**1**)en]$^{3+}$, since not only does the chxn ring match the λ conformation of the en ring but the five-membered ring involving the azetidine-N again is of λ conformation and that involving the ‘angular’ N is δ. The Flack parameter [0.15(4)] seems to indicate racemic twinning, but, since the value is not much larger than three times the error, the result cannot be considered as clear-cut [24]. We presume that the other complex present in the reaction mixture is the Λ-*cis*-β-species and that thus

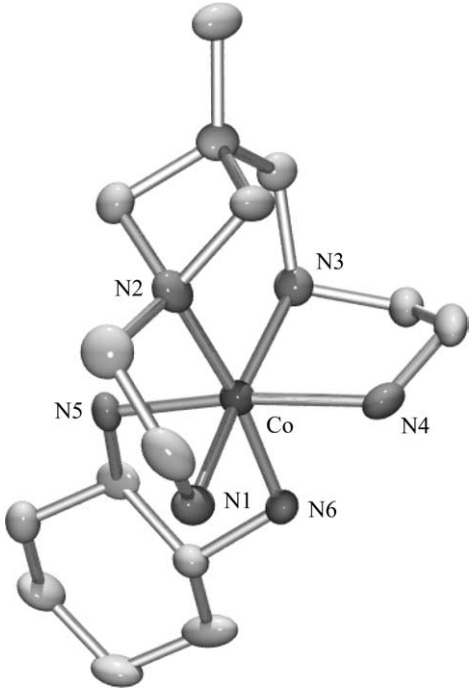

Fig. 2. View of Δ-*cis*-β-[Co(**1**)(*R*,*R*-chxn)]$^{3+}$. Displacement ellipsoids are drawn at the 40% probability level.

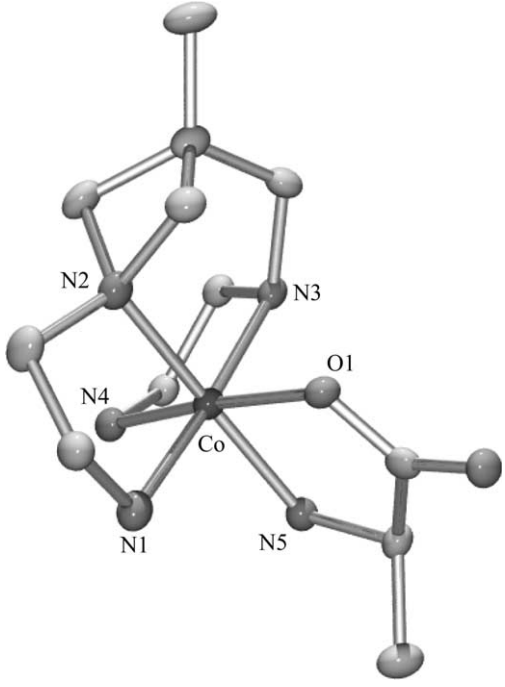

Fig. 4. View of Λ-*cis*-β_2-[Co(**1**)(*R*-ala)]$^{2+}$. Displacement ellipsoids are drawn at the 50% probability level.

there is only a very slight selectivity, be it kinetic or thermodynamic, for *R*,*R*-chxn between the enantiomeric forms of the Co(**1**) unit. Consistent with this, the circular dichroism of the total eluate material is quite weak, with $\Delta\varepsilon_{max} + 0.68\ M^{-1}\ cm^{-1}$ at 463 nm.

The lattice of Δ-*cis*-β-[Co(**1**)(*R*,*R*-chxn)]$Cl_2(ClO_4)$ can be regarded as composed of alternating layers of (cations + chlorides) and perchlorates, the layers lying parallel to the *ab* plane. Cl···HN bonding links cations within layers, while O_3ClO···HN bonding links cations between layers. The packing of the cations is such that the projecting, lipophilic cyclohexano substituents alternate in orientation so as to be rather remote from one another. This arrangement does, however, bring cyclohexano carbon atoms moderately close (3.9–4.0 Å) to both methyl and ethylene carbon atoms of **1**, so that lipophilicity may be of some importance in determining the form of the lattice.

The cations present in the crystal arrays of the two structurally characterised isomers of [Co(**1**)(*R*-ala)]-$(PF_6)_2 \cdot H_2O$ (*R*-ala = *R*-alanine = L-alanine) are shown in Figs. 3 and 4. Both compounds crystallize (with one

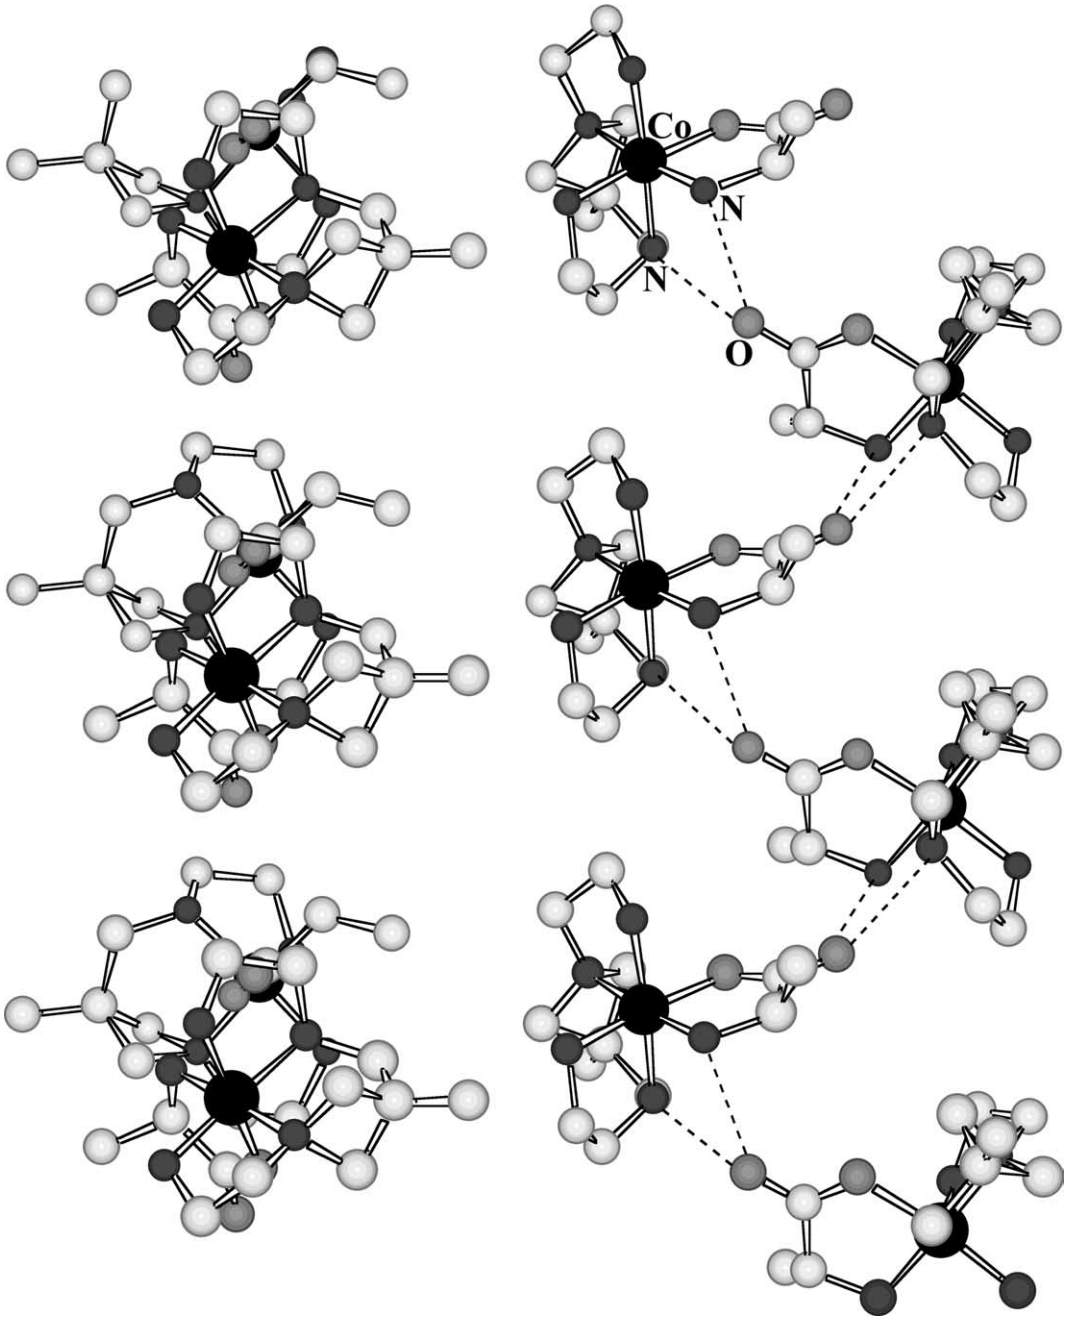

Fig. 5. Simplified view of portions of two adjacent helical arrays of the cations in Λ-*cis*-β_2-[Co(**1**)(*R*-ala)]$(PF_6)_2 \cdot H_2O$, with H-bonding interactions indicated (dashed lines) in one.

water molecule) in the orthorhombic space group $P2_12_12_1$, but with unrelated cell parameters. The variation in cell volume, about 1%, is, however, extremely small. The metal atom in both is in a distorted octahedral N_5O environment, the ligand **1** being quadridentate with the secondary nitrogen donor occupying the "angular" site in the Λ-*cis*-β configuration [22]. Apart from subtle differences in the geometry of ligand **1**, the two cationic species differ only in the position of the alanine chelate unit, with N5 in the crystals isolated from the third fraction, or O1 in those from the fourth, being *trans* to N4, i.e., the β_1 isomer is present in the third and the β_2 in the fourth. As a consequence of this difference in configuration, the intermolecular hydrogen bonding pattern is different in the two compounds, with N1 and N4 acting as donors towards O2 (in a neighbouring complex) and N1 and N5 towards the water oxygen atom in Λ-*cis*-β_1-[Co(**1**)(*R*-ala)]$(PF_6)_2 \cdot H_2O$, whereas, in Λ-*cis*-β_2-[Co(**1**)(*R*-ala)]$(PF_6)_2 \cdot H_2O$, N3 and N5 are bound to O2 (in another complex) and N4 and N5 are bound to the water molecule. In both species, fluorine atoms of the hexafluorophosphate units appear to be involved in H-bonding to both complex-NH and water entities. The NH-bond chelation of uncoordinated carboxylate-*O* (O2) in both cases, again, leads to the formation of polymeric, right-handed helical arrays of the cations. In Λ-*cis*-β_1-[Co(**1**)(*R*-ala)]$(PF_6)_2 \cdot H_2O$, double columns of cations which make up these helices lie in ruffled sheets parallel to the *ab* plane, in such a way that the methyl groups of **1** come into quite close contact (C···C 3.64 Å) with a methylene carbon (the non-azetidine C bound to the quaternary centre) of another ligand **1** in an adjacent helix. In Λ-*cis*-β_2-[Co(**1**)-(*R*-ala)]$(PF_6)_2 \cdot H_2O$, the situation is more complicated in that otherwise identical H-bonded helices can be considered to form an array in planes down *a* and parallel to the *bc* diagonal in which adjacent helices are rotated by 90° about the helix axis relative to one another (Fig. 5). If there are significant contacts to the methyl groups of ligands **1**, these appear to involve fluorine atoms of the anions (C···F 3.29 Å). Presumably by chance, these two complexes contain *R*-alanine and are of the Λ configuration, since the conditions of synthesis, initially hoped to be sufficiently harsh to result in azetidine ring opening, were certainly such as to render possible the racemisation of coordinated alanine [25] and the rather large number of isomeric species detected spectroscopically in the product mixture seems explicable only if both *R*- and *S*-alanine, as well as both configurations around Co(III), were present.

The cation in [Co(**3**)Cl]Cl[PF_6] $\cdot H_2O$ is represented in Fig. 6. The asymmetric unit contains two nearly identical independent molecules, denoted A and B, their form confirming that the expected macrocycle formation and nitro-group reduction reactions [4,12,23] had occurred in the synthesis. The primary amino group and the chlorine atom are in *trans* positions, the overall geometry being distorted octahedral. As is commonly the case with such reactions [4,23], it appears that one product isomer of the ligand is predominant. The Co(III) cation is asymmetric and both enantiomers occur in the lattice, though effectively in centrosymmetric pairs which are bridged by H-bonding either to chloride ions or to water/$[PF_6]^-$ units, explaining the subtly different forms A and B. Differences in geometry between the azetidine rings in A and B are as great as the full range of variation in these rings in all other known complexes of **1** [10,15], suggesting that any differences in reactivity resulting from coordination in different modes to Co(III) or to Cu(II) would be slight.

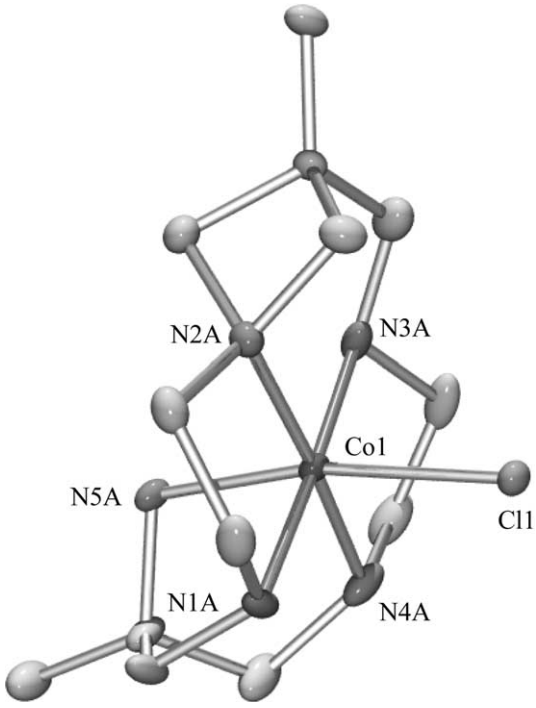

Fig. 6. View of one of the $[Co(\mathbf{3})Cl]^{2+}$ moieties. Displacement ellipsoids are drawn at the 20% probability level.

4. Conclusions

The results of the present and earlier [10,12,13,23] investigations suggest that coordination of an azetidine may in fact be a useful way of protecting it against ring-opening reactions. Thus, while it is of some interest to note that **1** may be stereochemically restrictive in its coordination as a quadridentate ligand, it is of greater interest that it may be efficiently converted to a macrocycle **3** via a familiar template process [5]. Removal of **3** from the metal (as shown presently) should enable free ligand reactions with a variety of nucleophiles to be performed, providing a range of pendent-arm macrocycles through ring-opening processes.

5. Supplementary information

Crystallographic data, in CIF format, have been deposited with the CCDC, deposition numbers 262992–262995. These data may be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033 or e-mail: deposit@ccdc.cam.ac.uk or on the web www: http://www.ccdc.cam.ac.uk.

their derivatives have aroused considerable interest because of interesting structure and reactivity [9–17], catalytic properties [7–9,18–20], antibacterial and antitumor activity [21–27].

2. Experimental

2.1. Materials

$[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$ was prepared according to the literature procedure [25]. ATP (disodium salt) was purchased from Aldrich.

2.2. NMR Spectroscopy

The ^1H, ^{13}C, ^{31}P and ^1H–^{15}N HMBC spectra were recorded on Bruker AMX 300 and Avance 500 spectrometers in D_2O phosphate buffers.

^1H NMR of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$ (D_2O, $c = 4.70 \times 10^{-3}$ M): 8.42 ppm (d; 2H; $^3J_{2,3} = {}^3J_{8,9} = 5.17$ Hz) – **H 2,9**; 8.19 ppm (d; 2H; $^3J_{3,4} = {}^3J_{7,8} = 8.40$ Hz) – **H 4,7**; 7.63 ppm (s; 2H) – **H 5,6**; 7.53 ppm (dd; 2H; $^3J_{3,4} = {}^3J_{7,8} = 8.40$ Hz; $^3J_{2,3} = {}^3J_{8,9} = 5.17$ Hz) – **H 3,8** (for abbreviations of phen protons see Fig. 1). Increase of complex concentration to $c = 2.24 \times 10^{-2}$ M (approximately 5 times) causes only very small change of chemical shifts (about 0.01 ppm).

^1H–^{15}N two-bond HMBC experiments were performed on a Bruker Avance 500 spectrometer using the standard 4-pulse HMBC sequence with the evolution time of 50 ms and 128 t_1 increments. The number of scans was 35 for pure ATP and 100 for ATP–Rh complex systems. The interpulse delay was 2 s, during which the water resonance was suppressed by low-power irradiation.

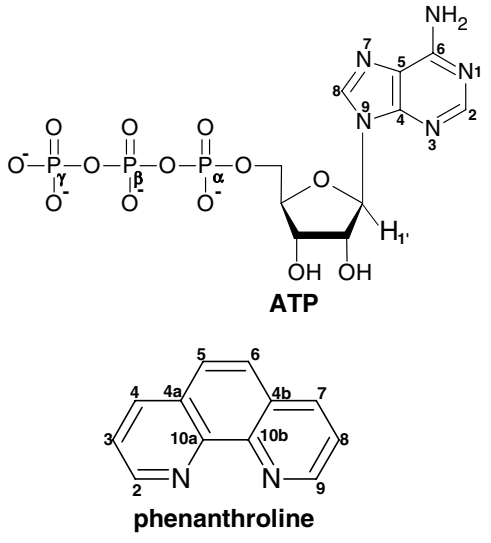

Fig. 1. Abbreviations of carbon, proton, phosphorus and nitrogen atoms in ATP and phenanthroline.

UV–Vis spectra were measured on Beckman DU 7500 spectrometer. The spectra have been recorded in the concentration range $5 \times 10^{-3} - 5 \times 10^{-4}$ M. Difference electronic spectra (Fig. 5) were obtained by subtracting the spectrum of $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ and the spectrum of ATP from the spectrum of the binary system Rh complex/ATP, measured in the same conditions.

The stability constants were determined for D_2O solutions containing $NaNO_3$ ($I = 0.1$ M, 25 °C), to keep ionic strength constant. The pD values were obtaining by adding 0.40 to the pH meter reading [34].

2.3. X-ray crystallographic study

Measurements were performed in low temperature using an Oxford Cryosystem device on Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo Kα radiation. Crystals were positioned at 65 mm from the CCD camera. Six hundred and twelve frames were measured at 0.75° intervals with a counting time of 20 s. Accurate cell parameters were determined and refined by least-squares fit of 3750 strong reflections. The data were corrected for Lorentz and polarization effects. Analytical absorption corrections were applied. Data reduction and analysis were carried out with the Oxford Diffraction (Poland) Sp. z.o.o (formerly Kuma Diffraction (Poland) programs. Structures were solved by heavy atom methods (program SHELXS97 [35]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL97 [36] programs. Nonhydrogen atoms were refined with anisotropic displacement parameters; hydrogen atoms were included from geometry of molecules and $\Delta\rho$ maps. They were fixed during refinement.

3. Results and discussion

3.1. ^1H NMR Spectroscopy

It is well established that stacking interaction of nucleotides with some metal complexes generates the upfield shifts of the ^1H NMR signals of the nucleobase protons due to ring current effects of some heteroaromatic ligands (e.g., bpy or phen) [28,29] which, indeed serve as a clear indication for stack formation.

^1H NMR spectrum of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$ in D_2O exhibits four signals in aromatic region (see Section 2). This indicates clearly that the corresponding pairs of protons H2,9, H4,7, H5,6 and H3,8 are both chemically and magnetically equivalent, and that protons abbreviated as H5,6 are referred to the A_2 part of the spectrum.

The ^1H NMR spectra for 4.70×10^{-3} and 2.24×10^{-2} M solutions of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$ in D_2O

show that the positions of all phenanthroline protons are not concentration dependent.

In the presence of ATP substantial changes are observed:

(a) all phenanthroline protons become magnetically nonequivalent after adding ATP and undergo upfield shifts for all ATP to $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ ratios used in experiments;
(b) the observed upfield shifts are concentration dependent, but different phenanthroline protons undergo different shifts. It is important to note, that for all chemically equivalent pairs of protons (H5,6, H4,7, H3,8, H2,9) one proton undergoes larger upfield shift than its chemically equivalent counterpart (Fig. 3). In the case of H5(6) concentration dependent upfield shifts are the largest;
(c) chemical shifts of ATP protons (H8 and H2) are also dependent on concentration and, as for phenanthroline protons, the increase in concentration of ATP (at the same ligand:complex ratio), causes the upfield shift of these protons (Fig. 2);
(d) chemical shifts of both phenanthroline and ATP protons depends on temperature. The increase of temperature causes the downfield shifts of all protons in aromatic region (Fig. 4);

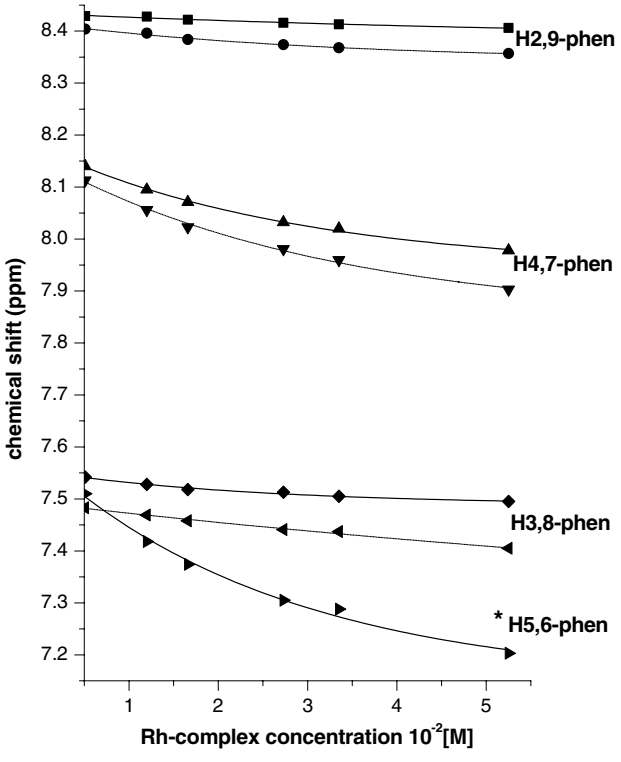

Fig. 3. Concentration dependence of chemical shifts for phenanthroline protons, of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$ in the presence of ATP, showing that phenanthroline protons became magnetically nonequivalent. *For protons H5,6 (A_2 pattern of spectrum), average chemical shifts are given. (The same solution as for Fig. 2, $T = 298$ K.)

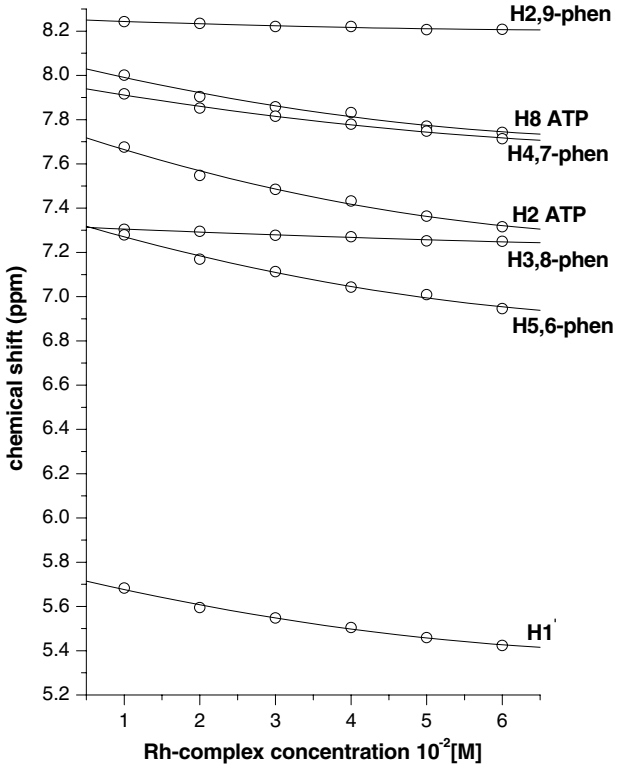

Fig. 2. Concentration dependence of chemical shifts for ATP and phenanthroline protons, of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$ in the presence of ATP. The spectra were made in buffered D_2O solution at pD 3.35, $T = 283$ K, and ATP:complex = 2:1 (average values of magnetically nonequivalent phenanthroline proton chemical shifts are given).

(e) after NMR measurements, both components (rhodium complex and ATP) can be separated easily. ATP is precipitated with methanol, and after evaporation of the solution the pure rhodium complex is recovered. This has been checked by NMR.

3.2. ^1H–^{15}N NMR HMBC experiments

The well resolved HMBC spectra have been obtained at high concentration of ATP and complex (3.33×10^{-1} M). However at lower concentrations not all nitrogen resonances appear in the spectrum of both ATP and ATP/$[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ mixture (ATP:$[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ = 1:1, pD 3.35 and concentration of both components equal to 5.25×10^{-2} M). Based on the literature data [30–32], assignment of the four ATP signals (for free ATP) is rather straightforward: N1, −155 ppm; N3, −165 ppm; N7, −149 ppm; and N9, −212 ppm ($c = 5.25 \times 10^{-2}$ M and pD 8.55). At $c = 5.25 \times 10^{-2}$ M and pD 3.35, the nitrogen chemical shifts are as follows: N1, −221 ppm; N3, −159 ppm; N7, – not observed; N9, −204 ppm; If the concentration is higher all nitrogen resonances are observed: N1, −224

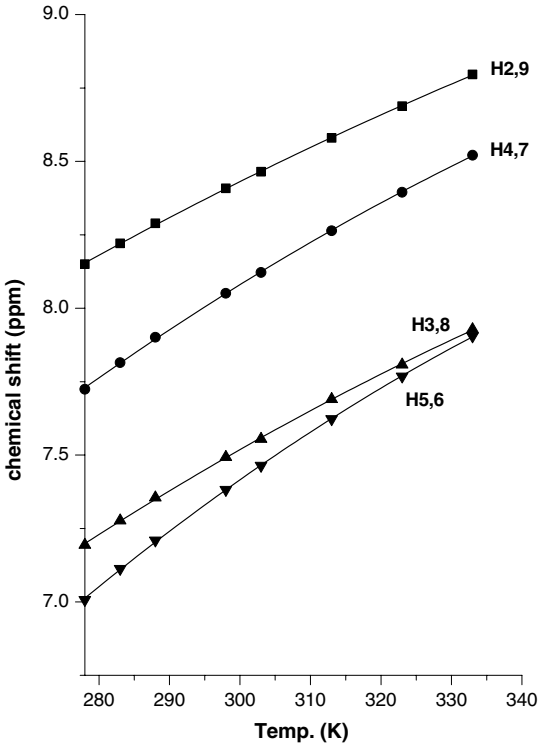

Fig. 4. The example of temperature dependence of chemical shifts of phenanthroline protons. On the plot average values for chemically equivalent protons are given. ATP:complex = 2:1, [compl.] = 2.71×10^{-2} M.

ppm; N3, −161 ppm; N7, −148 ppm; N9, −206 ppm ($c = 3.33 \times 10^{-1}$ M and pD 3.35) (Table 1).

From the above data it can be seen that N1 is very sensitive to pD change ($\Delta\delta$ = 66–68 ppm), while other nitrogens undergo only relatively small changes ($\Delta\delta$ = 1–6 ppm) when pD is changed. The data for the spectra at pD 3.35 at very different concentrations show that the influence of concentration is relatively low (2–3 ppm upfield for the $c = 3.33 \times 10^{-1}$ M as compared with $c = 5.25 \times 10^{-2}$ M) (Table 1).

The value of the pD induced chemical shift change equal 66–68 ppm is in agreement with the well known fact that N1 is the most basic nitrogen in ATP, and therefore this nitrogen atom is protonated in acidic solution. Binding of H^+ makes N1 more shielded, in accordance with the observation by Markowski [30], and up-field shift for protonation is observed.

