While a simplified description of the effect of the Me_2Si *ansa* bridge is that it causes the electron count of the molybdenum center in $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ to be reduced from 18 such that sulfur lone pair donation provides an important component to the bonding, a more complete understanding is provided by a molecular orbital analysis. In this regard, the electronic structure of a bent metallocene fragment is well established and the most important feature is that the three frontier orbitals that are available for interacting with additional ligands lie in the equatorial *xz* plane of the metallocene fragment [27,28]. None of these frontier orbitals, however, is of appropriate symmetry for interacting in a π-manner with a lone pair on sulfur. Rather, the only d orbitals that are of appropriate symmetry are the d_{xy} and d_{yz} orbitals, but

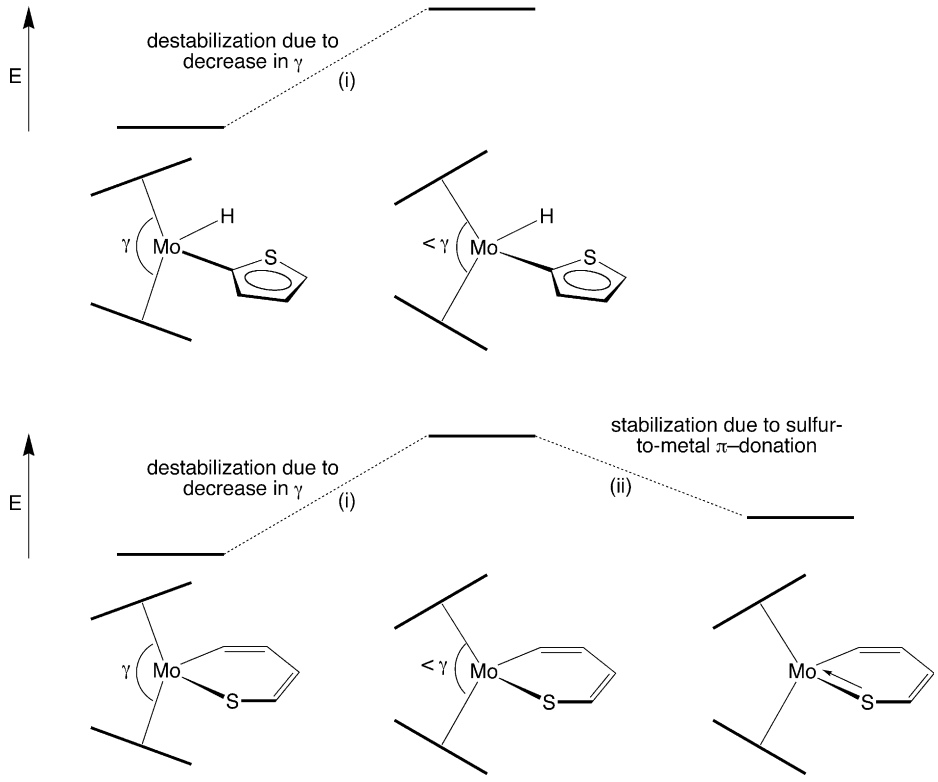

Fig. 5. Schematic illustration of (i) the destabilization of a molybdenocene fragment by bending a Cp–Mo–Cp fragment and (ii) the stabilization resulting from sulfur-to-metal π-donation. The latter interaction is not possible for the product of C–H bond cleavage and so is destabilized relative to that of C–S bond cleavage upon reducing γ.

these orbitals are involved in metal–cyclopentadienyl bonding. As such, π-donation from sulfur necessarily competes with metal–cyclopentadienyl bonding in a manner that is closely analogous to the perpendicular π-interaction in Cp_2MoO [29], $Cp_2Mo(NBu^t)$ [30] and $(\eta^3\text{-}Cp^*)_2Mo(N)(N_3)$ [31]. Specifically, π-donation from sulfur is a component of a 3-center 4-electron interaction involving the molybdenum, cyclopentadienyl, and $\eta^2\text{-}C,S\text{-}SC_4H_4$ fragments, as illustrated schematically in Fig. 6. Thus, the molybdenum d_{xy} orbital interacts with (i) an orbital combination of the cyclopentadienyl ligands and (ii) an orbital of the $\eta^2\text{-}C,S\text{-}SC_4H_4$ ligand, resulting in a bonding orbital, a "nonbonding" ligand based orbital [32], and an antibonding orbital, of which the lattermost is unoccupied (Fig. 6) [33]. Previous studies have shown that the interaction between the cyclopentadienyl orbital and d_{xy} orbital decreases as the Cp_{cent}–M–Cp_{cent} angle decreases [27], and, as a consequence, increased bending of the metallocene fragment provides a mechanism to increase π-donation from the sulfur atom. The two occupied molecular orbitals of the 3-center 4-electron interaction for both $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ and $Cp_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ are illustrated in Fig. 7, indicating that the Mo–S π-bonding interaction is greater for the *ansa* derivative $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$. Thus, for $Cp_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$, MO ⟨62⟩ is primarily a metal-$(\eta^2\text{-}C,S\text{-}SC_4H_4)$ nonbonding orbital that is localized on the ligand, whereas MO ⟨56⟩ is primarily a metal–cyclopentadienyl bonding orbital with little contribution from the $\eta^2\text{-}C,S\text{-}SC_4H_4$ ligand. In contrast, the corresponding orbital for $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$, i.e., MO ⟨104⟩, has a noticeably greater bonding component between the d_{xy} orbital and the p_π-orbitals on sulfur and carbon of the metallathiacycle. In accord with the enhanced π-bonding interaction, MO ⟨108⟩, which is the counterpart to the nonbonding orbital in $Cp_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ (⟨62⟩), possesses metal-$(\eta^2\text{-}C,S\text{-}SC_4H_4)$ antibonding character.

2.2. Experimental evidence for sulfur-to-metal π-donation within $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$: metallathiacyclohexa-1,3-diene versus metallathiabenzene character

In view of the possibility of sulfur-to-metal π-donation within metallathiacycles, two general classes of compounds have been identified according to whether or not the interaction is significant. These classes are distinguished according to whether or not the metal center is electronically saturated or unsaturated in the absence of lone pair donation [34]. The former class of metallathiacycle is identified by a single principal resonance structure corresponding to that of a metallathiacyclohexa-1,3-diene, whereas the latter class possesses additional resonance structures (Fig. 8). In view of the additional resonance structures, molecules in the latter class have been termed metallathiabenzenes [35]. Representative examples of these two classes of

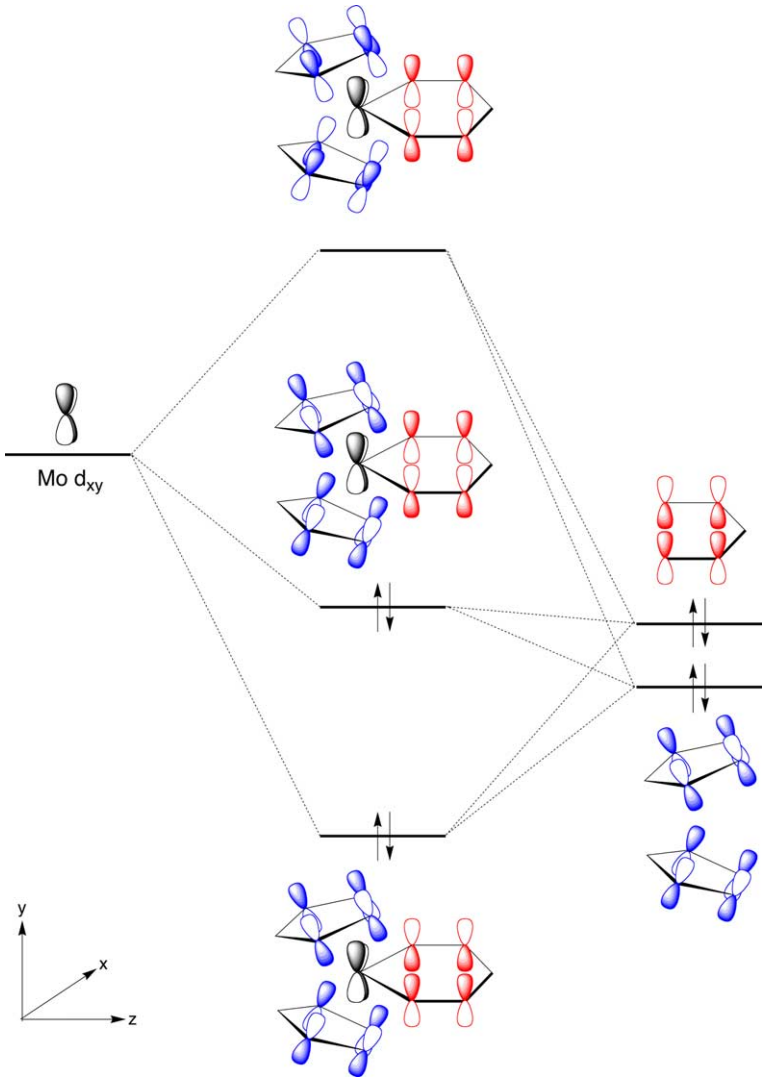

Fig. 6. 3-Center–4-electron interaction between a (Cp_2^R) fragment, a molybdenum d_{xy} orbital, and a η^2-*C*,*S*-SC_4H_4 ligand.

compounds are provided by the 2,5-dimethylthiophene derivatives, Cp*Ir(η^2-*C*,*S*-$SC_4H_2Me_2$)(PMe_2Ph) and Cp*Ir(η^2-*C*,*S*-$SC_4H_2Me_2$) (Fig. 9). Thus, the former complex is electronically saturated with an 18-electron configuration in the absence of lone pair donation from sulfur and is classified as a metallathiacyclohexa-1,3-diene derivative. In contrast, Cp*Ir(η^2-*C*,*S*-$SC_4H_2Me_2$) is electronically unsaturated with a 16-electron configuration in the absence of lone pair donation from sulfur and is classified as a metallathiabenzene derivative. It is important to note, however, that the concept of electronic saturation with respect to the feasibility of sulfur lone pair donation does not necessarily imply an 18-electron configuration. For example, square planar Ni and Pt favors 16-electron configurations and so complexes such as (PEt_3)$_2$Pt(η^2-*C*,*S*-SC_4H_4) [9f] and (dippe)Ni(η^2-*C*,*S*-SC_4H_4) [9b] are better described as metallathiacyclohexa-1,3-diene derivatives rather than metallathiabenzene complexes.

Calculations indicate that there is little electronic preference for favoring planar over bent metallathiacycles and that bent geometries are a consequence of steric interactions [36,37]. The planarity of a metallathiacycle cannot, therefore, be used as a definitive indication of metallathiabenzene character. Furthermore, in view of the twofold disorder that is prevalent in many metallathiacycles [38,39], the variation in bond lengths within the six membered ring can likewise not be used as a reliable indicator of metallathiabenzene character. It is, therefore, significant that Angelici has proposed that the ^{13}C NMR shift of the carbon attached to the metal center in a metallathiacycle may be used to provide a criterion to distinguish between localized and delocalized π-bonding [34]. Specifically, a large downfield shift of the ^{13}C signals for the carbon attached to the metal center is proposed to be indicative of a delocalized structure because the metal–carbon bond possesses more alkylidene character. The ^{13}C NMR spectroscopic data for a series of six-membered metallathiacycles are summarized in Table 2, from which it is evident that metallathiacyclohexa-1,3-diene complexes are characterized by ^{13}C NMR signals in the range 106–142 ppm, whereas bona fide

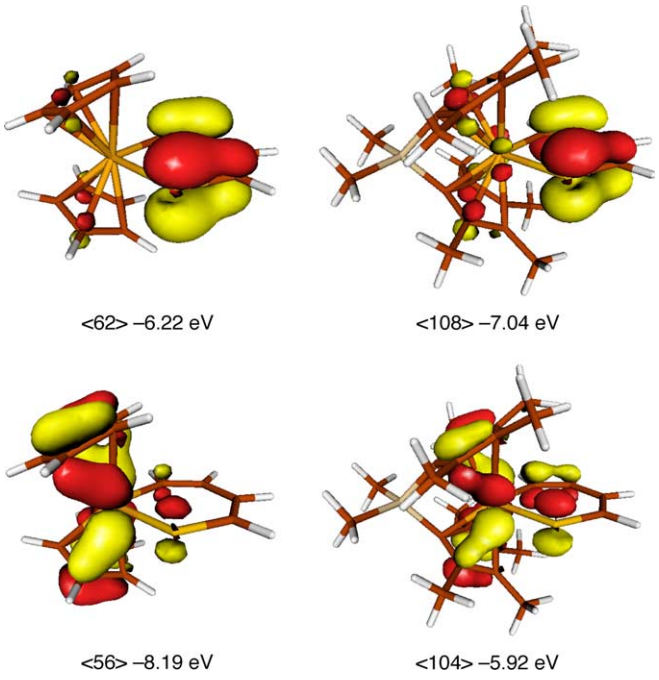

Fig. 7. The two occupied molecular orbitals of the 3-center–4-electron interaction for $Cp_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ (left) and $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ (right). MO ⟨62⟩ of $Cp_2Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ is primarily a metal-$(\eta^2\text{-}C,S\text{-}SC_4H_4)$ nonbonding orbital that is localized on the ligand, while MO ⟨56⟩ is primarily a metal–cyclopentadienyl bonding orbital with little contribution from the $\eta^2\text{-}C,S\text{-}SC_4H_4$ ligand. In contrast, ⟨104⟩, the corresponding bonding orbital for $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$, has a noticeably greater bonding component between the d_{xy} orbital and the p_π-orbitals on sulfur and carbon of the metallathiacycle.

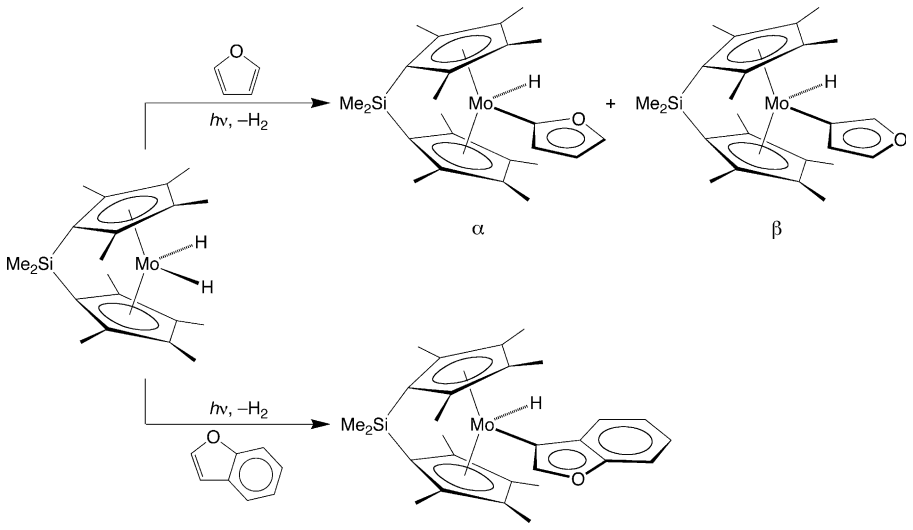
[a] Values for 2 isomers.
[b] Assignment of the carbon of the metallathiacycle attached to the metal not determined and so only an upper limit to the chemical shift is known.

metallathiabenzene complexes are characterized by ^{13}C NMR signals in the range 165–183 ppm. On this basis, the ^{13}C NMR chemical shift of 162.6 ppm for $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ is consistent with significant metallathiabenzene character and hence sulfur-to-metal π-donation.

2.3. Reactivity of $[Me_2Si(C_5Me_4)_2]MoH_2$ towards furan and selenophene

In order to obtain a more detailed appreciation of the factors that influence the energy surface relating the three isomeric thiophene complexes, we have investigated the reactivity of $[Me_2Si(C_5Me_4)_2]MoH_2$ towards furan and selenophene derivatives. Interestingly, furan exhibits reactivity which is distinct from that of thiophene (Scheme 3). Thus, rather than cleave the C–O bond, $[Me_2Si(C_5Me_4)_2]MoH_2$ reacts with the C–H bond of furan to give the furyl–hydride compound $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_4H_3O)H$ (Fig. 10) [40]. ^1H NMR spectroscopic analysis indicates that there is an approximately 2:1 selectivity for cleaving the two different types of C–H bonds, although it is not definitive whether this corresponds to α/β or β/α selectivity [41], preferential cleavage of the α-C–H bond has, however, been noted for other reactions of furan with transition metal compounds [42]. Benzofuran also reacts with $[Me_2Si(C_5Me_4)_2]MoH_2$ to give the β-isomer $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_8H_5O)H$ (Scheme 3 and Fig. 11). The observation of C–H bond cleavage in the reactions of furan and benzofuran with $[Me_2Si(C_5Me_4)_2]MoH_2$ provides further support for the notion that C–H bond cleavage of thiophene would not be kinetically prohibitive. Also of note, the oxidative addition of the C–H bond of furan is



Scheme 3.

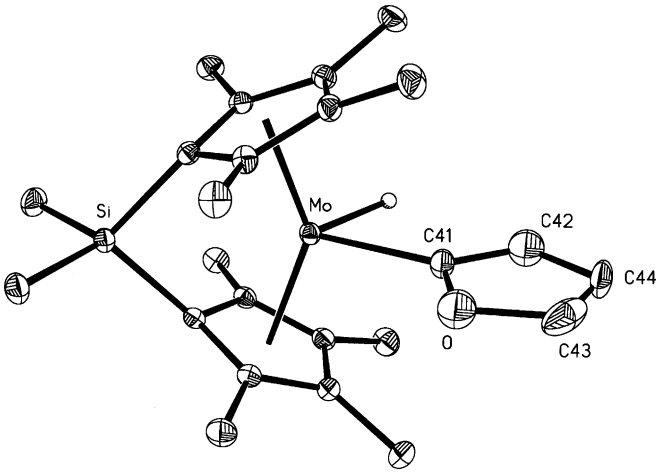


Fig. 10. Molecular structure of $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_4H_3O)H$. The $\eta^1\text{-}C\text{-}C_4H_3O$ ligand is disordered and only one of the disordered configurations is illustrated for clarity.

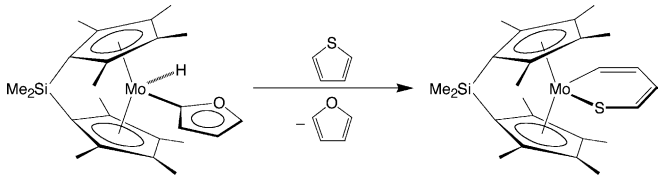

Scheme 4.

In contrast to the C–H bond cleavage reactions of $[Me_2Si(C_5Me_4)_2]MoH_2$ with furan and benzofuran, $[Me_2Si(C_5Me_4)_2]MoH_2$ reacts with selenophene and benzoselenophene to give the product of C–Se bond cleavage, namely $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ and $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_8H_6)$, as illustrated in Scheme 5. The molecular structures of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ and $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_8H_6)$ have been determined by X-ray diffraction, as

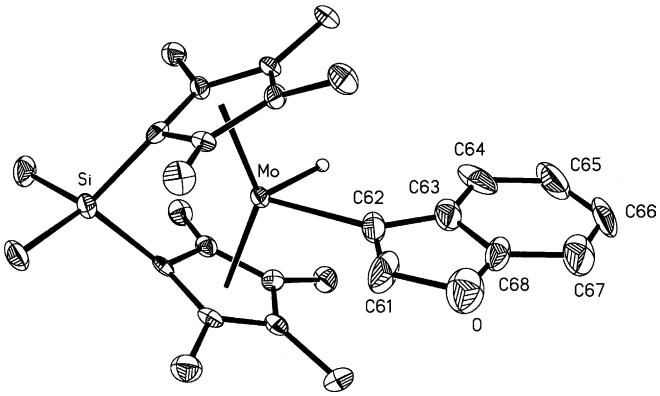

Fig. 11. Molecular structure of $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_8H_5O)H$.

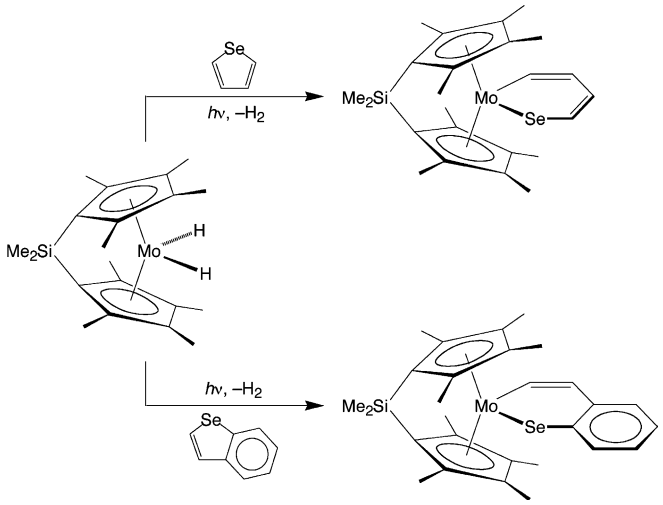
reversible and treatment of $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_4H_3O)H$ with thiophene yields $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ (Scheme 4).



Scheme 5.

illustrated in Figs. 12 and 13, and are analogous to the sulfur counterparts [10]. The reactivity of selenophene and benzoselenophene, therefore, corresponds closely to that of thiophene and benzothiophene [10]. By comparison to the C–S bond cleavage reactivity of thiophene, however, complexes derived from C–Se bond cleavage of selenophene are not common, although two notable examples are provided by Jones' $Cp^*Rh(PMe_3)(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ [43] and Angelici's $Cp^*Ir(\eta^2\text{-}C,Se\text{-}SeC_4H_2Me_2)$ [44,45]. The ^{13}C NMR chemical shift of the metallaselenacycle carbon atom attached to molybdenum in $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ is 163.1 ppm, comparable to the value of 162.6 ppm for the corresponding carbon atom in $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$. On the basis of the above discussion pertaining to the bonding within $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$, it is evident that $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ possesses a significant amount of metallaselenobenzene character. In this regard,

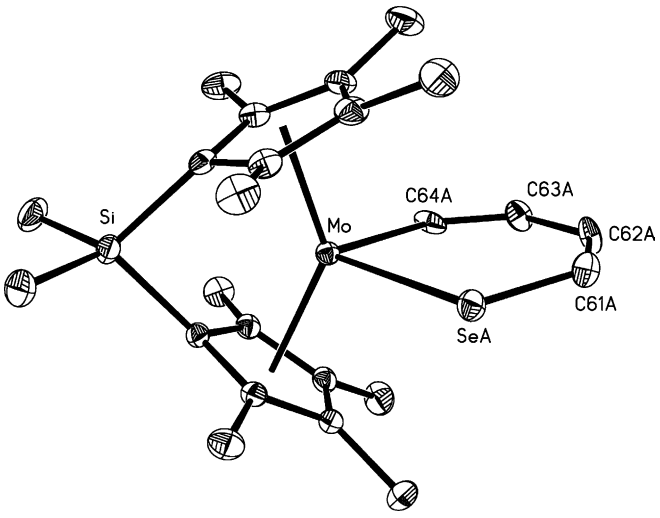


Fig. 12. Molecular structure of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$. The $\eta^2\text{-}C,Se\text{-}SeC_4H_4$ ligand exhibits a twofold disorder and only one of the disordered configurations is illustrated for clarity.

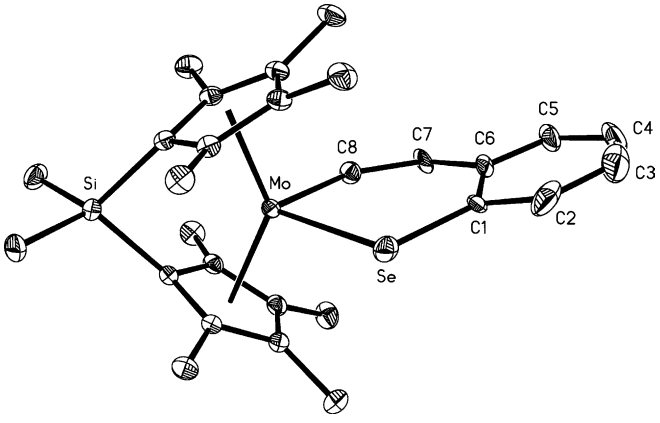

Fig. 13. Molecular structure of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_8H_6)$. The $\eta^2\text{-}C,Se\text{-}SeC_8H_6$ ligand exhibits a twofold disorder and only one of the disordered configurations is illustrated for clarity.

the ^{77}Se NMR spectroscopic signal for $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ is observed at 209 ppm, a value which is intermediate between those for $Cp^*Rh(PMe_3)(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ (31.9 ppm) [43], a metallaselenacyclohexa-1,3-diene derivative, and $Cp^*Ir(\eta^2\text{-}C,Se\text{-}SeC_4H_2Me_2)$ (905.4 ppm) [44], a bona fide metallaselenabenzene derivative.

The different reactivity of furan, vis-à-vis thiophene and selenophene, towards $[Me_2Si(C_5Me_4)_2]MoH_2$ poses an interesting question: specifically, why is the molybdenocene center incapable of cleaving the C–O bond? In this regard, DFT calculations indicate that C–E (E = O, S, Se) bond cleavage is thermodynamically more favored than C–H bond cleavage for all of the chalcogen derivatives (Table 1 and Fig. 2). As such, the calculations indicate that the inability to cleave the C–O bond in furan is a kinetic problem. In support of this notion, it is pertinent to note that six-membered metallaoxacycles, the products of formal furan C–O bond cleavage, e.g., $(\eta^2\text{-}C,O\text{-}OC_4H_2Me_2)Ir(PEt_3)_3X$ (X = H, Me, Cl) and $[(\eta^2\text{-}C,O\text{-}OC_4H_2Me_2)Ir(PEt_3)_3]^+$, have been reported [46], but these complexes are synthesized by metathesis with a potassium oxapentadienide derivative and not via reactions that involve cleavage of a C–O bond. Cleavage of the C–O bond in furan has, nevertheless, been observed in the reaction of $(Ph_3P)_2ReH_7$ with furan in the presence of $Bu^tCH{=}CH_2$, but the product obtained is a hydrogenated 1-oxapentadienyl derivative, $(Ph_3P)_2Re(\eta^5\text{-}C_4H_5O)(CO)$ [47].

Preferential C–H bond cleavage of furan and C–S cleavage of thiophene has been previously noted, as illustrated by the observation that $[Ir(PMe_3)_3(COD)][Cl]$ reacts with thiophene to give a metallathiacycle $Ir(PMe_3)_3(\eta^2\text{-}C,S\text{-}SC_4H_4)(H)Cl$, whereas furan gives the furyl–hydride complex $Ir(PMe_3)_3(\eta^1\text{-}C\text{-}OC_4H_3)Cl$ [8i]. However, in contrast to these reactions where the discontinuity in reactivity occurs between furan and thiophene, the reactions of $Os_3(CO)_{10}(MeCN)_2$ with furan, thiophene, selenophene and tellurophene exhibit a discontinuity between thiophene and selenophene. Thus, $Os_3(CO)_{10}(MeCN)_2$ reacts with furan and thiophene via C–H bond cleavage to give $Os_3(\mu\text{-}H)(\mu\text{-}2\text{-}C_4H_3E)(CO)_{10}$ (E = O, S), whereas the reactions with selenophene and tellurophene occur via C–E bond cleavage to give $Os_3(CO)_{10}(EC_4H_4)$ (E = Se, Te) [45b,45c].

3. Conclusions

In summary, DFT calculations provide evidence that the observation of C–S bond cleavage of thiophene by the *ansa* metallocene $[Me_2Si(C_5Me_4)_2]MoH_2$ but C–H bond cleavage by Cp_2MoH_2 is dictated by thermodynamic considerations. Specifically, the Me_2Si *ansa* bridge favors $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,S\text{-}SC_4H_4)$ over $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}SC_4H_3)H$ because the bridge promotes a shift in the coordination of the cyclopentadienyl rings from η^5-coordination towards η^3-coordination and this thermodynamically unfavorable modification is stabilized by

sulfur-to-metal π-donation within $[Me_2Si(C_5Me_4)_2]Mo(\eta^2$-*C*,*S*-$SC_4H_4)$. Selenophene reacts with $[Me_2Si(C_5Me_4)_2]$-MoH_2 in a manner analogous to that of thiophene, but furan reacts via C–H bond cleavage to give a furyl–hydride complex $[Me_2Si(C_5Me_4)_2]Mo(\eta^1$-*C*-$C_4H_3O)H$. DFT calculations indicate that C–E (E = O, S, Se) bond cleavage is thermodynamically favored for all of the chalcogens and thus the inability to cleave the C–O of furan derivatives is due to kinetic factors.

4. Experimental

4.1. General considerations

All manipulations were performed using a combination of glovebox, high-vacuum and Schlenk techniques under a nitrogen or argon atmosphere. Solvents were purified and degassed by standard procedures. ^1H and ^{13}C NMR spectra were measured on Bruker 300 DRX, Bruker 400 DRX, and Bruker Avance 500 DMX spectrometers. Chemical shifts are reported in ppm relative to $SiMe_4$ ($\delta = 0$) and were referenced internally with respect to the protio solvent impurity (δ 7.15 for C_6D_5H) and ^{13}C resonances (δ 128.0 for C_6D_6). ^{77}Se chemical shifts are reported in ppm relative to neat Me_2Se ($\delta = 0$) and were referenced using a solution of Ph_2Se_2 in C_6D_6 ($\delta = 460$) as external standard [48]. Coupling constants are given in hertz. Infrared spectra were recorded on Perkin–Elmer 1430 and 1600 spectrometers and are reported in cm^{-1}. $[Me_2Si(C_5Me_4)_2]MoH_2$ was prepared by the method previously reported [26].

4.2. Synthesis of $[Me_2Si(C_5Me_4)_2]Mo(\eta^1$-*C*-$C_4H_3O)H$

A solution of $[Me_2Si(C_5Me_4)_2]MoH_2$ (15 mg, 0.04 mmol) and furan (0.05 mL, 0.69 mmol) in cyclohexane (ca. 1 mL) was photolyzed with UV light for 2 days, resulting in the deposition of yellow crystals. The crystals were isolated, washed with pentane (2 × 0.3 mL) and dried in vacuo giving $[Me_2Si(C_5Me_4)_2]Mo(\eta^1$-*C*-$C_4H_3O)H$ (8 mg, 46%). Anal. Calc. for $C_{24}H_{34}OSiMo$: C, 62.3; H, 7.4. Found: C, 62.0; H, 7.1%. IR data (KBr pellet, cm^{-1}): 2901 (vs), 1817 (s), 1776 (s), 1644 (m), 1345 (s), 1296 (s), 1253 (vs), 1124 (s), 1020 (vs), 892 (m), 864 (m), 836 (s), 763 (s), 712 (m), 672 (m). ^1H NMR data (C_6D_6): Isomer A (minor): −6.18 [br m, 1H of $Mo(OC_4H_3)H$], 0.28 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.40 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.13 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.87 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.95 [d, $^4J_{H-H} = 3$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.99 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 6.41 [t, $^3J_{H-H} = 2$, 1H of $Mo(OC_4H_3)$], 6.54 [br, 1H of $Mo(OC_4H_3)$], 7.66 [br, 1H $Mo(OC_4H_3)$]. Isomer B (major): −6.22 [septet, $J_{H-H} = 3$, 1H of $Mo(OC_4H_3)H$], 0.29 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.37 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.12 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.76 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.83 [d, $^4J_{H-H} = 3$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.87 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 5.71 [br, 1H of $Mo(OC_4H_3)$], 7.34 [br, 1H of $Mo(OC_4H_3)$], 7.45 [br, 1H $Mo(OC_4H_3)$]. ^{13}C NMR data for the major isomer (B) (C_6D_6): 2.7 [q, $^1J_{C-H} = 115$, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.9 [q, $^1J_{C-H} = 125$, 1C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 11.5 [q, $^1J_{C-H} = 127$, 4Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 12.4 [q, $^1J_{C-H} = 131$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 13.4 [q, $^1J_{C-H} = 126$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 48.6 [s, 2C, $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 90.3 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 93.1 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 106.1 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 123.2 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 121.0 [d, $^1J_{C-H} = 158$, 1C of $Mo(OC_4H_3)$], 140.1 [d, $^1J_{C-H} = 194$, 1C of $Mo(OC_4H_3)$], 150.8 [d, $^1J_{C-H} = 199$, 1C of $Mo(OC_4H_3)$], 187.3 [s, $1C_{ipso}$ of $Mo(OC_4H_3)$].

4.3. Synthesis of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2$-*C*,*Se*-$SeC_4H_4)$

A solution of $[Me_2Si(C_5Me_4)_2]MoH_2$ (30 mg, 0.08 mmol) and selenophene (75 μL, 0.81 mmol) in cyclohexane (ca. 1 mL) was photolyzed with UV light for 1 day, resulting in the deposition of red crystals of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2$-*C*,*Se*-$SeC_4H_4)$ which were isolated and dried in vacuo (20 mg, 50%). Anal. Calc. for $C_{24}H_{34}SiSeMo$: C, 54.9; H, 6.5. Found: C, 54.8; H, 6.6%. IR data (KBr pellet, cm^{-1}): 2988 (s), 2900 (s), 1569 (w), 1449 (w), 1376 (m), 1349 (vs), 1305 (s), 1253 (m), 1127 (m), 1018 (s), 946 (vs), 813 (s), 796 (s), 769 (s), 675 (vs), 660 (vs), 642 (vs), 605 (m). ^1H NMR data (C_6D_6): 0.16 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 0.18 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.45 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.49 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.59 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.00 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 6.83 [m, 1H of Mo-$(SeC_4H_4)$], 6.94 [m, 1H of $Mo(SeC_4H_4)$], 7.18 [m, 1H of $Mo(SeC_4H_4)$], 7.19 [m, 1H of $Mo(SeC_4H_4)$] (the signals due to SeC_4H_4 are a complex ABCD multiplet that may be simulated with the following coupling constants: $J_{AB} = 10$, $J_{AC} = 5$, $J_{AD} = 3$, $J_{CD} = 10$.) ^{13}C NMR data (C_6D_6): 2.2 [q, $^1J_{C-H} = 120$, 1C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.4 [q, $^1J_{C-H} = 121$, 1C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 10.0 [q, $^1J_{C-H} = 126$, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 11.7 [q, $^1J_{C-H} = 126$, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 12.4 [q, $^1J_{C-H} = 128$, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 14.5 [q, $^1J_{C-H} = 128$, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 57.8 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 92.8 [s, 2C of $(CH_3)_2Si$-$\{C_5(CH_3)_4\}_2$], 94.2 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 119.1 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 124.5 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 113.4 [d, $^1J_{C-H} = 166$, 1C of Mo-(SeC_4H_4)], 130.7 [d, $^1J_{C-H}$ = obscured by solvent peak, 1C of $Mo(SeC_4H_4)$], 133.3 [d, $^1J_{C-H} = 188$, 1C of Mo-(SeC_4H_4)], 161.6 [d, $^1J_{C-H} = 140$, 1C of Mo-(SeC_4H_4)]. ^{77}Se NMR data (C_6D_6): 209 [s, $Mo(SeC_4H_4)$].

4.4. Synthesis of $[Me_2Si(C_5Me_4)_2]Mo(\eta^2$-*C*,*Se*-$SeC_8H_6)$

A solution of $[Me_2Si(C_5Me_4)_2]MoH_2$ (30 mg, 0.08 mmol) and benzoselenophene (14 mg, 0.083 mmol) in cyclohexane (ca. 1 mL) was photolyzed with UV light for

1 day, resulting in the deposition of dark red crystals. The crystals were isolated, washed with pentane and dried in vacuo giving $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_8H_6)$ (15 mg, 34%). Anal. Calc. for $C_{28}H_{36}SeSiMo$: C, 58.4; H, 6.3. Found: C, 58.5; H, 6.5%. IR data (KBr pellet, cm^{-1}): 2836 (vs), 1464 (s), 1444 (m), 1412 (s), 1376 (m), 1361 (m), 1343 (m), 1307 (m), 1253 (s), 1178 (w), 1129 (m), 1076 (w), 1052 (m), 1036 (m), 1014 (s), 839 (s), 812 (s), 770 (m), 745 (vs), 726 (s), 674 (s), 654 (m). ^1H NMR data (C_6D_6): 0.17 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$] 0.18 [s, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.35 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.47 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.56 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 1.89 [s, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 6.87 [t, $^3J_{H-H} = 7$; d, $^4J_{H-H} = 2$, 1H of $Mo(SeC_8H_6)$], 6.99 [t, $^3J_{H-H} = 7$; d, $^4J_{H-H} = 1$, 1H of $Mo(SeC_8H_6)$], 7.03 [d, $^3J_{H-H} = 8$; d, $^4J_{H-H} = 2$, 1H of $Mo(SeC_8H_6)$], 7.23 [d, $^3J_{H-H} = 12$, 1H of $Mo(SeC_8H_6)$], 7.73 [d, $^3J_{H-H} = 12$, 1H of $Mo(SeC_8H_6)$], 8.13 [d, $^3J_{H-H} = 7$, 1H of $Mo(SeC_8H_6)$]. ^{13}C NMR data (C_6D_6): 2.2 [q, $^1J_{C-H} = 120$, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 2.4 [q, $^1J_{C-H} = 119$, 1Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 9.9 [q, $^1J_{C-H} = 127$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 11.7 [q, $^1J_{C-H} = 127$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 12.5 [q, $^1J_{C-H} = 128$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 14.5 [q, $^1J_{C-H} = 127$, 2Me of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 57.6 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 92.3 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 94.7 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 118.4 [s, 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$], 123.1 [d, $^1J_{C-H} = 160$, 1C of $Mo(SeC_8H_6)$], 125.0 [s, 1C of $Mo(SeC_8H_6)$], 125.7 [d, $^1J_{C-H}$ = ca. 140, 1C of $Mo(SeC_8H_6)$], 131.7 [d, $^1J_{C-H} = 153$, 1C of $Mo(SeC_8H_6)$], 134.2 [d, $^1J_{C-H} = 151$, 1C of $Mo(SeC_8H_6)$], 140.5 [d, $^1J_{C-H} = 147$, 1C of $Mo(SeC_8H_6)$], 144.3 [s, 1C of $Mo(SeC_8H_6)$], 163.1 [d, $^1J_{C-H}$ = ca. 140, 1C of $Mo(SeC_8H_6)$], 2C of $(CH_3)_2Si\{C_5(CH_3)_4\}_2$ are obscured by solvent.

4.5. X-ray structure determinations

X-ray diffraction data were collected on a Bruker P4 diffractometer equipped with a SMART CCD detector and crystal data, data collection and refinement parameters are summarized in Table 3. The structures were solved using direct methods and standard difference map techniques, and were refined by full-matrix least-squares procedures on F^2 with SHELXTL (Version 5.10) [49]. The crystallographic data for $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_4H_3O)H$ (CCDC # 272896), $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_8H_5O)H$ (CCDC # 272894), $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ (CCDC # 272895) and $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_8H_6)$ (CCDC # 272893) have been deposited with the Cambridge Crystallographic Data Center. $[Me_2Si(C_5Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_4H_4)$ and $[Me_2Si(C_5\text{- }Me_4)_2]Mo(\eta^2\text{-}C,Se\text{-}SeC_8H_6)$ exhibit a two-fold disorder of the metallaselenacycle which is common to this type of complex [10,39,43]. $[Me_2Si(C_5Me_4)_2]Mo(\eta^1\text{-}C\text{-}C_4H_3O)H$ also exhibits disorder and was refined with occupancies as suggested by ^1H NMR spectroscopic analysis.

4.6. Computational details

All calculations were carried out using DFT as implemented in the Jaguar 6.0 suite of ab initio quantum

chemistry programs [50]. Geometry optimizations were performed with the B3LYP functional and the 6-31G** (C, H, S, Si), LAV3P (Se) and LACVP (Mo) basis sets. The energies of the optimized structures were reevaluated by additional single point calculations on each optimized geometry using the cc-pVTZ(-f) (C, H, S, Si, Se) and LACV3P (Mo) basis sets.

Acknowledgments

We thank the U.S. Department of Energy, Office of Basic Energy Sciences (DE-FG02-93ER14339) for support of this research.

[12] For another example of C–S bond cleavage of thiophene accompanied by hydrogenation, see: G.P. Rosini, W.D. Jones, J. Am. Chem. Soc. 114 (1992) 10767.
[13] Hydrogenation of thiophene without cleavage of the C–S bond has also been reported. For example, $[RuH_2(\eta^2\text{-}H_2)_2(PCy_3)_2]$ reacts with thiophene to give an η^4-thioallyl complex $(\eta^4\text{-}S,C\text{-}SC_4H_5)Ru(PCy_3)_2H$ and is an effective catalyst precursor for the homogeneous hydrogenation of thiophene to 2,3,4,5-tetrahydrothiophene. [32] For a symmetric AX_2 molecule in which the bonding utilizes, for simplicity, a single s orbital on each atom, it is well known that the molecular orbital pattern consists of three orbitals which have the following character: (i) A–X bonding with no nodes, (ii) A–X nonbonding with a single node, and (iii) A–X antibonding with two nodes. However, although the A–X nonbonding orbital for an AX_2 molecule is localized on the X ligands with no contribution from the central atom, the corresponding "nonbonding" orbital for an asymmetric X–A–Y species may have varying degrees of X–A and A–Y bonding or antibonding character. As such, it is not completely appropriate to describe the orbital as "nonbonding"; it is, nevertheless, still characterized by a single node.
[33] The d_{yz} orbital is also of appropriate symmetry to interact with the $\eta^2\text{-}C,S\text{-}SC_4H_4$ ligand, but the overlap is not significant.

Abstract

We report X-ray crystal structures of complexes of the membrane-permeable metal chelator *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)ethylenediamine (TPEN) with Cu(II) and Zn(II), and solution studies of the Zn(II) and Cd(II) complexes. $[Zn(II)(TPEN)](PF_6)_2$ exhibits a distorted octahedral geometry with hexadentate TPEN, whilst $[Cu(II)(TPEN)](PF_6)_2$ contains penta-coordinated Cu(II), with one pendant picolyl arm of TPEN. A survey of structures of metal–TPEN complexes reveals the versatility of the TPEN ligand. Complexes of V(V), Cr(III), Rh(III), Re(VII), Fe(II), as well as Cu(II) are known which contain hypodentate TPEN with 3–5 of its nitrogens coordinated to the metal. Solution NMR spectroscopic studies also suggest that there is dynamic conformational flexibility in the structures of the $[Zn(TPEN)]^{2+}$ and $[Cd(TPEN)]^{2+}$ complexes in aqueous solution.

1. Introduction

N,*N*,*N*′,*N*′-Tetrakis(2-pyridyl-methyl)ethylenediamine (TPEN, Fig. 1) is a potentially hexadentate ligand. The ability of TPEN to cross-natural and artificial membranes and to chelate d-block metals preferentially makes it a useful tool for investigating the role of these metals inside cells. It has thus been used extensively in the past 15 years to study metal ion, in particular zinc, homeostasis [1,2]. Studies using TPEN have demonstrated that intracellular zinc depletion causes oxidative stress and DNA damage [3], upregulates hundreds of genes [4], and leads to (programmed) cell death [5]. TPEN has also been shown to be active against botulinum neurotoxins A and B in vivo [6], by a mechanism which presumably involves abstraction of the active site Zn(II) from the metalloprotease component of the toxins. However, since this chelating action is not limited to the toxin, TPEN is also considerably cytotoxic.

Despite its ubiquitous use as zinc chelator in biological systems, no X-ray structure of the TPEN complex of Zn(II) had been reported until very recently [7] (and after preparation of this script had begun), and little is known about the solution properties of this complex. We report here NMR spectroscopic studies of the Zn(II) and Cd(II) complexes of TPEN in solution and a comparison of the X-ray structures of Zn(II) and Cu(II) complexes. We show that TPEN is highly versatile in terms of the denticity and geometry that it adopts in metal complexes.

Abbreviations: TPEN, *N*,*N*,*N*′,*N*′-tetrakis(2-pyridylmethyl)ethylenediamine; EDTA, ethylenediamine-tetraacetate.

2. Experimental

2.1. X-ray crystallography

Diffraction data for compounds were collected on a Bruker Smart APEX diffractometer equipped with an Oxford Cryosystems low-temperature device operating at 150 K. Absorption corrections were based on the multiscan procedure SADABS. Structures were solved by Patterson methods using DIRDIF [8]. A summary of X-ray crystallographic data for [Zn(TPEN)]$(PF_6)_2$ and [Cu(TPEN)]$(PF_6)_2$ is given in Table 1.

2.1.1. [Zn(II)(TPEN)]$(PF_6)_2$

TPEN (8.5 mg, 20 μmol) was dissolved in 2 ml H_2O at 353 K. $ZnCl_2$ (20 μmol) was added from a 0.2 M aqueous stock solution. NH_4PF_6 (40 μmol) was added from a 0.1 M aqueous stock solution, and the pH was readjusted to 8.0 using NaOH. Subsequently, MeOH was added dropwise at 353 K, until the appearance of a precipitate. Water was added to re-dissolve this precipitate, and the solution was left to cool, first at room temperature, then at 277 K. Colourless blocks suitable for crystallography formed within days.

Refinement of 425 parameters by full-matrix least-squares on F^2 using SHELX-97 [9] gave $wR_2 = 0.1142$ based on all data and $R_1 = 0.0448$, based on 6598 data with $F > 4\sigma(F)$, $S = 1.055$, maximum Δ/σ on last cycle 0.006, maximum/minimum residual electron density = +0.73/−0.50 Å^{-3}. All non-hydrogen atoms refined anisotropically; hydrogen atoms of the complex were placed in calculated positions and allowed to ride on their parent atoms.

2.1.2. [Cu(II)(TPEN)]$(PF_6)_2$

TPEN (8.5 mg, 20 μmol) was dissolved in 5 ml of H_2O by adding 1 M HCl and the pH of the solution was adjusted to 7.0. To this solution 1 ml of an aqueous solution of $CuCl_2 \cdot 2H_2O$ (3.4 mg, 20 μmol) was added slowly with constant stirring. After 30 min stirring at room temperature, an aqueous solution (1 ml) of NH_4PF_6 (6.5 mg, 40 μmol) was added slowly to the reaction mixture. A blue microcrystalline product was obtained by concentrating the resultant solution on a rotary evaporator. The product was filtered off, washed with cold water and methanol, dried in air, and recrystallised from water. Blue crystals for X-ray structure determination formed after 1 week at 277 K.

Refinement of 424 parameters by full-matrix least-squares on F^2 using SHELX-97 [9] gave $wR_2 = 0.1069$ based on all data and $R_1 = 0.0439$, based on 6203 data with $F > 4\sigma(F)$, $S = 1.027$, maximum Δ/σ on last cycle 0.002, maximum/minimum residual electron density = +0.64/−0.45 Å^{-3}. All non-hydrogen atoms refined anisotropically; hydrogen atoms of the complex were placed in calculated positions and allowed to ride on their parent atoms.

Table 1
Crystallographic data collection and refinement details

Complex	[Cu(II)(TPEN)]$(PF_6)_2$	[Zn(II)(TPEN)]$(PF_6)_2$
Formula	$C_{26}H_{28}CuF_{12}N_6P_2$	$C_{26}H_{28}F_{12}N_6P_2Zn$
Formula weight	778.02	779.85

Goodness-of-fit	1.027	1.055

2.2. ^1H NMR spectroscopy

^{1}H NMR experiments were carried out on 5 mM [Zn(TPEN)]Cl_2 solutions in either 10% D_2O at pH 7.1, or 100% D_2O at pH* 7.1, and on 2.5 mM [^{111}Cd(TPEN)]Cl_2 (^{111}Cd isotopic purity 95.29%, Oak Ridge National Laboratory, TN) in 10% D_2O at pH 7.4. No buffers were added to the solutions. In each case, the solutions were prepared by mixing the appropriate amounts of TPEN and the respective metal chloride.

^{1}H spectra were acquired at 298 K on a Bruker DMX 500 spectrometer (500.13 MHz for ^{1}H) using an inverse multinuclear probehead (TBI) with 16 k time domain data points over a frequency width of 10000 Hz (20 ppm), giving an acquisition time of 0.625 s, and a relaxation delay of 2 s. The water signal was suppressed by presaturation during the relaxation delay, or using excitation sculpting [10]. Data were zero-filled to 64 k, apodised by exponential multiplication, applying a line-broadening factor of 0.3 Hz prior to Fourier transformation.

2.3. ^{111}Cd NMR spectroscopy

For ^{111}Cd NMR experiments, the reference was external 0.1 M $Cd(ClO_4)_2$ (natural abundance). Spectra were acquired on a 2.5 mM enriched sample (95.29% ^{111}Cd; Oak Ridge National Laboratory, TN) of the TPEN complex in 10% D_2O, pH 7.4, on a Bruker DMX 500 spectrometer operating at 106.046 MHz for ^{111}Cd, using a multinuclear broad-band observe (BBO) probehead with a pulsewidth of 17.5 μs (90°), acquisition time of 387 ms, recycle-delay of 1.5 s, 1024 transients, and frequency widths of 100, 200, and 400 ppm with varying offset frequencies. Spectra were zero-filled, and apodised by exponential multiplication with a line-broadening factor of 3, 15 or 30 Hz. Spectra were acquired without and with ^{1}H decoupling using GARP; no $^3J(^1H–^{111}Cd)$ coupling could be resolved.

2.4. Electrospray mass spectrometry

A Micromass Platform II ESI-MS instrument operating in positive ion mode was used for recording mass spectra (source temperature 373 K, capillary 3.52, HV lens 6.5). For MS samples, $[Cu(TPEN)](PF_6)_2$ was dissolved in water to a concentration of 100 μM. The cone voltage was varied over the range 10–35 V. MASS-LYNX (version 2.3) software was used for data processing.

2.5. UV–Vis spectroscopy

A CARY 300 Scan UV–Vis spectrophotometer was used for recording UV–Vis spectra (200–800 nm) in 1 cm pathlength cells. Samples were prepared by dissolving $[Cu(TPEN)](PF_6)_2$ in water at a concentration of 1.3 mM.

3. Results and discussion

3.1. Structure of $[Zn(TPEN)](PF_6)_2$

$[Zn(TPEN)](PF_6)_2$ crystallises in the monoclinic space group $P2_1/c$. The complex is chiral, and the crystals are racemic, with one crystallographically independent molecule in the unit cell. Fig. 2(a) shows the structure of one of the two stereoisomers. The recently characterized perchlorate salt $[Zn(TPEN)](ClO_4)_2$ crystallises in the monoclinic space group $C2/c$ [7] and contains two crystallographically independent molecules, with slightly different structures, and different stereochemistry. In both the perchlorate and hexafluorophosphate salts, Zn(II) has distorted octahedral coordination, with two picolyl rings *trans* to each other (labelled 2 and 4 in Fig. 2(a)), and the other two *cis* to each other (labelled 1 and 3). Table 2 gives selected distances and angles. The Zn–N distances in $[Zn(TPEN)](PF_6)_2$ vary between 2.117(2) and 2.2185(19) Å, with the shortest distances being observed for the two nitrogens in the *cis* picolyl rings, and the longest for the two ethylenediamine nitrogens. The largest deviation from ideal octahedral geometry is observed for the angles in the equatorial plane defined by the "en" nitrogens and the two *cis* picolyl nitrogens (N31–Zn–N33 = 124.64(7)°, and N1–Zn–N4 = 80.67(7)°). The planes defined by the two *cis* picolyl rings are at an angle of 22.5°. In the perchlorate salt, twist angles of 8° and 16.4° are observed. The planes of the *trans* picolyl rings are almost perpendicular to one another, at an angle of 79.9° in the PF_6 salt.

3.2. Structure of $[Cu(II)(TPEN)](PF_6)_2$

$[Cu(TPEN)](PF_6)_2$ is blue in colour and soluble in water and methanol. The UV–Vis spectrum of an aqueous solution

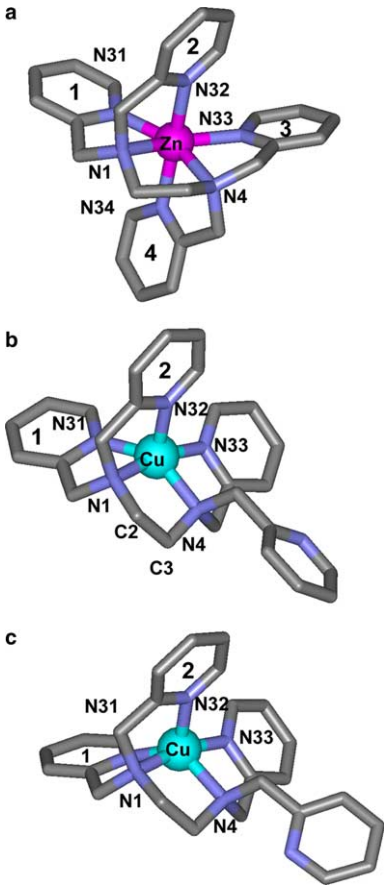

Fig. 2. View towards the "en" backbone of equivalent stereoisomers of the complex cations in (a) $[Zn(TPEN)](PF_6)_2$, (b) $[Cu(II)(TPEN)](PF_6)_2$, and (c) $[Cu(II)(TPEN)](ClO_4)_2$ [11]. The molecules have been positioned in such a way that ring 2, N1 and N4 are in similar orientations. Hydrogen atoms have been omitted for clarity. The comparison of (a) with (b) illustrates how differences in the conformation of the backbone allow for changes in the coordination number. The conformations of the five-membered chelate rings involving the "en" backbone can be described as "twist" (with C2 and C3 deviating from the plane defined by N1, Zn, and N4) for the Zn(II) complex, and as "envelope" for the Cu(II) complex, with C3 being the "flap" (the torsional angle between N4–Cu–N1–C2 is only 7°). As a consequence, the stereochemistry at N4 in $[Cu(TPEN)]^{2+}$ is inverted. The angle between the two "equatorial" picolyl rings (1 and 3) is 22.5° for the Zn(II) complex, and 51.0° for the Cu(II) complex. This larger angle in the Cu(II) complex is also a direct consequence of the stereochemistry at N4. A comparison of (b) and (c) demonstrates that the geometry of complex in the PF_6 salt is closer to tetragonal-pyramidal than trigonal-bipyramidal, as observed in the ClO_4 salt. This difference is mainly due to the altered position of ring 1 in relation to the rest of the molecule (see text).

For atom labelling schemes see Fig. 2.
[a] The labelling of atoms in this table has been adjusted for [Zn(II)(TPEN)](PF$_6$)$_2$ to facilitate comparisons between the zinc and copper complexes, and is not identical with the numbering in the deposited cif file (see Section 5).

of this complex at pH 7.0 shows a single absorption band with λ_{max} at 691 nm ($\varepsilon = 165\ M^{-1}\ cm^{-1}$) which is in agreement with the reported value [16]. The X-ray crystal structure of this complex is shown in Fig. 2(b). A summary of selected data are given in Table 1, and selected bond lengths and angles are given in Table 2. [Cu(TPEN)](PF$_6$)$_2$ forms triclinic crystals (space group $P\bar{1}$), and there are two molecules in the unit cell. The copper in this complex is five-coordinate, with one dangling, non-coordinating picolyl arm. The geometry is distorted, and can be described (see below) either as trigonal-bipyramidal, with N1 and N33 as axial ligands (N1–Cu–N33 = 168.01(8)°), or as tetragonal-pyramidal, with N32 as axial ligand, displaying a markedly longer bond distance (Cu–N32 = 2.109(2) Å) than the other four nitrogen ligands (1.9872(19)–2.0475(19) Å). The angles N33–Cu–N4, N31–Cu–N1, N1–Cu–N32 between picolyl and aliphatic nitrogen atoms are in the range of 82.0–82.9°, whereas the angle between the aliphatic nitrogens (N1–Cu–N4) is slightly larger, 86.5°. [Cu(TPEN)]$^{2+}$ is chiral, and the two molecules in the unit cell are enantiomers.

There are some interesting differences between the structures of the PF$_6$ salt of [Cu(TPEN)]$^{2+}$ reported here and that of the perchlorate salt reported recently [11]. The perchlorate salt is described as green in powder and crystalline forms, whereas the PF$_6$ salt is strongly blue in colour, as expected for all-nitrogen coordination. They crystallise in different space groups (monoclinic, $C2/c$ versus triclinic, $P\bar{1}$) with different packing.

In the perchlorate salt, the complex cation has a similar, but not identical, structure as that in [Cu(TPEN)](PF$_6$)$_2$ reported here. [Cu(TPEN)](ClO$_4$)$_2$ (Fig. 2(c)) has distorted trigonal-bipyramidal geometry with N1 and N33 (labelling according to Fig. 2) as the axial ligands, giving a N1–Cu–N33 angle of 167.3(2)°, very close to the corresponding angle in [Cu(TPEN)](PF$_6$), 168.01(8)°. A remarkable difference between the structures of the perchlorate and the hexafluorophosphate salts is the position of N31 in relation to N32 and N4 (the aliphatic nitrogen with the non-coordinating picolyl arm): In the perchlorate structure, the angles N31–Cu–N32, and N31–Cu–N4 are similar, 125.9(2)° and 127.2(2)°, respectively, whilst in the hexafluorophosphate structure, they differ considerably, with the N31–Cu–N4 angle being much larger (143.35(8)°) than the N31–Cu–N32 angle (104.63(7)°). Another striking difference is the bond length between Cu and N4: 2.148 Å in the perchlorate salt, the longest bond length in the complex, but only 2.0475(18) Å in the hexafluorophosphate salt, with the longest Cu–N bond length being that to the aromatic N32 (2.109(2) Å; the corresponding distance in the perchlorate salt is only 2.028(4) Å). In summary, the coordination geometry of the hexafluorophosphate structure is closer to tetragonal-pyramidal (with N32 as the apical ligand) than that of the perchlorate salt complex. The finding that the [Cu(TPEN)]$^{2+}$ complex can adopt various geometries in the solid state has implications for its solution behaviour.

Electrospray ionization mass spectra (ESI-MS) of [Cu(TPEN)]$^{2+}$ in water were recorded at different cone voltages (CV). At 10 or 15 V, a peak at 243.3 amu (m/z) clearly showed the presence of the [Cu(TPEN)]$^{2+}$ ion (calc. m/z 488/2 = 244). A peak at 486.9 amu corresponds to a species bearing one positive charge (calc. 487 Da). Upon using higher cone voltages (35 V), in-source fragmentation was observed, giving peaks at 92.5 amu, corresponding to a picolyl residue (calc. 92 amu) and at 393.6 amu, corresponding to the singly charged parent ion with one picolyl group less (calc. 395 amu). In contrast, there was no indication of Cu loss from the complex (no peaks detected for free TPEN). It is notable that the coordinative Cu(II)–N bonds remain intact whilst a C–N bond (305 kJ mol^{-1}) is cleaved. This demonstrates the high stability of these chelate complexes, and confirms that the pentadentate coordination mode is not only adopted in the solid state and solution, but also in the gas phase.

The variable denticity of TPEN has been noted previously, e.g., in the case of Fe(II), Cr(III), or Rh(III) complexes [12–15]. The pentadentate coordination of Cu(II) was predicted by Anderegg et al. [16] as early as 1977, who noticed that the Cu(II) complex was less stable than expected based on the Irving-Williams series. This is illustrated in Fig. 3. The maximum stability for octahedral [M(II)(TPEN)]$^{2+}$ complexes [16] would be expected for Cu(II), but the series observed for TPEN complexes peaks at Ni(II).

The versatility of TPEN was further highlighted by a survey of X-ray crystal structures of its complexes currently deposited in the Cambridge Crystallographic Database (version 5.26; November 2004), summarised in Table 3.

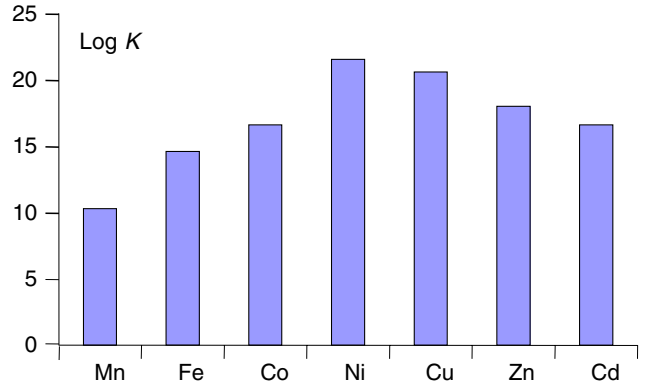

Fig. 3. Summary of stabilities of M(II) complexes of TPEN [16]. The stabilities do not strictly follow the Irving-Williams series. In particular, the Cu(II) complex is less stable than expected for octahedral coordination with Jahn–Teller distortion. This is attributable to its five-coordinate structure compared to the octahedral structure expected for the other metal ions.

The structures of mononuclear complexes $[M(TPEN)]^{n+}$ of M = Cr(III), Fe(II), Fe(III), Co(III), Ni(II), Zn(II), and Ru(II) have been reported [7,12–15,17–22]. All of these complexes have distorted octahedral geometry. Higher coordination numbers (7–10) for hexadentate TPEN complexes with additional ligands have been observed in mononuclear complexes of Mn(II), Cd(II), Sm(III), Tl(III), La(III) and Tb(III) [23–26]. Several examples for mononuclear complexes in which TPEN acts as a hypodentate ligand, coordinating metals via only 3 to 5 of its nitrogens, have been reported for V(V), Cr(III), Rh(III), Re(VII), Fe(II), and Cu(II) [11,12,14,15,18,27–29]. In every case, the "en" nitrogens are coordinated, and the hypodenticity is due to un-coordinated picolyl rings. In the complexes of V(V), Cr(III), Rh(III), Re(VII) and Fe(II), the hypodenticity is due to the presence of other competing ligands (Cl^-, oxo-O, sulfato-O, acetato-O), whereas the penta-coordinate Cu(II) complex is the only one with no additional ligands present. In this case, it is apparently the preference of Cu(II) for penta-coordination that governs the coordination geometry.

In addition, TPEN can form dinuclear complexes with the two symmetrical halves (comprising two pyridyl nitrogens and one aliphatic nitrogen) coordinating to one metal ion each. Depending on the nature of the metal and the additional ligands present, the two metals can be in close proximity, forming a metal–metal bond, as observed for complexes with Cu(I and II), Cr(III), Mn(III and IV), V(V), Mo(V) and W(V) [30–35]. The dinuclear complexes with metal–metal bonds have bridging oxo, hydroxo, and/or acetate ligands, with the exception of $[Cu(I)_2(TPEN)](BF_4)_2$ [30], (Cu–Cu 2.779 Å). Alternatively, the TPEN ligand can adopt an extended conformation, as in $[Cu(II)_2Cl_2(TPEN)](ClO_4)_2 \cdot H_2O$ (Cu–Cu 7.196 Å) [11], or $[Cu(II)_2Cl_4(TPEN)]$ (Cu–Cu 7.316 Å) [36]. A recent report has shown that Cu(II) interactions with TPEN in the presence of Cl^- can lead to the formation of $[Cu(II)_2Cl_2(TPEN)]^{2+}$ in solution [37].

In summary, depending on stoichiometry and conditions of the reaction, including the presence of competing ligands, TPEN shows a wide versatility in its interactions with metal ions, with Cu(I) and Cu(II) complexes displaying various features that are unparalleled in complexes with any other metal ions.

3.3. ^1H NMR spectroscopy of $[Zn(TPEN)]^{2+}$

Fig. 4 shows the 1-D ^1H NMR spectra of free TPEN, and mixtures of Zn(II) and TPEN, all at pH 7.1. The free ligand gives two resonances in the aliphatic, and four in the aromatic region. The peak assignments are also shown. In contrast to the other resonances, the line-width of the resonance for the ethylene "backbone" protons is temperature- and pH-dependent (at 298 K, 10% D_2O, pH 7.1: 7.8 Hz, pH 0: 4.2 Hz).

The reported pK_a values for TPEN are 7.19, 4.86, 3.35, and 2.95 [38]. Protonation occurs exclusively at the picolyl rings [16], as these exert a pronounced inductive effect on the tertiary amine nitrogens, making them much less basic than, e.g., triethylamine ($pK_a = 11$). This conclusion from solution data has been confirmed for the solid state; the X-ray structure of $H_4TPEN(ClO_4)_4$ shows four protonated picolyl residues [39]. No intramolecular H-bonds are observed, but the acidic protons show H-bonds to the counter-anions. From the protonation constants it can be concluded that at pH 7.1, about 50% of the TPEN molecules are protonated at one nitrogen (i.e., in total, ca. 13% of all picolyl nitrogens are protonated). The shift differences between the predominant species at pH 7.1 and the fully protonated form (observed at pH 0) are between 0.147 ppm for H6 and 0.583 ppm for H4. The methylene protons shift by 0.180 ppm and the ethylene protons by −0.227 ppm. All proton resonances shift downfield upon protonation, except for the ethylene protons, which shift upfield. Generally, downfield shifts are expected upon protonation, and the largest change in shift would be expected for the proton next to the protonation site (i.e., H6, which shifts only by 0.147 ppm); thus it is likely that the shift changes are influenced by changes in the preferred conformations of the protonated and deprotonated forms. Although caution must be applied when interpreting solution data based on solid-state structures, the X-ray crystal structures of protonated and deprotonated [40] TPEN are compatible with the upfield shift observed for the ethylene protons: in the structure of $H_4TPEN(ClO_4)_4$, all four ethylene protons are in a position to experience shielding from the electron cloud of the picolyl rings, whereas this is the case for only two protons in the deprotonated structure.

Complex formation between TPEN and Zn(II) in solution is rapid, as expected since the ligand is flexible. With substoichiometric amounts of zinc, two separate sets of ^1H NMR signals are observed for the free ligand and the complex. This indicates that exchange between these two species is slow on the NMR time scale, consistent with the reported high stability of the complex [16]; an upper

limit for the exchange rate can be estimated from the shift difference between the two closest peaks (for H3: 60.9 Hz). As the peaks are well resolved, the exchange rate must be well below 135 s^{-1}, corresponding to lifetimes for the two species of >7.4 ms. The protons of the side-arm methylene groups are magnetically inequivalent (diastereotopic) in the complex, as they are part of a chelate ring system. Interestingly, the singlet for the "en" CH_2 protons is much sharper (half-height width in 10% D_2O, 298 K, pH 7.1: 3.1 Hz) for the complex than for the free ligand (7.8 Hz under the same

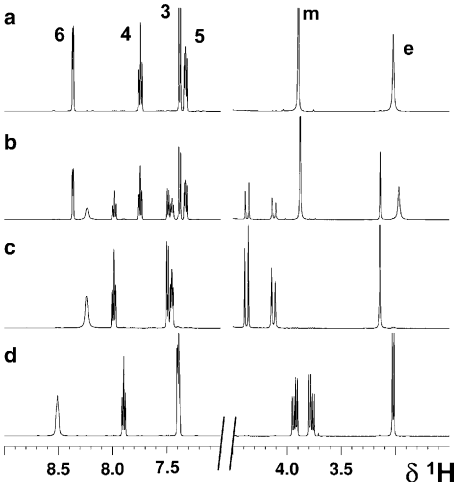

Fig. 4. 1-D ^{1}H NMR spectra of TPEN (pH* 7.1, 10% D_2O) (a) in the absence of metal ions, (b) with ca. 0.5 mol equiv. of $ZnCl_2$, (c) with 1 mol equiv. of $ZnCl_2$, (d) with 1 mol equiv. of $^{111}CdCl_2$ (prepared from ^{111}CdO by dissolution in 1 M HCl).

conditions); this suggests that the relative broadness of the signal in the free ligand is due to an exchange process that is no longer possible in the complex, e.g., rotation around the C–C bond.

In contrast, the H6 resonance is broader for the complex. For the free ligand, the width at half-height is ca. 6 Hz, and a small coupling to H5 (5.3 Hz) can be observed; this coupling is no longer resolved for the Zn(II) complex, for which the width at half-height is ca. 15 Hz. Exchange of the picolyl rings between equatorial (rings 1 and 3, Fig. 2(a)) and axial (rings 2 and 4) environments may account for some of the broadening. This exchange might occur through a trigonal prismatic ''twist'' mechanism, as has been reported for the Fe(II) complex [13]. The complex is stable at pH values as low as 2.0 (data not shown; spectra taken at this pH have essentially the same appearance as that shown in Fig. 4(c), and no peaks for free TPEN are observed). Addition of 10 M HCl is required to displace Zn(II) from the complex. Titrations with NaCl (data not shown) gave no indication of either additional binding of a seventh ligand in $[Zn(TPEN)]^{2+}$, or of the displacement of one picolyl ligand.

3.4. ^{1}H and ^{111}Cd NMR spectroscopy of $[Cd(II)(TPEN)]^{2+}$

The crystal structure of the Cd(II) complex of TPEN (as the nitrate salt) has been determined previously.[1] We have studied $[Cd(TPEN)]^{2+}$ in solution by ^{1}H and ^{111}Cd NMR spectroscopy. The ^{111}Cd NMR chemical shift of 151 ppm is within the expected range for Cd(II) coordinated to nitrogen ligands [41]. The half-height width of the ^{111}Cd peak in non-^{1}H decoupled spectra is ca. 80 Hz, precluding the resolution of coupling to ^{1}H, but heteronuclear coupling can be observed in the ^{1}H spectrum (Fig. 5). For both methylene and ethylene protons, ^{3}J coupling between ^{1}H and ^{111}Cd is easily observed. All heteronuclear $^{3}J(^{1}H–^{111}Cd)$ coupling constants for these protons are between 5 and 9 Hz. ^{3}J couplings are dependent on the torsional angle; thus, in principle two different coupling constants would be expected for coupling of ^{111}Cd to a pair of geminal protons, if the conformation in solution is rigid. However, only one coupling constant is observed for the two methylene protons, thus it appears that conformational changes occur rapidly on the NMR time-scale. The same is true for the ethylene protons. The coupling pattern for the methylene protons in $[Cd(TPEN)]^{2+}$ can be compared with that observed for $[Cd(EDTA)]^{2-}$ (Fig. 5). Two average $^{3}J(^{1}H–^{111}Cd)$ coupling constants can be determined for the methylene protons in $[Cd(EDTA)]^{2-}$ (11.3 and 13.3 Hz), whereas the corresponding coupling constant for $[Cd(TPEN)]^{2+}$ is only 8.7 Hz. The major difference between the EDTA and TPEN complexes is that there are two possible pathways for coupling between ^{111}Cd(II) and the methylene protons in $[Cd(TPEN)]^{2+}$, namely through the aliphatic nitrogens and/or the aromatic nitrogens, whereas for EDTA, the 3-bond coupling can occur only through the aliphatic nitrogens, as there are four bonds via the carboxylates. Four-bond couplings are expected to be too small to contribute to the observed coupling pattern. A comparison of the crystal structures of the two hepta-coordinate complexes $[Cd(H_2O)(EDTA)]^{2-}$ and $[Cd(NO_3)(TPEN)]^{2+}$ reveals that overall, the Cd–N–C–H torsional angles are similar in both complexes (70–90° and 150–170° for the two diastereotopic protons, respectively). Assuming that the ''sum'' of torsional angles is the same at any given time, the differences between the coupling constants observed in $[Cd(EDTA)]^{2-}$ and $[Cd(TPEN)]^{2+}$ might be attributable to contributions to the coupling via the aromatic nitrogens. Resolution enhancement allowed the peak at 8.44 ppm (H6), see Fig. 4(d) to be resolved into a pseudo-triplet, indicating that this proton is also coupled to ^{111}Cd, with a ^{3}J coupling

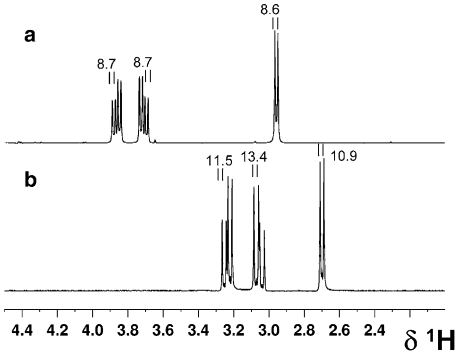

Fig. 5. Comparison of the $^{3}J(^{1}H–^{111}Cd)$ coupling in $[Cd(TPEN)]^{2+}$ (a) and $[Cd(EDTA)]^{2-}$ (b) (numbers given are in Hz). The homonuclear coupling between the geminal methylene protons is 15.8 Hz in $[Cd(TPEN)]^{2+}$, 16.4 Hz in $[Cd(EDTA)]^{2-}$, and 17.2 Hz in $[Zn(TPEN)]^{2+}$ (shown in Fig. 4(c)).

[1] The structure of $[Cd(II)(NO_3)(TPEN)](NO_3) \cdot$ acetone has been deposited in the CSD by M. Nieger, J. Ratilainen, K. Rissanen in 2002, but no literature reference is available.

constant of ca. 5 Hz. No coupling to other protons was detectable in the ^{1}H NMR spectrum.

4. Conclusions

TPEN forms very strong complexes with d-block metal ions and is often used to control the concentration of "free" metal ions, especially Zn(II), in biochemical experiments. The stability constant for $[Cu(TPEN)]^{2+}$ is anomalous in that it does not obey the Irving-Williams series for first row M(II) transition metal ions, with the Cu(II) complex being unexpectedly less stable than the Ni(II) complex (Fig. 3). We have crystallised $[Zn(TPEN)](PF_6)_2$ and $[Cu(TPEN)](PF_6)_2$. The Zn(II) complex is octahedral whereas the Cu(II) complex is five-coordinate with a dangling arm picolyl ring. The anomalous position of $[Cu(TPEN)]^{2+}$ in the Irving-Williams series can therefore be attributed to its five-coordinate structure compared to six-coordination for the other M(II) first-transition-series complexes. Moreover, it is apparent that these complexes possess considerable conformational flexibility. The perchlorate salt of $[Cu(TPEN)]^{2+}$ for example has a trigonal bipyramidal structure [11] which contrasts with the more closely tetragonal pyramidal structure of the hexafluorophosphate complex. Solution NMR studies also suggest that there is dynamic conformational flexibility in the structures of the $[Zn(TPEN)]^{2+}$ and $[Cd(TPEN)]^{2+}$ complexes in aqueous solution.

5. Supplementary data

The structures of $[Zn(II)(TPEN)](PF_6)_2$ and $[Cu(II)(TPEN)](PF_6)_2$ have been deposited in the Cambridge Crystallographic Data Centre under the accession numbers 273732 and 273733, respectively. Abstract

Reactions between K_4Ge_9, $Ni(CO)_2(PPh_3)_2$, and 2,2,2-crypt in ethylenediamine solutions give two different products depending on reaction conditions. The $[Ni_6Ge_{13}(CO)_5]^{4-}$ ion (**1**) is formed at low temperatures (~40 °C) and short reaction times whereas the $[Ge_9Ni_2(PPh_3)]^{2-}$ ion (**2**) forms at higher temperatures (~118 °C). Both complexes were isolated as $[K(2,2,2\text{-crypt})]^+$ salts and characterized by single-crystal X-ray diffraction, electrospray mass spectrometry (ESI-MS) and NMR studies (^{13}C and ^{31}P). **1** has a hypo-*closo* cluster electron count (Wades Rules) and adopts an interpenetrating biicosahedral structure with 17 vertices and 2 interstitials, which is unique in transition metal Zintl ion clusters. **2** also has a hypo-*closo* cluster electron count but displays an open, *nido*-like 10-vertex structure with a Ni interstitial. The composition of **2** was established through ESI-MS studies and corrects an earlier report that characterized the cluster as $[Ge_{10}Ni(PPh_3)]^{2-}$ with an interstitial Ge.

1. Introduction

Interest in "ligand-free" transition metal derivatives of Zintl ions has received much attention of late due to their close relationship to nanoparticles and fullercages [1–4], their remarkable molecular and electronic structures [5,6] and their utility in preparing low temperature alloys and intermetallics [7,8]. In particular, group 14 Zintl ions (i.e., Ge_9^{4-}, Sn_9^{4-}, Pb_9^{4-}) react with labile transition metal precursors to give high symmetry clusters that often contain centered transition metals. These include the $[M@Pb_{12}]^{2-}$ and $[M@Pb_{10}]^{2-}$ ions where M = Ni, Pd, Pt [9–11], and the recently reported $[Pd_2@Ge_{18}]^{4-}$ and $[Ni_3@Ge_{18}]^{4-}$ clusters [12,13]. The structures of these clusters depend on both the steric demands of the constituent elements and the cluster electron count. Many have structures similar to the boranes and are predicted by Wades rules [14] whereas others, such as $[Sn_9Pt_2(PPh_3)]^{2-}$, seem to violate Wade's structure prediction principles [15]. The latter complex has 20 cluster electrons with 10 surface vertices, which corresponds to a hypo-*closo* system in a Wade type analysis. The observed structure is not the anticipated closed, deltahedral type but a more open, *nido*-like framework [16] with fewer Sn–Sn contacts that predicted. This structural variance presumably results from the steric demands of the centered Pt atom and the weak nature of the Sn–Sn bonds. For comparison, the closely related $[Sn_9Ni_2(CO)]^{3-}$, which has a smaller Ni interstitial, adopts the expected closo structure in accord with its 21 electron, $2n + 1$ configuration [15].

Our initial studies with group 14 Zintl ions involved the use of ML_n subunits that did not contribute electrons to cluster bonding and were not expected to alter the cluster electron count or Zintl ion precursor framework structure. For example, the 9-vertex, 22-electron *nido*-Sn_9^{4-} complex forms the expected 10-vertex,

doi:10.1016/j.poly.2005.07.031

22-electron *closo*-$[Sn_9M(CO_3)]^{4-}$ series of complexes (M = Cr, Mo, W) [17]. The first transition metal polygermanide was prepared from the reaction between Ge_9^{4-} and $Ni(CO)_2(PPh_3)_2$ in ethylenediamine solvent. The product was characterized as $[K(2,2,2\text{-crypt})]_2[Ge_9(\mu_{10}\text{-Ge})Ni(PPh_3)]$ on the basis of X-ray analysis and Wade's electron counting principles [18]. By inserting an interstitial Ge instead of an interstitial Ni atom, one achieves a nido electron count that is consistent with the observed *nido*-like structure. With the discovery [15] of the isostructural $[Sn_9Pt_2(PPh_3)]^{2-}$ ion that violates Wades rules, we were prompted to reinvestigate the identity of the $[Ge_9(\mu_{10}\text{-Ge})Ni(PPh_3)]^{2-}$ ion by way of electrospray mass spectrometry (ESI-MS) and a new single-crystal X-ray analysis. During the course of our investigation, we discovered a new type of transition metal Zintl cluster, $[Ge_{13}Ni_6(CO)_5]^{4-}$, that possesses an interpenetrating biicosahedral structure [19,20]. Herein we report the synthesis and characterization of this cluster in addition to the correct structure and composition of the $[Ge_9Ni_2(PPh_3)]^{2-}$ ion that was previously described [18] as the $[Ge_9(\mu_{10}\text{-Ge})Ni(PPh_3)]^{2-}$ ion. The interconversion of these complexes and their relationships to other transition metal group 14 Zintl complexes are described.

2. Experimental

2.1. General data

All reactions were performed in a nitrogen atmosphere drybox (Vacuum Atmosphere Co.). The $^{31}P\{^1H\}$ NMR spectrum was recorded on a Bruker DRX400 spectrometer at 162 MHz. Electrospray Mass Spectra (ESI-MS) were obtained by direct injection of DMF solutions into a Finnigan mass spectrometer. Samples were detected in the negative ion mode. An AMRAY 1820K scanning electron microscope with a potential of 20 kV was used for energy dispersive X-ray (EDX) studies.

2.2. Chemicals

Melts of nominal composition K_4Ge_9 was made by fusion (at high temperature) of stoichiometric ratios of the elements. The chemicals were sealed in evacuated, silica tubes and heated carefully with a natural gas/oxygen flame. *CAUTION:* the synthesis of polygermanides can result in explosive mixtures and all fusion reactions should be conducted behind a blast shield inside of a well functioning hood. 4,7,13,16,21,24-Hexaoxa-1,10-diazobicyclo[8,8,8]-hexacosane (2,2,2-crypt) and $Ni(CO)_2(PPh_3)_2$ were purchased from Aldrich. Anhydrous ethylenediamine (en) and dimethylformamide (DMF) were purchased from Fisher, vacuum distilled from K_4Sn_9, and stored under dinitrogen.

2.3. Synthesis

2.3.1. Preparation of $[K(2,2,2\text{-crypt})]_4[Ni_6Ge_{13}(CO)_5]\cdot 1.5en$ (1)

In a vial K_4Ge_9 (54 mg, 0.07 mmol), 2,2,2-crypt (100 mg, 0.27 mmol), and $[Ni(CO)_2(PPh_3)_2]$ (84 mg, 0.14 mmol) were dissolved in 4 ml of en yielding a red/brown mixture. This mixture was heated ($35\ ^\circ C < T < 45\ ^\circ C$) and stirred for about 15 min. and filtered through a hot filter. After a week small thin black crystals of $[K(2,2,2\text{-crypt})]_4[Ni_6Ge_{13}(CO)_5]\cdot 1.5en$ precipitated. Yield: ~20 mg (~30%). EDX Ge:Ni:K = 3.8:1.7:1. ESI-MS data: (*m*/*z*, ion) 1850 $[K(2,2,2\text{-crypt})Ni_6Ge_{13}(CO)_5]^{1-}$; 1821 $[K(2,2,2\text{-crypt})Ni_6Ge_{13}(CO)_4]^{1-}$; 1296 $[Ni_6Ge_{13}]^{1-}$; 1214 $[K(2,2,2\text{-crypt})Ge_9Ni_2(CO)]^{1-}$; 838 $K[Ge_9Ni_2(CO)]^{1-}$; 810 $K[Ge_9Ni_2]^{1-}$; 770 $[Ge_9Ni_2]^{1-}$; 677 $K[Ge_4Ni_4(CO)_4]^{1-}$.

2.3.2. Preparation of $[K(2,2,2\text{-crypt})]_2[Ni_2Ge_9(PPh_3)]\cdot en$ (2)

In a vial K_4Ge_9 (54 mg, 0.007 mmol), 2,2,2-crypt (100 mg, 0.27 mmol), and $[Ni(CO)_2(PPh_3)_2]$ (84 mg, 0.14 mmol) were dissolved in 4 ml of en yielding a red/brown mixture. This mixture was boiled and stirred for about 15 min, and filtered through a hot filter. After 3–4 days block-shaped black crystals of $[K(2,2,2\text{-crypt})]_2[Ni_2Ge_9(PPh_3)]\cdot en$ started to precipitate. Yield: ~20 mg (~30%). EDX analysis on crystals showed presence of K, P, Ge, and Ni. ESI-MS data: (*m*/*z*, ion) 1447 $[K(2,2,2\text{-crypt})Ni_2Ge_9(PPh_3)]^{-1}$, 1072 $K[Ni_2Ge_9(PPh_3)]^{-1}$, 838 $K[Ni_2Ge_9(CO)]^{-1}$, 810 $K[Ni_2Ge_9]^{-1}$.

2.3.3. Interconversion studies

Conversion of ***1*** *to* ***2***. In a dry box, 36 mg of $[K(2,2,2\text{-crypt})]_4[Ni_6Ge_{13}(CO)_5]$ crystals were dissolved in 4 ml DMF. ESI-MS data were recorded to confirm the presence of $[Ni_6Ge_{13}(CO)_5]^-$ and $[K(2,2,2\text{-crypt})][Ni_6Ge_{13}(CO)_5]^-$, $[Ni_2Ge_9(CO)]^-$ and $[Ni_2Ge_9]^-$ ions before the interconversion experiments. 3 mg of PPh_3 was added to the starting solution and the reaction mixture was stirred for 30 min at ~118 °C. The resulting ESI-MS spectra showed signals of $K[Ni_2Ge_9(PPh_3)]^-$ and $[Ni_2Ge_9(PPh_3)]^-$ ions.

Attempted conversion of ***2*** *to* ***1***. In dry box, 20 mg of $[K(2,2,2\text{-crypt})]_2[Ni_2Ge_9(PPh_3)]\cdot en$ crystals were dissolved in 4 ml DMF. ESI-MS data were recorded to confirm the presence of $[Ni_2Ge_9(PPh_3)]^-$ and $[K(2,2,2\text{-crypt})][Ni_2Ge_9(PPh_3)]^-$ ions before the interconversion experiment. The solution was placed in a Schlenk flask, the head gases evacuated and the flask back filled with CO gas. The reaction mixture was stirred for 3 h under the CO atmosphere. The resulting ESI-MS spectra showed decomposition of the starting material but did not show the formation of **1** or the $[Ni_2Ge_9(CO)]^-$ ion.

2.4. Crystallographic studies

2.4.1. $[K(2,2,2\text{-crypt})]_4[Ni_6Ge_{13}(CO)_5]\cdot 1.5en$ (1)

A black plate with approximate orthogonal dimensions $0.260\times0.196\times0.101\ mm^3$ was placed and optically centered on the Bruker SMART CCD system at −80 °C. The initial unit cell was indexed using a least-squares analysis of a random set of reflections collected from three series of 0.3° wide ω-scans. Data frames were collected [Mo Kα] with 0.2° wide ω-scans, 40 s per frame and 909 frames per series. Five data series were collected at varying ϕ angles ($\phi = 0°$, 72°, 144°, 216°, 288°), and finally, a partial repeat of the first series, 300 frames, for decay purposes. The crystal to detector distance was 4.903 cm, thus, providing a complete sphere of data to $2\theta_{max} = 55.0°$. A total of 96 582 reflections were collected and corrected for Lorentz and polarization effects and absorption using Blessing's method as incorporated into the program SADABS [21] with 27 463 unique ($R_{int} = 0.0330$).

System symmetry, lack of systematic absences and intensity statistics indicated the centrosymmetric triclinic space group $P\bar{1}$ (no. 2). The structure was determined by direct methods with the successful location of the heavy atom cluster and a few potassium atoms using the program XS [22]. The structure was refined with XL [22]. A multitude of least-squares difference-Fourier cycles were required to locate the remaining non-hydrogen atoms. All non-hydrogen, full occupancy, atoms were refined anisotropically. All of the hydrogen atoms were placed in calculated positions. Various disorders were found for the potassium crypt-and cations and each was optimized independently. A full and half occupancy ethylenediamine molecules were located and also optimized. The final difference-Fourier map possessed several large peaks that were all near heavy atoms while the remainder of the map was featureless indicating that the structure is both correct and complete. An empirical correction for extinction was also attempted but found to be negative and therefore not applied.

2.4.2. $[K(2,2,2\text{-crypt})]_2[Ni_2Ge_9(PPh_3)]\cdot en$ (2)

A black block with approximate orthogonal dimensions $0.152\times0.139\times0.068\ mm^3$ was mounted as above and cooled −100 °C. The data collection was performed as described above. A total of 75 805 reflections were collected and corrected for Lorentz and polarization effects and absorption using Blessing's method as incorporated into the program SADABS with 17 295 unique ($R_{int} = 0.0615$).

The structure was solved and refined using the SHELXTL program package [22] as described above. An empirical correction for extinction was also attempted but found to be negative and therefore not applied. The final difference-Fourier map possessed several large peaks that were all near heavy atoms while the remainder of the map was featureless indicating that the structure is both correct and complete.

3. Results and discussion

K_4Ge_9 and $Ni(CO)_2(PPh_3)_2$ react in ethylenediamine (en) in the presence of 2,2,2-crypt to give two different products that depend on reaction conditions. At moderate temperatures (30 °C < T < 40 °C), the $[Ni_6Ge_{13}(CO)_5]^{4-}$ ion (**1**) formed as the $[K(2,2,2\text{-crypt})]^+$ salt in moderate yield. The $[K(2,2,2\text{- crypt})]^+$ salt of **1** forms small, thin dark brown crystals is air and moisture sensitive in solution and the solid state. The salt is highly soluble in DMF and CH_3CN and forms dark brown solutions. The 19-atom cluster has a fused biicosahedral capsule-like structure with 17 Ge/Ni vertices and 2 centered Ni atoms. The structure and properties of this cluster will be discussed in subsequent sections.

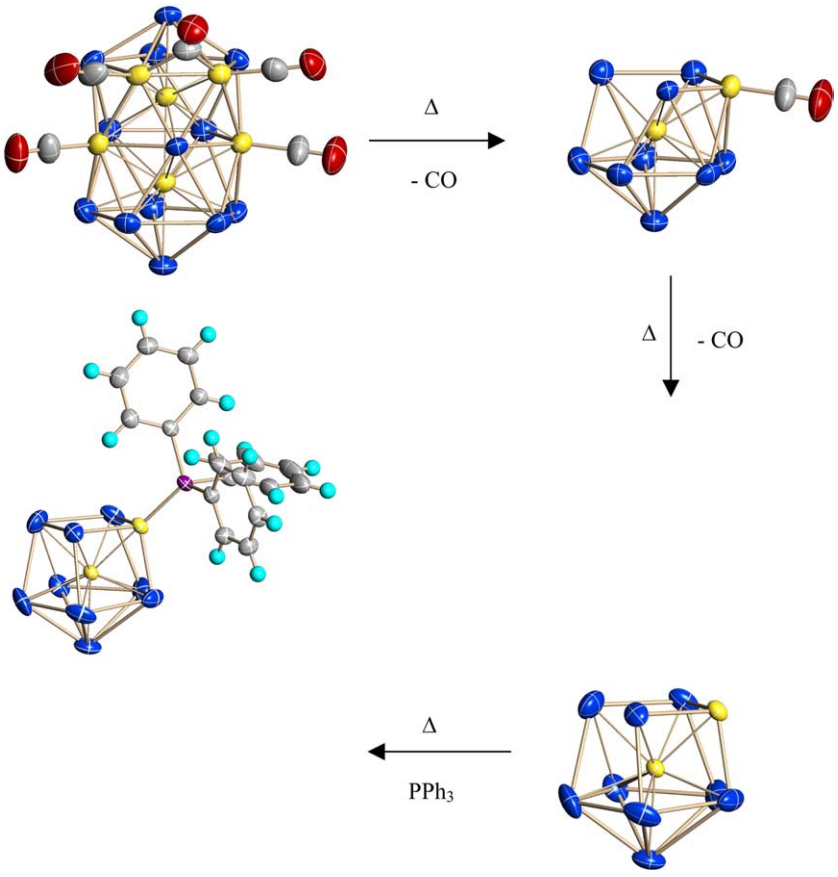
At higher temperatures ($T \sim 118$ °C), the same reaction yields the $[Ge_9Ni_2(PPh_3)]^{2-}$ ion (**2**) in moderate yields, which crystallizes as large, block-like dark brown crystals of the $[K(2,2,2\text{-crypt})]^+$ salt. The structure of the anion has 1 Ni and 9 Ge vertices with a centered Ni atom and will also be discussed in subsequent sections. Both complexes have been characterized by single-crystal X-ray diffraction, NMR spectroscopy (^{13}C and ^{31}P where appropriate), Energy dispersive X-ray analysis (EDX), electrospray ionization mass spectrometry (ESI-MS) and infrared spectroscopy. Both salts are highly soluble in DMF and CH_3CN and decompose upon exposure to air in the solid state or in solution.

A proposed scheme for the interconversion of anions **1** and **2** is illustrated in Scheme 1. The transformation involves the initial formation of the cluster anion $[Ni_6Ge_{13}(CO)_5]^{4-}$ (**1**) followed by an irreversible conversion to $[Ge_9Ni_2(PPh_3)]^{2-}$ (**2**). This conclusion is based on the following results and observations:

(i) The same Ni precursor, $Ni(CO)_2(PPh_3)_2$, is used in the synthesis of **1** and **2**. However, anion **1** is isolated from reactions conducted at relatively lower temperatures (35–40 °C) and short reaction times whereas the formation of **1** is favored at high temperatures and long reaction times.

(ii) Electrospray mass spectra of DMF solutions of **1** (see following section) show anion **1** as well as, $[Ge_9Ni_2(CO)]^-$ and $[Ge_9Ni_2]^-$, that result from fragmentation of the parent. These ions have the same Ge_9Ni_2 core composition of **2**.

(iii) Addition of PPh_3 to en solutions of pure $[K(2,2,2\text{-crypt})]_4[Ni_6Ge_{13}(CO)_5]$ results in the formation of **2** after ~30 min of reaction at 118 °C. The ESI-MS spectra of these solutions show signals



Scheme 1.

corresponding to $K[Ge_9Ni_2(PPh_3)]^{1-}$ and $[Ge_9Ni_2(PPh_3)]^{1-}$ ions, that coincide with those of the authentic sample.

(iv) Reactions between **2** and carbon monoxide result in cluster decomposition but do not regenerate **1** or result in the formation of $[Ge_9Ni_2(CO)]^-$ according to ESI-MS analysis.

While these experiments show that **2** can be generated from **1** under appropriate conditions, they do not preclude the direct formation of **2** from Ge_9^{4-} and $Ni(CO)_2(PPh_3)_2$.

Indeed, the synthesis of closely related clusters such as $[Sn_9Pt_2(PPh_3)]^{2-}$ appear to form directly from Sn_9^{4-} with sequential addition of Pt fragments (NMR analysis) [15] and do not seem to involve intermediates akin to **1**. Moreover, the proposed mechanism for the formation of the closely related $[Ni_3@Ge_{18}]^{4-}$ involves direct insertion of Ni into a Ge_9 cluster and a subsequent coupling [13].

3.1. Mass spectrometry

The electrospray mass spectrum for each sample was recorded in the negative ion mode from DMF solutions of crystalline $[K(2,2,2\text{-crypt})]^+$ salts. The distinctive mass envelopes arising from the multiple isotopes of Ge and Ni have been simulated to facilitate assignments and verify nuclearities. The spectrum for $K[Ge_9Ni_2(PPh_3)]^{1-}$ is shown in Fig. 1 as an example and the remaining spectra and simulations are given in the Supporting Information. The spectrum of **1** (Fig. S1) shows weak signals of the [K(2,2,2-crypt)]-coordinated molecular ion of $[Ni_6Ge_{13}(CO)_5]^-$ along with the decarbonyl loss products $Ni_6Ge_{13}(CO)_4^-$, $Ni_6Ge_{13}(CO)_2^-$ and ligand-free binary ion $Ni_6Ge_{13}^-$. Patterns of new compounds, $Ge_9Ni_2(CO)^-$ and $Ge_9Ni_2^-$ are also observed as well as peaks for the $Ge_4Ni_4(CO)_4^-$ cluster ion paired to K^+ and $[K(2,2,2\text{-crypt})]^+$.

The negative ion electrospray mass spectrum of DMF solution constituted from crystalline $[K(2,2,2\text{-crypt})]_2[Ge_9Ni_2(PPh_3)]$ shows an intense signal for the $K[Ge_9Ni_2(PPh_3)]^{1-}$ molecular ion with the expected mass envelope (Fig. 1). As is common for these types of Zintl ions, the potassium-coordinated ion pair, $K[Ge_9Ni_2(PPh_3)]^{1-}$, appears as the parent ion, (m/z 1072.1) and the fully charged anion is not observed. The ligand-free Ge–Ni cluster anion $K[Ge_9Ni_2]^{1-}$ was also observed as well as the CO substituted cluster, $K[Ge_9Ni_2(CO)]^{1-}$, which presumably results from a trace contamination in the sample.

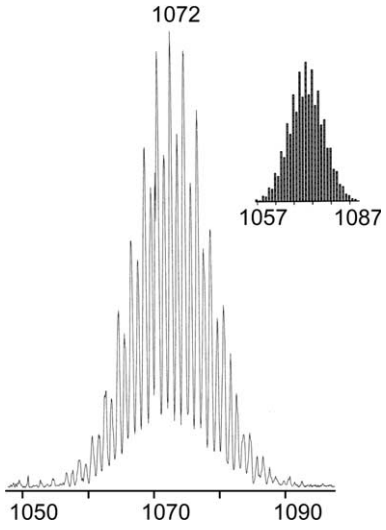


Fig. 1. ESI-mass spectrum of the $K[Ge_9Ni_2(PPh_3)]^{1-}$ molecular ion. The inset shows the simulated mass envelope.

3.2. Solid-state structures

The $[Ni_6Ge_{13}(CO)_5]^{4-}$ (**1**) and $[Ge_9Ni_2(PPh_3)]^{2-}$ (**2**) anions crystallize as the $[K(2,2,2\text{-crypt})]^{+}$ salts with triclinic crystal symmetry, space group $P\bar{1}$. The former has 1.5en solvate molecules per formula unit. A summary of the crystal data is given in Table 1, and selected bond distances are given in Tables 2 and 3, respectively. A previous report of the $[K(2,2,2\text{-crypt})]_2[Ge_9Ni_2(PPh_3)]$ structure was incorrectly characterized as having an anion formula $[Ge_{10}Ni(PPh_3)]^{2-}$. We correct this interpretation here and present a new refinement of the crystal structure from new X-ray data.

The $[Ni_6Ge_{13}(CO)_5]^{4-}$ anion possesses C_s point symmetry with a symmetry plane defined by Ge1, Ge8, Ge19 and the bridging carbonyl (Fig. 2). The anion is a 17-vertex deltahedral cluster defined by 13 Ge atoms and 4 Ni atoms. The cluster is centered by two additional interstitial Ni atoms. Each of the 4 vertex Ni atoms has a terminal CO ligand bound in a radial fashion with an additional bridging CO spanning the Ni2–Ni3 edge. The 17-atom deltahedron possesses 126 total valence electrons and has 32 cluster electrons according to Wades rules of electron counting [14]. According to Wades Rules, each of the Ge atoms contributes 2 electrons whereas each Ni(CO) vertex unit and interstitial Ni contributes zero electrons. The bridging CO ligand and the cluster charge contribute 2 and 4 electrons, respectively, to give 32 cluster electrons

$$13 \times 2(\text{Ge}) + 2(\text{CO}) + 4(\text{charge}) = 32\text{e}.$$

The 17-vertex, 32 electron cluster corresponds to a hypo-*closo* electron count and is consistent with the closed, deltahedral structure type.

The $[Ni_6Ge_{13}(CO)_5]^{4-}$ structure can be viewed as two interpenetrating icosahedral units (**Ih1** and **Ih2**) that share the central $Ge_3Ni_2(CO)_2$ penagonal ring and the 2 interstitial Ni atoms of the biicosahedral cluster (see Fig. 2(b)). **Ih1** has a composition $Ge_7Ni_6(CO)_5$ where Ni7 is interstitial and Ni13 occupies a vertex. **Ih2** has a $Ge_9Ni_4(CO)_2$ composition where Ni7 occupies a vertex and Ni13 occupies the interstitial site. This type of interpenetrating biicosahedral structure is new for transition metal Zintl clusters but is known in some of Teo's bimetallic Au–Ag and trimetallic Au–Ag–M; M = Pt, Pd, Ni supraclusters. In particular, the structure of **1** is highly

reminiscent of the *sss* rotamer of the $[(PPh_3)_{10}Au_{13}Ag_{12}Br_8]^+$ triicosahedral cluster [20].

The Ge–Ge, Ni–Ni, and Ni–Ge bond distances are in the range of 2.658(1)–2.894(1) Å (avg. 2.746(4) Å), 2.450(1)–2.771(1) Å (avg. 2.624(4) Å), and 2.381(1)–2.668(1) Å (avg. 2.522(5) Å), respectively (see Table 2). As expected, $Ni–CO_{(terminal)}$ contacts (avg. 1.718(8) Å) are shorter than the $Ni–CO_{(bridge)}$ contacts (avg. 1.879(8) Å). The structure is slightly flattened along the Ge8–Ge14 and Ge8–Ge5 vectors. This distortion is best illustrated by the differences between the 6 diagonal distances in each icosahedral subunit. In both of the icosahedral cages, diagonal distances involving Ge8, (Ge8–

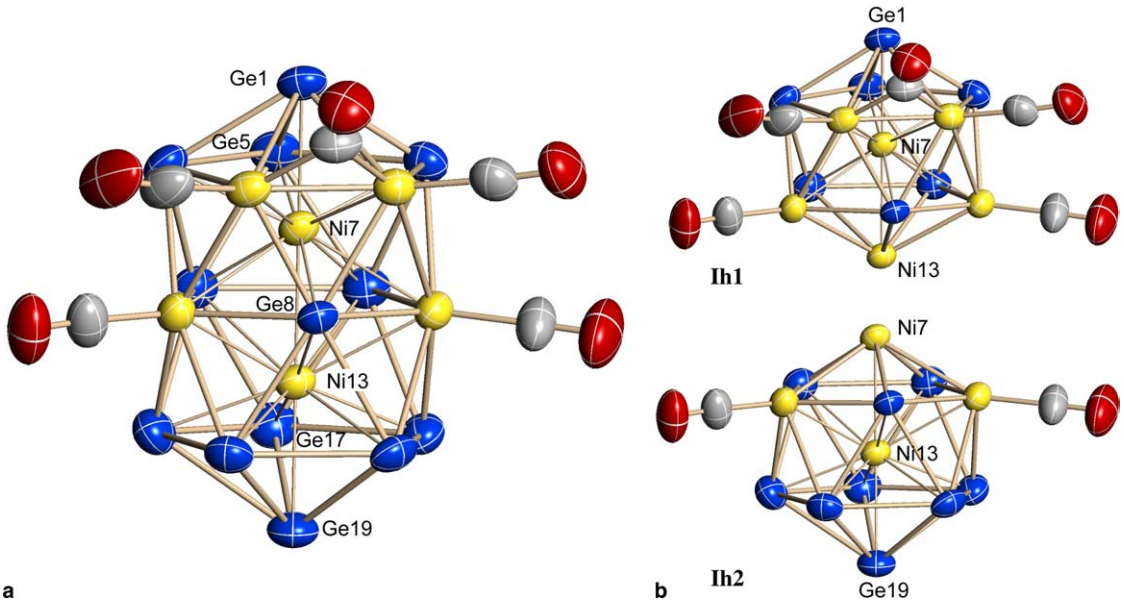

Fig. 2. (a) ORTEP drawing of the $[Ni_6Ge_{13}(CO)_5]^{4-}$ anion. Ni is yellow, Ge is blue, C is gray and oxygen is red. A fully labeled drawing is given in the Supporting material. (b) The two interpenetrating icosahedral subunits, Ih1 and Ih2.

Ge5 = 4.812(1) Å for **Ih1**, and Ge8–Ge17 = 4.878(2) Å for **Ih2**) are shorter than the other 5 diagonals in the respective subunits (5.087(5) Å, avg. for **Ih1**, and 5.115(4) Å avg. for **Ih2**).

The Ge–Ge bond distances for the anion **1** (2.6335(9)–2.9064(11); 2.750(6) Å avg.) are similar to those in other polygermenide clusters such as $[K(2,2,2\text{-crypt})]_3[P(C_6H_5)_3Ge_9]$, where Ge–Ge distances vary from 2.53 to 3.27 Å [23–25]. The Ni–Ge (2.3808(9)–2.6681(11) Å; 2.523(5) Å av.) and Ni–Ni (2.450(1)–2.771(1) Å, 2.624(4) Å av.) contacts are similar to the reported compounds (2.470–2.691 and 2.553–2.721 Å, respectively) [26].

