Scheme 1.

lead to the development of a series of spin 1/2 ladder systems [5].

Magneto-structural studies in dimeric $A_2Cu_2X_6$ compounds have been researched extensively in the past [6]. These compounds generally form stacks or chains of $Cu_2X_6^{2-}$ dimers based on the formation of two or one semi-coordinate bonds between adjacent dimers. The discussion of exchange pathways in these studies has focused on the through-bond pathways, i.e., intradimer and intrachain/stack interactions. Unfortunately, the discussion of the role of the close halogen–halogen (2H) contacts within these dimer structures has generally been ignored [7]. However, recently, two neutron scattering studies in $A_2Cu_2Cl_6$ salts have shown that the 2H pathways are stronger than the intrachain/stack interactions [8]. Since this is true in chloride salts, it is expected that the 2H pathway will play an even more significant role in bromide salts.

In this paper, we reexamine the structural and magnetic behavior in the $(MOR)_2Cu_2X_6$ compounds [9], where MOR denotes the morpholinium cation. The extended stack or chain structure is not assumed by these compounds since an oxygen atom on the morpholinium cations occupies one of the semi-coordination sites on each copper atom in the dimeric species, blocking the second semi-coordinate site (Scheme 1). Instead, N–H···X hydrogen bonds force short X···X contacts between dimers, forming non-bonded magnetic exchange pathways so that the compounds behave as alternating AFM chains. In this study, the structural and magnetic properties of both the $(MOR)_2Cu_2Cl_6$ and $(MOR)_2Cu_2Br_6$ end members are reexamined and the extension to a series of mixed $(MOR)_2Cu_2Cl_xBr_{6-x}$ compounds is reported.

2. Experimental

2.1. Synthesis

2.1.1. *(Morpholinium)$_2$Cu$_2$Cl$_6$, (MOR)$_2$Cu$_2$Cl$_6$ (**1**)*

Morpholinium hydrochloride (0.494 g, 4 mmol) and copper chloride dihydrate (0.682 g, 4 mmol) was added to a mixture of 5 mL conc. hydrochloric acid, 5 mL 2-propanol, and 5 mL water. The acidic solution was allowed to stir for 10 min. The red, pleochroic, nearly opaque crystals were collected after several days of evaporation, washed with 2-propanol, and allowed to dry.

2.1.2. *(Morpholinium)$_2$Cu$_2$Br$_6$, (MOR)$_2$Cu$_2$Br$_6$ (**9**)*

Morpholinium hydrobromide (0.672 g, 4 mmol) and copper bromide (0.893 g, 4 mmol) was added to a mixture of 5 mL conc. hydrobromic acid, 5 mL 2-propanol, and 5 mL water. The acidic solution was allowed to stir for 10 min. The violet, pleochroic, nearly opaque crystals were collected after several days of evaporation, washed with 2-propanol, and allowed to dry.

2.1.3. *(Morpholinium)$_2$Cu$_2$Cl$_{6-x}$Br$_x$, (MOR)$_2$Cu$_2$Cl$_{6-x}$Br$_x$ (**2**–**8**)*

The compounds were synthesized by combining the appropriate ratio of morpholinium hydrochloride/morpholinium hydrobromide (4 mmol total) salts and $CuCl_2 \cdot 2H_2O/CuBr_2$ (4 mmol total). This was added to a mixture of the appropriate ratio of conc. hydrochloric/hydrobromic acid (5 mL total), 5 mL 2-propanol, and 5 mL water. The acidic solution was allowed to stir for 10 min. The red-violet, pleochroic, nearly opaque crystals were collected after several days of evaporation, washed with 2-propanol, and allowed to dry. Yields of 25–50% were obtained, depending upon the amount of solvent that was allowed to evaporate.

2.2. X-ray crystallography

Crystals were attached to a glass fiber using glue. Datasets were collected at 293(2) K using a Bruker/Siemens SMART 1K instrument (Mo Kα radiation, $\lambda = 0.71073$ Å). Data were measured using omega scans of 0.3° per frame for 30 s, and a half sphere of data was collected. The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved using SMART [10] software and refined using SAINTPLUS [11] on all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPLUS software. Absorption corrections were applied using SADABS [12]. The structures were solved by direct methods and refined by least squares method on F^2 using the SHELXTL program package [13]. No decomposition was observed during data collection. Structure refinements were straightforward in both cases and no disorder was observed. Data collection parameters are given in Table 1 and significant bond distances and angles given in Table 2. Fig. 1 illustrates the contents of the asymmetric units of both salts, augmented to show the coordination geometry of the Cu(II) ions. Further details are provided in the Supporting Information.

The mixed halide salts all crystallize with the monoclinic $(MOR)_2Cu_2Br_6$ structure. Crystallographic data were collected on samples from seven different preparations (Samples **2**–**8**). The fractional occupancy for each of the six halide sites was varied independently. Consistent results were obtained between two refinement procedures: the first where the Cl and Br were constrained to be in the same location for each site; the second where the Cl and Br atoms were allowed to have different coordinates. The former process gave significantly lower R values, despite fewer variables, so it is those results that are reported here. In addition, that process defines a unique average X···X distance for correlation with the magnetic data. Refinement information is available in the Supplementary Data. The fractions of Cl and Br found from the refinements correlates well the observed unit cell volumes, as seen in Fig. 2 and the fractional occupancies of each site are plotted in Fig. 3.

2.3. Magnetic measurements

The susceptibility studies were done on crushed single crystal samples using a Quantum Design MPMS-XL SQUID Magnetometer. The magnetization of each sample was first determined at 1.8 K in fields between 0 and 5 T. The magnetization was linear with field up to at least 1 T for each compound. No hysteresis was detected for any of the compounds. For the determination of the molar magnetic susceptibility, χ_M, the magnetic moment of the compound in a field of 1000 Oe (0.1 T) was determined as a function of temperature between 1.8 and

325 K. Corrections for the small diamagnetic contribution of the sample holder were applied. Corrections to the molar susceptibility have been made for the temperature independent magnetization of the Cu(II) ion (60×10^{-6} emu/mol) and the diamagnetic contribution as calculated from Pascal's constants.

3. Structural properties

3.1. Crystal structures of the pure compounds

The crystal structures of the triclinic $(MOR)_2Cu_2Cl_6$ and the monoclinic $(MOR)_2Cu_2Br_6$ compounds are built up in nearly identical manners, although the resultant symmetries are different. The basic building blocks are the nearly planar bibridged $Cu_2X_6^{2-}$ anions. One morpholinium cation forms a semi-coordinate bond to each copper ion via the oxygen atom of the cation, with the two morpholinium cations arranged in a *trans* configuration in each dimer (Fig. 1). In the triclinic chloride compound, two independent, but nearly identical, centrosymmetric dimers exist, while only a single non-centrosymmetric dimer exists in the monoclinic bromide

salt. The coordination of the morpholinium cation imposes an elongated square pyramidal geometry on each copper ion. Thus the copper halide portion of the dimers is not strictly planar, but the central Cu_2X_2 linkages make angles of 11.0–12.7° with the terminal CuX_2 planes.

The $(MOR)_2Cu_2X_6$ species are assembled into layer structures via N–H···X synthons, as shown in Fig. 4

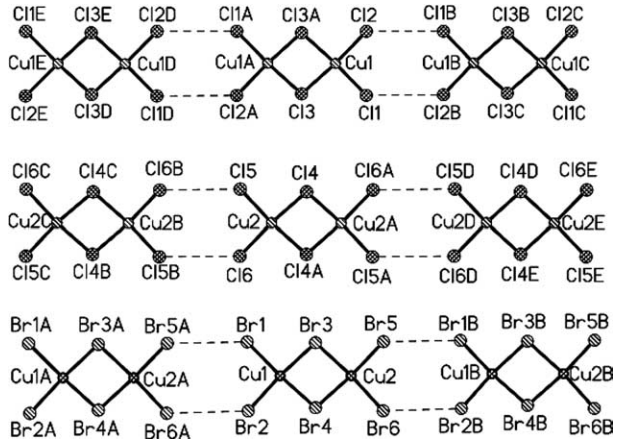

Fig. 5. Illustration of the magnetic chains in the $(MOR)_2Cu_2X_6$ salts. Top and middle: chains 1 and 2 in the chloride salt. Bottom: chain in the bromide salt.

for $(MOR)_2Cu_2Cl_6$ and $(MOR)_2Cu_2Br_6$. As is clear from the two illustrations, the two layers are isostructural, with identical geometrical arrangements, despite the differences in symmetry. The two protons on a given NH_2^+ group form bifurcated hydrogen bonds to the terminal halide ions on adjacent dimers, forcing close X···X contacts between the terminal pairs of halide ions. The N–H···Cl distances range from 3.244 to 3.391 Å while the N–H···Br distances show a slightly greater spread from 3.337 to 3.566 Å. The X···X contacts between dimers define alternating magnetic chains via alternating intradimer and 2H exchange pathways, as are illustrated in Fig. 5. These X···X distance are 3.962 and 3.985 Å for the two crystallographically independent chains in the chloride salt and 3.976 and 4.057 Å for the two independent distances in the pathway of identical chains in the bromide salt. These non-bonded contacts are of importance magnetically, and will be discussed in detail later in the paper.

Adjacent layers are held together weakly by C–H···X interactions. In the chloride salt, adjacent layers are translationally equivalent, while adjacent layers in the bromide salt are related by centers of inversion. The presence of only these weak non-traditional hydrogen

bonds between layers explains the very waxy nature of crystals of these compounds.

3.2. Structural analysis of the $(MOR)_2Cu_2Cl_{6-x}Br_x$ salts ($x > 2$)

The structural analyses for compounds **4**–**8** show that the substitution of Cl for Br in the structure is not random, but the Cl ions occupy certain sites preferentially, as documented in Table 3 and Fig. 3. The pattern of Cl substitution for Br in the Br structure appears to be dictated by the X···X contacts between dimers. The X2···X6 contact is typically ~0.07–0.10 Å shorter than the X1···X5 distance. Thus the smaller Cl atoms preferentially occupy the X2 and X6 positions. Intradimer X···X contacts then dictate that the chloride ions preferentially occupy the X3 position over the X4 position.

The interdimer X···X contacts show a general gradual decrease in distance as the Cl fraction increases. However, the average total decrease (Fig. 6) for these contacts is ~0.07 Å, significantly less than the decrease in van der Waals radii. Thus these X···X contact distances are largely determined by the packing and hydrogen bonding capabilities of the morpholinium cations.

3.3. Structural analysis of the $(MOR)_2Cu_2Cl_{6-x}Br_x$ salts ($x < 1$)

For the two mixed samples with the lowest Br content (**2** and **3**), a large residual peak (~3 e $Å^{-3}$) was found approximately halfway between the terminal halide ions on adjacent dimers. This additional residual was modeled as a Cu atom with partial occupancy. This lowered the *R* values by over 1%. The subsequent difference map showed two additional residuals near X5 and X6, in sites expected from disorder of the halide ions induced by the impurity. The partial occupancies of the copper impurity and the disordered sites were 5.7% for the $x = 0.92\%$ and 7.3% for $x = 0.70$ samples, respectively. Thus, the amount of copper ion impurity appears to increase as the chloride ion fraction increases. As seen in Fig. 7, the Cu impurity sits approximately halfway between adjacent dimers, with Cu–X distances of ~2.25–2.5 Å, but closer to Cu1 than to Cu2. N atoms from two morpholine moieties sit above and below, with Cu–N4 ~ 1.9 and Cu–N10 ~ 2.4 Å. This is a reasonable geometry for an axially compressed copper chloride coordination sphere – very unusual but not unknown as an impurity. To coordinate to the Cu, these two ammonium groups would each have to lose a proton, creating neutral morpholine species. This loss would offset the +2 charge on the Cu impurity. The inclusion of the copper ion impurity may explain why the Cl and Br structures are different. The Br structure can probably only accommodate a small percentage Cu impurity before it breaks down. The presence of this impurity may partially account for the greater shortening of the X···X contacts in these two salts as compared to the salts with higher Br content.

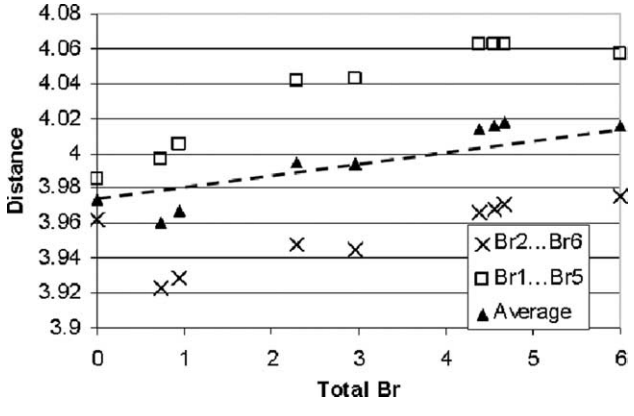

Fig. 6. Plot of halide···halide distances vs. total Br content. x denotes the X1···X5 distances, □ denotes X2···X6 the distances (see Fig. 3 for atom labels). Solid triangles are the average X···X distances for each structure. For the pure chloride salt, the two data points represent the Cl···Cl distances between the dimers in the two crystallographically different chains.

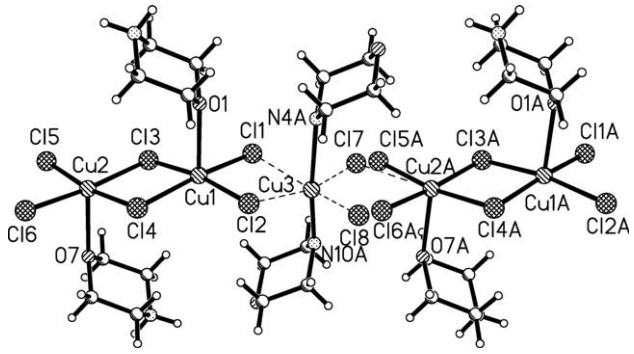

Fig. 7. Illustration of the site of the Cu impurity site in the low bromide content salts. Two pairs of disordered halide sites (label Cl5A/Cl7 and Cl6A/Cl8) induced by the Cu impurity are also shown.

4. Magnetic properties

4.1. Magnetic properties of the pure compounds

As described above, the structures of both the chloride and bromide salts contain isolated $(MOR)_2Cu_2X_6$ molecules that are hydrogen bonded into layer structures. Magnetically, these layers are expected to be well isolated from each other since the only close contacts are C–H···X interactions. Within the layers, the only possible significant exchange pathways between dimers are 2H X···X contacts between adjacent dimers that link these units together into a magnetic chain with alternating exchange pathways: the intradimer coupling, J_d, and the halide···halide coupling, J_{2H}.

Both the chloride and bromide salts exhibit dominant antiferromagnetic behavior as demonstrated by the continuously decreasing value of $\chi_M T$ versus T as the temperature is decreased. The results are in agreement with the experimental values reported earlier [9], with χ_{max} occurring at substantially higher temperature for the bromide salt than the chloride salt. Given the structural characteristics discussed above, the magnetic behavior of both salts was modeled as alternating antiferromagnetic chains (AAFM) with exchange constants J_1 and J_2, characterized by the Hamiltonian $H = -2J_1\sum[s_i \cdot s_{i+1} + \alpha s_{i+1} \cdot s_{i+2}]$ with $0 < \alpha < 1$ and $J_2 = \alpha J_1$. The data was fit with high temperature series expansions for χ_{AAFM} available in the literature [14], with a correction for the paramagnetic 'impurity' that is observed at very low temperatures, according to the equation $\chi_{dimer} = 2(1-f)\chi_{AAFM} + 2f(C/T)$, where f is the mole fraction impurity and C is the Curie constant for a spin 1/2 species. As with many other copper halide systems, the paramagnetic impurity is assumed to be intrinsic, due to defects in the crystal, rather than due to the presence of an impurity compound. The resulting fits are shown in Fig. 8 and the parameters given in Table 3. For the chloride salt, it is found that $J_1/k = -41.6(1)$ K and $J_2/k = -18(1)$ K, while the bromide salt has $J_1/k = -141.5(5)$ K and $J_2/k = -59(2)$ K. The fact that the exchange coupling in the bromide salt is substantially stronger than in the chloride analog, despite the very similar structures, is consistent with the previous report and with the general trend observed in isostructural copper halide dimers [6d].

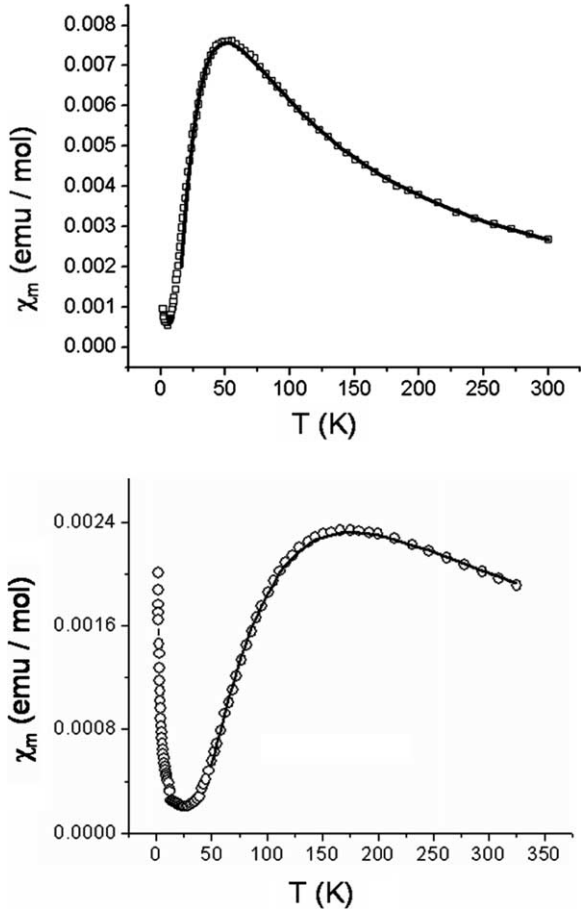

Fig. 8. Plot of χ_M vs. T for $(MOR)_2Cu_2Cl_6$ (top) and $(MOR)_2Cu_2Br$ (bottom). Solid lines are calculated fits to the AAFM model with parameters given in text.

4.2. Magnetic properties of the $(MOR)_2Cu_2Cl_{6-x}Br_x$ salts ($x > 2$)

These compounds all assume the monoclinic $(MOR)_2Cu_2Br_6$ structure with a non-statistical distribution of halide ions. Qualitatively, the magnetic behavior of these salts is similar to that of the pure compounds, with the temperature at which χ_{max} occurs increasing monotonically as the fraction of bromide ion in the salts increases. Since the distribution of halide ion is disordered (although not completely random), these systems are, in principle, examples of spin 1/2 system random chains with dimerization. For such Random Exchange in Heisenberg Antiferromagnetic Chain (REHAC) systems, the behavior $\chi \sim T^{-\gamma}$ is predicted at low temperature, with γ varying continuously. However, for this to be observed, the width of the distribution of exchange parameters must be greater than twice the value of the average exchange coupling [15]. This is not the case here. Thus, the data was analyzed in the same manner as the pure salts, modeled as an AAFM chain with a paramagnetic impurity. The percent impurity increased as the fraction of chloride ion increased, probably because of the presence of interstitial Cu^{2+} impurity ions as observed for samples **2** and **3**. The results are summarized in Table 3 and in Fig. 9. It is seen that J_1/k increases nearly linearly with the bromide content, to a maximum value near 130 K. Also it is noteworthy that one of J values remains nearly constant at $J/k \sim 40$–50 K.

4.3. Magnetic properties of the $(MOR)_2Cu_2Cl_{6-x}Br_x$ salt ($x = 0.70$)

The magnetic behavior of the mixed chloro/bromo salt with $x = 0.70$ exhibits dominant AFM coupling

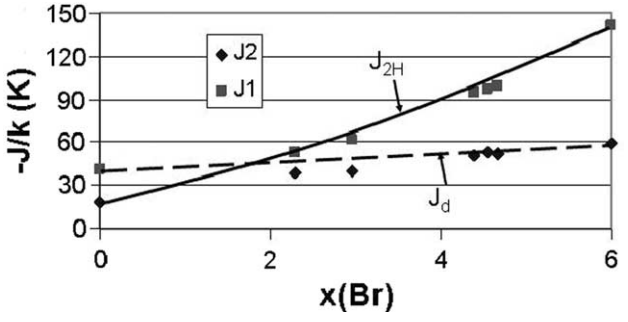

Fig. 9. Plot of the exchange constants for the alternating AFM chains.

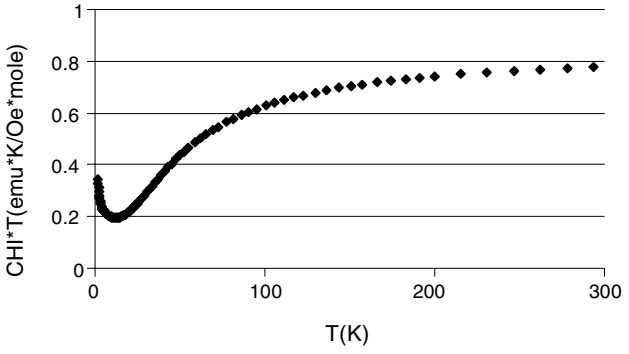
at high temperatures, just as all of the other salts. However, at very low temperatures, the behavior is very different. Instead of the $\chi_M T$ approaching zero as T approaches zero (neglecting the paramagnetic impurity contribution seen in all the samples), in this case the $\chi_M T$ value begins to diverge at low temperature. As seen in Fig. 10 the $\chi_M T$ versus T plot begins to diverge below $T = 12$ K. This indicates the presence of a FM interaction that becomes apparent at these low temperatures. Attempts to fit the high T data to the alternating chain model were inconclusive, but good fits could be obtained with $J_1/k = -38 \pm 5$ K and $J_2/k = -20 \pm 5$ K.

This low temperature behavior is extremely unusual. It cannot be due to REHAC-type behavior, since χT will be a decreasing quantity as the temperature is lowered. Thus, to explain the low temperature FM behavior, we examine the structure of the compounds with $x < 1$. As documented in the description of their crystal structure analysis, these compounds contain a copper(II) impurity ion with an associated disorder of the halide ions in the structure. This copper impurity is not located symmetrically between adjacent dimers, but is closer to one dimer than the other. Thus, when the impurity is present, there will be two additional exchange pathways, J'_1 and J'_2, linking the impurity to the neighboring dimers. Three cases can exist: (a) J'_1 and J'_2 are both FM; (b) J'_1 and J'_2 are both AFM; (c) one is FM and one AFM. These three cases are illustrated in Scheme 2, where the spins of the copper ions in the dimers are denoted by the solid arrows and the impurity spins are denoted by the dashed arrows. The ground state alternating AFM spin arrangement in a chain without impurity is shown in the top row. The next two rows show the effect on the spin arrangement when J'_1 and J'_2 have the same sign, FM and AFM, respectively. In these two cases, the presence of the impurity spin reverses the spin arrangement in the adjacent section of the chain. This forces the next impurity spin to be aligned antiparallel to the previous one. Thus, these two cases will lead to an AFM ground state. The last line shows the spin arrangements when J'_1 and J'_2 have alternating sites. Now the spin arrangement on adjacent sections is preserved and each impurity spin has the same orientation as the previous one. Thus this will yield a ferrimagnetic ground state, in agreement with the observed magnetic behavior.



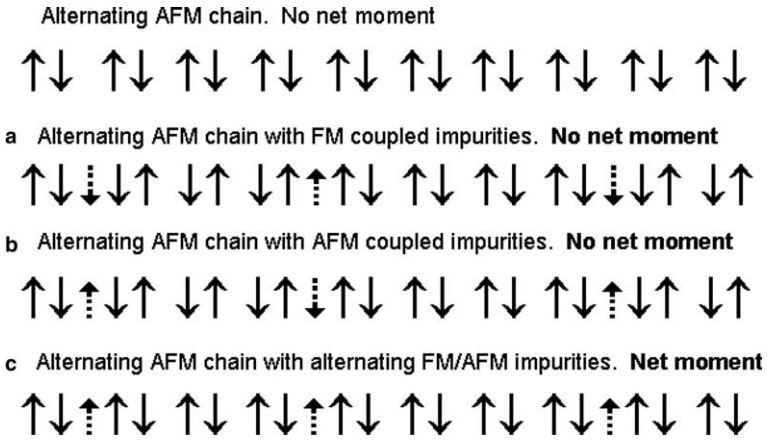


Fig. 10. Plot of $\chi_M T$ vs. T for $(MOR)_2Cu_2Cl_{6-x}Br_x$ $(x = 0.70)$, showing the effect of the weak ferromagnetism induced by the presence of Cu(II) impurities between dimers in the chains.

5. Discussion

The correlation of the structural and magnetic properties in the system reported here clearly shows the presence of two distinct magnetic exchange pathways. The only two possible pathways are the intradimer coupling, J_d, and the halide···halide coupling, J_{2H}. Unfortunately, the thermodynamic measurement of the magnetic susceptibility does not allow a definitive assignment correlation between the magnetic exchange parameters, J_1 and J_2, and the structural pathways, J_d and J_{2H}. Nevertheless, qualitative arguments can be made to support the assignments made in Fig. 9.

Scheme 2.

First, for the pure chloride system, the neutron scattering studies on $KCuCl_3$ and $(piperazinium)_2Cu_2Cl_6$, where the Cl···Cl distances are similar to those in the morpholinium salt, show that J_{2H} is less than J_d. Thus, the value of $J_1/k = 41.6$ K is assigned to J_d, while the $J_2/k = 18$ K value is assigned to J_{2H}. This value of J_d is 50% larger than that observed in $KCuCl_3$. However, the J_d value for the isostructural Tl(I) salt is 25% larger. Thus, the value of J_d appears to be quite sensitive to the environment of the dimer. In particular, with a $4 + 1$ coordination in $(MOR)_2Cu_2Cl_6$ as contrasted to $4 + 2$ in $KCuCl_3$, the basal Cu–Cl distances are shortened in the morpholinium salt, which should lead to more delocalization and stronger AFM coupling.

It has been observed in studies of the 2H exchange in the diammonium layer perovskite salts and in salts containing the distorted tetrahedral CuX_4^{2-} anions that the 2H exchange coupling is typically 5–7 times larger for bromide salts than the corresponding chloride salts when the X···X distances are the same [1–4]. Fig. 5 shows that the X···X distances increase only slightly when the chloride ligand is replaced by bromide. Thus, for the $(MOR)_2Cu_2Cl_{6-x}Br_x$ salts with $2 < x \leqslant 6$, the larger exchange constant, J_1, is clearly associated with J_{2H}.

Another important observation is that the distribution of halide ions is not totally random in the mixed Cl/Br salts. Rather, the chloride ions preferentially occupy the most sterically crowded sites. In these compounds, these are the X2 and X6 sites, where the shortest X···X contacts occur. Thus, J_{2H} should not be expected to vary linearly with the fraction of bromide, x, in the samples, since that is the average occupancy over all sites. Rather J_{2H} should be expected to initially increase at a somewhat slower rate, since the bromide occupancies in the X2 and X6 sites is less than the average occupancy. This is qualitatively represented by the solid line in Fig. 9.

In summary, this study has further elucidated the crucial role of the 2H exchange pathways in the determination of the magnetic behavior of copper halide dimers. The specific contribution of this study is the conclusion that the 2H pathway can become the dominant exchange pathway in the bromide dimers. Thus, discussions of the interpretation of the magnetic behavior of copper halide dimer systems must take this pathway into consideration. In particular, the explanation for the magnetic behavior of the mixed chloro/bromo $[(CH_3)_2CHNH_3]_2Cu_2Cl_{6-x}Br_x$ salts must involve contributions from the 2H exchange pathways. In these compounds, semi-coordinate Cu···X link the dimers into structural chains [16]. However, X···X contacts between chains provide for exchange pathways that define a two-dimensional magnetic lattice. Both pure end members appear to behave as one-dimensional magnetic systems [17]. However, an ordered magnetic phase appears at low temperature in the mixed halide salts [17]. Given the trends in the intradimer and 2H exchange observed in this study, a reasonable rationale can be put forward for the behavior in the $[(CH_3)_2CHNH_3]_2Cu_2Cl_{6-x}Br_x$ system. In the pure chloride salt, the magnetic and structural systems may be identical, that is, the exchange coupling within (J_d) and between (J_c) dimers are the dominant factors. In contrast, the 2H exchange pathway will be much enhanced in the pure bromide salt, so that the magnetic system no longer coincides with the structural chain, but rather consists of the dimer exchange (J_d) and the 2H pathway (J_{2H}). In the mixed halide systems, there could then be a regime where all three exchange pathways have comparable magnitude, giving rise to a two-dimensional magnetic system that can order at low temperatures.

In this paper, we present structural and magnetic results for a metallo-organic system, $(NBu_4)Ni(mnt)_2$, that exhibits a bistable spin-Peierls-type transition with a very high transition temperature, $T_{tr} = 172$ K. Two NBu_4^+ salts of Ni(mnt) are known: the triclinic $(NBu_4)_2$-$Ni(mnt)_2$, with Ni in the +2 oxidation state [4] and the monoclinic $(NBu_4)Ni(mnt)_2$, with a +3 oxidation state. [5]. The latter contains uniform segregated stacks of $(NBu_4)^+$ cations and $Ni(mnt)_2^-$ anions. Here we report on the properties of the monoclinic form. In that form, the high temperature phase already shows structural dimerization, but the magnetic interactions within that dimerized chain are nearly uniform. Thus it is structurally predisposed to form a spin-Peierls-like dimerized state. This fact, plus the presence of the large bulky cation that provides a softness to the lattice, allows the spin dimerization to occur at a much higher temperature than normally observed for such systems.

2. Experimental

2.1. Synthesis

The compound was prepared according to standard literature procedures [6].

2.2. Crystallography

Data were collected at 293(2) and 84(2) K using a Bruker/Siemens SMART APEX instrument (Mo Kα radiation, $\lambda = 0.71073$ Å) equipped with a Cryocool NeverIce low temperature device. Data were measured using omega scans of 0.3° per frame for 20 s, and a full sphere of data was collected. A total of 2132 frames were collected with a final resolution of 0.83 Å. The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved using SMART [7] software and refined using SAINTPLUS [8] on all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPLUS software. Absorption corrections were applied using SADABS [9]. The structure was solved by direct methods and refined by least squares method on F^2 using the SHELXTL [10] program package. The structures of both phases were solved in the space group $C2/c$ by analysis of systematic absences. All atoms were refined anisotropically. No decomposition was observed during data collection. Details of the data collection and refinement are given in Table 1. Further details are provided in the Supporting Information.

2.3. Magnetic measurements

Variable temperature susceptibility measurements were carried out on $(NBu_4)Ni(mnt)_2$ in the temperature range 2–300 K at a magnetic field of 0.1 T on a ground polycrystalline sample with a SQUID magnetometer (Quantum Design MPMS-XL-5). Different sweeping rates were used to determine the possible influence of the cooling and warming rates in the transition temperatures. The susceptibility data were corrected for the diamagnetic contributions of the sample as deduced by using Pascal's constant tables. The thermal variation of the heat capacity, in the 200–150 K range, was measured on several single crystals of the title compound (with a total mass of 0.8116 mg) in a Quantum Design Physical Properties Measurement System (PPMS-9). At each temperature the heat capacity was measured with 1% heating pulses and 5–10 averaged repetitions per point. The lattice heat capacity was subtracted by using a polynomial fit of the points above and below the peaks.

Table 1
Crystal data and structure refinement for $(NBu_4)Ni(mnt)_2$

Formula weight	581.53	581.53
T (K)	293(2)	84(2)
λ (Å)	0.71073	0.71073
Crystal system	monoclinic	monoclinic
Space group	$C2/c$	$C2/c$
Unit cell dimensions		
a (Å)	30.860(3)	31.073(3)

Goodness-of-fit on F^2	1.035	1.018
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0517$, $wR_2 = 0.1114$	$R_1 = 0.0442$, $wR_2 = 0.1101$
R indices (all data)	$R_1 = 0.0818$, $wR_2 = 0.1246$	$R_1 = 0.0679$, $wR_2 = 0.1000$

$R_1 = \sum||F_o| - |F_c||/\sum|F_o|$.
$wR_2 = (\sum w||F_o|^2 - |F_c|^2|/\sum w|F_o|^2)^{1/2}$.

3. Results

3.1. Crystal structure description

The room temperature crystal structure of the monoclinic phase was verified [6] and the low temperature structure determined at 84 K. At both temperatures, the crystals are monoclinic, space group $C2/c$, with eight formula units per unit cell. Both phases contain segregated stacks of planar $Ni(mnt)_2^-$ anions separated by bulky NBu_4^+ cations. Significant atomic displacements are observed between the two phases and the effect of these shifts is reflected in the magnetic behavior of this system. The room and low temperature molecular units

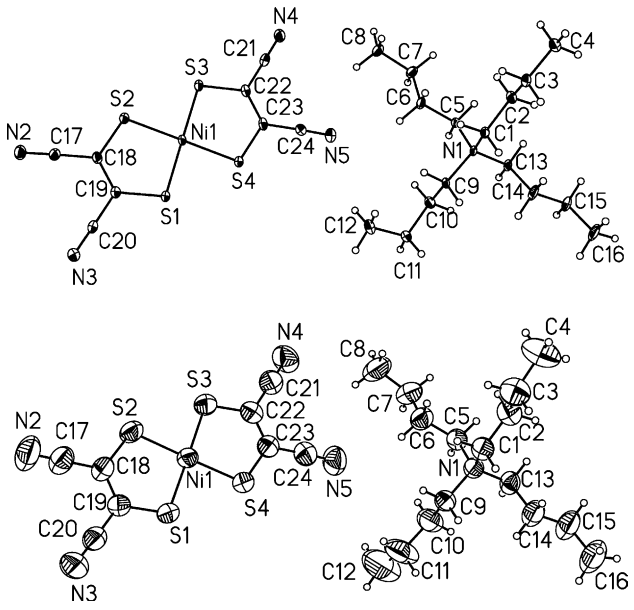

Fig. 1. Illustration of asymmetric unit: top–low temperature phase; bottom–high temperature phase. Thermal ellipsoids shown at the 50% probability level.

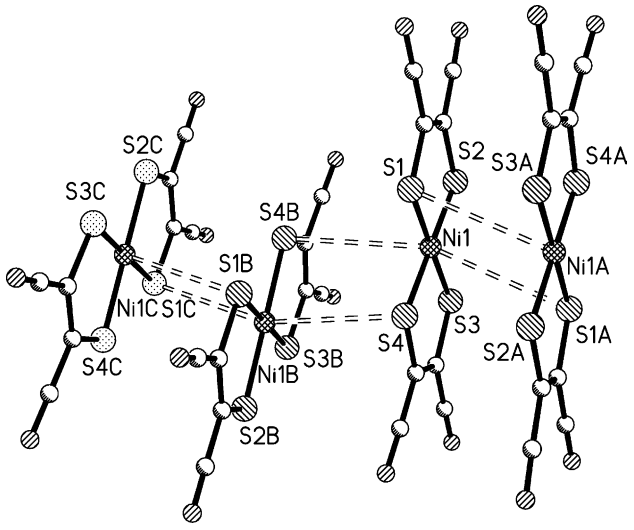

Fig. 2. Illustration of the stacking of the $Ni(mnt)_2^-$ anions. 84 K: Ni1···S1A = 3.648 Å, Ni1···S4B = 3.594 Å. Room T: Ni1···S1A = 3.717 Å, Ni1···S4B = 3.716 Å.

are illustrated in Fig. 1. Clearly evident in the figure for the low temperature phase is the presence of a *gauche* conformation of one arm (the C9–C12 arm). This is the conformation observed in the structure of the triclinic form. However, in the room temperature phase, all four of the butyl arms of the cation appear to have the sterically favorable all-*trans* conformation. However, also observable in the high temperature phase are the much larger thermal ellipsoids on all atoms of both the cation and anion, particularly in the C9–C12 arm. These larger thermal ellipsoids are anticipated when disorder is present, and thus it is concluded that the C12 methyl group is disordered between the *gauche* and the more energetically favorable *trans* conformation in the room temperature structure. The fact that there is no change in the space group, coupled with the observation of disorder of the C12 methyl group in the high temperature structure, implies that this represents an order–disorder transition. Associated with the disorder of the butyl arm of the cation are shifts in the stacking of the $Ni(mnt)_2^-$ anions, as discussed in the following paragraph.

In both phases, the salient feature of the structures is the existence of non-uniform stacks of the planar $Ni(mnt)_2^-$ anions, as shown in Fig. 2. The anions in these stacks are linked by long ($\geqslant$3.6 Å) Ni···S interactions. Pairs of anions, containing the Ni atoms Ni1 and Ni1A in Fig. 2, are related by centers of inversion. Adjacent pairs are generated by twofold rotation operations, generating the pair of anions containing Ni1B and Ni1C. In the room temperature phase, the two independent Ni···S distances within and between the centrosymmetric pairs are accidentally equal (Ni1···S1A = 3.717 Å, Ni1···S4B = 3.716 Å). However, in the low temperature phase, shifts in the positions of the anions have shortened these two distances to different extents, with Ni1···S1A = 3.648 Å and Ni1···S4B = 3.594 Å. The interplanar spacing between the centrosymmetric pair of anions decreases by 0.2 Å between the room temperature and 84 K structures (3.645 versus 3.462 Å. A second part of this structural change is a shift of the relative orientation of the adjacent pairs of anions. For the centro-

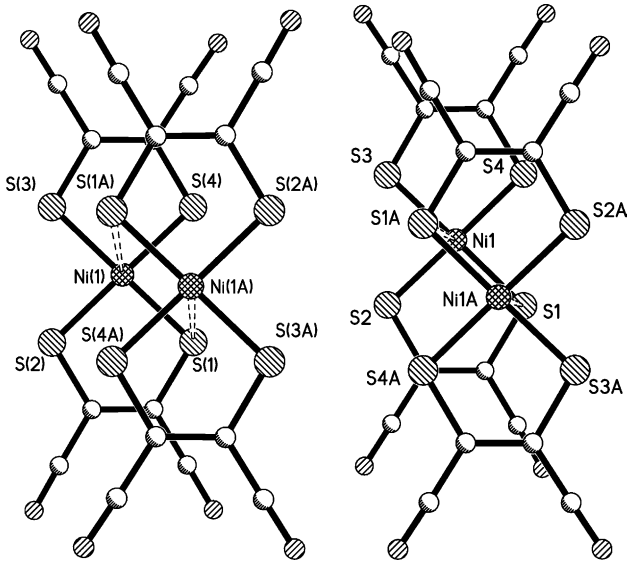

Fig. 3. Illustration of the two anions related by the center of inversion. Left: 84 K: Ni1···S1A = 3.648 Å, angle between NiS_4 plane and (Ni1–S1A) = 70.8°, distance between anion planes = 3.462 Å. Right: Room T: Ni1···S1A = 3.717 Å, angle between NiS_4 plane and (Ni1–S1A) = 80.6°, distance been anion planes = 3.645 Å. The plane of each anion is rotated by 9.1° between the room temperature and 84 K phases.

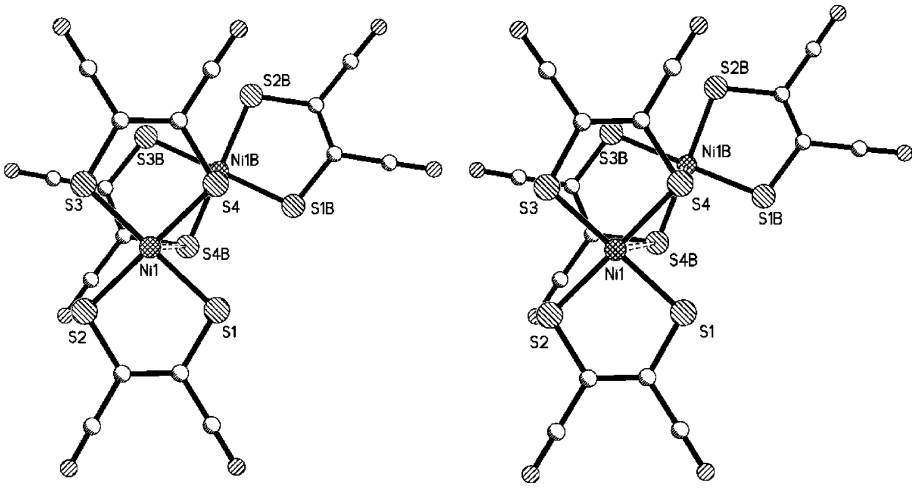

Fig. 4. View of the two anions related by 2-fold rotation axes. Left: 84 K. Ni1–S4B = 3.594 Å, dihedral angle between NiS_4 planes = 7.8°, angle between the mean plane of the anion and Ni1–S4B direction = 77.4°, distance between centroids of the overlapping NiS_2N_2 chelate rings = 3.786 Å. Right: Room T. Ni1–S4B = 3.716 Å, dihedral angle between NiS_4 planes = 15.3°, angle between the mean plane of anion and the Ni1–S4B direction = 76.1°, distance between centroids of the overlapping NiS_2N_2 chelate rings = 3.836 Å.

symmetric pair (Fig. 3), the planes of the anions are parallel by symmetry, but there is a substantial translation (~1 Å) of the two anions relative to each other. In the low temperature phase, the two sulfur atoms (S1 and S4) on one dimer are located approximately above (or below) the centroids of the NiS_2C_2 chelate rings on the adjacent anion. In the room temperature phase, sulfur atom S1 now is located nearly directly over the Ni atom in the adjacent anion. In addition, the planes of the anions are rotated by 9.1° about the *b* direction.

The situation for the pair of anions related by a two-fold symmetry operation is significantly different. For this pair, the molecular planes of the two anions are not required to be parallel by symmetry. Seen in projection (Fig. 4), there seems to be little change in the relative orientation. The two anions are somewhat closer together at 84 K than at room temperature, as measured by the distances between the centroids of the two overlapping NiS_2C_2 chelate rings, 3.836 versus 3.786 Å. This contraction of 0.06 Å is substantially less than the 0.20 Å decrease between the centrosymmetric pair. In addition, there is a 7.5° increase in the dihedral angle between the NiS_4 planes on the two anions.

The distances and angles within the $Ni(mnt)_2^-$ anion are consistent with other compounds containing this anion.

3.2. Magnetic properties

Fig. 5 shows a plot of $\chi_M T$ versus T for $(NBu_4)Ni(mnt)_2$ while Fig. 6 gives a plot of χ_M versus T, with an inset showing details of the temperature regime near the phase transition. For $T > 175$ K, the $\chi_M T$ plot exhibits its typical antiferromagnetic behavior. Upon cooling, a rapid drop in $\chi_M T$ (and in χ_M) occurs at 172 K, followed

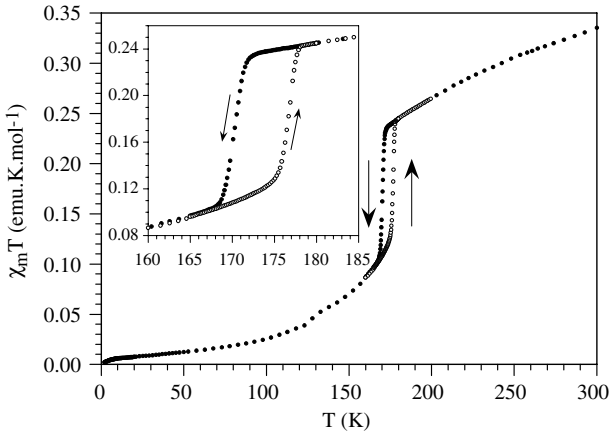

Fig. 5. Plot of χ_{mT} vs. T. Black circles: cooling scan, white circles: warming scan. Inset: the transition temperature region.

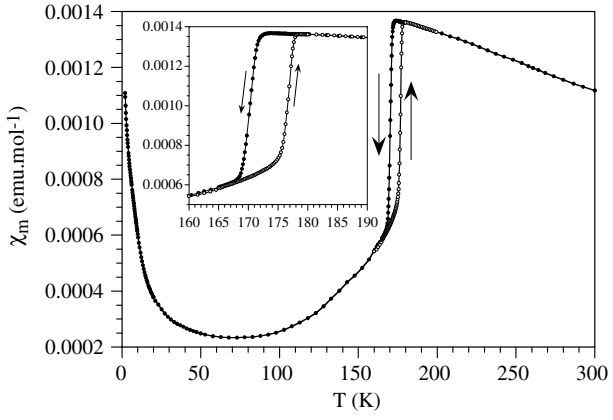

Fig. 6. Illustration of the hysteresis in the magnetic response. Black circles. cooling scan, white circles: warming scan. Inset: the transition temperature region.

by a slow decrease in χ_M in the regime 60–170 K. Below 60 K, a typical paramagnetic tail due to defects in the stacks is observed. Upon heating, the data reproduce the cooling data up to 168 K. The data indicates that the sample continues in the low temperature phase until 175 K, where a rapid rise in χ_M occurs until it merges with the cooling data at ca. 178 K. The derivative of both curves show peaks at 170.5 and 176.9 K, giving a hysteresis of ca. 6.5 K in the transition. Measurements around the transition at different cooling and warming rates indicate that the transition temperatures do not vary significantly (less than 1 K) with the cooling and warming rates in the range 0.5–5.0 K min^{-1}.

A comparison of Figs. 5 and 6 shows that, while the value of $\chi_M T$ decreases in both phases with decreasing temperature, the susceptibility does not drop to zero at the transition temperature. Rather, it drops by about 60%, and then gradually decreases towards zero. This indicates that the magnetic effects of the dimerization do not lead to the formation of an $S = 0$ ground state for the $Ni(mnt)_2^-$ stacks. Rather, there is an alternation in the exchange parameters, albeit with substantially stronger exchange coupling than in the high temperature phase. The behavior of the low temperature phase is consistent with that expected for a system of alternating antiferromagnetic spin 1/2 chains.

Fig. 7 shows the heat capacity results in the region of the phase transition. Although the data present some noise due to the small amount of sample used in the measurements (less than 1 mg) it can be clearly seen that there is a peak at ca. 168–169 K in the cooling scan and ca. 175–176 K in the warming one. Both peaks indicate the temperature of the spin-Peierls-like transition in the cooling and warming scans and are in very good agreement with the transition temperatures, as well as the hysteresis of ca. 7 K, observed in the in the SQUID measurements. The heat capacity measurements data are also different in the cooling and warming scans in the range 177–167 K (178–168 K in the SQUID measurements).

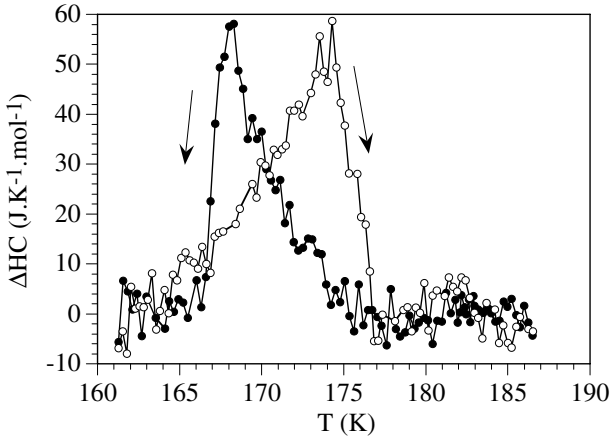

Fig. 7. Plot of the corrected heat capacity data obtained in the cooling (black points) and warming (white points) scans.

4. Discussion

The study of compounds containing $M(mnt)_2^{n-}$ species continues to be actively pursued [11]. A survey of the Cambridge Crystallographic Data Base revealed over 40 structures containing the $Ni(mnt)_2^-$ anion. These structures are very varied: mixed A:D stacks [12], uniform [5,13] and dimerized [14] segregated stacks, isolated dimers [12a,15] and isolated monomers [16]. In the vast majority of the structures, the long axes of the $Ni(mnt)_2^-$ anions have the same orientation. No systematic trends are observable in the distances between adjacent cations or the relative lateral displacement of adjacent cations. However, in one salt, the long axes of adjacent ions in the stacks are rotated by approximately 90°, similar to the arrangement seen for the adjacent pair of anions shown in Fig. 4.

Associated with these variations in structure is a corresponding variation in magnetic interactions. While most show dominant antiferromagnetic interactions [17], examples where the compounds are diamagnetic [18], exhibit ferromagnetic coupling within the chains [19], or undergo magnetic ordering at low temperature [20] have been reported. A number of salts have been reported that undergo dimerization type transitions [19b,21]. Perhaps the most fascinating is [1-(4′-fluorobenzyl)pyridinium]$Ni(mnt)_2$, where the compound undergoes a phase transition at 93 K, exhibiting ferromagnetic coupling above that temperature and becoming diamagnetic below that temperature [19b]. This magnetic behavior at the phase transition is presumed to be due to a dimerization process similar to that reported here. A $Pt(mnt)_2^-$ salt exhibits a rapid drop in the susceptibility at 247 K, although the drop appears to occur over a much larger temperature range than observed in this study [21a]. Crystallographic studies confirm the dimerization of the chain below the phase transition temperature. No hysteretic behavior in the transition is reported. However, the gradual decrease in susceptibility at temperatures below the phase transition is similar to that observed in our study.

It is the observation of hysteresis that makes the $(NBu_4)Ni(mnt)_2$ compound unique, since no other of the $ANi(mnt)_2$ compounds studied have shown the bistable regime associated with a structural and magnetic response at the phase transition. Since the crystal structure of both the room temperature phase and the 84 K phase have the same space group and lattice, with disorder observed in the high temperature phase, this implies that the phase transition is of the order–disorder type. This is supported by the nature of the heat capacity anomaly. The observation of hysteresis in the structural and magnetic properties at the phase transition indicates that the process is likely driven by the order–disorder behavior of the NBu_4^+ cations, and not by the spin dimerization process.

5. Supporting material available

Crystallographic data for the structures reported here have been deposited with the Cambridge Crystallographic Data Center as Supplementary Publication Nos. CCDC-252683 and CCDC-252684 for the room temperature and 84 K structure determinations, respectively. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www:http//www.ccdc.cam.ac.uk).

is an example of a difficult molecule; (iv) [Mn(III)-Cu(II)(Br-sap)$_2$Cl(MeOH)]: it is a small SMM [11]. We suggest the applicable region of the method from these results.

2. Calculation of ZFS parameters

Spin–orbit Hamiltonian is as the form

$$\hat{U} = \frac{1}{i}\sum_{j=1}^{N} \hat{\mathbf{V}}(\mathbf{r}_j)\cdot\hat{\mathbf{S}}_j, \quad \hat{\mathbf{V}}(\mathbf{r}) \equiv -\frac{1}{2c^2}\nabla\times\mathbf{E}(\mathbf{r}), \tag{2}$$

where $\hat{\mathbf{S}}_j$ is a spin operator of a jth electron and $\mathbf{E}(\mathbf{r})$ is the electronic field of the nuclei. The second-order perturbation energy of SOC (SOPT2 energy) from spin-polarized DFT (UDFT) wavefunction Ψ_0 is

$$E^{\mathrm{SOPT2}} = \sum_{\sigma,\tau}^{\alpha,\beta}\sum_{a}^{\sigma\mathrm{occ}}\sum_{s}^{\tau\mathrm{vir}} \frac{\langle\Psi_0|\hat{U}|\Psi_{a\sigma}^{s\tau}\rangle\langle\Psi_{a\sigma}^{s\tau}|\hat{U}|\Psi_0\rangle}{E_0 - E_{a\sigma}^{s\tau}} = \sum_{\sigma,\tau}^{\alpha,\beta}\sum_{p,q}^{\mathrm{x,y,z}}\sum_{s}^{\tau\mathrm{vir}} M_{pq}^{\sigma\tau}S_p^{\sigma\tau}S_q^{\tau\sigma}, \tag{3}$$

$$M_{pq}^{\sigma\tau} = \sum_{a}^{\sigma\mathrm{occ}}\sum_{s}^{\tau\mathrm{vir}} \frac{\langle\psi_a^{\sigma}|\hat{V}_p|\psi_s^{\tau}\rangle\langle\psi_s^{\tau}|\hat{V}_q|\psi_a^{\sigma}\rangle}{\varepsilon_s^{\tau} - \varepsilon_a^{\sigma}}, \tag{4}$$

$$S_p^{\sigma\tau} = \langle\sigma|\hat{S}_p|\tau\rangle \quad (\sigma,\tau = \alpha \text{ or } \beta), \tag{5}$$

where $|\Psi_{a\sigma}^{s\tau}\rangle$ and $E_{a\sigma}^{s\tau}$ are a 1-electron excited configuration (from subscript to superscript) and the energy, respectively, and $|\psi_a^{\sigma}\rangle$ and ε_a^{σ} are an ath σ-spin orbital and the orbital energy, respectively. This energy depends on the direction of the spin quantization axis. The spin matrix $\mathbf{S}_p$ is transformed under the rotation of the spin quantization axis as

$$\mathbf{S}'_p = \mathbf{R}\mathbf{S}_p\mathbf{R}^{\dagger}, \tag{6}$$

$$\mathbf{R} = \begin{pmatrix} e^{i\gamma}\cos\theta/2 & e^{i(\gamma-\phi)}\sin\theta/2 \\ -e^{-i(\gamma-\phi)}\sin\theta/2 & e^{-i\gamma}\cos\theta/2 \end{pmatrix}. \tag{7}$$

The expectation value of the spin operator is also transformed as

$$\langle\hat{\mathbf{S}}'\rangle = \frac{1}{2}\Delta N(\sin\theta\cos\phi, \sin\theta\sin\phi, \cos\theta), \tag{8}$$

where $\Delta N = 2\langle\hat{S}_z\rangle$. The SOPT2 energy is

$$E^{\mathrm{SOPT2}} = \langle\hat{\mathbf{S}}'\rangle^{\mathrm{T}}\mathbf{D}\langle\hat{\mathbf{S}}'\rangle, \tag{9}$$

where $\mathbf{D}$ is the ZFS tensor, which can be calculated as

$$\mathbf{D} \equiv \frac{1}{\Delta N^2}\begin{pmatrix} N_x + N'_y + N'_z & N_{xy} + N'_{xy} & N_{zx} + N'_{zx} \\ N_{xy} + N'_{xy} & N'_x + N_y + N'_z & N_{yz} + N'_{yz} \\ N_{zx} + N'_{zx} & N_{yz} + N'_{yz} & N'_x + N'_y + N_z \end{pmatrix}, \tag{10}$$

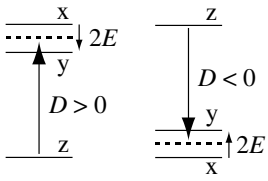

Fig. 1. The energy diagram of the magnetic anisotropy energies when the spin is on $\mathbf{u}_x$, $\mathbf{u}_y$, and $\mathbf{u}_z$ axis.

$$N_{pq} \equiv M_{pq}^{\alpha\alpha} + M_{pq}^{\beta\beta},\ N'_{pq} \equiv M_{pq}^{\alpha\beta} + M_{pq}^{\beta\alpha},\ N_p \equiv N_{pp},\ N'_p \equiv N'_{\mathrm{pp}}. \tag{11}$$

The ZFS tensor is diagonalized, when the spin of the system is in a particular direction.

$$E^{\mathrm{SOPT2}} = d_{xx}\langle\hat{S}''_x\rangle^2 + d_{yy}\langle\hat{S}''_y\rangle^2 + d_{zz}\langle\hat{S}''_z\rangle^2, \tag{12}$$

$$\mathbf{D} = \mathbf{U}\mathbf{d}\mathbf{U}^{\dagger},\ \langle\hat{\mathbf{S}}'\rangle = \mathbf{U}^{\dagger}\langle\hat{\mathbf{S}}'\rangle. \tag{13}$$

The diagonal elements are ordered as $|d_{zz} - d_{yy}| > |d_{yy} - d_{xx}|$ and $d_{yy} \in [d_{xx}, d_{zz}]$ (Fig. 1). The ZFS parameters, D and E, and the principal axis $\mathbf{a}$ are

$$D = d_{zz} - \frac{d_{xx} + d_{yy}}{2}, \quad E = \frac{d_{xx} - d_{yy}}{2}, \tag{14}$$

$$\mathbf{a} = \mathbf{u}_z, \quad \mathbf{U} = (\mathbf{u}_x\ \mathbf{u}_y\ \mathbf{u}_z). \tag{15}$$

The sign of E is not essential, since $\mathbf{u}_x$ and $\mathbf{u}_y$ can be swapped. Therefore, we ignore the sign of E in the present article.

3. Calculation and discussion

3.1. Triplet benzene and naphthalene

Triplet benzene and naphthalene are an example of organic radicals which has very little SOC contribution to D. It was shown that the SOC contribution to ZFS of aromatic hydrocarbons vanishes in view of the CNDO/S CI approximation [12]. This method can describe phosphorescent radiative lifetime for these molecules [9,10]. In the INDO CI method, the SOC contribution to the ZFS parameters of triplet benzene and naphthalene was estimated to be less than 0.01% of the experimental values.

We calculated triplet benzene and naphthalene and the SOC contribution to the D values with UHF, USVWN, UBLYP and UB3LYP [13] and cc-pVDZ basis set [14]. Each geometry is optimized with the method and the basis set. The results are shown in Table 1. All the results are very small, about 0.1% of the experimental values 0.1593 and 0.1003 cm^{-1}. Though these results are larger than the *semiempirical* CI results, they reproduce the fact that the SOC contribution is very small.

Table 1
The list of the estimated D values in cm^{-1}

Method	Benzene	Naphthalene	Carbene	Silylene	Oxygen	SMM
UHF	-2.14×10^{-4}	4.43×10^{-4}	0.00537	0.0774	0.198	0.039
USVWN	2.17×10^{-4}	-1.41×10^{-4}	0.04877	4.3369	2.066	
UBLYP	-1.50×10^{-4}	0.83×10^{-4}	0.04608	8.2780	1.780	−1.290
UB3LYP	-0.98×10^{-4}	1.16×10^{-4}	0.02219	0.4605	0.747	−0.589
UPW91						−1.204

3.2. Triplet carbene and triplet silylene

Triplet carbene and triplet silylene are examples of simple biradicals. It seems carbene and silylene are similar, but the spin multiplicities of the ground states are different; the ground state of the carbene is triplet and that of the silylene is singlet. According to the CASSCF/D95** study [4], the multiplicity of the ground state is changed at a particular bond angle. In case of carbene, the triplet state is stable. The equilibrium bond angle is 134.0°. The singlet state is stable in the region which bond angle is less than about 93°. In case of silylene, the singlet state is stable. The equilibrium bond angle is 118.4° on the level of large basis set CEPA calculations. However, the singlet and triplet states are degenerated at 113.0°, which is very close to the equilibrium bond angle.

The SOC contribution of these biradicals to D is drastically changed with the bond angle. In the CISDTQ/cc-pVDZ study [4], D is positive at the larger bond angle than the degeneration bond angle and negative at the smaller bond angle than it. The closer the bond angle is to the degeneration point, the larger the magnitude of D is, and D diverges at the degeneration point. In carbene, since the equilibrium geometry is quite far from the degeneration point, the SOC contribution to D is small as 0.023 cm^{-1}. In triplet silylene, however, since the equilibrium geometry is near the degeneration point, the SOC contribution to D is very large as 1–3 cm^{-1}. The SOC contribution to E is very small in both cases.

We performed UHF, USVWN, UBLYP and UB3LYP calculations with aug-cc-pVDZ basis sets to predict the SOC contribution to D at the equilibrium geometry. Each equilibrium geometry is optimized by the method and basis set. The results are shown in Table 1. In carbene, the DFT results are close to the CISDTQ result. The UHF method tends to underestimate D. The basis set dependency is small in all the methods. In triplet silylene, however, the UB3LYP result is quite different from the CISDTQ result. The result is caused by the fact that the equilibrium bond angle is far from the degeneration point in the UB3LYP method.

3.3. Triplet molecular oxygen

Triplet molecular oxygen is an example of a difficult system. In molecular oxygen, E is exactly equal to zero, since oxygen is a uniaxial molecule. The cheep methods failed to estimate the SOC contribution to D. In high-precision CASSCF(12,10)/aug-cc-pCVTZ study, the SOC contribution to D is 2.3145 cm^{-1} [5]. This study is in good agreement with the experiment.

We performed UHF, USVWN, UBLYP, UB3LYP calculations with aug-cc-pCVTZ basis set to calculate the SOC contribution to D of molecular oxygen. The results are shown in Table 1. The pure DFT results are very close to the CASSCF result, but the UHF and UB3LYP results are underestimated also in this case.

We also calculated the bond length dependency of D with UBLYP/aug-cc-pVDZ. In the CASSCF method, D monotonically increases as the bond is lengthened. In the UBLYP result, however, D negatively diverges at a bond length. Over the length, D jumps to positive infinity and decreases.

4. Small SMM

At last, we calculated a small SMM. Since SMMs are metal complexes, SOC mainly contributes to ZFS. Therefore, the computational results of the method of the present work can be directly compared with the experimental values. Pederson et al. calculated several SMMs, but they did not use the hybrid DFT methods. We also examined the validity of the hybrid DFT methods to SMM calculations.

We calculated [Mn(III)Cu(II)(Br-sap)$_2$Cl(MeOH)], which is a small SMM synthesized by Oshio et al. [11]. The spin multiplicity of the SMM is 5/2 and the D value is -1.81 cm^{-1}. We employed UHF, UBLYP, UPW91, and UB3LYP methods with Huzinaga's MIDI basis sets for metal atoms and 6-31G basis sets for the other atoms.

The geometry obtained by X-ray structure analysis was used. The results are shown in Table 1. The results of the UBLYP and UPW91 methods are close to the

experimental value. Also in this case, UB3LYP underestimates the D value. We suggest that the reason is that the energy gap, which is the denominator of Eq. (4), of the hybrid DFT methods tends to be wider than pure DFT methods.

5. Concluding remarks

We applied the Pederson's method to calculate the ZFS parameters to some radicals. The pure DFT results tended to be in good agreement with the results of the high-precision CI or MCSCF methods in the equilibrium region. However, the UB3LYP method, a hybrid DFT method, tends to underestimate D values in some cases. Though the pure DFT methods also failed out of the equilibrium region, this is practically acceptable for computation of D values.

Acknowledgments

This study was performed through a Grand-in-Aid for Scientific Research (No. 14204061) from Ministry of Education, Culture, Sports, Science and Technology.

namely $[Cu(2,3\text{-pydc})_2]_x[Mn(H_2O)_6]_x \cdot 2xH_2O$ (**3**) [3]. Unlike the situation in **1** and **2**, in **3** there is no coordinative link between the copper and manganese centers. While the copper ions are bridged in chains by the ligands in **3**, the manganese ions are present in the crystal lattice as isolated $Mn(H_2O)_6^{2+}$ entities in this compound [3]. The structures of both **1** and **2**, reported here in detail, reveal extended arrays of regularly alternating, coordinatively linked, paramagnetic centers of different spin ($S = 1/2$ and 5/2), a classical set-up for ferrimagnetism [4]. With this in mind in particular, we carefully examined the magnetic properties of these systems as well as the magnetic properties of two thermally condensed forms, $Cu(2,4\text{-pydc})_2Mn \cdot H_2O$ (**1d**) and $Cu(2,5\text{-pydc})_2Mn \cdot H_2O$ (**2d**).

2. Experimental

2.1. Syntheses

2,4-Pyridinedicarboxylic acid monohydrate and 2,5-pyridinedicarboxylic acid were used as supplied (Aldrich). Solutions of 0.10 M $Cu(NO_3)_2 \cdot 3H_2O$ (Baker) and 0.10 M $Mn(ClO_4)_2 \cdot 6H_2O$ (Alfa) were prepared in-house. 0.10 M NaOH (Fisher) was diluted according to package directions. Water was deionized in-house.

$[Cu(2,4\text{-pydc})_2Mn(H_2O)_4]_x$ (**1**) was prepared by dissolving 2,4-pydc$H_2 \cdot H_2O$ (1.0 mmol, 0.185 g) in H_2O and NaOH (2.0 mmol, 20 ml × 0.10 M) to a final volume of 100 ml. $Cu(NO_3)_2$ and $Mn(ClO_4)_2$ (each 0.5 mmol, 5.0 ml × 0.10 M) were combined and then added to the proligand solution. The reaction mixture turned bright blue. After sitting for several weeks at room temperature, the mixture was filtered to recover small blue crystals suitable for single-crystal X-ray studies. *Anal.* Calc. for $CuMnC_{14}N_2H_8O_9$: C, 36.0; H, 1.7; N, 6.0. Found: C, 35.8; H, 1.9; N, 5.9%.

$[Cu(2,5\text{-pydc})_2Mn(H_2O)_2]_x \cdot 4xH_2O$ (**2**) was prepared as above substituting 1.0 mmol (0.167g) 2,5-pydcH_2 in place of the 1.0 mmol 2,4-pydc$H_2 \cdot H_2O$. In this case small blue crystals suitable for single-crystal X-ray studies formed after only a few days and these were removed by filtration. *Anal.* Calc. for $CuMnC_{14}H_6N_2O_8 \cdot H_2O$: C, 36.0; H, 1.7; N, 6.0. Found: C, 35.7; H, 1.6; N, 6.0%.

$Cu(2,4\text{-pydc})_2Mn \cdot H_2O$ (**1d**) was prepared by heating a finely ground sample of **1** to 190 °C under dynamic vacuum for seven days to yield a dark blue powder. *Anal.* Calc. for $CuMnC_{14}N_2H_8O_9$: C, 36.0; H, 1.7; N, 6.0. Found: C, 35.8; H, 1.9; N, 5.9%.

$Cu(2,5\text{-pydc})_2Mn \cdot H_2O$ (**2d**) was prepared as above from a finely ground sample of **2**. Compound **2d** is also a dark blue powder. *Anal.* Calc. for $CuMnC_{14}H_6N_2O_8 \cdot H_2O$: C, 36.0; H, 1.7; N, 6.0. Found: C, 35.7; H, 1.6; N, 6.0%.

2.2. Physical measurements

All elemental analyses were performed on finely powdered samples. TGA data were recorded on a TA 51 thermogravimetric analyzer at a 10 °C/min ramp under a 100 cc/min stream of nitrogen. Magnetic susceptibilities were measured using a Quantum Design (MPMS) SQUID magnetometer. The sample holder and details regarding the use of the equipment have been described elsewhere [5]. Magnetic susceptibilities were corrected for background signal of the sample holder. Corrections for the diamagnetism of all atoms [6] came to -221×10^{-6} for **1**, -185×10^{-6} for **1d**, -245×10^{-6} for **2**, and -185×10^{-6} for **2d**. All magnetic measurements were done on finely powdered samples, and the data are reported here on a per mole copper basis. X-ray studies were performed on single crystals mounted on glass fibers. All measurements were made on a Rigaku/ASDC CCD area detector with graphite-monochromated Mo Kα radiation. The positions of hydrogen atoms bonded to carbon were calculated, while those bonded to oxygen were located by electron density.

3. Results and discussion

3.1. $[Cu(2,4\text{-pydc})_2Mn(H_2O)_4]_x$ (1)

Compound **1** was prepared by a one-step synthesis similar to that developed for **3** [3] and recovered as royal blue crystals suitable for single-crystal X-ray studies. TGA studies show **1** to be thermally robust, with no loss of mass until 205 °C, at which temperature a mass equivalent to four water molecules is lost (calc. 14%, obs. 15%). No further loss of mass is observed until 346 °C, at which temperature the compound decomposes.

Structurally, single-crystal X-ray studies show that **1** is a sheet polymer (see Fig. 1 for repeat unit, Fig. 2 for a portion of the sheet, Table 1 for crystallographic data and Table 2 for selected bond lengths and angles). As in the previously reported structure of **3** [3] the copper(II) centers in **1** are linked into chains. Each copper(II) center in **1** has a tetragonally distorted pseudo-octahedral coordination sphere with the equatorial plane occupied by two rotationally equivalent 2,4-pydc^{2-} moieties binding via the ring nitrogen and one 2-carboxyl oxygen, with respective bond lengths of 1.967(2) and 1.936(1) Å (as compared to the Cu–N and Cu–O1 bond lengths of 1.942(2) and 1.962(1) Å, respectively, for **3**). The axial positions are occupied by long bonds (2.664(2) Å, compared to 2.693(1) Å for **3**) to one oxygen of the 4-carboxyl group on adjacent repeat units, resulting in a double bridge linking the copper centers into a chain similar to that observed in the structure of **3** (Fig. 2). The 4-carboxyl in **1** twists at an

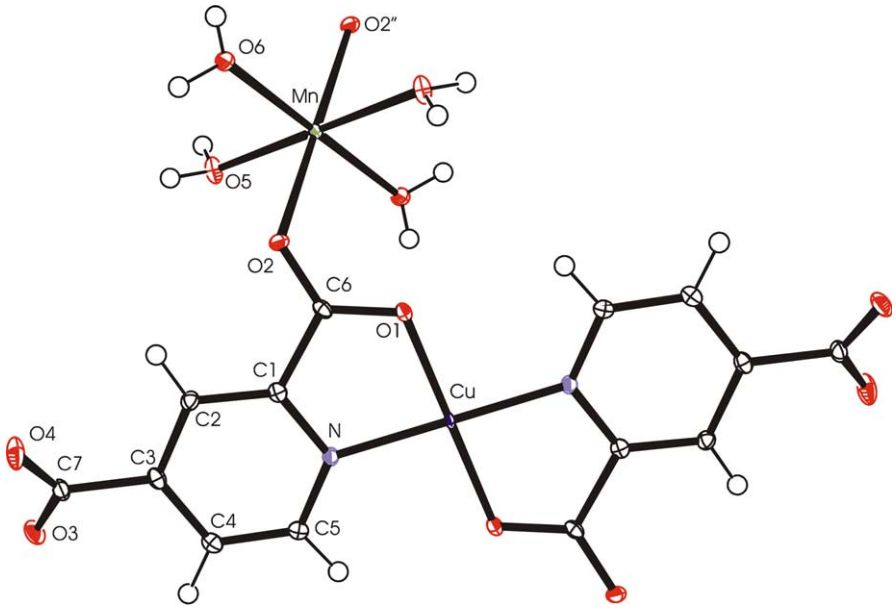

Fig. 1. Repeat unit of **1** with atom numbering scheme.

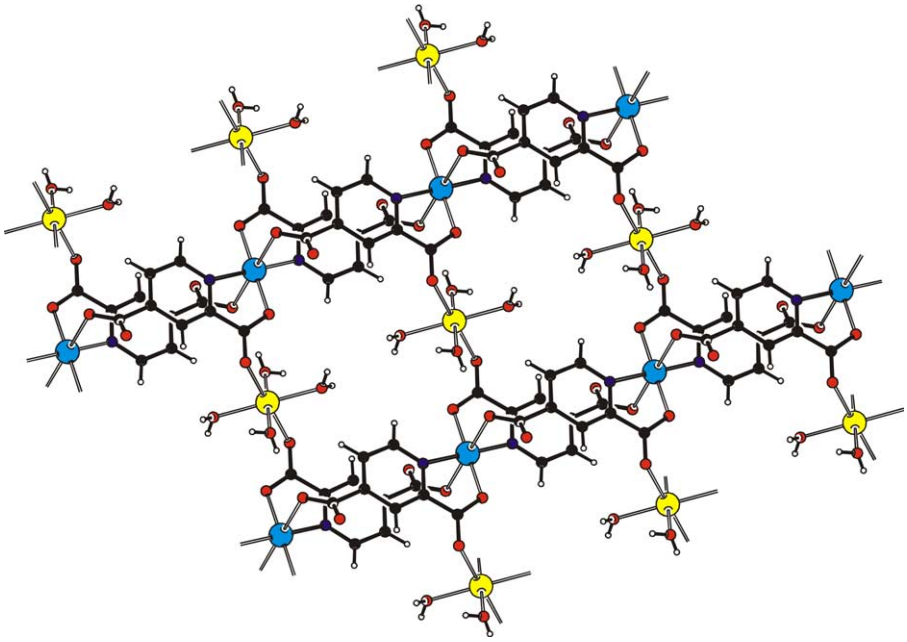

Fig. 2. Polymetallic sheet structure of **1**.

angle of 41.8(1)° to the ring to facilitate this bond; in **3** the 3-carboxyl twists at an angle of 77.3(2)°. As in **3**, the copper(II) chain structure of **1** is further stabilized by a π–π stacking interaction between the pyridine rings forming the double bridge (Table 3). Unlike **3**, however, the copper(II) chains of **1** are linked via covalent bonds into polymetallic sheets through the manganese(II) coordination spheres (Fig. 2), in a structure similar to that of the previously reported compound $[Cu(2,3\text{-pydc})_2Na_2(H_2O)_8]_x$, where copper(II) chains are linked into polymetallic sheets via $Na_2(H_2O)_8^{2+}$ ions [3]. Each manganese(II) center in **1** is ligated by four water molecules in two rotationally equivalent pairs, with the remaining two positions of the pseudo-octahedral coordination sphere filled by bonds to the second 2-carboxyl oxygen atoms of 2,4-$pydc^{2-}$ moieties in adjacent polymetallic chains. The Mn–O distances (2.158(2) and 2.197(2) Å for Mn–O5 and Mn–O6, 2.174(1) Å for Mn–O2) all fall within the range of Mn–O distances observed in the $Mn(H_2O)_6^{2+}$ ion in **3** [3]. This connectivity means that **1** is a sheet polymer consisting of copper(II) chains doubly bridged by 2,4-$pydc^{2-}$ ligands in one

DC magnetic susceptibility measurements for **1** were made from 300 to 2 K at an applied field of 10 000 G and from 100 to 2 K at 500 G. The observed increase in moment on decreasing temperature (Fig. 3) indicates ferromagnetic exchange. The data obtained at 10 000 G show the moment to pass through a maximum at 4 K, decreasing in value at lower temperatures. That this effect is likely the result of magnetic saturation at high applied fields is indicated by its absence in the lower field data, and also by the results shown in Fig. 4. Plots of magnetization versus applied field are shown in Fig. 4 for four different temperatures. These data clearly show the magnetization to saturate at high fields and low temperatures. That there is no long-range magnetic ordering in this system above 2K was indicated by AC susceptibility data taken from 50 to 1.8 K at an applied AC field of 1.0 G and frequencies of 10, 100, and 1000 Hz. This study showed no maxima in either χ' or χ''. This result was confirmed by identical zero-field cooled and field-cooled magnetization plots measured from 25 to 2 K and by the absence of magnetic hysteresis when the magnetization was measured at 1.8 K by sweeping the field between +2000 and −2000 G. The magnetization plots of Fig. 4 reveal that at 2.5 K the highest magnetization measured is 35 920 cm^3 G mol^{-1} at an applied field of 55 000 G. This value compares favorably with the saturation magnetization value of 34 070 cm^3 G mol^{-1} calculated [7] for a ferromagnetically coupled $S = 1/2 + S = 5/2$ system (assuming $g = 2.2$ and 2.0, respectively). Ferrimagnetic coupling is clearly ruled out by the fact that the calculated saturation magnetization for a $S = 5/2 - S = 1/2$ system is 21 780 cm^3 G mol^{-1}, significantly below the measured magnetization value.

It is somewhat unexpected that **1** proved to exhibit ferromagnetic behavior. The herringbone-type copper(II) chains seen in **1** were previously reported [3] to be weakly antiferromagnetic, suggesting that the Cu–Cu interaction is not dominating the magnetic behavior of **1**, instead that it is Cu–Mn coupling that dominates. Anti-parallel coupling between the $S = 1/2$ and the $S = 5/2$ centers would have generated the anticipated ferrimagnetic behavior for this system, whereas the observed coupling is clearly ferromagnetic. Adding

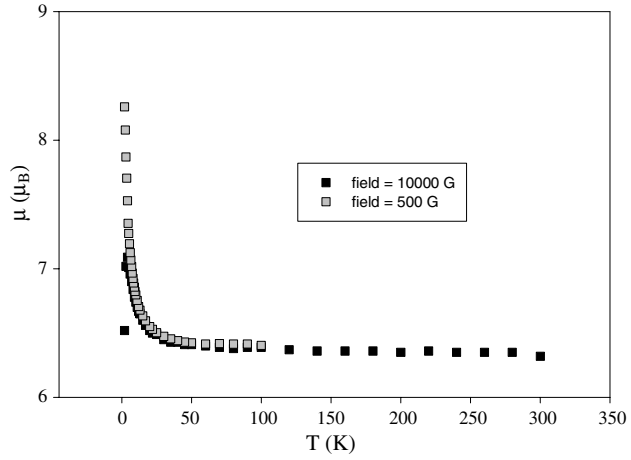

Fig. 3. Magnetic moment plots at 10 000 and 500 G for **1**.

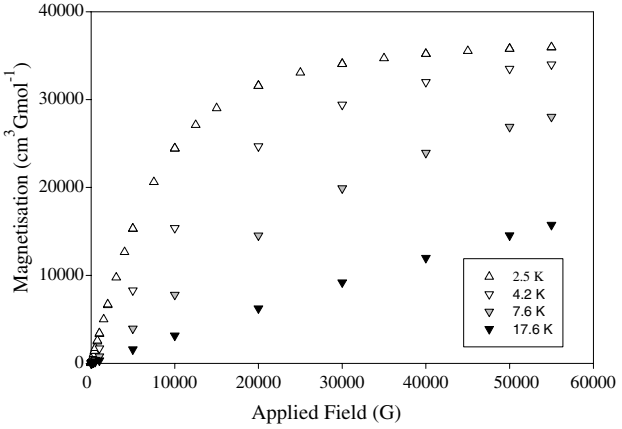

Fig. 4. Magnetization vs. field plots for **1**.

to the unexpected nature of these results is the fact that earlier studies by others on similar O–C–O bridged Cu/Mn systems have shown negligibly small interactions [8].

Heating a bulk sample of **1** at 190 °C under dynamic vacuum produces $Cu(2,4\text{-pydc})_2Mn \cdot H_2O$ (**1d**). DC magnetic susceptibility measurements were made on **1d** in an applied field of 10 000 G. The magnetic properties of **1d** are in sharp contrast to those of the parent compound **1**. The magnetic moment of **1d** decreases as *T* decreases, indicating antiferromagnetic behavior (Fig. 5). Attempts to model the data assuming a linear chain antiferromagnetic model for copper(II) coupled with a zero field splitting model for manganese(II) failed to produce an acceptable fit. It is likely that more complex exchange pathways are extant in this system. It seems reasonable to assume that the structure of **1d** retains the copper(II) chains observed in **1**, and that the changes to the structure are chiefly in the manganese(II) chromophore, which loses three ligating water molecules. An examination of the hydrogen-bonding interactions of the water molecules ligating manganese(II) in **1** shows that the 4-carboxyl oxygens on adjacent sheets are relatively near the manganese(II) ion, and suggests that the coordination sphere of manganese(II) in **1d** is filled by bonds to these atoms, resulting in O–C–O bridges between manganese(II) and copper(II) ions on adjacent polymetallic sheets. This adds another dimension to the connectivity in this "condensed form" of **1**, a connectivity which leads to overall antiferromagnetic behavior. Further speculation on the nature of the magnetic coupling in **1d** is not warranted in the absence of a definitive X-ray determined structure.

3.2. $[Cu(2,5\text{-pydc})_2Mn(H_2O)_2]_x \cdot 4xH_2O$ (2)

A one-pot synthetic approach, similar to that used to prepare **1**, gave compound **2** as dark blue crystals suitable for single-crystal X-ray studies. Thermogravimetric studies show **2** to be moderately thermally robust; it is stable up to 90 °C, at which temperature it loses a mass equivalent to two water molecules (calc. 6%, obs. 7%). A mass equivalent to the remaining four water molecules (calc. 13%, obs. 13%) is lost at 175 °C, and the dehydrated compound is then stable to 340 °C, at which temperature it decomposes. Heating a portion of **2** in a drying pistol at 190 °C yields the stable compound $Cu(2,5\text{-pydc})_2Mn \cdot H_2O$ (**2d**).

The structure of **2** consists of copper(II) ions and manganese(II) ions in pseudo-octahedral coordination spheres linked via the $2,5\text{-pydc}^{2-}$ ligands into a sheet polymer (see Fig. 6 for repeat unit, Fig. 7 for a portion of the sheet, Table 6 for crystallographic data and Table 7 for selected bond lengths and angles). Locally, each copper is chelated by two symmetrically equivalent $2,5\text{-pydc}^{2-}$ ligands via the ring nitrogen and one 2-carboxyl oxygen (Fig. 7). The axial positions of the pseudo-octahedral copper(II) coordination sphere are filled by long bonds to the second 2-carboxyl oxygens of the $2,5\text{-pydc}^{2-}$ moieties in adjacent repeat units, forming a double-O–C–O-bridged copper chain (Fig. 7). The manganese(II) ions are ligated in the equatorial plane by the 5-carboxyl oxygens of $2,5\text{-pydc}^{2-}$ ligands bound to copper(II), with each manganese(II) ion linked to two adjacent repeat units along two adjacent copper(II) chains, such that the manganese(II) ions are linked by double-O–C–O-bridges into chains and the separate copper and manganese chains are cross-linked by double ligand bridges to form an overall extended sheet structure (Fig. 7). The axial positions of the manganese(II) chromophores are filled by two ligated water molecules; the remaining four water molecules occupy crystal lattice positions. Both ligated and lattice water molecules participate in an extensive three-dimensional hydrogen-bonding network reinforcing the structure of the sheets and linking adjacent sheets (Table 8). Adjacent sheets are also linked by π–π stacking interactions, albeit weak ones (Table 9).

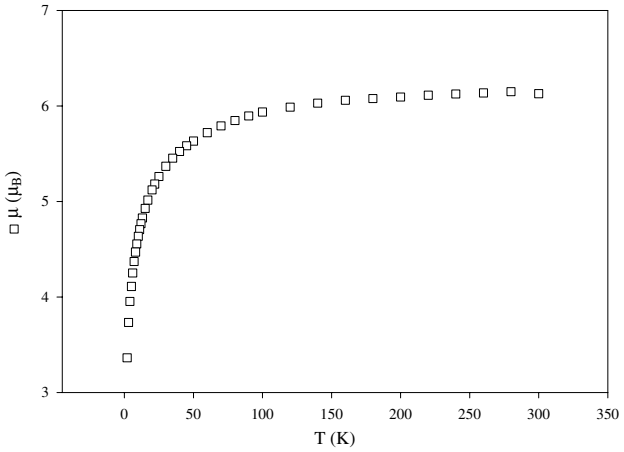

Fig. 5. Magnetic moment plot for **1d**.

DC magnetic susceptibility measurements were made on **2** from 300 to 2 K at 10000 G. The magnetic moment data (Fig. 8) show a regular decrease in value with decreasing temperature indicative of overall antiferromagnetic coupling. To model the magnetic properties, we made the initial simplifying assumption that magnetic coupling between Cu^{2+} and Mn^{2+} centers via the N–C_3–O ligand pathway is weak enough to be ignored. With this assumption, the overall model becomes one in which models for independent copper(II) and manganese(II) chains are simply added. The only justification for this approach comes with its ultimate success. To model the copper(II) chains in **2**, we considered that they have a bridging structure similar to that of $[Cu(2,4\text{-pydcH})_2]_x \cdot 2xCH_3OH$ [9]. This compound is weakly antiferromagnetic and its susceptibility data have been successfully modeled with the Weng model for copper(II) linear chains using the Hiller coefficients for $S = 1/2$ [10] and the parameters $J = -0.073(3)$ cm^{-1} and $g = 2.217(1)$, and a TIP correction of 0.000017(4) cm^3 mol^{-1}. These parameters were used with the Weng model to model the copper(II) chains within the polymetallic structure of **2**. No suitable structural model was found for the manganese(II) chains, so the magnetic data for **2** were initially modeled by adding the chosen model for the

for manganese(II) chains utilizing the Hiller coefficients for $S = 5/2$ and fixing g(Mn) at 2.00. J(Mn) was employed as the variable parameter. The goodness of fit was measured by the least squares fitting function, F:

$$F = \sqrt{\frac{1}{n}\sum_{1}^{n}\left(\frac{\chi_i^{calc} - \chi_i^{obs}}{\chi_i^{obs}}\right)^2}. \quad (1)$$

This time the fit, shown in Fig. 8, was reasonable ($F = 0.03$), with the parameter J(Mn) = −0.32(1) cm^{-1}. In summary, the magnetic data for **2** are reasonably well explained by weak coupling along each of the separate O–C–O bridged metal chains (J(Cu) = −0.073(3) cm^{-1} and J(Mn) = −0.32(1) cm^{-1}) with no significant Mn–Cu interactions between these chains.

In order to monitor the effect of thermal dehydration on the magnetic properties of **2**, magnetic data were collected for Cu(2,5-pydc)$_2$Mn · H$_2$O (**2d**). Data were taken from 300 to 2 K at a field of 10 000 G. The magnetic moment data for **2d** (Fig. 8) are very similar to those for **2**, the most noticeable difference being a slightly more pronounced decrease in moment with temperature for **2d** suggesting stronger antiferromagnetic coupling in this material. In order to analyze these data, certain assumptions were made about the structure of **2d**. The five water molecules removed from **2** by thermal treatment were assumed to be four lattice water molecules plus one of the two waters ligating manganese(II). The loss of these water molecules therefore would affect the

coordination environment of the manganese centers with the potential to affect the strength of the Mn–Mn exchange interactions, but would not be expected to significantly affect the copper(II) chain structure, or its capacity for mediating magnetic exchange. The structural model used for **2** was therefore assumed to also be valid for **2d**. Accordingly, the data were fit to the same equation used for **2**, the summed Weng models for copper(II) and manganese(II) with the fixed parameters as before and J(Mn) as the only variable parameter. The fit was successful ($F = 0.01$) with the variable parameter J(Mn) found to be $-0.55(1)$ cm^{-1}. This value is 23 standard deviations higher than that found for **2**, indicating that the loss of lattice and ligated water did increase the strength of antiferromagnetic exchange along the Mn–Mn chains in the material.

4. Summary and conclusions

This work has demonstrated the potential of 2,4-pydc^{2-} and 2,5-pydc^{2-} to bridge different kinds of metals, in this case copper(II) and manganese(II), and form extended arrays in which the metals exhibit a regular alternation. These ligands chelate via nitrogen and one 2-carboxyl oxygen to the "softer" metal of two and utilize one or more of the other carboxyl oxygen atoms to bridge to the "harder" metal. Analyses of the magnetic properties of **1** and **2** reveal that the N–C_4–O and N–C_3–O coordinative links between metals, involving the ring N and a 4- or 5-carboxyl oxygen, provide relatively weak pathways for magnetic exchange. More pronounced coupling appears associated with the O–C–O links in these systems. The result is ferromagnetic coupling between the copper and manganese centers in **1** and weak antiferromagnetic coupling within each of the copper and manganese chains in **2** with no measurable coupling between the two different metals in this latter compound.

On thermal dehydration, **1** forms a material **1d** in which the overall exchange is antiferromagnetic. This dramatic change from the overall ferromagnetism of the parent compound is likely caused by structural changes on dehydration opening up an additional pathway for antiferromagnetic exchange in the material. In contrast, the magnetic properties of **2** are little altered on dehydration indicating only marginal differences between the structures of **2** and **2d** such that the dominant antiferromagnetic pathways extant in **2** remain in **2d**.

Finally, it should be noted that in spite of the presence of regularly alternating $S = 1/2$ and $S = 5/2$ centers in both **1** and **2**, and presumed to be present in **1d** and **2d**, none of these systems gave evidence for ferrimagnetic behavior.

5. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Centre, CCDC No. 251776 for compound **1** and 251777 for compound **2**. Copies of this information may be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www. http://www.ccdc.cam.ac.uk).

Besides this general approach, our proposing approach is due to the expansion of spin units into a metal cluster building block. Recently, Ovcharenko et al. [21] have reported a two-dimensional compound derived from the assembly of a Mn_6 cluster, $[Mn_6O_2(t\text{-}BuCO_2)_{10}(THF)_4]\cdot THF$ (**1**) that possesses an $S_T = 0$ spin ground state itself, with a nitronyl nitroxide unit of 2,4,4,5,5-pentamethyl-4,5-dihydro-1*H*-imidazolyl-3-oxide-1-oxyl [22]. Interestingly, this material underwent a long-range order with $T_c = 3.5$ K. This fact indicates that the significant magnetic-coupling between Mn_6 and radical spin enables to create a new spin ground state.

Our first attempt to connect the Mn_6 cluster has been carried out by employing 4,4′-bipyridine linker to confirm stability of the core structure of Mn_6 subunit in a network skeleton [23]. Both results of Ovcharenko's one and ours proved that this type of Mn_6 clusters was potentially candidate as a building block for creating new molecular frameworks and assembled magnetic materials. Herein, we present a new discrete cluster of the Mn_6 cluster attaching two nitronyl nitroxide groups: $[Mn_6O_2(t\text{-}BuCO_2)_{10}(H_2O)(NNPy)_2]$ (**2**) (NNPy = 2-(*p*-pyridyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide). Synthesis, structure, and magnetic properties of **2** are described.

2. Experimental

All chemicals employed syntheses were of reagent grade. Benzene and *n*-hexane were distilled over Na/benzophenone ketyl and freshly distilled prior to use. All manipulations were performed under nitrogen atmosphere with standard Schlenk-tube techniques. The precursors of $[Mn_6O_2(t\text{-}BuCO_2)_{10}(THF)_4]\cdot THF$ (**1**) [21] and 2-(*p*-pyridyl)-4,4,5,5-tetramethylimidazoline-1-oxyl-3-oxide (NNPy) [24] were prepared by methods of the literatures, respectively.

2.1. Preparation of $[Mn_6O_2(t\text{-}BuCO_2)_{10}(H_2O)(NNPy)_2]$ (2)

A 10 ml of benzene solution containing compound **1** (52 mg, 0.03 mmol) was refluxed for 2 h and then cooled to room temperature. To a resulting brown solution was added a solid of NNPy (28 mg, 0.12 mmol), and stirred for an hour. The dark-blue solution was filtered and the filtrate was layered with *n*-hexane (20 ml) in a narrow glass tube. Dark-blue crystals of **2** were obtained after two days. Yield: 42 mg, 75%. Selected IR (KBr, cm^{-1}): *v* 2958(s), 1693(w), 1583(s), 1483(s), 1456(m), 1417(s), 1373(s), 1319(s), 1228(s), 1164(m), 1136(m), 1074(m), 1029(w), 1008(m), 937(w), 893(m), 831(m), 786(m), 613(s), 557(m). *Anal.* Calc. for $C_{74}H_{124}O_{27}N_6Mn_6$: C, 47.80; H, 6.72; N, 4.52. Found: C, 48.12; H, 6.52; N, 4.25%.

2.2. Physical measurements

An infrared spectrum was recorded on KBr pellet with a Shimadzu FT-IR-8600 spectrophotometer. Elemental analysis (C, H, N) was performed at Elemental Analysis Laboratory, Department of Chemistry, Tokyo Metropolitan University. The ESR spectra were recorded on a polycrystalline sample enclosed in a quartz tube at X-band frequency operating 8.96–8.97 GHz with a JEOL spectrometer (ES-TE200/BU). Magnetic susceptibility measurements were conducted by a Quantum Design SQUID magnetometer (MPMS-XL). The sample was put into a gelatin capsule and restrained using Nujol. The obtained data were corrected for the underlying diamagnetic susceptibility using Pascal's constants [25].

2.3. X-ray structure determination

Crystal data for **2** were collected on a Rigaku AFC7R diffractometer with graphite monochromated Mo Kα radiation and a rotating anode generator. The intensities were corrected for Lorentz and polarization effects. The structure was solved by a direct method (SIR-97) [26] and expanded using Fourier techniques. Non-hydrogen atoms were refined anisotropically, besides some carbon atoms on nitronyl nitroxide moiety. Hydrogen atoms were refined using the riding model. The final cycle of full-matrix least-squares refinement on F^2 was based on 10 567 observed reflections and 1085 variable parameters and converged (largest parameter shift was 0.00 times its esd) with unweighted and weighted agreement factors. The crystal data and collection parameters for **2** are summarized in Table 1.

3. Results and discussion

3.1. Structural description

A labeled ORTEP plot of **2** is depicted in Fig. 1(a). Selected interatomic distances and angles are listed in Table 2. Complex **2** crystallizes in the acentric triclinic space group *P*1 (No. 1). Complex **2** consists of a $[Mn_6O_2]^{10+}$ core and two NNPy moieties. Note that the $[Mn_6O_2]^{10+}$ core of the parent cluster **1** is preserved in **2**; the $[Mn_6O_2]^{10+}$ core is composed of six Mn ions positioned at vertices of edge-shared double-tetrahedron with two μ_4-O^{2-} ions at the center of each tetrahedron as shown in Fig. 1(b). The valence of six Mn ions is assigned to be trivalent and divalent, respectively, for two inner Mn ions (Mn(1), Mn(2)) occupying the edge-shared positions and four outer Mn ions (Mn(3), Mn(4), Mn(5), Mn(6)) situating the outer vertices. The coordination geometry around the inner Mn^{III} ions, Mn(1) and Mn(2), has an elongated octahedral

environment, where six positions are occupied by oxygen atoms of four pivalate bridging groups and two μ_4-O^{2-} ions. The bond distance corresponding to the elongated axes are found to be Mn(1)–O(3) = 2.308(4) Å, Mn(1)–O(5) = 2.208(4) Å, Mn(2)–O(11) = 2.243(4) Å, Mn(2)–O(13) = 2.183(4) Å, longer than those for the equatrial plane, Mn(1)–O(1,2,7,9) (average 1.916 Å) and Mn(2)–O(1,2,15,17) (average 1.927 Å), demonstrating the Jahn-Teller distortion typically observed for an octahedral high-spin d^4 ion. Among the four outer Mn^{II} ions, Mn(3) and Mn(5) ions that are present in *trans* position of the cluster have a distorted octahedral environment surrounded by five oxygen atoms arisen from four pivalate bridges [Mn(3)–O(3,8,12,19) (average 2.186 Å), Mn(5)–O(5,10,14,22) (average 2.192 Å)] and a μ_4-O^{2-} bridge [Mn(3)–O(1) = 2.175(5) Å, Mn(5)–O(2) = 2.194(5) Å], and one nitrogen atom of pyridine-N of NNPy molecule [Mn(3)–N(1) = 2.351(7) Å, Mn(5)–N(4) = 2.309(7) Å] (vide infra). Mn(4) also has a similar octahedral geometry, except capping of water molecule instead of NNPy, surrounded by six oxygen atoms from pivalate bridges [Mn(4)–O(6,13,16,20) (average 2.180 Å)], a μ_4-O^2 bridge [Mn(4)–O(1) = 2.186(4) Å] and a water molecule [Mn(4)–O(23) = 2.219(4) Å]. While, only Mn(6) is square-pyramidal five-coordinated with five oxygen atoms from pivalate bridges [Mn(6)–O(4,11,18,21) (average 2.140 Å)] and a μ_4-O^{2-} bridge [Mn(6)–O(2) = 2.063(3) Å].

Two NNPy ligands are coordinating to Mn(3) and Mn(5), respectively, in pyridine-N coordination mode to form a linear array of [(NNPy)–Mn_6–(PyNN)]. In each NNPy moiety, the dihedral angle between ON–C_{py}–NO moiety and pyridyl ring is 19.935° and 21.818°, respectively, for ones for Mn(3) and Mn(5). A packing diagram of **2** is depicted in Fig. 2. The closest

inter-cluster Mn···Mn distance is 10.289(1) Å in Mn(3)···Mn(5). The shortest contact between adjacent nitronyl nitroxide moieties is found to be 3.423(6) Å in O(25)···O(27).

3.2. Magnetic properties

DC magnetic measurements were carried out on a Nujol-restrained polycrystalline sample of **2** at 1 kOe in the temperature range of 1.81 to 300 K. The temperature dependence of the magnetic susceptibility χ and χT product is shown in Fig. 3. The $1/\chi_M$ versus T plot roughly obeys the Curie–Weiss law in the high-temperature region with $C = 17.6$ emu K mol^{-1} and $\theta = -36$ K. The Curie constant is smaller than the expected value, 24.3 emu K mol^{-1}, for a magnetically-diluted spin system of ($2Mn^{III}$, $4Mn^{II}$, 2radical) = ($S = 2 \times 2$, $5/2 \times 4$, $1/2 \times 2$) as $g = 2.00$. The value of negative Weiss constant is very similar to that observed in **1** ($\theta = -33$ K), indicating that antiferromagnetic coupling among Mn_6 ions is dominant. As noted in structural description, NNPy is coordinating to Mn^{II} ion in pyridine-N coordination mode. Therefore, the magnetic interaction between nitronyl nitroxide radical and Mn^{II} ion mediated by pyridine moiety is expected to be very weak [27].

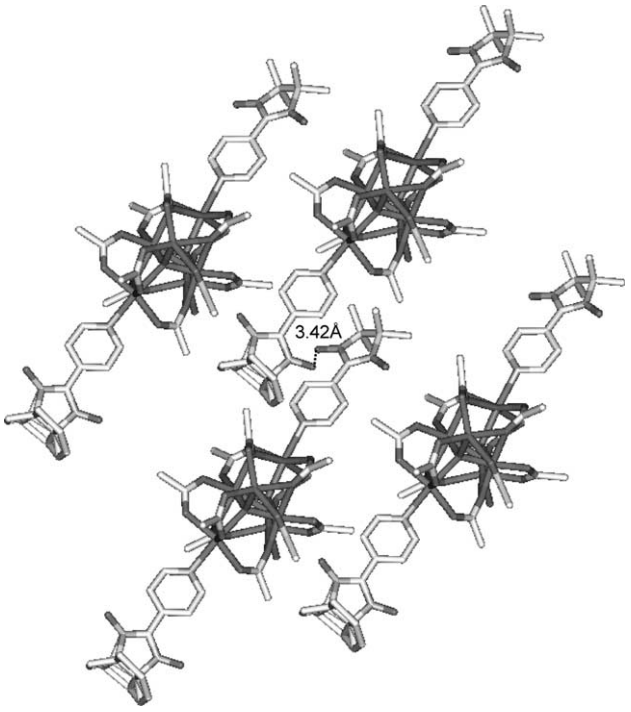

Fig. 2. Packing diagram of **2**.

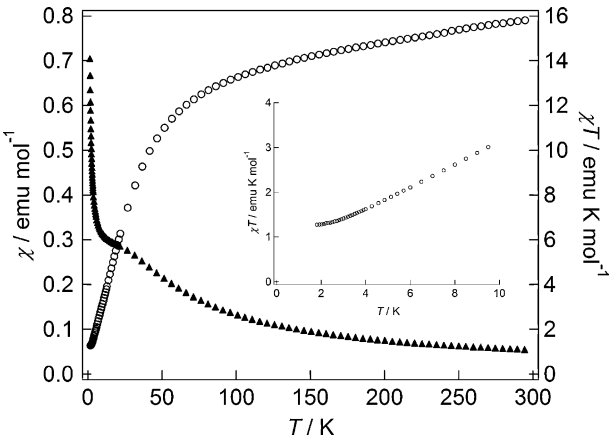

Fig. 3. The temperature dependence of magnetic susceptibility χ_M (close-triangle) and $\chi_M T$ products (open-circle) of **2** measured at 1 kOe. The inset shows $\chi_M T$ products in the low temperature region.

The $\chi_M T$ value of 15.85 emu K mol^{-1} at 300 K is smaller than the spin-only value of 24.25 emu K mol^{-1} ($g = 2.00$). Upon cooling temperature, the value of $\chi_M T$ decreases gradually to 11.00 emu K mol^{-1} at 50 K and more rapidly to 1.27 emu K mol^{-1} at 1.81 K. The whole feature of $\chi_M T$ versus T seems to be very similar to that in **1** (antiferromagnetic coupling among Mn_6 cluster). However, χ_M versus T behavior at low temperatures well expresses the magnetic system of **2**; the χ_M gradually increases from 300 to ca. 20 K, at which shows a kink (peak), then increases abruptly at low temperatures (Fig. 3). The increase of χ_M at lower temperatures indicates the presence of paramagnetic nitronyl nitroxide radicals. Actually, the susceptibility of **1** and a derivative $[Mn_6O_2(PhCO_2)_{10}(py)_2(MeCN)_2] \cdot 2MeCN$ continuously decreases below a broad peak at ca. 20 K [28]. For **2**, the magnetic contribution can be considered as following three possibilities; (i) intra-cluster antiferromagnetic contribution, i.e., magnetic coupling among Mn_6 ions, (ii) interaction between the radical and Mn^{II} ion via pyridine moiety, and (iii) inter-molecule interaction, probably via the O···O contact of adjacent nitronyl nitroxide moieties. The (i) should be the main contributor compared to others $J(Mn^{III}\cdots Mn^{III})/k_B = -60$ K, $J(Mn^{III}\cdots Mn^{II})/k_B = -1.2$ K, $J(Mn^{II}\cdots Mn^{II})/k_B = -3.5$ K for $[Mn_6O_2(PhCO_2)_{10}(py)_2(MeCN)_2] \cdot 2MeCN$ [28]. As mentioned above, the contribution (ii) could be very small as expected from previous reports [27,29–31]. The fact that the spin density on the nitrogen atom of the pyridine ring in NNPy is negligibly

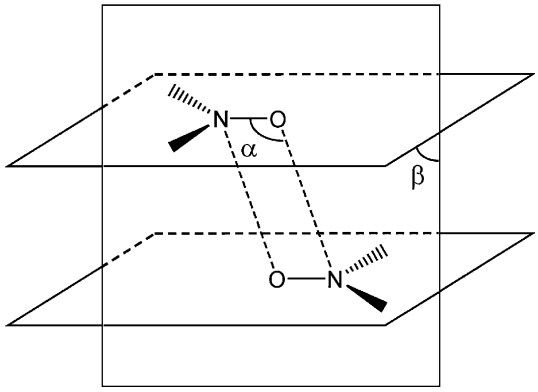

Fig. 4. The definition of the geometrical parameters α and β associating with intermolecular interaction on nitronyl nitroxide molecules.

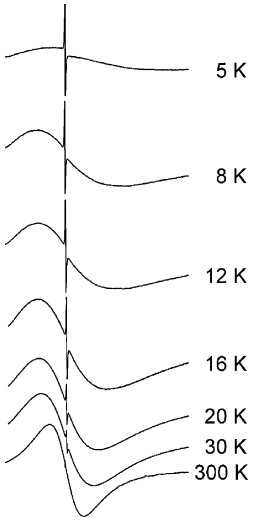

Fig. 5. The temperature dependence of ESR signals measured on a polycrystalline sample of **2** in the range of 300–5 K.

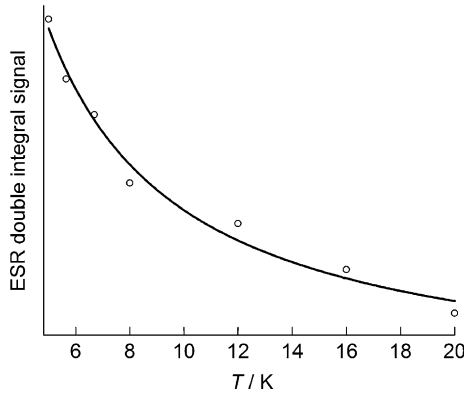

Fig. 6. The variation of double integral of the ESR signal as a function of temperature.

small supports our speculation [31]. Compared to (ii), the contribution of (iii) may be not negligible because of considerable short O···O separation with 3.42 Å of nitronyl nitroxide moieties in **2**. The magnitude of exchange interaction between aminoxyl units depends on their proximity and on the relative orientation of their π*-orbital where the unpaired electron is located. A good estimation for the latter is provided by the geometrical parameters α and β defined in Fig. 4 [32]. For **2**, the relevant parameters for two adjacent NO groups, the N···O distance of 3.46 Å, $\alpha = 143°$, $\beta = 65°$, are indicative of close, but more importantly, a significant decrease of α and β which significantly deviates from 90°, respectively. Consequently, the π*-orbitals are tilted and their overlap could be small. On that account, a weak exchange interaction is anticipated for (iii). Consequently, the nitronyl nitroxide radical acts as if an isolated paramagnetic unit in **2**, consistent with the observation of increase of χ_M below 20 K.

3.3. ESR measurement

The X-band electron spin resonance (ESR) spectra were measured on a polycrystalline sample of **2** at several temperatures in the range of 300–5 K (Fig. 5). ESR signal at 300 K shows a broad single line centered at $g = 1.98$ with peak to peak line width $\Delta H_{pp} = 106.58$ mT. This broad signal is observed in the entire temperature range measured, although the intensity slightly weakens with lowering temperature. This broad signal would be contributed from Mn_6 cluster subunit (metal origin). Below 30 K, a sharp signal is clearly detected at $g = 2.00$ and becomes observable with decreasing temperatures. This is indeed attributable to free radical species (nitronyl nitroxide radical) as suggested from χ_M behavior at low temperatures. The plots of the double integral for the $g = 2.00$ signal versus T display the profile of a paramagnetic species according to the Curie–Weiss law, in agreement with the susceptibility results (see Fig. 6) [33]. Thus, the increase of χ_M below 20 K is assigned to the contribution of nitronyl nitroxide radical as if a free radical. These magnetic results show that the magnetic interaction between the radical of NNPy moiety and Mn^{II} ion (i.e., Mn_6 cluster) is very small compare to the intra-cluster exchange interactions.

4. Conclusion

The assembly reaction of hexanuclear manganese cluster $[Mn_6O_2(t\text{-}BuCO_2)_{10}(THF)_4]\cdot THF$ (**1**) and pyridyl-substituted nitronyl nitroxide radical (NNPy) yielded a hetero-spin complex $[Mn_6O_2(t\text{-}BuCO_2)_{10}(H_2O)(NNPy)_2]$ (**2**) in which the parent cluster core was preserved. The data of temperature dependence of the magnetic susceptibility and ESR clarified the magnetic distribution in **2**; the Mn_6 cluster moiety and NNPy moiety act independently as paramagnetic magnetic centers, producing an $S_T = 0$ spin state for the former and an isolated $S = 1/2$ for the latter.

5. Supplementary material

Crystallographic data (excluding structure factors) for structure reported in this paper have been deposited at the Cambridge Data Centre as supplementary publication No. CCDC-254882 for **2**. This data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; or e-mail: deposit@ccdc.cam.ac.uk).

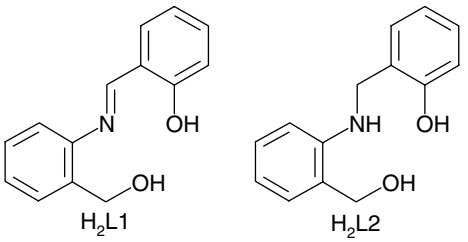

Chart 1.

2. Experimental

2.1. Preparation

All ordinary reagents and solvents were purchased and used as received, unless otherwise noted. Methanol was purified by distillation over magnesium turnings. Dichloromethane was dehydrated with CaH_2 and distilled before using. The ligand H_2L1 [9] and H_2L2 [10] were obtained by the literature methods.

2.1.1. *[Ni4Cl2(L1)2(HL1)2] (1)*

A solution of nickel(II) chloride hexahydrate (0.238 g, 1.0 mmol) and H_2L1 (0.227 g, 1.0 mmol) in methanol (15 cm^3) was stirred for 1 h at room temperature. The solution was evaporated to dryness under reduced pressure. The green residue was extracted by dichloromethane (5 $cm^3 \times 3$). The green microcrystals were obtained after 1 day. Recrystallization from dichloromethane–toluene (1:1 v/v) solution formed deep green crystals suitable for X-ray crystallography. $[Ni_4Cl_2(L1)_2(HL1)_2]$ (**1**); Yield: 15%. *Anal*. Calc. for $C_{56}H_{46}Cl_2N_4Ni_4O_8$: C, 55.65; H, 3.84; N, 4.64; Ni, 19.42. Found: C, 55.61; H, 3.84; N, 4.62; Ni, 18.7%.

2.1.2. *[Mn2Ni2Cl2(L1)4(H2O)2] (2)*

Manganese(II) chloride tetrahydrate (0.198 g, 1.0 mmol) and H_2L1 (0.227 g, 1.0 mmol) were dissolved in methanol (10 cm^3) and a solution of triethylamine (0.5 mmol) in methanol (5 cm^3) was added, and the mixture was stirred for 30 min. To the resulted solution was added a solution of nickel(II) chloride hexahydrate (0.238 g, 1.0 mmol) in methanol (5 cm^3) with stirring. The solution was evaporated to dryness under reduced pressure. The brown residue was extracted by dichloromethane (5 $cm^3 \times 3$). The oak brown microcrystals were obtained after 1 day. Recrystallization from dichloromethane–toluene (1:1 v/v) solution formed brown crystals suitable for X-ray crystallography. $[Mn_2Ni_2Cl_2(L1)_4(H_2O)_2]$ (**2**) $\cdot 2CH_2Cl_2 \cdot H_2O$; Yield: 42%. *Anal*. Calc. for $C_{58}H_{54}Cl_6Mn_2N_4Ni_2O_{11}$: C, 48.95; H, 3.82; N, 3.94; Mn, 7.72; Ni, 8.25. Found: C, 48.98; H, 3.31; N, 3.92; Mn, 7.91; Ni, 8.83%.

2.1.3. *[Ni4(L2)4(CH3OH)2] (3)*

A solution of nickel(II) chloride anhydrous (0.130 g, 1.0 mmol), H_2L2 (0.229 g, 1.0 mmol), and potassium *t*-butoxide (0.152 g, 2.0 mmol) in methanol (15 cm^3) was stirred for 1 h under nitrogen atmosphere. The solution was evaporated to dryness under reduced pressure. The residue was dissolved in dichloromethane, and the solution was filtered to remove insoluble materials. To the filtrate was added 5 cm^3 of methanol and allowed to stand. After a few weeks, the bright green crystals were obtained and collected by suction filtration. $[Ni_4(L2)_4(CH_3OH)_2]$ (**3**) $\cdot CH_2Cl_2 \cdot 2CH_3OH \cdot H_2O$; Yield: 66%. *Anal*. Calc. for $C_{61}H_{72}Cl_2N_4Ni_4O_{13}$: C, 53.29; H, 5.28; N, 4.07; Ni, 17.08. Found: C, 52.59; H, 4.85; N, 4.26; Ni, 17.63%.

2.2. Physical measurements

Elemental analyses for C, H and N were obtained at the Elemental Analysis Service Center, Kyushu University. Analyses of nickel and manganese were made on a Perkin Elmer AAnalyst 100 atomic absorption/flame emission spectrophotometer. Infrared spectra were recorded on a Perkin Elmer Spectrum 2000 FT-IR Spectrometer on KBr disks at the Instrumental Analysis Center, Saga University. The magnetic susceptibilities in the temperature range 2–300 K were measured on a Quantum Design MPMS XL SQUID susceptmeter under an applied magnetic field of 500 G. The susceptibilities were corrected for the diamagnetism of the constituent atoms using Pascal's constant [11]. The effective magnetic moments were calculated from the equation, $\mu_{eff} = [8\chi_M T^{1/2}]$ where χ_M is the molecular magnetic susceptibility.

2.3. X-ray crystallography

The diffraction data were measured on a Rigaku AFC5S automated four-circle diffractometer. The data were collected using the ω–2θ scan technique to a maximum 2θ value of 55°. Crystal data and data collection parameters: **1** $\cdot 4CH_2Cl_2$, $C_{30}H_{27}Cl_5N_2Ni_2O_4$, M = 774.22, triclinic, a = 11.563(3) Å, b = 11.834(4) Å, c = 12.449(3) Å, α = 108.31(2)°, β = 90.92(2)°, γ = 92.64(2)°, V = 1614.7(8) $Å^3$, space group $P\bar{1}$(#2), Z = 2, D_{calc} = 1.592 g/cm^3, T = 298 ± 1 K, F_{000} = 788.00, μ(Mo Kα) = 16.17 cm^{-1}, 5922 reflections observed, No. of variables = 390, final value for $R(I > 2\sigma(I))$ = 0.052/R_w(All reflections) = 0.172. **2** $\cdot 2CH_2Cl_2$, $C_{29}H_{26}Cl_3N_2NiMnO_5$, M = 702.53, triclinic, a = 9.207(2) Å, b = 11.495(3) Å, c = 15.060(5) Å, α = 68.26(3)°, β = 89.27(2)°, γ = 83.87(2)°, V = 1471.4(7) $Å^3$, space group $P\bar{1}$(#2), Z = 2, D_{calc} = 1.586 g/cm^3, T = 298 ± 1 K, F_{000} = 716.00, μ(Mo Kα) = 13.83 cm^{-1}, 6732 reflections observed, No. of variables = 371, final value for $R(I > 2\sigma(I))$ = 0.056/R_w(All reflections) = 0.179. **3** $\cdot CH_2Cl_2 \cdot 2CH_3OH$, $C_{61}H_{70}Cl_2N_4Ni_4O_{12}$, M = 1356.95, triclinic, a = 13.10(1) Å, b = 14.411(5) Å, c = 17.047(4) Å,

$\alpha = 81.05(6)°$, $\beta = 85.17(3)°$, $\gamma = 72.31(5)°$, $V = 3025(3)$ Å^3, space group $P\bar{1}(\#2)$, $Z = 2$, $D_{calc} = 1.490$ g/cm^3, $T = 298 \pm 1$ K, $F_{000} = 1412.00$, μ(Mo Kα) = 13.78 cm^{-1}, 13977 reflections observed, No. of variables = 759, final value for $R(I > 2\sigma(I)) = 0.088$/$R_w$(All reflections) = 0.276.

The structures were solved by direct methods and expanded using Fourier techniques [12,13]. The non-hydrogen atoms were refined anisotropically. All hydrogen atoms were located on the calculated positions and refined isotropically. The final cycle of full-matrix least-squares refinement on F was based on observed reflections and variable parameters and converged with unweighted and weighted agreement factors of R and Rw. All calculations were performed using the CrystalStructure [14] crystallographic software package of Molecular Structure Corporation.

3. Results and discussion

Analytical data of **1**–**3** gave 1:1 ratio of a metal and a ligand. The free H_2L1 ligand shows ν(C=N) vibrations at 1615 cm^{-1}, which shift to 1607–1609 cm^{-1} in **1** and **2**. Complex **3** shows ν(N–H) and ν(C–N) vibrations at 3055 and 1297 cm^{-1}, respectively.

3.1. Crystal structures

3.1.1. $[Ni_4Cl_2(L1)_2(HL1)_2]$ (**1**) · $4CH_2Cl_2$

The structure of **1** is illustrated in Fig. 1. The complex has a tetranuclear structure with an inversion center. The four nickel atoms are located at the four corners of a defective double-cubane core and bridged by each two μ_3-alkoxo, μ-phenoxo, and μ-chloro bridges. There are two types of deprotonated ligand anions ($L1^{2-}$ and $HL1^-$) in the complex. The dianionic ligands, $L1^{2-}$, give μ_3-alkoxo bridge by deprotonated O1 atom, and form bis-μ-alkoxo dinuclear $[Ni(L1)]_2$ unit at the center of the double-cubane core. The O3 atom of monoanionic ligand, $HL1^-$, is protonated and coordinates to Ni2 without bridging. The Ni···Ni distances of Ni1···Ni2, Ni1···Ni2*, Ni1···Ni1*, and Ni2···Ni2* pairs are 3.0671(8), 3.1172(9), 3.1790(7), and 5.3049(9) Å, respectively. Coordination geometries about Ni1 and Ni2 are described as an octahedron and a square pyramid, respectively, but each geometry is significantly distorted due to a longer Ni–Cl bond. The basal-plane of Ni1 is comprised of N1, O1, O2, and O1* and the axial axis is regarded as O4–Ni1–Cl1* direction. In the same way, O1, O3, O4, and N1 atoms define the basal-plane of Ni2, and Cl1 atom locates the apical position. The effect of the longer Ni–Cl bonds lead to large distortion of the double-cubane core compare with that observed for $[Cu(L1)]_4$ [8].

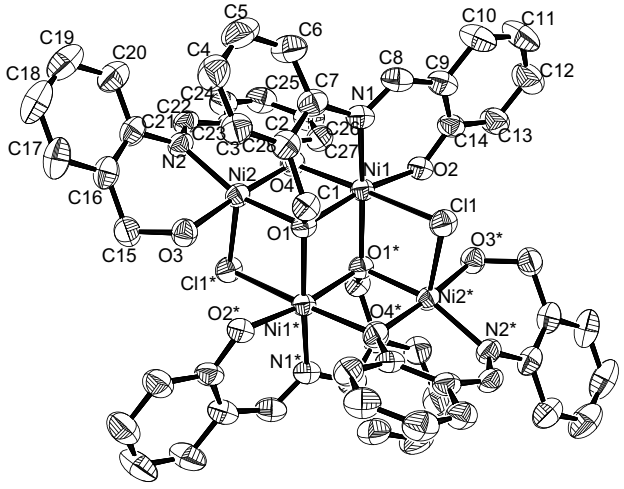

Fig. 1. An ORTEP view of **1** with the atom-numbering scheme. Selected distances (Å) and angles (°): Ni1–O1 2.043(3), Ni1–O2 1.980(3), Ni1–O4 2.090(3), Ni1–N1 2.016(4), Ni1–O1* 2.069(3), Ni1–Cl1* 2.589(1), Ni2–O1 2.009(3), Ni2–O3 2.068(3), Ni2–O4 1.967(3), Ni2–N2 1.986(4), Ni2–Cl1 2.330(1), Ni1···Ni2 3.0671(8), Ni1···Ni1* 3.1790(7), Ni1···Ni2* 3.1172(9), Ni2···Ni2* 5.3049(9); Ni1–O1–Ni2 98.4(1), Ni1–O4–Ni2 98.2(2), Ni1–O1–Ni1* 101.3(1), O1–Ni1–O1* 78.7(1), Ni1–O1*–Ni2* 99.7(1), Ni1–Cl1*–Ni2* 78.46(4), O1–Ni1–O4 79.8(1), O3–Ni2–Cl1 94.74(9).

3.1.2. $[Mn_2Ni_2Cl_2(L1)_4(H_2O)_2]$ (**2**) · $2CH_2Cl_2$

The structure of **2** comprised of a tetranuclear defective double-cubane core (Fig. 2). The asymmetric unit consists of one Ni^{II}, Mn^{III}, Cl^-, water molecule, and two $L1^{2-}$ anions. The two Ni^{II} and two Mn^{III} ions are located at the four corners of a defective double-cubane core and bridged by each two μ_3-alkoxo, μ-alkoxo, and μ-phenoxo bridges. Each Mn^{III} is positioned in both edges of double-cubane and each Ni^{II} resides in central position. Coordination geometries about Ni1 and Mn1

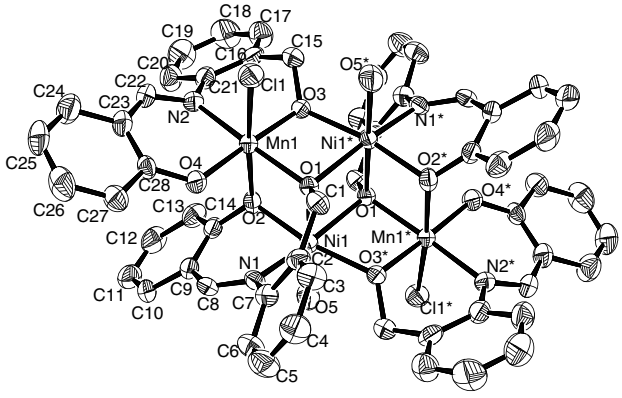

Fig. 2. An ORTEP view of **2** with the atom-numbering scheme. Selected distances (Å) and angles (°): Ni1–O1 2.026(4), Ni1–O3 2.068(3), Ni1–O3* 2.142(4), Ni1–O4 2.010(4), Ni1–O5 2.128(4), Ni1–N2 2.018(5), Mn1–Cl1 2.587(2), Mn1–O1 1.876(4), Mn1–O2 1.861(4), Mn1–O3 1.997(4), Mn1–O4 2.246(4), Mn1–N1 2.039(5), Ni1··· Mn1 3.096(1), Ni1···Ni1* 3.1311(9), Ni1···Mn1* 3.082(1), Mn1···Mn1* 5.326(1); Ni1–O1*–Mn1* 104.3(2), Ni1–O3*–Mn1* 96.2(2), Ni1–O3–Ni1* 96.1(2), O3–Ni1–O3* 83.9(1), Ni1–O3–Mn1 99.4(2), Ni1–O4–Mn1 93.2(2), O1–Mn1–O3 82.9(1), O3–Ni1–O4 85.8(2).

are described as octahedral geometries. The basal-plane of Ni1 is comprised of N1, O2, O1*, and O3*, and axial sites are occupied by O1 and water molecule (O5). Similarly, O1, O3, O4, and N2 atoms define the basal-plane of Mn1, and axial sites are occupied by O2 and chloride anion (Cl1). The Mn1–Cl1 [2.586(2) Å] and Mn1–O4 [2.247(4) Å] distances are elongated relative to the equatorial bond distances [1.862(4)–2.037(6) Å] owing to the Jahn–Teller effect. The M···M distances of Ni1···Mn1, Ni1···Mn1*, Ni1···Ni1*, and Mn1···Mn1* pairs are 3.096(1), 3.082(1), 3.1311(9), and 5.326(1) Å, respectively. The adjacent M···M distances are similar and bond angles around metal ions are close to orthogonal. As a result, the complex **1** has rather fine double-cubane structure compare with **1**, $[Cu(L1)]_4$, and other reported double-cubane complexes [15–18]. Most of tridentate ligands act as meridional forms in both mononuclear and polynuclear complexes [19,20]. In present case, the ligand $L1^{2-}$ coordinating to Ni1 is held as a facial form. This is the first example of structurally characterized facial coordination of $L1^{2-}$.

3.1.3. $[Ni_4(L2)_4(CH_3OH)_2]$ (**3**) · CH_2Cl_2 · $2CH_3OH$

Complex **3** is unstable under open atmosphere. The coordinating ligands $(L2)^{2-}$ in **3** are easily oxidized to $(L1)^{2-}$ as same as the reported complex $[Cu(L2)]_4$. Only a thin crystal of **3** was found to be applicable for X-ray analysis. Though the bond lengths and angles are insufficient for detailed structural discussion, the X-ray analytical results of **3** clearly reveal the geometry around the metal ions and tetranuclear core. A perspective drawing is given in Fig. 3. The complex has a cubane-like Ni_4 core structure. The structure is fundamentally regarded as a dimer-of-dimers structure composed by alkoxo-bridged dinickel units. However, coordination-planes of *ONO*-tridentate ligands in the dimmer unit are not occupied in same plane. The Ni···Ni distances for bis-μ-alkoxo units (3.112(2)–3.124(2) Å) are slightly longer than the other Ni···Ni distances (2.961(2)–3.114(2) Å). It is indicated that the symmetry of cubane-core for **3** is remarkably distorted. Coordination geometry of Ni1 and Ni3 is octahedral by the coordination of a methanol. On the other hand, the geometry of Ni2 and Ni4 is regarded as square-pyramid. The axial positions for Ni2 and Ni4 are covered by phenyl ring from the L2 ligand coordinating to Ni1 and Ni3, respectively. It is supposed that these unusual structural features are caused by sp^3 character of benzyl-C and amine-N atoms [10].

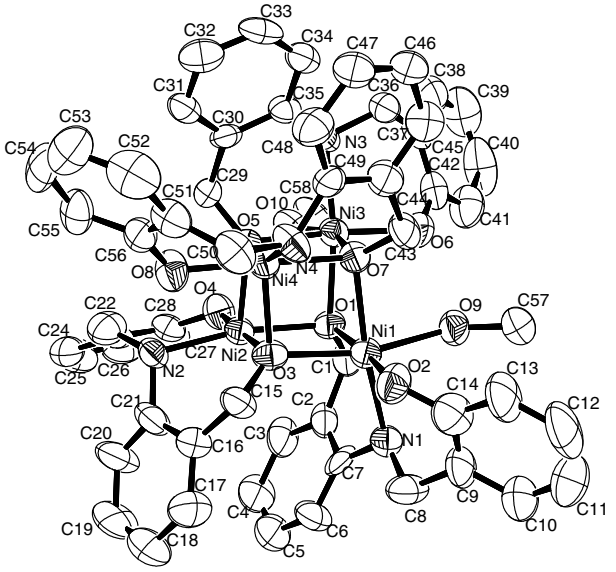

Fig. 3. An ORTEP view of **3** with the atom-numbering scheme. Selected distances (Å) and angles (°): Ni1–O1 2.028(8), Ni1–O2 1.98(1), Ni1–O3 2.089(7), Ni1–O7 2.103(6), Ni1–O9 2.189(7), Ni1–N1 2.138(9), Ni2–O1 2.035(7), Ni2–O3 2.038(9), Ni2–O4 1.94(1), Ni2–O5 2.026(6), Ni2–N2 2.029(8), Ni3–O1 2.060(6), Ni3–O5 2.027(6), Ni3–O6 1.946(8), Ni3–O7 2.103(8), Ni3–O10 2.20(1), Ni3–N3 2.111(8), Ni4–O3 2.059(7), Ni4–O5 2.031(8), Ni4–O7 2.027(6), Ni4–O8 1.954(8), Ni4–N4 2.04(1), Ni1···Ni2 3.124(2), Ni1···Ni3 3.114(2), Ni1···Ni4 3.087(2), Ni2···Ni3 3.016(2), Ni2···Ni4 2.961(2), Ni3···Ni4 3.112(2); Ni1–O1–Ni2 100.5(3), Ni1–O1–Ni3 99.2(3), Ni1–O3–Ni2 98.4(3), Ni1–O3–Ni4 96.2(3), Ni1–O7–Ni3 95.6(3), Ni1–O7–Ni4 96.7(2), Ni2–O1–Ni3 94.9(3), Ni2–O3–Ni4 92.6(3), Ni2–O5–Ni3 96.2(3), Ni2–O5–Ni4 93.8(3), Ni3–O5–Ni4 100.2(3), Ni3–O7–Ni4 97.8(3).

3.2. Magnetic properties

Tetranuclear Ni^{II} complexes **1** and **3** decompose easily even the solid state. Complex **1** change to dinuclear $[Ni(L1)]_2$ unit and mononuclear species and **3** change to Shiff base complex. Therefore, reliable temperature dependence data were not able to obtained. The effective magnetic moments of **1** and **3** are 2.79 and 3.21 B.M./Ni at room temperature. The obtained moments correspond to common values for mononuclear octahedral Ni^{II}-complexes. Judging from structural and magnetic data of $[Cu(L1)]_4$ and $[Cu(L2)]_4$, it is expected that magnetic interactions in **1** and **3** are fairly weak [10].

The $\chi_M T$ versus temperature plots for **2** (per $Ni^{II}_2Mn^{III}_2$) were shown in Fig. 4. The $\chi_M T$ values gradually increased with lowering temperature and reach to a nearly constant value ($\sim$22 $cm^3\,mol^{-1}\,K$) at 4 K. The calculated magnetic moment of 13.2 μ_B at 4 K suggests $S = 6$ spin state which corresponds to the sum of spins for two Ni^{II} ($S = 1$) and two Mn^{III} ($S = 2$) ions. This behavior indicates the presence of ferromagnetic interaction between metal ions in double-cubane core. The experimental data were interpreted by a least squares fit employing the Kambe's method [21] where only two dominant pathways are considered (Chart 2).

The Hamiltonian is written as

$$\hat{H} = -J_{\mathrm{NiMn}}(\hat{S}_{\mathrm{T}}^2 - 2\hat{S}_{\mathrm{A}}^2 - \hat{S}_{\mathrm{B}}^2) - J_{\mathrm{NiNi}}(\hat{S}_{\mathrm{A}}^2 - \hat{S}_1^2 - \hat{S}_3^2), \quad (1)$$

where

$$\hat{S}_{\mathrm{A}} = \hat{S}_1 + \hat{S}_3,\ \hat{S}_{\mathrm{B}} = \hat{S}_2 + \hat{S}_4 \quad \text{and} \quad \hat{S}_{\mathrm{T}} = \hat{S}_{\mathrm{A}} + \hat{S}_{\mathrm{B}}. \quad (2)$$

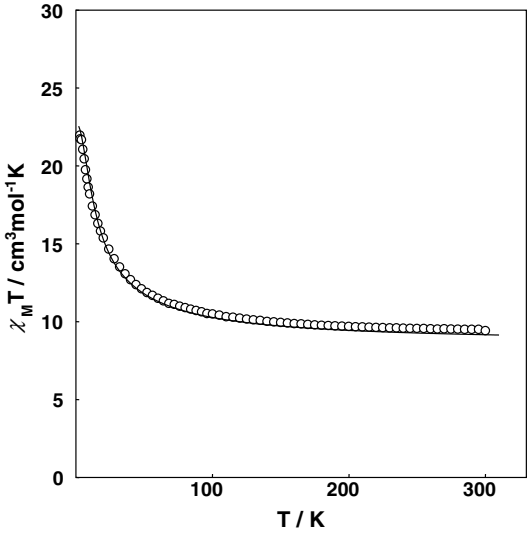

Fig. 4. Plots of $\chi_M T$ vs. T for **2**. The solid line represents a least squares fit of the data as described in the text.

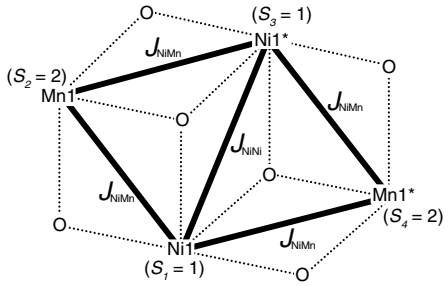

Chart 2.

The Kambe's equivalent operator approach gives the expression in Eq. (3)

$$E(S_T) = -J_{NiMn}[S_T(S_T+1) - S_A(S_A+1) - S_B(S_B+1)] - 2J_{NiNi}[S_A(S_A+1)]. \quad (3)$$

The results of fitting the experimental data are drawn as solid line. The obtained fitting parameters are $g = 2.08$, $J_{NiMn} = 1.5\ cm^{-1}$, $J_{NiNi} = 20\ cm^{-1}$. It is clearly demonstrated that **2** is ferromagnetically coupled between Ni^{II}–Mn^{III}, Ni^{II}–Ni^{II} centers to give the $S = 6$ ground state. The double-cubane structure of $[Cu(L1)]_4$ which shows antiferromagnetic coupling between Cu ions is fairly distorted to triclinic form. As compared this, structural distortion of **2** is quite smaller and metal ions are arranged at nearly ideal positions. The perpendicular arrangement of magnetic orbitals led to the results of the dominant ferromagnetic interactions J_{NiMn} and J_{NiNi} in **2**.

4. Conclusion

Tetranuclear complexes **1**–**3** have been synthesized by the reaction of metal sources with *ONO*-tridentate ligand H_2L1 or H_2L2. Complexes **1**–**3** have been characterized by X-ray crystal structure analyses. The structure analyses reveal that complexes **1** and **2** have a unique defective double-cubane core connected by μ_3-alkoxo bridges and **3** forms cubane core comprised by dimmer-of-dimmers of bis-μ-alkoxo units. The magnetic interactions in **2** are interpreted as ferromagnetic due to the orthogonality of the magnetic orbitals in $Ni^{II}_2Mn^{III}_2$ core.

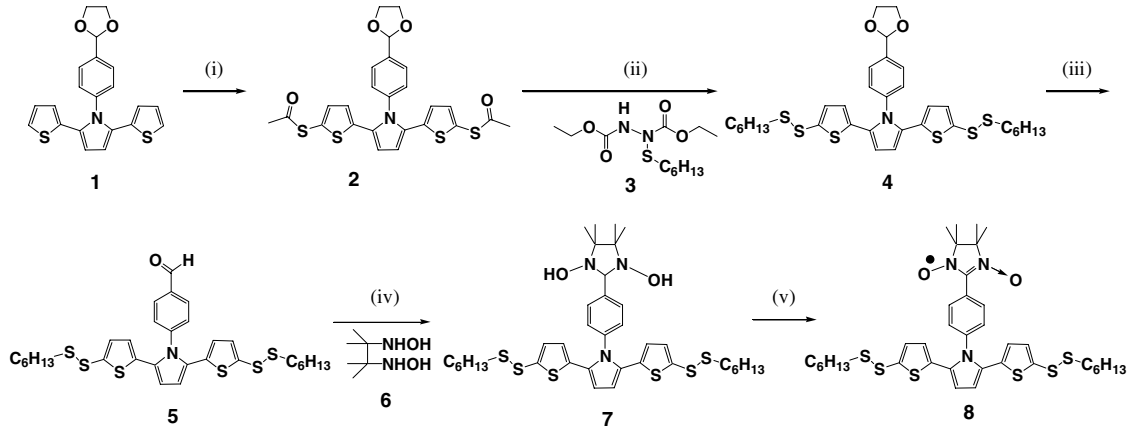
energy caused by the addition of an extra electron, amounts to 60 meV, which is larger than the thermal energy k_BT, e.g., 20 meV at 300 K. Such a small nanaoparticle must operate as a single electron transistor, if a tunnel barrier of the nanoparticle is larger than ca. $h/e^2 = 26\ k\Omega$. Such a nano-particle is expected to work as a single electron transistor. Therefore, it would be extremely interesting to connect these nanoparticles in a networked manner through the conducting molecular wires.

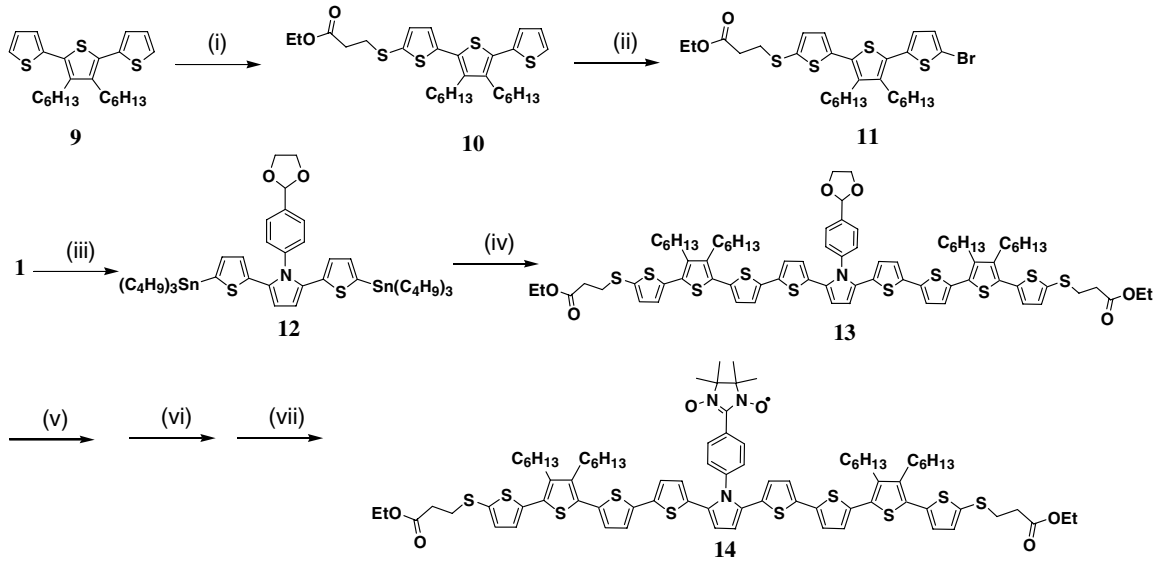
Recently we succeeded in preparing a network structure of gold nanoparticles with average diameter of 4 nm, being connected with molecular wires of oligothiophene 3*mer*, 9*mer*, or 15*mer*, and found that the network as a whole operates as a semiconductor with small activation energies of around 20 meV. Moreover, the contribution of electron tunneling becomes predominant at lower temperatures. The above results prompted us to make a network structure composed of gold nanoparticles and spin-polarized molecular wire. A unique point in this network is that a local spin resides on a π-conjugated molecular wire, whereas conduction electrons hop over or tunnel through gold nanoparticles in the network. We have prepared a pyrrole-based spin-polarized donor with two thienyl groups at α,α′-positions of the central pyrrole ring [8–11]. This wire is expected to interconnect the gold nanoparticle and also chemisorb to gold electrodes through thiol groups introduced at both terminals of the wire, operating as a spin-valve [12,13].

2. Results and discussion



2.1. Preparation of spin-polarized molecular wire

We prepared a spin-polarized molecular wire made of pyrrole-based spin-polarized core, carrying oligothiophens as a molecular wire (**1**). Synthetic route of the spin-polarized molecular wire is shown here (Scheme 1). One problem here is that when the acetylthio group of the radical ligand is deprotected, the generated thiolate kills the radical. Since it is known that this radical disulfide derivative safely chemisorbs on the gold surface, the new precursor, which has hetero-disulfide units at both ends, was synthesized [14]. The designed novel precursor, having disulfide group at both ends, is expected to form a network structure by interconnecting gold nanoparticles. Synthesis of spin-polarized molecular wire (**8**), having disulfide groups at both ends, was performed according to this reaction scheme. This acetal derivative (**4**), which is a precursor of the radical ligand, can also be utilized as a reference compound which does not have an unpaired electron.



As an perspective along this line, a longer spin-polarized wire with a thiophene–pyrrole hybrid nanomer was also prepared. Preparative rout of an elongated spin-polarized wire made of the hybrid nonamer was shown in Scheme 2. Terthiophene derivative with long alkyl chains and a protected-thiol group was prepared and it was brominated at the α-position (**11**). Then, the brominated trimer was coupled with a hybrid trimer with stanylated thienyl groups (**12**) at both ends to afford a precursor of the spin-polarized molecular wire (**14**) [9,11].

2.2. Preparation of the network structure of gold nanoparticles connected with spin-polarized molecular wire

Preparation of the network structure of gold nanoparticles connected with spin-polarized molecular wire is practically the same as the oligothiophene network [15–17]. Namely, dip the interdigitated electrodes with a gap of 100 μm in a solution of the molecular wire (0.31 mM) for 30 min, and then add a solution of surfac-

tant-stabilized gold nanoparticles (11.25 mM) and leave the mixture standing for 12 h. The resulted sample was washed with toluene and dried (Fig. 1). Since we use electrodes with a gap of 100 μm, it requires at least 1.8×10^4 nanoparticles to link the electrodes.

3. Characterization of network structure of gold nanoparticles connected with spin-polarized molecular wire

These are FE-SEM images of the networked structure of gold nanoparticles with the average diameter of 4 nm, connected by spin-carrying molecular wires on interdigitated electrodes with a gap of 100 μm (Fig. 2). As you see, the network structure covers over the electrodes. When an expanded image of the wire was examined it is to be noticed that the diameter of a granule is as large as 100 nm, which means that gold nanoparticle are assembled to form a cluster, and the clusters are interconnected to form a network.

In order to confirm this interpretation, a sample for the TEM measurement was prepared on a copper-grid (mesh) by drying a droplet out of a mixture of 1 ml of a toluene solution of the spin-polarized molecular wire (0.31 mM) and 1 ml of a toluene solution of TOAB-stabilized nanoparticles (11.25 mM). When the expanded image of the granule was examined it was found that it consisted of gold nanoparticles with the average diameter of 4 nm and that the gold nanoparticles in the granule were separated with each other by about 2 nm. The image is consistent with the network structure of gold nanoparticles connected by molecular wires with a length of 1.6 nm (see Fig. 3).

This a schematic picture to show how the network structure of gold nanoprticles are self-constructed in a hierarchical way. First, a gold atom obtained by the reduction of an aurate ion self-assembles to form a

nanoparticle with the average size of 4 nm; the nanoparticles is stabilized as this size by surfactants, such as tetraoctylammonium bromide. Then, nanoparticles are connected with molecular wires to form a cluster, the size of which is as large as 100 nm [18,19]. Finally clusters are further connected with molecular wires to end up with the network structure.

In order to confirm that gold nanoparticle were connected with "radical wires", temperature dependence of the magnetic susceptibility of the network was measured by means of a SQUID apparatus. These are the xT versus temperature plots of networks connected with spin-polarized wires and spinless wires (Fig. 4).

The horizontal plot indicates that radicals on the molecular wires behave paramagnetically, and the Curie constant evaluated from the intercept suggests that about 15 spins are on a nanoparticle in average. The result is consistent with the value estimated by the elemental analysis (C, 4.38%; H, 0.64%; N, 0.28%; ash, 91.3%. indicates that @Au1750:wire:*n*-hexanethiol:TOAB = 1:17:17:22). Since one wire is shared with two particles, at least 30 wires are coated on one nanoparticle. The plot below is derived from the network made of spinless wires. The Curie constant estimated from the plot suggests that one spin per nanoparticle exists in average. Since there are about 1750 gold atoms in one gold nanoparticle with the size of 4 nm, this paramagnetic spin is presumably due to the impurity spin locating at a defect inside of or more probably on the surface of the nanoparticle [20–22].

3.1. Conducting property of network of gold nanoparticles

Temperature dependence of the conductance of three types of the network structures was measured using interdigitated electrodes with a gap of 100 μm: the network connected with spinless molecular wires, spin-polarized molecular wires, and also alkanedithiol wires (σ-network) (see Fig. 5).

Wire	*E*a(H)	*E*a(L)
1,10-Decane-dithiol	21 meV	
Spinless molecular wire	10 meV 300–56 K	3 meV 18–9 K
Spin-polarized molecular wire	15 meV 300–70 K	5.2 meV 22–9 K

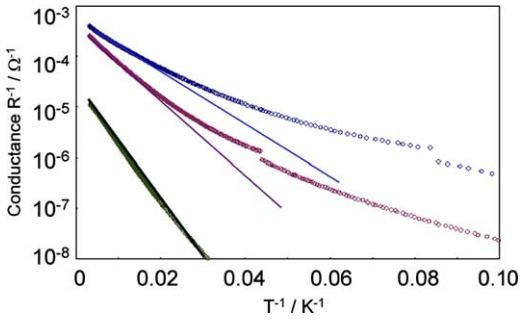

Fig. 5. Temperature dependence of conductance of three types of networked structure. From the top spinless molecular wire, spin-polarized molecular wire, and 1,10-decanedithiol wire.

There are three important characteristics. First, the conductance of these π-networks is much large than that of the σ-network. Second, while the plot for the σ-network shows a straight line, those of π-networks are deviated from the straight line at lower temperatures than 50 K. Third, the conductance of the network connected with the spinless wire is larger than that of the spin-polarized one. The activation energies of these networks are also listed here. The values are in accord with the observed tendency of the conductance of each network.

The non-linear temperature dependence of π-type networks may be interpreted in terms of the variable range hoping mechanism. Besides, the contribution of the electron tunneling through molecular wires to the whole transportation becomes more important at lower temperatures [15–17].

Fig. 6 is a schematic figure depicting the energy levels of frontier orbitals of σ-type wire, π-typle wire and those of the spin-polarized wire near the Fermi level of a gold particle. Among them, the electronic structure of the radical wire is spin-polarized. This means that frontier orbital should be SOMO (β) in the UHF description, provided that the singly occupying electron is α. Under such a circumstance, the tunneling current is expected to be spin polarized to β. Therefore, it is extremely interesting to measure the tunneling current, paying an attention to the effect of application of an external magnetic field.

3.2. Application of external magnetic field on the spin-polarized network

In order to examine the external magnetic field on the networked gold nanoparticle connected with spin-polarized wires, the conductance of the network was

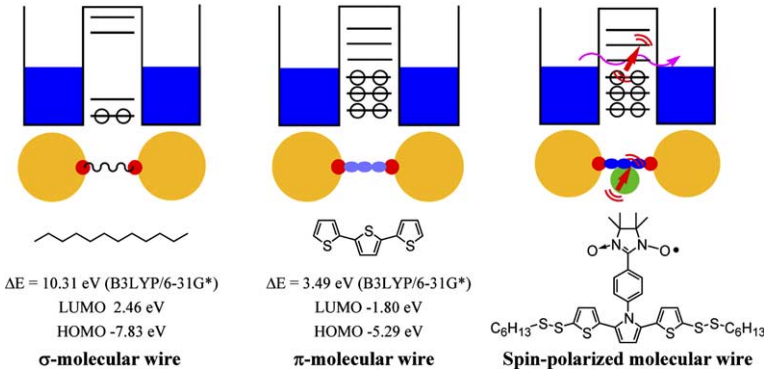

Fig. 6. Energy levels of frontier orbitals of σ-type wire, π-typle wire and the spin-polarized wire. Fermi level of gold is −5.1 eV.

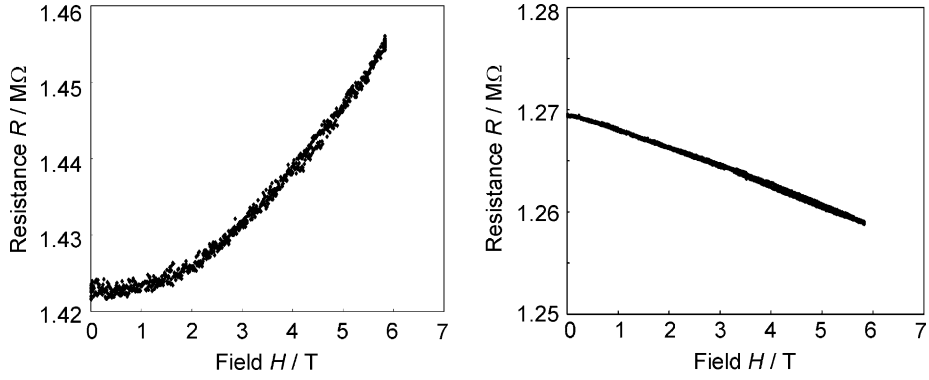

Fig. 7. Magneto resistance of networked gold nanoparticles with spinless molecular wire (left) and spin-polarized molecular wires (right) at 4.2 K.

measured using electrodes with a gap of 2 μm. The preparative method is practically the same as the previous one. It is estimated that 2 μm electrodes can be connected with at least about 360 nanoparticles.

The effect of an external magnetic field on the resistance of the network was examined by applying the field to the parallel direction in reference to the wires so that the Lorentz force does not operate. It was fond that the network made of spinless wires exhibited a small positive magneto resistance at 4 K under the external magnetic field in the range of 0–6 T. To the contrast, the magnetic field effect on the spin-polarized wires exhibited a negative magneto-resistance (Fig. 7). It means that the resistance of the wire decreases under the external magnetic field presumably because the fluctuation of the spins on the molecular wires is suppressed by the external magnetic field. Incidentally, the voltage to detect the conductance is 0.1 V. This voltage corresponds to the voltage to give a flat region in the *I–V* curve shown in the previous *I–V* plot.

4. Summary

Although the detail of the mechanism of electron transportation of the networked gold nanoparticles connected with molecular wires at cryogenic temperatures and of the magneto-resistance effect on the networks have not been fully understood yet, this is the first example that the negative magneto resistance was observed in an organic–inorganic nano-composite in which a local spin is located on the organic molecular wire. The network composed of such a small quantum dots connected with molecular wires in a three-dimensional manner should exhibit exotic non-linear conducting behaviors, including the Coulomb blockade, a memory effect caused by a recoding electric pulse, etc. and give rise to a fundamental results to molecule-based spinelectronic devices.

reflections [$I > 2\sigma(I)$] out of 4370 unique (R_{int} = 0.0154), GOF = 0.984.

3. Results and discussion

3.1. Descriptions of crystal structures

3.1.1. $[NO_2BzPy][Ni(dmit)_2]$ (1)

The ORTEP view of **1** in an asymmetric unit and the packing structure projected along *c*-axis are shown in Fig. 1(a) and (b). The bond lengths and angles in $[Ni(dmit)_2]^-$ anionic moiety are in good agreement with the reported compounds [1d]. The bond lengths in $[NO_2BzPy]^+$ moiety are close to the values in $[NO_2BzPy][Ni(mnt)_2]$ [4], and the dihedral angles between aromatic rings and the reference plane, C(13)/C(12)/N(1), are 67.0° for benzene ring, 88.2° for pyridine ring, respectively.

Two neighboring anions, which molecular planes are approximately perpendicular to *a*-axis, stack plane-to-plane with each other to form a dimer, the inter-planar distance (the anionic molecular plane is defined by coordination S atoms) is 3.72 Å, the nearest S···S contacts are 3.69 Å between S(3) and S(10)^i, 3.74 Å between S(2) and S(8)^i (symmetry code: i = 1 − *x*, 1 − *y*, 1 − *z*).

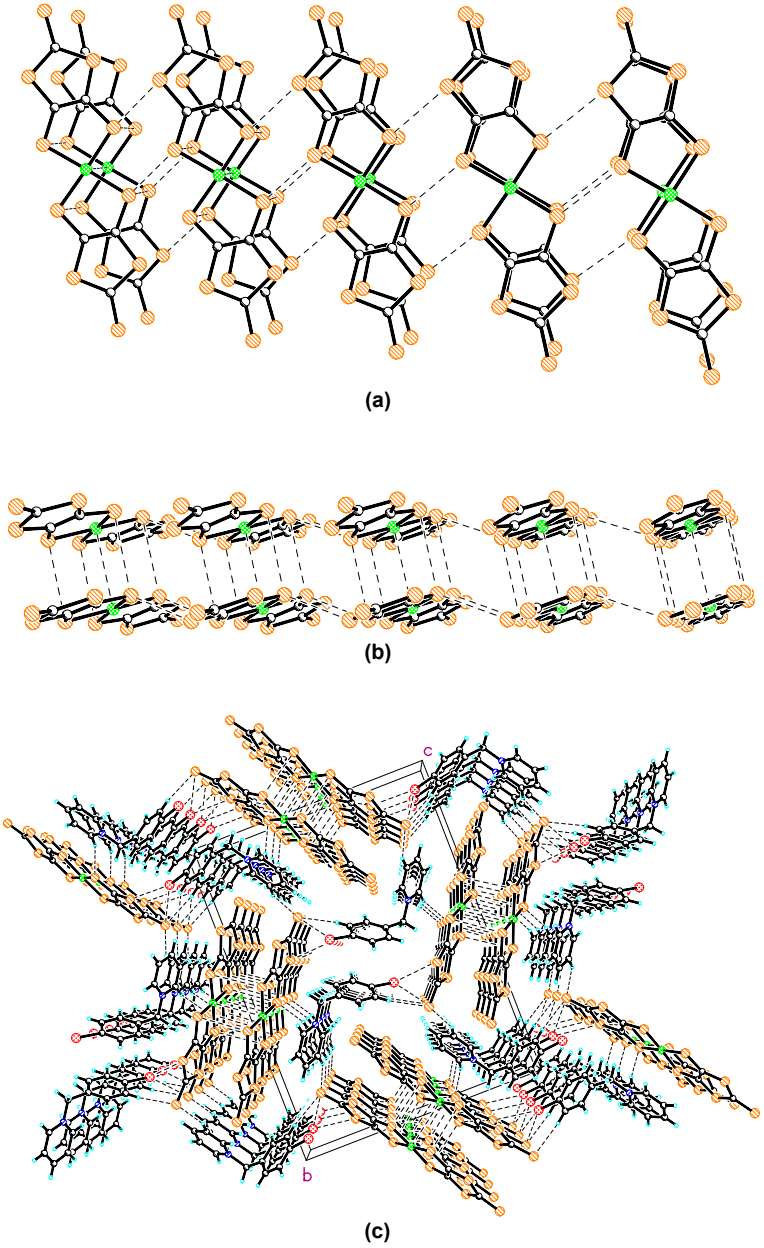

Fig. 3. (a) and (b) Spin ladder of $[Ni(dmit)_2]^-$ anions viewed along different directions (c) molecular packing diagram projected along *a*-axis in **2**.

This dimer develops further into two-leg ladder via terminal S···S interactions along *b*-axis [the shorter S···S separations are S(10)···S(4)^{j} = 3.52 Å, S(8)···S(4)^{j} = 3.38 Å, S(8)···S(5)^{j} = 3.69 Å (symmetry code: j = x, 1 + y, z)] (cf. Fig. 2(a)). Two neighboring $[NO_2BzPy]^+$ cations dimerize in a fashion of a chair-like conformation as illustration in Fig. 2(b). These distances of center-to-center between two benzene rings is 4.50 Å and the inter-planar separation is 3.59 Å, they are so larger that there is no any significant π···π stacking interaction between them. The anionic two-leg ladder is embraced by cationic dimers (Fig. 1(b)) with a van de Waals interactions.

3.1.2. [BrBzPy][Ni(dmit)$_2$] (2) [7]

Compound **2** crystallizes in *P*2(1)/*c* space group, an asymmetric unit contains a couple of anion and cation. The bond parameters in anion moiety are very similar to that in **1**, and those in $[BrBzPy]^+$ moiety are closed to the values in [BrBzPy][Ni(mnt)$_2$] [4]. Compared with **1**, the molecular geometry of $[BrBzPy]^+$ exhibits distinct difference from $[NO_2BzPy]^+$. The dihedral angles between aromatic rings and the reference plane, C(13)/C(12)/N(1), are 106.3° for benzene ring, 160.5° for pyridine ring, which are departures far from 90°. Two adjacent anions are eclipsed to overlap as a dimer as in **1**, whereas the correspondence inter-atomic separations and inter-planar distance are much less than that in **1** [Ni(1)···Ni(1)^{i} of 3.51 Å, S(1)···S(10)^{i} of 3.57 Å, S(5)···S(6)^{i} of 3.49 Å (symmetry code: i = $-x$, 1 − y, $-z$) and the inter-plane distance of 3.49 Å]. The lateral S···S interactions between neighboring anionic dimers lead them to form a two-leg ladder (Fig. 3(a)). Two-leg ladders are held together by intermediate cations via non-normal C–H···S H-bonding interactions to construct into 3D network (Fig. 3(b)) [7].

3.2. Magnetic properties

The temperature dependences of magnetic susceptibility for **1** and **2** are shown in Figs. 4 and 5. With respect to **1**, χ_m increases slowly as temperature goes down, and drops sharply below ~110 K to reveal a magnetic transition, the transition temperature is determined as 100.3 K in plot of $d(\chi_m T)/dT$ versus T (inset of Fig. 4). Above 110 K, AFM exchange interaction between neighboring spins dominates. Below 110 K, χ_m drops exponentially as temperature decreases to illustrate there is a spin energy gap in low-temperature phase. A paramagnetic Curie tail in low temperature region is attributed to the magnetic impurities of uncoupled spins. Based on crystal structural analysis, we try to fit magnetic susceptibility data in high-temperature phase by the exchange model, an isolated spin dimer of $s = 1/2$ or a spin ladder in high temperature limit, but all efforts fail.

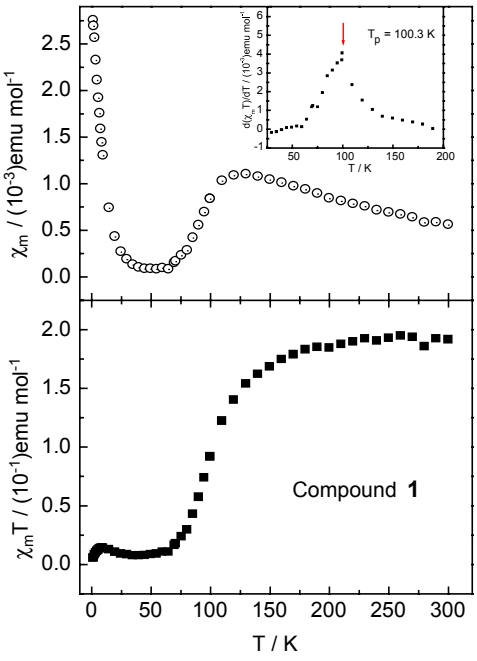

Fig. 4. Plots of $\chi_m - T$ and $\chi_m T - T$ of **1** ($T_{sp} \approx 100.3$ K).

The magnetic susceptibility of **2** increases as temperature deceases, and reaches a maximum with $\chi_m = 6.73 \times 10^{-3}$ emu mol^{-1} at 16.5 K, and then abruptly drops to indicate the character of antiferromagnetic

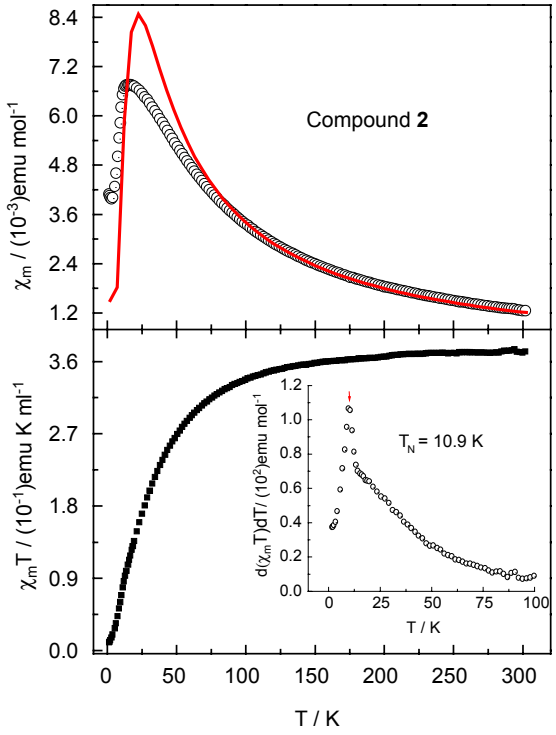

Fig. 5. $\chi_m - T$ and $\chi_m T - T$ of **2** as a function of T ($T_N \approx 10.9$ K), open circle (χ_m): experiment data; solid line (χ_m): theoretically reproduced with the fit parameters.

ordering. Theoretically, the long-range magnetic ordering cannot occur in a 1D magnetic system, as for **2**, the weak H-bonding interactions to connect spin ladders and cations into 3D network were observed, which provide the possible magnetic exchange paths between spin ladders to lead to long-range magnetic ordering [5b,9]. The χ_m value of 4.07×10^{-3} emu mol^{-1} at 2 K is somewhat less than 2/3 the value at the temperature at which it is a maximum. T_N is estimated as 10.9 K corresponding to the peak temperature in plot of $d(\chi_m T)/dT - T$ (inset of Fig. 4). From the viewpoint of structure, the magnetic coupled interaction is much larger within a dimer than between dimers, the formula of χ_m, thereby, in paramagnetic phase can be expressed below:

$$\chi_m = \frac{\chi_{dimer}}{[1 - (zJ'/Ng_2\beta^2)\chi_{dimer}]} + \frac{C}{T} + \chi_0 \quad (1)$$

and

$$\chi_{dimer} = \frac{Ng^2\mu_B^2}{k_B T} \cdot (3 + \exp(\Delta/k_B T))^{-1} \quad (2)$$

in Eq. (1), the first term is a contribution from a dimer of $s = 1/2$ based on spin Hamiltonian $H = -2J\hat{S}_1 \cdot \hat{S}_2$, in which Δ (=2|J|) is the energy gap between singlet and triplet spin state, and the coupled interaction between neighboring dimers is further treated using molecular field theory [10]. C/T and χ_0 show the contribution from the magnetic impurity and the sum of diamagnetic and possible van Vleck paramagnetic parts, respectively. The best fit magnetic susceptibility above 45 K to Eq. (1) gives rise to $\Delta/k_B = 36.1$ K, $zJ = -0.91$ K, $C = 3.2 \times 10^{-3}$ emu K mol^{-1} and $\chi_0 = -4.0 \times 10^{-6}$ emu mol^{-1} with g of 2.0 fixed.

4. Conclusion and remarks

Summarily, we have represented the crystal structural and magnetic susceptibility characterization for two compounds consisting of $[Ni(dmit)_2]^-$ and benzylpyridinium derivative. The anions in two compounds stack into dimers, and these dimers further construct into two-leg ladders via terminal S···S interactions in **1**, and by lateral S···S interactions in **2**. The two-leg ladders are held together by cations through weak H-bonding interactions of C–H···S in **2**, while only weak van de Waals interactions are present in **1**. The $\chi_m(T)$ in 2–300 K indicated that AFM exchange interactions dominate both **1** and **2**. A spin-Peierls-like transition occurs in **1** at ~ 100 K. An AFM ordering below ~ 11 K was found in **2**, and its magnetic behavior in paramagnetic phase can be demonstrated as a spin dimer of $s = 1/2$. In order to clarify the nature of the peculiar magnetic transition in **1** and AFM ordering in **2**, further structural determination in low-temperature phase and DSC/C_p measurements around the transition temperature for **1**, and AC magnetic susceptibility measurement for **2** are in progress.

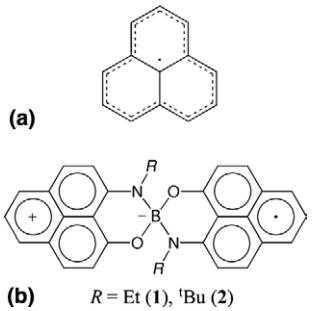

Fig. 1. Molecular structures of phenalenyl (a) and spiro-biphenalenyls (b).

over phenomena in the solids of these spiro-biphenalenyl. Our group have already reported papers for the electronic structures of phenalenyl dimeric pair [7,8]. In the present work, then, the electronic structures of dimeric pairs of **1** are studied in terms of quantum chemistry to examine the mechanism of the change in its magnetism. The structures of the dimeric pairs are derived from the X-ray crystallographic analysis of **1** at each temperature. The dimeric pairs are separated into two groups: π-dimers and not-π-dimers groups. First, the effective exchange integral of the Heisenberg model is calculated by the UHDFT (spin-polarized Kohn–Sham hybrid-density-functional theory) method for the π-dimers and not-π-dimers of **1**. This will show the variation of magnetic interactions within the dimeric pairs when temperature increases. Next, in order to understand electronic structures of the dimeric pairs, the natural orbital (NO) analysis is carried out based on the results of the UHDFT calculations. Investigation of the electronic structure of these radicals in terms of ab initio MO is of important in designing novel organic functional compounds.

2. Computations

2.1. Models

Spiro-biphenalenyl that is an organic neutral radical contain two phenalenyls binding with the spiro junction, the centre of which is a boron atom. The π-electrons on the two phenalenyls can conjugate through the spiro junction. It is said that spiro-biphenalenyls might not be just neutral but zwitter-ion type neutral radicals. In the crystal, spiro-biphenalenyls form π-dimers that consist of their enantiomers. It is interesting that all the nearest contacts of these π-dimers are almost equal or slightly larger than van der Waals radius of carbon.

The structures of π-dimers of **1** at 20, 100, 173 and 298 K have been based on its X-ray crystallographic data from Cambridge Structural Data-base (CSD) [9]. Those are denoted by **20π**, **100π**, **173π** and **298π** in turn (see Fig. 2). The π-orbitals on the phenalenyl moieties in the π-dimers overlap at most of the atoms where major robes place. The intermolecular magnetic interaction then should be antiferromagnetic. The intermolecular distance varies from 3.16 to 3.35 Å with the increase of temperature. Effect of temperature to electronic states was studied by using structures at each temperature, because quantum chemical calculations cannot treat temperature explicitly. The structures of the dimeric pairs (not-π-dimers) of **1** at 100 and 173 K, shown in Fig. 2, were also derived from CSD. They are labeled by **100-1**, **100-2**, **173-1** and **173-2**. These dimeric pairs consist of a molecule nearest to a π-dimer and one half of the π-dimer. The intermolecular magnetic interactions are predicted to be none or weak ferromagnetic since most of the π-orbitals are perpendicular one another.

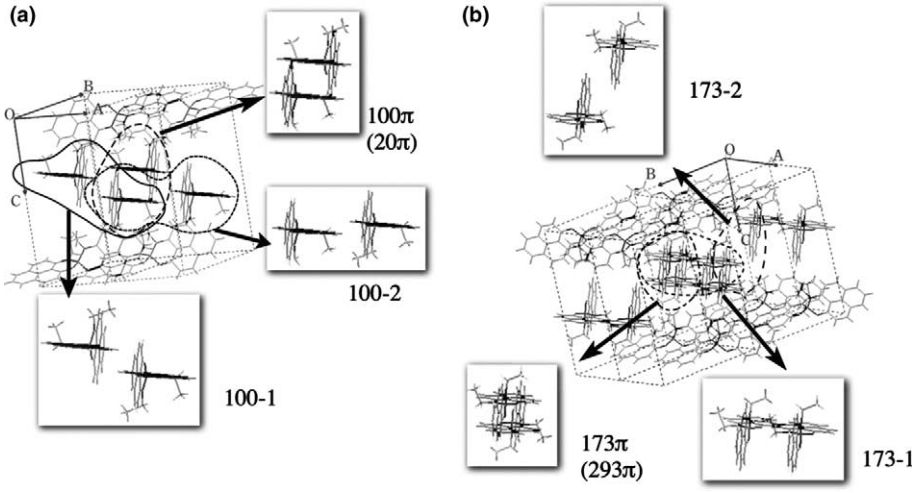

Fig. 2. Structures of π-dimers and not-π-dimers of **1**: (a) LT and (b) HT.

2.2. Methods

The Kohn–Sham hybrid-DFT [10] has been employed to elucidate electronic structures of **1**. It is obvious that this system has the spin-polarization since these dimeric pairs have the closest contacts longer than van der Waals radii of carbon atom at each temperature. In this case, the unrestricted wave functions can descript the electronic correlation better than the restricted ones do. Therefore, the UHDFT can investigate electronic structures of these dimeric pairs. Becke's three-parameter exchange [11] and Lee, Yang, Parr's correlation functionals [12] have been chosen for these compounds, since they are expected to produce feasible solutions judging from the results of our former studies [13]. Actually, UB3LYP/6-31G* has been employed.

3. Theoretical background

3.1. Effective exchange integral and AP

As widely known, the Heisenberg model is sufficient in understanding magnetic interaction between spins. The spin-Hamiltonian is defined as

$$H = \sum_{\langle ij \rangle} -2J_{ij}\mathbf{s}_i \cdot \mathbf{s}_j, \tag{1}$$

where $\mathbf{s}_i$ is a spin at ith radical site and $\langle ij \rangle$ means the summation is taken over the pairs of radical sites in the whole of system. A radical site is regarded as a source of spin-1/2 in this paper. The coefficent J_{ij} is the effective exchange integral between the radical sites i and j. The physical meaning is the energy difference between the singlet spin-state and the triplet spin-state. Negative J_{ij} means the antiferromagnetic interaction is dominant in the ground state, while positive J_{ij} the ferromagnetic interaction dominates the ground state. In most of molecular systems, the spin reduces to its z-component only. The transfer integral of the Hubbard model, denoted by t_{ij}, is related to J_{ij} for the Mott–Hubbard insulators as $J = -2t^2/U$, where $t_{ij} = t_{ji} = t$, $J_{ij} = J_{ji} = J$ and U (>0) is the on-site Coulomb repulsive potential. The U can be regarded as a kind of the difference between ionization potential and electron affinity. If J is large and negative, then t is also large, which means the electrons are delocalized between the pair rather than onto each molecule.

We face to the broken-symmetry (BS) problem in calculating by the unrestricted approach such as UHDFT, namely, eigenvalues of S^2 are not equal to the exact ones of the spin-states. The effective exchange integrals, however, have been evaluated approximately by a spin-projection called AP [14]. For two spin-sites,

$$J^{\mathrm{AP}} = -\frac{E^3 - E^{1(\mathrm{BS})}}{\langle S^2 \rangle^3 - \langle S^2 \rangle^{1(\mathrm{BS})}}, \tag{2}$$

where E is the total energy, $\langle S^2 \rangle$ represents eigenvalues of S^2 and the superscripts indicate spin multiplicities. Eq. (2) holds at any distance between the two spin sites.

3.2. Natural orbital analysis

Even though the unrestricted method describes the electron correlation better than the restricted one, the resultant orbitals are often different from familiar MOs, called the symmetry-adapted (SA) MOs. In order to obtain the SA MO picture from the BS solutions, the NO analysis has been carried out. The NOs are defined to diagonalize the spin-traced (or charge) density matrix [15,16] as

$$\rho(\mathbf{r}, \mathbf{r}') = \sum_i n_i \eta_i(\mathbf{r}) \eta_i(\mathbf{r}'), \tag{3}$$

where n_i (in [0,2]) denotes the occupation number of the i^{th} NO, η_i, which is an SA MO called UNO. The BS magnetic orbitals for up- and down spins (denoted by + and −, respectively) are expressed by

$$\chi^{\pm}(\mathbf{x}) = \cos\theta\eta_{\mathrm{b}}(\mathbf{r}) \pm \sin\theta\eta_{\mathrm{a}}(\mathbf{r}), \tag{4}$$

where η_{b} and η_{a} represent bonding and anti-bonding UNOs, respectively. The orbital overlap integral between the magnetic orbitals, denoted by $S^{\mathrm{mg}} = \langle \chi^+ | \chi^- \rangle$, rewrites the occupation numbers of bonding and anti-bonding UNO as

$$n_{\mathrm{b}} = 1 + S^{\mathrm{mg}} \quad \text{and} \quad n_{\mathrm{a}} = 1 - S^{\mathrm{mg}}. \tag{5}$$

Then the effective bond order is derived by

$$b^{\mathrm{eff}} = \frac{n_{\mathrm{b}} - n_{\mathrm{a}}}{2} (= S^{\mathrm{mg}}). \tag{6}$$

These indices are efficient to investigate natures of chemical bonding in terms of quantum chemistry.

4. Results and discussion

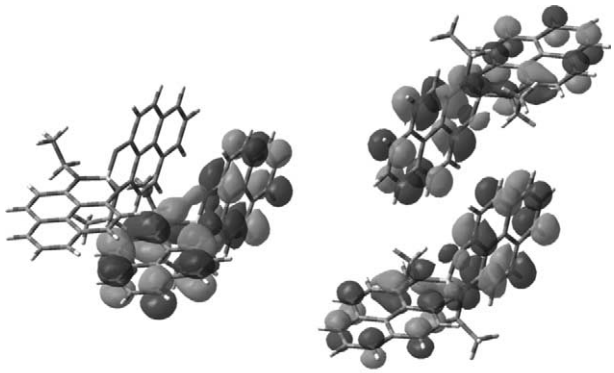
4.1. *J*s of π-dimers

As summarized in Table 1, the effective exchange integrals of **20π** and **100π** have been −447 and −444 cm^{-1} for LT, while **173π** and **293π** −133 and −126 cm^{-1} for HT, respectively. This means that the intermolecular antiferromagnetic interaction reduces to be about 30% in the amplitude by the transition when temperature increases. The magnetic interaction was evaluated to be antiferromagnetic at these ranges of temperature, although the experiment showed paramagnetism for **1** at HT. This result seems inconsistent with each other, whereas it can be understood as follows. The Average of the singlet-triplet energy gap ($-2J$) was about 890 cm^{-1} at LT, which is much larger than the energy of temperature 20 and 100 K (equal to 14 and 70 cm^{-1}, respectively). At HT, however, $-2J$ was

Table 1
Physical parameters and occupation numbers calculated for π-dimers

Model	D (Å)	J (cm^{-1})	ΔE^{h-l} (eV)	n_b	n_a	b^{eff}
20π	3.16	−477.3	0.741	1.623	0.376	0.623
100π	3.18	−443.8	0.740	1.606	0.394	0.606
173π	3.31	−133.5	0.771	1.352	0.648	0.352
293π	3.35	−126.3	0.774	1.342	0.658	0.342

calculated to be 260 cm^{-1}, which becomes closer to temperature 173 and 293 K (120 and 204 cm^{-1}, respectively). Hence, it is concluded that temperature-dependent paramagnetism may be a factor in the mechanism of the magnetism change within π-dimers.



The HOMO–LUMO gap ΔE^{h-l} has been evaluated to be about 0.74 eV for LT structures while 0.77 eV for HT, which grown approximately by 0.03 eV after the transition than before. This implies that the π-dimer becomes less conductive when temperature increases, which reproduces the experimental results. The difference in ΔE^{h-l} for LT and HT will increase when a larger number of molecules are considered in the calculation.

4.2. Js of not-π-dimers

Table 2 lists J-values for the not-π-dimers of **1** at 100 and 173 K. The magnetic interactions of them have been almost none for the structure at 100 K, which suggests that no interaction exist between the radical pair. Those for 173 K, however, have been very weak ferromagnetic for **173-2** and **173-1** has had rather strong ferromagnetic interaction of $J = 130$ cm^{-1}. This difference in J is due to spatial arrangement of the molecules of the not-π-dimers. As shown in Fig. 3, the phenalenyl parts of each molecule are separate from each other for all not-π-dimers except for **173-1**. The spin-density on each molecule has no relation to one another. On the contrary, the phenalenyl parts of each molecule orientate perpendicularly for **173-1**. The orbital-overlap effect vanishes and only the exchange potential effect remains at the structure, which leads strong ferromagnetic interaction [17]. This indicates where that the magnetic interactions cancel out as a whole and **1** becomes paramagnetic, considering that J of **173-1** is close to that of **173π**.

Table 2
Effective exchange integrals for not-π-dimers

Model	J (cm^{-1})
100-1	0.2
100-2	0.2
173-1	130.1
173-2	5.8

173-1 **173-2**

Fig. 3. Molecular orbitals for not-π-dimers of **1**.

4.3. Electron transfer in *1*

The ground state of **1** can be approximately formulated by the linear combination of two zwitter-ionic states as

$$\Psi_0 = c_R\psi_R + c_L\psi_L, \quad (7)$$
$$\Psi_0 : \{\mathrm{PhnlBPhnl}\}^{\bullet}, \quad \psi_R : \mathrm{Phnl}^{+}\mathrm{B}^{-}\mathrm{Phnl}^{\bullet},$$
$$\psi_L : \mathrm{Phnl}^{\bullet}\mathrm{B}^{-}\mathrm{Phnl}^{+}$$

where Phnl and B denote the phenalenyl part and the spiro junction, respectively. If $c_R = c_L$, then the unpaired electron transfer through the molecule without barriers. In this case, c_R is either larger or smaller than c_L because of the molecular geometry, which makes the intramolecular electron transfer harder. Though it is impossible to determine directly the difference between c_R and c_L, the difference may be estimated from ΔE_{loc}, the energy gap between E_0 and E_R (or E_L), where E_0 and E_R (or E_L) are the total energies of Ψ_0 and $\Psi_R \sim \psi_R$ (or $\Psi_L \sim \psi_L$), respectively. The UB3LYP/6-31G* calculated ΔE_{loc} to be 0.196 eV for 100 K and 0.278 eV for 173 K, indicating that the intramolecular electron transfer becomes unlikely to occur with the increase of temperature.

From the examination of the structures of **1** at each temperature, it is found that major geometrical change in the molecule has occurred at the spiro junction. Length of the bond connecting a phenalenyl group has been shorter at LT than at HT in the half side of the spiro junction. It seems that electronic states of one phenalenyl part in the molecule became more stable than

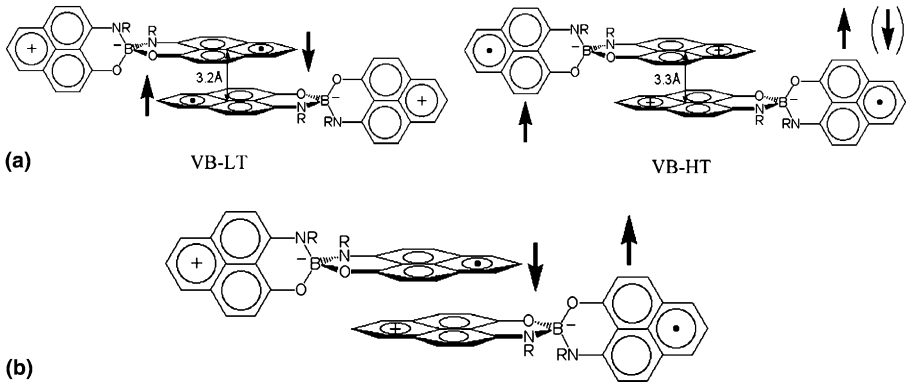


Fig. 4. Haddon's illustration in the valence bond (VB) picture (The down arrow in the round brackets was added by the authors): the VB mechanism and (b) A proposed VB structure for intermediate temperature in this work.

the other because of the geometrical variation. The difference of stability in the electronic state controls intermolecular electron transfer.

A remarkable study has already been reported by Kertesz and the co-workers for the change in conductivity of spiro-biphenalenyls [18]. They performed ab initio band structure calculation with plain-waves for them to reveals the conduction mechanism. In the MO view of us, the intramolecular electronic transfer may arise from the change in length of the spiro junction as described above. From our result it is found that intermolecular electronic transfer can take place for the π-dimers, considering that their effective exchange integrals at LT were rather negatively large. On the other hand, effective exchange integrals at LT for not-π-dimers were almost none, which indicates electrons hardly migrate over these molecular pairs. It is concluded that electrons can transfer through the π-dimer columns in **1** and **2**, although the determination of their conduction paths involves further investigations.

4.4. Electronic structures analyzed by natural orbitals

Haddon and his collaborators have proposed a mechanism for the bistability of spiro-biphenalenyls as shown in Fig. 4 (a). At LT limit, the unpaired electrons lie on the phenalenyl parts closely facing each other at a distance of about 3.2 Å, making a spin pair. This is a diamagnetic π-dimer that has strong antiferromagnetic interaction. At HT limit, the intermolecular distance increases and becomes near 3.3 Å. The unpaired electrons then reside in the outer phenalenyl units, interacting more weakly, which is a paramagnetic π-dimer. This mechanism is called the valence bond (VB) mechanism here.

Shown in Fig. 5 are relevant UNOs for **100π** and **173π**. Compared with the VB-LT, robes of UNO for **100π** are delocalized over the dimers. This can be interpreted as follows. In the VB-LT, the dots on the inter-phenalenyl parts represent a bond between the molecules, while in terms of UNO the bonding is

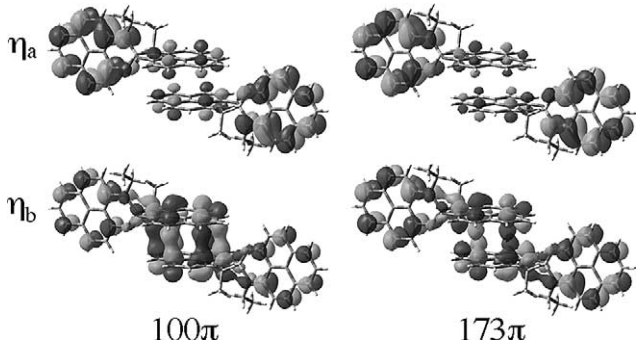

Fig. 5. Bonding and anti-bonding natural orbitals for π-dimers of **1** at 100 (left) and at 173 K (right). Contour value: 0.020.

expressed by connecting robes between the inter-phenaleyl parts. Indeed, the bond is not full since electron correlation mixes an anti-binding electron configuration into that of bonding. As seen in the rightmost column of Table 1, the effective bond orders for these π-dimers have been 0.7 and 0.6 at LT, though those for a full bond have been exact unity. Considering UNOs for **173π**, it is found that the VB-HT suggests the bond almost vanishing at HT. Their effective bond orders are about 0.3 at HT, which means the bond is weakened. It seems that the VB mechanism shows, in a word, binding molecules at LT and separate radicals at HT. If this variation in the bond is represented only by dots, the dots should be placed on the outer-phenalenyl parts. Above results show that both our MO picture and the VB mechanism describe the same fact essentially. The VB structure in Fig. 5-2 is proposed to express the electronic structure of spiro-biphanalenyls at intermediate temperature rather than the VB-HT.

5. Conclusion

Electronic structure and physical parameters have been evaluated for diethyl-substituted spiro-biphanenyl,

a multifunctional organic neutral radical, in order to inquire into a mechanism of the change in their magnetism and conduction. Intermolecular magnetic interaction was examined in terms of the effective exchange integral of the Heisenberg model for dimeric pairs of diethyl-substituted spiro-biphenalenyl. Variation of the magnetic interaction with respect to temperature have been evaluated based on their x-ray crystallographic structures at several temperature points in quantum chemical ways. The results have reproduced the experiments of spiro-biphenalenyl and given us some interesting information of their electronic structures. The intermolecular effective exchange integrals have been negative but reduced to be thirty percent in the magnitude between 100 and 173 K for the π-dimers. They have been almost none from 100 to 173 K except for one pair and the remaining pair had ferromagnetic interaction. Hence, it is concluded that the change in their magnetism is understood by temperature and the formation of a ferromagnetic dimer-pair at 173 K. Moreover, it is found that our natural orbital analysis for the electronic structure of diethyl-substituted spiro-biphenelenyl is equivalent to Haddon's valence bond explanation intrinsically.

For the mechanism of their conductions, ab initio MO results can illustrate it as follows. The conducting electrons go from a phenalenyl part to the other phenalenyl part in the molecule through the spiro linkage. They then transfer to the next molecule that is a half of the π-dimer. The result implied that a conduction path is the π-dimer column.

Acknowledgments

All the single-point energy calculations were performed by GAUSSIAN 98 program packages [19]. Fruitful discussions with the members in Nakasuji Lab. at Osaka University are sincerely appreciated. This work has been supported by Grants-in-aid for Scientific Research on Priority Areas (# 14204061 and 15750120) from the Ministry of Education, Culture, Sports, Science and Technology, Japan. T.T. has also been supported by a Grant-in-aid for JSPS Fellows.

[4,5]. The origin of the exchange interactions in such compounds has been studied and correlated to the Ni–O–Ni angle within the cubane [6]. In addition to the high spin number, many tetra-nickel cubane molecules also have high molecular symmetry. These characteristics make such molecules great candidates for detailed studies of the origin of zero-field splitting (zfs) and the mechanism for fast magnetization relaxation [7].

Recently, we found a series of Ni_4 cubane metal complexes, with hmp^- (mono-anion of 2-hydroxymethylpyridine) as the bridging ligand, having four-fold pseudo rotation (S_4) symmetry [8,9]. Here, we present data for this series of Ni_4 SMMs. Preliminary results of micro-SQUID magnetometry and high-frequency electron paramagnetic resonance (HFEPR) measurements on single crystals are presented to characterize these Ni_4 SMMs. Fast tunneling of the magnetization is observed in the hysteresis loops. To explore the reasons for the fast tunneling, as well as the origin of the zfs of the molecule, we set out to determine the zfs parameters of the individual Ni^{II} ions by doping small amounts of Ni^{II} into a Zn_4 cubane molecule matrix. Due to the observation of splitting of the peaks in the HFEPR spectra of one of these Ni_4 cubane complexes, heat capacity measurements and low temperature X-ray diffraction studies were also carried out to probe the possible cause of the splitting features.

2. Experimental

2.1. Syntheses

Crystalline samples of complexes **1**, **2**, and **3** ($[Ni(hmp)(ROH)Cl]_4$, R = methyl for **1**, ethyl for **2**, 3,3-dimethyl-1-butyl for **3**) were prepared as previously reported [8,9].

2.2. Physical measurements

High frequency (40–200 GHz) single crystal EPR measurements were carried out using a millimeter-wave vector network analyzer and a high sensitivity cavity perturbation technique; this instrumentation is described elsewhere [10]. Tunneling studies were performed by magnetization measurements on a single crystal using an array of micro-SQUIDs as described in the literature [11]. Specific heat at constant pressure (C_p) measurements at zero-field were made using a quantum design physical properties measurement system (QD PPMS) employing a relaxation method [12]. The platform was calibrated by use of a copper standard.

3. Results and discussion

3.1. Description of structures

In this paper, data are presented for the series of $[Ni(hmp)(ROH)Cl]_4$ complexes, where R stands for the Me, Et, or 3,3-dimethyl-1-butyl groups. An example drawing of the structure of the Ni_4 cubane molecule is shown in Fig. 1. The common feature of the structure of the Ni_4 cubane molecule is that the molecular core consists of four Ni^{II} cations occupying the alternating corners of a distorted cube with oxygen atoms on the other four corners. The four Ni^{II} ($S = 1$) ions ferromagnetically couple through the bridging oxygen atoms to give a $S = 4$ ground state. The structure of the Ni_4 cube is such that the molecule has S_4 site symmetry. As in the case for Mn_{12}, this four-fold symmetry can impose a uniaxial zfs D term, while the transverse E term should be equal to zero on symmetry grounds [13].

3.2. Magnetization hysteresis loops

Previously, we reported [8,9] that this series of complexes shows magnetization hysteresis loops. When the R groups on the alcoholic ligand are small, such as methyl or ethyl, weak intermolecular magnetic exchange interactions are present, leading to an exchange bias of the hysteresis loops, where the first step feature in the loops is significantly shifted from zero field. However, the intermolecular interactions can be turned off by introducing a more bulky aliphatic chain on the alcoholic ligands. Fig. 2 shows the magnetization hysteresis loop for complex **3**. It can be seen that the first magnetization tunneling step occurs essentially at zero field. Another important feature to note is that the rate of this quantum tunneling is very fast compared to other known SMMs such as the Mn_{12} and Mn_4 complexes.

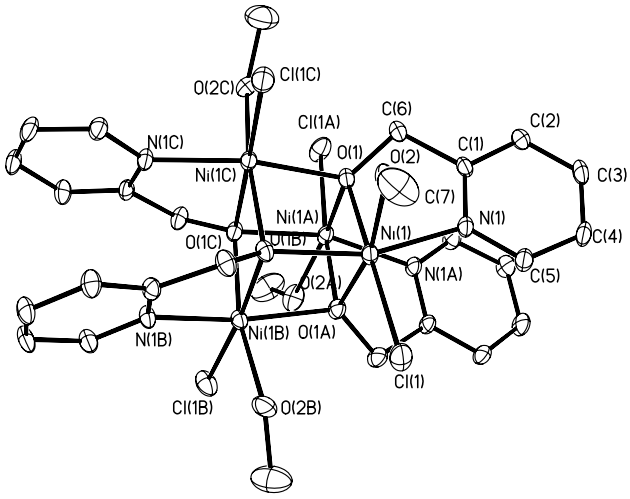

Fig. 1. ORTEP representation of $[Ni(hmp)(MeOH)Cl]_4$ showing 50% probability ellipsoids.

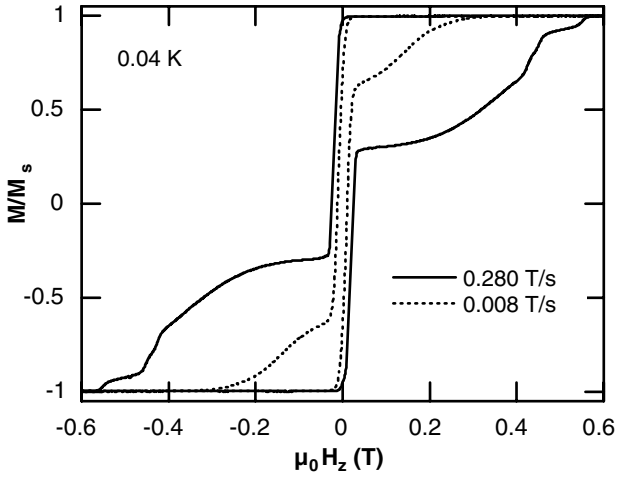

Fig. 2. Magnetization (M) of a single crystal of [Ni(hmp)(dmb)Cl]$_4$ (plotted as a fraction of the maximum value of M_s, the saturation magnetization) versus applied magnetic field ($\mu_0 H$). The magnetic field is parallel to the easy axis. The magnetization loops were obtained at 0.040 K at two different scan rates.

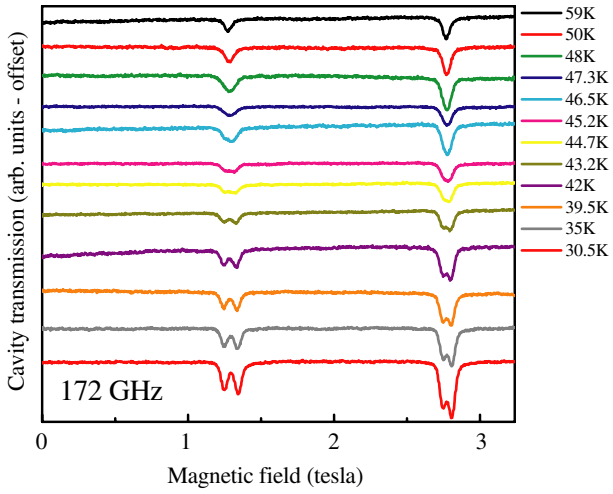

Fig. 3. Variable temperature HFEPR spectra obtained at 172 GHz for a single crystal of [Ni(hmp)(dmb)Cl]$_4$. The magnetic field is oriented parallel to the easy axis of magnetization of the crystal.

To explore the origin of this fast tunneling, a series of HFEPR experiments were performed on complex **3**.

3.3. High-frequency EPR data for the Ni_4 cubane molecule

Single-crystal HFEPR data were collected for complex **3**. The results of a preliminary analysis of these data reveal that these Ni_4 complexes have a $S = 4$ ground state and that the axial zero-field splitting parameter D is negative [8,9]. Due to the molecular S_4 symmetry, it is required that the rhombic zfs E term be zero. Therefore, the fast tunneling of magnetization can be the result of fourth order transverse zero-field interactions, namely the B_4^4 term [14]. The final effective spin Hamiltonian will thus be:

$$\hat{H} = g_z \mu_B \hat{B}_z \cdot \hat{S}_z + D\hat{S}_z^2 + B_4^0 \hat{O}_4^0 + B_4^4 \hat{O}_4^4. \quad (1)$$

The HFEPR spectra confirm the absence of the E term and a significant B_4^4 term for the molecule. In addition to the discovery of a large B_4^4 term, some interesting features have also been observed in the low temperature HFEPR spectra. Fig. 3 presents a few low temperature spectra. As the temperature is reduced from 60 to 30 K, fine structure resonances are observed to split into two features. The low temperature (12 K) X-ray structure confirmed that there are disordered ligand carbon atoms. It is likely that there is a dynamic ligand conformation at high temperatures that becomes frozen into a static disorder below about 50 K.

3.4. Heat capacity measurements

To find the origin of the HFEPR peak splitting observed for Ni_4 cubane complex **3** that occurs around 45 K, heat capacity measurements were performed on complex **3** in the temperature range 2–100 K. It can be seen from Fig. 4 that a peak shows up in the heat-capacity versus temperature plot. This peak indicates there is an order–disorder phase transition at 47 K. The fact that the peak in heat capacity occurs at the same temperature as the peak splitting in the HFEPR spectra further confirms that it is due to a static ligand disorder. Further analysis of the heat capacity data is in progress.

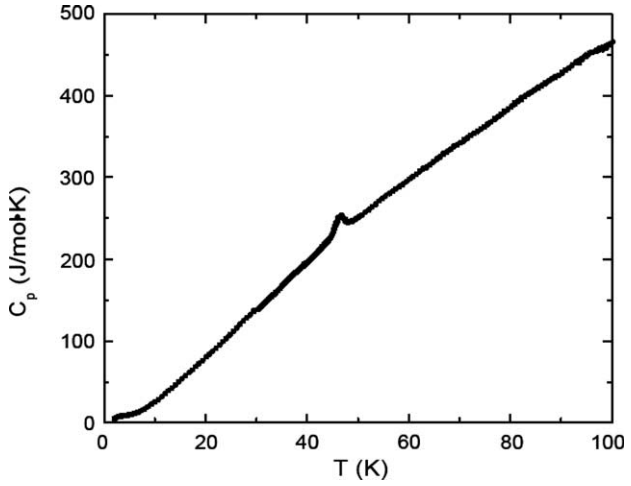

Fig. 4. Heat capacity at constant pressure versus temperature for a polycrystalline sample of complex **3**.

3.5. HFEPR of Ni^{II} doped [Zn(hmp)(dmb)Cl]$_4$ complex

Single-crystal data were collected to determine the zfs parameters of individual Ni^{II} ions in the cubane metal cluster. With the knowledge of the single-ion zfs parameters we may understand the fast tunneling, and the relationship between single-ion and molecular zfs parameters. We have chosen an analog of complex **3**,

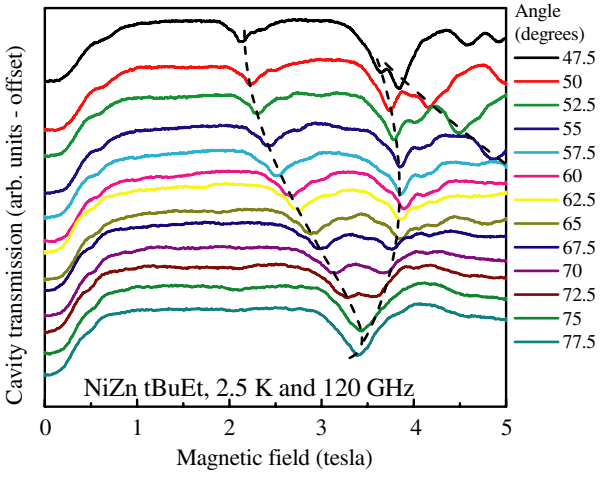

Fig. 5. Angle-dependent HFEPR spectra obtained at 120 GHz for a single crystal of a Ni^{II} doped $[Zn(hmp)(dmb)Cl]_4$ sample.

the Ni^{II} doped Zn_4 cubane molecule, as the candidate to study the zfs of individual Ni^{II} ions. The fact that there is only one symmetry independent molecule in the crystal lattice makes it easier to interpret the spectra. Furthermore, complex **3** contains no solvent in its structure, which could distort the EPR spectra.

The zfs parameters of the individual Ni^{II} ion were found by rotating the applied magnetic field about different crystallographic planes. Fig. 5 illustrates some of the angle-dependent HFEPR spectra for this sample. The angle-dependence, as well as frequency-dependent studies of the spectra, provide access to the zfs parameters for the Ni^{II} ion, $D_i = -5.27\ cm^{-1}$ and $E_i = -1.2\ cm^{-1}$. The z-axis of the individual Ni^{II} ions was also found to be tilted 15° away from the molecular easy axis. The Ni_4 molecular D term that is calculated from the single ion zfs parameters above is $D = -0.69\ cm^{-1}$, which is quite close to the experimental value found for the undoped Ni_4 complex ($D = -0.594\ cm^{-1}$ [8,9]). The tilt of the easy axis and significant E term for individual Ni^{II} ions also provides a possible explanation for the fast quantum tunneling of magnetization in this Ni_4 complex. Detailed analysis of these data will be presented elsewhere [14,15].

4. Conclusion

A series of molecules with the composition $[Ni(hmp)(ROH)Cl]_4$, where R = CH_3 for complex **1**, R = Et for complex **2** and R = 3,3-dimethyl-1-butyl for complex **3**, have been shown to be SMMs. Complex **3** shows no exchange bias in its magnetization hysteresis loop, with a clear step feature at zero magnetic field. The fast QTM process in complex **3** is likely the result of a significant B_4^4 term, and the tilting of the single Ni^{II} ion zfs tensor. Small structure changes cause the splitting of the HFEPR fine-structure resonances as confirmed by heat capacity data.

breaking responsible for the QMT in Mn_{12}-Ac [6–10]. Disorder associated with the acetic acid solvent leads to discrete local environments, resulting in a significant fraction of the molecules (>50%) possessing twofold symmetry with a rhombic crystal-field parameter $E \sim 0.01\ cm^{-1}$ (or $ED \sim 0.02$, where D is the uniaxial crystal-field parameter [7]).

Here, we present accurate angle-resolved high-frequency electron paramagnetic resonance (HFEPR) data collected for single-crystal samples of deuterated and undeuterated Mn_{12}-Ac. The spectra reveal multiple fine structures associated with the various Mn_{12} species in different local environments. Each of the fine structures exhibits a distinct dependence on the applied field orientation, thereby highlighting the discrete nature of the disorder, as well as suggesting that some of the Mn_{12}-Ac variants have their easy axes significantly tilted with respect to the global symmetry direction in the crystal [9]. We then compare these data with spectra obtained for two recently discovered high-symmetry (S_4) analogs of Mn_{12}-Ac, differing only in their ligand and solvent structures. The new complexes are $[Mn_{12}O_{12}(O_2CCH_2Br)_{16}(H_2O)_4]\cdot 4CH_2Cl_2$ [11–13] and $[Mn_{12}O_{12}(O_2CCH_2Bu^t)_{16}(CH_3OH)_4]\cdot CH_3OH$, abbreviated Mn_{12}-BrAc and Mn_{12}-*t*BuAc, respectively. None of the highly reproducible fine-structures seen in the Mn_{12}-Ac samples are found for the new Mn_{12} complexes, thus confirming the idea that the solvent structure significantly influences the QMT dynamics in Mn_{12}-Ac. Indeed, the HFEPR spectra for Mn_{12}-BrAc and Mn_{12}-*t*BuAc provide spectacular resolution, allowing for unique spectroscopic insights into high-symmetry giant spin SMMs.

2. Experimental

Single-crystal HFEPR measurements were carried out using a millimeter-wave vector network analyzer (MVNA) in combination with a cavity perturbation technique which we have described elsewhere [14]. In order to enable in situ two-axis rotation of the sample relative to the applied magnetic field, we employed a split-pair magnet with a 7 T horizontal field and a vertical access, together with a unique cylindrical cavity in which the sample may be rotated about a second orthogonal axis (this cavity is described in [15]). Single-axis rotation measurements were also performed in a 17 T axial superconducting magnet using the rotating cavity [15]. In both setups, the sample temperature was controlled using helium flow cryostats and calibrated Cernox™ resistance sensors. Mn_{12}-Ac samples were prepared separately by two groups according to the usual methods [5]: deuterated d-Mn_{12}-Ac samples were prepared at Florida State University and removed from their mother liquor prior to transportation to the University of Florida; h-Mn_{12}-Ac samples were prepared at the University of Florida and stored in their mother liquor right up until the time of the experiments. Mn_{12}-BrAc crystals were prepared by a ligand substitution procedure involving the treatment of Mn_{12}-Ac with an excess of $BrCH_2CO_2H$ [11–13]. Mn_{12}-*t*BuAc crystals were prepared via a method similar to the one in [16], albeit that CH_3OH solvent was used in the present case, thereby yielding the high symmetry complex (full details will be presented elsewhere [17]). With the exception of the d-Mn_{12}-Ac samples, all other crystals were handled identically with a view to avoiding solvent loss from the structure; the needle shaped single-crystals ($\sim 1.5 \times 0.4 \times 0.4\ mm^3$) were removed directly from their mother liquor and protected with grease before cooling under 1 atm of helium gas.

3. Results and discussion

3.1. Mn_{12}-Ac: in-plane field rotations

Fig. 1 displays experimental microwave absorption obtained for different field orientations within the hard (*xy*-) plane of a deuterated sample of Mn_{12}-Ac (i.e., d-Mn_{12}-Ac); the temperature is 15 K and the frequency is 51.3 GHz in every case. The peaks correspond to EPR. The data were obtained at 7.5° intervals, and the azimuthal angle ϕ represents the field orientation relative to one of the flat edges of the square cross-section

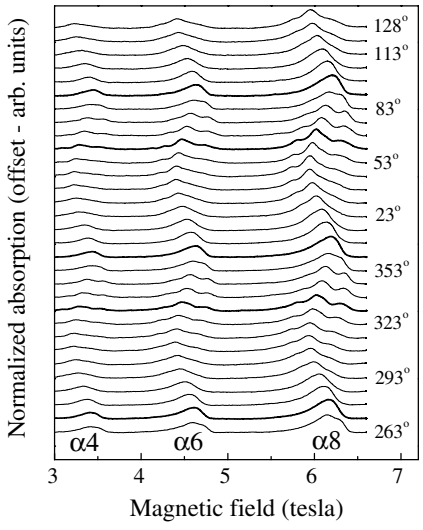

Fig. 1. Microwave absorption obtained for different field orientations within the hard (*xy*-) plane of a deuterated d-Mn_{12}-Ac sample; the temperature was 15 K and the frequency was 51.3 GHz in every case. The peaks in absorption correspond to EPR. The data were obtained at 7.5° intervals, where the angle ϕ refers to the field orientation relative to one of the flat edges of the square cross-section of the sample. The resonances have been labeled according to the scheme described in [9]. The bold traces correspond to field orientations approximately parallel to the hard axes of the $\hat{O}_2^2$ (3 peaks) and $\hat{O}_4^4$ (single peak) tensors.

of the sample. The resonances have been labeled according to the scheme described in [9]. For fields applied approximately parallel to the hard plane, only α-resonances are observed (β-resonances appear for field rotation away from the hard plane – see Figs. 3 and 4 below). The highest field peak, α8, corresponds to an excitation between levels which evolve from the $m_z = \pm 9$ zero-field doublet. The transition from the ground state (α10) is not observed within the available field range for these experiments; at 51 GHz, its expected position is at ~9 T. For a discussion of the resonance labeling scheme, as well as detailed explanations of the temperature, frequency, field and field orientation dependence of the EPR spectra for Mn_{12}-Ac, refer to [9].

Immediately apparent from the Fig. 1 is a fourfold variation in the positions of each band of resonances (α8, α6, etc.). Note that each peak exhibits fine structures (high- and low-field shoulders), which also depend on the field orientation ϕ; these fine structures are related to the disorder in the crystal, as discussed further below. The fourfold shifts are caused by the intrinsic fourth-order operator, $\hat{O}_4^4$, in the spin Hamiltonian [6–10], as has previously been established for h-Mn_{12}-Ac [7]. Fig. 2 shows a grayscale contour plot of the data in Fig. 1, i.e., absorption intensity versus magnetic field strength and the azimuthal angle ϕ. This figure can be compared directly with Fig. 1 of [7], which displays the same data for h-Mn_{12}-Ac. Superimposed on the absorption maxima are two kinds of fit to the ϕ-dependence of each peak. The solid lines were obtained simply by fitting the positions of the peaks obtained from Fig. 1: the central peaks were fit to pure sine functions having fourfold periodicity; meanwhile, the high- and low-field shoulders were fit with superpositions of phase-shifted sine functions having fourfold and twofold periodicities. The fits represented by horizontal bars were obtained by exact diagonalization of the Hamiltonian matrix and are described further below.

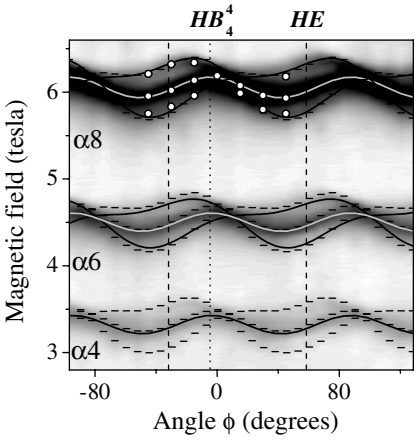

Fig. 2. Grayscale contour plot of the absorption intensity for d-Mn_{12}-Ac (see Fig. 1), vs. magnetic field strength and the azimuthal angle ϕ; the darker shades correspond to stronger absorption. Superimposed on the absorption maxima are fits to the ϕ-dependence of the central positions of each peak deduced from Fig. 1 (solid gray and black curves). The horizontal bars represent best fits to the peak positions based on exact diagonalization of the Hamiltonian matrix; the obtained Hamiltonian parameters are given in the main text. The open circles represent peak positions obtained for h-Mn_{12}-Ac at the same frequency and temperature (see Figs. 3 and 4). The approximate orientations of the hard axes corresponding to the $\hat{O}_2^2$ (*HE*, dashed lines) and $\hat{O}_4^4$ (HB_4^4, dotted line) tensors are indicated at the top of the figure.

We now briefly discuss the origin of the twofold contribution to the positions of the shoulders, which are very apparent in the ranges $\phi = 300$–$330°$ and $\phi = 30$–$60°$ in Fig. 1; a more in-depth discussion can be found in [7–10]. The high- and low-field shoulders are due to the $n = 1$ and $n = 3$ Mn_{12}-Ac hydrogen-bonding variants in Cornia's solvent disorder model [6]. These variants, which comprise 50% of the total molecules, are thought to possess a significant rhombic anisotropy due to the reduced symmetry of the surrounding hydrogen bonded acetic acid solvent molecules. The second-order operator, $\hat{O}_2^2$, associated with the rhombic distortion gives rise to the two-fold behavior, as was clearly demonstrated by del Barco et al. [8]. It is important to recognize that the disorder is discrete, since the acetic acid can only bond at four positions on the Mn_{12} molecule. Thus, one expects only two hard directions (HE_A and HE_B [9]) associated with the $n = 1$ and $n = 3$ low symmetry variants, which are separated by 90°. In HFEPR, the $\hat{O}_2^2$ operator causes shifts in the peak positions. When the applied field is parallel to one of the hard axes, it is obviously perpendicular to the other, which causes shifts in the HFEPR intensity to both the low- and high-field sides of the central peaks, i.e., the shoulders. When the field is applied in between these two directions, the EPR intensity due to the low-symmetry variants collapses into the central portion of the peak, hence the disappearance of the shoulders every 90° (see Figs. 1 and 2). In actual fact, this apparent fourfold behavior reflects the twofold nature of the rhombic distortion caused by the hydrogen bonding acetic acid molecules, with the EPR intensity for a given variant shifting from the low (high) to the high (low) field side of the main peak every 90°, i.e., the periodicity is actually 180°. This twofold behavior is then superimposed on the intrinsic fourfold periodicity, as can be seen from the curves in Fig. 2.

As we have previously reported, there is an offset (phase shift) between the fourfold modulation of the central peak positions, and the twofold pattern associated with the shoulders; the hard directions associated with the $\hat{O}_2^2$ and $\hat{O}_4^4$ operators are indicated, respectively, by dashed and dotted lines in Fig. 2. In fact, this is was one of the more important points discussed originally in [7], which has recently been backed up by theoretical calculations [18]. From the fits in Fig. 2, this offset is found to be $27 \pm 2°$, which is in good agreement with earlier studies of

h-Mn_{12}-Ac [7]. From the maxima and minima in the peak position shifts induced by the $\hat{O}_4^4$ operator, we estimate that the hard and medium directions associated with this intrinsic zero-field-splitting interaction are oriented at $-4.5° \pm 5°$ [$+(i \times 90°)$, where i = integer] and $40.5° \pm 5°$ [$+(i \times 90°)$], respectively, relative to the square edges of a typical single-crystal sample. Once again, this agrees with previous studies of h-Mn_{12}-Ac.

In order to make quantitative comparisons between the disorder-induced effects in h-Mn_{12}-Ac and d-Mn_{12}-Ac, we performed a single fit to the data in Fig. 2 via exact diagonalization of the Hamiltonian matrix [6–10]. This fit is represented by the horizontal bars in Fig. 2. Our procedure obviously takes into account the misalignments of the $\hat{O}_2^2$ and $\hat{O}_4^4$ tensors, as described in [10]. Thus, the employed Hamiltonian is subtly different from the standard form used by most spectroscopists [19–21], which may explain slight differences in the obtained Hamiltonian parameters. We start out by assuming accepted values for the zero-field parameters D and B_4^0 ($D = -0.455\ \mathrm{cm}^{-1}$ and $B_4^0 = -2 \times 10^{-5}\ \mathrm{cm}^{-1}$), which were verified independently from easy axis measurements. The only free parameters in the fit were then the E and B_4^4 coefficients (corresponding to the $\hat{O}_2^2$ and $\hat{O}_4^4$ tensors), for which we obtained the values $\pm 0.014(2)$ and $\pm 3.2(5) \times 10^{-5}\ \mathrm{cm}^{-1}$, respectively. The B_4^4 value is in precise agreement with that found for h-Mn_{12}-Ac [7]. However, the E value is significantly larger than the one obtained in earlier experiments (40% larger than the upper bound quoted in [7]). We attribute some of this difference to the modified Hamiltonian used in our more recent fits, which takes into account the misalignments of the $\hat{O}_2^2$ and $\hat{O}_4^4$ tensors. However, much of the difference appears to be real.

The larger E-value found from the present study is somewhat surprising. However, as will be seen below, more recent measurements on a fresh h-Mn_{12}-Ac sample are in excellent agreement with the value of $0.014(2)\ \mathrm{cm}^{-1}$. Thus, the difference is likely related to sample quality and/or solvent loss. A tell-tale sign of the higher sample quality is the observation of both high- and low-field shoulders on the main EPR peaks. In contrast, only high-field shoulders were seen in the earlier experiments on h-Mn_{12}-Ac. In fact, the absence of a low-field shoulder is discussed at some length in [9], where it is shown that this peak is unresolved from the broad low-field tail associated with the central portion of the peak. The reason for the asymmetry between the high and low-field shoulder is related to easy axis tilting caused by the solvent disorder (see below). Although both shoulders are seen in the present study, a clear asymmetry can be seen from the data in Fig. 1.

We suspect that the samples used in the earlier experiments may have suffered significant solvent loss, either upon cooling from room temperature under high vacuum, or simply as a result of being stored in air for more than 1 year prior to the measurements. Indeed, variations in the D-strain measured in different Mn_{12}-Ac samples has previously been reported by us [22]. Increased D-strain leads to broader EPR linewidths, thus probably explaining why the shoulders are clearly resolved in the present investigation, but not in [7]. Without two well resolved shoulders, it is likely that the E-strain was under-estimated in [7]. Based on experience working with SMMs containing considerably more volatile solvents, we have recently developed sample handling procedures which minimize solvent loss, e.g., encapsulating samples in oil prior to cooling under atmospheric helium gas. The differences between the present measurements and those reported in [7,9] highlight the importance of sample handling. Indeed, it is likely that Mn_{12}-Ac samples prepared by different groups, and studied by different techniques, exhibit significant differences in their solvent content, resulting in subtly different conclusions concerning the quantum dynamics. For this reason, it is advantageous to prepare Mn_{12} SMMs which do not exhibit such a dramatic dependence on solvent content, as is the case for two newer complexes discussed at the end of this article.

3.2. Mn_{12}-Ac: out-of-plane field rotations

We now consider the angle-dependence of the HFEPR spectra for out-of-plane field rotations. The experimental spectra in Fig. 3 were obtained for a fresh sample of h-Mn_{12}-Ac at a frequency of 51.7 GHz and a temperature of 15 K. Data were taken at 0.3° intervals in the polar angle θ, i.e., the field orientation is measured relative to the global easy axis of the crystal. The thick curve corresponds to field alignment within the hard

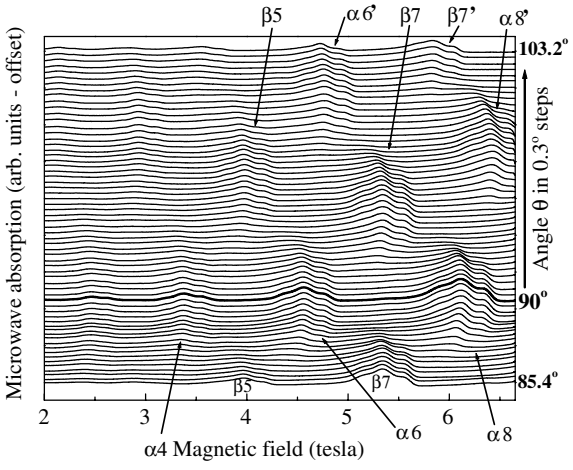

Fig. 3. Microwave absorption spectra obtained for out-of-plane (θ) rotations for a single crystal of h-Mn_{12}-Ac. The plane of rotation corresponds to the azimuthal angle $\phi \approx -15°$. In every case, the temperature is 15 K, the frequency is 51.7 GHz, and the traces are offset for clarity. The resonances are labeled according to the scheme developed in [9].

plane (to within 0.15°). The resonances have again been labeled according to the scheme developed in [9]. Using the two-axis rotation capability, this experiment was repeated for seven different planes of rotation, separated by $\Delta\phi = 15°$ (ϕ is the azimuthal angle). The grayscale contour plots in Fig. 4 display these data for five of the seven rotation planes. The peaks centered at $\theta = 90°$ correspond to α8 (at ~6 T) and α6 (at ~4.5 T); β7 is seen between about $\theta = 93°$ and 98°; β7 is then followed in order of increasing angle by α8′, α6′ and β7′. The data in Fig. 3 correspond to the $\phi = -15°$ orientation (middle trace in Fig. 4), which is approximately in between the hard axis of $\hat{O}_4^4$ and one of the hard $\hat{O}_2^2$ directions. The positions of the peaks and shoulders corresponding to the α8 resonances in Fig. 4 have been added to Fig. 2 for comparison with the measurements on the deuterated Mn_{12}-Ac crystal. As can be seen, the data for the dueterated and undeuterated complexes are in excellent agreement. Indeed, we estimate precisely the same E and B_4^4 values for the two complexes ($\pm 0.014(2)$ and $\pm 3.2(5) \times 10^{-5}$ cm^{-1}, respectively).

Fig. 5(a) displays a simulation of the out-of-plane angle-dependence of the EPR spectra for Mn_{12}-Ac, without disorder, i.e., no E-strain. The simulation was generated using the software package SIM [23], and with the Hamiltonian parameters quoted in the previous section (with $E = 0$); the frequency is 51.5 GHz and the temperature is 15 K. As can be seen from this simulation, there should be no angle overlap in intensity between neighboring α and β transitions; we note that adding a realistic E term does not affect the widths of the gaps between the α and β absorption bands in Fig. 5(a). In contrast, the data in Figs. 3 and 4 exhibit significant overlap of the α and β resonances. More importantly, the degree of overlap depends on the plane of rotation, i.e., the azimuthal angle ϕ. Note that the black contours represent 33% of the maximum absorption, while the white contours correspond to 66%. The reason for the overlapping of the α and β intensity has been discussed at great length in [9], and is attributed to a tilting of the easy axes of the low-symmetry Cornia variants away from the global crystallographic c-direction. The resulting distribution of easy axis directions leads to a smearing of the θ-dependence of the spectra, thereby accounting not only for the α and β overlap, but also for the lack of any curvature to the bands of absorption (compare, e.g., the simulations in Fig. 5(a) with the data in Fig. 4).

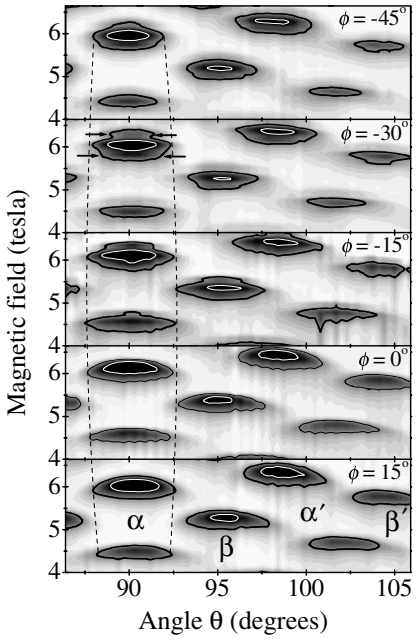

Fig. 4. Grayscale contour maps corresponding to out-of-plane (θ) HFEPR field rotation measurements for five different planes of rotation (indicated in the figures). The darker regions represent stronger EPR absorption. The data are plotted in this manner for direct comparison with subsequent simulations, and data obtained for other Mn_{12} complexes. The $\phi = -15°$ plot (middle panel) corresponds to the data in Fig. 3. The 66% and 33% of maximum absorption (corresponding to the peak of α8) contour lines are emphasized by light gray and black lines, respectively. The ϕ-dependent overlap of the α and β resonances suggests discrete easy-axis tilting; this behavior has been emphasized by the vertical dashed curves and the arrows in the $\phi = -30°$ panel. See main text, Fig. 5(b) and [9] for explanation.

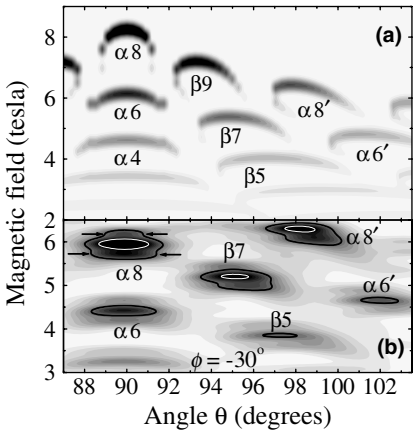

Fig. 5. (a) A simulation of the out-of-plane (θ) angle-dependence of the EPR spectra for d- and h-Mn_{12}-Ac, without disorder ($E = 0$). The simulation was generated using the software package SIM [23], and with the Hamiltonian parameters quoted in the main text; the frequency is 51.5 GHz and the temperature is 15 K. In contrast to the experimental spectra in Fig. 4, there is no angle overlap in intensity between neighboring α and β transitions. (b) A simulation of the $\phi = -30°$ data in Fig. 4. This simulation was generated by adding spectra corresponding to the 3 main species in Cornia's solvent disorder model [6]. The 66% and 33% of maximum absorption (corresponding to the peak of α8) contour lines are emphasized by light gray and black lines, respectively. The low-symmetry $n = 1$ and 3 variants contribute to the high- and low-field shoulders (see main text and Fig. 4). The flattening of the absorption bands (relative to Fig. 5(a)), and the angular overlap of the α and β resonances, is reproduced by convoluting the individual contributions to the spectrum with a Gaussian function with a half width of 1.3°. The arrows illustrate the different widths of the high- and low-field shoulders (see also 2nd panel of Figs. 4 and 6).

It was argued in [9] that the tilting directions associated with the $n = 1$ and $n = 3$ Cornia variants [6] are confined to orthogonal planes defined by the symmetry of the associated rhombic distortion (the $\hat{O}_2^2$ operator). The present study confirms this assertion. The profile of the absorption intensity, as a function of the angle θ (for a fixed field), can be fit reasonably well with a Gaussian function, as shown in Fig. 6 for the α8 peaks and shoulders corresponding to the data in Fig. 3. The full-width-at-half-maximum (FWHM) of the high-field shoulder ($\Delta\theta_H = 2.1°$) is almost 1° less than that of the low-field shoulder ($\Delta\theta_L = 3.0°$), in agreement with previously published results [9]. The reason for this asymmetry is connected with the fact that the molecules contributing to the high-field shoulder are tilted in a plane perpendicular to the field rotation plane, whereas those contributing to the low-field shoulder are tilted in a plane parallel to the rotation plane (see Fig. 6 of [9]). Thus, the full tilt distribution projects onto the field rotation plane for the low-field shoulder, but not for the high-field shoulder. Unfortunately, one cannot independently measure the widths of the shoulders (Δ_H and $\Delta\theta_L$) as one rotates far away from the azimuthal (ϕ) directions of maximum splitting (i.e., the hard $\hat{O}_2^2$ directions, *HE*), because the shoulders merge into the central peak. However, there is a tendency for the width of the high-field shoulder to increase as one rotates away from *HE* (the FWHM is 2.4° for $\phi = -45°$).

The vertical dashed lines in Fig. 4 illustrate the behavior of the 33% width of the central part of the α8 peak ($\Delta\theta_C$). Interestingly, $\Delta\theta_C$ exhibits a clear dependence on ϕ, suggesting that even the Cornia variants which do not possess a significant E term ($n = 0$, 2 and 4 [6]) are tilted. What is more, the maximum $\Delta\theta_C$ occurs fairly close to $\phi = 0°$, corresponding to the hard $\hat{O}_4^4$ direction. This suggests that the magnetic axes of these molecules may be tilted along or near to these orientations. We note that the $n = 2$ cis variants in Cornia's model, which comprise 25% of the molecules, are expected to exhibit significant tilting (~0.4° [6]), but no appreciable E-term.

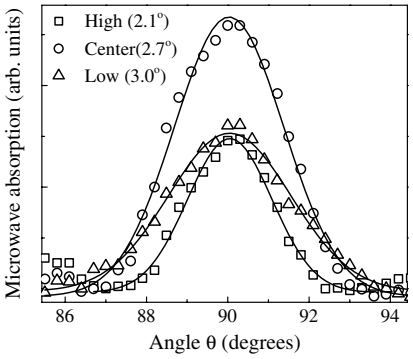

Fig. 6. Gaussian fits (solid curves) to the out-of-plane (θ) angle dependence of the HFEPR absorption intensity corresponding to the central peak (○), and the high (□) and low field (△) shoulders on the α8 resonance in Fig. 3. The FWHM of the three portions of the α8 resonance are indicated in brackets in the figure.

Based on the information in Fig. 6, one can deduce that FWHM of the tilt distribution for the $n = 1$ and $n = 3$ Cornia variants is *at least* 1°, i.e., that the half-width of the distribution is *at least* 0.5°. This is consistent with our previous studies, where it was shown that one could detect molecules in the tails of the distribution which were tilted by as much as 1.7°. In fact, the 0.5° value deduced above represents the magnitude of the solvent-disorder-induced tilting over and above any random tilting (the latter would not exhibit ϕ-dependence). Thus, the true half-width of the tilt distribution associated with the $n = 1$ and $n = 3$ Cornia variants should be larger than this value and, therefore, significantly larger than the value predicted by Cornia et al. (~0.3°) [6].

In order to estimate the actual amount of tilting, we have simulated the out-of-plane angle dependence for the $\phi = -30°$ plane of rotation (Fig. 5(b)), which corresponds approximately to the hard direction of the $\hat{O}_2^2$ tensor. The simulation was generated by adding spectra corresponding to the 3 main species in Cornia's solvent disorder model. We assume that 50% of the molecules possess no E term (the $n = 0$, 2 and 4 variants [6]), so that they contribute to the central portions of the EPR absorption bands. Of the remaining 50% (the $n = 1$ and 3 variants [6]), half possess an E value of $+0.014(2)\ cm^{-1}$, and the other half an E value of $-0.014(2)\ cm^{-1}$ (a change in the sign of E is equivalent to a 90° rotation of the hard and medium directions). These molecules contribute to the high- and low-field shoulders (see Fig. 3). The flattening of the absorption bands (relative to Fig. 5(a)), and the angular overlap of the and β resonances, is then reproduced by convoluting the individual contributions to the spectrum with a Gaussian function, $\exp[-(\theta - 90°)^2/2\sigma^2]$. The FWHM ($w \sim 2.35\sigma$) of the distribution used in Fig. 5(b) is 2.6°, i.e., a half width of 1.3°. Overall agreement with the experimental spectrum in Fig. 4(b) is very good, particularly concerning the widths of the high- and low-field shoulders (as indicated by arrows). We note also that, contrary to recent claims, this value *is* consistent with magnetic studies [24], as discussed at length in [9].

3.3. Mn_{12}-BrAc and Mn_{12}-tBuAc

We conclude this article by presenting data for the two recently discovered analogs of Mn_{12}-Ac: Mn_{12}-BrAc and Mn_{12}-*t*BuAc. The motivation for comparing these compounds is to investigate the influence of the solvent structure on the properties of the Mn_{12} core, which is virtually identical for the three complexes. Fig. 7 displays experimental spectra obtained for out-of-plane (θ-) rotations for Mn_{12}-BrAc, while Fig. 8 presents the same data in grayscale. Figs. 9 and 10 display

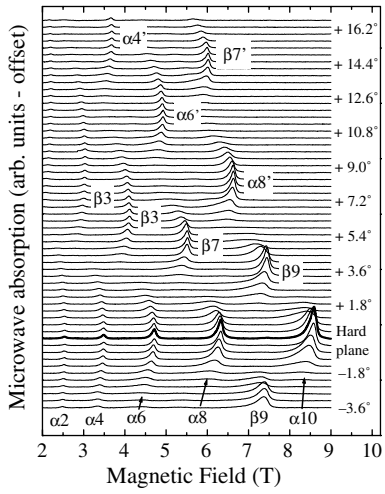

Fig. 7. Microwave absorption spectra obtained for out-of-plane (θ) rotations for a single crystal of Mn_{12}-BrAc. The angle step is 0.36°. In every case, the temperature is 15 K, the frequency is 51.5 GHz, and the traces are offset for clarity. The resonances are labeled according to the scheme developed in [9].

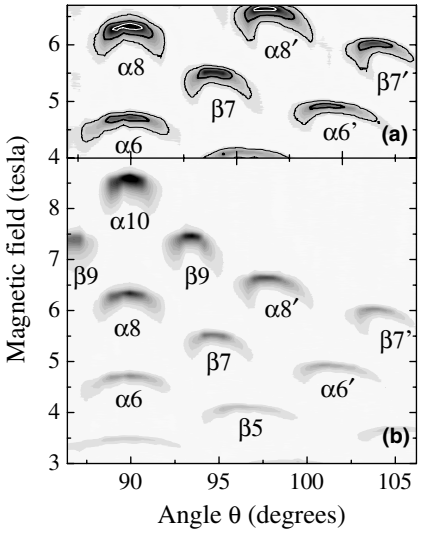

Fig. 8. Grayscale contour maps corresponding to the data in Fig. 7. The darker regions represent stronger EPR absorption. In order to aid comparisons with Fig. 4, (a) depicts an expanded region of the full angle dependence in (b). Contour lines corresponding to 66% (light gray), 33% (thick black) and 15% (thin black) of the maximum absorption (of the α8 peak) are superimposed on the absorption bands to aid the discussion in the main text.

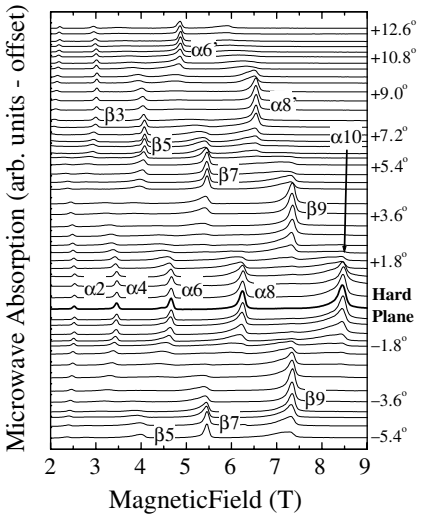

Fig. 9. Microwave absorption spectra obtained for out-of-plane (θ) rotations for a single crystal of Mn_{12}-*t*BuAc. The angle step is 0.36°. In every case, the temperature is 15 K, the frequency is 51.5 GHz, and the traces are offset for clarity. The resonances are labeled according to the scheme developed in [9].

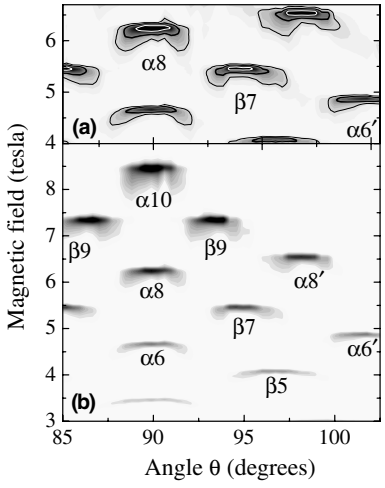

Fig. 10. Grayscale contour maps corresponding to the data in Fig. 9. The darker regions represent stronger EPR absorption. In order to aid comparisons with Fig. 4, (a) depicts an expanded region of the full angle dependence in (b). Contour lines corresponding to 66% (light gray), 33% (thick black) and 15% (thin black) of the maximum absorption (of the α8 peak) are superimposed on the absorption bands to aid the discussion in the main text.

the same measurements for the Mn_{12}-*t*BuAc complex. The frequency was 51.5 GHz and the temperature was 15 K for both sets of measurements. It is immediately apparent that the EPR peaks for the BrAc and *t*BuAc complexes are considerably sharper than those obtained for Mn_{12}-Ac. Furthermore, the fine structures (high- and low-field shoulders) are not seen for either of the newer complexes, irrespective of the choice of rotation plane (i.e., the ϕ angle). This strongly suggests that the complexities of the EPR spectra for Mn_{12}-Ac are strongly influenced by the hydrogen bonding acetic acid solvent. Given the corresponding *E*-strain associated with the low-symmetry species in Cornia's model [6], one can thus assume that the QMT dynamics in Mn_{12}-Ac are significantly affected by extrinsic factors related to the disorder. In contrast, the solvents in the BrAc and *t*BuAc structures do not hydrogen bond to the Mn_{12} core. Furthermore, the possibility for positional and/or orientational solvent disorder does not exist in

the way that it does for Mn_{12}-Ac (Cornia model [6]). In particular, the BrAc complex contains a full compliment of four symmetric CH_2Cl_2 solvents per formula unit. Meanwhile, the lone MeOH solvent associated with the Mn_{12}-*t*BuAc complex resides far from the Mn_{12} core, and is shared equally among four unit cells. Furthermore, crystals of the *t*BuAc complex do not contain any faster relaxing Mn_{12} species, as is known to be the case for Mn_{12}-Ac and even Mn_{12}-BrAc. The absence of complexity in the HFEPR spectra of Mn_{12}-BrAc and Mn_{12}-*t*BuAc suggests that detailed investigations of these compounds may reveal even more information concerning the quantum dynamics of large spins, e.g., a Berry phase associated with the $\hat{O}_4^4$ operator [25].

The linewidths are considerably narrower for the two newer complexes, as compared to the Mn_{12}-Ac. In fact, the $\theta = 90°$ line shape for the Mn_{12}-*t*BuAc complex fits somewhat better to a Lorentzian function than to a Gaussian, suggesting that the linewidth may be close to the intrinsic lifetime broadened limit (width $\approx$0.1 T, implying $\tau \approx 0.4$ ns). Furthermore, the linewidths are almost m_s independent. However, there are vestiges of evidence for inhomogeneous broadening mechanisms (g, D, and E strain), such as the asymmetric lineshapes for the Mn_{12}-BrAc complex, and a small, but measurable m_s dependence of the linewidths for both complexes. Determining the source of any inhomogeneous broadening will require extensive easy-axis measurements as a function of frequency, field (m_s) and temperature. Such an undertaking will represent the subject of a future paper.

Further comparison between the grayscale plots for the three complexes leads one to believe that there are essentially no measurable tilts for the BrAc and *t*BuAc complexes. Not only are there well defined gaps between the and β series' of resonances, in overall agreement with Fig. 5(a), there are also clear evidences for curvature at the edges of each absorption band. This has been emphasized by the 15% contour lines in Figs. 8 and 10. Simulations show that even a modest amount of easy axis tilting dramatically suppresses the curvature seen in the grayscale plots. This curvature is associated with level repulsion, or level mixing. In the high-field limit, the 21 states associated with $S = 10$ may be described in a basis in which the spin projection quantum number m_s refers to the projection of S onto the applied magnetic field axis. Furthermore, each m_s state is essentially pure in this high-field limit. Consequently, rotating the field should not produce dramatic shifts in the EPR peak positions, because the Zeeman term ($g\mu_B \boldsymbol{B} \cdot \hat{\boldsymbol{S}}$) represents the dominant interaction in the Hamiltonian, i.e., the magnitude of the Zeeman interaction does not change upon rotating the field if the spin is free to rotate with the field. However, in the intermediate regime (Zeeman interaction comparable to crystal field), tilting the magnetic field results in a complex interplay between the axial and transverse terms in the spin Hamiltonian, i.e., the transverse Zeeman interaction ($g\mu_B B\hat{S}_x$) may dominate when the field is exactly in the hard plane, whereas tilting of the field results in an out-of-plane magnetic field component which rapidly ($\alpha \sin\theta$) amplifies the axial ($\hat{S}_z$ containing) terms. This interplay results in strong level mixing of states (described in either an $\hat{S}_x$ or and $\hat{S}_z$ basis), and to a non-linear dependence of the resonance positions on the magnetic field strength, leading to the curvature seen in the edges of the absorption bands in Figs. 8 and 10. Therefore, these measurements constitute evidence for coherent superposition states, albeit involving fairly complex admixtures of the simple zero-field $S = 10$ basis states.

The spin Hamiltonian parameters for Mn_{12}-BrAc are very similar to those of Mn_{12}-Ac, and have been published previously by us [13]. Fig. 11 displays fits to single-crystal HFEPR data obtained with the magnetic field applied both parallel [Fig. 11(a)] and perpendicular [Fig. 11(b) and (c)] to the easy axis of the Mn_{12}-*t*BuAc complex. The frequencies used in these experiments span from 50 to 350 GHz. The fits in Fig. 11(a) and (b), together with hard-plane rotation experiments in Fig. 11(c), provide three separate constraints on the spin Hamiltonian

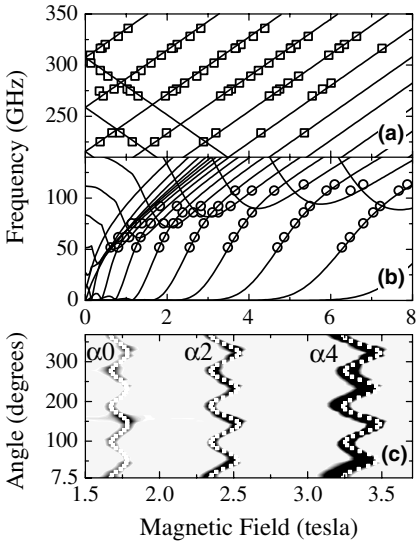

Fig. 11. (a) Fits to the frequency dependence of HFEPR peak positions obtained with the field applied precisely along the easy axis (to within ±0.5°) of a Mn_{12}-*t*BuAc single crystal; the temperature was 15 K for these measurements. Fits for this orientation constrain parameters corresponding to operators in the spin Hamiltonian that commute with $\hat{S}_z$, i.e., D, B_4^0 and g_z. (b) Fits to the frequency dependence of HFEPR peak positions obtained with the field applied precisely within the hard plane (to within ± 0.18°); the temperature was also 15 K for these measurements. Fits for this orientation constrain the transverse Landé factors, g_x and g_y. (c) Fits (white squares) to the fourfold peak-position shifts (dark shaded regions) for field rotations approximately within the hard plane of the sample. Fits for this orientation constrain the transverse term B_4^4, with no dependence on any of the other parameters in the spin Hamiltonian. All fits involved exact diagonalization of the Hamiltonian matrix, and ignored terms with twofold symmetry.

parameters, for which we obtain the following values: $D = -0.462(2)\ \mathrm{cm}^{-1}$, $B_4^0 = -2.5(2) \times 10^{-5}\ \mathrm{cm}^{-1}$, $B_4^4 = \pm 4.3(2) \times 10^{-5}\ \mathrm{cm}^{-1}$, $g_z = 2$, and $g_x = g_y = 1.94$. In contrast to the data for Mn_{12}-Ac, the data in Fig. 11(c) are restricted to lower fields. The reason has to do with the fact that the molecules are so well aligned that it is virtually impossible to rotate precisely in the hard plane. Thus, the high-field peaks exhibit a strong twofold distortion associated with the mis-alignment between the field rotation plane and the hard plane. Even for a 0.5° mis-alignment, the effect is dramatic for α10, α8 and α6. Because of the easy axis tilts in Mn_{12}-Ac, the data in Fig. 2 are relatively insensitive to minor mis-alignments of the rotation plane. However, the *t*BuAc complex is less forgiving. Nevertheless, the fits in Fig. 11 are sufficient for determining B_4^4.

4. Summary and conclusions

We use angle-resolved HFEPR spectroscopy to asses the influence of the solvent structure on the quantum properties of several high-symmetry Mn_{12} single-molecule magnets, including the most widely studied Mn_{12}-Ac. In spite of over 10 years of research, a clear picture has only recently emerged concerning the symmetry breaking responsible for the QMT in Mn_{12}-Ac [6–10]. Disorder associated with the acetic acid solvent leads to discrete local environments, resulting in a significant fraction of the molecules (>50%) possessing twofold symmetry with a rhombic zero-field-splitting term $E = \pm 0.014(2)\ \mathrm{cm}^{-1}$. Differences in the E values deduced from the present measurements and those reported in [7,9] highlight the importance of sample handling. Indeed, it is likely that Mn_{12}-Ac samples prepared by different groups, and studied by different techniques, exhibit significant differences in their solvent content (particularly powder samples), resulting in subtly different conclusions concerning the quantum dynamics. For this reason, it is advantageous to prepare Mn_{12} SMMs which do not exhibit such a dramatic dependence on solvent content. Indeed, we go on to show that all of the unusual solvent-induced anomalies reported for Mn_{12}-Ac are absent in the HFEPR spectra for two related high-symmetry Mn_{12} complexes, Mn_{12}-BrAc and Mn_{12}-*t*BuAc. The absence of complexity in the HFEPR spectra of the BrAc and *t*BuAc Mn_{12} complexes suggests that detailed investigations of these compounds may reveal even more information concerning the quantum dynamics of large spins, e.g., a Berry phase associated with the $\hat{O}_4^4$ operator [25].

orbitals on adjacent octahedra are constrained to be nearly orthogonal, leading to ferromagnetic coupling within each layer [8]. The intralayer exchange coupling is strongly correlated with the long semi-coordinate Cu···X bond distance, decreasing monotonically as the distance increases [9]. Also, since this semi-coordinate distance can vary in length from 2.8 Å to more than 3.3 Å, more complex cations can be incorporated into the Cu(II) perovskite structures. While the intralayer coupling is invariably ferromagnetic and relatively strong, the interlayer coupling is normally very weak and antiferromagnetic, although a few instances of ferromagnetic interlayer couplings are known [10].

An analogous series of layer perovskite structures can be formed with α,ω-diammonium dications, with the general formula $(NH_3RNH_3)MX_4$ [11]. Now the dications hydrogen bond between adjacent halometallate layers, tying the layers together and providing three dimensional stability to the crystalline lattice. These dications force adjacent layers into an eclipsed configuration and, as the hydrocarbon chains shorten, the X···X distances between layers decrease to the point where significant exchange coupling can occur in the magnetic systems [12]. However, with *N*,*N*′-substituted α,ω-diammonium cations, the layer perovskite structure can no longer be formed, since the $R_nNH_{4-n}^+$ groups (n = 2, 3 or 4) cannot be accommodated in the cavities formed by the non-bridging halide ions.

In this paper, we examine the structure and properties of two members of the copper halide layer perovskite family formed when the organic cation is a mono *N*-alkyl substituted ethylenediammonium dication. The cations involved are *N*-methylethylenediammonium (henceforth $MEDA^{2+}$) and *N*-ethylethylenediammonium (henceforth $EEDA^{2+}$). The compounds have the stoichiometric formulas $(REDA)_2CuCl_6$ (R = Me, Et), but are more appropriately formulated as $[(REDA)Cl]_2CuCl_4$, since two of the chloride ions are not coordinated to the Cu(II) ions but are hydrogen bonded to the dications.

2. Experimental

2.1. Preparation

The compounds are conveniently prepared by dissolution of a 2:1 mole ratio of the appropriate *N*-alkylethylenediamine:$CuCl_2 \cdot 2H_2O$ in a hot ethanol solution acidified with concentrated hydrochloric acid. Thin yellow crystals form after slow evaporation of the cooled solution.

2.2. X-ray studies

Crystals were attached to a glass fiber using glue. Datasets were collected at 293(2) K using a Bruker/Siemens SMART 1K instrument (Mo Kα radiation, λ = 0.71073 Å). Data were measured using ω scans of 0.3° per frame for 30 s, and a half sphere of data was collected. The first 50 frames were recollected at the end of data collection to monitor for decay. Cell parameters were retrieved using SMART [13] software and refined using SAINTPLUS [14] on all observed reflections. Data reduction and correction for Lp and decay were performed using the SAINTPLUS software. Absorption corrections were applied using SADABS [15]. The structures were solved by direct methods and refined by least squares method on F^2 using the SHELXTL program package [16]. No decomposition was observed during data collection. Structure refinements were straightforward in both cases and no disorder was observed. Data collection parameters are given in Table 1 and significant bond distances and angles given in Table 2. Fig. 1 illustrates the contents of the asymmetric units of both salts, augmented to show the coordination geometry of the Cu(II) ions. Further details are provided in the Supporting Information.

2.3. Magnetic measurements

Variable temperature susceptibility measurements were carried out in the temperature range 2–300 K with an applied magnetic field of 0.1 T on ground polycrystalline samples with a SQUID magnetometer (Quantum Design MPMS-XL-5). The susceptibility data were corrected for the diamagnetic contributions of the sample

as deduced by using Pascal's constant tables. Isothermal magnetization and hysteresis measurements were made at different temperatures, after zero field cooling, between 0 and 5 T. Variable temperature AC susceptibility were performed in the SQUID magnetometer with an alternating field of 0.395 mT at different frequencies (between 1 and 332 Hz) in the temperature range 1.8–15 K.

2.4. EPR measurements

EPR spectra were recorded on a Varian E-3 EPR spectrometer on powdered and single crystals at room temperature and 78 K.

3. Structure description

The basic structures consist of $(CuCl_4^{2-})_n$ perovskite layers sheathed by $[(REDA)^{2+}Cl^{-}]$ moieties. Both structures crystallize in monoclinic space groups, $P2_1/c$ for the MEDA salt and $C2/c$ for the EEDA salt. Despite the difference in space groups, the internal structure of the individual layers is identical in the two salts. Adjacent layers, which lie in the bc planes, are equivalent by translation in both cases. The inorganic framework, consisting of corner-shared tetragonally elongated $CuCl_6$ octahedra (Fig. 2), shows the prototypic layer structure of the $(RNH_3)_2MX_4$ perovskite salts. The short Cu–Cl bonds in the coordination sphere average 2.295 and 2.299 Å for the MEDA and EEDA salts respectively, while the longer semi-coordinate distances are 2.884(1) and 2.878(1) Å. As is always observed in the halocuprate perovskites, the semi-coordinate bonds are arranged in an antiferrodistortive fashion and lie nearly in the plane of the perovskite sheets. Hence the corner sharing linkages involve one short and one longer Cu–Cl bond. The bridging Cu–Cl···Cl angles are nonlinear, with values of 165.3° for both compounds, yielding the typical corrugated sheet structure, as seen in Fig. 2. This puckering of the layers is induced by the hydrogen bonding from the organic cations, as discussed below.

The sheathing of the perovskites layers by the $[(REDA)^{2+}Cl^{-}]$ moieties is stabilized via hydrogen bonding of the $-NH_3^{+}$ groups to the chloride ions in the inorganic framework. The hydrogen bonding scheme can be designated as bt^2, where b denotes an N–H···Cl bond to a bridging chloride ion and t denotes one to a terminal bond. This arrangement forces the cations to lie in planes running approximately parallel to [0 1 1] and [0 1 −1], assuming an antiferrodistortive arrangement reflective of the antiferrodistortive arrangement of the semi-coordinate bonds. The N–Cl distances range from 3.214 to 3.350 Å, with the shortest bonds being to the bridging chloride ions, while the N–H···Cl angles are in the range 160.6–166.4°, with the EEDA salt exhibiting slightly larger ranges than the MEDA salt. The hydrogen bonding is staggered on either side of a given layer, leading to the typical 'washboard' distortion of the layers, as seen in Fig. 2.

To achieve electroneutrality, lattice chloride ions are incorporated into the structure via N–H···Cl hydrogen bonds with the secondary ammonium ion, as also shown in Fig. 2. Each $-NH_2^{+}$ group hydrogen bonds to two lattice chloride ions, forming zigzag hydrogen bonded chains that run parallel to the c axis. These hydrogen bonding distances range from 3.083 to 3.123 Å, while the angles range from 169.5° to 177.4°, with the EEDA salt again showing the larger variations. The hydrogen bonding distances to the layer halide ions are 0.1–0.2 Å longer than those to the lattice chloride ions, indicating

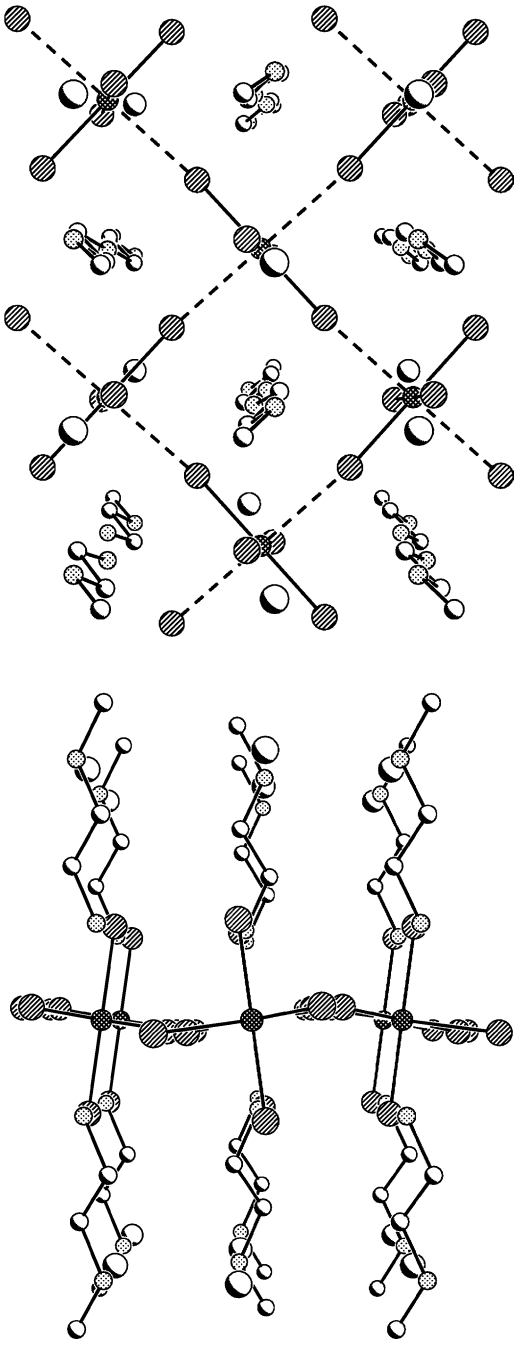

Fig. 2. Illustration of sheathed layer in $[(MEDA)Cl]_2CuCl_4$. Top: top view from (100) direction. Bottom: side view from (001) direction. Lattice chloride ions shown as large highlighted open circles, coordinated chloride ions shown as lined circle.

that the hydrogen bonding cavities in the perovskite layers are somewhat larger than optimal for the hydrogen bonding. In fact, the size of the cavities is more dictated by the packing requirements of the *R* groups than by the hydrogen bonding requirements.

In both compounds, steric repulsions between the terminal methyl groups on adjacent layers forces the layers to be arranged in a staggered conformation. However, this staggered conformation is obtained in a different manner in the two cases. In the MEDA salt, this is achieved by a translation of 1/2 unit cell parallel to the *b*-axis, while in the EEDA salt, this translation is parallel to the *c*-axis.

4. Magnetic results

The magnetic properties of the two salts are essentially indistinguishable from each other, consistent with the identical layer structures of the two salts. Both salts exhibit ferromagnetic coupling, as indicated by the rapid rise in the $\chi_m T$ values as the temperature is lowered. This is illustrated in Fig. 3, for the MEDA salt. The turnover in the value of $\chi_m T$ at low temperature is caused by saturation effects, and is not due to the effects of weak antiferromagnetic coupling, since no maximum is observed in the χ_m as the temperature is lowered to 2 K, as demonstrated in Fig. 4. Fitting of the high temperature data

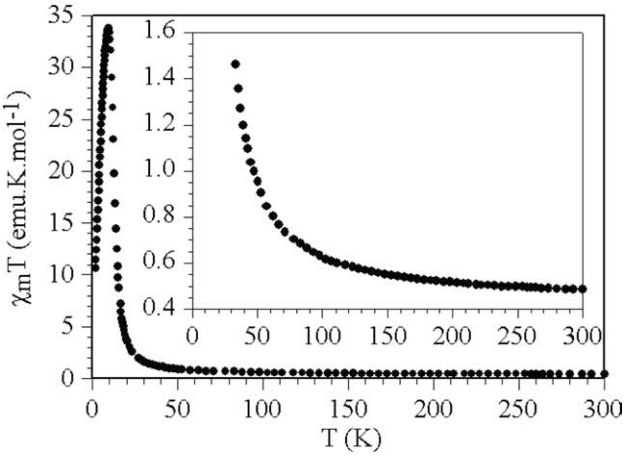

Fig. 3. Thermal variation of the $\chi_m T$ product for the MEDA salt. Inset: the high temperature region.

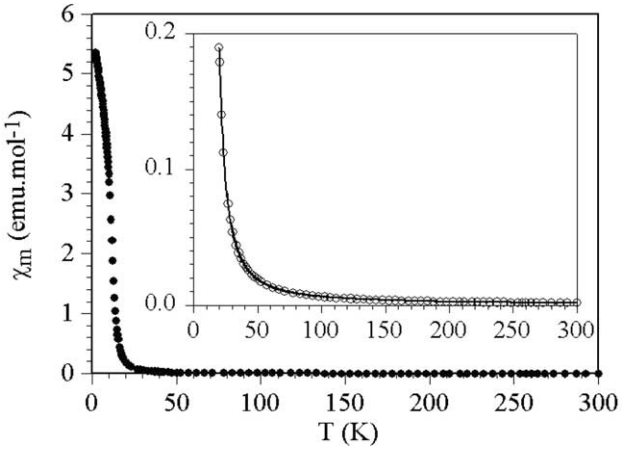

Fig. 4. Thermal variation of the molar magnetic susceptibility, χ_m, for the MEDA salt. Inset: the high temperature region. Solid line is the best fit to the model (see text).

($T > 20$ K, inset in Fig. 4), to the high temperature series expansion for a spin 1/2 two-dimensional ferromagnetic square lattice [17] yields values of $J/k = 19.29(1)$ K with $C = 0.4377(8)$ emu K mol^{-1} for the MEDA salt and $J/k = 19.0(4)$ K with $C = 0.412(1)$ emu K mol^{-1} for the EEDA salt, respectively.

Both salts show a sharp increase in the thermal variation of χ_m below approximately 9 K (Fig. 4), suggesting the presence of a ferromagnetic ordering. To confirm this long range ordering, we have performed ac susceptibility measurements. These measurements show a frequency independent peak in the in-phase signal (χ'_m) at approximately 9.0 K and an out-of-phase (χ''_m) signal in the *ac* susceptibility below that temperature, as shown in Fig. 5 for the EEDA salt. Additional proof is provided by the isothermal magnetizations at $T = 2$ K for both compounds, that show the presence of a rapid saturation at low fields (<0.1 T) with a value close to 1.0 μ_B, as expected for a $S = 1/2$ system (Fig. 6). These data also show the presence of a hysteresis loop for each compound with a coercive field of approximately 1 mT and a remnant magnetization of 0.17 μ_B for the MEDA salt and 0.12 μ_B for the EEDA salt (inset, Fig. 6).

The powder EPR spectrum of both salts consists of a single asymmetric absorption at room temperature, that sharpens to a typical axial spectrum at 78 K with $g = 2.17$ and $g = 2.05$. Single crystal measurements at room temperature gave an essentially axial spectrum with $g = 2.172$ and $g = 2.050$. These results are consistent with the results on previous systems studied [9]. These g values correspond to a Curie constant of 0.410, in good agreement with that found for the EEDA salt, but somewhat lower than that observed for the MEDA salt.

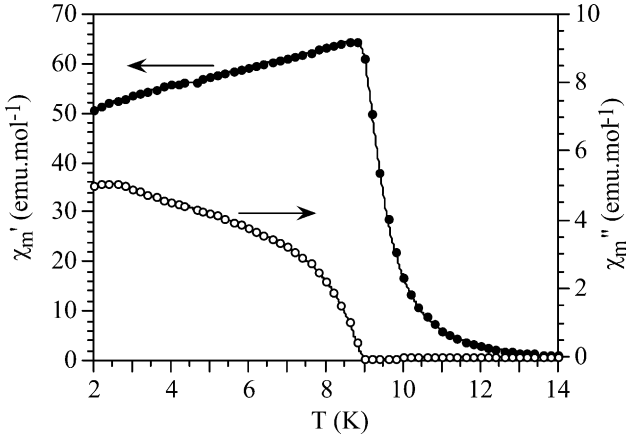

Fig. 5. Thermal variation of the in phase (χ'_m, filled symbols, left scale) and out of phase (χ''_m, empty symbols, right scale) molar AC susceptibility for the MEDA salt with an oscillating magnetic field of 0.395 mT at 10 Hz.

5. Discussion

Structurally, a significant feature of this structure is the orientation and relative rigidity of the organoammonium sheaths as a consequence of the presence of the lattice chloride ions. In the simple alkylammonium salts, the R groups typically contain a gauche conformation about one of the first C–C bonds in the alkyl chain and are frequently disordered. In contrast, the existence of strong hydrogen bonding between the secondary ammonium groups and the lattice chloride ions lock the *R*EDA groups into an all-*trans* configuration and provides rigidity to the sheaths. Similar behavior is observed in the $[NH_3(C_2H_4NH_2)_nC_2H_4NH_3 \cdot n\mathrm{Cl}]CuCl_4$ salts ($n = 1$, 2) [18]. Here, again, lattice chloride ions are incorporated into the structure to achieve charge neutrality. In fact, the structures of the $[(MEDA)Cl]_2CuCl_4$ salt can be naively envisioned as being derived from the $[NH_3(C_2H_4NH_2)_2C_2H_4NH_3 \cdot 2\mathrm{Cl}]CuCl_4$ salt by cleavage of the central C–C bond. However, now, due to the steric repulsions of the terminal methyl groups, adjacent layers are in a staggered configuration. As a consequence of the similarities in the structure of the organic sheaths in these two classes of layer perovskites that contain lattice chloride ions, the internal structure of the perovskite layers are virtually identical.

Magnetically, the high temperature data are quite consistent with the results of other copper chloride layer perovskite systems. The correlation of J with the semi-coordinate bond length is obeyed very well [9]. The values of $J/k \sim 19$ K corresponds very well, for example, with that for $[NH_3(C_2H_4NH_2)_2C_2H_4NH_3 \cdot 2\mathrm{Cl}]CuCl_4$, where a value of 19.4 K is observed [18b]. The ordering temperatures of 9.0 K are at the low end of the observed ranges for T_c, but again are in agreement with the values reported for $[NH_3(C_2H_4NH_2)_2C_2H_4NH_3 \cdot 2\mathrm{Cl}]CuCl_4$. That low value of T_c was attributed to the very small

amount of anisotropy present in the ferromagnetic exchange coupling. The nearly axial symmetry of the EPR g values observed for the *R*EDA salts suggests that the same argument holds for these systems.

The observation of the hysteresis loops for the two compounds clearly indicate the presence of ferromagnetic coupling between layers. This is only the second report of such observations, although ferromagnetic coupling between layers has been inferred in several other salts [10].

6. Supporting information

Crystallographic data for the structures reported here have been deposited with the Cambridge Crystallographic Data Center as Supplementary Publication Nos. CCDC-252685 and CCDC-252687 for the MEDA and EEDA compounds, respectively. Copies of this information may be obtained free of charge from: The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http//www.ccdc.cam.ac.uk).

systems, we have designed, synthesized the novel π-conjugated stable radical or biradicals, **1**–**8** shown in Fig. 1 and characterized their spin alignments [1–7]. The knowledge of photo-induced spin alignment on the excited states will give the guiding principles designing photo-induced/switching magnetic spin systems and the photo-control of the molecular magnetism. These studies will open the new strategy for the photomagnetic devices based on the organic materials.

Intramolecular spin alignment and exchange interaction through π-conjugation are quite important in the field of the molecular magnetism [10]. However, most studies are limited to ground state systems. Although radical (R) and excited-triplet (T) pairs in solution have been extensively investigated by TRESR technique, the direct detections of the excited high-spin states ($S \geqslant 3/2$) arising from the radical–triplet pair are still limited in the solid phase. The first direct TRESR detection of an excited quartet state of a radical–triplet pair was reported for a fullerene–mononitroxide radical system in solution [11] and for a tetraphenyl-porphilinatozinc (II) (ZnTPP) coordinated by *p*-pyridyl nitronylnitroxide (nitpy) system in a solid phase [12]. For homologous systems [13–15], excited high-spin states have been so far reported. However, in these systems, a stable radical couples weakly with the excited triplet chromophore through sigma bonds or coordination, in which the spin exchange interactions are small in magnitude. We reported the first observation of excited quartet ($S = 3/2$) and quintet ($S = 2$) states in purely organic π-conjugated spin systems [1–7], which are generated by a spin alignment through π-conjugation between dangling stable radicals ($S = 1/2$) and the excited triplet ($S = 1$) state of aromatic hydrocarbons. The π-conjugation leads to the strong exchange coupling between the triplet photo-excited state of the aromatic hydrocarbons and the dangling radicals. In the biradical systems, **5**–**8**, the stable radicals couple strongly through the spin coupler by π-conjugation making the robust spin alignment possible.

π-Conjugated spin systems have the following advantages in view point of the material science and molecular magnetism: (1) π-Conjugation leads to the strong exchange coupling which is one of the important conditions for the balk magnetism at finite temperature. (2) One can well design and synthesize the proper spin systems with the desired spin states using the well-established fine-synthetic chemistry. (3) An enhanced intersystem crossing (ISC) mechanism arising from the attachment of the radical species is available [2,6]. This leads to open a way of the direct ESR detection of the silent photo-excited states with little ISC to the triplet state. Actually, since phenyl or diphenylanthracene has very low efficiency of the ISC toward the triplet state, the triplet states can be not directly detected by TRESR. However, by attaching the radical species through π-conjugation, the excited high-spin states arising from the triplet state of phenyl or diphenylanthracene and the doublet state of radical were detected by TRESR as shown later. The photo-induced intra-molecular spin

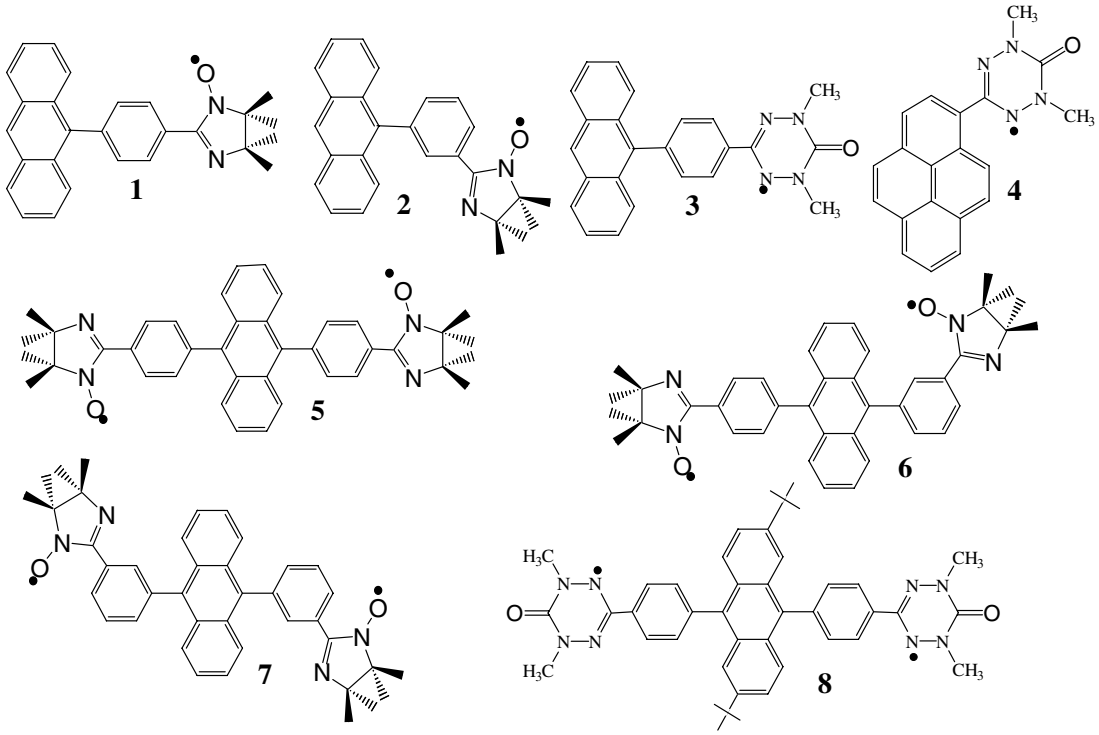

Fig. 1. π-Conjugated organic spin systems in which the photo-excited states were investigated.