In the presence of $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ relatively small changes in nitrogen atom chemical shifts of ATP are observed (Table 1). The only substantial change is observed for N1 proton of ATP at pD 3.35. The N1 nitrogen atom which is protonated in the absence of $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$, undergoes large downfield shift (53–62 ppm) in the presence of rhodium complex. The values of its chemical shift −162 and −168 ppm, (Table 1) strongly suggests that deprotonation of the N1 atom occurs after interaction with $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$. To confirm this information the stability constants of the stacking adducts in three different pH were calculated. In contrast to the numerous literature data the resulted values of log pK are practically the same: 1.27, 1.23, 1.27 at pH 3.40, 5.87 and 7.96, respectively.

When an excess of ATP is added to the solution containing rhodium complex the chemical shift of N1 increases and reaches value of −204 ppm, at pD 3.35

[a] Signals are not observed because of low concentrations of ATP.

(ATP:complex = 5:1) (Table 1). This is an average value between the free protonated ATP (−224 ppm) and chemical shift of −168 ppm, in solution where stacking interactions between ATP and complex are observed (ATP:complex = 1:1).

The lack of protonation at pD 3.35 in the presence of rhodium complex may be explained by the formation of hydrogen bonds between N1 atom and the water molecule coordinated to rhodium in axial coordination site. We have found that addition of $NaNO_3$ (to obtain ionic strength of 0.1 M) causes decrease of solubility of rhodium dimer, which finally leads to the crystallization of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](NO_3)_2$. The crystals growth depends on ATP concentration. At higher concentrations of ATP the crystallization process is slower, because of stacking adducts formation in solution. However the resulted crystals do not contain ATP molecule. Crystal structure of the resulted dimer shows the presence of water molecules in axial positions, which is well documented in the literature.

3.3. ^{31}P NMR Spectroscopy

Chemical shifts of phosphorous atoms of ATP undergo only very small changes in the presence of rhodium complex (both for pD 8.45 as well as 3.35). When the terminal γ-phosphate group of ATP participates in complex formation, the chemical shifts for γ-phosporous atom are order of several ppm (see e.g., figures in [33]). The largest difference in the chemical shift after adding of $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ is only 0.3 ppm (for the P_α in acid solution pD 3.35) (Table 2). Phosphorous resonances of ATP were found to be pD dependent in accordance with earlier observations [31]. However no significant variations are observed in the presence of $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$.

3.4. ^{13}C NMR Spectroscopy

Chemical shifts for carbon atoms in free ATP, as well as those of pure rhodium complex are only slightly changed when both compounds are mixed together (at 1:1 and 1:2 ATP:Rh complex molar ratios). The changes for ATP carbon atoms are more distinctive (Table 3). Down-field shifts are observed for C2, C4, C6 carbon atoms while C8 signal is up-field shifted.

After adding of ATP to the rhodium complex solution, phenanthroline carbon atoms become chemically nonequivalent, and separate signals with different chemical shifts are observed. The values of the chemical shifts at ATP:complex ratio equal to 1:1 are: C2,9 152.47 ppm (one signal), C3,8 126.46 and 126.35 ppm (0.11 ppm,

[a] $[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$ + ATP.

13.76 Hz), C4,7 138.59 and 138.40 ppm (0.19 ppm, 22.95 Hz), C5,6 127.62 ppm (one signal), C4a,4b 129.27 and 129.22 ppm (0.05 ppm, 5.74 Hz), C10a,10b 145.98 and 145.97 ppm (0.01 ppm, 1.14 Hz) (in parantheses the separations of signals in ppm and Hz are given). The separations between these signals are small: 0.01 – 0.19 ppm (1.14 – 22.95 Hz). When the ATP:compl. ratio = 2:1 the chemical shifts of phenanthroline carbons are as follows: C2,9 152.55 and 152.48 ppm (0.07 ppm, 9.24 Hz), C3,8 126.71 and 126.54 ppm (0.17 ppm, 20.81 Hz), C4,7 138.60 and 138.38 ppm (0.22 ppm, 27.73 Hz), C5,6 127.55 ppm (one signal), C4a,4b 129.21 and 129.11 ppm (0.1 ppm, 11.56 Hz), C10a,10b 145.80 and 145.71 ppm (0.09 ppm, 11.56 Hz), and separations of these peaks are only slightly larger (0.07 – 0.22 ppm) (see also Table 2). In the case of C5,6 and C2,9 only one signal is observed at ATP:compl. = 1:1. When this ratio is 2:1 one signal is observed for C5,6.

3.5. Crystal structure of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](NO_3)_2$

In the presence of $NaNO_3$ (which was added to obtain constant *I*) a crystalline compound appears. The crystallization is more easy in the presence of small amounts of ATP in the system under investigations. At higher concentrations of ATP the crystallization process is much slower. This observation suggests that stacking between ATP and phenanthroline ligands, makes the crystallization more difficult. However no ATP molecules crystallize together with rhodium complex. The crystal structures are shown on Figs. 6 and 7.

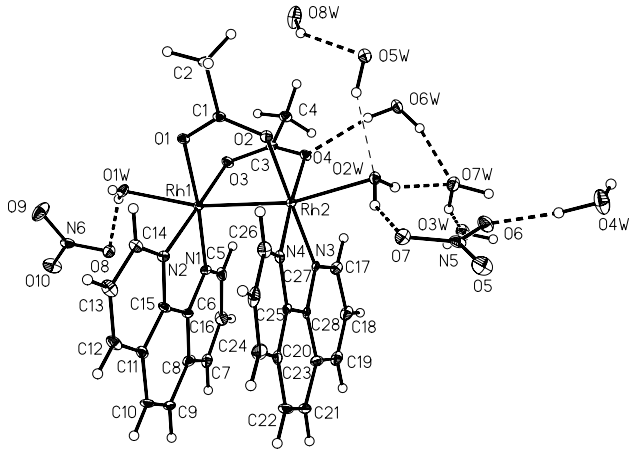

Fig. 6. Structure of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](NO_3)_2$ showing the atom numbering scheme. The atoms are shown as 30% thermal ellipsoids. Selected bond distances (Å): Rh(1)–N(2) 2.003(4), Rh(1)–N(1) 2.021(4), Rh(1)–O(3) 2.037(3), Rh(1)–O(1) 2.052(3), Rh(1)–O(1W) 2.222(3), Rh(1)–Rh(2) 2.5609(3), Rh(2)–N(3) 2.001(3), Rh(2)–N(4) 2.008(4), Rh(2)–O(2) 2.031(3), Rh(2)–O(4) 2.069(3), Rh(2)–O(2W) 2.296(3). Fig. 5. The difference electronic spectra of $[Rh_2(OAc)_2(phen)_2(H_2O)_2](OAc)_2$/ATP binary systems in water at molar ratio ATP:complex = 1:1 – (a) in 0.1 cm quartz cuvette, [compl.] = 5×10^{-4} M, (b) in 1 cm quartz cuvette, [compl.] = 5×10^{-3} M.

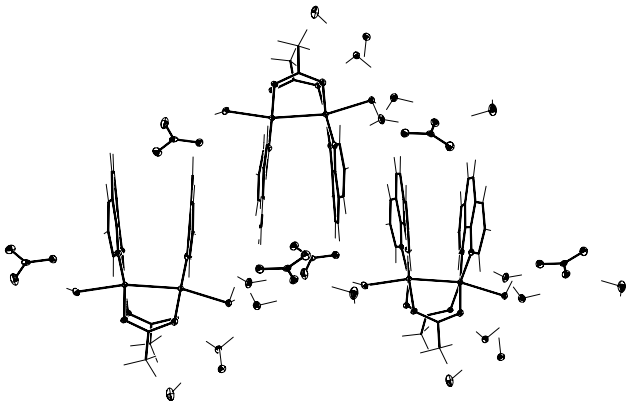

Fig. 7. Crystal structure showing stacking interactions between neighboring dimeric units. The shortest distances between neighboring carbon atoms (from phenanthroline rings) are 3.265–3.371 Å. In solution however no stacking interactions are observed, which was confirmed by NMR.

Fig. 6 shows that the axial positions are occupied by water molecules, which is well known from the literature data of analogous rhodium dimers ([7] and references therein). Difference electronic spectra (Fig. 5) also confirm this observation. This is probably the reason why in the presence of rhodium dimer deprotonation of N1 of the adenine ring takes place as a result of hydrogen bond formation with coordinated water molecule. This also explain why no interaction between rhodium and P_γ is observed in NMR. Fig. 7 shows that in the solid state stacking interactions between neighboring dimeric units occurs. This interaction is not observed in solution.

4. Conclusions

On the basis of above observations it can be concluded:

ATP interacts with $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ by stacking interactions with phenanthroline ligand coordinated with rhodium. This follows especially from the ^1H NMR spectra, which show that in the presence of $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ the ATP proton signals suffer upfield shifts which are ascribable mainly to the ring current effect of coordinated phenanthroline. The largest shift is observed for the H-2 signal. This indicate that this proton is located just above the aromatic rings of the coordinated phenanthroline ligand. The stacking of ATP molecule with coordinated phenanthroline ligand causes magnetic nonequivalence of phenanthroline protons, which also exhibit large upfield shifts. The largest shifts are observed for H5 and H4. This suggests that these protons are located below the six membered pyrimidine aromatic ring of ATP. The chemical shifts of these protons depend on the concentration of compounds and temperature (Figs. 2–4). The H5 and H6 protons, observed in pure rhodium complex at lower fields than H3,8 are shifted towards higher fields in the presence of ATP. As the temperature is increasing the stacking interactions are weaker, which is confirmed by the ^1H NMR spectra. The proton resonances of both phenanthroline and ATP undergo low field shifts when the temperature is increasing (Fig. 4).

The changes of ^{13}C resonances are smaller than in the case of proton resonances. Some signals are shifted towards higher fields and some towards lower fields (Table 3), depending on the relative locations of aromatic rings. However as in the case of proton resonances the phenanthroline carbons became magnetically nonequivalent, and occurs as a doublets (except of C5,6). All carbon atoms in six membered ring of ATP are shifted towards lower fields except of C5 resonance which does not change its position. On the basis of this observations it could be concluded that the largest stacking interactions occur between adenine six membered aromatic ring and phenanthroline rings carbons C4,7 and C5,6 because the protons H5,6 and H4,7 undergo the biggest upfield shift).

In the presence of $[Rh_2(OAc)_2(phen)_2(H_2O)_2]^{2+}$ there are also small changes for nitrogen chemical shifts of ATP apart from the N1 atom at pD 3.35 (Table 1). The signal of this atom observed at −224 ppm for free ATP at pD 3.35 is shifted to −162 ppm for the solution containing ATP and complex at the same acidity. Unexpected is the lack of protonation of N1 nitrogen in the presence of rhodium complex. A reasonable explanation of this is formation of the hydrogen bond N1 and the water molecule coordinated to rhodium in axial position. ^1H NMR Spectra as well as stability constants of the stacking adducts also confirm this observation.

The UV–Vis difference spectra (Fig. 5) as well as ^{13}P (Table 2) spectra suggest additionally that phosphate residue of ATP does not interact with the positively charged $[Rh]^{2+}$ core in axial position. The ^{31}P resonances for P_γ change only of about 0.3 ppm. In the ATP molecule interacting with Zn complexes with phenanthroline- and dipyridine-containing open chain or macrocyclic polyamine ligands analogous shifts for P_γ resonance (downfield) are about 2–3 ppm [32,33].

5. Supplementary material

Crystallographic data (excluding structure factors) for the structure reported in this paper have been deposited with Cambridge Crystallographic Data Centre CCDC No. 264728 Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, fax: +44 1223 336 033, e-mail: deposit@ccdc.cam.ac.uk or on the web http://www.ccdc.cam.ac.uk).

will HAS be formed [5]. To ensure that $Si(OH)_4$ is the reactant it is important that the solution is both below pH 9.0 (pK_a for $Si(OH)_4$ is about 9.6) and undersaturated with respect to the solubility of $Si(OH)_4$ (it will autocondense at $[Si(OH)_4] > 2.0$ mmol/L). When these criteria are met HAS of distinct stoichiometry and structure are formed and can be precipitated from solution [6]. There are only two basic types of HAS and which of these will form is dependent upon the ratio of $Si(OH)_4$ to Al in the parent solution. When Al is in excess HAS_A is formed. This has a Si:Al ratio of 0.5 and is composed of octahedral assemblies of Al atoms linked to Si through, predominantly, $Q_3(3Al)$ linkages. When $Si(OH)_4$ is present to a twofold excess or more HAS_B is formed. This has a Si:Al ratio of 1.0 and is composed of both octahedral and tetrahedral assemblies of Al atoms, in approximately equal amounts, linked to Si through, predominantly, $Q_3(1\text{-}2Al)$ linkages. The formation of HAS_B involves a dehydroxylation reaction which, at room temperature and pressure, appears to be fuelled by the excess of $Si(OH)_4$ in solution. When the concentrations of Al and $Si(OH)_4$ in parent solutions are either equal or favour $Si(OH)_4$ by less than a factor of two both types of HAS are present in the solid phase. The latter observation prompted the suggestion that HAS_B was formed via the competitive condensation of $Si(OH)_4$ across hydroxyl groups on HAS_A and subsequent research has tended to support this notion [6,7].

Both HAS_A and HAS_B appear to have analogues in the natural environment, protoimogolite and protoimogolite allophane, respectively [8], though their formation and persistence in natural waters has not been demonstrated unequivocally. There have been numerous references to the presence of HAS-like phases in natural environments without any direct confirmation that they are analogous to synthetic HAS. It is our contention that HAS similar in nearly all respects to HAS_A and HAS_B are significant secondary mineral phases which when formed in the natural environment are major players in the biogeochemical cycle of Al and in the biological availability of Al in general [9]. We have recently determined a solubility expression for HAS_B [10] which supports such a notion and will help to explain how Al is successfully retained within the lithospheric cycle and excluded from biota. However, if HAS are formed in nature then it is likely that, unlike in the laboratory, their form and persistence will be influenced by other ligands for Al, both organic such as humic and fulvic acids and inorganic such as fluoride and phosphate. We have taken the first steps to understand how the latter, fluoride and phosphate, when present at equimolar concentrations to $Si(OH)_4$, might influence the formation of synthetic HAS.

2. Experimental

2.1. Preparation of parent solutions

All reagents were of the highest purity available. Each of the parent solutions listed in Table 1 was prepared using ultra pure water (conductivity < 0.067 μS/cm, Elga UK) which included 100 mmol/L KNO_3 as a background electrolyte and was buffered at pH 6.0 with 25 mmol/L of piperazine-N,N′-*bis* (2-ethanesulphonic acid) (PIPES). $Si(OH)_4$ solutions, maximum concentra-

tion 2.0 mmol/L, were prepared by cation exchange of Na_4SiO_4 and either diluted as required (0.5 and 1.0 mmol/L) or used in place of pure water (2.0 mmol/L). Al was added from a freshly prepared 1 mol/L stock of $Al(NO_3)_3 \cdot 9H_2O$ in 1% HNO_3 and phosphate (HPO_4^{2-}) and fluoride (F^-) were added as $NaH_2PO_4 \cdot H_2O$ and NaF, respectively. We have used an established method of HAS preparation [2] in which the respective constituents of parent solutions are mixed at ca. pH 3.0 and then titrated to pH 6.0 using NaOH. In this way as soon as Al hydrolysis begins and hydroxy-aluminium templates are formed $Si(OH)_4$ will be available to react with them to give HAS.

To determine when any reaction involving the formation of HAS was complete and, therefore, facilitating thereafter the collection of the solid phase by filtration, pilot experiments were run for each parent solution in which the rate of formation of HAS was determined by measuring the change in $[Si(OH)_4]$ over time. One replicate of each solution was prepared in a 1 L PTFE container (Cowie Technology Ltd., UK) and placed in an incubator at 20.0 ± 0.1 °C. The solution was filtered periodically using syringe filters (Millipore) incorporating 0.1 μm polyvinylidene fluoride membrane filters (Durapore) and $[Si(OH)_4]$ determined as molybdate-reactive Si [11]. When $[Si(OH)_4]$ was observed to plateau (see Fig. 1 for representative examples) the reaction was considered complete and the requisite time period was chosen for the full scale experiments. In these the idea was to use the $[Si(OH)_4]$ at equilibrium with the solid phase to discriminate between the different parent solutions. Thus, if F^- were to influence the formation of HAS this might be evident from the equilibrium $[Si(OH)_4]$. To give this idea the greatest possibility of being effective nine replicates of each parent solution were prepared in 200 mL PTFE containers and placed in an incubator at 20.0 ± 0.1 °C. Following incubation of the solutions for the pre-determined time period (ca. 60 days) the equilibrium $[Si(OH)_4]$ was determined in each of the nine replicates though not following filtration (as in the pilot) but by using equilibrium dialysis. A dialysis chamber of volume 500 μL and MWCO 1000 Da (Spectra/Por® DispoDialyzer®) was immersed in the solution and allowed to equilibrate for 72 h. Previous control experiments had shown that $Si(OH)_4$ equilibrated across the membrane in this time interval and that the equilibrium was not influenced by the presence of 2.0 mmol/L F^- but that the same amount of HPO_4^{2-} resulted in an underestimation of the equilibrium $[Si(OH)_4]$. The latter resulted in filtration and not dialysis being used to determine the equilibrium $[Si(OH)_4]$ in parent solutions which included HPO_4^{2-}. Following equilibrium dialysis and the collection of samples for the determination of dialysable $Si(OH)_4$ and Al the solutions were filtered through 0.1 μm membrane filters (Durapore) and the filtered solutions were analysed for F^- and HPO_4^{2-} (see Table 1) whereas the solid phases were dried to a constant weight at 37 °C and stored in a desiccator for subsequent elemental composition by microprobe and solid state NMR.

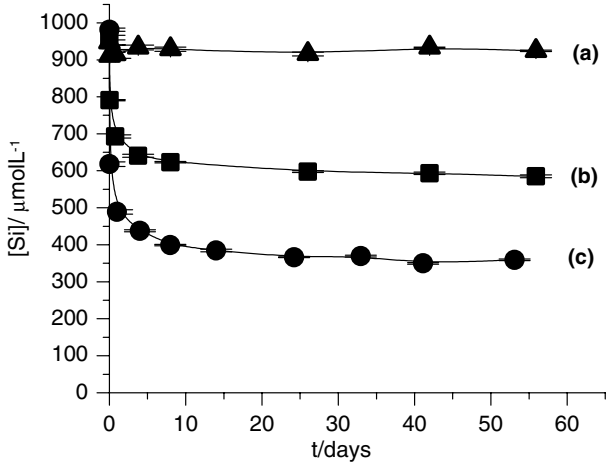

Fig. 1. Change in $[Si(OH)_4]$ during 60 days incubation at 20.0 ± 0.1 °C for: (a) 1 mmol/L $Si(OH)_4$/1 mmol/L Al + 1 mmol/L HPO_4^{2-}; (b) 1 mmol/L $Si(OH)_4$/1 mmol/L Al + 1 mmol/L F^-; and (c) 1 mmol/L $Si(OH)_4$/1 mmol/L Al + no added anion. Mean and SD are plotted, $n = 5$.

2.2. Determination of $Si(OH)_4$, Al, F^- and HPO_4^{2-} in solution

$Si(OH)_4$ was determined spectrophotometrically (λ_{max} 810 nm) as the reduced blue molybdosilicic acid complex [11]. Single use plastic cells of 10 mm pathlength were used. Calibration curves using standards prepared from a certified Si stock solution (1000 mg/L; Perkin–Elmer) were plotted for both semi-micro (1.5 mL) and standard (4.0 mL) cuvettes. Confidence limits (95%) for nine replicates at two different [Si] were: 0.6 mg/L Si – 0.603 ± 0.004 mg/L and 0.2 mg/L Si – 0.194 ± 0.003 mg/L.

Al was determined by graphite furnace atomic absorption spectrometry (GFAAS) using matrix-matched standards and a programme developed by the authors [12].

Total F^- was measured using an ion selective electrode (Sentek, UK) calibrated against standard solutions containing 0.1–100 mg/L F^-. It was measured by the method of standard additions after mixing the sample with total ionic strength adjustment buffer which included 15 g/L *trans*-1,2-diaminocyclohexane-*N*,*N*,*N*′,*N*′-tetraacetic acid monohydrate (CDTA) and 58 g/L NaCl in acetate buffer at pH 5.0.

Total HPO_4^{2-} was measured spectrophotometrically (λ_{max} 880 nm) as the blue heteropoly complex [13].

2.3. Elemental composition of solid phases

Electron microprobe analysis was conducted on a Cameca SX100 electron probe microanalyser. Ground samples were pressed into pellets and the contents of Si, Al, F and P were determined for 20 different 5 μm spots on each pellet. Average atomic percentages were calculated for each sample ($n = 20$, RSD $\leqslant 5\%$ for Al and Si) and normalized to Si = 1 (Table 1).

2.4. Solid state NMR

Solid state magic angle spinning (MAS) NMR was performed on a Varian UNITY Inova spectrometer with a 7.05 T Oxford Instruments magnet. Three probes have been used. The diameters of rotors are: 7.5 mm (Varian; ^{29}Si), 5 mm (Doty Scientific; ^{19}F with proton decoupling) and 4 mm (Varian; ^{27}Al, ^{31}P). Spin rates used were 5 kHz with the 7.5 mm probe, 11.6 kHz for the 5 mm probe and 10–14 kHz for the 4 mm probe. The frequencies for the individual nuclei are: ^{27}Al, 78.1; ^{29}Si, 59.6; ^{19}F, 282.1; ^{31}P, 121.4 MHz. Chemical shifts were referenced to: ^{27}Al, 1 M $AlCl_3$; ^{29}Si, $(CH_3)_4Si$; ^{19}F, $CFCl_3$; ^{31}P, 85% H_3PO_4. All spectra were obtained with direct-polarisation experiments and with 90° excitation pulses except for ^{27}Al where a 20° pulse was used. Recycle delays of 60–120 s were used for the ^{29}Si spectra, 1 s for the ^{19}F, 0.2 s for ^{27}Al and 60 s for ^{31}P.

3. Results

3.1. Influence of fluoride, F^-

Dialysis and membrane filtration were used to discriminate between HAS formed in the absence of F^- and HAS formed in the presence of equimolar F^- and $Si(OH)_4$. For each of the parent solutions the inclusion of F^- significantly increased dialysable $[Si(OH)_4]$ and [Al] whereas $[F^-]$ following filtration were reduced. For example, for parent solutions which included (in mmol/L) 1.0Si/2.0Al ± 1.0F dialysable $[Si(OH)_4]$ and [Al] were, respectively, 73 and < 1 μmol/L in the absence of F^- and 141 and 66 μmol/L in the presence of F^- whereas the $[F^-]$ following filtration had fallen from 1.0 mmol/L to 404 μmol/L (Table 1). Precipitates were collected by filtration from each combination of Al, $Si(OH)_4$ ± F^- except where the stoichiometry of the parent solution was 2.0Si/0.5Al/2.0F where no filterable precipitate was formed. Chemical composition using electron microprobe analysis confirmed the presence of F^- in solid phases (Table 1) and suggested the formation of HAS_A (Si:Al ca. 0.5) and HAS_B (Si:Al ca. 1.0) for parent solutions in which $[Al] \geqslant [Si(OH)_4]$ and $[Al] < [Si(OH)_4]$, respectively [6]. Solid phase Si:Al ratios which were significantly lower than 0.5, for example the parent solution of stoichiometry 0.5Si/2.0Al 0.5F, suggested that precipitates were composed of both HAS_A- and $Al(OH)_{3(s)}$-like phases. Solid state NMR (^{27}Al, ^{29}Si, ^{19}F) of precipitates (Figs. 2–4) identified the formation of $Al(OH)_{3(s)}$ (^{27}Al δ_{max} 0–10 ppm), HAS_A (^{27}Al δ_{max} 0–3.4 ppm and ^{29}Si δ_{max} ca. −78 ppm) and HAS_B (^{27}Al δ_{max} 0–3.4 ppm + ca. 55 ppm and ^{29}Si δ_{max} ca. −90 ppm) [6,14] and the incorporation of F^- (^{19}F δ_{max} −150 and −131 ppm) into solid phases [15] (Table 2).

3.2. Influence of phosphate, HPO_4^{2-}

The concentrations of filtered $Si(OH)_4$ were extremely high in solutions containing equimolar $Si(OH)_4$ and HPO_4^{2-} and, in all but one of the parent solutions

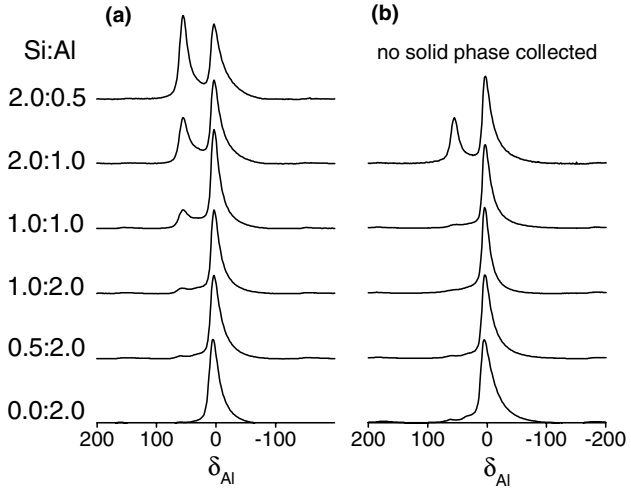

Fig. 2. ^{27}Al MAS NMR spectra of solid phases prepared in the absence (a) and presence (b) of F^-. Si:Al – indicates the concentrations of $Si(OH)_4$ and Al in parent solutions. For (b) $[F^-] = [Si(OH)_4]$ except, if $[Si(OH)_4] = 0$, then $[F^-] = 0.5$ mmol/L.

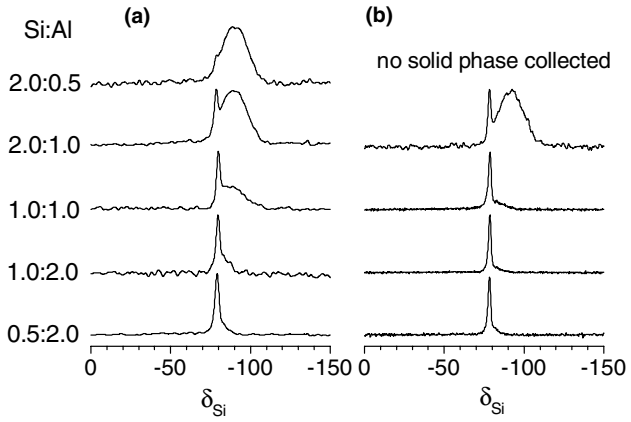

Fig. 3. ^{29}Si MAS NMR spectra of solid phases prepared in the absence (a) and presence (b) of F^-. Si:Al – indicates the concentrations of $Si(OH)_4$ and Al in parent solutions. For (b) $[F^-] = [Si(OH)_4]$.

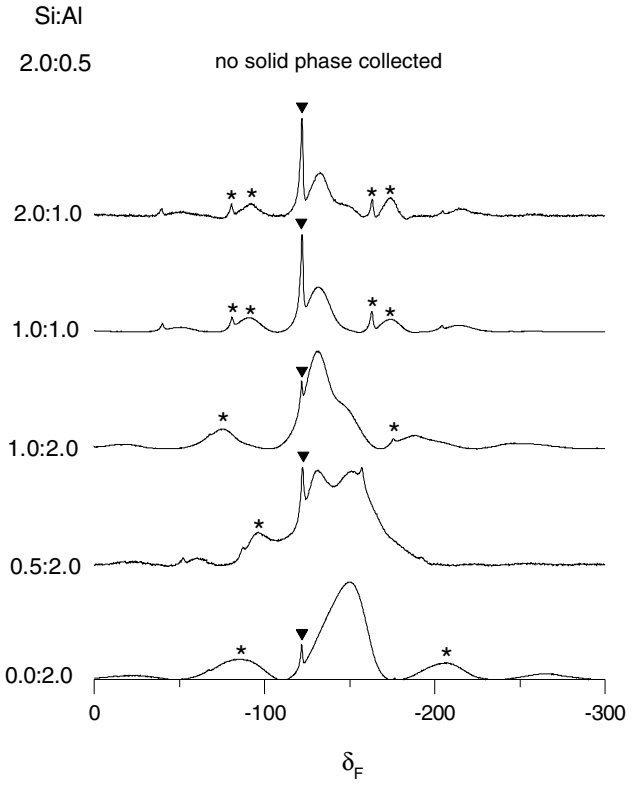

Fig. 4. ^{19}F MAS NMR spectra of solid phases prepared in the presence of F^-. Si:Al – indicates the concentrations of $Si(OH)_4$ and Al in parent solutions. $[F^-] = [Si(OH)_4]$ except, if $[Si(OH)_4] = 0$, then $[F^-] = 0.5$ mmol/L. Asterisks mark positions of sidebands and inverted triangles mark the position of chemical shift corresponding to contaminating PTFE.