As mentioned previously, the structure of the $[Ge_9Ni_2(PPh_3)]^{2-}$ ion, (**2**), was incorrectly reported to have the formula $[Ge_{10}Ni(PPh_3)]^{2-}$ in which the interstitial atom was refined as Ge. The formula has been unequivocally established by ESI-MS studies and the structure re-determined. The structure (Fig. 3) is identical to that previously reported except for the identity of the centered atom. The anion has virtual C_{3v} point symmetry and is isoelectronic and isostructural to $[Sn_9Pt_2(PPh_3)]^{2-}$ [15]. It is defined by nine surface Ge atoms, one interstitial Ni atom and a capping $[Ni(PPh_3)]$ fragment. The cluster is a 10-vertex 20-electron hypo-*closo* system that has an open, *nido*-like structure. For comparison, it is isostructural to the 24-electron 10-vertex $[Sb_7Ni_3(CO)_3]^{3-}$ ion that adopts a *nido*-type architecture [27]. Note that replacing the centered Ni atom with a Ge atom would add 4 electrons to cluster bonding and would be consistent with the observed structure. Although this does not occur, this

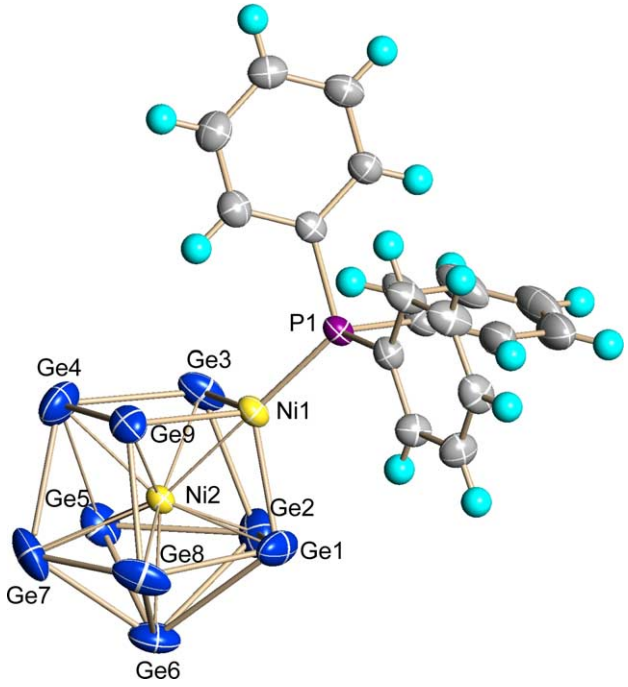

Fig. 3. ORTEP drawing of the $[Ge_9Ni_2(PPh_3)]^{2-}$ ion, (**2**). Ni is yellow, Ge is blue, C is gray, P is purple and H is turquoise.

electron counting rationale gave rise to the erroneous assignment in the original publication [18].

The centered Ni atom has nine Ni–Ge contacts in the range of 2.342(6)–2.447(6) Å. The 3 Ni–Ge bonds to Ni1 average 2.37(2) Å. The Ge–Ge contacts are in the range 2.594(1)–2.808(1) Å and are typical of polygerminide cages.

3.3. NMR spectroscopic studies

The ^{13}C NMR spectrum of $[Ni_6Ge_{13}(CO)_5]^{4-}$ (DMSO-d_6, 25 °C) shows carbonyl resonances at 194.6, 217.9, 224.9 ppm, which is consistent with the solid state structure.

The room temperature ^{31}P NMR spectrum of $[Ge_9Ni_2(PPh_3)]^{2-}$ crystals shows only free triphenylphosphine in DMF solution ($\delta = -5.1$ ppm), suggesting that PPh_3 ligand dissociation is fast on the NMR time scale. This observation is somewhat surprising in view of the static nature of the PPh_3 ligand in the isoelectronic, isostructural $[Sn_9Pt_2(PPh_3)]^{2-}$ ion and the electron deficient nature of the cluster.

4. Conclusions

In our original report, the centered atom of **2** was modeled as both Ni and Ge with ultimate selection of the latter. Due to the similarities in the scattering factors of Ni and Ge, the refinement of the X-ray data did not allow for the discrimination between the two models. The assignment of a centered Ge atom was primarily based on electron counting principles (Wades rules) and striking structural similarities to other clusters of the same nuclearity (e.g., $[Sb_7Ni_3(CO)_3]^{3-}$). With the discovery of $[Sn_9Pt_2(PPh_3)]^{2-}$, we were prompted to reinvestigate the Ni–Ge system and the identity of **2**. The higher precision CCD data reported here and, more importantly, the ESI-MS data unequivocally identify the ion as $[Ge_9Ni_2(PPh_3)]^{2-}$ with a centered Ni atom. The non-deltahedral *nido*-like structures of these hypo-*closo* clusters are presumably due to steric demands of the centered metal atom.

During our re-investigation of the synthesis of **2**, we found that the $[Ni_6Ge_{13}(CO)_5]^{4-}$ ion, **1**, was formed at lower temperatures and shorter reaction times. While we have shown that **2** can be formed from **1** (Scheme 1), it seems quite possible that it also forms directly from Ge_9^{4-} and the $Ni(CO)_2(PPh_3)_2$. The biicosahedral structure of **1** is unique to Zintl ion chemistry but is a known feature in bimetallic clusters of the coinage metals [20]. The recently reported $[Pd_2@Ge_{18}]^{4-}$ and $[Ni_3@(Ge_9)_2]^{4-}$ cluster anions also in this general class of compounds. The former is an 18 vertex, 2 focus, 40 electron cluster with the expected *closo* architecture ($2n + 2$ cluster electrons per focus) whereas the latter does not easily fit into a Wadian description. Interestingly, neither forms icosahedral structures and are structurally distinct from **1**.

Recently, we have shown that ligand-free deltahedral clusters of Pb and Sn that are compositionally similar to the ligand-free ions identified here. For example, $[Ni@Pb_{10}]^{2-}$ and the gas phase $[Ni@Pb_{10}]^{1-}$ ions are centered 10-vertex clusters [10] similar to $Ge_9Ni_2^{-1}$ (or $[Ni@Ge_9Ni]^{-1}$). The later presumably adopts the *nido*-like C_{3v} structure of **2** despite having *5 fewer electrons* than the 22-electron *closo*-$[Ni@Pb_{10}]^{2-}$ cluster. While many of Zintl clusters of the group 14 elements and their transition metal derivatives adopt Wadian like structures, there are now several examples that do not. It is certain that more exceptions will be discovered as research continues.

Acknowledgments

We dedicate this manuscript to Professor Malcolm Chisholm on the occasion of his 60th birthday. This material is based upon work supported by the National Science Foundation under Grant No. 0401850.

Appendix A. Supplementary data

Crystallographic data for the compounds have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 273776 (**1**) and 273777 (**2**). Abstract

The syntheses and crystal structures of the tetra- and hexanuclear Cr^{III} aggregates $(enH_2)[Cr_4(\mu\text{-}OH)_4(hpdta)_2]\cdot 5\frac{1}{2}H_2O$ (**1a**), $[Ba(OH_2)_5\{Cr_4(\mu\text{-}OH)_4(hpdta)_2\}]\cdot 13H_2O$ (**1b**) $[Cr_6(\mu\text{-}OH)_8(hpdta)_2(en)_2]\cdot 10H_2O$ (**2a**) and $[Cr_6(\mu\text{-}OH)_8(hpdta)_2(en)_2]\cdot 14H_2O$ (**2b**) (H_5hpdta = 2-hydroxypropane-1,3-diaminetetraacetic acid) are reported and discussed. The antiferromagnetic interactions mediated by the bridging hydroxo ligands have been quantified. The fact that there are only a few such examples in the literature with similar bridges leads to the conclusion that a meaningful magnetostructural correlation, such as that recently proposed for oxo- and hydroxo-bridged Fe^{III} aggregates, is not yet possible in the case of Cr^{III}.

1. Introduction

We have previously described how hydrolysis reactions controlled by the use of chelating organic ligands containing amino, carboxylato and often alkoxo functionalities can be used to obtain polymetal aggregates of iron(III) and aluminium(III) held together by oxygen bridges deriving from the solvent water with further oxygen bridges often provided by groups on the ligand [1,2]. The structures of the resulting compounds are often analogous, although not always strictly isostructural [1]. This is probably a reflection of the relative lability and Lewis acidity of the two metal ions. For example, we find that whilst oxide bridges are common in the iron(III) complexes, hydroxide bridges tend to predominate in the aluminium(III) systems. We also found that the proligand hydroxypropanediaminotetraacetic acid, H_5hpdta (Scheme 1) is useful for providing dinuclear metal units as the central alcohol function provides an alkoxide bridge between the two metal ions [3–5].

With this in mind, we thought it would be interesting to see if this type of chemistry can be extended to the chromium(III) ion. Although several bis-(hydroxo)dichromium complexes have been reported [6] there are currently very few examples of larger hydroxo-bridged chromium(III) aggregates in the literature, although

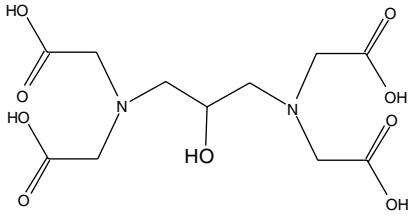

Scheme 1. The proligand H_5hpdta.

speciation studies suggest that hydrolytic clusters similar to those found for iron(III) and aluminium(III) should exist [7]. It is possible that the dual effects of the inertness of the chromium(III) ion and its tendency to form stable mononuclear octahedral complexes make the crystallisation of such aggregated species difficult. Thus, whilst mononuclear complexes of chromium(III) with chelating aminocarboxylate ligands have been extensively studied [8] only a few dinuclear hydroxo-bridged complexes with such ligands have been reported [9]. Apart from some tri- and tetranuclear complexes with ammine or cyclic polyamine ligands [10] the known higher nuclearity complexes are predominantly cyclic or cubane-based species in which the hydroxo bridges are supported by carboxylate co-ligands [11].

The magnetic interactions in the dinuclear hydroxo-bridged complexes have been extensively studied and it has been concluded that the magnitude of the antiferromagnetic interaction depends on the Cr–O(H) bond lengths, the Cr–O(H)–Cr angle and the extent to which the O–H bond is bent out of the Cr_2O plane [12]. The latter structural parameter, which reflects the nature of the hybridisation at the bridging oxygen, is at least as important as the other two which is in contrast to the situation for iron(III) complexes where a useful magnetostructural correlation was obtained using only the Fe–O–Fe bond lengths and angles [13]. More recently, ab initio DDCI2 methods have been used to calculate the magnitude of the magnetic interactions in such bis-(hydroxo)dichromium systems and these largely support the earlier correlations between the three geometrical parameters described above and the magnitude of the antiferromagnetic interaction [14].

In this paper, we report on the successful synthesis and isolation of tetranuclear and hexanuclear hydroxo-bridged chromium(III) aggregates using $hpdta^{5-}$ as the organic ligand. These have been structurally characterised using single crystal X-ray diffraction studies and their magnetic behaviour is described.

2. Experimental

H_5hpdta, $CrCl_3 \cdot 6H_2O$, $Cs(OH) \cdot H_2O$ and $BaCl_2 \cdot 2H_2O$ were purchased from Aldrich Chemical Co., 1,2-diaminoethane (en) (99%) from Lancaster Synthesis and all were used as received. $[Cr_3O(O_2CCH_3)_6(OH_2)_3]Cl \cdot 6H_2O$ was prepared by the method of Brauer [15]. All compounds gave satisfactory microanalyses.

2.1. Synthesis and characterisation

2.1.1. $(enH_2)[Cr_4(\mu\text{-}OH)_4(hpdta)_2] \cdot 5\frac{1}{2}H_2O$ (**1a**)

H_5hpdta (97 mg, 0.3 mmol) and 1,2-diaminoethane (72 mg, 80 μl, 1.2 mmol) in 10 ml water were stirred for 10 min. $CrCl_3 \cdot 6H_2O$ (160 mg, 0.6 mmol) was added with further stirring for 5 min. The solution was then heated to 85 °C under reflux with stirring for 24 h. After cooling, slow evaporation over 3–4 weeks gave purple crystals of **1a** in 15% yield.

2.1.2. $[Ba(OH_2)_5\{Cr_4(\mu\text{-}OH)_4(hpdta)_2\}] \cdot 13H_2O$ (**1b**)

H_5hpdta (97 mg, 0.3 mmol), $CrCl_3 \cdot 6H_2O$ (160 mg, 0.6 mmol), $BaCl_2 \cdot 2H_2O$ (37 mg, 0.15 mmol) and 1,2-diaminoethane (60 mg, 67 μl, 1.0 mmol) in 10 ml water were stirred for 10 min. The solution was heated to 85 °C under reflux with stirring for 20 h. The pH of the solution was then raised to 8.1 by dropwise addition of aqueous 1,2-diaminoethane followed by heating for a further 4 h. After cooling, slow evaporation over 2 weeks gave purple rod-shaped crystals of **1b** in 11% yield.

2.1.3. $[Cr_6(\mu\text{-}OH)_8(hpdta)_2(en)_2] \cdot 10H_2O$ (**2a**)

H_5hpdta (81 mg, 0.25 mmol) and 1,2-diaminoethane (66 mg, 74 μl, 1.1 mmol) in 10 ml water were stirred for 10 min. $[Cr_3O(O_2CCH_3)_6(OH_2)_3]Cl \cdot 6H_2O$ (362 mg, 0.5 mmol) was added, with further stirring until the trinuclear complex had dissolved. The solution was then heated to 85 °C under reflux with stirring for 4 h. The pH of the solution was then raised to 7.3 by dropwise addition of aqueous 1,2-diaminoethane followed by heating for a further 20 h. After cooling, slow evaporation over 2 weeks gave purple needle-shaped crystals of **2a** in 8% yield.

2.1.4. $[Cr_6(\mu\text{-}OH)_8(hpdta)_2(en)_2] \cdot 14H_2O$ (**2b**)

H_5hpdta (97 mg, 0.30 mmol), $CsOH \cdot H_2O$ (84 mg, 0.5 mmol) and 1,2-diaminoethane (30 mg, 34 μl, 0.5 mmol) in 10 ml water were stirred for 10 minutes. $CrCl_3 \cdot 6H_2O$ (160 mg, 0.6 mmol) was added with further stirring for 5 min. The solution was then heated to 85 °C under reflux with stirring for 24 h. The pH of the solution was then raised to 7.6 by dropwise addition of aqueous 1,2-diaminoethane, followed by heating for a further 1 h. After cooling, slow evaporation over 5 days gave purple block-shaped crystals of **2b** in 7% yield.

2.2. Crystal structure determinations

Data were measured on Stoe IPDS (**1a** and **1b**) and Bruker SMART Apex (**2a** and **2b**) area detector diffractomers, respectively, using graphite-monochromated Mo-Kα radiation ($\lambda = 0.71073$ Å). The structures were solved by direct methods and refined by full-matrix least-squares against F^2 for all data, using the SHELXTL software package [16]. In **1b** many water molecules (those coordinated to Ba and lattice waters) were two- or threefold disordered. All non-H atoms were refined anisotropically except for some disordered lattice water molecules; H-atoms bonded to O or N were refined isotropically; those bonded to C were placed in calculated positions. Crystal data and details of the data collection and structural refinement are summarised in Table 1.

2.3. Magnetic measurements

Magnetic susceptibility measurements on **1a** (5.6 mg), **1b** (10.6 mg), **2a** (1.67 mg) and **2b** (9.93 mg) were obtained on a finely ground polycrystalline sample with the use of a Quantum Design SQUID magnetometer MPMS-XL. The dc measurements were collected from 1.8 to 300 K and from −70 to 70 kOe. Experimental data were also corrected for the sample holder and for the diamagnetic contribution calculated from Pascal constants [17].

3. Results and discussion

3.1. Description of the structures

The structure of the tetranuclear complex in **1a** is shown in Fig. 1; a similar numbering scheme is used for that in **1b**. Each hpdta^{5-} ligand coordinates two Cr(III) centres with the alkoxo oxygen bridging between the two as expected. Each Cr(III) is ligated in a tetradentate fashion through the alkoxo and two carboxylato oxygens and the amino nitrogen. Two such $\{Cr_2(hpdta)\}^-$ moieties are linked by the four bridging hydroxo ligands, two of which coordinate to each Cr(III) in a *cis* relationship. The Cr–O(H) bond lengths for **1a** and **1b** all lie in the range 1.938–1.996 Å with the Cr–O(H)–Cr angles of 130.7–135.9°. The corresponding values for the alkoxo bridges are 1.947–1.992 Å and 131.3–132.0° reflecting the fact that the geometry of the alkoxo bridge is constrained by the overall coordination of the hpdta^{5-} ligand. The geometries of the hydroxo-bridges compare well with those previously reported for unsupported single hydroxo-bridges, which are all in the range 132–137° [10]. The $\{Cr_4(\mu\text{-}OH)_4(\mu\text{-}OR)_2\}$ core thus has approximate tetrahedral symmetry, although this is reduced if the organic ligand as a whole is considered. Bond lengths and angles for the aggregates in **1a** and **1b** are summarised in Table 2.

The tetranuclear aggregate is thus isostructural with the aluminium analogue in $(enH_2)[Al_4(\mu\text{-}OH)_4$-

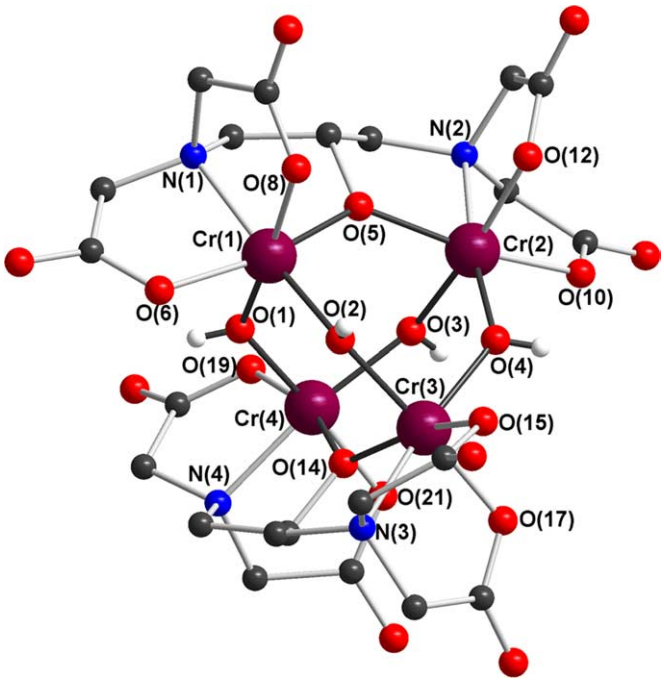

Fig. 1. Structure of the $[Cr_4(\mu\text{-}OH)_4(hpdta)_2]^{2-}$ aggregate in **1a**. The same numbering scheme is used in **1b**.

$(hpdta)_2] \cdot 7\frac{1}{2}H_2O$ [1]. In the corresponding tetrahedral iron(III) aggregates $X[Fe_4(\mu\text{-}O)(\mu\text{-}OH)_3(hpdta)_2] \cdot 5H_2O$ ($X = enH_2$, $pipH_2$) [2,18], one of these bridging hydroxo ligands is found to be deprotonated to an oxo bridge, which is probably a consequence of the higher Lewis-acidity of Fe(III) compared to Cr(III) or Al(III), noting that the relative acidities of metal ions can be judged from what is often termed the hydrolysis constant, which corresponds to the first pK_a for deprotonation of a coordinated water ligand with values of 2.1 for Fe(III), 4.0 for Cr(III) and 5.0 for Al(III).

In the crystal lattice of **1a**, the aggregates are linked via a three-dimensional network of hydrogen bonds. Three of the bridging hydroxo ligands (O(2), O(3) and O(4)) make hydrogen bonds to non-coordinated carboxylate oxygens of adjacent aggregates. In addition, one of the two NH_3^+ groups of the organic cation, N(31), forms hydrogen bonds to carboxylate oxygens from three different aggregates and three of the lattice waters also act as hydrogen-bonding linkages between different aggregates. In the lattice of **1b**, however, the aggregates are linked into chains via the Ba^{2+} countercations (Fig. 2). In each aggregate one carboxylate ligand, that involving O(6) and O(7), chelates to Ba(1), while O(7) also coordinates to the inversion-related Ba(1′) (at $-x$, $1-y$, $1-z$) such that two aggregates are linked through a dimeric $\{Ba_2(OH_2)_{10}\}^{4+}$ unit. Further coordination of the carboxylate oxygen O(16) to Ba(1″) (at $1-x$, $1-y$, $1-z$) leads to the one-dimensional motif in which two parallel rows of Cr_4 aggregates are joined through the dibarium units.

The structure of the hexanuclear Cr_6 aggregate in **2a** and **2b** is shown in Fig. 3. Unlike that in **1a** and **1b**, this aggregate has no direct analogue from our work with $hpdta^{5-}$ complexes of Fe(III) or Al(III). Selected bond lengths and angles are listed in Table 3; the same atom numbering system is used for the two isostructural aggregates. As before, a $hpdta^{5-}$ ligand chelates two chromium centres, Cr(1) and Cr(2), with the alkoxo oxygen bridging between them. Cr(1) is then linked to Cr(3) by two hydroxo ligands, O(1) and O(2), while Cr(2) is linked to Cr(3) by a further hydroxo bridge, O(3). Two such trichromium moieties form the centrosymmetric hexanuclear aggregate being joined by two further hydroxo bridges with O(4) bridging between Cr(2) and Cr(3′) and a corresponding bridge formed by its symmetry equivalent O(4′). The coordination sphere of Cr(3) is completed by the nitrogen atoms N(3) and N(4) of an ethylenediamine ligand. The geometries of the double bridges between Cr(1) and Cr(2), involving O(1) and O(2) are again comparable with previously reported systems [4,10]. However, unlike in **1a** and **1b**, the angles at the single hydroxo-bridges are now smaller than for such bridges in the literature [7,10], although still more obtuse than the angles reported for carboxylate-supported bridges [11]. To the best of our knowledge, the alkoxo-bridges at O(5) in **2a** and **2b** represent the first examples of single unsupported alkoxo-bridges between two chromium(III) centres. The unit cell parameters for **2a** and **2b** are closely related, and the packing of the Cr_6 aggregates in the lattice similar for both with extensive hydrogen bonding interactions in evidence through the lattice waters.

3.2. Magnetic behaviour

The magnetic susceptibilities of polycrystalline samples of **1a** and **1b** were measured over the temperature range 1.8–300 K at 1 kOe, and the results are shown in Fig. 4.

For each compound, the high temperature data above 100 K can be fitted to a Curie–Weiss law, with $C = 8.6$ and 9.5 cm^3 K/mol and $\theta = -98$ and -106 K for **1a** and **1b**, respectively. The estimation of the Curie constant is in good agreement with the presence of four $S = 3/2$ Cr(III) metal ions (expected value for $g = 2.0$ is $C = 7.5$ cm^3 K/mol). Moreover, the Weiss constant indicates dominating antiferromagnetic interactions between the magnetic centres. According to the molecular structure of these Cr_4 units (vide supra), four different hydroxo and two alkoxo groups link the magnetic centres, potentially resulting in six different magnetic interactions. Although it is known that the magnitudes of these interactions depend critically on (inter alia) the degree of out-of-plane bending of the O–H and O–R bonds we used a simplified model with only two different interactions, one for the hydroxo and one for the alkoxo bridges. A similar simplification has previously been used to interpret the magnetism of a tetranuclear complex with a $\{Cr_4(\mu\text{-}OH)_6\}$ core [10e]. Therefore, the susceptibility was calculated using the following Heisenberg spin Hamiltonian (see inset Fig. 4):

$$H = -2J\{S_1S_3 + S_1S_4 + S_2S_3 + S_2S_4\} - 2J_1\{S_1S_2 + S_3S_4\}.$$

Here J corresponds to the average magnetic interaction through the four hydroxo bridges, and J_1 to that through the two alkoxo bridges. Using this model, the simulation shown in Fig. 4 was obtained using the MAGPACK program [19]. The final values obtained were $J/k_B = -8.5(2)$ K ($-5.9(1)$ cm^{-1}), $J_1/k_B = -8.0(2)$ K ($-5.6(1)$ cm^{-1}), $g = 1.98$ for **1a**, and $J/k_B = -10.6(2)$ K ($-7.4(1)$ cm^{-1}), $J_1/k_B = -1.8(2)$ K ($-1.3(1)$ cm^{-1}), $g = 1.98$ for **1b**. It is worth noting that these values are robust in that they could be obtained from a range of different starting values.

For **1a**, the values of J and J_1 are very similar. It would seem that the larger out-of-plane bending of the O–H bonds (18–29°) compared to that for the O–C bonds (13.9° and 11.3°) is largely compensated by the replacement of the H substituent on the oxygen bridge by an alkoxo group. In the case of **1b**, however, it appears not to be so straightforward with J similar to that found for **1a**, but J_1 much smaller (-1.8 K compared to -8.0 K). Paine et al. reported the magnetic analysis of two related bis-(methoxy)-bridged dinuclear chromium complexes, in which the two $\{Cr_2(\mu\text{-}OMe)_2\}$ cores had very similar geometries but very different J values; however they attributed the difference to the presence of an additional hydrogen-bonded {Cr–MeOH···OMe–Cr} bridge [20]. For **1b**, a further possibility is that J_1 might not be assignable to the alkoxo bridges, but to two opposite hydroxo-bridges. Inspection of the structure of **1b** shows that the O–H bonds on O(1) and O(4) are substantially more bent out-of-plane (by 39° and 28°) than those on O(2) and O(3) (16° and 8°) and the small value for J_1 might reflect the possibly weaker coupling through O(1) and O(4) with J then assigned to the O(2) and O(3) and alkoxo bridges. Such arguments must, however, remain speculative, particularly as the out-of-plane O–H angles cannot be obtained with any degree of accuracy from even a low-temperature X-ray crystal structure. We merely note here that the observed susceptibilities can be simulated with just two J values. Ab initio calculations [20] using a structure obtained from neutron diffraction would probably be the only way to define precisely the magnetic interactions, but this is outside the scope of the present work.

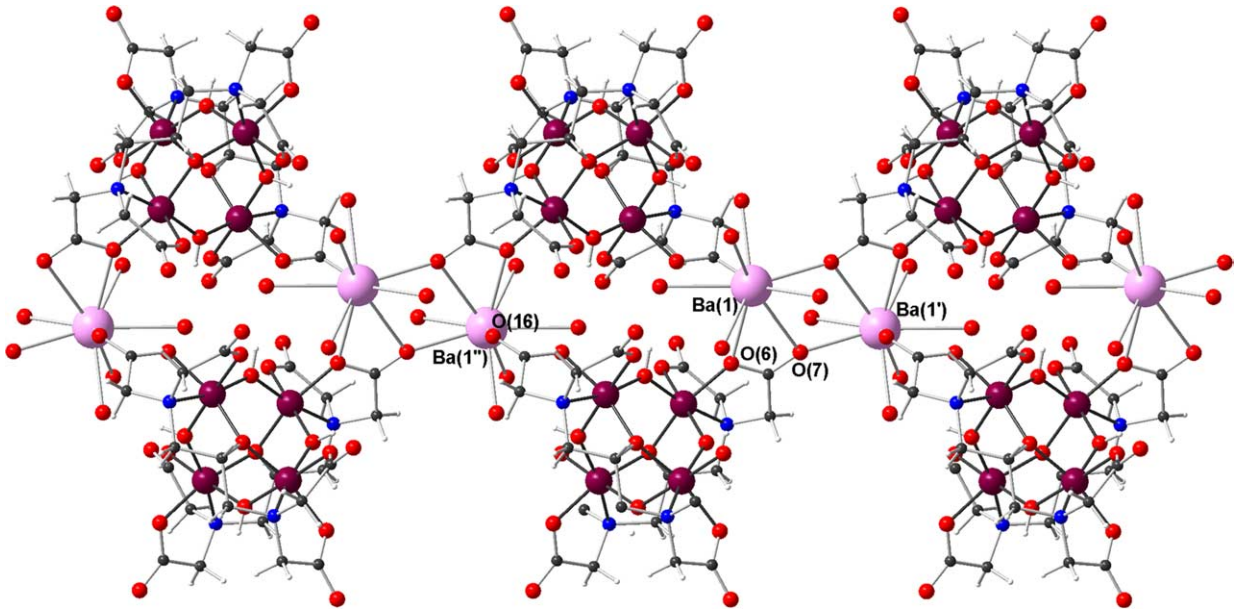

Fig. 2. Linkage of the Cr_4 aggregates by coordination of O(6), O(7) and O(16) to Ba^{2+} cations forming double-chains in the structure of **1b**.

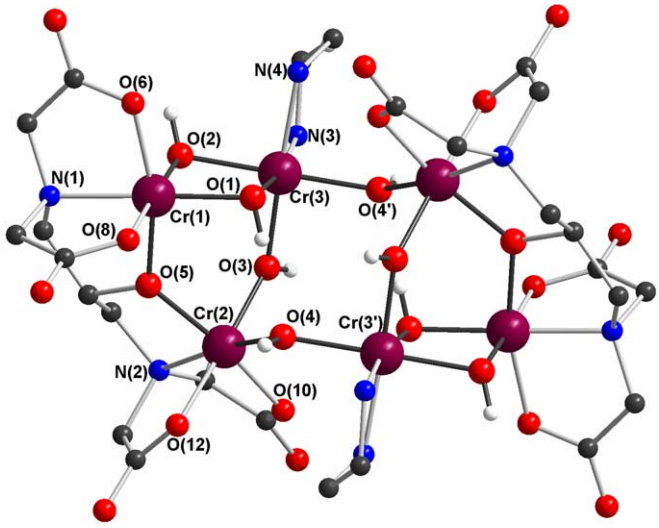

Fig. 3. Structure of the $[Cr_6(\mu\text{-}OH)_8(hpdta)_2(en)_2]$ aggregate in **2a**. The same numbering scheme is used in **2b**.

The magnetic susceptibilities of polycrystalline samples of **2a** and **2b** were similarly measured over the temperature range 1.8–300 K at 1 kOe, and the results are shown in Fig. 5. The high temperature data above 100 K can be fitted to a Curie–Weiss law for both compounds with $C = 12.0$ and 12.3 cm^3 K/mol and $\theta = -74$ and -105 K for **2a** and **2b**, respectively. The estimation of the Curie constants is in agreement with the presence of six $S = 3/2$ Cr(III) metal ions (expected value for $g = 2$ is $C = 11.25$ cm^3 K/mol). As before, the Weiss constants indicate dominating antiferromagnetic interactions. In the molecular structure of these Cr_6 units (vide supra), four chemically distinct types of bridges between the chromium(III) centres are present: the double hydroxo bridge between Cr(1) and Cr(3), the alkoxo bridge between Cr(1) and Cr(2), and the two single hydroxo bridges O(3) and O(4). However, the latter two bridges have very similar geometries and we have therefore considered only three different interactions in a simplified model. The susceptibility was thus calculated using the following Heisenberg spin Hamiltonian (see inset Fig. 5):

$$H = -2J_1\{S_1S_3 + S_5S_6\} - 2J_2\{S_1S_2 + S_4S_6\} - 2J_3\{S_2S_3 + S_3S_4 + S_4S_5 + S_2S_5\}.$$

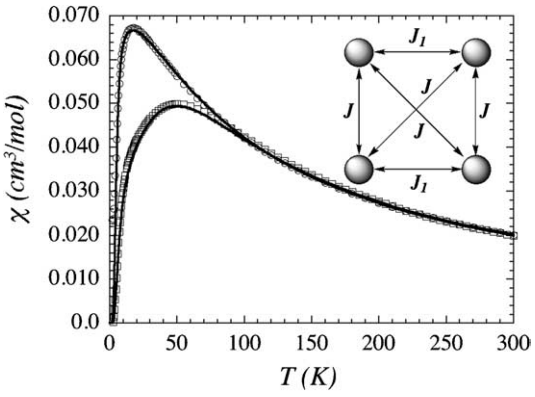

Fig. 4. Plots of magnetic susceptibility χ against temperature for compounds **1a** (○) and **1b** (□), the solid lines are the best fits using the models described in the text. Inset: Schematic view of the magnetic interaction topology.

Here J_1, J_2 and J_3 correspond to the magnetic interactions through the double-hydroxo, mono-hydroxo and alkoxo bridges, respectively. This Hamiltonian was fully diagonalized using MAGPACK [19] and the susceptibility calculated. The simulation agrees very well with the experimental data with $J_1/k_B = -15.0(2)$ K ($-10.4(1)$ cm^{-1}), $J_2/k_B = -6.6(2)$ K ($-4.6(1)$ cm^{-1}), $J_3/k_B = -4.5(2)$ K ($-3.1(1)$ cm^{-1}), $g = 1.98$ for **2a**, and $J_1/k_B = -12.0(2)$ K ($-8.3(1)$ cm^{-1}), $J_2/k_B = -9.6(2)$ K

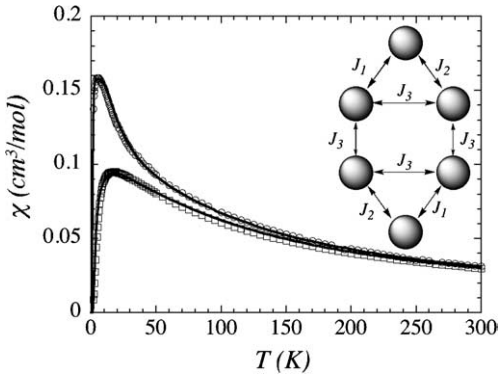

Fig. 5. Plots of magnetic susceptibility χ against T for compounds **2a** (○) and **2b** (□), the solid lines are the best fits using the models described in the text. Inset: Schematic view of the magnetic interaction topology.

($-6.7(1)$ cm^{-1}), $J_3/k_B = -7.6(2)$ K ($-5.3(1)$ cm^{-1}), $g = 1.98$ for **2b**. Although individual J values differ between the two compounds in both cases the interaction through the double-hydroxo bridges is the most strongly antiferromagnetic, followed by the mono-hydroxo and alkoxo bridges. In spite of the fact that the geometries of the aggregates in **2a** and **2b** are very similar, it is likely that even relatively small changes in the hydrogen-bonding environments of the (μ-OH) ligands, resulting from changes in the crystal packing, with concomitant effects on the extent to which the O–H bonds are bent out-of-plane, are responsible for the small differences in corresponding J values for the two compounds.

For iron(III) aggregates linked by (μ_3-O), (μ-OR) and (μ-OH) bridges a rather successful correlation between bridge geometry and magnetic interaction has been proposed, based on the Fe–O distances and Fe–O–Fe angles [13]. For the d^5 metal cation it was not found necessary to include the out-of-plane O–H bending to obtain a useful correlation. For chromium(III), by contrast, such a correlation is not practical for two main reasons. Firstly, the magnitudes of the J values are much less than for iron(III) and are indeed comparable to the degree of experimental scatter found for the iron system [13]. Secondly, while the M–O bond lengths and M–O–M angles can be determined to a good degree of precision in an X-ray structural analysis, this is not the case for the out-of-plane bend of the O–H bonds and the precise location of the hydrogen atom has been shown to have a dominant influence on the magnetic interaction in hydroxo-bridged chromium(III) complexes [21]. Furthermore, Glerup et al. [10e] have commented that it may be unwise to compare J values from chromium(III) complexes of differing nuclearity. We also note that, in contrast to iron(III) complexes, in the chromium complexes so far reported, the hydroxo-bridges have Cr–O–Cr angles that fall into three well-defined groups: double-hydroxo bridges with Cr–O–Cr ca. 96-99°, carboxylate-supported hydroxo-bridges with Cr–O–Cr ca.

120°, and unsupported hydroxo-bridges with Cr–O–Cr ca. 131–137°. In order to develop any sort of magneto-structural correlation a much wider spread of geometries is clearly required.

4. Conclusion

Overall these results indicate that the Cr(III) ion can be used to produce aggregates via hydrolytic routes similar to some of the Fe(III) and Al(III) compounds already known. The inert nature of the Cr(III) centre requires fairly harsh reaction conditions with compounds forming only when solutions are left refluxing and then in rather small yields compared with the other two metal ions. This inertness together with the fact that the compounds formed only have hydroxo bridges and no oxo bridges makes them more comparable to the Al(III) than the Fe(III) compounds previously observed. The magnetic behaviour of these new Cr(III) hydroxo-bridged systems can be modelled and the dominant interactions are antiferromagnetic. However, until further examples of aggregates containing three or more Cr(III) centres linked by hydroxo bridges are available it is not possible to propose any definitive rules for a magnetostructural correlation.

5. Supplementary material

Crystallographic data (excluding structure factors) for the structures in this paper have been deposited with the Cambridge Crystallographic Data Centre as supplementary publication nos. CCDC 273330–273333. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK: http://www.ccdc.cam.ac.uk/perl/catreq/catreq.cgi, e-mail: data_request@ccdc.cam.ac.uk, or fax: +44 1223 336 033.

Dedicated to Malcolm Chisholm, one of the giants in inorganic chemistry, on the occasion of his 60th birthday.

Abstract

The use of di-2-pyridyl ketone ($(py)_2CO$)/SCN^- "blend" in erbium(III) chemistry has yielded mononuclear and dinuclear complexes. The Er^{III}/SCN^-/$(py)_2CO$ reaction mixture in alcohols (MeOH, EtOH) gives complexes $[Er(NCS)_3\{(py)_2C(OR)(OH)\}_3]$ (R = Me (**1**), Et (**2**)), where $(py)_2C(OR)(OH)$ is the neutral hemiacetal derivative of $(py)_2CO$. Incorporation of hydroxides in the methanolic reaction system leads to the isolation of $[Er_2(NCS)_3\{(py)_2C(OMe)O\}_3(MeOH)]$ (**3**). Complex **3** can also be isolated by the reaction of **1** with three equivalents of NMe_4OH in MeOH. The crystal structures of $\mathbf{2}\cdot 0.3EtOH\cdot 0.4H_2O$ and $\mathbf{3}\cdot MeOH$ have been solved by single-crystal X-ray crystallography. The Er^{III} atom in the former is in a nine-coordinate, tricapped trigonal prismatic ligand environment. The $(py)_2C(OEt)(OH)$ molecules adopt the novel N(2-pyridyl), O(hydroxyl)-bidentate chelating mode, while three isothiocyanate ligands complete the coordination sphere of Er^{III}. In complex $\mathbf{3}\cdot MeOH$ the two Er^{III} atoms are triply bridged by the deprotonated hydroxyl oxygen atoms of the $\eta^1{:}\eta^2{:}\eta^1{:}\mu_2(py)_2C(OMe)O^-$ ligands; three 2-pyridyl nitrogen atoms belonging to three different ligands and two isothiocyanate anions complete eight-coordination at one Er^{III} atom, while eight-coordination at the other Er^{III} atom is completed by three 2-pyridyl nitrogen atoms, one isothiocyanate ligand and one MeOH molecule. The coordination polyhedra of the eight donor atoms about both Er^{III} atoms are best described as distorted dodecahedra. The complexes were studied by room-temperature effective magnetic moments and spectroscopic (IR, solid-state f–f) methods. All data are discussed in terms of the nature of bonding and known (**2**, **3**) or assigned (**1**) structures.

1. Introduction

Lanthanide elements (Ln), bearing special electronic and spectroscopic properties mainly associated with their 4f electronic configuration, represent a unique series of metals in the periodic table [1]. The paramagnetic and optical properties of trivalent lanthanides, their hard acid character and their high coordination numbers make lanthanide(III) complexes attractive for applications such as magnetic resonance imaging (MRI) contrast agents [2], mild reagents and catalysts in organic synthesis [3], molecular magnetic materials [4], in luminescence studies [1] and in solvent extraction of actinides(III) [5]. For example, due to the impressive luminescence characteristics of several Ln^{3+} ions, they

doi:10.1016/j.poly.2005.07.029

are increasingly used as highly efficient electroluminescent components for light emitting diodes [6], luminescence probes for analytes [7], labels for proteins and amino acids [8], and for molecular recognition and chirality sensing of biological substrates [9]. Moreover, by incorporating Ln^{3+} ions into liquid crystals, it is possible to obtain mesogenic complexes that are useful for the design of emissive liquid crystal displays and magnetically addressable liquid crystals [10]. Consequently, lanthanide coordination chemistry has been thoroughly investigated over the last twenty years [11–20], and the position of Ln(III) complexes, primarily mononuclear ones, in various technologically and medically important areas, has now been firmly established.

Despite the great progress in the synthesis and physical (mainly magnetic) properties of polynuclear complexes (clusters) of the d-block metals at intermediate oxidation states [21–25], the number of Ln(III) clusters is still rather limited [26–34]. Dinuclear and polynuclear Ln(III) complexes exhibit a fascinating variety of unusual symmetries and structural patterns, and are expected to find such important applications as precursors for metalloorganic chemical vapour deposition (MOCVD) [35] and sol–gel technology [36], synthetic nucleases [37], new biomedical imaging contrast agents [38] and single-molecule magnets [39], the last potential application being currently confined to 3d-4f mixed-metal clusters.

Almost all clusters are made from complex reaction mixtures, which provide metal ions, ligand or ligands, solvent molecules, counter-ions and, perhaps, traces of absorbed oxygen. Each component may influence the final product. Other variables include the pH and ionic strength of the solution, and the temperature of the reaction. One route to polynuclear complexes – a route perhaps best termed "designed assembly" – controls the reaction pathway by making a specific metal–ligand interaction the most significant in the system [40]. This approach finds limited application in Ln(III) chemistry. A complementary approach is "serendipitous assembly" [41], where the variables in the complex system are modified following certain rationales to influence the product found, rather than to control or design the target molecule [42].

The future of the field of 4f-metal clusters and the chances of identifying new complexes with interesting properties will both benefit from the development of new reaction systems with suitable organic ligands. Our group [43–49] and others [50–52] have been exploring reaction systems involving (i) the monoanion $(py)_2C(OH)O^-$, or the dianion, $(py)_2CO_2^{2-}$, of the *gem*-diol form (derivative), $(py)_2C(OH)_2$, of di-2-pyridyl ketone, $(py)_2CO$, or (ii) the monoanion, $(py)_2C(OR)O^-$ (R = Me, Et, etc.), of the hemiacetal form (derivative), $(py)_2C(OR)(OH)$, of di-2-pyridyl ketone in Mn, Fe, Co, Ni, Cu, Zn, and Cd chemistries. The formulae of these ligands and their abbreviations are shown in Fig. 1. The reactions of $(py)_2CO$ with 3d-metal ions have been well-studied over the last ten years or so [43]. There

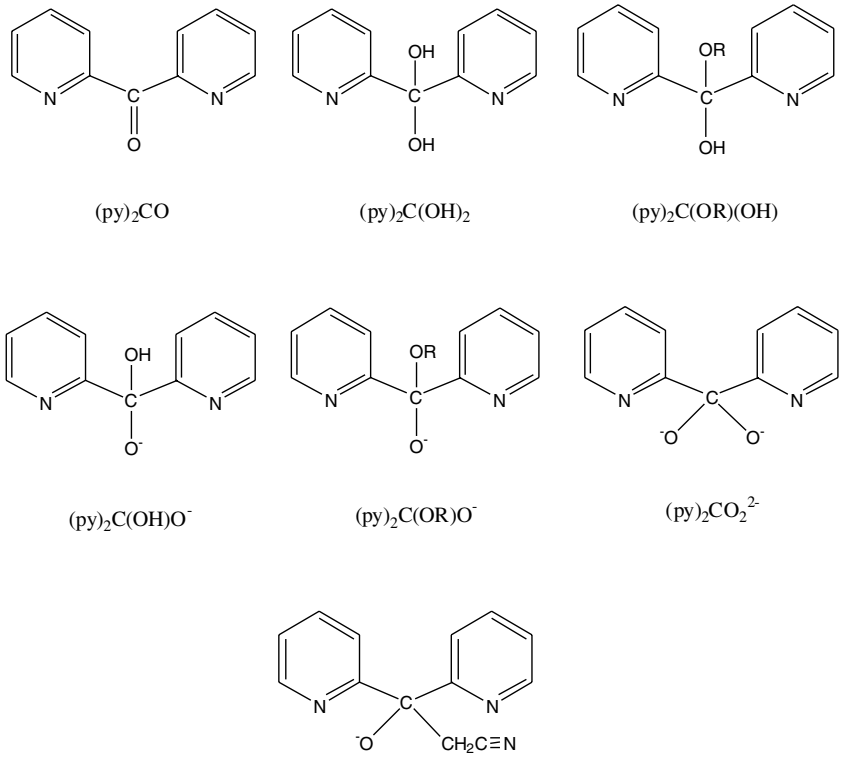

Fig. 1. The derivatives of di-2-pyridyl ketone, $(py)_2CO$, discussed in the text; note that $(py)_2C(OH)_2$, $(py)_2C(OR)(OH)$ and all four anions do not exist as free species – they exist only as ligands in their metal complexes.

is a chemical characteristic of $(py)_2CO$ that makes this molecule special as ligand; this is its carbonyl group. Water and alcohols (ROH) have been shown to add to the carbonyl group *upon coordination of the 2-pyridyl rings* forming the ligands $(py)_2C(OH)_2$ (the *gem*-diol form of $(py)_2CO$) and $(py)_2C(OR)(OH)$ (the hemiacetal form of $(py)_2CO$), respectively (Fig. 1). Recently [53] it has also been reported that the ligand $(py)_2C(OH)(CH_2CN)^-$, see Fig. 1, can be generated in situ during the preparation of a heterometallic $Ni_{12}K_4$ cluster by the reaction of CH_3CN and $(py)_2CO$ at room temperature under aerobic conditions. The neutral ligands coordinate to the metal ion as tridentate *N,N,O* chelates, with the M–O bond often being weak; therefore, both neutral ligands do not present interest from the cluster formation viewpoint [43]. Completely different and much more interesting (for cluster chemistry) coordination modes are seen when the ligands $(py)_2C(OH)_2$ and $(py)_2C(OR)(OH)$ are deprotonated. Upon deprotonation, the latter becomes monoanionic, whereas the former can function either as mono- or dianionic. The presence of deprotonated hydroxyl group(s) leads to a great coordinative flexibility, due to the well known ability of the negatively charged oxygen to bridge two or three 3d-metal ions. The immense structural diversity displayed by the complexes reported stems in part from the ability of $(py)_2C(OH)O^-$, $(py)_2CO_2^{2-}$ and $(py)_2C(OR)O^-$ to exhibit no less than nine distinct bridging coordination modes ranging from μ_2 to μ_5 [43]. Employment of carboxylates, β-diketonates or organic oxo anions (NO_3^-, SO_4^{2-}, etc.) as ancillary ligands in the reaction mixtures gives an extraordinary structural flexibility in the mixed-ligand systems, allowing the isolation of a variety of 3d-metal clusters with nuclearities ranging from 3 to 14 [43] and with interesting physical properties including single-molecule magnetism [46].

Surprisingly, however, $(py)_2CO$-based ligands have been completely ignored in Ln(III) chemistry. Here, we report some experiments that lead to the first members of the new and diverse family of Ln(III) complexes with $(py)_2CO$-based ligands.

2. Experimental

2.1. General and physical measurements

All manipulations were performed under aerobic conditions using materials (reagent grade) and solvents as received. For the preparation of the complexes, a methanolic solution of "$Er(NCS)_3$" (solution A) was prepared as follows: A solution (10 ml) of KSCN (6.0 mmol) in MeOH was treated with $ErCl_3 \cdot 6H_2O$ (2.0 mmol). The solid erbium(III) chloride soon dissolved, the mixture was stirred for 30 min and the white crystals of KCl were removed by filtration. The resulting filtrate (~11 ml) has a known concentration of "$Er(NCS)_3$". An ethanolic solution (~25 ml) of "$Er(NCS)_3$" (solution B) was prepared by an analogous manner using a solution (23 ml) of KSCN (6.0 mmol) in warm EtOH and $ErCl_3 \cdot 6H_2O$ (2.0 mmol). Solutions A and B contain less than 10% of the original Cl^- ions (in the form of KCl) as deduced by the potentiometric determination of chlorides. It seems that the chloride concentration in solutions A and B does not affect the reactions.

Microanalyses (C, H, N) were performed by the University of Ioannina (Greece) Microanalytical Laboratory using an EA 1108 Carlo Erba analyser. The metal content was determined volumetrically with ethylenediaminetetra-acetate using xylenol orange as indicator. IR spectra (4000–450 cm^{-1}) were recorded on a Perkin–Elmer 16 PC FT spectrometer with samples prepared as KBr pellets. Magnetic susceptibilities were measured at room temperature using the Faraday method with a Cahn-Ventron RM-2 balance standardized with $HgCo(NCS)_4$; diamagnetic corrections were estimated from Pascal's constants. Solid-state (diffuse reflectance) spectra in the 200–800 nm range were recorded on a Varian Cary 3 spectrometer equipped with an integration sphere.

2.2. Compound preparation

2.2.1. $[Er(NCS)_3\{(py)_2C(OMe)(OH)_3\}]$ (**1**)

To a pale pink solution A (1.1 ml, 0.2 mmol "$Er(NCS)_3$") was slowly added a solution of $(py)_2CO$ (0.074 g, 0.40 mmol) in MeOH (8 ml). The resulting almost colourless solution was kept under stirring at room temperature for about 5 min, and then layered with Et_2O (15 ml). Slow mixing gave a pink polycrystalline solid, which was collected by filtration, washed with ice-cold MeOH (1 ml) and Et_2O (2 × 5 ml), and dried in vacuo over silica gel. Yield: 62% (based on the ligand). *Anal.* Calc. for $C_{39}H_{36}ErN_9O_6S_3$: C, 47.30; H, 3.67; N, 12.73; Er, 16.89. Found: C, 47.45; H, 3.50; N, 12.81; Er, 17.44%. 2.2.2. $[Er(NCS)_3\{(py)_2C(OEt)(OH)\}_3] \cdot 0.3EtOH \cdot 0.4H_2O$ (**2** $\cdot 0.3EtOH \cdot 0.4H_2O$)

To a pale pink solution B (2.5 ml, 0.2 mmol "$Er(NCS)_3$") was slowly added a solution of $(py)_2CO$ (0.074 g, 0.40 mmol) in EtOH (7 ml). The resulting

homogeneous, almost colourless solution was allowed to stand undisturbed for one day at 5 °C, during which time X-ray quality pink crystals of the product were precipitated. The crystals were collected by filtration, washed with ice-cold EtOH (2 × 1 ml) and Et_2O (2 × 5 ml), and dried in vacuo over silica gel. Yield: 49% (based on the ligand). A sample for crystallography was covered with epoxy glou to prevent collapse. The vacuum-dried sample analysed as unsolvated. *Anal.* Calc. for $C_{42}H_{42}ErN_9O_6S_3$: C, 48.86; H, 4.11; N, 12.21; Er, 16.20. Found: C, 48.67; H, 4.20; N, 12.07; Er, 16.99%. IR (KBr, cm^{-1}): 3446 (mb), 3058 (w), 3045 (w), 2976 (w), 2930 (w), 2894 (w), 2062 (s), 1598 (s), 1572 (sh), 1468 (w), 1438 (m), 1336 (w), 1268 (w), 1236 (s), 1156 (w), 1118 (m), 1065 (sh), 1050 (s), 1018(m), 962 (w), 886 (w), 806 (w), 762 (s), 670 (sh), 642 (m), 628 (m), 572 (m), 532 (w), 486 (w), 464 (w). μ_{eff} (BM): 9.51 (20 °C). DRS (nm): 262, 365, 374 (sh), 380, 405, 448, 451, 489, 523, 529 (sh), 543, 553 (sh), 653, 659.

2.2.3. $[Er_2(NCS)_3\{(py)_2C(OMe)O\}_3(MeOH)] \cdot MeOH$ (**3** · MeOH)

2.2.3.1. Method A. Solids $(py)_2CO$ (0.037 g, 0.20 mmol), $LiOH \cdot H_2O$ (0.0084 g, 0.20 mmol) and $LiClO_4 \cdot 3H_2O$ (0.064 g, 0.40 mmol) were dissolved in MeOH (15 ml), resulting in a colourless solution. This was added to a pale pink solution A (1.1 ml, 0.2 mmol). The resulting new pinkish solution was stirred for about 1 h and filtered to remove a very small quantity of insoluble material. The filtrate was allowed to stand undisturbed for 4 days during which time the product slowly crystallized. The pink crystals were collected by filtration, washed with cold MeOH (1 ml) and Et_2O (2 × 5 ml), and dried in vacuo. Yield: 79% (based on the ligand). A sample for crystallography was kept in contact with the mother liquor to prevent interstitial MeOH loss. The air-dried sample analysed as unsolvated. *Anal.* Calc. for $C_{40}H_{37}Er_2N_9O_7S_3$: C, 40.49; H, 3.15; N, 10.63; Er, 28.19. Found: C, 40.61; H, 3.20; N, 10.99; Er, 27.71%. IR (KBr, cm^{-1}): 3430 (mb), 3072 (w), 2962 (w), 2930 (w), 2066 (s), 1600 (s), 1570 (m), 1472 (m), 1436 (s), 1340 (w), 1294 (m), 1258 (s), 1230 (s), 1124 (s), 1108 (sh), 1054 (s), 1038 (sh), 1010 (m), 984 (m), 968 (sh), 952 (sh), 778 (s), 752 (sh), 686 (s), 634 (s), 576 (w), 534 (w), 492 (w), 456 (m). μ_{eff} (BM): 9.54 (21 °C). DRS (nm): 269, 366, 379, 408, 442, 451, 488, 522, 525 (sh), 533 (sh), 543, 655, 670 (sh).

2.2.3.2. Method B. Treatment of a slurry of complex **1** (0.099 g, 0.10 mmol) in MeOH (20 ml) with NMe_4OH (0.054 g, 0.30 mmol) resulted in a pink solution. The solution was heated at 40 °C for 5 min, during which time no noticeable colour change was observed. The solution was filtered through celite and allowed to slowly evaporate at room temperature. The resulting microcrystalline solid was collected by filtration, washed with Et_2O (2 × 3 ml), and dried in vacuo over silica gel. Yield 30% (based on **1**). The dried solid analysed satisfactorily as **3**. The identity of the product was further confirmed by IR spectroscopic comparison with the authentic sample prepared by Method A.

2.3. Single-crystal X-ray crystallography

Crystals of **2** · 0.3EtOH · $0.4H_2O$ and **3** · MeOH were mounted in air and covered with epoxy glou, and in capillary, respectively. Diffraction measurements were made on a Crystal Logic Dual Goniometer diffractometer using graphite-monochromated Mo radiation. Complete crystal data and parameters for data collection and processing are reported in Table 1. Unit cell dimensions were determined and refined by using the angular settings of 25 automatically centered reflections in the range $11 < 2\vartheta < 23°$. Three standard reflections monitored every 97 reflections showed less than 3% variation and no decay. Lorentz, polarization and Ψ-scan absorption corrections were applied using Crystal Logic software.

[a] $R_1 = \sum(|F_o| - |F_c|)/\sum(|F_o|)$.
[b] $wR_2 = \{\sum[w(F_o^2 - F_c^2)^2]/\sum[w(F_o^2)^2]\}^{1/2}$.

The structures were solved by direct methods using SHELXS-86 [54] and refined by full-matrix least squares techniques on F^2 with SHELXL-97 [55]. For both structures, all hydrogen atoms were introduced at calculated positions as riding on bonded atoms. For **3** · MeOH, all non-hydrogen atoms were refined using anisotropic thermal parameters. For **2** · 0.3EtOH · 0.4H_2O, all non-hydrogen atoms – except those of the solvate molecules – were refined anisotropically.

3. Results and discussion

3.1. Synthetic comments

The chemical and structural identities of the products from the "Er(NCS)$_3$"/(py)$_2$CO reaction system in alcohols depend on the OH^- concentration. The mononuclear complexes **1** and **2** were isolated from the direct reaction between "Er(NCS)$_3$" and (py)$_2$CO, whereas employment of hydroxides leads to the dinuclear complex **3**. The formation of these Er(III) complexes can be summarized in balanced Eqs. (1) and (2).

$$\text{“Er(NCS)}_3\text{”} + 3(\text{py})_2\text{CO} + 3\text{ROH} \xrightarrow[\text{R=Me,Et}]{\text{ROH}} [\text{Er(NCS)}_3\{(\text{py})_2\underset{\mathbf{1,2}}{\text{C(OR)(OH)}}\}_3] \quad (1)$$

$$2\text{“Er(NCS)}_3\text{”} + 3(\text{py})_2\text{CO} + 3\text{LiOH} \cdot \text{H}_2\text{O} + 4\text{MeOH} \xrightarrow{\text{MeOH}} [\text{Er}_2(\text{NCS})_3\{(\text{py})_2\underset{\mathbf{3}}{\text{C(OMe)O}}\}_3(\text{MeOH})] + 3\text{LiNCS} + 6\text{H}_2\text{O} \quad (2)$$

The Er(III)-mediated addition of solvent (MeOH, EtOH) to (py)$_2$CO to give the neutral hemiacetal derivative of di-2-pyridyl ketone, (py)$_2$C(OR)(OH) (Fig. 1), in **1** and **2**, and the monoanion of this derivative, (py)$_2$C(OR)O^- (Fig. 1), in **3** involves a nucleophilic attack of the ROH molecule on the carbonyl group [43]. The electrophilic character of the carbonyl group of (py)$_2$CO is increased by coordination of the carbonyl oxygen to the metal ion (direct polarization) and/or coordination of the more remote 2-pyridyl sites (induced polarization) [43].

Two features of the reactions represented by Eqs. (1) and (2) deserve comments. First, the "wrong" stoichiometries employed for the preparation of **1**–**3** (see Section 2.2), compared to those required by Eqs. (1) and (2), obviously did not prove detrimental to the formation of the complexes. With the identities of **1**–**3** established, the "correct" stoichiometries, i.e., Er(III): (py)$_2$CO = 1:3, were employed and led to pure compounds in high yields. Second, the presence of $LiClO_4 \cdot 3H_2O$ in the reaction mixture that leads to **3** might imply that cationic complexes are capable of existing; we did *not* have such an evidence during our synthetic efforts. $LiClO_4 \cdot 3H_2O$ is beneficial only for the isolation of single crystals of **3**; in other words, its presence does not affect the identity of the product, but only its crystallization, most probably through the alteration of the ionic strength of the reaction solution. We have not performed experiments to see how different ratios of $LiClO_4$ affect the yield of **3**. If no $LiClO_4$ is added, the same product is isolated (elemental analyses and IR confirmation) in ~70% yield, but in the form of microcrystalline powder.

The fact that complexes **1** and **3** contain basically the same ligand set (the only difference being in the protonation state of the ligand), led us to suspect that **1** would be transformed to **3**; this has, indeed, turned out to be the case. This Brönsted acidity of **1** is summarized in Eq. (3).

$$2[\text{Er(NCS)}_3\{\underset{\mathbf{1}}{(\text{py})_2\text{C(OMe)(OH)}}\}_3] + 6\text{NMe}_4\text{OH} + \text{MeOH} \xrightarrow{\text{MeOH}} [\text{Er}_2(\text{NCS})_3\{\underset{\mathbf{3}}{(\text{py})_2\text{C(OMe)O}}\}_3(\text{MeOH})] + 3\text{NMe}_4\text{SCN} + 3\text{NMe}_4\{(\text{py})_2\text{C(OMe)O}\} + 6\text{H}_2\text{O} \quad (3)$$

3.2. Description of structures

Partially labelled plots of the mononuclear and dinuclear molecules present in complexes **2** · 0.3EtOH · 0.4H_2O and **3** · MeOH are shown in Figs. 2 and 4, respectively. The coordination polyhedra of the Er^{III} atoms are shown in Figs. 3 and 5. Selected interatomic distances and angles are listed in Tables 2 and 3.

The crystal structure of **2** · 0.3EtOH · 0.4H_2O consists of discrete [Er(NCS)$_3${(py)$_2$C(OEt)(OH)}$_3$] molecules and solvate molecules; the latter will not be further discussed.

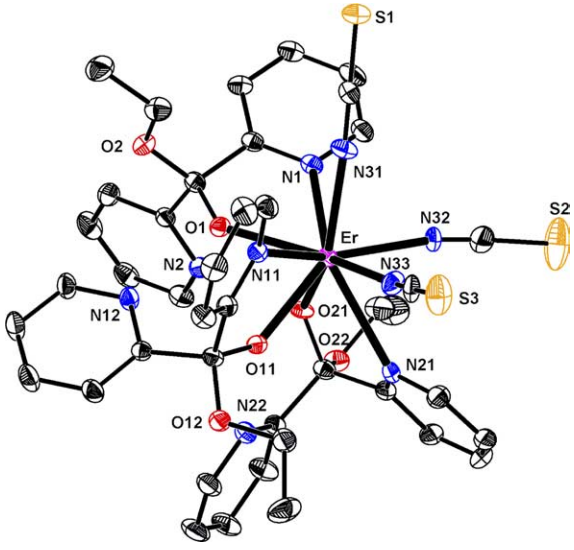

Fig. 2. The structure of the mononuclear complex molecule present in complex **2** · 0.3EtOH · 0.4H_2O.

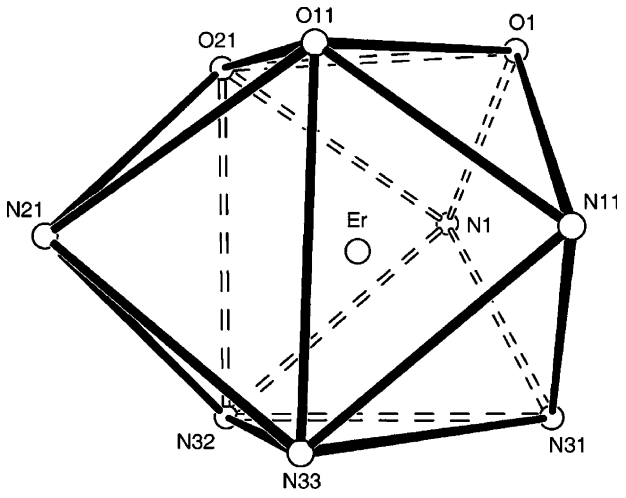

Fig. 3. A view of the inner coordination polyhedron of **2** · 0.3EtOH · $0.4H_2O$ showing the tricapped trigonal prismatic coordination of the Er^{III} atom.

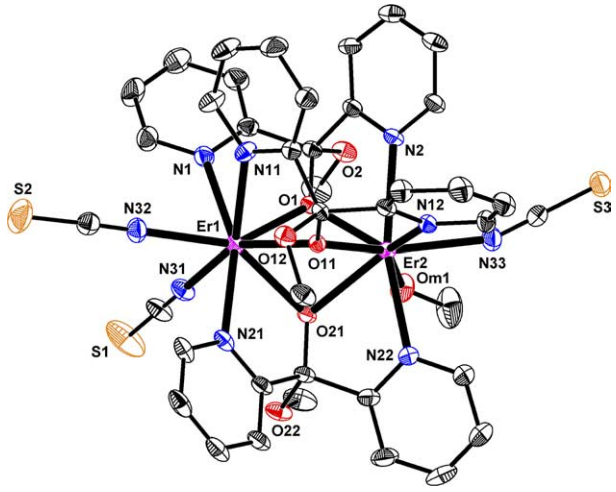

Fig. 4. The structure of the dinuclear molecule present in complex **3** · MeOH.

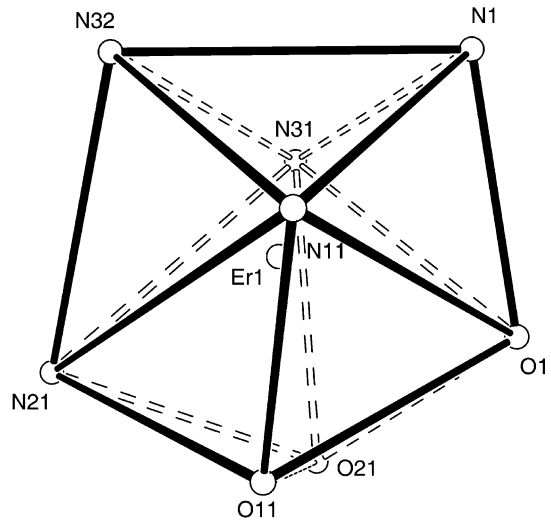

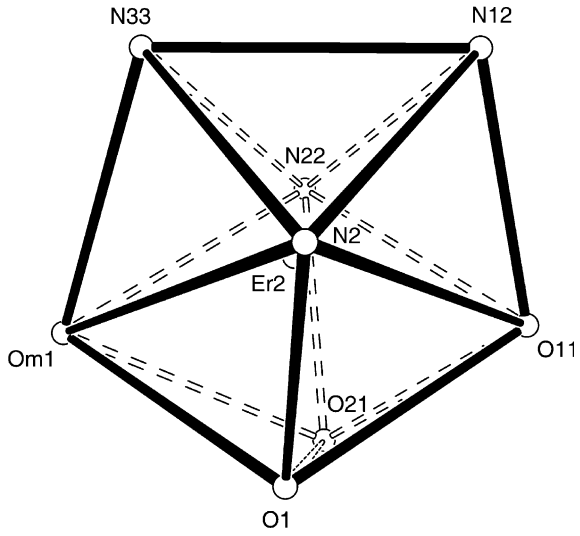

Fig. 5. The dodecahedral stereochemistry about the Er^{III} atoms in complex **3** · MeOH.

The Er^{III} atom is in a nine-coordinate ligand environment comprising three hydroxyl oxygen atoms and three 2-pyridyl nitrogen atoms from the three $(py)_2C(OEt)(OH)$ ligands, and the three nitrogen atoms from the isothiocyanate anions. The Er–N bond lengths fall into two distinct categories; those involving the organic ligands (2.707(10)–2.755(11) Å) and those involving the isothiocyanate ligands (2.356(11)–2.376(11) Å). The Er–N(isothiocyanate) distances have an average value of 2.364(11) Å which is slightly longer, as expected, than that of an eight-coordinated Er(III) complex containing terminal isothiocyanate ligands (2.327(6) Å) [56]. The SCN^- ions are not perfectly linear, the N–C–S bond angles being in the range 175.9(18)–179.0(12)°. The terminal isothiocyanate anions involving N(31) and N(33) as donor atoms are coordinated in a slightly bent fashion, as indicated by the Er–NC angles (160.7(11)°, 161.5(11)°); the third SCN^-ion is coordinated in a more linear fashion (Er–N(32)–C(62) = 170.5(14)°). No hydrogen bonds are involved in the crystal lattice.

The coordination polyhedron of the Er^{III} atom is best described as a distorted tricapped trigonal prism with the three 2-pyridyl nitrogen donor atoms, N(1), N(11) and N(21), forming the three rectangular face caps. The angle sum subtended by the three capping atoms at Er is 358.3°.

The $(py)_2C(OEt)(OH)$ molecules behave as $\eta^1{:}\eta^1$ ligands in **2**, see Fig. 6. The ethoxy oxygen atom remains unbound to the Er^{III} atom. The ligand forms one five-membered ErNCCO chelating ring. Ligands based on the *gem*-diol or the hemiacetal forms of di-2-pyridyl ketone have been observed in numerous ligation modes over the years [43], but the particular bidentate chelating coordination mode (Fig. 6) observed for $(py)_2C(OEt)$-

(OH) in **2** is unprecedented. In all the up-to-now structurally characterized d-metal complexes containing O-bound $(py)_2C(OR)(OH)$ ligands (R = Me, Et), the alkylated oxygen is the ligated atom [43,57,58].

Complex $3 \cdot MeOH$ crystallizes in monoclinic space group $P\bar{1}$. Its structure consists of dinuclear $[Er_2(NCS)_3\{(py)_2C(OMe)O\}_3(MeOH)]$ molecules and solvate MeOH molecules; the latter will not be further discussed. In the dinuclear molecule, the monoanionic hemiacetal form of the organic ligand bridges the metal centers through the deprotonated hydroxyl group and the –OMe group points away from the metals. The two Er^{III} atoms are triply bridged by the deprotonated hydroxyl oxygen atoms (O(1), O(11), O(21)) of the $(py)_2C(OMe)O^-$ ligands. Three 2-pyridyl nitrogen atoms (N(1), N(11), N(21)) and two isothiocyanate ligands complete eight-coordination at Er(1), while eight-coordination at Er(2)

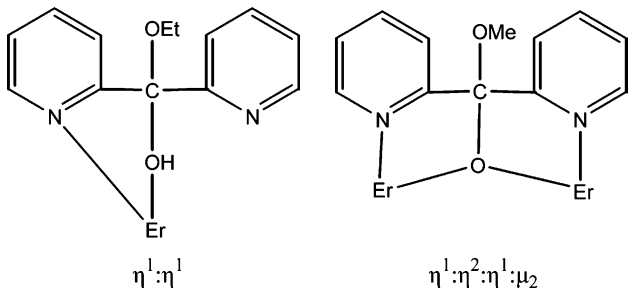

Fig. 6. The crystallographically established coordination modes of $(py)_2C(OEt)(OH)$ and $(py)_2C(OMe)O^-$ in complexes $\mathbf{2}\cdot 0.3EtOH\cdot 0.4H_2O$ and $\mathbf{3}\cdot MeOH$, respectively.

is completed by three 2-pyridyl nitrogen atoms (N(2), N(12), N(22)), one isothiocyanate ligand and one methanol molecule.

The Er–O distances are in the relatively narrow range 2.231(4)–2.380(5) Å; this range is typical for eight-coordinate Er(III) complexes [59–61]. The Er–N bond lengths again fall into two distinct categories; those involving the organic ligands (2.472(5)–2.589(6) Å) and those involving the isothiocyanate ligands (2.346(6)–2.367(6) Å). The Er–N(2-pyridyl) distances in $\mathbf{3}\cdot MeOH$ have an average value of 2.525(6) Å, which is shorter than the corresponding value in $\mathbf{2}\cdot 0.3EtOH\cdot 0.4H_2O$ (2.726(11) Å); the decreased Er–N(2-pyridyl) distances in the former are a consequence of the lower coordination number of the Er^{III} atoms compared to that in the latter (eight versus nine). However, an analogous trend does not hold true for the Er–N(isothiocyanate) distances. These bond distances have similar average values in $\mathbf{2}\cdot 0.3EtOH\cdot 0.4H_2O$ (2.364(11) Å) and $\mathbf{3}\cdot MeOH$ (2.359(6) Å). This discrepancy emphasizes the fact that in lanthanide complexes, where the bonding is regarded as being substantially ionic, the coordination number is determined by packing considerations, this in turn determining the bond lengths between the central metal ion and the atoms surrounding it [62]. The bridging Er–O distances involving O(11) are asymmetric (Er(1)–O(11) = 2.331(4) Å, Er(2)–O(11) = 2.231(4) Å). The terminal isothiocyanate ligands bind to Er(1) in an almost linear fashion, as indicated by the Er–N≡C angles (175.6(6)°, 177.5(6)°); the third isothiocyanate ligand binds to Er(2) in a slightly bent fashion (Er(2)–N(33)–C(63) = 159.5(6)°). The Er(1)···Er(2) distance is 3.380(2) Å.

The coordination polyhedra of the eight donor atoms about the Er^{III} atoms are best described as distorted dodecahedra [63], see Fig. 5. For example, if we consider the polyhedron of Er(2), atoms N(33), N(12), O(1), O(21) constitute a distorted tetrahedron that has been elongated along the fourfold inversion axis of the idealized polyhedron, whereas the set of atoms N(2), N(22), O(11), Om(1) form a distorted tetrahedron that has been squashed along the same axis. An alternative way of viewing the dodecahedron about Er(2) is to consider it [63] as two interpenetrating planar trapezoids N(12)N(33)O(11)Om(1) and N(2)N(22)O(1)O(21).

The $(py)_2C(OMe)O^-$ anions behave as $\eta^1{:}\eta^2{:}\eta^1{:}\mu_2$ ligands in **3**, see Fig. 6. The methoxy oxygen atom remains unbound to the metals. The monoanionic ligand forms two five-membered ErNCCO chelating rings with two different Er^{III} atoms; these rings share a common C–O edge. This ligation mode is common in the coordination chemistry of the hemiacetal forms of di-2-pyridyl ketone [43,44].

No hydrogen bonds are involved in the crystal structure of $\mathbf{3}\cdot MeOH$. The crystal structure is stabilized by two intermolecular π–π stacking interactions. The first involves the two 2-pyridyl rings that involve N(21) and is shown in Fig. 7; the centroid···centroid distance is 3.505 Å (the symmetry code is $-x$, $-y$, $-z+1$). The two rings are strictly parallel due to the presence of a crystallographically imposed inversion center at $c/2$. The second type of the π–π stacking interactions involves the two 2-pyridyl rings that involve N(2) and are in the symmetry relationship x, y, z and $-x+1$, $-y+1$, $-z$; the centroid···centroid distance is 3.653 Å. There also appears to be a weak intramolecular stacking interaction between the two 2-pyridyl rings involving N(2) and N(11), the centroid···centroid distance being 3.934 Å.

3.3. Magnetic moments, electronic and IR spectra

The experimental, room-temperature μ_{eff} values per Er^{III} for complexes **1**–**3** (see Section 2.2) show very little deviation from the theoretical value of 9.6 BM predicted by Eq. (4), suggesting that the 4f electrons in the com-

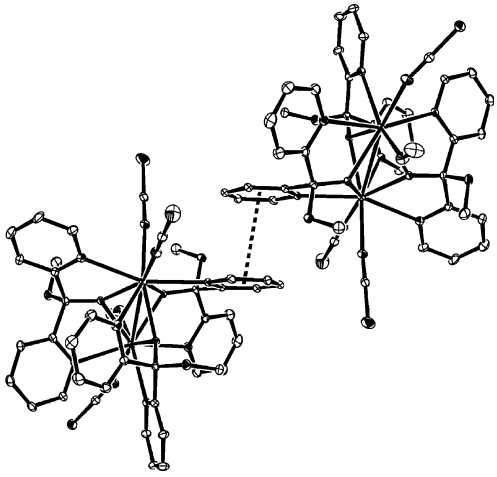

Fig. 7. A view of the intermolecular π–π stacking interaction between the parallel 2-pyridyl rings that involve N(21) in complex $\mathbf{3}\cdot MeOH$. The symmetry codes of the two rings are x, y, z and $-x$, $-y$, $-z+1$. Only two neighbouring dinuclear molecules have been drawn; the centroid···centroid distance is 3.505 Å.

plexed Er^{III} atoms are well-shielded by the outermost 5s and 5p electrons [64]

$$\mu_{eff} = g[J(J+1)]^{1/2}. \quad (4)$$

The solid-state (diffuse reflectance) electronic spectra of the prepared complexes involve mainly intraligand and f–f transitions. Detailed assignments of the main f–f-bands for complex **2** (considered as a representative example) are given in Table 4. The values of the bonding parameters $\bar{\beta}$ (nephelauxetic ratio), δ (Sinha's parameter) and $b^{1/2}$ (covalent factor), calculated [65–67] from the solid-state f–f spectra by Eqs. (5)–(7), are listed in Table 5. The values indicate that the interaction between Er^{III} and the ligands is essentially electrostatic and that there is a minor participation of the 4f orbitals in bonding [65–67]

$$\bar{\beta} = \frac{1}{2}\sum_{n=1}^{n}\frac{\bar{V}_{complex}}{\bar{V}_{aquo}}, \quad (5)$$

$$\delta\ (\%) = \frac{1-\bar{\beta}}{\bar{\beta}} \times 100, \quad (6)$$

$$b^{1/2} = \left[\frac{1}{2}(1-\bar{\beta})\right]^{1/2}. \quad (7)$$

The shape and fine structure of the f–f band assigned to the "hypersensitive" transition $^4I_{15/2} \rightarrow {}^2H_{11/2}$ (Er–I) are sensitive to coordination number [68]. By comparing the spectra of **1**–**3** with the spectra of Er(III) complexes of known structures [59,68,69] in the region of the above-mentioned transition, it is confirmed (complex **2**) or concluded (complex **1**) that the metal ion is nine-coordinate; similarly, this comparison confirms that the Er^{III} atoms in **3** are eight-coordinate (the bands/shoulders due to this transition appear at 522, 525 and 533 in the spectrum of **3**).

The IR spectra of **1** and vacuum-dried (solvent free) **2** exhibit a medium intensity band at 3420 (**1**) and 3446 (**2**) cm^{-1}, assignable to ν(OH) vibration of the $(py)_2C(OR)(OH)$ ligands [57]. The presence of coordinated MeOH in vacuum-dried **3** is manifested by the medium intensity band at 3430 cm^{-1} assigned to ν(OH) [70]. The spectra of the three complexes do not exhibit bands in the region expected for ν(C=O) vibration (1684 cm^{-1} for free $(py)_2CO$) with the nearest IR absorptions at 1598 (**1**, **2**) and 1600 (**3**) cm^{-1} assigned as a 2-pyridyl stretching mode raised from 1582 cm^{-1} on coordination, as observed earlier on complex formation involving alcoholysis or hydration of $(py)_2CO$ [44,71]. The bands at ~1050, ~770 and ~640 cm^{-1} can be assigned [58] to pyridyl ring breathing, pyridyl C–H out-of-plane bending and in-plane pyridyl ring deformation vibrations, respectively. The IR spectra of **1**–**3** exhibit the ν(CN) mode of the SCN^- ligands at ~2065 cm^{-1}; this wavenumber is typical of terminal isothiocyanate groups [72,73]. The expected ν(CS) and δ(NCS) bands could not be located and unambiguously assigned because they are obscured by $(py)_2C(OR)(OH)/(py)_2C(OMe)O^-$ absorptions.

Table 4
Main, solid-state f–f bands of the representative complex **2**

λ (nm)	Assignment
659, 653	$^4I_{15/2} \rightarrow {}^4F_{9/2}$
543	$^4I_{15/2} \rightarrow {}^4S_{3/2}$
529 (sh), 523	$^4I_{15/2} \rightarrow {}^2H_{11/2}$ (Er–I)[a]
489	$^4I_{15/2} \rightarrow {}^4F_{7/2}$
380, 374 (sh)	$^4I_{15/2} \rightarrow {}^4G_{11/2}$ (Er–II)[a]

[a] These transitions are "hypersensitive".

Table 5
Bonding parameters[a,b] for the Er(III) complexes **1**–**3**

Complex	$\bar{\beta}$	δ (%)	$b^{1/2}$
1	0.996	+0.40	0.045
2	0.995	+0.50	0.050
3	0.994	+0.60	0.055

[a] Calculated from solid-state f–f spectra taking into account the wavenumbers of the $^4I_{15/2} \rightarrow {}^4F_{9/2}$, $^4S_{3/2}$, $^2H_{11/2}$, $^4F_{7/2}$, $^4F_{5/2}$, $^4F_{3/2}$, (^2G, ^4F, $^2H)_{9/2}$ and $^4G_{11/2}$ transitions.

[b] For the definition of the bonding parameters $\bar{\beta}$, δ (%) and $b^{1/2}$, see text.

4. Conclusions and perspectives

Complexes $[Er(NCS)_3\{(py)_2C(OEt)(OH)\}_3]$ (**2**) and $[Er_2(NCS)_3\{(py)_2C(OMe)O\}_3(MeOH)]$ (**3**) cover a gap in the literature, because these are the first structurally characterized lanthanide(III) complexes with $(py)_2CO$-based ligands. Thus, the principal objective of our studies has been realized. Based on analytical and spectroscopic data, it seems that complex **1** has a similar molecular structure with that of **2**. It is also of interest that complex **2** (and presumably **1**) exhibits a novel coordination mode for the ligand $(py)_2C(OEt)(OH)$.

Although only mononuclear and dinuclear complexes have been discovered from our work, clearly the $Ln^{III}/(py)_2CO$ chemistry warrants further study and expansion to other solvents (e.g., H_2O, MeCN, DMF, etc.) that favour the formation of the *gem*-diol form of di-2-pyridyl ketone, $(py)_2C(OH)_2$ (Fig. 1). For example, the ability of this form to act as a dianionic ligand and to bridge 3, 4 or 5 metal ions [43] gives hopes for the isolation of high-nuclearity Ln(III) clusters. A ligand "blend" that might prove highly successful for this synthetic purpose is $(py)_2CO_2^{2-}/RCO_2^-$ [43]. The isothiocyanate terminal ligands present in **1**–**3** could have future utility as sites for facile incorporation of other monodentate ligands by metathesis, or as a means to access higher-nuclearity neutral or cationic clusters using bis(monodentate) and/or bis(bidentate) bridging

ligands, including aromatic heterocycles and dicarboxylates.

5. Supplementary data

Full crystallographic details have been deposited with the Cambridge Crystallographic Data Centre. Copies of the data can be obtained free of charge on request from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1233 336033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk) quoting the deposition numbers 274911 ($\mathbf{2}\cdot 0.3\mathrm{EtOH}\cdot 0.4\mathrm{H_2O}$) and 274912 ($\mathbf{3}\cdot \mathrm{MeOH}$).

Acknowledgements

K.A.T. and S.P.P. thank the Research Committee of the University of Patras (K. CARATHEODORY Program No. 3016) for financial support of this work. We also thank Prof. Kordoulis (Catalysis Laboratory, Department of Chemistry, University of Patras) for helpful discussions concerning the solid-state f–f spectra of the three Er(III) complexes.

Abstract

Two novel, thioether containing benzannulated enediyne ligands, 1,2-bis(3-(quinolin-8-ylsulfanyl)prop-1-ynyl)benzene (**1**), and 1,2-bis(3-(pyridin-2-ylmethylsulfanyl)prop-1-ynyl)benzene (**2**) have been synthesized and characterized along with their corresponding Cu(I), Ag(I), Cu(II), and Pd(II) metalloenediyne complexes (**3**–**10**). Single crystal X-ray structures of the d^{10} and d^8 N_2S_2 complexes show thioether coordination leading to distorted tetrahedral and *trans* square planar geometries about the metal centers, respectively. Based on their X-ray structures, all complexes are expected to exhibit high Bergman cyclization temperatures (>200 °C), and indeed this is the case for the Cu(I) and Ag(I) complexes (211–218 °C). In contrast, the corresponding divalent, tetragonal and *trans* square planar complexes of Cu(II) and Pd(II) exhibit more facile reactivity and lower solid state Bergman cyclization temperatures (186–190 °C) which more closely resemble values expected for *cis*-complexes. The unusual order in the thermal reactivities of these constructs can be attributed to a previously evaluated mechanism by which weak thioether coordination permits an elevated temperature *trans*-to-*cis* geometric rearrangement prior to Bergman cyclization.

1. Introduction

For over 30 years [1,2] the (*Z*)-hexa-3-ene-1,5-diyne unit has intrigued chemists due to the ability of this functionality to cyclize to form a highly reactive 1,4-benzenoid diradical intermediate [3]. The discovery of this reactive species within natural products isolated from microbial fermentation broths [4–8] reignited interest in systematically evaluating the geometric (e.g., alkyne termini separation, acyclic versus cyclic structures, H-bonding at the alkyne termini) and electronic contributions (e.g., benzannulation, electron donating/withdrawing groups at both *–ene–* and *–yne–* positions, through space electron lone-pair electron repulsion) to Bergman cyclization [3]. One fundamental and common goal of much of this work was to understand and gain control over the reactivity of the enediyne unit. To this end, photochemical cyclization strategies [9–12] have also been evaluated as a means to initiate cyclization in compounds with pronounced thermal stability such as benzannulated and aromatic acyclic enediyne constructs.

The principles derived from these geometric and electronic studies paved the way for the use of metal ions as reagents to activated enediynes toward Bergman cyclization [3,13]. The first key examples demonstrated that Bergman cyclization could be strongly influenced by metal ion coordination to a ligating enediyne framework. For example, binding of Hg^{2+} to a bipyridyl-enediyne conjugate forced the ligand into a planar conformation which labilized the enediyne toward cyclization [14,15].

In parallel, 1,2-bis(diphenylphosphinoethynyl)benzene was shown to cyclization spontaneously upon binding to divalent platinum or palladium [16]. In this case, later work on the same ligand showed that this effect was dependent upon the geometry of the metal center [17,18]; for chelating enediyne motifs, tetrahedral structures result in high cyclization temperatures relative to the much more facile reactivity of *cis* tetragonal or planar analogues [17,19,20]. The same guidelines also apply to a set of tetradentate enediyne ligands, but the effects of geometry on the cyclization temperature are not as pronounced [20–22]. Electronic effects, such as ancillary halogen lone pair donation [23,24], π-complexation at the alkyne carbons [25,26], as well as coordination of electron withdrawing, high valent metals near the alkyne termini (e.g., Mo^{IV}–S^{-} coordination), have also been shown to be capable of driving enediyne reactivity at ambient temperature [27]. The emerging theme from this body of work is that ligand design, and correspondingly, choice of metal ion activator, are critically important to the resulting Bergman cyclization kinetics and thermodynamics.

The conceptual developments highlighted above have fueled the syntheses of more diverse tetradentate chelating ligands containing mixed N,S coordination [28]. Structures containing coordinatively fluxional thiother ligands have not been previously examined and may yield unusual reactivity due to the weak thioether ligand. This work reports the syntheses of two benzannulated tetradentate thioether–imine (quinoline, pyridine) enediyne ligands and their corresponding Cu(I), Ag(I), Cu(II), and Pd(II) complexes. The thermal reactivities of these complexes are unusual and suggest an atypical reaction mechanism based on fluxional thioether coordination.

2. Experimental

2.1. General considerations

Compounds 1,2-bis-(3-bromopropynyl)benzene and pyridin-2-yl-methanethiol were prepared according to literature methods [29,30] All the metal salts (e.g., $Cu(MeCN)_4PF_6$, $Cu(BF_4)_2 \cdot XH_2O$, $AgPF_6$ and $Pd(MeCN)_4(BF_4)_2$) were purchased from Strem. Reactions were carried out under nitrogen using Schlenk line and drybox techniques. Hydrocarbon solvents such as diethyl ether and benzene were dried by distillation over sodium/benzophenone prior to use. Methylene chloride and *n*-butylamine were dried by distillation over calcium hydride. Organic enediynes were purified by flash chromatography using silica gel (200–440 mesh). All other chemicals and solvents were used as received from Aldrich, Strem, and Fluka.

^{1}H NMR and ^{13}C NMR spectra were recorded on a VXR 400 NMR spectrometer using the residual proton resonance of the solvent as an internal reference. Elemental analyses on all samples were obtained from Robertson Microlit Laboratories Inc., and mass spectra were measured at the Indiana University Mass Spectrometer Facility. Differential scanning calorimetry (DSC) traces were recorded on a V4.1 Dupont 910 calorimeter coupled to a Dupont thermal analyst 2100, or on a TA Instruments Q10 series calorimeter at a heating rate of 10 °C min^{-1}.

2.2. Ligand syntheses

2.2.1. 1,2-Bis(3-(quinolin-8-ylsulfanyl)prop-1-ynyl)-benzene (L, **1**)

A flask was charged with thioxine hydrochloride (1.6 g, 8.12 mmol) and dry dimethylformamide (30 mL). Anhydrous potassium carbonate (4.0 g, 28.9 mmol) was then added and the mixture was allowed to stir for 5 h at 20 °C. A solution of 1,2-bis-(3-bromopropynyl)benzene (1.2 g, 3.87 mmol) in dry dimethylformamide (20 mL) was then added dropwise over 1 h. The reaction mixture was stirred for 3 h at ambient temperature. After completion of the reaction, the solid was filtered and washed with dimethylformamide (2 × 10 mL). The combined organic layers were then poured into water (300 mL) and then extracted with methylene chloride (50 mL). The organic layer was washed with water (3 × 200 mL) and dried over anhydrous sodium sulfate. Finally, the solvent was removed under reduced pressure. The crude product was purified on a silica gel column with 1% methanol in methylene chloride. Yield: 0.70 g (35%); yellow solid. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm) 8.87 (s, 2H), 8.09 (d, 2H), 7.67 (d, 2H), 7.56 (d, 2H), 7.48 (d, 2H), 7.36 (m, 2H), 7.25 (m, 2H), 7.17 (m, 2H), 3.88 (s, 4H); ^{13}C NMR (400 MHz, CD_3CN) δ (ppm) 149.45, 145.74, 137.32, 136.58, 132.12, 128.39, 127.98, 127.02, 125.82, 125.69, 124.81, 121.87, 89.18, 82.03, 20.95. MS (EI, HRMS) 472.1066, Calc. 472.1067 (M^{+}).

2.2.2. 1,2-Bis(3-(pyridin-2-ylmethylsulfanyl)prop-1-ynyl)benzene (L′, **2**)

A flask was charged with pyridin-2-yl-methanethiol (1 g, 8.12 mmol) and dry dimethylformamide (30 mL). Sodium hydroxide (0.36 g, 9.00 mmol) was then added and the mixture was allowed to stir for 1 h at 0 °C. A solution of 1,2-bis-(3-bromopropynyl)benzene (1.2 g, 3.87 mmol) in dry dimethylformamide (20 mL) was then added dropwise over 1 h. The reaction mixture was stirred for 3 h at 0 °C. The combined reaction mixture was poured into water (300 mL) and then extracted with methylene chloride (50 mL). The methylene chloride layer was washed with water (3 × 200 mL) and dried over anhydrous sodium sulfate. Finally, the solvent was removed under reduced pressure. The crude product was purified on a silica gel column with 1% methanol in methylene chloride. Yield: 0.60 g (50%); yellow viscous oil. ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm) 8.53 (s, 2H),

7.61 (t, 2H), 7.40 (m, 2H), 7.35 (d, 2H), 7.22 (m, 2H), 7.12 (m, 2H), 4.03 (s, 2H), 4.04 (s, 4H); ^{13}C NMR (400 MHz, CD_3CN) δ (ppm) 158.17, 149.97, 136.78, 132.38, 128.07, 125.84, 123.35, 122.20, 89.39, 82.43, 37.69, 20.51. MS (EI, HRMS) 400.5667, Calc. 400.5682 (M^+).

2.3. Metalloenediyne syntheses

Metalloenediyne complexes (**3**–**10**) are all prepared by reaction of ligands **1** and **2** with appropriate metal salts following the same general method. The case of [Cu(L1)]PF_6 (**3**) is described in detail below.

Ligand **1** (0.25 mmol) was dissolved in 6 mL chloroform and an equimolar amount of the $(MeCN)_4CuPF_6$ was separately dissolved in 6 mL of MeCN. To a 100 mL Schlenk flask containing 25 mL MeCN, these ligand and metal salt solutions were slowly and simultaneously added dropwise (to avoid polymer formation) under nitrogen at ambient temperature. After the complete addition, the mixture was stirred for 30 min at ambient temperature. The volume of the solution was reduced to 15 mL and filtered to remove the insoluble components. To the filtrate, 50 mL of dry ether was added and the resulting solution kept in freezer for 3 h. The yellow precipitate was subsequently collected by filtration. Yield: 80% ^{1}H NMR (400 MHz, CD_3CN) δ (ppm) 8.81 (d, 2H), 8.37 (m, 4H), 8.11 (d, 2H), 7.81 (t, 2H), 7.51 (m, 2H), 7.10 (m, 2H), 6.99 (m, 2H), 4.23 (s, 4H). MS (ESI, HRMS): m/z 535.0360, Calc. 535.0364 ($M - PF_6$).

[Ag(L1)]PF_6 (**4**): Yield: 70% ^{1}H NMR (400 MHz, CD_3CN) δ (ppm) 8.83 (d, 2H), 8.33 (d, 2H), 8.09 (d, 2H), 7.95 (d, 2H), 7.68 (t, 2H), 7.44 (m, 2H), 7.12 (m, 4H), 4.01 (s, 4H); ^{13}C NMR (400 MHz, CD_2Cl_2) δ (ppm) 154.47, 146.55, 140.47, 138.62, 132.91, 132.53, 130.97, 130.89, 129.89, 128.77, 125.38, 123.69, 89.25, 85.42, 30.32. MS (EI): m/z 579 (^{107}Ag), 581(^{109}Ag) ($M - PF_6$). *Anal*. Calc. for $C_{30}H_{20}N_2S_2AgPF_6$: C, 49.67; H, 2.78; N, 3.86. Found: C, 49.81; H, 3.03; N, 3.64%.

[Cu(L1)]$(BF_4)_2$ (**5**): Yield: 65%, MS (EI): m/z 535(^{63}Cu), 537(^{65}Cu) ($M - 2BF_4$). *Anal*. Calc. for $C_{30}H_{20}N_2S_2Cu(BF_4)_2$: C, 50.76; H, 2.84; N, 3.94. Found: C, 50.25; H, 2.84; N, 3.94%.

[Pd(L1)]$(BF_4)_2$ (**6**): Yield: 90% ^{1}H NMR (400 MHz, $CDCl_3$) δ (ppm) 9.21 (d, 2H), 8.87 (d, 2H), 8.66 (d, 2H), 8.44 (d, 2H), 8.08 (t, 2H), 7.87 (m, 2H), 7.29 (m, 2H), 7.13 (m, 2H), 4.82 (d, 2H), 4.56 (d, 2H); ^{13}C NMR (400 MHz, $CDCl_3$) δ (ppm) 159.68, 153.76, 144.40, 139.03, 134.73, 132.57, 132.13,130.97, 127.22, 125.70, 123.63, 122.25, 89.88, 87.78, 39.32. *Anal*. 2.4. X-ray crystallography

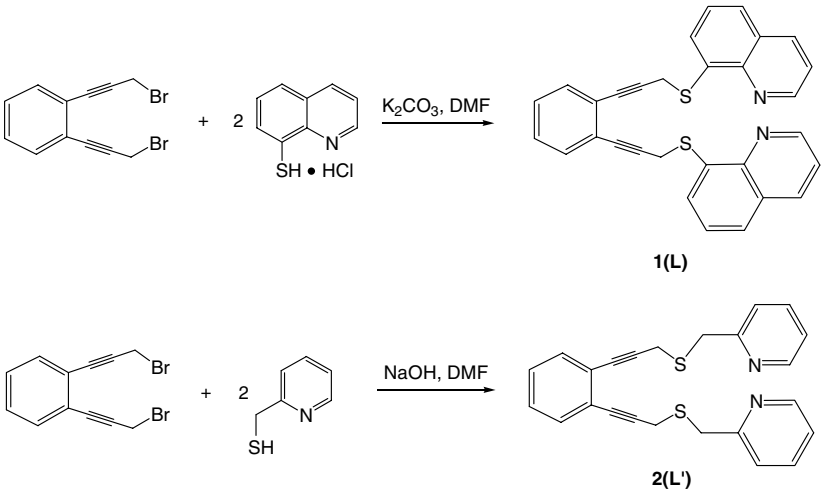
X-ray quality crystals of **1** were grown by slow evaporation from a methanol:dichloromethane mixture (1:1). For complexes **3**, **6**, **7**, **8a**, single crystals were obtained by slow vapor diffusion of diethyl ether into an acetonitrile solution of the complex at 0 °C. Suitable crystals were placed onto the tip of a 0.1 mm diameter glass capillary and mounted on a SMART6000 (Bruker) at 120 K. The data collection was carried out using Mo Kα radiation (graphite monochromator) and a detector distance of 5.0 cm. A randomly oriented region of reciprocal space was surveyed to at least the extent of a hemisphere, collection several major sections of frames with 0.30° steps in ω at 3 different ϕ settings and a detector position of −43° in 2θ. Final cell constants were calculated from the xyz centroids of strong reflections from the actual data collection after data reduction. The intensity data were corrected for absorption [31].

Space groups were determined based on intensity statistics and systematic absences. The structures were solved using SIR-92 [32] and refined with SHELXL-97 [33]. Direct-methods solutions were calculated which provided most non-hydrogen atoms from the E-map. Full-matrix least squares/difference Fourier cycles were performed, which located the remaining non-hydrogen atoms. All non-hydrogen atoms were refined with anisotropic displacement parameters. The hydrogen atoms were placed in ideal positions and refined as riding atoms with individual or relative isotropic displacement parameters.

3. Results

3.1. Synthesis and characterization

Acyclic enediyne ligands **1** and **2** were prepared by mixing 1,2-bis-(3-bromopropynyl)benzene [29] in DMF with the pre-formed Na^+ or K^+ salt of the desired thiol in a nucleophilic substitution reaction (Scheme 1). Strong base (NaOH) was employed for the preparation

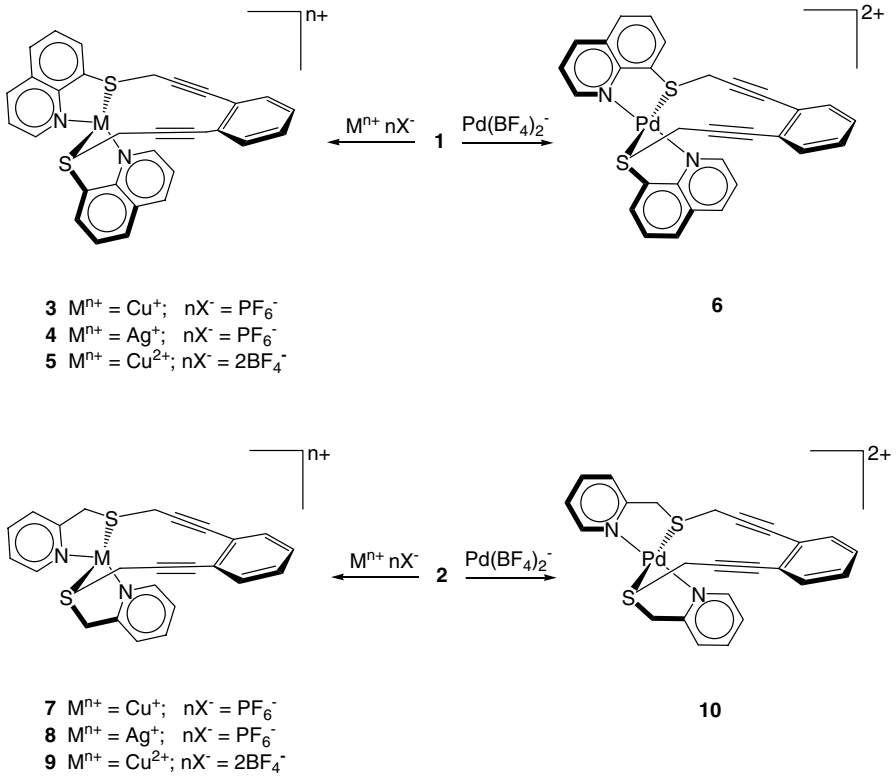


Scheme 1. Syntheses of tetradentate enediyne ligands **1** (L) and **2** (L′).

of **2** due to the sluggish reactivity of pyridin-2-yl-methanethiol with K_2CO_3. Both ligands can be isolated in moderate yields (35–50%).

Weakly coordinating, thioether metalloenediynes of soft metals (e.g., Pd(II), Cu(I), Ag(I)) can be readily prepared by complexation with the appropriate PF_6^- (e.g., Cu^+, Ag^+) or BF_4^- (Cu^{2+}, Pd^{2+}) salts (Scheme 2). These ions form the tetrahedral or tetragonal/square planar geometries that modulate the enediyne conformation. All the metal complexes were prepared following same general method. In order to avoid possible polymer formation ligand and appropriate metal salt were dissolved separately and simultaneously added at room temperature maintaining sufficient dilution. The reaction mixture was subsequently filtered to eliminate insoluble materials. The desired metalloenediyne complexes were isolated by recrystallization from diethylether in very good yields (70–90%).

Both ligands display well-resolved ^1H and ^{13}C NMR spectra in solution. In ^1H NMR spectra, all aromatic



Scheme 2. Preparation of metalloenediynes complexes **3**–**10**.

resonances appear between 7 and 9 ppm while the methylene protons adjacent to the enediyne linkage are detected below 3.8 ppm. Upon diamagnetic metal ion complexation, downfield shifts of all proton signals are observed. Due to thioether coordination and metal ion proximity, the methylene protons show dramatic shifts upon complexation. For Cu(I) and Ag(I), the downfield shift of the methylene protons signal is ~0.4 ppm, while for the Pd(II) complex, the shift is slightly larger (~0.7 ppm). In both cases, the shift serves as a useful diagnostic of metal coordination by the thioether linkage. Similarly, in the ^{13}C NMR spectra of these metalloenediyne complexes, the methylene carbon resonance is also markedly shifted from the free ligand value (~20 ppm) to ~30 ppm for the Ag(I) complex and ~39 ppm for the Pd(II) analogue, thereby revealing the Lewis acidity/electron withdrawing capability of the metal ion as a function of oxidation state. All other resonances are observed as expected.

3.2. Molecular structure

Ligand **1** was crystallized by slow evaporation of methanol-chloroform solution (Fig. 1, Table 1). X-ray quality crystals of metalloenediyne complexes of ligands **1** (**3**, **6**), and **2** (**7**, **8a**) were obtained by vapor diffusion of ether into an acetonitrile solution of the complexes (Figs. 2 and 3, Table 1). The Ag(I) complex **8** did not readily yield X-ray quality crystals; however counter ion exchange of PF_6 for SbF_6 afforded the desired single crystals (**8a**). Selected bond parameters are listed in Tables 2 and 3.

In the X-ray structure of ligand **1** (Fig. 1) the two thioxine (8-mercaptoquinoline) groups lie in a *syn* con-

figuration with respect to the enediyne plane with their rings oriented at ~45° to each other. The alkyne termini (C2···C7) separation is relaxed (3.76 Å) and shows no evidence of steric crowding as occurs in more rigid enediyne constructs with large metal binding functionalities near the alkyne termini, due in part to the flexibility engendered by the additional methylene linkage [20]. For d^{10} metalloenediynes **3**, **7** (Cu(I)), and **8a** (Ag(I)), the N_2S_2 ligand donor atoms coordinate in a distorted tetrahedral fashion. The N1–M–N2 and S1–M–S2 bond angles range from ~106° to 113° and ~113° to 123°, respectively, reflective of the structural flexibility of the ligand and the elongated M–S bond lengths (~0.15–0.3 Å) over their M–N counterparts (Tables 2 and 3). In contrast, the Pd(II) complex **6** is square planar with the two weakly coordinating thioether linkages in a *trans* relationship leading to S1–Pd–S2 and N1–Pd–N2 bond angles of ~175°. Although the *cis* conformation is also a plausible structure, it is energetically uphill by ~6–9 kcal/mol from the *trans* geometry [28]. Despite the coordination geometry differences between the complexes, the alkyne termini separation (C2···C7) is almost same for all complexes (~4 Å). This arises from the large S1–M–S2 bite angles that range from 113° to 175° across all complexes.

3.3. Thermal Bergman cyclization

The thermal Bergman cyclization temperatures of these enediyne compounds have been measured by differential scanning calorimetry (DSC) and are given in Table 4. DSC is a convenient technique for comparing and correlating the thermal reactivities of enediynes, and is especially useful for complexes that react with solvent and decompose under thermal conditions in solution.

[CuL′]$(BF_4)_2$ (**9**)	188
[PdL′]$(BF_4)_2$ (**10**)	189

Upon heating, ligand **1** exhibits a sharp, endothermic peak at 105 °C characteristic of a melting transition. At higher temperature, a broad exothermic peak is also observed at 230 °C, which is characteristic of and at the expected temperature for the Bergman cyclization reaction of the neat liquid (Fig. 4). Ligand **2**, which is a liquid at ambient temperature, displays a similar exotherm at 226 °C, indicative of diradical formation by a similar construct.

Unlike **1**–**2**, the metalloenediyne complexes are all solids and do not show melting endotherms at temperatures below the cyclization reaction. For these complexes, cyclization occurs in the solid state, whereas the ligands react as neat liquids. Thus, direct comparison of the specific cyclization temperatures between the ligands and complexes cannot be readily made. However, it should be noted that the ligand cyclization temperatures would likely be considerably higher if encapsulated within an inert matrix, thereby illustrating the ability of the metal to reduce the cyclization temperatures relative to the free ligands [17,19,20].

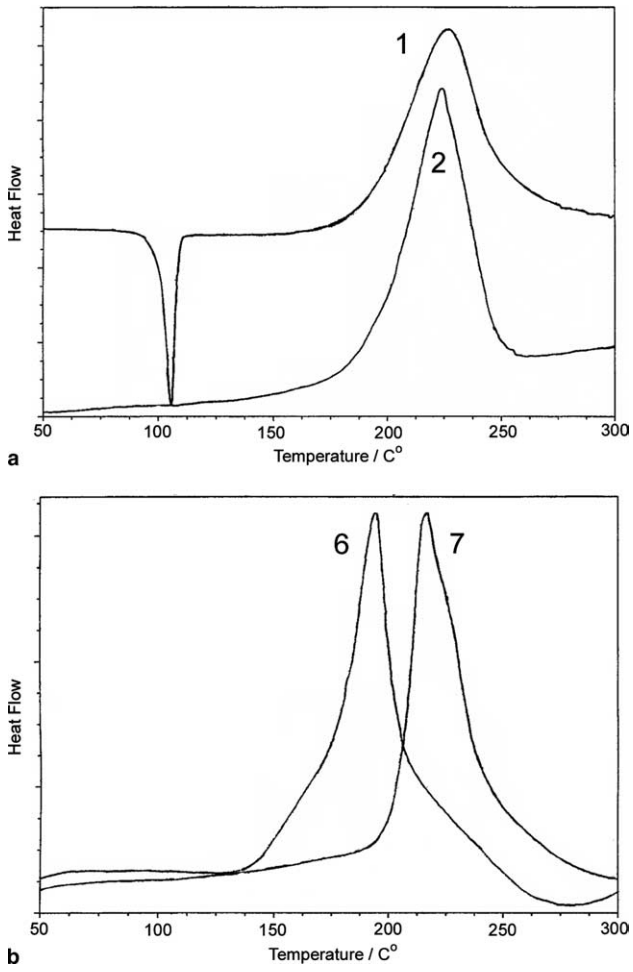

Fig. 4. Differential scanning calorimetry traces for the thermal cyclization of (a) **1**, **2** and (b) **6**, **7** in the solid state.