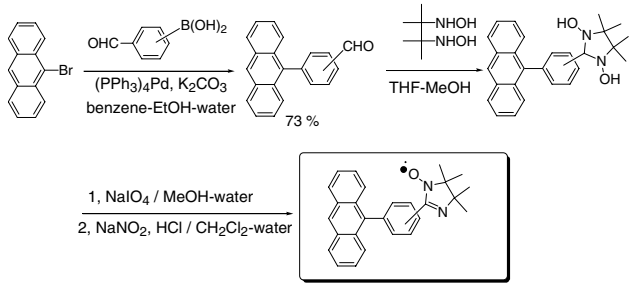
alignment through π-conjugation is one of the key processes for the photo-control of the molecular magnetism.

2. Experimental

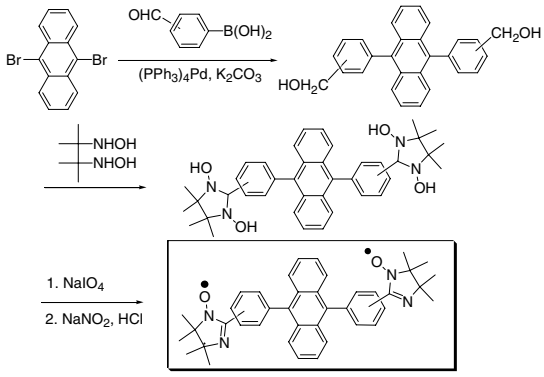
2.1. Materials

Typical synthetic procedures of monoradical and biradical are shown in Schemes 1 and 2, respectively. 2,3-Bis(hydroxyamino)-2,3-dimethyl-butane was prepared according to the literature method [16]. Other reagents were used as purchased.



2.2. TRESR measurements and simulation

The photo-excited states were examined by TRESR. A conventional X-band ESR spectrometer (JEOL TE300) was used in the measurements of TRESR spectra without field modulation. Excitation was carried out at 355 nm light using Nd:YAG pulse laser (Continuum Surelite II-10, pulse width <7 ns). The typical laser power used in the experiments was ca. 2–5 mJ. EPA, 2-MTHF, or isopentane–diethylether mixed glass matrix was used for the TRESR experiments. The measurements were carried out at 30–40 K. The typical microwave power was ca. 10 mW.



The spectral simulation was carried out by the eigenfield/exact-diagonalization hybrid method [16,17], taking dynamic electron spin polarization (ESP) into account [2]. The effective-exchange interaction between the triplet state of the aromatic hydrocarbon moiety and the dangling radicals is undoubtedly much larger than the Zeeman and fine-structure interactions in the π-conjugated systems. We have, therefore, used the following ordinary spin Hamiltonian of a pure spin state given in Eq. (1) (negligible quantum mixing of the different spin states) for the analysis:

$$H'_{\text{spin}} = \beta_e \boldsymbol{H}.\boldsymbol{g}.S + \boldsymbol{S}.\boldsymbol{D}.\boldsymbol{S}. \tag{1}$$

The resonance field $B_{Ms \leftrightarrow Ms+1}(\theta,\phi)$ for each transition was directly calculated by solving the following eigenfield equation [17]:

Scheme 1. Typical synthetic procedures of monoradical.

Scheme 2. Typical synthetic procedures of biradicals.

$$\boldsymbol{A}\cdot\boldsymbol{Z} = \boldsymbol{B}\boldsymbol{C}\cdot\boldsymbol{Z}, \tag{2}$$

where $\boldsymbol{A}$ and $\boldsymbol{C}$ are given by the following superoperators:

$$\boldsymbol{A} = \omega\boldsymbol{E}\otimes\boldsymbol{E} - \boldsymbol{F}\otimes\boldsymbol{E} + \boldsymbol{E}\otimes\boldsymbol{F} \tag{3}$$

and

$$\boldsymbol{C} = \boldsymbol{G}\otimes\boldsymbol{E} - \boldsymbol{E}\otimes\boldsymbol{G}^{*}. \tag{4}$$

Here, $\boldsymbol{E}$ is a unit matrix and ω is the given microwave frequency. The operators $\boldsymbol{G}$ and $\boldsymbol{F}$ are the field dependent and independent parts of the spin Hamiltonian (1), respectively. By solving the eigenfield equation (Eq. (2)), the resonance field B is obtained. The transition probabilities $I(\theta,\phi,\varphi)$ were evaluated by numerically diagonalization of the spin Hamiltonian matrix at the calculated resonance eigenfield [18,19]. Since the resonance field is independent of the third Euler angle, φ, the above procedure practically saves the computing time for the simulation. The line-shape function of the TRESR spectrum in the glass matrix is given by

$$g(B) = N\sum\int \mathrm{d}\varphi \int \mathrm{d}\phi \int \mathrm{d}\theta \sin\theta P_{Ms\leftrightarrow Ms+1}(\theta,\phi) \times I(\theta,\phi,\varphi) f[B - B_{Ms\leftrightarrow Ms+1}(\theta,\phi)]. \tag{5}$$

In the simulation, the dynamic electron polarization (ESP), $P_{Ms\leftrightarrow Ms+1}(\theta,\phi)$, on each spin sublevel in zero magnetic field was given as parameters. Thus, the relative populations of the Ms sublevels was taken into account as parameters. The simulation was carried out using a program written by the author on a personal computer. The details of the simulation procedures for the high-spin TRESR spectra were described in our previous paper [2].

3. Results and discussion

3.1. Photo-excited quartet high-spin states

Typical TRESR spectrum of **1** is shown in Fig. 2(a) [1,2]. The observed TRESR spectrum with well resolved

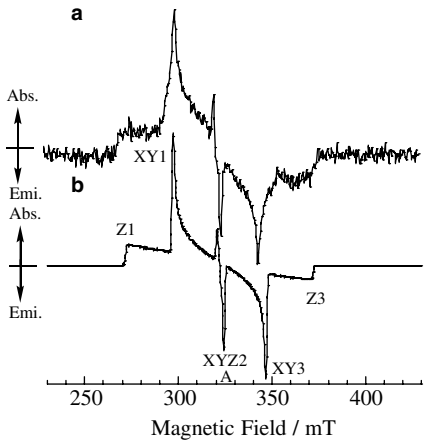


Fig. 2. Typical TRESR spectra of **1** at 30 K in EPA rigid glass matrix. (a) The observed spectrum of **1** at 0.8 μs after laser excitation. (b) The simulated spectrum of the excited quartet state.

fine structure splitting has been unambiguously analyzed to be a excited quartet ($S = 3/2$) state (Q) by the spectral simulation shown in Fig. 2(b). The determined g value, fine-structure parameters, and relative populations of the Ms sublevels are listed in Table 1. Similar excited quartet states were observed for **3** [5] and **4** [6]. The typical TRESR spectrum observed for the pyrene–verdazyl radical, **4**, is also shown in Fig. 3.

In these quartet systems the triplet state of the aromatic hydrocarbon moiety couples with the doublet state of the dangling stable radical by the spin-exchange interaction. In such a exchange-coupled system the wavefunction of the whole molecule $|\Psi(S,M)\rangle$ is approximately given by the direct product of the wavefunctions of the two isolated moieties, $|\mathrm{T}(S^{\mathrm{A}},m_{\mathrm{A}})\rangle$ and $|\mathrm{R}(S^{\mathrm{B}},m_{\mathrm{B}})\rangle$, as

$$|\Psi(S,M)\rangle = \sum C(S^{\mathrm{A}}S^{\mathrm{B}}S;m_{\mathrm{A}}m_{\mathrm{B}}M)|\mathrm{T}(S^{\mathrm{A}},m_{\mathrm{A}})\rangle| \times \mathrm{R}(S^{\mathrm{B}},m_{\mathrm{B}})\rangle, \quad \text{for } S^{\mathrm{A}}=1 \text{ and } S^{\mathrm{B}}=1/2, \quad (6)$$

where $C(S^{\mathrm{A}}S^{\mathrm{B}}S;\, m_{\mathrm{A}}m_{\mathrm{B}}M)$ is the Clebsch–Gordan coefficient. The radical–triplet pair has one quartet and one doublet states. The g and D values for the quartet state (Q) are given by the following relationship [20]:

$$\boldsymbol{g}(\mathrm{Q}) = (2/3)\boldsymbol{g}(\mathrm{T}) + (1/3)\boldsymbol{g}(\mathrm{R}) \quad (7)$$

and

$$\boldsymbol{D}(\mathrm{Q}) = (1/3)\{\boldsymbol{D}(\mathrm{T}) + \boldsymbol{D}(\mathrm{RT})\}. \quad (8)$$

Here, $\boldsymbol{D}(\mathrm{T})$ is the D tensor of the excited triplet moiety, $\boldsymbol{D}(\mathrm{RT})$ is the dipolar interaction between the dangling radical spin and the triplet moiety. Using these equations g and D values were calculated as shown in Table 1. The experimentally determined g, D and E values for the excited quartet state are in excellent agreement with the calculations.

3.2. Excited spin states of the π-topological isomers of *1*

In the ground state π-topology plays very important role in the spin alignment of the alternant hydrocarbons. Spin polarization effect governs the spin alignment and the spin multiplicity of the ground state depends drastically on the π-topology. In order to test the role of the π-topology on the spin alignment in the photo-excited state, TRESR experiments were performed for **2** [2], which is the π-topological isomers of **1**. In contrast to the result of **1**, no TRESR signal attributable to the high-spin excited state was observed for **2** and only a very weak absorptive signal due to the doublet state was observed as shown in Fig. 4. This agrees with the π-topological rule, indicating that the lowest excited state of **2** is a low-spin doublet ($S = 1/2$) spin state and the sign of the intramolecular exchange between the dangling radical spin and the excited triplet spin of the anthracene moiety is antiferromagnetic according to the spin polarization pathway through the dangling phenyl group. This finding shows that the sign of the intramolecular exchange interaction and the spin multiplicity of the lowest photo-excited spin state change drastically depending on the topological nature of π-electron network. Thus, the π-topological rule of the spin polarization established for the ground states of the aromatic hydrocarbons also plays an important role in the spin alignment on the photo-excited states.

Table 1

Here, $P_{Ms'}$ is the relative population of the spin sublevels in zero magnetic field, which magnetic quantum number corresponds to the value, Ms, in the high field limit.

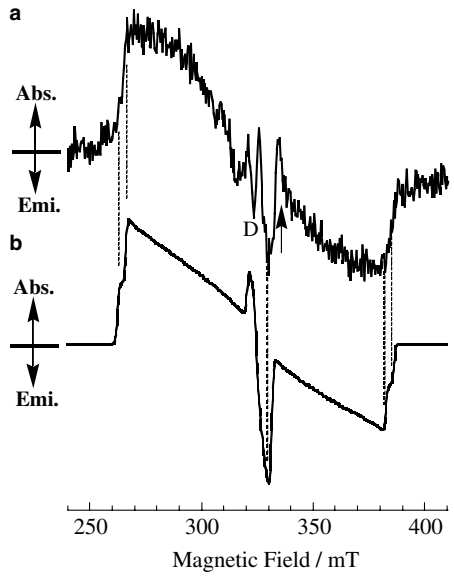

Fig. 3. Typical TRESR spectrum of pyrene–verdazyl radical, **4**.

3.3. Photo-induced spin alignment in diphenylanthracene-bis(radical) systems

In order to clarify the photo-induced spin alignment using the photo-excited molecular field, we investigated the photo-excited spin states of diphenyanthracene-bis(radical) systems which are illustrated in Fig. 5. In this spin system, the diphenylanthracene spin coupler between two dangling stable radical moieties becomes the photo-excited triplet state with two unpaired electrons upon the photo-excitation. Two dangling radicals are interacted with each other through the triplet spin coupler. The total spin Hamiltonian of the four spin system is given by

$$\begin{aligned}\boldsymbol{H}_{\text{spin}} =& \boldsymbol{H}_{\text{ex}} + \beta_e \boldsymbol{H}\cdot\boldsymbol{g}^{\text{T}}\cdot\boldsymbol{S}^{\text{T}} + \beta_e \boldsymbol{H}\cdot\boldsymbol{g}^{\text{R}_1}\cdot\boldsymbol{S}^{\text{R}_1} \\ &+ \beta_e \boldsymbol{H}\cdot\boldsymbol{g}^{\text{R}_2}\cdot\boldsymbol{S}^{\text{R}_2} + \boldsymbol{S}^{\text{T}}\cdot\boldsymbol{D}(\text{T})\cdot\boldsymbol{S}^{\text{T}} \\ &+ \boldsymbol{S}^{\text{R}_1}\cdot\boldsymbol{D}(R_1\text{T})\cdot\boldsymbol{S}^{\text{T}} + \boldsymbol{S}^{\text{R}_2}\cdot\boldsymbol{D}(R_2\text{T})\cdot\boldsymbol{S}^{\text{T}}, \qquad (9)\end{aligned}$$

$$\boldsymbol{H}_{\text{ex}} = -2J_1\boldsymbol{S}^{\text{R}_1}\cdot\boldsymbol{S}^{\text{T}} - 2J_2\boldsymbol{S}^{\text{T}}\cdot\boldsymbol{S}^{\text{R}_2}. \qquad (10)$$

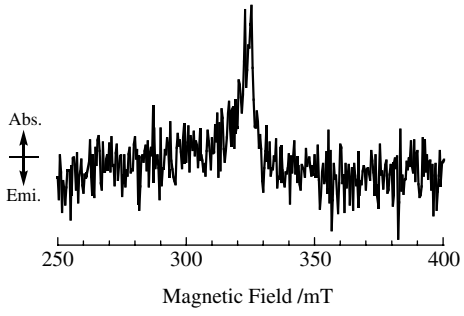

Fig. 4. Typical TRESR spectrum of **2** at 30 K in EPA rigid glass matrix.

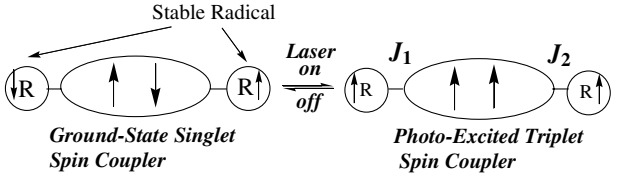

Fig. 5. Photo-induced intramolecular spin alignment.

Here, we omitted the dipolar interactions between two radicals moieties. The π-conjugated spin systems, the exchange interaction is much larger than other interactions in Eq. (9). The energies of each spin state in zero magnetic field were obtained to zero-th order by diagonalizing H_{ex}. The expectation values of the fine-structure terms of each spin states were calculated by using the eigenfunctions. There are two kinds of the triplet states (T_1 and T_2), one quintet state (Qu) and one singlet state (S). The energy versus J_2/J_1 diagram for each spin states are shown in Fig. 6 [7]. The fine-structure terms (D) of each spin states are related to the fine-structure tensor (D(T)) of the triplet state of anthracene by a reduction factor (f) ($D = f\cdot D$(T)). The reduction factor of each spin states are shown in Fig. 7 [7]. In this calculation, we omitted $D(R_1\text{T})$ and $D(R_2\text{T})$ in Eq. (10), because D(T) is much larger than them. As already shown in Sections 3.1 and 3.2, *para*-joint configuration between the iminonitroxide radical and the triplet excited state of the anthracene moiety leads to the ferromagnetic coupling and *meta*-joint configuration is antiferromagnetic coupling between them. Therefore, *para*-joint biradical **5** is expected to have a quintet state ($S = 2$) as the lowest photo-excited state and *meta*-joint biradical **7** has a singlet state ($S = 0$). An interesting lowest photo-excited triplet state arising from four unpaired electrons will be realized in **6** by the antiferromagnetic spin exchange coupling of the two dangling radical spins through the photo-excited triplet spin coupler (diphenylanthracene moiety). In order to prove this prediction, TRESR experiments were carried out for the π-topological isomers, **5**–**8** as shown later.

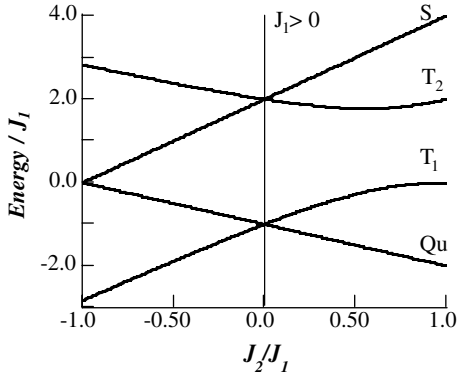

Fig. 6. Energy vs. J_2/J_1 diagram.

3.3.1. Photo-excited quintet high-spin states

Typical TRESR spectrum of the photo-excited quintet ($S = 2$) state (Qu) of the biradical system, **5** [1,2], is given in Fig. 8 together with the spectral simulation. The spin Hamiltonian parameters are also listed in Table 1. Similar excited quintet state was observed for a verdazyl biradical, **8** [5]. All the determined spin Hamiltonian parameters and relative population of the *Ms* sublevels of these excited high-spin states are summarized in Table 1.

According to a similar manner described in the case of the quartet state, the *g*, *D* and *E* values of the quintet state (Qu) have been estimated using the following equations, which are listed in Table 1:

$$\boldsymbol{g}(\mathrm{Qu}) = \{2\boldsymbol{g}(\mathrm{T}) + \boldsymbol{g}(\mathrm{R_1}) + \boldsymbol{g}(\mathrm{R_2})\}/4 \tag{11}$$

and

$$\boldsymbol{D}(\mathrm{Qu}) = (1/6)(\boldsymbol{D}(\mathrm{T}) + \boldsymbol{D}(\mathrm{R_1T}) + \boldsymbol{D}(\mathrm{R_2T}) + \boldsymbol{D}(\mathrm{R_1R_2})). \tag{12}$$

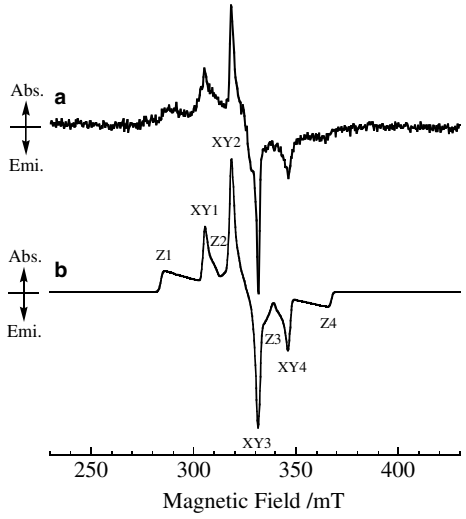

Fig. 8. Typical TRESR spectra of **5** at 30 K in 2-MTHF rigid glass matrix. (a) The observed spectrum of **5** at 0.8 μs after laser excitation. (b) The simulated spectrum of the excited quintet state.

Here, $\boldsymbol{D}(\mathrm{R_1R_2})$ is the dipolar interaction between the two radical spins. This was actually neglected in the estimation because of the small magnitude. The estimated values of the fine-structure parameters are quite well in agreement with the observed values, showing that the observed quintet state is a high-spin species originated from the triplet spin coupler and two dangling radicals.

The direct observations of the excited quintet states show that the photoinduced intramolecular spin alignment is realized between the excited triplet state ($S = 1$) of the diphenylanthracene moiety and the doublet spins ($S = 1/2$) of the dangling radicals as illustrated in Fig. 9. In Qu the photo-induced intramolecular ferromagnetic spin alignment between two dangling radicals is achieved through the photo-excited triplet ($S = 1$) spin coupler of the diphenylanthracene moiety [1,2].

3.3.2. Excited spin states and photo-induced spin alignment of π-topological isomers of 5

In order to test the role of the π-topology on the spin alignment in the photo-excited state, TRESR experiments were performed for **6** [7] and **7** [2], which are the π-topological isomers of **5**. A drastic change in the TRESR spectrum was observed for **6** and **7**. No TRESR signal for the excited spin state was observed in **7**, indicating that the lowest excited state is a low-spin singlet ($S = 0$) spin state, which is ESR silent. Therefore, the intramolecular spin exchange between two dangling radical spins and the excited triplet spin of the spin coupler is antiferromagnetic, similar to the case of **2**.

For the molecule **6**, TRESR signals arising from the lowest triplet photo-excited state (T_1) and the low-lying quintet spin state (Qu) closely above the triplet state were observed as shown in Fig. 10 [7]. The spin-Hamiltonian parameters for both spin states are also listed in Table 1. The magnitude of *D* of the triplet state is ca. 50% of that of anthracene. The unique triplet state has an interesting electronic structure, which *D* value is reduced by the antiferromagnetic spin alignment between two radical spins through the excited spin coupler. This small *D* value is characteristic nature of the unique triplet state, which is constructed from four unpaired electrons and explained well theoretically as already shown in Fig. 7 [7]. From the ratio $D(T_1)/D(Qu)$, determined in this experiment, the ratio of the exchange interactions, can be estimated that $J_2/J_1 = -0.05$. The sign and magnitude of the exchange coupling between the radical moiety and the triplet spin coupler is proportional to the product of the spin densities at linking positions. The sign of the spin densities of the spin coupler linked by two radical moieties is opposite and the spin density for R_2 is expected to be small. Therefore, the small negative value of J_2/J_1 is reasonable. The quintet state is located very closely above the triplet state in this case. The co-existence of the triplet and the quintet signals in the spectrum is well understood from the nearly

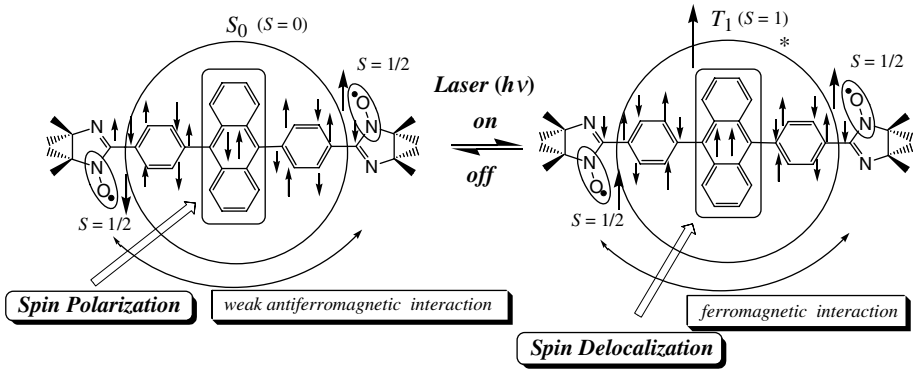

Fig. 9. Photo-induced intramolecular spin alignment and sign inversion of the effective exchange between two dangling radical spins.

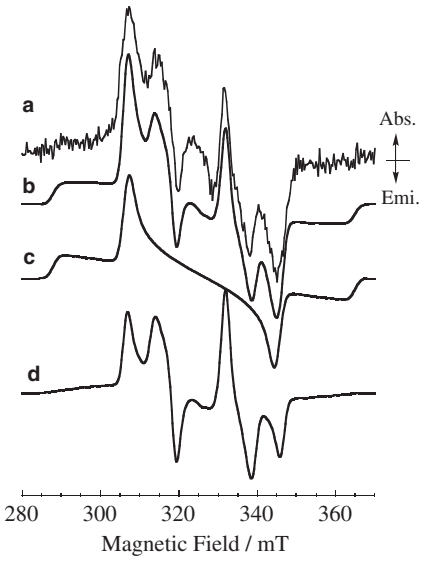

Fig. 10. Typical TRESR spectrum of **6**. (a) Observed spectrum at 0.5 μs after the laser excitation at 30 K in the glass matrix. (b) Simulated spectrum (super-imposed T_1 and Qu). (c) Simulation of T_1. (d) Simulation of Qu.

degenerated energy locations as predicted for the small negative J_2/J_1 value in Fig. 6 [7].

These findings agree with the spin prediction shown in Fig. 6. Thus, the two dangling radical spins can be manipulated through the photo-excited triplet spin coupler (diphenylanthracene moiety) by the photo-excitation. The π-topological rule of the photo-induced spin alignment is established on the excited states based on these findings.

3.4. Physical picture of photoinduced intra-molecular spin alignment in viewpoint of spin density distribution

In order to obtain the physical picture of the photo-induced intramolecular spin alignment, the ab initio molecular orbital calculations were carried out based on the density functional theory (DFT) using GAUSSIAN 98 [21]. In these calculations, an unrestricted Hartree–Fock method (Ubecke 3LYP/6-31G) was employed in order to clarify the role of the spin polarization effect.

Fig. 11 shows the calculated total spin densities on the atomic sites in the excited quartet state of **1** [4]. The mechanism of the spin alignment was clarified based on the spin distribution. In the excited quartet state the spin density distribution of the anthracene moiety is nearly symmetrical as shown in Fig. 11. The almost two net unpaired spins exist on the anthracene moiety and the remained one unpaired spin exists on the dangling radical. This shows that the excited quartet state is generated by the one-electron transition from the β-HOMO (π) to the α-LUMO (π*). These results are consistent with our experimental results, in which the magnitude of the observed fine-structure splitting has been well interpreted as the exchange coupled system constructed from the ππ* excited triplet state of anthracene and the dangling radicals. In the anthracene moiety, positive spin densities overcome the negative spin densities. This spin distribution shows that spin delocalization overcomes the spin polarization effect within the anthracene moiety. In contrast, the alternating sign of the spin density is realized on the dangling phenyl groups as shown in Fig. 11. This sign alternation of the spin densities shows that the spin polarization mechanism overcomes the spin delocalization within the dangling phenyl groups even in the excited state. Thus, through the spin polarization pathway in the dangling phenyl group, the unpaired spin on the dangling radical

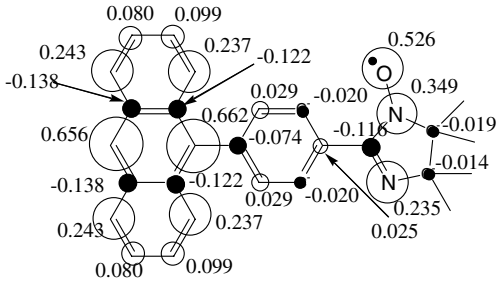

Fig. 11. The spin density distribution in the excited quartet state of **1**.

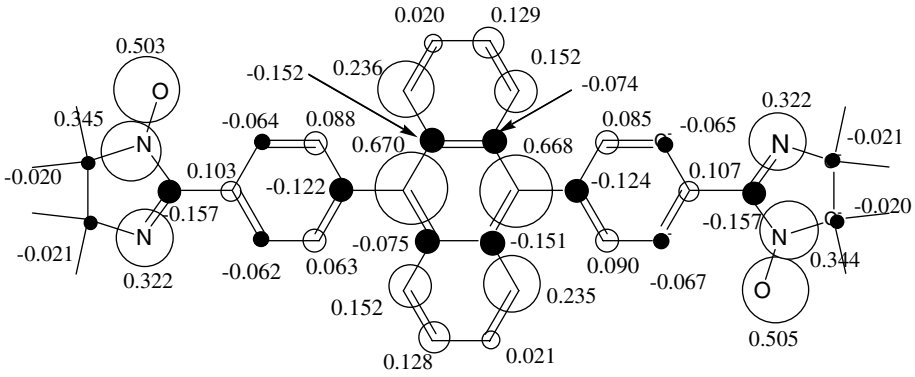

Fig. 12. Spin density distribution in the excited quintet state of **5**.

couples ferromagnetically to the excited triplet spins delocalized on the anthracene moiety, leading to the excited quartet high-spin state.

The calculated spin distribution of the excited quintet state of **5** [4] is shown in Fig. 12. The spin delocalization and spin polarization effects similar to the case of **1** occurred in the quintet state. The large positive spin densities at the 9 and 10 positions of the anthracene moiety are realized by the spin delocalization. Each dangling radical spin ($S = 1/2$) couples ferromagnetically to the large positive spin of the excited triplet spins on the anthracene moiety, through the spin polarization pathway in the phenyl groups. This mechanism leads to the ferromagnetic exchange between excited triplet state and two radical spins in **5**. As the results, the sign of the effective spin coupling of the two dangling radicals in **5** can be changed from antiferromagnetic to ferromagnetic as illustrated in Fig. 9 by the exchange coupling through the excited triplet moiety generated by the photo-excitation. Similar results were obtained for the quintet states of **8**.

3.5. Potential developments toward functional materials using photo-excited high-spin organic systems

The observations of the high-spin photo-excited states mean that the intersystem crossing (ISC) from low-spin state to high-spin states occurs efficiently. As previously reported in our paper [2,6], this effective ISC are generated by the attachment of radical species. The enhanced ISC mechanism is concerned with the π-conjugation between the pπ orbital of radical moiety and aromatic hydrocarbon moiety. The enhanced ISC to the high-spin photo-excited states will open a new channel to relax from the high-spin photo-excited state toward the ground/low-lying high-spin states. Moreover, since the high-spin photo-excited states have fairly long life-time (10–20 μs at 77 K), the energy

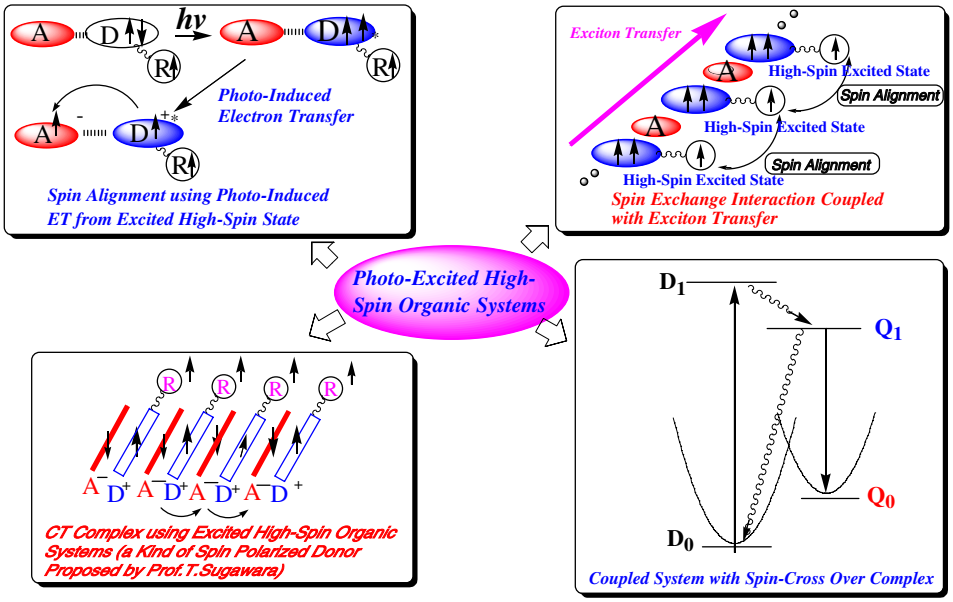

Fig. 13. Potential developments toward functionality materials using the π-conjugated organic spin system with photo-excited high-spin states.

transfer and the photo-induced electron transfer processes will be expected from such high-spin photo-excited states. These processes also channel a new pathway using the photo-excited state toward the new functionality materials.

There are some potential developments of the photo-excited high-spin organic systems toward the functionality materials shown in Fig. 13. In order to realize such functionality materials, it is necessary to develop the systems to superstructure materials. One of the ways is to make the charge-transfer complexes using the excited high-spin organic spin systems as the electron donor and to use the photo-induced electron transfer from the donor to the acceptor. In the intramolecular donor-acceptor linked systems using the photo-excited high-spin molecule are also potential candidates. Moreover, the cation of the photo-excited high-spin system is expected to have interesting electronic structure, in which the triplet state becomes the electronic ground state. Therefore, this system is a kind of the spin-polarized donor proposed by Sugawara et al. [22].

Since the photo-excited high-spin state has fairly long life-time, the exciton transfer is possible to occur in their crystals. The intermolecular photo-induced spin alignment of the dangling radical spins may be achieved by the exciton transfer. The combination with the metal complex will be one of the potential developments. It is special interest in the construction of the spin cross-over complex using the photo-excited high-spin organic molecules as their ligands. In the case, the photo-excitation of the ligand leads to open the new pathway to relax the high-spin ground state of the whole system. There will be also other potential applications of the π-conjugated organic spin systems with the photo-excited high-spin states.

4. Summary

The spin alignment in the photo-excited states of the purely organic π-conjugated spin systems and their topological isomers are reviewed. In the photo-excited states the photo-induced spin alignment is investigated by TRESR experiments and ab initio MO calculations. Role of the spin delocalization and the spin polarization effects are revealed in the spin alignment on the photo-excited states. The photo-induced spin alignment was achieved through the photo-excited triplet spin coupler. π-Topology plays very important role on the spin alignment on the photo-excited states as well as the ground states. One of the key processes for the photo-control of the organic molecular magnetism is established. The guiding principle designing the photo-excited high-spin system and the role of π-topology are clarified. Some ideas of the potential developments toward the functionality materials utilizing the π-conjugated organic spin systems with the photo-excited high-spin states are also proposed.

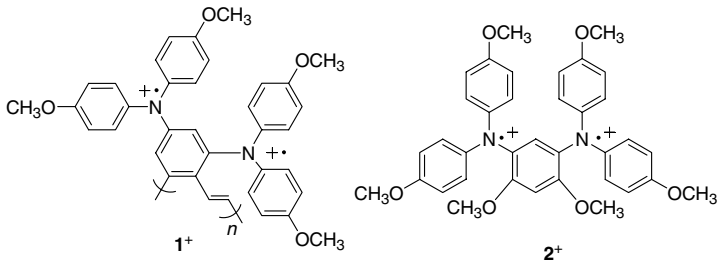

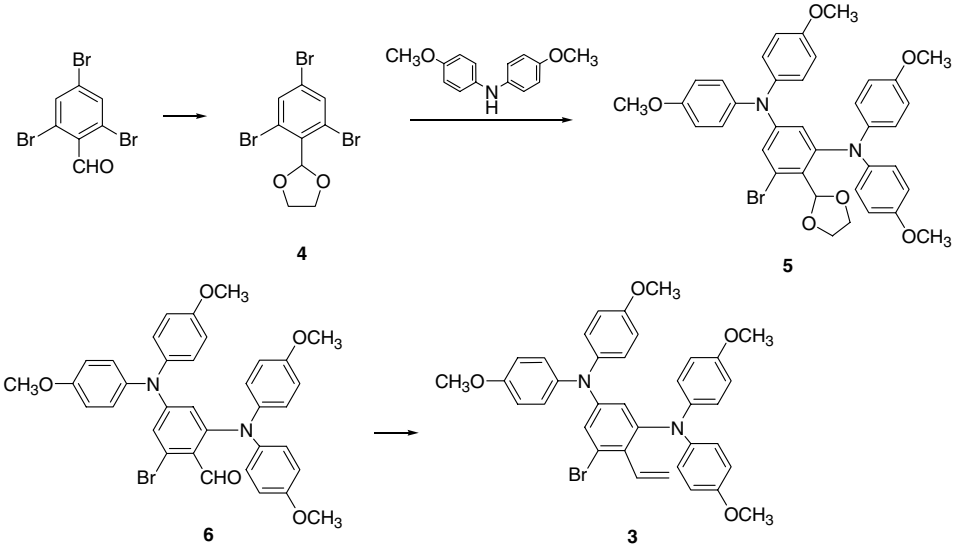

Chart 1.

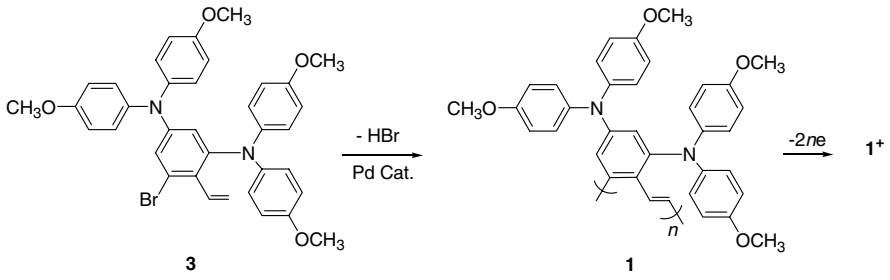

alignment among the pendant unpaired electrons by synthesizing poly(1,2-phenylenevinylene)s that are 4-substituted with stable diphenylaminium cation radicals [6]. The poly(1,2-phenylenevinylene) backbone is characterized as being relatively coplanar with an extended π-conjugation even after the introduction of the pendant radical group. Poly(4-diphenylaminium-1,2-phenylenevinylene) showed the spin quantum number of $S = (4 - 5)/2$ even at room temperature, because the triphenylaminium cation radical has both an excellent chemical stability and an efficient delocalized spin density into the aryl groups [7]. Beside these linear polyradicals, another synthetic approach focuses on the π-conjugated polymer bearing two pendant radicals in one monomer unit. Although these polyradicals are one-dimensional linear π-conjugated polymers, the spin coupling of the neighboring radical units is a ladder-liked connection, which can enhance the interaction between the neighboring (and even remote) pendant radicals [8]. In previous papers, a very strong ferromagnetic interaction was reported in the *m*-phenylene-coupled bis- and tris-phenylaminiums, realizing their triplet and quartet state [9]. This suggests that *m*-phenylene acts as a strong ferromagnetic coupler in an extended polyradical bearing a triplet biradical. In this study, we have synthesized poly[4,6-bis(bis(4-methoxyphenyl)aminium)-1,2-phenylenevinylene] $\mathbf{1}^+$ which has both a very strong ferromagnetic coupling through the *m*-phenylene unit and a moderately strong ferromagnetic coupling through the poly(1,2-phenylenevinylene) unit (see Chart 1).

2. Results and discussion

A head-to-tail linkage structure of the substituted radical group is essential for the non-Kekulé and non-disjoint or the following magnetic study. This was established through the polycondensation via the Heck reaction of the 4,6-disubstituted-2-bromostyrene derivative. 4,6-Bis(bis(4-methoxyphenyl)amino)-2-bromostyrene was synthesized as the monomer for the polycondensation. After the formyl group of 2,4,6-tribromobenzaldehyde was protected by the 1,3-dioxolane group, the palladium-catalyzed amination of **4** with *N,N*,-bis(4-methoxyphenyl)amine followed by deprotection yielded **6** (Scheme 1). The formyl group of **6** was converted to a vinyl group via the

Scheme 1.

Scheme 2.

Wittig reaction to afford the bromostyrene derivative **3** as the monomer.

The bromostyrene monomer **3** was polycondensed through the Heck reaction using the catalyst of palladium and tri(*o*-tolyl)phosphine in the presence of triethylamine and lithium chloride as a base and a source of chloride ion, respectively, in a DMF solution at 70 °C for 72 h (Scheme 2). This polymerization condition was selected for the selective *β*-arylation of the vinyl group with the aryl bromide in order to avoid the formation of chemical defects [6b]. The obtained polymer **1** was soluble in common solvents such as methylene chloride, chloroform, tetrahydrofuran, toluene, and DMF. The number average molecular weight and molecular weight distribution of **1** measured by GPC using polystyrene standards was 2.0×10^3 (1.2). The chloroform solution of the brownish yellow polymer **1** showed two UV/Vis absorption maxima at 301 and 432 nm, with molar absorption coefficient of $\varepsilon = 2 \times 10^4$ and $1 \times 10^4\ M^{-1}\ cm^{-1}$, respectively. They are ascribed to the triarylamine moiety (λ_{max} = ca. 300 nm) and the *trans*-stilbene moiety. The visible absorption was extended to 506 nm for **1**, in comparison with that of poly(1,2-phenylenevinylene) (ca. 430 nm). The solution of **1** exhibited a strong photoluminescence. The λ_{em} for **1** was 504 nm in the chloroform solution (λ_{ex} = 312 nm) and was bathochromically shifted in comparison with that of the model amine **2** (400 nm). The bathochromic shift of λ_{em} for **1** corresponds to the UV absorption edge of **1**, suggesting a developed π-conjugation for **1**.

Cyclic voltammetry of the polymer **1** and model amine **2** in the methylene chloride solution with tetrabutylammonium tetrafluoroborate as the electrolyte gave reversible waves which were repeatedly recorded in the potential sweeps of, e.g., 50 times at room temperature (Fig. 1). This voltammogram result means that the triarylamine groups are electrochemically oxidized to the aminium cationic radicals and reduced to the amines without any subsequent chemical side reactions, such as dimerization, to form a benzidine and a disproportionation. The cyclic voltammogram of **2** showed two waves ascribed to two amine sites ($E_p^{1/2}$ = 885 and 1083 mV). The cyclic voltammogram of **1** showed broader waves than that of **2**, which could be explained by the delocalization effect of the formed aminium cationic radical in the π-conjugation of the polymer.

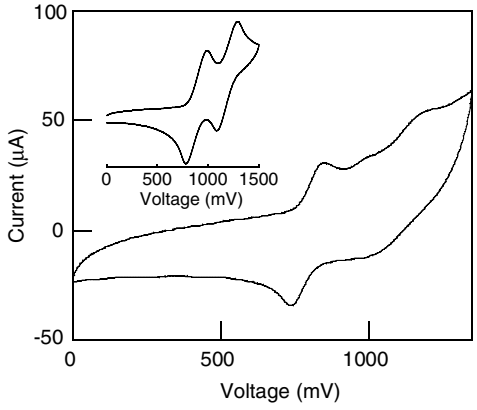

Fig. 1. Cyclic voltammogram of **1** in the methylene chloride solution at a sweep rate of 200 mV/s. Inset: cyclic voltammogram of **2**.

The triaryl aminium cationic radical salts, $\mathbf{1}^+$ and $\mathbf{2}^+$, were prepared by oxidizing the corresponding triaryl amines **1** and **2** with $NOPF_6$ or $SbCl_5$ [10,11]. The oxidation of **2** using $NOPF_6$ resulted in the spin concentration of 0.48 spin/amine unit, which showed a three-line ESR spectrum ascribed to the mono-aminium radical. On the other hand, the oxidation of **2** using $SbCl_5$ produced a spin concentration of 0.90 spin/amine unit and unimodal ESR spectrum, indicating the generation of the di-aminium radical. By considering the oxidation potential of **1**, $SbCl_5$ was selected as the oxidizing reagent of **1**. The color of the methylene chloride solution of **1** turned from pale yellow to deep blue,[1] which is characteristic of triphenylaminium cation radicals [12]. A deep blue-colored powder of $\mathbf{1}^+$ was obtained, of which the spin concentration was estimated to be 0.80 spin/monomer amine unit.[2] The half-life (τ) of the aminium cation

[1] The concentrated methylene chloride solution of $SbCl_5$ was added dropwise to the dilute methylene chloride solution of the amine polymer **1** to provide a high yield upon the aminium cationic radical formation. The $SbCl_6^-$ salt of $\mathbf{1}^+$ was isolated as a blue powder by pouring the methylene chloride solution of $\mathbf{1}^+$ oxidized with $SbCl_5$ into diethyl ether.

[2] Measured by the ESR signal intensity.

radical $\mathbf{1}^+$ in the powder state was 10 days at room temperature, which showed an excellent chemical stability.

The ESR spectrum of $\mathbf{1}^+$ with a low spin concentration gave a three-line signal at $g = 2.0034$ and changed to a strong unimodal signal with the increasing spin concentration, indicating a local high-spin concentration along the polymer backbone (see Inset of Fig. 2). The frozen glass of $\mathbf{1}^+$ gave a $\Delta M_s = \pm 2$ (half field and forbidden) transition at 160 mT which is assigned to a triplet species. The temperature-dependent ESR experiment of $\mathbf{1}^+$ gave a linear relation for the doubly integrated ESR intensity of the $\Delta M_s = \pm 2$ signal as a function of the reciprocal temperature ($1/T$) at higher temperature (>10 K), which was consistent with Curie's law (Fig. 2). However, the plots substantially deviated upward from the linearity observed in the lower temperature region (<10 K). This upward deviation suggests a ferromagnetic interaction between the triplet species.

The $SbCl_6^-$ salt of $\mathbf{1}^+$ was isolated in the presence of poly(styrenesulfonate tetrabutylammonium) as a diamagnetic diluent. This isolated sample of $\mathbf{1}^+$ was subjected to static magnetic susceptibility (χ) and magnetization (M) measurements using a SQUID magnetometer. χ was normalized to the χ_{mol} values with the radical concentration in the sample determined by the saturation magnetization (M_s) of M versus the magnetic field (H) plots. The normalized plots of magnetization (M/M_{sat}) for the diluted $\mathbf{1}^+$ are close to the Brillouin curves for 5/2, indicating a high-spin ground state for $\mathbf{1}^+$. The $\chi_{mol}T$ plots leveled off in the temperature range from 20 to 100 K (see Inset of Fig. 3). The flat $\chi_{mol}T$ plots means that the multiplet ground state for $\mathbf{1}^+$ is significantly large and that $\mathbf{1}^+$ is a paramagnetic molecule with an average $S = (4.5)/2$. These results concluded that a ferromagnetic and intramolecular spin-alignment is realized between the unpaired electrons of the polyaminium cationic radicals. Taking into account both the molecular weight or DP and the spin concentration of $\mathbf{1}^+$, all radical spins in each polymer chain are considered to be aligned. S is expected to proportionally increase with the DP of the poly(aminium cationic radical) $\mathbf{1}^+$.

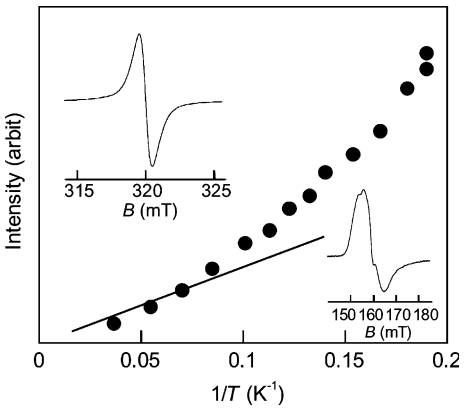

Fig. 2. Temperature dependency of the ESR signal intensity of the $\Delta M_s = \pm 2$ transition of $\mathbf{1}^+$ with 0.80 spins/unit in methylene chloride. The solid line is a least-square fitting to Curie's law (Intensity = C/T). Inset: ESR spectra of the $\mathbf{1}^+$ at room temperature, and the $\Delta M_s \pm 2$ spectrum of $\mathbf{1}^+$ in methylene chloride at 5.0 K.

Normalized plots of magnetization (M/M_s) vs. the ratio of the magnetic field and temperature ($H/(T-\theta)$) for the diluted $\mathbf{1}^+$ (DP = 3.3) with spin concentration = 0.73 spin/amine unit at 1.8 (○), 2.0 (●), 2.5 (□), 3.0 (■), and 5.0 (◇) K and theoretical Brillouin curves corresponding to the $S = 4/2$, 5/2, and 6/2 ($\theta = -0.5$ K). Inset: $\chi_{mol}T$ vs. T plots for the diluted sample of $\mathbf{1}^+$.

2.1. Materials

2,4,6-Tribromobenzaldehyde and 1,5-dibromo-2,4-dimethoxybenzene were prepared according to the literature [13,14]. The other reagents were used as received. The solvents were purified in the usual manners.

2.2. 1,5-Bis[N,N-bis(4-methoxyphenyl)amino]-2,4-dimethoxybenzene (2)

1,5-Dibromo-2,4-dimethoxybenzene (300 mg, 1.01 mmol), 4-methoxy-phenylamine (249 mg, 2.02 mmol) and 1-chloro-4-methoxy-benzene (302 mg, 2.12 mmol) were dissolved in toluene (8.1 ml). Sodium *tert*-butoxide (544 mg, 5.66 mmol), tris(dibenzylideneacetone)dipalladium (27.7 mg, 30.3 μmol), and P(*t*-Bu)$_2$-*o*-biphenyl (36.1 mg, 12.1 μmol) were added, and then the mixture was heated at 80 °C for 24 h. The reaction mixture was neutralized with 1 N aqueous ammonia, and extracted with chloroform. The organic layer was washed with brine, and evaporated to give the crude product, which was purified by HPLC to afford 221 mg of **2**: yield 36%. ^{1}H NMR (500 MHz, $CDCl_3$; ppm) δ 6.97 (s, 1H), 6.87–6.70 (m, 16H), 6.55 (s, 1H), 3.73 (s, 12H), 3.59 (s, 6H); ^{13}C NMR (500 MHz, $CDCl_3$; ppm) δ 154.5, 154.2, 141.8, 131.0, 129.8, 122.2, 114.2, 100.5, 56.4, 55.5. IR (KBr pellet, cm^{-1}) 1239 (ν_{C-O-C}), 1179 (ν_{C-N}), 1036 (ν_{C-O-C}); MS (EI) *m/e* 592, Calc. for $C_{36}H_{36}N_2O_6$: 592.7. *Anal.* Calc. for $C_{36}H_{36}N_2O_6$: C, 73.0; H, 6.1; N, 4.7. Found: C, 72.8; H, 6.0; N, 4.5%.

2.3. 4,6-Bis[N,N-bis(4-methoxyphenyl)amino]-2-bromobenzaldehyde (6)

The mixture of 2,4,6-tribromobenzaldehyde (900 mg, 2.63 mmol), 1,2-ethanediol (1.63 g, 26.3 mmol), benzene (5 ml), and *p*-toluenesulfonic acid monohydrate (2.50 mg, 0.0131 mmol) was refluxed until almost the theoretical amount of water was collected in the trap (ca. 6 h). The reaction mixture was then extracted with chloroform. The organic layer was dried over anhydrous sodium sulfate and evaporated. The crude product was purified using a silica gel column with a hexane eluent to give 2-(2,4,6-tribromophenyl)-1,3-dioxane (**4**) as a white solid (869 mg): yield 86%; m.p. 113 °C; ^{1}H NMR (500 MHz, $CDCl_3$; ppm) 7.74 (s, 1H), 6.32 (s, 1H), 4.31 (t, $J = 3.5$ Hz, 2H), 4.08 (t $J = 3.5$ Hz, 2H); ^{13}C NMR (500 MHz, $CDCl_3$; ppm) δ 206.8, 135.9, 131.9, 125.2, 123.9, 65.9. IR (KBr pellet, cm^{-1}) 940 (ν_{C-O-C}) cm^{-1}; MS (EI) *m/e* 383, 385, 387, 389 Calc. for $C_9H_7Br_3O_2$: 383.8.

4 (55.2 mg, 0.143 mmol) and bis-(4-methoxyphenyl)amine (65.4 mg, 0.285 mmol) were dissolved in toluene (2.2 ml). Sodium *tert*-butoxide (41.1 mg, 0.428 mmol), tris(dibenzylideneacetone)dipalladium (3.92 mg, 4.28 μmol), and (*S*)-(−)-2,2′-bis(diphenylphosphino)-1,1-binaphthyl (4.44 mg, 7.13 μmol) were added, and then mixture was heated at 100 °C for 40 h. The reaction mixture was neutralized with 1 N aqueous ammonia, and extracted with chloroform. The organic layer was washed with brine, and then evaporated to give the crude product, which was purified using a silica gel column with hexane/ethyl acetate (3/1) and HPLC to afford 23.4 mg of **5**: yield 24%. ^{1}H NMR (500 MHz, $CDCl_3$; ppm) δ 9.73–6.95 (m, 18H), 6.10 (s, 1H), 4.10–3.77 (m, 4H), 3.73 (s, 12H); ^{13}C NMR (500 MHz, $CDCl_3$; ppm) δ 156.4, 154.6, 150.7, 142.6, 142.1, 139.2, 126.8, 123.9, 123.3, 123.1, 122.6, 119.8, 114.5, 100.9, 65.3, 55.5, 55.4. IR (KBr pellet, cm^{-1}) 1180 (ν_{C-N}), 960 (ν_{C-O-C}); MS (EI) *m/e* 682, 684 Calc. for $C_{37}H_{35}N_2BrO_6$: 683.6. *Anal*. Calc. for $C_{37}H_{35}N_2BrO_6$: C, 65.0; H, 5.2; N, 4.1; Br, 11.7. Found: C, 64.9; H, 5.3; N, 4.1; Br, 11.8%.

5 (56.1 mg, 82.1 mmol) was dissolved in a mixture of acetone (28 ml) and water (0.90 ml) containing *p*-toluenesulfonic acid (4.68 mg, 24.6 mmol) and refluxed for 3 h. After evaporation, the mixture was extracted with ether. The organic layer was successively washed with aqueous sodium hydrogencarbonate and aqueous saturated sodium chloride and then evaporated. The crude product was purified using a silica gel column with hexane/ethyl acetate (3/1) to give **6** as an orange solid (38.3 mg): yield 73%. ^{1}H NMR (500 MHz, $CDCl_3$; ppm) δ 9.96 (s, 1H), 7.00–6.31 (m, 18H), 3.78 (s, 6H), 3.76 (s, 6H); ^{13}C NMR (500 MHz, $CDCl_3$; ppm) δ 188.2, 157.4, 155.4, 153.1, 142.1, 137.9, 127.7, 126.4, 125.0, 124.5, 119.7, 118.2, 115.4, 114.9, 114.6, 55.5, 55.4. IR (KBr pellet, cm^{-1}) 1680 ($\nu_{C=O}$); MS (EI) *m/e* 638, 640 Calc. for $C_{35}H_{31}N_2BrO_5$: 639.5. *Anal*. Calc. for $C_{35}H_{31}N_2BrO_5$: C, 65.7; H, 4.9; N, 4.4; Br, 12.5. Found: C, 65.9; H, 4.8; N, 4.5; Br, 12.3%.

2.4. 4-[N,N-bis(4-methoxyphenyl)amino]-2-bromostyrene (3)

To 3 ml of a dry THF solution of triphenylmethylphosphonium bromide (139 mg, 0.389 mmol), a 0.161 ml hexane solution of *n*-butyllithium (0.258 mmol) and a dry 0.25 ml THF solution of **6** (83.0 mg, 0.129 mmol) were dropwise added, and stirred at room temperature for 1 h. After evaporation, the crude product was extracted with diethyl ether, washed with brine, dried over anhydrous sodium sulfate, evaporated, and purified with a silica gel column with a hexane/ethyl acetate (20/1) to give 71.5 mg of **3** as a yellow solid: yield 85%. ^{1}H NMR (500 MHz, $CDCl_3$; ppm) δ 6.97–6.59 (m, 18H), 6.32 (dd, $J = 12$, 18 Hz, 1H), 5.51 (d, $J = 18$ Hz, 1H), 5.12 (d, $J = 12$ Hz, 1H), 3.77 (s, 6H), 3.76 (s, 6H); ^{13}C NMR (500 MHz, $CDCl_3$; ppm) δ 156.2, 154.6, 148.8, 147.4, 141.4, 139.7, 132.5, 129.3, 127. 3, 125.3, 123.3, 120.4, 120.0, 118.3, 114.8, 114.3, 55.5, 55.4. IR (KBr pellet, cm^{-1}) 1589 ($\nu_{C=C}$); MS (EI) *m/e*, 636, 638 Calc. for $C_{36}H_{33}N_2BrO_4$: 637.6. *Anal*. Calc. for $C_{36}H_{33}N_2BrO_4$: C, 67.8; H, 5.2; N, 4.4; Br, 12.5. Found: C, 67.6; H, 5.1; N, 4.5; Br, 12.3%.

2.5. Polymerization

The polymerization was carried out by modifying the procedure described in previous papers [6b]. Palladium acetate (1.40 mg, 6.24 μmol), tris(*o*-tolylphosphine) (7.58 mg, 24.9 μmol), triethylamine (104 μl), and lithium chloride (132 mg, 3.12 mmol) were added to the monomer **3** (397 mg, 623 μmol) solution of DMF (1.24 ml), and the mixture was then heated for 3 days to obtain a high molecular weight polymer. The polymerization mixture was poured into methanol, and the precipitated polymer powder was purified by reprecipitation twice from chloroform into the mixture of methanol/benzene (3/7) to afford the **1** polymer (119 mg). The number average molecular weight and molecular weight distribution of **1** measured by GPC (polystyrene gel column, eluent THF, polystyrene calibration) was 2.0×10^3 (1.2).

2.6. Magnetic measurements

The $SbCl_6^-$ salt of $\mathbf{1}^+$ was dissolved in the methylene chloride solution of poly(styrenesulfonate tetrabutylammonium), and then the solvent was thoroughly removed to give the isolated sample. The isolated sample was transferred to a diamagnetic plastic capsule after oxidation. The magnetization and static magnetic susceptibility were measured using a Quantum Design MPMS-7 SQUID magnetometer. The magnetization was

measured from 0.1 to 7 T at 1.8, 2.0, 2.5, 3.0, and 5.0 K. The static magnetic susceptibility was measured from 1.8 to 100 K in a 0.5 T field. The ferromagnetic magnetization ascribed to the impurities was determined by the Honda-Owen plots to be very low (<1 ppm) and subtracted from the overall magnetization. The diamagnetic susceptibility of the diluent and capsule was estimated by the Curie plots of magnetic susceptibility. The corrected magnetization data was fitted to Brillouin functions using the self-consistent version of the mean field approximation [3b].

2.7. Measurements

Cyclic voltammetry was carried out using a BAS 100B/W electrochemical analyzer in a CH_2Cl_2 solution with 0.1 M $(C_4H_9)_4NBF_4$ as the supporting electrolyte. A platinum working electrode and commercial Ag/AgCl electrode as the reference were used. The ESR spectra were taken using a JEOL JES-2XG ESR spectrometer with 100-kHz field modulation. The IR, NMR, mass, and UV spectra were measured using JASCO FT/IR-410, JEOL NMR 500 Λ, Shimazu GC-MS 17A, and JASCO V-550 spectrometers, respectively.

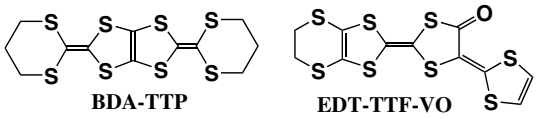

Fig. 1. Molecular structures.

undergoes a metal–insulator (M–I) transition at $T_{MI} = 113$ K, followed by an antiferromagnetic order of the anion spins at $T_N = 8.5$ K. This M–I transition is suppressed under pressure, and a superconducting phase appears above 4.5 kbar. When magnetic field is applied perpendicular to the conducting plane, an abrupt decrease of the resistance is observed at 6 T after the superconductivity is destroyed below 1 T. Though antiferromagnetic order under pressure has not been verified, this resistance anomaly is probably related to the magnetic order. Thus the magnetic order coexists with the superconducting phase.

Another interesting πd-compound is (EDT-TTF-VO)$_2$- $FeBr_4$ (EDT-TTF-VO: ethylenedithiotetrathiafulvalenoquione-1,3-dithiolenethide, Fig. 1) [12,13]. Though the donor is a bent molecule, the $FeBr_4$ salt is fairly conducting, and only weakly semiconducting below the broad resistance minimum around 170 K. The magnetic susceptibility follows the Curie–Weiss law with an antiferromagnetic Weiss constant $\theta = -3.9$ K at high temperatures. Below the minimum of χT at 15 K, χT shows a rapid ferrimagnetic increase. The magnetization saturates to 4.6 μ_B/Fe at 0.4 K, though the hysteresis is not clearly observed. The specific heat indicates a magnetic transition at 1 K. Thus this is the first ferrimagnetic system based on an inorganic anion like $FeBr_4$ (the anion is not a coordination compound). In addition, the π-electron is moderately conducting even at the temperature of the magnetic transition.

The third compound $(BEDT\text{-}TTF)_3(MnCl_4)_2$ has extraordinarily large πd-interactions to the donors incorporated in the anion layer. This compound is important because this is a parent compound of a recently found charge doped system $(BEDT\text{-}TTF)_3(CoCl_4^{2-})_{2-x}(GaCl_4^{-})_x$ [14].

This paper describes estimation of J in these compounds, emphasizing what is different in these compounds from the previous πd-systems.

2. Method of calculation

Transfer integrals of molecular conductors t are estimated from intermolecular overlap of molecular orbitals S (HOMO for donors), by using the relation $t = ES$, where E is the energy level of HOMO (usually −10 eV) [15]. We have used the extended Hückel method to calculate the HOMO, because we like to use the Slater-type atomic orbitals. The same method is applied to calculate the transfers between the donor molecule and the anion ($t_{\pi d}$), and those between the anions (t_d). From this, we can estimate the magnetic interactions J like $J = -2\Sigma t^2/n\Delta$ [7]. Because the $FeCl_4$ anion has five d-like orbitals (Fig. 2), we have to take the sum of the squares t^2 for each d-orbital, and divide the sum by the number of the combinations n. The d-like orbital spreads to Cl to some extent, and the overlap of the Cl orbital with the sulfur orbital of the donor gives rise to finite t. The Coulomb repulsion U, usually appearing in the denominator, is replaced by the difference of the energy levels between the donor HOMO and the d-orbitals, $\Delta = 1$ eV, because Δ is smaller than U of the d-orbital [16]. This calculation method only takes account of the negative (antiferromagnetic) potential exchange, and neglects the positive (ferromagnetic) kinetic exchange. This is somewhat justified by the low symmetry of these πd-systems, and orthogonal orbitals are less probable. The latter contribution is considered in more elaborate calculations [17–19].

To compare the calculated J with the experimentally obtained values, the mean-field theory is useful as the starting point. When the π-electron is localized, the mean-field theory of πd-systems is equivalent to that of ferrimagnets [7], and the Néel temperature T_N is given by

$$2T_N = C_d a_d + C_\pi a_\pi + \sqrt{(C_d a_d - C_\pi a_\pi)^2 + 4C_d C_\pi a_{\pi d}^2}, \quad (1)$$

where C_d and C_π are the Curie constants, and $a_d = 2J_d/N(g\mu_B)^2$ is the molecular field coefficient. When the π-electron is itinerant, this is replaced by

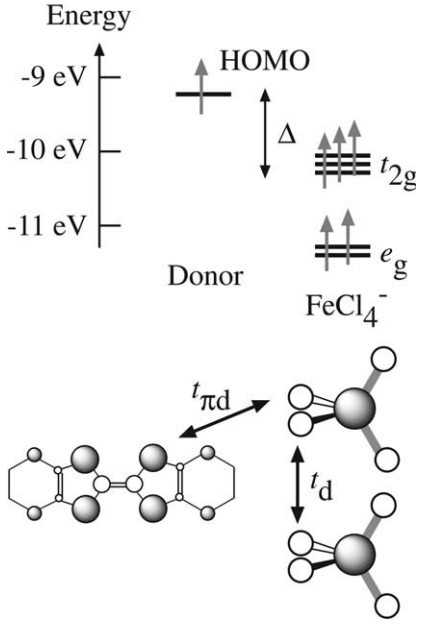

Fig. 2. Energy levels of a TTF-type donor and $FeCl_4$.

$$k_B T_N = 2/3S(S+1)[J_d + \chi_q J_{\pi d}^2]. \quad (2)$$

Then T_N is afforded by the sum of the direct anion–anion interaction (J_d) and the indirect interaction through the π-electron (the second term). If the staggered susceptibility χ_q is approximated by the density of states, and is roughly inverse of the band width W, the second term is approximately $J_{\pi d}^2/W$. Consequently this term is much smaller than $J_{\pi d}$ itself.

3. (BDA-TTP)$_2$FeCl$_4$

As shown in Fig. 3, this compound has a β-type donor arrangement. There are two crystallographically independent donor molecules, which will be hereafter designated as A and B. Then owing to the inversion symmetry (space group $P2_1/a$), a unit cell contains four donor molecules in a conducting layer. One $FeCl_4$ unit is crystallographically independent, and is approximately located on the a glide plane at $y = 1/4$. The anion is translated by this a glide plane to make a linear chain connected by the dd-interaction I along the a axis. This dd-interaction I is calculated to be fairly large (Table 1). There are several πd-interactions 1–5. All these interactions start from a single anion molecule; the interactions 3 and 4 go to the next donor sheet. Then the mean-field sum of $J_{\pi d}$ is given by the sum of all these πd-interactions. On the other hand, the mean-field sum of J_d is $2J_I$, because two equivalent interactions I start from an anion molecule (coordination number of $FeCl_4$ is 2).

We cannot directly compare J_d and $J_{\pi d}$, because we have to multiply different factors $3S(S+1)/2$ coming from the Curie constants. Fig. 4 is a comparison of these values with the BETS salts. If the π-electron is entirely itinerant, the contribution of $J_{\pi d}$ to T_N is very small, because such contribution is given by $J_{\pi d}^2/W$. Then T_N is practically given by J_d multiplied by $3S(S+1)/2$, which is plotted in the right scale of Fig. 4. Accordingly κ-(BETS)$_2$FeBr$_4$ and κ-(BETS)$_2$FeCl$_4$ respectively afford $T_N = 2.5$ and <1 K. In the same way, T_N of (BDA-TTP)$_2$FeCl$_4$ is expected to be 5 K. This agrees with the experiment because the reported $T_N = 8.5$ K corresponds to the maximum of χ, and χ starts to be anisotropic below about 5 K [10,11].

Table 1
Overlap integrals (S) and J values of (BDA-TTP)$_2$FeCl$_4$

Interaction		$S \times 10^{-3}$	$-J/k_B$ (K)
dd	I	2.15	0.43
πd	1 B	1.27	0.75
	2 B	0.68	0.21
	3 A	0.76	0.27
	4 A	0.53	0.13
	5 A	0.48	0.11

Donor A on (0.23, 0.03, 0.92), donor B on (0.72, 0.03, 0.67), and Fe on (0.89, 0.25, 0.38).
$J_d = 2J_I = 0.86$ K and $J_{\pi d} = J_1 + J_2 + J_3 + J_4 + J_5 = 1.49$ K.

The value $J_{\pi d}$ gives the center field of the field-induced superconductivity H_{sc} [7,9], which is shown in the upper scale of Fig. 4. The calculated $J_{\pi d}$ in λ-(BETS)$_2$FeCl$_4$ and κ-(BETS)$_2$FeBr$_4$ affords 36 and 15 T, respectively. Likewise, H_{sc} of the present compound is estimated to be 2 T, which is smaller than H_{c2}, and the field-induced phase is expected to be within the usual superconducting phase. This estimation is, however, based on the ambient-pressure structure, and under pressure in which the superconductivity appears actually, $t_{\pi d}$ and accordingly $J_{\pi d}$ are expected to be considerably enhanced.

In summary, (BDA-TTP)$_2$FeCl$_4$ is a system with large J_d and small $J_{\pi d}$ in comparison with the BETS systems. The small $J_{\pi d}$ is related to the molecular structure where the terminals of the BDA-TTP molecule are capped with inert trimethylene groups. The small $J_{\pi d}$ is also supported by the nearly identical phase diagram to the $GaCl_4$ salt, together with the absence of the splitting of the Shubnikov-de Haas oscillation [10,11].

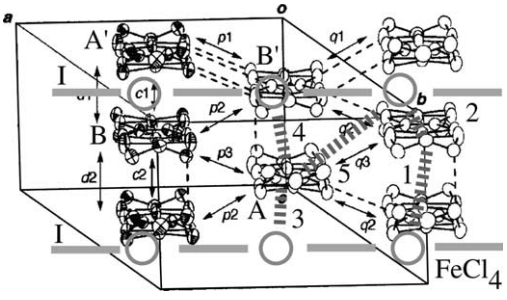

Fig. 3. Crystal structure and intermolecular interactions in (BDA-TTP)$_2$FeCl$_4$.

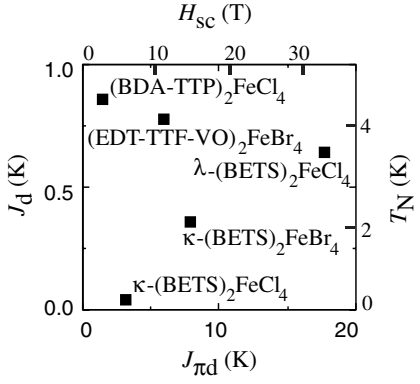

Fig. 4. Calculated J_d and $J_{\pi d}$ values of the present compounds compared with the BETS salts. In the right scale, J_d is converted to T_N according to Eq. (1), and in the upper scale $J_{\pi d}$ is converted to the center field of the field induced superconducting phase.

4. (EDT-TTF-VO)$_2$FeBr$_4$

This compound belongs to a noncentrosymmetric space group, $P1$. The unit cell contains one $FeBr_4$ anion, and two crystallographically independent donor molecules, A and B (Fig. 5). It is characteristic that all C=O bonds are directed in the same direction, so that this crystal is potentially ferroelectric. The HOMO of the donor has the same symmetry as the HOMO of the usual TTF, where the coefficients of all sulfur atoms have the same sign. The calculated interactions are listed in Table 2. The dd-interaction runs along the a (II) and b (I) axes (Fig. 5(a)), and form a square lattice. Then the dd-interactions favor alternating antiferromagnetic spin alignment. The πd-interactions are, however, much larger than the dd-interactions (Table 2); the mean-field sum of $J_{\pi d}$ is 6.04 K, and this is much larger than that of $J_d = 0.78$ K. In particular, the same donor bridges more than two anions; for example the interactions A2 and A3 are large, and bridge the anions 2 and 3. This makes a sharp contrast to the BETS salts, in which only one πd-interaction is overwhelmingly large, and a donor is closely connected with a particular anion [7].

When the π-electron is itinerant, the π-electron makes a very small contribution (of $J_{\pi d}^2/W$) to the magnetic order, leading to an antiferromagnetic order dominated by the dd-interaction, as in the BETS salts. However, when the π-electron is localized, the πd-interaction $J_{\pi d}$ works directly to result in ferrimagnetic order, as observed in some mixed-stack charge-transfer salts. The present compound is intermediate of these two extremes. When the Curie constant is multiplied, J_d and $J_{\pi d}$ give 4.55 and 10.3 K, respectively. The former value is comparable to the high-temperature Weiss temperature, −3.9 K. However, the latter value is larger, and the system prefers ferrimagnetic order if the π-electron is localized.

Table 2
Overlap integrals (S) and J values of (EDT-TTF-VO)$_2$FeBr$_4$ at 298 K

Interaction		$S \times 10^{-3}$	$-J/k_B$ (K)
dd	I//b	0.69	0.04
	II//a	1.94	0.35
πd	A2 [0 1 0]	1.84	1.57
	A3 [1 0 0]	2.05	1.95
	A4 [1 1 0]	0.17	0.01
	A5 [1 0 1]	0.50	0.12
	A6 [1 1 1]	0.26	0.03
	B1 [0 0 0]	0.53	0.13
	B3 [1 0 0]	0.18	0.02
	B5 [1 0 1]	2.18	2.21

Fe on the origin, A on (−0.12, 0.45, 0.62), and B on (−0.14, 0.07, 0.39). $J_d = 2J_I + 2J_{II} = 0.78$ K and $J_{\pi d} = J_{A2} + J_{A3} + J_{A4} + J_{A5} + J_{A6} + J_{B1} + J_{B3} + J_{B5} = 6.04$ K.

To investigate the origin of ferromagnetism, we have calculated the J values based on the low-temperature crystal structure (Fig. 6) [20]. The intra-stack ππ-overlap as well as $J_{\pi d}$ tends to increase at low temperatures, whereas the inter-stack ππ-overlap and J_d remain practically unchanged. It is worth noting that the calculated HOMO levels of the two independent donor molecules, A and B, differ at low temperatures, indicating that charge separation like $A^{1/2-\delta}B^{1/2+\delta}$ occurs at low temperatures. This is probably the origin of the low-temperature semiconducting state. The difference of the energy levels (ΔE), however, drops again at the lowest measured temperature (6.5 K). This suggests a new kind of structural change or rearrangement of the charge at this temperature.

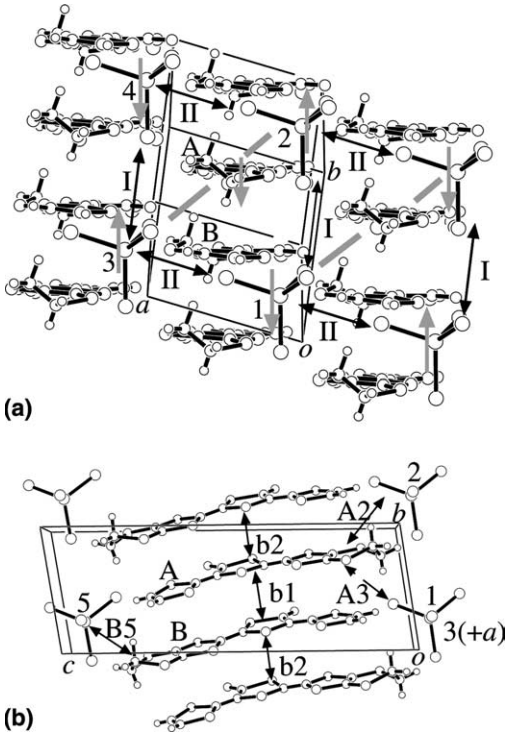

Fig. 5. Crystal structure and intermolecular interactions in (EDT-TTF-VO)$_2$FeBr$_4$.

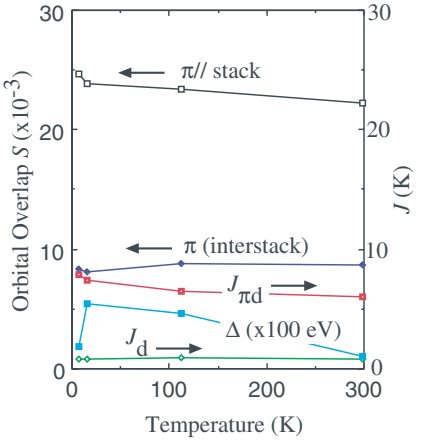

Fig. 6. Temperature dependence of the π-overlap integrals, J_d and $J_{\pi d}$ in (EDT-TTF-VO)$_2$FeBr$_4$. ΔE is the difference of HOMO energy levels.

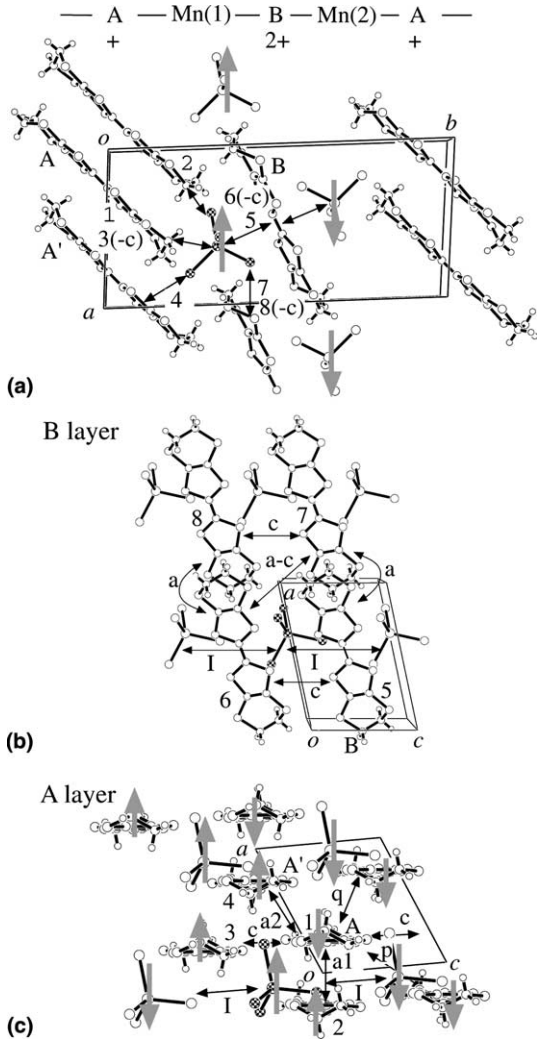

Fig. 7. Intermolecular interactions in $(BEDT\text{-}TTF)_3(MnCl_4)_2$. Nos. 1–8 are πd-interactions from the shaded anion to the numbered donor molecules (Table 3).

In summary, this compound is characterized by larger $J_{\pi d}$ than J_d. The bridging network of $J_{\pi d}$ as well as the practically localized π-electron owing to the charge separation is responsible to the ferrimagnetic order. Dimerization of the present compound is, however, very weak [17–19], and we can hardly determine the phase of the spin wave.

5. $(BEDT\text{-}TTF)_3(MnCl_4)_2$

As shown in Fig. 7(a), $(BEDT\text{-}TTF)_3(MnCl_4)_2$ is composed of the usual donor layer A with β′-structure, and the anion layer including a donor molecule B [21]. The donor charge is distributed as $A_2^{+}B^{2+}$; the B molecule neutralizes the large $MnCl_4^{2-}$ charge. Calculated overlap integrals S and magnetic interactions J are listed in Table 3. There is no ππ-interaction between the A and B molecules, and this compound is regarded as a double layer structure like A–Mn–B–Mn–. πd-interactions from the anion to the A molecules (1–4) are relatively small (the mean-field sum 3.33 K is comparable to 3.12 K in κ-$(BETS)_2FeCl_4$), but πd-interactions to the B molecules (5–8) are large (the mean-field sum 14.14 K is comparable to 17.74 K in λ-$(BETS)_2FeCl_4$ [7]). This is reasonable because the B molecules are incorporated in the anion layer. Since the B^{2+} molecule has no spin, the two large πd-interactions 5 and 6 are expected to mediate "superexchange" interaction, leading to antiferromagnetic coupling of the Mn(1) and Mn(2) anions bridged by the B molecule (Fig. 7(a)). By contrast, the A^{+} donors have spins, and result in antiferromagnetic alignment as shown in Fig. 7(c), particularly on account of the large a1 and a2 ππ-interactions [21]. Then the πd-interaction 1 determines the spin alignment of the anions in the *ac* plane.

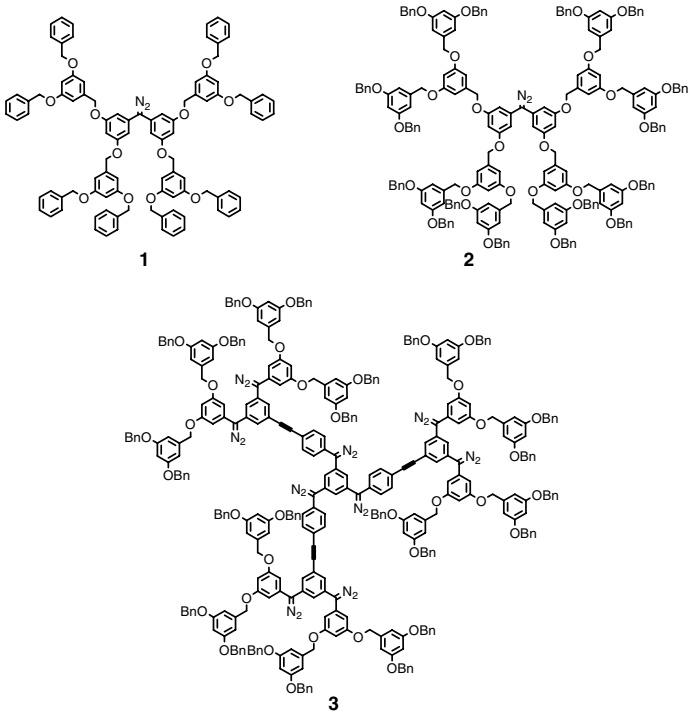
The dd-interaction I running along *c* is small; this is one-tenth of dd-interactions in λ-$(BETS)_2FeCl_4$ but comparable to κ-$(BETS)_2FeCl_4$ [7]. This contributes 0.30 K to the Néel and Weiss temperatures (Fig. 4). If the π-electrons on the molecules A are regarded as entirely localized, the large a1 and a2 ππ-interactions give rise to very high Néel temperature, but this is not likely.

Table 3
Overlap integrals (S) and J values of $(BEDT\text{-}TTF)_3(MnCl_4)_2$

		$S\times10^{-3}$	$-J/k_B$ (K)			$S\times10^{-3}$	$-J/k_B$ (K)
πd				ππ			
1	A (0, 0, 0)	2.23	2.31	A	a1	27.1	1704
2	A′ (−1, 0, 0)	0.76	0.27		a2	14.0	455
3	A (0, 0, −1)	0.13	0.01		c	6.1	86
4	A′ (0, 0, 0)	1.26	0.74		p	4.9	56
5	B (0, 0, 0)	3.37	5.27		q	−4.3	43
6	B (0, 0, −1)	4.24	8.34	B	a	−1.0	2.3
7	B (1, 0, 0)	0.79	0.29		c	−5.7	75.4
8	B (1, 0, −1)	0.72	0.24		a–c	−0.2	0.1
dd							
I	(0, 0, 1)	0.526	0.0257				

Mn on (0.62, 0.33, −0.02), A on (0.17, −0.03, 0.12), and B on (0.5, 0.5, 0.5).
$J_{\pi d}(A) = J_1 + J_2 + J_3 + J_4 = 3.33$ K and $J_{\pi d}(B) = J_5 + J_6 + J_7 + J_8 = 14.14$ K.

Then according to the itinerant π-electron approximation (Eq. (2)), the πd-interactions contribute 3.56 K to the Weiss temperature. However, the B molecules do not work in the same way, because the B molecules do not have spins. The A molecules only make 0.13 K contribution. The resulting small Weiss temperature (0.43 K) is consistent with the observation [22]. This is an extraordinary πd-system where the πd-interaction is very large, but the dd-interaction is very small.



Recently band-filling control has been reported for the isostructural $(BEDT\text{-}TTF)_3(CoCl_4^{2-})_{2-x}(GaCl_4^{-})_x$ [14]. If the excess electron is doped on the A layer, the magnetic property will not change basically. However, if the excess electron is incorporated in the B layer, this may significantly increase the magnetic interaction owing to the large πd-interactions to the B molecules. This probably happens in a ferrimagnetic compound $(BEDT\text{-}TTF)_3(CoCl_4^{2-})_{1.20}(FeCl_4^{-})_{0.80}$ [23].

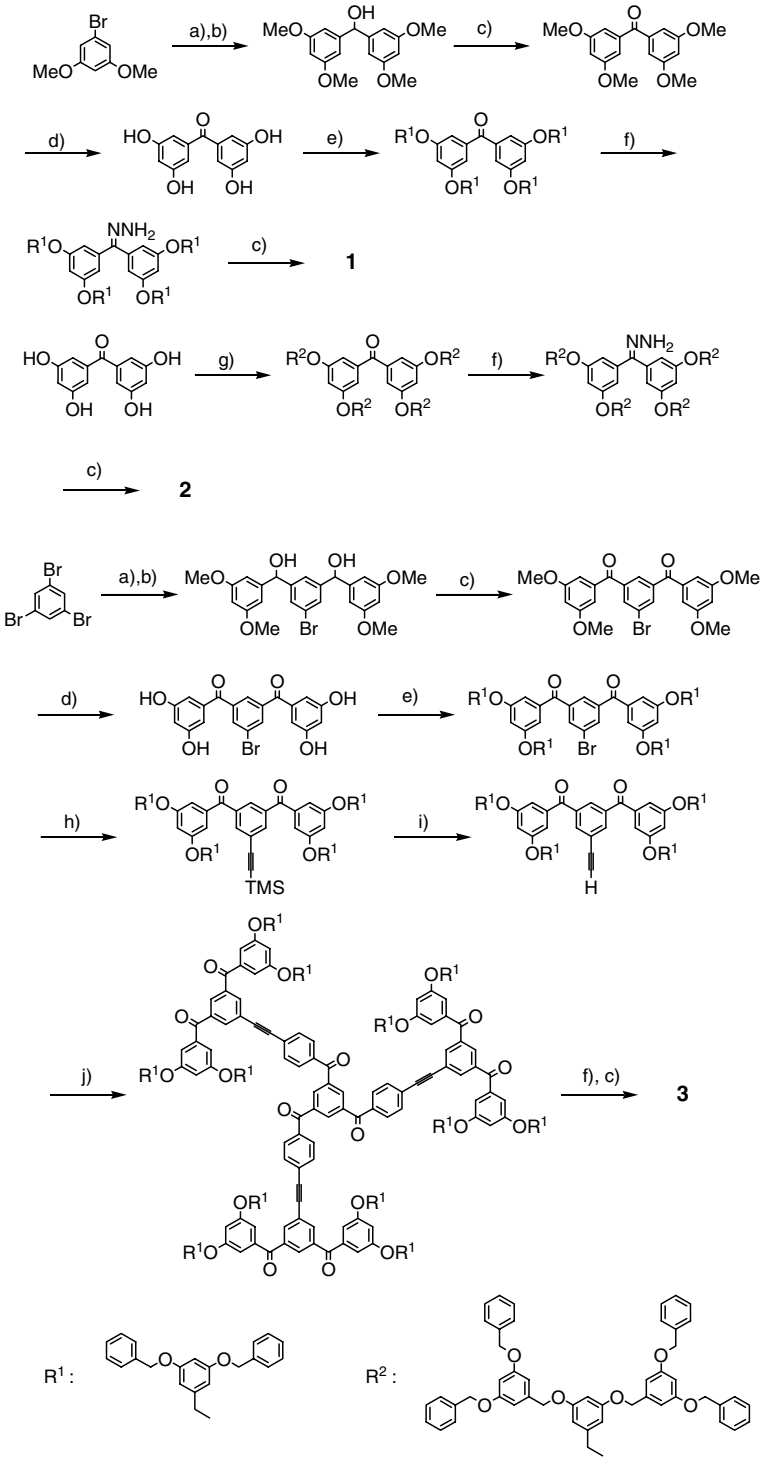
Scheme 1. Molecular structure of dendritic diazo compounds.

Preparations of the target compounds are summarized in Scheme 2. Benzophenone derivatives corresponding to **1** and **2** were prepared by reaction of tetrahydroxybenzophenone with commercially available dendritic benzylbromide derivatives. Nonaketone compound corresponding to **3** was prepared by Sonogashira coupling of an ethynyl derivative substituted by dendritic benzyl ether units with a triiodotriketone compound. Target diazo compounds were prepared by reaction of ketone derivatives with anhydrous hydrazine and hydrazine hydrochloride and following oxidation with manganese dioxide.



Clear amorphous films of the diazo compounds were easily obtained by evaporation of sample solutions in dichloromethane upon SQUID cells. Prepared films were introduced into SQUID cavity and photolized by an Ar ion laser (514 nm) through a silicate fiber under 15 K. Before irradiation, the samples exhibited negative magnetization due to the diamagnetic diazo compound. As photolysis proceeded, magnetization value got increased and reached plateau within 15 h.[1] Curve fitting of field dependences of magnetization to the Brillouin function provided average spin multiplicity S_{ave} as 0.86 and 0.90 for **1** and **2**, respectively, those are very close to expected value for magnetically isolated triplet carbene. Fig. 1 shows χT versus T plots after irradiation of **1** and **2**. χT values for both of **1** and **2** were almost constant at low temperature range (2 K $\sim$ 10 K), indicating that intermolecular spin interaction were very weak. These two results clearly exhibited that spin centers, i.e., diphenylcarbene parts of **1** and **2** are magnetically isolated from surrounding molecules each other by steric hindrance of the peripheral bulk substituents even in neat films.

In the same way, field dependences of magnetization on early stage of irradiation (2 min) and after irradiation (480 min) of **3** were shown in Fig. 2(a). Curve fitting of both data to the simple Brillouin function provided S_{ave} as 4.4 for early stage of irradiation and 3.1 for after irradiation with poor reproducibility.

When the experimental data were compared to the fitting curves, the systems seemed to be mixture of fast-saturated components and slow-saturated ones. Indeed, by using a model of mixture of two components having high S value and low one,[2] the observed data could be fitted with good agreement as shown in Fig. 2(a).

[1] The irradiation time required to photolize sample films and photolysis degrees of diazo groups depended on the film thickness and laser power. Photolysis degrees of measured samples were determined as 60% for **1**, 30% for **2**, and 30% for **3** based on saturated magnetization value at 2 K and 5 T. Because of the antiferromagnetic interaction of **3** at 2 K, photolysis of **3** should be much more than calculated value, but could not be determined properly.

[2] The fitting function was expressed by linear-combination of two Brillouin functions.

Scheme 2. Preparation of target compounds **1**–**3**: Reagents and conditions: (a) *n*-buthyllithium, diethyl ether, −78 °C; (b) 3,5-dimethoxybenzaldehyde, diethyl ether, −78 °C; (c) MnO_2, dichloromethane, r.t.; (d) BBr_3, dichloromethane, 0 °C; (e) 3,5-bis(benzyloxy)benzylbromide, K_2CO_3, acetone, reflux; (f) NH_2NH_2, NH_2NH_2HCl, dimethylsulfoxide, 90 °C; (g) 3,5-bis{3′,5′-bis(benzyloxy)benzyloxy}benzylbromide, K_2CO_3, acetone, reflux; (h) trimethylsilylacetylene, $Pd(PPh_3)_2Cl_2$, CuI, tetrahydrofuran, triethylamine, 40 °C; (i) K_2CO_3, dichloromethane, methanol, r.t.; (j) 1,3,5-tris(4′-iodobenzoyl)benzene, $Pd(PPh_3)_2Cl_2$, CuI, tetrahydrofuran, triethylamine, r.t.

A χT versus T plot after irradiation of **3** was again shown in Fig. 2(b). As the temperature was lowered from 10 K down to 2 K, χT value decreased gradually. These two results proposed that as the irradiation time prolonged and density of photolized molecules increased, amount of components interacting antiferromagnetically

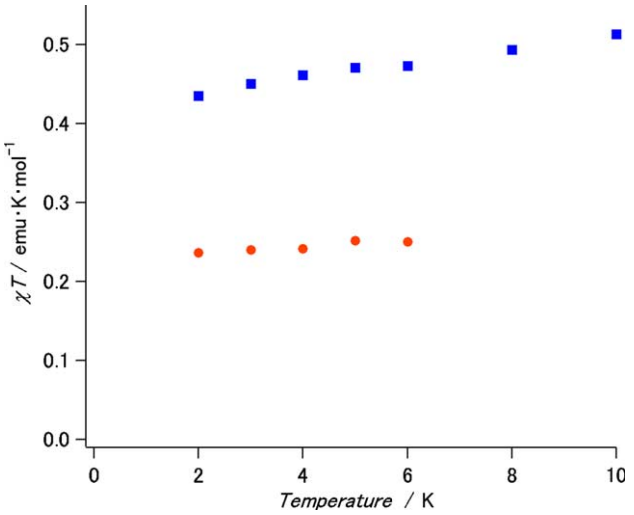


Fig. 1. Temperature dependences of χT value after irradiation of monodiazo compounds **1** (■) and **2** (●).

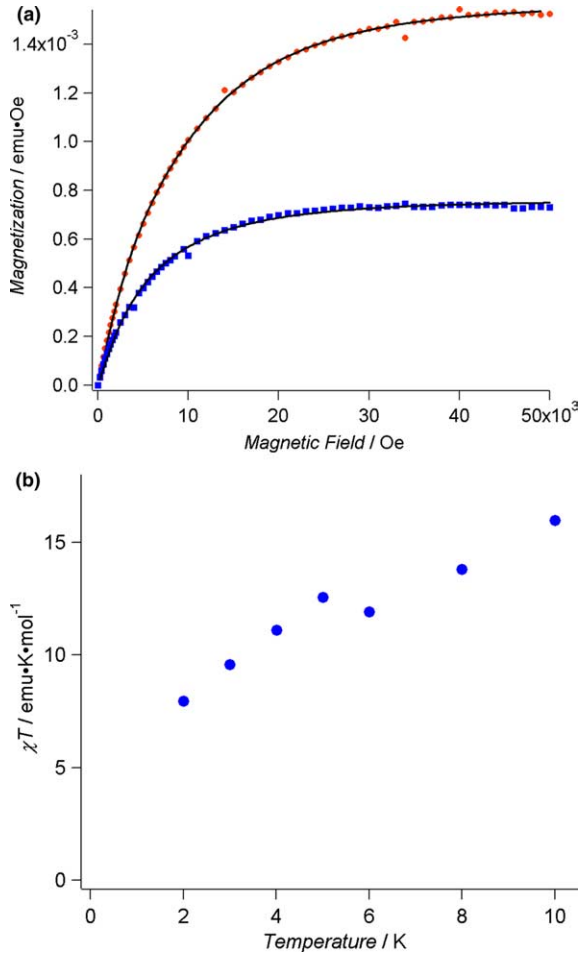

Fig. 2. (a) Field dependences of magnetization of **3** after irradiation for 2 min (■) and for 480 min (●). Solid lines show the fitting curve to two component model with S1 = 9 (N1 = 2.1×10^{15}), S2 = 2.6 (N2 = 8.3×10^{15}) for early stage and S1 = 9 (N1 = 2.9×10^{15}), S2 = 1.8 (N2 = 3.3×10^{16}) for after irradiation. (b) Temperature dependence of χT value after irradiation of nonadiazo compound **3**.

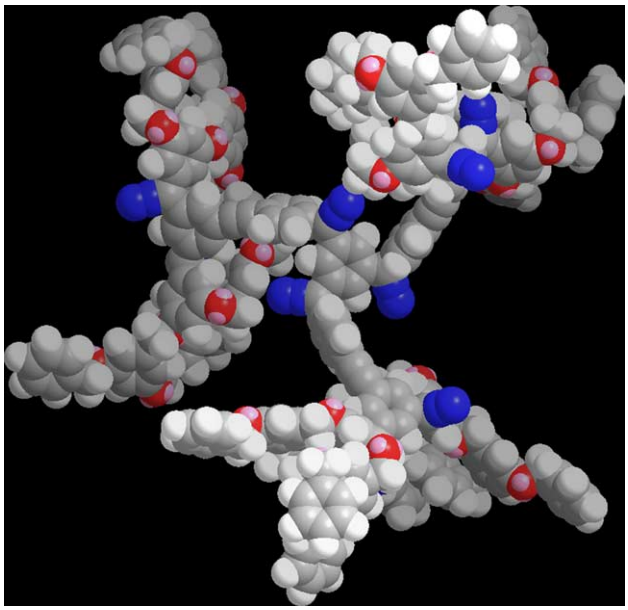

Fig. 3. One of the pseudo-stable structures of **3** obtained by MM2 calculation.

with neighboring molecules got increased, while components of large S value still remained.

Fig. 3 depicts a result of MM2 calculation for **3**, that exhibited the diazo groups (i.e., spin centers after irradiation) were sterically hindered considerably by the bulk peripheral groups, while apertures still found between branches and a few diazo groups were located on surface of the molecule.

Peripheral dendrons of larger generation such as in compound **2** will provide a more effective isolation of spin centers.

As the first example of stable neutral radicals definitely conjugated with a curved π-network, we have recently synthesized and isolated a new oxoverdazyl radical **2** conjugated with corannulene (**1**) [9]. Optical and ESR spectroscopies revealed a small but measurable spin delocalization onto the curved surface of corannulene. To gain more insight into the spin structure on the curved surface, we have carried out a systematic study on a variety of neutral radicals conjugated with the curved π-network of corannulene in terms of density functional theory (DFT) calculations.

2. Calculation method

All the calculations were carried out using the program GAUSSIAN03 [10]. Each structure was fully optimized by hybrid DFT calculations at the UB3LYP/6-31G level of theory [11] with no symmetry constraints. One-point calculations were implemented at the UB3LYP/6-31G(d) level for the optimized structures. Frequencies were calculated to verify energy minima for the optimized conformations.

3. Results and discussion

Our primary interest concerns the uniqueness of the spin density distribution spread over the curved surface structure of corannulene. To grasp this physical picture, we focused on a model system, corannulenoxyl (**3**), which is expected to show a significant spin delocalization from oxygen atom into corannulene. A DFT calculation for **3** showed that a large amount of spin density is actually delocalized over the corannulene moiety as shown in Fig. 1(a). The spin transmission from the radical substituent to the corannulene moiety exhibited a deflected nature on the curved surface, giving rise to spin-rich and spin-poor regions within the molecule (Fig. 1(a)). The largest positive spin density on the corannulene moiety occurred at the peripheral carbon atom of the 2-position (+0.538). This site agrees with the carbon site of the radical **2** where the hyperfine coupling of its neighboring proton was enough large to be detected in the ESR/ENDOR spectra [9]. On the other hand, the spin densities on the opposite side of the molecule are negligibly small in magnitude, namely, −0.002 for the 7-position and −0.008 for the 8-position. Spin polarization effect was robust enough to induce positive and negative spin densities alternately on the large part of the molecule, except for the above-mentioned region with negligibly small spin densities.

3 **4**

To confirm whether or not the unbalanced spin distribution of **3** is an inherent character of this class of curved π-radicals, we calculated a spin density distribution of coronenoxyl (**4**) which has a flat surface π-conjugated structure. It turned out that the spin densities of **4** are spread over the whole molecule rather evenly (Fig. 1(b)), in contrast with the uneven distribution of **3**. The comparison demonstrated that there is a marked difference between the planar and non-planar π-spin structures.

At this stage, we have two possible explanations for the occurrence of the unbalanced spin distribution of **3**, that is, it may be caused by either structural effect or topological effect. The former effect is associated with the non-planarity or curvature of the π-conjugation structure. As a planar π-radical undergoes distortion to have a non-planar geometry, there will be possibility that its spin density distribution can, more or less, be modulated. The latter effect arises from the connectivity of atoms in a molecule. The corannulenoxyl (**3**) has a five-membered ring in the molecular center, which forms a non-alternant π-conjugation network. Such π-connectivity might cause the unbalanced spin distribution, regardless of the structural deformation. Our preliminary study on the bowl-to-bowl inversion phenomenon for **3** showed that the unbalanced spin distribution is maintained even at the transition state having the planar geometry on the way from one bowl-shaped structure to the other. This indicates that the nature of spin distribution of **3** is governed by the molecular topological effect. The subtle contribution from the structural effect also needs to be assessed in detail.

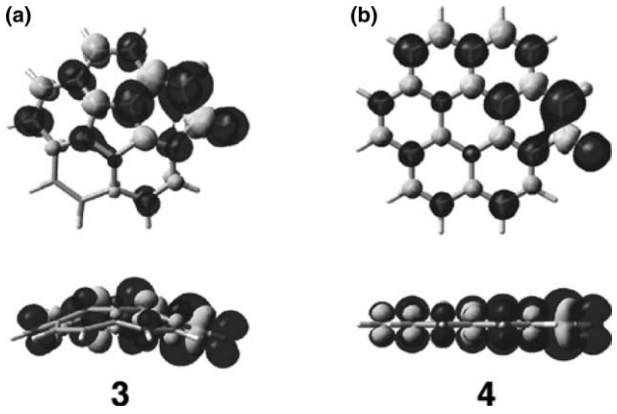

Fig. 1. Spin density distributions of (a) corannulenoxyl (**3**) and (b) coronenoxyl (**4**) calculated by density functional theory at the UB3LYP/6-31G(d)//UB3LYP/6-31G level of theory. Black and gray colors denote positive and negative spin densities, respectively.

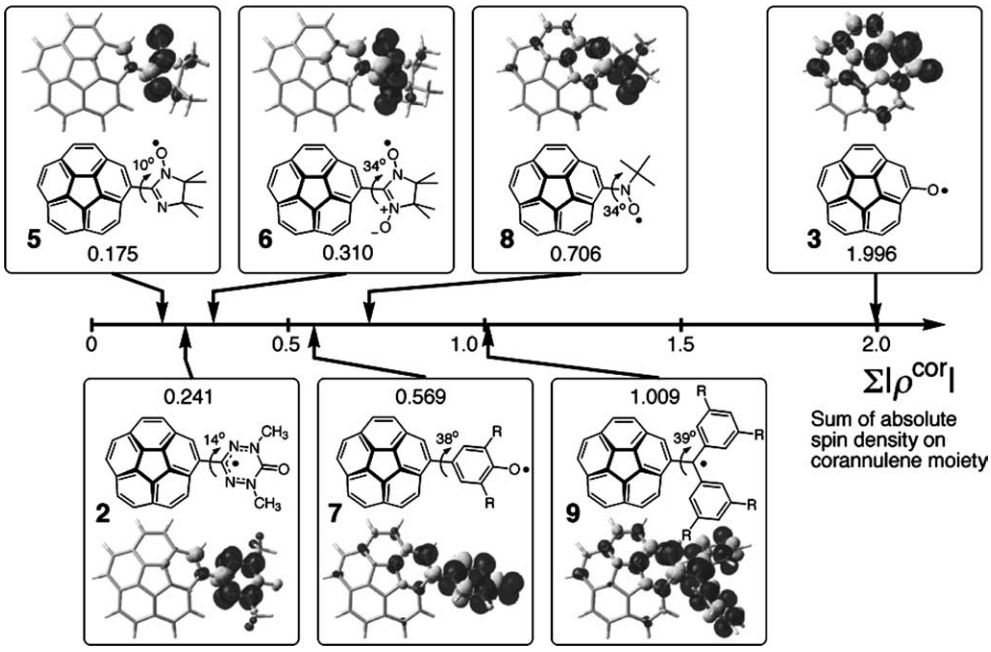

Fig. 2. Spin density distributions for a series of corannulene derivatives with various radical substituents (**2**, **3**, and **5**–**9** where R = H). Numerals plotted on the horizontal axis denote sums of absolute spin density on the corannulene moiety ($\Sigma|\rho^{cor}|$). Calculations were carried out at the UB3LYP/6-31G(d)//UB3LYP/6-31G level of theory. Black and gray colors denote positive and negative spin densities, respectively.

Although the corannulenoxyl (**3**) serves as a good model for evaluating the curved-surface π-spin structure, the radical is predicted to have a lesser kinetic stability because of the large spin densities on the corannulene. The exposed spin densities to the outer space are subject to possible σ-dimerization or unfavorable chemical reactions which yield non-magnetic materials. Synthesis and isolation of such reactive species will require further stabilization on the corannulene moiety such as steric protections as demonstrated in, for example, phenalenyl [12], diazaphenalenyl [13], oxophenalenoxyls [14], and triangulene [15].

Another alternative approach to realize stable and spin-delocalized curved π-systems is to introduce other stable radicals into corannulene. For the molecular design based on this approach, we carried out geometry optimizations and spin density calculations for a series of corannulene derivatives with various radical substituents (**5**–**9** as shown in Fig. 2). Unlike **3**, these derivatives have at least two metastable geometries with respect to the rotational motion of the radical moiety. Thus, we carefully determined the most stable geometry with a global energy minimum for the each derivative.

Fig. 2 summarizes the result of the DFT calculations. The each optimized structure has a non-zero dihedral angle (10–39°) between the radical moiety and the six-membered ring of the corannulene moiety. The dihedral angle may result from a subtle balance between the minimum steric repulsion among the neighboring protons and the maximum resonance stabilization between the two moieties. We evaluated these radicals by putting them in the increasing order of spin-delocalization into the corannulene, using a sum of absolute spin density on the corannulene moiety ($\Sigma|\rho^{cor}|$) (Fig. 2). The iminonitroxide (**5**) [16], oxoverdazyl (**2**), and nitronyl nitroxide derivatives (**6**) are categorized as relatively localized spin systems, while the phenoxyl (**7**), *tert*-butyl nitroxide (**8**), and diphenylmethyl derivatives (**9**) show intermediate spin delocalizations onto the curved surface of corannulene. As described above, corannulenoxyl (**3**) serves as the most spin-delocalized system of all. In spite of the difference in the magnitude of spin delocalization, all these systems showed the unbalanced nature in their spin distributions mentioned above. This trend of the spin delocalization partly supports our previous experiment on **2**, which demonstrated that the radical **2** has a relatively localized character but higher chemical stability in spite of no stabilization given for the corannulene moiety. If the chemical stability of **7**–**9** are enough high to be isolated, these radicals are expected to serve as suitable models to investigate not only the curved-surface π-spin structures in more detail but also magnetic interactions between the curved-surface π-electrons in the crystalline state.

4. Summary

On the basis of our previous experimental study on an oxoverdazyl radical directly conjugated with corannulene, we have carried out DFT calculations for a series of neutral organic π-radicals conjugated with

corannulene. It turned out that the unpaired electron spin is transmitted from the radical substituent into the corannulene moiety, forming an uneven spin distribution on the curved surface. The magnitude of spin delocalization into the corannulene moiety significantly varies, depending on the radical employed. From the experimental viewpoint, it will be of particular interest to study not only the stability and spin structures of largely delocalized systems, but also intermolecular magnetic interactions between the curved surface π-electrons in the crystalline state. Syntheses of these new radical species are in progress.

of the electronic state of Au nanocluster by the electron or hole doping might also have an effect on the magnetic interaction of the hybrid material that is composed of Au cluster and organic spin molecules. In order to examine this hole/electron doping effect, ab initio calculations for the Au_3 and Au_{13}-nitroxide hybrid model systems were examined. Implications of the computational results were discussed in relation to rational design of tunable molecular magnets.

2. Calculation method and models

2.1. Calculation method

All the computations were performed by GAUSSIAN-98 and GAUSSIAN-03 program packages [13]. Unrestricted hybrid DFT (UB3LYP) calculation was used for the model systems computations using D95** basis set for C, N, O, and H and the LANL2DZ basis set for Au.

The low spin state and high spin state (LS–HS) energy gap of the systems has been experimentally determined. The LS–HS energy gap of the system can be also calculated by the spin-polarized DFT energies [14,15].

In the case of organic radical molecules, the spin polarization and the spin delocalization of the π electrons are the dominant factors to determine the spin alignment between the localized radical spins while the spin polarization of the conduction electrons are also the important factor for the spin alignment in the case of metal clusters. This is so called RKKY mechanism.

2.2. Calculated models

In the real system, π-radical thiols that are one of phenyl sulfide derivatives (SPN-hex) were chemisorbed onto Au nanoparticles whose mean diameter was about 4 nm. Thus the obtained hybrid system was named SPN-hex@Au. The schematic diagram of this real model was shown in Fig. 1. From the detail analyses, it was found that the representative chemical formula was presented as Au_{1750} $(SPN\text{-}hex)_{125}$, It would be difficult to examine this real system using the ab initio method with current computer resources. However, because our interest is focused on the effects of electron/hole doping of the metal-organic hybrid system, a smaller model system is feasible for the elucidation of this subject. Hence the small model system shown in Fig. 2 was adopted. In the model system, the wire like Au_3 cluster and cubooctahedral Au_{13} cluster were used instead of a large Au cluster and SPN-hex was also modified to phenyl sulfide with simple nitronyl nitroxide group as shown in Fig. 2. The geometry of the organic spin molecule was based on the geometry of NPNN molecule.

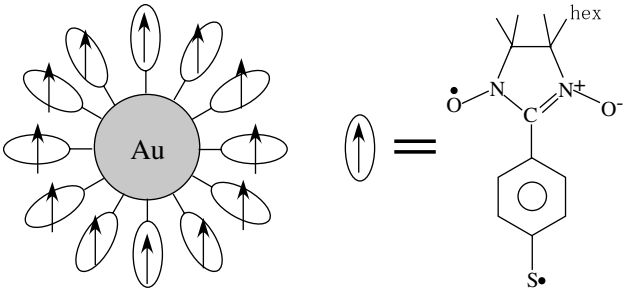

Fig. 1. The schematic diagram of SPN-hex@Au system.

3. Results and discussion

3.1. Au_3 model system

The Au_3 model system was composed of Au_3 cluster and radical fragments. The schematic diagram of this was depicted in Figs. 1 and 2. To begin with, $(SPN\text{-}hex)_2$ was decomposed into two isolated SPN-hex molecules on the surface of Au cluster in the process of the SPN-hex adsorption onto the surface of Au cluster. The S–S bond of $(SPN\text{-}hex)_2$ was cleaved in this process. Therefore, SPN-hex monomer has two radicals. One is

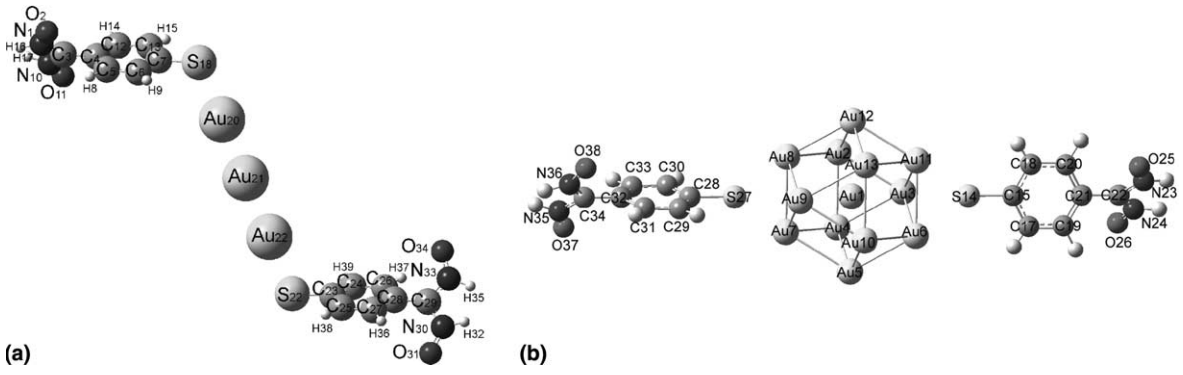

Fig. 2. The illustration of the Au-organic spin molecule hybrid model system: (a) Au_3 model system and (b) Au_{13} model system.

the nitroxide radical and the other was lone pair electron on S atom. The ab initio calculations showed that the ground state of isolated Au_3 cluster was a double state and that of the isolated organic radical fragment was a triplet state. The spin densities of these were shown in Table 2. (Note that only the spin densities of the heavy atoms are summarized in this table.) The neutral Au_3 type model cluster which was composed of the above mentioned fragments was examined. The obtained results were also shown in Table 1. As a doublet state was the ground state of this model system, it was found the low spin state was the ground state of the neutral one. The spin angular moments of the model systems were shown in Table 2. In this table, the spin densities of the heavy atoms were only summarized. In the case of the neutral Au_3 model system, the antiparallel spin moments were presented on the S atoms and nitroxide groups. This result suggests that the hetero-junction between Au cluster and the stable organic spin molecules has an effect on the spin alignment of the Au_3 model system.

With hole doping, it was found that the high spin state became the ground state. The calculated spin density showed that the spin polarization of the Au site was enhanced although the spin densities on the organic radical molecules were greatly decreased. Especially, it was found that the spin densities of the nitroxide groups and S atoms were extremely changed. Therefore, this suggests that the spin polarization for Au_3 and S atom sites of the small Au_3 model system was induced by the hole doping.

To understand the electronic state of the cationic hybrid model system, natural orbital (NO) analysis was carried out for the triplet state of the hole doped (cationic) hybrid model system. There are two natural orbitals whose occupation numbers are 1.0. The first NO is localized on the nitronyl nitroxide group and the second is localized on the region of Au cluster and S atoms. The schematic diagrams are shown in Fig. 3. From this

analysis, it was found that the high spin ground state of the cationic model was formed by the correlation between the radical spin of nitronyl nitroxide and the induced spin by hole doping on the Au cluster site. These results showed that the cationic ground state was not obtained by simple electron extraction from SOMO, meaning that the orbital reorganization occurred due to the hole doping. Therefore, it could be concluded that the correlation between the delocalized Au electrons and the localized spin moment on the organic spin molecule through the medium of the spin polarization is important.

3.2. Au_{13} model system

The Au_{13} model system was composed of Au_{13} cluster and radical fragments. The calculation results suggested that the ground state of isolated Au_{13} cluster was a double state. Mulliken analysis of the isolated Au_{13} cluster showed that the all the surface Au atoms had the negative charge population (ca. −0.5) and had positive spin densities whose net population was about 1. In the next, Au_{13} hybrid model cluster was also examined. The obtained results were shown in Table 3. The ground state of the neutral cluster was a quintet state. Therefore, it was found that the high spin state was the ground state of this neutral model system. The spin densities of the model systems were shown in Fig. 4. In this figure, the spin densities for each state were depicted. In the case of the quintet state of the neutral Au_{13} hybrid model system, the same sign of the spin moments were presented on two nitroxide groups and the surface Au atoms in Au_{13} cluster, while the spin densities of the hetero-junction sites between Au_{13} cluster and S atoms in organic radical molecules had small spin moments with same sign. This result suggests that the spin delocalization was occurred at the hetero-junction sites.

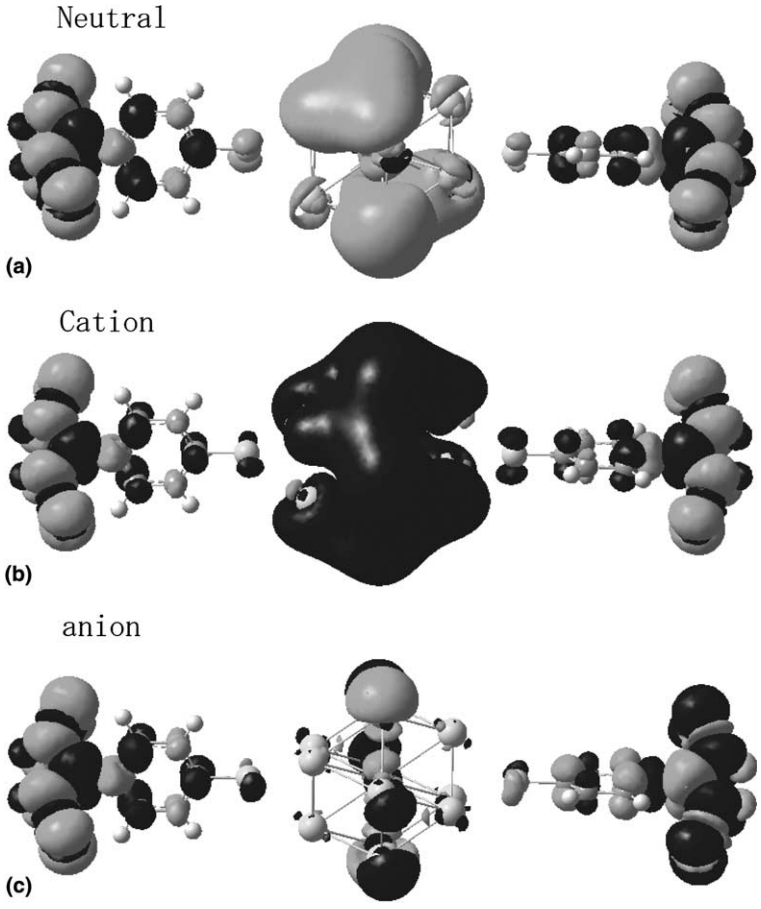

Fig. 4. The schematic diagram of the spin densities for (a) neutral, (b) cationic, and (c) anionic Au_{13} hybrid model systems.

In order to understand the electronic state of this hybrid model system, NO analyses were carried out for the quartet state of the neutral hybrid model system. There are three natural orbital whose occupation numbers are 1.0. The two NOs are localized on the nitroxide groups and the last one is localized on the region of Au cluster and S atoms. These schematic diagrams are shown in Fig. 5. From this analysis, it was found that the magnetic interaction between Au_{13} cluster and nitroxide radicals were the principal cause.

An electron doping into this Au_{13} model system was also examined. The calculated results showed that the low spin state was the ground state and the obtained ground state was a singlet state. The charge density analysis showed that the doped electron was mainly localized on Au cluster site as the total charge on Au_{13} cluster was about -0.64. The spin moment analysis which was depicted in Fig. 4 showed that the spin moments of Au cluster site were greatly decreased as the summation of spin moments in Au_{13} cluster was -0.0014. On the other hand, the two large spin moments were localized on the two nitroxide sites. Therefore, it could be concluded that the spin crossover was occurred by the electron doping into Au_{13}.

In the case of a hole doping, it was also found that the low spin state became the ground state. In this model, the obtained result showed that the doped hole was mainly located on Au_{13} site because the total charge on Au_{13} was about 0.58. On the other hand, the tendency of the spin density analysis was similar to that of Au_3 model system as the calculated spin density showed that the spin polarization of Au site was enhanced although the spin density on organic radical molecule was slightly decreased. Therefore, it could be concluded that the spin crossover was also induced by a hole doping to Au_{13} model system.

Possible models of (a) one-dimensional organometallic hybrid spin cluster with conductor network, (b) the cross-section of the nanospin system that is composed of the hybrid nanospin materials, (c) superconductor model by two-dimensional triangular ladder structure and (d) drug delivering system.

3.3. Rational design of tunable molecular magnets

These results suggested that the correlation between the delocalized Au electrons and the localized spin moment on the organic spin molecule through the medium of the spin polarization is important and the electron/hole doping into Au-organic spin molecule hybrid system could change the magnetic interaction of the ground state. On the analogy of these results, the other metal cluster, like Pt, Pd, Ir, Ag, Cu, and organic spin molecule hybrid system would also have unique and controllable magnetic interactions by hole/electron doping. However, the decomposition of the hybrid spin structure might be occurred as some of the above mentioned metals are easily oxidized. To prevent this problem, the egg shell type metal cluster hybrid system whose metal cluster is composed of the metal core and the inert Au outer shell might be promising. The schematic diagram of this model system was illustrated in Fig. 6.

The organic metal hybrid system with nanosize conductor, such as carbon nanotube and DNA, was depicted in Fig. 7(a). In this system, the local spin moments might be aligned by the induced current. The photo-induced organic magnets constructed of CT complexes were proposed in the previous our works [16]. Therefore, the photo-induction is also another possibility for the hole/electron doping. Lately, the newtechniques of laser manipulation and fixation of single Au nanoparticles were developed [17]. By use of this, organic metal hybrid system could be aligned on a certain substrates. Consequently, the new spintronics device as shown in Fig. 7(b) could be created. This material could be also controlled by the addition of an electric current that induced the hole/electron doping. Other possibilities to use this hybrid spin system are a superconductor and a drug delivering systems. If the hybrid spin system was arranged in a triangular ladder structure that was shown in Fig. 7(c), this system might be a spin mediated superconductor. On the other hand, the silica-based materials which can control the release of guest molecules with light have developed [18]. This kind of material can be easily modified by Au hybrid spin systems by use of the Au grafting methods [2–6]. This system was depicted in Fig. 7(d). Then, the obtained material could be guided to the goal by the induced magnetic field and the drug inside was released by light irradiation.

4. Conclusions

From the calculation results, it was found that the cationic Au_3 and neutral Au_{13} model systems have high spin ground states and the magnetic interaction of Au-organic spin molecule hybrid model systems were

dramatically changed depending on the hole or electron doping and were promising model systems for the nano-spin material, etc., that could be controlled by the induced external field.

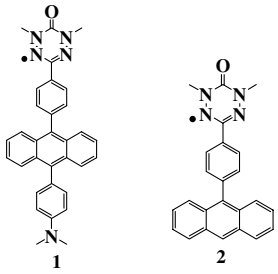

Fig. 1. Molecule studied in this work, **1** and previously reported stable radical, **2** with the excited quartet high-spin state.

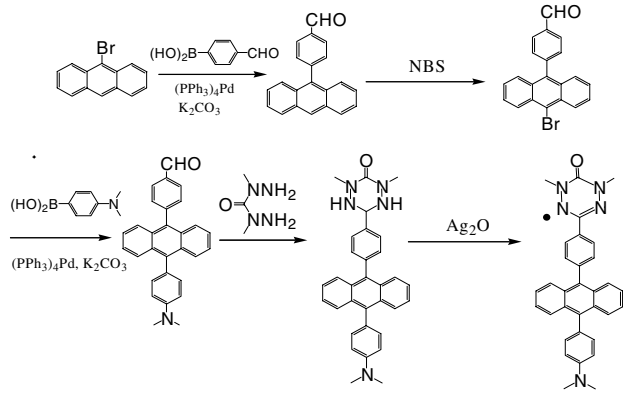
orbital calculation was also carried out bath of the ground and the photo-excited spin states. The spin alignment on the photo-excited state was investigated by a time-resolved ESR (TRESR) experiment. In this paper, we also report a CT complex which has been synthesized using **1** as an electron donor and tetrafluoro-1,4-benzoquinone as the electron acceptor.

2. Experimental

2.1. Synthesis of stable radical *1*

Calbonic acid bis(1-methylhydrazide) was prepared according to the literature method [13]. Other reagents were used as purchased. Column chromatography was performed on alumina (Merk Aluminum Oxide 60). **1** was synthesized according to Scheme 1.

Sample was purified by the column chromatography on dichloromethane. Repeating recrystallization from Hexan/Dichlorometan gave **1** as red powder: m.p. >300 °C (Found: C, 77.18; H, 5.79; N, 13.81% requires: C, 77.08; H, 5.66; N, 14.05%).



2.2. Preparation of CT complex

2.2.1. *1-BQF₄*

The CT complex was prepared under argon in 1,2-dichroloethane by mixing **1** with an excess argon in tetrafluoro-1,4-benzoquinone. The mixture was degassed in vacuum and cooled at −20 °C for three weeks. The mixture was evaporated under reduced pressure. The silver powder was purified by removing the contamination of tetrafluoro-1,4-benzoquinone in the precipitate using sublimation method.

2.3. Measurements

Oxidation potential of **1** was measured by the CV method using a Hokuto Dennko HSV-100 and UV–Vis absorption spectra were obtained with a Hitachi U-3000. Conventional ESR spectra were observed with a JEOL TE300 X-band ESR spectrometer. The ab initio

Scheme 1.

molecular orbital calculations were carried out based on the density functional theory (DFT) using GAUSSIAN 98 [14]. In the ab initio calculations, the STO 6-31G basis sets and UHF Becke 3LYP (UBecke 3LYP) hybrid method were employed. The photo-excited states were investigated by time-resolved ESR (TRESR) method. The detail of our TRESR setup was described in our previous paper [2]. The temperature in the ESR and TRESR measurements was controlled using an Oxford ESR 910 cold He gas flow system.

3. Results and discussion

The oxidation potential value of **1** in dichloromethane solution was 0.60 V on ferrocene which value was ca. 0.1 V smaller than **2**. The optical absorption band assigned to $\pi^* \leftarrow \pi$ transition arising from anthracene moiety was also shifted to longer wavelength. Their results were also supported by the ab intio calculation shown in Fig. 2. The calculated orbital energies and molecular orbitals of **1** and **2** were consistent with these experimental results. The energy location of π-HOMO of **1** becomes about 0.3 eV higher than that of **2**. These results show that the location of π-HOMO of **1** become

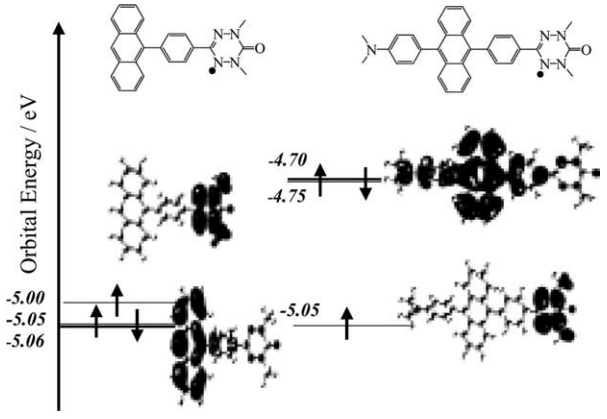


Fig. 2. Orbital energies and one-electron molecular orbitals of **1** and **3**.

higher in energy than that of **2** as the result of the attachment of dimethylamino group at the proper position. Although in **2** the energy of SOMO is located higher than that of HOMO, SOMO of **1** is located lower than the HOMO. This means that **1** will become more chemically stable compared with **2**.

The photo-excited state in **1** was investigated by TRESR experiments. Typical TRESR spectrum of **1** observed at 30 K in 2-MTHF glass matrix is shown in Fig. 3 together with the spectral simulation. The spectral simulation was carried out by the eigenfield/exact-diagonalization hybrid method [15–17] taking the electron spin polarization into account. The spectrum shows well resolved fine-structure splitting. The spectral simulation revealed that the observed TRESR spectrum of **1** has been unambiguously assigned as an excited quartet ($S = 3/2$) spin state (Q). The g value and fine-structure parameters for the quartet state have been determined to be $g(Q) = 2.0019$, $D(Q) = 0.0224\ \mathrm{cm}^{-1}$, $E(Q) = 0.003\ \mathrm{cm}^{-1}$.

The magnitude of the fine-structure parameter, D of **1** was 3% smaller than that of **2**. This result shows that the unpaired electron is slightly more delocalized in the whole molecule. However, no significant change was occurred in the molecular orbital with the unpaired electrons by an attaching dimethylamino group. The characteristic nature with the excited high-spin state is conserved in **2** and only the property of the electron donor is improved by an attaching dimethylamino group.

Fig. 4 shows the UV–Vis spectra of **1**, BQF_4 and **1**-BQF_4 charge-transfer complex. CT band was clearly observed in **1**-BQF_4.

X-band ESR spectra of **1**-BQF_4 complex in the ground state is shown in Fig. 5. This spectrum was observed at room temperature in solid phase. As shown in Fig. 5, this spectra was a very sharp line and the g value is determined to be 2.0019. This g value becomes a little smaller than the g value 2.0052 of **1**. This means that unpaired electron will move partially to the BQF_4 moiety as the result of the complex formation. Further experiments including the photo-excited state are in progress.

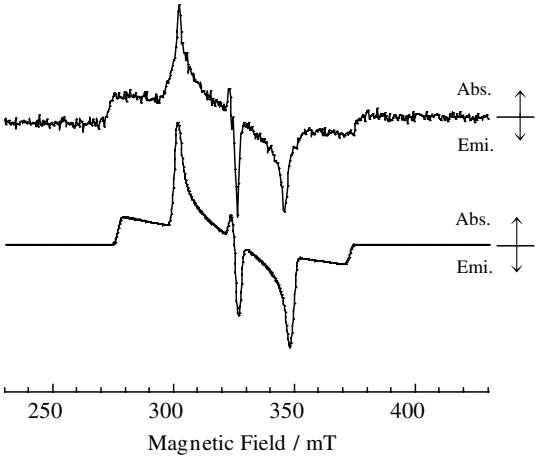

Fig. 3. Typical TRESR spectrum observed at 0.7 μs after LASER excitation.

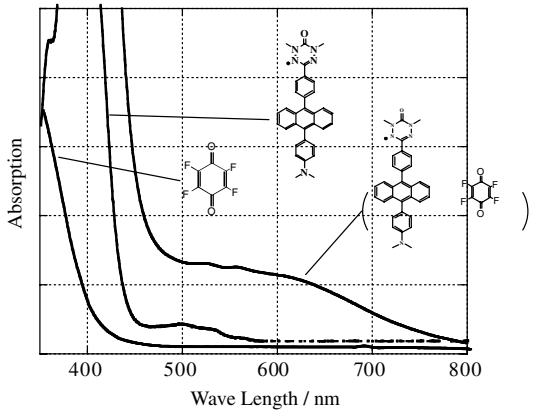

Fig. 4. Optical absorption spectra of **1**, BQF_4 and **1**-BQF_4 at room temperature. 1,2-Dichroloethane was used solvent.

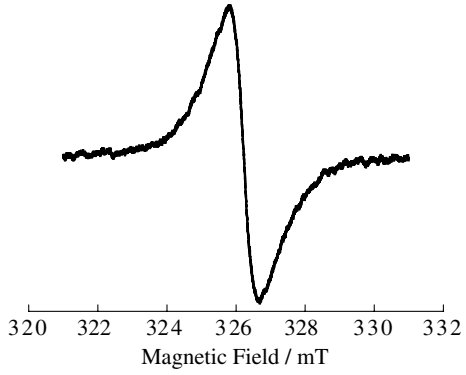

Fig. 5. X-band ESR spectra of **1**-BQF_4 observed at room temperature in solid phase. The microwave frequency is 9162.60 MHz.

4. Conclusions

1 was designed by the ab initio MO calculation and synthesized as the stable radical which electron donor property was improved compared with **1** and **2** previously reported. It is confirmed that **1** has the photo-excited high-spin quartet ($S = 3/2$) state as well as **2** by TRESR experiment. A CT complex **1**-BQF_4 was also synthesized using **1** as an electron donor.

[17] In the spectral simulation of the TRESR spectra, the calculation of ESP has been added as a subroutine to the computer program. More detailed procedures of the spectral simulation for high-spin organic molecules are similar to those described in our previous paper for the perturbation approach: Y. Teki, T. Takui, H. Yagi, K. Itoh, H. Iwamura, J. Chem. Phys. 83 (1985) 539.

vanadium–benzene, $V_n(C_6H_6)_{n+1}$ (see Fig. 1) [14–17], revealed that their magnetic moments increase monotonically with the layer number n [18]. The measured increase of magnetic moments indicates that the electron spins of the non-bonding d_σ electrons, localized on the V metal atoms, are aligned with a ferromagnetic ordering. This result provides the first example of magnetic spin alignment of magnetic sandwich complexes. The elucidation of the magnetic properties of isolated organometallic complexes will be an important task underlying the rational design of future novel magnetic materials, for example those based on single molecule magnets.

In this contribution, we present the results of Stern-Gerlach molecular beam deflection studies of 1D-organometallic multi-decker sandwich complexes: terbium–cyclooctatetraene $Tb_n(C_8H_8)_{n+1}$ (Fig. 1). Bonding in $Ln_n(C_8H_8)_{n+1}$ sandwich complexes (where Ln represents a lanthanide metal atom) has been found to be highly ionic in nature [19–21] as a result of charge-transfer from Ln metal atoms to C_8H_8 ligands. In the present study, terbium was selected from among the various lanthanide metals due to its large magnetic moment. Since 4f electrons are effectively shielded from interaction with external ligand fields by the outer-lying $5s^2$ and $5p^6$ electrons, the magnetic properties of Ln containing complexes are essentially ascribed to those of Ln free ions, Ln^{2+} and Ln^{3+}. Therefore, the unpaired 4f electrons within the Ln ions largely determine the magnetic properties of the $Ln_n(C_8H_8)_{n+1}$ complex, and the number of layers in a multi-decker sandwich complex, may provide a controllable parameter for the overall magnetic moments. There have been a few reports on the magnetic susceptibilities of the ionic sandwich lanthanide complexes: $K^+[Ln(C_8H_8)_2]^-$, $[Ln(C_8H_8)_2Cl\cdot 2THF]$ (Ln = Ce, Pr, Nd, Sm and Tb), $[(THF)_3K(C_8H_8)]_2$ Eu and $Ln(Pc)_2$ (Ln = Pr, Gd, Tb, Dy, Ho, Er, Tm, Yb and Lu; Pc = phthalocyanine) [22–26]. However, to our knowledge, there have been no reports on measurements of incremental magnetic moment for multi-decker sandwich complexes, except for the study of the f–f interactions in dinuclear lanthanide complexes [26]. In this work, we discuss the size dependence of magnetic moment for 1D $Tb_n(C_8H_8)_{n+1}$ complexes ($n = 1-5$) determined in a molecular beam employing the Stern-Gerlach deflection method.

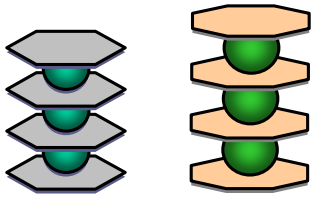

Fig. 1. Schematic structure of vanadium–benzene complex: $V_n(C_6H_6)_{n+1}$ and lanthanide–cyclooctatetraene complex: $Tb_n(C_8H_8)_{n+1}$ ($n = 3$).

2. Experimental

The magnetic moments of $Tb_n(C_8H_8)_{n+1}$ complexes were measured by molecular beam magnetic deflection – a variation on the classic Stern-Gerlach experiment used originally to determine the magnetic moments of atoms. In this approach, species that can be produced only in small quantities and/or that are highly reactive can be studied without the perturbing influences of solvents, matrices or self-reaction/polymerization. Furthermore, the use of a position-sensitive time-of-flight (PS-TOF) mass spectrometer for beam detection enables us to obtain deflection information for complexes with various compositions and sizes simultaneously. The experiments and analysis procedures have been described in detail elsewhere [27]. Briefly, metal atoms were produced by focusing the second harmonic output of Nd^{3+}:YAG laser (~30 mJ/pulse, 25 Hz) onto a metal rod of Tb within a fast flow source. The atomic vapor was carried by a continuous stream of helium into a flow tube reactor, where C_8H_8 (cyclooctatetraene) vapor was injected. The subsequent reaction of the metal atoms and C_8H_8 form a variety of product species, the dominant fraction of which consisted of the *full sandwich* complexes: $Tb_n(C_8H_8)_{n+1}$ The mixture of helium and organometallic complexes expanded into vacuum through a 1.5 mm diameter nozzle at the end of the flow tube. The resulting supersonic free jet was collimated into a molecular beam using a series of skimmers and orifices. The collimated molecular beam entered a high vacuum chamber, where it passed through the gap of a dipole gradient electromagnet capable of producing an inhomogeneous magnetic field, with gradients $\partial B/\partial z$ up to ~210 T/m and B fields up to ~1.2 T. The complexes were detected 0.9 m downstream of the deflection magnet using laser photoionization time-of-flight (TOF) mass spectrometry employing an ArF excimer laser as the photoionization source. The TOF spectrometer was operated in the position-sensitive mode [28], a technique which maps the spatial distribution of the molecular beam along the z axis (parallel to the magnetic field) onto the time domain. Between 800 and 2000 spectra were averaged in a digital oscilloscope with the magnetic field on, and then again with the field off. The deflection of the molecular beam was determined by quantitatively comparing the temporal profiles of the mass peaks in the field-on TOF spectrum with those of the field-off spectrum. The field-induced changes in PSTOF temporal profiles reflected shifts and/or broadening of the corresponding molecular beam spatial profiles.

In Stern-Gerlach studies of atoms and complexes such as those reported here, the z-component of magnetic moment μ_z of the species under investigation is given by

$$\mu_z = \frac{f}{t_{\mathrm{arr}}}\frac{mV^2}{LD\mu_{\mathrm{B}}}\frac{\Delta t}{\left(\frac{\partial B}{\partial z}\right)}, \qquad (1)$$

where the factor f is an instrumental constant, t_{arr} is the arrival time of the target complex, m is mass of the complex, V is a beam speed, D and L are the length of the magnet and the distance from the final collimating slit to the detector, Δt is the time difference (field-on versus field-off) of the TOF peak center of the complex, and $(\partial B/\partial z)$ is the magnetic gradient, respectively.

The quantity measured in determining net beam deflections is the change in the average position of deflected beam profile. Specifically, the beam deflections are quantitatively determined as the difference in first moments between the zero-field beam profile and the profile recorded with the field applied. For superparamagnetic complexes (i.e., those in which intramolecular spin relaxation occurs on a timescale faster than the flight time through the magnetic field) the peak shift can be described to good approximation the Langevin model [29], which can be simplified to the Curie Law under the condition of $\mu B \ll k_B T$,

$$\langle M_z \rangle = \frac{\mu^2 B}{3k_B T}. \quad (2)$$

Here, the time averaged effective magnetic moment $\langle M_z \rangle$ is related to the true moment μ. Then the magnetic moment μ in μ_B units can be obtained from the deformation of (1) with replacing μ_z into $\langle M_z \rangle$,

$$\mu = \frac{1}{\mu_B}\sqrt{\frac{f}{t_{arr}}\frac{mV^2}{LD}3k_B T\frac{\Delta t_{delay}}{B\left(\frac{\partial B}{\partial Z}\right)}}, \quad (3)$$

where Δt_{delay} is the shift of the peak, B is the magnetic field in T. The last term predicts that Δt_{delay} should be proportional to $B(\partial B/\partial z)$ in this model.

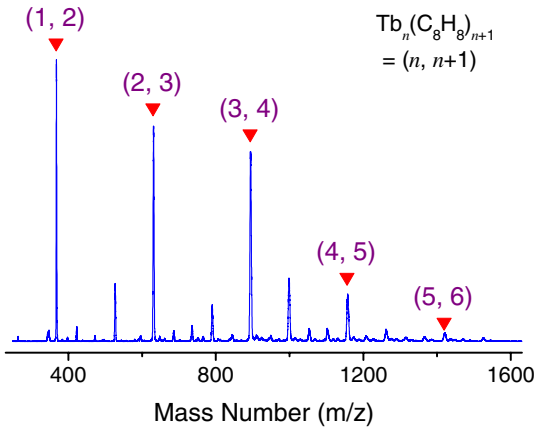

Fig. 2. Mass spectrum for $Tb_n(C_8H_8)_m$ complexes ($T = 146$ K). The regular progressions of mass peaks exhibit the dominant fraction of *full sandwich* complexes: $Tb_n(C_8H_8)_{n+1}$.

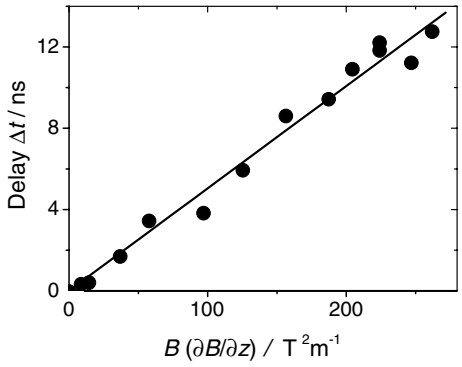

Fig. 3. Single-sided magnetic deflection of TOF peak delay Δt of $Tb_3(C_8H_8)_4$ at 150 K. Peak delay Δt varies linearly with the product of $B(\partial B/\partial z)$.

3. Results and discussion

Fig. 2 shows the photoionization mass spectra of terbium–cyclooctatetraene complexes generated at a source temperature of 146 K. Labeled peaks corresponding to "complete" sandwich $Tb_n(C_8H_8)_{n+1} = (n, n+1)$ complexes appear prominently. Small quantities of incomplete sandwich complexes (e.g., "half" sandwich complexes containing an uncapped metal atom, or complexes which contain excess ligand molecules) are also produced.

Fig. 3 shows a linear dependence of the spatial shift of the $Tb_3(C_8H_8)_4$ peak against the product of $B(\partial B/\partial z)$, as predicted by the Langevin/Curie model. It has been shown that many types of polynuclear metal clusters (Ni_n, Co_n, Fe_n and Gd_n) show one-side deflection behavior similar to that displayed by $Tb_3(C_8H_8)_4$ [6–12]. Other $Tb_n(C_8H_8)_{n+1}$ complexes ($n = 1, 2, 4, 5$) also exhibited one-sided peak shifts. These observations indicate the occurrence of spin relaxation and thus justifies the use of the Langevin model to determine the intrinsic moments of the $Tb_n(C_8H_8)_{n+1}$ complexes (vide infra). The occurrence of rapid spin relaxation demonstrates that the energy barrier for intramolecular spin reorientation due to internal magnetic anisotropy is negligible compared to $k_B T$ [30]. Intrinsic moments for $Tb_n(C_8H_8)_{n+1}$ obtained via Eq. (3), are plotted in Fig. 4. A monotonic increase of the magnetic moment with the size up to $n = 3$ is observed. Their absolute values are in the good agreement with the magnetic moment of a free Tb^{3+} ion ($4f^8$; 9.7 μ_B). Although the experimental uncertainty is large, deviation at $n = 1$ may attributed to the contribution of unpaired spins on the C_8H_8 ligands [31]. On the other hand, the magnetic moment drops at $n = 4$. For complexes of larger than $n = 4$, the increase in magnetic moment with each additional layer is about a half that measured for $n < 4$. This is ascribed to the particular oxidation states of Tb atoms comprising of the larger complexes. as reported previously [20,21], for longer sandwich complexes ($n > 2$), some of Tb atoms take on +2 oxidation states in addition +3 states since the

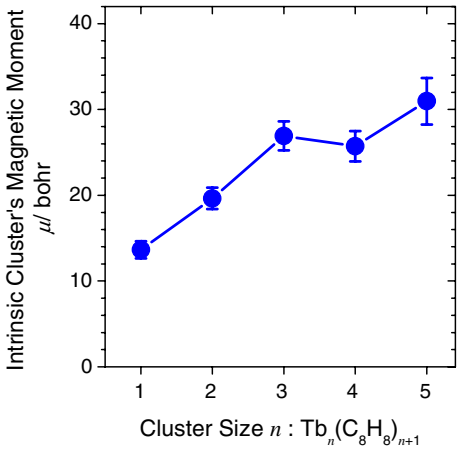

Fig. 4. Magnetic moments μ for $Tb_n(C_8H_8)_{n+1}$ ($n = 1 - 5$) complexes at $T = 146$ K.

C_8H_8 ligand can accommodate only two electrons. Although it is well known that Tb atom takes +3 and rarely +4 oxidation states in Tb complexes, unusual lower +2 oxidation state can exist for species isolated in a molecular beam. For $Tb(C_8H_8)_2$ and $Tb_2(C_8H_8)_3$, the oxidation state of Tb atom(s) is +3: the constituents of $Tb(C_8H_8)_2$ and $Tb_2(C_8H_8)_3$ can be formally expressed as $\{(C_8H_8)^{1.5-}\ Tb^{3+}\ (C_8H_8)^{1.5-}\}$ and $\{(C_8H_8)^{2-}\ Tb^{3+}\ (C_8H_8)^{2-}\ Tb^{3+}\ (C_8H_8)^{2-}\}$, respectively [33]. In the case of $Tb_3(C_8H_8)_4$, however, the oxidation states of the constituents can be formally expressed as $\{(C_8H_8)^{2-}\ Tb^{3+}\ (C_8H_8)^{2-}\ Tb^{2+}\ (C_8H_8)^{2-}\ Tb^{3+}\ (C_8H_8)^{2-}\}$, because four C_8H_8 ligands can accept 8 electrons in total. Similarly, for the case of $Tb_4(C_8H_8)_5$ complex, two Tb^{2+} ions exist in the middle of the complex, with the outermost Tb ions existing in +3 state. These charge distributions have reasonably been deduced from photoionization spectroscopy and chemical probe experiments [20,21]. Since the magnetic moment for Tb^{2+} ($4f^9$; 9.47 μ_B) is almost the same as that of Tb^{3+}, the lower magnetic moments measured for $Tb_4(C_8H_8)_5$ complex implies that interaction between the two central Tb^{2+} ions is antiferromagnetic. The increase of magnetic moment from $n = 4$ to $n = 5$ can be explained by the excess Tb^{2+} ion which cannot be coupled. Therefore, continued zigzag oscillation of magnetic moments is expected for $Tb_n(C_8H_8)_{n+1}$ complexes ($n \geqslant 3$). However, since only the entire magnetic moment is measured in the present molecular beam study, the size dependence may be blurred by coexistence of several low-lying electronic spin states.

The observed one-sided beam deflection behavior indicates that intramolecular spin relaxation (ISR) occurs for $Tb_n(C_8H_8)_{n+1}$ complexes. That ISR may occur at all in these Tb-COT systems is a result of their large density of rovibronic states ρ. In particular intramolecular spin relaxation can occur in isolated species only when the average spacing between rovibronic levels given by ρ^{-1} is less than spacing between Zeeman levels [32]. By comparison, the electronic structure of $V_n(C_6H_6)_{n+1}$ complexes are comparatively simple owing to the non-bonding character of d_σ orbitals which accommodate unpaired spin [17,18]. As a result, the density of states for $V_n(C_6H_6)_{n+1}$ complexes is sparse since there are no low-lying states which can be crossed in the magnetic field, and thus spin relaxation is not observed. In contrast, the density of states of $Tb_n(C_8H_8)_{n+1}$ complexes is dense due to existence of low-lying electronic states and mixing of these states in the presence of magnetic field [33]. It is thus reasonable to expect that this large density of states makes spin relaxation is facile in $Tb_n(C_8H_8)_{n+1}$ complexes. Note that it is very important to uncover the relationship between the magnetization relaxation and ligands through the control of degrees of vibrations and dimensionality. From our result on $Tb(C_8H_8)_2$, there appears to no evidence for slow magnetization relaxation, whereas $Tb(Pc)_2$ exhibits slow magnetization [34]. The observed one-side magnetic deflection of Tb-COT clusters is thus explained by fast magnetic relaxation. If these species showed slow spin relaxation (or none at all), magnetic deflection behavior should involve symmetric beam broadening as in isolated atoms. It is quite likely that the gas-phase magnetic beam deflection of $Tb(Pc)_2$ would be different from that of $Tb(C_8H_8)_2$.

In summary, the magnetic deflections of multiple-decker terbium–cyclooctatetraene organometallic complexes have been measured by a Stern-Gerlach molecular beam deflection method. $Tb_n(C_8H_8)_{n+1}$ sandwich complexes displayed one-side deflections which indicates the occurrence of fast intramolecular spin relaxation. The evolution of the magnetic moment with increasing size can be rationalized in terms of the number of Tb^{3+} ions. The drop of the magnetic moment for $Tb_4(C_8H_8)_5$ implies antiferromagnetic interaction of adjacent Tb^{2+} ions at the central portion of the complex. Size-selective soft-landing of gas-phase complexes onto nano-scale designed surfaces is an emerging approach [35] that is expected to open exciting new possibilities for exploiting these species as nano-sized magnetic building blocks in applications such as magnetic recording media.

thus the lowering of the lattice symmetry, and the presence of the rhombic (E) term in the spin Hamiltonian. It is thus of interest to examine, by solid state NMR spectroscopy, the role of the lattice-solvated molecules in the overall magnetic symmetry and structure of Mn_{12}–Ac and related compounds. To this effect, we have carried out ^{55}Mn NMR measurements on the recently synthesized compound $[Mn_{12}O_{12}(O_2CCH_2Br)_{16}(H_2O)_4]\cdot 4CH_2Cl_2$ (Fig. 1), henceforth as Mn_{12}–BrAc [19]. In particular, we examined the NMR spectra of single crystal as well as aligned powder of this compound. We found significant differences between the spectra from the single crystals versus aligned powder; specifically that the single crystals afford significantly higher spectral resolution than the aligned powder, and moreover, that the act of powdering introduces significant differences in the chemical structure of Mn_{12}–BrAc. Furthermore, angular dependence studies are now possible because of the use of single crystals. We conducted such studies with rotations in the *ac*-plane.

2. Synthesis and crystal growth

Mn_{12}–BrAc was synthesized by mixing Mn_{12}–Ac in toluene and then adding an excess of HO_2CCH_2Br, as described elsewhere [19]. Once the initial crystals of Mn_{12}–BrAc were formed, they were recrystallized by dissolving in dichloromethane and adding bromoacetic acid. Once dissolved, the solution was filtered and placed into small vials with a small amount of hexanes. A needle was pushed through the lid to assure slow evaporation. After a week, nice brick looking single crystals form.

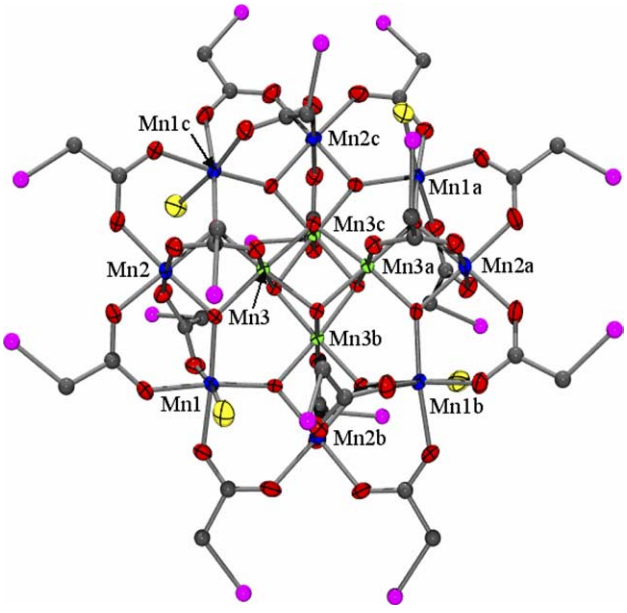

Fig. 1. ORTEP representation in PovRay format of Mn_{12}–BrAc.

3. NMR experimental details

^{55}Mn NMR measurements were made using a home built MAGRes2000 Integrated Wideband NMR spectrometer with quadrature detection and a home built high frequency probe [20,21]. The crystal samples were prepared by removing the crystal from its mother liquor and immediately covering in 5-min epoxy to prevent the sample from drying. Immediately after the epoxy was set, the sample was mounted into the coil and cooled in a dewar of liquid Helium. Aligned powder samples were made by crushing the crystals and then mixing with Stycast 1266 epoxy. On crushing the sample, it was noticed that the crystals went from a dark wet looking brown color to a light brown, dry powdery sample. The epoxy was then allowed to cure overnight at room temperature in a field of 8.5 T. Data was acquired for both samples at ~2 K, below the blocking temperature, T_B, of ~3 K because of fast T_2 times above this temperature. A Hahn echo pulse sequence was used while the frequency was scanned from 220 to 400 MHz, usually taking 0.1–0.2 MHz steps. Frequency scans were necessary because of the large peak widths (~5–20 MHz). Pulse lengths were on the order of hundreds of nanoseconds giving a bandwidth of roughly ~2 MHz. After the scan, the data was processed using a Fast Fourier Transform Sum (FFT Sum).

4. Results

We present here the comparison of single crystal ^{55}Mn NMR spectroscopic measurements of $[Mn_{12}O_{12}(O_2CCH_2Br)_{16}(H_2O)_4]\cdot 4CH_2Cl_2$ (Fig. 2, henceforth Mn_{12}–BrAc) and an aligned powder sample of Mn_{12}–BrAc. As will be seen, the ability to probe Mn sites represents a powerful tool to study factors such as symmetry-lower-

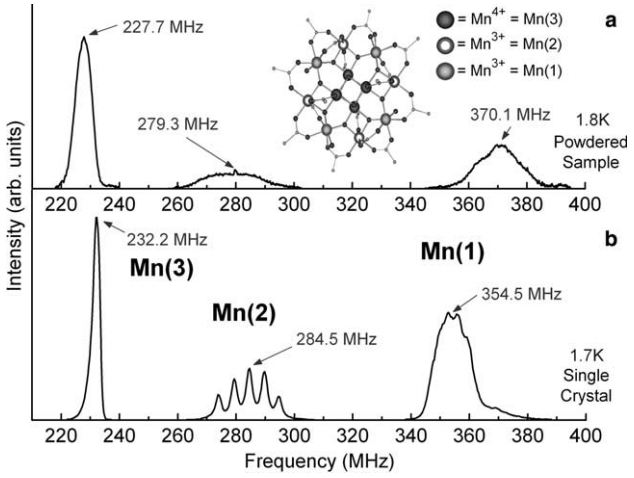

Fig. 2. Comparison of Mn_{12}–BrAc aligned powder vs. single crystal. Inset shows the core crystal structure and assigns the peaks.

ing in SMMs due to extrinsic perturbations and the ground state at each Mn ion. Mn_{12}–BrAc yield large single crystals suitable for ^{55}Mn NMR studies. Fig. 2 shows a comparison of ^{55}Mn NMR signals obtained from: (a) Mn_{12}–BrAc powder and (b) a Mn_{12}–BrAc single crystal, all in zero external field, $H_0 = 0$.

The aligned powder spectrum of Mn_{12}–BrAc, Fig. 2(a), shows three peaks corresponding to the three expected sites of the Mn ions [22,23]. The first peak (Mn(3)) at 227.7 MHz corresponds to the Mn^{4+} ions in the Mn_4O_4 core and has Full Width at Half Maximum (FWHM) of 6.52 MHz. The second peak (Mn(2)) at 279.3 MHz, with a FWHM of 24.74 MHz, is a result of four of the Mn^{3+} ions located in the crown of the molecule. No quadrupolar splitting is noticed. The last four Mn^{3+} ions located in the crown of the molecule produce the third peak (Mn(1)) at 370.1 MHz and a FWHM of 16.67 MHz. Again, no quadrupolar information can be extracted from this peak. Hyperfine fields can be calculated by using $\gamma_n^{55} = 10.5$ MHz/T resulting in fields of 21.69, 26.60, and 35.25 T corresponding to Mn(3), Mn(2), and Mn(1), respectively.

Upon examining the single crystal data (Fig. 2(b)) a sharp distinction is noticed. Resolution is far superior to that of the aligned powder and the peaks are actually shifted, up to ~16 MHz. The peak assignments are the same as the aligned powder. The narrow first peak has a frequency of 232.2 MHz, a FWHM of 2.89 MHz, and a hyperfine field of 22.11 T. The second quadrupolar split line has a central transition at 284.5 MHz, a FWHM of 2.91 MHz and an internal field of 27.10 T. Lastly, the third peak occurs at 354.5 MHz with a hyperfine field of 33.76 T. While the resolution is not great enough to measure the width of one of the quadrupolar split peaks, the FWHM for the entire peak is 13.82 MHz. All data should be contrasted with that obtained from the aligned powder.

The large resolution enhancement afforded by use of single crystals allows us to calculate the quadrupole coupling parameter e^2qQ for the second and third peaks through the quadrupole splitting, $\Delta\nu_Q$, and the equation for the energy [22,23]

$$\mathbf{E}_m = -\gamma_n \hbar H_0 m + \frac{e^2qQ}{4I(2I-1)}\left(\frac{3\cos^2\theta - 1}{2}\right)[3m^2 - I(I+1)],$$

where I and m are the nuclear spin and its projection quantum numbers, and θ the angle from the symmetry axis. From crystallographic data for Mn_{12}–BrAc, it is known that the local Jahn–Teller axes, and hence the principal hyperfine field directions of Mn(2) and Mn(1) ions are canted away from the c-axis at angles of 7.9° and 34.0°, respectively. With $I = 5/2$, $\Delta\nu_Q = 5.15 \pm 0.05$ MHz for the Mn(2) peak while $\Delta\nu_Q = 3.3 \pm 0.10$ MHz for the Mn(1) peak resulting in e^2qQ values of 35.33 ± 0.35 and 41.43 ± 1.26 MHz, respectively. No such information is obtainable from the oriented powder data (Fig. 2(a)).

Powdering the sample obviously changes the environment of the Mn ions, most likely due to the pressure and temperature change placed on the crystals when they are crushed. Further studies of these effects are underway to determine the exact cause of the transformation. More significant to this work is the knowledge that an aligned powder does not represent a statistical average of the crystal, as is seen by the large shift of the peaks in the aligned powdered spectra. It is thus suggested that work on aligned powders should be viewed with caution.

Yet another advantage to using single crystals is the ability to perform angular dependence studies. Angular dependence of the Mn(3) peak of Mn_{12}–BrAc was conducted from the easy to hard axis, as shown in Fig. 3. Rotation in the ac plane was prepared by cooling the crystal in zero field, so signals from both $m_s = \pm 10$ states are discernible, separated by twice the Zeeman frequency at the applied field (1 T here). The angular variation in the *ac*-plane is described by the following equation:

$$\textit{Peak Frequency} = \nu_{CF} \pm (^{55}\gamma/2\pi)(H_0)(\cos\theta).$$

ν_{CF} represents the central frequency and θ being the angle between H_0 and the c-axis. As the crystal is rotated, the effective field, H_{eff}, felt by the nuclei is just the sum of the projection of H_0 onto the hyperfine field, H_N ($H_{eff} = H_N \pm H_0\cos\theta$). Thus, a maximum in the splitting is seen when H_0 is parallel to the c-axis ($\theta = 0°$) while a minimum in the splitting is noticed when H_0 is perpendicular to the c-axis ($\theta = 90°$). One interesting result is the splitting observed when the crystallographic c-axis is perpendicular to the external field, H_0. When the crystal is in this configuration and an external field is applied, we observe two peaks as opposed to the expected one. We tentatively assign this to two different orientations of the hyperfine fields at the Mn^{4+} sites.

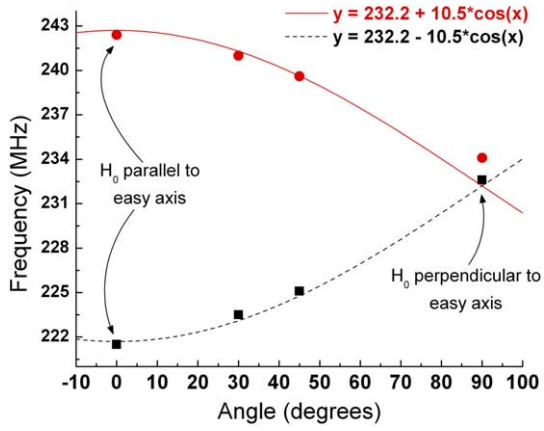

Fig. 3. Angular dependence in the *ac*-plane of a single crystal of Mn_{12}–BrAc.

5. Conclusion

Loss of information from aligned powdered samples is obvious by the shifts in frequency and loss of quadrupolar splitting. Single crystal measurements offer a new way to probe the magnetic properties of SMM by providing more accurate measurements of hyperfine fields and quadrupolar information. Angular dependence studies show that there is more work to be done to understand the magnetic structure of this molecule. The higher symmetry of Mn_{12}–BrAc, as a result of having no waters of hydration to allow hydrogen bonding, produces a less convoluted spectrum than Mn_{12}–Ac, suggesting that Mn_{12}–BrAc is a model system to study for understanding magnetic tunneling in the Mn_{12} family. Two recent studies [24–26] support this conclusion.

$(NH_4)_3CrO_8$ was synthesized by dissolving $(NH_4)_2CrO_4$ or CrO_3 in NH_4OH at room temperature. This solution was then cooled to −5 °C at which point H_2O_2 is added drop wise [6–10]. This process yields mm-size crystals. Crystals can be kept for more than a year at freezing temperatures. Decomposition occurs quickly if allowed to warm up and the compound can be explosive if pressure or heat is applied.

2.2. X-ray

Data were collected at 173 K on a Siemens SMART PLATFORM equipped with a CCD area detector and a graphite monochromator utilizing Mo Kα radiation ($\lambda = 0.71073$ Å). Cell parameters were refined using up to 8192 reflections. A full sphere of data (1850 frames) was collected using the ω-scan method (0.3° frame width). The first 50 frames were remeasured at the end of data collection to monitor instrument and crystal stability (maximum correction on I was <1%). Absorption corrections by integration were applied based on measured indexed crystal faces.

The structure was resolved by the Direct Methods in SHELXTL5, and refined using full-matrix least squares. The non-H atoms were treated anisotropically, whereas the hydrogen atoms located from a Difference Fourier map. N1 is located on a $\bar{4}$ symmetry center thus only one H atom exists in the asymmetric unit, and it was refined freely. N2 is located on a $\bar{4}2$ m center thus the four tetrahedrally oriented H atoms are heavily disordered. Two H atoms were found and were refined riding on their N2 atom. Because of symmetry, the H atoms around N2 are octahedrally oriented which is theoretically not correct for an ammonium cation but is close to two disordered sets that are related by 2-fold rotation or mirror symmetry. The asymmetric unit consists of 1/8 CrO_8^{3-} (located on a $\bar{4}2$ m center), 1/8 NH_4^+ (located on a $\bar{4}2$ m center), and another NH_4^+ ion located on a $\bar{4}$ symmetry element (1.4 in the asymmetric unit). Thus, the stoichiometry is $CrO_8(NH_4)_3$. The structure was also solved and refined in sub space groups of $I\bar{4}2$ m but these refinements did not provide any better results and did not remove the disorder of the H atoms around N2. A total of 26 parameters were refined in the final cycle of refinement using 254 reflections with $I > 2\sigma(I)$ to yield R_1 and wR_2 of 1.70% and 5.00%, respectively. Refinement was done using F^2.

2.3. Heat capacity and magnetization measurements

In order to detect a possible solid–solid or magnetic phase transition, we carried out heat capacity measurements over the range of 300 K down to 300 mK. These measurements were made with a Quantum Design Physical Properties Measurement System (QD PPMS) facility available at the National High Magnetic Field Laboratory in Tallahassee, Florida. dc magnetic susceptibility measurements were made using a Quantum Design SQUID magnetometer over a temperature range of 1.8–300 K.

2.4. Electron paramagnetic resonance spectroscopy

Electron paramagnetic resonance (EPR) spectroscopic measurements were carried out over a range of 2.8–295 K at X-band (~9.5 GHz), Q-band (35 GHz) and W-band (~93.5 GHz) using the Bruker (X- and Q-band) spectrometers; and a locally designed W-band system available as described earlier [11–14]. Both single crystals and powder samples were studied. Angular studies where done using a goniometer and the Q-band setup. The measured Zeeman splitting constants, g-values, clearly identified the compound as containing the Cr(5+) ion, based on our earlier reports [7,8,11–14].

3. Results and discussion

Fig. 1 shows a schematic of the CrO_8^{3-} moiety [11], which is the central part of our compound. Fig. 2 depicts the unit cell of $(NH_4)_3CrO_8$, based on our X-ray diffraction data as discussed above. The structure consists of essentially isolated Cr(5+), $3d^1$ ions and one thus expects little or no magnetic exchange interaction between the Cr(5+) ions, as we had envisaged. Indeed, magnetic susceptibility measurements, shown in Figs. 3 and 4, fully supported this behavior: the saturated magnetic moment corresponded to an $S = 1/2$ system (Fig. 3), while the magnetic susceptibility data followed the

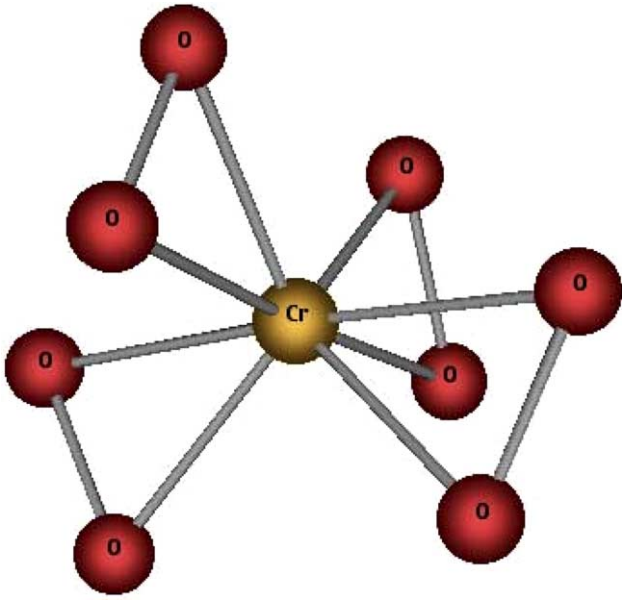

Fig. 1. Structure of CrO_8^{3-} ion.

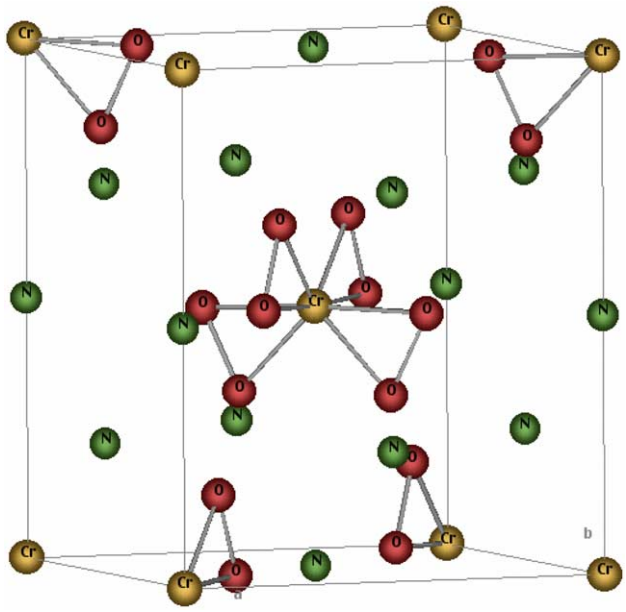

Fig. 2. Unit cell for $(NH_4)_3CrO_8$.

expected Curie–Weiss behavior (a straight line for the inverse susceptibility, $1/\chi$ versus T plot), as seen in Fig. 4. The Curie constant was $C = 0.320$ mol K/emu and $\theta = -0.8$ K showing a weak antiferromagnetic coupling, if any, similar to the other peroxychromates [7–13]. From the effective moment ($\mu_{eff}/\mu_\beta = 1.596$) we calculate, assuming $S = 1/2$, that $g_{iso} = 1.8429$, which was essentially in agreement with the variable temperature, variable frequency EPR data (Figs. 6 and 7, vide infra).

Heat capacity data (Fig. 5), on the other hand, exhibited a small but sharp peak at 137.5 K, which indicated the presence of some form of a order–disorder phase transition. $\Delta S = 4.70$ J/mol K was calculated over the peak by graphing $C_p * T$ versus T and then integrating; $\Delta S = \int C_p \frac{dT}{T}$. For a two state mixed system, the theoretically expected value is $\Delta S = R * \ln(2) = 5.76$ J/mol K,

which indicates that the phase transition can be ascribed to an order–disorder mechanism. The order–disorder process must involve the reorientational motion of the NH_4^+ groups. We rule out the order–disorder change in the CrO_8^{3-} units because other isostructural peroxychromates do not exhibit any such transition above 4 K. This postulate could be checked through X-ray structural studies around 137 K. The absence of any such anomaly in the magnetic susceptibility data (Fig. 4), clearly shows that the transition must be of a non-magnetic origin. This was supported by the absence of any noticeable anomalous change around 137.5 K in our detailed EPR measurements at the Q-band frequency (Fig. 7). The X, Q, and W-band EPR experiments yielded a $g_\parallel = 1.983 \pm 0.0005$ and $g_\perp = 1.950 \pm 0.0005$. These data yield $g_{iso} = \frac{1}{3}(g_\parallel + 2g_\perp) = 1.961 \pm$

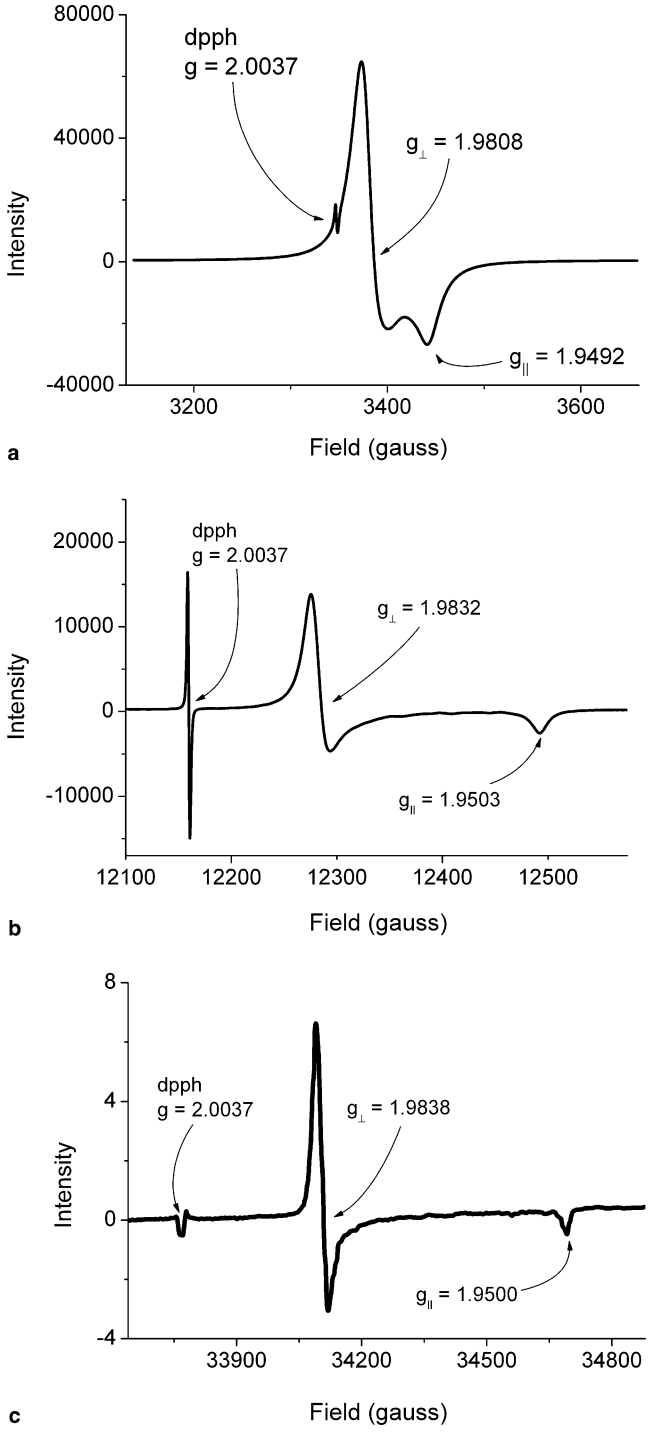

Fig. 6. EPR spectra of $(NH_4)_3CrO_8$ at: (a) X-band, 9.5 GHz; (b) Q-band, 34.5 GHz and (c) W-band, 94.5 GHz.

0.0005, in essential agreement with the above summarized magnetization measurements $g_{iso} = 1.843$. Angular dependence on a single crystal was done at Q-band frequency (Fig. 8). The crystal was rotated from the *c*-axis to the *a*-axis. The solid line corresponds to the fit of $g_{\text{eff}}^2 = g_{\perp}^2 \sin^2\theta + g_{\parallel}^2 \cos^2\theta$, giving $g_{\perp} = 1.9844 \pm 0.0005$ and $g_{\parallel} = 1.9522 \pm 0.0005$ which correspond well with the values calculated from the different frequencies measured. The line-width-at-half-height of the Q-band spectrum at 200 K, 9.84 gauss, allows calculation of an upper bound of the transverse relaxation; $T_2 = 5.8$ ns from the equation: $T_2 = \frac{1.3131\times10^{-7}}{g\Delta H_{\text{pp}}}$, where ΔH_{pp} is the width-at-half-height of the EPR peak. Further studies are needed to gain additional insight into the dynamics of this molecule. It is known that for a $3d^1$ ion in tetrahedral coordination the ground state can either be d_{z^2} or $d_{x^2-y^2}$ [10,15]. For the case of tetragonal elongation, $d_{x^2-y^2}$ is the ground state with $g_{\parallel} \approx g_e - \frac{8\lambda}{\Delta E}$ and $g_{\perp} \approx g_e - \frac{2\lambda}{\Delta E}$ where g_e is the free-electron *g*-value of 2.0023, and λ is the spin–orbit coupling constant. Thus, determination of the *g*-values will yield the ground state of this molecule. It was found for $(NH_4)_3CrO_8$ that $g_{\perp} > g_{\parallel}$ thus demonstrating that the ground state is indeed $d_{x^2-y^2}$ [7,8,15]. It should also be noted that no hyperfine interactions are seen as expected from the low percentage (9.50%) of Cr nuclei with nuclear spin.

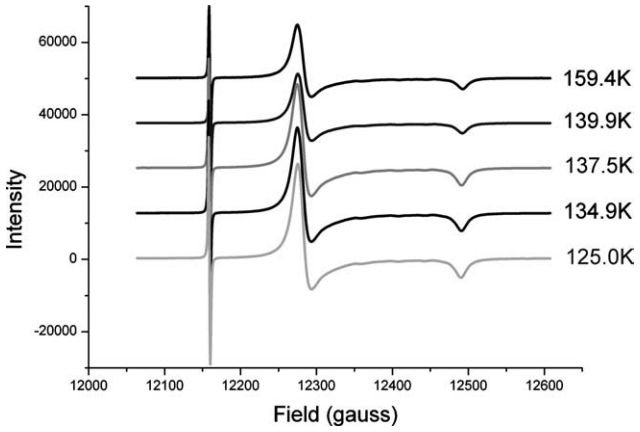

Fig. 7. Temperature dependence of Q-band EPR spectra for $(NH_4)_3CrO_8$. No change is noticeable at the phase transition temperature of 137.5 K.

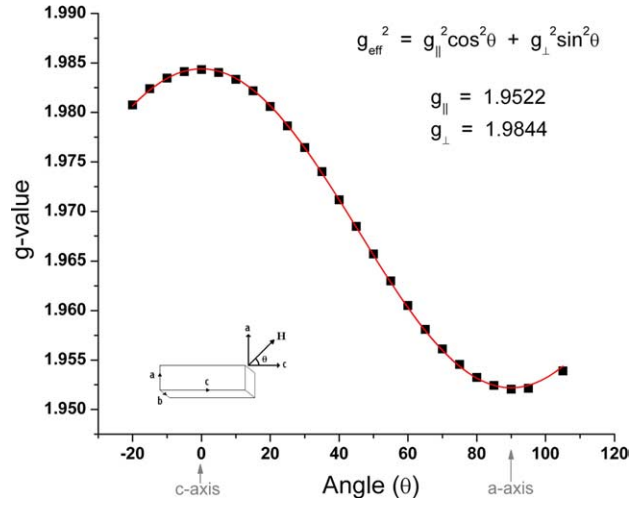

Fig. 8. Angular dependence of Q-band EPR spectra for $(NH_4)_3CrO_8$. Rotation is from the *c*-axis to the *a*-axis and was performed at 200 K.

4. Conclusion

The compound $(NH_4)_3CrO_8$, newly reported here, behaves as a simple $S = 1/2$ paramagnetic system, largely free from hyperfine and exchange interactions. Heat capacity, susceptibility, and EPR measurements support the hypothesis that the peak in the heat capacity is an order–disorder transition with no magnetic origin. Calculation of the entropy gives nice agreement to the theoretical prediction of a mixed two state system. This compound could serve as a model system and be a simple replacement for materials like V_{15}. Further studies along these lines should be fruitful.

ferrimagnetic regions upon cooling below T_C. In this dark state, the diamagnetic regions contain low spin (LS) Fe^{2+}($S = 0$) and Co^{3+}(LS, $S = 0$) pairs, and primordial ferrimagnetic regions consist of antiferromagnetically coupled Fe^{3+}(LS, $S = 1/2$) and high spin (HS) Co^{2+}($S = 3/2$) pairs. Although the concentration of alkali atoms and H_2O molecules contribute, the relative population of each region is mainly determined by the Co/Fe ratio in the synthesis process [10,11]. Upon irradiation, there is a charge transfer within a diamagnetic region from Fe^{2+}(LS, $S = 0$) to Co^{3+}(LS, $S = 0$), resulting in a ferrimagnetic region with Fe^{3+}(LS, $S = 1/2$) and Co^{2+}(HS, $S = 3/2$). This photoinduced charge transfer increases the relative population of ferrimagnetic regions, and thus increases the net magnetization [14,18,19]. In our magneto-optical investigations, film **1** showed an increase, while film **2** showed a *decrease*, in the photoinduced magnetization when the surfaces of the films were oriented perpendicular ($\perp$) to the external magnetic field (H_E). Moreover, when film **2** was oriented parallel ($\parallel$) to H_E, the photoinduced magnetization *increased*. In this paper, the contrasting magnetic behavior exhibited by the two films and the field orientation dependent anisotropic magnetization of film **2** are presented and discussed within a dipolar field model.

2. Experimental details

Two separate solutions of 5×10^{-3}mol of cobalt (II) nitrate aqueous solution, and a mixed solution of 2×10^{-2} mol potassium ferricyanide and 1.25×10^{-2} mol rubidium nitrate were prepared. For sample film **1**, a thin mylar sheet (thickness $\sim$ 100 μm) was immersed sequentially in one solution after the other for 20 cycles, and each immersion was performed by dipping the mylar sheet in and out of the solution for 3–4 times. Sample film **2** was prepared in a similar manner, except after each cycle of immersion, the film was rinsed by H_2O and methanol. The resultant films were dried with nitrogen gas and cut into small squares ($\sim$10.5 mm^2), and they were subsequently used in standard SEM and SQUID magnetometer measurements.

For the magneto-optical studies, a bundle of optical fibers was located near the sample films stacked in a gel-cap, and then connected to a room temperature light source using a homemade probe. The magnetometer was used to measure the dc magnetization while a commercial halogen lamp was used as an unfiltered visible light source. For each sample film, the time dependent magnetization was measured upon irradiation with visible light at 5 K with H_E = 200 G ($\perp$ films). The temperature dependent zero-field-cooled (zfc) and field-cooled (fc) magnetizations were also measured from 5 to 30 K with H_E = 200 G ($\perp$ films). Similar magnetic measurements were made only for film **2** when $H_E \parallel$ film. The background magnetic contributions from the container and mylar sheet were measured separately and subtracted from the signals obtained from the samples.

3. Results and discussion

The mixed metal cyanides generally form as powders. The cubic structure normally has small structural coherence, which is responsible for the cluster-glass magnetic behavior that is commonly observed. The synthesis protocol for film **2** included an additional step of rinsing with H_2O and methanol after each cycle of immersion to the solutions, whereas film **1** was fabricated without this rinsing process. The additional rinsing step for film **2** was expected to remove the excess powder residue attached to the film. As a result, for film **1**, the particles that make up the powder are randomly deposited, giving rise to a bulk-like texture, see the SEM image in Fig. 1(a). For film **2**, the particles are more uniformly arranged parallel to the films, resulting in a quasi-two-dimensional texture within continuous patches approximately 600 nm^2 as shown in the SEM image in Fig. 1(b). Furthermore, the long-range ($\sim$50 μm) quality of the samples was confirmed by additional SEM studies of each film.

The time dependent magnetization of film **1** is shown in Fig. 2(a) when $H_E \perp$ film. Upon irradiation at 5 K with H_E = 200 G, the magnetization of film **1** increased about 50%. This increase in the photoinduced magnetization is consistent with the results from bulk materials obtained by others [10,13,15] and reflects the powder-like nature of film **1**, see Fig. 1(a). The temperature dependences of the magnetizations in both the dark and photoinduced states are shown in Fig. 2(b). The increase in the fc values with decreasing temperatures and

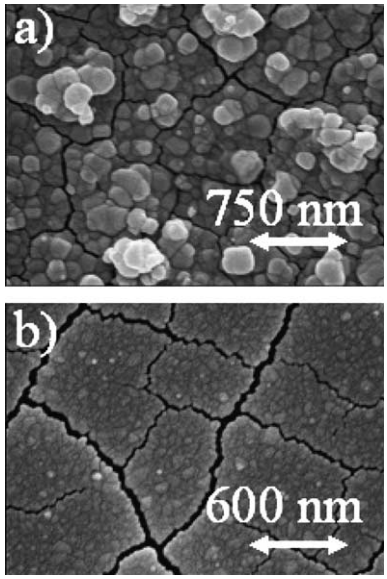

Fig. 1. SEM images of film **1** (a) and film **2** (b).

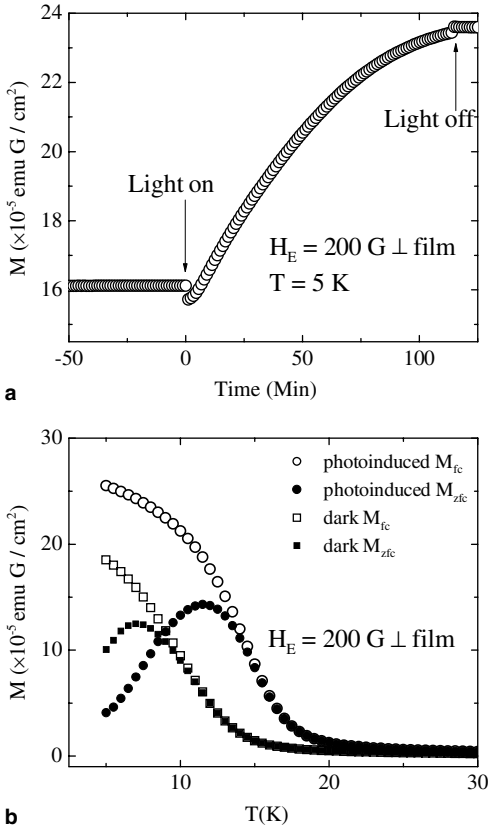

Fig. 2. Time dependent photoinduced magnetization (a) and temperature dependent magnetizations of film **1** when $H_E \perp$ film (b).

the maximum peak in the zfc magnetization are indications of cluster spin-glass behavior [16,21,22]. In a simple description specific to our samples, the cluster spin-glass state contains disordered interacting clusters, and each cluster consists of ferrimagnetically ordered Fe^{3+}(LS, $S = 1/2$) and Co^{2+}(HS, $S = 3/2$) regions. As a result of irradiation, the dark state $T_C \sim 15$ K increases to $T_C \sim 18$ K for the photoinduced state. In addition to the increase in T_C, the peak temperature (T_P) where the zfc magnetization value reaches its maximum has shifted from ~7 K in dark state to ~11.5 K in the photoinduced state. These changes in T_C and T_P in the photoinduced state can be easily interpreted within a cluster spin-glass description. More specifically, as a result of the irradiation, additional ferrimagnetic regions have been created, thereby resulting in increases in the size and concentration of the ferrimagnetic clusters. The larger clusters, whose magnetic correlation lengths are less restricted by the structural disorder (since T_C bulk ~ 21 K), are responsible for the increase of T_C in the photoinduced state. At the same time, the increased concentration of the clusters enhances the interactions between them and results in an increased T_P for the photoinduced states. Similar behavior was observed by another group in their study of a bulk material [16]. From the SEM images and the comparisons with the magnetic results of bulk materials reported by others, film **1** behaves as a powder-like film.

On the other hand, when film **2** was placed in $H_E \perp$ film, the magnetization of the film *decreased* upon irradiation, see Fig. 3(a). We previously used a dipolar field model to describe this type of decrease in the photoinduced magnetization [9]. In this model, a quasi-two-dimensional array of primordial ferrimagnetic regions produces a dipolar field that splays onto adjacent diamagnetic regions. Since the primordial ferrimagnetic moments are parallel to H_E, the direction of the dipolar field on the adjacent diamagnetic region is antiparallel to H_E when $H_E \perp$ film, and parallel to H_E when $H_E \parallel$ film. As a consequence, the net magnetic field seen by the diamagnetic region is a vector sum of the dipolar field and H_E. Upon irradiation when $H_E \perp$ film, the diamagnetic region undergoes a transition to a ferrimagnetic region, and the orientations of the net moment in the newly formed ferrimagnetic region will follow the net magnetic field. If the dipolar field is stronger than H_E, the net moment in the newly formed ferrimagnetic region will point antiparallel to H_E, and thus yield a *decrease* in the photoinduced net magnetization as experimentally shown in Fig. 3(a). An additional aspect of the dipolar field model is experimentally realized and is shown in Fig. 4,

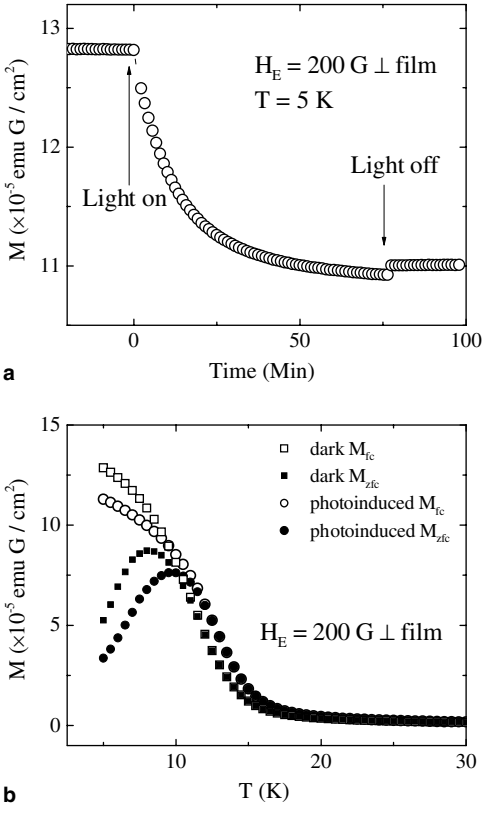

Fig. 3. Time dependent photoinduced magnetization (a) and temperature dependent magnetizations of film **2** when $H_E \perp$ film (b).

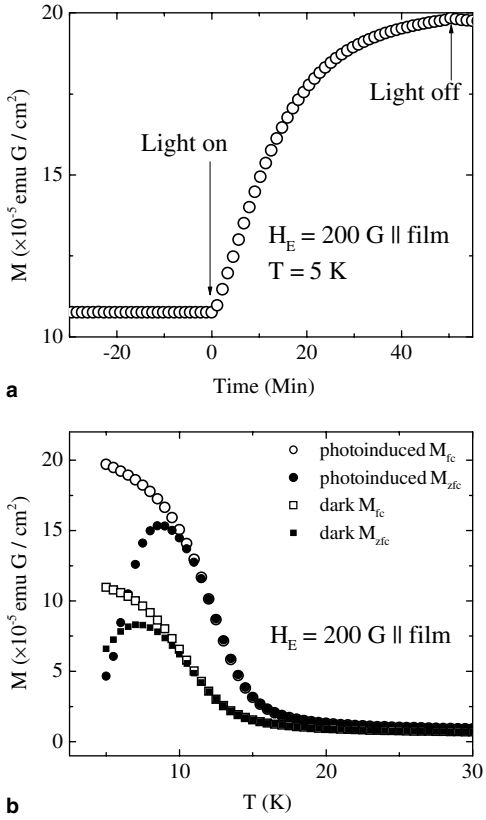

Fig. 4. Time dependent photoinduced magnetization (a) and temperature dependent magnetizations of film **2** when $H_E \parallel$ film (b).

where the photoinduced magnetization of film **2** *increases* when $H_E \parallel$ film.

In general, the behavior of the temperature dependent magnetization data of film **2** in both orientations (Fig. 3(b) for $H_E \perp$ film and Fig. 4(b) for $H_E \parallel$ film) is similar to the cluster spin-glass description of film **1**, Fig. 2(b). In both orientations of film **2**, the divergences between the zfc and fc magnetizations and the increases in T_P and T_C in the photoinduced state resemble the same behavior observed in film **1**. It is noteworthy that the photoinduced increase of T_C in film **2** ($H_E \perp$ film) is relatively smaller than the increases observed in film **1** ($H_E \perp$ film) and film **2** ($H_E \parallel$ film). This behavior of film **2** ($H_E \perp$ film) again indicates the quasi-two-dimensional nature of the film, where the dipolar field enhances the disorder within the cluster, and thereby yields a smaller increment of T_C in the photoinduced state when compared to the increase of T_C observed in the powder-like film.

4. Conclusions

We have generated magneto-optically active $Rb_jCo_k[Fe(CN)_6]_l \cdot nH_2O$ films using sequential deposition methods. The surface quality of the films was intentionally varied by modifying the synthesis protocol yielding a powder-like rough surface for film **1**, and a quasi-two-dimensional smooth surface for film **2**. Standard SEM images confirmed the quality of the film surfaces, and the dc magnetization measurements showed different photoinduced magnetic behavior between the two films. Upon irradiation at 5 K with an external magnetic field of 200 G perpendicular to the film surface, the magnetization of film **1** increased, whereas the magnetization of film **2** *decreased*. This contrasting behavior is consistent with a dipolar field model describing the phenomena and is related to the novel anisotropy of the photoinduced magnetism in film **2**, where the photoinduced magnetizations increases or decreases depending on the orientation of the film with respect to the external field. The ability to increase and decrease the photoinduced magnetization by reorientation of the film is a unique phenomenon that requires anisotropy. Consequently, the presence of this phenomenon allows us to differentiate between a quasi-two-dimensional film (film **2**) and a three-dimensional powder-like film (film **1**).

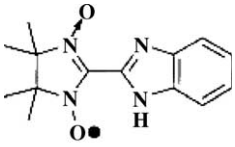

Fig. 1. The molecular structure of 2-BIMNN.

ESR measurements were carried out using a resonant cavity perturbation technique in combination with a broadband millimetre-wave vector network analyser (MVNA). The MVNA is a phase-sensitive, fully sweepable (8–350 GHz) super-heterodyne millimetre-wave source and detection system. A sample probe couples the network analyser via waveguides to a range of high-Q cavities situated in a 3He/4He cryostat inside the bore of a 17 T superconducting magnet. In comparison with conventional high-field ESR techniques, the system offers several advantages. The MVNA allows vector measurements, i.e., simultaneous measurements of both the amplitude and the phase of transmitted/reflected signal. The resonant cavity provides a well-defined millimetre-wave environment and substantially improved sensitivity to small samples over non-resonant methods. Careful coupling of radiation to and from the cavity (via the waveguide), combined with the ability to study very small samples, eliminates problems associated with standing waves in the sample probe. This, in turn, eliminates mixing of the dissipative and reactive responses of the sample under investigation and, when combined with a vector detection scheme, enables faithful extraction of ESR lineshapes (both the real and imaginary components), free from instrumental artifacts. The tunable cylindrical cavity gives the advantage of varying the frequency over quite a wide range, while the rectangular cavity allows angle-dependent experiments. The samples were oriented such that the applied magnetic field B was perpendicular to the c-axis, with the microwave field always parallel to the c-axis. Angle-dependence was also studied by rotating the c-axis away from B by an angle θ.

3. Results and discussion

We have performed electron spin resonance (ESR) measurements on 2-BIMNN single crystals in the temperature range 1.4–100 K (see Fig. 2). As the temperature was decreased from ~100 K, the linewidth was seen to broaden considerably below 20 K, reaching a maximum value at 10 K, and then decreasing again. This broadening of the linewidth at low temperature can be explained by a reduction of the exchange narrowing. The dominant broadening mechanism is the dipole–dipole interaction between adjacent spins along the c-axis. Other broadening mechanisms include the interchain exchange, interchain dipolar fields, hyperfine interactions, and possible single-ion anisotropies [6]. The maximum around 10 K has been reproduced in an experiment on a second crystal of 2-BIMNN. This feature may be due to a preferential alignment of spins below 10 K arising from the anisotropic dipolar interaction. Above 20 K, the ESR lines are Lorentzian, so the of the local field should be dynamic in this case.

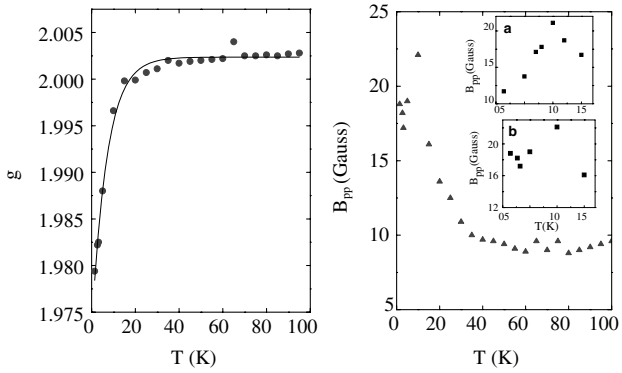

Fig. 2. Temperature dependence of the g value and the peak-to-peak linewidth B_{pp}. In the inset is shown the low temperature dependence of the linewidth for two different crystals.

A dramatic ESR lineshift to higher fields on cooling is observed below 20 K, corresponding to a decrease in the g-value. The g-value saturates above 20 K at the free electron value 2.00232. For ordinary free radicals, the difference in g between at low and high temperatures does not exceed 0.1%, whereas for the 2-BIMNN, the difference in g is an order of magnitude larger [7]. The downwards shift of the resonance field observed as the temperature decreases is what is expected in uniaxial low-dimensional magnetic systems, when the orientation of the crystal is orthogonal to the applied static field. Nagata et al. theorized that a weak uniaxial dipolar anisotropy was responsible for the g shift [8].

The g tensor is also related to the spin correlation function. Short-range magnetic order is known to have an increasing effect for low dimensions. Since the stacking axis of this 1-d radical magnet coincides with the long axis of the crystalline materials, one may conclude that magnetic effects due to short-range order could be responsible for the g-shift, but these effects are difficult to distinguish from those of the demagnetizing field [9,10].

An angle-dependent experiment was carried out on a single crystal. At 1.4 K, though the resonance field shows a pronounced angular dependence (Fig. 3), the linewidth is only weakly angle-dependent (Fig. 4). At 50 K, the g value changes slightly, though the trend is similar to that at 1.4 K; the linewidth can be considered to be constant. In the angular dependence of the g factor recorded at 1.4 and 50 K, we see that they cross each other at 44° and 146°. The angles are close to 90 ± 54°, where 54° is the magic angle. Fitting to the equation $g = g_1 + g_2\cos^2(\theta - \theta_0)$,

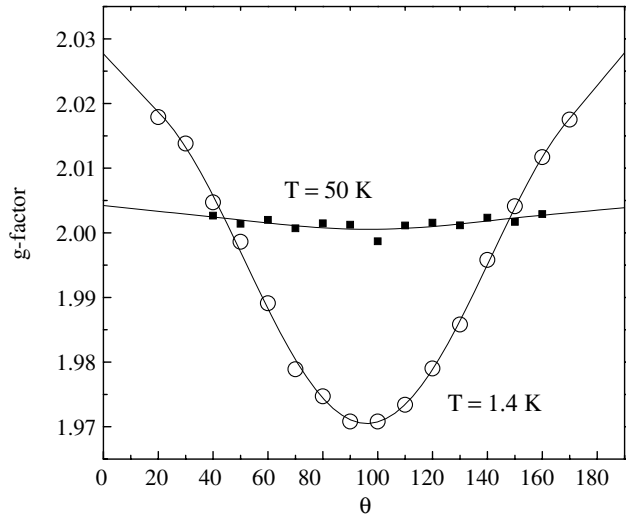

Fig. 3. The g-factors vs. θ at 1.4 and 50 K. The circles and squares are the experimental data at, respectively, 1.4 and 50 K. The lines show the fits to the data.

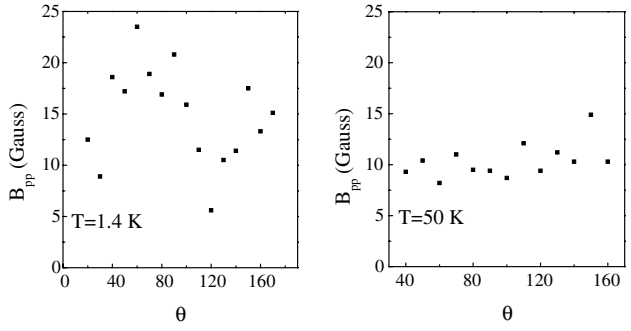

Fig. 4. The linewidths for different angles at 1.4 and 50 K, with resonance frequency 71.91 GHz.

we see that the data at 1.4 K gives a nice fit, giving the values $g_1 = 1.9704 \pm 0.0003$, $g_2 = 0.0511 \pm 0.0006$ and $\theta_0 = 6.1 \pm 0.3°$. The g-shift is seen to be more pronounced at low temperatures, where the effects of the short-range magnetic order are expected to become important in low-dimensional magnets. Boucher has shown that at least in the case of the 1-d antiferromagnetic compound TMMC, these effects should be attributed mostly to the anisotropy induced by the dipolar field rather than to the applied magnetic field [11].

We believe that the maximum observed in the temperature dependence of the linewidth of 2-BIMNN does not originate from a phase transition [6] but arises from the change of the dominant contribution from the long-time behaviour of the spin correlation function at high temperature to the short-time behaviour below 10 K. If this is the case, then we would expect the linewidth to be isotropic at 1.4 K, and from our experimental data where the errors on the linewidth for angular dependence studies are quite high, we can say that that is what we find. The angular dependence of the half-width follows the equation $\Delta H_{1/2} \propto |3\cos^2\theta - 1|^{4/3}$ at higher temperatures [4], but that is when the angular dependence of only the secular contribution is considered, which is expected to be dominant. In the low temperature data, we see no such dependence. The anisotropy of the linewidth not being detectable can be linked to the almost isotropic dipolar field expected from the highly symmetrical molecular arrangement [9].

Below 10 K, additional transitions in the ESR spectrum appear at fields below that of the main transition, as shown in Fig. 5. These features were observed in measurements on four different crystals of 2-BIMNN, and so we conclude that this is an intrinsic effect. They may be due either to a hitherto undiscovered structural phase transition [12] which sets in below 10 K or to the development of hyperfine structure [7] arising from the coupling between the substantially delocalised unpaired electron and the atomic nuclei on the nitronyl nitroxide group.

Frequency dependence studies were carried out at 1.4 and 50 K. The linewidth was not frequency dependent but the g-value changed slightly at 1.4 K, as shown in Fig. 6, increasing with frequency. This

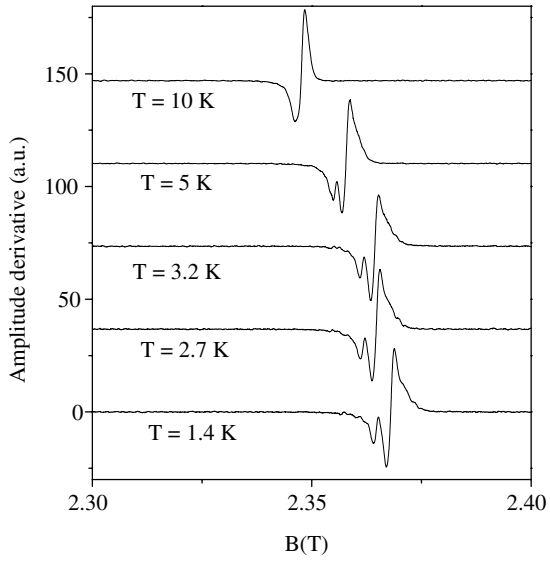

Fig. 5. The derivatives of the ESR absorption signals at different temperatures.

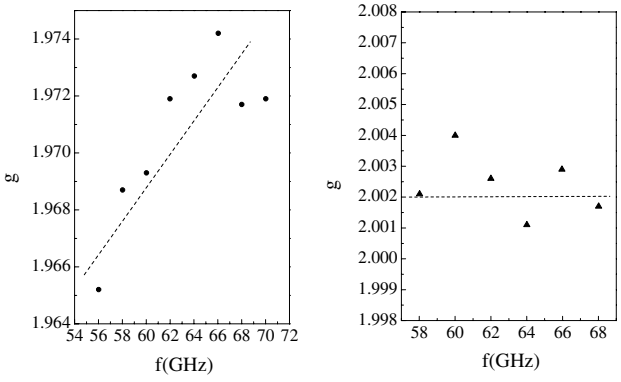

Fig. 6. g values at different frequencies at $T = 1.4$ K and $T = 50$ K.

possibly results from the field-dependence of the magnetic susceptibility which influences the difference of g from the free electron value.

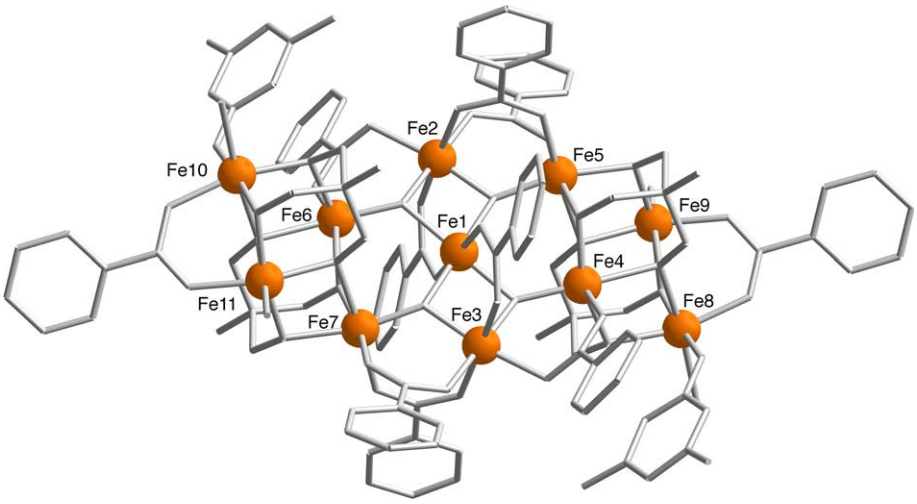

Fig. 1. Representation of the molecular structure of the Fe_{11} complex $[NEt_4][Fe_{11}O_4(O_2CPh)_{10}(thme)_4(dmhp)_2Cl_4]$ (H_3thme, 1,1,1-tris(hydroxymethyl)-ethane; dmhp, 4,6-dimethyl-2-hydroxypyrimidine). The Fe atoms are represented with spheres while the rest are indicated as sticks and the hydrogen atoms are omitted.

values, in order to advance in the understanding of the magnetic properties of such compound.

Due to the low symmetry of the complex, the spin Hamiltonian considering only the exchange coupling terms can be expressed as:

$$\begin{aligned}\hat{H} = &-J_1\left[\hat{S}_1\hat{S}_2 + \hat{S}_1\hat{S}_3\right] - J_2\left[\hat{S}_2\hat{S}_6 + \hat{S}_3\hat{S}_4\right] \\ &- J_3\left[\hat{S}_1\hat{S}_4 + \hat{S}_1\hat{S}_6\right] - J_4\left[\hat{S}_1\hat{S}_7 + \hat{S}_1\hat{S}_5\right] \\ &- J_5\left[\hat{S}_2\hat{S}_5 + \hat{S}_3\hat{S}_7\right] - J_6\left[\hat{S}_4\hat{S}_5 + \hat{S}_6\hat{S}_7\right] \\ &- J_7\left[\hat{S}_4\hat{S}_8 + \hat{S}_6\hat{S}_{10}\right] - J_8\left[\hat{S}_4\hat{S}_9 + \hat{S}_6\hat{S}_{11}\right] \\ &- J_9\left[\hat{S}_5\hat{S}_9 + \hat{S}_7\hat{S}_{11}\right] - J_{10}\left[\hat{S}_8\hat{S}_9 + \hat{S}_{10}\hat{S}_{11}\right], \end{aligned} \quad (1)$$

where $\hat{S}_i$ are the spin operators of each paramagnetic Fe(III) center. A detailed description of the procedure used to obtain the exchange coupling constants can be found in previous works [7–10] and a description of the Computational details is provided in Appendix A.

The large number of states ($6^{11} = 3.62 \times 10^8$ states) present in the Fe_{11} complex makes it impossible to perform a fitting of the measured magnetic susceptibility using the exact diagonalization approach to obtain all the J values as usually done for smaller molecules. In this case, the large number of exchange coupling constants also makes more difficult the fitting procedure because several sets of J values may fit perfectly the experimental data. Hence, the use of theoretical methods is especially important in this case to obtain a detailed description of the nature of the exchange interactions present in the Fe_{11} complex. The calculated exchange coupling constants using the PBE functional (see Appendix A for computational details) are presented in Table 1.

The calculated J values show similar trends to those obtained in the case of the Fe_8 and Fe_{19} complexes

Table 1
Description of the bridging ligands, average Fe···Fe distances and calculated exchange coupling constants J (cm^{-1}) for the Fe_{11} complex

	Bridging ligands	d(Fe···Fe) (Å)	J_{PBE}	J_{MCfit}
J_1	(μ_3-O)$_2$ (μ_2-O$_2$CPh)	2.846	−1.1	−0.14
J_2	(μ_3-O) (μ_2−O$_2$CPh)	3.414	−70.7	−70.4
J_3	μ_3-O	3.425	−48.5	−70.4
J_4	μ_3-O	3.478	−65.6	−70.4
J_5	(μ_3-O)$_2$ (μ_2-O$_2$CPh)$_2$	3.300	−70.5	−70.4
J_6	(μ_2-OR)$_2$	3.116	−16.9	−10.2
J_7	(μ_2-OR)$_2$	3.233	−19.7	−10.2
J_8	(μ_2-OR)$_2$	3.360	−16.8	−10.2
J_9	(μ_2-OR)$_2$	3.177	−13.1	−10.2
J_{10}	(μ_2-OR)$_2$ (μ_2-O$_2$CPh)	3.045	−14.6	−8.3

Values obtained using the classic Monte Carlo approach fitting of the experimental magnetic susceptibility curve are also indicated (J_{MCfit}).

[11,12]: (i) all the interactions are antiferromagnetic. (ii) The carboxylate ligands seem to play a minor role in comparison with the other bridging ligands. (iii) The single μ_3-O bridges (J_2, J_3, J_4 and J_5) usually provide the strongest coupling constants. (iv) Double oxo bridges, such as those corresponding to the J_1 interaction, result in weaker interactions than those provided by single bridges. This fact is probably due to the small Fe–O–Fe angle. (v) All the interactions through a double alkoxo bridge show similar strengths, with values close to $-20\ cm^{-1}$ (J_6, J_7, J_8, J_9 and J_{10}).

We have calculated the energies corresponding to all the single determinant distributions (2048 states), assuming that all the Fe(III) cations have M_s values of 5/2, using the calculated J values. We found that the ground state has $S = 15/2$ corresponding to the case in which the Fe4, Fe5, Fe6 and Fe7 atoms have opposite spin than the other iron atoms. The first excited single determinant state has $S = 5$ (Fe1, Fe2, Fe3, Fe9 and Fe11 with spin down), placed $126\ cm^{-1}$ above that the

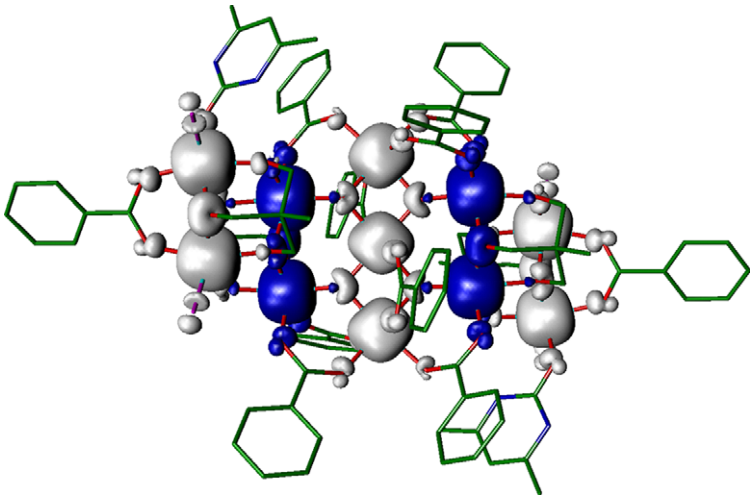

Fig. 2. Representation of the spin density map calculated at PBE level for the single-determinant ground state $S = 15/2$ of the Fe_{11} complex (clear and dark regions indicate positive and negative spin populations, respectively).

ground state. The spin density corresponding to the single determinant ground state is shown in Fig. 2. As expected, considering the d^5 electronic structure of the Fe(III) cation, the spin delocalization mechanism trough the σ system is the predominant one [13]. It is worth noting that in the case of the μ_3-O bridging ligands, the magnetic frustration is evidenced by a different sign of the spin density at the oxygen orbitals depending on their orientation relative to the Fe(III) cations with different spin sign. The presence of magnetic frustration could be responsible that the total spin of the system $S = 11/2$ cannot be described as a single determinant. In such cases, due to the frustration probably some M_s values of the Fe(III) cations will be smaller than 5/2 in order to stabilize the system.

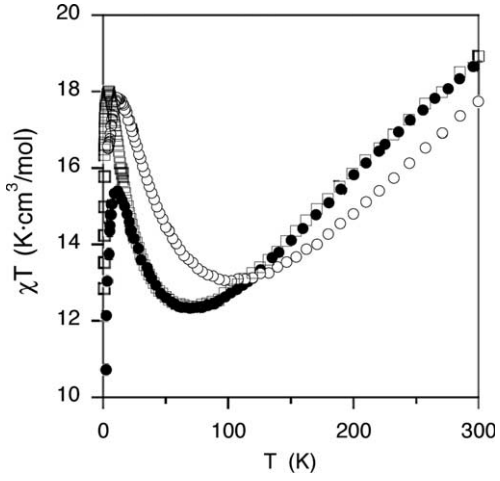

Fig. 3. Magnetic susceptibility curves of the Fe_{11} complex. The black circles correspond to experimental data. The white circles and squares were obtained directly from the DFT J values and from a fitting procedure using Monte Carlo simulations with the calculated values as starting point, respectively (see both sets of values in Table 1).

In order to compare our results with the available experimental data (see Fig. 3), we have performed Monte Carlo simulations to obtain a magnetic susceptibility curve based on the calculated J values (see Appendix A for a description of the simulations). The resulting susceptibility curve obtained from the calculated DFT J values nicely reproduces the expected values for a $S = 11/2$ ground state. The DFT results reproduce very well the experimental data taking into account that small changes in the J values modify considerably the shape of the magnetic susceptibility curve. The use of the calculated J values as starting point for a fitting procedure, using only four different J coupling constants corresponding to the exchange pathways through different bridging ligands, confirms that with small changes in the initial sets of values the experimental curve can be fitted (see Table 1). We have selected only four exchange coupling constants in order to avoid numerical problems during the fitting procedure.

2. Conclusions

The use of theoretical methods based on density functional theory provides a detailed knowledge of the exchange interaction present in the large Fe_{11} systems where it is not possible to extract such information from the magnetic susceptibility data. We have obtained basically the same trends and values than for other polynuclear Fe(III) complexes, [11,12] the μ_3-O bridging ligands are those with strongest antiferromagnetic coupling in comparison with the double oxo bridges. The use of the calculated J values in a Monte Carlo simulation gives a magnetic susceptibility curve very close to the experimental data despite of the limitations of the

classical Monte Carlo approach. Moreover, the fitting of the experimental results using as starting points the calculated J values results in a good fit with J values very close to those obtained from the DFT calculations.

Appendix A

Electronic structure calculations have been performed using the SIESTA (Spanish Initiative for Electronic Simulations with Thousands of Atoms) code [14–17]. The generalized-gradient approximation (GGA) functional proposed by Perdew, Burke and Erzernhof (PBE) [18] was employed and pseudopotentials were generated according to the procedure of Trouiller and Martins [19] (see [12] for a more detailed description). We have used a numerical basis set of triple-ζ quality with polarization functions for the iron atoms and a double-ζ one with polarization functions for the main group elements. The values of 50 meV for the energy shift and 250 Ry for mesh cutoff provide a good compromise between accuracy and computer time to estimate the exchange coupling constants according to a previous study [12]. This approach provides good results despite the use of a GGA functional, that is well-known to give too large J values due to an overestimation of the spin delocalization [8], because the use of pseudopotentials partially compensates this problem.

The 11 calculations performed in order to obtain the 10 exchange coupling constants: the high spin state and ten additional calculations inverting the spin of some atoms, to indicate such spin distributions, we will write within parenthesis the atoms with spin down (1), (2,3), (4,6), (5,7), (8,10), (9,11), (1,2,3), (1,4,6), (5,7,9,11) and (4,5,6,7). Moreover, we have also calculated the first excited single determinant corresponding to a (1,2,3,9,11) spin distribution.

The magnetic susceptibilities have been calculated using Monte Carlo simulations with the Metropolis algorithm [20,21]. A sampling of states was generated to obtain the average magnetization M using Eq. (2) that includes the configurations that bring important contributions at temperature T.

$$\langle M\rangle = \frac{\sum_{i=1}^{n} M_i e^{-E_i/kT}}{\sum_{i=1}^{n} e^{-E_i/kT}}. \quad (2)$$

Thus, the magnetic susceptibility, χ_m, can be obtained from the fluctuations in the magnetization by employing Eq. (3), where $\langle M\rangle$ and $\langle M^2\rangle$ are the mean values of M and M^2.

$$\chi = (\langle M^2\rangle - \langle M\rangle^2)/kT. \quad (3)$$

The number of steps in the Monte Carlo simulation is different for each temperature, being $10^7/T$ (T in K). Hence, we have more steps in the sampling at low temperature because it is more difficult to describe correctly the magnetic behavior at such temperatures. At the beginning of the simulation 10% of the steps are employed for the thermalization of the system.

crystal using as only data the (microscopic) magnetic pair interactions (J_{AB}) between A and B constituent radicals of the crystal. These J_{AB} exchange interactions are computed for all unique A–B pairs present in the crystal using theoretical methods. This calculation only requires the crystal structure data of the system to be studied. This *bottom–up* approach enables to connect the macroscopic properties (magnetic susceptibility, for instance) with their microscopic origin, the J_{AB} exchange interactions. Consequently, it provides a rational analysis of the magnetic properties of a crystal. This approach has been successfully applied to well-known molecule-based crystals having dominant ferromagnetic or antiferromagnetic properties, and also to bulk ferromagnets [4,5]. Recently, we have also applied this approach to the study of through-bond magnetic crystals [6]. Let us mention here that these studies have shown that the microscopic J_{AB} exchange interactions are not always equal to the experimental J constant obtained from fitting the magnetic susceptibility curves to an empirical expression. Often, such empirical model is an over-simplification of the true topology of the magnetic interactions, and the J values are only averaged or effective constants.

In this work, we will apply our *bottom–up* approach to study the magnetism of the *meta*-(methoxy)phenyl nitronyl nitroxide crystal, *m*-(OMe)PhNN (see Fig. 1(a)). This crystal is sometimes identified by its REFCODE name [7], YISCIM. Our interest in this crystal is many-fold. First of all, its magnetism is not fully understood, because no information is available on its magnetic exchange pathways and their topology. The only experimental study available [8] indicates that the magnetic susceptibility of YISCIM obeys the Curie–Weiss law, being the paramagnetic θ equal to -0.97 K. Furthermore, room-temperature EPR studies on YISCIM [8] have allowed to conclude that $|J| = 1.6\ \mathrm{cm}^{-1}$. On the other hand, the molecular structure of *m*-(OMe)PhNN radical is very close to the structure of *para*-(methylthio)phenyl nitronyl nitroxide radical, *p*-(SMe)PhNN, whose crystal behaves as a bulk ferromagnet. It would thus be very interesting to find connections between the magnetic properties of these two radicals and the structure of these radicals and their corresponding crystals. Finally, once the analysis of YISCIM had started, we found a feature that makes its study even more attractive: it presents ferro and antiferromagnetic pathways of similar strength. This fact makes impossible to predict its dominating magnetic behavior based on the usual qualitative considerations. Only by using a quantitative methodology, like the *bottom–up* procedure employed here, one can determine the tendency of the magnetic susceptibility curve. In this work, we will also perform numerical simulations trying to investigate the conditions under which the competition between the ferro and antiferromagnetic exchange pathways results in a dominating ferro or antiferromagnetic macroscopic behavior.

1.1. Computational details

Magnetism in organic solids is usually interpreted on a local (microscopic) scale via the exchange interaction J_{AB} between neighboring radicals A and B for all unique pairs present in the crystal. We have shown before [4–6] that it is possible to connect in a quantitative and accurate form the magnitude and topology of these J_{AB} pair exchange interactions with the macroscopic magnetic susceptibility $\chi(T)$, and other macroscopic magnetic properties (heat capacity $C_p(T)$, etc.). Such *bottom–up* procedure consists of the following four steps:

(1) *Analysis of the crystal packing*: All possible unique A–B radical pairs *di* present in the crystal that are good candidates to present sizable values of the microscopic magnetic interaction J_{AB} are identified.

(2) *Computation of the dimeric J_{AB} interactions*: The J_{AB} magnetic interactions are computed for all *di* pairs of radicals selected in the previous step, using the appropriate computational methods.

(3) *Definition of the magnetic topology of the crystal*: The magnetic topology is determined by inspection of the connectivity of the non-negligible J_{AB} pair interactions. Each radical can be seen as a point site, which is connected to another when $|J_{AB}|$ is larger than a given threshold (estimated as $|0.05|\ \mathrm{cm}^{-1}$ in our calculations).

(4) *Construction of a finite Heisenberg spin Hamiltonian that represents the problem and calculation of the macroscopic magnetic properties*: In this step, we search for the smallest subset of non-negligible J_{AB} pair interactions that describes the crystal magnetic topology in a balanced way (we have called it the *minimal magnetic model space*). Such model is then used to compute the matrix representation of the Heisenberg Hamiltonian[1]:

$$\hat{H} = -\sum_{A,B}^{N} J_{AB}\left(2\hat{S}_A \cdot \hat{S}_B + 1/2\hat{I}_{AB}\right), \qquad (1)$$

being $\hat{S}_A$ the spin operator associated with radical A, $\hat{I}_{AB}$ the identity operator, and N the number of radicals in the minimal magnetic model space. The only input data required to build this Heisenberg Hamiltonian are the J_{AB} values computed in step 2. The matrix representation of the Heisenberg Hamiltonian (1) is thus built in the basis of spin eigenfunctions of the minimal magnetic model space. It is then diagonalized and the resulting set of eigenvalues is used to compute the macroscopic magnetic property of interest (usually $\chi(T)$) applying the standard expressions of statistical mechanics.

This procedure, besides producing numerical values of $\chi(T)$ that present the same shape than the experimental $\chi(T)$ curve [4–6], provides a detailed understanding of the macroscopic measured properties in terms of J_{AB} pair interactions and their magnetic topology. One must realize here that both J_{AB} interactions and magnetic topology are only a function of the crystal packing. This is a specific advantage of the *bottom–up* procedure not encountered in many other methods currently available to analyze magnetic properties of crystals. The procedure is totally unbiased, and only requires an accurate crystal structure, which should be determined at a low enough temperature to avoid the distortion induced in the crystal by the thermal expansion. Otherwise, one can reach misleading conclusions [5c,6].

[1] The Heisenberg Hamiltonian (1) gives the same energy spectra than the usual one in which the second term is not present, but it is more convenient for our computer programs.

Besides the previous general considerations, it is interesting to comment a few specific points about how the above procedure has been applied to YISCIM crystal. First of all, concerning the selection of radical pairs (step 1), all *A–B* radical pairs whose ONCNO···ONCNO distance in YISCIM is smaller than 7.4 Å were selected to calculate their exchange interaction J_{AB}. This cutoff deliberately includes more pairs than the first nearest neighbors, which are the usual candidates in the literature. We chose the ONCNO···ONCNO distance because, in the case of the *m*-(OMe)PhNN radical, B3LYP/6-31+G(d) calculations indicate that the spin density is mostly delocalized on the ONCNO group (see Fig. 1). However, such large cutoff allowed us to investigate possible alternative magnetic pathways, as those involving the O of the CH_3O groups. The value of J_{AB} for all biradical pairs identified in step 1 was computed using density functional (DFT) methods [9]. More specifically, we used the B3LYP functional [10] and the 6-31+G(d) basis set [11]. The energy of the singlet was computed using the broken-symmetry approximation [12], which has been shown to give a reasonable good description of open-shell singlet states. The magnitude of J_{AB} was computed as $J_{AB} = E^{S}_{BS} - E^{T}$ because in our calculations the open-shell singlet state had both half-filled orbitals localized on one radical or on the other and, thus, their overlap was negligible ($S_{ab} = 0$). This fact reveals unnecessary the usual correction employed with Hartree–Fock wavefunctions (see [5c] and references therein for a more detailed discussion). All DFT calculations performed in this study were carried out using the GAUSSIAN 98 package [13].

2. Results and discussion

2.1. Electronic structure of the m-(OMe)PhNN radical

The *m*-(OMe)PhNN radical presents a doublet ground state at the geometry found in the YISCIM crystal. In such electronic state, the B3LYP/6-31+G(d) spin density (Fig. 1(b)) presents the usual spin distribution found within the nitronyl nitroxide family [14]: there is a region of high density on the ONCNO atoms of the five-membered ring (NO and central C atoms show positive and negative spin densities, respectively), and much smaller amounts on the C atoms of the phenyl Ph ring, with alternation of sign between adjacent atoms. In addition, the amount of spin on the C atom of the methoxy OMe group is negligible, and the spin density on the O atom of the same group is even smaller than that on the C atoms of the Ph skeleton. The spin density on all H atoms is negligible. The analysis of the atomic spin populations (obtained according to the Mulliken method) provides the same picture, as can be concluded by looking at the atoms having the

maximum of population: N(NO) = 0.31, O(NO) = 0.33, C(ONCNO) = −0.24, |C(Ph)| = 0.06, O(OMe) = 0.002, H < 0.001 electrons.

2.2. Determination of the magnetic topology

The crystal packing structure of the *m*-(OMe)PhNN radical (YISCIM crystal) has been determined at room-temperature by Angeloni et al. [8]. YISCIM crystallizes into the $P2_1$ space group (a = 6.391 Å, b = 11.230 Å, c = 10.228 Å, β = 107.78°) with two radical molecules per unit cell. The packing structure can be described by a set of *A* planes piled along the *c* axis (see Fig. 2(a)). Within each *A* plane the radicals are packed in a T shape, as shown in Fig. 2(b). Any given radical is related to four others by means of C–H···O hydrogen bonds. In two cases (indicated by I in Fig. 2(b)), the two radicals simultaneously form one C(sp^2)–H···ON and one C(sp^2)–H···OCH_3 hydrogen bonds (with H···O distances of 2.325 and 2.939 Å, respectively). In the other two cases (II in Fig. 2(b)), the radicals establish multiple C(sp^3)–H···ON involving the methyls and NO groups of the five-membered ring (the shortest H···O distance being 2.343 Å). Besides the hydrogen bonds, there are two other radicals related to the central radical by C–H···H–C interactions (III in Fig. 2(b)) (the shortest H···H distance being 2.473 Å). As a result of this packing there is no direct overlap between NO groups, being the shortest NO···ON distance within any *A* plane of 6.031 Å (later on this radical-pair will be identified as *d3*). However, there are many short NO···ON contacts between radicals in adjacent *A* planes, as we will see below.

A systematic analysis of the crystal packing, done by looking at the distances from a given radical to all its nearby surrounding radicals, shows that there are four radical pairs (identified below as *d1–d4*) whose ONCNO···ONCNO intermolecular distance is less than 7.4 Å. Notice that all pairs, except *d3*, correspond to contacts between radicals in adjacent *A* planes. In addition to the *d1–d4* pairs, we have also searched for those radical-pairs whose NO···OMe distance is shorter than 7.4 Å. For YISCIM, there is only one extra pair that has to be considered, hereafter identified as *d5*.

The *d1–d5* pairs of radicals define possible magnetic pathways for exchange interactions J_{AB} between the radicals. The topology of these *di* pairs within the crystal forms the complex three-dimensional network depicted in a schematic form in Fig. 3 (in this figure each radical is represented as a point site, for clarity purposes). The *d2* and *d5* pairs form planes along the crystallographic *ab*-axes, being these planes alternatively connected either by *d1, d3* or *d4* pairs. Notice the zigzag form of the connections made by *d1*, *d3* and *d4*.

The computed J_{AB} values for the *d1–d5* pairs are shown in Table 1: only three pairs, *J*(*d2*), *J*(*d3*) and

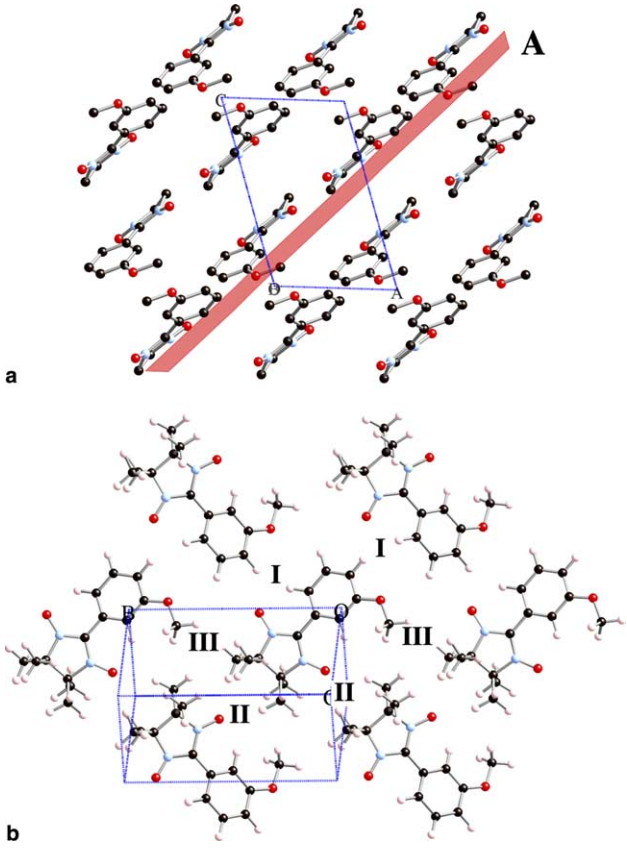

Fig. 2. View of the crystal structure of YISCIM: (a) view along the *b* axis, indicating one of the *A* planes; (b) view of one *A* plane along a perpendicular view (**I**, **II** and **III** refer to the different packing motifs within each *A* plane, see text for a more detailed description).

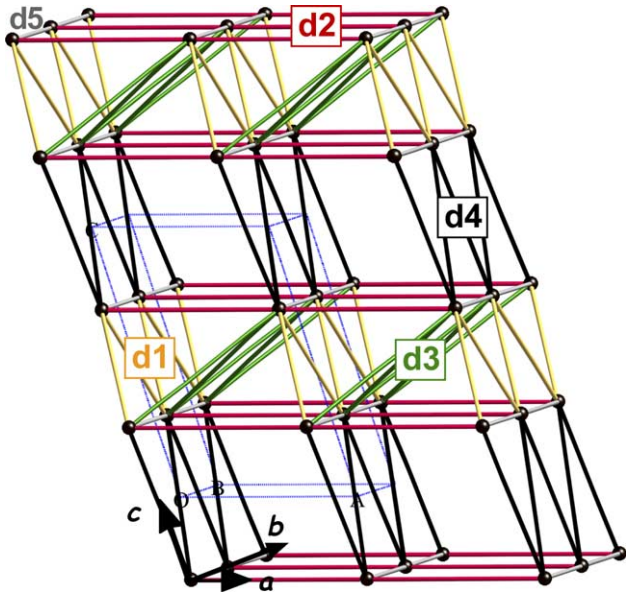

Fig. 3. Scheme of the packing of YISCIM, indicating the position and connectivity of the *di* radical-pairs that fulfill the distance cutoff criterion (*d1–d5*). Notice that each *m*-(OMe)PhNN radical has been replaced by a point site.

Table 1
Unrestricted DFT broken symmetry UB3LYP/6-31 + G(d) results for pair interaction $J(di)$ of all candidates (listed as shortest intermolecular NO···ON distance increases; the shortest NO···OMe distance is also given) for YISCIM

Dimer *di*	NO···ON (Å)	NO···OMe (Å)	$J(di)$ (cm^{-1})
d1	4.64	6.60	$\ll\|0.05\|$
d2	5.40	6.46	−0.20
d3	6.03	6.91	−0.11
d4	6.66	4.00	+0.22
d5	8.42	5.31	$\ll\|0.05\|$

Notice that *d1–d4* were chosen in terms of NO···ON distance criterion (<7.4 Å), while *d5* was selected due to presenting NO···OMe distances shorter than 7.4 Å (*d4* could have also been selected according to such criterion).

$J(d4)$, have values of J_{AB} larger than $|0.05|\ cm^{-1}$. It is worth noticing that the strength of J_{AB} is not proportional to the NO···ON distance, thus stressing the importance of the relative radical pair orientation, and/or of the other intermolecular interactions the radical pairs can establish between them.

The *magnetic topology* (Fig. 4(a)) is obtained by accounting for the connectivity of the radical-pairs having $J_{AB}(di)$ values larger than $|0.05|\ cm^{-1}$ (or by deleting those *di* pairs in Fig. 3 whose $J_{AB}(di)$ value is smaller than $|0.05|\ cm^{-1}$). In YISCIM (see Fig. 4(a)), the magnetic topology can be visualized as bent planes of connected $J(d3)$ and $J(d4)$ zigzag chains (green and black)

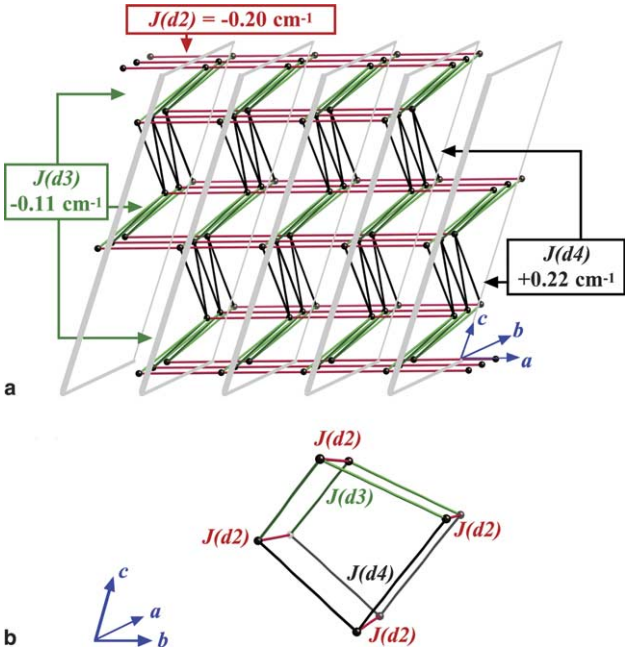

Fig. 4. (a) Magnetic topology of YISCIM: zigzag antiferromagnetic $J(d3)$ and ferromagnetic $J(d4)$ chains form bent *bc*-planes, that interact along the *a* axis through antiferromagnetic $J(d2)$ interaction. Notice that each *m*-(OMe)PhNN radical has been replaced by a point site. (b) Three-dimensional minimal magnetic model (8s), which consists of eight radicals forming a hexahedral figure.

running along the *bc* crystallographic axes, which are interconnected along the *a* axis by antiferromagnetic $J(d2)$ interactions (red). Within any *bc*-plane, one chain is ferromagnetic ($J(d4) = +0.22\ cm^{-1}$, in black), while the adjacent ones are antiferromagnetic ($J(d3) = -0.11\ cm^{-1}$, in green). The overall magnetic topology is three-dimensional, and does not follow any simple magnetic motif.

2.3. Construction of the Heisenberg Hamiltonian and calculation of the magnetic susceptibility

There are two conditions that one has to keep in mind when selecting the N magnetic centers (in this case of spin $S = 1/2$) that constitute the *minimal magnetic model space*: (i) the three-dimensional magnetic topology of the crystal must be recovered by extension of the minimal model along the (a,b,c) crystallographic axes, and (ii) all important J_{AB} interactions must be present with a weight and environment that mimics that found in the crystal (see Fig. 4(a)). When these considerations are applied to YISCIM, the smallest spin space that reproduces the magnetic topology of Fig. 4(a) is the hexahedral model depicted in Fig. 4(b). We have previously shown [5c] that a four sites model (hereafter identified as the 4s-model) is required to reproduce the magnetic susceptibility of a system whose magnetic topology is a two-dimensional layer (note that depending on J_{AB} values the 4s-model will be represented by a square, rectangle, or trapezoid). Thus, for YISCIM, two interacting layers should require two interconnected trapezoidal 4s-models as depicted in Fig. 4(b). We will identify such a minimal magnetic model as the 8s-model. Such 8s-model presents all types of J_{AB} interactions in a proportion and environment similar to that found in Fig. 4(a), and regenerates the zigzag planes by propagation along *b* and *c* axes, and the whole topology of Fig. 4(a) when further propagated along *a*.

With the set of spin eigenfunctions of the 8s-model and the values of the J_{AB} parameters of Table 1, we built the matrix representation of the Heisenberg Hamiltonian (1). The energy levels of this Heisenberg Hamiltonian were then computed by diagonalization of that matrix. These eigenvalues were used in the appropriate statistical formulae (see [4]) to compute the macroscopic magnetic susceptibility $\chi T(T)$ curve (Fig. 5(a)). This curve closely reproduces the experimental $\chi T(T)$ curve obtained in the 4.2–250 K temperature range (the experimental curve was obtained by taking the expression for the Curie–Weiss law, $\chi = C/(T-\theta)$, with $\theta = -0.97$ K [8] and using the Curie constant $C = 0.376$ emu K mol^{-1}). We have tested the convergence of our computed $\chi T(T)$ curves against an increase of the size of the minimal magnetic model space by extending the 8s-model space along (a,b,c) crystallographic axes (models $(8s) \times 1.5a$, $2a$, $2b$, $2c$, $1.5bc$). As shown in

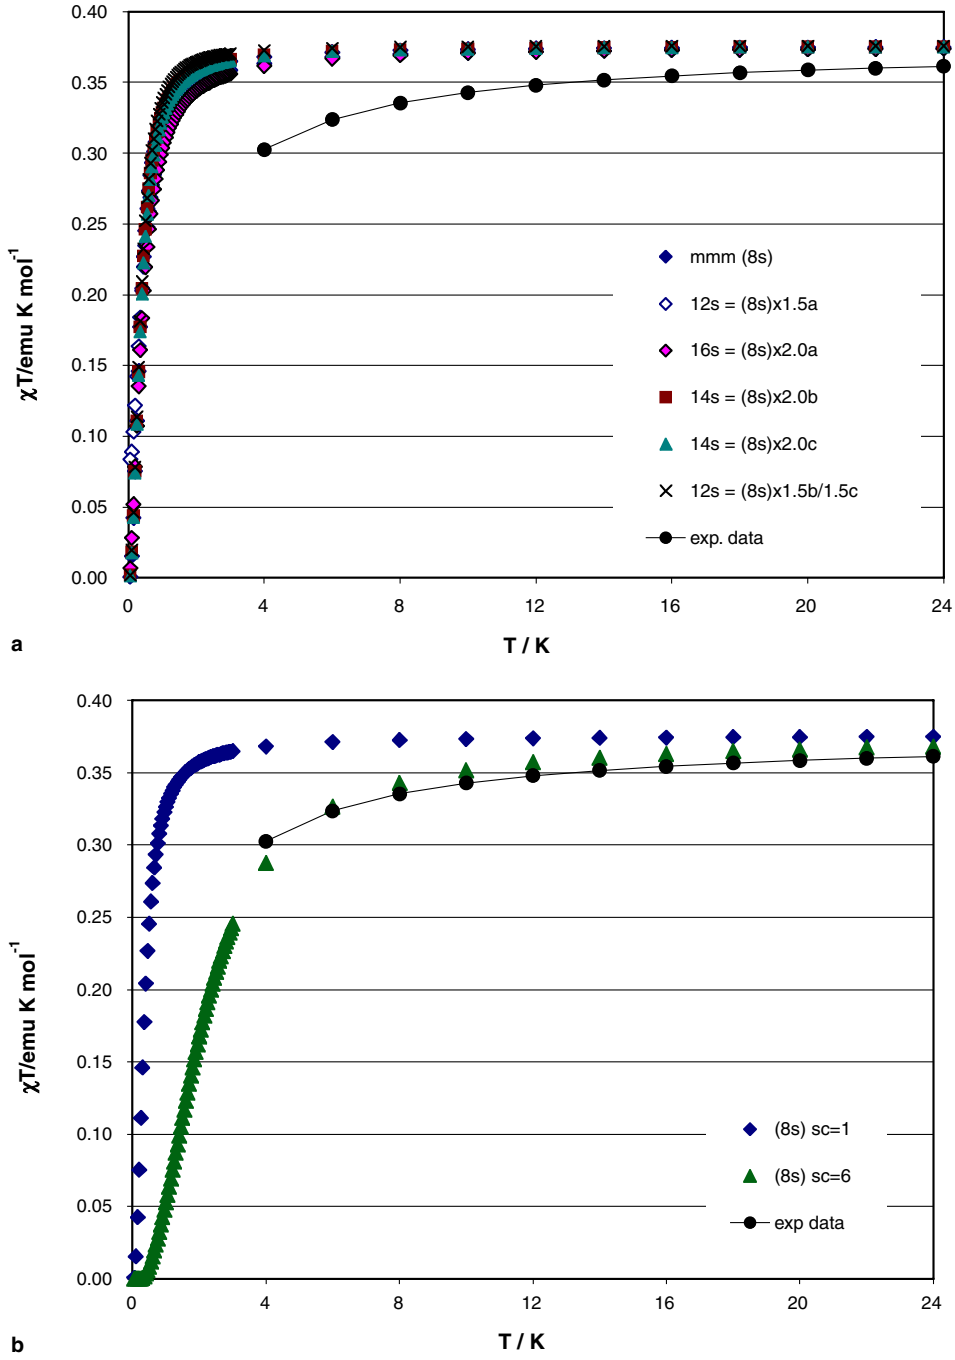

Fig. 5. Comparison between computed and experimental magnetic susceptibility $\chi T(T)$ of YISCIM: (a) results using (8s) model and its extension along (*a,b,c*) crystallographic axes; (b) an scaling factor of 6.00 is sufficient to reproduce the experimental curve.

Fig. 5(a), the $\chi T(T)$ curves obtained with the extended models nearly match the $\chi T(T)$ values computed using the 8s-model, although some numerical differences remain with the experimental curve. The small differences found between the computed and experimental curves can be recovered by the use of a scaling factor (Fig. 5(b)) as we will elaborate below. These magnetic susceptibility curves indicate that YISCIM behaves as a dominant antiferromagnet, despite the fact that it has one ferro and two antiferromagnetic J_{AB} interactions of similar magnitude and weight (Fig. 4(b)).

Let us focus now into the source of the difference between computed and experimental magnetic susceptibility curves. There are various possible causes. First of all [5a,6], we have recently come across the fact that the discrepancy between simulated and experimental data can be tracked down to the use of crystal coordinates determined at room temperature instead of using

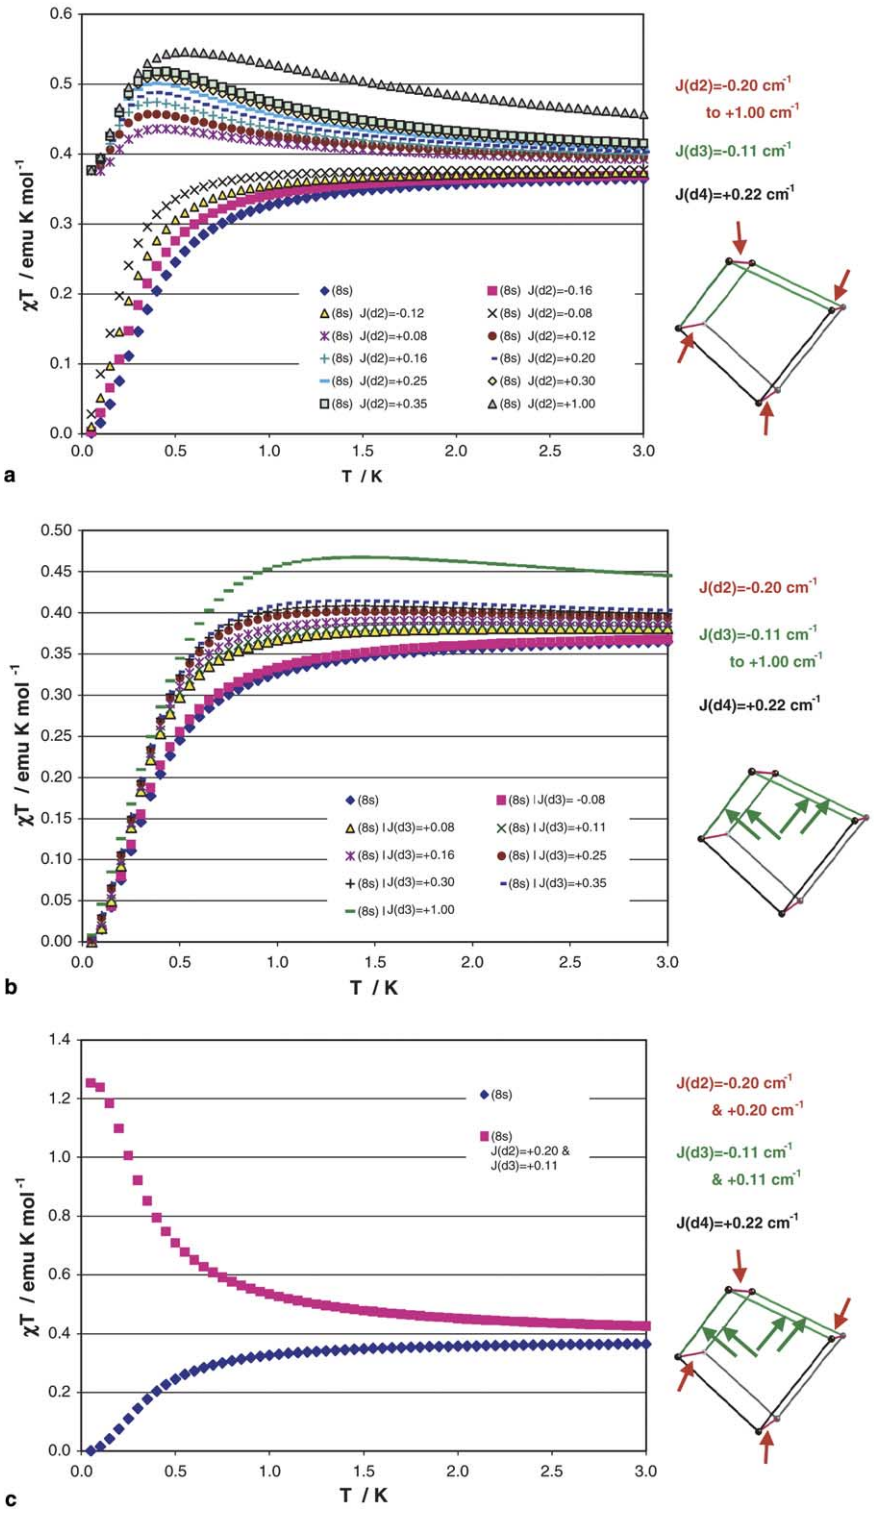

Fig. 6. Series of numerical simulations on the competition between FM and AFM J_{AB} pair interactions by systematically changing $J(d2)$ and $J(d3)$ values (see main text for discussion).

low-temperature structures. In another words, thermal expansion is not always isotropic and can induce subtle changes in the structure of the pairs that create non-negligible changes in the computed J_{AB} microscopic magnetic interactions. Besides the thermal expansion effect, there might be systematic errors in the computation of the J_{AB} due (i) to the use of DFT methods, instead of more sophisticated methods, or (ii) to collective

exchange effects, which are not considered in the dimer approach employed here. We have previously shown [4,5] that one can recover these discrepancies by multiplying the energies by a linear scaling factor, whose effect in the spectrum of energies of the Heisenberg Hamiltonian is just separating these energies uniformly. For YISCIM, the scaling factor that best matches the experimental data using the 8s-model is 6.0 (Fig. 5(b)). With this factor, the difference between the computed and experimental magnetic susceptibility curves becomes acceptable, specially considering that the computed $\chi T(T)$ curve has been obtained using the crystal structure determined at room temperature.

2.4. Numerical simulations on the competition between ferro and antiferromagnetic exchange pathways

Using the 8s minimal magnetic model space, we have carried out a few numerical studies changing systematically the values of the two antiferromagnetic J_{AB} pair interactions, in order to explore the reasons for the dominant antiferromagnetic behavior of the crystal and what pair interaction is the one responsible for the overall magnetic behavior. In all series of simulations, we have taken as a reference the values of $J(d2)$, $J(d3)$ and $J(d4)$ pair interactions computed using the room temperature crystal structure of YISCIM.

We first analyzed the effect of changing $J(d2)$ while keeping $J(d3)$ and $J(d4)$ constant using the computed values at room temperature ($J(d3) = -0.11$ and $J(d4) = +0.22\ \mathrm{cm}^{-1}$). Let us remind here that $J(d3)$ and $J(d4)$ define the topology of the *bc*-layer, which is represented by a trapezoidal 4s-model. Tests on such 4s-model showed that macroscopically has a dominant ferromagnetic behavior, contrarily to the antiferromagnetic behavior of the 8s minimal model. Therefore, we changed the $J(d2)$ parameter from -0.20 to $+1.0\ \mathrm{cm}^{-1}$, by steps of approximately $0.04\ \mathrm{cm}^{-1}$, expecting to achieve an overall ferromagnetic behavior. The computed magnetic susceptibility curves are collected in Fig. 6(a), together with that obtained using the original J_{AB} values computed using the YISCIM structure at room temperature. These curves show that by modifying the $J(d2)$ parameter it is possible to obtain the $\chi T(T)$ curve characteristic of a weak ferromagnet, but never the shape of a dominant ferromagnet.

We carried a second series of simulations (see Fig. 6(b)) changing the value of the $J(d3)$ parameter from -0.11 up to $+1.0\ \mathrm{cm}^{-1}$, while keeping $J(d2)$ and $J(d4)$ constant at their reference YISCIM values (-0.20 and $+0.22\ \mathrm{cm}^{-1}$, respectively). The conclusion is analogous to the previous simulation and no net dominant ferromagnetic behavior was obtained. With the changes introduced in this series, the *bc*-layers have become ferromagnetic and just the inter-layer antiferromagnetic $J(d2)$ interaction is responsible for the failure to obtain an overall ferromagnetic behavior. Only when all three J_{AB} parameters become ferromagnetic a net dominant ferromagnetic behavior for the magnetic susceptibility $\chi T(T)$ curve is finally obtained (see Fig. 6(c)).

We have thus found that small changes in the size of the $J(d2)$, $J(d3)$ and $J(d4)$ parameters close to the computed room temperature YISCIM values do not induce marked changes in the shape of the $\chi T(T)$ curves. This conclusion was unexpected to us, and suggests that more detailed and systematic studies should be done to determine the importance of the magnetic topology on these results. We plan to do so in a quantitative way, looking at the weight of the populations of the ferro versus antiferromagnetic states.

2.5. Comparing the magnetic properties of (OMe)PhNN and (SMe)PhNN crystals

The most remarkable similarity between the *m*-(OMe)PhNN radical and its thio-substituted counterpart is the nearly identical spin distribution that they present. Almost no spin density is present on the O and S atoms of the XMe (X = O or S) groups: the Mulliken spin population on the O(OMe) atom of the *m*-(OMe)PhNN radical and on the S(SMe) atom of the *m*-(SMe)PhNN radical is 0.002 and -0.007 electrons, respectively (the difference is almost negligible), while the population on the remaining atoms is nearly the same. Therefore, as the strength of the C–H···O and C–H···S intermolecular bonds is also similar, one could expect that the (OMe)PhNN and the (SMe)PhNN radicals would pack in a similar form and have similar magnetic properties. These expectations are confirmed in the *para* isomer of the radicals, as both present a dominant ferromagnetic behavior (in fact, the *p*-(SMe)PhNN crystal is one of the few purely organic bulk ferromagnets). A detailed study of these similarities is, however, out of the intended scope of this paper and will be the subject of a future communication.

3. Conclusions

A *bottom–up* theoretical procedure [4–6] has been applied to the room temperature crystal (YISCIM) of the *m*-(OMe)PhNN radical, a case of competing ferro and antiferromagnetic J_{AB} pair interactions whose overall behavior is that of a dominating antiferromagnet. We have computed the magnetic topology of this crystal and found it to consists of bent planes along the *bc*-directions, interconnected along the *a* axis by antiferromagnetic $J(d2)$ interactions. These *bc*-planes result from antiferromagnetic $J(d3)$ and ferromagnetic $J(d4)$ interactions forming zigzag chains.

The macroscopic magnetic susceptibility obtained from a magnetic topology like that of YISCIM cannot

be predicted using the usual qualitative considerations and requires of an appropriate numerical calculation, like that done in steps 3 and 4 of our bottom–up approach. For YISCIM, our computed magnetic susceptibility curve reproduces the overall shape of the experimental curve, although there are some numerical discrepancies between simulated and experimental $\chi T(T)$ data. These differences can originate from the use of a room temperature crystal structure (which surely presents thermal distortions with reference to the low temperature structure of interest), and/or small numerical errors due to the computational techniques employed. The discrepancies can however be recovered by the use of a linear scaling factor that multiplies the energy of all the magnetic states possible in our crystal. With a scale factor of 6.0 we have obtained the best agreement with the experimental $\chi T(T)$ data.

We have also explored, by means of numerical simulations in which the values of the J_{AB} pair interactions are slightly modified from the YISCIM computed values, forms of transforming the dominant antiferromagnetic behavior into a dominant ferromagnetic behavior. We have concluded that small changes in the antiferromagnetic $J(d2)$ and $J(d3)$ interactions do not induce a clear overall ferromagnetic behavior, but more detailed studies are required in order to understand why this is so.

Finally, a qualitative analysis has been done on the similarities between the (OMe)PhNN radical studied here and its sulphur-substituted counterpart, the (SMe)PhNN radical, which indicates that they should present a similar crystal packing and magnetic properties.

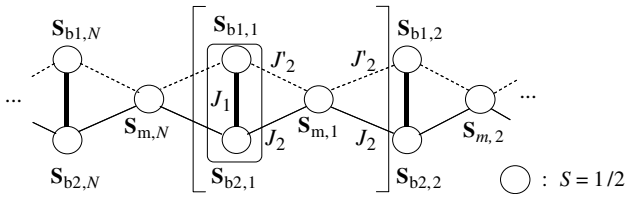

Chart 1. Schematic view of the Heisenberg spin Hamiltonian of the alternating biradical–monoradical chain system. The circles denote the $S = 1/2$ spins. J_1 represents the intramolecular coupling in the biradical, while J_2 and J'_2 denote the intermolecular exchange interactions.

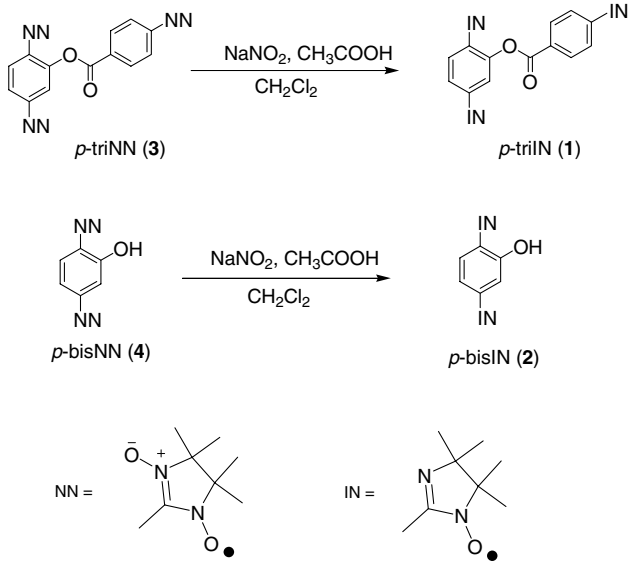

the generalized ferrimagnetism have never been disclosed until genuinely organic magnetism appeared.

The design of building blocks of molecule-based magnetic materials is one of the most important issues because the molecular packing of the building blocks in a crystalline solid state governs magnetic properties of the molecular assemblages. Referred to molecular crystal engineering, we have proposed an approach of single-component ferrimagnet, which consists of π-monoradical and π-biradical entities bridged by σ-bonds [4]. In this approach, the π-conjugation is effectively truncated at the σ-bond bridge and thus the amplitude of the exchange interactions between the two molecular entities $J(\sigma)$ and $J'(\sigma)$ are expected to be much smaller than that within the biradical entity $J(\pi)$, as illustrated in Chart 2:

$$|J(\sigma)|, \quad |J'(\sigma)| \ll |J(\pi)|. \tag{2}$$

The condition Eq. (2) gives the multiple magnetic degrees of freedom for the biradical and monoradical entities in the single molecule of the resultant triradical. When the triradical molecules are arranged to form a head-to-tail molecular packing, there is expected an alternating chain of the biradical and the monoradical moieties in a crystalline solid state, as depicted in Chart 2. The σ-bonds in the triradical are magnetically inactive as magnetic interaction pathway and play the role of only forming the structural framework, while the magnetic interactions are propagated by the through-space π-orbital overlaps between the molecular entities of the adjacent molecules in the crystalline solid. The conceptual advance of the molecular designing for the σ-bonded π-oligoradicals lies in the fact that inequivalent magnetic entities such as π-biradicals and π-monoradicals are forced to coexist in a crystalline solid state. A conventional ferrimagnetic spin alignment, i.e., an antiparallel coupling of $S = 1$ and $S = 1/2$ spins has been found for a triradical composed of a ground-state triplet biradical and a doublet monoradical [4]. In the present study, the approach of the σ-bonded π-oligoradicals is applied to the case of the constituent biradical entity with the singlet ($S = 0$) ground state, leading to a model compound for the generalized ferrimagnetism.

In our previous study, a nitronylnitroxide triradical (**3**, Scheme 1) has been synthesized and its magnetic properties examined [5]. In the triradical **3**, a π-conjugated biradical with a singlet ground state and a doublet monoradical are united by σ-bonds. The amplitude of $|J(\pi)|$ has been found to be larger than $|J(\sigma)|$ and $|J'(\sigma)|$ by three orders of magnitude; $2J(\pi)/k_B = -70$ K, $2|J(\sigma)|/k_B \sim 2|J'(\sigma)|/k_B \leqslant 0.01$ K [5]. The condition of Eq. (2) is fulfilled in the triradical **3**. The triradical **3** can be used as a building block for the generalized ferrimagnetism. We report here the designing and synthesis of a novel iminonitroxide triradical, *p*-triIN (**1**, Scheme 1), possessing a *para*-phenylene-based biradical moiety with a singlet ground

Scheme 1. Synthesis of *p*-triIN (**1**) and *p*-bisIN (**2**).

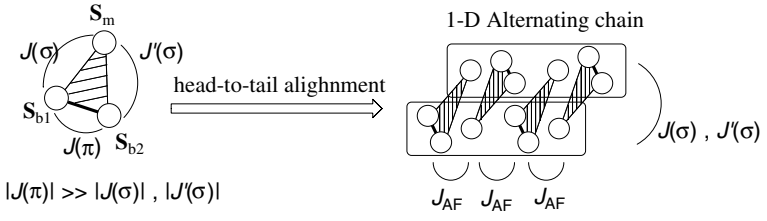

Chart 2. Schematic view of the single-component ferrimagnetic approach. The doubled chain with the intermolecular antiferromagnetic interactions J_{AF} (=J_2 and J'_2) is composed of the triradicals packed in a head-to-tail fashion. The exchange interactions between the chains correspond to the intramolecular magnetic couplings $J(\sigma)$ and $J'(\sigma)$.

state and a monoradical moiety as another model for the generalized ferrimagnetism. We present the magnetic properties of **1** and its parent biradical, *p*-bisIN (**2**, Scheme 1). Possible occurrence of the exotic ferrimagnetic spin alignment in the iminonitroxide triradical **1** is discussed from magnetic susceptibility measurements.

2. Experimental

2.1. Synthesis

The iminonitroxide triradical (**1**) and the biradical (**2**) were synthesized from the nitronylnitroxide triradical (**3**) [5] and biradical (**4**) [5], respectively, as shown in Scheme 1.

*p-triIN (**1**)*. Nitronylnitroxide triradical (**3**) (0.50 g, 0.75 mmol) was added to a suspension of $NaNO_2$ (0.47 g, 6.78 mmol) in CH_2Cl_2 (8 mL) and CH_3COOH (0.50 mL, 8.71 mmol). The reaction mixture was stirred for 10 min to give a bright orange solution. After filtration and neutralization with aqueous $NaHCO_3$, the organic layer was washed with water, and the aqueous phase was extracted with CH_2Cl_2 (100 mL). The combined organic phase was dried over $MgSO_4$. The solution was concentrated and chromatographed over a silica gel column. Elution with CH_2Cl_2/diethyl ether (9/1 in volume) followed by removal of the solvent in vacuo gave an orange product. Recrystallization from EtOH provided **1** as a pure orange solid (0.18 g, 0.29 mmol) (39%). Elemental analysis (C, H, N) of *p*-triIN (**1**). *Anal*. Calc. for *p*-triIN: C, 66.32; H, 7.04; N, 13.65. Found: C, 66.21; H, 7.11; N, 13.50%. IR(ν/cm^{-1}): 1375 (NO), 1741 (C=O). FAB$^+$ MS *m*/*z* 617.3 [M + 2H].

*p-bisIN (**2**)*. The biradical **2** was synthesized from **4** in the same way as that of **1**. Elemental analysis (C, H, N) of *p*-bisIN (**2**). *Anal*. Calc. for *p*-bisIN: C, 64.49; H, 7.58; N, 15.04. Found: C, 64.41; H, 7.59; N, 14.97%. Single crystals of **2** were obtained by recrystallization from a mixture of acetone and hexane.

2.2. Crystal structure analysis

Single-crystal diffraction data of **2** were collected on a Rigaku Mercury CCD diffractometer with graphite monochromated Mo Kα radiation at 108 K. The crystal structure was solved by using direct methods in a program package CRYSTALSTRUCTURE [6]. Anisotropic thermal parameters analysis was applied for non-hydrogen atoms. Hydrogen atoms with isotropic thermal parameters were refined as riding models.

2.3. Magnetic susceptibility measurements

Magnetic susceptibility was measured on a Quantum Design SQUID magnetometer MPMS-XL under the static magnetic field of 0.1 T in the temperature range down to 1.9 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constants.

3. Results and discussion

3.1. Crystal structure

The crystal data of *p*-bisIN (**2**) are listed in Table 1. Fig. 1 shows the molecular structure of **2**, which is located at the inversion center of the $P2_1/n$ lattice. A half of the molecule is crystallographically independent, indicating that the hydroxyl group of **2** (O2) is disordered in two positions with the occupancy ratio of 0.5:0.5, as found in the analogous compound **4** [5]. The oxygen atoms of nitroxide, O1 and O3, are disordered in two positions as well. The occupancy ratio of O3 (0.36) near the hydroxyl group is smaller than that of O1 (0.64) on the other side. In addition, the dihedral angle between the iminonitroxide plane (O1–N1–C1–N2–O3) and the phenyl plane (C8–C9–C10) is 18.21°, being smaller than that reported for **4** (33.37°) [5]. These are probably due to the difference in steric repulsion between the oxygen atoms of nitroxide and the hydroxyl group in the two positions.

3.2. Magnetic susceptibility

3.2.1. Biradical (**2**)

Magnetic susceptibility χ_m of **2** is shown in Fig. 2 in the $\chi_m T$ versus T plots. The $\chi_m T$ value at 298 K (0.73 emu mol^{-1} K) is slightly lower than that expected for two $S = 1/2$ spins (0.75 emu mol^{-1} K) with the *g*-factor of $g = 2.0$. With decreasing temperature the $\chi_m T$ value decreased to reach zero, as depicted in Fig. 2. These

[a] $R = \sum ||F_o| - |F_c|| / \sum |F_o|$.

[b] $R_w = \sqrt{\sum w((|F_o| - |F_c|)^2 / \sum w(F_c)^2)}$.

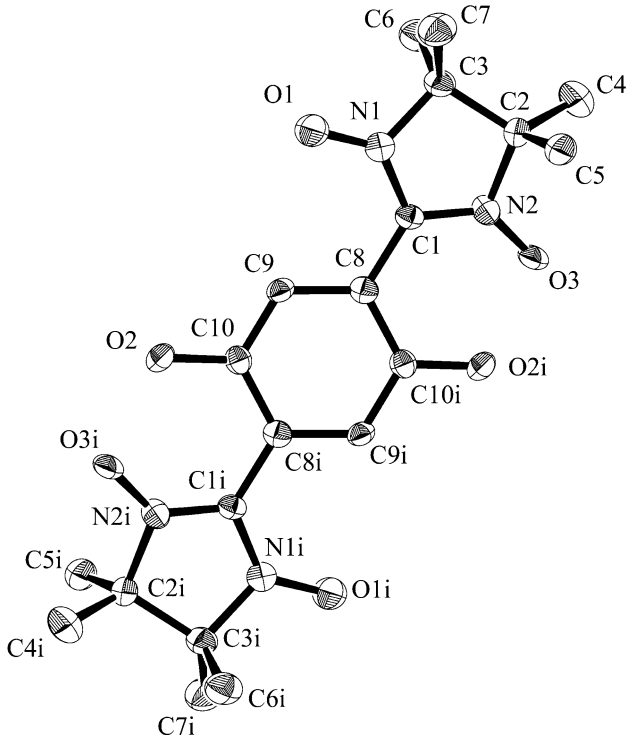

Fig. 1. ORTEP view of the molecular unit of *p*-bisIN (**2**) at the 50% probability level. Symmetry operation code for i is $-x+2$, $-y+1$, $-z+1$. The hydrogen atoms are omitted for the sake of clarity.

results indicate that a sizable intramolecular antiferromagnetic interaction is operative in **2**. The temperature dependence of magnetic susceptibility was analyzed by using the singlet–triplet model (the Bleany–Bowers model) [7]

$$\chi = \frac{Ng^2\mu_B^2}{3k_BT}\frac{2\alpha}{3+\exp(-2J(\pi)/k_BT)}. \quad (3)$$

The parameter $J(\pi)$ in Eq. (3) represents the intramolecular antiferromagnetic exchange interaction defined by the spin Hamiltonian of two $S = 1/2$ spins

$$H = -2J(\pi)S_1 \cdot S_2 \quad (4)$$

and α denotes the purity. The other symbols have their usual meanings. The *g*-factor is fixed as $g = 2.006$, which has been derived from an ESR spectrum. The best fit parameters are $\alpha = 0.96$, $2J(\pi)/k_B = -30.8 \pm 0.1$ K.[1]

[1] One of the disordered oxygen atoms (O3) of the nitroxide were found to have intermolecular short contacts with the other oxygen atom (O1) of the disordered nitroxide or the hydrogen atom attached to the phenyl carbon atom (C9) on the molecule neighboring along the *a*-axis: O3–O1 = 2.910(4) Å, O3–H(C9) = 2.747(1) Å. These contacts are expected to contribute to intermolecular antiferromagnetic interactions. The fitting with Eq. (3) has neglected the possible intermolecular interactions attributable to the contacts in order to avoid overparameterization. The amplitude of $2J(\pi)/k_B = -30.8$ K obtained from the fitting should contain the contribution form the intermolecular interactions and give only an estimate of the intramolecular exchange interaction.