(0.5Si/2.0Al/0.5P), showed that very little $Si(OH)_4$ was precipitated in solid phases (Table 1). All Al was precipitated from each of the parent solutions whereas the concentrations of soluble HPO_4^{2-} in equilibrium with solid phases loosely reflected the Al:P ratio of parent solutions. Chemical composition of precipitates using electron microprobe analysis confirmed the results of the solution studies and suggested that Al was precipitated as hydroxyaluminium phosphate from each of the parent solutions (Table 1). Si was only found as a significant component of the solid phase (Si:P ca. 0.5) when the concentration of Al in the parent solution exceeded the combined concentration of $Si(OH)_4$ and HPO_4^{2-} (2.0Si/0.5Al/2.0P). Solid state NMR (^{27}Al, ^{29}Si, ^{31}P) of this precipitate confirmed the formation of an hydroxyaluminium phosphate (^{27}Al δ_{max} 0.4 ppm; ^{31}P δ_{max} −10.6 ppm) and the probable 'contamination' of this phase with a small amount of HAS_A (^{29}Si δ_{max} −78.6 ppm) (Table 2).

4. Discussion

Dialysis demonstrated that HAS formed in the presence of equimolar F^- and $Si(OH)_4$ were in equilibrium with significantly higher concentrations of dialysable $Si(OH)_4$ and Al. The high concentrations of dialysable Al were most probably due to the formation of soluble complexes of aluminium fluoride and, possibly, hydroxyaluminium fluorides [16]. The assumption must be that whilst these complexes remain in solution there will be no opportunity for $Si(OH)_4$ to condense across hydroxyl groups on adjacent Al atoms to form HAS. As such the concomitant higher concentrations of dialysable $Si(OH)_4$ were probably indicative of F^- limiting the availability of hydroxyaluminium templates for the subsequent formation of HAS. The propensity for F^- to react with Al to form soluble complexes and so prevent the formation of HAS was best exemplified in the parent solution which included (in mmol/L) 2.0Si/0.5Al/2.0F in which approximately 50% of the original Al was dialysable and, consequently, no solid phase could be separated following filtration (Table 1). However, this was the only stoichiometry which appeared to prevent the formation of HAS and in each of the other parent solutions the evidence pointed towards the incorporation of F^-

Table 2
Assignments and abundances of ^{27}Al, ^{29}Si, ^{19}F and ^{31}P MAS NMR chemical shifts for each solid phase

Stoichiometry of parent solution (mmol/L)				$\delta^{27}Al$		$\delta^{29}Si$		$\delta^{19}F$		$\delta^{31}P$

into the solid phase and more particularly into HAS. To understand how F^- influenced HAS formation it is informative to compare solid phases formed for each parent solution stoichiometry in the absence and presence of fluoride.

(i) *0.5Si/2.0Al ± 0.5F* – In the absence of F^- the solid phase was predicted to be a mixture of HAS_A and $Al(OH)_{3(s)}$ and this was borne out by a Si:Al ratio of 0.27 in the solid phase. Further confirmation of the presence of HAS_A was that all Al was present in octahedral geometry (^{27}Al δ_{max} 2.5 ppm) and Si was present in equal mixture of $Q_3(3Al)$ (^{29}Si δ_{max} −79.1 ppm) and $Q_3(2Al)$ (^{29}Si δ_{max} −81.1 ppm). In the presence of F^- the Si:Al ratio of the solid phase was 0.25 which again suggested a mixed phase. Interestingly, the ratios of Si:F and Al:F in the solid phase were ca. 2.0 and 8.5, respectively, and these may prove to be helpful in identifying the location of F in the solid phases. Again all Al was in octahedral geometry (^{27}Al δ_{max} 2.7 ppm) and the presence of HAS_A was confirmed by Si NMR, though this time the proportion of $Q_3(3Al)$ (^{29}Si δ_{max} −78.2 ppm) was very much higher than $Q_3(2Al)$ (^{29}Si δ_{max} −82.1 ppm). ^{19}F NMR gave δ_{max} at −151.1 ppm, which, based upon the chemical shift (^{19}F δ_{max} −150.1 ppm) we obtained for a pure precipitate of aluminium hydroxyfluoride, was probably indicative of F associated with $Al(OH)_{3(s)}$, and −131.6 ppm which we believe showed F associated with HAS_A.

(ii) *1.0Si/2.0Al ± 1.0F* – In the absence of F^- the solid phase was predicted to be primarily HAS_A and this was supported by a Si:Al ratio of 0.43 and characteristic chemical shifts for both ^{27}Al NMR (δ_{max} 2.5 ppm) and ^{29}Si NMR (δ_{max} −79.6 and −82.3 ppm). In the presence of F^- the Si:Al ratio of the solid phase was 0.41 which was indicative of HAS_A and the Si:F and Al:F ratios were ca 2.0 and 5.5, respectively. The lower ratio of Al to F in this phase was probably indicative of a higher $[F^-]$ to [Al] in the parent solution whereas this effect was limited by a significant reduction in the proportion of aluminium hydroxyfluoride in the mixed phase as was suggested by the almost complete disappearance of the ^{19}F NMR chemical shift at ca. −150 ppm. Solid state ^{27}Al, ^{29}Si and ^{19}F NMR showed that this precipitate was almost identical to that isolated from the previous parent solution (0.5Si/2.0Al/0.5F) except that the majority of F was now associated with HAS_A (^{19}F NMR δ_{max} −131.1 ppm).

(iii) *1.0Si/1.0Al ± 1.0F* – In the absence of F^- the solid phase was predicted to be HAS_A with perhaps some HAS_B and the latter was borne out by a Si:Al ratio of 0.63. Again the presence of a proportion of HAS_B was supported by both ^{27}Al NMR, which indicated a small amount of Al in tetrahedral geometry (^{27}Al NMR δ_{max} 53.8), and ^{29}Si NMR which showed that Si was now coordinated through both $Q_3(3Al)$ and $Q_3(1\text{-}2Al)$ linkages [6]. The presence of F^- appeared to reverse the trend towards the formation of HAS_B such that structural (NMR) and compositional (microprobe) analyses of the solid phase showed that it was approximately identical to that precipitated from the previous parent solution (1.0Si/2.0Al/1.0F).

Thus in spite of quite obvious differences in the solid phases formed in the absence of added F^- the structure and composition of HAS formed in its presence were approximately identical, probably an HAS_A-like structure which included F in a single chemical environment (^{19}F NMR δ_{max} ca. −131 ppm) at a Si:F ratio of ca. 2–3 and Al:F ratio of ca. 5–6.

(iv) *2.0Si/1.0Al ± 1.0F* – In the absence of F^- the solid phase was predicted to be predominantly HAS_B and some HAS_A. The Si:Al ratio of the solid phase, ca. 0.94, confirmed the presence of the former and this was supported further by solid state ^{27} Al and ^{29}Si NMR which showed that Al was present in both octahedral (δ_{max} 2.5 ppm) and tetrahedral (δ_{max} 55.0 ppm) geometries and that Si was coordinated primarily through $Q_3(1\text{-}2Al)$ linkages (δ_{max} −90.3 ppm). Microprobe and NMR characterisation of the solid phase which formed in the presence of F^- showed that in respect of both Al and Si it was identical to that formed in the absence of F^-. This was unusual in that for previous parent solutions the additional presence of F^- had always resulted in structural changes manifested as increases in the proportion of $Q_3(3Al)$ linkages relative to $Q_3(1\text{-}2Al)$. No such changes occurred when F was incorporated into the predominantly HAS_B-like phase precipitated from this parent solution. However, the ^{19}F NMR chemical shift at δ_{max} −132.8 ppm was similar to those obtained for substitution of F^- into HAS_A-like structures (−131.6, −131.1 and −131.9 ppm) and this may indicate that F was present in a similar chemical environment in both HAS structures. The solid phase was different from the F-containing HAS_A -like solid phases in that the ratio's of Si:F (ca. 4) and Al:F (ca. 4) showed an increase in Si and a decrease in Al relative to F when compared with HAS_A-F. These apparently contradictory changes in the content of F in the solid phase relative to both Si and Al may actually be informative in respect of the mechanism of formation of HAS_B via HAS_A For example, it was assumed that the solid phase which formed in the absence of F^- was a mixture of HAS_B and HAS_A and this was supported by NMR. However, the Si:Al ratio of this 'mixed' phase was very close to 1.0 and this may indicate that the predominant forms of HAS were actually HAS_B (ca. 60% of the total) and an intermediate form HAS_{AB} (ca. 40% of the total) in which the further incorporation of $Si(OH)_4$ has not yet triggered the dehydroxylation reaction which would result in 50% of its constituent Al switching from an octahedral to a tetrahedral geometry (Fig. 5). It is our understanding to date that the rate at which dehydroxylation takes place is highly dependent upon the $[Si(OH)_4]$ which is free to

exchange with the solid phase. In the presence of F^- the Si:Al ratio of the mixed solid phase was very close to 1.0 whilst the NMR again suggested that Al was predominantly present in octahedral coordination. In addition, the presence of F^- in the parent solution did not influence the coordination of Si in the solid phase. In each of the previous parent solutions the presence of F^- promoted the coordination of Si through Q_3(3Al) as opposed to Q_3(1-2Al) linkages. Considering that this was the first parent solution in which $[F^-] > [Al]$ it is conceivable that a higher proportion of Al–OH will be replaced by Al–F in the solid phase and this would explain the observed increase in the ratio of F to Al. The reason why the F to Si ratio was concomitantly reduced could be that the HAS_B structure only has one potential binding site for F and this is associated with octahedrally coordinated Al in this structure whilst HAS_{AB}, which only includes octahedral Al, retains two potential binding sites for F. In this way, considering the relative proportions of HAS_B and HAS_{AB} in the solid phase, it was possible for the ratio of F to Si to be reduced and the ratio of F to Al to be increased relative to solid phases which were formed from parent solutions in which $[Al] \geqslant [F^-]$, the predominant precipitate would be HAS_A and the lower $[F^-]$ would dictate that Al–OH groups on this phase would only be partially substituted for Al–F.

(v) *2.0Si/0.5Al ± 2.0F* – In the absence of F^- a solid phase was precipitated with a Si:Al ratio of 1.1 and NMR chemical shifts which demonstrated that it was composed of at least 80% HAS_B. We would contend that the remainder was HAS_{AB} and that the higher proportion of tetrahedrally coordinated Al in this mixed phase was the result of an accelerated dehydroxylation reaction which was fuelled by a high concentration of free to exchange $Si(OH)_4$ (ca. 850 μmol/L as compared to ca. 600 μmol/L for the 2.0Si + 1.0Al parent solution). In the presence of F^- we were not able to collect any solid phase and this may have been due to the fourfold excess of F^- preventing the formation of hydroxyaluminium templates required for HAS formation or possibly the substitution of F into preformed HAS_B such that it prevented the aggregation of the solid phase towards a filterable size.

To try to identify the location of F in our HAS we have carried out F–Si CP NMR and we obtained the same spectrum as for DP NMR. The most likely explanation for this is that F was not specifically associated with Si and that the ^{19}F NMR chemical shift in the range −131 to −133 ppm was due to Al–F with Al being linked to Si through varying combinations of Q_3(1-3Al). We obtained further support for this possibility by carrying out F–Al CP NMR which strongly suggested that, not only was F coordinated through Al but that it was only associated with octahedral Al. The association of F with Al and not with Si was again supported by the observation that concomitant with an increase in the Si:Al ratio of the solid phase was an increase in the Si:F ratio and the propensity for F in the solid phase to promote the characteristic HAS_A (^{29}Si NMR δ_{max} −78 ppm) structure. Thus F^- may be competitive with $Si(OH)_4$ in inhibiting/promoting the formation of HAS_B via the putative intermediate HAS_{AB}. This competitive edge to F^- was lost when the rapid formation of HAS_B (via HAS_{AB}) was favoured (i.e., where the $[Si(OH)_4]$ of the parent solution was at least double that of the [Al]) and under these conditions the substitution of F for OH would be limited by the $Si(OH)_4$-directed dehydroxylation reaction in which up to 50% of octahedrally coordinated Al rearranges to give tetrahedrally coordinated Al in the solid phase. The probable role of F^- in the formation of HAS is summarised in the scheme in Table 3. It predicts the formation of a number of different solid phases which though unlikely to be

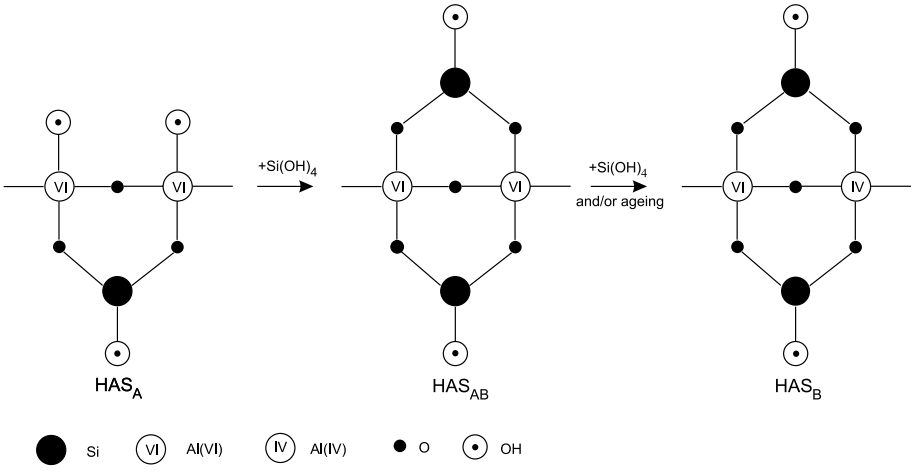

Fig. 5. Suggested scheme for the formation of HAS_B from HAS_A involving a transitional form, HAS_{AB}, which undergoes a dehydroxylation fuelled by either ageing or a significant excess of $Si(OH)_4$.

Table 3
Summary of the suggested role of fluoride in the formation of fluoride-substituted hydroxyaluminosilicates

Conditions	Reactants		Solid phase	Elemental ratio
$[F^-] < [Al]$ $[Si(OH)_4] = 0$	$Al^{3+}_{(aq)} + F^-_{(aq)}$	$\xrightarrow{OH^- \rightarrow pH\ 6.0}$	$Al_4(OH)_{12-x}F_x$	Al:F < 2.0
$[F^-] < [Al]$ $[Si(OH)_4] \leqslant [Al]$	$Al^{3+}_{(aq)} + F^-_{(aq)} + Si(OH)_4$	$\xrightarrow{OH^- \rightarrow pH\ 6.0}$	$(HAS_A)_4F$	Al:F = 8.0 Al:Si = 0.5 Si:F = 4.0
$[F^-] > [Al]$ $[Si(OH)_4] > [Al]$	$Al^{3+}_{(aq)} + F^-_{(aq)} + Si(OH)_4$	$\xrightarrow{OH^- \rightarrow pH\ 6.0}$	$(HAS_{AB})_4F_2$[a]	Al:F = 4.0 Al:Si = 1.0 Si:F = 4.0
$[F^-] < [Al]$ $[Si(OH)_4] > [Al]$	$Al^{3+}_{(aq)} + F^-_{(aq)} + Si(OH)_4$	$\xrightarrow{OH^- \rightarrow pH\ 6.0}$	$(HAS_B)_4F$	Al:F = 8.0 Al:Si = 1.0 Si:F = 8.0

[a] In the presence of an excess of $Si(OH)_4$ this phase will undergo a slow dehydroxylation in which up to 50% of the constituent Al adopts tetrahedral geometry and F will be titrated from the solid phase. The resulting phase will be a mixture of $(HAS_{AB})_4F_{2(s)}$ and $(HAS_B)_4F_{(s)}$.

precipitated as single phases are not too dissimilar in elemental composition and structure to those we have identified and characterised herein (Tables 1 and 2).

Further research will be required to understand fully the mechanism of formation of fluorine-substituted HAS whereas under the conditions used in this study HPO_4^{2-}, when equimolar to $Si(OH)_4$, prevented HAS formation in all but one of the parent solutions. When Al was present to a fourfold excess of HPO_4^{2-} (0.5Si/2.0Al/0.5P) the resulting solid phase included primarily aluminium hydroxyphosphate [17] but it also contained a significant component of HAS_A. Phosphate is a bulky ligand in comparison to F^- and its ligation by Al was generally sufficient to promote the precipitation of an hydroxyphosphate and to prevent any reaction of $Si(OH)_4$ across any remaining Al–OH groups. Whether HPO_4^{2-} would be competitive when $Si(OH)_4$ was present to excess remains to be determined.

In the experiments described herein both F^- and HPO_4^{2-} were present at equimolar concentration to $Si(OH)_4$ and, as such, were given maximal opportunity to influence the formation of HAS. The results have identified the formation of fluorine-substituted HAS, which may have some significance to both the biogeochemistry of Al and also to materials science, and the inhibition of the formation of HAS by HPO_4^{2-}. In the natural environment the concentration of $Si(OH)_4$ is likely to be significantly in excess of both F^- and HPO_4^{2-} and further experiments using more environmentally realistic concentrations of these ligands will be needed to confirm that fluorine-substituted HAS could form in soil and surface waters and similarly that HPO_4^{2-} might prevent or influence HAS formation.

Acknowledgements

This research was funded by NERC. D.C. Apperley is thanked for all his help with the solid state NMR which were obtained through the EPSRC solid state NMR service at Durham. D. Plant is thanked for electron microprobe analyses which were obtained through the NERC-supported Electron Microprobe Facility at Manchester.

those observed in the humic substances. Previous studies have shown that polyphenols and notably flavonoids are non-negligible components of organic matter [2–5]. For this reason, we have considered the flavonoids' family, belonging to the polyphenolic compounds, which are molecules that occur ubiquitously in plant kingdom. The flavonoids are characterized by a common structure, in C6–C3–C6, in which two benzene rings are connected by a carbonaceous chain C3, different according to nature from the compounds. Thus, the family of flavonoids is subdivided in various groups among which one can quote: flavones and derived, anthocyanes, chalcones, aurones, etc. [6–8]. The basic skeleton common to the elements of the flavones group is constituted of two benzene rings A and B connected to each other by an oxygenated heterocycle: the γ-pyrone ring (C ring). The simplest compound of the group is the flavone (Fig. 1).

These omnipresent molecules in the natural environment are found partially in the beginning of the organic matter of the soil and thus constitute perfect model molecules for the study and the comparison of the different metal complexation sites. The complexes composition obtained from these compounds with a large number of metal ions are reported in the literature [9–18], but so far no information was published concerning the chelation of lead (II). The main chelating sites involving in these compounds are the catechol, α-hydroxy-carbonyl and β-hydroxy-carbonyl functions.

In this work, we report the lead (II) complexation study with three ligands presenting only one binding site: 3-hydroxyflavone (3HF), 5-hydroxyflavone (5HF) and 3′,4′-dihydroxyflavone (3′4′diHF) (Table 1). The goals of this study are: (i) to determine the stoichiometric composition and estimate the stability of each complex obtained with these three ligands; (ii) to class the different sites according to their ability to form chelate with lead (II) in order to obtain complementary information concerning the potential chelating sites of Pb(II) in humic substances; and (iii) to compare the results with those obtained in ours previous studies concerning the chelation of Al(III) [19–23].

Quercetin	Q	OH	OH	OH	OH	OH

2. Experimental

2.1. Reagents and methods

Flavonoids (F) were purchased from Extrasynthese (France). Anhydrous lead chloride was used without purification. Because of the very low solubility of flavonoids in water, spectroscopic-grade methanol was used.

The molar ratio method has allowed us to determine the complexes composition in solution from spectrophotometric spectra. For this method, solutions containing a constant concentration (4×10^{-5} M) of F in methanol and variable concentration of $PbCl_2$ (from 4×10^{-7} to 4×10^{-2} M) were prepared. The complexes stoichiometry has also been verified by the method of continuous variation (Job's method).

2.2. Instrumentation

The UV–Vis spectra were recorded on a Cary-l (Varian) spectrophotometer with cells of 1 cm path length, at room temperature. A flow cell was used to allow successive additions of small amounts of lead (II) chloride directly in the flavonoid solution.

2.3. Calculations

The formation constants of the complexes were estimated by using a multivariate data analysis program for modelling and fitting equilibrium titration 3D data sets obtained from the spectrophotometric measurements. The UV–Vis spectra were refined using the Specfit software (version 3.0.32). The set of spectra obtained at variable Pb(II) concentration were treated by evolving factor analysis (EFA) method in order to determine the number of absorbing species in the system and the pure electronic spectrum of each complex [24]. The Specfit software [25] has also been used to estimate the stability constants (β). In order to obtain the best fit between the complexation model and the experimental data, several models of complexes with different stoichiometries have been envisaged for the refinement of the stability constants.

2.4. Methodology

The same methodology which was applied for the study of the complexation of the three ligands is as follows:

(i) The study by UV–Vis spectroscopy of the lead complexation with a ligand (F) in methanol by varying the $[PbCl_2]/[F]$ molar ratio, gives us a set of spectra. The stoichiometry of the formed complexes is determined by the molar ratio method. The curve representing the variation of the absorbance according to the ratio $R = [Pb(II)]/[F]$ at absorption maxima of the complex and the free molecule is representative of the complex composition [26].

(ii) The Job's method was used to validate the molar ratio method. In the Job's method, for a constant volume, one mixes in different proportions equimolar solutions of ligand and lead (II). The sum of the concentrations remains constant, while the molar fraction of the ligand varies. The results obtained from this method provide us one second set of spectra. Here, the stoichiometry corresponds to the change of slope of the variation curve representative to the molar fraction of ligand x_F or the Job's function $[A(\lambda_{max})_{complexed\ solution} - A(\lambda_{max})_F]$ [27].

(iii) From electronic spectra obtained by varying the molar ratio R, the determination of the spectroscopically distinct species is obtained by an experimental data processing by using the EFA method. The result of this calculation allows us to find the pure absorption spectrum of the molecule alone and the complexes. In order to determine the stability constants (β) of successively formed complexes, a numerical processing was carried out on a simple model containing Pb(II) metal, the ligand and the complexes. The stability constant estimation comes from the following reaction equation:

$$a\ Pb + b\ F \Longleftrightarrow Pb_aF_b$$

with the corresponding stability constant

$$\beta_F = \frac{[Pb_aF_b]}{[Pb]^a[F]^b}.$$

Whatever the site implied in the complexation process, a deprotonation of hydroxyl groups occurs in order to allow the coordination to Pb(II). However, this deprotonation has not been taking into account in the constant calculation insofar as the pH notion has no much sense in methanoic medium.

(iv) From these constants and extracted spectra, we simulate a theoretical spectroscopic assay and compare this one with the experimental spectra, so as to validate the initial model. Moreover, if several species are formed, the curves of the concentrations evolution can show if the complexes are formed simultaneously or successively.

3. Results and discussion

3.1. Chelation of lead (II) with hydroxyflavones

Typically, the electronic spectra of flavonoids are characterized by two strong absorption bands: the band I in the long wavelength (320–380 nm) and the band II (240–270 nm) [28].

3-Hydroxyflavone. Fig. 2 illustrates the evolution of the UV–Vis spectra of the 3HF–Pb(II) system for different $[Pb^{2+}]/[3HF]$ molar ratios. The intensity of band I, located at 344 nm, of free 3HF decreases with the amount of $PbCl_2$ added, whereas a new band appears at 405 nm. In the same time, the absorbance at 243 nm increases. The presence of an isosbestic point at 365 nm proves the existence of only two absorbing species in equilibrium. The curve of absorbance versus $[Pb^{2+}]/[3HF]$ molar ratio plotted at 344 nm (λ_{max} of free ligand) and 405 nm (λ_{max} of complex) allow us to find a stoichiometry 1:1 for the complex (Fig. 3). The Job's method of continuous variations has confirmed this result (not shown). To estimate the stability constant of the 1:1 complex, a numerical treatment of the electronic spectra has been carried out. The model best fitting the

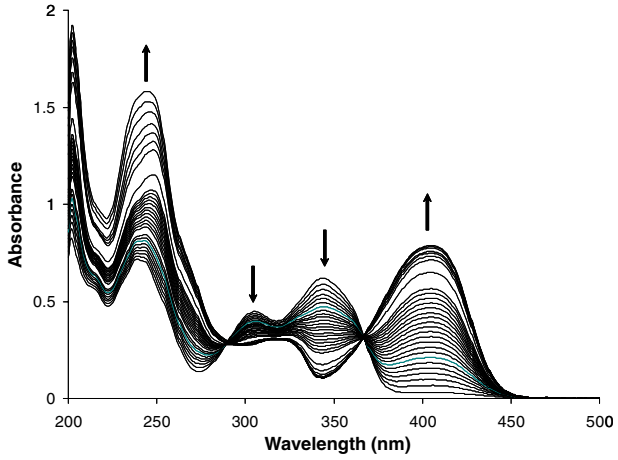

Fig. 2. UV–Vis absorption spectra of 3-hydroxyflavone in methanol in the absence and in the presence of $PbCl_2$. $[Pb^{2+}]/[3HF]$ molar ratios vary from 0 to 3.

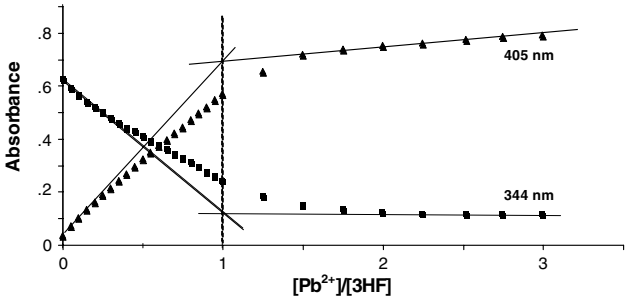

Fig. 3. Absorbance vs. $[PbCl_2]/[3HF]$ molar ratio plots at λ_{max} (3HF) = 344 nm and λ_{max} (complex) = 405 nm.

experimental data gives a stability constant: $\log\beta_{3HF} = 4.97 \pm 4 \times 10^{-6}$. As the chelation of lead occurs at the level of the α-hydroxy-carbonyl group with a complete deprotonation of the hydroxyl group, the formula of the complex is $[(3HF)Pb]^{+}$.

5-Hydroxyflavone. With the addition of lead, the evolution of the electronic spectra of this ligand differs widely from that observed for its homolog the 3HF molecule. The general shape of the free ligand spectrum is not at all modified by the addition of $PbCl_2$, only an increase in the absorbance, more or less important according to the wavelength, is observed (Fig. 4). However, a new band appearing at 241 nm differentiates the spectrum of the complex from that of the free ligand. Both the molar ratio and continuous variations methods give a stoichiometry 1:1 for the complex of 5HF, leading to a chelate $[(5HF)Pb]^{+}$. The treatment of the spectra with Specfit program allows us the determination of the stability constant of this complex: $\log\beta_{5HF} = 4.51 \pm 3 \times 10^{-2}$. So, the comparison of the stability constants indicates that the complex obtained with the 5HF molecule is slightly less stable than the one formed with 3HF.