To this end, the cyclization temperatures of monovalent metalloenediyne complexes such as those of Cu(I) and Ag(I) displaying tetrahedral geometries (211–218 °C) are ~20–25 °C higher than their corresponding divalent, tetragonal and *trans* square planar complexes of Cu(II) and Pd(II) (186–190 °C). This trend is invariant to ligand and virtually identical for both sets of complexes derived from ligands **1** and **2**, despite the change of pyridine for quinoline coordination. It is also noteworthy that the alkyne termini separation in the X-ray structures *increases* upon metal coordination, while the cyclization temperatures actually *decrease*. This behavior is in stark contrast to the typical relationship between cyclization temperature and alkyne termini separation that has been well-established for analogous chelating metalloenediyne constructs [18–22].

4. Discussion

Ligands **1** and **2**, and their corresponding metalloenediyne complexes **3**–**10** represent a new class of thioether-coordinated enediyne framework. These constructs are very intriguing because they generate possibilities for using the thioether to geometrically, electronically, or substitutionally modulate the bound enediyne conformation and hence the Bergman cyclization temperature.

Earlier studies have shown that tetradentate amine/imine enediyne ligands [21,22,34] could give rise to, in some cases, extremely facile Bergman cyclization at ambient temperature [34]. In this sense, use of the thioether linkage as a mechanism to draw the alkyne termini into close proximity has attractive potential. Yet similar studies also revealed the importance of metal geometry in controlling coordinated enediyne conformation [16–22,35]. It is now well-established that *cis*-planar structures often have markedly lower cyclization temperatures than their tetrahedral or more rarely, their *trans*-planar [35] counterparts. As shown in Table 4, these thioether coordinated complexes do not adhere to this clearly defined paradigm, but rather exhibit cyclization temperatures for the *trans*-planar complexes that are ~25 °C *lower* than their tetrahedral counterparts. Since these complexes exhibit the same trend as their non-benzannulated structures, albeit ~50–60 °C lower in temperature [28], the variational thermal reactivities of these constructs is clearly not disrupted by benzannulation. With the wealth of data of metalloenediyne complexes and the established relationships with geometric structure, why then do the *trans* planar complexes react more readily than the tetrahedral structures?

Bergman cyclization temperatures also exhibit electronic contributions to reduction or enhancement of the thermal barrier to cyclization [36–40]. More specifically, electron withdrawing functionalities at the alkyne termini have been shown both theoretically [38] and experimentally [40] to decrease the onset temperature for the cyclization reaction. Although these effects are relevant in metalloenediyne constructs, their observation typically requires careful synthetic isolation of geometric and electronic components by locking the ligand conformation in order to systematically evaluate such contributions [24]. Within this theme, such enhancements in reactivity have recently been shown to be accessible by high valent metal ion coordination (e.g., Mo^{IV}–S^{-}) near the alkyne termini [27]. Ligands such as **1** and **2** displa- ying thioether coordination in the vicinity of the alkyne termini have potential for just this mode of electronic enediyne activation. However, in these cases, the neutral charge of the thioether leads to long metal–ligand bond lengths and poor orbital overlap, which is the basis for electronic activation. Additionally, the tetrahedral or *trans* planar geometry (e.g., Pd(II)) negates significant electronic enhancement via less than favorable geometric considerations. Thus, these fundamental guidelines for metalloenediyne reactivity do not explain the thermal chemistry of thioether-coordinated constructs such as **3**–**10**.

In very recent work on the non-benzannulated derivatives of **3**–**6**, detailed NMR and DFT studies implicated elevated temperature formation of a *cis* isomer with reduced alkyne termini separation by dissociation of the thioether ligand and rotation about the M–N bond [28]. This species then serves as the active precursor to Bergman cyclization. In fact, ambient temperature cyclization can be initiated via competitive ligand exchange by addition of 1 eq of pyridine. Under these conditions, the methylene protons from the dissociated thioether ligand appear in the ^{1}H NMR (δ 3.9 ppm) and new resonances from the cyclized product between δ 6 and 7 ppm emerge [28]. In light of the increased cyclization temperatures and the parallel thermal reactivity trends between related metalloenediyne complexes, these benzannulated derivatives likely follow the same reaction pathway.

5. Conclusion

We have prepared two novel thioether-coordinated enediyne ligands and a set of metalloenediyne complexes of Cu(I), Ag(I), Cu(II), and Pd(II). The d^{10} species exhibit distorted but near tetrahedral geometries with weak thioether coordination, while the d^9 and d^8 species are likely *trans* tetragonal and square planar, respectively. Remarkably, the latter structures exhibit Bergman cyclization temperatures ~25 °C lower than their tetrahedral counterparts. These values are much lower than those expected for complexes with *trans* geometries. The rationale for this chemical behavior can be traced to the fluxional nature of the thioether linkage and a *trans* to pseudo *cis* conformational change about the metal center via M–N bond rotation. This reactivity reveals the complex and untapped potential for using metal coordination to activate enediyne ligands toward Bergman cyclization.

6. Supplementary material

Crystallographic data for the X-ray structure analyses have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 268 255 (**6**), 275 063 (**7**), 275 064 (**3**), 275 065 (**1**), and 275 066 (**8a**).

Dinuclear coordination of a novel four-electron reduced μ-η^1,η^3-allene ligand with β-agostic C–H···Ta interaction: Direct addition of allene to $(C_5Me_5)_2Ta_2(\mu\text{-}X)_4$ (X = Cl, Br), and molecular structure of $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$

Dedicated to Professor Malcolm Chisholm for his numerous creative contributions to and leadership in transition metal–metal multiple bond and dinuclear allene chemistries, and for advancing the metal–metal multiple bond paradigm from synthesis and structure to reactivity.

Abstract

The organoditantalum complexes $(\eta\text{-}C_5Me_5)_2Ta_2(\mu\text{-}X)_4$ (X = Cl, Br) react with 1–5 equiv. of allene under mild conditions to afford the fluxional allene adducts $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}X)X_3$ as shown by spectroscopic and spectrometric data. Low-temperature-limit proton NMR data at −95 °C for $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$ show a large chemical shift range for the inequivalent allene hydrogens, with a high-field value for one hydrogen at δ −0.36, and inequivalent Cp* groups. The low-temperature-limit ^{13}C NMR resonances for the allene ligand are found at δ 204.4 (central C), δ 70.3 (CH_2, $^1J_{CH} = 154$ Hz), and the substantially upfield value of δ 42.9. The latter resonance has remarkably different coupling constants ($^1J_{CH} = 173$, 154 Hz). The allene coordinates in a novel alkylidene-diyl fashion in the solid-state, as shown by X-ray diffractometry on $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$ at 200 K. One tantalum is doubly-bonded to the central allenic carbon (Ta1=C22 distance, 2.011(7) Å) and interacts with an allene hydrogen in a probable β-agostic manner (Ta1–H21A distance of 2.25(10) Å). The second tantalum is coordinated to the allene in a hybrid of η^3-allylic and sigma bonding, with Ta2–C distances to the allene methylenes of 2.206(8) and 2.276(9) Å and a Ta2–C22 bond distance to the central allenic carbon of 2.253(7) Å. The allene hydrogens are oriented above and below the C–C–C plane, consistent with appreciable σ-bonding between the Ta(2) and the allene methylenes. The bent allene ligand has a C–C–C angle of 106.0(6)° and can be viewed as reduced by four electrons, with concomitant oxidation of the two d^2 tantalum centers of the organoditantalum(III) reactant. The long Ta···Ta nonbonded distance of 3.3052(8) Å is consistent with two d^0 tantalum centers in an organoditantalum(V) product.

1. Introduction

There is considerable structural diversity in the products from reactions of the simplest cumulene, allene, and its derivatives with organotransition metal compounds. A variety of allene coordination modes (Scheme 1) and metal-mediated rearrangements have been observed in mononuclear [1] and dinuclear chemistries. The course of these reactions depends in part on the functional groups of the organotransition metal reactant. For example, migratory insertion of allene into metal hydride [2–5], μ-vinyl [6], and η^3-allyl [6] groups has

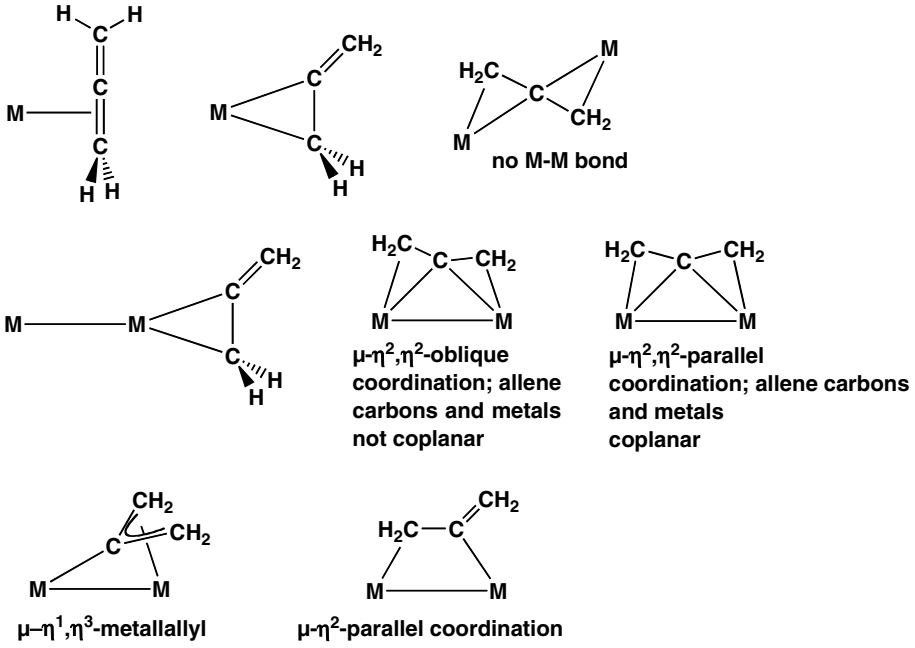

Scheme 1.

been shown to yield η^3-allyl complexes and other hydrocarbon-coupled products. Allene coupling with CO, phosphido [7], μ-methylene [8], and allene [9–11] ligands has also been reported.

There are only a small number of reported homo- and heterodinuclear allene adducts. Solid-state structures, as well as solution structures proposed on the basis of spectroscopic data, fall into several classes. These include η^2-coordination to one of the metal centers [12–17], μ-η^2,η^2-coordination oblique or parallel to the metal–metal vector (with or without metal–metal bonding) [12,18–28], μ-η^2-coordination (i.e., 1,2-dimetallacyclobutane with an exocyclic methylene group) [29,30], and μ-η^1,η^3-coordination [7,10,12,23,27,29,31–37]. The latter mode, which contains a formal doubly-reduced allene ligand, can be described as a 2-metallaallyl that is η^3-bonded to the second metal. In one case, a μ-η^1,η^3-coordinated allene has been described formally as quadruply-reduced (i.e., tetraanionic) [27]. Dinuclear allene adducts have been observed in matrix isolation experiments [38].

Dinuclear complexes with allene ligands have been prepared by a variety of methods, including: (1) direct addition of allene to dinuclear complexes, (2) sequential nucleophilic/electrophilic attack [39] or diazoalkane addition [9,40–42] to μ-vinylidene complexes, (3) rearrangements of μ-cyclopropylidene ligands [43,44], and (4) photochemical decarbonylation of a μ-η^1,η^3-β-carbonylallylic ligand [19]. Of the reports of direct allene addition to dinuclear reactants, only a few involve compounds possessing metal–metal multiple bonds.

The formally metal–metal doubly-bonded, mid-valent organoditantalum(III) complexes (η-$C_5Me_4R)_2$-$Ta_2(\mu\text{-}X)_4$ (**1**; R = Me, Cp*; R = Et; X = Cl, Br) react with a variety of substrates, including dihydrogen [45], borohydride [46], 3,3-disubstituted cyclopropenes [47], and 1-alkenes [48]. This reactivity may be associated with the fact that **1** possesses a d^2–d^2 electron poor double bond of $\sigma^2\delta^2$ electronic configuration (or the alternate [49] non-bonded $\sigma^2\delta^{*2}$, depending on the degree of interaction of the μ-halide lone pairs with the δ-symmetry d_{xy} orbitals and the concomitant destabilization of δ relative to δ*). $(C_5Me_4R)_2Ta_2(\mu\text{-}X)_4$ reacts under mild conditions (25 °C, 15 psi) with simple 1-alkenes ($H_2C{=}CHR'$) to give the organoditantalum complexes $(C_5Me_4R)_2Ta_2(\mu\text{-}CHCHR')(\mu\text{-}H)(\mu\text{-}X)X_3$, the formal products from vinylic C–H bond activation [48]. Olefins such as styrene or butadiene react at kinetically-convenient rates only at higher temperatures (80 °C) to yield mononuclear Ta(V) organometallics such as $Cp^*Ta(\eta^2\text{-}H_2CCHPh)X_2$ or the metallacyclopentene $Cp^*Ta(CH_2CH{=}CHCH_2)X_2$, respectively [45]. We investigated whether allene would react with **1** via a C–H activation pathway or via complexation in mononuclear or dinuclear products, and report here our results that represent an unusual coordination mode for allene in organodimetallic chemistry.

2. Results and discussion

2.1. Reaction of allene with $Cp^*_2Ta_2(\mu\text{-}X)_4$

The injection of 1–5 equiv. of allene via gas-tight syringe to a cooled (−78 °C) toluene solution of

$Cp^*_2Ta_2(\mu\text{-}X)_4$, **1**, followed by warming to room temperature and stirring overnight, converts the solution from the forest-green reactant color to deep red solutions from which the brownish-red allene adducts $Cp^*_2Ta_2(\mu\text{-}X)_4(H_2CCCH_2)$ (X = Cl, **2a**; X = Br, **2b**) can be isolated in 55% (X = Cl) or 53% (X = Br) yield via concentration and low-temperature fractional crystallization. The best yields are obtained from use of 2 equiv. of allene per equivalent of **1**. The reaction of excess allene, at greater than one atmosphere pressure in a pressure reaction vessel [50], with a toluene solution of $Cp^*_2Ta_2(\mu\text{-}X)_4$ yields a mixture of presently uncharacterized products. Elemental analysis and mass spectrometric data confirm that allene has added to **1**, and NMR spectroscopic data are consistent with formulation of **2** as dinuclear allene adducts rather than as products derived from vinylic C–H bond activation or mononuclear coordination via one C=C double bond.

2.2. Spectroscopic studies

The ^{1}H NMR spectra of the allene adducts **2** at 25 °C are simple, with resonances consistent with a single Cp* group and two types of allene protons. At 25 °C the allene hydrogen atoms in the chloride complex **2a** appear as broad singlets at δ 1.66 and δ 2.60 in C_6D_6, and as multiplets at δ 1.41 and δ 1.70 in CD_2Cl_2. For the bromide **2b**, the allene hydrogen atoms appear as broad singlets at δ 1.88 and δ 2.26 in C_6D_6. At lower temperatures the two Cp* groups and the four allene hydrogen atoms of **2a** are nonequivalent, with resonances over a surprisingly large chemical shift range (Fig. 1). At −95 °C (CD_2Cl_2) the four allene proton resonances are found at δ −0.36 (double doublet), δ 0.09 (doublet), and δ 2.60 (overlapped doublet and broad singlet). Homonuclear decoupling experiments at −95 °C establish that the two high-field resonances at δ −0.36 and δ 0.09 are geminal protons, and we postulate that they are H21A and H21B because of the unusual chemical shifts and structural features associated with the two hydrogen atoms on C21 in the solid-state structure (vide infra). Since the Cp* resonances become equivalent at room temperature, the fluxional process must involve a substantial reorganization of the C_3H_4 ligand to a symmetric intermediate followed by rearrangement to bond the central allene carbon atom to the other tantalum atom. Such fluxional behavior has been noted often in dinuclear allene coordination chemistry.

The ^{13}C NMR spectra of **2a** also change appreciably with temperature. Resonances for a single Cp* group and equivalent allene methylene groups are observed at 25 °C, with allene ligand chemical shifts of δ 62.9 (CH_2, $^1J_{CH}$ = 160 Hz) and δ 206.9 (central C). At −95 °C, the Cp* groups and allene methylenes become nonequivalent, with the inequivalent methylene carbon atoms appearing at δ 70.3 and the substantially upfield value of δ 42.9. The resonance at δ 42.9 has remarkably different C–H coupling constants ($^1J_{CH}$ = 173 and 154 Hz) to the geminal protons in the gated {^{1}H} spectrum, whereas the δ 70.3 resonance is a deceptively simple triplet with $^1J_{CH}$ = 154 Hz. The 19 Hz difference in the $^1J_{CH}$ coupling constants for the methylene carbon atom at δ 42.9 and the unusual spread of the proton NMR resonances for the four allene protons are suggestive of an agostic [51] interaction of one or more of the allene hydrogen atoms with a tantalum atom. The spread in $^1J_{CH}$ values for **2a** may be related to the fact that C21 is β to Ta1 and α to Ta2. $^1J_{CH}$ values for α-agostic interactions should be used with caution since the $^1J_{CH}$ for σ-bonded carbons depends on the electron density at the metal center [52].

Infrared spectroscopy has been used to characterize, with partial success, agostic interactions [51b]. Infrared spectra of **2a** and **2b** (recorded as KBr pellets and concentrated Nujol mulls) show no evidence of unusual C–H stretching absorptions in the 2750–2200 cm^{-1} range.

Allene ^{1}H NMR resonances in dinuclear complexes are related to the metal as well as coordination mode and allene carbon rehybridization, so chemical shifts are not a reliable indicator of the coordination mode in complexes with other metals. However, no other reported dinuclear allene complex has a slow-exchange-limit ^{1}H NMR spectral range with such high field values nor such a range of chemical shifts as those seen for **2a**. The ^{1}H chemical shifts of the allene ligand in **2a** are quite different from that of allene itself (δ 4.49 in C_6D_6, 25 °C). Among early transition metal complexes, an organodimolybdenum complex [18] with a $\mu\text{-}\eta^2,\eta^2$-oblique allene coordination had allene resonances in C_6D_6 at δ 3.67 and δ 2.52, versus δ 4.46 and δ 2.82 for the tungsten analog. A μ-parallel allene ligand in an organoditungsten complex had an allenic ^{1}H NMR chemical shift at δ 6.59 [12]. The proton chemical shifts for two ditungsten $\mu\text{-}\eta^1,\eta^3$-metallallyls ranged from δ 5.88 to δ 2.40 [12].

Carbon-13 NMR shifts for allene ligands in dinuclear complexes are also related to the metal and coordination mode. Of early transition metal examples, $Cp_2Mo_2(CO)_4(\mu\text{-}\eta^2,\eta^2\text{-}C_3H_4)$ had a central allene ^{13}C chemical shift of δ 197.0 and methylene carbon value of δ 36.7, with $^1J_{CH}$ values of 160 and 170 Hz; the tungsten analog had a central allene carbon resonance at δ 31.6 [18]. In one ditungsten $\mu\text{-}\eta^2,\eta^2$-parallel allene complex, the central allene carbon resonance was found at δ 249.7 and the methylene at δ 89.1, with $^1J_{CH}$ = 156 Hz [12]. Another ditungsten allene complex, $W_2(OCMe_3)_4(\mu\text{-}OCMe_3)_2$ ($\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4$) ($\eta^2\text{-}C_3H_4$) with a metallallyl allene coordination mode, had resonances for $C_{central}$ at δ 177.1 and CH_2 at δ 67.9 (interestingly, with two $^1J_{CH}$ values differing by 10 Hz) [12].

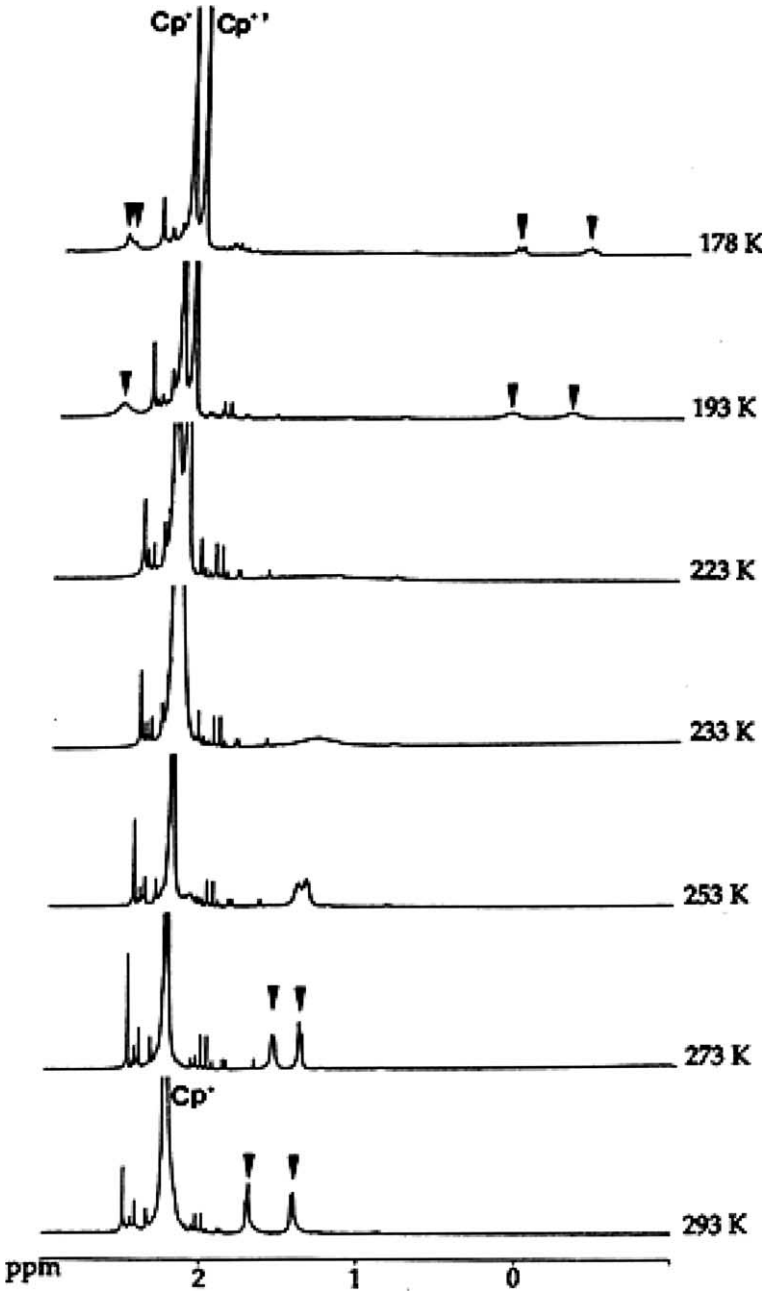

Fig. 1. Variable temperature ^{1}H NMR spectra of $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$ (**2a**) in CD_2Cl_2. The arrows denote resonances for the allene hydrogen atoms, Cp* denotes the methyl resonances of the C_5Me_5 groups. Remaining resonances are solvent impurities.

*2.3. Solid-state structure determination of **2a** by X-ray diffractometry*

The thermal ellipsoid plot in Fig. 2 depicts the molecular structure of **2a** as determined from single-crystal X-ray diffraction data collected at 200 K. Fig. 3 is the thermal ellipsoid plot obtained by rotating the structure in Fig. 2 by ~90° about the Ta1···Ta2 vector. Key bond distances and bond angles are listed in Tables 1 and 2, respectively, while crystallographic and data collection parameters are summarized in Section 4.

Important structural parameters include: (1) a nonbonded Ta1···Ta2 distance of 3.3052(8) Å, bridged by the allene ligand and one chlorine atom directly opposite the allene ligand, (2) an unsymmetric $\mu\text{-}\eta^1,\eta^3$-allene coordination mode with twisting of the C21–C22–C23 moiety with respect to the Ta1···Ta2 vector, (3) a small allene ligand C21–C22–C23 angle of 106.0(6)°, (4) a long allene C21–C22 distance of 1.537(10) Å and C22–C23 distance of 1.435(11) Å, respectively, (5) rotation of the allene hydrogen atoms on C21 and C23 out of the C21–C22–C23 plane, with

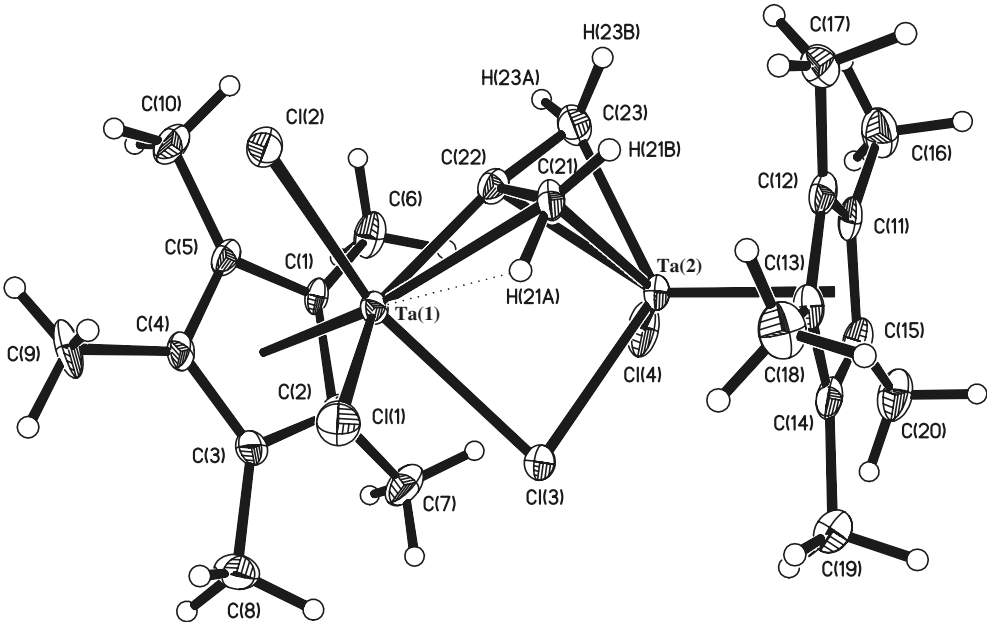

Fig. 2. Thermal ellipsoid plot of the molecular structure of $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$ (**2a**) viewed approximately perpendicular to the Ta1···Ta2 vector and Ta1–C22 bond. Ellipsoids are drawn at 35% probability level.

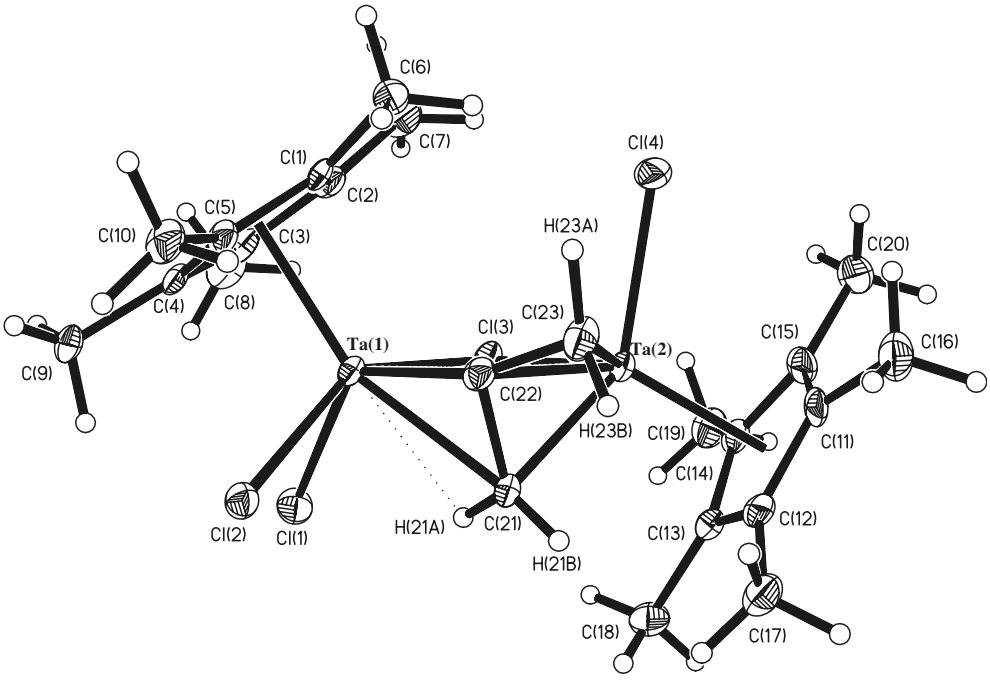

Fig. 3. Thermal ellipsoid plot of the molecular structure of $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$ (**2a**), rotated 90° about the Ta1···Ta2 vector from that in Fig. 2 and viewed perpendicular to the Ta1···Ta2 vector and parallel to a vector passing through C22 and the bridge chlorine CL3. Ellipsoids are drawn at 35% probability level.

dihedral angles between the H21A–C21–H21B plane and the C21–C22–C23 plane of 22.7° and between the H23A–C23–H23B plane and the C21–C22–C23 plane of 53.3°, (6) a short Ta1–C22 distance of 2.011(7) Å, (7) a nearly planar C22, with summation of angles (Ta1–C22–C21, Ta–C22–C23, and C21–C22–C23) of 354.5° and deviation of Ta1 from the C21–C22–C23 plane of 0.4606(1) Å, (8) Ta2 interaction with the three allene carbons, with Ta2–C21, Ta2–C22, and Ta2–C23 distances of 2.206(8), 2.253(7), and 2.276(9) Å, respectively, and (9) a short Ta1···H21A distance of 2.25(10) Å.

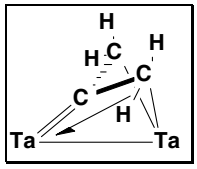
Cl(3)–Ta(2)–C(200)	116.3
C(23)–Ta(2)–Cl(3)	121.8(2)

C(100) and C(200) are the centroids of the C_5Me_5 rings. Standard deviations given in parentheses.

The structural data is consistent with an unusual coordination mode for an allene ligand in a dinuclear complex, which is depicted below in idealized fashion.

The actual structure has some twisting of the allene ligand which results in inequality of the C22–C23 (1.43(1) Å) and long C21–C22 (1.54(1) Å) distances. The four allene hydrogens are above and below the C21–C22–C23 plane, rather than in the C21–C22–C23 plane as would be expected for a $\mu\text{-}\eta^1,\eta^3$-metallaallyl ligand. This suggests a significant rehybridization of the allene methylene carbon atoms towards sp^3. The short Ta1=C22 distance of 2.011(7) Å is in the Ta=C double bond range, showing that tantalum–carbon multiple bonding competes with C=C double bonding. The near planarity of the central allene carbon C22 is consistent with this alkylidene formulation.



A number of $\mu\text{-}\eta^1,\eta^3$-metallallyl complexes have been studied by X-ray diffractometry. In the first reported structure, on $Fe_2(CO)_6(PPh_3)(C_3H_4)$, the two C–C distances were 1.45(2) and 1.41(2) Å and the C–C–C angle was 116(1)° [31,32]. Among earlier transition metal examples, the ditungsten complex $W_2(OCMe_3)_4(\mu\text{-}OCMe_3)_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\eta^2\text{-}C_3H_4)$ had allene C–C distances of 1.434(16) and 1.458(16) Å (average 1.45(2) Å), and an allene C–C–C angle of 109.8(10)° [12]. Interestingly, the allene ligand protons lie in the allene C–C–C plane, as would be expected for a normal metallallyl coordination. In both this structure and the related [12] carbonyl derivative $W_2(OCMe_3)_4(\mu\text{-}OCMe_3)_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(CO)_2$ the W–C σ-bonding distances to the central allene carbon were consistent with single bonds, and the allene C–C distances were 1.32(7) and 1.49(6) Å.

All four allene hydrogen atoms in **2a** were located and refined in the structure determination. The C–H distances were not constrained during refinement, and thus range from an unreasonably short though statistically acceptable 0.64(9) Å for C21–H21A (the postulated agostic hydrogen) to 0.8(1) Å for C23–H23A to 1.0(1) Å for both C21–H21B and C23–H23B. Because of the short C21–H21A distance, it is not possible to state with complete certainty that H21A is interacting with Ta1 in a β-agostic manner despite the short Ta1···H21A distance. However, an important criterion for the existence of an agostic interaction is the presence of a suitable acceptor orbital on the metal [51b]. Fig. 4 shows a partial molecular view through the top of the Cp* group (carbon atoms removed) along the Ta1–C100 ring centroid vector. The C21–H21A bond is located along one of the legs of the four-legged piano stool geometry about

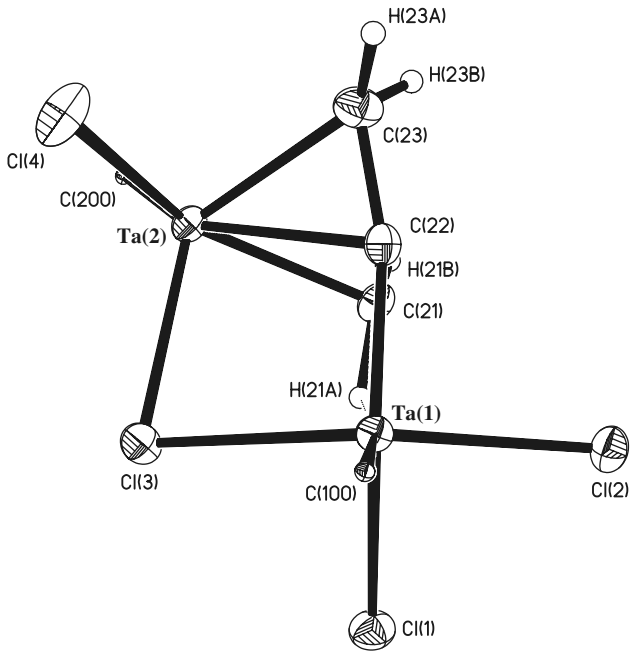


Fig. 4. Thermal ellipsoid plot emphasizing the Ta1 coordination sphere of $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$ (**2a**) as viewed down the centroid C100···Ta1 vector from above the Cp* group (with carbons removed for clarity). Ellipsoids are drawn at 35% probability level.

Ta1, with H21A pointing toward the location of the empty Ta1 orbital projecting from the base of the piano stool. Therefore, we conclude that the location of the C21–H21A bond in a coordination position on Ta1 and the short Ta1···H21A distance, combined with the unusual NMR spectroscopic data, are consistent with a β-agostic interaction of H21A with Ta1. A partially deuterated allene version of **2** is needed in order to confirm this conclusion.

β-Agostic interactions in Group 5 chemistry are rare, with the vast majority of agostic interactions being α-agostic interactions in alkylidene and alkyl complexes [51b]. Tantalum– and niobium–hydrogen distances in cases of α-agostic interactions are typically 2.13 [51b] to 2.36 Å [53]. There is one report [54] of a β-agostic interaction in tantalum chemistry, as postulated on the basis of an unusual upfield ^{1}H chemical shift (δ −0.09) and ^{13}C NMR spectroscopic data for the ethyl group in the alkylidene(ethyl) complex $Ta(CHCMe_3)(CH_2CH_3)Cl_2(PMe_3)_2$. β-Agostic interactions in dinuclear complexes are, to our knowledge, unknown, in contrast to the numerous reports of α-agostic interactions in dinuclear and particularly trinuclear cluster chemistry [51b,55]. While in most cases of agostic interactions the C–H bond is lengthened 5–10%, it is not always true that such bond lengthening is observed [51b]. The lack of possible back donation in **2a** from the d^0 Ta1 to the C21–H21A bond means that the postulated β-agostic interaction in **2a** would involve σ-activation without σ*-activation [56,57].

3. Conclusions

We have shown that allene reacts with **1** to give a new type of dinuclear allene coordination mode rather than mononuclear adducts or products derived from vinylic C–H bond activation. The allene ligand in **2a** is coordinated in a rarely observed bonding mode that can be described as a four-electron reduced metallallyl or, more properly, an alkylidene-diyl ligand. The remarkably short Ta1=C22 distance, planarity at C22, and twisting of the allene hydrogen atoms out of the C21–C22–C23 plane are consistent with this formulation. The probable existence of a β-agostic Ta1···H21A–C21 interaction is supported by the short Ta1···H21A distance, the location of the C21–H21A bond in a favorable position for interaction with an empty orbital on Ta1, the unusual high field ^{1}H NMR resonance for one allene hydrogen atom, and the disparate $^1J_{CH}$ values for the associated allene carbon atom.

We have shown recently that **2a** can be reduced by alkali metal amalgams in solution to the first propynylidene complex $(C_5Me_5)_2Ta_2Cl_2(\mu\text{-}H)_2(\mu\text{-}HCCCH)$ [58]. The proposed agostic C–H interaction in **2a** may assist the initial stages of this formal double C–H activation reaction.

The mechanism of reaction of allene with **1** is not known at present. The remote possiblility that **1** dissociates in solution to give solvated Cp^*TaX_2 which then reacts with allene to give a mononuclear allene adduct, followed by addition of a second equivalent of Cp^*TaX_2, has not yet been excluded. Addition of allene to the metal–metal triply-bonded $Cp_2Mo_2(CO)_4$ probably occurs by direct addition to the organodimolybdenum reactant, since no crossover product was noted [18] in the reaction of a mixture of $Cp_2Mo_2(CO)_4$ and $Cp_2W_2(CO)_4$ with allene.

4. Experimental

4.1. General

General procedures for glove box and Schlenk line manipulations, solvent purification, ligand preparation, mass spectrometry, infrared spectroscopy, and X-ray diffractometry have been published [59]. NMR spectroscopy was performed on a Bruker AMX-360 spectrometer operated in the internal deuterium lock mode with all chemical shifts reported in ppm (positive chemical shifts representing resonances at lower field strength than that of the standard). Proton spectra and selectively homodecoupled proton spectra at 360.17 MHz were referenced to the residual protio solvent impurity (C_6D_5H, δ 7.15; $CDHCl_2$, δ 5.32) in the respective perdeuterated solvent. Carbon-13 NMR spectra at 90.58 MHz were recorded in either the fully {^{1}H} or gated {^{1}H} mode and were

referenced to the solvent carbon-13 resonance (C_6D_6, δ 128.0; CD_2Cl_2, δ 53.8). Infrared spectra were recorded as either KBr pellets or concentrated Nujol mulls.

$Cp^*_2Ta_2(\mu\text{-}X)_4$ (X = Cl, Br) was prepared by sodium amalgam reduction [45] of Cp*TaX_4 [59] in toluene using mechanical stirring and filtration through oven-dried Celite prior to fractional crystallization. Allene (Matheson, Aldrich) was used as received.

4.2. Synthesis of $Cp^*_2Ta_2(\mu\text{-}Cl)Cl_3(\mu\text{-}C_3H_4)$

$Cp^*_2Ta_2Cl_4$ (0.50 g., 0.65 mmol) was dissolved in toluene (80 cm^3) in a 150 cm^3 2-neck flask equipped with magnetic stir bar, gas inlet adapter and septum. The flask was cooled to −78 °C and then allene (36 cm^3 at 20 °C, 1.5 mmol, 2.3 equiv.) was introduced into the green reactant solution via gas-tight syringe. The cooling bath was removed after one hour and the solution allowed to warm to room temperature with stirring. After 12 hours, the dark red solution was filtered to remove a very small quantity of insoluble impurity and the filtrate concentrated in vacuo to low volume. After cooling the solution to −35 °C, two crops of brown red crystals were collected by fractional crystallization and filtrate concentration, washed with hexane, and dried in vacuo. Total weight: 0.29 g (55% yield based on $Cp^*_2Ta_2Cl_4$). *Anal.* Calc. for $C_{23}H_{34}Cl_4Ta_2$: C, 33.93; H, 4.22; Cl, 17.41. Found: C, 34.13; H, 4.22; Cl, 15.74%. ^{1}H NMR (δ, C_6D_6, 25 °C): 1.66 (broad s, 2H, CH_2), 1.97 (s, 30H, C_5Me_5), 2.60 (broad s, 2H, CH_2). ^{1}H NMR (δ, CD_2Cl_2, 25 °C): 1.41 (m, 2H, CH_2), 1.70 (m, 2H, CH_2), 2.33 (s, 30H, C_5Me_5). ^{1}H NMR (δ, CD_2Cl_2, −95 °C, J_{HH} values based on selective decoupling of each allene ligand resonance): −0.36 (dd, 1H, CH, $^2J_{HH} = 14$ Hz, $^4J_{HH} = 10$ Hz), 0.09 (d, 1H, CH, $^2J_{HH} = 14$ Hz), 2.12 (s, 15H, C_5Me_5), 2.19 (s, 15H, C_5Me_5), 2.6 (overlapped d and broad singlet, *J* not resolvable, 2H, CHH). ^{13}C NMR (δ, gated {^{1}H}, CD_2Cl_2, 25 °C): 12.4 (q, $C_5\mathit{Me}_5$, $^1J_{CH} = 129$ Hz), 62.9 (t, CH_2, $^1J_{CH} = 160$ Hz), 122.5 (s, C_5Me_5), 206.9 (s, $CH_2=\mathit{C}=CH_2$). ^{13}C NMR (δ, gated {^{1}H}, CD_2Cl_2, −95 °C): 11.8 (q, C_5Me_5, $^1J_{CH} = 129$ Hz), 12.6 (q, $C_5\mathit{Me}_5$, $^1J_{CH} = 129$ Hz), 42.9 (dd, $\mathit{C}H_2=C=CH_2$, $^1J_{CH} = 173$, 154 Hz), 70.3 (t, $CH_2=C=\mathit{C}H_2$, $^1J_{CH} = 154$ Hz), 118.3 (s, C_5Me_5), 124.0 (s, C_5Me_5), 204.4 (s, $CH_2=\mathit{C}=CH_2$). MS (*m*/*e*): no parent ion observed; the highest ion, at *m*/*e* 776, was assigned to $Cp^*_2Ta_2Cl_3(C_3H_4)^+$ based on chlorine isotope pattern. IR (KBr pellet, concentrated Nujol mull): no discernible absorption between 2750 and 2200 cm^{-1}.

4.3. Synthesis and spectroscopic characterization of $Cp^*_2Ta_2Br_4(C_3H_4)$

The brown red bromide analog was prepared by the same procedure used for the chloride compound, by reaction of $Cp^*_2Ta_2$ (μ-Br)$_4$ (0.52 g, 0.55 mmol) with allene (26 cm^3 at 20 °C, 1.08 mmol, 2 equiv). Yield from two crops, 0.29 g (53%). ^{1}H NMR (δ, C_6D_6, 25 °C): 1.88 (s, broad, 2H, CH_2); 2.01 (s, 30H, C_5Me_5); 2.26 (s, broad, 2H, CH_2). ^{1}H NMR (δ, CD_2Cl_2, 25 °C): 1.30 (s, broad, 2H, CH_2); 1.49 (s, broad, 2H, CH_2); 2.32 (s, 30H, C_5Me_5). IR (KBr pellet, concentrated Nujol mull): no discernible absorption between 2750 and 2200 cm^{-1}.

4.4. X-ray data collection and structure determination

Crystals of **2a** were grown from toluene/hexane solution as dark red plates. A single crystal was mounted under nitrogen in a thin-walled glass capillary. Data was collected at 200 K on an Enraf-Nonius CAD-4 diffractometer and processed with the Enraf-Nonius MOLEN software package. Of 10090 total reflections collected in the range of $4° < 2\theta < 55°$, 5037 reflections with $F^2 > 2.0\sigma(I)$ were used in the structure solution and refinement.

4.4.1. Crystal data

$Ta_2Cl_4C_{23}H_{34}$, $M = 814.2$, triclinic, $a = 11.121(2)$ Å, $b = 16.979(4)$ Å, $c = 8.298(2)$ Å, $\alpha = 114.42(2)°$, $\beta = 105.49(2)°$, $\gamma = 105.01(2)°$; (35 reflections, $25° < 2\theta < 36°$, used in cell dimension determination), $D_c = 2.15$, $Z = 2$, space group $P\bar{1}$ (No. 2), $V = 1247(5)$, crystal dimensions = 0.17 × 0.28 × 0.34 mm, intensity standards decay = <2%, absorption coefficient = 9.20 mm^{-1}, analytical absorption correction method used, agreement between equivalent reflections = 0.035.

The structure was solved by direct methods. All the non-H atoms were refined with anisotropic thermal parameters, and the H atoms on C21 and C23 were located in a difference map and refined with $U_{iso} = 1.2 * U_{iso}$(carbon). The remaining H atoms on Cp* groups were included at calculated positions with calculated thermal parameters. $R = 0.054$ and $R_{w2} = 0.151$ with standard SHELXL97 weighting scheme $w = [\sigma^2(F_o^2) + (0.1105p)^2 + (4.9728p)]^{-1}$ (with $p = (F_o^2 + 2F_c^2)/3$) were obtained at final refinement. Standard deviation of unit weight was 1.071.

5. Supplemental material

Crystallographic data for structural analysis has been deposited with the Cambridge Crystallographic Data Center, CCDC 275641 for compound $(C_5Me_5)_2Ta_2(\mu\text{-}\eta^1,\eta^3\text{-}C_3H_4)(\mu\text{-}Cl)Cl_3$ (**2a**). Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 IEZ, UK (fax: +44-1223-336-033; e-mail: deposit@ccdc.cam.ac.uk or http://www.ccdc.cam.ac.uk).

Abstract

We report an investigation of the synthesis of a cobalt aluminate spinel composite from the heat-induced collapse of cobalt ion-exchanged sodium zeolite X. The work presented here adds to earlier studies by illustrating that by careful control of synthesis and reaction conditions, both the phase composition and crystallite size of the spinel can be controlled. The spinel crystallites grow within siliceous materials formed by the collapse of the zeolite framework, with the crystalline particles being completly shrouded by the siliceous matrix.

Keywords: Cobalt Aluminate; Synthesis; Zeolite; Transparent; Pigment; Ion-exchange

1. Introduction

Cobalt aluminate spinel, $CoAl_2O_4$, which imparts an intense royal blue colour arising from tetrahedral coordinated Co(II) ions, has been used extensively as an inorganic pigment [1–3]. This pigment is usually prepared by the calcination of the constituent oxides [4,5] or via a sol–gel reaction using mixed alkoxides or other metal organic compounds as starting materials [6–9].

Here we explore the potential of a process [10–14] which involves the heat-induced collapse of ion-exchanged zeolite X precursors for the synthesis of aluminate ceramics. Following the collapse of the framework structure, an amorphous phase is formed from the zeolite precursors, followed by the crystallisation of dense aluminate spinel particles. Interestingly, this synthesis route results in optically transparent aluminate micro-crystals which are completely shrouded by an amorphous siliceous phase from which the spinel particles have crystallised.

Zeolites [15–19] are microporous aluminosilicates which carry a counter cation to balance the negative framework charge that results from the substitution of silicon by aluminium. The materials reported in this paper were all prepared using sodium zeolite X – a Faujasite type zeolite having an approximate Si/Al ratio of 1.2 (Fig. 1). The extra-framework ions can be replaced by the process of ion-exchange and the balance of charge between this cation and the framework maintains charge neutrality. Therefore, assuming a complete ion-exchange of sodium zeolite X with cobalt(II) to synthesise cobalt zeolite X, the cobalt will be in a ratio of 1:2 with respect to the framework aluminium.

A Co(II)/Al(III) ratio of 1/2 for a fully ion-exchanged zeolite is therefore precisely the composition ratio of the cations in the target spinel phase. The ion-exchange procedure thus ensures that the elemental components of the aluminate are present in the correct stoichiometric ratio (see Scheme 1).

The elemental distribution of both constituent framework ions and guest (ion-exchange) cations is highly uniform since all of these elements are fixed at crystallographically defined sites. This perfect elemental distribution – on the atomic scale – ensures the uniform nucleation of phases from the zeolite 'precursor' [10,12]. Following the heat-induced

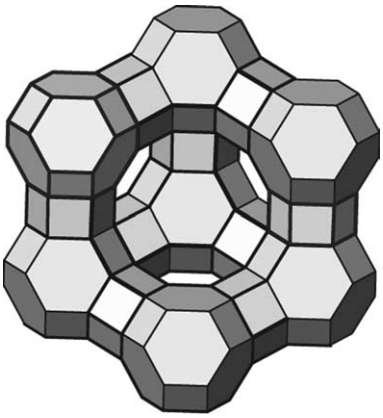

Fig. 1. A representation of zeolite X showing only the aluminosilicate framework. Extra-framework cations, for example Na^+, can be replaced by Co^{2+} (see Scheme 1) and this assembly forms the basis for the "precursor" for the cobalt aluminate spinel.

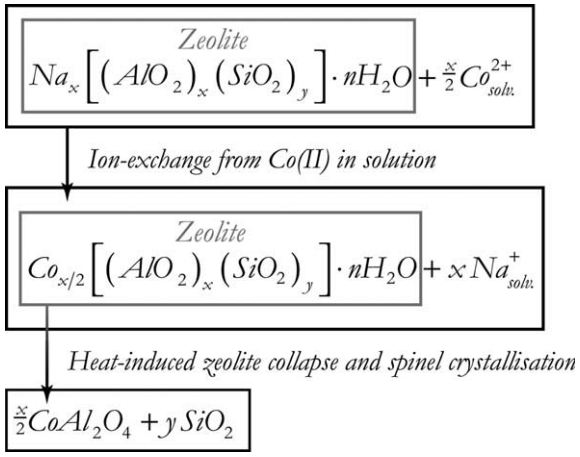

Scheme 1. A representation of the preparation of cobalt aluminate from a zeolite involving the process of (solution-based) ion-exchange and the heat-induced collapse of the ion-exchanged zeolite precursor to synthesise $CoAl_2O_4$ and siliceous materials.

collapse of the zeolite X framework, the elemental dispersion is maintained and the nucleation of the dense cobalt aluminate spinel phase precipitates homogeneously from within the amorphous matrix. By carefully adjusting the reaction and processing conditions, a high degree of control can therefore be exerted on the resulting cobalt aluminate micro-crystals.

The remaining framework silicon and oxygen form a siliceous shroud upon collapse that encases the micro crystals of cobalt aluminate. Thus, this synthesis route has the benefit of potentially limiting the escape of the harmful cobalt ion into the environment.

2. Experimental

Sodium zeolite X was prepared by a traditional hydrothermal synthesis route [19] using solutions of sodium metasilicate and sodium aluminate. The concentration of aqueous sodium metasilicate was increased slightly above the normal stoichiometric level to discourage the formation of zeolite A.

Cobalt zeolite X was prepared by ion-exchange, at 80 °C, of sodium zeolite X with an aqueous solution of cobalt chloride of concentration 0.1 M.

The cobalt-exchanged zeolite was then heated at various temperatures and samples interrogated using powder X-ray diffraction. Individual samples were synthesised at specific temperatures ranging from 200 to 1200 °C, for 12 h with a heating rate of 300 °C per hour.

X-ray diffraction measurements were carried out using a Bruker Axs D5005 diffractometer operating in reflection mode. The diffractometer was fitted with a Gobel Mirror, which produced a parallel Cu Kα beam of wavelength 1.5418 Å. Normally the D5005 is fitted with a position sensitive detector, PSD. For variable temperature work the PSD was replaced with a scintillation detector and an Anton-Parr HTK 1200 °C furnace was fitted. Phase identification was undertaken using the Diffrac-AT software and JCPDS database card system.

Electron microscopy images were obtained using a Philips CM20 transmission electron microscope (TEM), operating at a voltage of 100 kV, and a JEOL JSM-5410 Scanning Electron Microscope (SEM), using an operating voltage of 40 kV. UV–Vis measurements were obtained using a Unicam UV500 UV/Vis spectrometer operating in diffuse reflectance mode.

3. Results and discussion

Sodium zeolite X (Na–X) and corresponding cobalt zeolite X (Co–X) were examined by X-ray diffraction in order to assess their phase purity and crystallinity. The results are presented in Fig. 2.

These diffraction data reveal that the Na–X was highly crystalline, particularly evident in the sharp diffraction peaks at high angle. Conversely, the lack of high angle reflections in the Co–X zeolite suggests that the acidic cobalt ion-exchange solution has initiated some damage to the zeolite framework with a corresponding reduction in sample crystallinity. The diffraction data also demonstrate that no zeolite A is present.

As cobalt aluminate is a highly coloured material, it was apparent from visual examination that for samples fired at temperatures below 800 °C there was little or no evidence of cobalt aluminate formation (Fig. 3). This was evident in the marked colour difference between the sample synthesised at 700 °C, where the sample appears beige, and 800 °C where a blue colour can clearly be seen.

The conclusions drawn from the visual examination were confirmed using variable temperature X-ray diffraction; data were collected over a 20–70 ° 2θ range from 25 to 1100 °C in incremental steps of 25 °C (Fig. 4).

The variable temperature diffraction data reveal that diffraction peaks corresponding to the zeolite X completely disappeared before those corresponding to cobalt aluminate began to appear. Thus it appears that the cobalt aluminate

Fig. 3. Co–X materials thermally collapsed at various temperatures. The onset of a blue colouration, characteristic of cobalt aluminate formation, can clearly be seen for the sample fired at 800 °C.

and other phases crystallise from the initial amorphous phase which is synthesised as a result of the heat-induced zeolite collapse. We can further ascertain the temperature for the initiation of aluminate formation. The horizontal

box which runs parallel along the 2θ axis in Fig. 4 shows the position of this transition as being between 748 and 773 °C, which confirmed our visual observation that the sample synthesised at 700 °C contained no cobalt aluminate. The increase in relative intensity of the zeolite (111) peak at $2\theta = 6.372°$ is also noteworthy (highlighted by a vertical box in Fig. 4) and is due to the gradual dehydration of the zeolite. Because of the speed at which the X-ray diffraction scans were obtained, the data were of insufficient quality to provide further detailed information. Furthermore, due to the nature of the change in phase from Co–X zeolite, an open framework solid, to cobalt aluminate – a condensed solid – a decrease in sample volume occurred. As a result the surface of the alumina sample holder became exposed to the incident X-ray beam and a partial diffraction pattern of the alumina was recorded with that of the sample, further complicating any detailed interpretation.

X-ray data were therefore collected on a range of samples, each fired at a given temperature, from 800 to 1200 °C, to further probe the growth mechanism of the cobalt aluminate and associated phases (Fig. 5).

From Fig. 5 one can see that at synthesis temperatures below 1100 °C mullite [20] – general formula $Al_6Si_2O_{13}$ – was synthesised along with cobalt aluminate [21]. The reflections of cobalt aluminate have been identified by arrows in Fig. 5 bearing the *hkl* indices to which they relate. A reflection of mullite is highlighted in dark grey. At higher synthesis temperatures the mullite reflection disappears and is replaced by a diffuse diffraction peak running between 2θ values of 15° and 25°, highlighted in pale grey in Fig. 5. This is indicative of a poorly crystalline material and is attributed to siliceous material, since this is the most likely co-product given the composition of the amorphous phase formed by the zeolite collapse (Scheme 1). Finally, for samples prepared at 1200 °C there is evidence of the silica coe-

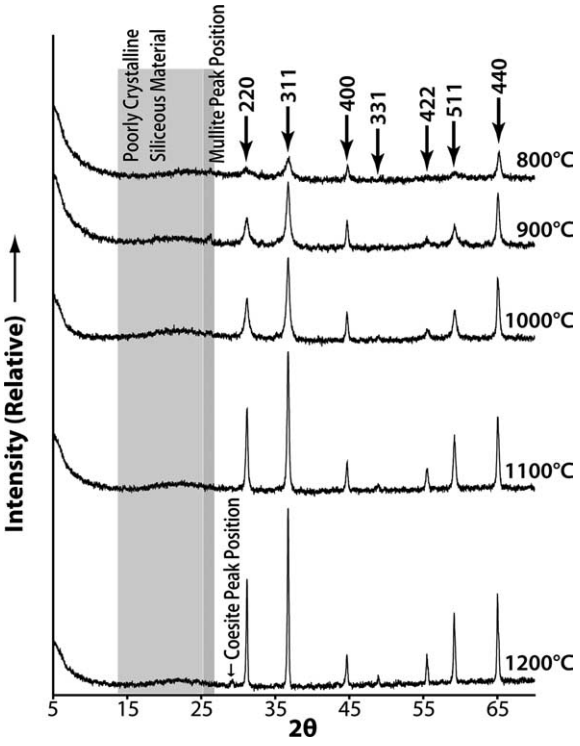

Fig. 5. X-ray diffraction data for separate materials synthesised from 800 to 1200 °C in 100 °C steps.

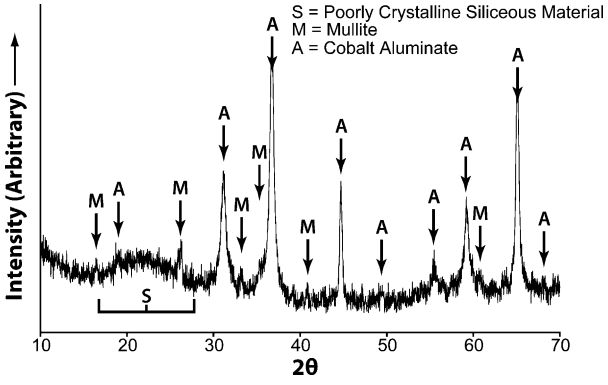

Fig. 6. X-ray diffraction data for cobalt aluminate synthesised at 900 °C.

site [22] of general formula SiO_2. The evidence for these phases can be more readily be seen by examining the individual patterns where the reflections are strongest (Figs. 6 and 7).

In Fig. 6 we can clearly identify mullite [20] and cobalt aluminate [21] as well as a diffuse diffraction peak that most likely represents some residual poorly crystalline siliceous material.

The formation of mullite, $Al_6Si_2O_{13}$ suggests that there was insufficient cobalt to allow all of the framework aluminium to be utilised in cobalt aluminate formation. This could possibly arise because of incomplete ion-exchange. If this is the case then sodium should also be present in the amorphous phase formed after zeolite collapse, represented by the diffuse diffraction peak, labelled 'S' in

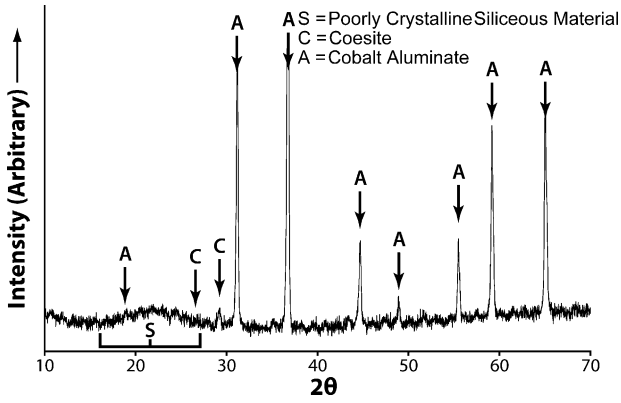

Fig. 7. X-ray diffraction data for cobalt aluminate synthesised at 1200 °C.

Fig. 6. Further elaboration of the composition of this amorphous phase is ongoing. Evidence of the presence of mullite was visible in the diffraction patterns of the samples synthesised in the range 800–1100 °C. Weidenthaler et al. [12] found only the reflections of cobalt aluminate in their collapsed Co–X materials at temperatures below 1100 °C and no evidence of mullite was reported.

As the synthesis temperature increases, the high temperature silica, coesite [22], gradually becomes visible (Fig. 7) together with a clear sharpening of the powder X-ray diffraction peaks for cobalt aluminate. The reflections from coesite are weak, however, and it is likely that the majority of the silica from the zeolite's framework is still poorly crystalline. This phase could also contain elements other than silicon and oxygen: aluminium and sodium, for example. At temperatures above 1100 °C Weidenthaler et al. [12] report finding the silica cristobalite, where we find coesite.

The growth of various phases and their subsequent disappearance can be partially explained in terms of Si/Al ratio, the ion-exchange level and the initial composition of the amorphous phase formed from the collapsed zeolite precursor. Once the zeolite has collapsed, there will exist a complex system of reactions, which result in the growth of many phases in competition each other. For example, the aluminium-containing mullite phase disappears at high temperature. It is possible that at high temperature the formation of cobalt aluminate becomes more favourable than that of mullite, thus the mullite phase is dissolved into the low crystallinity siliceous phase as the aluminium is scavenged by the formation of cobalt aluminate. At higher temperatures (above 1100 °C), a crystalline silicate, coesite, appeared. The growth of the coesite phase seems to coincide with the disappearance of the mullite phase. It could also be possible that the coesite is a product of the reconfiguration of the mullite, after sacrifice of the aluminium in the formation of cobalt aluminate.

The cobalt aluminate crystallite size was determined from the X-ray powder diffraction data (Fig. 5) using the Scherrer equation, below [23]

$$L_{hkl} = \frac{K\lambda}{\beta_{hkl}\cos\theta}$$

Table 1
A table of cobalt aluminate crystallite dimensions as calculated by the Scherrer equation

Synthesis temperature (°C)	Particle size in nm	
	$2\theta = 31.294$ (220) Peak	$2\theta = 36.743$ (311) Peak
800	14.6	12.5
900	14.3	19.6
1000	17.7	21.7
1100	28.8	32.1
1200	43.1	44.8

where K is a constant, normally equal to 1, λ is the wavelength of the incident X-ray radiation, 1.5418 Å in this case. The value θ is half of 2θ the position of the reflection, in radians, from which the value β_{hkl} is taken. β_{hkl} is the full width at half maximum height of the analysed reflection, given in angstroms and L_{hkl} is the particle diameter in angstroms. Table 1 shows the calculated particle diameters, in nm, for materials produced at various temperatures.

The Scherrer equation provides a volume-weighted statistical average of particle diameters. Thus it is best to treat the derived particle sizes obtained in this way as no more than a guide. However, one can readily discern that the spinel particle size increases with increasing synthesis temperature, as observed in earlier studies [12–14].

In Fig. 8 we show the trends in spinel crystallite size with increasing temperature of the synthesis process. Obviously, heating the material at higher temperatures leads to the formation of larger spinel micro-crystals, as indicated by the sharper powder X-ray diffraction reflections. We note that the rate of increase is approximately the same for each reflection. We have also used TEM (Fig. 9) to provide further direct information on crystallite size and morphology.

From these TEM data one can readily discern the cobalt aluminate micro-crystals suspended in, and covered by, a substrate which is more permeable to electrons; we believe that the particles consist of spinel micro-crystals covered by a siliceous matrix. This matrix shrouds the micro-crystals and blocks their surfaces. The micro-crystals, also noted by earlier workers [10–14], appear to be in the size regime

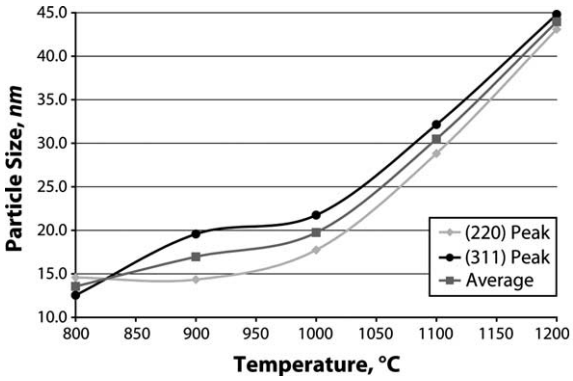

Fig. 8. A graph showing the trend in cobalt aluminate crystallite diameter against synthesis temperature.

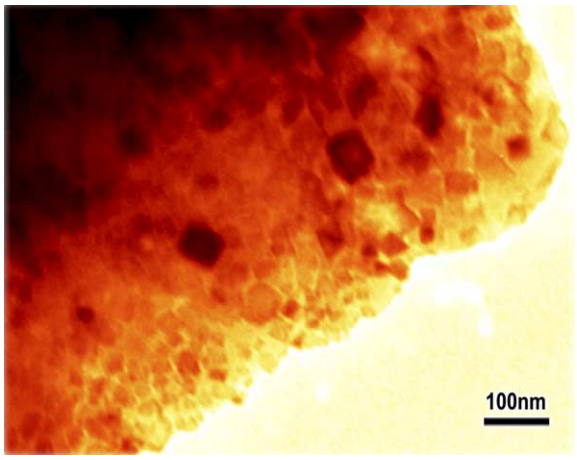

Fig. 9. A TEM micrograph of cobalt-exchanged zeolite X collapsed at 1000 °C. The cobalt aluminate spinel micro-crystals can clearly be seen in contrast to the encapsulating siliceous host.

between 15 and 60 nm, as suggested by the Scherrer equation.

SEM images were also obtained from samples produced at 800 °C (image 'a'), 900 °C (image 'b') and 1000 °C (images 'c' and 'd'). At lower temperatures the particles were irregular in shape and had uneven surfaces. As the synthesis temperature is increased the siliceous compounds start to become mobile and some of the particles exhibit a spherical shape. One such particle is shown enlarged in Fig. 10 image 'd'. The small white areas on the surface may be exposed areas of cobalt aluminate.

As our primary interest in these compounds was as potential pigment materials, UV/Vis spectroscopic measurements were also obtained for samples produced at 800 °C and above (Fig. 11).

The UV/Vis spectra reveal that the intensity of the cobalt aluminate colour centre increased with increasing synthesis temperature. This can be seen in the increase in absorbance in the 200–400 nm and 500–675 nm regions.

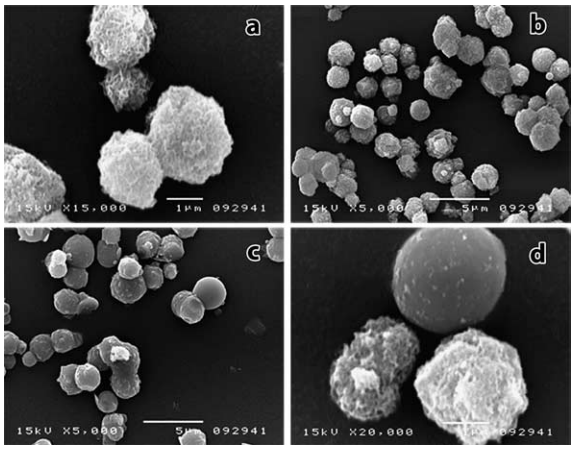

Fig. 10. Four SEM images from samples produced at 800 °C, image 'a', 900 °C, image 'b', and 1000 °C, images 'c' and 'd'. The scale bars represent 1 μm (a,d) and 5 μm (b,c).

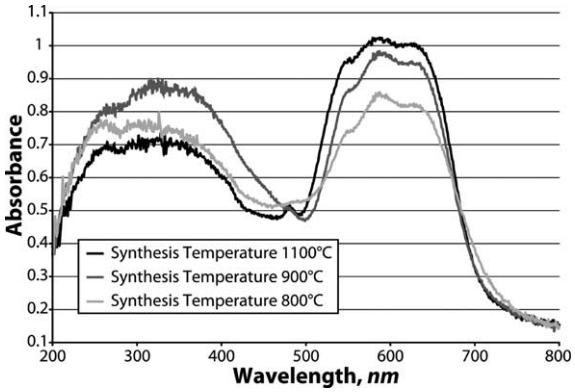

Fig. 11. Diffuse reflectance UV/Vis spectra of samples produced at various temperatures.

These data support our visual observation of the samples (Fig. 3) and also explain the paleness of the blue colour seen in samples produced at low temperature. This difference in colour intensity could be due to a particle size effect, the more divided the material, the more diffuse and less intense the colour [1], or simply due to the fact that less cobalt aluminate is present in the sample. If the particle size is small enough, however, there exists the possibility that the particles will be optically transparent [1].

In order to test this proposition, samples were suspended in silicone oil. The particular oil was chosen as it has a refractive index close to that of glass and is colourless and transparent. By observing the suspensions in front of cards of various colours and under various lighting conditions, it was possible to determine that the colour of the samples was due largely to transmitted light. For cobalt aluminate samples prepared at lower synthesis temperatures almost all the colour was the result of transmitted light. Further experimentation demonstrated the transparency of our samples within a polymer host (Fig. 12).

Fig. 12 shows our sample dispersed in a polymer and spread on a glass slide, part of which is black and part of which is white. The observation that the blue colouration was only evident on the white part demonstrated that the colour was due to transmission and not reflection.

Fig. 12. A film of micro crystals of cobalt aluminate dispersed in a polymer and deposited on a glass support.

4. Conclusions

We have shown that the controlled heat-induced collapse of cobalt zeolite X provides a highly effective route to producing micro crystals of cobalt aluminate shrouded in a coating of siliceous materials, which should help prevent leaching of cobalt into the environment. Schmidt et al. [13,14] found that the cobalt aluminate micro-crystals could be freed from their siliceous shroud for use as high surface area catalysts.

Our results suggest that the collapse of cobalt-exchanged zeolite X produced an amorphous phase in which a complex series of competing reactions take place to produce a dense spinel micro-crystals covered by a siliceous matrix. The fact that the work of Weidenthaler et al. [12] showed different crystalline phases is thus perhaps not surprising as there are many factors which could alter the components of the final crystalline phase after the collapse of the zeolite. These include; the Si/Al ratio of the original zeolite, the extent of ion-exchange, the temperature at which the zeolite was collapsed and, most probably, the duration of the heating of the amorphous phase after zeolite collapse. There exists here a system of great interest worthy of further study and experimentation.

This work, therefore, adds to the earlier pioneering work of Colyer et al. [10,11] in demonstrating the significant potential of materials prepared from the heat-induced collapse of ion-exchange zeolites for the synthesis of aluminosilicate-based ceramics.

Acknowledgements

We thank the EPSRC for their financial support. It is a great pleasure – and a great honour – to be part of these celebrations for our colleague Professor Chisholm on this very happy occasion.

In celebration of Professor Malcolm H. Chisholm, our inspirational friend, colleague and mentor, on the occasion of his 60th birthday.

Abstract

Density functional theory has been used to explore the bonding and geometric preferences of tris-Cp zirconium and hafnium compounds of the type Cp_3MX. In most cases, two primary isomers were found: a "**3-5**" isomer, which contains three η^5-Cp ligands, and a "**2-5,1-1**" isomer, which contains two η^5-Cp and one η^1-Cp ligands. The relative energies of these isomers are dependent upon the π-donor ability of the X ligand. For the tris-Cp methyl compounds, the "**3-5**" isomers are more stable by 1–4 kcal/mol. The "**2-5,1-1**" isomers of the tris-Cp alkoxide and amido compounds are more stable by 3–6 and 6–11 kcal/mol, respectively. Bonding analyses show these binding preferences can be understood in terms of π-competition between the tris-Cp ligand set and the lone pair of the X ligand. π-loading on the X ligand decreases the π-donor ability of the "**3-5**" tris-Cp ligand set, which increases the preference for the "**2-5,1-1**" ground state geometry in the complexes with strong π-donors. In addition, molecular orbital theory provides evidence for destabilization effects arising from filled–filled interactions between the "**3-5**" Cp_3M fragment and the X lone pair.

1. Introduction

The bonding of three cyclopentadienyl (Cp) ligands to a metal center in Cp_3MX (M = Zr, Hf; X = H, CH_3, OR, NR_2) compounds leads to a variety of different bonding modes. The three Cp ligands can all bind in an η^5 fashion, which we refer to as a "**3-5**" geometry. Another bonding mode involves two η^5-Cp ligands and one η^1-Cp ligand, which we refer to as a "**2-5,1-1**" geometry. Alternatively, two Cp ligands can bind in an η^5 fashion with the other Cp ligand binding in an η^2 fashion, which we refer to as a "**2-5,1-2**" geometry. These bonding modes are shown in Fig. 1.

Our current interest in tris-cyclopentadienyl (tris-Cp) compounds of the Group IV transition metals stems from our earlier theoretical work on tris-Cp f-element compounds [1]. tris-Cp lanthanide complexes have been structurally characterized and shown to exhibit interesting structural chemistry across the lanthanide series [2]. Although these complexes exhibit very little notable reactivity, Evans has recently shown that reductive chemistry can be induced in tris-Cp lanthanide complexes when the Cp ligands are replaced with larger pentamethylcyclopentadienyl (Cp*) ligands [3]. The availability of a variety of oxidation states in the actinide series leads to a much richer reaction chemistry involving tris-Cp actinide compounds relative to their lanthanide counterparts [4]. For example, tris-Cp actinide compounds have been used as precursors to compounds containing actinide-transition metal single

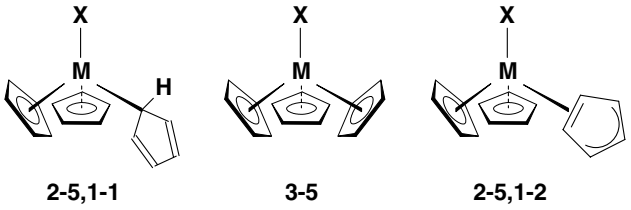

Fig. 1. Known bonding modes of three cyclopentadienyl (Cp) ligands around a transition metal center. Compounds containing two η^5-Cp and one η^1-Cp ligands (left) are referred to as having a "**2-5,1-1**" geometry. Compounds containing three η^5-Cp ligands (middle) are referred to as having a "**3-5**" geometry. Compounds containing two η^5-Cp and one η^2-Cp ligands (right) are referred to as having a "**2-5,1-2**" geometry.

bonds [5], and substituted tris-Cp actinide compounds were seminal in isolating the first terminal end-on actinide metal dinitrogen compound [6].

Despite the large number of tris-Cp lanthanide and actinide compounds that have been synthesized and structurally charaterized, only a few examples of tris-Cp compounds involving transition metals have been reported in the literature. Although tris-Cp compounds of Group III [7] and Group VI [8] transition metals are known, the Group IV transition metals provide the most examples and greatest diversity within the tris-Cp class of compounds. The crystal structure of Cp_3Ti exhibits a "**2-5,1-2**" structure [9], while the crystal structure of Cp_3Zr exhibits a "**3-5**" structure [10]; this structural difference is attributed to the larger size of zirconium, which is better suited to accommodate the sterically cumbersome "**3-5**" ligand set.

Oxidation of the M(III) Cp_3M compounds to M(IV) Cp_3MX compounds allows for a diverse set of Cp_3MX complexes, where X can be a hydride, alkyl, or halide. The tetrakis-Cp compounds, which can be viewed as a special case of tris-Cp compounds where X is a cyclopentadienyl ligand, are the most familiar examples within the organometallic community. The crystal structures of Cp_4Ti, which contains two η^5-Cp and two η^2-Cp ligands [11], and Cp_4Zr, which contains three η^5-Cp and one η^1-Cp ligands [12], are consistent with those observed for the Cp_3M(III) compounds. The crystal structure of Cp_4Hf shows that Cp_4Hf is isostructural with Cp_4Ti rather than Cp_4Zr [13]. Interestingly, this was the first example of analogous zirconium and hafnium compounds that exhibited significantly different structural chemistry. We have shown that the chloride complexes Cp_3ZrCl and Cp_3HfCl (Cp = cyclopentadienyl or substituted cyclopentadienyl) exhibit similar structural duality; the Zr complexes invariably adopt "**3-5**" structures whereas the Hf complexes exhibit "**2-5,1-1**" structures [14].

There have been relatively few studies of the structures of other Cp_3MX complexes. The synthesis of Cp_3MH (M = Zr, Hf) was reported by Brainina and co-workers [15]. Although no crystal structure data were obtained, IR spectroscopy indicated that both compounds exhibit a "**3-5**" structure. This "**3-5**" structure for Cp_3ZrH was supported by the X-ray structure of the triethyl aluminum adduct of Cp_3ZrH [16]. The efforts of Erker and co-workers [17] have led to the characterization of a large number of Group IV tris-Cp compounds. They have shown that the crystal structure of Cp_3ZrCH_3 exhibits a "**3-5**" tris-Cp geometry. In addition, Erker et al. [18] also reported a variety of Cp_3M^+ (M = Zr, Hf) cations stabilized by weak σ-donor ligands, all of which were shown to exhibit a "**3-5**" structure in the solid state. The addition of bulky substituents onto one of the Cp ligands in tris-Cp zirconium compounds can influence the overall binding preference of the tris-Cp ligand set. Lawless and co-workers [19] reported a crystal structure for $(C_5H_5)_2(C_5H_3t\text{-}Bu_2)ZrBr$, which possesses two η^5-Cp ligands and an asymmetrically bound η^2-C_5H_3t-Bu_2 ligand. This complex is the only reported tris-Cp zirconium compound that has been structurally characterized and does not have a "**3-5**" geometry.

The structural diversity exhibited by these Cp_3MCl complexes has caused us to ask what factors about the axial ligand X can affect the ultimate structure. Theoretical investigations have been used previously to explain the apparent exception to the 18-electron rule found for "**3-5**" Cp_3MX compounds [20], but few investigations have focused on the structural preferences for the bonding mode of the three Cp ligands around a transition metal center. Erker and Berke have shown that density functional theory (DFT) calculations of their Cp_3M^+ cations stabilized by weak σ-donor ligands correctly predict the "**3-5**" isomer to be more stable than the "**2-5,1-1**" isomer for all of these compounds [18], an observation that leads one to ask what factors of ligand X can cause the structure of the Cp_3M moiety to change. In their seminal studies of metal–alkoxide and metal–amido complexes, Chisholm and co-workers [21], and others, have demonstrated the influence of ligand π-donation on overall structure. In this contribution, we will use DFT to examine the importance of the π-donor ability of the X ligand in Cp_3MX compounds on the binding preferences of the tris-Cp ligand set. The relative bonding energies of the "**3-5**" and "**2-5,1-1**" isomers of tris-Cp metal hydride and alkyl compounds will be compared with those of the analogous tris-Cp metal alkoxide and amido compounds. Population analyses and molecular orbital theory will be used to explain the different ground state geometries calculated for these two groups of compounds.

2. Computational details

DFT calculations were performed using the Amsterdam density functional (ADF) package, Version

2003.01, developed by Baerends et al. [22–24]. All geometry optimizations were carried out with no symmetry constraints under the C_1 point group using the local exchange-correlation potential of Vosko et al. [25] and the non-local exchange and correlation corrections of Perdew and Wang (PW91) [26]. The frozen core approximation was applied to all atoms except H. 1s was frozen for C, N and O, 1s–3d was frozen for Zr, and 1s–4f was frozen for Hf. For H, C, N, and O, the ADF Basis TZ2P was used, which is a core double-ζ, valence triple-ζ Slater-type orbital (STO) doubly-polarized basis set. For Zr and Hf, the ADF Basis TZP was used, which is a core double-ζ, valence double-ζ STO doubly-polarized basis set. Relativistic effects were included in all calculations using the zero-order regular approximation (ZORA) formalism and ZORA basis sets [27–31]. All geometry optimizations were performed using an integration parameter of 6.0 and were optimized to a maximum gradient of no more than 0.0001 hartree/Å. Frequencies were calculated by numerical differentiation of the first derivatives of the energy gradients in slightly displaced geometries using double-sided displacements [32,33].

3. Results and discussion

3.1. MO description of the Cp bonding in 3-5 Cp_3MX compounds

First presented by Reynolds and Wilkinson [34] in relation to organoactinide compounds and Pappalardo and Jørgensen [35] in connection with tris-Cp lanthanide complexes, the bonding of "**3-5**" tris-Cp transition metal compounds has been discussed previously by Hoffmann [20] and our group [1e], but a brief review is warranted here. In "**3-5**" tris-Cp compounds, the major orbital interactions involve the doubly-degenerate π_2 orbitals of the Cp ligands and the valence metal d-orbitals. When three Cp ligands are bonded to a metal under C_{3v} symmetry, the set of six π_2 Cp orbitals transforms as $a_1 + a_2 + 2e$ with the a_2 orbital being the ligand–ligand anti-bonding HOMO. Under C_{3v} symmetry, the metal d-orbitals transform as $a_1 + 2e$. As a result, the Cp_3-based a_1 combination is allowed by symmetry to interact with the p_z and d_{z^2} metal valence orbitals, although these contributions are small; the d_{z^2} orbital interacts primarily in a σ-fashion with the X ligand. The lower energy Cp_3-based e orbital interacts with the $d_{x^2-y^2}$ and d_{xy} metal orbitals to form the 14e molecular orbital, while the higher energy Cp_3-based e orbital interacts with the d_{xz} and d_{yz} metal orbitals to form the 15e molecular orbital. The principal M–Cp_3 interactions that result are illustrated in Fig. 2.

Interestingly, the Cp_3-based $5a_2$ HOMO does not have the appropriate symmetry for interaction with a transition metal due to the threefold symmetry of the molecule. As a result, the π_2 $5a_2$ orbital is rigorously ligand–metal non-bonding for a transition metal (although the $5a_2$ is allowed to interact with an f orbital in Cp_3-actinide complexes). The tris-Cp ligand set is thus formally a 16-electron donor to a transition metal [20]. Therefore, with the donation of two electrons from the X ligand, "**3-5**" Cp_3MX complexes obey the 18-electron rule. Similar symmetry arguments have been used to explain the bonding in several $(acetylene)_3WCO$ compounds [36] and $Zr(BH_4)_4$ [37].

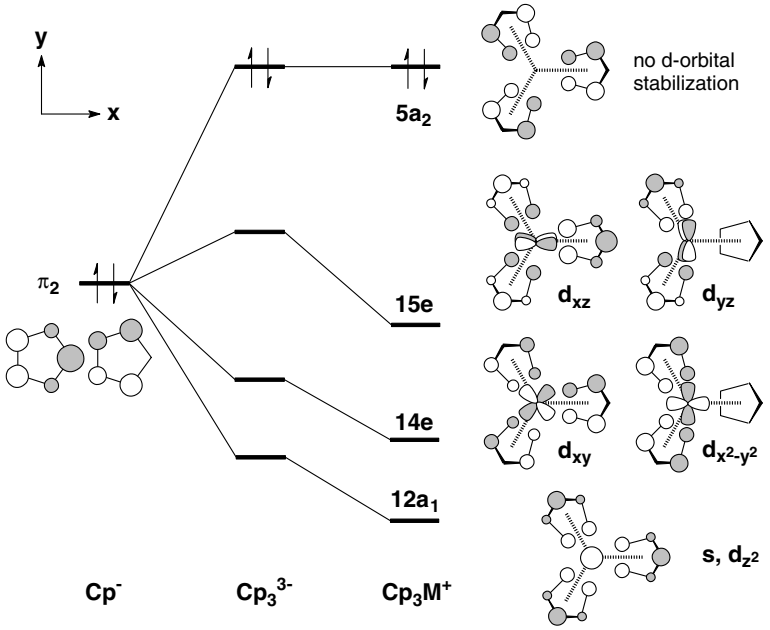

Fig. 2. Bonding interactions between the metal d-orbitals and the π_2 orbitals of the Cp_3 ligand set.

3.2. Calculated structures and relative energies

Full geometry optimizations of Cp_3ZrH (**1**) and Cp_3HfH (**2**) located the "**3-5**" structures along the potential energy surface. However, all attempts to locate either a "**2-5,1-1**" or "**2-5,1-2**" local-minimum geometry failed as these calculations always optimized to the "**3-5**" structure when no symmetry constraints were placed on the system.[1] Selected calculated bond distances and angles for **1** and **2** are compiled in Table 1. These results are consistent with IR data provided by Brainina and co-workers [15], which suggested that both **1** and **2** exhibit a "**3-5**" structure. A double-sided frequency calculation of **1** calculated a Zr–H stretching frequency of 1600 cm^{-1}, which is in excellent agreement with the experimental value of 1603 cm^{-1}. A similar frequency calculation of **2** determined a Hf–H stretching frequency of 1656 cm^{-1}, which agrees well with the experimental value of 1670 cm^{-1}. The good agreement between the calculated and experimental M–H stretching frequencies suggests that DFT is a viable tool for correctly predicting experimental observables of tris-Cp compounds.

In addition to the "**3-5**" isomers, full geometry optimizations located a "**2-5,1-2**" isomer for Cp_3ZrCH_3 (**3**), which has an asymmetrically bound η^2-Cp ligand,[2] and a "**2-5,1-1**" isomer for Cp_3HfCH_3 (**4**). **3** and **4** were found to be more stable in the "**3-5**" geometry by 4.3 and 1.3 kcal/mol, respectively, which is consistent with the crystal structure of **3** as reported by Erker [17]. The calculated Cent-Zr–Cent and Cent-Zr–CH_3 bond angles of 98° and 118°, respectively, are in agreement with the crystal structure data. Not surprisingly, the calculated average Zr–C(π) distances are 0.06 Å longer than those determined from the crystal structure (2.65 Å calculated versus 2.59 Å from the crystal data). Computational problems associated with correctly predicting M–C(π) bond distances involving Cp ligands have been well documented in the literature [38]. Surprisingly, the DFT calculations grossly overestimate the Zr–CH_3 length by 0.059 Å (2.354Å calculated versus 2.295 Å from the crystal data). All attempts to search for a geometry with a shorter Zr–CH_3 bond length while maintaining a "**3-5**" geometry failed. One may conclude that DFT does a poor job at reproducing the crystal structure of **3**, but the crystal structure determination of **3** was not without problems.[3] It is important to note that despite these shortcomings in predicting the Zr–CH_3 bond length, the relative bonding energies are consistent with the experimentally observed ground state structure of **3**.

Not unexpectedly, the calculated M–C(π) bond distances in the "**3-5**" structures are considerably longer than those calculated for the "**2-5,1-2**" and "**2-5,1-1**" structures due to the increased steric bulk of the "**3-5**" tris-Cp ligand set. This elongation of the M–C(π) bond distances in the "**3-5**" structures is consistent with X-ray crystal data, which shows considerably longer M–C(π) bond distances in Cp_4Zr [12], Cp_3ZrCl [14], and Cp_3ZrCH_3 [17] than in other bent bis-metallocene zirconium compounds [39]. The relief of steric congestion around the metal center is also responsible for shortening the Zr–Me bond length in the "**2-5,1-2**" structure.

A comparison of the total bonding energies of the "**3-5**" and "**2-5,1-1**" geometries of Cp_3ZrOH (**5**) and Cp_3HfOH (**6**) indicates that the "**2-5,1-1**" structures are more stable for **5** and **6** by 2.8 and 6.3 kcal/mol, respectively. Similar results are obtained for Cp_3ZrOCH_3 (**7**) and Cp_3HfOCH_3 (**8**), which are more stable as "**2-5,1-1**" isomers by 3.0 and 6.1 kcal/mol, respectively. One primary structural difference between the "**3-5**" and "**2-5,1-1**" geometries of complexes **5** through **8** is the M–O bond distance, which is much shorter in the "**2-5,1-1**" structures than in the "**3-5**" structures. Although this observation is consistent with the relief of steric congestion on going from a "**3-5**" geometry to a "**2-5,1-1**" geometry as was observed for **3** and **4**, a major contribution to the bond contraction in complexes **5** through **8** is the increase in π-donation from the hydroxide and alkoxide ligands to the electron-deficient metal center in the "**2-5,1-1**" geometry. The importance of π-donation is demonstrated by comparing the magnitude of the decrease in the M–X bond

[1] A "**2-5,1-1**" geometry for both Cp_3ZrH and Cp_3HfH was located when the molecules were forced to have C_s symmetry containing a mirror plane bisecting the Cent–M–Cent plane and lying in the C(σ)–M–H plane. In this conformation, the geometry optimization led to an unusual α-agostic interaction between the C(σ)–H bond of the η^1-Cp ligand with a M–C(σ)–H bond angle of less than 90°. A frequency calculation produced one imaginary frequency and is indicative of a transition state for the rotation about the M–C(σ) bond vector.

[2] The two Zr–C bond lengths involving the η^2-Cp ligand were calculated to be 2.488 and 2.673 Å. Although these distances indicate a much more asymmetrically bound η^2-Cp ligand than that found in the crystal structure of $Cp_2(\eta^2\text{-}C_5H_3tBu_2)ZrBr$, Erker and Berke reported a similar structure for Cp_3TiMe (see footnote 3 in [18]).

[3] The wR_2 for the final R indices was 0.1696 and the goodness-of-fit of F^2 was 1.121, both of which are unusually large values. The crystal structure indicates essentially five equivalent Zr–C(π) lengths, which vary by only 0.007 Å, and three symmetry-equivalent η^5-Cp ligands. This disagrees with our optimized geometry, which shows a variation of about 0.05 Å in the Zr–C(π) distances and three η^5-Cp ligands that are considerably distorted from an idealized C_3 symmetry. This calculated variation in the Zr–C(π) distances is consistent with other structurally characterized tris-Cp zirconium compounds, all of which show significant variations in their Zr–C(π) bond lengths. In addition, the fact that the Zr–C(σ) distance determined from the crystal structure of **3** is comparable to those found in bis-zirconocene compounds is bothersome. The increased steric demands of the "**3-5**" geometry would be expected to increase the Zr–C(σ) bond length in **3**. This trend is observed in all of our calculations, for the Zr–Cl distance in the crystal structure of Cp_2ZrCl_2 versus Cp_3ZrCl (see [14]), and for the M–C(σ) distances in the crystal structure of Cp_4Zr versus Cp_4Hf.

length, which is 0.02 Å in methyl complex **3** and 0.04 Å in hydroxide complex **5**. In addition, this increased π-donation is supported structurally by the observation that the dihedral angle between the C(σ)–M–O and M–O–H planes is 90° in **5** and **6**, a conformation that maximizes π-donation, and by an increase in the M–O–R bond angle of 18° and 13° in the "**2-5,1-1**" geometries of **7** and **8**, respectively. These calculated structural data are summarized in Table 1, and the calculated structures of **5** and **7** are shown in Fig. 3.

Similar binding preferences were observed for tris-Cp zirconium and hafnium amido complexes. Both "**3-5**" and "**2-5,1-1**" geometries were located on the potential energy surfaces for Cp_3ZrNH_2 (**9**) and Cp_3HfNH_2 (**10**), each preferring the "**2-5,1-1**" geometry by 6.3 and 9.9 kcal/mol, respectively. The geometry of the amido ligand nicely illustrates the change in π-donation in going from the electronically saturated metal center in the "**3-5**" geometry to the electron-deficient metal center in the "**2-5,1-1**" geometry. In the "**3-5**" structure of **9**, the amido ligand is pyramidalized as the Zr–N–Mid angle is 144°, where Mid is the midpoint between the two hydrogen atoms of the amido ligand. Although highly unusual, transition metal compounds containing pyramidal amido ligands are not unprecedented but are limited to electron-rich late-transition metal complexes [40]. In the "**2-5,1-1**" structure of **9**, the geometry of the amido ligand is trigonal planar as evidenced by a Zr–N–Mid angle of 180°, and the dihedral angle between the C(σ)–Zr–N and H-N–H planes is 90°, which is consistent with optimum π-donation into the metal center.

Comparable relative binding energies were obtained for $Cp_3ZrN(CH_3)_2$ (**11**) and $Cp_3HfN(CH_3)_2$ (**12**), which were more stable in the "**2-5,1-1**" geometry by 7.3 and 10.8 kcal/mol, respectively. However, the amido ligand is less pyramidalized in the "**3-5**" structure of **11** than in **9** as is shown by the increased Zr–N–Mid angle to 162° in **11**, where Mid is the midpoint between the two carbon atoms of the amido ligand. In addition, in the "**2-5,1-1**" structure of **11**, the dihedral angle between the C(σ)–Zr–N and Me–N–Me planes was calculated to be 73°, which is smaller than the 90° value calculated for **9**. This gearing of the amido ligand in **11** is caused by increased steric interactions between the larger methyl groups and the two η^5-Cp ligands and is consistent with X-ray crystal data of other bis-metallocene zirconium amido compounds reported by Bercaw and co-workers [41]. These structural data are summarized in Table 1, and the calculated structures of **9** and **11** are shown in Fig. 4.

3.3. Effect of π-loading on bonding energies and orbital interactions

Table 2 summarizes the relative bonding energies for the "**3-5**" and "**2-5,1-1**" isomers of complexes **1** through **12**. The binding preferences calculated for Cp_3MX (M = Zr, Hf; X = H, OR, NR_2) compounds in conjunction with the differences observed for the alkoxide and amido geometries in the "**3-5**" and "**2-5,1-1**" structures indicate that the π-donor ability of the X ligand is important in determining which isomer is more stable.

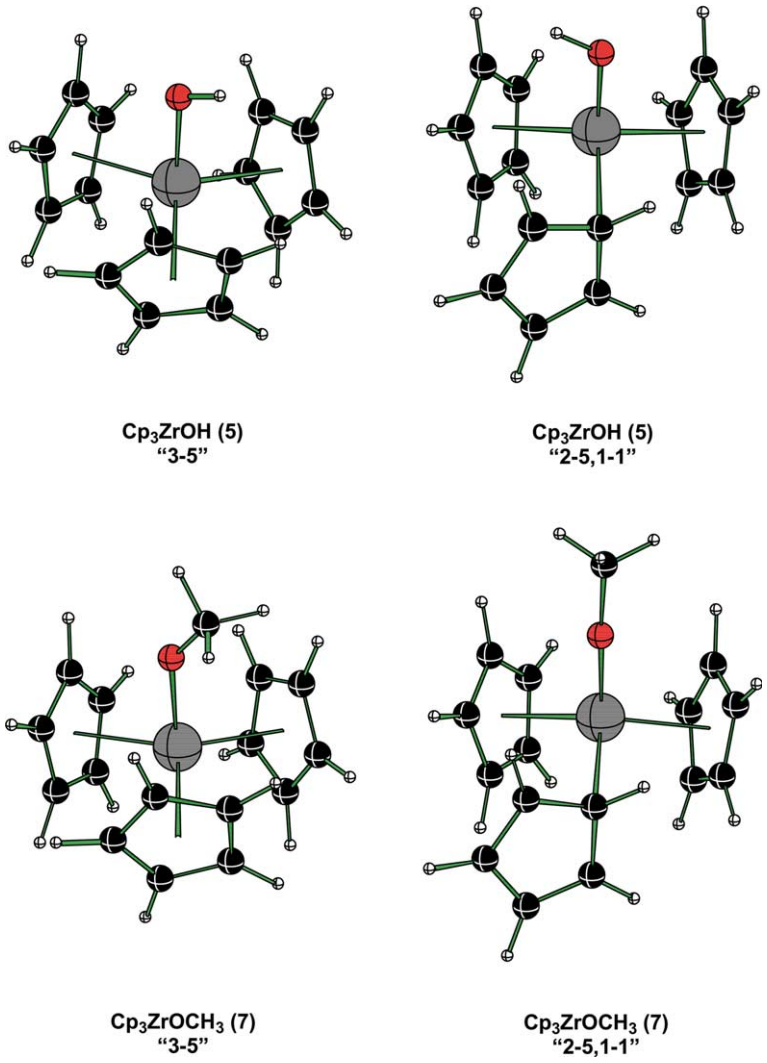

Fig. 3. Optimized geometries of the "**3-5**" and "**2-5,1-1**" structures of Cp_3ZrOH (**5**) and Cp_3ZrOCH_3 (**7**).

When X is not a π-donor, as is the case for **3** and **4**, the "**3-5**" isomer is calculated to be more stable than the "**2-5,1-1**" isomer. In contrast, when X is a strong π-donor, as in the alkoxide and amido compounds, the "**2-5,1-1**" isomers are found to be more stable than the "**3-5**" isomers. Interestingly, the amido compounds have a higher preference for the "**2-5,1-1**" geometry than the corresponding hydroxide and alkoxide complexes, which is consistent with an $–NR_2$ ligand being a stronger π-donor than an –OR ligand [42]. Notice also that in all cases, the Hf complex shows a greater preference for the "**2-5,1-1**" structure than does the corresponding Zr complex. This observation, which is consistent with the differing structures of the Zr and Hf complexes when X = Cp or Cl, will be the focus of a separate contribution.

Because "**3-5**" Cp_3MX compounds are electronically saturated, π-donation from the X ligand is minimized in comparison to the π-donation in the "**2-5,1-1**" isomers. This should be evident from inspection of the charges on the metal atom, the tris-Cp ligand set, and the X ligand in **3** through **6**, **9** and **10**, which are compiled in Table 3. Analysis of the Mulliken charges is not consistent with this expected increase in π-donation in the "**2-5,1-1**" geometries as there is no significant difference in the Mulliken charges of the X ligands in the "**3-5**" and "**2-5,1-1**" isomers. In fact, the Mulliken charges of the X ligands in all of these compounds are more negative in the "**2-5,1-1**" structures than in the "**3-5**" structures, indicating less electron donation from the X ligand in the "**2-5,1-1**" isomers. In light of these results, which are contrary to those expected from chemical intuition, and the well-documented problems associated with Mulliken population analyses involving diffuse basis sets [43], the Mulliken charges are not considered further in this study.

Hirshfeld [44] and Voronoi deformation density (VDD) [45] charges have been shown to be more useful than Mulliken charges in the interpretation of calculations involving other organometallic systems [46].

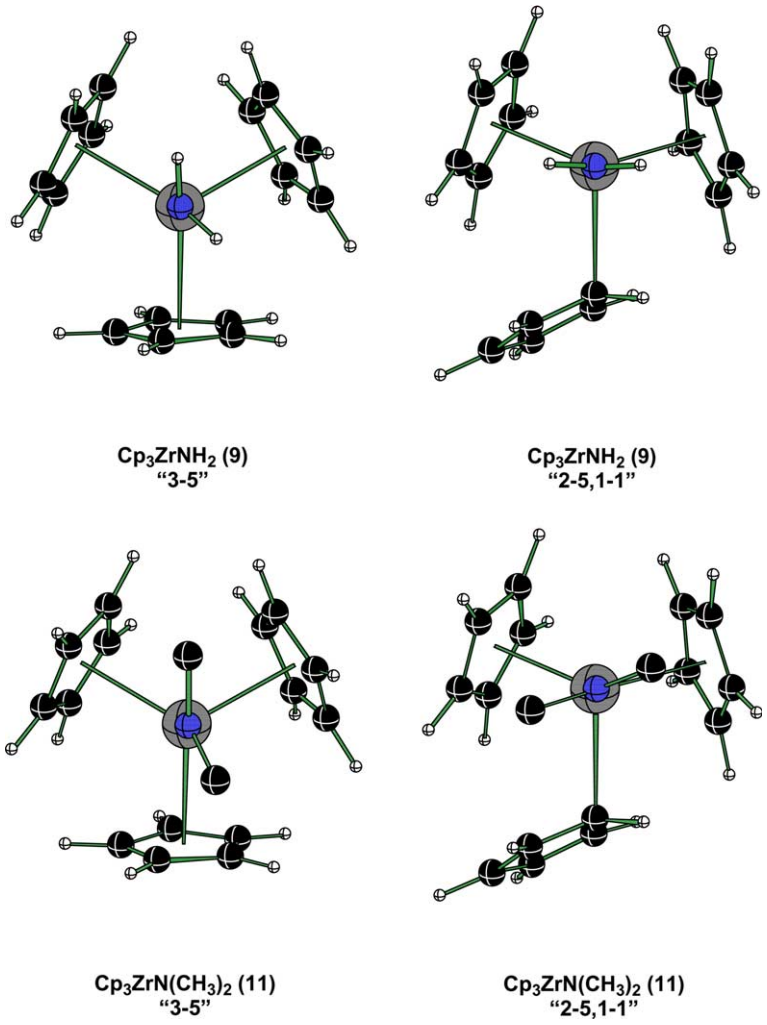

Fig. 4. Optimized geometries of the "**3-5**" and "**2-5,1-1**" structures of Cp_3ZrNH_2 (**9**) and $Cp_3ZrN(CH_3)_2$ (**11**). The view is shown along the Zr–N bond vector. In **11**, the hydrogen atoms of the amido methyl groups are omitted for clarity.

A comparison of the Hirshfeld and VDD charges of the "**3-5**" isomers of **3**, **5** and **9** indicates electron donation from the tris-Cp ligand set to the metal center is greatest for **3** and follows the order **3** > **5** > **9**. A similar trend is observed for the corresponding "**3-5**" hafnium compounds **4**, **6** and **10**. Inspection of the charges of the X ligands indicates that the electron donation from the X ligand to the metal center follows the order $NH_2 > OH \approx CH_3$. This is not unexpected as CH_3 is a stronger σ-donor than OH but OH is a stronger π-donor than CH_3 and NH_2 is a stronger π-donor than OH. In addition, both charge analyses show a smaller charge on the metal atom in the "**2-5,1-1**" structure than in the "**3-5**" structure for compounds **5**, **6**, **9**, and **10**. Because there are only slight variations in the tris-Cp donation in the "**3-5**" and "**2-5,1-1**" geometries, the decrease in the metal charge in the "**2-5,1-1**" isomer is primarily caused by greater donation from the –OH and $–NH_2$ ligands to the metal center.

Interestingly, the Hirshfeld and VDD charge analyses show that the charge of the metal center in the hafnium compounds is more positive than the charge of the metal center in the analogous zirconium complexes, which indicates more electron donation from the ligands in

Table 2
Relative bonding energies (kcal/mol) for complexes **1** through **10**

Compound	**3-5**	**2-5,1-1**
1	0.0	(–)
2	0.0	(–)

the zirconium compounds. This effect appears to be relativistic in nature [47]. Non-relativistic Hirshfeld and VDD charges indicate no difference in the metal charges of the analogous zirconium and hafnium compounds. These results are consistent with the relativistic destabilization of the 5d orbitals of hafnium relative to the 4d orbitals of zirconium, leading to a poorer energy match between the metal 5d orbitals and the ligand orbitals in the hafnium complexes.

The above population analyses indicate that the geometry preferences of tris-Cp Group IV transition metal compounds can be viewed as a competition between the π-donation of the X ligand and the third Cp ligand. This π-competition model is illustrated in Fig. 5. The calculations indicate that the alkoxide and amido groups are stronger π-donors than the third Cp ligand in Cp_3MX compounds. As the metal accepts more electron density from the π orbital of the X ligand, π-donation from the third η^5-Cp ligand is decreased to such an extent that it becomes a better electron donor as an η^1-Cp ligand. This model is consistent with the 90° orientation of the alkoxide and amide ligands relative to the η^1-Cp ligand in the "**2-5,1-1**" geometry as discussed in the previous section.

The stability of the "**2-5,1-1**" geometry in the alkoxide and amido compounds can also be explained using molecular orbital theory. Inspection of the molecular orbitals of the tris-Cp metal fragment in Fig. 2 shows that the 15e molecular orbital involving the metal d_{xz} orbital has the appropriate symmetry and orientation for interaction with the π-donor orbital of the X ligand. Because both the 15e orbital and the π orbital of the X ligand are filled, this leads to a filled–filled destabilizing interaction, which increases the energy of this molecular orbital. As a result, the degenerate 15e orbital in Cp_3ZrCH_3 is split into two non-degenerate orbitals in Cp_3ZrOH, with the one involving the metal d_{xz} orbital substantially increased in energy. In Cp_3ZrNH_2, the π-donation is strong enough that the energy of this

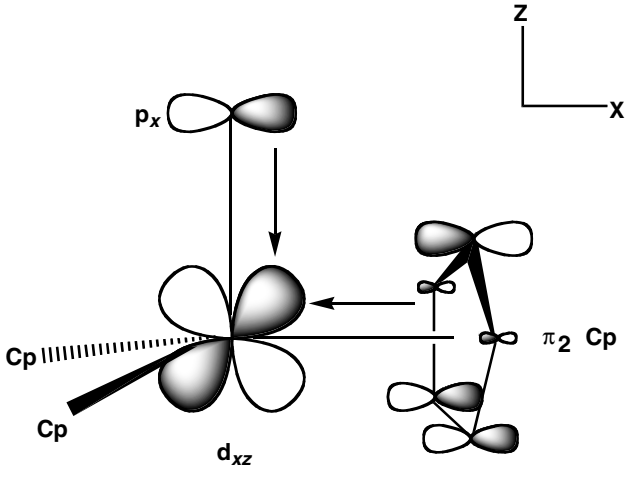

Fig. 5. Orbital interactions between the metal d_{xz} orbital, the π-donor orbital of X, and one of the π_2 orbitals of the third η^5-Cp ligand in Cp_3MX compounds. Increased π-donation from the X ligand decreases the π-contribution of the third Cp ligand, which becomes a pure σ-donor when X is an alkoxide or amido ligand. The other two η^5-Cp ligands are labeled as "Cp" for clarity.