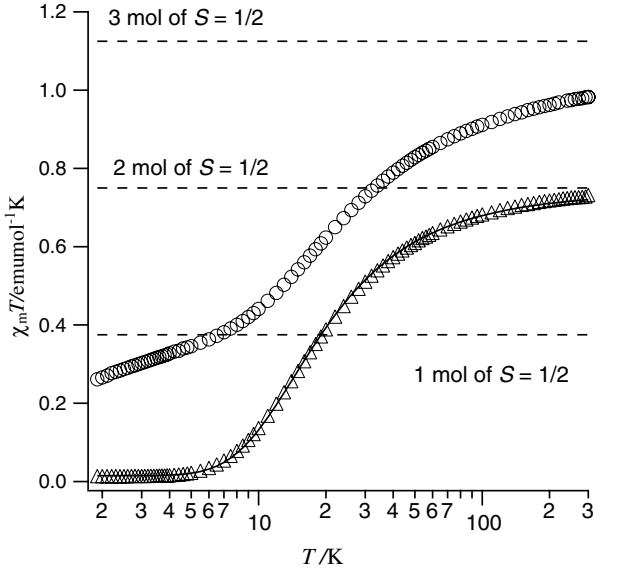

Fig. 2. Temperature dependence of the product χ_mT for *p*-triIN (**1**) (the circles) and *p*-bisIN (**2**) (the triangles). The solid line represents the theoretical calculation from Eq. (3). The horizontal dashed lines show the χ_mT values expected for 1, 2, and 3 moles of magnetically independent $S = 1/2$ spins.

The $2J(\pi)$ value of the iminonitroxide biradical **2** is smaller than that of previously reported nitronylnitroxide biradical **4** ($2J(\pi)/k_B = -82$ K) [5]. This result is consistent with previously reported theoretical calculations [8].

3.2.2. Triradical (*1*)

The temperature dependence of paramagnetic susceptibility χ_m for **1** is shown in Fig. 2 in the χ_mT versus T plots. At 298 K, the χ_mT value is 0.98 emu K mol^{-1}, which is slightly smaller than that for non-interacting three $S = 1/2$ spins (1.13 emu K mol^{-1}). Upon cooling, the χ_mT value for **1** decreased and passed across 0.38 emu mol^{-1} K, which is expected for one mol of $S = 1/2$ spin with $g = 2.0$, although the χ_mT value for **3** decreased down to a constant value of 0.38 emu mol^{-1} K below 10 K [9]. The magnetic behavior of **1** indicates that the ground state of the molecular assemblage of **1** in the crystal is diamagnetic.

In non-quantum terms, where the frustration effects inherent in the multicentered nature of the Hamiltonian in Chart 1 is neglected, the alternating assemblages of biradicals and monoradicals with three $S = 1/2$ spins in a repeating unit never affords any non-magnetic ground state. In this context, if the alternating molecular aggregation of the biradical and monoradical entities in **1** is made in the crystal, the non-magnetic ground state found in the susceptibility measurement is attributable to one of the exotic ground spin states that have been predicted in the theoretical model (Fig. 1) of the generalized ferrimagnetic spin assemblage. Another explanation of the non-magnetic ground state found for **1** is in possible interchain antiferromagnetic interactions.

Even when the single chain of **1** has the generalized ferrimagnetic spin alignment, interchain antiferromagnetic interactions bring about cancellation of magnetic moments as found in a ferrimagnetically short-range ordered chain [4]. The crystal structure analysis of **1** is currently underway in order to verify the occurrence of the generalized ferrimagnetism for **1** in the solid state.

4. Conclusion

The iminonitroxide triradical and biradical compounds **1** and **2** were synthesized by deoxygenation of the corresponding nitronylnitroxide radicals **3** and **4**, respectively. From the magnetic susceptibility measurements for **2**, the intramolecular exchange interaction within the *para*-phenylene-based biradical moiety has been found to be antiferromagnetic with the singlet–triplet energy gap of $2J(\pi)/k_B = -30.8$ K. The magnetic susceptibility of **1** in the crystalline solid state is indicative of the possible occurrence of an exotic non-magnetic ground state as predicted in the theory of generalized ferrimagnetism [3]. The occurrence of the non-magnetic ground state arises from the internal magnetic degree of freedom in the organic biradical and the multicentered intermolecular interactions, both of which have been neglected in conventional atom-based magnetics. The internal magnetic degree of freedom and the multicentered nature are essential in organic molecular-based magnetics.

5. Supplementary material

Full crystallographic details, excluding structure factors, have been deposited at the Cambridge Crystallographic Data Centre (http://www.ccdc.cam.ac.uk/). progress in terms of faculty of quantum chemistry computation enables us to run large size calculations. Not only accretion of CPU speed but also evolution of parallel execution are enable us to run huge MO calculations easily. Thus, we can apply theoretical calculation to large number of cluster size with sufficient numerical accuracy.

2. Molecular structures and calculation detail

The TTF-based donor salts are very familiar and important. Here, we employ the κ-$BETS_2FeCl_4$ crystal as one of the very interesting crystals that have been reported by many scientists. The X-ray structural study was measured in room temperature ($T = 295$ K) as experimental condition, although we have to employ the structural data for lower temperature [1,12]. Simple representation of BETS layers in κ-phases crystal was depicted in Fig. 1. In this figure, dimerized BETS pairs in two-dimensional donor sheet are found. Roman-face numbers (1, 2, 3,...) indicate each BETS molecule and italic-face alphabets (*A*, *B*, *p*, *q*) and numbers (*1*, *2*, *3*) indicate inter-molecule $J_{ab(M)}$ and inter-dimer $J_{ab(D)}$, respectively [13,14].

In this figure, some of clusters (i), (ii), (iii) and (iv) are worth studying. Cluster (i) has four BETS molecules with two holes and is a suitable model to investigate inter-dimer $J_{ab(D)}$ values. Clusters 56–78, 12–78 and 12–56 correspond to models for $J_{ab(D)}(n)$ ($n = 1, 2, 3$) values, respectively. In peculiar systems, triangular lattices with competitive antiferromagnetic J_{ab} values are important. Six BETS molecules with three holes are in cluster (ii), though spin frustration does not occur in this BETS complex. One-dimensional chain with periodic condition along this cluster is depicted in cluster (iii). This model is useful to investigate charge and spin density waves. For cluster (iv), larger size clusters are necessary, when eliminating edge-effects. If not only interacting pairs but also surrounding dimers are introduced in calculations, more accurate values can be given, though we encounter heavy calculations. As the following sections, we mainly discuss clusters (i) and (ii) and propose extended studies for clusters (iii) and (iv).

The effective exchange integrals based on Heisenberg Hamiltonian can describe spin properties. In series of our studies theoretical calculations by using of ab initio molecular orbital (MO) and density functional (DFT) methods were carried out [11]. Our calculations were carried out by GAUSSIAN-98 program packages, besides of periodic calculation by GAUSSIAN-03 Rev.C02 [15]. We used the simple basis sets included in Gaussian program packages. Moreover, our previous calculations

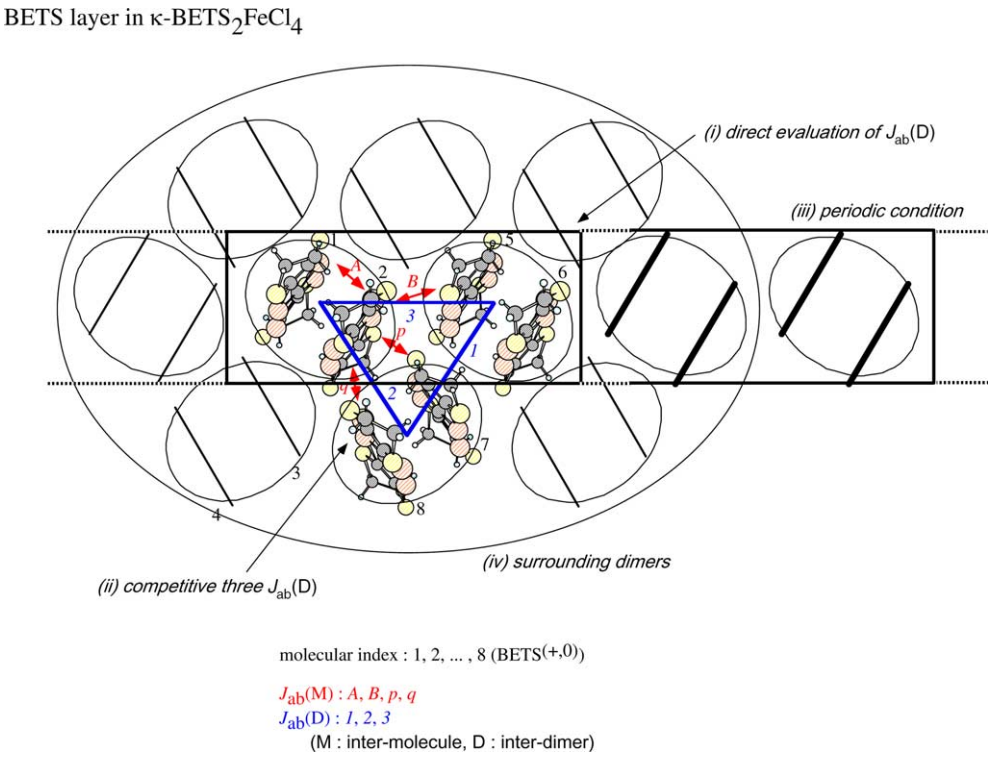

Fig. 1. Simple representation of BETS layers in κ-$BETS_2FeCl_4$ crystal. Roman-face numbers (1, 2, 3, ...) indicate each BETS molecule and italic-face alphabets (*A*, *B*, *p*, *q*) and numbers (*1*, *2*, *3*) indicate inter-molecule $J_{ab(M)}$ and inter-dimer $J_{ab(D)}$, respectively. Some of clusters (i), (ii), (iii) and (iv) are worth studying.

were concluded that our selection of the 6-31G basis set is suitable for these cases.

3. Theoretical background

In series of our studies, effective exchange integrals (J_{ab}) successfully describe magnetic interaction. The magnetic interaction between two localized electrons is usually described by the Heisenberg-type spin coupling Hamiltonian

$$H(HB) = -\sum 2J_{ab}S_a \cdot S_b, \tag{1}$$

where J_{ab} is the orbital-averaged effective exchange integral between the ath and bth sites with total spin operators S_a and S_b. Recent development of the ab initio computational techniques has made it possible to calculate the J_{ab} values directly. Broken-symmetry (BS) approach with the spin projected scheme [16], which eliminates the spin contamination problem, can evaluate J_{ab} values with the following equation:

$$J_{ab}^{(1)} = \frac{^{LS}E(X) - {}^{HS}E(X)}{^{HS}\langle S^2\rangle - {}^{LS}\langle S^2\rangle}, \tag{2}$$

where $^{Y}E(X)$ and $^{Y}\langle S_2\rangle(X)$ denote, respectively, total energy and total spin angular momentum for the spin state Y by the computational methods X.

Here, inter-molecule $J_{ab(M)}$ between two donor cations (namely, 2 holes in 2 molecules) and inter-dimer $J_{ab(D)}$ between two donor dimers (namely, 2 holes in 4 molecules) are defined as shown in Fig. 2(a). In our previous papers, we assume that $J_{ab(D)}$ values are related to $J_{ab(M)}$ values as the following equation (see our paper [11] in detailed).

$$J_{ab(D)} \cong \frac{1}{2}J_{ab(M)}(M_2M_3). \tag{3}$$

Here, we assume localization of spins in inner molecule (M_2,M_3) in system ($(M_1M_2)^{+}$–$(M_3M_4)^{+}$). However, in this assumption the interaction between two HOMOs from only inner molecules cannot describe whole of interaction $J_{ab(D)}$ as shown in Fig. 2(b). Thus, this procedure is remarkably insufficient to evaluate $J_{ab(D)}$ values. On the other hand, Fig. 2(c) shows that interaction between two MOs made from two HOMOs in each dimer ($(BETS_2)^{+\cdot}$) reproduces $J_{ab(D)}$ values correctly.

4. Detailed theoretical calculations

4.1. Direct evaluation of inter-dimer $J_{ab(D)}$ values

In this section, we focus on inter-dimer interaction in cluster (i) in Fig. 1, though all the results of these values were already reported : $J_1 = J_2 = -40.0\ cm^{-1}$ and $J_3 = -103.5\ cm^{-1}$ ($J_{ab(D)}(n) = J_n$) [11]. These values were reproduced from the calculated $J_{ab(M)}$ values with Eq. (3). In this paper, more extended treatment for $J_{ab(D)}$ is carried out. Now, our treatment is started for molecular pairs (12–56).

If we introduce two holes in four molecules ($(BETS_2)^{+\cdot}$–$(BETS_2)^{+\cdot}$), many types of spin structure

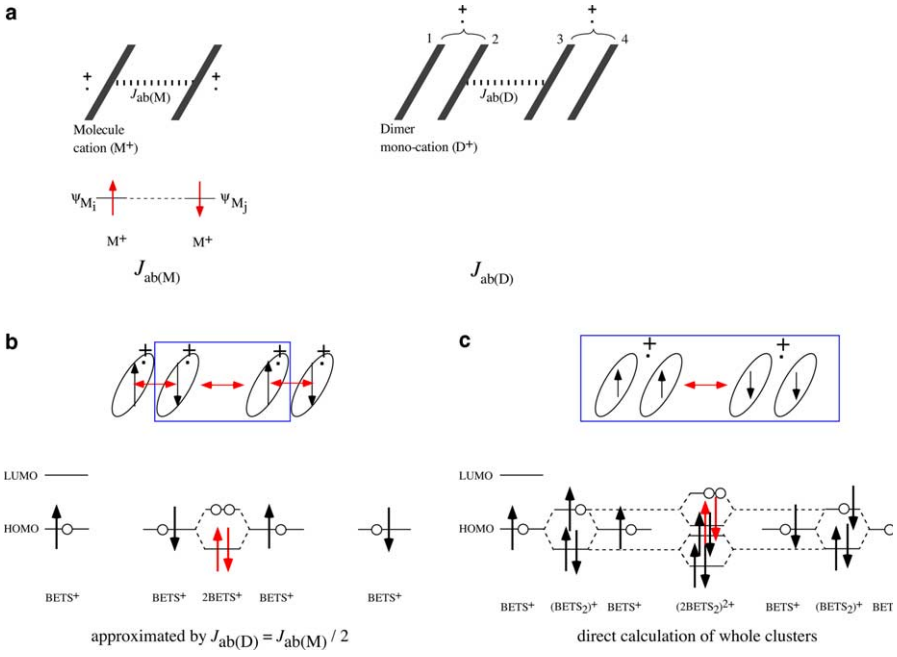

Fig. 2. (a) Simple illustration of inter-molecule $J_{ab(M)}$ and inter-dimer $J_{ab(D)}$ values. (b) Interaction between two HOMOs from only inner molecules contributes to $J_{ab(D)}$. (c) Interaction between two MOs made from two HOMOs in each dimer reproduces $J_{ab(D)}$.

are candidates for suitable magnetic interaction. In Fig. 3 several charge and spin density structure was illustrated. Initially, four types of spin structure +0–0+ (↑0–0↑, ↑0–0↓), 0+–+0 (0↑–↑0 and 0↑–↓0) were constructed with ab initio calculations. These structure is classified to the localized spin model, where holes exist in inner or outer positions. Ferro- or antiferro-magnetic spin arrangement is constructed in it. In Figs. 4(a) and (b) the obtained spin structure was summarized in order of total energies. These calculations were carried out under suppression of all geometrical symmetry. The UHF/6-31G methods in GAUSSIAN-98 program packages and SCF conversion were controlled in 10^{-5} level. In this threshold, more 1 cm^{-1} numerical accuracy for J values (1 a.u. = 2.194703205×10^5 cm^{-1}) is guaranteed.

However, in UB3LYP method, the localized spin structure is stabilized to the delocalized one during another types of SCF procedure as shown in Fig. 4(c). Each hole is shared in two BETS molecules and delocalized as Fig. 3. From these energy splitting between ↑↑–↑↑ and ↑↑–↓↓ states, J_3 value was successfully evaluated and antiferromagnetic interaction (-16.5 cm^{-1}) was concluded.

In addition, similar procedure was applied to molecular clusters 12–78 and 56–78, and $J_2 = -56.3$ cm^{-1} and $J_1 = -54.9$ cm^{-1} were evaluated as shown in Fig. 5. Though geometrical symmetry in BETS arrangement leads relation $J_2 = J_1$, there was slight difference between the obtained J_2 and J_1 values because of numerical error. If we compare these values to our previous reported values, it is found that all are antiferromagnetic and magnitude of J_3 values are slightly different.

4.2. Competition among J_1, J_2, J_3 interactions

In the previous section, three $J_{ab(D)}$ values could be evaluated in four molecular clusters. Competition among all dimers in two-dimensional BETS sheets is expected and more complicated. Next, in order to explain and understand correlation between three $J_{ab(D)}$ values, let us consider three dimer pairs as cluster (ii) in Fig. 1. Triangle structure is constructed by three types of $J_{ab(D)}$ parameters. For most peculiar example, Tamura and his co-workers reported frustrated spin structure, which is deduced from regular triangle geometry and all antiferromagnetic interaction [17]. In terms of theoretical studies, Yamanaka and his co-workers developed the GHF and GDFT methods that can calculate non-collinear type spins beyond RHF, UHF, etc., methods [18].

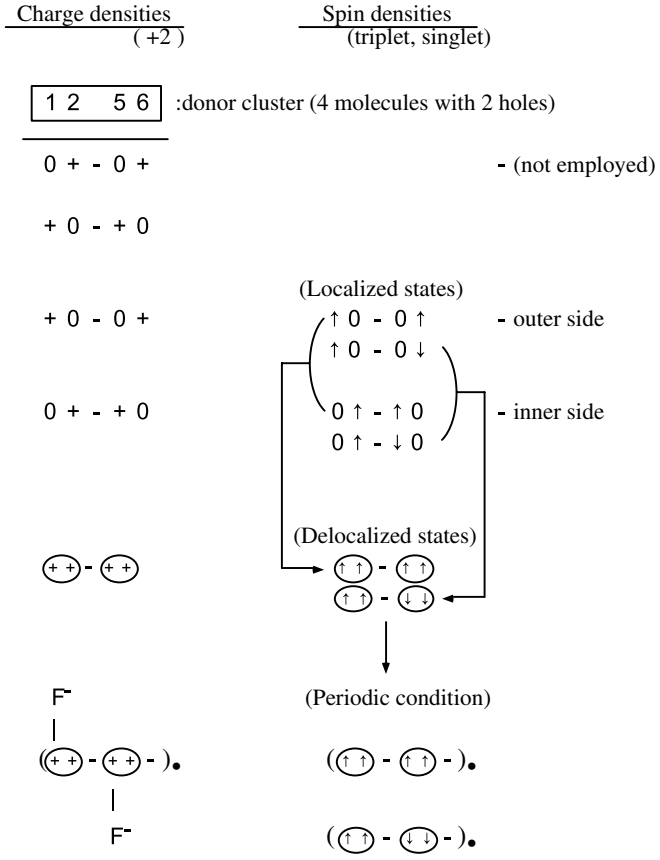

Fig. 3. All charge and spin density structure with localized, delocalized, periodic conditions.

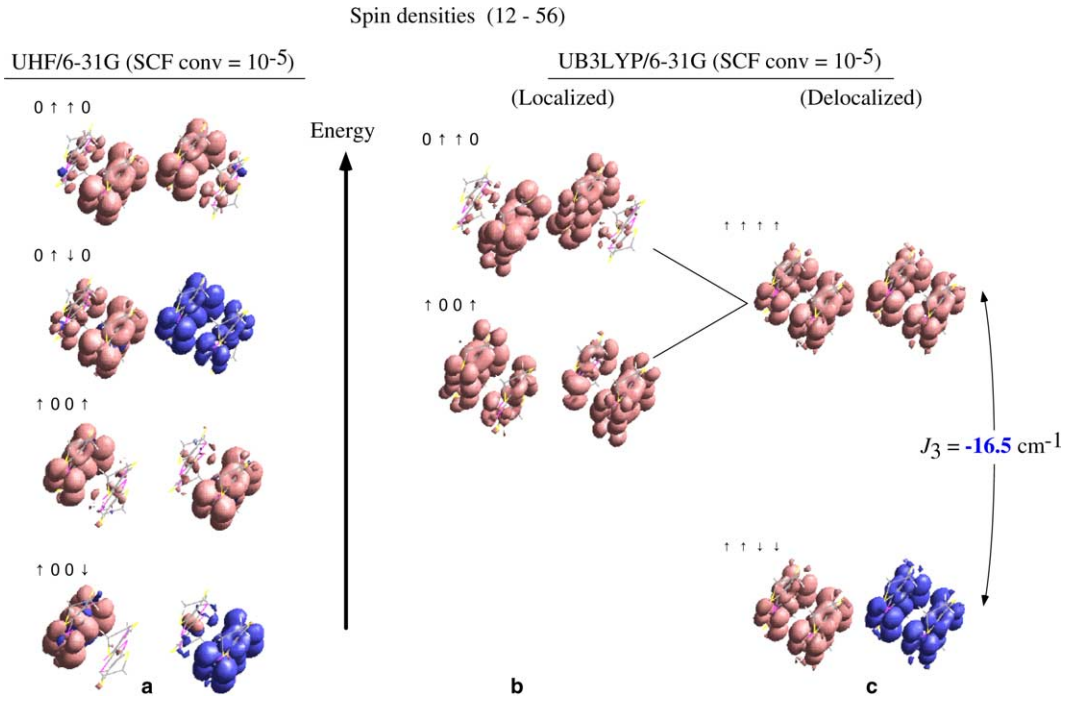

Fig. 4. Localized spin densities for cluster 12–56 by (a) UHF and (b) UB3LYP methods. (c) Delocalized spin densities and J_3 values.

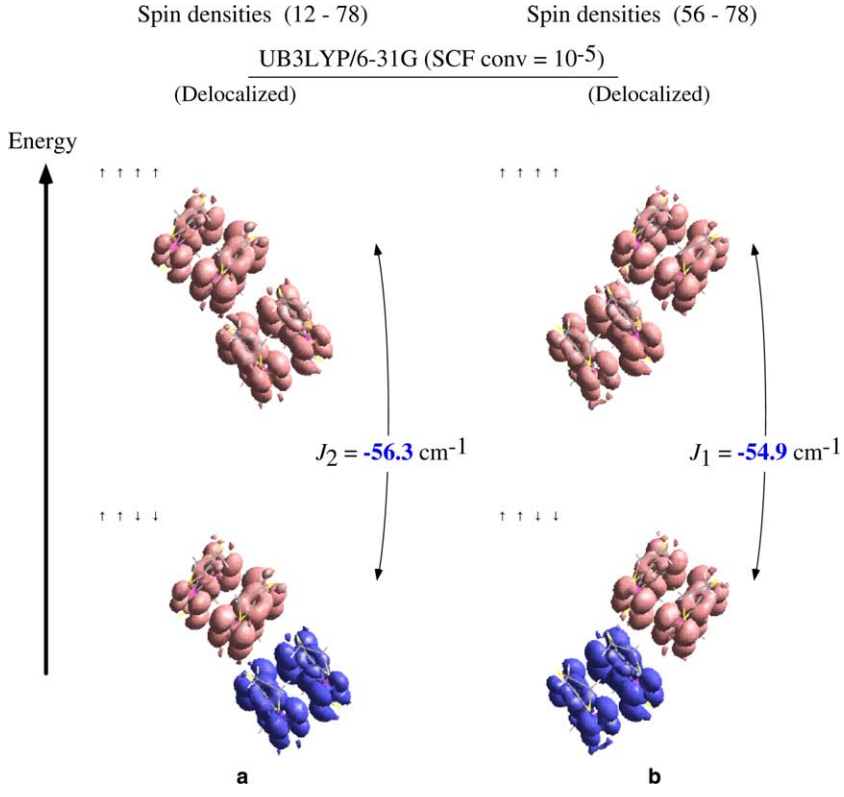

Fig. 5. Delocalized spin densities for cluster (a) 12–78 and (b) 56–78, and J_2 and J_1 values.

Fortunately, in this BETS system such extended treatment is not needed and spin frustration was not reported in experimental studies. All types of well controlled spin structure were illustrated in Fig. 6 by using of UB3LYP methods. In the spin structure, larger spin densities on inner molecules (2, 5, 7) were induced under SCF conversion ($= 10^{-5}$). Applying more tight SCF conversion ($= 10^{-7}$), larger spin densities moved

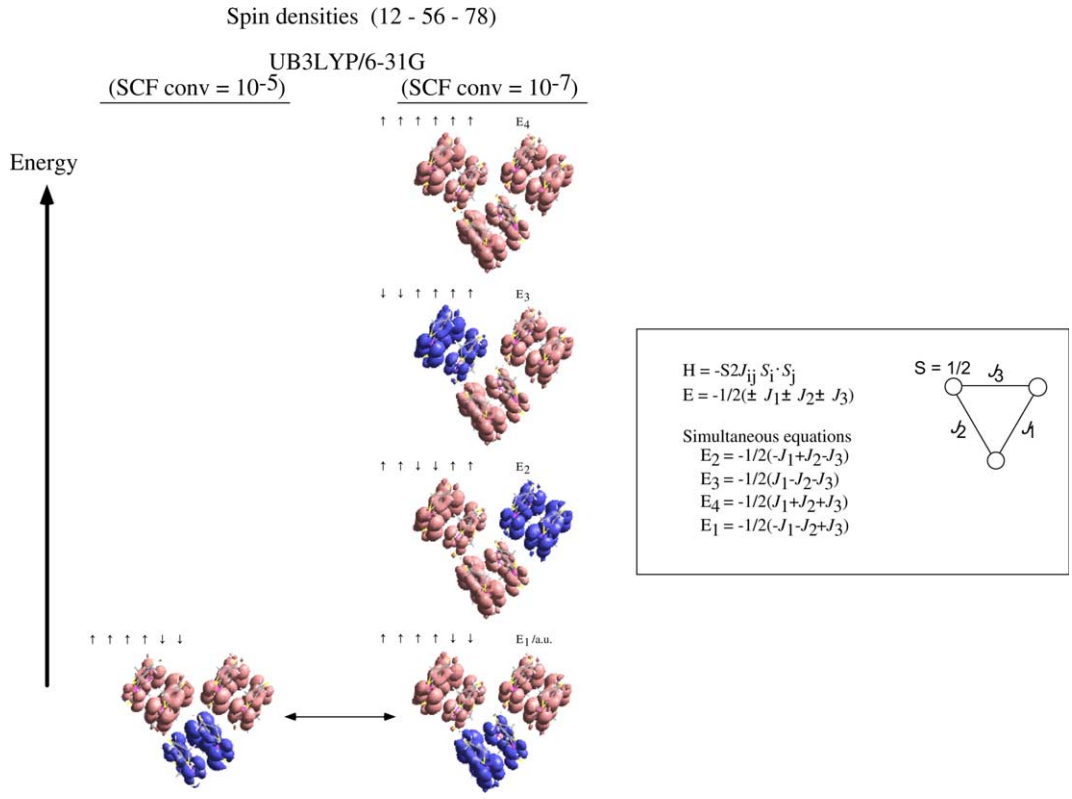

Fig. 6. All types of well controlled spin structure and simultaneous equations for J_1, J_2 and J_3.

to outer molecules (1, 6, 8). We can evaluate all $J_{ab(D)}$ values by solving simultaneous equations with total energy and spin structure. The results are $J_1 = -195.6\ cm^{-1}$, $J_2 = -185.0\ cm^{-1}$ and $J_3 = -174.8\ cm^{-1}$. Differ from the $J_{ab(D)}$ values obtained in the previous section is very large. Since complete delocalization of spins is not realized, large divergence of $J_{ab(D)}$ values appear. We report these values as tentative results and progress more accurate studies.

5. Discussion

Our calculations enabled us to obtain the accurate parameters $J_{ab(D)}$ as inter-dimer magnetic interaction in cluster models of BETS donors. Our direct calculations to large size of clusters were recognized very powerful way to obtain accurate magnetic interaction. The models of four BETS donors with two holes ($(BETS_2)^{+\cdot}$–$(BETS_2)^{+\cdot}$) is very good starting point. From the results, it is found that several spin structure appear and the localized and delocalized spin densities were induced according to calculated condition, such as initial SCF densities, SCF conversion criterion, etc. Three types of $J_{ab(D)}$ parameters, i.e. J_1, J_2 and J_3, were also given with total energies and simultaneous equation for total energy and spin structure.

In two-dimensional networks of BETS molecules, infinite BETS chains exist as cluster (iii) in Fig. 1. Usually, band calculations are most powerful and familiar treatment as well known. However, now we carried out ab initio MO calculation with periodic condition by newly introduced method in GAUSSIAN-03 program packages, though CRYSTAL program packages were used in our previous studies for calbene cluster etc. For example, chain $(12–56)_\infty$ is elongated, where one unit cell exhibits two holes par four BETS molecules as Fig. 3. Here, dummy two F^- anions introduced into unit cell for neutral charges. Both charge and spin density wave are very important physical properties and theoretical calculations for such chains can reveal them in detail. For example, delocalized spin densities in the highest spin ($(\uparrow\uparrow–\uparrow\uparrow)_\infty$) and the lowest spin ($(\uparrow\uparrow–\downarrow\downarrow)_\infty$) states appear in unit cell, where each hole delocalize in two molecules in one dimers.

In addition, calculations for each spin structure surrounding donors give more accurate results, since edge-effects are eliminated and valence between localized and delocalized electronic properties is well controlled. For example, number of molecules in cluster 12–56 with surrounding dimers for J_3 values is 20 as shown cluster (iv) in Fig. 1. In such calculations number of basis sets are very huge and SCF procedure is very difficult. However, we expect that calculations for large donor cluster will be feasible in near future.

in Sr_2RuO_4 has been discussed in relation to the band structure and spin susceptibility by using a two-dimensional Hubbard model for three bands crossing the Fermi level [19]. The origin of the pairing mechanism has been discussed by two-dimensional Hubbard models with studies of the nature of both the normal and superconducting states.

Recently, we have presented a two-dimensional two-sublattice system, and have investigated two-band effects in magnetism and superconductivity by using a Hubbard model and an extended Hubbard model [20]. We have found that the effective exchange integral is expressed by the square of the on-site repulsion times the effective spin susceptibility. The results suggest that the ferromagnetic order appears by two-band effect. By hole- or electron-doping into the two-band system, antiferromagnetic order appears with disappearing the ferromagnetic order.

In this study, we investigate 4-band effects in magnetism by using the tight-binding model and the Hubbard model. For hole-doping into the system, the spin susceptibility between sites is calculated by using Green's function techniques. We discuss magnetic structure of the hole-doped systems in relation to band structure.

2. Many-band effects in magnetism

In this section, we present a two-dimensional 4-sublattice model and electronic band structures for some parameters in the sublattice model. The expression of spin susceptibility of the sublattice system is derived within the tight-binding approximation. We discuss many-band effects in magnetism of the many-band system in relation to hole- or electron-doping to the sublattice system.

2.1. Two-dimensional 4-sublattice model

In this study, we consider a two-dimensional 4-sublattice model as shown in Fig. 1. Hamiltonian within the tight-binding approximation of this system is written as

$$H_0 = \sum_{\boldsymbol{k},\sigma} \sum_{i,j=1}^{4} t_{ij}(\boldsymbol{k}) a^{\dagger}_{\boldsymbol{k}i\sigma} a_{\boldsymbol{k}i\sigma}, \tag{1}$$

where

$$t_{12}(\boldsymbol{k}) = 2t_{12} \cos\frac{k_x}{2} \exp\left(\mathrm{i}\frac{k_x}{2}\right), \tag{2}$$

$$t_{13}(\boldsymbol{k}) = 4t_{13} \cos\frac{k_x}{2} \cos\frac{k_y}{2} \exp\left(\mathrm{i}\frac{k_x}{2}\right) \exp\left(-\mathrm{i}\frac{k_y}{2}\right), \tag{3}$$

$$t_{14}(\boldsymbol{k}) = 2t_{14} \cos\frac{k_y}{2} \exp\left(-\mathrm{i}\frac{k_y}{2}\right), \tag{4}$$

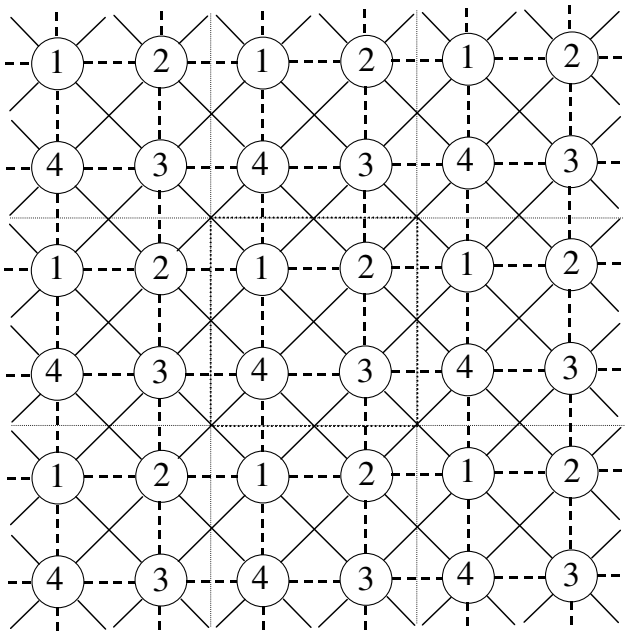

Fig. 1. Two-dimensional 4-sublattice system. The unit cell is composed of 4 sites. Transfer integral between sublattices i and j is t_{ij}.

$$t_{23}(\boldsymbol{k}) = 2t_{23} \cos\frac{k_y}{2} \exp\left(-\mathrm{i}\frac{k_y}{2}\right), \tag{5}$$

$$t_{24}(\boldsymbol{k}) = 4t_{24} \cos\frac{k_x}{2} \cos\frac{k_y}{2} \exp\left(-\mathrm{i}\frac{k_x}{2}\right) \exp\left(-\mathrm{i}\frac{k_y}{2}\right), \tag{6}$$

$$t_{34}(\boldsymbol{k}) = 2t_{34} \cos\frac{k_x}{2} \exp\left(-\mathrm{i}\frac{k_x}{2}\right). \tag{7}$$

t_{ij} $(i \neq j)$ is a transfer integral between the sublattices, and $t_{ji} = t^{*}_{ij}$. t_{ii} means a potential energy in each sublattice. Band structures of three cases in two-dimensional 4-sublattice system are shown in Fig. 2.

2.2. Spin susceptibility

In this subsection, we derive the expression of the spin susceptibility between sites within tight-binding approximation. From Eq. (1), the Green function for each band is written as

$$G_i(\boldsymbol{k}, \mathrm{i}\omega) = \frac{|\mathrm{i}\boldsymbol{k}\rangle\langle\mathrm{i}\boldsymbol{k}|}{\mathrm{i}\omega - \varepsilon_i(\boldsymbol{k})}. \tag{8}$$

Using the above equation and LCAO coefficients for site in sublattice, we obtain the Green function for site in sublattice as

$$g_{rs}(\boldsymbol{k}, \mathrm{i}\omega) = \sum_{i=1}^{4} \frac{\langle r|\mathrm{i}\boldsymbol{k}\rangle\langle\mathrm{i}\boldsymbol{k}|s\rangle}{\mathrm{i}\omega - \varepsilon_i(\boldsymbol{k})}. \tag{9}$$

From the above equation, the zz component of the spin susceptibility between sites is written as

$$\chi^{0}_{rs}(\boldsymbol{k}, \mathrm{i}\omega) = -\frac{1}{2}(g\mu_{\mathrm{B}})^2 F_{rs}(\boldsymbol{k}, \mathrm{i}\omega) \tag{10}$$

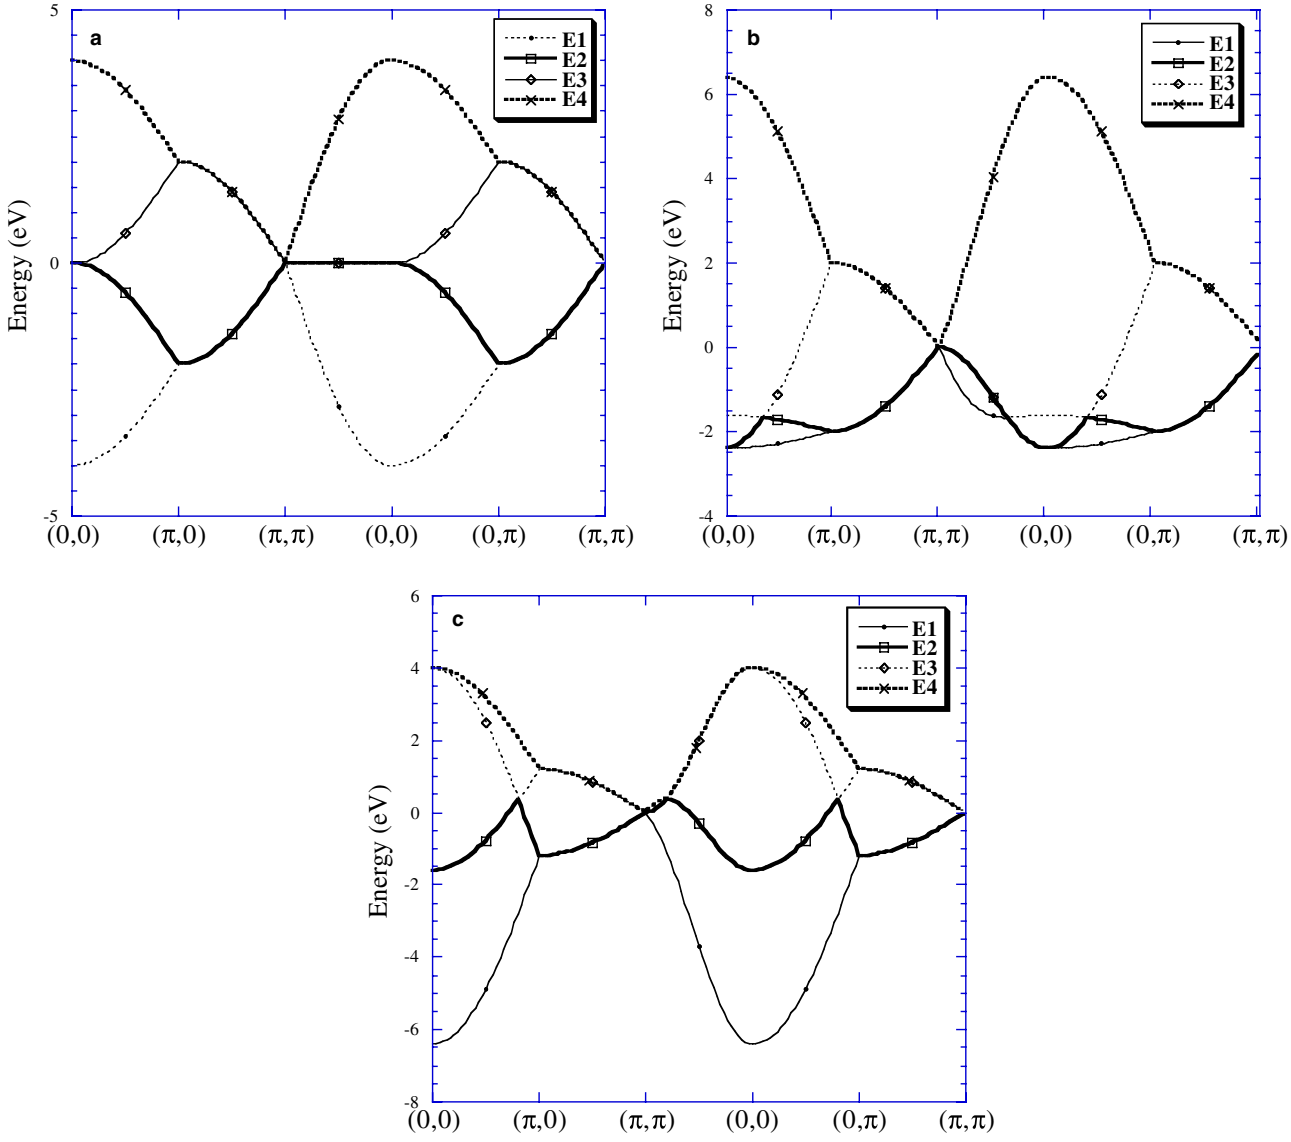

Fig. 2. Band structures: (a) $t_{12} = t_{14} = t_{23} = t_{34} = -1.0$ (eV), and other parameters are zero. This parameter set corresponds to square lattice system. The system is half-filling at $\mu = 0$; (b) $t_{13} = t_{24} = 0.6$, $t_{12} = t_{14} = t_{23} = t_{34} = -1.0$ (eV), and four potential energies are zero. Half-filling is at $\mu = -0.4$ eV. Fermi surface crosses three bands at half-filling. Some molecular crystals have similar band structure of this case; (c) $t_{13} = t_{24} = -1.0$, $t_{12} = t_{14} = t_{23} = t_{34} = 0.6$ (eV), and others are zero. Half-filling at $\mu = 0.18$ eV. Fermi surface crosses two-bands at half-filling.

with

$$F_{rs}(\boldsymbol{k}, \mathrm{i}\omega) = T \sum_{\boldsymbol{p}\nu} g_{rs}(\boldsymbol{p}, \mathrm{i}\nu) g_{sr}(\boldsymbol{p}+\boldsymbol{k}, \mathrm{i}\nu + \mathrm{i}\omega), \tag{11}$$

where r and s indicate site label in the unit cell as shown in Fig. 1. T is temperature, and g and μ_B are g-factor (=2.0023) and the Bohr magneton (=$|e|/2mc$), respectively. By summing over the Mastubara frequency ν, the spin susceptibility of Eq. (10) becomes

$$\chi^0_{rs}(\boldsymbol{k}, \mathrm{i}\omega) = -\frac{(g\mu_B)^2}{2} \sum_{\boldsymbol{p}} \sum_{i,j=1}^{4} \left[f(\varepsilon_i(\boldsymbol{p}+\boldsymbol{k})) - f(\varepsilon_j(\boldsymbol{p})) \right] \times \frac{\langle r|\mathrm{i}\boldsymbol{p}+\boldsymbol{k}\rangle\langle \mathrm{i}\boldsymbol{p}+\boldsymbol{k}|s\rangle\langle s|\mathrm{j}\boldsymbol{p}\rangle\langle \mathrm{j}\boldsymbol{p}|r\rangle}{\varepsilon_i(\boldsymbol{p}+\boldsymbol{k}) - \varepsilon_j(\boldsymbol{p}) - \mathrm{i}\omega}, \tag{12}$$

where f is the Fermi distribution function.

Fig. 3 shows the spin susceptibilities between sites $\mathrm{Re}\chi^0_{rs}(\boldsymbol{k}, \omega = 0)$ obtained from numerical calculations of Eq. (12) in the case of Fig. 2(a). Fig. 3(a) shows the real part of the spin susceptibility at half-filling. We find that χ^0_{11} for the same sublattice is positive with two sharp peaks at (0,0) and (π,π). The χ^0_{11} suggests that the direction of spin is parallel to the same site of other unit cells. From the spin susceptibility χ^0_{13} between sites 1 and 3, we can know that the direction of spins between diagonal states in unit cells is also parallel at half-filling. On the other hand, the spin susceptibility χ^0_{12} between nearest neighbor sites becomes negative, that is antiferromagnetic. Therefore, from Fig. 3(a), we find long-range antiferromagnetic order at half-filling.

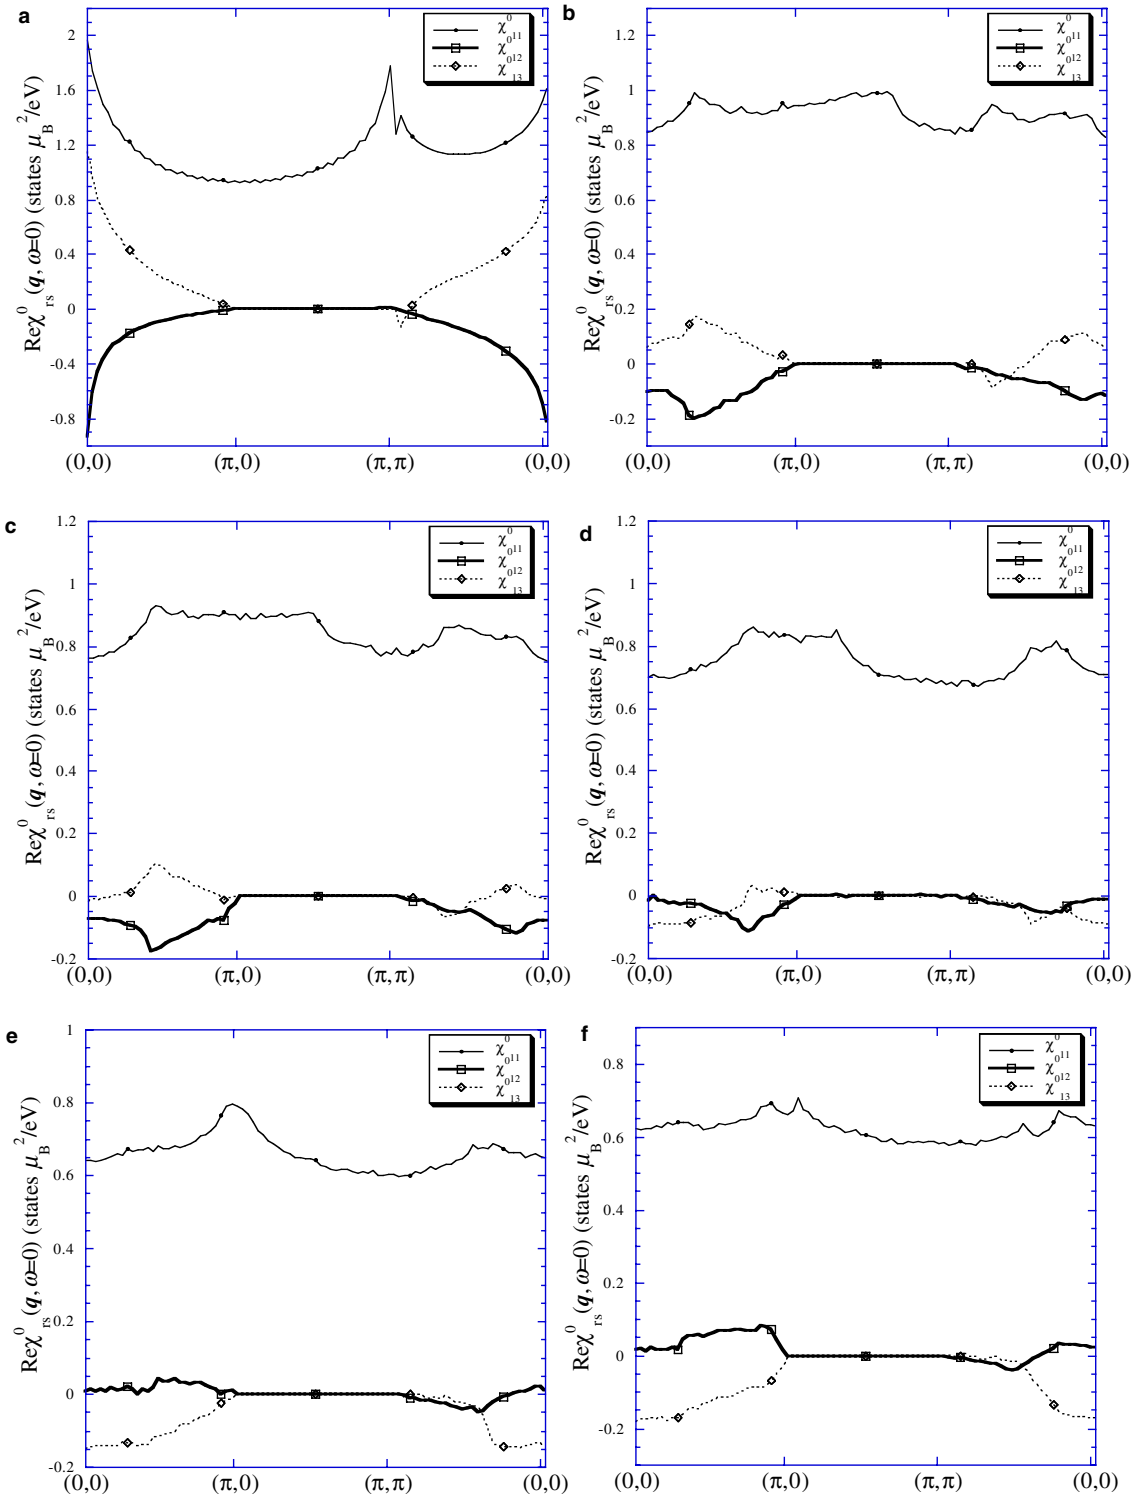

Fig. 3. Spin susceptibility in case $t_{12} = t_{14} = t_{23} = t_{34} = -1.0$ (eV) and others are zero: (a) spin susceptibility $\mathrm{Re}\chi^0_{rs}(\boldsymbol{q}, \omega = 0)$ at half-filling ($\mu = 0$); (b) $\mu = -0.5$ eV. The number of doped hole n_h away from half-filling per unit cell is 0.75; (c) $n_h = 1$ ($\mu = -2/3$); (d) $n_h = 1.5$ ($\mu = -1$); (e) $n_h = 2$ ($\mu = -4/3$); (f) $n_h = 2.25$ ($\mu = -1.5$).

Figs. 3(b)–(f) show the spin susceptibility of the system doped with holes away from half-filling. In Fig. 3(b), we find peaks around (π/3,0), (π,2π/3), and (2π/3,2π/3). These peaks arise from Fermi momenta of the hole-doped system. As increasing hole-doping, the spin susceptibilities of hole-doped system becomes smaller than those of half-filling as shown in Figs. 3(b) and (c). In Fig. 3(d), we can find region where the spin susceptibility between

diagonal sites becomes negative. The results as shown in Fig. 3(d) suggest that when we focus spin of a sublattice, the direction of spin of other sublattice is antiparallel except for the same site. In Fig. 3(e), we can find that the spin susceptibility between diagonal sites becomes negative and that χ^0_{12} almost vanishes. These results suggest that there is only antiferromagnetic spin correlation between diagonal sites. In Fig. 3(f), the spin susceptibilities of χ^0_{11} and χ^0_{12} are positive, and χ^0_{13} becomes negative. We can know ferromagnetic order along x-axis or y-axis, and also find antiferromagnetic order along orthogonal direction to the ferromagnetic order. From Fig. 3, we can find long-range antiferromagnetic order in the square lattice system around half-filling, and that the long-range antiferromagnetic order disappears in the case of hole-doped system. Interesting spin states appears, when the system is doped with holes.

2.3. Many-band systems

Next, we consider 4-band systems as shown in Figs. 2(b) and (c). Fig. 4 shows the spin susceptibilities of hole-doped system with the band structure as shown in Fig. 2(b). We find two peaks with negative value around $(0,3\pi/2)$ and $(3\pi/2,3\pi/2)$ in the spin susceptibility between diagonal sites as shown in Fig. 4(c), and from Fig. 4, we expect that the spin correlation of the system around half-filling weakly becomes almost antiferromagnetic. As increasing hole-doping, the system has antiferromagnetic order around chemical potential of $\mu = -1.0$. Fig. 5 shows the spin susceptibilities of the system as shown in Fig. 2(c). At half-filling, χ^0_{11} is positive in all region. On the other hand, χ^0_{12} and χ^0_{13} become negative around point (0,0). From Figs. 4 and 5, we can expect that magnetic properties of many-band system doped with hole become more complex and interesting than those of single- or two-band system.

2.4. Effective interactions and effective spin susceptibility in Hubbard model

In previous subsections, we have investigated the spin susceptibility of 4-band system doped with hole. From the spin susceptibility, we can know some physical

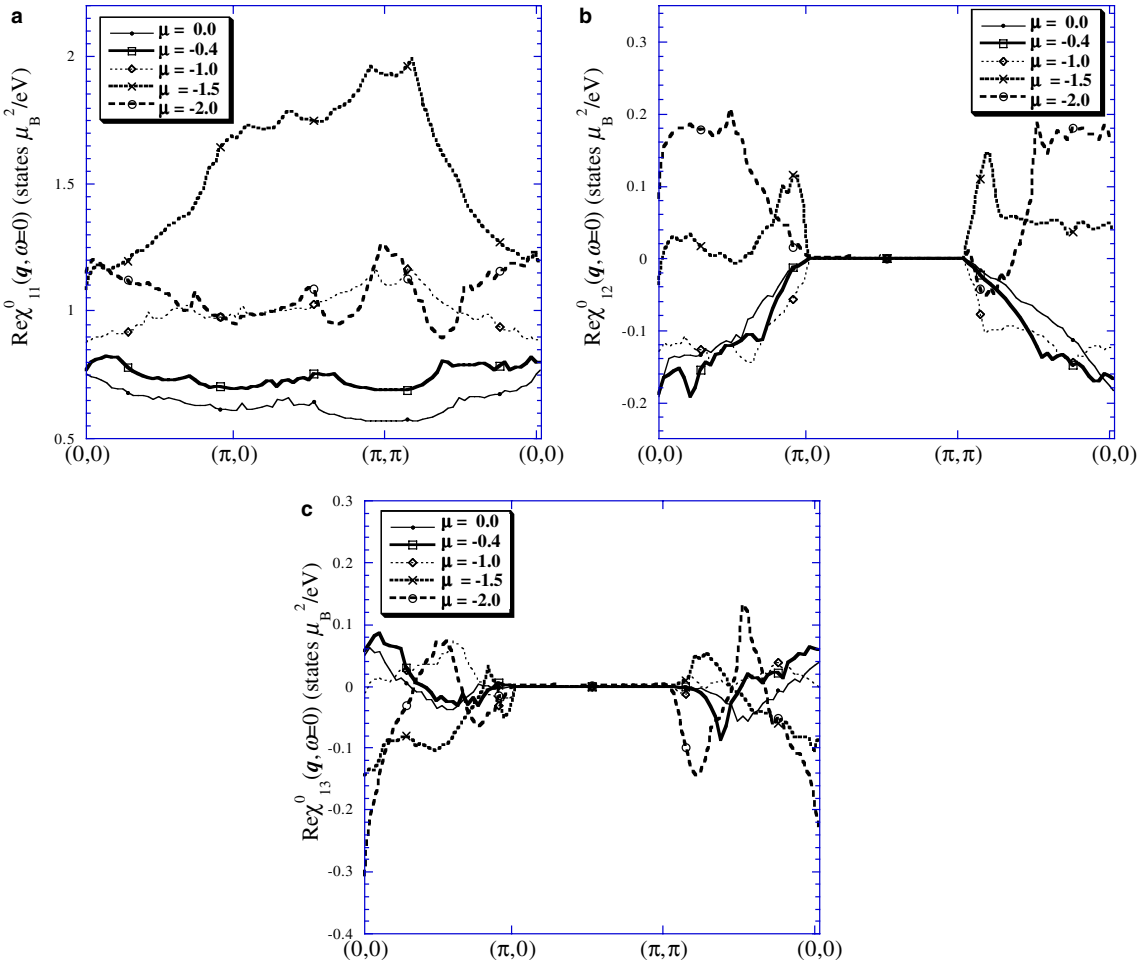

Fig. 4. Dependency of spin susceptibility on hole-doping in case $t_{13} = t_{24} = 0.6$, $t_{12} = t_{14} = t_{23} = t_{34} = -1.0$ (eV), and four potential energies are zero: (a) spin susceptibility $\chi^0_{11}(\boldsymbol{q})$; (b) spin susceptibility $\chi^0_{12}(\boldsymbol{q})$; (c) spin susceptibility $\chi^0_{13}(\boldsymbol{q})$.

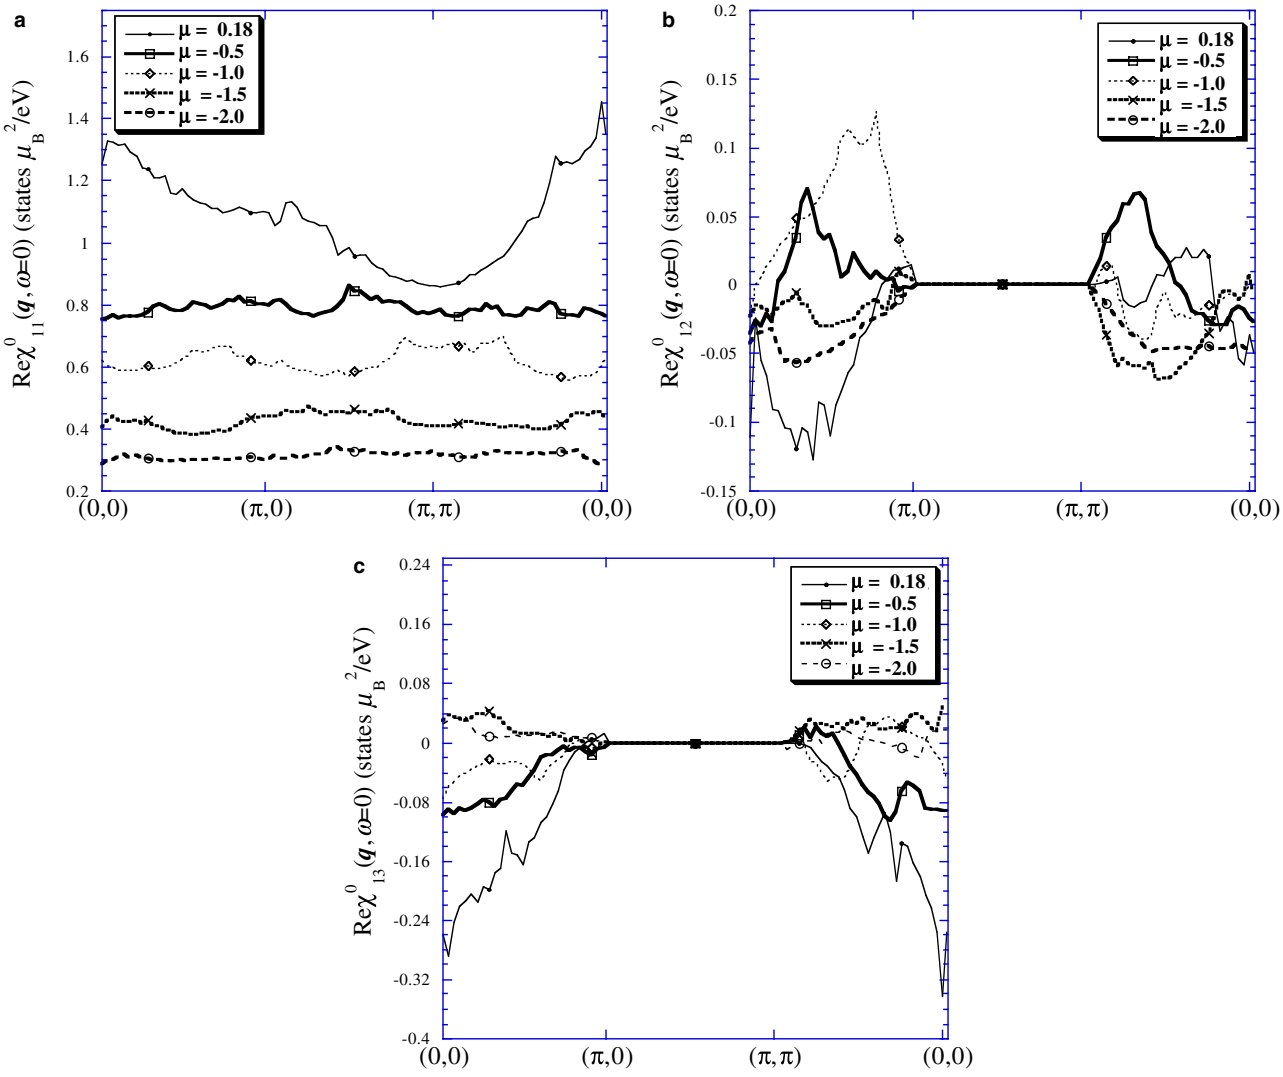

Fig. 5. Dependency of spin susceptibility on hole-doping in case $t_{13} = t_{24} = -1.0$, $t_{12} = t_{14} = t_{23} = t_{34} = 0.6$ (eV), and others are zero: (a) spin susceptibility $\chi^0_{11}(\boldsymbol{q})$; (b) spin susceptibility $\chi^0_{12}(\boldsymbol{q})$; (c) spin susceptibility $\chi^0_{13}(\boldsymbol{q})$.

properties such as effective interactions, magnetic properties and so on. In this subsection, we derive expressions of effective interactions by using the spin susceptibility within the random-phase approximation (RPA).

Effective interaction $V^{\sigma-\sigma}_{\text{eff}}(\boldsymbol{q})$ is written as

$$\begin{aligned} V^{\sigma-\sigma}_{\text{eff}}(\boldsymbol{q}) &= U + U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})U \\ &\quad + U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})U + \cdots, \\ &= U + U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})V^{\sigma-\sigma}_{\text{eff}}(\boldsymbol{q}), \\ &= \left[1 - U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})\right]^{-1}U, \end{aligned} \tag{13}$$

where U is a diagonal matrix ($U_{rs} = U_r\delta_{rs}$), and $\chi^0(\boldsymbol{q})$ is a matrix consisting of matrix element $\chi^0_{rs}(\boldsymbol{q})$. U_r means on-site coulomb potential at r-th site. Diagonal elements of $V^{\sigma-\sigma}_{\text{eff}}(\boldsymbol{q})$ mean the effective on-site coulomb potential.

By the similar procedure, we have effective interaction $V^{\sigma\sigma}_{\text{eff}}(\boldsymbol{q})$;

$$V^{\sigma\sigma}_{\text{eff}}(\boldsymbol{q}) = \left[1 - U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})\right]^{-1}U\chi^0(\boldsymbol{q})U. \tag{14}$$

Note that diagonal elements of the matrix $V^{\sigma\sigma}_{\text{eff}}(\boldsymbol{q})$ always vanish.

Effective spin susceptibility $\chi(\boldsymbol{q})$ is also easily shown by the similar procedure.

$$\chi(\boldsymbol{q}) = \chi^0(\boldsymbol{q})\left[1 - U\chi^0(\boldsymbol{q})U\chi^0(\boldsymbol{q})\right]^{-1}. \tag{15}$$

From Eqs. (13) and (14), we can approximately derive an expression of the effective exchange integral J in the Heisenberg model. Recently, several computational methods of J have been presented [21–28]. We can approximately define the expression of the effective exchange integral $J^{\text{eff}}_{ab}(\boldsymbol{q})$ as

$$J^{\text{eff}}_{ab}(\boldsymbol{q}) = \left(V^{\sigma-\sigma}_{\text{eff}}(\boldsymbol{q}) - V^{\sigma\sigma}_{\text{eff}}(\boldsymbol{q})\right)_{ab} \tag{16}$$

$$= \frac{1}{2}\left(V^{\sigma-\sigma}_{\text{eff}}(\boldsymbol{q})\left[1 - \chi^0(\boldsymbol{q})U\right]\right)_{ab}. \tag{17}$$

Using Eq. (15), we can rewrite Eq. (17) as

$$J_{ab}^{\mathrm{eff}}(\boldsymbol{q}) = \left(\left[\chi^0(\boldsymbol{q}) \right]^{-1} \chi(\boldsymbol{q}) U \left[1 - \chi^0(\boldsymbol{q}) U \right] \right)_{ab}. \tag{18}$$

From the above equation, we can find that the effective exchange integral is proportional to the effective spin susceptibility between sublattices.

3. Concluding remarks

We have presented a two-dimensional 4-sublattice square lattice system and have investigated 4-band effects in magnetism by using spin susceptibility. The spin susceptibility of the sublattice system has been calculated, and the expression of the effective exchange integral in Heisenberg model has been derived within the random-phase approximation by using Hubbard model and the spin susceptibility. The effective exchange interaction arises from the spin susceptibility and the on-site coulomb interaction.

The present results suggest that in many-band system doped with hole, we can expect new magnetic properties or new magnetic state. We also expect that new magnetic properties arise from many-band effect in systems with spin frustration such as kagome lattice, triangular lattice, and so on. The many-band effect in hole-doped systems with spin frustration will be presented elsewhere [29].

ferrimagnetic ring S_xs_x ($S = 5/2$, $s = 1/2$, $x = 2$–8). The Hamiltonian of this system is given by

$$\hat{H}_{\rm sys} = \hat{H}_0 + \hat{H}_{\rm DM} + \hat{H}_{\rm z}, \tag{1}$$

$$\hat{H}_0 = \sum_{i=1}^{x} J_1[\mathbf{S}_{2i-1}\cdot\mathbf{s}_{2i} + \mathbf{s}_{2i}\cdot\mathbf{S}_{2i+1}] + \sum_{i=1}^{x} J_2\mathbf{s}_{2i-1}\cdot\mathbf{s}_{2i+1}, \tag{2}$$

$$\hat{H}_{\rm DM} = \sum_{i=1}^{x}[\mathbf{D}_{2i-1,2i}\cdot\mathbf{S}_{2i-1}\times\mathbf{s}_{2i} + \mathbf{D}_{2i,2i+1}\cdot\mathbf{s}_{2i}\times\mathbf{S}_{2i+1}] + \sum_{i=1}^{x}\mathbf{d}_{2i-1,2i+1}\cdot[\mathbf{s}_{2i-1}\times\mathbf{s}_{2i+1}], \tag{3}$$

$$\hat{H}_{\rm z} = -h\sum_{i=1}^{x}(s^z_{2i-1} + S^z_{2i}). \tag{4}$$

The total Hamiltonian $\hat{H}_{\rm sys}$ consists of three parts. The first one is the Heisenberg Hamiltonian $\hat{H}_0$ which determines the position of steps of the magnetization process. The second one is the Dzyaloshinsky–Moriya (DM) interaction, $\hat{H}_{\rm DM}$, which determines the form of the magnetization process near steps. The third one is the Zeeman term, $\hat{H}_{\rm z}$, which describe the effect of the magnetic field. h represents the magnetic field which is assumed to be parallel to the z-axis. In all definitions, $\mathbf{S}_i$ and $\mathbf{s}_i$ represents the spin operator at an $S = 5/2$ spin site and an $s = 1/2$ spin site, respectively. The periodic boundary condition, $\mathbf{s}_{2x+1} = \mathbf{s}_1$, is imposed. J_1 and J_2 represent the coupling constant with Heisenberg exchange interaction. $|\mathbf{D}_{i,j}| = D_{i,j}$ and $|\mathbf{d}_{i,j}| = d_{i,j}$ are parameters for DM interaction. These parameters are controllable in the calculation. We take J_1 as an energy unit and define dimensionless parameters: $\tilde{h} = h/J_1$, $\tilde{d}_{i,j} = d_{i,j}/J_1$, $\tilde{D}_{i,j} = D_{i,j}/J_1$, $\tilde{J}_2 = J_2/J_1$. In this paper, we investigate the two cases for $\tilde{J}_2$. One is the non-frustrated system, $\tilde{J}_2 = 0$. The other is a frustrated system, $\tilde{J}_2 = 2.15$. This parameter is determined as the optimum parameter in Mn_6R_6 [4]. For the sake of simplicity, we take the condition that $\mathbf{D}_{2i-1,2i} = \mathbf{D}_{2i,2i+1}$, $\mathbf{d}_{2i-1,2i+1} = 0$ in the case of $\tilde{J}_2 = 0$, and that $\mathbf{D}_{2i-1,2i} = \mathbf{D}_{2i,2i+1} = \mathbf{d}_{2i-1,2i+1}$ in the case of $\tilde{J}_2 = 2.15$.

In order to determine the DM interaction, we have to discuss the symmetries of the molecule. First, we examine the case of Mn_6R_6. The crystallographic data of atomic position tells us four symmetries of the molecule. The first one is C_i with the inversion center at the center of the two hexagons; one is the inner-hexagon that is composed of $s = 1/2$ spins and the other is the outer-hexagon that is composed of $S = 5/2$ spins. The second one is S_6 with the axis that is perpendicular to the hexagon and that goes thorough the inversion center. The third one is C_3 with the same axis. In addition to the above three symmetries, there exists an approximate symmetry. That is C_2 with the axis going through two apexes and the center of the inner-hexagon.

By considering these four symmetries of Mn_6R_6, we determine the DM interaction for S_xs_x. After a simple analysis, one obtain an arrangement of $\mathbf{d}_{i,j}$ of S_6s_6 depicted in Fig. 1 as well as a set of uniform $\mathbf{d}_{i,j}$ perpendicular to the hexagon. Note that the projections of $\mathbf{D}_{i,i+1}$ and $\mathbf{D}_{i+1,i+2}$ to the xy-plane are directed to the same direction as that of $\mathbf{d}_{i,i+2}$. For other S_xs_x when x is even, we suppose the same arrangement of $\mathbf{d}_{i,j}$. That is, $\mathbf{d}_{i,j}$ is perpendicular to the each side of the inner-polygon and forms the alternated array with respect to the direction of the center of the polygon. A similar pattern of DM interaction was discussed in the case of the nanoscale antiferromagnetic rings [6]. For the S_xs_x when x is odd, we assume the following symmetries. Note that C_i and S_x does not exist in the case that x is odd. First, let us consider the arrangement of $\mathbf{d}_{i,j}$ of S_5s_5. We suppose C_5 with the axis that is perpendicular to the pentagon and that goes through the center of the pentagon. We also consider C_2. The axis of C_2 connects two apexes in the different pentagon, inner-pentagon and outer-pentagon and goes thorough the common center of these pentagons. After a simple analysis, one obtains an arrangement of $\mathbf{d}_{i,j}$ of S_5s_5 depicted in Fig. 1 as well as

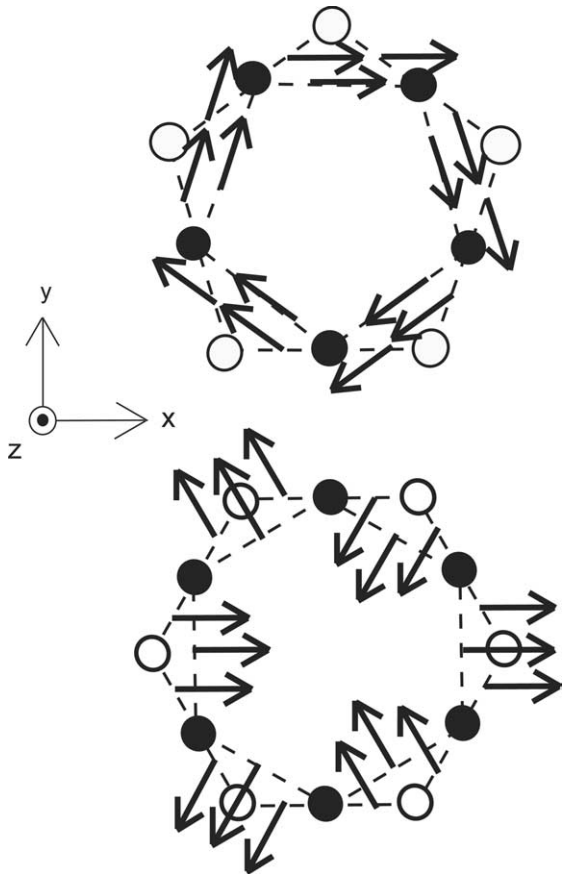

Fig. 1. The arrangement of $\mathbf{D}_{i,j}$ of S_5s_5 (upper side) and S_6s_6 (down side). The arrows show the projection of $\mathbf{D}_{i,j}$ on xy-plane. The black bullets represent $s = 1/2$ local spin sites and the white bullets represent $S = 5/2$ local spin sites.

a set of uniform $\mathbf{d}_{i,j}$. For the other odd-numbered S_xs_x ($x = 3, 7$), we also suppose the same symmetry and can obtain the same arrangement of $\mathbf{d}_{i,j}$. Considering the above arrangement of $\mathbf{D}_{i,j}$, we calculate the magnetization process ($T = 0$ [K]) and the field derivative of the magnetization, $\mathrm{d}M/\mathrm{d}\tilde{h}$ for the various size of S_xs_x. Applying the reduced matrix that is adopted by the effective basis method [7], we make the numerical diagonalization. The direction of the magnetic field is supposed to be perpendicular to the polygon in this paper. Therefore, components of $\mathbf{D}_{i,j}$ and $\mathbf{d}_{i,j}$ perpendicular to the polygons do not contribute to the magnetization process.

First, let us discuss the magnetization process and $\mathrm{d}M/\mathrm{d}\tilde{h}$.

In the non-frustrated case of S_xs_x ($\tilde{J}_2 = 0$, $\tilde{d}_{i,j} = 0$, $x = 2$–8), there is no width in all the peaks, that is, each peak forms the δ-function. Therefore, all the magnetization processes reveal step structures. In this case, regarding the peak structure, there is no qualitative difference among the systems with different x. That is, there is no remarkable size dependence of the magnetization process.

In the frustrated cases of S_xs_x ($\tilde{J}_2 = 2.15$, $\tilde{d}_{i,j} = 0.05$, $x = 2$–8), magnetization process and $\mathrm{d}M/\mathrm{d}\tilde{h}$ are drastically dependent on the size of the ring. We first discuss the magnetization process of S_6s_6 by comparing the experimental data of Mn_6R_6. Fig. 2(b) shows the magnetization process of S_6s_6. The magnetization M of the ground state at given field changes from $M = 12$ to $M = 18$. Every step indicates the position of the energy-level crossing between the case M and $M + 1$. The field derivative of the magnetization $\mathrm{d}M/\mathrm{d}\tilde{h}$ is shown in Fig. 2(a). The height of the peak increases from the first peak to the third peak. The height of the fourth peak is higher than the first peak and is lower than the second peak. The tendency of the former four peaks agrees with the four peaks that is experimentally observed for Mn_6R_6 [2], although the numerical third peak is comparably sharp. The main origin for the height of the experimental third peak may be the other factors, such as the thermal distribution and other anisotropy effects, for example, the dipole–dipole interaction. However, the DM interaction determined above is the primary origin for the peak structure that is experimentally observed. On the other hand, in the case of $\tilde{J}_2 = 0.0$ mentioned above, S_6s_6 is inconsistent with Mn_6R_6 with respect to the peak structure. For other cases of frustrated systems of S_xs_x, ($\tilde{J}_2 = 2.15$, $\tilde{d}_{i,j} = 0.05$, $x = 3, 5, 7$), Fig. 3 shows the magnetization process and the field derivative of magnetization. Interesting peak structure is observed in all cases, that is, changes of the height of the peaks in the magnetic fields is not monotonous. One of the present authors have reported that the lattice distortion makes the peak structure varied in antiferromagnetic ring [8]. But the origin for the curious peak structure in the present system is the frustration. In the case of S_xs_x, ($x = 4, 8$), all the peaks in each system form the δ-function. Therefore, the change of the number of the unit cell provides the drastic change of the magnetization process when the system has frustration. This size effect can be utilized as a finger print of each molecule.

Finally, we demonstrate another size dependence effect that is found in the translational quantum number, $k = (2\pi/x)n$ ($n = 0, 1, \ldots$), which is associated with the cyclic shift operation of the rings. The translational quantum number is a wave number in the wave function of a system. Because the DM interaction is generally small in comparison with exchange interaction, the wave

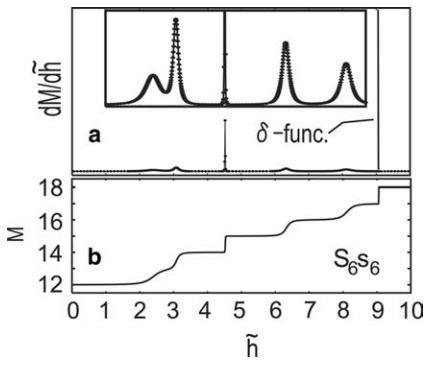

Fig. 2. The field derivative of magnetization, $\mathrm{d}M/\mathrm{d}\tilde{h}$, (a) and the magnetization process (b) in S_6s_6. The inset figure is enlarged one $1 < \tilde{h} < 8.7$. Only the sixth peak form the δ-function. This result is consistent with the experimental data of Mn_6R_6 [2].

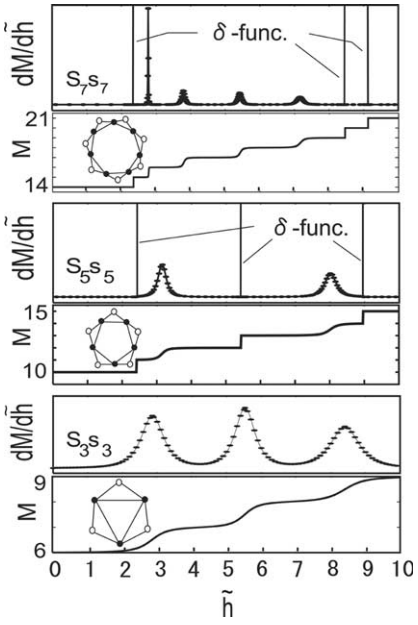

Fig. 3. The magnetization process and the field derivative of magnetization $\mathrm{d}M/\mathrm{d}h$ in S_xs_x ($x = 3, 5, 7$). The remarkable size dependence of magnetization process is observed.

number should not be affected by the DM interaction. Thus, we calculate k in the lowest energy eigenstate of $\hat{H}_0 + \hat{H}_z$ at given fields. The calculating results are divided into the following three features: (I) ($\tilde{J}_2 = 0$, $x = 2$–8): this parameter set corresponds to the non-frustrated case. In this case, $k = 0$ is always realized in the lowest energy eigenstate at any given field. Moreover, this feature does not depend on the number of unit cell; (II) ($\tilde{J}_2 = 2.15$, $x = 2, 4, 6, 8$): this parameter set corresponds to the frustrated case in which the number of the unit cell is even. In this system, k takes the value of 0 and π alternately; when M is even number, $k = 0$, when M is odd number, $k = \pi$; (III) ($\tilde{J}_2 = 2.15$, $x = 3, 5, 7$): this parameter set corresponds to the frustrated case in which the number of the unit cell is odd. Note that there are two kinds of frustration in this system. One is the triangle s–S–s, and another is the polygon which consists of s. Then, the feature of k is rather complicated. In case $x = 3$, while the magnetization of the lowest energy eigenstate is changed from $M = 6$ to $M = 9$, the k is realized $k = 0$, $\pm 2\pi/3$, $\pm 2\pi/3$, 0, respectively. In case $x = 5$, while the magnetization is changed from $M = 10$ to $M = 15$, the k is realized $k = 0$, $\pm 4\pi/5$, $\pm 2\pi/5$, $\pm 2\pi/5$, $\pm 4\pi/5$, 0, respectively. In case of $x = 7$, while the magnetization is changed from $M = 14$ to $M = 21$, the k is realized $k = 0$, $\pm 6\pi/7$, $\pm 2\pi/7$, $\pm 4\pi/7$, $\pm 2\pi/7$, $\pm 6\pi/7$, 0, respectively. The same result of the frustrated cases (II) and (III), is obtained in the $S = 1/2$ antiferromagnetic spin rings [9] in which the number of sites corresponds to the number of unit cell in the present systems. Note that, the drastic size dependence of $\mathrm{d}M/\mathrm{d}\tilde{h}$ appears in the situation of the parameter set of the feature (II) and (III). Therefore, the size dependence of the translational quantum number k appears only in the frustrated case but not in the non-frustrated case.

In summary, we have investigated the size dependence of the magnetic properties in nanoscale ferrimagnetic ring. We have investigated the two types of ferrimagnetic rings with Dzyaloshinsky–Moriya interaction. One is the frustrated system and the other is the non-frustrated system. As a result, in the non-frustrated case, the change of the number of unit cells does not provide the remarkable change about the magnetization process. On the other hand, in the frustrated cases, there are drastic size dependence of the magnetization process. This result indicates that the effect of frustration causes the size dependence of the magnetic properties in the ferrimagnetic ring. We also provide the information for the other aspect of the size dependence by calculating the translational quantum number in the lowest eigenstate at the given fields. It is clarified that the size dependence caused by the frustration is also found in the behavior of the translational quantum number of the ground state.

that of frequency domain magnetic resonance spectroscopy (FDMRS), which combines the zero-field advantage of INS with HFEPR sensitivity [8].

Magnetic resonance and neutron scattering studies have focussed on the determination of spin Hamiltonian parameters, i.e., the fitting of a certain spin Hamiltonian to the observed peak positions. Much less attention has been paid to the lineshape of the magnetic resonance lines. The (inhomogeneously broadened) magnetic resonance lineshape of two other single molecule magnets, $Mn_{12}Ac$ and Fe_8 has been studied using both HFEPR and time-domain THz spectroscopy. HFEPR studies on Fe_8 showed that both distributions in the internal dipolar fields, and in the zero-field splitting parameters contribute to the linewidth [9,10]. In the case of $Mn_{12}Ac$ is was shown that the contribution of the dipolar fields to the linewidth is relatively unimportant, and that it is mainly governed by distributions in the zero-field splitting parameter D [9–11]. In the latter sample, the situation is made more complicated by the presence of different isomers [12]. One reason for the relative scarcity of lineshape studies is that lineshapes are often distorted in experiments using the simpler single pass transmission HFEPR setups. Apart from information on distributions of the ZFS parameters in the case of inhomogeneously broadened lines, in the case of homogeneously broadened lines, the excited state lifetime can be obtained. These lifetimes are currently of great interest, since single molecule magnets were proposed as promising candidates for application in quantum computing. In this proposal, three microwave pulses of a duration of 10^{-7} s have to be applied within the lifetime of a coherently populated state [13]. However, little is known about the dynamics of the magnetic microstates of SMMs. A rough indication comes from the prefactor in the Arrhenius law type of temperature dependence of the magnetization relaxation rate. For published SMMs this prefactor usually lies between 10^{-7} and 10^{-9} s^{-1}.

Here, we present a preliminary study of the zero-field splittings and the magnetic resonance lineshapes and –widths of two published SMMs, namely (PPh_4)-$[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ ($[Mn_{12}^-]$) [14], and $[Mn_9O_7$-$(O_2CCH_3)_{11}(thme)(py)_3(H_2O)_2]$ ($[Mn_9]$) [15]. These systems are structurally rather similar, both having non-integer ground states, and idealized axial symmetry. $[Mn_{12}^-]$ has an $S = 19/2$ ground state, and $[Mn_9]$ an $S = 17/2$ ground state. The energy barriers towards relaxation of the magnetization were determined to be $\Delta E = 57$ K and $\Delta E = 27$ K for $[Mn_{12}]^-$ and $[Mn_9]$, respectively [14,15]. From magnetization measurements for $[Mn_9]$ a D value of $-0.29(3)$ cm^{-1} was determined [15], while a D value of -0.4 cm^{-1} was obtained for $[Mn_{12}^-]$ [14]. In the case of $[Mn_{12}^-]$, HFEPR measurements yielded a value of $D = -0.42$ cm^{-1} [14].

2. Experimental

The materials $[Mn_{12}]^-$ and $[Mn_9]$ were prepared as described [14,15]. Their identity and purity was checked by elemental analysis, X-ray unit cell determination, and IR-spectroscopy.

The FDMRS spectrometer has been described in the literature [8]. Briefly, it is a quasi-optical spectrometer in a Mach–Zehnder interferometer layout. It features backward wave oscillators as sources, which are vacuum tubes that produce strong, coherent radiation which is tunable over a wide frequency range. As detectors both room temperature Golay cells and helium-cooled Bolometers are used. The transmission spectra reported here employ only one arm of the interferometer; for phase spectra both arms are required. Measurements are possible with and without the application of a static external magnetic field, where the field can be parallel (Faraday geometry) or perpendicular (Voigt geometry) to the radiation propagation direction. The present measurements were performed in zero field on pressed powder pellets of 1 cm diameter and 3.449 mm thickness ($[Mn_{12}]^-$) and 1.456 mm thickness ($[Mn_9]$), respectively.

The analysis procedure was as follows: The spectra were normalised, i.e., divided by the highest temperature one, to remove the Fabry–Perot resonance induced oscillation of the baseline, and artefacts. Subsequently, the resonance frequencies were determined. The spin Hamiltonian parameters were fitted to these frequencies using matrix diagonalisation. Using the obtained parameters, the spectra were simulated using Fresnel formulas for transmission of a plane parallel sample, and the resonance line width was determined [8].

3. Results and discussion

In the transmission spectra for $[Mn_{12}]^-$ and $[Mn_9]$, two features were observed. First of all there is an oscillation in the baseline, which is due to Fabry–Perot-like interference of the radiation within the plan-parallel pellet. Second, several narrow lines are visible with intensities depending on the temperature. These narrow lines are attributed to magnetic resonance transitions between the magnetic microstates within the ground state $S = 19/2$ and $S = 17/2$ multiplets of $[Mn_{12}]^-$ and $[Mn_9]$, respectively. The spectra were normalised (Figs. 1 and 2) to remove the baseline oscillation. In this way, the resonance position can be determined with an accuracy of less than 1% or 0.03 cm^{-1}. For $[Mn_{12}]^-$, five resonance lines can be observed at 7.66, 7.04, 6.31, 5.41, and 4.71 cm^{-1}, respectively. Four resonance lines are present in the spectra recorded for $[Mn_9]$, namely at 3.79, 3.41, 2.95 and $\sim$2.50 cm^{-1}.

In general, the degeneracy of the magnetic microstates is lifted due to zero-field splitting, which, using a

spin Hamiltonian approach, can be described as functions of the spin operators. In many studies of the magnetic anisotropy of molecular magnets, it has proven necessary to include not only second-order terms but also additional higher-order ones. Usually Stevens operator equivalents are used for these higher-order terms. In the present case, the following spin Hamiltonian was used to fit the spectra:

$$H = D\left[\hat{S}_Z^2 - \frac{1}{3}S(S+1)\right] + B_4^0\hat{O}_4^0.$$

From the fact that the highest frequency line in both samples has the highest intensity at low temperatures, we can immediately conclude that the leading term in the spin Hamiltonian must be negative, i.e., $D < 0$. The position of the highest-frequency resonance line gives an estimate of the second-order axial ZFS parameter, i.e., $D = -0.425\ \mathrm{cm}^{-1}$ for $[Mn_{12}]^-$, and $D = -0.237\ \mathrm{cm}^{-1}$ for $[Mn_9]$. A least squares fit of the spin Hamiltonian parameters to the observed resonance frequencies resulted in the following parameters: $D = -0.454 \pm 0.004\ \mathrm{cm}^{-1}$ and $B_4^0 = (+1.01 \pm 0.05) \times 10^{-5}\ \mathrm{cm}^{-1}$ for $[Mn_{12}]^-$, and $D = -0.247 \pm 0.005\ \mathrm{cm}^{-1}$, $B_4^0 = (+4.6 \pm 0.1) \times 10^{-6}\ \mathrm{cm}^{-1}$ for $[Mn_9]$. The fit was not improved by introduction of transverse anisotropy either in second or in fourth order. These parameters fit quite well with published ones based on magnetization measurements, and, in the case of $[Mn_{12}]^-$ with HFEPR data. In these latter studies it was stated that inclusion of fourth-order ZFS parameters did not improve the fit. In our fits a significant improvement was found, however. Interestingly, the magnitude of the B_4^0 parameter of $[Mn_{12}]^-$ is almost 2 orders of magnitude smaller than in the case of the parent $[Mn_{12}Ac]$ molecule [4,16–18]. The zero-field splitting of a total spin state of a single molecule magnet is to a large extent a linear combination of the zero-field splittings of the single ions, where the coefficients depend on the exchange coupling scheme [19]. Therefore, this drastic drop in magnitude is unexpected since neither the single ion anisotropies nor the exchange couplings are likely to change dramatically. Since the fourth-order anisotropy in the case of $[Mn_9]$ is even smaller, it would be interesting to see if such small B_4^0 values are a general feature of exchange coupled clusters with non-integer spin ground states. Another feature of interest is the positive sign of B_4^0 in both cases. In many cases, this parameter is negative for single molecule magnets, e.g., in the case of the aforementioned $Mn_{12}Ac$ [18], Fe_8, [20], or the $[Mn_4]_2$ dimer [21]. However, other examples of positive B_4^0 parameter are known, e.g., for some Mn_4SMMs [5].

Using the obtained spin Hamiltonian parameters, the magnetic resonance spectra were simulated at the lowest temperature of $T = 1.8$ K as shown in Figs. 3 and 4 for $[Mn_{12}]^-$ and $[Mn_9]$, respectively. As can be seen, the resonance line of $[Mn_9]$ can best be described by a Gaussian function which shows better agreement with the experiment than a Lorentzian one, especially at the edges of the resonance line. Interestingly, the contrary is true for $[Mn_{12}]^-$, where the resonance line is clearly Lorentzian. The Gaussian (*inhomogeneously* broadened) lineshape in the case of $[Mn_9]$ suggests that the linewidth is determined by distributions in the sample either a distribution in ZFS parameters or a distribution in the local magneto dipolar field. Within experimental error, the linewidth ($0.06 \pm 0.02\ \mathrm{cm}^{-1}$) does not change with temperature, which indicates that the distribution in D is the main source of inhomogeneous broadening. This linewidth is slightly smaller than that found for $[Mn_{12}Ac]$ ($0.09 \pm 0.01\ \mathrm{cm}^{-1}$) [22].

In contrast, the highest-frequency resonance line of $[Mn_{12}]^-$ appears to be *homogeneously* broadened,

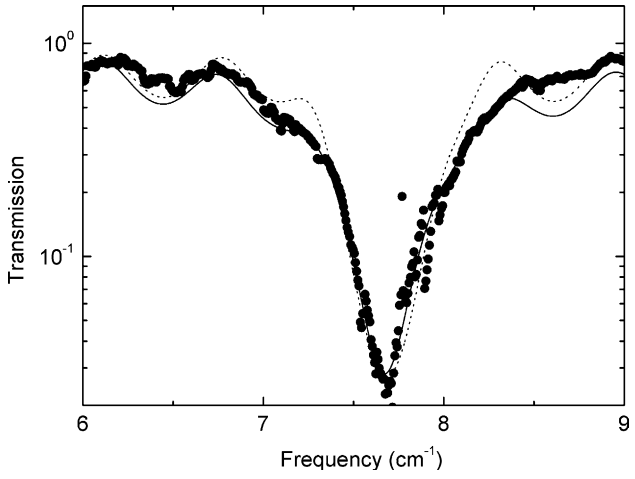

Fig. 3. FDMRS spectrum recorded on $[Mn_{12}^{-}]$ at $T = 1.8$ K, together with fits assuming Lorentzian (drawn) and Gaussian (dotted) lines.

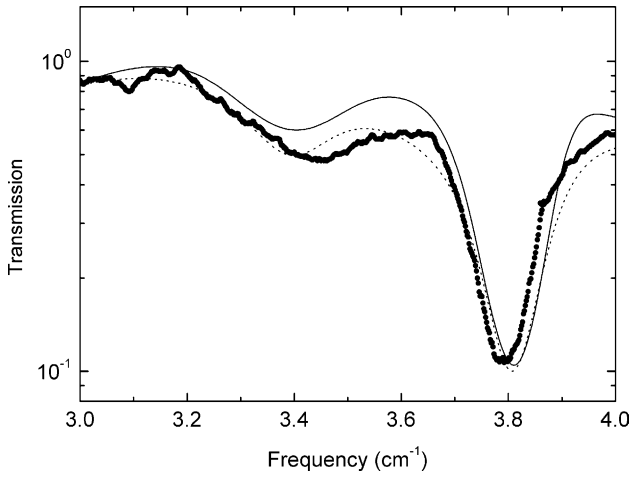

Fig. 4. FDMRS spectrum recorded on $[Mn_9]$ at $T = 1.8$ K, together with fits assuming Lorentzian (dotted) and Gaussian (drawn) lines.

which is quite uncommon. In fact most resonance lines recorded on molecular magnets by magnetic resonance spectroscopy (both HFEPR and FDMRS) are Gaussian shaped. The linewidth is slightly temperature dependent, going from 0.41 cm^{-1} (FWHM) at 1.8 K to 0.55 cm^{-1} at high temperatures. In case of homogeneously broadened resonance lines it is the excited state lifetime governed by spin–lattice or spin–spin relaxation, that determines the linewidth, through a Heisenberg type of uncertainty relation, which broadens the energies of short-lived states. In fact, on a quantitative level, the linewidth expressed as an angular frequency is given by $\omega = 2/\tau$, where τ is the relaxation time [23]. Conversely $\tau = \omega/2 = \pi\nu$. In the present case, that means that the excited state lifetime in the case of $[Mn_{12}^{-}]$ is 50–58 ps, depending on temperature. The prefactor in the Arrhenius analysis of the magnetization of the relaxation was determined to be 310 ps, which suggests that the dynamics of higher excited states are slightly slower. These lifetimes are short in comparison to other estimates of excited state lifetimes published in the literature. Thus, for certain Ni_4 clusters, spin–spin relaxation times of about 1 ns were reported [24]. In general, the relaxation from the excited state can take place through three types of processes [19]. The direct relaxation process is usually less important since the number of phonons is much smaller than the number of spins in concentrated magnetic media such as molecular magnets. Two two-phonon processes exist which rely on an intermediary state, which is real in the case of an Orbach process and virtual in the case of a Raman process. In exchange coupled clusters there are usually a number of levels present with energies comparable to kT. However, no large difference in exchange interactions, and therefore in number and energies of the excited spin levels is expected between $[Mn_{12}]^{-}$ and $[Mn_{12}Ac]$. This means that the origin of this short lifetime is as yet unclear.

In conclusion, we have determined the ZFS parameters of two non-integer single molecule magnets, $[Mn_9]$ and $[Mn_{12}]^{-}$, showing that frequency domain magnetic resonance spectroscopy (FDMRS) is excellently suited to this end. Furthermore, we have shown that the magnetic resonance linewidth is inhomogeneously broadened (Gaussian) in the case of $[Mn_9]$ and homogeneously broadened (Lorentzian) in the case of $[Mn_{12}]^{-}$. This allows the determination of the excited state lifetime in the latter case, which was determined to be 50–58 ps, depending on temperature. A consequence of such a short lifetime is that quantum computing schemes, based on coherent population of excited spin levels, will have to be carried out in shorter times than the excited state lifetime.

non-magnetic plate. The specimen was installed in the ^{3}He-refrigerator, so as to align the *b*-axis (the easy axis [6]) in the field direction of the magnetometer. The applied field, H_a, was corrected for the demagnetization effect to give the field seen by the sample, $H_{eff.}$. Only a rough estimation of demagnetization factor, N, was possible, because the shape is different piece by piece and is not ellipsoidal. However, the value of N does not affect any conclusion in this work. We applied N of approximately 0.4, to calculate, $H_{eff.} = H_a - 4\pi N M_V$, where M_V denotes the magnetization per unit volume.

While the new measurement system was being conceived, we always kept one thing in mind; ''Do not alter the MPMS.'' We have succeeded in designing a system that is easily attachable and detachable. Our MPMS is equipped with the ^{3}He cryostat only when temperatures lower than 1.8 K is necessary; otherwise it works just as a normal MPMS. The ^{3}He cryostat has been designed to be slim enough to fit into the sample space of Quantum Design's MPMS. The schematic drawing of the cryostat is shown in Fig. 1. It is the ''Sample in liquid''-type cryostat, meaning that the sample is soaked in the liquid ^{3}He. The lower end of the main pipe has a vacuum jacket to insulate the inside of the cryostat from the outside environment, which is actually the sample space in an ordinary usage of the MPMS and maintained at 1.6 K during the ^{3}He-temperature operation. Here the base temperature of the MPMS somewhat lower than the usual (around 1.8 K) is achieved by an auxiliary rotary pump, facilitating more efficient condensation of ^{3}He gas.

The principle of the measurement is that we scan the whole cryostat, including the sample, through the pick-up coil. In a way it is similar to magnetization measurements with a pressure cell. This method is advantageous in that the sample temperature is very stable during the scan. The problem is that the cryostat contributes to the background. It can be subtracted, however, unless it is too large. The current version has been designed for an Reciprocating Sample Oscillation (RSO)-type drive, although a version that is compatible with a standard DC-type drive is also possible. The present cryostat is supported at its neck by the top part of the moving rack of the RSO unit. On top of the drive we mount a box as a sample-space airlock, and a bellows inside the box interconnects between the ^{3}He cryostat and a flange, which is the port to a gas-handling system.

To hold a sample in position, we use the drinking straws that are used with the MPMS. Since the sample is thermally insulated from the outside of the cryostat, the temperature has to be measured in situ. To reduce the background from the thermometer, we have adopted a bare-chip Cernox (Lake Shore Cryotronics, Inc.) sensor, which gives a fairly small moment of 1×10^{-4} emu at 1.6 K and 1 T. It is accommodated in a polyimide tube and placed just above the sample. The total background from the current cryostat is about 6×10^{-4} emu at 0.5 K and 1 T. This is small enough to be neglected in the case reported herein and in most other cases. If necessary, we can subtract the background by measuring it separately.

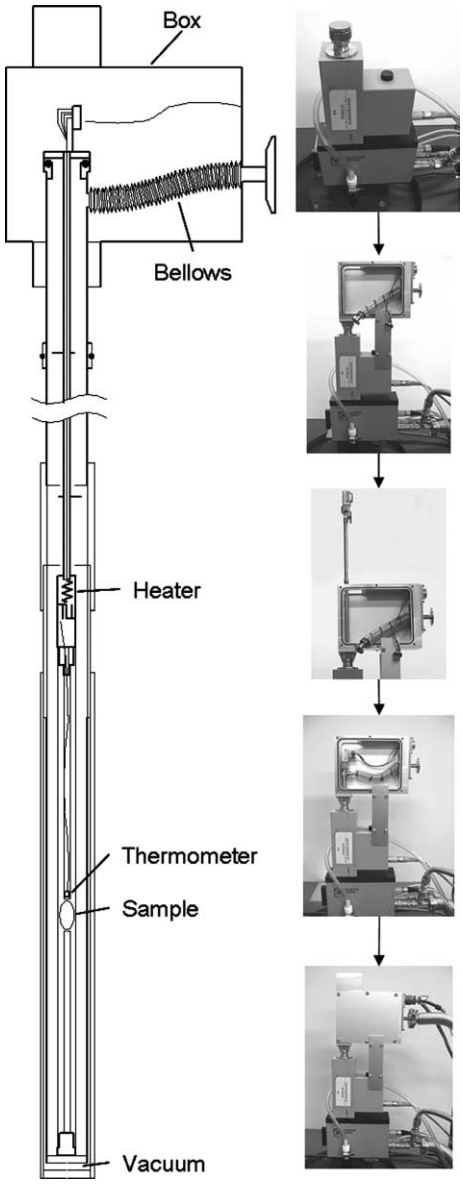

Fig. 1. (Left) Schematic drawing of our ^{3}He cryostat. (Right) Pictures showing the set-up procedure of the ^{3}He cryostat.

The usage of the new apparatus is as the following (see the pictures in Fig. 1). The normal MPMS has an O-ring seal made of acryl on the top opening of the RSO drive unit. We replace the seal with an O-ring compression fitting for a more secure connection. After warming up the sample space of the MPMS to around room temperature and venting with He gas, we fix the box on top of the RSO unit by inserting the bottom pipe of the box into the O-ring fitting. Then the ^{3}He cryostat is installed into the MPMS's sample space, and all the connections are made. When the box has been covered

and the inside of the ^{3}He cryostat has been evacuated, the system is ready to be cooled down.

Using ^{3}He gas as heat-exchange medium inside the cryostat, we first cool down the MPMS to around 5 K. Then the auxiliary rotary pump lowers the temperature to 1.6 K, at which ^{3}He gas is condensed. Finally the liquefied ^{3}He is pumped out to go below 0.5 K. We can reach 0.48 K within 30 min or so after starting to pump the liquid.

Fig. 2 shows the M–H characteristic of β-p-NPNN below and above T_c. The data above T_c, which were measured by a usual method without the ^{3}He-refrigerator, are consistent with those reported previously [4,5]. The saturation of the paramagnetic moment at the value close to $M_{sat}(1/2)$ was observed at 2 K. The static M–H curves below T_c clearly show that the ferromagnetic moment also saturates at $M_{sat}(1/2)$. Therefore, we conclude M_{sat} of β-p-NPNN is $M_{sat}(1/2)$ as expected for an ordinary spin-1/2 Heisenberg ferromagnet.

Another characteristic is the absence of hysteresis as shown in Fig. 3; the magnetization is almost reversible and the coercive force and residual magnetization are too small to be detected, unlike the previous result [4,5]. The small hysteresis observed by the dynamical method might have been an artifact due to the difference in the data-acquisition timing for M and H. Another thing that we would like to point out is that the field was applied along the easy axis in the present measurements to suppress the irreversible rotation of magnetization against the small dipolar anisotropy, whereas the field had not been along the easy axis in the previous ones. Thus β-p-NPNN is concluded to be a considerably soft magnet at least for the easy axis. This behavior is expected for an isotropic Heisenberg spins of the organic radicals, and is consistent with the specific heat [5] and μSR [6] results.

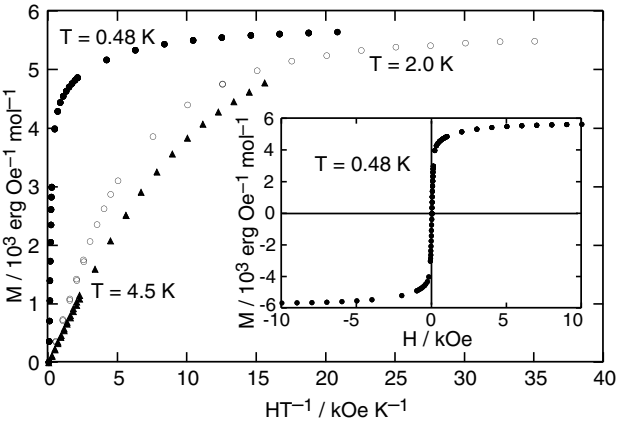

Fig. 2. Magnetization of β-p-NPNN below and above T_c plotted vs. H/T. The inset shows the overall M–H characteristic in the ferromagnetic state. Demagnetization correction is not made for the data in this figure.

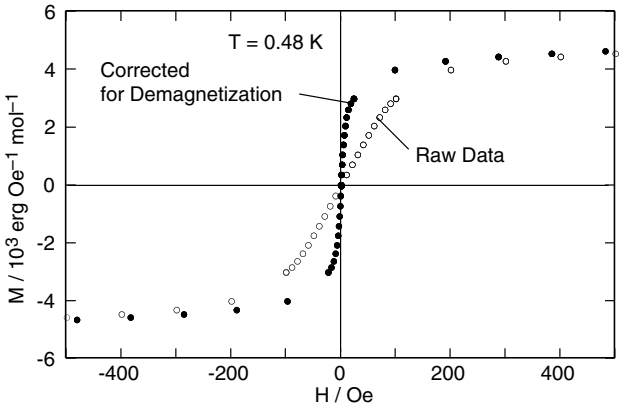

Fig. 3. Low field M–H curve of ferromagnetic β-p-NPNN at 0.48 K. The closed symbols show the data corrected for demagnetization effect, while open ones are without the correction. Both upward and downward field sweep data are shown. No hysteretic behavior is found.

In the ferromagnetic state, M rises rapidly below the applied field $H_a \approx 200$ Oe. It is also noted that M is still increasing slowly even in the high-field regime, $H_a > 1$ kOe, until it saturates near $H_a = 10$ kOe. This means that $H_a = 400$ Oe was too low to determine M_s. Since the magnetic anisotropy of β-p-NPNN is significantly small, the slow saturation can be related to the thermal fluctuation effect of a soft isotropic ferromagnet, rather than to the rotation of domain magnetization or to the domain wall displacement of hard magnets. If this is the case, the initial increase of M at low fields is regulated by the spontaneous magnetization, M_{sp}, which corresponds to the order parameter. This is followed by slow increase of M in the range, $M_{sp} < M < M_{sat}$, in the high field regime. The spontaneous magnetization $M_{sp}(T)$ decreases from $M_{sp}(0) = M_{sat}$ to zero as $T = T_c$ is approached. From the μSR measurement [7], $M_{sp} \approx 0.8\ M_{sat} = 4.5 \times 10^3$ erg Oe^{-1} mol^{-1} is inferred at $T = 0.48$ K ($T/T_c = 0.8$). This agrees with the initial rise of M observed in this work. In this way, the M–H characteristic of β-p-NPNN is understood in terms of the thermal fluctuation.

(0.24 g, 1.0 mmol) was added to the resulting slurry and the mixture was stirred for 63 h at 90 °C. The reaction mixture was quenched with 100 ml water and yellow suspension was extracted with dichloromethane. Organic phase was evaporated and obtained crude products was purified with silica-gel column chromatography with dichloromethane/hexane (1/1, v/v) as an eluent to yield 0.24 g of $dppFc_2$ as orange powder (0.41 mmol, 41%). *Anal*. Calc. for $C_{31}H_{25}N_5Fe_2$: C, 64.28; H, 4.35; N, 12.09. Found: C, 64.18; H, 4.62; N, 12.11%. ^{1}H NMR (270 MHz, $CDCl_3$, 25 °C): δ 8.51(d, $J = 2.7$, 2H, pz), 7.89 (m, 3H, py), 6.54 (d, $J = 2.7$, 2H, pz), 4.79 (s, 4H, Cp), 4.34 (s, 4H, Cp), 4.11 (s, 10H, Cp).

2.1.2. $[Fe(dppFc_2)_2](BF_4)_2$

A solution of $Fe(BF_4)_2 \cdot 6H_2O$ (44 mg, 0.13 mmol) in degassed acetone (5 ml) was added to the orange suspension of $dppFc_2$ (35 mg, 0.06 mmol) in acetone (5 ml) and stirred for 30 min to obtain deep orange solution. Addition of diethylether to the deep orange solution gave brown powder. Recrystallization from acetonitrile and diethylether gave deep red crystals of $[Fe(dppFc_2)_2](BF_4)_2$. *Anal*. Calc. for $C_{62}H_{50}B_2F_8Fe_5N_{10} \cdot 4H_2O$: C, 51.00; H, 4.00; N, 9.59. Found: C, 51.18; H, 3.91; N, 9.50%.

2.2. X-ray crystallography

Each crystal of $dppFc_2$ and $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$ was mounted on a glass capillary, and data were collected at −30 °C (Bruker SMART APEX diffractometer coupled with a CCD area detector with graphite monochromated Mo Kα($\lambda = 0.71073$ Å) radiation). The structure was solved by direct methods and expanded by using Fourier techniques using SHELXTL program. Crystal data: [$dppFc_2$]: $C_{31}H_{25}Fe_2N_5$, $M = 579.26$, monoclinic space group $P2_1/n$, $a = 14.246(2)$, $b = 9.793(1)$, $c = 17.910(3)$ Å, $\beta = 90.055(3)°$, $V = 2498.6(7)$ Å^3, $Z = 4$. A total of 10 770 were collected ($1.83° < \theta < 23.26°$) of which 3580 unique reflections ($R_{int} = 0.0546$) were measured. Residual R and wR were 0.0424 and 0.1297, respectively, from the refinement on F^2 with $I > 2\sigma(I)$. [$[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$]: $C_{62}H_{54}F_8Fe_5N_{13}B_2$, $M = 1506.11$, monoclinic space group $C2/c$, $a = 21.864(3)$, $b = 21.536(2)$, $c = 29.389(3)$ Å, $\beta = 102.721(2)°$, $V = 13498(3)$ Å^3, $Z = 8$. A total of 30 072 were collected ($1.34° < \theta < 23.30°$) of which 9712 unique reflections ($R_{int} = 0.0499$) were measured. Residual R and wR were 0.0539 and 0.1459, respectively, from the refinement on F^2 with $I > 2\sigma(I)$. Empirical absorption corrections by SADABS (G.M. Sheldrick, 1994) were carried out. In the structure analyses, non-hydrogen atoms were refined with anisotropic thermal parameters. Hydrogen atoms were included in calculated positions and refined with isotropic thermal parameters riding on those of the parent atoms.

2.3. Physical measurements

DC magnetic susceptibility data were collected by using a Quantum Design MPMS-XL SQUID magnetometer at temperatures ranging from 1.8 to 300 K. Cyclic voltammetry measurements were carried out in a standard one-compartment cell under N_2 equipped with a platinum-wire counter electrode, a grassy carbon electrode and a saturated calomel electrode (SCE) with an ALS 620A electrochemical analyzer.

3. Results and discussion

3.1. Descriptions of crystal structures: $dppFc_2$ and $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$

Single crystals of $dppFc_2$ for X-ray crystallography were obtained by slow evaporation of dichloromethane/hexane solution. An ORTEP diagram of $dppFc_2$ is shown in Fig. 1. $dppFc_2$ crystallizes in monoclinic space group $P2_1/n$. Two ferrocenyl groups are attached to 3-position of pyrazole rings and show an anti-parallel conformation with each other. Cyclopentadienyl rings are coplanar with three heterocyclic rings of tridentate ligand moiety, which indicates weak π-conjugation between them. $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$ crystallizes in monoclinic space group $C2/c$, and the unit cell contains two crystallographic independent molecules. Each central iron(II) ions show both significantly distorted octahedral surroundings composed of six nitrogen atoms from two tridentate $dppFc_2$ ligands (Fig. 2). Coordination bond lengths are in the range of 2.134(5)–2.190(4) Å, characteristic of bond lengths for a high spin iron(II) ion. Bite angles of tridentate ligands to iron(II) ion (N1–Fe1–N2 and N4–Fe1–N5) are 73.1(1)° and 72.67(9)°, respectively. Distortion can be quantified using Σ parameters defined by Guionneau et al. [19] Σ parameter is the sum of the deviations from 90° of the 12 bite angles in the coordination sphere, and the large Σ value represents large distortion of octahedron from ideal one. The Σ values are estimated to be 168.62° and 169.28° for two complex cations, which

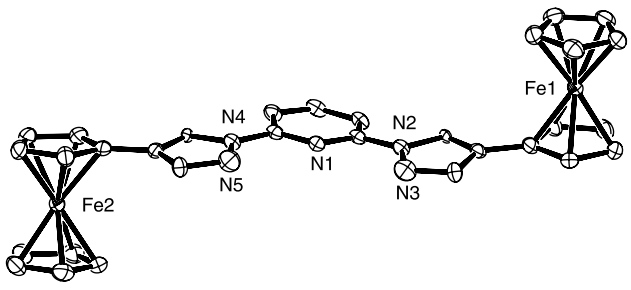

Fig. 1. ORTEP drawing of $dppFc_2$.

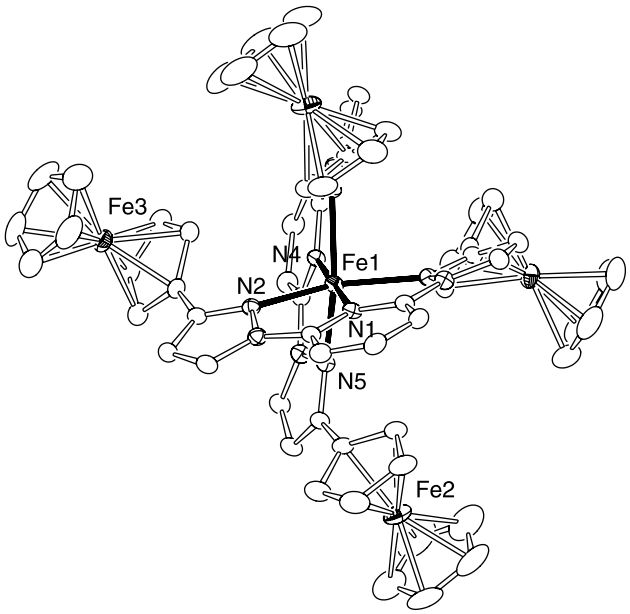

Fig. 2. ORTEP drawing of $[Fe(dppFc_2)_2]^{2+}$. Selected bond lengths (Å) and angles (°): Fe(1)–N(1) 2.134(5), Fe(1)–N(4) 2.135(5), Fe(1)–N(2) 2.181(4), Fe(1)–N(5) 2.185(3), Fe(2)–C(10) 2.018(4), N(1)–Fe(1)–N(2) 73.1(1), N(4)–Fe(1)–N(2) 106.9(1), N(1)–Fe(1)–N(5) 107.3(1), N(4)–Fe(1)–N(5) 72.67(9), N(2)#1–Fe(1)–N(5) 102.9(1), N(2)–Fe(1)–N(5) 87.1(1), N(1)–Fe(1)–N(5)#1 107.33(9), N(4)–Fe(1)–N(5)#1 72.7(1). Symmetry operation #1: $-x, y, -z + 1/2$.

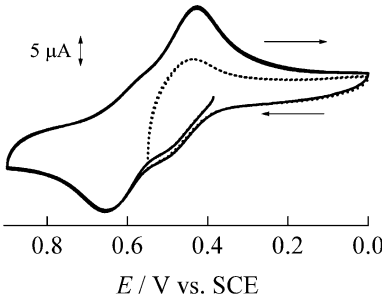
show good agreement with the values for high spin iron(II) complexes with tridentate nitrogen ligands. In $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$, conformations of two ferrocenyl groups in the ligand are anti-parallel and two cyclopentadienyl rings are distorted from three heterocyclic rings plane with torsion angles of C8–C9–C10–C14 being 140.0(5)°, which may be due to the steric hindrance between ferrocenyl groups.

3.2. Redox properties of $dppFc_2$ and $[Fe(dppFc_2)_2](BF_4)_2$

In the electrochemical measurements, the tridentate ligand $dppFc_2$ undergoes reversible one-step $2e^-$ oxidation on two ferronenyl groups at $E^{0'} = 0.47$ V versus SCE. In the cyclic voltammogram of $[Fe(dppFc_2)_2](BF_4)_2$ with potential scans between 0.00 and 0.90 V versus SCE showed two irreversible redox couples (Fig. 3). The first couple of oxidation and re-reduction waves was observed at $E_1^{0'} = 0.47$ V versus SCE, which is same as the value of $dppFc_2$. In the first couple, re-reduction current is much larger than that in oxidation wave. When the positive limit of the potential scan is 0.55 V, the large re-reduction wave does not appear (Fig. 3). While the second redox couple at $E_2^{0'} = 0.63$ V showed smaller re-reduction current than that in oxidation. By comparison of the redox potentials, the first redox couple



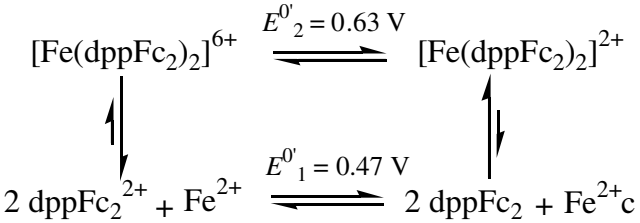


Fig. 3. Cyclic voltammogram of $[Fe(dppFc_2)_2](BF_4)_2$ at a glassy carbon electrode in 0.1 mol dm^{-3} $[Bu_4N][PF_6]$/MeCN at a scan rate of 0.1 V s^{-1}.

was assigned to $dppFc_2/dppFc_2^{2+}$ and irreversibility of two-step redox process in $[Fe(dppFc_2)_2]^{2+}$ can be interpreted by the EC mechanism and dissociation equilibrium in MeCN solution as shown in Scheme 1. Before oxidation of the two ferrocenyl moiety, $[Fe(dppFc_2)_2]^{2+}$ species is dominant in MeCN solution, while after the oxidation electronic repulsion between central iron(II) ion and ferrocenyl cations may cause the ligand dissociation.

3.3. Magnetic susceptibility measurements of $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$

Temperature dependence of magnetic susceptibilities for $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$ was measured in the temperature range of 2–300 K (Fig. 4). At room temperature the $\chi_m T$ value is 3.35 emu mol^{-1} K, which corresponds to the spin-only value for a non-interacting high spin Fe^{II} ion. $\chi_m T$ values are almost constant down to 80 K, followed by sudden decrease below 50 K which is due to the zero-field splitting of the high spin iron(II) ion. The temperature independent $\chi_m T$ values indicates $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$ is in the high spin state in all temperature range measured. An iron(II) complex with similar ferrocenyl-substituted tridentate ligand shows spin conversion between high- and low-spin state at T_c = ca. 370 K, in which ferrocenyl group attaches to 4-position on the pyridine ring with ester bond [20]. The absence of spin conversion in $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$ can be attributable to the steric hindrance

Scheme 1.

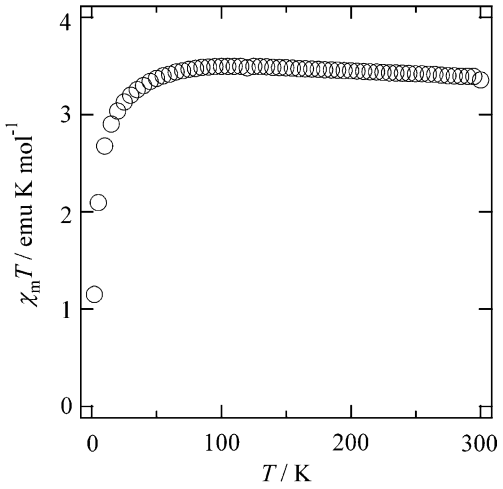

Fig. 4. Plot of $\chi_m T$ vs. T for $[Fe(dppFc_2)_2](BF_4)_2 \cdot 3CH_3CN$.

between ferrocenyl groups which causes significant distortion of coordination geometry and stabilizes the high spin state in the central iron(II) ion.

4. Conclusion

Tridentate ligand with two ferrocenyl groups give an opportunity to assemble four redox-active centre by coordination to iron(II) ion. The complex with four ferrocenyl groups undergoes two irreversible redox process in EC mechanism.

5. Supplementary material

Crystallographic data reported in this paper have been deposited with Cambridge Crystallographic Data Centre as supplementary publication no. CCDC 251833 and 251834. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336 033; or deposit@ccdc.cam.ac.uk).

observed that the magnetic coupling is predominantly one-dimensional and ferromagnetic along the chain direction, with the latter feature setting $MnNi(NO_2)_4(en)_2$ apart from the usual antiferromagnetic alignment in other bimetallic chains. From the study of the bulk properties the coupling strength has been determined to $J_{\parallel\text{chain}}/k_B = 1.9$ K. In addition, from the anisotropy of the magnetic properties a zero field splitting of $D/k_B = -0.45$ K has been derived. In the presence of the zero field splitting D and together with a finite inter-chain coupling $J_{\perp\text{chain}}$, the intra-chain coupling $J_{\parallel\text{chain}}$ causes the system to undergo an antiferromagnetic transition below $T_N = 2.3$ K. In the antiferromagnetic phase the spins point along the easy crystallographic c-direction, with a ferromagnetic alignment within the a–b-plane and antiferromagnetic coupling along the c-axis. Extending the work from [7], by means of a high-temperature series expansion [8] the susceptibility of $MnNi(NO_2)_4(en)_2$ has been fitted, yielding values $J_{\parallel\text{chain}} = 2.8$ K, $D = -0.36$ K and $J_{\perp\text{chain}} = -0.036$ K.

Here, we present measurements of the lattice parameters and the magnetization under pressure on $MnNi(NO_2)_4(en)_2$. From the pressure dependence of the lattice parameters we derive the bulk modulus, which turns out to be comparatively small, and as it is typical for molecule-based magnetic materials. Furthermore, from the magnetization experiments we determine the pressure dependence of the antiferromagnetic transition temperature. We find only a very small increase with pressures as high as 8.2 kbar, which combined with the structural data corresponds to an unusally small magnetic Grüneisen parameter of $\Gamma_{mag} = 0.5(5)$. Finally, we discuss possible explanations for this small Grüneisen parameter.

2. Experimental

We have performed neutron powder diffraction and magnetization experiments under applied hydrostatic pressure. The neutron diffraction experiments have been carried out on non-deuterated material $MnNi(NO_2)_4(en)_2$ at the Berlin Neutron Scattering Center (BENSC) of the Hahn-Meitner Institut, utilizing the Focusing diffractometer E6 with a neutron wavelength $\lambda = 2.448$ Å at $T = 2$ K. The pressure has been generated by means of a clamped pressure cell. The applied pressure has been determined from the lattice parameter of NaCl, of which some powder was included in the sample space.

The magnetization experiments have been performed in a commercial SQUID at temperatures ranging from 1.75 to 300 K. Here, for the pressure experiments a clamped pressure cell, fitting into the sample space of the SQUID and as described previously [1], has been employed. This cell allows the determination of the magnetization at pressures up to ~10 kbar. As a pressure medium we use Fluorinert FC77, while the applied pressure has been determined from the superconducting transition temperature of a piece of indium in the sample space.

3. Results and discussion

In Fig. 1, we plot the neutron diffraction spectra of $MnNi(NO_2)_4(en)_2$ taken at 2 K at ambient pressure and 3 kbar, respectively. In the plot, in addition to the Bragg reflections from $MnNi(NO_2)_4(en)_2$, those from the pressure standard NaCl can be observed as indicated. With the large experimental background from incoherent scattering by hydrogen and the pressure cell the signal-to-noise ratio is comparatively small, prohibiting a full refinement of the data and limiting the resolution of the experiment. Within these limits, however, we find no indication for a change of the crystallographic symmetry of the overall lattice. Moreover, the Bragg reflections shift with pressure. Using a profile matching technique, we obtain a reduction of the lattice parameters of $\Delta a/a = 0.36\%$, $\Delta b/b = 0.98\%$ and $\Delta c/c = 2.1\%$. The experimental resolution is insufficient to detect additional scattering contributions in the antiferromagnetically ordered state below T_N.

From the reduction of the lattice parameters we derive the bulk modulus $B = V\frac{\Delta p}{\Delta V}$, which we evaluate to 8.8 GPa. This is a very small value, reflecting the softness of this molecule-based material. Typical intermetallic compounds, for instance, generally have bulk moduli of the order of 100 GPa (for comparison see for instance [9,10]).

In Fig. 2(a), we plot the temperature dependence of the magnetization of $MnNi(NO_2)_4(en)_2$ in a field of 0.05 T at various pressure values $p \leqslant 8.2$ kbar. At ambient pressure the reported behavior [7] from the transi-

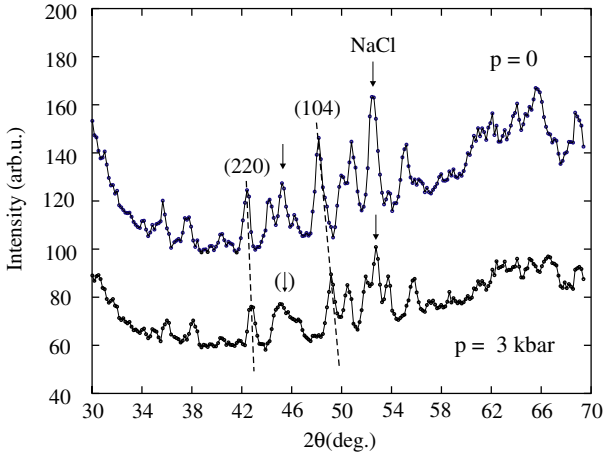

Fig. 1. The neutron diffraction spectra taken on $MnNi(NO_2)_4(en)_2$ taken at 2 K at ambient pressure and under applied pressure of 3 kbar. The positions of Bragg reflections from the pressure standard NaCl are indicated. Shifts of two selected reflections from the sample are marked by dashed lines. They differ considerably, indicating an anisotropic pressure response.

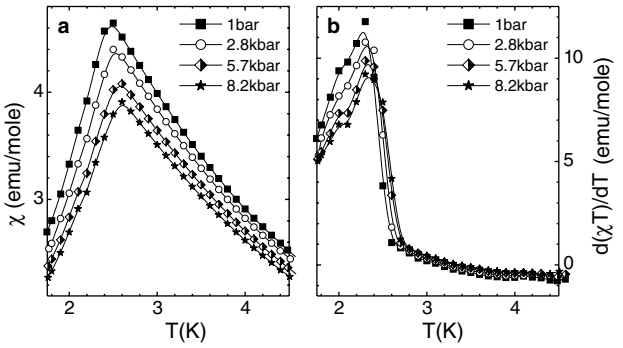

Fig. 2. (a) The temperature dependence of the magnetization of $MnNi(NO_2)_4(en)_2$ for externally applied pressure up to 8.2 kbar and an applied field of 0.05 T. (b) The temperature derivative $d(\chi T)/dT$ for the data from (a); for details see text.

tion into the antiferromagnetic state at low temperatures is reproduced. Within mean-field theory, the antiferromagnetic transition temperature is derived from the maximum of $d(\chi T)/dT$. Accordingly, in Fig. 2(b), we plot $d(\chi T)/dT$ as function of temperature, from which we obtain $T_N = 2.30$ K at ambient pressure.

With increasing pressure the antiferromagnetic peak shifts up slightly in temperature. From Fig. 2(b), we find an increase of T_N up to 2.41 K in 8.2 kbar, corresponding to an increase of T_N by less than 5(±4)%. The pressure response of T_N is summarized in Fig. 3.

To assess the relative strength of the pressure response it is common to determine the magnetic Grüneisen parameter defined as $\Gamma_{mag} = -\frac{d(\ln(T^*/T_0))}{d(\ln(V^*/V_0))}$. Here, T^* denotes the transition temperature under applied pressure with a unit cell volume V^*, while T_0 and V_0 represent the ambient pressure values. Assuming that the volume compression at low temperatures is linear with pressure up to 8.2 kbar, we obtain $\Gamma_{mag} = 0.5(5)$. This value is surprisingly small. For comparison, in our previous study on $FePM_2Cl_2$, we found $\Gamma_{mag} \sim 4$–7, which is a typical value for common magnets.

The antiferromagnetic transition temperature is determined by three energy scales, i.e., the values of $J_{\parallel chain}$, D and $J_{\perp chain}$. The zero field splitting D is a single ion effect and not expected to be strongly pressure dependent. The pressure effects on the inter- and intrachain coupling we can model by calculating "anisotropic" Grüneisen parameters, this way incorporating the highly anisotropic compression in our analysis.[1] Considering that $V^*/V_0 = (1-\frac{\Delta a}{a})(1-\frac{\Delta b}{b})(1-\frac{\Delta c}{c})$, we

[1] We have attempted to directly determine the pressure dependence of $J_{\parallel chain}$ and $J_{\perp chain}$ by fitting χ using high temperature series expansion as in [8]. Here, we assumed that the sample is aligned in the pressure such that the magnetic field B is parallel to the a-axis. Unfortunately, the pressure induced changes to χ in the temperature range relevant for the fit, 10–25 K, are too small, and thus the error bars to $J_{\parallel chain}$ and $J_{\perp chain}$ too large, as to allow an unambiguous conclusion on the pressure response of the magnetic exchange in $MnNi(NO_2)_4(en)_2$.

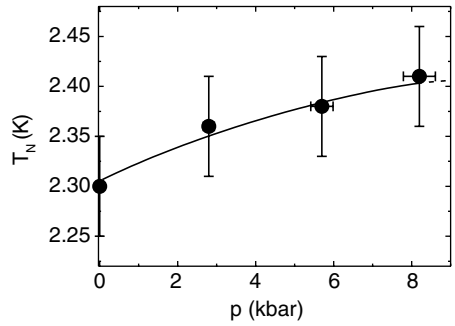

Fig. 3. The pressure dependence of T_N of $MnNi(NO_2)_4(en)_2$, as determined from the maximum of $d(\chi T)/dT$.

can derive corresponding expressions for the compression of the a–b-plane diagonal (the chain direction) and the c-axis. With the a–b-plane diagonal $d = \sqrt{a^2+b^2}$, we get $\Delta d/d = 0.50\%$. We define $\Gamma_{mag}(d) = -\frac{d(\ln(T^*/T_0))}{d(\ln((1-\frac{\Delta d}{d})^3))}$ and $\Gamma_{mag}(c) = -\frac{d(\ln(T^*/T_0))}{d(\ln((1-\frac{\Delta c}{c})^3))}$ and obtain values $\Gamma_{mag}(d) \sim 1$–2 and $\Gamma_{mag}(c) \sim 0.2$–0.3.

The very low value of $\Gamma_{mag}(c)$ indicates that in particular the c-axis compression is ineffective regarding the antiferromagnetic transition temperature. Then, one scenario to account for the small Grüneisen parameter would imply that any pressure induced increase of the magnetic exchange along the c-axis, which is mediated along van der Waals-bonded paths, is compensated by canting of the atoms and molecules making up the bond. In contrast, a second scenario would postulate magnetic frustration on the chain, where competing magnetic exchanges (for instance between nearest and next-nearest neighbors) limit the effect of pressure on the antiferromagnetic transition temperature. This latter scenario, however, appears to be very unlikely, since from the susceptibility study there is no evidence for frustration.

To test the scenario on the c-axis exchange high-resolution diffraction experiments under pressure would be necessary, this way to resolve the actual positions of all atoms and molecules. In addition, a uniaxial pressure experiments would be useful, as we would predict that for pressure applied along the c-axis almost no net increase of T_N should be observed, in contrast to an experiment with pressure along the a–b-diagonal.

4. Conclusions

In conclusion, we have performed high pressure experiments on the crystallographic structure and antiferromagnetically ordered phase of the bimetallic chain compound $MnNi(NO_2)_4(en)_2$. We obtain the bulk modulus at low temperatures, thus establishing the softness of the material. We determine the pressure response of the antiferromagnetic transition temperature T_N, which hardly increases up to 8.2 kbar. This weak response we tentatively attribute to the pressure effect of the magnetic exchange along the

crystallographic *c*-axis. Our findings demonstrate the importance in pressure experiments on molecule-based magnetic materials to establish at the same time the structural and magnetic properties as function of pressure.

in Fig. 1 [8,9]. The structure is cubic *Pm3m* at room temperature and elongated tetragonal or orthorhombic structure in the low temperature region both for NH_4MnF_3 and NH_4ZnF_3 [7,10–12]. Neutron magnetic scattering indicated that the antiferromagnetic ordering is essentially of the G-type according to Pickart et al. [13] and Gersch and Koeler [14] and in this arrangement, the magnetic lattice of Mn(II) ions is doubled in the three directions and each positive spin is surrounded by six negative spins. However, irregularity of the scattering suggests multi-axis structure of magnetic lattice [13]. We probed the magnetic characters of the magnetic lattice made by Mn(II) ions with local magnetic field caused by the Mn(II) spin at the deuterium site of ammonium ion. In this paper, we report characteristic behaviors of near-surface and inner spins of nano-particles determined by magnetic susceptibility measurement, and solid-state high-resolution and wide-line deuterium NMR spectrum. Particularly, internal magnetic field and critical behavior with approaching to Néel temperature in the antiferromagnetic phase were studied by solid-state wide-line deuterium NMR.

2. Experiments

2.1. Sample preparation

The bulk polycrystalline samples of ND_4MnF_3 (**1**) and $ND_4Mn_{0.5}Zn_{0.5}F_3$ (**3**) were prepared after a similar method reported by Silver [15] with using deuterated compounds, i.e., ND_4F and heavy water, instead of normal compounds. For the magnetically diluted compound **3**, a mixture of $MnCl_2$ and $ZnCl_2$ in equal mole was used as reactant. Nano-particle sample of ND_4MnF_3 (**2**) was synthesized by a reversed micelle method according to Roth and Hempelmann [16] with using deuterated reactant and deuterated ammonium-AOT as a surfactant. The surfactant of AOT-NH_4 was prepared by a cation exchange method reported in [17] and AOT-NH_4 was deuterated by several times of recrystallization from heavy water and AOT-ND_4 was dried in vacua.

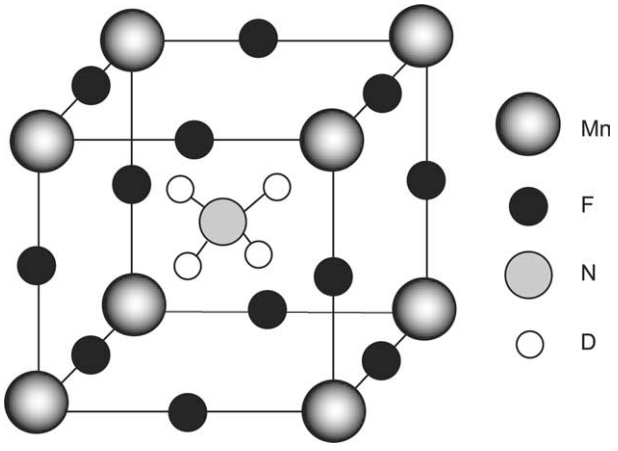

Fig. 1. Crystal structure of ND_4MnF_3. Cubic perovskite structure *Pm3m* in the room temperature phase and elongated tetragonal in the low temperature phase.

2.2. SEM and magnetic susceptibility measurements

The crystallite size was determined by scanning electron microscope (SEM) image. The particles were dispersed on mica and were coated by osmium by sputtering method.

Magnetic susceptibilities were measured with a MPMS SQUID magnetometer for samples of 29.9 mg of **1**, 12.4 mg of **2** and 27.4 mg of **3** between 5 and 300 K. The measurement was carried out with increasing temperature after cooling down to 5 K under zero external field (ZFC) or after field cooling (FC). The magnetic susceptibility of bulk compounds **1** and **3** was measured under magnetic field of 0.1 T, while under magnetic filed of 0.01, 0.1 and 1 T for the nano-particle **2**.

2.3. Solid-state high-resolution and wide-line deuterium NMR

Solid-state high-resolution deuterium NMR spectra in the paramagnetic phase were measured with magic angle spinning by a similar method described in [18] at the resonance frequency of 46.1 kHz and at spinning speed of ~7 kHz with a Bruker DSX300 spectrometer. The thermometer of the MAS NMR probe and an effect of spinning speed on temperature increase were carefully calibrated [18,19]. The MAS technique gives an isotropic shift of deuterium. The D-NMR shift was measured from the external second reference of CD_3OD (CD_3: 3.35 ppm).

Assuming a small zero field splitting, the observed isotropic shift δ_{iso} consists of the Fermi contact term, the dipole interaction term (pseudo contact) and the temperature independent diamagnetic term (chemical shift) as follows [20,21]:

$$\delta_{iso} = \delta_{Fermi} + \delta_{Pseudo} + \delta_{dia}, \quad (1)$$

$$\delta_{Fermi} + \delta_{Pseudo} = \frac{\mu_B}{3k_B T} \cdot \frac{A_C}{\gamma_D/2\pi} \cdot S(S+1). \quad (2)$$

Electron spin induced on the deuterium nucleus by electron spin of a magnetic metal ion causes a Fermi contact shift of the NMR resonance line, while anisotropy of the *g*-tensor of magnetic metal ions gives a pseudo contact shift. In the present case, the pseudo contact term (dipole term) is considered to be dominant. The coefficient A_C in Eq. (2) is defined as the hfcc of the deuterium

nucleus in Hz unit, which include principal values of anisotropic *g*-tensor.

Wide-line deuterium NMR spectra were measured for antiferromagnetic phase of **1**, **2** and **3** with a TECHMAG APOLLO NMR system at an external field of 7.0 T. The spectrum was measured by echo method. Since powder spectral width is extremely broadened in the antiferromagnetic phase, we measured echo signals at many different irradiation frequencies. The envelope of all the echo signals shows a line shape of the powder spectrum. In this measurement, a laboratory made cryostat was used for liquid helium temperature region.

3. Results and discussion

3.1. Determination of the crystallite size and structure

Powder X-ray diffraction pattern at room temperature was in agreement with a reported cubic *Pm3m* structure for all of the samples **1**, **2** and **3**. For the nano-particle sample **2**, broad diffraction peaks due to small size were observed in comparison with the bulk sample **1**. The size of the particle was determined to be ca. 30 nm by SEM as described below. In addition to the diffraction of ND_4MnF_3, a small amount of reactant of ND_4F was found as shown in Fig. 2. The amount of ND_4F was estimated to be 4% by solid-state high-resolution deuterium NMR spectrum as described in Section 3.2.

SEM images are shown in Fig. 3(a)–(c) for the sample **1**, **2** and **3**, respectively. This figure shows a smallest and isolated particle in what we found. Although major parts of nano-particles are closely assembled, each particle seems small as the isolated particle as shown in Fig. 3(b). TEM image is better to determine the size distribution of the nano-particles.

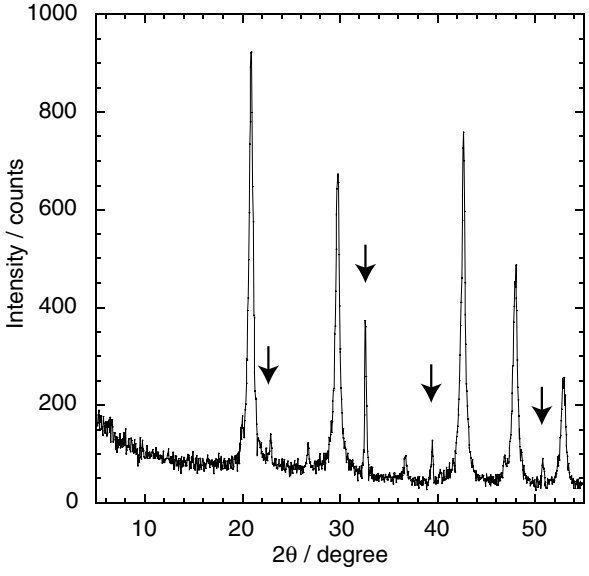

Fig. 2. X-ray powder diffraction pattern of nano-particles of ND_4MnF_3 (**2**). Small and sharp peaks indicated by arrows are due to a small amount of reactant of ND_4F.

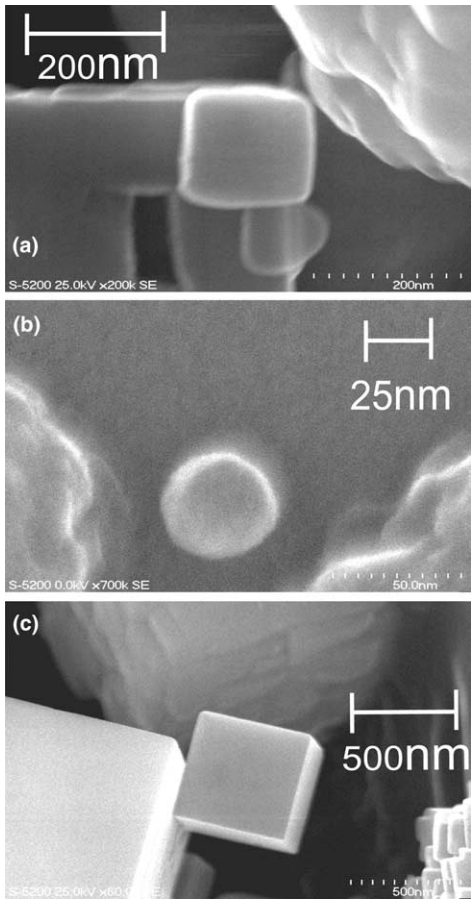

Fig. 3. Typical SEM images of **1** (a), **2** (b) and **3** (c).

3.2. Magnetic susceptibility

Magnetic susceptibility measured for **1**, **2** and **3** under ZFC condition was plotted as a function of temperature in Fig. 4(a). Magnetic susceptibility of sample **2** shows different behavior in the temperature region lower than ca. 20 K from that of bulk sample **1**. This difference can be ascribed to magnetic dipole moments made from near-surface spin. In a typical case of nano-particle of antiferromagnetic $KMnF_3$, magnetic susceptibility shows different behaviors for ZFC and FC, i.e., blocking of an orientation of residual magnetic moment near 10 K [1]. A similar behavior was reported for quenched ferrofluid system [6]. On the contrary, magnetic susceptibility of **2** under ZFC and FC showed almost the same temperature dependence and ZFC measurement showed no blocking behavior above 5 K. Namely, the blocking temperature is lower than 5 K for **2**. This result may be

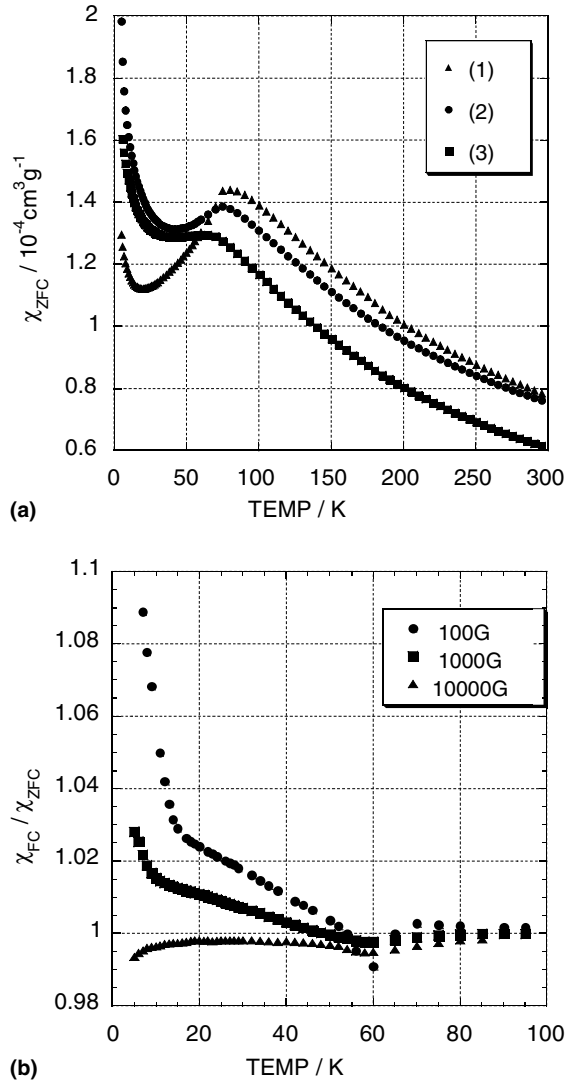

Fig. 4. (a) Magnetic susceptibility of **1**, **2** and **3** measured under zero field cooling and applied magnetic field of 0.1 T. (b) Field dependence of the ratio of magnetic susceptibility under field cooling (χ_{FC}) to that under zero field cooling (χ_{ZFC}) of 30 nm ND_4MnF_3 at different magnetic field of 0.01, 0.1 and 1 T.

ascribed to a relatively short relaxation time of orientation of the residual magnetic moment of **2**. Even in such a short relaxation time, the relaxation phenomena may be detected by field dependence of the magnetic susceptibility. So we measured in detail the susceptibility of nano-particle **2** under different applied fields of 0.01, 0.1 and 1 T. Fig. 4(b) shows the ratio of magnetic susceptibility under FC (χ_{FC}) to that under ZFC (χ_{ZFC}) for 30 nm particles. The ratio decreased with increasing external field and became almost unity at 1 T. This result means that the relaxation time of the orientation of the magnetic moment becomes shorter as the external magnetic field is increased. For example, magnetic moments, which were randomly oriented after ZFC, immediately align with respect to a direction of the external magnetic field of 1 T even at 5 K. The field dependence is particularly remarkable below 20 K. For investigating the near-surface spin state in a microscopic view point, we measured solid-state deuterium NMR spectrum. Magnetic behavior of Mn(II) ions can be detected through deuterium atom of ammonium ion.

3.3. Solid-state high-resolution deuterium NMR

Fig. 5 shows a comparison of solid-state high-resolution deuterium NMR spectra of **1**, **2** and **3** measured with the same experimental condition at 300 K in the paramagnetic phase. In order to compare the spectral line shapes among the three samples, peak positions of all the spectra were adjusted to the observed shift of the spectrum **2**. Particular attention was paid to the spectral shape and width. Compared with a spectrum of bulk ND_4MnF_3 (**1**), the signal of **2** has broad component as a tail, and the signal of **3** is remarkably asymmetric and skewed in the low frequency side. Now we consider the differences in the line shapes of the spectra. Width of the bulk sample **1** is the smallest and a center of this peak is shifted to higher frequency from diamagnetic ND_4F due to hyperfine coupling described in Eqs. (1) and (2). This hfc is brought about dominantly by eight Mn(II) ions in nearest neighbor around the ammonium ion shown in Fig. 1. For a bulk sample of magnetically diluted $ND_4Mn_{0.5}Zn_{0.5}F_3$, number of magnetic Mn(II) ions in the nearest neighbor is randomly distributed from 8 to 0 for individual ND_4^+ ion. For the smaller number of Mn(II) ion around the ND_4^+

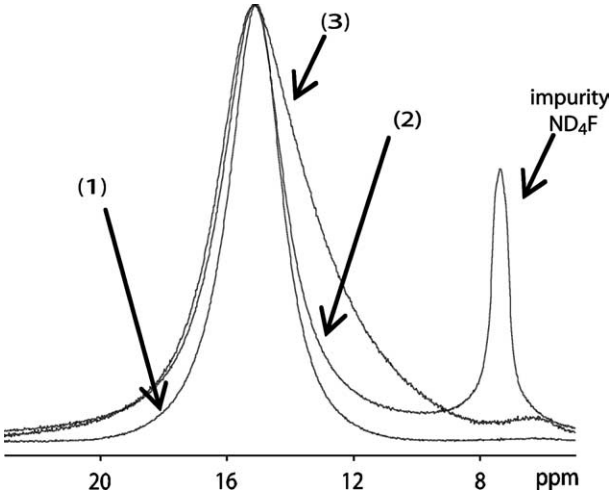

Fig. 5. Solid-state high-resolution deuterium NMR spectra of **1**, **2** and **3** at 300 K in the paramagnetic phase. In order to compare the spectral line shapes among the three samples, peak positions of all the spectra were adjusted to the observed shift of the spectrum **2**: −0.3 ppm and +1.0 ppm give the original shift of **1** and **3**, respectively.

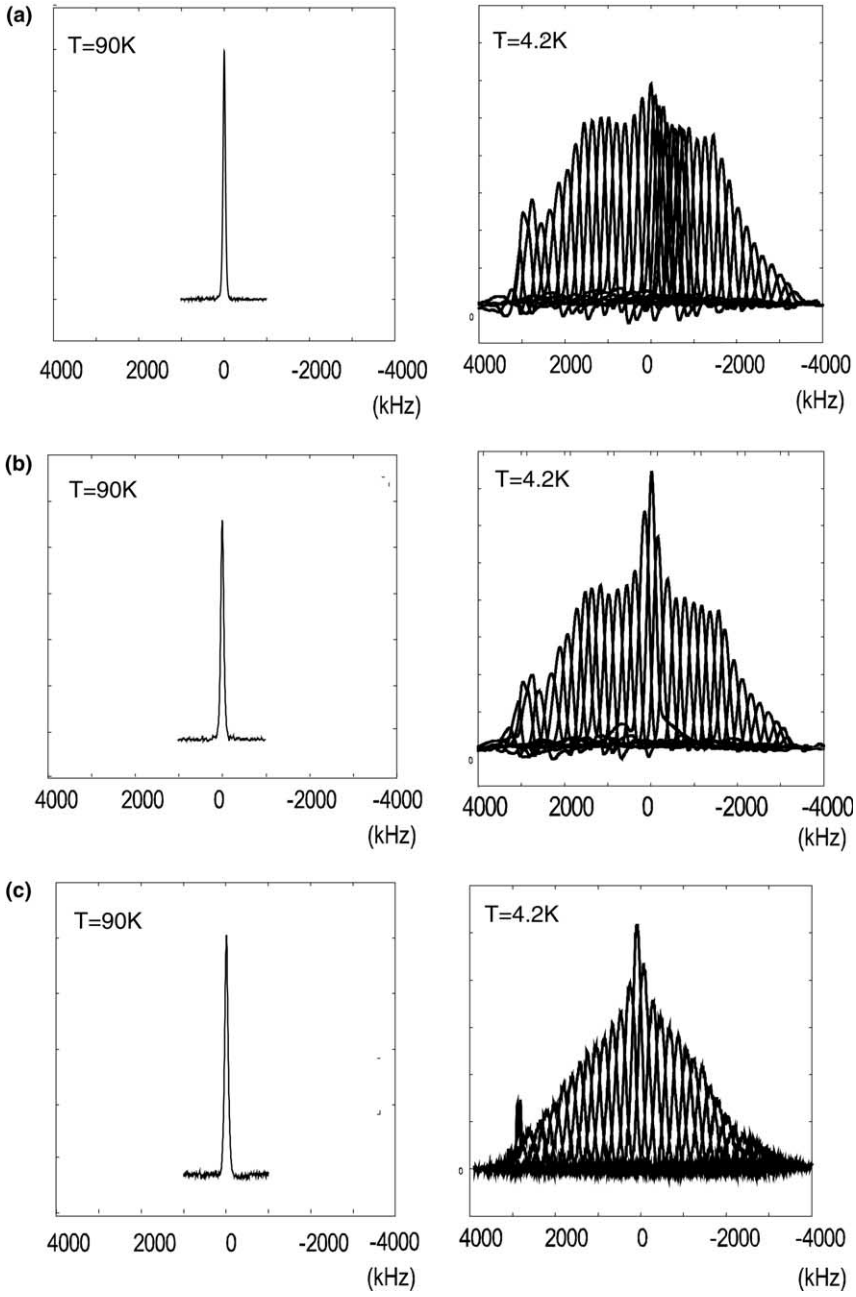

Fig. 6. Solid-state wide-line deuterium NMR spectra of **1** (a), **2** (b) and **3** (c) at 4.2 K in the antiferromagnetic phase and at 90 K in the paramagnetic phase. For the spectrum at 4.2 K, many echo signals measured with different irradiation frequencies were illustrated and a whole envelope is a powder pattern of the spectrum.

ion, the deuterium NMR of the ND_4^+ ions shows the lower frequency shift. Therefore, the deuterium NMR spectrum of $ND_4Mn_{0.5}Zn_{0.5}F_3$ has a long tail to the diamagnetic position. The spectrum of 30 nm ND_4MnF_3 (**2**) can be decomposed into two components, i.e., a sharp and a broad bottom components. We assigned broad component to the near-surface ammonium ions. The broadness may be brought about by a distribution of anisotropic *g*-tensor of Mn(II) ion near the surface. In addition, we also measured temperature dependence of these shift between 170 and 370 K. Slope of the peak shift plotted as a function of inverse temperature gave hfcc. The peak shift of sharp and broad component for nano-particle **2** gave small and almost the same values of hfcc = +8.4 and +8.6 kHz, respectively. Since deuterium atom of ND_4^+ has no direct bond with Mn(II) ion, a major origin of hfcc is magnetic dipole term.

3.4. Internal magnetic field and critical behavior determined by solid-state wide-line deuterium NMR

Fig. 6 shows wide-line deuterium NMR spectra of **1**(**a**), **2**(**b**) and **3**(**c**) at 90 K in the paramagnetic phase[1] and at 4.2 K in the antiferromagnetic phase. Full-width at half-maximum of the spectrum drastically broadened to 4 MHz in the antiferromagnetic phase. NMR signal of ND_4F as an impurity was not observed in the spectrum of **2**, because relaxation time of ND_4F is much longer than the repetition time for accumulation of the signal. The spectrum shows that deuterium atom of ND_4^+ ion looks at internal magnetic field of antiferromagnetically ordered electron spins of Mn(II) ions. In the spectrum of nano-particle **2**, narrow component with the width of 470 kHz was clearly observed, while such a narrow component was scarcely observed for bulk sample **1**. We assigned this narrow signal of the nano-particle **2** to the ammonium ions located in near-surface positions of the nano-particle. The narrow signal intimates a small internal magnetic field of near-surface region. The spectrum of magnetically diluted sample **3** is very different from the spectrum of the nano-particle **2**, since internal magnetic field distributes due to a random replacement of magnetic manganese ions with non-magnetic zinc ions.

In Fig. 7, temperature dependence of the spectrum width is shown for each sample. This figure represents the temperature dependence of the internal magnetic field for each sample **1**, **2** and **3**. The temperature variation of the internal magnetic field f can be written by the following empirical equation [24]:

$$f = f_0[1 + (T/T_N)^{\alpha}]^{\beta}. \quad (3)$$

The above function can be fitted to the bulk sample **1** as shown in Fig. 7(a). The value of $f_0 = 4100$ kHz was obtained for the internal magnetic field looked at the position of deuterium atom of ND_4^+ ion at zero temperature and the Néel temperature was determined to be $T_N = 70$ K. Parameter of $\alpha = 3.2$ represents the low temperature part of the internal magnetic field. The value of $\beta = 0.4$ is determined mainly by the internal magnetic field in the temperature range near T_N and closely related to the critical exponent. The function with the same parameters as for the bulk sample **1** is shown in Fig. 7(b) as dotted curve for comparing the critical behavior of the nano-particle **2** with the bulk sample **1**. In the nano-particle **2**, the internal magnetic field begins to decrease in the lower temperature region and shows a tail with approaching to 70 K, while the internal magnetic field in the low temperature limit is almost the same as that of the bulk sample. This behavior of the internal magnetic field of the nano-particle **2** does not resemble a behavior of magnetically diluted specimen **3**, in which much more gentle slope of temperature

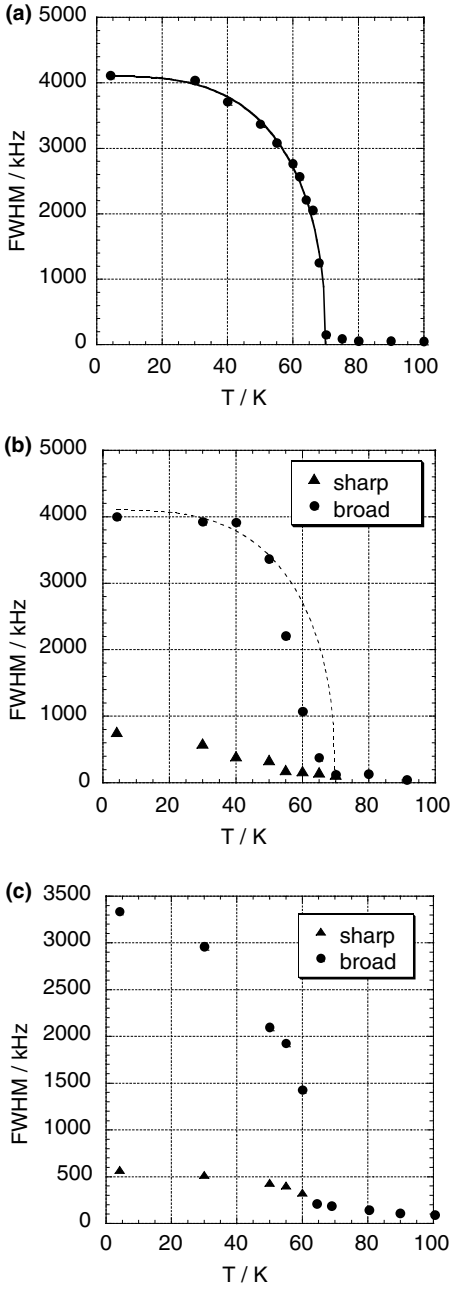

Fig. 7. Temperature variation of the internal magnetic field of **1** (a), **2** (b) and **3** (c) determined by temperature dependence of the full-width at half-maximum of wide-line deuterium NMR spectrum.

[1] Spectral shape can be expressed by a single gaussian for all of the sample and a half-width at half-maximum is 58, 69 and 92 kHz for **1**, **2** and **3**, respectively. The width is smaller than the peak to peak frequency of Pake doublet expected for the powder pattern of deuterium atom with quadrupole coupling of $e^2Qq/h = 180$ kHz of ND_4^+ ion without rotational motion [22,23]. This result indicates rapid rotational motion of the ND_4^+ ion in the crystalline lattice at 90 K for all of **1**, **2** and **3**. A rotational motion of the ND_4^+ ion may be expected in the lower temperature region as in the case of NH_4ZnF_3 [10]. However, the motion is not so rapid to average the internal magnetic field of ca. 4 MHz.

variation was observed as shown in Fig. 7(c). This behavior may be ascribed to a wide distribution of the magnetic domain size due to a random distribution of diamagnetic Zn(II) ions in the lattice. The near-surface spins of nano-particle **2** do not behave like a non-interacting curie spins, but have some ordering in small extent. If the near-surface spin of **2** had behaved as a curie spin, the width of the narrow component of deuterium NMR spectrum of **2** would be proportional to inverse temperature.

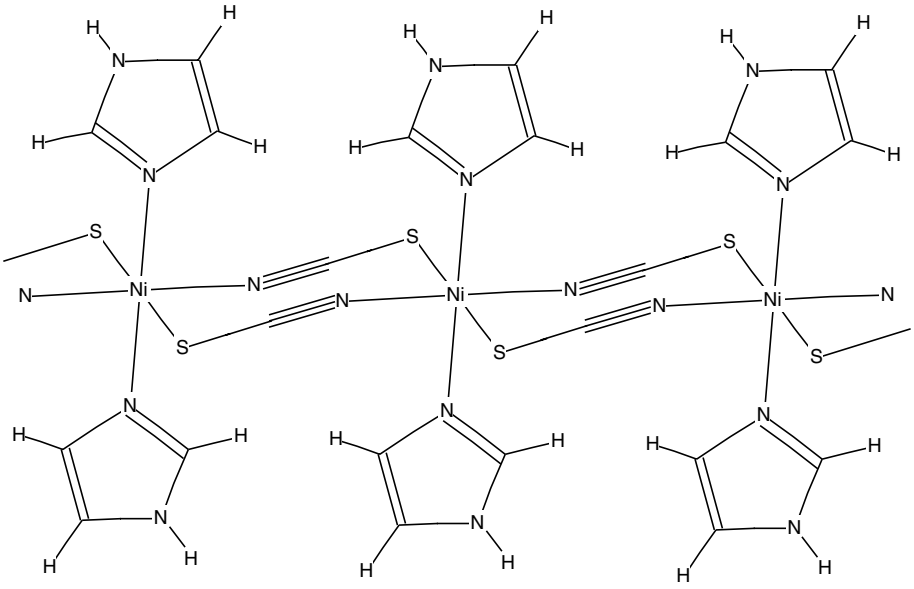

Fig. 1. One-dimensional chain structure of $Ni(NCS)_2(Him)_2$.

verify this theory are necessary to understand the intermolecular magnetic interaction in coordination compounds. In this work, we have employed Density functional theory (DFT) and NMR experiment [9] to elucidate role of the imidazole ligand in long range ordering.

Di-μ-thiocyanatobis(imidazole)nickel(II), $Ni(NCS)_2(Him)_2$, is a ferromagnet ($T_C = 5$ K) which consists of NCS-bridged one-dimensional Ni(II) chains as shown in Fig. 1 with the intrachain exchange interaction parameter ($2J$) of 8.0 cm^{-1} [3]. In this work, we determined electron spin density distribution of imidazole ligand in the compound by measuring solid-state high-resolution ^1H, ^2H, and ^{13}C NMR spectra in order to elucidate the interchain magnetic interaction essential for long-range order in the crystal. Partially or fully deuterated imidazole was used to prepare the sample and magic angle spinning (MAS) technique was employed to measure temperature dependence of the isotropic shifts of NMR signals. These experimental results indicate that unpaired electrons in the d-orbitals of the octahedral nickel(II) ion delocalize over the imidazole ligand. Consequently, we proposed an interchain superexchange pathway through N–H···S hydrogen bond.

2. Experimental

2.1. Preparations

1,2-Dideutero-imidazole was prepared by the literature method [10]. The degree of deuteration was estimated to be 70–80%. $Ni(NO_3)_2 \cdot 6D_2O$ was recrystallized from deuterium oxide. 1,2,4,5-Tetradeutero-imidazole (98% D, Cambridge Isotope Laboratories) and the other reagents were used as supplied. Non-deuterated sample of $Ni(NCS)_2(Him)_2$ (**1**) was prepared by a similar method described in [3]. $Ni(NO_3)_2 \cdot 6H_2O$ (2 mmol) and NaSCN (4 mmol) were dissolved in water (2 cm^3), then the aqueous solution was added to methanol solution (1 cm^3) of imidazole (4 mmol). The resulting blue solution was left to stand under N_2 gas flow at room temperature. Green crystal of $Ni(NCS)_2(Him)_2$ was obtained with violet crystal of $Ni(NCS)_2(Him)_4$. The products were separated by hand, washed with water and acetone, and dried in vacuo. Fully deuterated sample of $Ni(NCS)_2$(1,2,4,5-tetradeutero-Him)$_2$ (**4**) was prepared from 1,2,4,5-tetradeutero-imidazole with deuterated solvents of D_2O and CH_3OD. Partially deuterated samples of $Ni(NCS)_2$(1,2-dideutero-Him)$_2$ (**3**) and $Ni(NCS)_2$(2-deutero-Him)$_2$ (**2**) were prepared from 1,2-dideutero-imidazole with deuterated and protonated solvents, respectively.

2.2. NMR measurements

Solid-state high-resolution ^1H, ^2H, and ^{13}C NMR spectra of **1**–**4** were measured at a resonance frequencies of 300, 46.1, and 75.4 MHz, respectively, with a Bruker DSX300 spectrometer and a 4-mm CP/MAS probe. Temperature dependence of the spectra were measured for **3** from 300 to 200 K. MAS technique was used to obtain high-resolution spectra for the powder samples, whereas cross polarization or ^1H decoupling was not employed. The spinning rates of the samples were 9–10 kHz. The free induction decay (FID) of ^1H-MAS-NMR was accumulated from the first rotational echo after a $\pi/2$ pulse. For ^2H- or ^{13}C-MAS-NMR, π pulse

was applied at the first rotational echo after a π/2 pulse,then the FID was accumulated from the second rotational echo. The repetition time for each spectrum was 0.5 s. The thermometer of the MAS probe was calibrated against the isotropic chemical shift of the ^{207}Pb-MAS-NMR spectrum of $Pb(NO_3)_2$ [11]. The uncertainty of the temperature measurement after the calibration was 4 K, and the temperature fluctuation during the accumulation was within 1 K. The differences between the sample temperature T and the bearing gas temperature T_b, which was read from the thermometer, were 27 K at T = 202 and 7 K at T = 304 K for a spinning rate of 9 kHz.[1] ^{1}H, ^{2}H, and ^{13}C NMR shifts were measured from tetramethylsilane.

2.3. Computational methods

Using the GAUSSIAN-98 software package [12], we performed UB3LYP calculation on $[Ni(NCS)_2(SCN)_2(Him)_2]^{2-}$ as a molecular model for the coordination polymer. The geometric structure of the model was extracted from the crystal structure [3] determined by X-ray diffraction. The Wachters–Hay basis set [13,14] was used for Ni atom and the 6-31G(d,p) basis set was used for H, C, N, S atoms.

3. Results and discussion

3.1. NMR peak assignment

The observed isotropic lines in the ^{2}H-MAS-NMR spectra were accompanied by typically 30 spinning sidebands (SSBs) spaced at the spinning frequencies. This is because the anisotropic quadrupole interactions of the deuterons are much larger than the spinning frequencies. We confine ourselves to the isotropic part of the spectra though it is possible, in principle, to analyze the SSBs to deduce the anisotropic hyperfine interaction [15]. Fig. 2(a) shows the central part of the ^{2}H NMR spectrum of **3** measured at a spinning frequency of 9 kHz. Two isotropic lines corresponding to 1,2-deuterons of the imidazole ligand were observed at 69 and 46 ppm. A signal at 6 ppm was assigned to a trace of solvent because it flanked no SSBs. In the ^{2}H NMR spectrum of **2**, in which only 2-position of the imidazole ligand is deuterated, the peak at 69 ppm was disappeared. Thus, we assigned this peak to 1-deuteron and the peak at 46 ppm to 2-deuteron of imidazole. Fig. 2(b) shows the ^{1}H NMR spectrum of **3** measured at a spinning frequency of 9 kHz. An isotropic line at 52 ppm was assigned to unresolved signals of 4,5-protons of the imidazole ligand. This overlap of the two

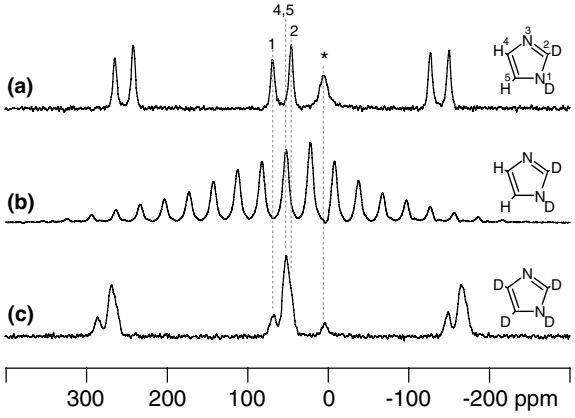

Fig. 2. (a) ^{2}H-MAS-NMR spectrum of **3** at 9 kHz and 304 K. (b) ^{1}H-MAS-NMR spectrum of **3** at 9 kHz and 304 K. (c) ^{2}H-MAS-NMR spectrum of **4** at 10 kHz and 306 K. Asterisk indicates trace of solvent.

peaks could not be removed in the ^{2}H-MAS-NMR spectrum of fully deuterated **4** at a spinning frequency of 10 kHz as shown Fig. 2(c). In this spectrum, the signal of 2-deuteron also overlapped those of 4,5-deuterons. We, therefore, measured temperature dependence of ^{2}H- and ^{1}H-MAS-NMR spectra of **3** to obtain the hyperfine coupling constants of the hydrogen atoms of the imidazole ligand.

Fig. 3(a) shows ^{13}C-MAS-NMR spectrum of **1** at a spinning frequency of 10 kHz and 306 K. Three isotropic lines were observed at 564, 318, 278 ppm though four inequivalent carbon sites exist in the crystal. We considered that the signal of ^{13}C in the thiocyanate ligand broadened out to baseline because of its fast transverse relaxation rate T_2^{-1} caused by large hyperfine coupling constants (hfcc) of this nucleus. We, consequently, assigned all the observed three lines to ^{13}C in the imidazole ligand. The peak at 318 ppm and its SSBs sharpened when protons of 1,2-position were substituted by

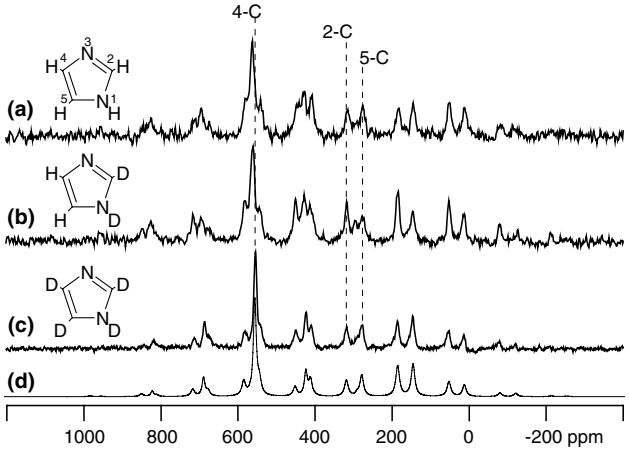

Fig. 3. ^{13}C-MAS-NMR spectra of: (a) **1**, (b) **3**, (c) **4** at a spinning frequency of 10 kHz and 306 K. Three isotropic lines of 561, 318 and 277 ppm are assigned to 4-, 2-, and 5-carbon, respectively. (d) ^{13}C-MAS-NMR spectrum synthesized with the parameters Δ^{calc} and η^{calc}.

[1] The difference $T - T_b$ originates from frictional heating, heat from the driving gas of room temperature, and uncalibrated T_b.

Table 1
Anisotropic and asymmetric parameters in 2,4,5-carbon of the imidazole ligand of $Ni(NCS)_2(Him\text{-}d_4)_2$ at 306 K

Position	δ_{iso} (ppm)	Δ^{exp} (ppm)	Δ^{calc} (ppm)	η^{exp}	η^{calc}
2-Carbon	318	520	530	0.8	0.4
4-Carbon	555	240	207	0.8	0.6
5-Carbon	278	440	450	0.7	0.6

deuterons as shown in Fig. 3(b). This narrowing is explained by the facts that (i) ^{13}C–^{1}H dipolar interaction is not completely removed under our MAS condition and (ii) the nuclear–nuclear dipolar interaction can be reduced chemically by deuteration. The degree of the reduction should be most significant for the adjacent carbon. Thus, we assigned the peak at 318 ppm to 2-carbon. When all the protons were substituted by deuterons, all the lines in ^{13}C NMR spectrum sharpened as shown in Fig. 3(c). We analyzed the SSB pattern of this spectrum to assign the remaining two peaks. In general, we can extract the principal values δ_{xx}, δ_{yy}, δ_{zz} of the NMR shift tensor from SSB pattern of ^{13}C-MAS-NMR spectrum [16]. These parameters can be expressed by another set of parameters, $\delta_{iso} = (\delta_{xx} + \delta_{yy} + \delta_{zz})/3$, $\Delta = \delta_{zz} - \delta_{iso}$, $\eta = (\delta_{xx} - \delta_{yy})/\Delta$, where $|\delta_{zz}| \geqslant |\delta_{xx}| \geqslant |\delta_{yy}|$. Using WIN-FIT [17] program, we fitted the ^{13}C-MAS-NMR spectrum of **4** with CSA mas model. The optimized parameters, δ_{iso}, Δ^{exp}, η^{exp}, are listed in Table 1. We found that the position of the isotropic line δ_{iso} of the signal at the highest frequency shifted from 564 ppm for **1** and **3** to 555 ppm for **4** by deuteration. The other two peak (318 and 278 ppm) remained the same within experimental errors. The cause of this shift is not fully understood at present. we guess that it was due to a slight modification of the crystal structure caused by deuterium substitution. The anisotropic parameter Δ^{exp} of the highest frequency peak was smaller than those of the other peaks, indicating this signal can be assigned to 4-carbon of which distance from nickel atom is long. To confirm this speculation, we computed anisotropic parameter Δ^{calc} and the asymmetric parameter η^{calc} for each carbon site from crystal structure parameters as discussed below.

Supposing the nuclear–nuclear dipolar interaction is decoupled, the NMR shift tensor is given as a sum of the hyperfine tensor and the chemical shift tensor [18]. The anisotropic part of the hyperfine tensor, which comes from electron–nuclear dipolar interaction, can be estimated by a point dipole model [19]. We put a point dipole bearing effective moment of $\mu_{eff} = g\sqrt{S(S+1)} = 2.18\sqrt{2}$ on each octahedral NiS_2N_4 unit. The spin distribution was taken to be 76% (nickel), 5% (sulfur), 4% (nitrogen of the thiocyanate), and 3% (nitrogen of the imidazole) on the basis of the DFT calculation. NiS_2N_4 units within 30 Å of the carbon were taken into account to calculate the dipolar field at 2,4,5-positions of the imidazole. The chemical shift tensor of each carbon was estimated from UB3LYP calculation on the molecular model. The hyperfine and the chemical-shift tensors were added together and diagonalized to obtain Δ^{calc} and η^{calc}. The parameters computed for each carbon site are listed in Table 1. The computed anisotropic parameters Δ^{calc} were consistent with Δ^{exp}, whereas agreement between asymmetric parameters η^{calc} and η^{exp} was not very good. This is probably due to low accuracy of the estimates of the chemical shift tensor. However, the agreement was sufficient for the purpose of assigning the two signals at 555 and 278 ppm to 4-carbon and 2-carbon, respectively. The ^{13}C-MAS-NMR spectrum of **4** is well reproduced by a spectrum synthesized with the parameters Δ^{calc} and η^{calc} (Fig. 3(d)), supporting the peak assignment.

3.2. Determination of the hyperfine coupling constants

The hfcc of the ^{1}H, ^{2}H and ^{13}C of the imidazole ligand were determined from the temperature dependence of the isotropic NMR shifts δ_{iso} measured for **3** using the following procedure.

The isotropic shift of a ligand nucleus in a paramagnetic metal complex consists of the Fermi contact term, the pseudo-contact term, and the diamagnetic term

$$\delta_{iso} = \delta_{Fermi} + \delta_{pc} + \delta_{dia}. \quad (1)$$

Kurland and McGarvey [20] gave a expressions for δ_{Fermi} and δ_{pc} of tetragonally distorted octahedral Ni^{2+} ($S = 1$) complex as

$$\delta_{Fermi} = \frac{2g_{iso}\mu_B A}{3k_B T(\gamma_{nuc}/2\pi)}\left[1 - \frac{g_\parallel - g_\perp}{9g_{iso}}\frac{D}{k_B T}\right], \quad (2)$$

$$\delta_{pc} = \frac{2\mu_B^2(g_\parallel^2 - g_\perp^2)}{9k_B T}\frac{3\cos^2\Omega - 1}{R^3}\left[1 - \frac{g_\parallel^2 - g_\perp^2/2}{3(g_\parallel^2 - g_\perp^2)}\frac{D}{k_B T}\right], \quad (3)$$

where A is the hfcc in hertz, T is the absolute temperature, γ_{nuc} is the gyromagnetic ratio of the nucleus, $g_\parallel$ and $g_\perp$ are the parallel and perpendicular components of the g tensor, D is the zero field splitting parameter, R is the length of a vector from the metal to the nucleus, Ω is the angle between the vector and z-axis, and the other terms have their usual meanings. The zero field splitting of $Ni(NCS)_2(Him)_2$ is so small ($D/k_B T < 2 \times 10^{-3}$ for $T > 200$ K) that we dropped the second terms of these equations. The intrachain magnetic interaction of the coordination polymer was included by substituting $T \to T - \theta$ where θ is the Weiss temperature. Then we obtained

$$\delta_{Fermi} = \frac{2g_{iso}\mu_B A}{3k_B(T - \theta)(\gamma/2\pi)}, \quad (4)$$

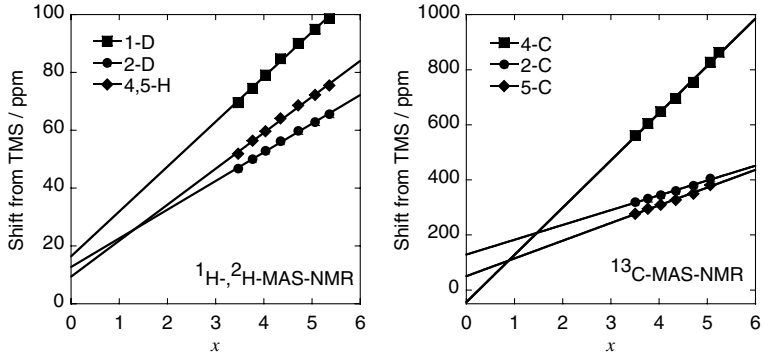

Fig. 4. Temperature dependence of the isotropic shifts of ^{1}H-, ^{2}H- and ^{13}C-MAS-NMR of **3**. The variable x is defined to be $x = 1000/(T/\mathrm{K} - 15.3)$ and is proportional to the magnetic susceptibility. The solid lines are the result of fitting to Eq. (9).

$$\delta_{\mathrm{pc}} = \frac{2\mu_{\mathrm{B}}^2(g_{\parallel}^2 - g_{\perp}^2)}{9k_{\mathrm{B}}(T-\theta)} \frac{3\cos^2\Omega - 1}{R^3}. \tag{5}$$

To determine A from the temperature dependence of δ_{iso}, we estimated the other parameters $g_{\parallel}$, $g_{\perp}$, and θ from published data. The Weiss temperature were estimated from the intrachain magnetic coupling constant $2J = 8.0\ \mathrm{cm}^{-1}$ [3], using

$$\theta = \frac{2zS(S+1)}{3k_{\mathrm{B}}}J, \tag{6}$$

where z is the number of the neighboring atoms and is equal to two for a simple magnetic chain. The estimated value of θ is 15.3 K. The g values of tetragonally distorted octahedral Ni^{2+} ($S = 1$) complex can be expressed as

$$g_{\perp} = 2.0023 - \frac{8\lambda}{\Delta E(^3\mathrm{B}_{1\mathrm{g}} \rightarrow {}^3\mathrm{E}_{\mathrm{g}})}, \tag{7}$$

$$g_{\parallel} = 2.0023 - 8\frac{8\lambda}{\Delta E(^3\mathrm{B}_{1\mathrm{g}} \rightarrow {}^3\mathrm{B}_{2\mathrm{g}})}, \tag{8}$$

where λ is the spin–orbit coupling constant and ΔE are the excitation energies. Using the literature values of $\Delta E(^3\mathrm{B}_{1\mathrm{g}} \rightarrow {}^3\mathrm{E}_{\mathrm{g}}) = 7480\ \mathrm{cm}^{-1}$, $\Delta E(^3\mathrm{B}_{1\mathrm{g}} \rightarrow {}^3\mathrm{B}_{2\mathrm{g}}) = 12\,130\ \mathrm{cm}^{-1}$, and $g_{\mathrm{iso}} = 2.18$ [3], we obtained $g_{\perp} = 2.21$ and $g_{\parallel} = 2.13$. The geometric parameters R were taken from the crystal structure, whereas Ω were approximated by zero for all the nuclei in the imidazole ligand, on the assumption that S–Ni–S was the symmetric axis. We finally obtained an expression of the isotropic NMR shift as

$$\delta_{\mathrm{iso}}/\mathrm{ppm} = \left[\frac{22.9 \times A/\mathrm{MHz}}{\gamma_{\mathrm{nuc}}/\gamma_{^1\mathrm{H}}} + \frac{47}{(R/\text{Å})^3}\right]x + \delta_{\mathrm{dia}}/\mathrm{ppm}, \tag{9}$$

where x is defined as

$$x = \frac{1000}{T/\mathrm{K} - 15.3}, \tag{10}$$

and δ_{dia} is assumed to be independent of temperature.

Temperature dependence of the isotropic shifts of ^{1}H-, ^{2}H- and ^{13}C-MAS-NMR of **3** were fitted by Eq. (9) as shown in Fig. 4. The experimental values of A are listed in Table 2 where the hfccs of deuteron were converted to those of proton by multiplying by the gyromagnetic ratio $\gamma_{^1\mathrm{H}}/\gamma_{^2\mathrm{H}}$. We observed that A of H and C are all positive values. The sign of A^{calc} obtained from DFT calculation were also positive and the $(A^{\mathrm{calc}} - A^{\mathrm{exp}})/A^{\mathrm{exp}}$ were within ±20% for carbon. This agreement between the experimental and theoretical hfcc encouraged us to utilize the calculated atomic spin density ρ^{calc} for discussing the spin density distribution of the imidazole ligand.

3.3. Spin density distribution of the imidazole ligand and possible interchain pathway

The positive signs of A of H and C can be explained by σ spin delocalization mechanism [21]. An octahedral Ni^{2+} ($S = 1$) complex has a $(t_{2g})^6(e_g)^2$ configuration and e_g orbitals are the SOMO of this complex. One of the e_g orbitals is composed of $d_{x^2-y^2}$ orbital of the nickel ion and σ orbitals of the ligand

$$e_{\mathrm{g}} = c_{\mathrm{d}}d_{x^2-y^2} + \sum_{k=1}^{4} c_k\sigma_k, \tag{11}$$

where c_{d} and c_k are appropriate coefficients. In the case of nickel–imidazole complexes, one of the σ orbitals is the n-orbital or a molecular orbital occupied by lone

Table 2
Hyperfine coupling constant A (MHz) and atomic spin density ρ of the imidazole ligand in $Ni(NCS)_2(Him)_2$ crystal

Position	A^{exp}	A^{calc}	ρ^{calc}
1-^{14}N		+0.81	+0.001
2-^{13}C	+0.57	+0.46	−0.007
3-^{14}N		+18.5	+0.057
4-^{13}C	+0.69	+0.85	−0.003
5-^{13}C	+1.88	+1.88	+0.003
1-^{1}H	+0.66	+0.45	
2-^{1}H	+0.37	+0.52	
4-^{1}H	+0.48	+0.63	
5-^{1}H	+0.53	+0.36	

electron-pair, which is mainly composed of an atomic orbital (AO) of 3-nitrogen. The coefficients of Eq. (11) is related to the spin delocalization from nickel into 3-nitrogen and the degree of the delocalization was $|c_{\mathrm{Him}}|^2 \simeq 0.06$ for $Ni(NCS)_2(Him)_2$ as is seen in Table 2. The electron spin is delocalized over the whole imidazole ligand because the n-orbital is not only composed of the AO of 3-nitrogen, but also of s-orbitals of hydrogen atoms and sp^2 orbitals of carbon atoms of the ligand. Though the contributions from these other AOs are small compared to that of the 3-nitrogen, the result that *all* of the observed A of H and C are positive values indicates that the σ spin delocalization is the dominant mechanism.

The other possible mechanism that induces spin density distribution is spin polarization mechanism, originally introduced by McConnell and Chesnut [22] to explain negative spin densities in aromatic radicals. It states that in molecular orbital theory the most likely spot to find a negative spin density is on a carbon atom which has zero spin density in the ground state configuration. Subsequently, it was extended to deal with non-aromatic radicals such as nitroxide or nitronyl nitroxide. It is sometimes referred to as alternation rule because the sign of the spin density alternates through successive bonds [23]. In the imidazole ligand of $Ni(NCS)_2(Him)_2$, the spin source that induces π spin polarization is the p_z orbital of 3-nitrogen of which electron spin is induced by n–π spin polarization. The alternation rule predicts negative spin densities on 2- and 4-carbon atoms and positive spin densities on 1-nitrogen and 5-carbon from this spin source. The calculated atomic spin densities ρ^{calc} listed in Table 2 are explained by this alternation rule but the experimental and theoretical hfccs are not. We thus concluded that the spin polarization dominates atomic spin densities of the π-electron systems in the imidazole ligand but the σ-electron systems is dominated by σ spin delocalization. The effect of the spin polarization on the σ-electron systems can be seen from the difference between hfcc of 5-carbon and those of 2,4-carbon in magnitude. Larger hfcc of 5-carbon indicates that the σ spin delocalization and the π spin polarization work cooperatively at this site but counterwork on 2,4-carbon atoms. It should be emphasized that the effect of the π spin polarization is negligible on hydrogen atoms, judging from the value of hfcc, and this positive spin densities of s-orbitals of the hydrogen atoms are brought by the σ spin delocalization. In other words, SOMO of this complex extends into the whole imidazole ligand.

The observed spin density distribution of the imidazole ligand in $Ni(NCS)_2(Him)_2$ qualitatively agreed with those of $[Ni(Him)_6]^{2+}$ [21] and $Cu(Him)_2Cl_2$ [24]. The nature of σ delocalization is independent of environment. Here, we briefly discuss the intermolecular magnetic interaction via the imidazole ligand. On the basis of above discussion, the $d_{x^2-y^2}$-based SOMO of $Ni(NCS)_2(Him)_2(SCN)_2$ unit is extended to 1-hydrogen that forms hydrogen bond with a sulfur atom of an adjacent chain as shown in Fig. 5(a). A p-orbital of this sulfur atom has MO coefficient of the other SOMO mainly composed of d_{z^2} of the nickel atom. Therefore, orthogonal SOMO–SOMO interaction occurs at N–H···S hydrogen bond. This causes a ferromagnetic interaction between the chains. In the case of $Cu(Him)_2Cl_2$, the $d_{x^2-y^2}$-based SOMO extended to 1-hydrogen has finite overlap integral between the SOMO of the adjacent Cu(II) complex (Fig. 5(b)). Thus, antiferromagnetic interaction occurs at N–H···Cl hydrogen bond. Imidazole ligand acts as either ferromagnetic or antiferromagnetic exchange coupler, depending on the crystal packing.

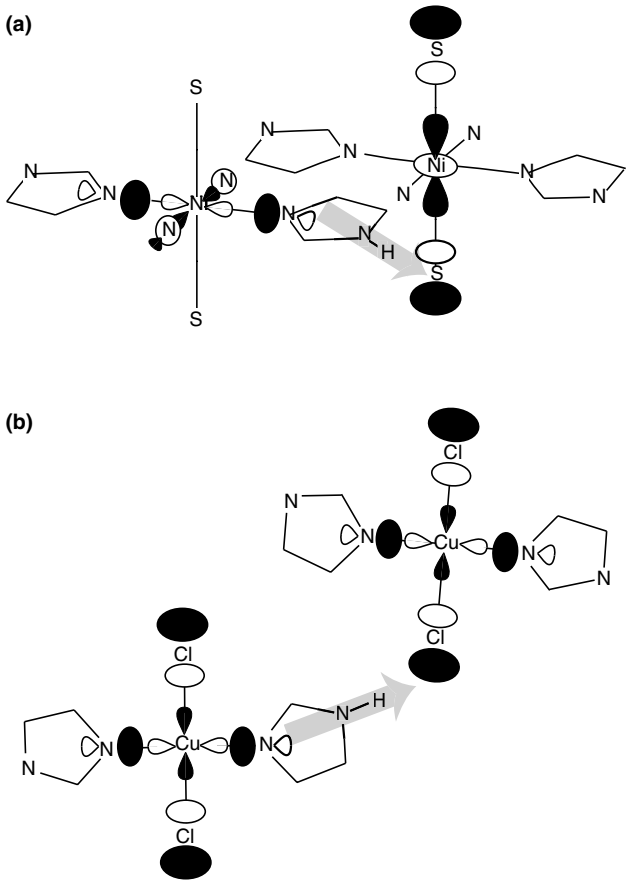

Fig. 5. Interchain SOMO–SOMO interactions via imidazole ligands in (a) $Ni(NCS)_2(Him)_2$ and (b) $Cu(Him)_2Cl_2$. Black and white represent opposite signs of the SOMO. The gray arrows indicate the delocalized SOMOs which extend onto the chain-bridging imidazole ligands. (a) Ferromagnetic interaction between the $d_{x^2-y^2}$-based and the d_{z^2}-based SOMOs. N–H bond is directed toward the *node* of the p-orbital of the sulfur. N···S distance is 3.38 Å and N···S–Ni angle is 92.7° [3]. (b) Antiferromagnetic interaction between the $d_{x^2-y^2}$-based SOMOs. N–H bond is directed toward the outer *lobe* of the p-orbital of the chlorine. N···Cl distance is 3.16 Å and N···Cl–Cu angle is 135.2° [7].

are seven structurally-characterized polynuclear copper(II) complexes which are bridged by two unsubstituted pyrazolate anions, $C_3H_3N_2^-$, (Fig. 1(a)) [23–27]. These are antiferromagnetically-coupled coordination polymer [23] and binuclear complexes [24–27] with $-2J$ values of 143–270 cm^{-1}. The superexchange pathway has been proposed to be the π system of the pyrazolates for the polymeric complex [23], while the σ system has been proposed for the others on the basis of extended Hückel MO calculations.

In this paper, we investigate poly- and bi-nuclear copper(II) complexes $[Cu(pz)_2]_n$ (**1**) and $[Cu_2(pz)_2(NO_3)(H_2O)(phen)_2]NO_3$ (**2**) (Hpz = pyrazole, phen = 1,10-phenanthroline) which have simple pyrazolate ligands as bridges. In **1**, coordination geometry around the copper atom is a distorted tetrahedron having exact D_2 symmetry and in **2** is the geometry between trigonal bipyramidal and square pyramidal. These complexes have electron spin of $S = 1/2$ at copper(II) ion. It has been reported that the $-2J$ value of **1** and **2** is 162, 143 cm^{-1}, respectively, indicating the existence of an antiferromagnetic interaction. Delocalized or polarized electron spin of the bridging pyrazolate is believed to mediate antiferromagnetic exchange interaction [23,27]. There is continuing interest in molecular orbitals that determine the local magnetic structures of paramagnetic complexes. We measured solid-state high-resolution NMR spectra of deuterated analogues of the complexes to elucidate which molecular orbital works as superexchange pathway.

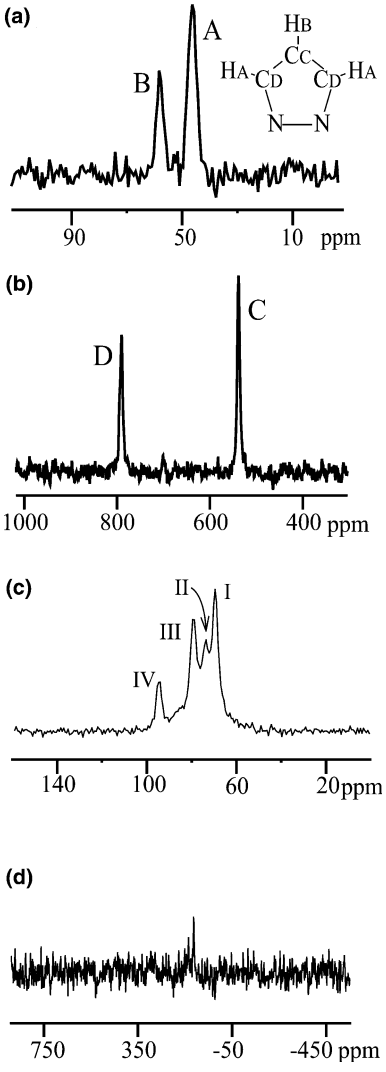

Fig. 1. Solid-state high-resolution NMR spectra of deuterated complexes **1**-d_6 and **2**-d_6: (a) ^2H NMR spectrum of **1**-d_6 at 276 K, (b) ^{13}C NMR spectrum of **1**-d_6 at 276 K, (c) ^2H NMR spectrum of **2**-d_6 at 190 K, (d) ^{13}C NMR spectrum of **2**-d_6 at 300 K. Additionally, alphabetical scheme for the hydrogen and carbon atoms of pyrazolate ligand is described for (a) and (b).

2. Experimental

2.1. Sample preparation

Perdeuterated pyrazole was prepared by catalytic exchange reaction [28]. Deuterated analogues of **1** and **2** were prepared in a similar manner to the literature methods [23,27] using the perdeuterated pyrazole. The samples **1**-d_6 and **2**-d_6 were identified with elemental analysis and powder X-ray diffraction.

2.2. Solid-state high-resolution NMR

^2H MAS NMR and the ^{13}C MAS NMR spectra of **1**-d_6 and **2**-d_6 were measured by a modified TOSS pulse sequence[1] [29] for powder crystalline samples at an external magnetic field of 7.05 T with a Bruker DSX300 spectrometer. A simple π-echo pulse sequence was also employed to measure the spinning sideband patterns. The spinning speeds of the samples were 7 and 9 kHz for **1**-d_6 and **2**-d_6, respectively. The ^2H and ^{13}C NMR spectra were measured from 190 to 350 K. The thermometer of the MAS NMR probe and an effect of the spinning speed on temperature-increase were carefully calibrated using $Pb(NO_3)_2$. The uncertainty of the temperature measurement after the calibration was 4 K, and the temperature fluctuation during the accumulation was within 1 K [12]. The NMR shifts were measured from TMS using methanol-d_4 (^2H) and hexamethylbenzene (^{13}C) as the second reference.

2.3. Electronic structure calculations

Density functional theory (DFT) calculations were performed at the level of UB3LYP/LanL2DZ using GAUSSIAN 98 program package [30]. We used $[Cu_2(pz)_2Cl_4]^{2-}$ as a molecular model of **1** because

[1] Cross polarization and ^1H-decoupling, which were usually implemented in TOSS sequences, were not employed in our experiments.

DFT calculations of one-dimensional polymeric complex is difficult. In the model molecule, copper atoms are bridged by two pyrazolate ligands and each copper ion is coordinated by two chlorine atoms. As a model of **2** $[Cu_2(pz)_2(NO3)(H_2O)(phen)_2]^+$ itself was used. The geometrical parameters were taken from their crystal structures.

3. Results and discussion

3.1. Spin densities of polynuclear copper(II) complex $[Cu(pz)_2]_n$

Figs. 1(a) and (b) show ^2H and ^{13}C MAS NMR spectra of **1**-d_6 at 276 K, respectively. Two peaks were observed both in ^2H NMR spectrum (A and B in Fig. 1(a)) and in ^{13}C NMR spectrum (C and D in Fig. 1(b)). These peaks were assigned to nuclei of the pyrazolate ligand as shown in Fig. 1. This assignment was based on the relative intensity of the NMR signals including spinning sidebands (data not shown). High frequency shifts were observed for the four NMR signals, indicating positive HFCCs of these nuclei. Since paramagnetic shift δ_{para} is proportional to the magnetic susceptibility χ

$$\delta_{iso} = \delta_{para} + \delta_{dia} = \frac{A_N \cdot \chi}{N_A(\gamma_N/2\pi)g\beta} + \delta_{dia}, \quad (1)$$

where the HFCC (A_N in hertz) can be determined from the temperature dependence of the isotropic shift δ_{iso} with the help of the magnetic susceptibility. In Eq. (1), N_A is the Avogadro constant, γ_N is gyromagnetic ratio of the nucleus, g is the isotropic g value of the complex, β is the Bohr magneton, and δ_{dia} is the temperature-independent chemical shift [31]. Temperature dependences of ^2H and ^{13}C NMR spectra of **1**-d_6 are summarized in Figs. 2(a) and (b). The NMR signals were shifted to higher frequencies with decreasing temperature. Magnetic susceptibility of **1** was interpreted in terms of one-dimensional antiferromagnetic Heisenberg model [32]:

$$\chi = \frac{N_A g^2 \beta^2}{kT} \cdot \frac{0.250 + 0.14995x^{-1} + 0.30094x^{-2}}{1 + 1.986x^{-1} + 0.68854x^{-2} + 6.0626x^{-3}}, \quad (2)$$

where $x = kT/|J|$. The magnetic-exchange coupling constant, $-2J$ and the g value of **1** are reported as 162 cm^{-1} and 2.13, respectively [23]. Because the paramagnetic shift is proportional to the magnetic susceptibility, the observed ^2H NMR isotropic shifts of **1**-d_6 were plotted as a function of the magnetic susceptibility of **1** (Fig. 3). From the slope of the line, we determined the HFCCs of deuteron in the use of Eq. (1) as listed in Table 1. The HFCCs of carbon were also deduced in the same manner. Here, we mention the observed

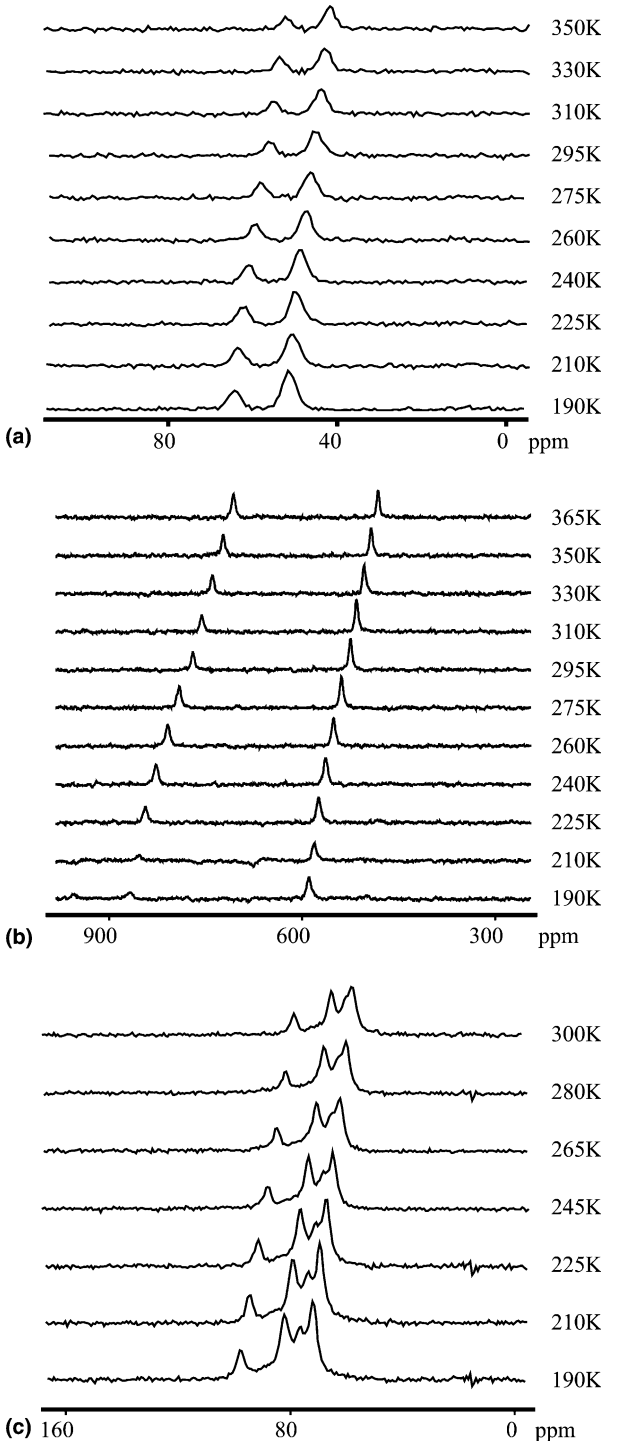

Fig. 2. Temperature dependence of the MAS NMR spectra: (a) ^2H NMR spectra of **1**-d_6, (b) ^{13}C NMR spectra of **1**-d_6, (c) ^2H NMR spectra of **2**-d_6.

HFCCs (A_N) is composed of the Fermi contact (A_{Fermi}) and the pseudo contact (A_{pseudo}) terms [31]

$$A_N = A_{Fermi} + A_{pseudo}, \quad (3)$$

$$A_{pseudo} = \frac{1}{3}\frac{\gamma_N}{2\pi} g\beta \left(\frac{g_\parallel^2}{g^2} - \frac{g_\perp^2}{g^2}\right) \frac{1}{r^3}(3\cos^2\theta - 1), \quad (4)$$

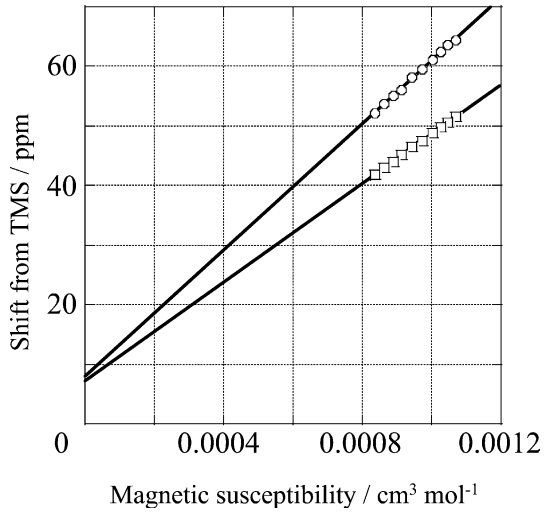

Fig. 3. A plot of the isotropic shifts as a function of magnetic susceptibility in ^{2}H NMR spectra of **1**-d_6: ○, the shifts derived from peak B; □, the shifts derived from peak A.

where r is the length of a vector r from the copper ion to the nucleus, θ is the polar angles of the vector with respect to the principal axis of g-tensor. However, values of the A_{pseudo} were estimated to be less than 0.05 and 0.1 MHz for ^{2}H and ^{13}C NMR shifts of **1**-d_6, respectively, which shows the contribution of A_{pseudo} to the observed A_N is vanishingly low. Thus, we can regard the observed HFCCs as Fermi contact term A_{Fermi}. Then the s-electron spin densities for H and C atoms of **1**-d_6 were determined from A_N as

$$A_{\text{Fermi}} = \rho^{\text{s}} A_{\text{f}}, \tag{5}$$

where ρ^{s} is the s-electron spin density of the atom and A_{f} is the value of the HFCC when the s orbital is singly occupied ($\rho^{\text{s}} = 1$). The experimental s-electron spin densities and computed atomic spin densities ρ^{atom} are also listed in Table 1.

Table 1
HFCCs and electron spin densities in **1**-d_6 and **2**-d_6

	NMR experiment		DFT calculation	
	HFCC (MHz)	s-Electron spin density	HFCC (MHz)	Atomic spin density
1-d_6				
A	+0.31	+0.001	+0.29	+0.001
B	+0.39	+0.002	+0.24	+0.000
C	+7.81	+0.003	+5.58	+0.006
D	+5.30	+0.002	+9.79	−0.001
2-d_6				
I	+0.32	+0.001		
II	+0.37	+0.002		
III	+0.38	+0.002		
IV	+0.44	+0.002		
H1			+0.28	+0.001
H2			+0.37	+0.001
H3			+0.45	+0.001
H4			+0.45	+0.001
H5			+0.40	+0.001
H6			+0.42	+0.001

3.2. Magnetic interaction path of polynuclear copper(II) complex $[Cu(pz)_2]_n$

We found that the s-electron spin densities of carbon and hydrogen atoms in pyrazolate are all positive values. Here, we discuss the magnetic interaction path of **1** on the basis of the NMR results with the help of molecular orbitals. There are two candidates for the interaction pathway in terms of molecular orbital theory: π-electron system and σ-electron system in the pyrazolate anion. The π-electron system of the anion is a 6-electron 5-orbital system including HOMO and LUMO of an imaginary isolated pyrazolate ligand. The σ-electron system of the anion is a 4-electron 2-orbital system mainly composed of two lone electron-pair of the two nitrogen atoms. We obtained these orbitals by extended Hückel MO calculations on an isolated pyrazolate anion and the qualitative character of these systems was not changed by higher level of calculation. When the pyrazolate coordinates to paramagnetic metal ions, electron spin densities is induced by delocalization and/or polarization mechanisms and the spin density distribution of the ligand depends on which mechanism is dominant. In the π-system, the s-electron spin densities of H and C atoms in pyrazolate ligand are zero at the first approximation because they are on the node of the π-orbitals. However, the s-electron spin density can be finite on the constituent atoms due to spin polarization mechanism [33]. Spin polarization is that on any CH σ-bond unpaired electron in 2p π-orbital attracts the electron of the same spin of CH σ-bonding electron pair. As a result, the sign of s-electron spin density of a carbon atom is equal to that of π-electron spin density, and the adjacent hydrogen atom has the opposite sign to the unpaired π-electron. Therefore, CH σ-bonding spin on the H site is consequently opposite in sign to the s-electron spin on the C site if the π-spin polarization is dominant. On the other hand, in the σ-system, s-orbitals of H and C atoms have non-zero MO coefficients of the nonbonding orbitals which are mainly localized on N atoms. Thus the signs of the s-electron spin densities on the H and C sites become all positive when the N atoms have positive spin densities. In experimental NMR data, the signs of s-electron spin densities on the H and C sites of pyrazolate ligand were all positive. Therefore the magnetic interaction path of **1** cannot be the π-system on the assumption that the magnetic interaction path should dominate the local magnetic structure of the ligand. Consequently, the path of **1** is the σ-system in view of the property of the σ-orbitals. We obtained the HFCCs (A_{Fermi}) and atomic electron spin densities ρ^{atom} of **1** using the DFT calculations. The calculated values of A_{Fermi} were 0.29, 0.24, 5.58 and 9.79 MHz

for the peak A, B, C and D, respectively, and atomic spin densities were positive except for peak D. This small negative value of ρ^{atom} indicates that π-spin polarization occurs slightly with the dominant σ-delocalization mechanism. We concluded that the dominant magnetic interaction path in **1** is the σ-electron system of the pyrazole ligand.

3.3. Spin densities and magnetic interaction path of binuclear copper(II) complex $[Cu_2(pz)_2(NO_3)(H_2O)(phen)_2]NO_3$

Figs. 1(c) and (d) illustrate ^2H and ^{13}C MAS NMR spectra of **2**-d_6 at 190 and 300 K, respectively. As shown in Fig. 1(d), we could not observe a ^{13}C NMR signal of **2**-d_6 under our experimental condition. A peak around 150 ppm is probably due to impurity or background. The reason is ascribable to longer electron spin relaxation time T_{1e} of **2**-d_6 or heteronuclear dipole–dipole interactions between protons in 1,10-phenanthroline ligand and carbon nuclei. We observed four ^2H NMR signals of I, II, III and IV as shown in Fig. 1(c). Because $[Cu_2(pz)_2(NO_3)(H_2O)(phen)_2]^+$ has no symmetry element, complex **2**-d_6 has six non-equivalent deuterium atoms in the two pyrazolate ligands. One-to-one assignment of the four peaks to the six hydrogen of the pyrazolate ligands could not be achieved. It is, however, obvious that all of the four signals have positive HFCCs from their high frequency shifts as is observed for **1**-d_6. The temperature dependence of ^2H MAS NMR spectrum is shown in Fig. 2(c). All of the four peaks were shifted to higher frequencies with decreasing temperature. Magnetic susceptibility of **2** was interpreted with singlet–triplet model [27].

$$\chi = \left(\frac{N_A g^2 \beta^2}{kT}\right)\left[3 + \exp\left(\frac{-2J}{kT}\right)\right]^{-1}, \quad (6)$$

where $-2J$ and g value of **2** are reported as 143 and 2.14 cm^{-1}, respectively [27]. The four paramagnetic shifts in the ^2H MAS NMR spectrum of **2**-d_6 were plotted as a function of the magnetic susceptibility, then the HFCCs and electron spin densities in **2**-d_6 were obtained in a similar manner to **1**-d_6. The HFCCs and the spin densities are listed in Table 1. As were obtained for **1**, the pseudo contact term was evaluated for **2** using Eq. (4). Values of the A_{pseudo} are estimated to be less than 0.05 MHz for ^2H shifts. As compared to the HFCCs on Table 1, contribution of the A_{pseudo} to the obtained HFCCs is vanishingly low again. Therefore the experimental HFCCs in **2**-d_6 can be also thought of as Fermi contact term. The HFCCs and atomic spin densities from the DFT calculations in **2** were obtained as shown in Table 1, and the numbering scheme for the hydrogen atoms is shown in Fig. 4. Here, we compared the result of the calculations with the experimental

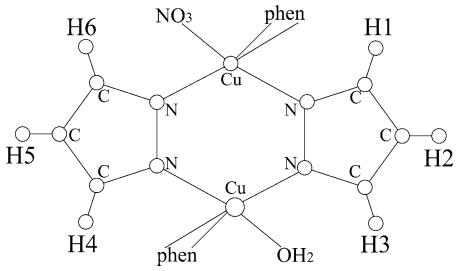

Fig. 4. Numbering scheme for the hydrogen atoms of **2**.

values in **2**-d_6 to assign I, II, III and IV to hydrogen atoms of the pyrazolate ligands. The one-to-one assignment could not be also achieved. However, the experimental HFCC fell within 0.32–0.44 MHz and the calculated HFCC fell within 0.28–0.45 MHz. We concluded that the HFCCs of the pyrazolate ligands are similar positive values to each other.

Electron spin densities on H sites in **2**-d_6 as well as in **1**-d_6 were all positive values. As discussed in the magnetic interaction of **1**, either σ or π orbital of pyrazolate ligand is the magnetic interaction path in the binuclear complex **2**. If π-orbitals are used, signs of the spin densities on H sites in **2**-d_6 would not be all the same. The signs deduced from the experiment on **2**-d_6 correspond with properties of the σ-system. The magnetic interaction path of **2**-d_6 is also σ-orbitals of pyrazolate ligands.

It should be noted that the HFCCs of **1**-d_6 and **2**-d_6 are almost the same values, which indicates that the spin density distribution are almost the same at the pyrazolate ligands in the both compounds. Moreover, the $-2J$ values of the these compounds are approximately the same though they are very different in coordination geometry. Plass et al. [21] reported that their mono-imidazolate-bridged binuclear copper(II) complexes $[Cu_2(dien)_2(L)](ClO_4)_3$ (L:imizolate or substituted imidazolates) have no simple magneto-structural correlation and concluded that the magnetic interactions between the copper(II) ions is dominated by the σ exchange pathway through the bridging imidazolate ligand. However, it should be stressed that there *is* a magneto-structural correlation in bis-pyrazolate-bridged copper(II) complex [27]. Matsushima et al. found that square–planar and square–pyramidal complexes, which have the well-defined $d_{x^2-y^2}$ orbital as the magnetic orbital, have larger $-2J$ values than trigonal bipyramidal complexes. The magnetic orbitals of the latter compounds are so distorted from the $d_{x^2-y^2}$ orbital that the orbital-overlap integrals between copper(II) centers and pyrazolate ligands decrease. The distorted tetrahedral geometry around the copper atom in **1** also deviate the magnetic orbital from the ideal $d_{x^2-y^2}$ orbital. This is the reason why antiferromagnetic interaction in **1** is as weak as in **2**.

4. Conclusion

We investigated magnetic interaction paths for complex **1** and **2**, which include heterocyclic ligand, by means of solid-state MAS NMR measurement. We found the electron spin of $S = 1/2$ of Cu(II) ion in **1** and **2** delocalize over the pyrazolate ligand via σ-orbitals. The experimental values of HFCCs agreed with those calculated on the basis of DFT. It is important that the observed s-electron spin densities are all positive values in **1**-d_6 and **2**-d_6. Taking molecular orbitals of pyrazolate ligand into account, the NMR result cannot be explained by π-spin polarization. We concluded that the magnetic interaction paths of **1** and **2** are not π but σ-electron system of the pyrazolate.

BH_3) [16,17]. We found the changes of the spin-crossover temperature T_c with S/BH_3 substitution depends on the enthalpy, presumably arising from the ligand-field strength. To get the further insight into the cooperativity between dinuclear complexes and the synergy between the intra-dimer magnetic exchange coupling and the spin-crossover phenomenon, we report here the synthesis and magnetic characterization of $[\{M(NCS)(4\text{-Phpy})\}_2(\mu\text{-bpypz})_2]$ ($M = Co^{2+}$ and Fe^{2+}). As the additional axial pyridine derivatives and the metal ions are replaceable for the bpypz-bridged dinuclear complexes, the role of these items on the spin-crossover is investigated.

2. Experimental

2.1. Syntheses

2.1.1. Preparation of the starting complexes

The starting complex *trans*-$[Fe(NCS)_2(py)_4]$ was obtained by a method given in the literature [18]. *trans*-$[Co(NCS)_2(py)_4]$ was obtained by the analogous method to *trans*-$[Fe(NCS)_2(py)_4]$; to an aqueous solution (250 mL) containing 14.58 g of $Co(NO_3)_2 \cdot 6H_2O$ and pyridine (20 mL) was slowly added an aqueous solution (100 mL) containing 8.04 g of NaNCS. The pink precipitate obtained was filtered off and washed with 10 mL portions of ethanol–pyridine (9:1). After drying in vacuo, a pink powder was obtained.

2.1.2. $[\{Co(NCS)(4\text{-Phpy})\}_2(\mu\text{-bpypz})_2]$

A methanolic solution (2 mL) of *trans*-$[Co(NCS)_2(py)_4]$ (3 mmol L^{-1}) was transferred to a glass tube, and then a methanolic solution of 2 mL of Hbpypz (3 mmol L^{-1}) and 4-Phpy (10 mmol L^{-1}) was poured into the glass tube without mixing the solutions. Orange crystals began to form at ambient temperature in 2 weeks. One of these crystals was used for X-ray crystallography. Physical measurements were conducted on a polycrystalline powder that was synthesized as follows: Hbpypz (0.022 g, 0.099 mmol) was dissolved in 12 mL of a methanol solution of 4-Phpy (0.022 g, 0.14 mmol) with a 10% methanol solution of tetra-*n*-butylammonium hydroxide $(n\text{-Bu})_4NOH$ (0.26 g, 0.10 mmol). To this solution was added 15 mL of a methanol solution of *trans*-$[Co(NCS)_2(py)_4]$ (0.049 g, 0.10 mmol) under an N_2 stream. An orange precipitate was obtained and after stirring this reaction mixture for 2 h, the precipitate was filtered off and washed with methanol. The solid was then dried in vacuo. Yield 71%. Calc. for $C_{50}H_{36}N_{12}S_2Co_2$: C, 60.85; H, 3.68; N, 17.04. Found: C, 59.61; H, 3.48; N, 17.54%. The homogeneity of the powder sample was confirmed by comparison of the observed powder diffraction pattern with that calculated from the single-crystal data.

2.1.3. $[\{Fe(NCS)(4\text{-Phpy})\}_2(\mu\text{-bpypz})_2]$

Hbpypz (0.074 g, 0.033 mmol) was dissolved in 36 mL of a methanol solution of 4-Phpy after deprotonating with a 10% methanol solution of tetra-*n*-butylammonium hydroxide $(n\text{-Bu})_4NOH$ (0.87 g, 0.34 mmol). To this solution was added 15 mL of a methanol solution of *trans*-$[Fe(NCS)_2(py)_4]$ (0.16 g, 0.33 mmol) under an N_2 stream. A yellow precipitate was obtained and after stirring this reaction mixture for 2 h, the precipitate was filtered off and washed with methanol. The solid was then dried in vacuo. Yield 71%. Calc. for $C_{50}H_{36}N_{12}S_2Fe_2$: C, 61.23; H, 3.70; N, 17.14. Found: C, 60.10; H, 3.52; N, 16.72%.

2.2. Physical measurements

Magnetic susceptibility data were recorded over the temperature range from 2 to 300 K in the presence of a magnetic field between 50 and 5000 G with a SQUID susceptometer (Quantum Design, San Diego, CA). All data were corrected for diamagnetism, which was calculated from Pascal's tables. Least squares fitting of the magnetic susceptibility to appropriate equations with Heisenberg Hamiltonian ($H = -JS_i \cdot S_i$) were performed for the cobalt complex. X-ray powder diffraction data were collected on a Rigaku MultiFlex diffractometer by using Cu Kα radiation.

2.3. Crystallographic data collection and refinement of the structure

Data collection of **1** was carried out by a Rigaku Mercury charge coupled device (CCD) system with graphite-monochromated Mo Kα radiation. Crystallographic data are given in Table 1. The structure was solved by a standard direct method (TEXSAN crystallographic software package of the Molecular Structure

Corp. and Rigaku). Full-matrix least-squares refinements were carried out with anisotropic thermal parameters for all non-hydrogen atoms. All the hydrogen atoms were placed in the calculated positions and fixed. CCDC reference number is CCDC 251440.

3. Results and discussion

3.1. Structure of [{Co(NCS)(4-Phpy)}$_2$(μ-bpypz)$_2$] (1)

An ORTEP drawing of the structure around the cobalt ions in **1** with the atom numbering scheme is shown in Fig. 1(a). The structure of **1** shows that the desired coordination has been achieved with the cobalt atoms being coordinated to two bpypz to form a dinuclear complex [19]. The dinuclear unit is centrosymmetric, thus, the only one kind of cobalt and ligands exist in the molecule. Each cobalt atom is bound to the four nitrogen atoms of two pyridyl and two pyrazolate moieties in bpypz in the basal plane and two nitrogen atoms of 4-Phpy and NCS^- anion at the axial positions (2.190(4) Å (Co–N(1)), 2.059(3) Å (Co–N(2)), 2.046(3) Å (Co–N(3)), 2.216(4) Å (Co–N(4)), 2.168(4) Å (Co–N(6)), 2.095(4) Å (Co–N(21))) forming a distorted octahedral environment as clearly seen from the top and side views of the molecule. The dihedral angle between pyridyl and phenyl rings in 4-Phpy is 20°, the value of which is smaller than those of [Ta(NMe$_2$)Cl$_3$(4-Phpy)] (40°) [20] and [Ni(4-Phpy)$_2$(DBM)$_2$] (DBM = dibenzoylmethane) (30°) [21]. The efficient packing presumably compensates for

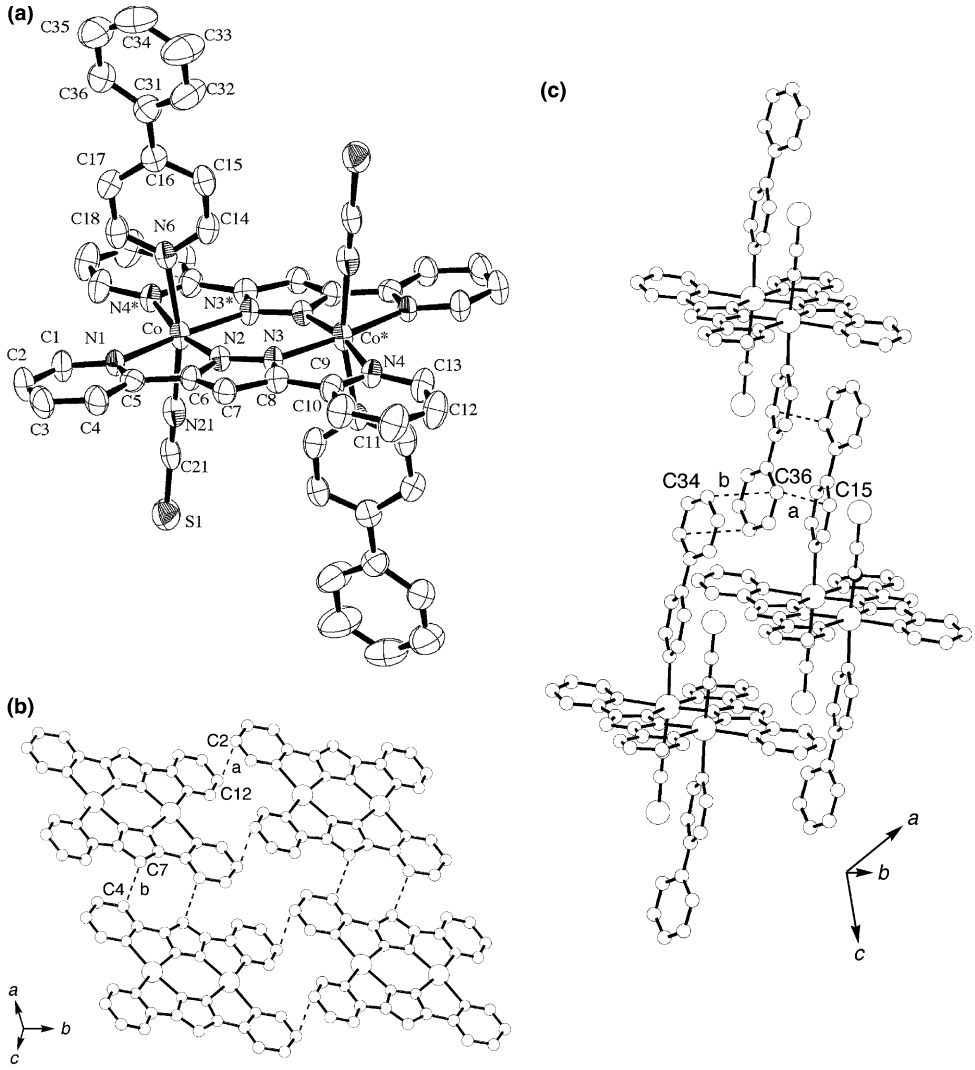

Fig. 1. (a) ORTEP drawing of **1** with atom numbering scheme. Thermal ellipsoids are set at 50% probability and hydrogen atoms have been omitted for clarity. Selected bond distances (Å): Co–N1 2.190(4), Co–N2 2.059(3), Co–N3* 2.046(3), Co–N4* 2.216(4), Co–N6 2.168(4), Co–N21 2.095(4). (b) Emphasizing the π–π stacking interactions between two bpypz ligands of consecutive **1** dimers: *a* (C2–C12) = 3.46 Å, *b* (C4–C7) = 3.42 Å. 4-Phenylpyridine ligands and NCS^- anions have been omitted for clarity. (c) Emphasizing π–π stacking interactions between consecutive 4-phenylpyridine ligands: *a* (C15–C36) = 3.51 Å, *b* (C34–C36) = 3.73 Å.

any unfavorable H—H contact that results in the coordinated 4-Phpy (vide infra). Interestingly, **1** forms a layer by the two types of π–π stacking interactions between the adjacent bpypz ligands of the neighbor dimers (Fig. 1(b)): (1) between pyridyl rings and (2) between pyridyl and pyrazole rings on the adjacent complexes. The layers are connected by additional π–π stacking interactions between adjacent 4-Phpy ligands (Fig. 1(c)) to form a three-dimensional structure.

3.2. Structure of [{Fe(NCS)(4-Phpy)}$_2$(μ-bpypz)$_2$] (2)

Despite many efforts, we did not succeed in growing single crystals of **2** suitable for single crystal X-ray analysis and we used powder diffraction pattern to determine the structure. Fig. 2 shows the diffractograms of compounds **1** and **2** accompanied with the simulated pattern obtained from the crystal structure of **1**. The X-ray diffraction patterns show **1** and **2** to be isomorphous at room temperature, and thus, the dinuclear iron(II) structure is confirmed to be formed.

3.3. Magnetic properties

Fig. 3 shows temperature dependence of the magnetic susceptibilities of the compounds **1** and **2**. The $\chi_M T$ value of **1** in the higher temperature region is about 5.4 emu K mol^{-1}, which is larger than the spin only value for two Co(II) site (3.752 emu K mol^{-1}). This behavior is typical of the high spin Co(II) ion in a distorted octahedral environment, and a large orbital contribution to the magnetic moment should be considered. However, at lower temperature the $\chi_M T$ value dramatically decreases in a manner indicative of intramolecular antiferromagnetic coupling between high spin cobalt(II) ions with a low-lying spin singlet as the ground state. Thus we have attempted to fit the essential feature of the experimental susceptibility by using the simple classical spin approach ($H = -JS_A \cdot S_B$), to give a fitting with $J = -8.78$ cm^{-1} and $g = 2.49$. No spin transition occurs in **1** while J value correlates well to the related high spin cobalt(II) dinuclear complexes reported [22].

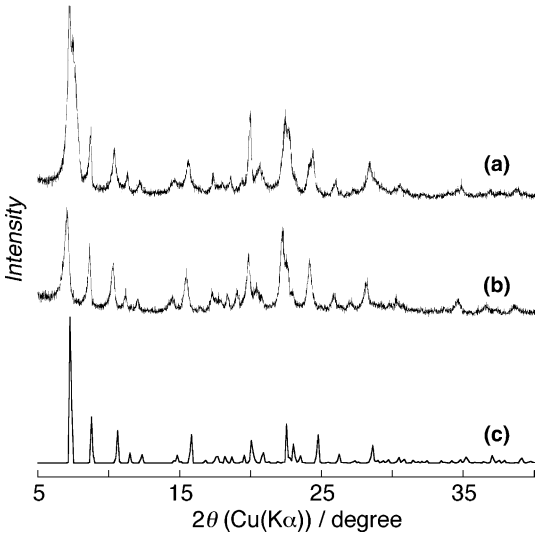

Fig. 2. Powder X-ray diffraction patterns of **1** (a) and **2** (b). (c) shows the simulated pattern obtained from the crystal structure of **1**.

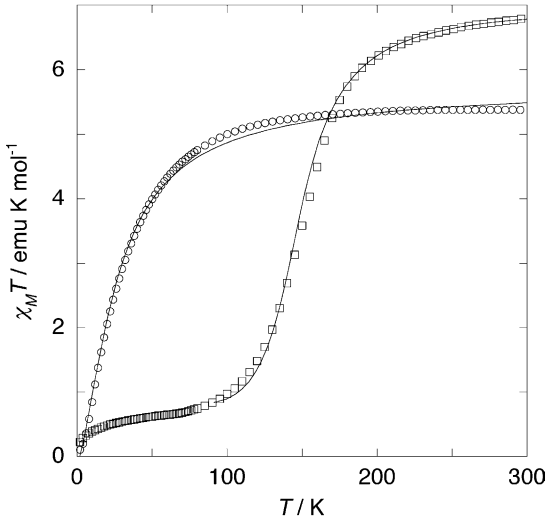

Fig. 3. Temperature dependence of $\chi_M T$ plots for **1** (○) and **2** (□). The solid lines are the fit of the data; see the text for the fitting parameters.

On the other hand, compound **2** shows a spin-crossover phenomenon. The substitution of the metal ion from cobalt to iron leads to the emergence of the spin-crossover. This may be due to the difference in the stability of the low spin phases. The temperature dependence of the $\chi_M T$ value is reversible in both the cooling and warming mode with no hysteresis. The $\chi_M T$ value decreases on lowering the temperature, and then it remains nearly constant at 0.6 emu K mol^{-1}, the value of which corresponds to a mixture of low spin and high spin ions, with the molar fractions 0.17 and 0.83, respectively. Below 40 K, the $\chi_M T$ value slightly decreases, reaching a value of 0.2 emu K mol^{-1} at 2 K. This decrease in the low temperature range may be attributed to the antiferromagnetic coupling of the residual HS sites as seen in the cobalt complex shown above. The spin-crossover temperature T_c (150 K) of complex **2** is higher than that of [{Fe(NCS)(py)}$_2$(μ-bpypz)$_2$] (127 K) [23]. The detailed comparison in spin-crossover behavior between these two complexes could be made by the least-squares fitting of the magnetic susceptibility using the regular solution model through Eq. (1) [24].

$$\ln[(1-\gamma_{HS})/\gamma_{HS}] = \Delta H_{HL} + \Gamma(1-2\gamma_{HS})/RT - \Delta S_{HL}/R, \quad (1)$$

where γ_{HS} is the high spin fraction, Γ is an interaction parameter, and ΔH_{HL} and ΔS_{HL} are the enthalpy and entropy change associated with the spin transitions.

The cooperative factor of the spin transition is defined by $C = \Gamma/2RT_c$. A good simulation of the magnetic susceptibility is achieved with $\Delta H_{HL} = 7.18$ kJ mol^{-1}, $\Delta S_{HL} = 47.9$ J K^{-1} mol^{-1}, $\Gamma = 1.08$ kJ mol^{-1} and $C = 0.433$ as indicated by the solid curve in Fig. 3. ΔH_{HL} for **2** is larger than that for [{Fe(NCS)(py)}$_2$(μ-bpypz)$_2$] (5.96 kJ mol^{-1}) whereas ΔS_{HL} is similar to each other ($\Delta S_{HL} = 46.6$ J K^{-1} mol^{-1} for [{Fe(NCS)(py)}$_2$-(μ-bpypz)$_2$]) [23]. Thus, the difference of T_c with the substitution of pyridine moiety for [{Fe(NCS)(X-py)}$_2$-(μ-bpypz)$_2$] is attributed in their enthalpy difference. This is similar to the replacement of NCS^- to $NCBH_3^-$ moiety for [{Fe(NCX)(py)}$_2$(μ-bpypz)$_2$], but is different from the case for the series of compounds [Fe(PM-L)$_2$(NCX)$_2$] in which ΔS_{HL} is significantly affected by the S/Se substitution of X in NCX^- [24]. Interestingly, the cooperative factor C of **2** is smaller than that of [{Fe(NCS)(py)}$_2$(μ-bpypz)$_2$] indicating that the spin-crossover behavior for **2** is more gradual than that for [{Fe(NCS)(py)}$_2$(μ-bpypz)$_2$] [23]. This may reflect the difference in the crystal packing structure due to the substitution from py to 4-Phpy. Moreover, the spin-crossover in the present dinuclear complex occurs apparently in terms of a single molecular basis rather than by intermolecular interactions as claimed for *cis*-[Fe(NCBH$_3$)$_2$(phen)$_2$] [25]. On the other hand, we have very recently revealed that [{Fe(NCBH$_3$)(4-Phpy)}$_2$-(μ-bpypz)$_2$] shows the non-stepwise direct two step spin-crossover through the intermediate magnetic state with the coexistence of [HS–HS] and [LS–LS] dinuclear spin states while the X-ray diffraction patterns show [{Fe(NCX)(4-Phpy)}$_2$(μ-bpypz)$_2$] (X = S, BH$_3$) to be isomorphous at room temperature [17]. Therefore, the intermediate magnetic state can be affected by the subtle change in the molecular structure or the intermolecular interactions such as π–π stacking interactions.

4. Conclusions

We have described the synthesis, structure and magnetic properties of dinuclear complexes using bpypz as the linking ligand. The iron(II) complex exhibits that the spin-crossover occurs with a single HS–HS to LS–LS process, as in the case of the μ-pypz complex [15] while no spin transition occurs in the cobalt(II) complex. The changes in the thermodynamic parameters on the spin-transition of the iron complex are in accordance with those for the corresponding spin-crossover mononuclear iron(II) complexes. The difference of T_c with the substitution of pyridine moiety from py to 4-Phpy for [{Fe(NCS)(X-py)}$_2$(μ-bpypz)$_2$] is attributed in their enthalpy difference. This is similar to the replacement of NCS^- to $NCBH_3^-$ moiety for [{Fe(NCX)(py)}$_2$-(μ-bpypz)$_2$]. However, the spin transition behavior of the dinuclear complexes cannot be easily understood as exemplified in the comparison between [{Fe(NCX)-(4-Phpy)}$_2$(μ-bpypz)$_2$] since it can be affected by the synergy between the inter- and intramolecular interactions. Therefore, further exploration into this series of compounds could give a clue to deeper understanding spin-crossover phenomena in dinuclear complexes.

CCDC 224233.

2.1.5. Synthesis of $[Mn_{13}O_{12}(Me_2Bta)_{12}F_6(MeOH)_{10}(H_2O)_2] \cdot 3\ MeOH \cdot H_2O$ (5)

Anhydrous MnF_3 (0.5 g) and dimethylbenzotriazole (Me_2BtaH) (1.6 g) were heated in methanol (20 ml, 50 °C) under aerobic conditions for 20 min. The resulting black solution was filtered and upon evaporation in air, black crystals of **4** were obtained after 24 h. Elemental *Anal*. Calc. for $C_{106}H_{140}N_{36}O_{24}F_6Mn_{13}$: C, 40.67; H, 4.51; N, 16.11; F, 3.64. Found: C, 39.83; H, 4.12; N, 16.58; F, 4.21%. Crystal data for **5**: $C_{110.5}H_{155.5}F_6Mn_{13}N_{36}O_{27}$, $M_r = 3252.43$, crystal dimension = 0.06 × 0.04 × 0.01 mm^3, triclinic, space group, $P\bar{1}$ $a = 17.5604(13)$, $b = 17.7334(13)$, $c = 30.679(2)$ Å, $\alpha = 89.695(2)$, $\beta = 73.548(2)$, $\gamma = 60.850(2)°$, $V = 7901.1(10)$ Å^3, $T = 150(2)$ K, $Z = 2$, $\rho = 1.37$ Mg/m^3, 29859 reflections collected, 19051 unique ($R_{int} = 0.0426$), $R(F) = 0.0849$ and $wR_2 = 0.2400$ using 13869 reflections with $I > 2\sigma(I)$. The data were collected on SRS at CCLRC Daresbury using a Bruker AXS SMART CCD area detector. CCDC 224232.

3. Results and discussion

3.1. Description of structures

The structure of $[Mn^{III}_{26}O_{17}(OH)_8(OMe)_4F_{10}1111(Bta)_{22}(MeOH)_{14}(H_2O)_2]$ (**1**) is shown in Fig. 1. The $[Mn^{III}_{26}O_{17}(OH)_8(OMe)_4]^{32+}$ core of **1** can be described as a central distorted tetra-face-capped octahedron

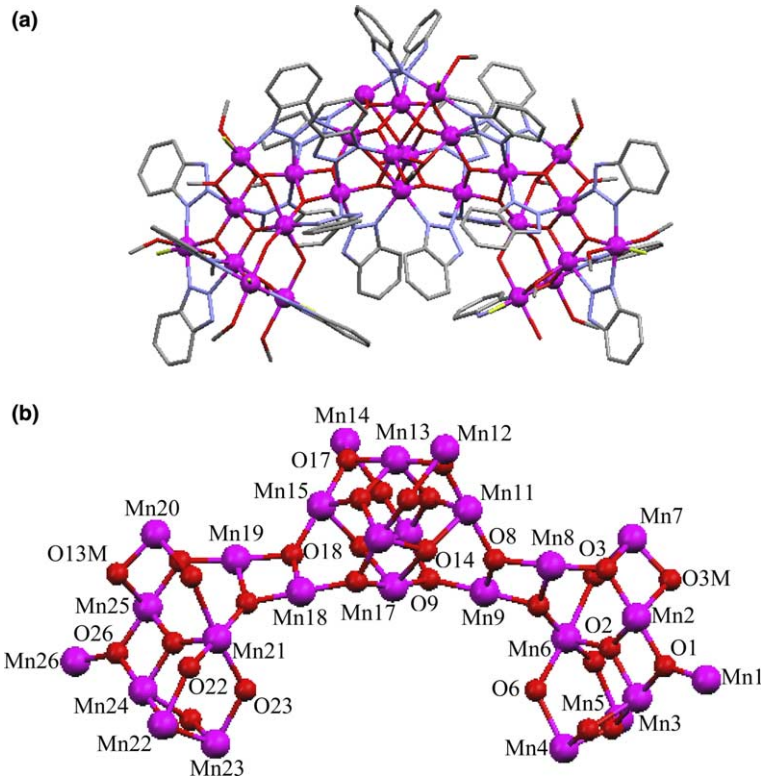

Fig. 1. The structure of complex **1** (a) and its metal-oxygen core (b) showing the aggregated $\{Mn_3O\}$ units (Mn = pink, O = red, N = blue, F = green, C = grey).

(Mn9–Mn18), either side of which are attached two vertex-sharing tetrahedra (Mn2–Mn8 and Mn19–Mn25), centred on Mn6 and Mn21. A pseudo C_2-axis passes through the direction defined by Mn13 and Mn17, situated at the "top" of the molecule. The O^{2-} ions all bridge in their usual μ_3-fashion forming $\{Mn_3O\}^{7+}$ units. The OH^- ions are of two types: four are μ_3-bridging (O10, O11, O14, O16) and are situated within the tetra-face-capped octahedron, while the remaining ions are μ_2-bridging (O5, O6, O12, O15, O22, O23) and are situated both in the tetra-face-capped octahedron (O12 and O15) and within the two vertex-sharing tetrahedra (O5, O6, O22 and O23). The 22 deprotonated Bta^- ligands are of two types: four use all three nitrogens to bond to three Mn^{3+} centers while the remaining 18 use only two nitrogen atoms to bond to two Mn^{3+} centers, the third nitrogen atom H-bonds to adjacent MeOH, H_2O or OH^- ligands. The four MeO^- ions are all μ_2-bridging, but there are also two MeOH molecules which act as μ_2-bridges (O7M, O12M) between Mn6–Mn7 and Mn20–Mn21, respectively. In each case, the O-atom of the MeOH molecule is not deprotonated, as confirmed by the observed bond lengths (2.393–2.476 Å), BVS analysis and the presence of a H-bond between each O-atom and an unbound N-atom of a μ_2-bridging Bta^- ligand (e.g., O7M–N73, 2.738 Å). The 10 F^- ions are all terminal with bond lengths ranging from 1.800(8) to 1.844(8) Å. The Mn centers all lie in distorted octahedral geometries and display the Jahn–Teller elongations expected for high spin Mn^{3+}, although these axes are not co-parallel.

The structure of $[Mn^{III}_{10}O_6(OH)_2(Bta)_8(py)_8F_8]$ (**2**) is shown in Fig. 2. The core of the decametallic structure of **2** can be described as a "super-tetrahedron", consisting of a tetrahedral array of Mn^{3+} ions (Mn1, Mn5, Mn7 and Mn9), with Mn^{3+} ions Mn2, Mn3, Mn4, Mn6, Mn8 and Mn10 capping each edge (Fig. 2(b)). The Mn ions comprising the tetrahedron are each bonded to three edge capping Mn ions via one μ_3-oxide (O1, O5, O6 and O7) and one μ_2-fluoride bridge (F5–F8). The F^- bridges are all asymmetric displaying one short (~1.86 Å) and one long (~2.1–2.14 Å) bond length, as a consequence of at least one Mn–F bond lying on a Jahn–Teller axis. The edge-capping metal centers are bonded to each other via a combination of μ_3-oxides and μ_3-hydroxides. The OH^- ions (O2, O3, O4 and O8) only bridge between the edge-capping centers. Each Bta^- anion bridges between apex and edge-capping Mn^{3+} centers in a μ_2-fashion, while each pyridine ligand bonds terminally. The co-ordination at each apical Mn ion is completed by a terminal fluoride ion (F1–F4). These F^- ions H-bond to water molecules in the lattice, which in turn H-bond to the MeOH molecules of solvation, which in turn H-bond to the BtaH molecule of crystallization. Each Mn center displays a distorted

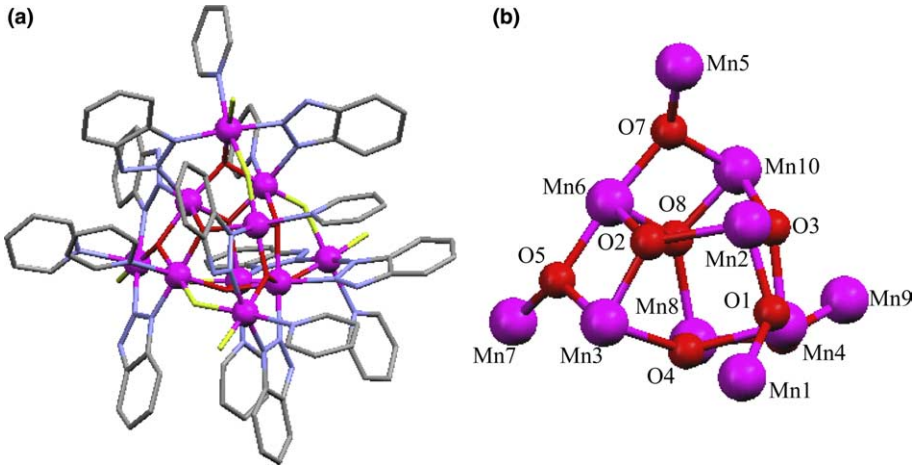

Fig. 2. The structure of complex **2** and its metal-oxygen core of aggregated $\{Mn_3O\}$ units (Mn = pink, O = red, N = blue, F = green, C = grey).

octahedral geometry, with the expected Jahn–Teller elongations.

The structure of the anion of $[NHEt_3]_2[Mn^{III}{}_3O(Bta)_6F_3]$ (**3**) is shown in Fig. 3. The $[Mn_3O(Bta)_6F_3]^{2-}$ anion in **3** consists of three Mn^{3+} centers arranged in a triangle, linked by one central μ_3-oxide (O3). Each μ_2-Bta^- ligand bridges two Mn centers along one edge of the triangle. The co-ordination at each metal center is completed by a terminal fluoride ion (F1–F3). The Mn^{3+} ions are in Jahn–Teller distorted octahedral geometries, but the JT axes are not co-parallel, defined by N2–Mn1–N5; N17–Mn2–N14 and N8–Mn3–N11. The angles around the central O^{2-} range from 119.3° to 120.6°. Despite each edge of the triangle having the same bridges, the $\{Mn_3O\}$ unit tends towards being isosceles with the Mn3–Mn1 and Mn3–Mn2 distances being 3.260 Å in length with the Mn1–Mn2 distance slightly shorter at 3.226 Å. The MeOH solvent molecules are H-bonded to either an unbound N-atom of a Bta^- ligand (e.g., N18–O1, 2.737 Å) or to the cation (e.g., N20–O1, 2.695 Å).

$[Mn^{III}{}_8O_4(Me_2Bta)_6(OMe)_2F_8(Me_2BtaH)(MeOH)_8]$ (**4**, Fig. 4) crystallizes in good yield after 2 weeks, in the monoclinic space group $P2_1/c$. The core of **4** consists of a central $[Mn_4O_2]^{8+}$ butterfly unit (Mn3–Mn6), the body atoms of which (Mn3, Mn6) are also part of a peripheral $[Mn_3O]^{7+}$ triangular unit. The $[Mn_4O_2]$ butterfly is near planar with Mn4 and Mn5 approximately 10° above the 'plane' defined by Mn3, Mn6, O8 and O12. The two peripheral $[Mn_3O]$ triangles are perpendicular to this plane, attached via an O^{2-} ion (O2, O11) forming a $[Mn_8O_4]^{16+}$ core. Two MeO^- (O1, O10) and two F^- (F7, F8) ions act as μ_2-bridges, the MeO^- bridging one side of the $[Mn_3O]$ unit and the F^- linking the $[Mn_3O]$ unit to the central $[Mn_4O_2]$ butterfly. The F^- bridges are asymmetric as, in each case, one Mn–F bond lies on a Jahn–Teller axis. The six Me_2Bta^- ligands all bond in a μ_2-fashion and the remaining six F^- ions and eight MeOH molecules all are terminal. There is one protonated Me_2BtaH ligand present, bonded in a monodentate fashion to Mn7. It H-bonds to a terminal F^- ion on an adjacent molecule (e.g., N19–F6, 2.629 Å). The Mn^{3+} ions are all six-coordinate and in distorted octahedral geometries, with one exception: Mn7 is 5-coordinate and square-based pyramidal with the nearest atom to the 'vacant' coordination site the oxygen of a MeOH molecule bonded to Mn5 (O13–Mn7, 2.701 Å). All the Mn ions display the Jahn–Teller elongations expected of high spin Mn^{3+} ions, although these are not all co-parallel.

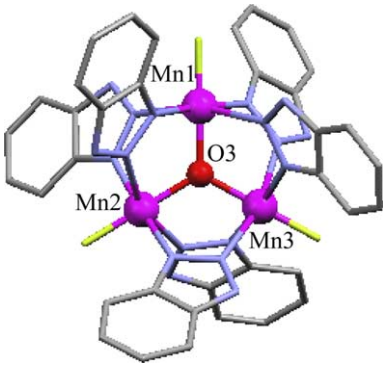

Fig. 3. The structure of complex **3** (Mn = pink, O = red, N = blue, F = green, C = grey).

$[Mn^{IV}{}_3Mn^{III}{}_{10}O_{12}(Me_2Bta)_{12}F_6(MeOH)_{10}(H_2O)_2]$ (**5**, Fig. 5) crystallizes, after 2 weeks, in the triclinic space group $P\bar{1}$. The core of **5** consists of a $[Mn^{IV}{}_3Mn^{III}{}_4O_{12}]$ hexagon centered on Mn1. The Mn^{4+} ions (Mn1, Mn3, Mn3A) form a linear $[Mn_3O_4]$ trimer through the center of the hexagon with the Mn^{3+} ions (Mn2, Mn4 and symmetry equivalents) attached on either side. The 12 O^{2-} ions are all μ_3-bridging and are of two types: six are bound to the central Mn^{4+} ion and link this ion to the outer six Mn ions of the hexagon. The remaining six O^{2-} ions bridge between the

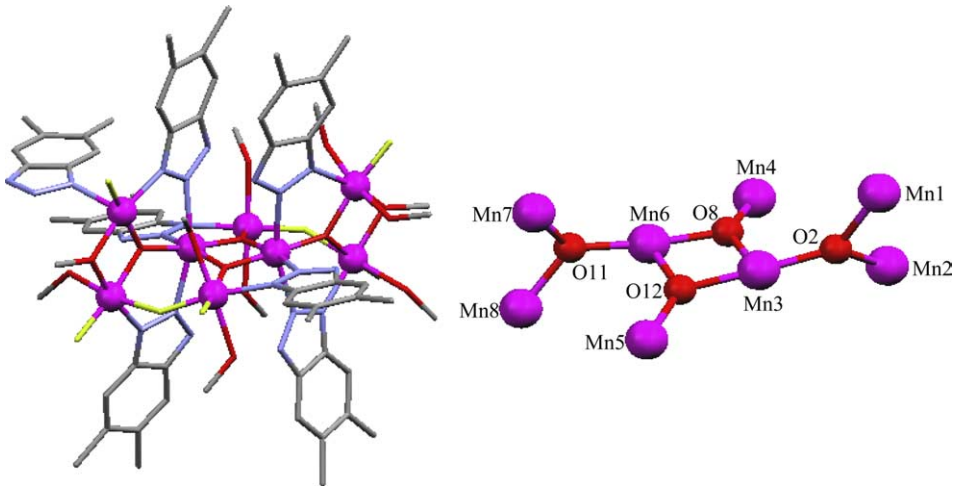

Fig. 4. The structure of complex **4** and its metal-oxygen core showing the aggregated $\{Mn_3O\}$ units (Mn = pink, O = red, N = blue, F = green, C = grey).

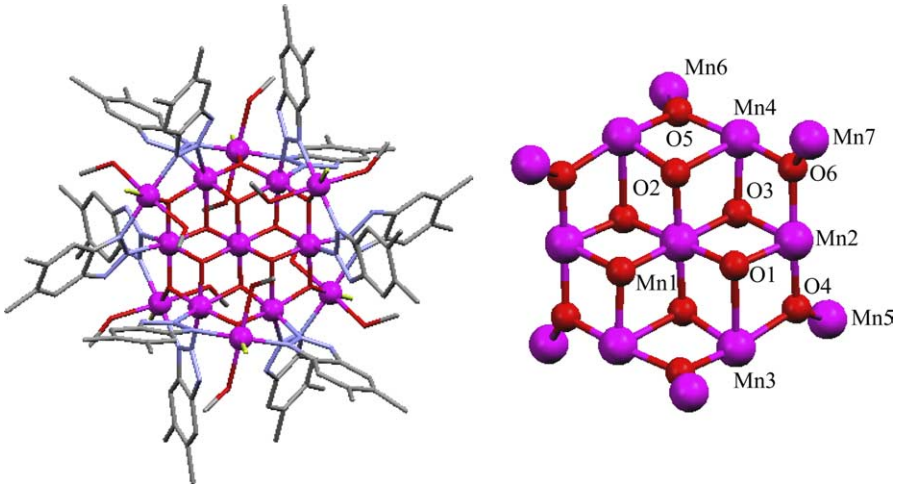

Fig. 5. The structure of complex **5** and its metal-oxygen core showing the aggregated $\{Mn_3O\}$ units.

outer Mn ions of the centered-hexagon and the remaining six Mn^{3+} ions (Mn5, Mn6, Mn7) that are located, alternately, above and below the plane of the $[Mn^{IV}{}_3Mn^{III}{}_4O_{12}]$ core. The μ_2-Me_2Bta^- ligands are all deprotonated and link the Mn ions in the central hexagon to the Mn ions above and below this plane. The coordination of these six Mn ions is completed by a terminal F^- ion and either two MeOH molecules (for example, Mn6, Mn7) or one MeOH and one H_2O molecule (Mn5). All the Mn^{3+} ions show the expected Jahn–Teller elongations, although they are not co-parallel.

The oxidation states of the Mn ions in each compound were determined by a combination of bond lengths (the observed Jahn–Teller elongations), charge balance considerations and bond valence sum (BVS) calculations. The inorganic bridges were determined in a similar fashion, in conjunction with microanalysis. Full details of bond lengths and angles for complexes **1**–**5** can be found in the deposited cif files.

3.2. Discussion and structural comparison

As in most Mn cluster chemistry it is extremely unlikely that complexes **1**–**5** are the only ones present in solution at any one given time. Thus, the loss of F^- ions and the appearance of OH^-, O^{2-} and MeO^- ions, is also likely to involve the deprotonation/protonation, structural rearrangements and redox chemistry of other species present in solution.

However, complexes **1**–**5** can all be described as aggregated $\{Mn_3O\}$ triangular units: **1** consists of 20 triangular units; **2** is made from eight edge-sharing units; **3** consists of one triangular unit; **4** contains four edge- and vertex-sharing units; and **5** contains 12 such units. This perhaps suggests that triangular $[Mn_3OF_3]^{4+}$ units may

be present in all of the above solutions and that the identity of the isolated crystalline product is then dependent on the nature of the added ligand or base.

For complexes **1**–**3**: the reaction performed with no base produces the largest cluster (**1**) with the lowest Mn:F ratio and was isolated in the lowest yield. The introduction of a weakly coordinating base (py, $pK_a = 5.25$) produces the second largest cluster (**2**), and the introduction of a strong non-coordinating base (NEt_3, $pK_a = 11.01$) that also acts as a cation on protonation produces the smallest cluster (**3**) in the largest yield. When NEt_3 is added, complex **3** is isolated instantly in high yield, as it not only deprotonates the BtaH ligands, but the resultant cations $\{HNEt_3\}^+$ stabilize the complex. Pyridinium ions, on the other hand, are 'poor' cations (in crystallization terms) but pyridine molecules are frequently seen to act as terminal ligands in Mn^{3+}clusters. This allows time for the hydrolysis and aggregation of the $\{Mn_3OF_3\}$ units into larger fragments, crystallizing as complex **2** after 1 week in a comparitively moderate yield. When no base is added (and thus there is no direct deprotonation of the BtaH ligands) the hydrolysis process is even longer (~2 weeks) and complex **1** crystallizes, but in poor yield.

The reaction which produces complex **4** is similar to that which produces **1**, but where the BtaH has been replaced by Me_2BtaH. Thus, it is reasonable to assume that the observed differences in the product must be due to the effect of the methyl substituents on both the reactivity of the ligand itself and the changes in intermolecular interactions/packing/solubility. For example, in complex **1** the Bta^- ligands bond in both a μ_3 and μ_2-fashion whereas in complex **4** the Me_2Bta^- ligands all bond in a μ_2-fashion.

Complex **4** is related to complex **5** and could be thought of as an 'intermediate' in the formation of **5**: again both clusters are comprised of aggregated $\{Mn_3O\}$ units and the $[Mn_8O_4]$ unit present in **4** can be seen three times in the core of **5**. For example, in **5**, the unit containing Mn1, Mn2, Mn3 and Mn5 forms the $[Mn_4O_2]$ butterfly unit with O1 and O4, with the peripheral $[Mn_3O]$ units sharing Mn2 and Mn3 with the butterfly and containing Mn4A, Mn7A and O5, and Mn4, Mn6 and O5, respectively. The three fused $[Mn_8O_4]$ units all share the central Mn atom, Mn1. Each $[Mn_8O_4]$ then shares a $[Mn_4O_2]$ unit with its nearest neighbour with only one Mn ion in each unit unshared (e.g., Mn5, Mn7 and Mn6A).

The central $[Mn^{IV}_3Mn^{III}_4O_{12}]$ core of **5** is reminiscent of the hexagonal close-packed structure present in CdI_2 and is similar to the cores found in $[Mn_7(OH)_3Cl_3(hmp)_9]^{2+}$ [6], $[Mn_7(OMe)_{12}(dbm)_6]$ [7] and the alkali metal containing species $[NaMn_6(OMe)_{12}(dbm)_6]^+$[8] as well as larger molecules such as $[Mn_{16}]$ [9], and $[Mn_{21}]$ [10].

Full analysis of the magnetic data for complexes **1**–**5** will be given elsewhere.

4. Conclusions

Complexes **1**–**5** represent the first examples of manganese clusters derived from MnF_3 and are rare examples of Mn^{3+} and Mn^{4+}/Mn^{3+} clusters stabilized by N-donor ligands.

Our original approach was to use 'melt' type reactions whereby the MnF_3 and organic ligand mixture was heated to the melting point of the organic ligand under an inert atmosphere. As the reaction proceeds the MnF_3 dissolves in the organic ligand and the product can be extracted from the 'melt' into a number of solvents. The reason for choosing a 'melt' type of reaction was to overcome the relative insolubility of MnF_3 in common organic solvents. The formation of complexes **1**–**5** directly from hot MeOH solutions thus provides an alternative and potentially much simpler route from which to obtain high nuclearity Mn clusters.

This work shows therefore that MnF_3 is an excellent precursor for synthesizing high nuclearity Mn^{3+} clusters. It provides a source of Mn^{3+} without the need for oxidising Mn^{2+} species or the use of the triangular $[Mn_3O(O_2CR)_6(L)_3]^{0/+}$ species. Complexes **1**–**5** were all made from similar reactions, where the identity of the cluster isolated is controlled by the nature of the ligand and base added. Complex **1** is the third largest Mn cluster reported; complex **2** is rare example of a cluster with a 'supertetrahedral' metal core; complex **3** is a rare example of an oxo-centered trimetallic cluster in which the M^{3+} centres are bridged by ligands other than carboxylates and complex **5** is only the second example of a tridecametallic Mn cluster.

5. Supplementary material

Crystallographic data have been deposited with the Cambridge Crystallographic Data Centre. Copies of this information may be obtained from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Acknowledgments

This work was supported by Lloyd's of London Tercentenary Foundation and the EPSRC. We also thank the EPSRC-UKCCF for computer time on the Columbus system, and CCLRC for access to Station 9.8 for data collection.

2.2. X-ray crystallography and structure solution

A crystal was mounted using a drop of fomblin (perfluoropolymethylisopropyl ether) oil in a Hamilton Cryoloop and data were collected on a Bruker Smart Apex CCD diffractometer at 100 K using Mo radiation. The structure was solved by direct methods.

The asymmetric unit contains half the dimer, together with a ClO_4^- ion. The non-H atoms were refined anisotropically. H atoms bonded were included in calculated positions. It was clear from the diffraction pattern that the crystal was a non-merohedral twin, and the *R* value initially was about 9.9%. However, accounting for the twinning using the matrix −1000−10−0.489−0.3051 (a 180° rotation about the 001 reciprocal lattice direction) and including the BASF and HKLF 5 commands, led to a refined scale factor of 0.275 for the twinned component, and a much improved R value of 5.86%. CCDC 255232. Crystallographic parameters are collected in Table 1.

2.3. Crystal structure

The centrosymmetric cation of **1** (Fig. 1) contains two Mn^{III} ions (Mn···Mn separation, 3.0964(14) Å) bridged by two μ_2-oxygens from the two $Hthme^{2-}$ ligands. The other two arms are both terminal but differ in that one is deprotonated (O3···Mn, 1.798(3) Å) and one is protonated (O1···Mn, 1.990(4) Å), with the protonated arm H-bonded to the ClO_4^- counter ion (O1···O4, 3.022(4) Å). The coordination sphere of each manganese centre is completed by a chelating bpy ligand. The Mn^{III} ions are in distorted octahedral geometries (*cis*, 78.0–98.7°; *trans*, 167.4–168.7°) but do not display an obvious Jahn-Teller elongation, with each of the six bonds distinctly different (Table 2). It appears that the trigonal field of the $Hthme^{2-}$ ligand causes a rhombic distortion of the Mn^{III} ion preventing the expected Jahn-Teller elongation along O1–Mn1–O2A: although the Mn–O2A bond is much longer (2.114 Å) than the other bonds, the Mn–O1 bond (1.990 Å) is not.

temperature is decreased until ca. 150 K when it begins to increase to a maximum value of 7.6 cm^3 K mol^{-1} at 25 K before decreasing rapidly to 6.5 cm^3 Kmol^{-1} at 5 K. This suggests that the exchange between the metal centres is ferromagnetic with the low temperature decrease assigned to zero-field splitting and/or intermolecular interactions. In order to fit the data, the Hamiltonian given in Eq. (1) was employed.

$$\hat{H} = -2J\hat{S}_{1a}\hat{S}_{1b}. \quad (1)$$

The fit at high temperatures (>50 K) to the experimental $\chi_M T$ data suggests a ground state spin of $S = 4$ with the following parameters: $g = 1.99$ and $J = +2.13$ cm^{-1}.

In order to confirm the ground state spin, magnetization data were collected in the ranges 1.8–10 K and 10–70 kG (Fig. 3). The data were fit, assuming only the ground state is populated, to give $S = 4$, $g = 1.71$ and

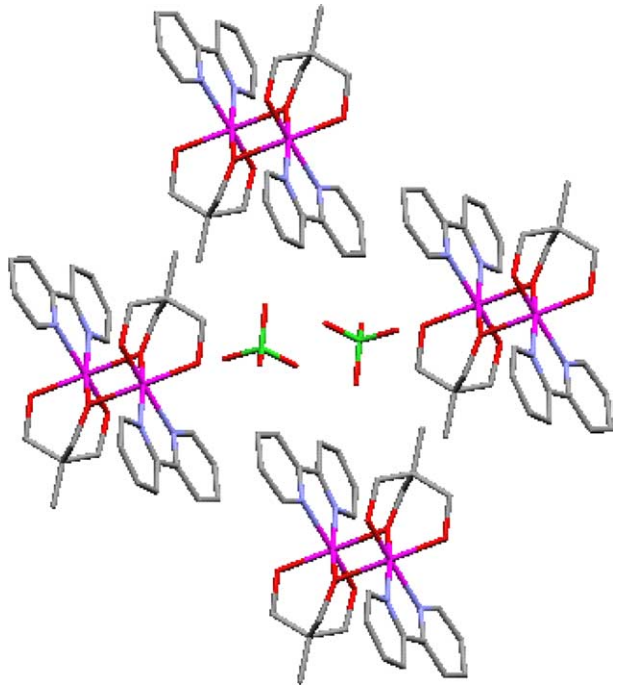

Fig. 2. The packing of **1** in the crystal.

$D = -0.65$ cm^{-1}. Given the value and sign of S and D, ac magnetization measurements were performed to see if **1** acts as an SMM. However measurements taken in the 1.8–10 K range in a 3.5 G ac field oscillating at 50–1000 Hz gave no out-of-phase signal. The obtained g-value is rather low for Mn^{III} and multi-frequency EPR and INS experiments are currently underway to probe the magnetic behaviour of **1** more thoroughly.

3.2. Single crystal measurements

Single crystal magnetic measurements were performed on **1** using an array of micro-squids. Fig. 4 shows hysteresis loops for **1** at temperatures below 1.2 K and at various sweep rates, with the field applied in

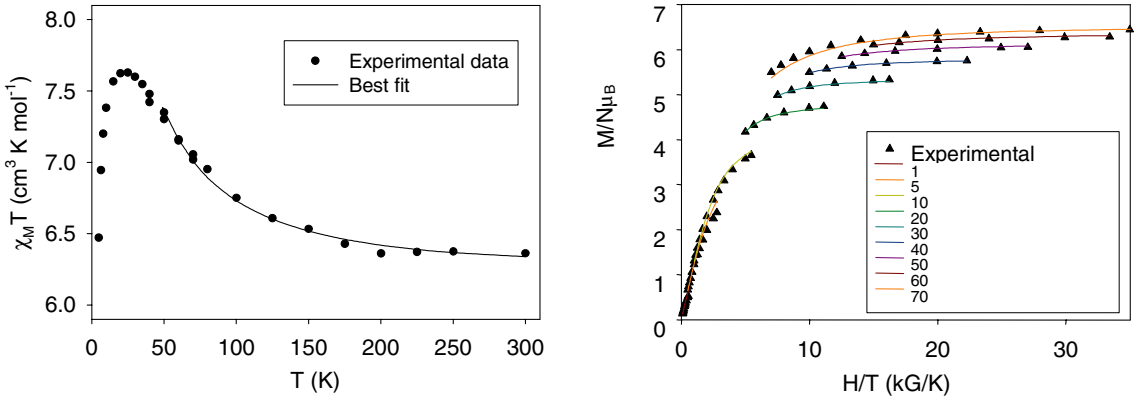

Fig. 3. Plot of $\chi_M T$ vs. T for complex **1**. The solid line is a fit to the data with $J = +2.13$ cm^{-1} and $g = 1.99$ (left). Plot of reduced magnetization vs. H/T for **1**, in the temperature range 1.8–10 K and 10–70 kG. The solid lines are fits of the data to an $S = 4$ state with $g = 1.71$ and $D = -0.65$ cm^{-1} (right).