3′,4′-Dihydroxyflavone. The behaviour of 3′4′diHF in the presence of Pb(II) still differs from that found in the previous compounds. The first spectrum obtained in the absence of Pb(II) is characteristic of the ligand in methanol solution and presents some bands at 343, 306, 244 and 213 nm (Fig. 5). The addition of an increasing quantity of lead chloride to the solution of 3′4′diHF induces a decrease of the intensity of the band at 343 nm relating to the free flavonoid and an appearance of a new band located at 399 nm whose absorbance increases with the quantity of Pb(II) added. The series of spectra does not present a clearly definite isosbestic point, which would tend to mean that several species coexist in solution. The molar ratio plots at 343 and 399 nm (Fig. 6) show inflection at $[Pb^{2+}]/[3'4'diHF] = 0.5$ and 1 (the break at 1 appears clearly on the plot at 399 nm), indicating the formation of two complexes of stoichiometry 1:2 and 1:1. This result is corroborated by the Job's method. From the UV–Vis spectra, the determination of the number of different absorbing species was estimated by the EFA method with the Spectfit software. Three distinct components were found corresponding to the free 3′4′diHF and the two complexed forms $[Pb(3'4'diHF)_2]^{2-}$ and Pb(3′4′diHF). The electronic absorption spectra of these different pure species are presented in Fig. 7. The spectra of the two complexed species are very close, however, an additional intense band located at 237 nm characterizes the Pb(3′4′diHF) form. From these pure species spectra, the stability constants have been estimated and the model which provides the best fit to the experimental data gives: $\log\beta_{3'4'diHF} = 8.82 \pm 0.15$ and $\log\beta_{3'4'diHF} = 5.09 \pm 0.10$ for $[Pb(3'4'diHF)_2]^{2-}$ and Pb(3′4′diHF), respectively. The concentration variations of the free and complexed ligands versus quantity of lead added is illustrated in Fig. 8. The curves show that two complexes are simultaneously formed from the very beginning of the lead addition, however, the Pb(3′4′diHF) species is largely predominant. If the formation of the complex 1:2 is in the minority, it is

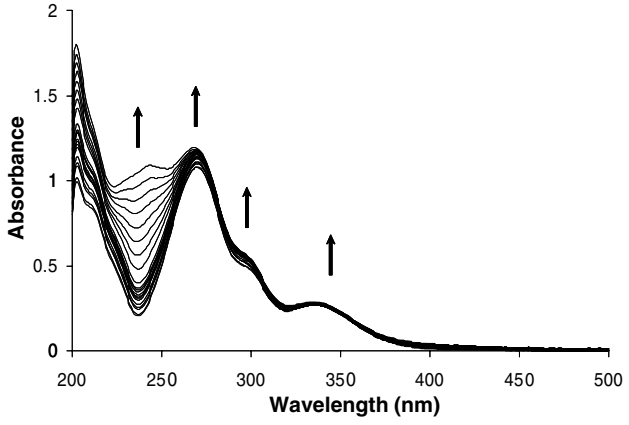

Fig. 4. UV–Vis absorption spectra of 5-hydroxyflavone in methanol in absence and in presence of $PbCl_2$. $[Pb^{2+}]/[5HF]$ molar ratios vary from 0 to 5.

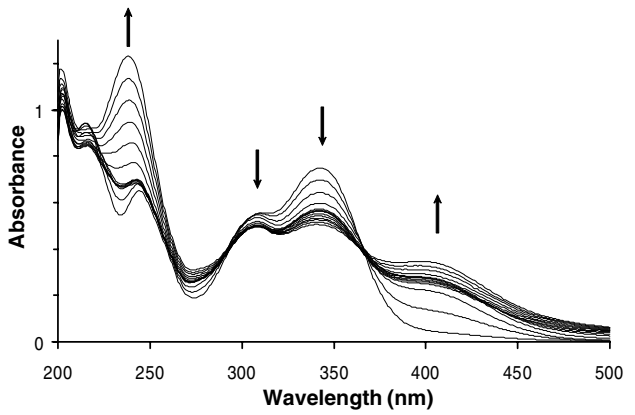

Fig. 5. UV–Vis absorption spectra of 3′,4′-dihydroxyflavone in methanol in absence and in presence of $PbCl_2$. $[Pb^{2+}]/[3'4'diHF]$ molar ratios vary from 0 to 4.

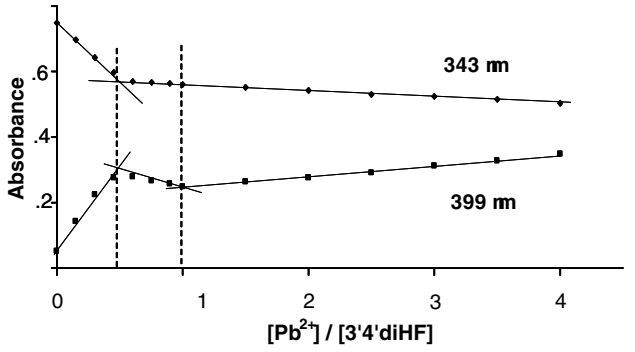

Fig. 6. Absorbance vs. $[PbCl_2]/[3'4'diHF]$ molar ratio plots at λ_{max} (3′4′diHF) = 343 nm and λ_{max} (complex) = 399 nm.

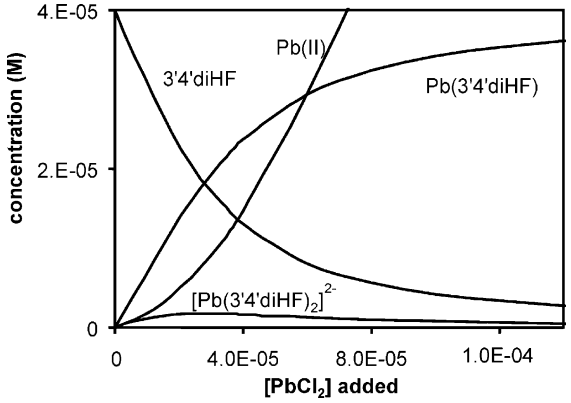

Fig. 8. Distribution curves of the concentration (M) of lead complexes with 3′4′diHF in methanol as a function of $[PbCl_2]$ added.

sufficient to have a significant role in the complexation mechanism of Pb(II) by 3′4′diHF, in particular in the presence of small amounts of lead. The graph also indicates that it remains 32% of free molecules in solution for a molar ratio of 1.

Among the three flavonoids, 3′4′diHF is the only compound which leads to the formation of species of high stoichiometry (1:2) in methanol, and moreover, the stability of its complex 1:1 is higher than those of 3HF and 5HF. These results suggest that the catechol group presents a chelating power with respect to Pb(II) higher than that of other studied functions. Thus, it is possible to classify the three sites of fixation of Pb(II) according to their chelating capacity in the following way: catechol > α-hydroxy-carbonyl > β-hydroxy-carbonyl.

3.2. Comparison of Pb(II)- and Al(III)-hydroxyflavone systems

In a similar way, our preceding works [29] had made it possible to obtain a classification of these three sites with respect to their power of complexation of Al(III), under the same physico-chemical conditions. The comparative results of the two systems are reported in Table 2. It is obviously observed that the behaviour of the three studied sites is very different according to the metal ion implied in the complexation process. With regard to Al(III)-hydroxyflavone systems, it is the α-hydroxy-carbonyl site which presents the greatest affinity for aluminium ion and gives a complex of stoichiometry (metal:ligand) 1:2. The catechol function leads to the formation of a complex 1:1 with Al(III) which has a greater stability than that obtained with the β-hydroxy-carbonyl function. Thus, it is observed that the change of Al(III) by Pb(II) in the system provokes an inversion of the chelating power of the catechol and α-hydroxy-carbonyl sites.

The electronic spectra of the predominant complexes obtained for the three hydroxyflavones with both Al(III) and Pb(II) are presented in Fig. 9. Except for the $[Pb(5HF)]^+$ complex, the electronic spectra of the different complexed species obtained with both Al(III) and Pb(II) exhibit a bathochromic shift of the band I compared to the free molecule spectra. This observation seems to indicate that the complexation mechanism of lead (II) by the β-hydroxy-carbonyl group is very different from that observed with aluminium (III). The hyperchromic effect on the absorption bands of the spectrum of the 5HF solution occurring with the addition of $PbCl_2$ tends to show that low electronic changes at the level of the ligand are generated by complexation. It is interesting to notice that the electronic spectra of the complexes obtained with Al(III) or Pb(II) and the 3HF molecule (which present different stoichiometries but the same charge) are almost similar. That would like to say that the absorption bands of the complexes come from electronic transitions involving only molecular orbitals localized on the ligand, and that no metal–ligand charge transfer is observed.

Table 2
Comparison of the stoichiometry and stability constants of the complexes of hydroxyflavones obtained with Pb(II) and Al(III)

Compounds	λ_{max} (nm)	Pb(II) complexes			Al(III) complexes		
		Pb:L	λ_{max} (nm)	log(β)	Al:L	λ_{max} (nm)	log(β)
3HF	344	1:1	405	4.97	1:2	402	12.3
5HF	270	1:1	268/241	4.51	1:1	397	6.5
3′4′diHF	342	1:2	399	8.82	1:1	384	6.7
		1:1		5.09			

The wavelengths of the band I (in the long wavelength) are given for the free ligand and for all the complexes.

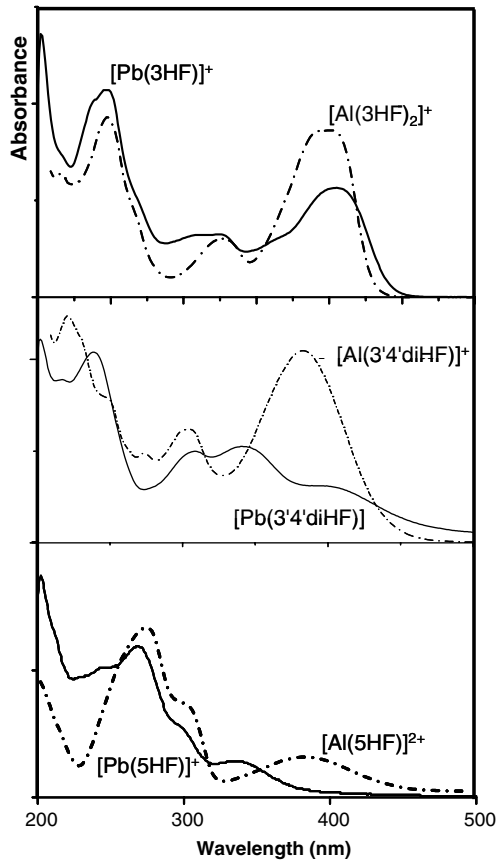

Fig. 9. Comparison of the spectra of the major complexes obtained with Al(III) and lead (II) and hydroxyflavones in methanol.

4. Conclusion

This study made it possible to establish a classification of various chelating sites of humic substances with respect to lead (II) in methanol solution. The interactions between lead (II) and hydroxyflavones had never yet been studied, however, this paper reports the first step of our work. In a second time, we will focus our attention on the complexation mechanism of a molecule presenting simultaneously the functions catechol, α-hydroxy-carbonyl and β-hydroxy-carbonyl: the quercetin molecule (Table 1). That will make it possible to observe if classification obtained with these results remains valid when the three sites are in competition within the same molecule. Moreover, for reasons of solubility this study was carried out in methanol solution. If our preceding studies concerning Al(III) showed that the results obtained in water are comparable with those obtained in methanol, we will study these three molecules in a mixed solvent water–methanol in order to be able to observe the influence of the pH on the capacity of complexation of Pb(II) by these functions.

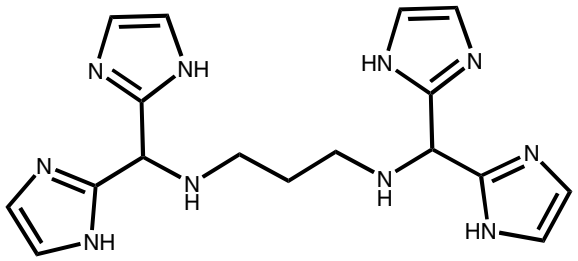

Fig. 1. The molecular structure of the ligand 1,1,7,7-tetrakis(imidazol-2-yl)-2,6 -diazaheptane (H_4L).

field of great interest within the scientific community [6–11].

Since the imidazole is ubiquitous in almost all of the copper proteins, the development of model complexes with imidazole-containing ligands have captured our interest for many years. As a continuation of the study, we present here an investigation of a new copper complex with a potential dinucleating imidazole-containing ligand, 1,1,7,7,-tetrakis(imidazol-2-yl)-2,6-diaza-heptane (H_4L) [12] (see Fig. 1).

Recently, we reported that the reaction of H_4L with $Cu(OAc)_2$ led to an unprecedented imidazolato- and acetato-bridged dodecanuclear complex [12], in which the C–N bonds in the original ligand have been oxidized to C=N bonds upon coordination with copper(II) acetate. However, when $CuCl_2$ is used for the coordination, another interesting 1D tetranuclear-based polymer is formed. In this contribution, the synthesis, crystal structure, spectroscopic and magnetic properties of the copper(II) polymeric compound have been discussed.

2. Results and discussion

The bis(imidazole-2-yl)nitromethane [13] is an interesting intermediate for the synthesis of a variety of new chelating ligands and it can be obtained in five steps by a ring-opening and double ring-closure reaction. Coupling 1,3-diaminopropane with the bis(imidazole-2-yl)-nitromethane intermediate results in the formation of a potential dinucleating ligand H_4L as shown in Fig. 1.

The polynuclear compound of formula $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]Cl_2 \cdot 5H_2O$ was obtained by reaction of one equivalent of the ligand H_4L with three equivalents of copper(II) chloride in acetonitrile. Diethyl ether diffusion into the acetonitrile solution resulted in the formation of blue square crystals suitable for X-ray diffraction analysis. A molecular plot representing one unit of the complex together with the atom-labeling scheme is shown in Fig. 2.

2.1. Description of structure $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]Cl_2 \cdot 5H_2O$

The compound consists of polymeric chains built up by dicationic subunits $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]^{2+}$ containing four metal ions, two nitrogen donor ligands, three coordinated chlorine atoms and two coordinated

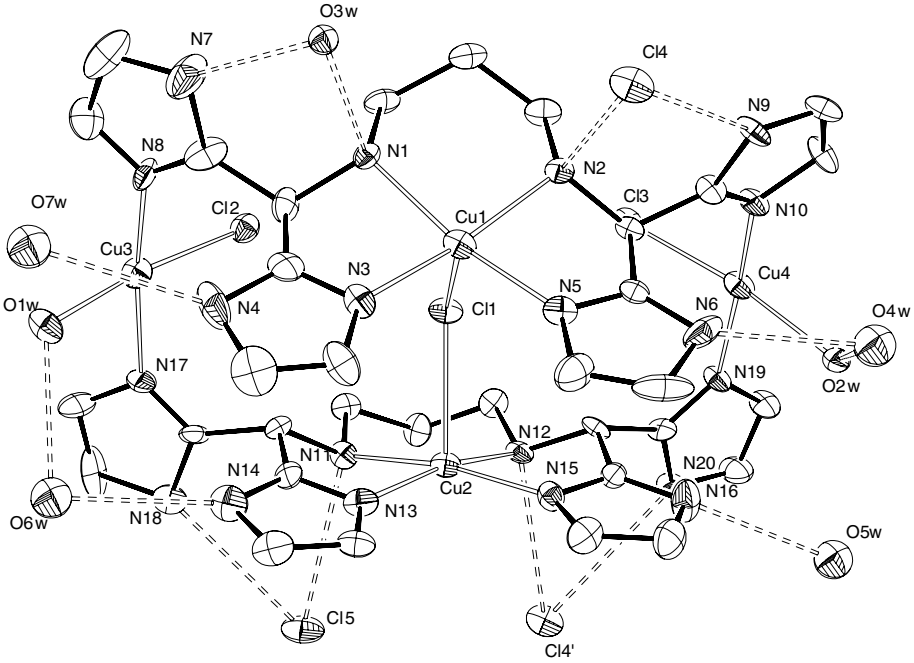

Fig. 2. Thermal ellipsoid plot (20% probability level) of the asymmetric subunit $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]^{2+}$ together with the two chloride counter ions, one chloride ion (Cl4′) from an adjacent subunit and the five crystallization water molecules; the hydrogen atoms have been omitted for clarity. The hydrogen bond network is indicated with dotted double lines.

water molecules. A view of the asymmetric subunit together with the two chloride counter anions and five lattice water molecules is shown in Fig. 2. The Cu1 and Cu2 atoms, both equatorially coordinated by two diamine nitrogens (Cu1–N1 = 2.069(4), Cu1–N2 = 2.061(4) Å; Cu2–N11 = 2.062(4), Cu2–N12 = 2.090(4) Å) and two imidazolate nitrogens (Cu1–N3 = 2.015(4), Cu1–N5 = 1.992(4) Å; Cu2–Nl3 = 2.018(5), Cu2–N15 = 1.986(4) Å), are symmetrically bridged in a square pyramidal configuration by the axial Cl1 chloride (Cu1–Cl1 = 2.576(1) and Cu2–Cl1 = 2.571(2) Å) (N_4Cl donor set, $\tau_1 = 0.013$, $\tau_2 = 0.033$, where $\tau = 0$ and 1 for perfect square-pyramidal and trigonal-bipyramidal geometry [14], respectively). Each ligand bridges to the Cu3 and Cu4 metal ions using two nitrogen atoms of different imidazole rings [Cu3–N8 = 1.959(5), Cu3–N17 = 2.007(5) Å; Cu4–N10 = 1.994(4), Cu4–N19 = 2.015(4) Å] giving rise to a sharing of the two organic ligands between four metal ions. A chloride anion and a water molecule contribute to form an equatorial N_2ClO arrangement around the Cu3 and Cu4 metal centers (Cu3–Cl2 = 2.341(2), Cu3–O1w = 2.244(3) Å; Cu4–Cl3 = 2.320(2), Cu4–O2w = 2.244(3) Å). The coordination environment around Cu3 and Cu4 is completed to square pyramidal by the Cl2 and Cl3 atoms from two neighbouring tetranuclear units (Cu3–Cl2′ = 2.618(2), Cu4–Cl3′ = 2.655(2) Å) (N_2Cl_2O donor set, $\tau_3 = 0.023$ and $\tau_4 = 0.033$). These contacts give rise to a tetranuclear-based polymeric chain. which shows (Fig. 3) an alternate arrangement of dinuclear units in which the copper atoms (Cu1 and Cu2) are connected by a single and symmetric chloride bridge, and other dinuclear units in which the metal centres (Cu3, Cu3′ and Cu4, Cu4′) are linked by two asymmetric chloride bridges. In the dinuclear single bridged moiety the Cu1–Cu2 distance is 4.499(1) Å, while in the dinuclear doubly bridged moieties the copper–copper distance is 3.472(1) Å for Cu3–Cu3′ and 3.491(1) Å for Cu4–Cu4′. The copper atoms Cu1 and Cu2 lie in a plane orthogonal to the planes containing the doubly bridged Cu3–Cu3′ and Cu4–Cu4′ (91.4(1)° and 91.6(1)°, respectively). The Cu···Cu distances between copper ions belonging to different dinuclear moieties, range from 5.843(2) Å to 6.0136(1) Å. Stacking interactions between neutral imidazole rings contribute to the polymeric chain stabilization.

A most unusual feature of the chain of tetranuclear building blocks concerns the charge (and therefore the degree of dehydronation) of the imidazole moieties. In fact (on average, as calculated from 4 Cu(II) ions and 5 chloride ions as much as three H^+ ions from the eight imidazole rings have ionized (all rings involve those coordinated to Cu1 and Cu2). The remaining 5 imidazole acidic hydrogen atoms are disordered and statistically distributed (with SOF = 0.50) over the imidazolate free nitrogens N4 and N6 or N14 and N16. From a stoichiometric point of view in the tetranuclear subunit one ligand is monoanionic and the other is in its dianionic state. It is noteworthy that the imidazolate moieties of the two organic ligands are monodentate. A uninegative behaviour of a ligand similar to that present in our cationic complex, has been reported earlier in the compound $[Cu_6(tidah)_2Cl_{10}(H_2O)_4] \cdot 6H_2O$ where Htidah = 1,1,6,6-tetrakis-(imidazol-2-yl)-2,5-diazahexane [15]. However, in this neutral complex, in which four single and asymmetric chloride bridges play a cooperative role in the metal atoms connection, the dehydronated imidazole ring of each monoanionic tidah ligand acts as a bridging moiety between two copper atoms; all the other undehydronated imidazole rings are monodentate. Bridging behaviours for imidazolate moieties have also been found in the dodecanuclear copper(II) complex $[Cu_{12}(tidhd)_4(MeOH)_8(CH_3COO)_8](MeOH)_{0.8}$ (Htidhd = 1,1,7,7-tetrakis(imidazol-2-yl)-2,6-diaza-1,6-heptadiene) [12] in which all the tidhd ligands are in the dianionic state.

The present polymeric compound is also stabilized by stacking interactions between imidazole moieties and by intermolecular hydrogen bonds. Of the five lattice water

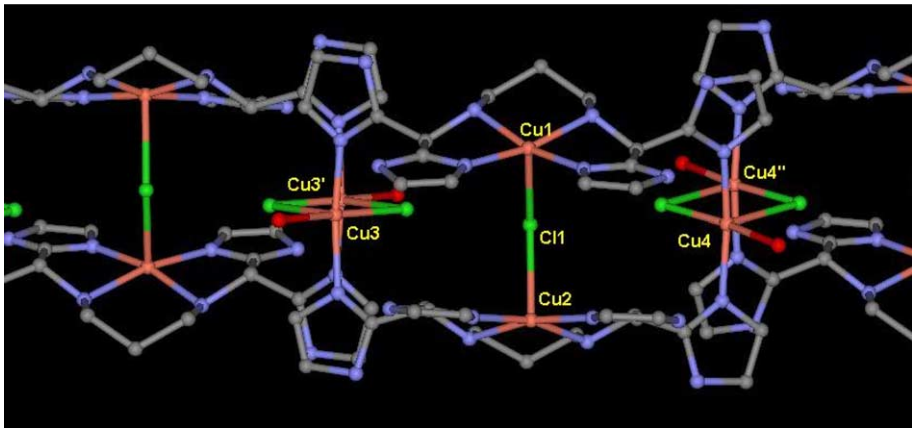

Fig. 3. View of the 1D polymer chains formed by dicationic tetranuclear subunits.

molecules, four interact via O–H···N and O–H···O hydrogen bonds with imidazolate uncoordinated nitrogens (O4w···N6, O5w···N16, O6w···N14, O7w···N4) and coordinated water molecules (O4w···O2w, O6w···O1w). The remaining water molecule and the chloride counter anions are involved, as acceptor atoms, in intermolecular N–H···O and N–H···Cl hydrogen bonds with the N–H groups from amine moieties and undehydronated imidazoles rings (N1···O3w, N7···O3w, N2···Cl4, N9···Cl4, N11···Cl5, N18···Cl5, N12···Cl4′, N20···Cl4′). Weak C–H···Cl interactions contribute to the packing of the chains.

2.2. Electronic properties, ESI-MS and EPR studies

The pattern of the absorption bands in the infrared spectrum of the copper compound is quite different from the free ligand, and some of the ligand bands split or shift as a result of coordination (see Section 2). The diffuse-reflectance spectrum shows a broad band, ca 15.9×10^3 cm^{-1}, and another two bands at 24.4×10^3 and 38.1×10^3 cm^{-1} in agreement with such geometries. The UV–Vis spectrum (25 °C) of the complex dissolved in MeOH shows a shoulder peak at 365 nm (4188 cm^{-1} M^{-1}), and a broad band at 615 nm (308 cm^{-1} M^{-1}). The former peak may be due to the LMCT, while the weak absorption of the latter one is assigned to be d–d transition [16]. The difference between the solid and solution spectra of the complex indicates that the complex may partially dissociate in MeOH.

ESI-MS measurement of the complex has been performed in methanol solution. The observed peak at m/z = 563 g mol^{-1} corresponds to the $[Cu_4(H_3L)(H_2L)Cl_3]^{2+}$ and the most intensive peak at m/z = 428 g mol^{-1} is that with one ligand and one Cu, which indicate that the complex decomposes in MeOH.

X-band EPR spectra of a powdered polycrystalline sample of the complex at room temperature shows a fairly broad isotropic copper(II) signal centered at a g value of 2.11. At 77 K, the signal of the complex becomes sharper, but no resolution of $g_\parallel$ and $g_\perp$ is observed. EPR spectra of the complex dissolved in MeOH shows $g_\parallel = 2.43$, $g_\perp = 2.08$ and $A_\parallel = 120$ mT, which appears to originate from a hexakis(MeOH)Cu(II) species. Another group of signal is quite weak and shows $g_\parallel = 2.38$, $g_\perp = 2.06$ and $A_\parallel = 125$ mT, which must originate from the dissociated mononuclear species.

2.3. Magnetic susceptibility

The magnetic properties of polycrystalline $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]Cl_2 \cdot 5H_2O$ are represented in Fig. 4 as χT versus T plot at 1000 G applied field and M versus field plot at 1.83 K, where $\chi = M/H$ is the molar magnetic susceptibility. The value χT, corresponding to four uncoupled $S = 1/2$ spins with $g \sim 2.2$, remains

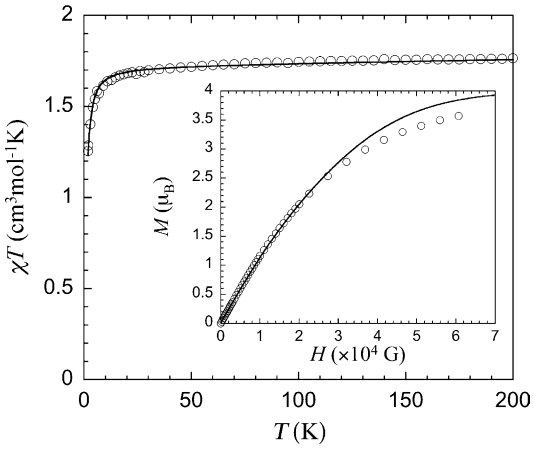

Fig. 4. Temperature dependence of the product χT at 1000 G for the complex $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]Cl_2 \cdot 5H_2O$. Inset: field dependence of the molar magnetization at 1.83 K. Full lines are the best-fit to a model taking into account interactions within Cu(II) pairs and the influence of the applied field (see text).

practically constant at about 1.70–1.76 cm^3 mol^{-1} K down to 30 K. Below 25 K, χT decreases markedly down to 1.25 cm^3 mol^{-1} K at 2 K, indicating the presence of dominant weak antiferromagnetic interactions among the Cu(II) ions in the present complex. The N–C–C–C–N bridges through the ligand L are unlikely to produce any significant magnetic interaction (large Cu–Cu distances, polyatomic unconjugated pathway). The structure of the present complex can be viewed, from the magnetic viewpoint, as pseudo-isolated dinuclear Cu(II) units with either planar dichlorodicopper (Cu4–Cu4′ and Cu3–Cu3′ pairs) or monochlorodicopper bridging pathway (Cu1–Cu2 pair). The former can be expected to be weakly antiferromagnetically coupled on the basis of the ratio of Cu–Cl–Cu angle/Cu–Cl distance, magneto-structural correlations for such topologies [17] and the fact that only one of the Cl$^-$ ions is present in an equatorial position. The monochloro bridged pair, on the other hand, is likely to present extremely small exchange coupling constant, since the bridging chloride ion is in axial coordination site for both Cu1 and Cu2 atoms, at which the electron density is expected to be very small for a square-pyramidal Cu(II) ion. Thus, we have considered the following expression for the magnetization of each Cu(II) pair, derived from the Hamiltonian $\hat{H} = -2J\hat{S}_1 \cdot \hat{S}_2 + g\mu_B H(\hat{S}_1 + \hat{S}_2)$ for a pair of exchanged coupled $S = 1/2$ ions including the effect of the external field, H [18].

$$M = \frac{N_A g \mu_B \sinh(g\mu_B H/k_B T)}{1 + \exp(-2J/k_B T) + 2\cosh(g\mu_B H/k_B T)}. \quad (1)$$

To avoid over-parameterization we have considered only one g-factor for all Cu(II) ion and the same exchange coupling constant J_1 for the two dichloro-bridged pairs (Cu3–Cu3′ and Cu4–Cu4′), J_2

representing the exchange coupling constant for the monochloro bridged (Cu1–Cu2) pair, and fitted the experimental data (with χM/H) to the expression $M = M_1 + M_2$. The best results (corresponding to the full line in Fig. 4) were obtained for $g = 2.25(1)$, $2J_1/k_B = -4.2(7)$ K, $2J_2/k_B = 1.2(9)$ K and a term for Temperature Independent Paramagnetism TIP = $3.3(1) \times 10^{-4}$ cm^3 mol^{-1}, reasonable for four Cu(II) ions. The same set of parameters also fits correctly the magnetization versus field data at 1.83 K (see inset in Fig. 4). Only a slight misfit is observed at high fields, possibly arising from the neglecting of interpair interactions [18]. With the present data, only little significance should be attached to the positive value for $2J_2$. Indeed correct fits can be obtained for $|2J_2|/k_B < 1.2$ K. Overall, these results are in agreement with the structural parameters and show that the magnetic behaviour of $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]Cl_2 \cdot 5H_2O$ is that of weakly antiferromagnetically coupled Cu(II) pairs aside virtually uncoupled Cu(II) ions.