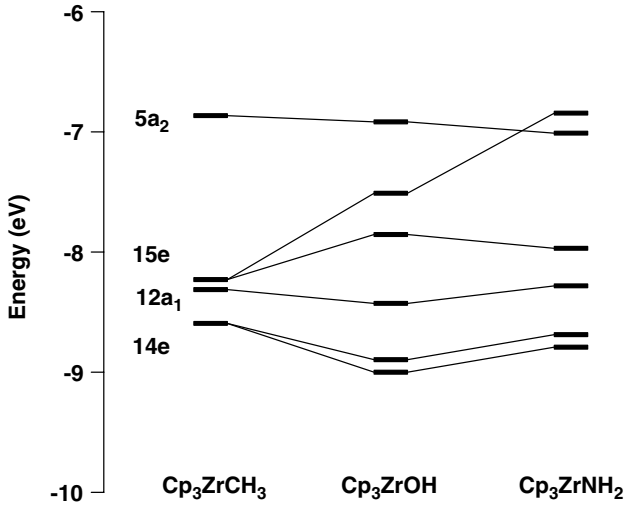

Fig. 6. Molecular orbital energies of **3**, **5** and **9**.

orbital rises above the $5a_2$ orbital. This destabilization is responsible for the relative stability of the "**2-5,1-1**" isomers of the tris-Cp alkoxide and amido compounds. The molecular orbital energies of Cp_3ZrX ($X = CH_3$, OH, NH_2) are shown in Fig. 6.

4. Conclusion

The DFT calculations presented here indicate that the bonding of the tris-Cp ligand set in transition metal compounds of the type Cp_3MX ($M = Zr$, Hf) is dependent upon the nature of the X ligand. When X is a pure σ-donor (e.g., H, CH_3), the complexes are more stable in a "**3-5**" geometry. However, the preference for a "**2-5,1-1**" geometry increases as the π-donor ability of the X ligand increases. Thus, when X is an alkoxide or amido ligand, the tris-Cp ligand set prefers a "**2-5,1-1**" geometry. This preference for the "**2-5,1-1**" geometry can be understood in terms of a π-competition model, which indicates that the π-donor ability of the alkoxide and amido ligands is greater than that of the third η^5-Cp ligand. Molecular orbital theory also suggests that the presence of strong π-donor X ligands in Cp_3MX complexes leads to filled–filled interactions between the π orbital of the X ligand and one of the 15e orbitals of the Cp_3M fragment. This unfavorable interaction destabilizes the "**3-5**" geometry and contributes to the relative stability of the "**2-5,1-1**" isomers of Cp_3MOH and Cp_3MNH_2.

Abstract

We report the synthesis and characterization of a dendrimer-based Co_{32} nanocluster molecule and its use as uniform-size catalytic seed for diameter-controlled growth of single-walled carbon nanotubes.

Keywords: Cluster molecule; Cobalt; Nanoparticles; Chemical vapour deposition; Single-walled carbon nanotubes

1. Introduction

Cobalt (Co) nanoparticles have been under intense investigation because of their importance in the development of nanoscale ferromagnets [1,2], high-density magnetic memory storage materials [3,4], and as catalytic seeds in the growth of single-walled carbon nanotubes (CNTs) [5]. As far as the single-walled CNTs are concerned, the control of the tube diameter has been a challenge to the scientific community for a decade since their discovery in 1993 [6]. Although the exact mechanism involved in their growth remains incompletely understood, it has been demonstrated that the diameter of single-walled CNTs often matches the size of the catalytic metal nanoparticles employed [7–10]. Thus, in the control of the nanotube diameter, the first and most critical step is the control of the size of the catalytic metal nanoparticles.

To date, metal nanoparticles (Co, Fe or Ni) are produced either from colloids [7,11,12], or by thermal decomposition of metal-containing precursors of inorganic or organometallic salts [13–18,23]. Despite great efforts by several research groups, no uniform-size metal nanoparticles down to a scale of ~1.0 nm have been prepared from either a colloidal system or a salt precursor. For applications that require monodispersed Co small particles, and in particular, for seeking diameter-controlled growth of single-walled CNTs, it is clearly desirable to develop new synthetic approaches to control the particle size and molecular structure. Here we report the synthesis and characterization of a dendrimer-based Co_{32} nanocluster molecule. The ability of precisely controlling the cluster size, the number of metal atoms and surface functionality distinguishes such molecules from Co colloidal nanoparticles and other cobalt nanoparticles formed from decomposition of salt precursors. As an initial and preliminary application study, we also demonstrate the employment of such nanoclusters as uniform-size catalytic particles for diameter-controlled growth of single-walled CNTs.

2. Experimental

2.1. General technique in synthesis and characterization

All reactions were carried out with the exclusion of air under an argon atmosphere using standard vacuum-line techniques. Solvents were freshly distilled prior to use. Except tetracobalt carbonyl that was purchased from

Strem Chemicals Ltd., other chemicals were obtained from the Aldrich. IR spectra were recorded on a FT-IR spectrometer (Perkin Elmer, RX I system) using a CaF_2 sample cell. ^{31}P NMR spectra were recorded on a 400-MHz Bruker spectrometer. The employed SiO_2/Si substrates (commercial chips) were first cleaned by a mixture of ethanol and acetone, then by water. All substrates were polished by O_2 plasma for 10 min before use. Atomic force microscopy (AFM) images were acquired on a digital dimensional 3100 AFM mechine equiped with the nanoscope IV controller.

2.2. Synthesis of compound *1*

The synthesis was based on a literature method but with some modification [19]. Briefly, 0.34 g of paraformaldehyde and 2.0 ml diphenylphosphine was heated in methanol (20 ml) at 60–65 °C for 30 min. The reaction mixture was cooled to room temperature and treated with a solution of DAB-dendr-$[NH_2]_8$ (0.50 ml dendrimer in 5 ml methanol). After half an hour of stirring at room temperature, toluene (40 ml) was added. Temperature was raised to 60 °C, and the solution was kept at that temperature for an hour. The volume of the reaction mixture was then reduced to 3 ml under a reduced pressure. Cold methanol was added to yield a glassy colorless solid, DAB-dendr-$[N(CH_2PPh_2)_2]_8$ (**1**). The product was washed by methanol and dried under high vacuum at 40 °C for at least 17 h. ^{31}P NMR (CD_2Cl_2, δ): −27.9 ppm (sharp, closely-nested doublet).

2.3. Synthesis of compound *2*

0.146 g of tetracobalt carbonyl was dissolved in 30 ml of dichloromethane. The resulting solution was stirred at room temperature for 30 min. A dichloromethane solution of compound **1** (0.105 g) was then added in drop wise. After about 24 h of stirring at room temperature, the volume of the reaction mixture was reduced to 3 ml under a reduced pressure. Separation of the product, DAB-dendr-$[N(CH_2PPh_2)_2Co_4(CO)_9]_8$ (**2**), was achieved by precipitation using hexane. The un-purified product contains Co_4 metal clusters (already in excess as the starting reactant). They were removed by washing using hexane. The remaining solution containing unreacted cluster was discarded and the entire process was repeated 3–5 times. The solid product has a dark brown color. It was dried under high vacuum for 3 h. IR (cm^{-1}): 2060(s), 2017(vs), 1979(m), 1956(m), 1887(m), 1825(w) and 1804(w). ^{31}P NMR (CD_2Cl_2, δ in ppm): 37.4 (main), 25.0 (weak). Elemental *Anal.* Calc. (wt%): C, 48.9; H, 3.5; N, 2.5; P, 6.3. Found: C, 45.6; H, 3.7; N, 2.5; P, 5.7%.

2.4. Growth of the carbon nanotubes

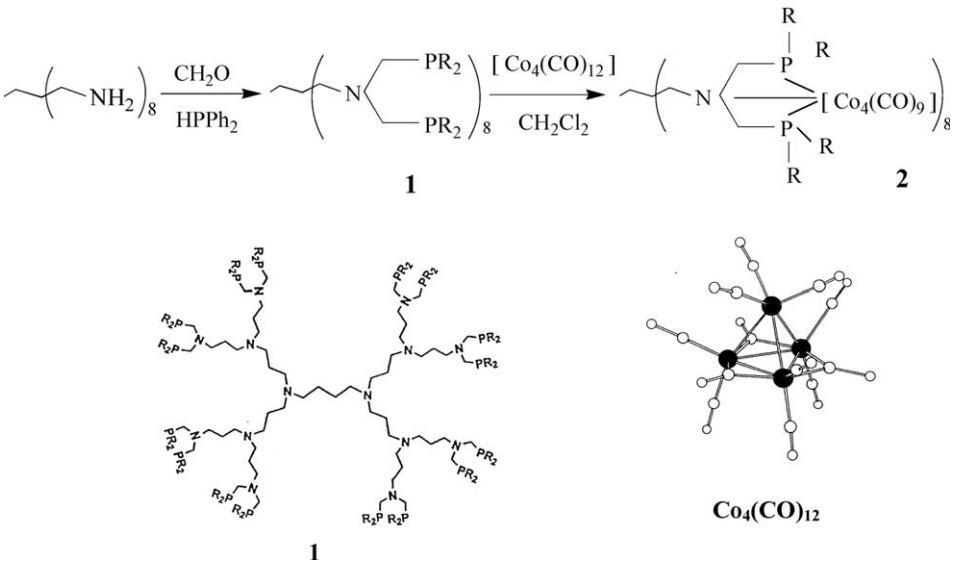
The SiO_2/Si wafers employed were first cleaned by ethanol. The dendrimer-based Co_{32} nanocluster molecules were deposited onto the substrate from their CH_2Cl_2 solution, with an approximate concentration of 8×10^{-5} M or less. After dipped into the solution for 10 min, the substrate was rinsed by dichloromethane and dried by nitrogen. The sample was then transferred into a quartz boat, which was placed in a tube-shape reactor under a flow of argon. The sample was first heated at 300–400 °C. Such heating treatment of the cluster molecules made their organic dendritic-core and all the carbonyl ligands burned off and subsequently, the formed gaseous species were taken out of the reactor by the flow of argon. This process was immediately followed by the introduction of methane (CH_4) into the reactor to initiate the growth of the carbon nanotubes. The temperature of the reactor was kept at 850 °C during the carbon deposition. The flow rate of the methane was 1.1 L min^{-1}. The carbon deposition lasted for 30 min.

3. Results and discussion

The Co_{32} nanocluster was constructed on a host dendrimer molecule, DAB-dendr-$[N(CH_2PPh_2)_2]_8$ (**1**), which was prepared in situ by double phosphinomethylation of each of the eight peripheral amino groups of a commercially available dendrimer, DAB-dendr-$[NH_2]_8$, through the use of Ph_2PCH_2OH prepared from HCHO and $HPPh_2$. This synthesis was based on a literature method with some modification [19], and its successful double phosphinomethylation is evident by the observation of the ^{31}P NMR spectrum which shows a sharp peak at $\delta = -27.9$ ppm. Binding eight $Co_4(CO)_{12}$ cluster units onto the 8[P–N–P] tridentate terminals of compound **1** leads to formation of a nanoscale dendrimer-based supercluster, with each produced molecule containing 32 Co atoms (see Scheme 1).

The coordination reaction of the dendrimer and cluster was monitored by infrared spectroscopy (IR) in the (CO) region. On comparison with the starting cluster, a new set of absorption bands at 1956, 1979 and 2017 cm^{-1} gradually emerged, indicating formation of the product. The band at 2060 cm^{-1} is a strong carbonyl absorption which arises from the parent cluster. The band at 1887 cm^{-1} is medium in intensity for the product, but weak for the parent cluster. Bands of 1824 and 1804 cm^{-1} are weak for the product and not obvious for the starting cluster. To ensure a full coordination of all the tridentate terminals by the $Co_4(CO)_{12}$ clusters, it was found necessary to keep the clusters in excess and the reaction under mild conditions. A normally encountered problem may be a partial coordination, which was also found in our previous studies using other metal clusters [20,21].

Successful completion of the coordination herein is evident from the ^{31}P NMR spectrum. The original resonant peak at $\delta = -27.9$ ppm, corresponding to non-coordinated phosphorous atoms in the parent dendrimer, has disappeared completely (Fig. 1). Donation of the electron density from the P atoms to the Co centers leads to a significant downfield shift in the coordinated product. Elemental analysis is in agreement with that expected for each



Scheme 1. Synthetic route to compound **2**. In this scheme are also shown the molecular structures of **1** and the starting tetracobalt cluster R = Ph.

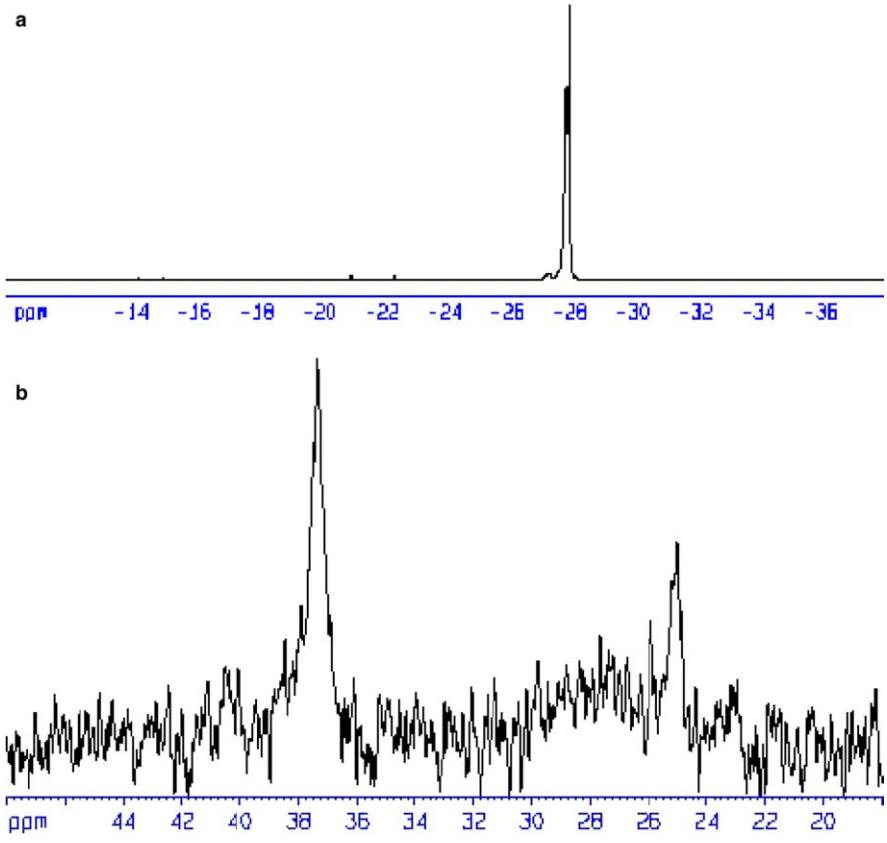


Fig. 1. NMR spectrum of the compound **1**: (a) at $\delta = -27.9$ ppm; and of the compound **2**; (b) at $\delta = 25.0$ and 37.4 ppm. The spectra were taken by dissolving the compounds into CD_2Cl_2 solvent. The relatively low ratio of signal to noise in the spectrum (b) arises from the low weight percentage (6.3%) of the phosphorous within the supermolecular structure of compound **2**.

dendrimer molecule containing eight tetracobalt cluster units. Whilst the analysis results for H, N and P are close to their calculated values, the C value is over 3% lower. This may possibly result from the Co–C reaction at high temperatures in the burning process of the analysis, which made some part of C to be transformed into metal carbide, bearing in mind that a large percentage of Co metal (~24 wt%) exists in the molecular structure. In this case, not all the carbon would form CO_2 gas for counting in the analysis. A lower C value from the measurement is thus expected. A second minor peak in the ^{31}P NMR spectrum of the product was frequently observed in our studies using

the same type of dendrimer to react with metal clusters (Co, Fe, Ru and Au). The two peaks reported in this work are believed to arise from two different coordination modes between the chelating dendritic ligands and the Co4 cluster units [20–22], but with the one corresponding to the peak at 37.4 ppm in dominance. Integration of the major and minor peak gives relative sizes in a ratio of about 4:1.

To acquire the molecular size and morphology information, atomic force microscopy (AFM) was carried out for the molecules deposited onto a SiO_2/Si substrate. The deposition was performed by dipping the substrate into a CH_2Cl_2 solution of the complex for 2 min, followed by washing with CH_2Cl_2 and evaporation. The topographic image indicated that upon evaporation of solvent, the Co_{32} nanocluster molecules did not crystallize into grains. Instead, the molecules existed as isolated single entities on the substrate (Fig. 2). Topographical height measurements revealed a dominant height of ~1.5 nm for such single molecules. Considering these dendrimer-based molecules are soft and may be flattened when adsorbed onto the substrate, we believe that the molecular diameter may be slightly larger than the measured height. The isolated cluster molecules arose from their electronically neutral nature, coupled with the large molecular size. In addition, the hydrogen bonding between the OH groups on the SiO_2/Si substrate and the CO ligands of the clusters might have played an important role because these bonds were able to enhance the surface adsorption, which helped to anchor the clusters on the substrate.

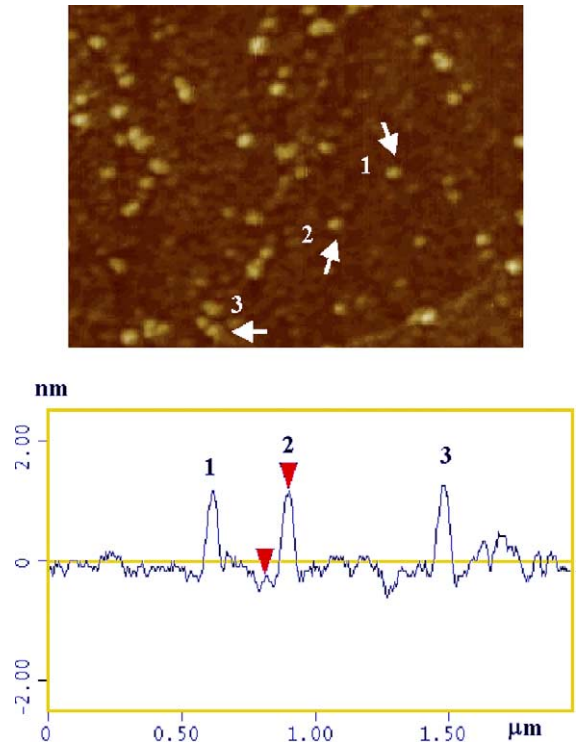

Fig. 2. Top: the AFM topographic image of the dendrimer-based Co_{32} nanoclusters on a SiO_2/Si surface. Bottom: topographical height measurements showing the size of the clusters. In this case, the measured heights correspond to the three single molecules indicated by arrows on the top image.

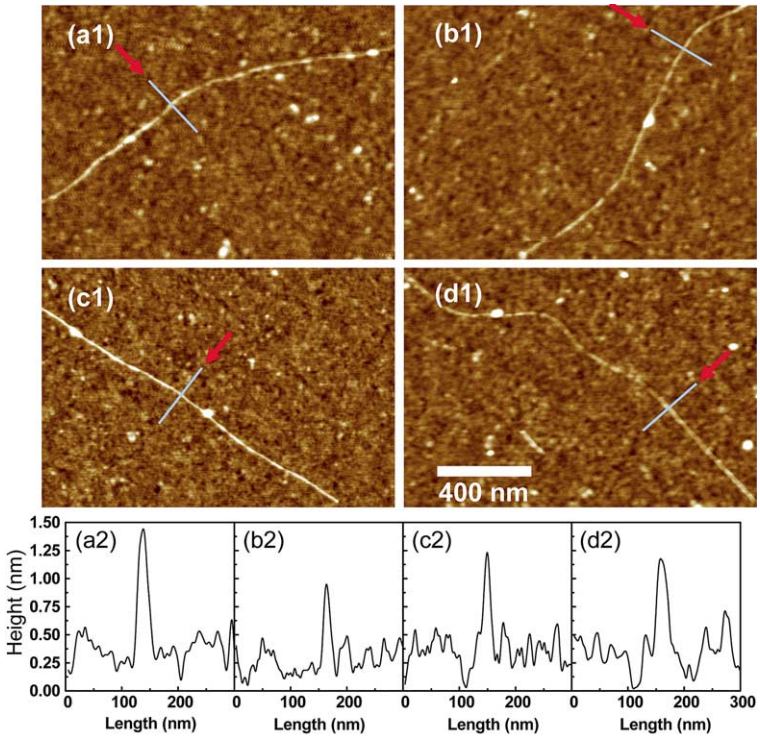

Fig. 3. Top (a1–d1): images of the single-walled carbon nanotubes under AFM (tapping mode); Bottom (a2–d2): the corresponding topographical height measurements for the diameters of the nanotubes.

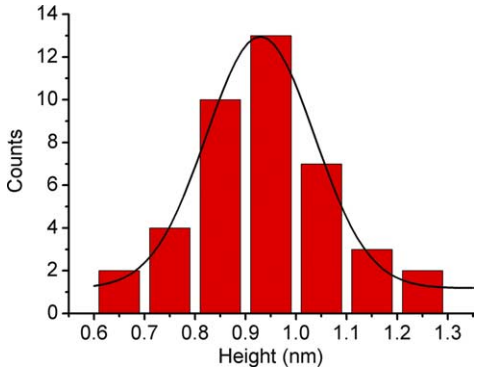

Fig. 4. The measured topographical heights of more than 40 single-walled CNTs on the substrate, showing the tube diameters and distribution. The nanotubes were grown in a CVD process at 850 °C using CH_4 as the carbon feedstock.

We would stress that the existence as isolated single molecules on the SiO_2/Si substrate may be regarded as a bonus in view of a potentially diameter-controlled growth of single-walled CNTs. Metallic Co_{32} nanoparticles may be obtained from the corresponding single parent molecules after burning off the organic dendritic core and carbonyl ligands at elevated temperatures. By such means, each produced Co nanoparticle may be identical in size due to the fixed number of metal atoms in the molecules. This nanocluster molecule may be also compared with colloidal nanoparticles or other nanoparticles produced from an inorganic or organometallic salt. For a given colloidal system, a size distribution is almost certainly unavoidable due to the complex kinetic factors involved in the formation of the colloids, particularly at the atomic nucleation and aggregation stages. When an inorganic or organometallic salt is used, the two electronically opposite ions within a salt tend to attract each other and thus force the molecules to crystallize into grains when the solvent is dried up. As the consequence of crystallization, solid-state grains with varied sizes are formed. This size difference in the grains finally leads to the size variation of the metal nanoparticles formed from thermal decomposition of the crystal grains.

For a preliminary application study, we have employed these synthesized Co_{32} nanoclusters as catalytic seeds in the growth of single-walled CNTs. Examination of the growth product by tapping mode AFM indicated that individually distributed CNTs were formed on the substrate (Fig. 3). Along with the topography, phase mode images of the CNTs were simultaneously recorded. The result displayed similar nanotube morphologies. Topographical height measurements for more than 40 such nanotubes showed a narrow diameter distribution (Fig. 4), and none of the tubes was thicker than 1.3 nm. Such small diameters indicate that the produced tubes are single-walled because no measured height reaches the threshold diameter of a double-walled CNT ($d = 1.4$ nm). Fig. 4 also shows that the average height is ~0.95 nm, the best representation of the nanotube diameter, taken all the possible errors in the measurements into account. This measured diameter clearly matches the size of a single Co_{32} metallic nanoparticle, ~0.9 nm, calculated by assuming that the particle takes a sphere shape and all the 32 Co atoms are closely packed. This result suggests that at least, the majority of the individually distributed single-walled CNTs seeded from their corresponding Co_{32} single clusters.

4. Conclusion

To summarize, we have successfully synthesized a dendrimer-based Co_{32} nanocluster molecule. Since the molecules possess uniform size and well-defined molecular structure, they are fundamentally different from Co colloids or other nanoparticles formed from decomposition of a salt precursor. The existence as isolated single molecules on the SiO_2/Si wafer is an interesting feature of such nanoclusters, which is of significant appeal in a potential application where monodispersed Co nanoentities are important. We have also demonstrated that individual single-walled CNTs can be obtained utilizing these molecules as uniform-size catalytic precursor, and the measured average tube diameter matches the size of a single Co_{32} cluster seed. In addition, the success of this synthetic route also offers feasibility of making similar metal nanoclusters with precisely controlled cluster sizes, for example, using the same cobalt starting cluster but changing the generation number of the dendrimer host molecules to prepare metal clusters with different sizes. Given all these, we believe that such development paves a new way for the exploration of utilizing uniform-size cobalt nanoclusters for applications, and in particular, for future studies of seeking an entirely diameter-controlled growth of single-walled carbon nanotubes.

We are pleased to mark Professor Malcolm Chisholm's many significant contributions to Inorganic Chemistry, using the occasion of his 60th birthday to congratulate him on his achievements, wishing him health, happiness, and continued scientific success.

Abstract

Four new $[Au(dithiolene)_2]^-$ complexes, each involving two asymmetrically substituted dithiolene ligands (SC(H)C(R)S; R = phenyl, pyridin-2-yl, pyridin-3-yl, or pyridin-4-yl), have been synthesized by reacting $K[AuCl_4]$ with the corresponding dithiolene, generated by base hydrolysis of the thione-protected 1,3-dithiolate. Each complex has been isolated as its $[PPh_4]^+$ salt and the structures of these $[PPh_4][Au(dithiolene)_2]$ compounds have been determined by X-ray crystallography; each anion possesses a square planar $\{AuS_4\}$ core with a *cis*-arrangement of the R groups for R = phenyl and pyridin-2-yl complexes, but a *trans*-arrangement for R = pyridin-3-yl and pyridin-4-yl. In each compound, the lengths of the C–C (1.34 ± 0.01 Å) and C–S (1.75 0.03 Å) bonds of the metallocycle are consistent with the ene-1,2-dithiolate form of the dithiolene, i.e., these are [Au(III)bis(ene-1,2-dithiolate)]$^-$ complexes. Each compound is diamagnetic and ^{1}H NMR studies indicate that, in solution in d^6-acetone, both the *cis* and *trans* isomers of the $[Au(SC(H)C(R)S)_2]^-$ anion are present and do not interconvert at room temperature. Each $[Au(dithiolene)_2]^-$ complex undergoes an oxidation ($80 < E_p^a < 230$ mV) and a reduction ($-1880 < E_p^c(red) < -2020$ mV; versus $[Fc]^+/[Fc]$); the particular potentials observed correlate with the electron withdrawing ability of the dithiolene substituent (R), as expressed by the Hammett σ_p-parameter. Comparison of the information obtained in these studies with that determined for related systems leads to the conclusion that the oxidation is a ligand-based process and that reduction involves addition of an electron to an orbital that possesses both metal and ligand character.

1. Introduction

An extensive range of bis-dithiolene complexes of Au and their properties have been reported [1–31]; the majority are $[Au(dithiolene)_2]^-$ complexes with a square planar $\{AuS_4\}$ core, diamagnetic, and generally considered to involve a Au(III) (d^8) centre. The redox properties of $[Au(dithiolene)_2]^-$ complexes have been investigated and related $[Au(dithiolene)_2]^z$ ($z = 0$ or $2-$) complexes identified [2–4,7,8,12,15–18,23,25,26,30,31]; the electronic structure of these systems, notably the role of the dithiolene ligands in the redox processes, has been probed by ab initio and density functional calculations [21,32].

There are a range of strategies available to synthesize dithiolene complexes [33]. We have adapted the procedure developed by Davies et al. [34,35] to synthesize four new $[Au(dithiolene)_2]^-$ complexes, each of which involves the metal coordinated by two asymmetrically substituted dithiolenes.

2. Experimental

Anhydrous *N*,*N*-dimethylformamide (DMF), over molecular sieves, was purchased from Fluka and used as received. Potassium *O*-isopropyl xanthate [36], 4-(phenyl)-1,3-dithiol-2-one [37], 2-bromoacetylpyridine hydrobromide, 3-bromoacetylpyridine hydrobromide and 4-bromoacetylpyridine hydrobromide [38,39] were prepared by the literature methods or modifications thereof.

2.1. Synthesis of 4-(pyridin-2-yl)-1,3-dithiol-2-one

2–Bromoacetylpyridine hydrobromide (8.41 g, 29.9 mmol) was suspended in CH_2Cl_2 (60 cm^3) and triethylamine (3.64 g, 36.0 mmol) added to give a pink solution. Potassium *O*-isopropyl xanthate (6.26 g, 36.0 mmol) was added and the orange suspension stirred for 2 h. The reaction was quenched by the addition of water (100 cm^3) and the CH_2Cl_2 layer separated. The aqueous phase was washed with CH_2Cl_2 (2×10 cm^3), the CH_2Cl_2 phases were combined, dried ($MgSO_4$), filtered, and the filtrate evaporated in vacuo to give a brown solid. The solid was treated with H_2SO_4 (10 cm^3, 98%) resulting in an exothermic reaction. After 5 min, ice was added to the reaction until no further heat was generated. The solution was diluted with water and then neutralised with $NaHCO_3$. The pale precipitate was extracted into CH_2Cl_2, the organic phase dried ($MgSO_4$), and the filtrate evaporated to dryness to yield a pale brown solid. Recrystallization from hot EtOH afforded a cream colored solid (0.80 g, 14%). Elemental *Anal*. Calc. for $C_8H_5NOS_2$: C, 49.27; H, 2.58; N, 7.18. Found: C, 49.18; H, 2.57; N, 6.98%. EI-MS *m*/*z*: 195 ($C_8H_5NOS_2^+$), 167 ($C_7H_5NS_2^+$), 123 ($C_6NSH_5^+$), 78 ($C_5H_4N^+$). ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ_H 8.60–8.58 (m, 1H, H^6), 7.79–7.73 (m, 1H, H^3), 7.53–7.50 (m, 1H, H^4), 7.36 (s, 1H, H^{dithio}), 7.28–7.24 (m, 1H, H^5).

2.2. Synthesis of 4-(pyridin-3-yl)-1,3-dithiol-2-one

This compound was prepared as for 4-(pyridin-2-yl)-1,3-dithiol-2-one from 3-bromoacetylpyridine hydrobromide (8.11 g, 28.9 mmol), triethylamine (3.51 g, 34.8 mmol), potassium *O*-isopropyl xanthate (6.06 g, 34.8 mmol) and H_2SO_4 (10 cm^3, 98%), and obtained as a cream colored solid 0.90 g (16%). Elemental *Anal*. Calc. for $C_8H_5NOS_2$: C, 49.27; H, 2.58; N, 7.18. Found: C, 49.26; H, 2.52; N, 7.18%. EI-MS *m*/*z*: 195 ($C_8H_5NOS_2^+$), 167 ($C_7H_5NS_2^+$), 122 ($C_6NSH_4^+$), 78 ($C_5H_4N^+$). ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ_H 8.73–8.72 (m, 1H, H^2), 8.63–8.60 (m, 1H, H^6), 7.73–7.69 (m, 1H, H^4), 7.38–7.33 (m, 1H, H^5), 6.94 (s, 1H, H^{dithio}).

2.3. Synthesis of 4-(pyridin-4-yl)-1,3-dithiol-2-one

This compound was prepared as for 4-(pyridin-2-yl)-1,3-dithiol-2-one from 4-bromoacetylpyridine hydrobromide (7.63 g, 27.2 mmol), triethylamine (3.30 g, 32.7 mmol), potassium *O*-isopropyl xanthate (5.57 g, 32.0 mmol) and H_2SO_4 (10 cm^3, 98%), and obtained as a cream colored solid (1.14 g, 22%). Elemental *Anal*. Calc. for $C_8H_5NOS_2$: C, 49.27; H, 2.58; N, 7.18. Found: C, 48.88; H, 2.52; N, 6.97%. EI-MS *m*/*z*: 195 ($C_8H_5NOS_2^+$), 167 ($C_7H_5NS_2^+$), 122 ($C_6NSH_4^+$), 78 ($C_5H_4N^+$). ^{1}H NMR (300 MHz, $CDCl_3$, 298 K): δ_H 8.67 (dd, 2H, H^2, H^6, J_{H-H} 4.5, 1.7 Hz), 7.30 (dd, 2H, H^3, H^5, J_{H-H} 4.4, 1.6 Hz), 7.15 (s, 1H, H^{dithio}).

2.4. Synthesis of [PPh_4][Au(sdt)$_2$] (**1**)

4-Phenyl-1,3-dithiol-2-one (0.10 g, 0.5 mmol) and NaOH (0.10 g, 2.5 mmol) were suspended in EtOH (10 cm^3). A solution of K[$AuCl_4$] (0.10 g, 0.3 mmol) in water (10 cm^3) was added and a dark yellow colored solution was obtained. This solution was heated at reflux for 3 h and then allowed to cool to room temperature. A solution of [PPh_4]Br (0.20 g, 0.5 mmol) in water (10 cm^3) was then added and a pale brown solid precipitated. The volume of the solvent was reduced in vacuo and the precipitate collected by filtration. This solid was recrystallized from a CH_2Cl_2 solution layered with *n*-hexane; the product was isolated by decantation of the mother liquor and then dried in vacuo to yield a golden crystalline solid (0.11 g, 51%). Elemental *Anal*. Calc. for $AuS_4PC_{40}H_{32}$: C, 55.29; H, 3.71. Found: C, 54.35; H, 3.69%. FAB-MS *m*/*z*: 530 $[Au(sdt)_2]^-$. ^{1}H NMR (300 MHz, $(CD_3)_2CO$, 298 K): δ_H 8.03–7.94 (m, 4H, PPh_4), 7.88–7.82 (m, 16H, PPh_4), 7.57 (m, 4H, H^2, H^6), 7.19 (m, 4H, H^3, H^5), 7.08 (m, 2H, H^4), 6.63, 6.62 (2s, 2H, H^{dithio}).

2.5. Synthesis of [PPh_4][Au(2-pedt)$_2$] (**2**)

This compound was prepared as described for **1** from 4-(pyridin-2-yl)-1,3-dithiol-2-one (0.10 g, 0.5 mmol), NaOH (0.10 g, 2.5 mmol) and K[$AuCl_4$] (0.10 g, 0.3 mmol). Addition of a solution of [PPh_4]Br (0.20 g, 0.5 mmol) in water (10 cm^3) to the dark yellow solution resulted in the precipitation of a pale brown solid. The volume of the solvent was reduced in vacuo, the precipitate was collected by filtration and then recrystallized from a solution in CH_2Cl_2 layered with *n*-hexane. The product was isolated by decantation of the mother liquor and then dried in vacuo to yield a golden crystalline solid (0.04 g, 18%). Elemental *Anal*. Calc. for $AuS_4N_2PC_{38}H_{30}$: C, 52.41; H, 3.47; N, 3.22. Found: C, 52.21; H, 3.34; N, 3.04%. FAB-MS *m*/*z*: 532 $[Au(2\text{-}pedt)_2]^-$. ^{1}H NMR (300 MHz, $(CD_3)_2CO$, 298 K): δ_H 8.32 (m, 2H, H^6), 8.03–7.96 (m, 4H, PPh_4), 7.89–7.81 (m, 16H, PPh_4), 7.62, 7.61 (2s, 2H, H^{dithio}), 7.60–7.58 (m, 4H, H^3, H^4), 6.99 (m, 2H, H^5).

2.6. Synthesis of [PPh_4][Au(3-pedt)$_2$] (**3**)

This compound was prepared as described for **1** from 4-(pyridin-3-yl)-1,3-dithiol-2-one (0.10 g, 0.5 mmol), NaOH (0.10 g, 2.5 mmol) and K[$AuCl_4$] (0.10 g, 0.3 mmol).

Addition of a solution of $[PPh_4]Br$ (0.20 g, 0.5 mmol) in water (10 cm^3) to the dark yellow solution resulted in the precipitation of a pale brown solid. The volume of the solvent was reduced in vacuo, the precipitate was collected by filtration and then recrystallized from a solution in CH_2Cl_2 layered with *n*-hexane. The product was isolated by decantation of the mother liquor and then dried in vacuo to yield a golden crystalline solid (0.08 g, 37%). Elemental *Anal*. Calc. for $AuS_4N_2PC_{38}H_{30}$: C, 52.41; H, 3.47; N, 3.22. Found: C, 52.26; H, 3.49; N, 3.10%. FAB-MS *m*/*z*: 532 $[Au(3\text{-pedt})_2]^-$. ^1H NMR (300 MHz, $(CD_3)_2CO$, 298 K): δ_H 8.80 (d, 2H, H^2, J_{H-H} 2.1 Hz), 8.30 (dd, 2H, H^6, J_{H-H} 4.9, 1.6 Hz), 8.03–7.97 (m, 4H, PPh_4), 7.89–7.83 (m, 18H, PPh_4, H^4), 7.19 (m, 2H, H^5) 6.79, 6.78 (2s, 2H, H^{dithio}).

2.7. Synthesis of $[PPh_4][Au(4\text{-pedt})_2]$ (4)

This compound was prepared as described for **1** from 4-(pyridin-4-yl)-1,3-dithiol-2-one (0.10 g, 0.5 mmol), NaOH (0.10 g, 2.5 mmol) and $K[AuCl_4]$ (0.10 g, 0.3 mmol). Addition of a solution of $[PPh_4]Br$ (0.20 g, 0.5 mmol) to the dark yellow solution resulted in the precipitation of a pale brown solid. The volume of the solvent was reduced in vacuo, the solid was separated by filtration and then recrystallized from a solution in CH_2Cl_2 layered with *n*-hexane. The product was isolated by decantation of the mother liquor and then dried in vacuo to yield a golden crystalline solid (0.04 g, 18%). Elemental *Anal*. Calc. for $AuS_4N_2PC_{38}H_{30}$: C, 52.41; H, 3.47; N, 3.22. Found: C, 51.99; H, 3.48; N, 3.15%. FAB-MS *m*/*z*: 532 $[Au(4\text{-pedt})_2]^-$. ^1H NMR (300 MHz, $(CD_3)_2CO$, 298 K): δ_H 8.36 (dd, 4H, H^2, H^6, J_{H-H} 4.7, 1.6 Hz), 8.03–7.94 (m, 4H, PPh_4), 7.89–7.83 (m, 16H, PPh_4), 7.49 (dd, 4H, H^3, H^5, J_{H-H} 4.9, 1.6 Hz), 7.15, 7.14 (2s, 2H, H^{dithio}).

3. Physical characterization

Elemental analyses of the compounds isolated in these studies were accomplished by the Microanalytical Laboratory of the School of Chemistry, the University of Nottingham, and by the Elemental Analysis Service at London Metropolitan University. FAB and EI mass spectra were recorded on a Fisons VG Trio 200 or a Fisons VG Autospec spectrometer. ^1H NMR spectra were recorded on a Bruker DPX300 NMR spectrometer and UV/Vis spectra were recorded on a Perkin–Elmer Lambda 16 spectrophotometer.

The cyclic voltammogram of each compound (1 mM) in DMF, containing $[N^nBu_4][BF_4]$ (0.2 M) as the background electrolyte, was recorded at room temperature using a glassy carbon working electrode, a Pt wire secondary electrode, and a saturated calomel reference electrode. To avoid overlapping redox couples, the $[(Me_5C_5)_2Fe]^+$/$[(Me_5C_5)_2Fe]$ ($[Fc^*]^+$/Fc^*]) couple was used as the internal reference and the potentials of the redox processes observed were referenced to that of the $[Fc]^+$/[Fc] couple by an independent calibration ($\Delta E_{1/2}$, $[Fc]^+$/[Fc] versus $[Fc_2^*]^+$/$[Fc_2^*]$, = 0.475 V). Measurements were performed using an Autolab PGSTAT20 potentiostat and compensation for internal resistance was not applied.

Golden, single crystals of **1**, **2**, **3** and **4** were grown by dissolution of the corresponding compound in CH_2Cl_2 followed by the slow diffusion of *n*-hexane into the solution. Details of the unit cell dimensions, data collection, and refinement are given in Table 1. Data for the structures of **1**, **2** and **3** were collected on a Bruker SMART 1000 CCD area detector diffractometer, whilst data for **4** were collected on a Bruker SMART APEX detector diffractometer. Both systems were equipped with an Oxford Cryosystems open flow cryostat. Structures **1** and **2** were solved by direct methods and structures **3** and **4** by Patterson heavy-atom

methods, using SHELXS-97 [40]. In each case, a full-matrix least-squares refinement was carried out using SHELXL-97 [41]. All hydrogen atoms were placed in geometrically calculated positions and thereafter refined using a riding model with $U_{iso}(H) = 1.2U_{eq}(C)$, unless otherwise stated. All non-hydrogen atoms were refined with anisotropic atomic displacement parameters (adps), except partially occupied atoms of **2** and **4**. Compound **2** had a disorder in the pyridine ring containing the atoms C13–C18. The initial refined values of the isotropic adp (U_{iso}) suggested a misassignment of the carbon and nitrogen atoms C18 and N2. However, further investigation suggested an electron density intermediate between C and N at both sites. Therefore, the ring was modeled with two coincident half-occupied sites, with attendant half-occupied hydrogen atom positions corresponding to those of the C atoms. Compound **4** had a disorder in the anion containing Au2. All atoms of this anion, except the gold and sulfur, were positioned in two sites with occupancies of 0.70 and 0.30. Geometric restraints were applied to the distances in all the partial occupancy disorder models, such that the bond lengths were restrained to be the same in each component. Hydrogen atoms were geometrically placed.

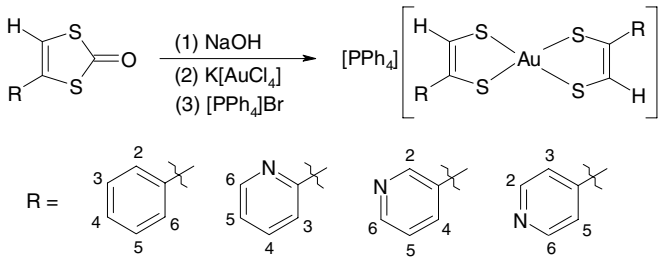
4. Results and discussion

4.1. Syntheses

Each of the $[Au(SC(H)C(R)S)_2]^-$ (R = phenyl, pyridin-2-yl, pyridin-3-yl, or pyridin-4-yl: dithiolene abbreviations = sdt, 2-pedt, 3-pedt, and 4-pedt, respectively) complexes have been prepared (Scheme 1) by reacting $K[AuCl_4]$ with the appropriate dithiolene, generated by base hydrolysis of the corresponding thione-protected 1,3-dithiolate. Each $[Au(SC(H)C(R)S)_2]^-$ complex has been isolated as its $[PPh_4]^+$ salt (compounds **1**, **2**, **3**, and **4**, respectively) in a reasonable (18–51%) yield.

4.2. Structural information

The asymmetric unit of compounds **1** and **2** each comprises a $[PPh_4]^+$ cation and a $[Au(dithiolene)_2]^-$ (dithiolene = sdt or 2-pedt) anion, each of which has a *cis*-configuration (Fig. 1(a) and (b)). The asymmetric unit of compounds **3** and **4** each comprises a $[PPh_4]^+$ cation and two independent half $[Au(dithiolene)_2]^-$ (dithiolene = 3-pedt or 4-pedt) anions, the Au atoms of which are situated on an inversion center, i.e., each anion has a *trans*-configuration (Fig. 1(c) and (d)). The dimensions of each $[Au(dithiolene)_2]^-$ complex are presented in Table 2. In each anion, the AuS_4 center is essentially square planar: the length of the four Au-S bonds is essentially the same (2.30 ± 0.02 Å); the S–Au–S angles are all close to 90°; and the AuS_4 array is precisely planar in compounds **3**



Scheme 1. Route used for the synthesis of $[PPh_4][Au(dithiolene)_2]$ (dithiolene = SC(H)C(R)S, R = phenyl (sdt), pyridin-2-yl (2-pedt), pyridin-3-yl (3-pedt) and pyridin-4-yl (4-pedt)) compounds. The numbering scheme for the various ligand substituents has been used in the assignment of the ^1H NMR spectra of these compounds.

The labelling of the atoms is shown in Figure 1 and Au(A) corresponds to Au(1) for **1** and **2** (the asymmetric unit of which involve one $[Au(dithiolene)_2]^-$ anion) and Au(2) for **3** and **4** (the asymmetric unit of which involve two independent half $[M(dithiolene)_2]^-$ anions).

and **4** and very close to planar in compounds **1** and **2** (the maximum deviation of an atom from the AuS_4 plane is 0.044 Å in **1** and 0.043 Å in **2**). Also, each {AuSCCS} metallodithiolene ring is essentially planar with the maximum displacement from the mean plane being $\leqslant 0.05$ Å. These structural details are in good agreement with those reported for other $[Au(dithiolene)_2]^-$ anions [6,9,13,16,19,20,22,29–31], as are the C–S (1.75 ± 0.03 Å) and dithiolene C–C (1.34 ± 0.01 Å) bond lengths (provided that the C–C bond is not part of an aromatic ring).

The four crystal structures described herein are the first such examples of gold bound to two asymmetrically substituted dithiolenes; also, $[Au(sdt)_2]^-$ and $[Au(2\text{-}pedt)_2]^-$ represent the first *cis*-isomers of a bis-dithiolene complex to be structurally characterized. The essential equivalence of the four M–S and four C–S bonds of each $[Au(dithiolene)_2]^-$ (dithiolene = sdt, 2-pedt, 3-pedt, or 4-pedt) complex indicates that the asymmetric nature of the dithiolene does not significantly affect the nature of the metal–sulfur interactions. However, the asymmetric nature of the dithiolene ligands *is* reflected in the S–C–C interbond angles; the S–C(H)–C(R) angles (125.1(6)–126.2(3)°) are significantly larger than the S–C(R)–C(H) angles (116.2(10)–121.7(4)°).

An important aspect to the nature of a dithiolene complex is the "non-innocence" of this ligand, the two extreme forms being the ene-1,2-dithiolate ($^-S–C{=}C–S^-$) and the dithioketone (S=C–C=S) [42]. Thus, the lengths of the C–C and C–S bonds can be used to comment on the nature of a dithiolene ligand in a complex, especially when – as in the present cases – the dithiolene ring is not fused to an aromatic ring. For sp^2 hybridized carbon atoms, typical bond lengths are: C–C, 1.43–1.48 Å; C=C, 1.30–1.36 Å; C–S, 1.71–1.75 Å; and C=S 1.67–1.68 Å [43]. Thus, the length of both the C–C (1.34 ± 0.01 Å) and the C–S (1.75 ± 0.03 Å) bonds of the ligands in each of the compounds **1**–**4** are consistent with the ene-1,2-dithiolate form of the dithiolene. Therefore, these $[Au(dithiolene)_2]^-$ anions can, to a first approximation, be formulated as Au(III) bis(ene-1,2-dithiolate) complexes, as proposed for $[Au(1,2\text{-}C_6H_4S_2)_2]^-$ by Ray et al. on the basis of the C–S bond lengths of this complex (average 1.762 Å) [31]. Consistent with this proposal, the electronic spectrum of compound **1** contains two weak absorptions at ca. 720 nm ($\varepsilon \sim 100\ M^{-1}\ cm^{-1}$) and ca. 465 nm ($\varepsilon \sim 260\ M^{-1}\ cm^{-1}$), similar to those of $[Au(1,2\text{-}C_6H_4S_2)_2]^-$ and related $[Au(dithiolene)_2]^-$ complexes [21,31].

4.3. ^1H NMR spectroscopy

The dithiolene proton of these $[Au(SC(H)C(R)S)_2]^-$ complexes provides a valuable probe of the nature of these complexes in solution. In the ^1H NMR spectrum of each $[PPh_4][Au(dithiolene)_2]$ (dithiolene = sdt, 2-pedt, 3-pedt, or 4-pedt) compound in $(CD_3)_2CO$ at 298 K the dithiolene (H^{dithio}) resonances were observed as two singlets, consistent with the presence of both *cis* and *trans* isomers of the square-planar anion in solution. The resonances observed and the ratio of the integrals were: $[PPh_4][Au(sdt)_2]$, 6.63 and 6.62 ppm, ca. 1:1; $[PPh_4][Au(2\text{-}pedt)_2]$, 7.62 and 7.61 ppm, ca. 1:1; $[PPh_4][Au(3\text{-}pedt)_2]$, 6.79 and 6.78 ppm, ca. 9:1; and $[PPh_4][Au(4\text{-}pedt)_2]$, 7.16 and 7.15, ca. 1:1. These H^{dithio} resonances vary with the nature of the dithiolene as 2-pedt > 4-pedt > 3-pedt > sdt, as observed for the $[MO(dithiolene)_2]^{2-}$ (M = Mo or W) complexes of these ligands. This order is consistent with nature of the ligands, in respect of: (i) inductive effects and (ii) the relative ability of the aromatic substituent to stabilize a resonance form in which a positive charge is localized at the C atom carrying the dithiolene proton [34,35].

The resolution of two environments for the dithiolene protons of compounds **1**–**4** contrasts with the ^1H NMR spectra observed for $[Ni(sdt)_2]$, in CD_2Cl_2; at >198 K a single dithiolene resonance is manifest but, at 198 K two resonances, of relative intensity ca. 1:1 and separated by 9.8 Hz are resolved. This latter information is consistent with a rapid interconversion of the *cis* and *trans* isomers of $[Ni(sdt)_2]$ at >198 K and has been attributed to a facile rotation of the ligand(s) around the metal [44]. Noting these results, the ^1H NMR spectrum of $[PPh_4][Au(sdt)_2]$ in $(CD_3)_2SO$ was recorded at ca. 298, 320, 330, 340, 355 and 365 K. At each temperature, the dithiolene proton resonances appeared as two singlets with a relative intensity of ca. 1:1. The splitting between these two singlets decreased slightly as the temperature was increased, from 3.28 Hz at 298 K to 2.96 Hz at 365 K, suggesting that coalescence may occur at >365 K. However, it is clear that the

activation energy for the interconversion of the *cis* and *trans* isomers of $[Au(sdt)_2]^-$ is significantly greater than that for the corresponding process of $[Ni(sdt)_2]$ [44]; this could be due to stronger metal–ligand bonds for Au (a 5d-metal) than Ni (a 3d-metal).

The presence of essentially equal amounts of the *cis* and *trans* isomers of $[Au(sdt)_2]^-$, $[Au(2\text{-pedt})_2]^-$, and $[Au(4\text{-pedt})_2]^-$ in solution and the lack of any significant interconversion of these isomers at room temperature suggests that solid samples of their $[PPh_4]^+$ salts contain an essentially equal amounts of the two isomers. However, from the structural studies, it appears that one isomer of the anion may preferentially crystallize and/or been present in the crystal selected for X-ray analysis. In respect of $[PPh_4][Au(3\text{-pedt})_2]$, we presume that the *trans* isomer identified by X-ray crystallography predominates in the sample for which the ^1H NMR spectrum was recorded.

4.4. Redox behavior

The cyclic voltammogram of each $[PPh_4][Au(\text{dithiolene})_2]$ (dithiolene = sdt, 2-pedt, 3-pedt, or 4-pedt) compound has been recorded in dmf solution containing $[N^nBu_4][BF_4]$ (0.2 M) as the background electrolyte. Each compound (Table 3) exhibits both an oxidation and a reduction process.

The oxidation of the compounds **1**–**4** occurs in the range $80\text{ mV} < E_p^a(\text{ox}) < 230\text{ mV}$ (versus $[Fc]^+/[Fc]$). The relative values of these potentials (Table 3) correlates with the electron withdrawing nature of the substituent (R), as measured by the Hammett parameter, σ_p [45]; thus, **1** (R = Ph; $\sigma_p = -0.01$) is the easiest to oxidize ($E_p^a(\text{ox}) = 80\text{ mV}$) and **4** (R = pyridin-4-yl; $\sigma_p = 0.44$) is the most difficult to oxidize ($E_p^a(\text{ox}) = 230\text{ mV}$). For each compound **1**–**4**, a variation in the scan rate (from 20 to 300 mV s^{-1}), monitoring the wave profile, the separation of the peak potentials (ΔE generally >70 mV), and the ratio of the cathodic and anodic currents ($-I_p^c : I_p^a \neq 1.0$) indicated that the oxidation is not electrochemically reversible. The most promising results were obtained for compound **1** (Fig. 2). At a scan rate >50 mV s^{-1}, ΔE is ca. 70 mV and comparable with that of the $[Fc^*]^+/[Fc^*]$ couple used as an internal standard. Also, the oxidation was monitored by UV/Vis spectroscopy and the profile seen to change through a series of isosbestic points. However, application of a potential sufficient to reverse the oxidation did not reproduce the original UV/Vis spectrum (even at 243 K). Therefore, the product of the oxidation of **1** is not stable within the timescale of the bulk electrolysis experiment. Also, oxidation of **1** with I_2 did not produce a stable product.

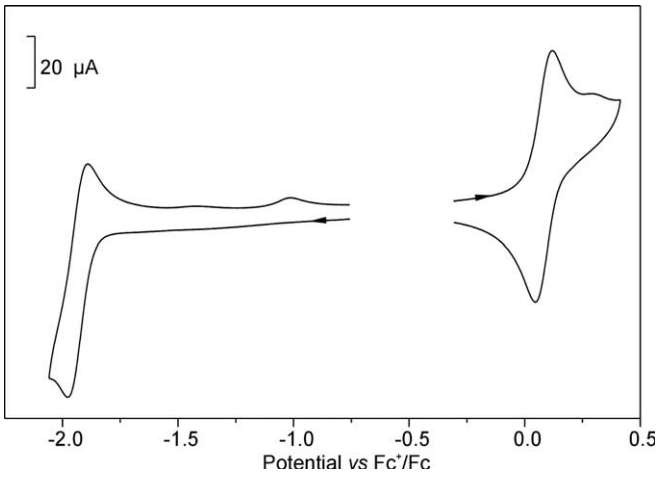

Fig. 2. Cyclic voltammogram of $[PPh_4][Au(sdt)_2]$ (**1**) (1 mM), at room temperature in DMF containing $[N^nBu_4][BF_4]$ (0.2 M), recorded using a glassy carbon working electrode, a Pt wire secondary electrode, and a saturated calomel reference electrode; potentials are vs. the $[Fc]^+/[Fc]$ couple.

The reduction of the compounds **1**–**4** occurs in the range $-1880\text{ mV} < E_p^c(\text{red}) < -2020\text{ mV}$ (versus $[Fc]^+/[Fc]$). As for oxidation of these compounds, the relative values of these reduction potentials (Table 3) correlate with the electron withdrawing nature of the dithiolene substituent (R), as measured by the Hammett parameter, σ_p [45]; thus, **1** is the most difficult to reduce ($E_p^c(\text{red}) = -2020\text{ mV}$) and **4** is the easiest to reduce ($E_p^c(\text{red}) = -1880\text{ mV}$). For each compound the reduction wave is accompanied by a corresponding oxidation wave upon reversal of the potential (Fig. 2). The electrochemical characteristics of the process were examined for a range of scan rates (20–300 mV s^{-1}) and, in each case, the reduction was not reversible. Also, following the reduction of each compound, scans at a more positive potential revealed other, relatively minor, oxidation processes, suggesting that each reduced species is reactive and/or unstable.

The cyclic voltammogram (CV) of **1** (Fig. 2) is remarkably similar, in respect of both the overall profile and the potentials of the redox processes, to the CV of $[Au(3,5\text{-di-}tert\text{-butyl-}1,2\text{-benzenedithiolate})_2]^-$ ($[Au(3,5\text{-}(^tBu)_2bdt)_2]^-$) [31]. This latter complex, in CH_2Cl_2 solution, undergoes two, reversible, one-electron processes; an oxidation at 74 mV and a reduction at −2280 mV (versus $[Fc]^+/[Fc]$). The correspondence in redox behavior and the one-electron nature of both redox couples of $[Au(3,5\text{-}(^tBu)_2bdt)_2]^-$ implies that oxidation of **1** involves the

Table 3
Potentials (vs. $[Fc]^+/[Fc]$) observed for the oxidation and reduction of $[PPh_4][Au(sdt)_2]$ (**1**), $[PPh_4][Au(2\text{-pedt})_2]$ (**2**), $[PPh_4][Au(3\text{-pedt})_2]$ (**3**), and $[PPh_4][Au(4\text{-pedt})_2]$ (**4**) (1 mM) at room temperature in DMF containing $[N^nBu_4][BF_4]$ (0.2 M)

Compound	$E_p^a(\text{ox})$	$E_{1/2}(\text{ox})$	$E_p^c(\text{red})$	$E_{1/2}(\text{red})$	$\Delta E([Fc^*]^+/[Fc^*])$
1	80	50(70)	−2020	−1970(90)	70
2	120		−1970	−1920(90)	80
3	180		−1920	−1880(90)	70
4	230	200(70)	−1880	−1840(90)	70

The shape of the voltammogram observed for the oxidation of **2** and **3** does not allow an accurate determination of $E_{1/2}$. For each compound, other redox processes were observed outside the potential range 1000 to −2100 mV.

$[Au(dithiolene)_2]/[Au(dithiolene)_2]^-$ couple and reduction involves the $[Au(dithiolene)_2]^-/[Au(dithiolene)_2]^{2-}$ couple.

The nature of the frontier orbitals of $[Au(dithiolene)_2]^-$ complexes has been investigated by performing ab initio calculations for $[Au(bdt)_2]^-$ [21] and the results of density functional calculations for $[Au(bdt)_2]^z$ ($z = 0$ or 1) and related complexes of Ni, Pd, Pt, and Cu [32]. Schiødt et al. [21] showed that, as observed by Schultz et al. [12], the two highest occupied molecular orbitals (HOMOs) of $[Au(bdt)_2]^-$ have π-character and comprise the antisymmetric and symmetric combination of the ligand HOMOs with 4 and 0% contribution from Au orbitals, respectively; each of these orbitals is C–S antibonding and C–C bonding in character. The LUMO of $[Au(bdt)_2]^-$ has σ-character, is the antibonding combination of the metal d_{xy} and ligand $1b_{1g}$ orbitals with significant contributions from both the metal (Au d_{xy} ca. 48%) and the ligand orbitals [21]. Similar results were obtained by density functional calculations accomplished for $[Au(bdt)_2]^z$ ($z = 0$ or 1) [32].

As described in 4.2, the length of the C–C and C–S bonds of the dithiolene ligands of compounds **1**–**4** are consistent with formulation as $[Au(III)(ene\text{-}1,2\text{-}dithiolate)_2]^-$, as indicated by structural [31] and theoretical [32] studies of $[Au(bdt)_2]^-$. One-electron oxidation of a $[Au(dithiolene)_2]^-$ complex, electrochemically or chemically (e.g., I_2), yields the corresponding, paramagnetic, $[Au(dithiolene)_2]$ complex, examples of which have been structurally characterized [12,16,30]. Dautel et al. [30] and Ray et al. [31] have compared the dimensions of a $[Au(dithiolene)_2]^-$ complex with those of its a $[Au(dithiolene)_2]$ counterpart and shown that conversion of the former to the latter leaves the Au–S bond length essentially unchanged, but the C–S bond shortens and the C–C bond lengthens. These structural changes are consistent with the loss of an electron from the HOMO of a $[Au(dithiolene)_2]^-$ complex, i.e., this ligand-based orbital[1] is Au–S non-bonding, C–S antibonding, and C–C bonding [21,32].

One-electron reduction of a $[Au(dithiolene)_2]^-$ complex yields the corresponding $[Au(dithiolene)_2]^{2-}$ complex that possesses one unpaired electron and EPR spectra of several of these systems have been reported [2,7,8,25,26]. A single-crystal EPR-ENDOR study of ^{13}C enriched $[^nBu_4N]_2[Au(mnt)_2]$ diluted in $[^nBu_4N]_2[Ni(mnt)_2]$ found that the majority (ca. 64%) of the unpaired spin density is located on the *S*-atoms [25,26]. This information is in qualitative agreement with the significant involvement of ligand orbitals in the LUMO of $[Au(dithiolene)_2]^-$ complexes [21,32].

A comparison of redox potentials for $[Au(L)_2]^-$ (L = sdt, 2-pedt, 3-pedt or 4-pedt) with those of their $[M(L)_2]^-$ (M = Ni, Pd or Pt) analogs [43] indicates that oxidation is less sensitive to a change in the metal than that of the corresponding reduction process. This is consistent with an oxidation being predominantly ligand-based and reduction involving an orbital with both ligand and metal character (vide infra). The trends within this series of $[Au(L)_2]^-$ complexes indicate a tuning of the ligand energy levels by the appended aromatic substituents.

5. Conclusions

Four new $[Au(dithiolene)_2]^-$ complexes, each involving two asymmetrically substituted dithiolene ligands (SC(H)-C(R)S; R = phenyl, pyridin-2-yl, pyridin-3-yl, or pyridin-4-yl) have been synthesised, isolated as the $[PPh_4]^+$ salt and structurally characterized. The lengths of the C–C and C–S bonds of the ligands in each $[Au(dithiolene)_2]^-$ complex is consistent with the dithiolene being present as an ene-1,2-dithiolate and, hence these are [Au(III)bis(ene-1,2-dithiolate)]$^-$ complexes. Each compound is diamagnetic and ^1H NMR studies indicate that, in solution in d^6-acetone, both the *cis* and *trans* isomers of the $[Au(SC(H)C(R)S)_2]^-$ anion are present and do not interconvert at room temperature. Each $[Au(dithiolene)_2]^-$ complex undergoes a ligand-based oxidation process and a reduction that involves the addition of an electron to an orbital that possesses considerable ligand character. These $[PPh_4][Au(dithiolene)_2]$ compounds are suitable diamagnetic hosts that facilitate EPR studies of corresponding $[M(dithiolene)_2]^-$ (M = Ni, Pd, or Pt) complexes [46].

[1] Ray et al. [31,32] favor a description of the oxidized species as $[Au^{III}(L)(L^{\cdot})]$ (L = dithiolene). This implies that oxidation of a $[Au(dithiolene)_2]^-$ complex removes an electron from *one* ligand, *whereas* the theoretical results [12,21,32] indicate that the electron is lost from an orbital that involves an equal contribution from each ligand and the dimensions observed for $[Au(dithiolene)_2]$ complexes provide no such distinction between the ligands [12,16,30].

Abstract

A series of azathia- and azaoxathiacrown ether macrocycles have been prepared in good yields via the use of *N*-boc-bis(2-chloroethyl)amine as a precursor, which minimises undesirable side reactions and facilitates subsequent deprotection to the free cyclic amine. The mono-aza macrocycles, [12]aneNS$_3$, [12]aneNOS$_2$, [15]aneNS$_4$, [15]aneNO$_2$S$_2$ and [16]aneNS$_4$ have been prepared via this route. The single-crystal X-ray structure of [12]aneNS$_3$ · HBr · 2H$_2$O confirms the macrocycle to be distorted quadrangular with the S-centres lying along the edges and six out of 12 torsion angles less than 90°. The synthesis of di-aza macrocycles utilising the diamide precursors, *N*,*N*′-bis(chloroacetyl)-1,2-diaminoethane and *N*,*N*′-bis(chloroacetyl)-1,3-diaminopropane, affords the free macrocycles [12]aneN$_2$S$_2$, [15]aneN$_2$S$_3$, [15]aneN$_2$OS$_2$, [16]aneN$_2$S$_3$ and [19]aneN$_2$S$_4$ after reduction of the intermediate cyclic amides. Reaction of 3,6-dioxa-1,8-octanediamine with the dimethyl ester of thiadiglycolic acid followed by reduction affords [15]aneN$_2$O$_2$S, while the hydroxy-substituted macrocycles [20]aneS$_6$(OH)$_2$, [13]aneS$_4$(OH), and [26]aneS$_8$(OH)$_2$ have been prepared by reaction of 1,3-dichloro-2-hydroxypropane with the appropriate dithiol. The crystal structure of [20]aneS$_6$(OH)$_2$ shows two endo- and four exo-dentate S-centres as observed in the parent [18]aneS$_6$. The *N*-aryl substituted macrocycles *N*-4-NO$_2$Ph-[12]aneNS$_3$ (*N*-4-nitrophenyl-7-aza-1,4,10-trithiacyclododecane) and *N*-4-NH$_2$COPh-[12]aneNS$_3$ (*N*-4-benzamido-7-aza-1,4,10-trithiacyclododecane) have been prepared by reaction of 4-substituted bis-tosylated *N*,*N*-bis(2-hydroxyethyl)aniline with 3-thia-1,5-pentanedithiol.

1. Introduction

The ability of oxygen donor crown ethers to co-ordinate specifically to cations has been used extensively to bind and isolate alkali and alkaline earth metal ions from solution [1,2]. Macrocycles containing nitrogen and/or sulfur donor atoms are of interest as they exhibit high affinities towards heavy transition metal ions, and their selectivity is readily tunable by altering the composition of the donor-atom set and ring size. Mixed *N*,*O*,*S*-donor crowns, therefore, form an interesting class of compounds, which have found use as selective extractants for soft metal cations [3,4], and as models for the active sites of some enzymes [5]. The availability of mixed-donor crowns, however, is often limited by synthetic difficulties and many different approaches have been developed. We describe herein new synthetic routes to the formation of mixed *N*,*O*,*S*-donor crowns in reasonable yields. Such ligands have proven to be valuable in the selective extraction of transition-metal ions after immobilisation of these ligands onto organic polymeric resins, where the selectivity can be tuned by variation of the macrocyclic ligand [6,7]. Furthermore, *N*-substituted mixed-donor crown ethers may find application as redox chemosensors [8,9] or as hosts for the simultaneous binding of anions and cations [10,11].

Crown ethers containing only oxygen donors are generally accessible by reaction of the appropriate diol with a dihalide or ditosylate species in the presence of a base,

for example NaOH [1]. This type of ring closure is relatively successful due to a strong template effect of the alkali metal ions with the polyether units. The synthesis of sulfur analogues, however, is less straightforward due to the absence of such a template effect, which can be attributed to the much lower affinity of sulfur for alkali metal ions compared to oxygen. Thus, the reaction of 3-thia-1,5-pentanedithiol with 1,2-dichloroethane in the presence of NaOH in EtOH affords low yields (0.04%) of the cyclic product [9]aneS$_3$ [12].

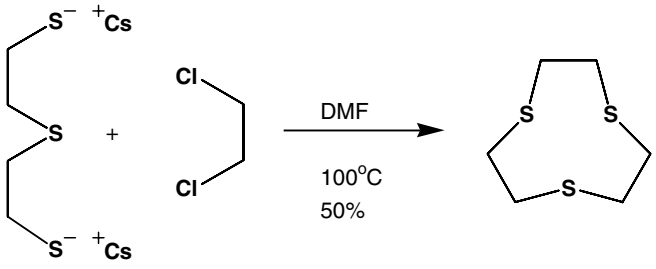
More recently, an improved method for the synthesis of thiacrown ethers has been developed by Buter and Kellogg [13] (Scheme 1). This method involves the Cs_2CO_3-mediated cyclisation of a dithiol and a dihalide in DMF under high-dilution conditions coupled with prolonged reaction times. It is believed that the Cs^+ ions form relatively weak ion pairs with the thiolate moieties, thereby making the sulfur atom highly nucleophilic and hence more reactive. Using this method [9]aneS$_3$ can be synthesised in multigram quantities in 50% yield [14]. Similarly, by variation of the dithiol or the dihalide species, oxathiacrown ethers and macrocycles bearing substituents have become available [15–17].

N-Tosylated amines are generally used for cyclisation reactions involving C–N bond formation [3] as dialkylation and quaternisation can result when unprotected amines are used. Thus, the cyclisation reaction is generally undertaken either in the presence of Cs_2CO_3 or by employing the disodium salts of the tosylated diamine. Ditosylates rather than dihalides are often used as the co-cyclisation reagents in these reactions [18] and an example is shown in Scheme 2. The major disadvantage of this method of cyclisation is the deprotection step that is necessary to obtain the tosylate-free macrocycle. Vigorous conditions such as concentrated H_2SO_4 at 90 °C [19], prolonged refluxing in HBr/acetic acid [20] or lithium in liquid ammonia [21] are required to remove the protecting group, but these can result, depending upon the ligand system, in degradation of the macrocyclic product. A variation on this method is provided by the reaction between a ditosylate and a dithiol (instead of a ditosylated diamine) in which [9]aneNS$_2$ can be synthesised from tritosylated diethanolamine and ethane dithiol, using Cs_2CO_3 in DMF [22].

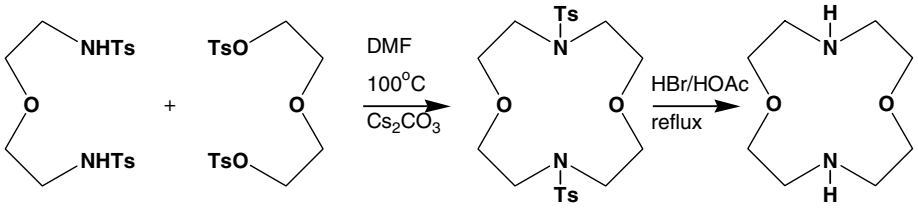
Alternative synthetic procedures for azathiacrown ethers, which avoid tosylated intermediates, have also been reported. [15]aneNS$_4$ has been prepared directly from 3,6-dithia-1,8-octanedithiol and 1,5-dichloro-3-azapentane under high dilution conditions in DMF in the presence of Cs_2CO_3 [23] (Scheme 3(i)), although the yield of the macrocycle was rather low. [12]aneNS$_3$, [15]aneNS$_4$ and [18]aneNS$_5$ have been prepared from the 1,5-dichloro-3-azapentane and the appropriate dithiols (Scheme 3(ii)) with yields in the range from 26% to 39% [24]. Similarly, [12]aneNOS$_2$ can be prepared from 3-oxa-1,5-pentanedithiol and 1,5-dibromo-3-azapentane in MeOH in the presence of NaOMe (Scheme 3(iii)) [25]. The occurrence of *N*-alkylation and competing polymerisation reactions appear to be the major disadvantages of using a dithiol and an unprotected bis(2-haloethyl)amine.

An entirely different approach to unsubstituted oxaazathiacrown ethers involves the reaction of a diamine with a diacid chloride. Thus, Pelissard and Louis [26] have described the synthesis of a wide range of potentially pentadentate macrocycles using the same general procedure (Scheme 4). The reduction of the diamide is accomplished by either $LiAlH_4$ or BH_3 in THF. An alternative to this method is provided by the reaction of diamines with dimethyl esters instead of diacid chlorides [27], where only medium dilution conditions are required with reagent concentrations of the order of 0.1 mol/L, and the reaction proceeds under ambient conditions using MeOH as the solvent, typically over 7 days at 25 °C. Unlike the reactions involving diacid chlorides, non-protected polyamines can also be utilised in this type of cyclisation reaction due to the higher reactivity of the terminal primary amines compared to the internal secondary amines. Again, the resulting diamide may be reduced either by $LiAlH_4$ or by BH_3 in THF to afford the macrocyclic amine [27]. The fact that neither nitrogen protection nor high dilution conditions are required makes this method very attractive.

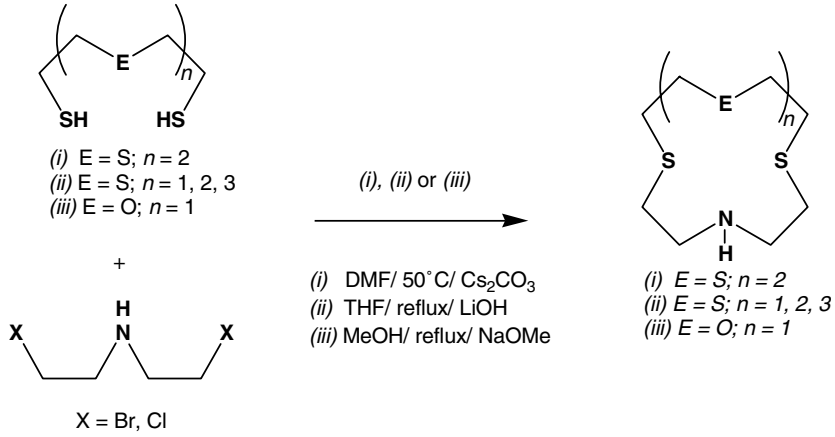
A series of 16–19-membered mixed-donor dibenzocrown ethers has been synthesised via the Schiff-base condensation of a linear diamine with dialdehyde [28]. The resulting



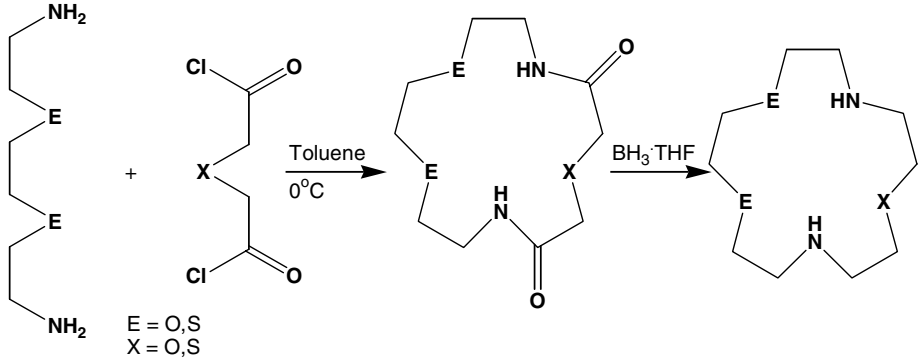
Scheme 1. Cs_2CO_3-mediated cyclisation of [9]aneS$_3$.



Scheme 2. Scheme for the synthesis of an oxa-azacrown ether.



Scheme 3. Synthesis of mixed-donor crown ethers without the use of protecting groups.



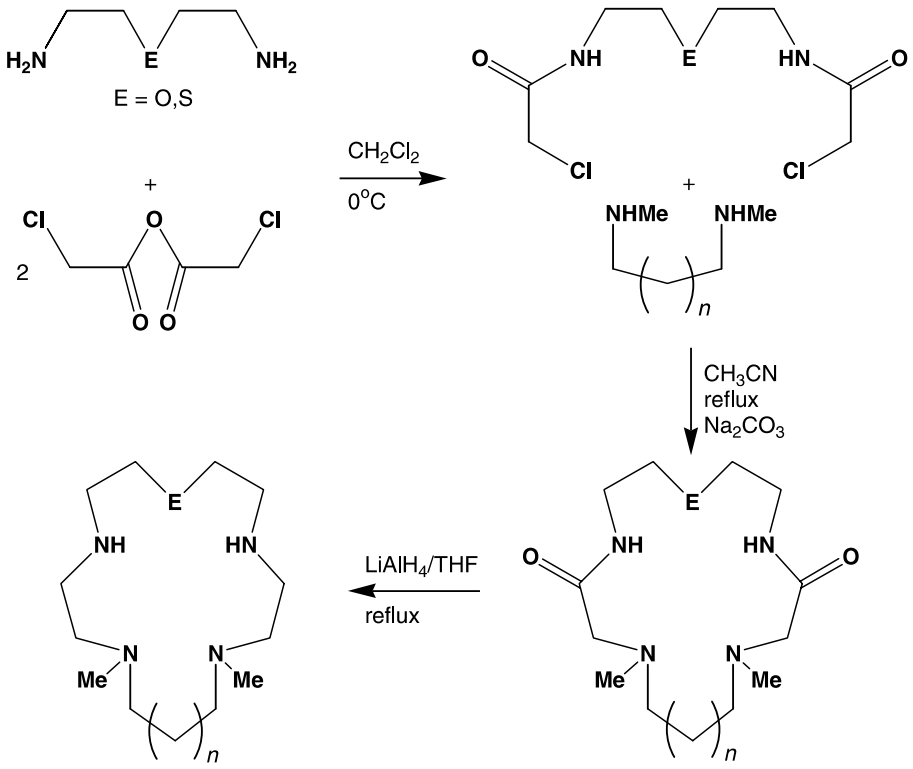
Scheme 4. Synthesis of 15-membered macrocycles from diamines and diacid chloride precursors.

diimines can be subsequently reduced with $NaBH_4$ to give the saturated macrocycles. Protection of the nitrogen atoms is not necessary as the initial formation of the imine species prevents undesired dialkylation reactions. Izatt and co-workers have used a different strategy to avoid side-reactions involving *N*-centres [29]. In this method a bis(α-chloroamide), prepared from the appropriate diamine by acylation using chloroacetic anhydride, undergoes ring-closure in a reaction with bis-secondary amines. The final reduction to yield the tetraamine can be achieved by reaction with $LiAlH_4$ (Scheme 5).

Metal templates have also been used to facilitate ring closing reactions; for example [9]aneS_3 has been prepared using the $Mo(CO)_3$ fragment with reaction between 1,2-dibromoethane and a 3-thia-1,5-pentanedithiol molybdenum adduct giving the cyclic product in good yield. This reaction can be made catalytic in terms of molybdenum [30].

Thus, the synthetic challenges in macrocycle synthesis are the result of: (i) elaborate protection and deprotection steps prior to and after ring closure, (ii) side reactions resulting in branched and polymeric products, and (iii) high-dilution conditions or simultaneous addition of two reagents. The tosyl group is the most widely used protective group in macrocyclic synthesis and has the advantages of high stablity towards harsh reaction conditions and ease of purification [19]. The main disadvantage is the often troublesome removal of the tosyl groups from mixed-donor crown ethers [21], particularly in the presence of oxidisable *S*-centres.

In order to overcome difficulties in deprotection, we have chosen to use a *t*-butyloxycarbonyl (boc) group to protect secondary amines in cyclisation reactions. The advantages of boc groups are that: (i) they can be readily introduced into secondary amines, (ii) they are not removed during cyclisation reactions, (iii) boc-protected crown ethers can be easily purified by column chromatography, and (iv) boc groups are generally removed under mild acidic conditions without affecting the macrocycle. We report herein the use of *N*-boc-bis(2-chloroethyl)amine (**1**) as the key intermediate for the synthesis of a series of unsubstituted oxamonoazathiacrown ethers. Secondly, a series of diazathiacrown ethers is presented, prepared by reaction of *N*,*N*′-bis(chloroacetyl)-diaminoalkanes with dithiols. In this way, no branched side products are formed during the cyclisation reaction as the nitrogen atoms are protected by the amide bond, and subsequent mild reduction in borane–THF affords the unsubstituted diazathiacrown ethers. Finally, we also report the synthesis of hydroxy-substituted thiacrown ethers and of *N*-aryl-substituted monoazathiacrown ethers.



Scheme 5. Synthesis of polyaza-crown ethers via a diamide intermediate.

2. Results and discussion

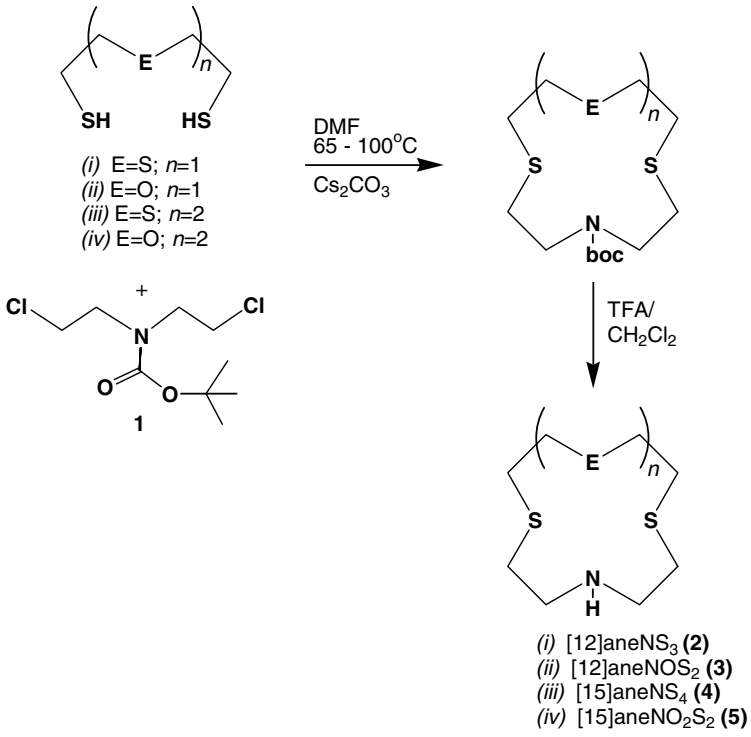
2.1. Macrocycle synthesis

Reaction of **1** with the corresponding dithiol was carried out in a rapidly stirred suspension of Cs_2CO_3 in DMF, usually at concentrations in the range from 50 to 100 mmol/L at temperatures ranging from 65 to 100 °C, following the procedure of Buter and Kellogg [13]. The synthesis of the macrocyles [12]aneNS$_3$ (**2**), [12]aneNOS$_2$ (**3**), [15]aneNS$_4$ (**4**) and [15]aneNO$_2$S$_2$ (**5**) is illustrated in Scheme 6. Similarly, [16]aneNS$_4$ (**6**) was prepared from **1** and 3,7-dithia-1,9-nonanedithiol. The crude boc-protected products were purified by column chromatography yielding 35–40% of the pure boc-protected macrocycle, or by crystallisation (boc-**2**, 55% yield). In each case boc deprotection was carried out by stirring the boc-protected crown ethers with a TFA/CH_2Cl_2 mixture to give the deprotected macrocycle in 90% isolated yield.

A series of mixed-donor macrocycles containing two adjacent N-centres, [12]aneN$_2$S$_2$ (**7**), [15]aneN$_2$S$_3$ (**8**), [15]aneN$_2$OS$_2$ (**9**), [16]aneN$_2$S$_3$ (**10**) and [19]aneN$_2$S$_4$ (**11**) has been prepared utilising the precursors *N*,*N*′-bis(chloroacetyl)-1,2-diaminoethane and *N*,*N*′-bis(chloroacetyl)-1,3-diaminopropane (Scheme 7). The cyclisation is mediated by Cs_2CO_3 in DMF under medium dilution conditions using a dithiol as the co-cyclisation reagent. The intermediate macrocyclic diamide is readily separated from the polymeric material formed in competition with the macrocycle by extraction with CH_2Cl_2, with the exception of [12]aneN$_2$S$_2$ (**7**). Yields of the 15-membered diamide macrocycles were high (60–70%) while the yield of 1,4-dithia-7,10-diazacyclododecane-6,11-dione was lower and was difficult to estimate due to the presence of polymeric material.

The saturated macrocycles were obtained in good yield by reduction of the diamide precursors with borane–THF and, in the case of [12]aneN$_2$S$_2$ (**7**), no difficulty was experienced in the separation from the polymeric material. The reaction time is important in the reduction step with shorter times (8–12 h) giving optimum yields and longer times (20–40 h) resulting in lower yields (5–10%). The crude material was suitable, in most cases, for further use without purification, although column chromatography can be used to obtain analytically pure samples. We also report here the reduction of 7,13-diaza-1,4-dioxa-10-thiacyclopentadecane-8,12-dione, prepared from 3,6-dioxa-1,8-octanediamine and the dimethylester of thiadiglycolic acid in dry MeOH [31] using the same procedure. The reduction step is effective and affords the macrocycle [15]aneN$_2$O$_2$S (**12**) in 60% yield.

Employing the same methodology as used to prepare the other aza-thioether macrocyles with the intermediate **1**, the macrocycles [20]aneS$_6$(OH)$_2$ (**13**, Scheme 8), [13]aneS$_4$(OH) (**14**) [32] and [26]aneS$_8$(OH)$_2$ (**15**) (Scheme 9) were prepared via reaction of 1,3-dichloro-2-hydroxypropane with the appropriate dithiol. The preparation of the 20-membered macrocycle, **13**, also afforded small amounts of the [1+1] 10-membered macrocycle which proved difficult to purify, while the 13- and 26-membered macrocycles were obtained



Scheme 6. Synthesis of (oxa)monoazathia crown ethers **2**, **3**, **4** and **5** from boc-protected bis(2-chloroethyl)amine **1**.

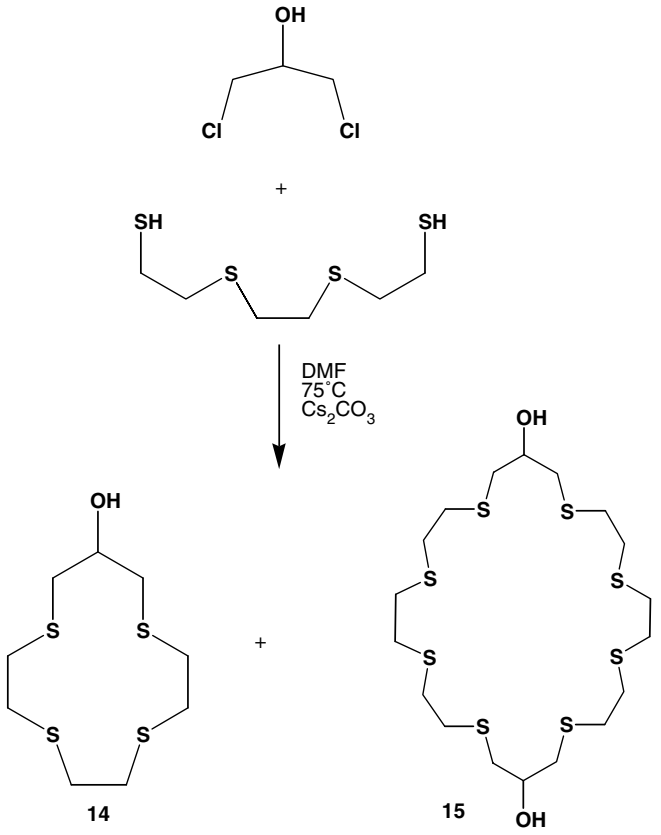
from the same reaction mixture and were separated by column chromatography on silica gel. These macrocycles are obtained as a mixture of *syn*/*anti* isomers which we were unable to resolve; however, due to the crystalline nature of [20]aneS$_6$(OH)$_2$ (**13**) crystals suitable for X-ray analysis could be grown.

While modifications to the aza moiety in macrocycles is often facile and accompanied in some cases with high yields [15–17], attempts to introduce aryl groups directly onto the

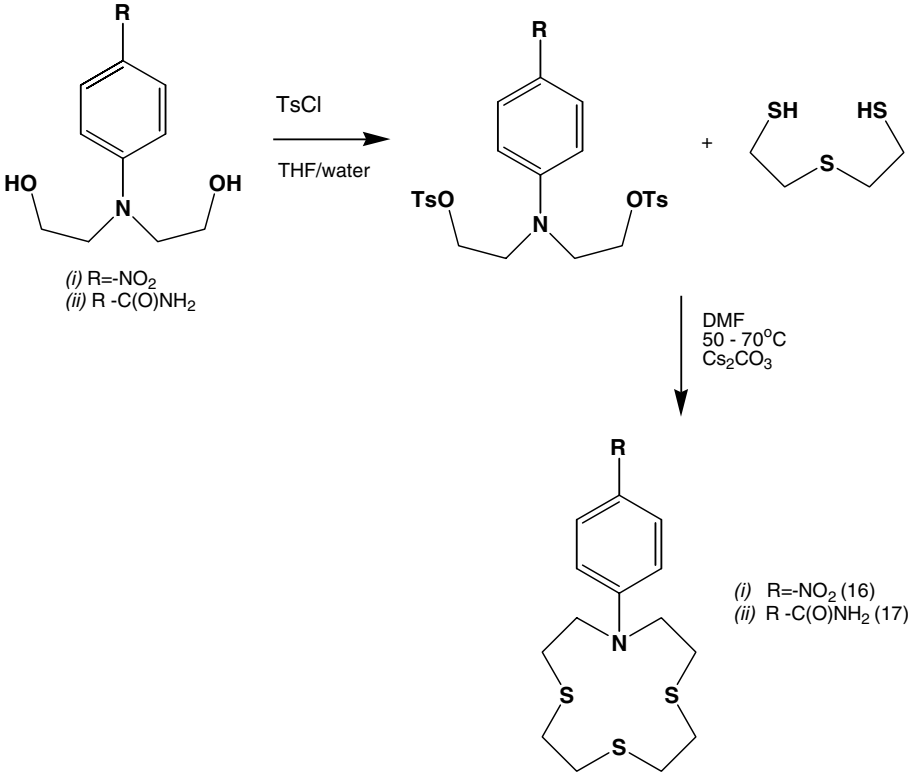


Scheme 9. Synthesis of hydroxy-substituted [13]aneS$_4$(OH) (**14**) and [26]aneS$_8$(OH)$_2$ (**15**).

macrocylic N-centre of the parent macrocycle is often problematic, even via Pd-catalysed coupling reactions which give good yields in analogous oxacrown ethers [33]. The main setback to Pd-catalysed routes to *N*-aryl-substituted azathiacrowns appears to be the high affinity and binding of these macrocycles to the palladium centre, thus rendering the catalyst ineffective. There are, however, some reports of aryl-subsitituted aza-thioether macrocycles in the literature: although their preparative routes and yields vary [17,34] they tend to utilise *N*-aryl substituted precursors.

Our interest in these types of macrocycles lies in their many potential uses, for example selective metal sensors, enhanced metal extraction and molecular switches. We, therefore, developed another route to aryl-substituted aza-thioether macrocycles in reasonable yields using tosylate leaving-groups, which is based upon the general cyclisation procedure already discussed above. This methodology also uses *N*-aryl substituted precursors and tosylates under Kellogg conditions [13]. Although it has been noted that tosylates are not as reactive toward thiolates as iodide leaving groups under the conditions used [34d], in our hands the macrocycles were obtained in satisfactory yields after a straightforward workup.

Thus, when a mixture of the ditosylated derivative of *N*,*N*-bis(2-hydroxyethyl)-4-nitroaniline, prepared in good yield from the reaction of the parent diol with tosyl chloride in a THF/water mixture, and 3-thia-1,5-pentanedithiol in DMF were added slowly to a rapidly stirred sus-



Scheme 10. Synthesis of *N*-4-NO$_2$Ph-[12]aneNS$_3$ (**16**) and *N*-4-NH$_2$COPh-[12]aneNS$_3$ (**17**).

pension of Cs_2CO_3 in DMF at 70 °C (Scheme 10), the resulting macrocyclic product *N*-4-NO_2Ph-[12]aneNS$_3$ (*N*-4-nitrophenyl-7-aza-1,4,10-trithiacyclododecane) (**16**) was obtained in 47% yield after purification by recrystallisation. The addition of Cs_2CO_3 is necessary for the reaction to take place smoothly, and heating to 50–70 °C was necessary to avoid the recovery of starting materials and/or polymeric material. In a similar fashion, *N*-4-NH_2COPh-[12]aneNS$_3$ (*N*-4-benzamido-7-aza-1,4,10-trithiacyclododecane) (**17**) was also prepared, the presence of the amide functionality allowing facile subsequent derivatisation via reduction to an amino group.

2.2. Single crystal structures of [12]aneNS$_3$ · HBr · 2H$_2$O (**2** · HBr · 2H$_2$O) and [20]aneS$_6$(OH)$_2$ (**13**)

A single-crystal X-ray structure of the HBr salt of [12]aneNS$_3$, **2** · HBr · 2H$_2$O (Fig. 1) was determined with the unit cell containing four molecules of **2** · HBr and eight molecules of water. The geometry of the molecule is rather unusual and may be described as a distorted quadrangular crown. The tendency of sulfur atoms in macrocyclic ligands to occupy the corners of quadrangular type structures is well documented [35], and in the majority of cases the sulfur atoms are oriented with their lone pairs pointing out of the ring (exodentate). This has been attributed to the preference of C–S bonds to adopt *gauche* conformations [35–37] while the C–C bonds take up the more energetically favourable *anti* conformations. In the structure of **2** · HBr · 2H$_2$O, the sulfur atoms do not occupy the corners of a quadrangle as found in [12]aneS$_4$ [35] and many other structures [38,39]; rather, they lie along the edges of a distorted crown. Significantly, there are only two *gauche* C–S conformations and three unfavorable eclipsed C–S conformations, while the remaining C–S torsion angle approaches a more favourable *anti* conformation (−158.9°). It has been noted [35] that an asymmetric distribution of donor atoms can make conformational preferences of ring segments act in opposition to each other which, in conjunction with amine protonation and hydrogen-bonding to the water molecules in the unit cell, may explain the abnormal conformation observed. Thus, six out of 12 torsion angles in the macrocyclic ring are less than 90°. Interestingly, the S atom (S7) lies out of the plane defined by N1, S4 and S10; however, all donor atoms are endodentate, an unusual orientation in thioether macrocycles although endodentate S centres have been observed in the structures of [9]aneS$_3$ [37] and [18]aneS$_6$ [35]. The transannular S···S distances in **2** · HBr · 2H$_2$O (3.476 and 3.600 Å for S4···S7 and S7···S10, respectively) are also shorter than the sum of the van der Waals radius of two sulfur atoms (3.7 Å) [40], and all C–C distances are slightly shorter than that expected for a C–C single bond (1.54 Å) as is commonly observed in other macrocyclic thioethers [35–37]. Selected bond distances, angles and torsion angles are given in Table 1. The extended structure of **2** · HBr · 2H$_2$O is a three-dimensional network of macrocycles, water molecules and bromide ions linked by N–H···O, O–H···O and O–H···Br interactions. Part of this network is shown in Fig. 2.

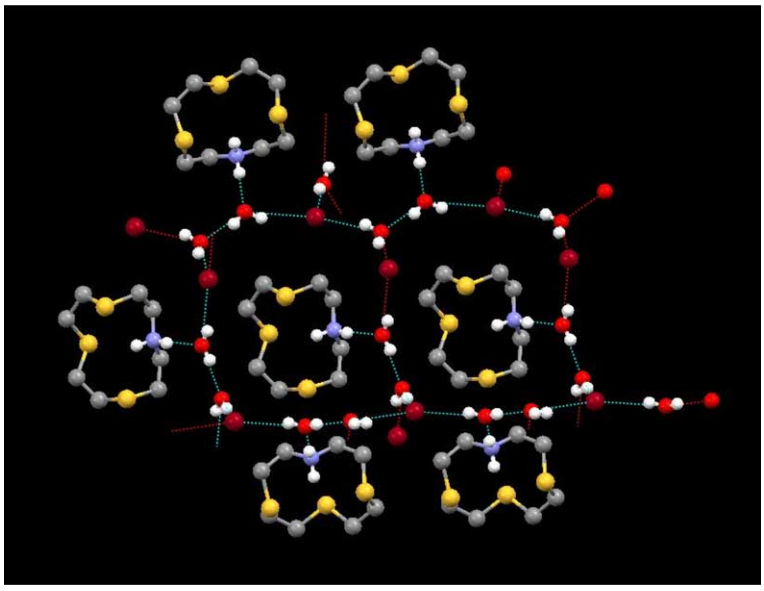

Fig. 2. Packing diagram of **2** · HBr · $2H_2O$. O: red, S: yellow, C: grey, H: white, N: blue. Hydrogens on carbon have been omitted for clarity.

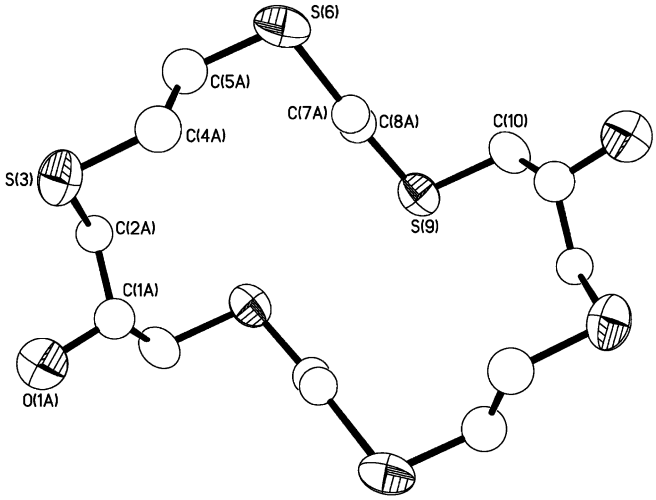

Fig. 3. Structure of **13** showing one disordered component. Carbon and oxygen atoms, except C(10) are isotropic, sulfur atoms are anisotropic (thermal ellipsoids shown at 50% probability level). Hydrogen atoms have been omitted for clarity.

The structure of [20]ane$S_6(OH)_2$ (**13**) is rather disordered, as may be expected from a mixture of isomers. Although the weakness of the diffraction resulted in a structure of limited precision, the main features of the compound are easily discernable. For clarity only the major (85%) disorder component is shown in Fig. 3. With two S atoms endodentate and four exodentate, the structure of [20]ane$S_6(OH)_2$ is reminiscent of that of [18]aneS_6 [35]. The molecule lies across a crystallographic twofold axis. Molecules are linked into a two-dimensional array by O–H···O hydrogen bonding interactions, as shown in Fig. 4.

3. Conclusions

We have demonstrated that mixed azathiacrown ether and oxaazathiacrown ether macrocycles can be obtained in good yields by utilising simple precursors under Kellogg conditions [13]. The methods described here are gen-

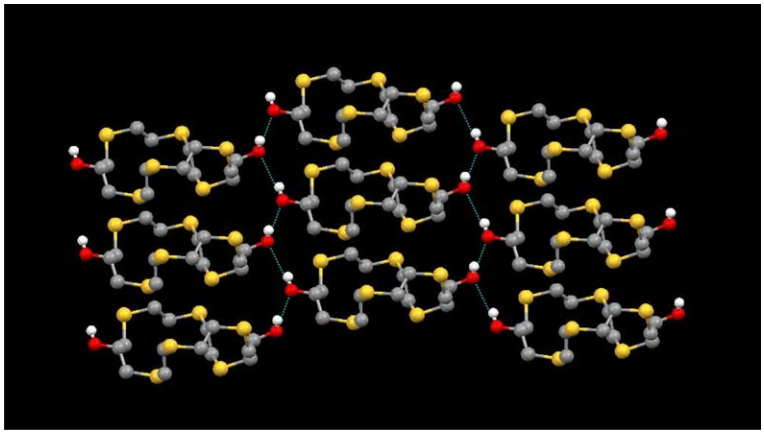

Fig. 4. Packing diagram of **13**. O: red, S: yellow, C: grey, H: white. Hydrogens on carbon have been omitted for clarity.

erally applicable to a wide range of mixed donor macrocyles and we are currently further exploring their derivatisation, co-ordination chemistry and applicability to metal ion extraction. The structure of [12]aneNS$_3$ · HBr · 2H$_2$O is found to be unusual compared to its homoleptic thioether analogues in that the macrocycle is rather distorted and contains endodentate donor atoms and few *gauche* C–S conformations which we attribute to protonation of the nitrogen donor. The structure of [20]aneS$_6$(OH)$_2$, although of limited precision, shows features similar to those in [18]aneS$_6$. Two *N*-aryl substituted aza-thioether macrocycles, *N*-4-NO$_2$Ph-[12]aneNS$_3$ and *N*-4-NH$_2$COPh-[12]aneNS$_3$, have also been prepared and are, due to their ease of purification, amenable to large scale synthesis.

4. Experimental

4.1. General remarks

All reagents and solvents were purchased from commercial sources and were used as received, unless stated otherwise. DMF was stored under an atmosphere of N_2 over molecular sieves. Elemental analyses (C, H, N, S) were carried out using the analytical facilities at the School of Chemistry, University of Nottingham, at Leiden University and University College Dublin. ^{1}H NMR and ^{13}C NMR spectra were recorded on either 200 MHz JEOL JNM FT NMR or Bruker AX 300 FT NMR spectrometers. Chemical shifts are quoted with respect to TMS as an internal reference. Mass spectra were recorded on either a Finnigan MAT TSQ-700 or a Finnigan MAT 900 XLT equipped with a custom-made electrospray interface (ESI), and by the EPSRC National Mass Spectrometry Facility at the University of Wales, Swansea. Single crystal *X*-ray data collections were performed on a Bruker SMART APEX CCD area detector diffractometer.

4.2. Single-crystal X-ray structural analyses of [12]aneNS$_3$ · HBr · 2H$_2$O [2 · HBr · 2H$_2$O] and [20]aneS$_6$(OH)$_2$ (**13**)

Single crystals of [12]aneNS$_3$ · HBr · 2H$_2$O suitable for analysis by X-ray diffraction were grown from a solution containing HBr/acetic acid and *N*-boc-[12]aneNS$_3$, which had been stirred at room temperature for 1 h. The solvent was reduced in vacuo and the colourless columnar crystals formed immediately at room temperature.

4.2.1. Crystal data

$C_8H_{22}BrNO_2S_3$, $M = 340.36$, tetragonal, $a = 8.609(3)$ Å, $c = 19.591(8)$ Å, $V = 1882.2(13)$ Å^3, $T = 220$ K, space group $P4_1$ (No. 76), $Z = 4$, μ(Mo Kα) = 3.247 mm^{-1}, $D_{calc} = 1.557$ g cm^{-3}, 1622 reflections measured, 1317 unique ($R_{int} = 0.037$) which were used in all calculations. The H atoms of the water molecules were found from the difference map and were given distance and angle restraints. The final *wR* (all F^2) was 0.0717, R_1 [1232 $F \geqslant 4\sigma(F)$] was 0.0327, and the Flack parameter refined to 0.00(3).

Lath-like single crystals of [20]aneS$_6$(OH)$_2$ were grown by slow evaporation of an ethyl acetate/hexane solution.

4.2.2. Crystal data

$C_{14}H_{28}O_2S_6$, $M = 420.72$, monoclinic, $a = 17.370(2)$ Å, $b = 5.4019(6)$ Å, $c = 22.146(3)$ Å, $\beta = 106.617(2)°$, $V = 1991.2(4)$ Å^3, $T = 150$ K, space group *I*/2*a* (alt. *C*2/*c*, No. 15), $Z = 4$, μ(Mo Kα) = 0.690 mm^{-1}, $D_{calc} = 1.403$ g cm^{-3}, 6961 reflections measured, 2558 unique ($R_{int} = 0.021$) which were used in all calculations. The crystal gave only weak diffraction and extensive disorder of the methylene and hydroxy groups was observed. All carbon atoms except C10 adopt extreme displacement parameters unless they remain isotropic, and C–C, C–O and C–S distances were refined subject to distance restraints of 1.52, 1.42 and 1.82 Å, respectively. The final *wR* (all F^2) was 0.333, R_1 [1575 $F \geqslant 4\sigma(F)$] was 0.103. Crystallographic Information Files (CIFs) for both structures have been deposited with the Cambridge Crystallographic Data Centre, UK.

4.2.3. *N*-Boc-bis(2-chloroethyl)amine (**1**)

Bis(2-chloroethyl)amine hydrochloride (36.0 g, 202 mmol) was added to a solution of NaOH (32.3 g, 807 mmol) in water (500 mL) at 0 °C. Di-*tert*-butyl dicarbonate [(Boc)$_2$O] (48.4 g, 222 mmol) was carefully added over a period of 30 min and the reaction mixture was stirred overnight at room temperature. The product was extracted with EtOAc (3 × 300 mL), dried over MgSO$_4$ and concentrated in vacuo to obtain the protected amine *N*-boc-bis(2-chloroethyl)amine as a pale yellow oil (45.2 g, 187 mmol, 93%); ^{1}H NMR ($CDCl_3$): δ (ppm) = 1.46 (s, 9H, C(CH$_3$)$_3$), 3.59 (m, 8H, CH$_2$); FAB-MS *m*/*z* ($C_9H_{18}Cl_2NO_2$, 242): 242 (M^+), IR (KBr disc) ν/cm^{-1} 2977, 1697. The product can also be obtained by heating the reagents under reflux in MeOH with the addition of a slight excess of triethylamine.

4.2.4. [12]aneNS$_3$(7-aza-1,4,10-trithiacyclododecane) (**2**)

N-Boc-[12]aneNS$_3$ was prepared by slowly adding a solution of 3-thia-1,5-pentanedithiol (16.4 g, 106 mmol) and *N*-boc-bis(2-chloroethyl)amine (25.6 g, 106 mmol) in dry DMF (1 L) to a suspension of Cs_2CO_3 (53.3 g, 164 mmol) in DMF (1.5 L) at 65 °C over a period of 96 h. Solvent was then removed in vacuo and the crude product dissolved in CH_2Cl_2 (300 mL) and washed with water to remove cesium salts. After drying over MgSO$_4$, filtering, and evaporation of the solvent, the crude product was purified by recrystallisation from warm toluene, yielding *N*-boc-[12]aneNS$_3$ (18.8 g, 58.1 mmol, 55%) as white crystals.