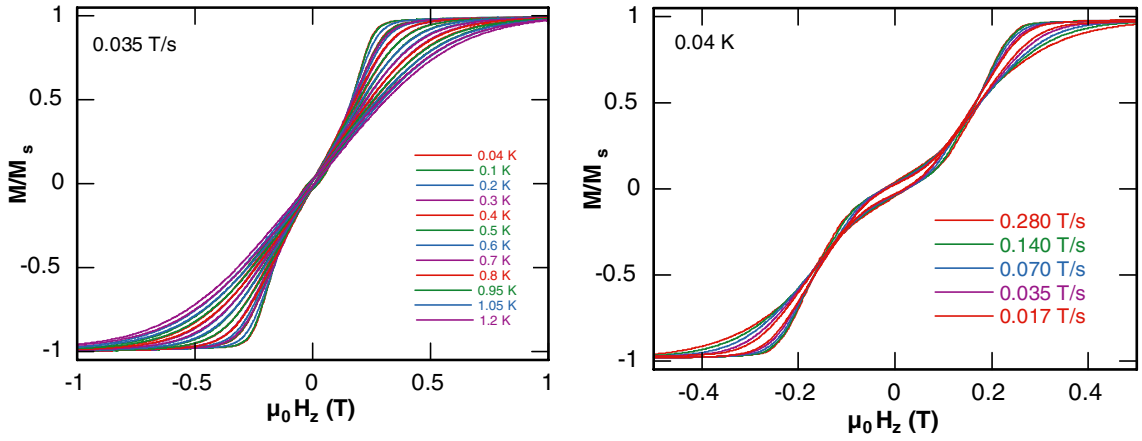

Fig. 4. Magnetization (M) of **1** (plotted as fraction of maximum value M_s vs. applied field $\mu_0 H$). The resulting loops are shown at different temperatures (left) and different field sweep rates (right).

the direction of the easy axis of the molecule. The hysteresis loops have a small coercive field and two step-like features. These step-like features however, do not originate at zero-field, the first step being shifted by approximately −0.2 T. The measurements taken at 0.04 K in particular show small openings in the loops at different sweep rates indicative of slow relaxation of the magnetization. The small coercive field and the overall shape of the loops suggest the presence of strong intermolecular interactions consistent with the extensive intermolecular interactions throughout the crystal lattice as mediated via the π–π stacking of the bpy rings and the H-bonding interactions of the ClO_4^- ions. In principle therefore, complex **1** can be regarded as an exchange-biased SMM [8] although it is clearly difficult to separate the intermolecular interactions and the SMM behaviour. Studies of analogues of complex **1** that contain different peripheral ligands and which pack differently are currently in progress and will be reported in full elsewhere.

4. Theoretical calculations

The broken symmetry model developed by Noodleman [9] has been widely used to compute J-values using HF or DFT calculations. For binuclear transition metal complexes the following equation has been advocated by Ruiz et al. [10]:

$$J = \frac{2(E_{BS} - E_{HS})}{S_{HS}(S_{HS} + 1)}. \quad (2)$$

The combination of a hybrid B3LYP [11] functional with Ahlrichs' TZV [12] basis set as implemented on GAUSSIAN 98 [13] has been shown previously to give good numerical estimates of J-values, and therefore all the calculations on complex **1** were performed using this methodology. To avoid convergence problems, the initial guess for the calculations was generated using JAGUAR [14] and this guess was then transferred to GAUSSIAN to proceed further. Calculations performed on the full structure of **1**, ($[Mn_2(Hthme)_2(bpy)_2](ClO_4)_2$), gives the estimate of $J = -0.55$ cm^{-1}. The calculations thus support a weak exchange between the metal centres, but give the wrong sign in comparison to the experimental data – although the overall numerical difference between the two is small, making the change in sign unsurprising. Over-estimation of J-values using the DFT-BS approach has been encountered previously [10,15]. Calculations were also performed on a model complex of **1**, in which the terminal bpy ligands were replaced with NH_3 molecules and including only the cation: $[Mn_2(Hthme)_2(NH_3)_4]^{2+}$. This gives $J = -1.1$ cm^{-1}, suggesting that the terminal ligands have significant influence on the coupling.

Spin density distributions provide information about the mechanism of the exchange interaction. The high spin state spin density plot of **1** is shown in Fig. 5. The white

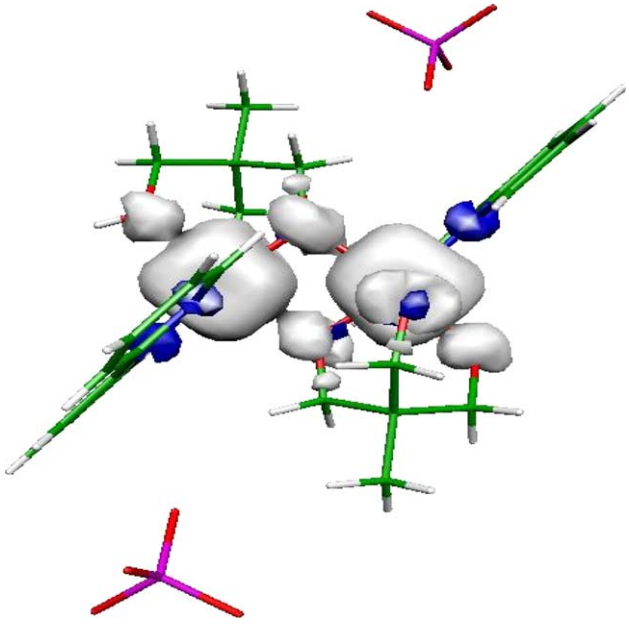

Fig. 5. The high spin state spin density plot of complex **1**.

colour represents a positive spin density and the blue colour represents a negative spin density. It is clear from the figure that in this case both spin delocalisation and spin polarisation mechanisms operate. Previously we have shown that for Mn(III) ions, the Jahn-Teller axis favours a spin delocalisation mechanism with the other axes favouring spin polarisation [16]. Here the O1–Mn1–O2A axis favours spin delocalisation, and the others show a predominantly spin polarisation mechanism. Therefore we can conclude that the O1–Mn1–O2A axis is indeed the Jahn-Teller axis of the molecule.

5. Conclusions

Reaction of H_3thme with $[Mn_2O_2(bpy)_4](ClO_4)_3$ produces the dimetallic complex $[Mn_2(Hthme)_2(bpy)_2](ClO_4)_2$. Magnetic measurements suggest the presence of a weak ferromagnetic interaction between the Mn^{III} ions. Low temperature single crystal measurements show the co-existence of SMM behaviour and strong intermolecular interactions. DFT calculations support a weak exchange between the metal centres, and also provide an insight into the mechanism of the exchange. Spin density distributions help to identify the Jahn-Teller axis of the Mn ions.

as a function of momentum and energy transfer provides useful information on the magnetic scattering function $S(Q,\omega)$, which contains the details about the magnetic exchange interactions and anisotropy splittings [6]. The focus of the present study is aimed at the determination of the anisotropy splitting of the ground state of **1**.

To date no experimental study has provided direct information on the nature and energies of energy splitting in the ground state of **1**. As a first approximation a giant spin model can be used to describe the ground state, assuming that it is well isolated from the excited spin states. An effective Hamiltonian then describes the zero field splitting of the giant spin ground state. The low C_1 symmetry of **1** allows for many higher order crystal field terms in the effective spin Hamiltonian. The fact that the Jahn–Teller axes of the four Mn^{III} ions all lie roughly perpendicular to the plane of the $[Mn_4^{III}Mn_2^{II}O_6]$ ring justifies the use of an axial Hamiltonian in first order

$$H_{\text{axial}} = D[\hat{S}_z^2 - S(S+1)/3] + B_4^0\hat{O}_4^0 \quad (1)$$

with $\hat{O}_4^0 = 35\hat{S}_z^4 - [30S(S+1) - 25]\hat{S}_z^2 - 6S(S+1) + 3S^2(S+1)^2$. The first term of (1) splits the ground state in $S + 1/2$ Kramer's doublets. For a negative D value the $M_S = \pm S$ doublet lies lowest in energy.

A ground state spin of $S = 17/2$ has been postulated for **1** on the basis of magnetic powder measurements [4]. Eq. (1) splits this ground state into nine $\pm M_S$ Kramer's doublets. An alternative solution with $S = 19/2$ has also been postulated, which would give rise to 10 Kramer's doublets [4]. The INS selection rule $\Delta M_S = \pm 1$ predicts eight or nine transitions for an $S = 17/2$ or $S = 19/2$ ground state, respectively. The intensity for an $|M_S| \rightarrow |M_S + 1|$ INS transition can be calculated as [7]

$$I(|M_S| \rightarrow |M_S+1|) \propto P(\pm M_S) \cdot \begin{pmatrix} S & 1 & S \\ -M_S & 1 & M_S+1 \end{pmatrix} \cdot \begin{pmatrix} S & 1 & S \\ -M_S-1 & 1 & M_S \end{pmatrix} \quad (2)$$

with $P(\pm M_S)$ being the Boltzmann population of the initial state $\pm M_S$. The brackets are 3-j symbols.

2. Experimental

2.1. Synthesis

$[Mn_3O(OAc)_6(py)_3] \cdot py$ was dissolved in MeCN with 1 equivalent of the ligand 1,1,1-tris(hydroxymethyl)ethane (H_3thme) and stirred for 12 h. The solution was then filtered and Et2O added slowly. Crystals of $[Mn_9O_7(OAc)_{11}(thme)(py)_3(H_2O)_2]$ (**1**) were obtained after 1 week.

2.2. Physical measurements

The INS experiments were performed on the inverted geometry time-of-flight spectrometer IRIS at the pulsed neutron spallation source ISIS at the Rutherford Appleton Laboratory, UK, using the PG002 graphite analyser with an analysing energy of 1.84 meV. Data were collected at three temperatures 1.6, 12, and 20 K and corrected for the background and detector efficiency by means of empty cell measurements and a vanadium reference. The time-of-flight to energy conversion and the data reduction were done using the program GUIDE. The instrumental resolution derived from a vanadium metal reference at the elastic position was 18 eV. On IRIS, the ZnS detector banks cover the angular range $2\theta = 20$–$160°$ giving access to a momentum transfer range $Q = 0.3$–1.8 Å^{-1} at the elastic position.

A 2.5 g fresh polycrystalline sample of undeuterated $[Mn_9O_7(OAc)_{11}(thme)(py)_3(H_2O)_2]$ was used. The sample was placed under Helium in an aluminum hollow cylinder can with an outer diameter of 23 mm and a sample thickness of 2 mm. The container was inserted in a standard ILL orange cryostat.

3. Results and discussion

Fig. 1 shows the INS spectra of **1** measured at 1.6 K (10 h), 12 K (31 h) and 20 K (25 h), summed over all scattering angles. Positive and negative energy transfer corresponds to neutron energy loss and gain, respectively. The 1.6 K spectrum exhibits one strong band at 3.72 cm^{-1} on the loss side with a second one coming up as a shoulder at lower energy. A series of hot bands is observed at 12 and 20 K. At this latter temperature,

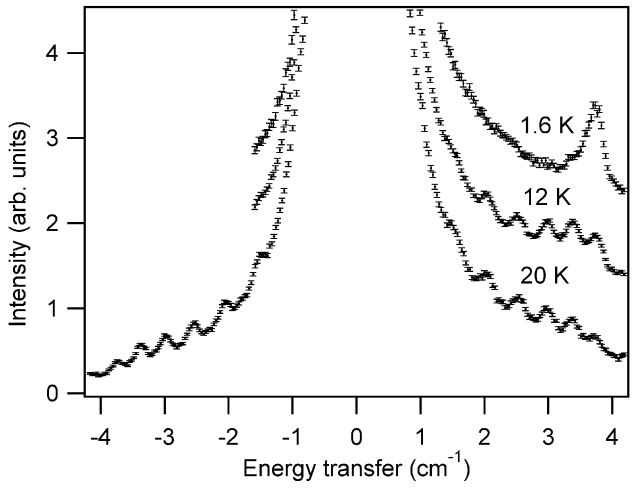

Fig. 1. INS spectra measured on IRIS with an analysing energy of 1.84 meV at 1.6 K (10 h), 12 K (31 h) and 20 K (25 h), summed over all scattering angles.

we measured the energy gain and the loss side. The peak energies are the same on both sides, and we can identify six distinct maxima and a shoulder on the elastic line on either side of the spectrum. The peaks exhibit an almost regular picket fence pattern with decreasing peak separations towards higher energy transfer. On the basis of their temperature and Q-dependence it is possible to assign the 14 observed bands to $\Delta M_S = \pm 1$ transitions within the ground state multiplet. The progression of the peak positions is limiting the possible number of transitions in the ground state multiplet to exactly eight on either side. Therefore, we can clearly rule out the possibility of an $S = 19/2$ ground state. Our data unambiguously confirms the $S = 17/2$ ground state.

Fig. 2(a) shows the spectrum measured at 20 K after subtracting the non-magnetic background. The peaks labelled I–VII correspond to the transitions shown in Fig. 3, which shows the energy splitting pattern of the $S = 17/2$ derived from our data. Least-squares calculations using Eq. (1) and the peak positions determined by INS yield the following best parameter set: $D = -0.249(5)\ \mathrm{cm}^{-1}$, $B_4^0 = 7(4) \times 10^{-6}\ \mathrm{cm}^{-1}$. The value

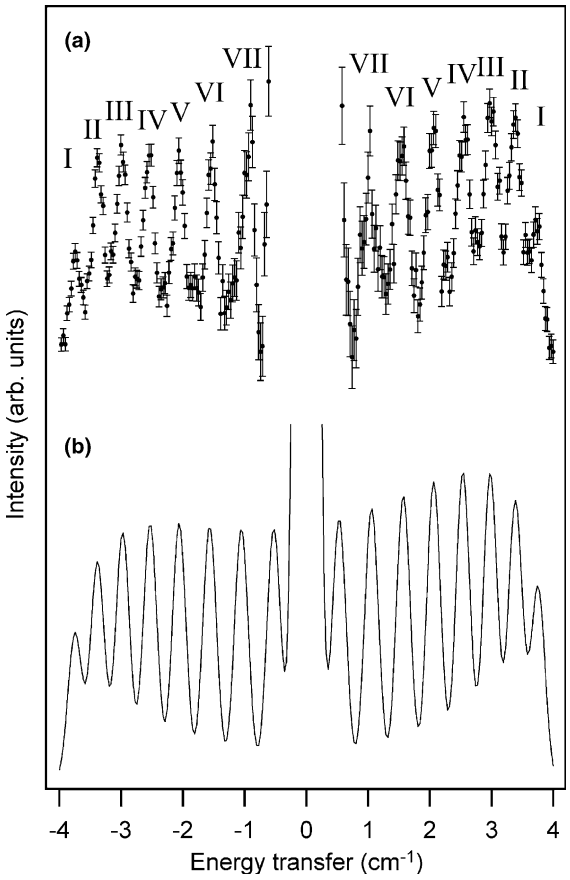

Fig. 2. (a) INS spectrum of Mn_9 measured at 20 K and corrected for background. (b) Calculated spectrum at 20 K using Eqs. (1) and (2) with the parameters $D = -0.249\ \mathrm{cm}^{-1}$ and $B_4^0 = 7 \times 10^{-6}\ \mathrm{cm}^{-1}$. The labelling of the peaks corresponds to the transitions in Fig. 3.

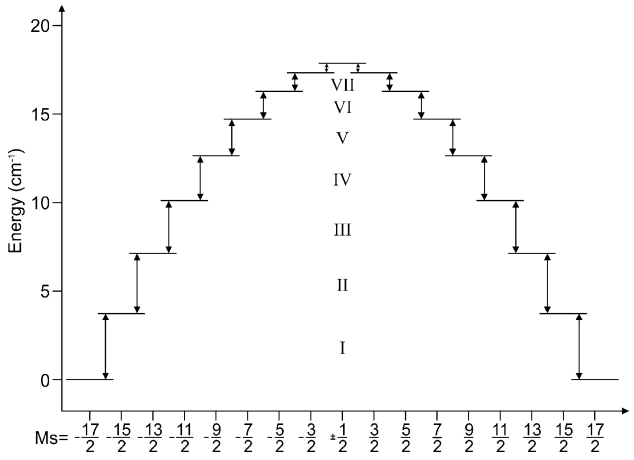

Fig. 3. Calculated anisotropy splitting of the $S = 17/2$ ground state according to the Hamiltonian of Eq. (1) with parameter values $D = -0.249\ \mathrm{cm}^{-1}$ and $B_4^0 = 7 \times 10^{-6}\ \mathrm{cm}^{-1}$ The double arrows correspond to the allowed $\Delta M_S = \pm 1$ INS transitions.

of the axial anisotropy parameter D is in good agreement with the D values of -0.29 and $-0.25\ \mathrm{cm}^{-1}$ derived from powder and single crystal magnetic measurements, respectively [8]. A Hamiltonian without the fourth order term $B_4^0 \hat{O}_4^0$ could not account for the observed decrease of the energy intervals with increasing energy transfer. The B_4^0 parameter must be positive, which is not without precedent in the spin cluster literature. Positive B_4^0 values have been reported for example for the classical single molecule magnet Fe_8 and for a Mn_4 butterfly single molecule magnet [9,10].

Fig. 2(b) shows a calculated spectrum at 20 K using Eqs. (1) and (2) with the best fit parameters. The peak positions and relative intensities are in excellent agreement with the experimental data shown in Fig. 2(a). For energy transfers below $\pm 1\ \mathrm{cm}^{-1}$ the experimental data are dominated by the elastic line, and the eighth peak predicted by the calculations is not observable. The non-magnetic scattering is orders of magnitude more intense than the magnetic scattering in the region of the elastic line, thus swamping the magnetic part.

Physically, the strong central line with the pronounced tails in Fig. 1 originates from elastic and quasi-elastic non-magnetic scattering processes. Its intensity is enhanced by the presence of a large number of hydrogen atoms in the measured sample. Hydrogen is a strong incoherent nuclear scatterer. This is exploited in molecular vibrational spectroscopy [11]. At the low energy transfer of our experiment, it leads to an enhanced elastic line including tails as well as a higher background. For a more accurate determination of the peak VII in Fig. 2(a), it would be necessary to measure a deuterated sample. The incoherent nuclear scattering cross-section of deuterium is 40 times smaller than the one of hydrogen; therefore, the effects described above are reduced

drastically. Deuteration is often considered a prerequisite for a successful magnetic INS experiment, but the present study shows that data of remarkable quality can be obtained with an undeuterated sample in the energy transfer range between 1 and 4 cm^{-1} also. We have recently studied a number of undeuterated molecular spin clusters by INS and made similar observations [12,13]. The energy transfer region, in which magnetic cluster excitations can be observed despite the presence of hydrogen atoms, covers the range from about 1 to 30 cm^{-1}. We ascribe this to a low density of vibrational states with significant hydrogen contribution in this "lucky window".

4. Conclusions

INS measurements unambiguously prove the $S = 17/2$ ground state of **1**. Analysis of the INS transitions within the zero field split ground state lead to a very accurate determination of the axial anisotropy parameter D and the crystal field parameter B_4^0. The experimental INS results of this study are of remarkable quality, despite the presence of a large number of hydrogen atoms in the sample.

2. The model

Each magnetic cluster can be described by the following spin Hamiltonian:

$$H = \sum_{i>j} J_{ij}\mathbf{s}_i \cdot \mathbf{s}_j + \sum_i \sum_{k,q} b_k^q(i) O_k^q(\mathbf{s_i}) + \sum_{i>j} \mathbf{s}_i \cdot \mathbf{D}_{ij} \cdot \mathbf{s}_j - g\mu_B \sum_i \mathbf{B} \cdot \mathbf{s}_i, \quad (1)$$

where $\mathbf{s}_i$ are spin operators of the ith ion in the molecule ($s_i = 5/2$ for Fe^{3+}). The first term is the isotropic Heisenberg exchange interaction; the exchange constants J_{ij} used in this work are those determined from susceptibility [12]. In the second term, which describes the local crystal-fields (CFs), the Stevens operator equivalents $O_k^q(\mathbf{s_i})$ and the CF parameters $b_k^q(i)$ for the ith ion appear [13]. The rank k is even and not larger than 4 for d-electrons, and $q = -k,\ldots,k$. The third term represents the dipolar anisotropic intra-cluster spin–spin interactions. The last term is the Zeeman coupling with an external field $\mathbf{B}$.

The rotationally invariant Heisenberg term conserves the modulus $\sqrt{S(S+1)}$ of the total spin $\mathbf{S} = \sum_i \mathbf{s}_i$. Hence, when this term is dominant (*strong-exchange limit*), the energy spectrum of H consists of several multiplets with an almost definite value of S. On the other hand, the crystal fields and the anisotropic dipolar interactions are responsible for S mixing. When the latter is neglected, H can be projected onto each S multiplet to give $H_{ZF} + H_Z$, where the zero-field Hamiltonian (for the approximate D_2 symmetry of Fe_8) is

$$H_{ZF} = B_2^0 O_2^0(\mathbf{S}) + B_2^2 O_2^2(\mathbf{S}) + B_4^0 O_4^0(\mathbf{S}) + B_4^2 O_4^2(\mathbf{S}) + B_4^4 O_4^4(\mathbf{S}), \quad (2)$$

and $H_Z = -g\mu_B \mathbf{B} \cdot \mathbf{S}$ is the Zeeman contribution. The parameters B_K^Q are calculated from $b_k^q(i)$ and $\mathbf{D}_{ij}$ by CF and dipolar projection coefficients. This approach, applied to the $S = 10$ ground manifold of Fe_8, has allowed to interpret inelastic neutron scattering (INS) data very satisfactorily [7,8]. For a cluster of interacting spins, the magnetic cross-section is given by [14]

$$\frac{\partial^2\sigma}{\partial\Omega\,\partial\omega} \propto \sum_{n,m} \exp\left(-\frac{E_n}{kT}\right) \sum_{\alpha,\beta} \left(\delta_{\alpha,\beta} - \frac{Q_\alpha Q_\beta}{Q^2}\right) \times \sum_{l,j} \{g_l F_l(Q)\}\{g_j F_j(Q)\} \exp(i\mathbf{Q}\cdot\mathbf{R}_{lj}) \times \langle n|s_l^\alpha|m\rangle\langle m|s_j^\beta|n\rangle \delta(\hbar\omega + E_n - E_m), \quad (3)$$

where $\mathbf{R}_{lj} = \mathbf{R}_l - \mathbf{R}_j$, $\mathbf{Q}$ is the scattering vector, $F_l(Q)$ is the magnetic form factor and g_l the g-factor of the lth ion, $\alpha,\beta = x,y,z$, and $|n\rangle$ is a cluster wavefunction with energy E_n. Within a single multiplet with well-defined total spin S, the matrix elements of the local spin operators $\mathbf{s}_l$ which appear in Eq. (3) are proportional to those of the total spin $\mathbf{S}$, with proportionality coefficients d_l. As a consequence, putting $\mathbf{z}' = \mathbf{Q}/Q$, the cross-section can be rewritten as

$$\frac{\partial^2\sigma}{\partial\Omega\,\partial\omega} = A(Q) \sum_{n,m} \exp\left(-\frac{E_n}{kT}\right) \delta(\hbar\omega + E_n - E_m) |\langle n|S_\perp|m\rangle|^2, \quad (4)$$

where $S_\perp$ is the component of $\mathbf{S}$ perpendicular to $\mathbf{Q}$ and the first factor, which depends only on Q, is given by

$$A(Q) \propto \sum_{l,j} \{d_l g_l F_l(Q)\}\{d_j g_j F_j(Q)\} \exp\left(iQR_{lj}^{z'}\right). \quad (5)$$

For a powder sample, the physical quantity of interest is the average of the cross-section made over all the possible orientations of $\mathbf{Q}$ in space. In principle, the above factorization is not possible in this framework. However, it can still be shown that

$$\frac{\partial^2\sigma}{\partial\Omega\,\partial\omega} \propto \frac{2}{3}\left(|\langle n|S_x|m\rangle|^2 + |\langle n|S_y|m\rangle|^2 + |\langle n|S_z|m\rangle|^2\right) \quad (6)$$

if one of the following conditions is met: (i) the studied molecule has uniaxial anisotropy (z being the symmetry direction), or (ii) $Q \simeq 0$.

The analysis of experimental INS spectra for Fe_8 by means of Eqs. (2) and (6) allowed to obtain a reliable set of CF parameters ($B_2^0 = -9.75\times10^{-2}$ K, $B_2^2 = -4.66\times10^{-2}$ K, $B_4^0 = 1.0\times10^{-6}$ K, $B_4^2 = 1.2\times10^{-7}$ K, $B_4^4 = 8.6\times10^{-6}$ K) [7,8]. Although Fe_8 does not meet condition (i), the calculated eigenfunctions are not too different from those of an uniaxial system, suggesting that use of Eq. (6) as a satisfactory approximation is allowed. Moreover, the maximum value of Q (1.28 $Å^{-1}$) relative to the INS experiment in question is small enough to reproduce the correct intensity ratios by using this simple equation. We have numerically checked that the INS spectrum calculated by using Eq. (6) agrees well with that computed by the rigorous treatment. Very similar sets of parameters were later found by optical spectroscopy [9] and electron paramagnetic resonance (EPR) [10]. Diagonalization of the Hamiltonian (2) also allows to estimate the tunnel splitting Δ once the CF parameters are known; for instance, with the above parameters, the zero-field gap between the two lowest-lying levels is $\Delta_0 = 4.44\times10^{-11}$ K.

A precise value of the tunneling gap can be obtained by magnetization measurements. In particular, Δ was estimated for Fe_8 by saturating the sample, then measuring the fraction of clusters which reversed their spin at a level anticrossing induced by an applied field swept at a constant rate (dB/dt) [6]. The tunneling probability Π is linked to Δ through the Landau–Zener formula

$$\Pi = 1 - \exp\left(-\frac{\pi\Delta^2}{4\hbar g\mu_B S(dB/dt)}\right). \quad (7)$$

Unfortunately, the so-obtained magnitude of the tunneling gap is not compatible with the estimates based on

spectroscopic data; for instance, the zero-field gap is of the order of 10^{-7} K, more than three orders of magnitude larger than the calculated value. This huge discrepancy seriously hinders any attempt to reach a satisfactory theoretical modeling of the quantum tunneling of the magnetization.

On the other hand, Eq. (2) is known to be valid only in the strong-exchange limit. In order to evaluate S-mixing effects, we followed the method developed in [15], in which S-mixing is included up to the second order in the anisotropy by a unitary transformation applied to the complete Hamiltonian (1). The system can be still described as an effective spin $S = 10$, provided the spin-Hamiltonian (2) is properly modified. The perturbational procedure consists in performing a unitary transformation on H such that the off-diagonal blocks (i.e., those responsible for S mixing) of the transformed Hamiltonian are zero up to second order in the anisotropy. Hence, in the new basis, states belonging to different multiplets are uncoupled and the system can be described as an effective spin multiplet, like in the strong-exchange limit. The advantage of using this method with respect to large-scale numerical diagonalization (e.g., using the Lanczos algorithm) is that it allows to reduce drastically the calculation times and to recover the simple and physically transparent single-spin formalism. The modified Hamiltonian H'_{ZF} can be written as

$$H'_{\mathrm{ZF}} = \sum_{K,Q} C_K^Q O_K^Q, \tag{8}$$

where $K \leqslant 8$ and even, and $-K \leqslant Q \leqslant K$. The new C_K^Q parameters are obtained by adding the mixing contribution $\tilde{B}_K^Q$ to the old B_K^Qs; this implies that the CF parameters determined by INS are to be regarded as C_K^Qs, rather than B_K^Qs. Apart from renormalizing the value of the parameters which appear in Eq. (2), S mixing adds new terms, otherwise forbidden (those with $K > 4$), to the effective Hamiltonian, thus opening new highly efficient tunneling channels. The parameters $\tilde{B}_K^Q$ are given by linear combinations of products of matrix elements of the tensor operators $T_{q'}^{(k')}$ and $T_{q''}^{(k'')}$ which describe the local CF and dipole–dipole coupling [16], with $Q = q' + q''$ and $K \leqslant k' + k''$. Concerning the local CF term, we do not include the b_4^0s and b_4^2s since the corresponding parameters in the projected Hamiltonian (2) have been found negligible and/or not relevant to calculate the tunnel splitting. By combining the tensor operators related to the remaining local parameters, three new Stevens operators appear in Eq. (2) (O_6^4, O_6^6, and O_8^8), whose coefficients are given by

$$\tilde{B}_6^4 = \sum_{i,j} b_2^0(i) b_4^4(j) \Xi_{(1)}(i,j) + \sum_i b_4^4(i) \Upsilon_{(1)}(i), \tag{9a}$$

$$\tilde{B}_6^6 = \sum_{i,j} b_2^2(i) b_4^4(j) \Xi_{(2)}(i,j) + \sum_i b_4^4(i) \Upsilon_{(2)}(i), \tag{9b}$$

$$\tilde{B}_8^8 = \sum_{i,j} b_4^4(i) b_4^4(j) \Xi_{(3)}(i,j) \tag{9c}$$

with

$$\Xi_{(1)}(i,j) = \sqrt{6} \sum_{S''=S-2}^{S+2} e_{64}^{S-S''} \times \sum_{\alpha''} \frac{\langle \alpha S \| T^{(2)}(i) \| \alpha'' S'' \rangle \langle \alpha S \| T^{(4)}(j) \| \alpha'' S'' \rangle}{E_{0\alpha''S''} - E_0}, \tag{10a}$$

$$\Xi_{(2)}(i,j) = \sum_{S''=S-2}^{S+2} c_{66}^{S-S''} \times \sum_{\alpha''} \frac{\langle \alpha S \| T^{(2)}(i) \| \alpha'' S'' \rangle \langle \alpha S \| T^{(4)}(j) \| \alpha'' S'' \rangle}{E_{0\alpha''S''} - E_0}, \tag{10b}$$

$$\Xi_{(3)}(i,j) = \sum_{S''=S-4}^{S+4} c_{88}^{S-S''} \times \sum_{\alpha''} \frac{\langle \alpha S \| T^{(4)}(i) \| \alpha'' S'' \rangle \langle \alpha S \| T^{(4)}(j) \| \alpha'' S'' \rangle}{E_{0\alpha''S''} - E_0}, \tag{10c}$$

$$\Upsilon_{(1)}(i) = -\sum_{j,k} J_{jk}^v \sum_{S''=S-2}^{S+2} e_{64}^{S-S''} \times \sum_{\alpha''} \frac{\langle \alpha S \| T^{(2)}(11|jk) \| \alpha'' S'' \rangle \langle \alpha S \| T^{(4)}(i) \| \alpha'' S'' \rangle}{E_{0\alpha''S''} - E_0}, \tag{10d}$$

and

$$\Upsilon_{(2)}(i) = -\sqrt{2} \sum_{j,k} J_{jk}^u \sum_{S''=S-2}^{S+2} c_{66}^{S-S''} \times \sum_{\alpha''} \frac{\langle \alpha S \| T^{(2)}(11|jk) \| \alpha'' S'' \rangle \langle \alpha S \| T^{(4)}(i) \| \alpha'' S'' \rangle}{E_{0\alpha''S''} - E_0}. \tag{10e}$$

In the preceding expressions i, j and k label magnetic ions, $T^{(k)}(i)$ and $T^{(2)}(11|jk)$ are the tensor operators describing the local CF and dipole–dipole interactions [16] respectively. $J_{jk}^{u,v}$ are defined in terms of the elements of the dipole–dipole tensor $\mathbf{D}_{ij}$ in [16]. The $c_{kk}^{S-S''}$ and $e_{kq}^{S-S''}$ coefficients are defined according to the theory developed in [15,17] as

$$c_{66}^{\Delta S} = \frac{a_6^{\Delta S}}{\sqrt{\prod_{\ell=-3}^{+3} (2S - n - \Delta S)(2S - n - \Delta S + 2)}} \tag{11a}$$

and

$$c_{88}^{\Delta S} = \frac{a_8^{\Delta S}}{\prod_{\ell=-4}^{+4} (2S - n - \Delta S + 1)}, \tag{11b}$$

Table 1
The numerical coefficients $a_k^{\Delta S}$ which appear in Eqs. (11a) and (11b)

ΔS	$a_6^{\Delta S}$	$a_8^{\Delta S}$
0	$-4\sqrt{105}$	-140
±1	$8\sqrt{14}$	112
±2	$-4\sqrt{7}$	-56
±3	0	16
±4	0	2

with $e_{64}^{\Delta S} = (\sqrt{6}/11)c_{66}^{\Delta S}$ and the numerical coefficients $a_k^{\Delta S}$ listed in Table 1. Similar expressions are found for rank-4 mixing contributions, which renormalize the "bare" values of the B_4^q parameters in Eq. (2).

3. Results and discussion

According to the theory outlined in the previous section, new higher-order terms appear in the effective Hamiltonian describing the ground multiplet. We will now estimate the effect of these terms on the zero-field tunnel splitting. In order to compute the C_K^Qs, it is necessary to know both the local CF parameters $b_k^q(i)$ and the dipole–dipole coupling $J_{jk}^{u,v}$. While the point-dipole approximation is generally appropriate for the latter, the $b_k^q(i)$s cannot be determined ab initio reliably. Therefore, by numerically inverting the second-order functions $C_K^Q(\{b_k^q(i)\})$, we determine the possible sets of local parameters $\{b_k^q(i)\}$ consistent with INS, i.e., such that the values $C_K^Q(\{b_k^q(i)\})$ for $K \leqslant 4$ coincide with those determined by INS (within experimental error bars). Even by neglecting all $b_k^q(i)$ with $q \neq 0,2,4$ (i.e., those not contributing to H_{ZF}) and by imposing the D_2 molecular symmetry on the local CF, there are still more unknown parameters than constraints, and we find therefore that there are infinitely many sets allowed by INS. For these sets, the distribution of the calculated values of the tunnel splitting Δ is shown in Fig. 1 by a histogram of the log-increments $\log(\Delta/\Delta_0)$. In Fig. 1(a) the local CF parameters $b_k^q(i)$ vary on a grid bounded by $|b_2^q(i)| < 8$ K, $|b_4^q(i)| < 0.4$ K, whilst Fig. 1(b) the grid bounds are restricted to $|b_2^q(i)| < 4$ K, $|b_4^q(i)| < 0.04$ K. Although no upper bound for the $b_k^q(i)$s can be directly deduced from experiments, local second-order parameters of a few K are a reasonable choice for Fe^{3+} in low-symmetry environments [18]; typical ratios of fourth- to second-order CF parameters range (in modulus) between 0.01 and 0.1. Fig. 1 shows that the effect of S mixing is huge, since it enhances the tunnel splitting by several orders of magnitude. In particular, the arrows indicate the ratio between the measured value of Δ and Δ_0, which falls well inside both distributions.

By itself, this proves that S mixing can recover the discrepancy between the measured and computed zero-field value of Δ. It remains to be proven that also the measured oscillations of Δ in a transverse magnetic field and its behavior in correspondence of anticrossings with excited states can be accounted for. Once again, we have more free parameters than needed; however, numerical calculations show that, among the new parameters, the most influent on Δ are those of sixth-order (in our case, C_6^4 and C_6^6). The CF parameters with $K \leqslant 4$ must obviously be kept fixed as determined by INS spectroscopy. The measured oscillations of Δ as a function of the transverse field are well reproduced with the choice $C_6^4 = -1.8 \times 10^{-7}$ K and $C_6^6 = -1.15 \times 10^{-7}$ K, which give a zero-field value $\Delta = 1.1 \times 10^{-7}$ K. We stress that this is not the unique possible set; however, to show that the order and sign of these parameters are realistic in Fe_8, the distribution $P(C_6^6)$ of values of C_6^6 calculated on the same grids as described above are reproduced in the insets of Fig. 1. The same numerical check was performed for C_6^4. It must be noticed that the computed

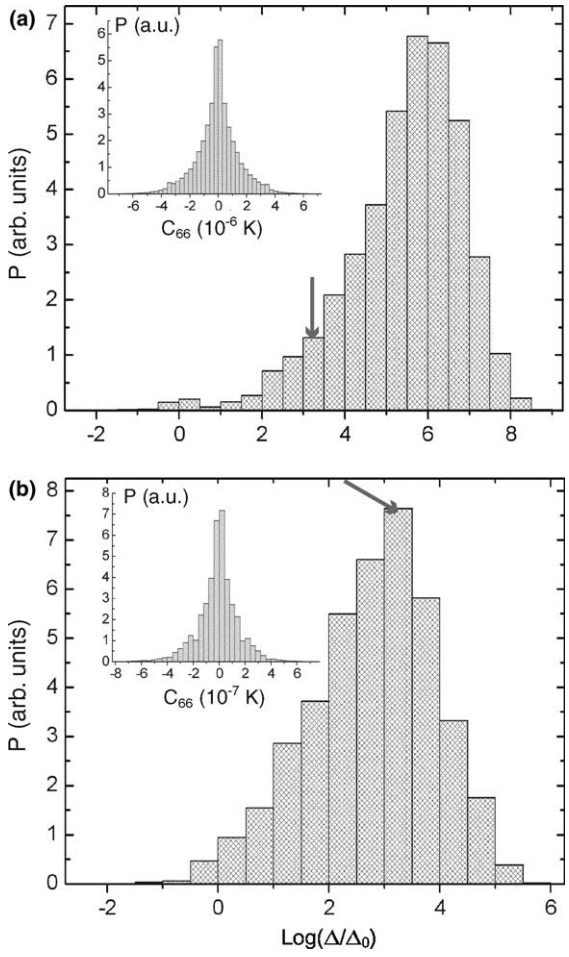

Fig. 1. Calculated distribution of values of the zero-field tunnel splitting Δ normalized to the value $\Delta_0 = 4.44 \times 10^{-11}$ K obtained without S-mixing. The local CF parameters $b_k^q(i)$ vary on grids [different in (a) and (b)] as defined in the text. Arrows indicate the measured ratios. Insets show the distribution of values of C_6^6 on the same grids.

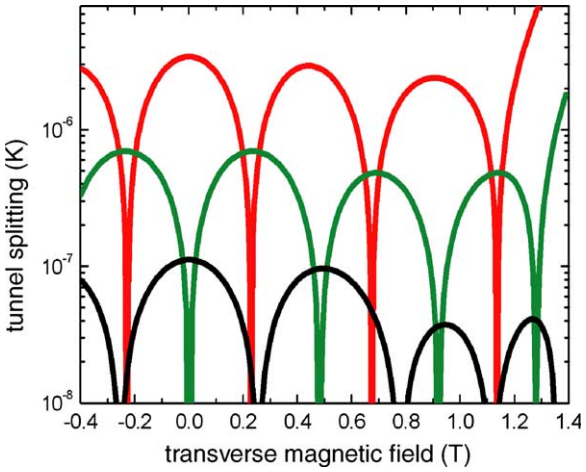

Fig. 2. Calculated tunnel splitting as function of an applied transverse magnetic field with $B_z = 0$ ($n = 0$), and AC gaps involving the excited states $|-10\rangle$ and $|10 - n\rangle$ ($n = 1, 2$) with $B_z = B_{AC} \sim n \cdot 0.22$ T ($n = 1, 2$); the parameters used are given in the text.

INS spectra are indistinguishable when the additional parameters are included or not, apart from an irrelevant shift (~20 μeV) of the shoulder at 0.16 meV [11] (see Fig. 2).

4. Conclusions

By accounting for *S*-mixing perturbatively, we have shown that the discrepancy between spectroscopic and relaxation measurements in Fe_8 can be overcome. Although a unique determination of the C_K^Qs is not possible, the crucial point we demonstrated is that high-rank terms, which are allowed only if *S*-mixing is considered, are essential to describe consistently relaxation and spectroscopic data, since they open highly efficient tunnel channels. Since Fe_8 displays a relatively small degree of *S*-mixing, we expect the tunnel splitting of many magnetic clusters to be influenced even more heavily by such a mechanism. In particular, the degree of *S*-mixing is strongly influenced by the topology of the molecule; therefore this feature, together with the height of the anisotropy barrier, must be taken into account when designing new nanomagnets.

field (H_{SF}) and the AF-P transition field (H_C) with high accuracy.

2. Experiments

γ-Phase single crystals were grown by the evaporation method. The acetonitrile solution of NPNN has been kept in an incubator at 60°. Several dark-greenish single crystals, having typical dimension of $0.5 \times 0.5 \times 0.2\ mm^3$, are obtained within 24 h. The previous paper reported the instability of γ-phase under the room temperature [3]. To avoid the degeneration to the stable β-phase, we held the γ-phase crystals in a refrigerator. Before performing the experiments, we carefully selected single crystals without twin boundary and contaminations of the other phase by X-ray diffraction.

In the ESR measurements, homemade LC resonator with the resonant frequency of ~300 MHz was used. The resonant frequency ($2\pi f = 1/\sqrt{LC}$) can be tuned from 200 to 300 MHz (EPR resonance field corresponds to about 70–100 G) by adjusting the capacitance of flat condenser. The samples were directly cooled by the ^{3}He. The temperature was monitored by the vapor pressure of ^{3}He gas and by the Cernox resistive thermometer equipped around LC resonator. The lowest temperature attained is about 0.4 K. ESR absorption signals were obtained by monitoring the reflection intensity from the resonator through the scalar network analyzer (Agilent Technology, 8719ET). In this experiment, the radio frequency (RF) is set to be about 286 MHz.

In the magnetic torque measurements [4], we used a piezo-resistive cantilever, which is fabricated by Seiko Instruments Inc. for atomic force microscopy (AFM). The small sample is attached at the tip of cantilever using epoxy, and placed at the center of magnet. The sample mounted on the cantilever is shown in the inset of Fig. 1. The magnetic torque is proportional to the off-balance voltage of the bridge circuit, which detected by the lock in amplifier (Stanford Research System SR830). The sample mounted on cantilever is directly cooled by the ^{3}He. The system is so sensitive to observe a spin–flop transition even if the very small sample, whose dimension was $0.25 \times 0.10 \times 0.10\ mm^3$, was used. The magnetic field applied to the *bc*-plane in the torque measurements.

3. Results and discussion

3.1. ESR

The EPR signals are broadened with decreasing temperature, independently from the magnetic field direction, and disappeared below 0.6 K. At the lowest temperature, no trace of the ferromagnetic resonance,

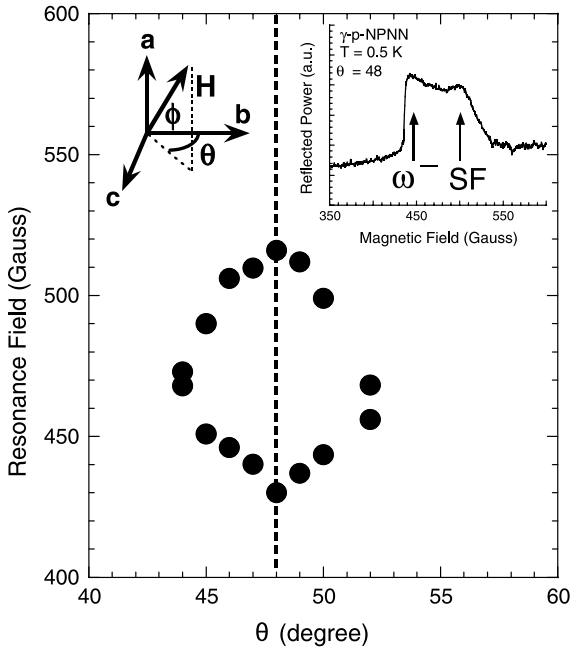

Fig. 1. Angular dependence of the resonance field of ω^- and SF-mode. The inset figure shows the typical AFMR signal. The resonance positions of ω^- and spin–flop (SF)-mode are depicted by the arrows. The angles, θ and ϕ are shown in the inset.

which was observed in the β-phase crystals, is obtained. After EPR signals disappeared, the AFMR signals emerge in different magnetic field. The observed AFMR signal is decomposed by two resonant modes: the lower-field edge of AFMR signal corresponds to the ω^- mode and the higher-field edge corresponds to the spin–flop (SF) mode. Fig. 1 shows the observed AFMR signal and the angular dependence of the ω^- and SF-mode. The angles for applied magnetic field, θ and ϕ, relative to the crystal axis are defined in the inset. These AFMR signals can be observed in the narrow angular region: $44° < \theta < 55°$ and $0° < \phi < 60°$. The typical angular dependence of AFMR around the spin-easy axis was clearly observed within the *bc*-plane. Around $\theta = 48 \pm 10$ and $\phi = 0°$, the maximum separation between the resonance fields for two AFMR modes is obtained. This result indicates that the spin-easy axis is parallel to this direction. It is noted that the spin-easy axis almost points toward the phenyl ring from the ONCNO fragments.

Fig. 2 shows the frequency (ω/γ)-field (H) relation of the AFMR. The resonance field of low-field edge signal increases with decreasing the RF frequency. The inseparability of signals is possibly because the measured temperature is approximate to the Neel temperature. To investigate the AFMR, we applied the two-sublattice model with orthorhombic anisotropy [5]. This assumption is reasonable because that the magnetic coupling in the *bc*-plane is ferromagnetic and the dominant anisotropy term should be caused by the dipole–dipole

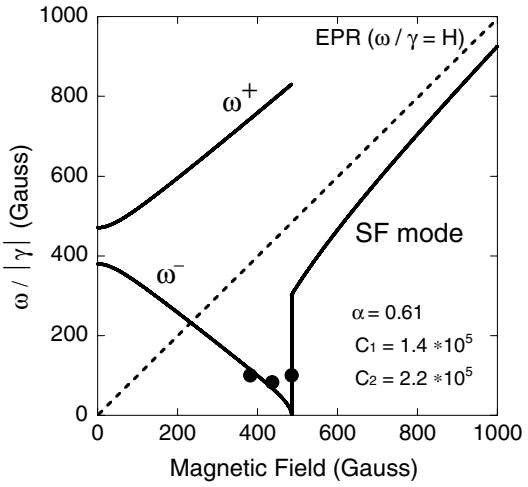

Fig. 2. Frequency (ω/γ)-field relation. The solid lines are the fitting curves with $C_1 = 1.4 \times 10^5$, $C_2 = 2.2 \times 10^5$ and $\alpha = 0.61$. The dashed line indicates the EPR relation; $\omega/\gamma = H$.

interaction. Using this model, the frequency–field relation is well reproduced (see Fig. 2). The solid lines are the fitting curves with the parameters as follow:

$$AK_1 = 7.2 \times 10^4(\mathrm{G}^2), \quad AK_2 = 1.1 \times 10^5(\mathrm{G}^2), \ \alpha = 0.61,$$

where A is the molecular field coefficient, K_1 and K_2 are the orthorhombic anisotropy parameters and $\alpha = 1 - \chi_{\|}/\chi_{\perp}$. The specific heat measurements under the applied magnetic field indicated the existence of one-dimensional ferromagnetic fluctuation. The overall temperature dependences of the specific heat had been well understood by the mean-field theory incorporated in the one-dimensional Heisenberg model [3]. Two interchain couplings were estimated to be $J' = (J_{13}) = 0.224$ K and $J'' = -0.176$ K. Using the antiferromagnetic interchain-coupling constant; we evaluate the orthorhombic anisotropy parameters and get $K_1/M = 55$ G and $K_2/M = 84.6$ G. The spin–flop field, H_{SF} is estimated to be 486 G, which is larger than H_{SF} (~50 G) for the high-pressure antiferromagnetic phase of β-phase [6]. The resonance field of the spin–flop mode hardly depended on temperature while that of ω^- mode depended on temperature. To investigate the magnetic parameters precisely, experiment at lower temperature is required.

3.2. Magnetic torque measurement

Fig. 3 shows the magnetic torque curve as a function of magnetic field. The angle θ is defined in the inset of Fig. 1 and the magnetic field is rotated in the *bc*-plane. At 1.5 K, the magnetic torque approximately increases proportional to the square of magnetic field strength. No structure was observed up to 8000 G (see the inset of Fig. 3). On the contrary, at 0.4 K ($<T_N$), two structures clearly emerge at 470 and 2100 G when the magnetic field is applied around $\theta = 40°$. The lower-field structure has a remarkable angular dependence. This anomaly around 470 G was observed in a very narrow angular region. The most pronounced structure was obtained around $\theta = 40°$. This direction corresponds well to the spin-easy axis observed in AFMR measurements. The magnetic field of 470 G is also consistent with the spin–flop transition field. The higher-field structure is observed in all magnetic field directions with weak angular dependence. Therefore, we assign H_C as the transition filed between AF and paramagnetic phase. The obtained H_C is consistent with the calculated result using the quasi-one-dimensional Heisenberg ferromagnetic model, in which H_C was estimated about 2200 G at 0.4 K [3].

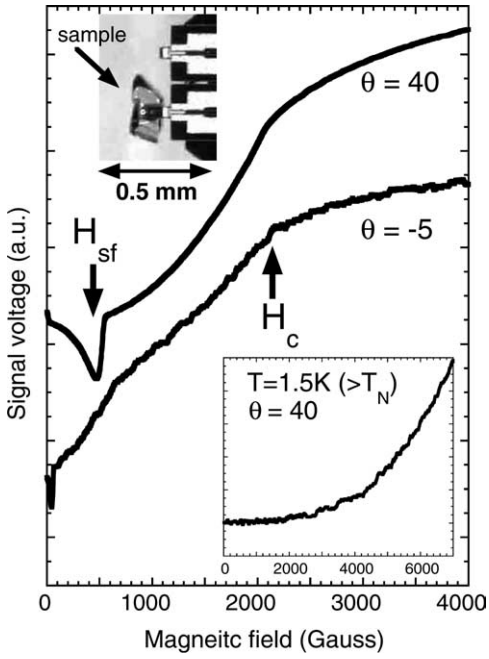

Fig. 3. Magnetic field dependence of the magnetic torque of γ-phase single crystal at 0.4 K. The inset figure shows the torque curve at 1.5 K. The magnetic field direction, θ, is defined in Fig. 1. The picture shows the sample mounted on the cantilever.

4. Conclusion

We have performed low-temperature ESR and magnetic torque measurements of γ-*p*-NPNN. Using the low frequency and low-temperature ESR technique, two AFMR modes along spin-easy axis can be observed for the first time. The frequency–field relation is well reproduced by the usual AFMR theory with the orthorhombic anisotropy parameters. We estimated the exchange and anisotropy parameters. In the magnetic torque measurement using small single crystal, we can observe the SF and AF-P transitions at 470 and 2100 G, respectively. Both AFMR and magnetic torque

measurements directly establish the antiferromagnetic ground state of γ-*p*-NPNN.

reported [7]. The typical shape of single crystal for the low-frequency (LF) ESR experiment is depicted in the inset of Fig. 1(a), whose diameter is about 0.6 mm. The alignment of crystal axes was also determined by the X-ray diffraction measurement.

In order to avoid the saturation effects, we developed the LF-ESR system. The resonator was constructed by the LC circuit, in which both the condenser (C) and pick-up coil (L) are put in parallel. The resonance frequency ($2\pi f = 1/\sqrt{LC}$) can be tuned by adjusting the capacitance and we mainly used the LC resonator with the resonant frequency of ~300 MHz, which corresponds to the EPR resonance field of about 100 G. The magnetic field is controlled by the Bruker ER032M and is monitored by the Hall magnetometer. As the high power of oscillating magnetic field easily saturate the resonance line [7], we adjusted the rf power carefully so that the line shapes might not be distorted. The samples were directly cooled by the ^{3}He. The temperature was monitored by the vapor pressure of ^{3}He gas (MKS Baratron) and by the Cernox resistive thermometer equipped around the LC resonator. The lowest temperature attained is about 0.4 K. ESR absorption signals were obtained by monitoring the reflection intensity from the resonator through the scalar network analyzer (Agilent Technology, 8719ET).

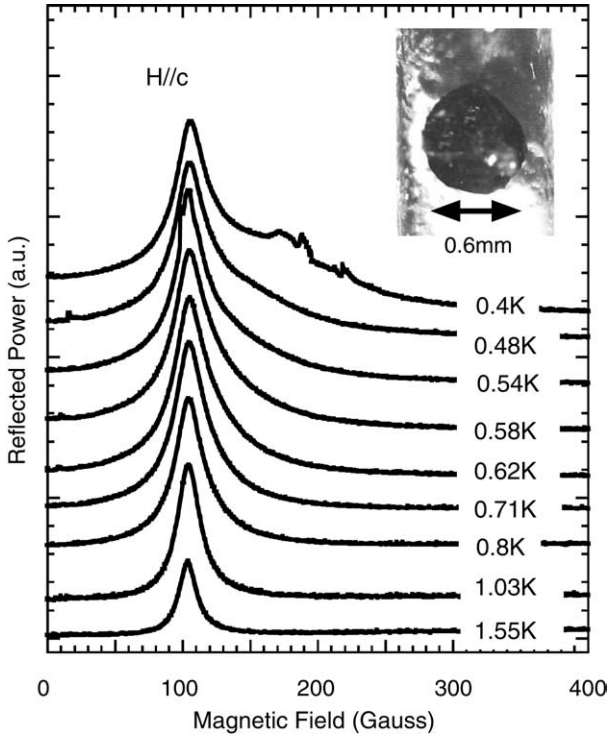

Fig. 1. Temperature dependence of ESR spectra for H//*c*. The inset shows the picture of spherically molded single crystal of β-*p*-NPNN, whose diameter is about 0.6 mm.

3. Results and discussion

Fig. 2 shows typical ESR absorption signals at different temperatures for H//*c*. The applied rf is about 289 MHz, corresponding to the EPR resonance field of 103 G. As temperature is decreased, the signals at EPR position increase its intensity with slight increase of the line-width, but are observed at the lowest temperature. Below 0.8 K, new absorption signals are gradually developed at the higher field shoulder of EPR signals. These absorption signals can be observed in all magnetic field direction. We marked these signals HF. The observed spectra were well fitted by assuming two symmetric

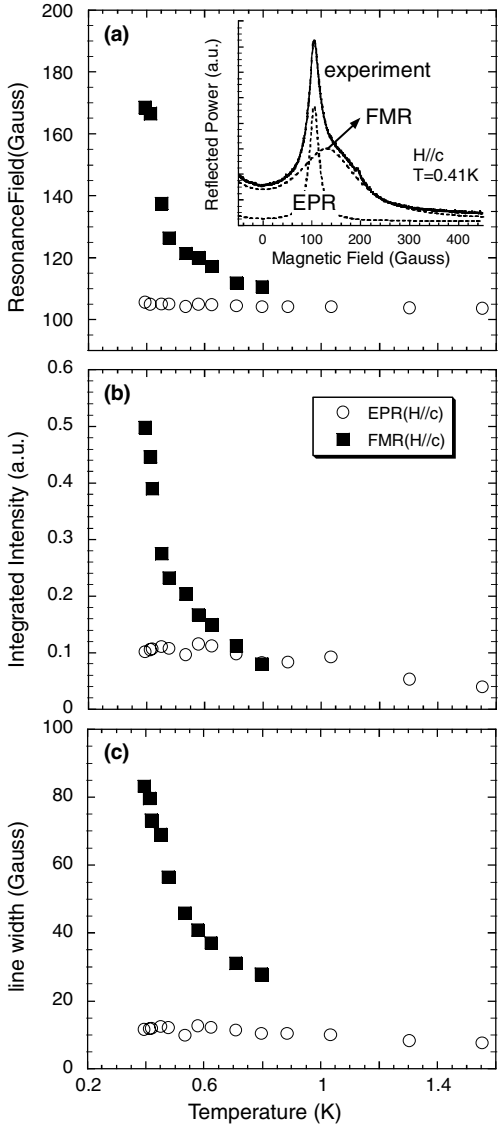

Fig. 2. Temperature dependence of ESR parameters for H//*c*. (a) The resonance fields, (b) the integrated intensity and (c) the line width are shown. The inset figure in (a) shows the typical spectrum at 0.5 K. The ESR spectra were decomposed by two symmetric Lorentzian absorption; EPR and HF(FMR). The open circles and closed squares are parameters for EPR and HF(FMR) components, respectively.

Lorentzian signals. In the inset of Fig. 2(a), both the spectrum and the decomposed two Lorentzian signals are indicated. Figs. 2(a)–(c) show the temperature dependences of resonance fields, integrated intensity and line width for two components, respectively, where the magnetic fields are applied parallel to the *c*-axis. Because the resonance fields of lower field signals are almost independent from temperature as well as the angle between the magnetic field and the crystal axis, we could assign these signals at low temperatures as residual EPR signals. The sample preparation procedure for making the spherical shape may cause some impurities on the surface of the crystals. Contrary to the EPR signals, the parameters for HF signals have remarkable temperature dependence. The resonance fields shift to the higher field side, i.e., the lower *g*-factor side as the temperature is decreased. This result indicates the existence of internal magnetic field acting on the spin system. The integrated intensity of HF signal is several times stronger than that of EPR signal. The resonance fields of HF signals also depend on the magnetic field direction. The angular dependence of resonance fields at the lowest temperature for H//*bc*-plane is presented in Fig. 3. When the magnetic field is tilted away from the *c*-axis, it is difficult to estimate the resonance field of HF signals correctly due to the overlapping of HF signals on the EPR signals. Contrary to the *bc*-plane, it should be noted that the ESR spectra are nearly isotropic in the *ab*-plane. This suggests

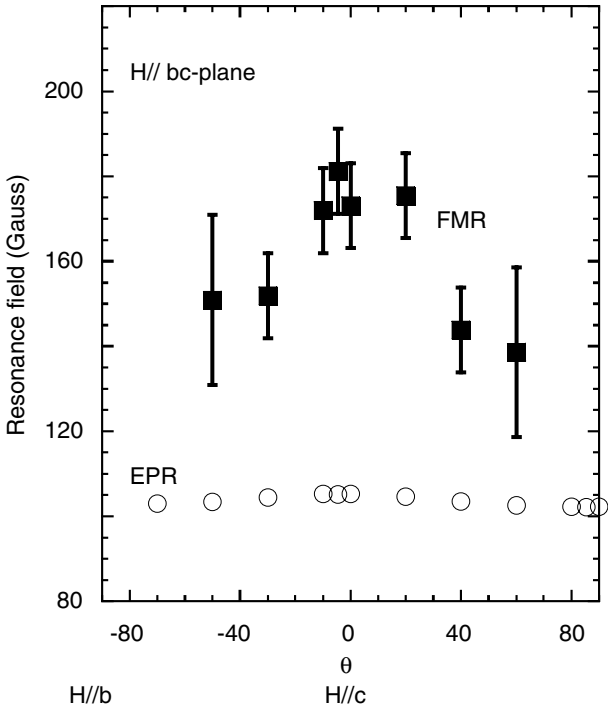

Fig. 3. Angular dependence of resonance fields at 0.4 K. The magnetic field is applied within the *bc*-plane. The open circles and closed squares indicate the resonance fields for EPR and HF(FMR) components, respectively.

that the HF signals should have no clear angular dependence. From these experimental results, we can judge the HF signals as a ferromagnetic resonance (FMR). This is the first evidence for observing the symmetric FMR signals in the β-*p*-NPNN. The higher field shift for H//*c* as well as the isotropic behavior in the *ab*-plane indicate that the *spin hard* axis aligns parallel to the *c*-axis. The dipolar field calculation also supports this result [1].

In order to estimate the FMR, we assume a uniaxial anisotropy and ignore the demagnetizing field term in a magnetic free energy density because the crystal has a roughly spherical shape. When the magnetic field is applied perpendicular to the spin-easy axis, the FMR relation is written by the usual Kittel's formula

$$\frac{\omega}{\gamma} = \sqrt{H(H - 2H_K)}, \quad H > 2H_K,$$

where $H_K = KM$ is the anisotropy field and M is the spontaneous magnetization. Using this expression, we can estimate the anisotropy field as $2H_K = 121 \pm 20$ G. This result may be consistent with the small saturation field of magnetization as well as with the small coercive force [2,3]. However, this value is smaller than the calculated results of dipole interaction [1]. Since the magnetic anisotropy field depends on the spontaneous magnetization, it should be compared with the extrapolated value toward $T = 0$. The temperature dependence of spontaneous magnetization had been estimated by the temperature dependence of muon spin precession frequency [4]. Their temperature dependence follows $[1 - (T/Tc)^{\alpha}]^{\beta}$ formula with the exponents; $\alpha = 1.86$ and $\beta = 0.32$. Therefore, the reduced factor of spontaneous magnetization at 0.4 K, at which our LF-ESR measurements have been done, is estimated to be about $M(T)/M_0 \approx 0.86$. Though there may not be a formula on the temperature dependence of the magnetic anisotropy, which can be applied to all systems, we apply the temperature dependence of uniaxial anisotropy for localized spin magnet model [8]. In this model, the anisotropy constant depends on the following formula; $K(T)/K_0 \propto [M(T)/M_0]^3$ at low temperatures, whilst $K(T)/K_0 \propto [M(T)/M_0]^2$ at higher temperatures, where $M(T)$ is the spontaneous magnetization at T. Therefore, in the case of β-*p*-NPNN, the magnetic anisotropy at $T = 0$ is obtained to be $H_K(0) \approx 130$ G. This value is rather consistent with the calculation for the dipole-sum, but it is necessary to measure FMR at lower temperature in order to investigate the anisotropy constant correctly.

4. Conclusion

The low-temperature and radio-frequency (rf) ESR were performed using the spherically-molded single crystals of β-*p*-NPNN. The FMR signals could be observed below 0.8 K, especially for H//*c*. The higher field

shift of FMR for H//c indicates that the spin-hard axis is parallel to this direction. We applied the usual Kittel's FMR relation with uniaxial anisotropy and estimate the magnetic anisotropy field of H_K = 61 G at 0.4 K.

calculation, the non-collinear magnetic clusters, which has a three-dimensional magnetic arrangement, was obtained as the ground state at Fe_3O_5 [2].

The atomic structure of charged clusters could be different from that of neutral cluster. To compare with the available experimental data of EA [3], in the present work, we report the ground state geometry and magnetic structure for the anion iron oxide clusters, $Fe_nO_m^-$ $(n = 3, 4)$ and their vertical detachment energies (VDE). We discuss the dependence of VDE with respect to the number of oxygen atoms.

2. Calculation method

We have used the first principles molecular dynamics [6], which is based on the density functional theory [7,8] with ultra-soft pseudo potentials [9–11] and plane-waves, to optimize the configuration of clusters. This scheme allows us to take the simultaneous optimization in both of atomic and electronic degrees of freedom. The clusters were placed in a large cubic cell of side 20 a.u. with the periodic boundary condition. The energy cutoffs are 24 Ry for plane-wave expansion of electron wave functions at the Γ point and 250 Ry for the augmented electron density [10,11]. We used the generalized gradient approximation (called PW91) for the exchange-correlation energy [12]. To treat the metallic property that there are some degenerate states around the Fermi level, as in the calculation of neutral clusters, we introduced the additional freedom of partial occupations [13–15]. Consequently, the values presented for magnetization were obtained by integrating spin densities, resulting in non-integer value. The contribution of uniform charge to the Hartree potential has been evaluated with the real space integration in the real cell, as used in the previous study [16].

In pure iron clusters, there are ferromagnetic and antiferromagnetic interactions between magnetic moments on atoms [17,18]. Due to this property, non-collinear magnetic structures could appear in the optimization process of atomic and electronic configurations. Therefore, we have used the scheme of non-collinear magnetism [17,19], as well as the usual spin polarized scheme for density functional calculations. Because iron oxide clusters having many oxygen atoms favor antiferromagnetic configurations, the collinear scheme sometimes encounters the difficulty that the system falls down to a metastable spin configuration. The non-collinear scheme, in which the atomic magnetic moments could rotate gradually at the cost of low energies, efficiently seek the ground state spin configuration.

3. Results and discussion

3.1. $Fe_3O_m^-$

The stable sites for O atoms are categorized into the bridge and surface sites. The latter is a site above the center of the triangle consisting of Fe atoms. The edge site of O (the oxygen atom is bonded at a single Fe atom) usually gives a higher energy. We present the geometry and magnetic arrangement of the ground state

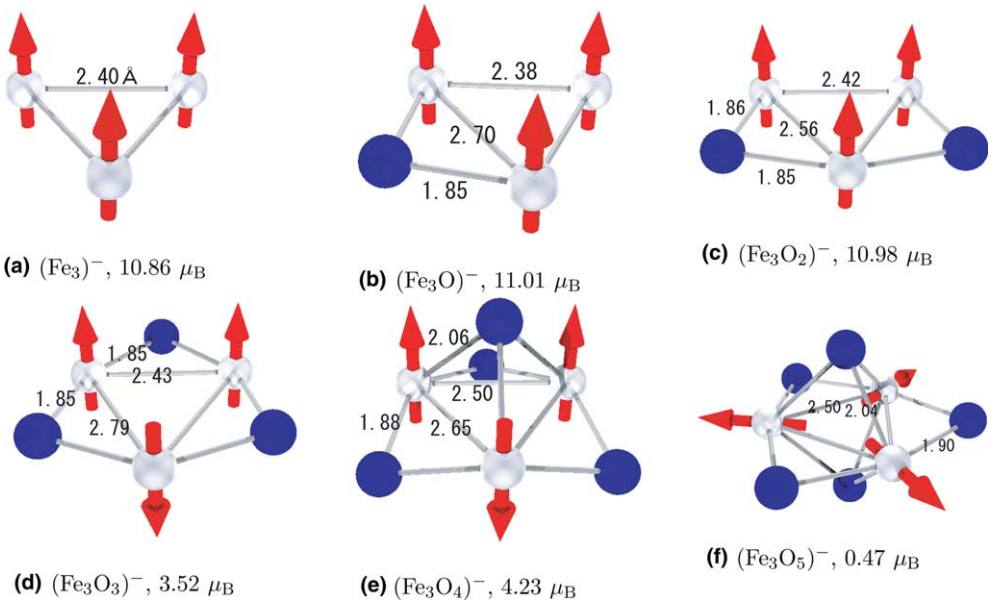

Fig. 1. The ground state geometry and magnetic configuration for the anion clusters, $Fe_3O_m^-$ $(m = 0–5)$, with the bond length in Å and the magnetization in μ_B: (a) $(Fe_3)^-$, 10.86 μ_B; (b) $(Fe_3O)^-$, 11.01 μ_B; (c) $(Fe_3O_2)^-$, 10.98 μ_B; (d) $(Fe_3O_3)^-$, 3.52 μ_B; (e) $(Fe_3O_4)^-$, 4.23 μ_B; (f) $(Fe_3O_5)^-$, 0.47 μ_B.

configurations for $Fe_3O_m^-$ ($m = 0$–5) in Fig. 1. Oxygen atoms favor the bridge site in $Fe_3O_m^-$ ($m = 1$–3). When adding O atoms ($Fe_3O_m^-$ ($m = 4, 5$)), they occupy into the surface site. This shows a similar configuration as in the neutral clusters [2].

The pure anion Fe cluster has the ferromagnetic ground state. The ferromagnetic arrangement survives to $Fe_3O_2^-$. Increasing the number of O atoms, the arrangement changes to antiferromagnetic one at $m \geqslant 3$, as shown in Fig. 2. This is due to the antiferromagnetic interaction of superexchange mechanism through O atoms. Whereas this antiferromagnetic interaction between Fe atom may become strong as the number of oxygen atoms increases.

At the largest number of O atoms, the cluster of $Fe_3O_5^-$ (see Fig. 1(f)) has non-collinear magnetic arrangement as the neutral one [2]. The atomic magnetic moments on Fe form the angle of 120° in a plane. The stability of non-collinearity results from a competition among the strong symmetric antiferromagnetic interactions between Fe atoms.

In comparison with the neutral clusters, generally, effects of additional electron gives longer bond lengths. In the ferromagnetic clusters, $Fe_3O_m^-$ ($m = 0$–2), the Fe–Fe bond becomes longer by about 0.15 Å than that in the corresponding neutral one. In the antiferromagnetic cluster of $Fe_3O_m^-$ ($m = 3, 4$), the ferromagnetic bond between Fe atoms (the Fe–Fe bond with ferromagnetic arrangement) becomes longer by about 0.05 Å, while the antiferromagnetic bond becomes longer by 0.1 Å. As a general tendency in antiferromagnetic clusters, the adding electron increases antiferromag-

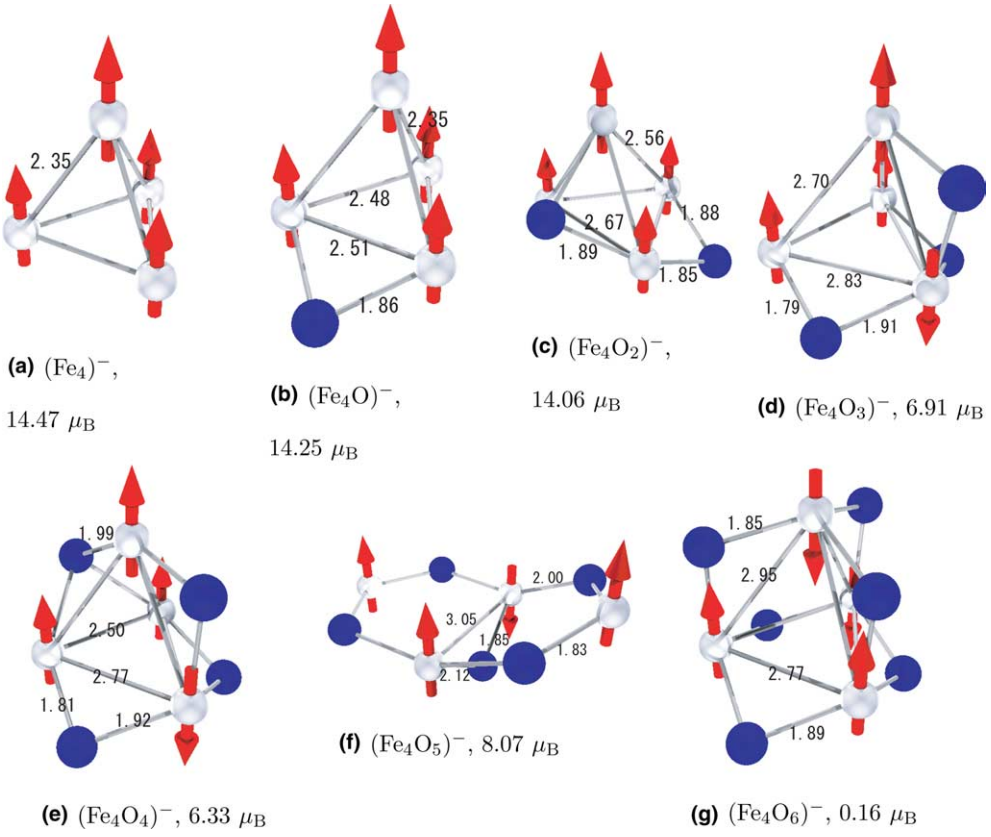

Fig. 3. The ground state geometry and magnetic configuration for the anion clusters, $Fe_4O_m^-$ ($m = 0$–6), with the bond length in Å and the magnetization in μ_B: (a) $(Fe_4)^-$, 14.47 μ_B; (b) $(Fe_4O)^-$, 14.25 μ_B; (c) $(Fe_4O_2)^-$, 14.06 μ_B; (d) $(Fe_4O_3)^-$, 6.91 μ_B; (e) $(Fe_4O_4)^-$, 6.33 μ_B; (f) $(Fe_4O_5)^-$, 8.07 μ_B; (g) $(Fe_4O_6)^-$, 0.16 μ_B.

netic bonds between Fe atoms more than ferromagnetic bonds.

3.2. $Fe_4O_m^-$

The geometry and magnetic arrangement for the ground state clusters, $Fe_4O_m^-$, are shown in Fig. 3. The low energy configurations for Fe_4^- have tetrahedral (Fig. 3(a)) and plane structures. The former is more stable by 2.75 eV than the latter. Three stable clusters were obtained for Fe_4O^-; the most stable is shown in Fig. 3(b), the second stable one has an O atom at a surface site (+0.28 eV), and the third one has a plane structure (+1.79 eV vs. the most stable one).

In the neutral cluster of Fe_4O_3, two O atoms are added to the bridge sites between two Fe atoms and the other O atom is added to the surface site. In the anion cluster, unlike the neutral one, three O atoms are added to the bridge sites, and the magnetic arrangement changes from ferromagnetic to antiferromagnetic one, as shown in Fig. 4. This indicates that the adding electron induces antiferromagnetic interaction.

We obtained the stable cluster of plane structure, as well as the three-dimensional structure for $Fe_4O_4^-$. The former is at the energy of 1.7 eV above the most stable one (Fig. 3(e)). For $Fe_4O_5^-$, we obtained the stable cluster of plane-like structure (Fig. 3(f)). The plane structure might be due to an incommensurate situation on the number of O atoms. While the tetrahedron of Fe_4 has six Fe–Fe bonds, which reserves six bridge sites, an unoccupied bridge site of O atom would deform a three-dimensional structure for $Fe_4O_5^-$. In deed, for $Fe_4O_6^-$, all of the bridge sites are occupied by O atoms, resulting to the stable cluster.

As in $Fe_3O_m^-$, effects of the additional electron appeared in the longer bond lengths by about 0.1 Å for Fe–Fe bond and by about 0.05 Å for Fe–O bond.

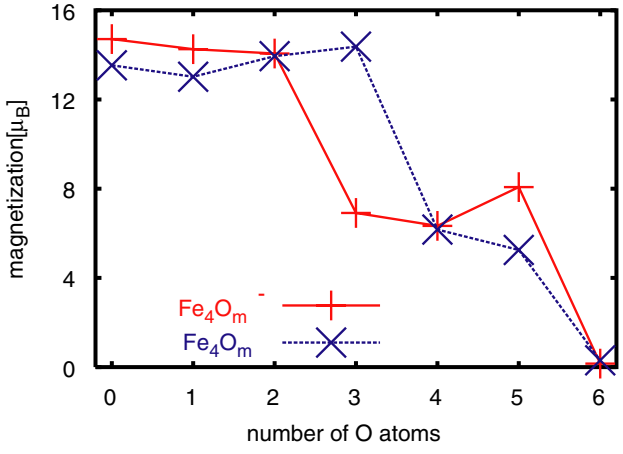

Fig. 4. The oxidation dependences of total magnetization for Fe_4O_m and $Fe_4O_m^-$ ($m = 0$–6).

3.3. Vertical detachment energy

The VDEs of the ground state geometry for $Fe_nO_m^-$ ($n = 3, 4$) are shown as a function of the number of O atoms in Fig. 5. The VDE of $Fe_3O_m^-$ is in agreement with the experimental data [3] without $Fe_3O_5^-$. In the photoelectron spectrum of $Fe_3O_5^-$ [3], there is a relatively long tail in the low binding energies, which implies the existence of minor clusters having low EAs. To extract this implication in experimental data, we estimated the length of tail from the spectrum and present a vertical bar in Fig. 5.

For $Fe_4O_m^-$, the calculated VDEs generally are lower than the experimental one. This shows a contrast with a general property of local density functional calculations which usually gives larger energies [16,20].

The VDE of $Fe_4O_m^-$ is in fair agreement with the experimental data in the tendency of oxidation [3]. However, some clusters show a difference between calculation and experiment. As a general property, spectrum

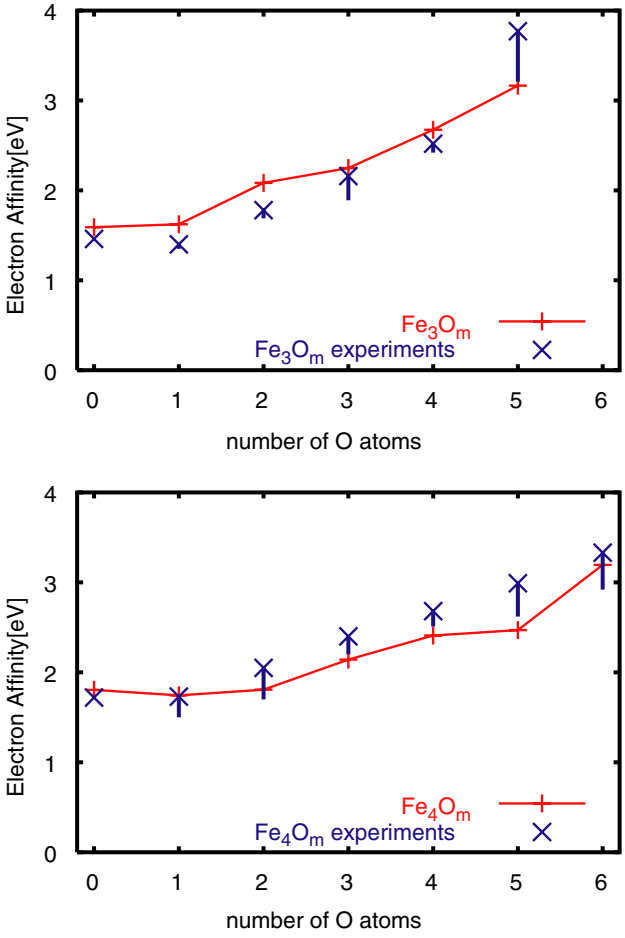

Fig. 5. The vertical detachment energy of $Fe_3O_m^-$ and $Fe_4O_m^-$ clusters as a function of the number of O atoms. The plus and cross specify the calculated VDE and the EA of experiment[3], respectively. The lines are for the guide of eye. The vertical bar from the cross indicates a length of low-energy tail in the photoelectron spectrum by Wang et al.

of $Fe_4O_m^-$ have longer tail than the smaller clusters, $Fe_nO_m^-$ ($n = 1$–2). This seems to be correlated with the large difference in $Fe_4O_m^-$.

4. Summary

We have determined the ground state geometry and magnetic arrangement for the anion iron clusters, $Fe_3O_m^-$ ($m = 1$–5) and $Fe_4O_m^-$ ($m = 1$–6), which had been obtained in the gas phase experiment. In the structural optimization, the first O atom favors a bridge site, and the second O atom occupies another bridge site in $Fe_3O_2^-$ and the surface site in $Fe_4O_2^-$. These behaviors are similar to the neutral clusters. Compared with the neutral clusters, the anion clusters are stabilized with bond elongation by $\sim$0.1 Å for Fe–Fe bonds and $\sim$0.05 Å for Fe–O bonds. We evaluated the VDEs and discussed the behavior with respect to the number of O atoms. The VDE of $Fe_3O_m^-$ is in good agreement with the experimental data without $Fe_3O_5^-$. For $Fe_4O_m^-$, the calculated VDEs generally show lower values than the experimental one.

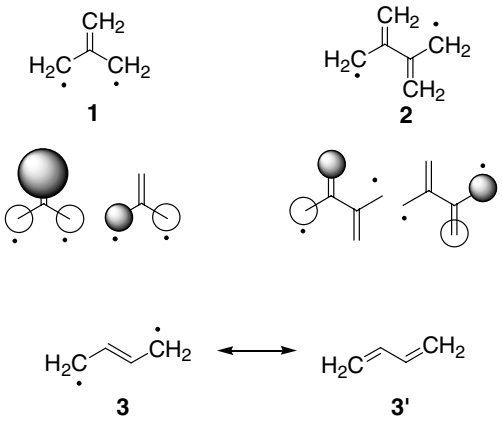

Fig. 1. The molecular structure and the shape of the orbitals of trimethylenemethane (**1**), tetramethyleneethane (**2**), and butadiene (**3′**).

molecule therefore exists as a normal closed-shell Kekulé molecule. 1,3-Butadiene (**3′**) is an example of a normal Kekulé molecule; it has the resonant biradical structure, 2-butene-1,4-diyl (**3**). In this case, the closed-shell structure **3′** is the ground state, so the ground electronic state has no unpaired electrons. In other words, the magnetic interaction between the two spins in the structure **3** is strongly antiferromagnetic.

The magnetic interactions in the disjoint and non-disjoint biradicals have been theoretically and experimentally investigated to conclude that while TMM (**1**) has a ground triplet state, the singlet and triplet states of TME (**2**) are nearly degenerate [7,8].

Photochromism is a reversible phototransformation of a chemical species between two forms having different absorption spectra [9–11]. Photochromic compounds reversibly change not only the absorption spectra but also their geometrical and electronic structures. The geometrical and electronic structural changes induce some changes in physical properties, such as fluorescence, refractive index, polarizability, and electric conductivity. When the photochromic compounds are used as "spin couplers", the magnetic interaction can be controlled by photoirradiation. Not only our group but also others [12–17] have recently been interested in the photocontrol of magnetism of organic radical-based magnetic materials.

Diarylethenes with heterocyclic aryl groups are well known as thermally irreversible, highly sensitive, and fatigue-resistant photochromic compounds (Fig. 2) [18].

The difference in color is due to the differences in the geometrical and electronic structures. In the open-ring isomer, free rotation is possible between the ethene moiety and the aryl group. Therefore, the open-ring isomer is non-planar and the π-electrons are localized in the two aryl groups. On the other hand the closed-ring isomer has bond-alternative polyene structure and the

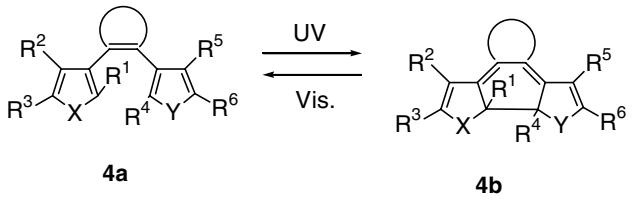

Fig. 2. Photochromism of diarylethene.

π-electrons are delocalized throughout the molecule. These geometrical and electronic structural differences resulted in some differences in the physical properties. For example, the closed-ring isomer has a high polarizability, because the closed-ring isomer has more delocalized π-electrons [19,20]. Not only the change in polarizability, but also the switching in fluorescence [21] and electronic conduction [22] have been developed.

2. Diarylethene as a photoswitch

There is a characteristic feature in the electronic structural changes of diarylethenes. Fig. 3 shows the open-ring isomer **5a** and closed-ring isomer **5b** of the radical-substituted diarylethenes with simplified structures. While there is no resonant closed-shell structure for **5a**, there does exist **5b′** as the resonant quinoid-type closed-shell structure for **5b**. **5a** is a non-Kekulé biradical, and **5b** is a normal Kekulé molecule. In other words, **5a** has two unpaired electrons, while **5b** has no unpaired electrons. The calculated shapes of two SOMOs of **5a**

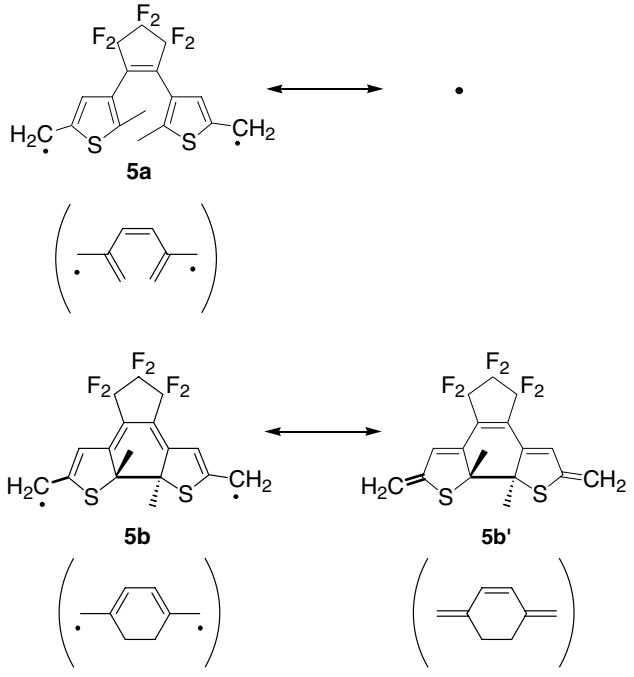

Fig. 3. The open-ring isomer **5a** and the closed-ring isomer **5b** of the radical-substituted diarylethene.

are separated in the molecule and there is no overlap. This configuration is a typical disjoint biradical, in which the intramolecular radical–radical interaction is weak. In the open-ring isomer, the bond-alternation is discontinued at the 3-position of the thiophene rings. This is the origin of the disjoint nature of the electronic configuration of **5a**. **5a** is a disjoint non-Kekulé biradial and corresponds to tetramethyleneethane (**2**) in the former example. However, the closed-ring isomer **5b**′ is a normal Kekulé molecule. In this case, the ground electronic state has no unpaired electrons. In this singlet ground state, the magnetic interaction is strongly antiferromagnetic. **5b**′ corresponds to butadiene **3**′ in the former example.

The electronic structural change of radical-substituted diarylethenes accompanying the photoisomerization is the transformation of a disjoint non-Kekulé structure to a closed-shell Kekulé structure. One may infer from the above consideration that the interaction between spins in the open-ring isomer of diarylethene is weak, while significant antiferromagnetic interaction takes place in the closed-ring isomer. In other words, the open-ring isomer is "OFF" state and the closed-ring isomer is "ON" state.

3. Photoswitching of magnetic interaction

Photochromic biradical **6a** was designed and synthesized by choosing 1,2-bis(2-methyl-1-benzothiophen-3-yl)perfluorocyclopentene as a photochromic spin coupler and nitronyl nitroxides as spin sources (Fig. 4) [23,24]. The schematic representation is also shown in Fig. 4.

In solution, **6a** showed ideal photochromic behavior by irradiation with UV and visible light (Fig. 5). Although the radical moiety absorbs in the region from 550 to 700 nm, this did not prevent the photochromic reaction. Almost 100% photochemical conversions were observed in both the cyclization from open-ring isomer **6a** to closed-ring isomer **6b** and the cycloreversion from **6b** to **6a**. For the practical use of photochromic devices, high conversion is one of the most important characteristics.

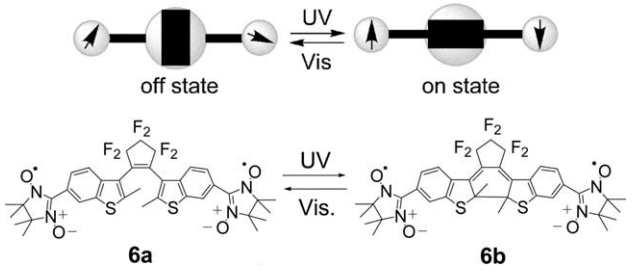

Fig. 4. Photoswitching of intramolecular magnetic interaction. top: schematic representation, bottom: synthesized molecule.

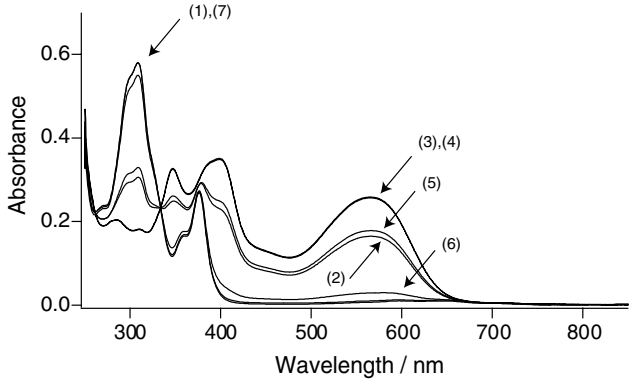

Fig. 5. The photochromic reaction of **6** (in EtOAc, 1.7×10^{-5} M): (1) the open-ring isomer; (2) irradiated with 313 nm light for 1 min; (3) for 5 min; (4) for 10 min; (5) irradiated with 578 nm light for 5 min; (6) for 30 min; (7) for 60 min.

Magnetic susceptibilities of **6a** and **6b** were measured on a SQUID susceptometer in microcrystalline form. χT–T plots are shown in Fig. 6. The data were analyzed in terms of a modified singlet–triplet two-spin model (the Bleaney–Bowers-type), in which two spins ($S = 1/2$) couple antiferromagnetically within a biradical molecule by exchange interaction J. The best-fit parameters obtained by means of a least-squares method were $2J/k_B = -2.2 \pm 0.04$ K for **6a** and $2J/k_B = -11.6 \pm 0.4$ K for **6b**. Although the interaction ($2J/k_B = -2.2$ K) between the two spins in the open-ring isomer **6a** was weak, the spins of **6b** have a remarkable antiferromagnetic interaction ($2J/k_B = -11.6$ K).

The open-ring isomer **6a** had a twisted molecular structure and a disjoint electronic configuration. On the other hand, the closed-ring isomer **6b** had a planar molecular structure and a non-disjoint electronic configuration. The photoinduced change in magnetism agrees well with the prediction that the open-ring isomer has an "OFF" state and the closed-ring isomer has an "ON" state.

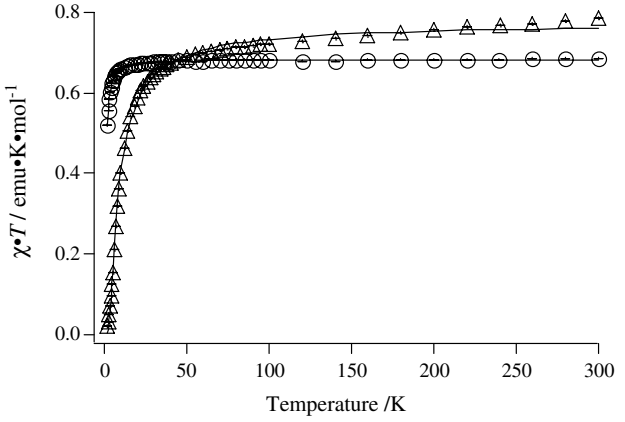

Fig. 6. Temperature dependence of the magnetic susceptibility of **6a** (O) and **6b** (Δ) (χT–T plot).

Although the switching of exchange interaction was detected by a susceptibility measurement of biradical **6**, both open- and closed-ring isomers **6a** and **6b** had 9-line ESR spectra because the exchange interaction between the two radicals was much stronger than the hyperfine coupling constant in both isomers. For one to detect the change of the exchange interaction by ESR spectroscopy, the value of the interaction should be comparable to the hyperfine coupling constant. Therefore, biradicals **7** ($n = 1, 2$), in which *p*-phenylene spacers are introduced to control the strength of the exchange interaction, were designed and synthesized (Fig. 7) [25,26].

As described earlier, when two nitronyl nitroxides are magnetically coupled via an exchange interaction, the biradical gives a 9-line ESR spectrum. If the exchange interaction is weaker than the hyperfine coupling, the two nitroxide radicals are magnetically independent and give a 5-line spectrum. In intermediate situations, the spectrum becomes complex.

Diarylethenes, **7a**, ($n = 1, 2$) also underwent reversible photochromic reactions by alternative irradiation with UV and visible light. The changes in the ESR spectra accompanying the photochromic reaction were examined for diarylethenes, **7a**, ($n = 1, 2$). Fig. 8 shows the ESR spectra at different stages of the photochromic reaction of **7a** ($n = 1$). The ESR spectrum of **7a** ($n = 1$) showed a complex of 15 lines. This suggests that the two spins of nitronyl nitroxide radicals were coupled by an exchange interaction that is comparable to the hyperfine coupling constant. Upon irradiation with 366 nm light, the spectrum converted completely to a 9-line spectrum, corresponding to the closed-ring isomer **7b** ($n = 1$). The 9-line spectrum indicates that the exchange interaction between the two spins in **7b** ($n = 1$) is much stronger than the hyperfine coupling constant.

The ESR spectral change was also observed for **7a** ($n = 2$). The open-ring isomer **7a** ($n = 2$) had a 5-line spectrum, while the closed-ring isomer **7b** ($n = 2$) had a distorted 9-line spectrum. A simulation of the ESR spectra was performed. The exchange interaction decreases with the increase in the π-conjugated chain length, as shown in Table 1. The exchange interaction change in **7a** ($n = 1, 2$) upon photoirradiation was more than 30-fold. This result shows a very large switching effect of diarylethenes and suggests the superiority of diarylethenes as molecular switching units. Although the absolute value of the exchange interaction is small, the information of the spins can be clearly transmitted through the closed-ring isomer, and the switching can be detected by ESR spectroscopy.

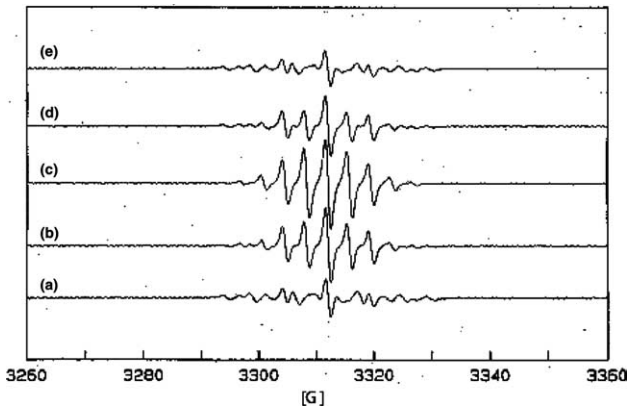

Fig. 8. ESR spectral change of **7a** ($n = 1$) along with photochromism (benzene solution, 1.1×10^{-4} M): (a) initial; (b) irradiation with 366 nm light for 1 min; (c) 4 min; (d) irradiation with >520 nm light for 20 min; (e) 50 min.

Oligothiophenes are good candidates for conductive molecular wires. The thiophene-2,5-diyl moiety has been used as a molecular wire unit for energy and electron transfer and can serve as a stronger magnetic coupler than *p*-phenylene [27,28]. Therefore, diarylethenes, **8a**, ($n = 1, 2$) having one nitronyl nitroxide radical at each end of a molecule containing oligothiophene spacers was synthesized and their photo- and magnetochemical properties were studied (Fig. 9).

Photochromic reactions and an ESR spectral change was also observed for **8a** ($n = 1, 2$). Table 1 lists the exchange interaction between the two diarylethene-bridged

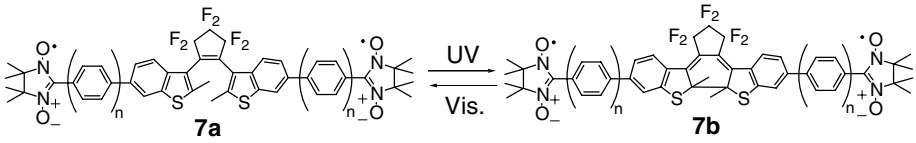

Fig. 7. Photoswitching using *p*-phenylene spacer.

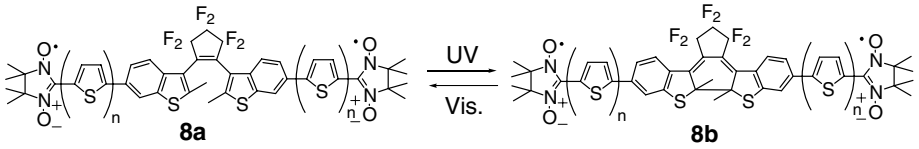

Fig. 9. Photoswitching using thiophene-2,5-diyl spacer.

nitronyl nitroxide radicals. For all five biradicals, the closed ring isomers have stronger interactions than the open-ring isomers. The exchange interactions through oligothiophene spacers were stronger than the corresponding biradicals with oligophenylene spacers. The efficient π-conjugation in thiophene spacers resulted in strong exchange interactions between the two nitronyl nitroxide radicals. In the case of bithiophene spacers, the exchange interaction difference between open- and closed-ring isomers was estimated to be more than 150-fold.

4. Reversed photoswitching using bis(2-thienyl)ethene

Photoswitching using bis(2-thienyl)ethene (**9**) (Fig. 10), in which 2-thienyl group is connected to the perfluorocyclopentene ring, was performed [29]. In the case of regular bis(3-thienyl)ethenes, the bond alternation is discontinued in the open-ring isomer, but in the closed-ring isomer, the π-electron is delocalized throughout the molecule. Therefore the open-ring isomer is in "OFF" state due to the disconnection of the π-system and the closed-ring isomer is in "ON" state due to the delocalization of the π-conjugated system. The situation is reversed when thiophene rings are substituted to the ethene moiety at 2-position. The bond alternation is continued throughout the molecule in the open-ring isomer, while in the closed-ring isomer two aryl rings are separated by the sp^3 carbon and sulfur atoms. The magnetic interaction between the two unpaired electrons at 5-positions in the closed-ring isomer is expected to become much weaker than that in the open-ring isomer. In other words, the open-ring isomer is in "ON" state and the closed-ring isomer in "OFF" state.

The synthesized bis(2-thienyl)ethene (**9a**) did not undergo photochromism, but the precursor underwent photochromic reaction. The closed-ring isomer of the precursor was obtained and the closed-ring isomer was transformed to the desired molecule. The obtained closed-ring isomer **9b** was converted to the open-ring isomer **9a** by irradiation with visible light. The ESR spectrum of the closed-ring isomer **9b** was a five-line spectrum, but the spectrum of the open-ring isomer **9a** was a distorted 9 lines. This suggests that there are stronger magnetic interaction in the open-ring isomer than in the closed-ring isomer. The switching direction is reversed by using bis(2-thienyl)ethene.

5. Photoswitching using array of photochromic molecules

In the previous section it was demonstrated that the exchange interaction between two nitronyl nitroxide radicals located at either end of a diarylethene was photoswitched reversibly by alternate irradiation with ultraviolet and visible light. The difference in the exchange interaction between the two switching states was more than 150-fold. ESR spectra can be used as a good tool for detecting small magnetic interaction changes in the molecular systems. In this section photoswitching of intramolecular magnetic interaction using a diarylethene dimer will be presented [30].

When a diarylethene dimer is used as a switching unit, there are three kinds of photochromic states: open–open (OO), closed–open (CO), and closed–closed (CC). From the analogy of an electric circuit, one may infer that the dimer has two switching units in series. Diarylethene dimer **10**, which has 28 carbon atoms between two nitronyl nitroxide radicals, was synthesized (Fig. 11). When the two radicals are separated by the 28 conjugated carbon atoms, the 5-line and 9-line spectra were clearly distinguishable upon irradiation. A *p*-phenylene spacer was introduced so that the cyclization reaction could occur at both diarylethene moieties. Bond alternation is discontinued at the open-ring moieties of **10(OO)** and **10(CO)**. As a result, the spins at either end of **10(OO)** and **10(CO)** cannot interact with each other. On the

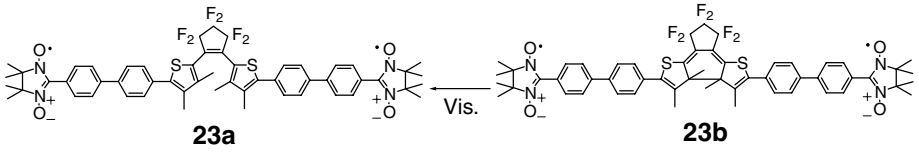

Fig. 10. Photoswitching using bis(2-thienyl)ethene.

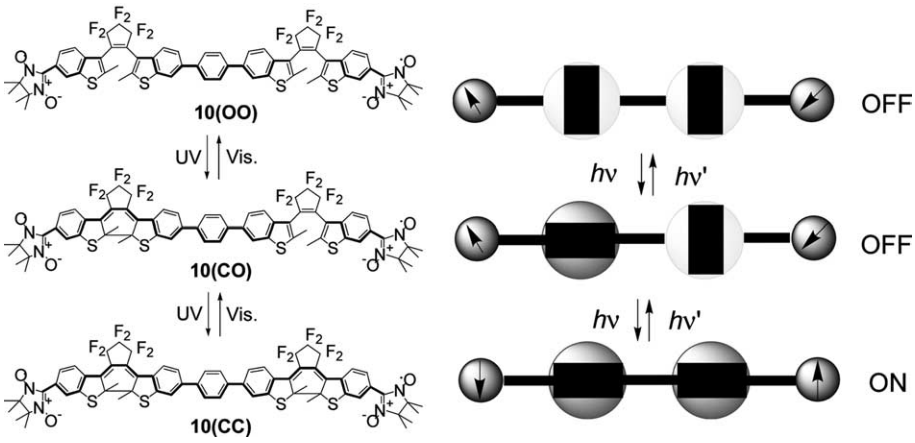

Fig. 11. Photochromic reaction and schematic illustration of diarylethene **10**.

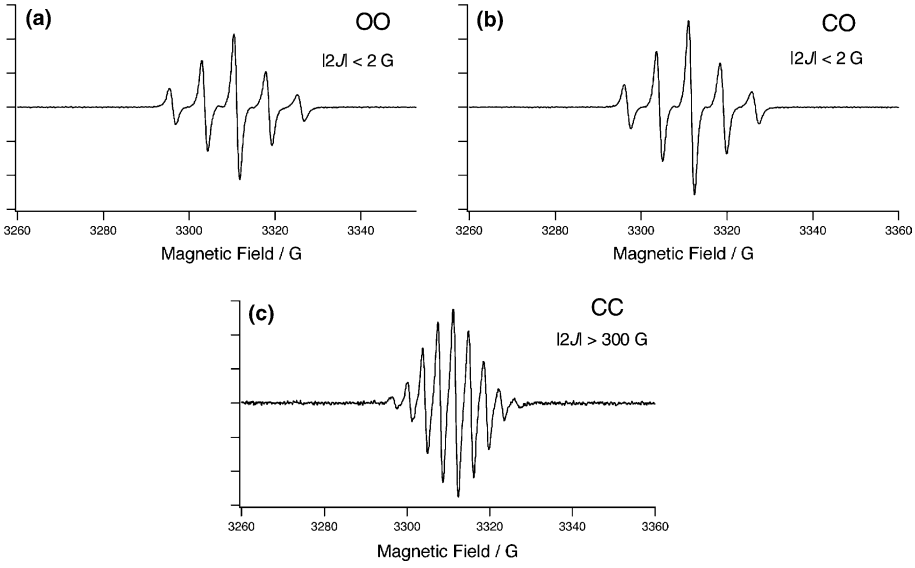

Fig. 12. ESR spectra of (a) **10(OO)**, (b) **10(CO)**, and (c) **10(CC)**.

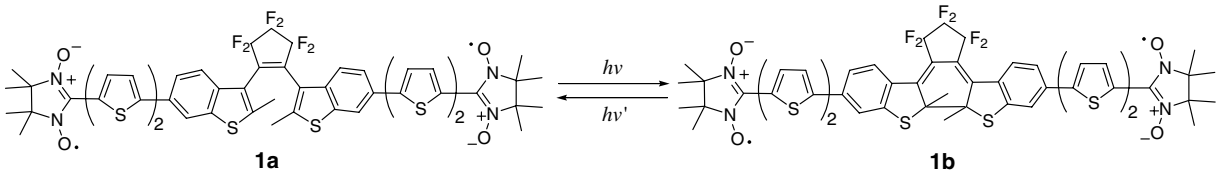
other hand, the π-system of **10(CC)** is delocalized throughout the molecule and the exchange interaction between the two radicals is expected to occur.

ESR spectra of isolated **10(OO)**, **10(CO)**, and **10(CC)** were measured in benzene at room temperature (Fig. 12). The spectra of **10(OO)** and **10(CO)** were 5-line spectra, suggesting that the exchange interaction between the two nitronyl nitroxide radicals is much weaker than the hyperfine coupling constant ($2J/k_B < 3 \times 10^{-3}$ K).

However, the spectrum of **10(CC)** was a clear 9-line spectrum, indicating that the exchange interaction between the two spins is much stronger than the hyperfine coupling constant ($2J/k_B > 0.04$ K). The result indicates that each diarylethene chromophore serves as a switching unit to control the magnetic interaction. The magnetic interaction between terminal nitronyl nitroxide radicals was controlled by the switching units in series.

6. Conclusions



Since the report of the quintet ground state of *m*-phenylenebis(phenylmethylene), the field of molecular magnetism has emerged. This inherently interdisciplinary field has developed by expanding its scope to organic, inorganic, physical chemistry, and solid state physics. Starting from some basic considerations of the interaction mechanism, several aspects of the intramolecular magnetic interaction has been overviewed. The difference between the disjoint and non-disjoint biradicals brought to fruition the realization of the reversible photoswitching system. The photochromism of diarylethene is suitable for the switching system. This system has the possibility to be applied to the molecular-scale information processing system [31].

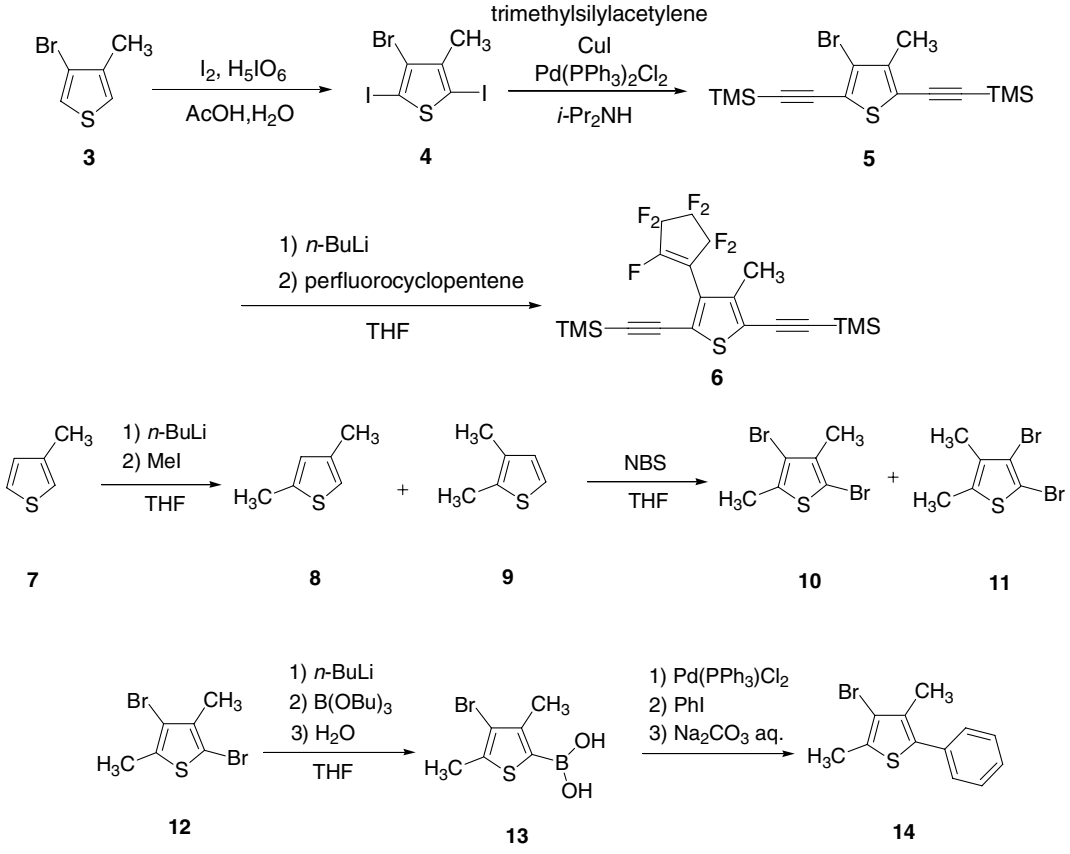
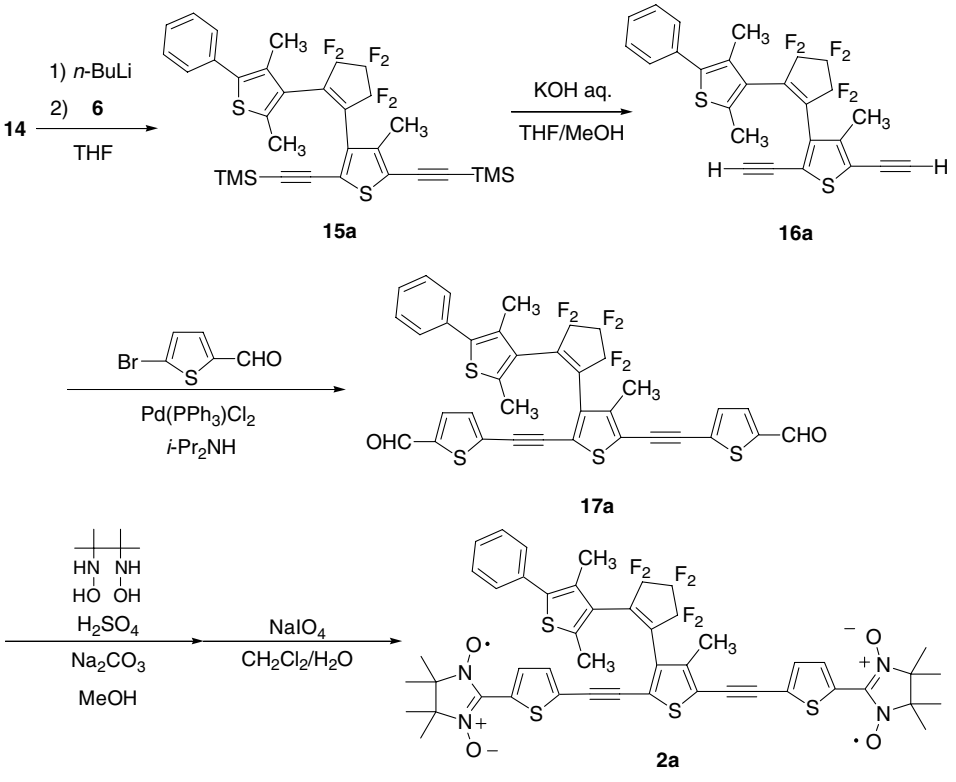
Scheme 1. Photochromism of diarylethene possessing long π-conjugated chains.

Scheme 2. Photochromic reaction of diarylethene **2** which has extended π-conjugated chain at the 2,5-position of the thiophene unit.



undergo photochromic reaction. In the open-ring isomer, two nitronyl nitroxide radicals are connected by the π-conjugated chain. When the open-ring isomer undergoes photocyclization upon irradiation with UV light, π-conjugated chain is disconnected at the 2-position of the thiophene ring and the intramolecular magnetic interaction may be suppressed. In other words, the open-ring isomer is in the ON state and the closed-ring isomer is in the OFF state.

In the open-ring isomer, the thiophene ring keeps its structure, so the π-conjugated chain is not perturbed by the introduction of the photochromic unit. In the closed-ring isomer, the hybridization of the carbon atom at the 2-position of the thiophene ring change from sp^2 to sp^3. The π-system is disconnected in this form (Scheme 2).



2.2. Synthesis of diarylethene diradical

In this study, we use a bis(ethynyl)-substituted diarylethene as a core component of the diradical. Thienylene–ethynylene unit was introduced because this unit is a building block of the π-conjugated polymers or oligomers [5]. Synthesis of **2a** was performed according to Schemes 3 and 4. Syntheses of thiophene units **6** and **14** were performed according to Scheme 3 [2]. A thiophene unit with extended π-conjugated chain, **5**, was prepared from 3-bromo-4-methylthiophene by two steps. Iodination of 3-bromo-4-methylthiophene **3** by iodine and orthoperiodic acid in acetic acid and water (3:2) gave 3-bromo-1,5-diiodo-4-methylthiophene **4** (96% yield). 3-Bromo-4-methyl-2,5-bis(trimethylsilylethynyl)thiophene **5** was given by Sonogashira coupling reaction of trimethylsilylacetylene with diiodothiophene **4** at the 2,5-position of thiophene ring (40%). Another unit, **14**, was prepared from 3-bromo-4-methylthiophene in three steps. Methylation of 3-methylthiophene **7** gave 2,4-dimethylthiophene **8** and 2,3-dimethylthiophene **9** as a mixture (85%). Bromination of the mixture of **8** and **9** by *N*-bromosuccinimide in THF gave 2,4-dibromo-3,5-dimethylthiophene **10** and 2,3-dibromo-4,5-dimethylthiophene **11** in 90% yield. Compounds **10** and **11** can be separated easily by column chromatography(eluent: *n*-hexane). 3-Bromo-2,5-dimethyl-4-phenylthiophene **14** was given by Suzuki coupling reaction of thienyl boronic acid **13** and iodobenzene (81%).

Unsymmetrical diarylethene **15a** was synthesized by the coupling of lithiated **14** with **6** (79%). Diarylethene protected by trimethylsilyl substituent **15a** can be easily desilylated by KOH aq. in THF/MeOH to give **16a** quantitatively. Sonogashira coupling with 2-bromothiophenecarboxaldehyde gave the dialdehyde **17a** (20%), which was converted in two steps into nitronyl nitroxide radical **2a** as a green amorphous solid by 9%. For all compounds, the structures were confirmed by NMR, elemental analysis and mass spectrometry.

Scheme 3. Syntheses of thiophene unit **6** and **14**.

Scheme 4. Synthesis of diarylethene diradical **2a**.

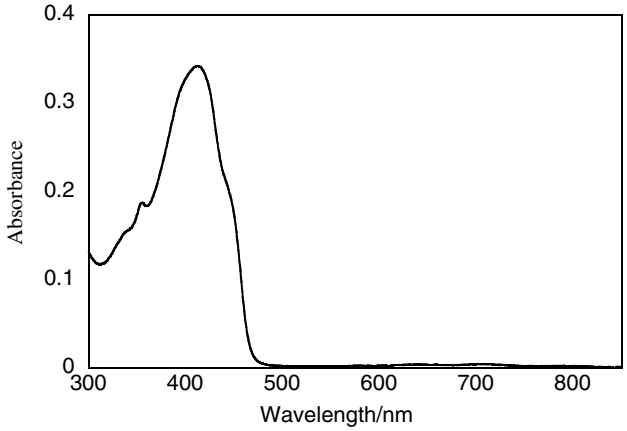


Fig. 1. Absorption spectrum of diradical **2a** (8.9×10^{-5} M ethyl acetate solution).

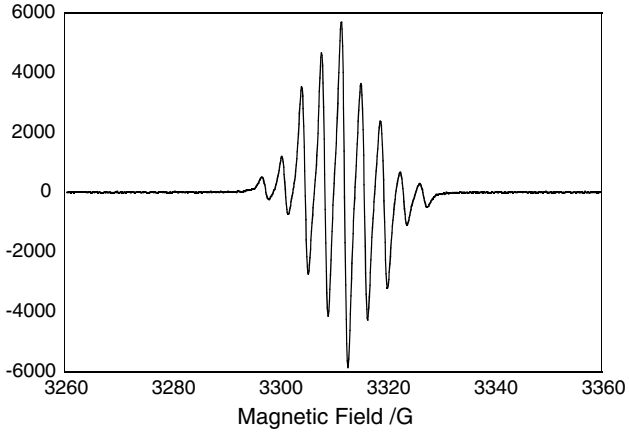

Fig. 2. ESR spectrum of diradical **2a** in toluene at room temperature (9.32 GHz). $g = 2.0065$, $a_N = 7.5$ G.

2.3. Absorption and ESR spectra of diradicals *2a*

Fig. 1 shows the absorption spectrum of **2a**. The small absorption around 550–650 nm is due to nitronyl nitroxide substituents [4c]. The absorption maximum of **2a** was located at 409 nm. A long π-conjugated chain composed of two nitronyl nitroxide radicals, two ethynyl groups, and three 2,5-thienyl groups contributes to the absorption band.

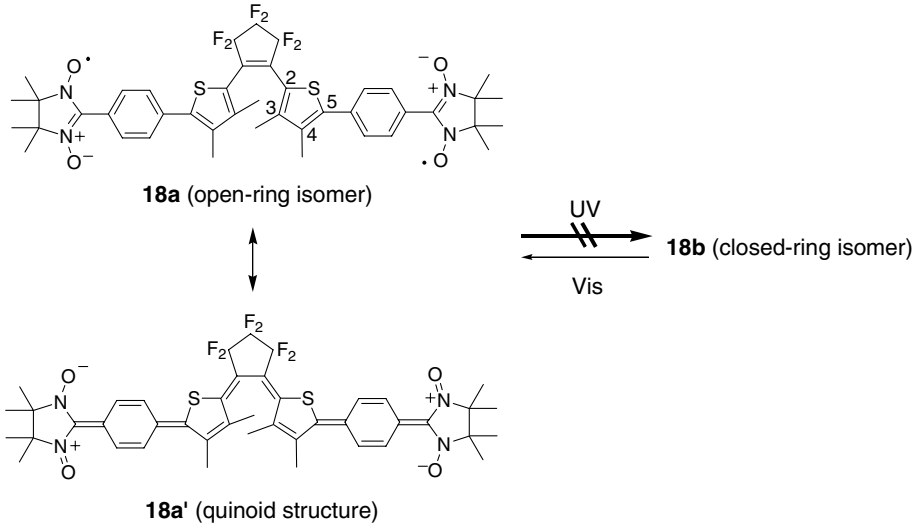

Fig. 2 shows the ESR spectrum observed for the open-ring isomer **2a** in toluene. **2a** has a nine-line spectrum, suggesting that the exchange interaction between the two nitronyl nitroxide radicals is larger than the hyperfine coupling constant ($0.04\ \mathrm{K} < |2J/k_B|$).

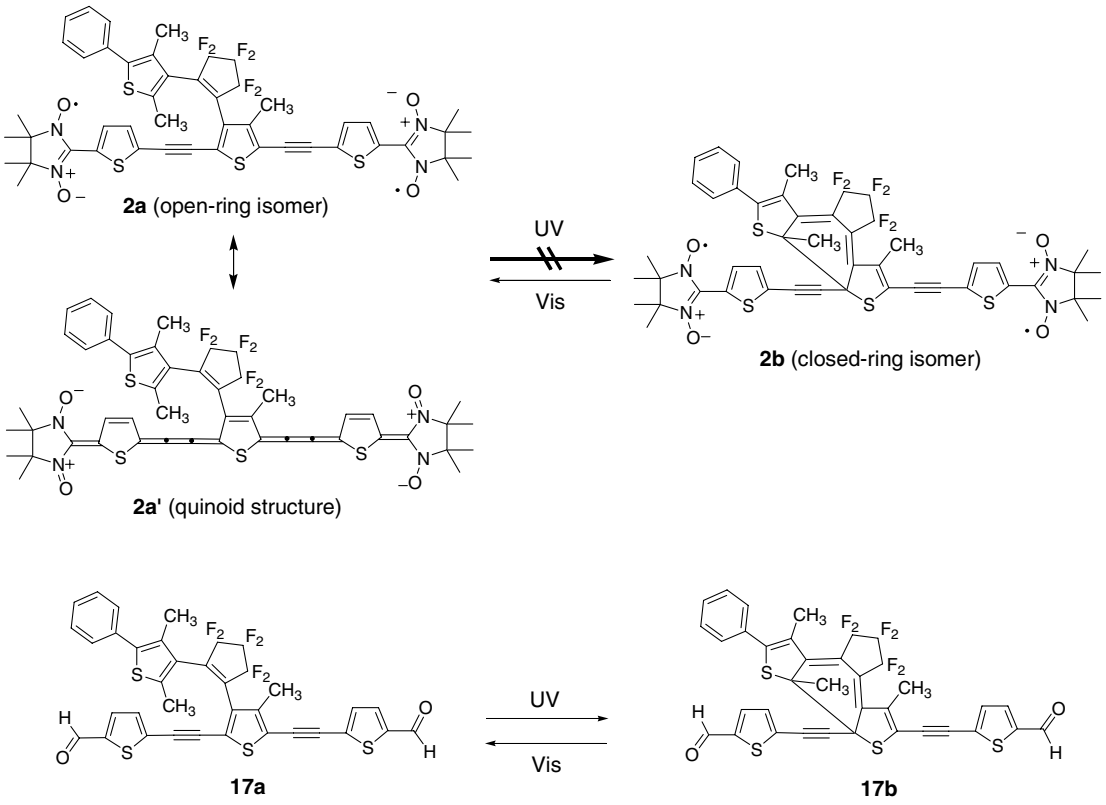
2.4. Photochemical behavior of diradical *2a*



2a did not show any absorption spectral change upon irradiation with 365 nm light. Bis(2-thienyl)ethene having two nitronyl nitroxide **18a** has been reported not to undergo photocyclization [4f]. As discussed in the report, the open-ring isomer of bis(2-thienyl)ethene diradical **18a** has a resonant quinoid structure. The contribution of the quinoid structure **18a′** stabilizes the open-ring isomer and suppresses photocyclic reaction (see Scheme 5).

2a has similar quinoid structure **2a′**, as shown in Scheme 6. Therefore, stabilization of the open-ring isomer **2a** due to the formation of the quinoid structure **2a′** is considered to suppress the photocyclization of diarylethene **2a** and the solution of **2a** did not change the color.

Precursors of **2a**, such as **15a**, **16a** and **17a**, showed photochromism upon irradiation with UV light. Fig. 3 shows the absorption spectral change of compound **17a**. Upon irradiation with 365 nm light, a new 614 nm band due to **17b** appeared. Upon irradiation with 578 nm light, the spectrum converted back to the original one. The difference in the structure of the end groups controlled the photochromic reactivity. Dialde-

Scheme 5. Nitronyl nitroxide **18a** [4] and the photoreaction mechanism.

Scheme 6. Possible photoreaction mechanism of diarylethene **2** and **17**.

hyde **17a** does not have a resonant quinoid structure, wile diradicals **2a** has the quinoid structure which suppressed the photochromic reaction.

3. Summary

A new diarylethene diradical having 4-methyl-2, 5-bis(thienylethynyl)-3-thienyl unit **2a** was synthesized. The ESR spectrum of **2a** showed nine lines, suggesting that there is a strong interaction in the π-conjugated chain. Diarylethene **2a** did not show any photochromic reactivity upon irradiation with UV light, because the resonant quinoid structure **2a**′ suppressed the photocyclic reaction. The photoreactivity of the diarylethenes were found to be largely affected by the structure of the end groups.

4. Experimental

4.1. General

^{1}H NMR spectra were recorded on Varian Gemini 200 instruments. UV–Vis spectra were recorded on a Hitachi U-3310 spectrophotometer. Mass spectra were obtained on JEOL JMS-GC mateII. Melting points were not corrected.

All reactions were monitored by thin-layer chromatography carried out on 0.2-mm E. Merck silica gel plates (60F-254). Column chromatography was performed on silica gel (Kanto, 63-210 mesh).

4.2. Synthetic procedure

4.2.1. 3-Bromo-2,5-diiodo-4-methylthiophene (*4*)

To a solution of 3-bromo-4-methylthiophene (5.0 g, 28.2 mmol) in acetic acid (30 mL) was added water (22 mL), conc. H_2SO_4 (5.2 mL), orthoperiodic acid (2.0 g, 8.8 mmol), and iodine (6.76 g, 26.6 mmol). The reaction mixture was refluxed for 3 h and cooled down to room temperature. After the addition of ice water, the reaction mixture was neutralized with sodium hydroxide, poured into water, extracted with ethyl acetate, washed with water, dried over magnesium sulfate, and concentrated. Column chromatography (silica, hexane:ethyl acetate = 5:1) gave compound **4** (11.19 g, 92%) as a colorless needle: m.p. 79.5–80.5 °C; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 2.34 (s, 3H). *Anal.* Calc. for $C_6H_3BrI_2S$: C, 14.00; H, 0.71. Found: C, 14.05; H, 0.70%.

4.2.2. 3-Bromo-4-methyl-2,5-bis(trimethylsilylethynyl)thiophene (*5*)

To a solution of diiodinated compound **7** (9.43 g, 22 mmol) in triethylamine (40 mL) was added

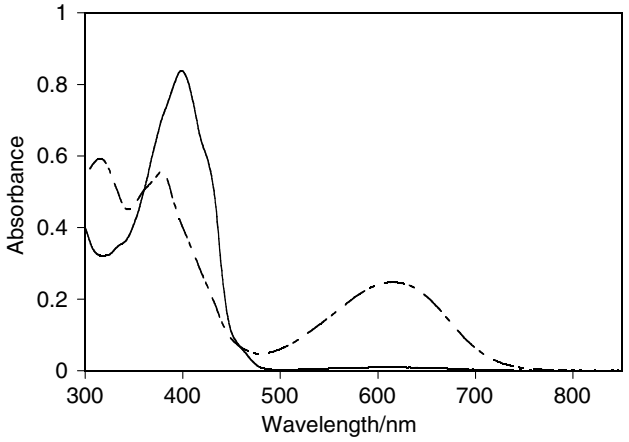


Fig. 3. Absorption spectra of diarylethene **17** (1.9×10^{-5} M ethyl acetate solution): open-ring isomer **17a** (——), in the photostationary state under irradiation with 365 nm light (– – –).

$Pd(Ph_3P)_2Cl_2$ (0.93 g, 1.3 mmol) and CuI (0.34 g, 1.8 mmol). A solution of trimethylsilylacetylene (4.32 g, 44 mmol) in triethylamine (440 mL) was added dropwise to the reaction mixture at room temperature, and stirred for 4 h at 60 °C. The reaction mixture was cooled down to room temperature, filtered out brown solid. The solution was poured into water, extracted with ether, washed with water, dried over magnesium sulfate, and concentrated. Column chromatography (silica, hexane) gave compound **5** (3.42 g, 42%) as a colorless needle: m.p. 104.5–106.5 °C; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 0.26 (s, 9H), 0.27 (s, 9H), 2.25 (s, 3H). *Anal.* Calc. for $C_{15}H_{21}BrSSi_2$: C, 48.76; H, 5.73. Found: C, 48.78; H, 5.73%.

*4.2.3. 1-[4-Methyl-2,5-bis(trimethylsilylethynyl)-3-thienyl]-perfluorocyclopentene (**6**)*

n-Butyllithium in hexane (1.6 N, 4.59 mL, 7.04 mmol) was added to a solution of bromothiophene derivative **5** (2.59 g, 7.0 mmol) in THF (200 mL) at −78 °C under argon atmosphere. After the mixture was stirred for 30 min, perfluorocyclopentene (4.58 g, 21 mmol) was added in one portion. The solution was allowed to warm to 10 °C with stirring. Water was added to the reaction mixture. The reaction mixture was extracted with ether, washed with water, dried over magnesium sulfate, and concentrated. Column chromatography (silica, hexane) gave compound **6** (2.75 g, 79%) as a colorless wax: ^{1}H NMR ($CDCl_3$, 200 MHz) δ 0.21 (s, 9H), 0.26 (s, 9H), 2.21 (s, 3H). *Anal.* Calc. for $C_{20}H_{21}F_7SSi_2$: C, 49.77; H, 4.39. Found: C, 50.07; H, 4.50%.

*4.2.4. 1-[2,4-Dimethyl-5-phenyl-3-thienyl]-2-[4-methyl-2,5-bis(trimethylsilylethynyl)-3-thienyl]-perfluorocyclopentene (**15a**)*

n-Butyllithium in hexane (1.6 N, 3.03 mL, 4.84 mmol) was added to a solution of 3-bromo-2,5-dimethyl-5-phenyl thiophene **14** (2.59 g, 4.4 mmol) in THF (25 mL) at −78 °C under argon atmosphere. After the mixture was stirred for 30 min, solution of monosubstituted perfluorocyclopentene **6** (1.93 g, 3.95 mmol) in THF (10 mL) was added dropwise. The solution was allowed to warm to 10 °C with stirring. Water was added to the reaction mixture. The reaction mixture was extracted with ether, washed with water, dried over magnesium sulfate, and concentrated. Column chromatography (silica, hexane:CH_2Cl_2 = 10:1) gave compound **15a** (2.35 g, 76%) as a colorless powder: m.p. 57.5–59.5 °C; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 0.09–0.15 (m, 18H), 1.95–2.52 (m, 9H), 7.24–7.44 (m, 5H). *Anal.* Calc. for $C_{32}H_{32}F_6S_2Si_2$: C, 59.05; H, 4.96. Found: C, 58.80; H, 4.99%.

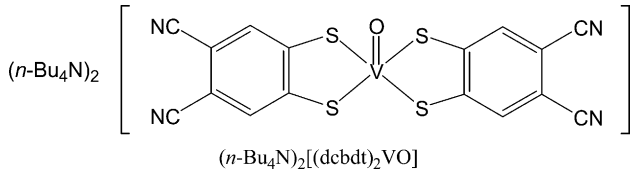
*4.2.5. 1-[2,5-Bis(5-formyl-2-thienylethynyl)-4-methyl-3-thienyl]-2-[2,4-dimethyl-5-phenyl-3-thienyl]-perfluorocyclopentene (**17a**)*

To a solution of diarylethene **15a** (651 mg, 1.0 mmol) in THF (20 mL) and methanol (10 mL) was added potassium hydroxide in water (20 wt%, 0.25 mL) with stirring. After the mixture was stirred for 30 min, the reaction mixture was extracted with ether, washed with water, dried over magnesium sulfate, and concentrated. Column chromatography (silica, hexane) gave desilylated compound **16a** (461 mg, 86%) as a dark brown wax.

A solution of desilylated compound **16a** (461 mg, 0.86 mmol) in diisopropylamine (20 mL) was added to solution of 2-bromo-5-thiophenecarboxaldehyde (172 mg, 0.9 mmol), $Pd(PPh_3)_2Cl_2$ (151 mg, 0.22 mmol) and copper iodide (41 mg, 0.22 mmol) in diisopropylamine (10 mL) at room temperature under argon atmosphere and then stirred for 5 h at 60 °C. The reaction mixture was cooled down to room temperature, filtered out brown solid. The solution was poured into water, extracted with ether, washed with water, dried over magnesium sulfate, and concentrated. Column chromatography (silica, hexane:ethyl acetate = 3:2) gave compound **17a** (129 g, 20%) as a dark green powder: m.p. 60.5–62.5 °C; ^{1}H NMR ($CDCl_3$, 200 MHz) δ 2.05–2.55 (m, 9H), 7.20–7.50 (m, 7H), 7.69 (d, J = 4.2 Hz, 2H), 9.89 (s, 2H). UV–Vis (AcOEt) $\lambda_{max}(\varepsilon)$ 399 (4.4×10^4) nm; FAB HRMS (*m*/*z*) $[M]^+$ Calc. for $C_{40}H_{20}F_6N_4O_2S_4$: 726.0250. Found: 726.0231.

*4.2.6. 1-[2,4-Dimethyl-5-phenyl-3-thienyl]-2-[4-methyl-2,5-bis(5-(1-oxyl-3-oxide-4,4,5,5-tetramethylimidazolin-2-yl)-thienylethynyl)-3-thienyl]hexafluorocyclopentene (**2a**)*

A solution of bisformylated derivative **17a** (129 mg, 0.18 mmol), 2,3-bis(hydroxyamino)-2,3-dimethylbutane sulfate (262 mg, 1.07 mmol), potassium carbonate (152 mg, 1.10 mmol) in dry methanol (10 mL) and benzene (5 mL) was refluxed for 18 h. The reaction mixture was poured into water, extracted with ethyl acetate, washed with water, dried over magnesium sulfate, and concentrated to give tetrahydroxylamine as an orange solid. Purification was not performed.



To a solution of tetrahydroxylamine in dichloromethane (10 mL) was added a solution of sodium periodate (34 mg, 0.16 mmol) in water (20 mL). The mixture was stirred for 30 min in the open air. The organic layer was separated, washed with water, dried over magnesium sulfate, and concentrated. Purification was performed by column chromatography (silica, CH_2Cl_2:ethyl acetate = 100:1). **2a** was obtained as a green amorphous solid (15 mg, 9%): m.p. 98.5–100.5 °C; EPR (toluene) 1:4:10:16:19:16:10:4:1, nine lines, $g = 2.0065$, $a_N = 7.5$ G. UV–Vis (AcOEt) $\lambda_{max}(\varepsilon)$ 358 (2.5×10^4), 409 (3.9×10^4) nm; FAB HRMS (*m*/*z*) $[M + 2]^+$ Calc. for $C_{48}H_{44}F_6N_4O_4S_4$: 982.2150. Found: 982.2166.

$(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$

Scheme 1.

Here we report the synthesis, crystal structure, magnetic susceptibility, ESR spectrum and its theoretical investigation of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$ (see Scheme 1).

2. Experimental

2.1. Synthesis of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$

4,5-Dicyanobenzene-1,2-dithiol (H_2dcbdt) (135.0 mg, 0.702 mmol) prepared in accordance with literature [10] was dissolved in 5 ml in methanol solution of NaOMe (83.4 mg, 1.54 mmol). To this solution a solution of anhydrous VCl_3 (55.2 mg, 0.35 mmol) in 5 ml of tetrahydrofuran was added and this solution was exposed to air. After exposure for 30 min n-Bu_4NBr (905.2 mg, 2.81 mmol) was added. The dropwise addition of 20 ml of water caused precipitation of the product as light brown powder. This precipitate were recrystallized from acetone–i-PrOH (1:2) and dried in air to give 283.5 mg (87%) of product. The composition of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$ was determined by X-ray structure analysis.

2.2. The X-ray crystallographic study of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$

The X-ray diffraction data were collected at 90 K on a Bruker ASX APEX CCD area detector with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). Data collection and cell refinement were performed on Bruker SMART and Bruker SAINT programs [15,16]. Crystallographic data are gathered in Table 1.

The structure was solved by direct methods (SHELXS-97) [17] and refined on F_o^2 with full-matrix least squares analysis. The calculations were carried out with Bruker SHELXTL crystallographic package [18]. The final cycle of least-square refinement on F_o^2 for 5802 data and 283 parameters converged to $wR_2(F_o^2) = 0.1081$ for all data and to $R = 0.0465$ for 4470 data with $I \geqslant 2\sigma(F^2)$. H-atom positions were calculated at C–H distances of 0.95 Å for benzene rings and 0.99 Å for alkyl groups and they were included in the final calculations but not refined. The drawings of the molecular structures were produced using ORTEP-III [19]. The atomic scattering factors were taken from International Tables for X-ray Crystallography [20].

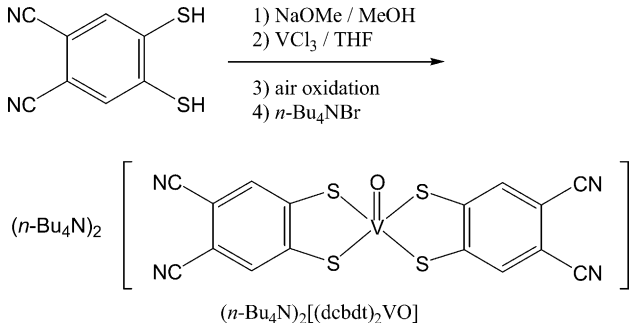
2.3. ESR and magnetic susceptibility measurement



The powder ESR spectrum of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$ was recorded by using Bruker 300E spectrometer at room temperature.

Magnetic susceptibilities (χ_{obs}) were measured in the temperature range 4–300 K at applied field of 500 Oe using SQUID magnetometer (MPMS XL, Quantum Design). The paramagnetic susceptibility (χ_p) was obtained by subtracting the diamagnetic contributions, calculated using Pascal's constant, from χ_{obs}.

3. Result and discussion

3.1. Synthesis of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$

The H_2dcbdt was synthesized in accordance with the literature [10]. The $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$ was obtained by the reaction of VCl_3 with Na_2dcbdt. VCl_3 in a THF solution was added to a MeOH solution containing 2 equiv. of Na_2dcbdt. After the solution was stirred for

Scheme 2.

30 min and exposed to air for 30 min at room temperature, to the obtained deep purple solution water was added to give light brown powder. Recrystallization from acetone–*i*-PrOH resulted the isolation of light brown platelet crystals in 87% yield (see Scheme 2).

U_{eq} is defined as one third of the trace of the orthogonalized U_{ij} tensor.

3.2. Molecular and crystal structure of $(n\text{-Bu}_4\text{N})_2[(\text{dcbdt})_2\text{VO}]$

Final atomic coordinates for the non-hydrogen atoms are in Table 2.

The asymmetric unit contains one *n*-Bu_4N entity and half molecule of $[(\text{dcbdt})_2\text{VO}]$. The structure of $[(\text{dcbdt})_2\text{VO}]^{2-}$ is depicted in Fig. 1.

The selected bond lengths for the $[(\text{dcbdt})_2\text{VO}]^{2-}$ ion are in Table 3.

The vanadium atom is in a square-pyramidal coordination environment, the basal positions being occupied by sulfur atoms (S1, S4A, S1*, S4A* or S1, S4B, S1*, S4B*) of two bidentate dcbdt^{2-} ligands, and possesses idealized C_{2v} symmetry which disorders the VO group about two positions with 66% and 34% occupancies. The V(1A)–O(2A) distance [1.628(5) Å] is consistent with the presence of a vanadium–oxygen double bond (i.e., the vanadyl $V{=}O^{2+}$ moiety) but is slightly longer than that normally found in this geometry ($\leqslant$1.60 Å) in the absence of a sixth ligand *trans* to the oxygen [21]. The V–S bond lengths, V(1A)–S(1) 2.3772(6) Å, V(1A)–S(4A) 2.3755(8) Å, V(1B)–S(1) 2.3731(7) Å and V(1B)– S(4B) 2.3742(9) Å, are in the typical range, 2.36–2.38 Å of other bis(dithiolato) oxovanadium complexes [22,23].

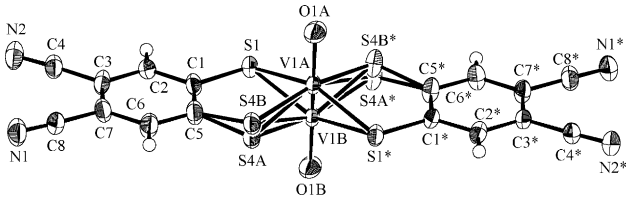

Fig. 1. Atomic numbering scheme for $[(\text{dcbdt})_2\text{VO}]$ anion of $(n\text{-Bu}_4\text{N})_2[(\text{dcbdt})_2\text{VO}]$.

C(4)–N(2)	1.145(3)

Figs. 2(a) and (b) show projections of the crystal structure down to the *ac* and *ab* planes.

The structure consists of layers of $[(dcbdt)_2VO]^{2-}$ ions in the *ac* plane alternating with layers of *n*-Bu_4N^+ ions along the *b* direction. $[(dcbdt)_2VO]^{2-}$ ions are separated by *n*-Bu_4N^+ ions layer preventing any short anion-anion interactions. Some van der Waals contacts are observed between $[(dcbdt)_2VO]^{2-}$ ions and *n*-Bu_4N^+ ions. Indeed interatomic distances rather shorter than the sum of van der Waals radii of S···H (2.90 Å), C···H (2.79 Å) and N···H (2.63 Å) are observed between sulfur, carbon and nitrogen atoms of dcbdt ligands and hydrogen atoms of *n*-Bu_4N^+ ions [24].

3.3. Powder ESR spectrum of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$ and its theoretical analysis

Fig. 3(a) shows the powder ESR derivative spectrum of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$ measured at room temperature with a microwave frequency $\nu = 9.372844$ GHz. The spectrum consists of eight hyperfine structure lines due to the interaction of the unpaired electron with the ^{51}V nuclear spin ($I = 7/2$, 100%) as will be described below. The isotropic *g* value and hyperfine coupling constant $A(^{51}V)$ are $g = 1.990$ and $|A| = 84.6 \times 10^{-4}\ cm^{-1}$. These data indicate the valence state of V atom is IV.

We theoretically analyze the observed ESR derivative spectrum using a simple model of an electron spin **S** with

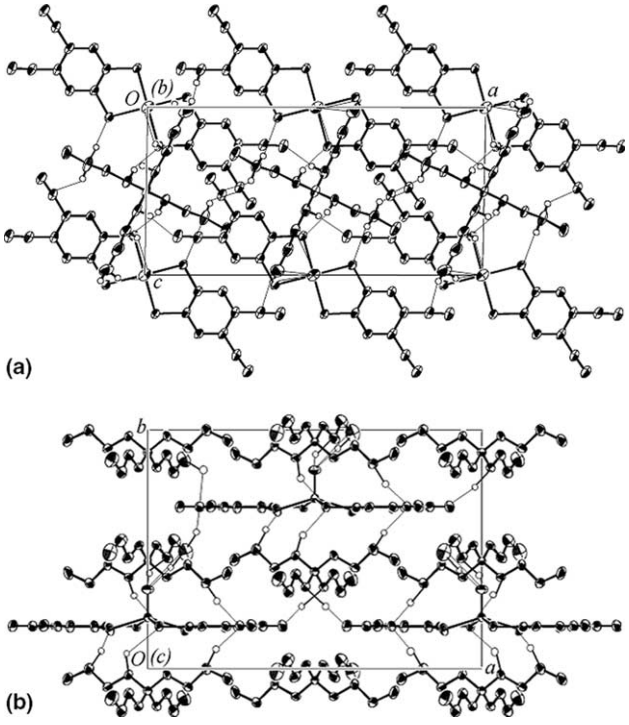

Fig. 2. Crystal structure of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$: (a) projection down the *ac* plane and (b) projection down the *ab* plane. In (a) and (b), thin solid lines show van der Waals contacts.

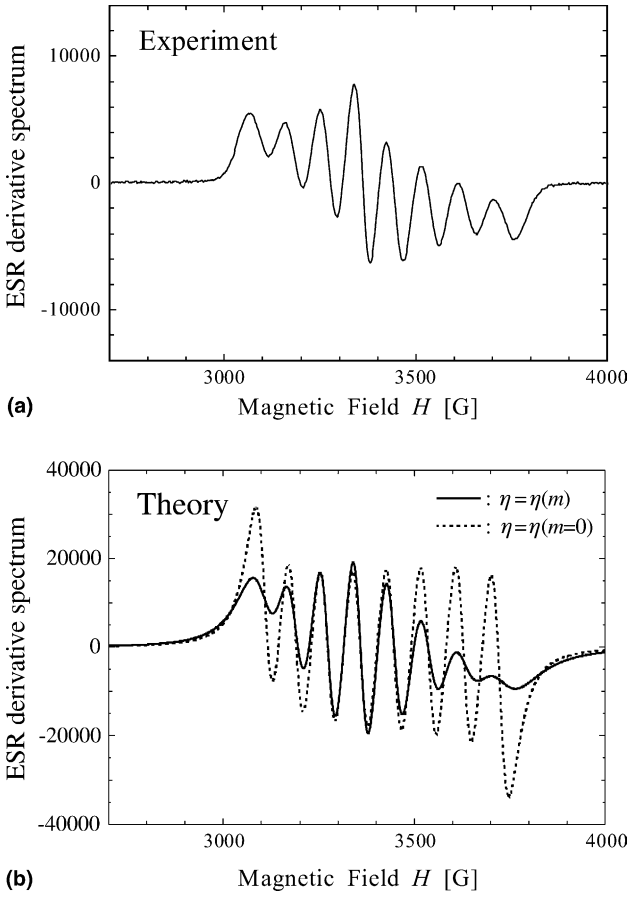

Fig. 3. ESR derivative spectrum vs. magnetic field *H*. (a) Experimental spectrum and (b) calculated spectrum, $dI(H)/dH$. In (b), spectra with $\eta(m)$ and $\eta(m = 0)$ are shown by the solid curve and the dotted one, respectively.

$S = 1/2$ coupled to a nuclear spin **I** with $I = I$. The Hamiltonian is given by,

$$\hat{H} = hS_z - h'S_z + A\mathbf{I}\cdot\mathbf{S}, \tag{1}$$

with $h = g\mu_B H$, and $h' = g_N\mu_N H$, where g (g_N) is the electron *g*-factor (the nuclear *g*-factor), $\mu_B(\mu_N)$ is the Bohr magneton (the nuclear magneton), and *A* is the hyperfine coupling constant. The first, second, and third terms represent the Zeeman interaction for **S**, that for **I**, and the hyperfine interaction, respectively. When the base of the Hamiltonian is represented by $|M,m\rangle$, which is a state with $S_z = M$ and $I_z = m$, eigenvalues and eigenstates within the second order perturbation are obtained as $E_{M,m}$ and $|M,m)$, respectively:

$$E_{-1/2,m} = -\varepsilon(m) - \zeta(m), \tag{2}$$

$$|-1/2,m) = C_1(m)|-1/2,m\rangle, \tag{3}$$

for $S_z = -1/2$ and $I_z = m$, and

$$E_{1/2,m} = \varepsilon(m) - \zeta(m), \tag{4}$$

$$|1/2,m) = C_2(m)|1/2,m\rangle, \tag{5}$$

for $S_z = 1/2$ and $I_z = m$, with

$$\varepsilon(m) = \frac{h + Am}{2} + \frac{A^2[I(I+1) - m^2]}{4(h+h')}, \tag{6}$$

$$\zeta(m) = \left[h' + \frac{A^2}{4(h+h')}\right]m, \tag{7}$$

$$C_1(m) = 1 - \frac{A\sqrt{I(I+1) - m(m-1)}}{2(h+h')} \times \left[1 - \frac{A(2m-1)}{2(h+h')} + \frac{A\sqrt{I(I+1) - m(m-1)}}{4(h+h')}\right], \tag{8}$$

$$C_2(m) = 1 + \frac{A\sqrt{I(I+1) - m(m+1)}}{2(h+h')} \times \left[1 - \frac{A(2m+1)}{2(h+h')} - \frac{A\sqrt{I(I+1) - m(m+1)}}{4(h+h')}\right]. \tag{9}$$

Within the linear response theory [25], we obtain an analytic expression of the intensity, which corresponds to an imaginary part of the dynamical susceptibility [26], as follows:

$$I(H) = \frac{1}{\sum_{m'} \exp[\beta\zeta(m')]\cosh[\beta\varepsilon(m')]} \times \sum_m \frac{\exp[\beta\zeta(m)]\sinh[\beta\varepsilon(m)][C_1(m)C_2(m)]^2\eta}{[h\nu - 2\varepsilon(m)]^2 + \eta^2}, \tag{10}$$

with $\beta = 1/(k_B T)$, where η is the infinitesimal quantity. Note here that the transition is allowed only for $|-1/2,m) \rightarrow |1/2,m)$.

The above model is now applied to the present system. We use $I = 7/2$, $\nu = 9.372844$ GHz, $T = 300$ K, and $g_N = 1.47$ [23]. Furthermore, we choose $A = -79.44 \times 10^{-4}$ cm^{-1}, $g = 1.97$, and $\eta = 40.73 \times 10^{-4}$ cm^{-1} so as to fit the peak position of experimental results. In Fig. 3(b), the calculated derivative spectrum $dI(H)/dH$ is shown by the dotted curve. The eight peaks appear reflecting the transition of $|-1/2,m) \rightarrow |1/2,m)$ for $m = -7/2, -5/2, -3/2, \ldots, 7/2$. Based on the agreement of the number of peaks between the calculated spectrum and the experimental one, we understand that this transition was actually observed in the experiment. On the other hand, heights and widths of peaks are largely different from the experimental ones. We therefore try to reproduce them partially well by assuming η to be $\eta(m) = \eta(1 + am + bm^2)$, where a and b are considered to arise from the anisotropy of g and A [27]. When $a = 0.1$ and $b = 0.075$ are chosen, the calculated spectrum agrees fairly well with the experimental one [see solid curve of Fig. 3(b)].

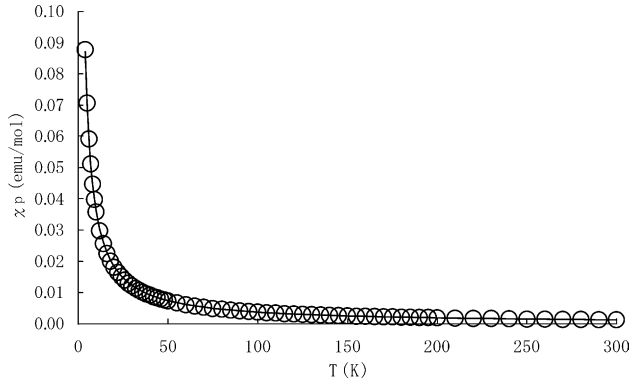

Fig. 4. Temperature dependence of paramagnetic susceptibility (χ_p) for $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$. The solid lines was reproduced by choosing appropriate values of the C and θ values in the equation $\chi_p(T) = C/(T - \theta)$.

3.4. Magnetic susceptibility of $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$

The temperature dependence of the paramagnetic susceptibility (χ_p) was investigated in the temperature range 5–300 K for $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$ and result is shown in Fig. 4.

The temperature dependence of χ_p obeyed a Curie-Weiss law, $\chi_p = C/(T - \theta)$, where C is the Curie constant and θ the Weiss temperature. By fitting C and θ values in $\chi_p = C/(T - \theta)$ the observed χ_p versus T behavior was well reproduced for the complex using the values of $C = 0.372$ emu K mol^{-1} and $\theta = -0.371$ K. The obtained C value correspond to the value (0.373 emu K mol^{-1}) that calculated by the equation of $C = N\mu_B^2 g^2 S(S+1)/3k_B$, where N is Avogadro number, μ_B the Bohr magneton, k_B Boltzmann constant, S the spin magnetic quantum number ($S = 1/2$ for V(IV)), and g an average g factor of the V(IV) spin (1.99 from ESR measurement of the complex), respectively. The C and θ values obtained suggest that a complete $S = 1/2$ spin resides on oxovanadium complex and that the intermolecular spin–spin interaction is very weakly antiferromagnetic. Such spin–spin interaction can be well understood from its crystal structures, in which there is no direct contact between the neighboring oxovanadium complex anions.

4. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 273084 for $(n\text{-}Bu_4N)_2[(dcbdt)_2VO]$. Copies of this information may be obtained free of charge on application to The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

Acknowledgements

We thank Dr. Kenji Yoza, Bruker AXS for the crystal structure analysis. This work was partially supported by a grant-in-aid for scientific research (No. 16750114) from JSPS and Joint Studies Program with Professor Katsuya Inoue of the Institute for Molecular Science.

Metal–complex compounds are constructed with metal ions and organic ligands, and various high-Tc ferromagnets and ferrimagnets have been reported in Prussian Blue type of system as follows: $CsMn^{II}[Cr^{III}(CN)_6]$ (ferrimagnet, Tc = 90 K) [16], $CsNi^{II}[Cr^{III}(CN)_6]$ (ferromagnet, Tc = 90 K) [17], $Cs_2Mn^{II}[V^{II}(CN)_6]$ (ferrimagnet, Tc = 125 K) [18], $Cs_{0.75}Cr_{1.125}^{II}[Cr^{III}(CN)_6]$ (ferrimagnet, Tc = 190 K) [19], $Cr_3^{II}[Cr^{III}(CN)_6]_2 \cdot 10H_2O$ (ferrimagnet, Tc = 240 K) [19], and $V[Cr(CN)_6]_{0.86} \cdot 2.8H_2O$ (ferrimagnet, Tc = 315 K) [20]. They possess large spontaneous magnetization due to the high spin state. However, their crystal structures have not been solved yet, and the correlation between magnetic property and crystal structure has been unknown.

Dimetallic ferrimagnet $[Mn(L)]_3[Cr(CN)_6]_2 \cdot n_2O$ [21,22] series have an eminent transition temperature of about 70 K in the structurally characterized molecule-based magnets; (1) L = en (ethylenediamine), n = 4, Tc = 69 K, (2) L = glya (glycine amide), n = 2.5, Tc = 71 K, (3) no L, n = 12, Tc = 63 K. This dimetallic system has an ideal three-dimensional network, extended by Cr^{III}–CN–Mn^{II} linkage, and the antiferromagnetic interaction between Cr^{III} ion and Mn^{II} one results in the appearance of huge spontaneous moment for S = 9/2. The crystal structure with the antiferromagnetic molecule stacking is assumed to be generally stable under external stress. Thus, we have focused our attention on this series as a target of material control for high Tc by using pressure, and have investigated the pressure effects on $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$ firstly.

2. Experimental

The preparation of $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$ has been described elsewhere [21]. Fig. 1 shows a cubic picture of the unit cell. The crystal structure belongs to a monoclinic system of space group $C2/c$ (#15) with lattice parameters a = 24.505(7) Å, b = 11.323(4) Å, c = 14.810(4) Å, β = 120.69(2)° and V = 3533(1) Å^3. Three-dimensional network is constructed by the alternative array of $[Cr(CN)_6]^{3-}$ and $[Mn(en)]^{2+}$ ions. The network comprises defective cubes with three Cr atoms, three Mn(1) atoms, and one Mn(2) atom at the seven corners and eight Cr–CN–Mn edges. The Mn–N–C bond angle ranges between 145.7(3)° and 167.4(3)°. The shortest Cr···Mn(1), Cr···Mn(2), and Mn(1)···Mn(2) distances are 5.1553(8), 5.2842(8), and 6.659(1) Å, respectively. The water molecules reside in cavities of the network and form hydrogen bonds with the cyano nitrogen atoms as O–H···N.

The magnetic measurements have been performed in the pressure region up to P = 4.7 GPa and the temperature range from 5 to 200 K. Pressure has been attained using a diamond anvil cell (DAC) [23], which can be inserted into a superconducting quantum interference device (SQUID) magnetometer (Quantum Design, MPMS-5S). The tip diameter of diamond anvils was 0.5 mm. In the center of the gaskets made of Cu–Be, the sample space with diameter 0.2 mm was holed. A very small quantity of sample and some pieces of ruby were held with a transmitting medium into the sample space. The value of pressure was determined by the measurement of the shift of R1 ruby fluorescence at room temperature [24]. The pressure-increase by cooling down to liquid-helium temperature has been estimated to be at most about 14% of the pressure value at room temperature [23]. The magnetic measurements have been done under magnetic field H = 0.5 T, which is enough to saturate the magnetic moment in the ordered state of $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$.

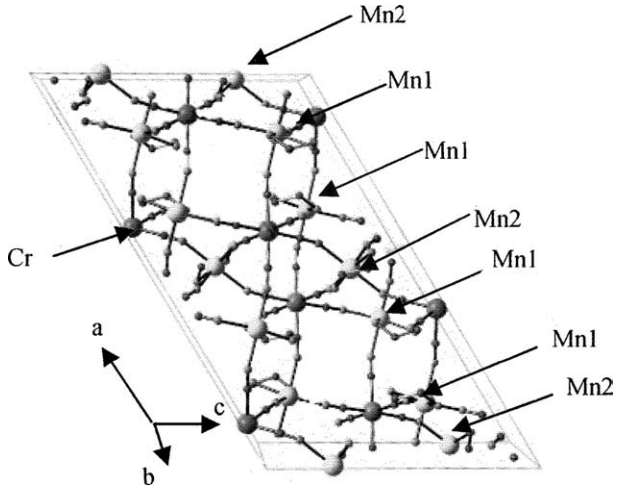

Fig. 1. Projection of the 3D network structure of $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$ (en and H_2O are omitted).

3. Experimental results and discussion

Fig. 2 shows temperature dependence of the magnetization for $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$ at H = 0.5 T in the pressure region up to 4.7 GPa. The accurate weight of the used sample could not be measured, but it is estimated to be about 4 μg from the value of magnetization at low temperature. Therefore, M in the vertical axis represents the actual measurement value. At ambient pressure, M rapidly increases below 80 K. For the sake of convenience, here we define Tc as the temperature below which M rapidly starts to increase. Fig. 3 shows pressure dependence of Tc for $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$. With increasing pressure, the development of magnetization shifts toward higher temperatures. For $P \leqq 3.0$ GPa, Tc linearly increases against pressure as dTc/dP = +15.3 K/GPa, which is smaller than dTc/dP = +21.9 K/GPa of the similar antiferromagnetic system, the genuine organic radial week-ferromagnet, p-NC · C_6F_4 · CNSSN

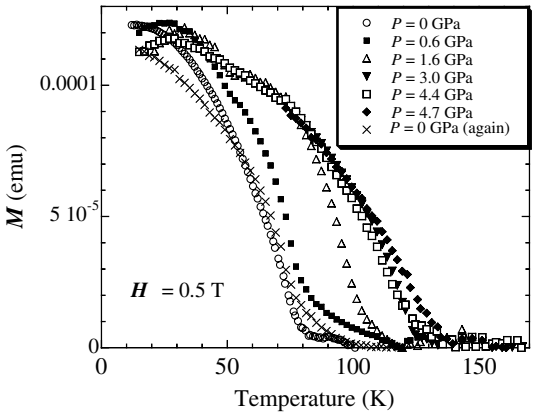

Fig. 2. Pressure dependence of magnetization (M) for $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$ in the pressure region up to 4.7 GPa. The measurement has been done under the external magnetic field of $H = 0.5$ T.

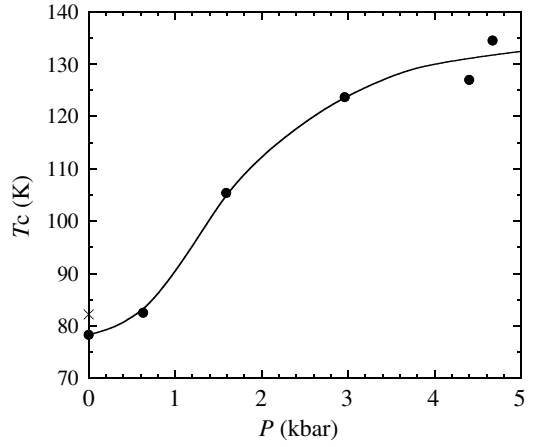

Fig. 3. Pressure dependence of the transition temperature (Tc) for $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$. The value of Tc after releasing pressure of 4.7 GPa is marked with a cross.

[6]. The enhancement of Tc tends to saturate for $P \geqq 3.0$ GPa. Finally at $P = 4.7$ GPa, Tc reaches 136 K, which would be a record of Tc in the structurally characterized molecule-based magnet system. As for the state after releasing pressure of 4.7 GPa, the value of Tc is nearly consistent with that of the initial state as shown in Fig. 2. On the other hand, the amount of saturated magnetization hardly changes in the considered pressure region. To sum up, it is assumed that the antiferromagnetic state of $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$ does not have high sensitivity, comparing to the organic system, and remains stable keeping elasticity under pressure. The latter characteristic is desirable for the artificial material control using pressure.

Here, we discuss the mechanism for the pressure dependence of Tc. The enhancement of Tc must be triggered by the enhancement of intermolecular interaction due to the increase of orbital-overlapping. The linearity of dTc/dP is not maintained for $P \geqq 3.0$ GPa, where the intermolecular shrinkage might be restricted, due to the effect of van der Waals force. This makes us expect that any change in the structural data appears at around $P = 3.0$ GPa. The structural analysis experiment under pressure is currently underway. Here we stress that the saturated moment hardly changes in the pressure region up to $P = 4.7$ GPa. The result suggests that the interaction network is not destroyed in the considered pressure region. In fact, there is reproducibility of magnetic properties after leasing pressure of 4.7 GPa, and it can be concluded that the crystal structure of this compound is strong against huge external stress. In the recent powdered structural analysis experiment, remarkable broadening of diffraction peak is observed for $P > 3.0$ GPa, where the sign of transformation to an amorphous state appears. We suppose that the state with Tc of 136 K at $P = 4.7$ GPa has some structural defect, but the interaction network itself survives.

4. Conclusion

We have studied the pressure effects on the dimetallic ferrimagnet $[Mn(en)]_3[Cr(CN)_6]_2 \cdot 4H_2O$ through the magnetic measurements in the pressure region up to $P = 4.7$ GPa. This ferrimagnet originally has an eminent transition temperature Tc of 69 K at ambient pressure. The artificial control by applying hydrostatic pressure makes Tc largely increase up to 136 K at $P = 4.7$ GPa, which would be a record of Tc in the structurally characterized molecule-based magnet system. As for the saturated moment, the amount hardly changes for $P \leqq 4.7$ GPa. There might remain large possibility in the material control by using the external stress under the further pressure. The powdered structural analysis experiments are being performed. The Rietveld structural analysis would clear the mechanism for the pressure-induced enhancement of Tc.

intermolecular linkages through S···S or S···N interatomic contacts. In some cyclic thiazyl, ferromagnetic and weak-ferromagnetic ordered states with high transition temperature above 1.0 K have been found in such compounds as *p*-O_2N–C_6F_4–CNSSN (T_C = 1.3 K) [16] and *p*-NC–C_6F_4–CNSSN (T_N = 35.5 K) [17,18]. Thus, intermolecular linkages through the S···S or S···N interatomic contacts may allow strong intermolecular magnetic interactions to take place. In the pressurized sulfur-based system, there might be a risk of collapse of the ferromagnetic molecular stacking, but a remarkable enlargement of molecular overlapping should occur. In any case, as a method of searching high-T_C magnets, pressure experiments must constitute a very attractive physical approach. In this study, pressure effects on the organic ferromagnet, γ-BBDTA · $GaCl_4$, have been investigated through ac magnetic susceptibility measurements in the pressure region up to 16.2 kbar.

2. Experimental

The thiazyl organic crystal, BBDTA · $GaCl_4$, was prepared according to the procedure described elsewhere [8]. The molecular structure is shown in Fig. 1. The γ-phase crystallizes in the monoclinic system *C*2/*c* with a = 11.260(5) Å, b = 10.851(6) Å, c = 13.209(7) Å, β = 114.853(2)° and V = 1464.44(13)Å^3. On the other hand, the diamagnetic α- and β-phases crystallize in the triclinic system.

Measurements of the ac magnetic susceptibilities, χ_{ac}, were performed with the ac field of amplitude 2 Oe (peak-to-peak) and frequency 100 Hz using a superconducting quantum interference device (SQUID) magnetometer (Quantum Design MPMS-5S). Pressure was attained using a piston-cylinder type of pressure cell (Kyowa-Seisakusho Co. Ltd., CR-PSC-KY05-1) in the region up to 16.2 kbar. The powdered sample of the γ-phase of BBDTA · $GaCl_4$ was held into a Teflon cell, which prevented leakage of pressure, with a pressure transmitting medium, Apienzon-J grease, and a piece of superconducting metal, Sn. The pressure value at liquid helium temperature was estimated from the shift of the superconducting transition temperature of Sn [19]. A series of ac magnetic measurements have been performed through three runs, whose pressure region is as follows: 0–8.22 kbar for the first, 0–8.45 kbar for the second and 0–16.2 kbar for the third.

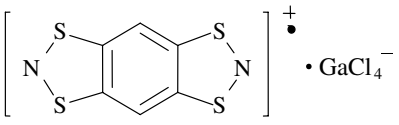

Fig. 1. Molecular structure of the γ-phase of BBDTA · $GaCl_4$.

3. Results and discussion

The temperature dependence of the real component (χ') of χ_{ac} for the γ-phase BBDTA · $GaCl_4$ in the first run is shown in Fig. 2. The enlarged one for 1.96–8.22 kbar is done in the inset of Fig. 2. A part of results for the second and third runs is shown in Fig. 3. At ambient pressure, a rapid increase of the magnitude of χ' appears at around 7.0 K of T_C. We estimate the value of T_C as the temperature, in which the extrapolating lines in the region with the rapid increase of χ' and in the paramagnetic region cross.

Under hydrostatic pressure, the magnitude of χ' is remarkably suppressed, and decreases down to about a half of the initial with little pressure of 0.10 kbar. At around 2.0 kbar, there remains only the magnetic signal

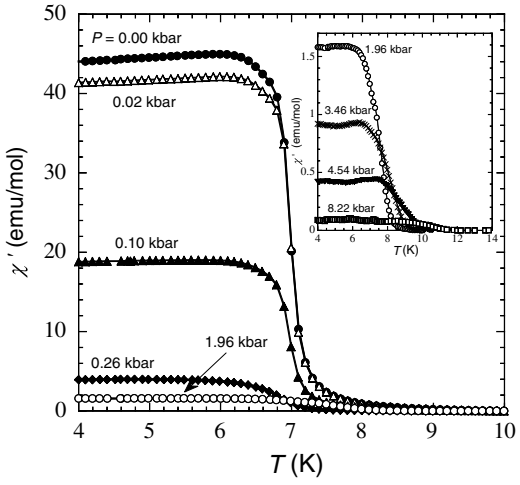

Fig. 2. Temperature dependence of the real component of the ac magnetic susceptibility, χ', for the γ-phase of BBDTA · $GaCl_4$ in the first run. The inset is the enlarged figure for $0.63 \leqq P \leqq 8.22$ kbar.

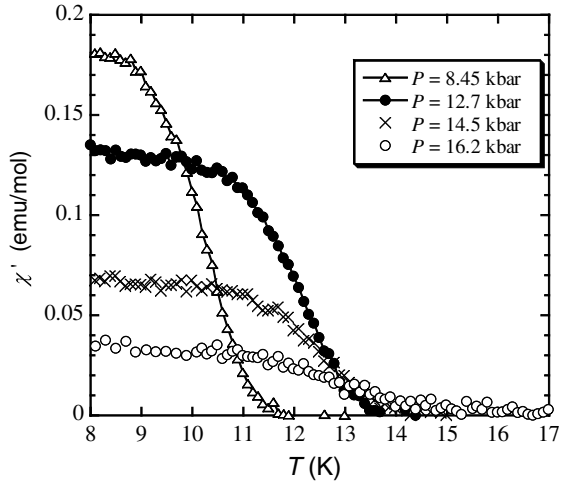

Fig. 3. Temperature dependence of χ' for the γ-phase of BBDTA · $GaCl_4$ in the second and third runs ($P \leqq 16.2$ kbar).

for 3.5% of the initial, and the amount is finally suppressed down to 0.07% of the initial at 16.2 kbar. Thus, γ-BBDTA · $GaCl_4$ is extremely unstable against the external stress.

The application of pressure suppresses the magnitude of χ', while it enhances the T_C. The pressure dependence of T_C is shown in Fig. 4, and T_C increases with linear fashion against pressure in the considered pressure region. The amount of the gradient, dT_C/dP, is estimated to be $+5.1 \times 10^{-1}$ K/kbar. The normalized gradient with the value of $T_C(P = 0)$, $dT_C/T_C(P = 0)/dP$, is $+7.3 \times 10^{-2}$/kbar, which is larger than those in few ferromagnets, whose T_C's increase under pressure; $dT_C/T_C(P = 0)/dP = +1.8 \times 10^{-2}$/kbar for 2,5-difluorophenyl-α-nitronyl nitroxide (2,5-DFPNN; $T_C(P = 0) = 0.45$ K) [6] and $+5.0 \times 10^{-2}$/kbar for *p*-O_2N–C_6F_4–CNSSN ($T_C(P = 0) = 1.3$ K) [20]. The γ-BBDTA · $GaCl_4$ is sensitive to pressure, comparing to the other organic radical ferromagnets. Finally, T_C of the γ-phase BBDTA · $GaCl_4$ arrives at 14.5 K at $P = 16.2$ kbar, and nearly approaches 16 K for TDAE-C_{60} [21]. The tremendous increase of T_C could be realized just on the base of compact intermolecular linkage through S···S and S···N paths. This experiment might be evaluated as a valuable artificial material control using external stress like pressure.

Here, we will discuss the mechanism for both (1) the pressure-induced suppression of the magnetic signal and (2) the enhancement of T_C. These phenomena are inconsistent each other in the case of the bulk-ferromagnet, and these origins have to be considered each other. As for the origin of (1), we assume the structural transition from the ferromagnetic γ-phase to diamagnetic α- and/or β-phases, whose structure has originally higher stability than that of the γ-phase. The structural analysis experiments under pressure are being performed now, and the direct proof will be detected soon. Next, as for (2), we suppose that the pressure-induced enhancement of intermolecular interaction in the surviving γ-phase results in the enhancement of T_C. In fact, T_C could exceed 16 K, T_C of TDAE-C_{60}, at around 18 kbar. The measurements in the further pressure region are, however, very difficult from both the view points of the measurement sensitivity and the limit of pressure in the piston cylinder type of cell.

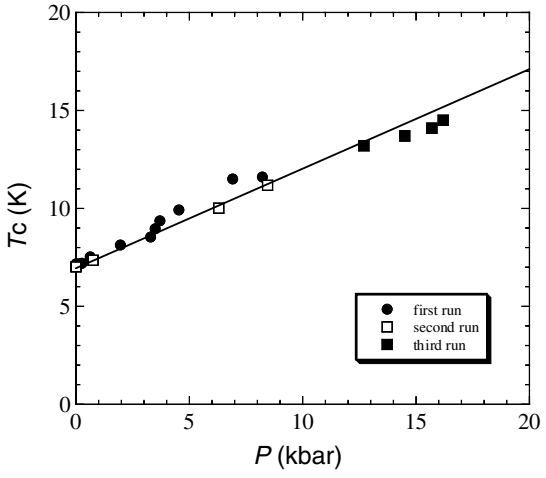

Fig. 4. Pressure dependence of the Curie temperature T_C for the γ-phase of BBDTA · $GaCl_4$. The straight line has the gradient of $dT_C/dP = +5.1 \times 10^{-1}$ K/kbar.

4. Summary

The pressure effects on the thiazyl organic ferromagnet, γ-BBDTA · $GaCl_4$, with $T_C = 7.0$ K, have been investigated through ac magnetic susceptibility measurements under the hydrostatic pressure region up to 16.2 kbar. The Curie temperature is enhanced by applying pressure and reached to 14.5 K at 16.2 kbar. Under further pressure, this material might show a ferromagnetic transition over 16 K, which is the highest T_C in the organic materials. On the other hand, the real component of the ac susceptibility decreases with increasing pressure; it is suppressed to 3.5% of the initial value at 2.0 kbar and 0.07% at 16.2 kbar. Those pressure effects could be explained with two factors: a pressure-induced structural transformation from the ferromagnetic γ-phase to diamagnetic α- and/or β-phases and an enhancement of intermolecular interactions in the surviving γ-phase.

known [1–10], there is a continuing need for new examples to improve our understanding of this phenomenon. Efforts along these lines have been concentrated in two directions: (i) development of synthetic routes to new high nuclearity metal complexes [4,5], and (ii) modifications of known SMMs in a controlled fashion [6–10]. The best and most thoroughly studied SMMs to date are members of the $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ ($[Mn_{12}]$) family. A number of $[Mn_{12}]$ derivatives have been prepared in their neutral [1,6–8], one-electron [6f,9] or two-electron [10] reduced versions with a variety of carboxylate [6,9,10], mixed carboxylate [7], and mixed carboxylate/non-carboxylate [8] ligands. In all such modifications, the $[Mn_{12}(\mu_3\text{-}O)_{12}]$ core remains essentially the same.

In the present work, we report three new developments: (i) A new synthetic procedure in Mn cluster chemistry involving reductive aggregation of permanganate (MnO_4^-) ions in MeOH/benzoic acid solution; (ii) the products of this synthetic procedure which include two new compounds, the $N^nBu_4^+$ salts of the new $[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2]^{2-}$ (**2**) cluster anion, a structural derivative of the well studied $[Mn_{12}]$ complexes, and the polymer $[Mn(OMe)(O_2CPh)_2]_n$ (**3**); and (iii) the establishment that the anion of **2** is a new SMM.

2. Experimental

2.1. Syntheses

All manipulations were performed under aerobic conditions with the use of materials as received unless otherwise indicated; water was distilled in-house. Elemental analyses were performed by the in-house facilities of the Chemistry Department, University of Florida.

2.1.1. Preparation of $(N^nBu_4)_2[Mn_{12}O_{12}(O_2CPh)_{16}(OMe)_2(H_2O)_2]$ (2)

Freshly prepared $(N^nBu_4)MnO_4$ (1.0 g, 2.8 mmol) was added in small portions to a solution of benzoic acid (5.0 g, 40.9 mmol) in MeOH (15 ml), and the mixture stirred for ~5 min. The resulting purple solution was left undisturbed at room temperature overnight. During this time, the color slowly turned dark brown, and black crystals slowly formed. The latter, which were found to be poor diffractors of X-rays, were collected by filtration, washed with MeOH (2 × 10 ml) and dried in vacuo. The material was recrystallized from CH_2Cl_2/hexanes to give a mixture of diamond-shaped crystals of $2 \cdot 2H_2O \cdot 4CH_2Cl_2$ (**2a**) and needle-shaped crystals of $2 \cdot 2H_2O \cdot CH_2Cl_2$ (**2b**) in an overall yield of 0.12 g (15 % based on Mn). These were collected by filtration, washed with hexanes, and dried in vacuo. Both **2a** and **2b** were good diffractors of X-rays, as long as they were kept in contact with the mother liquor to prevent solvent loss. *Anal.* Calc. for $C_{146}H_{166}N_2O_{50}Mn_{12}$ ($2 \cdot 2H_2O$): C, 51.45; H, 4.91; N, 0.82. Found: C, 51.26; H, 4.72; N, 0.70%. Selected IR data (KBr, cm^{-1}): 3430(s, br), 3065(w) 2965(w), 2925(w), 2875(w), 1598(s), 1560(s), 1532(s), 1492(m), 1448(m), 1417(s), 1306(w), 1177(m), 1069(w), 1026(m), 838(w), 718(s), 675(s), 625(m, br), 499(m).

2.1.2. Preparation of $[Mn(OMe)(O_2CPh)_2]_n$ (3)

Compound **3** was prepared by employing the same synthetic procedure as for **2** with the only difference being that the purple solution was left to stand at room temperature for a long period of time (~2 weeks). The yield was 70%. *Anal.* Calc. for $C_{15}H_{13}MnO_5$ (**3**): C, 54.90; H: 3.99. Found: C, 54.67; H, 3.83%. Selected IR data (KBr, cm^{-1}): 3421(m, br), 3065(m), 3023(w), 2940(w), 1693(m), 1592(s), 1552(s), 1491(m), 1448(m), 1386(s), 1306(m), 1177(m), 1159(w), 1143(w), 1069(m), 1026(m), 992(m), 937(w), 841(w), 816(w), 716(s), 683(m), 610(m), 558(m), 483(m).

3. Results and discussion

3.1. Syntheses

The synthesis of normal $[Mn_{12}]$ compound **1** consists of the comproportionation reaction between $Mn(O_2CMe)_2 \cdot 4H_2O$ and $KMnO_4$ in 60% aqueous acetic acid [11]. In contrast, the new synthetic procedure in the present work is part of a wider investigation of the reduction of MnO_4^- in alcohol/carboxylic acid mixtures. The present results were obtained from a MeOH/$PhCO_2H$ medium. Thus, addition of $(N^nBu_4)MnO_4$ to a methanolic solution of benzoic acid results in the formation of a dark brown solution from which subsequently were obtained essentially black crystals. Recrystallization from CH_2Cl_2/hexanes results in the formation of two types of black crystals in a total, overall yield of 15% yield. When the dark brown solution was left for ~2 weeks to stand at room temperature brown crystals of **3** were formed in high yield. Since the average oxidation state of **2** (8 Mn^{III}, 4 Mn^{IV}) is higher than that of **3** (Mn^{III}), it seems reasonable to assume that the formation of the latter is a result of further reduction of Mn^{IV} ions by MeOH, i.e., the longer crystallization times allow the formation of products that are further reduced.

3.2. Description of structures

3.2.1. $[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2]^{2-}$

Both types of crystals of **2**, diamond-like **2a** and needle-like **2b**, were crystallographically characterized, and found to be $(N^nBu_4)_2[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2] \cdot 2H_2O \cdot 4CH_2Cl_2$ (**2a**) and $(N^nBu_4)_2[Mn_{12}O_{12}$-

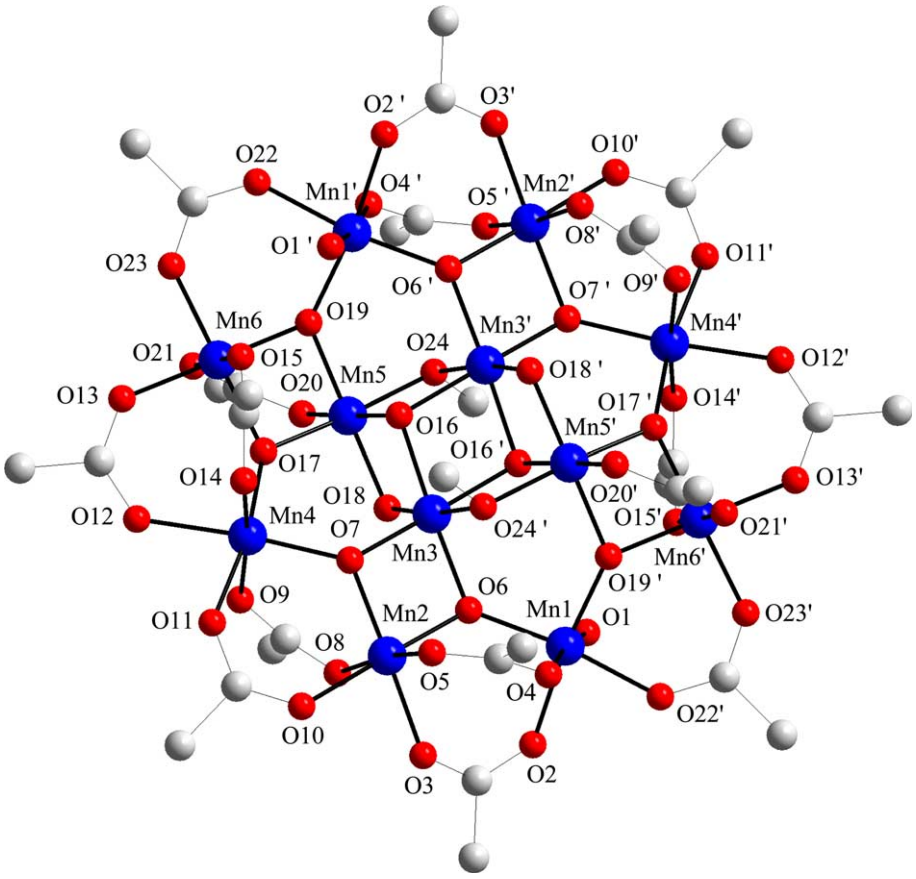

Fig. 1. Labeled ORTEP plot (at the 50% probability level) of the anion of **2a**. For clarity, the benzoate rings have been omitted, except for the *ipso*-carbon atom of each ring. Color scheme: Mn (blue), O (red), C (grey).

$(OMe)_2(O_2CPh)_{16}(H_2O)_2]\cdot 2H_2O\cdot CH_2Cl_2$ (**2b**). Both contain the same dianion, abbreviated $[Mn_{12}']^{2-}$. Complex **2a** crystallizes in the orthorhombic space group *Pbca* with its asymmetric unit containing half the $[Mn_{12}']^{2-}$ cluster and one $N^nBu_4^+$ cation, as well as one H_2O and two disordered CH_2Cl_2 solvent molecules. The $[Mn_{12}']^{2-}$ anion of **2a** (Fig. 1) contains a central $[Mn^{IV}_4(\mu_3\text{-}O)_2(\mu\text{-}O)_2(\mu\text{-}OMe)_2]^{6+}$ unit surrounded by a non-planar ring of eight Mn^{III} atoms that are connected to the central Mn_4 unit by eight bridging $\mu_3\text{-}O^{2-}$ ions. The metal oxidation states and their trapped-valence nature were determined by inspection of the Mn–O bond lengths, Mn bond valence sum calculations[2] [12] and the presence of Mn^{III} Jahn–Teller elongation axes for the Mn atoms in the outer ring. The outer Mn_8 ring is very similar to that in normal $[Mn_{12}]$ compound **1**, but the latter has a central $[Mn_4(\mu_3\text{-}O)_4]^{8+}$ cubane. The central $[Mn^{IV}_4O_4(OMe)_2]^{6+}$ unit of **2a** comprises a planar Mn_4 rhombus with two $\mu_3\text{-}O^{2-}$ ions (O16, O16′), one above and one below the Mn_4 plane, and a $\mu\text{-}O^{2-}$ (O18, O18′) or $\mu\text{-}MeO^-$ (O24, O24′) ion bridging each edge of the rhombus. The central unit can thus be described either as a face-sharing dicubane unit with two missing vertices, or as two edge-sharing, oxide-capped Mn_3 triangular units. Tetranuclear complexes possessing a core very similar to this central unit of the anion of **2a** have been observed previously with Mn [5a,5b], as well as with other transition metals [13]. Peripheral ligation is completed by 16 bridging benzoate groups and two terminal water molecules. All Mn atoms are six-coordinate with near octahedral geometries.

Complex **2b** crystallizes in the triclinic space group $P\bar{1}$, and its asymmetric unit consists of a half cluster and two halves of $N^nBu_4^+$ cations disordered around inversion centers, as well as one disordered H_2O molecule and half a CH_2Cl_2. The structure of the anion of **2b** is essentially identical to that of **2a**, except for some disorder in the peripheral benzoate rings.

For both **2a** and **2b**, there are Jahn–Teller (JT) distortions at the Mn^{III} ions in the outer ring, consistent with high-spin Mn^{III} in near-octahedral geometry. The JT distortion takes the form of an axial elongation, with the elongation axes axial to the Mn_{12} disk-like core and thus roughly parallel to each other. Axially elon-

[2] Bond valence sum calculations for Mn^{III} and Mn^{IV} ions of **2a** and **2b** gave oxidation state values of 2.89–3.02 and 4.00–4.18, respectively.

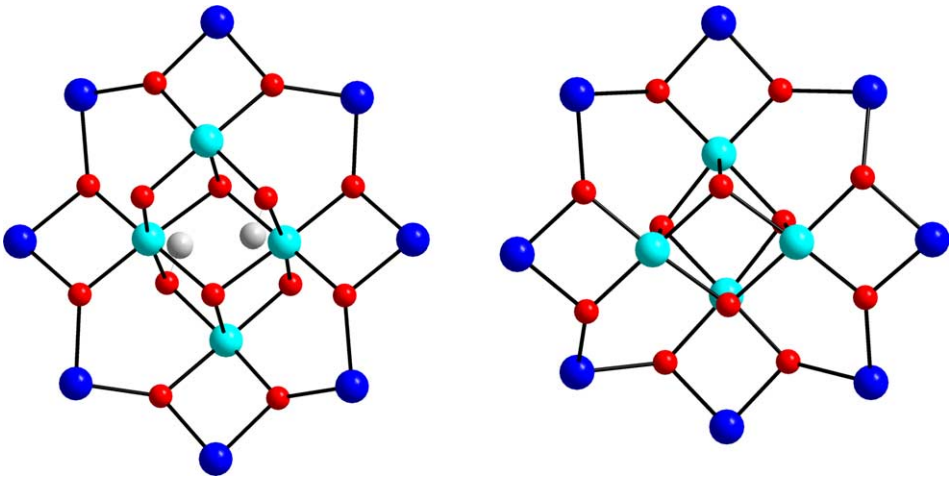

Fig. 2. Comparison of the cores of the anion of **2a** (left) and normal [Mn_{12}] complex **1** (right). Color scheme: Mn^{4+} (cyan), Mn^{3+} (blue), O (red), C (grey).

gated Mn–O bonds are typically at least 0.1–0.2 Å longer than the others. However, there is one anomaly: for **2a** (Fig. 1), the JT elongated bonds at Mn4 (Mn4–O9 = 2.074(4), Mn4–O14 = 2.080(5) Å) are not as long as those at the other Mn^{III} ions (2.112(5)–2.250(5) Å), and *trans* bonds Mn4–O7 (1.958(4) Å) and Mn4–O12 (2.060(5) Å) are longer than expected, especially Mn–O7, which is unusually long for a Mn–O^{2-} bond (compare Mn–O^{2-} bonds at the other Mn^{III} ions of 1.876(4)–1.905(4) Å). A similar anomalous situation is present at Mn1 of **2b**. This structural feature at Mn atoms Mn4 of **2a** and Mn1 of **2b** will prove crucial to understanding the magnetic data below, and we will thus return to this point later.

The anions of complexes **2a** and **2b** are remarkably similar to normal [Mn_{12}] clusters, such as **1**, with the main difference being the structure of the central cores. These are compared in Fig. 2. In fact, the core of the anions of **2a** and **2b** could be considered the result of partial methanolysis of the central $[Mn_4O_4]^{8+}$ cubane of **1**, leading to incorporation of two MeO^- bridges and a change in the core structure (although we do not claim that this corresponds to its means of formation in the reaction mixture). It is also interesting to note that complexes **1** and **2** are the smallest nuclearity members of a larger family of [Mn^{III}_x, Mn^{IV}_y] clusters in which there is an outer Mn^{III}_x ring around a central Mn^{IV}_y core. This family currently comprises normal [Mn_{12}] complexes (such as **1**) and **2a/2b** ($x = 8, y = 4$), the Mn_{16} cluster $[Mn_{16}O_{16}(OMe)_6(O_2CMe)_{16}(MeOH)_3(H_2O)_3]$ ($x = 10$, $y = 6$) [4c,14], and the Mn_{21} cluster $[Mn_{21}O_{24}(OMe)_8(O_2CCH_2{}^tBu)_{16}(H_2O)_{10}]$ ($x = 12, y = 9$) [15].

3.2.2. $[Mn(OMe)(O_2CPh)_2]_n$

Compound **3** crystallizes in the triclinic space group $P\bar{1}$ and its asymmetric unit consists of a [Mn(μ-O_2CPh)$_2$(μ-OMe)Mn] portion of the chain. The compound contains a linear chain of repeating [Mn^{III}(μ-OMe)(μ-O_2CPh)$_2$$Mn^{III}$] units (Fig. 3). The structure of **3** is similar to that of {[Mn(OH)(O_2CMe)$_2$] · HO_2CMe · H_2O} (**4**) reported recently [16], which is also a linear chain, except that (i) there are OMe^- bridging groups instead of OH^-, (ii) the carboxylate ligands are $PhCO_2^-$ instead of $MeCO_2^-$, and (iii) there are no solvents of crystallization in contrast to **4** where solvents of crystallization are participating in the formation of a hydrogen-bonding network between chains. The Mn···Mn separations in **3** are 3.388(1) Å, identical to the 3.384(1) Å value of those in **4**. All the $PhCO_2^-$ groups are in their familiar *syn*,*syn*-bridging modes. The metal oxidation state and its trapped-valence nature were determined by inspection of the Mn–O bond

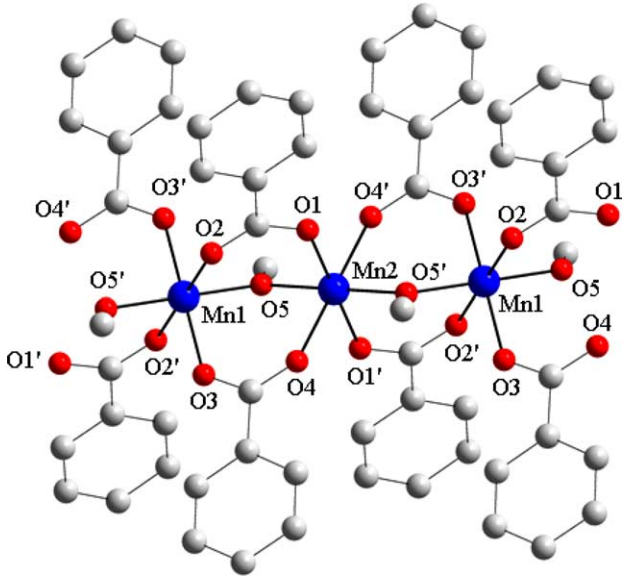

Fig. 3. Labelled ORTEP plot (at the 50% probability level) of a small section of the polymeric chain of [Mn(OMe)(O_2CPh)$_2$]$_n$ (**3**).

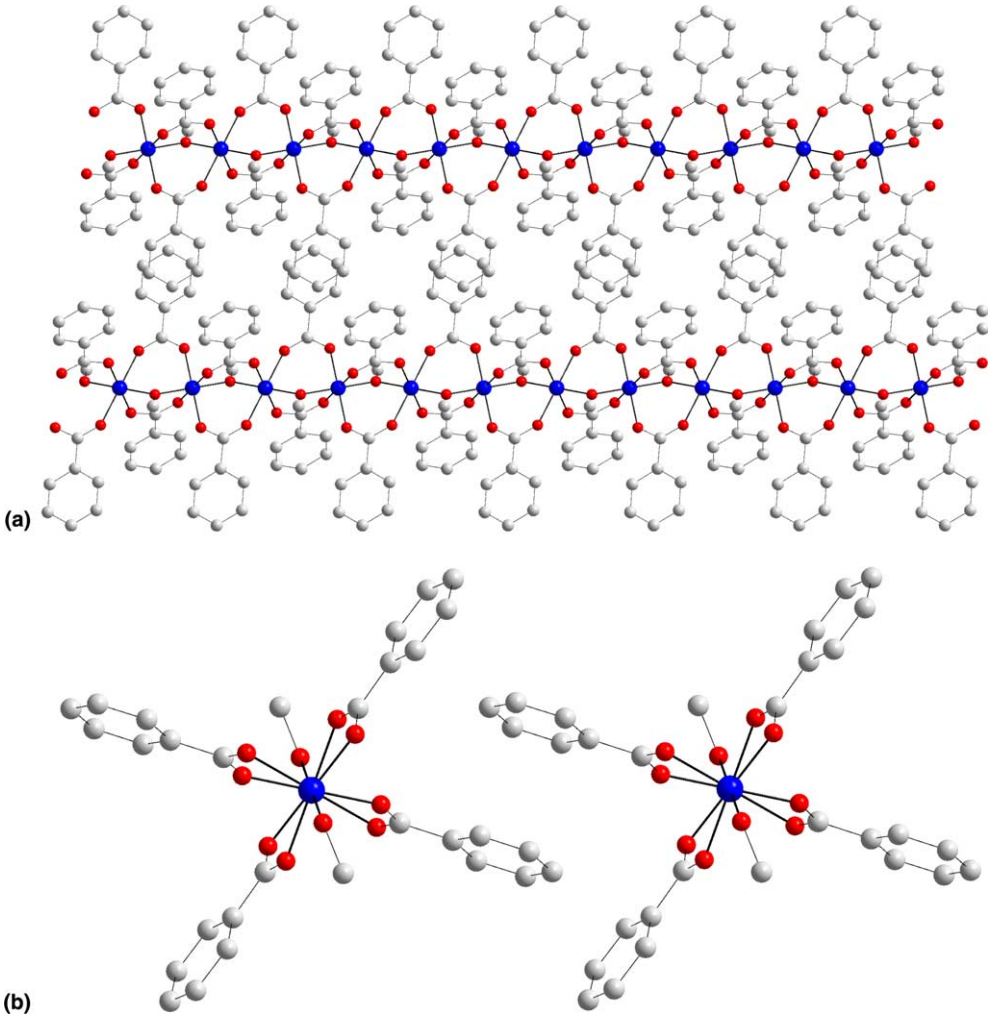

Fig. 4. (a) A section of two adjacent chains of **3** emphasizing (i) the π-stacking between the benzoate rings of the two neighboring chains, (ii) the fact that the chains run parallel in the crystal. (b) A view along the chain axis of **1**.

lengths, Mn bond valence sum calculations[3] [12] and the presence of Mn^{III} Jahn–Teller elongation axes for the two independent Mn atoms of the chain. The Jahn–Teller elongation axes are the O(2)–Mn(1)–O(2′) and O(4′)–Mn–O(2), which are parallel. It is interesting to note that the [Mn(μ-OMe)(μ-$O_2CR)_2$Mn] triply bridged unit is unprecedented in any Mn cluster of any nuclearity. This could be partially due to the fact that the list of Mn complexes containing methoxy groups is not extensive. A close examination of the packing of **3** shows that the chains all run parallel in the crystal, and in the absence of solvent molecules of crystallization there are no hydrogen-bonding interactions holding the neighboring chains together. However, a closer look reveals the existence of π-stacking interactions between the benzoate rings of neighboring chains (average C···C separation = 3.719 Å). This is emphasized in Fig. 4, which shows a small part of two adjacent chains from a viewpoint perpendicular to the chains (Fig. 4(a)) and along the chains (Fig. 4(b)).

3.3. Magnetism studies

3.3.1. $[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2]^{2-}$

The structural similarity between complexes **1** and **2** suggested the possibility that the latter might also be a SMM, just like the former. This was therefore investigated by AC magnetic susceptibility measurements on a polycrystalline sample of **2** (containing both **2a** and **2b**) in the temperature range 1.8–10 K using a 3.5 G AC field oscillating at 5–500 Hz frequencies (ν). These studies revealed two frequency-dependent out-of-phase χ''_m AC signals (Fig. 5), one in the higher temperature (HT) range of 3–5 K, and a second one at lower temperatures (LT) whose peaks clearly occur at temperatures below the operating limit of our SQUID (superconducting quantum interference device) instrument (1.8 K).

[3] Bond valence sum calculations for the two independent Mn^{III} ions of **3** gave oxidation state values of 2.98 for both of them.

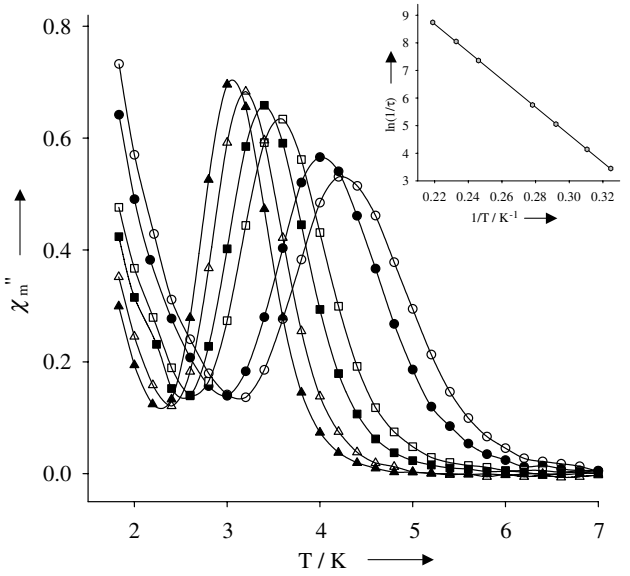

Fig. 5. Plot of χ''_m vs. T for a microcrystalline sample of **2** at 500 (○), 250 (●), 50 (□), 25 (■), 10 (△), 5 (▲) Hz. Inset: Plot of the natural logarithm of relaxation rate, $\ln(1/\tau)$ vs. inverse temperature using the χ''_m vs. T data for the slower-relaxing species (higher temperature data). The solid line is a fit to the Arrhenius equation; see the text for the fitting parameters.

The LT and HT χ''_m signals correspond to faster and slower relaxation rates, respectively. The peak of a χ''_m versus T plot represents the temperature at which the magnetization relaxation rate equals the angular frequency $\omega(=2\pi\nu)$, and the χ''_m versus T data at different frequencies (ν) were therefore used as a source of kinetic data to construct an Arrhenius plot (Fig. 5, inset) based on the Arrhenius equation of Eq. (1), where $1/\tau$ is the relaxation rate (τ is the relaxation time), $1/\tau_0$ is the pre-exponential factor, U_{eff} is the effective relaxation barrier,

$$1/\tau = 1/\tau_0 \exp(-U_{eff}/kT) \quad (1)$$

and k is the Boltzmann constant. The fit of the data to Eq. (1) gave $U_{eff} = 50.1$ K and $1/\tau_0 = 3.61 \times 10^8$ s^{-1}. This U_{eff} value is smaller than that of normal [Mn_{12}] complexes; complex **1**, for example, has a U_{eff} of 60–65 K.

The observation of out-of-phase AC signals suggests that **2** might be an SMM, although such signals by themselves are not proof of an SMM. It is also tempting to assume that the two χ''_m signals in Fig. 3 are due to the two crystal forms, diamond-like **2a** and needle-like **2b**. To confirm whether **2a** and/or **2b** are indeed SMMs, and to assess any difference between the two forms, magnetization versus DC field sweep studies were performed on single crystals of **2a** and **2b** using a micro-SQUID apparatus [17]. The resulting hysteresis loops are shown in Fig. 6, and their coercivities (i) increase with decreasing T at a constant field sweep rate, and (ii) increase with increasing sweep rate at a constant T

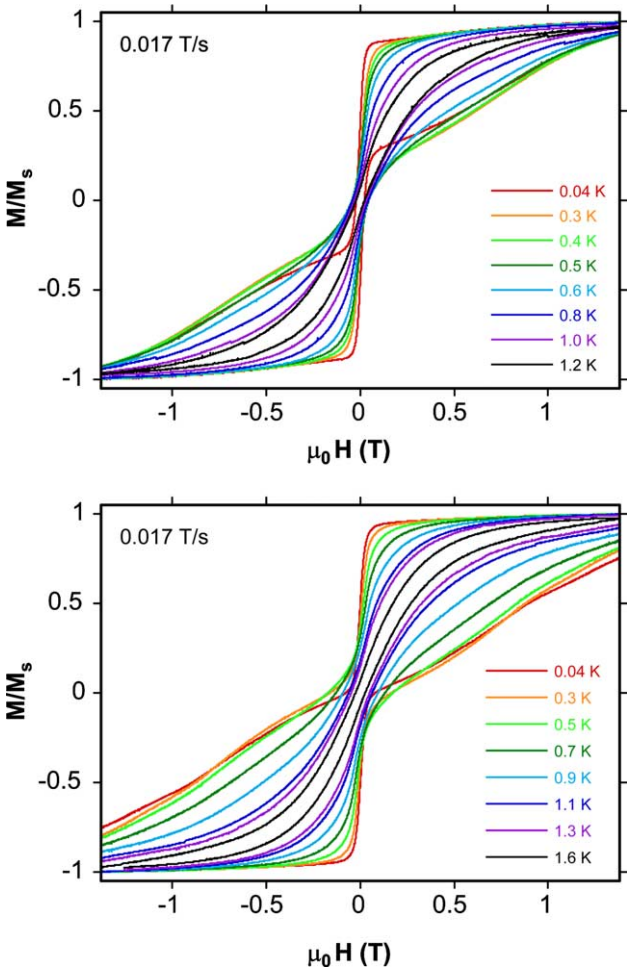

Fig. 6. Magnetization (M) vs. applied magnetic field ($\mu_0 H$) hysteresis loops for a single crystal (wet with mother liquor) of **2a** (top) and **2b** (bottom) at the indicated temperatures. M is normalized to its saturation value, M_s.

(not shown). This is as expected for the superparamagnet-like properties of a SMM.

However, it is clear that the observed properties (hysteresis loops) of **2a** and **2b** are very similar, and this is totally inconsistent with the two very different AC signals in Fig. 5 and the at-first-glance 'obvious' conclusion that the two signals are due to the two crystal forms. In fact, the hysteresis loops of both **2a** and **2b** each suggest a mixture of faster-relaxing (LT) and slower-relaxing (HT) forms, the former being responsible for the large decrease in magnetization at zero field, and the latter being responsible for the subsequent feature at higher fields. The relative proportions of these two features suggest comparable amounts of the LT and HT forms in each crystal, with perhaps a slightly greater amount of the former, and this is again consistent with the relative proportion of LT and HT AC signals in Fig. 5. Note that the AC and hysteresis studies were performed on wet single-crystals and microcrystals suspended in solid eicosane, respectively, and thus not strictly speaking on

the same material. Nevertheless, we conclude that (i) complex **2** is a new SMM; (ii) the different space groups of diamond-like **2a** and needle-like **2b** lead to only small differences in the magnetic properties of the $[Mn_{12}O_{12}(OMe)_2(O_2CPh)_{16}(H_2O)_2]^{2-}$ anion; and (iii) there are faster- and slower-relaxing forms of complex **2** that co-crystallize in the same crystal. In fact, point (iii) has long been known to also be the case for **1**, whose crystals contain about 5% of the faster-relaxing form; complex **2** thus differs from **1** only in the relative amounts of the two forms.

For normal $[Mn_{12}]$ complexes, we have reported elsewhere that crystals of pure faster-relaxing forms can be prepared with, for example, ^{t}butylacetate as the carboxylate group [6d,6g]. Crystallography on such crystals has allowed the origin of the faster-relaxing form to be identified as the abnormal orientation of one of the Mn^{III} JT elongation axes being disposed equatorial rather than axial to the Mn_{12} disk-like plane, and thus pointing to a core O^{2-} ion. We have named this 'Jahn–Teller isomerism'. The same is likely to be the origin of the two forms of **2**. Indeed, this takes us back full circle to the crystal structures described above, because it rationalizes the unusual Mn–O bond lengths at Mn4 for **2a** and Mn1 for **2b**. For **2a**, for example, an approximately equal mixture of (a) slower-relaxing species with the JT axis at Mn4 in the normal position along the O9–Mn4–O14 axis, and (b) faster-relaxing species with the JT axis at Mn4 abnormally aligned along the O7–Mn4–O12 axis will lead to the crystallographic average result that the O9–Mn4–O14 and O7–Mn4–O12 bond lengths are shorter and longer, respectively, than they should be, which is what is seen. Similarly for **2b**, we thus feel that the crystallographic data support the conclusion from the magnetic studies that crystals of **2a** and **2b** comprise a mixture of slower- and faster-relaxing species resulting from normal and abnormal orientations, respectively, of a Mn^{III} JT elongation axis. As with normal $[Mn_{12}]$ complexes, it will require crystallization of pure crystals of the different forms of **2** to allow more detailed study, and this is a current objective.

3.3.2. $[Mn(OMe)(O_2CPh)_2]_n$

Solid state dc magnetic susceptibility data were collected in the 5.0–300 K range in a 5 kG (0.5 T) field. The data for **3** are plotted as $\chi_m T$ versus T in Fig. 7. The $\chi_m T$ value of 2.59 $cm^3\ mol^{-1}$ K at 300 K is lower than the expected value of 3 $cm^3\ mol^{-1}$ K for an isolated Mn^{III} center, and decreases steadily to 0.18 $cm^3\ mol^{-1}$ K at 8 K, and then increases smoothly to 0.21 at 5 K. These data suggest that the existence of strong antiferromagnetic interactions between the Mn^{III} centers of the chain resulting in a diamagnetic ground state (S = 0). This is not surprising because triply bridged Mn_2^{III} (and $Mn^{II}Mn^{III}$) dinuclear units are almost always antiferromagnetically coupled, although a dinuclear complex with the $[Mn(\mu\text{-}OMe)(\mu\text{-}O_2CR)_2Mn]$ core is not known for direct comparison. The very small increase at $T < 8$ K could be due to weak ferromagnetic interactions between the chains. This behavior is very similar to that observed for **4**, where however this behavior is more pronounced, presumably due to the stronger interactions between chains mediated by the strong hydrogen-bonding in **4**.

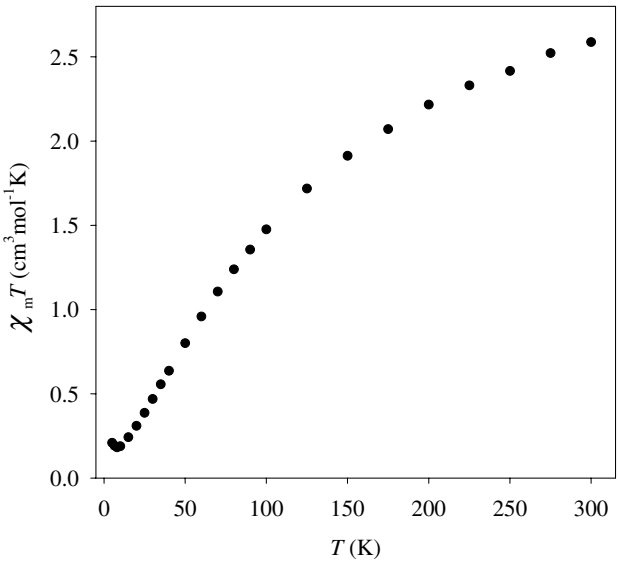

Fig. 7. A plot of $\chi_m T$ vs. T for **3**.

4. Conclusions

The new reductive aggregation procedure has led to two new compounds. The first is a variant of the $[Mn_{12}]$ family of SMMs and the second a Mn^{III} polymer. The latter is an antiferromagnetically coupled chain. In contrast, the anion of **2** is a structural variant of normal $[Mn_{12}]$ complexes, and like them is an SMM. It also displays both faster- and slower-relaxing magnetization dynamics that we assign to the presence of JT isomerism. We have in the past obtained many derivatives of $[Mn_{12}]$ complexes, for example by carboxylate substitution [6,7], one- and two-electron reduction [6f,9,10], introduction of non-carboxylate ligands [8], etc., and similar derivatization of **2** may also prove possible, in which case it is merely the prototype of what could become a large new family of related SMMs.

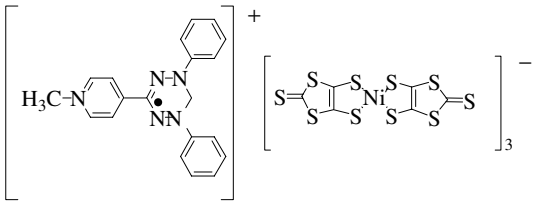
semiconductors consisting of open-shell radical cation donor and metal complex anion acceptor have been reported for the (1:1) salt of $Ni(dmit)_2$ anion with the *p*-EPYNN (*p*-*N*-ethylpyridinium α-nitronyl nitroxide) and the Me_3N^+–TEMPO (=*N*,*N*,*N*-trimethyl(1-oxyl-2,2,6,6-tetramethylpiperidine-4-yl)ammonium) radical cations [8,9].



Verdazyl radicals show a high chemical and thermal stability and can be isolated as solvent-free pure radicals in crystalline states [10]. The magnetic properties of these verdazyl radical crystals have been studied extensively, and several interesting magnetic properties such as ferromagnetism, weak ferromagnetism, antiferromagnetism, spin-Peierls transition, and spin frustration have been reported [11–17]. Recently, first two examples of molecular paramagnetic semiconductors consisting of verdazyl radical cation and metal complex anion have been reported for the $Ni(dmit)_2$ salts of 3-[4-(trialkylammonio)phenyl]-1,5-diphenyl-6-oxoverdazyl radical cations [18,19]. Further, we prepared the (1:1) and (1:2) salts of 3-(4- and 3-alkyl-pyridinium)-1,5-diphenylver-dazyl (alkyl = ethyl and methyl) radical cations with TCNQ anion, and found that the (1:2) salts are genuine organic paramagnetic semiconductors [20,21]. However, the examples of the molecular complexes between the open-shell radical cation and electron acceptor anion are very limited. In the present work, we prepared five kinds of (1:1) and (1:3) salts **1**–**5** of 3-(4- and 3-alkyl-pyridinium)-1,5-diphenylverdazyl (alkyl = ethyl and methyl) radical cations with $Ni(dmit)_2$ anion (see Fig. 1), and studied the structural, magnetic and conducting properties of these radical salts.

$R = C_2H_5$: $[p\text{–EtPyDV}]^+[Ni(dmit)_2]^-$ (1)
$R = CH_3$: $[p\text{–MePyDV}]^+[Ni(dmit)_2]^-$ (3)

$R = C_2H_5$: $[m\text{–EtPyDV}]^+[Ni(dmit)_2]^-$ (2)
$R = CH_3$: $[m\text{–MePyDV}]^+[Ni(dmit)_2]^-$ (4)

$[p\text{-MePyDV}]^+[Ni(dmit)_2]_3^-$ (5)

Fig. 1. Chemical structures of the (1:1) and (1:3) salts of 3-(4- and 3-alkyl-pyridinium)-1,5-diphenylverdazyl radical cations (alkyl = ethyl and methyl) with $Ni(dmit)_2$ anion.

2. Experimental

2.1. Syntheses

The preparations of 3-(4-pyridyl)-1,5-diphenyl-verdazyl (*p*-PyDV) and 3-(3-pyridyl)-1,5-diphenyl-verdayl (*m*-PyDV) radicals were reported in a previous work [17]. The preparations of the iodide salts, 3-(4- and 3-alkyl-pyridinium)-1,5-diphenylverdazyl iodides (alkyl = ethyl and methyl), $[p\text{-EtPyDV}]^+I^-$ (**6**), $[m\text{-EtPyDV}]^+I^-$ (**7**), $[p\text{-MePyDV}]^+I^-$ (**8**), and $[m\text{-MePyDV}]^+I^-$ (**9**), were reported in previous papers [20,21].

Preparations of the charge transfer salts **1**–**5** are as follows.

2.1.1. $[p\text{-}EtPyDV]^+[Ni(dmit)_2]^-$ (*1*)

To stirred solution of $[p\text{-EtPyDV}]^+[I]^-$ (47.0 mg, 0.100 mmol) in methanol (50 ml), $[n\text{-}Bu_4N]^+[Ni(dmit)_2]^-$ (69.4 mg, 0.100 mmol) in methanol (250 ml) was added and stirring was continued for 2 h under nitrogen atmosphere. The black-violet solids precipitated were filtered and washed with diethyl ether. Recrystallization of the residue from acetonitrile–diethyl ether afforded the product as black-violet prismatic crystals (43 mg, 54%): m.p. = 190.0–191.5 °C; UV (acetonitrile) λ_{max} ($\log\varepsilon$): 747 (3.37), 617 (3.59), 543 (4.03), 436 (4.26), 380 (4.56), 315 (4.59), 241 (4.64). *Anal.* Calc. for $C_{27}H_{21}N_5S_{10}Ni$: C, 40.80; H, 2.66; N, 8.81. Found: C, 40.58; H, 2.62; N, 8.46%.

The radical salts **2**, **3**, and **4** were prepared similarly.

2.1.2. $[m\text{-}EtPyDV]^+[Ni(dmit)_2]^-$ (*2*)

Dark-green powder crystals: m.p. = 199.0–201.0 °C; UV (acetonitrile) λ_{max} ($\log\varepsilon$) 735 (3.59), 625 (3.64), 443 (4.31), 389 (4.39), 314 (4.64), 240 (4.58). *Anal.* Calc. for $C_{27}H_{21}N_5S_{10}Ni$: C, 40.80; H, 2.66; N, 8.81. Found: C, 40.67; H, 2.61; N, 8.71%.

2.1.3. $[p\text{-}MePyDV]^+[Ni(dmit)_2]^-$ (*3*)

Dark-green powder crystals: m.p. > 300.0 °C; UV (acetonitrile) λ_{max} ($\log\varepsilon$) 747 (3.36), 619 (3.59), 543 (4.13), 436 (4.26), 379 (4.56), 350 (4.51), 315 (4.60),

240 (4.65). *Anal*. Calc. for $C_{26}H_{19}N_5S_{10}Ni$: C, 39.99; H, 2.45; N, 8.97. Found: C, 40.82; H, 2.57; N, 9.14%.

2.1.4. [m-MePyDV]$^+$[Ni(dmit)$_2$]$^-$ (4)

Black-violet powder crystals: m.p. > 300.0 °C; UV (acetonitrile) λ_{max} (log ε) 736 (3.34), 619 (3.61), 439 (4.30), 392 (4.41), 315 (4.58), 241 (4.63). *Anal*. Calc. for $C_{26}H_{19}N_5S_{10}Ni$: C, 39.99; H, 2.45; N, 8.97. Found: C, 40.15; H, 2.55; N, 9.05%.

2.1.5. [p-MePyDV]$^+$[Ni(dmit)$_2$]$_3^-$ (5)

For the preparation of (1:3) salt **5**, the air oxidation of a solution containing the [*p*-MePyDV]$^+$[Ni(dmit)$_2$]$^-$ (**3**) (30 mg), acetic acid (20 ml) and acetic anhydride (20 ml) in acetone (300 ml) was carried out at room temperature [6,7]. Black fine crystals obtained show a high melting point and are insoluble in the usual organic solvents. The result of the elemental analysis indicates the formation of a (1:3) salt, [*p*-MePyDV]$^+$[Ni–(dmit)$_2$]$_3^-$ (**5**) [7]. M.p. > 300 °C; *Anal*. Calc. for $C_{38}H_{19}N_5S_{30}Ni_3$: C, 27.11; H, 1.14; N, 4.16. Found: C, 26.85; H, 1.27; N, 3.97%.

2.2. Measurements

The magnetic susceptibility (χ_M) was measured in the temperature range of 1.8–300 K by a SQUID magnetometer. The χ_M of all samples has been corrected for the diamagnetic contribution ($\chi_{dia} = -0.399 \times 10^{-3}$ emu/mol for salts **1** and **2**, -0.388×10^{-3} emu/mol for salts **3** and **4**, and -0.757×10^{-3} emu/mol for salt **5**), calculated by Pascal's method. The conductivity measurements of salts **1**–**5** were performed for the pressed pellet samples of salts, using the standard dc four-probe method.

2.3. Structure determination

The X-ray measurements of the [*p*-EtPyDV]$^+$[Ni(dmit)$_2$]$^-$ salt (**1**) and [*p*-EtPyDV]$^+$I$^-$ salt (**6**) were carried out on a Rigaku AFC5R diffractometer with graphite-monochromated Mo Kα (λ = 0.71069 Å) radiations. The structure was solved by the direct method.

3. Results

3.1. UV–Vis spectra of salts 1–5

Absorption spectra of [*m*-MePyDV]$^+$[Ni(dmit)$_2$]$^-$ (**4**), [*m*-MePyDV]$^+$I$^-$ (**9**), and [*n*-Bu$_4$N]$^+$[Ni(dmit)$_2$]$^-$ salts are measured in acetonitrile solvent. As shown in Fig. 2, the absorption spectrum of **4** can be well explained by the addition of [*m*-MePyDV]$^+$I$^-$ (**9**) and [*n*-Bu$_4$N]$^+$[Ni(dmit)$_2$]$^-$, suggesting the (1:1) complex formation between the [*m*-MePyDV]$^+$ cation and the [Ni(dmit)$_2$]$^-$ anion [18]. Similarly, the absorption spectra of salts **1**–**3** in acetonitrile can be well explained by an addition of those of corresponding iodide salts and [*n*-Bu$_4$N]$^+$[Ni(dmit)$_2$]$^-$, respectively. The electronic structures of the verdazyl radical cation and Ni(dmit)$_2$ anion moieties in salts **1**–**4** are thought to be similar to those in corresponding iodide salts **6**–**9** and [*n*-Bu$_4$N]$^+$[Ni(dmit)$_2$]$^-$, respectively. The (1:3) salt **5** crystals are insoluble in the usual organic solvents, and we could not measure the optical spectrum of salt **5** in solution.

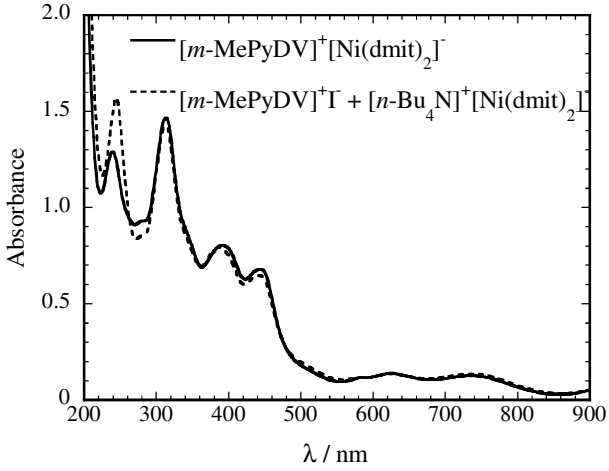


Fig. 2. UV–Vis spectra of the (1:1) [*m*-MePyDV]$^+$[Ni(dmit)$_2$]$^-$ salt (**4**) in acetonitrile.

3.2. Crystal structures of salts 1 and 6

The crystal structure could be determined for the [*p*-EtPyDV]$^+$[Ni(dmit)$_2$]$^-$ salt (**1**) and the [*p*-EtPyDV]$^+$-I$^-$ salt (**6**) (see Table 1). The crystal structures of salts **1** and **6** are shown in Fig. 3(a) and (b), respectively. The bond lengths and bond angles of verdazyl moieties (N1–N2–C1–N3–N4–C2) in salts **1** and **6** are similar to corresponding those of the neutral 1,3,5-triphenylverdazyl (TPV) (data are not shown) [22]. However, the dihedral angles (8.965° and 2.380°) between least-squares plane (N1–N2–N3–N4 plane) of verdazyl ring and those of N1- and N4-phenyl rings in salt **1** are much smaller than those of the iodide salt **6** (9.255° and 28.925°) and TPV (27.8(4)° and 40.2(4)°), respectively. In TPV, the verdazyl ring has an unsymmetrical boat configuration, with both C1 and C2 out of the nitrogen plane on the same side. C1 is displaced by only +0.099 Å, while C2 is displaced by +0.590 Å. The verdazyl ring in iodide salt **6** also shows similar structure to that of TPV. On the other hand, in salt **1**, the deviations (−0.007(16) and +0.140(17) Å) of C1 and C2 atoms out of N1–N2–N3–N4 plane are very small, indicating that the verdazyl molecule has planar structure.

The bond lengths and bond angles of the Ni(dmit)$_2$ anion in salt **1** are also similar to corresponding those in the [*n*-Bu$_4$N]$^+$[Ni(dmit)$_2$]$^-$ salt (data are not shown) [23]. The result indicates that the Ni(dmit)$_2$ moiety in salt **1** is considered to exist as monoanion [Ni(dmit)$_2$]$^-$ with $S = 1/2$ [8]. The dihedral angles between least-squares planes of two dmit rings in salt **1** is 4.683°, indicating the planarity of the Ni(dmit)$_2$ moiety.

Molecular packing of salt **1** is shown in Fig. 4. The unit cell of salt **1** contains two Ni(dmit)$_2$ anions and two verdazyl cations [*p*-EtPyDV]$^+$. The Ni(dmit)$_2$ anion molecules in salt **1** form a dimer ([Ni(dmit)$_2$] (A)–[Ni(dmit)$_2$] (B)) having intra-dimer contacts of ca. 3.6–3.8 Å (see Table 2). The dimer molecules are sandwiched between two verdazyl cation molecules, forming a linear tetramer ([*p*-EtPyDV]$^+$ (A)–[Ni(dmit)$_2$] (A)–[Ni(dmit)$_2$] (B)–[*p*-EtPyDV]$^+$ (B)) in the crystal. The Ni(dmit)$_2$ anion dimers are connected to each other through short S–S contacts (S8–S9 = 3.566(4) Å, S9–S9 = 3.811(7) Å, and S5–S8 = 3.934(5) Å) between Ni(A) and Ni(C).

3.3. Conductivities of salts 1–5

The room-temperature conductivities (σ_{RT}'s) for salts **1**, **2**, **3**, and **4** are 2.3×10^{-5}, 1.1×10^{-3}, 1.4×10^{-5}, and 5.4×10^{-6} S cm^{-1}, respectively, as listed in Table 3. As shown in Fig. 5, the salts **1**, **2**, **3** and **4** show semiconductive behavior with activation energy values (E_A's) of 0.28, 0.52, 0.21 and 0.33 eV at the temperature range of 219–298, 250–283, 246–279 and 269–298 K, respectively. The conductivity of the (1:3) salt **5** at 20 °C was $\sigma = 1.0$ S cm^{-1} with an activation energy $E_A = 0.048$ eV (data are not shown), and is three to five orders of magnitude larger than those of the (1:1) salts **1**–**4**.

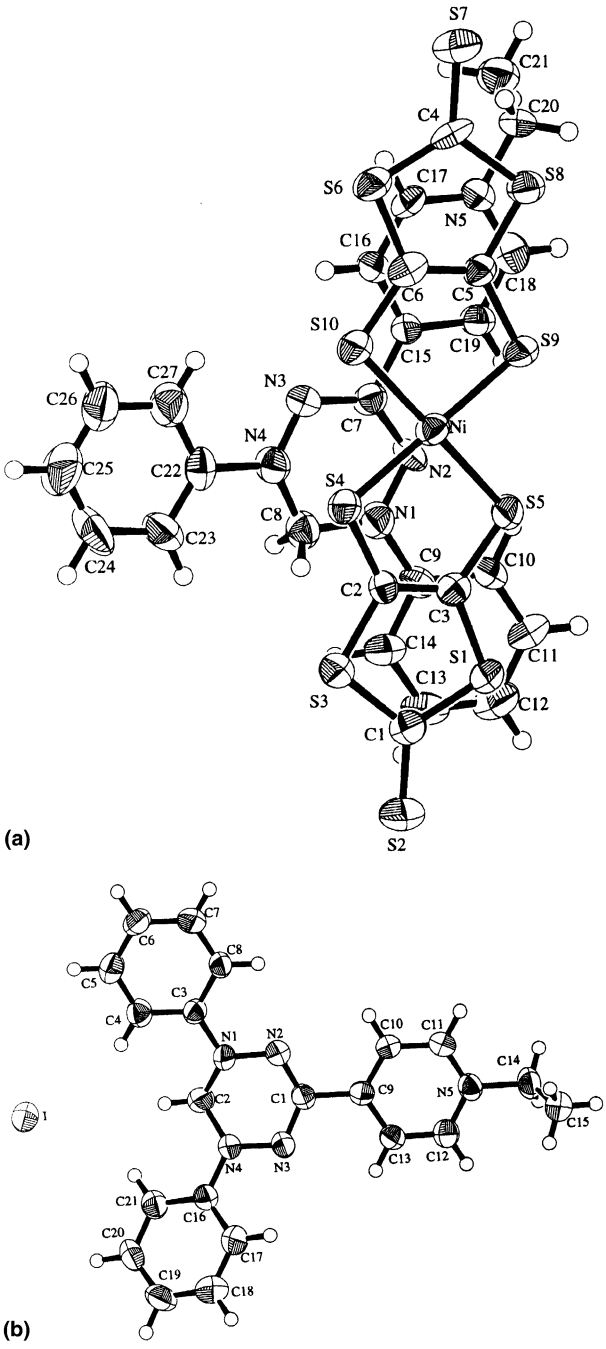

Fig. 3. Molecular structures of (a) the Ni salt **1** and (b) the iodide salt **6** with the atom numbering scheme.

3.4. Magnetic susceptibilities of salts 1–5

Fig. 6 shows a plot of $\chi_M T$ versus T for salts **1**–**5**. The value of $\chi_M T$ for the [*p*-EtPyDV]$^+$[Ni(dmit)$_2$]$^-$ salt (**1**) is 0.243 K emu/mol at 300 K (see Table 3), and decreases

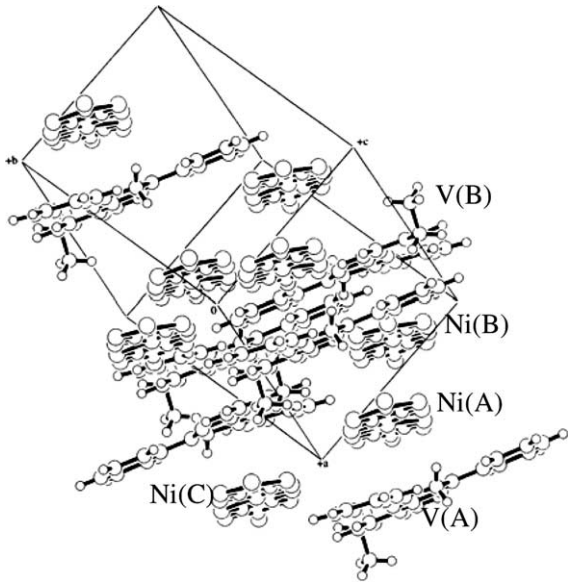

Fig. 4. Molecular packing in salt **1**, showing the formation of magnetic linear tetramer, [verdazyl cation (A)–Ni(dmit)$_2$ anion (A)–Ni(dmit)$_2$ anion (B)–verdazyl cation (B)].

by lowering the temperature, indicating AFM interaction in salt **1**. As shown in Fig. 7, the χ_M of salt **1** decreases slowly by lowering the temperature from 300 K, shows a minimum around 160 K, and increases rapidly below 20 K.

The value of $\chi_M T$ for the [*m*-EtPyDV]$^+$[Ni(dmit)$_2$]$^-$ salt (**2**) is 0.685 K emu/mol at 300 K, and is close to the sum of those (0.376 and 0.392 K emu/mol) expected for non-interacting $S = 1/2$ spin system with *g*-values $g_V^+ = 2.0032$ for [*m*-EtPyDV]$^+$I$^-$ [21] and $g_{Ni}^- = 2.0472$ for [*n*-Bu$_4$N]$^+$[Ni(dmit)$_2$]$^-$ [18], respectively, suggesting that both the spins of verdazyl cation and Ni(dmit)$_2$ anion contribute to the magnetism of salt **2**. $\chi_M T$ for salt **2** decreases gradually by decreasing the temperature, shows the plateau between 30 and 60 K, and increases by decreasing the temperature. Below 30 K, the susceptibility of salt **2** follows the Curie–Weiss law with a Curie constant of 0.376 K emu/mol and a positive Weiss constant of $+2.2 \pm 0.2$ K (see Fig. 8(b)). The $\chi_M T$ (0.388 K emu/mol) of salt **2** at the plateau (30–60 K) amounts to about one half of the value (0.768 emu K/mol) calculated on the basis of two $S = 1/2$ spins per one formula unit of the salt, as shown in Fig. 8(a). The additional susceptibility above 60 K is considered to be a thermally activated species which is nonmagnetic at lower temperatures. This magnetic contribution is tentatively assigned to the dimer of the Ni(dmit)$_2^-$ radical anions. The susceptibility at lower temperatures is, therefore, attributed to the verdazyl radical cations.

The χ_M of the [*p*-MePyDV]$^+$[Ni(dmit)$_2$]$^-$ salt (**3**) decreases gradually by decreasing temperature from 300 K, and shows a minimum at about $T_{min} = 170$ K (data are not shown). The susceptibility increases by

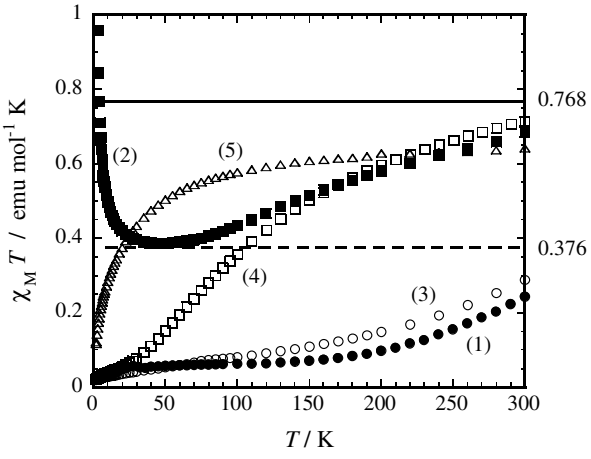

Fig. 6. Temperature dependence of the product $\chi_M T$ for salts **1**–**5**.

decreasing temperature below 170 K. The value of $\chi_M T$ for **3** is 0.288 K emu/mol at 300 K, and decreases by lowering the temperature, indicating AFM interaction in **3**, as shown in Fig. 6. The magnetic behavior of salt **3** is very similar to that of salt **1**.

The χ_M of the $[m\text{-MePyDV}]^+[Ni(dmit)_2]^-$ salt (**4**) shows a broad maximum at $T_{max} = 100 \pm 2$ K, as shown in Fig. 9. An increase in susceptibility below 26 K was observed, which is probably due to Curie impurities. The value (0.713 K emu/mol) of $\chi_M T$ at 300 K observed for salt **4** is similar to the sum of those (0.376 and 0.392 K emu/mol) for $S = 1/2$ spin system with $g_V^+ = 2.0033$ [21] and $g_{Ni}^- = 2.0472$ [18], suggesting that both the spins of verdazyl cation and $[Ni(dmit)_2]^-$ anion contribute to the magnetism of salt **4**.

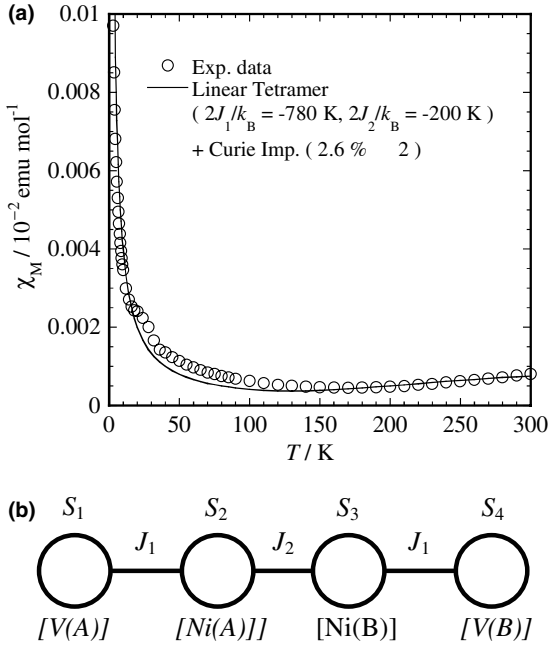

Fig. 7. (a) Temperature dependence of the magnetic susceptibility of salt **1**. The solid curve is the theoretical susceptibility calculated using Eq. (2) in [24]. (b) Scheme 1.

The χ_M of the $[p\text{-MePyDV}]^+[Ni(dmit)_2]_3^-$ salt (**5**) increases monotonically by lowering the temperature, and follows the Curie–Weiss law with $C = 0.684$ K emu/mol and $\theta = -17.0$ K.

4. Discussion

4.1. Magnetic properties of salts *1* and *3*

The χ_M of salt **1** is shown in Fig. 7. As described in a previous section, the $Ni(dmit)_2$ anion molecules in salt **1** form a dimer ($Ni(dmit)_2$ (A)–$Ni(dmit)_2$ (B)) with short intra-dimer contacts of ca. 3.6–3.7 Å, suggesting strong AFM exchange interaction. However, the χ_M of **1** can not be explained by a simple dimer model. In salt **1**, the dimer molecules are sandwiched between two verdazyl cation molecules, forming linear tetramer ($[p\text{-EtPyDV}]^+$ (A)–$[Ni(dmit)_2]^-$ (A)–$[Ni(dmit)_2]^-$ (B)–$[p\text{-EtPyDV}]^+$ (B)) (see Fig. 4 and Table 2). As described in a previous section, the verdazyl cation molecule in salt **1** has planar structure, and we can expect close contacts between verdazyl cation and $Ni(dmit)_2$ anion molecules. In fact, there are many short contacts between the Ni, S(i) and C(i) atoms in the $Ni(dmit)_2$ anions and the N(j) atoms (j = 1, 2, 3, and 4) in the hydrazidinyl moiety (N1–N2–C7–N3–N4–C8), having large unpaired spin densities, of verdazyl cations [17]. The result suggests strong exchange interaction between the verdazyl cation and the $Ni(dmit)_2$ anion molecules.

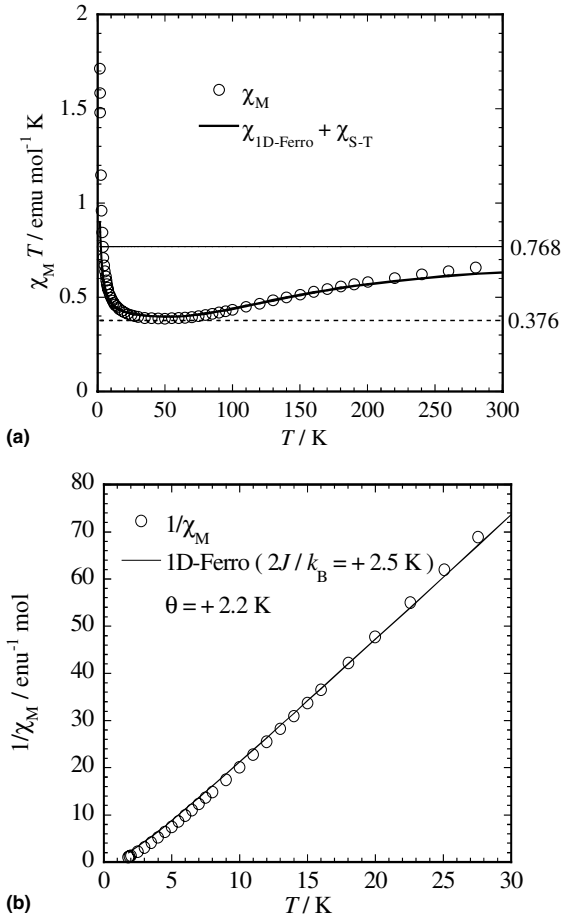

Fig. 8. (a) Temperature dependence of the product $\chi_M T$ (○) for salt **2**. The solid curve is the theoretical susceptibility calculated using Eq. (2). (b) Inverse molar magnetic susceptibility ($1/\chi_M$) of salt **2** at low temperatures. The observed values (open circles) obey the theoretical results for the 1D isotropic Heisenberg ferromagnet (Eq. (3)) with $2J/k_B$ = +2.5 K indicated by the solid line.

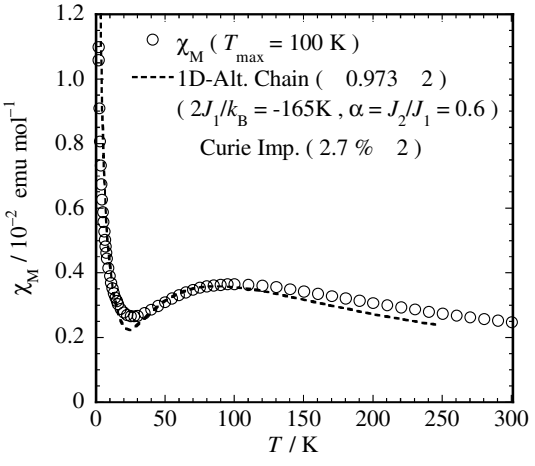

Fig. 9. Temperature dependence of the magnetic susceptibility (χ_M) (○) of salt **4**. The dashed curve is the theoretical susceptibility calculated by using Eq. (5).

In such a case, the χ_M of salt **1** may be explained by a four-spin Heisenberg Hamiltonian,

$$H = -2J_1(S_1S_2 + S_3S_4) - 2J_2S_2S_3,$$
$$S_1 = S_2 = S_3 = S_4 = 1/2, \quad (1)$$

where J_1 is the exchange interaction between an edge verdazyl cation and a central Ni(dmit)$_2$ anion and J_2 is the interaction between two central Ni(dmit)$_2$ anions. The model is shown in Fig. 7(b). This Hamiltonian has been solved exactly by Rubenacker et al. [24] to obtain the energy levels and magnetic susceptibility. Using the Eq. (2) in [24], we have fitted our data to this model, where the g-value (g = 2.0221 at 300 K) observed for salt **1** was used tentatively for the calculation of the susceptibility. The calculated susceptibility is shown by solid curve in Fig. 7(a). The best fit parameters obtained are $2J_1/k_B = -780$ K and $2J_2/k_B = -200$ K. The $2J_2/k_B$ value (−200 K) for the dimer is similar to that (−320 K) for the Ni(dmit)$_2$ dimer in salt **2**, as described later. The Ni(dmit)$_2$ (A) molecule connects with the Ni(dmit)$_2$ (C) molecule with short inter-dimer S···S contacts (see Fig. 4 and Table 2). Therefore, we can expect some interaction between two Ni(dmit)$_2$ molecules (A) and (C). The difference between the experimental and theoretical values of susceptibility of salt **1** may be due to such an interaction.

The susceptibility of the [*p*-MePyDP]$^+$[Ni(dmit)$_2$]$^-$ salt (**3**) is similar to that of salt **1**. The result suggests that salt **3** also forms a magnetic linear tetramer as observed for salt **1**.

4.2. Magnetic property of salt 2

The susceptibility of salt **2** can be explained by the two term contributions (Eq. (2)).

$$\chi_M = \chi_{1D\text{-}Ferro} + \chi_{S\text{–}T}, \quad (2)$$

where the first and second terms represent the contributions from quasi one-dimensional (1D) FM Heisenberg linear-chain system [25] and singlet–triplet (S–T) equilibrium system, respectively. $\chi_{1D\text{-}Ferro}$ and $\chi_{S\text{–}T}$ are given by Eqs. (3) and (4), respectively.

$$\chi_{1D\text{-}Ferro} = (N_o g^2 \mu_B^2 / 4k_B T)[1 + (J/k_B T)], \quad (3)$$

$$\chi_{S\text{–}T} = (N_o g^2 \mu_B^2 / k_B T)[1/(3 + e^{-2J/k_B T})]. \quad (4)$$

The susceptibility of salt **2** follows the Curie–Weiss law with positive Weiss constant of +2.2 K in the temperature region between 10 and 40 K. A plot of $1/\chi_M$ against T is no longer linear at low temperature (<10 K). Therefore, the low-temperature behavior of the susceptibility of salt **2** was analyzed on the basis of the quasi-1D FM Heisenberg model. In fact, the susceptibilities of salt **2** below 40 K are well reproduced by Eq. (3) with $2J/k_B$ = +2.5 ± 1.0 K and g = 2.00, as shown in Fig. 8(b). Above ca. 50 K, however, χ_MT increases with increasing

temperature, as shown in Fig. 8(a). This increase indicates that thermal magnetic excitation occurs in addition to the 1D FM linear-chain spins. The experimental data are interpreted by the S–T model (Eq. (4)) with $2J/k_B = -320$ K. As shown in Fig. 8(a), the experimental curve can be well reproduced by Eq. (2).

4.3. Magnetic property of salt 4

The susceptibility of salt **4** shows a broad maximum at $T_{max} = 100 \pm 2$ K. The susceptibility of **4** can be well explained by the sum of the two contributions;

$$\chi_M = C_{1D\text{-}Alt}\chi_{1D\text{-}Alt} + C_{Curie}\chi_{Curie}, \quad (5)$$

where $C_{1D\text{-}Alt} + C_{Curie} = 2$, and the first and second terms represent the contributions from the 1D AFM Heisenberg alternating-chain system [26] and from the Curie impurity, respectively. C_i is the fraction of each term. The dashed curve in Fig. 9 is a theoretical curve with $C_{1D\text{-}Alt} = 2 \times 0.973$ and $C_{Curie} = 2 \times 0.027$ and $2J_1/k_B = -165$ K (alternation parameter $\alpha = J_2/J_1 = 0.6$). The result shows that both the spins of verdazyl cation and $Ni(dmit)_2$ anion contribute to the magnetism of salt **4**.

4.4. Conducting properties of salts 1–5

Recently, we prepared several kinds of (1:1) and (1:3) salts of open-shell 6-oxoverdazyl radical cations with $Ni(dmit)_2$ anion, and found that the (1:3) salts are molecular paramagnetic semiconductors [18,19]. On the other hand, the (1:1) salts showed the property as paramagnetic insulators, as observed for the usual (1:1) salts of $Ni(dmit)_2$ anion with closed-shell electron donor cations, such as tetra-alkyl-ammonium cations, alkali metal cations, etc [6,7].

However, in the present work, all the (1:1) salts **1**–**4** studied were found to be semiconductors, against to our expectation. As described above, salt **1** forms a magnetic linear tetramer in which the strong exchange interaction between $Ni(dmit)_2$ (A) and verdazyl (B) spins in addition to that between $Ni(dmit)_2$ (A) and (B) spins was observed. Such an interaction will induce a delocalization of conduction electron from $Ni(dmit)_2$ dimer moieties to verdazyl moieties, and, thus, a decrease in the on-site Coulomb repulsion. Further, comparatively short S–S contacts were observed between $Ni(dmit)_2$ (A) and (C) anions, as listed in Table 2. As a result, salt **1** may show semiconductive behavior. Salt **3** showed the magnetic property similar to that of salt **1**. Further, strong interaction between verdazyl cation and $Ni(dmit)_2$ anion was observed for salt **4**, suggesting a decrease in the on-site Coulomb repulsion in **4**. The crystal structure analyses will be necessary to discuss the details of the semiconductive behavior observed for the (1:1) salts **2**–**4**. On the other hand, the conductivity of the (1:3) salt **5** at 20 °C was $\sigma = 1.0$ S cm^{-1} with an activation energy $E_A = 0.048$ eV. This value is three to five orders of magnitude larger than those of the (1:1) salts **1**–**4**.

The examples of the organic/inorganic hybrid system which shows the magnetism and conductivity are very limited, because of the difficulty in molecular design of the complexes. The present work provides five examples of new molecular magnetic semiconductors consisting of open-shell verdazyl radical cation and metal complex anion. Especially, FM interaction was observed for salt **2** at 1.8–40 K. We may expect FM order for salt **2** at lower temperature.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, deposition number CCDC No. 249719. Fig. 1. Kekulé and biradical structures of phenalenyl-based amphoteric redox compounds.

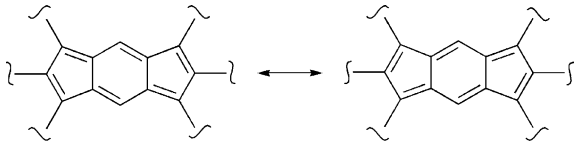
Yanagimoto P1100 spectrometer. Cyclic voltammogram of the compound was recorded with glassy carbon working electrode and Pt counter electrode in CH_2Cl_2 containing 0.1 M $(n\text{-}Bu)_4NClO_4$ as the supporting electrolyte. The experiments employed a saturated calomel electrode (SCE) as a reference. Electrochemical experiments were done under an argon atmosphere at room temperature. For the X-ray crsytal structure analysis, data collection were performed on Enraf-Nonius CAD-4 diffractometer (Mo Kα, $\lambda = 0.71069$ Å) at 9 K for **1** and on Rigaku AFC7R diffractometer (Mo Kα, $\lambda = 0.71069$ Å) at rt for **3**.

2.1. Computational detail



All calculations reported in this paper were performed with the GAUSSIAN 98 program [6]. All geometry optimizations were carried out at the B3LYP level of density functional theory with the 6-31G** basis set. Excitation energy was computed using time-dependent density funcutional theory (TD-RB3LYP) with 6-31G** basis set in the RB3LYP optimized geometry. Singlet biradical character was estimated with the symmetry-broken UB3LYP/6-31G** method with a geometry optimization and with the CASSCF(2,2) method in the RB3LYP optimized geometry.

3. Results and discussion

3.1. Calculated biradicaloid character of *1a–3a*

3.1.1. Closed- and open-shell singlet state

Optimization at the RB3LYP/6-31G** level gave structures in C_{2v}, C_{2v}, and D_{2h} symmetry for **1a**, **2a**, and **3a**, respectively. Strong bond alternations are observed in the central conjugated rings for **1a** and **2a** as shown in Fig. 2 (Kekulé structure). In the restricted DFT solution, thienoquinodimethane and *o*-quinodimethane structures contribute largely to the ground electronic state in **1a** and **2a**. In the case of **3a**, the bond alternation is slightly reduced due to the resonance of the following structures.

However, *p*-quinodimethane structure would contribute to the ground electronic state in **3a**. The RDFT calculations of **1a**–**3a** reveal quite small HOMO–LUMO gaps; 1.238, 0.851, 1.251 eV for **1a**, **2a**, and **3a**, respectively. As shown in Fig. 3, the frontier orbitals of **1a**–**3a** retain the NBMO character of phenalenyl radical and the spatial overlap between HOMO and LUMO are quite large.

As mentioned above, quinoid compounds tend to show biradicaloid characters. The contribution of quinoid structures to the ground electronic state of **1a**–**3a** will lead to the biradicaloid character for **1a**–**3a**. The frontier orbitals of **1a**–**3a** support this idea. For a compound with a large spatial overlap and a small energy gap between HOMO and LUMO, a large exchange

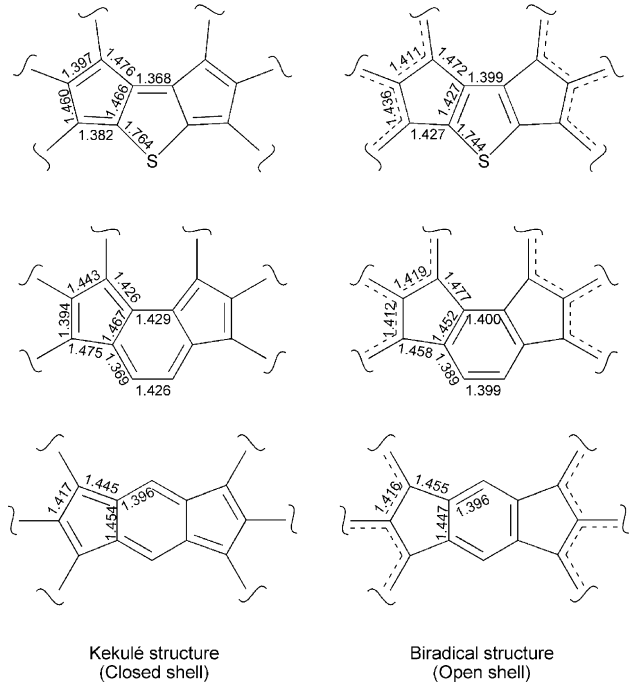


Fig. 2. Calculated geometries of closed- and open-shell singlet state for **1a**–**3a**.

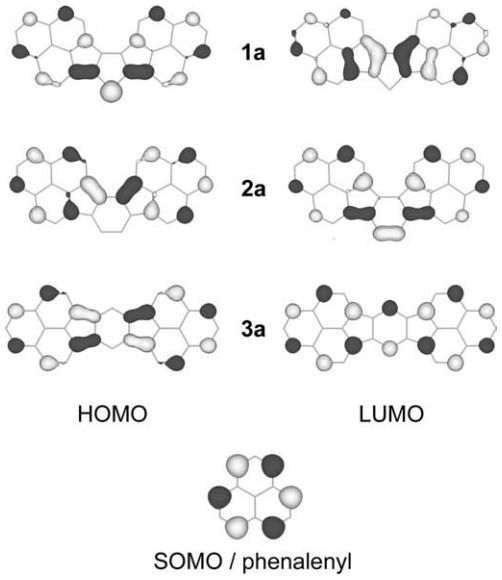

Fig. 3. Molecular orbitals of **1a**–**3a** and phenalenyl radical calculated with RB3LYP/6-31G**.

interaction ($K_{H,L}$) of the frontier orbitals is expected and should lead to a pronounced biradical character of the system. Whereas the exchange interaction $K_{H,L}$ is generally related to the stabilization of a triplet biradical state, a large $K_{H,L}$ will also contribute to the substantial admixture of a doubly excited configuration into a ground state configuration, i.e. a singlet biradical character [7].

The singlet biradical character of a molecule can be estimated by the energy-lowering of the symmetry broken unrestricted DFT solution compared to the restricted DFT solution [8]. The broken symmetry UB3LYP/6-31G** calculation of **1a**–**3a** with the re-optimized geometries gave the substantial energy lowering as summarized in Table 1. The open-shell UB3LYP solutions are 6.42–35.38 kJ/mol below the closed-shell RB3LYP solutions. Natural orbital analysis of the broken symmetry UB3LYP solution reveals the LUMO-occupation numbers of 0.72, 0.99, and 0.37 for **1a**, **2a**, and **3a**, respectively. These occupation numbers suggest the order of increasing biradicaloid character as **3a** < **1a** < **2a** [11]. Qualitatively similar trend is found in the spin contamination $\langle S^2\rangle$. The molecular geometries of **1a**–**3a** show the reduced bond alternations and the revival of aromaticity in the central thiophene and benzene ring. The averaged bond length between the central aromatic ring and the phenalenyl moieties become close to that of the sp^2–sp^2 single bond (1.48 Å). Spin densities of the open-shell singlet (singlet biradical) state of **1a**–**3a** show a similar distribution pattern to that of phenalenyl radical (Fig. 4). Unpaired electrons mainly reside on the two phenalenyl moieties with anti-parallel spins in the each molecule. These findings indicate that phenalenyl-based amphoteric redox compounds **1a**–**3a** possess the singlet biradical character in the ground state, which is best described as the resonance structure of Kekulé and biradical form shown in Fig. 1.

Table 1
Energy gaps (kJ/mol) between the singlet and the triplet state, and the spin contamination of the open-shell singlet state and the triplet state

	1a	2a	3a
ΔE (CS–OS)[a]	7.08	35.38	6.42
$\langle S^2\rangle$[b]	1.01	1.09	0.65
ΔE (T–OS)[c]	3.99	0.96	29.56
$\langle S^2\rangle$[d]	2.07	2.07	2.08

[a] Closed-shell singlet (CS) minus open-shell singlet (OS) energy.
[b] Spin contamination of the open-shell singlet.
[c] Triplet (T) minus open-shell singlet energy. Open-shell singlet energies were scaled to correct for the spin contaminations in the singlet states using ΔE (T–OS)=ΔE (T–OS)^{unscaled} $\langle S^2\rangle_T/(\langle S^2\rangle_T - \langle S^2\rangle_{OS})$ [9,10].
[d] Spin contamination of the triplet.

3.1.2. Triplet state

A large exchange interaction ($K_{H,L}$) of the frontier orbitals lead to the stabilization of the triplet state. Table 1 shows the energy gap between the ground open-shell singlet and the excited triplet state of **1a**–**3a**. The ΔE (T–OS) of **1a** and **2a** are substantially small, whereas **3a** gives a relatively large gap. This implies the small preference for the promotion of an electron from the HOMO to the LUMO in **3a**. As mentioned above, the singlet biradical character of **3a** is smaller than those of **1a** and **2a**. These findings suggest the smaller biradicaloid character of **3a** in comparison with **1a**

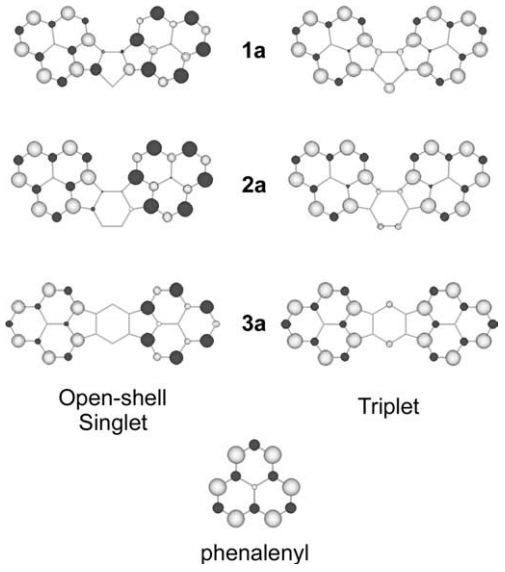

Fig. 4. Spin densities of open-shell singlet and triplet state for **1a**–**3a** along with that of phenalenyl radical (UB3LYP/6-31G**). Light and dark surfaces represent positive and negative spin densities, respectively.

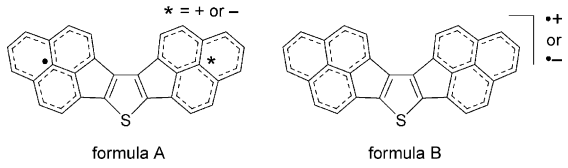
and **2a**. One reason for the difference may be derived from the HOMO–LUMO gaps. TD-RB3LYP calculation for the singlet states (CS) gave the order of increasing transition energy as **2a** (0.614 eV) < **1a** (0.815 eV) ≪ **3a** (1.594 eV), which originated mainly from single-electron HOMO–LUMO excitations.

Unpaired electrons mainly reside on the two phenalenyl moieties with parallel spins in the each molecule (Fig. 4). Similar to the open-shell singlet states, the distribution pattern of the unpaired electrons for the excited triplet state is almost identical to that of phenalenyl radical. Thus, the triplet state is best described as the biradical form shown in Fig. 1.

3.2. Experimental biradicaloid character of *1b–3b*

In general, planer conjugated polycyclic compounds are sparingly soluble in most organic solvents. Furthermore, biradicaloid compounds are highly reactive species, which prevents the isolation and purification of the compounds. In order to overcome these negative aspects, we have introduced *tert*-butyl groups into the parent system of **1a**–**3a** [3–5].

3.2.1. Singlet state



There are few ways of probing singlet biradical characters. ESR spectroscopy, which is a most powerful method for investigating open-shell species, usually gives a negative result for singlet biradical species due to the absence of signals. Cyclic voltammetry would provide suggestive information to the singlet biradical character, because electronic coupling of two unpaired electrons should be different between Kekulé and biradical structures. The Kekulé structure, in which two unpaired electrons are strongly coupled, will give the delocalized frontier orbitals over the entire molecules, which lead to a relatively large difference between the first and second redox potentials (ΔE^{ox} and ΔE^{red}, see Table 2) due to the on-site coulomb repulsion. On the other hand, the biradical structure, in which the electronic coupling is small or non-existing, will provide the frontier orbitals localized on the each radical moiety, which lead to substantially small ΔE^{ox} and ΔE^{red} values [12].

Table 2
Electrochemical data of amphoteric redox compounds (V vs. SCE)

	E_2^{ox}	E_1^{ox}	E_1^{red}	E_2^{red}	ΔE^{oxa}	ΔE^{redb}	E_1^{sumc}
1b	+0.94	+0.47	−0.53	−0.90	0.47	0.37	1.00
2b	+0.75	+0.42	−0.58	−0.96	0.33	0.38	1.00
3b	+0.84	+0.48	−0.67	−1.25	0.36	0.58	1.15

[a] $\Delta E^{ox} = E_2^{ox} - E_1^{ox}$.
[b] $\Delta E^{red} = E_1^{red} - E_2^{red}$.
[c] $E_1^{sum} = E_1^{ox} + (-E_1^{red})$.

The amphoteric redox compounds **1b**–**3b** shows the relatively large values for ΔE^{ox} and ΔE^{red}; indicating the strong coupling of the two electrons. The delocalization of the frontier orbitals could be estimated from the spin distribution pattern of the redox species, i.e. the radical cation and radical anion species of **1b**–**3b**. The ESR spectroscopy of the monovalent radical species revealed the spin delocalization over the entire molecules, which is best described as the formula B instead of the formula A.

formula A formula B

According to the Robin and Day scheme [13], the monovalent radical species of **1b**–**3b** can be placed in the class III category that includes fully-delocalized system. Thus the CV and ESR studies imply the large contribution of the Kekulé structure to the ground singlet state of **1b**–**3b**.

However, the trend of the calculated singlet biradicaloid character is qualitatively in line with those of the E_1^{sum} values and the HOMO–LUMO electron transition energies for **1b**–**3b**. The smallest biradicaloid **3b** shows the largest E_1^{sum} value (Table 2) and HOMO–LUMO transition energy (0.92, 1.00, and 1.64 eV for **1b**, **2b**, and **3b**, respectively). The largest HOMO–LUMO gap for **3b** may be responsible for the smallest biradicaloid character.

In contrast to the CV and ESR results, the indicative result for the singlet biradical contribution to the ground state has been obtained by X-ray crystallographic analysis for **1b**. The X-ray analysis reveals that **1b** forms two kinds of dimeric pairs with substantially short non-bonding contacts of ~3.1 Å between each thiophene rings as shown in Fig. 5. Terminal rings are separated by over 4.2 Å due to the steric repulsion between *tert*-Bu groups and six-membered rings. The van der Waals contact of carbon atoms only exists within central dicyclopenta[*b*; *d*]thiophene units. Attractive interaction for the dimerization should be an intermolecular charge-transfer (CT) interaction through the double excitation configuration $^1\Phi_{H,H\rightarrow L,L}$, i.e. a singlet biradical contribution. Based on the CASSCF(2,2) calculation of **1b**, the occupation numbers of HOMO and LUMO are 1.9 and 0.1, respectively. In this case, a LUMO–LUMO interaction will lead to a stabilization of the system, because a newly formed 'LUMO' of the dimer, which is more stabilized than the original LUMO, can accommodate at least 0.2 electron (Fig. 6). In addition, a HOMO–HOMO interaction seems to contribute the stabilization

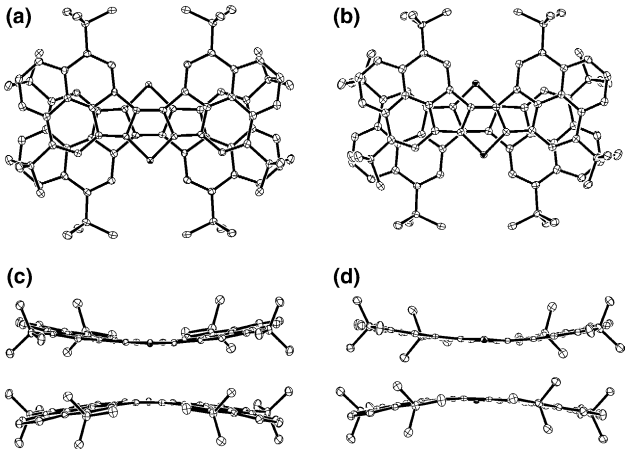


Fig. 5. Crystal structures of **1b**. Top view of the dimeric pair A (a) and B (b), and side view of the dimeric pair A (c) and B (d). Hydrogen atoms were omitted for clarity.

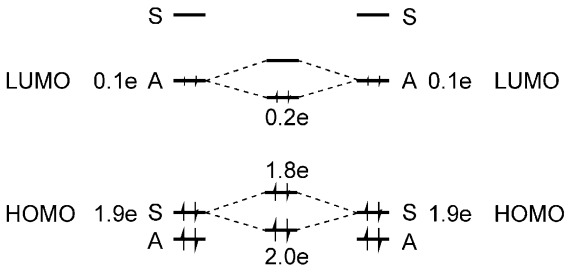

Fig. 6. Schematic drawing of the molecular orbital interaction of the dimeric **1b** through the double excitation configuration $^1\Phi_{H,H\rightarrow L,L}$. 'S' and 'A' denote the symmetry of the molecular orbitals.

of the system, because a newly formed 'HOMO' of the dimer would contain only 1.8 electrons, which result in the suppression of a four-electron repulsion generally arisen from the interaction between fully occupied orbitals.[1]

The large discrepancy is found in the LUMO occupation numbers between the broken-symmetry UB3LYP and the CASSCF(2,2) calculations (0.72e versus 0.1e) for **1a**. On the basis of the CV and ESR results, the UB3LYP calculation seems to overestimate the static electron correlation. The molecular geometry obtained by the X-ray analysis is almost in the middle point between the Kekulé and biradical structures calculated by the B3LYP method (Fig. 7). To estimate more accurate biradical characters, larger size of post HF calculations are highly demanded.

[1] In general, the π–π interaction of aromatic systems is affected by various electronic factors. The well-known attractive forces are derived from electrostatic interactions between electron-deficient and electron-rich sites. However, this interaction is not likely effective for the dimers of **1b**, because the overlap of positive and negative charges is small on the basis of the Mulliken charge analysis.

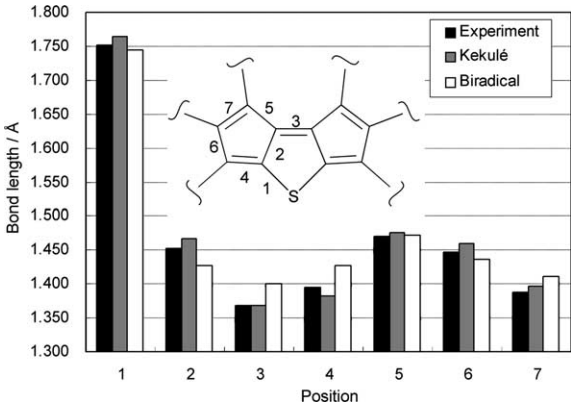

Fig. 7. Experimental and theoretical bond lengths of the central rings of **1b**. The experimental data are the averaged bond lengths.

3.2.2. Triplet state

As described above, **1a** and **2a** possess the substantially small energy gaps between the singlet and triplet state. This finding suggests that **1b** and **2b** should be in thermal equilibrium with triplet states even at room temperature. ^{1}H NMR spectra of **1b** and **2b** give no signals in the aromatic region at room temperature. Although on cooling a broad band appears in the aromatic region, sharp signals can not be obtained even at −90 °C. The equilibrium with the thermally accessible triplet state would cause the line broadening of the NMR signals. The ESR measurement of the solid **1b** affords typical spectra for triplet species ($|D|$ = 17.2 mT, $|E|$ = 3.9 mT) and temperature dependence of the half-field signal indicates the thermal excitation to the triplet state with the energy gap (ΔE_{S-T}) of ~5 kJ/mol. From the D value, the average distance between the two interacting spins can be estimated to be 5.5 Å, which is smaller than the intramolecular distance between the centers of the two phenalenyl moieties of **1b** (8.4 Å).