3. Conclusions

In this paper, the synthesis, structure and magnetic properties of a 1D copper(II) polymer have been presented. The results have clearly demonstrated that the potential dinucleating ligand H_4L does not coordinate to copper(II) in the expected way to form a dinuclear copper(II) complex; however, the unique architecture of a tetranuclear-based, chloro-bridged polymer, in which all the imidazolate moieties are monodentate, has been formed by ligand sharing. The chain shows an alternate arrangement of dinuclear units with Cu atoms connected by a single and symmetric chloride bridge, and dinuclear units in which two asymmetric chloride bridges link the metal atoms. Further investigations with ligands containing the bis-(imidazole-2-yl) unit to obtain dinuclear copper complexes are in progress. The ionic ligands can be explained by extensive hydrogen bond interactions in the crystal lattice.

3.1. Synthesis of the ligand and the complex

The ligand 1,1,7,7-tetrakis(imidazol-2-yl)-2,6-diazaheptane (H_4L) was prepared as described in the literature reported by some of us [12].

A solution of the ligand H_4L (36.6 mg, 0.1 mmol) in 5 mL of MeCN was added to a solution of $CuCl_2$ (51 mg, 0.3 mmol) in 5 mL of MeCN. The reaction mixture was stirred at room temperature for 30 min, and it was filtered. Diethyl ether diffusion in to the filtered solution resulted in the formation of blue crystals of sufficient quality for X-ray structure determination. Yield: 30%. *Anal.* Calc. for $C_{34}H_{55}Cu_4N_{20}O_7Cl_5$: C, 31.7; H, 4.2; N, 21.7; Cu, 19.7. Found: C, 31.3; H, 3.8; N, 21.2; Cu, 19.2%. 3.2. General remarks

All reagents and solvents were purchased from commercial sources and used as received. C, H, N analyses were carried out on a Perkin–Elmer 2400 series II analyzer. Infrared spectra were recorded on a Perkin–Elmer Paragon 1000 spectrophotometer equipped with a Golden Gate Diamond ATR device, using the diffuse reflectance technique. X-Band EPR spectra were recorded at room temperature and at 77 K on a Jeol RE2X electron spin resonance spectrometer using DPPH ($g = 2.0036$) as a standard. The UV/Vis spectrum of the compound was recorded in the 250–800 nm range on a Cary 50 Varian UV/Vis/NIR spectrometer. Electrospray ionization mass spectra (ESI-MS, positive ion) in a methanol solution were recorded on a Thermo Finnigan AQA apparatus. The conductivity measurement was performed using a Philips PW 9526 digital conductivity meter and PW 9551/60 measuring cell with 1 mM solution of the complex in methanol.

The molecular structure of $[Cu_4(H_3L)(H_2L)Cl_3(H_2O)_2]Cl_2 \cdot 5H_2O$ was determined by single-crystal

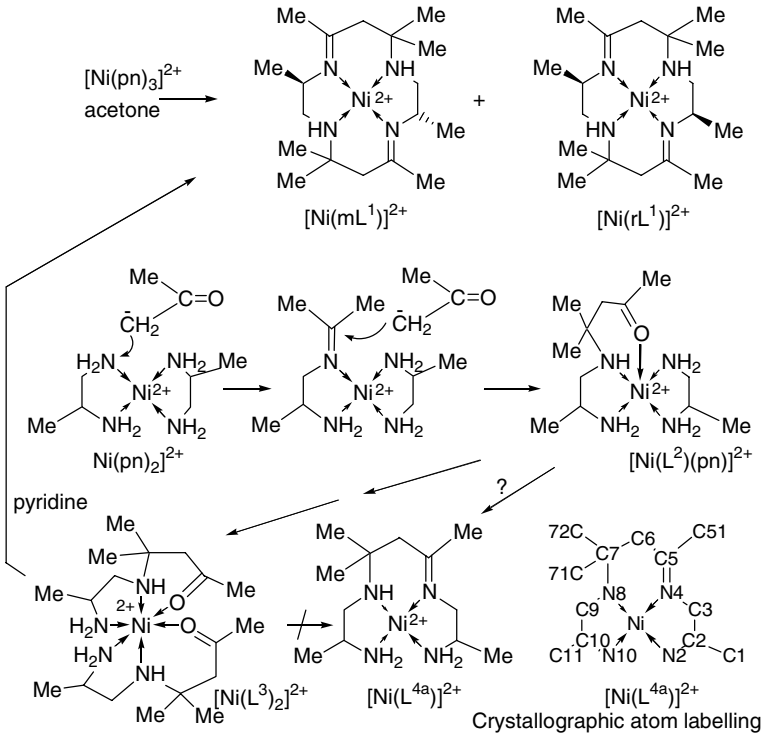
X-ray diffraction methods. Crystallographic and experimental details for the structure are summarized in Table 1. Intensity data and cell parameters were recorded at room temperature (25 °C) on a Bruker AXS Smart 1000 single-crystal diffractometer (Mo Kα radiation) equipped with a CCD area detector. The data reduction was performed using the SAINT [19] and SADABS [20] programs. The structure was solved by Direct Methods using the SIR97 program and refined on F_o^2 by full-matrix least-squares procedures, using the SHELXL-97 program (see Tables 2 and 3).

All non-hydrogen atoms were refined with anisotropic atomic displacements with the exception of the five crystallization water molecules. The H atoms from N–H or C–H groups, including the hydrogen atom statistically distributed (SOF = 0.5) between N4 and N6 or, alternatively, between N14 and N16, were placed in calculated positions and refined riding on the corresponding nitrogen or carbon atoms. The weighting scheme used in the last cycle of refinement was $w = 1/[\sigma^2 F_o^2 + (0.0397P)^2 + 13.3003P]$ (where $P = (F_o^2 + 2F_c^2)/3$). Molecular geometry calculations were carried out using the PARST97 program [21]. Drawings were obtained by ORTEP3 in the WinGX suite [22] and by the program DS ViewerPro 5.0. All calculations were carried out on a DIGITAL Alpha Station 255 computer.

4. Supplementary material



Crystallographic data (excluding structure factors) for the structure reported have been deposited with the Cambridge Crystallographic Data Center as supplementary publication no. CCDC-264342 and can be obtained free of charge on application to the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK. (Fax: (internat.) +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or on the web www: http://www.ccdc.cam.ac.uk.)

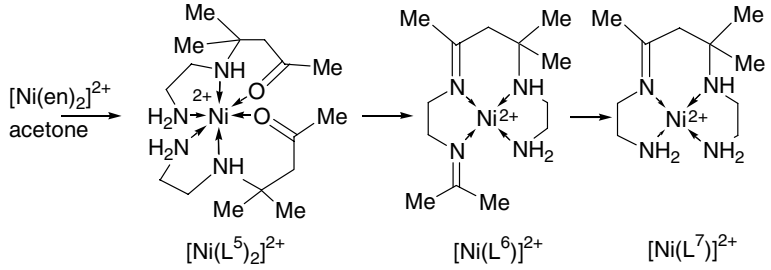
Scheme 1.



4,8-diazadec-4-ene-2,10-diamine, L^{4d} = 2,4,6,6-tetramethyl-3,7-diazadec-3-ene-1,9-diamine and L^{4e} = 2,4,6,6,8-pentamethyl-3,7-diazanon-3-ene-1,9-diamine are possible, each potentially existing as chiral isomers.

Analogous reactions of $[Ni(en)_2](ClO_4)_2$ with acetone initially form the bis(β-amino ketone) cation $[Ni(L^5)_2]^{2+}$, see Scheme 2. In the presence of ligands that compete with the ketone group for the axial coordination sites, a ketone donor group can be displaced, allowing intramolecular imine formation to occur, giving a tetradentate ligand with one β-aminoketone group [7]. Reverse aldol hydrolysis of this β-aminoketone group would form the tetradentate bis-imine ligand cation $[Ni(L^6)]^{2+}$, for which hydrolysis of the *N*-isopropylidine function would form $[Ni(L^7)]^{2+}$. Reaction of $[Ni(en)_2(NCS)_2]$ with acetone yields $[Ni(L^6)(NCS)_2]$ from which hydrolysis of the *N*-isopropylidine imine group forms $[Ni(L^7)(NCS)_2]$ [8]. Structures have been reported for $[Ni(L^5)_2](ClO_4)_2$, $[Ni(L^6)][ZnCl_4]$ and $[Ni(L^7)(NO_2)]ClO_4$ [7]. Reaction of $[Ni(l\text{-}pn)_2](ClO_4)_2$ with acetone forms $[Ni(l\text{-}L^4)_2](ClO_4)_2$, which cyclizes in pyridine to form $[Ni(ll\text{-}rL^1)]^{2+}$ [9].

In this communication, the reaction of $[Ni(pn)_2(NCS)_2]$ with acetone is described and the structure of the product reported.

2. Results

Reaction of $[Ni(pn)_2(NCS)_2]$ with acetone yields orange, singlet ground state, $[Ni(L^4)](NCS)_2$ for which

Scheme 2.

the structure has been determined. This confirms the ligand as 5,7,7-trimethyl-4,8-diazaundec-4-ene-2,10-diamine, L^{4a}, with both propane-1,2-diamine residue methyl substituents adjacent to the terminal primary amine groups.

In contrast $[Ni(L^7)](NCS)_2]$ exists as a blue-violet, triplet ground state, solid with coordinated thiocyanate. Both $[Ni(L^{4a})](NCS)_2$ and $[Ni(L^7)](NCS)_2]$ form yellow solutions with dissociated thiocyanate in polar solvents (water, lower alcohols, nitromethane, etc.), and blue-violet solutions with coordinated thiocyanate in low-polarity solvents (acetone, acetonitrile, dichloromethane, etc.).

3. Structural study

The structure of a crystal of orange $[Ni(L^{4a})](NCS)_2$, grown from methanol, was determined by X-ray diffractometry, see Section 5.2 for details.

The asymmetric unit consists of the cation (5,7,7-trimethyl-4,8-diazaundec-4-ene-2,10-diamine)nickel(II) and two thiocyanate ions, see Fig. 1. The cation has tetrahedrally twisted square-planar coordination {displacements/Å from the N2, N4, N8, N10 coordination plane: N2 0.0480(5), N4 −0.0472(5), N8 0.0469(5), N10 −0.0477(5), Ni1 −0.0113(6), C2 −0.428(2), C3 0.278(2), C5 −0.049(2), C6 0.204 (2), C7 0.9021(2), C9 0.3709(2), C10 −0.3993(2), C11 −0.0588(2), C51 −0.3284(2), C71 2.3185(2), C72 0.9602(2), with methyl group C71 axially oriented and the other methyl groups equatorially oriented}. The C2–H2 and C7–C71 (axial component of *gem*-dimethyl group) are oriented towards one side of the plane, and N8–H8 and C10–H10 towards the other side. The Ni–N distances (Table 1) are within the usual range for singlet ground state nickel(II), with the bond to the imine nitrogen N4 shorter than the bonds to the amine nitrogen atoms by ca. 0.02 Å, as is usual. The chiral centres C2, N8, C10 all have the *S* configuration.

The thiocyanate ion S2–C32–N32 is located with S32 near the tetragonal axis of the nickel(II) ion (N–Ni1–S32 = 89–92°), on the side of the "molecular plane" opposite to the axial methyl group C71, with Ni1–S32 = 3.0500(5) Å and C32–S2–Ni1 = 100.80(5)°. The closest approach to the nickel on the other side is S2 (x, 1 + y, z) at 4.275 Å. Hydrogen-bond N8–H8···N31 links the cation to the second thiocyanate ion. Other hydrogen bonds form a network (Table 2). The structurally distinct thiocyanate ions give rise to doublet ν(C≡N) absorption in the IR spectrum (see Section 5.1).

4. Conclusions

Facile reaction of $[Ni(pn)_2(NCS)_2]$ with acetone forms the cation $[Ni(L^{4a})]^{2+}$ with the tetradentate ligand 5,7,7-trimethyl-4,6-diazaundec-4-ene-2,10-diamine, which has the propane-1,2-diamine residue methyl groups remote from the amine–imine bridge group linking these residues. This indicates that the cation $[Ni(L^{4a})]^{2+}$ is not formed via the bis(β-aminoketone) cation $[Ni(L^{3})]^{2+}$ by intramolecular imine formation followed by hydrolysis of one β-aminoketone function. It could be formed via the cation $[Ni(L^{2})(pn)]^{2+}$ by intramolecular imine formation, all reactions occurring at the amine nitrogens remote from the methyl substituents. The cation $[Ni(L^{4a})]^{2+}$ cannot be a precurser of the macrocyle $[Ni(L^{1})]^{2+}$ which has the propane-1,2-diamine methyl substituents adjacent to the imine functions. The overall condensation is stereospecific, forming $[Ni(L^{4a})](NCS)_2$ as the 2*SR*, 8R*S*, 10*SR* isomer.

5. Experimental

5.1. (5,7,7-Trimethyl-4,8-diazaundec-4-ene-2,10-diamine)nickel(II) thiocyanate $[Ni(L^{4a})](NCS)_2$

$[Ni(pn)_2(NCS)_2]$ (5 g) was refluxed in methanol (25 cm^3) and acetone (25 cm^3) for 8 h. The solution was then rotary evaporated and the orange residue recrystallised from methanol/propan-2-ol, yield near quantitative. Visible spectra: the compound forms a yellow, fully dissociated, solution in water {λ_{max}/nm (ε/dm^3 mol^{-1} cm^{-1}), 433 (54)} and a blue-violet solution with coordinated thiocyanate in acetone {539 (12), >900 (c. 9)}. *Anal.* Calc. for $C_{14}H_{28}N_6NiS_2C$, 41.7; H, 7.0; N20.8. Found: C, 41.9; H, 6.7; N, 20.8%. IR spectrum {ν_{max}/cm^{-1}} ν(NH) 3274, 3198, 3081, ν(C≡N) (2052, 2039) vs, ν(N=C) (1658), δ (NH_2) 1996, 1574.

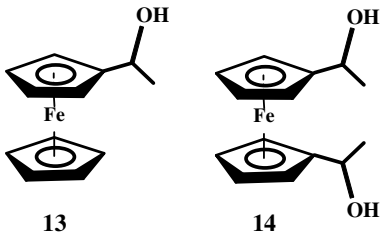
of the alcohol series Fc–$(CH_2)_m$–OH with $m = 1$–4, Fc–CH(OH)–CH_3 and $Fe(C_5H_4$–CH(OH)–$CH_3)_2$. Results are expressed relative to ferrocene itself and are compared with the related acid series, Fc–$(CH_2)_n$–COOH, $n = 0$–3.

2. Experimental

2.1. Equipment and materials

Ferrocene (**1**, Strem), $LiAlH_4$ (Merck), $AlCl_3$ and other solid reagents (Aldrich) were used without further purification. Dry acetonitrile was obtained by refluxing under nitrogen over CaH_2, distilled onto alumina for storage, and redistilled just prior to use. THF and ether was dried by refluxing under a nitrogen atmosphere over sodium wire and distilled directly before use. Organic solvents were distilled prior to use, water was double distilled. Ferrocene carboxylic acids **2**–**5** [5], **6** [3], the ester **7** [3] and the aldehyde, **8** [6] were synthesised as described before and used as precursors to the alcohols **9**–**12**, Scheme 1. Alcohol **9** was synthesised by $NaBH_4$ reduction of **8** in 90% yield as described by Broadhead [1] but on a 10 times larger scale. The secondary alcohols 1-hydroxyethylferrocene (**13**) and 1,1′-bis(hydroxyethyl)ferrocene (**14**) Fig. 1, was obtained utilising the literature methods [3]. Chromatography was performed on Fluka silica gel 60 grade 60741. The electrolyte tetrabutylammonium tetrakis(pentafluorophenyl)borate was prepared as described [7]. Melting points were determined with a Reichert Thermopan Microscope with a Koffler hot-stage and are uncorrected. ^1H NMR spectra at 20 °C were recorded on a Bruker Advance DPX 300 NMR spectrometer at 300 MHz with chemical shifts presented as δ values referenced to $SiMe_4$ at 0.00 ppm utilising $CDCl_3$ that was made acid free by passing it through basic alumina immediately before use. IR spectra (cm^{-1}) were recorded on a Hitachi spectrophotometer Model 270-50 with data processor. For solid state spectra a KBr matrix was used, while NaCl plates were used for thin films of liquid samples. Elemental analysis was conducted by the Canadian Microanalytical Service, Ltd.



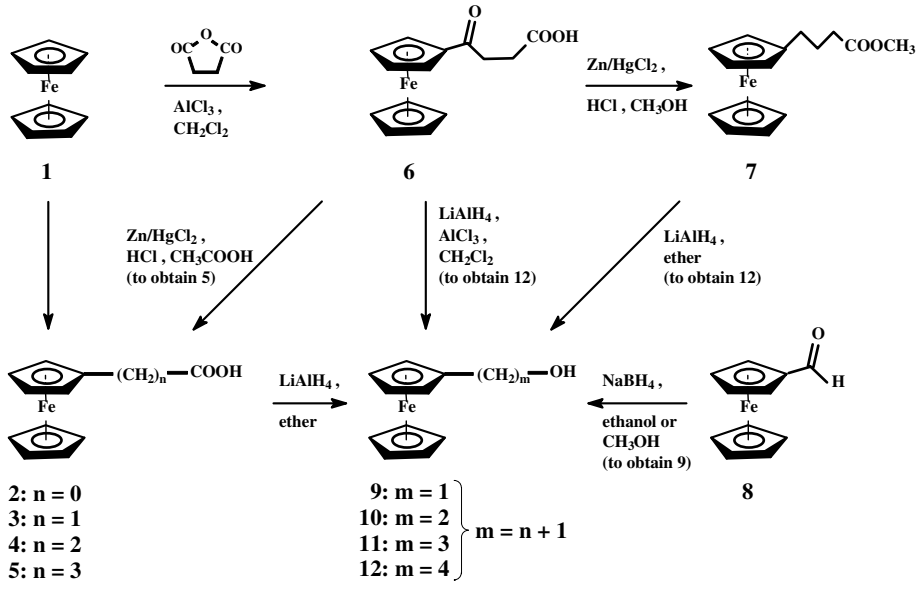


Fig. 1. Structures of secondary alcohols **13** and **14**.

2.2. Synthesis

2.2.1. Fc–$(CH_2)_m$–OH, with m = 1 (9), 2 (10), 3 (11) and 4 (12), utilising $LiAlH_4$ reduction of acids 2–5

The synthesis of 3-ferrocenylpropanol (**11**) may serve as an example. To a $LiAlH_4$ suspension in dry ether (3.42 g, 90 mmol in 100 cm^3) was slowly added a solution of 3-ferrocenylpropanoic acid (**4**, 3 g, 12.6 mmol) in dry ether (110 cm^3) while slight boiling was maintained. After refluxing the mixture for 13 h at 50 °C, a 1:1 ethanol:ether mixture (50 cm^3) was very carefully added to destroy the excess $LiAlH_4$. The reaction mixture was slowly poured into an excess of ice cold 2 M

Scheme 1. Different routes that may be followed to obtain ferrocene-containing alcohols **9**–**12**.

NaOH solution (1 l) and the ether and aqueous phases separated. The aqueous phase was washed with ether after which the combined ether fractions were washed with 1 M NaOH solution (400 cm^3) and twice with equal volumes of water. Drying of the ether layer with $MgSO_4$ and removal of the solvent under reduced pressure gave **11** as a reddish-brown oil (2.86 g, ~100%) that was clean enough for most purposes. A purification column may be employed with ethyl acetate–hexane (1:4) as eluent ($R_f = 0.36$). ^1H NMR (300 MHz, $CDCl_3$): δ_H 4.14 (5H, s, C_5H_5), 4.11 (2H, s, C_5H_4), 4.08 (2H, s, C_5H_4), 3.69 (2H, s, –CH_2–OH), 2.44 (2H, t, Fc–CH_2–), 1.80 (2H, m, –CH_2–). IR (NaCl-discs), ν_{max}/cm^{-1}: 3352 (–OH), 2926 (–CH_2–), 1104 (C–O). $C_{13}H_{16}OFe$ requires: C, 64.0; H, 6.6. Found: C, 63.9; H, 6.3%.

Characterisation data for ***9***: Chromatography on silica with ethyl acetate–hexane (1:4) as eluent ($R_f = 0.28$) gave **9** in 89% yield as a yellow solid, m.p. 76 °C. ^1H NMR (300 MHz, $CDCl_3$): δ_H 4.35 (2H, d, C_5H_4), 4.27 (2H, t, C_5H_4), 4.21 (5H, s, C_5H_5), 4.20 (2H, s, Fc–CH_2–OH). IR (KBr), ν_{max}/cm^{-1}: 3227 (–OH), 2932 (–CH_2–), 1102 (C–O). $C_{11}H_{12}OFe$ requires: C, 61.2; H, 5.6. Found: C, 61.4; H, 5.4%.

Characterisation data for ***10***: Chromatography on silica with ethyl acetate–hexane (1:4) as eluent ($R_f = 0.25$), gave **10** as a low melting solid in 93% yield, m.p. 32–33 °C. ^1H NMR (300 MHz, $CDCl_3$): δ_H 4.13 (9H, m, –C_5H_4 and C_5H_5), 3.75 (2H, m, –CH_2–OH) and 2.62 (2H, t, Fc–CH_2–). IR (NaCl discs), ν_{max}/cm^{-1}: 3408 (–OH), 2935 (C–H), 1038 (C–O). $C_{12}H_{14}OFe$ requires: C, 62.6; H, 6.1. Found: C, 62.6; H, 5.8%.

Characterisation data for ***12***: Chromatography on silica with ethyl acetate–hexane (1:4) as eluent ($R_f = 0.49$), gave **12** as a thick dark yellow liquid in 94% yield. ^1H NMR (300 MHz, $CDCl_3$): δ_H 4.12 (5H, s, C_5H_5), 4.06 (4H, d, C_5H_4), 3.68 (2H, t, CH_2–OH), 2.37 (2H, t, Fc–CH_2), 1.60 (4H, m, $2 \times CH_2$). IR (NaCl-discs), ν_{max}/cm^{-1}: 3346 (–OH), 2800–2900 (C–H), 1104 (C–O). $C_{14}H_{18}OFe$ requires: C, 65.1; H, 7.0. Found: C, 65.3; H, 6.9%.

*2.2.2. Fc–(CH$_2$)$_4$–OH (**12**) utilising LiAlH$_4$/AlCl$_3$ reduction of the γ-ketoacid (**6**)*

To a suspension of $LiAlH_4$ (0.267 g, 6.99 mmol) in dry ether (5 cm^3) was added $AlCl_3$ (0.228 g, 1.63 mmol), also suspended in dry ether (45 cm^3) under nitrogen. 3-Ferrocenoylpropanoic acid (**6**, 0.208 g, 0.699 mmol) was added and additional $AlCl_3$ (0.189 g, 1.39 mmol) suspended in dry ether (9 cm^3) was added over a 5 min interval. The reaction mixture was stirred for 30 min at room temperature and refluxed for 3 h. To the cooled reaction mixture was added water (8 cm^3) and 6 mol dm^{-3} H_2SO_4 (5 cm^3). The mixture was extracted with ether (3×80 cm^3), dried with $MgSO_4$ and solvent removal afforded a yellowish oil of 4-ferrocenylbutanol (**12**) (0.18 g, 97%).

*2.2.3. Fc–(CH$_2$)$_4$–OH (**12**) from LiAlH$_4$ reduction of ester 7*

Solid $LiAlH_4$ (2.7 g, 71 mmol) was added to a solution of **7** (6.32, 22.1 mmol) in 80 cm^3 dry ether over 20 min. The reaction mixture was refluxed for 16 h before the excess $LiAlH_4$ was destroyed by careful addition of a 1:1 ethanol:ether mixture (100 cm^3). The ether layer was washed successively with HCl (2×200 cm^3, 2 mol dm^{-3}), NaOH (200 cm^3, 2 mol dm^{-3}) and water, and dried with $MgSO_4$, to give after solvent removal **12** (5.31 g, 93%).

2.3. Cyclic voltammetry

Cyclic voltammetric (CV) experiments were performed on ca. 1 mM solutions of **9**–**14** in dry CH_3CN/0.100 M $N(^nBu)_4PF_6$, utilising a standard three-electrode cell with a Pt-working electrode of surface area 2.01 mm^2 and pre-treated by polishing on a Beuhler microcloth first with 1 micron and then with 1/4 micron diamond paste, a Pt-wire counter electrode and a Ag/Ag^+ reference electrode (a Ag wire immersed in 0.010 M $AgNO_3$ in CH_3CN utilising a Luggin capillary with vicor tip) under argon at 25.0 °C in a Faraday cage connected to a BAS CV-27 cyclic voltammograph interfaced with a personal computer. Some experiments were also conducted on a glassy carbon electrode of surface area 7.07 mm^2. Obtained formal reduction potentials were essentially the same. Data, uncorrected for junction potentials, were collected with an Adalab-PC™ and Adapt™ data acquisition kit (Interactive Microwave, Inc.) with locally developed software, and analysed with Hyperplot (JHM International, Inc.). All potentials in this study, however, are presented referenced against Fc/Fc^+ as recommended by IUPAC [8]. The Fc/Fc^+ couple exhibited $E^{o'} = 0.087$ V versus Ag/Ag^+, $i_{pc}/i_{pa} = 0.98$, $\Delta E_p = 74$ mV under our experimental conditions. Successive experiments under the same experimental conditions have shown that potentials were reproducible within 3 mV. CV experiments with **9** in CH_2Cl_2/0.100 M $[N(^nBu)_4][B(C_6F_5)_4]$, utilising a glassy carbon electrode of surface area 0.79 mm^2, were experimentally referenced against a Ag/AgCl reference electrode.

3. Results and discussion

3.1. Synthesis

The alcohol series **9**–**12** were synthesised according to Scheme 1. Ferrocenylmethanol (**9**) was synthesised from ferrocenecarboxaldehyde (**8**), utilising $NaBH_4$ as reducing agent in high (~90%) yield. $NaBH_4$ is somewhat safer to use in large quantities than $LiAlH_4$. However, $NaBH_4$ is not a strong enough reducing agent to reduce

carboxylic acids or esters. Hence, for the reduction of **2**–**5** and **7**, $LiAlH_4$ was used. All these reactions were essentially quantitative.