N-Boc-[12]aneNS$_3$ was deprotected with a mixture of TFA (60 mL) and CH_2Cl_2 (60 mL) for 15 min at room temperature. After evaporation of excess TFA and CH_2Cl_2, water was added (50 mL) and the reaction mixture was adjusted to pH 14 with Na_2CO_3 and NaOH. After

extraction with CH_2Cl_2 (5×50 mL), drying over $MgSO_4$, filtering, and removal of the solvent in vacuo, [12]aneNS$_3$ was obtained as a white solid in a 76% yield. *Anal*. Calc. for $C_8H_{17}NS_3$: C, 43.01; H, 7.67; N, 6.27; S, 43.05. Found: C, 43.11; H, 7.62; N, 5.98; S, 43.61%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 1.98 (br s, 1H, NH), 2.69–2.90 (m, 16H, CH_2); ^{13}C NMR ($CDCl_3$): δ (ppm) = 31.15, 32.23 (CH_2–S), 49.81 (CH_2–N); ESI-MS *m*/*z* ($C_8H_{17}NS_3$, 223): 223 ($M^{+\cdot}$).

4.2.5. [12]aneNOS$_2$ (7-aza-1-oxa-4,10-dithiacyclododecane) (**3**)

3-Oxa-1,5-pentanedithiol (12.9 g, 93.3 mmol) was reacted with *N*-boc-bis(2-chloroethyl)amine (22.6 g, 93.3 mmol), using the same procedure as for *N*-boc-[12]aneNS$_3$, yielding *N*-boc-[12]aneNOS$_2$ (15.0 g, 48.9 mmol, 52%) as a colourless oil. After deprotection with TFA/CH_2Cl_2, the crude product was purified by column chromatography on SiO_2 eluting with CH_2Cl_2:methanol (20:1) to afford [12]aneNOS$_2$ in 39% yield. NMR analysis of the column fractions revealed that partial decomposition of the product on the column had occurred. No attempts were made to optimise the purification of the deprotected product. Analytical data for [12]aneNOS$_2$ have been reported previously [25a].

4.2.6. [15]aneNS$_4$ (7-aza-1,4,10,13-tetrathiacyclopentadecane) (**4**)

3,6-Dithia-1,8-octanedithiol was prepared by converting 3,6-dithia-1,8-octanediol to the dithiol according to the literature procedure [41]. *N*-Boc-[15]aneNS$_4$ was prepared by reacting *N*-boc-bis(2-chloroethyl)amine (4.23 g, 17.5 mmol) with the 3,6-dithia-1,8-octanedithiol (3.75 g, 17.5 mmol) in the same manner as for the syntheses of *N*-boc-[12]aneNS$_3$ and *N*-boc-[12]aneNOS$_2$. The product was purified by column chromatography on SiO_2 eluting with CH_2Cl_2. Yield: 2.32 g (6.05 mmol, 35%). The boc-protected product was deprotected with a 50% TFA-solution in CH_2Cl_2 for 15 min at room temperature (90% yield). *Anal*. Calc. for $C_{10}H_{21}NS_4$: C, 42.36; H, 7.47; N, 4.94; S, 45.23. Found: C, 42.39; H, 7.27; N, 4.27; S, 45.26%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 1.86 (br s, 1H, NH), 2.60–2.90 (m, 20H, CH_2); ^{13}C NMR ($CDCl_3$): δ (ppm) = 32.26, 32.58, 32.73 (CH_2–S), 48.64 (CH_2–N); ESI-MS *m*/*z* ($C_{10}H_{21}NS_4$, 283): 284 $(M+H)^+$.

4.2.7. [15]aneNO$_2$S$_2$ (10-aza-1,4-dioxa-7,13-dithiacyclopentadecane) (**5**)

3,6-Dioxa-1,8-octanedithiol (2.80 g, 15.4 mmol) was reacted with *N*-boc-bis(2-chloroethyl)amine (3.72 g, 15.4 mmol), via the same procedure described above for *N*-boc-[15]aneNO$_2$S$_2$, resulting in a 35% yield after column chromatography on SiO_2. Deprotection was carried out using a TFA/CH_2Cl_2 mixture to give the product in 87% yield. *Anal*. Calc. for $C_{10}H_{21}NO_2S_2$: C, 47.76; H, 8.43; N, 5.57. Found: C, 47.55; H, 8.45; N, 5.18%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.19 (br s, 1H, NH), 2.71–2.89 (m, 12H, CH_2–S and CH_2–N), 3.63 (s, 4H, CH_2–O), 3.70 (t, 4H, CH_2–O); ^{13}C NMR ($CDCl_3$): δ (ppm) = 32.11, 33.22 (CH_2–S), 48.35 (CH_2–N), 70.75, 72.01 (CH_2–O); ESI-MS *m*/*z* ($C_{10}H_{21}O_2NS_2$, 251): 251 ($M^{+\cdot}$).

4.2.8. [16]aneNS$_4$(7-aza-1,4,10,13-tetrathiacyclohexadecane) (**6**)

A mixture of 3,7-dithia-1,9-nonanedithiol [41] (3.74 g, 16.4 mmol) and *N*-boc-bis(2-chloroethyl)amine (3.97 g, 16.4 mmol) in dry DMF (50 mL) was slowly added to a well-stirred suspension of Cs_2CO_3 (5.99 g, 18.4 mmol) in DMF (70 mL) at 100 °C over 10 h under N_2. Stirring and heating was continued for a further 10 h, and the reaction mixture was filtered, and the DMF removed in vacuo. The crude product was extracted with CH_2Cl_2 (50 mL) and dried over $MgSO_4$. The volume of the yellow solution was then reduced to 25 mL and the product purified by column chromatography on SiO_2 eluting with CH_2Cl_2, affording *N*-boc-[16]aneNS$_4$ in 36% yield as a colourless oil which crystallised upon standing. ^{1}H NMR ($CDCl_3$): δ (ppm) = 1.45 (s, 9H, $C(CH_3)_3$), 1.94 (p, 2H, CH_2–C*H*$_2$–CH_2), 2.65–2.84 (m, 16H, CH_2–S), 3.44 (t, 4H, CH_2–N).

Deprotection was carried out using a TFA/CH_2Cl_2 mixture to give the product in 90% yield. *Anal*. Calc. for $C_{13}H_{24}F_3NO_2S_4$ ([16]aneNS$_4$ · TFA): C, 37.94; H, 5.88; N, 3.40; S, 31.16. Found: C, 37.91; H, 5.77; N, 3.40; S, 30.25%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 1.91 (p, 2H, CH_2–C*H*$_2$–CH_2), 2.44 (br s, 1H, NH, absent on adding D_2O), 2.65–2.83 (m, 16H, CH_2–S), 2.83–2.93 (m, 4H, CH_2–N), ^{13}C NMR ($CDCl_3$): δ (ppm) = 30.01 (CH_2–*C*H$_2$–CH_2), 30.62, 32.41 (CH_2–S), 48.15 (CH_2–N); ESI-MS *m*/*z* ($C_{11}H_{23}NS_4$, 297): 298 $(M+H)^+$.

4.2.9. [12]aneN$_2$S$_2$ (7,10-diaza-1,4-dithiacyclododecane) (**7**)

The preparation of 7,10-diaza-1,4-dithiacyclododecane followed the analogous procedure as for the preparation of 10,13-diaza-1,4,7-trithiacyclopentadecane, with the exception that the diamide precursor, 7,10-diaza-1,4-dithiacyclododecane-6,11-dione, was not purified before use. The yield of the product, which was obtained as a pale yellow solid, was 30%. Analytical data for [12]aneN$_2$S$_2$ have been reported previously [42].

4.2.10. [15]aneN$_2$S$_3$ (10,13-diaza-1,4,7-trithiacyclopentadecane) (**8**)

The procedure for preparation of 10,13-diaza-1,4,7-trithiacyclopentadecane (using 3-thia-1,5-pentane dithiol) followed the procedure for preparation of 1-oxa-7,10-diaza-4,13-dithiacyclopentadecane with the exception that the crude product from the cyclisation was first isolated by filtration after addition of water. The cyclic diamide, 10,13-diaza-1,4,7-trithiacyclopentadecane-9,14-dione, was purified by Soxhlet extraction into CH_2Cl_2 in 60% yield, and the reduced product was extracted with ethyl acetate. The yield of the reduction step to give 1,4,7-trithia-10,13-diazacyclopentadecane as a pale yellow oil was 77%. The product was pure enough for further reactions, but an analytically

pure sample was obtained by column chromatography on SiO_2, eluting with CH_2Cl_2:MeOH (20:1), followed by crystallisation as the dihydrochloride salt from a methanol–water mixture.

10,13-diaza-1,4,7-trithiacyclopentadecane-9,14-dione. *Anal*. Calc. for $C_{10}H_{18}N_2O_2S_3$: C, 40.79; H, 6.16; N, 9.51. 4.2.11. [15]aneN_2OS_2 (1-oxa-7,10-diaza-4,13-dithiacyclopentadecane) (**9**)

To a rapidly stirred suspension of Cs_2CO_3 (43 g, 132 mmol) in DMF (800 mL) at 55 °C was added dropwise over 6 h a solution of 3-oxa-1,5-pentanedithiol (10.9 mL, 88 mmol) and *N*,*N*′-bis(chloroacetyl)-1,2-diaminoethane [43] (18.7 g, 88 mmol) in DMF (450 mL). After the addition was completed the mixture was stirred for 15 h at 55 °C and the solvent was then evaporated. Addition of water (300 mL) and extraction with CH_2Cl_2 afforded 1-oxa-7,10-diaza-4,13-dithiacyclopentadecane-6,11-dione in 67% yield as a white solid after evaporation of the solvent.

1-oxa-7,10-diaza-4,13-dithiacyclopentadecane-6,11-dione (6.8 g, 24.4 mmol) in 1 M borane–THF (80 mL) was heated under reflux for 15 h followed by careful addition of MeOH to quench excess borane. The volatile components were removed in vacuo which was repeated 4 times with the addition of MeOH (40 mL) before each evaporation cycle. To the resulting white solid was added 3 M HCl (150 mL) and the mixture heated under reflux for 5 h after which time the resulting solution was filtered through celite and basified to pH 13 with 5 M NaOH solution. The aqueous mixture was extracted with CH_2Cl_2 and dried over $MgSO_4$ to obtain 1-oxa-7,10-diaza-4,13-dithiacyclopentadecane in 84% yield as a colourless oil after evaporation of the solvent and drying under reduced pressure. The product was pure enough for further reactions. Analytical data for [15]aneN_2OS_2 have been reported previously [26].

4.2.12. [16]aneN_2S_3 (10,14-diaza-1,4,7-trithiacyclohexadecane) (**10**)

The preparation of 10,14-diaza-1,4,7-trithiacyclohexadecane (using 3-thia-1,5-pentanedithiol and *N*,*N*′-bis(chloroacetyl)-1,3-diaminopropane[1]) followed the same procedure as for the preparation of 10,13-diaza-1,4,7-trithiacyclopentadecane. The unsaturated macrocyclic precursor, 10,14-diaza-1,4,7-trithiacyclohexadecane-9,15-dione, was formed in 67% yield after purification by extraction into CH_2Cl_2, while the reduced product was extracted with $CHCl_3$. The yield at the reduction step to give 10,14-diaza-1,4,7-trithiacyclohexadecane as a pale yellow oil was 59%. Although this product was pure enough for most further applications, an analytically pure sample was obtained by column chromatography on SiO_2, eluting with CH_2Cl_2:MeOH (20:1).

10,14-diaza-1,4,7-trithiacyclohexadecane-9,15-dione. ^{1}H NMR ($CDCl_3$): δ (ppm) = 1.78 (tt, 2H, CH_2–CH_2–CH_2), 2.83 (m, 8H, CH_2–S), 3.25 (s, 4H, CH_2–CO), 3.44 (q, 4H, CH_2–N); ^{13}C NMR ($CDCl_3$): δ (ppm) = 109.67 (C=O), 49.06, 48.36, 32.92, 32.76, 32.25, 29.08 (CH_2–CH_2–CH_2); EI-MS *m/z* ($C_{11}H_{20}N_2O_2S_3$, 308) 308 ($M^{+\cdot}$).

10,14-diaza-1,4,7-trithiacyclohexadecane. ^{1}H NMR ($CDCl_3$): δ (ppm) = 1.70 (quin, 2H, CH_2–CH_2–CH_2), 1.98 (br s, 2H, NH), 2.74 (m, 8H, CH_2N), 2.80 (s, 12H, CH_2S); ^{13}C NMR ($CDCl_3$): δ (ppm) = 48.95, 48.28, 33.10, 32.84, 32.27, 28.93; FAB$^+$-MS *m/z* ($C_{11}H_{24}N_2S_3$, 280) 281 $(M+H)^+$.

4.2.13. [19]aneN_2S_4 (14,17-diaza-1,4,8,11-trithiacyclononadecane) (**11**)

The procedure for preparation of 14,17-diaza-1,4,8,11-trithiacyclononadecane (using 3,7-dithia-1,9-nonanedithiol and *N*,*N*′-bis(chloroacetyl)-1,2-diaminoethane) followed same procedure as for the preparation of 10,13-diaza-1,4,7-trithiacyclopentadecane. The unsaturated macrocyclic precursor, 14,17-diaza-1,4,8,11-trithiacyclononadecane-13,18-dione, was purified by extraction into CH_2Cl_2 and isolated in 37% yield. The crude reduced product was extracted into $CHCl_3$ and after evaporation of the solvent, a yellow oil was obtained which was purified by repeated extraction into Et_2O. Subsequent reduction gave 14,17-diaza-1,4,8,11-trithiacyclononadecane as a pale yellow oil in 47% yield.

14,17-diaza-1,4,8,11-trithiacyclononadecane-13,18-dione. ^{1}H NMR ($CDCl_3$): δ (ppm) = 7.38 (br s. 2H, NHCO), 2.9–2.65 (m, 12H, CH_2–S), 2.69 (t, 4H, CH_2–N); ^{13}C NMR ($CDCl_3$): δ (ppm) = 170.0, 53.5, 40.6, 38.7, 33.5, 31.6, 31.0, 30.4; EI-MS *m/z* ($C_{13}H_{24}N_2O_2S_4$, 366) 366 ($M^{+\cdot}$).

14,17-diaza-1,4,8,11-trithiacyclononadecane. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.80–2.55 (m, 24H, CH_2), 1.93 (br s, 2H, NH), 1.82 (quin, 2H, CH_2–CH_2–CH_2); ^{13}C NMR ($CDCl_3$): δ (ppm) = 48.7, 48.5, 33.0, 32.7, 32.6, 30.7 ppm; FAB$^+$-MS *m/z* ($C_{13}H_{28}N_2S_4$, 340) 341 $(M+H)^+$.

4.2.14. [15]aneN_2O_2S (7,13-diaza-1,4-dioxa-10-thiacyclopentadecane) (**12**)

This procedure is similar to the one used by Gryko et al. [31] for the preparation of the corresponding dione but to the best of our knowledge the reduction to the saturated macrocycle has not been reported.

3,6-Dioxa-1,8-octanediamine (16.0 g, 108 mmol) and the dimethylester of thiadiglycolic acid (19.2 g, 108 mmol,

[1] Prepared using the same procedure as *N*,*N*′-bis(chloroacetyl)-1,2-diaminoethane.

1 eq.) were dissolved in dry MeOH (1 L) and the mixture was heated at reflux under N_2 for 7 days. The solvent was removed in vacuo and the product, 7,13-diaza-1,4-dioxa-10-thiacyclopentadecane-8,12-dione, was recrystallised from a mixture of CH_2Cl_2 and hexane yielding the cyclic diamide as white crystals in 21% yield. *Anal.* Calc. for $C_{10}H_{18}N_2O_4S$: C, 45.78; H, 6.92; N, 10.67. Found: C, 45.72; H, 6.81; N, 10.51%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 3.32 (s, 4H, CH_2–S), 3.51 (m, 4H, CH_2–N), 3.61 (t, 4H, CH_2–O), 3.65 (s, 4H, CH_2–O); ^{13}C NMR ($CDCl_3$): δ (ppm) = 37.00 (CH_2–S), 39.42 (CH_2–N), 68.98 (CH_2–O), 69.59 (CH_2–O), 167.70 (C=O); FAB$^+$-MS *m/z* ($C_{10}H_{18}N_2O_4S$, 262): 263 $(M+H)^+$.

7,13-Daza-1,4-dioxa-10-thiacyclopentadecane-8,12-dione (5.90 g, 22.5 mmol) was reduced with a 1.0 M solution of borane in THF (125 mL) by heating the mixture at reflux for 24 h under a N_2. The excess borane was quenched with MeOH and the solvent was removed in vacuo. The crude product was treated with MeOH (25 mL) and evaporated again in order to remove low-boiling borates. The product was then heated at reflux for 4 h in a mixture of 2 M HCl and MeOH (1:1). The reaction mixture was cooled and basified (pH 13) with a KOH solution. The product was extracted with CH_2Cl_2 (5 × 30 mL), the solution dried over $MgSO_4$, filtered, and the solvent removed in vacuo. The product was purified by column chromatography on SiO_2, eluting with CH_2Cl_2:MeOH (4:1) to give [15]aneN_2O_2S as a light yellow oil in 61% yield. *Anal.* Calc. for $C_{10}H_{22}O_2N_2S$: C, 51.25; H, 9.46; N, 11.95; S, 13.68. Found: C, 49.29; H, 8.87; N, 10.28; S, 12.26%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.70 (s, 4H, CH_2–S), 2.73 (m, 8H, CH_2–N), 2.86 (br s, 2H, NH), 3.55 (m, 8H, CH_2–O); ^{13}C NMR ($CDCl_3$): δ (ppm) = 33.61 (CH_2–S), 47.85 (CH_2–N), 48.98 (CH_2–N), 69.75 (CH_2–O), 69.92 (CH_2–O); FAB$^+$-MS *m/z* ($C_{10}H_{22}N_2O_2S$, 234): 235 $(M+H)^+$.

4.2.15. [20]ane$S_6(OH)_2$ (1,11-Dihydroxy-3,6,9,13,16,19-hexathiacycloeicosane) (**13**)

To a rapidly stirred suspension of Cs_2CO_3 in DMF (550 mL) at 75 °C was added a solution of 3-thia-1,5-pentanedithiol (5.45 mL, 42 mmol) and 1,3-dichloro-2-hydroxypropane (5.42 g, 42 mmol) in DMF (42 mL) at a rate of 1.2 mL/hr. After the addition was complete the reaction mixture was heated at 75 °C for a further 12 h. The solution was allowed to cool, was filtered and the resulting yellow solution evaporated to yield a yellow oil which solidified on standing. Addition of CH_2Cl_2 afforded a white solid which was filtered off and washed with CH_2Cl_2. Slow evaporation of the filtrate afforded white crystals which were washed with hexane and recrystallised from EtOH–hexane (50:50). Further product was obtained by recrystallisation of the evaporated mother liquor from EtOH–hexane (50:50) to remove small quantities of the 1+1 macrocycle. Total isolated yield was 1.97 g (22%). Resolution of the two isomers was not achieved. *Anal.* Calc. for $C_{14}H_{28}O_2S_6$: C, 39.96; H, 6.71. Found: C, 39.99; H, 6.64%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.65–2.70 (m, 4H, CH_2), 2.80–2.89 (m, 20H, CH_2), 3.90 (m, 2H, CH); ^{13}C NMR ($CDCl_3$): δ (ppm) = 32.27, 32.97, 38.26 (CH_2–S), 70.25 and 70.30 (CH–OH); FAB$^+$-MS *m/z* ($C_{14}H_{28}O_2S_6$, 420): 421 $(M+H^+)$, CI$^+$-MS *m/z* ($C_{14}H_{28}O_2S_6$+NH_4, 438): 438 $(M+NH_4)^+$.

4.2.16. [13]aneS_4(OH) (1-Hydroxy-3,6,9,12-tetrathiacyclotridecane) (**14**) and [26]ane$S_8(OH)_2$ (1,14-dihydroxy-3,6,9,12,16,19,22,25-octathiacyclohexacosane) (**15**)

The preparations of 1-hydroxy-3,6,9,12-tetrathiacyclotridecane and 1,14-dihydroxy-3,6,9,12,16,19,22,25-octathiacyclohexacosane (using 3,6-dithiaoctane-1,8-dithiol) followed the same cyclisation procedure and used reagents on the same millimolar scale as for the preparation of 1,11-dihydroxy-3,6,9,13,16,19-hexathiacycloeicosane. Purification of the product was achieved through column chromatography on SiO_2 with an EtOAc:hexane (50:50) eluent. The first band to be eluted was [13]aneS_4(OH) (1.85 g), [26]ane$S_8(OH)_2$ (0.32 g) being obtained from the second band after evaporation. Total yield of combined products was 2.17 g (17%). Resolution of the isomers was not achieved.

1-Hydroxy-3,6,9,12-tetrathiacyclotridecane. *Anal.* Calc. for $C_9H_{18}OS_4$: C, 39.96; H, 6.71. Found: C, 39.75; H, 6.52%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.60 (d, 1H, CH_2), 2.64 (d, 1H, CH_2), 2.77–2.95 (m, 14H, CH_2), 3.87 (m, 1H, CH–O); ^{13}C NMR ($CDCl_3$): δ (ppm) = 31.52, 31.70, 32.23, 37.71 (CH_2–S), 67.55 (CH–OH); FAB$^+$-MS *m/z* ($C_{18}H_{36}O_2S_8$, 270): 270 (M^+).

1,14-dihydroxy-3,6,9,12,16,19,22,25-octathiacyclohexacosane. *Anal.* Calc. for $C_{18}H_{36}O_2S_8$: C, 39.96; H, 6.71. Found: C, 39.73; H, 6.79%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.65–2.82 (m, 32H, CH_2), 3.88 (m, 2H, CH_2); ^{13}C NMR ($CDCl_3$): δ (ppm) = 32.40, 32.92, 32.97, 38.26 (CH_2–S), 69.93 (CH–OH); FAB$^+$-MS *m/z* ($C_{18}H_{36}O_2S_8$, 540): 541 $(M+H)^+$.

4.2.17. N,N-Bis(hydroxyethyl)-4-nitroaniline

To a solution of 4-nitroaniline (12.88 g, 93.2 mmol) in glacial acetic acid (80 mL) was added ethylene oxide (30 g, 680 mmol) and the bright yellow mixture stirred for 2 days at room temperature. The solvent was removed at 40 °C and a mixture of water (50 mL) and CH_2Cl_2 (50 mL) added to the resulting oil from which a yellow solid precipitated. The precipitate was filtered and washed with water then CH_2Cl_2 and dried in vacuo (7.2 g). Further product (6 g) was obtained by concentration and cooling of the CH_2Cl_2 filtrate. The total yield of the yellow product was 13.2 g (63%). *Anal.* Calc. for $C_{10}H_{14}N_2O_4$: C, 53.09; H, 6.24; N, 12.38. Found: C, 52.39; H, 6.10; N, 12.26%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 3.71 (t, 4H, CH_2), 3.81 (t, 4H, CH_2), 4.19 (m, 2H, OH), 6.84 (m, 2H, Ar), 8.01 (m, 2H, Ar); ^{13}C NMR ($CDCl_3$): δ (ppm) = 54.86 (CH_2), 59.85 (CH_2), 111.69 (CH), 126.46 (CH), 137.34 (C_{quat}), 154.40 (C_{quat}); FAB$^+$-MS *m/z* ($C_{10}H_{14}N_2O_4$, 226): 227 $(M+H)^+$.

4.2.18. N,N-Bis(tosylethyl)-4-nitroaniline

To an aqueous NaOH solution (1.1 M, 100 mL) was added *N*,*N*-bis(hydroxyethyl)-4-nitroaniline (5.9 g, 26.1 mmol) in THF (80 mL) and the mixture cooled to 0 °C in an ice-salt bath. Tosyl chloride (9.94 g, 52.2 mmol) in THF (50 mL) was added dropwise to the cooled solution ensuring that the temperature remained below 3 °C. The resulting suspension was stirred for 1 h at 5 °C and then for 15 h at room temperature. The bright yellow precipitate was filtered, washed with water and dried (7.8 g, 56%). Further product was obtained by recrystallisation of the residue derived from the filtrate from a dichloromethane–hexane mixture. *Anal*. Calc. for $C_{24}H_{26}N_2O_8S_2$: C, 53.92; H, 4.90; N, 5.24. Found: C, 53.73; H, 4.71; N, 5.28%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.40 (s, 6H, CH_3), 3.69 (t, 4H, CH_2), 4.15 (t, 4H, CH_2), 6.42 (d, 2H, Ar), 7.25 (d, 4H, Ar), 7.68 (d, 4H, Ar), 8.00 (d, 2H, Ar); ^{13}C NMR ($CDCl_3$): δ (ppm) = 21.57 (CH_3), 50.25 (CH_2), 65.87 (CH_2), 110.67 (CH_{phenyl}), 126.01 (CH_{phenyl}), 127.78 (CH_{tosyl}), 129.93 (CH_{tosyl}), 132.25 (C_{quat}), 138.24 (C_{quat}), 145.37 (C_{quat}), 150.93 (C_{quat}); FAB$^+$-MS *m*/*z* ($C_{24}H_{26}N_2O_8S_2$, 534): 535 $(M+H)^+$.

4.2.19. N-4-NO_2Ph-[12]aneNS$_3$(N-4-Nitrophenyl-7-aza-1,4,10-trithiacyclododecane) (**16**)

The preparation of *N*-4-nitrophenyl-7-aza-1,4,10-trithiacyclododecane (using *N*,*N*-bis(tosylethyl)-4-nitroaniline) followed the same procedure as for the preparation of 7-aza-1,4,10-trithiacyclododecane using reagents on the same millimolar scale. Purification of the product was achieved by recrystallisation from CH_2Cl_2–hexane. The isolated yield of the yellow solid was 0.63 g (47%). *Anal*. Calc. for $C_{14}H_{20}N_2O_2S_3$: C, 48.81; H, 5.85; N, 8.13. Found: C, 47.55; H, 5.59; N, 7.94%. ^{1}H NMR ($CDCl_3$): δ (ppm) = 2.82–2.92 (m, 12H, CH_2), 3.71 (m, 4H, CH_2), 6.68 (d, 2H, Ar), 8.13 (d, 4H, Ar); ^{13}C NMR ($CDCl_3$): δ (ppm) = 28.48 (CH_2), 31.49 (CH_2), 31.50 (CH_2), 51.14 (CH_2), 110.48 (CH_{phenyl}), 126.40 (CH_{phenyl}), 145.47 (C_{quat}), 152.14 (C_{quat}); FAB$^+$-MS *m*/*z* ($C_{14}H_{20}N_2O_2S_3$, 344): 345 $(M+H)^+$.

4.2.20. N,N-Bis(hydroxyethyl)-4-benzamide

Using the procedure outlined for the preparation of *N*,*N*-bis(hydroxyethyl)-4-nitroaniline and reagents on the same millimolar scale, the product was obtained as a white powder (60%). *Anal*. Calc. for $C_{11}H_{16}N_2O_3$: C, 58.91; H, 7.19; N, 12.49. Found: C, 58.22; H, 7.13; N, 11.62%. ^{1}H NMR (CD_3OD): δ (ppm) = 3.59 (t, 4H, CH_2), 3.73 (t, 4H, CH_2), 6.75 (d, 2H, Ar), 7.72 (d, 2H, Ar); ^{13}C NMR (CD_3OD): δ (ppm) = 54.73 (CH_2), 60.17 (CH_2), 112.01 (CH), 120.97 (C_{quat}), 130.46 (CH), 152.38 (C_{quat}), 172.63 (CO); EI-MS *m*/*z* ($C_{11}H_{16}N_2O_3$, 224): 224 ($M^{+\cdot}$).

4.2.21. N,N-Bis(tosylethyl)-4-benzamide

Using the procedure outlined for the preparation of *N*,*N*-bis(tosylethyl)-4-nitrobenzamide and reagents on the same millimolar scale, recrystallisation from methanol to remove mono-tosylated product yielded the product as a white solid (3.3 g, 48%). *Anal*. Calc. for $C_{25}H_{28}N_2O_7S_2$: C, 56.37; H, 5.30; N, 5.26. Found: C, 56.14; H, 5.24; N, 5.21%. ^{1}H NMR (CD_3OD): δ (ppm) = 2.35 (s, 6H, CH_3), 3.56 (t, 4H, CH_2), 4.11 (t, 4H, CH_2), 6.39 (d, 2H, Ar), 7.24 (d, 4H, Ar), 7.60 (m, 6H, Ar); FAB$^+$-MS *m*/*z* ($C_{25}H_{28}N_2O_7S_2$, 532): 533 $(M+H)^+$.

4.2.22. N-4-NH_2COPh-[12]aneNS$_3$(N-4-Benzamido-7-aza-1,4,10-trithiacyclododecane) (**17**)

The preparation of *N*-4-benzamido-7-aza-1,4,10-trithiacyclododecane (using *N*,*N*-bis(tosylethyl)-4-benzamide) followed the cyclisation procedure and used reagents on the same millimolar scale as for the preparation of 7-aza-1,4,10-trithiacyclododecane. Purification was achieved by extraction into hot toluene followed by slow cooling to obtain the product as a white microcrystalline solid (0.40 g, 23%). *Anal*. Calc. for $C_{15}H_{22}N_2OS_3$: C, 52.60; H, 6.47; N, 8.18. Abstract

The synthesis, structure and magnetic properties are reported of Fe_2Ln_2, Fe_2Y_2, Mn_2Yb_2 and Mn_2Y_2 complexes. The compound $[Fe_2Ho_2(OH)_2(teaH)_2(O_2CPh)_4(NO_3)_2]$ (**1**), where $teaH_3$ is triethanolamine, was obtained from the reaction of eight equivalents of $teaH_3$ with one equivalent each of $Ho(NO_3)_3$ and $[Fe_3O(O_2CPh)_6(H_2O)_3](O_2CPh)$ in MeCN/MeOH. The use instead of $Dy(NO_3)_3$ or $Tb(NO_3)_3$ leads to the structurally similar products $[Fe_2Dy_2(OH)_2(teaH)_2(O_2CPh)_6]$ (**2**) and $[Fe_2Tb_2(OH)_2(teaH)_2(O_2CPh)_6]$ (**3**). The compounds $[Fe_2Y_2(pdmH)_6Cl_4]Cl_2$ (**4**) and isostructural $[Fe_2Ho_2(pdmH)_6Cl_4]Cl_2$ (**5**), where $pdmH_2$ is pyridine-2,6-dimethanol, were prepared from the reaction of four equivalents of $pdmH_2$ with two equivalents of YCl_3 or $HoCl_3$, respectively, and $FeCl_2$ in MeOH. The compounds $[Mn_2Y_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4]$ (**6**) and $[Mn_2Yb_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4]$ (**7**) were prepared by methanolysis of (NBu^n_4)-$[Mn_4O_2(O_2CPh)_9(H_2O)]$ in the presence of $Yb(NO_3)_3$ or $Y(NO_3)_3$, respectively. Complexes **1**–**3**, **6** and **7** contain a 'defect dicubane' M_4 core (including the first mixed 3d/4f examples of this type to contain Fe^{III} or Mn^{IV}), whereas **4** and **5** have a U-shaped core. Variable-temperature solid-state magnetic susceptibility studies of **1**–**6** in the temperature range 5.00–300 K were carried out, and for all the complexes predominantly antiferromagnetic exchange interactions between the metal centers was observed. Magnetization versus applied field sweeps on single crystals of **1** and **2** at low temperature reveal hysteresis loops, confirming these species to be new examples of single-molecule magnets (SMMs). Thus, complexes **1** and **2** are the first examples of Fe/4f SMMs.

1. Introduction

A major reason for the current intense interest by many groups around the world in polynuclear 3d transition metal clusters is the often unusual and even novel magnetic properties such species possess. In particular, some of these clusters have been found to be single-molecule magnets (SMMs), which are individual molecules capable of functioning as nanoscale magnetic particles and which thus represent a molecular approach to nanomagnetism [1–3]. In addition, there continues to be a great bioinorganic chemistry interest in 3d metal clusters, which are of relevance to objectives such as understanding the assembly of the multinuclear Fe/O core of the iron-storage protein ferritin, and elucidating the nature and mechanism of action of the Mn_4Ca core of the water oxidizing complex of

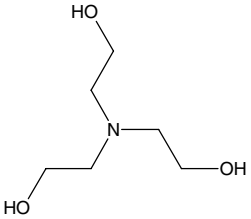
doi:10.1016/j.poly.2005.08.029

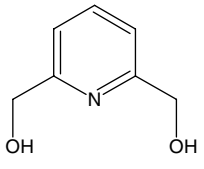
photosystem II [4–8]. For these and other areas, there continues to be a great need for synthetic methods to new examples of homometallic and heterometallic metal clusters, to increase our knowledge of the structural, magnetic, and other properties of high nuclearity paramagnetic species.

The present paper reports results of relevance to the nanomagnetism field. SMMs, which are molecular superparamagnets, derive their properties from the combination of a large ground state spin (S) value and a large and negative magnetoanisotropy (negative zero-field splitting parameter, *D*). This combination results in a significant energy barrier to magnetization reversal, and hence slow relaxation of the magnetization is observed at low temperatures. The latter can be detected as: (i) frequency-dependent signals in AC susceptibility measurements; (ii) hysteresis in magnetization versus applied DC field sweeps [1–3,9–12]. There are now many homometallic SMMs, most of them Mn species [13], and new approaches into heterometallic species have been more recently explored as a route to distinctly different properties. As a result of such work, we and others have recently reported some mixed transition metal/lanthanide SMMs [14–16]. In this paper, we report the extension of our studies along these lines and describe new Fe/Ln and Mn/Ln clusters. Not all of these are new SMMs, but they are all nevertheless valuable new additions to the growing family of mixed 3d/4f clusters possessing a variety of structural and other properties. We also have extended this work to Y instead of Ln, which has proven useful for understanding the magnetic properties of the isostructural Ln-containing species.

To facilitate the formation of polynuclear products, this work has employed the polydentate chelate-forming molecules triethanolamine ($teaH_3$) and pyridine-2,6-dimethanol ($pdmH_2$). Both molecules contain alcohol arms, which are good metal-bridging groups on deprotonation and thus foster formation of polynuclear products [17–20]. In addition, since lanthanides show strong affinity towards oxygen donors [23], both chelates were thought likely to lead to mixed 3d/4f products, and this has proven to be the case. We herein report the synthesis, crystallographic characterization and magnetic properties of a family of mixed 3d/4f M/Ln (M = Mn, Fe) and mixed M/Y (M = Mn, Fe) complexes. These are also the first crystallographically characterized tetranuclear Fe^{III}/Ho^{III}, Fe^{III}/Y^{III}, Mn^{IV}/Yb^{III} and Mn^{IV}/Y^{III} complexes in general.



$teaH_3$



$pdmH_2$

2. Experimental

2.1. Compound preparations

All manipulations were performed under aerobic conditions using materials and solvents as received. $[Fe_3O(O_2CR)_6(H_2O)_3](O_2CR)$ and $(NBu^n_4)[Mn_4O_2(O_2CPh)_9(H_2O)]$ complexes were prepared using the procedures reported previously [24,25].

2.1.1. $[Fe_2Ho_2(OH)_2(teaH)_2(O_2CPh)_4(NO_3)_2]\cdot 6MeCN$ (**1**·6MeCN)

Solutions of $[Fe_3O(O_2CPh)_6(H_2O)_3](O_2CPh)$ (0.26 g, 0.25 mmol) in MeCN (30 mL), and $Ho(NO_3)_3\cdot 5H_2O$ (0.11 g, 0.25 mmol) and $teaH_3$ (0.298 g, 2 mmol) in MeCN/MeOH (50/5 mL) were mixed to give a yellow/orange solution. This was layered with Et_2O and left undisturbed at room temperature. After 7 days, small yellow rectangular crystals of **1**·6MeCN were collected in 40% yield and dried in vacuum. *Anal.* Calc. for **1**: C, 34.85; H, 3.51; N, 4.06. Found: C, 34.99; H, 3.54; N, 4.38%. Selected IR data (cm^{-1}): 3510 (br), 2860 (s), 1595 (s), 1541 (m), 1381 (m), 1095 (s), 909 (s), 723 (m), 674 (m), 595 (s), 460 (s).

2.1.2. $[Fe_2Dy_2(OH)_2(teaH)_2(O_2CPh)_6]\cdot 4MeCN\cdot 3H_2O$ (**2**·4MeCN·3H$_2$O)

This was prepared in a similar way as **1**, but using $Dy(NO_3)_3\cdot 6H_2O$ instead of $Ho(NO_3)_3\cdot 5H_2O$. After 2 days, pale yellow rectangular crystals of $\mathbf{2}\cdot 4MeCN\cdot 3H_2O$ were collected in 52% yield and dried in air. *Anal.* Calc. for $\mathbf{2}\cdot 4MeCN\cdot 3H_2O$: C, 43.55; H, 4.47; N, 4.91. Found: C, 43.48; H, 4.20; N, 4.90%. Selected IR data (cm^{-1}): 3420 (br), 2860 (m), 1595 (s), 1544 (m), 1448 (m), 1095 (m), 1025 (s), 907 (s), 721 (m), 674 (s), 594 (s), 460 (s).

2.1.3. $[Fe_2Tb_2(OH)_2(teaH)_2(O_2CPh)_6]\cdot 4MeCN\cdot 3H_2O$ (**3**·4MeCN·3H$_2$O)

This was prepared in a similar way as **1**, but using $Tb(NO_3)_3\cdot 6H_2O$ instead of $Ho(NO_3)_3\cdot 5H_2O$. After 2 days, pale yellow rectangular crystals of $\mathbf{3}\cdot 4MeCN\cdot 3H_2O$ were collected in 49% yield and dried in air. *Anal.* Calc. for $\mathbf{3}\cdot 4MeCN\cdot 3H_2O$: C, 43.73; H, 4.49; N, 4.93. Found: C, 43.66; H, 4.15; N, 4.86%. Selected IR data (cm^{-1}): 3380 (br), 2860 (m), 1595 (s), 1545 (m), 1448 (m), 1094 (m), 1025 (s), 905 (s), 718 (m), 674 (s), 593 (s), 459 (s).

2.1.4. $[Fe_2Y_2(pdmH)_6Cl_4]Cl_2\cdot 2MeOH$ (**4**·2MeOH)

Solutions of $FeCl_2\cdot 4H_2O$ (0.10 g, 0.50 mmol) in MeOH (20 mL), and $YCl_3\cdot 6H_2O$ (0.15 g, 0.50 mmol) and $pdmH_2$ (0.14 g, 1.0 mmol) in MeOH (20 mL) were mixed to give a yellow solution. This was layered with Et_2O and left undisturbed at room temperature. After 7 days, small yellow rectangular crystals of **4**·2MeOH were collected in 42% yield and dried in vacuum. *Anal.* Calc. for **4**: C, 37.87; H,

4.05; N, 6.02. Found: C, 37.51; H, 3.93; N, 5.87%. Selected IR data (cm^{-1}): 3376 (br), 3075 (br), 1607 (m), 1579 (s), 1447 (m), 1368 (s), 1360 (s), 1163 (s), 1072 (m), 1046 (m), 783 (m), 654 (s), 554 (s), 497 (s).

2.1.5. $[Fe_2Ho_2(pdmH)_6Cl_4]Cl_2 \cdot 2MeOH$ (**5** · 2MeOH)

Solutions of $FeCl_2 \cdot 4H_2O$ (0.10 g, 0.50 mmol) in MeOH (20 mL), and $HoCl_3 \cdot 6H_2O$ (0.19 g, 0.50 mmol) and $pdmH_2$ (0.14 g, 1.0 mmol) in MeOH (20 mL) were mixed to give a yellow/green solution. This was layered with Et_2O and left undisturbed at room temperature. After 7 days, small yellow/green rectangular crystals of **5** were collected in 37% yield and dried in vacuum. *Anal.* Calc. for **5**: C, 34.15; H, 3.65; N, 5.43. Found: C, 34.23; H, 3.54; N, 5.26%. Selected IR data (cm^{-1}): 3437 (br), 3317 (br), 3007 (br), 2834 (br), 2713 (br), 2621 (br), 1609 (m), 1582 (s), 1448 (m), 1310 (m), 1042 (m), 797 (s), 725 (s), 667(s), 576(s), 475(s).

2.1.6. $[Mn_2Y_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4] \cdot 2MeOH$ (**6** · 2MeOH)

$(NBu^n_4)[Mn_4O_2(O_2CPh)_9(H_2O)]$ (0.50 g, 1.0 mmol) was dissolved in a solution of $Y(NO_3)_3 \cdot 6H_2O$ (0.24 g, 2.0 mmol) in MeCN/MeOH (20/5 mL) and stirred for 25 min to give a brown solution. This was filtered and more MeOH (10 mL) added to the filtrate. The resulting solution was left undisturbed at room temperature for a week to slowly produce orange crystals of **6** · 2MeOH, which were collected in 25% yield and dried in vacuum. The same product was obtained using $YCl_3 \cdot 6H_2O$ instead of $Y(NO_3)_3 \cdot 6H_2O$. *Anal.* Calc. for **6**: C, 46.24; H, 4.50. Found: C, 46.15; H, 4.46%. Selected IR data (cm^{-1}): 3412 (br), 1594 (m), 1545 (s), 1448 (w), 1391 (s), 1025 (w), 718 (s), 681 (m), 623 (s), 540 (m), 474 (w).

2.1.7. $[Mn_2Yb_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4] \cdot 2MeOH$ (**7** · 2MeOH)

$(NBu^n_4)[Mn_4O_2(O_2CPh)_9(H_2O)]$ (0.50 g, 1.0 mmol) was dissolved in a solution of $Yb(NO_3)_3 \cdot 5H_2O$ (0.31 g, 2.0 mmol) in MeCN/MeOH (20/5 mL) and stirred for 25 min to give a brown solution. This was filtered and more MeOH (10 mL) added to the filtrate. The resulting solution was slowly concentrated by evaporation at room temperature for 5 days, during which time brown crystals of **7** · 2MeOH slowly grew. These were collected in 10% yield and dried in vacuum. *Anal.* Calc. for **7**: C, 40.94; H, 3.99. Found: C, 40.87; H, 3.96%. Selected IR data (cm^{-1}): 3426 (br), 1600 (m), 1540 (m), 1384 (s), 1026 (w), 718 (s), 682 (m), 624 (s), 545 (m), 476 (w).

2.2. General and physical measurements

Elemental analyses (C, H and N) were performed in the in-house facilities of the University of Florida Chemistry Department. Infrared spectra in the 400–4000 cm^{-1} range were recorded in the solid state (KBr pellets) on a Nicolet Nexus 670 FTIR spectrometer. Variable temperature DC magnetic susceptibility data down to 5.0 K were collected using a Quantum Design MPMS-XL SQUID susceptometer equipped with a 7 T DC magnet. Pascal's constants were used to estimate the diamagnetic corrections, which were subtracted from the experimental susceptibilities to give the molar magnetic susceptibilities (χ_M). Microcrystalline samples were restrained in eicosane by suspending the solid for 15 min in eicosane maintained at a temperature above its melting point (35–37 °C), and then the temperature was gradually decreased below the melting point to solidify the eicosane. Low-temperature (<1.8 K) hysteresis loop and DC relaxation measurements were performed at Grenoble using an array of micro-SQUIDs [26].

2.2.1. X-ray crystallography and solution of structures

Data were collected at 173 K on a Siemens SMART PLATFORM equipped with a CCD area detector and a graphite monochromator utilizing Mo Kα radiation ($\lambda = 0.71073$ Å). Cell parameters were refined using up to 8192 reflections. A full sphere of data (1850 frames) was collected using the ω-scan method (0.3° frame width). The first 50 frames were re-measured at the end of data collection to monitor instrument and crystal stability (maximum correction on I was <1%). Absorption corrections by integration were applied based on measured indexed crystal faces.

The structures were solved by the direct methods in SHELXL6 [27], and refined using full-matrix least squares. The non-hydrogen atoms were refined anisotropically, whereas the hydrogen atoms were placed in ideal, calculated positions and refined isotropically as riding on their respective carbon atoms. For complex **1** · 6MeCN, a total of 405 parameters were refined in the final cycle of refinement using 5899 reflections with $I > 2\sigma(I)$. For complex **4** · 2MeOH, a total of 365 parameters were refined in the final cycle of refinement using 4504 reflections with $I > 2\sigma(I)$. For complex **5** · 2MeOH, a total of 365 parameters were refined in the final cycle of refinement using 4670 reflections with $I > 2\sigma(I)$. For complex **6** · 2MeOH, a total of 378 parameters were refined in the final cycle of refinement using 2803 reflections with $I > 2\sigma(I)$. For complex **7** · 2MeOH , a total of 378 parameters were refined in the final cycle of refinement on F^2 using 4821 reflections with $I > 2\sigma(I)$. Unit cell data and the final refinement indices R_1 and wR_2 are listed in Table 1.

3. Results and discussion

3.1. Syntheses

The reaction of a $[M_3O(O_2CR)_6L_3]^{0,+}$ (M = Mn, Fe; L = py, H_2O, etc.) complex with a chelating ligand represents a commonly employed and successful route to a wide range of higher nuclearity clusters of Fe and Mn. For example, the use of triethanolamine ($teaH_3$) or 2-(hydroxymethyl)pyridine (hmpH) has led to a large variety of products, depending on the precise reaction conditions and ratios, including Mn_4 [28], Mn_6 [21], Fe_8 [22], Mn_7 [29], Mn_{10} [30], Mn_{12} [31], and Fe_6 [32] clusters. As stated earlier, the alkoxide arms of the tea^{3-} and hmp^- ligands normally adopt bridging modes, fostering formation of higher nuclearity products. Thus, we have employed $[Fe_3O(O_2CPh)_6(H_2O)_3]^+$ or $FeCl_2$ and a lanthanide Ln^{3+} (or Y^{3+}) source in reactions with $teaH_3$ or $pdmH_2$ in MeOH or a mixed MeOH/MeCN solvent system (to ensure adequate solubility of all reagents).

The reaction of $[Fe_3O(O_2CPh)_6(H_2O)_3](O_2CR)$, $Ln(NO_3)_3$ (Ln = Ho, Dy, Tb) and $teaH_3$in a 1:1:8 molar ratio in MeCN/MeOH gave yellow solutions from which yellow rectangular crystals of $[Fe_2Ho_2(OH)_2(teaH)_2(O_2CPh)_4(NO_3)_2]$ (**1**), $[Fe_2Dy_2(OH)_2(teaH)_2(O_2CPh)_6]$ (**2**) and $[Fe_2Tb_2(OH)_2(teaH)_2(O_2CPh)_6]$ (**3**) slowly formed in ~40–50% yields. If the reaction solutions were left undisturbed for longer periods (~2 weeks), orange crystals of the known homometallic complex $[Fe_8O_3(O_2CPh)_9(tea)(teaH)_3]$ were also obtained [22]. The reactions are likely complicated equilibria involving several species of various nuclearities, both homo- and heterometallic, and the crystallization of the main product directly from the reaction solution is probably beneficial in providing pure material. In all cases, the filtrates are still colored, but we have not pursued isolation of other species (other than $[Fe_8O_3(O_2CPh)_9(tea)(teaH)_3]$).

Treatment of an equimolar mixture of $FeCl_2$ and YCl_3 in MeOH with two equivalents of $pdmH_2$ gave a yellow solution, and layering this with Et_2O gave small rectangular yellow crystals of $[Fe_2Y_2(pdmH)_6Cl_4]Cl_2$ (**4**) in 42% yield. The same reaction but with $HoCl_3$ gave the analogous $[Fe_2Ho_2(pdmH)_6Cl_4]Cl_2$ (**5**) complex in 37% yield. Small changes to the Fe:Ln:$pdmH_2$ ratio still gave the same products.

A different strategy was used for the Mn reactions. In this case, neither $teaH_3$ or $pdmH_2$ were employed, the reaction instead comprising the methanolysis of a Mn^{III} species in the presence of a Yb^{3+} or Y^{3+} source. The chosen Mn starting material was the readily prepared, tetranuclear $(NBu^n_4)[Mn_4O_2(O_2CPh)_9(H_2O)]$ ($4Mn^{III}$) complex [25], and treatment of this with $Yb(NO_3)_3 \cdot 5H_2O$ in a 1:2 molar ratio in MeCN/MeOH led to brown crystals of $[Mn_2Y_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4]$ (**6**) or $[Mn_2Yb_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4]$ (**7**) in 10–25% yields. Note that in both these Mn-containing complexes that there are also MeO^- groups from the MeOH solvent, whereas none of the Fe-containing complexes **1**–**5** contain MeO^- groups. Again, there are likely other products from these complicated reactions in the colored filtrates, but we have not pursued any further separations.

3.2. Structural description of $[Fe_2Ho_2(OH)_2(teaH)_2(O_2CPh)_4(NO_3)_2]$ (1)

A labeled ORTEP plot and stereoview of the $[Fe_2Ho_2(OH)_2(teaH)_2(O_2CPh)_4(NO_3)_2]$ (**1**) are provided in Fig. 1. Selected bond distances and angles are listed in Table 2. Complex **1** · 6MeCN crystallizes in triclinic space group $P\bar{1}$, the cluster lying on an inversion center and consisting of a planar Fe_2Ho_2 rhombus. Each Fe_2Ho trinuclear sub-unit is bridged by a μ_3-OH^- ion (oxygen atoms O1 and O1a). Each of the two $teaH^{2-}$ ligands binds in a tetradentate chelate fashion to Ho1 or Ho1a, with their protonated alcohol arms (O8 and O8a) binding terminally to the Ho, and their two deprotonated alkoxide arms each bridging to an adjacent Fe atom (O3 bridging Fe1/Ho1, and O5 bridging Fe1a/Ho1). There is also a chelating NO_3^- group on each Ho atom, and ligation is completed by a *syn*, *syn*, bridging benzoate group across each of the four HoFe edges of the rhombus. The Fe and Ho atoms are six- and nine-coordinate, respectively.

The overall structure of the core of complex **1** can be described as two face-sharing $[M_4O_4]$ cubanes with a metal atom missing from one vertex in each cubane. Such a 'defect double-cubane' unit with a resulting planar M_4 rhombus is relatively common in both homo- and heterometallic cluster chemistry, and is often on a crystallographic center of symmetry. Such examples are known

with different transition metals [28,33], and there are also a very few examples of mixed 3d/4f examples [14b,34], but no mixed iron–lanthanide complexes have previously been obtained. We also carried out preliminary X-ray crystallographic studies on complexes **2** and **3** and found that they are isostructural with **1** except that the two chelating NO_3^- groups have been replaced by two chelating $PhCO_2^-$ groups, as we had suspected from the similar formulas and IR spectra of **1**–**3**. For this reason, the structures of **2** and **3** will not be discussed further here.

3.3. Structural descriptions of $[Fe_2Y_2(pdmH)_6Cl_4]Cl_2$ (**4**) and $[Fe_2Ho_2(pdmH)_6Cl_4]Cl_2$ (**5**)

Labeled ORTEP plots and stereoviews of the cations of complexes **4** · 2MeOH and **5** · 2MeOH are shown in Figs. 2 and 3, respectively. Selected bond lengths and angles are listed in Tables 3 and 4, respectively. The complexes both crystallize in monoclinic space group $I2/a$, with the cations on a crystallographic C_2 rotation axis; the two complexes are isostructural. The cores of the cations (Fig. 4) can best

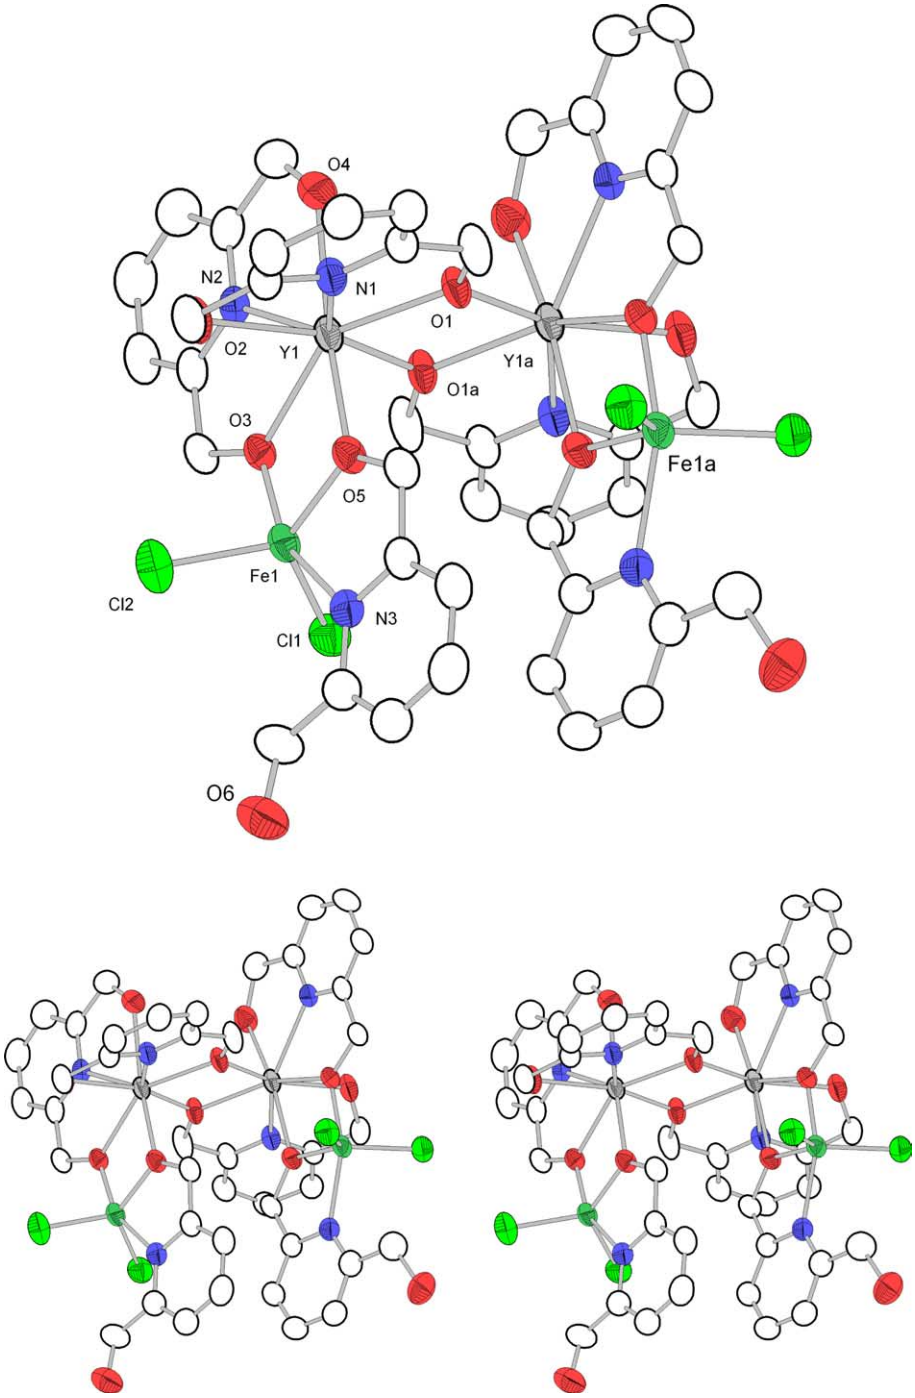

Fig. 2. ORTEP representation and stereopair of the cation of complex **4** at the 50% probability level. All H atoms have been removed for clarity.

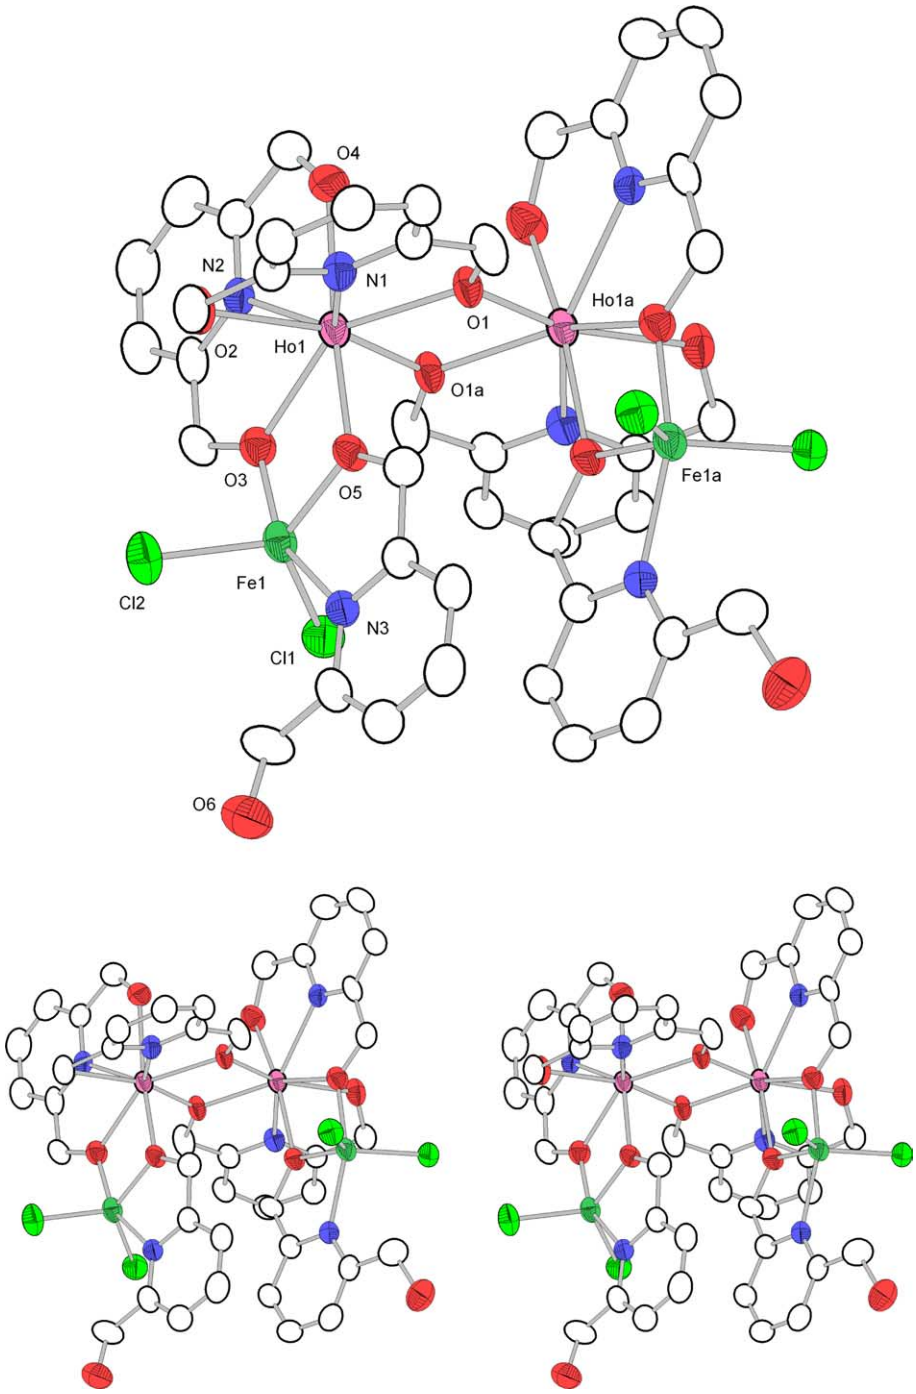

Fig. 3. ORTEP representation and stereopair of the cation of complex **5** at the 50% probability level. All H atoms have been removed for clarity.

be described as twisted U-shaped, with the Fe^{III} atoms at the two ends, and either two Y^{III} (complex **4**) or two Ho^{III} (complex **5**) atoms on the inside. Each pair of adjacent metal atoms is bridged by two alkoxide O atoms from monodeprotonated $pdmH^-$ groups. There are two of the latter as tridentate chelates on each of the inner Y^{III} (**4**) or Ho^{III} (**5**) atoms, with their alkoxide arm bridging to an adjacent atom (O1, O3), as mentioned, and their protonated (alcohol) arm (O2, O4) and N atom binding terminally. There are two additional $pdmH^-$ groups, attached in a bidentate chelate fashion to the Fe^{III} atoms, their alkoxide arm (O5) bridging to an inner metal and their protonated arm unligated (O6). Ligation is completed by two terminal Cl^- ions on each of the Fe^{III} atoms. The two Fe atoms are five-coordinate and the two inner Y^{III} or Ho^{III} atoms are eight-coordinate. There are intramolecular π–π stacking interactions, and many intermolecular hydrogen-bonds involving the $pdmH^-$, MeOH and Cl^- groups, the latter serving to bridge separate $Fe_2Y_2(Ho)_2$ clusters. For example for **4**, the unbound $pdmH^-$ alcohol group (O6) hydrogen-bonds to interstitial MeOH atom O7 ($O6\cdots O7 = 2.695$ Å), with the latter also hydrogen-bonding to free

Cl^- ion Cl3 (O7···Cl3 = 3.072 Å). In addition, this Cl^- ion hydrogen-bonds to bound pdm^{2-} O atom O2 (Cl3···O2 = 2.976 Å) of a neighboring cluster.

The U-shaped core seen in these complexes is not common, although it is with precedent, for example in the complex $[Mn_4(6Me\text{-}hmp)Cl_4]\cdot 4H_2O$ (6Me-hmp = 6-methyl-2-(hydroxymethyl)pyridine) [35].

3.4. Structural descriptions of $[Mn_2Y_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4]$ (6) and $[Mn_2Yb_2O_2(O_2CPh)_6(OMe)_4(MeOH)_4]$ (7)

Labeled ORTEP representations of the centrosymmetric structures of **6** · 2MeOH and **7** · 2MeOH are presented in Fig. 5, and selected bond distances and angles are listed in Table 5. The two complexes both crystallize in the monoclinic space group $P2_1/c$ with the molecules lying on an inversion center; the two complexes are isostructural. The cores of the complexes possess the defect-dicubane

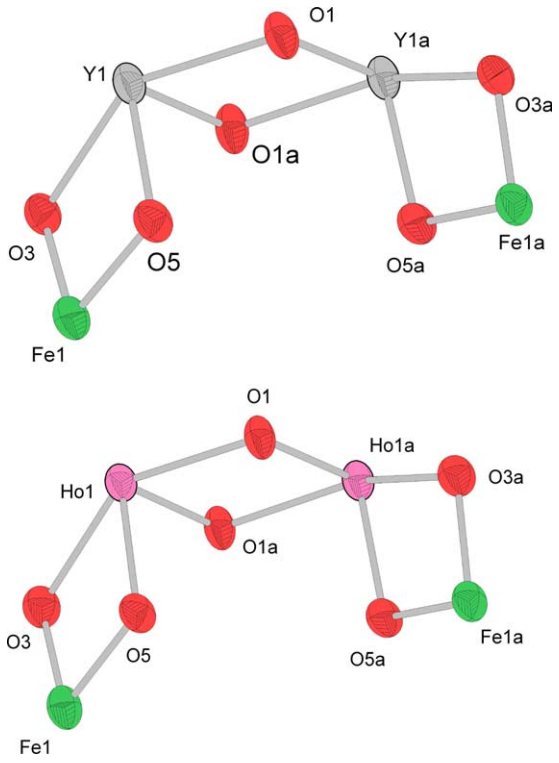

Fig. 4. Comparison of the cores of the cations of complexes **4** (top) and **5** (bottom).

structure of complex **1**, with two Mn^{IV} atoms at the central positions and either two $2Y^{III}$ (complex **6**) or two Yb^{III} (complex **7**) atoms at the end positions. However, there are two major differences between the cores of **6**/**7** and that of **1**: First, the two μ_3-O atoms (O8, O8a) capping each triangular sub-unit are O^{2-} ions rather than OH^- ones; and secondly, each of the four edges of the M_4 rhombus in **6**/**7** is bridged by a MeO^- ion (O7, O7a, O11, O11a) rather than an alkoxide arm of a chelate. The fully labeled cores of **6** and **7** are provided in Fig. 6, which emphasize the near superimposibility of the mixed 3d/4d complex **6** with the mixed 3d/4f complex **7**. Peripheral ligation about the cores is provided by four *syn*, *syn* bridging benzoate groups bridging each Y/Mn or Yb/Mn edge of the rhombus, two monodentate benzoate groups, one on each of the Y/Yb atoms, and four terminal MeOH molecules, two on each of the Y/Yb ions. As a result, the Y^{III} and Yb^{III} atoms of **6** and **7**, respectively, are eight-coordinate, and the Mn^{IV} atoms are six-coordinate. There are intramolecular OH···H hydrogen bonds between the unbound O atom (O1) and the terminal MeOH ligand (O1···O10 = 2.577 Å). In addition, there are intermolecular OH···H hydrogen bonds between the bound MeOH (O9) and interstitial MeOH (O12) molecules (O9···O12 = 2.656 Å), and between this interstitial MeOH and the unbound O atom (O1) of a neighboring cluster (O12···O1 = 2.687 Å). Thus, the hydrogen-bonding through the interstitial MeOH molecules links adjacent metal clusters in the crystal, which also likely provides a pathway for superexchange interactions between molecules (vide infra).

It should be noted that mixed Mn_2Ln_2 complexes with the same kind of defect-dicubane core have previously been reported for Ln = Dy, Gd and Tb [14b,34]. However, in all of these previous cases, the Mn atoms were in the Mn^{III} oxidation state, so **6** and **7** are the first to instead contain Mn^{IV}. The Mn^{IV} oxidation level is suggested by overall charge considerations and inspection of metric parameters; in particular, Mn–O bond distances all lie in the range 1.84–1.97 Å, as expected for Mn^{IV}, and thus do not show the Jahn-Teller axial distortion expected for Mn^{III} in near octahedral geometry. The Y–O and Yb–O bond distances are very similar, lying in the 2.30–2.42 and 2.27–2.38 Å ranges, respectively, consistent with eight-coordinate Y^{III}/Yb^{III} centers. The Mn^{IV} oxidation states and the protonation levels of the O^{2-}, MeO^- and MeOH were confirmed by bond valence sum (BVS) calculations, shown in Tables 6 and 7. The BVS values for the Mn atoms are clearly ~4, confirming the Mn^{IV} oxidation level. Values of ~2 are expected for O atoms in the O^{II-} oxidation level and that have no attached atoms that cannot be seen in X-ray crystallography (i.e., H atoms). This confirms that O7, O8 and O11 are MeO^-, O^{2-}, and MeO^-, respectively. In contrast, if there is a H atom which is not visible and its contribution to the BVS of that O atom is therefore not included, a lower BVS value is expected, typically 1–1.5 (depending on the degree of its participation in hydrogen-bonding); this is clearly the case for O9 and O10, which are therefore confirmed as MeOH groups.

Table 6
Bond valence sums (BVS)[a] for the Mn atoms of complexes **6** (Y) and **7** (Yb)

Atom	Mn^{II}	Mn^{III}	Mn^{IV}	Assignment
Mn1 (**6**)	4.132	3.779	3.967	Mn^{IV}
Mn1 (**7**)	4.124	3.772	3.959	Mn^{IV}

[a] The underlined value is the one closest to the charge for which it was calculated. The oxidation state of a particular metal is the nearest whole number to that value.

Table 7
Bond valence sums (BVS) for the O atoms of complexes **6** (Y) and **7** (Yb)

Atom	BVS (**6**)	BVS (**7**)	Assignment
O7	1.972	1.972	MeO^-
O8	1.898	1.859	O^{2-}
O9	1.210	1.198	MeOH
O10	1.339	1.342	MeOH
O11	2.038	2.016	MeO^-

The occurrence of Mn^{IV} in **6** and **7** is noteworthy given that the reaction employed a Mn_4^{III} starting material and either Y^{III} or Yb^{III}, neither of which are good oxidizing agents. This points to either the participation of atmospheric O_2 gas as the oxidizing agent or the disproportionation of Mn^{III} to Mn^{IV} and Mn^{II}. We favor the latter possibility given the low yields of these complexes, but we have not sought Mn^{II} species in the filtrates to confirm this.

4. Magnetochemistry

4.1. DC magnetic susceptibility

The magnetic properties of **1**–**6** were investigated by solid state magnetic susceptibility (χ_M) measurements in the 5.0–300 K range in a 0.1 tesla (T) DC field. The resulting data for complexes **1**–**3**, **4**–**5** and **6** are shown as $\chi_M T$ versus T plot in Figs. 7–9, respectively. For complex **1**, the $\chi_M T$ value of 33.1 cm^3 K mol^{-1} at 300 K is slightly less than the value expected for $2Fe^{III}$ ($S = 5/2$, $g = 2$) and $2Ho^{III}$ ($S = 2$, $L = 6$, $^5I_8$) non-interacting ions of 36.9 cm^3 K mol^{-1}, consistent with antiferromagnetic exchange interactions, and decreases steadily to 24.2 cm^3 $kmol^{-1}$ at 50 K and then 13.7 cm^3 $kmol^{-1}$ at 5.0 K. Complexes **2** and **3** behave in a similar fashion to complex **1**. For complex **2**, the $\chi_M T$ value of 37.1 cm^3 $kmol^{-1}$ at 300 K is essentially that expected for $2Fe^{III}$ ($S = 5/2$, $g = 2$) and $2Dy^{III}$ ($S = 5/2$, $L = 5$, $^6H_{15/2}$) non-interacting ions of 36.94 cm^3 $kmol^{-1}$, and it decreases with decreasing temperature to 30.3 cm^3 $kmol^{-1}$ at 50 K, and then to 23.8 cm^3 $kmol^{-1}$ at 5.0 K. For complex **3**, the $\chi_M T$ value of 35.5 cm^3 $kmol^{-1}$ at 300 K is slightly greater than that expected for $2Fe^{III}$ ($S = 5/2$, $g = 2$) and $2Tb^{III}$: $S = 3$, $L = 3$, $^7F_6$ non-interacting ions of 32.4 cm^3 $kmol^{-1}$, and it decreases with decreasing temperature to 29.1 cm^3 $kmol^{-1}$ at 50 K, and then to 22.4 cm^3 $kmol^{-1}$ at 5.0 K. The data suggest predominantly antiferromagnetic exchange interactions within all three

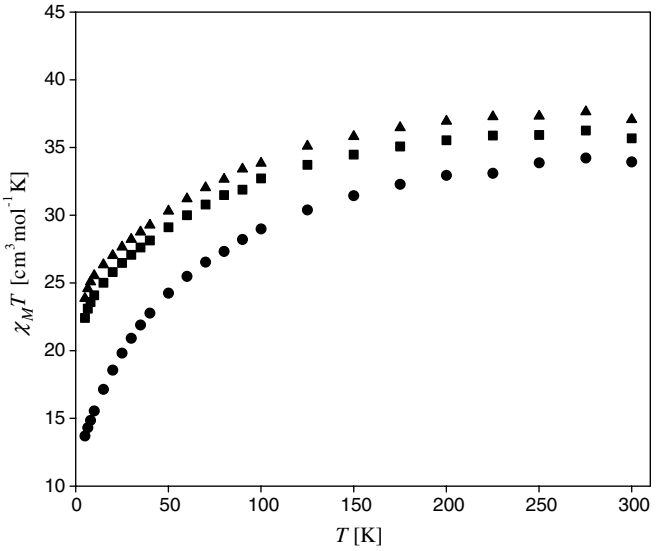

Fig. 7. Plot of $\chi_M T$ vs. T for complexes **1** (●), **2** (▲) and **3** (■).

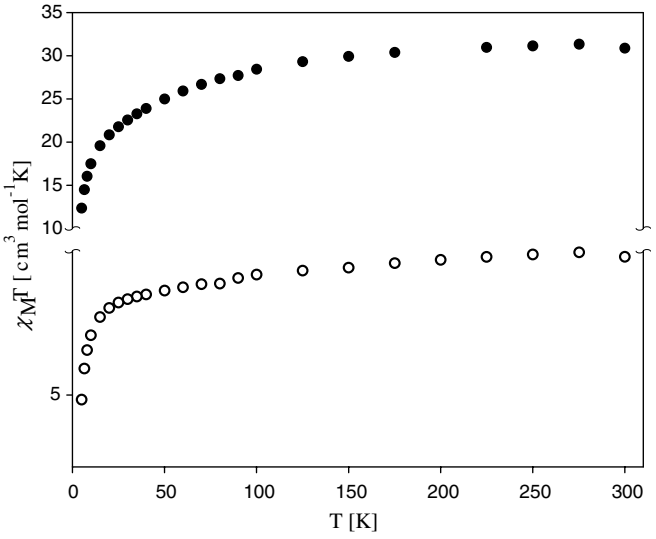

Fig. 8. Plot of $\chi_M T$ vs. T for complexes **4** (○) and **5** (●).

complexes, but with perhaps some ferromagnetic contributions. The presence of strong spin–orbit coupling effects in these three lanthanide derivatives makes the fitting of the data to obtain $Fe^{III}Fe^{III}$ and $Fe^{III}Ln^{III}$ exchange parameters far from straightforward. Such an analysis would in fact greatly benefit from the availability and parallel study of the corresponding Gd^{3+} ($S = 7/2$, $L = 0$) and Y^{3+} ($S = 0$) derivatives, but unfortunately neither of these are available at the present time. A more complete magnetic analysis of complexes **1**–**3** and other derivatives is thus the objective of future work.

Complex **4** has a $\chi_M T$ value at 300 K of 6.9 cm^3 $kmol^{-1}$ which is less than that expected for two non-interacting Fe^{III} centers of 8.8 cm^3 $kmol^{-1}$ with $g = 2$, and it decreases only slightly with decreasing temperature to 6.3 cm^3 $kmol^{-1}$ at 35 K, but then much more rapidly to 4.9 cm^3 $kmol^{-1}$ at 5.0 K (Fig. 8). This behavior is probably due to a very weak

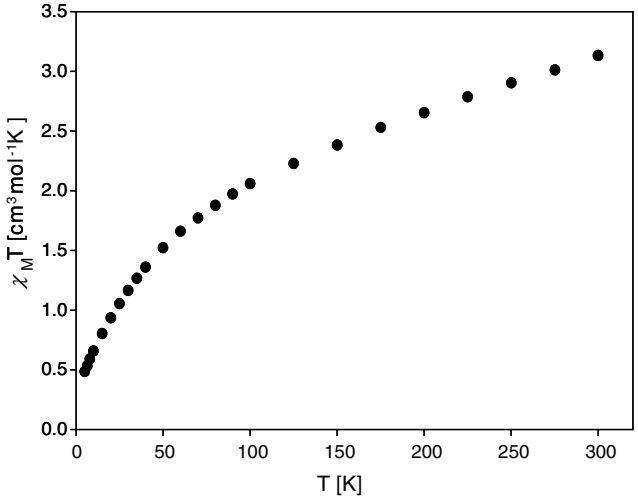

Fig. 9. Plot of $\chi_M T$ vs. T for complex **6**.

antiferromagnetic exchange interaction between the Fe^{III} ions via the intervening, diamagnetic Y^{III} ions, but we cannot get a good fit of the data over the entire temperature range to the Van Vleck equation for a $S_1 = S_2 = 5/2$ dimer. We suspect this is due to the exchange interaction being so weak as a result of the large separation between Fe^{III} atoms that it is thus comparable in magnitude to intermolecular interactions mediated by the multiple intermolecular hydrogen-bonds between adjacent clusters, as described above. Complex **5** has a $\chi_M T$ value of 30.8 $cm^3\,kmol^{-1}$ at 300 K, which, as for **1**, is again less than the 36.9 $cm^3\,kmol^{-1}$ expected for two Fe^{III} ($S = 5/2$) and two Ho^{III} ($S = 2$, $L = 6$, $^5I_8$) non-interacting ions; it then decreases to 28.4 $cm^3\,kmol^{-1}$ at 100 K, and then more rapidly to 20.8 $cm^3\,kmol^{-1}$ at 20 K then finally to 12.3 $cm^3\,kmol^{-1}$ at 5.0 K (Fig. 8). The overall behavior is consistent with antiferromagnetic exchange interactions between the constituent metal atoms.

Complex **6** has a $\chi_M T$ value that steadily decreases almost linearly from 3.13 $cm^3\,kmol^{-1}$ at 300 K to 1.52 $cm^3\,kmol^{-1}$ at 50 K, and then more rapidly decreases to 0.49 $cm^3\,kmol^{-1}$ at 5.0 K (Fig. 9). The value at 300 K is less than the expected spin-only ($g = 2$) value for a complex consisting of two non-interacting Mn^{IV} ions ($S = 3/2$; the $2Y^{III}$ ions are diamagnetic) of 3.75 $cm^3\,kmol^{-1}$, indicating an antiferromagnetic exchange interaction between the Mn^{IV} ions and a resultant $S = 0$ spin ground state. Attempts to fit the $\chi_M T$ versus T data using the isotropic Heisenberg–Dirac–van Vleck Hamiltonian described by $\mathscr{H} = -2J\hat{S}_1\hat{S}_2$, where $S_1 = S_2 = 3/2$ and J is the magnetic exchange interaction gave poor fits that did not reproduce the data over the whole temperature range, particularly the higher T data. However, it did suggest the J value is relatively weak, in the $J = -10$ to $-15\ cm^{-1}$ range, which in fact is consistent with the relatively acute Mn^{4+}–O^{2-}–Mn^{4+} (Mn1–O8–Mn1a) angles of 97.52°. As for **4**, we believe the problem is intermolecular exchange interactions, via the hydrogen-bonding network described above, which are not incorporated in the model. These points are being considered further as we seek to reach a more detailed magnetic understanding of this whole family of mixed-metal species, as well as others being prepared.

4.2. AC magnetic susceptibility

AC magnetic susceptibility measurements are a very convenient method to assess whether a molecule exhibits a slow magnetization relaxation rate, which is a necessary (but not sufficient) property of a species that might be a single-molecule magnet (SMM). Thus, such measurements were carried out in the 1.8–10 K range using a 3.5 G AC field oscillating at 50–1000 Hz, seeking the detection of a non-zero out-of-phase AC susceptibility signal (χ''_M). The latter indicates that the sample's magnetization vector cannot relax (reorient) fast enough to keep up with the oscillating field. None of the complexes in this work gave a clear χ''_M signal above 1.8 K, the operating minimum of our SQUID magnetometer, but complex **2** showed a weak, frequency-dependent tail of what might be a peak lying at <1.8 K. We thus chose **1** and **2** for more detailed studies involving single-crystal magnetization versus applied DC field sweeps on a micro-SQUID apparatus down to millikelvin temperatures [26]. The observation of hysteresis loops in such studies is the classical diagnostic property of a magnet.

The magnetization versus applied DC field sweeps for a single crystal of complex **1** · 6MeCN are shown in Fig. 10. At very low temperatures (0.3 K and below) and at a 0.14 T/s applied field sweep rate, hysteresis loops are observed with a very small coercivity and only a slight temperature dependence. The small coercive field and the overall shape of the loops suggest the presence of intermolecular interactions and some degree of ordering as the main source of the hysteresis. Indeed, a closer examination

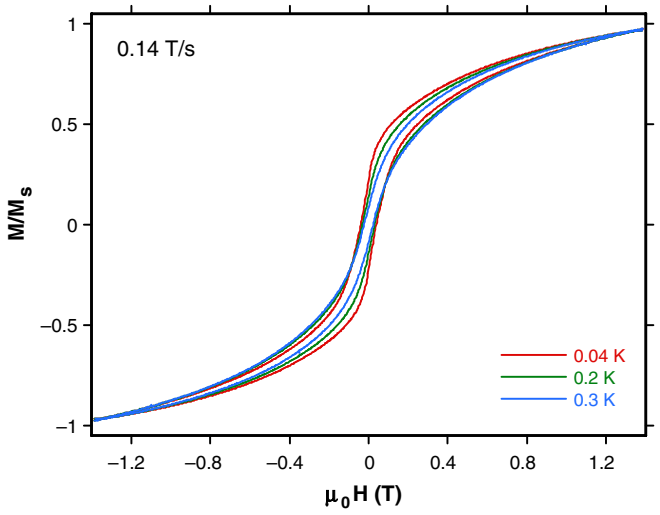

Fig. 10. Magnetization (M) vs. applied DC field hysteresis loops for a single crystal of **1** · 6MeCN at the indicated temperatures and a 0.14 T/s sweep rate. The magnetization is normalized to its saturation value, M_S.

of the crystal structure of **1** · 6MeCN reveals intermolecular π–π stacking overlaps (~3.7 Å) between the aromatic rings of benzoate groups, and this is likely the pathway for intermolecular exchange interactions. At best, therefore, complex **1** could be regarded as an exchange-biased SMM [36], although it is clearly difficult to separate the intermolecular interactions and the SMM behavior.

Clearer evidence for a SMM was observed when the same studies were performed on **2** · 4MeCN · $3H_2O$. Hysteresis loops were again obtained, and now they were much more characteristic of a SMM. The hysteresis loops obtained with a field sweep rate of 0.14 T/s and at various temperatures below 1.1 K are shown in Fig. 11 (top), and those obtained from a sweep rate dependence at a constant temperature of 0.04 K are shown in Fig. 11 (bottom). The coercivities increase with decreasing temperature and with increasing sweep rate, as expected for the superparamagnet-like behavior of a SMM. The dominating feature in these loops is the large relaxation step at zero-field, which can be assigned to fast quantum tunneling of the magnetization (QTM) through the barrier to relaxation. This is commonly seen in previous SMMs containing lanthanide ions [14b]. In fact, this very fast QTM step at zero field makes the magnetization decay very rapidly in zero field and prevents magnetization versus time decay data being collected and used to construct an Arrhenius plot; the latter kinetic analysis is commonly used to determine the effective barrier to relaxation. Again, this is as found for previous mixed 3d/4f SMMs, which show fast QTM at zero field. Steps at other field positions are also expected, but they are poorly resolved, almost unobservable, and this is assigned to broadening effects from a distribution of molecular environments, which would give a distribution of relaxation barriers and thus a distribution in step positions. Additional broadening is also expected from intermolecular interactions from both dipolar and superexchange pathways.

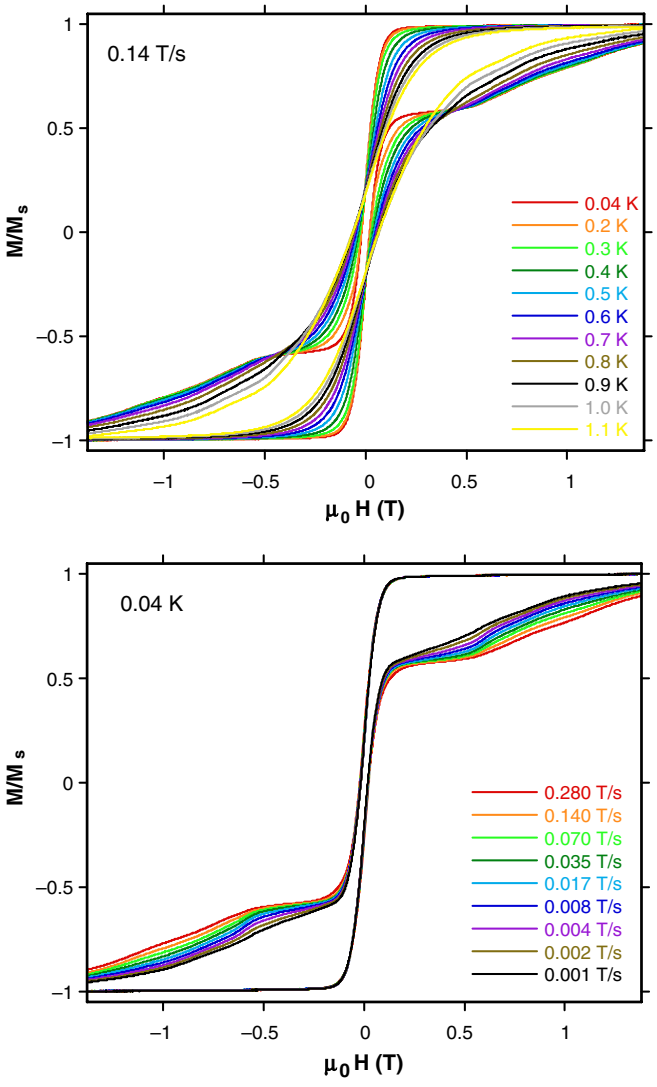

Fig. 11. Magnetization (M) vs. applied DC field hysteresis loops for a single crystal of **2** · 4MeCN · $3H_2O$ at (top) the indicated temperatures and a 0.14 T/s sweep rate, and (bottom) at the indicated field sweep rates and a temperature of 0.04 K. The magnetization is normalized to its saturation value, M_S.

5. Conclusions

A new group of mixed 3d/4f and 3d/4d tetranuclear clusters have been synthesized from the reactions of Fe^{III} or Mn^{III} sources with $teaH_3$ or $pdmH_2$, or simply by methanolysis. These products represent new additions to what is still a very small family of such mixed-metal species. While the magnetic properties are complicated by the large spin–orbit coupling effects of most Ln^{III} ions, making difficult the quantitative elucidation of the magnitude of the exchange parameters within these molecules and their resulting ground state description, hysteresis loop determinations have established that additional examples of SMMs have been provided from this area. However, lanthanide-containing SMMs still suffer from the disadvantage of fast QTM rates. This represents a diminution of the effective barrier for magnetization relaxation, and thus the temperature below which the relaxation is blocked and the complex will function as a SMM. Nevertheless, the use of lanthanides to modulate the magnetic properties of transition metal SMMs is still an interesting area that promises much new science as it matures.

Abstract

For the first time, stable but coordinatively unsaturated Cu(II) complexes $[Cu(2,2'\text{-bpy})X_2]\cdot xH_2O$ (X = ClO_4, NO_3, CH_3COO and 2,2′-bpy = 2,2′-bipyridyl) have been found to promote the hydrolysis of C–N(2) bond of thiosemicarbazide (tsc) at 25 °C and at neutral pH yielding monomeric $[Cu(2,2'\text{-bpy})(NCS)_2]$. Direct reaction between $[Cu(2,2'\text{-bpy})_2]Cl_2\cdot 6H_2O$, KSCN and $CuCl_2$ results in polymeric $[Cu(2,2'\text{-bpy})(NCS)_2]_n$ [1] [Inorg. Chim. Acta. 286 (1999) 108]. Similarly tsc is cleaved by Cu(I) complex $[Cu(\phi_3P)_2(CH_3CN)_2]ClO_4$ [ϕ_3P = triphenylphosphine] which itself is converted into dimeric $[Cu(\phi_3P)_2(NCS)]_2$.

1. Introduction

In the past considerable attention has been paid to study the complexation behavior of various thiosemicarbazides and thiosemicarbazones(tscz) because of their broad pharmacological activity [2–12]. Such ligands generally act as bidentate chelating through hydrazinic N(1) and S [13–17] [$H_2N(1)$–N(2)H–C(3)S–N(4)H_2].

Only a few complexes are known with tsc acting as monodentate ligand binding through S [18–22]. The strength of S-donor atom has been found to be the most important single factor affecting the biological activity of such ligands [23]. The donor properties of S are modulated by nature of metal ion and stereochemistry of the complex which in turn are monitored by the substitution on N [4] of tsc and tscz [23]. Because of good σ donor properties and π-bonding abilities supplemented by the chelate and steric effects; 2,2′-bpy is expected to substantially affect the stability of M–S bond. With a view to study the effect of 2,2′-bpy on the stability of M–S bond and hence its biological activity, we employed tsc in combination with 2,2′-bpy in the syntheses of Cu(II) complexes.

2. Experimental

Thiosemicarbazide, 2,2′-bipyridyl, hydrazine hydrate and triphenyl phosphine were purchased from CDH Lab., Bombay and copper(II) perchlorate was purchased from Aldrich Chemical Co. Copper(I) perchlorate [24] and phenylisothiocyanate [25] were prepared by known methods and their purity was checked through IR spectra. All other chemicals were of reagent grade and were used as such without further purification.

IR spectra were recorded on FTIR-NICOLET 320, Fourier-Transform spectrometer using KBr pellets. Elemental analyses were performed by Regional Sophisticated Instrumentation Centre, Punjab University, Chandigarh on Carlo Erba model 1106. HPLC was

performed on 501 Waters pump with C-18 bonda packed column using Waters 484 UV detector.

2.1. X-ray crystallography

The single-crystal X-ray diffraction was done with Nonius Kappa CCD diffractometer with graphite monochromatized Mo Kα($\lambda = 0.71073$ Å) radiation. Collect–software was used in the measurement and DENZO-SMN in the processing of the data. The structures were solved and refined by full-matrix least-squares on F^2 with WinGX-software package [26] utilizing SHELXS-97 [27] and SHELXL-97 [28] modules. Hydrogen atoms were refined by a riding model. Empirical absorption correction was performed for the compound **2**. The graphic presentations of the structures were created with the software Diamond [29].

2.2. Preparative method

2.2.1. Preparation of 4-phenylthiosemicarbazide

It was prepared by reacting hydrazine with phenylisothiocyanate in chloroform. Its purity was checked by melting point 135 °C (136 – 138 °C) and IR spectrum 3395m, 3100s(ν_{N-H}), 1650s(δ_{N-H}) and 820w(ν_{C-S}) cm^{-1}.

2.2.2. Preparation of [Cu(2,2′-bpy)(NCS)$_2$] (*1*)

To the acetonitrile solution of $[Cu(2,2'\text{-bpy})(ClO_4)_2]\cdot 4H_2O$ (0.0489 g, 0.1 mmol) was added tsc (0.018 g, 0.2 mmol) in methanol. The reaction contents were refluxed for half an hour and filtered. The resulting solution was left undisturbed. After two days green needles of 1 separated out which were filtered and dried over calcium chloride. Yield 30% based upon $[Cu(2,2'\text{-bpy})(ClO_4)_2]\cdot 4H_2O$. *Anal.* Calc. for $C_{12}H_8CuN_4S_2$: C, 42.9; H, 2.3; N, 16.7. Found: C, 42.5; H, 2.0; N, 16.0%. IR spectrum 2080s ($\nu_{C\equiv N}$), 1620s ($\nu_{C=N}$) and 828w (ν_{C-S}) cm^{-1}.

In analogous reactions all other Cu(II) salts (X = NO_3, Cl and CH_3COO) resulted in the formation of $[Cu(2,2'\text{-bpy})(NCS)_2]$, which were analyzed through CHN, IR spectral and X-ray crystal (in case of ClO_4, NO_3, and Cl complexes) studies.

2.2.3. Preparation of [Cu(ϕ_3P)$_2$(NCS)]$_2$ (*2*)

Solution of $[Cu(CH_3CN)_4]ClO_4$ (0.032 g, 0.1 mmol) and ϕ_3P (0.026 g, 0.1 mmol) in methanol–acetonitrile mixture was refluxed for half an hour. It was followed by addition of tsc (0.018 g, 0.2 mmol) in methanol and further refluxed, cooled and filtered. The filtrate was left undisturbed. Colorless crystals suitable for X-ray studies were obtained after 2 days which were filtered, washed with methanol and dried over calcium chloride. Yield 40% based upon $[Cu(CH_3CN)_4]ClO_4$. *Anal.* Calc. for $C_{37}H_{30}CuNP_2S$: C, 68.7; H, 4.6; N, 2.1. Found: C, 68.4; H, 4.8; N, 2.4%. IR spectrum 2120s ($\nu_{C\equiv N}$), 1090m (ν_{P-C}), 820w, 745s and 700 cm^{-1} (due to bridging ν_{C-S}).

2.2.4. Preparation of [Cu(2,2′-bpy)(4-tscph)][ClO$_4$]$_2$ (*3*)

Addition of methanolic solution of 4-tscph (0.016 g, 0.1 mmol) to the refluxing solution of $[Cu(2,2'\text{-bpy})(ClO_4)_2]\cdot 4H_2O$ (0.0489 g, 0.1 mmol) resulted in the formation of immediate precipitates of complex which were separated by filtration, washed with methanol and dried in vacuo. Yield 55% based upon $[Cu(2,2'\text{-bpy})(ClO_4)_2]\cdot 4H_2O$. *Anal.* Calc. for $C_{17}H_{16}CuN_5SCl_2O_8$: C, 40.7; H, 3.2; N, 13.9. Found: C, 39.9; H, 4.0; N, 13.6%. IR spectrum 3365b, 3090s(ν_{N-H}), 1632s(δ_{N-H}), 835w(ν_{C-S}), 1100s($\nu_{3\ ClO_4}$) and 600w ($\nu_{4\ ClO_4}$) cm^{-1}.

2.2.5. Preparation of [Cu(ϕ_3P)$_2$ (4-tscph)][ClO$_4$] (*4*)

The corresponding reaction of 4-tscph with $[Cu(\phi_3P)_2(CH_3CN)_2]ClO_4$ under analogous conditions yielded white precipitates of **4**. Yield 60% based upon $[Cu(\phi_3P)_2(CH_3CN)_2]ClO_4$. Anal. Calc. for $C_{43}H_{39}CuN_3P_2SClO_4$: C, 60.3; H, 4.6; N, 4.9. Found: C, 59.7; H, 3.9; N, 4.6%. IR spectrum 3370b(ν_{N-H}), 1625s(δ_{N-H}), 840w(ν_{C-S}), 1100s($\nu_{3\ ClO_4}$) and 600w($\nu_{4\ ClO_4}$)cm^{-1}.

2.2.6. Preparation of precursor complexes

The precursor complexes $[M(N\text{–}N)X_2]\cdot xH_2O$ [N–N = 2,2′-bpy, M = Ni(II), Co(II), Cu(II) and Zn(II), X = NO_3, ClO_4, Cl and CH_3COO and N–N = 1, 10-phenanthroline (1, 10-phen), ethylenediammine (en) and $2NH_3$, M = Cu and X = NO_3, ClO_4] and Cu(2,2′-bpy). $(ClO_4)_2(L')$ [4-tscph, 2thiourea(tu) and semicarbazide(sc)] were prepared by known methods.

3. Results

For the preparation of mixed donor ligand complex of the type $[Cu(2,2'\text{-bpy})(tsc)][ClO_4]_2$, we reacted $[Cu(2,2'\text{-bpy})(ClO_4)_2]\cdot 4H_2O$ with stoichiometric amount of tsc in methanol–acetonitrile. But to our unexpected surprise the reaction yielded green complex of composition $[Cu(2,2'\text{-bpy})(NCS)_2]$. The IR spectrum of 1 reports $\nu_{C\equiv N}$ at 2080 cm^{-1} and ν_{C-S} at 828 cm^{-1} diagnostic of N bonded thiocyanate. Further, various absorption bands in the region 3400–3100 cm^{-1} (ν_{N-H}), characteristic of tsc and 1100 cm^{-1} (ν_3) and 600 cm^{-1} (ν_4) consistent with presence of ClO_4 anion are entirely absent [30]. Peaks for $\nu_{C=N}$ (2,2′-bpy) appears at ca. 1620 cm^{-1}. The structure of complex has been confirmed X-ray crystallography.

represented in Table II. The coordination geometry around Cu(II) center can be described as a distorted square planar. It coordinates to 2 N from 2,2′-bpy and 2 N from thiocyanate (Fig. 1). The inter pyridyl planar dihedral angle is 80.96°. The Cu7–N8 bond is in 71.3° angle to the normal of the plane formed by bipyridyl, while the angle of the thiocyanate group from normal of above mention plane is 60.1°. The angle between these two lines is 11.2°. The two thiocyanate groups are 119.9° degree in respect to each other. The individual molecules are arranged in zigzag chains in herringbone design with 2,2′-bpy and thiocyanate alternating on either side of the stack making a head to tail arrangement (Fig. 2). The bipyridyl double rings are coplanar, except for 0.7° twist inside the molecule. The pairs of symmetry related chains are packed in 2D sheets. The most intriguing feature is that a chain within a particular layer and molecules within a chain are unsupported by any interaction. The molecules are linked together in chains or sheets through π–π interactions between aromatic units of the immediate layers (Fig. 3(a) and (b)). The layers are arranged

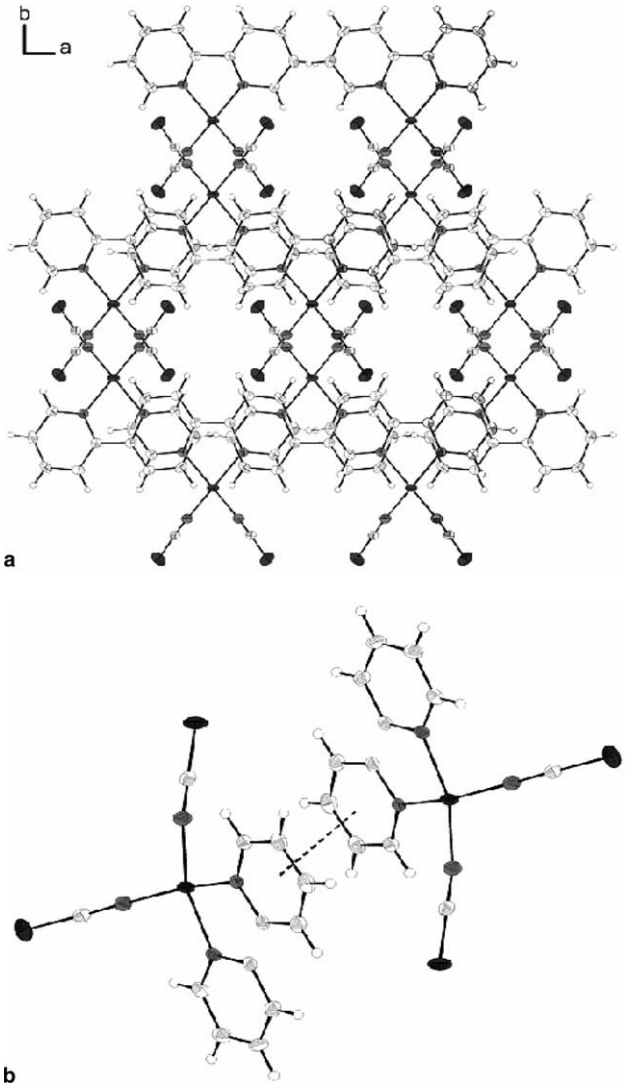

Fig. 3. (a) Two layers of network of 1, (b) a view along *c*-axis showing the stacking of layers.

in rare face to face (OFF) motif [31]. The superimposed bipyridyl rings are half the width of bipyridyl unit so that each 2,2′-bpy molecule interacts with the two 2,2′-bpy molecules of the adjacent layer covering one half of each molecule (Fig. 3(a)). The distance from one bipyridyl ring to the other calculated between C2 and C4 of the neighboring molecules is 3.29 Å. This mode of packing not only links two layers together but also keeps the molecules of the adjacent layer in position.

There is also a weak hydrogen bond between S10 and H3 of the adjacent molecule. The D–H···A and D···H distances are 3.042 and 3.699 Å, respectively. The D–H···A angle is 128.98°.

To investigate the probable mechanism of this unusual cleavage, series of experiments as tabulated below were carried out and were followed through IR spectroscopy for the presence or absence of thiocyanate peak.

3.1.1. Role of metal ion

The role of metal ion in hydrolysis of tsc was investigated by reacting $[M(2,2'\text{-bpy})X_2]\cdot xH_2O$, [M = Co, Ni, Cu and Zn and X = Cl, NO_3, ClO_4, CH_3COO] with tsc in methanol–acetonitrile mixture.

3.1.2. Effect of anion

A range of $[Cu(2,2'\text{-bpy})X_2]\cdot xH_2O$ precursors were reacted with tsc where X ranges from very weak to strong coordinating anion. The reaction completion is indicated by change of initial brown color to green color characteristic of $[Cu(2,2'\text{-bpy})(NCS_2]$.

3.1.3. Participation of co-ligand(N–N)

The participation of co-ligand to assist the cleavage of tsc in $Cu(N\text{–}N)(ClO_4)_2\cdot xH_2O$ was studied by employing π-bonding bulky ligands and non-π-bonding non-bulky ligands. The following sets of experiments were carried out.

3.1.4. Role of O/S and N/S ligand

Finally the reaction of $Cu(2,2'\text{-bpy})(ClO_4)_2\cdot 4H_2O$ with other similar ligands containing O/N or S/N donor atoms were employed. As indicated by IR studies only tsc is cleaved.

The above observations suggest that

(a) The hydrolysis is promoted only by copper complexes (Table 1).
(b) The stronger the coordinating ability of the anion, longer is the time taken to yield thiocyanate complex (Table 2).
(c) The hydrolysis is catalysed only with strong π-bonding and sterically hindered co-ligand (Table 3).

(d) The thiosemicarbazide species are hydrolysed only under special conditions. 4-Phenyl thiosemicarbazide and other similar ligands fail to undergo cleavage (Table 4).

4. Discussion

The common mode of bidentate coordination in tsc is through hydrazinic N(1) and S. However, based upon the above results it is possible that in the presence of 2,2′-bpy or other bulky π-bonding ligands both nitrogen atoms N(1) and N(4) instead of N(1) and S coordinate to Cu(II) due to the following reasons:

(1) In the presence of bulky amine ligands like 2,2′-bpy and 1,10-phen, Cu ion may react preferentially through amidic N(4) instead of S due to steric clashes. With non-bulky co-ligands like en, NH_3 the conventional S, N chelation may be dominating. Such effects

P(24)–Cu(1)–S(2)	111.23(3)
P(5)–Cu(1)–S(2)	104.89(3)

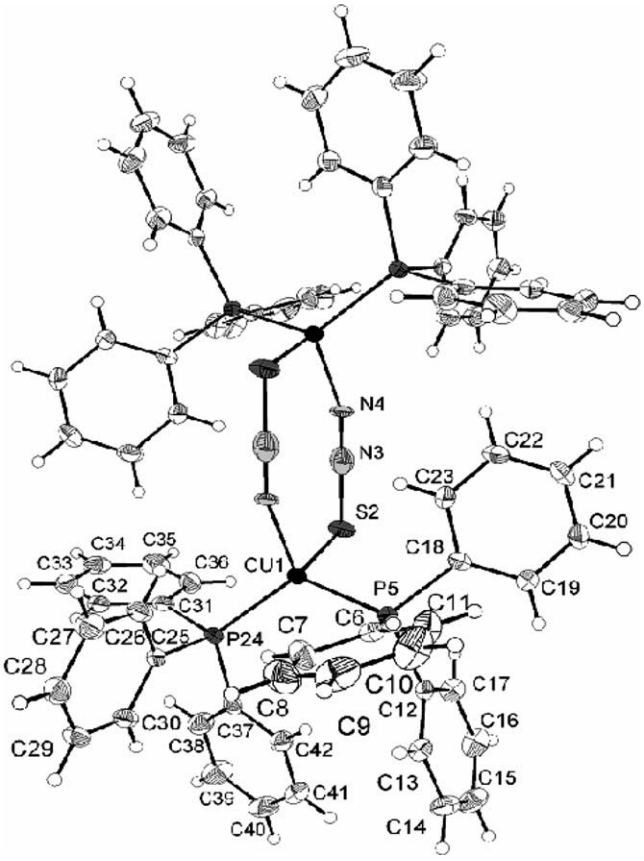

Fig. 4. The local coordination environment around Cu(I) ion in **2**.

have already been observed by Williams et al. in Pt(II) diammine complexes with methionine and *N*-acetyl methionine [32]. In the presence of bulky diammine ligands Pt(II) bind through S, N or S, O instead of S, S atoms due to interligand clashes. Their studies are also supported by molecular mechanics calculations.

(2) Copper being a borderline metal ion should preferentially coordinate through S of thiosemicarbazide. But this mode of bonding may be reversed in presence of strong π-acceptor ligands like 2,2′-bpy or 1,10-phen. Their strong π-acceptor nature makes the d-orbitals of Cu ion in $Cu(2,2'\text{-bpy}) \cdot X_2 \cdot xH_2O$ less available for bonding with π orbitals of sulphur. Therefore, metal orbitals of Cu(II) in $Cu(2,2'\text{-bpy}) \cdot X_2 \cdot xH_2O$ are not quite as basic as that of Cu(II) tsc, making the N(4) amidic nitrogen to coordinate to Cu(II) instead of S. Similar effects have also been observed earlier in [Pd(2,2′-bpy)(NCS)(SCN)] complex [33,34]. Although the soft nature of Pd(II) calls for bonding of SCN through its S end but for the second thiocyanate the bonding through N is preferred, because the less availability of electron density on Pd(II) due to back bonding with 2,2′-bpy makes Pd(II)–S bond interaction very weak.

(3) Bonding through N instead of S may also be preferred due to symbiotic effects.