The less biradicaloid **3b** also shows the NMR signal broadening at room temperature. In contrast to **1b** and **2b**, on cooling to −30 °C the broad signals become sharp and four peaks appear at 7.69, 7.10, 7.04, and 6.98 ppm. The ESR spectrum of the solid **3b** affords the fine structure typical for triplet species ($|D|$ = 9.6 mT, $|E| \leqslant 0.2$ mT, ΔE_{S-T} = 20.4 kJ/mol) above room temperature.

4. Conclusion

The phenalenyl-based amphoteric redox compounds show appreciable biradicaloid characters. The most biradicaloid compounds are very reactive and then are observable only in a low-temperature matrix, whereas **1b**–**3b** can be isolated in air at room temperature. The difference of the stability should be arisen from the spin delocalization over the phenalenyl units. The connection

of two phenalenyl radical units with various quinoid compounds will lead to the wide variety of biradicaloid compounds isolable in air. The stable biradicaloid compounds will open the opportunity to investigate the solid state properties such as crystal packing, magnetism, and electro-conductive behavior on the basis of the new sort of idea.

observed for the protonated complexes **1**–**3** in comparison with the corresponding unprotonated complexes. Geometries for N–H ⋯ O, i.e. $d_{NH\cdots O}$ = 1.67 − 1.88 Å, $d_{N\cdots O}$ = 2.65 − 2.69 Å, θ_{N-H-O} = 166.1°–178.5°, are almost same as the values found in pyridine–carboxylic acid dimers [2]. The N ⋯ O distances of 2.65–2.69 Å indicate strong hydrogen bond interactions between the metal complexes and trifluoroacetate molecules. The four trifluoroacetate molecules binds to the one metal complex and the trifluoroacetate is hydrogen bonded to another metal complex. The two metal complexes are almost orthogonal, with an angle of about 89° between the two planes. Thus, the complexes **1**–**4** form the 2D zigzag sheet through hydrogen bonds.

Regarding the interaction between the 2D sheet, the trifluoroacetate molecules play an important role in binding the sheets as shown in Fig. 3. Negative trifluoroacetate molecules come close to the positive pyrazine rings whose charges are induced by protonation. An oxygen atom and three fluorine atoms of the trifluoroacetate point to the positive pyrazine ring. Table 3 shows the distance of C–F ⋯ π and C–O ⋯ π. To estimate the inter-

sheet interaction, electrostatic potential was calculated using the DFT method (UB3LYP/LANL2DZ). The electrostatic potential shown in Fig. 4 reveals that the pyrazine rings are more positive relative to the central MS_4 unit and Et groups. On the other hand, negative charges would reside on the F and O atoms of the trifluoroacetate molecules. This electrostatic interaction (cation–anion) is responsible for stacking of the 2D sheets.

3.2. Magnetic behavior of *1*

As described above, hydrogen bond has been extensively demonstrated not only to be a useful tool for

Fig. 4. Electrostatic potential surface for **1** calculated with UB3LYP/LANL2DZ: More positive site (dark), less positive site (light).

crystal engineering but also to propagate ferromagnetic interactions. To estimate magnetic exchange coupling through TFA, the magnetic susceptibility measurement of **1** was carried out using a SQUID magnetometer at 2–290 K. The χT value at room temperature equals 0.381 emu K mol^{-1}, which is close to the calculated value for uncorrelated $S = 1/2$ spins. In the whole temperature range the χT value shows no dramatic changes, indicating the absence of strong magnetic interactions between the Cu complexes (Fig. 5). The DFT calculation (UB3LYP/LANL2DZ) of the Cu complex surrounded by eight trifluoroacetate molecules indicates that an unpaired electron resides mainly on the central CuS_4 unit (93%) and that no spin density is localized on oxygen atoms of the trifluoroacetate (<1%). Fig. 6 shows the spin density of **1** · 8TFA. Furthermore, long Cu–Cu distance of 8.61 Å and no van der Waals contact between the CuS_4 units prevent strong magnetic interactions. The absence of the strong magnetic interaction results in the isolated spin sites. Thus, the Cu complex **1** shows paramagnetic behavior at 2–290 K.

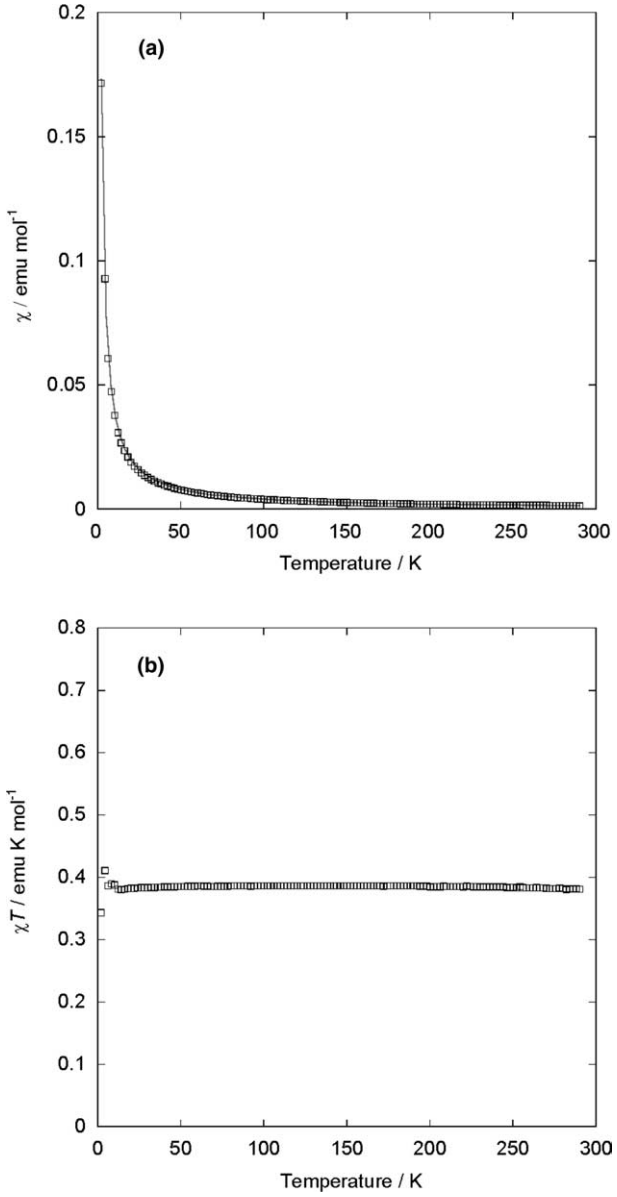

Fig. 5. Temperature dependence of the magnetic susceptibility of **1**. (a) χ–T plot and (b) χT–T plot.

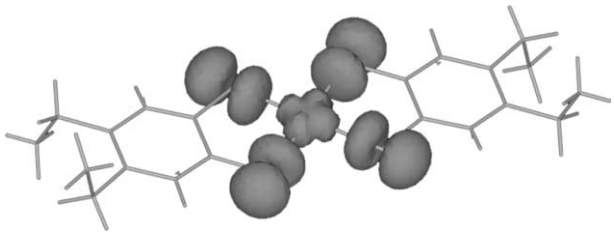

Fig. 6. Spin density of **1** · 8TFA. TFA molecules are omitted for clarity.

4. Conclusions

The bis(pyrazinedithiolate)metal complex have formed the 2D zigzag sheet structure bridged by trifluoroacetic acid molecules. The SQUID measurement has revealed that the Cu complex shows the paramagnetic behavior. The DFT calculation has suggested the spin localization on the CuS_4 core with no contribution of TFA molecules to propagating the spin.

5. Supplementary material

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 200418, 200419, 200420, and 200421. $(n\text{-Bu}_4\text{N})_2[(\text{dcbdt})_2\text{VO}]$

$(n\text{-Bu}_4\text{N})_2[(\text{dmit})_2\text{Zn}]$

Scheme 1.

2. Experimental

$(n\text{-Bu}_4\text{N})_2[(\text{dmit})_2\text{Zn}]$ was used as purchased from Tokyo-Kasei Ltd. $(n\text{-Bu}_4\text{N})_2[(\text{dcbdt})_2\text{VO}]$ was prepared as follows. 4,5-dicyanobenzene-1,2-dithiol (H_2dcbdt) (135.0 mg, 0.702 mmol) prepared in accordance with the literature [9] was dissolved in 5 ml methanol solution of NaOMe (83.4 mg, 1.54 mmol). To this solution, a solution of anhydrous VCl_3 (55.2 mg, 0.35 mmol) in 5 ml of tetrahydrofuran was added and exposure of this solution to air. After exposure for 30 min n-Bu_4NBr (905.2 mg, 2.81 mmol) was added. The dropwise addition of 20 ml of water caused the product to precipitate as light brown powder. This precipitate were recrystallized from acetone–i-PrOH (1:2) and dried in air to give 283.5 mg (87%) of product. The composition of $(n\text{-Bu}_4\text{N})_2[(\text{dcbdt})_2\text{VO}]$ was determined by X-ray structure analysis [8].

Silicon (Si (1 0 0)) (Shin-etsu Silicon, Japan), magnesium oxide and glass (Matsunami, Japan) substrates were used as purchased. Dipping process was performed as follows. A solution of bisdithiolene metal complexes (1.0×10^{-2} mol) in freshly distilled acetone (2.5 ml) was introduced into a weighing bottle. To this bottle, substrates were dipped under ambient and highly humidified condition. Deposits of corresponding bisdithiolene metal complexes grew on the surface of several substrates during solvent evaporation.

The deposits were examined with an analytic scanning electron microscope (JSM-6360LA, JEOL Ltd.) and a scanning probe microscope (SPI 3700, SII Nanotechnology Inc.).

3. Results and discussion

An X-ray structure analysis indicated that $[(\text{dcbdt})_2\text{VO}]$ moieties were surrounded by n-Bu_4N cations and there was no direct interaction among these moieties. Although there was no direct interaction among them, several S···H, C···H and N···H van der Waals contacts between n-Bu_4N cations and $[(\text{dcbdt})_2\text{VO}]$ moieties were observed. The ESR and SQUID measurement showed that the vanadium atom is in the state of V(IV) ($S = 1/2$) and these magnetic moments interacted with each other very weakly antiferromagnetically (−0.371 K of Weiss temperature). The detail of molecular and crystal structure, and magnetic properties of newly obtained $(n\text{-Bu}_4\text{N})_2[(\text{dcbdt})_2\text{VO}]$ have been reported separately [8].

Fig. 1 shows SEM images of the $(n\text{-Bu}_4\text{N})_2[(\text{dmit})_2\text{Zn}]$ deposits on a polished surface of silicon substrates. The shapes of deposits are largely affected by the experimental conditions. The deposits of this complex is formed by well defined diamond and hexagonal shaped micro-sized (almost millimeter sized) crystals under ambient condition (Fig. 1(a)). On the other hand, the deposits under highly humidified condition consist of

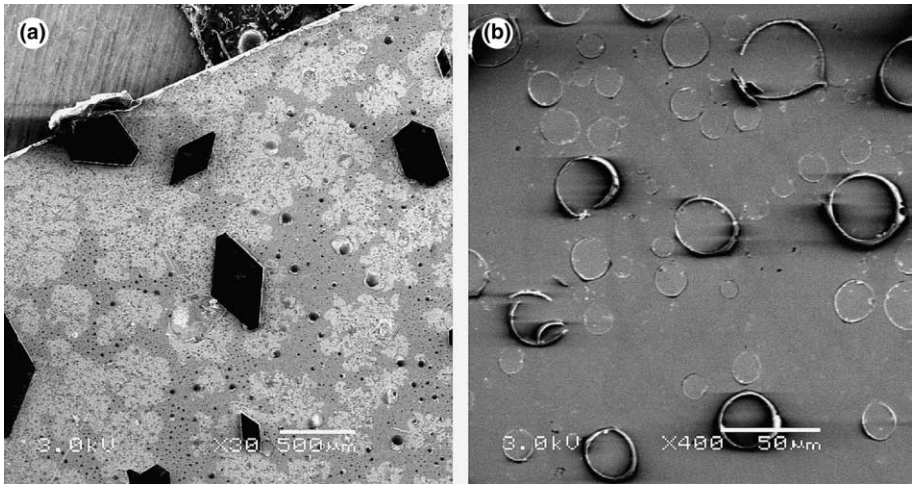

Fig. 1. SEM images of deposits of $(n\text{-Bu}_4\text{N})_2[(\text{dmit})_2\text{Zn}]$ on a polished surface of silicon substrates under (a) ambient and (b) highly humidified conditions.

micro-scale rings. The internal and external diameter lies from 10 and 30 μm, and from 15 to 40 μm (Fig. 1(b)).

On the contrary to the zinc complex, deposits of (n-$Bu_4N)_2$[$(dcbdt)_2VO$] show quite different morphologies under ambient condition. On glass substrate prismatic micro-crystals are observed under an optical microscope as was seen from the deposits of the zinc complex. SEM images of the micro-crystals show that a lot of micro-scale porous structures exist on the surface of it (Fig. 2). The diameter of these pores lies from 2 to 180 μm. On magnesium oxide substrate the deposit consists of bead structures with a diameter around 5 μm (Fig. 3). When a non-polished surface of a silicon substrate is used, the surface is covered with a two-dimensional network (Fig. 4). Furthermore when a polished surface of silicon substrates is used, two kinds of morphologies are observed (Fig. 5(a)). One of them is a needle like micro-crystal with the thickness of 5–8 μm and the length of 20–150 μm (Fig. 5(b)). The other one is a micro-scale ring (Fig. 5(c)). The internal diameter lies from 1 to 10 μm and the external diameter lies from 10 to 20 μm. The AFM image reveals that the micro-scale ring with a diameter of 20 μm has 640 nm thickness. Same procedure under highly humidified condition diminish the size of the micro-scale rings. Mainly obtained smaller rings have an internal diameter around 2.0 μm and an external diameter around 4 μm (Fig. 5(d)).

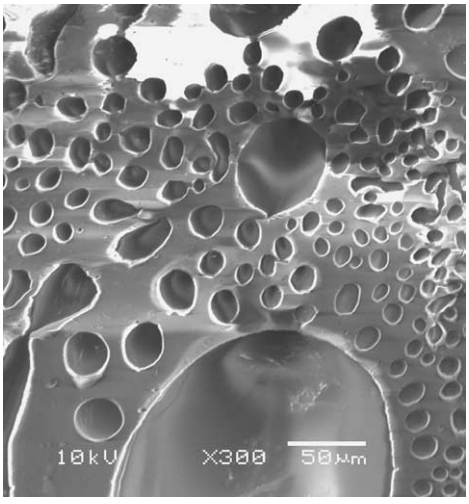

Fig. 2. A SEM image of deposits of (n-$Bu_4N)_2$[$(dcbdt)_2VO$] on a glass substrate.

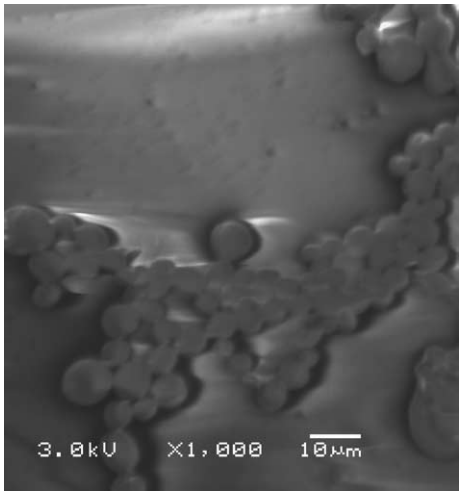

Fig. 3. A SEM image of deposits of (n-$Bu_4N)_2$[$(dcbdt)_2VO$] on a magnesium oxide substrate.

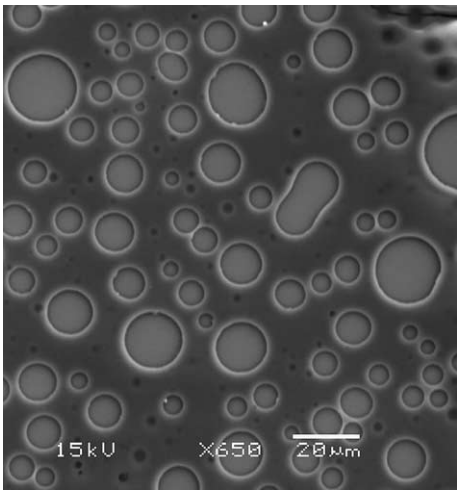

Fig. 4. A SEM image of deposits of (n-$Bu_4N)_2$[$(dcbdt)_2VO$] on a non-polished surface of a silicon substrate.

Although any explanation for formation of micro-scale rings on polished silicon surface must remain somewhat speculative at this stage, the observed micro-scale ring is reminiscent of the micro-porous films formed in the solvent evaporation of many materials, such as block copolymers, amphiphilic polyion complexes, such as organic/inorganic hybrids and homopolymers, such as polystyrene [10]. In these systems, water droplets condensed from moisture on the evaporating solutions act as the template to direct formation of the honeycomb patterns. The speculative formation of the new micro-scale rings could be explained as follows. The micrometer sized droplets of acetone solution of dithiolene metal complexes disperse on the polished surface of the silicon wafer randomly. The evaporation of the acetone leads to a cooling of the solution due to the heat of evaporation and water vapor condenses on the surface of the acetone solution droplets. Micro-sized water droplets grow in the middle of the solution droplets by further evaporation of acetone. This water droplet acts as the template to form the hole of the micro-scale rings.

4. Summary

We have successfully fabricated porous, bead, two-dimensional network and micro-scale rings structures of $(n\text{-}Bu_4N)[(dcbdt)_2VO]$ and $(n\text{-}Bu_4N)_2[(dmit)_2Zn]$ on several substrates using a simple and easy chemical deposition method for the first time. We believe that this simple and easy fabrication method makes it suitable for practical applications such as new information storage and low cost nano-scale lithography as well as scientific research.

In particular, we take strong interest in an application of the ring to the magnetic storage, because each vanadium atom in the ring has the magnetic moment and these moments interact with each other. For example, when nano-scale rings can be two-dimensionally arrayed, they could become a high density storage media. Here, for each ring, the record may be performed by changing the magnetic state, where the change is realized by changing the magnitude of exchange interactions, and so on. On the other hand, the read may be done by microscopy utilizing the electron spin resonance [11] or the spin dependent transport [12].

We are now theoretically investigating properties about the magnetic storage, and the results will be reported elsewhere.

Similar π-systems are constructed by connecting bulky π-radicals. Poly(π-radical anion) of oligo(9,10-anthrylenes) is a good example [7]. In this case, π-radicals reside on anthracene π-planes, which are aligned sterically in an almost orthogonal orientation, and thermally excited high-spin states were observed. In order to realize a high-spin state as a ground state, perfect orthogonality is necessary, and the torsional angle between the spin-carrying π-systems should be close to 90°.

Recently, directly *meso*-linked porphyrin arrays have been synthesized and investigated [8,10–12]. The characteristics of these porphyrin arrays are orthogonal orientation of π-systems derived from steric hindrance between adjacent porphyrin macrocycles. The torsional angles of the neighboring π-planes have been estimated to be nearly 90° in a solution, based on the excitonic coupling of the Soret band absorption [10,11,13]. X-ray crystallographic analyses of another derivative of directly *meso*-linked dimer revealed that the torsional angle is also large in a crystal [12]. Therefore, this π-system is convenient for spin alignment based on spacially orthogonal alignment of molecular orbitals. For the formation of π-radical cation, Zn(II) porphyrin derivatives have been well investigated since the central zinc atom is inactive to the redox reaction. Furthermore, π-radical cations of Zn(II) porphyrin derivatives are relatively stable because of the electron donating character.

From these viewpoints, we have investigated the poly(π-radical cation)s of directly *meso*-linked Zn(II) porphyrin arrays. In our preliminary report [8], high-spin states of the poly(π-radical cation)s of the porphyrin arrays were observed in terms of ESR spectroscopy. It was also found that bis(π-radical cation) of directly *meso*-β-linked Zn(II) porphyrin dimer is a triplet species which obeys Curie law [9]. For the further investigation of directly *meso*-linked porphyrin dimer, substituent effect at the *meso*-position was confirmed. Since the highest occupied molecular orbital (HOMO) of ordinary tetraphenylporphyrin derivative has A_{2u} symmetry, the spin density of the π-radical cation is high at the *meso*-position. The magnetic interaction between two π-radicals which reside each porphyrin unit should be strongly dependent on the spin density at the *meso*-positions of the nearest neighbor. If the electron-donating ability of the *meso*-aryl substituents is increased, electron density at the *meso*-positons is also increased, leading to larger magnetic interaction between two π-radical cations. In order to discuss about this effect, a series of directly *meso*-linked Zn(II) porphyrin dimers bearing various *meso*-substituents (**1**–**5**) were prepared, and the property of the bis(π-radical cation) of dimer **2** is compared with that of dimer **1**, which carries *meso*-(3,5-di-*tert*-butylphenyl) substituents.

2. Experimental

These porphyrin dimers were prepared by oxidative coupling of corresponding Zn(II) 5,10,15-triphenylporphyrin derivatives. Chloroform solution of $NaAuCl_4$ was prepared by dipping $NaAuCl_4 \cdot 2H_2O$ powder into same volume of dimethylformamide followed by dilution with chloroform. ESR spectra were recorded on a JEOL JES-TE300 spectrometer, equipped with an RMC liquid helium transfer system and a Scientific Instruments 9650 digital temperature controller. Zero field splitting parameters were evaluated from high field approximation.

3. Results and discussion

3.1. Preparation and characterization of dimers

Directly *meso*-linked porphyrin arrays have been prepared by either of cyclization reaction using *meso*-formylporphyrins [10a] or oxidative coupling reaction [10b,11]. For oxidative coupling method, silver ion salts are commonly used, since further oxidation of the resulted porphyrin arrays leads the formation of ring-fused species [11]. In this study, however, silver ion salts were not effective for the oxidation of triarylporphyrins with electron-withdrawing substituents. Therefore, these triarylporphyrins were oxidized electrochemically, and corresponding dimers were successfully obtained with relatively good yields. Usually, the resulted dimer is more oxidizable than the starting monomer. If the

oxidation reaction is performed continuously, oxidation of dimer should occur more frequently than that of monomer. Electron-donating substituents will contribute to this tendency while electron-withdrawing substituents will disturb it. This effect might be the reason for the relatively good yield of the electrochemically generated dimers.

UV–Vis absorption spectra of these directly *meso*-linked porphyrin dimers showed split Soret bands around 420 and 460 nm (Table 1), that is, one lower-energy absorption of the excitonically coupled transition dipole parallel to the *meso–meso* linkage and the other higher-energy absorption of the transition dipoles perpendicular to the linkage. The higher-energy absorption is sensitive to the torsional angle. If the dipoles are uncoupled by the rectangular crossing due to the orthogonal structure, the excitation energy is similar to the corresponding monomer. In fact, as seen in Table 1, the higher-energy Soret bands of dimers **1**–**5** is similar to the corresponding monomers **6**–**10**.

Cyclic voltammograms of these dimers showed two reversible redox waves (Table 2). The first oxidation potentials of these dimers are distributed to wide range while the separations between the first and the second potentials are almost same. The similarity and small value of ΔE indicate that these oxidation processes are successive oxidation from each porphyrin rings and that the Coulombic effect between two porphyrin rings is similar in these dimers.

3.2. Chemical oxidation of dimers to mono(π-radical cation)s

When a chloroform solution of dimer **1** was treated with a small amount of $NaAuCl_4$ in chloroform, the lower energy absorption of Soret band (450 nm) decreased, whereas the higher energy absorption of Soret band (410 nm) remained, as shown in Fig. 1(a). Based on the exciton coupling theory, the former absorption is assigned to the coupled transition dipole parallel to the *meso–meso* linkage of the neutral dimer, and the latter one is assigned to the transition dipole perpendicular to the linkage, which resides on one neutral porphyrin macrocycle. Therefore, the decrease of the higher energy absorption of Soret band indicates that the loss of the coupled transition dipole. The broad absorption band appeared at longer wavelength region (~650 nm) is derived from π-radical cation of a porphyrin. Oxidation of either porphyrin moiety of the dimer to a π-radical cation causes the loss of the exciton coupling. The remaining slightly increased higher energy absorption of Soret band indicates that the other porphyrin moiety is kept neutral.

The ESR spectrum of the oxidized species was observed as a single peak at 10 K, indicating the generation of mono(π-radical cation) $\mathbf{1}^{+\cdot}$. At room temperature, the

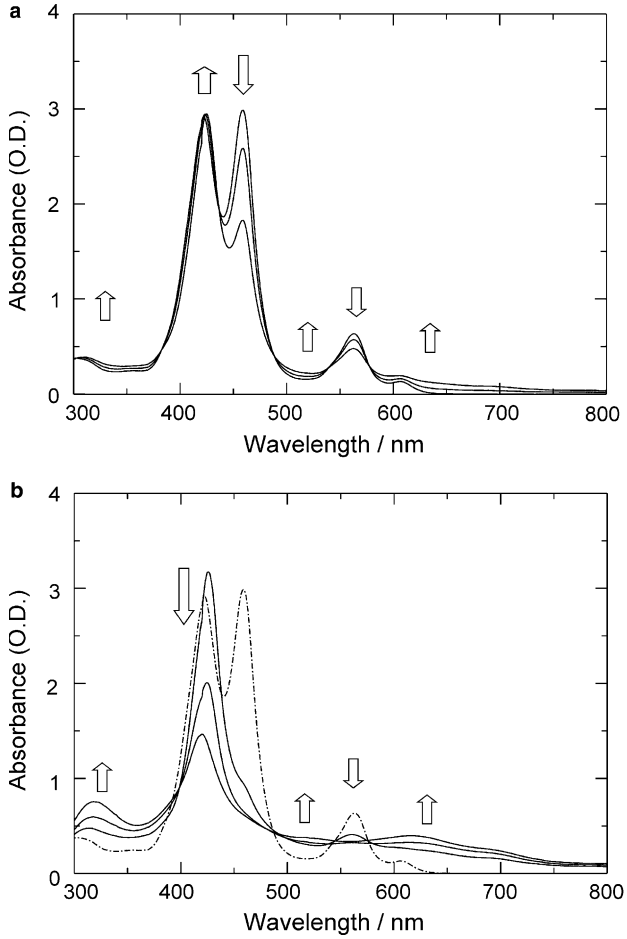

Fig. 1. In situ absorption spectral changes due to the progress of the oxidation of dimer **1** at room temperature by the treatment with $NaAuCl_4$ in chloroform. (a) The first oxidation stage from **1** to $\mathbf{1}^{+\cdot}$ and (b) the second oxidation stage from to $\mathbf{1}^{+\cdot}$ to $\mathbf{1}^{2+\cdot\cdot}$. The dotted broken line corresponds to the starting neutral dimer **1**.

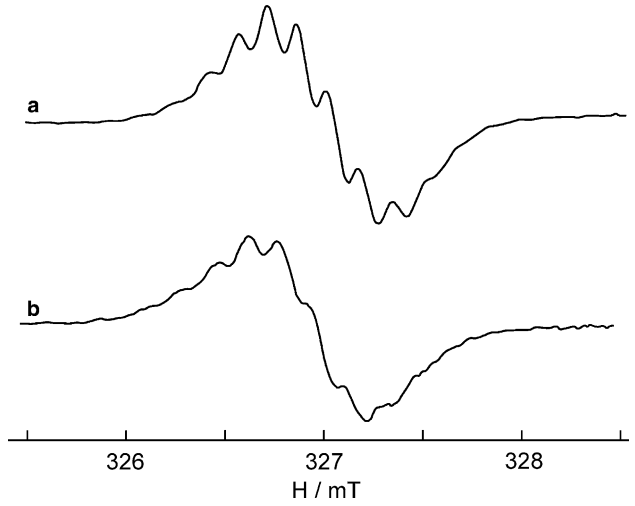

Fig. 2. ESR spectra of (a) π-radical cation of monomer **6**, and (b) mono(π-radical cation) of dimer **1** in chloroform at room temperature. 9.1662 GHz (1 mW) microwave and 63 μT field modulation were used.

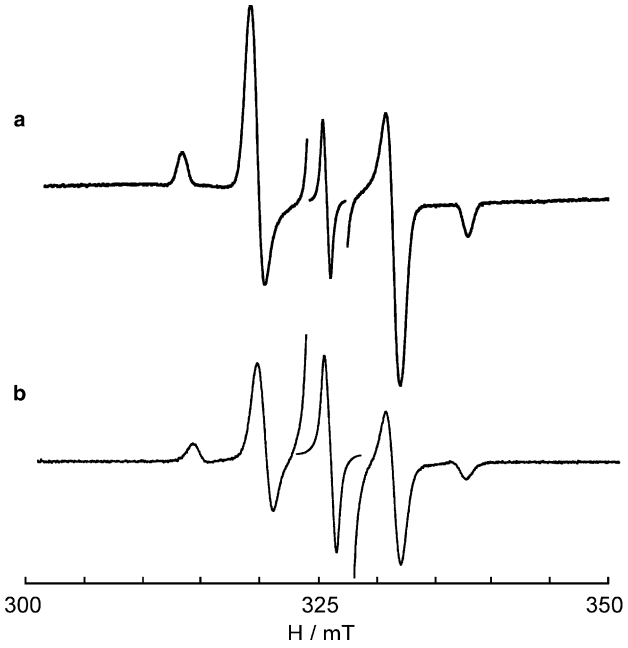

Fig. 3. ESR spectra of bis(π-radical cation) of (a) dimer **1**, and (b) dimer **2** in chloroform at 100 K. 9.1492 GHz (for **1**) or 9.1504 GHz (for **2**) microwave (0.2 mW) and 1 mT field modulation were used.

ESR signal showed a hyperfine-splitting structure due to four equivalent nitrogen atoms as shown in Fig. 2(b). The hyperfine coupling constant and g value ($a_N = 1.57$ G, $g = 2.0037$) are almost the same as those of the corresponding monomer **6** ($a_N = 1.51$ G, $g = 2.0031$, Fig. 2(a)). These results suggest that the π-radical remains on the single porphyrin ring and hardly penetrates the adjacent porphyrin ring because of the small overlap integral between the orthogonal π-systems.

3.3. Diradical formation of dimers

A cyclic voltammogram of dimer **1** has a pair of reversible peaks at 0.47 and 0.60 V versus Ag^+/Ag. The small difference in these potentials suggests that the redox processes are successive one-electron oxidations of each porphyrin ring of dimer **1**, that is, the first one is the formation of mono(π-radical cation) $\mathbf{1}^{+\cdot}$ at one porphyrin ring, and the second one is the oxidation at the other ring to bis(π-radical cation) $\mathbf{1}^{2+\cdot\cdot}$. This is not the case of the formation of a single porphyrin π-dication connected with a neutral porphyrin in the dimer, where the unsymmetrical oxidation is energetically unfavorable. Therefore, further oxidation of mono(π-radical cation) $\mathbf{1}^{+\cdot}$ should afford diradical species. In the CV time scale, diradical $\mathbf{1}^{2+\cdot\cdot}$ is stable enough to give a reversible voltammogram, whereas continuous electrolysis affords the ring-fused compounds, as reported recently [11]. The redox potentials of dimer **2** were observed at 0.43 and 0.55 V, which were lower than those of dimer **1**. Such tendency is derived from electron donating nature of the octyloxy groups, and the result indicates that generation of bis(π-radical cation) of dimer **2** is easier than dimer **1**. The difference between the first and the second potentials of dimer **2** is almost same as that of dimer **1**, indicating that the difference is caused by Coulombic effect.

An additional treatment of the solution of the mono(π-radical cation) of dimer **1** by $NaAuCl_4 \cdot 2H_2O$ caused a spectral change in low temperature ESR. Along with the decreased central monoradical signal, a set of fine-structured signals due to a triplet diradical were observed, as shown in Fig. 3(a). Half-field forbidden transition ($\Delta m_s = \pm 2$) signal was also observed at $g = 4.003$. The zero-field-splitting parameters at 110 K were determined to be $|D| = 1.19 \times 10^{-2}$ cm^{-1} and $|E| = 3.0 \times 10^{-4}$ cm^{-1}, respectively. Although these values slightly deviated with a change of temperature, the spectral line shape was qualitatively kept. The large D value indicates that each component of the diradical resides nearby, and the small E value is due to an axis symmetry. On the basis of the point dipole approximation, the D value is translated as two spins with ca. 6.0 Å distance. The distance calculated from the ESR D value is shorter than the center-to-center distance of two porphyrins (8.4 Å). Such tendency may be derived from the contribution of spin density at the *meso*-positions of the nearest neighbor.

During the second stage of oxidation, the higher energy absorption of the Soret band (410 nm) assigned to the remaining neutral porphyrin macrocycle decreased, indicating the formation of a bis(π-radical cation) $\mathbf{1}^{2+\cdot\cdot}$ (Fig. 1(b)).

The bis(π-radical cation) of dimer **2** was also generated by the same manner, and it showed similar ESR

spectrum (Fig. 3(b)). The similar zero-field-splitting parameter values of these two bis(π-radical cation)s indicate that the structure or the distribution of each π-radical is almost same.

3.4. Singlet–triplet energetics of π-diradicals

The temperature dependence of the $\Delta m_s = \pm 1$ signal intensity is unprecedented feature, as shown in Fig. 4. At temperatures lower than 120 K, the triplet spectrum kept almost the same signal, although the intensity increased gradually as the temperature increased. On the other hand, an abrupt increase and decrease of the signal intensity was observed at 130–190 K with keeping the similar line shape. This behavior is reversible with increasing and decreasing the temperatures. The temperature where signal intensity grows up is higher for dimer **2** than dimer **1**. Maximum signal intensity of $\mathbf{1}^{2+\bullet\bullet}$ was observed at 165 K, and that of $\mathbf{2}^{2+\bullet\bullet}$ was at 180 K.

The plots of the triplet ESR signal intensity versus the inversed temperature, however, cannot be rationalized as a thermally excited species with a single energy gap, which is represented by the following equation:

$$I = (C/T)[\exp(-\Delta E/k_B T)/\{1 + 3\exp(-\Delta E/k_B T)\}]. \quad (1)$$

Although the intensity change at the lower temperature region may be reproduced as a summation of plural components with different singlet–triplet energy gaps, at least three components ($\Delta E/k_B = 200$, 100, and 40 K, with a ratio of 2.5:1.2:1, for $\mathbf{1}^{2+\bullet\bullet}$) are needed for the good fit (Fig. 5). In this case, the number of components (three) does not have any meaning, and there should be a large number of components. These three components are just representatives of various components. The singlet–triplet energy gap depends on the overlap integral, which are closely related with the dihedral angle between two spin-carrying sites. If there are several kinds of bis(π-radical cation)s of the *meso*-linked dimers with different dihedral angles in the frozen solution, these bis(π-radical cation)s should exhibit various singlet–triplet energy gaps. The temperature dependence at lower temperatures indicates such situation. When the temperature is raised up to 130 K, molecular motion around the *meso–meso* linkage may take place. Under this circumstance, the averaged molecular symmetry is considered to be nearly D_{2d}, and the dihedral angle between two porphyrin rings should be almost 90°. Therefore, the singlet–triplet energy gap is minimized to cause the abrupt increase of the signal intensity.

The rotation around the *meso–meso* linkage will cause changes in zero-field splitting parameters. In fact, slight shift of signal positions was observed between 120–160 K. In the case of symmetrical diradicals, such as C_{60}^{2-}, it has been discussed that some nearly degenerated states are averaged dynamically with variable factors to cause change in ESR spectra along with temperature variation [14]. The dynamic Jahn–Teller effect may operate in the present case.

When orbital interaction between the neighboring *meso*-positions is considered, the magnitude of the

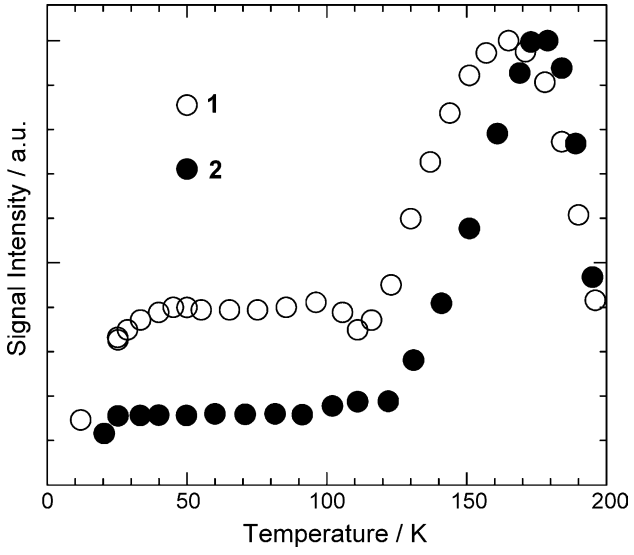

Fig. 4. Temperature dependence of triplet ESR signal intensity of bis(π-radical cation) of dimer **1** (open circles) and dimer **2** (closed circles) in chloroform.

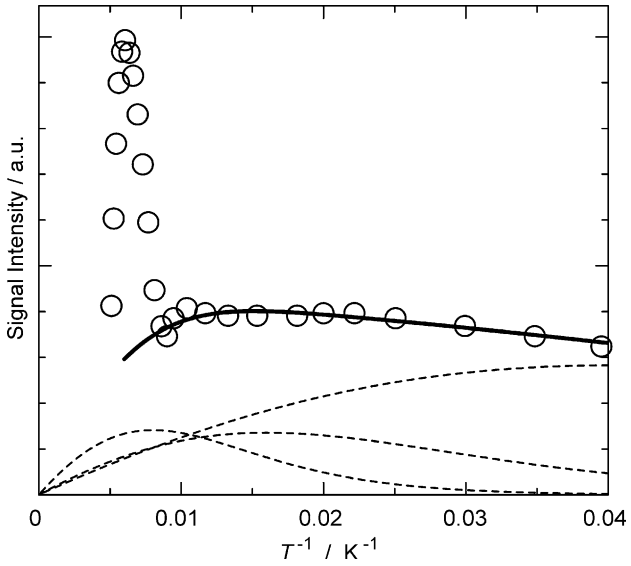

Fig. 5. Fitting of temperature dependence plots of triplet ESR signal intensity of bis(π-radical cation) of dimer **1**. The open circles are experimental data and the solid line shows the summation of three components, which are drawn with dotted lines. The dotted lines show the theoretical curves derived from Eq. (1) for singlet–triplet energy gap $\Delta E/k_B$ = 200, 100, or 40 K, with a factor (included in C) of 2.5, 1.2, or 1.0, respectively.

interaction depends on the orbital coefficients at the *meso*-positions of the nearest neighbor. If electron-donating ability of the *meso*-substituents is increased, the electron density at the *meso*-positions is also increased. Therefore, magnetic interaction in bis(π-radical cation) of dimer is expected to be modulated with the electron-donating ability of the *meso*-substituents. In fact, replacement of *meso*-(3,5-di-*tert*-butylphenyl) group of dimer **1** to *meso*-octyloxypheny group (**2**) caused the shift of the characteristic temperatures to the higher side (Fig. 4).

Drastic change in magnetic susceptibility is frequently found in the crystalline state. Such phenomena are usually based on cooperative effects. Sometimes the balance of enthalpy and entropy contributions causes a phase-transition like behavior. In spin-crossover systems, high temperature high-spin phase and low temperature low-spin phase are observed. The temperature dependence of the bis(π-radical cation)s of directly *meso*-linked porphyrin dimers reminds us such behavior.

4. Conclusion

A series of directly *meso*-linked Zn(II) porphyrin dimers were prepared, and two of them were chemically oxidized to bis(π-radical cation)s. The temperature dependence of ESR triplet signal intensity showed anomalous feature, which was rationalized in terms of molecular motion. This result may imply that the orthogonality between two porphyrin rings is not yet enough. If the perfect orthogonality is achieved in a moment of the rotation around the *meso–meso* linkage at high temperature, degeneracy or crossover between singlet and triplet states may take place. Comparison of diradical $\mathbf{2}^{2+\bullet\bullet}$ with diradical $\mathbf{1}^{2+\bullet\bullet}$ revealed that the magnetic interaction in these π-diradicals is modulated by the electron-donating ability of the *meso*-aryl substituents.

2. Experimental

2.1. Materials

The monomers, 2,7-bis(4-acetoxy-3,5-di-*tert*-butylphenyl)-10-bromo-9-(3-hydroxy-3-methyl-1-butynyl)anthracene (**A1a**) and 2,7-bis(4-acetoxy-3,5-di-*tert*-butylphenyl)-9-bromo-10-(3-hydroxy-3-methyl-1-butynyl) anthracene (**B1a**), were synthesized as previously described [2]. Other conventional reagents were used as received or purified by conventional method.

2.2. Polymerization and fractionation

Polymerization was carried out by modifying the conditions described in [2,4]. The monomer **A1a** (166 mg, 0.2 mmol), tetrakis(triphenylphosphine)palladium(0) (2.3 mg, 0.002 mmol), and copper iodide (0.38 mg, 0.002 mmol) were placed in an Schlenk tube under a nitrogen atmosphere. Freshly distilled toluene (2 ml) was transferred to the tube, and the monomers were dissolved with stirring. 5 M KOH methanol solution (0.02 ml) was added to the monomer solution, and the mixture was heated at 110 °C for 3 h. After cooling, the reaction mixture was poured into methanol to yield polymer precipitate. The methanol soluble fraction was purified by silica gel column separation with chloroform and hexane/ethyl acetate (16/3 v/v) as an eluent to give the dimer **A2a** and the trimer **A3a**. The precipitate was purified by preparative GPC with chloroform as an eluent to give the monodisperse oligomers **A2a**–**A5a**. The dimer **B2a** was synthesized as described above.

A2a: Yield 8.7%. TLC (hexane/ethyl acetate = 4/1 v/v): $R_f = 0.28$. 2.3. Deprotection and oxidation

The dimer **B2a** (23 mg, 0.015 mmol) was dissolved in THF (2 ml) under a nitrogen atmosphere. DMSO (6 ml) was added to the solution, then aqueous 2.5 M KOH (0.6 ml) was added to its suspension. The mixture was stirred at 50 °C for 12 h, cooled to room temperature, and neutralized with aqueous 3 N HCl. The organic product was extracted with chloroform, washed with water, and dried over anhydrous sodium sulfate. The solvent was evaporated, and the crude product was purified by silica gel column separation with hexane/ethyl acetate (4/1 v/v) as an eluent to give the dimer **B2b**.

B2b: Yield 27%. TLC (hexane/ethyl acetate = 4/1 v/v): R_f = 0.27. IR (KBr, cm^{-1}) 3636 (ν_{O-H}), 3315 ($\nu_{\equiv C-H}$), 2970–2860 (ν_{C-H}, *tert*-butyl). ^{1}H NMR ($CDCl_3$, 500 MHz; ppm) δ 1.26 (s, 36H, *tert*-butyl), 1.38 (s, 36H, *tert*-butyl), 4.13 (s, 1H, $\equiv$C–H), 5.28 (s, 2H, OH), 5.38 (s, 2H, OH), 7.63 (s, 4H, PhH), 7.67 (s, 4H, PhH), 7.81 (dd, 2H, J = 9.0, 1.7 Hz, ArH), 7.97 (dd, 2H, J = 9.0, 1.7 Hz, ArH), 8.73 (d, 2H, J = 9.0 Hz, ArH), 8.76 (d, 2H, J = 1.7 Hz, ArH), 8.95 (d, 2H, J = 9.0 Hz, ArH), 9.08 (d, 2H, J = 1.7 Hz, ArH). ^{13}C NMR ($CDCl_3$; ppm): δ 29.70, 30.22, 30.37, 34.43, 34.55, 80.50, 89.49, 94.08, 99.28, 117.17, 117.82, 118.55, 123.57, 124.16, 124.45, 124.95, 126.95, 127.64, 127.72, 131.04, 131.35, 131.54, 131.82, 131.96, 132.93, 136.42, 136.48, 140.18, 140.93, 154.05, 154.09.

The dimer **B2c** was prepared by chemical oxidation of the corresponding hydroxyl precursors with PbO_2 under nitrogen in a glovebox as follows. A degassed toluene solution of the dimer **B2b** (10 mM per phenol unit) was treated with 10 equivalents of recently prepared PbO_2, and was vigorously stirred for 1 h. After filtration the solution was used for spectroscopic and magnetic measurement.

2.4. Measurements

Solutions for ESR experiments were prepared under nitrogen in a glovebox and placed in quartz tubes sealed with septa and Parafilm. ESR spectra were taken on a JEOL JES-2XG ESR spectrometer with 100 KHz field modulation in the X-band frequency region. Signal positions were calibrated against an external standard of Mn^{2+}/MgO (g = 1.981). The 77 K ESR spectra were measured for the toluene glass sample using a small Dewar flask containing the liquid nitrogen, which was inserted into the cavity of the spectrometer. The spin concentrations of each sample were determined by careful double integration of the ESR signal calibrated with that of the 2,2,6,6-tetramethyl-1-piperidinyloxy (TEMPO) standard solution.

For magnetic measurement, the solution of polyradical immediately after oxidation was used to give the sample diluted with diamagnetic toluene. The sample solution was contained in a diamagnetic capsule. Magnetization was measured using a Quantum Design MPMS-7 SQUID magnetometer. The magnetization was measured from 0.5 to 7 T at 2 K. The static magnetic susceptibility was measured from 2 to 100 K in a field of 0.5 T. The mean-field correction parameter, θ, corresponding to small intermolecular (antiferro)magnetic interaction was determined from curve fitting using the product of molar magnetic susceptibility (χ_{mol}) and T versus T data. The spin concentrations of each sample were determined by analyzing the saturated magnetization at 2 K using a SQUID magnetometer.

IR spectra were obtained using a Hitachi IR 270-30 spectrometer. NMR (^{1}H, ^{13}C) spectra were measured using a Varian Unity 500SW (500 MHz). UV–Vis absorption spectra were recorded on a JASCO Ubest V-550DS UV–Vis spectrometer.

3. Results and discussion

3.1. Synthesis and characterization of oligomers

We synthesized monomers, 2,7-bis(4-acetoxy-3,5-di-*tert*-butylphenyl)-10-bromo-9-(3-hydroxy-3-methyl-1-butynyl)anthracene (**A1a**) and 2,7-bis(4-acetoxy-3,5-di-*tert*-butylphenyl)-9-bromo-10-(3-hydroxy-3-methyl-1-butynyl)anthracene (**B1a**), which had ethynyl and bromo groups to be linked with head-to-tail bonds by self-condensation. The polymerization of these monomers were carried out in the presence of the Pd(0) complex catalyst and the appropriate base, combining the deprotection of the ethynyl group and the cross-coupling to the aromatic halide to circumvent an oxidative coupling side reaction to produce diyne linkages. The methanol-soluble reddish brown solid and the methanol-insoluble dark blue solid were obtained by precipitation from the polymerization mixtures into methanol. The methanol-soluble fraction was further purified by silica gel column separation to give the dimer **A2a** and the trimer **A3a**. The monodisperse oligomers **A2a**–**A5a** were fractionated from the methanol-insoluble fraction

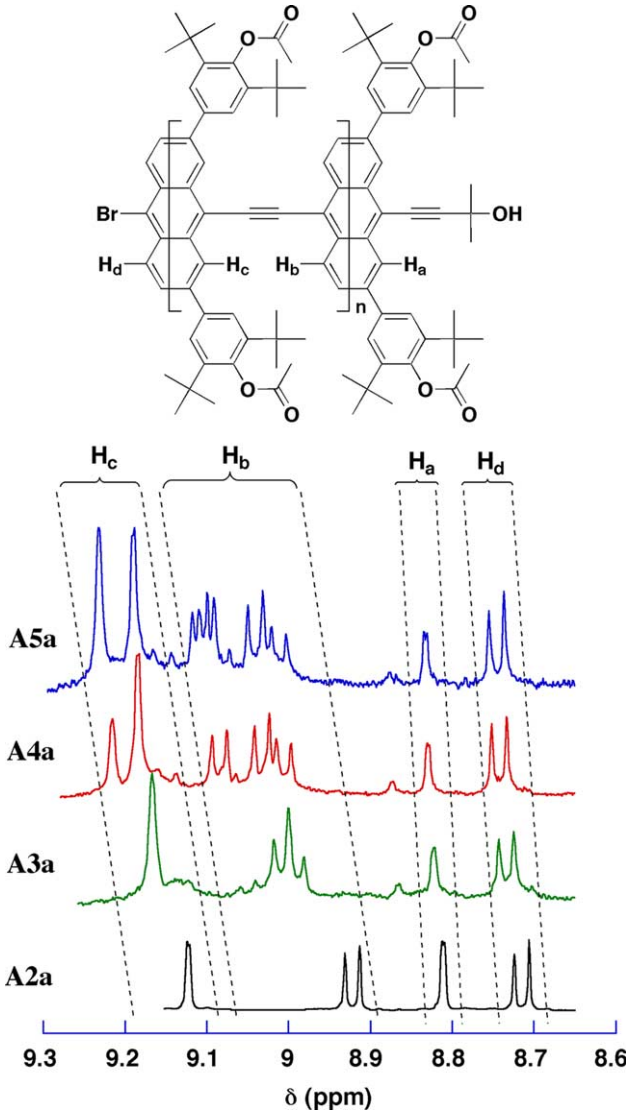
by preparative GPC. The relative amounts of oligomers in the methanol-insoluble fraction were calculated from the chromatogram of GPC as **A2a/A3a/A4a/A5a** = 9/20/19/11. The precise degree of polymerization was determined from ^{1}H NMR; the ratio of the peak areas of the terminal hydroxyisopropyl group and the aromatic region, and the number of chemical shifts in the aromatic region (Fig. 1). The degree of polymerization was controlled by amount of the base, and the dimer **A2a** was obtained in 8.7% yield when 0.5 equiv. of KOH was used (see Scheme 1).

The oligomers were soluble in organic solvent such as chloroform, tetrahydrofuran, aromatic hydrocarbons. The color of chloroform solution changed with degree of polymerization as orange (**A2a**), reddish orange (**A3a**), red (**A4a**) and reddish violet (**A5a**). The UV–Vis spectra of oligomers **A2a**–**A5a** show absorption maxima (λ_{max}) at 480 (**A2a**), 515 (**A3a**), 534 (**A4a**) and 543 (**A5a**) nm, respectively (Fig. 2). The λ_{max} of **A5a**, i.e., even 5-mer, shifted to longer wavelength compared with the previously reported λ_{max} for poly(1,4-phenyleneethynylene)s (360–450 nm) and poly[(9,10-anthryleneethynylene)-alt-(1,4-phenyleneethynylene)]s (450–540 nm) [5], which suggests that the electronic structure of the planar and π-conjugated anthracene skeleton contributes to developing the π-conjugation system throughout the backbone.

3.2. Polyradical formation of dimer

The dimer **B2a** was converted to the corresponding hydroxyl dimer **B2b** after complete elimination of the protecting acetyl group by treatment with alkaline solution. The dimer **B2c** was obtained by oxidizing **B2b** by treatment of the solution with fresh PbO_2. The dimer **B2c** was appropriately stable for maintaining the initial spin concentration under the ESR and SQUID measurement conditions, although the spin concentration of **B2c** was ca. 0.2 spin/phenoxyl unit in this oxidative condition (see Scheme 2).

The ESR spectrum of **B2c** showed broad hyperfine structures at g = 2.0041 indicating the formation of the phenoxyl radical, and the coupling of the protons of the phenoxyl ring and the anthracene skeleton, although it was difficult to analyze the spectrum because of the mono-, di- and triradical species included in **B2c** at



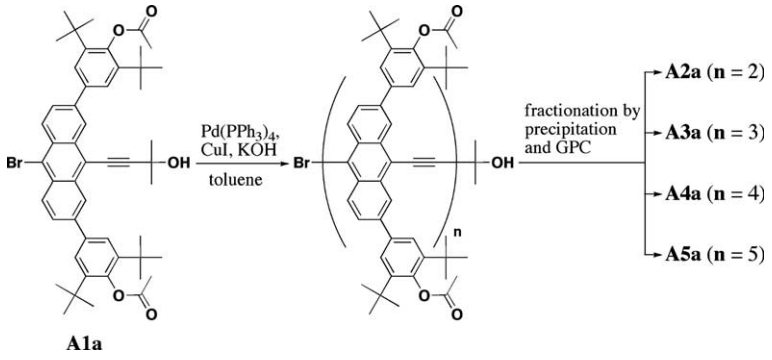


Fig. 1. ^{1}H NMR (500 MHz) spectra of **A2a**, **A3a**, **A4a** and **A5a**.

Scheme 1.

Scheme 2.

low spin concentration. The $\Delta m_s = \pm 2$ forbidden transition is clearly observed at $g = 4$ in frozen toluene glass of **B2c** at 77 K, although clear fine-structures that give zero-field splitting parameters D or E are not detected at $g = 2$ because of the presence of the several conformers and/or the mono-, di- and triradical species (Fig. 3).

3.3. Magnetic interaction of polyradical dimer

The magnetization (2–15 K, 0.5–7 T) and magnetic susceptibility (2–100 K at 0.5 T) of dimer **B2c** were measured using a SQUID magnetometer in order to estimate the intramolecular spin coupling in the polyradical. The sample was prepared as the frozen glass diluted in diamagnetic toluene to minimize intermolecular interactions. The magnetization (M) normalized by saturated magnetization (M_s), M/M_s, versus the ratio of magnetic field (H) and the effective temperature ($T - \theta$) plots of **B2c** were located almost on the theoretical Brillouin curves of $S = 2/2$, which was consistent with the low spin concentration of **B2c** including the mono-, di- and triradical species. The $\chi_{mol}T$ versus T plots of **B2c** are shown in Fig. 4, where χ_{mol} is the molar paramagnetic susceptibility based on per mol of exact phenoxyl. We have already reported that the $\chi_{mol}T$ value of monomeric diradical, 4,4′-(2,7-anthrylene)bis(2,6-di-*tert*-butylphenoxyl), was an approximately constant value below 100 K, which was larger than the theoretical value for $S = 1/2$ ($\chi_{mol}T = 0.375$) and almost agreed with the value for $S = 2/2$ ($\chi_{mol}T = 0.5$). The $\chi_{mol}T$ value of monomeric diradical indicated strong ferromagnetic coupling ($2J' > 10^2\ cm^{-1}$) between two phenoxyls through the anthracene unit. Therefore, the spin coupling constant through the dianthrylacetylene unit, J, of **B2c** was determined by curve fitting of the $\chi_{mol}T$ versus T data in consideration of a large enough spin coupling constant between two phenoxyls through the

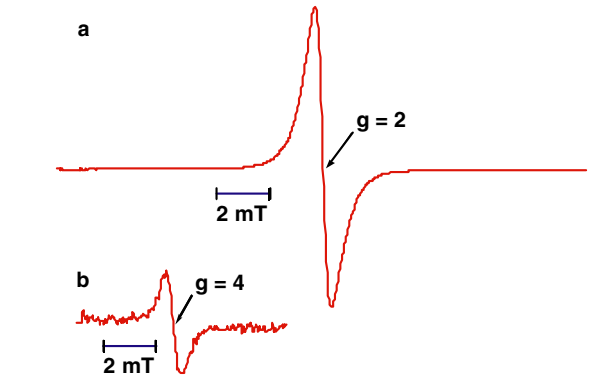

Fig. 3. ESR spectra of **B2c** (10 mM, spin conc. = 0.20 spin/phenoxyl unit) in frozen toluene glass at 77 K: (a) at $g = 2$ and (b) at $g = 4$.

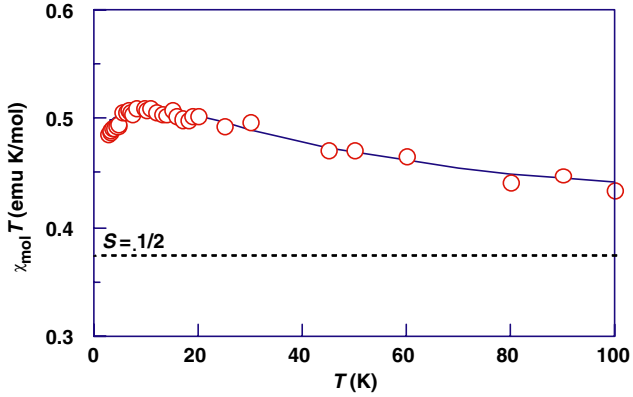

Fig. 4. $\chi_{mol}T$ vs. T plots (○) of **B2c** (10 mM, spin conc. = 0.20 spin/phenoxyl unit) in frozen toluene glass. Solid line: Theoretical curve calculated using Eq. (1) with $2J = 34\ cm^{-1}$, $\theta = -0.1$ K, $x_1 = 0.58$, $x_2 = 0.22$, $x_3 = 0.018$, $x'_1 = 0.15$, and $x'_2 = 0.037$.

anthracene unit ($J' \gg kT$). The curve fitting of the $\chi_{mol}T$ versus T data was performed using an expression for the sum of the mono-, di-, tri- and tetraradical species.

$$\chi_{mol}T = \frac{N_A g^2 \mu_B^2 T}{k(T-\theta)} \left\{ \frac{x_3(10+2\exp(-4J/kT))}{4(5+3\exp(-4J/kT)+\exp(-6J/kT))} + \frac{x_2(10+\exp(-3J/kT))}{3(8+4\exp(-3J/kT))} - \frac{x_1}{(3+\exp(-2J/kT))} + \frac{x_2'}{3} + \frac{x_1'}{4} \right\}, \quad (1)$$

where θ, x_1, x_2 and x_3 are the Weiss constant for a weak intermolecular magnetic interaction, and the fractions of the di-, tri- and tetraradical species, respectively, and x_1' and x_2' are the fractions of the mono- and diradical species without the spin coupling through the dianthrylacetylene unit. The $2J$ value of **B2c** was $34 \pm 1\ cm^{-1}$, which agreed with the $2J$ value of the corresponding oligomeric diradical which had one pendant phenoxyl in one anthracene unit ($2J = 31 \pm 3\ cm^{-1}$) [6]. It has been known that the coplanarity of π-conjugated pendant polyradicals throughout the backbone and the pendant side chain is significantly effective in the magnitude of the spin coupling constant [1]. For example, the expected ferromagnetic interactions have not been observed for any poly(phenylacetylene)-based pendant polyradicals, because the coplanarity both in the poly(phenylacetylene) skeleton itself and in the dihedral angle with a pendant radical were significantly distorted by the sterically bulky pendant groups [7]. The $2J$ value of **B2c** indicates that the poly(9,10-anthryleneethynylene)-based polyradical has less steric hindrance between the side chain radicals and the poly(9,10-anthryleneethynylene) backbone even if the polyradical has two pendant phenoxyls in one anthracene unit.

4. Conclusions

The poly(9,10-anthryleneethynylene)s with pendant phenol residue at the 2- and 7-positions were synthesized via polymerization of the corresponding bromoethynylanthracene monomer in the presence of the Pd(0) complex catalyst and the appropriate base. The degree of polymerization was controlled by amount of the base, and the monodisperse oligomers **A2a**–**A5a** were fractionated by precipitation into methanol followed by preparative GPC. The $2J$ value of **B2c**, $34 \pm 1\ cm^{-1}$, verified the moderately strong ferromagnetic coupling through the dianthrylacetylene unit for the corresponding poly(9,10-anthryleneethynylene)-based polyradical **Anc**.

Acknowledgments

This work was partially supported by a Grant-in-Aid for Exploratory Research (Nos. 16655083 and 15655039), and for Scientific Research (No. 16350061) from JSPS, by a Grant for the Promotion of Niigata University Research Projects, and by the Asahi Glass Foundation. We thank for Prof. H. Nishide (Waseda Univ.) for the use of their SQUID magnetometer.

The three-dimensional structure for the first time of a plant-type [2Fe–2S] Fd was reported in a crystallographical approach by Fukuyama et al. A small cluster modeling the active center of the Fd have been proposed by Tsukihara et al. [2], which is a peptide having twenty amino acid residues. It consists of the Fe_2S_2 core and the amino acid chain of the first shell in Fd. The details of the atomic structure revealed the existence of hydrogen bonds around the Fe_2S_2 core, which implied the stability of the local structure around the active site. Ten years later, the model peptide was reproduced by Ueyama et al. [3] by using a chemical procedure in a solvent of *N*,*N*-dimethylformamide (DMF). This cluster indicated the value of redox potential to be similar to that of natural Fd.

The theoretical approach to the active center of Fd has been progressed in the study of the series for Fe_2S_6, Fe_3S_7, Fe_4S_8 clusters. The applications of the localized spin systems have been successfully contributed to the understanding of antiferromagnetic arrangement about Fe magnetic moments in these clusters [4,5]. The results of density functional theory have also supported results of the magnetic structure of clusters [5,6]. The total number of residues in Fd's is usually about a hundred, the whole of which is too demanding to calculate with ab initio approach. Taking solvent effects, the environment effect has been studied for quantitative explanation of the redox potential [7].

As a first step from the previous work on the understanding of electronic structures, we study the Fe_2S_6 cluster which includes amino acid residues explicitly. Inclusion of residues would be important for the understanding of electron transfer because some of the residues around the Fe_2S_2 core is on the surface of Fd, as shown in experiment [1].

The antiferromagnetic coupling in Fe_2S_2 core has been one of the central issues of the model system. The relationship with amino acid residues has never been definitive in the electronic structure study. In this work, by using a state-of-the-art ab initio density functional calculation [8,9], we show the electronic structure of active site including the first shell of residues and speculate on the process of electron transfer from Fd to FNR.

2. Model system and calculation method

In this work, we required the properties of the model system: (1) that the cluster had several amino acid residues, which are accessible by the present ability of ab initio electronic structure calculation, (2) that the cluster had a hydrogen bond in itself, (3) that the cluster was expected to show a realistic property for redox potential, and (4) that the cluster had been synthesized with a chemical method artificially. Fortunately, there was a peptide, which was designed by Tsukihara et al. [2] and reproduced by Ueyama et al. [3]. This peptide sequence of cluster is based in our work.

To set up an atomic coordinate of the model cluster, we took the coordinate of a crystallographic data [10].[1] The coordinate of hydrogen atoms was assumed by the routine in AMBER code [11]. This treatment has given reasonable results for all clusters calculated in this work. In the Fd, the successive chains, Pro 38–Gly 51 and Leu 77–Val 80 were used for the model cluster. The sulfur atoms at the side chains in Cys's 41, 46, 49, and 79 are bridged to Fe atoms in the Fe_2S_2 core cluster. The two residues, Pro and Leu were inserted between Gly 51 and Leu 77, forming a structure of beta turn with a NH–O hydrogen bond. Consequently, the model cluster keeps a single successive chain, which may stabilize it even if in solvent. The N-terminus and C-terminus were terminated with the acetyl group (CH_3CO–) and the amino group (–NH_2), respectively, as the cluster obtained in [3]. The resulting configuration of cluster seems to be very similar to that of Fig. 12 in [2]. The full representation of the molecule is given in Table 1 and the schematic diagram is shown in Fig. 1. As shown in Fig. 2, one of the Fe atoms is indirectly connected with the other Fe atoms through the bridging of two S atoms ("bridging sulfur"). Each Fe atom is tetrahedrally surrounded by four S atoms, two of which bridge sulfur and the other two ("cysteine sulfur") come from the cysteine amino acid residues. The atomic structure of the two termini and the two inserted residues is locally optimized by using the forces on atoms and all the other parts of atomic configurations are fixed on the experimental data 1 in the present electronic structure calculation. The theoretical determination of structural properties for clusters could be an interesting problem, but we mainly kept the experimental configuration to see the environmental dependence of amino acid.

The peptide molecule of 20 amino acids (call 20-peptide), which is mentioned above, has three NH–S hydrogen bonds around the Fe_2S_6 cluster. These hydrogen bonds are connections between S(1) and N in Ala 6, S(5) and N in Ser 3, and S(5) and N in Arg 5. These N atoms are of the main chain of the peptide. The distances are 3.0–3.3 Å. It is known that the hydrogen bonds induce large distortion in the resulting structure of the experiment [10].

The structural properties of the local coordinate around the Fe_2S_6 cluster are summarized in Table 2, which reveal that the tetrahedral coordination around each Fe atom is distorted largely. The core cluster of Fe_2S_2 form a plane in an ideal cluster [6], but the real

To examine the role of amino acid residues, we have prepared five other model molecules, which preserve the local coordinate of Fe_2S_6 cluster, but have a different environment. The two molecules have the hydrogen and CH_3 termini, respectively, for the four termini of S atoms on Fe_2S_6. Another molecule has four Cys residues and one other molecule has four Cys and three residues. In the latter, the three residues are connected to the first Cys. The last molecule is a complex between the molecule of 20 amino acids and the Glu residue, forming a salt-bridge between the Arg and the Glu. The termini of amino acid residues in all of the five molecules are terminated with the acetyl and amino groups for N-terminus and C-terminus, respectively, as performed in the peptide of 20 amino acids. These clusters are summarized in Table 1.

To construct models for the electron transfer about Fd, the termination of Fe_2S_6 is presumably important. It is known that the extension of orbitals is observed in electronic structure calculations for the reducing electron [6]. For example, the electron was delocalized onto the CO groups in the Cys terminus [12]. In the real system, the terminus locates outside the first peptide shell. Therefore, to minimize the effect of terminus and to coincide with the synthetic molecules [3], this work uses the Ac and NH_2 groups for terminus on residue, which form a bond similar to that of the peptide bond.

The electronic structure calculation for the model clusters is based on the density functional approach [8,9]. We used ultrasoft-type pseudo-potentials [13–15] to include core–valence interactions and plane-wave basis to represent wave functions and electron densities. These pseudo-potentials are capable to deal with valence electrons in magnetic transition metal elements as well as other organic elements. The energy cut-offs of 25 and 250 Ry were taken for wave function and electron density, respectively. We used the exchange-correlation functional by Perdew et al. [16], which is known as PW91. To optimize the electronic degrees of freedom, we used the damped dynamics of Car–Parrinello's scheme [17,18], which has the property that the wave function could be updated from a scratch.

The molecule of interest was placed at the center of a cubic box and the wave function was solved with the periodic boundary condition. The molecule was separated by more than 6 Å with that in periodic image cells. This separation never disturbs the structure of valence electrons due to the fully damped electron density at the edge of the molecule. In biological molecules, the number of electrons assumed is important. The oxidized state studied here corresponds to the anion cluster having charges of 2− except for the 20-peptide molecule. The latter has 1− due to the formal charge of +1 at the side chain of Arg.

To analyze molecular orbitals, we introduced the quantity of local orbital component, which is defined as the sum of number of electrons contributed from specified orbitals. The contribution of local orbital components to magnetization can be estimated for each molecular level. The magnetization on atoms is estimated by integrating the spin density within the radius: 0.90, 0.90, 0.69, 0.69, 0.74, and 0.42 Å for Fe, S, O, N, C, and H, respectively.

3. Results

3.1. 20-Peptide molecule

The damped dynamics of Car–Parrinello scheme [17,18] provided that the system was converged to an antiferromagnetic cluster. The total magnetization of the whole cluster was vanishing. To find any other lower-energy magnetic configuration, we used the efficient scheme of non-collinear magnetism [19,20], however, obtaining the same antiferromagnetic configuration. In Fig. 3, we present the energy levels of the eigenstate and the local components around the Fermi level.

Asymmetry distribution of eigenvalues between spin-up and spin-down states (top panel in Fig. 3) is caused by the distortion on the tetrahedral geometry of S atoms. The exchange splitting of ~5 eV in Fe 3d orbitals stabilizes the system of the cluster. The level structure on

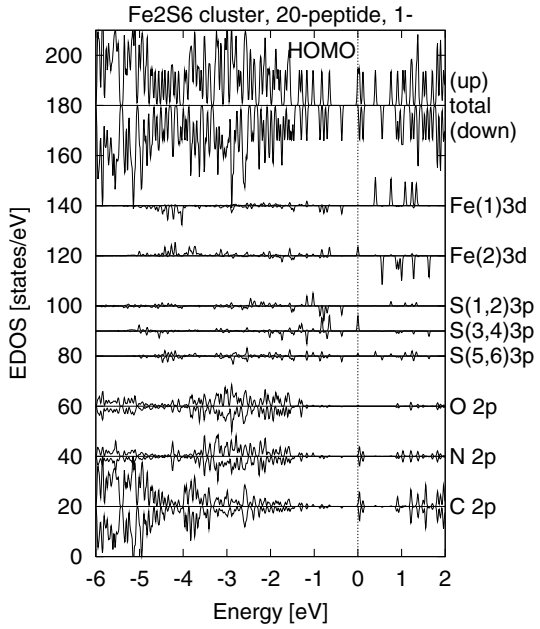

Fig. 3. Energy levels of eigenstate and their local components in the oxidized state for the 20-peptide clusters. In each panel the level of spin-up and spin-down states is shown separately. The origin of energy is taken at the HOMO level. The energy levels are broadened by the Gaussian function of the width 0.02 eV. The vertical dotted line indicates the HOMO level.

Fe atoms shows a consistency with the formal valence of Fe^{3+}, showing five levels above the Fermi level clearly. The characteristic field induced by tetrahedral geometry of S atoms is not so impressive. The S 3p orbitals are mainly just below the Fermi level, which reveals that the closed shell electron configuration forms on S atoms. The orbital components of O 2p, N 2p and C 2p exists mainly below the Fermi level.

The occupied molecular orbitals below the Fermi level mainly consist of S 3p orbitals. These orbitals show a strong hybridization with Fe 3d orbitals in the same spin state, resulting in an induction of polarized spin density on cysteine S atoms (see Table 3). At the highest occupied molecular orbital (HOMO) levels in both spin states, there exists the Fe 3d component which belongs to the spin state parallel to the magnetization of Fe atoms (majority spin state).

The unoccupied molecular orbitals above the Fermi level are the hybridized states between N 2p and C 2p and the minority spin states of Fe 3d orbitals. The former is identified to the orbitals on the side chain of Arg, which is placed just above the HOMO level, and on the main chain around the residues of Ala 13, Gly 14 and Pro 15, which are at the energies above 0.8 eV. It is noted that the empty energy level of Arg corresponds to a plus charge on the side chain of it. The lowest unoccupied molecular orbital (LUMO) level of this molecule is formally determined to be the state of Arg.

Table 3
Energy level differences (in eV) of S 3p(HOMO(up))–Fe 3d(the lowest minority spin state) and HOMO(up)–HOMO(down), and atomic magnetization (in μ_B) in Fe_2S_6 cluster for calculated molecules

Molecule	S 3p–Fe 3d	HOMO(up)–HOMO(down)	Fe(1)	Fe(2)	S(1)	S(2)	S(3)	S(4)	S(5)	S(6)
H-terminus	0.98	0.14	−3.08	3.11	−0.10	−0.09	0.09	0.10	−0.04	0.02
CH_3-terminus	0.76	0.17	−3.06	3.09	−0.12	−0.11	0.11	0.12	−0.01	−0.01
Cys-terminus	0.53	0.28	−3.04	3.09	−0.15	−0.11	0.13	0.11	0.00	−0.01
7-Peptide	0.46	0.35	−3.05	3.08	−0.14	−0.11	0.14	0.13	−0.01	−0.03
20-Peptide	0.40	0.37	−3.06	3.08	−0.13	−0.12	0.15	0.14	−0.02	−0.04
20-Peptide + Glu	0.40	0.38	−3.06	3.08	−0.13	−0.12	0.15	0.14	−0.02	−0.04

The latter is estimated to be an integration of spin density within the atomic radius defined in Section 2.

Fig. 3 shows that, above the Fermi level, the hybridization with S 3p orbitals on the cysteine sulfur (S(1)–S(4)) is relatively weak compared with that of the bridging sulfur. This implies weaker bonds between Fe and cysteine sulfurs and stronger bonds between Fe and bridging sulfurs. This indication is consistent with the picture that the Fe_2S_2 core is not bonded to a polypeptide protein, but rather bound in it. The lowest unoccupied level of Fe 3d is localized on single Fe atom. This orbital has distributions to the direction in which the vector to S atoms does not exist.

3.2. Comparison with the 20-peptide + Glu complex

In the electronic structure of 20-peptide cluster, the orbitals of Arg are indicated to be placed just on the Fermi level. Taking into account the location of Arg, which is on the surface of Fd, the Arg state could vary depending on the environment of Fd. As explicitly pointed out by Kurisu et al., the salt-bridge between the Arg and Glu in Fd plays an important role in stabilizing Fd. To see effects of the salt-bridge, we constructed the complex of 20-peptide + Glu cluster (Table 1) and also performed the electronic structure calculation. The atomic configuration of Glu is taken from the result of X-ray diffraction for Fd 1.

Fig. 4 shows the energy levels of the complex in the same way as for the 20-peptide molecule. It clearly indicates that the state of Arg disappears from the vicinity of the Fermi level. This state, which has provided a plus charge on Arg, is raised above 2 eV due to the occupied orbitals of the Glu residue. The apparent characteristic for the orbitals on Glu appeared below the HOMO level, as observed at O 2p in Fig. 4.

3.3. Comparison with the smaller molecules

Unlike the 20-peptide molecule, the 7-peptide molecule has decouplings in the main peptide chain. This structural property might lower the stability of the molecule. It, however, still keeps the three NH–S hydrogen bonds in the 20-peptide molecule, while the Cys-terminus molecule has only one NH–S hydrogen bond of connection between S(5) and N of the amino group at C-terminus on the first Cys.

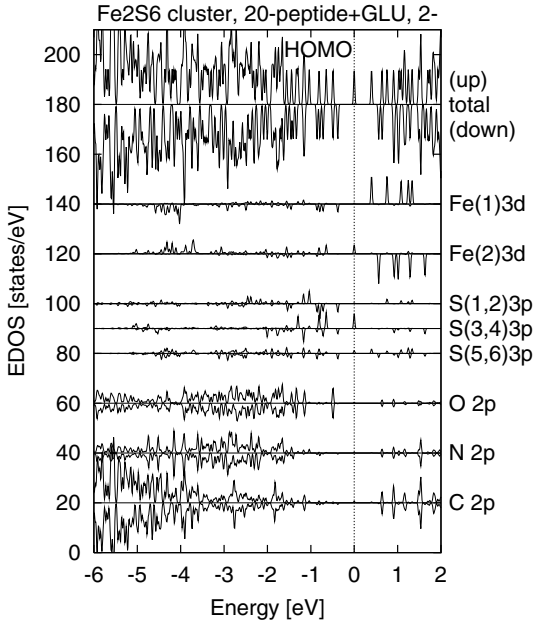

Fig. 4. Energy levels of the eigenstate and their local components in the oxidized state for the 20-peptide + Glu complex. See Fig. 3 for the scheme of the figure.

Figs. 5 and 6 present the eigen energy levels of electrons for the 7-peptide and Cys-terminus molecules, respectively. These molecules seem to almost keep the electronic structure of larger molecules (20-peptide, 20-peptide + Glu) on Fe_2S_6. The Fe 3d component in the energies at about −4 eV shows sharpening of the level compared with the larger molecules. This indicates a stronger hybridization with S 3p orbitals in the larger molecules. Although there are eight termini for residues in the smaller molecules, the orbitals originated from the terminus are not observed in vicinity of the Fermi level.

The HOMO and LUMO levels change gradually from the small molecules to the larger molecules. In Table 3, we reported the gap between the HOMO(S 3p) and the lowest Fe 3d minority-spin level. This indicates the energy necessary to place an electron at the Fe 3d level, if each electron orbital does not change (Koopmans theorem). In the real system, adding of electrons changes orbitals of the electron. In the present case the energy much larger than the gap was usually necessary to place an electron (preliminary calculations indicate

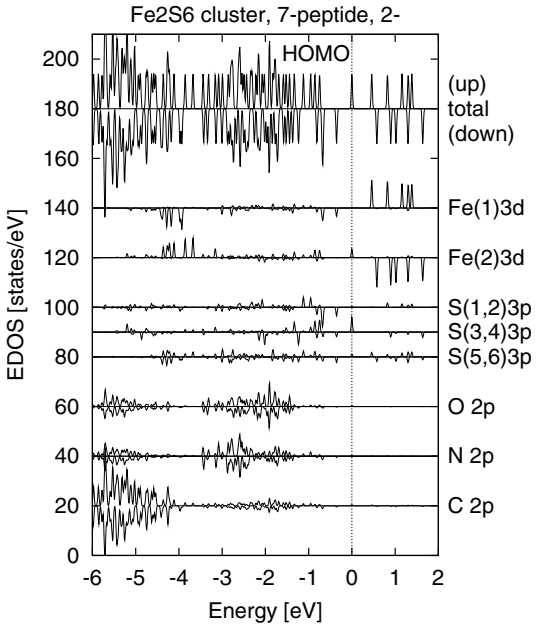

Fig. 5. Energy levels of the eigenstate and their local components in the oxidized state for the 7-peptide molecule. See Fig. 3 for the scheme of the figure.

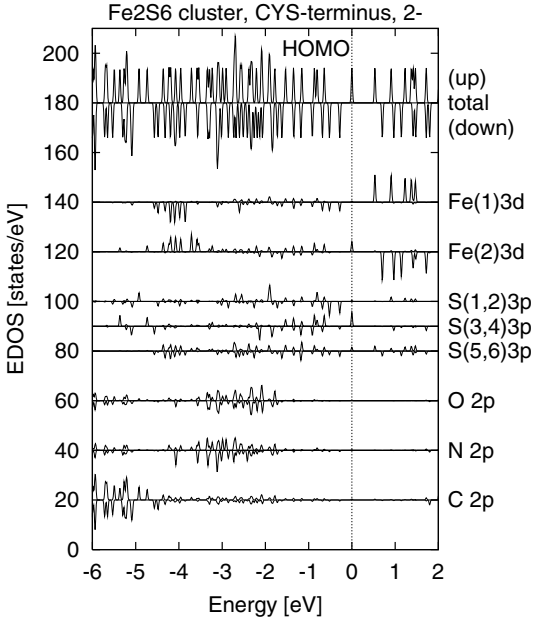

Fig. 6. Energy levels of the eigenstate and their local components in the oxidized state for the Cys-terminus molecule. See Fig. 3 for the scheme of the figure.

2–3 eV for the free standing molecules). The gap of S 3p–Fe 3d for H-terminus (0.98 eV) agrees with the value of Noodleman and Baerends (0.89 eV) [6]. This value decreases as the size of the molecule increases.

Table 3 also reports the level difference between the HOMOs of spin-up and spin-down states. This value scales the asymmetry of spin-up and spin-down states at the Fermi level. The value increases as the size of the molecule increases. Although we used the same configuration for the local coordinate in the Fe_2S_6 cluster, the change in value appeared. The asymmetry at the Fermi level is attributed to the NH–S hydrogen bonds, which are concentrated in the region of Fe(1) having spin-down polarization. These bonds relatively stabilize the levels of 3p orbitals on S(1) and S(2), resulting in lowering the HOMO level of spin-down state. As shown in Table 3, the Cys-terminus molecule which gets a hydrogen bond shows larger increase from the value of CH_3-terminus one. At the 7-peptide molecule which has full three hydrogen bonds, the value increases significantly.

3.4. Magnetic configuration

The antiferromagnetic configuration of Fe atomic magnetic moments is obtained for all molecules. The hybridization between Fe 3d and S 3p orbitals induces spin polarization on S atoms. In Table 3, atomic magnetizations are reported. The molecular dependency is not remarkable. The magnetizations on S(5) and S(6) are averaged on atomic region, resulting in small values.

4. Discussion and summary

While the Arg residue in a salt-bridge was proposed in the experiment for stabilizing electrostatically Fd itself or the complex between Fd and FNR, our calculation shows the existence of its levels around the Fermi level and implies interesting roles in the process of electron transfer. The state on Arg provides a hole orbital to the carrier electron. When the salt-bridge breaks, the electron could be around the side chain of Arg with help of a small energy perturbation. The occupation of the electron in the hole of Arg (the plus charge on Arg is compensated with the electron charge) cancels the electrostatic energy contributed from the carrier electron. If the salt-bridge is formed with help of other strong energies, the electron would overflow into Fe sites and be ready to transfer to FNR. Thus, as a speculation, the orbitals on Arg could be an electron sink and the salt-bridge on Arg could be a switch of electron transfer.

In summary, we have studied electronic structures of the model molecule, which have 20 amino acids, for the oxidized active site of Fd. The antiferromagnetic configuration has been obtained for the couple of Fe magnetic moment. The HOMO level of the molecule lies at the top of S 3p orbitals. Reflecting the distortion of Fe_2S_6 cluster, the asymmetry of spin-up and spin-down states is observed at the HOMO level and is found to correlate with the existence of hydrogen bonds. The electronic structure on Fe atoms is consistent with the formal valence of Fe^{3+}, implying that the reducing electron

occupies the minority spin state of Fe 3d orbitals unless the Arg residue in the molecule breaks its salt-bridge with Glu residue. The result of our work greatly supports an important relation between the salt-bridges and the mechanism of electron transfer. The study on reduced states is under calculation.

Acknowledgments

The calculation in this work was partially carried out using the facilities of the Supercomputer Center, Institute for Solid State Physics, University of Tokyo. The authors acknowledge the computational resources by the Research Center for Computational Science, Okazaki National Research Institutes. yield chemically pure crystals of either the HT or LT forms. In some cases, ac susceptibility measurements show that a single-crystal can either have a HT or LT peak, but *not* both. The majority of crystal structures reported for $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ complexes exhibit HT behavior and have activation energies towards magnetization reversal of $U_{eff} = 60–70$ K. A much smaller family of $[Mn_{12}O_{12}(O_2CR)_{16}(H_2O)_4]$ are LT and have activation energies in the 20–40 K range. Crystal structures of each isomer can be solved. The LT form has an abnormally oriented Jahn–Teller axis in the coordination geometry of one or more of the Mn^{III} ions. These abnormal Jahn–Teller axes are oriented towards a μ_3-oxide which, topographically, reside near the plane of the disc-like shape of the $[Mn_{12}O_{12}]$ core. The HT form does not have an abnormally oriented Jahn–Teller axis at a Mn^{III} ion. This phenomenon has been coined "Jahn–Teller isomerism" (JTI). In this paper, we report the characterization of a new LT complex, $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}CH_3)_{16}(H_2O)_4] \cdot S$.

2. Experimental

2.1. Synthesis

All solvents and reagents were used as received. All reactions were performed under aerobic conditions.

$[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}CH_3)_{16}(H_2O)_4] \cdot CH_2Cl_2 \cdot 2H_2O$ (complex **1**). Multiple treatments of a toluene slurry of $Mn_{12}Ac$ (4.0 g, 1.94 mmol) with a large excess of 2-methylbenzoic acid (8.7 g, 63.9 mmol) followed by solvent removal and washing of the excess carboxylate ligand with ethanol yields the product $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}CH_3)_{16}(H_2O)_4]$. *Anal.* calc. for $C_{128}H_{120}Mn_{12}O_{48}$: C, 49.8; H, 3.9. Found: C, 50.3; H, 3.8%. Crystallization solvents were saturated with 2-methylbenzoic acid before their use. Crystallization is achieved by layering a CH_2Cl_2 solution of complex **1** with hexanes. Over a period of three weeks, block shaped crystals with the formula $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}CH_3)_{16}(H_2O)_4] \cdot 2H_2O \cdot CH_2Cl_2$ precipitate from the solution.

2.2. Physical measurements

High frequency electron paramagnetic resonance (HFEPR) measurements were performed on home made instrumentation described elsewhere [26]. Low temperature magnetization versus field data were collected using a micro-Hall effect magnetometer which is described in [27]. Practical considerations of the crystal morphology for complex **1** meant that the magnetic field orientation for the data presented in both the single-crystal HFEPR and single-crystal magnetization studies was ~45° away from the easy axis of **1**.

3. Results and discussion

3.1. Description of structure

Several relevant crystal structure parameters are listed in Table 1 for complex **1**. The crystal structure for $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}CH_3)_{16}(H_2O)_4] \cdot CH_2Cl_2 \cdot 2H_2O$ (**1**) is illustrated in Fig. 1. Complex **1** crystallizes in the monoclinic *C2/c* space group. The atoms Mn(5) and Mn(5a), which are related by a crystallographic C2 axis, have an unusually oriented Jahn–Teller axis. This abnormally oriented Jahn–Teller axis contains an oxide ion, O(1), a situation which is highly unusual: JT elongation axes usually orient so as to avoid the strong Mn(III)–O^{2-} bonds, normally the shortest bonds about a Mn(III) ion. These abnormally oriented Jahn–Teller axes reside nearly in the plane of the ring formed by the the eight Mn(III) surrounding the cubane core. The other six Mn(III) ions have their Jahn–Teller elongation axis situated essentially parallel to each other and orthoganol to the plane of the ring of Mn(III) ions.

3.2. Alternating current magnetic susceptibility studies

Ac magnetic susceptibility data were collected for a single-crystal sample of complex **1** in the 1.8–10 K range with a 3 Oe ac field oscillating in the frequency range of 50–1000 Hz. The external dc magnetic field was fixed at zero. Complex **1** is a LT form and exhibits an out-of-phase peak in its ac susceptibility in the 2–4 K region as seen in Fig. 2. The appearance of frequency dependent peaks in the out-of-phase ac susceptibility is evidence for slow magnetization relaxation dynamics relative to the frequency of the applied oscillating ac field. The magnetization relaxation rates can be

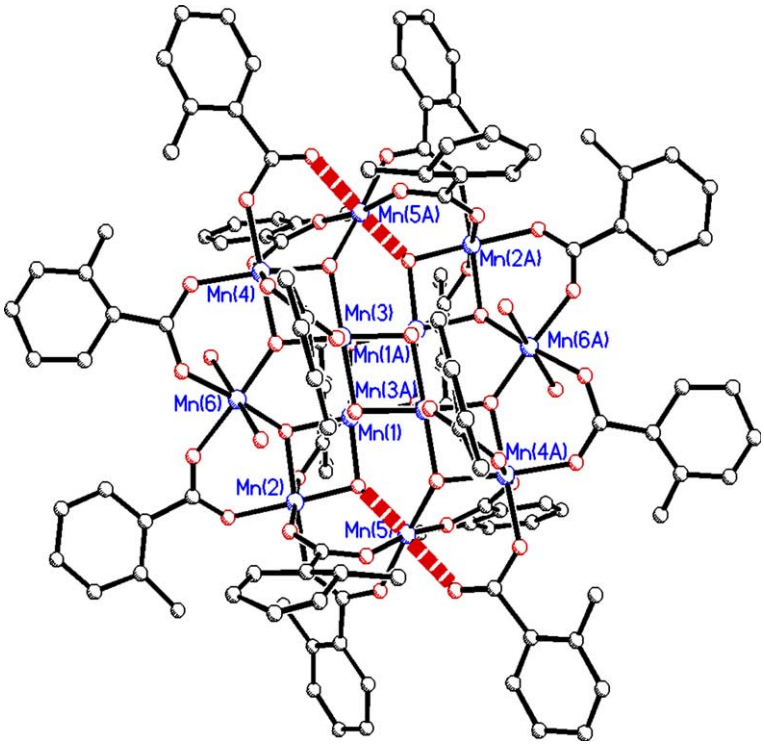

Fig. 1. ORTEP representation of the LT complex $[Mn_{12}O_{12}(O_2CC_6H_4\text{-}2\text{-}CH_3)_{16}(H_2O)_4]\cdot CH_2Cl_2\cdot 2H_2O$ (complex **1**). The thick dashed lines represent abnormally oriented Jahn–Teller axes.

quantified by analyzing the frequency dependencies of the χ''_M signals for the two complexes as shown in Fig. 2. Data were collected for several ac frequencies in the 50–1000 Hz range and the maxima of the χ''_M were used in conjunction with the Arrhenius equation

$$\ln(1/\tau) = \ln(1/\tau_0) - U_{\text{eff}}/kT \quad (1)$$

to calculate the barrier towards magnetization reversal as $U_{\text{eff}} = 29$ K for complex **1**. Complex **1** has an activation energy towards magnetization reversal, U_{eff}, that is nearly half of its parent compound, $Mn_{12}Ac$, which has an activation energy of $U_{\text{eff}} = 62$ K.

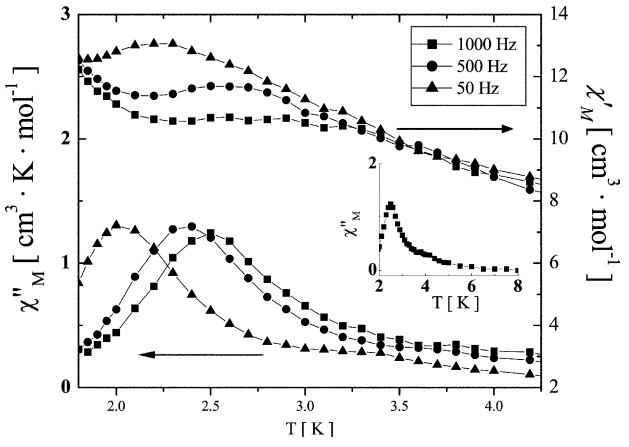

Fig. 2. Plot of the variable-temperature ac susceptibility for a single crystal of complex (**1**) collected for several frequencies. The in-phase responses are shown in the upper part of the plot, whereas the out-of-phase responses are shown in the lower part.

3.3. Magnetization versus magnetic field hysteresis

Fig. 3 shows the single-crystal magnetization hysteresis data for complex **1** measured at 0.38 K for two

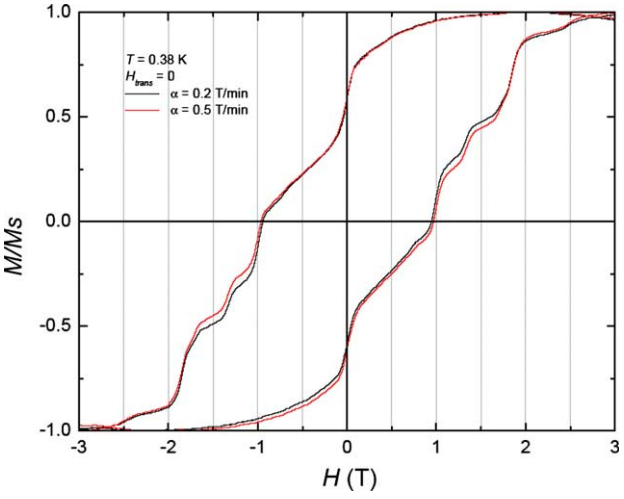

Fig. 3. Plot of the normalized magnetization (M/M_S) vs. magnetic field (H), where M_S is the saturation magnetization. Data were collected on a single crystal at a temperature of 0.38 K and scanning rates of 0.2 and 0.5 T/min with the longitudinal magnetic field ~45° away from the easy axis.

different sweep rates, 0.2 and 0.5 T/min. The applied magnetic field was ~45° away from the easy axis of magnetization. A complex hysteresis loop is observed. The observation of an appreciable coercive field along with magnetic field sweep rate dependent steps in the hysteresis loop for the field interval between 1 and 3 T confirms the single-molecule magnet behavior of **1**. The steps are due to quantum tunneling of the magnetization. There is also a large step observed at zero magnetic field.

3.4. High frequency EPR (HFEPR) studies

In order to determine the ground state spin Hamiltonian parameters for complex **1**, HFEPR data of a single-crystal sample were collected. The spectra are shown in Fig. 4 for a microwave frequency of 324 GHz and at temperatures of 2, 4, 6, 8, 10, 12, 14, and 16 K. The frequency dependence of several resonances were simulated using an $S = 10$ spin Hamiltonian. The Zeeman interaction, axial zero-field splitting, $D(\hat{S}_z^2)$, and the fourth order zero-field term, $B_4^0\hat{O}_4^0$, were included in the analysis. Fig. 5 depicts the results obtained from the simulations of the resonances, which are consistent with the following parameters: $g_z = g_x = g_y = 2.0$, $D = -0.47$ cm^{-1}, and $B_4^0 = -2.0 \times 10^{-5}$ cm^{-1}.

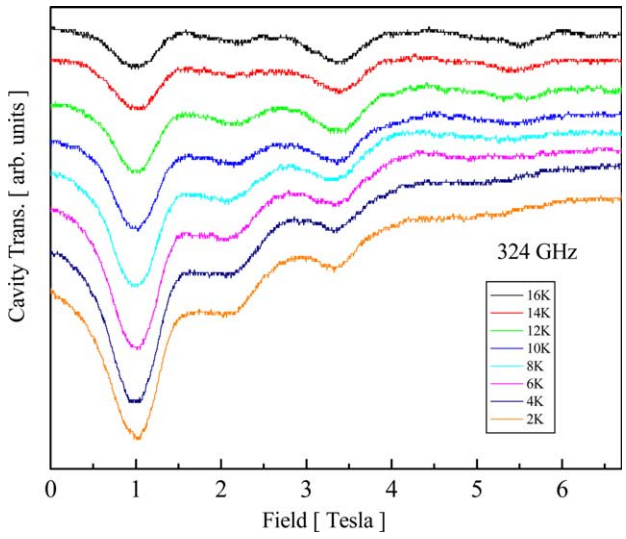

Fig. 4. HFEPR spectra measured at 324 GHz for a single-crystal sample of complex **1**. Data were collected at the temperatures of 2, 4, 6, 10, 12, 14, and 16 K with the magnetic field oriented ~40° to the easy axis direction.

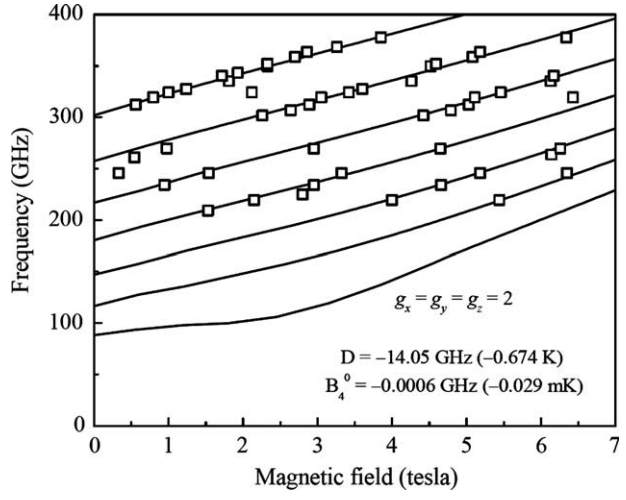

Fig. 5. Zeeman diagram for the spin Hamiltonian associated with the $S = 10$ ground state of complex **1** with the magnetic field oriented ~40° to the easy axis direction. The solid lines represent the energy spectrum obtained from the simulation to the resonances.

4. Conclusion

The synthesis and crystal structure of a LT Mn_{12} complex are reported. Steps, with the most pronounced having field intervals of ~0.8 T, are observed in magnetization hysteresis plots collected for a single crystal at millikelvin temperatures. These steps confirm that **1** behaves as a single-molecule magnet. HFEPR data collected on this sample allowed for the quantitative characterization of the spin Hamiltonian parameters $g_z = g_x = g_y = 2.0$, $D = -0.47$ cm^{-1}, and $B_4^0 = -2.0 \times 10^{-5}$ cm^{-1}. The resonance positions of the steps seen in the magnetization hysteresis plot are consistent with the parameters obtained from the EPR studies when the ~45° angle between the easy axis and magnetic field is taken into consideration ($0.8\cos(45°) \approx 0.5$).

during the time evolution. The most powerful quantum algorithms, such as the one by Shor for factorizing large integers, where shown to require proper sequences of single- and two-qubit gates, i.e., unconditional rotations of single subsystems and unitary transformations of interacting couples [2]. Indeed, this selective addressing of the different qubits and the timely tuning of the couplings between them are among the most experimentally demanding achievements on the way to the QIP implementation.

Very recently, Meier, Levy, and Loss [3] have asserted the suitability to the application of this approach of those antiferromagnetic spin clusters characterized by a ground-state doublet, each cluster corresponding to an effective two-level system. One of the main advantages with respect to previously proposed single-spin encodings (i.e., one qubit per electron spin) [4] would arise from the largest size of the molecules, and from the resulting reduction of the spatial resolution which is required for the selective addressing of the qubits by means of pulsed magnetic fields. On the other hand, a number of issues arising from the multi-spin encoding of the qubit remains to be considered. In particular, an unwanted population loss from the ground-state doublet to the higher states (leakage) might occur during the manipulation: can the energy separation between the computational and the additional states of each molecule, as well as the molecule symmetries, be engineered in order to keep the leakage negligible throughout the time evolution? Besides making the higher energy levels harmless, is it possible to exploit them as a computational resource, and to develop a system-specific route to the implementation of the quantum gates? More generally, do the permanent intercluster couplings (such as the ones demonstrated in analogous molecular magnets [5]) allow the realization of both the conditional and unconditional dynamics?

In the present paper, we address some of these open questions. In particular, we consider the antiferromagnetic heterometallic ring $\{[Me_2NH_2]^+[Cr_7NiF_8(O_2CCMe_3)_{16}]^-\}$, Cr_7Ni in short [6], where the substitution of one $Cr^{III}(S = 3/2)$ ion with a $Ni^{II}(S = 1)$ provides an extra spin to the otherwise compensated molecule. We first show that Cr_7Ni is a suitable candidate for the qubit encoding, for it possesses an energetic spectrum and symmetries that allow to perform the required rotations within the computational space, while keeping the occupation of the excited states negligible. We also report preliminary characterization of Cr_7Ni-dimers in which couples of Cr_7Ni clusters are linked by diamines. Finally, we propose a scheme for selectively turning on and off the effective qubit–qubit coupling, by exploiting the presence of specific auxiliary states which belong to the excited $S = 3/2$ quadruplet, and in spite of the permanent nature of the intercluster interaction.

2. The molecular Cr_7Ni ring as qubit

In order to characterize the lowest-lying states of the Cr_7Ni molecule, we have performed low-temperature specific heat measurements. This is a powerful technique, since the observed Schottky anomaly is directly related to the pattern of the lowest energy eigenvalues. Measurements at zero magnetic field are particularly important, since they are obtained without any perturbing field. Although the energy level scheme is similar for most of these cyclic spin system, the presence of a huge lattice contribution and the need to simultaneously determine different microscopic parameters of the spin Hamiltonian require more experimental data. The lattice contribution is dominant above ~5 K and it does not change upon the application of a magnetic field, so it can be essentially determined by fitting data at high temperature. Conversely, the Schottky anomaly dominates at low temperatures and it changes upon the application of an external field **B**, as a consequence of Zeeman splitting of the lowest multiplets (see Fig. 1). Thus, the independent fit of few experimental curves obtained at different values of **B** allows the determination of the microscopic parameters appearing in the following spin Hamiltonian:

$$\mathscr{H} = \sum_{i=1}^{8} J_i \mathbf{s}_i \cdot \mathbf{s}_{i+1} + \sum_{i=1}^{8} d_i [s_{z,i}^2 - s_i(s_i+1)/3] + \sum_{i<j=1}^{8} \mathbf{s}_i \cdot \mathbf{D}_{ij} \cdot \mathbf{s}_j + \mu_B \sum_{i=1}^{8} g_i \mathbf{B} \cdot \mathbf{s}_i,$$

the first term corresponds to the dominant antiferromagnetic Heisenberg exchange between nearest neighbouring spins, with an antiferromagnetic character; the second and third anisotropic terms account for the

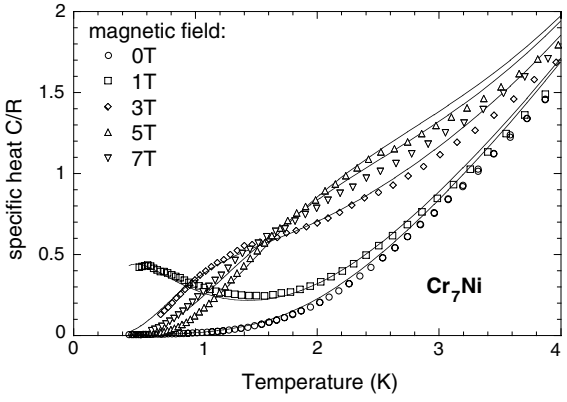

Fig. 1. Temperature dependence of the specific heat $C(T,H)$ (normalized to the gas constant R) of molecular Cr_7Ni ring: the evolution of the magnetic contribution (Schottky anomaly) in different magnetic fields should be noted. Unbroken lines are the best fit curves of the experimental data obtained as described in the text.

intracluster dipole–dipole interaction and for the coupling to the crystal field, respectively; finally, we consider the Zeeman coupling to the external field, with $g_{Cr} = 1.98$ and $g_{Ni} = 2.2$, respectively. The microscopic parameters entering the spin Hamiltonian were determined by fitting the magnetic-field dependent specific heat data: $J_{Cr}/k_B = (17.0 \pm 1.5)$ K, $J_{Ni}/J_{Cr} = 0.9$, $|d_i|/k_B = (0.3 \pm 0.15)$ K (for all the spin sites). The resulting ground state at zero field consists in a doublet with total spin $S = 1/2$, whilst the first excited multiplet approximately corresponds to $S = 3/2$. In fact, the presence of the anisotropy and Zeeman terms mixes different multiplets, and the total spin S is no longer a good quantum number (our two-step procedure, developed in [7], allows us to properly take into account such S-mixing). We have recently performed high-field torque-magnetometry experiments on a Cr_7Ni single crystal [8], and found that S-mixing has important effects at the level (anti-) crossing. Conversely, our calculations show that the mixing of different multiplets is little at low fields and does not significantly influence the implementation of the qubit operations; in particular, the ground state doublet has an approximated Kramers nature, imposed by the system symmetry, and an energy separation of $\Delta_0/k_B = 13$ K from the $S = 3/2$ multiplet. Further inelastic-neutron-scattering (INS) [9] and high field torque-magnetometry experiments agree well with the above estimates and allow a refined estimate of the exchange and anisotropy parameters (the accuracy of the specific heat data fit gives an error bar of 10% for the microscopic parameters, error that largely accounts for the values independently obtained by different experiments, cfr. [8,9]). In particular, the sign of the torque signal showed that the $S = 3/2$ multiplet has an easy plane anisotropy thus implying a negative d_i. Also the INS-data confirm the dominant axial character of the anisotropy, and the irrelevance of further (i.e., rhombic or higher order) anisotropic terms to the fitting of the experimental results. We thus conclude that the influence of such terms on the dynamics of this spin system and can be safely neglected for the purpose of the QIP implementation.

Based on these results, we identify the computational basis with the ground-state doublet $S = 1/2$: $|0\rangle \equiv |S_z = -1/2\rangle$ and $|1\rangle \equiv |S_z = +1/2\rangle$. The energy separation between these states and the next excited one, $\Delta_0/k_B \approx 13$ K, allows the cluster to be considered as an effective two-level system; the application of a static magnetic field perpendicular to the ring plane, $\mathbf{B}_0 = B_0\mathbf{z}$, reduces the value of Δ_0. On the other hand, the qubit initialization to its $|0\rangle$ state requires the ring to be cooled at a temperature which is much lower than the energy splitting between the computational states, i.e., $T < \mu_B B_0/k_B$, and it is therefore favoured by a high B_0. A reasonable compromise turns out to be $B_0 \approx 2T$, which implies $T \leqslant 1$ K.

Any quantum algorithm can be obtained by combining general one-qubit rotations with a non-trivial two-qubit gate (a CNOT, or an equivalent one). In the present case, the gating can be realized by applying sequences of pulsed magnetic fields $\mathbf{B}_1(t)$ orthogonal to the static field $\mathbf{B}_0$. As already mentioned, one of the main sources of errors that comes with the use of effective, rather than true, two-level systems is represented by the population loss to the cluster excited states, the so-called "*leakage*", which is given by $L = 1 - [|\langle 0|\psi(t)\rangle|^2 + |\langle 1|\psi(t)\rangle|^2]$. Quite generally, the longer are the field pulses that are used for the state manipulation, the better they spectrally resolve the required transitions, thus avoiding leakage. However, our simulations show that the relatively large value of Δ_0 in the present systems, allows to keep L below 10^{-4} even for a gating time (i.e., pulse duration) of the order of 150 ps [10].

On long enough time scales, the coupling of the system with the solid-state environment spoils its coherent evolution and causes decoherence. A quantitative evaluation of the decoherence rate for the present system requires specific experimental and theoretical work, that still needs to be carried out. Here, we simply point out that that the main decoherence source for the Cr_7Ni rings is expected to consist in the (super-)hyperfine coupling between the Cr electron spin and the closest nucleus of F. A preliminary evaluation of the decoherence time can be obtained by magnetization measurements with resonant photon absorbtion on Cr_7Ni, which give $\tau_d \sim 25$ ns [11] . This, however, should only be considered as a lower bond for τ_d, since these experiments are carried out on bulk crystals, whose coherence is limited by the inhomogeneous broadening, i.e., from possible differences between the rings of the bulk. Thus, while the chemical substitution of F with other chemical groups might certainly contribute to an increase of τ_d, the present value of the τ_d/τ_c ratio is already large enough for a large number of quantum gates to be performed in these systems. It is also worth mentioning that working in the *mK* temperature region and using static fields $\mathbf{B}_0$ of few Tesla, it is possible to polarize the nuclear spins and make large the mismatch between nuclear and electronic energy gaps thus, in principle, vanishing the effects of this mechanism of decoherence.

3. Possible routes for implementation of multiple-qubit gates

The implementation of the two-qubit gate in molecular magnets does certainly provide further challenging issues. In fact, not only it requires the realization of intercluster molecular links, such as the ones that have been demonstrated between Mn_4 dimers [5], but also a timely switch (on and off) of the coupling during gating. Here, we firstly report preliminary experimental results

on "Cr_7Ni-dimers", and then we propose a computational scheme that allows the above switching even in presence of an untuneable intercluster interaction.

We measured the magnetic and thermal properties of two "Cr_7Ni-dimers", namely $\{[Cr_7NiF_8(O_2CCMe_3)_{16}]_2[H_3N(CH_2)_9NH_3]\}$ (labelled as GT67) and $\{[Cr_7NiF_8(O_2CCMe_3)_{16}]_2[H_3N(CH_2)_8NH_3]\}$ (labelled as GT100) whose unit cell comprises two Cr_7Ni rings linked by diamines of different lengths. The preparation and structural characterization of these derivatives will be reported elsewhere [12]. In Fig. 2, we plot the ac susceptibility χ_{ac} measured on ca. 50 mg powders of each derivative and we compare them with that of Cr_7Ni. In Fig. 3, we report the dc magnetization measured at 0.4 K on small grains (ca. $200 \times 200 \times 200\ \mu m^3$) of each compound by mean of home-made Hall micro-probes. Only half unit cell of GT100 and GT67 was considered for a proper data normalization. It turns out that the behaviour of these two derivatives is very close to that of the original molecular Cr_7Ni ring in the range of temperature (0.4–100 K) and magnetic field we explored. Briefly, the $\chi_{ac}T$ product saturates to the value of the Curie constant $g^2\mu^2N_AS(S+1)/3k_B$ correspondent to $S = 1/2$ at low temperature whilst the bump at ~40 K in the χ_{ac} versus T curve is due to the population of excited states. The magnetization measured at 0.4 K fits the Brillouin curve calculated for $S = 1/2$ and no anomaly is evident at low field. In Fig. 4, we also report the low temperature specific heat $C(T)$ of the GT67 and GT100 compounds and we compare results with data obtained for molecular Cr_7Ni wheels after proper normalization. The experimental data, overlap each others except for the deviation of the specific heat curve of GT100 below 1 K. Different samples were measured and according to our experience the $C(T)$ behaviour below 1 K turns out to be sample dependent and it also change upon the application of weak magnetic field (~0.1 T). This is not surprising since the absolute value of $C(T)$ drops below 1 K – even for Cr_7Ni – so it is likely that the $C(T)$ is influenced by the presence of even very small amount of magnetic impurities or defected wheels. Further work is thus needed in order to probe the presence of an intercluster coupling. However, these results show that the basic Cr_7Ni wheels are essentially preserved in all these derivatives if looked at large energy scale and we may, at

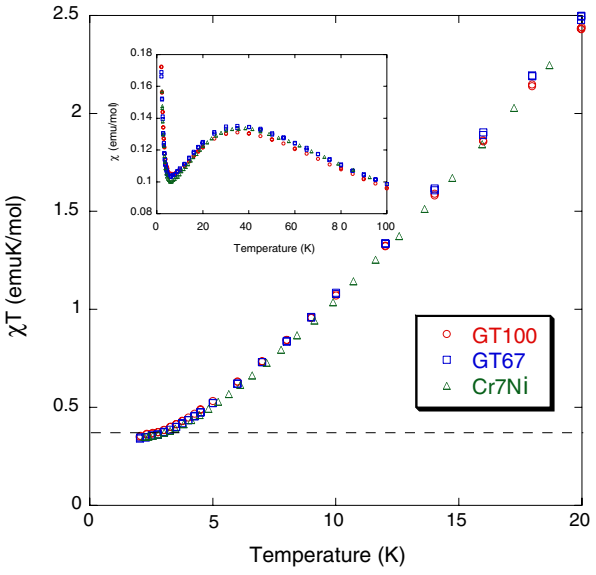

Fig. 2. The behaviour of ac susceptibility χ_{ac} measured at $f = 90$ Hz and $H_{ac} = 15$ Oe. In the main graph, the product χT as a function of temperature of Cr_7Ni and (Cr_7Ni)-dimers, referred as GT67 and GT100, respectively, in the text, is plotted. Note that χT tends to saturate close to the value of the Curie constant $g^2\mu^2N_AS(S+1)/3k_B$ correspondent to $S = 1/2$ at low temperature. Inset: temperature dependence of the ac susceptibility χ_{ac} for the same derivatives.

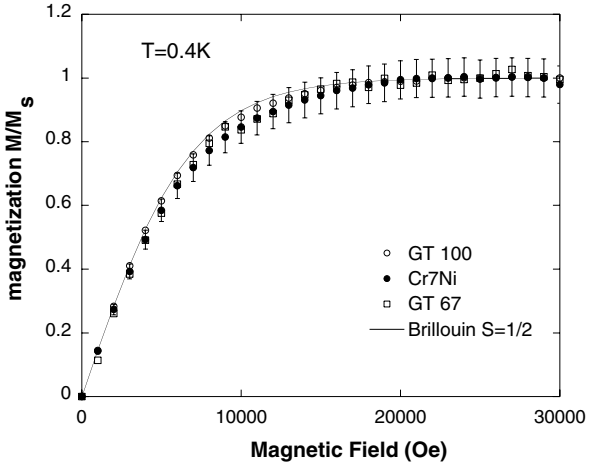

Fig. 3. Magnetization, normalized to the saturation values, of the Cr_7Ni ring and two (Cr_7Ni)-dimers, referred as GT67 and GT100 in the text, measured at 0.4 K. The observed behaviours for the different compounds are close, within our experimental accuracy, one to the others and to the Brillouin curve calculated for $S = 1/2$.

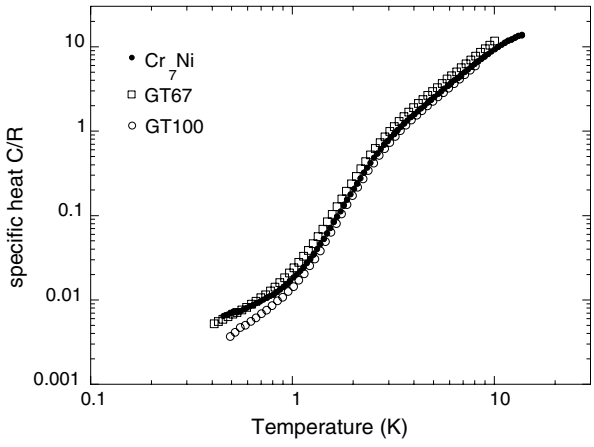

Fig. 4. Specific heat C, normalized to the gas constant R, of the molecular Cr_7Ni ring and the two (Cr_7Ni) dimers named GT67 and GT100, respectively, in the text.

least, give an upper bond of c.a. 1 K for such coupling between Cr_7Ni wheels in the studied dimers. A close inspection of the crystal structure of these derivatives also shows little overlap between the wavefunctions of the Cr ions and the diamines and this further corroborates the weakness of the expected coupling. We believe that the preparation and characterization of molecular dimers will be an interesting issue to pursue in the next years. We just mention here that other chemical strategies are currently explored and results will be presented elsewhere [12] and in the following we briefly present a possible scheme for the implementation of the required two-qubit gate, namely the CNOT.

We assume that a permanent link exists between two molecular qubits, hereafter named A and B, both characterized by the above-mentioned antiferromagnetic ordering of the respective ground states, and thus by an (approximately) antiparallel alignment of two sublattices (see Fig. 5). We assume the link to be preferentially coupled to one of the two sublattices of A, while it interacts – weakly asymmetrically – with the two sublattices of B, e.g., via local interactions to the neighbouring spins i and $i+1$. In this case, the overall effective interaction is proportional to the $\langle \mathbf{s}_i \rangle + \langle \mathbf{s}_{i+1} \rangle$, and thus vanishes when B is in its ground state (being $\langle \mathbf{s}_i \rangle \approx -\langle \mathbf{s}_{i+1} \rangle$), whilst it becomes finite if B is driven to an excited states (say $|2\rangle$) lacking such antiparallel alignment of the neighbouring spins. The $S = 1/2$ and $S = 3/2$ spin eigenstates of Cr_7Ni, for example, fulfil such requirements. The resulting energetic spectra of the AB system allows the implementation of a controlled-Z gate, which is equivalent to CNOT and is defined by the following transformation of the basis states: $|0\rangle_A \otimes |0\rangle_B \rightarrow |0\rangle_A \otimes |0\rangle_B$, $|0\rangle_A \otimes |1\rangle_B \rightarrow |0\rangle_A \otimes |1\rangle_B$, $|1\rangle_A \otimes |0\rangle_B \rightarrow |1\rangle_A \otimes |0\rangle_B$, $|1\rangle_A \otimes |1\rangle_B \rightarrow -|1\rangle_A \otimes |1\rangle_B$, as depicted in the true table of Fig. 5(b). In fact, the energy of the transition from $|1\rangle_B$ to $|2\rangle_B$ are renormalized by the interaction between A and B; the applied magnetic field frequency can thus be tuned depending in such a way that it is in resonance with the above transition only if cluster A is in the $|1\rangle_A$ state. The sequential application of two such π-pulses, separated by proper time delay τ, thus excites and de-excites B, inducing an additional phase $\theta = [-\tau(E_2 - E_1)2\pi/h]$ to $|1\rangle_A \otimes |1\rangle_B$ (in particular the controlled-Z corresponds to $\theta = \pi$). Numerical simulations with sequences of pulsed magnetic fields indicate that the time required to excite molecule in its auxiliary state is only few times longer than the single qubit gating time estimated in equivalent condition whilst the leakage to the lowest stats out of the computational basis remain very low ($L < 10^{-4}$). The details of this scheme as well as numerical simulations with the actual energy level of Cr_7Ni rings and possible exchange coupling between A and B will be presented elsewhere [10,13]. The important point we would like to stress here is that excited states of molecular qubit that can be efficiently exploited for the quantum-gate implementation.

In conclusion, we show that heterometallic molecular clusters with dominant antiferromagnetic internal coupling are suitable electronic spin systems for the implementation of the Shor's quantum algorithm. One main advantage in using molecular clusters is the size of the qubit that will help in the addressing to single quantum object. We also underlined a further resource of molecular clusters made by their excited states that in a proper computational scheme may constitute an important feature to consider.

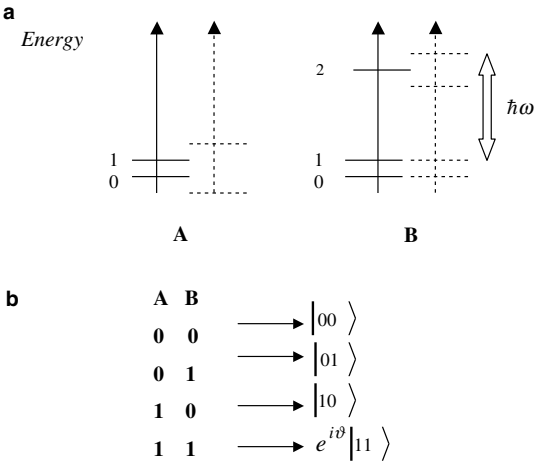

Fig. 5. Scheme for two qubit gate. (a) Continuous lines represent the energy levels for isolated cluster qubits; dotted lines sketch a possible patter of the energy levels when B is excited to its auxiliary state $|2\rangle$ and the coupling between the A and B molecules is active. By making use of the axilliary state $|2\rangle$ of molecule B and suitable time for rotation it can be possible to realize a controlled-Z as depicted in the true table (b).

example are the molecular-based Gd(hfac)$_3$NITR chains recently synthesized [6,7] [hfac is hexafluoro-acetylacetonate and NITR is 2-R-4,4,5,5-tetramethyl-4,5-dihydro-1H-imidazolyl-1-oxyl 3-oxide], where R = isopropyl, ethyl, methyl, phenyl (hereafter denoted by *i*Pr, Et, Me, Ph, respectively). Their magnetic properties are determined by Gd^{3+} rare-earth ions (with spin $S = 7/2$), and nitronyl nitroxide organic radicals R (with $s = 1/2$), alternating along the chain and interacting via competing nearest neighbour (NN) and next nearest neighbour (NNN) exchange coupling (see Fig. 1). EPR measurements [8] confirmed the 1D nature of the structure, while X-ray diffraction data showed that the chains are well separated from each other, with an interchain Gd–Gd distance of 10.5 Å. As a consequence, the interchain interactions, of dipolar nature, turn out to be much weaker with respect to the intrachain ones.

The first experimental magnetic susceptibility data in the various compounds with different organic radical R [9] showed a quite different behaviour of the quantity $\chi_M T$, depending on the radical nature. In fact for the compounds with R = *i*Pr and Et, $\chi_M T$ was found to decrease with decreasing T, a behaviour which resembles that of an antiferromagnet; in contrast, for the compounds with R = Me and Ph, $\chi_M T$ was found to diverge with decreasing T, a typical ferromagnetic behaviour.

The model Hamiltonian for these compounds can be represented as

$$H = H_{\text{intra}} + H_{\text{inter}}. \tag{1.1}$$

The first term on the right hand side of Eq. (1.1) includes the competing exchange interactions along the chains ($J_{z1} > 0$ is the NN ferromagnetic intrachain exchange, while $J_{z2} < 0$ and $J'_{z2} < 0$ are the NNN antiferromagnetic ones, see Fig. 1), as well as an effective single-ion anisotropy ($D > 0$) acting on the Gd $S = 7/2$ spins and favouring them to lie in the xy plane perpendicular to the chain axis, z:

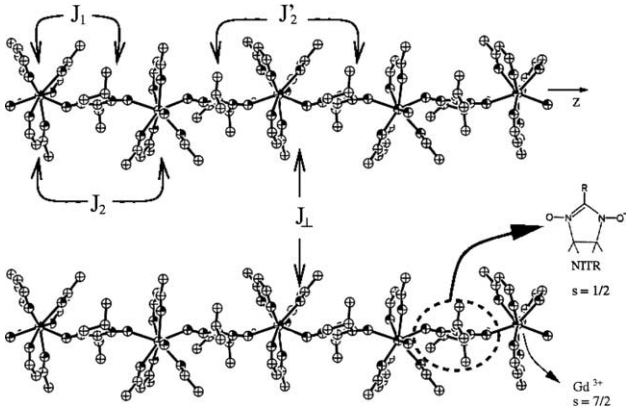

Fig. 1. Structure representation of the compound Gd(hfac)$_3$NITR [8]: gadolinium atoms with spin $S = 7/2$, and the group structure NITR with total spin $s = 1/2$. Here, it is also reported J_{z1} (ferromagnetic), $J_{z2}J'_{z2}$ (antiferromagnetic), and $J_\perp$ (ferro or antiferromagnetic) as NN, NNN intrachain and NN intrachain interaction, respectively.

$$H_{\text{intra}} = \sum_{i=1}^{M}\sum_{n=1}^{N/2}\Big[-J_{z1}(\vec{S}_{i,2n-1}\cdot\vec{s}_{i,2n} + \vec{s}_{i,2n}\cdot\vec{S}_{i,2n+1}) + D(S^z_{i,2n-1})^2 - J'_{z2}(\vec{S}_{i,2n-1}\cdot\vec{S}_{i,2n+1}) - J'_{z2}(\vec{s}_{i,2n}\cdot\vec{s}_{i,2n+2})\Big]. \tag{1.2}$$

The index n refers to the spin position along the ith chain. Different chains interact through a weak ferromagnetic (or antiferromagnetic) exchange ($|J_\perp/J_{z1,2}| \ll 1$):

$$H_{\text{inter}} = \sum_{\langle i,j\rangle}\sum_{n=1}^{N} -J_\perp(\vec{X}_{i,n}\cdot\vec{X}_{j,n}), \tag{1.3}$$

where $\vec{X}_{i,n} = \vec{S}_{i,n}(Gd^{3+}), \vec{s}_{i,n}(\text{NITR})$. Thus, the total Hamiltonian is a collection of M weakly interacting chains [10].

For the planar 1D model with equal spins and competing NN and NNN exchange interactions, Harada [11] showed that, for sufficiently strong NNN exchange, a helical ground state is energetically favored, with a twofold chiral degeneracy associated with the clockwise and counter-clockwise turn of the spins along the chain (see Fig. 2). The chirality order parameter related to a NN spin pair can be defined as (a is the lattice step and Q is the pitch of the helix)

$$k_i = \frac{[\vec{S}_i\cdot\vec{S}_{i+1}]^z}{|\sin aQ|}, \tag{1.4}$$

and for the planar 1D model it takes the values ± 1 at $T = 0$. In the present case of two different kinds of spins alternating along the chain, the wave number Q that determines the pitch of the helical order is found to be (hereafter we put $a = 1$)

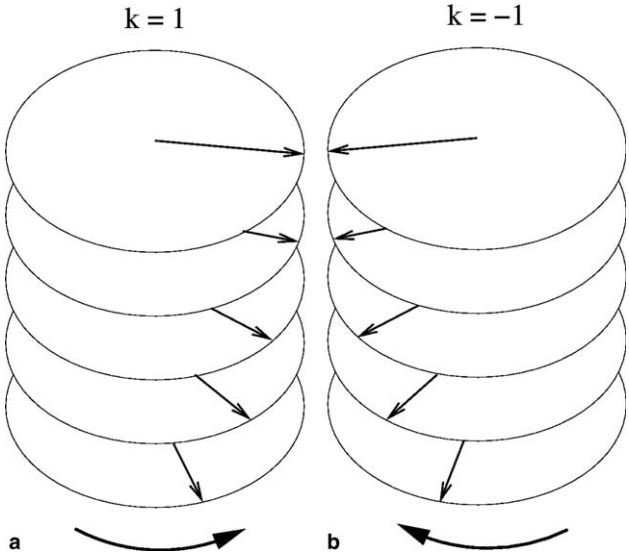

Fig. 2. Helical ground state configuration of a spin chain with easy-plane anisotropy and $S = s$ at $T = 0$. (a) Helical ground state with counter-clockwise turn of the spins ($k = 1$); (b) helical ground state with clockwise turn of the spins ($k = -1$).

$$\pm Q = \pm\cos^{-1}\left(\frac{1}{2(\delta+\delta')}\right), \quad (1.5)$$

where $\delta' = (|J_{z2}|S^2)/(J_{z1}sS)$ and $\delta = (|J'_{z2}|s^2)/(J_{z1}sS)$. Therefore the helical order is possible only if the ratio between NNN and NN exchange coupling exceeds a threshold value, i.e. $2(\delta+\delta') > 1$.

By transfer matrix computations of the model (1.2), it was possible to provide a first classification according to the different nature of the organic radical R [9]. The chains with helix pitch Q (at $T = 0$) close to $\pi/2$ are called *fully frustrated* magnetic chains: this is the case of the molecular chains with R = *i*Pr ($Q = 0.399\pi$) and R = Et ($Q = 0.397\pi$). In contrast, the chains with helix pitch Q significantly smaller than $\pi/2$ are called *weakly frustrated* magnetic chains: this is the case of the molecular chains with R = Me ($Q = 0.206\pi$) and R = Ph ($Q = 0.175\pi$).

In this paper we present recent specific heat and muon spin relaxation data in the molecular-based Gd(hfac)$_3$NITR chains with R = *i*Pr and R = Ph, and we compare their magnetic properties according to their different degree of frustration.

For Gd(hfac)$_3$NITiPr (hereafter denoted by Gd-*i*Pr), recent specific heat data [12] are reported in Fig. 3 versus temperature. The heat capacity of thin pellets of pressed microcrystals was measured in different cryogenic systems and using three different calorimeters and techniques. In zero field a λ-type anomaly is clearly visible at $T_0 = 2.08$ K, while below 1 K the specific heat scales to zero with a quasi-linear T-law. Moreover such λ-type anomaly is completely removed by the application of an external magnetic field of 5 T, thereby proving the magnetic origin of the transition. A further feature of the λ-peak is the absence of latent heat, which indicates that the phase transition is of the second order. An analysis of the residual magnetic entropy removed in the low-temperature region $T < T_0$ below the λ-anomaly provides a rather high value (59% of the total magnetic entropy). This result suggests the absence of a strong short-range order at these temperatures, in contrast with the usual behaviour of quasi-1D magnets (like TMMC, see [13]).

The low-temperature susceptibility data for Gd–*i*Pr reported in [10] clearly showed that $\chi(T)$ does not present any anomaly at $T \sim 2$ K. Such an experimental result quite excludes the possibility of a phase transition to 3D helical long range order. The behaviour [10] observed in the susceptibility data is in full agreement with more recent measurements of the muon longitudinal relaxation rate λ of Gd–*i*Pr as a function of temperature [12], for both $H = 0$ and for a longitudinal field $H = 500$ Oe. In fact, as shown in Fig. 4, no divergence is observed in $\lambda(T)$ close to 2 K, where the specific heat shows the anomaly previously discussed, thus indicating that this temperature does not mark any transition to a long-range order for the two-spin correlation function. Moreover, see inset of Fig. 4, the analysis of the zero-field muon asymmetry $A(t)$ versus time below T_0 (analyzed by a stretched exponential decay $A(t) \approx A_0 e^{-\sqrt{\lambda t}}$) shows the absence of long range magnetic order at muon site in the whole investigated T-range. In presence of long-range magnetic order, one should observe an oscillation in the asymmetry, caused by the precession of the muon spin around the local field itself.

It clearly appears that, while the four-spin correlation function (probed by the magnetic specific heat, Fig. 3) unequivocally shows a magnetic phase transition at $T \sim 2$ K, the two-spin correlation function (probed by susceptibility [10], and by μ^+ SR, Fig. 4) does not show any anomaly related to a transition to conventional 3D helical long range order. Taking also into account that

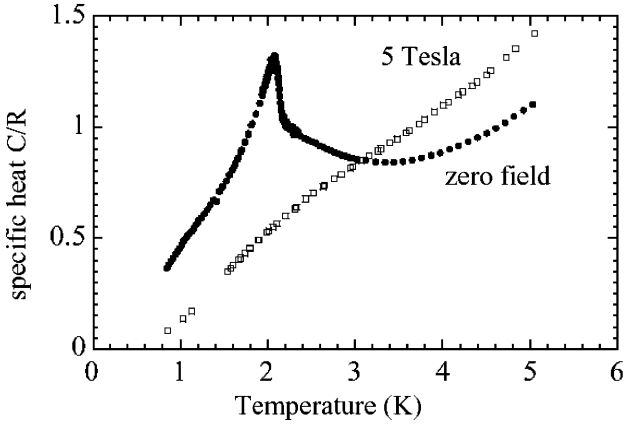

Fig. 3. Specific heat vs. temperature of Gd–*i*PR. Filled circles: zero field measurements; open squares: 5 T measurements.

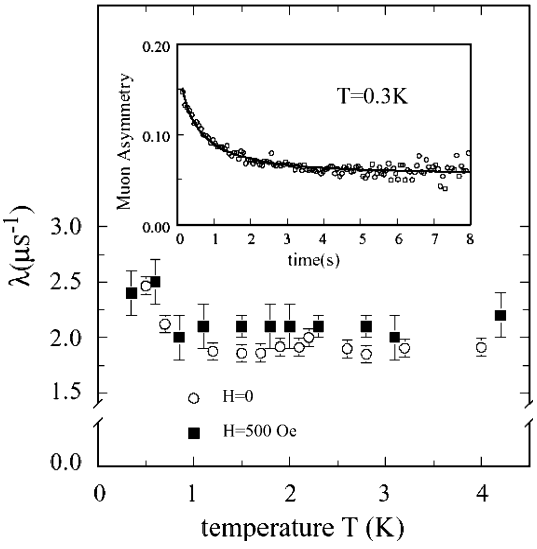

Fig. 4. Muon longitudinal relaxation rate measured in Gd–*i*Pr as a function of temperature with field $H = 0$ (open circles) and $H = 500$ Oe (filled squares). Inset: measured muon asymmetry below T_0 (open circles) and fit (line).

at very low temperatures (0.175–0.8 K) a linear T-dependence of the magnetic specific heat was observed in Gd–*i*Pr (a clear indication for isotropic 1D magnetic behaviour), one can reasonably conclude that our new experimental data in this molecular magnetic compound provide evidence for the onset, below $T_0 = 2.08$ K, of an ordered chiral phase in the absence of 3D helical long-range order.

New specific heat in the range 29–200 mK have been performed, quite recently. Such data (which will be published soon in a next article [14]) present, for $T_N = 39$ mK, an anomaly which cannot be reproduced by a Schottky-like contribution. In contrast, such anomaly displays a sharp λ-shape, signaling the onset of a phase transition to 3D helical long-range order, well separated in temperature from the chiral transition at $T_0 = 2.08$ K.

Such experimental data in Gd–*i*Pr fully confirm Villain's conjecture. In fact, some years ago he suggested [15] that quasi-1D planar helimagnets may have – in addition to the low-temperature 3D helimagnetic phase and to the high-temperature paramagnetic one – a chiral phase, stable at intermediate temperatures $T_N < T < T_0$, characterized by spontaneous breaking of the translational invariance without violation of the overall invariance with respect to spin rotation and time reversal. The chiral phase is similar to a collection of cork-screw all turning concordantly, whereas their phase are random (see Fig. 5).

Due to the Ising nature of chirality, T_0 results greater than T_N, because the chirality–chirality correlation function is stronger than the usual spin–spin correlation one. In fact the chiral correlation length ξ_k, defined via the chirality–chirality correlation function:

$$\langle k_n k_{n+p} \rangle \propto e^{-\frac{|p|}{\xi_k}}, \tag{1.6}$$

diverges exponentially as temperature is decreased (J is the exchange constant)

$$\xi_k \propto e^{\frac{|J|}{k_B T}}, \tag{1.7}$$

while the spin–spin correlation function

$$\langle \vec{s}_1 \cdot \vec{s}_{2n+1} \rangle \propto e^{-\frac{2n}{\xi_{XY}}}, \tag{1.8}$$

diverges as a power law

$$\xi_{XY} \propto \frac{Js^2}{k_B T}. \tag{1.9}$$

The Villain's conjecture appears to be verified in the molecular magnetic chain Gd–*i*Pr: in fact, an anomaly is expected at T_0 for the physical properties related to Eq. (1.6) (such as the magnetic specific heat), while the quantities related to Eq. (1.8) (such as the magnetic susceptibility and μ^+SR) are expected to behave critically only at T_N.

In order to interpret the experimental results in Gd–*i*Pr, a theoretical approach based on Villain's conjecture has been developed [16]. The model is built by rescaling on the XY spin variables; consequently, one obtains an order parameter with Ising-like symmetry that describes the chiral order, investigable by mean field approach. Such order is established by a second order phase transition, as experimentally observed in the specific heat data. Further indication for a second order chiral phase transition is provided by a more refined renormalization group analysis. Besides, preliminary numerical analysis via the Monte-Carlo technique seem to confirm the presence of two well-separated transition temperatures, as estimated both experimentally and theoretically [17].

It is worth noticing that such a behavior is peculiar of Gd–iPr chains. In fact, for the Gd(hfac)$_3$NITPh molecular magnetic chain (hereafter denoted by Gd–Ph), where the frustration is smaller than for Gd–*i*Pr, the new specific heat data, shown in Fig. 6(a), suggest the existence of a single λ-anomaly at $T_N = 0.63$ K. Below T_N, at very low temperature $C(T) \propto T^\alpha$ (where α is between 2 and 3), displaying an evident crossover to a linear behaviour when the temperature increases (see Fig. 6(b)). Such a behaviour can be easily understood in terms of a free spin wave contribution within a 3D model with strongly anisotropic interactions [18]. In Fig. 6(b) we show that spin wave theory is able to correctly reproduce the measured temperature dependence of the specific heat of Gd–Ph. Furthermore, providing an exact solution for the single chain by the transfer matrix method and treating the interchain interactions in a mean-field approximation, we find a transition temperature

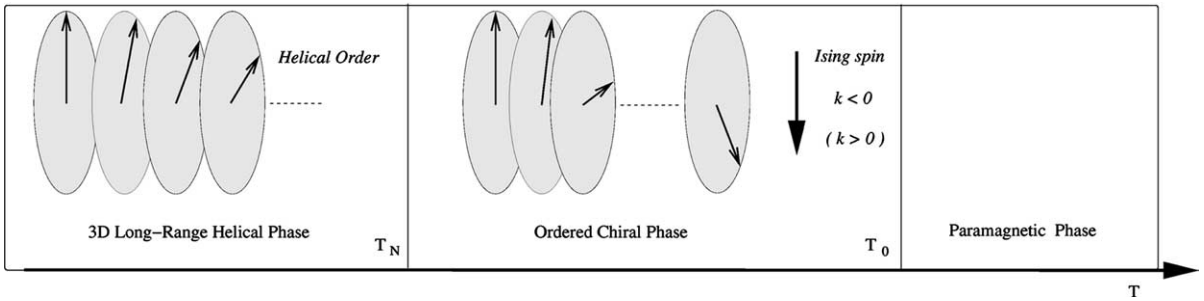

Fig. 5. Schematic representation of Villain's conjecture for the phase diagram of a quasi-one-dimensional helimagnet.

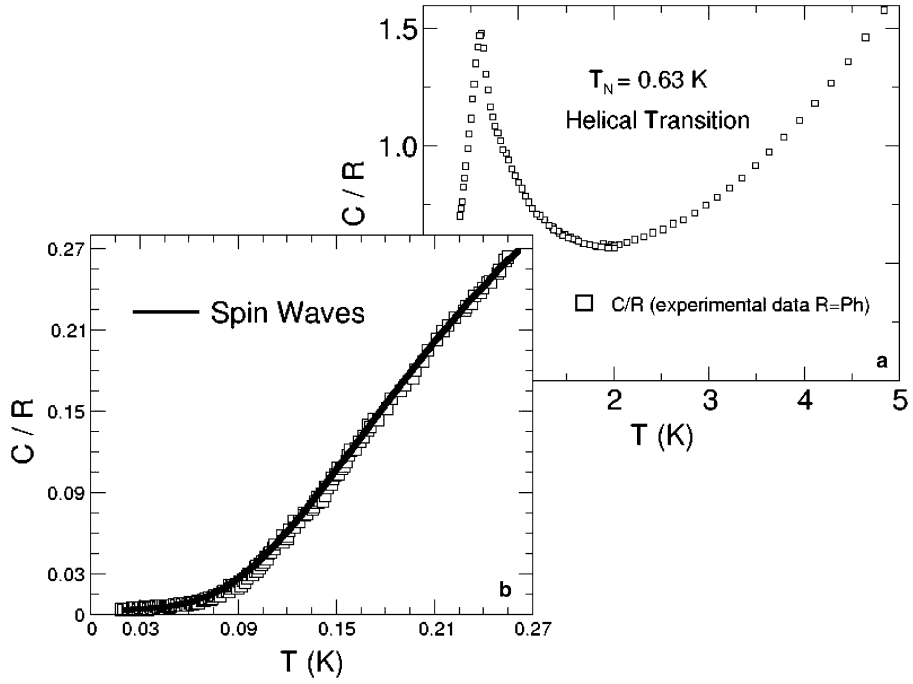

Fig. 6. (a) Specific heat data for Gd–Ph. (b) Fit obtained by 3D spin wave theory (solid line) and specific heat data (open squares) at temperatures below T_N.

$T_N^{\text{theor}} = 0.64$ K, in close agreement with the experimental value [18]. In conclusion, differently from the fully frustrated compound Gd–*i*Pr, the weakly frustrated Gd–Ph magnetic chain does not show the presence of a chiral order at any temperature. Rather, our theoretical analysis suggests that the phase transition observed at $T_N = 0.63$ K is related to the onset of the usual 3D helical long range order.

long-range magnetic order below $T_N = 1.87$ K, probably of antiferromagnetic nature.

The communication is organized as follows. Firstly, we introduce the Reader to the magnetocaloric effect. In the following section, we describe the magnetic structure of the Fe_{14} cluster core. Then, we present and discuss the magnetization and specific heat experiments, whose results are used in the last section to calculate the MCE parameters.

Magnetization measurements down to 2 K and specific heat measurements using the relaxation method down to ≈0.35 K, were carried out in a PPMS (Quantum Design Inc.) apparatus for the $0 < H < 7$ T magnetic field range. Magnetization and susceptibility measurements below 2 K were performed by means of a home-made Hall probe appositely installed in the same commercial apparatus. In this case the samples used consisted of a collection of small grains of ca. 10^{-3} mm^3.

2. Magnetocaloric effect

When a material is magnetized by application of a magnetic field H, the entropy associated with the magnetic degrees of freedom, S_m, is changed as the field changes the magnetic order of the material. The MCE and the associated principle of adiabatic demagnetization is readily understood looking at Fig. 1. The system, assumed to be a paramagnetic material, is initially in state A(T_i, H_i), at temperature T_i and field H_i. Under adiabatic conditions (i.e., when the total entropy of the system remains constant during the magnetic field change), the magnetic entropy change must be compensated for by an equal but opposite change of the entropy associated with the lattice, resulting in a change in temperature of the material. That is, the adiabatic field change $H_i \rightarrow H_f$ brings the system to state B(T_f, H_f) with the temperature change $\Delta T_{ad} = T_f - T_i$ (horizontal arrow in Fig. 1). If otherwise the magnetic field is isothermally changed to H_f in a reversible process, the system goes to state C(T_i, H_f) with the magnetic entropy change ΔS_m (vertical arrow in Fig. 1). Both ΔS_m and ΔT_{ad} represent the characteristic parameters of the MCE. It is easy to see that if the magnetic change ΔH reduces the entropy ($\Delta S_m < 0$), then ΔT_{ad} is positive, whereas if ΔH is such that $\Delta S_m > 0$, then $\Delta T_{ad} < 0$ (Fig. 1).

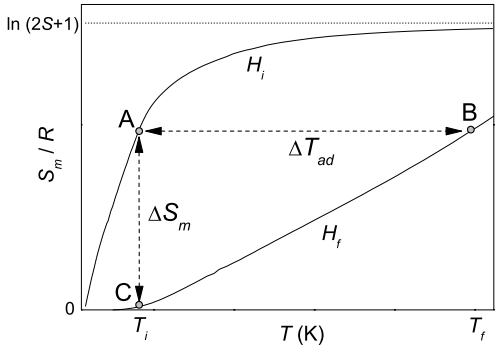

Fig. 1. Molar magnetic entropy of a (super)paramagnet with spin S per formula unit, as a function of temperature, for magnetic field H_i and $H_f > H_i$. AB process: adiabatic magnetization providing ΔT_{ad}. AC process: isothermal magnetization providing ΔS_m.

Large magnetic moments are often attainable in superparamagnetic clusters, resulting therefore in large entropies. Moreover, for certain ranges of field, temperature and cluster size, it is easier in superparamagnets than in pure materials to change the magnetic entropies by application of a field [6,7]. Obviously, this leads to an interest in superparamagnets in terms of MCE. The picture depicted in Fig. 1 is still valid for a superparamagnet with S as net cluster moment, provided that it is at temperatures above the blocking temperature. The cluster magnetic anisotropy, which indeed determines the blocking temperature, can be considered as a drawback in the MCE efficiency of superparamagnets. This because, by shifting the maxima of $\Delta S_m(T)$ and $\Delta T_{ad}(T)$ towards higher temperatures, it tends to lower the values of the MCE response [6,7,12]. Ideal candidates for MCE applications, would then be magnetic clusters with large S and small anisotropy.

3. Fe_{14} molecular nanocluster

In what follows, we focus on the Fe_{14} compound, nominally $Fe_{14}(bta)_6O_6(OMe)_{18}Cl_6$ [11]. Fig. 2 shows the highly symmetric core, comprising 14 Fe^{3+} $s = \frac{5}{2}$ spins, which can be described as a hexacapped hexagonal bipyramid with the caps on alternate faces. The three face capping iron ions [Fe2, Fe3, Fe4 and symmetry equivalents] and the apical iron [Fe1 and symmetry equivalent] on either half of the molecule form two $[Fe_4(bta)_3Cl_3]$ units each separated from a central $\{Fe_6\}$ ring, which has an almost planar symmetry. The Fe–O–Fe bridges fall into two categories: those that connect the apical iron ions [Fe1 and symmetry equivalent] to the face cap and equatorial iron ions, and those characterized by much smaller angles that connect all other iron ions. If we assume that the larger angles will lead to the strongest antiferromagnetic exchange, thus dominating the other interactions, then we are left with a situation whereby the spins on Fe1 and symmetry equivalent are antiferromagnetically coupled to all other spins, which should lead to 12 $s = \frac{5}{2}$ spins up and two $s = \frac{5}{2}$ spins down, and an overall $S = 25$ cluster spin ground-state (Fig. 2). Although a full description of the electronic configuration of the Fe_{14} cluster core is still not available, preliminary density functional and Monte Carlo calculations [13] support such a very large value for the spin ground-state.

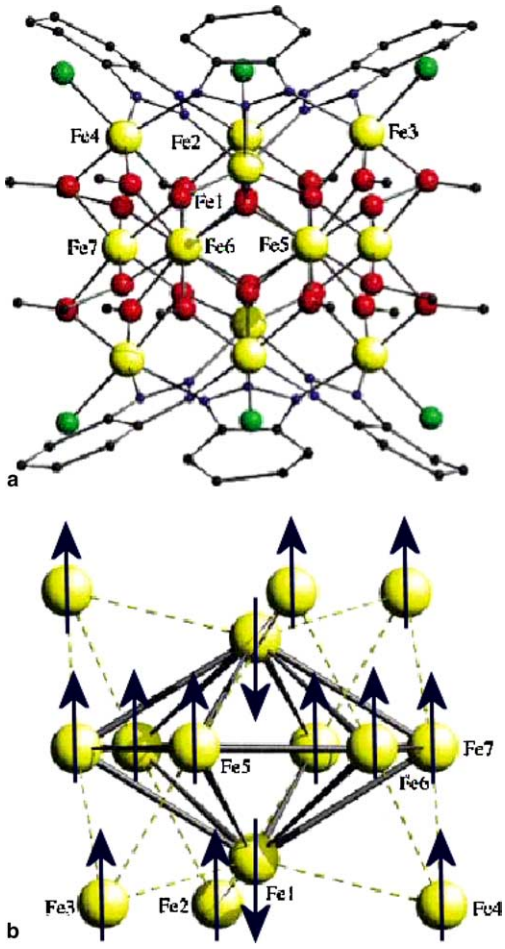

Fig. 2. (a) Molecular structure of $Fe_{14}(bta)_6O_6(OMe)_{18}Cl_6$. Colour scheme: Fe, yellow; O, red; N, blue; Cl, green. After [11]. (b) Sketch of the symmetric core containing 14 exchange-coupled Fe^{3+} ions, yielding a total spin $S = 25$. The arrows illustrate the alignment of the Fe^{3+} $s = \frac{5}{2}$ spins inside the cluster.

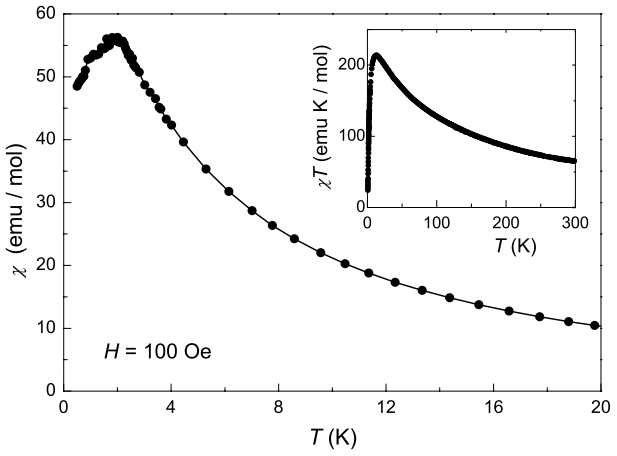

Fig. 3. Temperature dependence of the DC-susceptibility of Fe_{14} taken for $H = 100$ Oe, showing the transition to a long-range ordered state at $T_N = (1.9 \pm 0.1)$ K. Line is guide to the eye. Inset: temperature dependence of χT.

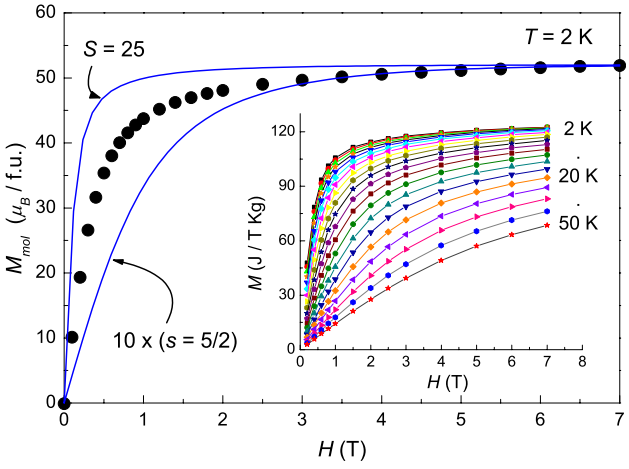

Fig. 4. Field dependence of the experimental molar magnetization for $T = 2$ K together with the calculated magnetizations for a single $S = 25$ spin and for the uncoupled sum of 10 $s = \frac{5}{2}$ spins. Inset: Magnetization isotherms used to estimate the entropy change ΔS_m shown below in Fig. 7.

4. Experimental results

Fig. 3 shows the temperature dependence of the DC-susceptibility of Fe_{14} measured for an applied field of $H = 100$ Oe. Data down to 2 K are collected using a commercial calibrated magnetometer, whereas data from ~10 K down to 0.35 K are taken with Hall micro-probe. The latter, initially in arbitrary units, are successively properly scaled with the high-T data taken with the commercial magnetometer. The main feature of Fig. 3 is given by the sharp peak at $T_N = (1.9 \pm 0.1)$ K, that, in view also of the specific heat data presented below, we tentatively attribute to the transition to a long-range magnetically ordered phase. The maximum value of χ at T_N corresponds to $\chi_{max} \simeq 56$ emu/mol (Fig. 3), which is smaller than that expected for paramagnetic $S = 25$ spin,[2] suggesting that a full ordered $S = 25$ magnetic state inside the cluster is not achieved at T_N. The observed behaviour is compatible with an antiferromagnetic nature of the ordered phase, as evidenced by the sharp decrease in the temperature dependence of χT below 13 K (inset of Fig. 3). Fig. 4 shows the molar saturation magnetization which tends to the limiting value of $M_{mol} \simeq 50\ \mu_B$ (for $T = 2$ K), in agreement thus with spin $S = 25$ and $g = 2$. However, the magnetization does not vary according to the Brillouin function for $S = 25$, that is displayed in the Figure for comparison. On basis of the ordered arrangement of Fig. 2, one should expect a net total spin per cluster resulting from the sum of 10 iron spins. Together with the experimental magnetization, therefore, we also plotted the magnetization of 10 uncoupled $s = \frac{5}{2}$

[2] For $S = 25$ and assuming $g = 2$, the Curie constant has the value of $C = 162$ emu/Kmol. Therefore, the expected susceptibility at $T_N = 1.9$ K should not be less than $C/T_N \approx 85$ emu/mol, which is not observed.

spins (Fig. 4, for $T = 2$ K). It can be observed that the experimental data lie above the uncoupled case and below the magnetization for $S = 25$. In agreement with susceptibility data, such a behaviour suggests that superexchange intracluster interactions tend to align the iron spins as depicted in Fig. 2. However, this is not fully achieved without applying the field, likely because (i) degrees of freedom inside the cluster allow spin states other than $S = 25$ to contribute, and/or (ii) intercluster interactions, responsible for the long-range ordering, are similar in magnitude to the intracluster ones. In the inset of Fig. 4, we also plot systematic magnetization measurements, in the magnetic field range $0 \leqslant H \leqslant 7$ T and in the temperature range $2 \leqslant T \leqslant 50$ K, that we shall use below to estimate the MCE of the Fe_{14} molecular nanocluster.

Fig. 5 shows the collected specific heat data C/R of the molecular Fe_{14} compound as a function of temperature for applied magnetic field $H = 0$ and 7 T. The main feature is the λ-type anomaly in the zero-field specific heat at $T_N = (1.87 \pm 0.02)$ K, revealing the onset of long-range ordering and corroborating the interpretation of the susceptibility data. This anomaly is quickly removed by the application of an external field of 1 T (not shown here), proving its magnetic origin. The λ-type anomaly is more clearly seen in Fig. 6, where we show the specific heat C_{order} associated only with electronic spins contributing to the ordering mechanism. Such a curve is obtained as depicted in the inset: we drew a linear contribution of the specific heat at low temperatures that we subtracted to the total specific heat obtaining the residual C_{order}. The relative height of the transition peak amounts to $\approx 1.2R$. This value is apparently a bit too low for a very large spin as that of Fe_{14}. However, this is understandable if one

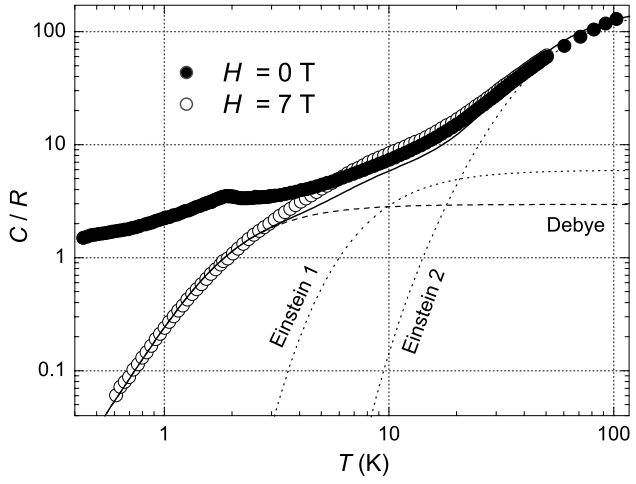

Fig. 5. Temperature dependence of the total specific heat of Fe_{14} for applied magnetic field $H = 0$ and 7 T. Solid line is the total lattice contribution, whereas the dashed and dotted lines are the Debye and Einstein contributions, respectively.

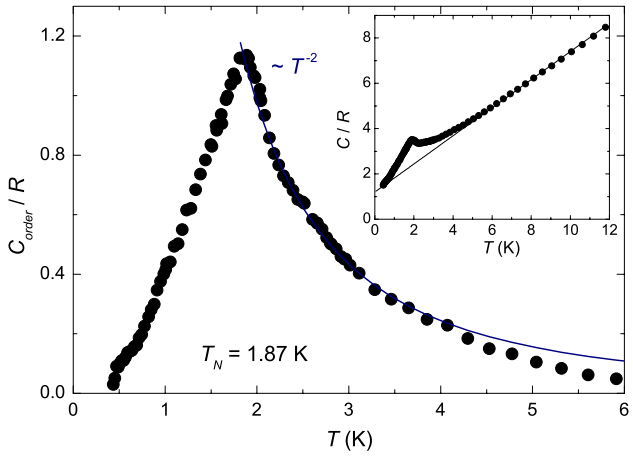

Fig. 6. Temperature dependence of the ordering specific heat C_{order}, from which the ordering temperature $T_N = (1.87 \pm 0.02)$ K is deduced. Solid line is a fit to $C_m \propto T^{-2}$ (see text). Inset: total specific heat vs. T in linear coordinates showing the linear contribution (solid line) used to obtain C_{order}.

considers that the large specific heat contribution that we subtracted to get C_{order}, leaves a relatively small amount of entropy for the electronic spins to order. Above the transition temperature, C_{order} is well described by an asymptotic term of the magnetic anomaly [14] according to $C_{order}/R = a\ T^{-2}$, where $a = 3.9$ K^2 (Fig. 6).

We estimated the lattice contribution C_{latt} for the specific heat data of Fig. 5. This contribution can be modelled with the sum of a Debye curve, which describes the contribution of acoustic modes, plus an Einstein oscillator term that probably arises from intramolecular vibrational modes. The overall fit provides $\theta_D \simeq 10$ K and $\theta_E^{(1)} \simeq 25$ K for the Debye and Einstein temperatures, respectively. The specific heat data measured above 20 K show a second step-like increase, indicating the existence of higher energy vibrational modes, that we modelled with an additional Einstein term providing $\theta_E^{(2)} \simeq 68$ K . The determination of these modes has some uncertainty since the analysis of the specific heat data has different free parameters in this temperature range. We note that these values of θ_D and $\theta_E^{(i)}$, although commonly found in the specific heat analysis of molecular magnets, are very low. It is also worth noting that small amount of disordered solvent contained in the molecular crystal may also contribute to C_{latt} at these temperatures. These facts question the consistency of the Debye–Einsten model itself and we believe that the θ_D and $\theta_E^{(i)}$ values should be considered as phenomenological parameters rather than true features of the acoustic and optical phonon modes. Moreover, anticipating the discussion below, an excess of entropy is seen to occur in the temperature range around 6 K, introducing therefore an additional uncertainty in the determination of θ_D and $\theta_E^{(i)}$.

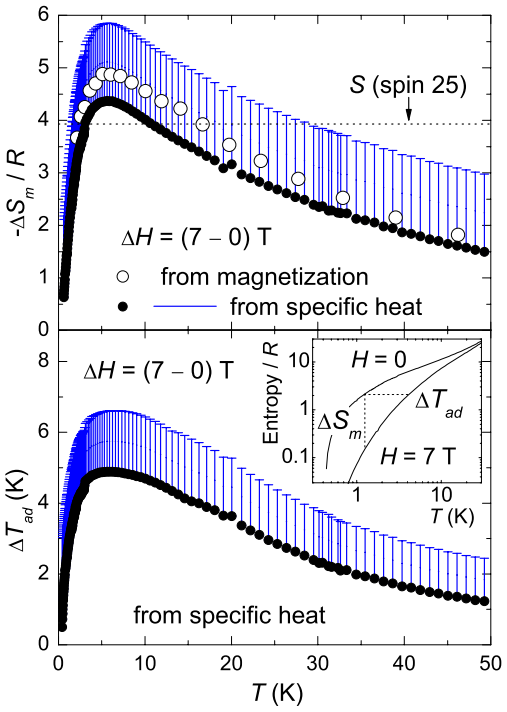

Fig. 7. (Top) Temperature dependence of the isothermal magnetic entropy change ΔS_m as obtained from specific heat (filled dots and bars, see text) and magnetization data (empty dots), both for $\Delta H = (7–0)$ T. Shown as dotted line is the limiting entropy of a $S = 25$ spin system. (Bottom) Temperature dependence of the adiabatic temperature change ΔT_{ad} as obtained from specific heat data (filled dots and bars, see text) for $\Delta H = (7–0)$ T. In the inset: experimental entropy of Fe_{14} vs. temperature for $H = 0$ and 7 T.

5. Evaluation of MCE

In what follows, we evaluate the magnetocaloric effect for the Fe_{14} molecular compound from experimental data, as described in [15,16]. This procedure includes the evaluation of the isothermal magnetic entropy change ΔS_m and adiabatic temperature change ΔT_{ad} from measured specific heat. For comparison, we evaluate ΔS_m also from magnetization data.

MCE from specific heat. From the specific heat data of Fig. 5 we firstly determine the total entropies at applied magnetic fields $H = 0$ and 7 T as functions of temperature using the following equation:

$$S(T)_H = \int_0^T \frac{C(T)_H}{T} \mathrm{d}T. \qquad (1)$$

The result of the numerical integration $S(T)_H$ is plotted in the bottom inset of Fig. 7 for both applied fields. Then we calculate the magnetic entropy change and adiabatic temperature change, for this field change $\Delta H = (7–0)$ T, as $\Delta S_m(T)_{\Delta H} = [S(T)_{7\,T} - S(T)_0]_T$ and $\Delta T_{ad}(T)_{\Delta H} = [T(S)_{7\,T} - T(S)_0]_S$, respectively.[3] The results are displayed as filled dots in Fig. 7. It can be seen that, for $\Delta H = (7–0)$ T, Fe_{14} reaches a maximum $-\Delta S_m$ of $\approx 4.5R$ (or equivalently ≈ 15.9 J/kg K) and ΔT_{ad} of ≈ 5 K, both at $T \simeq 6$ K. It is worth to mention that we calculate the entropy starting from the lowest experimentally achieved temperature (≈ 0.35 K) and, obviously, not from $T = 0$ K as requested by Eq. (1). Therefore, the so-obtained $\Delta S_m(T)$ and $\Delta T_{ad}(T)$ should be considered as underestimates. Upper limits are roughly obtained by extrapolating linearly the experimental specific heat below T_N for $T \to 0$ K. The results, plotted in Fig. 7 as bars, show that we estimate at $T = 6$ K for $\Delta H = (7–0)$ T the magnetic entropy change and adiabatic temperature change as $-\Delta S_m = (5.0 \pm 0.8)$ R, or equivalently (17.6 ± 2.8) J/kg K, and $\Delta T_{ad} = (5.8 \pm 0.8)$ K, respectively. It is important to note that, since the entropy expected for a $S = 25$ spin system is $R \ln(2S + 1) \simeq 3.9R$, the experimental magnetic entropy change is much larger than the maximum allowed (shown in the top panel of Fig. 7 as dotted line) assuming a spin $S = 25$ for the Fe_{14} nanocluster. Obviously, the maxima in $-\Delta S_m(T)$ and $\Delta T_{ad}(T)$ are originated to large extent by this excess of magnetic entropy which is then removed by the applied field. One may thus wonder where this excess of magnetic entropy is coming from. Recalling the incomplete achievement of the $S = 25$ spin state deduced from magnetization and susceptibility measurements, it is reasonable to formulate the hypothesis that spin states other than $S = 25$ are contributing in this low-temperature range. Additionally, the transition to the long-range magnetic ordered state is certainly contributing as well to the MCE parameters below ~ 2 K. However, on basis of the relatively low values of the C_{order} data of Fig. 6, we do not expect this contribution to be the dominant one. Indeed, no apparent anomaly is seen in $\Delta S_m(T)$ and $\Delta T_{ad}(T)$ at T_N.

MCE from magnetization. In an isothermal process of magnetization, the total magnetic entropy change ΔS_m due to the application of a magnetic field, can be derived from Maxwell relations by integrating over the magnetic field change $\Delta H = H_f - H_i$, i.e.,

$$\Delta S_m(T)_{\Delta H} = \int_{H_i}^{H_f} \left(\frac{\partial M(T,H)}{\partial T}\right)_H \mathrm{d}H. \qquad (2)$$

From the magnetization data of Fig. 4, we therefore calculate $\Delta S_m(T)$ using Eq. (2). The so-obtained magnetic entropy change for the magnetic field change $\Delta H = (7–0)$ T[4] is displayed as function of temperature in the top panel of Fig. 7, together with ΔS_m as obtained from specific heat data for comparison. It can be noticed that, within the bars, the result fully agrees with the

[3] Note that the estimation of the lattice contribution is irrelevant for our calculations, since we consider the difference between the total entropies at different fields.

[4] For practical reasons, the measurements at the lowest applied field were carried out for $H_i = 10^{-3}$ T, which in our calculations was approximated to zero-applied field.

previous estimate inferred from specific heat, suggesting that both (independent) procedures can be effectively used to characterize the Fe_{14} molecular nanocluster with respect to its magnetocaloric properties.

6. Concluding remarks

The values of $\Delta S_m(T)$ and $\Delta T_{ad}(T)$ obtained in Fe_{14} are exceptionally large, even more than the ones obtained with intermetallic materials known to be, so far, the best magnetic refrigerant materials in the temperature range below 10 K [2,17]. For instance, the best representative is the recently studied [17] $(Er_{1-x}Dy_x)Al_2$ alloy that, for $x \geqslant 0.5$ concentrations, presents MCE parameters below 10 K which are at least 30% smaller than that of Fe_{14}. Among systems of superparamagnetic particles and molecular magnets, the gap is even more pronounced. For instance, because of their well-defined spin ground-state in this temperature and field range, it is easy to show that the well known Fe_8 and Mn_{12}-ac molecular nanoclusters, i.e., cannot exceed values of $-\Delta S_m \simeq 12.5$ and 11 J/kg K, respectively, thus much smaller than that of Fe_{14}. Moreover in these materials, as in most molecular magnets, an additional complication (with respect to MCE parameters) is added by the cluster magnetic anisotropy. Because of this, cluster spins are usually blocked in the liquid helium temperature range, causing the spin–lattice relaxation to slow down dramatically. Therefore, cluster spins tend to loose thermal contact with the lattice [18–20] resulting in lower magnetic entropies and, consequently, lower MCE parameters. Ideally, it is desirable to keep the spin–lattice relaxation at sufficiently high rates down to lowest temperatures, in order to have a more efficient material in terms of MCE. This route was already recently tried [21] with heterometallic octanuclear molecular rings of type Cr_7Cd, that can be seen as an ordered arrangement of well-separated paramagnetic spins, having fast relaxations in the whole (experimental) temperature range. In terms of MCE parameters, the only limitation of this material is given by the cluster spin value itself ($S = \frac{3}{2}$) allowing not more than $-\Delta S_m \simeq 5.1$ J/kg K as experimentally reported to occur for $T < 2$ K [21].

Summing up, the above-reported experiments on the Fe_{14} molecular nanocluster show that for a better description of its magnetic and thermal properties we should go beyond the standard giant spin model to take into account internal degrees of freedom inside the cluster. Nevertheless, in this preliminary communication we can already conclude that Fe_{14} is unique in terms of MCE due to the combination of the following characteristics: (i) unusually large spin ground-state; (ii) very low cluster magnetic anisotropy; (iii) excess of entropy coming from low-lying excited S states; (iv) long-range magnetic ordering. For these reasons, Fe_{14} has therefore high potentiality to work as magnetic refrigerant within a temperature range below 10 K.

To date, five different crystal structures, based upon four structurally similar perfluoroaryl-dithiadiazolyl radicals, have been reported in which the tendency for dimerization has been inhibited [6–11].

The magnetic behaviour of these paramagnetic compounds is extremely varied and strongly dependent on the crystal structure. One of the most interesting, the β-phase of the *p*-$NCC_6F_4CNSSN^{\cdot}$, exhibits weak ferromagnetism below 36 K [12]. In this compound, the magnetic interactions are antiferromagnetic but the magnetic space group allows the canting of the spins, which results in a weak ferromagnetism. Both the α-phase of this dithiadiazolyl radical [7] and *p*-$BrC_6F_4CNSSN^{\cdot}$ [9] are paramagnetic with negative Curie–Weiss constants, also indicative of dominant antiferromagnetic interactions. In contrast, the *p*-$O_2NC_6F_4CNSSN^{\cdot}$ radical shows dominant ferromagnetic interactions and a ferromagnetic transition at 1.32 K [10]. Recently, we reported the perfluorobiphenyl derivative, *p*-$NCC_6F_4C_6F_4CNSSN^{\cdot}$, which is also monomeric but exhibits near perfect Curie behaviour indicative of negligible magnetic exchange between paramagnetic centres [11].

In this work we have performed an ab initio study of the magnetic interactions in the first four compounds described above. This study has provided us with a good theoretical understanding of the magnetic exchange pathways which provide a clear rationale of not only the long- or short-range nature of the magnetic order, but also whether the ordering is ferro or antiferromagnetic. The enhanced understanding of the exchange pathway is of great importance in order to develop new synthetic targets in which the magnetic interactions can be predicted in a well-defined manner based on the nature of the intermolecular geometry.

The magnetic behaviour of these compounds has been investigated by the use of the Heisenberg–Dirac–van Vleck spin Hamiltonian:

$$H = -\sum_{ij} J_{ij} S_i \cdot S_j,$$

where J_{ij} is the magnetic coupling constant between the i and j magnetic centres with total spin operators S_i and S_j, respectively.

The theoretical analysis of the exchange pathway under the Heisenberg model for isotropic exchange can be divided into two steps. The first step is to identify all the radical pairs whose magnetic coupling constants could be considered significant. Since both the direct exchange and dipolar exchange depend strongly on intermolecular separation r between the magnetic centres (as $\exp(-r)$ [13] and r^{-3}, respectively), pair selection has been performed using a simple distance cut-off criterion. As almost all the spin density is located on the dithiadiazolyl ring [14,15], only radical pairs with an intermolecular contact between heterocyclic rings shorter than 7 Å have been selected. In the second step, the magnetic coupling constants for the selected radical pairs have been computed. The magnetic coupling constant, J, has been determined within the DFT broken-symmetry approach using the scheme proposed by Yamaguchi [16] in which the magnetic interaction constant is calculated by

$$J = -\frac{(E_{BS} - E_{HS})}{(\langle S^2\rangle_{BS} - \langle S^2\rangle_{HS})},$$

where E_x and $\langle S^2\rangle_x$ denote the total energy and the total spin angular momentum, respectively, for the spin state X (i.e., the broken symmetry singlet and high spin triplet states). All the calculations have been carried out using the hybrid exchange-correlation functional B3LYP [17] and the 6-311G* basis set [18] implemented in the GAUSSIAN98 package [19].

Table 1
Computed magnetic coupling constants for the four dithiadiazolyl compounds studied in this work

Units: cm^{-1}	α-NC–	β-NC–	O_2N–	Br–
J_1	7.578	−31.380	1.1457	−7.618
J_2	0.004	−0.035	0.0351	7.519
J_3	−8.801	−0.007	−0.0263	−8.250
J_4	0.189	<±0.005	−0.0373	−0.087
J_5	<±0.005			−0.107
J_6	<±0.005			0.010
J_7	<±0.005			0.063
J_8	<±0.005			
J_9	−0.017			

In the following sections we analyse the magnetic behaviour of each of the four structures with respect to the magnetic coupling constants obtained from our computations (see Table 1).

1. β-Phase of p-NC–C_6F_4–$CNSSN^{\cdot}$

The β-phase of *p*-$NCC_6F_4CNSSN^{\cdot}$ exhibits a transition to a canted antiferromagnetic phase at 36 K [12] resulting in a weak spontanous magnetization. This weak-ferromagnetic transition has been established by different experimental techniques including neutron diffraction, heat capacity, magnetic measurements [12] single-crystal EPR and muon experiments [20–22]. Previously, the magnetic system has been described with only one antiferromagnetic interaction which propagates in a diamond-like network. Furthermore, the possible magnetic pathway via the contact between the cyano group and the dithiadiazolyl ring has been proved experimentally to be negligible [23]. Finally, the magnetic susceptibility at high temperature follows a Curie–Weiss law with $\theta = -59$ K.

Four possible magnetic exchange pathways are obtained based on the distance cut-off criterion. Fig. 1 illustrates how three of these interactions propagate the magnetic exchange through the lattice. The fourth magnetic pathway has been omitted for clarity but generates

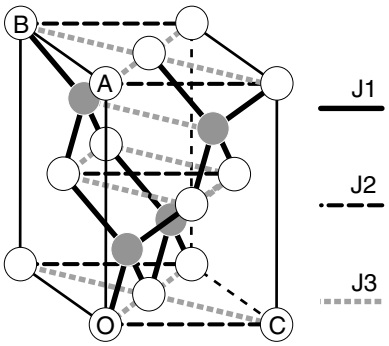

Fig. 1. Scheme showing the magnetic exchange pathway proposed for the β-phase of the *p*-NC–C_6F_4–CNSSN$^{\cdot}$ radical. It can be observed that the J_1 pathway propagates as a diamon-like 3D network.

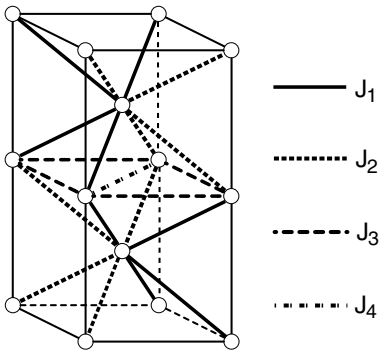

Fig. 2. Scheme representing the four magnetic pathways that fulfil the distance cut-off criterium for the ferromagnetic *p*-O_2N–C_6F_4–CNSSN$^{\cdot}$ radical.

a diamond-like network in a similar manner to J_1. The DFT calculations of the magnetic coupling constants for these four possible magnetic pathways are presented in Table 1. They indicate a single dominant exchange pathway (J_1) via the closest intermolecular S···N contact between heterocyclic rings ($d_{S\cdots N} = 3.488$ Å) which propagates through the lattice in a diamond-like motif. This is in agreement with the analysis made by Antorrena et al. [9]. The mean-field approximation, using the value of the computed J_1 interaction, predicts an antiferromagnetic transition at 45 K, a value in good agreement with the experimental value of 36 K.

2. *p*-O_2N–C_6F_4–CNSSN$^{\cdot}$

The *p*-$O_2NC_6F_4CNSSN^{\cdot}$ radical [10] is one of two S-based free radical ferromagnets; the other being the radical cation [BBDTA][$GaCl_4$]·MeCN [24]. The high temperature magnetic susceptibility of *p*-$O_2NC_6F_4CNSSN^{\cdot}$ shows Curie–Weiss behaviour with $\theta = 1.6 \pm 0.1$ K. The positive value of the Curie–Weiss constant indicates the presence of ferromagnetic interactions between the $S = 1/2$ centres. Low temperature a.c. magnetic susceptibility studies on a single crystal confirm a long-range ferromagnetic transition at 1.32 ± 0.02 K.

This derivative also exhibits four magnetic pathways which fulfil the distance cut-off criterion. These are represented in Fig. 2. Whilst the J_1 and J_2 magnetic pathways generate a 3D network connecting radicals in different planes perpendicular to the *c*-axis, the remaining two interactions connect radicals within the *ab* plane. The computations of the magnetic coupling constants for the four interactions (see Table 1) show that the J_1 magnetic interaction is the dominant one and should lead to ferromagnetic interactions propagating through 3D. In a mean-field approximation calculation with the J_1 magnetic interaction determined by our ab initio calculations, we calculate a ferromagnetic transition at 1.64 K, very close to the experimental ferromagnetic transition temperature (1.3 K).

In both of these two structures, there is a single magnetic interaction which propagates throughout the 3D structure giving rise to long-range magnetic order. The DFT calculations not only reproduce the sign of the exchange interaction but also good estimates of the strength of the exchange interaction (evidenced by the ordering temperatures). As with other organic radicals, the spin can be considered to be Heisenberg-like (with very little single-ion anisotropy) and is only expected to exhibit long-range order once a 3D network is established. The dominant exchange pathway determined for both these radials also predicts the correct (3D) lattice dimensionality. We now turn our attention to two other dithiadiazolyl radicals which show no clear evidence for long-range magnetic order.

3. α-Phase of it p-NC–C_6F_4–CNSSN$^{\cdot}$

This compound has been successfully crystallized once and appears to be a meta-stable phase. Its crystal structure has been reported and the temperature dependence of the magnetic susceptibility measured on a Faraday balance [7]. Above 100 K, the susceptibility follows a Curie–Weiss law with $\theta = -25$ K, whereas in the low temperature range there is a maximum in χ around 8 K.

The low symmetry of the space group (triclinic $P\bar{1}$) leads to a large number of chemically distinct pairs of near-neighbour contacts. In addition to a magnetic pathway (J_9) extending through CN···S contacts (analogous to the β-phase which is determined to be of the order of 10^{-2} cm^{-1}), there are a further eight other possible magnetic pathways which fulfil the distance cut-off criterion. The computed magnetic coupling constants are listed in Table 1. The two strongest interactions J_1 and J_3 are 1–2 orders of magnitude greater than the other exchange interactions and form a linear chain with alternating ferromagnetic and antiferromagnetic interactions. The effect of the other interactions would be a dimensionality crossover from 2D to 3D behaviour, and would be expected below 1 K. The

magnitude of J_1/k_B and J_3/k_B obtained are of similar value to the temperature of the maximum in the magnetic susceptibility. However, with the calculated J_1 and J_3 magnetic coupling constants the Curie–Weiss constant at most would be about -1 K, instead of $\theta = -25$ K. However, because of problems with the accuracy of the temperature control in the reported magnetic measurements [7] a more detailed analysis should be reserved until more reliable data are available.

4. *p*-Br–C_6F_4–CNSSN$^{\bullet}$

In this compound, the magnetic susceptibility above 60 K follows a Curie–Weiss law with $\theta = -27$ K. With this value of θ, the mean-field approximation predicts an antiferromagnetic transition at 27 K, whereas in a low-dimensional system a broad peak around 27 K would be expected. Nevertheless, the experimental magnetic susceptibility down to 1.8 K shows neither an antiferromagnetic transition nor a broad peak, but increases continually with decreasing temperature [9]. The absence of a λ-type maximum in χ mitigates against a long-range antiferromagnetically ordered phase, but gives little evidence on the true nature of the exchange interactions and lattice dimensionality.

Amongst the seven possible magnetic pathways obtained from the distance cut-off criterion, there appear to be three significant interactions (Table 1) which are 1–2 orders of magnitude stronger than the remaining interactions. The magnetic motif, see Fig. 3, generated by these three strongest interactions is strongly 2D and can be described as a square network, where the J_3 interaction propagates along the column and J_1 and J_2 alternate through the rows. Each $\ldots J_1$–J_2–J_1–$J_2\ldots$ row is shifted with respect to the neighbouring rows. The 2D nature of the magnetic network clearly explains the lack of magnetic order above 1.8 K. Furthermore, the magnetic network exhibits clear frustration which may explain the lack of a broad maximum in χ characteristic of the short-range ordering of low-dimensional systems without frustration. However, the complexity of the exchange pathway currently precludes a simple analysis of the data and further modelling of the susceptibility data using Monte Carlo methods is planned.

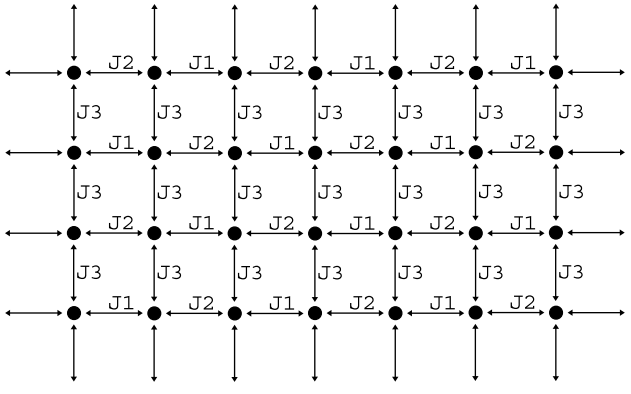

Fig. 3. 2D square network generated by the three strongest computed interactions in the *p*-Br–C_6F_4–CNSSN$^{\bullet}$ radical. The J_3 interaction propagates along the column, and J_1 and J_2 alternate through the rows.

We have shown that ab initio calculations of the magnetic exchange may provide a better understanding of the mechanisms which govern both the nature and strength of the interaction between thiazyl-based radicals. Moreover, a consideration of the dimensionality of the exchange pathway provides an excellent correlation with the observation (or absence) of bulk magnetic order. Notably, these calculations have demonstrated the existence of both ferro and antiferromagnetic coupling constants >10 K. Judicious control of the nature of the crystal structure may lead to organic magnets with high transition temperatures. Further studies are in progress.

The magnetic measurements were measured on a Faraday Balance. A sample of the β-phase of p-$NCC_6F_4CNSSN^{\bullet}$ measured on the same equipment appeared to order at 38 K (cf. transition temperatures recorded with a variety of other techniques at 35.5–36.0 K). This small discrepancy in temperature underlines the need for further investigations of the α-phase.

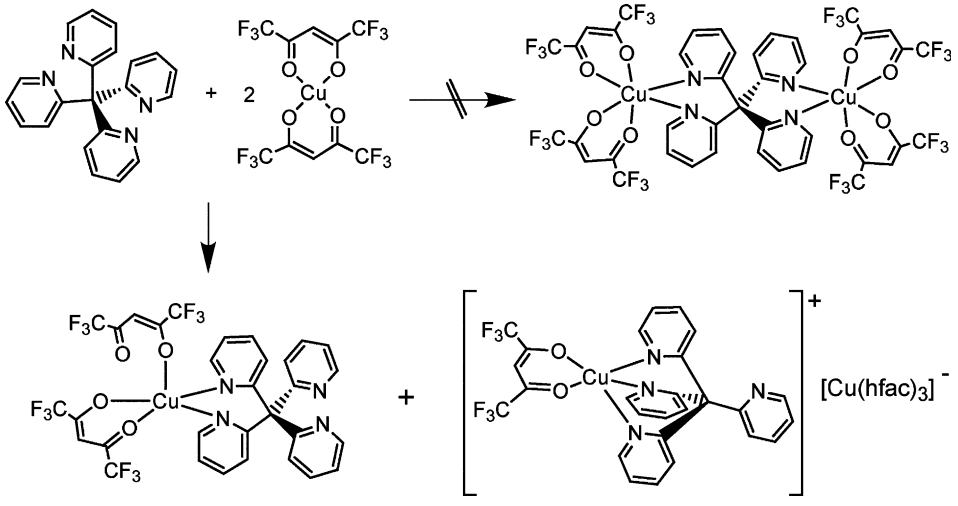
py_4C (8.1 mg; 0.025 mmol) and an ether solution (1 mL) of dehydrated $Cu(hfac)_2$ (23.9 mg; 0.050 mmol) were combined and heated at 40 °C for 24 h after diluted with 3 mL of hexane. Greenish blue plates of $[Cu(hfac)_2(py_4C)]$ were precipitated and separated on a filter. The yield was 16.7 mg (83%). *Anal.* Calc. for $C_{31}H_{18}N_4O_4Cu_1F_{12}$: C, 46.42; H, 2.26; N, 6.99. Found: C, 45.85; H, 2.27; N, 6.84%.

Similarly a reaction mixture was prepared and refluxed in hexane for 1 day. After the mixture was allowed to stand at room temperature for a few days, green plates of $[Cu(hfac)(py_4C)\cdot Cu(hfac)_3]$ were precipitated and isolated on a filter. The yield was 6.2 mg (19%). *Anal.* Calc. for $C_{41}H_{20}N_4O_8Cu_2F_{24}$: C, 38.48; H, 1.58; N, 4.38. Found: C, 38.27; H, 1.63; N, 5.31%.

X-ray diffraction data of a single crystal of $[Cu(hfac)_2(py_4C)]$ and $[Cu(hfac)(py_4C)\cdot Cu(hfac)_3]$ were collected on a Rigaku R-axis RAPID diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71069$ Å). The structures were solved by direct methods and expanded using Fourier techniques in the CrystalStructure program package [16]. Thermal displacement parameters were refined anisotropically for non-hydrogen atoms. Hydrogen atoms were located at calculated positions. CCDC reference numbers 252026 and 252027.



Magnetic susceptibilities of randomly oriented polycrystalline samples were measured on a Quantum Design MPMS SQUID magnetometer at an applied field of 5×10^3 Oe in a temperature range 1.8–100 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constants.

3. Results and discussion

We planned to prepare the target dinuclear copper(II) complex $[\{Cu(hfac)_2\}_2(py_4C)]$ in which two pyridine nitrogen atoms are coordinated to each copper(II) ion, as shown in Scheme 1. However, we obtained so far only $[Cu(hfac)_2(py_4C)]$ and $[Cu(hfac)(py_4C)\cdot Cu(hfac)_3]$ instead of $[\{Cu(hfac)_2\}_2(py_4C)]$. Their molecular structures were unequivocally determined by means of X-ray crystallographic analysis (Fig. 1). Selected crystallographic parameters are listed in Table 1.

The copper(II) ion in $[Cu(hfac)_2(py_4C)]$ is penta-coordinate, giving a square pyramidal configuration. Two nitrogen atoms (N1 and N2) are coordinated to Cu1 at equatorial sites, while N3 and N4 are free from coordination. One hfac ligand forms a chelate ring on the equatorial plane. The other hfac located at the axial site in a monodentate manner. The axial Cu1–O3 bond (2.156(4) Å) is longer than the equatorial bonds (1.955(3), 1.950(3), 1.981(4), and 1.960(4) Å for Cu1–O1, Cu1–O2, Cu1–N1, and Cu1–N2, respectively).

We could not elucidate the molecular structure of $[Cu(hfac)(py_4C)\cdot Cu(hfac)_3]$ only from the elemental analysis which should be the same as that of the target compound, but the molecular structure was clarified by means of X-ray crystallographic analysis as depicted in Fig. 1(b). The product consists of an ion pair: $[Cu(hfac)(py_4C)]^+$ and $[Cu(hfac)_3]^-$. The copper(II) ion (Cu1) in $[Cu(hfac)(py_4C)]^+$ is penta-coordinate. Two nitrogen atoms (N1 and N2) are coordinated to Cu1 at equatorial sites, and one nitrogen (N3) occupies an axial position. The Cu1–N3 bond length (2.205(4) Å) is considerably longer than those of Cu1–N1 and Cu1–N2 (1.973(5) and 1.969(4) Å, respectively). One hfac ligand forms a chelate ring on the equatorial plane. The Cu1–O1 and Cu1–O2 bond lengths are 1.946(3) and 1.952(5) Å, respectively.

Scheme 1.

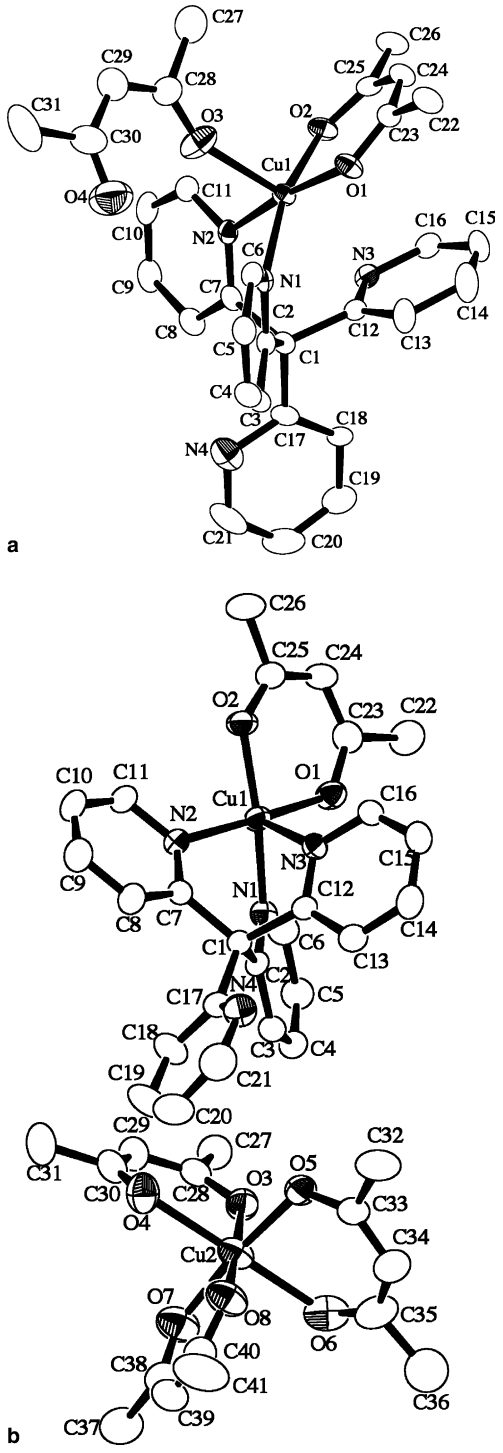


Fig. 1. Ortep drawings of: (a) $[Cu(hfac)_2(py_4C)]$; and (b) $[Cu(hfac)(py_4C)\cdot Cu(hfac)_3]$ with thermal ellipsoids at the 50% and 30% probability levels, respectively. Hydrogen and fluorine atoms are omitted for the sake of clarity.

The counter anion consists of a paramagnetic copper(II) ion and three hfac ligands. The Cu2–O4 and Cu2–O6 are assigned as axial because these bond lengths (2.236(5) and 2.219(6) Å, respectively), are much longer than other Cu2-O bonds (1.951(4)–2.041(4) Å).

Table 1
Selected crystallographic parameters

Compounds	$[Cu(hfac)_2(py_4C)]$	$[Cu(hfac)(py_4C)\cdot Cu(hfac)_3]$
Formula	$C_{31}H_{18}CuF_{12}N_4O_4$	$C_{41}H_{20}Cu_2F_{24}N_4O_8$
Crystal system	monoclinic	triclinic
Space group	$P2_1/n$	$P\bar{1}$
a (Å)	18.643(8)	12.6518(5)
b (Å)	8.657(4)	14.3309(5)
c (Å)	18.748(9)	14.4301(5)
α (°)	90	74.170(1)
β (°)	95.26(4)	78.1090(7)
γ (°)	90	78.012(1)
V (Å)^3	3012(2)	2431.0(2)
Z	4	2
μ (mm^{-1})	0.846	1.022
d_{calc} (g cm^{-3})	1.768	1.748
$R(F)(I > 2\sigma(I))$[a]	0.058	0.070
$R_w(F^2)$ (all data)[b]	0.087	0.088
T (K)	90	296

[a] $R = \sum(\|F_o\|-|F_c\|)/\sum|F_o|$.
[b] $R_w = [\Sigma w(|F_o|-|F_c|)^2/\sum w|F_c|^2]^{1/2}$.

The magnetic properties were obtained on a SQUID magnetometer. The magnetic susceptibility of $[Cu(hfac)_2(py_4C)]$ obeyed the Curie-law. The Curie constant in $\chi_{mol} = C/T$ was determined to be 0.436 cm^3 K mol^{-1}, which corresponds to $S = 1/2$ species with $g = 2.16$. No appreciable magnetic interaction was observed, being in agreement with the crystal structure determined.

The magnetic susceptibility of $[Cu(hfac)(py_4C)\cdot Cu(hfac)_3]$ also behaved as an ideal paramagnet. The Curie constant was 0.883 cm^3 K mol^{-1}, which corresponds to the sum of two $S = 1/2$ species with $g = 2.13$ on the average of the cationic and anionic paramagnetic portions.

In summary, the desired spiro-fused structure was not characterized in obtained complexes. Usually copper(II) ions are ready to undergo Jahn-Teller distortion which stabilizes a penta-coordinate square pyramid or a square plane. The proposed synthetic scheme is based on hexa-coordinate metal ions and we have unsuccessful results on the dinuclear copper(II) complex containing a py_4C bridge. Steric congestion of hfac ligands should also be taken into consideration for further study. We tried to prepare oxovanadium(II) derivatives using $VO(hfac)_2$ in place of $Cu(hfac)_2$, but no meaningful products were separated. Very recently we have found that the reaction of py_4C and $Mn(hfac)_2$ afforded dinuclear complex. Details will be reported elsewhere [17].

Scheme 1. M–dmg–Ln and M–dpk–Ln building blocks.

2. Experimental

The starting materials, [Ni(dpk)$_2$(phen)] and [Ni(dpk)$_2$(py)$_2$], were prepared according to the method of [Ni(pao)$_2$(py)$_2$] (pao = pyridine-2-aldoximate) [11]. The following complexation procedure is typical. After azeotropic distillation of *n*-heptane and water from a *n*-heptane solution (150 mL) containing 328 mg (0.40 mmol) of [Dy(hfac)$_3$(H$_2$O)$_2$] [12], ca. 10 mL of dry ether was added to the residue to give a yellow clear solution. A dry dichloromethane solution (10 mL) containing 128 mg (0.20 mmol) of [Ni(dpk)$_2$(phen)] was added to the above solution and the combined solution was allowed to stand at room temperature after the removal of orange powder precipitated. Orange crystals of [{Ln(hfac)$_3$}$_2${Ni(dpk)$_2$(phen)}] (**1Dy**) were grown and collected on a filter. The yield was 255 mg (0.12 mmol; 58%).

X-ray diffraction data of a single crystal of **1Ln** and **2Ln** were collected on a Rigaku R-axis RAPID diffractometer with graphite monochromated Mo Kα (λ = 0.71069 Å) radiation at 90 K. The structures were solved by direct methods and expanded using Fourier techniques in the CRYSTALSTRUCTURE program package [13]. Thermal displacement parameters were refined anisotropically for non-hydrogen atoms. Hydrogen atoms were located at calculated positions. Selected crystallographic parameters are as follows. **1Dy**: $C_{64}H_{38}Dy_2F_{36}N_8O_{18}Ni_1$, monoclinic, *C*2/*c*, a = 25.44(1) Å, b = 16.119(9) Å, c = 21.91(1) Å, β = 112.29(4)°, V = 8310(7) Å^3, Z = 4, d_{calc} = 1.818 g cm^{-3}, μ(Mo Kα) = 2.155 mm^{-1}, $R(F)$ ($I > 2\sigma(I)$) = 0.066, and $R_w(F^2)$ (all data) = 0.102 for 8940 unique reflections. **2Dy**: $C_{62}H_{32}Dy_2F_{36}N_8O_{14}Ni_1$, monoclinic, $P2_1/n$, a = 10.963(6) Å, b = 14.812(8) Å, c = 23.73(1) Å, β = 100.63(5)°, V = 3786(3) Å^3, Z = 2, d_{calc} = 1.912 g cm^{-3}, μ(Mo Kα) = 2.357 mm^{-1}, $R(F)$ ($I > 2\sigma(I)$) = 0.056, and $R_w(F^2)$ (all data) = 0.069 for 7988 unique reflections.

Magnetic susceptibilities of polycrystalline samples of **1Ln** and **2Ln** were measured on a Quantum Design MPMS SQUID magnetometer at an applied magnetic field of 500 Oe over a temperature range 1.8–300 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constant. Ac magnetic susceptibility was measured on a Quantum Design PPMS ac/dc magnetometer in a temperature range down to 2.0 K. The polycrystalline sample of **1Ln** and **2Ln** were fixed with mineral oil in all magnetic measurements.

3. Results and discussion

3.1. Crystal structure analysis

We prepared ten kinds of complexes, **1Ln** and **2Ln** (Ln = La, Tb, Dy, Ho, Er). The crystal structures of **1Ln** (Ln = Tb, Dy, Ho, Er) and **2Ln** (Ln = Dy, Ho) were analyzed by means of single-crystal X-ray diffraction study. Fig. 1(a) and (b) shows the ORTEP drawings of **1Dy** and **2Dy**, respectively, indicating that three metal ions are arranged in a linear array, and also that the ligands or metal ions did not scramble during the synthesis. The central [Ni(dpk)$_2$ (L)$_2$] ((L)$_2$ = phen, (py)$_2$) structure was completely remained from the starting materials. The cell parameters of other complexes are summarized in Table 1. Compounds **1Tb**, **1Ho**, and **1Er** have isomorphous crystal structures to **1Dy**. Actually, though the *R* factors in the refinement were somewhat unsatisfactory ($R \geqslant 0.1$), the molecular structures of **1Tb**, **1Ho**, and **1Er** were preliminarily solved and refined to be practically the same molecular structures as that of **1Dy**. Unfortunately, **2Tb** and **2Er** did not afford good single crystals suitable for X-ray diffraction study. Preliminary X-ray diffraction analysis indicated that **2Dy** and **2Ho** were isomorphous to each other.

The molecular structure of **1Dy** (Fig. 1(a)) has a two-fold axis along the center of phen and Ni1. The Ni1 ion has an octahedral geometry with a slight Jahn–Teller distortion, which is characteristic of high-spin Ni^{II} (S = 1), as indicated by the Ni–N bond-lengths of 2.082(9)–2.110(9) Å. The Ni and Dy ions are bridged by the N–O groups from dpk with the Dy1–O1–N3–Ni1 torsion angle of −138.1(6)°. The N2–Ni1–N2# and N3–Ni1–N3# angles are 100.1(3)° and 175.1(3)°, respectively (the symmetry operation code for # is $-x$, $+y$, $1/2 - z$). Owing to the molecular symmetry, three metal ions are arranged in a V-shaped manner, but actually the Dy1–Ni1–Dy1# array was very close to linear, as indicated by the Dy1–Ni1–Dy1# angle of 177.14(5)°. The Dy1 are octa-coordinate with three hfac chelates and additional N and O atoms from dpk. The O1–Dy1 distance (2.246(9) Å) is shorter than other O–Dy1 bonds (2.347(8)–2.389(9) Å).

The molecular structure of **2Dy** (Fig. 1(b)) has an inversion center at the Ni ion, and therefore three metal ions are arranged in a strictly linear manner. The N$_6$ geometry around N1 also shows a small Jahn–Teller

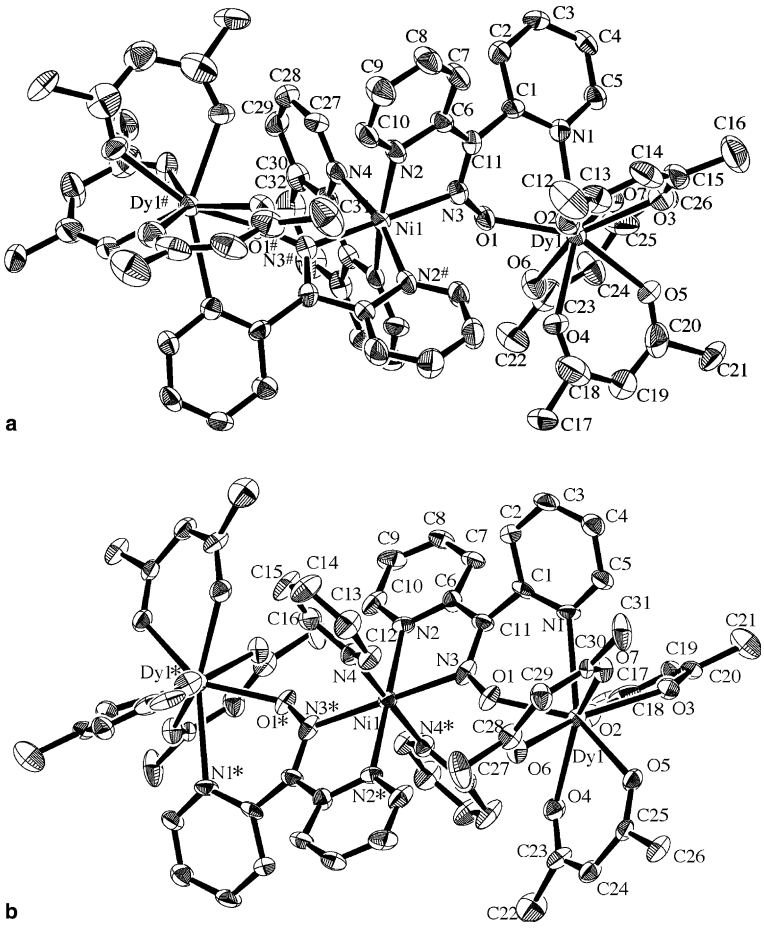

Fig. 1. ORTEP drawings of **1Dy** (a) and **2Dy** (b) with thermal ellipsoids at the 50% probability level. Hydrogen and fluorine atoms are omitted for the sake of clarity. The symmetry operation codes for # and * are $-x$, $+y$, $1/2 - z$, and $-x$, $1 - y$, $-z$, respectively.

Table 1
Cell parameters of **1Ln** (Ln = Tb, Dy, Ho, Er) and **2Ln** (Ln = Dy, Ho)

Compounds	**1Tb**	**1Dy**	**1Ho**	**1Er**	**2Dy**	**2Ho**
Space group	*C*2/*c*	*C*2/*c*	*C*2/*c*	*C*2/*c*	$P2_1/n$	$P2_1/n$
a (Å)	25.56(2)	25.44(1)	25.885(3)	25.579(2)	10.963(6)	10.871(7)
b (Å)	15.80(1)	16.119(9)	15.967(2)	15.994(1)	14.812(8)	14.773(8)
c (Å)	21.79(2)	21.91(1)	22.020(2)	21.899(2)	23.73(1)	23.50(2)
β (°)	112.65(7)	112.29(4)	112.844(4)	112.737(2)	100.63(5)	100.50(7)
V (Å^3)	8122(10)	8310(7)	8387(1)	8262(1)	3786(3)	3710(4)
Z	4	4	4	4	2	2
T (K)	90	90	100	100	90	100

distortion (the Ni1–N bond lengths are 2.118(9)–2.155(8) Å). The Ni and Dy ions are bridged by the N–O groups from dpk with the Dy1–O1–N3–Ni1 torsion angle of −143.7(5)°. The Dy1 are octa-coordinate like **1Dy**. The O1–Dy1 distance is the shortest (2.221(7) Å) among all of the O–Dy1 bonds (2.359(7)–2.440(7) Å).

3.2. Magnetic properties

In order to elucidate whether magnetic coupling between Ni–Ln is ferro- or antiferromagnetic, we measured temperature dependence of the dc magnetic susceptibility. Fig. 2(a) and (b) shows the temperature dependence of the product $\chi_{mol}T$ for **1Ln** and **2Ln** (Ln = Tb, Dy, Ho, Er), respectively. The observed $\chi_{mol}T$ decreases on cooling are due to the single-ion property such as the crystal field effect reducing the orbital angular momentum of the Dy ions and also due to magnetic coupling effects between the Dy and Ni ions. For all of the complexes, the $\chi_{mol}T$ value showed a monotonic decrease, indicating the absence of ferro- or ferrimagnetic coupling. Furthermore, rapid decreases below ca. 5 K suggest the presence of weak antiferromagnetic coupling

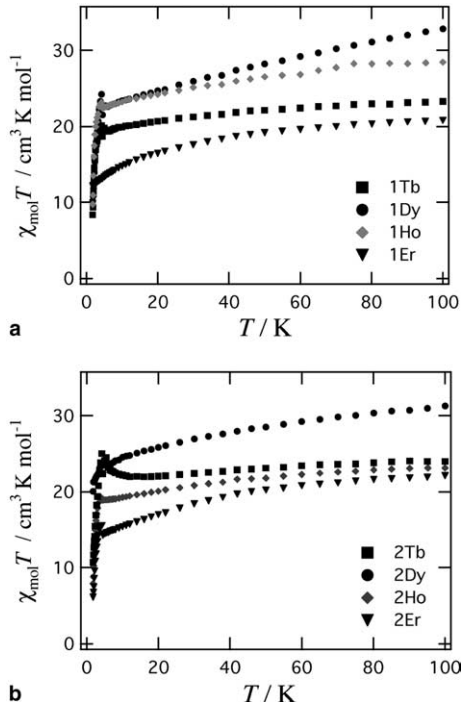

Fig. 2. Temperature dependence of the product $\chi_{mol}T$ for **1Ln** (a) and **2Ln** (b).

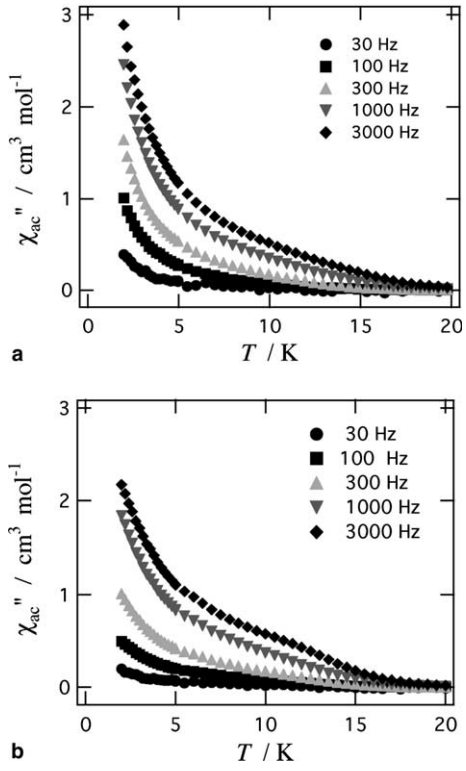

Fig. 3. Temperature and frequency dependence of the out-of-phase ac magnetic susceptibility χ''_{ac} for **1Dy** (a) and **2Dy** (b).

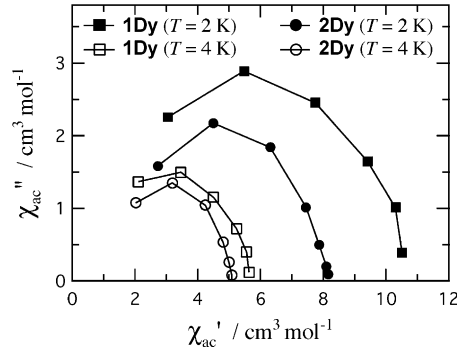

Fig. 4. Cole–Cole diagram (χ''_{ac} vs. χ'_{ac} plot) for **1Dy** and **2Dy** measured at 2.0 and 4.0 K.

between the Ln and Ni ions. Small humps are found around 5 K, which are accompanied by some wasted time in the cryostat process around 4.5 K. The Ni^{II} high spin state ($S = 1$) was confirmed by the magnetic measurements on **1La** and **2La**.

We measured the ac magnetic susceptibility (χ'_{ac} and χ''_{ac} for in-phase and out-of-phase susceptibilities, respectively) of **1Ln** and **2Ln**. The data were obtained with 5 G ac fields (10–10^4 Hz) at a zero dc field. Fig. 3(a) and (b) shows the frequency dependence of χ''_{ac} for **1Dy** and **2Dy**. Upon cooling, the χ''_{ac} of **1Dy** showed a notable increase below ca. 20 K (Fig. 3(a)), whereas those of **1Tb**, **1Ho**, and **1Er** did not show any meaningful increase. Furthermore, the χ''_{ac} frequency dependence of **1Dy** was very significant; the χ''_{ac} value showed drastic upsurge as the ac field frequency was elevated from 10 to 10^4 Hz.

As for the series of **2Ln**, **2Dy** similarly exhibited an increase of χ''_{ac} below ca. 17 K (Fig. 3(b)). The measurements on **2Tb**, **2Ho**, and **2Er** gave results similar to the case of the series of **1Ln**; only the Dy derivative showed a significant χ''_{ac} increase and frequency dependence. This frequency dependence seems to be an indication of blocking behavior usually observable for SMMs due to slow magnetization relaxation [2].

According to analysis of the Cole–Cole diagram [14], we plotted the χ''_{ac} data against χ'_{ac} at 2.0 and 4.0 K for **1Dy** and **2Dy** (Fig. 4). They clearly show semicircles, suggesting the χ''_{ac} increase is due to relaxation slowing down. The decrease of χ''_{ac} value in Fig. 4 is incomplete because the ac field could be applied in a frequency range up to 10^4 Hz. These findings suggest that **1Dy** and **2Dy** might become SMMs, but it will take place only at a very low temperature; i.e., the blocking temperature (T_B) will be much lower than 2 K. From a close look at Fig. 3(a) and (b), rather long tails of χ''_{ac} could be found in spite of the low T_B. There seems to be a shoulder around 12 K in Fig. 3(b). The origin is not clear so far.

Matsumoto et al. [7] developed the tetranuclear $[CuLTb(hfac)_2]_2$ and $[CuLDy(hfac)_2]_2$ as SMMs involving intramolecular ferromagnetic coupling. We have very recently reported pentanuclear $[Tb_4Cu_1]$ with a ground high-spin state behaving as an SMM [6].

Intramolecular ferro- and/or ferrimagnetic interactions leading to ground high-spin states are preferable for slowing the magnetization relaxation, because the energy barrier can be described as $\Delta = |D|S^2$ [2]. On the other hand, Kaizu et al. [9] reported the mononuclear phthalocyanine Tb and Dy salts were SMMs. They discussed the advantage of Tb and Dy ions over other lanthanide ions in the single-ion level. The situation of the present complexes **1Dy** and **2Dy** seems similar to that of the phthalocyanine-salts case, since no ferromagnetic coupling was characterized within a molecule. However, the SMM properties of **1Dy** and **2Dy** could not be attributed solely to Dy single-ion properties. We confirmed that the starting material $Dy(hfac)_3(H_2O)_2$ showed no frequency dependence of the χ''_{ac}. Very recently, we found that an isomorphous copper(II) derivative exhibited much slower magnetization relaxation; an obvious χ''_{ac} peak appeared above 2 K [10]. The role of 3d metal ions is essential.

4. Summary

We have reported the structural and magnetic characterization of **1Ln** and **2Ln**. The dpk monoanion works as a coupler between 3d and 4f metal ions. Lanthanide ions are supposed to be promising candidates for the SMM elements because of the large spin and oribital angular momenta and large magnetic anisotropy. We have developed **1Dy** and **2Dy** as a new class of SMMs.

2. Experimental

The new ligand 5bpno was prepared by lithiation of 5-bromo-2,2′-bipyridine [16] followed by the reaction with 2-methyl-2-nitrosopropane to give 5-(*N*-*t*-butylhydroxylamino)-2,2′-bipyridine in 59% yield. Mp. 124–125 °C. Subsequent oxidation of the hydroxylamine with freshly prepared Ag_2O in benzene gave 2,2′-bipyridin-5-yl *t*-butyl nitroxide (5bpno) in 15% yield. Mp. 139–141 °C (dec.). ESR (r.t., benzene) $g = 2.0063$, $a_N = 12.3$ G. The moleuclar structure was confirmed by means of X-ray crystallographic analysis.[1]

In a typical procedure, 50 mg of 5bpno and stoichiometric amount of metal salts were dissolved in 3 mL of methanol, and the resultant solution was kept in a refrigerator overnight giving the polycrystals of the desired complex in 10–30% yield. The products were isolated on a filter and subjected to elemental analysis, X-ray diffraction study, and magnetic measurements without further purification.

The elemental analysis measured on a Fisons EA-1108 by a usual combustion method indicated the following composition. $[Mn^{II}(5bpno)_3(ClO_4)_2]$: Calc. for $C_{42}H_{48}N_9O_{11}Cl_2Mn$: C, 51.44; H, 4.93; N, 12.85. Found: C, 51.00; H, 5.08; N, 12.17%. $[Mn^{II}(5bpno)(CH_3OH)_2Cl_2]$: Calc. for $C_{16}H_{24}N_3O_3Cl_2Mn$: C, 44.46; H, 5.60; N, 9.72. Found: C, 45.90; H, 5.57; N, 9.99%. $[Cu^{II}(5bpno)_2(ClO_4)_2]$: Calc. for $C_{28}H_{32}N_6O_{10}Cl_2Cu$: C, 45.02; H, 4.32; N, 11.25. Found: C, 45.56; H, 4.66; N, 10.98%. $[Cu^{II}(5bpno)Cl_2]$: Calc. for $C_{44}H_{16}N_3OCl_2Cu$: C, 44.63; H, 4.28; N, 11.15. Found: C, 43.62; H, 4.24; N, 10.28%.

X-ray diffraction data of a single crystal of $[Cu(5bpno)_2(ClO_4)_2]$ were collected on a Rigaku R-axis RAPID diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71069$ Å) at 100 K. The structure was solved by direct methods and expanded using Fourier techniques in the CrystalStructure program package [17]. Numerical absorption correction was used. Thermal displacement parameters were refined anisotropically for non-hydrogen atoms and isotropically for hydrogen atoms. All the hydrogen atoms were found experimentally. Full-matrix least-squares methods were applied using all of the unique diffraction data. Selected crystallographic parameters of $[Cu(5bpno)_2(ClO_4)_2]$ are: $C_{56}H_{64}Cl_4Cu_2N_{12}O_{20}$, monoclinic, $P2_1/n$, $a = 15.012(6)$, $b = 14.469(4)$, $c = 15.881(6)$ Å, $\beta = 114.07(3)°$, $V = 3149(2)$ Å^3, $Z = 2$, $d_{calc} = 1.575$ g cm^{-3}, μ (Mo Kα) = 0.929 mm^{-1}, $R(F)(I > 2\sigma(I)) = 0.042$, and $R_w(F^2)$ (all data) = 0.069 for 7145 unique reflections. CCDC reference number 250190.

Magnetic susceptibilities of polycrystalline samples were measured on a Quantum Design MPMS SQUID magnetometer at an applied magnetic field of 5 kOe over a temperature range 1.8–300 K. The magnetic responses were corrected with diamagnetic blank data of the sample holder obtained separately. The diamagnetic contribution of the sample itself was estimated from Pascal's constant.

3. Results

3.1. Crystal structure analysis

As Fig. 1 shows, the Cu ion in $[Cu(5bpno)_2(ClO_4)_2]$ was tetra-coordinate with four nitrogen atoms forming two chelate rings like bpy complexes, while the nitroxide groups did not participate in coordination. The Cu1 coordination sphere is basically assigned to a square plane, being in agreement with the divalent copper geometry. The axial sites are practically vacant; however, there seem very weak interactions as indicated by rather long Cu1–O4, Cu1–O6, Cu1–O3$^{\#}$, and Cu1–O5$^{\#}$ distances (3.070(2), 3.147(2), 3.020(2), and 2.891(2) Å, respectively), where the symmetry operation code of # is $3/2 - x$, $-1/2 + y$, $1/2 + z$. Two five-membered chelate rings are inclined as indicated by the dihedral angle of 39.5(1)° between the two averaged plane (Cu1–N1–C1–C6–N2 and Cu1–N4–C15–C20-N5) probably owing to the van der Waals repulsion between H3–H19 and H7–H23 and also between the *t*-Bu-N(O·) groups.

Interestingly, two 5bpno ligands have a *syn* configuration, i.e., two nitroxide groups are closely located with the inter-atomic O1–O2 distance of 4.593(3)Å. The magnetic study on $[Cu(5bpno)_2(ClO_4)_2]$ revealed the presence of antiferromagnetic interaction (see below). The intramolecular O1–O2 through-space orbital contact may lead to antiferromagnetic interaction and disturb interpretation of through-bond metal–radical magnetic interactions. Since the square planer geometry is characteristic of copper(II) complexes and the N–O–O–N proximity is expected only for this geometry, the observed magnetic interactions in the other complexes, $[Mn(5bpno)_3(ClO_4)_2]$, $[Mn(5bpno)(CH_3OH)_2Cl_2]$, and $[Cu(5bpno)Cl_2]$, can be attributed mainly to the metal–radical interactions.

[1] We found polymorphism in the crystals of 5bpno. Phase α: $C_{14}N_3O_1H_{16}$, monoclinic, $P2_1/n$, $a = 6.1429(3)$, $b = 12.9498(3)$, $c = 15.9699(7)$ Å, $\beta = 96.148(6)°$, $V = 1263.09(9)$ Å^3, $Z = 4$, $d_{calc} = 1.274$ g cm^{-3}, μ(Mo Kα) = 0.083 mm^{-1}, $T = 100$ K, $R(F)(I > 2\sigma(I)) = 0.059$, and $R_w(F^2)$ (all data) = 0.027 for 2862 unique reflections. Phase β: $C_{14}N_3O_1H_{16}$, orthorhombic, *Pbca*, $a = 8.406(4)$, $b = 10.191(4)$, $c = 30.60(1)$ Å, $V = 2621(1)$ Å^3, $Z = 8$, $d_{calc} = 1.228$ g cm^{-3}, μ(Mo Kα) = 0.080 mm^{-1}, $T = 100$ K, $R(F)(I > 2\sigma(I)) = 0.060$, and $R_w(F^2)$ (all data) = 0.043 for 2889 unique reflections. CCDC reference numbers 250188 and 250189. The *t*-Bu-N(–O·) groups in the α- and β-phase crystals have *anti*- and *syn*-conformations of the nitroxide oxygen atom, respectively, with respect to the adjacent pyridine ring.

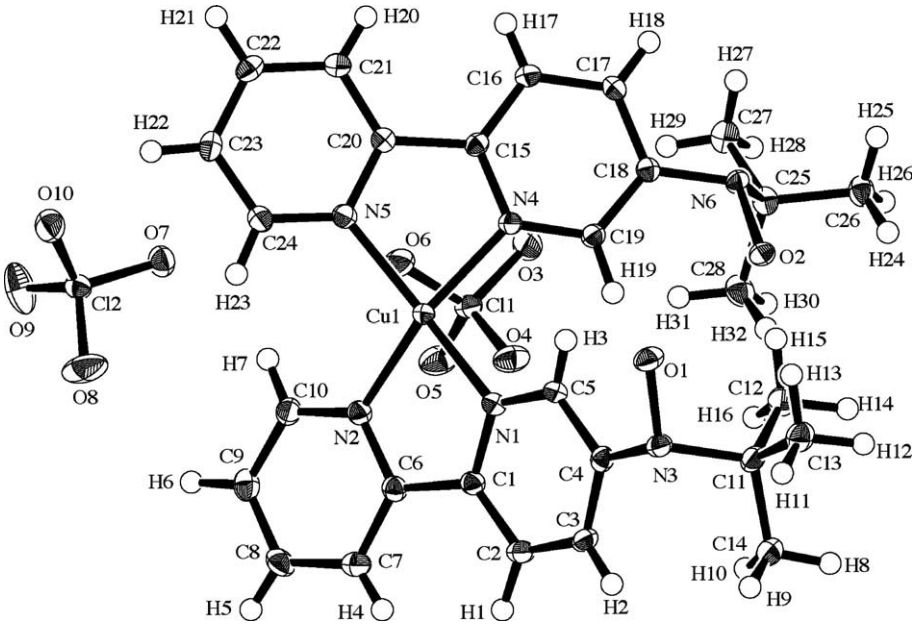

Fig. 1. Ortep drawing of $[Cu(5bpno)_2(ClO_4)_2]$ with thermal ellipsoids at the 50% probability level for non-hydrogen atoms. Atom numbering scheme is also shown.

Relatively short intermolecular radical–radical contacts were found with the O2–N6‡ and O2–O2‡ distances of 2.804(4) and 3.167(3) Å, which are shorter than or close to the sum of the van der Waals radii (3.07 and 3.04 Å for N–O and O–O, respectively [18]; the symmetry operation code for ‡ is $5/2 - x$, $3/2 + y$, $1/2 - z$). Antiferromagnetic coupling is expected as in the case of the intramolecular one at O1–O2.

Unfortunately, only $[Cu(5bpno)_2(ClO_4)_2]$ gave good crystals suitable for single-crystal X-ray diffraction analysis.

3.2. Magnetic properties

Fig. 2 shows the results of magnetic measurements on four complexes investigated here. In a high temperature region, the observed $\chi_{mol}T$ value of $[Mn(5bpno)_3(ClO_4)_2]$ was 5.5 cm^3 K mol^{-1}, which agrees well with the theoretical spin only value of 5.5 cm^3 K mol^{-1} for a species containing one $S_{Mn} = 5/2$ and three $S_{radical} = 1/2$ spins. The presence of ferromagnetic interaction was clearly indicated by the upsurges of the $\chi_{mol}T$ values on cooling. The $\chi_{mol}T$ value reached to a maximum 6.34 cm^3 K mol^{-1} at 14 K and then decreased sharply owing to secondary antiferromagnetic interaction.

Although the X-ray crystallographic analysis on $[Mn(5bpno)_3(ClO_4)_2]$ was unsuccessful, we assume a tris(bpy)-type N_6-coordination structure, and a Mn-centered triangular model can be proposed for the spin–spin exchange interaction. The three radical sites may not be crystallograpihcally equivalent and there may be some isomers of $[Mn(5bpno)_3^{2+}]$, but one exchange

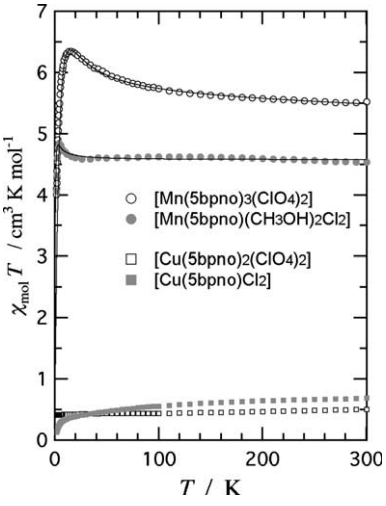

Fig. 2. Temperature dependence of the product $\chi_{mol}T$ for $[Mn(5bpno)_3(ClO_4)_2]$, $[Mn(5bpno)(CH_3OH)_2Cl_2]$, $[Cu(5bpno)_2(ClO_4)_2]$, and $[Cu(5bpno)Cl_2]$. The solid lines represent calculated curves. See the text for the equations and parameters.

parameter J is introduced as an average. Accordingly, we obtained the Heisenberg spin Hamiltonian $H = -2J(S_1 \cdot S_2 + S_1 \cdot S_3 + S_1 \cdot S_4)$ and the following expression of the molar magnetic susceptibility (Eq. (1)), by application of Kambe's vector coupling method [19] and the van Vleck equation:

$$\chi_{mol} = \frac{N_A g^2 \mu_B^2}{3k_B(T-\theta)} \frac{A}{B}, \quad (1)$$

where $A = 180 + 84\exp(-8J/k_BT) + 168\exp(-5J/k_BT) + 30\exp(-14J/k_BT) + 60\exp(-11J/k_BT) + 6\exp(-18J/k_BT)$,

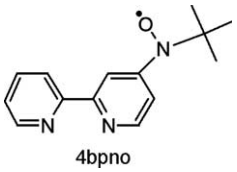
$B = 9 + 7\exp(-8J/k_BT) + 14\exp(-5J/k_BT) + 5\exp(-14J/k_BT) + 10\exp(-11J/k_BT) + 3\exp(-18J/k_BT)$.

The intermolecular interaction is evaluated by a Weiss mean-field parameter θ. The best-fit curve is superposed in Fig. 2 with the optimized parameters of $J/k_B = +3.73(6)$ K, $g = 2.01(1)$, and $\theta = -4.67(4)$ K. The fit seems considerably good, indicating that the proposed model is plausible.

The observed $\chi_{mol}T$ value of [Mn(5bpno)-$(CH_3OH)_2Cl_2$] was 4.5 cm^3 K mol^{-1} at 300 K, which is slightly smaller than the theoretical spin only value of 4.75 cm^3 K mol^{-1}. With a decrease of temperature the $\chi_{mol}T$ reached to 4.84 cm^3 K mol^{-1} at 4.2 K which is larger than the spin only value, indicating the presence of ferromagnetic interaction in spite of possible impurity contaminated. Intramolecular ferromagnetic and intermolecular antiferromagnetic interactions are assumed since the $\chi_{mol}T$ value decreased in a lower temperature region just like $[Mn(5bpno)_3(ClO_4)_2]$.

Despite the lack of structural information on $[Mn(5bpno)(CH_3OH)_2Cl_2]$, a hexa-coordinate structure around the Mn ion is rationally proposed by the ligation of two nitrogens from 5bpno, two oxygens from metanol, and two chloride ions. Theoretical fit to a two-centered model for S_{Mn} and $S_{radical}$ (Eq. (2)) gave the optimized parameters as follows: $J/k_B = +0.76(11)$ K, $g = 1.96(1)$, and $\theta = -0.359(6)$ K. The calculated curve successfully reproduced the experimental data (Fig. 2). The optimized g value is somewhat lower than expected for the average of manganese(II) and radical spins, probably because the specimen contains some impurity. Assuming the g value of 2.00, the purity factor is estimated to be 0.96.

$$\chi_{mol} = \frac{N_A g^2 \mu_B^2}{k_B(T-\theta)} \frac{28 + 10\exp(-6J/k_BT)}{7 + 5\exp(-6J/k_BT)} \quad (2)$$



On the other hand, the $\chi_{mol}T$ value of $[Cu(5bpno)Cl_2]$ monotonically decreased on cooling, indicating the presence of dominant antiferromagnetic interaction. The observed $\chi_{mol}T$ value was 0.69 cm^3 K mol^{-1} at 300 K, which is slightly smaller than the theoretical spin only value of 0.75 cm^3 K mol^{-1} from $S_{Cu} = 1/2$ and $S_{radical} = 1/2$. The data were analyzed on the singlet–triplet model [20], only giving an unsatisfactory fit. The exchange parameter J/k_B was preliminarily estimated to be ca. −8 K. Because of the lack of structural information on $[Cu(5bpno)Cl_2]$, we could not propose any magnetic exchange models, but nonetheless the experimental results strongly suggest that the Cu–5bpno interaction is antiferromagnetic, in sharp contrast to the ferromagnetic Mn–5bpno.

The observed antiferromagnetic interaction in $[Cu(5bpno)_2(ClO_4)_2]$ is much larger than [Cu(5bpno)-Cl_2]. The $\chi_{mol}T$ value of $[Cu(5bpno)_2(ClO_4)_2]$ was 0.50 cm^3 K mol^{-1} at 300 K, which is very small for three-1/2 spin species and actually smaller than that of $[Cu(5bpno)Cl_2]$ having two 1/2-spins (Fig. 2). With a decrease of temperature the $\chi_{mol}T$ value decreases but the temperature dependence is somewhat insensitive to reach 0.41 cm^3 K mol^{-1} at 2 K. This value corresponds to $S = 1/2$ and $g = 2.1$, being typical of copper(II) ions. Therefore, two radical spins are antiferromagnetically correlated. As the X-ray crystallographic analysis suggested (Fig. 1), a possible explanation is that the observed antiferromagnetic coupling is assigned to the intramolecular O1–O2 contacts. The Cu–5bpno magnetic interaction is buried with the strong radical–radical interaction.

4. Discussion

The mutual geometry between radical and metal spins is designed to be a "*meta*" position in the present study. High-spin organic molecules in which the *meta*-phenylene bridges are used as a ferromagnetic coupler are accessible when non-bonding molecular orbitals are present due to π-topological symmetry [21–24]. The application of the spin-polarization mechanism of organic high-spin molecules to transition metal complexes is not sufficiently understood with respect to limitation of the π-conjugation regime [25–32]. Iwamura and co-workers [33–35] have reported the pioneering works on the magnetic exchange interactions between radical and metal spins across a pyridine skeleton. Two manganese(II) complexes have been proposed using 3-pyridyl and 4-pyridyl *t*-butyl nitroxide radicals (3NOPy and 4NOPy, respectively), and actually they obtained $[Mn(hfac)_2(3NOPy)]_2$ and $[Mn(hfac)_2(4NOPy)_2]$ (hfac denotes 1,1,1,5,5,5-hexafluoropentane-2,4-dionate). The latter clearly showed antiferromagnetic coupling between Mn and radical spins across the 4-pyridyl group. In the former complex, however, the nitroxide oxygen atoms are coordinated to the Mn ions giving strong antiferromagnetic coupling, and therefore the magnetic coupling across the 3-pyridyl group could not be determined [33,34]. The present work on $[Mn(5bpno)_3(ClO_4)_2]$ and $[Mn(5bpno)(CH_3OH)_2Cl_2]$ recovers their missing data; it was proved to be ferromagnetic.

Most important discussion arises in comparison of the present results with those of isomeric structures. The magnetic interactions across a 4-pyridyl group have been investigated by using 2,2′-bipyridin-4-yl *t*-butyl nitroxide (abbreviated as 4bpno hereafter) [35]. Antiferromagnetic and ferromagnetic couplings have been characterized in $[M(hfac)_2(4bpno)]$ for $M = Mn^{II}$ and Cu^{II}, respectively. The X-ray crystallographic analysis revealed that the nitrogen atoms in the bpy moiety were coordinated to the Mn ion while the nitroxide group were free from coordination [35].

The observed magnetic exchange interactions are qualitatively summarized in Table 1. The sign of the intramolecular exchange interactions are altered:

(1) By replacing metal ions between Mn^{II} and Cu^{II}.
(2) By changing the substituted positions between *meta* and *para*.

In phenyl nitroxide derivatives, it is well known that positive spin densities are polarized at *ortho* and *para* carbons while negative spin densities are at *meta* carbons in the adjacent phenyl ring [36–39]. Similar spin-polarization may take place in pyridyl nitroxide derivatives. The copper $d_{x^2-y^2}$ magnetic orbital has a σ-character and cannot participate in the π-conjugation. On the other hand, the high-spin Mn^{II} has magnetic t_{2g} orbitals, which can afford dπ–pπ conjugation with the pyridine N atom. As Fig. 3(a) shows, the ferromagnetic coupling in the Mn–5bpno complexes is interpreted based on the spin-polarization mechanism like *meta*-phenylene-bridged high-spin organic compounds. The orthogonal geometry between $2p_z$(N) and $3d_{x^2-y^2}$(Cu) leads to the spin-polarization at the Cu ion with the same sign of the N atom (Fig. 3(b)). Since the N atom has negative spin density, the Cu ion is negatively spin-polarized. Thus, the nitroxide radical and copper spins are antiferromagnetically correlated. Furthermore, the change of magnetic interactions between 5bpno and 4bpno complexes is perfectly explained by spin-alternating character throughout the π-electron system.

The manganese(II) ion simultaneously has dπ and dσ spins. A σ-type spin-polarization pathway is also possible. The magnetic interaction is more complex because many kinds of magnetic interactions are present, and the total magnetic exchange interaction is defined with the sum of ferromagnetic and antiferromagnetic terms [40]. The experimental results suggest that the ferromagnetic term surpasses the antiferromagnetic terms in $[Mn(5bpno)_3(ClO_4)_2]$ and $[Mn(5bpno)(CH_3OH)_2Cl_2]$.

Table 1
Magnetic interaction between paramagnetic ligands and metal spins

	5bpno	4bpno
Mn^{II} (d^5)	Ferromagnetic	Antiferromagnetic
Cu^{II} (d^9)	Antiferromagnetic	Ferromagnetic
Reference	This work	Ref. [35]

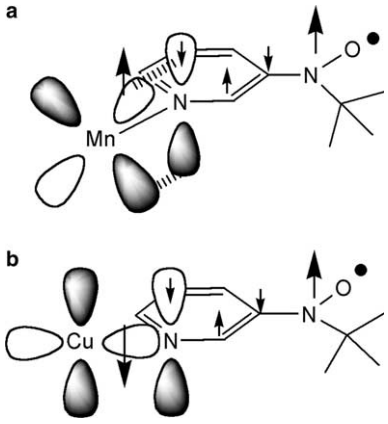


Fig. 3. Spin-polarization mechanisms in (a) Mn– and (b) Cu–5bpno complexes. An additional pyridine ring in 5bpno is omitted for the sake of clarity.

In summary, the magnetic measurements revealed the presence of ferromagnetic couplings in $[Mn^{II}(5bpno)_3(ClO_4)_2]$ and $[Mn^{II}(5bpno)(CH_3OH)_2Cl_2]$. The magnetic exchange couplings between the manganese(II) and radical spins through the intervening pyridine ring can be explained in terms of the spin-polarization involving pπ–dπ-type conjugation. The metal–radical magnetic interactions are controllable by means of designing the substitution positions. This work may provide a molecular design using 4-pyridyl and 5-(2,2′-bipyridyl) groups for organic–inorganic hybrid ferromagnetic materials.

Ferromagnetic ordering with blue light irradiation at low temperature was found for $Cu_2[Mo(CN)_8]\cdot 8H_2O$ [2,3]. The critical temperature was 35 K and this photoinduced phase was transformed to the original form with increasing temperature up to 200 K. Reversible change of the magnetism with blue and red light irradiation was found at low temperature [3]. In this change of the magnetism, a reduction of Cu(II) to Cu(I) occurs by electron transfer from Mo(IV) ion with blue light irradiation. The coordination structure of this reducible Cu(II) ion before irradiation must be crucial for the photoinduced ferromagnetism. However, detailed structure of this compound is not known. Therefore, we tried to elucidate the local structure of $Cu_2[Mo(^{13}CN)_8]\cdot 8H_2O$ (**1**) by a measurement of hyperfine coupling constant (hfcc) of ^{13}C atoms of ^{13}C enriched cyanide ions. The hfcc of a CN ligand must be sensitive to its coordination bond and local magnetic structures of a variety of polycyanide complexes [8,9]. We studied the plus and minus sign and the magnitude of hfcc of ^{13}C enriched cyanide ions of **1** and of closely related structure-known polycyanide complexes of $Fe_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**2**), $Mn_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**3**), $[Cu^{II}(bpy)_2]_2[Mo^{IV}(^{13}CN)_8]\cdot 5H_2O\cdot CH_3OH$ (**4**), UV-irradiated $K_4[Mo^{IV}(^{13}CN)_8]\cdot 2D_2O$ (**5**), $Cs_3[Mo^{V}(^{13}CN)_8]\cdot 2H_2O$ (**6**), $[Cu_2^{II}(tren)_2{}^{13}CN](BF_4)_3$ (**7**), and $[Ni_2^{II}(tetren)_2{}^{13}CN](ClO_4)_3$ (**8**) by temperature dependence of solid-state ^{13}C NMR spectrum.

Broad-line ^{13}C NMR spectrum of higher spin system has been reported for Mn_{12}-acetate cluster [10–12]. Methyl groups of acetate ions were enriched with ^{13}C isotope. Although the methyl carbon atoms are apart from the magnetic Mn ions, the spectrum width is larger than 4000 ppm for powder sample at 250 K and no magic angle spinning spectrum was reported. In our case, the carbon atoms of cyanide ions closely locate to magnetic metal ions.

2. Experimental

2.1. Sample preparations

2.1.1. $K_4[Mo^{IV}(^{13}CN)_8]\cdot 2H_2O$ (5)

Warning! Although we have experienced no difficulties, this procedure may produce HCN gas. 99% ^{13}C enriched specimen was synthesized by a similar method reported for normal compound [13]. 1.0 g of MoO_3 and 4.6 g of 99% ^{13}C enriched $K^{13}CN$ were milled in a mortar. 7.5 ml of H_2O was slowly added to the milled mixture in drop-wise at 0 °C and then 1.1 g of 85% aqueous $(NH_2)_2$ was added. Under ambient temperature, 4.5 ml conc. HCl was added very slowly to the above solution in 1 h. Resulting solution was heated up to 86 °C for 1 h and was cooled down to room temperature. Pouring the solution into 85 ml of CH_3OH results in immediate precipitation of brown yellow powder. 12.5 ml aqueous solution of the filtered powder was heated to boil with activated carbon. The solution was filtered and poured into 85 ml of CH_3OH results in immediate precipitation of yellow powder. The treatment with activated carbon and recrystallization were repeated three times. The last treatment with D_2O instead of H_2O gave a deuterated analogue of $K_4[Mo^{IV}(^{13}CN)_8]\cdot 2D_2O$. *Anal*. Calc. for **5**: C, 20.6; H, 0.79; N, 22.2. Found: C, 19.25; H, 0.96; N, 22.95%.

2.1.2. $Cu_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (1)

Slow addition of 0.2 M aqueous solution of $CuCl_2$ to 0.2 M aqueous solution of $K_4[Mo^{IV}(^{13}CN)_8]$ gave red-purple powder [2]. Filtrated powder was dried in a desiccator. *Anal*. Calc. for **1**: C, 16.70; H, 2.80; N, 19.48. Found: C, 16.95; H, 2.58; N, 19.97%. The same procedure with heavy water solution and deuterated analogue of **5** gave $Cu_2[Mo(^{13}CN)_8]\cdot 8D_2O$.

2.1.3. $Fe_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (2)

Compound **2** was synthesized after the reference [14] with 99% ^{13}C enriched **5** instead of normal compound. *Anal*. Calc. for **2**: C, 17.44; H, 2.77; N, 20.35. Found: C, 15.88; H, 2.86; N, 18.80%. Powder X-ray diffraction pattern agreed well with the structure determined for a single crystal [15]. The compound **2** may be oxidized in the air. A fresh yellow powder sample became blue in a few days in the air. Evacuation of the virgin yellow powder led to color change to green-yellow. Electronic sate may be changed due to a loss of crystal water. Therefore, for the NMR measurement, a fresh yellow sample was sealed into a glass ample with N_2 gas for preventing a loss of crystal water and an effect of oxygen.

2.1.4. $Mn_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (3)

Compound **3** was synthesized after the reference [15] with 99% ^{13}C enriched **5** instead of normal compound. *Anal*. Calc. for **3**: C, 17.22; H, 2.86; N, 20.09. Found: C, 16.66; H, 2.55; N, 20.05%.

2.1.5. $[Cu^{II}(bpy)_2]_2[Mo^{IV}(^{13}CN)_8]\cdot 5H_2O\cdot CH_3OH$ (4)

Polycrystalline sample of **4** was obtained after the method of reference [1] with 99% ^{13}C enriched **5** instead of normal compound. *Anal*. Calc. for **4**: C, 49.98; H, 3.91; N, 19.62. Found: C, 47.31; H, 4.08; N, 18.53%. Powder X-ray diffraction pattern agreed well with the structure determined for a single crystal [1].

2.1.6. $Cs_3[Mo^{V}(^{13}CN)_8]\cdot 2H_2O$ (6)

Polycrystalline sample of **6** was obtained after the method of reference [16] with 99% ^{13}C enriched **5** instead of normal compound. *Anal*. Calc. for **6**: C, 13.00; H, 0.55; N, 15.17. Found: C, 12.96; H, 0.72; N, 15.18%. Powder X-ray diffraction pattern agreed well with the structure determined for a single crystal [17].

2.1.7. $[Cu_2^{II}(tren)_2{}^{13}CN](BF_4)_3$ (7) and $[Ni_2^{II}(tetren)_2{}^{13}CN](ClO_4)_3$ (8)

Blue crystals of **7** and purple crystals of **8** were obtained after the methods of reference [18] by slow evaporation of the solvent. Colorless crystals also appeared and were taken off. *Anal.* Calc. for **7**: C, 22.12; H, 5.14; N, 17.86. Found: C, 21.85; H, 5.06; N, 17.64%. *Anal.* Calc. for **8**: C, 24.35; H, 5.73; N, 18.38. Found: C, 24.65; H, 5.46; N, 18.73%. Powder X-ray diffraction patterns of **6** and **7** agreed well with the respective structure reported for each single crystal [18].

2.2. Solid-state NMR

The ^{13}C NMR spectrum was measured by an echo pulse sequence for static powder crystalline sample at an external magnetic field of 7.05 T with a Bruker DSX300 spectrometer. Various irradiation frequencies were used to cover the wide spectrum. The envelope of all the echo signals displays a whole spectral line shape. When a line shape is almost symmetric, we assume that the isotropic shift is the center of the spectrum. The shift was measured from external second reference of the powder crystalline sample of $K^{13}CN$ (169.6 ppm from TMS). Assuming a small zero-field splitting, the observed isotropic shift δ_{iso} consists of the Fermi contact term, the dipole interaction term (pseudo contact) and the temperature independent diamagnetic term (chemical shift) as follows [19,20]:

$$\delta_{iso} = \delta_{Fermi} + \delta_{Pseudo} + \delta_{dia}, \quad (1)$$

$$\delta_{Fermi} + \delta_{Pseudo} = \frac{\mu_B}{3k_B T}\frac{A_C}{\gamma_C/2\pi}S(S+1). \quad (2)$$

Electron spin induced on the ^{13}C nucleus by electron spin of a magnetic metal ion causes a Fermi contact shift of the NMR resonance line, while anisotropy of the *g*-tensor of magnetic metal ions gives a pseudo-contact shift. The coefficient A_C in Eq. (2) is defined as the hfcc of the ^{13}C nucleus in Hz unit, which includes principal values of anisotropic *g* tensor.

Magic angle spinning ^{13}C and ^{2}H NMR (MAS NMR) spectra were measured by a similar method described in reference [21] at a resonance frequency of 75.4 and 46.1 MHz, respectively, and at a magic angle spinning speed of ca. 9 kHz with a Bruker DSX300 spectrometer. The MAS technique gives a high resolution spectrum with an isotropic shift in some cases. The thermometer of the MAS NMR probe and an effect of spinning speed on temperature increase were carefully calibrated [21,22]. Uncertainty of the temperature measurement was within ±2 K. The ^{2}H NMR shift was measured from the external second reference of CD_3OD (CD_3: 3.35 ppm).

3. Results and discussion

3.1. Hyperfine coupling constants of cyanide ions and local coordination structures of 1

Fig. 1 illustrates a typical ^{13}C NMR spectrum of cyanide ions of **1**. We found two distinct signals corresponding to two different electronic states of the cyanide ions. Largely shifted values from the diamagnetic shift of $K^{13}CN$ (origin of abscissa) indicates an effect of electronic spins of Cu^{II} ions in this compound **1**, in which Mo^{IV} ions are diamagnetic. Since each peak exhibited a small anisotropy and was almost symmetric, the isotropic shift described in Eqs. (1) and (2) was determined as the maximum point of the peak. Temperature dependence of the isotropic shift is plotted as a function of inverse temperature in Fig. 2 for both high and low frequency peaks. This figure indicates a good linear relation between the isotropic shift and inverse temperature as suggested in Eqs. (1) and (2). The hfcc of each peak was determined from the slope of this figure to be +19 and −2.0 MHz for high and low frequency peak, respectively. The plus and minus sign of the hfcc indicates that there are two different coordination structures for the cyanide ions. Nitrogen atoms of the cyanide ions are coordinated to Cu^{II} ions. Intensity ratio of the two signals suggests almost 3:1 population of different coordination structures.

To estimate the coordination structures of cyanide ions around magnetic metal ions, we determined the hfcc of cyanide ions for two other compounds **2** and **3**, which have a similar unit formula to **1**. The crystal structure of **2** is known, and **2** and **3** are believed to be isomorphous [1]. The coordination structure of **2** is illustrated in Fig. 3, where Fe^{II} ion has square-planner N-coordination of four cyanide ions and axial coordination of two water molecules. Typical ^{13}C NMR spectrum is shown in Fig. 4(a) and (c) for **2** and **3**, respectively. Only a single peak was observed both for

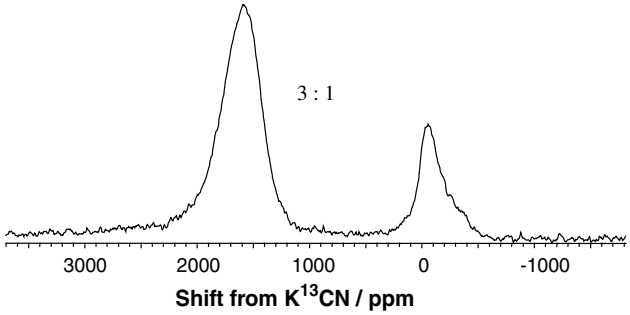

Fig. 1. Typical ^{13}C NMR spectrum of 99% ^{13}C enriched cyanide ions of $Cu_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**1**) at 294 K. The spectrum was measured with a spin echo technique. The envelope of many echo signals is illustrated. Magic angle spinning (MAS) at 10 kHz indicated no resolution enhancement for the higher frequency peak, whereas MAS technique was effective for the low frequency signal.

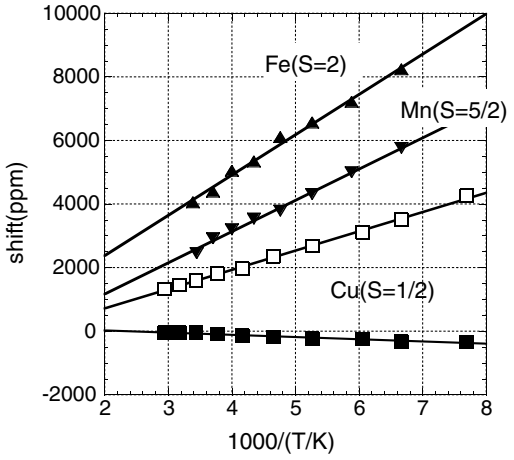

Fig. 2. Temperature dependence of isotropic ^{13}C NMR shift of $Cu_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**1**) ■, low frequency peak and □, high frequency peak; ▲, $Fe_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**2**); ▼, $Mn_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**3**). The origin of the abscissa is the diamagnetic shift of polycrystalline sample of $K^{13}CN$. The hyperfine coupling constants determined from the slopes of this figure with Eqs. (1) and (2) are +19 MHz (high frequency peak) and −2.0 MHz (low frequency peak) for **1**, +4.9 MHz for **2**, and +2.3 MHz for **3**.

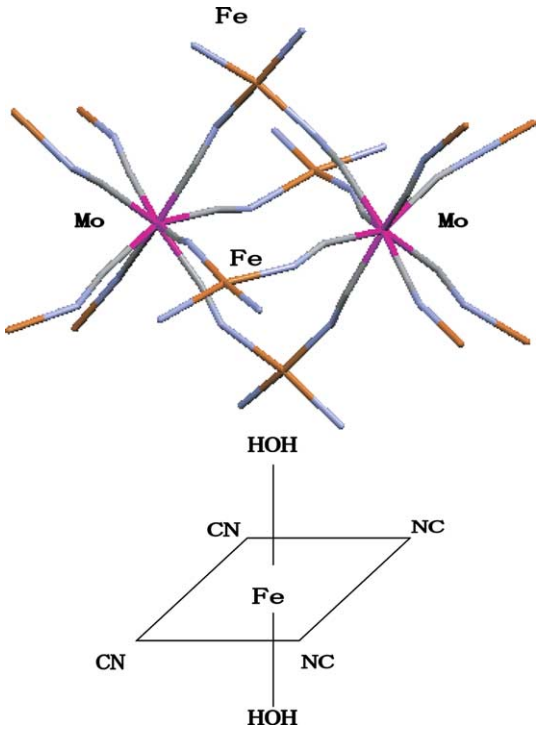

Fig. 3. Structure of coordination network of $Fe_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**2**) after reference [12].

2 and **3**. A small signal near 0 ppm is impurity due to slight decomposition.[2] The spectrum is almost symmetric and the isotropic shift was determined as the center of the signal. Temperature dependence of the ^{13}C NMR shifts is plotted in Fig. 2 for **2** and **3** together with **1**. Positive slope for **2** and **3**, which have square planar N-coordination structure around the magnetic metal center, resembles the slope of high frequency peak of **1**. Thus we assigned the high frequency peak of ^{13}C NMR spectrum of **1** to the cyanide ions that have square planar like N-coordination to Cu^{II} ion in **1**. The derived values of hfcc are summarized in Table 1.

Low frequency peak of **1** indicates that a part of cyanide ions of **1** exhibits negative hfcc and their N-coordination structures are different from the square planar structure. The negative hfcc was observed for **4**, which has an N-coordination to Cu(II) ion in an equatorial plane of trigonal bipyramidal structure as shown in Fig. 5. A typical ^{13}C NMR spectrum of **4** is illustrated in Fig. 6. Three different isotropic peaks, i.e. α, β, γ, were identified. Two of eight cyanide ions of **4** are directly coordinated to magnetic Cu(II) ions and their ^{13}C NMR signals should exhibit broader width and largest magnitude of hfcc, while other six cyanide ions are free of coordination. The peak γ, which shows largest width, was assigned to the cyanide ions coordinated to Cu(II) ions. Fig. 7 shows their shifts plotted as a function of inverse temperature and the peak γ exhibits the largest magnitude of hfcc. The sign of the hfcc of the peak γ is negative, which is similar to the low frequency peak of **1**. It is considered that the N-coordination geometry of the cyanide ion with a negative hfcc of **1** is largely deformed from the square planar. It is not clear at present whether two distinct Cu(II) ions exist in **1**, one of which is a square planar type and the other is largely deformed from the square planar, or all the Cu(II) ions are deformed form the square planar, in which three of the four N-coordination bonds are similar to the square planar and the rest one is deformed from the square planar type. Any how, such native deformation of N-coordination bond from the square planar structure in **1** is probably relevant to stabilize the reduced Cu(I) ion, which is produced by blue light irradiation.

We also investigated the motional behavior of crystal water molecules of deuterated analogue of **1**. Solid-state ^2H NMR spectrum is narrow, which indicates rapid and almost isotropic rotation of the crystal water molecule (D_2O) at 295 K. A similar behavior was observed for Prussian-blue analogue [23,24]. Magic angle spinning ^2H NMR spectrum showed an intense peak at 6.5 ppm at 295 K. This shift value is almost typical for diamagnetic

[2] The compound **2** decomposed in the air. A fresh yellow powder sample became dark blue in a few days in the air. The blue sample exhibited a completely different ^{13}C NMR signal from virgin yellow sample as shown in Fig. 4(b). The signal of blue sample locates near 0 and 3000 ppm, one of which near 0 ppm is the almost the same shift observed as a small peak in Fig. 4(a). Evacuation of the virgin yellow powder led to color change to yellow-green. Electronic sate of **2** may be slightly hanged due to a loss of crystal water. Therefore, for the NMR measurement of **2**, a fresh yellow sample was sealed into a glass ample with N_2 gas for preventing a loss of crystal water and an effect of oxygen.

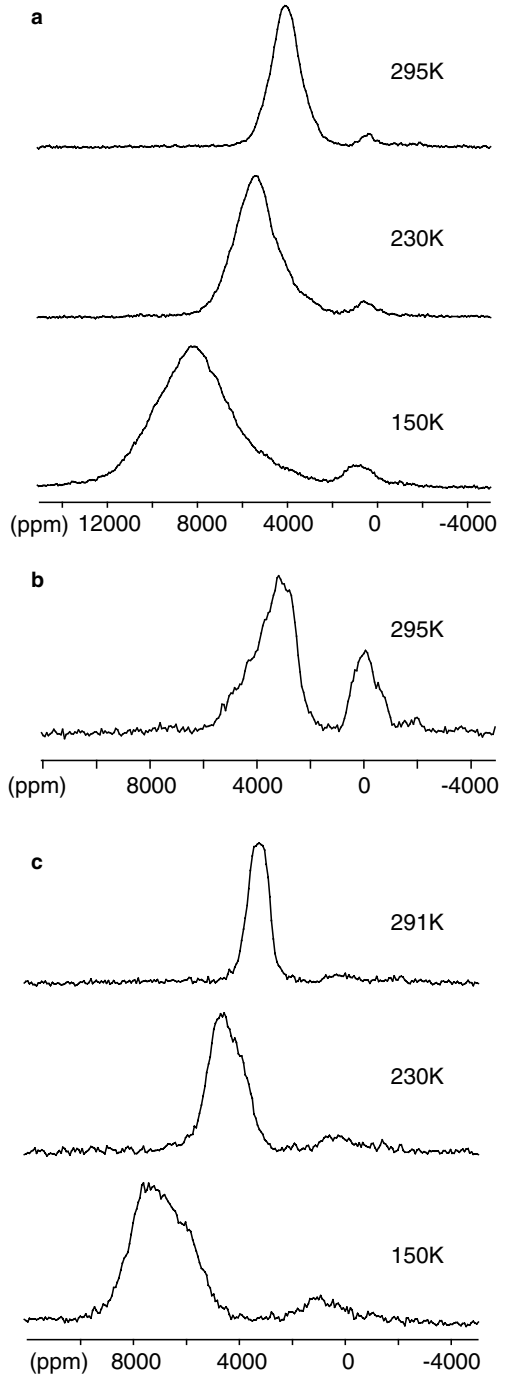

Fig. 4. Typical ^{13}C NMR spectrum of 99% ^{13}C enriched cyanide ions of: (a) $Fe_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**2**), (b) a specimen of **2** stored in the air and (c) $Mn_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**3**). Each spectrum is constructed with many echo signals measured with different excitation frequencies. The origin of the abscissa is the diamagnetic shift of polycrystalline sample of $K^{13}CN$.

compounds and suggests no strong interaction between the crystal water molecules and the magnetic Cu(II) ion in contrast to the crystal structure of Fe(II) compound **2**, in which crystal water molecules directly coordinate to the Fe(II) ion. A small peak of MAS ^2H NMR was also observed at 28 ppm. However, the intensity was only 3%

Table 1
Hyperfine coupling constant of ^{13}C nucleus of compounds **1**, **2**, **3**, and **4**

Compound	**1**	**2**	**3**	**4**
Spin S of magnetic metal ion	Cu(II)	Fe(II)	Mn(II)	Cu(II)
	1/2	2	5/2	1/2
Hfcc	+19 MHz (not known)	+4.9 MHz (SQP)	+2.3 MHz (SQP)	
				+0.44 MHz
				−0.24 MHz
	−2 MHz (not known)			−0.79 MHz (EP-TBP)

Compounds are $Cu_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**1**), $Fe_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**2**), $Mn_2^{II}[Mo^{IV}(^{13}CN)_8]\cdot 8H_2O$ (**3**), and $[Cu^{II}(bpy)_2]_2[Mo^{IV}(^{13}CN)_8]\cdot 5H_2O\cdot CH_3OH$ (**4**). SQ represents the square planer structure and EP-TBP means equatorial plane of trigonal bipyramidal.

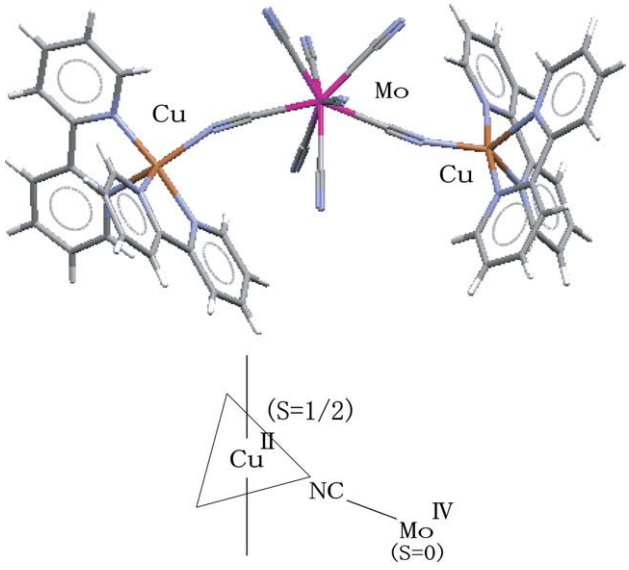

Fig. 5. Molecular and coordination structure of $[Cu^{II}(bpy)_2]_2[Mo^{IV}(^{13}CN)_8]\cdot 5H_2O\cdot CH_3OH$ (**4**) [1].

of the peak at 6.5 ppm and the small peak was tentatively assigned to an impurity.

*3.2. Photoreaction of **5** in aqueous solution and in the crystalline phase, and ^{13}C NMR spectrum of $[Mo^V(^{13}CN)_8]^{3-}$ ion*

To obtain an information about hfcc of ^{13}C atom given by photoinduced Mo(V) ion ($S = 1/2$) in the crystalline phase of $K_4[Mo^{IV}(^{13}CN)_8]\cdot 2D_2O$ (**5**), we measured ^{13}C NMR spectrum for ca. 50 mg of light irradiated powder specimen of **5**. By irradiation with a light (ca. 300–800 nm) of a Xe lamp at room temperature for a few days, we observed a very broad ^{13}C NMR spectrum overlapped by a sharp central line of a diamagnetic species of **5** as shown in Fig. 8(a). Signal-to-noise ratio is

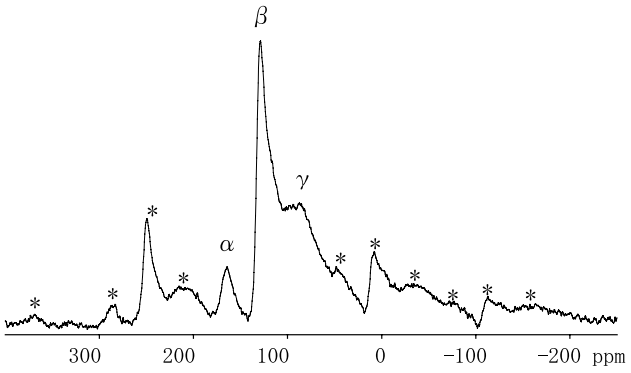

Fig. 6. A typical magic angle spinning ^{13}C NMR spectrum of cyanide ions of 99% ^{13}C enriched sample of $[Cu^{II}(bpy)_2]_2[Mo^{IV}(^{13}CN)_8]\cdot 5H_2O\cdot CH_3OH$ (**4**), which was measured at 300 K with a spinning speed of 9 kHz. The shift was measured from TMS and a second reference of $K^{13}CN$ (169.6 ppm from TMS) was used. α, β and γ indicate signals of isotropic shift. Peaks indicated by asterisks are spinning side bands, which were clearly distinguished from the isotropic shifts by using several different spinning speeds.

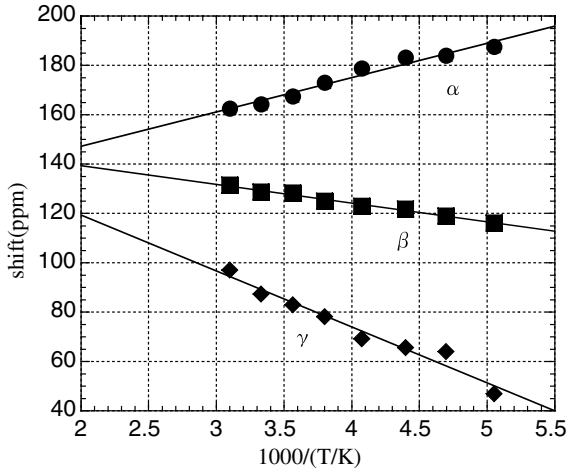

Fig. 7. Temperature dependence of the isotropic shift of ^{13}C NMR lines indicated by α, β and γ in Fig. 6. Each temperature slope gave hfcc of +0.44 (α), −0.24 (β) and −0.79 MHz (γ), respectively.

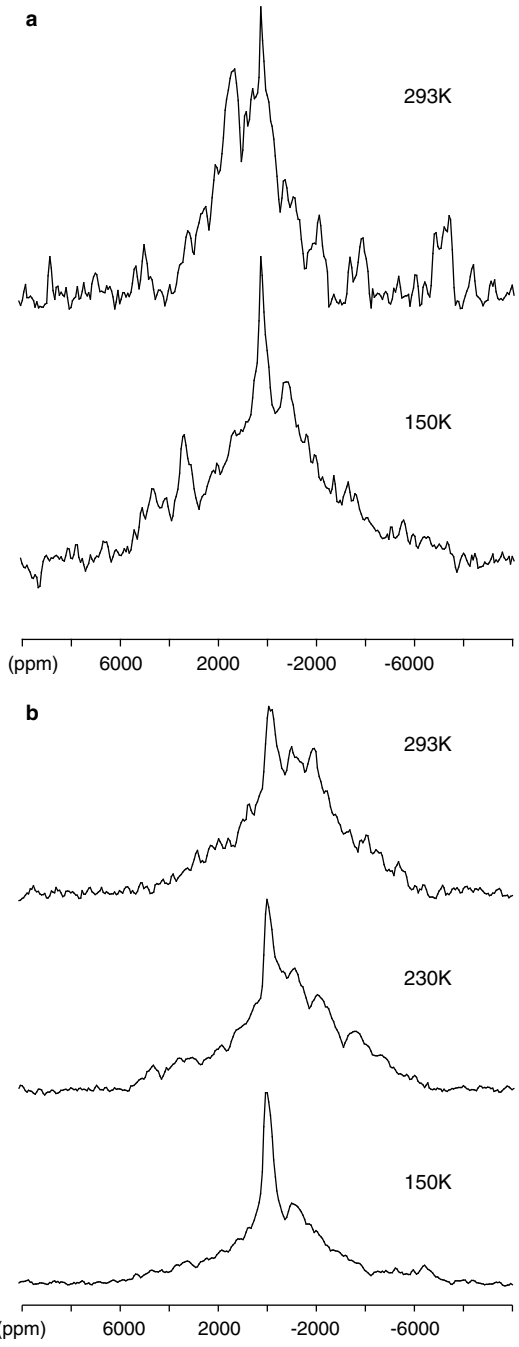

Fig. 8. ^{13}C NMR spectrum of cyanide ion of $[Mo^V(^{13}CN)_8]^{3-}$ of (a) UV-irradiated $K_4[Mo^{IV}(^{13}CN)_8]\cdot 2D_2O$ (**5**) and (b) $Cs_3[Mo^V(^{13}CN)_8]\cdot 2H_2O$ (**6**). The origin of the abscissa is the diamagnetic shift of polycrystalline sample of $K^{13}CN$. The signal near 0 ppm was assigned to decomposed fragment, which is diamagnetic.

bad because of conversion from Mo(IV) to Mo(V) is not enough. The amount of the conversion from Mo(IV) to Mo(V) was estimated to be ca. 1.4% from the MAS ^2H NMR spectrum of OD^- ion produced by a reduction of D_2O molecule as shown in Fig. 9.[3] Intensity of the sharp signal of diamagnetic **5** with long relaxation time was diminished by short repetition time for accumulation of the signal. The signal of ^{13}C NMR of $[Mo^V(^{13}CN)_8]^{3-}$ is very broad and a center of the broad signal is almost temperature independent in contradiction to a prediction by Eqs. (1) and (2). To clarify this behavior, we also studied ^{13}C NMR spectrum of $Cs_3[Mo^V(^{13}CN)_8]\cdot 2H_2O$ (**6**) in the crystalline phase. The spectrum is also very broad and almost temperature independent as illustrated in

[3] It is noted that reduction of the crystal water molecule hydrogen-bonded to the N atom of Mo(IV)–CN by an electron transfer from Mo(IV) ion with UV-irradiation was concluded in the crystalline phase. Such a reaction was proposed in solution and in the solid state [7].

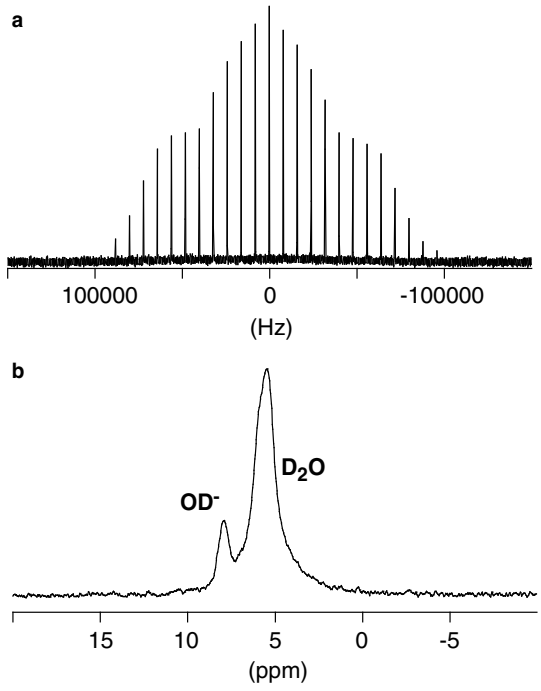

Fig. 9. Magic angle spinning ^{2}H NMR spectrum of UV-irradiated $K_4[Mo^{IV}(^{13}CN)_8]\cdot 2D_2O$ (**5**). (a) Full-width spectrum including spinning side bands and (b) isotropic shift. The full width spectrum (a) indicates 180° flip motion of D_2O molecule in the solid state around the molecular C_2 axis. A small signal at 7.9 ppm of (b) was assigned to OD^- ion produced by UV-irradiation, $Mo^{IV} + D_2O \rightarrow Mo^{V} + OD^- + 1/2D_2$ (↑). The intensity of this signal is 1.4% of total intensity of D signals including all of the spinning side bands. A large signal at 5.4 ppm is crystal water molecule, which is independent of UV-irradiation. The signal of OD^- ion showed no spinning side band, which indicates rapid isotropic rotation of OD^- ion in the crystalline lattice of **5**.