The yield-limiting step in obtaining alcohols **9**–**12** from ferrocene is centred on the success rate in obtaining the acid or other precursors. Hence the preparation of **9** from aldehyde **8** gave a much better overall yield (71% in a two-step syntheses) based on the initial amount of ferrocene used, than the preparation utilising the acid, **2** (ca. 49% yield at least in a three-step syntheses). Because $LiAlH_4$ reduction of the present ferrocene acid series is so facile, there is nothing gained in terms of yields by synthesising alcohols **9**–**12** utilising ester precursors. This is demonstrated for the synthesis of 4-ferrocenylbutanol (**12**) from ester **7**. It is also unnecessary to obtain **5** for the synthesis of **12**, since this alcohol can directly be obtained by the reduction of the γ-ketoacid (**6**). However, in this latter reaction, $LiAlH_4$ does not liberate the alcohol **12** because $LiAlH_4$ does not reduce the γ-keto group of **6** to a CH_2 group. Rather, the formation of an α-alcohol intermediate possessing the molecular fragment Fc–CH(OH)– and follow-up degradation occurs. To obtain **12** from **6**, the use of the mixed reducing system $AlCl_3/LiAlH_4$ leads to simultaneous Clemenson reduction of the γ-keto group to $–CH_2–$ and the carboxylic acid group to $–CH_2–OH$. This reaction is also essentially quantitative. The long term stability of the alcohols with spacers $(CH_2)_m$ and $m = 2$, 3 and 4 is excellent. However, the shelf-life of $Fc–CH_2–OH$ (**9**) and also the secondary alcohols **13** and **14** (Fig. 1), is less impressive. This is the result of the high electron donating power of the ferrocenyl group (group electronegativity of Fc is $\chi_{Fc} = 1.89$ [9,10]), which tend to stabilise ferrocyl cations ($= Fc–CH_2^+$) [11,12]. This promotes decomposition of **9** by water elimination under very mild conditions as follows:

$$Fc–CH_2–OH + H^+ \rightarrow Fc–CH_2–(OH_2)^+ \rightarrow Fc–(CH_2)^+ + H_2O$$

The ferrocenyl group cannot stabilise cations of this nature in **10**–**12**.

3.2. Cyclic voltammetry

CV experiments in dry CH_3CN/0.100 M $N(^nBu)_4PF_6$ indicated reversible electrochemical behaviour for the ferrocenyl group in compounds **10**–**14** with $\Delta E_p = E_{pa} - E_{pc} \leqslant 80$ mV at scan rates up to 250 mV s^{-1} in acetonitrile (Table 1, Fig. 2). Determined peak cathodic/peak anodic current ratios for **10**–**14** were in the range $0.94 < i_{pc}/i_{pa} < 1$ and the formal reduction potentials, $E^{o'} = 1/2\,(E_{pa} + E_{pc})$, were scan rate independent between 50 and 250 mV s^{-1}.

Compound **9**, though, exibited $\Delta E_p = 110$ mV, much larger than for the other alcohols. Close inspection of the CV of **9** hinted on two poorly resolved ferrocene-based waves (Fig. 3) despite the fact that **9** gave satisfactorily elemental analyses and having a clean ^1H NMR spectrum. In an attempt to prove that their really are two peaks associated with the CV of **9**, Osteryoung Square Wave Voltammetry (OSWV) was performed on this complex. The OSWV peaks were certainly broadened, but no clear-cut indication towards two redox peaks could be demonstrated. It then was suspected that the use of the coordinating solvent CH_3CN and 0.100 M $N(^nBu)_4PF_6$ as supporting electrolyte masked some key features of the CV of **9**. Reports by Geiger and co-workers [13] that poorly resolved peaks in CH_3CN/0.100 M $N(^nBu)_4PF_6$ often becomes well resolved in the system dichloromethane utilising the hyper uncoordinative and poorly nucleophylic salt $[N(^nBu)_4][B(C_6F_5)_4]$ as supporting electrolyte, caused us to repeat the CV of **9** in

Table 1
Selected potentials (V) and current (μA) data for ca. 1.0 mM solutions of the indicated compounds in CH_3CN/0.100 M $N(^nBu)_4PF_6$ at 25.0 °C

Compound	E_{pa}	ΔE_p	$E^{o'}$	i_{pa}	i_{pc}/i_{pa}
9 (peak 1)	−0.017[a]	[b]	0.016[c]	[b]	[b]
9 (peak 2)	0.093	[b]	0.060[c]	[b]	[b]

[a] E_{pc} value.
[b] A poorly defined oxidation wave in peak 1 and reduction wave in peak 2 made current and ΔE_p measurements impossible.
[c] $E^{o'}$ were estimated by assuming $\Delta E_p = 66$ mV, the value obtained for **13** and **14**.

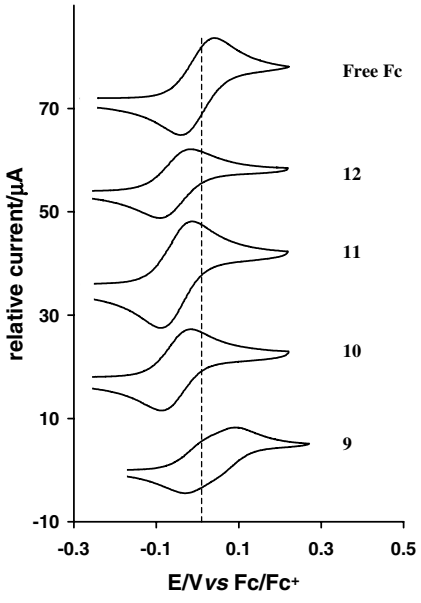

Fig. 2. CV's of **9**–**12** in CH_3CN/0.100 M $N(^nBu)_4PF_6$ at 25.0 °C and a scan rate of 100 mV s^{-1} at a Pt-working electrode.

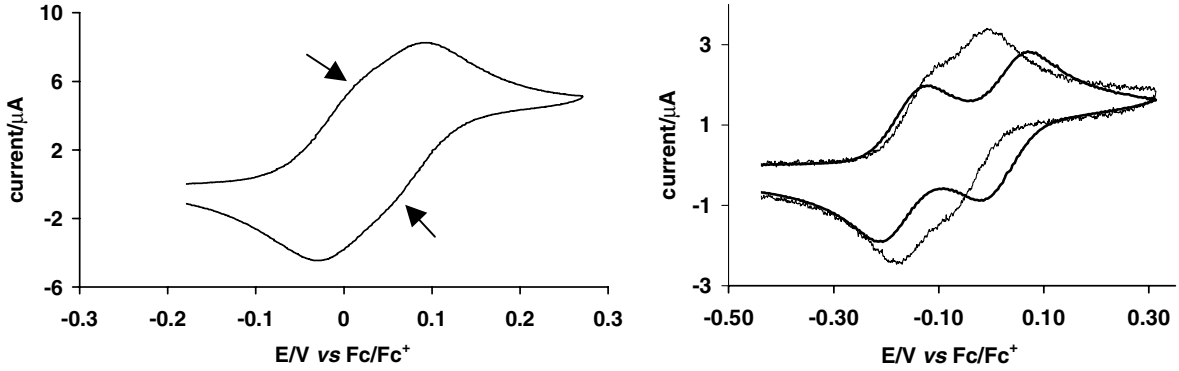

Fig. 3. CV of **9** in CH_3CN/0.100 M $N(^nBu)_4PF_6$ (left) showing two poorly resolved peaks. In CH_2Cl_2/0.100 M $[N(^nBu)_4][B(C_6F_5)_4]$ (right, bold line), two peaks with $\Delta E_p \sim 89$ mV are clearly seen. Upon addition of 0.100 M $N(^nBu)_4PF_6$ to this solution, the CV collapsed into one showing two poorly resolved peaks (right, less bold line).

the system CH_2Cl_2/0.100 M $[N(^nBu)_4][B(C_6F_5)_4]$ with spectacular success.

Fig. 3, right, clearly shows two very well-defined reversible CV waves for **9** in this medium. In a separate test, the stability of **9** in acetonitrile was investigated by ^1H NMR. This compound did not show any degradation within 24 h. The two observed waves in Fig. 3, right, are typical of those associated with a symmetrical dimer, which generates a mixed valent intermediate upon oxidation or reduction. Different formal reduction potentials for side groups on symmetrical complexes in which mixed-valent intermediates are generated are well known in systems that allow electron delocalisation, either through bridge mediated paths or from a direct metal–metal interaction [10,14]. The inequivalence of the ferrocenyl and ferrocenium groups of such a mixed valent intermediate is highlighted in terms of their group electronegativities [9,10]: $\chi_{Fc} = 1.87$, $\chi_{Fc+} = 2.82$. The electron withdrawing power of the ferrocenium group is almost as high as that of the CF_3 group ($\chi_{CF3} = 3.01$). We therefore propose the formation of a dimeric species of **9** in solution that electrochemically are oxidised according to the following electron transfer processes:

$$[2FcCH_2OH \rightleftharpoons (FcCH_2OH)_2] \rightleftharpoons (Fc^+CH_2OH)\text{–}(FcCH_2OH) \rightleftharpoons (Fc^+CH_2OH)_2 \quad (1)$$

It is instructive to observe that **10**–**14** do not show the double peaks in their CV's as **9** had. This implies that the structural effects that was discussed and interpreted above as dimerisation for **9** is absent in **10**–**14**. This observation is consistent with the fact that the longer chain of **10**–**12** introduces so much flexibility into the side chains of these molecules compared to what is expected for **9**, that a dimeric product may not be stable enough to allow its detection in noticeable amounts on a CV time scale. As for **13** and **14**, it is conceivable that the methyl groups in the side chain is bulky enough to impose so much steric constraints on the molecules that dimerisation as it is realised for **9** is not as feasible in **13** and **14**.

The structure of the mixed valent species in Eq. (1) above can only be speculated on at this stage, but in view of the known hydrogen bonding capabilities of alcohols and the fact that the ferrocenyl group are known to interact with protons [15], a hypothetic structure as in Fig. 4 would be consistent with our results.

It would allow a symmetrical dimer to account for the shape of the CV. It would allow communication of the Fe^{II} and Fe^{III} species through space and through conjugation, and it disallows a similar communication pattern of longer chain alcohols in two ways. Firstly, in $–(CH_2)_m–$ chains with $m \geqslant 2$, electron delocalisation through conjugation or inductive effects along the side chains would be very weak indeed. Secondly, through space communication of the Fe^{II} and Fe^{III} species, or the $Fe^{II}\cdots H–O–CH_2–Fc$ interaction in Fig. 4 would be very unlikely over the distances that will be required for the longer side chains.

The lower $E^{o'}$ for **10** compared to **9** (Table 1) clearly indicates that there is much less communication between the hydroxyl group and the ferrocenyl moiety of **10** than in **9**. In particular, for $E^{o'}$ of **10** to be 46 mV more negative than $E^{o'}$ of ferrocene itself, the side-chain of **10**, $–CH_2CH_2OH$, has to become electron-donating relative to H. This is consistent with a conclusion that $–CH_2CH_2–$ and larger alkyl spacers effectively isolates the –OH group from the ferrocenyl

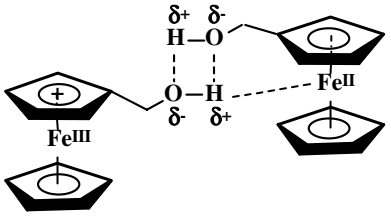

Fig. 4. Possible mixed valent intermediate in the oxidation of **9**.

group, but that a single $–CH_2–$ group does not. This also means that electron-donating properties of the $–CH_2CH_2–$ part of the side-chain in **10** dominates over the electron-withdrawing properties of the –OH moiety of **10**.

Further increases in the side chain length to that of **11** and **12**, lowered the $E^{o'}$ values further, but not nearly as dramatically as did **10**, probably because the $–(CH_2)_m–$ chains became so long that they are very effective isolators: the ferrocenyl group is really existing independent of any through-space or through-bond inductive effects that the OH group may have. The only thing that the slight lowering of the formal reduction potentials of **11** and **12** are thought to imply is a slight increase in the electron donating power of the alkyl chains with increasing chain length.

The $E^{o'}$ of the secondary alcohols **13** and **14** is more negative than that of **9**. This is because they have additional electron-donating methyl groups in the side-chains compared to **9**. It is also instructive to note that our $E^{o'} = -0.011$ V for **13** corresponds very well with the chronopotentiometric determined $E_{1/4} = -0.009$ V value that was reported by Kuwana and co-workers [16]. Alcohol **14** is more easily oxidised than **13** which is what one may expect when the number of electron donating side chains, here two $–CH(CH_3)OH$ groups, are doubled.

Fig. 5 demonstrates a few final key points pertinent to compounds of the type $Fc–(CH_2)_n–COOH$ and $Fc–(CH_2)_m–OH$.

Firstly, it can clearly be seen how the value of $E^{o'}$ decreases as the alkyl chain of the carboxylic acid series **2–5** and the ferrocenylalcohol series **9–12** becomes longer. Secondly, the electron withdrawing properties of both the carbonyl group of –COOH and the OH group in $Fc–(CH_2)_{n/m}$-compounds see to it that $E^{o'}$ are much more drastically affected at short chain length than in compounds with longer side chains. Finally, it can be noted that ferrocenyl alcohols are more easily oxidised than the parent carboxylic acids **2–5**.

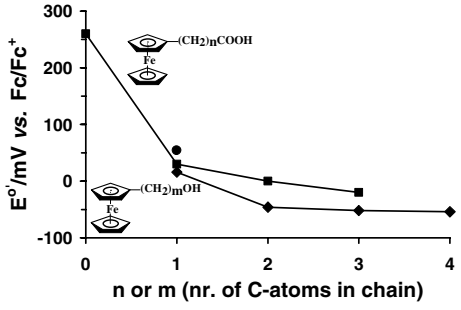

Fig. 5. Graph of $E^{o'}$ vs. number of carbon atoms in the alkyl chain linking the ferrocenyl group with functional groups for $Fc–(CH_2)_n–COOH$ (■) and $Fc–(CH_2)_m–OH$ (♦). The point ● refers to the second couple of **9**.

In conclusion, the yield-limiting step to obtain ferrocenylalcohols is centred in the successful high yield synthesis of suitable precursors. Reduction reactions of these precursors to obtain ferrocenyl alcohols are very efficient. The ferrocenylalcohols under discussion have smaller reduction potentials than the carboxylic acid analogues, and they become easier to oxidise with increasing alkyl chain length. Ferrocenylmethanol undergo solution molecular pairing to a notable extent. A forthcoming publication [17] will provide the details of how more beneficial cytotoxic properties for potential cancer treatment by **9–12** are observed with increasing side chain length and decreasing ferrocenyl formal reduction potential.

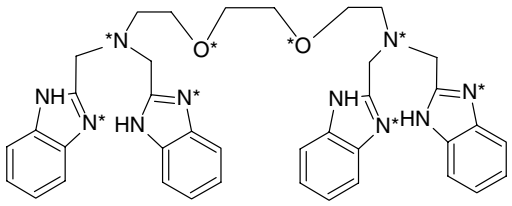
hydroxylation of monophenol to form *o*-diphenol and subsequent oxidation to *o*-quinone (as a catecholase) [2]. These reactions are of great importance in plant and animal defense systems and signal transfer, which are involved in cuticular melanizations such as coloration of skin and hair, sclerotization of exoskeleton and lignin formation. Recently, it was found that these play a pivotal role in the defense reactions of plants against insect, bacteria, fungi and virus attack and abiostresses [3]. The oxidation of phenols under mild conditions is also of great interest in industrial catalysis and for the degradation of aromatic compounds for environmental ecology [4]. Therefore, there has been sequential interest in the study of PPO model compounds. In this paper we report that the oxidation of pyrogallol and catechol is catalyzed by the model compounds $[Cu_2(EGTB)(H_2O)_2(ClO_4)_2](ClO_4)_2 \cdot 6H_2O$ (I) and $[Co_2(EGTB)Cl_2](ClO_4)_2 \cdot 5H_2O$ (II).



2. Experimental

2.1. Physical measurements

Elemental analyses for C, H and N were carried out on a Perkin–Elmer 2400. Electronic spectra were measured on a Shimadzu UV-265 spectrophotometer. The X-ray data for complexes I and II were collected on a Simens P4 and a Nonius Kappa CCD diffractomer, respectively. The structures were solved by direct methods and refined by least squares method on F^2_{obs} by using the SHELXTL-PC software package. Cyclic voltammetry (CV) was performed with a BAS-100 electrochemical analyzer on a conventional three-electrode cell, i.e., a glassy carbon electrode serving as the working electrode, a platinum wire as the counter electrode and an Ag/AgCl electrode as the reference. The supporting electrolyte, tetrabutylammonium perchlorate (TBAP), was recrystallized twice from methanol and dried overnight in a vacuum. The solvent *N*,*N*-dimethyl formamide (DMF) was sufficiently pure. Electrospray ionization (ESI) mass spectra were recorded on an API 2000 LC/MS/MS system.

2.2. Ligand synthesis

N,*N*,*N*′,*N*′-tetrakis(2′-benzimidazolylmethyl)-1,4-diethylene amino glycol ether (EGTB) was synthesized according to a similar method reported in the literature [5]. Ethylene glycol-bis-(β-aminoethylene)-*N*,*N*,*N*′,*N*′-tetraacetic acid (EGTA) and *o*-phenylenediamine (PDA) in a molar ratio of 1:4 were refluxed in glycol at 180 °C for 6–8 h until no water vapor was evolved. After cooling, a reddish crude product was precipitated by adding water, which was recrystallized a few times in ethanol, yielding a white power or colorless crystals.

EGTB

2.3. Synthesis of the complexes

EGTB (0.67 g, 1.0 mmol) and copper(II) perchlorate (0.74 g, 2.0 mmol) were, respectively, dissolved in methanol, and then were mixed. A blue precipitate formed after stirring at 50 °C for 5 h, and this was collected by filtration. This solid was dissolved in methanol and left standing for several days, yielding a blue crystal suitable for X-ray analysis. *Anal*. Calc. for $[Cu_2(EGTB)(H_2O)_2(ClO_4)_2](ClO_4)_2 \cdot 6H_2O$ (I) ($Cu_2C_{38}H_{56}N_{10}Cl_4O_{26}$): C, 36.02; H, 3.792; N, 11.06. Found: C, 36.47; H, 3.772; N, 11.24. UV–Vis [λ_{max}, nm (ε, $M^{-1}\,cm^{-1}$)] in MeOH: 271(24900), 671(233). CV data: $E_c = 0.026$ V, $E_a = 0.250$ V.

The complex $[Co_2(EGTB)Cl_2](ClO_4)_2 \cdot 5H_2O$ (II) was prepared by a similar method using $CoCl_2 \cdot 6H_2O$ and $NaClO_4 \cdot 6H_2O$ rather than $CoClO_4 \cdot 6H_2O$. *Anal*. Calc. for $Co_2C_{38}H_{50}N_{10}Cl_4O_{15}$: C, 45.60; H, 4.84; N, 14.00. Found: C, 45.57; H, 4.59; N, 14.01. UV–Vis [λ_{max}, nm (ε, $M^{-1}\,cm^{-1}$)] in DMF: 275(21860), 598(643). CV data: $E_a = 0.944$ V.

2.4. Measurements of polyphenol oxidase activities

The kinetics of the reactions were studied spectroscopically. Oxidative reactions of pyrogallol and catechol were carried out in methanol–Tris (i.e., trihydroxymethyl amino methane)–HCl buffer solution. The solution pH value and the reaction temperature were varied in the range 7.3–8.0 and 30–40 °C, respectively. Stock solutions of pyrogallol and catechol were prepared in 0.15 mM phosphoric acid to prevent autooxidation. The assay wavelength of pyrogallol and catechol oxidation were chosen to be 320 and 484 nm, respectively.

3. Results and discussion

3.1. The crystal structures

A summary of the crystallographic parameters and selected bond distances and angles of complex I are listed in Tables 1 and 2, respectively. The crystal structure is shown in Fig. 1. The coordination geometry

around each copper atom is distorted octahedral formed by three nitrogen atoms from the EGTB ligand and a coordinated water molecule in the basal plane, an EGTB ether oxygen and one perchlorate oxygen atom in the axial coordination sites. Cu–N(benzimidazole, bzim) bond lengths are 1.964(2) and 1.961(2) Å, Cu–N(amino) is 2.083(2) Å and the Cu–O(coordinated water) distance is 1.975(2) Å. Axial Cu–O bonds lengths are 2.4070(19) and 2.610(8) Å, which are significantly further away from the central Cu(II) ion than the planar oxygen and nitrogen atoms. Therefore, the axial bindings are weaker. The axial and other bond angles show, respectively, slight departure from 180° and 90°, so the coordination geometry of the copper is a long distorted octahedron. The Cu···Cu distance of the complex is 8.038(8) Å, which is too long to have binuclear coupling.

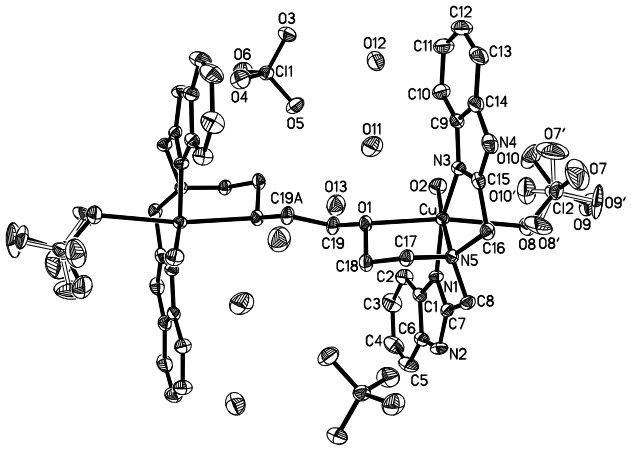

Fig. 1. ORTEP view of complex $[Cu_2(EGTB)(H_2O)_2(ClO_4)_2](ClO_4)_2 \cdot 6H_2O$ (CCDC No. 234479).

As shown in Fig. 2, each cobalt(II) center of complex II has a five coordinated trigonal bipyramidal geometry, which has been reported by us [6]. The average bond lengths of Co–N(bzim), Co–N(amino), Co–O(ether) and Co–Cl are 2.0325, 2.2844, 2.0845 and 2.2937 Å, respectively. The axial positions are occupied by the aliphatic amino nitrogen atom and the chloride ion. The Co···Co distance is 5.7138(10) Å, which is shorter than that of complex I. This internuclear distance may be in the range of negligible binuclear coupling [7].

3.2. CV data

The cyclic voltammogram (CV) of complex I contains a cathodic peak at 0.026 V and an anodic peak at 0.250 V, which are assigned to a two-electron redox process of $Cu(II)_2 \leftrightarrow Cu(I)_2$. For complex II, the $E_a = 0.944$ V is assigned to the oxidative peak of $Co(II)_2 \rightarrow Co(III)_2$.

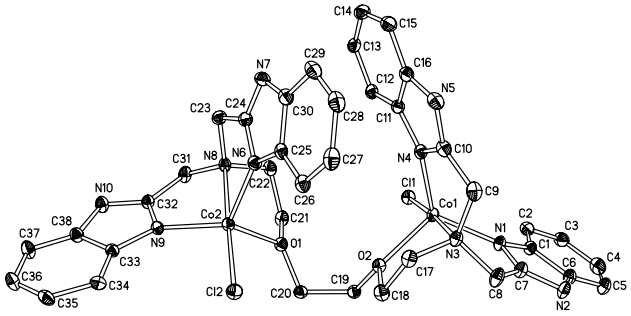

Fig. 2. ORTEP view of complex $[Co_2Cl_2(EGTB)]^{2+}$ (CCDC No. 176342).

Catechol and pyrogallol are sensitive to dioxygen in alkaline solution ($E = -0.23$ and -0.20 V versus SCE, respectively). They are easily oxidized to semiquinone and quinone. The anodic potentials of the two complexes are higher than that of the two substrates, therefore, the two complexes can oxidize catechol and pyrogallol.

3.3. Study on polyphenol oxidase activities

Assuming V_i is the initial velocity, it is found that V_i follows saturation kinetics with respect to substrate concentration [S]. At sufficiently low [S], a plot of V_i versus [S] is linear. When [S] becomes sufficiently high, the catalyst (here is model compound or mimetic enzyme, M) is saturated, the rate of reaction is zero-order and tends toward a limiting value, maximum velocity V_{max}. The kinetics is expressed quantitatively in the Michaelis–Menten equation.

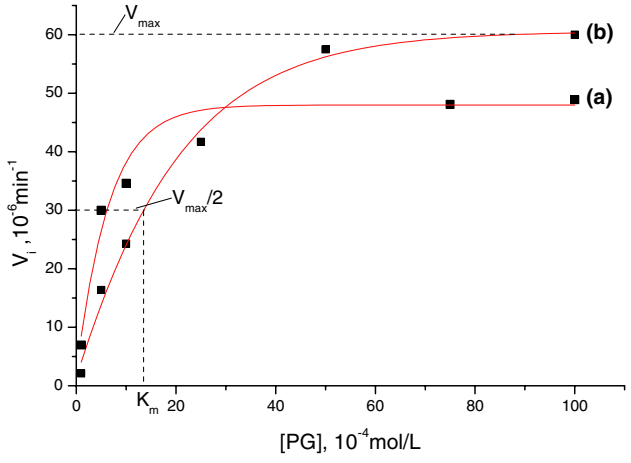

Fig. 3. Plot of initial rate V_i vs. [S]: (a) complex I; (b) complex II: [complex] = 2.5e(−5) mol/L, $T = 30$ °C, pH 8.0.

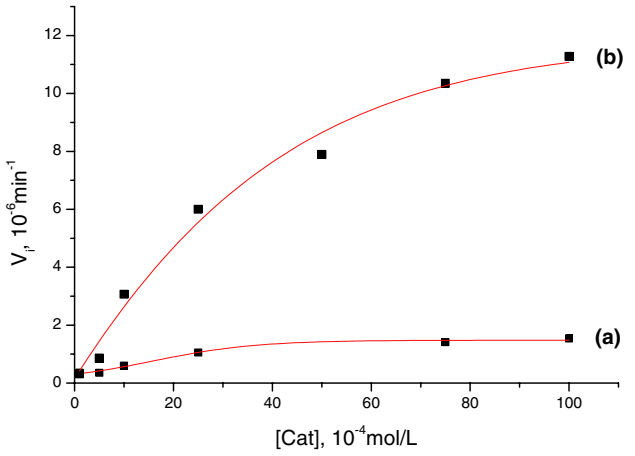

Fig. 4. Plot of initial rate V_i vs. [S]: (a) complex I; (b) complex II: [complex] = 1.0e(−4) mol/L, $T = 40$ °C, pH 8.0.

$$V = \frac{k_{cat}[M][S]}{K_m + [S]} = \frac{V_{max}[S]}{K_m + [S]} \quad \text{here } V_{max} = k_{cat}[M],$$

$$K_m = \frac{k_{-1} + k_2}{k_1} \text{ for reaction } M + S \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} MS \xrightarrow{k_2} M + P$$

where k_{cat} is the turnover number, that is the number of moles of substrate converted to product (P) per minute per mole of the model compound. It is a pseudo-first-order rate constant of catalyst–substrate complex MS conversion to products. K_m is the Michaelis constant, k_1, k_{-1} and k_2 are the rate constants for MS formation, dissociation and product formation, respectively.