The participation of π bonding in catalyzing the cleavage of tsc is further proved by substituting 2,2′-bpy with ϕ_3P- another π bonding ligand. The $[Cu(\phi_3P)_2(CH_3CN)_2]ClO_4$ was reacted with tsc under similar conditions and here again tsc is cleaved to generate $[Cu(\phi_3P)_2(NCS)]_2$. Another support to the proposed mechanism comes from the failure of both $[Cu(2,2'\text{-bpy})(ClO_4)_2] \cdot 4H_2O$ and $[Cu(\phi_3P)_2(CH_3CN)_2]ClO_4$ to hydrolyse 4-tscph and yield $[Cu(2,2'\text{-bpy})(4\text{-tscph})][ClO_4]_2$ and $[Cu(\phi_3P)_2(4\text{-tscph})]$-

Evolution of hydrazine was confirmed through HPLC.

Scheme 1. Proposed mechanism of hydrolysis of tsc.

(ClO_4) respectively. Due to the presence of bulky phenyl group N(4) is both sterically hindered and electron deficient. Here 4-tscph probably binds through S and hydrazinic N which is supported by shifting of C=S peak from 820w cm^{-1} in 4-tscph to ca. 840 cm^{-1} in the complexes. As the coordinated sulphur is difficult to cleave, the hydrolysis of 4-tscph fails. Similarly other similar ligands tu (binding through S) sc binding through (O or O and N) are not hydrolyzed.

*4.1. Crystal structure of [Cu(ϕ_3P)$_2$ (NCS)]$_2$ (**2**)*

The crystal data and structure refinement and important bond length and angles are reported in Tables I and III, respectively. The molecule exists as a dimer in which each of the Cu(I) is significantly deviated from idealised tetrahedral geometry towards square planar (Fig. 4). Two Cu(I) ions are bridged by two NCS groups through S and N atoms. The tetrahedral geometry is completed by coordination of each Cu atom to two triphenyl phosphines. The $Cu_2(NCS)_2$ forms 8 membered ring and has inversion center between two copper atoms. Packing of various layers is shown in Fig. 5.

5. Proposed mechanism

Based upon above observations that in case of $[Cu(2,2'\text{-bpy})X_2]\cdot xH_2O$, Cu perhaps bind through N(1), N(4) instead of N, S and binding through N(4) withdraws most of the electron density from S making it electropositive and susceptible to hydrolysis. The following mechanism is proposed (Scheme 1).

6. Conclusion

The ability of copper ion to promote the hydrolytic cleavage of tsc when coordinated to π acceptor ligands has been noticed for the first time. Both electronic and steric effects may be playing a significant role.

7. Supplementary data

Supplementary data are available from the Cambridge Crystallographic Data Center, 12 Union Road, Cambridge CB2 1EZ, UK (fax: (+44)1223-336-033; e-mail: deposit@ccdc.cam.ac.uk) quoting the deposition numbers 208696 and 208697.

Abstract

A series of luminescent Zn(II) and Cd(II) complexes have been prepared based on three different π-conjugated ligands, 2-(2-pyridyl)-imidazole (HL1), 2-(2-pyridyl)-benzimidazole (HL2) and 2,6-bis(benzimidazol-2yl)-pyridine (H_2L3). The PL spectra of the ligands exhibit a bathochromic shift in agreement with the extended π-conjugation of the ligand. The spectra of the complexes with the ligands follow the same rule. The structures of $Zn(L2)_2H_2O$ (**5**), $[Cd(L2)_2(H_2O)_2]\cdot 2DMSO$ (**6**), $Zn(HL3)_2$ (**9**) and $Cd(HL3)_2$ (**10**) have been established by X-ray crystallography. The structure of **5** can be best described as a square pyramid. The coordination geometries of **6**, **9** and **10** can be described as distorted octahedrons. In the solid state and in DMSO, these complexes show emission maxima in the blue region. The complexes have a bathochromic shift of the emission energy in sharp contrast to the free ligands. They display blue luminescence and have high luminescence quantum efficiency. A theoretical study reveals that the emissions are assigned to intraligand transitions of the deprotonated L2 and HL3 ligands, and the metal ions in the complexes play a key role in stabilizing the ligand and promoting the luminescence, which is consistent with the experimental results.

1. Introduction

Since Tang and Van Slyke [1] reported the first double-layer green organic electroluminescent devices (OELDs) using Alq_3 (q = 8-hydroxyquinolinyl) in 1987, there has been intense research activity in organic EL devices [2,3]. Studies on OELDs have proliferated because of their application in the next generation of full-color flat panel displays, and extensive studies have been performed on the use of small molecular complexes to make organic EL devices with high brightness, multi-color emission, improved durability and desirable efficiency [4,5]. Research into ligand design for EL materials has been dominated by the 8-hydroxyquinoline, dipyridine and azaindole moiety. Despite recent advances in red and green light OLEDs, useful blue electroluminescent materials are still sparse and sought-after in the literature, with notable examples being Zn(II) metal–organic compounds [6]. Che and Wang groups [7] have reported a series of Zn(II) compounds containing 7-azaindole or 2,2′-dipyridylamine ligands, which display blue light photoluminescence. However, practical applications of these compounds in OELDs would require a new generation of organic ligands that are inexpensive and robust.

In organic polymers, such as poly(*p*-phenylene vinylene) (PPV) and polythiophenes, etc., the length,

doi:10.1016/j.poly.2005.07.021

substitution, regioregularity and degree of conjugation can be modulated to tune color. A common approach to control the emitted color of organic materials is to append fluorescent chromophores to a polymeric backbone or to blend dyes into inert polymeric matrices [8]. Similarly, the emission wavelength of most metal–organic complexes can be tuned or changed by adjusting the length of conjugation of the ligand since fluorescent emission is mostly dominated by the coordinated ligand transition [9–11].

Imidazole and its derivatives were found to have a broad scope of biological activity. For example, they were found to be essential in the biosynthesis of purine nucleotides and DNA binding studies of their complexes [12,13]. On the other, transition metal complexes with imidazole and its derivatives have attracted much attention due to not only their interesting structural and chemical properties but also their applications in materials science [14,15]. Recently, homoleptic rare earth 2-(2-pyridyl)-benzimidazole [16], *cis*-dichloro (2-pyridyl)-benzothiazole platinum (II) [17] and [Cu(pmda)(2-(2-pyridyl)-benzimidazole)] were obtained [18]. Only a few transition metal complexes of 2-(2-pyridyl)-imidazole (HL1), 2-(2-pyridyl)-benzimidazole (HL2) and 2,6-bis(benzimidazol-2yl)-pyridine (H_2L3) are known [16–19]. By integrating the design features described above, we have prepared three different conjugated length ligands including imidazole, HL1, HL2 and H_2L3, which are inexpensive and commercially available. As far as we know, there are no reports about the crystal structures of the neutral Cd(II), Zn(II) complexes in the literature until now.

According to these considerations, We designed and synthesized theses ligands, which can coordinate to Cd(II) and Zn(II) ions via the nitrogen atoms in a bidentate or tridentate mode. At the same time molecular orbital calculations are performed to study the structures and spectra of the complexes.

2. Experimental

2.1. Syntheses

2.1.1. Preparation of ligand HL1

HL1 was prepared according to the literature procedures [20]. A solution of 20 g (190 mmol) of pyridine-2-carboxaldehyde and 20 ml of 95% ethanol was cooled to 0 °C and added to a solution of 27 ml of 40% aqueous glyoxal in 20 ml of 95% ethanol, also at 0 °C. The mixture was stirred in an ice bath, and 64 ml of cold aqueous NH_3 (30%) was added as quickly as possible while maintaining the temperature of the entire mixture below about 5 °C. The stirring solution gradually turned brown and was allowed to warm to room temperature after 1 h. The volume was reduced by gentle warming under vacuum, and the remaining solution was extracted several times with ether, and the ether was then removed under vacuum to yield a brown oil which was distilled under vacuum. A clear yellow oil was obtained and then recrystallized from ethyl acetate yielding 9 g (33%) of light yellow needles.

2.1.2. Preparation of ligand HL2

A mixture of 2-picoline (0.1 mol), *o*-phenylenediamine (0.1 mol) and sulfur (0.3 mol) was heated at 170 °C for 10 h. After the reaction was over, the reaction mixture was concentrated in vacuo, becoming gummy. The residue was extracted with hot ethanol. The extract was evaporated in vacuo and recrystallized after purification with active charcoal [21].

2.1.3. Preparation of ligand H_2L3

According to the literature procedures [26], pyridine-2,6-dicarboxylic acid (3.35 g) was stirred with *o*-phenylenediamine (4.7 g) in syrupy phosphoric acid (40 ml) at ca. 230 °C for 4 h. The colored molten mixture was poured into and vigorously stirred in cold water. When cooled the bulky blue-green precipitate was collected by filtration and then stirred in hot, 10% aqueous sodium carbonate solution (300 ml). The resulting solid was filtered off and recrystallized from methanol to give long, white prisms (3.3 g, 53%).

2.1.4. $Zn(L1)_2 \cdot H_2O$ (**1**)

A solution of 2-(2-pyridyl)imidazole (1.5 mmol) in methanol (20 ml) was heated to boiling, mixed with a solution of zinc (II) acetate dihydrate (1 mmol in 30 ml methanol), and triethylamine (1 ml) was added. A white precipitate was obtained after filtration. Yield: 36%. *Anal*. Calc. for $C_{16}H_{14}N_6OZn$: C, 51.70; H, 3.80; N, 22.61. Found: C, 51.64; H, 3.79; N, 23.70%. IR (cm^{-1}) 1539, 1529, 1308, 744, 640.

2.1.5. $Cd(L1)_2 \cdot 2H_2O$ (**2**)

Complex **2** was synthesized using the same method as for complex **1**. Yield: 39%. *Anal*. Calc. for $C_{16}H_{16}N_6O_2Cd$: C, 40.00; H, 3.69; N, 18.33. Found: C, 39.96; H, 3.64; N, 18.33%. IR (cm^{-1}) 1599, 1500, 1218, 784, 633.

2.1.6. $[Zn(HL1)_2]Cl_2$ (**3**)

A solution of 2-(2-pyridyl)imidazole (1.5 mmol) in methanol (20 ml) was heated to boiling and then mixed with a solution of $NaClO_4$ and $ZnCl_2 \cdot 2H_2O$ (1 mmol in 30 ml methanol). A white precipitate was obtained after filtration. Yield: 36%. *Anal*. Calc. for $C_{16}H_{14}N_6ZnCl_2$: C, 45.47; H, 3.31; N, 18.76. Found: C, 45.45; H, 3.29; N, 18.76%. IR (cm^{-1}) 1540, 1510, 1218, 765, 609.

2.1.7. $[Cd(HL1)_2]Cl_2$ (**4**)

Complex **4** was synthesized using the same method as for complex **3**. A white precipitate was obtained after

filtration. Yield: 38%. *Anal*. Calc. for $C_{16}H_{14}N_6$- $CdCl_2$: C, 40.58; H, 2.98; N, 17.74. Found: C, 40.54; H, 2.96; N, 17.73%. IR (cm^{-1}) 1560, 1489, 1268, 801, 703.

2.1.8. $Zn(L2)_2 \cdot H_2O$ (**5**)

A solution of 2-(2-pyridyl)benzimidazole (1.5 mmol) in methanol (20 ml) was heated to boiling, mixed with a solution of zinc (II) acetate dihydrate (1 mmol in 30 ml methanol) and then triethylamine (1 ml) was added. A white precipitate (yield 40%) was obtained after filtration, crystals of $Zn(L2)_2 \cdot H_2O$ were obtained by slow evaporation of a DMSO solution of the precipitate. Yield: 43%. *Anal*. Calc. for $C_{24}H_{18}N_6OZn$: C, 61.10; H, 3.84; N, 17.81. Found: C, 61.02; H, 3.69; N, 17.95%. IR (cm^{-1}) 1604, 1445, 1424, 796, 746.

2.1.9. $[Cd(L2)_2(H_2O)_2] \cdot 2DMSO$ (**6**)

The complex **6** was prepared in exactly the same way as for complex **5**. The crystals of $[Cd(L2)_2 \cdot (H_2O)_2] \cdot 2DMSO$ were obtained by slow evaporation of a DMSO solution. Yield: 39%. *Anal*. Calc. for $C_{28}H_{32}N_6O_4S_2Cd$: C, 48.55; H, 4.62; N, 12.13. Found: C, 48.13; H, 4.38; N, 12.02%. IR (cm^{-1}) 1599, 1500, 1418, 744, 643.

2.1.10. $[Zn(HL2)_2](ClO_4)_2$ (**7**)

A solution of 2-(2-pyridyl) benzimidazole (1.5 mmol) in methanol (20 ml) was heated to boiling and then mixed with a solution of $NaClO_4$ and $ZnCl_2 \cdot 2H_2O$ (1 mmol in 30 ml methanol). A white precipitate (yield 40%) was obtained after filtration. Yield: 33%. *Anal*. Calc. for $C_{24}H_{18}N_6O_8Cl_2Zn$, C, 44.03, H, 2.77, N, 12.84. Found: C, 44.15, H, 2.62, N, 12.65%.

2.1.11. $[Cd(HL2)_2](ClO_4)_2$ (**8**)

The complex **8** was prepared in exactly the same way as for complex **7**. Yield: 33%. *Anal*. Calc. for $C_{24}H_{18}N_6O_8Cl_2Cd$: C, 41.08, H, 2.56, N, 11.98. Found: C, 41.15, H, 2.63, N, 11.60%.

2.1.12. $Zn(HL3)_2$ (**9**)

Zinc(II) chloride dihydrate (5.5 mmol) was heated in glycerol (50 ml) under nitrogen for 1 h at 150 °C. To the resulting solution was added solid 2,6-bis(benzimidazol-2yl)pyridine (10 mmol) and triethylamine (3 ml), and then the mixture was heated for 5 h at 200 °C. After dilution of the resulting solution with water (100 ml), $NaClO_4$ (5.6 mmol) was added to give a precipitate, which was collected and recrystallized from methanol. Yield: 35%. *Anal*. Calc. for $C_{38}H_{24}N_{10}Zn$: C, 66.53; H, 3.53; N, 20.41. Found: C, 66.51; H, 3.52; N, 20.41%. IR (cm^{-1}) 1601, 1502, 1437, 744, 669.

2.1.13. $Cd(HL3)_2$ (**10**)

The complex **10** was prepared in exactly the same way as for complex **9**. Yield: 43%. *Anal*. Calc. for $C_{38}H_{24}N_{10}Cd$: C, 62.26; H, 3.30; N, 19.11. Found: C, 62.14; H, 3.49; N, 18.91%. IR (cm^{-1}) 1574, 1500, 1437, 744, 670.

2.2. Materials and physical measurements

All solvents and reagents were of commercially analytical grade and used without further purification. The starting materials were purchased from Aldrich and used without further purification. Infrared spectra were recorded from KBr plates in a MAGNA-560 spectrometer. Excitation and emission spectra were recorded on a Cary Eclipse fluorescence spectrophotometer. Elemental analyses were performed on a Perkin–Elmer 240c analyzer. Absorption spectra were recorded at 293 K using a Cary-Varian 500 Spectrophotometer in the 220–700 nm range.

2.3. X-ray crystallographic analyses

Crystals, which were obtained directly from solution, were suitable for X-ray diffraction study. Diffraction intensities for these complexes were collected on a Rigaku RAXIS–RAPID image plate diffractometer using the ω scan technique with Mo Kα radiation ($\lambda = 0.71073$ Å). Absorption corrections were applied using the multi-scan technique [22]. The structures were solved with the direct method of SHELXS-97 [23] and refined with full-matrix least-squares techniques using the SHELXL-97 program [24]. Non-hydrogen atoms were refined anisotropically. The hydrogen atoms on carbon atoms were generated geometrically, while the aqua hydrogen atoms were not located. An analytical expression of neutral-atom scattering factors was employed and anomalous dispersion correction incorporated [25]. The crystallographic data for complexes **5**, **6**, **9** and **10** are given in Table 1. Selected bond lengths and angles are given in Tables 2–5.

3. Results and discussion

3.1. Syntheses

3.1.1. Ligands

Our previous work has established that the deprotonated benzimidazole ligand is an efficient blue emitter when bonded to a central atom in a bridging mode [26]. Based on the inherent character of the benzimidazole group which allows easy derivation and potentially strong π–π stacking interactions to form supramolecular structures, we have now synthesized three derivatives of the imidazole ligand, the bidentate or tridentate ligands HL1, HL2 and H_2L3 (Scheme 1), with increasing extended conjugation.

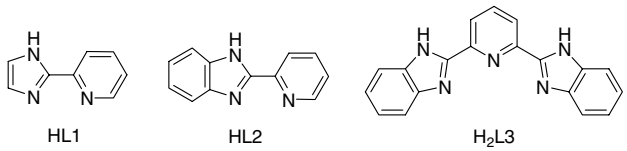

Scheme 1. Illustration of the three ligands.

3.1.2. Complexes

These complexes were synthesized by the reaction of the corresponding ligands (HL1, HL2, H_2L3) with the metal ion M^{2+} ($M^{2+} = Cd^{2+}$, Zn^{2+}). They are either neutral complexes or ionic ones due to deprotonation of HL1, HL2, H_2L3 (with additional triethylamine). We compared the properties of these complexes and found that the neutral complexes are more stable than the ionic complexes, especially as they have melting points greater than 240 °C, which is a highly desired property for the practical application in electroluminescent devices [27]. The crystal structures of **5**, **6**, **9** and **10** have been determined by X-ray diffraction.

3.2. Crystal structures of the complexes

3.2.1. $Zn(L2)_2 \cdot H_2O$ (**5**)

The structure of **5** can be best described as a square pyramid surrounded by O(1), N(1), N(2), N(4) and N(5). Two L1 ligands are chelated to the Zn(II) center (Fig. 1). The shortest bond is between Zn(II) and the negatively charged imidazole atom N(2), 1.993(2) Å, while the longest bond is 2.242(2) Å, between Zn(II) and the pyridine N atom. Zinc complexes with the bipyridine ligand commonly have Zn–N bond lengths ranging from 2.1 to 2.2 Å [28]. Five-coordinated Zn(II) complexes are quite common and many examples have been reported previously [27,28].

3.2.2. $[Cd(L2)_2(H_2O)_2] \cdot 2DMSO$ (**6**)

Each Cd(II) ion is six-coordinated by four nitrogen atoms from the two bidentate L2 anions and two water molecules. The coordination geometry of the Cd(II) ion can be described as a distorted octahedral (Fig. 2). The average Cd–O (water) distance of 2.329 Å is near to the values found in other Cd(II) complexes [29,30]. Cd–N (pyridine)distance of 2.395 Å is longer than the Cd–N (imidazole) distance (2.256 Å). Each deprotonated ligand L2 coordinates to one Cd(II) ion through its pyridine N atom and imidazole N atom. The $[Cd(L1)_2(H_2O)_2]$ molecules are linked through hydrogen bonds between water molecules and nitrogen atoms. All of the other bond distances and angles are similar to those found for the related rhenium (I) polypyridyl complexes [31].

3.2.3. $Zn(HL3)_2$ (**9**)

The molecular structure of **9** with the atom numbering is shown in Fig. 3. The structure contains one zinc atom and two $HL3^-$ anionic ligands. N(3) and N(8) are deprotonated with Zn(1)–N(3) 2.321(8) and Zn(1)–N(8) 2.294(8) Å, respectively. The corresponding protonated nitrogens, as expected, form marginally longer bonds with Zn(1)–N(2) 2.329(9) and Zn(1)–N(7) 2.411(8) Å. The coordination geometry shows considerable distortion from a regular octahedron as is evident from the bond

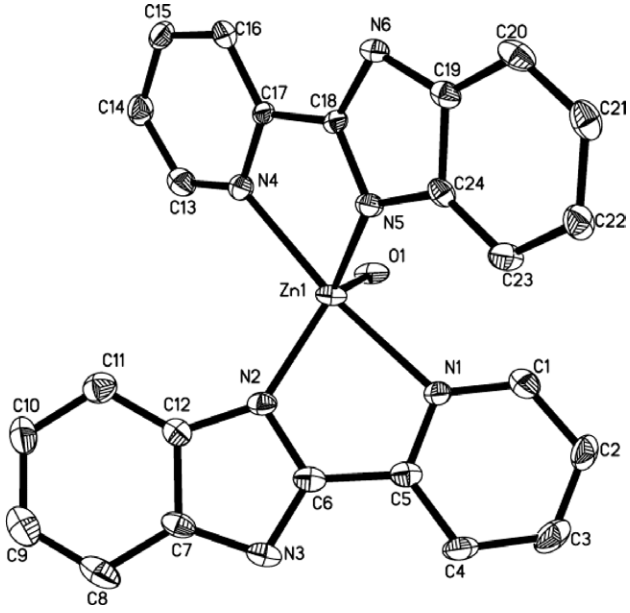

Fig. 1. The molecular structure of complex **5**. Thermal ellipsoids are plotted at the 30% probability level and the hydrogen atoms are omitted for simplicity.

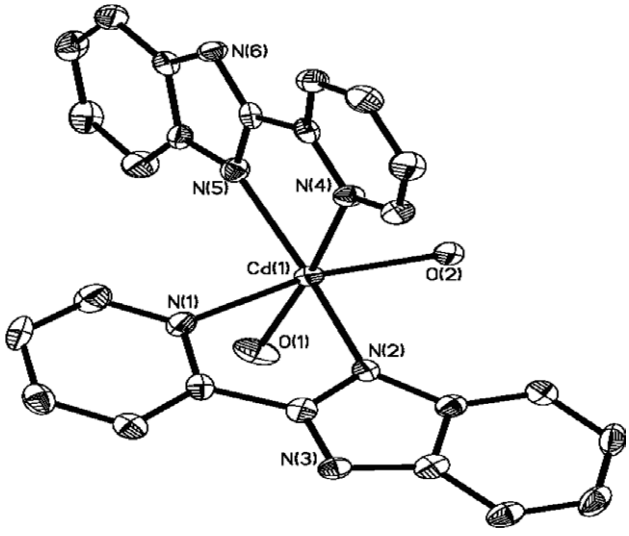

Fig. 2. The molecular structure of complex **6**. Thermal ellipsoids are plotted at the 30% probability level and the hydrogen atoms are omitted for simplicity.

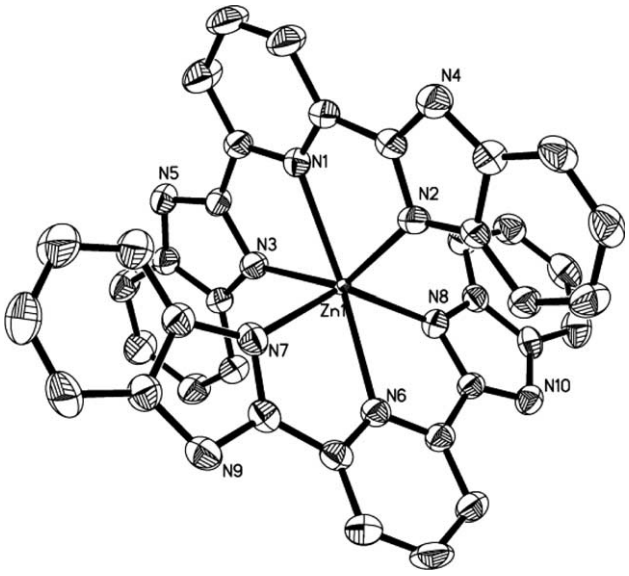

Fig. 3. The molecular structure of complex **9**. Thermal ellipsoids are plotted at the 30% probability level and the hydrogen atoms are omitted for simplicity.

angles around zinc: N(3)–Zn(1)–N(1) 70.30(3)° is considerably smaller than the ideal 90°. The molecular structure of **9** is similar to the Mn(II) complex [32].

3.2.4. $Cd(HL3)_2$ (*10*)

The molecular structure of **10** with the atom numbering is shown in Fig. 4. The structure of $Cd(HL3)_2$ is similar to that of $Zn(HL3)_2$ (**9**). N(4) and N(9) are deprotonated with Cd–N(4) 2.303(4) and Cd–N(9) 2.277(4) Å, respectively. The corresponding protonated nitrogens, as expected, form marginally longer bonds with Cd–N(1) 2.337(4) Å and Cd–N(6) 2.425(4) Å. The coordination geometry shows considerable distortion from a regular octahedron as is evident from the bond angles around cadmium: N(3)–Cd–N(1) 70.49(13)° is considerably smaller than the ideal 90°. The previously reported structure of $Cd(H_2L3)Cl_2$ can be best described as a distorted trigonal bipyramidal geometry. The ligand affords three N atoms to coordinate to Cd(II) and two chloride ions lie each side of the planar pyridine ring [33].

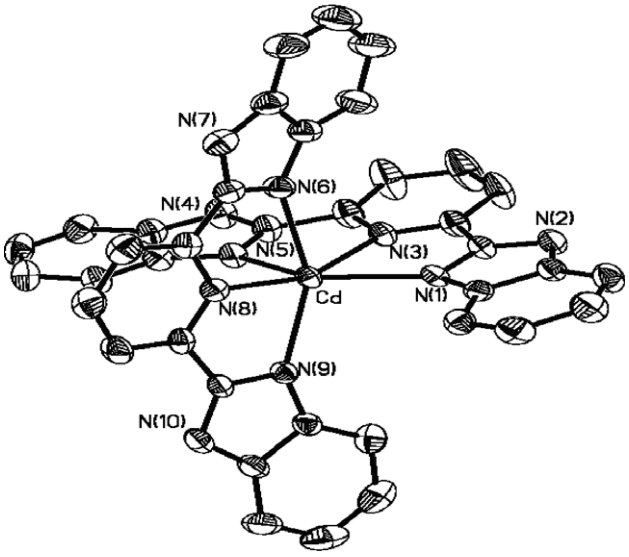

Fig. 4. The molecular structure of complex **10**. Thermal ellipsoids are plotted at the 30% probability level and the hydrogen atoms are omitted for simplicity.

3.3. Luminescent properties

Compounds HL1, HL2 and H_2L3 have a similar structures, however the bathochromic shifts of the emission energy of compound HL2 ($\lambda_{max} = 369$ nm), compared to that of HL1 ($\lambda_{max} = 363$ nm), is due to the extended conjugation through the phenyl units. In the same way the emission energy of compound H_2L3 ($\lambda_{max} = 407$ nm) exhibits more obvious bathochromic shifts. The emission energy of H_2L3 has 38 and 44 nm bathochromic shifts relative to that of HL1 and HL2, respectively. H_2L3 is much more π-conjugated than HL1 and HL2, which apparently decreases the π–π* energy gap, thus resulting in a bathochromic shift in emission wavelength.

Complexes with L1 emit a purple or blue color in the solid state and in solution. The dramatic bathochromic shift of the emission energy of complexes with HL1 in comparison to that of free HL1 can be attributed to the coordination of the central metal and the ligand HL1. The excitation and emission spectra for all the complexes **1**–**10** are showed in Fig. 5, and the excitation and emission data of the complexes in the solid state and DMSO are shown in Table S1 in ESI.

While each of the complexes gives a blue emission in the solid state and in solution. The emission energy for

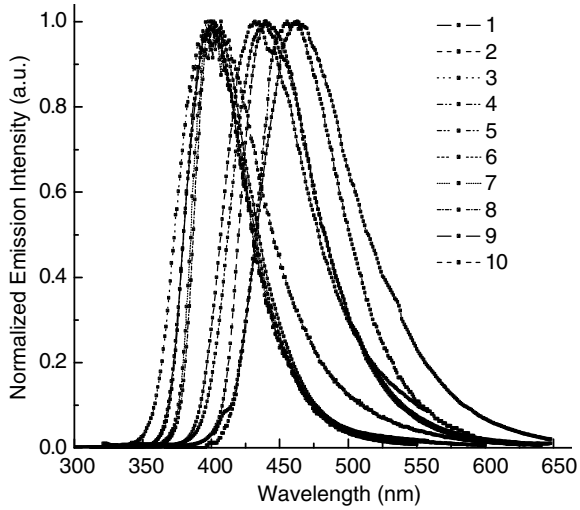

Fig. 5. Normalized solid PL spectra of the complexes **1**–**10**.

these complexes is similar despite the differences of the geometry and ligand environment of the complexes. This is not surprising because the blue luminescence of the complexes is believed to originate from a π*–π transition of the ligands. The luminescent curves of these complexes are in sharp contrast to that of the free ligands which have either no emission at all in the visible region or a weak emission. For complexes with HL1, **1** ($\lambda_{max} = 402$ nm) and **2** ($\lambda_{max} = 432$ nm) have a larger red shift in emission energy than the corresponding values for **3** ($\lambda_{max} = 398$ nm) and **4** ($\lambda_{max} = 400$ nm), because the deprotonation of the ligand decreases the π*–π gap. The same phenomena has been found for the complexes (**5**–**8**) with HL2. In comparison to the free HL2 ligand, a bathochromic shift for the complexes was observed. This bathochromic shift is undoubtedly due to the deprotonation of the ligand when forming the neutral complexes, which is consistent with the results of Wang's work in luminescent 7-azaindole complexes [34].

Complexes **9** and **10** exhibit blue-fluorescent emission in the solid state and in solution. As a result of the same reason, there are dramatic bathochromic shifts of the emission energies of the complexes in comparison to that of free H_2L3, which is consistent with the results of complexes **1**–**8**. The role of the central ion in complexes **1**, **2**, **5**, **6**, **9** and **10** is simply to stabililize the negatively charged ligand via the formation of coordination bonds. Their bidentate and tridentate complexes have the same luminescent properties. The emission properties of these complexes are attributed to the L–L (ligand–ligand) charge transfer, and the metal ions in the complexes play a key role in increasing the ligands' conformational rigidity, thereby reducing the non-radiative decay of the intraligand (π–π* transition) excited state. Similar to other complexes containing the benzimidazole group, the luminescence for the ligand is predominantly π–π* transition fluorescence [33,35].

In order to obtain blue luminescence, we have to make adjustments by chemical means to obtain the emission maximum (π-conjugation) according to the fact that the greater the conjugation is, the less the emission energy is, and the maximum emission shows a bathochromic shift. To understand the effect on the emission energy on going from the free ligand to the complex, we performed DFT calculations for the free ligand HL2 (2-(2-pyridyl)benzimidazole) and complex **6** at the DFT/B3LYP level using the SDD [36] basis set employing the GAUSSIAN 98 suite of programs [37]. The geometric parameters were taken from the X-ray diffraction crystal structural data for complex **6** and optimized employing B3LYP/6-31g(d) for HL2. The energies of the frontier molecular orbitals (FMOs) of the free ligand and complex **6** are ploted in Fig. 6. As one may see, the FMOs of complex **6** are significantly different from those of HL2; the highest occupied molecular orbital (HOMO) of HL2 is a π orbital with contributions from 2p orbitals of the carbon atoms in benzimidazole and pyridine rings, with the latter contributing less than the former. Analogously, the HOMO of complex **6** is also a π orbital, localized on the lone pair of non-coordinating nitrogen atoms (N(3), N(6)) and the carbon atom in the benzimidazole ring, owing to the low symmetry (C_1). Compared with the free ligand, the electronic density is more concentrated at the benzimidazole ring again. The nodal structure of the HOMO of the ligand, however, is not compatible with that of the complex. The energy of the HOMO level of the complex is much lower

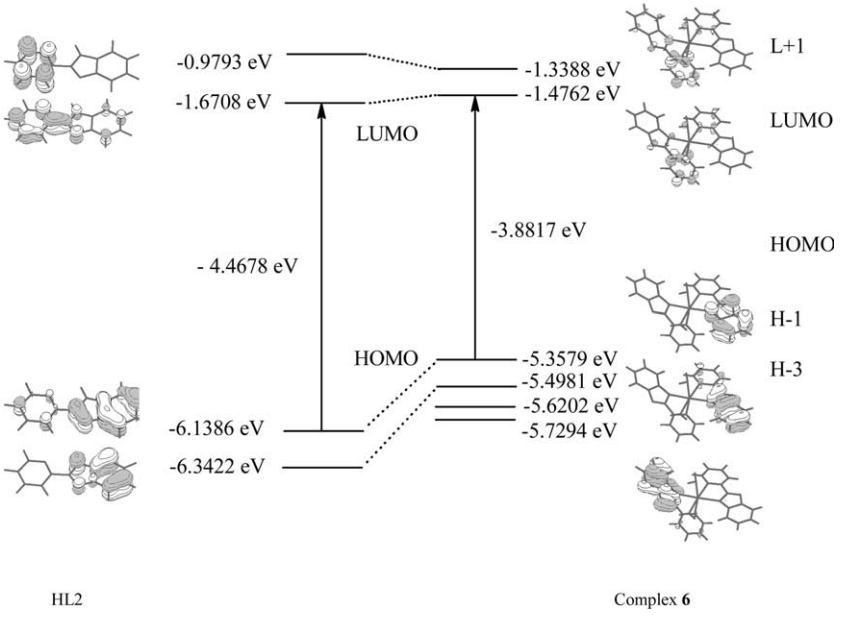

Fig. 6. Frontier molecular orbitals of HL2 and complex **6**.

than that of the free ligand. The lowest unoccupied molecular orbital (LUMO) of the free ligand is a π* orbital with contributions from both benzimidazole and pyridyl rings, while the LUMO of the complex is a π* orbital consisting of mostly atomic orbitals from one of the non-coordinated pyridyl rings. There are essentially few contributions from the benzimidazole ring in the LUMOs of the complex. The role of the Cd(II) ion is to stabilize the negatively charged ligand and decrease the π–π* energy gap, leading to a bathochromic shift in the transition energy from HL2 to $Cd(L2)_2$. The excitation energies were obtained at the density functional level by using the time-dependent perturbation theory approach (TDDFT) [38] with the adiabatic local density approximation, which have high reliability in obtaining accurate predictions for excitation energies and oscillator strengths. It was found that the absorption spectrum of the complex $Cd(L2)_2$ predicts an absorption maximum at 320.62 nm and therefore is in good agreement with the experimental values of 323 nm. The dominant contribution to this peak were assigned as ligand-to-ligand charge transfer (LLCT) which is associated with excitations from HOMO − 3 to LUMO + 1.

The quantum yields of **1**–**10** in solution were determined to be 0.17, 0.09, 0.06, 0.04, 0.59, 0.34, 0.28, 0.11, 0.25 and 0.26, respectively, relative to that of quinine sulfate (0.55) [39]. The quantum yields of complexes **1**, **2**, **5**, **6** are higher than those of the corresponding complexes **3**, **4**, **7**, **8** containing chloride anions, respectively. The quantum yields of complexes **6**, **7**, **9** and **10** are similar to those of the related compounds $(Me_2PyrPy)_2Zn$ (0.32) and $(^iPr_2PyrPy)_2Zn$ (0.31) [28]. Complex **5** shows the highest quantum field (0.59) among these complexes.

In compounds **5** and **6**, a water molecule is involved in the metal complex. In order to know the effect of the water molecule on luminescence, we measure their luminescence intensities. The results show that the intensity of the complexes with coordinated water is three times greater than that of complexes without water. Although there is a water molecule in the direct environment of the luminescent complex, the efficiency of the emission is relatively high [40]. In our paper, complex **5** and **6** have relatively high photoluminescent efficiencies. It has been reported that the coordination of a water molecule makes luminescence lifetimes fall and result in luminescence decay [41], but we think that the existence of water molecules may increase coplane and conformational rigidity in the molecule structure.

4. Conclusion

Three different ligands including imidazole, 2-(2′-pyridyl)imidazole (HL1), 2-(2′-pyridyl)benzimidazole (HL2) and 2,6-bis(benzimidazol-2yl)pyridine (H_2L3) have been designed and synthesized so as to increase the π-conjugation, based on the fact that a large π-conjugation of the ligand decreases the π–π* energy gap, and thus leads to a bathochromic shift in emissive spectra. At the same time complexes with these ligands, including Cd^{2+} and Zn^{2+}, have been obtained in the neutral or ionic state, and their absorption and fluorescent spectra have been studied. Also the photoluminescent efficiencies of the complexes have been determined. Among them, complex **5**, with HL2, has the most efficient PL property. We are applying the new complexes in an electroluminescent device and are further improving electroluminescent performances in our future work.

Appendix A. Supplementary data

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 268938, 198727, 237768 and 237767 for **5**, **6**, **9** and **10**, respectively. These data can be obtained free of charge at www.ccdc.cam.ac.uk/conts/retrieving.html (or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK; fax: (internat.) +44 1223/336 033; e-mail: deposit@ccdc.cam.ac.uk). Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2005.07.021.

Abstract

Cadmium(II) nitrate tetrahydrate – a metal ion template, tris(2-aminoethyl)amine (tren) – a tripodal amine and thiocyanate – a versatile intermediatary in a 3:2:6 mole ratio in water afford a homopolymer, $[Cd_3(tren)_2(NCS)_6]_n$ (**1**). Replacement of two equivalents of cadmium(II) salt by two equivalents of nickel(II) nitrate hexahydrate results in the heteropolymer, $[Ni_2Cd(tren)_2(NCS)_6]_n$ (**2**). Compound **1** crystallizes in the monoclinic $C2/c$ space group with $a = 20.3480(17)$ Å, $b = 10.8796(9)$ Å, $c = 16.3495(10)$ Å, $\beta = 110.009(7)°$ and $Z = 4$; **2** crystallizes in the same space group as in **1** with $a = 19.584(5)$ Å, $b = 11.034(3)$ Å, $c = 15.760(4)$ Å, $\beta = 100.712(4)°$ and $Z = 4$. **1** and **2** are new examples of homo- and hetero-polymers with the multiconnecting molecular ion bridge $[Cd(NCS)_6]^{4-}$ in different geometric configurations. The single crystal X-ray structures of both neutral polymers consist of infinite two-dimensional sheets with two alternating environmentally different octahedral metal ion [M(II) = Ni(II)/Cd(II)] coordination spheres connected by four 1,3-thiocyanato bridging *cis*-/*trans*-$[Cd(NCS)_2(SCN)_4]^{4-}$. The Cd(1) centres in **1** and **2** with the CdN_2S_4 chromophore are surrounded by four S atoms of the bridging thiocyanate and two terminal N atoms of the pseudohalide, while the CdN_6 chromophore of Cd(2) in **1** and NiN_6 chromophore of Ni(1) in **2** are completed by four tren N atoms and two N atoms of the bridging NCS^- in *cis* alignment. In **1**, the three tripodal amine N atoms and two bridging S atoms are engaged in strong intermolecular hydrogen bondings, which is responsible for the conformation and stability of the supramolecular network. The absence of such hydrogen bonding in **2** is due to a difference in the orientation of the tripodal amine from that in **1** in the polymeric net. The magnetic property of **2** has been investigated over the 2–300 K temperature range. The feature is characteristic of a Curie law for a typical magnetically isolated nickel(II) ion with very weak antiferromagnetic interactions ($J < 0.01$ cm^{-1}). The presence of a diamagnetic molecular ion with two 1,3-thiocyanate bridges may be one of the major reasons to hinder effective coupling of the paramagnetic centres.

1. Introduction

A vast majority of current work centres around the use of molecular components to prepare inorganic-organic hybrid [1,2] functional materials [3–9] of different shapes and sizes [10] through control and manipulation of covalent bonds [11,12] with malleable coordination spheres and multiple lateral non-covalent forces [13–19] like hydrogen bonding, C–H...π and π...π interactions. One of the popular approaches in the synthetic strategy to the construction of these materials has been the use of two complementary building blocks like cyanometallates $[M(CN)_n]^{z-}$ ($M = V^{II}$, Cr^{III}, Mn^{III} and Fe^{III}, $n = 6$, $z = 4$ or 3; $M = Ni^{II}$, $n = 4$, $z = 2$; $M = Mo^{V}$, $n = 8$, $z = 3$) as bridging units in combination with other metal templates containing potential coordination site(s) [20–33]. Hexacyanometallates [20–29] with potential donor sites are used extensively as multiple bridging units and polyamine or Schiff base transition metal complexes, as complementary units with potential acceptor site(s). A sizeable number of one-dimensional (1D), two-dimensional (2D) and three-dimensional (3D) extended arrays of homo- and hetero-polymers have been characterized with novel structures and physicochemical [34,35] properties. To the best of our knowledge no such report is found with other hexapseudohalogenometallates like $[M(X)_6]^{n-}$ ($X^- = N_3^-$, NCS^-, NCO^- and $NCSe^-$). We are interested in extending this view to a molecular ion, $[Cd(NCS)_6]^{4-}$, as a bridging unit with other transition/non-transition metal templates containing controlled vacant coordination site(s) to prepare multidimensional homo- and heterometallic coordination polymers and polymer-based superstructures [36,37]. Diamagnetic cadmium(II) is chosen for its d^{10} configuration, permitting a wide variety of geometries and coordination numbers [38–40]. The ambidenticism of the thiocyanate ligand [41,42], with a hard nitrogen and a soft sulfur donor centre, tends to form homo- and hetero-polymeric chains with both hard and soft transition and non-transition metal ions. The tripodal amine [28,43] tris(2-aminoethyl)amine (tren), with its four nitrogen centres may be used as a blocker to control the dimensionalities and architectures of polymers and superstructures. The in situ preparation of the $[Cd(NCS)_6]^{4-}$ unit may have dynamic Cd(II) and NCS^- linkages of the type $[Cd(NCS)_{6-n}(SCN)_n]^{4-}$ ($n = 0$–6) in solution which in the presence of varied complementary units may result in different coordination matrices like $[Cd(NCS)_6]^{4-}$, $[Cd(NCS)_5(SCN)]^{4-}$, *cis*-/*trans*-$[Cd(NCS)_4(SCN)_2]^{4-}$, *fac*-/*mer*-$[Cd(NCS)_3(SCN)_3]^{4-}$, *cis*-/*trans*-$[Cd(NCS)_2(SCN)_4]^{4-}$, $[Cd(NCS)(SCN)_5]^{4-}$ and $[Cd(SCN)_6]^{4-}$. The present work stems from our interest to isolate polymeric complexes with the use of this molecular ion in combination with different complementary units having variable potential vacant site(s). Successfully we have synthesized and X-ray structurally characterized a homonuclear polymer of the type $[Cd_3(tren)_2(NCS)_6]_n$ (**1**) and a heteronuclear analogue of the type $[Ni_2Cd(tren)_2(NCS)_6]_n$ (**2**), where respectively *cis*-$[Cd(NCS)_2(SCN)_4]^{4-}$ and *trans*-$[Cd(NCS)_2(SCN)_4]^{4-}$ geometries are engaged in propagating the 1,3-thiocyanato bridges among the environmentally different metal ions. The presence of strong interchain N–H...S hydrogen bondings in **1** leads to the formation of a polymer based superstructure whereas such non-covalent forces are absent in **2** arising from the difference in the orientation of the tripodal amine in the lattice. The details of the synthesis, spectroscopic, magnetic and some physicochemical properties of these complexes are described below.

2. Experimental

2.1. Materials

Cadmium nitrate tetrahydrate (E. Merck, India), nickel nitrate hexahydrate (E. Merck, India), tris(2-aminoethyl)amine (tren) (Lancaster, UK) and ammonium thiocyanate (E. Merck, India) were purchased from the respective concerns and used as received. All other chemicals and solvents for preparative and spectroscopic work were of reagent grade and were used as received.

2.2. Physical measurements

IR spectra (KBr discs, 4000–200 cm^{-1}) were recorded on a Jasco FTIR model 420 spectrophotometer. Microanalyses (C, H and N) were done with a Perkin–Elmer 2400 CHNS/O elemental analyzer. The diffuse reflectance spectrum was run at room temperature on a Jasco UV–Vis–NIR V-570 spectrophotometer in the 200–1000 nm range. Magnetic measurements on powdered samples were performed in the temperature range 2–300 K using a Quantum Design MPMS-7 SQUID magnetometer in a magnetic field of 0.1 T. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal tables).

2.3. Preparation of the complexes

2.3.1. $[Cd_3(tren)_2(NCS)_6]_n$ (1)

An aqueous solution (5 cm^3) of NH_4NCS (0.456 g, 6 mmol) was added dropwise to $Cd(NO_3)_2\cdot 4H_2O$ (0.308 g, 1 mmol) in the same solvent (5 cm^3) in a container. A solution (5 cm^3) of $Cd(NO_3)_2\cdot 4H_2O$ (0.616 g, 2 mmol) in water was added to an aqueous (5 cm^3) solution of tren (0.252 g, 2 mmol). These two solutions were mixed slowly to result in a colourless solution which was filtered through a fine glass frit. Well-formed faint yellow single crystals of **1** appeared on allowing the

resulting solution to evaporate slowly at room temperature. Yield: 0.024 g (75%) based on cadmium. *Anal.* Calc. for $C_{18}H_{36}N_{14}S_6Cd_3$ (978.26) (**1**): C, 27.92; H, 3.04; N 30.21. Found: C, 27.77; H, 3.07; N, 30.43%. IR (KBr)/cm^{-1}: ν(CN) 2108, 2089, 2068; ν(N–H) 3327, 3275. Λ_M (DMF, ohm^{-1} cm^2 mol^{-1}): 5. UV–Vis (λ, nm): 275.

2.3.2. $[Ni_2Cd(tren)_2(NCS)_6]_n$ (2)

This is prepared similarly as in **1**. To a solution (10 cm^3) of NH_4NCS (0.456 g, 6 mmol) and $Cd(NO_3)_2\cdot 4H_2O$ (0.308 g, 1 mmol), a mixture of $Ni(NO_3)_2\cdot 6H_2O$ (0.594 g, 2 mmol) and tren (0.252 g, 2 mmol) in water (10 cm^3) was added dropwise. The final blue violet solution was filtered through a fine glass frit. Violet single crystals of **2** were isolated on evaporation of this solution at room temperature. Yield: 0.027 g (75%) based on cadmium. *Anal.* Calc. for $C_{18}H_{36}N_{14}S_6Ni_2Cd$ (870.79) (**2**): C, 24.92; H, 3.01; N, 32.21. Found: C, 24.77; H, 3.00; N, 32.49%. IR (KBr)/cm^{-1}: ν(CN) 2138, 2121, 2066; ν(N–H), 3329, 3278. Λ_M (DMF, ohm^{-1} cm^2 mol^{-1}): 8. UV–Vis (λ, nm): 359, 563, 890.

2.4. X-ray crystallographic study

Suitable single crystals of the title complexes **1** and **2** for X-ray analyses were mounted on diffractometers equipped with a graphite monochromated Mo Kα(λ = 0.71073 Å) radiation source. The intensity data were corrected for Lorentz and polarization effects and an empirical absorption correction was also employed using the SAINT program [44]. A summary of the crystallographic data and structure refinement parameters is given in Table 1. The structure was solved by the Patterson method using SHELXS-97 [45] followed by Fourier and difference Fourier synthesis. Full-matrix least-squares refinements on F^2 were carried out using SHELXL-97 [46] with anisotropic displacement parameters for all non-hydrogen atoms. The hydrogen atoms were fixed geometrically and refined using a riding model. In the final difference Fourier map the residual maxima and minima were 0.516 and −1.197 (**1**) and −0.425 and 5.096 (**2**) e Å^{-3}. The maximum residual density 5.096 e Å^{-3} of **2** is 1.114 Å away from Ni1 and so it is not possible for any other type of heavy atom or molecule to be present there and this does not create any problem in structure solution. All calculations were carried out using SHELXL-97, ORTEP-3 [47] and PLATON-99 [48] programs.

3. Results and discussion

3.1. Synthesis and formulation

Homonuclear $[Cd_3(tren)_2(NCS)_6]_n$ (**1**) and heteronuclear $[Ni_2Cd(tren)_2(NCS)_6]_n$ (**2**) polymers were synthesized by the reaction of $[M(tren)(S)_2]^{2+}$ (M = Cd in **1**, Ni in **2**; S = H_2O) with $[Cd(NCS)_{6-n}(SCN)_n]^{4-}$ (n = 0–6) at room temperature (298 K). The molecular ion, $[Cd(NCS)_{6-n}(SCN)_n]^{4-}$, was generated in solution by the addition of six moles of ammonium thiocyanate to

one mole of cadmium(II) nitrate tetrahydrate in water. The complementary units $[Cd(tren)(S)_2]^{2+}$ and $[Ni(tren)(S)_2]^{2+}$ were prepared by dropwise addition of two moles of tren to a two molar cadmium(II) nitrate tetrahydrate solution in water and another two moles of tren to a two molar nickel(II) nitrate hexahydrate in separate containers. **1/2** resulted through union of *cis*-$[Cd(NCS)_2(SCN)_4]^{4-}$/*trans*-$[Cd(NCS)_2(SCN)_4]^{4-}$ and *cis*-$[Cd(tren)(S)_2]^{2+}$/*cis*-$[Ni(tren)(S)_2]^{2+}$ in a 1:2 ratio of these building blocks. The details of the sequential reactions are summarized in Scheme 1.

The principle involved is the union of two complementary units viz. $[Cd(NCS)_{6-n}(SCN)_n]^{4-}$, a molecular ion with multiconnectors behaving as potential donors and the $[M(tren)(OH_2)_2]^{2+}$, disolvento species with two labile reaction sites acting as potential acceptors. Use of the tetradentate tripodal amine, tren in $[M(tren)(OH_2)_2]^{2+}$ in conjunction with cadmium(II) or nickel(II) generates hexacoordinated metal cores facilitating polymers. The displacement of the weakly bound solvent molecules from the solvento complexes in $[M(tren)(OH_2)_2]^{2+}$ by the putative pseudohalide bridging unit in $[Cd(NCS)_{6-n}(SCN)_n]^{4-}$ triggers such multinuclear homomer and heteromer formation. The mole ratios are adjusted so as to have neutral homo- and heteropolymers, avoiding counter ions which might inter alia disrupt the solid state packing due to additional cation–anion interactions that would be difficult to control [49].

The preparation of homonuclear **1** and heteronuclear **2** were also achieved in good yield by single-pot [50,51] reactions using stoichiometric amounts [3:2:6 molar ratio of $Cd(NO_3)_2\cdot 4H_2O$, tren and NH_4NCS for **1** and 1:2:2:6 molar ratio of $Cd(NO_3)_2\cdot 4H_2O$, $Ni(NO_3)_2\cdot 6H_2O$, tren and NH_4NCS for **2**] of the individual metal ion template, organic blocker and the pseudohalide bridge/terminal. It is worth noting that an aqueous solution of a 1:2:2:6 molar ratio of $Ni(NO_3)_2\cdot 6H_2O$, $Cd(NO_3)_2\cdot 4H_2O$, tren and NH_4NCS to generate complementary units, $[Ni(NCS)_6]^{4-}$ and $[Cd(tren)(OH_2)_2]^{2+}$ and thereby to isolate a heteropolymer of the type $[Ni_2Cd(tren)_2(NCS)_6]_n$ also resulted in **2** in low yield, reflecting its special stability. This shows that molecular scrambling occurs and the result is the formation of $[Ni(tren)(OH_2)_2]^{2+}$ and $[Cd(NCS)_6]^{4-}$, which accounts for the low yield of **2**.

The complexes were characterized using microanalytical, spectroscopic, magnetic and some physicochemical properties. They are stable over long periods of time in powdery or crystalline states and are insoluble in water and other common organic solvents. However they are soluble in warm dimethylformamide and dimethylsulfoxide. In dimethylformamide they behave as non-electrolytes as evident from their low conductivity values [52]. In IR spectra three well resolved ν_{CN} bands (at 2108, 2089, 2068 cm^{-1} in **1** and at 2138, 2121, 2066 cm^{-1} in **2**) are observed indicating the existence of different force constants of the thiocyanato groups [53] in the crystal lattice. The band corresponding to the ν_{CS} stretching frequency appears at 765 cm^{-1} in **1** and 759 cm^{-1} in **2**. Bands belonging to the deformation frequency δ_{NCS} are found as doublets (at 468, 472 cm^{-1} for **1** and 450, 465 cm^{-1} for **2**). The ν_{NH} stretching frequency of the NH_2 group is observable at 3327 and 3275 cm^{-1} in **1** and at 3329 and 3278 cm^{-1} in **2**. Several weak bands in the range 2980–2807 cm^{-1} assignable to the aliphatic C–H stretching vibration are routinely observed.

The electronic spectrum of **2** in the solid state (Nujol mull) as well as in DMF solution show bands at λ_{max} values of 563 and 359 nm, assignable to spin allowed transitions $^3T_{1g} \leftarrow {}^3A_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$ respectively, typical of octahedral nickel(II). The close similarity in d–d maxima reflects similar gross structure and electronic structure in the solid state and in solution. The shoulder at around 890 nm originates from the spin-forbidden $^1E_g \leftarrow {}^3A_{2g}$ transition, frequently observed in Ni(II) octahedral complexes [54]. **1** exhibits a strong band at 275 nm presumably [55] belonging to a ligand based charge transfer.

$$n\,Cd(NO_3)_2.4H_2O + 6n\,NH_4NCS \longrightarrow n\,(NH_4)_4[Cd(NCS)_6] + 2n\,NH_4NO_3 + 4n\,H_2O \quad \ldots (1)$$

$$2n\,Cd(NO_3)_2.4H_2O + 2n\,tren \longrightarrow 2n\,[Cd(tren)(OH_2)_2](NO_3)_2 + 4n\,H_2O \quad \ldots (2)$$

$$2n\,Ni(NO_3)_2.6H_2O + 2n\,tren \longrightarrow 2n\,[Ni(tren)(OH_2)_2](NO_3)_2 + 8n\,H_2O \quad \ldots (3)$$

$$n\,(NH_4)_4[Cd(NCS)_6] + 2n\,[Cd(tren)(OH_2)_2](NO_3)_2 \longrightarrow [Cd_3(tren)_2(NCS)_6]_n + 4n\,NH_4NO_3 + 4n\,H_2O \quad \ldots (4)$$

$$n\,(NH_4)_4[Cd(NCS)_6] + 2n\,[Ni(tren)(OH_2)_2](NO_3)_2 \longrightarrow [Ni_2Cd(tren)_2(NCS)_6]_n + 4n\,NH_4NO_3 + 4n\,H_2O \quad \ldots (5)$$

Scheme 1.

3.2. Structure description

3.2.1. $[Cd_3(tren)_2(NCS)_6]_n$ (1)

X-ray crystallography was performed for the exact definition of the coordination sphere as well as the long range structure. A perspective view of the asymmetric unit with the atom numbering scheme of **1** is shown in Fig. 1. The polymeric network of the complex with alternating CdN_6 and CdN_2S_4 chromophores are shown in Fig. 2 and its projection onto the *b*-axis with hydrogen bonding is shown in Fig. 3. Selected bond lengths and angles with their estimated standard deviations are listed in Table 2.

In the structure, each *cis*-$[Cd(NCS)_2(SCN)_4]^{4-}$ is connected to four $[Cd(tren)]^{2+}$ units through 1,3-thiocyanate bridges in the *ab*-plane, leading to a two-dimensional (2D) sheet with two alternating environmentally different octahedral cadmium(II) coordination spheres. The geometry around the 4d ion, Cd(1), is a distorted octahedron with a relatively soft *cis*-CdN_2S_4 matrix produced from four S atoms of four different bridging NCS^- ligands and two N atoms of the two terminal pseudohalides. Cd(2) of $[Cd(tren)]^{2+}$ is also in a distorted octahedral environment with a hard CdN_6 chromophore produced through attachment of four N atoms of the tripodal amine and two N atoms of two bridging NCS ligands in a *cis* alignment (Fig. 1). The sequence in one branch is represented as –Cd(1)–S(1)–C(1)–N(1)–Cd(2)–N(2*)–C(2*)–S(2*)–Cd(1*)– (Fig. 2).

The equatorial plane of Cd(1) consists of three of the four sulfur atoms [S(1*), S(2), S(2*); * indicates a symmetry operation $-x$, y, $1/2 - z$] of the bridging thiocyanates and one (N3*) of the two terminal pseudohalide nitrogens. Axial positions are occupied by S(1) and N(3). Cd(1)–S bond lengths lie within the range 2.6666(7)–2.8819(8) Å whereas Cd(1)–N bond lengths

Symmetry code: * $-x$, y, $1/2 - z$.

lie within the range 2.226(3)–2.242(3) Å. The range of *cisoid* angles [78.40(2)–98.00(2)°] and that of the *transoid* angles [163.21(3)–168.35(9)°] reflect the deviation of the chromophore from an ideal octahedron. Two pendant pseudohalide arms around Cd(1) are mutually in a *cis* orientation [N(3)–Cd(1)–N(3*), 98.00(2)°]. Four bridging thiocyanate nitrogens [N(1), N(1*), N(2), N(2*)] of $[Cd(NCS)_6]^{4-}$ coordinate to the adjacent $[Cd(tren)]^{2+}$ forming a 2D sheet. Three amine nitrogens [N(4), N(6), N(7)] of the tripodal amine and a bridging thiocyanate nitrogen [N(2)] constitute the equatorial plane of Cd(2) in each $[Cd(tren)]^{2+}$. The tertiary nitrogen [N(5)] of the blocker and another bridging nitrogen [N(1)] occupy the axial sites. Cd(2)–N bond lengths of this unit lie within a close range [2.227(3)–2.441(2) Å] and are similar to those of Cd(1)–N. Bond angles around Cd(2) are indicative of large deviation from ideality [*cisoid* angles: 73.94(10)–111.02(10)°; *transoid* angles: 124.23(9)–165.44(10)°]. The intrachain Cd...Cd separation is 6.006(6) Å for Cd(1)...Cd(2) and 11.7359(10) Å for Cd(2)...Cd(2*) whereas the Cd...Cd separation between two sheets is 9.767 Å.

Three distinct hydrogen bonds (Table 3) involving three tripodal amine N atoms [N(4), N(6) and N(7)] and bridging S(1) atoms are present in this polymer leading to a superstructure; of the three, two are intrachain N–H...N–H-bonds [H(7B)···N(2) 2.360 Å, ∠N(7)–H(7B)···N(2) 147.6°; H(4B)···N(2) 2.493 Å, ∠N(4)–H(4B)···N(2) 120.8°] and the other is a N–H...S [40] interchain bonding [H(6B)···S(1) 2.713 Å, ∠N(6)–H(6B)···S(1) 164.7°]. The latter arises due to the specific orientation of the tripodal ligand of one sheet towards the bound thiocyanate sulfur in the molecular ion of the adjacent sheet. This type of non-covalent interaction throughout the lattice is responsible for the conformation and stability of supramolecular framework. The 2D sheets are stacked along the *c*-axis by such multiple interactions, forming a 3D network (Fig. 3).

3.2.2. $[Ni_2Cd(tren)_2(NCS)_6]_n$ (2)

The polymer **2** bears a fair resemblance to **1** in the asymmetric unit. An ORTEP diagram of this unit, the two-dimensional (2D) sheet found in the covalently bonded polymer and the arrangement of these sheets perpendicular to the *a*-axis are respectively shown in Figs. 4–6. Selected bond distances and bond angles are set in Table 4. The two different metal centres [diamagnetic 4d ion, cadmium(II) and paramagnetic 3d ion, nickel(II)] with varied coordination environments are propagated in an alternate fashion bridged by thiocyanates in an end-to-end motif. Each *trans*-$[Cd(NCS)_2(SCN)_4]^{4-}$ is connected to four $[Ni(tren)]^{2+}$ units to yield the heteropolymeric network in contrast to **1** where a homopolymer is the result. The geometry around Cd(1) is a distorted octahedron with a *trans*-CdN_2S_4 chromophore instead of a *cis*-CdN_2S_4 chromophore, and it lies on an inversion centre. Ni(1) has a hard NiN_6 chromophore in a distorted octahedral environment. Cd(1) is attached to four sulfur atoms [S(2), S(2^c), S(3), S(3^c); ^{c} indicates a symmetry operation $-x+1/2, -y+1/2, -z$] of the bridging thiocyanates in

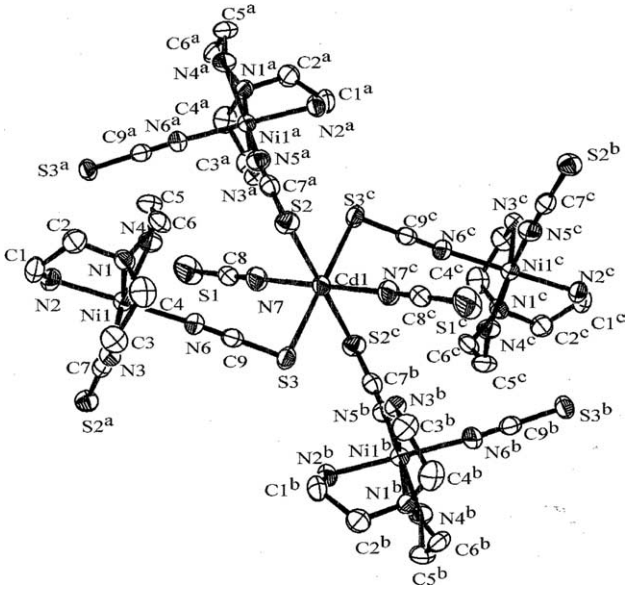

Fig. 4. ORTEP diagram of **2** with the atom numbering scheme. Symmetry code: $^a -x+1/2,\ y+1/2,\ -z+1/2$; $^b x,\ -y,\ z+1/2$; $^c -x+1/2,\ -y+1/2,\ -z$.

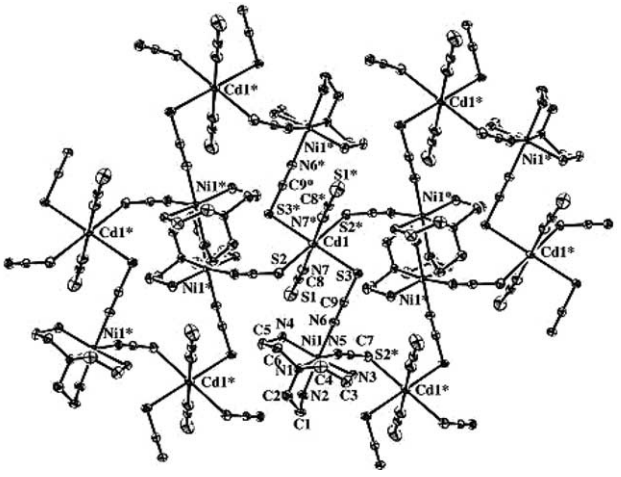

Fig. 5. Perspective view of the 2D sheet in **2**. Symmetry code: $^a -x+1/2, y+1/2, -z+1/2$; $^b x, -y, z+1/2$; $^c -x+1/2, -y+1/2, -z$.

the equatorial plane and two nitrogen atoms [N(7), N(7^c)] of the terminal pseudohalides in axial positions (Fig. 4). The sequence of the arrangement of the atoms in polymeric **2** is –Cd(1)–S(3)–C(9)–N(6)–Ni(1)–N(5)–C(7)–S(2^c)–Cd(1^c)– (Fig. 5). Ranges of Cd(1)–S [2.7587(16)–2.7621(14) Å] and Cd(1)–N [2.254(5) Å] bond lengths are similar to those of **1**. *Transoid* angles around Cd(1) are exactly 180.00° but *cisoid* angles are of variable magnitude [87.21(14)–92.79(14)°], but are close to 90.00°. The two pendant pseudohalide arms around Cd(1) are mutually in a *trans* orientation with a N(7)–Cd(1)–N(7^c) angle of 180.0(3)°. The environment around Ni(1) is comparable to Cd(2) of **1** with three amine nitrogens [N(2), N(4), N(6)] of the tripodal amine and a bridging thiocyanate nitrogen [N(3)] constituting the equatorial plane. The remaining bridging nitrogen, N(1) and tertiary nitrogen [N(5)] of the blocker occupy axial positions of the paramagnetic 3d metal ion. Ni(1)–N bond lengths lie within a close range [2.046(5)–2.122(4) Å]. Bond angles around Ni(1) are indicative of deviation from ideality [*cisoid* angles: 81.68(17)–96.02(18)°; *transoid* angles: 161.53(18)–176.9(2)°]. The Cd...Ni separation is 5.6837(17) Å whereas the shortest Cd...Cd and Ni...Ni distances are 9.619(3) and 5.7705(18) Å respectively within the discrete sheet. The N atoms of the tripodal amine in one sheet are housed into the spaces (holes) below cadmium centres of another adjacent sheet and N–H...S type of hydrogen bonding as is present in **1** is inhibited due to such an orientation (Fig. 6).

3.3. Magnetic behaviour of $[Ni_2Cd(tren)_2(NCS)_6]_n$ (2)

The magnetic behaviour in the form of $\chi_m T$ versus T and χ_m versus T (inset) plots indicates (Fig. 7) that the $\chi_m T$ value (1.188 $cm^3\,mol^{-1}\,K$ at 300 K) remains constant down to 10 K and then decreases to 0.181 $cm^3\,mol^{-1}\,K$ at 2 K. The global feature is characteristic of a Curie-law typical for a magnetically isolated nickel(II) ion ($S=1$ with $g=2.16$–2.18) with a very

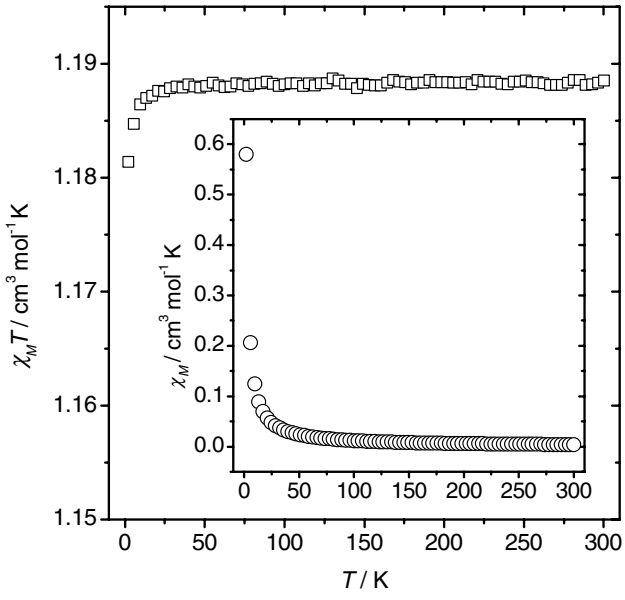

Fig. 7. Plots of (a) $\chi_m T$ vs. T and (b) χ_m vs. T.

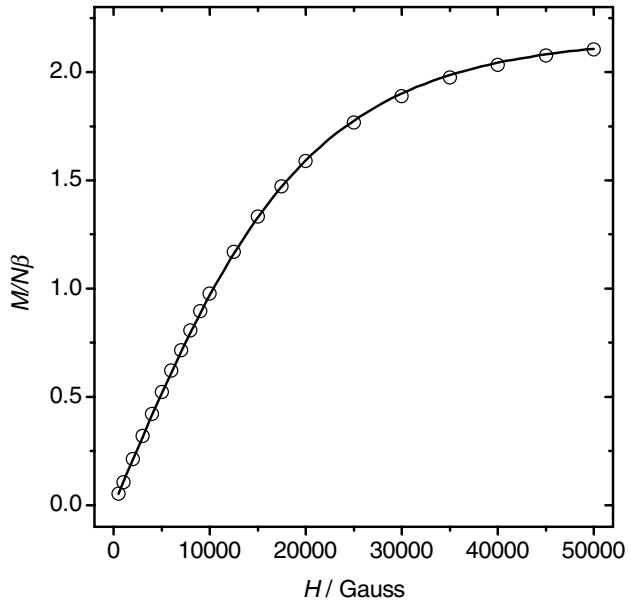

Fig. 8. Field dependence magnetization plot for **2**.

small zero-field splitting (D parameter typical for an $S = 1$ system) or a very weak antiferromagnetic interaction ($J < 0.01\ cm^{-1}$). The χ_M curve starts at $0.004\ cm^3\ mol^{-1}$ at room temperature and increases in a uniform way to $0.58\ cm^3\ mol^{-1}$ at 2 K. The reduced molar magnetization ($M/N\beta$) per nickel(II) entity tends to two electrons (Fig. 8). Assuming an isolated nickel(II) system, the fit to the Brillouin formula gives $g = 2.17$ with $R = 2.04 \times 10^{-5}$ (agreement factor, R, being defined as $\chi_i[(\chi_m T)_{obs} - (\chi_m T)_{calc}]^2/\chi_i[(\chi_m T)_{obs}]^2$). The lack of coupling among paramagnetic centres linked by complex species of diamagnetic ions is known for $[M(CN)_n]^{z-}$ systems [M = Ni(II), Co(III), etc.] with either weak ferro- or antiferromagnetic coupling [25,28].

4. Conclusion

1 and **2** are good examples of inorganic organic hybrid polymers where the ambidentate intermediary thiocyanate is the dynamic molecular ion $[Cd(NCS)_6]^{4-}$ bridges in different geometries (*cis*/*trans*) of the formulation $[Cd(NCS)_2(SCN)_4]^{4-}$. The versatility of the pseudohalide connectors in the cadmium(II) bound state is revealed through coordination as terminal and end-to-end bridging motifs. The polymers show significant differences in molecular and crystalline architectures. The fundamental difference between **1** and **2** is the orientations of the tripodal amine in the crystals that result in hydrogen bonded superstructures in **1** and inhibits such non-covalent forces between adjacent sheets in **2**. The latter represents the first report of a molecular ion bridged species involving 3d and 4d transition metal ions. The variable temperature magnetic study of **2** show weak antiferromagnetic interactions hindered by the diamagnetic molecular ion. We are currently investigating how to extend such work on paramagnetic molecular ions $[M(X)_6]^{z-}$ ($M = Fe^{III}$, Mn^{II}, Co^{II}, etc.) containing pseudohalides (X^-) like N_3^-, NCO^- and $NCSe^-$ with other paramagnetic complementary units to create extended paramagnetic homo-/heteropolymeric networks resulting in new supramolecular magnetic materials, particularly nanomagnets.

5. Supplementary data

Crystallographic data for the structural analyses have been deposited with the Cambridge Crystallographic Data Center, CCDC Nos. 200290 (**1**) and 200289 (**2**). Copies of this information can be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 IEZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or www.ccdc.cam.ac.uk).

Abstract

Reactions of $Et_3Al \cdot Et_2O$ with bidentate Schiff base ligands in 1:1 and 1:2 molar ratios in diethyl ether yield $Et_2Al\{O(C_6H_4)CH{=}NC_6H_5\}$, $EtAl\{O(C_6H_4)CH{=}NC_6H_5\}_2$, $Et_2Al\{OC(R){=}CHC(R^1){=}NC_6H_5\}$ and $EtAl\{OC(R){=}CHC(R^1){=}NC_6H_5\}_2$ (where $R = R^1{=}CH_3$, C_6H_5; $R = CH_3$, $R^1 = C_6H_5$). The reaction of Et_2AlBr with $HO(C_6H_4)CH{=}NC_6H_5$ in a 1:4 molar ratio in diethyl ether yields $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)CH{=}NC_6H_5\}_2]Br$. All the above complexes are soluble in common organic solvents and have been characterized by elemental analysis, as well as IR and multinuclear NMR (^1H, ^{13}C and ^{27}Al) spectroscopy. Molecular weight measurements in refluxing benzene show the monomeric nature of the monoethyl complexes and dimeric nature of the diethyl complexes, which is further supported from the FAB mass spectra of three representative compounds, $Et_2Al\{O(C_6H_4)CH{=}NC_6H_5\}$, $Et_2Al\{OC(CH_3){=}CHC(CH_3){=}NC_6H_5\}$ and $EtAl\{O(C_6H_4)CH{=}NC_6H_5\}_2$. ^{27}Al NMR spectra show that in both types of complex, the aluminium is pentacoordinated. The crystal structure of $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)CH{=}NC_6H_5\}_2]Br$ displays a unique octahedral symmetry with the ligand bonded in two different patterns to the aluminium(III) center.

Keywords: Aluminium complexes; Schiff base ligands; Salicylaldiminato-N,O chelates; Salicylaldimine complexes

1. Introduction

Aluminium alkyls as well as their heteroleptic derivatives are important industrial chemicals. Triethylaluminium, for example, is an activator in the Z–N polymerization of olefins [1], while methylaluminoxanes (MAO) are used as co-catalysts for the homogeneous polymerization of olefins [2,3].

In Schiff base complexes of aluminium, the coordination environment at the metal center can be modified by attaching different substituents to the ligand, providing useful steric and electronic properties [4] essential for the fine tuning of structures and reactivity. Therefore, it is not surprising that p-block metal derivatives of Schiff bases have been shown to catalyze a wide variety of reactions [5,6]. For example, aluminium based complexes which are closely related to the compounds reported in this paper have been used as catalysts in the polymerization of ethylene [7] and methacrylate [8,9], as well as the ring opening polymerization of heterocyclic monomers [10].

Furthermore, our choice of target complexes was also based on the fact that the organometallic chemistry of

doi:10.1016/j.poly.2005.07.028

group 13 elements with bidentate salicylideneminate ligands remains relatively poorly investigated. The structurally characterized four coordinated aluminium complexes of this type are only reported with sterically encumbered ligands [11,12]. Recently, structural investigations of complexes of aluminium and indium with Schiff bases have been investigated [13].

In our recent publications [14–18], it has been shown that binuclear metallo-organic complexes with bidentate ligands usually adopt unsymmetrical structures containing aluminium atoms with the coordination numbers four and six, rather than a symmetric five coordinated structure. More recently, we have also reported the five coordinate heteroleptic metallo-organic complex $Al[\{O(C_6H_4)CH{=}NC_6H_5\}_2Al\{ON{=}C(CH_3)C_4H_3S\text{-}2\}]$ [19].

In a continuation of our systematic studies, we report here the synthesis and structure elucidation of organoaluminium(III) complexes with Schiff bases and the crystal structure of a unique hexacoordinated aluminium(III) complex $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)CH{=}NC_6H_5\}_2]Br$.

2. Experimental

All the complexes described in the present investigation were manipulated in a vacuum line or in a purified argon atmosphere. The solvents and reagents were purified by conventional techniques. The $Et_3Al \cdot Et_2O$ and Et_2AlBr were synthesized and purified according to the literature methods [20]. The Schiff base ligands were prepared by condensing salicylaldehyde, acetylacetone, benzylacetone and dibenzoylmethane with the appropriate aniline and distilled prior to use. Aluminium was estimated gravimetrically as the oxinate [21] and bromide was estimated by Volhard's method [21]. Microanalyses were carried out on a Perkin–Elmer C, H, N & S II series 2400 analyzer. The IR spectra were recorded as Nujol mulls on a Nicolet Magna-550 spectrometer in the range 4000–400 cm^{-1}. ^1H, ^{13}C and ^{27}Al NMR spectra were recorded in 5 mm NMR tubes as freshly prepared $CDCl_3$ solutions on a Bruker DPX-300 spectrometer operating at 300, 75.5 and 111.9 MHz, respectively. Spectra were referenced with the internal chloroform peak (*7.26 for ^1H and 77.0 for ^{13}C). Molecular weight measurements in anhydrous benzene were carried out by the elevation in boiling point method using Beckmanns Thermometer fitted in a glass assembly. The instrument was calibrated using samples of known molecular weight such as naphthalene/benzophenone/benzil in anhydrous benzene ($M = 1000\ K_b w/\Delta T_b W$, where M is the molecular weight, w is the weight of solute in g, K_b is the molar elevation constant, W is the weight of solvents in g, ΔT_b is the elevation in boiling point).

2.1. Preparation of $Et_2Al\{O(C_6H_4)CH{=}NC_6H_5\}$ (1)

A solution of $Et_3Al \cdot Et_2O$ (1.49 g, 7.91 mmol) in 20 ml of anhydrous diethyl ether was slowly added to an etheral solution of $HO(C_6H_4)CH{=}NC_6H_5$ (1.57 g, 7.95 mmol) under an argon atmosphere and the reaction mixture was stirred at room temperature for 4h. The solvents were evaporated under vaccum and the product was washed (2×10 ml) with *n*-hexane. The compound was dried under vaccum to give a yellow solid (Yield 97%), which was recrystallized from a mixture of dichloromethane and *n*-hexane (7:1).

The diethylaluminium(III) complexes **3**, **5** and **7** were prepared using a similar route. Their synthetic details and analytical data are summarized in Table 1.

2.2. Preparation of $EtAl\{O(C_6H_4)CH{=}NC_6H_5\}_2$ (2)

An ethereal solution of $Et_3Al \cdot Et_2O$ (1.29 g, 6.85 mmol) was gradually added to an ethereal solution of $HO(C_6H_4)CH{=}NC_6H_5$ (2.72 g, 13.78 mmol) under an argon atmosphere. The reaction mixture was stirred at room temperature for 4 h. After removal of the solvent under reduced pressure the product obtained was washed (2×10 ml) with *n*-hexane and dried in vacuum to afford a yellow solid (Yield 96%), which was recrystallized from a mixture of dichloromethane and *n*-hexane (7:1).

The monoethylaluminium(III) complexes **4**, **6** and **8** were prepared using a similar route. Their synthetic details and analytical data are also summarized in Table 1.

2.3. Preparation of $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)\text{-}CH{=}NC_6H_5\}_2]Br$ (9)

A solution of Et_2AlBr (0.74 g, 4.48 mmol) in 20 ml of anhydrous diethyl ether was slowly added to an ethereal solution of $HO(C_6H_4)CH{=}NC_6H_5$ (3.55 g, 17.96 mmol) under an argon atmosphere and the reaction mixture was stirred at room temperature for 4 h. The solvents were evaporated under vacuum and dried to give a yellow coloured paste, which was washed (2×10 ml) with petroleum ether to give a yellow solid (89%). The solid product obtained was recrystallized from a mixture of dichloromethane and *n*-hexane (7:1). After several hours, shiny yellow crystals were obtained. *Anal.* Calc.: Al, 3.02; N, 6.27; Br, 8.94. Found: Al, 3.00; N, 6.24; Br, 8.90% (see Table 2).

2.4. X-ray diffraction analysis

Single crystals of **9** suitable for X-ray diffraction analysis were obtained by covering a solution of **9** in CH_2Cl_2 with a layer of *n*-hexane. A pale yellow, needle shape crystal of $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)\text{-}$

$CH{=}NC_6H_5\}_2$]Br was mounted on a glass fiber. The data collection and cell refinement gave cell constants corresponding to a monoclinic cell whose dimensions are given in Table 6 along with other experimental and refinement parameters. The structure was solved by direct methods using SIR97 [22], and refined with SHELX-97 [23]. The graphical representation of the molecular structure of **9** was generated with ORTEP [24].

3. Results and discussion

3.1. Syntheses

All the above reactions were carried out under a strictly anhydrous and inert atmosphere. Reactions of $Et_3Al{\cdot}Et_2O$ with the corresponding Schiff base ligands in 1:1 and 1:2 molar ratios in diethyl ether afforded products of the types $Et_2Al\{O(C_6H_4)CH{=}NC_6H_5\}$ (**1**), $EtAl\{O(C_6H_4)CH{=}NC_6H_5\}_2$ (**2**), $Et_2Al\{OC(R){=}CHC(R^1){=}NC_6H_5\}$(**3**, **5**, **7**) and $EtAl\{OC(R){=}CHC(R^1){=}NC_6H_5\}_2$ (**4**, **6**, **8**) ($R = R^1 = CH_3$, C_6H_5; $R = CH_3$, $R^1 = C_6H_5$), whereas the reaction of Et_2AlBr with $HO(C_6H_4)CH{=}NC_6H_5$ in a 1:4 molar ratio in diethyl ether afforded the product $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)CH{=}NC_6H_5\}_2]Br$ (**9**). The general reactions may be illustrated schematically as:

$$Et_3Al\cdot Et_2O + nLH \xrightarrow[\text{stirring}]{Et_2O} \underset{\mathbf{1\text{–}8}}{Et_{3-n}AlL_n} + nEtH$$

$$LH{=}HO(C_6H_4)CH{=}NC_6H_5; HOC(R){=}CHC(R^1){=}NC_6H_5$$
$$(R = R^1 = CH_3, C_6H_5; R = CH_3, R^1 = C_6H_5; n = 1, 2)$$

$$Et_2AlBr + 4HO(C_6H_4)CH{=}NC_6H_5 \xrightarrow[\text{stirring}]{Et_2O} \underset{\mathbf{9}}{[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)CH{=}NC_6H_5\}_2]Br} + 2EtH$$

All the above complexes are yellow or orange solids or pastes (Table 1) and are soluble in common organic solvents. These compounds were purified by recrystallization from a mixture of dichloromethane and *n*-hexane. Molecular weight measurements indicate the monomeric nature of the monoethyl complexes (**2**, **4**, **6** and **8**) and the dimeric nature of the diethylaluminium(III) complexes (**1**, **3**, **5** and **7**) in refluxing benzene.

3.2. FAB mass spectra

The FAB mass spectra of three representative compounds, $Et_2Al\{O(C_6H_4)CH{=}NC_6H_5\}$ (**1**), $EtAl\{O(C_6H_4)CH{=}NC_6H_5\}_2$ (**2**) and $Et_2Al\{OC(CH_3){=}CHC(CH_3){=}NC_6H_5\}$ (**3**) have been recorded and the characteristic signals for the fragmentation of these compounds are summarized in Table 3.

The FAB mass spectral studies of the representative compounds suggest the monomeric nature of the monoethyl complexes and the dimeric nature of the diethyl complexes. The molecular ion peaks for the dimeric complexes (**1**) and (**3**) appear at the expected positions. However, the FAB mass spectrum of complex (**2**) exhibits signals with higher *m*/*e* than the molecular ion peak, suggesting that the complex is associated in the solid state.

3.3. IR spectra

Tentative assignments of the important IR bands have been made and are summarized in Table 4. Broad stretching vibrations at $\sim$2900 cm^{-1} due to the –OH group of the free Schiff bases (Table 2) disappeared in the IR spectra of the above derivatives, suggesting the deprotonation of the –OH group and formation of Al–O bonds. Formation of Al–O [25,26] bonds is further supported by the appearance of a band of medium to strong intensity in the 684–725 cm^{-1} region.

Table 4
Some relevant IR spectral data of aluminium(III) complexes **1**–**8** (in cm^{-1})

S.No.	Complexes	Schiff base moiety ν(C=N)	ν(Al–C)	ν(Al–O)	ν(Al–N)	ν(Al–O–Al)
1	$Et_2Al\{O(C_6H_4)CH{=}NC_6H_5\}$	1580 s	550 w	725 s	683 s	750 vs
2	$EtAl\{O(C_6H_4)CH{=}NC_6H_5\}_2$	1550 s	550 m	708 m	683 m	
3	$Et_2Al\{OC(CH_3){=}CHC(CH_3){=}NC_6H_5\}$	1583 s	600 m	684 s	634 m	750 vs
4	$EtAl\{OC(CH_3){=}CHC(CH_3){=}NC_6H_5\}_2$	1583 s	550 m	700 s	616 m	
5	$Et_2Al\{OC(CH_3){=}CHC(C_6H_5){=}NC_6H_5\}$	1550 s	600 w	684 m	634 w	750 vs
6	$EtAl\{OC(CH_3){=}CHC(C_6H_5){=}NC_6H_5\}_2$	1540 s	600 w	700 m	649 w	
7	$Et_2Al\{OC(C_6H_5){=}CHC(C_6H_5){=}NC_6H_5\}$	1550 s	550 m	708 m	616 m	750 vs
8	$EtAl\{OC(C_6H_5){=}CHC(C_6H_5){=}NC_6H_5\}_2$	1566 s	583 m	718 s	633 s	

The shifting of ν(C=N) stretching frequencies to lower wave numbers as compared to the free ligand moieties (Table 2), indicates the coordination of the nitrogen atom of the ligand to aluminium. This was further confirmed by the appearance of a new medium-sized band in the 616–683 cm^{-1} region, which may be assigned to the ν(Al–N) mode [14,16]. The weak to medium absorptions in the 550–600 cm^{-1} region were assigned to ν(Al–C). In the 1:1 complexes, an additional medium-sized band at 750 cm^{-1} was also observed and assigned as ν(Al–O–Al) [15,16].

3.4. ^1H NMR spectra

The important signals in ^1H NMR spectra of these derivatives are summarized in Table 4. A comparison of the spectra of the free Schiff bases (Table 2) with the spectra of the corresponding derivatives (Table 5) shows the absence of –OH signals, indicating deprotonation of the hydroxy group of the Schiff bases and formation of Al–O bonds occurred. This is supported by the significant shift of the methyl, phenyl and CH signals of the ligand moiety. The ^1H NMR spectra of these derivatives exhibit characteristic peaks and peak multiplicities for the Et–Al and ligand protons [27,28], whereby the CH_2 and CH_3 protons of the Et–Al group appear in the δ 0.06–0.19 ppm and δ 1.07–1.58 ppm range, respectively. Other resonances appeared at their expected positions (Table 4).

3.5. ^{13}C NMR spectra

The mode of bonding suggested above has also been confirmed by the ^{13}C NMR spectral data (Table 5). In the ^{13}C NMR spectra of the complexes, the CH_2 and CH_3 carbon signals of the EtAl group appear in the ranges δ 0.92–1.09 ppm and δ 9.30–20.30 ppm, respectively. The azomethine (C=N) carbon is deshielded on complexation and a signal appears in the δ 160.0–176.5 ppm range. This deshielding provides further support for the coordination of the ligand through the azomethine nitrogen to the aluminium atom (see Fig. 1).

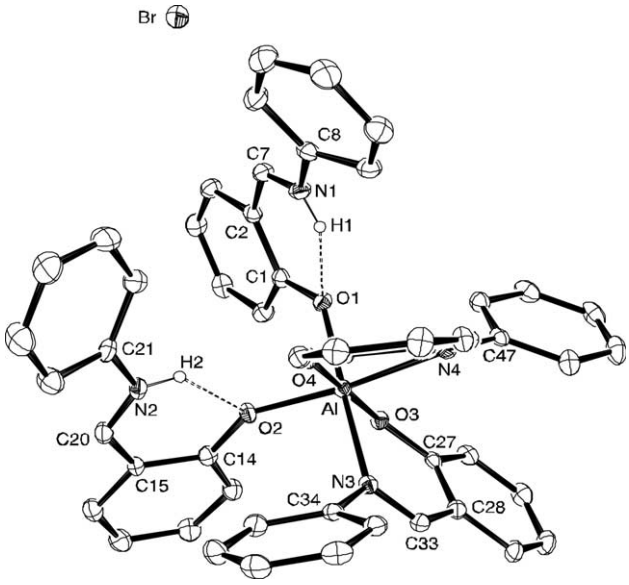

Fig. 1. Molecular structure of $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)CH{=}NC_6H_5\}_2]Br$ (**9**).

3.6. ^{27}Al NMR spectra

^{27}Al NMR spectra of the complexes **1**–**8** exhibit a broad signal in the region δ 68.0–71.2 ppm, indicating that the central aluminium atom is pentacoordinated [28–32]. It is interesting to mention here that in contrast

to the above, the crystal structure analysis of the dimethyl corresponding derivative, Me_2AlL, suggests a monomeric nature and tetracoordination around the central aluminium(III) atom in the solid state [13,32]. This difference in behavior appears to be quite unusual and difficult to explain without single crystal X-ray analysis. As mentioned earlier, the molecular weight measurement in boiling benzene suggest a monomeric nature for the complexes of the type $EtAlL_2$ (**2**, **4**, **6** and **8**) but a dimeric nature for Et_2AlL (**1**, **3**, **5** and **7**), this observation gets further support from the FAB mass spectral studies of the three representative compounds (Table 3).

Therefore, on the basis of the above studies the following tentative structures may be proposed (Figs. 2 and 3) see Table 6.

3.7. Molecular structure of $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)\text{-}CH{=}NC_6H_5\}_2]Br$ (9)

The most important bond lengths and angles of **9** are given in Table 7, and its molecular structure is shown in Fig. 1. Octahedrally coordinated by 4 oxygen and 2 nitrogen atoms, the Al(III) center is surrounded by two anionic salicylaldiminato ligands, acting as bidentate N,O-chelates and two O-bound salicylaldimine ligands in *cis*-positions (O1–Al1–O2 = 89.2(1)°). The latter ones coordinate in a *trans*-position to the N atom of the chelate system (O1–Al1–N3 = 175.18(11)° and O2–Al1–N4 = 172.99(11)°). The four Al–O bond lengths vary between 1.81 and 1.89 Å, whereas both Al–N bonds are almost constant (Al1–N3 = 2.107(3) and Al1–N4 = 2.102(3) Å). The distortion of the octahedron at Al1 mainly results from the different angles, e.g., those from the monodentate O1 or O2 to the O or N atoms of the chelates vary between 86.43(11)° (O–Al1–N4) and 96.58(10)° (O2–Al1–O3). It is noteworthy that only three angles are almost 90° (O1–Al1–O2 = 89.20(10)°, O3–Al1–N4 = 89.33(10)° and N3–Al1–N4 = 90.69(10)°), whereas the two angles resulting from the chelating function are somewhat smaller than 90° (O3–Al1–N3 = 88.19(10°) and O4–Al1–N4 = 87.76 (10)°).

Two facts must be emphasized: first, within both monodentate salicylaldiminato-O ligands strong hydrogen bridges exist between the atoms O1 and N1 or O2 and N2. Their lengths are about 2.61 Å, whereby in both

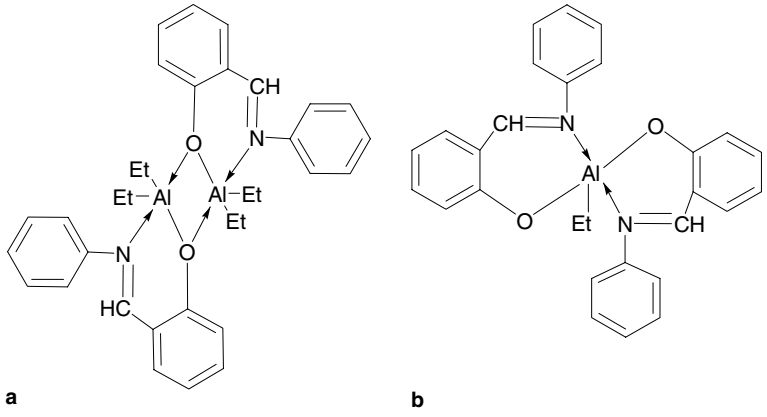

Fig. 2. Proposed structures of $Et_2Al\{O(C_6H_4)CH{=}NC_6H_5\}$ (a) and $EtAl\{O(C_6H_4)CH{=}NC_6H_5\}_2$ (b).

cases the hydrogen atoms come significantly closer to nitrogen (N–H ≈ 0.8 Å) than to oxygen (O···H ≈ 2.0 Å). Again this hydrogen bonding interaction gets weakened on complexation with the central aluminium(III) atom in comparison to the free ligand (O–N: 2.598(8) Å) [33]. Furthermore, in the free state the salicylaldimine molecule is nearly planar. In **9**, however, the two planes of each of the four ligands are distorted to each other as indicated in Table 7 [C_{Ph2}–C_{Ph8} = 23.6(2), C_{Ph18}–C_{Ph21} = 33.4(2), C_{Ph27}–C_{Ph34} = 50.47(18) and C_{Ph40}–C_{Ph47} = 37.95(18)]. The dihedral angles between both planes in the monocoordinated ligands are significantly smaller (C1–C13: 23.6(2)° and C14–C26: 33.4(2)°) than those in the bidentate ligands (C27–C39: 50.47(18)° and C40–C52. 37.95(18)°). The reason may be due to steric hindrance of the two chelating ligands in the *cis*-position.

4. Conclusion

Above studies indicates that in all ethylaluminium(III) (both Et_2AlL and $EtAlL_2$) complexes the central aluminium atom is pentacoordinated, either by inter or intramolecular coordinating interactions. However, the existence of pentacoordination in dimeric Et_2AlL type complexes is in contrast to what was reported for their corresponding dimethyl derivatives (monomeric and tetracoordinated). The crystal structure analysis of compound **9** revealed the presence of two types of ligand moieties in the complex. The dihedral angles between the two rings of all four ligand moieties are

increased on complexation with the aluminium atom. The hydrogen atom of the monodentate ligands are much closer to the nitrogen atom in comparison to the oxygen atom.

5. Supplementary material

The crystal code for $[Al\{O(C_6H_4)CH{=}NC_6H_5\}_2\{HO(C_6H_4)CH{=}NC_6H_5\}_2]Br$ is CCDC No. (gn 147) 258319. Supplementary data are available from the Director, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 336033, e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk on request, quoting the deposition number (gn 147) 258319 Additional material available from the Cambridge Crystallographic Data Centre comprises the final atomic coordinates for all atoms, parameters and a complete listing of bond distances and angles.

Abstract

$MnCl_2 \cdot 4H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, tris(2-aminoethyl)amine (tren) and NH_4NCS in a 1:4:4:10 molar ratio in aqueous solution results a bimetallic compound of the type $[Cu(tren)(NCS)]_4[Mn(NCS)_6]$ (**1**) which has been characterized by microanalytical, physicochemical, spectroscopic and magnetic results. The structure of the complex is determined by X-ray diffraction study. Some pertinent crystal data are: monoclinic, space group $P21/c$, $a = 11.0442(9)$ Å, $b = 14.4923(12)$ Å, $c = 19.2505(16)$ Å, $\beta = 91.95(10)°$, and $Z = 4$. The crystal structure consists of a hydrogen bonded 3D network of $[Cu(tren)(NCS)]^+$ and $[Mn(NCS)_6]^{4-}$ ions. Manganese(II) has an MnN_6 chromophore bound by six N atoms of the terminal thiocyanates. Each copper(II) centre is five coordinated by one N atom of terminal thiocyanate and four N atoms of the tripod ligand. Four copper(II) units are hydrogen bonded to form a hydrogen bonded tetramer. Each manganese(II) in turn is further engaged in hydrogen bonding to four such tetramers leading to the 3D network. Variable-temperature magnetic study shows no significant magnetic interactions among the metal ions connected by hydrogen bonding.

1. Introduction

In recent times great effort has been devoted to the self-assembly of organic and inorganic molecules in the solid state because it extends the range of new solids with desirable physical and chemical properties [1]. The range and variety of self-assembled inorganic structures that can be constructed relies on suitable metal–ligand interactions and hydrogen bondings [2,3] and the various types of polymeric structures include 1D, 2D and 3D networks [4]. Cyanometallates with multiple connectors have been used to prepare such multidimensional polymers and supramers in combination with suitable complementary units containing potential acceptor site(s) [5–7]. We are interested in extending this view with other hexapseudohalogenometallates specially thiocyanate and have reported on the use of the molecular ion $[Cd(NCS)_6]^{4-}$ as multiple connector in combination with suitable complementary unit containing 3d/4d metal ion centres ligated by tris(2-aminoethylamine) (tren) and with potential acceptor sites [8]. Cadmium(II) [9] being a d^{10} ion does not permit any magnetic interaction between the paramagnetic centres. The present work stems from our interest to synthesize coordination compounds with a molecular ion containing paramagnetic metal centre, for example $[Mn(NCS)_6]^{4-}$ to observe its role on

doi:10.1016/j.poly.2005.08.009

magnetic exchange between the paramagnetic [Cu(tren)-$(OH_2)]^{2+}$ complementary units. Copper was specifically chosen [10,11] as it offers a variety of geometries, like tetrahedral, square pyramidal or trigonal-bipyramidal coordination environment of comparable stability and this often leads to significant differences in the metal–ligand geometry and molecular overall shape. This metal ion as well as manganese(II) also finds significant use in bioinorganic chemistry [12] and magnetism [13]. Using $[Mn(NCS)_6]^{4-}$ as building block in conjunction with $[Cu(tren)(OH_2)]^{2+}$, results a bimetallic complex of the type $[Cu(tren)(NCS)]_4[Mn(NCS)_6]$ (**1**) instead of covalently bonded trinuclear entity $[Cu_2Mn(tren)_2(NCS)_6]$ or polymeric $[Cu_2Mn(tren)_2(NCS)_6]_n$. X-ray crystallography study shows the presence of discrete $[Cu(tren)(NCS)]^+$ and $[Mn(NCS)_6]^{4-}$ ions hydrogen bonded to form a 3D supramolecular continuum. Although the magnetic behaviour of this complex is less important yet its structure establishes the fact that non-covalent forces play a vital role in structure determination. The details of synthesis, structure and properties are described below.

2. Experimental

2.1. Materials

High purity tris(2-aminoethyl)amine (Fluka, Germany), copper nitrate trihydrate (E. Merck, India), manganese chloride tetrahydrate (E. Merck, India), and ammonium thiocyanate (E. Merck, India) were purchased from respective concerns and used as received. All other chemicals and solvents were AR grade and were used as received.

2.2. Physical measurements

Elemental analyses (carbon, hydrogen and nitrogen) were performed on a Perkin–Elmer 2400 CHNS/O elemental analyzer. IR spectra (KBr discs, 4000–300 cm^{-1}) were recorded using a Perkin–Elmer model RX 1 spectrometer. Molar conductance was measured using a Systronics conductivity meter where the cell constant was calibrated with 0.01 M KCl solution and dry MeOH was used as solvent. Ground state absorption measurements were made with a Jasco model V-530 UV–Vis spectrophotometer. Magnetic susceptibilities at room temperature were measured with a PAR 155 vibrating sample magnetometer with $Hg[Co(SCN)_4]$ as the reference. Measurements on powdered samples were performed in the temperature range 2–300 K using a Quantum Design MPMS-7 SQUID magnetometer in a magnetic field of 0.1 T. The experimental susceptibilities were corrected for the diamagnetism of the constituent atoms (Pascal Tables).

2.3. Preparation of $[Cu(tren)(NCS)]_4[Mn(NCS)_6]$

The bimetallic complex was synthesised by the reaction of $MnCl_2 \cdot 4H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, tren and NH_4NCS in aqueous solution at room temperature using four different procedures with varied yields. These are described below. Powder X-ray diffraction of the compounds obtained from the different methods have been performed and all the four powder X-ray diffraction (PXRD) data are identical. It indicates that all four compounds are same and are in same phase. X-ray crystallography was performed with the compound obtained from Method D.

2.3.1. Method A

An aqueous solution (5 cm^3) of NH_4NCS (0.457 g, 6 mmol) was added to a solution of $MnCl_2 \cdot 4H_2O$ (0.197 g, 1 mmol) in the same solvent (10 cm^3) with the formation of a colourless solution. In an another container $Cu(NO_3)_2 \cdot 3H_2O$ (0.483 g, 2 mmol) and tren (0.293 g, 2 mmol) were mixed together in water (10 cm^3) producing a bluish green solution. This coloured solution was added dropwise to the above colourless solution. The final bluish green mixture was filtered and left for slow evaporation in air. Bluish green rectangular crystals of **1** suitable for X-ray diffraction were formed after a week. Yield: 0.221 g (30%). *Anal.* Calc. for $C_{17}H_{36}N_{13}S_5Mn_{0.5}Cu_2$ (**1**): C, 27.63; H, 4.90; N, 24.67. Found: C, 27.56; H, 4.81; N, 24.47%. IR (KBr, cm^{-1}): ν(NCS) 2124, 2075, 2048. Λ_M (DMF, $ohm^{-1}\,cm^2\,mol^{-1}$): 139. UV–Vis (λ, nm): 260, 675, 885.

2.3.2. Method B

$MnCl_2 \cdot 4H_2O$ (0.197 g, 1 mmol), $Cu(NO_3)_2 \cdot 3H_2O$ (0.483 g, 2 mmol), tren (0.293 g, 2 mmol) and NH_4NCS (0.457 g, 6 mmol) were mixed in a single container containing 20 cm^3 water, which resulted a bluish green solution. The mixture was filtered and left for slow evaporation in air. Bluish green rectangular crystals were formed after a week. Yield: 0.235 g (32%). *Anal.* Calc. for $C_{17}H_{36}N_{13}S_5Mn_{0.5}Cu_2$ (**1**): C, 27.63; H, 4.90; N, 24.67. Found: C, 27.49; H, 4.79; N, 24.46%. IR (KBr, cm^{-1}): ν(NCS) 2125, 2074, 2048. Λ_M (DMF, $ohm^{-1}\,cm^2\,mol^{-1}$): 141. UV–Vis (λ, nm): 265, 675, 885.

2.3.3. Method C

$Cu(NO_3)_2 \cdot 3H_2O$ (0.242 g, 1 mmol), $MnCl_2 \cdot 4H_2O$ (0.394 g, 2 mmol), tren (0.293 g, 2 mmol) and NH_4NCS (0.457 g, 6 mmol) were mixed in a single container containing 20 cm^3 water, which resulted a bluish green solution. The mixture was filtered and left for slow evaporation. Bluish green crystals were formed after a few days. Yield: 0.294 g (40%). *Anal.* Calc. for $C_{17}H_{36}N_{13}S_5Mn_{0.5}Cu_2$ (**1**): C, 27.63; H, 4.90; N, 24.67. Found: C, 27.49; H, 4.85; N, 24.50%. IR (KBr, cm^{-1}):

ν(NCS) 2124, 2075, 2048. Λ_M (DMF, ohm^{-1} cm^2 mol^{-1}): 140. UV–Vis (λ, nm): 262, 670, 887.

2.3.4. Method D

To an aqueous solution (10 cm^3) of tren (0.966 g, 4 mmol) a solution of $Cu(NO_3)_2 \cdot 3H_2O$ (0.586 g, 4 mmol) in same solvent (5 cm^3) was added slowly in a glass beaker. In an another container, solution (10 cm^3) of NH_4NCS (0.761 g, 10 mmol) was added to $MnCl_2 \cdot 4H_2O$ (0.197 g, 1 mmol) in water (10 cm^3). The former blue solution was added dropwise to the latter colourless solution yielding a bluish green mixture. This was filtered and left for slow evaporation in air. Bluish green rectangular crystals of **1** suitable for X-ray diffraction were formed after two weeks. Yield: 0.626 g (85%). *Anal.* Calc. for $C_{17}H_{36}N_{13}S_5Mn_{0.5}Cu_2$ (**1**): C, 27.63; H, 4.90; N, 24.67. Found: C, 27.52; H, 4.82; N, 24.48%. IR (KBr, cm^{-1}): ν(NCS) 2124, 2075, 2048. Λ_M (DMF, ohm^{-1} cm^2 mol^{-1}): 140. UV–Vis (λ, nm): 262, 675, 883.

2.4. X-ray crystallography

Single crystals were obtained by slow evaporation of an aqueous solution of the reaction mixture. The crystal data and data collection parameters are listed in Table 1. Bluish green crystals suitable for X-ray crystallographic analyses were selected following examination under a microscope. Diffraction data were collected on a Bruker-AXS SMART APEX/CCD diffractometer using Mo Kα radiation, which were corrected for Lorentz and polarization effects and for absorption using the SADABS program [14]. The structure was solved by direct methods and the structure solution and refinement were based on $|F|^2$. All non-hydrogen atoms were refined with anisotropic displacement parameters whereas hydrogen atoms were placed in calculated positions and given isotropic U values 1.2 times that of the atom to which they are bonded. The crystallographic calculations were conducted with the SHELXTL v.6.1 program package [15].