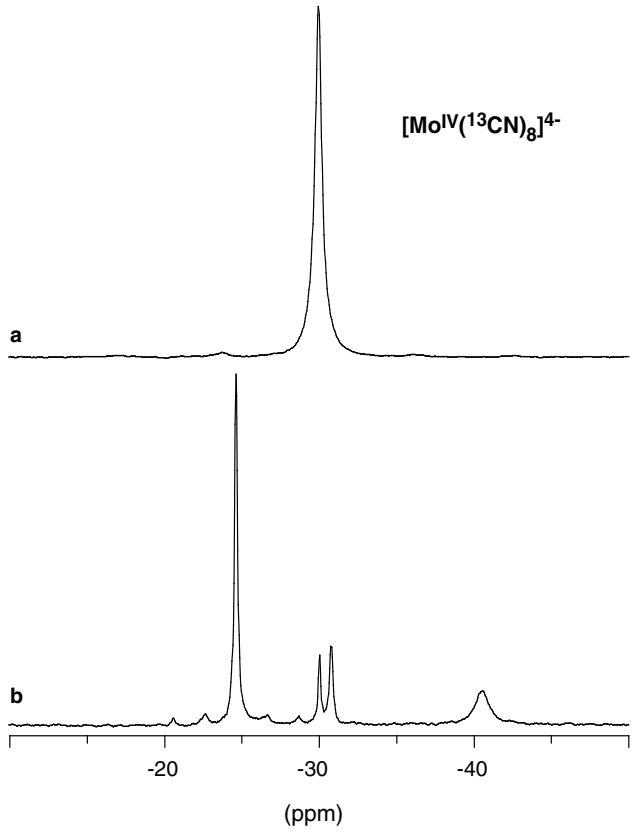

Fig. 10. ^{13}C NMR spectrum of cyanide ion of D_2O solution of $K_4[Mo^{IV}(^{13}CN)_8]\cdot 2D_2O$ (a) before and (b) after UV-irradiation. The origin of the abscissa is the diamagnetic shift of polycrystalline sample of $K^{13}CN$. Since the reaction product was not identified, signal assignment was impossible for spectrum (b). Two spectra were measured with MAS NMR probe for solid.

Fig. 8(b). For these compounds, relaxation time of electron spin may not be matched to the assumed condition to derive the Eqs. (1) and (2) for ^{13}C NMR in the solid state.

In contrast to the above result for the crystalline phase, well resolved ^{13}C NMR signals were observed for light irradiated D_2O solution of a deuterated analogue of **5** as illustrated in Fig. 10. Color of the solution changed immediately from yellow to green by light irradiation under a similar condition to the polycrystalline phase. The observed shifts of ^{13}C NMR signals for the irradiated solution are not so large, suggesting that the paramagnetic species of $[Mo^{V}(^{13}CN)_8]^{3-}$ was not detected. The hfcc of carbon nucleus of $[Mo^{V}(^{13}CN)_8]^{3-}$ was estimated from quantum mechanical calculation based on UB3LYP/LanL2DZ for an anti-prism coordination structure of $[Mo^{V}(^{13}CN)_8]^{3-}$ in crystalline phase of **6**. The values are −26.9 to −31.7 MHz. All the values are negative and the magnitude is similar to the value of |33| MHz determined by ESR for the $[Mo^{V}(CN)_8]^{3-}$ ion in an aqueous solution of $K_3[Mo^{V}(CN)_8]$ [25].

3.3. A possible effect of polymeric sequential coordination structure on the linewidth of ^{13}C NMR spectrum of cyanide ion

To investigate further what is the origin of very broad and almost temperature independent ^{13}C NMR spectrum observed for UV irradiated **5** and for **6**, we tried to measure the ^{13}C NMR spectrum for Cu(II) and Ni(II) dimmer compounds of **7** and **8** in their crystalline phase. We suspected that isolated electron spin or localized exchange interactions closed within a molecule would bring about a very broad ^{13}C NMR spectrum. Our ^{13}C NMR measurements for three-dimensional polymeric cyanide complexes such as Prussian-blue analogues [25] and for one-dimensional Ni(II) and Cu(II) chain complexes [26,27], which have extended exchange interactions, showed narrower and temperature dependent spectrum and we were able to apply Eqs. (1) and (2). An exception is hexacyanoferrate ion $[Fe^{III}(^{13}CN)_6]^{3-}$ in the solid state [23]. This compound showed relatively narrow and temperature dependent ^{13}C NMR spectrum. The compounds **7** and **8** are dinuclear complex of Cu(II) and Ni(II), in

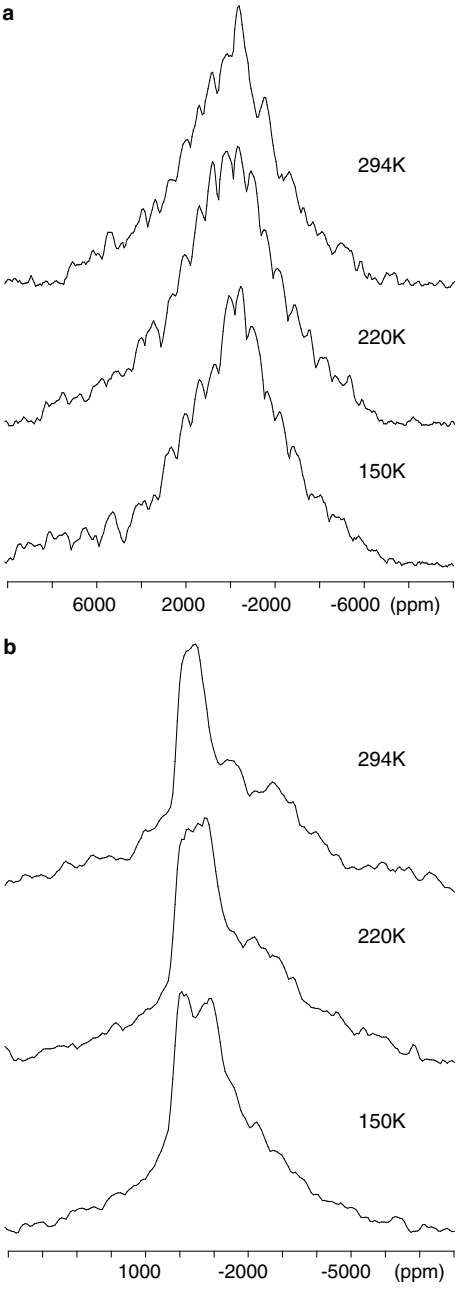

Fig. 11. ^{13}C NMR spectrum of cyanide ion of (a) $[Cu_2^{II}(tren)_2{}^{13}CN](BF_4)_3$ (**7**) and (b) $[Ni_2^{II}(tetren)_2{}^{13}CN](ClO_4)_3$ (**8**). The origin of the abscissa is the diamagnetic shift of polycrystalline sample of $K^{13}CN$.

which two identical magnetic metal ions are linked by a cyanide ion and relatively large antiferromagnetic interaction is closed within a molecule in the solid state [18]. Typical ^{13}C NMR spectra for **7** and **8** are illustrated in Fig. 11. Very broad and almost temperature independent spectrum was found both for Cu(II) (**7**) and Ni(II) (**8**). A condition of relaxation time of electron spin may be not matched with an assumption for Eqs. (1) and (2). It requires a detailed investigation of spin-lattice relaxation of electron spin to clarify the mechanism of this behavior.

rautomerism, in which the electron transfer is limited within a small molecule. Transition metal complexes of Mn [1–3], Co [3–8] and Rh [9] with ligands derived from 1,2-benzoquinone show this type of valence tautomerism in solution and in the solid state in some cases [5,8].

A cobalt complex with two 3,5-di-*t*-butyl-1,2-benzoquinone and a chelating nitrogen donor ligand of 2,2-bipyridine (bpy) has been reported to undergo a valence tautomeric interconversion between *low-spin* $[Co^{III}(SQ)(Cat)(bpy)]$ and *high-spin* $[Co^{II}(SQ)_2(bpy)]$ in solution and also in the solid state [4,5]. In this molecule an intramolecular electron transfer converts the high-spin Co(II) into a low-spin Co(III) ion, and one of the ligands is reduced from a SQ to a Cat ligand by one electron. The dynamic processes that are possible for such a valence tautomeric complex are illustrated in Fig. 1. Transition of a spin state occurs in 1,2-benzoquinone moiety and in cobalt ion. Respective change can be observed independently by solid-state high-resolution NMR spectrum. Interconversion dynamics between SQ and Cat may be detected directly by ^{13}C NMR spectrum of these ligands, while the spin state of cobalt ion can be monitored by ^{2}H NMR spectrum of deuterated bpy ligand. We also intend to take an information about magnetic coupling among the three spin species, i.e., two SQ ($S = 1/2$) and Co(II) ion ($S = 3/2$) in the high spin isomer.

Magnetic susceptibility of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · $x(C_6H_5CH_3)$ in the solid state has been reported by two groups [5,10]. The temperature behavior of effective moment is slightly different between them. This compound includes toluene as a crystal solvent. The valence tautomeric interconversion is known to be sensitive to molecular environment and an amount of crystal solvent [8]. Therefore, we investigated stable and metastable phases of this compound, which include toluene molecules as a crystal solvent in different amount.

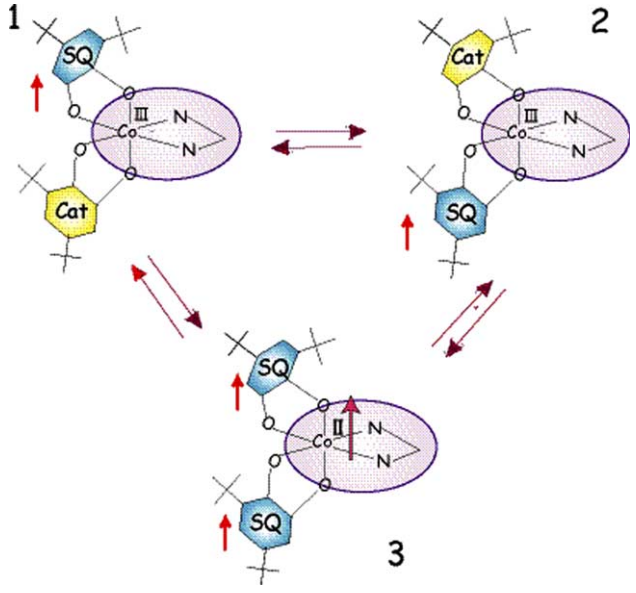

Fig. 1. Possible intramolecular electron transfer processes present for a valence tautomeric complex [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)].

2. Experiment

2.1. Sample preparation

[Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · $0.5(C_6H_5CH_3)$ was prepared from a tetramer $[Co^{II}$(3,5-di-*t*-butyl-1,2-benzoquinone)$_2]_4$ according to the procedure reported in [4]. Fifteen ml toluene solution of 0.061 g of 2,2′-bpy was added drop-wise to a 50-ml toluene solution of 0.20 g of the tetramer under stirring and argon atmosphere. After 3.5 h reaction, solvent was evaporated. For the preparation of partially deuterated compound of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$-(2,2′-bipyridine-d_8)] · $0.5(C_6H_5CH_3)$, fully deuterated 2,2′-bpy was used instead of normal 2,2′-bpy. The tetramer $[Co^{II}$(3,5-di-*t*-butyl-1,2-benzoquinone)$_2]_4$ was prepared according to the procedure reported in [11]. All manipulations were carried out under argon atmosphere. Elemental analysis gave C: 70.57% (71.02), H: 8.32% (7.47), N: 3.48% (3.99), and C: 69.41% (70.23), H: 8.41% (8.50), N: 3.41% (3.95), for normal and deuterated bpy-d_8, respectively, where the values in parentheses are calculated for a formula of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · $0.5(C_6H_5CH_3)$ and [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine-d_{18})] · $0.5(C_6H_5CH_3)$. The normal sample once heated up to 390 K showed a loss of relative content of C and H, and an increase of N, i.e., C: 69.62%, H: 8.22%, N: 3.52%, indicating a partial loss of toluene molecule.

2.2. Powder X-ray diffraction, TG–DTA and magnetic susceptibility measurements

Powder X-ray diffraction was measured at room temperature to monitor the phase change on thermal treatment by use of Cu Kα irradiation with Rint 2000 (Rigaku) equipped at Inorganic Chemistry Laboratory. Thermogravimetry combined with differential thermal analysis (TG–DTA) was measured between 290 and 480 K with TG/DTA 220U (Seiko Epson) under argon gas flow condition. Speed of temperature increase was 10 K/min. Direct current magnetic susceptibility was measured between 6 and 390 K at an external magnetic field of 1 T with SQUID magnetometer (Quantum Design MPMS 5) equipped at Inorganic Chemistry Laboratory.

2.3. Solid-state high-resolution ^{13}C and ^{2}H NMR

The magic angle spinning ^{13}C and ^{2}H NMR spectra were measured between 197 and 367 K for polycrystalline sample at a magic angle spinning speed of ca. 9 kHz and at a resonance frequency of 75.4 and 46.1 MHz, respectively, with a Bruker DSX300 spectrometer. Polycrystalline sample was packed into the center of a zirconia rotor of 4 mm diameter within a length of ca. 5 mm to minimize the temperature gradient of the sample. The thermometer of the MAS NMR probe and an effect of spinning speed on temperature increase were carefully calibrated [12,13]. The shifts of ^{13}C and ^{2}H NMR lines were measured from an external second reference of hexamethylbenzene (CH_3: 17.17 ppm) and from an external second reference of CD_3OD (CD_3: 3.35 ppm), respectively.

3. Results and discussion

3.1. Irreversible phase transformation, stable and metastable phase

Powder X-ray diffraction patterns of virgin samples of normal and bpy-deuterated compounds agreed with the reported crystal structure [4]. Thermogravimetry combined with differential thermal analysis (TG–DTA) indicated an exothermic peak accompanied with 1.5% and 2% weight loss at 369 and 359 K for normal and bpy-deuterated virgin sample, respectively, as shown in Fig. 2(a) and (b). The exothermic peak in DTA indicates a transformation from metastable to stable crystal phase. It is noted that the virgin crystal is in metastable state. The weight loss is probably due to partial loss of toluene as crystal solvent. Elemental analysis of the specimen once heated up to 390 K showed a small decrease of relative content of C and H, and an increase of N compared with the virgin sample. Further increase of temperature induced melting at 459 and 460 K accompanied with 12% and 15% weight loss for normal and bpy-deuterated sample, respectively. All crystal solvent molecules were lost and partial decomposition of the sample occurred. The normal compound once heated up to 390 K showed no anomaly around 370 K and exhibited a melting temperature 461 K as shown in Fig. 2(c). This melting was accompanied with 10% weight loss. Powder X-ray diffraction pattern of the compound once heated up to 390 K, i.e., the stable phase, was different from the pattern of the virgin sample both for normal and bpy-deuterated specimens as indicated in Fig. 3. The virgin sample in metastable phase showed no valence tautomeric interconversion, whereas the specimen in stable phase exhibited reversible interconversion as described below.

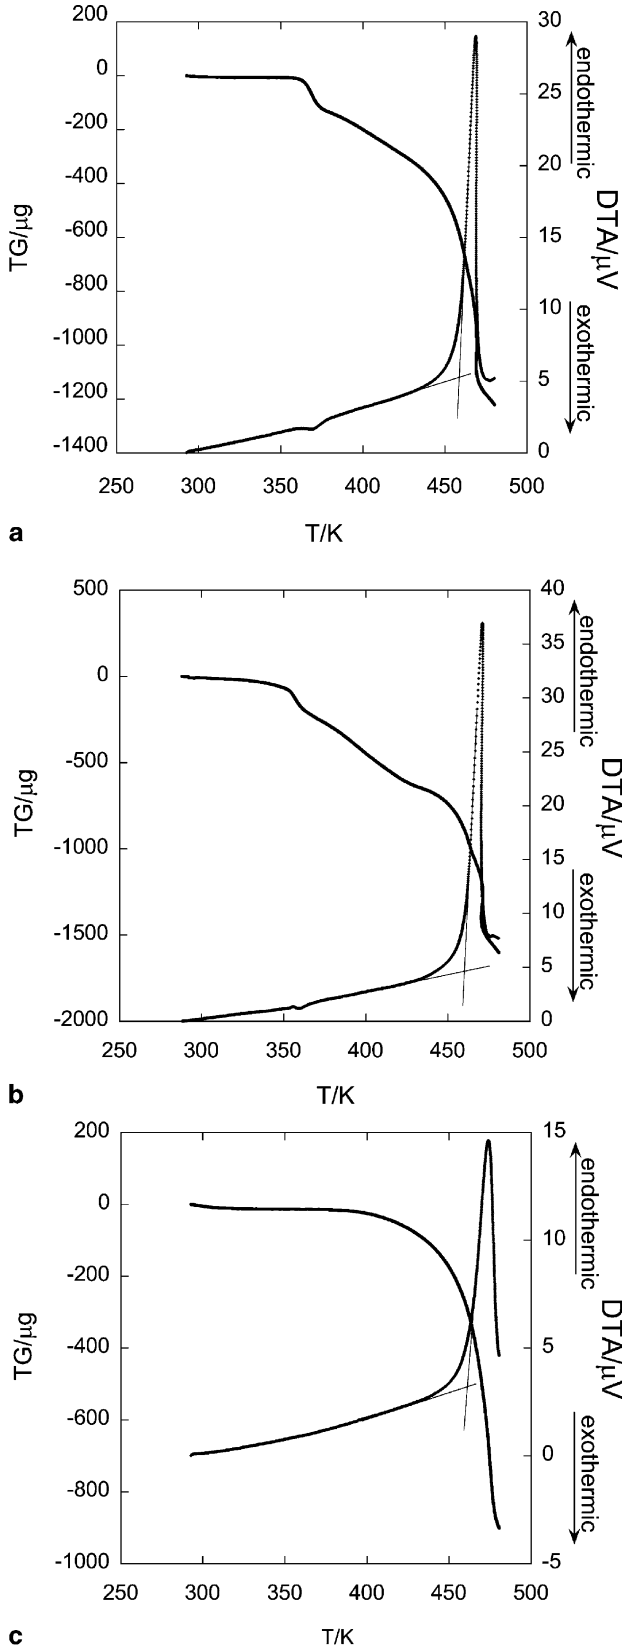

Fig. 2. TG–DTA curves of: (a) normal, (b) bpy-deuterated and (c) once heated up to 390 K sample of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · x($C_6H_5CH_3$). Speed of temperature increase is 10 K/min.

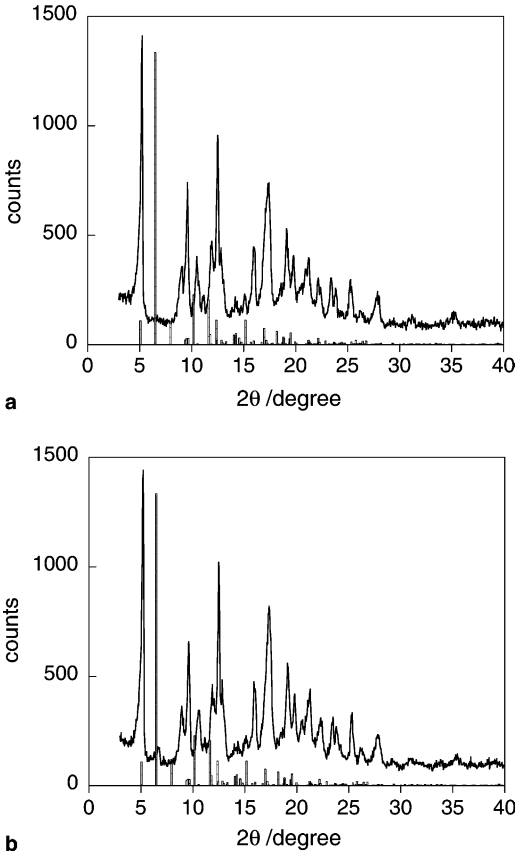

Fig. 3. Powder X-ray diffraction pattern of: (a) normal and (b) bpy-deuterated [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · x($C_6H_5CH_3$) in the stable phase, which were once heated up to 390 K. Vertical lines drawn on the abscissa are diffraction peaks calculated from a reported crystal structure [4].

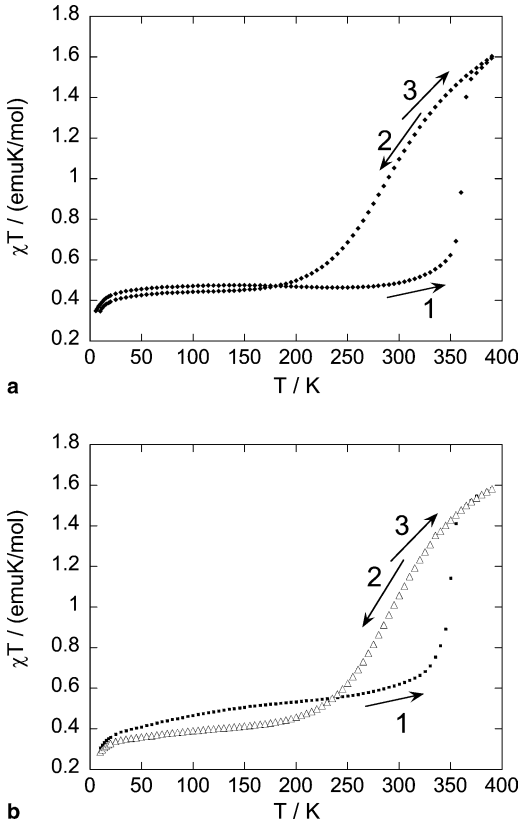

Fig. 4. Thermal hysteresis of magnetic susceptibility χ of: (a) [Co-(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · x($C_6H_5CH_3$) and (b) its bpy-deuterated analogue. Three successive runs 1, 2 and 3 in order were carried out to ensure the thermal hysteresis of χ. Molecular formula [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · 0.5 ($C_6H_5CH_3$) or its bpy-duterated analogue of the virgin sample was used to calculate the values of χ, although 1.5 ~ 2% weight loss occurred after heating up to 390 K during the first run.

3.2. Valence tautomeric interconversion in the stable phase

Thermal hysteresis of magnetic susceptibility is shown in Fig. 4(a) and (b) for normal and bpy-deuterated compound, respectively. After the sample was cooled down to 6 K from room temperature, three runs for the measurements were continued. In the first step, the magnetic susceptibility was measured in a heating process up to 390 K. Then, two successive measurements were continued on cooling down to 6 K and again on heating up to 390 K both for normal and bpy-deuterated sample. The first run for the virgin sample, which is metastable phase and its crystal structure is known [4], indicated onset of an increase of effective magnetic moment near 300 K. This may be a low temperature tail of valence tautomeric interconversion in the metastable phase or a pre-transition effect related to the metastable to stable transformation. A sharp increase of the effective magnetic moment around 360 K is due to the phase transformation to the stable phase.

After the phase change occurred, a reversible temperature dependence of the effective magnetic moment was observed, which is the valence tautomeric interconversion between *low-spin* [Co^{III}(SQ)(Cat)(bpy)] · x($C_6H_5CH_3$) and *high-spin* [Co^{II}(SQ)$_2$(bpy)] · x($C_6H_5CH_3$) in the new crystalline phase as mentioned in Section 3.1. For a valence tautomeric equilibrium between the two different spin species a (low temperature form) and b (high temperature form), which exhibit magnetic susceptibility χ_a and χ_b, respectively, the observed magnetic susceptibility χ can be expressed in a following formula:

$$\chi = \chi_a f_a + \chi_b f_b = \frac{C_A}{T} f_a + \frac{C_B}{T} f_b,$$
$$\chi T = 0.125 \left(\frac{\mu_{eff}}{\mu_B}\right)^2 = C_A f_a + C_B f_b, \quad (1)$$

where the fractions f_a and f_b can be written by

$$f_a = \frac{\exp(-\frac{\Delta S}{R} + \frac{\Delta H}{RT})}{1 + \exp(-\frac{\Delta S}{R} + \frac{\Delta H}{RT})},$$
$$f_b = \frac{1}{1 + \exp(-\frac{\Delta S}{R} + \frac{\Delta H}{RT})}. \quad (2)$$

Eq. (1) was fitted to the observed magnetic susceptibility as shown in Fig. 5 to deduce the values of entropy and enthalpy change related to the valence tautomeric interconversion and to estimate the total spin of the high temperature species in the stable phase. The best fit gave the values of $\Delta S = 53\ \mathrm{J\ K^{-1}\ mol^{-1}}$ and $\Delta H = 17\ \mathrm{kJ\ mol^{-1}}$, which are smaller than those reported for a phase probably different from the present study [5,10]. Preliminary measurement of heat capacity for the stable phase showed a very broad anomaly around 280 K. The behavior is similar to the heat capacity of similar compound of [Co(3,6-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)], for which similar values of $\Delta S = 48\ \mathrm{J\ K^{-1}\ mol^{-1}}$ and $\Delta H = 15\ \mathrm{kJ\ mol^{-1}}$ were reported [14]. Magnitude of spin for the high temperature species was estimated to be $S = 3/2$, since the values of $(\mu_{\mathrm{eff}}/\mu_{\mathrm{B}})$ for the low and high temperature species were determined to be 1.9 and 4.0, respectively. Assuming an isotropic g tensor ($g = 2$), effective moment $(\mu_{\mathrm{eff}}/\mu_{\mathrm{B}})$ is 1.7, 3.9 and 5.9 for $S = 1/2$, 3/2 and 5/2, respectively. Entropy difference between the two species due to a change of spin multiplicity is $11.5\ \mathrm{J\ K^{-1}\ mol^{-1}}$, which is much smaller than the observed value of $53\ \mathrm{J\ K^{-1}\ mol^{-1}}$. This large entropy change may be ascribed to a change of vibrational density of state, since metal ligand coordination bond length of *high-spin* Co(II) form is longer than that of *low spin* Co(III) form by ca. 0.02 nm, and vibrational frequencies becomes smaller for high temperature high spin Co(II) species [4,8,15,16]. The valence tautomeric interconversion can be characterized as entropy driven process. Since the total spin of [Co$^{\mathrm{II}}$(SQ)$_2$(bpy)] as the high temperature species is composed of two SQ ($S = 1/2$) moieties and one Co$^{\mathrm{II}}$ ion ($S = 3/2$), an expected maximum spin state will be $S = 5/2$ in the case of parallel alignment of all of the spin components. However, the experimentally estimated value is $S = 3/2$. Thus, a strong antiferromagnetic coupling is expected among some of the spin components. The spin coupling will be elucidated by solid-state high-resolution NMR spectrum.

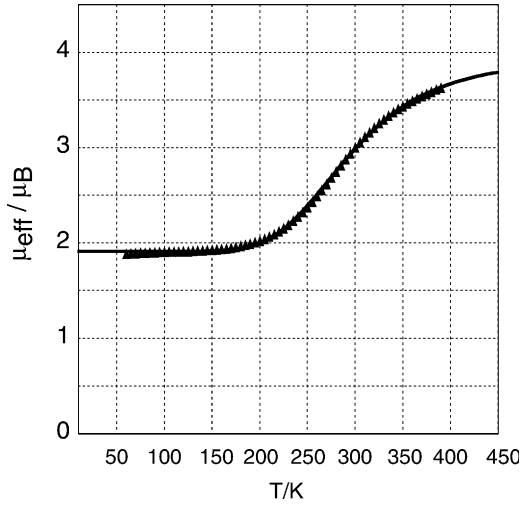

Fig. 5. Temperature dependence of effective magnetic moment due to valence tautomeric interconversion in the stable phase for normal compound. Solid curve is the result of fitting. Values of $\Delta S = 53\ \mathrm{J\ K^{-1}\ mol^{-1}}$ and $\Delta H = 17\ \mathrm{kJ\ mol^{-1}}$ were deduced for the conversion. For the bpy deuterated compound, almost the same results were obtained as those for the normal compound.

3.3. Interconversion between Cat and SQ, and antiferromagnetic interaction between two SQ ligands

Temperature variation of solid-state high-resolution ^{13}C MAS NMR spectrum measured with magic angle spinning (MAS) for a metastable virgin sample is illustrated in Fig. 6. The measurement was conducted from 303 K down to 186 K for the first run followed by the second run from 316 to 353 K. In the low temperature region such as 186 K, a relatively sharp peak (γ) at 30 ppm, which is temperature independent, was clearly observed. Since this shift is typical for methyl carbon of diamagnetic 3,5-di-*t*-butyl-1,2-benzoquinone [17], the diamagnetic Cat ligand was distinguished from spin bearing SQ ligand. Broad peaks (α and β) around $100 \sim 150$ ppm at 186 K were tentatively assigned to methyl carbons of SQ overlapped by some other carbon

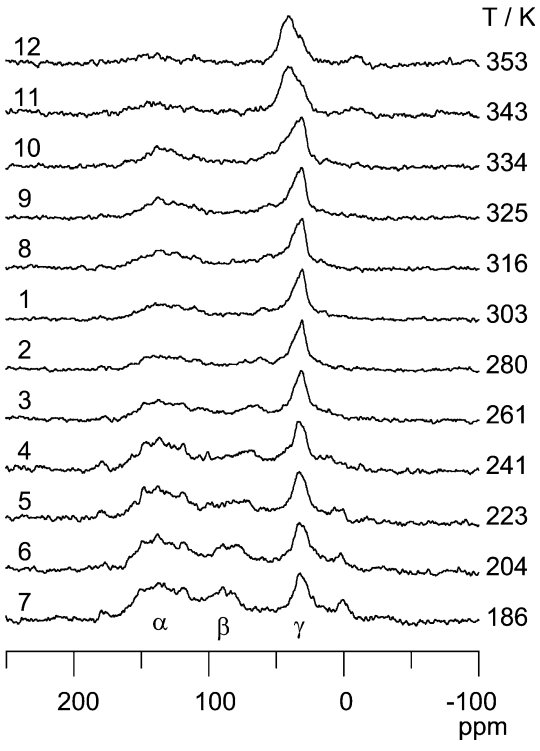

Fig. 6. Temperature variation of ^{13}C MAS NMR spectrum of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · x($C_6H_5CH_3$) in the virgin metastable phase. To make the phase relation clear, successive measurements were carried out from number 1 to 12 in order. Above 343 K partial phase change occurred from metastable to stable phase. α and β were assigned to the signals of SQ ($S = 1/2$) and γ was assigned to Cat ($S = 0$).

signals. The peak at 30 ppm of Cat is temperature independent up to 325 K. This result indicates that no interconversion between Cat and SQ states occurs below 325 K. The profile of SQ signals is temperature dependent because of hyperfine coupling in a SQ ligand. No dynamic process of interconversion between Cat and SQ occurred below 325 K in the metastable phase. Sudden change was observed at 343 K, which indicates a partial phase change. This thermal treatment brought about additional peaks in the spectrum at 303 K, which was measured after heating up to 353 K, due to mixing of stable and metastable phases. Although an onset of increase of effective moment was observed in the metastable virgin sample below 325 K as indicated in Fig. 4, the dynamic process is slower than $10^3\ s^{-1}$, even if it occurs. ^2H MAS NMR spectrum of the metastable virgin sample of deuterated bpy-d_8 analogue is illustrated in Fig. 7. The peak near 8 ppm is temperature independent and indicates that the central metal ion directly bonded to bpy-d_8 is diamagnetic Co(III) state up to 331 K.

In contrast to the metastable phase, ^{13}C MAS NMR signals of stable phase were observed near 55 (b) and 95 ppm (a) at 186 K, just in between the signals of Cat and SQ. The peak (b) at 55 ppm is an average of 30 (Cat, γ) and 90 (SQ, β) ppm peaks and the peak (a) at 95 ppm is an average of 30 (Cat, γ) and 150 (SQ, α) ppm peaks in Fig. 6. Both 55 and 95 ppm signals are temperature dependent as shown in Fig. 8. This result clearly indicates that dynamic interconversion between Cat and SQ states were directly observed by the NMR spectrum.

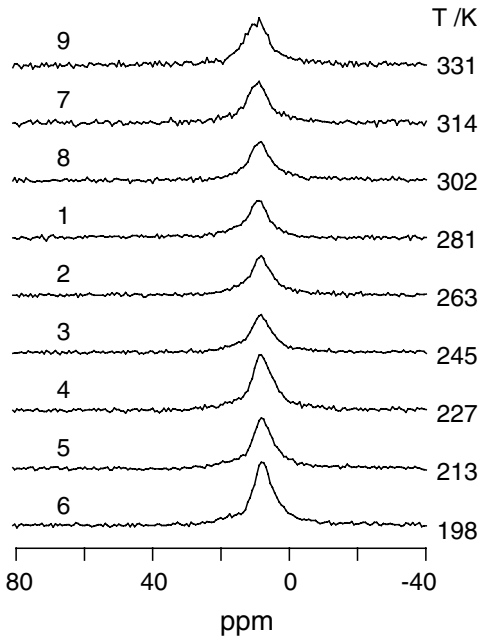

Fig. 7. Temperature variation of ^2H MAS NMR spectrum of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine-d_8)] · $x(C_6H_5CH_3)$ in the virgin metastable phase. To make the phase relation clear, successive measurements were carried out from number 1 to 9 in order.

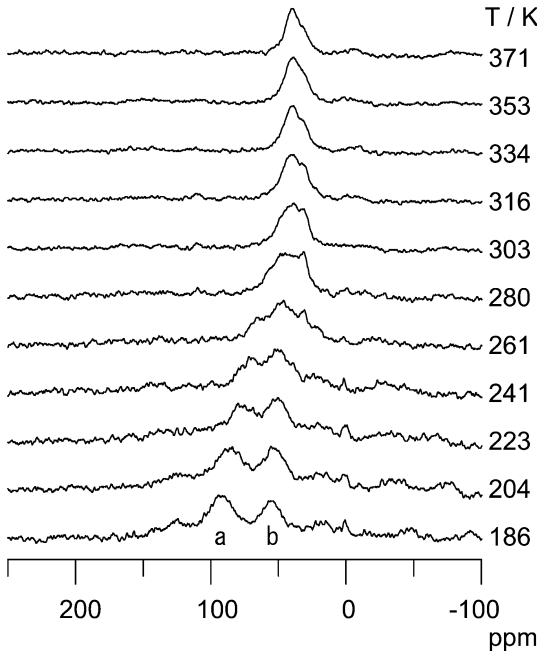

Fig. 8. Temperature variation of ^{13}C MAS NMR spectrum of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$(2,2′-bipyridine)] · $x(C_6H_5CH_3)$ in the stable phase. Reversible change of the spectrum was confirmed. The signals (a) and (b) were assigned to the methyl groups of 5-*t*-Bt and 3-*t*-Bt, respectively, in averaged state of Cat ($S = 0$) and SQ ($S = 1/2$).

The conversion rate is much larger than NMR time scale of ca. $5 \times 10^4\ s^{-1}$ even in the low temperature region such as 186 K. This conversion is associated with a small energy difference between the two relevant species, since the averaged shift is almost the midpoint between the Cat and SQ. It is suggested that the energy difference between *low-spin* [Co^{III}(Cat)(SQ)] (**1**) and *low-spin* [Co^{III}(SQ)(Cat)] (**2**) shown in Fig. 1 is small enough in the stable phase. The two peaks at 55 (b) and 95 ppm (a) at 186 K in the stable phase were assigned to methyl groups of 3-*t*-Bt group and those of 5-*t*-Bt group of 3,5-di-*t*-butyl-1,2-benzoquinone as an averaged state of Cat ad SQ. Since 3,5-di-*t*-butyl-1,2-semiquinone ($S = 1/2$) has an electronic structure to exhibit a smaller hyperfine coupling on 3 and 6 positions and larger hyperfine coupling on 4 and 5 positions [18], a smaller and a larger paramagnetic shift are expected for 3 and 5 position, respectively.

Assuming a small zero field splitting, the temperature dependence of the paramagnetic isotropic shift δ_{iso} can be written by the Fermi contact term, the dipole interaction term (pseudo contact) and the temperature independent diamagnetic term (chemical shift) as follows [19,20]:

$$\delta_{iso} = \delta_{Fermi} + \delta_{Pseudo} + \delta_{dia},$$
$$\delta_{Fermi} + \delta_{Pseudo} = \frac{\mu_B}{3k_B T}\frac{A}{\gamma_C/2\pi}S(S+1). \quad (3)$$

Electron spin induced on the ^{13}C nucleus brings about a Fermi contact shift of the NMR resonance line, while

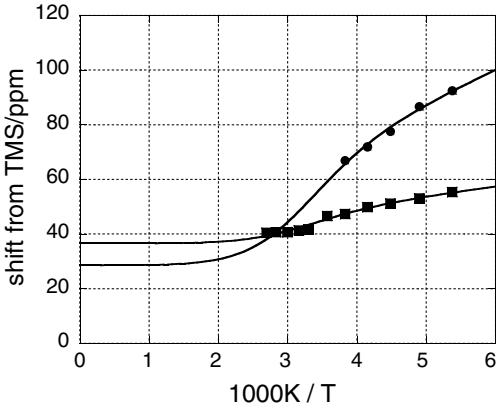

Fig. 9. Temperature dependence of the isotropic shift of ^{13}C MAS NMR of methyl groups of [Co(3,5-di-*t*-butyl-1,2-benzoquinone)$_2$-(2,2′-bipyridine)] · $x(C_6H_5CH_3)$ in the stable phase. Closed circles represent the sift of 5-*t*-Bt groups in averaged state of Cat ($S = 0$) and SQ ($S = 1/2$) ((a) in Fig. 8), while closed squares show the shift of 3-*t*-Bt groups ((b) in Fig. 8). Solid curves are fitting of Eq. (4) for the valence tautomeric interconversion between *low-spin* Co(III) form and *high-spin* Co(II) form.

anisotropy of the *g*-tensor of electron spin gives a pseudo-contact shift. The coefficient A in Eq. (3) is defined as the hyperfine coupling constant (hfcc) of the ^{13}C nucleus in Hz unit for a given electron spin S. In the case of valence tautomeric interconversion, the observed isotropic shift can be written in the same formula as Eqs. (1) and (2):

$$\begin{aligned}\delta_{\mathrm{obs}} &= \delta^{\mathrm{a}}_{\mathrm{iso}} f_{\mathrm{a}} + \delta^{\mathrm{b}}_{\mathrm{iso}} f_{\mathrm{b}} \\ &= \frac{\mu_{\mathrm{B}}}{3k_{\mathrm{B}}T}\frac{1}{\gamma_{\mathrm{C}}/2\pi}\left(A_{\mathrm{a}}S^{\mathrm{a}}(S^{\mathrm{a}}+1)f_{\mathrm{a}}\right. \\ &\quad \left. + A_{\mathrm{b}}S^{\mathrm{b}}(S^{\mathrm{b}}+1)f_{\mathrm{b}}\right) + \delta_{\mathrm{dia}}. \end{aligned} \quad (4)$$

Here, A_{a} and A_{b} are effective hyperfine coupling constants of the low and high temperature valence tautomeric isomers, respectively. Fractions of the two isomers were determined by magnetic susceptibility measurement as described in Section 3.2. Almost negligible hfcc for the high temperature isomer gave a fit to the observed temperature dependence of the isotropic shift as illustrated in Fig. 9. The negligible hfcc of the SQ ($S = 1/2$) for the high temperature [$Co^{II}(SQ)_2$] isomer suggests that strong antiferromagnetic interaction operates between the two SQ ligands to cancel the polarized spins on their *t*-Bt groups and the spin of $S = 3/2$ of Co^{II} ion remains in the *high-spin* [$Co^{II}(SQ)_2$] isomer. The effective hfcc's of methyl groups were estimated to be 0.11 and 0.38 MHz for 3 and 5 position of averaged state of Cat and SQ in the low spin [Co^{III}(Cat)(SQ)] isomer in the stable phase. Increase of the averaged magnitude of electron spin of cobalt ion as temperature increased was detected by ^2H MAS NMR of deuterated bpy-d_8, which is directly coordinated to the cobalt ion. Although the quality of the spectrum is not enough for quantitative discussions, splits of the peak accompanied by broadening were observed as the temperature was increased.

2. Results and discussion

2.1. Preparation and magnetic properties of azoxy- and azobenzene derivatives with aminoxyls

4,4′-Dihydroxyazoxybenzene **1a** [7] prepared by the zinc reduction of *p*-nitrophenylacetate followed by the alkaline hydrolysis of the acetyl groups was reacted with two molar amounts of aminoxyl-substituted bromoundecanoxycarbonyl derivatives (**3**, **4**) to give the corresponding biradical **5a** and **5b** in 34%, 42% yields, respectively. Similar reaction of 4-hydroxyazobenzene **2a** [8] prepared by the treatment of *p*-hydroxybenzene diazonium chloride with ammoniac cupric sulfate solution gave the biradicals with an azobenzene core (**6a**, **6b**) in 31%, 29% yields, respectively. By the derivatization of commercially available 4-hydroxyazobenzene with **2b**, the monoradicals with an azobenzene core (**8a**, **8b**) were prepared in the similar manner in 71% yield for **8a** and 72% yield for **8b** [9], while the monoradicals with an azoxybenzene core (**7a**, **7b**) were obtained from 4-hydroxylazoxybenzene **1b**, which was derived from the oxidation of the azobenzene **2b** with *m*-chloroperbenzoic acid (MCPBA), in 76% and 53% yield, respectively (Scheme 1). The thermotropic properties of the radicals thus prepared were examined by the DSC measurements and no endothermic peak but that of melting point could so far be discerned for any monoradicals as well as biradicals thus prepared.

The magnetic data were obtained by using SQUID susceptometer between the temperature range from 2 to 300 K and the data for the biradicals and the monoradicals are summarized in Table 1. Thus, antiferromagnetic interactions were observed in all of the biradical compounds **5** and **6** and the behavior being based on Curie–Weiss (CW) law was apparent for the PROXYL-based derivatives, i.e., **5b** and **6b**. On the contrary, the behavior being well expressed by singlet–triplet (ST) model was found for the TEMPO-based biradicals **5a** and **6a** with relatively large *J*-values of −33.9 K for **5a** and −38.5 K for **6a**, respectively. Since similar magnetic behaviors have also been observed in the related biradicals with a naphthalene or a biphenyl core [10], the molecules in the biradicals with extended long alkyl groups could be well anticipated to have the similar structural features in the solid-state with a hand-in-hand fashion especially for the TEMPO-based biradicals **5a** and **6a**, although their crystal structures are not clarified yet because of the lack of single crystals suitable for the X-ray analysis. On the contrary, weak intermolecular magnetic interactions were observed for the corresponding monoradicals **7** and **8**, in which only weak ferromagnetic interactions based on CW model were found for **8a**, while antiferromagnetic interactions on ST model were dominant for the other monoradicals.

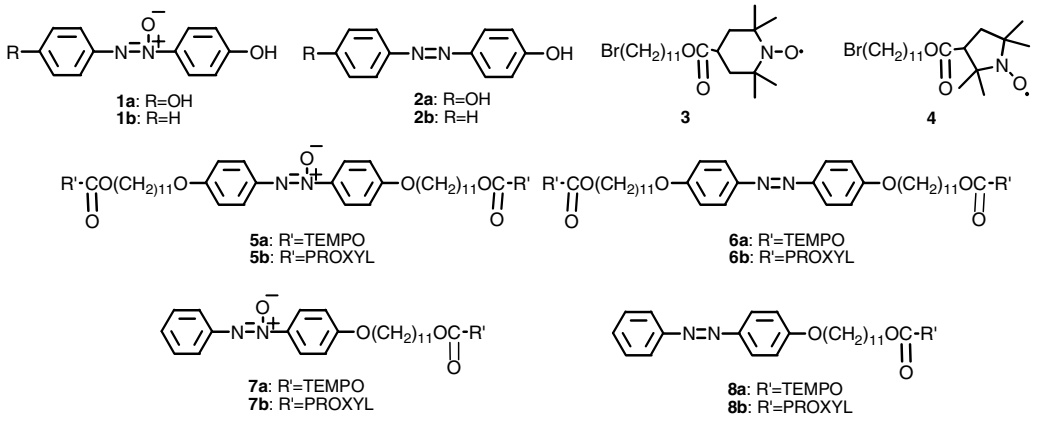

Table 1
Magnetic data of radical compounds

Compound	Magnetic interaction	C (emu K mol^{-1})	θ (K)	J (K)
5a	antiferromagnetic[a]			−33.9
5b	antiferromagnetic[b]	0.77	−1.07	
6a	antiferromagnetic[a,c]			−38.5
6b	antiferromagnetic[b,c]	0.76	−2.72	
7a	antiferromagnetic[a]			−14.8
7b	antiferromagnetic[a]			−3.7
8a	ferromagnetic[b,c]	0.38	0.09	
8b	antiferromagnetic[a,c]			−4.2

2.2. Photo-responsive properties of the azobenzene derivatives

An azobenzene unit is known to give in a molecular/supramolecular system not only a mesogenic property but also a photo-responsive property and hence latter

Scheme 1.

properties of the azobenzene derivatives thus prepared were studied at the same time. Irradiation of the *trans*-isomers of the biradicals **6a** or **6b** with the light of 365 nm in dichloromethane solution gave gradually the corresponding *cis*-isomers, which could be isolated in the solid-state. However, the corresponding *cis*-isomers were found to be fairly unstable and they were smoothly reverted back to the original *trans*-isomers even when kept in the dark and stored in a refrigerator. We then turned our attention to the monoradicals with an azobenzene unit **8a** or **8b**.

When the *trans*-isomer of the monoradical with a TEMPO-substituent (**8a**) was irradiated with the light of 365 nm in dichloromethane solution, an absorption maximum at around 350 nm shifted gradually to a newly developed absorption at around 440 nm with an isosbestic point at 410 nm, while the reverse change was found to occur by irradiation of the latter solution with a fluorescent lamp or merely exposing the solution in the diffused light (Scheme 2). The forward and the backward reaction could be repeated for several times without appreciable decay as shown in Fig. 1 and the *cis*-isomer **9a** with the absorption at 440 nm could be isolated in the solid states. Fortunately, the *cis*-isomer **9a** was found to be more stable and durable than the previous *cis*-isomers of the biradicals **6a** or **6b** without appreciable change when kept in the dark and stored in a refrigerator. In turn, the backward reaction took place by the exposure of the solid material in the diffused light at ambient temperature for several hours and hence a reversible system could be constructed in this case [9]. At the same time, the original magnetic behavior of CW model with only weak ferromagnetic interactions ($\theta = 0.09$ K) was found to be changeable to the behavior of ST model with relatively strong magnetic interactions ($J = -37$ K) as shown in Fig. 2. Thus, an organic photo-responsive spin system has been available, in which photo-induced switching behavior of their intermolecular spin–spin interactions is observed.

The photo-isomerization of the *trans*-isomer of the azobenzene derivative with a PROXYL group (**8b**) was next examined and found to occur similarly by irradiation to give the corresponding *cis*-isomer **9b** as a relatively stable solid. The magnetic behavior of the *trans*-isomer **8b** was being based on ST model with relatively small intermolecular magnetic interactions

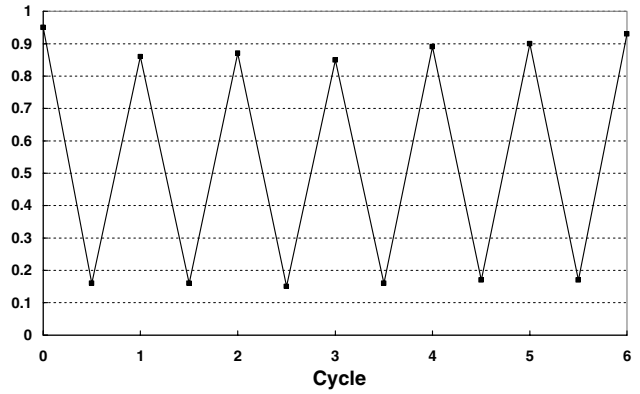

Fig. 1. Absorption changes observed at 346 nm by alternating irradiation at 365 nm and with a fluorescent light in dichloromethane over 6 cycles.

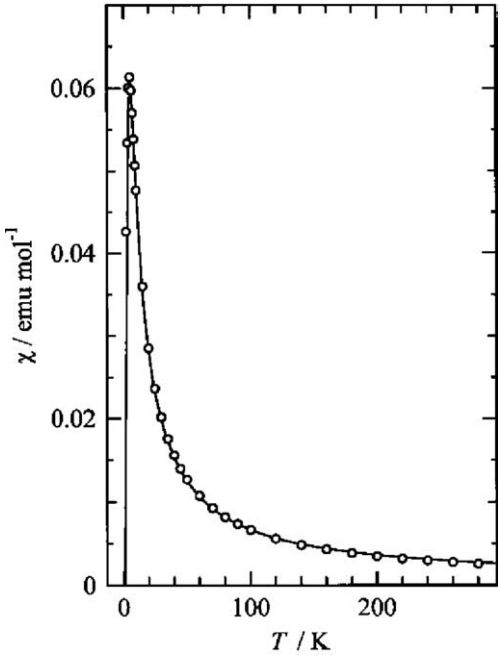
($J = -4.2$ K) and larger magnetic interactions with $J = -7.7$ K was observed in the corresponding *cis*-isomer, even though the behavior was also that of ST



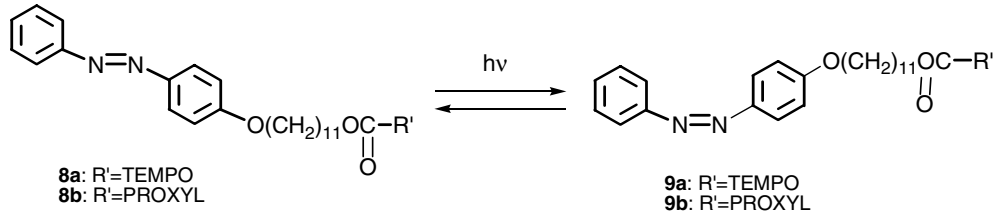


Fig. 2. Temperature dependence of magnetic susceptibility for a polycrystalline sample of *cis*-azobenzene derivative with TEMPO-substituent **9a**. The solid line corresponds to the best fit to a ST model with $J = -36.7$ K (spin concentration is estimated to be 64.3%).

Scheme 2.

model. The *cis*-isomer **9b** was found to give more slowly back to the *trans*-isomer **8b** than that of the corresponding biradical **6b** described above at ambient temperature and hence it could be handled at usual condition like the *cis*-isomer with TEMPO-substituent **9a**.

In summary, we have prepared several aminoxyl radicals and biradicals having an azoxy- or azobenzene core on one hand and a long alkyl group on the other hand and found that the biradicals with TEMPO substituents at their ends showed relatively large antiferromagnetic interactions being well expressed by ST model, while only weak antiferromagnetic interactions were observed in the corresponding PROXYL derivatives. The photoresponsive magnetic properties were observed in a couple of monoaminoyl-substituted azobenzene derivatives **8a** and **8b** and more appreciable change of the intermolecular magnetic interactions could be discerned in the TEMPO derivatives (**8a** and **9a**) than that of the PROXYL derivatives (**8b** and **9b**).

clarified its spin structure and crystal structure [9]. It turned out that the incorporation of nitrogen atoms induced small but measurable change of spin density distribution on phenalenyl, which led to a difference of crystal structure and physical properties between **6** and **2** [9a,b]. For further elucidation of the heteroatomic effects on the properties and spin structure of phenalenyl system, we have designed *tert*-butylated 4,9-dimethoxy-1,3-diazaphenalenyl (**7**) as the first example of an azaphenalenyl system having alkoxy substituents. We expected that the introduction of methoxy groups at 4- and 9-positions could strongly affect the electronic spin structure of the 1,3-diazaphenalenyl π-system and their properties, because large spin densities of 1,3-diazaphenalenyl system exist at 1-, 3-, 4-, 6-, 7-, and 9-positions. In this paper, we report on the first generation of dimethoxy-substituted azaphenalenyl radical **7** and effects of the methoxy group in a 1,3-diazaphenalenyl π-system.

2. Experimental

2.1. General

All chemicals were reagent grade and used without further purification. 2,7-Di-*tert*-butyl-3,6-dimethoxynaphthalene (**8**) was prepared from 2,7-dimethoxynaphthalene according to the reported procedure [7b]. *p*-Chloranil was recrystallized from benzene. Active PbO_2 was prepared according to the reported procedure [7b,10]. All reactions requiring anhydrous conditions were performed under argon atmosphere. Toluene and *N*,*N*-dimethylacetamide (DMA) were dried and distilled over CaH_2 under argon prior to use. Xylene (mixture of isomers) was dried by the filtration through the Alumina Super I (ICN BIOMEDICALS) column. ^{1}H NMR spectra were recorded on a JEOL EX-270 spectrometer with $CDCl_3$ and Me_4Si as an internal standard. EI-MS spectra were recorded at 70 eV on a Shimadzu QP-5000. Infrared spectra were recorded using KBr plates and CCl_2CCl_2 solution on Perkin–Elmer FT 1640 IR. Melting points were recorded with a Yanaco micro melting point apparatus and were uncorrected. The liquid-phase ESR spectra were recorded at 270–290 K on an X-band Bruker ESR/ENDOR spectrometer ESP300/350. R_f values on TLC were recorded on E. Merck precoated (0.25 mm) silica gel 60 F_{254}. The plates were sprayed with a solution of 10% phosphomolybdic acid in 95% EtOH and then heated until the spots became clearly visible. Silica gel 60 (100–200 mesh) was used for column chromatography. Deactivated silica gel was prepared by mixing silica gel with 6% water.

2.2. Synthesis of 3,6-di-tert-butyl-1,8-dinitro-2,7-dimethoxynaphthalene (*9*)

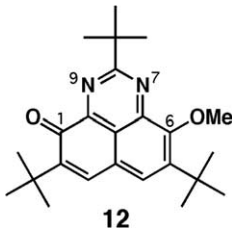
2,7-Di-*tert*-butyl-3,6-dimethoxynaphthalene (**8**) (10 g, 33 mmol), $Cu(NO_3)_2 \cdot 3H_2O$ (16.0 g, 66 mmol) and acetic anhydride (300 mL) were placed in a 1-L three-necked round-bottomed flask and stirred at room temperature for 14 h. Most of the acetic anhydride was removed by distillation at 60 °C, and the residue was mixed with H_2O (~300 mL). The resulting mixture was stirred for 30 min, and was mixed with CH_2Cl_2. The organic layer was separated, and the aqueous layer was extracted with CH_2Cl_2. The combined organic layer was washed with saturated aqueous $NaHCO_3$, and dried over Na_2SO_4, then filtered and concentrated under reduced pressure, to give the desired compound (11.6 g, 90%) as a yellowish orange solid: mp 203–205 °C; TLC R_f 0.40 (5:1 hexane/ethyl acetate); ^{1}H NMR (270 MHz, $CDCl_3$) δ 1.47 (s, 18H), 3.89 (s, 6H), 7.86 (s, 2H); *m*/*z* 390 (M^+, 9%), 344 ($M^+ - NO_2$, 58%); *Anal.* Calc. for $C_{20}H_{26}N_2O_6$: C, 61.53; H, 6.71; N, 7.18. Found: C, 61.37; H, 6.71; N, 7.21%.

2.3. Synthesis of 1,8-diamino-3,6-di-tert-butyl-2,7-dimethoxynaphthalene (*10*)

Dinitro derivative **9** (1.99 g, 5.12 mmol), Sn (2.61 g, 22.0 mmol) and $SnCl_2 \cdot 2H_2O$ (9.06 g, 40.2 mmol) were placed in a 300-mL round-bottomed flask equipped with reflux condenser. To this mixture was added concentrated HCl (50 mL) and acetic acid (100 mL) at room temperature. This reaction mixture was stirred at 90 °C for 6.5 h. After being cooled to room temperature, the resulting mixture was extracted with CH_2Cl_2/hexane solution and the organic layer was washed with 2 M HCl aq, 0.1 M pH 7.0 phosphate buffer solution, saturated aqueous $NaHCO_3$ and 10% aqueous NaOH, successively. The organic layer was dried over Na_2SO_4,

then filtered and concentrated under reduced pressure. The residual solid was subjected to deactivated silica gel column chromatography with a 20:1–15:1 mixture of hexane and ethyl acetate as eluent, to give diamino derivative **10** (957 mg, 59%) as deep orange powder. This compound was used for next reaction without further purification due to its low stability: TLC R_f 0.63 (2:1 hexane/ethyl acetate); ^{1}H NMR (270 MHz, $CDCl_3$) δ 1.44 (s, 18H), 3.82 (s, 6H), 4.4–4.6 (br, 4H), 7,06 (s, 2H); EI-MS, *m*/*z* 330 (M^+, 42%), 315 ($M^+ - CH_3$, 100%).

2.4. Synthesis of 2,5,8-tri-tert-butyl-4,9-dimethoxy-1,3-diazaphenalene (*11*)



Diamino derivative **10** (162 mg, 0.49 mmol) was placed in a 50-mL Schlenk tube equipped with a reflux condenser and mixed with xylene (5 mL), pivalaldehyde (0.1 mL, 0.9 mmol), *p*-TsOH · H_2O (27 mg) and 5% Pd/C (270 mg). This mixture was refluxed at 160 °C for 15 h. After being cooled to room temperature, this reaction mixture was directly treated with the Na_2SO_4 and passed through a Celite column to removed water and Pd/C, and rinsed with CH_2Cl_2. After being concentrated under reduced pressure, the residual solid was subjected to deactivated silica gel column chromatography with a 5:1 mixture of hexane and CH_2Cl_2 as eluent, to give 1,3-diazaphenalene derivative **11** (121 mg, 63%) as orange powder: m.p. 71–73 °C; TLC R_f 0.57 (5:1 hexane/ethyl acetate); TLC (alumina) R_f 0.61 (5:1 hexane/ethyl acetate); ^{1}H NMR (270 MHz, $CDCl_3$) δ 1.38 (s, 9H), 1.39 (s, 9H), 1.41 (s, 9H), 3.72 (s, 3H), 4.03 (s, 3H), 6.93 (s, 1H), 7.0–7.1 (br, 1H), 7.04 (s, 1H); EI-MS, *m*/*z* 396 (M^+, 71%), 381 ($M^+ - CH_3$, 100%); *Anal*. Calc. for $C_{25}H_{36}N_2O_2 \cdot (CH_2Cl_2)_{0.05}$: C, 75.07; H, 9.08; N, 6.99. Found: C, 75.01; H, 9.04; N, 6.82%.

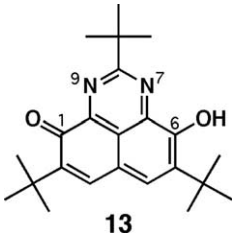
2.5. ESR/ENDOR/TRIPLE spectroscopies of the radical 7

A toluene solution of 1,3-diazaphenalene derivative **11** (8×10^{-5} M) and *p*-chloranil (ca. 0.5 mg) was placed in an ESR tube, degassed by the freeze-pump-thaw method, and sealed. ESR measurements were performed at 290 K. ^{1}H and ^{14}N ENDOR/TRIPLE spectra were measured at 270 K.

2.6. Preparation of the radical 7 in the solid state

1,3-Diazaphenalene derivative **11** (10 mg, 0.026 mmol) was placed in a 50-mL Schlenk tube and dissolved with degassed toluene (3 mL). To this mixture was added active PbO_2 (30 mg, 0.13 mmol), then this mixture was degassed and filled with argon. After being stirred at room temperature for 1 min, the resulting mixture was filtered through a Celite column under argon atmosphere, and rinsed with degassed toluene. The filtrates were concentrated in vacuo, to give the crude radical as a green solid (about 1:1 mixture of radical **7** and phenalenone derivative **12** in TLC spectroscopy): TLC (alumina) R_f 0.82 for **7**, and 0.61 for **12** (5:1 hexane/ethyl acetate).

12



2.7. Generation of 7,9-diazaphenalenone derivative *12*

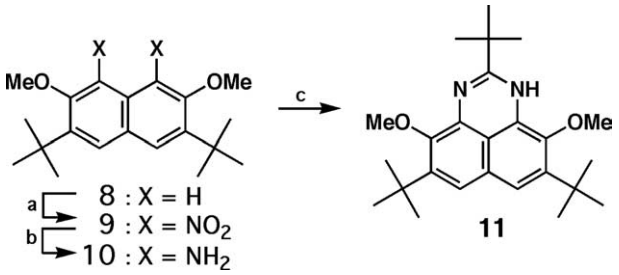
1,3-Diazaphenalene derivative **11** (10 mg, 0.026 mmol) was placed in a 50-mL Schlenk tube and dissolved with degassed toluene (3 mL). To this mixture was added active PbO_2 (60 mg, 0.25 mmol), and then this mixture was degassed and filled with argon. After being stirred at room temperature for 45 min, the resulting mixture was filtered through a Celite column under argon atmosphere, and rinsed with toluene. The filtrates were concentrated in vacuo, to give the phenalenone **12** as a reddish orange solid (13 mg, quant). Analytically pure sample was prepared by deactivated silica gel column chromatography with a 250:1 mixture of hexane and ethyl acetate as eluent: m.p. 173–175 °C; TLC R_f 0.60 (5:1 hexane/ethyl acetate); TLC (alumina) R_f 0.61 (5:1 hexane/ethyl acetate); ^{1}H NMR (270 MHz, $CDCl_3$) δ 1.41 (s, 9H), 1.51 (s, 9H), 1.60 (s, 9H), 4.46 (s, 3H), 7.46 (s, 1H), 7.63 (s, 1H); EI-MS, *m*/*z*380 (M^+, 65%), 365 ($M^+ - CH_3$, 100%); IR (KBr) 2960, 1644 cm^{-1}; *Anal*. Calc. for $C_{24}H_{32}N_2O_2$: C, 75.75; H, 8.48; N, 7.36. Found: C, 75.48; H, 8.48; N, 7.25%.

2.8. Conversion of *12* to 6-hydroxy-7,9-diazaphenalenone derivative *13*

7,9-Diazaphenalenone derivative **12** (13 mg) was placed in a 30-mL round-bottomed flask and dissolved with DMA (2.0 mL). To this mixture was added LiI (91 mg, 0.68 mmol) and stirred at 180 °C for 3 h. After being cooled to room temperature, 0.1 M, pH 7.0, phosphate buffer solution was added to this mixture. The resulting mixture was extracted with ethyl acetate. The organic layer was washed with saturated aqueous NaCl and water, and dried over Na_2SO_4, then filtered and concentrated under reduced pressure, to give 6-hydroxy-7,9-diazaphenalenone **13** as a deep red solid (11 mg, crude yield 88%). Analytically pure sample was prepared by

recrystallization from a mixture of hexane and CH_2Cl_2: m.p. 206–208 °C; TLC R_f 0.52 (5:1 hexane/ethyl acetate); ^{1}H NMR (270 MHz, $CDCl_3$) δ 1.41 (s, 9H), 1.53 (s, 9H), 1.59 (s, 9H), 7.47 (s, 1H), 7.62 (s, 1H), 8.5–8.6 (br, 1H); *m/z* 366 (M^+, 100%); IR (KBr) 3386, 2958, 1652 cm^{-1}; IR (CCl_2CCl_2) 3389, 2959, 1653 cm^{-1}; *Anal.* Calc. for $C_{23}H_{30}N_2O_2 \cdot (CH_2Cl_2)_{0.05}$: C, 74.67; H, 8.18; N, 7.56. Found: C, 74.44; H, 8.32; N, 7.48%.

13



3. Results and discussion

3.1. Synthesis of the radical precursor *11*

The radical precursor, 1,3-diazaphenalene derivative **11**, was synthesized from di-*tert*-butyl-dimethoxynaphthalene **8** in three steps (Scheme 1).[1] Two nitro groups were effectively introduced to dimethoxynaphthalene **8** at the 1,8-positions with $Cu(NO_3)_2 \cdot 3H_2O$ and acetic anhydride [11]. Dinitro derivative **9** was converted to diamino derivative **10** with Sn and $SnCl_2 \cdot 2H_2O$ under acidic conditions. Condensation with pivalaldehyde in the presence of *p*-TsOH · H_2O followed by dehydrogenation with Pd/C gave 1,3-diazaphenalene derivative **11** [12].

3.2. Stability of the radical 7 in a solution and the solid state

The ESR signal intensity of radical **7** generated by treatment of **11** with *p*-chloranil in a degassed toluene solution decreased to one-fifth of its original magnitude at −30 °C after a week in a sealed ESR tube. The radical **7** was also generated by the treatment of active PbO_2 in degassed toluene solution. When the reaction time was longer than 1 min, the radical **7** was transformed completely to the 7,9-diazaphenalenone derivative **12** as proven by NMR, IR, and EI-MS spectra. The molecular structure of **12** was also confirmed by conversion to 6-hydroxy-7,9-diazaphenalenone derivative **13**.[2] The

Scheme 1. Synthesis of **11**. Reagents and conditions: (a) 2 equiv $Cu(NO_3)_2 \cdot 3H_2O$, Ac_2O, rt, 14 h, 90%; (b) 4.5 equiv Sn, 7.8 equiv $SnCl_2 \cdot 2H_2O$, conc. HCl aq–AcOH (1:2), 100 °C, 6.5 h, 59%; (c) 1.8 equiv *t*-BuCHO, cat Pd/C, cat *p*-TsOH · H_2O, xylene, reflux, 5 h, 63%.

mixture of **7** and **12** as a green solid was obtained when the reaction was worked up within 1 min (TLC spectroscopy indicated that the ratio of **7**:**12** was about 1:1). TLC spectroscopy showed that the crude radical solid stored at −30 °C under air atmosphere for a week was completely transformed to **12**. These observations indicate that the stability of **7** in a degassed solution and the solid states is lower than the parent 1,3-diazaphenalenyl **6**, which is stable in degassed solution and the solid state for a long period of time [9a,b].

3.3. Clarification of spin structure in terms of ESR/ENDOR/TRIPLE spectroscopies

A hyperfine ESR spectrum of the radical **7** observed from a degassed toluene solution of radical precursor **11** (8×10^{-5} M) with *p*-chloranil at 290 K is shown in Fig. 1(a). In order to determine the magnitudes and relative signs of hyperfine coupling constants (hfcc's), the liquid-phase ^{1}H and ^{14}N ENDOR/TRIPLE spectra were measured (Fig. 1(c) and (d)). The ^{1}H and ^{14}N ENDOR spectrum showed four pairs of lines which were attributable to two protons and two nitrogen atoms on the phenalenyl skeleton, the methoxy group's protons, and *tert*-butyl protons, respectively. Furthermore, the ^{1}H and ^{14}N TRIPLE spectrum confirmed the relative signs of hfcc's of the protons and nitrogen atoms except for the *tert*-butyl protons. The observed ESR spectrum was successfully simulated by the use of the hfcc's obtained from ^{1}H and ^{14}N ENDOR spectrum (Fig. 1(b)). The experimental and calculated values of hfcc's and *g*-value of **7** were summarized in Table 1. Assignments were carried out with the help of theoretically calculated hfcc's (Fermi contact analysis using DFT calculation). The calculated values underestimate the observed ones, but the trend of relative magnitude and absolute signs reproduce well the experimental results. These observed hfcc's suggest that the unpaired electron of the radical delocalizes on the phenalenyl skeleton and the oxygen atoms of the methoxy group.

[1] 1,3-Diazaphenalene **11** was a synthetic intermediate of the 7,9-diaza-6-oxophenalenoxyl derivative, see Section 2.4 and [7f].

[2] 6-Hydroxy-7,9-diazaphenalenone derivative **13** was also a synthetic intermediate of the 7,9-diaza-6-oxophenalenoxyl, see Section 2.8 and [7f].

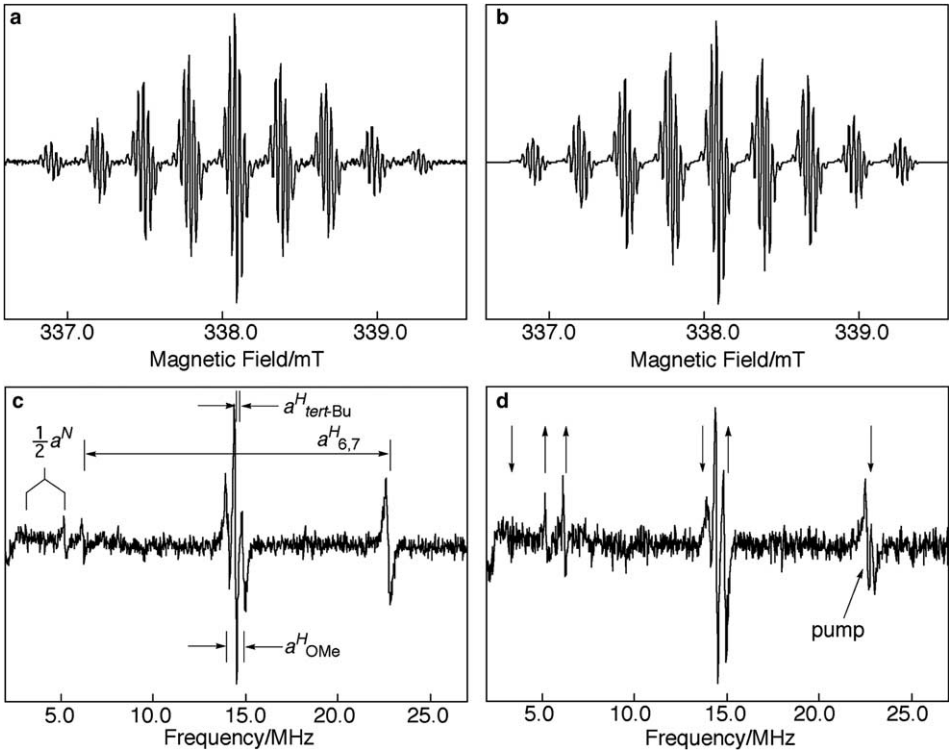


Fig. 1. Observed hyperfine ESR (a, 290 K), simulated (b), ^{1}H and ^{14}N ENDOR (c, 270 K), and ^{1}H and ^{14}N TRIPLE (d, pump frequency: 22.71 MHz, 270 K) spectra for **7** generated by the treatment of **11** with *p*-chloranil in a toluene solution (8×10^{-5} M). The microwave frequency used for the ESR measurement was 9.489354 GHz. The observed *g*-value is 2.0035.

Table 1
Hyperfine coupling constants (hfcc's) of ^{1}H and ^{14}N nuclei[a] and *g*-values

Radical	a^H					a^N	*g*-value
	4,9	6,7	OMe	2-*t*-Bu	5,8-*t*-Bu	1,3	
7		−0.590 (−0.452)	+0.032 (+0.146)[c]	±0.0025[b] (+0.0046)	±0.0025[b] (−0.0008)	+0.299 (+0.260)	2.0035
6[d]	−0.638	−0.715		+0.006	+0.021	+0.292	2.0033

[a] The experimental hfcc's were determined by spectral simulation with the help of ^{1}H and ^{14}N ENDOR in a toluene solution. The relative signs of the hfcc's were determined in terms of ^{1}H-TRIPLE spectroscopy. Values in parentheses were results of Fermi contact analysis by the DFT method (using GAUSSIAN-03 at the UBLYP/6-31G**//UBLYP/6-31G**) [13].
[b] The sign was experimentally unknown.
[c] The marked deviation seen in the protons on the methoxy groups is likely because the calculation does not take the dynamic rotational motion into consideration.
[d] Ref. [9a].

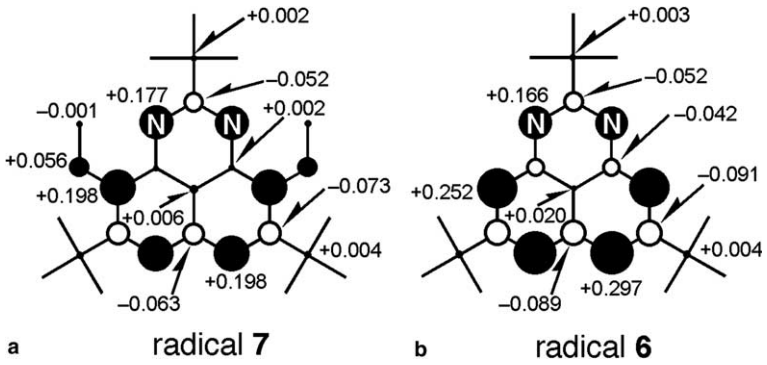

Fig. 2. Spin density distributions calculated at the UBLYP/6-31G**//UBLYP/6-31G** level of theory for (a) radical **7** and (b) **6**. Vacant and filled circles denote negative and positive spin densities, respectively.

3.4. Comparison of the spin densities of 7 with those of 6

The experimental values of hfcc's and *g*-value of the parent 1,3-diazaphenalneyl radical **6** are also summarized in Table 1 [9a,b]. The slightly larger *g*-value (2.0035) of **7** than that of **6** (2.0033) indicates the contribution of unpaired electrons on the oxygen atoms of the methoxy group. Interestingly, the hfcc's of the protons at the 6- and 7-positions of **7** are smaller than those of **6**. This observation shows that the spin densities at the 6- and 7-positions decrease.

In order to clarify the difference of the electronic spin structures between **7** and **6**, we have carried out density functional theory calculations for **7** and **6** by using GAUSSIAN-03 at the UBLYP/6-31G**//UBLYP/6-31G** level (Fig. 2(a) and (b)) [13]. It showed that a robust π-spin polarized and delocalized nature similar to the parent 1,3-diazaphenalenyl **6** is maintained in **7**, and that large spin densities exist on not only nitrogen and carbon atoms at 1-, 3-, 4-, 6-, 7-, and 9-positions but also the two oxygen atoms at the methoxy groups of **7**. By comparing the spin densities of **7** with those of **6**, it turns out that the spin densities at the 6- and 7-positions decrease. This is consistent with the hfcc's of the protons at the 6- and 7-positions described above. In addition, the small but measurable increase in the spin density of nitrogen atoms in the DFT calculation corresponds to the small increase of observed hfcc's on nitrogen atoms of the radical **7**.

4. Summary

Dimethoxy-substituted 1,3-diazaphenalenyl radical **7** was generated, and its solution and solid-state stability has been studied. The stability of **7** in both solution and solid states was found to be lower than the parent 1,3-diazaphenalenyl **6** that showed a high stability enough to be isolated in air. The spin structure was clarified by ESR/ENDOR/TRIPLE spectroscopies and theoretical calculation, which shown that the unpaired electron of **7** delocalizes onto the phenalenyl skeleton and oxygen atoms of methoxy groups. By comparing the hfcc's obtained by ESR measurements and the spin densities calculated by DFT method of **7** with those of **6**, it is clarified that the spin densities at 6- and 7-positions of **7** decrease while those of the 1- and 3-positions (on nitrogen atoms) increase. We believe that this study will be helpful to design new heteroatom-incorporated phenalenyl derivatives, and to control their electronic-spin structure and properties. The origin of the instability of **7** is under consideration, and the syntheses of other azaphenalenyl derivatives are in progress.

Drawing 1.

supramolecular assemblies based on 4,4′-Bim system by the introduction of alkyl substituents with the aim to control H-bonding pattern and networks in terms of the steric effects. Recently, Turnbull and coworkers [10] have reported the crystal structures of methyl-substituted 4,4′-Bim (Me-4,4′-Bim) as the dihydrate and trifluoroacetic acid salt including their H-bonded networks. In this report, we have newly synthesized 2-ethyl-substituted 4,4′-Bim (Et-4,4′-Bim), and revealed its crystal structure together with its hydrate. Moreover, we have disclosed crystal structure of anhydrous Me-4,4′-Bim, demonstrating a substantial effect of water molecule on forming H-bonded networks. These continuous and systematic studies provide a unique opportunity for the creation of supramolecular assemblies based on 4,4′-Bim system (see Drawing 1).

2. Experimental

2.1. Materials and methods

^{1}H NMR spectra were recorded on a JEOL EX-270 spectrometer with Me_4Si as an internal standard. Infrared spectra were recorded using KBr plates on JASCO FT/IR-660M. EI-MS spectra were recorded at 70 eV on a Shimadzu QP-5000. Melting points were measured by a Yanaco micro melting point apparatus and were uncorrected. Elemental analyses were performed at the Analytical Center of Graduate School of Science, Osaka University. R_f values on TLC were recorded on E. Merck precoated (0.25 mm) silica gel 60 F_{254}. The plates were sprayed with a solution of 10% phosphomolybdic acid in 95% EtOH and then heated until the spots become clearly visible. Triphenylmethyl (Tr)-protected Me-4,4′-Bim was prepared by the reported procedure [11]. DMF was dried over CaH_2 and distilled under reduced pressure prior to use. The reaction requiring anhydrous conditions was performed under an argon atmosphere.

2.2. Synthesis of Me-4,4′-Bim and Et-4,4′-Bim

2.2.1. 2-Ethyl-4,5-diiodoimidazole (2)

Iodine (26.8 g, 106 mmol) was placed in a 1-L round-bottomed flask and dissolved with $CHCl_3$ (130 mL). To this solution was added 2-ethylimidazole (**1**) (5.04 g, 52.4 mmol) in 2 M NaOH aqueous solution (130 mL, 260 mmol), and the mixture was stirred at room temperature for 18 h. To the resulting mixture was added a saturated $Na_2S_2O_3$ aqueous solution (100 mL), then the $CHCl_3$ layer was separated. The aqueous layer was neutralized to pH 7 with acetic acid. The resulting solid was collected by filtration and then washed with water (100 mL), to give **2** (17.7 g, 97%) as light reddish yellow powder: R_f 0.49 (1:3 hexane/ethyl acetate); ^{1}H NMR ($CDCl_3$) δ 1.28 (t, 3H, J = 7.7 Hz), 2.78 (q, 2H, J = 7.7 Hz); IR (KBr) 3100–2300, 2974, 1550 cm^{-1}; EI-MS, *m/z* 348 (M^+, 100%).

2.2.2. 2-Ethyl-4-iodoimidazole (3)

Diiodoimidazole **2** (12.9 g, 37.1 mmol) and Na_2SO_3 (39.1 g, 310 mmol) were placed in a 2-L round-bottomed flask and suspended in 30% EtOH aqueous solution (620 mL). This mixture was refluxed for 17 h. EtOH was removed by distillation under reduced pressure. The residue was extracted with ethyl acetate (600 mL). The organic layer was washed with a saturated NaCl aqueous solution (600 mL) and dried over Na_2SO_4, then filtered and concentrated under reduced pressure to give **3** (7.39 g, 90%) as light yellow powder: m.p. 146–147 °C; R_f 0.49 (ethyl acetate); ^{1}H NMR ($CDCl_3$) δ 1.31 (t, 3H, J = 7.7 Hz), 2.78 (q, 2H, J = 7.7 Hz), 7.01 (s, 1); IR (KBr) 3100–2400, 2975, 1564 cm^{-1}; EI-MS, *m/z* 222 (M^+, 100%). *Anal.* Calc. for $C_5H_7IN_2$: C, 27.05; H, 3.18; N, 12.62. Found: C, 27.45; H, 3.13; N, 12.73%.

2.2.3. N-triphenylmethyl-2-ethyl-4-iodo-imidazole (4)

Iodoimidazole **3** (5.05 g, 22.9 mmol) and Et_3N (6.40 mL, 46.0 mmol) were dissolved in DMF (50 mL) in a 100-mL round-bottomed flask. To this solution was add TrCl (12.8 g, 45.8 mmol) and stirred at room temperature for 51 h. The resulting mixture was poured into water (100 mL) and extracted with ethyl acetate (300 mL). The organic layer was washed with a saturated NaCl aqueous solution (300 mL) and dried over Na_2SO_4, then filtered and concentrated under reduced pressure. The residue was recrystallized from ethyl acetate/ether to give **4** (5.31 g, 50%) as a white powder: m.p. 191–192 °C; R_f 0.21 (CH_2Cl_2); ^{1}H NMR ($CDCl_3$) δ 0.77 (t, 3H, J = 7.4 Hz), 1.90 (q, 4H, J = 7.4 Hz), 6.70 (s, 1), 7.07–7.18 (m, 6), 7.29–7.37 (m, 9); IR (KBr) 3160, 2986, 2966 cm^{-1}; FAB-MS, *m/z* 465 ($M^+ + 1$). *Anal.* Calc. for $C_{24}H_{21}IN_2$: C, 62.08; H, 4.56; N, 6.03. Found: C, 62.15; H, 4.47; N, 6.06%.

2.2.4. N,N′-bis(triphenylmethyl)-2,2′-diethyl-4,4′-biimidazole (5)

Tr-protected 4-iodo-imidazole **4** (1.00 g, 2.16 mmol), Et_3N (0.60 mL, 4.31 mmol) and $Pd(PPh_3)_4$ (132 mg, 0.11 mmol) were placed in a 10-mL thick-walled ampule tube and dissolved with DMF (3 mL). The reaction

mixture was degassed by a repeated freeze-pump-thaw method, then the tube was sealed. After being stirred at 110 °C for 45 h, the tube was opened at room temperature, and the precipitate was collected by filtration. The combined solid were washed with water (20 mL), ethyl acetate (10 mL) and ether (10 mL) to give **5** (394 mg, 58%) as a grayish white powder: m.p. 265–268 °C; R_f 0.62 (ethyl acetate); ^{1}H NMR ($CDCl_3$) δ 0.74 (t, 6H, J = 7.4 Hz), 1.90 (q, 4H, J = 7.4 Hz), 7.14–7.20 (m, 14 H), 7.24–7.30 (m, 18H); IR (KBr) 2922 cm^{-1}; FAB-MS, m/z 674 (M^+ + 1).

2.2.5. 2,2′-Dimethyl-4,4′-biimidazole (Me-4,4′-Bim)

Tr-protected 2,2′-dimethyl-4,4′-biimidazole (1.94 g, 3.01 mmol) and EtOH (22.5 mL) were placed in a 100-mL round-bottomed flask. To this suspension was added 1 M HCl aqueous solution (12 mL, 12 mmol) and this mixture was refluxed for 3 h. EtOH was removed by distillation under reduced pressure. Water (20 mL) was added to the residue, then filtered. The filtrate was neutralized with a saturated K_2CO_3 aqueous solution. The mixture was concentrated under reduced pressure. The residue was dissolved with EtOH (20 mL) and filtered, then the filtrate was concentrated under reduced pressure, to give Me-4,4′-Bim (403 mg, 83%) as a white powder: m.p. 260–262 °C (dec.); R_f 0.30 (MeOH); ^{1}H NMR (DMSO-d_6, 80 °C) δ 2.25 (s, 6H), 6.90 (s, 2H), 11.4 (brs, 2H); IR (KBr) 3500–2400, 3064, 1680, 1560 cm^{-1}; EI-MS, m/z 162 (M^+, 100%). *Anal.* Calc. for $C_8H_{10}N_4 \cdot (H_2O)_{0.3}$: C, 57.33; H, 6.37; N, 33.43. Found: C, 57.50; H, 6.43; N, 33.30%.

2.2.6. 2,2′-Diethyl-4,4′-biimidazole (Et-4,4′-Bim)

Following the same procedure as that for Me-4,4′-Bim, Et-4,4′-Bim was obtained as a white powder (94% yield): m.p. 269–271 °C; R_f 0.46 (MeOH); ^{1}H NMR (DMSO-d_6, 80 °C) δ 1.21 (t, 6H, J = 7.4 Hz), 2.61 (q, 4H, J = 7.4 Hz), 6.92 (s, 2H); IR (KBr) 3300–2300, 2973, 1647, 1578 cm^{-1}; EI-MS, m/z 190 (M^+, 100%). *Anal.* Calc for $C_{10}H_{14}N_4$: C, 63.13; H, 7.42; N, 29.45. Found: C, 62.97; H, 7.25; N, 29.17%.

2.3. X-ray crystallographic studies of Me-4,4′-Bim, Et-4,4′-Bim and Et-4,4′-Bim dihydrate

X-ray crystallographic measurements for single crystals were made on Rigaku Mercury CCD area detector with graphite monochromated Mo Kα radiation (λ = 0.7107 nm). All structures were determined by direct method using SHELXLS-86 and refined by least squares on F^2 with SHELXL-97. All non-hydrogen atoms were refined anisotropically and all hydrogen atoms were included but not refined. Crystal data and experimental details of the structure determination are listed in Table 1.

Table 1
Crystal data and structure refinement parameters for Me-4,4′-Bim, Et-4,4′-Bim and Et-4,4′-Bim · 2H_2O

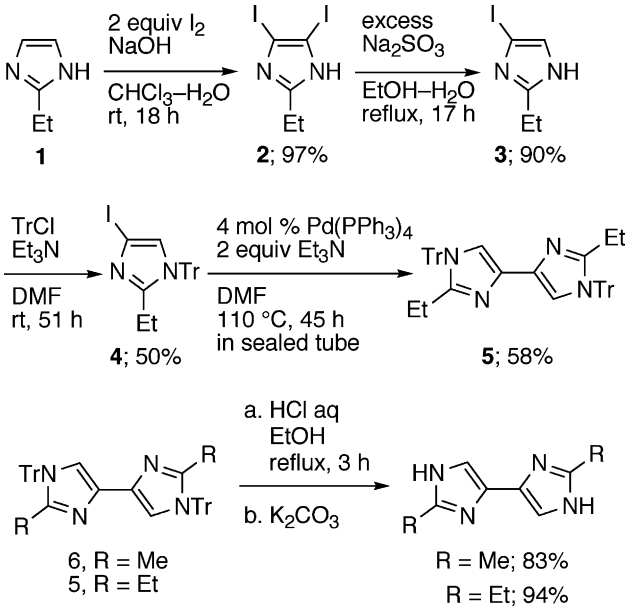
3. Results and discussion



3.1. Syntheses of R-4,4′-Bim

Tr-protected Et-4,4′-Bim (**5**) were synthesized in four steps from 2-ethylimidazole (**1**) according to the procedure for Tr-protected Me-4,4′-Bim (Tr = triphenylmethyl) [11]. Imidazole **1** was converted into 2-ethyl-4-iodoimidazole (**3**) by iodination followed by the reductive removal of iodine atom at 5-position. The amino group of **3** was protected by TrCl using Et_3N, to give Tr-protected iodoimidazole **4**. Homo-coupling reaction of **4** in the presence of catalytic amount of $Pd(PPh_3)_4$ and excess amount of Et_3N in a sealed tube gave Tr-protected Et-4,4′-Bim **5**. The deprotection reaction of **5** and Tr-protected Me-4,4′-Bim **6** were carried out by the treatment with excess HCl and following neutralization using K_2CO_3, to give neutral Me- and Et-4,4′-Bim (Scheme 1). Single crystals of anhydrous Me- and Et-4,4′-Bim suitable for X-ray crystal structure analysis were obtained by vapor-diffusion method from MeOH solution using $CHCl_3$ and acetone, respectively. Dihydrate Et-4,4′-Bim was crystallized by cooling of hot aqueous solution of Et-4,4′-Bim.

3.2. Crystal structures of Me-4,4′-Bim, Et-4,4′-Bim and Et-4,4′-Bim · 2H_2O

3.2.1. Me-4,4′-Bim

Me-4,4′-Bim anhydrate crystallized in the trigonal system. The molecular structure is nearly planar with

Scheme 1.

the dihedral angle of 1.4 °, and the methyl group lies in the plane of imidazole ring (Fig. 1(a)). The molecule possesses *trans*-conformation with the inversion center on the central C–C bond. The planar molecular structure with *trans*-conformation in this crystal structure shows the resemblance to those of Me-4,4′-Bim dihydrate and trifluoroacetic acid salt [10]. Interestingly, the imidazole rings of Me-4,4′-Bim molecules are linked by direct N(1)–H···N(2) H-bondings to form a six-membered cyclic motif in each imidazole ring (Fig. 1(b)). The closest N(1)···N(2) distance is 2.85 Å, and the dihedral angle between two imidazole rings linked by the H-bond is ca. 76°. The cyclic motif stacks along the *a*-axis to construct a tube-like cavity surrounded by methyl groups with ~3 Å of diameter. The interplanar distance of the stacking is 3.5 Å, and noticeable overlap on the biimidazole skeleton is not found (Fig. 1(c)). The H-bonding interactions construct a three-dimensional network in the crystal (Fig. 1(d)).

3.2.2. Et-4,4′-Bim

In the crystal structure of Et-4,4′-Bim anhydrate, one imidazole-ring and ethyl group are crystallographically independent. Similar to the molecular structure of Me-4,4′-Bim, Et-4,4′-Bim possesses the nearly planar molecular structure (dihedral angle of 1.3°) and the *trans*-conformation (Fig. 2(a)). The hydrogen atoms of N–H groups (H1a and H1b) are positionally disordered

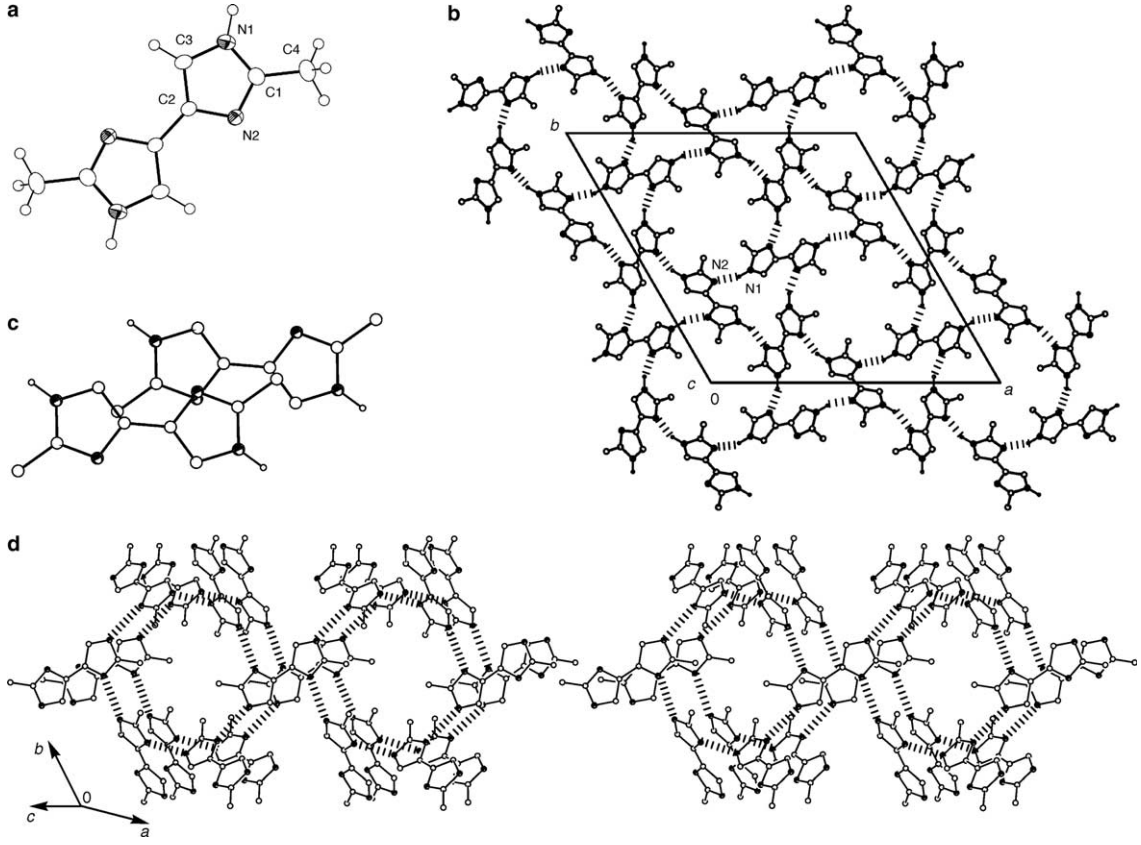


Fig. 1. Crystal structure of Me-4,4′-Bim. ORTEP view of the molecular structure, showing the atomic labelling scheme (a). Perspective view along the *c*-axis, showing the H-bonded cyclic motifs and cavity (b). Overlap mode in a stacking structure (c). Stereoview of the crystal packing, showing the three-dimensional H-bonded network (d). Dotted lines show the H-bonding interactions. H-bonding distances (D···A in Å): N(1)···N(2), 2.85.

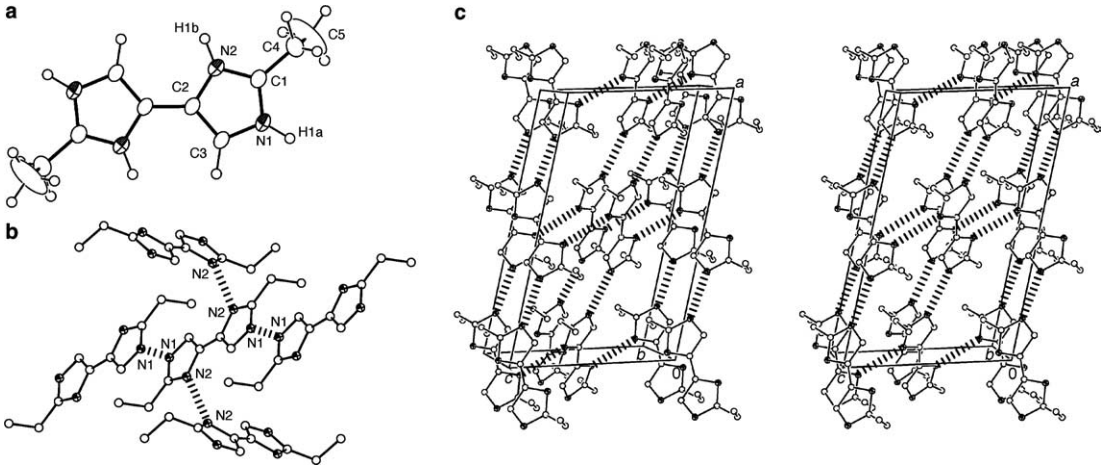

Fig. 2. Crystal structure of Et-4,4′-Bim. ORTEP view of the molecular structure, showing the atomic labelling scheme (a). Partial packing of Et-4,4′-Bim, illustrating the H-bonding scheme (b). Stereoview of the crystal packing, showing the three-dimensional H-bonded network (c). The hydrogen atoms of N–H groups (H1a and H1b) were located and refined as half-occupancy atoms. Dotted lines show the H-bonding interactions. H-bonding distances (D···A in Å): N(1)···N(1), 2.81; N(2)···N(2), 2.92.

and were treated as half occupancy atoms during refinement (Fig. 2(a)). In this structure, two types of H-bonding interaction are observed (Fig. 2(b)). One is N(1)–H···N(1) interaction which connect Et-4,4′-Bim molecules along the [1 1 0] and [−1 1 0] directions. The other is N(2)–H···N(2) interaction elongated along the

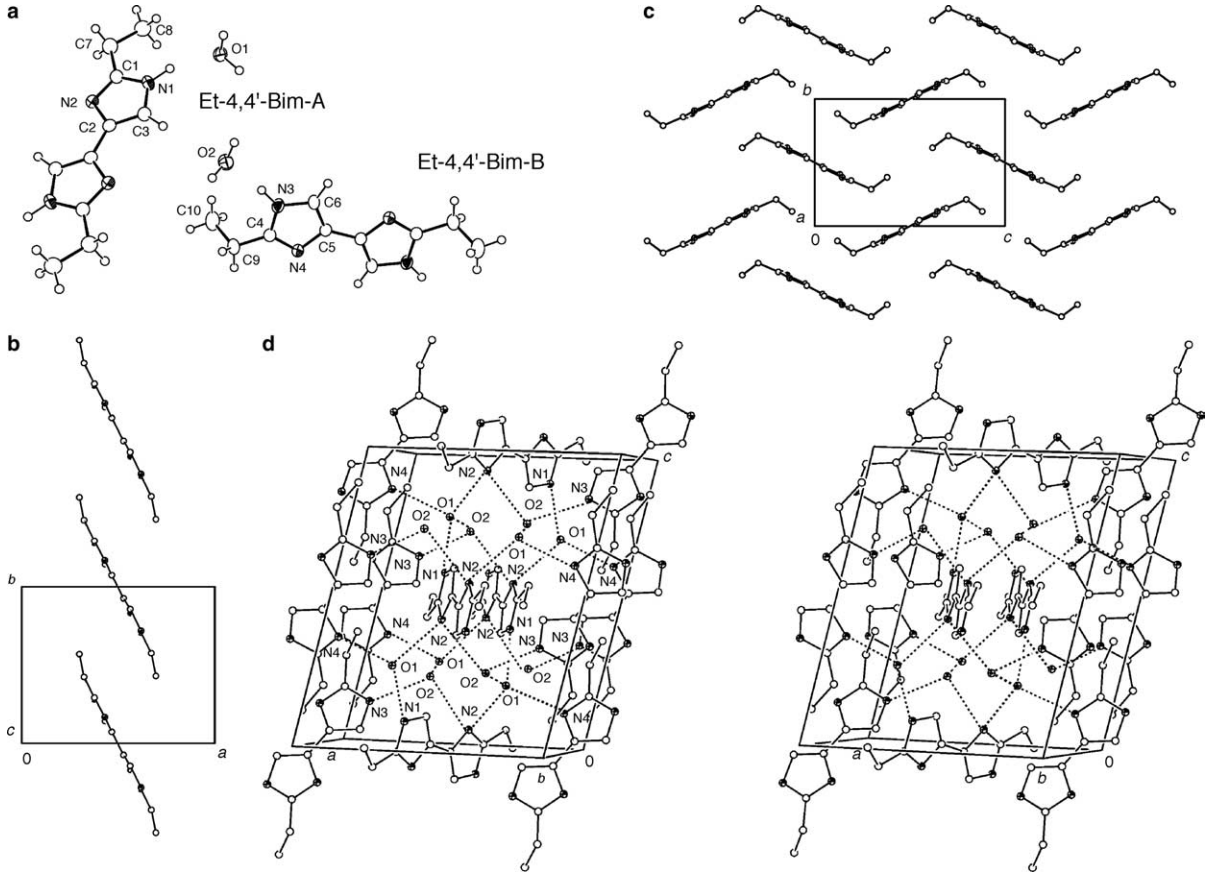

Fig. 3. Crystal structure of Et-4,4′-Bim · $2H_2O$. ORTEP view of the molecular structure, showing the atomic numbering scheme (a). Stacking structure of Et-4,4′-Bim-B molecules viewed along the *c*-axis (b). Arrangement of Et-4,4′-Bim-B molecules in the *bc* plane (c). Stereoview of the crystal packing, showing the H-bonding interactions and a channel structure (d). Dotted lines show the H-bonding interactions. H-bonding distances (D···A in Å): N(1)···O(1), 2.87; N(2)···O(1), 2.94; N(2)···O(2), 2.98; N(3)···O(2), 2.88; N(4)···O(1), 2.79; O(1)···O(2), 2.89.

a-axis. The distances of N(1)–H···N(1) and N(2)–H···N(2) H-bondings are 2.81 and 2.92 Å, respectively. Neighboring Et-4,4′-Bim molecules linked by N(1)–H···N(1) H-bonding are parallel, while dihedral angle between those linked by N(2)–H···N(2) H-bonding 82° (Fig. 2(b)). These H-bonding interactions build up a three-dimensional network (Fig. 2(c)). Notably, the formation of H-bonding interactions between same kinds of nitrogen atoms is the most noticeable difference with the H-bonding nature of Me-4,4′-Bim in which the H-bonding is formed between different nitrogen atoms, N(1) and (2).

3.2.3. Et-4,4′-Bim · $2H_2O$

With in a unit cell, there are two crystallographically independent Et-4,4′-Bim (Et-4,4′-Bim-A and -B) and water molecules. Both of Et-4,4′-Bim-A and -B molecules possess the inversion centers on central C–C bonds (Fig. 3(a)). Their planar structures with *trans*-conformation is similar to that shown in the crystal structure of Et-4,4′-Bim anhydrate. The Et-4,4′-Bim-A molecule stacks with 3.9 Å of face-to-face distance to form columnar structure parallel to the *b*-axis (Fig. 3(b)). Within this column, noticeable overlap is not found. On the other hand, Et-4,4′-Bim-B molecules are arranged in herringbone structure along the *bc* plane (Fig. 3(c)). In contrast to the formation of direct N–H···N H-bonding in anhydrous Et-4,4′-Bim, all nitrogen atoms on Et-4,4′-Bim molecules of this crystal form H-bondings with water molecules. These H-bonding interactions through water molecules connect Et-4,4′-Bim molecules, resulting in the construction of three-dimensional H-bonded network (Fig. 3(d)). In addition to these structural features, a channel structure parallel to the *b*-axis was observed in this crystal structure, which is fulfilled by the water molecules (Fig. 3(d)).

4. Conclusion

The synthesis and crystal structural analysis of new 4,4′-Bim derivative, Et-4,4′-Bim, including its dihydrate were demonstrated. Furthermore, we revealed the characteristic H-bonded structure of anhydrous Me-4,4′-Bim. In these crystal structures, the difference of alkyl-substituent strongly affects the H-bonding pattern, N(1)···N(2) in anhydrate Me-4,4′-Bim, and N(1)···N(1) and N(2)···N(2) in anhydrate Et-4,4′-Bim. In the crystal structure of dihydrate Et-4,4′-Bim, including of water molecules prevented the formation of direct N–H···N H-bondings and changed the H-bonded network and molecular packing. The construction of channel structures of anhydrate Me-4,4′-Bim and dihydrate Et-4,4′-Bim shows their potential to bind small guest molecules. These observations indicate that 4,4′-Bim system is useful and interesting ligands of assembled metal complexes and component molecule of H-bonded charge-transfer complexes exhibiting interesting conducting, magnetic and host–guest properties based on the characteristic H-bonding structures. Further studies on 2,2′-substituted-4,4′-Bim system is in progress for the construction of their assembled metal complexes and CT complexes.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with Cambridge Crystallographic Data Centre, CCDC Reference Nos. 250710–250712. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1233 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

optical and electric properties and crystal structures of IDTPY itself, H_2NRAL complex with a diaqua oxonium ($H_5O_2^+$) and NO_3^- salt of IDTPY.

2. Experimental

2.1. Materials and methods

IDTPY was synthesized according to our previous report [7]. Chlorobenzene used for electrooxidation was distilled over CaH_2. All chemicals were of reagent grade and used without further purification. Infrared and electronic spectra were recorded using KBr pellets on Perkin–Elmer 1600 series FT-IR and Shimadzu UV-3100PC, respectively. The alternating current electric conductivity measurements for compressed pellets were performed by a conventional two-probe method using gold paint and Au wire (25 μm ∅). Melting points were measured by a Yanaco micro melting point apparatus and were uncorrected. Elemental analyses were performed at the Analytical Center of Graduate School of Science, Osaka University.

2.2. General procedure for syntheses of the CT complexes of IDTPY

IDTPY was placed in a 20-mL round-bottomed flask and dissolved with CH_2Cl_2. To this solution was added the CH_2Cl_2 solution of acceptor, and the resulting precipitates were collected.

2.2.1. IDTPY–DDQ complex

Dark violet powder. m.p. 218–219 °C (dec); IR (KBr) 2212, 1560, 1515, 1472 cm^{-1}; UV (KBr) 1252, 532 nm; *Anal*. Calc. for $(C_{14}H_7S_2I)(C_8N_2O_2Cl_2)$: C, 44.54; H, 1.19; N, 4.72. Found; C, 44.87; H, 1.23; N, 5.16%.

2.2.2. IDTPY–$(H_2CNAL)_{1.5}$ complex

Dark violet powder. m.p. 238–240 °C (dec); IR (KBr) 2227, 2212, 1540, 1516, 1472 cm^{-1}; UV (KBr) 1246, 538, 268 nm; *Anal*. Calc. for $(C_{14}H_7S_2I)(C_8H_2N_2O_4)_{1.5}$: C, 47.94; H, 1.55; N, 6.45. Found: C, 47.85; H, 1.59; N, 6.33%.

2.2.3. $IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^+$ complex

Dark green microcrystals. m.p. 133–135 °C (dec); IR (KBr) 1560, 1514, 1472 cm^{-1}; UV (KBr) 1058, 544, 240 nm; *Anal*. Calc. for $(C_{14}H_7S_2I)(C_6N_2O_8)(H_5O_2)$: C, 38.05; H, 1.92; N, 4.44. Found: C, 38.25; H, 1.86; N, 4.80%.

2.3. Synthesis of the $IDTPY^{\bullet+} \cdot NO_3^-$ salt

IDTPY (7.3 mg, 0.020 mmol) was placed in a 20-mL round-bottomed flask and dissolved with chlorobenzene (10 mL). To this solution was added $Bu_4N^+NO_3^-$ (18.3 mg, 0.060 mmol) and transferred to a 10-mL V-shape tube. Electrooxidation was conducted under constant current of 3 μA for 10 days at room temperature, to give the $IDTPY^{\bullet+} \cdot NO_3^-$ salt (3.7 mg) as black microblocks. mp 154–156 °C (dec); IR (KBr) 1678, 1552, 1515, 1476 cm^{-1}; UV (KBr) 1158, 542 nm; *Anal*. Calc. for $(C_{14}H_7S_2I)(NO_3)$: C, 39.27; H, 1.65; N, 3.27. Found; C, 40.02; H, 1.79; N, 3.00%.

2.4. X-ray structure analyses of IDTPY, $IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^+$ complex, and $IDTPY^{\bullet+} \cdot NO_3^-$ salt

Single crystals of IDTPY suitable for X-ray analysis were obtained by slow evaporation of its CH_2Cl_2 solution at room temperature. X-ray data of IDTPY and $IDTPY^{\bullet+} \cdot NO_3^-$ were collected on a Rigaku/MSC Mercury CCD with graphite monochromated Mo Kα ($\lambda = 0.71070$ Å) radiation. Crystallographic measurement for $IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^+$ was made on Rigaku RAXIS-RAPID Imaging Plate with graphite monochromated Mo Kα ($\lambda = 0.71075$ Å) radiation. The structures were solved by direct methods using SIR92 [10] for IDTPY and $IDTPY^{\bullet+} \cdot NO_3^-$, and SHELXS-86 [11] for $IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^+$, and refined by full-matrix least squares methods based on F^2. The non-hydrogen atoms were refined anisotropically. The crystallographic data are summarized in Table 1. The extent of disorder in the $IDTPY^{\bullet+} \cdot NO_3^-$ salt was determined by refining the site occupancies of the I1, I2, S1, S2, C2 and C8 sites which were at averaged positions as follows: 50.4 electrons at I1, 2.6 electrons at I2, 14 electrons at S1 and S2, and 10 electrons at C2 and C8.

3. Results and discussion

3.1. Syntheses of CT complexes and salt of IDTPY

The CT complexes of IDTPY with DDQ, H_2CNAL and H_2NRAL were synthesized by the mixed method. The $IDTPY^{\bullet+} \cdot NO_3^-$ salt was prepared and crystallized by the electrooxidation in a chlorobenzene solution under a constant current of 3 μA. The molecular ratios of

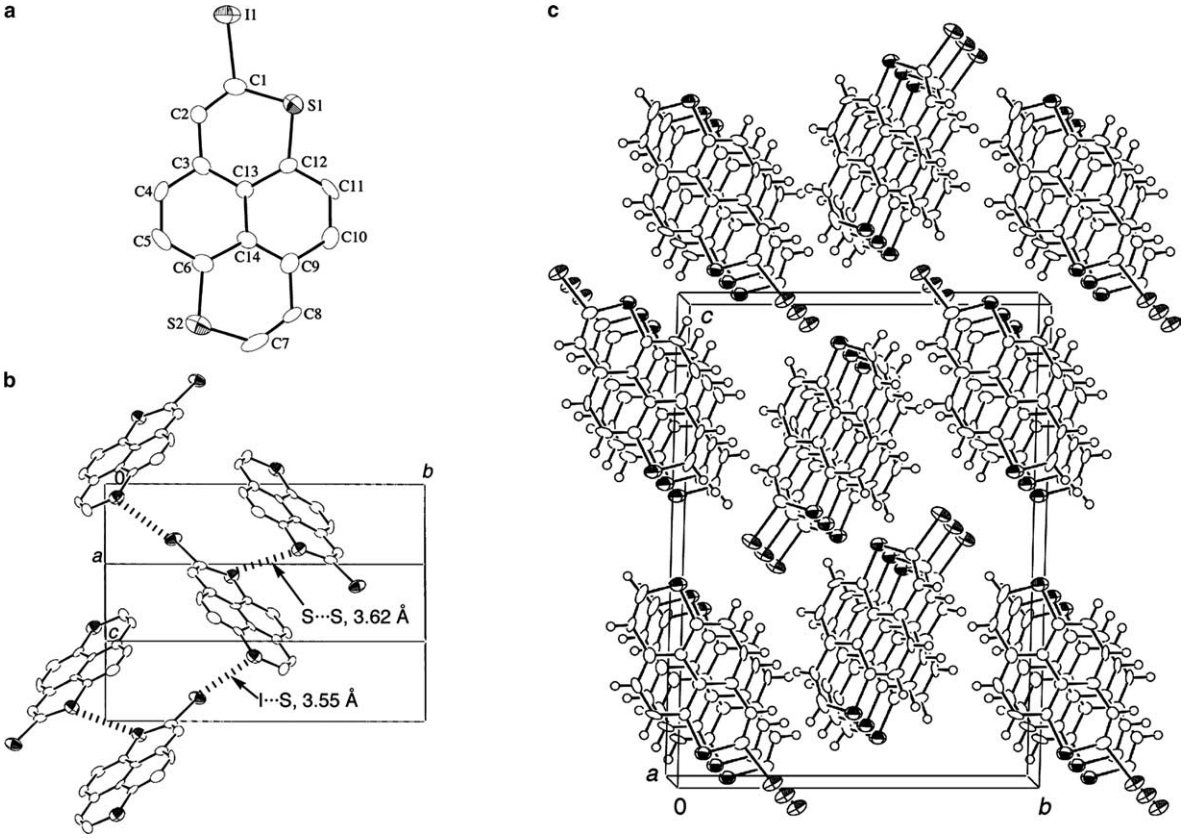

Fig. 1. Crystal structure of IDTPY. Molecular structure of IDTPY with atomic numbering (a), intermolecular strong I···S (3.55 Å) and weak S···S (3.62 Å) interactions (b), and packing diagram along the *a*-axis (c). Hydrogen atoms in (a) and (b) are omitted for clarity.

donor and acceptor of their CT complexes and salt were determined by elemental analyses and X-ray analyses.

3.2. X-ray diffraction studies of IDTPY, $IDTPY^{\bullet+}\cdot NRAL^{2-}\cdot H_5O_2^{+}$ and $IDTPY^{\bullet+}\cdot NO_3^{-}$

3.2.1. Crystal structure of IDTPY

IDTPY crystallizes in a monoclinic system, $P2_1/c$. A crystal structure of IDTPY was shown in Fig. 1. There are intermolecular strong I···S (3.55 Å) and weak S···S (3.62 Å) interactions within the sum of van der Waals radii (3.78 and 3.60 Å, respectively), forming the two-dimensional sheet structure through these interactions (Fig. 1(b)). IDTPY forms a uniform columnar structure along the *a*-axis with an interplanar distance of 3.5 Å (Fig. 1(c)). These non-covalent interactions such as halogen-bonding and π···π interaction shown in the crystal of IDTPY were also observed in that of DIDTPY [7].

3.2.2. Crystal structure of $IDTPY^{\bullet+}\cdot NRAL^{2-}\cdot H_5O_2^{+}$

The CT complex crystallizes in a triclinic system, $P\bar{1}$. The H_2NRAL complex of IDTPY with $H_5O_2^{+}$ is composed of $IDTPY^{\bullet+}$, $NRAL^{2-}$, and $H_5O_2^{+}$ in 1:1:1 ratio (Fig. 2(a)). In bond distances of the IDTPY molecule, S(1)–C(1) and C(12)–S(1) bonds are shortened by 0.05 Å, and C(1)–C(2) and C(2)–C(3) bonds are elongated by 0.02–0.06 Å compared with those of IDTPY (Tables 2 and 3), indicating that an ionicity of IDTPY is +1 [6b]. Furthermore, a very strong hydrogen-bond-

C(1)–I(1)	2.076(10)

ing (O···O distance, 2.43 Å) observed between crystal waters suggests the existence of $H_5O_2^+$ [12]. Considering molecular ratio of these components, the ionicity of the H_2NRAL moiety is determined as −2.

A dimeric structure of $IDTPY^{\bullet+}$ with intra- and interdimer distances of 3.4 and 3.6 Å is formed in the crystal (Fig. 2(b) and (c)). Multiple hydrogen-bondings (2.73–2.85 Å) between $H_5O_2^+$ and $NRAL^{2-}$ molecules, and dimeric pair of $NRAL^{2-}$ molecules with an intradimer distance of 3.4 Å were constructed, resulting in the formation of one-dimensional chain structure along the *b*-axis (Fig. 2(d)). There are two short I···O contacts (2.90 and 3.12 Å) between $IDTPY^{\bullet+}$ and $NRAL^{2-}$ molecules (Fig. 2(e)). The dimer of $IDTPY^{\bullet+}$ was connected with a weak S···S interaction (3.67 Å) along the *b*-axis (Fig. 2(f)). These π···π, I···O and S···S interactions might hamper the alternated stacking motif.

3.2.3. Crystal structure of the $IDTPY^{\bullet+} \cdot NO_3^-$

In the NO_3^- salt of IDTPY, a molecular ratio of donor and counter anion is 1:1, indicating that an ionicity of IDTPY is +1. $IDTPY^{\bullet+} \cdot NO_3^-$ crystallizes in a

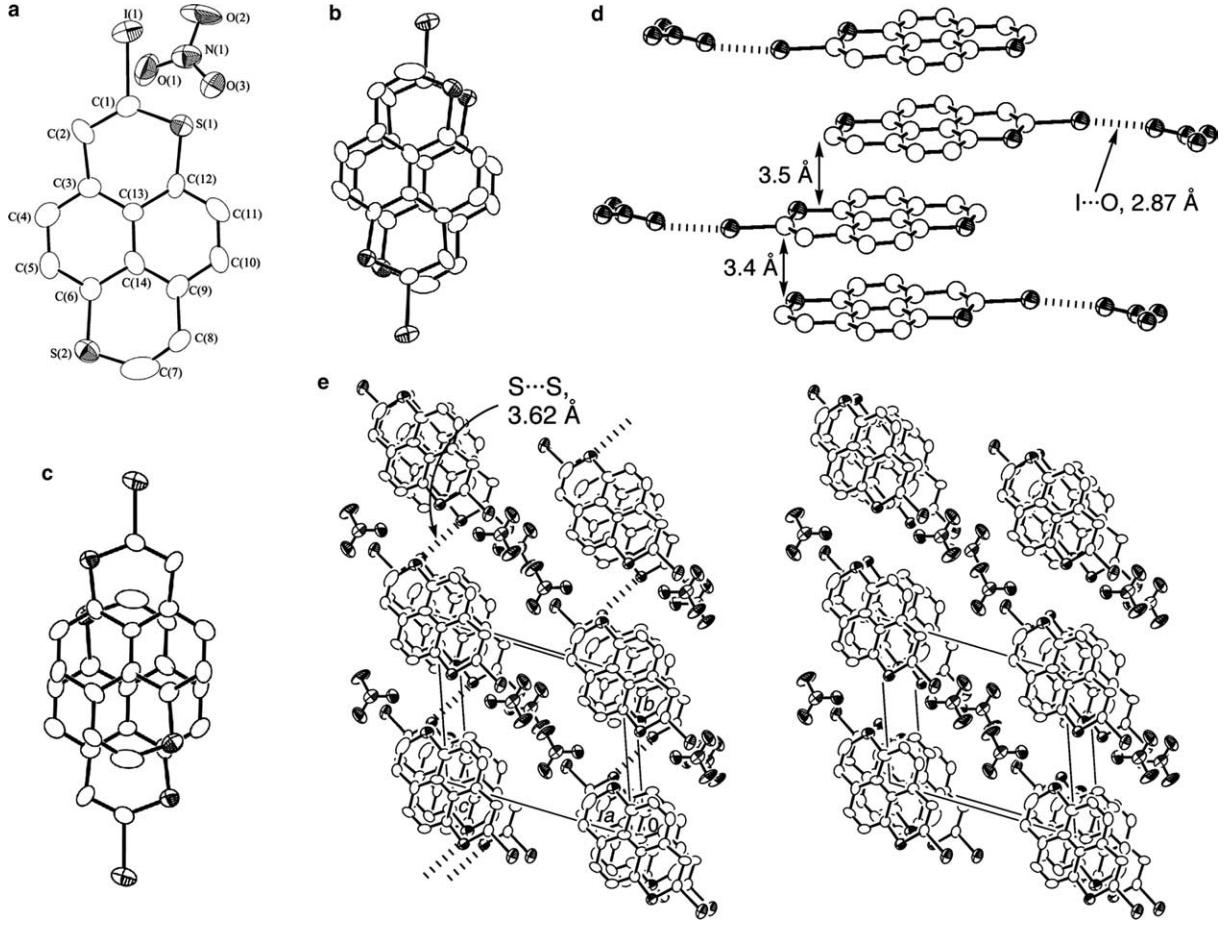

Fig. 3. Molecular structure of $IDTPY^{\bullet+} \cdot NO_3^-$ with atomic numbering (a), overlap modes of intradimer and interdimer of $IDTPY^{\bullet+}$ ((b) and (c), respectively), columnar stacking structure of $IDTPY^{\bullet+}$ and short I···O interaction between $IDTPY^{\bullet+}$ and NO_3^- (d), and packing diagram along the *a*-axis (e). Hydrogen and disordered iodine (except for (a)) atoms are omitted for clarity.

Table 4
Selected physical data for CT complexes and salt of IDTPY

	IDTPY–DDQ	IDTPY–$(H_2CNAL)_{1.5}$	$IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^+$	$IDTPY^{\bullet+} \cdot NO_3^-$

triclinic system, $P\bar{1}$. Iodine (I1, I2), sulfur (S1, S2) and carbon (C2, C8) atoms of $IDTPY^{\bullet+}$ are disordered by the ratio of 95:5 (in I1 and I2) and 3:1 (in S1 and C2, S2 and C8), respectively (Fig. 3(a)). $IDTPY^{\bullet+}$ forms a columnar structure with a dimeric pair of $IDTPY^{\bullet+}$ with intradimer and interdimer distance of 3.4 and 3.5 Å, respectively (Fig. 3(b)–(d)). There is a short I···O contact (2.87 Å) between $IDTPY^{\bullet+}$ and NO_3^- (Fig. 3(d)). Furthermore, a weak S···S interaction (3.62 Å) between columns of $IDTPY^{\bullet+}$ was shown, resulting in the construction of a two-dimensional sheet structure (Fig. 3(e)).

3.3. Optical properties

In order to elucidate and characterize electronic structures of the CT complexes and salt of IDTPY, we measured infrared and electronic spectra in KBr pellets. In the infrared spectra of the IDTPY–$(H_2CNAL)_{1.5}$ complex, nitrile stretching frequencies due to H_2CNAL moieties were observed at 2212 and 2227 cm^{-1} (Table 4), suggesting the co-existence of two chemical species of $HCNAL^-$ and H_2CNAL.[1] In the IDTPY–DDQ complex, the CN stretching frequency of 2212 cm^{-1} indicates a completely charge-transfered ionic nature of this complex [13].

Electronic spectra of these CT complexes and salt were shown in Fig. 4. An intramolecular transition due to $IDTPY^{\bullet+}$ was shown at 18 000 cm^{-1} in the electronic spectrum of IDTPY–DDQ (Fig. 4(a)). In other CT complexes and salt of IDTPY, the strong absorptions (18000 cm^{-1}) due to the intramolecular transition of $IDTPY^{\bullet+}$ (Fig. 4(b)–(d)) suggest that ionicities of IDTPY moieties were to be +1. In the H_2NRAL complex and NO_3^- salt of IDTPY, CT bands due to the intradimer transitions of the $IDTPY^{\bullet+}$ dimer were observed around 8000–9500 cm^{-1} (Table 4 and Fig. 4(c) and (d)). In other CT complexes of IDTPY, CT bands were measured around 8000 cm^{-1}, which might be assignable to the CT transition between donors, or donor and acceptor (Fig. 4(a) and (b)).

[1] In the IR spectra, the nitrile stretching frequencies due to $Bu_4N^+ \cdot HCNAL^-$ and $H_2CNAL \cdot 6H_2O$ are observed at 2206 and 2236 cm^{-1}, respectively. See also [4a].

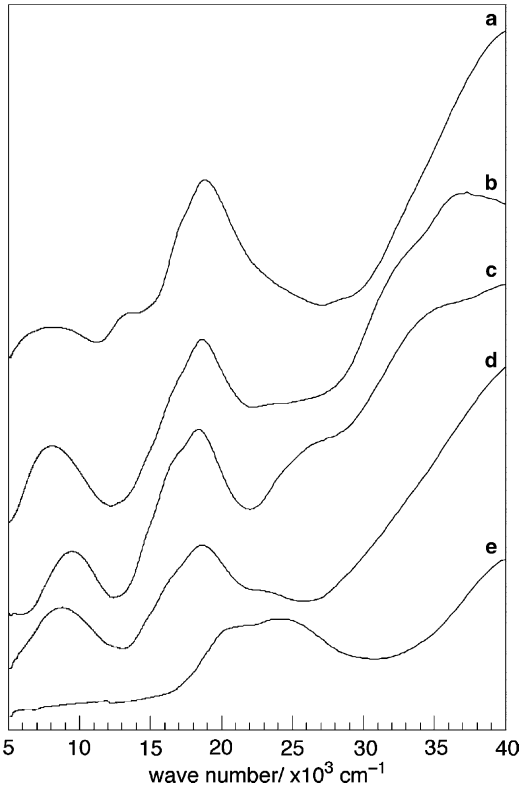

Fig. 4. Electronic spectra of IDTPY–DDQ (a), IDTPY–$(H_2CNAL)_{1.5}$ (b), $IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^+$ (c), $IDTPY^{\bullet+} \cdot NO_3^-$ (d) and IDTPY (e) in KBr pellets.

3.4. Electric conductivities

Electric conductivities of the CT complexes and salt of IDTPY were measured by two-probe method in compressed pellets. Their room temperature electric conductivities (σ_{rt}) and activation energies (E_a) are summarized in Table 4. These CT complexes and salt were semiconductors with 1.5×10^{-2}–7.3×10^{-6} S cm^{-1}.

4. Conclusion

The new CT complexes and salt of IDTPY with DDQ, H_2CNAL, $NRAL^{2-}$ and NO_3^- were synthesized. These CT complexes and salt with CT bands around 8000–9500 cm^{-1} were semiconductors. We demonstrated that strong intermolecular halogen-bondings through the iodine atom of IDTPY played an important

role in the formation of multi-dimensional structures of IDTPY, $IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^{+}$ and $IDTPY^{\bullet+} \cdot NO_3^{-}$. These results urge us to synthesize further DTPY derivatives with an iodine atom and to explore their CT complexes and salts, which contributes to not only the conductive materials science but also supramolecular chemistry.

5. Supplementary data

Crystallographic data for the structural analyses has been deposited with the Cambridge Crystallographic Data center, CCDC Nos. 251160–251162 for IDTPY, $IDTPY^{\bullet+} \cdot NRAL^{2-} \cdot H_5O_2^{+}$ and $IDTPY^{\bullet+} \cdot NO_3^{-}$. Copies of these informations may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 IEZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

6.65; N, 17.34. Found: C, 69.50; H, 6.78; N, 17.45%. ESR (benzene): $g = 2.0066$, $a_N = 11.70$, $a_H = 2.11$ (2H) and 0.94 G (2H). UV–Vis (λ_{max}, THF; nm [M^{-1} cm^{-1}]): 319 [37 000], 500 [5400].

3. Crystallographic characterization

Analysis was carried out on a Bruker-Nonius KappaCCD diffractometer using Mo Kα radiation, $\lambda = 0.71073$ Å, $\mu = 0.081$ mm^{-1}, $T = 293$ K. Red needle, formula $C_{14}H_{16}N_3O$, MW = 242.3, $0.65 \times 0.35 \times 0.15$ mm, triclinic, $P\bar{1}$, $a = 8.6102(2)$ Å, $b = 12.2878(3)$ Å, $c = 12.5928(3)$ Å, $Z = 4$, $V = 1293.19(5)$ $Å^3$, density (calc.) = 1.245 g/cm^3, $F(000) = 516$, N = unique 4512 reflections were measured using ω scans to $2\theta_{max} = 50.02°$. The structure was solved by direct methods and refined on F_0^2 (with full-matrix least-squares using SHELXTL97 [6]) using 325 parameters with 358 reflections having $I > 2\sigma$ to give $R_1 = 0.0466$, $wR_2 = 0.1188$: for all reflections, $R_1 = 0.0604$, $wR_2 = 0.1298$. See Table 1 for selected bond lengths and angles. Fig. 1 gives an ORTEP representation with the numbering scheme used in this article. Full crystallographic details may be found in CIF format with the Cambridge Crystallographic Databank, CCDC Deposition No. 178242.

4. Magnetic characterization

Magnetization measurements for **1** were carried out on a Quantum Design SQUID MPMS magnetometer at the University of Massachusetts Amherst Nanomagnetics Characterization Facility (NSF CTS-0116498) on polycrystalline samples placed in gelatin capsules and held in place with a small amount of cotton. Measurements were made using an external magnetic field of 1000 Oe over a temperature range of 1.8–300 K. Before measurements, a helium purge procedure was carried out to avoid oxygen contamination. Final measurements were corrected for temperature independent contributions. The results are discussed in the following section.

5. Results and discussion

In the crystal structure of **1**, there are two distinct geometries, which we shall denote **1a** and **1b**. The major difference between the forms is the nitroxide-phenyl torsional angle, 23.9° and 8.4° in **1a** and **1b**, respectively. The interannular torsional angles are quite similar, 35.8° and 37.1° in **1a** and **1b**, respectively. Throughout the lattice, **1** forms chains through an aryl C–H to pyrimidine nitrogen contacts along the *b*-axis, via (**1a**)*meta*-CH···ON(**1b**) contacts of 2.71 Å, and (**1b**)NO···*ortho*-HC(**1a**) of 2.81 Å. The chains align in

antiparallel fashion, held together by contacts from the nitroxide oxygens of **1b** to the aryl CH *meta* to the nitroxide of **1a**′ in an adjacent chain, with (**1a**′)NO···HC-pyrimidine(**1b**) 2.95 Å. The latter contacts yield a set of approximately in-plane dimerization contacts between **1a** and **1b** forms. The intrachain NO···H(C) angles are 170.8° (**1a**–**1b**) and 118.4° (**1b**–**1a**), and the interchain angle 135.3° (**1a**′–**1b**). These alternating **1a**–**1b** 1-D chains yield fairly close intermolecular contacts that are possible sites for exchange interactions. The various intra-chain and inter-chain contacts are shown in Fig. 2.

In addition to the nitroxide to HC contact chains described above, pseudo-*para* **1a**:**1a**′ stacked pairs occur among the **1a** sites only, with 3.77 Å between phenyl rings, as is also shown in Fig. 2. This should provide some degree of π-overlap between the phenyl units of the **1a**:**1a**′ dimers. There is *no* comparable stacking or dimeric association of the **1b** molecules.

Finally, there are no nitroxide–nitroxide contacts closer than 5.8 Å to provide more direct spin-pairing contacts between these main spin density sites of **1**. Any intermolecular exchange mechanisms must therefore occur by more indirect pathways, such as spin polarization across close interatomic contacts between sites of small to modest spin population.

In the magnetic measurements, the high temperature limit of χT is reasonably close to the value of 0.375 emu K/Oe mol expected for $S = 1/2$ spin carriers, as shown in Fig. 3. A Curie–Weiss fit of $1/\chi$ versus T for $T > 100$ K gives $C = 0.342$ emu K/Oe mol, $\theta = (+)0.02$ K. The value for the Curie constant corresponds to $S = 1/2$ spin carriers with $g = 1.91$. The Weiss constant shows that the high temperature behavior is essentially paramagnetic. As the temperature drops below 100 K, however, there is significant antiferromagnetic (AFM) deviation from ideal Curie–Weiss behavior, indicating significant intermolecular exchange.

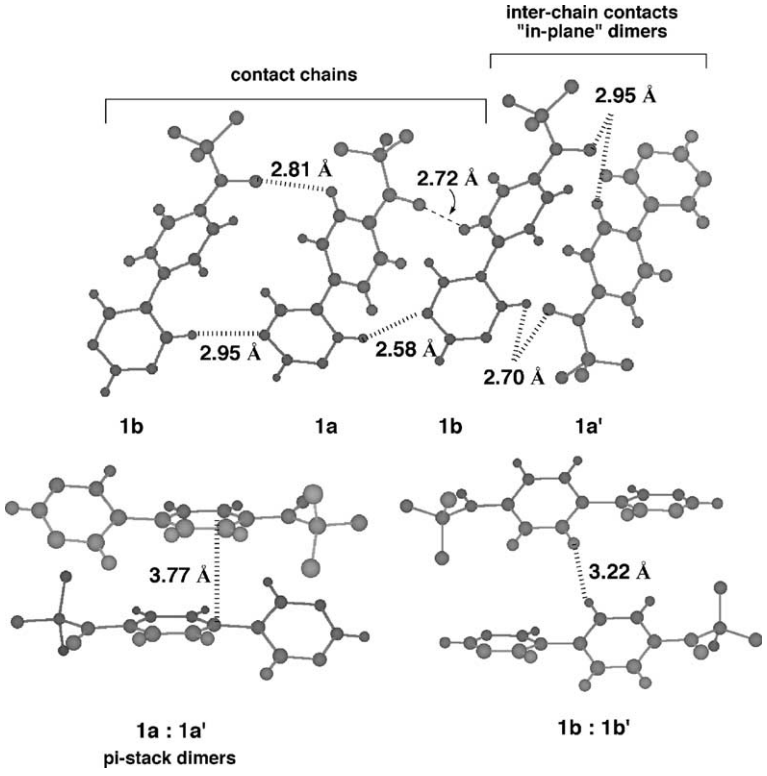

Fig. 2. Scheme of crystallographic contacts in **1**.

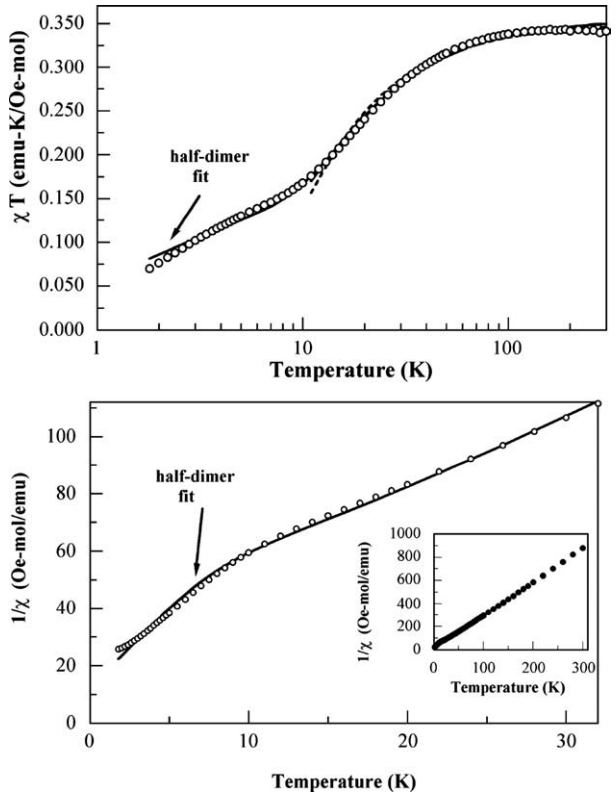

Fig. 3. χT vs. T (above) and $1/\chi$ vs. T (below) plots for **1** at 1000 Oe. The upper plot shows fits to Eqs. (1) (---) and (2) (-●-) for $T > 10$ K, to Eq. (3) (—) across the full temperature range measured. Eqs. (1) and (2) fits virtually overlap. The lower plot shows the fitted curve from Eq. (3) (—). The inset in the lower plot shows the full temperature range $1/\chi$ vs. T data.

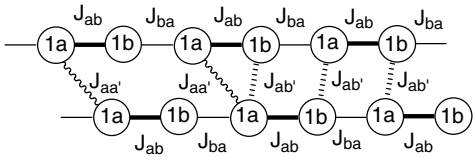
Based on the close contacts models shown in Fig. 2, the magnetic behavior could reasonably be fit either to alternating chain or dimer models. The **1a**···**1b**···**1a** contacts could provide an alternating 1-D chain exchange mechanism throughout the solid, involving all molecules. The **1a**′(CH)···**1b**(ON) contacts (Fig. 2) could provide a spin-pairing contact mechanism between all **1a**′:**1b** pairs. Quite differently, the π-stacked **1a**:**1a**′ dimers could provide spin pairing of half of the molecules in the cell, with no obvious analogous mechanism for **1b**:**1b**′ spin pairing. A **1a**:**1a**′ spin-pairing mechanism could be further aided by the planarity of the **1a** form – which thus should be more spin-delocalized – by comparison to the twisted **1b** form. It is not clear based on inspection which (if any) of these interactions would dominate the magnetic behavior of the overall material, or whether the result would be a complex mix of all these interactions.



We fit the χT versus T data to both Bleaney–Bowers [7] dimer (**1a**′–**1b** pairings) and Bonner–Fisher [8] 1-D AFM chain (**1a**–**1b**) models. The former is the typical, simple spin-pairing model given by Eq. (1) with exchange constant $J_{ab'}/k$ between **1a** and **1b**. The latter models an alternating 1-D Heisenberg chain system of $S = 1/2$ spin units with two different, alternating exchange constants J_{ab}/k and $J_{ba}/k = \alpha \cdot J_{ab}/k$ using Eq. (2) [8c]. Finally, we fit the data to the model of Eq. (3) in which half the spins are paired with a significant exchange constant $(J/k)_{aa'}$(**1a**:**1a**′), and the others have paramagnetic, Curie-type behavior, a "half-dimer" model, with a mean field term (θ) included. The constants and variables used in the equations are defined as follows: N is the Avogadro's number, g the Lande factor, β the Bohr magneton constant, k the Boltzmann constant, T the Kelvin temperature, χ the paramagnetic susceptibility, θ the mean field term, J/k the exchange energy. The coefficients A–F for Eq. (2) are given elsewhere [8c], and incorporate $\alpha = J_{ab}/J_{ba}$ as a fittable exchange alternation parameter. Scheme 1 shows the possible interactions involved

$$\chi_{BB} = \frac{N_{dimer} g^2 \beta^2}{kT}(1/(3 + e^{-2J/kT})) \quad (\text{where } J = J_{ab'}), \tag{1}$$

$$\chi_{BF} = \frac{N g^2 \beta^2}{kT}\left(\frac{A + Bx + Cx^2}{1 + Dx + Ex^2 + Fx^3}\right) \quad (\text{where } x = |J_{ab}/kT|), \tag{2}$$

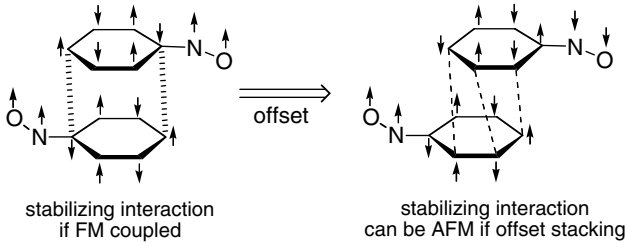
$$\chi_{half-dimer} = \frac{g^2 \beta^2}{k(T - \theta)} \times \left[0.5 N_{dimer}(1/(3 + e^{-2J/kT})) + 0.5 N_{monomer}\frac{g^2 \beta^2}{k}\right] \quad (\text{where } J = J_{aa'}). \tag{3}$$

Fig. 3 and Table 2 summarize the results. The single Bleaney–Bowers and alternating chain fits in the figure are shown only for $T > 10$ K, since both models gave substantial deviations from the $\chi T(T)$ data at lower temperatures. The fit to the half-dimer model was by far the best over the full temperature range studied, yielding a half-dimeric AFM spin-pairing interaction of $J/k = (-)15.9$ $K = (-)130$ J/mol, with $g = 1.95$ and a mean field Weiss constant of $\theta = (-)2.2$ K. Based on the superior agreement of experiment to this fit combined with the crystallographic evidence, we feel that the half-dimer spin pairing through the **1a**:**1a**′

Scheme 1. Potential close exchange contacts in **1**. See Fig. 3 and Eqs. (1) and (2).

Table 2
Exchange constants derived from fits of Eqs. (1)–(3) to data of Fig. 3

Model	Exchange (J/k)	θ	g(calc.)
BB	(−)9.8 K		1.94
BF	(−)7.0 K ($\alpha = 0.82$)		1.95
Half-dimer	(−)15.9 K	(−)2.2 K	1.95



Eqs. (1) and (2) fits (BB and BF, respectively) were out carried for $T > 10$ K, the fit to Eq. (3) is across the full range of data. For the BF model, $J = J_{ab}$, $\alpha J = J_{ba}$.

dimer-stacks is the dominant magnetic exchange interaction in the crystal, although additional weaker interactions may be present.

We were initially surprised that the half-dimer model fit the magnetic behavior as well as Fig. 3 shows, given the multiple possible exchange paths that are present. But, the close π-stacking overlap in the **1a**:**1a**′ pairs appears to provide the most effective exchange among a set of weak exchange mechanisms, with the **1b** molecules having no effective intermolecular exchange interactions detectable under our conditions. ESR hyperfine analysis and computational modelling show [5b] that no site on the pyrimidine ring of **1** has >0.6% absolute spin population, so the (**1a**′)NO···HC-pyrimidine(**1b**) contact is unlikely to be a significant exchange contributor, consistent with the poor fit to the single spin-pairing model of Eq. (1). By comparison, UB3LYP/6-31G* computations [9][2] on the **1a**:**1a**′ dimer stacks at the crystallographic geometry show that the AFM exchange coupled state is favored over the FM coupled triplet by 100 J/mol, which corresponds to $2J/k = (-)12$ K. This is less than half the experimental half-dimer model exchange coupling of $2J/k = (-)260$ J/mol, but qualitatively correct. Given that the intradimer stacking may become smaller with stronger interactions at very low temperatures, the agreement of theory and experiment is encouraging.

Interestingly, a simple McConnell I model analysis of the **1a**:**1a**′ dyads predicts that they would be FM coupled *if* perfectly pseudo-*para* stacked (Scheme 2) [10]. However, the **1a**:**1a**′ dyads are offset relative to perfect *para*-packing. Yamaguchi et al. [11] have shown computationally that such offsets have a strong influence on qualitative application of the McConnell I approach, which accounts for the fact that this model is very difficult to apply in experimental practice. The offset apparently leads to AFM exchange that we attribute to the half of the molecules in the solid that form the **1a**:**1a**′ dyads, based on the computations described above.

[2] Computations were carried out at the fixed crystallographic geometry of a π-stacked A–A′ dyad of **2**, using a broken-symmetry wavefunction for the singlet state, replacing the *tert*-butyl groups with hydrogen atoms, and ignoring zero point energy corrections. For the singlet multiplicity computation of the π-stacked dyad, $\langle S^2 \rangle = 1.02$.

Scheme 2. FM exchange of aryl nitroxide radicals stacked in perfect pseudo-*para* orientation, vs. possible AFM exchange if the stacking is offset.

6. Conclusions

Multiple intermolecular contacts between small spin density sites in organic solids can confound the expectations of simplified explanations that seek to correlate overlap between large spin density sites with magnetic behavior, as others have noted [3]. Studies such as this one can help to determine which kinds of interactions tend to dominate in such situations, when multiple exchange pathways are plausible based on crystallography.

2. Experimental

2.1. 1-Bromo-3-N-tert-butyl-N-hydroxylaminobenzene (3)

A solution of 11.3 mL (17.0 mmol) *n*-butyllithium (1.5 M in hexanes) was added to a solution of 4.00 g (17.0 mmol) 1,3-dibromobenzene in diethyl ether (80 mL) under argon at −78 °C. The suspension was allowed to stir for 30 min, warmed to room temperature at which time it went into solution, and then cooled to −78 °C. A solution of 2.22 g (25.4 mmol) of 2-methyl-2-nitrosopropane in diethyl ether (15 mL) was added, and the reaction was left to stir overnight at ambient temperature. Aqueous saturated ammonium chloride (25 mL) was added and the organic layer was separated and washed with water. The aqueous layer was extracted with diethyl ether and the combined organic layers were dried over magnesium sulfate. Evaporation of the solvent yielded pale yellow crystals (air-sensitive!) that were dried under vacuum and used immediately in the next step.

2.2. 1-Bromo-3-N-(tert-butyl-N-tert-butyldimethylsiloxylamino)benzene (4)

All of product **3** from the previous step was dissolved in DMF (20 mL) and added to 5.11 g (33.9 mmol) of *tert*-butylchlorodimethylsilane plus 3.46 g (50.8 mmol) of imidazole in a dry flask. The resulting solution was stirred under argon for 24 h at 50 °C. Distilled water (20 mL) was added, and the solution was extracted with hexanes. The combined organic layers were dried over magnesium sulfate and evaporated under reduced pressure. Purification by column chromatography on silica gel with hexanes yielded 5.35 g (89%) of protected hydroxylamine **2** as a clear colorless oil. ^{1}H NMR (200 MHz, $CDCl_3$): δ −0.12 (broad s, 6H), 0.90 (s, 9H), 1.09 (s, 9H), 7.04–7.24 (m, 3H), 7.43 (s, 1H).

2.3. 1-[N-tert-Butyl-N-(tert-butyldimethylsiloxy)amino]-3-benzoic acid (5)

A solution of 9.1 mL of *tert*-butyllithium (1.5 M solution, 13.7 mmol) was added dropwise to 2.23 g (6.21 mmol) of **4** in dry THF at −78 °C, and allowed to stir 2 h. The solution was allowed to warm to room temperature, then cooled to −78 °C, added to an excess of Dry Ice via cannula, and left to stir until all CO_2 bubbling ceased. HCl (20 mL of a 1 M solution) was added and the solution was extracted with dichloromethane, concentrated, and recrystallized from hot dichloromethane to yield 0.982 g (49%) of clear colorless crystals, m.p. 157–158 °C. ^{1}H NMR (400 MHz, $CDCl_3$): δ −0.12 (broad s, 6H), 0.92 (s, 9H), 1.11 (s, 9H), 7.33 (t, 1H, $J = 7.84$ Hz), 7.52 (broad d, 1H, $J = 6.32$ Hz), 7.84–7.87 (doublet of triplets, 1H), 7.99 (broad s, 1H). *Anal*. Calc. for $C_{17}H_{29}NO_3Si$: C, 63.12; H, 9.04; N, 4.33. Found: C, 62.92; H, 8.97; N, 4.30%. IR (KBr, cm^{-1}) 1697 (C=O).

2.4. 3-(N-tert-Butyl-N-hydroxylamino)benzoic acid (6)

Concentrated HCl (5 mL) was added to a solution of 0.555 g (1.72 mmol) of protected *meta*-benzoic acid in 10 mL of ethanol. The solution was stirred until deprotection was complete as evidenced by thin layer chromatography, concentrated under vacuum and then diluted with distilled water (5 mL). The resulting solution was brought to pH 2–3 with 2 M sodium hydroxide and extracted with ethyl acetate. The combined organic portions were dried over magnesium sulfate and evaporated under reduced pressure to a pale yellow crystalline powder. This was recrystallized from acetone to yield 0.228 g (64%) of **6** as pale orange crystals, m.p. 197–199 °C. ^{1}H NMR (400 MHz, DMSO): δ 1.07 (s, 9H), 7.34–7.41 (m, 2H), 7.63–7.66 (doublet of triplets, 1H), 7.80 (t, 1H), 8.42 (s, 1H), 12.8727 (s, 1H). IR (KBr disk, cm^{-1}): 3275 (strong, N–OH), 3100–2500 (medium, broad, OH overlaying C–H stretch), 1701 (strong, C=O stretch). *Anal*. Calc. for $C_{11}H_{15}NO_3$: C, 63.14; H, 7.23; N, 6.69%. Found: C, 62.93; H, 7.27; N, 6.51%. The structure of this compound was confirmed by single crystal X-ray diffractometry, the details of which were submitted to the Cambridge Crystallographic Databank, CCDC deposition # 251475.

2.5. 3-N-(tert-Butyl-N-aminoxyl)benzoic acid (2)

A solution of 0.15 g (0.072 mmol) of **6** in 30 mL of distilled ether was vigorously stirred under argon with 0.34 g (0.14 mmol) of lead dioxide for 1 h. A product-isolation flask was pre-treated with a dilute solution of dichlorodimethylsilane in dichloromethane, then dried under nitrogen. (If the isolation flask is not silanized, the final product sticks tenaciously to the sides, and cannot be scraped off.) The red solution of product was then filtered through a glass frit into the isolation flask. Evaporation of the solvent gave an essentially quantitative yield of red crystalline solid **2** that was used as is for magnetic and crystallographic analysis. Decomposition point 83–86 °C. UV (MeOH, $\lambda_{max}(\varepsilon = M^{-1}\,cm^{-1})$): 289 nm (4700), 393 nm (790). UV (benzene, $\lambda_{max}(\varepsilon = M^{-1}\,cm^{-1})$): 298 nm (7800), 400 nm (1100). IR (KBr, cm^{-1}) 3420 (strong, OH stretch), 1695 (strong, C=O). High resolution MS (EI, m/z): Calc. for $C_{11}H_{14}NO_3$: 208.0974. Found: 208.0972. *Anal*. Calc. for $C_{11}H_{14}NO_3$: C, 63.45; H, 6.78; N, 6.73. Found: C, 60.25; H, 6.59; N, 6.20%. ESR (9.653 GHz, toluene, room temperature): $a(N) = 12.24$ gauss (1 N), $a(H_1 = 1.97$ gauss (3H), $a(H_2 = 0.90$ gauss (1H). Details

of single crystal X-ray diffraction studies are given in a subsequent section below.

3. Synthesis and characterization

The synthesis of **2** is shown in Fig. 1. 1,3-Dibromobenzene was treated with butyl lithium followed by 2-methyl-2-nitrosopropane [5] to make the corresponding hydroxylamine **3**, which was protected with *tert*-butylchlorodimethylsilane to make previously reported [6] compound **4**. This was metallated, treated with CO_2 to give **5**, and deprotected to **6**, a colorless solid that was oxidized with PbO_2 in diethyl ether to give the desired radical **2** as a red crystalline solid. The product nitroxide appears to be highly stable, and can be stored without apparent decomposition for months.

The UV–Vis spectrum of **2** shows absorptions at 290–300 and 390–400 nm, which di not exhibit substantial solvent polarity effects in methanol versus benzene. Interestingly, addition of silica gel completely decolorized benzene solutions of **2**, as we shall describe further below. The infrared spectrum of **2** in KBr shows a strong OH stretching mode as well as the expected carbonyl stretch at 1695 cm^{-1}. The IR and the crystallography (below) show that the carboxylic acid OH groups are strongly hydrogen bonded. The solution ESR spectrum at 9.8 GHz shows hyperfine coupling (hfc) as follows: $a(N) = 12.2$ gauss, $a_1(3H) = 2.0$ gauss, $a_2(1H) = 0.9$ gauss, all obtained in toluene solvent. The larger protic hfc are attributed to the C–H that are *ortho* and *para* to the nitroxide, the smaller to the *meta* C–H. Line broadening of ESR spectra was observed under some room temperature conditions, but typically could be resolved to restore the monoradical spectrum upon cooling to 200–220 K, so long as the concentration was not so high as to give collisional line broadening. We did not observe any peaks consistent with triplet state radical pair formation in toluene at room temperature,

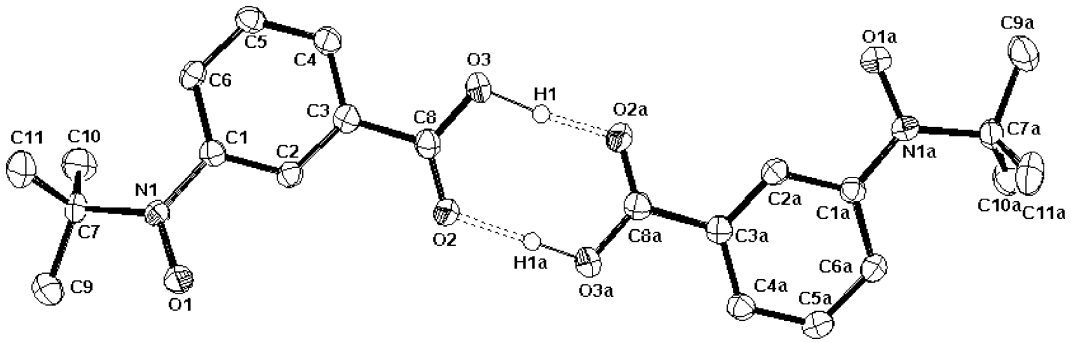

Fig. 2. Crystallographic numbering scheme for **2**. See also Table 1. Form B to left, form A to right.

nor any triplet state turning points or a half-field transition in frozen toluene or in KBr matrices at 77 K.

4. Crystallography

Crystals of **2** were obtained by crystallization in dichloromethane using glassware silanized with dichlorodimethylsilane. Crystallographic details are given below and in Table 1. Fig. 2 shows an ORTEP style representation.

4.1. Radical (2)

Analysis was carried out on a Bruker-Nonius KappaCCD diffractometer using Mo Kα radiation, $\lambda = 0.71073$ Å, $\mu = 0.092\ \mathrm{mm}^{-1}$, $T =$ 100(2) K. Red needle, formula $C_{11}H_{14}NO_3$, $M_w =$ 208.23, $1.10 \times 0.15 \times 0.03$ mm, orthorhombic, $Pca2_1$ (#29), $a =$ 18.5303(7) Å, $b = 6.2148(2)$ Å, $c = 18.9709(7)$ Å, $Z =$ 8, $V = 2184.73(14)$ Å^3, $D_{calc} = 1.266$ g/cm^3, $F(000) = 888$, $N =$ unique 3561 reflections were measured using ω scans to $2\theta_{max} = 50.06°$. The structure was solved by direct methods and refined on F_0^2 (full matrix least squares using SHELXTL97 [7]) using 279 parameters with 2848 reflections having $I > 2\sigma$ to give $R_1 = 0.0481$, $wR_2 = 0.0956$: for all reflections, $R_1 = 0.0718$, $wR_2 = 0.1059$. The absolute structure parameter was −0.9(15). The COOH hydrogens were located from the difference Fourier analysis and refined freely at an isotropic level. Full details were deposited in CIF format with the Cambridge Crystallographic Databank, CCDC deposition # 251476.

5. Magnetic studies

Magnetization measurements for **2** were carried out on a Quantum Design SQUID MPMS magnetometer on polycrystalline samples placed in gelatin capsules and held in place with a small amount of cotton. Measurements were made using external magnetic fields of 500–1000 oersted over a temperature range of 1.8–300 K. Before measurements, a helium purge procedure was carried out to avoid oxygen contamination. Final measurements were corrected for temperature independent contributions. Fig. 3 shows the results.

6. Results and discussion

There are two different structures that form a classic carboxylic acid hydrogen bonded dimer of **2** in its crystal lattice, shown as A and B in Fig. 4. The nitroxide group is nearly coplanar with the phenyl ring in one structure (form A), and somewhat twisted in the other (form B, Table 1). The carboxylic acid moieties are nearly coplanar in both structures, with dihedral torsions of only 3.3° and 5.4°. Save for the difference in nitroxide torsions, the dimer would be essentially centrosymmetric. The two phenyl rings are twisted only 4.7° relative to one another in the hydrogen bonded dyad. Within the crystal structure are no intermolecular nitroxide to nitroxide contacts closer than 6 Å. Thus, there are no spin pairing contacts involving sites of large spin density in the lattice of **2**. There are also no coplanar or nearly coplanar phenyl–phenyl stacking interactions. But, in addition to the hydrogen bonded dimers, **2** forms 1-D chains of nitroxide oxygens to one of the *ortho* aryl CH units. The (N)–O···H–(C) distances are 2.5 Å in one chain, 2.7 Å in the other. The phenyl groups of Ph–NO···H–Ph–NO chains are not coplanar, but rather are all canted about 34° relative to the vector of chain formation, the crystallographic *b*-axis (see Fig. 4). Overall, each crystallographic form of **2** forms chains (A–A–A, B–B–B), which are then linked in an antiparallel fashion by the carboxylic acid hydrogen bonds. There are no π-stacking contacts, but rather formation of herringbone type arrays among the 1-D chains. The combination of the hydrogen bonds and 1-D chain contacts gives rise to ribbons of close contacts between the nitroxide NO units and aryl C–H moieties (Fig. 4).

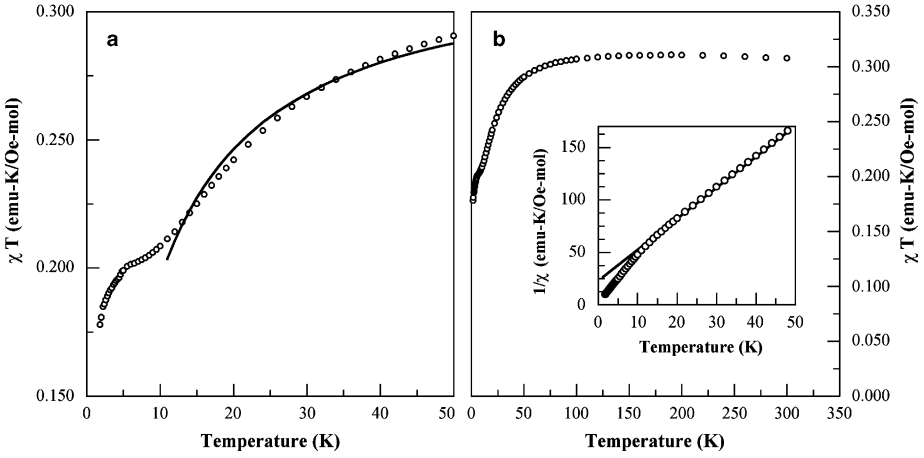

Fig. 3. χT versus T plot at 1000 Oe for **2** at lower temperatures (a) and across full temperature range measured (b). Solid line to left is fit to a spin pairing model for $T > 10$ K data. Inset to left is $1/\chi$ versus T plot, showing the Curie–Weiss fit for $T > 20$ K as a solid line.

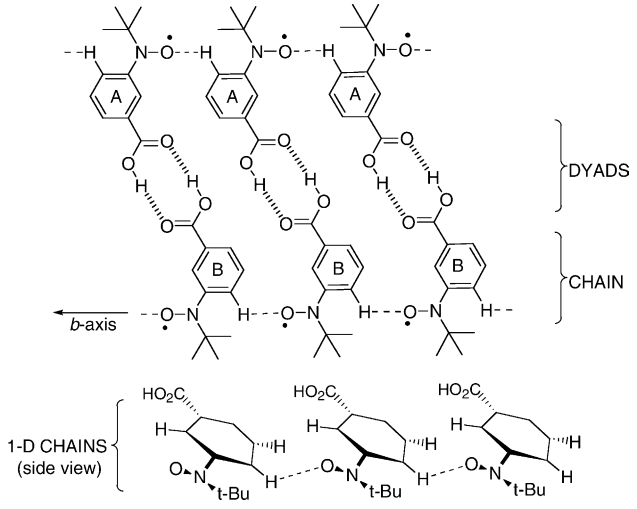

Fig. 4. Schematic representation of close contact motifs in crystalline **2**. Labels "A" and "B" refer to crystallographically distinguishable forms of **2**.

The χT versus T plot for **2** exhibits a higher temperature plateau consistent (though somewhat low) with the value expected for discrete $S = 1/2$ species, but turns down at lower temperatures, showing the onset of antiferromagnetic exchange interactions. The $1/\chi$ versus T plot (Curie–Weiss plot) shows a change in slope at about 10 K. The data correspond to $C \sim 0.31$ emu-K/Oe-mol with $\theta = (-)3.8$ K in the higher temperature range, and C ~ 0.23 emu-K/Oe-mol with $\theta = (-)1.5$ K below 10 K. These results were closely reproducible for three separately synthesized and purified samples of **2**. Elemental analyses for **2** also were reproducible, but low in carbon, commensurate with the low Curie constant. Despite the low carbon in the elemental analysis, the reproducibility of magnetic behavior argues that sample composition is consistent.

The low value of the high temperature Curie constant may be due to water adsorption in the samples, although we could not find solvation water (or any other solvent incorporation) in the crystal diffraction analysis, even at 100 K. The affinity of **2** for some hydrogen bonding environments is notable, particularly its tendency to adsorb to silica based materials out of nonpolar solvents. When isolated by solvent evacuation, radical **2** adsorbs tenaciously to Pyrex, unless the Pyrex is first silanized to reduce the presence of surface hydroxyl groups. Also, dilute solutions of **2** in benzene are completely decolorized by addition of silica gel; a decrease in color is observed for ether solutions, though not complete decolorization. Filtration of the resultant yellow silica gels and stirring in methanol recovers a yellow-colored solution. Fig. 5 shows the ESR spectra of silica gel with **2** adsorbed from benzene and ether solutions. both show the radical, albeit in somewhat different environments with different lineshapes. The results show that **2**

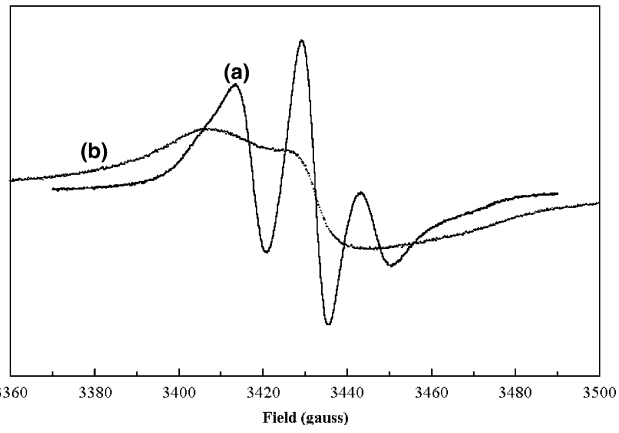

Fig. 5. ESR spectra of **2** adsorbed onto silica gel from benzene (a) and diethyl ether (b). Both spectra shown at room temperature at 9.647 GHz (the spectra do not change significantly upon cooling to 77 K).

adsorbs strongly to silica. We intend to investigate the scope of this effect for covering surfaces and nanoparticles with **2**.

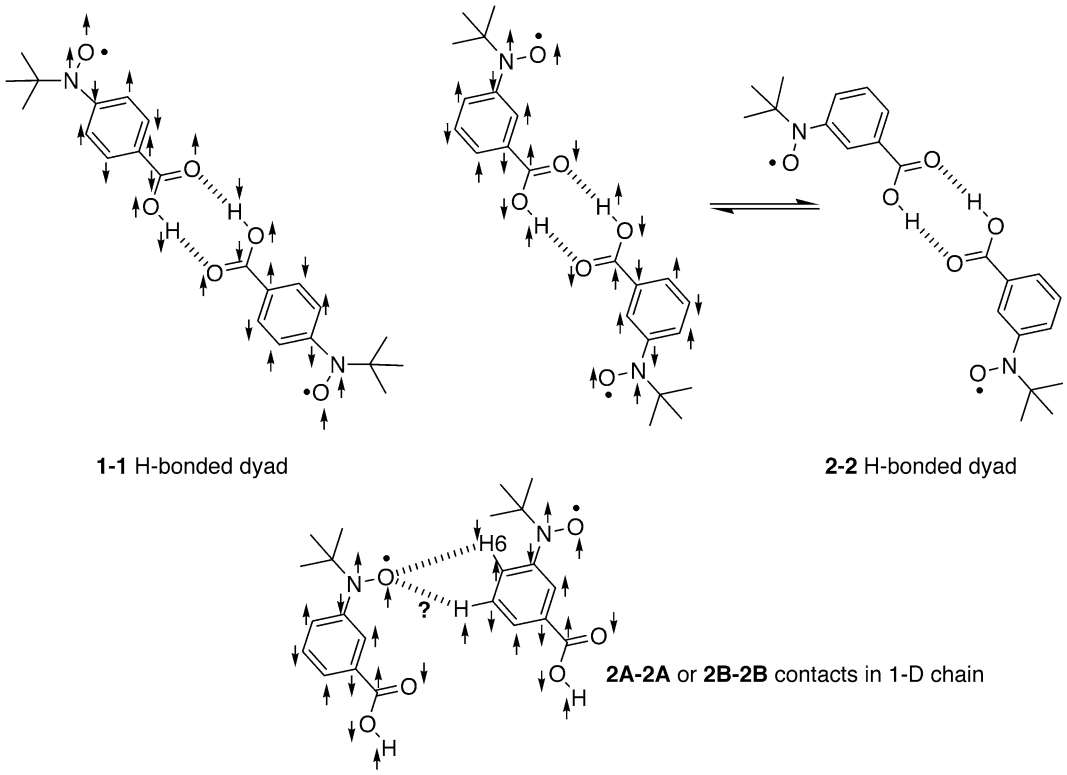
The lower temperature antiferromagnetic (AFM) downturn in **2** shows that there are intermolecular exchange interactions. Since there are no close nitroxide–nitroxide contacts, the exchange pathway presumably follow some indirect spin polarization or similar pathway. Based on the crystallography, either spin pairing through the carboxylic acid hydrogen bond, or 1-D chains along the nitroxide to aryl CH contacts, seem possible.

The analysis is complicated by the change in slope at 10 K, which indicates a change in behavior. For the data above 10 K, a Bleaney–Bowers spin-pairing model [8] represented by Eq. (1) gives a moderately good fit for $J/k = (-)1.6$ K, $\theta = (-)5.0$ K, where all the physical constants have the usual meanings and values. But, the large value of the Weis constant shows that the model does not well represent all the interactions within the sample,

$$\chi = \left(\frac{Ng^2\beta^2}{kT}\right)\frac{2e^{2J/kT}}{1+3e^{2J/kT}}. \quad (1)$$

The change in behavior at $T < 10$ *K* is consistent with the presence of at least two different exchange mechanisms [9]. There are two crystallographically different molecules of **2**, but the closest dimeric contacts all occur between forms A and B, not for A–A or B–B dyads (at least down to 100 K). The only close A–A and B–B type contacts occur along the nitroxide to aryl CH chains. However, the χT versus T data do not fit well to a simple Bonner–Fisher 1-D antiferromagnetic chain over the full temperature range [10]. Possibly some sort of conformational or phase change occurs at 10 K to alter the array of close contacts between molecules of **2**, resulting in the observed alteration of the Curie–Weiss plot. Alternatively, the change in slope may mirror lower and higher temperature limits for two exchange mechanisms (whether or not there is a change in structure at 10 K). We can crudely estimate the presumptive exchange strengths in the two temperature ranges using Eq. (2) [11], where J/k is an exchange constant, $S = 1/2$, and z is the number of nearest neighbors interacting with a $S = 1/2$ site. Using the Weiss constants of $(-)3.8$ K and $(-)1.5$ K for the higher and lower temperature portions of the Curie–Weiss plot (see above), $J_1/k = (-)7.6$ K $= (-)63$ J/mol at higher temperature, $J_2/k = (-)3.0$ K $= (-)25$ J/mol at lower temperature, both assuming that $z = 1$. It is reasonable to relate these to the spin pairing and chain exchange mechanisms that are

$$\theta = \frac{2zJS(S+1)}{3k} \quad (2)$$



based on the crystallography of **2**, even though this is difficult to prove outright from the data. Still, this leads to questions about the proposed exchange mechanisms. Is the AFM exchange mechanism dominated by close contacts in the carboxylic acid hydrogen bonded dyads? Does the 1-D chain of nitroxide to aryl HC contacts play an identifiable role?

The overall AFM exchange in polycrystalline **2** is worth comparing to the behavior of **1** reported by Veciana and coworkers [4], who *also* observed net AFM downturn in the solid state, but who observed triplet radical pair ESR spectra for **1** *in solution*. The triplet ESR signal variation of **1** with temperature in frozen solution indicated that the triplet–singlet splitting was 4 K (33 J/mol) favoring the triplet state. They interpreted the triplet spectrum as occurring by a spin polarization mechanism that exchange links the nitroxide units in a ferromagnetic (FM) manner through the hydrogen bonded carboxylic acid groups. Scheme 1 shows the qualitative spin polarizations in the dyad. They suggested that this same FM interaction in the solid state is overwhelmed by an additional, AFM interaction, giving the net overall AFM exchange behavior of **1** in the solid. They tentatively suggested that the solid state AFM interaction occurred by π–π overlap mechanism between stacked dyads. There are no π-stacks in **2**, by comparison.

We found no evidence of triplet radical pairing for **2** in solution either at room temperature or at 77 K, even in nonpolar solvents, even though a similar spin polarization analysis to that carried out for **1** again suggests the possibility of FM exchange linkage. In solution, the presence of multiple conformational isomers of **2**–**2** dyads (see Scheme 1) may broaden below detection any ESR lines from triplet spin pairing, an effect that should be less pronounced in pseudo-*para* **1**–**1** dyads.

The solid state results for **2** are difficult to explain qualitatively by clear relationship to a single crystallographic feature or motif. UB3LYP/6-31G* computations [12][1] using the 100 K crystallographic geometry of **2** (but replacing the *tert*-butyl groups with hydrogens) favor the triplet over the singlet state by only by 35 J/mol, and show no more than 0.5% absolute value of spin densities on carboxylic acid O2, C8, O3, and H1 in Fig. 2. These computations thus do not seem to explain the observed bulk AFM (not FM) magnetic behavior. Qualitatively, the chains of 1-D contacts in **2** might also be considered to lead to FM exchange (Scheme 1), although the canting of the phenyl rings within the 1-D chains could alter the nature of this exchange mechanism. But, model dyad computations for

[1] Computations were carried out at the fixed crystallographic geometry of dyads of **2**, using a broken-symmetry wavefunction for the singlet state, replacing the *tert*-butyl groups with hydrogen atoms, and ignoring zero point energy corrections. For the singlet multiplicity calculation of the hydrogen bonded dyad, $\langle S^2\rangle = 1.016$; for the dyads of the A–A–A and B–B–B chains, $\langle S^2\rangle = 1.016$ and 1.019, respectively.

Scheme 1. Putative spin polarization exchange mechanisms for **1** and **2** based on qualitiative expected spin density distribution in each. The 1-D chain model shows both the closest contact between NO and an *ortho* C–H, and a possible contact to a *meta* C–H – as pictured, the *ortho*-contact is assumed to dominate. See the text for additional discussion.

the A–A–A and B–B–B chains instead give slight AFM exchange preferences (singlet state preferred) by 20 and 6 J/mol, respectively [12][1].

The latter results suggest that the simple FM chain exchange model of Scheme 1 – analyzed as proceeding solely through the C–H bonds *ortho* to the nitroxides – is oversimplified, maybe due to noncoplanarity of the aryl nitroxide units in the chains. Interaction through the *meta* C–H bonds also might contribute to the bulk AFM behavior seen in **2** (dotted interaction in Scheme 1). In principle, the two slightly different chains in **2** might even correlate with the multiple AFM exchange constants that are suggested by the magnetic data. This would be consistent with the computational and crystallographic evidence, but we cannot confidently advance a two-chain model as clearly explaining the observed magnetic behavior[2]. For example, we might also get increased geometric difference between the molecules in the two chains at reduced temperatures, even leading to a phase change in the crystal structure. The situation is just too complex to resolve clearly with the data available at present.

The clearest conclusion from the data is that multiple, competing exchange mechanisms exist in **2**. Spin polarization pathways that are most easily identified by the close atomic contacts in the crystal structure are weak, and may even be overwhelmed by through-space dipolar, mean-field type AFM exchange interactions in the bulk solid, giving the overall observed behavior.

7. Conclusions

3-(*N*-*tert*-Butyl-*N*-aminoxyl)benzoic acid has a number of crystallographic similarities to previously [4] reported isomer 4-(*N*-*tert*-butyl-*N*-aminoxyl)benzoic acid, but behaves rather differently in terms of solution ESR spectroscopy. Polycrystalline magnetic susceptibilities of both show AFM dominant exchange behavior, although the change in molecular connectivity has a substantial effect on the solution dyad ESR behavior. The similarity of solid state magnetic behaviors suggests that multiple weak exchange forces are involved in **1**–**2** that are subtly balanced, rendering any solid state

[2] Efforts to fit the magnetic behavior of **2** to a 1:1 mix of Bonner–Fisher [9] chains with two different exchange constants were not a significant improvement over other fits that we attempted, unless an unexpectedly large paramagnetic term was added. In the latter situation, the difference between the two fitted 1-D chain exchange constants was very large, with one being only about 0.05 J/mol and the other about 14 J/mol. We felt that this difference between exchange constants in a two-chain fit was not physically reasonable given the geometric similarity of the two chains at 100 K, unless a phase change or molecular geometry change causes a substantial difference between the A and B forms of **2** at low temperatures.

structure-property analysis quite difficult, as well as extrapolation in solution experiments or by computation from simplified dyad models to solid state behavior.

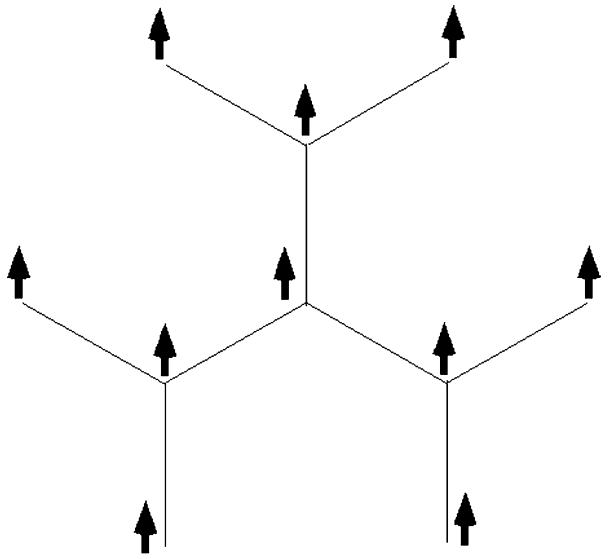

Fig. 1. Sample of the dendritic architecture of the spin aggregate. This structure is called Cayley-tree type.

For the diagonalization of the Hamiltonian, we utilize the basis which constructed from a direct product of a state vector for each spin $\{|\varphi_{i_k}^k\rangle\}$:

$$\left|\varphi_{i_1}^1\varphi_{i_2}^2\cdots\varphi_{i_N}^N\right\rangle \equiv \left|\varphi_{i_1}^1\right\rangle \otimes \left|\varphi_{i_2}^2\right\rangle \otimes \cdots \otimes \left|\varphi_{i_N}^N\right\rangle, \tag{2}$$

where i_k represents a state for each spin:

$$|\varphi_1^k\rangle \equiv |\alpha^k\rangle \quad \text{(up spin)}, \tag{3}$$

$$|\varphi_2^k\rangle \equiv |\beta^k\rangle \quad \text{(down spin)}. \tag{4}$$

By diagonalizing the Hamiltonian H_0, we obtain new states with eigenenergies $\{E_k\}$ and eigenstates $\{|i\rangle\}$;

$$H_0\,|i\rangle = E_i\,|i\rangle. \tag{5}$$

In order to perform the spin dynamics from a ferromagnetic state to a thermally-stable state, we choose the lowest M (=$2S+1$) states with the same value of the multiplicity $\boldsymbol{S}^2 = S(S+1) = (N/2)(N/2+1)$. These states are represented by

$$\begin{aligned} |1\rangle &= |\alpha^1\alpha^2\cdots\alpha^N\rangle,\\ |2\rangle &= \frac{1}{\sqrt{10}}\left(|\beta^1\alpha^2\cdots\alpha^N\rangle + |\alpha^1\beta^2\cdots\alpha^N\rangle + \cdots |\alpha^1\alpha^2\cdots\beta^N\rangle\right),\\ &\vdots\\ |M\rangle &= |\beta^1\beta^2\cdots\beta^N\rangle. \end{aligned} \tag{6}$$

The total spin Hamiltonian is assumed to be

$$H_{\mathrm{S}} = H_0 + H', \tag{7}$$

where

$$H' = -d_z\sum_i (S_i^z)^2 - \omega\sum_{i<j}\frac{3(\boldsymbol{S}_i\cdot\boldsymbol{e}_{ij})(\boldsymbol{e}_{ij}\cdot\boldsymbol{S}_j) - \boldsymbol{S}_i\cdot\boldsymbol{S}_j}{r_{ij}^3}. \tag{8}$$

The first sum represents a uniaxial anisotropy, here, for $d_z>0$, favoring the z axis as easy axis of the system [10]. The second sum is the dipole–dipole interaction with the strength ω . The $\boldsymbol{e}_{ij}$ are unit vectors pointing from a spin i to j, and r_{ij} is the distance between these spins. By using the states $|i\rangle$ as a basis and diagonalizing the Hamiltonian H', we get a new model involving an anisotropic effect;

$$H'\,|\psi_k\rangle = \omega_k\,|\psi_k\rangle. \tag{9}$$

These spins interact with nuclear vibration, i.e., phonons whose states are represented by $\{|q_{(i,j)}\rangle\}$ with the frequency $\{\Omega_{q_{(i,j)}}\}$ · $q_{(i,j)}$ means the phonon state coupled with both of the bases i and j. The Hamiltonian, H_{R}, for the phonon is given by

$$H_{\mathrm{R}} = \sum_{(i,j)}\sum_{q_{(i,j)}} \Omega_{q_{(i,j)}} c^+_{q_{(i,j)}} c_{q_{(i,j)}}, \tag{10}$$

where $\sum_{(i,j)}$ means the summation over all possible pairs of i and j . $c^+_{q_{(i,j)}}$ and $c_{q_{(i,j)}}$ represent the creation and annihilation operators concerning a phonon state $|q_{(i,j)}\rangle$, respectively. These operators satisfy the following commutation relations:

$$\left[c_{q_{(i,j)}}, c^+_{q'_{(i',j')}}\right] = \delta_{ii'}\delta_{jj'}\delta_{q_{(i,j)}q'_{(i',j')}}(1-\delta_{ij}) + \delta_{ij'}\delta_{ji'}\delta_{q_{(i,j)}q'_{(i',j')}}, \tag{11}$$

$$\left[c_{q_{(i,j)}}, c_{q'_{(i',j')}}\right] = \left[c^+_{q_{(i,j)}}, c^+_{q'_{(i',j')}}\right] = 0. \tag{12}$$

The interaction Hamiltonian, H_{SR}, for spin–phonon coupling is assumed to be [11]

$$H_{\mathrm{SR}} = \sum_{i,j,q_{(i,j)}} |i\rangle\langle j|\,(\kappa^*_{(i,j),q_{(i,j)}} c^+_{q_{(i,j)}} + \kappa_{(i,j),q_{(i,j)}} c_{q_{(i,j)}}),\quad (i,j=1,2,\ldots,M), \tag{13}$$

where $\kappa_{(i,j),q_{(i,j)}}$ represents a coupling constant between a pair of spins (i and j) and phonon $q_{(i,j)}$.

The total Hamiltonian, H, is described by

$$H = H_{\mathrm{S}} + H_{\mathrm{R}} + H_{\mathrm{SR}}. \tag{14}$$

In order to examine the spin dynamics [12,13] involving the effects of the interaction between spins and phonons, we can use a reduced density operator, ρ, for the spin system;

$$\rho = \mathrm{tr}_{\mathrm{R}}[\chi], \tag{15}$$

where χ is the density operator for the total system, and $\mathrm{tr}_{\mathrm{R}}[\,]$ represents that we take the trace over the phonon states, that is, $\mathrm{tr}_{\mathrm{R}}\{\cdots R_0\}$, when R_0 is the thermal-equilibrium density operator of phonon states.

2.2. Quantum master equation approach involving spin–phonon coupling

We start with a quantum master equation (in the interaction picture) in the Born–Markov approximation [13,14]:

$$\tilde{\rho} = -\int_0^t \mathrm{d}t' \mathrm{tr}_\mathrm{R}\left\{\left[\widetilde{H}_\mathrm{SR}(t), \left[\widetilde{H}_\mathrm{SR}(t'), \tilde{\rho}(t)R_0\right]\right]\right\}, \tag{16}$$

where $\tilde{\rho}$ denotes the reduced density operator of spin system in the interaction picture. The interaction Hamiltonian in the interaction picture $\widetilde{H}_\mathrm{SR}(t)$ is defined as

$$\widetilde{H}_\mathrm{SR}(t) = \mathrm{e}^{\mathrm{i}(H_\mathrm{S}+H_\mathrm{R})t} H_\mathrm{SR} \mathrm{e}^{-\mathrm{i}(H_\mathrm{S}+H_\mathrm{R})t}. \tag{17}$$

Using Eqs. (10), (13) and (17), we have

$$\widetilde{H}_\mathrm{SR}(t) = \sum_{i,j,q_{(i,j)}} \mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|i\rangle\langle j| \times \mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}\left\{\kappa^*_{(i,j),q_{(i,j)}} c^+_{q_{(i,j)}} \mathrm{e}^{\mathrm{i}\Omega_{q_{(i,j)}}t} + \kappa_{(i,j),q_{(i,j)}} c_{q_{(i,j)}} \mathrm{e}^{-\mathrm{i}\Omega_{q_{(i,j)}}t}\right\}, \tag{18}$$

where we have used

$$\mathrm{e}^{\mathrm{i}H_\mathrm{R}t} c^+_{q_{(i,j)}} \mathrm{e}^{-\mathrm{i}H_\mathrm{R}t} = c^+_{q_{(i,j)}} \mathrm{e}^{\mathrm{i}\Omega_{q_{(i,j)}}t}, \tag{19}$$

$$\mathrm{e}^{\mathrm{i}H_\mathrm{R}t} c_{q_{(i,j)}} \mathrm{e}^{-\mathrm{i}H_\mathrm{R}t} = c_{q_{(i,j)}} \mathrm{e}^{-\mathrm{i}\Omega_{q_{(i,j)}}t}. \tag{20}$$

The right-hand side of Eq. (16) has four terms:

$$\rho^{\tilde{V}} = -\int_0^t \mathrm{d}t' \mathrm{tr}_\mathrm{R}\left\{\widetilde{H}_\mathrm{SR}(t)\widetilde{H}_\mathrm{SR}(t')\tilde{\rho}(t)R_0 - \widetilde{H}_\mathrm{SR}(t')\tilde{\rho}(t)R_0\widetilde{H}_\mathrm{SR}(t) - \widetilde{H}_\mathrm{SR}(t)\tilde{\rho}(t)R_0\widetilde{H}_\mathrm{SR}(t') + \tilde{\rho}(t)R_0\widetilde{H}_\mathrm{SR}(t')\widetilde{H}_\mathrm{SR}(t)\right\}. \tag{21}$$

Using Eq. (18), the first term in the right-hand side of Eq. (21) is rewritten as

$$\begin{aligned} &-\int_0^t \mathrm{d}t' \mathrm{tr}_\mathrm{R}\left\{\widetilde{H}_\mathrm{SR}(t)\widetilde{H}_\mathrm{SR}(t')\tilde{\rho}(t)R_0\right\} \\ &= -\sum_{i,j,q_{(i,j)}} \int_0^t \mathrm{d}t' \left\{\mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|i\rangle\langle j|\mathrm{e}^{-\mathrm{i}H_\mathrm{S}(t-t')}\,|i\rangle \right. \\ &\times \langle j|\mathrm{e}^{\mathrm{i}H_\mathrm{S}(t-t')}\rho\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}(1-\delta_{ij}) + \mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|i\rangle\langle j|\,\mathrm{e}^{-\mathrm{i}H_\mathrm{S}(t-t')}|j\rangle \\ &\times \left.\langle i\,|\mathrm{e}^{\mathrm{i}H_\mathrm{S}(t-t')}\rho\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}\right\}\left[\left|\kappa_{(i,j),q_{(i,j)}}\right|^2\left\{\bar{n}(\Omega_{q_{(i,j)}},T)\mathrm{e}^{\mathrm{i}\Omega_{q_{(i,j)}}(t-t')} \right.\right. \\ &\left.\left. + (\bar{n}(\Omega_{q_{(i,j)}},T)+1)\mathrm{e}^{-\mathrm{i}\Omega_{q_{(i,j)}}(t-t')}\right\}\right] \end{aligned} \tag{22}$$

where we have used

$$\mathrm{tr}_\mathrm{R}\left(c^+_{q_{(i,j)}} c^+_{q'_{(i',j')}} R_0\right) = \mathrm{tr}_\mathrm{R}\left(c_{q_{(i,j)}} c_{q'_{(i',j')}} R_0\right) = 0, \tag{23}$$

$$\mathrm{tr}_\mathrm{R}\left(c^+_{q_{(i,j)}} c_{q'_{(i',j')}} R_0\right) = \left\{\delta_{ii'}\delta_{jj'}\delta_{q_{(i,j)}q'_{(i',j')}}(1-\delta_{ij}) + \delta_{ij'}\delta_{i'j}\delta_{q_{(i,j)}q'_{(i',j')}}\right\}\bar{n}(\Omega_{q_{(i,j)}},T), \tag{24}$$

$$\mathrm{tr}_\mathrm{R}\left(c_{q_{(i,j)}} c^+_{q_{(i',j')}} R_0\right) = \left\{\delta_{ii'}\delta_{jj'}\delta_{q_{(i,j)}q'_{(i',j')}}(1-\delta_{ij}) + \delta_{ij'}\delta_{i'j}\delta_{q_{(i,j)}q'_{(i',j')}}\right\}\left(\bar{n}(\Omega_{q_{(i,j)}},T)+1\right), \tag{25}$$

with

$$\bar{n}(\Omega_{q_{(i,j)}},T) = \left[\mathrm{e}^{(\Omega_{q_{(i,j)}}/k_\mathrm{B}T)} - 1\right]^{-1}. \tag{26}$$

$\bar{n}(\Omega_{q_{(i,j)}},T)$ denotes the mean phonon number for a phonon with frequency $\Omega_{q_{(i,j)}}$ in thermal equilibrium at temperature T. Because H_S remains in the right-hand side of Eq. (22), we insert the completeness relation with respect to eigenstates of H_S:

$$\sum_k |\psi_k\rangle\langle\psi_k| = 1 \tag{27}$$

into Eq. (22). As a result, Eq. (22) now becomes

$$\begin{aligned} &-\int_0^t \mathrm{d}t' \mathrm{tr}_\mathrm{R}\left\{\tilde{H}_\mathrm{SR}(t)\tilde{H}_\mathrm{SR}(t')\tilde{\rho}(t)R_0\right\} \\ &= -\sum_{i,j,q_{(i,j)}}\sum_{k,m,n}\int_0^t \mathrm{d}t' \left\{\mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|i\rangle\langle j|\psi_k\rangle\langle\psi_k|i\rangle\langle j|\psi_m\rangle \right. \\ &\times \langle\psi_m|\rho|\psi_n\rangle\langle\psi_n|\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}(1-\delta_{ij}) + \mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|i\rangle\langle j|\psi_k\rangle \\ &\times \left.\langle\psi_k|j\rangle\langle i|\,\psi_m\rangle\langle\psi_m|\rho|\,\psi_n\rangle\langle\psi_n|\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}\right\} \\ &\cdot \left[\left|\kappa_{(i,j),q_{(i,j)}}\right|^2\left\{\bar{n}(\Omega_{q_{(i,j)}},T)\mathrm{e}^{\mathrm{i}(\Omega_{q_{(i,j)}}-\omega_k+\omega_m)(t-t')} \right.\right. \\ &\left.\left. + (\bar{n}(\Omega_{q_{(i,j)}},T)+1)\mathrm{e}^{\mathrm{i}(-\Omega_{q_{(i,j)}}-\omega_k+\omega_m)(t-t')}\right\}\right]. \end{aligned} \tag{28}$$

In the Markov approximation, it is possible to evaluate the time integral in the right-hand side of Eq. (28). This approximation is acceptable when the order of t is much larger than that of t' [13]. In this case, we can assume t to be infinity. Under this approximation, Eq. (28) is expressed by

$$\begin{aligned} &-\int_0^t \mathrm{d}t' \mathrm{tr}_\mathrm{R}\left\{\tilde{H}_\mathrm{SR}(t)\tilde{H}_\mathrm{SR}(t')\tilde{\rho}(t)R_0\right\} \\ &= -\sum_{i,j}\sum_{k,m,n}\left(\mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|i\rangle\langle j|\psi_k\rangle\langle\psi_k|i\rangle\langle j|\psi_m\rangle \right. \\ &\times \langle\psi_m|\rho\,|\psi_n\rangle\langle\psi_n|\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}(1-\delta_{ij}) + \mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|i\rangle\langle j|\psi_k\rangle \\ &\times \left.\langle\psi_k|j\rangle\langle i|\psi_m\rangle\langle\psi_m|\rho|\psi_n\rangle\langle\psi_n|\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}\right)\gamma_{(i,j)}(\omega_m-\omega_k), \end{aligned} \tag{29}$$

where

$$\gamma_{(i,j)}(\omega_m-\omega_k) = \sum_{q_{(i,j)}}\left|\kappa_{(i,j),q_{(i,j)}}\right|^2\left\{\bar{n}(\Omega_{q_{(i,j)}},T)\delta(\Omega_{q_{(i,j)}}-\omega_k+\omega_m) + (\bar{n}(\Omega_{q_{(i,j)}},T)+1)\delta(-\Omega_{q_{(i,j)}}-\omega_k+\omega_m)\right\}. \tag{30}$$

Similarly, from the second, third and fourth terms in the right-hand side of Eq. (21), we, respectively, obtain

$$\begin{aligned} &-\int_0^t \mathrm{d}t' \mathrm{tr}_\mathrm{R}\left\{-\tilde{H}_\mathrm{SR}(t')\tilde{\rho}(t)R_0\tilde{H}_\mathrm{SR}(t')\right\} \\ &= -\sum_{i,j}\sum_{k,m,n}\left(-\mathrm{e}^{\mathrm{i}H_\mathrm{S}t}\,|\psi_k\rangle\langle\psi_k|i\rangle \right. \\ &\times \langle j|\psi_m\rangle\langle\psi_m|\rho|\psi_n\rangle\langle\psi_n|i\rangle\langle j|\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}(1-\delta_{ij}) \\ &- \mathrm{e}^{\mathrm{i}H_\mathrm{S}t}|\psi_k\rangle\langle\psi_k|i\rangle\langle j|\psi_m\rangle \\ &\times \left.\langle\psi_m|\rho|\psi_n\rangle\langle\psi_n|i\rangle\langle j|\mathrm{e}^{-\mathrm{i}H_\mathrm{S}t}\right)\gamma_{(ij)}(\omega_m-\omega_k), \end{aligned} \tag{31}$$

$$
\begin{aligned}
&-\int_0^t \mathrm{d}t' \mathrm{tr}_{\mathrm{R}}\{-\tilde{H}_{\mathrm{SR}}(t')\tilde{\rho}(t)R_0\tilde{H}_{\mathrm{SR}}(t')\}\\
&\quad=-\sum_{i,j}\sum_{k,m,n}\big(-\mathrm{e}^{\mathrm{i}H_{\mathrm{S}}t}|i\rangle\langle j|\psi_m\rangle\\
&\qquad\times\langle\psi_m|\rho|\psi_n\rangle\langle\psi_n|i\rangle\langle j|\psi_k\rangle\langle\psi_k|\mathrm{e}^{-\mathrm{i}H_{\mathrm{S}}t}(1-\delta_{ij})\\
&\qquad-\mathrm{e}^{\mathrm{i}H_{\mathrm{S}}t}|i\rangle\langle j|\psi_m\rangle\langle\psi_m|\rho|\psi_n\rangle\\
&\qquad\times\langle\psi_n|i\rangle\langle j|\psi_k\rangle\langle\psi_k|\mathrm{e}^{-\mathrm{i}H_{\mathrm{S}}t}\big)\gamma_{(ij)}(\omega_m-\omega_k),
\end{aligned}
\tag{32}
$$

and

$$
\begin{aligned}
&-\int_0^t \mathrm{d}t' \mathrm{tr}_{\mathrm{R}}\{\tilde{\rho}(t)R_0\tilde{H}_{\mathrm{SR}}(t)\tilde{H}_{\mathrm{SR}}(t')\}\\
&\quad=-\sum_{i,j}\sum_{k,m,n}\big(\mathrm{e}^{\mathrm{i}H_{\mathrm{S}}t}|\psi_m\rangle\langle\psi_m|\rho|\psi_n\rangle\langle\psi_n|i\rangle\langle j|\psi_k\rangle\\
&\qquad\times\langle\psi_k|i\rangle\langle j|\mathrm{e}^{-\mathrm{i}H_{\mathrm{S}}t}(1-\delta_{ij})+\mathrm{e}^{\mathrm{i}H_{\mathrm{S}}t}|\psi_m\rangle\langle\psi_m|\rho|\psi_n\rangle\\
&\qquad\times\langle\psi_n|i\rangle\langle j|\psi_k\rangle\langle\psi_k|i\rangle\langle j|\mathrm{e}^{-\mathrm{i}H_{\mathrm{S}}t}\big)\gamma_{(ij)}(\omega_m-\omega_k).
\end{aligned}
\tag{33}
$$

Using Eqs. (29), (31), (32) and (33), we get the quantum master equation involving the spin–phonon coupling in the Schrödinger picture:

$$
\begin{aligned}
\rho^{\dot{\tilde{V}}}_{\alpha\beta}&=-i(\omega_\alpha-\omega_\beta)\rho_{\alpha\beta}-\sum_{m,n}^{M}\Gamma_{\alpha\beta;mn}\rho_{mn}\\
&\quad+iB\sum_{n}^{M}(S_{\alpha n}\rho_{n\beta}-\rho_{\alpha n}S_{n\beta})\quad(\alpha\neq\beta)
\end{aligned}
\tag{34}
$$

and

$$
\rho^{\dot{\tilde{V}}}_{\alpha\alpha}=-\sum_{m}^{M}\Gamma_{\alpha\alpha;mm}\rho_{mm}+iB\sum_{n}^{M}(S_{\alpha n}\rho_{n\alpha}-\rho_{\alpha n}S_{n\alpha}),
\tag{35}
$$

where

$$
\begin{aligned}
\Gamma_{\alpha\beta;mn}&=\sum\nolimits_{k}^{M}\sum_{i,j}^{N}\Big[\delta_{\beta n}\{(1-\delta_{ij})C^*_{\alpha i}C_{kj}C^*_{ki}C_{mj}\\
&\quad+C^*_{\alpha i}|C_{kj}|^2C_{mi}\}\gamma_{(i,j)}(\omega_m-\omega_k)\\
&\quad+\delta_{\alpha m}\{(1-\delta_{ij})C^*_{ni}C_{kj}C^*_{ki}C_{\beta j}\\
&\quad+C^*_{ni}|C_{kj}|^2C_{\beta i}\}\gamma_{(i,j)}(\omega_n-\omega_k)\Big]\\
&\quad-\sum_{i,j}^{N}\Big[\{(1-\delta_{ij})C^*_{\alpha i}C_{mj}C^*_{ni}C_{\beta j}+C^*_{\alpha i}C_{mj}C^*_{nj}C_{\beta i}\}\}\\
&\quad\times\{\gamma_{(i,j)}(\omega_m-\omega_\alpha)+\gamma_{(i,j)}(\omega_n-\omega_\beta)\}\Big],
\end{aligned}
\tag{36}
$$

$$
\begin{aligned}
\Gamma_{\alpha\alpha;mm}&=\delta_{\alpha m}\sum_{k}^{M}\sum_{i,j}^{N}\Big[2\{(1-\delta_{ij})C^*_{\alpha i}C_{kj}C^*_{ki}C_{\alpha j}\\
&\quad+|C_{\alpha i}|^2|C_{kj}|^2\}\gamma_{(i,j)}(\omega_m-\omega_k)\Big]\\
&\quad-\sum_{i,j}^{N}\Big[2\{(1-\delta_{ij})C^*_{\alpha i}C_{mj}C^*_{mi}C_{\alpha j}\\
&\quad+|C_{\alpha i}|^2|C_{mj}|^2\}\gamma_{(i,j)}(\omega_m-\omega_\alpha)\Big]
\end{aligned}
\tag{37}
$$

and

$$
\gamma_{(i,j)}(\omega)=\frac{2\gamma^0_{(i,j)}}{1+\exp(-\omega/k_{\mathrm{B}}T)}.
\tag{38}
$$

This factor $\gamma_{(i,j)}(\omega)$ is taken to satisfy the thermal equilibrium condition [11]; $\gamma^0_{(i,j)}$ indicates the high-temperature limit of $\gamma_{(i,j)}(\omega)$ and k_{B} is the Boltzmann constant. The third and second terms on the right-hand side of Eqs. (34) and (35) represent the interaction between the spin-aggregate system and the external magnetic field, respectively. B represents the magnetic amplitude. We have solved Eqs. (34) and (35) numerically using the fourth-order Runge–Kutta method.

3. Concluding remarks

We formulated a master equation approach involving the effects of the interaction between spins and phonons in the Markov approximation. This calculation relates to the method of the calculation in the quantum computer. Coherent states of spins have received current interest in relation to quantum computing [14]. For example, the resonating state of spins is expressed by the superposition of two states $|\alpha\rangle$ and $|\beta\rangle$:

$$
|\Psi\rangle=\cos\theta\,|\,\alpha\rangle+\mathrm{e}^{\mathrm{i}\phi}\sin\theta|\beta\rangle,
\tag{39}
$$

where ϕ is the phase factor. If the states $|\alpha\rangle$ and $|\beta\rangle$ are regarded as classical bits 0 and 1, respectively, in conventional computer, the quantum bit (qubit) in quantum computer is defined as the above superposed state $|\Psi\rangle$. A quantum computer based on electron spins as qubits have actively studied [15,16]. Recently, we have reviewed spin and pseudo spin models for several kinds of two-level systems in relation to quantum computing [8]. However, the control of decoherence between monomers is one of the bottle necks for many qubit systems in future quantum devices. In fact, the coherence in the mesoscopic quantum systems is rapidly destroyed by coupling with other freedom of reservoirs such as phonons [17–21]. We consider that the dynamics is important for understanding the relation between the architectures and the function of the spin aggregate. As for such a device, it is necessary to perform the spin dynamics involving the effect of the reservoirs for the several spin systems which possess the many novel architectures. At the next stage, therefore, we apply the present approach to the dendritic spin systems, as well as aggregates with other spatial dimensions, in order to elucidate the structure dependence (dipole–dipole interaction) of spin dynamics.

$[Ru_2(O_2CR)_4]^+$; R = CMe_3 (piv) and Et (pro)

Fig. 1. Chemical structures of ruthenium(II,III) carboxylates and pyridyl nitronyl nitroxides.

interaction through the pyridyl group is weak, it plays an important role in their magnetic properties because *m*- and *p*-nitpy magnetically couple with the Ru(II,III) dimer through the coordinating pyridyl groups with the opposite ways; *m*-nitpy gives the antiferromagnetic interaction and *p*-nitpy the ferromagnetic interaction. The ferromagnetic behavior observed for **1** was interpreted by taking into consideration that the *p*-nitpy ferromagnetically interacts with Ru(II,III) dimer through the pyridyl nitrogen ($J' = 0.45$ cm^{-1}) as well as through the nitroxide oxygen ($J = 20$ cm^{-1}). In this manner, the antiferromagnetic behavior of $[Ru_2(piv)_4(m\text{-nitpy})]_n(BF_4)_n \cdot nH_2O$ was considered to be due to the antiferromagnetic interaction ($J' = -0.4$ cm^{-1}) through the coordinated pyridyl group in spite of the ferromagnetic interaction through the N–O group ($J = 0.3$ cm^{-1}). At the stage, however, we did not have the crystal structure of the Ru(II,III) polymer with *m*-nitpy at hand. In the present study, we employed ruthenium(II,III) propionate as the dimer and obtained polymer chain complexes $[Ru_2(pro)_4(m\text{- and } p\text{-nitpy})]_nX_n$ and adduct dimer complexes $[Ru_2(pro)_4(m\text{- and } p\text{-nitpy})_2]X$ ($X = BF_4$ and PF_6) as in the case of ruthenium(II,III) pivalate with the pyridyl radicals. Herein, we report on the magnetic properties of these complexes. The crystal structures of the polymer complex of *m*-nitpy and adduct dimer of *p*-nitpy were also determined.

2. Experimental

2.1. Synthesis

All manipulations were performed under anaerobic conditions using standard Schlenk techniques. The tetrafluoroborate and hexafluorophosphate salts, $[Ru_2(pro)_4(H_2O)_2]BF_4$ and $[Ru_2(pro)_4(H_2O)_2]PF_6$, were prepared according to a method described in the literature [25]. The axial water molecules of these salts were removed before use by heating under vacuum. The nitronyl nitroxide radicals, *p*-nitpy and *m*-nitpy, were obtained according to a method described in the elsewhere [26,27].

2.1.1. $[Ru_2(pro)_4(m\text{-nitpy})]_n(PF_6)_n \cdot nCH_2Cl_2$ (**4**)

A 10.0 mg (0.0148 mmol) portion of $[Ru_2(pro)_4(H_2O)_2]PF_6$ was employed for a reaction with *m*-nitpy (3.5 mg, 0.015 mmol) in CH_2Cl_2 (5 cm^3) under argon. Onto the reacted solution was slowly added hexane–dichloromethane (13 cm^3); the resulting solution was allowed to stand for two weeks at room temperature to deposit deep blue crystals, which were collected by filtration. The yield was 7.9 mg (59% based on $[Ru_2(pro)_4(H_2O)_2]PF_6$). *Anal.* calc. for $C_{25}H_{38}PCl_2F_6N_3O_{10}Ru_2$ (**4**): C, 31.32; H, 4.00; N, 4.38. Found: C, 31.27; H, 4.05; N, 4.32%. IR (cm^{-1}): $\nu(CH_3)$ 2991, 2948, ν(asym-(COO)) 1454, ν(sym(COO)) 1431, ν(NO) 1377, $\nu(PF_6^-)$ 846. Diffuse reflectance spectrum λ_{max}/nm 266, 369, 626sh, 962br. μ_{eff} (300 K)/μ_B 4.66.

2.1.2. $[Ru_2(pro)_4(m\text{-nitpy})_2]BF_4$ (**5**)

This compound was obtained as deep blue crystals by the reaction of $[Ru_2(pro)_4(H_2O)_2]BF_4$ (20.0 mg, 0.0324 mmol) of *m*-nitpy (15.4 mg, 0.0657 mmol) in CH_2Cl_2/hexane using the same method as that of **4**. The yield was 24.6 mg (72.3% based on $[Ru_2(pro)_4(H_2O)_2]BF_4$). *Anal.* calc. for $C_{36}H_{52}BF_4N_6O_{12}Ru_2$ (**5**): C, 41.19; H, 4.99; N, 8.01. Found: C, 41.03; H, 4.96; N, 7.95%. IR (cm^{-1}): $\nu(CH_3)$ 2979, 2943, ν(asym(COO)) 1465, ν(sym(COO)) 1421, ν(NO) 1376, $\nu(BF_4^-)$ 1055. Diffuse reflectance spectrum λ_{max}/nm 260, 359, 599, 652sh, 906br. μ_{eff} (300 K)/μ_B 4.85.

2.1.3. $[Ru_2(pro)_4(p\text{-nitpy})]_n(BF_4)_n \cdot nCH_2Cl_2$ (**6**)

This compound was obtained as deep green crystals by the reaction of $[Ru_2(pro)_4(H_2O)_2]BF_4$ (10.2 mg, 0.0165 mmol) of *p*-nitpy (4.1 mg, 0.018 mmol) in

CH_2Cl_2/hexane using the same method as that of **4**. The yield was 8.7 mg (61% based on $[Ru_2(pro)_4(H_2O)_2]BF_4$). *Anal.* calc. for $C_{25}H_{38}BCl_2F_4N_3O_{10}Ru_2$ (**6**): C, 33.34; H, 4.25; N, 4.67. Found: C, 33.32; H, 4.23; N, 4.56%. IR (cm^{-1}): $\nu(CH_3)$ 2984, 2948, ν(asym(COO)) 1471, ν(sym(COO)) 1429, ν(NO) 1374, $\nu(BF_4^-)$ 1057. Diffuse reflectance spectrum λ_{max}/nm 232, 639sh, 983br. μ_{eff} (300 K)/μ_B 4.50.

2.1.4. $[Ru_2(pro)_4(p\text{-nitpy})_2]BF_4$ (7)

This compound was obtained as deep green crystals by the reaction of $[Ru_2(pro)_4(H_2O)_2]BF_4$ (20.0 mg, 0.0324 mmol) of *p*-nitpy (15.4 mg, 0.0657 mmol) in CH_2Cl_2/hexane using the same method as that of **4**. The yield was 25.3 mg (74.3% based on $[Ru_2(pro)_4(H_2O)_2]BF_4$). *Anal.* calc. for $C_{36}H_{52}BF_4N_6O_{12}Ru_2$ (**7**): C, 41.19; H, 4.99; N, 8.01. Found: C, 41.12; H, 5.01; N, 8.29%. IR (cm^{-1}): $\nu(CH_3)$ 2986, 2943, ν(asym(COO)) 1458, ν(sym(COO)) 1430, ν(NO) 1376, $\nu(BF_4^-)$ 1066. Diffuse reflectance spectrum λ_{max}/nm 266, 363, 429, 633sh, 1142br. μ_{eff} (300 K)/μ_B 5.21.

2.2. Measurements

Elemental analyses for carbon, hydrogen, and nitrogen were conducted using a Perkin–Elmer 2400 Series II CHNS/O Analyzer. Infrared spectra were measured with a JASCO MFT-2000 FT-IR Spectrometer in the 4000–600 cm^{-1} region. The electronic spectra were measured with a Shimadzu UV–Vis-NIR Recording Spectrophotometer Model UV-3100. The temperature dependence of the magnetic susceptibilities was measured with a Quantum Design MPMS-5S SQUID susceptometer operating at a magnetic field of 0.5 T over a temperature range of 4.5–300 K. The susceptibilities were corrected for the diamagnetism of the constituent atoms using Pascal's constants [28]. The effective magnetic moments were calculated from the equation $\mu_{eff} = 2.828\sqrt{\chi T}$, where χ is the magnetic susceptibility per mole of $Ru^{II,III}{}_2$-radical unit.

2.3. X-ray crystal structure analyses

Diffraction data were collected on an Enraf-Nonius CAD4 diffractometer using graphite-monochromated Mo Kα radiation at 25 ± 1 °C. Crystal data are given in Table 1. The structure was solved by direct methods, and refined by full-matrix least-squares methods. All non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms were inserted at their calculated positions and fixed there. All of the calculations were carried out on a VAX station 4000 90A computer utilizing the MoLEN program package [29].

3. Results and discussion

3.1. Description of crystal structures

3.1.1. $[Ru_2(pro)_4(m\text{-nitpy})]_n(PF_6)_n \cdot nCH_2Cl_2$ (4)

The crystal structure of **4** is depicted in Fig. 2. The selected bond distances and angles are listed in Table 2. The zigzag chain structure is built up by alternated arrangement of Ru(II,III) dimer and *m*-nitpy, like the case of $[Ru_2(piv)_4(p\text{-nitpy})]_n(BF_4)_n$ [23]. One of the two N–O groups of *m*-nitpy coordinates to the Ru(II,III) dimer by the Ru1–O9 separation of 2.295(4) Å. The other nitroxide oxygen designated by O10 is free from the coordination. The pyridyl nitrogen alternatively participates in the coordination with an axial Ru2–N3 distance of 2.271(5) Å. The N–O bond lengths of the *m*-nitpy molecule (1.297(7) Å for N1–O9 and 1.256(8) Å for N2–O10) indicate that the nitroxide is in a free radical form, although the coordinated N–O bond (N1–O9) is slightly elongated due to the axial coordination similarly to the case of $[Ru_2(piv)_4(p\text{-nitpy})]_n(BF_4)_n$ [23]. The Ru1–Ru2 bond distance of the dimer core, the axial sites of which are occupied by the nitroxide oxygen and pyridyl nitrogen, is 2.278(1) Å, which is nearly the same as that (2.272(1) Å) for $[Ru_2(piv)_4(p\text{-nitpy})]_n$-$(BF_4)_n$ [23].

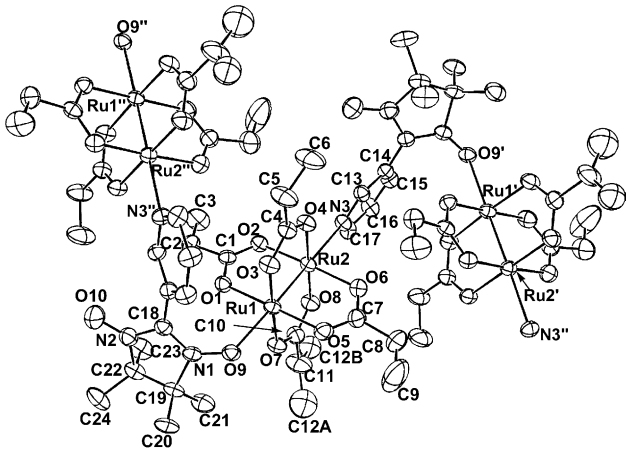

Fig. 2. ORTEP drawing of the structure of **4**. The hydrogen atoms, PF_6^- ions, and CH_2Cl_2 molecules are omitted for clarity.

Ru′–Ru–N3	174.7(2)

3.1.2. $[Ru_2(pro)_4(p\text{-nitpy})_2]BF_4$ (7)

The bis-niroxide adduct structure of **7** is depicted in Fig. 3. A crystallographic inversion center is located at the midpoint of the Ru–Ru′ bond of the Ru(II,III) core. The Ru–Ru′ and axial Ru–N3 distances are 2.277(1) and 2.294(8) Å, respectively, which are comparable to the corresponding ones in the previously reported bis-adduct complex of *p*-nitpy [22]. The two N–O groups

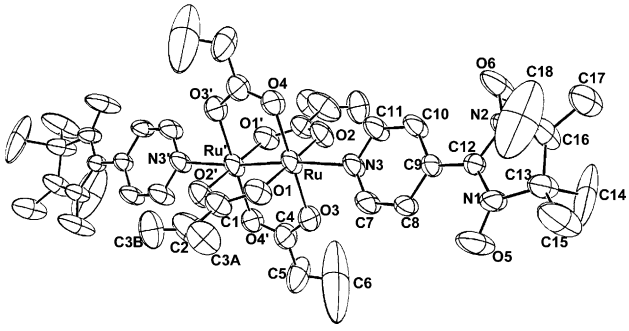

Fig. 3. ORTEP drawing of the structure of **7**. The hydrogen atoms and BF_4^- ions are omitted for clarity.

of *m*-nitpy are both free from the coordination and their bonds lengths 1.25(1) Å (for N1–O5) and 1.26(1) Å (for N2–O6) indicate that the *p*-nitpy molecule exists as a free radical [22]. The nearest O···O distance between the N–O groups of the radicals of the neighboring Ru(II,III) cationic units is 3.48(1) Å for O6···O6 $(1-x,-y,-z)$, which is relatively shorter than that (3.79(1) Å) for **3** [22].

3.2. Structural comparison of Ru(II,III) complexes with pyridyl nitroxide radicals

In Table 3, structural parameters of Ru(II,III) dimers with pyridyl nitoroxide radicals are listed. The structural effect on the polymer and bis-adduct structures due to the change from *t*-butyl to propyl group in the dimeric core cannot be found. The Ru–Ru bond distances are nearly the same (2.27–2.28 Å) and the axial Ru–N_{py} and Ru–O_{ax} distances and Ru–O_{ax}–N angle are similar among the listed complexes (Ru–N_{py} = 2.27–2.30 Å; Ru–O_{ax} = 2.286(7) and 2.295(4) Å; Ru–O_{ax}–N = 125.3(6)° and 120.3(3)°). It is also noticeable that there is no significant difference in the Ru–Ru and Ru–N_{py} distances between the polymer complexes (**1** and **4**) and bis-adduct complexes (**2**, **3**, and **7**). This may be related to the fact that polymer and bis-adduct complexes were obtained only by changing the molar ratio of the radicals and Ru(II,III) cationic dimers employed for the reactions.

3.3. Magnetic properties

Temperature dependences of magnetic moments are shown for complexes **4**–**7** in Figs. 4–7, respectively, in which the solid lines are drawn with the parameters listed in Table 4 (g_M and g_R are the *g* factors of the Ru(II,III) core and the nitroxide radical, respectively. *D* is the parameter for the zero-field splitting for the Ru(II,III) core. *J*, *J*′, and *J*″ are the parameters for the magnetic interaction defined in Fig. 8). The magnetic models for the analyses are illustrated in Fig. 8, details of the quantum treatments for each model being found

Table 3
Structural parameters of Ru(II,III) dimers with pyridyl nitroxide radicals

elsewhere [22,23]. Table 4 contains the used model types as well as the magnetic parameters for the complexes **1**–**7**. The magnetic moment of **6** gradually decreases with lowering of temperature and reaches a minimum value around 90 K (Fig. 6). Upon further cooling, the magnetic moment increases gradually, reaching a maximum value of 4.81 μ_B at 14 K, and then decreases. In Fig. 6, the dashed line is drawn by the equation based on the model A, the parameters being set at $g_M = 2.06$, $g_R = 2.0$, $J = 20$ cm^{-1}, $J' = 0.4$ cm^{-1}, and $D = 80$ cm^{-1}. Unfortunately, we could not simulate the temperature-dependent profile properly. However, the behavior below 100 K is very similar to that of **1** [23]. Hence, it is certain that **6** has a polymer structure and *p*-nitpy ferromagnetically couples with Ru(II,III) dimer through the N–O and pyridyl groups. In fact, the positive J and J' values were also obtained in the best fitting using $D = 300$ cm^{-1}, which could support the existence the ferromagnetic interaction through the N–O and pyridyl groups. On the contrary, the magnetic moment of **4** de-

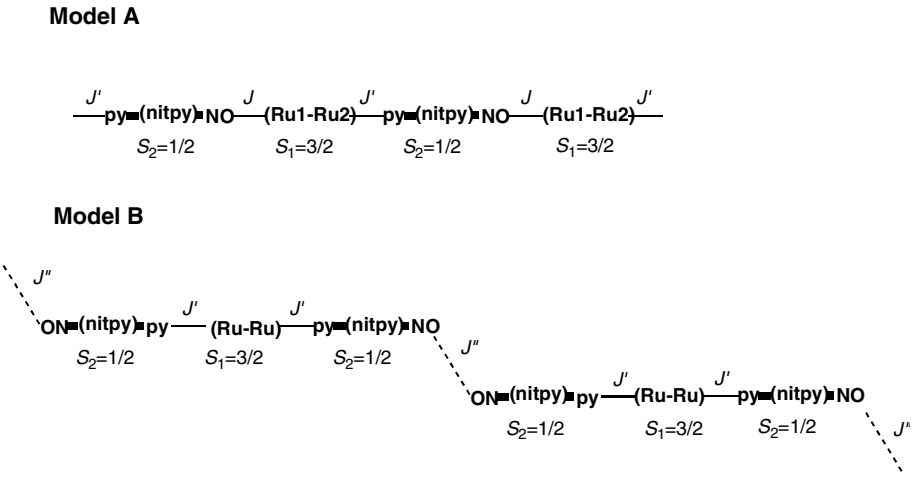

Fig. 8. Spin coupling models.

creases steadily with lowering of the temperature. This behavior obviously comes from the antiferromagnetic interaction through the pyridyl group of *m*-nitpy ($J' = -1.7$ cm^{-1}) because the interaction through the N–O group is ferromagnetic ($J = 5$ cm^{-1}). According to our previously reported proposal [24], the axial bond angle value of ∠Ru1–O9–N1 = 120.0(3)° is in the range for the ferromagnetic interaction between the ruthenium(II,III) core and the radical. In Table 4, two pairs of bis-adduct complexes consisting of *m*- and *p*-nitpy are included. A pair of **2** and **5** has the antiferromagnetic interaction through pyridyl group of *m*-nitpy [$J' = -1.0$ (for **2**) and −1.6 cm^{-1} (for **5**)]. The other pair of **3** and **7** has the ferromagnetic interaction through pyridyl group of *p*-nitpy [$J' = 1.4$ (for **3**) and 1.45 cm^{-1} (for **7**)]. The difference can be interpreted by the consideration for the number of carbon and nitrogen atoms on the π-system between the Ru(II,III) dimer and the N–O group based on the spin-polarization mechanism [22].

4. Conclusions

In this study, we obtained adduct polymer complexes $[Ru_2(pro)_4(m\text{- and }p\text{-nitpy})]_nX_n$ and dimer complexes $[Ru_2(pro)_4(m\text{- and }p\text{-nitpy})_2]X$ ($X = BF_4$ and PF_6) as in the case of ruthenium(II,III) pivalate with the pyridyl radicals. It was found that the difference of alkyl group on the carboxylate ion of the Ru(II,III) dimer core does not give any important effect on the structures and magnetic properties for the obtained polymer and bis-adduct complexes. The magnetic investigations on the pyridyl nitroxide complexes of ruthenium(II,III) propionate and ruthenium(II,III) pivalate show that the pyridyl group can mediate ferro- or antiferromagnetically the interaction depending on the position on the coordinated nitrogen atom on the pyridyl ring; *m*-nitpy gives the antiferromagnetic interaction and *p*-nitpy the ferromagnetic interaction in combination with Ru(II,III) dimer.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 256932 and 256933 for complexes **4** and **7**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or on the web: http://www.ccdc.cam.ac.uk).

residues, which are His46, Cys112, His117, Met121, and Gly45. The copper ion is strongly coordination to His46, Cys112, and His117 and is weakly bonding to other residues. The active site of azurin has a distorted trigonal bipyramidal structure.

The geometry of the active site of azurin has been estimated by the density functional theory (DFT) with B3LYP method [8] and quantum mechanics/molecular mechanics (QM/MM) method [9]. The hyperfine coupling constants in the active site has been calculated by DFT with UB1LYP [10] and B3LYP [11] methods, and also by QM/MM approach [12]. The electronic structure and the g-tensor of the active site of azurin have been investigated by ab initio multireference determinantal configuration interaction (MRD-CI) calculations [13].

In this study, we present a cluster model for the active site of oxidized azurin and investigate the electronic structure of the cluster model by the density functional methods. Dependency of electronic properties such as partial charge and partial spin densities in the cluster model on the cluster structure is investigated. We estimate force constants between the copper ions and coordinate-bonded atoms in residues around the copper ion. We discuss the electronic structures of the cluster model in relation to the active site of oxidized azurin by a simple Hubbard model for the active site.

2. Model and method

We consider a cluster model which consists of a copper ion and five residues as shown in Fig. 1. For the configuration of the cluster model, we use the coordinate of atoms around the active site of *Pseudomonas aeruginosa* azurin in Protein Data Bank (PDB), code 4AZU, which is determined by X-ray diffraction at pH 5.5 [7]. The configuration of hydrogen atoms in the cluster model is determined by HF/3-21G* geometry optimization with fixed other all atoms. Ligand distance, angle, and dihedral angle of our cluster model used in this study are summarized in Table 1. In this study, we calculate electronic properties of the cluster model in a condition that the total charge of the cluster model is +1 as $[Cu(His46)(Cys112)(His117)(Met121)(Gly45)]^{+}$ with the geometry as shown in Fig. 1.

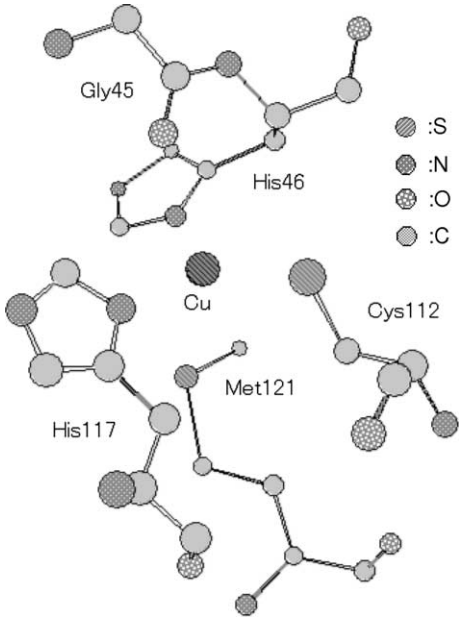

Fig. 1. Cluster model of oxidized azurin.

Table 1
Ligand distances, angles, and dihedral angles of active site model used in this study

	Parameter
Distance (Å)	
Cu–O(Gly45)	2.955
Cu–N(His46)	2.064
Cu–S(Cys112)	2.267
Cu–N(His117)	1.978
Cu–S(Met121)	3.164
Angle (°)	
N(His117)–Cu–N(His46)	108.3
S(Cys112)–Cu–N(His117)	123.7
S(Cys112)–Cu–S(Met121)	110.5
S(Cys112)–Cu–O(Gly45)	100.3
Dihedral angle (°)	
N(His117)–Cu–S(Cys112)–C_β	91.6
S(Cys112)–Cu–N(His46)–C_γ	−13.6
S(Cys112)–Cu–N(His117)–C_γ	−40.7
S(Cys112)–Cu–S(Met121)–C_γ	46.9
S(Cys112)–Cu–O(Gly45)–C	82.8

We perform density functional calculations with Becke's three-parameter hybrid exchange functional [14] and the Lee–Yang–Parr correlation functional [15] (B3LYP) for the cluster model by GAUSSIAN98 program package [16]. We calculate the distribution of partial charge and partial spin densities on some atoms by Mulliken population analysis (MPA) and natural population analysis (NPA) [17] with 6–31G** basis set [18]. The potential energy surfaces are also calculated by B3LYP with 6–31G** basis.

3. Results and discussion

In this study, we calculate electronic properties such as total energy, partial charge and spin densities for various cluster structures, and discuss the dependency of those properties on the cluster structure.

3.1. Potential energy surface and parameters

We show potential energy surfaces (PES) for Cu–X (X = S(Cys112), N(His117), S(Met121)) by B3LYP/6-31G** in Fig. 2(a). These calculations are performed to construct PES along the Cu–X. The internal coordi-

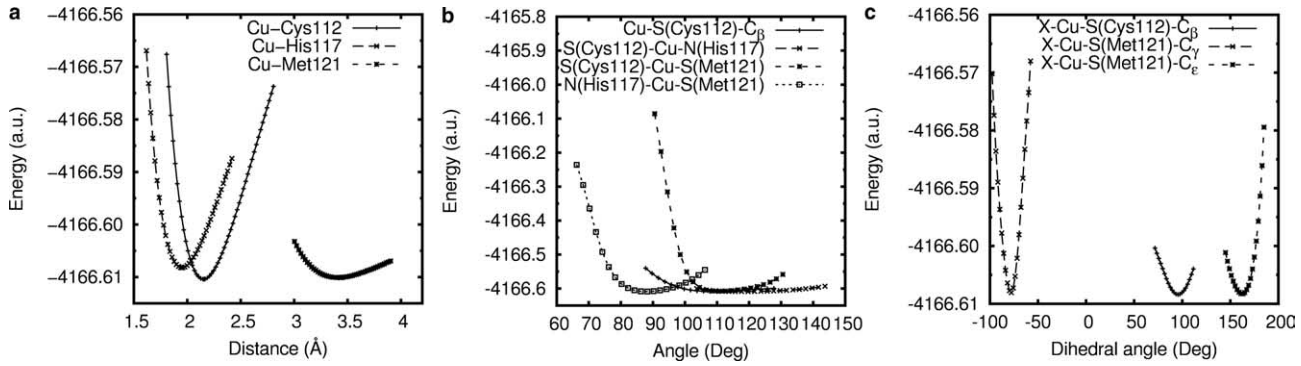

Fig. 2. Potential energy surfaces. (a) Potential energy surface for distance between Cu and X (X = S(Cys112), N(His117), S(Met121)). (b) Potential energy surface for angle X–Cu–Y ((X,Y) = (S(Cys112),N(His117)), (S(Cys112),S(Met121)), (N(His117),S(Met121))). (c) Potential energy surface for dihedral angle X–Cu–Y–Z (X = N(His117), (Y,Z) = (S(Cys112),C_β), (S(Met121),C_γ), (S(Met121),C_ϵ)).

nates other than the varying ones are fixed at the initial geometry. We find that the equilibrium bond lengths of Cu–S(Cys112) and Cu–N become 2.157 and 1.948 Å, respectively. These equilibrium distances are shorter than those of experimental structures. The equilibrium bond length of Cu–S(Met121) becomes 3.342 Å which is longer than that of X-ray diffraction crystallography.

Fig. 2(b) shows PESs for angle of X–Cu–Y ((X,Y) = (S(Cys112),N), (S(Cys112),S(Met121)), (N,S-(Met121))) and for Cu–S(Cys112)–C_β. The equilibrium angles are 119.687°, 110.536°, 88.231°, and 107.736°, respectively. The angle of S(Cys112)–Cu–N is smaller than that of the experimental result, and N–Cu–S(Met121) is larger than that. Other two angles become just values of experimental data.

Fig. 2(c) shows PESs for dihedral angle of X–Cu–Y–Z (X = N, and (Y,Z) = (S(Cys112),C_β), (S(Met121),C_γ), (S(Met121),C_ϵ)). These equilibrium dihedral angles are 95.625°, −77.727°, and 163.075°, respectively. The present results of PES for distance, angle, and dihedral angles summarizes in Table 2.

From these PES calculations, we estimate parameters of model potentials for distance, angle, and dihedral angle related to the copper ion. Potential of the distance is often evaluated by Morse and harmonic potential functions, $V_M(r)$ and $V_H(r)$, written as:

$$V_M(r, D_e) = D_e(1 - \exp[-\alpha(r - r_c)])^2, \quad (1)$$

$$V_H(r, K_r) = K_r(r - r_c)^2, \quad (2)$$

where D_e and α are constant fitting parameters, and r_c means equilibrium bonding distance, and K_r is a constant parameter. Potentials for angle and dihedral angle are evaluated by:

$$V(\theta, K_\theta) = K_\theta(\theta - \theta_c)^2, \quad (3)$$

$$V(\phi, K_\phi) = K_\phi[1 - \cos(\phi - \phi_c)], \quad (4)$$

where K_θ and K_ϕ are fitting parameters, and θ_c and ϕ_c are equilibrium angle and dihedral angle, respectively.

Table 2
Ligand distance, angle, and dihedral angle, and fitting parameters

Distance	r_c (Å)	r_{PDB} (Å)	K_r (kcal/mol)
Cu–S(Cys112)	2.157	2.267	130.948
Cu–N(His116)	1.948	1.978	128.449
Cu–S(Met121)	3.342	3.164	29.150
Angle	θ_c (°)	θ_{PDB} (°)	K_θ (kcal/mol rad^2)
Cu–S(Cys112)–C_β	107.736	107.736	34.857
S(Cys112)–Cu–N(His117)	119.687	123.686	11.950
S(Cys112)–Cu–S(Met121)	110.536	110.536	95.530
N(His117)–Cu–S(Met121)	88.231	86.231	112.133
Dihedral angle	ϕ_c (°)	ϕ_{PDB} (°)	K_ϕ (kcal/mol rad^2)
N(His117)–Cu–S(Cys112)–C_β	95.625	91.625	0.255
N(His117)–Cu–S(Met121)–C_ϵ	163.075	165.075	0.425
N(His117)–Cu–S(Met121)–C_γ	−77.727	−77.727	1.772
S(Cys112)–Cu–S(Met121)–C_ϵ	−72.252	−70.252	0.428
S(Cys112)–Cu–S(Met121)–C_γ	46.946	46.946	1.773
S(Met121)–Cu–S(Cys112)–C_β	−9.892	−7.892	0.255

These fitting parameters determined from these calculations as shown in Fig. 2 are summarized in Table 2.

3.2. Charge density and spin density

Fig. 3 shows dependency of partial charge and spin densities on various cluster structures estimated by Mulliken population analysis. We show partial charge densities on the copper ion, the sulfur and nitrogen ions for various distances between Cu and X (X = S(Cys112), N(His117), S(Met121)) in Fig. 3(a)–(c), respectively. From Fig. 3(a), we can find that the partial charge on Cu ion becomes larger, when the distance between Cu and S(Cys112) increases. On the other hand, the partial charge on S ion in Cys112 becomes smaller. Partial charge on other ions hardly varies. From Fig. 3(b) and (c), we also find that each partial charge is almost constant for change of distance between Cu and N(His117) or Cu and S(Met121).

Dependency of partial spin on the distance between Cu and X (X = S(Cys112), N(His117), S(Met121)) is shown in Fig. 3(d)–(f), respectively. We can find that

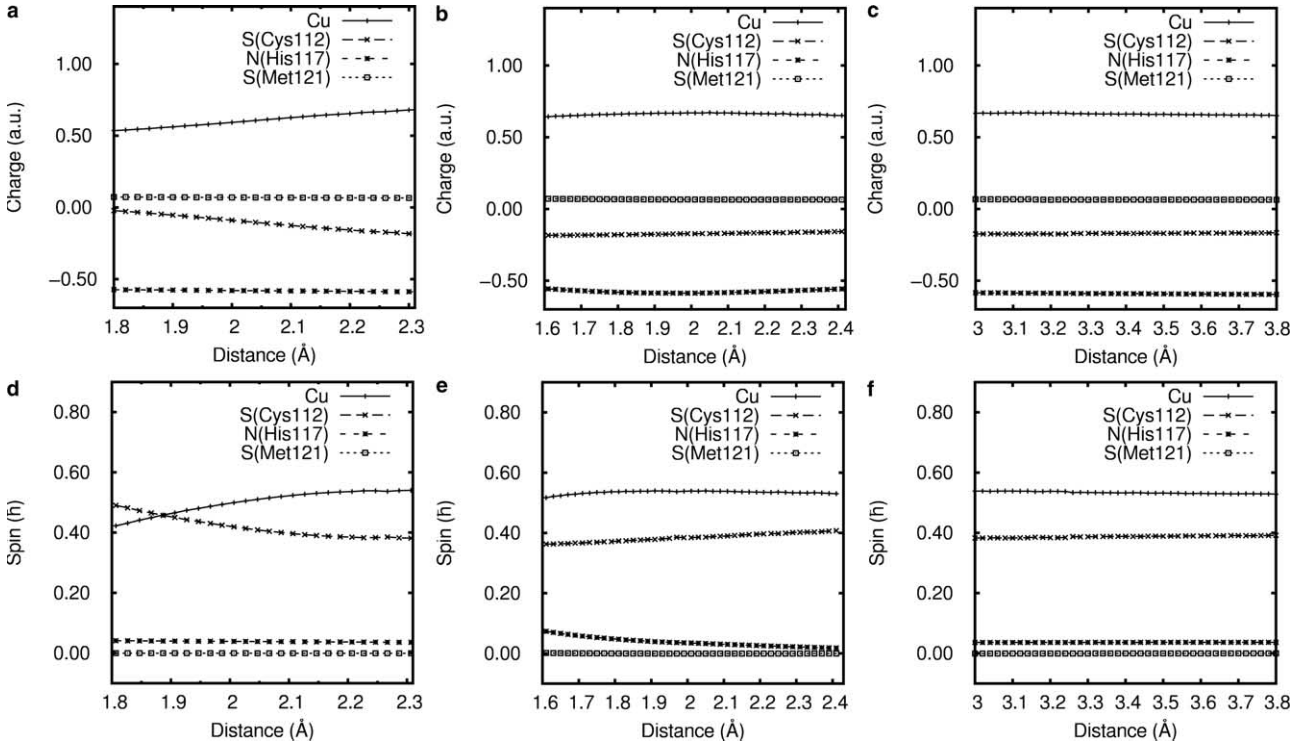

Fig. 3. Atomic charge and spin density. (a) Partial charge densities of Cu, S(Cys112), N(His117), and S(Met121) for various distances between Cu and S(Cys112) atoms. (b) Partial charge densities for various distances between Cu and N(His117) atoms. (c) Partial charge densities for various distances between Cu and S(Met121) atoms. (d) Partial spin densities of Cu, S(Cys112), N(His117), and S(Met121) for various distances between Cu and S(Cys112) atoms. (e) Partial spin densities for various distances between Cu and N(His117) atoms. (f) Partial spin densities for various distances between Cu and S(Met121) atoms.

the partial spin on copper ion increases, if the distance between Cu and S(Cys112) becomes larger, and that the partial spin density on the sulfur ion in Cys112 decreases. Others are almost constant for varying the distances. From Fig. 3, we can find that partial charge and spin depend upon the varying distance between the copper and sulfur(Cys112) ions.

3.3. Simple Hubbard model for active site

In this section, we present a simple Hubbard model to understand the electronic structure of the active site of oxidized azurin, and discuss charge and spin densities around the active site by using the simple model in relation to a strongly correlated electron systems. In this study, we focus on $d_{x^2-y^2}$ orbital of the copper ion and p_y orbital of sulfur ion in Cys112 in the active site as shown in Fig. 4(a), and we consider a Hubbard Hamiltonian of this model (see Appendix A).

From the Hubbard model for the active site of azurin, we can find the ground state energy for 3-electron and 4-electron systems as shown in Fig. 4(b) (see Appendix A). When $t/U < 1$, the ground state energy becomes larger than that of $t/U > 1$ because of the on-site repulsion U. The ground state energy of 4-electron system is larger than that of 3-electron system. The partial electronic charge on each orbital is shown in Fig. 4(c). When $t/U < 1/3$, partial charge of p-orbital is larger than that of d-orbital because of the on-site repulsion U, and the partial charge of d-orbital becomes 1 in the case of $t/U \ll 0$. On the other hand, from Fig. 4(d), partial spin of p-orbital is smaller than that of d-orbital, when $t/U < 1/3$.

When the distance between copper and sulfur ions increases, the transfer integral t becomes smaller. Therefore, t/U becomes smaller as the increase of the distance. From Fig. 4(c), we can find the tendency of the decrease of partial electronic charge in copper ion. The decrease implies that partial charge on the copper ion becomes larger. On the other hand, From Fig. 4(d), partial spin becomes larger as the increase of the distance. In this case, we can estimate $t/U \sim 0.29$ form Fig. 3(a) and (b). These tendency derived from the simple Hubbard model are good agreement with those from quantum chemical calculations.

In the high-Tc superconductivity, copper ions play an important role of the strong electron correlation, and it is well known that the on-site repulsion U of the copper ion is large (about 8 eV). In the case of the active site of oxidized azurin, we can expect that the copper ion also play a chemical role of electronic structure, functionalities in azurin.

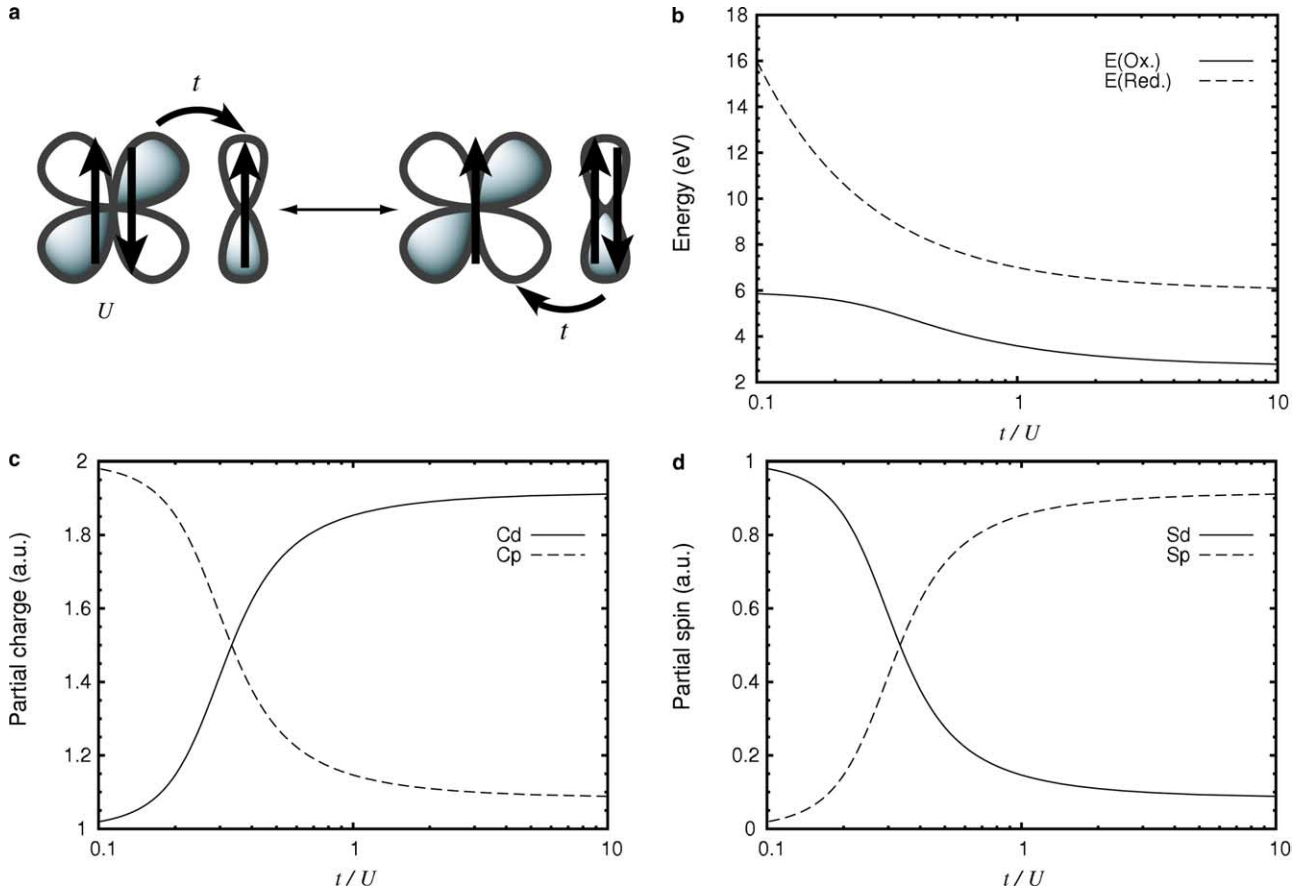

Fig. 4. Simple Hubbard model for active site of azurin. (a) 2-Site 3-electron system with $d_{x^2-y^2}$ of the copper ion and p_y of the sulfur ion in Cys112. (b) Total energy for 3- and 4-electron systems. We use parameters of $\epsilon_d = 0.0$, $\epsilon_p = 3.0$, $t = 1.0$ (eV). (c) Partial charge on each orbital. (d) Partial spin on each orbital. We have $C_d = C_p$ and $S_d = S_p$ in $t/U = 1/3$ form Eqs. (A.16) and (A.17).

4. Concluding remarks

We have presented a cluster model for the active site of oxidized azurin and have investigated electronic structure of the cluster model by density functional calculations. We have calculated the potential energy surfaces for distances between the copper and coordinate-bonded atoms, angles, and dihedral angles related the copper ion. Partial charge and spin densities on each atom have been also calculated. The dependency of the partial charge and spin densities on the change of the distance has been discussed in relation to the strong electron correlation on d-orbital of the copper ion. The partial charge and spin on the copper and sulfur ions in Cys112 depend upon only the distance between them. Partial charge and spin densities on other atoms are almost constant. We have estimated parameters of some effective energy potentials for distance, angle, and dihedral angle. The contributions of electronic structure from excellent basis set and methods will be presented elsewhere.

Appendix A

Here, we briefly present the simple Hubbard model for the active site of azurin. The Hubbard Hamiltonian of the model is written as

$$H = H_0 + H_1 + H_2, \tag{A.1}$$

where

$$H_0 = \sum_\sigma (\varepsilon_d d^\dagger_\sigma d_\sigma + \varepsilon_p p^\dagger_\sigma p_\sigma), \tag{A.2}$$

$$H_1 = t \sum_\sigma \left(d^\dagger_\sigma p_\sigma + p^\dagger_\sigma d_\sigma\right), \tag{A.3}$$

$$H_2 = U d^\dagger_\uparrow d^\dagger_\downarrow d_\downarrow d_\uparrow. \tag{A.4}$$

H_1 means kinetic part between d and p orbitals with the transfer integral t, and H_0 is the unperturable Hamilton with orbital energies ε_d and ε_p for d and p orbitals, respectively. H_2 indicates interaction part with on-site coulomb repulsion U on the d-orbital. $d^\dagger_\sigma$ (d_σ) is a creation (annihilation) operator at $d_{x^2-y^2}$ orbital with spin σ, and $p^\dagger_\sigma$ and p_σ mean a creation and an annihilation operator at p_y orbital, respectively.

For this model, we consider two electronic states as:

$$|\varphi_1\rangle = d^\dagger_\uparrow d^\dagger_\downarrow p^\dagger_\uparrow |0\rangle, \tag{A.5}$$

$$|\varphi_2\rangle = d^\dagger_\uparrow p^\dagger_\uparrow p^\dagger_\downarrow |0\rangle. \tag{A.6}$$

State $|\varphi_1\rangle$ includes two d-electrons and one p-electron, and state $|\varphi_2\rangle$ includes one d-electron and two p-electrons. We consider a superposition of two states as

$$|\phi\rangle = \frac{1}{\sqrt{1+g^2}}(|\varphi_1\rangle + g|\varphi_2\rangle). \tag{A.7}$$

By using the wavefunction of Eq. (A.7) and Hamiltonian of Eq. (A.1), we obtain the eigenvalue problem as

$$\boldsymbol{H}|\phi\rangle = E|\phi\rangle, \tag{A.8}$$

where

$$\boldsymbol{H} = \begin{pmatrix} 2\varepsilon_d + \varepsilon_p + U & -t \\ -t & \varepsilon_d + 2\varepsilon_p \end{pmatrix}. \tag{A.9}$$

From Eq. (A.8), we have the eigenvalue and the wavefunction of the ground state as

$$E_{GS} = -\frac{1}{2}\left[\sqrt{(\varepsilon_d - \varepsilon_p + U)^2 + 4t^2} - 3(\varepsilon_d + \varepsilon_p) - U\right] \tag{A.10}$$

and

$$|\phi_{GS}\rangle = \frac{t|\varphi_1\rangle + \left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)|\varphi_2\rangle}{\sqrt{t^2 + \left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}}. \tag{A.11}$$

Here, we define a partial charge and a partial spin of each orbital as:

$$C_d = \langle\phi|\sum_\sigma d^\dagger_\sigma d_\sigma|\phi\rangle, \tag{A.12}$$

$$C_p = \langle\phi|\sum_\sigma p^\dagger_\sigma p_\sigma|\phi\rangle, \tag{A.13}$$

$$S_d = \langle\phi|(d^\dagger_\uparrow d_\uparrow - d^\dagger_\downarrow d_\downarrow)|\phi\rangle, \tag{A.14}$$

$$S_p = \langle\phi|(p^\dagger_\uparrow p_\uparrow - p^\dagger_\downarrow p_\downarrow)|\phi\rangle, \tag{A.15}$$

where C_d (S_d) and C_p (S_p) mean partial charge (spin) on the d and p orbitals, respectively. From Eqs. (A.11)–(A.15), we have:

$$C_d = \frac{2t^2 + \left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}{t^2 + \left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}, \tag{A.16}$$

$$C_p = \frac{t^2 + 2\left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}{t^2 + \left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}, \tag{A.17}$$

$$S_d = \frac{\left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}{t^2 + \left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}, \tag{A.18}$$

$$S_p = \frac{t^2}{t^2 + \left(2\varepsilon_d + \varepsilon_p + U - E_{GS}\right)^2}. \tag{A.19}$$

bonding residues near the metal site to assist in catalysis, and (10) imposing a unique geometry on the metal site.

Recently, the blue copper proteins including azurin have been investigated experimentally and theoretically by many groups [1,6–12]. The geometry of the active site of azurin has been estimated by the density functional theory (DFT) with B3LYP method [7] and quantum mechanics/molecular mechanics (QM/MM) method [8]. The hyperfine coupling constants in the active site have been calculated by DFT with B1LYP [9] and B3LYP [10] methods, and also by QM/MM approach [11]. The electronic structure and the *g*-tensor of the active site of azurin have been investigated by ab initio multireference determinantal configuration interaction (MRD-CI) calculations [12].

Solvent effects on electronic structure of molecules have been investigated by many chemists and physicists to understand molecular structure, mechanism of chemical reactions in solution, etc. by using quantum-chemical calculations and molecular dynamics simulations. Physical properties such as geometry of molecules and charge distribution in solution often vary from those in vacuum [13]. Ryde et al. [7] have also performed a geometry optimization of the active site of blue copper proteins including azurin by quantum-chemical calculations with polarizable continuum model (PCM) [14]. Their results suggest that weak axial bond of Cu–S(Met121) in solution is more elongated than that in vacuum.

In this study, we investigate solvent effects on electronic structure of active site of oxidized azurin by density functional calculations. A cluster model for the active site of oxidized azurin is presented, and we calculate physical properties such as charge density and spin density of the model cluster involving solvent effects. We also present the dependence of those properties on the dielectric constant. Finally, we discuss the charge or electron transfer in the active site of azurin in relation to solvent effect.

2. Computational method

We present a cluster model for the active site of oxidized azurin and methods used in this study.

2.1. Computational model for active site

We consider a cluster model, which consists of a copper ion and five residues as shown in Fig. 1, for the active site of oxidized azurin. In the configuration of the cluster model, we use the coordinate of atoms around the active site of *Pseudomonas aeruginosa* azurin (code 4AZU) in Protein Data Bank, which is determined by X-ray diffraction results at pH 5.5 [6]. The configuration of all hydrogen atoms in the cluster model is determined by Hartree–Fock/3-21G* geometry optimization with fixed configuration of other all atoms. Ligand distances, angles, and dihedral angles of the cluster model used in this study are summarized in Table 1. In the calculations of this study, we use a condition that the total charge of the cluster model is +1.

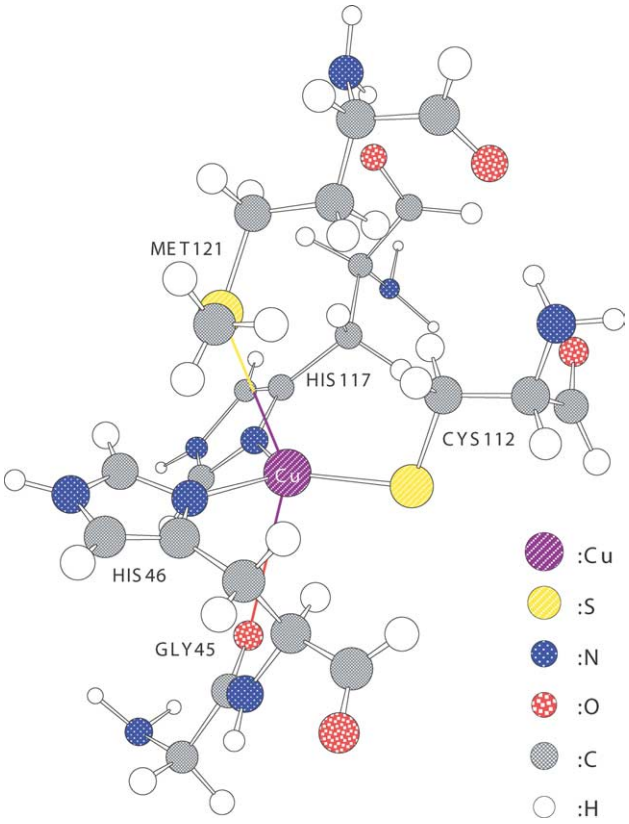

Fig. 1. Cluster model for active site of oxidized azrin.

2.2. Solvent effect using polarizable continuum model

We perform density functional calculations with Becke's three-parameter hybrid exchange functional [15] and the Lee–Yang-Parr correlation functional [16] (B3LYP) for the cluster model as shown in Fig. 1 by GAUSSIAN 03 program package [17]. We calculate partial charge and partial spin density on each atom by Mulliken population analysis (MPA) and natural population analysis (NPA) [18] with 6-31G* split-valence basis set [19].

For investigation of electronic structure of the active site of oxidized azurin in solution, we use polarizable continuum model (PCM) [14] in DFT calculations. An integral equation formulation model (IEF-PCM) [20] is adopted. In present calculations, values of dielectronic constant ϵ_r are arbitrarily selected in the region from 2 to 78.

3. Results and discussion

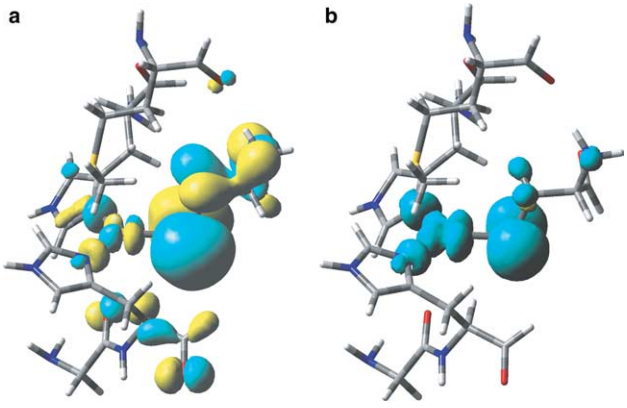

Fig. 2. SOMO and spin density of the cluster model. (a) Distribution of SOMO (isovalue = 0.02 a.u., and orbital energy = −9.1931 eV). (b) Distribution of spin density (isovalue = 0.0012 a.u.).

31G* calculation. We can find $3d_{x^2-y^2}$ orbital π antibonded to the sulfur atom in the Cys112 and σ antibonded to the nitrogen atoms in His46 and His117. SOMO distributes on the nitrogen atoms in His46 and His117, and is not much on other atoms in His46 and His117. On the other hand, we can find that the distribution of SOMO widely lies over Cys112. SOMO largely distributes on the sulfur atom, two H atoms in $C_\beta H_2$ in Cys112, and the nitrogen atom in backbone of Cys112. We also find small distribution of SOMO around O atom in Gly45. Fig. 2(b) shows the spin density of the cluster model. The spin density distributes around copper ion, S(Cys112), N(His46) and N(His117) atoms, and we also find small distribution of spin density on the H atoms in $C_\beta H_2$ and the nitrogen atom in backbone of Cys112. In three coordination bonds to copper ion, SOMO widely distributes to only the bonding direction to the side of Cys112. These results suggest that histidine or imidazole has a role of restraint of spatial distribution for the direction of the coordination-bonding of the nitrogen atom to the copper ion.

Table 2 summarizes the atomic charge and spin density of the cluster model in vacuum by MPA and NPA. From partial spin density by MPA in Table 2, we find the largest value about 53.2% on the copper ion and the second largest value about 38.8% on the sulfur ion in Cys112. From NPA, we find that the valence of the copper ion becomes 1.26. Atomic charges and Mulliken spin densities of the similar cluster model to the present model in vacuum have been presented in [12].

3.2. Spin density and atomic charge in solution

Tables 3 and 4 show the spin densities and the charge distribution for various dielectric constants, respectively. The dielectric constants ϵ_r is varied from 2 to 78. In general, $\epsilon_r = 78$ corresponds to water molecule. We find asymptotical changes of spin density and atomic charge between the copper ion and the sulfur ion in Cys112. As increasing ϵ_r, the spin density of Cu ion becomes increasing, and the spin density of S_γ(Cys112) is decreasing. On the other hand, the atomic charge of Cu ion increases from 0.644 to 0.681, and the atomic charge of S_γ(Cys112) decreases from −0.160 to −0.233. These changes of atomic charge and spin densities suggest that electron with β spin on copper ion slightly moves to the sulfur ion in Cys112 in the case of increasing the dielectric constant. From this electron transfer, the spin density of the copper ion becomes larger than that in vacuum, and the charge distribution also becomes larger.

3.3. A simple model for solvent effect

In this subsection, we briefly discuss the solvent effects of electronic properties presented in previous subsection by using a simple Hubbard model [21–23]. In this study, we focus $d_{x^2-y^2}$ orbital of the copper ion and p_y orbital of sulfur ion in Cys112 in the active site of azurin. We assume on-site repulsion U on only copper site, because it is well known that the on-site coulomb repulsion U of the copper ion is large (about 8 eV). Therefore, for the most simple case, we can consider a 2-site system with 3 electrons as a simple model for the active site. By solving electronic structure of this simple model, we can find that partial charge of d orbital becomes larger than that of p orbital, when $t/U \gg 1$, and that partial spin of d orbital becomes smaller. On the other hand, in the case of $t/U \ll 1$, partial charge on d orbital becomes smaller, and partial spin on d orbital becomes larger, because of the large on-site repulsion. In the case of the active site of oxidized azurin,

Table 2
Partial atomic charges and partial spin densities on each atom by Mulliken population analysis (MPA) and natural population analysis (NPA)

Residue	Atom	MPA		NPA
		Atomic charge (a.u.)	Spin density (%)	Atomic charge (a.u.)

	$N_{\delta1}$	−0.5264	3.601	−0.6627
	$C_{\delta2}$	0.2308	−0.424	0.1899
	$C_{\epsilon1}$	0.0138	0.341	−0.0742
	$N_{\epsilon2}$	−0.5239	0.047	−0.5012
Gly45	C	0.5979	−0.015	0.6871
	O	−0.5303	0.022	−0.7012
	C_α	−0.2391	−0.001	−0.3368
Met121	C_γ	0.1987	−0.023	−0.5907
	S_δ	0.0769	−0.051	0.1822
	C_ϵ	−0.1603	0.005	−0.5678

we can expect that the transfer integral becomes smaller than the on-site repulsion on the copper ion in the active site.

Next, we consider a simple model for solvent effects. We assume the effective electron–electron interaction W between sites in the system and solvent molecules. The effective interaction is clearly related to the polarization of the solvent molecules. If solvent molecules have large dielectric constant, the effective interaction W becomes large. In the frame work of a random phase approximation [24,25], the effective on-site coulomb potential U_{eff} on the d orbital can be written as

$$U_{\text{eff}} = \frac{U}{1 - U^2 W^2}. \quad (1)$$

From Eq. (1), we find that the effective interaction U_{eff} becomes larger than the bare interaction U, when the dielectric constant is larger than that in vacuum. Therefore, from Eq. (1), we can expect that spin density of copper ion in the active site of oxidized azurin in solution with large dielectric constant becomes larger than that in vacuum. This effect arises from the strong electron correlation on the copper ion. Since on-site coulomb interactions of p orbitals are small, the solvent effects of electronic correlation in p orbital might be small.

4. Concluding remarks

In this study, we have presented a computational model for the active site of oxidized azurin and have investigated the electronic structure of the active site model by using the density functional methods with polarizable continuum model. The partial atomic charge and spin density on some ions have been calculated for various dielectric constants. We have presented a simple model for the active site of oxidized azurin by a Hubbard model, and have discussed the dependence of the charge and spin distributions on the dielectric constants.

For the cluster model in vacuum, the distribution of SOMO and the spin density widely lie over Cys112. The distribution of them over histidines is not so much.

In solution, the partial spin and charge of the copper ion become larger than that in vacuum, when the dielectric constant is larger. The spin and charge of sulfur ion in Cys112 become smaller. These results suggest that electron with β spin moves from the copper ion to the sulfur ion, if the dielectric constant becomes larger. We have found the electron moving because of the strong electron correlation on the copper ion by using a Hubbard model.

Since the active site of azurin is surrounded by many residues, the electronic structure of active site of azurin is weakly interacted with solvent molecules. We need to consider larger systems and to use other excellent computational methods such as QM/MM method. The contribution to the electronic structure of the active site of azurin from neighbor residues around the active site will be presented elsewhere. Electronic structure of another cluster model terminated by H atoms for N- and C- termini in each residue in the cluster model presented in this study will be also presented elsewhere. The electronic structure of the new model also becomes the same tendency to the present model.

2. Methods

We write the Ising spin Hamiltonian in the form

$$H = -\sum_{(ij)} J_{ij} S_i S_j. \quad (1)$$

where $S_i = \pm 1$ denotes the two states of the site i. We call the two states the L state for $S_i = -1$ and the H state for $S_i = 1$, respectively. The parameter $J_{ij}(>0)$ is the coupling energy between the nearest neighbor sites i and j. As the impurities, we introduce fixed spins that only have a single state, $S_i = 1$, or -1. Even in the presence of the fixed spins, the ground state is doubly degenerate 'ferromagnetic' phase where all of the variable spins are in the same state. We call these two global states the L and H phases, respectively.

In this paper, we consider a simple cubic spin lattice with three-dimensional periodic boundary conditions. The location of the fixed spins is schematically shown in Fig. 1. The system is identified by three parameters, N_a, N_i, and N_p. Fig. 1(a) and (b) shows the structures for the case of $N_p = 1$ and $N_p = 4$, for example. N_a indicates the number of spins on a side of cubic lattice. The system includes N_a^3 spins. In this paper, we fixed $N_a = 48$. In the case of $N_p = 1$ as shown in Fig. 1(a), we introduce fixed spins as two clusters whose size is $N_i \times N_i \times N_i$. One of the clusters I_H is located at the position of $(1/4, 1/4, 1/4)$, where the length unit is the side of the cubic. The other, I_L, is at $(3/4, 3/4, 3/4)$. The Ising spins in I_L and those in I_H is fixed with $S_i = -1$ and $S_i = 1$, respectively. In the case of $N_p > 1$, the system forms $N_p \times N_p \times N_p$ superstructure of the system of $N_p = 1$ as shown in Fig. 1(b). The number of clusters I_L and I_H are, respectively, given by N_p^3. The number of the fixed spins in each cluster is given by N_i^3 as well as the $N_p = 1$ case.

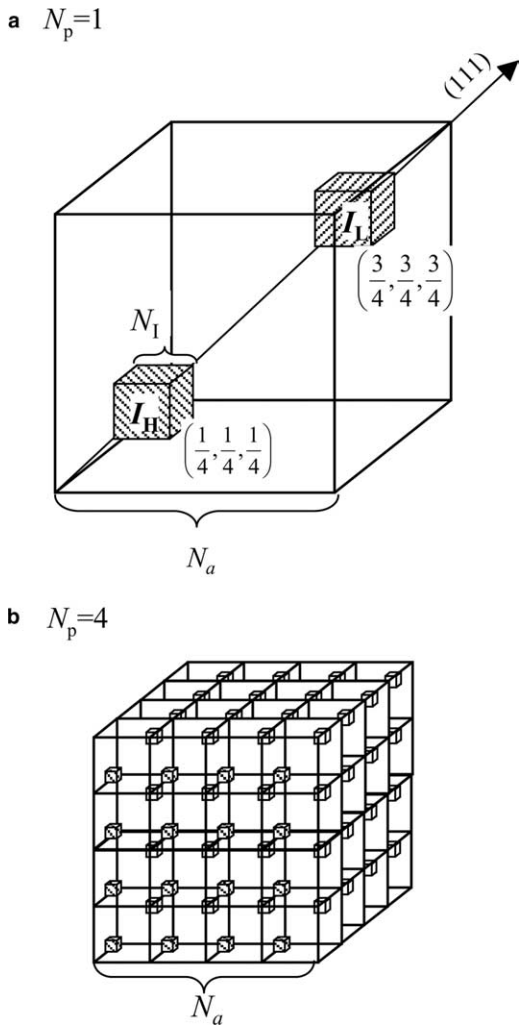

Fig. 1. Schematic structure of the calculated model for (a) $N_p = 1$ and (b) $N_p = 4$.

We studied the phase switching kinetics from one phase to another at finite temperatures by a means of a classical Monte Carlo simulation technique. The effect of photoexcitation is incorporated by external random flippings. Details of the actual procedure of the Monte Carlo simulations were described elsewhere [22,25]. In this paper, we assume the L phase as the initial state of the system and that the excitation occurs only when the spin is in the initial (L) state. Note that the backward transition from the H phase exhibits the same behavior because of symmetry with respect to the inversion of the spin direction.

The spin flipping rate at each site j is the sum of the external and thermal terms: $w_j = w_j^P + w_j^T$. The external term w_j^P corresponds to the selective photoexcitation. We consider selective excitation from L to H state, we set $w_j^P(L \to H) = W$ and $w_j^P(H \to L) = 0$. In each Monte Carlo step (MCS), both thermal and external spin-flip trials are performed at every site once on average. For the thermal flipping rate w_j^T, the heat bath model is used. We use $k_B T = J$, which is chosen lower than the order–disorder phase transition (Curie) temperature T_C, above which the bistability is lost. For example, $T_C = 4.51J$ for a cubic lattice with $N_i = 0$.

3. Result

We investigated the kinetics of the photoinduced switching with the excitation rate suddenly raised at $t = 0$ from 0 to a constant value W. The fraction of the H state, n_H, is plotted for $N_p = 1$ as a function of the excitation time t for strong and weak excitation ($W = 0.13$ and 0.10/MCS) in Fig. 2. For comparison, we draw the cases of $N_i = 12$ (doping fixed spins) and $N_i = 0$ (no fixed spins). At $t < 0$, the system is in an equilibrium state with $n_H \sim 0$. After the start of excitation at $t = 0$, n_H increases and approaches almost unity in some cases, indicating the completion of phase switching. With $W = 0.13$/MCS, the phase switching accomplishes

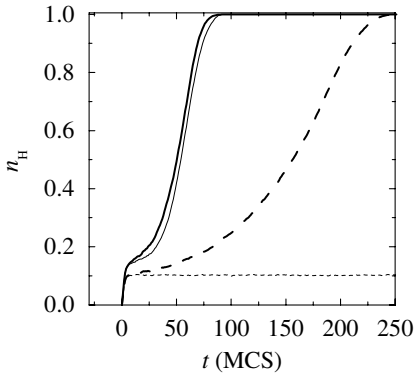

Fig. 2. Time evolution of n_H under continuous excitation on the system of $N_p = 1$ and $N_a = 48$ at $k_B T = J$. The thick and thin lines represent the cases with $N_i = 12$ and that with $N_i = 0$ (without fixed spins), respectively. The solid and broken lines are drawn for the excitation rate $W = 0.13$/MCS and for $W = 0.10$/MCS. The continuous excitation corresponding to photoirradiation is applied only at $t > 0$.

in almost the same time in the both cases. In the case of $W = 0.10$/MCS, on the other hand, the phase switching is observed only in the $N_i = 12$ case, indicating that the phase switching occurs under weaker excitation in the presence of fixed spins than the case without fixed spins.

The time of continuous excitation required for the phase switching, t_p, depends on the excitation intensity W. The W dependence of t_p is shown in Fig. 3 for various N_i with $N_p = 1$. Here, t_p is defined as the time of n_H exceeding $1 - n_H^0$, where n_H^0 represents n_H in an equilibrium state at $W = 0$. We used the average of 10 Monte Carlo samples to derive t_p. There is a threshold excitation rate W_c only above which the phase switching occurs for each N_i, and t_p diverges at above W_c. The threshold W_c is reduced significantly with increasing N_i.