By applying traditional the Michaelis–Menten approach, values of the kinetic parameters V_{max}, K_m, k_{cat} and k_{cat}/K_m were obtained from the corresponding plot of V_i versus [S] (see Figs. 3, 4 and Table 3). Here k_{cat}/K_m is an apparent constant. It is not a true microscopic rate constant except in the extreme case, in which the rate-determining step in the reaction is dependent on both of catalyst and substrate. For pyrogallol, $k_{cat} = 1.92$(I), 2.42(II) min^{-1} and $K_m = 0.43e - 3$(I),

Table 3
The kinetic data of complexes

Complex	Substrate	T (°C)	pH	k_{cat} (min^{-1})	V_{max} (10^{-6} mol L^{-1} min^{-1})	K_m (10^{-3})	k_{cat}/K_m (min^{-1})
Control	pyrogallol	30	8.0		0.2		
I			8.0	1.92	48.0	0.43	4465
			7.6	1.50	37.5	0.39	3846
			7.3	1.10	27.5	0.35	3142
II			8.0	2.42	60.5	1.34	1805
			7.6	1.72	43.0	1.28	1343
			7.3	0.33	8.25	1.07	308
Control	catechol	40	8.0		0.1		
I			8.0	0.018	1.8	2.15	8.4
			7.6	0.004	0.4	2.03	1.9
			7.3	0.002	0.2	1.98	1.0
II			8.0	0.117	11.7	2.77	42.2
			7.6	0.019	1.9	2.51	7.5
			7.3	0.015	1.5	2.47	6.1

1.34e − 3(II) at pH 8.0 and 30 °C for complex I and II, respectively. While for catechol, k_{cat} = 0.018(I), 0.117(II) min^{-1} and K_m = 2.15e − 3(I), 2.77e − 3(II) at pH 8.0 and 40 °C. In Michaelis–Menten kinetics, the experimentally determined value K_m is considered a constant and is characteristic of catalyst and substrate under specific conditions. It is an apparent dissociation constant and reflects the affinity of the catalyst for the substrate [8]. As described above, the rate constants k_{cat} toward pyrogallol catalyzed by complex II are higher than the corresponding values for complex I. Moreover, K_m (II) values are higher than K_m (I), which suggest that dissociation of MS leaving oxidative products for complex II is easier. Whereas for catechol oxidation, the K_m values are close to each other and the catalytic rate constant k_{cat} of complex I is much lower than that of complex II. This is due to looser unsaturated coordination of the cobalt ion and a short nuclear distance. Moreover, complex II can bind and activate oxygen molecules based on the appearance of an ultraviolet absorption peak at 320 nm, when O_2 was bubbled through a complex-DMF solution for 10 min at room temperature. This peak is assigned to the π^*_σ orbit of the peroxide ion $O_2^{2-} \rightarrow$ Co(II) $d_{x^2-y^2}$ LMCT (ligand to metal charge transfer) transition. However, complex I cannot directly bind and activate oxygen before reduction. A steric match between the substrate and complex is believed to require a close enough binuclear distance (2.9–3.6 Å) in a typical catalysis of binuclear copper tyrosinase, because the first step involves two nuclear bindings with two hydroxyl groups of catechol [9,10]. The lower activity of complex I shows that its binuclear distance is too long to catalyze cooperatively. Moreover, it is found that catalytic activities toward pyrogallol are much higher than those of catechol under the same conditions.

The oxidation rate constants increase with increasing pH values. The rate-determining step of the reactions is considered to be the first proton of a polyphenol being abstracted to form the corresponding semiquinones [11,12], hence, in the pH range 7.3–8.0, the higher the pH value, the better the activities.

3.4. Oxidative mechanisms

In order to approach the oxidative mechanism of pyrogallol (PG) and catechol (Cat), their oxidative products have been checked by ESI mass spectra in the positive mode (see Figs. 5 and 6). The oxidation mechanism of pyrogallol is supposed as shown in Scheme 1. Pyrogallol is first deprontonated and oxidized resulting in quinone(a), further it is followed by cyclo-opening and degradation to produce a formyl ion (m/z = 29) and methyl pentenate (b, m/z = 65) [13]. Then the cyclo-opened intermediate is condensed with a pyrogallol to form purpurogallin [14], which dimerizes to give a dimer (m/z = 436) by linking through hydrogen

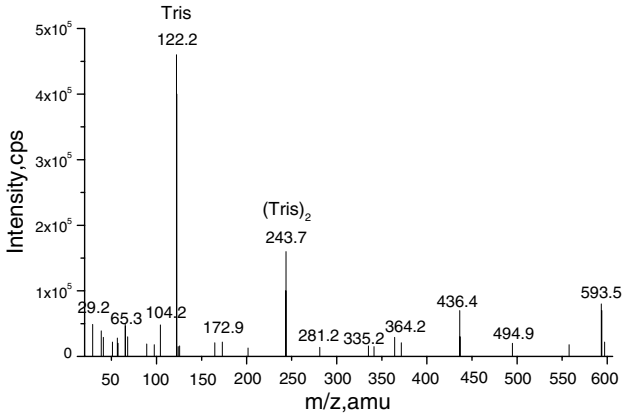

Fig. 5. ESI mass spectra of the oxidative products of pyrogallol catalyzed by complex I.

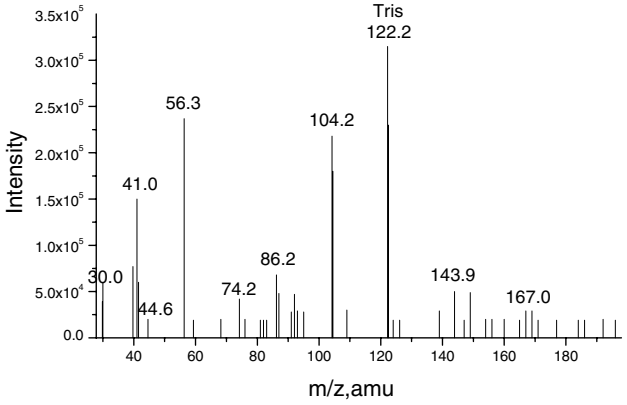

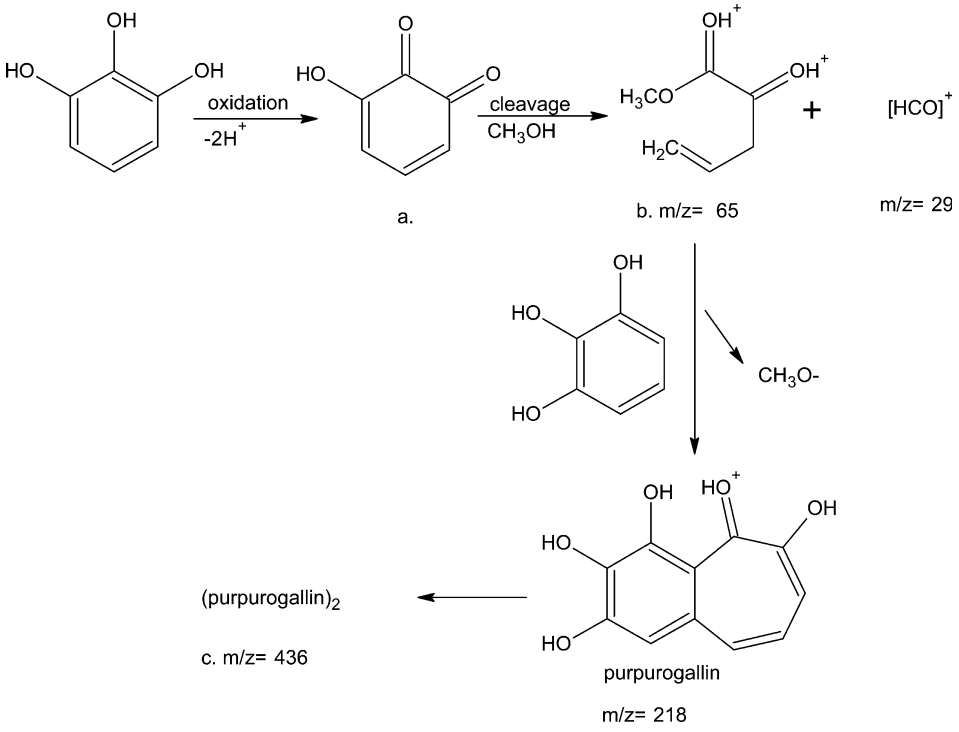

Fig. 6. ESI mass spectra of the oxidative products of catechol catalyzed by complex I.

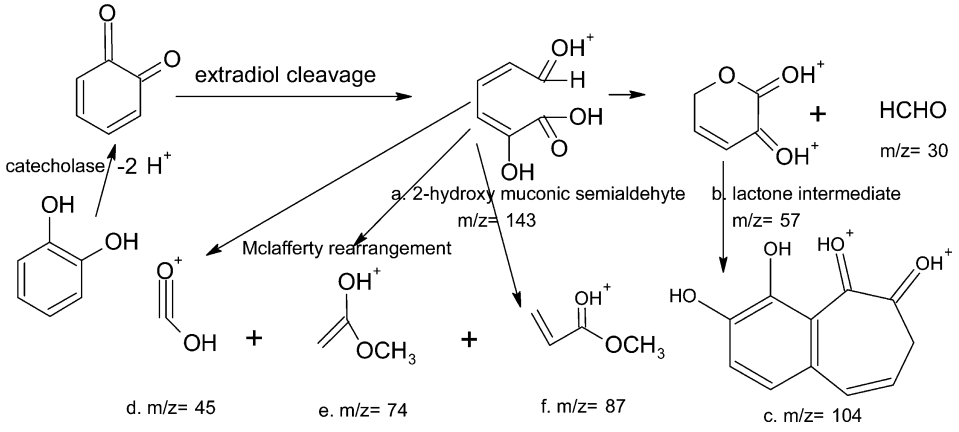

bonds. The molecular ion peaks at m/z = 594 and 495 might be assigned to $[(EGTB)Cu_2(H_2O)_2(ClO_4)_2(PG–O_2)]^{2+}$ and $[(EGTB)Cu_2(H_2O)_2(PG–O_2)]^{2+}$, respectively. Their existences indicate that pyrogallol oxidation may be companied with changes of the coordination structure and oxidative state of the copper ions, such as loss of a coordinated ClO_4^- and formation of a copper(I) complex ion.

The possible mechanism of catechol oxidation is shown in Scheme 2. The formation of *o*-quinone is similar to other reports [15,16], following it is the cyclo-opening which results in 2-hydroxy muconic semialdehyde (a, m/z = 143). It is followed by dehydration and cyclization, forming a lactone intermediate (b, m/z = 57) and formaldehyde (m/z = 30). Then the lactone intermediate is condensed with catechol to form a purpurogallinoid (m/z = 104). All of the processes are similar to the oxidation of pyrogallol. The molecular ion peaks at m/z = 45, 74 and 86 might be produced from the products of a McLafferty rearrangement [17].

The oxidative products of pyrogallol and catechol catalyzed by the two complexes are similar, which

Scheme 1. Proposed mechanism of pyrogallol oxidation.

Scheme 2. Proposed mechanism of catechol oxidation.

indicate that the catalytic mechanisms of the complexes are analogical, i.e., pass an extradiol mechanism [18]. The difference in mechanisms is the first hydrogen atom to be abstracted. For complex I, it may be an hydroxyl ion that abstracts the first proton of polyphenol. The hydroxyl ion is from dissociation of a coordinated water due to a hydrogen bonding interaction with perchlorate or the other water molecule. While complex II abstracts the proton using its bound and activated oxygen, which is a peroxide type ion and a stronger proton acceptor. Hence, the oxidative mechanism of polyphenol catalyzed by complex I is similar to that of the mononuclear non-heme tyrosinase rather than binuclear copper tyrosinase, while the catalytic mechanism of complex II is more similar to coupled binuclear copper tyrosinase.

4. Supplementary data

The crystallographic structural data of the two complexes have been deposited with the Cambridge Crystallographic Data Center as supplementary publication CCDC No. 234479 (I) and CCDC No. 176342 (II). Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@

NMR and UV spectroscopy is accomplished, in particular, the linear-dichroic infrared (IR-LD) spectral analysis is applied for the identification of the IR bands corresponding to the structural fragments of the 4-APH$^+$ imino-form. A spectral technique permitting the orientation of the solid samples as a liquid crystal suspension is applied for the measurements by IR polarized light.

2. Experimental

2.1. Synthesis

The complex salt 4-aminopyridinium tetrachloropalladate(II) ($[C_5H_7N_2]_2\cdot[PdCl_4]$) is prepared as follow: 5 ml methanol solution containing 0.8977 g 4-AP (Merck) and 0.0987 g $(NH_4)_2PdCl_4$ (Sigma), corresponding to a molar ratio Pd:4-AP = 1:1, was added to 5×10^{-1} M H_2SO_4 in the same solvent. From the thus produced orange solution, after 10 days brown crystals were obtained, which were filtered, washed with methanol and dried over P_2O_5 in air at 298 K. Yield: 34%. (*Anal.* Calc. for $[C_5H_7N_2]_2[PdCl_4]$: C, 27.3; H, 3.7; N, 12, 7; Cl, 32.2. Found: C, 27.2; H, 3.7; N, 12.8; Cl, 32.2%.) The most intensive signal in the mass spectrum of the protonated salt is the peak at *m*/*z* 95.01, characteristic of the singly charged 4-aminopiridinium cation (4APH$^+$) with a molecule weight of 95.01.

2.2. Methods

The IR spectra were measured on a Bomem-Michelson 100 FT-IR spectrometer (4000–400 cm^{-1}, ±2 cm^{-1} resolution, 150 scans) equipped with a Perkin–Elmer wire-grid polarizer. The non-polarized solid-state IR spectra were recorded using the KBr disk technique. The oriented samples were obtained as a suspension in a nematic 4′-cyano-4′-alkylbicyclohexyl mixture (ZLI 1695 in the Merck notation), mesomorphic at room temperature. The poor IR spectrum makes it possible to record the guest-compound bands in the whole 4000–400 cm^{-1} range. The presence of an isolated nitrile stretching IR band at 2233 cm^{-1} additionally serves as an orientation indicator. The effective orientation of the solid-state sample was achieved through the following procedure: about 5 mg of the compound studied was added to the appropriate liquid crystal substance until a slightly viscous mixture was obtained. The suspension thus prepared was pressed between two KBr-plates rubbed out in advance in one direction by means of fine sandpaper. The grinding of the prepared mull in the rubbing direction promotes an additional orientation of the sample [16,17].

The grounds of the IR-LD spectroscopy and in particular the *difference-reduction* procedure used for polarized IR spectra interpretation is described at length in [18–21]. It consists in subtraction of the perpendicular spectrum (IRs, resulting from 90° angle between the polarized light beam electric vector and the orientation of the sample) from the parallel one (IRp) obtained with a co-linear mutual orientation (Fig. 1). The recorded *difference* (IRp-IRs) spectrum (Fig. 1) divides the corresponding parallel (Ap) and perpendicular (As) integrated absorbancies of each band into positives originating from transition moments which form an average angles with the orientation direction (**n**) between 0° and 54.7° (magic angle), and negative ones corresponding to transition moments between 54.7° and 90°. As the next operation, the perpendicular spectrum, multiplied by the parameter **c**, is subtracted from the parallel one and **c** has to vary until up to a band or set of bands are eliminated. The simultaneous disappearance of bands in the obtained (IRp-cIRs) *reduced* IR-LD spectrum indicates a co-linearity of the corresponding transition moments, thus giving rise to information regarding the mutual disposition of the molecular fragments. This elimination method is graphically carried out using a subtracting procedure attached to the program for processing of IR spectra.

The ^{1}H NMR measurements were made at 298 K with a Bruker DRX-400 spectrometer using 5 mm tubes and D_2O as solvent. The chemical shift reference was sodium 3-(trimethylsilyl)tetradeuteriopropionate. The UV spectra (2.5×10^{-4} aqueous solutions, 1 cm quarz cell) were recorded on a Perkin–Elmer Lambda 15 UV–Vis spectrophotometer.

The X-ray diffraction intensities were measured on a Siemens P4 diffractometer equipped with Mo Kα radiation (λ = 0.71073 Å). The structure was solved by a direct method [22] and refined against – F^2 [23]. An ORTEP plot illustrates the anion and cation structures at the 50% probability level. Relevant structure data and refinement details are presented in Table 1, selected bond distances and angles – in Table 2. The hydrogen atoms were positioned on geometrical grounds in all shown structures.

The elemental analysis was performed by standard procedures for C and H (as CO_2 and H_2O), N by the Dumas method and Cl by titration with $Hg(NO_3)_2$ after wet digestion of the sample. The FAB mass spectra

3. Results

3.1. Crystal structure of $[C_5H_7N_2]_2\cdot[PdCl_4]$

The salt is formed by discrete groups consisting of the $PdCl_4^{2-}$ anion and two N_{py} protonated $C_5H_7N_2^+$ cations without appreciable Pd···N interactions (Fig. 2). The coordination around the Pd(II) ion is square planar with Pd–Cl(1) and Pd–Cl(2) bonds 2.2940(11) and 2.3073(14) Å, respectively. The corresponding Cl–Pd–Cl

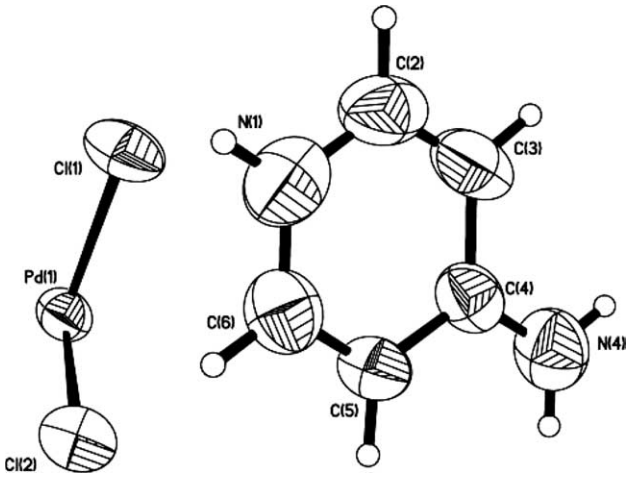

Fig. 2. ORTEP plot of $[C_5H_7N_2]_2[PdCl_4]$ with 50% thermal ellipsoids; hydrogen atoms are shown as spheres of arbitrary radii.

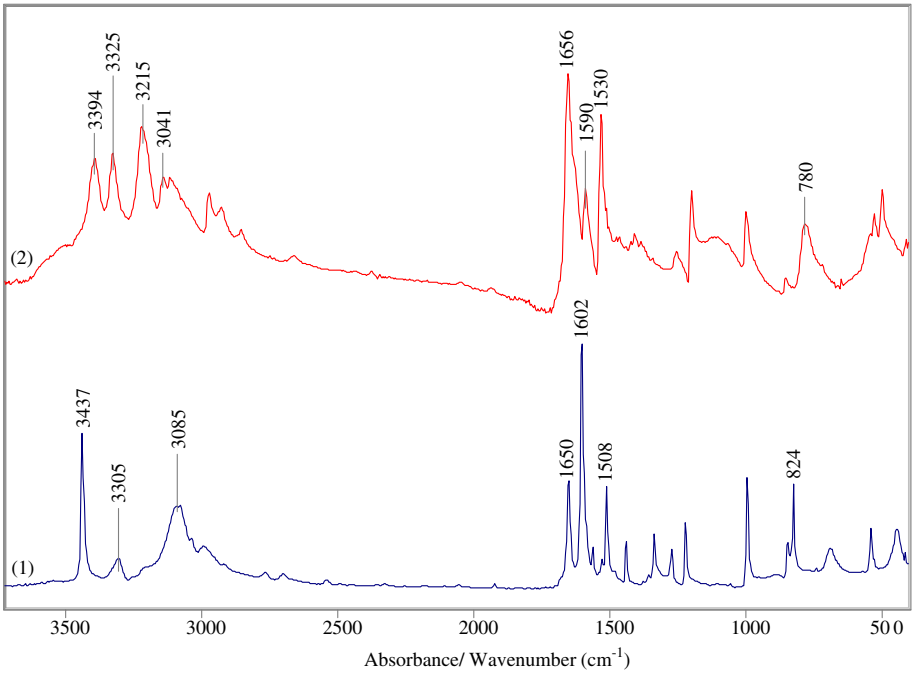
angles are 180.00°, 89.99(5)° and 90.01(5)° (Table 2). The data are similar to those observed for tetrachloropalladate(II) salts of similar organic compounds [13,14]. The corresponding distances and angles for $C_5H_7N_2^+$ (Table 2) are typical of the protonated forms of 4AP derivatives [13–15].

3.2. IR-LD spectral analysis

The IR spectral evidence about the aromatic character of the 4-AP pyridine ring is summarized in our previous papers [17,24]. The most typical features in this respect are the characteristic bands of the pyridine skeleton vibrations at 1602 and 1508 cm^{-1}, and the out-of-plane peak at 824 cm^{-1} (Fig. 3), signed according to Wilson notation [25] as 8a, 19a and 11-γ_{CH}, respectively. These bands are absent in the 4-aminopyridinium tetrachloropalladate(II) IR spectrum, instead three new peaks at 1590, 1530 and 780 cm^{-1} are at hand (Fig. 3). According to [9,10], the first two maxima correspond to mixed $\nu_{C=N+}$ and $\nu_{C=C}$-vibrations of the imino-form (Scheme 1). In the IR spectrum of 1-methyl 1,4-dihydro-4-imino-pyridine (Scheme 1), where this form is fixed, the maxima are observed at 1656 and 1542 cm^{-1} [10]. The band at 780 cm^{-1}, which in our case (Fig. 3) should be assigned to the $\gamma_{=CH}$ out-of-plane mode, exhibits at 806 cm^{-1} in the 4-aminopyridine hydrochloride spectrum [9,10].

To the NH_2-stretching bands in the solid IR of 4-aminopyridine belong the peaks at 3437 ($\nu^{as}{}_{NH_2}$) and 3305, 3085 cm^{-1} ($\nu^{s}{}_{NH_2}$), the doublet $\nu^{s}{}_{NH_2}$-band structure is Fermi resonance provoked as result of $NH\cdots N_{py}$ hydrogen bond formation [17,24]. The analogous maxima in the 4-aminopyridinium tetrachloropalladate(II) spectrum is observed at 3394 ($\nu^{as}{}_{NH_2}$) and 3325, 3120 cm^{-1} ($\nu^{s}{}_{NH_2}$). In this case the Fermi resonance splitting is probably caused by a $(H)N^+–H\cdots Cl$ hydrogen bond (with a $H\cdots Cl$ distance of 2.58 Å). The new band at 3215 cm^{-1} (Fig. 3) should be assigned to a ν_{NH}-vibration created by the protonated N_{py}–H bond (Fig. 2). With regards to the scissoring (δ_{NH_2}) band at 1650 cm^{-1} in the 4-AP spectrum (Fig. 2), the corresponding peak for tetrachloropalladate(II) salt is insignificantly high-frequency shifted to 1656 cm^{-1} (Fig. 3).



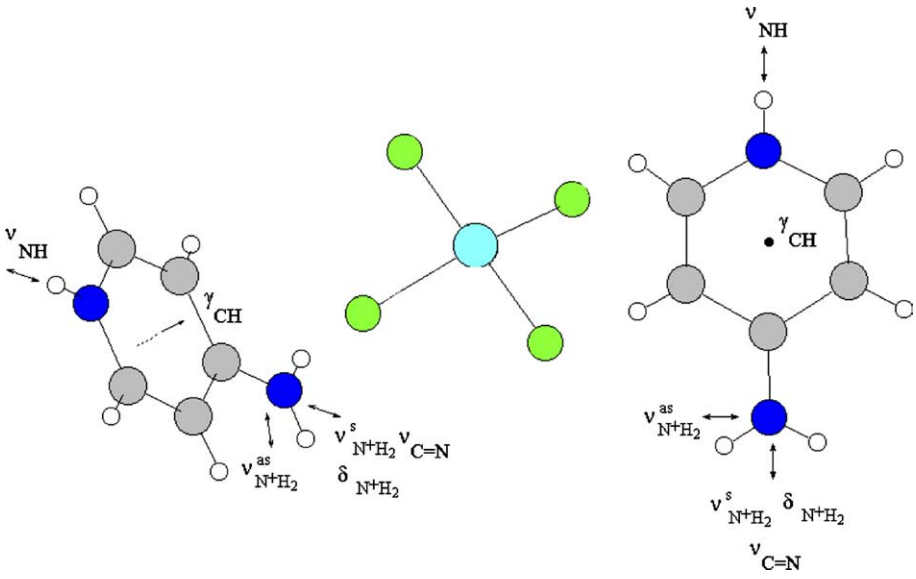


Fig. 3. 4000–400 cm^{-1} solid-state IR spectra of 4-aminopyridine (1) and the 4-aminopyridinium tetrachloropalladate(II) complex salt (2).

The assumed above-characteristic band assignment of the $4APH^+$ structural fragments is confirmed by IR-LD spectral analysis using the difference-reducing procedure described in the experimental part. However, the result interpretation is difficult due to of two different oriented $4APH^+$ moieties in the unit cell of the tetrachhloropalladate(II) lattice (see Table 1, respectively, Scheme 2). This supposed the presence of pairs of corresponding maxima as is shown in Fig. 4, containing the curve-fitted IR spectrum of the tetrachloropalladate(II) salt as a suspension in liquid crystal ZLI 1695. Expecting this precondition, the following results by means of a reducing procedure are obtained. The elimination of the δ_{N+H_2} intensive peak at 1645 cm^{-1} (Fig. 4) must provoke the disappearance of all bands belonging to the transition moments along same direction (Scheme 2). These are the doublet $\nu^s{}_{NH_2}$ band at 3323 and 3143 cm^{-1}, the ν_{NH}-maximum at 3222 cm^{-1}, and also the connected by mixed $\nu_{C=N+}$ and $\nu_{C=C}$-vibration bands at 1632, 1588 and 1532 cm^{-1} (Fig. 4). Simultaneously, the corresponding peaks of the other differently oriented $4APH^+$ cation (Scheme 2) of the same unit cell are revealed (Fig. 4)

Scheme 2.

3.3. ^1H NMR data

The suggested imino-tautomeric form of the compound studied is also obtained from ^1H NMR spectra in D_2O. The chemical shifts for the pyridine proton signals of 4-AP, belonging to C(3)H and C(2)H (Fig. 2) are at 6.92 (2H, q) and 8.04 (2H, q) ppm, respectively. The solution of the protonated salt shows two downfield shifted doublet peaks at 7.18 and 8.23 ppm, thus indicating a redistribution of the electron density. The last result is compared to the analogous data of the 4-AP/D_2SO_4 system, characterized by pairs of doublets at 8.44 and 7.22 ppm. The obtained chemical shifts are similar to the previous data of 4-AP salts [10,11] and other protonated aminopyridine derivatives [12].

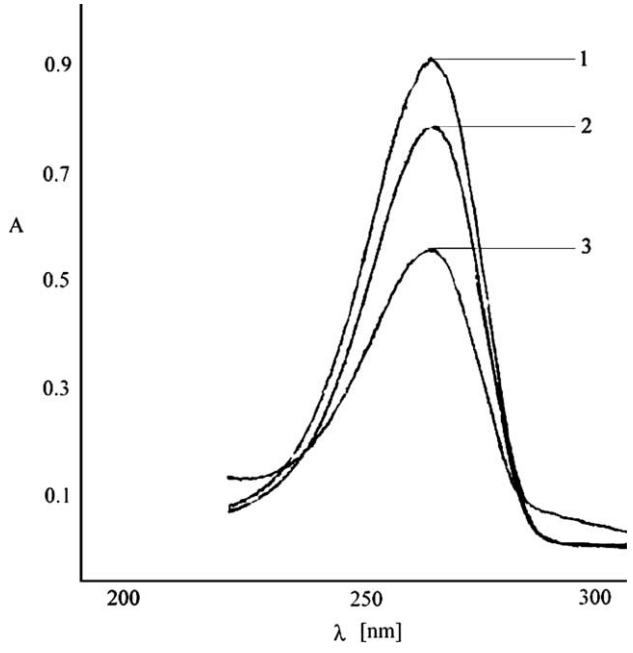

Fig. 6. UV spectra of 4-AP in 10% (1), 40% (2) and 98% H_2SO_4 (3).

3.4. UV spectra

In accordance to the data in the literature [10,12,26], the electronic spectrum of 4-AP shows two characteristic to pyridine aromatic system bands at 246 (ε = 11 056 l mol^{-1} cm^{-1}) and 264^{sh} nm (ε = 788 l mol^{-1} cm^{-1}) (Fig. 5). The spectrum of the protonated compound as an aqueous solution (Fig. 5) contains one broadband at 255 nm (ε = 10 460 l mol^{-1} cm^{-1}), also observed for solutions of neutral 4-AP in 10%, 45% and 98% H_2SO_4 (Fig. 6).