3. Results and discussion

3.1. Synthesis and formulation

The bimetallic complex (**1**) was initially synthesised by reaction of $[Cu(tren)(OH_2)]^{2+}$ with $[Mn(NCS)_6]^{4-}$ at room temperature (298 K) with the aim to obtain heteropolymer $[Cu_2Mn(tren)_2(NCS)_6]_n$ or heterotrinuclear $[Cu_2Mn(tren)_2(NCS)_6]$. However, to our surprise a bimetallic compound of the type $[Cu(tren)(NCS)]_4[Mn(NCS)_6]$ (**1**) was obtained in low yield. The molecular ion, $[Mn(NCS)_6]^{4-}$, was generated in solution by addition of six moles of ammonium thiocyanate to one mole of manganese(II) chloride tetrahydrate in water. The complementary unit $[Cu(tren)(OH_2)]^{2+}$ was prepared by dropwise addition of two moles of tren to a two molar copper(II) nitrate trihydrate solution in water in separate containers. **1** resulted in low yield through union of $[Mn(NCS)_6]^{4-}$ and $[Cu(tren)(OH_2)]^{2+}$ building blocks (Method A; see Section 2.3.1). The details of the sequential reactions are summarised in Eqs. (1)–(3).

$$MnCl_2 \cdot 4H_2O + 6NH_4NCS \rightarrow (NH_4)_4[Mn(NCS)_6] + 2NH_4Cl + 4H_2O \quad (1)$$

$$2Cu(NO_3)_2 \cdot 3H_2O + 2tren \rightarrow 2[Cu(tren)(OH_2)](NO_3)_2 + 2H_2O \quad (2)$$

$$(NH_4)_4[Mn(NCS)_6] + 2[Cu(tren)(OH_2)](NO_3)_2 \rightarrow [Cu(tren)(NCS)]_4[Mn(NCS)_6] \quad (3)$$

The principle involved is the union of two complementary units viz. $[Mn(NCS)_6]^{4-}$, a molecular ion with multiconnectors behaving as potential donor and $[Cu(tren)(OH_2)]^{2+}$, monosolvento species with one labile reaction site acting as potential acceptor. The displacement of the weakly bound solvent molecule from the solvento complex in $[Cu(tren)(OH_2)]^{2+}$ by putative pseudohalide unit in $[Mn(NCS)_6]^{4-}$ triggers such complex. The mole ratios are so adjusted as to have neutral complex avoiding counter ions which might inter alia disrupt the solid state packing due to additional cation–anion interactions that would be difficult to control [16]. The preparation of **1** was also achieved by single-pot

[17] reaction using 1:2:2:6 molar ratio of $MnCl_2 \cdot 4H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, tren and NH_4NCS, respectively (Method B; see Section 2.3.2). It is to note that an aqueous solution of 1:2:2:6 molar ratio of $Cu(NO_3)_2 \cdot 3H_2O$, $MnCl_2 \cdot 4H_2O$, tren and NH_4NCS to generate complementary units, $[Cu(NCS)_6]^{4-}$ and $[Mn(tren)(OH_2)_2]^{2+}$ and thereby to isolate a heterocomplex also resulted **1** in low yield reflecting its special stability (Method C; see Section 2.3.3). However reactant ratio (1:4:4:10) of $MnCl_2 \cdot 4H_2O$, $Cu(NO_3)_2 \cdot 3H_2O$, tren and NH_4NCS corresponding to the product stoichiometry affords (Eq. (4)) **1** in good yield (Method D; see Section 2.3.4).

$$MnCl_2 \cdot 4H_2O + 4Cu(NO_3)_2 \cdot 3H_2O + 4tren + 10NH_4NCS \rightarrow [Cu(tren)(NCS)]_4[Mn(NCS)_6] + 2NH_4Cl + 8NH_4NO_3 + 16H_2O \quad (4)$$

The air-stable moisture-insensitive complex is moderately soluble in methanol, ethanol, acetonitrile, dimethylformamide and dimethylsulfoxide and the solubility increases on warming. However it is insoluble in water but soluble in polar organic solvents which indicates strong hydrogen bonding between the cations and anions. In methanol it shows conductivity value of 140 $ohm^{-1}\,cm^2\,mol^{-1}$ which reflects molecular association of the complex ions [18]. In IR three well resolved peaks are observed at 2124, 2075, 2048 cm^{-1} attributed to the ν(NCS) stretching mode [19]. Although all the pseudohalides are present as terminals but both N- and S- of the thiocyanates are engaged in different types of hydrogen bondings with the amine nitrogens. Presence of multiple bands is in line with different force constants of the thiocyanates. A band corresponding to ν(CS) stretching frequency appears at 769 cm^{-1}. The bands belonging to deformation frequency δ(NCS) are found as doublets at 468 and 472 cm^{-1}. The bimetallic assembly shows bands around 3325–3265 cm^{-1} due to N–H stretching of the NH_2 groups and weak bands in the range 2980–2900 cm^{-1} are assignable to the aliphatic C–H stretching vibration [20]. The complex displays multiple absorption bands and shoulders in the 200–1000 nm range in MeOH solution. A band at 883 nm is assignable to a d–d transition ($d_{x^2-y^2}, d_{xy} \rightarrow d_{z^2}$) of copper(II) moieties in trigonal bipyramidal (tbp) geometry. A higher energy shoulder is observed at 675 nm which is typical of copper(II) complexes with tbp geometry [21]. Absorption at 262 nm may be assigned due to ligand origin. The solid state reflectance spectrum shows a good correspondence to the solution spectrum indicating similar gross geometric and electronic structure in solid state and in solution.

3.2. Structure

$[Cu(tren)(NCS)]_4[Mn(NCS)_6]$ (**1**) exhibits a hydrogen bonded network of the asymmetric unit containing $[Cu(tren)(NCS)]^+$ and $[Mn(NCS)_6]^{4-}$ ions. An ORTEP plot of the asymmetric unit, a view of the supramolecular tetramer formed by four $[Cu(tren)(NCS)]^+$ units and a 3D network formed by N–H···N and N–H···S hydrogen bondings are shown in Figs. 1–3, respectively. Selected interatomic distances and angles are given in Table 2.

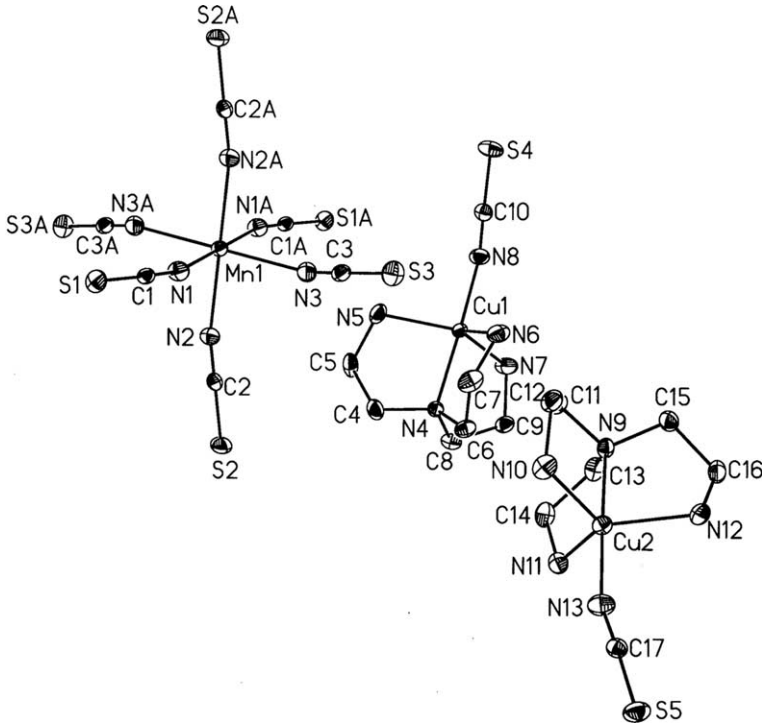

Fig. 1. ORTEP representation of the asymmetric unit in $[Cu(tren)(NCS)]_4[Mn(NCS)_6]$ (**1**).

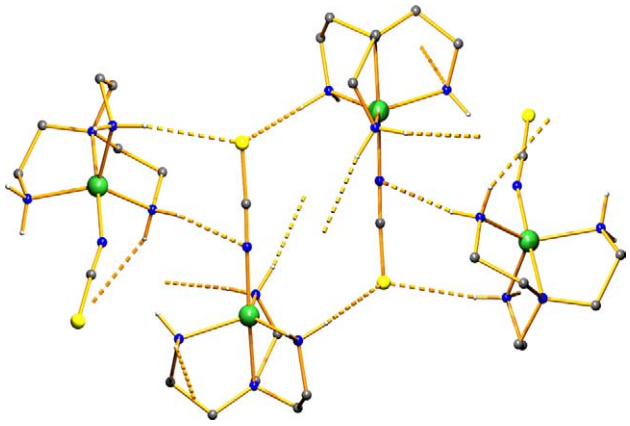

Fig. 2. Intermolecular N–H···S and N–H···N hydrogen bonded supramolecular tetramer formed by four $[Cu(tren)(NCS)]^{+}$ units. The dotted lines indicate N–H···X (X = N/S) hydrogen bonding.

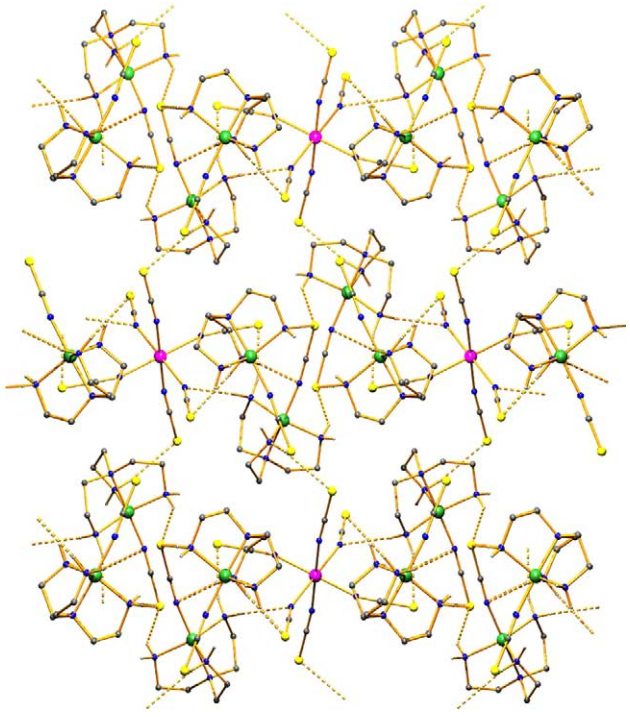

Fig. 3. 3D network formed by intermolecular N–H···S and N–H···N hydrogen bondings between the supramolecular tetramers and $[Mn(NCS)_6]^{4-}$ units. The dotted lines indicate N–H···X (X = N/S) hydrogen bonding.

The geometry around the manganese(II) atom in tetraanionic $[Mn(NCS)_6]^{4-}$ is best described as distorted octahedron with an MnN_6 chromophore. Manganese(II) is coordinated by N atoms of six terminal thiocyanate ligands (Fig. 1). The Mn-N bond lengths lie within a close range [2.208(2)–2.264(2) Å]. *Transoid* angles around Mn are exactly 180.00° whereas the *cisoid* angles [89.10(8)–90.90(8)°] are also close to ideal value (90°). The N–C–S angles [178.1(2)–179.8(2)°] of the six thiocyanates show their linear coordination.

Table 2

N(3*)–Mn(1)–N(3)	180.00

The coordination geometry of the two types of copper(II) centres [Cu(1) and Cu(2)] in the asymmetric unit is best described as distorted trigonal bipyramid (tbp) with a CuN_5 chromophore (Fig. 1). Primary amine nitrogen atoms [N(5), N(6), N(7) for Cu(1), and N(10), N(11), N(12) for Cu(2)] of each tren occupy the equatorial positions around the metal ion. The tertiary amine nitrogen [N(4) for Cu(1) and N(9) for Cu(2)] is

located in the axial position *trans* to the pseudohalide nitrogen [N(8) for Cu(1) and N(13) for Cu(2)]. The bivalent metal centres are displaced [0.210 Å for Cu(1) and 0.206 Å for Cu(2)] from the equatorial plane towards the thiocyanate ligand. There is significant variation of the Cu–N distances [2.033(19)–2.156(2) Å] in the equatorial plane and these are longer compared to the Cu–N distances [1.941(2)–1.952(2) Å] of the pseudohalide. For Cu(2), the N–Cu–N bond angles in the equatorial plane [116.92(9)–124.42(9)°] span tight around 120°; whereas around Cu(1) these angles show greater deviation [111.54(11)–131.25(11)°]. The N(amine)–Cu–N(NCS) angles in the Cu(II) moieties are close [176.94(9)–177.35(9)°] to ideal value as found in regular tbp geometry [21b]. Distances between Cu(1)···Cu(1), Cu(2)···Cu(2) and Cu(1)···Cu(2) within the tetramer are 6.620, 6.078 and 5.550 Å, respectively. Shortest Mn(1)···Cu(1) and Mn(1)···Cu(2) distances are 6.999 and 7.018 Å, respectively.

The hydrogen bonding network that connects the thiocyanates and tren primary amines is an important feature of **1** (Table 3). Establishment of the network seems to be aiding the crystallization. Two sets of hydrogen bondings among different Cu(1) and Cu(2) centres form a supramolecular tetramer (Fig. 2). Within the tetramer, Cu(1) and its symmetry related counterpart participates in N–H···S hydrogen bonding [22] to form a cyclic motif, with $R_2^2(12)$ in Etter's graph notation [23]. This is further linked to Cu(2) and to its symmetry counterpart through two N–H···N hydrogen bonds [24] to complete the tetrameric form (Fig. 2). Each tetramer is alternately placed with the $[Mn(NCS)_6]^{4-}$ molecular ion and the pendant S atoms and bound N atoms of the manganese(II)-bound NCS groups are engaged in hydrogen bonding as detailed below.

In Cu(1) all the three primary amine nitrogen atoms [N(5), N(6) and N(7)] are engaged in hydrogen bonding of which one N–H···N and three N–H···S hydrogen bondings are present. N(5) involves in hydrogen bonding to a bound nitrogen [N(3)] of a terminal thiocyanate of the adjacent $[Mn(NCS)_6]^{4-}$ unit. Another N–H···S bond is formed between N(5) and pendant S(1) of the same $[Mn(NCS)_6]^{4-}$ unit. N(6) participates in N–H···S bonding with S(2), a terminal sulphur atom of a different $[Mn(NCS)_6]^{4-}$ unit. [N(7)] is engaged in hydrogen bonding with a terminal thiocyanate sulphur [S(4)] of its symmetry related counterpart which is one of the two N–H···S bonds forming the cyclic loop in the tetramer (Fig. 2). In contrast to Cu(1), in Cu(2) only two primary amine nitrogen atoms [N(10) and N(11)] are involved in hydrogen bonding. An N–H···S type of bonding is noticed between N(10) of Cu(2) and S(4) of Cu(1), completing the loop in the tetramer and the other between N(11) and S(3) of $[Mn(NCS)_6]^{4-}$ unit of the same layer. Bound nitrogen N(8) of the terminal thiocyanate of Cu(1) forms hydrogen bond to N(11) of Cu(2) within the tetramer. In summary, each of the supramolecular tetramers formed by $[Cu(tren)(NCS)]^{+}$ units, are hydrogen bonded to four $[Mn(NCS)_6]^{4-}$ units, and these each in turn hydrogen bonded to four such tetramers leading to an infinite 3D network (Fig. 3).

Table 3
Hydrogen bond distances (Å) and angles (°) for**1**

D–H···A	D–H	H···A	D···A	∠D–H···A
N(5)–H(5C)···N(3)	0.9200	2.5800	3.471(3)	164.00

N(11)–H(11D)···N(8)[d]	0.9200	2.4700	3.376(3)	170.00
C(12)–H(12A)···S(1)[e]	0.9900	2.8300	3.735(2)	152.00

Symmetry code: [a] $1-x, 1-y, 1-z$; [b] $1-x, 1/2+y, 1/2-z$; [c] $1-x, 2-y, -z$; [d] $x, 3/2-y, 1/2+z$; [e] $-x, 1/2+y, 1/2-z$.

3.3. Magnetism

Variable-temperature magnetic susceptibility measurements were performed in the range of 2–300 K. The thermal variation of molar susceptibility χ_M together with a plot of $\chi_M T$ versus T of the complex is shown in Fig. 4. The magnetic moment (μ_{eff}) per copper(II) and manganese(II) centre is same as that expected for an isolated paramagnetic system [$S = 1/2$ ($\mu_{eff} = 1.732$ BM) for copper(II) and $S = 5/2$ ($\mu_{eff} = 5.916$ BM) for manganese(II)]. **1** consists of four copper(II) and one manganese(II) ion as its basic unit. For each copper(II), $\chi_M T$ is, as indicated, close to 0.4 $cm^3\ mol^{-1}$ K and for manganese(II) is close to 4.4 $cm^3\ mol^{-1}$ K. Thus the total value should be 6.0 $cm^3\ mol^{-1}$ K. The experimental value is 5.9 $cm^3\ mol^{-1}$ K at room temperature. At 4 K the value is 5.5 $cm^3\ mol^{-1}$ K. This shows coupling between the paramagnetic centres is negligible. Each magnetic centre

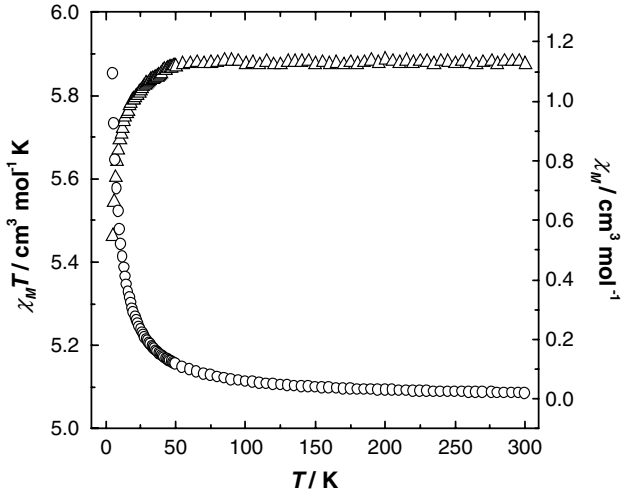

Fig. 4. Plots of $\chi_M T$ vs. T and χ_M vs. T in **1**.

behaves as discrete unit which implies that hydrogen bonded bridges have no effect on magnetic exchange.

4. Conclusion

The formation of such bimetallic compound [Cu(tren)(NCS)]$_4$[Mn(NCS)$_6$] (**1**) with hydrogen bonded network structure instead of covalently bonded polymers shows that hydrogen bond is a masterkey interaction in superstructure formation with a novel architecture. Presence of acidic hydrogen in the organic ligand and pendant arm with basic centre in pseudohalide lead to different varieties of architectures with different metal ions. The variable temperature magnetic study of **1** show negligible magnetic interactions due the formation of discrete units bridged by non-covalent hydrogen bonds.

5. Supplementary data

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Centre, CCDC No. 212268 (**1**). Copies of this information can be obtained free of charge from the Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or on the web www.ccdc.cam.ac.uk).

Abstract

Two Ni(II) complexes, [Ni(Me-sal)$_2$dpt] (**1**) and [Ni(Me-sal)dpt]Cl (**2**), with penta- and tetradentate ligands ((H_2L^1)=H_2(Me-sal)$_2$dpt=*N*,*N*-bis(α-methylsalicylidene)dipropylenetriamine and (HL^2)=H(Me-sal)dpt=*N*-(α-methylesalicylidene)dipropylenetriamine) containing N_3O_2 and N_3O donor sets, respectively, have been synthesized and characterized by elemental analyses, FT-IR and UV–Vis spectroscopy. The green five coordinate complex [Ni(Me-sal)$_2$dpt] (**1**) forms on reaction of H_2(Me-sal)$_2$dpt with $Ni^{II}(OAc)_2 \cdot 4H_2O$ in boiling methanol, whereas at reflux temperature in ethanol the red diamagnetic [Ni(Me-sal)dpt]Cl (**2**) is formed on reaction of H_2(Me-sal)$_2$dpt with $NiCl_2 \cdot 6H_2O$. In the ligand (Me-sal)dpt one of the imine groups is hydrolysed resulting in a new tetradentate N_3O ligand. Complex (**2**) is also prepared in a higher yield by the direct reaction of H(Me-sal)dpt with $NiCl_2 \cdot 6H_2O$. The crystal and molecular structures of (**1**) and (**2**) were determined by X-ray crystallography. Complex (**1**) crystallizes in the monoclinic space group $P2_1/c$ and complex (**2**) crystallizes in the triclinic space group $P\bar{1}$. The coordination polyhedron about the Ni(II) center in complex (**1**) is best described as distorted trigonal bipyramidal and that of complex (**2**) as distorted square planar. The FT-IR and UV–Vis spectra of the complexes are also discussed.

Keywords: Schiff base complexes; Nickel(II); Half unit ligand; Crystal structures

1. Introduction

The chemistry of multidentate Schiff base ligands has been studied extensively [1–8] owing to their potential for binding to one, two or more metal centers and their use in the synthesis of homo and heteronuclear metal complexes with interesting stereochemistry [9–12]. Among others, the synthesis of Schiff base ligands through the 1:1 condensation of diamines to form "half-unit" ligands has attracted much attention in recent years [13–16]. These ligands, apart from being used in the synthesis of metal complexes, afford the possibility of synthetic routes to additional unsymmetrical tetradentate and pentadentate [14] Schiff base ligands.

Nickel can exhibit several oxidation states and Schiff base ligands have been employed in the development of new Schiff base complexes containing nickel with different oxidation states [17]. Such complexes play an important role in bioinorganic chemistry and redox enzyme systems [18] and may provide the basis of models for active sites of biological systems [19] or act as catalysts [20–23]. In the present paper, we describe the synthesis of pentadentate H_2L^1 and tetradentate HL^2 ligands (Fig. 1) and their Ni(II) complexes. An interesting feature observed during this work was the hydrolysis of the coordinated pentadentate Schiff base ligand L^1 in the presence of KOH under reflux conditions in an ethanolic solution, leading to the formation of the [Ni(L^2)]Cl complex.

H_2L^1 HL^2

Fig. 1. Schematic presentation of the ligands H_2L^1 and HL^2.

2. Experimental

All chemicals were used as supplied by Merck and Fluka without further purification. Solvents were either of reagent or spectroscopic grade and were dried by conventional procedures prior to use.

2.1. Physical measurements

Elemental analyses were performed by using a Heraeus CHN-O-RAPID elemental analyzer. UV–Vis spectra were recorded on a JASCO V-570 spectrophotometer, λ_{max} (ε) in nm. Infrared spectra (KBr pellet) were obtained on a FT-IR JASCO 680 plus spectrophotometer. The ^{1}H NMR spectrum of the ligand was obtained on a BRUKER AVANCE DR X500 (500 MHz) spectrometer. Proton chemical shifts are reported in parts per million (ppm) relative to an internal standard of Me_4Si.

2.2. Synthesis

2.2.1. H_2(Me-sal)$_2$dpt (H_2L^1) ligand

N,*N*-bis(α-methylsalicylidene)dipropylenetriamine (H_2(Me-sal)$_2$dpt) was prepared by following the syntheses outlined for related Schiff base ligands [6], via the condensation of (394 mg, 3.00 mmol) dipropylenetriamine (dpt) with (817 mg, 6.00 mmol) 2-hydroxyacetophenone in methanol (or ethanol) at room temperature, and was purified by recrystallization from hot ethanol [24–26]. Yield: 1.05 g (95%). IR (KBr, cm^{-1}): ν_{max} 3300–3400 (m, br, OH), 3295 (s N–H), 1613 (s, C=N). UV–Vis: λ_{max} (nm) (ε, M^{-1} cm^{-1}) (methanol): 362 (12 100), 337 (14 500). ^{1}H NMR (CD_3COCD_3, 500 MHz):δ = 7.58 (2H, d, J_{HH} = 8 Hz, H_e), 7.26 (2H, t, J_{HH} = 8 Hz, H_g), 6.78 (2H, d, J_{HH} = 8 Hz, H_h), 6.75 (2H, t, J_{HH} = 8 Hz, H_f), 3.63 (4H, t, J_{HH} = 6.8 Hz, H_c), 2.71 (4H, t,J_{HH} = 6.8 Hz, H_a), 2.34 (6 H, s, H_d), 2.15 (1H, br, N–H), 1.88 (4H, m, J_{HH} = 6.8 Hz, H_b).

2.2.2. H(Me-sal)dpt (HL^2) ligand

N-(α-methylesalicylidene)dipropylenetriamine (H(Me-sal)dpt) was prepared according to a procedure for similar "half-unit" ligands, by the condensation of dipropylenetriamine with 2-hydroxyacetophenone (1:1 molar ratio) at room temperature [15]. To a solution of dipropylenetriamine (dpt) (131 mg, 1.00 mmol) in 10 ml chloroform was added dropwise a solution of 2-hydroxyacetophenone (136 mg, 1.00 mmol) in 10 ml chloroform over a 30 min period and the mixture was stirred for 1 h. The solvent was then evaporated under vacuum leaving a yellow oil (HL^2). The resulting yellow oil was used for the synthesis of complex (**2**) by method 2.

2.2.3. [Ni(Me-sal)$_2$dpt] (**1**)

To a boiling solution of H_2(Me-sal)$_2$dpt (367 mg, 1.00 mmol) in 10 ml dichloromethane was added slowly a solution of $Ni^{II}(OAc)_2 \cdot 4H_2O$ (249 mg, 1.00 mmol) in 10.0 ml methanol, and the resulting solution was stirred until the dichloromethane evaporated. Solid KOH (112 mg, 2.00 mmol) was then added to the remaining solution and the mixture was stirred for an additional 5 min. A green precipitate was finally obtained. The reaction mixture was cooled to room temperature and the green precipitate was filtered off and washed with methanol. The product was then recrystallized from hot toluene. Yield: 280 mg (66%). *Anal*. Calc. for $C_{22}H_{27}N_3NiO_2$: C, 62.3; H, 6.42; N, 9.91. Found: C, 62.2; H, 6.40; N, 9.40%. IR (KBr, cm^{-1}): ν_{max} 3176 (m, NH), 1608 (s, C=N). UV–Vis: λ_{max} (nm) (ε, M^{-1} cm^{-1}) (chloroform): 1218 (18.04), 974(5.88), 877(2.94), 600(59.03).

2.2.4. [Ni(Me-sal)dpt]Cl (**2**) method 1

Solid KOH (112 mg, 2.00 mmol) was added to a solution of H_2(Me-sal)$_2$dpt (367 mg, 1.00 mmol) in 25 ml ethanol and the mixture was refluxed for 5 min. A solution of $Ni^{II}Cl_2 \cdot 6H_2O$ (238 mg, 1.00 mmol) in 10 ml methanol was then added and a green precipitate appeared which instantly dissolved to form a deep red solution. The solution was refluxed for 1 h and then cooled to room temperature and filtered off. The solvent of the resulting filtrate was evaporated under vacuum to give a red precipitate. Crystals of (**2**) suitable for X-ray crystallography were obtained by the diffusion of diethyl ether into a saturated solution of the red product in

ethanol at room temperature. Yield: 65.1 mg (19%). *Anal*. Calc. for $C_{14}H_{22}ClN_3NiO$: C, 47.5; H, 6.14; N, 12.8. Found: C, 48.6; H, 6.5; N, 12.0%. IR (KBr, cm^{-1}): ν_{max} 3229, 3197 (m, NH), 1597 (s, C=N). UV–Vis: λ_{max} (nm) (ε, $M^{-1}\,cm^{-1}$) (chloroform): 510 (127), 450 (160), 393 (2968).

2.2.5. [Ni(Me-sal)dpt]Cl (2) method 2

To a solution of 1.00 mmol (249 mg) of the freshly prepared H(Me-sal)dpt (as described in Section 2.2.2.) in 25 mmol ethanol was added a solution of triethylamine (101 mg, 1.00 mmol) in ethanol and the mixture was refluxed for 5 min. A solution of $Ni^{II}Cl_2 \cdot 6H_2O$ (238 mg, 1.00 mmol) in 10 ml methanol was then added upon which the color of the solution turned deep red. The reflux was continued for an additional 1 h. The final reaction mixture was cooled to room temperature and filtered off. The solvent of the resulting filtrate was evaporated under vacuum to give a red precipitate. Crystals of (**2**) suitable for X-ray crystallography were obtained by the diffusion of diethyl ether into a saturated solution of the red product in ethanol at room temperature. Yield: 151 mg (40%). *Anal*. Calc. for $C_{14}H_{22}ClN_3NiO$: C, 47.5; H, 6.14; N, 12.8. Found: C, 48.3; H, 6.5; N, 12.2%. IR (KBr, cm^{-1}): ν_{max} 3229, 3197 (m, NH), 1597 (s, C=N). UV–Vis: λ_{max} (nm) (ε, $M^{-1}\,cm^{-1}$) (chloroform): 510 (127), 450 (160), 393 (2968).

2.3. X-ray crystallography

Green crystals of [Ni(Me-sal)$_2$dpt] (**1**) suitable for X-ray crystallography were grown by slow evaporation of a hot toluene solution of the complex at 78 °C and red crystals of [Ni(Me-sal)dpt]Cl (**2**) suitable for X-ray crystallography were grown by slow diffusion of diethylether vapour into a saturated solution of the complex in ethanol at room temperature. The crystals were mounted on glass fibers. Data collections were carried out on a Stoe IP diffraction system at 293 K using graphite monochromatized Mo Kα radiation (λ = 0.71073 Å). A crystal-to-detector distance of 100 cm was chosen and 180 one-degree-wide images were exposed for 5 min for (**1**) and 10 min for (**2**). Crystal data and details of the structure determination are given in Table 1. The data were corrected for Lorentz and polarization effects and a numerical absorption correction (Stoe X-Red 1.24) was applied [27]. The structures were solved with the help of DirDif-96 for (**1**) [28] and SHELXL-97 for (**2**) [29a]. The structure refinement was performed using the full-matrix against F^2 method (SHELXL-97) [29b]. Anisotropic displacement parameters were refined for non-hydrogen atoms, all hydrogen atoms were made to ride on their carrier atoms.

3. Results and discussion

3.1. Synthesis

The ligand H_2L^1 was synthesized and reacted with nickel salts in an attempt to prepare five or four coordinate species as have been reported for related ligands [19,30]. Our first attempt on the synthesis of [Ni(Me-sal)$_2$dpt] (**1**) was based on the procedure reported by

Kawamoto and co-workers [30], and H_2(Me-sal)dpt was reacted with $NiCl_2 \cdot 6H_2O$. Instead, a diamagnetic red product with a low yield (19%) was obtained that was assumed to be a four coordinate nickel complex similar to [Ni(2,6Bis[2-acetylphenyl)carbamoyl]pyridine)] [30]. The presence of only one Me-sal coupled with dipropylenetriamine is evident from the elemental analysis data and the IR spectrum of this complex. In addition, the structural analysis of the red crystals of the product by X-ray crystallography (vide infra) proved that one of the imine fragments of the ligand H_2L^1 had been removed, presumably by undergoing hydrolysis in the presence of KOH while the reaction mixture was refluxed. The product was identified as the four coordinate [Ni(Me-sal)dpt]Cl (**2**). In an alternative method for the synthesis of [Ni(Me-sal)$_2$dpt] (**1**), described in Section 2, a green product was obtained. The X-ray crystal structure analysis showed that this compound was a five coordinate nickel complex, (**1**), with a distorted trigonal bipyramidal geometry.

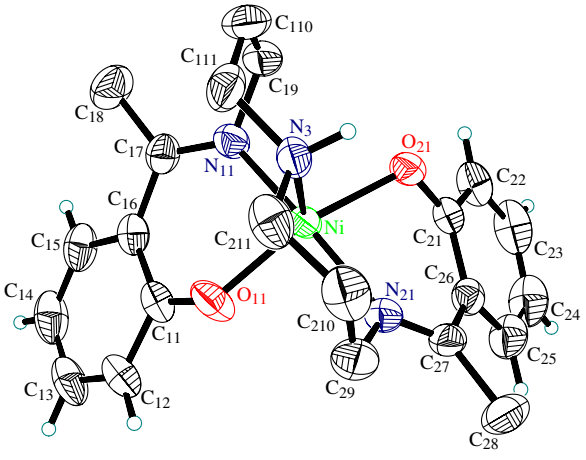

Fig. 2. Representation of molecular structure of **1** with the atom labelling scheme. Ring labels B and C are used in the text.

In order to have a more consistent procedure and to get a higher yield of the red complex an alternative method was developed for the synthesis of H(Me-sal)dpt and the complex [Ni(Me-sal)dpt]Cl (**2**), as described in Section 2. In this method, 2-hydroxyacetophenone and dipropylenetriamine were reacted in a 1:1 molar ratio and the resulting yellow oily product was used directly for the synthesis of the complex. The yield was improved from 19% in method 1 to 40% in method 2.

3.2. Description of structures

The structure of [Ni(Me-sal)$_2$dpt] (**1**) consists of isolated NiL^1 units in which the nickel is coordinated by three nitrogen and two oxygen atoms of the quinquedentate (Me-sal)$_2$dpt ligand (Fig. 2). The geometry of the $\{NiO_2N_2N'\}$ coordination core is that of a distorted trigonal bipyramid with two imine nitrogen atoms N(11) and N(21) being located in the axial positions, subtending an angle N(11)–Ni–N(21) of 173.82(5)°. The secondary amine nitrogen atom N(3) lies in the position just perpendicular to the near linear N(11)–Ni–N(21) arrangement with angles N(11)–Ni–N(3), 91.98(5)° and N(21)–Ni–N(3), 94.16(5)°. The donor oxygen atoms are bound equatorially and form the angle O(11)–Ni–O(21), 158.38(5)°. The whole molecule is butterfly shaped but offers enough space for the coordination of a sixth ligand.

In the conformation adopted by the (Me-sal)$_2$dpt ligand, the phenyl rings are unsymmetrically bent away from the axial position occupied by N(3) due to the difference in the conformations of the six membered rings linking the salycilidene rings to the secondary amine nitrogen N(3). A boat conformation for the chain to ring B and a chair conformation for the chain to ring C is observed (Fig. 2). The set of torsion angles for both the boat and chair ring conformations are presented in Table 2. The angles between the normal to the equatorial plane [Ni, O(11), O(21), N(11), N(21)] and the normals to the benzene rings C(11) → C(16) (ring B)

and C(21) → C(26) (ring C) are 38.64(6)° and 61.17(6)°, respectively.

Selected bond lengths and angles for (**1**) are presented in Table 3. The Ni–O_{av} (1.93 Å), Ni–N_{av} (2.03 Å) and Ni–N(3) (2.049 Å) bond lengths are comparable with the corresponding bond lengths reported for analogous structures [31]. By comparing the structural parameters of (**1**) with those of Ni(salMedpt) [31] (Table 4), and most notably the O–Ni–O angle, one can conclude that [Ni(Me-sal)$_2$dpt] (**1**) shows a greater tendency to form a square pyramidal arrangement than Ni(salMedpt). The square pyramidal structure with the metal atom above the basal plane cannot be attained presumably because the N(11)–Ni–N(3) angles are bound to be close to 90°. Some evidence in support of this interpretation is given by the strain present in the trimethylene chains, where the angles of the carbon atoms are larger than the expected tetrahedral value. For example, C(19)–C(110)–C(111) = 116.6 (2)°. The same steric factors would prevent the O–Ni–O angle from attaining higher values through a rotation of the sal ring around the Ni–N bonds.

The X-ray structure of [Ni(Me-sal)dpt]Cl (**2**) shows that the nickel ion is in a distorted square planar environment, formed by a primary and a secondary amine, an imino nitrogen and a phenolic oxygen group (Fig. 3). The average displacement of the O(11), N(11), N(3), and N(21) atoms from the least-squares plane through these atoms is 0.124 Å, consistent with this geometry. In the conformation adopted by the (Me-sal)dpt ligand in (**2**), the N(11)–C(19)–C(110)–C(111)–N(3)–Ni and the N(21)–C(29)–C(210)–C(211)–N(3)–Ni chelate rings of dpt, adopt a boat and a chair conformation, respectively (Fig. 3). The set of torsion angles for both the boat and chair ring conformations are presented in Table 2.

Selected bond distances and angles for (**2**) are given in Table 3. The bond distances and angles are in agreement with the values for tetracoordinate low-spin divalent nickel complexes. The Ni–O(11) (1.8269(14) Å), Ni–N(11) (1.8966(16) Å), Ni–N(3) (1.9285(17) Å) and Ni–N(21) (1.9207(16) Å) distances are comparable with the corresponding Ni–O (1.79 Å) and Ni–N(imine) (1.88 Å) distances in [Ni($Me_2NCH_2CH_2N$(Me)-C_6H_4O)N_3] [32], and Ni–N (*sec*-amine) (1.94 Å) [19] and Ni–N(amine) (1.91 Å) in [Ni(*N*-(thiobenzenylidene)-diethylenetriamine)]Cl, respectively.

3.3. Spectral studies

The splitting of the terms of the Ni(II) ion in crystal fields of D_{3h} and C_{4v} symmetry has been calculated and the spectra of several complexes have been measured experimentally [6,33,34]. It has been shown that for a similar set of donor atoms in a regular trigonal bipyramidal configuration only one band is expected in the near infrared region at ca. 7000 cm^{-1} (1428 nm) while two bands are expected for a regular square pyramidal configuration at ca. 7200 cm^{-1} (1388 nm) and ca. 10 800 cm^{-1} (925 nm). The reported experimental data are in good agreement with the theoretical predictions [6,33,34]. The spectrum of [Ni(Me-sal)$_2$dpt] (**1**) complex in dichloromethane shows a band at 1218 nm and a shoulder at 974 nm in the near infrared region which

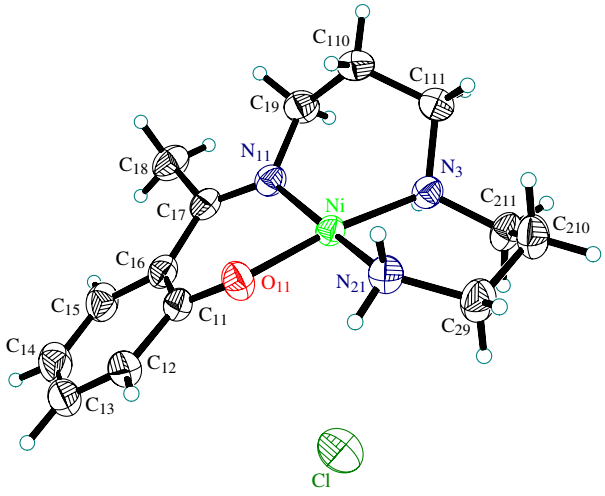

Fig. 3. Representation of the molecular structure of **2** with the atom labelling scheme.

is in accord with a distorted square pyramidal configuration [6] and confirmed by the X-ray crystal analysis.

The red [Ni(Me-sal)dpt]Cl (**2**) complex shows two shoulders at 510 and 450 nm, which are characteristic of square planar diamagnetic Ni(II) complexes [34], and resemble the absorption bands observed in the spectrum of an analogous Ni(II) complex, [Ni(*N*-(thiobenzyline)-ethylenetriamine)]Cl, reported by Bouwman [19]. A third band which is expected to appear at a higher energy is apparently hidden under the CT band.

In the IR spectrum of the H_2(Me-sal)$_2$dpt ligand, a broad band characteristic of the OH group at 3300–3400 cm^{-1} is observed. The disappearance of this band in the IR spectra of the complexes is indicative of the fact that the equatorial ligand is coordinated in its deprotonated form. The ν(C=N) band of H_2(Me-sal)$_2$dpt at 1615 cm^{-1} also shifts to 1608 cm^{-1} in [Ni(Me-sal)$_2$dpt] (**1**) correspondingly due to the loss of the intramolecular hydrogen bonding and the formation of a new chelate ring between the imine nitrogens and Ni(II). The ν(C=N) stretching of [Ni(Me-sal)dpt]Cl (**2**) appears at 1597 cm^{-1}. The bands corresponding to the amine ν(N–H) stretching vibrations of the free (Me-sal)$_2$dpt (H_2L^1) appears at 3295 cm^{-1}. This band, as expected, is shifted by about 119 cm^{-1} in the complex [Ni(Me-sal)$_2$dpt] (**1**) relative to the uncoordinated amine. The complex [Ni(Me-sal)dpt]Cl (**2**) shows two medium bands at 3229 and 3197 cm^{-1} that correspond to ν(N–H) stretching vibrations of the primary and secondary amines of the coordinated ligand.

4. Conclusion

We have prepared two nickel complexes of different geometries by reacting the Schiff base ligand H_2(Me-sal)$_2$dpt with nickel acetate and nickel chloride. Interestingly, the reaction with nickel acetate under milder conditions led to a green five coordinate ($N_2N'O_2$) complex with a distorted trigonal bipyramidal geometry. However, nickel chloride under more severe conditions, gave an orange four coordinate ($NN'N''O$) complex with a distorted square planar structure containing a ''half unit'' ligand (Me-sal)dpt, resulting from the hydrolysis of one imine fragment of (Me-sal)$_2$dpt. The ''half unit'' ligand H(Me-sal)dpt was also prepared and used freshly for the direct synthesis of [Ni(Me-sal)dpt]Cl in which the yield improved significantly relative to the indirect method.

Abstract

Equilibrium studies of the mixed-ligand complexes of the Cu^{2+} ion with polyamines {ethylenediamine (1,2-diaminoethane, en), diethylenetriamine (bis(2-aminoethyl)amine, dien) or pentamethyldiethylenetriamine (*N*,*N*,*N*′,*N*″,*N*″-pentamethyl-[bis(2-aminoethyl)amine], Me_5dien)} as a primary ligand A, and DL-aspartic acid-β-hydroxamic acid (*N*-hydroxyasparagine, Asp-β-ha) as a secondary ligand L were performed by potentiometric titration and UV–Vis and EPR spectroscopy. The results show that the parent and two mixed-ligand complexes, [CuA(HL)] and [CuA(L)], are formed. In the first [CuA(HL)] species the amino nitrogen and carboxylate oxygen of Asp-β-ha are the coordinating donor atoms (glycine-like coordination) and in the second [CuA(L)] species the amino and hydroxamate nitrogens are the coordinating donor atoms of this ligand. The first manner of coordination predominates in acidic and neutral solutions while the second one in basic solution.

Absorption (UV–Vis) and EPR spectra at various pH values indicate a five-coordinate structure of the formed complexes with a geometry close to a square-pyramid in the case of dien and trigonal bipyramid in the case of Me_5dien. In the binary copper(II)–aspartic acid-β-hydroxamic acid system the occurrence of a pentanuclear complex was confirmed.

1. Introduction

Mixed-ligand copper(II) complexes in which polyamines play a role as a primary ligand and aminohydroxamic acid as a secondary one have been studied by us since 1998 [1–4]. The studies allowed us to ascertain that in these mixed-ligand complexes the geometry around the copper(II) is controlled first of all by the polyamines, i.e., by the number of nitrogen atoms of the polyamines which may occupy coordination sites [3].

Now we are interested in ternary systems with polyamines in which the secondary ligand possesses two donor groups: amino-acid and hydroxamate. These two groups are bidentate and have their own different geometries – hydroxamate is planar [5,6] and amino acid is less planar, e.g., in the glycine molecule the N_α (amino) atom is deviated from the plane defined by the O–C=O atoms [7]. The acidities of these groups are: $pK_{NHOH} = 9.27$ [8] and $pK_{NH_3^+} + pK_{COOH} = 11.91$ [9] for acetohydroxamic acid ($CH_3CONHOH$) and glycine, respectively.

Aspartic acid β-hydroxamic acid – $HO_2CCH(NH_2)$-$CH_2CONHOH$ – (Asp-β-ha) may be considered as a derivative of aspartic acid in which the hydroxamate group is in a β-position to the amino group. Then, the mutual influence between the amino and the hydroxamate

doi:10.1016/j.poly.2005.07.043

group is negligible [10,11]. The binary copper(II)–aspartic acid β-hydroxamic acid system has been studied by several authors [12–14] who obtained different equilibrium models. To render the situation relating to this system more comprehensive, and to acquire more reliable data, we have performed new studies on binary and ternary systems containing aspartic acid β-hydroxamic acid. Our aim is to answer the following question: what coordination mode, glycine-like or aminohydroxamate-like, will be preferred for Asp-β-ha in the ternary system with polyamines. In order to resolve this problem we undertook studies on the complexes equilibria in the systems: Cu^{2+}–(Asp-β-ha), Cu^{2+}–en–(Asp-β-ha), Cu^{2+}–dien–(Asp-β-ha), Cu^{2+}–Me_5dien–(Asp-β-ha) using pH-metric, spectrophotometric and EPR methods. The obtained results are compared with those for β-alaninehydroxamic acid (β-Alaha) [1,3].

2. Experimental

2.1. Materials

Aspartic acid β-hydroxamic acid monohydrate (Asp-β-ha · H_2O) and ethylenediamine dihydrochloride (en · 2 HCl) were purchased from Sigma (USA). Diethylenetriamine (dien) was used from Aldrich (Germany), *N*,*N*′,*N*″,*N*″-pentamethyldiethylenetriamine (Me_5dien) was from Fluka (Switzerland). All ligands were used without further purification and their purity was greater than 99%.

The exact concentrations of the ligand solutions were determined by the Gran method [15]. Copper(II) chloride solution was purchased from Merck as a Titrisol ampoule. Carbonate-free potassium hydroxide (the titrant) was prepared and standardized against a standard potassium hydrogenphthalate solution.

All solutions were prepared with deionized water. The study of aspartic acid β-hydroxamic acid was difficult because of the relative instability of its aqueous solution. Given the relative instability of stock solutions of Asp-β-ha, its solutions as well as amines were prepared immediately prior to use for each experiment.

2.2. Methods

2.2.1. Potentiometric measurements

The potentiometric measurements were carried out at 25.0 ± 0.1 °C using a constant-temperature water-bath. A summary of the experimental details is given in Table 1. The data for the Cu^{2+}-amines binary systems can be found in our early papers [1–3,16]. The metal ions:ligand molar ratios were 1.2:1, 1.14:1, 1:1, 1:2 and 1:4 for the Cu^{2+}–(Asp-β-ha) binary system. Within the whole studied pH range (i.e., from ca. 2 to 11), no precipitate was observed even if the copper(II) to Asp-β-ha molar ratio was 1.2:1. Titration emf data, together with E^0 and pK_w, were used to calculate the hydrogen ion concentration, [H^+].

For clarity, the charges of the complexes are omitted in the text and tables. It has to be mentioned, however, the fully deprotonated form of aspartic acid β-hydroxamic acid (Asp-β-ha) is L^{2-} while the amines are neutral.

2.2.2. Spectroscopic studies

The electronic absorption spectra were recorded on a SPECORD M-40 (Vis) spectrophotometer using 2 or 1-cm quartz cells at room temperature. The individual spectra of the copper(II) complexes were calculated according to the law of additivity of absorption. To extract the net ligand-field absorption band of each mixed-ligand species, the spectrum measured at a pH value where each of these species exhibits maximal contribution was resolved into the components corresponding to the individual

species existing at that pH (as described in [1]). The molar absorptivity for the individual species was then calculated taking into account their distribution.

EPR measurements were performed on a Bruker 300E X-band spectrophotometer equipped with a Bruker NMR gaussmeter ER 035M and a Hewlett–Packard frequency counter HP 5350B at 77 K in water/ethyleneglycol (4:1 v/v) solution. The EPR parameters were calculated by computer simulation of the experimental spectra using Bruker's WIN-EPR SimFonia Software Version 1.25. The metal ion concentrations for both spectroscopic measurements were 4×10^{-3} M and metal-to-ligand molar ratios were the same as for the potentiometric measurement.

3. Results and discussion

The acid dissociation constants of the studied ligands are given in Table 2. The totally protonated aspartic acid-β-hydroxamic acid (Asp-β-ha, H_3L^+) can release three protons in the measurable pH region.

The first value, $pK_1 = 2.12$, is assigned to the dissociation of the –COOH group, but the other two processes overlap each other which means that the pK_2 and pK_3 macroconstants are not characteristic of the real acidity of the $-NH_3^+$ and –NHOH groups. It is well known that dissociation microconstants for β-alaninehydroxamic acid show that the $-NH_3^+$ group is less acidic than –NHOH in contrast to α-alaninehydroxamic acid [11]. For Asp-β-ha the dissociation constants are: $pK_{COOH} = 2.12$, $pK_{NHOH} = 8.24$, $pK_{NH_3^+} = 9.45$.

Additionally, from the data in Table 2, it is seen that the presence of the carboxylate group in Asp-β-ha causes the increase of acidity of both $-NH_3^+$ and –NHOH groups when compared to those of β-Alaha.

The general four-component equilibria can be written as

$$pCu + qA + rL + sH \leftrightarrows Cu_pA_qL_rH_s$$

where p, q, r and s are the stoichiometric coefficients corresponding to the copper(II) metal ion, A = dien or Me_5dien, L = Asp-β-ha, and H, respectively; charges are omitted for simplicity.

The cumulative formation constants are defined as

$$\beta_{pqrs} = [Cu_pA_qL_rH_s]/[Cu]^p[A]^q[L]^r[H]^s.$$

The β_{1111} and β_{1110} constants express the stability of the [CuAHL] and [CuAL] mixed-ligand species, respectively.

3.1. Copper(II)–DL-aspartic acid-β-hydroxamic acid system

The evaluation of the experimental pH-metric data for the Cu^{2+}–(Asp-β-ha) system demonstrates that two different equilibrium models yield acceptable fittings (Table 3). Model I is the same as the model presented by Careri et al. [14]. In this model, only two species exist in the whole pH range. The first species, $[Cu(H\text{-}Asp\text{-}\beta\text{-}ha)]^+$, is seen above pH 2 whereas above pH 4.5 only one species, $[Cu_5(Asp\text{-}\beta\text{-}ha)_4H_{-4}]^{2-}$, exists. This equilibrium model is identical with that for the copper(II)–β-alaninehydroxamic acid system [17].

$\log\beta[Cu(Asp\text{-}\beta\text{-}ha)_2]^{3-}$	9.08(4)				

The major difference between model II and the model presented by Farkas and Buglyo [13] concerns the formation of the pentanuclear species; according to our model II, this species is formed and reaches a maximum concentration (ca. 50%) at pH 4.5. Additionally, the stability constants for the $[Cu_4(Asp\text{-}\beta\text{-}ha)_4H_{-2}]^{2-}$ and $[Cu_4(Asp\text{-}\beta\text{-}ha)_4H_{-3}]^{3-}$ species obtained in [13] and in this work are different.

Plots of $\bar{n}_H$ versus pH ($\bar{n}_H$ = means number of bound protons per mole of ligand) are given in Fig. 1. From this, we can see that in the system with metal ions 'extra' deprotonation of the hydroxamate group of Asp-β-ha occurs, already in acidic solution. With an excess of Cu^{2+}, the values of $\bar{n}_H$ are close to −1 (above pH 4). Hence, such 'extra' deprotonation leads to the formation of the LH_{-1} form of the ligand as it has been observed during the formation of polynuclear complexes with other aminohydroxamic acids [17,18].

The absorption spectra in the d–d region exhibit a distinctive band at 617 nm in the 4.5–11 pH region, the energy of which is independent on the metal-to-ligand molar ratios (Fig. 2). This indicates that in the whole pH range only one species exists. A plot of absorbance at 617 nm versus $c_{Cu^{2+}}/c_{Asp\text{-}\beta\text{-}ha}$ (Fig. 3) indicates a copper(II)-to-Asp-β-ha ratio of 1.25:1. Hence, we can describe this species as $[Cu_5L_4]$. Due to the fact that $L = LH_{-1}$, the real formula of this species is

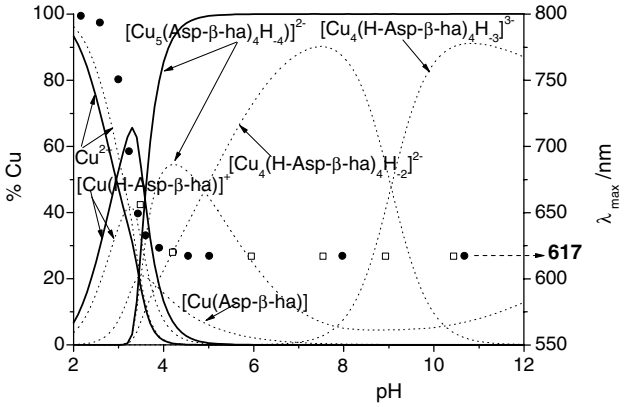

Fig. 2. Concentration distribution curves as a function of pH and variations of visible absorption maximum wavelength for the Cu^{2+}–(Asp-β-ha) system at 1:2 molar ratio; model I – solid line and circles; model II – dotted line and squares; $c_{Cu} = 4 \times 10^{-3}$ M.

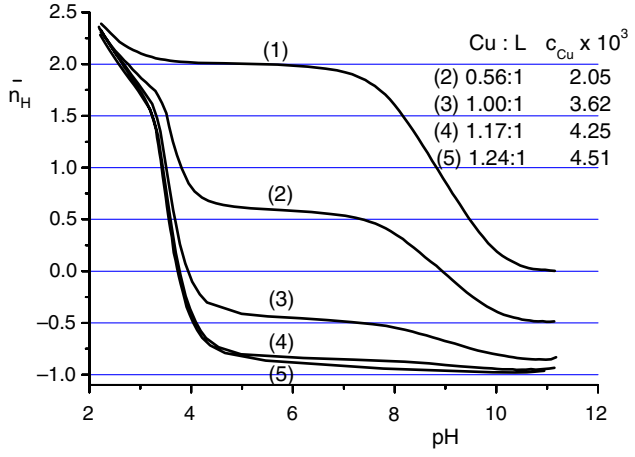

Fig. 1. Mean number of bound protons per mole of ligand, $\bar{n}_H$, for Asp-β-ha (L) alone (1) and in the presence of Cu^{2+} (2-5); $c_{Asp\text{-}\beta\text{-}ha} = 3.64 \times 10^{-3}$ M.

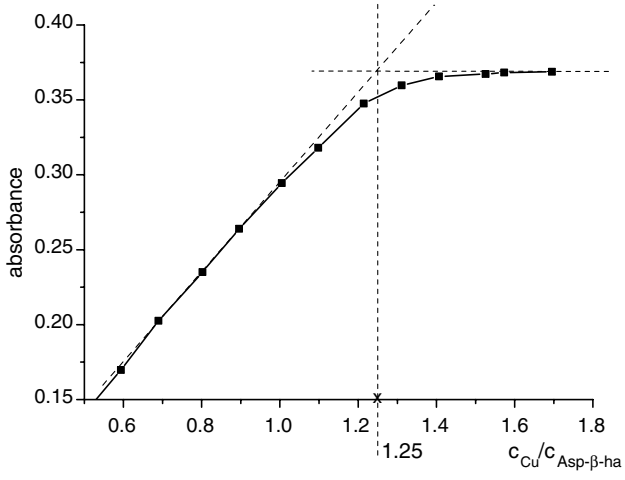

Fig. 3. Dependence of the absorbance of the d–d transition at 617 nm on the copper(II)-to-(Asp-β-ha) molar ratio; $c_{Asp\text{-}\beta\text{-}ha} = 5 \times 10^{-3}$ M; 1 cm cells.

$[Cu_5(LH_{-1})_4]$. From the above considerations, the most probable species in the pH range 4.5–11 is the pentanuclear species $[Cu_5(Asp\text{-}\beta\text{-}ha)_4H_{-4}]^{2-}$ in which the carboxylato groups are not coordinated [14]. Thus, we can see that model I in Table 2 is preferred.

The molar absorption coefficient (ε) for the $[Cu_5(Asp\text{-}\beta\text{-}ha)_4H_{-4}]^{2-}$ species may be calculated from a plot of absorbance versus Cu^{2+}-concentration for a series of samples with Asp-β-ha. This relation exhibits a linear behaviour from 0.5 to 5.5 mM with the slope of the line giving $\varepsilon = 61\ dm^3\ mol^{-1}\ cm^{-1}$, calculated per Cu^{2+} ion.

3.2. Copper(II)-amine-DL-aspartic acid-β-hydroxamic acid systems

In the Cu^{2+}–en–(Asp-β-ha) system, the mixed-ligand complexes are not formed. The results of potentiometric studies on the ternary systems with triamines are collected in Table 4, together with our previous stability constants values concerning ternary systems with β-alaninehydroxamic acid [1,3]. Concentration distribution curves for these systems are presented in Figs. 4(a) and (b) together with their variations of visible absorption maximum wavelengths with pH.

The calculated concentrations of the copper(II) complex species for the Cu^{2+}–dien–(Asp-β-ha) 1:1:2 molar ratio system as a function of pH (shown in Fig. 4(a)) indicate that under these conditions, the $[Cu(dien)]^{2+}$ species is present in concentration ca. 95% in the 4–6 pH range. The $[Cu(dien)_2]^{2+}$ complex is formed in significant concentration at copper(II):dien:Asp-β-ha molar ratios of 1:2:2 and 1:2:1, but at the discussed 1:1:2 molar ratio it is a minor product (ca 1%), so it can be regarded as negligible.

From comparative analysis of potentiometric data and EPR spectra for the Cu^{2+}–dien–(Asp-β-ha) system, it may be established that in the 7–11 pH range two mixed-ligand complexes, $[Cu(dien)(H\text{-}Asp\text{-}\beta\text{-}ha)]^{+}$ and $[Cu(dien)(Asp\text{-}\beta\text{-}ha)]$ exist (Fig. 4(a)). The EPR spectra of the species formed in the Cu^{2+}–dien–(Asp-β-ha) system depending on pH are demonstrated in Fig. 5. The spectra observed within pH range 2.5 and 4.5, with parameters $g_{\|} = 2.334$, $A_{\|} = 158 \times 10^{-4}\ cm^{-1}$ (Table 5), are ascribed to the first complex $[Cu(H\text{-}Asp\text{-}\beta\text{-}ha)]^{+}$ being in equilibrium with Cu^{2+}_{aqua} (Fig. 4(a)). The parameters are close to those found for Cu^{2+} with β-Alaha at pH 3 [1]. Between pH 3.56 and 5.51, the spectrum with parameters $g_{\|} = 2.234$, $A_{\|} = 190 \times 10^{-4}\ cm^{-1}$ is characteristic for $[Cu(dien)]^{2+}$. It is still observed to a small extent at pH 7.58. At this pH a new spectrum with $g_{\|} = 2.218$, $A_{\|} = 190 \times 10^{-4}\ cm^{-1}$ is dominant. These parameters are close to those for $[Cu(dien)_2]^{2+}$ ($g_{\|} = 2.214$, $A_{\|} = 186 \times 10^{-4}\ cm^{-1}$, Table 5) and are different from those observed for the Cu^{2+}–dien-β-Alaha system ($g_{\|} = 2.244$, $A_{\|} = 183 \times 10^{-4}\ cm^{-1}$) at pH 7 [1]. It suggests that the coordination sphere in the Cu^{2+} plane in $[Cu(dien)(H\text{-}Asp\text{-}\beta\text{-}ha)]^{+}$ consists of four nitrogen atoms whereas the oxygen of Asp-β-ha may

occupy an axial position leading to a geometry close to square-pyramid. So, the most probable explanation is that Asp-β-ha in $[Cu(dien)(H\text{-}Asp\text{-}\beta\text{-}ha)]^{+}$ coordinates in a bidentate manner through N_{amino} and $O_{carboxylate}$ donor atoms (Scheme 1), whereas three nitrogens of dien complete the coordination in the Cu^{2+} plane. The formation of this complex is reflected by a slight change in visible spectra in comparison with those manifested by $[Cu(dien)]^{2+}$ and $[Cu_5(Asp\text{-}\beta\text{-}ha)_4H_{-4}]^{2-}$ species separately (Fig. 6). The spectrum of this mixed-ligand species exhibits one band with a maximum at 618 nm with $\varepsilon = 75\ dm^3\ mol^{-1}\ cm^{-1}$, which is more asymmetric in the wavelength region 700–900 nm than that for $[Cu(dien)]^{2+}$. Such asymmetry is characteristic of the five-coordinate complexes. The coordination of the

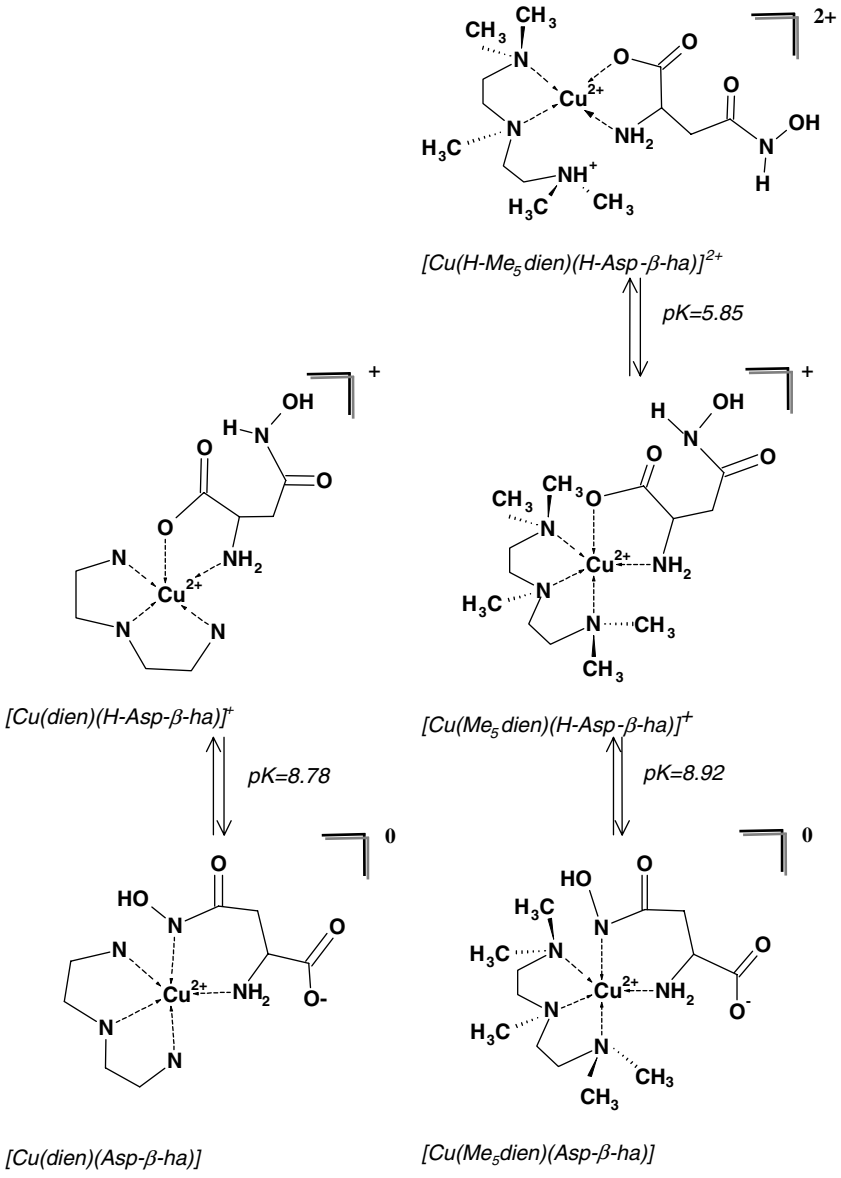
The anisotropic parameters are estimated on the basis of computer simulation of the experimental spectra measured at 77 K. Parameters A are given in $[10^{-4}\ cm^{-1}]$.



Scheme 1.

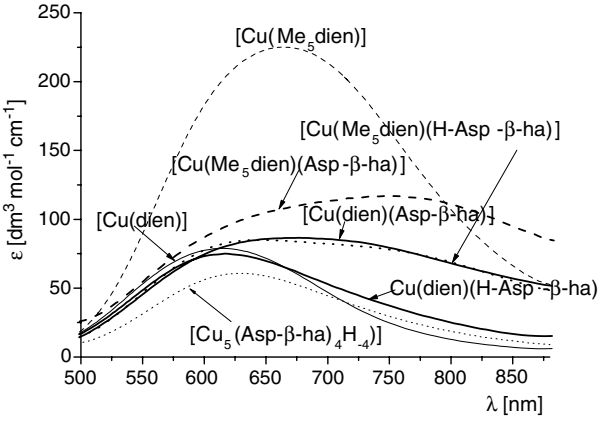


Fig. 6. Calculated electronic spectra of individual mixed-ligand species.

nitrogen donor atom in an equatorial position generally causes a blue-shift (ca. 40 nm) of the d–d absorption band relative to λ_{max} for $[Cu(dien)]^{2+}$, while in an axial position – a red-shift, more widely than for an oxygen donor atom. As a result of the two opposite effects (blue and red-shift), a 7 nm shift to lower energies occurs in λ_{max} of the spectrum for $[Cu(dien)(H\text{-}Asp\text{-}\beta\text{-}ha)]^{+}$ as compared to that for $[Cu(dien)]^{2+}$.

Thus H-Asp-β-ha in $[Cu(dien)(H\text{-}Asp\text{-}\beta\text{-}ha)]^{+}$ is coordinated via $O_{carboxylate}$ and N_{amino} donor atoms in a glycine-like mode (the neutral hydroxamate group is not coordinated), whereas in $[Cu(dien)(H\text{-}\beta\text{-}Alaha)]^{2+}$ it is bound via oxygen donor atoms from the hydroxamate group, and the amino group is protonated [1]. In both cases five-membered chelate rings are formed. A comparison of the basicity-adjusted stability constants

of [Cu(dien)(H-Asp-β-ha)]$^{+}$ and [Cu(dien)(H-β-Ala-ha)]$^{2+}$ shows that the stability of the former complex is lower than that of the latter (Eqs. (6) and (7) in Table 4). This relation is similar to those observed for [Cu(dien)(acetohydroxamic acid)]$^{+}$ and [Cu(dien)(glycine)]$^{+}$, their basicity-adjusted stability constants are −5.67 (obtained from data published in [19]) and −7.42 (obtained from data published in [20]), respectively. From the above considerations it is possible to ascertain that in the ternary Cu^{2+}–dien–Asp-β-ha system at pH ca. 7.5, the glycine-like coordination is chosen for Asp-β-ha, although this group forms less stable complexes.

The deprotonation of [Cu(dien)(H-Asp-β-ha)]$^{+}$ results to the formation of [Cu(dien)(Asp-β-ha)] above pH 8. This process is reflected by a distinct change in visible spectra starting from pH 8 (circles in Fig. 4(a)). Additionally, the isolated electronic absorption spectrum for the [Cu(dien)(Asp-β-ha)] species demonstrates a broad band in the wavelength range 600–800 nm. The EPR spectra at pH 9.7 and 10.6, where [Cu(dien)(Asp-β-ha)] is dominant, (Fig. 5) differ from that at pH about 8 (ascribed to the previous mixed-ligand species) by the presence of a weak rhombic distortion ($A_x \neq A_y$ and $g_x \neq g_y$) together with smaller A_z and g_z parameters. These spectral changes are indicative of some lowering of the geometry from square-pyramid towards trigonal bipyramid. The structural transformation around the copper(II) centre is consistent with participation of the hydroxamate nitrogen instead of the carboxylate oxygen donor atom. The modification of bonding mode from five-membered (N_{amino}, $O_{carboxylate}$) to six-membered (N_{amino}, $N_{hydroxamate}$) chelate-ring leads also to the geometry distortion. The tentative structures for the discussed mixed-ligand species are presented in Scheme 1.

The stability constants obtained for the complexes formed in the Cu^{2+}–Me_5dien–(Asp-β-ha) system are given in Table 4. The concentration distribution curves for this system are presented in Fig. 4(b). From Table 4, it can be seen that the equilibrium model contains parent and mixed-ligand species: [Cu(Me_5dien)(H-Asp-β-ha)]$^{+}$, [Cu(Me_5dien)(Asp-β-ha)], similar to those observed in the Cu^{2+}–dien–Asp-β-ha system, and an additional [Cu(H-Me_5dien)(H-Asp-β-ha)]$^{2+}$ species at lower pH.

The EPR spectra for the Cu^{2+}–Me_5dien–Asp-β-ha system are presented in Fig. 7. At pH 3.19 two sets of signals of parallel and perpendicular orientations should be assigned to the equilibrium between Cu^{2+}-aqua ions ($g_{\parallel} = 2.413$ and $A_{\parallel} = 125 \times 10^{-4}$ cm^{-1}) and the first Cu(II) complex whose parameters ($g_{\parallel} = 2.332$ and $A_{\parallel} = 160 \times 10^{-4}$ cm^{-1}) are consistent with coordination of one chelating H-Asp-β-ha molecule to Cu^{2+}. The spectrum due to the first complex is also seen at pH 3.92 in equilibrium with new spectra. One of them, almost similar to that observed for [Cu(Me_5dien)]$^{2+}$,

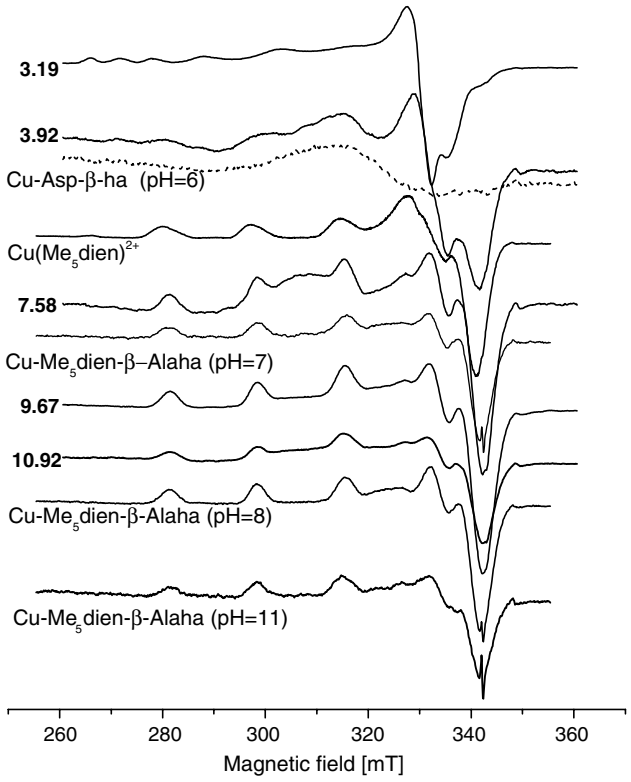

Fig. 7. EPR spectra of Cu^{2+} complexes formed in the Cu^{2+}–Me_5dien–(Asp-β-ha) system as a function of pH. For comparison, spectra for the [Cu(Me_5dien)(H-β-Alaha)]$^{2+}$ and [Cu(Me_5dien)(β-Alaha)]$^{+}$ species are added.

should be assigned to the first mixed-ligand species, [Cu(H-Me_5dien)(H-Asp-β-ha)]$^{2+}$, predicted at this pH. Its spectrum was fitted using axial symmetry parameters ($g_{\parallel} = 2.240$, $g_{\perp} = 2.055$ and $A_{\parallel} = 175 \times 10^{-4}$ cm^{-1}, $A_{\perp} = 15 \times 10^{-4}$ cm^{-1}), whereas for [Cu(Me_5dien)]$^{2+}$ the presence of rhombic distortion is evident ($g_z = 2.240$, $g_x = 2.060$, $g_y = 2.045$ and $A_z = 175$, $A_x = 30$, $A_y = 15 \times 10^{-4}$ cm^{-1} [3]). The EPR parameters suggest that the coordination in the Cu^{2+} plane in this mixed-ligand complex may be realized by two nitrogens of triamine as well as nitrogen and oxygen donors of H-Asp-β-ha. In the pH range 3.9–7 the signals corresponding to the monomeric species are overlapped by the broad line associated with formation of the polynuclear [Cu_5(Asp-β-ha)$_4H_{-4}$]$^{2-}$ complex. The broadening and small intensity of the spectrum results from the strong spin–spin interaction between Cu^{2+} centers. The same weak and broad spectrum is observed at pH 6 in the binary Cu^{2+}–(Asp-β-ha) system (Fig. 7). The change of the EPR spectrum observed at pH 7.58 supports that a new complex, predicted as [Cu(Me_5dien)(H-Asp-β-ha)]$^{+}$, is formed with parameters $g_z = 2.235$, $g_x = 2.055$, $g_y = 2.030$ and $A_z = 174$, $A_x = 30$, $A_y = 15 \times 10^{-4}$ cm^{-1}. A rhombic character of the parameters indicate that the geometry distortion for [Cu(Me_5dien)(H-Asp-β-ha)]$^{+}$ species is higher than for the mixed-ligand complex

containing dien. The visible spectrum, calculated for this complex, shows a broad band in the 600–800 nm range with two shoulders: at 610 nm ($\varepsilon = 85$) and 750 ($\varepsilon = 78$) (Fig. 6) indicating again a rhombic distortion of the geometry towards trigonal bipyramid.

At pH about 11 the intensity of the EPR signals observed for the monomeric species decreases more than two times as compared to that at pH 9.5. This explains the increase of concentration of polynuclear $[Cu_5(Asp\text{-}\beta\text{-}ha)_4H_{-4}]^{2-}$ species in basic solution. Thus, the distribution curve of the pentanuclear species has two maxima and one minimum in which two mixed-ligand species are formed (as observed in our previous work [3]). Such a situation is often observed in various systems in which polynuclear and mixed-ligand species are formed [21].

A comparison of the basicity-adjusted stability constants shows that the stability of $[Cu(Me_5dien)(H\text{-}Asp\text{-}\beta\text{-}ha)]^{+}$ is lower than that for $[Cu(Me_5dien)(H\text{-}\beta\text{-}Alaha)]^{2+}$ (Eqs. (6) and (7) in Table 4). This relation is similar to those observed for $[Cu(Me_5dien)(acetohydroxamic\ acid)]^{+}$ and $[Cu(Me_5dien)(glycine)]^{+}$. Their basicity-adjusted stability constants are −3.18 [22] and −6.61 (calculated from data published in [20]), respectively. Hence, it is possible to ascertain that in the ternary Cu^{2+}–Me_5dien–Asp-β-ha system, at pH ca. 7.5, for Asp-β-ha the glycine-like coordination is chosen which results in formation of less stable complexes as was observed in the ternary systems with dien (see above). An increasing distortion of the $[Cu(Me_5dien)H_2O]^{2+}$ complex geometry in comparison with $[Cu(dien)H_2O]^{2+}$ is the reason for the higher stability of the mixed-ligand complexes with Me_5dien than those with dien (Table 4).

The absorption curve for the next mixed-ligand species, $[Cu(Me_5dien)(Asp\text{-}\beta\text{-}ha)]$, which exhibits a broad band with a maximum at 750 nm, is different from that for the previous species. The molar absorption coefficient, ε, equal to 117 $dm^3\ mol^{-1}\ cm^{-1}$, is higher than for $[Cu(Me_5dien)(H\text{-}Asp\text{-}\beta\text{-}ha)]$. The EPR spectrum (at pH 9.67), corresponding to formation of $[Cu(Me_5dien)(Asp\text{-}\beta\text{-}ha)]$, displays a higher degree of rhombic distortion (Table 5) as compared to that observed for the previous mixed-ligand complex. A similar trend is found for the complexes present in the Cu^{2+}–Me_5dien–β-Alaha system [3]. This spectral behavior reveals a structural transformation around the copper(II) ion, suggesting the participation of all nitrogen-donor atoms in the coordination sphere in the $[Cu(Me_5dien)(Asp\text{-}\beta\text{-}ha)]$ species.

4. Conclusion

In the ternary Cu^{2+}–dien–(Asp-β-ha) and Cu^{2+}–Me_5-dien–(Asp-β-ha) systems at pH ca. 7.5, H-Asp-β-ha coordinates to $[Cu(dien)]^{2+}$ as well as to $[Cu(Me_5dien)]^{2+}$ by the carboxylate group, in addition to the amino nitrogen (glycine-like coordination), whereas the hydroxamate group remains in the form CONHOH. At higher pH the hydroxamate ligand is coordinated by N_{amino} and $N_{hydrox.}$ donor atoms.

The presence of the carboxylate group in Asp-β-ha causes the changes in the bonding mode of Asp-β-ha in the mixed-ligand species in relation to β-Alaha (in the binary systems both aminohydroxamic acids form stable pentanuclear species over a wide pH range). The basicity-adjusted stability constants for the complexes with Asp-β-ha are higher than those with β-Alaha (Eq. (9) in Table 4) because of the neutral charge of $[Cu(amine)(Asp\text{-}\beta\text{-}ha)]$, while the charge of $[Cu(amine)\beta\text{-}Alaha]^{+}$ is positive. An increasing distortion of the $[Cu(Me_5dien)H_2O]^{2+}$ complex geometry in comparison with $[Cu(dien)H_2O]^{2+}$ results in a higher stability of the mixed-ligand complexes with Me_5dien compared to that with dien.

Abstract

The compounds of 1,1-cyclobutanedicarboxylic acid with cobalt(II), copper(II) and zinc(II) ions have been prepared in aqueous solutions. The complexes were characterized by elemental analysis, IR spectroscopy, thermal analysis (TG, DSC/DTA and TG-FTIR) and X-ray analysis. The polycrystalline cobalt(II) and zinc(II) complexes were obtained as the hydrated compounds $Co(C_6H_6O_4)\cdot 2H_2O$ and $Zn_2(C_6H_6O_4)_2\cdot 3H_2O$, whereas the polycrystalline copper compound is anhydrous $Cu(C_6H_6O_4)$. During slow recrystallization we obtained single crystals of cobalt(II) and copper(II) compounds where the number of water molecules is different from that of the polycrystalline compounds and the formula are $[Co_2(C_6H_6O_4)_2(H_2O)_3]$ (**1**) and $[Cu(C_6H_6O_4)H_2O]$ (**2**). The polycrystalline cobalt(II) and copper(II) complexes crystallize in the monoclinic system, the zinc(II) compound crystallizes in the triclinic system. During heating the hydrated complexes lose water molecules and become anhydrous. Next the anhydrous compounds decompose to the corresponding oxides. The thermal decomposition is connected with the release of water molecules (328 K), carbon dioxide (502 K) and cyclobutanecarboxylic acid (546 K). The IR spectra of the salt are discussed.

1. Introduction

There has been major interest in metal carboxylates in the last few years [1–7]. Metal carboxylates exhibit interesting biological properties, antibacterial and antifungal activities. Moreover, the carboxylate ion often participates as an important ligand in many metalloenzymes [4,8–10]. Carboxylate metal complexes are also interesting from a structural point of view. The carboxylate group can adopt a wide range of coordination modes. These are very attractive for the study and design of metal-organic framework solids. Polycarboxylates compounds are of particular significance [9,11].

Metal compounds with 1,1-cyclobutanedicarboxylic are the subjects of our research. The 1,1-cyclobutanedicarboxylate ligand has been often used as a component of platinum complexes, studied as potential antitumor drugs. The most common compound is platinum(II) *cis*-diamin(1,1-cyclobutanedicarboxylate), carboplatin, widely used as a drug in cancer chemotherapy [12–17]. Lanthanide complexes were first studied by us [18,19]. We also studied transition metal compounds. In a previous paper [20], we presented a manganese(II) complex with 1,1-cyclobutanedicarboxylic acid which is isostructural with the cobalt(II) complex ($[Co_2(C_6H_6O_4)_2(H_2O)_3]$) presented in this paper. The manganese(II)

doi:10.1016/j.poly.2005.07.044

complex crystallizes in the monoclinic system and in the space group $C2/c$. The polymeric structure comprises dimeric units bridged by carboxylate groups. The metal ions in dimeric units are bonded with one water molecule and carboxylate groups [20].

The present work reports the properties of cobalt(II), copper(II) and zinc(II) complexes with 1,1-cyclobutanedicarboxylic acid. We have synthesized and characterized the compounds by X-ray crystallography, IR spectra and thermal analysis. Polycrystalline cobalt(II) and copper(II) compounds with 1,1-cyclobutanedicarboxylic acid were also investigated by Allan and Dalrymple [3]. They obtained complexes with a different number of water molecules from that presented in this paper. Polycrystalline cobalt(II) and copper(II) 1,1-cyclobutanedicarboxylates were obtained as monohydrate compounds whereas the complexes synthesized by us are dihydrate and anhydrous, $Co(C_6H_6O_4)\cdot 2H_2O$ and $Cu(C_6H_6O_4)$.

2. Experimental

2.1. Synthesis

1,1-Cyclobutanedicarboxylic acid was dissolved in boiling water and neutralized by the addition of the corresponding metal(II) carbonate. The solution was filtered to remove any excess of metal carbonates and the filtrate was then reduced in volume to yield the polycrystalline metal complexes. The contents of carbon and hydrogen were determined on the basis of elemental analysis using a CHN 2400 Perkin–Elmer analyzer. Chemical analysis confirms the composition (Table 1). Single crystals were obtained by recrystallization from an aqueous solution of the compounds after a few weeks. Crystals were isolated, washed with ethanol and dried at room temperature.

2.2. Magnetism

Magnetic susceptibility measurement was conducted at 294 K using a magnetic susceptibility balance MSB-MKI, Sherwood Scientific Ltd., Cambridge. The data were corrected for diamagnetic susceptibilities. The effective magnetic moment was calculated from the equation $\mu_{eff} = 2.828(\chi_{cor}T)^{1/2}$.

2.3. IR

The IR spectra of complexes were recorded over the range 4000–400 cm^{-1} using a FTIR 1725X Perking–Elmer spectrometer. The samples were prepared as KBr discs.

2.4. X-ray powder diffraction

The powder diffraction data were collected on a PHILIPS XPERT PRO (Holland) automated X-ray diffractometer. The experimental conditions were: Cu target X-ray tube operated at 45 kV and 30 mA, 6° take-off angle, 1° divergence slit, 0.15 mm receiving slit, curved graphite diffracted beam monochromator and scintillation counter with pulse height analyzer. The powder diffraction pattern was collected by step scanning between 4° and 70° in 2θ with a step equal to 0.02° and a count time of 10 s/step. The diffractometer was calibrated by using a SRM 1976 standard. Throughout the measurement, the ambient temperature was maintained at 20 ± 1 °C. The XRAYAN program was used for determining peak intensities and positions. Pattern indexing was carried out with the PC-version of the TREOR program [21]. For this sample, all the 2θ peak positions were used. The unit cell data are presented in Table 2.

2.5. X-ray structure determination

Both crystals, $Co_2(C_6H_6O_4)_2(H_2O)_3]$ (**1**) and $[Cu(C_6H_6O_4)H_2O]$ (**2**), were mounted on a glass fiber and then flash-frozen to 100 K (Oxford Cryosystem-Cryostream Cooler). Preliminary examination and intensity data collections were carried out on a Kuma KM4CCD κ-axis diffractometer with graphite-monochromated Mo Kα radiation. The crystallographic data and the refinement procedure details are given in Table 3. All data were corrected for Lorentz, polarization and absorption effects [22]. The structures were solved by direct methods (program SHELXS97 [23,24]) and refined by the full-matrix least-squares method on all F^2 data using the SHELXL97 [25] programs. Hydrogen atoms were found by Fourier syntheses (all in **1** and OH in **2**) or included in calculated positions (in **2**) with the isotropic thermal parameters

proportional to those of the connected carbon atoms. Unfortunately, we could not obtain untwinned single crystals with a good quality for compound **2**, and the data of the X-ray analysis were poorer than the other crystals. In the case of the structure of the cobalt complex, the water molecule O21 is disordered occupying two statistical positions represented by O21 and O21′ with site occupancy factors of 0.55 and 0.45. Crystal structures of complexes **1** and **2** are shown in Figs. 1–4.

2.6. Thermal analysis

The thermal stability and decomposition of the prepared complexes in air were determined with the aid of Setsys 16/18, recording TG, DTA and DTG curves. Samples (8.24–9.90 mg) were heated in Al_2O_3 crucibles at 293–1273 K in flowing air atmosphere with a heating rate of 10 K min^{-1}. The products of decomposition were calculated from TG curves (Figs. 5 and 6).

Using a Netzsch TG apparatus coupled with a Bruker FTIR IFS66 spectrophotometer, the gas-phase products of decomposition were identified (Fig. 7). The samples (7.40–19.38 mg) were heated to 1250 K, using Al_2O_3 crucibles, in an argon atmosphere, at a heating rate of 10 K min^{-1}.

3. Results and discussion

The polycrystalline 1,1-cyclobutanedicarboxylates of cobalt(II) and zinc(II) were obtained as hydrated

compounds whereas the polycrystalline copper complex is anhydrous. The characterization data of polycrystalline cobalt(II), copper(II) and zinc(II) 1,1-cyclobutanedicarboxylates are listed in Table 1. For cobalt(II) and copper(II) 1,1-cyclobutanedicarboxylates we obtained single crystals. Both single crystals contain a different number of water molecules from that of the polycrystalline complexes. In the case of polycrystalline cobalt(II) 1,1-cyclobutanedicarboxylate $Co(C_6H_6O_4)\cdot 2H_2O$, the molar ratio of metal to water is 1:2 but in the single crystal it is 1:1.5 and general formula is $[Co_2(C_6H_6O_4)_2(H_2O)_3]$ (**1**). Polycrystalline copper(II) is anhydrous whereas the single crystal was obtained as the monohydrate $[Cu(C_6H_6O_4)H_2O]$ (**2**).

The magnetic moment of $Co(C_6H_6O_4)\cdot 2H_2O$ (5.12 μ_B) is in the range of values expected for a high-spin complex. This value indicates the influence of orbital moment on the effective magnetic moment that it is characteristic of cobalt ions with octahedral geometry. The magnetic moment of $Cu(C_6H_6O_4)$ equals 1.94 μ_B. This value is characteristic of an antiferromagnetic compounds of copper.

The IR spectrum of 1,1-cyclobutanedicarboxylic acid shows a strong band, observed at 1698 cm^{-1}, due to COOH-groups. This band is absent in the complexes due to the formation of COO^- groups. Values of the frequency separation ($\Delta\nu$) between COO^- asymmetric and symmetric stretching vibrations $\nu(COO^-)$ can be used for predicting the coordination mode of the carboxyl group. In $Co(C_6H_6O_4)\cdot 2H_2O$, the $\Delta\nu$ value is lower than that of the sodium salt, which suggests that the carboxylate groups are bidentate chelating. In the structure of cobalt(II) 1,1-cyclobutanedicarboxylate, the carboxyl groups occur as monodentate and tridentate-bridging. This disagreement results from the fact that the coupling mode of symmetric $\nu_{as}(COO)$ and $\delta(CH_2)$ makes it difficult to estimate the coordination mode based on the IR spectrum. In $Cu(C_6H_6O_4)$, the asymmetric stretching vibration $\nu(COO^-)$ splits, giving both greater and lower $\Delta\nu$ values than those of the sodium salt. According to Nakamoto [26], they indicate monodentate and chelating carboxyl groups, respectively. In $Zn_2(C_6H_6O_4)_2\cdot 3H_2O$, the asymmetric stretching vibration $\nu(COO^-)$ is also split and the calculated $\Delta\nu$ values are similar and as well as lower than those of the sodium salt. Thus, the COO^- groups can coordinate to the metal atom in a bridging and chelating fashion [26]. The polycrystalline cobalt(II) and zinc(II) compounds spectra show strong bands characteristic for water molecules; the bands at 3404 cm^{-1} for the Co(II) and 3516 cm^{-1} for the Zn(II) complexes are assigned to OH stretching vibrations. This band does not occur the polycrystalline copper(II) compound spectrum.

The X-ray diffraction patterns show excellent quality. The unit cell data are presented in Table 2. The crystal structures of Co(II) and Cu(II) 1,1-cyclobutanedicarboxylates depends on the method of crystallization. During precipitation of the Co(II) compound from aqueous solution there forms a dihydrated complex which crystallizes in the monoclinic system. After dissolution of $Co(C_6H_6O_4)\cdot 2H_2O$ in water and recrystallization we obtained single crystal $[Co_2(C_6H_6O_4)_2(H_2O)_3]$ (**1**) which also crystallize in the monoclinic system. The values of elemental cell parameters of both compounds are similar; they change by about 1%. Engaging one water molecule to bind cobalt ions in dimeric units may cause the decrease of the water molecule number in the monocrystal structure. The polycrystalline $Cu(C_6H_6O_4)$ complex crystallizes in the monoclinic system. Slow recrystallization from the water solution gives a different form of complex. The monocrystal is hydrated $[Cu(C_6H_6O_4)H_2O]$ (**2**) and crystallizes in the orthorhombic system. Polycrystalline zinc(II) 1,1-cyclobutanedicarboxylate crystallizes in the triclinic system.

The crystal structure of compound **1** consists of infinite chains that run parallel to the *a*-axis (Fig. 1), where neighboring chains are connected via hydrogen bonds. A fragment of crystal structure is shown in Fig. 2. The chains comprise dimeric $[Co_2(C_6H_6O_4)_2(H_2O)_3]$ repeating units, which are linked by two carboxylate groups from two different ligands. The cobalt ions in dimeric units are bonded by bridging carboxylate groups and a water molecule, and the distance between them is 3.4995(9) Å. The distance between neighboring Co(II)

atoms in chains is 3.2700(6) Å, the shortest interchain Co···Co separation is 5.3791(12) Å. Each cobalt(II) cation is surrounded by two water oxygen atoms and four carboxylate oxygen atoms from three different 1,1-cyclobutanedicarboxylic anions, exhibiting a significantly distorted octahedron. The Co–$O_{carboxyl}$ distances vary in the range 2.048(2)–2.145(2) Å while the Co–O_{water} bond lengths are 2.140(10) Å for O(21), 2.043(12) Å for O(21)′ and 2.125(1) Å (Table 4). The *cis* angles around the metal center change between 78.58(7)° and 104.10(7)°, whereas the *trans* angles vary from 163.70(7)° to 177.32(5)°. The carboxylate groups in this complex have the tridentate-bridging (O(3)–C(6)–O(4)) and monodentate (O(1)–C(5)–O(2)) character. The carboxylate groups O(3)–C(6)–O(4) and O(1)–C(5)–O(2) are rotated by 60.7(3)° and 57.5(3)° from the C1–C2–C4 plane of the cyclobutane ring. The length of C–O bonds are in the range 1.232(3)–1.291(3) Å and the O–C–O angles are 123.9(2)° and 124.3(2)°. The water molecule, which bridges two metal ions, is located in a particular position on a twofold axis of symmetry. Additionally, this water molecule acts as a proton donor in a strong hydrogen bond; the O(11)–H(1)···O(2) length is 2.610(2) Å. The water molecule O(21) is also engaged in three weak hydrogen bonds as a proton donor; the hydrogen bond length distances are in the range 2.691(10)–3.164(10) Å (Table 5).

The crystal structure of compound **2** comprises a chain in which bridging carboxylate groups bind copper ions. The structure is shown in Figs. 3 and 4. The shorter distance between two neighboring Cu(II) atoms in the chain is 4.8390(5) Å. Each copper ion is surrounded by four oxygen atoms of carboxylate groups from three different 1,1-cyclobutanedicarboxylate ligands and one water oxygen achieves the coordination number 5. The

coordination polyhedron around the Cu(II) ion takes the form of a tetragonal pyramid. The Cu–$O_{carboxyl}$ distances are 1.940(2) and 1.958(2) Å while the Cu–O_{water} bond length is longer, 2.377(4) Å (Table 4). Copper ions, the cyclobutane ring and the water molecule are situated in a particular position on the symmetry plane. The carboxylate groups are located over and under plane. The carboxylate groups in this complex have bidentate bridging character with a *syn-anti* conformation. The lengths of the C–O bond are equal to 1.270(3) and 1.253(4) Å; the O–C–O angles are 122.6(3)°.

The carboxylate groups of 1,1-cyclobutanedicarboxylic ligands take part in hydrogen bond formation as proton acceptors in O–H···O bonds, where a water molecule is the proton donor, but only hydrogen atom H1 is engaged in hydrogen bonds. In the structure of the copper(II) complex, a weak C–H ··· O hydrogen bond is also observed (Table 5).

1,1-Cyclobutanedicarboxylates of cobalt(II), copper(II) and zinc(II) are stable at room temperature (Table 6, Figs. 5 and 6). On heating to about 324–393 K, the hydrated compounds lose the molecules of

water. For the zinc(II) complex and for single crystals of the cobalt(II) and copper(II) compounds the dehydration process proceeds in one stage and the compounds become anhydrous. In the case of polycrystalline cobalt(II) 1,1-cyclobutanedicarboxylate, the dehydration proceeds in two stages; first it loses part of one half the water molecules and then the remaining part of the water molecules. In the first stage, the dehydration process is reflected by the FTIR spectra of the gaseous product decomposition. The characteristic valence and deformation vibration bands of water molecules appear at 328–365 K in the wavenumber ranges 3950–3500 and 2000–1350 cm^{-1}, respectively. These bands do not occur in the FTIR spectra of the gaseous decomposition of $Cu(C_6H_6O_4)$, confirming the anhydrous character of the polycrystalline copper(II) compound (Fig. 7). The anhydrous compounds are stable at 485–541 K, but upon heating above these temperatures they decompose to the corresponding oxides. The polycrystalline cobalt(II) complex decomposes to Co_3O_4 with the intermediate formation of unstable $CoCO_3$. Decomposition is connected with the release of carbon dioxide and cyclobutanecarboxylic acid, and for cobalt(II) also water molecules. The bands characteristic of carbon dioxide molecules appear at 490–530 K in the wavenumber ranges 2350–2250 and 750–600 cm^{-1}, due to valence and deformation vibrations, respectively. At 545–581 K bands characteristic for cyclobutanecarboxylic acid appear in the FTIR spectra of the gaseous products. Bands characteristic for water molecules occurred at 597–722 K in the FTIR spectra of gaseous products of $Co(C_6H_6O_4) \cdot 2H_2O$ decomposition. Above 1100 K Co_3O_4 transforms into CoO. The decomposition scheme for complexes can be presented as follows:

$$Co(C_6H_6O_4) \cdot 2H_2O \xrightarrow{Endo} Co(C_6H_6O_4) \cdot 1.5H_2O \xrightarrow{Endo} CoC_6H_6O_4 \xrightarrow{Exo} CoCO_3 \xrightarrow{Exo} Co_3O_4 \xrightarrow{Endo} CoO$$

$$[Co_2(C_6H_6O_4)_2(H_2O)_3] \xrightarrow{Endo} Co_2(C_6H_6O_4)_2 \xrightarrow{Exo} Co_3O_4 \xrightarrow{Endo} CoO$$

$$Cu(C_6H_6O_4) \xrightarrow{Exo} CuO$$

$$Cu(C_6H_6O_4) \cdot H_2O \xrightarrow{Endo} Cu(C_6H_6O_4) \xrightarrow{Exo} CuO$$

$$Zn_2(C_6H_6O_4)_2 \cdot 3H_2O \xrightarrow{Endo} Zn_2(C_6H_6O_4)_2 \xrightarrow{Exo} ZnO$$

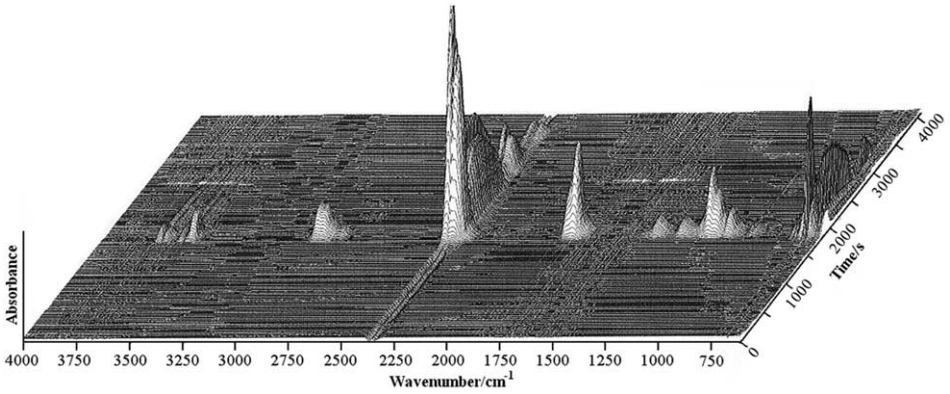

Fig. 7. FTIR spectra of gaseous products from the thermal decomposition of $Cu(C_6H_6O_4)$.

Abstract

The solid state structures of several compounds in the homologous series of alkyltriphenylstannanes of general formula $Ph_3Sn(CH_2)_{n-1}CH_3$ have been determined. For *n* in the range 4–10 the structures are monoclinic with space group $P2_1/c$. For *n* greater than 10 they are, instead, triclinic with space group $P\bar{1}$. The structural difference between the two classes is attributable to a change in the degree of control over the packing of the molecules exerted by the triphenylstannyl entity on the one hand and the alkyl chain on the other.

Keywords: Alkyltriphenylstannane; Homologous series; X-ray structures

1. Introduction

Tetraorganotin compounds, with few recognized exceptions, have near tetrahedral geometries and four coordinate tin centres, even for compounds having quite distinct organic groups, an example being $Ph_3SnCH_2CMe_2Ph$ [1]. The exceptions arise when suitably positioned donor centres are located in the molecules, which allow tin–donor intramolecular interactions. Examples include (*Z*)-3,4,4-trimethylstannyl)-1-pentene-3-ol [2], bis[3-pyridine-2-yl-thien-2-yl]bis(*p*-tolyl)stannane [3] and 1,2:5,6-di-*O*-isopropylidene-3-C-triphenylstannylmethyl-α-D-allofuranose [4].

As part of a study concerned with the properties and structures of organotin compounds having long-chain alkyl groups, we have prepared a number of compounds of general formula $Ph_3Sn(CH_2)_{n-1}CH_3$ (**1**: $n = 4$, 6, 8, 10, 12, 14, 18 and 22). While we understood that the geometries about tin will be distorted tetrahedral in all cases, we wished to investigate such matters as how the alkyl chains, in particular the longer alkyl chains, will pack, the influence throughout the series of π-intermolecular interactions involving the phenyl groups and whether disorder would, in some cases, be an intractable problem. Comparatively few of the solid state structures of **1** have been reported. Indeed, recourse to the Cambridge Structural Database (version 5.26) [5], accessed by means of the Chemical Database Service of the EPSRC [6] reveals only

two relevant entries. These are the structures of ethyltriphenyltin, (**1**: $n = 2$), [7] and triphenyltetradecylstannane, (**1**: $n = 14$), [8]. We now report the solid state structures of (**1**: $n = 4$–12 and $n = 18$). In addition infrared and NMR spectra are reported.

2. Experimental

Infrared spectra were recorded in KBr or CsI disks on a Nicolet-Magna IR 760 instrument. NMR spectra were recorded on Bruker 250 MHz and Varian 400 MHz instruments. Melting points were measured using a Kofler hot-stage microscope.

2.1. Preparation of compounds

To the Grignard reagent from alkyl bromide (4.3 mmol) and Mg (4.5 mmol) in Et_2O (30 ml) was added a solution of Ph_3SnCl (1.54 g, 4.0 mmol) in Et_2O (20 ml). The reaction mixture was refluxed for 30 min and water carefully added. The organic layer was collected, dried over magnesium sulfate and evaporated. The residues were purified by a combination of column chromatography (on silica gel with petroleum ether as eluent) and recystallizations from EtOH.

intensities of the medium-strong bands at 1479 and 1470 cm^{-1} decreased as n increased, such that the 1470 cm^{-1} band was by far the weaker for $n = 4$ but became the more intense for $n = 14$. The weak band at 863–850 cm^{-1} becomes progressively weaker as n increases from $n = 4$.

2.2. X-ray structure determinations

2.2.1. Data collection

Intensity data for all of the structures presented here were obtained with Mo Kα radiation ($\lambda = 0.71073$ Å) from colourless crystals, at 120 K for (**1**: $n = 4$), 100 K for (**1**: $n = 18$) and 150 K for the remainder, by means of the Enraf Nonius Kappa CCD area detector diffractometer of the National Crystallography Centre of the EPSRC at Southampton. Data collection, cell refinement and data reduction were all achieved by means of the programs DENZO [10] and COLLECT [11]. Correction for absorption by comparison of the intensities of equivalent reflections was carried out by means of the program SORTAV [12,13].

2.2.2. Structure solution and refinement

All of the structures were solved by application of the direct methods routine of SHELXS97 [14] and the initial solutions completed and the structures fully refined on F^2 with SHELXL97 [15]. In all cases, in the final stages of refinement, hydrogen atoms were introduced in calculated positions with C–H bond lengths set to 0.95, 0.98 and 0.99 Å for phenyl, methyl and methylene hydrogen atoms, respectively, and refined with a riding model with the isotropic displacement parameter of hydrogen set to 1.5 times for methyl, or 1.2 times otherwise, the equivalent isotropic displacement parameter of the carbon atom to which the hydrogen is attached. The rotational orientation of the methyl groups was also refined. The refinement of the structure of (**1**: $n = 10$) was slightly complicated by disorder over pairs of sites of equal occupancy of carbon atoms C(4), C(6), C(8) and C(10). The disordered atoms in each pair are distinguished by suffix D and E as C(4D)/C(4E) and the disorder taken into account in the placement of the hydrogen atoms. The program ORTEP-3 for Windows [16] was used in the preparation of Figs. 2–5 and PLATON [17] was used to generate the data for

3. Results and discussion

3.1. Synthesis

The Grignard synthesis of compounds, **1**, proceeded readily. However, for the longer chain compounds, i.e. (**1**: $n > 12$), separation from other long chain material, such as any unreacted alkyl bromide or the alkane formed on hydrolysis of the Grignard reagent, was more troublesome and purification required repeated crystallizations. As expected for members of a homologous series, compounds **1** exhibited similar spectral properties, see Section 2. Particularly noteworthy, in this respect, were the IR spectra, in general, and specifically in the NMR spectra, the δ ^{119}Sn values (all ~100 ppm), the $J(^{119,117}\mathrm{Sn}–^{13}\mathrm{C})$ values for the *ipso*-aromatic and α-aliphatic carbons, 478/458 and 398/381 Hz, respectively. It is apparent from these data that the tin environment is similar throughout the studied series.

The melting points of $Ph_3Sn(CH_2)_{n-1}CH_3$ cover a relatively short range, from 49–50 to 75–77 °C. Interestingly, the melting points of **1** show a slight U-shaped dependence on n (Fig. 1), with the lowest melting point obtained for (**1**: $n = 10$). In contrast, the similar shaped graphs for compounds of the series $X(CH_2)_{n-1}CH_3$ (X = H, Br or OH) show overall larger ranges of m.p. and a general increase in m.p. with, however, reducing increments as n is increased (see Fig. 1). For each of the four series, $X(CH_2)_{n-1}CH_3$ (X = H, Br, OH and $SnPh_3$), there appears to be a convergence of melting point values. Of interest, the m.p.s show little differences for $n = 22$ between the values for each series. It is clear that as n increases, the specific effects of the Ph_3Sn group have diminishing influences on the m.p.s.

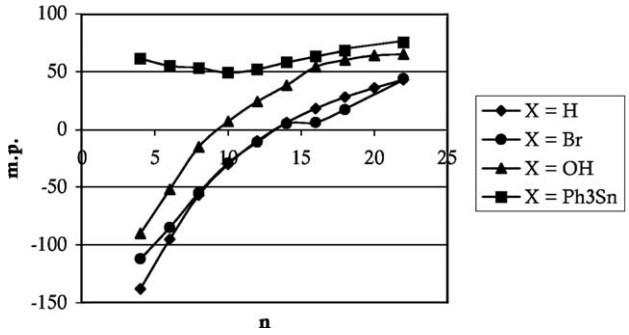

Fig. 1. Melting points (°C) for $X(CH_2)_{n-1}CH_3$ for n even and X = Ph_3Sn, OH, Br and H. See Supplementary Table S1 for numerical values.

The slight U-shaped melting point dependence for the organotin derivatives suggests opposing factors are at play, e.g., as n increases, the significance of the Ph_3Sn moiety is initially reduced and later overtaken by an increasing influence of the long chain alkyl groups. As we now report below, the structure determinations reveal two distinct packing arrangements, with the space group change occurring as n changes from 10 to 12.

3.2. Crystallography

3.2.1. Atom labelling scheme

Fig. 2 shows, as an example of the molecular conformation and atom labelling scheme of the molecules of all of the compounds whose structures are described in this paper, the molecule of (**1**: $n = 8$). In all cases, the carbon atoms of the alkyl group are numbered from 1 to n with C(1) bonded to tin. The sole exception to this is the use of suffices D and E to distinguish between individual atoms in the disordered pairs which, as noted above, occur in the structure of (**1**: $n = 10$). In all cases, the carbon atoms of the phenyl groups are numbered cyclically with C(1) bonded to tin. The phenyl groups are then distinguished by suffix a, b and c. No attempt has been made,

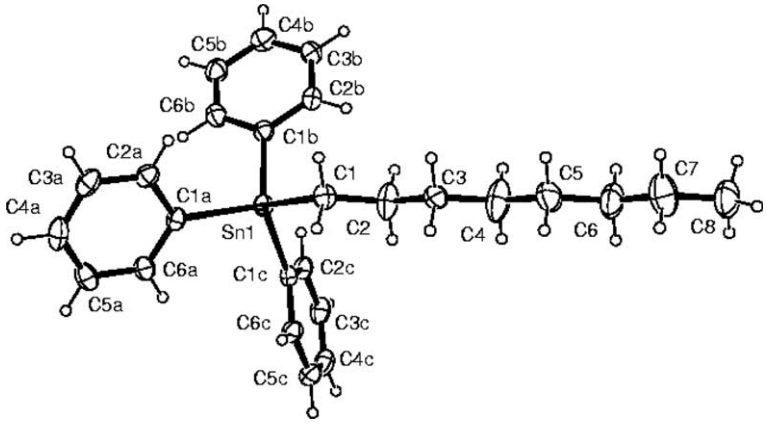

Fig. 2. The labelling scheme exemplified by the molecule of (**1**: $n = 8$). Ellipsoids are drawn at the 30% probability level and hydrogen atoms are shown as small spheres of arbitrary radii.

however, to ensure the use of completely consistent clockwise or anticlockwise cyclical order nor have the suffices been applied with strict regard to subtle variations in the functionality of the phenyl groups.