The dependence of the threshold W_c on N_i and N_p is plotted in Fig. 4. We investigated two kinds of fixed spin distribution: (a) various N_i with fixing $N_p = 1$ and (b) various N_p with fixing $N_i = 1$. The x-axis in Fig. 4 means

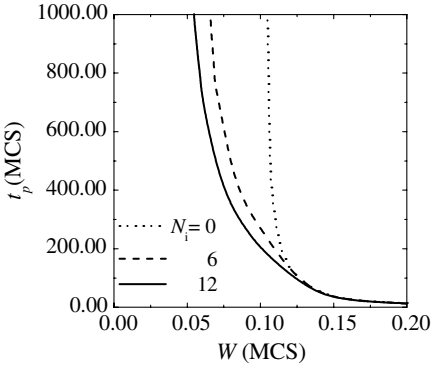

Fig. 3. Dependence of conversion time t_p on the excitation intensity W for various fixed spin cluster sizes N_i with $N_p = 1$ and $N_a = 48$ at $k_B T = J$.

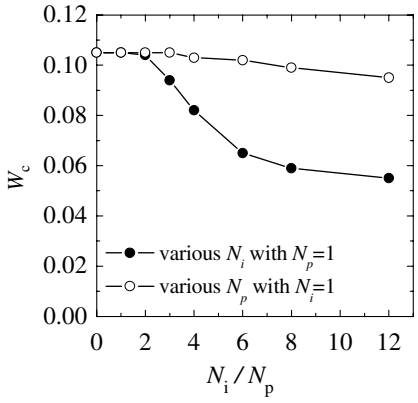

Fig. 4. Dependence of the threshold excitation rate W_c upon N_i and N_p at $k_B T = J$.

N_i for (a) and N_p for (b), respectively. Because number of fixed spins in the system is given by $N_i^3 N_p^3$, the same position along the x-axis indicates the same number of fixed spins in the system. The dependence of W_c on the number of fixed spins are clearly different between two systems. In the (a) case, W_c significantly decreases as N_i increases. At $N_i = 12$, W_c reaches about a half intensity compared with the case of $N_i = 0$. However, W_c is almost independent on N_p in the (b) case. These result shows W_c does not depend on the fraction of the fixed spins but the size of fixed spin clusters.

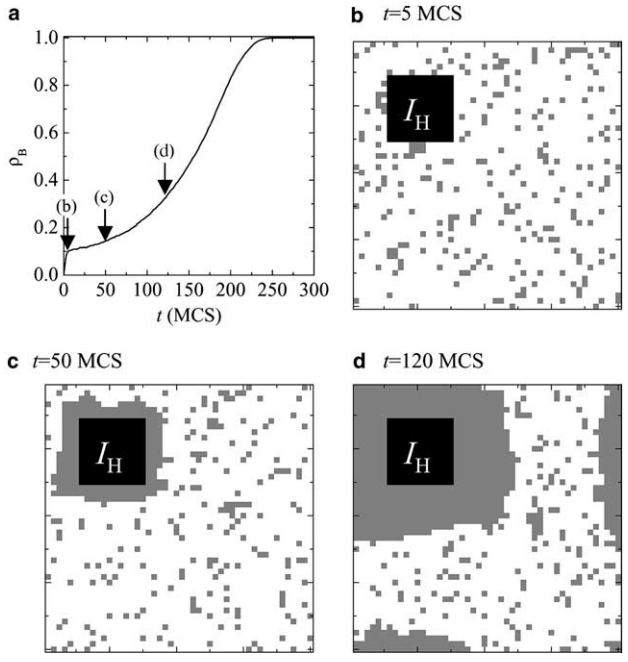

Fig. 5. (a) Fraction of the units in the H state n_H during the process of a photoinduced switching from the L phase to the H phase of the $48 \times 48 \times 48$ simple cubic lattice with $N_i = 12$ and $N_p = 1$. (b)–(d) Snapshots along the plane on $z = 1/4$ at $t = 5$,50, and 120 MCS with excitation rate $W = 0.12$/MCS. The white and gray region represent the units in $S_i = -1$ (initial) and in $S_i = -1$ (final), respectively. The region I_H represents the fixed spins with $S_i = 1$.

The reason why W_c depends on the cluster size is understood from the mechanism of the photoinduced switching. In our model, the photoinduced switching proceeds as a nucleation of the final phase and following its growth [24,25]. In the initial stage of the switching, the nucleus of the final phase appears. When the size of nucleus goes beyond a threshold, the growth of the final phase proceeds drastically. If the assembly of the final phase exists in advance, it can behave as the nucleus in the phase switching. For example, in the switching from the L phase to the H phase, the fixed spin cluster I_H plays a role of the nucleus. How the phase switching proceeds in the presence of the cluster is clearly understood with snapshots of the spin states in the switching process shown in Fig. 5. In Fig. 5(c), we found that the phase switching starts around the I_H cluster. The nucleus grows only when its size beyond a threshold in the switching. Therefore, as N_i increases, the switching is easy to appear as shown in Fig. 4

4. Conclusion

We demonstrated that the threshold of excitation intensity required for the phase switching can be reduced by introducing fixed spin clusters whose state is the same as the final phase. Our result implies that the photoinduced switching property of the complexes can be controlled by introducing impurities, although researchers generally try to exclude impurities to make a good sample in material synthesis. We expect that our idea will be a new guideline to improve properties of inorganic complexes.

the magnetic moment, is the essential feature for a molecule to function as an SMM. A twelve-nuclei manganese complex Mn_{12}-ac is one of the most extensively-studied SMM with the largest energy barrier of 66 K due to its $S = 10$ ground state and large negative D parameter [3]. Although there are many efforts to find new SMMs [4], Mn_{12} complex family still possesses the best structural and magnetic properties for showing single-molecular magnetic behavior at the highest temperature, and they have been paid a great deal of attention.

Chemical modifications so far done for Mn_{12}-ac complex include substitutions of bridging acetates to other carboxylates [1,2,5] and partial substitutions of a peripheral Mn^{III} ion to an Fe^{III} ion [6a] or a Cr^{III} ion [6b]. A substitution of carboxylate anions to non-carboxylate oxo anions such as NO_3^-, RSO_3^-, and $R_2PO_2^-$ would expand the possibility of the chemical modification in Mn_{12} complexes [7]. Although most of Mn_{12} complexes have four coordinating water molecules, only few examples, such as $[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_3]\cdot 4H_2O$ [5a], $[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_3]$ [8a], $(Ph_4P)[Mn_{12}O_{12}(O_2CH_2Cl)_{16}(H_2O)_3]$ [8b], $(PhP_4)_2[Mn_{12}O_{12}(O_2CH_2Cl)_{16}(H_2O)_3]$ [8c], and $(Ph_4P)[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(H_2O)_2]$ [5f], are known to have two or three coordinating water molecules with five-coordinating Mn^{III} ions. Herein, we report eight Mn_{12} derivatives with diphenylphosphate bridges including one-electron reduced anion complexes. Two crystal structures among them were determined by single crystal X-ray analyses [7e,7f].

2. Experimental

2.1. Compound preparation

All chemicals and solvents were used as received. The $[Mn_{12}O_{12}(CH_3COO)_{16}(H_2O)_4]\cdot 4CH_3COOH\cdot 2H_2O$ [9] (Mn_{12}-ac), $[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_3]\cdot 4H_2O$ [5a] (Mn_{12}-pr), and $[Mn_{12}O_{12}(PhCOO)_{16}(H_2O)_4]\cdot PhCOOH\cdot CH_2Cl_2$ [4c] (Mn_{12}-bz) were prepared by the literature method.

2.2. $[Mn_{12}O_{12}(OAc)_{12}(dpp)_4]\cdot 6.1CH_2Cl_2\cdot 0.4H_2O$ (**1**$\cdot 6.1CH_2Cl_2\cdot 0.4H_2O$)

To a solution of Mn_{12}-ac (1.86 g, 1.0 mmol) in CH_3CN (100 ml) was added 4 equiv of diphenylphosphate (dppH, 1.01 g, 4.0 mmol). The mixture was stirred overnight in a closed flask and the solution was evaporated to dryness. To the residue was added toluene (100 ml), and the solution was stirred for 4 h, and then it was evaporated to dryness. The addition and removal of toluene were repeated four times. The residue was dissolved in CH_2Cl_2 (20 ml) and filtered. Hexane was added to the filtrate and the solution was allowed to stand at room temperature for two weeks. Black block-shaped crystals of **1**$\cdot 6.1CH_2Cl_2\cdot 0.4H_2O$ suitable for X-ray analysis were obtained from CH_2Cl_2/hexane. The crystals were isolated by filtration and dried in vacuo. The yield was 2.35 g (89%). *Anal.* Calc. for **1** ($C_{72}H_{76}Mn_{12}O_{52}P_4$): C, 33.83; H, 3.00. Found: C, 33.70; H, 3.14%. Selected IR data (KBr pellet cm^{-1}): 3069(w), 1581(s), 1491(s), 1441(s), 1379(m), 1330(m), 1201(m), 1092(s), 936(m), 670(m), 644(m), 611(m).

2.3. $[Mn_{12}O_{12}(OAc)_8(dpp)_8(H_2O)_2]$ (**2**)

A method similar to that used for synthesis of **1** was employed but using 8 equiv dppH. As a large amount of hexane was added to the filtrate of CH_2Cl_2 solution, the brown precipitate was collected by filtration, and washed with hexane, and dried in vacuo. The yield was 92%. *Anal.* Calc. for **2** ($C_{112}H_{108}Mn_{12}O_{62}P_8$): C, 40.12; H, 3.25. Found: C, 40.19; H, 3.28%. Selected IR data (KBr pellet cm^{-1}): 3069(w), 1591(s), 1491(s), 1440(m) 1382(m), 1332(m), 1198(s), 1107(s), 940(m), 779(m), 689(m), 532(m).

2.4. $[Ph_4P][Mn_{12}O_{12}(OAc)_{12}(dpp)_4(H_2O)_4]$ (**3**)

To a stirred dark brown solution of complex **1** (256 mg, 0.1 mmol) in CH_3CN (50 ml) was added solid Ph_4PI (46.7 mg, 0.1 mmol). The solution was stirred for 1 h. The I_2 in the resultant solution was removed by extraction in hexane (25 ml) for six times, and the solution was evaporated to dryness. The residue was dissolved in CH_2Cl_2 (6 ml). The brown powder was collected by filtration after addition of a large amount of hexane, and washed with hexane, and dried in vacuo. The yield was 249 mg (86%). *Anal.* Calc. for **3** ($C_{96}H_{104}Mn_{12}O_{56}P_5$): C, 38.85; H, 3.53. Found: C, 38.95; H, 3.36%. Selected IR data (KBr pellet cm^{-1}): 3067(w), 1590(s), 1491(s), 1440(s) 1389(m), 1334(m), 1203(m), 1095(s), 932(m), 779(m), 690(m), 669(m), 612(m), 528(m).

2.5. $[Ph_4P][Mn_{12}O_{12}(OAc)_8(dpp)_8(H_2O)_4]$ (**4**)

A method similar to that used for synthesis of **3** was applied to but replacing **1** with **2**. The yield was 90%. *Anal.* Calc. for **4** ($C_{136}H_{132}Mn_{12}O_{64}P_9$): C, 43.81; H, 3.57. Found: C, 44.06; H, 3.55%. Selected IR data (KBr pellet cm^{-1}): 3066(w), 1591(s), 1491(s), 1440(s) 1387(m), 1334(m), 1201(s), 1105(s), 1026(m), 934(m), 779(m), 690(m), 607(m), 529(m).

2.6. $[Mn_{12}O_{12}(OBz)_{12}(dpp)_4(H_2O)_4]\cdot 4CH_2Cl_2$ (**5**$\cdot 4CH_2Cl_2$)

To a solution of Mn_{12}-bz in CH_2Cl_2 was added 4 equiv of diphenylphosphate. The mixture was stirred about 1 h. Hexane was added to the filtrate; then the solution was

allowed to stand at room temperature for five days. Black block crystals $\mathbf{5}\cdot 4CH_2Cl_2$ suitable for X-ray analysis were obtained from CH_2Cl_2/hexane. The crystals were isolated by filtration and dried in vacuo. The yield was ca. 30%. *Anal.* Calc. for **5** ($C_{132}H_{108}O_{56}P_4Mn_{12}$): C, 47.00; H, 3.23; Mn, 19.54. Found: C, 46.84; H, 3.28; Mn, 18.89%. Selected IR data (KBr pellet cm^{-1}): 3066(w), 1595(m), 1562(m), 1491(s), 1415(s), 1348(m), 1201(m), 1088(s), 1025(w), 938(m), 687(m), 616(w), 517(m).

2.7. $[Mn_{12}O_{12}(OBz)_8(dpp)_8(H_2O)_4]$ (6)

A method similar to that used for synthesis of **5** was employed but using 8 equiv dppH. As a large amount of hexane was added to the filtrate of CH_2Cl_2 solution, the brown precipitate was collected by filtration, and washed with hexane, and dried in vacuo. The yield was 79%. *Anal.* Calc. for **6** ($C_{152}H_{128}Mn_{12}O_{64}P_8$): C, 46.98; H, 3.32; Mn, 16.79. Found: C, 46.84; H, 3.49; Mn, 15.94%. Selected IR data (KBr pellet cm^{-1}): 3067(w), 1592(s), 1560(w), 1492(s), 1415(s) 1355(m), 1199(s), 1105(s), 1025(w), 941(m), 779(m), 719(m), 688(m), 615(w), 523(m).

2.8. $[Ph_4P][Mn_{12}O_{12}(OBz)_{12}(dpp)_4(H_2O)_4]$ (7)

To a stirred dark brown solution of complex **5** (337 mg, 0.1 mmol) in CH_3CN (50 ml) was added solid Ph_4PI (46.6 mg, 0.1 mmol). The solution was stirred for 1 h. The I_2 in the resultant solution was removed by extraction in hexane (25 ml) for six times, and the solution was evaporated to dryness. The residue was dissolved in CH_2Cl_2 (6 ml). The brown powder was collected by addition of a large amount of hexane, and washed by hexane, and dried in vacuo. The yield was 333 mg (90%). *Anal.* Calc. for $\mathbf{7}\cdot CH_2Cl_2$ ($C_{157}H_{130}Cl_2Mn_{12}O_{56}P_5$): C, 49.65; H, 3.45; Mn, 17.36. Found: C, 49.47; H, 3.60; Mn, 16.96%. Selected IR data (KBr pellet cm^{-1}): 3065(w), 1594(m), 1560(m), 1518(m), 1492(s), 1416(s), 1361(m), 1202(m), 1092(s), 1026(w), 933(m), 720(s), 688(m), 616(w), 526(m).

2.9. $[Ph_4P][Mn_{12}O_{12}(OBz)_8(dpp)_8(H_2O)_4]$ (8)

A method similar to that used for synthesis of **7** was applied to but replacing **5** with **6**. The yield was 91%. *Anal.* Calc. for **8** ($C_{176}H_{148}Mn_{12}O_{64}P_9$): C, 50.03; H, 3.53; Mn, 15.60. Found: C, 49.54; H, 3.65; Mn, 16.05%. Selected IR data (KBr pellet cm^{-1}): 3065(w), 1593(m), 1560(m), 1523(m), 1492(s), 1416(s), 1361(m), 1202(m), 1105(s), 1026(m), 934(m), 778(m), 720(m), 689(m), 614(w), 526(m).

2.10. $[Mn_{12}O_{12}(O_2CC_2H_5)_{12}(dpp)_4(H_2O)_4]$ (9)

A similar method to the synthesis of **1** was applied but using Mn_{12}-pr (2.09 g, 1.0 mmol) in CH_3CN (100 ml) and 4 equiv of diphenylphosphate (dppH, 1.01 g, 4.0 mmol). The brown precipitates were collected after 1 week and dried in vacuo. The yield was 80%. *Anal.* Calc. for **2** ($C_{84}H_{108}Mn_{12}O_{56}P_4$): C, 36.07; H, 3.89. Found: C, 35.15; H, 3.69%.

2.11. Physicochemical measurements

Direct current (dc) and alternating current (ac) magnetic susceptibility data were collected on fresh microcrystalline samples restrained in eicosane to prevent torquing on a Quantum Design MPMS2 or MPMS7 SQUID magnetometer equipped with a 1 or 7 T magnet and capable of achieving temperatures of 1.7–400 K. A diamagnetic correction to the observed susceptibilities was applied using Pascal's constants. The magnitude of ac field was fixed to 0.3 mT, oscillating at frequency in the range of 5–997 Hz. Infrared spectra were recorded on KBr pellets using a JASCO FT/IR-430 spectrophotometer. ^1H NMR spectra were measured on a JEOL GSX 270 FT NMR spectrometer at room temperature. Tetramethylsilane was used as an internal reference for ^1H NMR measurement. Metal composition ware analyzed by Shimadzu AA-6200 Atomic Absorption Flame Emission Spectrophotometer.

2.12. X-ray structure analysis

Diffraction data for $\mathbf{1}\cdot 6.1CH_2Cl_2\cdot 0.4H_2O$ and $\mathbf{5}\cdot 4CH_2Cl_2$ were collected at −123 °C on a Rigaku/MSC Mercury CCD area detector with Rigaku AFC10 diffratometer equipped with graphite monochromated Mo Kα radiation. Crystal data and details of measurements for $\mathbf{1}\cdot 6.1CH_2Cl_2\cdot 0.4H_2O$ and $\mathbf{5}\cdot 4CH_2Cl_2$ are summarized in Table 1, and selected bond lengths and angles for **1** and **5** are given in Tables 2 and 3, respectively. The both structures were solved by direct method and expanded using Fourier techniques. The non-hydrogen atoms were refined anisotropically. Hydrogen atoms were included but not refined. Reliability factors are defined as $R = \sum||F_o| - |F_c||/\sum|F_o|$ and $R_w = \left[\sum w(F_o^2 - F_c^2)^2 / \sum w(F_o^2)^2\right]^{1/2}$. The final R and R_w values are also listed in Table 1.

3. Results and discussion

3.1. Crystal structure of $[Mn_{12}O_{12}(OAc)_{12}(dpp)_4]\cdot 6.1CH_2Cl_2\cdot 0.4H_2O$ ($\mathbf{1}\cdot 6.1CH_2Cl_2\cdot 0.4H_2O$)

The complex crystallizes in the monoclinic space group $P2_1/n$, with four formula units in the unit cell. A molecular core structure of **1** is shown in Fig. 1 together with the numbering scheme for some selected

atoms. The eight Mn^{III} ions can be divided into two groups: four Mn^{III} ions with six coordination and four Mn^{III} ions with square pyramidal five coordination, which are arranged in 1:1:1:1 form with alternating up and down positions. The peripheral bridging ligands are categorized in three groups. They are eight equatorial acetates, four axial acetates and four axial dpp. The axial acetate groups are bridging Mn^{IV} and Mn^{III} ions whereas the dpp are bridging two types of Mn^{III} ions with alternating up and down positions. Each Mn^{III} ion in square pyramidal coordination is located about 0.2 Å above from the basal plane towards the apical oxygen atom. The exact distances are 0.215, 0.209, 0.200, and 0.187 Å for Mn8, Mn6, Mn10, and Mn12, respectively. The most interesting feature of this complex is the absence of any coordinating water molecules. This is the first observation in Mn_{12} complexes so far reported. The central $[Mn^{IV}{}_4O_4]^{8+}$ cubane and the outer ring of eight Mn^{III} ions are connected by eight μ^3-O^{2-} bridges. It should be noted that one phenoxy hydrogen atom of each dpp^- ligand is located near the vacant site of each five-coordinate Mn^{III} ion, as if it blocked water coordination. This situation is different from the case of **5**, where all phenoxy groups of dpp^- are directed to the out side of the molecule (vide infra). Those Mn···H distances are 3.490, 3.373, 3.170, and 3.158 Å for Mn8, Mn6, Mn10, and Mn12, respectively. This order is parallel to the decrease of the dislocation from the basal plane for each five-coordinate Mn^{III} ions (vide supra), indicating a strong correlation between them. This implies there is non-negligible Mn···H interaction.

3.2. Crystal structure of $[Mn_{12}O_{12}(OBz)_{12}(dpp)_4(H_2O)_4]\cdot 4CH_2Cl_2$ ($\mathbf{5}\cdot 4CH_2Cl_2$)

The complex crystallizes in the monoclinic space group $P2/n$, with two formula units in the unit cell. A molecular core structure of **5** is shown in Fig. 2 together with the numbering scheme for some selected atoms. Just like most of Mn_{12} complexes, the central $[Mn^{IV}{}_4O_4]^{8+}$ cubane and the outer ring of eight Mn^{III} ions are connected by eight μ^3-O^{2-} bridges. The peripheral bridging ligands are categorized in three groups. They are eight equatorial benzoate, four axial benzoate, and four axial dpp. The axial benzoate groups are bridging Mn^{III} and Mn^{IV} ions whereas the dpp are bridging two types of Mn^{III} ions with alternating up and down positions. In contrast to **1**, complex **5** contains four coordinating water molecules that are arranged in the 1:1:1:1 fashion with alternating up and down positions. All phenoxy groups of dpp are directing outwards, which enables water coordination. Four water oxygen atoms are involved in the elongated Mn–O bonds. The eight Jahn–Teller axes of Mn^{III} ions are roughly parallel to the crystallographic b-axis with angles of 15–38°. This is consistent with the observation of only a high-temperature (HT) phase in ac magnetization measurement.

3.3. ^1H NMR spectroscopy

In order to understand the coordinating condition of the five-coordinating Mn^{III} ions, the NMR method was applied to **1**. The ^1H NMR spectrum of **1** in CD_2Cl_2 is shown in Fig. 3(a). A broad signal **A** at 12.2 ppm was observed together with CH_3 (equatorial) protons (40–50 ppm), CH_3 (axial) protons (15–18 ppm), and phenyl protons (6–10 ppm). When a small amount of H_2O was added (Fig. 3(b)), a broad signal **B** due to coordinated water protons appeared at 28.5 ppm and the signal **A** shifted to higher field (10.3 ppm). A subsequent addition of a small amount of D_2O induced a disappearance of the signal **B** and a coalescence of the signal **A** into phenyl protons (Fig. 3(c)). These observations suggest that the signal **A** is due to a part of phenyl protons in the vicinity of Mn^{III} vacant sites, which are affected by the water coordination. Changes in spectral features of both CH_3 protons during the addition of water together with the observation of the signal **A** indicate that at least one phenoxy group of each dpp is almost fixed near the Mn^{III} vacant site during the NMR time scale and disturbing water coordination to the Mn^{III} ion. This is the first observation of an Mn_{12} complex with stable vacant sites on Mn^{III} ions in solution, which implies that **1** is a good candidate for a building block to form an

assemblage of an Mn_{12} SMM. On the other hand, in the ^1H NMR spectrum of **9** in CD_2Cl_2 shown in Fig. 4, a signal assigned to the coordinating water proton can be observed at around 32 ppm. This signal was disappeared when a small amount of D_2O was added, indicating the validity of the assignment. This clearly shows **9** contains coordinating water molecules similar to **5**. This means phenoxy groups of dpp in **9** are directed to

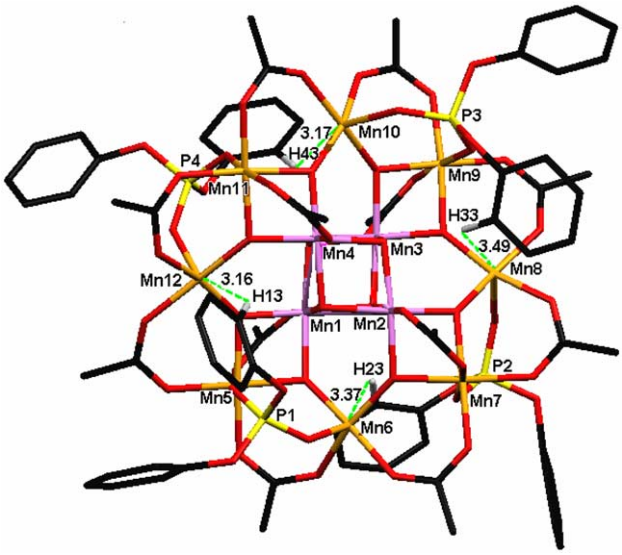

Fig. 1. A drawing of a molecular structure of complex **1**, with the atom numbering scheme for selected atoms. Four Mn^{III} ions, Mn6, Mn8, Mn10, Mn12, show five-coordination together with four Mn···H approaches. Other hydrogen atoms are omitted for clarity.

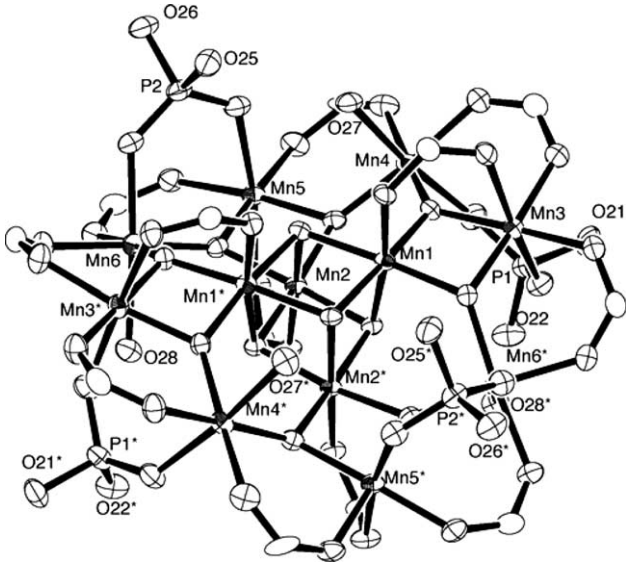

Fig. 2. An ORTEP view of **2** with atom numbering scheme for selected atoms. Phenyl groups and hydrogen atoms of water molecules are omitted for clarity.

outwards of the molecule like **5** as shown in Fig. 2, while those in **1** are in the proximity of the Mn12 core. The difference comes from the alkyl chain lengths of carboxylates, methyl and ethyl. A possible explanation is the difference of the extent of a hydrophobic space generated by alkyl chains of peripheral carboxyl groups. Compared to **9**, the extent of a hydrophobic space in **1** is small, which causes such a drastic change in locations of phenoxy groups and disturbances of water-coordination.

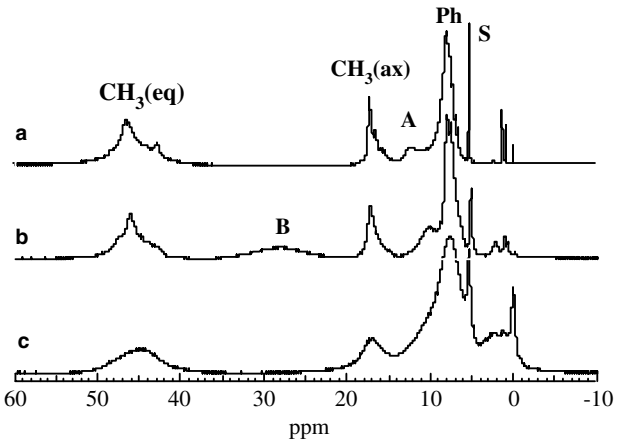

Fig. 3. The ^{1}H NMR spectra of complex **1** in CD_2Cl_2 during addition of water. (a), initial, (b) after adding a small amount of H_2O, and (c) after a subsequent addition of a small amount of D_2O.

3.4. Dc magnetic susceptibility

Solid-state, variable temperature magnetic susceptibility measurements were performed on a freshly prepared sample of **1**–**9** (figure see supporting materials), suspended in eicosane to prevent torquing. Dc magnetic susceptibility (χ_M) data were collected from 2 to 280 K at 1.0 T magnetic field. As the temperature increase, the $\chi_M T$ value of **1** shown a maximum of 43.4 cm^3 K mol^{-1} at 13.3 K and a broad minimum of 16.0 cm^3 K mol^{-1} at around 200 K and again increases slightly to 16.9 cm^3 K mol^{-1} at 280 K. Similar behaviors were observed for complex **2**–**9** and the data were summarized in Table 4.

3.5. Ac magnetic susceptibility

The observation of frequency-dependent out of phase signal, χ''_M , in ac magnetic susceptibility is an important indicator of SMMs, which show slow magnetization relaxation. Therefore, ac susceptibility data can be used not only to determine whether a molecule functions as a SMM but also to obtain the effective energy barrier U_{eff} for the magnetization relaxation. Ac magnetic susceptibility measurements of freshly prepared complexes **1**–**9** at several frequencies for the temperature range of 1.7–10.0 K were carried out to investigate the dynamic behavior of their magnetic moments. Figs. 5 and 6 show plots of $\chi'_M T$ vs T (top) and χ''_M vs T (bottom) for neutral complexes **1** and **5**, respectively, where χ'_M is in-phase ac susceptibility. Ac magnetic susceptibilities for other complexes are shown in supplemental data as Figure S3–S9. As temperature decreases, these values start to decrease at certain temperature depending on frequency. As expected for SMMs, the decrease of $\chi'_M T$ value corresponds to the appearance of out-of-phase signal (χ''_M). For most of neutral Mn_{12} complexes, there are two χ''_M peaks: high-temperature (HT) and low-temperature (LT) phases. On the other hand, only one peak was detected in reduced salts of Mn_{12} complexes. It is quite interesting that there is only a peak (HT) for neutral dpp substituted complexes **1**, **2**, and **5**. This indicates the substitution of dpp^- from axial position induces a parallel alignment of J–T axes of Mn(III) ions. The reason for a presence of a small amount of LT phase in complexes 6 and 9, as shown Figure S6 and S9, respectively, is probably ascribed to a presence of dpp^- substitution isomers in equatorial position [7b].

Table 4
Dc magnetic susceptibility for **1**–**8**

	$(\chi_M T)_{max}$ (T)	$(\chi_M T)_{min}$ (T)	$(\chi_M T)_{280\,K}$
1	43.4 (13.3)	16.0 (200)	16.9
2	48.2 (10.0)	17.2 (200)	17.7
3	49.4 (10.0)	17.6 (180)	18.6
4	48.3 (10.0)	18.3 (180)	19.6
5	50.6 (14.0)	18.7 (200)	19.6
6	42.7 (10.0)	16.5 (160)	18.3
7	53.3 (10.0)	19.6 (180)	21.1
8	52.6 (10.0)	19.4 (180)	20.4
9	45.5 (14.0)	16.8 (200)	17.8

The frequency dependence of the χ''_M peak temperature can be analyzed by Arrhenius law. On the basis of the plots of the natural logarithm of the relaxation time τ evaluated from $1/(2\pi\nu)$, where ν is the ac frequency, versus the inverse of the χ''_M peak temperature T, the effective energy barrier U_{eff} and the pre-exponential factor τ_0 can be estimated by the following equation [10]:

$$\tau = \tau_0 \exp\left(\frac{U_{eff}}{k_B T}\right), \quad (1)$$

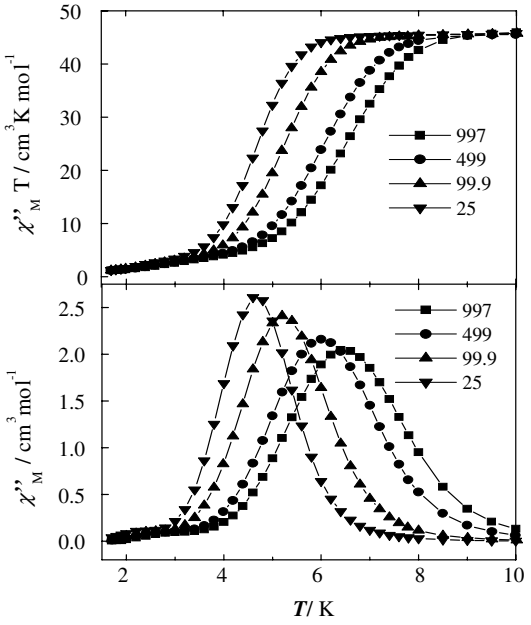

Fig. 5. Plots of $\chi'_M T$ vs T (top) and χ''_M vs T (bottom) for a polycrystalline sample of complex **1** in a 0.3 mT ac field oscillating at the indicated frequencies.

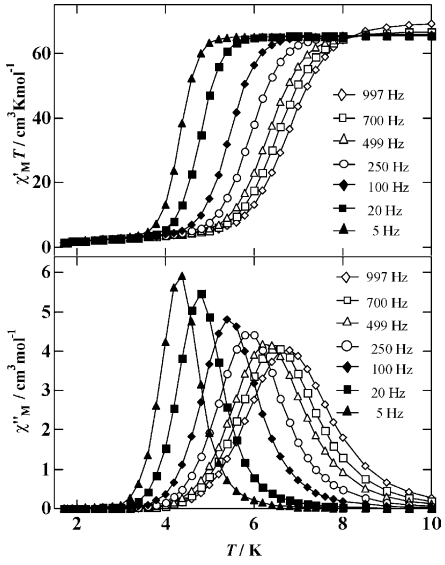

Fig. 6. Plots of $\chi'_M T$ vs T (top) and χ''_M vs T (bottom) for complex **5** in a 0.3 mT ac field oscillating at the indicated frequencies.

where k_B is the Boltzmann constant. The Arrhenius plots for **1**–**9** are shown in Fig. 7. The solid lines show the results of least-squares fits of the ac susceptibility relaxation data to Eq. (1). The pre-exponential factors τ_0 and the effective energy barriers U_{eff} of HT phases for **1**–**9** are given in Table 5. These values are somewhat smaller than those obtained for neutral Mn_{12} complexes, such as $[Mn_{12}O_{12}(NO_3)_4(O_2CCH_2\ Bu^t)_{12}(H_2O)_4]$ (72 K [7a]), and for the one-electron reduced Mn_{12} complexes, such as $(Ph_4P)[Mn_{12}O_{12}(O_2CEt)_{16}(H_2O)_4]$ (60.2 K [11]), $(Ph_4P)[Mn_{12}O_{12}(O_2CC_4H_3S)_{16}(H_2O)_2]$ (57.1 K [5f]) or

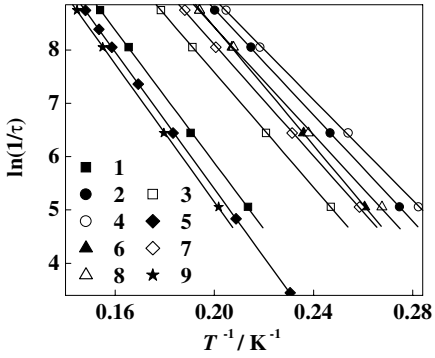

Fig. 7. Plots of the natural logarithm of the inverse of the magnetization relaxation time $\ln(1/\tau)$ vs the inverse of the absolute temperature of the χ''_M peaks for complexes **1**–**9**, solid lines represent least-squares fits of the data to the Arrhenius equation (see the text).

Table 5
The U_{eff} and τ^0 for complexes **1**–**8**

Complex	τ^0/s	U_{eff}/K
1	1.09×10^{-8}	62.5
2	7.47×10^{-9}	49.7
3	1.06×10^{-8}	53.9
4	1.03×10^{-8}	47.2
5	1.21×10^{-8}	64.2
6	3.27×10^{-9}	55.5
7	8.66×10^{-9}	52.3
8	9.05×10^{-9}	50.5
9	1.05×10^{-8}	64.6

$(Ph_4P)[Mn_{12}O_{12}(O_2CPh)_{16}(H_2O)_4]$ (55 K [12], 57.5 K [13]). To investigate the effect of the substitution of dpp^- ligands, the energy barriers of a freshly prepared Mn_{12}ac, **1** and **2** were compared. They are 72.7 K[1], 62.5 to 53.9 K, respectively. As the number of substituted dpp^- ligands increases, the U_{eff} values decrease monotonically. This rule was also observed about complexes Mn_{12}-bz, **5** and **6**, whose U_{eff} values decrease from 73.8 K,[1] 64.2 to 55.5 K, respectively. Since a U_{eff} is expressed as $|\mathbf{D}|S^2$ and an $S = 10$ ground state is also valid for complexes Mn_{12}-ac, **1** and **2** from low-temperature dc magnetization data, a molecular **D** is responsible to account for the decrease of U_{eff}. A molecular **D** can be estimated as a sum of single-ion **D**'s of Mn(III) ions, then both the alignment of J–T axes [14] and single-ion D-values [15] are important factors. Although we compared alignments of J–T axes of Mn(III) ions in complexes Mn_{12}-ac and **1** thoroughly, there are no significant differences between them. Therefore, a decrease of the single-ion D-values of each Mn(III) ion coordinated by dpp^- is the main reason for decrease of U_{eff} values.

[1] We measured the ac magnetic susceptibility of the freshly prepared Mn_{12}-ac and Mn_{12}-bz, and analyzed the data by Arrhenius law to obtain the effective energy U_{eff} of 72.7 and 73.8 K, respectively.

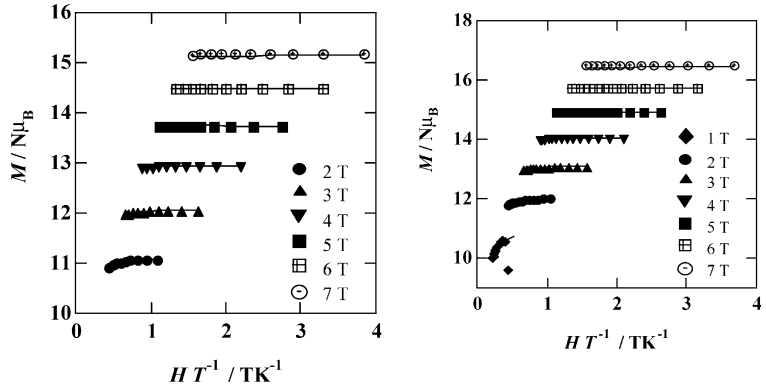

Fig. 8. Reduced magnetization data for **1** (left) and **5** (right) with different external fields. Lines show the best-fit assuming $S = 10$, $g = 1.78$, and $D = -0.60$ K for **1** and $S = 10$, $g = 1.92$, and $D = -0.63$ K for **5**.

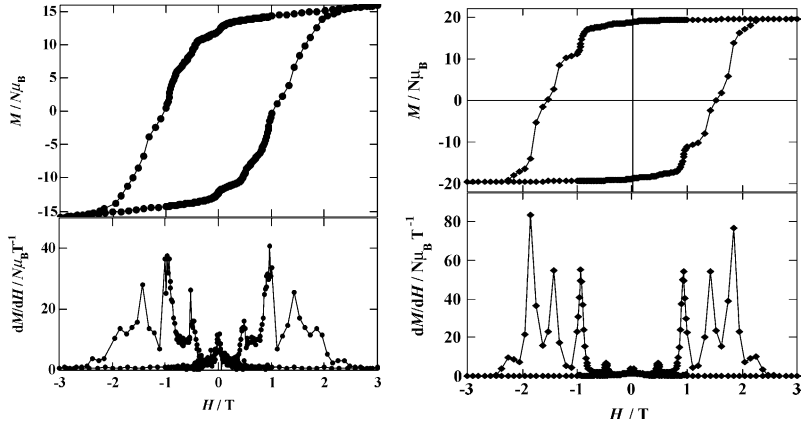

Fig. 9. A magnetization hysteresis loop for oriented crystals of **1** (left) and **5** (right) in an eicosane matrix measured at 1.9 K (top) and the corresponding first derivatives dM/dH (bottom).

3.6. Reduced magnetization

In order to determine S and D values, magnetization data $M/(N\mu_B)$ were collected for **1** and **5** fixed with an eicosane matrix under a 2–7 T field at temperatures between 1.9 and 4.5 K. The observed data were fitted with a magnetization fitting program "axfit" [16] assuming an $S = 10$ ground state. The lines in Fig. 8 shows the best fit for an $S = 10$ ground state with the parameters of $g = 1.78$ and $D = -0.60$ K for **1** and for an $S = 10$ ground state with the parameters of $g = 1.92$ and $D = -0.63$ K for **5**, respectively. Although a fit with a similar quality was also obtained by using $g = 1.98$ and $D = -0.74$ K assuming $S = 9$ ground state for **1**, this possibility might be excluded because the largest $|D|$ value of 0.74 K so far reported for Mn_{12} complexes is somewhat mysterious for **1** containing four five-coordinate Mn^{III} ions. Our model calculations using the AOM method[2] [17] showed that a single ion $|D|$ value for a five-coordinate Mn^{III} ion (2.0 cm^{-1}) is clearly smaller than those for six-coordinate Mn^{III} ions (2.3–3.2 cm^{-1}). The results of magnetization hysteresis loop also testified this conclusion and HF-EPR measurements will give more definitive conclusion.

3.7. Magnetization hysteresis loops

Especially for SMM, step-like sudden decreases of magnetization can be also seen, which are attributed to the quantum tunneling of magnetization. Since complex **1** and **5** are SMMs, it was of interest to investigate their magnetization response to a changing dc field. This experiment was performed using some single crystals of **1** or **5** that had been placed in a capsule with eicosane and oriented with their easy axes parallel by exposing them to a 7.0 T external magnetic field at 325 K, then allowed eicosane to cool and solidify at room temperature, to trap the crystals of **1** or **5** in their parallel orientation.

$$H_{S,-S+n} = nD/(g\mu_B). \quad (2)$$

The magnetization hysteresis loop measured for the field-oriented single crystals at 1.9 K are shown in Fig. 9 (left: **1**; right: **5**). The magnetization saturates

[2] A program ZAOM was used for calculation. AOM parameters were adopted from Ref. [17].

completely at fields above 2.3 T to ca. 16 $N\mu_B$. Hysteresis is seen with a coercive field of 1.0 T. In the bottom of the Fig. 9 are shown the first derivatives of the hysteresis plots. As the field is decreased from +3 T, the first step can be seen at zero fields, followed by steps at −0.49, −0.98, −1.43, and −2.38 T for **1**, and −0.47, −0.93, −1.42, −1.84, and −2.26 T for **5**. The steps correspond to increases in the rate of the change of the magnetization, and are attributable to resonant tunnelings between two sublevels of $m_s = S$ and $m_s = -S + n$, where $n = 0$, 1, 2, 3, and 4. Since the condition that the quantum tunneling occurs can be expressed as Eq. (2), [4b] we can predict a step interval of 0.50 T calculated as $|D|/(g\mu_B)$ using D (−0.60 K) and g (1.78) obtained from the reduced magnetization analysis of **1**. This value is in agreement with the observed one (about 0.49 T), indicating the validity of the reduced magnetization analysis. If using D (−0.74 K) and g (1.98), the step value can be calculated to be 0.56 T, which is inconsistent with the observed results, indicating the conclusion with $S = 10$ is valid for **1**. Similar to **1**, using the observed ΔH of 0.46 T for **5**, we estimate the value $|D|/g$ to be 0.31 K, which is fairly comparable to 0.33 K calculated by using the g and D values obtained from the reduced magnetization experiment.

4. Conclusion

Nine Mn_{12} derivatives with diphenylphosphate bridges, **1**–**9**, have been successfully isolated and studied, which indicate SMM behavior on ac susceptibility, and two complexes (**1** and **5**) were characterized by X-ray. Complex **1** has no coordinating water with four five-coordinate Mn^{III} ions while complex **5** has water coordination as usual. This is the first Mn_{12} derivative without coordinating water molecules. The difference comes from directions of phenoxy groups of dpp, which is induced by a difference of carboxylates. A contraction of a hydrophobic space in **1** compared to **5** or **9** causes a drastic change in locations of phenoxy groups and disturbances of water-coordination. NMR measurements of **1** showed a water coordination occurs when water was added in CD_2Cl_2 solution. The magnetization hysteresis loops of **1** and **5** show the quantum tunneling of magnetization. The substitution of dpp ligands results in the decrease of U_{eff}.

value of the paramagnetic center (roughly as $S(S+1)$), as well as on the concentration of the paramagnetic agent in the media. At low concentrations there is a linear dependence of R_1 and R_2 on the concentration.

The notion of relaxivity is used to allow one to compare the effectiveness of different relaxation agents (contrast agents) independently of the concentration used. It is defined as $r_{1,2} = R_{1,2}/c$, where c is the concentration. A competitive value in medical diagnostics is 4–5 s^{-1} mM^{-1}, recorded at magnetic fields of 2–3 T [1].

Recently, superparamagnetic iron oxide particles have attracted much attention as contrast agents, due to their extremely large spin values [2]. Single-molecule magnets, by contrast, offer superparamagnetism in uniquely small particles [3,4], that would be very powerful as contrast agents. Our attention was attracted to a report that the classic compound "Fe_8" provided contrast similar to that offered by the commercial compound Magnevist (GdDTPA) [5], and we report here a critical examination of its usefulness.

2. Experimental

2.1. Synthesis

The intermediate complex $Fe(tacn)Cl_3$ and crystals of Fe_8 ($C_{36}H_{120}O_{23}N_{18}Fe_8Br_8$) were obtained according to the method of Wiegardt [6,7]. The bright yellow precipitate formed from reacting tacn (1,4,7-triazacyclononane) ligand, purchased from Aldrich, and $FeCl_3 \cdot 6H_2O$ in ethanol, and was isolated and dried. The product was dissolved in a mixture of H_2O and pyridine. After 15 min, NaBr was added to the solution and the mixture was cooled to 200 °C and allowed to stand for 24 h. The brown crystals were isolated, washed and subjected to physical studies.

2.2. Physical measurements

Low temperature (0.4 K) magnetization versus field data were collected using a micro-Hall effect magnetometer which is described in [8].

Relaxivity measurements were conducted at 9.4 T on a Bruker AV 400 MHz narrow-bore NMR spectrometer in a standard 5 mm quartz tube. T_1 and T_2 were determined by routine inversion-recovery and CPMG sequences, respectively. The relaxation agents were dissolved in 99% D_2O to avoid both receiver saturation and radiation damping effects due to the appearance of a strong H_2O signal in the NMR measurements [9]. The water relaxation rates reported refer to the residual H_2O in the sample. All NMR measurements were taken at 25 °C.

The pH was adjusted in the samples by adding small amounts of NaOH to the solution. pH determinations were conducted with a standard glass combination pH electrode. The values reported are uncorrected for the presence of D_2O as the main solvent (pD = pH − 0.4). Physical studies comparing the relaxivity of the compounds and their dependence on concentration were done in 0.1 M HEPES buffer at pH 7 (purchased from Sigma). The lyophilized sample of Fe_8 was prepared by dissolving the crystals in water and immediately freezing them using dry ice. The water was removed using a standard lyophilizer.

3. Results and discussion

3.1. Characterization of Fe_8

Crystals of Fe_8 gave magnetic behavior consistent with that previously reported [10]. Steps in the hysteresis curves were observed at regular field intervals consistent with the $S = 10$ ground state and the spin-Hamiltonian parameters reported for Fe_8. We note that the hysteresis steps, while well defined, were broad, perhaps indicative of crystal defects.

3.2. Determination of relaxivity

As shown in Fig. 1, relaxivity was measured in aqueous solutions buffered at a pH of 7. Fe_8 gave a much

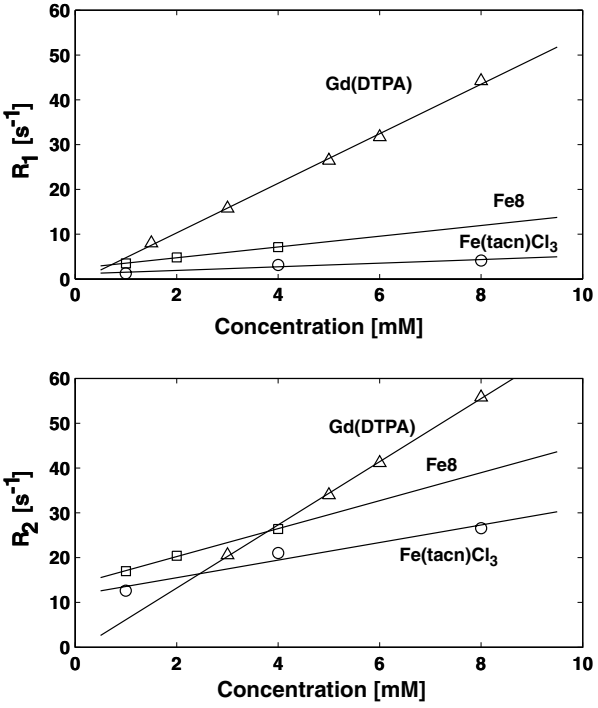

Fig. 1. Plot of R_1 and R_2 parameters vs. concentration of aqueous solutions of Gd(DTPA), $Fe(tacn)Cl_3$, and Fe_8, determined by inversion recovery and CPMG sequences on a 400 MHz NMR spectrometer.

lower T_1 relaxivity ($1.2\ s^{-1}\ mM^{-1}$) than the commercially used reference, GdDTPA ($5.5\ s^{-1}\ mM^{-1}$). Since this is in contrast to previous studies [5] we also investigated the relaxivity of the precursor complex $Fe(tacn)Cl_3$ ($0.4\ s^{-1}\ mM^{-1}$). The relaxation constants were monitored over a 24 h period, and were found to be approximately constant in solutions buffered at neutral pH. The r_2 parameters were measured as $3.1\ s^{-1}\ mM^{-1}$ (Fe_8), $7.0\ s^{-1}\ mM^{-1}$ (GdDTPA), and $2.0\ s^{-1}\ mM^{-1}$ ($Fe(tacn)Cl_3$).

3.3. Examination of solution species

Aqueous solution equilibria of iron complexes can be complex, and it would be appropriate to question the nature of solution species that would form upon dissolving the Fe_8 complex [11,12]. The relaxivity data indicate that Fe_8 does not decompose fully and exclusively to form $Fe(tacn)Cl_3$. If complete decomposition took place its relaxivity would be at least six times larger than the one for $Fe(tacn)Cl_3$ (considering the presence of only six ligands in Fe_8). Indeed, Fe(III) itself can show appreciable relaxivity in aqueous solution (for a review, see [13]). The fairly weak relaxivity shown for the solution prepared from Fe_8 suggests that some clustering of Fe persists in solution, resulting however in antiferromagnetic coupling, lower overall spin, and therefore lower contrast.

Among the many experiments that were attempted to shed light on solution speciation, perhaps the most definitive was that the Fe_8 was dissolved in water at a concentration of 1 mM and immediately frozen, then lyophilized to remove the water in the gentlest manner possible. A brown powder was obtained that was examined for superparamagnetism. The data indicated that the powder did not have a significant amount of Fe_8 (Fig. 2). It appeared to be a low-spin substance, with spin ~3/2. At 0.4 K there was no (or very small) hysteresis. The data were noisy because of the small amount of material.

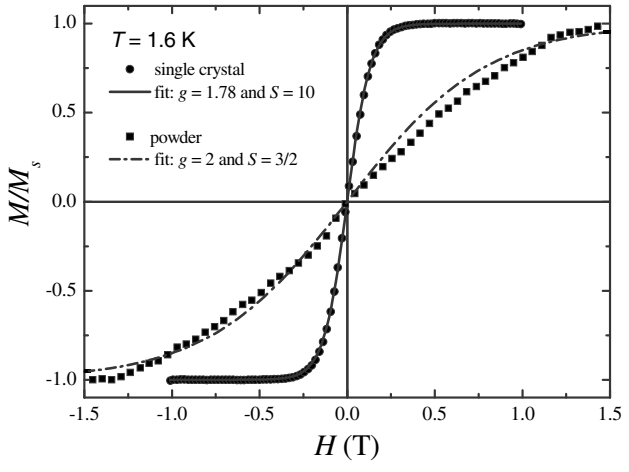

Fig. 2. Hysteresis curves for a single crystal of Fe_8 and grains/powder resulting from lyophilization of an aqueous solution of Fe_8 at 1.6 K. The powder appeared to be a low-spin ~3/2 at 0.4 K with no (or very small) hysteresis.

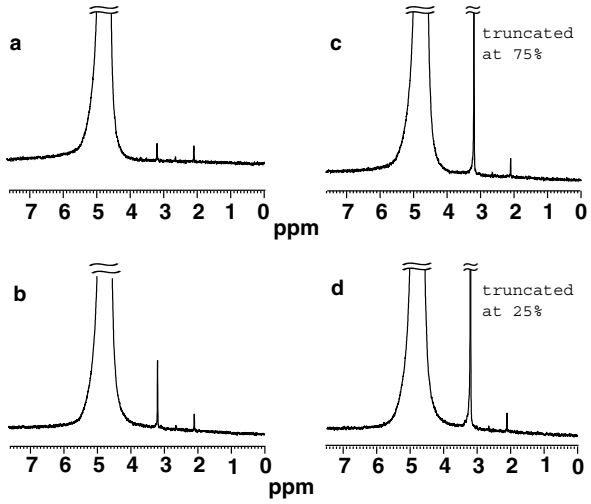

Fig. 3. ^1H NMR spectra of Fe_8 (at $c = 4$ mM) in 99% D_2O, at (a) immediately after dissolving, (b) 30 min (c) 120 min, and (d) 240 min after dissolving.

The ^1H NMR spectra of the solutions of the Fe_8 complexes were examined to assess whether a solution species could be assigned. The single peak at δ 3.2 increased substantially in intensity over 3 h as illustrated in Fig. 3. This peak coincides in shift with the one observed for $Fe(tacn)Cl_3$ and we therefore conclude that at least partial decomposition into this precursor compound occurs. Signals corresponding to that of free ligand (δ 2.8 ppm) were not observed.

3.4. Environmental dependence of relaxivity

During the course of examination of the solution species formed by Fe_8, a very strong dependence on pH was observed. As shown in Fig. 4, an increase of pH from neutral to 11 resulted in more than a 5-fold increase in R_1 for the Fe_8 complex. In contrast, the R_1 for GdDTPA was nearly constant over this range, and decreased for $Fe(tacn)Cl_3$. This data provides additional evidence for decomposition/rearrangement processes of Fe_8 in solution. The R_2 parameters, however, did not change as dramatically over this pH range.

The increase in pH of the solutions of Fe_8 were accompanied by complex changes in ^1H NMR spectra. At neutral pH, a single peak at δ 3.2 dominated the spectrum, while a smaller peak at δ 2.2 was present. At pH 7.6 a peak at 2.9 ppm appeared. The peak at 2.2 ppm grows larger up to a pH of 9 and becomes smaller again when approaching a pH of 10.7. At pH 11.3 small peaks appear at 3.0, 2.9, and 2.8 ppm (apparently

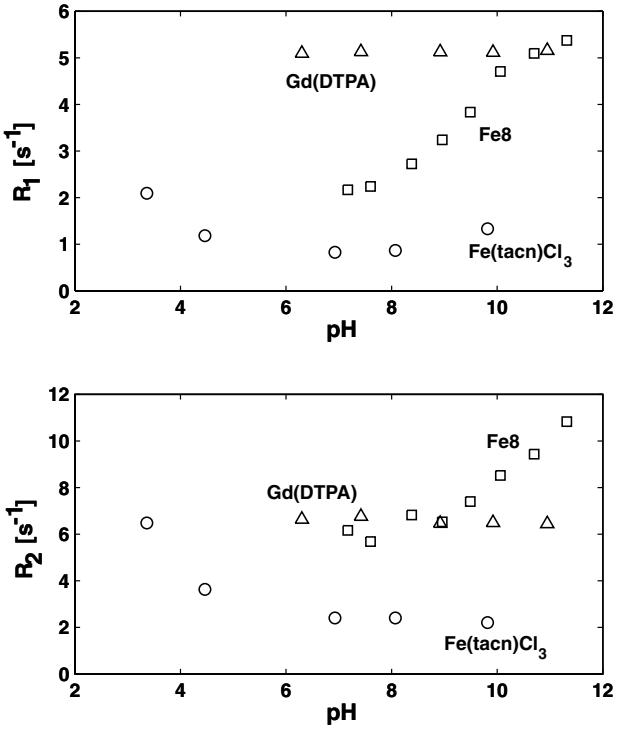

Fig. 4. pH-dependence of the relaxation parameters R_1 and R_2 for Fe_8 (squares), $Fe(tacn)Cl_3$ (circles), and Gd(DTPA) (triangles) (pH values are uncorrected for the presence of the large D_2O concentration).

corresponding to free ligand). In addition, a large peak is visible at 2.23 ppm. Thus, significant changes in solution speciation occurred with increasing pH, and some of these new species are likely to be responsible for the increased relaxivity.

Dependence of relaxivity on pH is of interest in the burgeoning field of molecular imaging in which "smart" contrast agents are desired as reporters of molecular processes in living systems [14,15]. However, further work will be required to determine whether Fe clusters may be of use for such purposes.

4. Conclusion

In contrast to the earlier report [5], Fe_8 in neutral, aqueous solution did not show stronger relaxivity than GdDTPA. This is corroborated by measurements of the magnetic properties before and after dissolving Fe_8, as well as solution NMR spectra and measured R_1 and R_2 parameters under various conditions. However, we found the relaxation properties of this compound to be highly dependent upon pH, a behavior that is of interest in the development of environment-sensitive contrast agents.

(spin 1), and four alkoxide hmp-oxygen atoms at alternating corners. The molecule has S_4 site symmetry. Ferromagnetic exchange interactions between the four Ni^{II} ions lead to a $S = 4$ ground state at low temperature, which has been confirmed by high frequency Electron Paramagnetic Resonance (EPR) and magnetic relaxation experiments [12,13]. These molecules have a zero field splitting of the form $-DS_z^2$. This uniaxial anisotropy term in the Hamiltonian leads to an energy barrier $DS^2 \sim 12$ K that separates opposite projections of the spin of the molecule along the easy axis, $S_z = \pm 4$.

The spin Hamiltonian of Ni_4 is to first approximation:

$$H = -DS_z^2 - \mu_B \overrightarrow{S} \cdot \hat{g} \cdot \overrightarrow{H} + H'. \quad (1)$$

The second term is the Zeeman energy ($\hat{g} = (g_x, g_y, g_z)$, $\mu_0 = 1$ and H is in tesla). The last term includes high order transverse anisotropy terms (i.e., $C(S_+^4 + S_-^4)$). An external magnetic field, H_z, applied along the easy axis of the molecules tilts the double well potential favoring those spin projections aligned with the field. When the magnitude of the longitudinal field is $H_z = kD/g\mu_B$ (with k an integer), spin levels on opposite sides of the barrier have the same energy. These field values are known as *resonant fields*. The inset of Fig. 2 shows the behavior of the lowest states as a function of longitudinal magnetic field in the vicinity of resonance $k = 0$ ($H_z = 0$). When the system is near this resonance off-diagonal terms in the Hamiltonian, such as a Zeeman term due to an external transverse magnetic field lead to an energy splitting between symmetric, $|S\rangle$ and anti-symmetric $|A\rangle$ linear combinations of |up⟩ and |down⟩ states, known as the tunnel splitting, Δ. The frequency of QTM between |up⟩ and |down⟩ states is proportional to the tunnel splitting ($f = \Delta/h$). It is possible to write the energy eigenstates as:

$$\begin{aligned} |S\rangle &= \frac{1}{2}(|\text{up}\rangle + |\text{down}\rangle), \\ |A\rangle &= \frac{1}{2}(|\text{up}\rangle - |\text{down}\rangle), \end{aligned} \quad (2)$$

where

$$\begin{aligned} |\text{up}\rangle &= \frac{\sqrt{2}}{2}\sum_m (a_m + b_m)|m\rangle, \\ |\text{down}\rangle &= -\frac{\sqrt{2}}{2}\sum_m (a_m - b_m)|m\rangle. \end{aligned} \quad (3)$$

The value of the coefficients, a_m and b_m, depend on the external applied field. At zero longitudinal field ($k = 0$) and in the absence of transverse fields, all coefficients are zero except for a_{+4} and b_{-4}. In this situation, the two lowest levels are $|S\rangle = \frac{1}{\sqrt{2}}(|+4\rangle + |-4\rangle)$ and $|A\rangle = \frac{1}{\sqrt{2}}(|+4\rangle - |-4\rangle)$, corresponding to superpositions of opposite spin projections along the easy magnetic axis. In the presence of a strong transverse field this situation changes. Now, the states |up⟩ and |down⟩ are tilted away from the easy axis but still have well defined and opposite z-axis magnetizations, provided the transverse field is less than the anisotropy field, $H_a = 2DS/(g\mu_B) = 4.5$ T.

A transverse field is necessary to increase the tunnel splitting into a range where it is comparable or larger than the thermal energy ($k_B T$). In the experiments described below we use transverse fields from 2.2 to 3.6 T, for which the tunnel splitting ranges from 5 to 30 GHz.

2. Experimental

The experiment consists in sweeping an external longitudinal field across resonance $k = 0$ and measuring the magnetization of the sample in the presence of microwave radiation (see inset of Fig. 2). Photon induced transitions (PIT) between symmetric and anti-symmetric spin-states lead to changes of the average magnetization of the sample when the radiation energy coincides with the energy separation between levels. Note that this is only possible when the longitudinal field is not zero. When $H_z = 0$, both symmetric and anti-symmetric superposition states have zero z-axis projection and therefore transitions between them will not change the magnetization of the sample.

In order to induce transitions between $|S\rangle$ and $|A\rangle$ states the magnetic field component of the electromagnetic radiation, H_{ac}, must be aligned with the easy axis direction, $\hat{z}$. In this case, the rate of PITs (at $T = 0$) is given by:

$$\Gamma = \frac{\pi}{2}\left(\frac{g\mu_B}{\hbar}H_{ac}\right)^2 |\langle S|S_z|A\rangle|^2 f(\omega), \quad (4)$$

where $\langle S|S_z|A\rangle$ is the matrix element coupling the external radiation field and the spin of the molecule. On one hand, this probability depends on the magnitude of the ac field (i.e., the radiation power), which is determined by both the source power and the device that is used to irradiate the sample (i.e., the quality factor of the antenna). On the other hand the PIT probability depends on the magnitude of the external magnetic fields as follows: (1) for a given longitudinal field, the larger the transverse field (i.e., the larger tunnel splitting) the higher the probability, and (2) for a given transverse field, the probability increases as the longitudinal field decreases (see inset of Fig. 3), being maximum for $H_L = 0$. However, in this case, as mentioned above, PIT do not induce changes in the magnetization. A picture of the range of longitudinal fields for which PITs are allowed can be seen in the inset of Fig. 2. The departure of the energy splitting from a straight line (i.e., the simple Zeeman splitting), illustrated with the dashed line in this figure is due to the tunnel splitting.

In the experiment we sweep the longitudinal field at a given rate, $\alpha = dH_L/dt$, across the resonance, in the

presence of a constant transverse field, H_T, while we monitor the magnetization. For high transverse fields one finds the equilibrium magnetization, $M_{eq}(H_L,H_T,T)$. However, when the energy difference, E, between the two states matches the energy of the radiation, $\hbar\omega$, PITs change the populations of each state and thus the sample magnetization. This effect is manifested as a dip or peak in the magnetization curve whose shape is determined by $f(\omega)$, which is a Lorentzian function:

$$f(\omega) = \frac{1}{\pi}\frac{\tau_2}{1+(\omega-\omega_0)^2\tau_2^2}, \quad (5)$$

where $\omega_0 = E/\hbar$ and τ_2 is the transverse relaxation time. Therefore, the width of the peak will give us information about the decoherence time.

At a finite temperature, $T > 0$, the ratio between equilibrium populations of the two lowest states is $N_2/N_1 = \exp(-E/k_BT)$. Any non-equilibrium population will decay exponentially according to $d(n_2 - n_1)/dt = [(N_2 - N_1) - (n_2 - n_1)]/\tau_1$, where n_1 and n_2 are the instantaneous level populations and τ_1 is the energy longitudinal relaxation time. In the presence of radiation the evolution of the populations of these states is determined by the PIT rate, Γ, given in Eq. (4) in the form $d(n_2 - n_1)/dt = -2\Gamma(n_2 - n_1)$. Combining these two expressions we find:

$$n_d = n_0\left(1 - \frac{1}{1+2\tau_1\Gamma}\right)e^{-(\tau_1+2\Gamma)t/\tau_1} + \frac{n_0}{1+2\tau_1\Gamma}, \quad (6)$$

where $n_d = n_2 - n_1$ and $n_0 = N_2 - N_1$. From this is it clear that n_0 must not be zero. In other words, we need to work at a temperature for which the excited state population is small. Taking into account that the lowest temperature we can achieve in our experiment is 0.38 K, we need to work with frequencies of at least $f = E/h = 10$ GHz, in order to have $n_0 > 0.7$ (for 20 GHz, $n_0 = 0.91$).

We have used a high sensitivity micro-Hall magnetometer [14] to measure the longitudinal component of the magnetization of a millimeter-sized single crystal of Ni_4 that is placed over the magnetometer, with one of its faces parallel to the plane of the sensor. A thin superconducting circular loop ($\phi \sim 2$ mm) is placed perpendicular to the easy anisotropy axis of the crystal (see inset of Fig. 1). This loop shorts the end of a 2.4 mm coaxial line, connecting the inner and outer conductors. The coaxial line is made up of Cu and Stainless Steel sections to minimize power losses (~15 dB) and thermal conduction. The line is about 1.5 m long and connects the loop to an Agilent PNA 50 GHz Vector Network Analyzer. This system allows us to work with frequencies up to 50 GHz and makes possible the characterization of the resonances of the loop. All the measurements were done by using different loop resonances to maximize the power that is converted to ac magnetic field

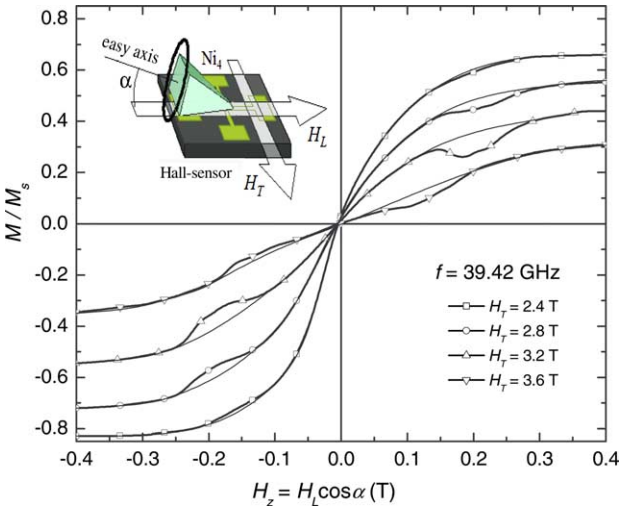

Fig. 1. Several magnetization curves recorded by sweeping the longitudinal field at a constant rate across zero field resonance in the presence of CW microwave radiation of $f = 39.8$ GHz for transverse fields values from 2.4 to 3.6 T. The thin lines correspond to equilibrium magnetization in the absence of radiation. The inset shows the setup.

at the sample position. A high field superconducting vector magnet was used to apply magnetic fields in arbitrary directions with respect to the axes of the crystal. In this case, both transverse and longitudinal magnetic fields were applied in the plane of the magnetometer. A ^{3}He cryostat is used to cool the sample to a temperature of 0.38 K.

3. Results and discussion

Fig. 1 shows several magnetization curves measured in presence of continuous wave (CW) microwave radiation of $f = 39.42$ GHz. The longitudinal magnetic field, H_z[2], was swept at a constant rate from −0.4 to 0.4 T. Different curves correspond to different transverse fields from $H_T = 2.4$–3.6 T. The thin lines represent the equilibrium magnetizations (or magnetization in the absence of microwave radiation). Deviations of the magnetization from M_{eq} are observed (peaks/dips) at opposite polarities of the longitudinal magnetic field[3], indicating PITs between spin levels with opposite net magnetization. The temperature of the sample was monitored during the whole field sweep and showed variations that

[2] The longitudinal magnetic field, H_z, represented in Fig. 1 has been calculated taking into account the misalignment, $\alpha = 20°$, between the applied field, H_L, (in the plane of the sensor) and the easy-axis of the single crystal, and is given by the relation $H_z = H_L\cos\alpha$.

[3] The small asymmetries observed between the longitudinal field positions and magnitudes of the peak and dip at opposite polarities is due to a second misalignment, $\theta = 5.3°$, between H_L and the projection of the easy axis of the crystal into the plane of the sensor. This misalignment produces variations of the transverse field felt by the molecules when the longitudinal field varies, explaining the asymmetry between PITs at opposite polarities of H_z.

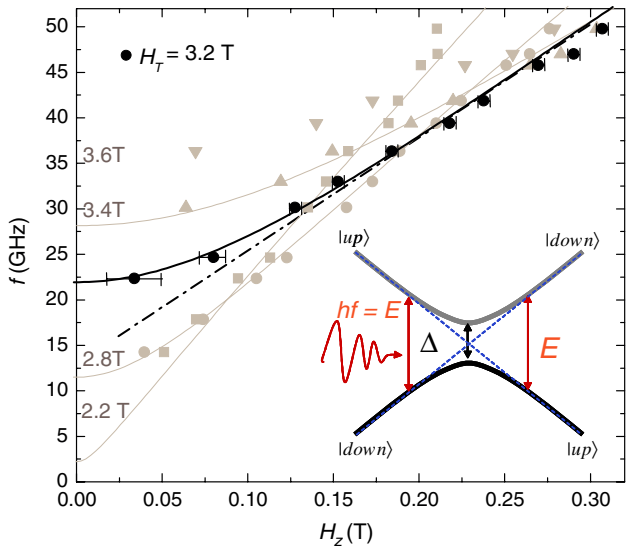

Fig. 2. Frequency-field plot of the positions of the PIT's dips of the sample magnetization. The result corresponding to $H_T = 3.2$ T has been highlighted (back solid circles) in order to show the curvature of the PITs frequency-field behavior in the vicinity of zero-field resonance. Grey circles correspond to other transverse field values. The solid lines are fit of the data using Hamiltonian of Eq. (1). The inset shows energies of the lowest lying levels of the Ni_4 molecule close to zero-field.

were less than 0.01 K at the positions of the peaks and dips. Note that a change of temperature of 1 K would be necessary to explain the magnetization changes observed in the peaks/dips, indicating that these magnetization variations are induced by population changes induced by absorption of microwave radiation and not by heating of the sample. The observed structure of the peaks/dips (each peak/dip is indeed composed by three peaks) is discussed in [10] and has also been observed in high-frequency EPR measurements [13] and ascribed to different Ni_4 species or microenvironments with slightly different values of the uniaxial anisotropy parameter, D.

We repeated the same measurements for different microwave frequencies from 14 to 50 GHz for the transverse fields, $H_T = 2.2$–3.6 T. For this experiment we chose the microwave powers so that the sample temperature was the same in all the measurements[4]. In Fig. 2 we show the behavior of the PIT dips (positive field polarity) in a frequency-field plot. In this figure results corresponding to $H_T = 3.2$ T (black solid circles) has been highlighted in order to clearly show the characteristics with microwave frequency and longitudinal field. (Results for negative polarities of H_z and a more detailed discussion can be found in [10].) It is clear that the PIT dip position deviates from the linear behavior (dashed line) on approaching the center of the resonance. This result is a direct measurement of the behavior of the energy difference between the two lowest spin states of the molecule (inset of Fig. 2) and *the curvature at the vicinity of the zero-field resonance constitutes an unambiguous signature of quantum superposition states with opposite magnetizations*. The solid lines are fits of the data by direct diagonalization of Hamiltonian of Eq. (1) using $D = 0.765$ K, $B = 7.9 \times 10^{-3}$ K, $C = 3.25 \times 10^{-5}$ K, $g_z = 2.3$, $g_x = g_y = 2.23$. These values are in excellent agreement with those found from high frequency EPR experiments [13]. This illustrates that the tunnel splitting, Δ (at $H_z = 0$), varies from 2 to 35 GHz for transverse fields ranging from 2.2 to 3.6 T [10].

Fig. 3 shows curves corresponding to the difference $M - M_{eq}$ for several frequencies from 18 to 47 GHz measured while a transverse field of 3 T was applied. The curves have been normalized by the equilibrium magnetization, $M_{eq}(H_z)$. This normalization allows the behavior of the magnitude of the PITs dip as a function of the longitudinal field to be seen. The magnitude of the PITs dip for different field values gives an estimate of the absorption of microwave radiation of a given frequency. The results show that the dip maximum amplitude decreases with field (see dashed line connecting dip's maxima in Fig. 3). From Eq. (4) we know that the maximum amplitude of the PIT's dip, which occurs at $\omega = \omega_0$, depends on the magnitude of the microwave field, on the matrix element coupling the external radiation field

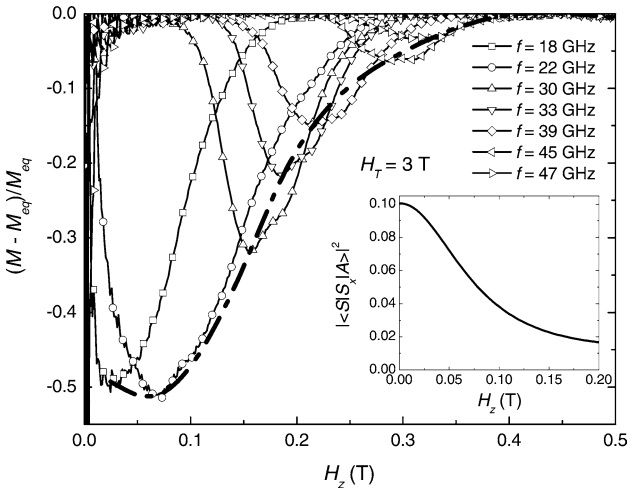

Fig. 3. Normalized change of the magnetization due to PITs at different microwave frequencies in the presence of a 3 T transverse applied field. The dashed-dotted line connecting the dip amplitudes has a minimum at ~0.06 T, which is not expected if the amplitude is governed solely by the matrix element in Eq. (4). The inset shows the square of this matrix element as a function of the longitudinal magnetic field for a transverse field of 3 T.

[4] For frequencies over 40 GHz the temperature of the sample was slightly smaller than at lower frequencies due to limitations of the microwave source at high frequencies and higher losses in the coaxial lines. Nevertheless, this temperature difference is not crucial for the analysis of this paper.

and the spin of the molecule, $\langle S|S_z|A\rangle$, and on τ_2, through the Lorentzian function of Eq. (5). While H_{ac} is independent of the longitudinal field and frequency,[4] the matrix element decreases with the longitudinal field as shown in the inset of Fig. 3, having a maximum at zero-field, indicating that the amplitude of the PIT's dip should monotonically decrease with longitudinal field as seen in the experiment. We note that a varying τ_1 would affect the behavior of the PIT's dips/peaks amplitude since the instantaneous population difference $n_d = n_1 - n_2$, and thus the magnetization, are τ_1-dependent, as seen in Eq. (6). This could explain the slight decrease of the peak's amplitude observed at $f = 18$ GHz in Fig. 3, which would be due to an increase in the longitudinal relaxation rate, $1/\tau_1$, in the vicinity of the resonance.

A signature of an increase of the longitudinal relaxation time, τ_1, with field or frequency is clearly observed in Fig. 4, which shows several $(M - M_{eq})/M_{eq}$ curves measured at different sweep rates of the longitudinal field and two different sweep directions: from negative to positive (up) and from positive to negative (down). The measurements were done in the presence of microwave radiation of 39.8 GHz and a transverse field of 3.2 T. The curves depend on the field sweep direction. When the field is swept from negative to positive the peak's ($H_z < 0$) amplitude decreases with increasing sweep rate (the peak's width remains almost constant) while the dip's ($H_z > 0$) width increases with increasing sweep rate (the dip's amplitude remains almost constant). The result for the opposite sweep direction is just equivalent but inverted. This broadening of the peaks/dips with increasing sweep rate is indicative of slow energy relaxation processes of the excited state (antisymmetric state). An estimation of the longitudinal relaxation time, from the width of the peaks shown in Fig. 4, gives $\tau_1 \sim 13$ s for negative-to-positive sweep direction and $\tau_1 \sim 19$ s for positive-to-negative sweep direction. The difference in these relaxation times is probably related to the transverse field, which varies slightly with the longitudinal field due to a misalignment of the sample with respect to the applied longitudinal field direction[3]. Moreover, this shows that τ_1 increases with longitudinal field, and thus with frequency, because the broadening only appears in one side of the peaks/dips (far from the resonance). This trend has also been observed in measurements with pulsed-microwave radiation (see [10] for details).

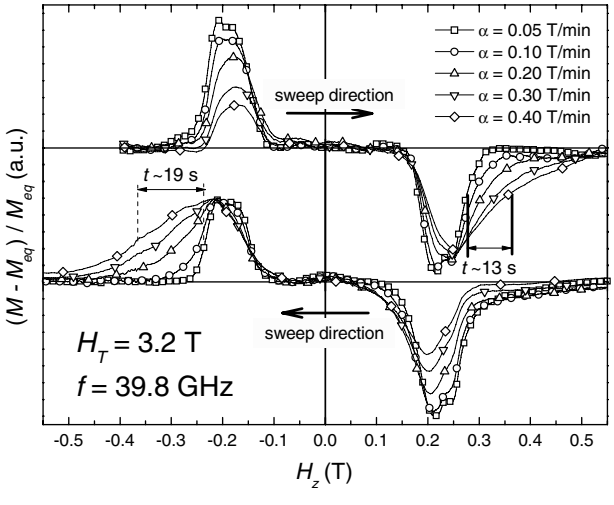

Fig. 4. $(M - M_{eq})/M_{eq}$ curves for different longitudinal field sweep rates from 0.05 to 0.4 T/min measured in the presence of microwave radiation of 39.8 GHz and a transverse field of 3.2 T. The asymmetric broadening of the peaks/dips for high sweep rates is indicative of a long energy relaxation time which increases with field and thus with frequency.

Relaxation processes must transfer energy to the environment, leading, for example, to generation of phonons or photons. The occurrence of each of these phenomena depends on the energy of the transitions and the temperature of the system (i.e., energy distribution of phonon or photon modes). The extracted relaxation times found here may indicate a very long spin-lattice relaxation time. However, slow relaxation processes could also be associated with poor thermal coupling between the sample and bath. We note that the phase space available for phonon generation increases with frequency. Therefore, since our experiments show that energy relaxation time increases with frequency, this result is not consistent with a spin-phonon bottleneck of the type studied in [15]. These experiments constitute an excellent means for studying the spin-environment coupling that govern quantum dynamics in SMMs.

We also note that the width of the PITs peaks/dips at different microwave powers provide a lower bound on the decoherence time, $\tau_\phi > 0.5$ ns (see [10]). Interestingly, a very similar decoherence time, $\tau_\phi = 1$ ns, has been recently reported by Hill et al. [16] through high frequency EPR experiments carried out in a single crystal of Mn_4-based SMMs ($S = 9/2$), in which exchange interaction between pairs of adjacent molecules (dimers) generate entanglement of the spin states of both molecules.

Improvement of the resonance circuit used to irradiate the sample, higher radiation powers and short pulses of radiation are necessary to carry out spin-echo experiments and to create Rabi oscillations. The Rabi frequency is determined by the magnitude of the ac magnetic field, $\Gamma_R \approx \frac{g\mu_B}{h} H_{ac} S$, and in our best case (at present) is of the order of ~100 kHz. Antiferromagnetic molecular magnets with an uncompensated electronic or nuclear spin that tracks the Neel vector for readout are also excellent candidates for long coherence times in mesoscopic spin-systems and for use in quantum computation [17,18].

The similar structures in the active site have been found in several proteins such as ribonucleotide reductase [18,19], methane monooxygenase [20], purple acid phosphatase [21] and rubrerythrin [22]. Inorganic models as $[Fe_2O(CH_3CO_2)_2(Hbpz_3)_2]$ [23–26], $[Fe_2O(CH_3CO_2)_2(Me_3TACN)_2]$ [27] and their derivatives [28–30] were synthesized [31–33]. These μ-oxo bridged iron complexes show strong antiferromagnetic coupling. Interestingly, these magnetic interactions are particularly sensitive to the electronic environments over μ-oxo. The protonation of the μ-oxo remarkably decreases the magnetic interactions. This characteristic change is common to all μ-oxo-bridged binuclear iron complexes.

It is hard to treat the magnetic properties of transition metal oxides with computational calculations, because strong electron correlations and spin correlations are involved in these problems. Detail theoretical investigations about magnetic interactions and chemical bonds in these compounds are necessary and interesting from the view point of quantum chemistry. For past decades, we have investigated several metal oxides using both broken-symmetry (BS) and symmetry-adapted (SA) methods, and the reliabilities of these methods were examined. Recent development of BS density-functional methods enabled us to perform first-principle calculations to whole realistic transition metal oxides, which are synthetic models of Hr and manganese compounds [34,35]. Previously, magnetic interactions and nature of chemical bonds in μ-oxo bridged diiron model compound of Hr have been clarified based on density-functional theory. These compounds contain the symmetric coordination environment, but which are definitely different from the real proteins of Hr. Some other theoretical calculations have been reported. Chen et al. calculated on the dependence of the magnetic interactions on Fe–O distance [36]. Rodriguez et al. performed fundamental studies of magnetic interactions on Hr model compounds [37]. The bioxygen binding mechanisms of Hr are studied by Solomon et al. [11,38]. Using quantum mechanical/molecular mechanical (QM/MM) method, the binding energy of dioxygen to Hr were calculated by Wirstam et al. [10]. All these theoretical calculations use BS methodology to describe the electronic and magnetic structures in diiron cores.

In this work, electronic structures and magnetic interactions of the binuclear iron center in oxy-Hr, deoxy-Hr, and met-Hr are studied with density-functional theory. The effective-exchange integrals, J are calculated and the differences in the magnetic interaction are analyzed in terms of molecular orbitals. The magnetic interactions are compared with the one from the model compounds, and relations to the role in electron- and proton-transfer in oxygen bonding process in Hr are examined. This study would be also helpful to the magnetic properties for other metalloproteins containing μ-oxo-bridged binuclear irons.

2. Theoretical backgrounds

2.1. Hybrid DFT computations

The density-functional theory (DFT) is based on Hohenberg-Kohn theorems [39]. These theorems state that ground state energy (E) of Schrödinger equation is determined by only minimizing electron density $\rho(\mathbf{r})$,

$$E_G = \underset{\rho}{\mathrm{Min}}[\rho]. \tag{1}$$

The practical treatment of Eq. (1) was provided by Kohn and Sham. They introduced molecular orbital ϕ to obtain total electron density which satisfy the one-electron equation as,

$$\rho = \sum_i^N \int \phi_i^*(\mathbf{r})\phi_i(\mathbf{r})\,\mathrm{d}r, \tag{2}$$

$$\left(-\frac{1}{2}\nabla^2 + v_{\mathrm{eff}}(\mathbf{r})\right)\phi_i = \varepsilon_i\phi_i, \tag{3}$$

where v_{eff} is effective potential, which contain exchange-correlation potentials, classical coulombic interactions and nuclear interactions. The exchange-correlation potentials are defined by

$$E_{\mathrm{XC}} = C_1E_{\mathrm{X}}^{\mathrm{HF}} + C_2E_{\mathrm{X}}^{\mathrm{Slater}} + C_3\Delta E_{\mathrm{X}}^{\mathrm{Becke88}} + C_4E_{\mathrm{c}}^{\mathrm{VWN}} + C_5\Delta E_{\mathrm{c}}^{\mathrm{LYP}}, \tag{4}$$

where C_i are mixing coefficients. B2LYP method [40] using in this study has optimized exchange-correlation potential term for magnetic interaction in μ-oxo diiron inorganic model compounds [34]. The parameter sets are $(C_1,\ C_2,\ C_3,\ C_4,\ C_5) = (0.25,\ 0.75,\ 0.75,\ 1.0,\ 1.0)$. The parameter sets in other methods are (0.5, 0.5, 0.5, 1.0, 1.0) and (0.2, 0.8, 0.72, 1.0, 0.81) for BHandHLYP and B3LYP, respectively.

2.2. Effective-exchange integrals

The effective-exchange interactions between spins at iron atoms are described by spin Hamiltonian, the Heisenberg model (HB),

$$H(\mathrm{HB}) = -2\sum J_{\mathrm{ab}}\mathbf{S}_{\mathrm{a}}\cdot\mathbf{S}_{\mathrm{b}}, \tag{5}$$

where $\mathbf{S}_{\mathrm{a}}$ and $\mathbf{S}_{\mathrm{b}}$ represent spins at sites a and b, respectively. The effective-exchange integrals J_{ab} are experimentally determined by the measurement of magnetic susceptibility. J_{ab} values are estimated from the approximate spin projection (AP) procedure as

$$J_{\mathrm{ab}}(\mathrm{AP}-X) = \frac{E_{\mathrm{X}}^{\mathrm{LS}} - E_{\mathrm{X}}^{\mathrm{HS}}}{\langle \boldsymbol{S}^2\rangle_{\mathrm{X}}^{\mathrm{HS}} - \langle \boldsymbol{S}^2\rangle_{\mathrm{X}}^{\mathrm{LS}}}, \tag{6}$$

where $\langle \boldsymbol{S}^2\rangle$ is the expectation value of squared magnitudes of spin angular momentums and subscript X means calculation methods such as HF and DFT [41–43].

2.3. Natural orbital analysis

Natural orbital (NO) is obtained by eigenvector of diagonalization of all electron density as

$$\rho(\mathbf{x}',\mathbf{x}) = \sum_i n_i \varphi_i^*(\mathbf{x}')\varphi_i(\mathbf{x}). \tag{7}$$

Each eigenvalue for NOs corresponds to occupation number n_i. NO is symmetry adapted and is useful for orbital interaction analysis in broken-symmetry calculations using unrestricted orbitals. Chemical indices indicate the characteristic feature of orbitals and enable us to perform quantitative analysis of chemical bonds or magnetic interactions [34,44]. They are the effective bond order b, the information entropy I_n, the diradical character Y, the spin density Q, unpaired electron density U and the projected effective bond order B. In these chemical indices, only effective bond orders b and B are discussed here.

The spin-polarized orbitals of BS solution have the following relationship with natural orbitals and its occupation numbers,

$$\varphi_\pm = \frac{1}{\sqrt{2(1 \pm T)}}(\phi_\alpha \pm \phi_\beta), \tag{8a}$$

$$n_\pm = 1 \pm T, \tag{8b}$$

where φ_+ (φ_-) is (anti)bonding natural orbital and n_+ (n_-) is its occupation numbers. T is the orbital overlaps between alpha and beta spin-polarized orbitals. These occupation numbers are projected to $n_\pm^{\mathrm{AP}}$ by the AP procedure,

$$n_\pm^{\mathrm{AP}} = \frac{4n_\pm^2}{4 + (n_+ - n_-)^2}. \tag{9}$$

The effective bond order b and the projected effective bond order B are defined by difference between the occupation numbers of the bonding and antibonding natural orbitals,

$$b = \frac{n_+ - n_-}{2} \tag{10}$$

$$B = \frac{n_+^{\mathrm{AP}} - n_-^{\mathrm{AP}}}{2}. \tag{11}$$

If the bond-order value is equal to 0.0, spin is localizing in one site and its orbital is complete diradical. In contrast, the bond-order value is equal to 1.0, spin is delocalizing over sites and their orbitals are complete closed-shells. The b value is equal to the orbital overlap T and the B value is always larger than the b value. The orbital which has the largest bond-order value is the main interaction pathway among spin sites. The bond-order values reveal strength of orbital interactions. Magnetic interactions become clear by this natural orbital analysis.

As the similar procedure for natural orbitals, spin natural orbital (SNO) is obtained by diagonalization of all electron spin density matrix. Each eigenvalue for SNOs corresponds to spin occupation number n_i^{SNO} with alpha spin considered positive. The spin natural orbital illustrates broke-symmetry and is useful for the analysis for BS solution. The spin natural orbitals of BS solution are composed of natural orbitals with the following relationship as

$$\varphi_\pm^{\mathrm{SNO}} = \frac{1}{\mathrm{Norm}}(C\phi_\alpha + \phi_\beta), \tag{12a}$$

$$n_\pm^{\mathrm{SNO}} = \pm\sqrt{1 - T^2}, \tag{12b}$$

$$C = -\frac{1 \pm \sqrt{1 - T^2}}{T}, \tag{12c}$$

where Norm is normalization factor. These SNOs are especially useful for the analysis of spin densities at BS states. The occupation number of SNO n_+^{SNO} is the same as unpaired electron density U of chemical indices.

2.4. Computational detail

All the calculations were performed with GAUSSIAN98 program package [45]. 6-31G* basis sets given by Pople et al. [46,47] were used for hydrogen, carbon, nitrogen and oxygen atoms. Huzinaga MIDI basis plus Hay's diffuse basis were used for iron atoms [48,49]. All the position coordinates of non-hydrogen atoms were taken from the X-ray crystallographic structures in the Protein Data Bank (PDB). The PDB codes used in this study are 1HMO, 1HMD and 2HMQ for oxy-Hr, deoxy-Hr and met-Hr, respectively. These Hrs were obtained from *Themiste Dyscrita* (Sipunculid worm) and its structures are determined at 1.66 Å resolution of the met-Hr and at 2.0 Å of the oxy-Hr or deoxy-Hr [13,14]. The Hr model structures used in this study are shown in Fig. 1.

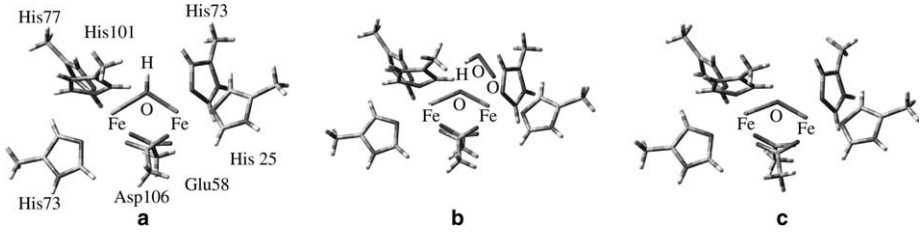

Fig. 1. The active site structure of Hr: (a) oxy form (PDB code: 1HMO) (b) deoxy form (1HMD) and (c) met form (2HMQ).

3. Calculated results

3.1. Met form

3.1.1. Effective-exchange integral

Calculated effective-exchange integral by UB2LYP method is $-J(\mathrm{AP}) = 131.6\ \mathrm{cm}^{-1}$ which is in agreement with experimental value $134\ \mathrm{cm}^{-1}$ [50]. Calculated $-J$ values are 18.92, 69.33, 153.98 and $318.19\ \mathrm{cm}^{-1}$ by UHF, UBHandHLYP, UB3LYP and UBLYP, respectively. These methods have different weight of Hartree-Fock exchange term in exchange-correlation potential. The pure DFT BLYP overestimates more than double while Hartee-Fock underestimate it less than one-seventh. Among these methods, hybrid-DFT as UB2LYP and UB3LYP is in qualitatively agreement with experimental values. The magnetic interactions J have a tendency to be smaller by the weight of Hartree-Fock exchange term in exchange-correlation potential. The B2LYP has larger share of Hartree–Fock exchange potential than B3LYP. The B2LYP predicts appropriate strength of magnetic interaction, this method can depict proper shapes of magnetic orbitals than other methods. Next, orbital interactions from UB2LYP are analyzed.

3.1.2. Orbital interactions

There are five bonding NOs and five antibonding NOs involving a magnetic interactions in met-Hr. They consist of iron d-orbitals and ligand orbitals, which are spin site orbitals and their delocalizing orbitals. The bonding and antibonding orbitals are different in the node at spin site and are pairing in a type of interactions. There are five types in this d-electron interacting system. They are named as σ, π_1, π_2, δ_1, δ_2 as elements from an approximate C_{2v} symmetry group in the active site. In Fig. 2 these NOs are shown in the order of their occupation numbers. The B values, which are projected effective bond order, for π_1, σ, π_2, δ_2, δ_1 are 0.29, 0.27, 0.24, 0.04, 0.026, respectively. This result indicates that σ and π interaction through p orbitals at μ-oxo are fairly stronger than δ interactions through carboxylic group of acetate. Strong antiferromagnetic interactions are mediated by μ-oxo bridge. Mulliken spin densities on the iron sites in BS state are 4.16 and −4.06. These spin densities are typical for high spin Fe(III) system of d5 electrons because contributions for the spin density are 0.799, 0.773, 0.845, 0.826, 0.943 from each interactions π_1, σ,π_2, δ_2, δ_1, respectively. The orbital interactions contribute to decrease to the spin density in iron spin sites.

3.2. Deoxy form

3.2.1. Effective-exchange integral

Calculated effective-exchange integral by UB2LYP method is $-J(\mathrm{AP}) = 18.88\ \mathrm{cm}^{-1}$ which is in agreement with experimental value $13\ \mathrm{cm}^{-1}$ [38]. Weak antiferromagnetic interactions between diirons are computationally reproduced. Calculated $-J$ values are −3.15, 9.64, 22.44 and $19.85\ \mathrm{cm}^{-1}$ by UHF, UBHandHLYP, UB3LYP and UBLYP, respectively. There is the same tendency to these results that the pure DFT BLYP overestimates while Hartee-Fock underestimates the J value.

3.2.2. Orbital interactions

The electron configurations in iron sites of deoxy-Hr are d6 high spin state and δ_1 orbitals are double occupied. For this reason, the types of interacting orbitals are other orbital interactions as σ, π_1, π_2, δ_2. These NOs (not shown) are similar in shape to that of Met-Hr in Fig. 2. These B values by UB2LYP are 0.2007, 0.1180, 0.0663, 0.0259, respectively. Compared with the B values of met-Hr and Oxy-Hr, these B values are smaller. Especially B value for π_1 becomes small. π_1 orbital interaction is superexchange (SE) interaction through protonated p orbital at μ-hydroxo. The SE interaction through μ-hyroxo in deoxy-Hr are smaller than the SE interaction through μ-oxo. The spin densities at iron sites are 3.78 and −3.73. This spin densities are close to the high spin Fe(II) system of d6 electrons. This is the reason that the spins in iron sites are localizing and their orbital interactions are small. Other electron configuration state as the distal iron having π_1

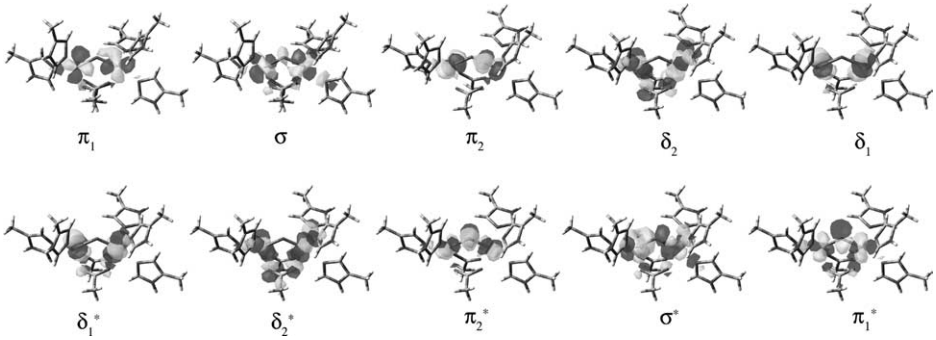

Fig. 2. Natural orbitals for the antiferromagnetic spin state of Met-Hr by UB2LYP/DZP. These orbitals are in the order of their occupation numbers.

double occupied electrons and proximal iron having δ_1 electrons which are important configuration to react with dioxygen are 1.78 kcal mol^{-1} above the δ_1 double occupied configuration one by UB3LYP at antiferromagnetic coupling state. These state are nearly degenerating in deoxy-Hr.

3.3. Oxy form

3.3.1. Effective-exchange integral

Calculated effective-exchange integral by UB2LYP method is $-J(\mathrm{AP}) = 75.60\ \mathrm{cm}^{-1}$ which is in agreement with experimental value 77 cm^{-1} [50]. The strong antiferromagnetic interactions between diirons are computationally reproduced. Calculated $-J$ values (cm^{-1}) by UHF, UBH and HLYP, UB3LYP and UBLYP are 30.46, 50.91, 121.94 and 334.13, respectively. There is also the same tendency to these results that the pure DFT BLYP overestimates while Hartee-Fock underestimates the J value. The calculated J values are given in Table 1 with experimental values.

3.3.2. Orbital interactions

As is the met form, the orbital interactions are π_1, σ, π_2, δ_1, δ_2 according to the strength. The B values for π_1, σ, π_2, δ_1, δ_2 are 0.89, 0.41, 0.33, 0.05, 0.03, respectively. As is the met form, σ and π interactions through p orbitals at μ-oxo are fairly stronger than δ interactions through carboxylic group of acetate. Strong antiferromagnetic interactions are mediated by μ-oxo bridge in oxy-Hr. Natural orbitals for σ and π_1 are mixing for orbital interactions to dioxygen. These orbital interactions to dioxygen are discussed in next section. Mulliken spin densities on the iron sites in BS state are 3.98 and −3.70. These spin densities are contributed by 0.451, 0.822, 0.915, 0.913, 0.928 from each interactions π_1, σ, π_2, δ_1, δ_2, respectively. The spin densities in iron sites depend on method. The iron spin density is 4.70, 4.31, 3.93, 3.60 by UHF, UBHandHLYP, UB3LYP and UBLYP, respectively. Molecular orbitals and their orbital interactions are also highly depending on methods. We discuss these properties by UB2LYP method which properly represents magnetic interactions in consistent with experimental values. In Table 2, the occupation numbers with assignments of orbital symmetries for met-Hr, deoxy-Hr, and oxy-Hr are given.

Table 1
Effective-exchange integrals[a] J calculated[b] for hemerythrin active site

3.3.3. Oxygen binding states in oxy-Hr

Natural orbitals in oxy-Hr are dissymmetric for the interactions with oxygen orbitals. The double occupied orbitals in dioxygen are delocalizing over iron spin sites. They are σ bonding and π bonding with proximal iron named as $\sigma(\mathrm{Fe}(\pi_1^*) + \mathrm{O}_2)$, and π $(\mathrm{Fe}(\delta_2) + \mathrm{O}_2)$, respectively, and their occupation numbers are 1.9966 and 1.9944. Strong orbital delocalization from hydroperoxide to iron atoms are seen (Fig. 3).

3.4. Comparison to Hr model compounds

Magnetic interaction analysis for Hr model compounds as $[Fe_2O(CH_3CO_2)_2(Hbpz_3)_2]$ and $[Fe_2O(CH_3CO_2)_2(Me_3TACN)_2]$ have reported [34]. Their magnetic interactions in μ-oxo are σ, π_1, π_2, δ_1, δ_2 type in the order of strength. In μ-hydroxo state, all the SE interaction are weakened and especially π_1 type interaction drastically reduced by protonation over μ-oxo, just as Hr active sites in this study. These magnetic interaction changes in Hr are essentially identical to Hr model compounds, which have no dioxygen bonding capability. Then the magnetic interactions are through μ-oxo and their changes are inherent to the Fe–O–Fe core.

3.5. ET process in Hr

The dioxygen binding mechanism in Hr had been studied by Solomon et al. using DFT calculations [11]. In their results, ETPT process is indicated, which is coupling mechanism of electron transfer (ET) and proton transfer (PT). The mechanism is composed of two step electron transfers (Fig. 4). In the first step one electron transfer from distal iron to dioxygen and proton tunnel-

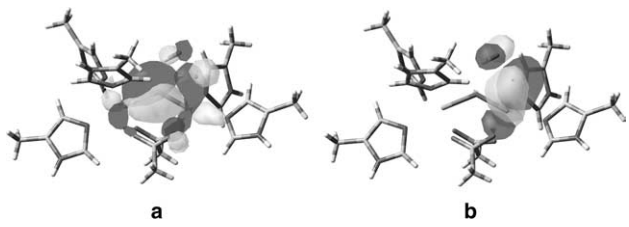

Fig. 3. Double occupied natural orbitals for the antiferromagnetic state of oxy-Hr by UB2LYP/DZP. (a) σ bonds $(\mathrm{Fe}(\pi_1^*) + \mathrm{O}_2)$ and (b) π bonds $(\mathrm{Fe}(\delta_2) + \mathrm{O}_2)$.

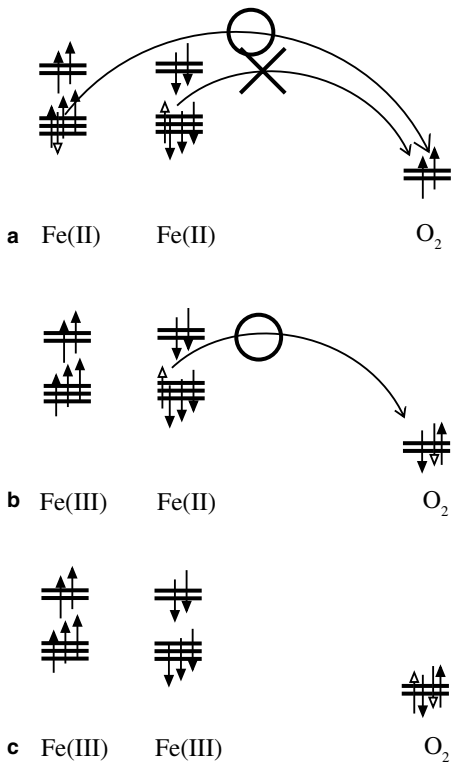

Fig. 4. Reversible dioxygen binding mechanism (ETPT) proposed by Solomon et al. for Hr. (a) deoxy-Hr. (b) Mixed-valence intermediate state. (c) Oxy-Hr.

ing occur at the same time from hydroxy to peroxide (ETPT). Then σ bond is formed between iron and oxygen of hydroperoxide. In the second step, one electron transfer occur from the proximal iron and π bonding is formed. The double occupied natural orbital in Fig. 3 are corresponding to the two step ET interactions.

4. Conclusion

The active sites from Hrs were calculated by DFT to clarify the oxygen binding states and its relation to magnetic properties. Natural orbitals were utilized for orbital interactions. The following results are concluded:

1. Calculated effective-exchange interactions in B2LYP method were in good agreement with experimental values for deoxy-Hr, oxy-Hr and met-Hr.
2. From natural orbital analysis, magnetic interactions in oxy-Hr, deoxy-Hr and met-Hr are elucidated. The iron spin sites are interacting each other in a form of The σ, π_1, π_2, δ_1, δ_2 type in met-Hr and in deoxy-Hr. The σ, π_1, π_2 type interactions were through μ-oxo and these interactions are relatively strong in oxy-Hr and met-Hr compared to the δ_1, δ_2 type interactions through carboxyl group of acetic acids. But in deoxy-Hr, main orbital interactings as σ, π_1, π_2 are decreased. Especially at π_1, whose intermediate orbital is protonated p orbital of oxygen at μ-hydroxo in deoxy-Hr. For this reason, magnetic interactions in deoxy-Hr are weakened.
3. Natural orbitals in oxy-Hr allowed to understand oxygen binding state well. π_1 type interaction orbital also plays key role in a process of dioxygen binding process. The natural orbital $\sigma(Fe(\pi_1) + O_2)$ represents first step electron transfer path in ETPT process. By this electron transfer from distal iron to dioxygen, σ bond between dioxygen and proximal iron atom is formed. Then π bond form by second electron transfer from δ_2 type orbital from proximal iron atom and they corresponds to $\pi(Fe(\delta_2) + O_2)$ of natural orbital.

It is necessary for the accurate investigations of such compounds to calculate and explain such interactions as SSC interactions within molecular orbital levels, since most of triplet carbenes were determined by the usage of EPR. Especially, high level ab initio studies can be significantly useful not just for inquiring into the origin of magnetic anisotropy but also to the flexible and systematic molecular designs, as well as the interpretation of spectra and the determination of molecular structures.

It was difficult to study ZFSs theoretically, because the electron correlation problems are deeply involved and even more so in excited spin states. Only ab initio studies of ZFSs have been carried out for such small molecules as CH_2, SiH_2, O_2, H_2CO [11–14]. Although semi-empirical methods have often been used and ab initio calculations are still difficult due to the much computing costs for aromatic and heterocyclic hydrocarbons.

In this study, theoretical studies of zero-field splitting energies from the spin–spin coupling contributions for ground triplet molecules [15] are reported. An efficient method for ZFS by the hybrid-density-functional theory (HDFT) is proposed, which can be applied up to relatively large molecules. First, this procedure is discussed for typical organic biradicals. Next, its detailed applications for traditional problems of such carbenes as vinylmethylene, phenylcarbene, and diphenylcarbenes are discussed from the viewpoint of the calculated ZFSs parameters, magnetic axes and spin orbitals.

2. Theoretical backgrounds

2.1. Anisotropy in spin hamiltonian

An anisotropic term in spin-Hamiltonian is constructed from the total spin operators as the form

$$H_{\mathrm{AS}} = \sum_{i,j} \mathbf{D}_{ij} S_i S_j, \quad (i,j = x,y,z), \tag{1}$$

where $\mathbf{D}_{ij}$ is a traceless symmetric rank-two tensor. Diagonalization of the $\mathbf{D}$ tensor can represent Eq. (1) in a principal axis (X, Y, Z) coordinate system as

$$H_{\mathrm{AS}} = D\left(S_Z^2 - \frac{1}{3}S^2\right) + E(S_X^2 - S_Y^2), \tag{2}$$

where D and E are the independent parameters: $D = -3/2\boldsymbol{D}_{ZZ}$ and $E = 1/2(\boldsymbol{D}_{YY} - \boldsymbol{D}_{XX})$. The Z is the main axis. D is the principle value and $E < |D/3|$, which represents anisotropy within XY plane. D and E values for organic radical are experimentally determined by EPR fine structure around the large signal $g = 2.0$. The magnetic axis is rarely determined by EPR study in solid crystals. The axes direction and the sign of E value change depending on the orientation definitions. The labels of the axes of EPR are conventionally chosen so as to make $DE < 0$. The energy surface of spin anisotropy is an ellipsoid with two different axes. The spin ellipsoid looks like a disc if $D > 0$, and the spin ellipsoid resembles a bar or a rugby ball if $D < 0$.

2.2. The origin of anisotropy in real Hamiltonian

The SOC and SSC expressions for the magnetic anisotropy are obtained under relativistic correction of the Breit–Pauli Hamiltonian [16–20]. The spin–orbit term is

$$\widehat{\mathbf{H}}^{\mathrm{SO}} = \frac{e^2\hbar}{2m^2c^2}\left(\sum_{n,i} Z_n \frac{\mathbf{S}(i)\cdot\mathbf{M}^n(i)}{\mathbf{r}_{ni}^3} - \sum_{i\neq j}\frac{2\mathbf{S}(i)\cdot\mathbf{M}^i(j) + \mathbf{S}(i)\cdot\mathbf{M}^j(i)}{\mathbf{r}_{ij}^3}\right), \tag{3}$$

where $\mathbf{S}(i)$ is a spin angular momentum operator. $\mathbf{M}^n(i)$ is a gauge-invariant angular momentum operator of ith electron defined as

$$\mathbf{M}^n(i) = \mathbf{r}_{in}\cdot\mathbf{p}_i. \tag{4}$$

The first term in Eq. (3) is the sum over the one-electron SOCs in the Coulomb field of nuclei n. The second term is the interaction of electron spin i with the magnetic field induced by the orbital current of jth electron. In most of organic free radicals, the orbital angular momentum is quenched and SOC is much smaller than SSC.

The spin–spin term is

$$\widehat{\mathbf{H}}^{\mathrm{SS}} = \frac{e^2\hbar^2}{m^2c^2}\sum_{i<j}\frac{\mathbf{r}_{ij}^2(\mathbf{S}(i)\cdot\mathbf{S}(j)) - 3(\mathbf{r}_{ij}\cdot\mathbf{S}(i))(\mathbf{r}_{ij}\cdot\mathbf{S}(j))}{\mathbf{r}_{ij}^5}, \tag{5}$$

which means the spin–spin dipolar coupling. This term is the main interaction of the ZFSs in organic radicals and the g-factors is near to the value for a free electron ($g_e = 2.0023$).

2.3. Spin orbitals

The unrestricted wave function method is employed in this HDFT study. These orbitals are spin-polarized and negative spin density is found over atoms. The spin orbitals are obtained from natural (spin) orbitals with occupation number 1.0, so-called singly occupied natural orbital (SONO). Natural orbitals (NOs) are obtained as an eigenvector by the diagonalization of all electron (or charge) density as

$$\rho(\mathbf{r}',\mathbf{r}) = \sum_i n_i\varphi_i^*(\mathbf{r}')\varphi_i(\mathbf{r}). \tag{6}$$

Each eigenvalue of NOs corresponds to occupation number n_i ($0 \leqslant n_i \leqslant 2$). Similar procedure to Eq. (6) provides spin natural orbital (SNO) from all electron spin density. Each eigenvalue of SNOs corresponds to spin occupation number n_i^{SNO} (in [0, 1]) where α spin is defined to be positive. The SONOs and HOMOs of α orbitals are almost the same, but this NO procedure

theoretically means the spin projection into pure high spin states from spin-contaminated states. These non-SONO NOs (i.e., HONOs) and its occupation numbers can analyse spin polarizations and magnetic interactions quantitatively [21,22].

The total spin orbitals are derived by the antisymmetrization of spin orbitals. An expectation value of an operator $\widehat{O}$ for magnetic properties is obtained as:

$$E = \langle \Phi | \widehat{O} | \Phi \rangle. \tag{7}$$

For the triplet states of organic biradicals, only two SONOs affect for their magnetic properties. The total spin orbitals are

$$|^3\Phi\rangle = |\varphi_i\varphi_j\rangle = \frac{1}{\sqrt{2}}(\varphi_i\varphi_j - \varphi_j\varphi_i), \tag{8}$$

and the anisotropic **D** tensor is obtained by the SSC contribution to the ZFS, as

$$\mathbf{D} = \mathbf{H}^{SS} = \langle {}^3\Phi | \widehat{\mathbf{H}}^{SS} | {}^3\Phi \rangle. \tag{9}$$

3. Computational procedures

The present study was started with coding a new computer programs called "GSO-ZFS", in order to calculate SSC. The two electron integrals in Eq. (1) were calculated by differentiating two-electron integrals based on the Obara–Saika methodology [23–26]. This computational procedure is described as below. First, ab initio MO calculations are performed for the molecular structures of the ground triplet state and spin orbitals with GAUSSIAN 98 program packages [27] using UB3LYP//6-31G method [28,29]. The **D** of SSC interaction is then evaluated by GSO-ZFS. ZFS parameters D, E and magnetic axis are provided by the diagonalization of **D**. the g-factor is fixed to be 2.0.

In the triplet states, two SONOs were selected for the SSC calculation. In general $2S$ spin orbitals are necessary for the SSC calculation in the highest $2S+1$ spin multiplicity state. The SNOs are necessary for evaluating SCC from unrestricted orbital calculations because of the separation from the slight spin contaminations by spin polarization. The SSC interactions between these spin orbitals were evaluated by the effective total spin wave functions of the antisymmetrized spin orbitals. If the spin state is of the excited one, multi-reference configuration interaction (MR-CI) and MR-SCF calculations will be necessary for the SSC calculations.

4. Calculated results and discussions

4.1. Applications to typical organic biradicals

D and E for typical organic biradicals depicted in Fig. 1 [5,16] were calculated by the method described above.

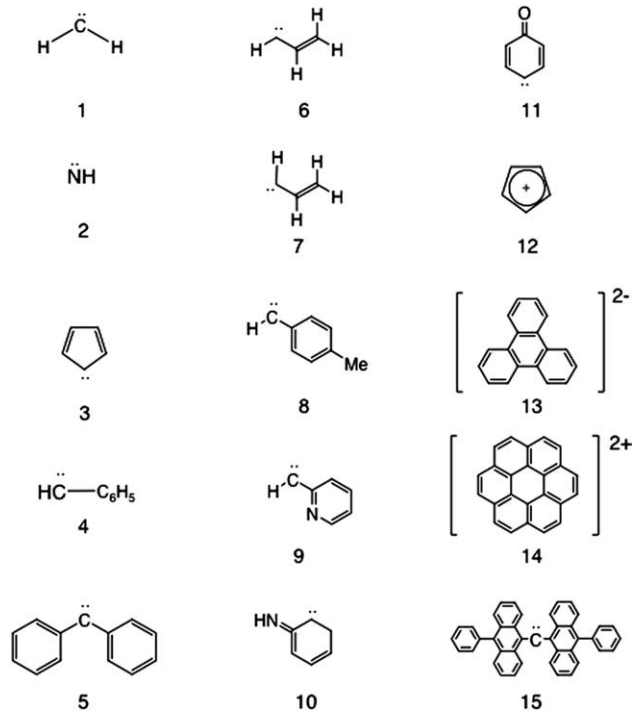

Fig. 1. Molecular structures of typical organic biradicals (**1**: carbene, **2**: nitrene, **3**: cyclopentadienylidene, **4**: phenylcarbene, **5**: diphenylcarbene, **6**: vinylcarbene (s-*E*), **7**: vinylcarbene (s-*Z*), **8**: *p*-tolylcarbene, **9**: pyridylcarbene, **10**: iminocyclohexadienylidene, **11**: 4-oxo-2,6-cyclohexadienylidene, **12**: ferrocene cation, **13**: triphenylene, **14**: coronene dication, **15**: bis[9-(10-phenyl)anthryl]carbene).

The results are summarized in Table 1 with their experimental values, indicating these calculated D and E values were in good agreements with their experimental values. All of these organic biradicals have positive D values because their spin orbitals distribute over one ring. In contrast of such spin distributions, if spins stay away each other, the D value is expected to have negative sign by the application of the point dipole approximation. These D values are often used for the experimental measurement between two spin sites.

The largest D value was obtained for **2** because the spin orbitals are the closest to each other. Also the D of carbene (**1**) was large for the same reason. Among carbene derivatives, the smallest D was obtained for **15** because each spin orbital at carbene centre is delocalized over the anthryl moieties and spins are distant each other [3,30,31]. E value shows how bending the carbene centre is. Such linear biradicals as **15** and **2** have characteristically 0 values of E, so do such molecules with more than C_3 symmetry as **12** and **13**.

Cyclopropenyl cation **13** has a 4π-electron cyclic system. It has the triplet ground state in order to keep C_5 symmetry of the molecular structure [32–35]. Coronene **14** takes thermally accessible triplet state in dication state [36], which is extremely stable at ambient room temperature, decomposing above 50–70 °C. The molec-

[a] Spin–spin coupling contributions.

ular structure of this dication spin state has D_{6h} symmetry, but the structure of the ground state with the singlet spins has D_{2h} symmetry under the influence of its Jahn–Teller distortions. We implemented geometry optimization for **14** to evaluate the structural distortion effect and the S-T gas. UB3LYP//6-31G showed that the total energy of the singlet state with D_{2h} was more stable than the one of the triplet spin state with D_{6h} by 147.5 kcal mol^{-1}. The Jahn–Teller distortions had small contributions to molecular stability for the singlet state of **14**, since the energy gap between the singlet structure and that of the triplet was only 8.4 kcal mol^{-1}. Hence, it is found that the observed EPR signals for $\mathbf{14}^{2+}$ are arise from its thermally excited triplet spin state. The temperature dependency in EPR signal intensity experimentally estimated S–T gap to be 1.4 kcal mol^{-1}. Also $\mathbf{14}^{2-}$ takes the thermally excited biradical state with 23 kcal mol^{-1} S–T gap [37]. In contrast, our UB3LYP//6-31G calculations evaluated the triplet spin state of $\mathbf{14}^{2-}$ to be slightly more stable by 2.1 kcal mol^{-1} (UB3LYP//6-31 + G* also did by 1.6 kcal mol^{-1}). Such phenomena as triplet stability in dianion and dication states resulted from the doubly degeneration of HOMO and LUMO orbitals in the neutral state of coronene.

Thermally excited triplet spin states were also observed in dianion state on strong Jahn–Teller distortions in hexabenzocoronene (HBC) derivatives that are more conjugated polycyclic aromatic hydrocarbons [38]. The HBCs have some characteristic features that HOMOs and LUMOs are nearly triple degenerated, and take such high-oxidized state as tetra anion. EPR observation then indicated that HBCs took quartet spin state, not triplet. These biradicals have π-conjugated spin orbitals and their magnetic hard axis (*Z*) is vertical to the aromatic rings from the result of our calculations. As the number of aromatic ring increases, *D* values decreases, simply due to the spin orbitals delocalized over the aromatic ring and increase in average spin-spin distances. EPR observed *D* and *E* value from HBC dianions are so small: 0.00145 and 0.00005, respectively. Since the molecular structure of coronene (**14**) has C_3 symmetry and the observed *E* value is characteristic zero value.

Only bis[9-(10-phenyl)anthryl]carbene **15** [3,39]was calculated by UB3LYP//4-31G because it is a relatively large molecule. The optimized bond angle at the carbene centre (θ) was evaluated to be 179.7°. The carbene was slightly bent and had small *E* value. The spin orbitals were much delocalized to each side of anthryl moieties. It is concluded that the weak carbene nature makes the carbene centre almost linear geometry.

More detailed discussions for triplet carbene, vinylmethylene and diphenylcarbene are given below.

4.2. Triplet carbene

Bond angles at the carbene centre (θ) have been experimentally estimated based on *E*/*D* values [39,40], which is also important for the delocalization nature of the spin orbitals at the carbene centre. The relationship of the ZFS values to θ was investigated by the calculations using UHF, UBHandHLYP, UB3LYP, and UBLYP. CH bond length was fixed to 1.10 Å. The results are displayed in Fig. 2. At the linear structure, $D = 0.8$ and $E = 0$. When θ decreases from 180°, *D* decreases while *E* increases. Therefore, *E*/*D* values decrease with the bond angle θ (Fig. 3). The decrease in *E*/*D* values is that spin orbitals are inhomogeneous between *YZ*-plane and *ZX*-plane where carbene locates because of the presence of hydrogen. The differences in

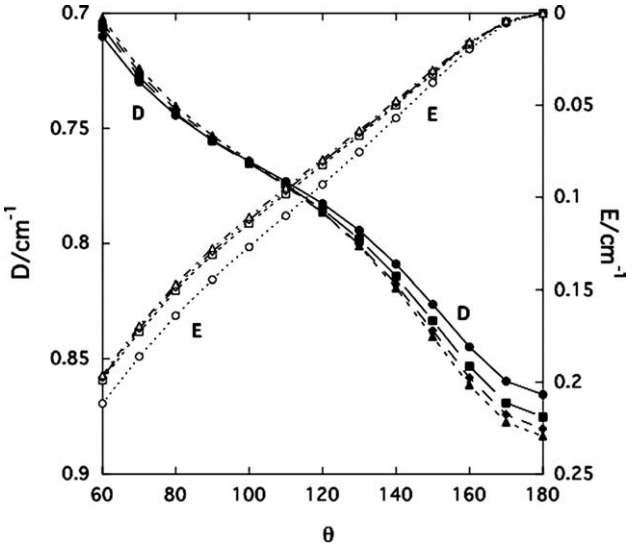

Fig. 2. D (solid symbols) and E (open symbols) values dependence of carbene as a function of the bond angle θ of carbene centre. D values are UHF (●), UBHandHLYP (■), UB3LYP (♦) and UBLYP (▲). E values are UHF (○), UBHandHLYP (□), UB3LYP (◇) and UBLYP (△).

computational methods of HF, BHandHLYP, B3LYP, BLYP are small, indicating that the differences in the shape of spin orbitals are almost the same as the ones for the SSC interactions. The total spin orbitals are then antisymmetrized by the Slater determinants in the process of the SSC calculation. Consequently, the spin correlations exist for all the spin orbitals, even by the pure

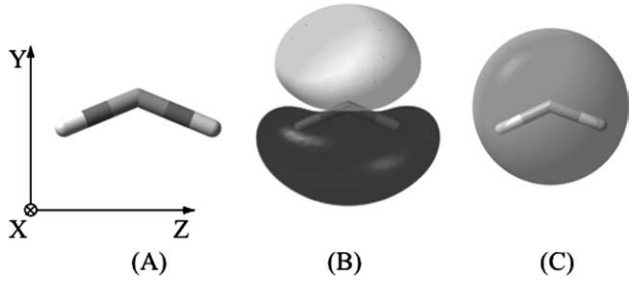

Fig. 4. Triplet carbene. The optimized molecular structure with the magnetic axes (A) and spin orbitals (B, C).

DFT (BLYP). Magnetic hard axis (Z) was parallel to the line connecting the two hydrogen atoms, while Magnetic easy plane (XY-plane) was vertical to the Z-axis. Therefore, two spin orbitals of carbenes are consisted of p_x and p_y orbitals, respectively (Fig. 4). The ZFS values D/cm^{-1} and E/cm^{-1} in the optimized structure were 0.8104 and −0.0576, respectively, as shown in Table 1. These values are slightly larger than experimental values: 0.7567 and −0.0461, respectively. Havlas et al. have reported $D = 0.8043\ \mathrm{cm}^{-1}$ and $E = -0.0428\ \mathrm{cm}^{-1}$ for carbene by CISDTQ/cc-pVDZ methods [11], which is comparable to our values. The SOC interaction causes a slightly smaller contributions than SSC by $D' = D + 0.0023\ \mathrm{cm}^{-1}$ and $E' = E + 0.0001\ \mathrm{cm}^{-1}$ [11,20].

4.3. Isomers of vinylmethylene

There are two isomers of vinylmethylene: s-E and s-Z, and EPR signals for each of these isomers have been observed. It is interest that whether we can theoretically distinguish the difference in fine structures of ZFS for those isomers, or not. Geometry optimizations were performed for each isomer. The θ s were 136.0° and 136.6° for s-E and s-Z, respectively. Fig. 5A displays that the spin orbital perpendicular to the methylene plane is delocalized over the π-orbitals for each s-E and s-Z isomers. The spin orbital populations on the C_2 atom were almost zero at the node of the spin orbitals. On the contrary, the other spin orbitals (σ type spin orbital) parallel to methylene plane localized at carbene centre (see Fig. 5C). The calculated D value of s-Z was larger than that of s-E, while E values of s-Z were smaller than that of s-E (Table 1). These results were consistent with experimental ones. Magnetic axis and spin orbitals are shown in Fig. 5A. As is already pointed by R.S. Hutton et al. [40], spin orbitals spread into Z-axis of the s-E isomer and the corresponding spin orbitals spread over XZ direction of the s-Z isomers. These spin orbitals clearly shows that the difference in delocalization direction affects the D value. The UB3LYP/6-31G calculated the s-E isomer to be more stable than s-Z by $0.207\ \mathrm{kcal\ mol}^{-1}$. The signal rates of s-$Z$/s-E in EPR are

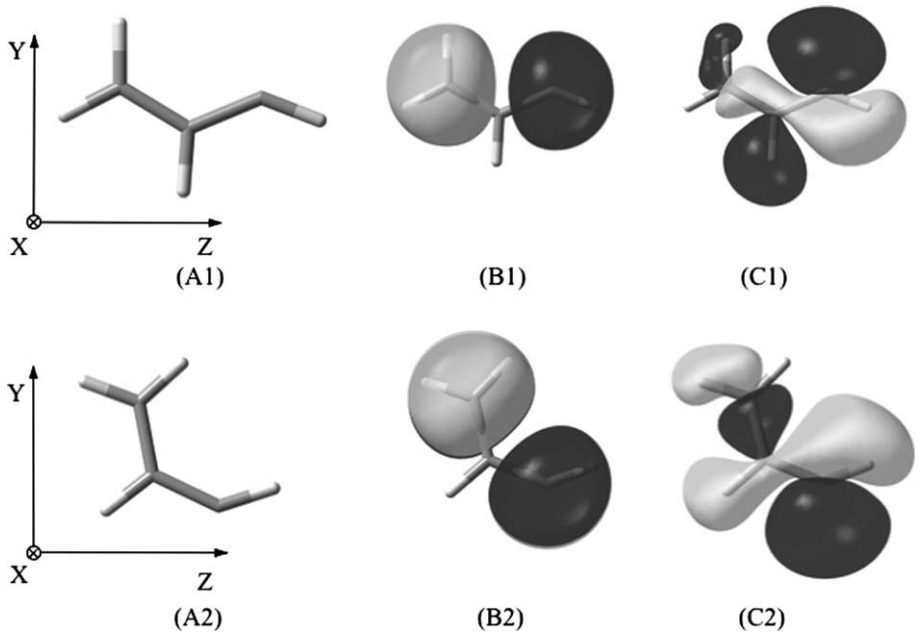

Fig. 5. Vinylcarbene of s-*E* (1) and s-*Z* (2) isomers. Each optimized molecular structures with their magnetic axes (A) and two spin orbitals (B, C).

0.05–0.65 depending on temperature and solvents. This experimental result agrees with our calculation result, showing s-*E* is thermodynamically more stable.

4.4. Phenylcarbene

The ground state structure of phenylcarbene is investigated by ZFSs. The molecular structure of phenylcarbene is considered to be either: the phenyl group is parallel or vertical to carbene C–H plane (denoted by **q0** and **q90**, respectively). Each of these structures wass theoretically optimized. It was revealed that **q0** was more stable than **q90** by 4.335 kcal mol^{-1}. The stable optimized structure **q0** was in agreement with other ab initio calculation results by Geise et al. [41]. For isomers **q0** and **q90**, $(D,\ E) = (0.5193, -0.0346)$ cm^{-1} and $(0.6005, -0.0308)$ cm^{-1}, respectively. The D for **q0** was closer to the experimental value $|D| = 0.5150$ cm^{-1}, while the experimental value $|E| = 0.024$ cm^{-1} was smaller than the calculated results. These spin orbitals for each isomer resembled each other and ZFS values were relatively equal (Fig. 6).

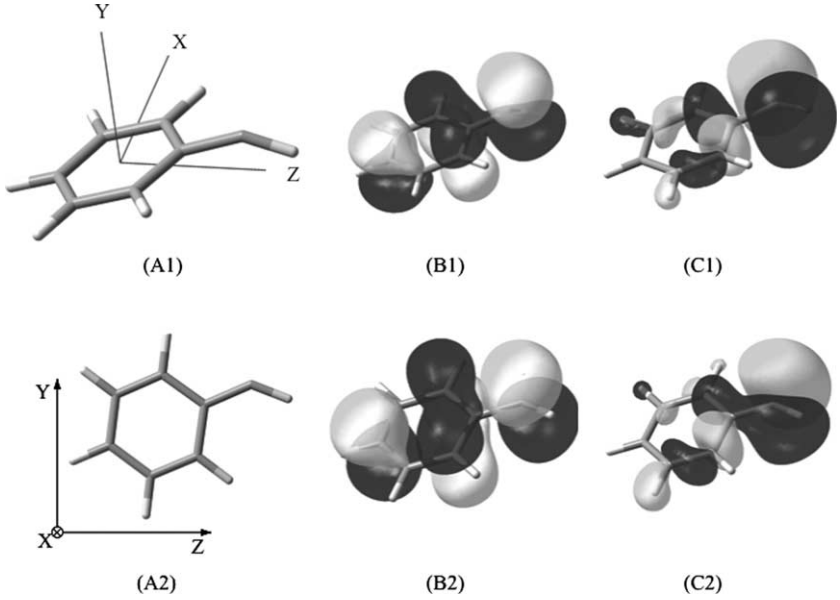

Fig. 6. Phenylcarbene of **q90** (1) and **q0** (2). Each optimized molecular structures with their magnetic axes (A) and two spin orbitals (B, C).

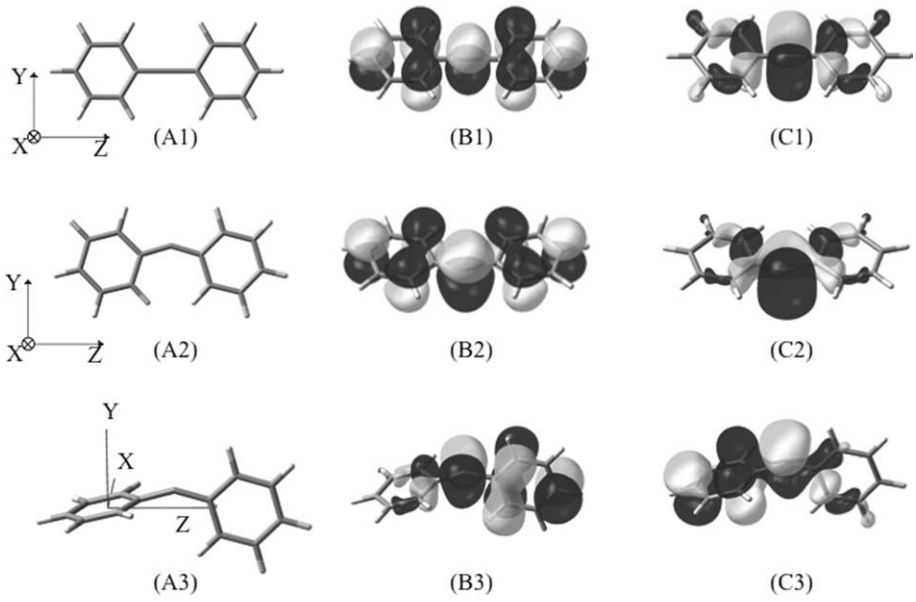

Fig. 7. Structures of diphenylcarbene: **a1** (1), **a2** (2) and **b** (3). Each optimized molecular structures with their magnetic axes (A) and two spin orbitals (B, C).

4.5. Diphenylcarbene

The molecular structure of diphenylcarbene is classical problem in EPR studies [5,17,18,31,43]. There are three conceivable structures. The first one (**a1**) is that phenylcarbenes are parallel each other and carbene centre is liner, i.e., $\theta = 0°$ (Fig. 7-2). The second one (**a2**) is that **a1** is bent at carbene centre in the phenyl ring plane so as the whole structure is within one plane (Fig. 7-1). The third one (**b**) is that the phenyl ring is vertical each other and carbene centre is bent (Fig. 7-3). The experimental ZFS values proposed that ground state is **a2.** (The most stable structure seems to **b**, because two spin orbitals at carbene centre can spread over each phenyl rings) We then decide the structure theoretically, especially using the calculated ZFS values.

In optimizing the forth geometry **a1**′, which is bent at carbene centre in the vertical direction, **a1**′ fell into the geometry **a1** and was revealed to be unstable. The angle θ optimized to be 147.0° and 149.0° for **a2** and **b**, respectively. The most stable structure of these three structures was decided to be **a2** by UB3LYP//6-31G. Energy gap between **a2** and **a1** was 85.58 kcal mol^{-1}, and that between **a2** and **b** were 81.28 kcal mol $^{-1}$. In **a1** and **a2**, one spin orbital vertical to the phenyl ring was delocalized onto π-orbitals over both phenyl rings and the other spin orbital was localized at the carbene centre. The carbene centre was in line and $E \approx 0$ at the structure **a1**. ZFS values were as $(D, E) = (0.3740, -0.00185)$ cm^{-1} and $(0.3774, -0.01657)$ cm^{-1} for **a1** and **a2**, respectively. On the other hand, the spin orbital at the carbene centre was delocalized over the next phenyl rings each other at the structure **b**. And the D value is rather smaller because average distances between spins are relatively longer than **a1** and **a2**. ZFS values for **b** were evaluated to be $(D, E) = (0.3569, -0.01254)$ cm^{-1}, while Experimental ZFS values are $|D| = 0.4055$ cm^{-1} and $|E| = 0.0194$ cm^{-1} [39]. Spin orbitals and magnetic axis are shown in Fig. 7. The most stable structure of phenylcarbene was estimated as **a2**, which reproduces experimental values. It is proved that molecular structure can be determined from the ab initio calculation of ZFS values.

5. Conclusion

The results of this approach were in good agreement with experimental values at moderate computational cost. By using this method, theoretical applications to organic biradicals are further examined for carbene structures, isomers of vinylcarbenes and diphenylcarbenes. We showed this calculation procedure was accurate enough for these the ZFS calculations and effective for the theoretical investigations for organic radicals. This means that high spin states in organic radicals are close to that of the single particle picture. It was also found that the SSC between spin orbitals are the dominant factor for the ZFS and the contributions from the SOC to the ZFS will be vanishingly small. This method has been quit valid in studies of organic ferromagnets.

temperature and orientation of the crystal. The ESR spectrum is significantly deformed by pressurization and the experimental results suggest that there are some different kinds of spins in the salt under pressure.

2. Experimental

2.1. Sample preparation

The salt, MEM–$[TCNQ]_2$, is made by a standard method and its single crystals are grown by slow cooling of acetonitrile solution of the salt. Being cut into a small rectangular single crystal of about $0.3 \times 0.3 \times 0.5$ mm^3, it is fixed in Stycast 1226 as schematically shown in Fig. 2(a), where a polyester sheet is used to arrange the crystal axis of the single crystal. The sample used for the ESR measurement is 1.0 mm in diameter and 1.0 mm in length. A very small piece of lead is inserted near the single crystal in order to determine the pressure by observing the change of the superconducting transition temperature. The uniaxial pressure is applied along the length of the sample.

2.2. ESR measurements under uniaxial pressure

The ESR spectra under uniaxial pressure were measured by a conventional X-band ESR instrument, JOEL JES-RE2X, with a cryostat and a hand-made pressure cell in the temperature range from 1.5 to 300 K. As shown in Fig. 2(b), the pressure cell is pressure-clamping type and made by ourselves. It is made of a kind of hard plastic material supplied by Nippon Polypenco Ltd. As the cell is inserted into the center of the cylindrical cavity of the ESR instrument, it should be made of non-magnetic, non-conductive and low-dielectric loss material. We tested some kind of material supplied by Nippon Polypenco Ltd. and selected suitable one for the pressure cell. As the cell is rather small, we need skilful techniques to make it. The maximum pressure obtained in the cell is up to 2 kbar. However, more pressure is not necessarily indispensable for the salt, MEM–$[TCNQ]_2$, because the salt shows the significant change in the susceptibility even below 2 kbar.

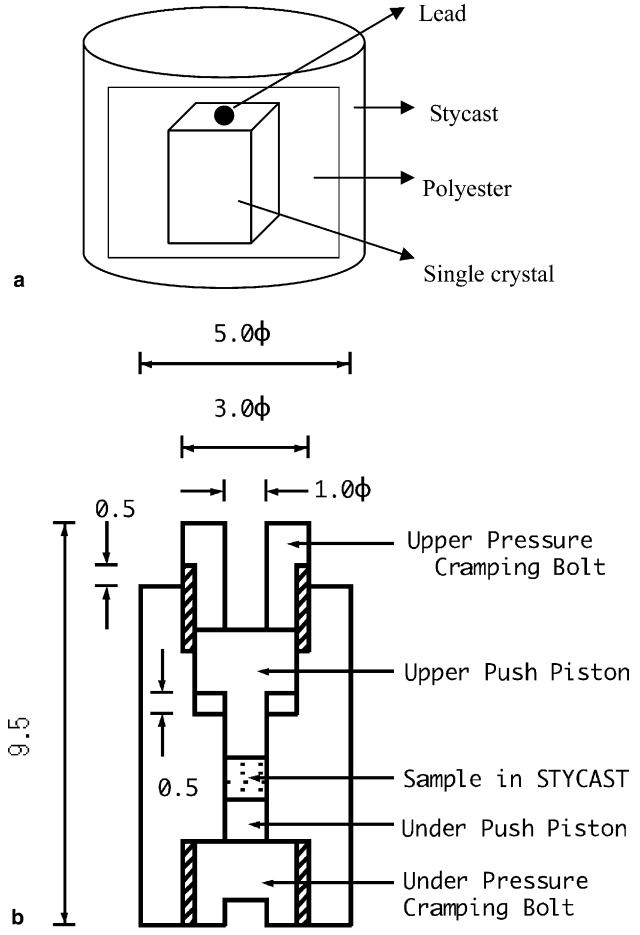

Fig. 2. (a) Schematic figure of the sample for the measurement of ESR under uniaxial pressure. A single crystal is fixed in Stycast 1226 with a small piece of lead for pressure measurement. The sample is 1.0 mm in diameter and 1.0 mm in length. (b) Design of a pressure cell for the ESR measurement under uniaxial pressure. The cell is made of a kind hard plastic material supplied by Nippon Polypenco Ltd.

3. Results and discussion

Under ambient pressure (1 bar), each ESR spectrum of a single crystal of the salt shows a single and symmetrical absorption at any temperatures and orientations of the crystal, though the linewidth of the absorption rather depends on the temperature and orientation. Even if a single crystal is fixed in Stycast 1226, the ESR spectrum of the crystal at ambient pressure is not so different from that of the crystal free from Stycast. No ESR absorption resulting from Stycast is observed at any temperatures. On the other hand, the ESR spectrum is deformed by pressurization. The ESR spectra at 300 K of a single crystal under uniaxial pressure of 1 kbar along *a*-axis are shown in Fig. 3, where the angle is the one between *c*-axis and the external field. The ESR spectrum under uniaxial pressure is deformed and rather different from that under ambient pressure. There are at least two absorptions in the

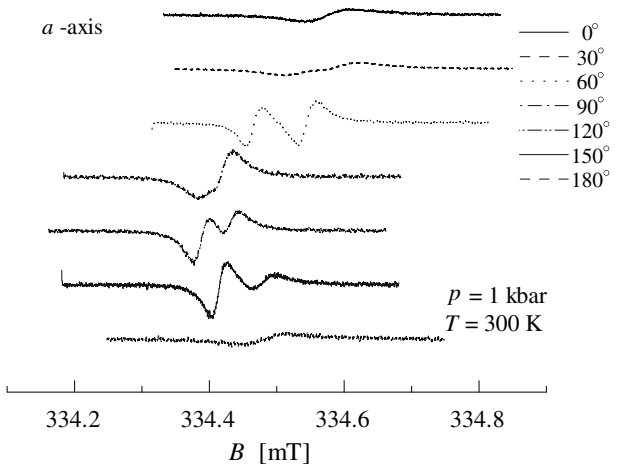

Fig. 3. Angular variations of the ESR spectrum at 300 K of a single crystal under uniaxial pressure of 1 kbar along *a*-axis.

spectrum and the spectrum fairly depends on the orientation. In the liquid helium temperature region, the ESR spectrum becomes more complicated and also significantly depends on the orientation for the external field. The spectrum shown in Fig. 4(a) is an example which shows three absorptions.

The deformed ESR spectrum at low temperatures can be well separated into three independent single absorptions under the assumption that the spectrum is composed of three independent Lorentzian absorptions as follows:

$$I(B) = \frac{a}{1 + b(B - B_0)^2}$$

(Lorentzian absorption),

$$I'(B) = \frac{-2ab(B - B_0)}{[1 + b(B - B_0)^2]^2}$$

(The derivative form of Lorentzian absorption).

The parameters a and b are related to the intensity and the linewidth of the ESR absorption, respectively. The parameter B_0 is the center field of the ESR absorption. These parameters of the three Lorentzian absorptions were determined so as to fit the measured ESR spectrum at each temperature and orientation. The obtained three absorptions (Absorp.-1, -2 and -3) at 4.2 K are shown in Fig. 4(b) with the measured ESR spectrum. The fitting seems to be very well. The same analyses were carried out and the temperature dependence of the linewidth and intensity of these three absorptions were obtained.

At low temperatures, both of the intensity and linewidth of Absorp.-3 fairly increase as the temperature is decreased, which suggests that Absorp.-3 results from the free spins produced by pressurization. On the other hand, the other two absorptions, Absorp.-1 and Absorp.-2, seem to result from the spin-pairs.

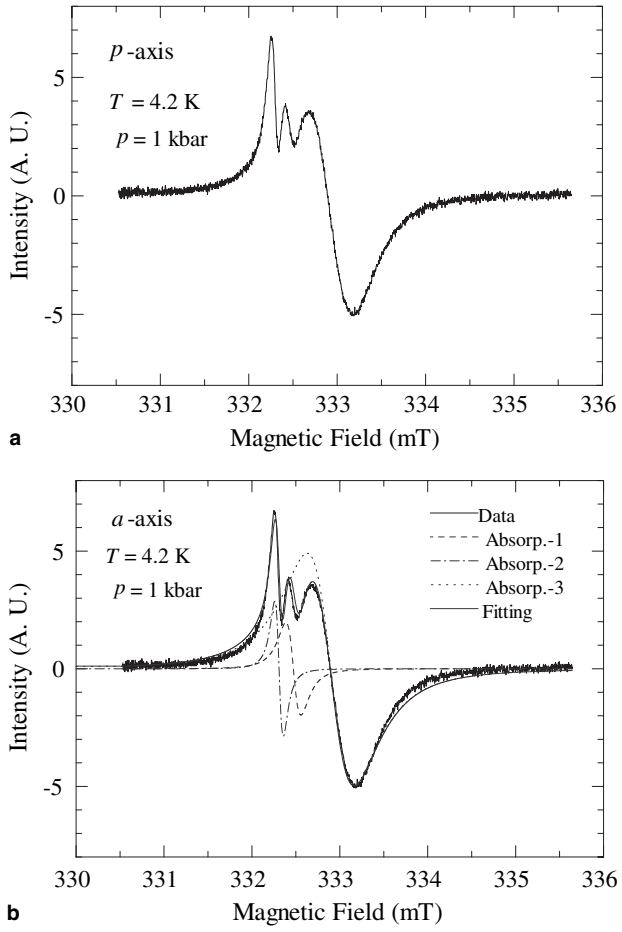

Fig. 4. (a) ESR Spectrum at 4.2 K of a single crystal under uniaxial pressure of 1 kbar along *a*-axis. (b) ESR Spectrum shown in (a) is separated into three single absorptions.

4. Conclusion

The ESR spectrum of a single crystal of a salt, MEM–$[TCNQ]_2$, under uniaxial pressure of 1 kbar is rather deformed compared to that under ambient pressure and it fairly depends on the temperature and orientation of the crystal. The spectrum at low temperatures can be well separated into three independent absorptions, Absorp.-1, -2 and -3. The intensity and linewidth of Absorp.-3 increase with decreasing temperature, which suggests that the origin of the increase of the static susceptibility at low temperatures is the free spins and related to Absorp.-3. The other two absorptions, Absorp.-1 and Absorp.-2, seem to result from the spin-pairs.

Acknowledgements

This work was partially supported by a Grant-in-Aid for Scientific Researches from the Ministry of Education, Culture, Sports, Science and Technology, Japan. The hard plastic material used for the pressure cell for the ESR measurements under uniaxial pressure was

supplied by Nippon Polypenco Limited. The ESR measurements were carried out at The center for Instrumental Analysis, Kyushu Institute of Technology.

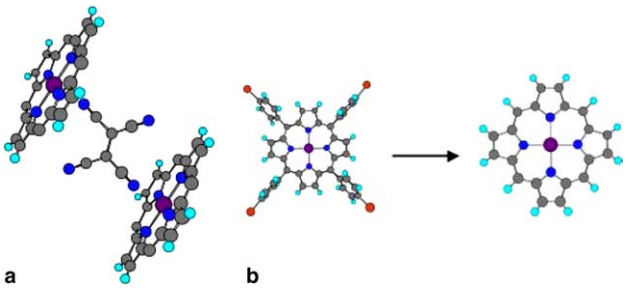

Fig. 1. Structure of the reduced model complex which is calculated in this work (a) and the way to cut ligands from the porphyrin ring (b).

In this study, we introduce a model complex which consists of two porphyrin rings and one TCNE as illustrated in Fig. 1(a). We calculate the electronic states of the model complex by using unrestricted hybrid DFT (UB3LYP, UB2LYP [5]) and UHF. We compared calculated results with experimental one. In the model complex MnTBrPP–TCNE ring was reduced to the manganese porphyrin as illustrated in Fig. 1(b). All calculations were performed by using GAUSSIAN 98 program package [6].

2. Theoretical background

2.1. Effective exchange integrals

The Heisenberg Hamiltonian is employed to describe localized spin interaction defined as

$$\widehat{H} = -2\sum_{a,b} J_{ab}\mathbf{S_a}\mathbf{S_b}, \tag{1}$$

where $\mathbf{S_c}$ ($\mathbf{c} = \mathbf{a}$ and $\mathbf{b}$) denotes the spin operator at the site c, and J_{ab} is the effective exchange integrals between sites a and b. The 3-site model Hamiltonian can be written as

$$H = -2\sum_{ab} J_{ab}\mathbf{S_a}\mathbf{S_b} = -2J(\mathbf{S_1}\mathbf{S_2} + \mathbf{S_2}\mathbf{S_3}). \tag{2}$$

The spin site of $\mathbf{S}_1$ and $\mathbf{S}_3$ are on the manganese, and $\mathbf{S}_2$ is on TCNE as illustrated in Fig. 2. The effective exchange integral between site 1 and 3 (J_{13}) assumed to be zero, and J_{12} equals to J_{23}. This assumption comes from the fact that experimental result was discussed only the neighboring spin sites in the one-dimensional chain molecule. The manner of spin alignment is shown in Fig. 3. The total spin operator is given by:

$$\mathbf{S} = \mathbf{S_1} + \mathbf{S_2} + \mathbf{S_3}, \tag{3}$$

$$\mathbf{S^2} = \mathbf{S_1^2} + \mathbf{S_2^2} + \mathbf{S_3^2} + \mathbf{2S_1S_2} + \mathbf{2S_2S_3} + \mathbf{2S_1S_3}. \tag{4}$$

Using the expression of (4), the model Hamiltonian can be written as

$$-2J(\mathbf{S_1}\mathbf{S_2} + \mathbf{S_2}\mathbf{S_3}) = J(-\mathbf{S^2} + \mathbf{S_1^2} + \mathbf{S_2^2} + \mathbf{S_3^2} + \mathbf{2S_1S_3}). \tag{5}$$

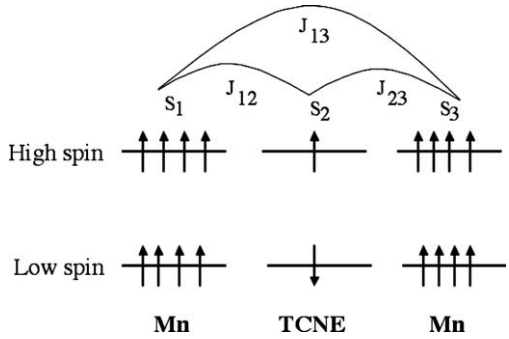

Fig. 2. The two types of electron configuration namely, high-spin and low-spin states.

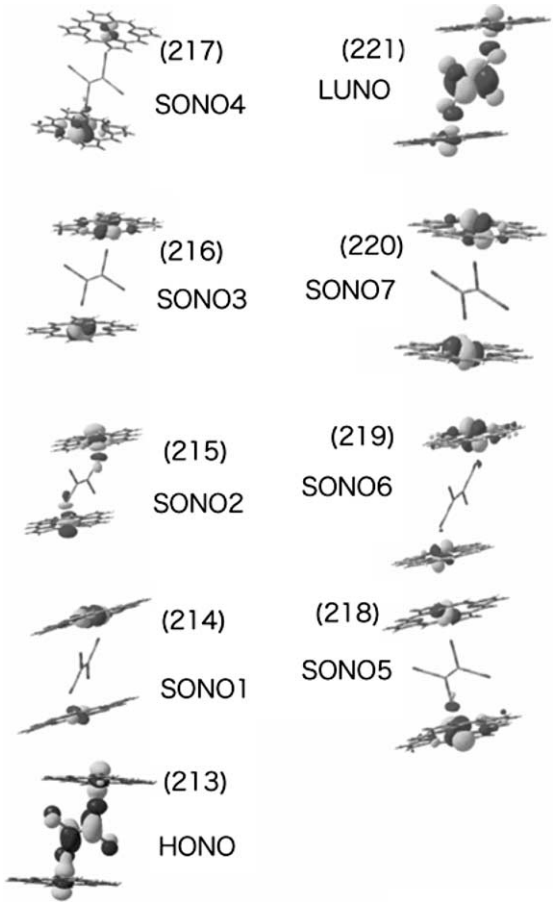

Fig. 3. The picture of natural orbitals and their orbital number.

Then we can obtain energy expectation values for the low spin (LS) and high spin (HS) states as:

$$E_{LS} = J(-\langle\mathbf{S^2}\rangle_{LS} + \langle\mathbf{S_1^2}\rangle_{LS} + \langle\mathbf{S_2^2}\rangle_{LS} + \langle\mathbf{S_3^2}\rangle_{LS} + 2\langle\mathbf{S_1S_3}\rangle_{LS}), \tag{6}$$

$$E_{HS} = J(-\langle\mathbf{S^2}\rangle_{HS} + \langle\mathbf{S_1^2}\rangle_{HS} + \langle\mathbf{S_2^2}\rangle_{HS} + \langle\mathbf{S_3^2}\rangle_{HS} + 2\langle\mathbf{S_1S_3}\rangle_{HS}). \tag{7}$$

The $\langle\mathbf{S_1S_3}\rangle$ term is the same in both high and low spin state as illustrated in Fig. 2.

From Eqs. (6) and (7) we can derive approximate spin projected (AP) J scheme

$$J = \frac{E_{LS} - E_{HS}}{\langle \mathbf{S^2} \rangle_{HS} - \langle \mathbf{S^2} \rangle_{LS}}. \quad (8)$$

2.2. Computational methods

2.2.1. Hybrid density functional theory

The Kohn–Sham (KS) density functional theory (DFT) [7] is one of the most popular approaches in computational chemistry. The energy expression is given by

$$E = T_0[\{\psi_i\}] + V_{Ne}[\rho] + V_{clmb}[\rho] + E_{xc}[\rho], \quad (9)$$

where T_0, V_{Ne} and V_{clmb} are the kinetic energy of electron, nuclear attraction energy and classical coulomb term, respectively. The exchange correlation potentials are generally defined by

$$E_{xc} = C_1 E_X^{HF} + C_2 E_X^{Slater} + C_3 E_X^{Becke88} + C_4 E_C^{VWN} + C_5 E_C^{LYP}, \quad (10)$$

where E_X^{HF}, E_X^{Slater}, and $E_X^{Becke88}$ denote the HF, Slater, and Becke's exchange functionals, respectively. E_C^{VWN} and E_C^{LYP} denote the Vosko, Wilk, and Nusair (VWN) [8] and Lee, Yang, and Parr (LYP) [9] correlation functionals, respectively. $\{C_i\}_{i=1-5}$ are the parameters. They are 0.2, 0.8, 0.72, 1.0, 0.81 and 0.5, 0.5, 0.5, 1.0, 1.0, for UB3LYP and UB2LYP, respectively [10].

2.2.2. The basis sets

Calculations were performed by the use of Huzinaga's MIDI + P basis sets (533(21)/53(21)/(41)) for transition metals and 6-31G* basis sets by Pople et al. for other molecules [11].

2.3. Natural orbital analysis

In order to understand the magnetic interaction between manganese and TCNE, it is desirable to use the picture of the molecular orbital because the Heisenberg model is closely related to the valence-bond picture. The natural orbital (NO) is determined by diagonalizing their first-order density matrix as

$$\rho(r, r') = \sum n_i \phi_i(r) \phi_i(r')^*, \quad (11)$$

where n_i and ϕ_i denote the occupation number and NO, respectively. The occupation numbers of bonding and antibonding orbitals take 2.0 and 0.0, respectively. Occupation numbers of magnetic NOs take near 1.0. The bonding magnetic orbitals are generally given by the in- and out-of phase combination of the bonding (ϕ_i) and antibonding (ϕ_i^*) orbitals

$$\psi_i^{\pm} = \cos\theta \phi_i \pm \sin\theta \phi_i^*, \quad (12)$$

where θ is the orbital mixing coefficient. The mixing provides magnetic orbitals (ψ_i^+ and ψ_i^-) which are localized on different magnetic sites. The orbital overlap (T_i) [12,13] between magnetic orbitals is defined to elucidate their localizability.

$$T_i = \langle \psi_i^+ | \psi_i^- \rangle = \cos^2\theta - \sin^2\theta = \cos 2\theta. \quad (13)$$

The occupation numbers of NOs are given by the orbital overlap as

$$n_i = 1 + T_i. \quad (14)$$

2.4. Chemical indices

Several chemical indices have been introduced by the use of occupation numbers of SONO in order to investigate character of magnetic orbitals. Using chemical indices we can elucidate a nature of a chemical bond by broken symmetry (BS) calculations. Chemical indices are equally defined both by BS and symmetry adapted (SA) methods. The examples of SA methods are CI, CASCI, and CASSCF.

The effective bond order (b_i) [12,13] is defined by

$$b_i = \frac{n_i - n_i^+}{2} = T_i. \quad (15a)$$

It varies from zero to one, depending on the strength of a covalent bond. The information entropy [14–16] is employed to express the character of a chemical bond. The Jaynes information entropy (I_i) is modified as the measure of a chemical bond.

$$I_i = \frac{2\ln 2 - n_i \ln n_i}{2\ln 2}. \quad (15b)$$

Since α and β spins occupy the different MOs in Eq. (12), under the BS approximation, the spin density index (Q_i) [12,13] appears only in the LS state as

$$Q_i = \sqrt{n_i(2 - n_i)} = \sqrt{1 - T_i^2}. \quad (15c)$$

This means that the α and β spins are populated on each magnetic orbital. The unpaired electron density (U_i) [18] is defined as the deviation of SA or BS wave functions from the single Slater determinant and can be expressed as

$$U_i = n_i(2 - n_i) = 1 - T_i^2. \quad (15d)$$

The U_i value is responsible for the electron localization via the Coulomb repulsion in diradical species. The diradical character (Y_i) is defined by the weight of the doubly excited configuration (W_D) as

$$Y_i = 2W_D = 1 - \frac{2T_i}{1 + T_i^2} = \frac{n_i^2 - 4n_i + 4}{n_i^2 - 2n_i + 2} \quad (15e)$$

3. Result and discussion

3.1. Effective exchange integrals

We performed ab initio calculation of the manganese porphyrin dimer which is a reduced model of one dimensional chain molecules. We deduced total energy and the square of spin magnitude, $\langle \mathbf{S}^2 \rangle$ from calculation for the estimation of effective exchange integrals. The J values calculated by three calculation methods are shown in Table 1.

All results show antiferromagnetic coupling, i.e., all of the J value are negative. The experimental value is $-178\ \mathrm{cm}^{-1}$ by Seiden expression model [2]. The UB3LYP calculation reproduced the antiferromagnetic nature of chain magnet. The strength of antiferromagnetic interactions of the model complexes increase in the order $|J(\mathrm{APUHF})| < |J(\mathrm{APUB2LYP})| < |J(\mathrm{APUB3LYP})|$. This tendency stems from a degree of correction in dynamical correlation effect and it is consistent with our previous result [17].

3.2. Spin and charge density populations

Table 2 shows the spin density population in case of low-spin state. The table shows the result of three methods, namely, UHF, UB2LYP and UB3LYP. The spin density populations on TCNE are net spin on itself. The magnitudes for one α spin ($S = 1/2$) and β spin ($S = -1/2$) are defined to be 1.0 and −1.0, respectively. Here, we define the spin populations on manganese as positive and define the spin populations on TCNE as negative. The spin population shows that manganese has four spin moments ($S = 4/2$) and TCNE has one spin moment ($S = 1/2$). This shows clearly the electronic structure of $\mathrm{Mn^{III}}$–$\mathrm{TCNE^{-}}$–$\mathrm{Mn^{III}}$.

Table 3 shows the Mulliken charge density populations of the results by three methods. Charge density populations labeled TCNE and porphyrin in the table are net charge. The charge density populations indicate $\mathrm{Mn^{III}}$ and $\mathrm{TCNE^{-}}$.

Table 1
The calculated J (in cm^{-1}) values by three methods

Method	UHF	UB2LYP	UB3LYP
	−26.67	−52.21	−106.7

Table 2
Spin density population on Mn and TCNE

	Mn(1)	Mn(2)	TCNE
UB3LYP	3.99	3.99	−0.86
UB2LYP	4.11	4.11	−0.90
UHF	4.25	4.25	−0.80

The value of TCNE is summed for all atoms which construct TCNE.

Table 3
Charge density population on Mn, TCNE and porphyrin ring

	Mn(1)	Mn(2)	TCNE	Porphyrin
UB3LYP	1.20	1.20	−0.56	−0.84
UB2LYP	1.43	1.43	−0.68	−1.18
UHF	1.79	1.79	−0.80	−1.78

The values of TCNE and porphyrin ring are summed for all atoms which construct them.

The charge density populations on manganese do not correspond to its formal charge III, but it is about 1.5 indeed. This tendency comes from donations by porphyrin ring. This is consistent with our previous result which used manganese(III) porphyrin dimer [17]. The population of charge density is symmetric.

3.3. Gross orbital population

Table 4 shows the gross orbital population of d-orbitals of manganese for low-spin state. The calculation method is UB3LYP. Since Mn(III) have four electrons in five d-orbitals, it has one hole in the d-orbitals. Table 4 shows that the hole is in $d_{x^2-y^2}$ which orients to the porphyrin ring. This hole in $d_{x^2-y^2}$ orbital stems from the energy splitting due to the ligand field.

3.4. Natural orbital analysis and occupation number

The NOs and their orbital numbers are schematically depicted in Fig. 3. The numbers of NOs and their occupation numbers are shown in Table 5 in case of low-spin state. Fig. 3 depicts NOs of magnetic orbitals that have

Table 4
The gross orbital population for manganese d-orbital

	Mn(1)	Mn(2)
d_{z^2}	0.842	0.842
d_{xz}	0.824	0.824
d_{yz}	0.826	0.826
$d_{x^2-y^2}$	0.474	0.474
d_{xy}	0.799	0.799

The calculation method is UB3LYP.

Table 5
Occupation numbers and their chemical indices

The number of NO	Occupation number	Q_n	U_n	I_n	Y_n
221	0.70				
220	1.00	100	100	100	100
219	1.00	100	100	100	100
218	1.00	100	100	100	100

216	1.00	100	100	100	100
215	1.00	100	100	100	100
214	1.00	100	100	100	100
213	1.30	95	91	75	56

All chemical indices are multiplied by 100 and expressed in %.

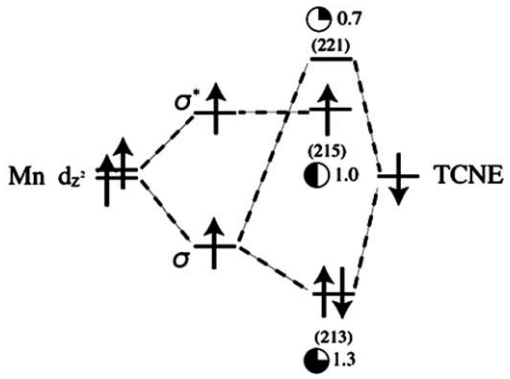

Fig. 4. Schematic view of orbitals. Their bond numbers and occupation numbers.

the occupation numbers around 1.0 (SONO) . The other NO's occupation number are almost 2.0 or 0.0. Eight electrons in d-orbitals of manganese, and one electron of TCNE are the origin of the nine NOs. The way of interaction between SONOs is shown in the pictures. Fig. 4 illustrates the way of construction of the σ-type bonding and antibonding SONOs. They are constructed from two electrons in d_{z^2} orbitals and one electron from TCNE. This one electron on TCNE is the result of charge transfer from manganese. First, two d_{z^2} orbitals on manganese make one bonding and one antibonding orbitals, namely in-phase and out-of-phase orbitals. Next, the in-phase orbital between two manganese interacts with the orbital on TCNE and three σ-type orbitals, bonding, nonbonding, and antibonding orbitals are exhibited.

The SONOs which have π and δ-type interactions take 1.0 in occupation numbers and do not interact with TCNE. This tendency stems from the ferrimagnetic behavior of the system, namely the net spin moment is not zero. From these results, we elucidated a ferrimagnetic structure of one-dimensional manganese porphyrin systems.

3.5. Chemical indices

Using the occupation number of magnetic orbitals, the chemical indices can be obtained. Table 5 shows the chemical indices such as information entropy (I), spin density index (Q), unpaired electron density (U), and diradical character (Y) are deduced from the occupation number of NOs. The orbital numbers of the NOs are from 213 to 220. The method of calculation is UB3LYP. The all chemical indices are expressed in percentage. The bonding interaction between manganese and TCNE occurs through the σ-type orbital, so our main interest is focused on the chemical indices of the number 213. Large Q and U values of the orbital number 213 show that spin density on manganese atom exists and the electron localization is significant. The Y value shows instability in chemical bonds. The smaller diradical character (56%) shows the slight stability of the orbital 213.

4. Conclusions

We discussed on the magnetic character of a manganese porphyrin dimer which is a reduced model of 5,10,15,20 tetrakis(4-bromophenyl)porphyrinatomanganese(III)tetracyanoethenide, ([MnTBrPP][TCNE]). The original one-dimensional chain molecules were converted into two manganese porphyrin and one TCNE. Ab initio calculations were performed to estimate the electronic structure and effective exchange integrals. Our model successfully reproduced the antiferromagnetic interactions and showed ferrimagnetic character. From the viewpoint of natural orbital analysis and its occupation number, the interaction between manganese and TCNE was through the σ-type orbitals.

sometimes called the counterintuitive pulse method. However, this method has some attractive advantages on the formation of the pulse shape. Namely, it has very flexible conditions for the laser parameters such as amplitude, frequency, pulse width, and so on. Due to the robustness with respect to the laser parameters, we have already applied the STIRAP method [17–19] to the control of proton motion in some molecular systems with the hydrogen bond and the laser control of *cis–trans* isomerization reaction, and have showed that the STIRAP method is very effective and experimentally promising to the quantum control of molecular systems by laser pulses.

The ground state of molecules is usually a spin-singlet state ($|\mathbf{S}| = 0$), where up and down spins are in pairs, and in the exited state there appears the spin-triplet state ($|\mathbf{S}| = 1$) with two parallel spins. In the light absorption process in molecule, the singlet–triplet transition is generally forbidden by the spin selection rule. That is, the direct transition from the singlet ground state to a triplet excited state is not allowed by absorbing one photon. It is, however, well known that singlet and triplet states could be mixed due to the spin–orbit interaction in an excited state of molecules [20,21]. This spin–orbit coupling causes the intersystem crossing of the molecular excited states in the intramolecular relaxation process, and plays a very important role in the radiationless transition from a singlet state to a triplet state.

In this study, we pay attention to the role of the spin–orbit interaction in the light absorption process, and use this coupling to produce efficiently the triplet state from the singlet state. By the STIRAP simulation with the spin-mixed intermediate state, we simulate the complete transfer from a singlet ground state to a triplet excited state. This paper is organized as follows. In Section 2, we briefly summarize the electronic state calculation of Cl_2 molecule by taking into account the spin–orbit coupling. In Section 3, some numerical results of the STIRAP simulations for the control of singlet–triplet transition are shown, and Section 4 gives the concluding remarks.

2. Electronic state calculation of Cl_2 molecule

Let us briefly consider the origin of the spin–orbit interaction. In molecule, the electron with the spin angular momentum (**s**) and the electric charge (−e) moves around the atomic nucleus with the charge (+e). It could be considered that the atomic nucleus rotates around the electron with radius r and frequency v from the other point of view. Then the magnetic field and the electric current induced by the moving atomic nucleus at the position of the electron become $\mathbf{B} = \frac{\mu_0 I}{2r}\mathbf{n}$ and $I = e\frac{v}{2\pi r}$, respectively. Therefore

$$\mathbf{B} = \frac{\mu_0}{2r}\cdot\frac{ev}{2\pi r}\mathbf{n} = \frac{\mu_0}{4\pi m r^3}\mathbf{l}, \tag{1}$$

where **l** and **n** mean the angular momentum operator and its unit vector, respectively. This magnetic field interacts with the magnetic moment ($\boldsymbol{\mu}$) induced from the electron spin angular momentum (**s**), and this interaction energy is given by

$$H_{\mathrm{so}} = -\boldsymbol{\mu}\cdot\mathbf{B} = \left(\frac{\mu_{\mathrm{B}}\mu_0 e}{2\pi m r^3 \hbar}\right)(\mathbf{l}\cdot\mathbf{s}). \tag{2}$$

This Hamiltonian (H_{so}) is called a spin–orbit interaction.

Total Hamiltonian (H_{m}) of the molecular system is composed of the electronic Hamiltonian (H_0) without the spin operator and the spin–orbit interaction Hamiltonian (H_{so}). The eigenstates of H_0 are simultaneously the eigenstate of the spin operator (**s**), but the eigenstates of the total Hamiltonian (H_{m}) are no longer the spin eigenstate, namely , the spin–orbit interaction generates the spin-mixed states as the eigenstates of H_{m}.

The transition between states with a different spin multiplicity such as the singlet–triplet transition is generally forbidden by the spin selection rule. However, the spin–orbit interaction breaks this selection rule, for this interaction can mix the states with the different spin multiplicity. Therefore, an electronic state of a triplet state could have the character of a singlet state, and we could utilize this spin-mixed states to achieve the singlet–triplet transition in molecules.

Here, we have calculated the electronic state of Cl_2 molecule with MCSCF/6-31G method by GAMESS software package, taking into account the spin–orbit interaction. Using HF optimized geometry, we have calculated singlet and triplet states by configuration interaction (CI) method and singlet–triplet mixed states by spin–orbit configuration interaction (SOCI). From above calculations, we have evaluated the energy level of these states, the matrix elements of the spin–orbit coupling between singlet and triplet states, and the transition dipole moment between these states, which are shown in Tables 1 and 2, respectively. The energy level diagram is depicted in Fig. 1. We have found that the singlet excited states $\{|S_1\rangle, |S_2\rangle\}$ and $\{|S_3\rangle, |S_4\rangle\}$ are degenerate, respectively. The triplet states $\{|T_1\rangle, |T_2\rangle\}$ and $\{|T_3\rangle, |T_4\rangle\}$ are also degenerate. These degeneracies come from the symmetry of the x and y axis perpendicular to the molecular axis. We could similarly find out a lot of the degenerate state in the singlet–triplet mixed states.

3. STIRAP simulation

First let us briefly explain the STIRAP method in three-level system. The STIRAP method uses two laser pulses to achieve a complete population transition from

an initially populated state to a target state via an intermediate state. The first irradiated pulse called Stokes pulse makes a coherence between the intermediate and target states, then the second pump pulse corresponding to the transition between the initial and intermediate states induces the complete population transfer from the initial state to the target state without the population of the intermediate state. The overlap of the two pulses should be sufficiently large, and the pulse area is also sufficiently larger than the π pulse.

The interaction of the laser field and the molecular system is described by the time-dependent Schrödinger equation. Total Hamiltonian of the system is described $H = H_m + V(t)$, where H_m is the unperturbed molecular Hamiltonian and $V(t)$ means the interaction energy of electrons with the external electric field, and is explicitly described as $V(t) = -\boldsymbol{\mu} \cdot \mathbf{E}(t)$, where $\boldsymbol{\mu}$ and $\mathbf{E}(t)$ mean the electric dipole moment and the external electric field, respectively. In our simulation, the pulse shape of the electric field is assumed to be a gaussian shape. The wavefunction of the time-dependent Schrödinger equation is described as $|\Psi(t)\rangle = \sum C_n(t)|n\rangle$ by the superposition of the eigenfunction $|n\rangle$ of H_m. The expansion coefficient $C_n(t)$ is the probability amplitude of finding the eigenstate $|n\rangle$, and the corresponding probability density is given by $P_n(t) = |C_n(t)|^2$. The Schrödinger equation for the expansion coefficients becomes

$$i\hbar \frac{d\mathbf{C}(t)}{dt} = V(t)\mathbf{C}(t), \tag{3}$$

where $\mathbf{C}(t)$ means the set of the expansion coefficient, and $V(t)$ is the interaction operator of the electric field and the molecular system in the interaction picture. The matrix elements of the perturbation operator is given by

$$V_{mn}(t) = -\sum_n \langle m|\mu|n\rangle E(t) \exp\left(-\frac{i\omega_{mn}t}{\hbar}\right), \tag{4}$$

where $\langle m|\mu|n\rangle$ is the transition dipole moment between the states $|m\rangle$ and $|n\rangle$, ω_{mn} is the energy difference between two states $|m\rangle$ and $|n\rangle$.

In the simulation of the singlet–triplet transition, judging from the data of spin–orbit coupling and transition dipole moment, we can find out four reaction pathways from the singlet ground state to the triplet excited state. These four pathways are schematically shown in Fig. 2. In reaction pathways (a) and (b), we first adopt the π pulse to generate the singlet 1st excited state from the singlet ground state, and then we apply the STIRAP method to the achievement of the complete singlet–triplet transition, where the spin-mixed intermediate state is utilized. The difference of the cases (a) and (b) comes from the direction of the dipole moment, i.e., the x or y component of the dipole moment. On the other hand, reaction pathways (c) and (d) use only the STIRAP method to induce the transition from the singlet ground state to the triplet excited state. The difference between cases (c) and (d) is also due to the direction of the dipole moment.

Figs. 3(1) and (2) show the population dynamics of the reaction pathways (a) and (c), respectively. The reaction pathway (a) corresponds effectively to the transition $\{|S_0\rangle \rightarrow |T_1\rangle\}$, because the initial state $|1\rangle$ equals eventually to $|S_0\rangle$, and the main component of the target state $|4\rangle$ is $|T_1\rangle$. The π pulse ω_1 is resonant with the transition from state $|1\rangle$ to $|8\rangle$. The pump pulse ω_2 and the Stokes

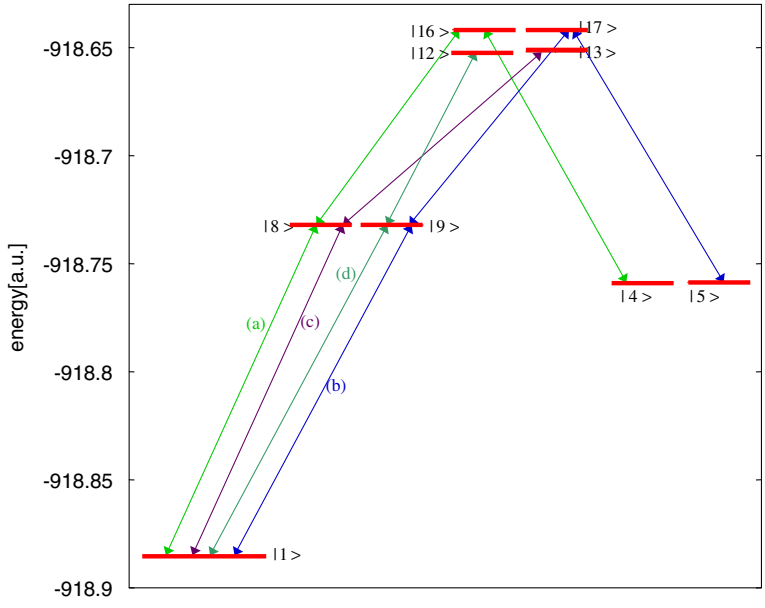

Fig. 2. Four reaction pathways. Cases (a) and (b) utilize the π pulse and STIRAP pulse sequence to generate the transition from the singlet ground state to the lowest triplet state. Cases (c) and (d) adopt only the STIRAP method to induce the transition to the 2nd highest triplet state.

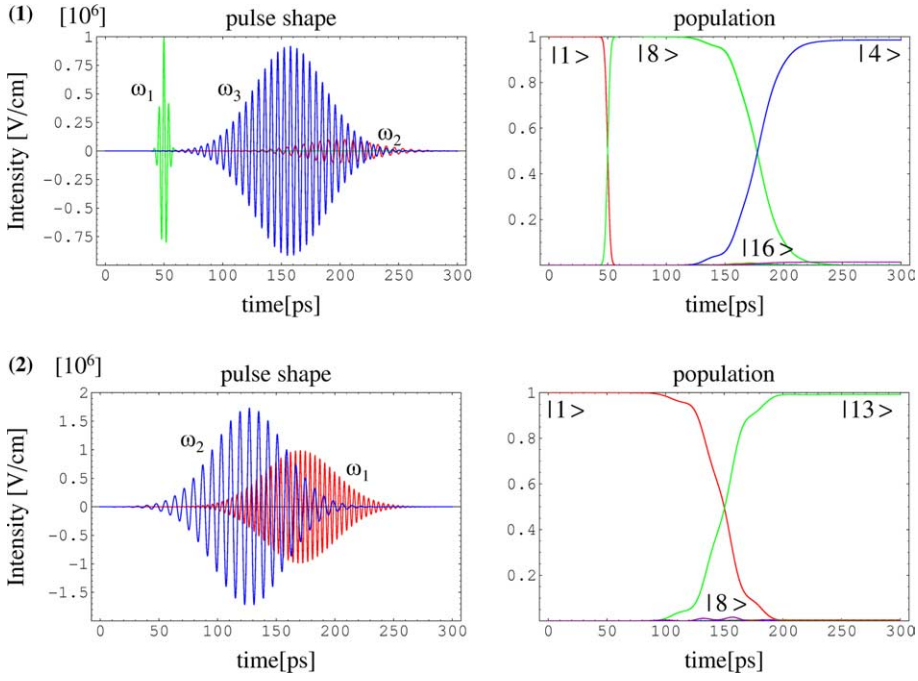

Fig. 3. Time evolution of the field intensity and population: (1) and (2) correspond to two reaction pathways (a) and (c), respectively.

pulse ω_3 are resonant with the transition from the state $|8\rangle$ to $|16\rangle$, and the transition from the state $|16\rangle$ to $|4\rangle$, respectively. The laser frequency, Rabi frequency, the field intensity, and the temporal center of the laser are shown in Table 3(1), respectively. The pulse width and the pulse area are set as $\sigma = 42.9$ ps and $A = 10\pi$, respectively. The numerical results of the STIRAP simulation shown in Fig. 3(1) show that the final product yield of the $|T_1\rangle$ is 98.5%, so we could realize the complete transfer from $|S_0\rangle$ to $|T_1\rangle$. Next, we consider the population dynamics for third reaction pathway (c) $\{|S_0\rangle \rightarrow |T_3\rangle\}$, where the target state $|12\rangle$ includes significantly the state $|T_3\rangle$. In this case, we could directly apply the STIRAP method to the population transition from the singlet ground state to the triplet excited state. The pump pulse ω_1 and the Stokes pulse ω_2 are resonant with the transition from the state $|1\rangle$ to $|9\rangle$, and the transition from the state $|9\rangle$ to $|12\rangle$, respectively. The laser

Table 3
Laser parameters of STIRAP simulation in (1) $\{|S_0\rangle \rightarrow |T_1\rangle\}$ (2) $\{|S_0\rangle \rightarrow |T_3\rangle\}$ pathway

	Frequency (cm^{-1})	Rabi frequency (a.u.)	Intensity (W/cm^2)	Temporal center (ps)
(1)				
π-Pulse (ω_1)	33566.5	1.0×10^{-5}	1.29175×10^{9}	50.0
Pump (ω_2)	19831.8	1.0×10^{-5}	1.3713×10^{7}	200.0
Stokes (ω_3)	25655.7	1.0×10^{-5}	1.11936×10^{9}	157.1
(2)				
Pump (ω_1)	33566.5	1.0×10^{-5}	1.29175×10^{9}	170.0
Stokes (ω_2)	17578.1	1.0×10^{-5}	3.98233×10^{9}	127.1

parameters and the result are also shown in Table 3(2) and Fig. 3(2), respectively. The values of the pulse width and area are the same as in the previous simulation. The final product yield of the $|T_3\rangle$ is 99.3% in this case. The results of the reaction pathway (b) $\{|S_0\rangle \rightarrow |T_2\rangle\}$ and (d) $\{|S_0\rangle \rightarrow |T_4\rangle\}$ are almost the same as the cases (a) and (c), respectively, so that we here omit these results.

4. Concluding remarks

We have performed the STIRAP simulation of the singlet–triplet transition in Cl_2 molecule by taking into account the spin–orbit coupling, and have found that the two-step sequential model of π pulse and the STIRAP methods using the spin-mixed intermediate state makes it possible to achieve a highly effective transition from the singlet ground state to the lowest triplet excited state.

We have calculated the spin-mixed excited state of Cl_2 molecule by using GAMESS software package, and have found four reaction pathways from the singlet ground state to the triplet excited state by investigating numerical data of the spin–orbit coupling and transition dipole moment. In cases (a) and (b), π pulse is first applied to generate the singlet 1st excited state, and then STIRAP method realizes the effective transition to the triplet lowest state. On the other hand, cases (c) and (d) show the transition from the singlet ground state to the triplet 2nd excited state only by the STIRAP method. In both cases, we could also induce the transition to the lowest triplet state by applying the π pulse method.

In this simulation, we have found that, in order to realize the transition from the singlet stable ground state to the lowest triplet state, we need to the π pulse in addition to the STIRAP pulse sequence. We had already made a STIRAP simulation of the four-level system with three laser pulses [16]. Thus, we could apply the four-level STIRAP method to this problem, and might obtain almost the same results as ones in this simulation.

In anyway, from the simplicity and the robustness of the STIRAP method with respect to the laser parameters, we could expect the more applications of this method to various molecular systems. The lowest triplet state has generally a long lifetime, so that such a molecular system with the STIRAP method could be a candidate of the molecular device in future.

*2.1.1. General synthetic method for $[M_2A(L)_2(NO_3)_2]\cdot n(sol)$ (**1**–**6**)*

To a methanolic solution (200 ml) of H_2L (124 mg, 0.5 mmol) and triethylamine (101 mg, 1.0 mmol) was added a mixture of $M(NO_3)_2\cdot mH_2O$ (M = Cu, Ni, Co; 0.5 mmol) and $A(NO_3)_2$ (A = Pb, Ba; 0.25 mmol) in hot methanol (200 ml) including a small amount of water, and the mixture was heated for several minutes. The resulting solution was allowed to stand for several days to give single crystals (**1′**–**6′**) which are suitable for X-ray structure analysis. They were collected by suction filtration and dried in vacuo to obtain compounds **1**–**6** which were used for physical measurements.

2.2. X-ray crystallography

Data were collected at −90 °C on a Rigaku/MSC Mercury CCD diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71070$ Å). The maximum 2θ value was 55.0°. A total of 1240 oscillation images were collected on five sweeps setting. Absorption correction was applied and the data were corrected for Lorentz and polarization effects.

Crystal data for $[Cu_2Pb(L)_2(NO_3)_2(MeOH)_2]$ (**1′**): $C_{28}H_{28}Cu_2N_4O_{16}Pb$, FW = 1010.84, green block, monoclinic, space group $P2_1/c$ (#14), $a = 11.128(2)$, $b = 14.443(1)$, $c = 11.411(2)$ Å, $\beta = 115.563(5)°$, $V = 1654.5$ $Å^3$, $Z = 2$, $D_c = 2.029$ g cm^{-3}, μ(Mo Kα) = 64.39 cm^{-1}, $R = 0.053$, $Rw = 0.102$.

Crystal data for $[Ni_2Pb(L)_2(NO_3)_2(MeOH)_2(H_2O)_2]$ (**2′**): $C_{30}H_{42}N_4Ni_2O_{20}Pb$, FW = 1103.28, green platelets, triclinic, space group $P\bar{1}$ (#2), $a = 9.825(2)$, $b = 10.222(2)$, $c = 11.811(2)$ Å, $\alpha = 74.33(1)°$, $\beta = 81.28(1)°$, $\gamma = 57.674(7)°$, $V = 965.1$ $Å^3$, $Z = 1$, $D_c = 1.898$ g m^{-3}, μ(Mo Kα) = 54.10 cm^{-1}, $R = 0.070$, $Rw = 0.095$.

Crystal data for $[Co_2Pb(L)_2(NO_3)(MeOH)_4](NO_3)\cdot MeOH$ (**3′**): $C_{31}H_{39}Co_2N_4O_{19}$ Pb, FW = 1096.73, orange platelets, triclinic, space group $P\bar{1}$ (#2), $a = 9.267(3)$, $b = 14.308(5)$, $c = 14.856(5)$ Å, $\alpha = 91.660(6)°$, $\beta = 90.306(5)°$, $\gamma = 94.612(5)°$, $V = 1962.5$ $Å^3$, $Z = 2$, $D_c = 1.856$ g cm^{-3}, μ(Mo Kα) = 52.05 cm^{-1}, $R = 0.075$, $Rw = 0.130$.

Crystal data for $[Cu_2Ba(L)_2(NO_3)_2(MeOH)_2]\cdot MeOH$ (**4′**): $C_{28}H_{30}BaCu_2N_4O_{16}$, FW = 942.98, green platelets, triclinic, space group $P1$ (#1), $a = 9.283(1)$, $b = 9.784(2)$, $c = 11.067(2)$ Å, $\alpha = 113.176(3)°$, $\beta = 92.615(3)°$, $\gamma = 115.443(3)°$, $V = 806.1$ $Å^3$, $Z = 1$, $D_c = 1.942$ g cm^{-3}, μ(Mo Kα) = 25.98 cm^{-1}, $R = 0.057$, $Rw = 0.106$.

Crystal data for $[Ni_2Ba(L)_2(NO_3)_2(MeOH)_2(H_2O)_3]\cdot MeOH$ (**5′**): $C_{29}H_{39}BaN_4Ni_2O_{20}$, FW = 1018.37, green prisms, triclinic, space group $P\bar{1}$ (#2), $a = 10.562(2)$, $b = 11.240(2)$, $c = 17.500(4)$ Å, $\alpha = 78.995(8)°$, $\beta = 74.975(7)°$, $\gamma = 70.573(7)°$, $V = 1879.0$ $Å^3$, $Z = 2$, $D_c = 1.799$ g cm^{-3}, μ(Mo Kα) = 21.14 cm^{-1}, $R = 0.087$, $Rw = 0.205$.

Crystal data for $[Co_2Ba(L)_2(NO_3)_2(MeOH)_2(H_2O)_2]\cdot MeOH$ (**6′**): $C_{29}H_{32}BaCo_2N_4O_{19}$, F. W. = 995.78, orange blocks, triclinic, space group $P\bar{1}$ (#2), $a = 9.97(5)$, $b = 14.141(8)$, $c = 14.113(7)$ Å, $\alpha = 79.25(2)°$, $\beta = 74.21(1)°$, $\gamma = 85.08(2)°$, $V = 1884.8$ $Å^3$, $Z = 2$, $D_c = 1.754$ g cm^{-3}, μ(Mo Kα) = 19.76 cm^{-1}, $R = 0.121$, $Rw = 0.246$.

3. Results and discussion

3.1. Crystal structures

X-ray crystallography for **1′**–**6′** reveals that two ligands and two M(II) ions form a 16-membered metallaazacrown-like structure and one A(II) ion is located in the cavity. An ORTEP drawing for **2′** with atom numbering scheme is shown in Fig. 1.

The structure of **2′** contains a planer $Ni_2Pb(L)_2$. The asymmetric unit consists of the half of $[Ni_2Pb(L)_2(NO_3)_2(MeOH)_2(H_2O)_2]$, and Pb ion locates on an inversion center. Two Ni atoms in the 1,3-diketone sites have an octahedral geometry together with water and methanol molecules. The Pb atom in the 2,6-diacylpyridine site has a 10-coordinate geometry together with oxygen atoms of nitrate ions. The intrametallic Ni···Ni* and Ni···Pb separations are 7.452 and 3.726 Å, respectively. The Ni–O2–Pb and Ni–O3–Pb angles are 104.97° and 106.22°, respectively. The O_4 plane and the N_2O_4 plane form a dihedral angle of 3.51°. Each Ni deviates from the least-squares plane of O_4 by 0.014 Å whereas the Pb locates on the least-square plane of N_2O_4.

Side views of ORTEP drawings for **1′**–**6′** are shown in Fig. 2. In all the M(II)Pb(II)M(II) complexes (**1′**–**3′**) the trinuclear core forms a near coplane. Average M–O, A–O and A–N distances and deviation of A atom from the central N_2O_4 plane for **1′**–**6′** are listed in Table 1. The Pb of **1′** and **2′** shows no displacement from the least-squares plane defined by two 2,6-diacylpyridine moieties whereas the Pb of **3′** is 0.281 Å displaced for the least-squares plane. The side views of the M(II)-Ba(II)M(II) complexes (**4′**–**6′**) clearly indicate non-planar trinuclear core, effected by a large displacement of Ba (0.592–0.81 Å) from the least-squares plane. Obviously Pb(II) with a moderate ionic radius (1.32 Å) can reside within the central cavity formed by two 2,6-diacylpyridine moieties whereas Ba(II) with a large ionic radius (1.50 Å) cannot reside within the cavity. It is also found that Co(II)A(II)Co(II) complexes (**3′** and **6′**) assume a dimeric structure bridged by nitrate ions. It appears that Co(II) with ionic radius (0.88 Å) larger than the ionic radii of Ni(II) (0.84 Å) allows the dimerization of the trinuclear units in **3′** and **6′**. Such dimerization must be difficult in the Cu(II)A(II)Cu(II) complexes because of the Jahn-Teller of Cu(II) ion.

3.2. Magnetic property

Magnetic susceptibilities for **1**–**6** were measured in the temperature range of 2–300 K under an applied field of 500 G. The $\chi_M T$ versus T plots for **1**–**3** and **4**–**6** are given in Figs. 3 and 4, respectively. The results suggest

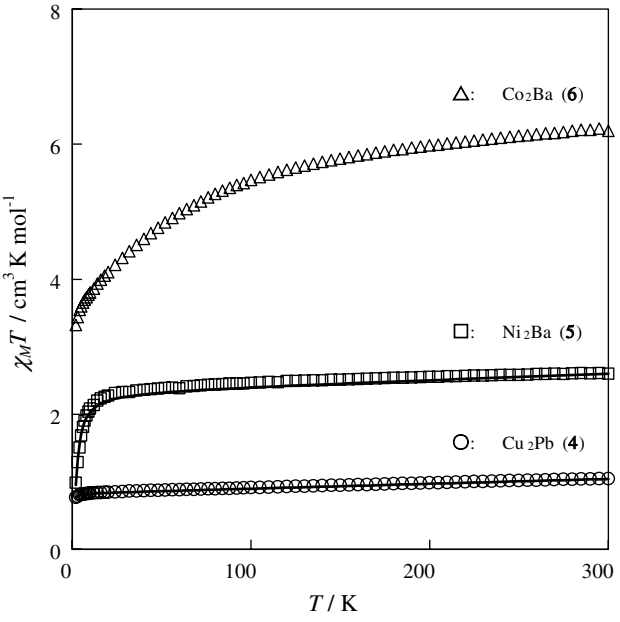

Fig. 4. Plots of $\chi_M T$ vs. T for **4** (○), **5** (□) and **6** (△). The solid lines show best-fitting of the data as described in the text.

that a weak antiferromagnetic interaction operates between the terminal M(II) ions in all the compounds. In the case of **1** and **4**, magnetic analyses were made based on the Bleaney–Bowers equation to obtain the best-fit parameters of $J = -0.98\ \mathrm{cm}^{-1}$ and $g = 2.09$ for **1** and $J = -0.19\ \mathrm{cm}^{-1}$ and $g = 2.10$ for **4**. Similarly, magnetic analyses for **2** and **5** were carried out based on the isotropic Heisenberg model to obtain the best-fit parameters of $J = -0.72\ \mathrm{cm}^{-1}$ and $g = 2.18$ for **2** and $J = -0.67\ \mathrm{cm}^{-1}$ and $g = 2.16$ for **5**. On the other hand, the magnetic behavior of **3** and **6** could not be reproduced by the isotropic Heisenberg model probably because of an orbital contribution of high-spin Co(II) ion. A similar antiferromagnetic interaction has also been observed between the terminal M(II) ions of the M(II)–Ln(III)–M(II) analogous with a diamagnetic Ln ion [13,14].

4. Conclusion

A series of trinuclear compounds, $[M_2A(L)_2(NO_3)_2]\cdot n(\mathrm{sol})$, have been synthesized using 2,6-bis(acetoacetyl)pyridine (H_2L) and their structures and magnetic properties have been characterized. The trinuclear structure comprises a metallaazacrown-like structure derived by two M(II) ions and two L^{2-} ligands with a large Pb(II) or Ba(II) cation in the central cavity. All the compounds show a weak antiferromagnetic interaction between the terminal M(II) ions through Pb(II) or Ba(II) ion.

Together with the previous results of the Cu_2Ln complexes [13,14], the M_2L_2 metallaazacrown accommodate divalent and trivalent metal ions with a wide range of ionic radius from Lu(III) (1.17 Å) to Ba(II) (1.50 Å), affording linear M(II)A(II)M(II) complexes of different combinations of metal ions.

5. Supplementary material

Crystallographic data for **1′**–**6′** has been deposited at the Cambridge Crystallographic Data Centre as the publication citation and deposition numbers CCDC 251924–251929 (**1′**–**6′**). Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, fax: (+44)1223 336 033, e-mail: deposit@ccdc.cam.ac.uk or on the web http://www.ccdc.cam.ac.uk.

the three pairs in the hexagon have strong AF interaction of $J \sim -800$ K, the magnetic properties of the V15 cluster at low temperature are determined only by the three V^{4+} spins on the triangle. The energy scheme at low temperature is given by the ground state of $S = 1/2$ and the excited state of $S = 3/2$ which lies ~3.8 K above [10]. By the application of an external magnetic field, the ground state can be changed from two $S = 1/2$ doubly degenerate states to a $S = 3/2$ state. Magnetization measurements at low temperature clearly exhibit below ~0.5 K the magnetization step at a critical field $H_c \sim 2.8$ T where the two $S = 1/2$ doubly degenerate ground state changes to $S = 3/2$ ground state [11].

In this paper, we have carried out proton nuclear magnetic resonance (NMR) measurements at low temperature in order to shed light from a microscopic point of view on the static and dynamical properties of the V^{4+} spins ($S = 1/2$) on the triangle with the different ground states. In addition, we pay our attention to magnetic properties at the level crossing field $H_c \sim 2.8$ T. In Section 2, we present the experimental results of ^{1}H-NMR spectrum, proton spin–lattice relaxation and spin–spin relaxation rates. In Section 3.1, hyperfine fields at the proton sites are derived. The dynamical properties of the V^{4+} spins are discussed based on an analysis of the relaxation data in Section 3.2. In Section 3.3, we analyze relaxation data to elucidate magnetic properties at the level crossing field in the V15 cluster. Finally, we give a summary of the paper in Section 4.

2. Experimental

Polycrystalline samples of $(K_6[V_{15}As_6O_{42}(H_2O)]8\text{-}H_2O)$ were prepared as described in [12]. The temperature dependence of magnetic susceptibility measured in the samples agrees with the one reported previously [6,8]. The ^{1}H-NMR measurements were carried out utilizing a phase-coherent spin echo pulse spectrometer in the magnetic field range 0.24–8.2 T above 1.5 K. The ^{1}H-NMR spectra were obtained by sweeping the external magnetic field at constant frequency, while the spin echo intensity was averaged using a boxcar integrator. The nuclear spin–lattice relaxation time T_1 was measured by the saturation method with the frequency tuned at the highest peak position in ^{1}H-NMR spectrum. The nuclear magnetization recovery was found to be nonexponential in most measurements, which is due to the existence of protons with inequivalent spatial locations. Such a non exponential behavior in ^{1}H-NMR in the V15 was already reported by Procissi et al. [13]. T_1 values were determined from the initial slope of the recovery behavior, which corresponds to a weighted average relaxation rate of the nonequivalent protons [14]. The nuclear spin–spin relaxation time T_2 was determined by spin–echo decay curve.

2.1. ^{1}H-NMR Spectra

Fig. 1 shows several ^{1}H-NMR spectra at different frequencies measured at $T = 1.5$ K. The observed ^{1}H-NMR spectrum is narrow and its full-width of half amplitude (FWHA) is about 30 Oe below ~2 T and slightly increases with increasing external magnetic field. The FWHA and its magnetic field dependence up to ~5 T at $T = 1.5$ K are in agreement with the result reported previously [13]. However, when the magnetic field is increased above 5 T, the spectrum changes drastically from a single line to a structured spectrum where several peaks can be identified as shown in Fig. 1. Clearly at least 4 peaks (P1–P4) are apparent in the spectrum at high magnetic field (i.e., above ~6 T). The inset shows the H_0 dependence (i.e., resonance frequency dependence) at 1.5 K of $\Delta H = H_0 - H_i$, where H_i is the magnetic field at each peak (P_i). The fact that the absolute shift for each peak is almost field independent above ~6 T indicates that the shift arises from a spontaneous static internal field at the proton sites from a frozen V^{4+} spins configuration on the triangle. The internal field at each proton site is estimated to be 140, ~0, −108 and 335 Oe for P1, P2, P3 and P4, respectively.

2.2. Proton spin–lattice relaxation time T_1 and spin–spin relaxation time T_2

Fig. 2 shows the temperature dependence of $1/T_1$ measured at various external magnetic fields. At low magnetic field (i.e., below ~0.5 T), $1/T_1$ does not depend

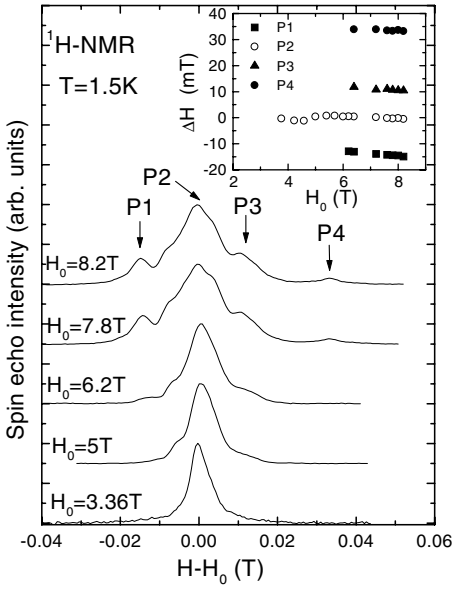

Fig. 1. ^{1}H-NMR spectra in the V15 powder sample at $T = 1.5$ K with different resonance frequencies. The horizontal axis for each spectrum is shifted by the corresponding Lamor field H_0. The inset shows the H_0 dependence of $\Delta H = H_0 - H_i$, where H_i is the magnetic field at each peak (P_i).

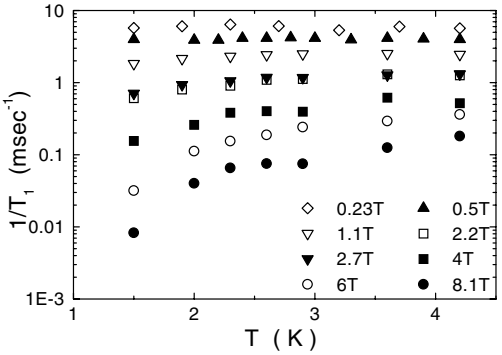

Fig. 2. Temperature dependence of ^1H–$1/T_1$ at different fields.

on temperature. On the other hand, for magnetic fields above 1 T, $1/T_1$ decreases with decreasing temperature at a rate which increases with increasing magnetic field. The external magnetic field dependence of $1/T_1$ at $T = 1.5$ and 4.2 K is plotted in Fig. 3. With increasing magnetic field, $1/T_1$ decreases gradually and shows a peak around $H = 2.7$ T for both temperatures as shown in the figure. A similar behavior was reported by Yoneda et al. [14] in a region of $H = 0.34$–3.3 T. The small but clear peak in $1/T_1$ is observed around $H \sim 2.7$ T which is very close to the reported critical magnetic field $H_c \sim 2.8$ T where the ground state changes from $S = 1/2$ to 3/2. Thus we consider that the enhancements of $1/T_1$ around 2.7 T is due to the level crossing between $S = 1/2$ and 3/2 states.

Fig. 4 shows the magnetic field dependence of $1/T_2$ at $T = 1.5$ and 4.2 K. With increasing magnetic field, $1/T_2$ increases and shows a dip around the level crossing critical field of 2.7 T for both temperatures. Interestingly, $1/T_2$ at $T = 1.5$ K exhibits a broad peak around 6 T, which is contrast to the monotonic decrease of $1/T_1$ with increasing magnetic field as shown in Fig. 3.

In Fig. 5 we report the temperature dependence of $1/T_2$ at several magnetic fields. The behavior of $1/T_2$ changes from being almost T-independent below 1 T

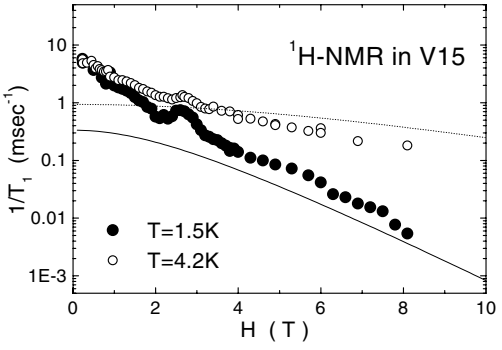

Fig. 3. The external magnetic field dependence of ^1H–$1/T_1$ measured at $T = 1.5$ and $T = 4.2$ K. The solid and broken lines are the calculated curves for $T = 1.5$ and 4.2 K, respectively, with a set of parameters discussed in the text.

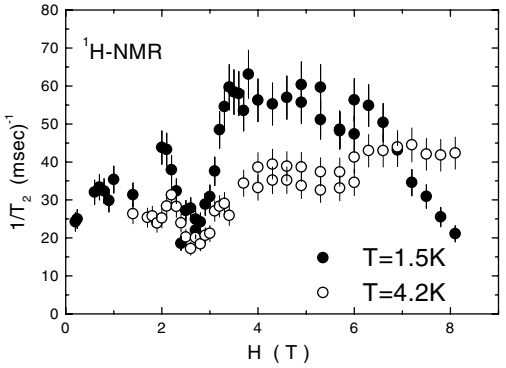

Fig. 4. Magnetic field dependence of ^1H–$1/T_2$. •, $T = 1.5$ K; ○, $T = 4.2$ K.

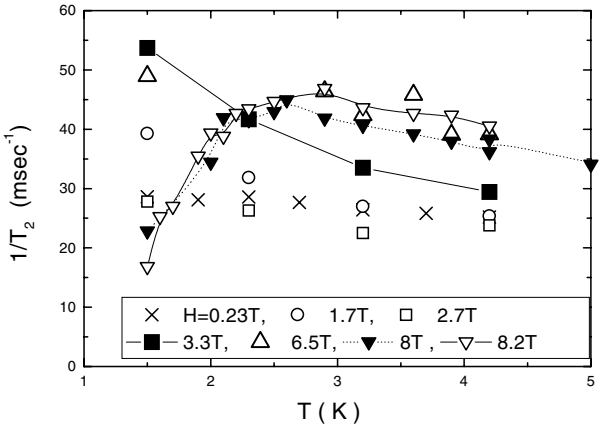

Fig. 5. Temperature dependence of $1/T_2$ at different fields. The solid and dotted lines are guides to the eye.

to an increase by lowering temperature in the field range $H = 1$–6 T. and a behavior with a broad maximum at 2.6 K for a field of 8 T. This is in sharp contrast to the temperature dependence of $1/T_1$ at the same magnetic field region. It is noted that $1/T_2$ around $H \sim 2.7$ T is almost temperature independent, which is considered to be originated from the level crossing between $S = 1/2$ and 3/2 states.

3. Discussion

3.1. Hyperfine fields at proton sites and spin freezing

As shown in Fig. 1, we have observed static internal fields at proton sites at low temperature. In general, there are two possibilities for the origin of the hyperfine field at proton sites, that is, dipolar fields and contact hyperfine fields from the V^{4+} spins. In the case of powder sample, the dipolar fields yield a broadening (and/or shoulder) of the line but no net shift, while the net shift of the line can be produced by the contact hyperfine fields due to the overlap of the s electron wave function

at the proton site with the d electron (V^{4+}) wave function. In the V15 cluster ($K_6[V_{15}As_6O_{42}(H_2O)]8H_2O$), two classes of protons can be mainly classified, that is, eight solvent waters between the clusters and one H_2O molecule inside the core of the cluster. Thus the almost unshifted line (P2) originates from the protons which are coupled to V^{4+} spins with dipolar interaction only, corresponding to the protons in the solvent water between the clusters. On the other hand, the shifted lines (P1, P3 and P4) can be ascribed to the protons in the H_2O molecule inside the core coupled by isotropic hyperfine interaction to the V^{4+} spins. Our experimental results suggest that there are several (at least 3) protons with different contact hyperfine fields, although there is only one H_2O molecule inside the core of the cluster. This implies that the H_2O molecule is located in more than one stable position.

The observation of static hyperfine fields at nuclear sites depends on the fluctuating frequency of the magnetization (spins). Whenever the fluctuating frequency of the magnetization is much smaller than the NMR frequency ($\sim 10^{7-8}$ Hz), one can observe static hyperfine fields at nucleus sites, while the hyperfine fields are time averaged to zero when the fluctuating frequency is higher than NMR frequency. The observation of the static internal fields at proton sites clearly indicates that fluctuating frequency of the V^{4+} spins on the triangle is less than NMR frequency at low temperature, which provides the direct evidence of the spin freezing in the system by the application of the external magnetic field.

Such spin freezing at low temperature is observed in other large spin magnetic molecules like Mn12-ac and Fe8 which have relatively large energy barriers ($\sim$60 K for Mn12 and $\sim$25 K for Fe8) for the reorientation of the spins. On the contrary, the V15 cluster has no energy barrier for the spin rotation. As was pointed out previously in our papers [15–17], fluctuating frequency of the spins is determined by not the energy barrier but transition probability between the ground state and first excited magnetic sublevel. Our experimental results suggest the transition probability between ground state and first excited states is small in the V15 cluster at low temperature under high magnetic field. As will be discussed in next section, such small transition probabilities at high magnetic field are originated from the spin–phonon interaction alone, which is characteristic of isolated magnetic clusters whose intermolecular interaction such as dipolar interactions are negligibly small.

3.2. Very slow fluctuations of V^{4+} spins and spin–phonon interaction

Let us discuss spin dynamics of V^{4+} spins on the triangle based on an analysis of the $1/T_1$ and $1/T_2$ data. The relaxation rates are related to the electron spin–spin correlation function. With an assumption of a simple exponential form of the correlation function $\langle h_\perp(t)h_\perp(0)\rangle = \langle h_\perp^2\rangle \exp(-t/\tau_c)$, where τ_c is correlation time of the fluctuating hyperfine field at proton sites and $\langle h_\perp^2\rangle$ is the average square of the transverse components of the effective hyperfine field due to the interaction of the protons with the local moments of the V^{4+} ions, the nuclear spin–lattice relaxation rate is given as $1/T_1 = \gamma_N^2\langle h_\perp^2\rangle\tau_c/(1+(\omega_N\tau_c)^2)$ [18,19]. Here ω_N is proton Lamor frequency and γ_N is the nuclear gyromagnetic ratio.

Regarding the nuclear spin–spin relaxation rate $1/T_2$, two main contributions to $1/T_2$ are generally present. The first is temperature and magnetic field independent and is due to nuclear dipole–dipole interaction among the ^{1}H nuclei ($(1/T_2)_{dip}$) [18,19]. The second is a temperature (and H) dependent contribution which relates to the correlation time τ_c. With an assumption of weak collision [18,19], the contribution can be expressed as $1/T_2 = \gamma_N^2\langle h_z^2\rangle\tau_c$ when $\gamma_N h_z\tau_c$ is smaller than unity. Here h_z is the z-component of the effective hyperfine fields at proton sites fluctuating very slowly of the order of $\gamma_N h_z$. On the other hand, as discussed below, when $\gamma_N h_z\tau_c > 1$ corresponding to a situation for strong collision, $1/T_2$ can be expected to be proportional to $1/\tau_c$. In any case, the experimentally observed $1/T_2$ originates mainly from the second contribution as can be inferred from the fact that it is T and H dependent and that the first contribution $(1/T_2)_{dip}$ can be estimated to be less than 1 $(ms)^{-1}$ [20].

In the case of $\omega_N\tau_c \ll 1$ (fast motion limit), both $1/T_1$ and $1/T_2$ is proportional to τ_c. Then $1/T_1$ and $1/T_2$ should have the same temperature dependence. On the other hand, if $\omega_N\tau_c \gg 1$ (slow motion limit) and $\gamma_N h_z\tau_c < 1$, $1/T_1 \sim 1/\tau_c$ has an inverse behavior in comparison with $1/T_2$. As shown before, in a region of H = 1–6 T, $1/T_1$ and $1/T_2$ show the opposite temperature and magnetic field dependences. Thus our experimental results can be explained simply by assuming that the correlation time of the hyperfine field fluctuations becomes slower than the Lamor period although remaining faster than the precession time along the local field, i.e., $\omega_N\tau_c > 1$ and $\gamma_N h_z\tau_c < 1$. The increases of $1/T_2$ and decreases of $1/T_1$ with increasing magnetic field and decreasing temperature are reasonably understood as due to an increase of τ_c, which corresponds to slowing of the fluctuations of the V^{4+} spins.

In order to analyze the $1/T_1$ data more quantitatively, we adopt a model in terms of spin–phonon interaction, which seems to explain both the T and H dependences of $1/T_1$ in Mn12 [16,17,21] and Fe8 [15]. In this model, it is assumed that thermal fluctuations of the magnetization among the different quantum number m sublevels of the total spin S state due to spin–phonon interaction give rise to the transverse components of the time-dependent hyperfine field $h_\perp(t)$ at the nuclear sites via the hyperfine interaction between the nuclei and local

electronic spins. In this case, $(1/T_1)_{\text{s–ph}}$ originated from the spin–phonon interaction is given by

$$(1/T_1)_{\text{s–ph}} = \frac{1}{2}\gamma_N^2 \int \langle h_\perp(t)h_\perp(0)\rangle \exp(i\omega_N t)\, dt = \frac{A}{Z}\sum_m \frac{\tau_m \exp\left(-\frac{E_m}{k_B T}\right)}{1+\omega_N^2\tau_m^2}, \quad (1)$$

where τ_m is the life time broadening of the magnetic mth sublevels originating from the spin–phonon interactions. Z is the partition function and A is a parameter related to the hyperfine coupling constants. The life-time τ_m for each individual m state is determined by $1/\tau_m = P_{m\to m+1} + P_{m\to m-1}$. The transition probabilities due to the spin phonon interactions [22] can be expressed by $P_{m\to m+1} = C\Delta^3/\{\exp(\Delta/k_BT)-1\}$ and $P_{m\to m-1} = C\Delta^3/\{1-\exp(-\Delta/k_BT)\}$ and C is the spin–phonon coupling constant and Δ is energy difference between m and $m \pm 1$ sublevels. In the case of the V15 cluster, there are two total spin states, that is, $S = 1/2$ and 3/2 so that $1/T_1$ can be expressed by sum of the two contributions due to the two $S = 1/2$ and 3/2 states as

$$(1/T_1)_{\text{s–ph}} = (B_{1/2}(1/T_1)_{\text{s–ph}}^{S=1/2} + B_{3/2}(1/T_1)_{\text{s–ph}}^{S=3/2})/Z = \frac{B_{1/2}A}{Z}\sum_{m=-1/2}^{1/2}\frac{\tau_m \exp(-E_m/k_BT)}{1+(\omega_N\tau_m)^2} + \frac{B_{3/2}A}{Z}\sum_{m=-3/2}^{3/2}\frac{\tau_m \exp(-E_m/k_BT)}{1+(\omega_N\tau_m)^2}, \quad (2)$$

where $B_{1/2}$ and $B_{3/2}$ is the Boltzmann factor for the two states of $S = 1/2$ and 3/2, respectively, including the two fold degeneracy for the $S = 1/2$ states. The solid and broken lines in Fig. 3 show the calculated results for $T = 1.5$ and 4.2 K, respectively, with a set of parameters of $C = 2.4\times10^4$ (Hz/K^3) and $A = 4.0\times10^{14}$ (rad/s)^2, which reasonably reproduce both H and T-dependences of $1/T_1$ above the level crossing field $H_c \sim 2.7$ T. This indicates that spin dynamics in the system at low temperature is governed by the spin–phonon interaction above H_c where the ground state of the cluster is $S = 3/2$. On the other hand, the "spin–phonon interaction" model can not reproduce the experimental results below H_c, especially below 1 T, where the ground state is formed by two $S = 1/2$ doubly degenerate states. In this low field region the spin dynamics of the V15 cluster must be governed by a mechanism different than the spin–phonon interaction.

Next we consider the observation of a broad peak in the field dependence of $1/T_2$ around 5 T at $T = 1.5$ K (see Fig. 4). It is known that $1/T_2$ estimated by spin–echo decay curve exhibits a peak ($1/T_2 \sim \gamma_N h_z$) when $\gamma_N h_z \tau_c \sim 1$ in the slow motion limit [23,24]. This corresponds to a cross over between weak collision regime ($\gamma_N h_z \tau_c \ll 1$) and strong collision regime ($\gamma_N h_z \tau_c \gg 1$). It is obvious that τ_c above ~6 T is much longer than the reciprocal of NMR frequency because of the observation of the static internal fields at proton sites as shown in the ^{1}H-NMR spectrum. In addition, the $1/T_1$ at $T = 1.5$ K decreases monotonically with increasing magnetic field across 6 T. These results indicate the gradual shortening of $1/\tau_c$ with increasing the magnetic field. Thus the peak of $1/T_2$ around 6 T at 1.5 K can be attributed to the cross over from weak collision to strong collision regime with increasing the magnetic field. This indicates that $\gamma_N h_z \tau_c$ becomes unity around 6 T where $1/\tau_c$ ($=\gamma_N h_z/2\pi$) is estimated to be $\sim 60\times10^3$ (s^{-1}). The value of $1/\tau_c$ is in good agreement with $1/\tau \sim 60\times10^3$ (1/s) for the ground state magnetic level ($m = -3/2$) in the $S = 3/2$ states at $H = 6$ T using the relation of $1/\tau = C\Delta^3/\{\exp(\Delta/k_BT)-1\}$ with the same value of C used in the analysis of $1/T_1$ data. If the correlation time at $T = 1.5$ K becomes longer by the application of the magnetic field, one can expect that with increasing temperature τ_c becomes shorter and $\gamma_N h_z \tau_c$ approaches unity thus generating a peak of $1/T_2$ as a function of temperature for high magnetic fields. This is indeed observed around 2.6 K at $H = 8$ T as shown in Fig. 5. Therefore the peak of $1/T_2$ as a function of the magnetic field is a direct evidence of the very gradual slowing down of V^{4+} spin fluctuations following the application of the magnetic field.

It should be noted that the above expression of $1/T_2$ is valid only for weak collision regime so that it can not be used for $H > 6$ T at low temperature where the strong collision regime is realized. To clarify the situation, we estimate tentatively the H-dependence of τ_c at $T = 1.5$ K from the $1/T_1$ and $1/T_2$ data, assuming $1/T_1 \sim 1/\omega_N^2\tau_{T_1}$ and $1/T_2 \sim \tau_{T_2}$, respectively. Fig. 6 shows the estimated H-dependences of both $1/\tau_{T_1}$ and $1/\tau_{T_2}$ which are normalized to the value obtained at $H = 2.7$ T for

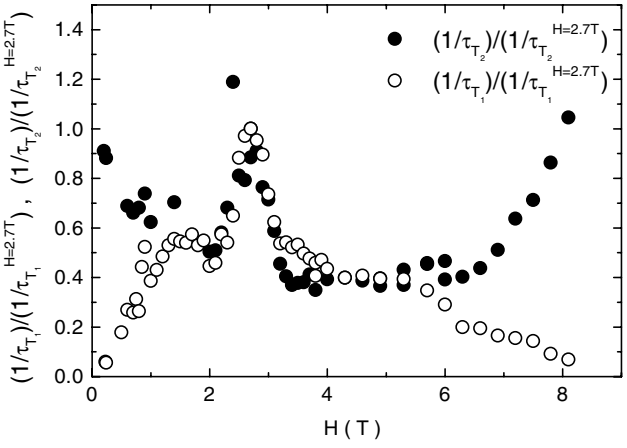

Fig. 6. External magnetic field dependence of $1/\tau_{T_1}$ and $1/\tau_{T_2}$ at $T = 1.5$ K from a relation of $1/T_1 \sim 1/\omega_L^2\tau_{T_1}$ and $1/T_2 \sim \tau_{T_2}$, respectively. Note each value is normalized by a value obtained at $H = 2.7$ T.

each. The two set of data coincide rather well in the field range $H = 1$–6 T, while for at $H > 6$ T one finds the opposite H-dependence for the two quantities. These results are consistent with the assumption that the relation $1/T_2 \sim \tau$ breaks down for $H > 6$ T. As pointed out by Goto et al. [25] for the analysis of $1/T_2$ in Mn12, $1/T_2$ is proportional to $1/\tau_c$ in the strong collision regime. In fact, $1/T_1$ and $1/T_2$ data above $H > 6$ T can be explained qualitatively by their idea. This confirms again the cross-over from the weak collision and strong collision regime around $H = 6$ T as a function of H at $T = 1.5$ K.

It is noted that $1/\tau_{T_1}$ has a different H-dependence from that of $1/\tau_{T_2}$ at low field below ~1 T. In order to check whether the difference originates from our assumption of $1/T_1 \sim 1/\omega_N^2\tau_{T_1}$, we estimated H-dependence of τ_{T_1} using a relation of $1/T_1 \sim \tau_{T_1}/(1+\omega_N^2\tau_{T_1}^2)$ without taking any assumption of the slow motion or the fast motion limit. However, we could not find any reasonable H-dependence of τ_{T_1} to resolve the crucial difference of the H-dependence between the $1/\tau_{T_1}$ and $1/\tau_{T_2}$. This suggests that our simple formula for $1/T_1$ (Eq. (2)) is not applicable for the low magnetic field below $H \sim 1$ T. As shown in Fig. 3, both H- and T-dependences of $1/T_1$ below H_c, especially below 1 T, can not be explained at all by the model in terms of the spin–phonon interaction. This implies the presence of an additional contribution to $1/T_1$, becoming dominant with decreasing magnetic field. It is interesting to point out that both $1/T_1$ and $1/T_2$ are almost independent of temperature at low magnetic field, as shown in Figs. 2 and 4. Similar temperature independent $1/T_1$ at $H = 0.34$ T was reported by Yoneda et al. [14] and they have pointed out a predominance of relaxation process due to level crossings at $H \sim 0$. Alternative possibility is due to quantum effects which originate from $S = 1/2$ triangular lattice of three V^{4+} ions. According to Kawamura [26], the ground state of triangular spins has twofold degenerate according to the two chiralities (different spin configurations) due to the frustration effects. In this sense, two $S = 1/2$ doubly degenerate states might be considered as the two chiralities in the V15 cluster. Since the fluctuations between two chiral states with different spin structures would give rise to a local field fluctuation at proton sites, this could be a relaxation mechanism. In contrast, such a fluctuation would not influence the magnetization measurements because both chiral states have the same $S = 1/2$ states macroscopically. It would be very interesting if the T-independent $1/T_1$ were due indeed to the quantum fluctuation, although we can not establish this for sure from the present data. Further experiments at low temperature below 1 K using a dilution refrigerator will give us information to elucidate the origin of peculiar behavior of $1/T_1$ at low magnetic field. Such measurements are now in progress.

3.3. Level crossing between $S = 1/2$ and $S = 3/2$ at $H_c \sim 2.7$ T

Following our consideration described above, the observations of a peak in $1/T_1$ and a dip in $1/T_2$ as a function of the magnetic field around the level crossing field $H_c \sim 2.7$ T are understood naturally by the idea of slow motion limit. This indicates clearly that the fluctuating frequency of V^{4+} spins in the triangle is less than the NMR frequency at the level crossing field around $H_c \sim 2.7$ T.

The enhancement of $1/T_1$ due to level crossings were reported in other magnetic molecules such as antiferromagnetic rings Fe10 [27,28] and Fe6(Li) [27,29]. In both cases, $1/T_1$ shows a peak at level crossing field as a function of the magnetic field at constant temperature. The H-dependence of $1/T_1$ around crossing fields are well fitted by a phenomenological model [29] in which $1/T_1$ is expressed by $1/T_1 = A\Gamma/(\Gamma^2 + (\omega_L - \Delta(H))^2)$. A is the same parameter as in Eq. (1) which relates to the hyperfine coupling constants, Γ is a temperature dependent damping factor associated with level broadening and $\Delta(H)$ is magnetic field dependent energy difference between the ground and first exited states. Near the level crossing field $\Delta(H)$ can be expressed by $\Delta(H) = \{g\mu_B(H_c - H)^2 + \Delta^2\}^{1/2}$, where Δ is an energy gap at level crossing field. It is noted that Γ affects only the magnitude of $1/T_1$ when Γ is small, while the width of $1/T_1$ peak is determined by the gap Δ.

Using the same expression, we analyze the $1/T_1$ in the V15 cluster at level crossing field. Before doing the fitting, we subtract first from the experimental data the spin–phonon contribution $(1/T_1)_{s-ph}$. The magnetic field dependence of $1/T(_1)_{LC} = (1/T_1) - 1/T(_1)_{s-ph}$ at $T = 1.5$ K is shown in Fig. 7. The FWHA of the $(1/T_1)_{LC}$ peak is ~0.6 T at $T = 1.5$ K. There are several possible origins for the width of the $1/T_1$ peak in our

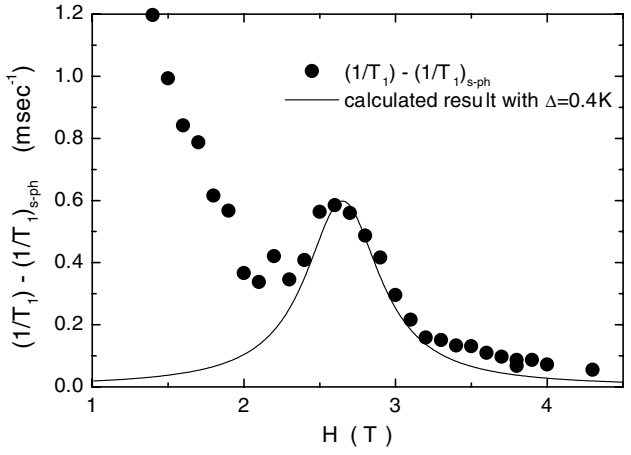

Fig. 7. External field dependence of $(1/T_1)_{LC} = (1/T_1) - (1/T_1)_{s-ph}$. The solid is a calculated curve with $\Delta = 0.4$ K with a set of parameters described in the text.

powder sample. The anisotropy of the electronic g-factor ($g_\perp = 1.953$, $g_\parallel = 1.981$) [30] produces a distribution of the level crossing field in the powder sample. This effect, however, is estimated to be about 0.07 T which is too small to explain the width. The intercluster dipolar and/or hyperfine field distributions (about 0.001 and 0.04 T, respectively [11]) can not account for the FWHA. In addition, the contribution of the thermal broadening to the width should be small because the FWHA at $T = 4.2$ K is a little bit smaller than that at $T = 1.5$ as shown in Fig. 3. On the other hand, the width can be simply explained if we assume the existence of the gap (Δ). The solid line in the figure is best fit to the data with a set of parameters: $\Gamma = 6.3 \times 10^8$ (1/s), $\Delta = 0.40$ K and $H_c = 2.65$ T using the same coupling constant of $A = 4.0 \times 10^{14}$ (rad/s)^2 as in the previous section. The width of $1/T_1$ peak suggests the existence of a gap at the level crossing field, namely of a level anticrossing in the V15 cluster. It should be emphasized that the measurements of $1/T_1$ around the level crossing field will be very useful to elucidate the structure of the magnetic level at H_c.

A gap at the level crossing field requires an interaction which mixes the $S = 1/2$ and $S = 3/2$ states. One possible interaction to be considered is the Dzyaloshinski–Moriya (DM) interaction. The DM interaction is allowed by a symmetry in the V15 cluster [31]. The width of the magnetization step at the level crossing field ~2.8 T measured at $T = 0.1$ K in a single crystal was reported to be ~0.7 T, which was explained by taking the DM interaction into considerations [11]. Recent theoretical calculations using the degenerate perturbation theory also reproduced the width of the magnetization step by including the DM interaction [32]. Thus we consider that the DM interaction play an important role to produce the level anticrossing in the V15 cluster.

Since the measurements were performed in a powder sample the level crossing field is expected to have a distribution of values due to the distributions of the angle between the magnetic field and DM vector axis in the powder sample. The magnitude of the gap $\Delta = 0.4$ K estimated here must be regarded just as a order of the magnitude. In order to make a more quantitative discussion of the structure of the magnetic level at H_c in the V15 cluster, detailed measurements on a single crystal are needed.

4. Summary

We have investigated the spin dynamics in the V15 cluster at low temperature by proton NMR measurements. The observation of the static internal fields at proton sites clearly indicates spin freezing at low temperature. The temperature and magnetic field dependences of T_1 and T_2 indicate very slow spin fluctuations of V^{4+} spin on the triangle less than the NMR frequency (10^{7-8} Hz) at low temperature. The fluctuating frequency becomes smaller and smaller by the application of a magnetic field. At the critical field $H_c \sim 2.7$ T for level crossing between the $S = 1/2$ and $S = 3/2$ states, an enhancement of $1/T_1$ is observed whereby the fluctuating frequency of the V^{4+} spins is revealed to be less than NMR frequency at the level crossing field. The width of the $1/T_1$ peak at the level crossing field suggest the existence of level anticrossing in the V15 cluster.

Both the H- and T-dependences of $1/T_1$ are well explained by a model in terms of the spin–phonon interaction above H_c where the ground state of the cluster is $S = 3/2$. On the other hand, the T_1 data can not be explained by the model in the low magnetic field region where the ground state is two $S = 1/2$ doubly degenerate states, suggesting an existence of another contribution to $1/T_1$. Temperature independent $1/T_1$ and $1/T_2$ at low magnetic field might be originated from the level crossing at $H \sim 0$ and/or quantum fluctuations, which is related to peculiarities of $S = 1/2$ triangle configuration in the V15 cluster.

Acknowledgements

The authors thank Prof. F. Borsa and Dr. A. Lascialfari for fruitful discussions and critical reading of the manuscript. The present work was in part supported by a Grand-in-Aid for Science Research from the Ministry of Education, Science, Sports, and Culture of Japan.

2. Formulations

Hubbard Hamiltonian is determined by transfer integral (t_{ij}) and on-site Coulomb repulsion (U) as follows,

$$H = -\sum_{\langle i,j\rangle}\sum_{\sigma} t_{ij}c^{+}_{i\sigma}c_{j\sigma} + U\sum_{i=1}^{N} n_{i\uparrow}n_{i\downarrow}, \tag{1}$$

where $c^{+}_{\sigma i}$ and $c_{\sigma i}$ are creation and annihilation operators for spin σ on the site i, respectively [2]. $n_i\uparrow$ and $n_i\downarrow$ are number operators for up and down spins, respectively. For the application to the metal (M) and non-metal (X) bonding (M–X bond), let us define molecular orbitals (MOs) using atomic orbitals (AOs). If atomic orbital of metal (M) and non-metal (X) are described as χ_M and χ_X, respectively, symmetry adapted (SA) bonding and anti-bonding orbitals are defined as [2–5]

$$\phi = \cos\theta\chi_M + \sin\theta\chi_X, \tag{2a}$$
$$\phi^* = -\sin\theta\chi_M + \cos\theta\chi_X, \tag{2b}$$

where ϕ is bonding and ϕ^* is anti-bonding orbitals, respectively, as illustrated in Fig. 2(a) [2]. In the broken-symmetry method, α and β orbitals are expressed by mixture of bonding and anti-bonding symmetry-adapted (SA) orbitals as follows [2–5],

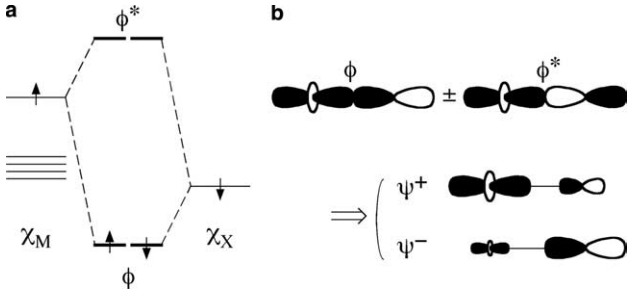

Fig. 2. (a) Spin adapted (SA) bonding (ϕ) and anti-bonding (ϕ^*) orbitals expressed using atomic orbitals of metal (χ_M) and ligand (χ_X). (b) Occupied α (ψ^+) and β (ψ^-) orbitals in broken symmetry method.

$$\psi^+ = \cos\omega\phi + \sin\omega\phi^*, \tag{3a}$$
$$\psi^- = \cos\omega\phi - \sin\omega\phi^* \quad \left(0 \leqslant \omega \leqslant \frac{\pi}{4}\right), \tag{3b}$$

as illustrated in Fig. 2(b) [2]. The wavefunction of the system is expressed by using BS wavefunctions as follows,

$$|\psi_0\rangle = |\psi^+\psi^-\rangle. \tag{4}$$

Because Hamiltonian of the system is defined as

$$\widehat{\mathbf{H}}_0 = \widehat{\mathbf{H}} + \widehat{\mathbf{G}}, \tag{5}$$

by using 1-electron Hamiltonian (**H**) and 2-electron Hamiltonian (**G**), total energies of the system becomes

$$E^{\text{total}} = \langle\psi^+\psi^-|\widehat{\mathbf{H}}_0|\psi^+\psi^-\rangle = \langle\psi^+\psi^-|\widehat{\mathbf{H}}|\psi^+\psi^-\rangle + \langle\psi^+\psi^-|\widehat{\mathbf{G}}|\psi^+\psi^-\rangle. \quad (6)$$

Because ψ^+ and ψ^- are expressed using χ_M and χ_X as follows,

$$\psi^+ = \cos\omega(\cos\theta\chi_M + \sin\theta\chi_X) + \sin\omega(-\sin\theta\chi_M + \cos\theta\chi_X) = \cos(\omega+\theta)\chi_M + \sin(\omega+\theta)\chi_X \quad (7a)$$

$$\psi^- = \cos\omega(\cos\theta\chi_M + \sin\theta\chi_X) - \sin\omega(-\sin\theta\chi_M + \cos\theta\chi_X) = \cos(\omega-\theta)\chi_M + \sin(\theta-\omega)\chi_X, \quad (7b)$$

the energies of α and β electrons of one-electron part become

$$\langle\psi^+|\widehat{\mathbf{H}}|\psi^+\rangle = \langle\cos(\omega+\theta)\chi_M + \sin(\omega+\theta)\chi_X|\widehat{\mathbf{H}}| \times \cos(\omega+\theta)\chi_M + \sin(\omega+\theta)\chi_X\rangle = \cos^2(\omega+\theta)\varepsilon_M + \sin^2(\omega+\theta)\varepsilon_X + \sin(2\omega+2\theta)\beta \quad (8a)$$

$$\langle\psi^-|\widehat{\mathbf{H}}|\psi^-\rangle = \langle\cos(\omega-\theta)\chi_M + \sin(\theta-\omega)\chi_X|\widehat{\mathbf{H}}| \times \cos(\omega-\theta)\chi_M + \sin(\theta-\omega)\chi_X\rangle = \cos^2(\omega-\theta)\varepsilon_M + \sin^2(\theta-\omega)\varepsilon_X + \sin(2\theta-2\omega)\beta, \quad (8b)$$

respectively. In Eqs. (8a) and (8b), $\langle\chi_M|\widehat{\mathbf{H}}|\chi_M\rangle = \varepsilon_M$, $\langle\chi_X|\widehat{\mathbf{H}}|\chi_X\rangle = \varepsilon_X$ and $\langle\chi_M|\widehat{\mathbf{H}}|\chi_X\rangle = \beta$.

While, in the two-electron part, only Coulomb repulsion is effective.

$$(\psi^+)^2 = \cos^2(\omega+\theta)\chi_M^2 + \sin(2\omega+2\theta)\chi_M\chi_X + \sin^2(\theta+\omega)\chi_X^2, \quad (9a)$$

$$(\psi^-)^2 = \cos^2(\omega-\theta)\chi_M^2 + \sin(2\theta-2\omega)\chi_M\chi_X + \sin^2(\theta-\omega)\chi_X^2. \quad (9b)$$

By ignoring overlap ($\langle\chi_v(1)|\chi_v(1)\rangle = 0$) and applying an approximation ($\langle(\chi_M)^2|\widehat{\mathbf{G}}|(\chi_X)^2\rangle = 0$), energy of two electron part becomes

$$\begin{aligned}\langle(\psi^+)^2|\widehat{\mathbf{G}}|(\psi^-)^2\rangle &= \cos^2(\omega+\theta)\cos^2\langle(\chi_M)^2|\widehat{\mathbf{G}}|(\chi_M)^2\rangle + \sin^2(\theta+\omega)\sin^2(\theta-\omega)\langle(\chi_X)^2|\widehat{\mathbf{G}}|(\chi_X)^2\rangle \\ &= \cos^2(\omega+\theta)\cos^2(\omega-\theta)U_M + \sin^2(\theta+\omega)\sin^2(\theta-\omega)U_X, \end{aligned} \quad (10)$$

where $\langle(\chi_M)^2|\widehat{\mathbf{G}}|(\chi_M)^2\rangle = U_M$ and $\langle(\chi_X)^2|\widehat{\mathbf{G}}|(\chi_X)^2\rangle = U_X$, respectively. From the results, total energy becomes

$$\begin{aligned}\langle\widehat{\mathbf{H}}_0\rangle = \langle\widehat{\mathbf{H}}\rangle + \langle\widehat{\mathbf{G}}\rangle &= \cos^2(\omega+\theta)\varepsilon_M + \sin^2(\omega+\theta)\varepsilon_X + \sin(2\omega+2\theta)\beta + \cos^2(\omega-\theta)\varepsilon_M + \sin^2(\theta-\omega)\varepsilon_X + \sin(2\theta-2\omega)\beta \\ &\quad + \cos^2(\omega+\theta)\cos^2(\omega-\theta)U_M + \sin^2(\theta+\omega)\sin^2(\theta-\omega)U_X \\ &= 2\varepsilon_M - \{\sin^2(\theta+\omega) + \sin^2(\theta-\omega)\}(\varepsilon_M - \varepsilon_X) + \sin(2\omega+2\theta)\beta + \sin(2\theta-2\omega)\beta \\ &\quad + \cos^2(\omega+\theta)\cos^2(\omega-\theta)U, \end{aligned} \quad (11)$$

where we introduce the assumption as $U_M = U$, $U_X = 0$. The assumption means that on-site Coulomb repulsion on ligand sites is negligible. The energy is renormalized as follows;

$$\begin{aligned}\mathbf{E} &\equiv \frac{E - 2\varepsilon_M}{U} \\ &= \{\sin^2(\theta+\omega) + \sin^2(\theta-\omega)\}y - \frac{1}{2}\{\sin(2\omega+2\theta)\beta + \sin(2\theta-2\omega)\beta\}x + \cos^2(\omega+\theta)\cos^2(\omega-\theta). \end{aligned} \quad (12)$$

Here, we define the parameters x and y as follows,

$$\begin{cases} y = \dfrac{-\Delta\varepsilon}{U} = \dfrac{-(\varepsilon_M - \varepsilon_X)}{U}, & \text{(a)} \\ x = \dfrac{-2\beta}{U}. & \text{(b)} \end{cases} \quad (13)$$

The parameter x means an index for covalent bond (M–X), while y means an index for charge transfer (M^+–X^- or M^-–X^+). Next, we variationally obtain functions of x and y by regarding the total energy as a function of parameters ω and θ as follows,

$$\begin{aligned}\frac{\partial\mathbf{E}}{\partial\omega} &= \{2\sin(2\omega+2\theta) + 2\sin(2\omega-2\theta)\}\frac{y}{2} + 2x\sin2\theta\sin2\omega - \sin(2\omega+2\theta)\left\{\frac{1+\cos(2\omega-2\theta)}{2}\right\} - \left\{\frac{1+\cos(2\omega+2\theta)}{2}\right\}\sin(2\omega-2\theta) \\ &= 2y\cos2\theta\sin2\omega + 2x\sin2\theta\sin2\omega - \sin2\omega\cos2\theta - \frac{1}{2}\sin4\omega \end{aligned} \quad (14)$$

$$\begin{aligned}\frac{\partial\mathbf{E}}{\partial\theta} &= \{2\sin(2\omega+2\theta) - 2\sin(2\omega-2\theta)\}\frac{y}{2} - 2x\cos2\theta\cos2\omega - \sin(2\omega+2\theta)\left\{\frac{1+\cos(2\omega-2\theta)}{2}\right\} + \left\{\frac{1+\cos(2\omega+2\theta)}{2}\right\}\sin(2\omega-2\theta) \\ &= 2y\sin2\theta\cos2\omega + 2x\cos2\theta\cos2\omega - \sin2\theta\cos2\omega - \frac{1}{2}\sin4\theta \end{aligned} \quad (15)$$

Then total energy becomes

$$\mathbf{E} = \{2 - \cos(2\omega+2\theta) - \cos(2\omega-2\theta)\}\frac{y}{2} - x\sin2\theta\cos2\omega + \left\{\frac{1+\cos(2\omega+2\theta)}{2}\right\}\left\{\frac{1+\cos(2\omega-2\theta)}{2}\right\}, \quad (16)$$

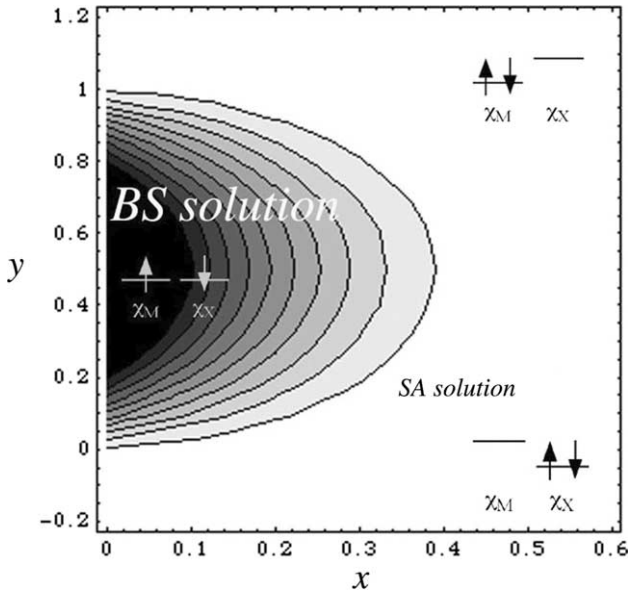

Fig. 3. Calculated phase diagram. In the dark area, BS solution (M·–X·) is more stable than SA solution. In upper white area ($y > 0.5$) is expressing M^-–X^+ and lower white area ($y < 0.5$) expresses M^+–X^-.

and we obtain energy function $E(x,y)$, which satisfies the conditions as follows,

$$\begin{cases} \dfrac{\partial \mathbf{E}}{\partial \theta} = 0 \rightarrow 2y\cos 2\theta \sin 2\omega + 2x \sin 2\theta \sin 2\omega \\ \qquad - \cos 2\theta \sin 2\omega - \frac{1}{2}\sin 4\omega = 0, \qquad \text{(a)} \\ \dfrac{\partial \mathbf{E}}{\partial \varpi} = 0 \rightarrow 2y\sin 2\theta \cos 2\omega + 2x \cos 2\theta \cos 2\omega \\ \qquad - \sin 2\theta \cos 2\omega - \frac{1}{2}\sin 4\theta = 0. \qquad \text{(b)} \end{cases} \tag{17}$$

This is an expression of total energy in terms of SA and BS methods. By solving Eqs. $(17)_{a,b}$ with ω and θ, and substituting them for Eq. (16), then we can obtain a function $E(x,y)$. By subtracting RHF energy (in case of $\omega = 0$) from UHF energy (in case of $\omega \neq 0$), we can obtain potential surface that is depicted in Fig. 3. In the dark area, BS solution is more stable than SA solution. In upper white area ($y > 0.5$), electron is transferred from ligand to metal, while lower white area ($y < 0.5$) electron is transferred from metal to ligand.

3. Calculations

We applied above formulations to the cobalamin system, in which single bond between adenosyl group and cobalt ions dissociate homolyticaly, forming radical pairs [1]. UB3LYP calculations were carried out to elucidate dissociation nature such as potential curves, charge densities and so on.

4. Computational details

Atomic coordinations of complexes were taken from date of X-ray crystal structure analysis of methylmalonyl-CoAMutase (PDB code: 4REQ [6]) that was available in the Protein Data Bank (PDB). We constructed two types of model structures. One is small model (model **1**) and another is realistic model (model **2**) as illustrated in Fig. 1(c) and (d), respectively. In case of the small model complex (model **1**), calculations were performed by the use of Tatewaki-Huzinaga MIDI (533(21)/53(21)/(41)) basis set for Co atoms, 6-31 + G* basis set for ligand atoms. On the other hand, calculations were performed by the use of Tatewaki-Huzinaga MIDI (533(21)/53(21)/(41)) basis set for Co atoms, 6-31G basis set for ligand atoms in case of the realistic model complex (model **2**). All calculation was carried out using UB3LYP [7], which is an unrestricted hybrid density functional theory (UHDFT), on GAUSSIAN98 [8].

5. Calculated results and discussion

The potential curve of small model (model **1**) complex is depicted in Fig. 4(a). From the figure, we could not find any bond formation because there is no minimum in the curve. This result suggests that Corrin ring is necessary to bond formation. The Mulliken charge densities on nitrogens are depicted in Fig. 4(b). Mulliken charges on nitrogen are slightly positive, although formal charges of nitrogens are neutral. It is showing that small model could not reproduce chemical environment of the active site. In the case of model **2**, there is a minimum around $r_{M-X} = 2.1$ Å and a stabilization energy is about 0.85 eV. In contrast with small model, charge densities on nitrogens are negative. Especially charge density on axial nitrogen (N5) is largest, while ones of small model in almost zero. Although Mulliken charges are not adequate for quantitative discussions, this result strongly suggests that axial nitrogen (N5) plays important role in the reactions of cobalamin. Natural orbital analysis was carried as illustrated in Fig. 5. There is an interaction between Co–C bond and corrin ring in case of realistic model, while there is not in case of small model. This result also supports that corrin ring is essential for the Co–C bond formation. From the occupation numbers of natural orbital, instability in Co–C chemical bond (y_i) is estimated using an equation as follows [2],

$$y_i = \frac{n_i^2 - 4n_i + 4}{n_i^2 - 2n_i + 2}, \tag{18}$$

where n_i is occupation number of natural orbital. The calculated y_i values were plotted in Fig. 6. The y_i values show that bond instability (radical dissociation) occurs at about 2.1 Å. In other words, BS solutions are stable

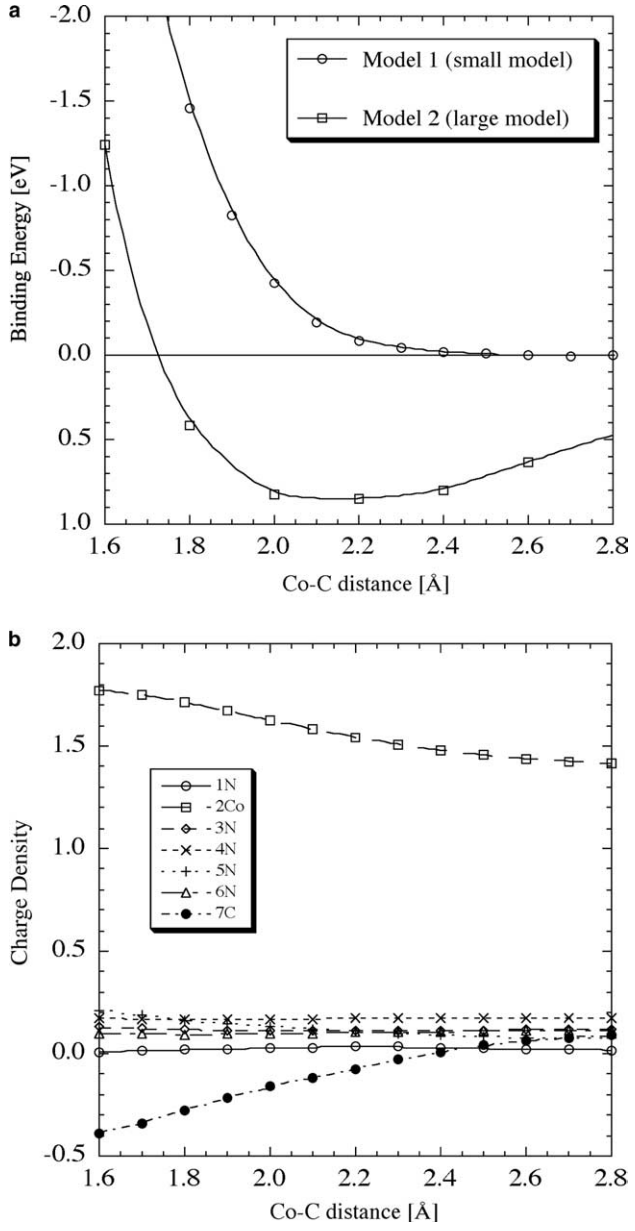

Fig. 4. (a) Calculated potential curve of Co–C bond on small model (model **1**) and realistic model (model **2**). (b) Calculated Mulliken charge densities on model **1**.

where Co–C distances are longer than 2.1 Å. Therefore the potential minimum of Co–C bond belongs to the SA region, showing that Co–C bond is covalent bond. The potential minimum, however, located the boundary between SA solution and BS solution.

The transfer integral (t) and on-site Coulomb repulsion energy on metal ion (U) in Hubbered Hamiltonian were estimating by fitting the parameter using the equation [2],

$$J = \frac{1}{4}\left(\Delta\varepsilon + U - \sqrt{(\Delta\varepsilon + U)^2 + 16t^2}\right), \tag{19}$$

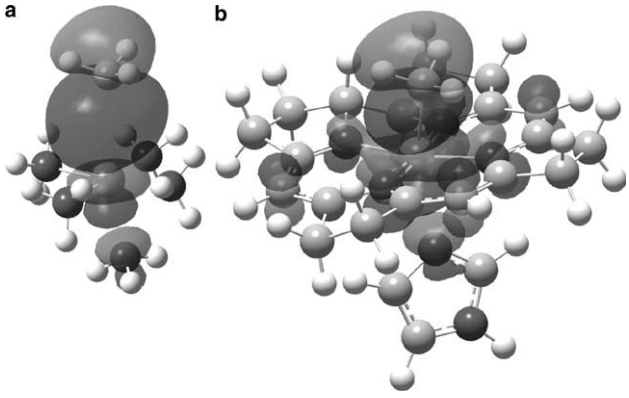

Fig. 5. Calculated natural orbitals (NOs) of small model (model **1**) (a) and realistic model (model **2**) (b), respectively.

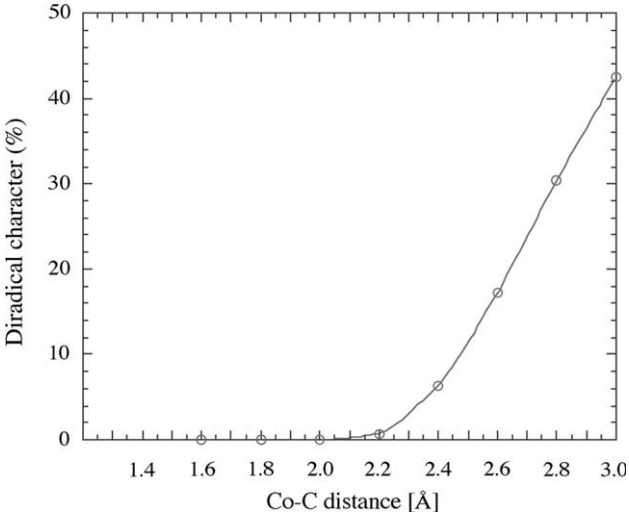

Fig. 6. Calculated instabilities in Co–C bond (y_i) by Eq. (18) using occupation number of natural orbital.

where J is effective exchange integrals, $\Delta\varepsilon$ is an energy gap between α-HOMO and β-HOMO. The J value is calculated by [4,5]

$$J = \frac{E^{\mathrm{LS}} - E^{\mathrm{HS}}}{\langle S^2\rangle_{\mathrm{HS}} - \langle S^2\rangle_{\mathrm{LS}}}. \tag{20}$$

The estimated values are $U = 1.29$ eV and $t = 1.07$ eV. From the estimated t and U, x and y values were also estimated as $x = 1.5$ and $y = 0.1$. By plotting the estimated x and y values in Fig. 3, it becomes obvious that the calculated x value is too large. There are several assumptions such as on-site Coulomb repulsion could be negligible. Those assumptions seem to influence on the overestimation. In addition, this result is suggesting that UB3LYP calculation overestimated the stability of anti-ferromagnetic coupling that have been reported previous paper [9–11]. MEDF approach seems

effective to the analyses of bond breaking in the system [9–11].

6. Conclusion

In this paper, we formulated the M–X bond formation and its dissociation analytically to obtain phase diagram. By estimating x (covalent bond parameter) and y (ionic parameter) values, we could discuss the nature of M–X bond using the phase diagram. The electronic structure of cobalamin, which involves Co–C bond, was calculated by using UB3LYP method. Those calculations revealed that corrin ring was essential for the Co–C bond. Co–C bond in the active site was covalent bond but potential minimum was on a bifurcation point between BS and SA. The covalent bond parameter (x) and ionic parameter (y) were estimated by using calculated J, t and U values. The estimated x was overestimated, suggesting that more appropriate approximation must be needed. On the other hand, Freindorf et al. [12] proposed the elongation (and/or shrinkage) mechanism of Co–N_{axial} bond by using QM/MM calculation results. In the paper, they summarized that elongation of Co–N_{axial} bond makes the radical formation easy. In this study, the Co–N_{axial} bond-length was constant although the Co–C bond-length was only variable. To analyze the phase diagram qualitatively, Co–N_{axial} bond-length also should be considered.

inner nickel(II) ions were considered to be low spin states ($S = 0$) [10]. However, more details about their electronic structures need to be elucidated. In addition, potentials of these complexes for molecular devices are also interesting issue in the scientific field of coordination chemistry.

In this study, we focused on the magnetic interactions in aligned $Ni(II)_5$ and $Ni(II)_7$ complexes, i.e. $[Ni_5(tpda)_4Cl_2]$ (**1**) and $[Ni_7(teptra)_4Cl_2]$ (**2**), respectively as illustrated in Fig. 1. Their electronic structures were calculated by unrestricted hybrid density functional theory (UHDFT) method, and the magnetic couplings were discussed by using effective exchange integrals (J_{ab}) values. Natural orbitals (NO) and their occupation numbers were analyzed in order to elucidate the mechanism of anti-ferromagnetic interactions. In comparison with those results, we elucidated the effects of bridge-ligands, axial-ligands and a chain length. Finally, the possibility of these complexes for the magnetic electron conductor (or semi-conductor) was discussed theoretically by estimating J_{ab} value of an electron-doped model.

2. Theoretical background

2.1. Effective exchange integrals (J_{ab})

The magnetic properties of transition metal complexes were usually investigated by the use of the Heisenberg–Dirac–van Vleck spin Hamiltonian. For example, the effective exchange interaction between localized spins in binuclear transition metal complexes is described by the total spin form of the spin-coupling Hamiltonian [11–15]

$$H = -2\sum J_{ab}\mathbf{S_a}\cdot\mathbf{S_b}, \tag{1}$$

where J_{ab} is the orbital-averaged effective exchange integral between the metal 'a' and 'b' with total spin operators $\mathbf{S_a}$ and $\mathbf{S_b}$. J_{ab} can be experimentally determined by magnetic susceptibility. Recent development in computational quantum chemistry enabled us to perform large ab initio calculations of J_{ab} values by using broken-symmetry (BS) approach such as UHF or UDFT [14,15]. The BS approach can be performed at a low computing cost. In singlet biradicals and low-spin species, however, it suffers from the spin contamination of high-spin states, leading to spin-projection procedures. Our group proposed spin projection scheme as follows:

$$J_{ab} = \frac{E(\mathrm{LS}) - E(\mathrm{HS})}{\langle S^2\rangle(\mathrm{HS}) - \langle S^2\rangle(\mathrm{LS})}, \tag{2}$$

where $E(X)$ and $\langle S^2\rangle(X)$ denote the total energy and total spin angular momentum for the spin state X, respectively [14,15]. In this paper, the magnetic interactions between Ni(II) ions were discussed using the equation.

2.2. Natural orbital analyses

Usual orbital-correlation diagram, which helps us to understand orbital interactions, is not obtained by the BS calculation because of the DODS approach [16]. In order to clarify the effective exchange interactions in the complexes using expression like the closed-shell MO, we introduced natural orbitals (NOs), which were determined by diagonalizing their first order density matrices as

$$\rho(r, r') = \sum n_i\{\phi_i(r)\}^*\phi_i(r'), \tag{5}$$

where n_i denoted the occupation number of NO ϕ_i [16,17]. If an occupation number of a magnetic orbital is close to 1.0, then two electrons in the orbital are almost localized on each spin site. On the other hand, n_i should be equal to 2.0 if stable chemical bond exists.

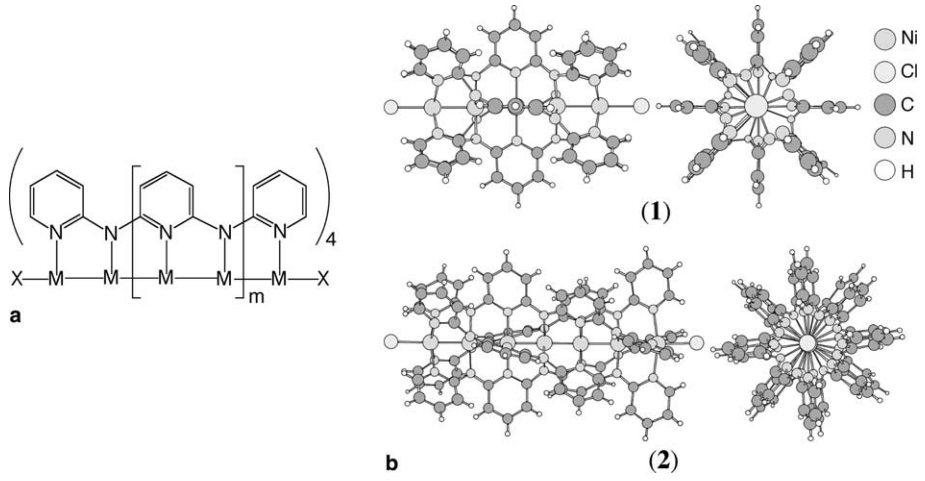

Fig. 1. (a) Illustration of metal chain complexes using oligo-α-pyridylamino ligands. (b) $[Ni_5(tpda)_4Cl_2]$ (**1**) and $[Ni_7(teptra)_4Cl_2]$ (**2**).

In other words, the occupation numbers of the BS method contains an important information to understand the stability in chemical bond.

To assess this instability (diradical character), instability value (y_i) for orbital type i ($i = \sigma$, δ and so on) is introduced here as follows [18]:

$$y_i = 2W_D^2 = \frac{n_i^2 - 4n_i + 4}{n_i^2 - 2n_i + 2}, \quad (9)$$

where n_i and n_i^* are occupation numbers of bonding and anti-bonding NO, respectively and W_D denotes the weight of double excitation for orbital i. If a chemical bond of orbital i is stable, y_i is close to zero. On the other hand, if a chemical bond of orbital i is unstable and spins are localized at metal sites, then y_i is close to unity. Especially, $y_i/2$ is consistent to a weight of the doubly exited configuration in the MCSCF theory.

In this way, metal–metal bond natures and degrees of electron correlation effect, which causes spin-localization are discussed in terms of instabilities in chemical bonds using these indices.

2.3. Computational details

Atomic coordinations of complexes were taken from data of X-ray crystal structure analyses that were available in the Cambridge Structural Database (CSD). Those calculations were performed by the use of Tatewaki-Huzinaga MIDI (533(21)/53(21)/(41)) basis set for Ni atoms, 6-31+G* basis sets for axial ligand atoms and 6-31G basis sets for bridge ligand atoms. All calculation was carried out using GAUSSIAN98 [19].

3. Calculated results

3.1. Effective exchange integrals of $[Ni_5(tpda)_4Cl_2]$ and $[Ni_7(teptra)_4Cl_2]$ complexes

The electronic structures for low spin (singlet) states and high spin states (quintet) of the complexes **1** and **2** were calculated by UB3LYP method [20]. Calculated Mulliken charge densities and spin densities of $[Ni_5(tpda)_4Cl_2]$ (**1**) were summarized in Table 1. Although charge densities on each Ni ion are almost equivalent, spin densities are only appeared on the terminal Ni ions in both cases of high-spin and low-spin state. Calculated Mulliken charge densities and spin densities of $[Ni_7(teptra)_4Cl_2]$ were summarized in Table 2. In this complex, spin densities are also localized on terminal Ni ions. These results are showing that terminal Ni ions are open-shell ($S = 1$) and other inner Ni ions are closed-shell ($S = 0$) structures that are consistent with experimental results. It is showing spin localized structures on the end Ni ions.

Table 1
Calculated charge density and spin densities of $[Ni_5(tpda)_4Cl_2]$ for low spin state (LS) and high spin state (HS)

Atom[a]	Charge density		Spin density	
	LS	HS	LS	HS
Ni1	0.65	0.65	1.58	1.58
Ni2	0.84	0.84	0.12	0.13
Ni3	0.70	0.70	−0.01	0.03
Ni4	0.83	0.83	−0.13	0.15
Ni5	0.64	0.64	−1.57	1.56

[a] Cl–Ni1–Ni2–Ni3–Ni4–Ni5–Cl.

Table 2
Calculated charge density and spin densities of $[Ni_7(teptra)_4Cl_2]$ for low spin state (LS) and high spin state (HS)

Atom[a]	Charge density		Spin density	
	LS	HS	LS	HS
Ni1	0.64	0.64	1.59	1.59
Ni2	0.77	0.77	0.10	0.10
Ni3	0.70	0.70	0.02	0.02
Ni4	0.76	0.76	0.00	0.01
Ni5	0.70	0.70	−0.01	0.01
Ni6	0.79	0.79	−0.10	0.10
Ni7	0.64	0.64	−1.60	1.60

[a] Cl–Ni1–Ni2–Ni3–Ni4–Ni5–Ni6–Ni7–Cl.

The spin densities on open-shell Ni ions of $[Ni_5(tpda)_4Cl_2]$ and $[Ni_7(teptra)_4Cl_2]$ are equivalent, suggesting weak exchange-coupling, which depends on chain length. The effective exchange integrals (J_{ab}) values between spins on terminal Ni ions were calculated by Eq. (2) and they are summarized in Table 3. Total energies and expectation values of the operator $\mathbf{S}^2$ ($\langle S^2 \rangle$) used in the equation are also summarized in the table. Experimental week anti-ferromagnetic couplings are reproduced by UB3LYP calculations well. Both experimental and calculated results indicate that J_{ab} value decreases against an increase of chain length. On the other hand, from computational view point, this result is showing that it is possible to reproduce small J_{ab} values well in such large complexes by unrestricted DFT calculations.

3.2. Natural orbital analyses

Natural orbitals (NOs) and their occupation numbers by UB3LYP method were analyzed in order to elucidate the mechanism of anti-ferromagnetic interactions. The magnetic orbitals are σ type and δ type orbitals (σ orbital and δ orbital, respectively) as illustrated in Fig. 2. In the complexes, σ orbitals were delocalized to axial ligand, while δ orbitals were not. In other words, the character of axial ligands conspicuously appears in the σ orbitals in terms of magnetic property. As a consequence, a dependence upon axial ligands in J_{ab} values that are reported in the references stems from the change

Table 3
Calculated and experimental effective exchange integrals (J_{ab})[a] for $[Ni_5(tpda)_4Cl_2]$ and $[Ni_7(teptra)_4Cl_2]$

Complex	Low-spin state		High-spin state		J_{ab} (calc.)	J_{ab} (expt.)
	Total energy	$\langle S^2\rangle$	Total energy	$\langle S^2\rangle$		
$[Ni_5(tpda)_4Cl_2]$	−11866.2713346	2.2847	−11866.2711053	6.2900	−12.6	−8.3
$[Ni_7(teptra)_4Cl_2]$	−16089.8500892	2.2636	−16089.8499729	6.2551	−6.4	−3.8

of σ orbitals. The δ orbitals have spiral structure that reflects the spiral structure of bridge ligands. This result indicated that the structure of bridge ligands strongly affected shape of δ orbitals because overlaps between atomic orbitals of each Ni ions in δ bonds are small.

Occupation numbers and instability values (y) of magnetic orbitals were summarized in Table 4. Occupation numbers of magnetic orbitals were almost unity, showing that spins were almost localized Ni(II) ions of the both ends. And y values were almost 100%, indicating that direct exchange coupling between spins on the Ni ions is quite small. It means that weak anti-ferromagnetic coupling mainly derived from interactions through bridge ligands. In other words, decrease of exchange-coupling in $[Ni_7(teptra)_4Cl_2]$ in comparison with $[Ni_5(tpda)_4Cl_2]$ comes from the decrease of exchange interactions through bridge ligands. Ni_7 chain and Ni_5 chain are relatively long, therefore the direct exchange between Ni spins of the both ends seemed to be negligible. However, direct exchange coupling might become domestic, in shorter chain complex such as Ni_3, which has larger anti-ferromagnetic coupling.

3.3. Molecular orbitals and their orbital energies near HOMO–LUMO

Molecular orbitals of $[Ni_5(tpda)_4Cl_2]$ and $[Ni_7(teptra)_4Cl_2]$ near HOMO–LUMO are depicted in Fig. 4. HOMOs of both complexes are σ-orbitals. LUMO of Ni_5 complex **1** consists of π-conjugated orbital of bridge ligands, while LUMO of Ni_7 complex **2** is d-orbital of the Ni ions. Orbital energies of

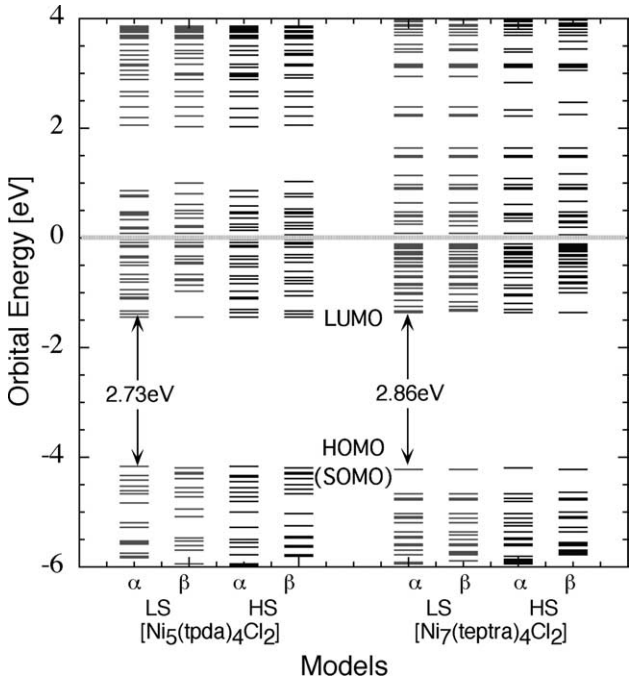

Fig. 3. The α and β orbital energies of $[Ni_5(tpda)_4Cl_2]$ (**1**) and $[Ni_7(teptra)_4Cl_2]$ (**2**) for low-spin state (LS) and high-spin state (HS), respectively. The HOMO–LUMO gaps of them are 2.73 and 2.86 eV, respectively.

$[Ni_5(tpda)_4Cl_2]$ and $[Ni_7(teptra)_4Cl_2]$ obtained by UB3LYP calculations were depicted in Fig. 3. HOMO–LUMO gaps of $[Ni_5$- $(tpda)_4Cl_2]$ and $[Ni_7(teptra)_4Cl_2]$ are 2.73 and 2.86 eV, respectively. These HOMO–LUMO gaps are larger than usual semi-conductors such as Si (1.17 eV) and Ge (0.744 eV) [21]. Interestingly, orbital energies of LUMO and many unoccupied orbitals are negative, showing their high electron affinities. It means electrons are easily doped in the complexes.