4. Discussion

The X-ray analysis of the 4-aminopyridinium tetrachloropalladate(II) complex salt directly confirms the previous theoretical and experimental data concerning the formation of the 4-AP cation through a proton attached to the ring nitrogen [7,8,13–15]. It is more complicated to reveal its electronic structure and the charge distribution within it. As it is stated above, our IR spectral results are in accordance with the conclusions published in [9,10] which suggest an imino-form stabilization in 4-aminopyridinium hydrochloride with a proton added to the exocyclic nitrogen (see Scheme 1). It is assumed that this charge location is due to the electron-donation effect of the amino group [9,10].

The conclusions thus discussed are grounded on the investigation of solid 4-aminopyridine salts. Like our results, the published ^1H NMR spectral data of solutions of 4-AP in D_2SO_4 or trifluoroacetic acid show a downfield shift for the signals of the pyridine hydrogens [10–12]. This effect is assumed as a redistribution of the electronic structure and a removal of the tautomeric equilibrium to the imino-form.

In this respect the UV spectral study of the 4-aminopyridinium tetrachloropalladate(II) complex salt requires particular discussion. As a rule the protonated aminopyridines are obtained as solutions in strong acids (most often H_2SO_4) and this procedure leads N_{py} monocations being obtained. However, dissolving in concentrated H_2SO_4 stabilized the dication structure and the corresponding effects in the aminopyridine UV and NMR spectra are examined in [10–12]. Although the problem is not clearly discussed, the authors suggest a 4-aminopyridinium monoprotonation in up to 80% H_2SO_4 and only 98% H_2SO_4 caused an additional protonation on the exocyclic nitrogen. Our previous study of the protonated 2-aminopyridine confirms these conclusions [27]. However, the UV spectra of 2-aminopyridinium sulfate dissolved in 10% H_2SO_4 are very close to those of the non-charged 2-aminopyridine, both

exhibiting two maxima at about 230 (π-band) and 290–305 nm range (α-band) [27]. This result indicates a preservation of the aromatic character of the pyridine ring. In concentrated H_2SO_4 2-aminopyridinium sulfate shows only one band at 258 nm ($\varepsilon = 5600\ l\ mol^{-1}\ cm^{-1}$) and this effect is not explain by the formation of the imino-structure, but by eliminations of the n–π conjugation and hypsochromic shift of the π-spectral band, both as a result of the blockage of the amino nitrogen [27] (see also [11]).

The UV spectral data of the 4-aminopyridinium tetrachloropalladata(II) complex salt are different. Its UV spectrum in 0.1 M aqueous solution (equivalent to solution in 40% H_2SO_4) exhibits only the broadband at 255 nm ($10\,460\ l\ mol^{-1}\ cm^{-1}$) (Fig. 5), like the same results obtained for solutions in H_2SO_4 irrespectively of the acid concentration (Fig. 6). The parameters of this absorption maxima are typical for the imino-forms and are very near to those of 1-methyl-1,4-dihydro-4-imino-pyridine (Scheme 1) and 1-methyl-4-amino-pyridinium salts [10,26].

All the presented data assumed a stabilization of the imino-form of the protonated 4-AP in the solid state as well as in solution. These data correlated well also with the known theoretical ones [9,10], also indicating positive charge location on the NH_2-group and stabilization of the thus experimental confirmed imino-form after N_{py}-protonation. Next a more detailed comparative structural investigation of protonated aminopyridines and their derivatives should additionally confirm the conclusions thus suggested.

5. Supplemental materials

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC 220756. Copies of this information may be obtained from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

coordination spheres of transition metal ions allows control of the molecule forms and shapes, thus providing selectivity for complexation of isoxazolidine species. The literature precedents for a tetrahedral intermediate consisting of the catalyst with the nitrone around a copper–metal center [7], and a trigonal bipyramidal geometry for the transition structure of a Ni–substrate complex [8] may allow the interpretation of the observed selectivity and it indicates the dependence of catalytic efficiency on the coordination environment at the metal center of the catalyst. However, the ligand properties of the isoxazolidines themselves remain very scarcely investigated [9–11] and some of the isolated species involve only a non-coordinated isoxazolidine frame [12–14].

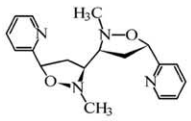
Even more versatile possibilities are offered by biisoxazolidines, new objects possessing a doubled number of chiral centers. Four adjacent N,O-heteroatoms of the biisoxazolidine frame, especially in combination with donor atoms of functionalized substituents (cf. pyridyl) offer various coordination possibilities for either five- or six-membered chelation of metal ions as well as different monodentate coordination modes. The ability of aryl pendants to afford different π,π-stacked arrays could also be involved in controlling the molecular conformations. In this paper we report experimental details for the synthesis of 3,3′-biisoxazolidines species and a set of metal complexes, targeted to validate their coordination behaviour.

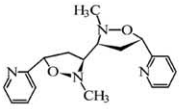
2. Results and discussion

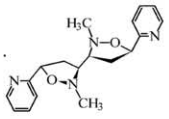
2.1. Synthesis and structure of the ligands

Glyoxal *N*-methylnitrone readily undergoes 3 + 2 1,-3-dipolarophil cycloaddition reactions with styrene and 2-vinylpyridine under mild conditions yielding complicated mixtures of the products. Addition of acetone or 2-propanol into a mixture of the stereoisomeric adducts promotes crystallization of the most symmetrical *cis*-,*cis*-isomer in a pure form that was used for preparation of the coordination compounds. Thus, we will conditionally omit the *cis*-,*cis*-notation for this configuration of the 3,3′-biisoxazolidines and metal complexes thereof.

(mixture of stereoisomers)







Ar = 2-Py (L^1); Ph (L^2)

Unfortunately, ultraviolet and IR spectroscopy were of little diagnostic value to establish the structure of the biisoxazolidines and to identify the coordination mode of the ligands in the metal complexes. NMR measurements remain most applicable for this purpose and gave abundant information. The positions of the C-5 proton signals at δ 5.1–5.4 ppm as doublet of doublets with close vicinal coupling magnitudes (L^1: $J_{5,4}$ = 8.8 Hz, $J_{5,4'}$ = 8.4 Hz; L^2: $J_{5,4} = J_{5,4'}$ = 8.0 Hz) demonstrate high regioselectivity of the reactions and in turn the formation of a five-substituted isoxazolidine ring. This agrees well with the fact that the direction of dipolarophil cycloaddition is sensitive to the functionality of the dipolarofile (electron withdrawing or donating substituent near the terminal carbon atom) [1,15]. Attribution of H^4 and $H^{4'}$ signals in the spectrum of L^1 was provided by the literature data suggesting that $J_{cis} > J_{trans}$ [1]. Therefore, the signal centered at δ 2.49 ppm corresponds to H^4, while the signal at δ 3.01 ppm corresponds to $H^{4'}$. This observation may be extended for other types of biisoxazolidines. The similarity of the chemical shifts for *cis–cis*-isomers of L^1 and L^2 indicate the close resemblance of the structural features of the compounds. For L^1 the mixture of *cis–trans*- and *trans–trans*-isomers was separated by chromatography on silica gel. The data of ^{1}H NMR spectra gave a possibility to suggest the structure of the biisoxazolidine isomers (Table 1).

The biisoxazolidines crystallize in centrosymmetric space groups and thus the crystal lattices comprise both RSRS and SRSR stereoisomers of the ligands that are related by a crystallographically imposed center of inversion. Compounds L^1 (**1**) and L^2 (**2**) are not isomorphous owing to a different manner of supramolecular aggregation in the crystals (Figs. 1 and 2). Molecules L^2 pack in chains with a set of very weak C–H/π hydrogen bonds ("edge-to-face stacking") [16] between phenyl pendants (H···π 2.84 Å; ∠CH···π 149°), while structure of supramolecular chains in the 2-pyridyl derivative L^1 is supported by a weak slipped π,π-stacking [17] of aromatic groups (Table 2).

The molecular geometries of the biisoxazolidines L^1 (**1**) and L^2 (**2**) are closely related. In both cases the isoxazolidine ring has an envelope conformation. The mean deviation of the atoms from the corresponding mean plane is very similar in both cases and it is approximately 0.153(8) Å. The largest deviation has N1 0.243(8) Å for L^1 and 0.236(2) Å for L^2. The pyridine group is located synclinal with the C3–C4 bond (dihedral angle 68.5°). At the same time the dihedral angle between the planes of the phenyl and isoxazolidine rings is 103.9°, that also corresponds to their synclinal situation. The organic frames possess a *cis–cis*-configuration and the molecules adopt a centrosymmetric structure with two equivalent (aryl)isoxazolidine parts related by a center of

inversion (Fig. 1). Thus, the torsion angles N1–C2–C2a–N1a of $\varphi = 180°$ reflect a *trans*-conformation that is not favorable for *N*,*N*-chelate coordination of the biisoxazolidines in metal complexes.

This solid-state geometry of the organic frame agrees well with a semiempirical computational study applying the AM-1 method [18]: the optimal conformation of L^1 molecule is at $\varphi = 180°$ (Fig. 3). However, the relative energies for local minimums corresponding to two *gauche* conformers with φ at ±62–63° are very similar ($\Delta E = 11$ kJ mol$^{-1} \approx 3RT$) and the energy barriers between these three favorable molecule conformations do not exceed 43 kJ mol^{-1}, reflecting ease of rotation around the central C^3–C^3 bond. The energy maximum that occurs at $\varphi = 42°$ corresponds to a maximal interference of *N*-methyl substitutes, the energy barrier between two *gauche* conformations, 73 kJ mol^{-1}, is comparable to the parameter for rotation around a C–N bond in dimethylacetamide ($\Delta E = 75$ kJ mol^{-1}) [19]. The *gauche* conformation N–C–C–N is typical for aliphatic moieties forming five-membered chelates, i.e., ethylenediamine, and thus the calculation suggests conformational flexibility of the biisoxazolidines and their utility as *N*,*N*-chelating ligands in coordination compounds.

2.2. Coordination compounds

^{1}H NMR spectra for the iridium(III) complexes were of use for primary assignment of the coordination modes of the ligands. Thus, NMR spectra of the complex [Cp*Ir(L^2)Cl]Cl feature low-field shifts of almost all the isoxazolidine resonances, excepting $H^{4'}$ signals, as may be compared with data for the non-coordinated ligand. The largest deshielding was observed for H^3 and CH_3 protons ($\Delta\delta$ 1.35 and 0.92 ppm, respectively) that appear to be most closely situated to the nitrogen donor centers, and this indicates bidentate-chelate coordination of the ligand (compare with molecular structure **3**)

In the ^{1}H NMR ($CDCl_3$, 20°) spectrum of [(Cp*$IrCl_2$)$_2${L^1}], the relative intensities for CH_3 signals of Cp* and biisoxazolidine ligands (5:1) are in agreement with the binuclear structure. Significant deshielding for the α-Py proton (δ 8.90 ppm) clearly indicates coordination via the pyridine nitrogen donor and this is also consistent with a low field shift of the H^5 signal as may be compared with the spectrum of L^1 ($\Delta\delta$ 0.28 ppm). The CH_3 and H^3 resonances, which are most sensitive to the coordination of the isoxazolidine-N donor, in the present case remain almost unaffected. Thus, the spectra reflect a bidentate-bridging coordination of the ligand, employing only pyridine-N functions. This conclusion agrees with the NMR spectral assignment of mono-/bidentate coordination modes of 2-methyl-3-ferrocenyl-5-(2-pyridyl)isoxazolidine in palladium chloride complexes [9,10]. However, broadening of α-Py, H^5 and H^3 signals may be suggestive of certain dynamic

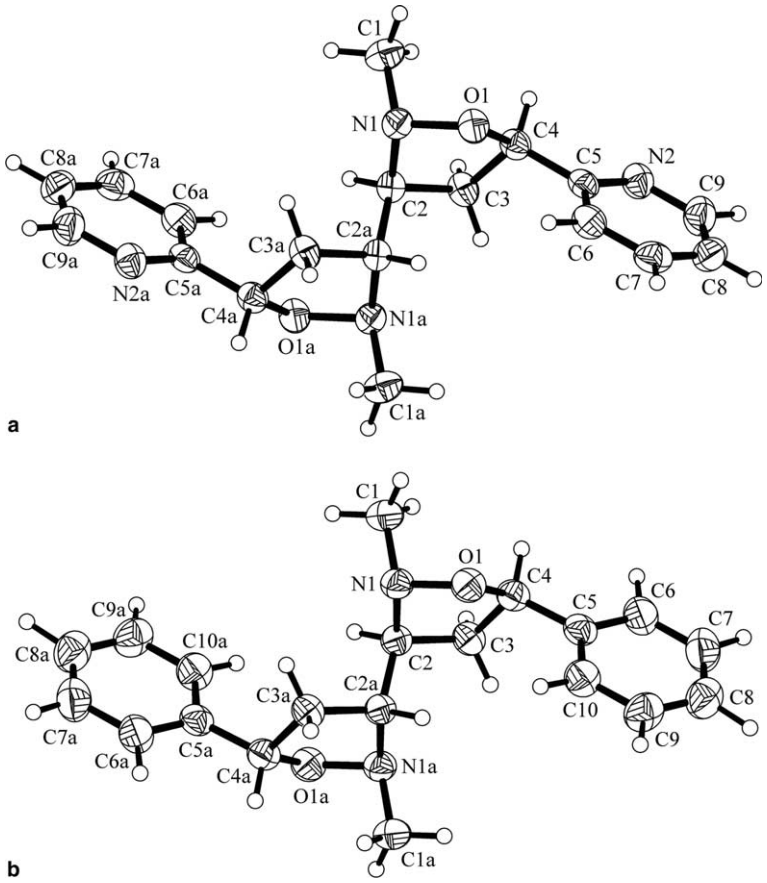

Fig. 1. Molecular structure of biisoxazolidines L^1 (Ar = 2-Py; a) and L^2 (Ar = Ph; b) showing the atom labelling schemes. Thermal ellipsoids are at the 50% probability level. For L^2 only one of the two independent molecules is shown.

processes in the solution which could include elimination of the chloride ligand from the coordination sphere and formation of iridium pyridyl/isoxazolidine chelates. For 2-methyl-3-phenyl-5-(2-pyridyl)isoxazolidine, involving "half" of the L^1 functionality, we were able to stabilize such a coordination mode by replacement of one chloride ligand with a non-coordinating BPh_4^- anion [9].

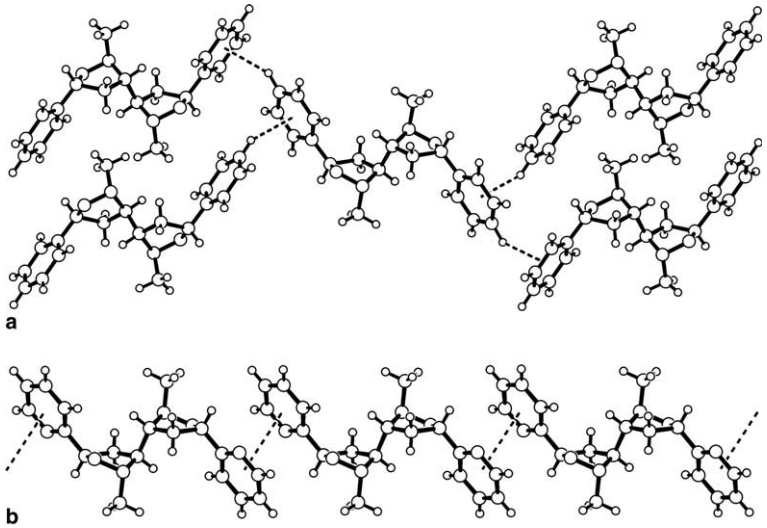

Fig. 2. Supramolecular structure of the biisoxazolidines, which is dominated by CH/π hydrogen bonding for L^2, Ar = Ph (a), and by π,π-stacking between pyridyl groups for L^1 (b).

Table 2
Geometry of π,π-stacking interactions[a]

Compound	Group 1/group 2	ipd (Å)	ccd (Å)	sa (°)
L^1 (**1**)	[N2, C5-9]/[N2, C5-9] (1 − *x*, −*y*, 2 − *z*)	3.462(5)	3.869(4)	26.5(1)
$Cu\{L^2\}Cl_2 \cdot CHCl_3$ (**3**)	(C9-14)/(C9-14) (1 − *x*, −*y*, −*z*)	3.674(6)	4.105(4)	26.5(1)
$[Ni\{L^1\}(H_2O)(NO_3)](NO_3)$ (**4**)	(N4, C14-18)/(N4, C14-18) (−*x*, −*y*, −*z*)	3.385(4)	4.015(4)	32.5(1)

[a] ipd is the interplanar distance (distance from one plane to the neighboring centroid), ccd is the center-to-center distance (distance between ring centroids) and sa is the slippage angle (angle subtended by the intercentroid vector to the plane normal) [17]. In each case the interacting aryl groups are related by inversion and their planes are parallel.

2.3. Crystal structure of the metal complexes

The copper(II) chloride complex $Cu\{L^2\}Cl_2 \cdot CHCl_3$ (**3**) represents a molecular chelate formed by coordination of two isoxazolidine nitrogen atoms to a metal center at typical distances of 2.009(3) and 2.053(3) Å (Table 3, Fig. 4). The organic frame adopts the same configuration as in the structure of the non-coordinated ligands **1** and **2**, while a suitable for chelate function conformation of the molecule is provided by rotation around the 3,3′-carbon–carbon bond. The torsion angle N1–C1–C5–N2 (−52.8°) corresponds to a *gauche* conformation versus centrosymmetric *trans*-conformation for **1** and **2**. A comparable geometry of the chelate fragment was observed for closely related zinc chloride complexes with 2,2′-bipyrrolidine ligands (NCCN −52.8°, NMN 86.9° versus 85.7° for **3**) [20]. The distorted tetrahedral environment of the copper ions is completed with two chlorine atoms situated at 2.203(1) and 2.231(1) Å. Two *N*-methyl groups lie in *cis*-positions in the chelate plane and their steric effect precludes the characteristic dimerization of the complex moieties by secondary Cu···Cl interactions seen in the related structure of the 2-methyl-3-phenyl-5-(2-pyridyl)isoxazolidine ligand [21]. Therefore, there is an evident lack of strong intermolecular interactions and the crystal structure is sustained with a set of weaker slipped π,π-stackings (Table 2) and C–H/π hydrogen bonds (H···π 3.22 Å; ∠CH···π 141°) between the phenyl groups. These interactions arrange the molecules into supramolecular hexa-

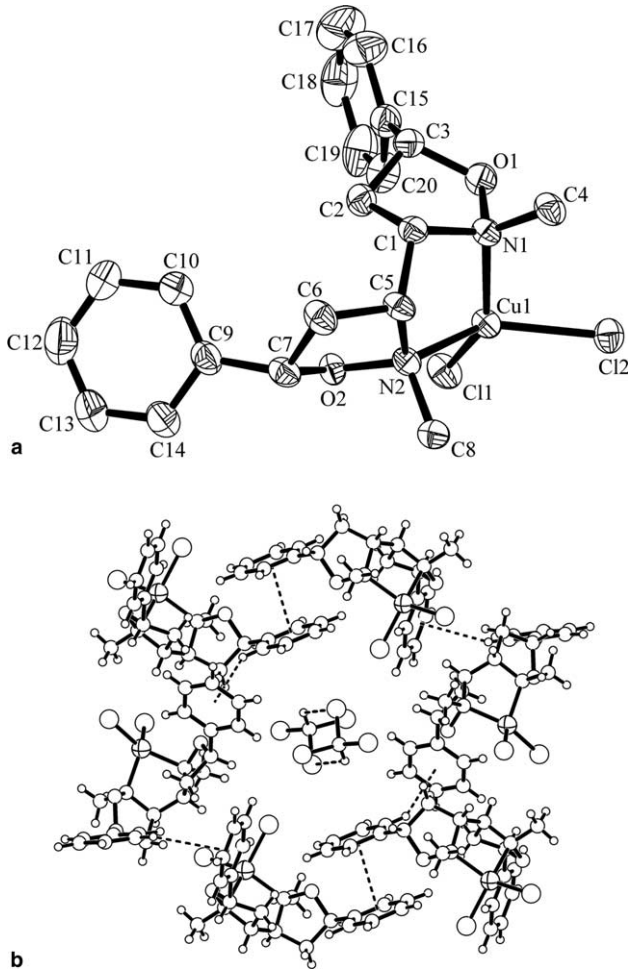

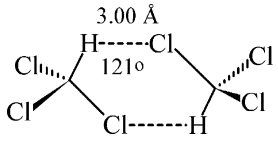

Fig. 4. Molecular structure of the $Cu\{L^2\}Cl_2 \cdot CHCl_3$ (**3**) complex with 50% thermal ellipsoids and the hydrogen atoms omitted for clarity (a); association of $Cu\{L^2\}Cl_2$ molecules into supramolecular hexagons with extensive CH/π hydrogen bonding and π,π-stackings between the phenyl groups and immobilization of a CH···Cl bonded chloroform dimer inside the cage (b).

gons possessing a large internal cavity with inner dimensions 4 × 5 Å [22]. The cage is populated with a hydrogen bonded (CH···Cl 3.58 Å) dimer of chloroform molecules (Fig. 4(b)). Such self-association of chloroform guests held inside the large host voids was observed also for other lattice clathrates [23].

2-Pyridyl functionalized ligand L^1 provides a greater number of possibilities for chelation of metal ions, involving tridentate bis-chelate functions. Therefore, we have examined a complex of the nickel(II) ion that

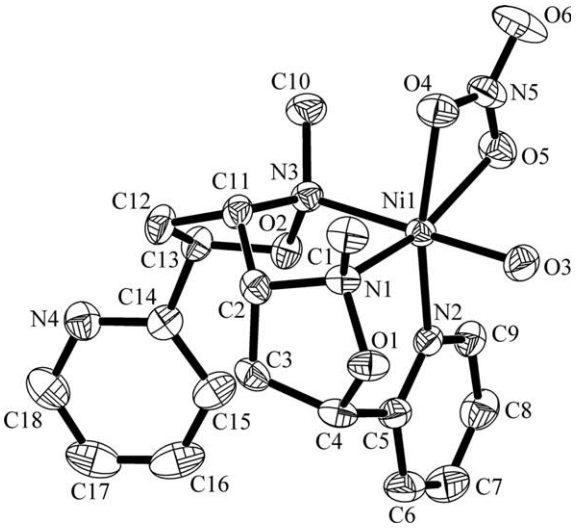

Fig. 5. Structure of the complex cation in $[Ni\{L^1\}(H_2O)(NO_3)]NO_3$ (**4**), with 45% ellipsoids and hydrogen atoms omitted for clarity. Note the facial arrangement of three nitrogen donors within the coordination octahedron and the nearly orthogonal disposition of two pyridyl cycles supporting weak C(15)–H/π hydrogen bonding.

typically supports an octahedral coordination geometry, suitable for a facial arrangement of three nitrogen donors within the coordination sphere. In the $[Ni\{L^1\}(H_2O)(NO_3)]NO_3$ (**4**) complex the ligand wraps around the central atom forming two chelate cycles (Table 3, Fig. 5). Both isoxazolidine nitrogen donors are engaged into coordination forming a five-membered chelate cycle and an additional donor site is provided by one of the 2-pyridyl groups. Thus, three nitrogen atoms occupy MN_3 facial positions in the coordination octahedron, which is a rare feature of flexible tridentates as may be compared with geometrically rigid complexes of 1,4,7-triazacyclodecane [24]. The coordination mode of the organic ligand demonstrates high flexibility of biisoxazolidines and their adaptibility to the coordination preferences of the metal ions. The torsion angle N1–C2–C11–N3 46.8° corresponds to a *gauche* conformation, similar to the one observed for complex **3**. A weak intramolecular C–H/π hydrogen bond between two pyridyl groups (H···π 2.96 Å; ∠CH···π 160°) may also contribute to the stabilization of the ligand conformation (Fig. 5).

The shortest Ni–N separations (2.03 Å) are observed within the six-membered chelate fragment involving pyridyl and isoxazolidine donors, while the coordination interaction with the second isoxazolidine group is slightly weaker (2.14 Å). The distorted octahedral environment of the nickel ions is completed with oxygen atoms of a bidentate nitrate group and of a water molecule. The nitrate ligand is coordinated in an actually isobidentate fashion (Ni–O 2.09 and 2.12 Å), similarly to one found for the *mer*-N_3 octahedral aquanickel(II)

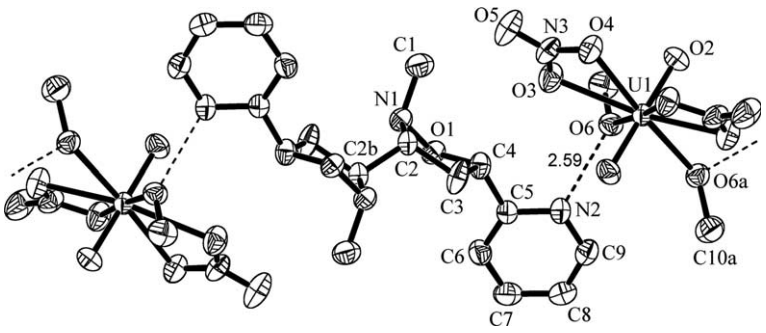

Fig. 6. Fragment of the supramolecular chain in the structure of the adduct $[UO_2(CH_3OH)_2(NO_3)_2]\cdot L^1$ (**5**) employing the centrosymmetric biisoxazolidine molecule as a hydrogen bond acceptor. The ellipsoids are drawn at the 50% probability level and hydrogen atoms are not shown.

nitrate complex with a macrocyclic nitrogen tridentate [25]. The lattice consists of cationic metal–organic complexes $[Ni\{L^1\}(H_2O)(NO_3)]^+$ and non-coordinated nitrate anions. The cations are associated into chains by means of OH···N hydrogen bonds (O···N 2.79 Å, ∠OH···N 175°) involving the non-coordinated pyridyl nitrogen atom and hydrogen atoms of aqua ligands. Weak intermolecular π,π-stacking interactions between these non-coordinated 2-pyridyl groups (Table 2) are also important for the crystal packing.

3,3′-Biisoxazolidine ligands do not form stable coordination compounds with p- and f-block metal ions, though they can afford molecular adducts acting as a hydrogen bond acceptor. Thus, 3,3′-biisoxazolidine (L^1) easily cocrystallizes with uranyl nitrate yielding $[UO_2(CH_3OH)_2(NO_3)_2]\cdot L^1$ (**5**). This associate involves molecular bis-methanol uranyl nitrate moieties and non-coordinated organic ligands (Fig. 6). The uranium atoms have a typical hexagonal bipyramidal eight-fold coordination constituting of two isobidentate nitrate groups (U–O 2.524(4), 2.529(4) Å) and two *cis*-situated methanol molecules in the equatorial plane. This molecular moiety $[UO_2(CH_3OH)_2(NO_3)_2]$ is an unprecedented feature of uranyl nitrate chemistry, as in all known 1:2 uranyl nitrate adducts the neutral ligands are *trans*-situated, for example in $[UO_2(THF)_2(NO_3)_2]$ [26]. The methanol ligands provide hydrogen bond donor sites for interaction with entrapped biisoxazolidine molecules. The latter ones adopt a most symmetrical conformation that is similar to the one observed in structures **1** and **2**, with two identical parts of the molecule related by inversion. The relatively strong OH···N hydrogen bonds (O···N 2.59 Å; ∠OH···N 157°) with 2-pyridyl nitrogen acceptors unite the molecular components into zig-zag chains. Such a discrimination of the isoxazolidine-N versus pyridine-N acceptor sites is predetermined by steric availability and higher basicity of the pyridyl functions. This hydrogen bonded isoxazolidine pattern possibly may be involved also as a model for the bidentate-bridging coordination of the ligand in the $[(Cp^*IrCl_2)_2\{L^1\}]$ complex.