3.4. Possibility of magnetic electron conductor using the one-dimensional complexes

The one-dimensional complexes are one of the promising compounds for the magnetic electron conductor [22]. For example, three-terminal devices by using these complexes were proposed as illustrated in Fig. 5(a) [22]. One of the approaches is σ-metal and δ-spin approach as illustrated in Fig. 5(a). In this approach, electrons in σ-orbitals (σ-electron) that have relatively large overlap bear conductivity, while electrons in δ-orbitals (δ-electrons) that act as localized spins bear magnetism. The charge on metal ions, however, changes in a process of charge-doping or electron transfer. It would cause the structural change such as Peierls transition, leading the change in magnetic interaction. In addition, change in formal charge of Ni(II) ions might cause electronic change such as Motto transition that is a transformation to an insulator. Therefore it seems to be better to dope carrier without change in formal charge on metal ions.

There are two ways to dope carrier for the conductivity, one is hole-dope and another is electron-dope. As mentioned before, the complex **1** has HOMO derived from Ni(II) d-orbitals and LUMO derived from π-conjugated ligand orbitals as illustrated in Fig. 4(a). In this system, if hole is doped, charges of Ni ions are changed. On the other hand, if electron is doped, charge is doped in ligand orbitals. In this case, charges on the Ni ions do not change. Therefore, conductivity might appear without a disorder of magnetic interactions between metal ions in the complex. In case of the complex **2**, however, both HOMO and LUMO derive from metal d-orbitals. Therefore, both hole-dope and electron-dope change charges of Ni ions.

To confirm the idea, we carried out UB3LYP calculations using electron-dope model of $[Ni_5(tpda)_4Cl_2]$, in which LUMO was ligand orbital as illustrated in Fig. 4. In order to hold a number of spins, singlet-paired two-electrons were doped in the complex. Calculated result is summarized in Table 5. The negative J_{ab} value of the neutral model is slightly strengthened in electron-dope model because through-ligand interactions (super-exchange interaction) are enhanced by electron-dope. However, the anti-ferromagnetic coupling is not broken by the electron-dope into the ligand orbitals. By using bridge-ligand which was designed for electron conducting, the system of ligand–metal Ni-spin model seemed to be possible. Tanaka and Shionoya et al. [23–25] reported that the one-dimensional metal

complex using DNA as ligand. If DNA-ligands conduct the electron, the complex might be most possible candidate of out strategy.

4. Concluding remarks

In this study, weak anti-ferromagnetic J_{ab} values were reproduced and their mechanism was clarified. Recent development of quantum chemistry and computational method makes it possible to calculate J_{ab} values of large complexes, quantitatively [26–29]. The calculation of J_{ab} value is one of the strategies for the investigations of their electronic structures [30–32].

We also carried out the calculations using electron-doped model complex. From the results, we proposed the possible method for the magnetic electron conductors. The calculations have several weak points that can not be ignored. For example, structure of the complex may change by the electron doping but it is not included in the calculations. Electron conductivity is not also calculated. However, bridge-ligands are usually π-conjugated systems and rigid and high-conducting bridge-ligands will be presented.

well as inorganic complexes [66,67]. Fig. 2 illustrates our theoretical efforts toward molecule-based magnetic conductors. Applicability of the field-effect transistor (FET) configuration has been also discussed in relation to the so-called molecular spintronics [64,68].

In order to elucidate electron-donating properties and ionization potentials (IP) of purine and pyridine bases in DNA, we have already performed ab initio MO calculations of guanine (G), adenine (A), thymine (T) and cytosine (C), and their paired oligomers $(GC)_n$ $(AT)_m$ [69–71]. The calculated IP values have been found to become lower and lower for (GG), (GGG) and (GGGG) oligomers, in agreement with experiments [21–34]. The oxidation of these oligomers, however, entails a difficult problem that their reactivities with oxygen, metal ion [71], etc. should be suppressed to obtain stable soft materials for molecular electronics and devices based on DNA. As a continuation of previous works [69–71], we wish to examine three key points theoretically:

(1) structural modification of guanine molecule for the suppression of oxidation damage,
(2) magnetic modification of such guanine derivatives (G) with the introduction of spin sources ($R^{\bullet}$) such as nitroxide and metal complexes,
(3) construction of molecular magnetic conductors and molecular solenoids with G–$R^{\bullet}$ components.

Finally, implications of these computational results will be discussed in the relation to DNA-based magnetic materials.

2. Ab initio computation of effective exchange integrals

2.1. Theoretical models

Band models based on the extended Hückel tight-binding approximation work well for theoretical understanding of many molecular conductors such as TTF-derivatives [72]. Recent experiments, however, have revealed that antiferromagnetic state appears even in organic systems such as phenalenyl dimer [73] because of the strong electron correlation, and resulting Mott insulators that usually entail localized spins. Magnetism is also one of key issues in phenalenyl-derivatives and other related species. Their magnetic properties have been investigated by the Heisenberg-type spin coupling Hamiltonian [74–76]

$$H(\mathrm{HB}) = -\sum_{ab} 2J_{ab}\mathbf{S}_a \cdot \mathbf{S}_b, \quad (1)$$

where J_{ab} is the orbital-averaged effective exchange integral between the ath and bth radical sites with total spin operators $\mathbf{S}_a$ and $\mathbf{S}_b$. Recent development of the ab initio computational techniques has made it possible to calculate the J_{ab} values for phenalenyl derivatives [73]. These methods are classified into two types. One is the spin-symmetry adapted (SA) perturbational and configuration interaction (CI) approach. Use of the SA method is desirable for the quantitative computations of J_{ab} but it is hardly applicable to transition-metal complexes because of the high computational costs. The other is the broken-symmetry (BS) approach [73–76], which is often used for such systems because of their lower computational costs, though the spin contamination problem occurs in the low-spin (LS) state [76].

Broken-symmetry (BS) calculations of J_{ab} for molecule-based magnets have been performed on the basis of different computational schemes such as Eqs. (2a)–(2c).

$$J_{ab}^{(1)} = \frac{^{LS}E(X) - {}^{HS}E(X)}{S_{max}^2}, \tag{2a}$$

$$J_{ab}^{(2)} = \frac{^{LS}E(X) - {}^{HS}E(X)}{S_{max}(S_{max}+1)}, \tag{2b}$$

$$J_{ab}^{(3)} = \frac{^{LS}E(X) - {}^{HS}E(X)}{^{HS}\langle S^2\rangle - {}^{LS}\langle S^2\rangle}, \tag{2c}$$

where $^{Y}E(X)$ and $^{Y}\langle S^2\rangle(X)$ denote, respectively, total energy and total spin angular momentum for the spin state Y by the method X (=UHF, UDFT, etc.). The first scheme $J_{ab}^{(1)}$ has been derived by Noodleman [74], Noodleman and Davidson [75] (ND), while the second scheme $J_{ab}^{(2)}$ has been proposed by ND, Bencini [77] and others. $J_{ab}^{(1)}$ is derived when the overlap of magnetic orbitals is sufficiently small, while $J_{ab}^{(2)}$ is applicable when the overlap is sufficiently large. $J_{ab}^{(3)}$ by our approximate spin projection (AP) procedure [76] is close to $J_{ab}^{(1)}$ by ND if $^{HS}\langle S^2\rangle = S_{max}(S_{max}+1)$ and $^{LS}\langle S^2\rangle S_{max}$, where S_{max} is the spin size for the HS state. $J_{ab}^{(3)}$ becomes equivalent to $J_{ab}^{(2)}$ in the strong overlap region, where $^{LS}\langle S^2\rangle \approx 0$ [76]. Therefore, our scheme [43] involves others [74,75,77] as the strong and weak correlation limits.

As shown previously [78], our AP scheme can be extended to trinuclear, and more larger clusters, though $J_{ab}^{(1)}$ and $J_{ab}^{(2)}$ do not work for them. On the other hand, $J_{ab}^{(4)}$ without spin projection is given for both linear and ring forms by

$$J_{ab}^{(4)} = \frac{^{LS}E(X) - {}^{HS}E(X)}{4(N-1)S_aS_b}, \tag{3}$$

where N is the total spin site number and S_c is the size of spin S_c ($c = a, b$). This equation is applicable to periodic systems involving the same cluster unit cells [79].

2.2. Computational methods

The hybrid-DFT method calculated properties of these derivatives by using B3LYP functional that has Becke's exchange [80] involving the gradient of the density and Vosko, Wilk and Nusair (VWN) [81] correlation functional, and the last term is the correlation correction of Lee, Yang and Parr (LYP) correlation functional [82]. All hybrid density functional (HDFT) calculations were performed by using GAUSSIAN 98 program [83] package.

3. Hubbard, Heisenberg and RKKY models for strong correlation systems

3.1. Model Hamiltonians and electronic properties

In this section we briefly summarize theoretical background for a reduction of ab initio results to model Hamiltonians. Previously, we have examined electronic structures of high-T_C copper oxides using ab initio MO methods [45,84], showing the necessity of N-band models for the systematic descriptions of magnetism, conductivity and superconductivity of the species. Some organometallic and organic systems (isoelectronic to copper oxides) have been also proposed on the basis of the ab initio results [45–48] as shown in Fig. 1. N-band models often reduce to the two-band model, which has been used for the elucidation of Kubo–Inagaki [85,86] mechanism of ferromagnetism and other magnetic states, and Suhl–Kondo mechanism [87,88] and related multi-band models [45–48] for superconductivity.

In previous papers [89,90], the two-band model combined with the temperature Green's function technique has been applied to elucidate phase diagrams of charge density wave (CDW), spin density wave (SDW), singlet superconductivity (SSC), triplet superconductivity (TSC) and ferromagnetism (FM). Instead of the two-band model, Anderson lattice model [91] or Kondo lattice model [92] can be used for the theoretical descriptions of ferromagnetic metals, paramagnetic metals, spin liquid of electron of hole-doped conducting polymers interacting with coordination compounds with spins ($M^{\bullet}$) [93] and the donor (D)–acceptor (A) complexes, where D or A are interacting with the magnetic species ($M^{\bullet}$). The so-called RKKY model [94–96] is used for theoretical description of effective exchange couplings of spins via the spin polarization of conduction electrons. The RKKY model has been employed for theoretical studies of ferromagnetism, antiferromagnetism, helical spin structure and spin glass of organic, organometallic and biomolecular magnetic materials.

3.2. Hubbard models for p–d, π–d and π–R systems

Ab initio calculations of large magnetic clusters in Section 1 are often time-consuming. Therefore, the extended Hubbard Hamiltonian [97–100] can be generally used for p–d, π–d and π–R systems that are insulators because of electron correlation effects

$$H = H_q + H_r + H_{qr}, \tag{4}$$

where H_q denotes the Hamiltonian for (pπ)- or d-electrons, and H_{qr} is the interaction Hamiltonian between them as follows:

$$\begin{aligned} H_q &= \sum_q T_q a_q^{\dagger} a_q + \sum_{qr} U_{qr} a_q^{\dagger} a_q b_r^{\dagger} b_r, \\ H_{qr} &= \sum_{qr} T_{qr}\left(a_q^{\dagger} b_r + b_r^{\dagger} b_q\right), \end{aligned} \tag{5}$$

where $a^{\dagger}$ and $b^{\dagger}$ create electron (or hole) on the qth site and the rth site, respectively (q, r = p, π and d). U_{qq} and U_{qr} (=V) are on-site and inter-site Coulomb repulsions, and T_{qq} (=ε_{qq}) and T_{qr} are orbital energy and transfer

integral between (pπ)- and d(R)-orbitals, respectively. The parameters used in Eq. (5) were estimated from the ab initio results and spectroscopic data as shown previously [45,98–100]. The CT excitation energy (Δ_{qr}) from the donor site to the acceptor vacant orbital is given under the Hubbard model as

$$\Delta_{qr} = (\varepsilon_{rr} - \varepsilon_{qq}) + (U_{rr} - U_{qq}). \tag{6}$$

Therefore, the on-site Coulomb repulsion plays an important role for CT excitation. Then careful examination of these parameters is crucial for rational design of CT complexes near the neutral-ionic transition (see below).

3.3. Heisenberg model

The Hubbard model often reduces to the Heisenberg spin Hamiltonian in the case of strong electron correlation systems. The exact diagonalization (full CI) of singlet and triplet CI matrices of the Hubbard model provide the effective exchange integral in Eq. (1) as

$$E_{\mathrm{CI}}(\text{singlet}) - E_{\mathrm{CI}}(\text{triplet}) = 2J_{dd}. \tag{7}$$

If the effective exchange integral (Eq. (7)) between transition metal ions is weak, it can be approximately given by the perturbation theory as

$$J_{dd} = -\frac{2T_{pd}^4}{\Delta_{pd}}\left\{\frac{1}{\Delta_{pd}^2} + \frac{1}{U_{dd}\Delta_{pd}}\right\}$$

$$= -2(t_{dd})^2\left\{\frac{1}{\Delta_{pd}} + \frac{1}{U_{dd}}\right\}, \tag{8a}$$

$$= \frac{-2(t_{dd})^2}{\Delta_{pd}}\left(t_{dd} = \frac{T_{pd}^2}{\Delta_{pd}}\right). \tag{8b}$$

From Eq. (8a), J_{dd} is sensitive to the magnitude of Δ_{pd} and U_{dd}. Its magnitude increases sharply with the decrease of Δ_{pd} as in the case of copper oxide, and it is approximately given by Eq. (8b). J_{dd} in Eq. (8a) is reduced to the following familiar form if $U_{dd} < \Delta_{pd}$: namely the Mott–Hubbard case.

$$J_{dd} = -\frac{2t_{dd}^2}{U_{dd}}. \tag{9}$$

These situations are similar even for π–R systems in Fig. 2.

3.4. Anderson and Kondo lattice models

As shown in Fig. 1, molecular systems described by multi-band models are our theoretical targets to realize multifunctional materials. Previously, we have used Anderson and Kondo lattice models [45,57,93] for molecular design of doped-magnetic polymers and segregated columns of CT complexes coupled with coordination compounds with spins (M$^{\bullet}$). Very recently, antiferromagnetic and ferromagnetic metal states were discovered for organic-inorganic hybrid systems [101–105]. The Anderson model Hamiltonian for these species is given by

$$H = \sum_{\mathbf{k}\sigma}\varepsilon_{\mathbf{k}}c_{\mathbf{k}\sigma}^{\dagger}c_{\mathbf{k}\sigma} + \sum_{j\sigma}E_{\mathrm{R}}R_{j\sigma}^{\dagger}R_{j\sigma}$$
$$+ U\sum_{i}R_{i\uparrow}^{\dagger}R_{i\uparrow}R_{i\downarrow}^{\dagger}R_{i\downarrow} + T\sum_{i\mathbf{k}\sigma}R_{i\sigma}^{\dagger}c_{\mathbf{k}\sigma} + c_{\mathbf{k}\sigma}^{\dagger}R_{i\sigma}$$
$$= \sum_{\mathbf{k}\sigma}\varepsilon_{\mathbf{k}}c_{\mathbf{k}\sigma}^{\dagger}c_{\mathbf{k}\sigma} + \sum_{j\sigma}E_{\mathrm{R}}R_{\mathbf{k}\sigma}^{\dagger}R_{\mathbf{k}\sigma}$$
$$+ \frac{U}{N}\sum_{\mathbf{k}\mathbf{k}'\mathbf{q}}R_{\mathbf{k}+\mathbf{q}\uparrow}^{\dagger}R_{\mathbf{k}'-\mathbf{q}\downarrow}R_{\mathbf{k}'\downarrow}^{\dagger}R_{\mathbf{k}\uparrow} + T\sum_{\mathbf{k}\sigma}R_{\mathbf{k}\sigma}^{\dagger}c_{\mathbf{k}\sigma} + c_{\mathbf{k}\sigma}^{\dagger}R_{\mathbf{k}\sigma}, \tag{10}$$

where $\varepsilon_{\mathbf{k}}$ is the energy level of conduction electron and U and E_{R} denote the on-site Coulomb repulsion of spin site (R) and SOMO energy level of R, respectively, and T is the interaction matrix element between conduction electron and SOMO electron. The electronic structures of the Anderson lattice model are highly dependent on relative magnitudes of $\varepsilon_{\mathbf{k}}$, E_{R} and U as discussed previously [93]. The so-called Kondo regime [88] is defined as a specific state where the SOMO level (E_{R}) is deeper than the Fermi level (ε_{F}), even if the band width (Γ) of radical electrons is taken into account ($\varepsilon_{\mathrm{F}} - E_{\mathrm{R}} \gg \Gamma$), where $E_{\mathrm{R}} + U - \varepsilon_{\mathrm{F}} \gg \Gamma$ because of the strong on-site repulsion U of radical sites. This implies that subtle balances of the Fermi (HOMO) levels of conducting polymers (or CT complexes) and SOMO levels of coordination compounds, together with U for spin sites are necessary for achievements of Kondo regime. So, we must examine the energy levels of G-spin (R$^{\bullet}$) systems by the ab initio calculations as shown previously [65]. The situation was similar to the case of some TTF-derivatives plus transition metal complexes [45,101–105].

In this situation, spins on the spin sites are alive under chemical doping and physical doping in FET configuration to generate conduction electrons [64,65]. Therefore, several spin-mediated electronic states such as ferromagnetic metal, dense Kondo system, etc. are expected in Kondo regime. Slave boson method, which eliminates the double occupancy of radical states (see [106]), can be used to solve the Anderson lattice model [67] to depict the phase diagram. Some SOMO electrons on radical sites are almost localized in the Kondo regime, only their spin freedom remains, leading to the Kondo lattice model as follows:

$$H_{\mathrm{KM}} = \sum_{\mathbf{k}\sigma}\varepsilon_{\mathbf{k}\sigma}c_{\mathbf{k}\sigma}^{\dagger}c_{\mathbf{k}\sigma} + J_{\mathrm{CM}}\sum_{i}\sigma_i\cdot\mathbf{S}_i, \tag{11}$$

where $\mathbf{S}_i$ means spin localized at radical site i and $\boldsymbol{\sigma}_i$ denotes the spin of conduction electron

$$\mathbf{S}_i = \frac{1}{2}\sum_{\sigma\sigma'}c_{i\sigma}^{\dagger}\tau_{\sigma\sigma'}c_{i\sigma'}, \tag{12}$$

where $\tau = (\tau_x, \tau_y, \tau_z)$ is Pauli spin matrix. The Kondo lattice model has been used for molecular design of organic Kondo and dense Kondo systems, together with π–d conjugated systems [57].

Since localized spin $\langle \mathbf{S}_i \rangle$ at site i induces the local magnetic field $(-J_{\mathrm{CM}}\langle \mathbf{S}_i \rangle)$ on conduction electrons, the spin polarization on site j is given by

$$\langle \mathbf{S}_j^{\alpha} \rangle = -J_{\mathrm{CM}} \sum_{\beta=x,y,z} \chi^{\alpha\beta}(j,i) \langle \mathbf{S}_i^{\beta} \rangle, \tag{13}$$

where $\chi_{ab}(j,i)$ denotes the local magnetic susceptibility. Then the magnetic interaction of localized spin $\langle \mathbf{S}_j^{\alpha} \rangle$ at site j with $\langle \mathbf{S}_j^{\beta} \rangle$ is defined by

$$H_{\mathrm{RKKY}} = -J_{\mathrm{CM}}^2 \sum_{\langle ij \rangle} \sum_{\alpha\beta} \mathbf{S}_j^{\alpha} \chi^{\alpha\beta}(j,i) \mathbf{S}_i^{\beta}, \tag{14a}$$

$$= -\sum_{\langle ij \rangle} 2J_{ij} \mathbf{S}_j \cdot \mathbf{S}_i, \tag{14b}$$

where

$$\frac{1}{2} J_{\mathrm{CM}}^2 \chi^{\alpha\beta}(j,i) = J_{ij} \delta_{\alpha\beta}. \tag{15}$$

Thus the exchange couplings between radical spins via the spin polarization of conduction electrons are described by the RKKY type spin Hamiltonian [94–96]. The RKKY model has been used for molecular design of several magnetic states of magnetic polymers and crystals as shown below.

4. DFT calculations of DNA-radical system

4.1. Molecular design of DNA-based magnetic conductors

We have theoretically examined possible organic, organometallic analogs to copper oxides [45] and magnetic conductors on the basis of both ab initio and Hubbard model calculations as described above. In fact, several strategies are presented; (1) magnetic modification of TTF derivatives [45,57,65], (2) magnetic modification of conducting polymer [53–56], (3) magnetic modification of Ni(dimt) systems [66,67], and (4) construction of organic RVB [45,55]. Past decade, experimental results for the first systems (1) have been reported. Hence, we wish to extend these results to DNA-based magnetic materials.

4.2. Magnetic modifications of DNA wires

We considered some guanine and adenine derivatives introducing radical subtituents, which are depicted in Fig. 3. First, since guanine and adenine are known to be damaged easily upon oxidation, benzene has been introduced into them according to Saito' s studies [52]. The radical substituents have been nitroxides that are rather stable radical groups.

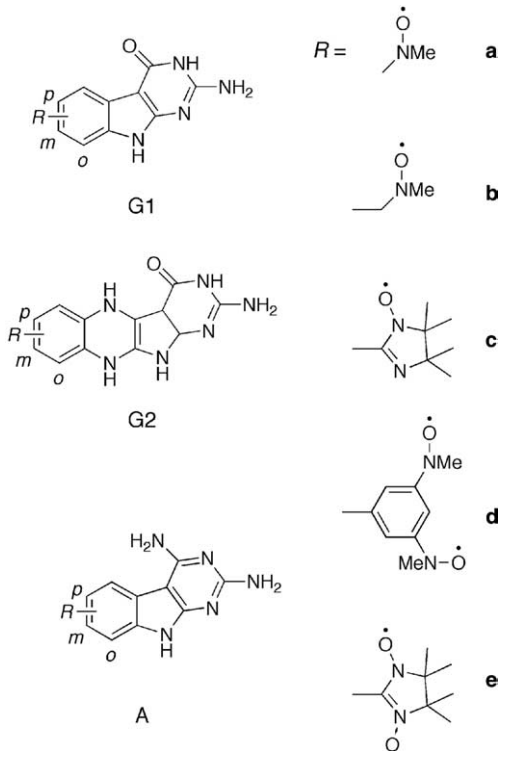

Fig. 3. Molecular structures for guanine and adenine derivatives.

Derivatives ${}_m\mathrm{G1}_a$, ${}_p\mathrm{G1}_a$, ${}_m\mathrm{A1}_a$ and ${}_p\mathrm{A1}_a$ (where the suffices distinguish positions substituted by radical groups) are the simplest models of our magnetic modifications. G2 have dihydrophenazine-like structure that enhances its performance as an electronic donor. ${}_{op}\mathrm{G1}_{aa}$ and $\mathrm{G1}_d$ have the radical group regarded as an almost $S = 1$ spin-site, so that spin moment remains when doped a hole whichever the intramolecular magnetic interaction is ferro or antiferro. $\mathrm{G1}_c$ and $\mathrm{G1}_e$ have iminonitroxide and nitronylnitroxide radicals that are well-known stable radicals. $\mathrm{G1}_b$ is a expansion of $\mathrm{G1}_a$ with methyl group inserted between G1 and the radical. The methyl radical is expected to reduce the intramolecular magnetic interaction.

For the models above, the intramolecular magnetic interactions have been evaluated with hole-doping as well as ionization potentials. These models have been geometry-optimized by using the energy gradient technique based on UB3LYP/6-31G* in the neutral doublet states.

4.3. IP and Js for the models

Summarized in Table 1 are ionization potentials (IP) and intramolecular effective exchange integrals for the guanine and adenine derivatives. IPs are within the energy of ultraviolet (UV). Comparing ${}_m\mathrm{G1}_a$ and ${}_p\mathrm{G1}_a$ (also ${}_m\mathrm{G2}_a$, and ${}_p\mathrm{G2}_a$), IPs are smaller for the *m*-subustituted ones. This is because intramolecular CT occurs more easily for ${}_m\mathrm{G1}_a$ (${}_m\mathrm{G2}_a$) than ${}_p\mathrm{G1}_a$ (${}_p\mathrm{G2}_a$). On the other hand, no difference in IP were found for ${}_m\mathrm{A1}_a$

Table 1
Total energies (a.u.), total angular momentums and effective exchange integrals (cm^{-1}) for guanine and adenine derivatives with radical substituents

Num.	Code	IP/eV	J_1	J_2	J_3
1	${}_pG1_a$	6.316	−5910	−2955	−2905
2	${}_mG1_a$	6.198	−7175	−3588	−3710
3	${}_pA_a$	6.604	−7508	−3754	−3724
4	${}_mA_a$	6.607	−7686	−3843	−3845
5	${}_pG1_b$	6.776	−2370	−1185	−1671
6	${}_pG1_c$	6.722	−2031	−1016	−1386
7	${}_pG2_a$	5.530	−1864	−932	−1456
8	${}_mG2_b$	5.708	−632	−316	−534
9	${}_pG1_d$	6.451	−3542	−1771	−1343
10	${}_{op}G1_a$	6.296	−6074	−3037	−2093
11	${}_pG2_c$	5.710	263	132	260
12	${}_pG2_e$	5.355	285	142	287

and ${}_pA1_a$. The difference in G and A is due to the difference in the inductive effect of carboxyl and ammonia groups. G is negatively inductive, namely it tends to withdraw electrons on the purine site, but A is inclined to provide electrons.

All the models have very strong antiferromagnetic interactions in contrast to phenazine derivatives of the previous study [107,108]. In order to elucidate the origin of these strong antiferromagnetic interactions, we have performed the natural orbital (NO) analyses of the broken-symmetry UB3LYP solutions. Seeing DFT-NOs in Fig. 4(a), it is found that these strong interactions have been orbital overlap effect. Especially for $G1_a$ and $G1_b$, the unpaired electrons on the radical sites were drifted to G and A sites, respectively. In deed, their Mulliken charge densities are $G1^{+0.7}$–$R^{+0.3}$ for instance. Depending on the position of the radical groups, J varies by near 20%. It is found that this variation obeys the McConnell spin-polarization rule because these molecular structures were not far from planar. Since dihydrophenazine-frame of G2 stabilize cationic state of G-site as described above, the effect of orbital overlap reduced and the amplitude of J decreased. By employing stable

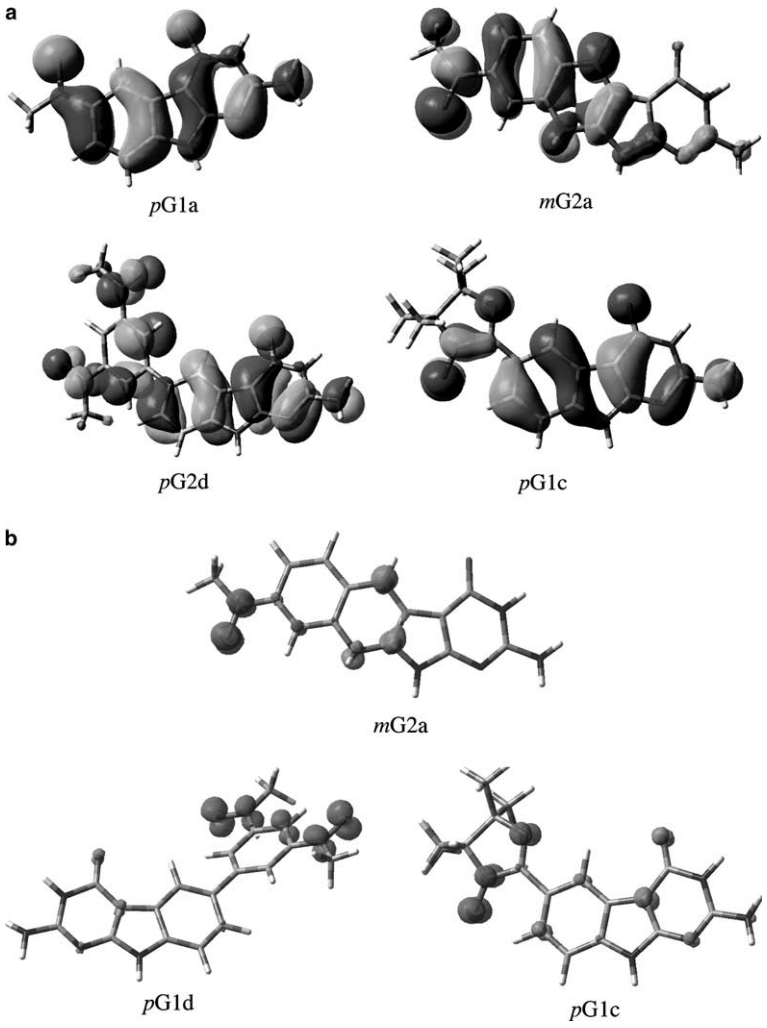

Fig. 4. Natural orbitals (a) and spin density distributions (b) for several guanine derivatives, the contour values of which are 0.0200 and 0.01, respectively.

radicals, antiferromagnetic interaction was weakened by 50% for $G1_c$ than for $G1_a$. By inserting methyl group, $G1_b$ also has 50%-weakened antiferromagnetic interaction than $G1_a$. For ${}_{op}G1_a$ and $G1_d$, ferromagnetic interaction between *N*-methyl nitroxide groups successfully remained and these almost $S = 1$ spin-site interact with G site that has totally $S = 1/2$ in the antiferromagnetic fashion.

Shown in Fig. 4 are spin densities for several models that have clearly spin-polarized ground states. Small spin density was delocalized to guanine site for $G2_a$, which shows intramolecular magnetic interaction is controlled by the delocalization effect. On the other hand, it is found that density of the up- and down-spins distributed alternately along the bonds for ${}_{op}G1_a$ and $G2_d$. Also it is found that spin-polarization is weaker for ${}_{op}G1_a$ than for $G1_d$, which is due to the difference in the way the radicals added. The radicals of ${}_{op}G1_a$ is introduced directly into the protected-G site with the benzene ring, while that of $G1_d$ is separated from the G site by the aryl.

For $G1_c$ and $G2_e$ that are G2 with stable neutral radical, intermolecular ferromagnetic interactions were successfully obtained. It is obvious that large HOMO-(donor)–LUMO(acceptor) gap is needed in deriving the Kondo model for such as G and A derivatives. Success of G2 is arise from its phenazine-like structure.

These models showed strong or very strong intramolecular magnetic interactions when doped a hole. By inserting methyl group or substituting aromatically stable radial, however, the interaction reduces to be moderate value. Their IPs were as large as UV energy. Intermolecular magnetic interaction between G(A)–R through G(A) chain is to be determined in the next works. The following is, however, note worthy. The merit of DNA wires and chains is that using self-organization procedures of G–R sites can easily control these interactions.

5. Discussions and concluding remarks

5.1. Molecular solenoids

The synthesis of chiral magnets is a current topic in molecular magnetism. The DNA wire is one of the helical conducting polymers [10,109,110]. The DNA wire involving guanine site with organic radical in Fig. 1(a) may be paramagnetic before the hole doping in the FET configuration. By the way, after hole (carrier)-doping, moving electrons should entail the intrinsic magnetic field, which can induce the parallel arrangement of organic radical. Thus there is a theoretical possibility to obtain the electronic-field induced molecule-based ferromagnet, the molecular solenoid. In bitro condition we can have telomeric tetramer of guanine as shown in Fig. 1(c). So the tetramer of (G–R) may be formed in the condition: note that $(G–R)_4$ is formally isoelectronic to $(CuO)_4$. To our knowledge, there seems no experimental approach to molecular solenoid based on the DNA wires.

5.2. Organic Kondo and dense Kondo systems and organic ferrimagnets

The effective exchange interaction between doped hole (carrier spin) and localized spin on R is antiferromagnetic. Therefore, we may have organic Kondo and dense Kondo systems if appropriate DNA sheets are constructed like the copper oxide sheets in Fig. 1. To this end, cytosine group should be modified to accept one-electron from G–R group by introducing electron acceptor (A), likely $\{\uparrow R^{\bullet}–G^{\bullet+}(\downarrow)\cdots C–A^{-\bullet}(\uparrow)\}_n$. The organic dense Kondo system may become a precursor of superconductor via electron correlation (EC) effect.

The G site with R may exhibit hydrogen bonding interaction with C-like partner with electron acceptor (A). Therefore, we may construct organic CT complexes, (R–G)(C–A), which are near neutral and ionic transition. So the photo-switching type organic ferrimagnets $(R^{\bullet}–G)(C–A)\leftrightarrow(R^{\bullet}–G^{+\bullet})(C–A^{-\bullet})$ seem feasible if C–A partner is well selected.

5.3. Concluding remarks

Present theoretical results suggest several possibilities of DNA wires, sheets and related materials. One of the key points in our proposal is use of its helicity, together with self-organization. Then organic solenoid is a new target, in addition to conventional magnetic conductors based on the RKKY magnetism.

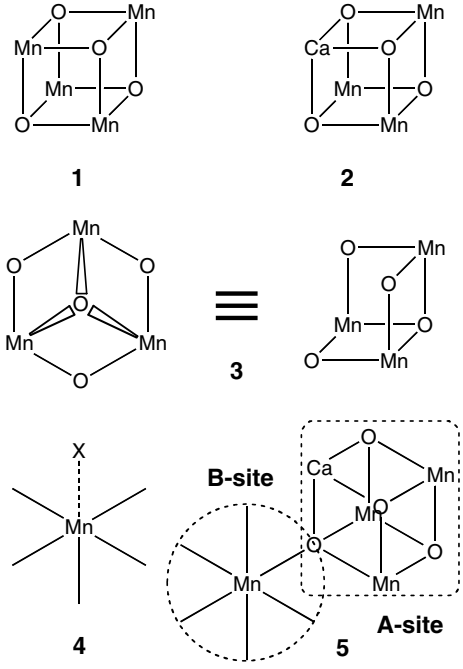

Fig. 2. Core structures of manganese clusters (**1**–**5**) in OEC of PS II.

already been published to elucidate them on the basis of accumulated results. Although cubane structure Mn_4O_4 (**1**) in Fig. 2 has been proposed in these reviews as an active site of OEC, **1** is largely different from cubane-like calcium manganese cluster $CaMn_3O_4$ (**2**) in Fig. 2. Therefore, possible reaction mechanisms of OEC based on **2** might be quite different from those on **1**. The Mn_2 dimer coupled model (so-called Klein model) [7,12,13] $(Mn_2O_2)O(Mn_2O_2)$ (**6**), is also different from **2** as shown in Fig. 3. The butterfly model (Mn_4O_2) (**7**) and cubane model (Mn_4O_3Cl) (**8**) by Hendrickson and Christou and their synthesized model complexes (**7**, **8**) have different molecular structures from **2** (see Fig. 3), though trinuclear Mn complexes Mn_3O and Mn_3O_4 (**3**) in Fig. 2 are used as precursors of **8** [14,15]. The spin frustration problem in distorted cubane $Mn(IV)Mn(III)_3$ is also discussed on the experimental ground [15].

Several theoretical studies on the Mn complexes have been carried out to elucidate the electronic structures of Mn OEC. The LCAO Xα calculation of the tetranuclear manganese complex $Mn(IV)Mn(III)_3Cl_7(O_2CCCH_3)_3]^{3-}$ (**9**), a cubane complex, has been carried out to elucidate its electronic and spin states in relation to the model cluster (**8**). The calculated high-spin ($S = 9/2$) ground state for **9** has been in agreement with the experiment [16]. Blomberg et al. [17] have performed a density functional theory (DFT) study on hydrogen abstraction from manganese-coordinated water by a tyrosyl radical ($Tyr_{Z^{\bullet}}$), proposing a radical mechanism for oxygen evolution

$$4Tyr_{Z^{\bullet}} + 2H_2O \rightarrow 4Tyr_Z + O_2 \quad (2)$$

However, several view points for possible roles of $Tyr_{Z^{\bullet}}$ have been presented on the experimental grounds [3–11].

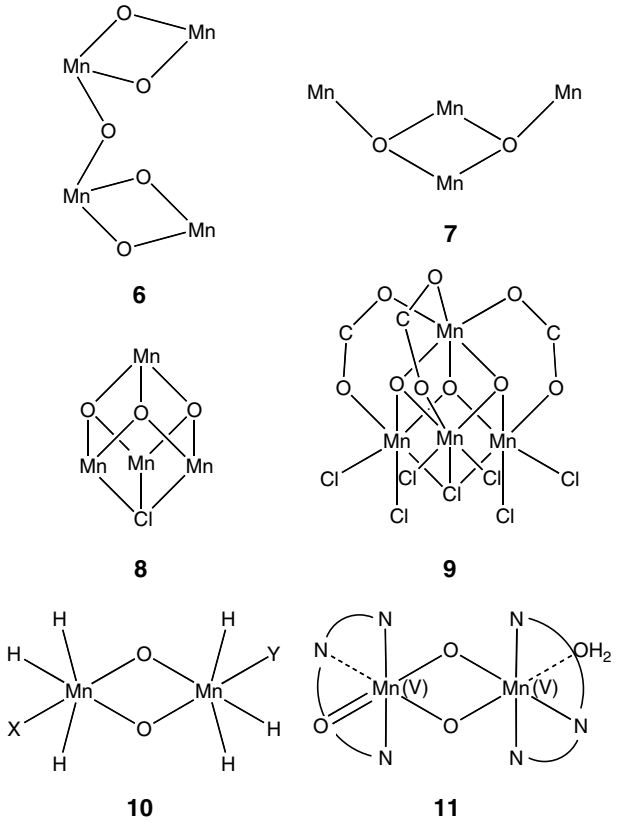

Fig. 3. Molecular structures of manganese model clusters (**6**–**11**) for OEC.

The X-ray structure by Ferreira et al. [1] have denied the possibility of the process in Eq. (2) for OEC. Belinskii [18] has carried out the theoretical studies on the mixed-valence $Mn(III)_3Mn(IV)$ and $Mn(IV)_3Mn(III)$ clusters on the basis of the quantum Heisenberg models, assuming trapezoid, butterfly, bent, T-type and distorted tetrahedron structures, which are different from **2** and **5**. Possible ground spin states for these five structures have been elucidated, changing effective exchange interactions between manganese ions.

We have examined possible spin structures of tetranuclear (**1**) [19] and trinuclear (**3**) [20] manganese clusters in Fig. 2 on the basis of the spin vector model [21]. The strong spin frustration [15] in **3** has provided non-collinear spin structures such as triangular spin structure in Fig. 4, on the assumption of the experimentally determined effective exchange integrals (J_{ij}). The J_{ij} values for the binuclear manganese complexes [22,23] have been calculated using the hybrid DFT method to elucidate the mechanisms for effective exchange interactions between Mn ions [24]

$$J_{ij} = \frac{^{LS}E(\mathbf{X}) - {}^{HS}E(\mathbf{X})}{^{HS}\langle\widehat{S}^2\rangle(\mathbf{X}) - {}^{LS}\langle\widehat{S}^2\rangle(\mathbf{X})}, \tag{3}$$

where $^{Y}E(\mathbf{X})$ and $^{Y}\langle\widehat{S}^2\rangle(\mathbf{X})$ are the total energy and total angular momentum for the state Y (=LS; the lowest spin state, HS; the highest spin state) by the method **X** (=UHF, UMPn, UDFT, etc.). It was shown that the sign

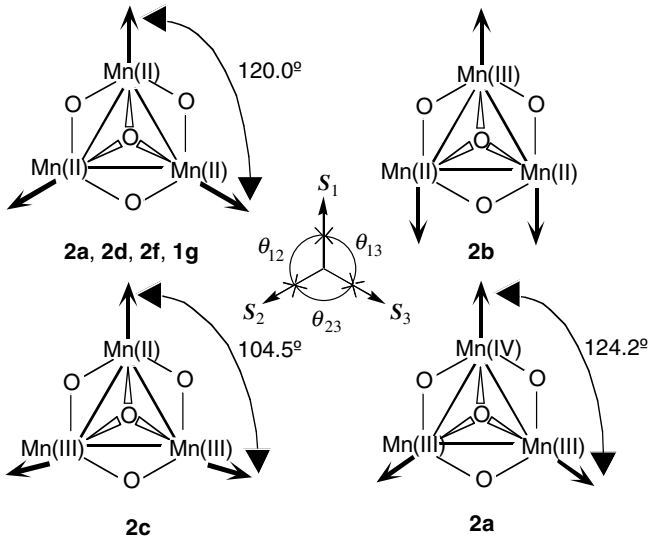

Fig. 4. Schematic illustrations of classical spin structures of the ground state of $CaMn_3O_4$ (**2**).

of J_{ij} is negative because of the greater stability of LS than HS, and the magnitude of J_{ij} values is variable with the oxidation numbers of Mn ion. The calculated J_{ij} values have been consistent with the experiments available. Very recently, Yamanaka et al. [25] have performed the DFT calculation of cubane-type $Mn(II)_4$ cluster (**1**) using the general spin orbitals (GSO), namely, two component spinor.

$$\varphi = \varphi^{+}\alpha + \varphi^{-}\beta, \tag{4}$$

where φ^{+} and φ^{-} denote the up- and down-spin components, respectively. The GSO-DFT calculation by the GSO-X program package [26] has exhibited the 3-dimensional (3D) T_d-type spin densities responsible for spin frustration. This is consistent with the conclusion by the spin vector model, namely, classical Heisenberg model [21]. The negative J_{ij}-value calculated for **1** by GSO DFT has been consistent with the experiment [25] that **1** has the LS ground state.

The variations of charge and spin populations of manganese oxo (MnO) bonds with the oxidation number of Mn ion were also examined by the UHF method. It was concluded that the nature of oxygen atom in the manganese oxo bond (X=O in **4**) varies from nucleophilic to electrophilic with the change of formal charge of Mn from low (II) to high (V) valent. The oxygen atom in the Mn(V)O core exhibited the radical character responsible for the radical reactivity for water [24,27].

As a first step toward theoretical approaches to water oxidation in OEC, Isobe et al. [27] have performed the DFT calculation of the model compound $XH_3Mn(IV)$-$O_2Mn(IV)H_3Y$ (X, Y = O, H) (**10**) for the Limburg compound $[(terpy)(H_2O)Mn(\mu\text{-}O)_2Mn(terpy)(H_2O)]^{3+}$ (**11**) [28] as shown in Fig. 3. It was found that electron correlation plays a crucial role to determine the nature of manganese–oxygen bonds in **8**. Diradical or nonradical

mechanism is found to be feasible for the oxygen atom transfer from water to high-valent manganese–oxo bond Mn(V)═O in **10**. The environmental effects such as solvent are considered to play an important role for control of the mechanism. As a continuation of previous work [24–27], we here perform theoretical studies on manganese clusters (**2**–**5**) in OEC. The electronic structures of these species are investigated from the view point of magnetic interactions. Implications of the calculated results are discussed in relation to possible mechanisms of oxygen evolution in OEC. Our previous [22–27] and present calculations conclude that Mn(V)═O (**4**) plays a crucial role in both native and artificial OEC systems.

2. Theoretical backgrounds and computational results

The construction of possible theoretical models for manganese clusters in OEC is a first step for understanding the mechanism of water oxidation in PS II. Here, we assume that the trinuclear manganese cluster (**3**) in Fig. 2 plays an important role as the electron buffer (pool) group, whereas the mono-nuclear manganese ion (**4**) and calcium ion in **2** are reaction sites for oxygen evolution in OEC. Then, we here investigate two fragments **2** and **4** in the composite cluster **5** in Fig. 2. As previously [20,21], both classical and quantum Heisenberg models are first applied to **2** and **5**. Next, the GSO Hartree–Fock (HF) calculation of **2** is conducted to confirm theoretical conclusions by the HB models. In this paper, we do not touch important roles of photo-excitation of P680 and related proton-electron transfer reactions via tyrosine to control of oxidation states of **5** [3–11].

2.1. Heisenberg model for 2

Possible spin structures of **2**, which is referred to as the A-site of **5**, are investigated by both classical and quantum HB models. Since calcium ion (Ca^{2+}) is non-magnetic, the HB Hamiltonian of **2** is equivalent to that of trinuclear manganese cluster (**3**) [20] in Fig. 2 as

$$H_A = -2J_{12}\boldsymbol{S}_1\cdot\boldsymbol{S}_2 - 2J_{23}\boldsymbol{S}_2\cdot\boldsymbol{S}_3 - 2J_{31}\boldsymbol{S}_3\cdot\boldsymbol{S}_1, \quad (5)$$

where J_{ij} is the effective exchange integral between manganese ions i and j, and $\boldsymbol{S}_i$ denotes the spin operator for manganese ion i. According to our previous hybrid DFT results for binuclear manganese complexes [22,23], the J_{ij} values of Mn(X)–Mn(Y) pairs are simply assumed to be −1, −50, −100, −150 and −200 (cm^{-1}) for Mn(II)–Mn(II), Mn(II)–Mn(III), Mn(III)–Mn(III), Mn(III)–Mn(IV) and Mn(IV)–Mn(IV), respectively. These assumed values are also consistent with the observations [7–11].

If spin operators in Eq. (5) are regarded as classical spin vectors, the Heisenberg Hamiltonian in Eq. (5) is converted as

$$H_A^C = -2J_{12}S_1S_2\cos\theta_{12} - 2J_{23}S_2S_3\cos\theta_{23} - 2J_{31}S_3S_1\cos\theta_{31}, \quad (6)$$

where θ_{ij} is the angle between spin vectors i and j as illustrated in Fig. 4. The sizes (S_i) of spins are taken to be 5/2, 4/2, 3/2 and 2/2 for Mn(II), Mn(III), Mn(IV) and Mn(V), respectively, assuming the high spin state of each manganese ion. The spin structures of **2** by the classical HB model are summarized in Table 1. The ground spin structures of **2** are triangular ($\theta_{12}=\theta_{13}=120°$) and/or noncollinear ($\theta_{12}$, $\theta_{13}\neq 0°$ (parallel) or 180° (antiparallel)) except for **2b** as shown in Fig. 4. Thus, the spin frustration effects are very important for the low-spin (LS) states of **2** like **3**. This implies that the low-spin ground states of **2** are not available by the conventional DFT model which can describe parallel or antiparallel (axial) spin alignments like **2b**. It is noteworthy that the S_z component of $\boldsymbol{S}_2$ and $\boldsymbol{S}_3$ is −2/2 instead of −4/4 in **2a** as illustrated in Fig. 4, and total S_z becomes zero ($S_z=(4-2-2)/2=0$) (see also Fig. 6 below). On the other hand, the S_x component is $+(-)2\sqrt{3}/2$ for $\boldsymbol{S}_2$ ($\boldsymbol{S}_3$) and total S_x becomes also zero. In order to obtain the S_x component, general spin orbitals (GSO) given by Eq. (4) are essential in the case of molecular orbital calculations as shown previously [20,25,26]. The noncollinear spin structure is nothing but the classical presentation of singlet-type spin correlation, $K=\langle\boldsymbol{S}_i\cdot\boldsymbol{S}_j\rangle<0$, between Mn spins [20].

Since the classical HB model predicts the noncollinear spin structures, the exact diagonalization of the quantum HB Hamiltonian given by Eq (5) is desirable to elucidate the ground spin states of **2**. For example, Fig. 5 shows the energy levels calculated for trinuclear manganese cluster Mn(II)Mn(III)$_2$ (**2c**) by the exact diagonalization method. The ground (G) and first-excited (FE) states are quintet ($S_A(G)=3/2$) and doublet ($S_A(FE)=1/2$), respectively. It is noteworthy that axial spin vector model (**2c$_a$**) in Fig. 6 predicts the higher spin state: $S=(4+4-5)/2=3/2$. However, the local spin structure between $\boldsymbol{S}_2$ and $\boldsymbol{S}_3$ is ferromagnetic (F) in **2c$_a$** like **2b**, though all the spin pairs are antiferromagnetic (AF) in the case of **2c** as illustrated in Fig. 6. The discrimination between **2c$_a$** and **2c** by spectroscopic methods is an interesting problem. The ground and first excited states of **2** by the method are summarized in Table 1. The low-spin states become the ground states of **2** except for **2b**, for which the axial spin vector model is

Table 1
Spin structures of manganese clusters ($CaMn_3O_4$) by classical and quantum Heisenberg models

Type	Valence[a]	$S_A(G)$[b]	$S_A(FE)$[b]	Spin structure
2a	(II, II, II)	1/2	3/2	Triangular ($\theta_{12}=\theta_{13}=120°$)
2b	(II, II, III)	6/2	4/2	Axial ($\theta_{12}=\theta_{13}=180°$)
2c	(II, III, III)	3/2	1/2	Helical ($\theta_{12}=\theta_{13}=104.5°$)
2d	(III, III, III)	0/2	2/2	Triangular ($\theta_{12}=\theta_{13}=120°$)

applicable: $S_A(G) = (5 + 5 - 4)/2 = 6/2$. The relatively low-spin (LS) ground states of **2** are consistent with the ESR experiments for the native manganese clusters in OEC [3–11], though synthetic model clusters often have the relatively high-spin (HS) ground states such as $S = 9/2$ for **9** [14,15].

2.2. Heisenberg model for 5

Here, we have employed the cyclic trinuclear (A)–mononuclear (B) Mn_4 model for **5** to elucidate its spin structure. The total spin Hamiltonian H_T for **5** composed of **2** and **4** are therefore given by

$$H_T = -2J_{AB}\boldsymbol{S}_A \cdot \boldsymbol{S}_B, \tag{7}$$

where $\boldsymbol{S}_A$ denotes the total spin operator of the cluster **2** (A-site): $\boldsymbol{S}_A = \boldsymbol{S}_1 + \boldsymbol{S}_2 + \boldsymbol{S}_3$, and $\boldsymbol{S}_B$ is the spin operator for the manganese ion **4** (B-site) in Fig. 2. Here, we assume the antiferromagnetic exchange interaction ($J_{AB} < 0$) between A and B sites. The oxidation states of **4** are changed from Mn(II) ($S_B = 5/2$) to Mn(V) ($S_B = 2/2$) through Mn(III) ($S_B = 4/2$) and Mn(IV) ($S_B = 3/2$). Both classical

Table 2
Spin states of total manganese clusters ($CaMn_4O_4$) by Heisenberg model

Type	A	S_A(G)	S_{A+B}(G)[a]				Spin structure
			(S_B)[b]	5/2	4/2	3/2	2/2	
5a	**2a**, **2e**, **2g**	1/2		0/2	1/2	0/2	1/2	Helical
5b	**2b**	6/2		(1/2)	(2/2)	(3/2)	(4/2)	Axial[c]
5c	**2c**	3/2		0/2	1/2	0/2	1/2	Helical

[a] Spin quantum number of the total manganese clusters (A + B). The ground spin structure by the axial spin model is given in the parentheses.
[b] Variations of valence states of the B-site (Mn (X); X = II, III, IV and V).
[c] Axial spin structure is the ground state.

and quantum HB models are applied to **5**. The ground spin states and spin structures of **5** are summarized in Table 2. The low-spin (LS) states such as singlet ($S_{A+B} = 0/2$) and doublet ($S_{A+B} = 1/2$) are predicted by the quantum HB model, though relatively high-spin (HS) states become the ground states by the axial spin vector model as shown in parentheses in Table 2. On the other hand, the LS states of **5** are expressed by the noncollinear spin structures **12** and **13** under the general spin vector model as shown in Fig. 6, in accord with our previous work [20].

The above conclusions are derived from the isotropic spin Hamiltonian in Eq. (7). The ESR experiments have shown that the anisotropic terms (see Eq. (10) below) are not negligible for the Mn oxide clusters [7]. This implies that the Ising model is also worthy of consideration for **5**. The low-spin states of **5** can be constructed by using the axial spin vector models where $\theta_{ij} = 0°$ or 180° in Eq. (6). We assume that the oxidation state of Mn at the B-site is variable from divalent (II) to pentavalent (V), and each manganese ions in A and B sites are high-spin. Table 3 summarizes possible spin states of **5**, which are obtained by the spin coupling between A and B sites. The total singlet and doublet spin-coupled states are feasible by appropriate combinations of axial spins (see for example **14** and **15** in Fig. 6). Then these are also candidates of $\mathbf{S}_i$ sites in OEC. However, it is noteworthy that the local HS (parallel) couplings appear in **14** and **15** in contrast to **12** and **13** where all the spin couplings are antiparallel (LS).

2.3. GSO-HF calculations

In order to confirm the preceding results by the HB model, the generalized Hartree–Fock calculations [22] by the use of general spin orbitals (GSO) in Eq. (4) are performed for the simplest model **2a**, namely, $CaMn(II)_3O_4$ cluster. The MIDI basis sets for M, O and Ca by Tatewaki and Hujinaga [29] have been used for GSO HF calculations. The X-ray structure [1] for **2** in **5** of OEC in PS II is used even for **2a** in the ab initio GSO calculation. Fig. 7 shows the molecular structure, Löwdin charge density, spin density and 3D plot of spin density of **2a** by GSO-HF. The Mn–O bond lengths of the $Mn_1Mn_2Mn_3O_8$ core are short (~1.8 Å), showing the strong bonding nature. While the Ca–O bond lengths of $CaO_5O_6O_7$ core are relatively long (~2.5 Å). The Mn–O bond lengths of the $Mn_2Mn_3Mn_BO_6$ core are about 1.9 Å. The charge density of O_5 and O_6 is about −0.81, and it is 0.71 for Mn_2. The charge and spin populations are unsymmetrical because of the distorted cubane structure. The 3D plot of spin density shows the triangular spin structure, in accord with the classical HB model. Judging from the results in Table 1, similar results are also expected for other oxidation states of **2**, together with **5**. The magnitude of local spin ($S = 5/2$) of Mn(II) ion is largely quenched by the anti-ferromagnetic exchange couplings in **2**(**3**) in the LS state. However, the naked cluster (**2a**) is too simple to discuss chemical reactivity of **5**. Effects of ligand coordination and other environmental effects should be examined for further discussions. For example, axial spin states in Table 3 are obtained by the spin-unrestricted HF (UHF) method based on the different-orbitals-for-different-spins (DODS) approximation. Detailed results of the GSO-HF, UHF and UDFT calculations will be published elsewhere.

Table 3
Spin structures of **5** obtained by the axial spin vector model

5i	**2g**	2/2	1/2	0/2	1/2

3. Possible mechanisms of oxygen evolution

3.1. Possible electronic structures of OEC

The HB and GSO-HF calculations have provided the ground spin structures of **2** and **5** as summarized in Tables 1–3. These theoretical results are utilized to elucidate possible electronic structures of the OEC complex in PS II, in combination with available experimental results [3–11]. As shown in Fig. 1, there are six carboxyl anion ligands and four oxygen dianion around the Mn_4Ca core (**2**) in OEC. Therefore, the formal charges of the active sites are −1, 0 and 1 for the [Ca(II)Mn(III)$_3$Mn(II)], [Ca(II)Mn(III)$_4$] and [Ca(II)Mn(IV)$_2$Mn(III)] cores, respectively. Experimentally, the first and third cores have been regarded as the zeroth step ($\mathbf{S}_0$) of the water-oxidation cycle in Scheme 1. On the other hand, the second core with the neutral charge is responsible for the S_1 stage. However, if chloride anion is participated even in the S_0 state, the [Ca(II)Mn(IV)$_2$Mn(III)Mn(II)Cl] core becomes neutral. Therefore, we have two different starting oxidation states; [Ca(II)Mn(III)$_3$Mn(II)] and [Ca(II)Mn(IV)$_2$Mn(III), Mn(II)], for the S_0-state. The key point is that the Mn ion at the B-site is divalent in both starting points. Both noncollinear and collinear (axial) spin vector models are feasible for **5** from Tables 1–3. The former model provides

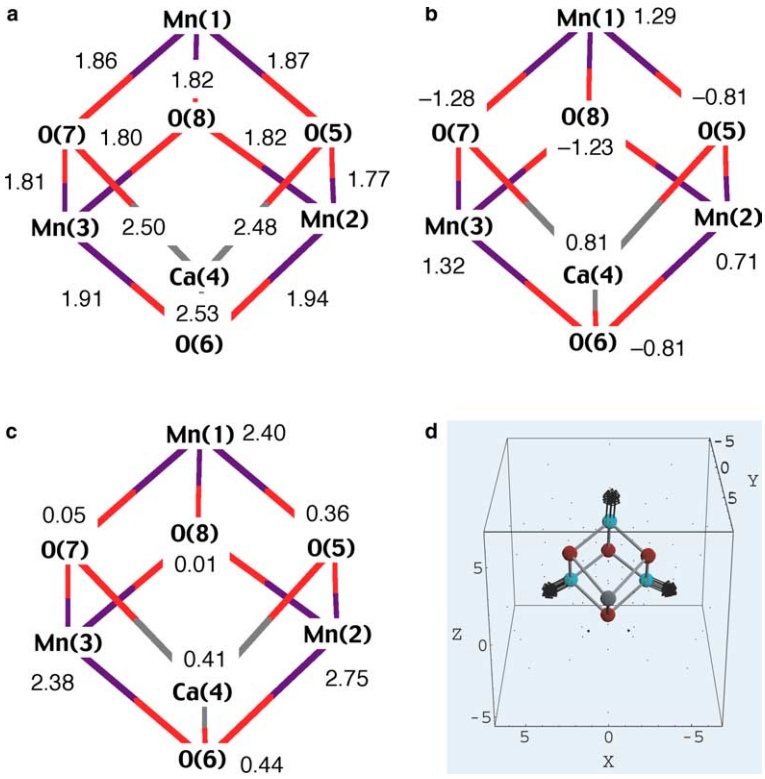

Fig. 7. Molecular structure, Löwdin charge and spin densities and 3D plots of spin density of $CaMn(II)_3O_4$ (**2a**) by GSO-HF.

Table 4
Possible electronic and spin structures of manganese calcium clusters ($CaMn_4O_4$) by noncollinear spin vector models

Type	A ($S^z_A(\mathbf{G})$)	B($S^z_B(\mathbf{G})$)	A + B ($S^z_{A+B}(\mathbf{G})$)
S_0	$CaMn_3$(III, III, III) (0/2)	Mn(II) (1/2)	$CaMn_4$(III, III, III, II) (1/2)
S_1	$CaMn_3$(III, III, III) (0/2)	Mn(III) (0/2)	$CaMn_4$(III, III, III, III) (0/2)
S_2	$CaMn_3$(III, III, IV) (1/2)	Mn(III) (0/2)	$CaMn_4$(III, III, IV, III) (1/2)
S_3	$CaMn_3$(III, III, IV) (1/2)	Mn(IV) (1/2)	$CaMn_4$(III, III, IV, IV) (0/2)
S_{4a}	$CaMn_3$(III, IV, IV) (0/2)	Mn(IV) (1/2)	$CaMn_4$(III, IV, IV, IV) (1/2)

S_{4c}	$CaMn_3$(III, III, IV) (1/2)	Mn(V) (0/2)	$CaMn_4$(III, III, IV, V) (1/2)

the distorted T_d-like spin structure **12** ($S_z = 0$) for the S_0, S_2 and S_4-stages and **13** ($S_z = 1/2$) for the S_1 and S_3-stages, respectively. All the spin coupling pairs are antiferromagnetic in these structures, in conformity with antiferromagnetic exchange interactions. On the other hand, the axial spin vector model concludes the axial spin structure **14** for the S_0, S_1, S_3 and S_{4c} stages and **15** for the S_2, S_{4a}, S_{4b} and S_{4d} stages, respectively. The electronic and spin structures of **5** by these analyses are summarized in Tables 4 and 5.

The so-called S_2-state of **5** is predicted to be doublet ($S_{A+B}(G) = 1/2$), in accord with the ESR experiment [12], while the higher spin state ($S_{A+B} = 5/2$ or 3/2) often assumed for the so-called multiline spectra is the excited

Table 5
Possible electronic and spin structures of manganese calcium clusters ($CaMn_4O_4$) by the axial spin vector models

State	(S_1, S_2, S_3, S_B)	(S_{A+B})
S_0	(−4/2, 4/2, −4/2, 5/2)	(1/2)
	(−3/2, 3/2, −4/2, 5/2)	(1/2)
S_1	(−4/2, 4/2, −4/2, 4/2)	(0/2)
	(−3/2, 3/2, −4/2, 4/2)	(0/2)
S_2	(4/2, −4/2, 4/2, −3/2)	(1/2)
	(3/2, −3/2, 4/2, −3/2)	(1/2)
S_3	(−4/2, 4/2, −3/2, 3/2)	(0/2)
	(−3/2, 3/2, −3/2, 3/2)	(0/2)
S_{4a}	(4/2, −3/2, 3/2, −3/2)	(1/2)
S_{4b}	(4/2, −4/2, 3/2, −2/2)	(1/2)
S_{4c}	(−3/2, 3/2, −3/2, 4/2)	(1/2)
S_{4d}	(3/2, −3/2, 3/2, −2/2)	(1/2)

state. These conclusions are independent on the starting oxidation states, together with the collinear and noncollinear spin models (see Tables 4 and 5). The S_0-state is predicted to be doublet, being consistent with the ESR experiment [30]. On the other hand, the S_1- and S_3-states are singlet in our model calculations. Experimentally, the thermally excited triplet state can be detected for both states [31,32]. The observed singlet–triplet energy gaps are 1.5 and 2.5 K for the S_1- [31] and S_3-[32] states, respectively. Our theoretical results are in consistent with the experiments [3–11]. Three possible electronic structures are concluded for the final state S_4 in the Kok cycle (see Scheme 1) [2] as shown in Tables 4 and 5 if the S_0 state is assumed to be [Ca(II)Mn(III)$_3$Mn(II)]. On the other hand, the S_{4d} structure is available from the other starting S_0 state. These are closely related to the mechanisms of water oxidation in OEC as discussed below.

3.2. A new mechanism for oxygen evolution

The computational results in Tables 4 and 5 enable us to propose a possible mechanism of oxygen evolution in the OEC system as illustrated in Fig. 8. The manganese ion at the B-site in the S_0-state is divalent (Mn(II)), while the A-site is regarded as the Mn(III)$_3$ or Mn(III)Mn(II)$_2$ cluster. The B-site becomes trivalent, Mn(III), followed by the coordination of OH anion in the S_1-state. This is consistent with various experiments. However, we cannot touch the mechanism of photo-induced proton and electron transfers in P680 and related species (see Scheme 1). The electron buffer group (A-site) is further one-electron oxidized in the S_2-state. The Mn(IV) ion close to histidine (His) (see Fig. 1) may extract one electron from His, to afford Mn(III)$_3$ His$^{+\cdot}$ or Mn(III)Mn(IV)$_3$ His$^{+\cdot}$. In fact, this possibility has been proposed on the experimental ground [3–11]. The manganese ion in the B-site is oxidized to be tetravalent, Mn(IV), in the S_3-state. Therefore, chloride anion would play an important role to suppress the reactivity of Mn(IV) in the B-site, which may extract one electron from surrounding coordination ligands (L) in Fig. 1

$$\mathrm{Mn(IV)} + \mathrm{L} \rightarrow \mathrm{Mn(III)L^{+\cdot}} \quad (8a)$$

$$\mathrm{ClMn(IV)} + \mathrm{L} \rightarrow \mathrm{ClMn(III)L^{+\cdot}} \quad (8b)$$

This is also compatible with available experiments [3–11]. However, we cannot explain the tyrosyl radical mechanism in Eq. (2) discussed by Blomberg et al. [17]. The X-ray results by Ferreira et al. [1] is not consistent with their proposal. Detailed theoretical and experimental studies are necessary for further discussion on the role of tyrosyl radical in OEC.

Experimentally, the electronic structure of the final state S_4 is unknown because of very short lifetime. Theoretically, three possible electronic structures are conceivable as shown in Tables 4 and 5, and Fig. 8 if the initial state of S_0 is regarded as Mn(III)$_3$Mn(II). While, only S_{4d} state, Mn(IV)$_3$Mn(V), in Table 5 is available if

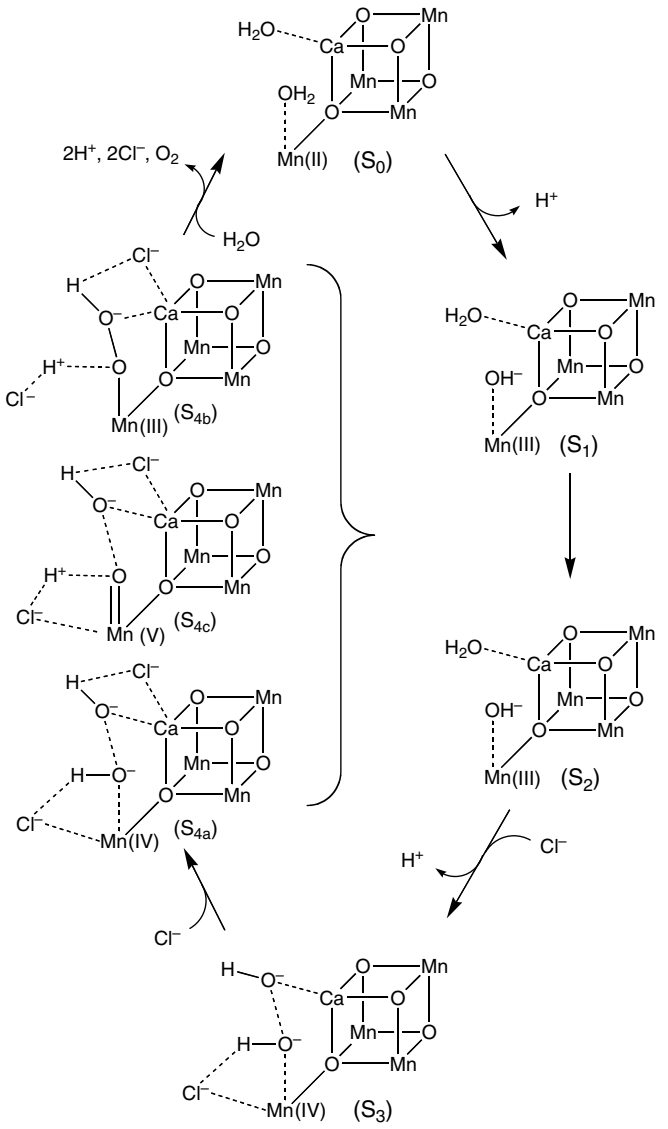

Fig. 8. Schematic illustration of possible mechanisms of oxygen evolution in the OEC system.

S_0 is considered to be Mn(IV)$_2$Mn(III)Mn(II). The dioxygen bridge $(OH^-)_2$ may be formed between the Mn(IV) and Ca(II) ions in the S_{4a} model, where chloride anions play an important role for stabilization of the reaction site. The manganese oxo Mn(V)=O bond may be formed if the deprotonation of hydroxide anion is induced by the participation of chloride anion in the S_{4c} state in Table 4 and S_{4d} state in Table 5. Our previous ab initio calculations [24] have indicated that the high-valent manganese oxo Mn(V)=O bond in S_{4c} exhibits electrophilic behavior [27]. Then it can undergo the electrophilic addition with the other hydroxide anion to generate the hydroperoxide anion inserted between Mn(V) and Ca(II) ions in the S_{4b} state. The chloride anion-assisted deprotonation of HOO^- may generate molecular oxygen–manganese complex Mn(II)O_2, which can evolve O_2 at the final stage of water oxidation in OEC: $S_4 \rightarrow S_0$ as illustrated in Fig. 8.

The key point of our proposal is the participation of calcium ion [33] for formation of the oxygen–oxygen bridge with the manganese ion, which is a crucial step for the O_2 evolution.

3.3. Importance of the Mn(V)=O bond

Past two decades [23–27,34], Yamaguchi et al. elucidated electronic structures and spin states of transition-metal oxides on the basis of ab initio broken-symmetry (BS) (UHF UDFT, GHF and GDFT) calculations followed by the approximate spin projection. It was found that the oxygen atom in the metal-oxo species MO (M = Cr, Mn, Fe) exhibits the nucleophilic character M^+O^- in the case of the lower-valent stage of M^+; M(II) and Mn(III). For example, the Mn(III) ion forms an ionic bond with hydroxide anion, $[Mn(III)–OH]^{2+}$, as shown in Fig. 8. On the other hand, the oxygen atom in the high-valent metal-oxo species such as Mn(V)=O may have singlet or triplet oxygen atom (O) character, showing an electrophilic property to many substrates, for example:

$$Mn(V) = O + {}^{-}OH \rightarrow Mn(IV) - OOH \quad (9a)$$

$$Mn(V) = O + H\text{-}OH \rightarrow Mn(IV) - OH + {}^{\bullet}OH \quad (9b)$$

$$Mn(V) = O + H\text{-}OH \rightarrow Mn(III) + HOOH \quad (9c)$$

The reaction (9a) may be operative in the S_{4b} stage in Scheme 1 to generate the O–O bond. The hydrogen abstraction from water by Mn(V)=O is also conceivable from our theoretical view point.

Isobe et al. [27] have performed the DFT calculations of the model compound (**10**) for the Limburg compound (**11**). They have found that the metal–oxo bonds (Mn(V)=O) in **10** show the diradical character ·Mn–O·, and therefore the oxygen atom in Mn(V)=O in **11** may undergo electrophilic reactions with substrates in Eq. (9). Several evidence [30] suggest that chloride anion plays an important role for oxygen evolution in Limburg reaction systems like native OEC in Fig. 8.

Koizumi et al. [35] have carried out the DFT calculations of dimer of manganese-oxo (MnO) porphyrin (PO) synthesized and characterized by Naruta's group [36]. They have investigated variations of the electronic structures of POMn(X)=O with the change of oxidation number (X) of the Mn ion. It was found that the Mn(V)=O bond in Naruta's oxygen evolution system has the oxygen-diradical character, which may entail the oxygen-atom radical coupling as follows:

$$(POMn(V) = O)_2 \rightarrow POMn(IV)–O–O–Mn(IV)PO \rightarrow (POMn(III))_2 + O_2 \quad (9d)$$

Thus, our theoretical studies on native OEC and artificial OEC [27,28] systems have revealed the crucial role of the high-valent Mn(V)=O bonds as illustrated in Fig. 9. Further theoretical studies on Mn(X)=O in many manganese complexes are interesting for rational design of effective catalysts for oxygen evolution from water.

4. Discussion and concluding remarks

4.1. ESR experiments

There are many ESR studies on manganese oxide clusters [37–41] and tyrosyl radical in OEC. In addition to the Heisenberg Hamitonians in Eqs. (5) and (7), several terms must be included for analysis of the ESR spectra

$$H_{\text{total}} = H_{\text{exch}} + H_0, \quad (10a)$$

where

$$H_{\text{exch}} = -2\sum J_{ij}\boldsymbol{S}_i \cdot \boldsymbol{S}_j, \quad (10b)$$

$$H_0 = \sum \beta \boldsymbol{S}_i \cdot \boldsymbol{g}_j \cdot \boldsymbol{H}_0 + \sum \boldsymbol{S}_i \cdot \boldsymbol{A}_i \cdot \boldsymbol{I}_i + \sum \boldsymbol{S}_i \cdot \boldsymbol{D}_i \cdot \boldsymbol{S}_i + \sum \boldsymbol{S}_i \cdot \boldsymbol{D}_{ij} \cdot \boldsymbol{S}_j. \quad (10c)$$

The first to fourth terms in Eq. (10c) denote the Zeeman, hyperfine, anisotropic and dipole–dipole interactions, respectively. Recently, theoretical calculations of the anisotropic [42,43] and dipole–dipole [44] terms have been performed on the basis of the DFT and hybrid DFT schems. The spin Hamiltonian in Eq. (10c) may be reduced to the following Hamiltonian

$$H_0 = g\beta \boldsymbol{H}_0 \cdot \boldsymbol{S}_{A+B} + A\boldsymbol{I} \cdot \boldsymbol{S}_{A+B} + D[S_z^2 - S_{A+B}(S_{A+B}+1)] + E[S_x^2 - S_y^2], \quad (11)$$

where D and E represent the axial and rhombic zero-field splitting parameters, respectively [42,43].

Goodson et al [45] have reported that the effective exchange integrals in Eq. (10b) are -87, $-140 \sim -151$ and $-87 \sim -144\ \text{cm}^{-1}$ for the $Mn(III)O_2Mn(III)$, $Mn(III)O_2Mn(IV)$ and $Mn(IV)O_2Mn(IV)$ clusters. Our calculated results [22,23] are consistent with these observed values. These parameters are also parallel to those in this paper. The ESR experiments [37–41] have revealed the hyperfine terms in Eq (10c). However, detailed discussions on them are out of concern in this paper. They are calculated in our other papers.

4.2. Relations to other theories

Very recently [46], Lundberg and Siegbahn have performed the UB3LYP calculations of the low-spin (LS) and high-spin (HS) states of the $Mn(IV)_3Mn(III)$ model complex for OEC. It was found that the total energy of the LS state with axial spin structure (**14** or **15** in Fig. 6) is 17 kcal/mol higher than the HS state with parallel spin structure (**16** in Fig. 6), strongly indicating that the HS state is the ground state of the cubane-type structure of the tetranuclear Mn complex. Although the artificial complex (**9**) is certainly high-spin [14,15], the native Mn core of OEC is doublet or singlet by the EPR experiments [31,32]. Our GSO DFT calculations of **1** [25] and **2** indicate that the LS state is more stable than the HS state. Generally, the spin densities of the II, III, IV and V oxidation states of Mn ions in the HS state are about 5, 4, 3 and 2, respectively, and the spin density of oxygen sites is often −1 because of the very strong spin polarization effect by the Mn ions. The UB3LYP results of the HS states by Lundberg and Siegbahn [46] are consistent with this general tendency. On the other hand, the spin densities of the Mn(X) ions become largely reduced in the LS state by GSO DFT as illustrated in Fig. 7. The spin densities on the oxygen atoms are positive (see Fig. 7(c)), showing the spin delocalization effect. This implies that nonradical electrophilic reaction of the high-valent Mn(V)=O with water [27] is feasible in the LS state instead of the radical reaction in the HS state [46]. Further theoretical investigations of the transition structures by GSO DFT are necessary for elucidation the mechanism of oxygen evolution in OEC [47,48].

4.3. Concluding remarks

Theoretical studies on the electronic and spin structures of manganese clusters, **1**, **2**, **3**, **4** and **5**, in Fig. 2 have been carried out on the basis of the Heisenberg models followed by the ab initio molecular orbital calculation by the use of general spin orbitals (GSO). The computational results, together with available experiments, enable us to confirm a high-valent manganese-oxo (Mn(V)=O) model [27,35] for oxygen evolution from water in OEC of PS II as illustrated in Fig. 9. This model is consistent with the present theoretical studies on the basis of recently presented X-ray structure of OEC [1], together with previous theoretical results [24,27,35] for model complexes by Limburg [28] and Naruta [36]. It is also in agreement with the Mn(V)-oxo model for oxygen evolution in OEC by Baber and Iwata [47,48] proposed on the experimental grounds. However, detailed theoretical studies on the surrounding coordination sphere are necessary for further refinements of the model.

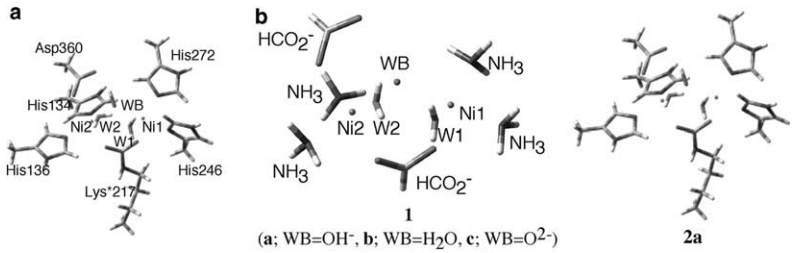

Fig. 1. (a) X-ray crystal structure of active site in *K. aerogenus* (PDB code: 1FWJ) and (b) small model of active site. Model **1a** (WB = OH^-) is depicted here. Realistic model of active site of OH^- bridge model (**2a**).

magnetic coupling between Ni ions. Three possibilities of bridging WB, i.e., H_2O, OH^- and O^{2-} were examined by calculations of their J_{ab} values using the unrestricted hybrid density functional theory (UHDFT) method. First, we constructed the simplest model as illustrated in Fig. 1(b). Next, we carried out theoretical calculations using more realistic models and larger basis sets to obtain more reliable results. Natural orbitals and their occupation numbers were analyzed to explain the antiferromagnetic interactions and elucidate the character of the active site of urease. From the results, we discussed the chemical species of WB. Finally, we proposed one of the theoretical approaches for the active sites of metalloproteins in terms of magnetic interactions.

2. Theoretical background

2.1. Effective exchange integrals (J_{ab})

The magnetic properties of transition metal complexes were usually investigated by the use of the Heisenberg–Dirac–van Vleck spin Hamiltonian. For example, the effective exchange interaction between localized spins in binuclear transition metal complexes is described by the total spin form of the spin-coupling Hamiltonian [7–9]

$$H = -2\sum J_{ab} S_a \cdot S_b, \tag{1}$$

where J_{ab} is the orbital-averaged effective exchange integral between the metal a and b with total spin operators S_a and S_b. J_{ab} can be experimentally determined by magnetic susceptibility. Recent development in computational quantum chemistry enabled us to perform large ab initio calculations of J_{ab} values using broken-symmetry (BS) approach such as UHF or UDFT [10,11]. The BS approach can be performed at a low computing cost. In singlet biradicals and low-spin species, however, it suffers from the spin contamination of high-spin states, leading to spin-projection procedures. Our group proposed spin projection scheme as follows;

$$J_{ab} = \frac{E(\mathrm{LS}) - E(\mathrm{HS})}{\langle S^2\rangle(\mathrm{HS}) - \langle S^2\rangle(\mathrm{LS})}, \tag{2}$$

where $E(X)$ and $\langle S^2\rangle(X)$ denote the total energy and total spin angular momentum for the spin state X, respectively [10,11]. In this paper, the magnetic interactions between Ni(II) ions were discussed using the equation.

3. Natural orbital analyses

Usual orbital-correlation diagram, which helps us to understand orbital interactions, is not obtained by the BS calculation because of the DODS approach [12]. In order to clarify the effective exchange interactions in the complexes using expression like the closed-shell MO, we introduced natural orbitals (NOs), which were determined by diagonalizing their first order density matrices as

$$\rho(r, r') = \sum n_i \{\phi_i(r)\}^* \phi_i(r'), \tag{5}$$

where n_i denoted the occupation number of NO ϕ_i [12,13]. If an occupation number of a magnetic orbital is close to 1.0, then two electrons in the orbital are almost localized on each spin site. On the other hand, n_i should be equal to 2.0 if stable chemical bond exists. In other words, the occupation numbers of the BS method contains an important information to understand the stability in chemical bond.

To assess this instability (diradical character), instability value (y_i) for orbital type i ($i = \sigma$, δ and so on.) is introduced here as follows [14]:

$$y_i = 2W_D = \frac{n_i^2 - 4n_i + 4}{n_i^2 - 2n_i + 2}, \tag{9}$$

where n_i and n_i^* are occupation numbers of bonding and anti-bonding NO, respectively and W_D denotes the weight of double excitation for orbital i. If a chemical bond of orbital i is stable, y_i is close to zero. On the other hand, if a chemical bond of orbital i is unstable and spins are localized at metal sites, then y_i is close to unity. Especially, $y_i/2$ is consistent to a weight of the doubly exited configuration in the MCSCF theory [14].

In this way, metal–metal bond natures and degrees of electron correlation effect, which causes spin-localization are discussed in terms of instabilities in chemical bonds using these indices.

4. Computational details

Atomic coordinations of complexes were taken from data of X-ray crystal structure analysis of *Klebsiella aerogenus* (PDB code: 1FWJ) that was available in the Protein Data Bank (PDB). We constructed two types of model structure in size, one is small model and another is realistic model. In case of the small model complex, calculations were performed by the use of Tatewaki–Huzinaga MINI (5333/533/5) basis set for Ni atoms, STO-3G basis set for ligand atoms. In these models, combinations of WB, W1 and W2 are **1a** (OH^-, H_2O, OH^-), **1b** (H_2O, OH^-, OH^-), and **1c** (O^{2-}, H_2O, H_2O), respectively. On the other hand, calculations were performed by the use of Tatewaki–Huzinaga MIDI (533(21)/53(21)/(41)) basis set for Ni atoms, 4-31G basis set for ligand atoms in case of the realistic model complex. In this realistic model, both W1 and W2 are H_2Os. All calculation was carried out using GAUSSIAN-98 [15].

5. Results and discussion

5.1. Calculated results using small model of urease

First, the electronic structure of active site in urease was examined using smallest models **1a**, **1b** and **1c** as illustrated in Fig. 1(b). The singlet states ($S = 0$) and quintet states ($S = 2$) were computed by UB3LYP method [16] to calculated the effective exchange integrals (J_{ab}). However we could not obtain appropriate electronic states of oxo-bridge model **1c**. Suárez et al. [6] reported that oxo-bridge model was unstable and oxygen of oxy-bridge drew hydrogen from W3, which existed around W1 and W2. Our calculated results are consistent with their results. The result is suggesting that there is little possibility of the oxo-bridge. So, we focused on **1a** and **1b** models.

Table 1
Calculated Mulliken charge densities and spin densities of **1a**, **1b** and **2a** for low-spin state (LS) and high-spin state (HS)

WB	Atom	Charge density		Spin density	
		LS	HS	LS	HS
1a	Ni1	1.269	1.271	1.733	1.741
	Ni2	1.233	1.233	−1.707	1.706
	O(WB)	−0.612	−0.613	−0.050	0.162
1b	Ni1	1.311	1.311	1.744	1.747
	Ni2	1.245	1.245	−1.722	1.721
	O(WB)	−0.119	−0.119	−0.023	0.061
2a	Ni1	0.819	0.821	1.735	1.755
	Ni2	0.866	0.866	−1.747	1.751
	O(WB)	−0.835	−0.836	0.029	0.146

Calculated Mulliken charge densities and spin densities of **1a** and **1b** were summarized in Table 1. Charge densities on Ni ions, especially Ni1, of **1a** are smaller than ones of **1b** because of negative charges on WB oxygen. However a difference in changes on Ni2 between **1a** and **1b** is very small. In other words, electron density on Ni1 is susceptible to the WB in comparison with Ni2. While spin densities on Ni1 and Ni2 of **1a** and **1b** are comparable, respectively.

The effective exchange integrals (J_{ab}) values between spins on terminal Ni ions were calculated by Eq. (2) as summarized in Table 2. Total energies and expectation values of the operator $\hat{S}^2$ ($\langle \hat{S}^2 \rangle$) used in the equation are also summarized in the table. UB3LYP calculations reproduced experimental week anti-ferromagnetic coupling [5]. An order of absolute values of J_{ab} is as follows,

$$|J_{ab}(\mathbf{1a})| > |J_{ab}(\text{expt.})| > |J_{ab}(\mathbf{1b})|.$$

Experimental value is middle between J_{ab}(**1a**) and J_{ab}(**1a**). From the result, it is difficult to decide which model is more reliable.

Natural orbitals of **1a** and **1b** are depicted in Fig. 2 and their occupation numbers are summarized in Table 3. The highest occupied NO (HONO) and lowest unoccupied NO (LUNO) of **1a** are showing interactions through formic acid (through-FA). HONO-1 and LUNO+1 orbitals are indicating interactions through OH^- (through-OH^-). The y values are close to 100%, showing localized spin structure on the both Ni ions. The relation of the y values is

$$y(\text{through-FA}) > y(\text{through-OH}^-).$$

On the other hand, HONO and LUNO of **1b** are through-H_2O interactions and HONO-1 and LUNO+1

Table 2
Calculated total energies[a], $\langle S^2 \rangle$ values and effective exchange integrals (J_{ab})[b] for **1a**, **1b** and **2a**

Model	Low spin state		High spin state		J_{ab}
	Total energy	$\langle S^2 \rangle$	Total energy	$\langle S^2 \rangle$	
1a	−3848.44572772	1.9946	−3848.44552018	6.0051	−11.4
1b	−3848.81240645	2.0024	−3848.81235961	6.0043	−2.6
2a	−4933.76187872	1.9951	−4933.76157408	6.0066	−16.7
Experiment[c]					−6.3

J_{ab} values were calculated by Eq. (2) in the text.
[a] In atomic unit.

Table 3
Occupation numbers and instability values[a] of natural orbitals for **1a**, **1b** and **2a**

Orbital	**1a**		**1b**		**2a**	
	Occupation numbers	y	Occupation numbers	y	Occupation numbers	y
HONO	1.0217	95.7	1.0256	94.9	1.0236	95.3
HONO-1	1.0988	86.3	1.0355	92.9	1.1027	79.7

HONO and HONO-1 in the table are magnetic orbitals.
[a] In %.

orbitals are through-FA interaction. And the relation of the y values is

$$y(\text{through-}H_2O) > y(\text{through-FA}).$$

This means that anti-ferromagnetic interactions through hydroxide are stronger than ones of through formic acid but through-water interaction is weaker than ones of through-FA. Accordingly, the strength of anti-ferromagnetic couplings are

$$OH^- > \text{ formic acid } > \text{water}.$$

It is explained by charge delocalization, which helps super-exchange interaction. The negatively charged hydroxide bears stronger super-exchange interactions.

6. Calculated results using large model of urease

To clarify the details about electronic structure of active site in urease, UB3LYP calculations are carried out using more realistic model and larger basis set. The hydroxide bridging model (**2a**) and oxo-bridging model (**2b**) are examined. The model structure of **2a** is illustrated in Fig. 1. Calculated charge densities and spin densities are summarized in Table 1. Spin densities on Ni ions of **2a** are almost equivalent to ones of **1a**, while charge densities are decreased. From the result, it is found that a degree of spin localization is not so much affected by ligands realities in case of **2a**. Natural orbitals of **2a** are depicted in Fig. 2. The magnetic orbitals

of **2a** are similar to ones of **1a**. NOs tend to localize around Ni ions except for bridge-FA, WB and Asp360. This is a reason of small difference between **1a** and **2b** in spin densities on Ni ions. Occupation numbers and calculated y values are summarized in Table 3. The y value of HONO-1 (through-OH^- interaction) decreases in comparison with one of **1a**. Because HONO-1 expresses anti-ferromagnetic interaction through-OH^-, it is expected that anti-ferromagnetic interaction is enlarged. Actually, calculated J_{ab} of **2a** is larger than **1a**, as summarized in Table 2. Calculated effective exchange integrals (J_{ab}) is larger than experimental value. In these calculations, geometry of hydrogen of OH^- is only optimized. It is reported that hydrogen bond plays important role for the reaction in the system [6]. Therefore position of hydrogen atoms around Ni ions must be optimized to carry out quantitative calculations.

We could not appropriate electronic structure of oxo-bridging model (**2b**). An electron on Ni1 is transferred to the Asp360 as a result of iterative self consistent field (SCF) calculation. Suárez et al. [6] reported that one hydrogen atom of bridge H_2O was drawn by Asp360 on model-**2b** after the structural optimization. Consequently, Ni1–H_2O–Ni2 became Ni1–OH^-–Ni2. So, our calculations are also consistent with their results. Interestingly, NOs exhibiting through-FA interaction are delocalized WB and Asp360 in all models. Especially, the NOs distribute on hydrogen of WB. This orbital seemed to be associated with the hydrogen subtraction.

7. Concluding remarks

The electronic structure of active site in urease and chemical species of bridge oxygen, i.e., WB was examined by theoretical calculations in terms of magnetic interactions between Ni(II) ions. In case of small model complexes, experimental weak anti-ferromagnetic interaction was reproduced by WB ligand of H_2O and OH^-. However we could not obtain appropriate electronic state by using H_2O ligand in case of realistic model complexes. Therefore it is concluded that hydroxide is the most possible candidate for the WB ligand. On the other hand, Day et al. [17] reported that there was no evidence for exchange coupling between the two Ni ions. We have to investigate their electronic states and magnetic interactions carefully. Because J_{ab} value is a quantity, which is very sensitive to electronic structure as mentioned before. There are not so much such physical properties that we can use, so J_{ab} value is one of the important crews for the investigation of electronic structure in the metalloprotein. Recent development of quantum chemistry and computational method makes it possible to calculate J_{ab} values quantitatively [18–20]. If there are some candidate of chemical species, position of hydrogens and so on, quantum chemical calculations are powerful way to elucidate them. The calculation of J_{ab} value is one of the strategies for the investigations of active sites in metalloproteins.

phases and new phase transitions different to the usual AFM and FM systems [9]. Indeed, the peculiar critical exponent values are observed for phase transitions of triangular lattice compounds such as VBr_2, VCl_2, $CsMnBr_3$ [10–12].

The relation between magnetism and superconductivity has also been attracted much attention in relation to the high T_c superconductivity of La_2CuO_4 from the viewpoint of the pre-existing entangled spin pairs in a RVB phase [7,8]. In such a context, $Na_{0.35}Co_2O_4$-$(H_2O)_{1.3}$ is an interesting compound in the points that (i) it has a equilateral triangular lattice of spin sources and that (ii) it is recently reported to exhibit the superconductivity [13]. The fundamental electronic properties such as magnetism and superconductivity are thought to be originated from the Co_2O_4 layers having 2-D hexagonal structure. It is also noteworthy that the electronic doping to this layer, which is regulated by Na ions and H_2O, could become the chemical pressure to determine the electronic phase of Co_2O_4. Previously, Yamaguchi and co-workers [14–18] examined the possible mechanism of high-T_c superconductivity on the hypothesis that the cooperative mechanism of electron-phonon, electron correlation, and multiband effects. From the *J*-model used in these previous studies, the magnetic interactions between Co ions play essential role in the superconductivity of this compound. Although the electronic properties of $Na_xCo_2O_4(H_2O)_y$ are determined by its *x*- and *y*-values, the theoretical study on the fundamental magnetic features of Co_2O_4 might provide the important information. As for an ab initio approach applicable for the spin-frustrated systems, we developed the general spin orbital (GSO) version of density functional theory (DFT) and successfully applied for the various classes of non-collinear molecular magnetism [18–23]. Thus, in this study, we start to examine the spin structure of the cluster model for triangular Co_2O_4 layers by ab initio general spin orbital (GSO) density functional theory (DFT) [24] computations. For the purpose, the new calculational scheme of the effective exchange integrals based on spin correlation functional values, which can be applied for the homogenous spin-frustrated systems in general, is presented. The computational *J* values are used to estimate T_c via the previously proposed *J*-model [14–18].

2. Theoretical background

2.1. General spin orbital version of DFT

In this section, we briefly describe the theoretical background of GSO-DFT approach used in our study.

The most essential feature of GSO-DFT is that the fundamental variable is not usual α and β spin densities, $\rho_\alpha(\mathbf{r})$, $\rho_\beta(\mathbf{r})$, but the 2×2 spin density matrix

$$\rho(\mathbf{r}) = \begin{pmatrix} \rho_{\alpha\alpha}(\mathbf{r}) & \rho_{\alpha\beta}(\mathbf{r}) \\ \rho_{\beta\alpha}(\mathbf{r}) & \rho_{\beta\beta}(\mathbf{r}) \end{pmatrix} = n(\mathbf{r}) + \sum_m^{x,y,z} \rho_m(\mathbf{r}). \tag{1}$$

Minimization of KS energy functional is implemented over all non-interacting N-representable spin density matrices such that [24]

$$E_{KS} = \min_{\mathrm{Tr}\rho(\mathbf{r})=N} \left\{ T_S[\rho(\mathbf{r})] + \int d\mathbf{r} \mathrm{Tr} V_{\mathrm{eff}}(\mathbf{r})\rho(\mathbf{r}) \right\}. \tag{2}$$

Here, $T_S[\rho(\mathbf{r})]$ is the non-interacting KS kinetic energy functional involving the effective potential, which we denote $V_{\mathrm{eff}}(\mathbf{r})$. By introducing an exchange-correlation (XC) functional $E_{XC}[\rho(\mathbf{r})]$, the set of coupled equations for KS orbitals that construct a KS single-determinant wavefunction,

$$\sum_{\sigma_2} \left[\delta_{\sigma_1\sigma_2} \left\{ -\frac{\nabla_i^2}{2} + \int d\mathbf{r}' \frac{n(\mathbf{r}')}{|\mathbf{r}-\mathbf{r}'|} \right\} + \frac{\delta E_{XC}}{\delta \rho_{\sigma_2\sigma_1}}(\mathbf{r}) + V_{\mathrm{ext}}^{\sigma_1\sigma_2}(\mathbf{r}) \right] \psi_i^{\sigma_2}(\mathbf{r}) = \varepsilon_i \psi_i^{\sigma_1}(\mathbf{r}), \tag{3}$$

can be obtained. Here, σ_i ($i = 1,2$) is a spin variable (α or β).

In order to make full use of the non-collinearity of this extension of DFT, the GSO version of XC functional of the localized spin density approximation (LSDA) [18–23,25] expressed by

$$E_{XC}^{\text{GSO-LSDA}}[\rho_+, \rho_-] = \int d\mathbf{r}(\rho_+(\mathbf{r}) + \rho_-(\mathbf{r}))\varepsilon(\rho_+(\mathbf{r}), \rho_-(\mathbf{r})) \tag{4}$$

with the localized up (ρ_+) and down (ρ_-) spin densities,

$$\rho_\pm(\mathbf{r}) = n(\mathbf{r}) \pm |\mathrm{Tr}\vec{\sigma}\rho(\mathbf{r})|/2, \tag{5}$$

must be employed, where $\vec{\sigma}$ is the vector of Pauli matrices. The dependency of $\rho_\pm(\mathbf{r})$, so of the XC functional, on the off-diagonal terms of spin density matrices, $\rho(\mathbf{r})$, makes the KS equations to be coupled equations like Eq. (3). In the case of usual collinear magnetic systems, the equation and XC functional is reduced to that of the standard spin-unrestricted DFT (UDFT).

It is well recognized that the LSDA fails to describe the strongly correlated systems just as Na_xCoO_2-$(H_2O)_y$. We here cover the weak point of LSDA by hybridizing with generalized gradient approximation (GGA) and Hartree–Fock (HF) methods. The GSO version of GGA or hybrid XC functional can be straightforwardly derived by a similar manner of LSDA. We examined the familiar exchange-correlation functionals of three classes: (i) Hartree–Fock (HF), (ii) Becke88 [26] + LYP [27] (BLYP) as a gradient-corrected approximation, and (iii) B3LYP [28] as a hybrid approximation. All GSO-DFT computations are of the linear combination of gaussian type orbitals where MINI basis sets [29] are employed.

2.2. An estimation scheme of J value for homogeneous triangular lattices

In previous study of molecular magnetism, we use the equation

$$J = \frac{E^{\mathrm{HS}}_{\mathrm{GSO\text{-}DFT}} - E^{\mathrm{LS}}_{\mathrm{GSO\text{-}DFT}}}{\langle \hat{S}^2 \rangle^{\mathrm{HS}}_{\mathrm{GSO\text{-}DFT}} - \langle \hat{S}^2 \rangle^{\mathrm{LS}}_{\mathrm{GSO\text{-}DFT}}} \tag{6}$$

in order to estimate J value by using ab initio GSO-DFT computational results. However, this J scheme based on $\langle \hat{S}^2 \rangle$ required the addition complicated correction terms to the denominator in order to apply for the general systems. We use, in this study, the alternative and simple estimation scheme based on spin correlation functions. To derive the formula, we need to take two assumptions: (i) all of nearest interactions are equivalent each other and (ii) the non-nearest neighbor interactions are small enough to neglect. We then note that the expectation values of Heisenberg model for any arbitrary spin state (X), are given by

$$E^{X}_{\mathrm{HB}} = -2JN\langle \hat{S}_i \cdot \hat{S}_{i+1} \rangle^{X}. \tag{7}$$

Here, N is the number of the nearest neighbor spin pairs in the systems. By mapping the GSO-DFT computational results into Eq. (7), the J value can be determined by

$$J = \frac{E^{\mathrm{HS}}_{\mathrm{GSO\text{-}DFT}} - E^{\mathrm{LS}}_{\mathrm{GSO\text{-}DFT}}}{2N\left\{ \langle \hat{S}_i \cdot \hat{S}_{i+1} \rangle^{\mathrm{HS}}_{\mathrm{GSO\text{-}DFT}} - \langle \hat{S}_i \cdot \hat{S}_{i+1} \rangle^{\mathrm{LS}}_{\mathrm{GSO\text{-}DFT}} \right\}}. \tag{8}$$

Note that spin correlation function between nearest neighbor sites, i and $i+1$, are equivalent for all i by our assumption, (i). Thus, for the case of the triangular lattice, this estimation equation works with the HSDW solutions of GSO-DFT, but not with the AFM solutions of the usual UDFT, since the UDFT provides distinct (AFM and FM coupled) spin correlation functions for n.n. pairs of spin-frustrated systems.

As compared with the previous scheme given in Eq. (6), there are two superior points in that of Eq. (8). First, if we focus our attention on the local two sites, we note that the spin delocalization effect can be taken into account by Eq. (8). That is to say, $\langle \hat{S}^2_i \rangle^{\mathrm{HS}} = \langle \hat{S}^2_i \rangle^{\mathrm{LS}}$, which is a assumption to derive Eq. (6) from the Heisenberg model, does not always hold since the $\langle \hat{S}^2_i \rangle^{\mathrm{LS}}$ shrinks in general, due to spin delocalized effect. The details of such considerations on diradical systems were described in the previous paper [30], while we shall examine the more general case elsewhere. Here, we would like to emphasize another improved point of this scheme that Eq. (8) can be utilized for any homogeneous spin systems with no modification, while the system-dependent revision is required for Eq. (6) to apply a large homogeneous spin systems. Here, by the term, "homogeneous spin systems", we mean the systems which satisfy the above two assumptions (i) and (ii). Many examples such as, Kagome lattice, the icosidodecahedral magnetic cluster, $Mo_{72}Fe_{30}$, as well as the hypothetical clusters-and-lattices are listed in [18]. Note that the CoO_2 layer of the target compounds in this study, which constitutes of three hexagonal sheets is also one of such "homogenous" spin systems.

2.3. Computational results

The $Na_xCoO_2(H_2O)_y$ ($x = 0.35$, $y = 1.3$) compound consists of three layers as illustrated in Fig. 1(A). The CoO_2 layer is responsible for the electronic and magnetic properties while Na and H_2O layers are thought to regulate the hole-doping rate into the CoO_2 layer. This CoO_2 layer further divided into a Co layer and two O layers, which form sandwiched structure as shown in Fig. 1(A). All of Co and O layers have the hexagonal structure within the plane. From the fact that the distance between two distinct Co layers along the c-axis is larger than 10 Å with intercalating by Na and H_2O layers, this system can be considered as an isolated two-dimensional spin frustrated systems. As shown in Fig. 1(B), the local environment surrounding Co^{4+} ion that is the spin source of this compounds, is trigonally distorted octahedral field consisting of six O^{2-} ions. Thus, an elementary picture of electronic structure for an individual Co is explained as follows. In the octahedral field, five d-orbitals are split into e_{1g} and t_{1g} ones. Due to the trigonal distortion of O_h field, the latter is further divided into A_{1g} and E_g orbitals, with the slight hybridization between e_{1g} and E_g, as shown in the right side of Fig. 1(C). Therefore, the local spins on Co ions has A_{1g} character, which is the singly occupied state of Co^{4+} ion.

The structural parameters used in our ab initio computation are those reported by Takada et al.: $a = b = 2.8230$ Å are intra-layer lattice constants for both of Cos and Os layers, $c = 19.6207$ Å for the c-axis perpendicular to those layers. The Os layer is on 0.0451c (0.88494 Å) to Co layer along the c-axis. The modeled clusters we here examine are illustrated in Fig. 2. A most fundamental unit, which exhibit spin-frustration and preserve the local distorted O_h field for Co^{4+} ion, is $Co_3{}^{4+}O_{2-}{}^{13}$ in Fig. 2(A). However, to avoid

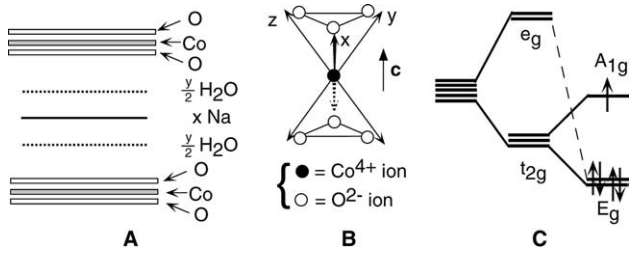

Fig. 1. (A) The layered structure of $Na_xCo_2O_4(H_2O)_y$. (B) The local environment of Co^{4+} ion. (C) Energy splitting of 3d orbitals of Co^{4+} ion due to the ligand field.

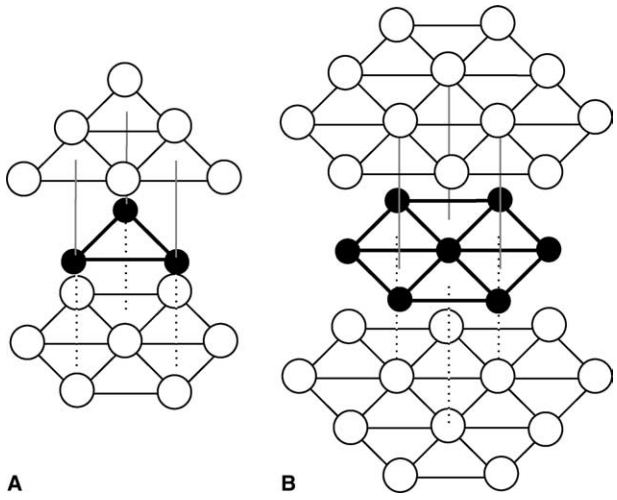

Fig. 2. Model clusters preserved the distorted O_h field for Co^{4+} ions. (A) A triangular unit, $Co_{4+}{}^{3}(2e^{-})_{13}$. (B) A hexagonal unit, $Co_{4+}{}^{7}(2e^{-})_{24}$. Here, white spheres represented oxygen anions, but are replaced point charges 2^{e-} in the actual computation.

the convergence problem of KS-DFT computation due to excess electrons, we replace oxygen anions, O^{2-}, by classical point charges, $2e^{-}$. We also examined a hexagonal unit in Fig. 2(B) with similar replacement oxygens by point charges.

Fig. 3 shows the diagonal part of spin density of ground spin states of those clusters, of $Co_{4+}{}^{3}$ and $Co_{4+}{}^{7}$, $\vec{\rho}_s(\mathbf{r}) = \sum_\mu \vec{P}_{\mu\mu}\chi_\mu(\mathbf{r})^2$, where $\vec{P}$ are spin density matrix vector and $\{\chi_\mu\}$ is the basis set, respectively. Note that the global spin axis is arbitrary, so to be easy to see, we choose the global spin axis for $\vec{\rho}_s(\mathbf{r})$ aligning within the Co planes. We can see that those stable spin structures are obviously helical spin density wave (HSDW) that is localized on the Co atoms due to the d-character of open-shell electrons. Indeed, for all of HSDW solutions obtained using GSO computations, the spin correlation functional values are calculated to be nearly -0.125, which are corresponds to those of classical spin solutions aligned with a relative $\pi/3$ orientation. By using Eq. (8) with those spin correlation values, we estimated the J values. Those results are listed in Table 1, being much smaller than the estimated value from the Curie temperature of $Na_{0.5}CoO_2$, $-56\ cm^{-1}$ [31]. Previously, Yamaguchi and co-workers proposed for the high T_c superconductivity of the layered copper oxides, that the strong superexchange interactions induced the spin-mediated superconductivity and that the transition temperature can be estimated by using the effective exchange integral value, J, via the relation,

$$T_c = CJ, \tag{9}$$

where C is a proportional constant, of which an explicit expression depends on a theoretical model [14–18]. We here listed calculated T_c values by using Eq. (9) in Table 1, all of which are quite smaller than the experimental value. Obviously those differences on the J and T_c values are partially due to an approximation oxygen anions as point charges in this initial work, which imply neglecting of the superexchange interactions.

In order to estimate the effect of superexchange interactions, we implement the comparative computations of J values between the dinuclear Co^{4+} ions, of which interatomic distance is fixed to be 2.823 in accordance with the above GSO-DFT computations: (i) with two bridged oxygen anions and other 8 point charges and (ii) with 10 point charges, both of which anions and point charges form the O_h field for two Co^{4+} ions. It is obvious that the ratio of J(i) and J(ii), i.e., J(i)/J(ii) is roughly close to the ratio of superexchange + direct and direct-only exchange interactions. The computational results of J(i)/J(ii) are, 1240.6, 165.0, and, 181.6, respectively, for HF, BLYP, and B3LYP methods. The simple scaling to J values leads to J(GHF) = −3980, J(BLYP) = −645, and J(B3LYP) = −479.4 (unit: cm^{-1}) of $Co_{4+}{}^{3}$ and J(GHF) = −6774, J(BLYP) = −2706, and J(B3LYP) = −1949 (unit: cm^{-1}) of $Co_{4+}{}^{7}$, all of which overestimate the experimental AFM interaction. Indeed, Zhang et al. [32] added the artificial uniform positive background to balance the itinerant electrons to describe band gaps of CoO_2 layer in LSDA and LSDA + U bands calculations. Thus, we speculate that the actual

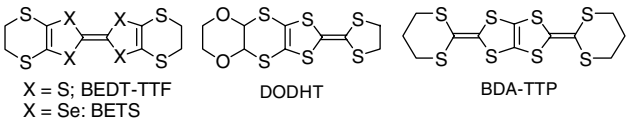
magnetic interactions of the results of the compromise between superexchange interactions and those suppression by the Na^+ and H_2O environments and required some artifice in ab initio computations.

2.4. Discussion and concluding remarks

In order to treat the homogeneous spin frustrated systems, we present the new scheme for J values connected with GSO-DFT computational results. We apply this scheme for the model clusters of $Na_xCoO_2(H_2O)_y$ ($x = 0.35$, $y = 1.3$). For both of triangular and hexagonal clusters of Co_n ($n = 3.7$) plus point charges, we found that the HSDW solutions are the ground spin states, being consistent with classical spin vector models. However, as for the quantitative aspects, due to an approximation oxygen anions as point charges in this initial work, which imply neglecting of the superexchange interactions, we obtained the considerably small J values as compared to experimental ones. On the other hand, introducing of the effects of bare oxygen anions leads to convergence problems or overestimation of J values, which implies that the some device are required to regulate the amount of the itinerant electrons.



Finally, we would like to emphasize that, although the GSO-DFT provides the classical spin picture, the estimated J value using Eq. (8) is of the spin-corrected, in other words, of the quantum spin state. Thus, the GSO-DFT with the J scheme will work for almost all of spin-frustrated systems, which are not only classical states, but also quantum spin states like the RVB phase.

2. Experimental

2.1. Synthesis

DODHT was synthesized according to the method reported previously [3,4]. $(DODHT)_2FeCl_4$ was prepared by electrocrystallization at a constant current of 0.2 μA in *m*-dichlorobenzene with 5% acetone at 5 °C. Concentration of DODHT and $TEA \cdot FeCl_4$ were 0.044 and 0.28 mM, respectively.

2.2. Electrical conductivity

Temperature dependence of resistance was measured for a single crystal of $(DODHT)_2FeCl_4$ by the four-probe dc method using gold wire contacted to the crystal by carbon paste.

2.3. X-ray crystallography

Crystal data for $(DODHT)_2FeCl_4$: $C_{20}H_{20}S_{12}O_4{-}FeCl_4$, FW = 906.8; black plate, triclinic, space group $P\bar{1}$, $a = 5.6701(9)$, $b = 16.247(3)$, $c = 19.185(3)$ Å, $\alpha = 106.720(3)$, $\beta = 93.527(3)$, $\gamma = 94.698(3)°$, $V = 1654.0(5)$ Å^3, $Z = 2$, $R = 0.0337$, $R_w = 0.0899$. CCDC-258294 containing the supplementary crystallographic data for $(DODHT)_2FeCl_4$ can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB21EZ, UK; fax +44 1223 336033; or deposit@ccdc.cam.ac.uk.

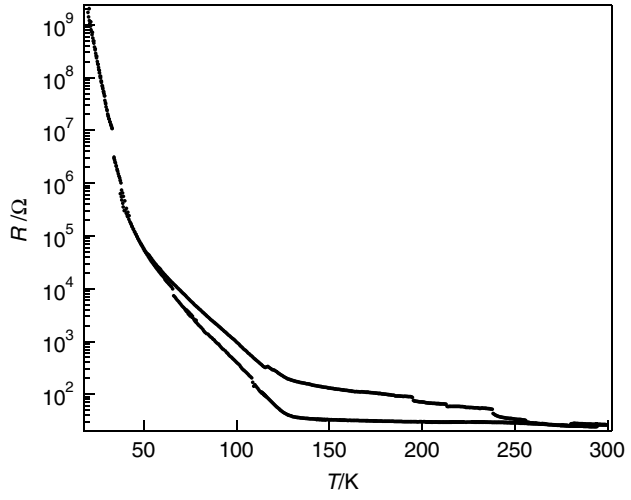

Fig. 1. Temperature dependence of resistence of $(DODHT)_2FeCl_4$.

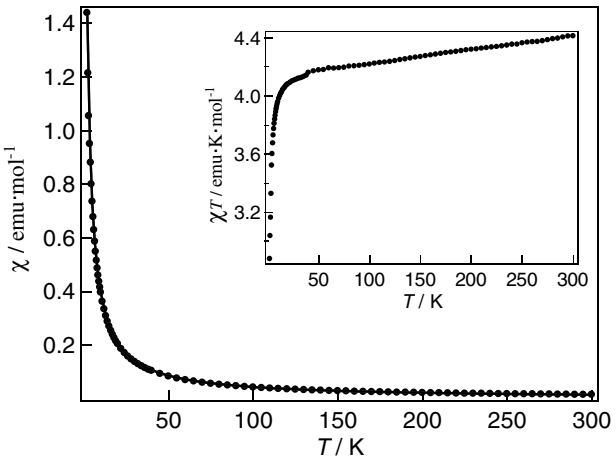

Fig. 2. Temperature dependence of magnetic susceptibility of $(DODHT)_2FeCl_4$. The solid line is a fit by Curie–Weiss law. Inset: $\chi_m T$ vs. temperature plot.

3. Results and discussion

3.1. Electrical and magnetic properties

Fig. 1 shows the resistance of $(DODHT)_2FeCl_4$ as a function of temperature. The electrical conductivity at room temperature was 7.5 S cm^{-1}. As seen in Fig. 1, the temperature dependence of resistance was extremely weak or almost independent of temperature from room temperature to 130 K. Below 130 K, the resistance increased rapidly and turned to be an insulator. The activation energy below 80 K was 32 meV.

In order to investigate magnetism, especially interaction between the conduction electron and the localized magnetic moment on Fe^{3+} ion, so-called π–d interaction, temperature dependence of the magnetic susceptibility of this salt was measured by using a SQUID magnetometer at 10,000 Oe from 300 to 2 K (Fig. 2). The susceptibility was well reproduced by the Curie–Weiss law over the whole temperature range, and the Curie constant and Weiss temperature are 4.39 emu K mol^{-1} and −1.1 K, respectively. The fitted value of Curie constant is almost same to the spin-only value of 4.38 emu K mol^{-1} calculated for a high-spin Fe^{3+} ion ($S = 5/2$, $g = 2.0$), thus the measured magnetization was dominated by the local moment of the Fe in $FeCl_4^-$ anion. Inset of Fig. 2 shows $\chi_m T$ versus temperature plot. The $\chi_m T$ value decreased gradually from 300 K to ca. 30 K, and decreased rapidly at low temperature, which indicates the weak antiferromagnetic interaction exists. The magnetic behavior is well reproduced by the Curie–Weiss law through whole temperature range indicating that the interaction of $\theta = -1.1$ K exists from

room temperature to 2 K. In both plots, there is no anomaly at around 130 K, where the transition from the semiconductor or semimetal to the insulator occurred. This result suggests the π–d interaction in $(DODHT)_2FeCl_4$ is not existing or extremely weak.

3.2. Crystal structure

Fig. 3 shows the crystal structure of $(DODHT)_2FeCl_4$ consisting of one $FeCl_4^-$ anion and two crystallographically independent DODHT molecules as the asymmetric unit. The conducting donor layer of DODHT and the insulating layer of $FeCl_4^-$ anions are arranged alternately along the *b*-axis. In the donor layer, the donor arrangement belongs to the β″-type, similarly to those of superconducting salts, $(DODHT)_2X$ (X = PF_6, AsF_6 and $BF_4 \cdot H_2O$). Donor molecules are stacked along the [1 0 1] direction with a fourfold period in a head-to-tail manner and dimerized with interplanar distances of $d_1 = 3.66$, $d_2 = 3.60$ and $d_3 = 3.99$ Å (Fig. 3(a)). There are several intermolecular S···S contacts shorter than the sum of the van der Waals radii (3.70 Å) between stacks, whereas no S···S contact is observed within a stack. These structural characteristics are seen in the DODHT salt with the same tetrahedral anion, $(DODHT)_2BF_4 \cdot H_2O$, however, interplanar distances of $(DODHT)_2BF_4 \cdot H_2O$ are slightly smaller (3.57, 3.85 and 3.81 Å) than those of $FeCl_4$ salt. Contrarily, intermolecular sulfur contacts along molecular side-by-side direction are shorter in $FeCl_4$ salt (3.368–3.620 Å) than in BF_4 salt (3.414–3.647 Å). As a result, the system of $FeCl_4$ salt is more one-dimensional along molecular side-by-side direction than that of BF_4 salt.

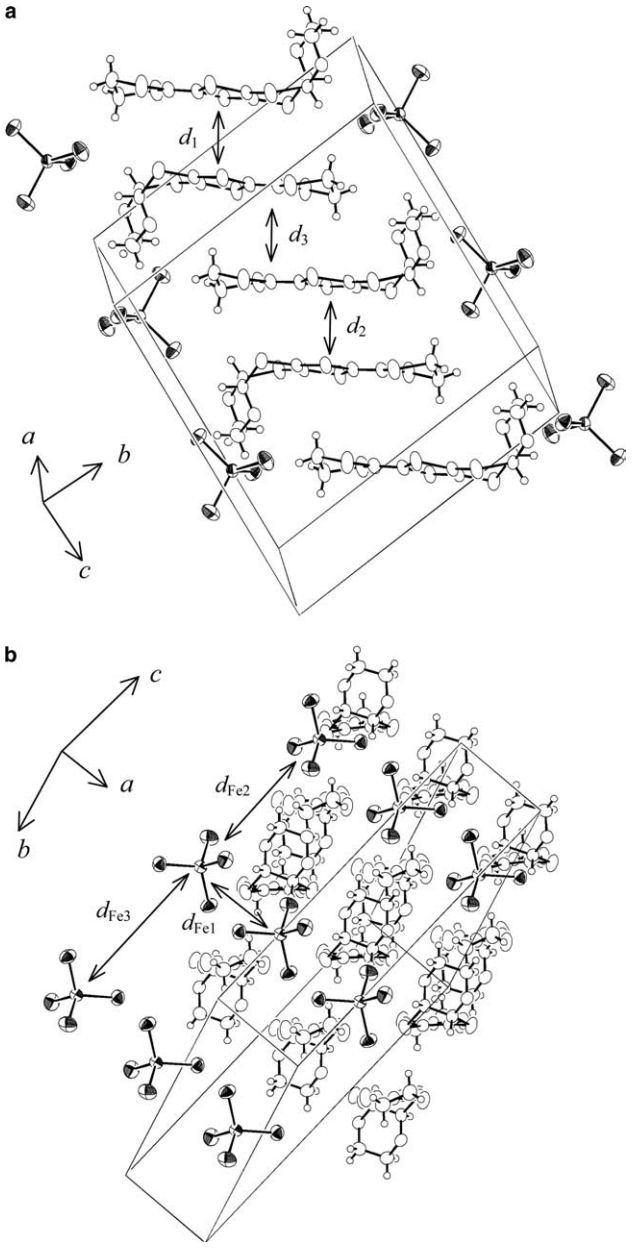

Fig. 3. Crystal structure of $(DODHT)_2FeCl_4$. (a) intermolecular distance: $d_1 = 3.66$, $d_2 = 3.60$, $d_3 = 3.99$ Å. (b) Viewed along donor long axis with $FeCl_4$ anions. Interatomic distance between Fe ions: $d_{Fe1} = 5.607$, $d_{Fe2} = 9.685$, $d_{Fe3} = 9.501$ Å.

In the insulating layer formed by $FeCl_4^-$ anions, interatomic distances between Fe ions are $d_{Fe1} = 5.607$ along *a*-axis, and $d_{Fe2} = 9.685$ and $d_{Fe3} = 9.501$ Å along *c*-axis, respectively (Fig. 3(b)). These distances are rather long to consider the direct interaction between Fe ions. Furthermore, there is no contact between the Cl atoms of the $FeCl_4^-$ anion and DODHT. These facts are consistent with the result of magnetic measurement; long range order of the magnetic moment of Fe ions was not observed and there was no anomaly at the temperature where the transition to the insulator occurred in the temperature dependence measurement of electrical resistance.

4. Conclusion

An electrical conducting radical salt comprising of π-reduced organic donor, DODHT, and an inorganic magnetic anion, $FeCl_4^-$, has newly prepared, and its crystal structure, electrical and magnetic properties were investigated. From the crystal structure, intermolecular interaction between DODHT and $FeCl_4^-$ anions dose not seem to exist, which supports the results of the electrical and the magnetic measurements. Transition temperature from semiconductor or semimetal to insulator of $(DODHT)_2FeCl_4$ is much lower than those observed for superconducting salt, $(DODHT)_2X$ (X = PF_6, AsF_6 and $BF_4 \cdot H_2O$), at ambient pressure. The nature of insulating state of the DODHT superconductors has recently been revealed to be a charge-ordered insulating state with alternating antiferromagnetic chain. Therefore, it is important to investigate the insulating state of $FeCl_4$ salt. Furthermore, since $(DODHT)_2X$ (X = PF_6, AsF_6 and $BF_4 \cdot H_2O$) exhibited superconducting

transition under pressure, the electrical property under pressure of $FeCl_4$ salt must be examined. Further work on this issue is ongoing.

*b**-axis. Obviously, magnetic torque enables us much more precise determination of both the orientation of the AF easy axis and the value of the spin-flop field. However, its sensitivity is not sufficient for the study of much smaller mixed crystals $(BETS)_2Fe_{1-x}Ga_x$-$Cl_{4-y}Br_y$.

In this paper we will report the measurements of spin-flop transitions in antiferromagnetic organic molecular conductor λ-$(BETS)_2FeCl_4$, using a commercial self-sensing piezoresistive micro-cantilever for atomic force microscopy (AFM) developed by Seiko Instruments Inc. [5]. Ohmichi and Osada [6] reported that this AFM cantilever can be utilized as a sensitive torque magnetometer under pulsed high magnetic fields up to 38 T. Recently, we used it as a sensitive torque magnetometer under steady magnetic fields up to 45 T and succeeded in observation of the de Haas–van Alphen oscillations in a single-component molecular conductor [Ni(tmdt)$_2$] for the first time [7]. Since the magnetic torque is proportional to the magnetic field, its sensitivity decreases under low magnetic fields, where spin-flop transition usually occurs. So far, nobody tried to apply this AFM cantilever to the study of spin-flop transition in antiferromagnets. We have succeeded, for the first time, in observation of spin-flop transitions of tiny single crystals including λ-$(BETS)_2FeCl_4$ as small as less than 1 μg.

2. Experimental

In this study we used a commercial self-sensing piezoresistive micro-cantilever developed by Seiko Instruments Inc. for AFM [5].

Fig. 1 shows the AFM cantilever (left) with a sample mounted and a reference lever (right). A tiny single crystal ($55 \times 20 \times 300$ μm, 0.8 μg) of λ-$(BETS)_2FeCl_4$ is mounted at the end of the beam, on the opposite side of the AFM tip. A reference lever (right) without AFM tip is incorporated on the same platform. This monolithic construction is advantageous for precise measurement, since the background signal originating from the temperature and magnetic field dependence of the piezoresistance of cantilevers can be canceled out, using a Wheatstone bridge circuit. The bridge circuit is fully balanced at zero field, and the deviation (out of balance) signal is measured as a function of applied magnetic field using a Lock-in Amplifier (SR830) operating at a low frequency. The reference output signal of the Lock-in Amplifier was used as a current source fed to the bridge circuit.

The AFM cantilever with a sample was attached to a uniaxial rotator, so that the orientation of the crystal to the magnetic field can be changed precisely.

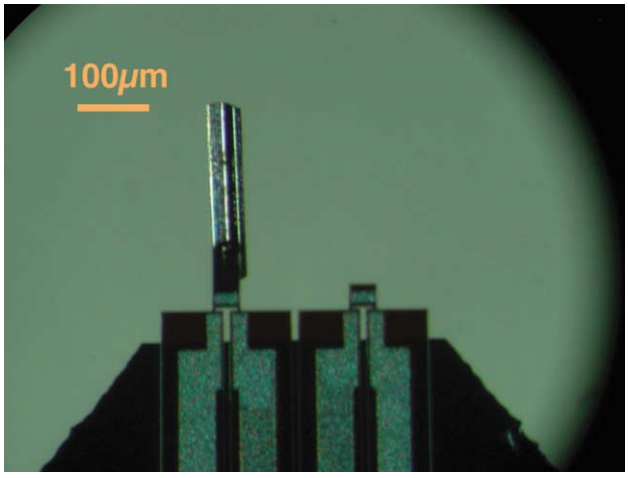

Fig. 1. Piezoresistive AFM cantilever with a sample mounted (left) and a reference lever (right). A tiny single crystal ($55 \times 20 \times 300$ μm, 0.8 μg) of λ-$(BETS)_2FeCl_4$ is glued to the back of AFM tip with epoxy.

3. Results and discussion

Fig. 2 shows the magnetic torque curves of a single crystal of λ-$(BETS)_2FeCl_4$ at 0.5 K in the magnetic field direction with the angle tilted from the *c*- to *b**- axis. For the angle of 30.0° a very sharp structure appears at $H = 1.2$ T, resulting from the spin-flop (SF) transition

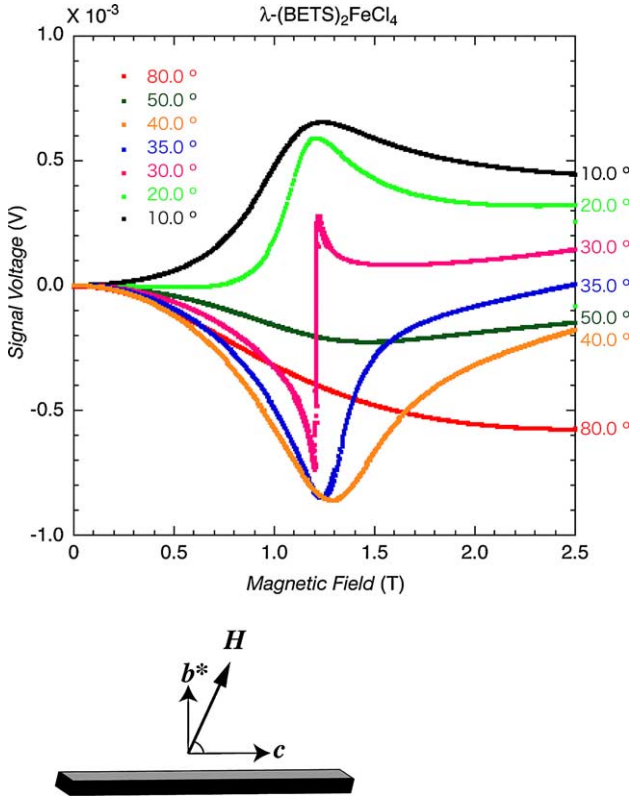

Fig. 2. Magnetic torque curves of a single crystal of λ-$(BETS)_2FeCl_4$ at 0.5 K.

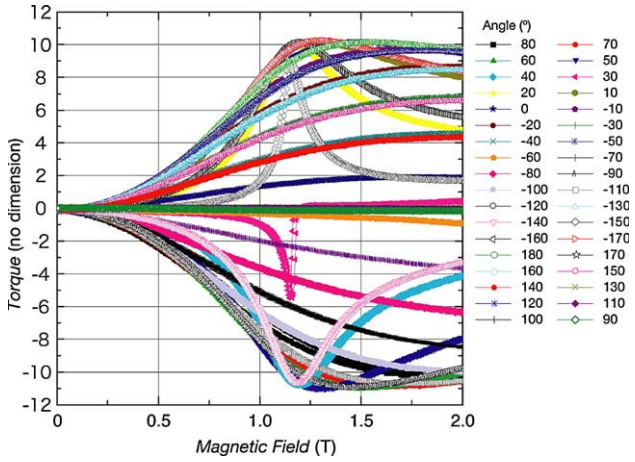

Fig. 3. Magnetic torque curves of a single crystal λ-$(BETS)_2FeCl_4$ at 2 K.

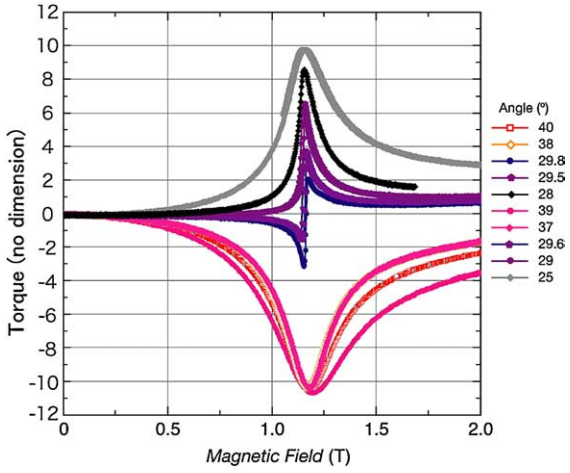

Fig. 4. Magnetic torque curves of a single crystal of λ-$(BETS)_2FeCl_4$ at 2 K.

between the AF in low magnetic field and the canted AF (CAF) in high magnetic field. Tilted from the angle, the structure at the SF transition becomes broader. For the angle of 50° and 80°, the SF transition does not occur and changes to the gradual spin rotation.

The overall results are consistent with the capacitive magnetic torque study on relatively large single crystals (>30 μg) reported by Sasaki et al. [4]. The only difference is that we can now measure considerably smaller crystals.

Fig. 3 shows the magnetic torque curves of a single crystal of λ-$(BETS)_2FeCl_4$ at 2.0 K in the magnetic field direction with the angle tilted from the *c*- to *b**-axis. The sample was rotated fully for the angle of 0° to ±180°. A very sharp structure due to SF transition was observed only at about 30° and a less sharp one near −150°. Fig. 4 shows the magnetic torque curves of a single crystal of λ-$(BETS)_2FeCl_4$ at 2.0 K when the magnetic field was applied in directions close to the easy axis. Near 30°, a very small change in the angle (even less than 1°) caused a drastic change in the magnetic torque curve. Moreover, the sign or polarity changes from positive to negative, or vice versa, when the magnetic field is tilted across the AF easy axis, which enable us a precise determination of the easy axis of antiferromagnets.

Akutsu et al. [8] studied mixed crystals of λ-$(BETS)_2FeBr_xCl_{4-x}$ using SQUID magnetometer. The anisotropy of the magnetic susceptibility was measured by using the oriented (//c) thin needle crystals put in thin quartz capillaries (0.7 mm ϕ). They found that the direction of AF easy axis of λ-$(BETS)_2FeBr_xCl_{4-x}$ is varied according to the Br content (x). Around x = 0.3–0.5, the direction of the easy axis of the AF spin structure changed from parallel to the *c*-axis ($x < 0.2$) to perpendicular to it ($x > 0.6$), suggesting that the direction of AF easy axis is varied according to the magnitude of π–d coupling. Obviously, we need a measurement using a single crystal. As already explained, a torque magnetometry is useful for precise determination of the easy axis as well as the spin-flop field. However, lack of sensitivity of capacitive type cantilever has hindered such measurements so far. It is now necessary to reexamine the direction of AF easy axis of λ-$(BETS)_2FeBr_xCl_{4-x}$ in order to study the effect of π–d coupling more systematically. Measurements on single crystals of λ-$(BETS)_2FeBr_xCl_{4-x}$ are now in progress, and the results will be published separately.

2. Experimental

The acidic **H0**H, **H1**H, **H2**H, **H3**H, and **M2**H were prepared by the condensation reaction of TEMPOCOOH with HO_3SNH_2, $HO_3SCH_2NH_2$, $HO_3SCH_2CH_2NH_2$, $HO_3SCH_2CH_2CH_2NH_2$, and $HO_3SCH_2CH_2NH(CH_3)$, respectively, in the presence of dicyclohexylcarbodiimide (DCC) and dimethylaminopyridine (DMAP) in 30 mL of CH_2Cl_2 at room temperature with stirring over a few days. Metathesis with $PPh_4 \cdot Br$ yielded their PPh_4 salts, as orange crystals (34–48% yields). TTF (**1**) (tetrathiafulvalene) salts of **H1**, **H2**, and **M2** were prepared by metathesis of $(TTF)_3(BF_4)_2$ and the corresponding PPh_4 salts in acetonitrile for **H1** and acetone for **H2** and **M2**. The TMTSF (**2**) (tetramethyltetraselenafulvalene) and BEDT-TTF salts of **H1** were prepared by electrocrystallization in PhCl + 5% of acetone with the corresponding donor and the PPh_4 salt of **H1**. The materials were characterized by X-ray analysis. They were measured using a Quantum CCD area detector on a Rigaku AFC-7R diffractometer or a Rigaku AFC-5R 4-circle diffractometer, at room temperature. All calculations were carried out using teXsan for Windows version 1.06 and CRYSTALS version 12. Electrical resistivity measurements were done by the conventional four probe method. The magnetic susceptibility measurements using polycrystalline samples were measured with a Quantum Design MPMS5SH magnetometer, from 2 to 300 K.

3. Results and discussion

3.1. PPh_4 salt

The crystal data of five PPh_4 salts are listed in Table 1. All anions form dimers with hydrogen bonds between an oxygen atom of the sulfonate group and N–H or N–CH_3 of the nearest anion. For example, the structure of the **H3** dimer in $PPh_4 \cdot$ **H3** is shown in Fig. 1.

The intradimer $O_{TEMPO}\cdots O_{TEMPO}$ distances are in the range of 14.2–17.5 Å, indicating no magnetic interaction via this interdimer route. Furthermore, the nearest $O_{TEMPO}\cdots O_{TEMPO}$ distances for the **H0**, **H1**, **H2**, **H3**, and **M2** salts are 6.36(1), 8.709(9), 7.16(1), 6.594(6), and 6.229(5) Å, respectively, which are too long to allow any significant magnetic interactions because each dimer is surrounded by the relatively large PPh_4 cations. Actually, the temperature-dependent magnetic susceptibilities have Curie–Weiss behaviours with small Weiss constants ($C/\theta = 0.336/0.01$, 0.391/0.01, 0.337/−1.01, 0.381/−0.02, and 0.387 emu K mol^{-1}/−1.14 K, respectively). In addition, there

is positional disorder of the TEMPO part in $PPh_4 \cdot$ **H3** and the TEMPO atoms apart from O, N, and C of methine were refined over two possible positions. It appears to be due to a rotational disorder along the O–N···C axis.

3.2. TTF salts

The crystal data of three TTF salts are shown in Table 2. The general description of all the crystal structures is as follows. The ratio of TTF to anion is 1:1, indicating that each TTF is a monocation. Each TTF forms a face-to-face dimer and so appears to form a spin singlet. The details of the each crystal structure together with the physical properties are described in the following individual sections.

3.2.1. (TTF)(*H1*) · $2H_2O$

The crystal structure of (TTF)(**H1**) · $2H_2O$ is shown in Fig. 2. There are one TTF cation, one anion and two water molecules in the asymmetric unit. The TTF cations form dimers with many short S···S contacts (see Fig. 2). The dimer interacts with adjacent ones with only a weak S···S contact (see Fig. 2), suggesting that the conduction pathway is very poor. Actually, the room-temperature electrical resistivity of 8×10^6 Ω cm was observed.

There is not shorter contact than the sum of van der Waals radii between the TEMPO parts, although the observed $O_{TEMPO}\cdots O_{TEMPO}$ contact of 4.581(5) Å is magnetically somewhat short. Furthermore, there are short contacts between S or C atoms of TTF and the spin centre O atom of TEMPO (see Fig. 2). Thus, the TEMPO radicals seem to form a spin dimer via the TTF dimer (TEMPO···TTF···TTF···TEMPO). The temperature dependence of magnetic susceptibility is shown in Fig. 3. It can be fitted by a Singlet–Triplet model with $C = 0.330$ emu K mol^{-1} and $J = 5.7$ K. The spin interaction between the TEMPO radicals appears to be mediated through the direct O···O contact and/or via the TTF dimer.

the crystal. As observed in (TTF)(**H1**) · $2H_2O$, (TTF)(**H2**) · H_2O has a short contact between an S atom of TTF and an O atom of TEMPO, as shown in Fig. 4. However, the distance is 0.2 Å longer than in the **H1** salt. The magnetic susceptibility data fitted the Curie–Weiss model with a Curie constant of 0.384 emu K mol^{-1}, and a Weiss constant of −0.09 K, indicating that the spin interaction is very weak.

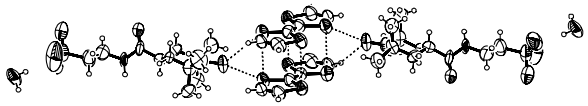

Fig. 4. Structure of TEMPO···TTF···TTF···TEMPO. Dashed lines indicate short S···S (<3.70 Å) and S···O (<3.35 Å) contacts.

3.2.3. (TTF)(**M2**) · 0.50H_2O

The crystal structure is shown in Fig. 5. In the crystal, TTF cations form a stair-like stack with two alternating kinds of overlaps: (i) between two TTF moieties with no lateral shift; (ii) between halves of dithiole rings only, as shown in Fig. 6. There are many short S···S contacts in the case of (i), whilst there is only a short S···S contact in (ii) (see Fig. 6). Moreover, no short contacts between the columns are observed (see Fig. 6). These results indicate that the crystal is not so conductive.

There are no short contacts between TEMPO and TTF as observed in the previously described TTF salts, although direct interaction between TEMPOs are observed (Fig. 7). The spin centre of the TEMPO moiety interacts with a methyl group of another TEMPO moiety (>N–O···H_3C–), giving a 1D magnetic network

along the *n*-axis (see Fig. 7). According to McConnell's theory [24], the contact can mediate the ferromagnetic interaction. The temperature dependence of magnetic susceptibility is actually explained by the 1D ferromagnetic Heisenberg model with $C = 0.362$ emu K mol^{-1} and $\theta = 0.55$ K (Fig. 8). In addition, there is positional disorder of the O atom of the carbonyl group, the methylamino group, and the adjacent methylene group, and these atoms were refined over two positions. The position of the incorporated water molecule is partially occupied, to be 0.50.

3.3. TMTSF and BEDT-TTF salts

Only the anion **H1** has thus far provided crystalline TMTSF and BEDT-TTF salts. For the TMTSF salt, we reported the crystal structure only and not any physical properties, because we obtained the crystals as very thin needles and only have much less than 1 mg at present.

3.3.1. (TMTSF)(*H1*) · 2H_2O · PhCl

The crystal structure is shown in Fig. 9. One TMTSF, one anion, two H_2O, and one PhCl are independent. TMTSF forms a dimer about the centre of symmetry. The dimer stacks along the *a*-axis to form 1D conducting column. Between the columns, there are no side-by-side interactions because each column is surrounded by the anions and the incorporated molecules. Usually, a CT salt containing the 1D stack consisting of a dimerized donor having a charge of +1 is a band insulator. So the TMTSF salt appears to be a band insulator and the donor part is non-magnetic.

There are no short contacts not only between TMTSF and TEMPO but also between TEMPOs, indicating that no magnetic interaction is likely between spins on the TEMPO moieties. In addition, we adopted a rigid model for the incorporated PhCl in the refinement procedure because of its rotational disorder, and there is positional disorder of the TEMPO moiety, which is similarly observed in PPh_4 · **H3**.

3.3.2. α-(BEDT-TTF)$_5$(*H1*)$_2$ · 6H_2O

The crystal structure is shown in Fig. 10. There are two centrosymmetric pentamers of BEDT-TTF, four anions, and 12 water molecules in the unit cell. A formal charge of +2/5 on each BEDT-TTF and +2 on each pentamer are calculated. The pentamers interact with each other to form an α-type 2D conducting sheet (Fig. 11). The structures of two independent pentamers together with the TEMPO anions, the O atoms of which are in contact with the terminal ethylene groups of BEDT-TTF, are shown in Fig. 12. The BEDT-TTF molecules B, C, E, and F are almost planar, which is typical for cations. In contrast, molecules A and D are not planar, as is the case for neutral BEDT-TTF. These results suggest that the positive charge is unequally distributed over the BEDT-TTF molecules. Thus the system has charge disproportionation, suggesting poor conductivity. The temperature-dependent electrical resistivity is semiconductive with $\rho_{RT} = 9 \times 10^3$ Ω cm and $E_a = 0.4$ eV.

The short contacts between BEDT-TTF and TEMPO, as shown in Fig. 12, are not so important for

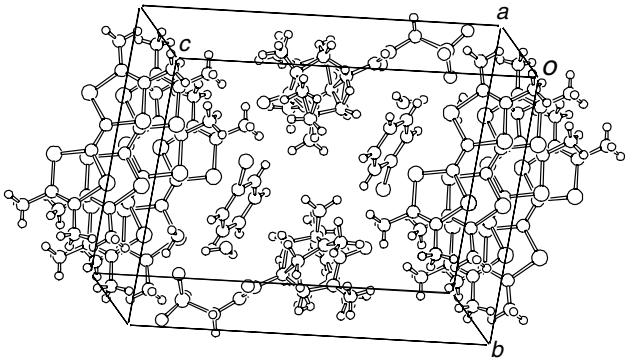

Fig. 9. Crystal structure of (TMTSF)(**H1**) · 2H_2O · PhCl.

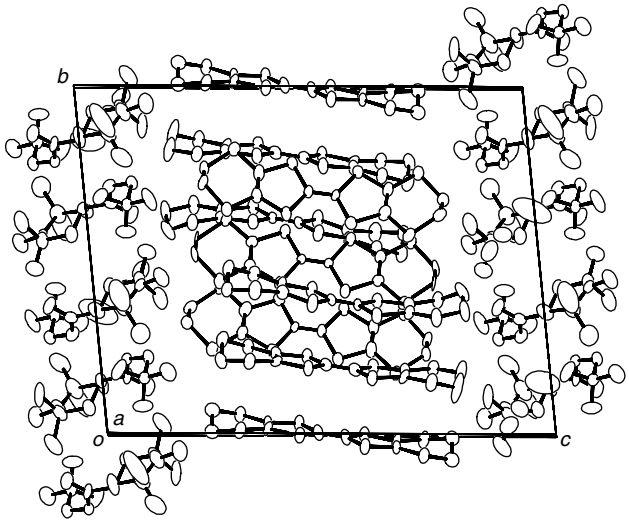

Fig. 10. Crystal structure of α-(BEDT-TTF)$_5$(**H1**)$_2 \cdot 6H_2O$.

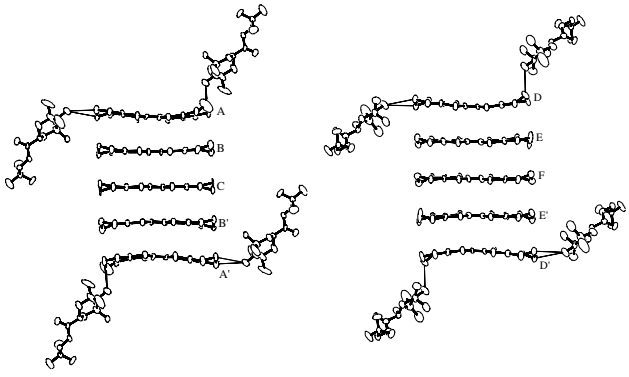

Fig. 12. Structures of the two independent BEDT-TTF pentamers together with the close TEMPO anions.

magnetic interactions because there are no electrons on the terminal ethylene groups. Furthermore, no short contacts between TEMPOs are observed (O···O ≫ 7 Å), which compounds the magnetic isolation of the TEMPO parts. The $\chi T - T$ graph is shown in Fig. 13 where χ is the magnetic susceptibility per a half of the asymmetric unit [(BEDT-TTF)$_{2.5}$ (**H1**) $\cdot 3H_2O$]. The dashed grid lines indicate the degree of spin concentration. The figure indicates that there are two spins at room temperature. As mentioned above, a BEDT-TTF pentamer has an average charge of +2 so that it is possible that a half of a pentamer has one spin (two spins per pentamer). Thus, the observed two spins at room temperature appear to be from a TEMPO molecule and a half of a BEDT-TTF pentamer. The spin concentration gradually decreases with decreasing temperature and reaches to approximately 1.0 at 2 K. To explain the magnetic behaviour, we assumed that the two spins on the BEDT-TTF pentamer interacts with each other in a Singlet–Triplet (S–T) model. On the other hand, the magnetic susceptibility of the spins on a TEMPO molecule were assumed to obey a Curie–Weiss (C–W) model, since they were crystallographically isolated from the other spins, as mentioned above. The magnetic susceptibility is then well explained by the 1:1 combination of a S–T and a C–W model with $J_{S-T} = -41$ K and $\theta_{C-W} = -0.3$ K, as shown in Fig. 14. The fact that the π electrons are not itinerant but localized on the BEDT-TTF pentamer is consistent with the relatively poor conductivity of this 2D-type BEDT-TTF salt.

In conclusion, we have found new TTF-, TMTSF-, and BEDT-TTF-based CT salts that include organic magnetic anions consisting of the TEMPO radical and sulfonates. The relationships between the crystal structures and physical properties are well characterized,

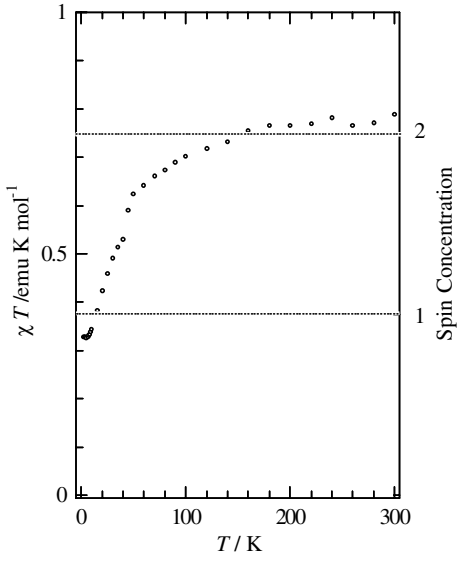

Fig. 13. $\chi T - T$ graph of α-(BEDT-TTF)$_5$(**H1**)$_2 \cdot 5H_2O$, where the χ is the magnetic susceptibility per (BEDT-TTF)$_{2.5}$(**H1**)$_2 \cdot 3H_2O$.

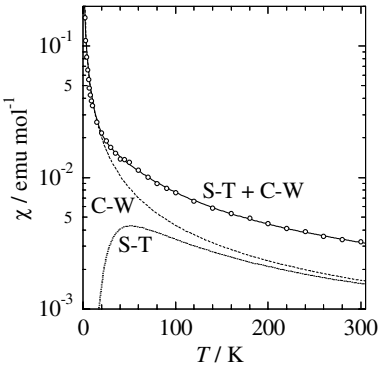

Fig. 14. Temperature dependence of magnetic susceptibility of α-(BEDT-TTF)$_5$(**H1**)$_2 \cdot 6H_2O$. Solid line is calculated on the basis of a 1:1 combination of a Singlet–Triplet and Curie–Weiss models.

but the interplay between π and localized electrons has not provided any new physical phenomena. The previously reported CT salts showing interesting physical properties [1–4], were found to be high conducting. Therefore, further experiments to obtain highly conductive CT complexes is in progress.

2. Experimental

Preparation of crystals of $GdB_{18}Si_5$ which were measured in this work were carried out in the following way. First of all, GdB_6 powder was prepared by the borothermal reduction method of rare earth oxide under vacuum using BN crucibles:

$$Gd_2O_3 + 15B \rightarrow 2GdB_6 + 3BO \quad (1)$$

The Si flux method was used to obtain crystals, with a starting composition of Gd:B:Si of around 1:20:100 in molar ratio. The desired amounts of boron and silicon were added to GdB_6. The mixture was heated to a temperature of around 1923 K for 10 h, then cooled to 1573 K at a rate of 50 K/h, after which the heat was switched off and the crucible cooled to room temperature. The excess silicon was removed by a mixture of hydrofluoric acid and nitric acid to obtain crystals of $GdB_{18}Si_5$. Pieces of crystals were broken off and crushed into powder which was then measured with a high resolution powder X-ray diffractometer (Rigaku Co., RINT2000) with Cu Kα radiation which confirmed the single phase of the samples.

The structure of $GdB_{18}Si_5$ is rhombohedral (space group *R3m*) with lattice constants of $a = b = 10.07$ Å, $c = 16.45$ Å. Views of the structure are depicted in Fig. 1. The structure of rare earth boron-rich icosahedral compounds can basically be understood in that the boron icosahedra form a particular arrangement with rare earth atoms occupying sites in spaces among the icoasahedra. In the case of $GdB_{18}Si_5$, in the shortest metal–metal spacing, the gadolinium sites form a zigzag chain along the [1 1 0] axis with a separation of 5.04 Å. The [0 0 1] alignment of the crystals was

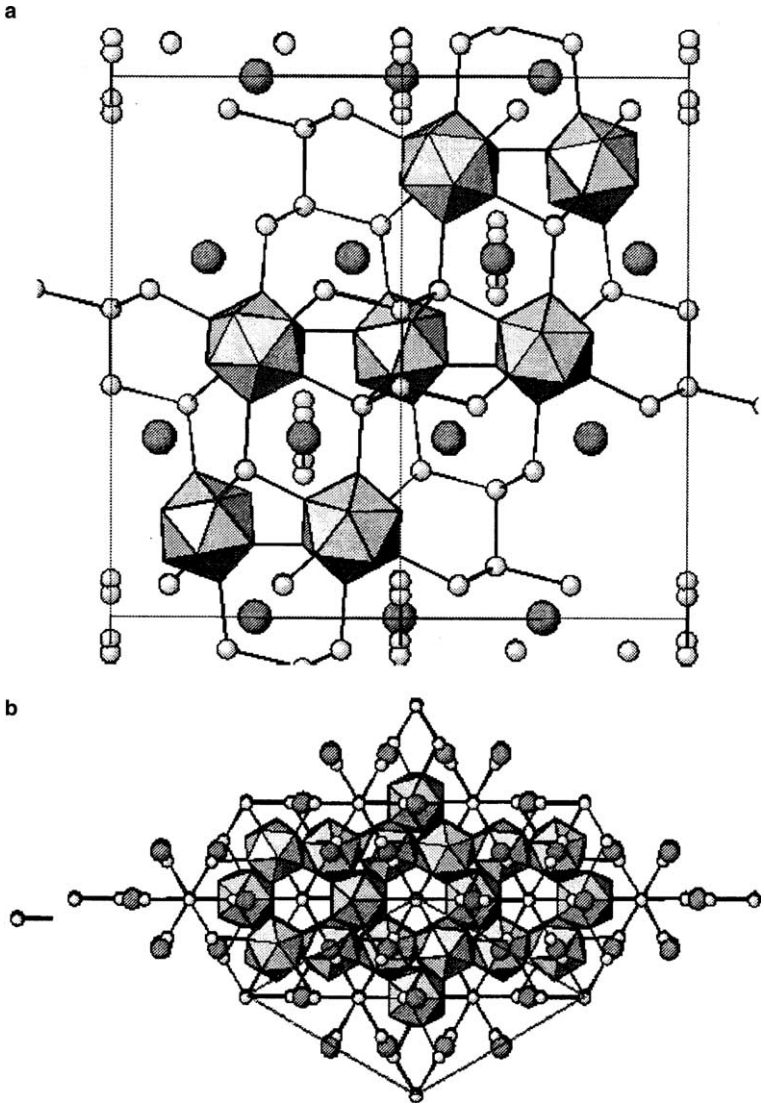

Fig. 1. Crystal structure of $GdB_{18}Si_5$, projected onto the (a) [1 1 0] plane and (b) [0 0 1] plane. The polyhedrons are B_{12} icosahedra, small gray circles indicate silicon atoms, and the large black circles indicate gadolinium atoms.

successfully determined with the [0 0 1] plane forming large faces, however, we could not assign the explicit in-plane alignment of the crystals by Laue photography techniques. Such difficulty has been noticed for other boron-rich systems like $MgAlB_{14}$ and TbB_{50}-type compounds [13] and is generally attributed to the complicated structure and weakness of reflection of boron-rich compounds. However, in the case of the $GdB_{18}Si_5$ crystals, it appears that there are multigrains within the in-plane alignment which are aligned in different directions in-plane (whereas these grains are uniformly ordered along the [0 0 1] direction with the [0 0 1] plane forming orderly). This is indicated from magnetic measurements where the susceptibility below T_N did not differ largely despite incrementally rotating the magnetic field direction in-plane, i.e., the spins are antiferromagnetically aligned in-plane in a certain direction [11] but due to the multigrains aligned in different directions in-plane, the observed susceptibility is a sum of parallel and also perpendicular susceptibility components. Despite not being able to resolve the particular in-plane alignment of a single crystal piece, the in-plane measurements carried out in this work are still important because they obviously contain a component of the parallel susceptibility and reflect its behavior under magnetic field.

Magnetic susceptibility was measured by using a Quantum Design MPMS-XL SQUID magnetometer from 1.8 to 300 K, with fields up to 70 kG. The magnetization was measured with the magnetic field applied along the [0 0 1] *c*-axis and in-plane.

3. Results and discussion

3.1. Magnetic field applied along the c-axis

The temperature dependence of the magnetic susceptibility with the field applied along [0 0 1] for various fields is plotted in Fig. 2. The *c*-axis is perpendicular to the direction the spins are aligned [11] and accordingly little temperature dependence of the *c*-axis susceptibility is observed below the transition temperature. As is typical for antiferromagnetic transitions, the transition temperature shifts to lower temperatures as the magnetic field is increased. We define T_N as the intercept of the lower and higher temperature region extrapolations. The magnetic phase diagram is plotted in Fig. 3. The magnitude of the magnetic field corresponds well with the temperature scale observed here.

The magnetization curve at 1.8 K with field applied along the *c*-axis is shown in Fig. 4. The magnetization increases linearly as the field is increased until it reaches a critical field H_C around 15 kG (as can be estimated from Fig. 3) after which the magnetization rapidly saturates to reach the full moment expected for the $^8S_{7/2}$ ground state of Gd^{3+}.

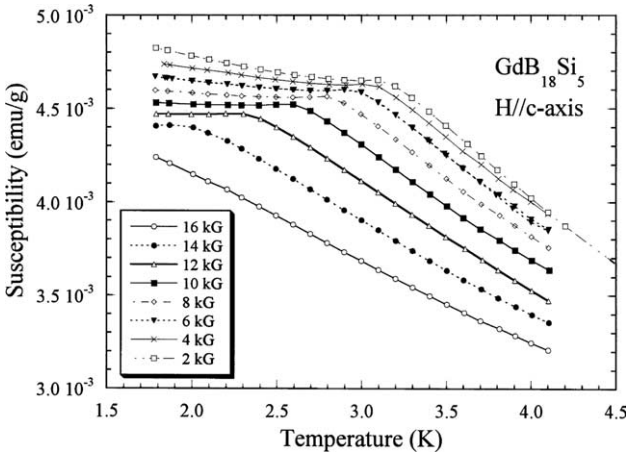

Fig. 2. Temperature dependence of the *c*-axis magnetic susceptibility of $GdB_{18}Si_5$ for 16 kG (open circles), 14 kG (closed circles), 12 kG (open triangles), 10 kG (closed squares), 8 kG (open diamonds), 6 kG (closed triangles), 4 kG (crosses), and 2 kG (open squares). The lines are guides to the eye.

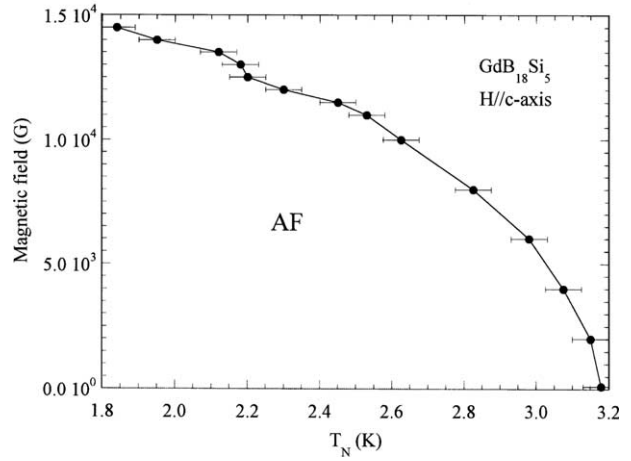

Fig. 3. Magnetic phase diagram of $GdB_{18}Si_5$ with the field applied along the *c*-axis. AF indicates the antiferromagnetic phase. The line is a guide to the eye.

3.2. Magnetic field applied in-plane

As noted in Section 2, the crystals of $GdB_{18}Si_5$ appeared to be composed of multigrains which were not uniformly aligned along a particular direction in the in-plane direction (whereas the alignment of these grains along the *c*-axis was uniformly very good owing to large crystal planes of [0 0 1]). Due to the various alignment of the multigrains leading to a summation of both parallel and perpendicular components, a rotation of the magnetic field within the in-plane

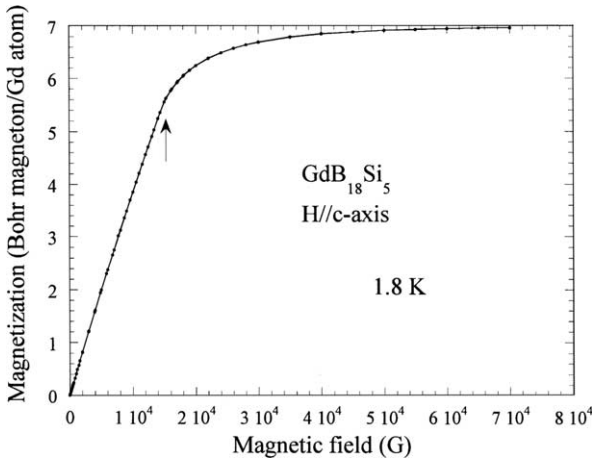

Fig. 4. Magnetization curve of $GdB_{18}Si_5$ with the field applied along the *c*-axis at 1.8 K. The arrow indicates the critical field of 15 kG. The line is a guide to the eye.

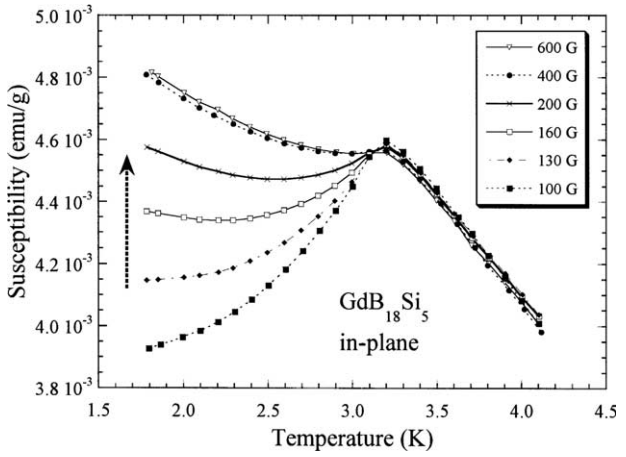

Fig. 6. Temperature dependence of the magnetic susceptibility of $GdB_{18}Si_5$ with field applied in-plane for 600 G (open triangles), 400 G (closed circles), 200 G (crosses), 160 G (open squares), 130 G (closed triangles), and 100 G (closed squares). The lines are guides to the eye.

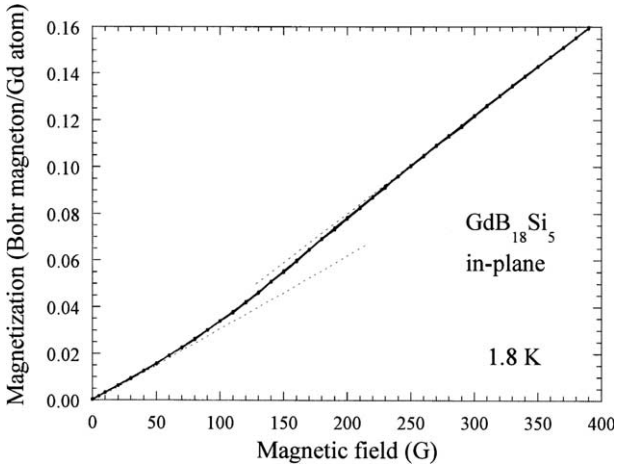

Fig. 5. Low field magnetization curve of $GdB_{18}Si_5$ with the field applied in-plane at 1.8 K. The arrow indicates the critical field of 15 kG. Both field increasing and decreasing data points are plotted together.

direction did not cause a large difference in observed susceptibility. Therefore, although it was not possible to directly measure only the parallel susceptibility, the in-plane measurement was carried out by fixing the magnetic field in a certain direction of the crystal perpendicular to [0 0 1] and varying the magnitude. Since the measured susceptibility can be observed to obviously contain a component of the parallel susceptibility, this gives a measure of the parallel susceptibility behavior under magnetic field.

First of all, the magnetization curve of the in-plane magnetization at low fields is shown in Fig. 5. An interesting dependence at low fields is observed. As field is increased above 50 G the magnetization shows an upper curvature and shifts to a larger regime above 300 G. This behavior can be seen more clearly in the temperature dependence of in-plane susceptibility given for various fields in Fig. 6. The susceptibility above 300 G is similar to the perpendicular (*c*-axis) susceptibility. It appears that a reorientation of the spin direction, a spin flip is achieved at these low fields. We do not think this is a spurious result since the sample is rigidly fixed and the movement of the sample at such low fields (and with this small susceptibility difference) is extremely unlikely. Furthermore, after measurements, the sample was always checked and the physical orientation observed not to have altered at all. The magnetization curve shown in Fig. 5 was measured with a maximum magnetic field of 1 kG (not shown) and there was no hysteresis.

To summarize, the results indicate that a very low field dependence of the parallel susceptibility exists in the $GdB_{18}Si_5$ system with a reorientation of the spin-axis appearing to occur below 300 G. The unusual points of this behavior of the in-plane susceptibility (the parallel susceptibility) are the gradual nature of the shift to higher magnetization and the low field dependence. The origin of this behavior is likely due to the round spin of the gadolinium ions, but the actual observation of a spin flip at such low magnetic fields is rare.

Obtaining more information on the explicit magnetic ordering of $GdB_{18}Si_5$ is desirable. Neutron scattering is a powerful technique to investigate the magnetic structure, but due to the extremely large cross sections of both natural boron and gadolinium this is impossible for the as-prepared samples. We have previously succeeded in synthesizing extremely ^{11}B isotopic pure samples of the even more boron-rich $TbB_{44}Si_2$ sample and carried out neutron diffraction measurements [14]. The procurement of isotope gadolinium is presently being investigated. We are also considering alternate methods using hot neutrons.

4. Conclusions

The magnetic field dependence of the antiferromagnetic transition in the rare earth B_{12} icosahedral cluster compound $GdB_{18}Si_5$ was investigated. Below $T_N = 3.2$ the spins are antiferromagnetically aligned in-plane, perpendicular to the *c*-axis. The magnetic phase diagram was determined with the magnetic field applied along the *c*-axis. Typical dependence of an antiferromagnetic system was observed, with T_N shifting to lower temperatures as field is increased. The magnitude of magnetic field corresponds well to the temperature scale. Rapid saturation to the full moment value for $^8S_{7/2}$ of Gd^{3+} was observed in the magnetization curve above a critical field. An interesting dependence at low magnetic fields was observed when the field was varied in-plane, with a reorientation of the spin-axis appearing to occur at fields below 300 G. The dependence at very low magnetic fields is likely due to the round spin of the gadolinium ion, but such a spin flip actually being observed at these low fields is rare. The observed behavior merits further investigation of the detailed magnetic structure of this compound which is the only system in the rare earth boron icosahedral cluster compounds where three dimensional long range order has been observed, and interestingly has a relatively low partial occupancy of the gadolinium sites.

situation arises due to the possibility that the compounds exhibiting the effect of spin canting derived from chirality to spin structure are much clearer than that of ferro- or ferrimagnets. However, since the effects of chirality on physical properties are poorly understood, theoretically and experimentally, it is quite difficult to identify the experimental results obtained as it. Thus, it is necessary to study achiral compound with similar structure to equivalent chiral compound and make a comparative study between them. The present report describes the synthesizes, crystal structures and magnetic properties of two-dimensional chiral and achiral layered compounds with magnetic ordering, $[Cr(CN)_6][Mn(R)\text{-pnH(DMF)}] \cdot (2H_2O)$ (**1**) and $[Cr(CN)_6][Mn(racemi)\text{-pnH(DMF)}] \cdot (2H_2O)$ (**2**); (pn = 1,2-diaminopropane).

2. Experimental

All chemicals were obtained from Aldrich, Tokyo Kasei or Nacalai Taesuque, and used without purifications. The measurements of temperature and field dependence of the magnetization of the complex were performed on Quantum Design MPMX-XL SQUID operating in the temperature range 2–300 K and an applied field up to 5 T.

3. Preparations of $[Cr(CN)_6][Mn(R)\text{-pnH(DMF)}] \cdot (2H_2O)$ (1) and $[Cr(CN)_6][Mn(racemi)\text{-pnH(DMF)}] \cdot (2H_2O)$ (2)

The syntheses were carried out in the grove box under argon atmosphere, because manganese ion is air sensitive in the KOH solution. Green block-like crystals of **1** were obtained by slow diffusion of $MnCl_2 \cdot 4H_2O$ (5.1 mmol), (*R*)-1,2-diaminopropane dihydrochloride ((*R*)-pn · 2HCl, 6.8 mmol), and KOH (6.8 mmol) in a H_2O/*N*,*N*-dimethylformamide mixture (1:1) into $K_3[Cr(CN)_6]$ (1.5 mmol) in a H_2O/EtOH (1:1) mixture for several weeks. Achiral compound **2** was also obtained as green block-like crystals with racemic pn under the same experimental condition as in **1**.

4. X-ray crystal structure analyses

A single crystals of **1** and **2** were glused on the top of a glass fiber. Data were collected at room temperature on a Brucker SMART APEX CCD area detector with ω scan mode. The diffractometer employs graphite monochromated Mo Kα radiation (0.7107 Å). The data were corrected for Lorentz and polarization effects. The absorption correction was based on symmetry equivalent reflections using the SADABS programs. The structures were solved by direct method and refined by full-matrix least squares against F^2 of all data, using SHELXTL software. All non-hydrogen atoms of **1** and **2** were refined anisotropically. Hydrogen atoms of **1**, except for the water hydrogen atoms, were placed in calculated positions but not refined. The hydrogen atoms of terminal amino group of pn as well as the water hydrogen atoms in **2** were not placed due to the disorder of nitrogen.

Crystal data for (*R*)-isomer **1**: $C_{12}H_{22}N_9O_3Cr_1Mn_1$, M_w = 447.30, orthorhombic, $P2_12_12_1$, a = 7.662(2) Å, b = 14.581(4) Å, c = 19.747(6) Å, V = 2206.2(11) Å^3, T = 293 K, Z = 4, ρ_{calc} = 1.347 g cm^{-3}, μ(Mo Kα) = 1.093 mm^{-1}, R_1 = 0.0440 for 2919 data ($I > 2\sigma(I)$), wR_2 = 0.1245 for 3190 unique data (R_{int} = 0.0254).

Crystal data for **2**: $C_{12}H_{22}N_9O_3Cr_1Mn_1$, M_w = 447.30, orthorhombic, *Pnma*, a = 14.5459(8) Å, b = 7.6509(8) Å, c = 19.723(2) Å, V = 2194.9(4) Å^3, T = 293 K, Z = 4, ρ_{calc} = 1.354 g cm^{-3}, μ(Mo Kα) = 1.098 mm^{-1}, R_1 = 0.0556 for 3975 data ($I > 2\sigma(I)$), wR_2 = 0.1675 for 2418 unique data (R_{int} = 0.0267).

5. Results and discussion

X-ray crystal structure analysis (Fig. 1) of the (*R*)-isomer revealed that compound **1** consists of two-dimensional bimetallic sheets, a situation similar to that of the 2D chiral ferrimagnet $[Cr(CN)_6][Mn(S)\text{-pnH}(H_2O)] \cdot (H_2O)$ with Tc = 38 K [3c]. Each $[Cr(CN)_6]^{3-}$ ion utilizes four cyanide moieties in order to form bridges to four adjacent Mn^{2+} ions within the *ab* plane. The nearest and next nearest neighbor Cr–Mn distances through cyanide bridges within the *ab* plane are 5.366(1) and 5.409(1) Å, respectively, which are nearly identical to those distances in $[Cr(CN)_6][Mn(S)\text{-pnH}(H_2O)] \cdot (H_2O)$. In addition to Mn^{2+} and $[Cr(CN)_6]^{3-}$ ions (one of each), an asymmetric unit in this crystal contains a single molecule each of mono-protonated (*R*)-diaminopropane ((*R*)-pnH) and DMF and two water molecules. An octahedron around the Mn^{2+} ion is completed by coordination of the primary amino group of (*R*)-pnH and the DMF molecules (Mn–O and Mn–N separations are 2.181(3) and 2.323(4) Å, respectively), which separate adjacent bimetallic sheets along the *c*-axis. The two water molecules in **1** occupy gaps between two-dimensional sheets. The shortest and the second shortest inter-sheet metal separations are observed between the homo-metallic atoms (Cr–Cr and Mn–Mn distances are 7.3114(1) and 7.5424(2) Å, respectively). On the other hand, the shortest inter-sheet Mn–Cr separation is 9.2963(7) Å. This observation suggests that this inter-sheet separation is small enough to allow a magnetic interaction between bimetallic sheets in compound **1** and the contact between atoms with the same number of spins is expected to lead an intersheet antiferromagnetic interaction. In the 2D chiral ferrimagnet

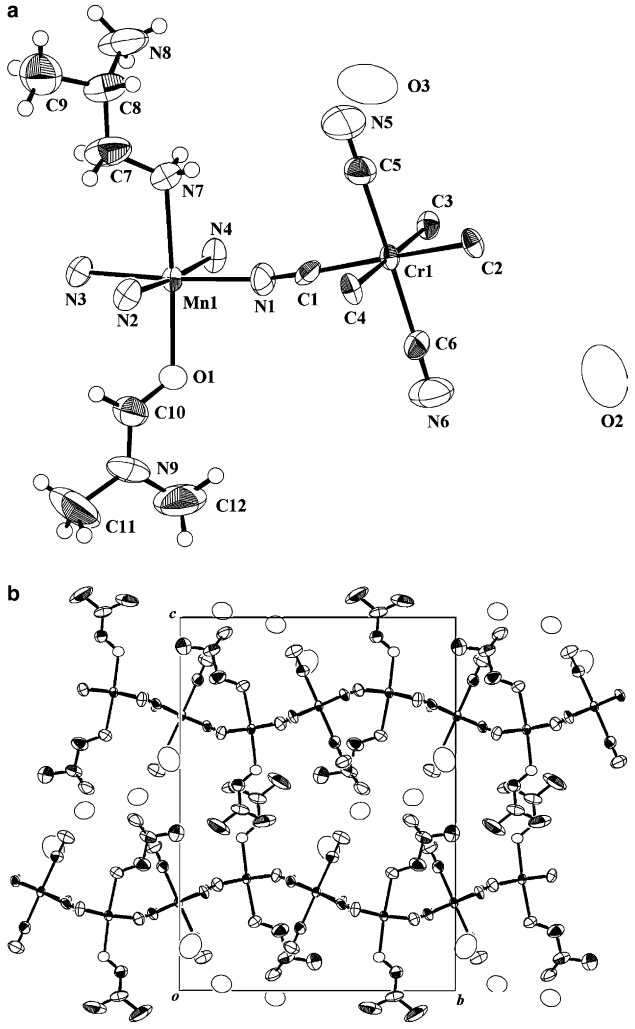

Fig. 1. (a) ORTEP drawing of an asymmetric unit of $[Cr(CN)_6]$-$[Mn(R)$-pnH(DMF)$] \cdot (2H_2O)$ (**1**) with 50% probability level. (b) Crystal structure of $[Cr(CN)_6][Mn(R)$-pnH(DMF)$] \cdot (2H_2O)$ (**1**). Views of the enantiopure layer along the *ab*-plane. Hydrogen atoms are omitted for clarity.

$[Cr(CN)_6][Mn(S)$-pnH$(H_2O)] \cdot (H_2O)$, the inter-sheet homo-metallic separation is beyond 8 Å, while the shortest inter-sheet metal separation between the Cr and the Mn atoms is 7.3105(4) Å. This is probably advantageous to the ferromagnetic interaction between 2D sheets from the point of view of a magnetic dipole interaction [3c].

X-ray crystal structure analysis (Fig. 2) of achiral compound revealed that compound **2** also consists of similar two-dimensional bimetallic sheet to that of chiral compound **1**. The bond distances within the bimetallic sheet in compound **2** are almost the same bond distances as those of compound **1**. The nearest and next nearest neighbor Cr–Mn distances through cyanide bridges within the *ab*-plane are 5.3582(6) and 5.3906(6) Å. However, the inter-sheet separations in compound **2** are quite longer than those in compound **1**. Even shortest metal–metal separation in compound **2** is beyond 8 Å (Mn–Mn, Cr–Cr and Cr–Mn distances are 8.7958(11), 10.5710(8) and 9.278(1) Å, respectively). In such a case, probably, the magnetic interaction between bimetallic sheets is negligible and weak magnetic dipole–dipole interaction is expected to be operative.

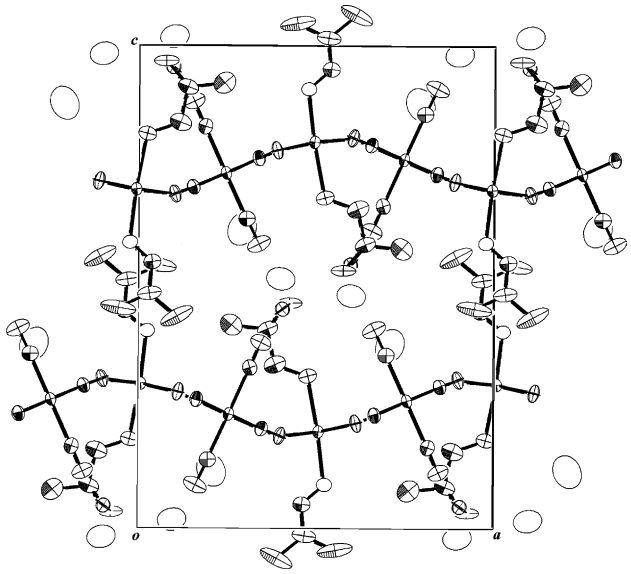

Fig. 2. Crystal structure of $[Cr(CN)_6][Mn(racemi)$-pnH(DMF)$] \cdot (2H_2O)$ (**2**). Views of the bimetallic layer along the *ab*-plane. Hydrogen atoms are omitted for clarity.

The magnetic behavior of polycrystalline samples of compound **1** at 5000 G is presented in Fig. 3 in the form of $\chi_{mol}T$ versus T and effective magnetic moment versus $1/T$ plots. The $\chi_{mol}T$ value, which is 4.92 cm^3 K/mol (6.28 μ_B) at room temperature, decreases with decreasing temperature to a minimum value of 3.53 cm^3 K mol^{-1} (5.31 μ_B) at 82 K. Upon further cooling, the $\chi_{mol}T$ value increases to a maximum value of 36.19 cm^3 K mol^{-1} (17.02 μ_B) at 27 K; subsequently, the $\chi_{mol}T$ value decreases below 27 K. The $1/\chi_{mol}$ versus T plot in the range from 300–120 K obeys Curie–Weiss law with a

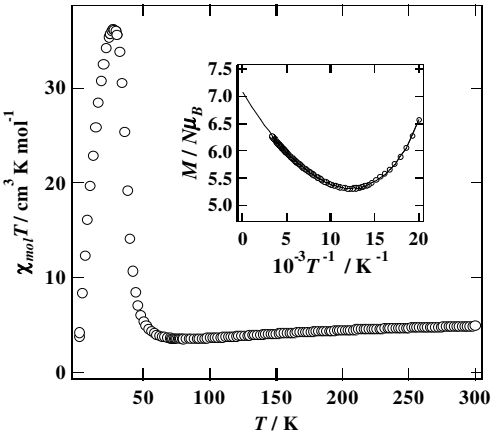

Fig. 3. $\chi_{mol}T$ versus T plot at 5000 G of $[Cr(CN)_6][Mn(R)$-pnH-(DMF)$] \cdot (2H_2O)$ (**1**). Inset: plot of effective magnetic moment versus $1/T$.

Weiss temperature $\theta = -73.5$ K. This finding indicates that antiferromagnetic interaction operates between nearest neighbor Cr^{3+} and Mn^{2+} ions through cyanide bridges. The abrupt increase in the $\chi_{mol}T$ value around 30 K suggests the onset of three-dimensional magnetic ordering. The extrapolated effective magnetic moment value is 7.07 μ_B, which corresponds to the theoretical spin-only value of non-coupled paramagnetic high spin in the high temperature limit (Fig. 3, inset). The $\chi_{mol}T$ versus T plot at 5000 G of compound **2** also display similar behavior to that of compound **1**.

Low-field magnetization measurements of polycrystalline samples of compound **1** at an applied field of 5 G in the temperature range of 1.8–100 K were performed to confirm long range magnetic ordering around 30 K (Fig. 4). Both the zero field-cooled magnetization (ZFCM) and the field-cooled magnetization (FCM) curves display abrupt increases in M below 40 K, which reach a maximum at 28.5 K, followed by a decline below this temperature. Thus, the magnetic phase transition temperature T_N of 28.5 K was determined.

The magnetization versus field (M–H) plot of polycrystalline samples at 2 K exhibits a sigmoid curve in **1**, which is typical of a metamagnet. This result is attributable to a spin-flip transition based on intersheet antiferromagnetic coupling (Fig. 5). The saturation magnetization, $M_S = 2\ \mu_B$, agrees closely with the theoretical value of antiferromagnetic coupling between Cr^{3+} and Mn^{2+} ions (5/2 − 3/2 = 2/2).

On the other hand, both low-field and field dependent magnetization curves of polycrystalline samples in compound **2** show different behaviors from those in compound **1** (Fig. 6). Both the zero field-cooled magnetization (ZFCM) and the field-cooled magnetization (FCM) curves display a long range ferrimagnetic ordering below 28 K. The magnetization versus field (M–H) plot increases sharply with applied field to show the theoretical saturation magnetization value, $M_S = 2\ \mu_B$, of antiferromagnetic coupling between Cr^{3+} and Mn^{2+} ions (Fig. 6, inset).

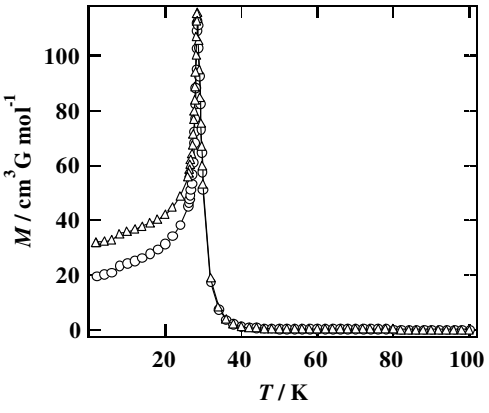

Fig. 4. Temperature dependence of magnetization of $[Cr(CN)_6]$-$[Mn(R)$-pnH(DMF)$] \cdot (2H_2O)$ (**1**). The FC (△) and ZFC (○) magnetizations at 5 G are shown.

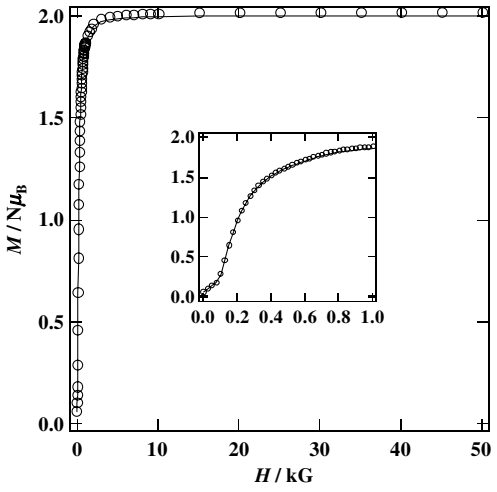

Fig. 5. Field dependence of $[Cr(CN)_6][Mn(R)$-pnH(DMF)$] \cdot (2H_2O)$ (**1**) at 2 K. Inset: the enlarged view in the lower field region.

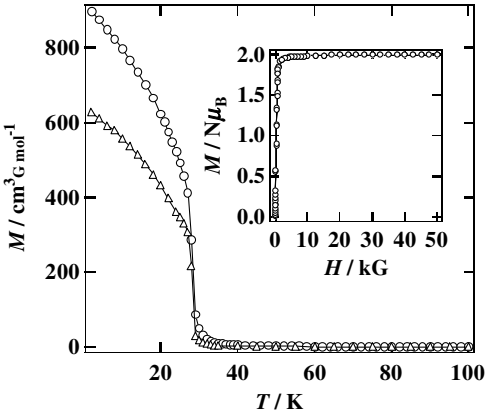

Fig. 6. Temperature dependence of magnetization of $[Cr(CN)_6]$-$[Mn(racemi)$-pnH(DMF)$] \cdot (2H_2O)$ (**2**). The FC (○) and ZFC (△) magnetizations at 5 G are shown. Inset: field dependence of $[Cr(CN)_6]$-$[Mn(racemi)$-pnH(DMF)$] \cdot (2H_2O)$ (**2**) at 2 K.

In conclusion, we successfully constructed the novel chiral and achiral bimetallic compounds $[Cr^{III}(CN)_6]$-$[Mn^{II}(R)$-pnH(DMF)$] \cdot (2H_2O)$ (**1**) and $[Cr^{III}(CN)_6]$-$[Mn^{II}(racemi)$-pnH(DMF)$] \cdot (2H_2O)$ (**2**), respectively. The sharp peak in Fig. 4 and the noticeable escalation of the magnetization at very low fields in the inset of Fig. 5 clearly demonstrate that **1** is a metamagnet with T_N of 28.5 K, on the other hands, Fig. 6 demonstrates that **2** is just a ferrimagnet with T_c of 28 K. These magnetisms are attributed to the slight difference of intersheet arrangement and orientation between compounds **1** and **2**, which phenomena are often observed in the two-dimensional cyanide bridging system [4]. Compound **1** among chiral cyanide-bridged systems is the first example exhibiting antiferromagnetic order and shows very interesting magnetic behavior at low

temperature. Neither the ZFCM nor the FCM of **1** drops to zero below T_N, a quality that is distinct from that of an ordinary metamagnet. This finding suggests that all magnetic moments do not wholly cancel one another between all spins in **1**. The possibilities exist that the magnetic moments in the ground state are canted by the electronic dipole field or by D–M (Dzyalonshisky–Moriya) interaction due to the chiral structure. Magnetization measurements, μSR and neutron diffraction of a single crystal will lead to characterization of the details of chiral spin structure in **1**. Moreover, the study of achiral spin structure in compound **2** as well as compound **1** will be also needed for the purpose of verifying the effect of chirality on spin structure. The experiments are in progress.

negative θ value of about 85 K, and the effective magnetic moment per ion was found to be about 4.4 μ_B.

It is known that Co_3O_4 bulk crystal exhibits antiferromagnetism, with a T_N of 33 K [5].

Recently, we reported a magnetic study of Co_3O_4 nanoparticles 2 or 3 nm in size [6]. No Néel temperature could be observed at 33 K, and transition temperatures between 7.5 and 12.0 K were found instead. Ferromagnetic behavior with slight hysteresis below the transition temperature T_t was observed, and a effective magnetic moment per ion expected at 4.14 μ_B was estimated to be much larger, 8.12 μ_B.

In this paper, magnetization measurements were performed in order to clarify the size dependence of the magnetic properties of Co_3O_4 nanoparticles ranging from 3 to 30 nm in size.

2. Experiment

The Co_3O_4 particle surrounded by an amorphous SiO_2 network precursor was chemically precipitated by mixing a cobalt chloride ($CoCl_2 \cdot 6H_2O$) aqueous solution and a sodium metasilicate nonahydrate ($Na_2SiO_3 \cdot 9H_2O$) aqueous solution. A cobalt chloride ($CoCl_2 \cdot 6H_2O$) aqueous solution mixed with a sodium hydroxide (NaOH) aqueous solution without a metasilicate nonahydrate was also prepared. The resulting pink-colored precipitates were washed several times with distilled water and dried at about 350 K. The obtained glassy solids were crushed into a powder and calcined between 573 and 1023 K in air. The particle sizes were controlled through the annealing temperatures and the concentration of the silicates. The varied mole ratios of Co/Si in the samples were 1, 1.5, 2, and a sample without Si was also prepared. Particle sizes between 3 and 30 nm were obtained.

X-ray powder diffraction patterns were obtained by room temperature Cu Kα radiation. Magnetization was measured by VSM and SQUID magnetometer under a ±50 kOe magnetic field, at temperatures from 2 to 300 K.

3. Results and discussion

3.1. X-ray analysis

Fig. 1 shows the X-ray powder diffraction patterns of samples with particle sizes of 3, 9.7, 12 nm and bulk crystal.

The X-ray diffraction patterns of the prepared particles indicate the formation of the spinel phase of Co_3O_4, without any observable traces of either cobalt hydroxides ($Co(OH)_2$) or cobalt monoxide (CoO). The broad peak at around 25° for the 3 nm particles is associated with the amorphous SiO_2. The lattice constants were found to be between 0.808 and 0.817 nm, depending on the particle size. Using the Scherrer equation, the particle sizes were roughly estimated at between 3 and 30 nm. These sizes are in good agreement with the TEM image given in Fig. 2. The relationship between lattice constants and particle sizes were summarized in Fig. 3.

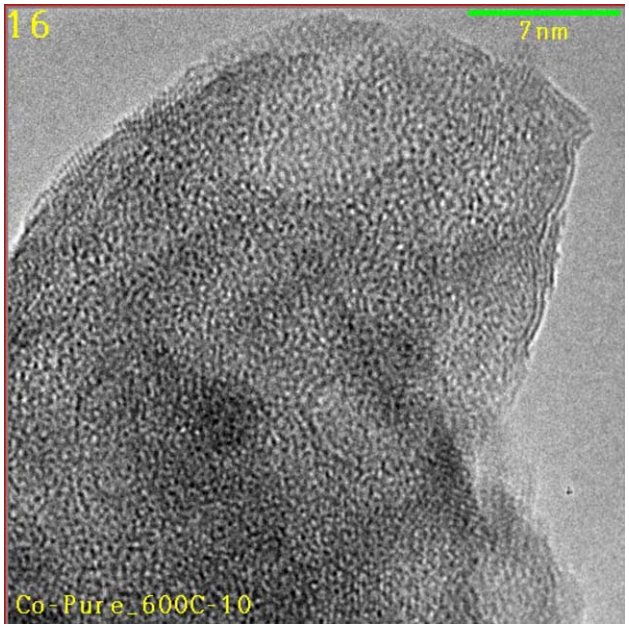

Fig. 2. TEM image of sample no. 1. The scale bar in the picture is 7 nm.

3.2. Magnetization measurements

The temperature dependence of the magnetization in under field-cooled (FC) and zero-field-cooled (ZFC)

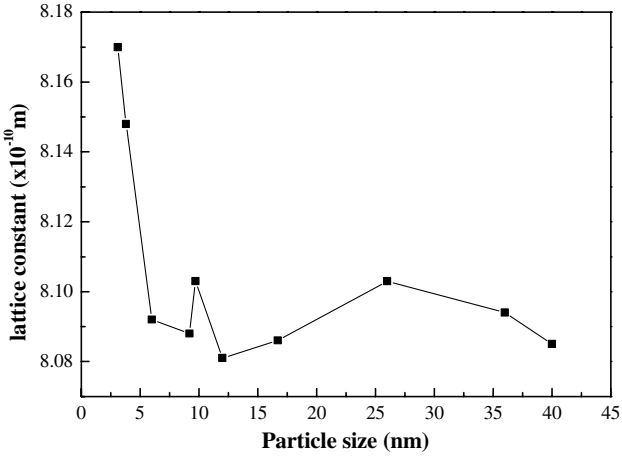

Fig. 3. Dependence of the lattice constant on particle size.

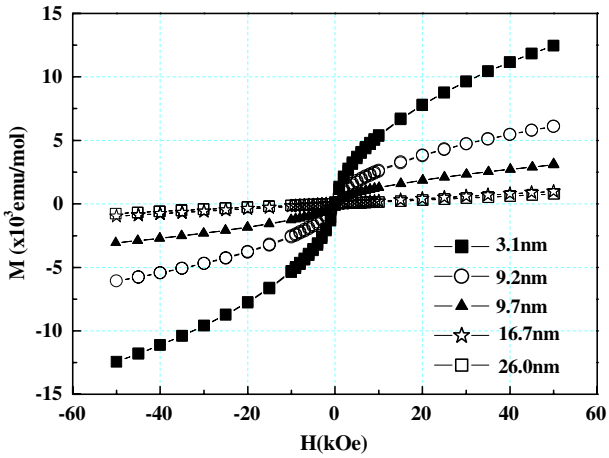

Fig. 5. Magnetization curves for various particle sizes at 5 K.

conditions was examined for all samples. All of these particles could be considered to form a single domain, ordered antiferromagnetically below T_N = 33 K. Fig. 4 shows the M–T curves of both FC and ZFC for the samples 3.1 and 9.2 nm in size. T_N could not be observed at around 33 K; however, the FC and ZFC curves were strongly bifurcated at 12 K for the 3.1-nm sample and at 4 K for the 9.2-nm sample. This bifurcated temperature of FC and ZFC was defined as the blocking temperature T_b. Above 50 K, the plot of χ^{-1} versus T is linear, indicating that the magnetization obeys the Curie–Weiss law, with a negative θ value of about 34 K for the 9.2-nm sample and 48 K for the 3.1-nm sample.

The magnetization curves were measured at temperatures from 5 to 300 K under a ±50-kOe field. The M–H curves for various particle sizes at a temperature of 5 K are given in Fig. 5. It is obvious that the magnetization increases as the particle size decreases, and that it behaves ferromagnetically. Coercivity was observed in the 3.1-nm sample as 110 Oe, and in the 9.2-nm as 150 Oe.

Magnetizations far above T_b were paramagnetic, just above T_b were superparamagnetic forming a magnetization curve. Below T_b ferromagnetic behavior with slight hysteresis was observed and this could be explained by uncompensated surface spins of the Co_3O_4 nanoparticle.

The effective magnetic moment per ion μ_{eff} could be estimated for all the samples from the χ–T plot, and are summarized as a function of particle size in Fig. 6. The saturation magnetization values M_s are also indicated. It is remarkable that both M_s and μ_{eff} increased dramatically below the particle size of about 10 nm. The value of the effective magnetic moment μ_{eff} per ion for the 3.1-nm particle was estimated to be 8.12 μ_B, and this estimation was twice as large as expected (4.14 μ_B). Because uncompensated surface spins behave superparamagnetically, the total magnetic spins became easy to order, and as a result magnetizaion increased.

Co_3O_4 has a normal spinel structure with antiferromagnetic exchange between ions occupying the tetrahedral A sites and the octahedral B sites. The Co^{3+} ions have no moment at the B sites, while the Co^{2+} ions at the A sites have a permanent moment of 3.25 μ_B, as found in neutron diffraction experiments [7]. However, the large effective magnetic moment μ_{eff} estimated from the inverse susceptibility of 8.12 μ_B could not be explained only on the basis of the Co^{2+} ion. Normally, Co^{3+} ions have no magnetic moment because of the large crystal field splitting of the 3d orbitals by the octahedral cubic field. In a small particle system, it is thought that Co^{3+} ions owe their magnetic moment to the defect of oxygen as well as the distortion of the crystal symmetry, though they normally exhibit no magnetic moment. An expansion of the lattice constant according to the downsizing of the particle, shown in Fig. 3, suggests an alteration of the geometry of the spinel structure.

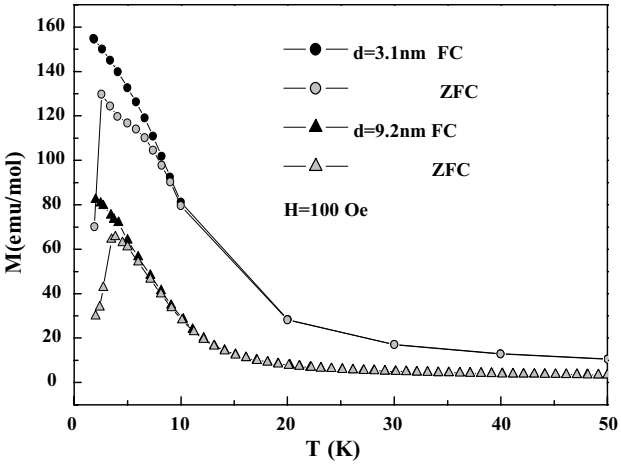

Fig. 4. Temperature dependence of FC (open marks) and ZFC (closed marks) magnetization for each particle size.

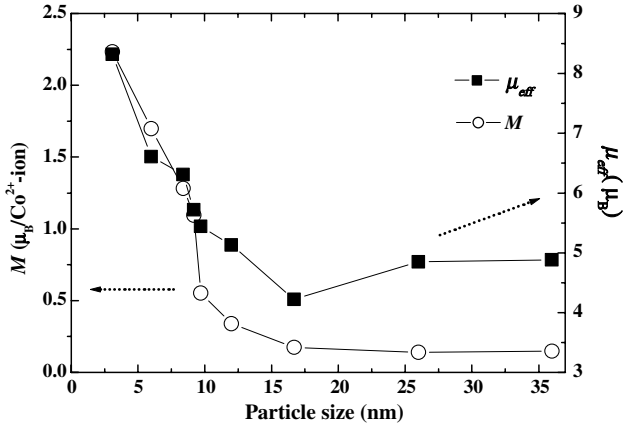

Fig. 6. Dependence of the saturation magnetization and effective magnetic moment on particle size.

4. Conclusion

The Co_3O_4 particles with an average size ranging from 3 to 30 nm were prepared and their magnetic properties depending on particle sizes were reported. Both M_s and T_b increased dramatically below the particle size of about 10 nm. Because uncompensated surface spins behave superparamagnetically, the total magnetic spins became easy to order. The value of the effective magnetic moment μ_{eff} per ion for the 3.1-nm particle was estimated to be 8.12 μ_B, and this estimation was twice as large as expected. This could be also thought that Co^{3+} ions owe their magnetic moment to the defect of oxygen as well as the distortion of the crystal symmetry in a small particle system.

Acknowledgments

The authors thank Ms. K. Yabuta, Mr. S. Konuma and Mr. M. Uzaki for producing the TEM images, and Ms. Y. Itoh for her chemical analysis of the Co-O nanoparticles. The useful discussion with Prof. Y. Kimishima is also appreciated. This study was partially supported by a Grant-in-Aid for Scientific Research offered by the Japan Society for the Promotion of Science (C) (2) (No. 15510089).

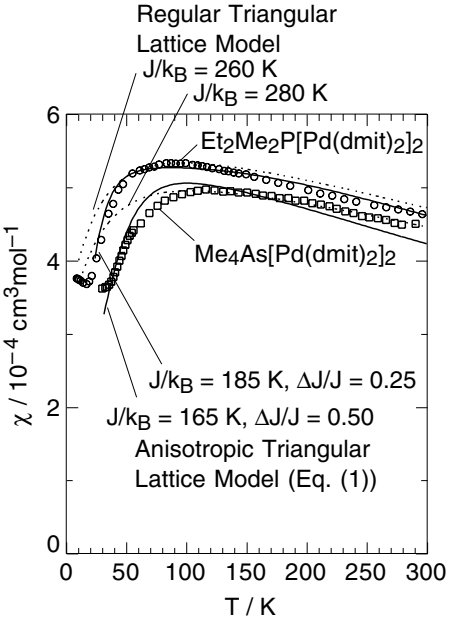

Fig. 2. Temperature dependence of χ of the Me_4As and Et_2Me_2P salts, as compared with the values calculated using the regular triangular lattice model (broken curves) and the phenomenological model for anisotropic triangular lattice (solid curves) with the indicated parameters.

broken symmetry for example. This is the main origin of unorthodox physical behavior of the frustrated systems.

The stability of the metallic state is ruled by the competition between the cost by the intradimer electron repulsion, U_{dimer}, and the kinetic energy gain corresponding to the bandwidth, W. If U_{dimer}/W is sufficiently large, the spin-localized AF state attains more stability by the exchange couplings, J, so that the system becomes insulating. The frustration in the insulating state eliminates the exchange energy gain and provides higher entropy, by suppressing the spin correlation. Thus the frustration operates to stabilize the metallic state relatively. Therefore, the metallic state can appear by a small increase in W, when the system is close to the completely frustrated regular triangular lattice. This tendency is in fact observed in the $[Pd(dmit)_2]$ series [4–6]. For instance, the Me_4P and Me_4As salts, which have the most anisotropic lattice, cannot be metallic under hydrostatic pressure, whereas the Et_2Me_2P and Me_4Sb salts, which are closer to the regular triangular arrangement, readily become metallic under pressure lower than 1 GPa.

At ambient pressure, U_{dimer}/W remains large enough to preclude the metallic state in these salts. As shown in Fig. 2, the temperature dependence of magnetic susceptibility (χ) of these salts can be well explained by the spin-1/2 Heisenberg triangular antiferromagnet model [7], particularly above the temperature where a round maximum of χ appears (T_{max}). The most significant feature of the frustrated spin system, from an experimental viewpoint, is that T_{max} is much lower than the mean-field Weiss temperature θ, estimated from the Curie–Weiss-like high-temperature χ tail [7,8]. In a system without frustration, $T_{max} \approx \theta$ is usually expected, because T_{max} is a measure of the temperature below which the AF correlation grows beyond the lattice spacing. The frustration prevents the AF correlation from growing so as to keep the system "paramagnetic" (or a spin liquid) down to considerably low temperature, which explains the low T_{max}.

As temperature decreases below T_{max} the χ behavior gradually deviates from the regular triangular model. There appears a steep decrease of χ, like in a spin-gapped system, until χ turns to be rather flat at the Néel point [9,10]. The steep decrease of χ indicates a rapid growth of the AF correlation. There should be a crossover from the frustrated paramagnetic state to an antiferromagnetically correlated one, by which the frustration is released. The crossover temperature, as well as the Néel temperature (T_N), shifts to higher, as the lattice deviates from the regular triangular lattice depending on the cation. This magneto-structural correlation indicates that the crossover originates from the lattice anisotropy. As shown in Fig. 1(a), the $[Pd(dmit)_2]$ salts can be modeled as the isosceles system interpolating between the square lattice ($\Delta J \gg J$) and the triangular lattice ($\Delta J = 0$), where ΔJ is the deviation from the regular triangular lattice.

According to theoretical calculations [11,12], the spin excitation spectra of the interpolating system has dip minima leading to long-wavelength AF correlation, and short-wavelength weak dispersion lies approxi-

mately ΔJ above the minimum, which explains the high-temperature paramagnetic behavior due to the frustration. Therefore, ΔJ plays like the spin gap separating the long-wavelength spin-wave excitations predominant at low temperatures and the short-wavelength magnon excitations significant at high temperatures. If this is the case, the frustration is released by the AF correlation growing at low temperatures, $T < \Delta J/k_B T$. Our aim is to describe the temperature dependence of χ, on the basis of this picture. We have proposed an interpolating formula [13]

$$\chi(T) = [z_{tri} J \chi_{tri}(k_B T/J) f(T, \Delta J) + z_{sq} \Delta J \chi_{sq}(k_B T/\Delta J)] / [f(T, \Delta J) + 1](z_{tri} J + z_{sq} \Delta J), \quad (1)$$

where χ_{tri} and χ_{sq} stand for the χ of the triangular lattice (J-lattice) and that of the square lattice (ΔJ-lattice), respectively, $f(T, \Delta J) = 1/[\exp(\Delta J/k_B T) - 1]$ denotes the Bose distribution, and $z_{tri} = 6$ and $z_{sq} = 4$ are the numbers of the neighboring sites. The long- and short-wavelength contributions are approximated by χ_{sq} and χ_{tri}, respectively, in this phenomenology. This explains the observed crossover behavior, as indicated in Fig. 2. The crossover has a characteristic temperature, $T \approx \Delta J/k_B$ which is related to the structural features. In these cases, the frustration is released by the growth of the square-lattice-like AF correlation due to the deviation from the regular triangular lattice.

From the viewpoint of molecular magnetism, it is worth noting that even a small size model of a frustrated spin system exhibits some features showing relevance to the frustration-release crossover. Appearance of a common feature for the small model and the infinite lattice is suggested by the short correlation-length in the frustrated state. The key feature is the energy structure having low-lying antiferromagnetically correlated states and the short-range excitations with weak dispersion. The weak dispersion implies a considerably isolated spin distribution. Let us consider here, for example, the minimal model, i.e., a three-spin Heisenberg model on an isosceles triangle (Fig. 3). At $\Delta J = 0$ (the regular triangle), doubly degenerate $S = 1/2$ states are the lowest. This degeneracy means the complete frustration. As ΔJ increases, one of the $S = 1/2$ levels shifts lower, while the other remains not shifted. There is an energy separation of ΔJ between them. The lower state has antiferromagnetically correlating spin distribution over the triangle, suggesting relevance to the long-range correlation, while the other one has an isolated spin on the center. This is in fact analogous to the excitation spectra considered for the isosceles triangular lattice. It is noteworthy that this low-energy structure is dominated only by the distortion parameter ΔJ, not by J.

The AF correlation grows exponentially like in a square lattice AF below the crossover temperature, so as to spread over large area. This causes another cross-

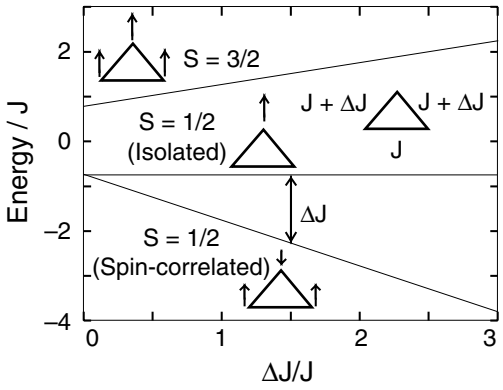

Fig. 3. Energy diagram of a three-spin Heisenberg model on an isosceles triangle as a function of the anisotropy, ΔJ. The spin distributions, being independent of ΔJ, are also depicted.

over to a three-dimensional long-range ordered state, assisted by weak interlayer couplings [13]. The observed Néel temperatures correspond to this dimensional crossover.

Finally, we briefly mention the valence state of a peculiar case, the Et_2Me_2Sb salt, which is closest to the regular triangular lattice. This salt undergoes a first-order phase transition at 70 K. The low-temperature phase is non-magnetic (Fig. 4(a)) and has two types of dimers. Clearly the spin frustration is released by this transition. We have attributed this transition to the charge separation (disproportionation),

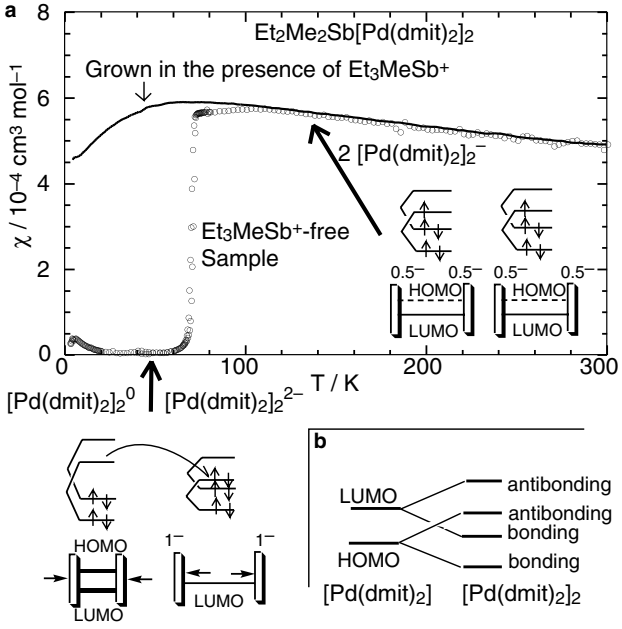

Fig. 4. (a) Temperature dependence of χ of the two types of the Et_2Me_2Sb salt samples. The electronic structures of the dimers above and below the 70 K phase transition are displayed. (b) Energy diagram for the dimerization of $[Pd(dmit)_2]$ to explain the HOMO–LUMO interchange.

$2[Pd(dmit)_2]_2^- \rightarrow [Pd(dmit)_2]_2^0 + [Pd(dmit)_2]_2^{2-}$, accompanied by electron pairing on half of the dimers [14]. The key factor to understand this transition is the unique two-level structure of the $[Pd(dmit)_2]_2$ dimer. The anti-bonding level of the HOMO's and the bonding level of LUMOs interchange due to strong dimerization (Fig. 4(b)) [15,16]. For this reason, the neutral dimer $[Pd(dmit)_2]_2^0$ possesses considerable stability owing to the double-bonding [14]. We have shown, that the energy gain of the double-bonding can compensate the cost for electron pairing on another dimer, by model calculations assuming variation of dimerization for the different dimers [14]. The Et_2Me_2Sb salt is so close to the regular triangle lattice that it cannot release the frustration by growing AF correlation. However, this salt changes the electron occupancy in the two-level structure, so as to escape from the frustration and to achieve a stable non-magnetic ground state. We have noticed a strong impurity effect on this transition. When the crystals are grown in the presence of Et_3MeSb^+ cations, the non-magnetic state is easily broken to let the frustrated paramagnetic state survive down to low temperature, though the content of Et_3MeSb^+ in the crystals is quite small (Fig. 4(a)). The origin of this impurity effect stabilizing the frustrated state is still an open question.

temperature or of pressure. When the magnitude of the intermolecular interactions overcomes the threshold value, the spin-crossover phenomenon undergoes co-operativity. In such a case, the spin transition between the low-spin and high-spin states is not only very abrupt, but also occurs with a hysteresis effect [7]. The design of molecules exhibiting bistability is one of the main challenges in molecular material science in order to utilise them for information processing and information storage [8]. Furthermore the design of spin-crossover compounds with multi-function, supramolecular structure and porous materials, has been noted because of leading specific magnetic or optical properties [9,10]. For some iron(II) spin-crossover (high-spin ($S = 2$) ↔ low-spin ($S = 0$)) compounds, light-induced low-spin → high-spin conversion can be observed by green light illumination into a d–d or MLCT (metal-to-ligand charge transfer) absorption band at temperatures well bellow the thermal transition temperature. A mechanism for this phenomenon, denoted as "light-induced excited spin state trapping" (LIESST), has been proposed [11,12]. The development of novel compounds exhibiting LIESST is one of the main challenges in this field [7,13,14]. The LIESST compounds can be used as optical switching molecular devices, and various functional materials including the optical switches can be constructed.

Here we focused on the spin-crossover iron(II) compounds in order to control liquid crystals not only by temperature but also magnetic field and photo-illumination. The spin-crossover iron(II) compounds exhibit spin conversion between diamagnetism ($S = 0$) and paramagnetism ($S = 2$), and the LIESST effect. The design of metallomesogens containing spin-crossover iron(II) center stimulates producing unexpected advanced materials by combining spin-crossover and LIESST with liquid-crystal properties [15].

The iron(II) compounds $[Fe(1C16\text{-}L)_2(NCS)_2]$ (**1**) $[Fe(2C16\text{-}L)_2(NCS)_2]$ (**2**) and $[Fe(3C16\text{-}L)_2(NCS)_2]$ (**3**) were designed in order to construct a spin-crossover and LIESST material with liquid-crystal properties, where 1C16-L, 2C16-L and 3C16-L are Schiff-base bidentate ligands derived from the condensation of 4-hexadecyloxyaniline, 3,4-bis(hexadecyloxy)aniline and 3,4,5-tris(hexadecyloxy)aniline with pyridine-2-carboxyaldehyde (Fig. 1). Because the iron(II) compound *cis*-bis(thiocyanato)-bis [*N*-(2-pyridylmethylene)aniline]iron (II) exhibits spin-crossover and LIESST effect, the ligand of the complex was modified as Schiff-base ligand with elongated substituents [16].

Fig. 1. Structure of the ligands.

2. Experimental

2.1. Preparations of the ligands [17,18]

2.1.1. Preparation of 1,2-didodecyloxybenzene (*2C16*)

Catechol (1.1 g, 10 mmol), K_2CO_3 (3.45 g, 25 mmol), 1-bromohexadecane (7.63 g, 25 mmol), and KI (0.1 g, 0.60 mmol), were mixed in DMF (50 ml). The mixture was stirred at 80 °C for one day. After cooling to room temperature, the mixture was poured into ice/water. The white precipitation was filtrated and washed with acetone; yield: 4.72 g (85%); white needle. ^{1}H NMR ($CDCl_3$): $\delta = 6.90$ (s, 4H), 3.96 (t, $J = 6.5$ Hz, 4H), 1.86–1.26 (m, 56H), 0.88 (t, $J = 6.4$ Hz, 6H). 1,2,3-Tris(hexadecyloxy) benzene (**3C16**) was prepared same as **2C16**; yield: 6.50 g (81%); white solid. ^{1}H NMR ($CDCl_3$): $\delta = 6.90$ (t, $J = 8.3$ Hz, 1H), 6.53 (d, $J = 8.3$ Hz, 2H), 3.96 (t, $J = 6.5$ Hz, 4H), 3.94 (t, $J = 6.7$ Hz, 2H), 1.86–1.26 (m, 84H), 0.88 (t, $J = 6.7$ Hz, 9H).

2.1.2. Preparation of p-nitrohydroxybenzene (*1C16-NO_2*)

p-Nitrohydroxybenzene (1.39 g, 10 mmol), 1-bromohexadecane (4.58 g, 15 mmol), and KI (0.1 g, 0.60 mmol), were mixed in DMF (50 ml). The mixture was stirred vigorously at 80 °C for one day. After cooling to room temperature, the mixture was poured into ice/water. The pale yellow precipitation was filtrated and recrystallized from acetone; yield: 3.5 g (96%); pale yellow needle. ^{1}H NMR ($CDCl_3$): $\delta = 8.20$ (d, $J = 9.5$, 2H), 6.95 (d, $J = 9.5$, 2H), 4.04 (t, $J = 6.5$, 2H), 1.86–1.26 (m, 28H), 0.88 (t, $J = 7.0$, 3H).

2.1.3. Preparation of 1-nitro-3,4-didodecyloxybenzene (*2C16-NO_2*)

To a suspension of silica gel (2.0 g) in $CHCl_3$ (30 ml) were added conc. HNO_3 (30 ml) and then a solution of **2C16** (4.00 g, 7.2 mmol) in $CHCl_3$. The mixture was stirred for 30 min. and the silica gel was removed by filtration. The orange filtrate was washed with H_2O and was concentrated to 15 ml. The product was precipitated by addition of MeOH; yield: 4.2 g (97%); pale yellow solid. ^{1}H NMR ($CDCl_3$): $\delta = 7.84$ (dd, $J = 2.8$, 9.0 Hz, 1H), 7.69 (d, $J = 2.5$ Hz, 1H), 6.84 (dd, $J = 3.0$, 9.0 Hz, 1H), 4.04 (d, $J = 6.5$ Hz, 4H), 1.86–1.26 (m, 56H), 0.88 (t, $J = 6.4$ Hz, 6H). 3,4,5-Tris(hexadecyloxy)nitrobenzene (**3C16-NO_2**) was prepared same as **2C16-NO_2**; yield: 3.64 g (86%); pale yellow solid. ^{1}H NMR ($CDCl_3$)

δ = 7.47 (s, 2H), 4.05 (m, 6H), 1.86–1.26 (m, 84H), 0.88 (t, J = 6.9 Hz, 9H).

2.1.4. Preparation of 4-n-hexadecyloxyaniline (*1C16-NH$_2$*)

A mixture of **1C16-NO$_2$** (2.0 g, 5.5 mmol) and palladium (0.10 g, 10% on carbon) was added to 50 ml absolute EtOH in a 200 ml two-necked round bottomed flask. A solution of hydrazine monohydrate (2.64 g, 44 mmol) diluted with 40 ml of absolute EtOH was slowly added to the flask and the reaction mixture was refluxed for 24 h. The reaction was followed by TLC. The reaction mixture was filtered while is hot to remove insoluble solid. The filtrate was cooled in room temperature. The crude product was recrystallized from EtOH; yield: 1.58 g (86%); white solid. ^{1}H NMR ($CDCl_3$): δ = 6.75 (dd, J = 6.5, 2.5 Hz, 2H), 6.65 (dd, J = 6.5, 2.5 Hz, 2H), 3.89 (t, J = 7.0 Hz, 2H), 1.86–1.26 (m, 28H), 0.88 (t, J = 7.0 Hz, 3H). *Anal.* Calc. for $C_{22}H_{39}NO \cdot 0.75H_2O$: C, 76.13; H, 11.76; N, 4.04. Found: C, 76.35; H, 11.74; N, 3.87%. 1-Amino-3,4-didodecyloxybenzene (**2C16-NH$_2$**) and 3,4,5-tris(hexadecyloxy)aniline (**3C16-NH$_2$**) were prepared same as **1C16-NH$_2$**. For **2C16-NH$_2$**; yield: 1.60 g (84%); white solid. ^{1}H NMR ($CDCl_3$): δ = 6.71 (d, J = 8.3 Hz, 1H), 6.28 (d, J = 2.5 Hz, 1H), 6.19 (dd, J = 2.6, 8.2 Hz, 1H), 3.89 (t, J = 6.5 Hz, 4H), 3.40 (s, 2H), 1.84–1.22 (m, 56H), 0.88 (t, J = 6.9 Hz, 6H). *Anal.* Calc. for $C_{38}H_{71}NO_2$: C, 79.52; H, 12.47; N, 2.44. Found: C, 79.37; H, 12.40; N, 2.52%. For **3C16-NH$_2$**, yield: 1.80 g (94%); white solid. ^{1}H NMR ($CDCl_3$): δ = 6.03 (s, 2H), 3.91 (t, J = 6.5 Hz, 4H), 3.85 (t, J = 6.6 Hz, 2H), 1.86–1.26 (m, 84H), 0.88 (t, J = 6.9 Hz, 9H). *Anal.* Calc. for $C_{54}H_{103}NO_3 \cdot 0.5EtOH$: C, 78.88; H, 12.75; N, 1.67. Found: C, 78.76; H, 12.53; N, 1.89%.

2.1.5. Preparation of 4-hexadecyloxy-N-(2-pyridinylmethylene)-benzenamine (*1C16-L*)

1C16-NH$_2$ (500 mg, 1.5 mmol) and pyridine-2-carboxyaldehyde (160 mg, 1.5 mmol) were mixed in 100 ml of $CHCl_3$. The mixed solution was refluxed for 3 h. The solution was concentrated to 10 ml, the product was precipitated by addition of MeOH, filtered, washed MeOH and dried; yield: 539 mg (85%); yellow solid. ^{1}H NMR ($CDCl_3$): δ = 8.70 (d, J = 4.0 Hz, 1H), 8.63 (s, 1H), 8.20 (d, J = 8.0 Hz 1H), 7.81 (td, J = 7.5 Hz, 1.5 Hz, 1H), 7.35 (m, 3H), 6.95 (dd, J = 6.5, 2.0 Hz, 2H), 3.98 (t, J = 6.5 Hz, 2H), 1.86–1.26 (m, 28 H), 0.88 (t, J = 7.0 Hz, 3H).

Selected FT-IR data (ν/cm^{-1}) using KBr disk: 3064, 2847, 1625, 1579, 1503, 1464, 1246, 836. 3,4-bis-hexadecyloxy-*N*-(pyridinylmethylene)-benzenamine (**2C16-L**) and 3,4,5-tris(hexadecyloxy)-*N*-(pyridinylmethylene)-benzenamine (**3C16-L**) were prepared same as **1C16-L**. For **2C16-L**; yield: 462 mg (80%); yellow solid. ^{1}H NMR ($CDCl_3$): δ = 8.71 (d, J = 5.8 Hz, 1H), 8.64 (s, 1H), 8.20 (d, J = 8.0 Hz, 1H), 7.81 (td, J = 7.5 Hz, 1.5 Hz, 1H), 7.36 (ddd, J = 7.5, 4.5, 0.75 Hz, 1H), 6.97 (d, J = 1.8 Hz, 1H), 6.92 (d, J = 2.5 Hz, 1H), 6.91 (s, 1H), 4.04 (t, J = 6.8 Hz, 2H), 4.03 (t, J = 6.8 Hz, 2H), 1.84–1.22 (m, 56H), 0.88 (t, J = 7.0 Hz, 6H). Selected FT-IR data (ν/cm^{-1}) using KBr disk: 2918, 2849, 1512, 1467, 1265, 1232, 1125. For **3C16-L**; yield: 750 mg (75%); yellow solid. ^{1}H NMR ($CDCl_3$): δ = 8.71 (d, 1H), 8.62 (s, 1H), 8.18 (d, 1 H), 7.81 (td, J = 7.5 Hz, 1.5 Hz, 1H), 7.37 (ddd, J = 7.5, 5.0, 1.5 Hz, 1H), 6.58 (s, 2H), 4.00 (t, J = 6.5 Hz, 4H), 3.97 (t, J = 6.6 Hz, 2H), 1.86–1.26 (m, 84H), 0.88 (t, J = 6.9 Hz, 9H). Selected FT-IR data (ν/cm^{-1}) using KBr disk: 2917, 1583, 1504, 1469, 1432, 1125.

2.2. Preparation of the iron(II) compounds

2.2.1. Preparation of [Fe(1C16-L)$_2$(NCS)$_2$] (*1*)

To a mixture solution of $FeCl_2 \cdot 4H_2O$ (70 mg, 0.35 mmol) and KNCS (69 mg, 0.71 mmol) in $CHCl_3$/MeOH (10 cm^3) was added $CHCl_3$/MeOH solution (20 cm^3) of **1C16-L** (300 mg, 0.71 mmol). The reaction mixture was stirred for a few minutes. The resulted dark green precipitate was collected by filtration and dried in vacuo. Yield: 259 mg (72%). *Anal.* Calc. for $C_{58}H_{84}Fe_1O_2S_2 \cdot 1.5H_2O$: C, 66.70; H, 8.39; N, 8.05; Fe, 5.35. Found: C, 66.97; H, 8.13; N, 8.05; Fe, 5.23%. Selected FT-IR data (ν/cm^{-1}) using KBr disk: 2919, 2850, 2065, 1598, 1505, 1251, 831. [Fe(2C16-L)$_2$(NCS)$_2$] (**2**) and [Fe(3C16-L)$_2$(NCS)$_2$] (**3**) were prepared same as **1**. For **2**; yield: 291 mg (86%). *Anal.* Calc. for $C_{90}H_{148}N_6O_4S_2 \cdot 0.5CHCl_3$: C, 67.57; H, 9.29; N, 5.20; Fe, 3.45. Found: C, 67.46; H, 9.33; N, 5.20; Fe, 3.14%. Selected FT-IR data (ν/cm^{-1}) using KBr disk: 2918, 2850, 2061, 1594, 1513, 1469, 1263, 1133. For **3**; yield: 259 mg (72%). *Anal.* Calc. for $C_{58}H_{84}Fe_1O_2S_2 \cdot 1.5H_2O$: C, 66.70; H, 8.39; N, 8.05; Fe, 5.35. Found: C, 66.97; H, 8.13; N, 8.05; Fe, 5.23. Selected FT-IR data (ν/cm^{-1}) using KBr disk: 2919, 2850, 2065, 1598, 1505, 1251, 831.

2.3. Measurements

Elemental analyses of carbon, hydrogen, and nitrogen were carried out at The Service Center of Elemental Analyses of Kyushu University. Metal analyses were done on a Shimadzu AA-625-11 Atomic Absorption/Flame Emission Spectrometer.

Infrared spectra were measured using KBr disk with a JASCO FT-IR-410.

^{1}H NMR were measured on a Bruker AVANCE SERIES DPX 400 instrument operating at 400 MHz (using the deuterated solvent as the lock and the residual solvent or tetramethylsilane as the internal reference).

Magnetic susceptibilities of ground samples were measured on a Quantum Design MPMS-5S. Samples were put into a gelatin capsule, mounted inside the

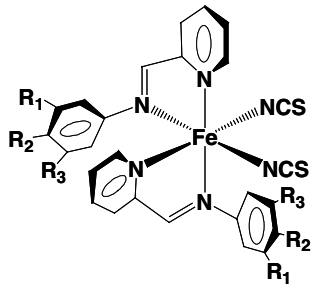
straw, and then fixed to the end of the sample transport rod. Illumination experiment was done with using an Hg–Xe lamp ($\lambda = 550$ nm, 1.5 mW/cm^2) as a light source. The light passing through IR and green filters was guided via an optical fiber into the SQUID magnetometer. The sample was placed on the edge of the optical fiber.

The Mössbauer spectra (isomer shift versus metallic iron at room temperature) were measured using a Wissel MVT-1000 Mössbauer spectrometer with a ^{57}Co/Rh source in the transmission mode. All isomer shifts are given relative to α-Fe at room temperature. The measurements at low temperature were performed with a closed-cycle helium refrigerator cryostat (Iwatani Co., Ltd.).

Differential Scanning Calorimetry (DSC) thermal analysis was carried out on a SHIMADZU DSC50 differential scanning calorimeter.

X-Ray powder diffraction (XRD) studies were performed on a Rigaku X-ray diffractometer RAD-2A with a 2.0 kW Cu Kα X-ray.

Optical polarized microscopy was carried out on a Nippon Chemical Industrial corporation polarization microscope OPTICAL POL with a Yanagimoto factory MODEL MP-J3 micro melting point meter.



3. Results and discussion

3.1. Structure of the compounds

Single crystals of the compounds **1**–**3** were not synthesized, therefore geometry optimization for the compounds were performed by computer simulation. Létard et al. [19] reported that a iron atom was surrounded by six nitrogen atoms belonging to two NCS^- groups in *cis* positions and two bidentate ligands. Because the iron(II) compound *cis*-bis(thiocyanato)-bis[*N*-(2-pyridylmethylene)aniline]iron(II) exhibits spin-crossover and LIESST effect, the ligand of the complex was modified as Schiff-base ligand with elongated substituents (Fig. 2) [16]. In consideration of the structure of the spin-crossover iron(II) compounds, that of the compounds **1**–**3** have been optimized. The resulted geometry structure has been shown in Fig. 3. A twisted-structure or starfish-like geometry have been proposed for the molecular structures of **1**–**3**.

3.2. Differential scanning calorimetry (DSC)

Phase transition enthalpies were measured by carrying out DSC thermal analysis for the compounds **1**–**3**. The DSC curves of **1**–**3** are shown in Fig. 4. Two peaks were observed for **1** at 365 and 445 K. The DSC peak at 365 K ($\Delta H = 65.9$ kJ mol^{-1}) to a crystal–mesophase transition, and that at 445 K ($\Delta H = 27.7$ kJ mol^{-1}) is assigned to a mesophase–liquid transition. Two peaks were observed for **2** at 363 and 407 K. The first peak at 363 K ($\Delta H = 92.3$ kJ mol^{-1}) to a crystal–mesophase transition, and the second peak at 407 K ($\Delta H = 13.5$ kJ mol^{-1}) is assigned to a mesophase–liquid transition. Two peaks were observed for **3** at 345 and 400 K. The first peak at 345 K $\Delta H = 78.3$ kJ mol^{-1} to a crystal–mesophase transition, and the second peak at 400 K ($\Delta H = 14.7$ kJ mol^{-1}) is assigned to a mesophase–liquid transition. The compounds **1**–**3** exhibit two endothermic peaks in the heating cycles. A large peak at low temperature is assigned to the solid-to-mesophase transition, and a small peak at high temperature, assigned to mesophase-to-liquid transition. DCS were measured in the temperature range from crystal to liquid crystal on the warming and cooling mode reversibly. On cooling, the transition temperatures from mesophase to crystal for the compounds **1**–**3** are 332, 330 and 325 K, respectively. Free ligands, **1C16-L**, **2C16-L** and **3C16-L**, exhibit only one peak, being assigned solid-to-liquid transition.

1: $R_2 = OC_{16}H_{33}$, R_1, R_3 = H
2: R_1, $R_2 = OC_{16}H_{33}$, R_3 = H
3: R_1, R_2, $R_3 = OC_{16}H_{33}$

Fig. 2. Chemical structure of the compounds **1**–**3**.

3.3. Polarizing optical microscopy (POM)

The mesophase was studied by hot-stage polarized optical microscopy (POM), and the texture of liquid-crystal state was observed by optical microscopy. The compounds **1**–**3** are solid state at room temperature. Being heated on the stage of the optical microscope under polarized light, the compounds exhibited mesomorphism. On heating, the compounds undergo a transition from the solid to birefringent viscous fluid, and exhibited a characteristic mosaic texture. When the compounds were cooled from the isotropic liquid to room temperature, the same mosaic texture as before heating was observed. An example of the texture under crossed polarizers for **3** is shown in Fig. 5. The identification of the phase of the liquid-crystal state based on the texture observed by optical microscopy has been not possible.

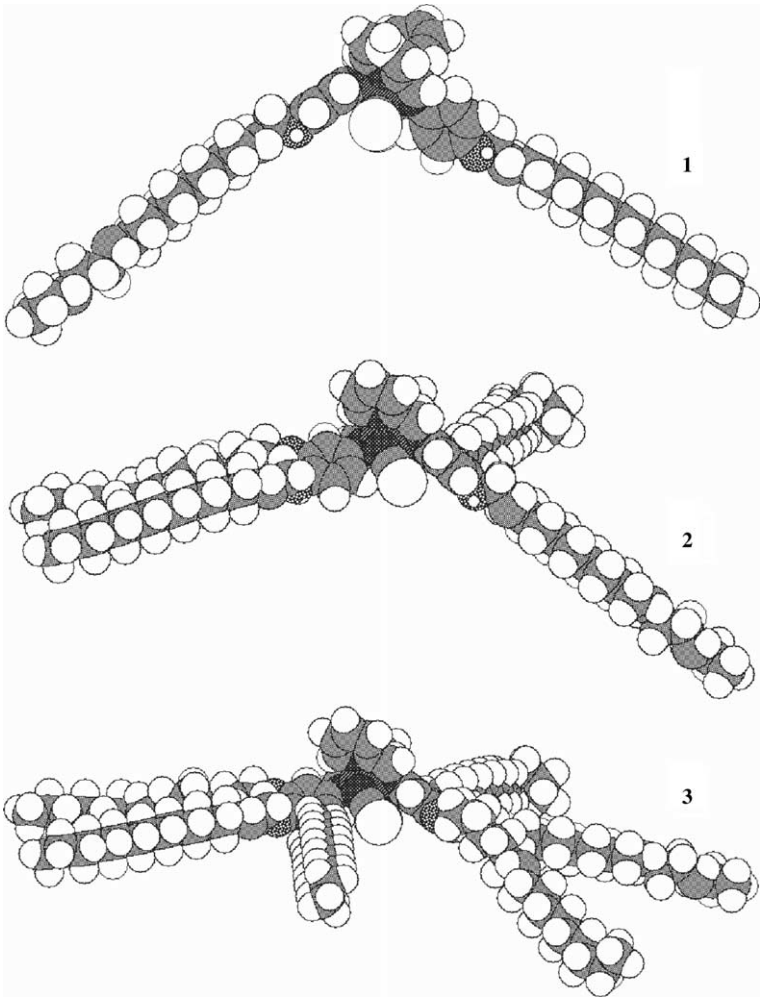


Fig. 3. Computer simulation of the molecular structure of the compounds **1**–**3**.

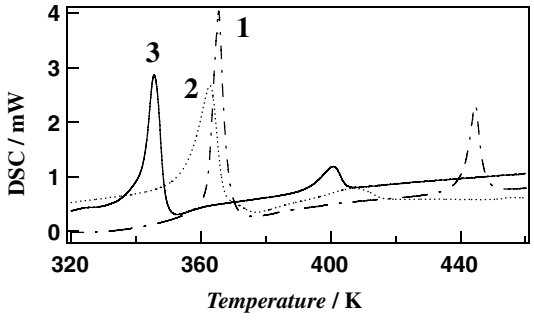

Fig. 4. DSC of the compounds **1**–**3**.

3.4. Powder X-ray diffractions

Temperature-dependent X-ray diffraction measurements were carried out to confirm this mesophase. Fig. 6 shows the powder X-ray diffraction patterns of the crystal and mesophase states for the compound **3** observed in the temperature range from 300 to 380 K. A sharp reflection in the small-angle ($2\theta = 4.1°$) with *d*-spacing of 21.4 Å was detected at 300 and 325 K. This *d*-spacing may correspond to the length of elongated substituents ($l = 21.4$ Å). At 345 K, the peak of $2\theta = 4.1°$ disappeared and a new peak appeared at $2\theta = 2.7°$ ($d = 32.7$ Å). The peak of $2\theta = 21.5°$ ($d = 4.1$ Å) observed below 325 K becomes broad at the same time. The formation of the mesophase is completed at 345 K in accordance with the result observed DSC.

3.5. Magnetic properties

The spin-crossover phenomenon between the high-spin and low-spin states for the compounds **1**–**3** were followed by measurements of the molar magnetic susceptibility χ_M and Mössbauer spectra as a function of temperature. The $\chi_M T$ versus T plots for **1**–**3** are given in Fig. 7.

The $\chi_M T$ value for **1** was 3.04 cm^3 K mol^{-1} at 50 K, and was 3.10 cm^3 K mol^{-1} at 150 K. The $\chi_M T$ values are nearly constant in the temperature range from 50 to 380 K. Spin-crossover phenomenon was not observed,

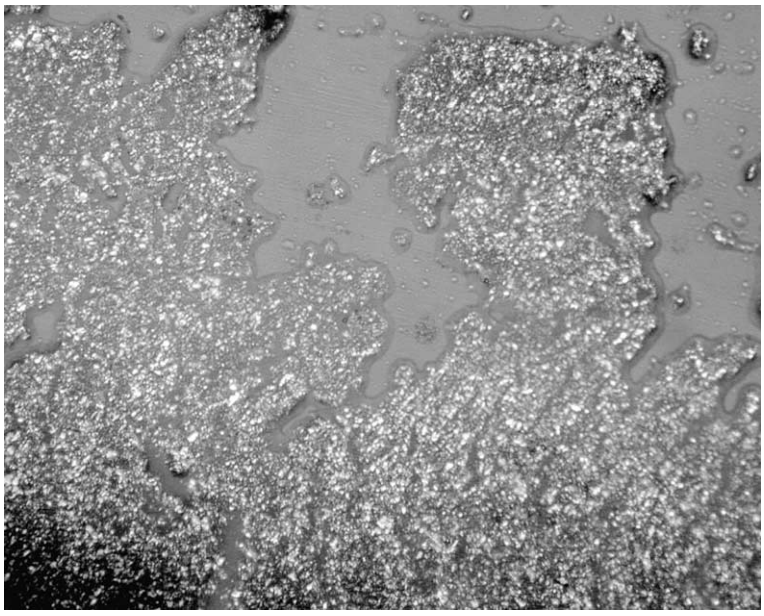

Fig. 5. Texture of the compound **3** under crossed polarizers at 380 K.

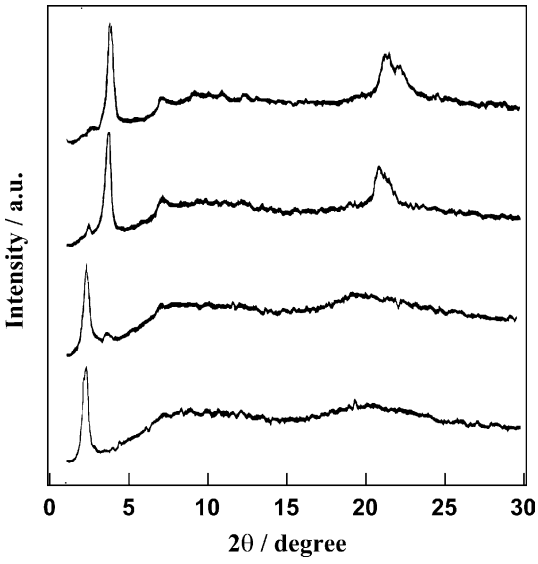

Fig. 6. Temperature dependence of powder XRD pattern of the compound **3**.

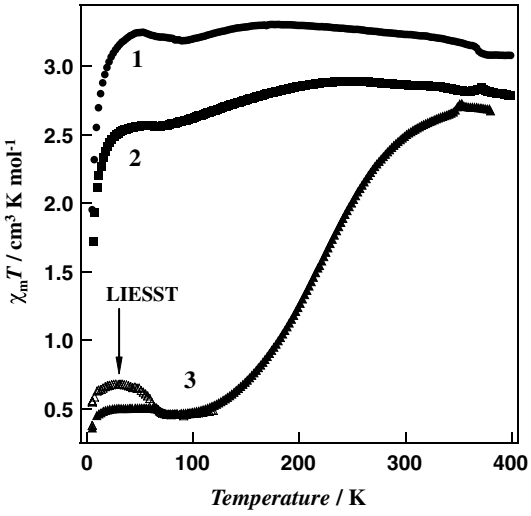

Fig. 7. $\chi_M T$ vs. T plots for the compounds **1**–**3**. $\chi_M T$ vs. T plots for LIESST experiment were recorded in the warming mode (△).

and the compound **1** was in high-spin state ($S = 2$). It is thought that the decrease of $\chi_M T$ value below 50 K is due to zero-field splitting. A decrease of $\chi_M T$ value was observed at 365 K. The temperature is in accordance with the crystal to mesophase transition temperature in the DSC data. The decrease may be explained as molecular orientation due to the mesophase transition.

The $\chi_M T$ value for **2** was 2.56 $cm^3\,K\,mol^{-1}$ at 65 K, and slightly increased with increasing temperature to 2.89 $cm^3\,K\,mol^{-1}$ at 245 K. An incomplete gradual spin-crossover phenomenon was observed. As well as **1**, an increase of $\chi_M T$ value was observed at 370 K. The temperature is in accordance with the crystal to mesophase transition temperature in the DSC data. The increase may be explained as molecular orientation due to the mesophase transition.

The $\chi_M T$ value for the compound **3** is equal to 0.47 $cm^3\,K\,mol^{-1}$ below 100 K, which shows that about 15% of the iron(II) ions remain in the high-spin state. On warming, the $\chi_M T$ values were almost constant from 5 to 100 K, then gradually increased at around spin transition temperature $T_{1/2} = 217$ K. The $\chi_M T$ value at 345 K was ca. 2.73 $cm^3\,K\,mol^{-1}$, showing that the spin transition from the low-spin to the high-spin state is induced. The Mössbauer spectra measured in the temperature range between 5 and 300 K support the existence

of iron(II) in the high-spin and low-spin states and the occurrence of spin-crossover behavior. Mössbauer spectrum at 80 K reveals two doublet peaks, one is a narrow quadrupole-split doublet (quadrupole-splitting ΔQ = 0.57 mm s^{-1}, isomer shift δ = 0.48 mm s^{-1}) representing the low-spin state, and another is a wide doublet (ΔQ = 3.06 mm s^{-1}, δ = 1.13) representing the high-spin state. Mössbauer parameters at 300 K are ΔQ = 0.50 mm s^{-1}, δ = 0.13 mm s^{-1} for low-spin state, and ΔQ = 2.35 mm s^{-1}, δ = 0.93 mm s^{-1} for high-spin state. The $\chi_M T$ value at 300 K is higher than that calculated from the Mössbauer data, suggesting that the recoilless fraction of the high-spin species is smaller than that of the low-spin species near the temperature at which the crystal phase turns to the mesophase. A increase of $\chi_M T$ value associated with the crystal–liquid crystal phase transition was observed at 350 K. The jump indicates the crystal–liquid crystal phase transition may be due to liquid crystal alignment.

3.6. LIESST effect

When the samples for the compound **3** were illuminated at 5 K for 1 h, the $\chi_M T$ value was increased (Fig. 7). The change in the $\chi_M T$ value persisted for many hours, even after the illumination was stopped. This suggests that the transition from the low-spin state to the high-spin state can be induced by illumination. The relaxation temperature of the LIESST effect is defined as T (LIESST) [20], the temperature dependence of $\chi_M T$ after illumination shows that the $\chi_M T$ value decreases with the increase in temperature and that the thermal relaxation to the ground state occurs. The T (LIESST) is 60 K, the compound **3** can exhibit photoswitching below 60 K. About 10% high-spin fraction were induced by illumination.

4. Conclusion

The iron(II) compounds **1**–**3** with long alkyl chains have been synthesized, properties of these compounds were characterized. The compounds **1**–**3** exhibited liquid-crystal property that was confirmed from the results of DSC, XRD diffractions, and texture of under crossed polarizers. The compound **1** was in the high-spin state. On the other hand, The compounds **2** and **3** exhibited spin-crossover phenomena. Furthermore the compound **3** exhibited LIESST effect, i.e., three physical properties, spin-crossover, LIESST effect and liquid-crystal properties, can coexist in a single compound for **3**. Geometrical flexibility in the molecules is very important in order to achieve co-occurrence of various physical properties in the functional molecular-based materials. We believe that our approach, i.e., the co-occurrence of spin-crossover, LIESST and liquid-crystal properties, can be widely applied, not only in the design of LIESST compounds with liquid-crystal properties but also in the design of a variety of optically switchable molecular compounds.

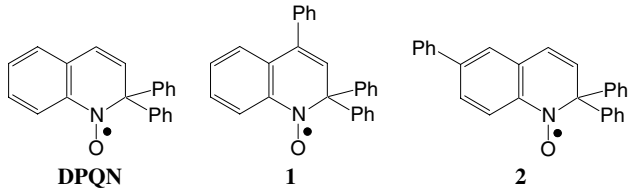
between spin centers [8]. To overcome these problems, we have focused on a kind of aromatic *N*-oxyl, 2,2-diphenyl-1,2-dihydroquinoline-*N*-oxyl (DPQN) originally synthesized by Colonna et al. (Chart 1) [9].



Because DPQN has a characteristic fused structure, the N–O spin center is involved in conjugation with the adjacent aryl group. DPQN is fairly stable due to the two bulky phenyl rings at the 2-position. The diphenyl substituents and the fused coplanar structure could synergistically contribute to the prevention of the direct close contact between the N–O moieties. In addition, the magnetically effective multipoint close contacts between the spin sites are also expected for the DPQN derivatives. Though the synthesis and crystal structure of DPQN have already been reported [9,10], its magnetic property in the solid state has not been reported. Previously, we reported the paramagnetic behavior for DPQN [11]. In the crystal, DPQN has no appropriate close contacts between the spin sites. In the present study, novel aromatic *N*-oxyl derivatives, 2,2,4-triphenyl-1,2-dihydroquinoline-*N*-oxyl (**1**), and its positional isomer, 2,2,6-triphenyl-1,2-dihydroquinoline-*N*-oxyl (**2**), were synthesized, and their crystal structures and magnetic properties were studied.

2. Results and discussion

2.1. Synthesis

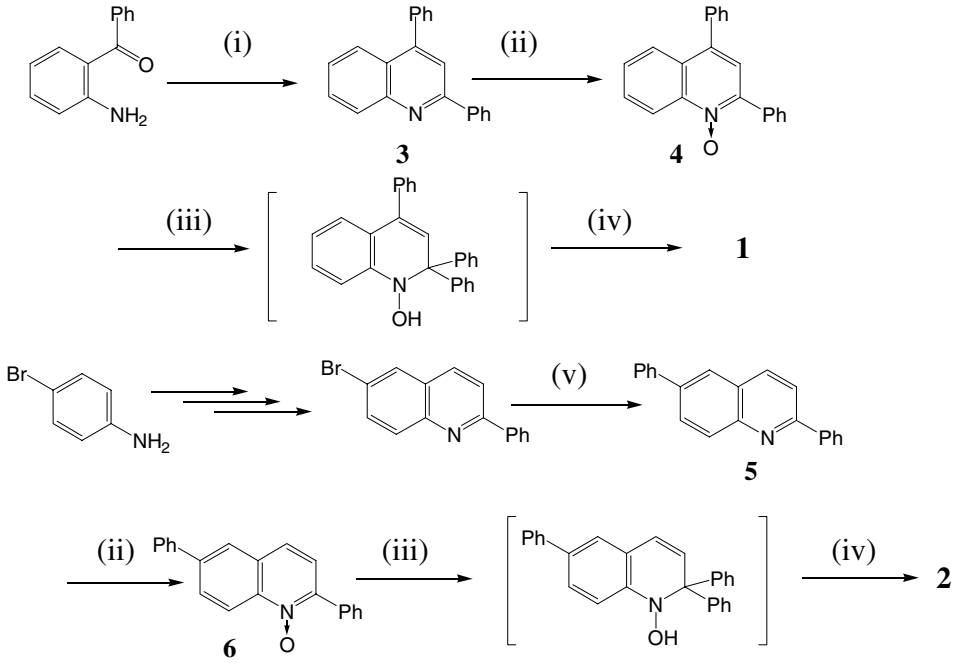
The synthetic routes for **1** and **2** are described in Scheme. **1** was obtained via a 4-step synthesis. First, 2,4-diphenylquinoline **3** was derived from commercially available 2-aminobenzophenone according to the literature [12]. The oxidation of the nitrogen atom of the quinoline ring by *m*-chloroperbenzoic acid (*m*-CPBA) gave the *N*-oxide compound **4**. The subsequent reaction with phenylmagnesium bromide, followed by air oxidation in chloroform gave the dark red-colored solid of **1**, see Scheme 1.

Its positional isomer **2** was obtained via a 7-step synthesis. The quinoline skeleton was synthesized according to the reported methods [13,14]. The introduction of a phenyl group at the 6-position was performed via the nickel(0)-catalyzed cross-coupling reaction of **5** with phenylmagnesium bromide. The following procedure, similar to that of **1**, gave the dark red-colored solid of **2**. Interestingly, two types of solids (**2-α**, **2-β**) were obtained due to the polymorphism. They exhibited different melting points (**2-α**: 204–206 °C, **2-β**: 158–160 °C) and showed different vibration modes for the N–O sites (**2-α**: 1368 cm^{-1}, **2-β**: 1375 cm^{-1}).

DPQN **1** **2**

Chart 1.

In the ESR measurements in toluene solutions, both **1** and **2** exhibited a complex pattern due to the presence of many magnetically non-equivalent aromatic nuclei. A computer simulation of the spectra of **1** and **2** gave small a_N values of 1.01 and 0.97 mT, respectively. Generally, the dialkyl *N*-oxyl radicals exhibit hfccs of ca. 1.4–1.5 mT for the *N*-oxyl nitrogen, and these values indicate that the spin density is localized on the N–O group. The observed small a_N values for **1** and **2** confirmed the delocalization of the unpaired electron over the π-conjugation systems.



2.2. X-ray crystallographic analysis

The single crystal of **1** suitable for X-ray analysis was obtained from an ethanol solution by cooling. The single crystal of **2** was obtained by slow evaporation of the mixed solvent of dichloromethane/*n*-hexane = 1/1 and found to be **2-α**.[1] Their ORTEP drawings and the crystallographic parameters are summarized in Fig. 1 and Table 1, respectively. As seen in Fig. 1, the dihedral angles between the N–O group and the adjacent aromatic rings are very small due to the characteristic fused structure (**1**: 8.02°, **2-α**: 8.08°), which could increase the spin density over the aromatic rings [15,16]. The dihedral angles between the substituted phenyl ring and quinoline ring are 86.6° (4-position) and 32.4° (6-position) for **1** and **2-α**, respectively. In the case of **1**, a steric effect between the phenyl ring at 4-position and hydrogen atom at the 5-position would increase the dihedral angle between the phenyl ring and quinoline rings to 86.6°. In contrast, **2** has a reduced dihedral angle of 32.4° between the phenyl ring at the 6-position and the quinoline ring. In the crystals of **1** and **2**, close contacts between the N–O spin centers were not observed.

2.3. DFT calculation

In order to estimate the spatial distribution of SOMO and the spin density, we performed the molecular orbital calculations based on the density functional theory (DFT) using the coordinates obtained by X-ray analysis. The popular unrestricted B3LYP hybrid functional [17,18] with the standard split valence 6-31G(d) basis set was used for the computation using the GAUSSIAN 03 program package [19]. The calculated spin densities are

[1] Crystallographic data of **1** and **2-α** in CIF format are available at CCDC. Deposition numbers of **1** and **2-α** are 259384 and 259385, respectively.

Fig. 3, the $\chi_m T$ value of **1** decreased below 50 K, exhibiting an intermolecular antiferromagnetic interaction. This behavior was analyzed using the Bleaney–Bowers equation for a dimer model (Eq. (1)) [20]. The best-fit parameters were a correction factor of $f = 0.86$ and a singlet–triplet energy gap of $2J = -4$ cm^{-1}. In the case of **2**, the obtained two phases exhibited different magnetic behaviors. The $\chi_m T$ value of **2-α** was virtually constant above 20 K (Fig. 4(a)), suggesting that **2-α** has a nearly isolated doublet state in the crystal. In contrast, the $\chi_m T$ value of **2-β** increased as the temperature decreased and reached a maximum around 2 K (Fig. 4(b)), indicating the existence of an intermolecular ferromagnetic interaction. The observed magnetic interaction of **2-β** was preliminary analyzed using a dimer model. The best-fit parameter was a singlet–triplet energy gap of $2J = +2.5$ cm^{-1}.

$$\chi_m = f \frac{N_A g^2 \beta^2}{k_B T[3 + \exp(-2J/k_B T)]}. \quad (1)$$

[a] UB3LYP/6-31G(d).

2.5. Magneto-structural correlation

In the crystal of **2-α**, the nearest O···O distance is 7.33 Å and there is no effective contact for intermolecular magnetic interactions, supporting the observed isolated doublet state of **2-α**. The N–O sites of **1** are also separated and its nearest O···O distance is 6.50 Å. There seems to be almost no direct interaction between the N–O sites [21]. However, **1** has a short contact with the adjacent molecule through the H(8) atom (Fig. 5). The DFT calculation for **1** gave a relatively large negative spin density for the H(8) atom. Therefore, the observed antiferromagnetic interaction for **1** could be qualitatively interpreted by McConnell's theorem [7].

3. Conclusions

Two aromatic *N*-oxyl radicals bearing the quinoline skeleton, 2,2,4-triphenyl-1,2-dihydroquinoline-*N*-oxyl (**1**) and 2,2,6-triphenyl-1,2-dihydroquinoline-*N*-oxyl (**2**), were newly synthesized. They were isolated as solids, indicating their high stability. The ESR measurements and DFT calculations for **1** and **2** revealed the delocalization of the unpaired electron in the π-conjugation system. Based on the SQUID measurement, **1** exhibited a weak antiferromagnetic interaction in its crystal. The negatively spin-polarized hydrogen atoms probably play a role in the magnetic interaction. In the case of **2**, two types of solids were obtained due to polymorphism. The α-phase of **2** showed a paramagnetic behavior; however, the β-phase of **2** exhibited a ferromagnetic interaction. The observed ferromagnetic interaction was analyzed by a dimer model, and a singlet–triplet gap was estimated to be $2J = +2.5$ cm^{-1}. Further investigations on the magneto-structural correlation of **2-β** are now in progress.

4. Experimental

4.1. Magnetic measurements

The magnetic properties of the microcrystalline sample radicals were measured by a Quantum Design MPMS-5 SQUID susceptometer at the field strength

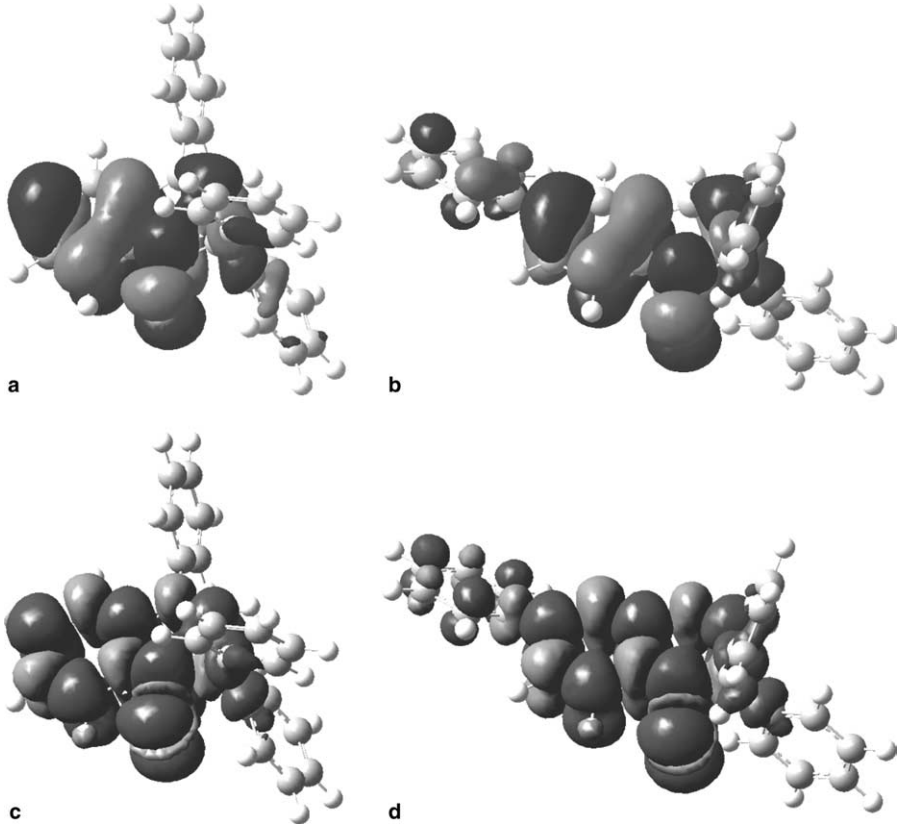

Fig. 2. SOMOs (a, b) and spin density distribution (c, d) for **1** and **2**-α, respectively. The positive spin densities are shown in dark gray and the negative ones are in pale gray.

of 0.5 T. In addition to the correction of the diamagnetic contribution from the sample holder, the diamagnetic contribution from the sample was estimated using the Pacault method (2.41×10^{-4} emu/mol for **1** and **2**) [22].

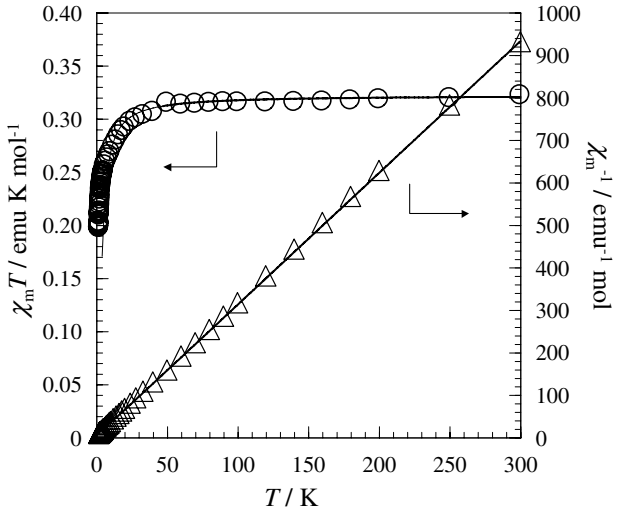

Fig. 3. Temperature dependence of $\chi_m T$ and $\chi_m{}^{-1}$ for **1**. Solid lines correspond to calculated curves ($2J = -4$ cm^{-1}).

4.2. X-ray diffraction analysis

The single crystals were mounted on a glass fiber and measured using a Rigaku four-circle AFC-7R diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structure was solved by a direct method [23] and refined by SHELXL-97 [24] with the program system teXsan [25].

4.3. Synthesis

The infrared spectra were recorded using an FT/IR-4000 spectrometer (Jasco Co. Japan). The ^{1}H NMR spectra were measured using a JNM-LA 300 spectrometer (JEOL Co., Japan). Chemical shifts were expressed in parts per million downfield from Me_4Si as the internal standard. Elemental analyses were performed at the Central Laboratory of the Faculty of Science and Technology, Keio University. Tetrahydrofuran was refluxed over and distilled from $LiAlH_4$. All other commercially available reagents were used without further purification, unless otherwise stated. 6-Bromoquinoline was synthesized according to the literature [13,14].

4.3.1. 2,4-Diphenylquinoline (*3*)

In 300 ml round-bottom flask, 2-aminobenzophenone (5.0 g, 25 mmol) and acetophenone (3.0 ml, 25 mmol)

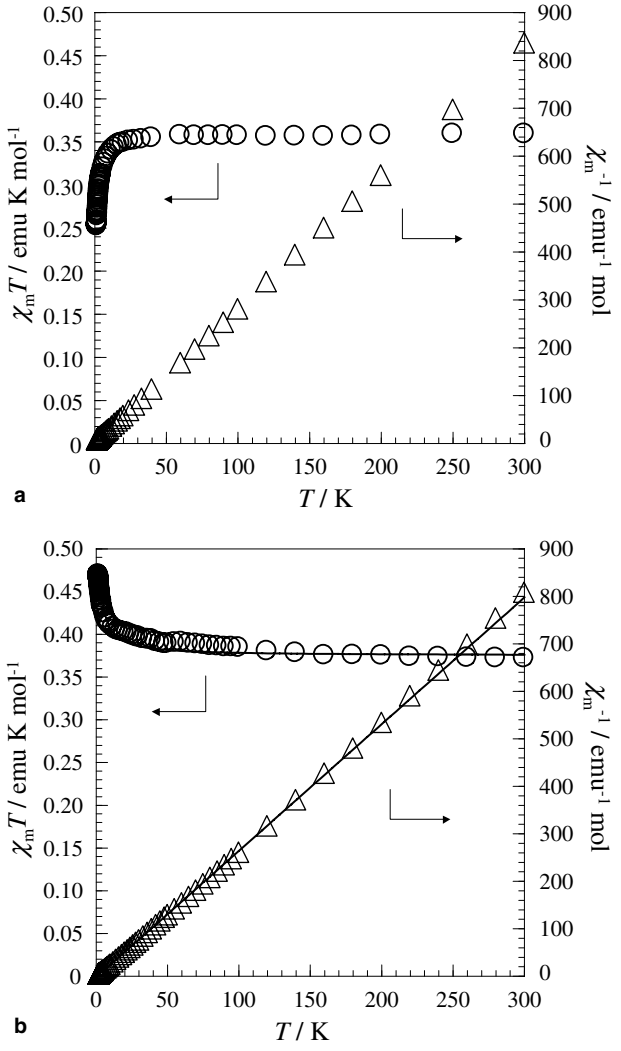

Fig. 4. Temperature dependence of $\chi_m T$ and χ_m^{-1} for **2-α** (a) and **2-β** (b). Solid lines correspond to calculated curves ($2J = +2.5$ cm^{-1}).

were dissolved in acetic acid (100 ml). Sulfuric acid was added to this solution (0.25 ml). The flask contents were refluxed for 18 h. After cooling to room temperature, the solution was neutralized with aqueous ammonia. The resulting solution was extracted with chloroform and the organic layer was dried over $NaHCO_3$ and evaporated to dryness. This crude residue was purified by column chromatography on silica gel eluting with chloroform. The yellow band was collected and evaporated to dryness, giving a yellow solid. Yield: 3.1 g, 44%. M.p.: 115–118 °C. ^{1}H NMR (300 MHz, acetone-d_6): δ 8.41–8.37 (2H, m), 8.20 (1H, d), 8.02 (1H, s), 7.92 (1H, d), 7.80 (1H, t), 7.68–7.48 (9H, m). FAB-MS (3-NBA), Calc. for $C_{21}H_{15}N$: 281.1, Found: 281 $[M]^+$. *Anal.* Calc. for $C_{21}H_{15}N$: C, 89.65; H, 5.37; N, 4.98. Found: C, 89.65; H, 5.26; N, 4.93%.

*4.3.2. 2,4-Diphenylquinoline-N-oxide (**4**)*

A chloroform solution of 1.5 g of *m*-CPBA was gradually added to an ice-cooled, stirred solution of **3** (1.4 g, 5.3 mmol) in chloroform (100 ml). The stirring was continued overnight at room temperature and then basified with a KOH aqueous solution. The organic layer was washed several times with water and dried over Na_2SO_4. After evaporation of the solvent, the residue was purified by column chromatography on silica gel eluting with EtOAc/*n*-hexane = 1/1. Subsequent removal of the solvent gave the yellow solid of **4**. Yield: 1.3 g, 83%. M.p.: 177–180 °C. FAB-MS (3-NBA, *m*/*z*). Calc. for $C_{21}H_{15}NO$: 297.1, Found: 298 $[M + H]^+$. ^{1}H NMR (300 MHz, acetone-d_6): δ 8.88 (1H, d), 8.19–8.15 (2H, m), 7.99 (1H, d), 7.88 (1H, t), 7.75–7.47 (10H, m). IR (KBr pellet): 1216 cm^{-1} (N–O). *Anal.* Calc. for $C_{21}H_{15}NO$: C, 84.82; H, 5.08; N, 4.71. Found: C, 84.40; H, 5.00; N, 4.60%.

*4.3.3. 2,2,4-Triphenyl-1,2-dihydorquinoline-N-oxyl (**1**)*

To a solution of **4** (2.6 g, 8.7 mmol) in 100 ml of dry tetrahydrofuran was added the phenylmagnesium bromide THF solution (17.5 ml, 17.5 mmol) with stirring in a nitrogen atmosphere. After 1 h, the mixture was treated with NH_4Cl aq. and extracted with $CHCl_3$. The organic layer was washed with water and dried over Na_2SO_4. After removal of the solvent, the residue was purified by column chromatography on silica gel eluting with ethyl acetate/*n*-hexane = 1/2. Subsequent recrystallization from ethanol gave the microcrystalline red solid of **1**. Yield: 500 mg, 15%. M.p.: 156–159 °C. IR (KBr pellet): 1382 cm^{-1} (N–O). *Anal.* Calc. for $C_{27}H_{20}NO$:

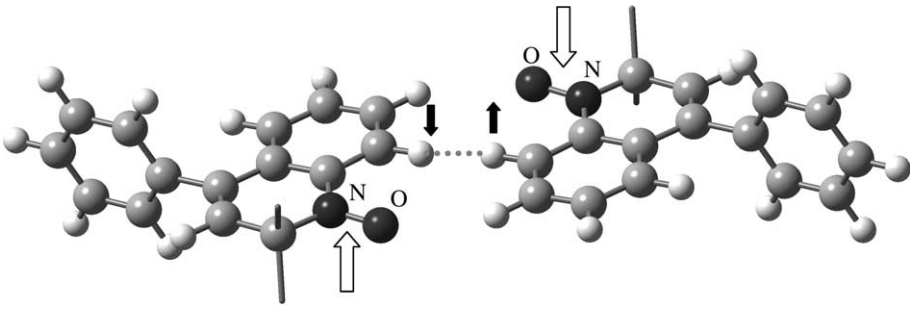

Fig. 5. Qualitative representation of plausible exchange pathway for the dimer of **1**. Phenyl rings at the 2-position are omitted for clarity.

C, 86.60; H, 5.38; N, 3.74. Found: C, 86.38; H, 5.13; N, 3.68%.

4.3.4. 2,6-Diphenylquinoline (**5**)

In a three-necked flask equipped with a reflux condenser, 6-bromo-2-phenylquinoline (1.0 g, 3.5 mmol) and [1,3-bis(diphenylphosphino)propane]nickel(II) chloride (7.9 mg, 0.015 mmol) were dissolved in dry tetrahydrofuran under a nitrogen atmosphere. The phenylmagnesium bromide THF solution (4.4 ml, 4.4 mmol) was then gradually added to the solution. The resulting solution was stirred for 20 min at room temperature and refluxed for 20 h. After cooling, the solution was neutralized to pH 7 with diluted HCl aq. and extracted with diethyl ether. The organic layer was washed with $NaHCO_3$ aq. and then with water several times. The organic layer was separated and dried over Na_2SO_4 and evaporated to dryness. This crude product was purified by column chromatography on silica gel eluting with chloroform/*n*-hexane = 1/3. Subsequent removal of the solvent gave the white solid of **5**. Yield: 0.66 g, 65%. M.p: 206–208 °C. ^{1}H NMR (300 MHz, $CDCl_3$), δ 8.23–8.29 (m, 2H), 8.19 (dd, 2H), 7.99–8.02 (m, 2H), 7.91 (d, 1H), 7.75 (dd, 2H), 7.38–7.57 (m, 6H). *Anal*. Calc. for $C_{21}H_{15}N$: C, 89.65; H, 5.37; N, 4.98. Found: C, 89.21; H, 5.37; N, 4.89%.

4.3.5. 2,6-Diphenylquinoline-N-oxide (**6**)

This compound was synthesized in the same manner as **4** using 140 mg of **5** (0.5 mmol) and 180 mg of *m*-CPBA in a chloroform solution. The desired compound was purified by column chromatography on silica gel eluting with EtOAc/chloroform = 3/1. Subsequent removal of the solvent gave the pale yellow solid. Yield: 140 mg, 96%. M.p.: 242–244 °C. ^{1}H NMR (300 MHz, $CDCl_3$), δ 8.90–8.94 (m, 1H), 7.99–8.06 (m, 3H), 7.82 (d, 1H), 7.74 (d, 2H), 7.42–7.57 (m, 8H). IR (KBr pellet): 1348 cm^{-1} (N–O). *Anal*. Calc. for $C_{21}H_{15}NO$: C, 83.56; H, 5.18; N, 4.64; O, 6.63. Found: C, 83.79; H, 4.66; N, 4.70%.

4.3.6. 2,2,6-Triphenyl-1,2-dihydroquinoline-N-oxyl (**2**)

This compound was synthesized under the condition similar to **1** using 140 mg of **6** (0.47 mmol) and 1 ml of phenylmagnesium bromide THF solution (1 mmol). The obtained crude product was purified by column chromatography on silica gel eluting with chloroform/*n*-hexane = 2/1 followed by recrystallization to give the dark red solid of **2**. Yield: 71% (**2-α**), 53% (**2-β**). M.p., **2-α**: 204–206 °C, **2-β**: 158–160 °C. IR (KBr pellet), **2-α**: 1368 cm^{-1} (N–O), **2-β**: 1375 cm^{-1} (N–O). *Anal*. Calc. for $C_{27}H_{20}NO$: C, 86.60; H, 5.38; N, 3.74. Found for **2-α**: C, 86.17; H, 5.14; N, 3.60%. Found for **2-β**: C, 86.39, H, 5.48; N, 3.53%.