3.2.2. Molecular geometry

Selected bond lengths and bond angles for the compounds are given in Table 3. In all cases tin is in a slightly distorted tetrahedral environment with, in all but two cases, the Sn–C_{alkyl} bond the longest bond to tin. The C–Sn–C angles are in the range 106.6(2)–113.9(3)°, where these limiting values are found in the data for (**1**: $n = 2$) [7]. The bond lengths and bond angles in the phenyl groups and the alkyl chains are generally within the normal ranges and do not merit detailed discussion although the Sn(1)–C(1)–C(2) angles in the range 113.7(2)–115.6(7)° are of some interest.

3.2.3. Molecular packing and intermolecular contacts

For convenience, in what follows the structures of (**1**: $n = 4$–10) are designated type M (for monoclinic, with space group $P2_1/c$) and those of (**1**: $n = 12$, 14 and 18) type T (for triclinic, with space group $P\bar{1}$).

In the type M structures, as shown for (**1**: $n = 6$) in Fig. 3 in which two adjacent layers are seen edge on, the molecules form layers parallel to (1 0 0) with the alkyl groups directed towards the centre of the layer and the phenyl groups on the layer surfaces. Similar layers

The bond and angle designations are those of (**1**: $n = 8$) as in Fig. 1. The Sn–C_{phenyl} bonds are arranged in increasing order of length and the suffices, as used in the refinements of the structures, are appended to the table entries, where appropriate, in order to identify which C_{phenyl} atoms, and therefore phenyl groups, are involved in each case.

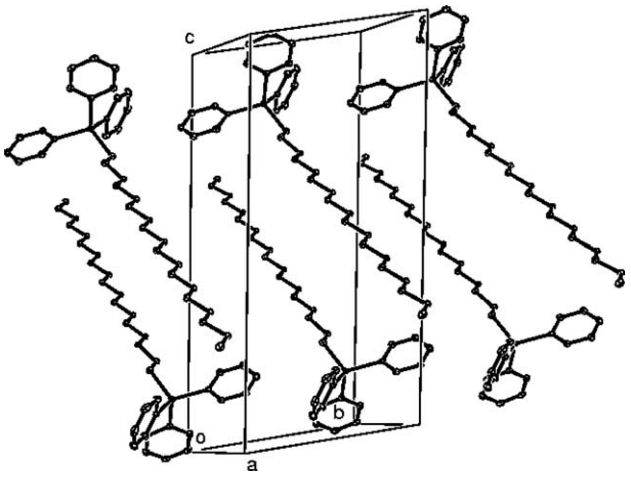

Fig. 4. A section, one unit cell thick in the direction of *a*, through a layer of molecules in a type T structure. The example shown is (**1**: $n = 18$). Ellipsoids are shown at the 20% probability level and hydrogen atoms have been omitted for clarity.

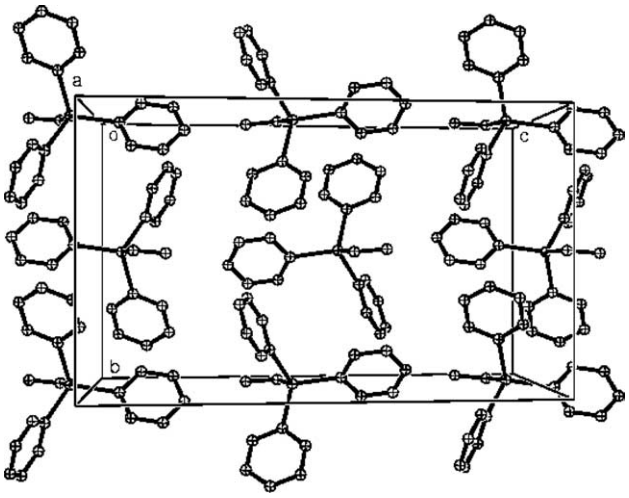

Fig. 5. Molecules in (**1**: $n = 2$) in columns propagated in the direction of *b*. Ellipsoids are shown at the 20% probability level and hydrogen atoms have been omitted for clarity.

(Fig. 4) are found in the type T structures but the layers are much thicker and the alkyl chains oriented in a different manner with respect to the thickness of the layer.

The molecules in the type T structures are packed in layers parallel to (0 0 1). In this case crystallographic centres of symmetry are the only factor, other than unit cell translations, relating the molecules throughout the structure. In the layers of the type M structures, the centrosymmetric relationship between the molecules within the layers is augmented by the operations of a crystallographic *c*-glide plane (extending the layers in the direction of *c*) and a crystallographic twofold screw axis extending the layers in the direction of *b*. The compound (**1**: $n = 2$) [7] is a very different case from the type M and type T structures. Here, although the unit cell is monoclinic the space group is $C2/c$ and the molecules, related to one another by the operation of a crystallographic twofold screw axis, are found in columns (Fig. 5).

Another difference between the type M and type T structures is to be found in the lists of intermolecular C–H···π interactions exemplified in Tables 4 and 5 for (**1**: $n = 8$) and (**1**: $n = 18$), respectively, and available in Supplementary Tables S3–S7 for the other **1** noted in Tables 1 and 2. In the type M structures (Table 4), there are six intermolecular contacts which satisfy the PLATON [17] criteria but only four are found for the type T structures (Table 5). The implication of this is that the presence of the longer alkyl chains in the type T structures creates greater separation between the triphenyl groups at the surface of the layers of molecules. Supplementary Table S2 shows the presence of five C–H···π contacts in the case of (**1**: $n = 2$). Casas et al. [7] have discounted the significance of the C–H···π contacts in the structure of (**1**: $n = 2$) on the grounds of the length of the H···Cg distances but this does not preclude their use as an estimate, allbeit crude, of the degree of association of the phenyl groups.

It is of interest to consider the increment in the volume occupied by a single molecule as the alkyl chain increases in length. In the transition from (**1**: $n = 2$) to (**1**: $n = 4$) it is of the order of only 25 Å^3 which is very small for the addition of two methylene groups when the volume commonly associated with one carbon atom is 20 Å^3. In this case the lengthening of the alkyl chain

is, however, accompanied by a dramatic change of structure and of the way in which the molecules pack together. As n increases from 4 to 10 the volume changes start at 52 $Å^3$ and reduce progressively to 49 $Å^3$. On further increase of chain length from 10 to 18 the volume changes remain comparatively constant in the range 41–44 $Å^3$, now much as would be expected for a two carbon increment in chain length. These changes in the volume of individual molecules suggest that in (**1**: $n = 12$–18) increase in alkyl chain length has no more effect than to increase the thickness of the layers of molecules. The small volume increase as n changes from 2 to 4 is accounted for, in general terms, by the change in molecular packing which occurs at this point. The comparatively large, but decreasing, volume changes accompanying the change of n from 4 to 10 is taken to imply optimum packing of the phenyl groups accompanied by comparatively inefficient packing of the alkyl chains, culminating in the disorder in the alkyl chain for (**1**: $n = 10$) noted above.

4. Conclusions

The occurrence of the minimum m.p. at (**1**: $n = 10$) and the abrupt change in symmetry from monoclinic to triclinic as n changes from 10 to 12 are clearly indicative of a significant change in molecular packing at the break-point. The decrease in m.p. accompanied by rather large, but decreasing, values of incremental changes in volume per molecule as n changes from 4 to 10 suggests that in this region the increase in chain length is accommodated in a comparatively inefficient manner which increases the internal energy of the structure without affecting the packing of the Ph_3Sn groups. For $n = 12$ and upwards, however, the comparatively regular increase in m.p. with increasing molecular weight is characteristic of a homologous series in which van der Waals interactions are becoming increasingly important as the number of atoms increases as shown, for example, by the alkane series (X = H) in Fig. 1. This taken together with the more or less constant incremental molecular volume suggests that efficient packing of the alkyl chains is now in operation.

Abstract

Two dinucleating ligands $H_3L_I^x$ (subscript I for imidazolidine; $x = 1, 2$) having pendant imidazolidine rings have been reacted with cobalt salts in aqueous methanol at room temperature to obtain the mononuclear complexes $[Co^{III}L^1]Cl \cdot 2H_2O$ ($\mathbf{1} \cdot 2H_2O$) and $[Co^{III}L^2]ClO_4 \cdot H_2O$ ($\mathbf{2} \cdot H_2O$) of hydrolyzed ligands H_2L^x. Expected dicobalt complexes were not obtained due to the coordination induced hydrolytic cleavage of the central substituted imidazolidine rings. The complexes $\mathbf{1} \cdot 2H_2O$ and $\mathbf{2} \cdot H_2O$ were structurally characterized by X-ray crystallography. Both *mer*- and *fac*-ON_2 binding modes of the two halves of the hexadentate ligands have been identified in these complexes. The mononuclear complexes have CoN_4O_2 coordination spheres with a N_4O_2 donor atom set of the two hexadentate ligands, forming isomeric distorted octahedral coordination geometries around the metal atoms. As a result, the imine nitrogen pairs coordinated trans to each other in $[CoL^1]^+$, whereas the phenolic oxygens are trans in $[CoL^2]^+$. In complex $\mathbf{1} \cdot 2H_2O$ the average Co–N(imine), Co–N(amine), and Co–O(phenolate) distances are 1.910, 1.959, 1.894 Å, respectively, and in $\mathbf{2} \cdot H_2O$ the corresponding average distances are 1.944, 1.991 and1.887 Å, respectively. Both the cobalt(III) complexes are diamagnetic. The UV–Vis spectra of the end products, after the imidazolidine ring hydrolysis, is different from the spectrum of the initial reaction mixture containing the μ-bis(tetradentate) ligands, $H_3L_I^x$ ($x = 1, 2$) and metal salts.

1. Introduction

Among various products from the condensation of aromatic aldehydes with α,ω-tetramine containing both primary and secondary amino groups is a binucleating Schiff base ligand with a in-built spacer imidazolidine ring, which can take up two same or different metal ions [1,2]. Chiral imidazolidine ring grafted ligands are important for the development of various enantioselective catalysts [3]. Intermolecular nucleophilic attack on incoming aldehyde carbon atom by imine nitrogens of the parent hexadentate ligand lead to the formation of saturated heterocyclic ring in place of the ethylenediamine part of the parent hexadentate ligands. Terminal imidazolidine rings are not formed in the first step of reaction with 2-hydroxy benzaldehyde/acetophenone as observed previously with 2-pyridinecarboxaldehyde-*N*-oxide [4]. The use of such binucleating ligands for

doi:10.1016/j.poly.2005.07.030

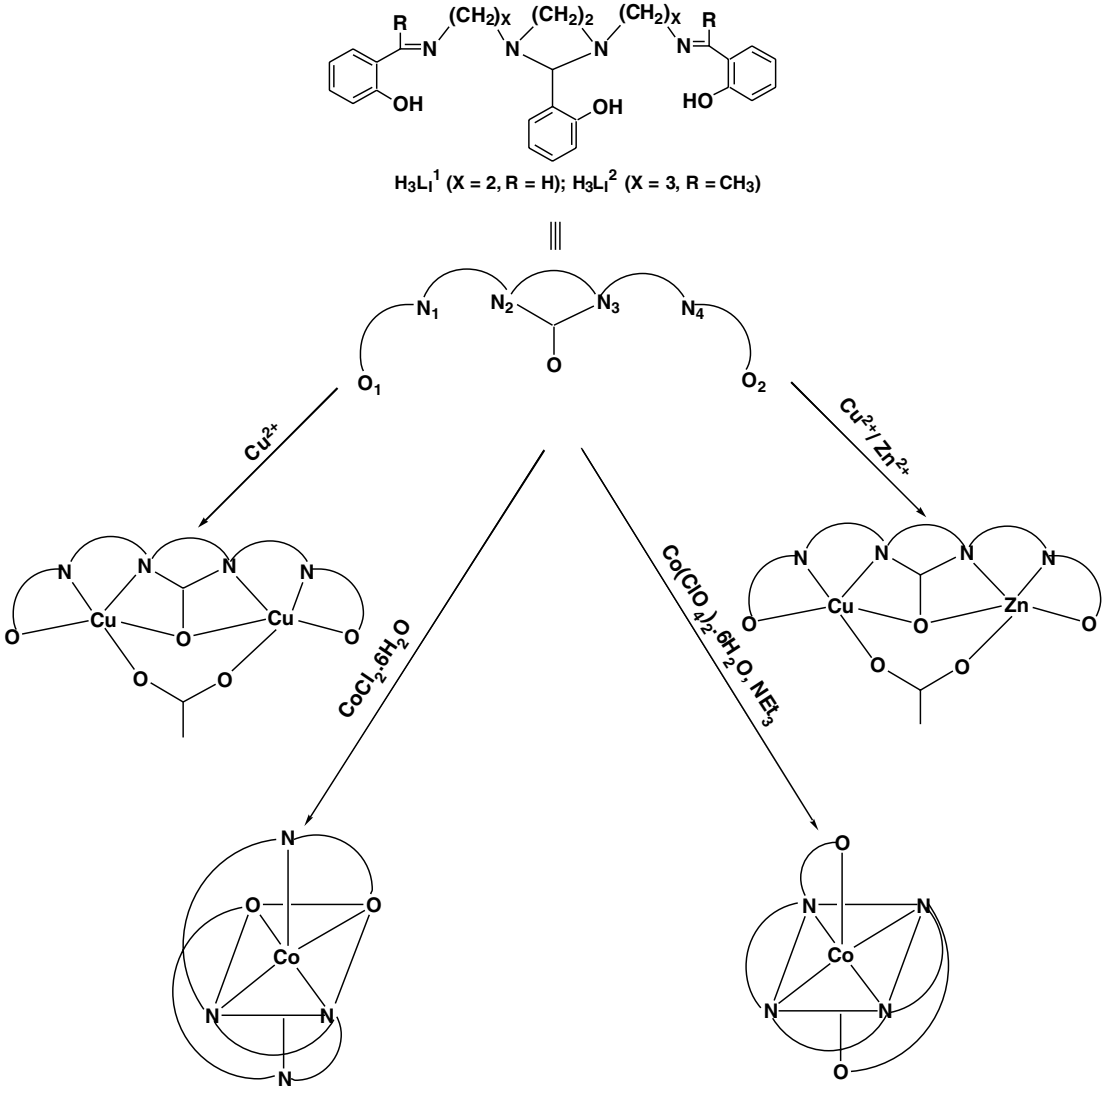
the synthesis of new family of di-3d-metal complexes has been receiving considerable attention in recent years. In view of the importance of the imidazolidine ring formation and its cleavage in various fields, [3] we examined the complexation behavior of two 2′-hydroxy-2-phenyl imidazolidine ring containing ligands toward cobalt salts to identify the stabilization of the ligand heterocyclic backbone to bridge hard cobalt(III) ions.

In the present work a pair of functionally dinucleating bis(tetradentate) type ligands incorporating amine, imine, and phenol functions have been used for mononuclear binding of cobalt(III) ions establishing the selective role of metal ions for ligand hydrolysis. As a result the corresponding Co_2^{II} or Co_2^{III} complexes are not obtained in this study (Scheme 1). Both the mononuclear complexes, as the end products of the complexation reactions, have been structurally characterized revealing the $Co^{III}N_4O_2$ coordination spheres in two different geometrical forms. The meridional or facial coordination of the ONN halves of the ligands, before hydrolysis, does not contribute much to the imidazolidine ring stabilization. In dinuclear $Cu^{II}Zn^{II}$ and $Cu^{II}Cu^{II}$ complexes this coordination was meridional due to the presence of semi-rigid imidazolidine ring. We report the synthesis and structural characterizations of two isomeric mononuclear cobalt complexes as the end product of the reactions of known H_2L^1 and hitherto unknown H_2L^2 ligands with two different cobalt salts.

2. Experimental

2.1. Physical measurements

Triethylenetetramine (trien) was obtained from S.D.Fine Chem, India. Salicylaldehyde and Cobaltous



Scheme 1.

chloride were purchased from SRL, India. All other chemicals and solvents were reagent grade materials and were used as received without further purification. Purification of acetonitrile and preparation of tetraethylammonium perchlorate (TEAP) for electrochemical work was performed as reported in the literature [5]. Microanalyses (C, H, N) were performed using a Perkin–Elmer 240C elemental analyzer. IR spectra were obtained on a Perkin–Elmer 883 spectrometer (200–4000 cm^{-1}) prepared as KBr pellets. The commercial grade KBr was used after being dried in air oven at 110 °C followed by cooling to room temperature in a desiccator before use. Electronic spectra were recorded on a Shimadzu UV/Vis/NIR 3100 (190–3200 nm) (1 cm quartz cell) spectrophotometer. Diamagnetic corrections for ligand susceptibilities were made using Pascal's constants. ^1H and ^{13}C NMR spectra were obtained on a Bruker AC 200 NMR spectrometer using TMS as the internal standard. 2D CH-COSY spectrum is recorded on Brucker DRX-400 spectrometer. Electrochemical measurements were made using a PAR model 173 potentiostat/galvanostat, 175 universal programmer, 178 electrometer, and 377-cell system. A planar Beckman 39273 platinum disk working-electrode, a platinum-wire auxiliary-electrode, and an aqueous saturated calomel reference electrode (SCE) were used in a three-electrode configuration. A digital series 2000 Omni Graphic recorder was used to trace the voltammograms. Electrochemical measurements were made under a dinitrogen atmosphere. All chemical data were collected at 298 K and are uncorrected for junction potentials. Solution electrical conductivity was measured using a Unitech type UI31C digital conductivity meter with a solute concentration of about 10^{-3} M.

2.2. Preparation of $H_3L_I^1$

The ligand has been prepared following a modified literature procedure [6]. The product was collected by filtration, washed with hexane, diethyl ether and dried in air. Comparing the analytical and spectroscopic data with the literature values has checked identity and purity of the ligand.

2.3. Preparation of $H_3L_I^2$

A solution of *N*,*N*′-bis-(3-aminopropyl)ethylenediamine (2.0 g, 11.47 mmol) in methanol (50 ml) was added to a solution of 2-hydroxyacetaphenone (3.1 g, 22.95 mmol) in methanol (20 ml). The resulting pale-yellow solution was refluxed for ca. 5 h to give a yellow solid (H_2L^2) on evaporation. The product was isolated by filtration, washed with Et_2O, and finally dried in vacuo over fused $CaCl_2$ for a total yield of 4.0 g (86%), m.p. 89–90 °C. $C_{24}H_{34}N_4O_2$ (410.27): Calc. C, 70.21; H, 8.35; N, 13.65. Found: C, 70.06; H, 8.26; N, 13.57%. Mass spectrum (EI): *m*/*z* 410 ($M^+ = L^+$); Relative intensity of $M^+ = 40\%$. Infrared spectrum (cm^{-1}, KBr disk): *ν*(phenolic OH) 3439(b); *ν*(C=N) 1604(s); *ν*(phenolic CO) 1445(s); *ν*(CH_2) 850(m); *ν*(aromatic CH) 753(s). ^1H NMR ($CDCl_3$, ppm): *δ*(phenolic OH) 16.35(s, 2H); (H_8) 3.63 (t, 4H); (H_{25}) 6.69–7.51 (m, 8H); (H_9) 1.68 (m, 4H); (H_{10}) 2.73 (t, 4H); (H_{11}) 1.98 (t, 4H); (H_{12}) 2.33 (s, 6H); (amine NH) 2.63 (s, 1H). ^{13}C NMR ($CDCl_3$, ppm): *δ* (C_1) 157.16; (C_2) 116.80; (C_3) 131.92; (C_4) 121.77; (C_5) 128.06; (C_6) 123.40 (C_7) 161.07; (C_8) 43.52; (C_9) 30.62; (C_{10}) 46.38; (C_{11}) 49.96; (C_{12}) 14.21.

In the next step, a solution of salicylaldehyde (0.3 g, 2.43 mmol) in methanol (25 ml) was added to the solution of H_2L^2 (1 g, 2.43 mmol) in methanol (25 ml). The yellow solution was then stirred at room temperature for 30 min to give a yellow solid ($H_3L_I^2$). The product was isolated by filtration, washed with water and hexane, and finally dried in vacuo over fused $CaCl_2$ for a total yield of 1 g (78%), m.p. 160 °C. $C_{31}H_{38}N_4O_3$ (514.66): Calc. C, 72.35; H, 7.44; N,10.89; found C, 72.51; H, 7.32; N, 10.51%. Mass spectrum (EI): *m*/*z* 514 ($M^+ = L^+$); Relative intensity of $M^+ = 40\%$. Infrared spectrum (cm^{-1}, KBr disk): *ν*(phenolic OH) 3418(b); *ν*(C=N) 1625(s); *ν* (phenolic CO) 1438(s); *ν*(CH_2) 877(m); *ν*(aromatic CH) 753(s). ^1H NMR ($CDCl_3$, ppm): *δ*(terminal phenolic OH) 16.62(s, 2H); *δ*(pendent phenolic OH) 10.95(s, 1H); (H_8) 3.53 (m, 4H); (H_{16-19}) 7.22–7.46 (m, 8H); (H_9) 1.72 (m, 4H); (H_{10}) 3.32 (t, 4H); (H_{11}) 2.37 (m, 4H); (H_{12}) 2.22 (s, 6H); (H_{13}) 3.67 (s, 1H); (H_{2-5}) 6.58–6.94 (m, 4H); ^{13}C NMR ($CDCl_3$, ppm): *δ* (C_1) 157.96; (C_{15}) 165.68 (C_2) 118.43; ($C_{3,5}$) 121.09; (C_4) 117.51; (C_6) 132.40; (C_7) 171.28; (C_8) 44.52; (C_9) 28.70; (C_{10}) 46.38; (C_{11}) 49.96; (C_{12}) 14.21; (C_{13}) 89.55; (C_{14}) 129.91; (C_{16}) 132.37 (C_{17}) 134.87; (C_{18}) 127.43; (C_{19}) 129.76.. UV–Vis spectra (MeOH), [λ_{max}, nm (*ε*, 1 mol^{-1} cm^{-1})]: 389 (9980), 273 (18 880), 254 (18 645).

2.4. Preparation of $[Co^{III}L^1]Cl \cdot 2H_2O$

To a solution of $H_3L_I^1$ (0.5 g, 1.09 mmol) in methanol (30 ml), aqueous solution of $CoCl_2 \cdot 6H_2O$ (0.5 g, 2.18 mmol) was added dropwise with stirring. The reaction mixture was then stirred at ambient temperature for 2 h. Resulting deep brown color solution was then evaporated in air. The brown color solid separated was collected by filtration through glass frit and washed thoroughly with hexane.The compound was finally dried in vacuo over P_4O_{10}. Yield: 0.6 g (95%). *Anal*. Calc. for $C_{20}H_{26}ClCoN_4O_4$ (480.89): C, 49.95; H, 5.45; N, 11.65; Co, 12.26. Found: C, 49.96; H, 5.69; N, 11.45; Co, 11.80%. IR (KBr, cm^{-1}): $\nu = 3376$(s), 1632(vs), 1597(vs), 1535(s), 1452(s), 1306(s), 1203(s), 1057(s), 760(vs). Molar conductance, Λ_M: (MeOH solution) 95 Ω^{-1} cm^2 mol^{-1}. UV–Vis spectra [λ_{max}, nm (*ε*, 1 mol^{-1} cm^{-1})]: (MeOH solution) 605 (180), 490 (500), 392 (1706), 251 (17 515), 219 (17 071).

2.5. Preparation of $[Co^{III}L^2]ClO_4 \cdot H_2O$

To a solution of $H_3L_I^2$ (0.5 g, 0.97 mmol) in methanol (30 ml), aqueous solution of $(Co(ClO_4)_2 \cdot 6H_2O)$ (0.6 g, 2.18 mmol) was added dropwise with magnetic stirring during 15 min. After half-an-hour, a methanolic solution of NEt_3 (0.2 g, 1.16 mmol) was slowly added to the previous solution during 10 min. The reaction mixture was then stirred for another 30 min. The deep green color solid was separated on solvent evaporation in air. The product was collected by filtration through glass frit and washed thoroughly with hexane. The compound was finally dried in vacuo over P_4O_{10}. Yield: 0.5 g (82%). *Anal.* Calc. for $C_{24}H_{32}ClCoN_4O_7$ (582.98): C, 49.44; H, 5.53; N, 9.61; Co, 10.11. Found: C, 49.56; H, 5.69; N, 9.56; Co, 10.20%. IR (KBr, cm^{-1}): $\nu = 3480$(s), 1597(vs), 1547(s), 1438(s), 1327(s), 1106(vs), 760(s), 607(s). Molar conductance, Λ_M: (MeOH solution) 92 Ω^{-1} cm^2 mol^{-1}. UV–Vis spectra [λ_{max}, nm (ε, 1 mol^{-1} cm^{-1})]: (MeOH solution) 630 (212), 555 (259), 386 (5182), 438 (2327).

2.6. X-ray data collection and structural determination

Diffraction data for complexes $\mathbf{1} \cdot 2H_2O$ and $\mathbf{2} \cdot H_2O$ were collected at 293(2) K on Bruker-Nonius Mach3 CAD4 X-ray diffractometer using graphite-monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The intensities of three reference reflections of each complex were monitored every one-hour though out the data collection shows no sign of crystal deterioration. The structures was solved by direct method SHELXS-97 [7], followed by successive Fourier synthesis and least-square refinement using SHELXS-97 program [8]. Direct phase determination yielded Co, and most of the C, N, O atoms. Anisotropic thermal parameters are used for the nonhydrogen atoms and isotropic parameters for the hydrogen atoms. For the complex $\mathbf{2} \cdot H_2O$ the two hydrogen atom of the uncoordinated water molecule were detected in the process of successive refinement stages during structure determination. The crystallographic data and other pertinent information are summarized in Table 1. Due to the crystal instability absorption correction was not applied on the collected reflections, as a result the minute hole seems to be big.

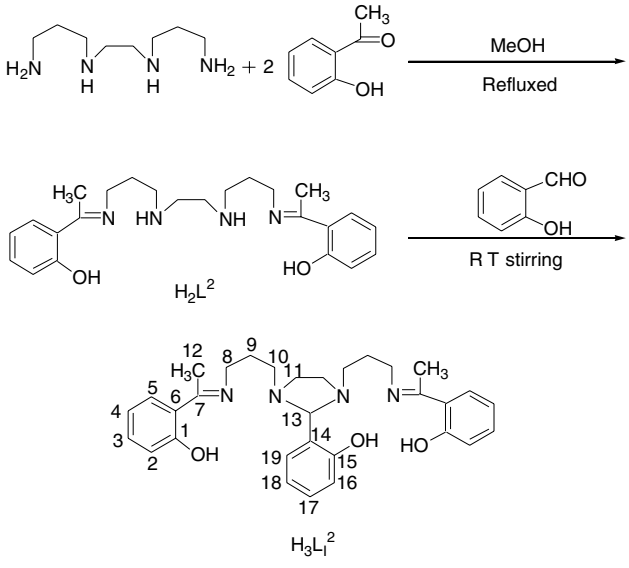
3. Results and discussion

3.1. Synthesis

The ligands used in this work belong to a family of μ-bis(tetradentate) type with a semi-rigid 2-hydroxyphenyl substituted five-membered imidazolidine spacer and has easy synthetic accessibility. The five-membered imidazolidine ring is introduced inside the hexadentate precursor to act as a spacer-cum-bridging-cum-heterocyclic backbone unit. The ligand $H_3L_I^2$ is new. Earlier we reported a similar symmetrical binucleating ligand having unsymmetrical compartments containing 1-methyl-3-oxobut-1-enyl end groups [9]. Synthesis of $H_3L_I^2$ has been achieved by the introduction of 2-hydroxy phenyl substituted imidazolidine ring in the second step of the reaction with 2-hydroxy benzaldehyde as shown in Scheme 2. Terminal imidazolidine rings are not formed at the two ends of the tetramine during ligand synthesis, which is also another possibility.



Scheme 2.

The ligand $H_3L_I^2$ is characterized by elemental analysis, IR, ^1H, ^{13}C and CH-COSY NMR and mass spectral analyses. In IR spectrum, a strong band at 1625 cm^{-1} indicates the $\nu_{C=N}$ stretching frequency. The ^1H NMR spectrum of $H_3L_I^2$ in $CDCl_3$ shows a characteristic signal of the imidazolidine ring proton (H_{13}) at 3.67 ppm. The 2D CH-COSY NMR spectrum confirms the atom connectivity of $H_3L_I^2$ as assigned from the ^1H and ^{13}C spectra. In COSY the signal at δ 171.28 is due to the imine carbon C_7 and at 165.68 and 157.96 are for C_{15} and C_1 which are not connected to any proton (Fig. 1). The signals at δ 134.87, 132.37, 129.91 and 127.43 is due to the pendent phenolic carbons (C_{16-19}) attached to the protons (H_{16-19}) at δ 7.22–7.46 and the next four signals at 121.09 (two peaks), 118.43 and 117.51 are due to the terminal phenolic carbons (C_{2-5}) attached to the protons (H_{2-5}) at δ 6.58–6.94. The peak at δ 89.55 is assigned to the C_{13} attached to H_{13} at δ 3.67 ppm. The δ 49.96 peak corresponds to C_{11} bonded to H_{11} (δ 2.37 ppm). The peaks at δ 46.38 and 44.52 are due to C_{10} and C_8 connected to the respective protons at δ 3.32 and 3.53, respectively. Among the up field signals the peak at δ 28.70 can be assigned to the carbon C_9 connected to the corresponding proton at δ 1.72 ppm and the most up field peak at δ 14.21 is for the methyl carbon C_{12} connected the protons at δ 2.22 ppm.

In mass spectrum the molecular ion peak (*m*/*z*) is observed at 514, which indicates the formation of the desired imidazolidino Schiff base ligand.

The mononuclear complexes have been obtained by reacting the ligands with cobalt(II) chloride hexahydrate and cobalt(II) perchlorate hexahydrate, respectively, in aqueous methanol in air. All the solution measurements reported in this work were made in methanol and DMF. Two $Co^{III}N_4O_2$ complexes of the parent hexadentate ligands (H_2L^1 and H_2L^2) have been obtained from two binucleating ligands $H_3L_I^1$ and $H_3L_I^2$. The phenyl substituted imidazolidine rings are removed completely instead of reductive-cleavages to any 2-hydroxy-*N*-benzyl derivative of the parent hexadentate ligand [10]. Recently, similar trisphenolate ligand was reported from borohydride reduction of imidazolidino reduced Salen ligand [11]. The mononuclear complexes having $Co^{III}N_4O_2$ coordination sphere have been structurally characterized to establish the coordination driven imidazolidine ring hydrolysis.

3.2. Crystal and molecular structures of the complex

Atom labeling scheme and molecular views of the mononuclear complexes is shown in Fig. 2. Selected bond lengths and angles around the metal center are listed in Table 2. Both the monomeric complexes are composed of an approximate octahedral $[Co^{III}L^{1-2}]^+$ cation with Cl^- and ClO_4^- anions. The metal center in

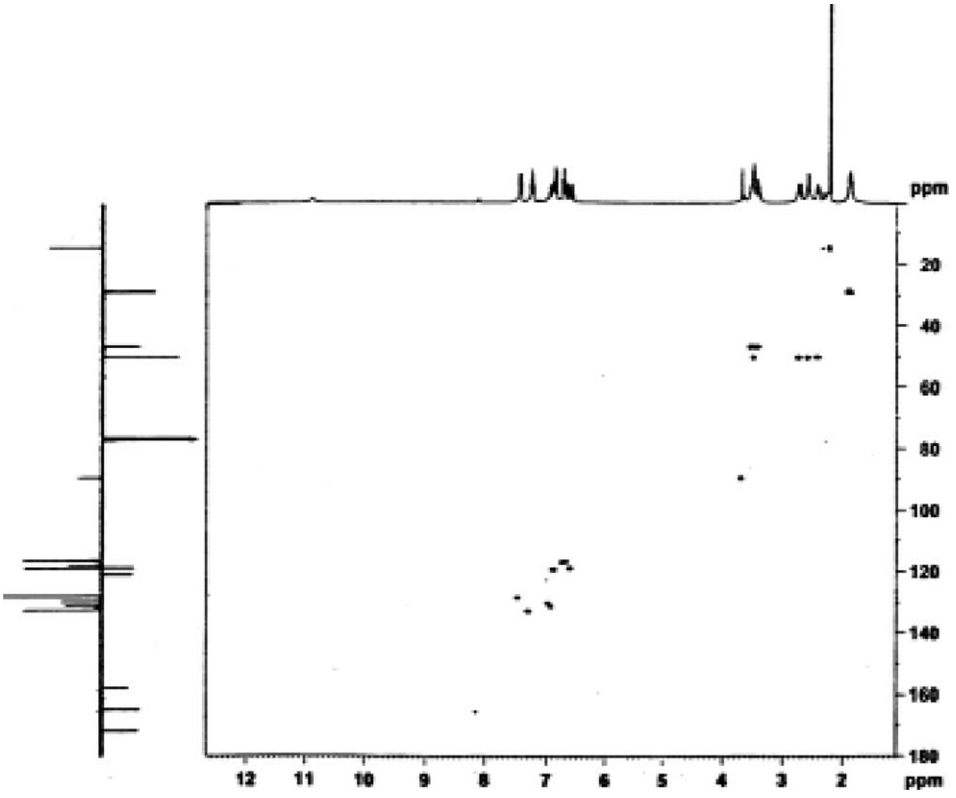


Fig. 1. 2D CH-COSY spectrum of $H_3L_I^2$ recorded on Bruker DRX-400 specrtometer in $CDCl_3$.

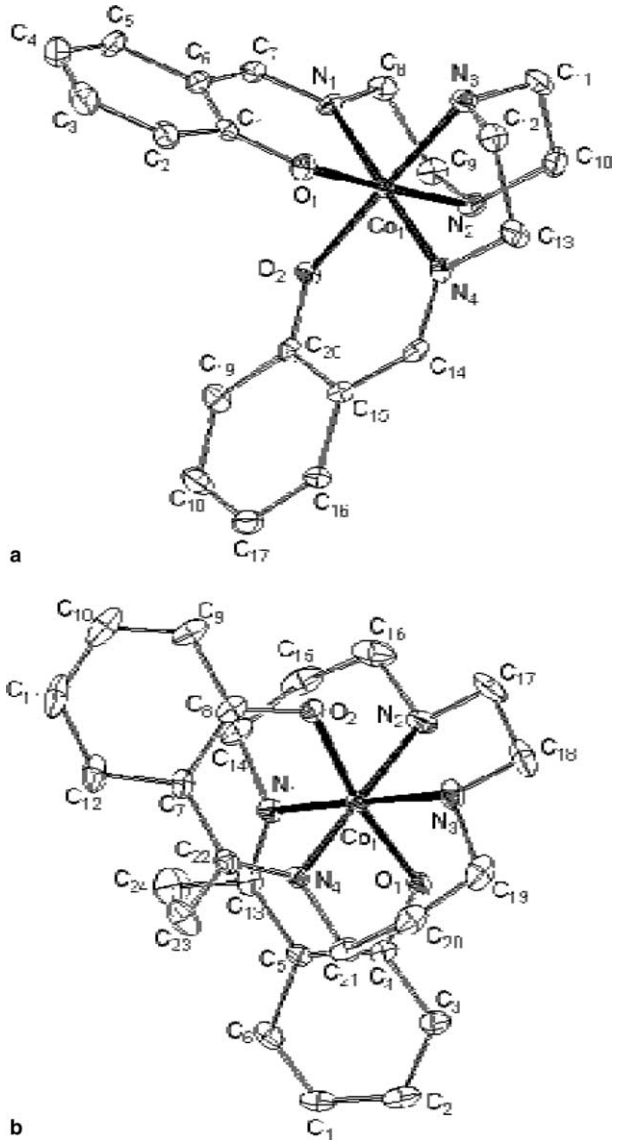

Fig. 2. ORTEP views of (a) $[Co^{III}L^1]^+$ and (b) $[Co^{III}L^2]^+$ cations with atom numbering scheme and thermal ellipsoids drawn at 30% probability level. Hydrogen atoms are omitted for clarity.

both the structures are in distorted octahedral CoN_4O_2 environment from two different types of ligand chelation. There are, however, four ways in which the linear tetramine based hexadentate ligand can span octahedral position through meridional (A) and facial (B–D) (Chart 1) binding of two tridentate N_2O halves of

hexadentate ligands. Out of three possible structures B–D in facial binding mode only B is obtained exclusively. The fundamental geometric difference between the two structures lies in the isomeric nature of coordination spheres. The imine nitrogen pairs are coordinated trans to each other in $\mathbf{1} \cdot 2H_2O$, and the remaining four atoms (two cis amine and two cis phenolic oxygen) complete the coordination sphere where as the phenolic oxygens are trans in $\mathbf{2} \cdot H_2O$ and the remaining four nitrogen atoms (two cis amine and two cis imine) complete the coordination sphere. The two coordinating ONN ligand halves are meridional in complex

$\mathbf{1} \cdot 2H_2O$ but are facial in complex $\mathbf{2} \cdot H_2O$ The difference is sustained by the greater flexibility of the trimethylene chains compared to dimethylene chains. Of the five chelate rings two are six-membered and three are five-membered in complex $\mathbf{1} \cdot 2H_2O$, and the corresponding numbers in complex $\mathbf{2} \cdot H_2O$ are four and one, respectively. The dimethylene bridges in complex $\mathbf{1} \cdot 2H_2O$ have the gauche configuration, and the six-membered trimethylene containing rings in complex $\mathbf{2} \cdot H_2O$ have chair like configurations.

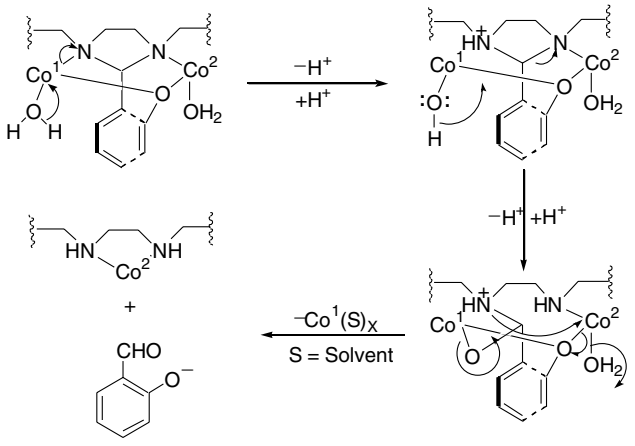
The coordinated $\geq$C=N– pairs from the terminal imine groups with the two adjacent carbon atoms, in both the complexes, are planar within experimental error. The Co–N(imine) bond distances are equal 1.910 (4) Å in complex $\mathbf{1} \cdot 2H_2O$ and 1.940 (7), 1.949 (8) in complex $\mathbf{2} \cdot H_2O$ which are significantly shorter than Co–N(amine) distances 1.958 (4), 1.960 (4) Å in $\mathbf{1} \cdot 2H_2O$ and 2.012 (9), 1.970 (8) Å in $\mathbf{2} \cdot H_2O$. The Co–O(phenolic) distances lie in the range 1.882(6)–1.905(3) Å which are consistent with those reported for other similar structurally characterized mononuclear Schiff base Co^{III} complexes [12]. The facial chelation of ONN halves in $\mathbf{2} \cdot H_2O$ is responsible for greater N–C–C–N torsion angle (57.82°) of the central ethylenediamine part of H_2L^2 compared to meridional spanning of H_2L^1 in $\mathbf{1} \cdot 2H_2O$ (37.74°).

Intramolecular hydrogen bonding is observed between the Cl^- anions with the amine nitrogen and uncoordinated water molecule in complex $\mathbf{1} \cdot 2H_2O$. The same uncoordinated water molecule forms intermolecular hydrogen bonding with the amine nitrogen atom of the neighboring molecule to form hydrogen bonded chain like structure as shown in the Fig. 3. No hydrogen bonding is observed between ClO_4^- anion and the uncoordinated water molecules in complexes $\mathbf{2} \cdot H_2O$, in which the perchlorate anion is at a distance of 3.835 Å from the uncoordinated water molecule.

There are significant difference in bond lengths between the equatorial Co–O(phenolic), Co–N(amine) pairs and the axial Co–N(imine) pairs in complex $\mathbf{1} \cdot 2H_2O$ as well as in the equatorial Co–N(imine), Co–N(amine) pairs and the axial Co–O(phenolic) pairs in complex $\mathbf{2} \cdot H_2O$. The chloride and perchlorate anions are at 4.495 and 4.692 Å distance from the cobalt centers in $\mathbf{1} \cdot 2H_2O$ and $\mathbf{2} \cdot H_2O$, respectively. The perchlorate ion in the complex $\mathbf{2} \cdot H_2O$ have the expected regular tetrahedral geometry, with the average Cl–O bond lengths and the average O–Cl–O bond angles of 1.326 Å and 108.40°, respectively. Oxygen disorders are not observed, which is very common otherwise.

3.3. Stability of the imidazolidine ring towards cobalt(III) coordination

In solution, the expulsion of one mole of 2-hydroxy benzaldehyde molecule takes place when cobalt(III) ions react with the ligands $H_3L_I^1$ and $H_3L_I^2$, which are different from the selective imidazolidine ring opening reaction as observed earlier in a different ligand system with no loss of aldehyde molecule [4]. This type of imidazolidine ring-cleavage reaction with removal of one aldehyde molecule was not observed earlier for reactions of similar binucleating imidazolidine based ligands with vanadium, iron, copper and zinc [1,13–15]. Air oxidation of the starting +2 state of cobalt is responsible for the imidazolidine ring hydrolysis for hardness matching and the transformation is dependent on the metal ion and coordinated acidic water molecules (pK_1 for $Co(H_2O)_6^{3+}$ is 1.75) [16] (Scheme 3). The coordinated water has a pK_a sizably lower than free water and can release a proton easily. Protonation of first imidazolidine nitrogen atom followed by nucleophilic attack of $[Co–OH]^{2+}$ to the 2-imidazolidinyl carbon leads to the resulting ring hydrolysis. Cobalt(III) coordination driven imidazolidine ring hydrolysis transforms



Scheme 3.

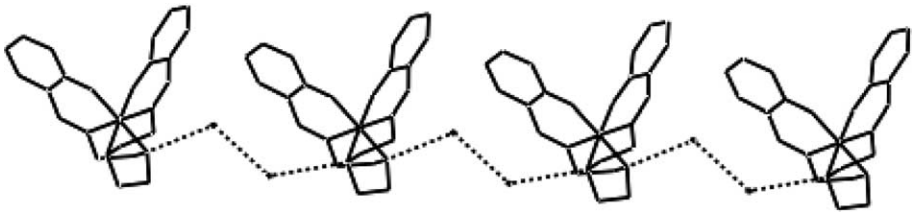


Fig. 3. 1-D hydrogen bonding chain in complex $\mathbf{1} \cdot 2H_2O$.

ethylenediamine (part of the imidazolidine ring) bridging coordination to a favored chelating coordination. Recently, we have identified polynuclear bridging coordination against chelating coordination of the central ethylenediamine part of any polydentate ligand. Ligands $H_3L_I^1$ and $H_3L_I^2$ are stable in methanol, acetonitrile and DMF against any hydrolytic cleavage for weeks. Greater hardness (η; Pearson) [17], of the central cobalt (III) ion (which also serves as a measure of the Lewis acidity) is responsible for the hardness-matched monocobalt complex formation with parent hexadentate ligands following hydrolytic cleavage of the ligands $H_3L_I^1$ and $H_3L_I^2$.

3.4. Physical characterizations

The molar conductivity (Λ_M) values of complexes $\mathbf{1}\cdot 2H_2O$ and $\mathbf{2}\cdot H_2O$ in MeOH are 95 and 92 $\Omega^{-1}\,cm^2\,mol^{-1}$ indicating a behavior attributable to 1:1 electrolytes. In IR spectra of the complexes a strong C=N stretching frequency due to the coordinated imine functions are observed at 1632 and 1597 cm^{-1} in $\mathbf{1}\cdot 2H_2O$ and $\mathbf{2}\cdot H_2O$, respectively, which are shifted from the free ligand values at 1642 and 1625 cm^{-1}. Broad bands at around 3376 and 1535 cm^{-1} in $\mathbf{1}\cdot 2H_2O$ are assigned to the stretching and bending vibrations of the uncoordinated water molecule and the corresponding values for $\mathbf{2}\cdot H_2O$ are 3480 and 1547 cm^{-1}, respectively. The strong unsplit band (ν_{ClO4^-}) at around 1106 cm^{-1} in $\mathbf{2}\cdot H_2O$ suggests no coordination of perchlorate ions [9], but presence of the same outside the coordination sphere.

The electronic spectra of $H_3L_I^1$ and $H_3L_I^2$ show characteristic $n\rightarrow\pi^*$ and $\pi\rightarrow\pi^*$ transitions at 285 and 321 nm ($\varepsilon\sim 5520$ and 4555 $l\,mol^{-1}\,cm^{-1}$) and 254 and 273 nm ($\varepsilon\sim 18\,880$ and 18 645 $l\,mol^{-1}\,cm^{-1}$), respectively. The spectrum observed immediately after addition of the metal salt to the methanolic solution of ligand $H_3L_I^1$ in air shows bands at 630 nm ($\varepsilon\sim 65\,l\,mol^{-1}\,cm^{-1}$), 512 nm ($\varepsilon\sim 230\,l\,mol^{-1}\,cm^{-1}$), 327 nm ($\varepsilon\sim 6780\,l\,mol^{-1}\,cm^{-1}$), 254 nm ($\varepsilon\sim 28\,590\,l\,mol^{-1}\,cm^{-1}$) and 222 nm ($\varepsilon\sim 29\,205\,l\,mol^{-1}\,cm^{-1}$). After 24 h of mixing the initial spectrum changes to one which exactly matches with the solution spectrum of the crystals of the corresponding mononuclear complex $\mathbf{1}\cdot 2H_2O$. It shows several shifted absorption bands at 605 nm ($\varepsilon\sim 180\,l\,mol^{-1}\,cm^{-1}$), 490 nm ($\varepsilon\sim 500\,l\,mol^{-1}\,cm^{-1}$), 392 nm ($\varepsilon\sim 1705\,l\,mol^{-1}\,cm^{-1}$), 251 nm ($\varepsilon\sim 17\,515\,l\,mol^{-1}\,cm^{-1}$) and 219 nm ($\varepsilon\sim 17\,070\,l\,mol^{-1}\,cm^{-1}$). Similarly the spectrum after 24 h from time of metal salt addition to the methanolic solution of ligand $H_3L_I^2$ shows transitions at 630 nm ($\varepsilon\sim 170\,l\,mol^{-1}\,cm^{-1}$), 560 nm ($\varepsilon\sim 202\,l\,mol^{-1}\,cm^{-1}$), 386 nm ($\varepsilon\sim 4155\,l\,mol^{-1}\,cm^{-1}$), which are shifted from 645 nm ($\varepsilon\sim 76\,l\,mol^{-1}\,cm^{-1}$), 391 nm ($\varepsilon\sim 2685\,l\,mol^{-1}\,cm^{-1}$), 362 nm ($\varepsilon\sim 10\,800\,l\,mol^{-1}\,cm^{-1}$) obtained after immediate addition. It also matches with the solution spectrum of the isolated single crystals of $\mathbf{2}\cdot H_2O$.

The redox behavior of both the mononuclear complexes in solution was examined electrochemically in DMF solution at a glassy carbon working electrode. The complexes are electroactive with respect to the metal center and exhibit one redox processes each. in the potential range ±1.5 V versus a saturated calomel electrode (SCE) (tetraethylammonium perchlorate as supporting electrolyte, at 298 K). A quasi-reversible one-electron response is observed at $E_{1/2}=1.33$ V versus SCE (ΔE_p, 150 mV) and $E_{1/2}=1.38$ V versus SCE (ΔE_p, 160 mV) for complexes $\mathbf{1}\cdot 2H_2O$ and $\mathbf{2}\cdot H_2O$, respectively.

4. Conclusion

Cobalt(III) coordination driven imidazolidine ring hydrolysis following air oxidation of the metal centre transforms *N*,*N*-imidazolidine bridging coordination to a favored *N*,*N*-chelating coordination with a change in hardness of the nitrogen donors. The greater the hardness of the cobalt center (which also serves as a measure of the Lewis acidity), the greater the preference to form $[Co^{III}L^x]^+$ complex with the hexadentate ligand. Thus expected dicobalt(II/II) complexes can be obtained when weak Lewis acids such as Co^{2+} are incapable of splitting of imidazolidine rings and favor imidazolidine nitrogen coordination. Both the ligands presumably bind two Co^{2+} centers initially in solution. Metal ion coordination driven imidazolidine ring hydrolysis is responsible for an increase in nitrogen donor basicity. Imidazolidine nitrogen donors present in binucleating ligands are soft bases compared to the secondary amine nitrogens in hexadentate ligands. Both *mer*- and *fac*-ON_2 binding modes of the two halves of the parent ligands have been identified in two structure determinations establishing no conformational preference for ligand hydrolysis.

5. Supplementary material

Further details of the structure determinations, including atomic coordinates, bond lengths and angles and thermal parameters of all non-hydrogen atoms for the structure are available on request as supplementary material from The Director, Cambridge Crystallographic Data Center, 12, Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit @ccdc.cam.ac.uk) (CCDC Deposition Nos. 268225 and 268226).

Abstract

Some new phosphoramidates with formula 4-F-$C_6H_4C(O)N(H)P(O)X_2$, $X = NC_4H_8$ (**1**), NC_5H_{10} (**2**), 4-CH_3-NC_5H_9 (**3**), NC_4H_8O (**4**), NC_6H_{12} (**5**), $N(CH_2CH_3)_2$ (**6**), $N(CH_2CH_2CH_3)_2$ (**7**) were synthesized. The reaction of compound **2** with dimethyltin(IV) dichloride leads to an octahedral organotin(IV) complex, $SnCl_2(CH_3)_2$[4-F-$C_6H_4C(O)N(H)P(O)(NC_5H_{10})_2]_2$ (**8**) with equal ligands in *trans* positions. These compounds were characterized by IR, ^1H, ^{13}C, ^{31}P, ^{119}Sn NMR, mass spectroscopy and elemental analysis. The structures have been determined for compounds **1**, **2**, **4**, **5** and **8**. Compound **2** exists as four symmetrically independent molecules in the crystalline lattice. Compounds **1**, **4** and **5** form dimmers via intermolecular –P=O···H–N– hydrogen bonds that in **1** is centrosymmetric. In compound **2**, two dimmers were formed; each of them was produced between two adjacent independent molecules. In compounds **1**, **2**, **3**, **4** and **8**, containing five- and six-membered ring amine groups, $^3J(P,C_{aliphatic}) > {}^2J(P,C_{aliphatic})$. Compound **5** with seven-membered ring amine, similar to compounds **6** and **7** with acyclic aliphatic amines, shows that $^2J(P,C_{aliphatic}) > {}^3J(P,C_{aliphatic})$. Mass spectra of these compounds indicate the 4-F-$C_6H_4CO^+$ and 4-F-$C_6H_4CN^+$ fragments.

Keywords: X-ray crystallography; NMR spectroscopy; Phosphoramidate; Organotin(IV) complex

1. Introduction

The chemistry of phosphoramidates is recently developed due to the biological activity [1–3] and also the coordination chemistry [4–6] of these compounds. Some of them with $RC(O)N(H)P(O)R^1_2$ formula were used as *O*,*O*′-donor ligands for metal ions, particularly for rare earth metal cations [7,8]. Although the crystal structures of several phosphoramidates and their complexes are already known [4–6,9–12], there are little discussions about the substituent effects on the structural and NMR parameters. Among coordination compounds, the organometallic compounds of tin(IV) are very important antitumor agents [13,14]. Organotin(IV) compounds have been extensively used as wood preservatives, agrochemical fungicides and biocides [15,16]. The coordination compounds of organotin(IV) are a matter of interest in recent researches [17–20]. In our previous studies, we obtained some structures with two conformers in the lattice [21–23]. Cain et al. reported the crystal structure of compound {(5*R*,4*S*)-*N*-Pr-ephedrine}P(S)[NH(Si)$(CH_3)_3$] that has three independent molecules in the unit cell [24]. The first phosphoramidate with four crystallographically independent molecules in the crystalline network was $C_6H_5C(O)N(H)P(O)(NC_5H_{10})_2$ [25] and in this work we report its analogous compound 4-F-$C_6H_4C(O)N(H)P(O)(NC_5H_{10})_2$ (**2**). There are several articles that have been discussed

on noticeable information on the coupling constants between ^{31}P and ^{13}C (or ^{1}H) nuclei [26,27]. Herein, we represent the synthesis of some new phosphoramidates with general formula 4-F-$C_6H_4C(O)N(H)P(O)X_2$, X = NC_4H_8 (**1**), NC_5H_{10} (**2**), 4-NC_5H_9-CH_3 (**3**), NC_4H_8O (**4**), NC_6H_{12} (**5**), $N(CH_2CH_3)_2$ (**6**), $N(CH_2CH_2CH_3)_2$ (**7**). Also, we studied the behavior of **2** as *O*-donor ligand to interaction with $SnCl_2(CH_3)_2$ and an octahedral organotin(IV) complex, $SnCl_2(CH_3)_2$[4-F-$C_6H_4C(O)$-$N(H)P(O)(NC_5H_{10})_2]_2$ (**8**) was prepared. The structures of compounds **1**, **2**, **4**, **5** and **8** were determined by X-ray crystallography. Furthermore, we discussed on structural, NMR and Mass spectral parameters in these compounds and their analogous derivatives.

2. Experimental

2.1. Materials

Dipropylamine (⩾99%), morpholine (>98%) (Merck) and 4-fluorobenzamide (98%), formic acid (98%), phosphorus pentachloride (⩾98%), pyrrolidine (>98%), piperidine (⩾99.5%), hexemethyleneimine (⩾97%), diethylamine (⩾99.7%), dimethyltin dichloride (~95%) (Fluka) were used as supplied. In all reactions, the low temperature condition was used.

2.2. X-ray measurements

X-ray data of compounds **1**, **2**, **5** and **8** were collected on a Bruker SMART 1000 CCD [28] and for compound **4** on a Siemens P3/PC [29] single crystal diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å). The structures were refined with SHELXL-97 [30] by full-matrix least-squares on F^2. The positions of hydrogen atoms were obtained from the difference Fourier map. Routine Lorentz and polarization corrections were applied and an absorption correction was performed using the SADABS program [31].

2.3. Spectroscopic measurements

All reactions were performed under argon atmosphere and in dry solvents. ^{1}H, ^{13}C, ^{31}P and ^{119}Sn NMR spectra were recorded on a Bruker Avance DRS 500 spectrometer. ^{1}H and ^{13}C chemical shifts were determined relative to internal TMS, ^{31}P chemical shifts relative to 85% H_3PO_4 as external standard and ^{119}Sn chemical shift relative to $Sn(CH_3)_4$ solution. Infrared (IR) spectra were recorded on a shimadzu model IR-60 spectrometer. Elemental analysis was performed using a Heraeus CHN-O-RAPID apparatus. High resolution mass spectra were obtained with a Shimadzu model QP-1100EX spectrometer (EI, 70 eV). 4-F-$C_6H_4C(O)NHP(O)Cl_2$ was prepared according to the literature method [32].

2.4. Syntheses

2.4.1. General procedure for synthesis of compounds 1–8

Compounds **1**–**7** were prepared by the reaction of 10 mmol *N*-(4-fluorobenzoyl) phosphoramidic dichloride with 40 mmol of corresponding amines in dry chloroform and stirred at −5 °C. After about 5 h, the solvent was removed and product was washed with H_2O and recrystallized from methanol/chloroform. Compound **8** was synthesized by the reaction of 20 mmol of **2** with 10 mmol dimethyltin(IV) dichloride in methanol at room temperature.

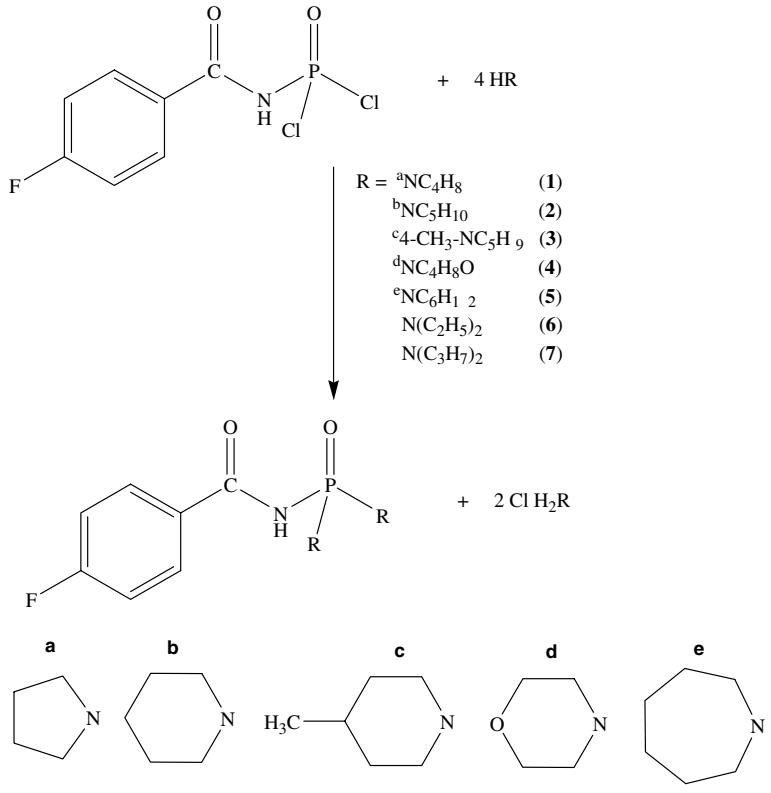
3. Results and discussion

3.1. NMR and IR study

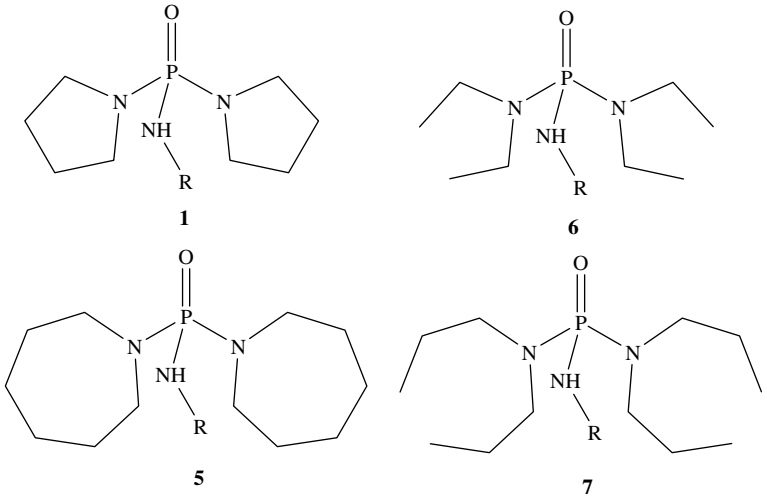
Synthesis of compounds **1**–**7** were performed by the reaction of *N*-(4-fluorobenzoyl) phosphoramidic dichloride [32] with corresponding amines, Scheme 1. Compound **8** was obtained from the reaction of compound **2** with dimethyltin(IV) dichloride. ^{13}C NMR spectra of compounds **1**, **2**, **3**, **4** and **8**, containing five- and six-membered ring amine groups, show that $^{3}J(P,C_{aliphatic})$ is greater than $^{2}J(P,C_{aliphatic})$. For compound **5** with seven-membered ring amine, similar to compounds **6** and **7** with acyclic aliphatic amines, $^{2}J(P,C_{aliphatic}) > {}^{3}J(P,C_{aliphatic})$. Compound **6** shows an opposite result for $^{2,3}J(P,C_{aliphatic})$ relative to compound **1** (with diethylamine group), Scheme 2. Also, it is observed from Table 1 that with increasing the ring size of amine groups in compounds **1**–**5**, the $^{3}J(P,C_{aliphatic})$ becomes smaller and it varies from 8.0 Hz in **1** to 3.8 Hz in **5**. These results are in good agreement with our previous studies on the similar compounds **9**–**12**, Table 1. The carbon atoms of C=O groups in compounds **6**, **7**, **8** and **10** couple with their related phosphorus atoms with $^{2}J(P,C(O))$ coupling constant values in the range from 1.9 Hz in **6** and **8** to 3.9 Hz in **10**. The *ipso* carbon atoms of phenyl rings in compounds **1**–**12** show $^{3}J(P,C_{aromatic})$ coupling constants in the range from 7.6 Hz in **3** to 8.9 Hz in **6** and **7**.

^{13}C NMR spectrum of compound **3** indicates eight peaks for the two unequivalent aliphatic rings of 4-methylpiperidinyl groups. The four doublet signals with two various $^{2}J(P,C_{aliphatic})$ [and also $^{3}J(P,C_{aliphatic})$] coupling constant values are related to the carbon atoms with two and three bond distances from phosphorus atom, Table 1 and Fig. 1.

The δ (^{31}P) of compounds **1**, **2** and **5** indicates that with increasing the ring size of amine groups, it shifts to down fields (Table 1). The phosphorus-31 chemical



Scheme 1. Preparation of compounds **1**–**7**.



Scheme 2. The formula of compounds **1**, **5**–**7**.

shifts of compounds **1**, **2** and **5** with 4-fluorobenzoyl moiety are in upfields relative to their analogous compounds **10**–**12** with formula $C_6H_5C(O)N(H)P(O)R_2$ ($R = NC_4H_8$, NC_5H_{10}, NC_6H_{12}). The δ (^{31}P) of compounds **2** and its organotin(IV) complex, **8**, are close to each other, 10.34 ppm in **2** and 10.15 ppm in **8**. ^{119}Sn NMR of compound **8** shows a signal at −210.75 ppm for the Sn atom. ^1H NMR spectrum of this molecule indicates two separate signals for the NH protons of two ligands. The fluorine substituent couple with aromatic carbon and proton atoms of phenyl ring and we observed $^{1-4}J(F,C_{aromatic})$ and $^4J(F,H_{aromatic})$ in compounds **1**–**8**.

IR spectra of compounds **1**–**8** show that the $\nu_{P=O}$; $\nu_{P-N(amine)}$; $\nu_{P-N(amide)}$ and $\nu_{C=O}$ frequencies are in the range from 1162 in **8** to 1215 in **1**; 870 in **1** to 964 in **4**; 752 (**1**) to 757 (**5** & **8**) and 1661 (**5**) to 1680 (**8**), respectively. The C=O frequency in structurally similar com-

pounds **1**, **6** and also in **5**, **7** (see Scheme 2) are very close to each other. The P=O stretching frequency in complex **8** (1162 cm^{-1}) is weaker than in its ligand **2** (1178 cm^{-1}), but for C=O frequency an opposite result was obtained (1680 cm^{-1} in **8** and 1668 cm^{-1} in **2**). The two bands at 542 and 511 cm^{-1} are related to the asymmetric and symmetric stretching frequencies of Sn–C bonds, respectively [33] and the band at 467 cm^{-1} corresponds to the vibration of Sn–O bond [34].

3.2. X-ray crystallography investigation

Single crystals of compounds **1**, **2**, **4**, **5** and **8** were obtained from a solution of methanol and chloroform after slow evaporation at room temperature. The crystal data and the details of the X-ray analysis are given in Tables 2 and 3, selected bond lengths and angles in Tables 4 and 5. Molecular structures of these compounds are shown in Figs. 2–6.

The two aliphatic rings of pyrrolidine groups in compound **1** have puckered shape and they are not planar. Compound **2** with six-membered ring amine group exists as four symmetrically independent molecules in the crystal lattice. This is due to the differences in similar torsion angles of these four independent molecules. This phenomenon was also observed for compound $C_6H_5C(O)N(H)P(O)(NC_5H_{10})_2$ [25]. The complexation of compound **2** with dimethyltin dichloride (compound **8**) produced a coordination compound with two symmetrically equal phosphoramidate ligands, Fig. 6.

Compounds **1**, **4** and **5** each contain one amidic hydrogen atom and form dimmers via intermolecular –P=O···H–N– hydrogen bonds that in **1** is a centrosymmetric dimmer (Table 6). In compound **2** (with four independent molecules in the unit cell), the two conformers labeled with P(1), P(1A) [and also the two others labeled with P(1B), P(1C)] are connected to each other via two different –P=O···H–N– hydrogen bonds and form a noncentrosymmetric dimmer. The earlier studied *N*-benzoyl, phosphoric triamides exist either in the form of dimmeric aggregates [35] or as polymeric chains [36].

In molecules **1**, **2**, **4**, **5** and **8** the phosphoryl and the carbonyl groups are anti, Figs. 2–6. The phosphorus atoms in these structures have slightly distorted tetrahedral configuration. The bond angles around P(1) atoms

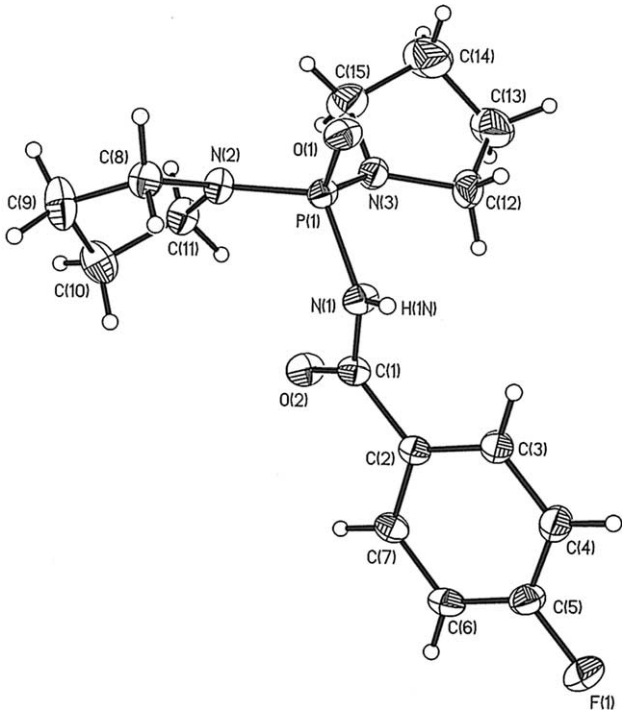

Fig. 2. Molecular structure and atom-labeling scheme for P(O)(4-F-$C_6H_4C(O)NH)(NC_4H_8)_2$, compound **1** (50% probability ellipsoids).

in these compounds are in the range from 119.59(6)° in **1** to 100.7(3)° in **5**, for the angles O(1)–P(1)–N(3) and N(2)–P(1)–N(3), respectively, Tables 4 and 5. In these compounds, the angles OPN_{amide} (N_{amide} is the nitrogen atom of P(O)N(H)C(O) moiety) are lower than the angles OPN_{amine} (N_{amine} is the nitrogen atom of P(O)NR moiety). The P=O bond lengths in molecules **1**, **2**, **4**, **5** and **8** are 1.4863(10), [1.480(2), 1.479(2), 1.471(2), 1.475(3)], 1.4801(17), 1.472(2) and 1.5012(14) Å that are larger than the normal P=O bond length (1.45 Å) [37]. The P=O bond lengths in our previously reported structures are in the range from 1.4875(14) Å in **12** to 1.459(12) Å in **10** (Table 7). The P=O and $P–N_{amide}$ bond lengths in complex **8** is longer than those of ligand **2**, but the C=O bond length in **8** is shorter than in **2**, Table 7. The C=O bond length in compound **5** with seven-membered ring amine group has the longest, 1.328(4) Å, and in compound **4**, 1.212(2) Å, has the lowest value.

The $P–N_{amide}$ bond lengths are longer than the $P–N_{amine}$ bond lengths, because of the resonance interaction of the N_{amide} with the C=O π system that cause a partial multiple bond character in $C–N_{amide}$ (the $C–N_{amide}$

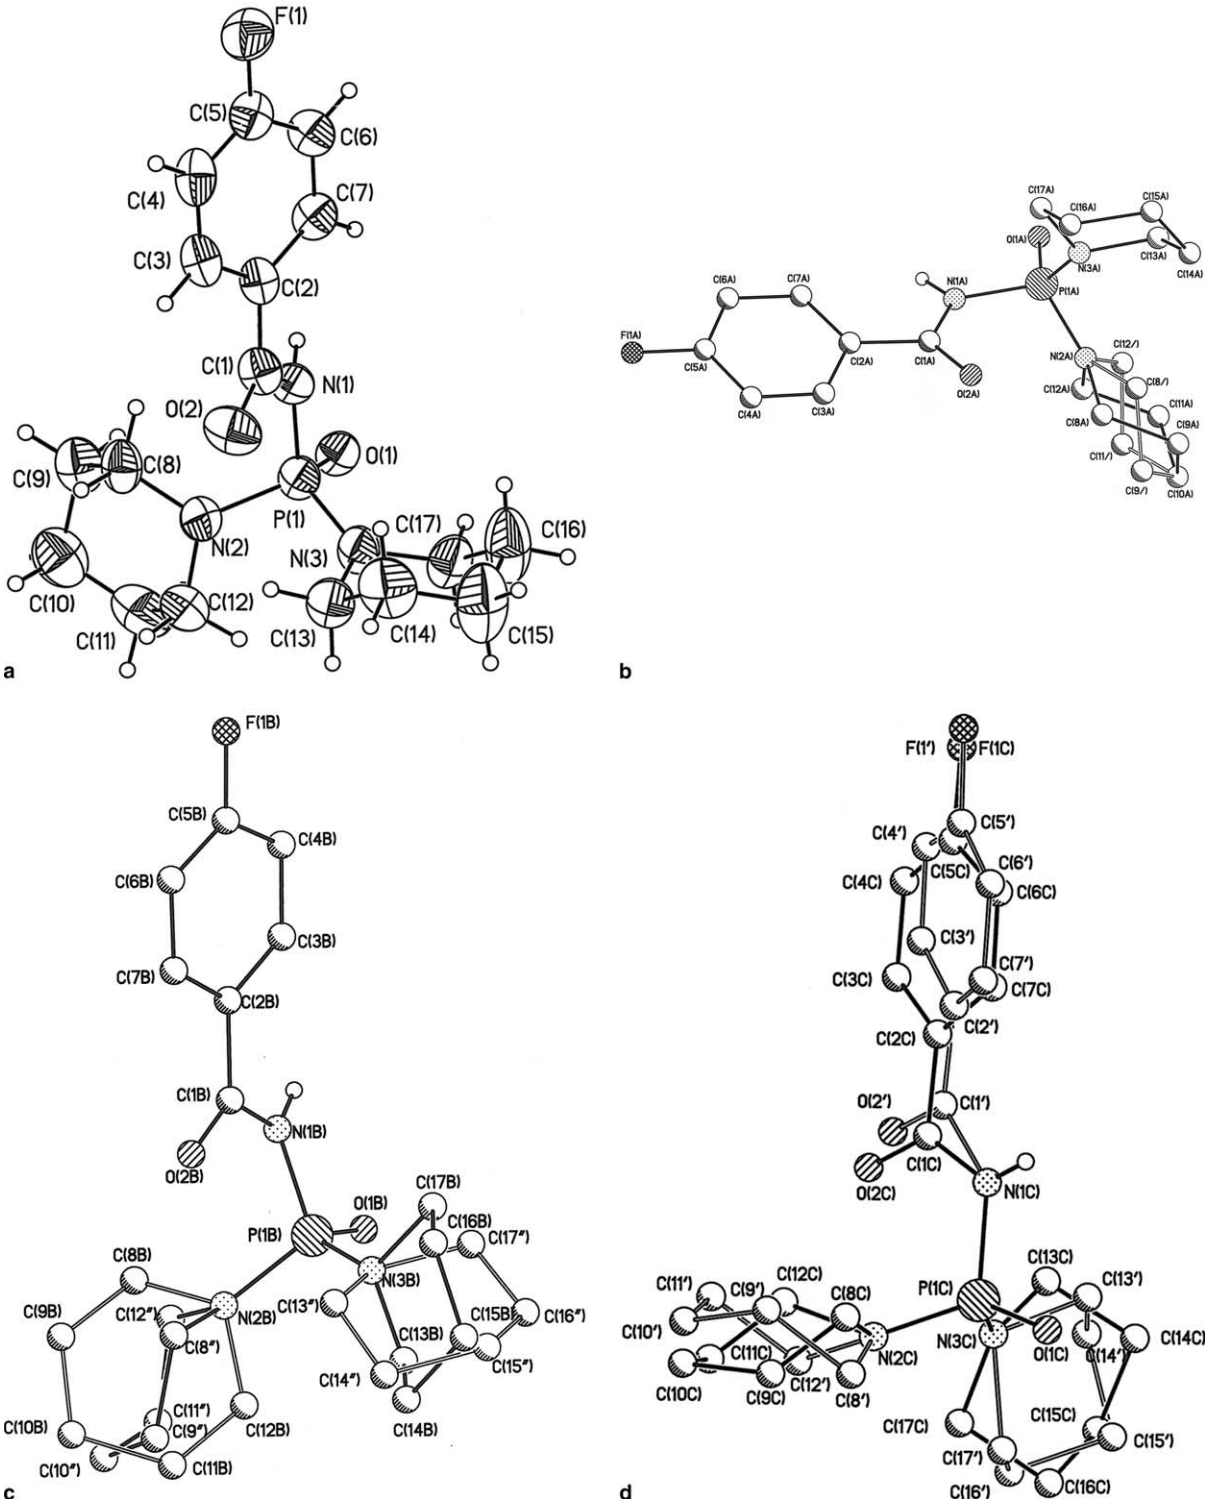

Fig. 3. Molecular structure and atom-labeling scheme for $P(O)(4\text{-}F\text{-}C_6H_4C(O)NH)(NC_5H_{10})_2$, compound **2** showing four crystallographically independent molecules in the lattice three of them have disordered forms (50% probability ellipsoids).

bond lengths are shorter than the $C–N_{amine}$ bond lengths). All of these P–N bonds are shorter than the typical P–N single bond length (1.77 Å [37]). This is likely due to the electrostatic effects (polar bonds) which overlap with P–N σ bond [38]. The P–N bond lengths in the previously reported structures were in the range from 1.6916(16) Å ($P–N_{amide}$ in **12**) to 1.590(15) Å ($P–N_{amine}$ in **10**), respectively (Table 7).

The environment of the nitrogen atoms is practically planar. In compound **1** the angles C(11)–N(2)–C(8),

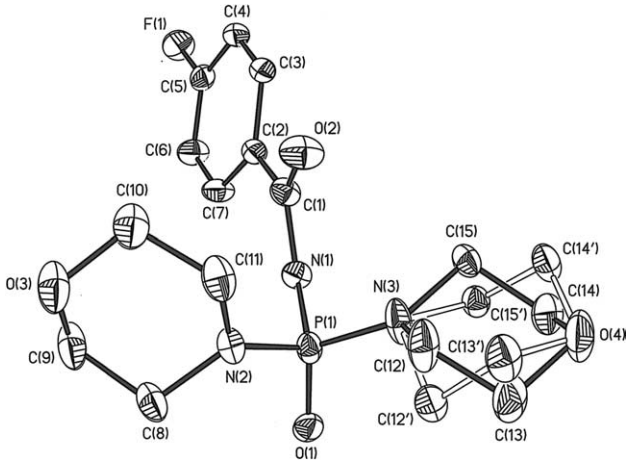

Fig. 4. Molecular structure and atom-labeling scheme for P(O)(4-F-$C_6H_4C(O)NH)(NC_4H_8O)_2$, compound **4** (50% probability ellipsoids).

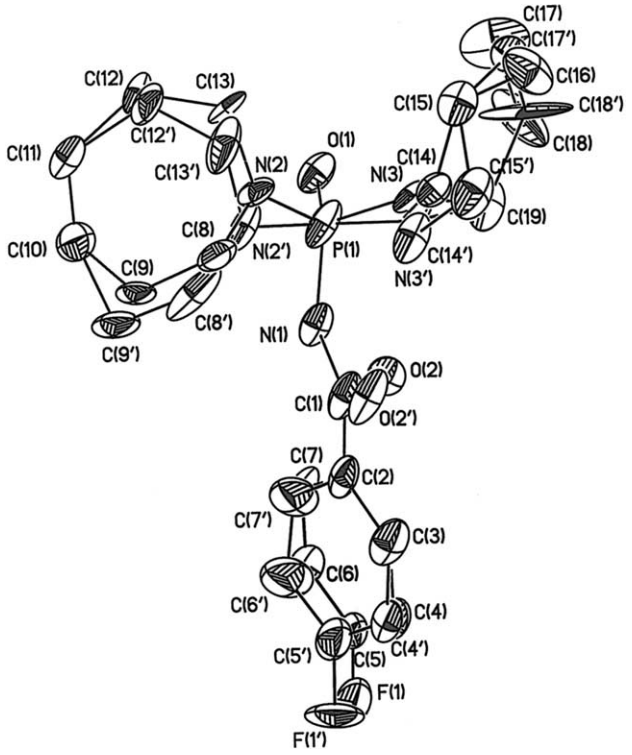

Fig. 5. Molecular structure and atom-labeling scheme for P(O)(4-F-$C_6H_4C(O)NH)(NC_6H_{12})_2$, compound **5** (50% probability ellipsoids).

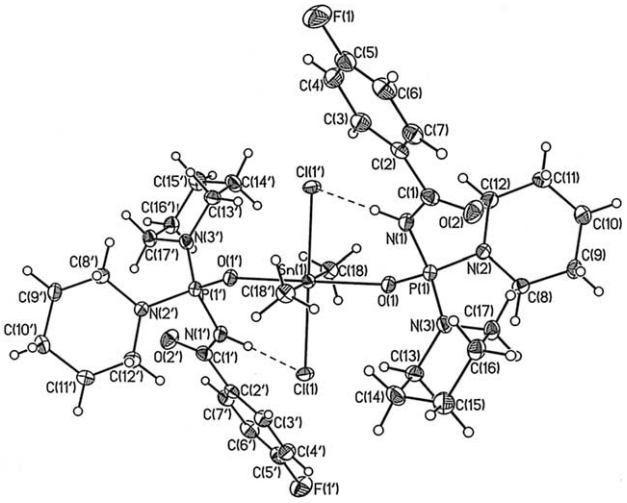

Fig. 6. Molecular structure and atom-labeling scheme for $Sn(CH_3)_2Cl_2[P(O)(4\text{-}F\text{-}C_6H_4C(O)NH)(NC_5H_{10})_2]_2$, compound **8** (50% probability ellipsoids).

C(11)–N(2)–P(1) and C(8)–N(2)–P(1) are 110.39(10)°, 126.80(9)° and 118.78(8)°, respectively, with average 118.7°. The sum of surrounding angles around N(1) and N(3) atoms are 359.99° and 351.69°, respectively. Similar results were obtained for the nitrogen atoms of other structures that confirm the sp^2 hybridization for the N atoms, although due to the repulsion and steric interactions, some angles are greater, and the others are smaller than 120°.

In compound **8**, the structure is symmetric and the central Sn atom has octahedron coordination. The two methyl groups (and also the two phosphoramidates and the two chlorine atoms) are in *trans* positions and the C(18)–Sn(1)–C(18)#1, O(1)–Sn(1)–O(1)#1 and Cl(1)–Sn(1)–Cl(1)#1 bond angles are 180.0° and the C–Sn–O, C–Sn–Cl and O–Sn–Cl bond angles are about 90°, Table 5. The Sn–C bond lengths (both are 2.1238(19) Å) are quite close to those reported in the literature [39]. The Sn–Cl bond lengths are 2.5617(6) Å lying in the normal covalent radii 2.37–2.60 Å [40]. The Sn–O bond lengths are 2.2176(13) Å that are shorter than sum of the van der Waals radii of Sn and O atoms (3.70 Å) [41].

Abstract

A new tripodal ligand *cis*,*cis*-1,3,5-tris[(2,3-dihydroxybenzylamino)aminomethyl] cyclohexane (TMACHCAT), bearing three catechol units attached to a tris-methylaminocyclohexane (TMACH) ring has been synthesized and characterized by elemental analyses, UV–VIS, IR and ^{1}H NMR spectral data. The lowest energy molecular geometry of TMACHCAT was obtained through empirical followed by quantum mechanical treatment. Theoretical UV–VIS, IR and ^{1}H NMR spectral data were calculated from the energy-minimized structure by applying semi-empirical ZINDO, PM3 and TNDO/2 method, respectively and compared with the experimental data. The complexation behaviour of the ligand with H^+, La(III), Gd(III) and Lu(III) in an aqueous medium of 0.1 M KCl at 25 ± 1 °C was studied by potentiometric and spectrophotometric methods. Six protonation constants were determined for the ligand and used as input data to evaluate the formation constants of the metal complexes. The formation of complexes between the partially protonated ligand and lanthanide ions of the types MLH_3, MLH_2, MLH, ML_2H_6 have been observed. The solution structures of the metal complexes were proposed through experimental evidences along with the calculated minimum strain energy through molecular mechanics calculation using CAChe's augmented MM3 force field.

Keywords: Tripodal polycatechol-amine ligand; Lanthanum; Gadolinium; Lutetium; Protonation constants; Formation constants; Molecular mechanics and semi-empirical method

1. Introduction

Lanthanide (III) coordination chemistry has recently received growing interest because of the numerous applications of lanthanide (III) complexes, such as relaxation agents in nuclear magnetic resonance imaging [1], luminescent probes in biology and medicine [2] or catalysts for the cleavage of RNA and DNA [3,4]. While dealing with such applications, the greatest interest is focused on the use of these complexes, gadolinium compounds in particular, as contrast agents in magnetic resonance imaging (MRI) [5], due to its effective magnetic moment and electronic relaxation time associated with the f^7 configuration. For this purpose, the most stringent requirement is high thermodynamic stability and possibly kinetic inertness, which can be achieved by complexation of suitable designed ligands. Much of this work has been based on the application of gadolinium complexes of poly(aminocarboxylate) ligands such as Gd-DTPA (DTPA = diethylenetriaminepentaacetic acid) [6] and Gd-DOTA (DOTA = 1,4,7,10-*N*,*N*′,*N*″,*N*‴-tetraacetic acid) [7] and their derivatives [8]. Recently, efforts have been taken to synthesize multidentate tripodal ligands because of their intermediate chelation between open chain ligands and those based on macrocycles, where metal can be encapsulated by three arms of the suitably designed ligand [9–12]. Among such ligands,

the natural occurring siderophore, enterobactin has a tripodal architecture with one catechol binding unit in each arm [13,14] shows the highest binding constants [15]. This led not only to model it through simple artificially synthetic molecules for the ultimate development of iron removal drugs for therapeutic use [16] and to mimic the various biological functions such as redox, spectroscopic, binding or assimilation [17] but also the study of the coordination chemistry of catechol-based ligands with 3d transition elements [18], trivalent group 13 metal ions [19], actinides [20] and trivalent lanthanides [21,22].

Again, the complexation of lanthanide ions in aqueous medium has been studied mostly with carboxylato- and phosphonato-oxygen donors because of their oxoplilicity [23]. Very less attention has been given to the phenolato-group as anionic oxygen donor for these metal ions [24,25]. The main reason why the coordination of lone phenol is hindered is the weak acidity of the hydroxy group (pK_a of phenol ~10) [24] and since the lanthanide aqueous ions are themselves weak Lewis acids, they generally cannot compete with the hydrogen ion for complexation of phenol in water and precipitate as hydroxides above pH 8. Thus, a ligand containing only amines and phenols could not be expected to be a particularly good ligand for aqueous lanthanide chelation as it should simply be too basic. Nevertheless, it has been reported that introduction of phenol groups into a well-preorganized structure allows the ligand to form strong lanthanide (III) complexes [25,26]. Coordination chemistry of different sulfonated water soluble tripodal amino-phenolate ligands tris-((2-hydroxy-5-sulfobenzylamino)ethyl)amine (TRNS), 1,1,1-tris-(((2-hydroxy-5-sulfobenzyl)amino)-methyl)ethane (TAMS), 1,2,3-tris-((2-hydroxy-5-sulfobenzyl)amino)propane (TAPS) have been investigated by Orvig et al. in solution where it was found that Ln(III) was encapsulated by podands possessing short and rigid tripods to give $[Ln(TAPS)]^{3-}$ and $[Ln(TAMS)]^{3-}$, while the more flexible TREN spacer in TRNS prevented regular wrapping of the chelating side arms around Ln(III), thus leading to monocapped $[Ln(H_3TRNS)(H_2O)_x]$ and bicapped $[Ln(H_3TRNS)_2]^{3-}$ podates (Fig. 1) [25,26]. Recently, Di Bernardo and others suggested that introduction of catechol group in tris((2,3-dihydroxybenzyl-amino)ethyl) amine (TRENCAT) as binding units instead of phenolate donor showed high complexing ability towards lanthanide metal ions at nearly physiological pH [27,28].

Based on these above facts we were interested to study the coordination behaviour of a new polycatechol-amine ligand by changing the spacer unit TREN into a cyclohexane based tripod tris-aminomethylcyclohexane (TMACH), which is expected (i) to increase the degree of freedom and flexibility of podants and (ii) to reduce the steric constraints within the tripod thus favouring regular wrapping of the binding side arms. Thus, in this communication, we present the synthesis and structural characterization of a multidentate tripodal ligand *cis*,*cis*-1,3,5-tris[(2,3-dihydroxybenzyl-

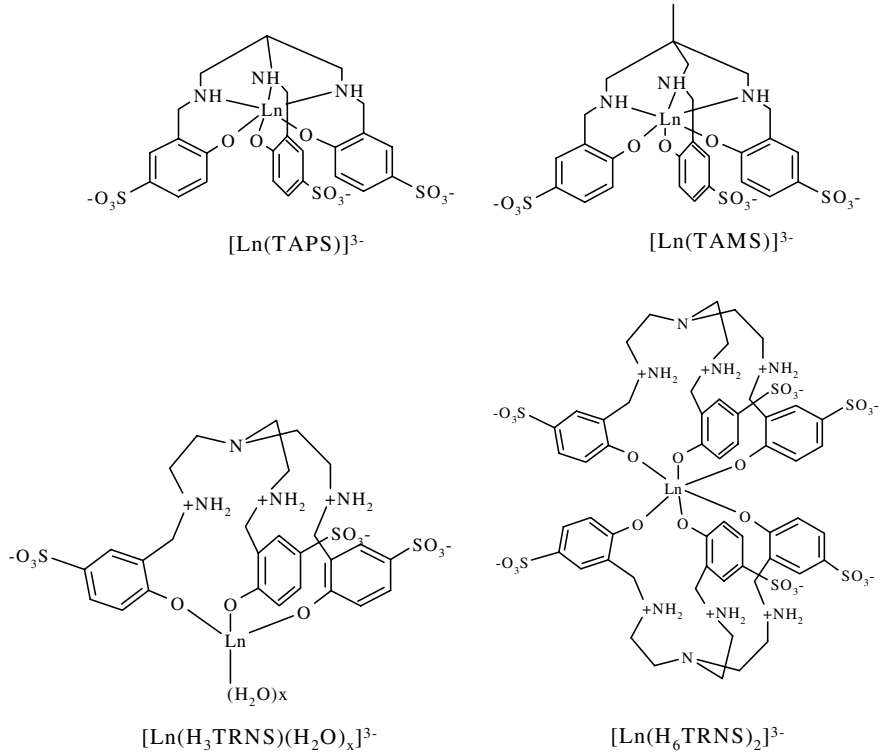

Fig. 1. Coordination modes of lanthanide metal ions with different tripodal aminophenolate ligands in solution.

amino)aminomethyl]cyclohexane (TMACHCAT) having three catechol units linked through methylene moieties to the backbone of TMACH. We were also interested to study the coordination behaviour of the ligand with some lanthanide ions in aqueous solution to see if coordination geometries are function of pH and whether phenolato coordination could provide an anchoring effect, which would enable the amine nitrogen atoms to coordinate in water. The complexation behaviour of the newly synthesized ligand towards La(III), Gd(III) and Lu(III) in water and the solution structures of the metal complexes were proposed through the molecular modeling calculations.

2. Experimental

2.1. Materials and measurements

The compound *cis*,*cis*-1,3,5-tris(methylamino)cyclohexane (TMACH) was synthesized as in Scheme 1 [29]. All chemicals: 1,3,5-benzenetricarboxylic acid, platinum dioxide, lithiumaluminiumhydride, *p*-toluenesulphonyl chloride, sodium azide, 2,3-dihydroxybenzaldehyde and sodiumborohydride were obtained from Sigma–Aldrich and used directly. Nitrate salts of lanthanides (purity > 99.9%) were obtained from Indian Rare Earths Ltd., India. The absolute ethanol (99.9%) was obtained from Les Alcools Commerce Inc., Canada. Dry solvents (methanol and THF), KOH, HCl, KCl were obtained from Ranbaxy Chemicals Ltd., India.

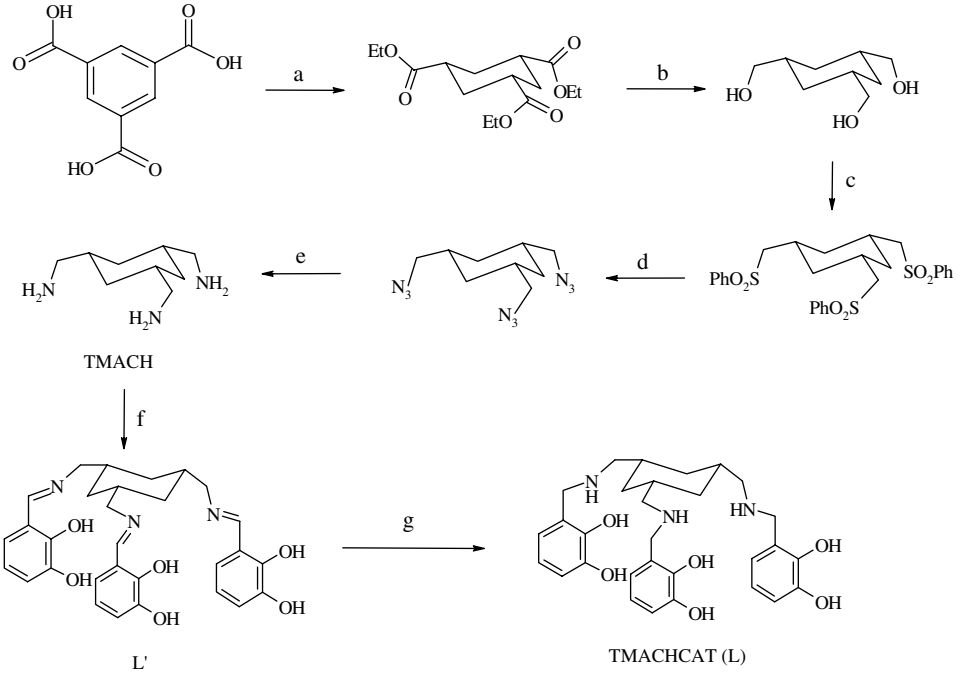
Proton and ^{13}C NMR spectra were recorded on a Brucker DPX-300 spectrometer in $CDCl_3$ or D_2O and chemical shifts were reported relative to Me_4Si. IR (KBr pellets, 450–4000 cm^{-1}) spectra were recorded on Perkin–Elmer RX I FT-IR spectrometer. The electronic spectra were recorded on an Agilent-8453 diode array spectrometer. Elemental analyses were determined for C, H and N using the Exeter Analytical CE-440. FAB mass spectra were recorded on a Jeol-SX-102 spectrometer.

2.2. Synthesis of cis,cis-1,3,5-tris(methylamino)-cyclohexane

cis,*cis*-1,3,5-Tris(methylamino)cyclohexane was synthesized as per Scheme 1 [29]. Mass spectra (CI+): $m/z = 172$ (calc. 171.3); ^1H NMR (D_2O, δ ppm): 0.53 (3H, q, CH_2 axial), 1.41 (3H, m, CH_2 equatorial), 1.75 (3H, d, CH axial), 2.44 (6H, d, CH_2 of $–NH_2$); ^{13}C NMR (D_2O, δ ppm): 34.38 (ring CH_2), 39.38 (ring CH), 47.57 (CH_2 of NH_2).

2.3. Synthesis of cis,cis-1,3,5-tris[(2,3-dihydroxy-benzylidene)aminomethyl]cyclohexane (L′)

To a magnetically stirred solution of TMACH (0.3 g, 1.75 mmol) in 10 ml absolute ethanol, 2,3-dihydroxybenzaldehyde (0.75 g, 5.43 mmol) in 5 ml absolute ethanol was added drop wise. A bright yellow precipitate obtained, which was filtered off and washed with cold ethanol followed by ether and then dried in vacuum.



Scheme 1. Reagents and conditions: (a) (i) EtOH, dry HCl and (ii) PtO_2/H_2, room temp, 24 h; (b) (i) $LiAlH_4$, dry THF; (c) $PhSO_2Cl$; (d) NaN_3; (e) $LiAlH_4$, dry THF; (f) 2,3-dihydroxybenzaldehyde/EtOH; (g) $NaBH_4$/MeOH, conc. HCl/MeOH.

Yield = 92%; IR (KBr pellet, cm^{-1}): 3401, 2918, 2833, 2717, 1632, 1596, 1508, 1458, 1384, 1363, 1276, 1227, 1163, 853, 777, 739; ^1H NMR ($CDCl_3$, δ ppm): 0.84 (3H, q), 1.81 (3H, b), 1.93 (3H, d), 3.49 (6H, d), 8.24 (3H, s), 6.60 (3H, t), 6.77 (3H, d), 6.88 (3H, d); ^{13}C NMR ($CDCl_3$, δ ppm): 34.21, 37.52, 62.98, 116.47, 116.63, 121.37, 145.74, 153.05, 164.86; Mass spectrum (FAB): $m/z = 532$.

2.4. Synthesis of cis,cis-1,3,5-tris[(2,3-dihydroxybenzylamine)aminomethyl]cyclohexane (L)

To a suspension of L′ (0.699 g, 1.31 mmol) in 50 ml dry methanol, sodium borohydride (0.155 g, 4.09 mmol) was added with stirring over a period of 2 h under N_2 atmosphere. When the solid phase disappeared and the solution became colourless, an excess of conc. HCl in methanol was added and kept overnight at −40 °C. A white residue was removed by filtration. The solvent was evaporated under reduced pressure. The crude product obtained was dissolved in dry methanol and evaporated. This process was repeated thrice. Then, the residue was dissolved again in dry methanol and to it decolourizing charcoal was added which was filtered after vigorous shaking. When the solvent was evaporated under reduced pressure, a white product was obtained, which was dried under vacuum. Yield = 77%; IR (KBr pellet, cm^{-1}): 3401, 3230, 2923, 2831, 2715, 1597, 1508, 1479, 1384, 1361, 1285, 1208, 836, 776, 738; ^1H NMR (D_2O, δ ppm): 0.79 (3H, q), 1.77 (3H, d), 1.86 (3H, b), 2.90 (6H, d), 4.17 (6H, s), 6.78 (3H, t), 6.84 (3H, d) and 6.94 (3H, d); Elemental analysis: *Anal.* Calc. for $C_{30}H_{39}N_3O_6 \cdot 3HCl \cdot 2H_2O$: C, 52.85; H, 6.81; N, 6.17. Found: C, 52.67; H, 6.82; N, 6.14%.

2.5. Titration procedure

The protonation constants of the ligand and the formation constants of the metal complexes were determined by potentiometric and spectrophotometric titrations at 25 ± 1 °C maintained from a double wall glass jacketed titration cell connected to a constant temperature circulatory bath. For all titrations, the observed pH was measured as $-\log[H^+]$ using a ThermoOrion $720A^+$ pH meter equipped with a combined glass electrode. The electrode was calibrated to read pH according to the classical method [30]. A standard hydrochloric acid solution was titrated with a standard KOH solution and the calculated hydrogen ion concentrations ($pK_w = 13.77 \pm 0.05$) was used to convert the pH-meter reading to hydrogen ion concentration.

All solutions were prepared prior to the experiments in double distilled deoxygenated water. KOH solution of 0.1 M was prepared and standardized against potassium hydrogen phthalate. HCl solution (0.1 M) was prepared and standardized against standard KOH. The ionic strength was maintained at 0.1 M by adding appropriate amount of 1 M KCl. Solutions of 0.01 M ligand and 0.01 M metal ions were also prepared in deoxygenated water. Final concentration of ligand (1×10^{-3}M) and metal (1×10^{-3}M and 5×10^{-4}M) were maintained for the different titrations. Following titrations with metal-to-ligand molar ratios: $C_M/C_L = 0{:}1$; $C_M/C_L = 1{:}1$, 1:2 (M = La^{+3}, Gd^{+3} and Lu^{+3}) were carried out. The protonation constants of the ligand and the formation constants of the metal complexes were determined using computer program Hyperquad 2000 [31].

The apparatus and method used for the potentiometric and spectrophotometric titrations are very similar except dilute solutions of ligand (4.02×10^{-5}M) and metal ions (4.02×10^{-5}M or 2.02×10^{-5}M) were used. After each adjustment of pH, an aliquot was removed and spectra were recorded. The protonation constants and formation constants were calculated by global fitting of the whole spectral data using a non-linear least-square fitting program, pHAb [32].

2.6. Molecular modeling calculation

All calculations were carried out on a Pentium IV 3.0 GHz machine on windows 2000 environment using the computer program CAChe version 6.01 [33] and/or GAUSSIAN-03 [34]. The initial geometry of TMACHCAT leading to minimum strain energy was achieved through molecular mechanics calculation using MM3 force field and then reoptimized by semi-empirical PM3 self-consistent fields (SCF) method, at the Restricted Hartree–Fock (RHF) level. The geometry optimizations were obtained by the application of the Polak–Ribiere method with convergence limit of 0.0001 kcal/mol and RMS gradient of 0.001 kcal/mol. The full vibrational analysis was carried out for the various acid–base species of TMACHCAT to obtain the free energy in vacuo by applying semi-empirical PM3 Hamiltonian. The ^1H NMR of TMACHCAT was calculated through TNDO/2 (Typed Neglect of Differential Overlap) semi-empirical method (with convergence limit 0.001 and maximum iterations 50) using the program HyperNMR Version 7.0 [35].

The structures of the lanthanide complexes were optimized through the molecular mechanics calculation using CAChe augmented MM3 force field. CAChe's augmented force field automatically estimates any missing parameters for any element in the molecule. These estimated parameters will be less accurate than either MM2 or MM3, however it allows calculations on structures containing any element up to 103. A coordination scan [36] was tried for the species MLH_3 but no suitable curve was obtained to ascertain the coordination number. Hence, based on the available literature [37], a nine-coordinated structure was drawn for the metal

complexes for optimization. Both equatorial and axial conformer for the ligand was taken for optimization for each metal complex.

3. Results and discussion

3.1. Ligand synthesis

The synthetic procedure of TMACHCAT is given in Scheme 1. The reduced TMACHCAT was tried to isolate in its organic-form by precipitating the crude reduced product in aqueous NH_4OAc/NH_4Cl, but it was found that the catechol groups got oxidized in basic conditions giving light pink colour. So the ligand was isolated as hydrochloride salt and care was taken to avoid contact with atmosphere throughout the procedure. The compound is highly hygroscopic, soluble in water, methanol and ethanol but insoluble in chloroform, ether and acetonitrile. The ligand was characterized on the basis of elemental analyses, electronic, IR, ^{1}H NMR spectral data (Fig. 2(a)).

The infrared spectra of L′ showed strong band at 1632 cm^{-1}, characteristic of imine Schiff base. Upon reduction, infrared spectrum of L (Fig. 3(a)) showed the disappearance of the characteristic imine C=N band at 1632 cm^{-1} and appearance of a new band at 3230 and 1497 cm^{-1} were observed from N–H stretching and bending vibrations, respectively. These observations confirm that the C=N bonds were reduced to the –NH–CH_2– linkage. The ligand (L) showed a broad ν_{O-H} stretching vibration at 3401 cm^{-1}. This is an indication for intramolecular hydrogen bonding, because the normal position for stretching vibration of non-hydrogen bonded or free hydroxyl group absorbs strongly in the range of 3700-3584 cm^{-1} [38]. The deformation δ_{O-H} peaks were observed at 1384 and 1361 cm^{-1}. The bands observed at 1208 cm^{-1} was attributed to ν_{C-O}. Aromatic carbon–carbon stretching vibrations were observed at 1597 and 1508 cm^{-1}, whereas two bands at 836 and 776 cm^{-1} were assigned for ring substituted bending vibration and one band at 738 cm^{-1} obtained for ring bending vibration. Theoretical infrared spectrum of L calculated using semi-empirical PM3 Hamiltonian is shown in Fig. 3(b) and assignment was made through the structural animation at every peak. The PM3 force field is the most widely used functional for predicting infrared spectrum compared to other semi-empirical methods [39]. The computed vibrational frequencies in comparison to the experimental values showed the closest correspondence for bending vibrations but slightly higher values were noted for stretching vibrations. However, the trends are consistent with the experiment and helpful for interpreting the different modes of vibrations.

Experimental ^{1}H NMR spectra of L′ displayed a resonance signal at 8.25 ppm due to imine hydrogens. Upon reduction, the characteristic imine band disappeared and the ^{1}H NMR spectra of TMACHCAT (Fig. 4(a)) showed the presence of benzylic signals at 4.17 ppm. The spectrum showed three distinct peaks for the three different kinds of protons found in cyclohexane ring. A quartet and doublet was obtained at 0.73 and 1.77 ppm for the axial and equatorial protons attached with the three methylene groups, respectively, whereas a broad peak at 1.86 ppm was observed for the three axial protons attached with the appended groups in the cyclohexane ring, which confirm the *cis,cis*-configuration for TMACHCAT. Theoretical ^{1}H NMR spectrum of TMACHCAT obtained from the PM3 optimized structure through semi-empirical TNDO/2 method is shown in Fig. 4(b). Due to virtual memory problem, after calculating shielding constant and chemical shift, only the noted 14 protons were considered for calculation of the spectrum. The methylene protons in cyclohexane ring shows two peaks in the spectrum at 2.97 and 3.26 ppm for the axial and equatorial protons,

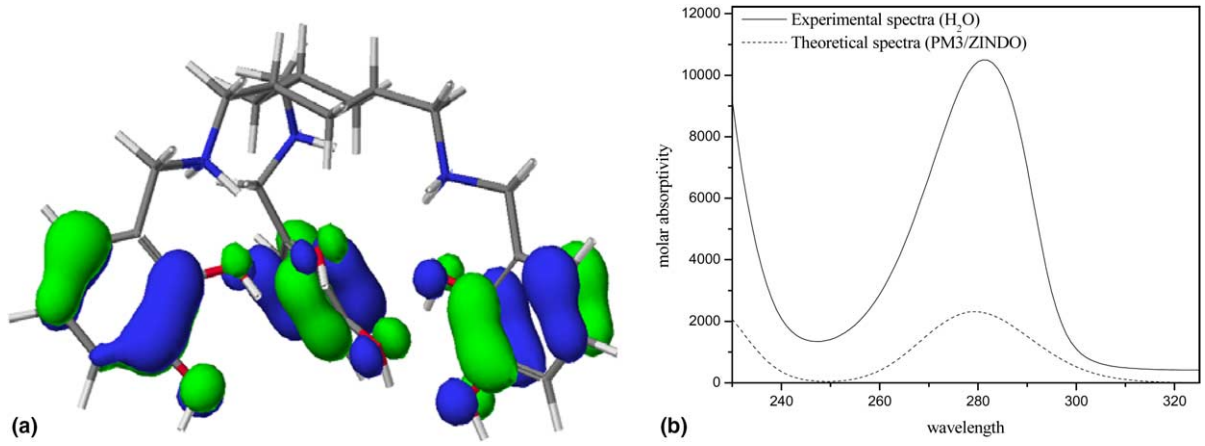


Fig. 2. (a) The HOMO molecular orbital diagrams at λ_{max} 279 nm (calculated applying semiempirical ZINDO method and (b) experimental and theoretical spectra for TMACHCAT.

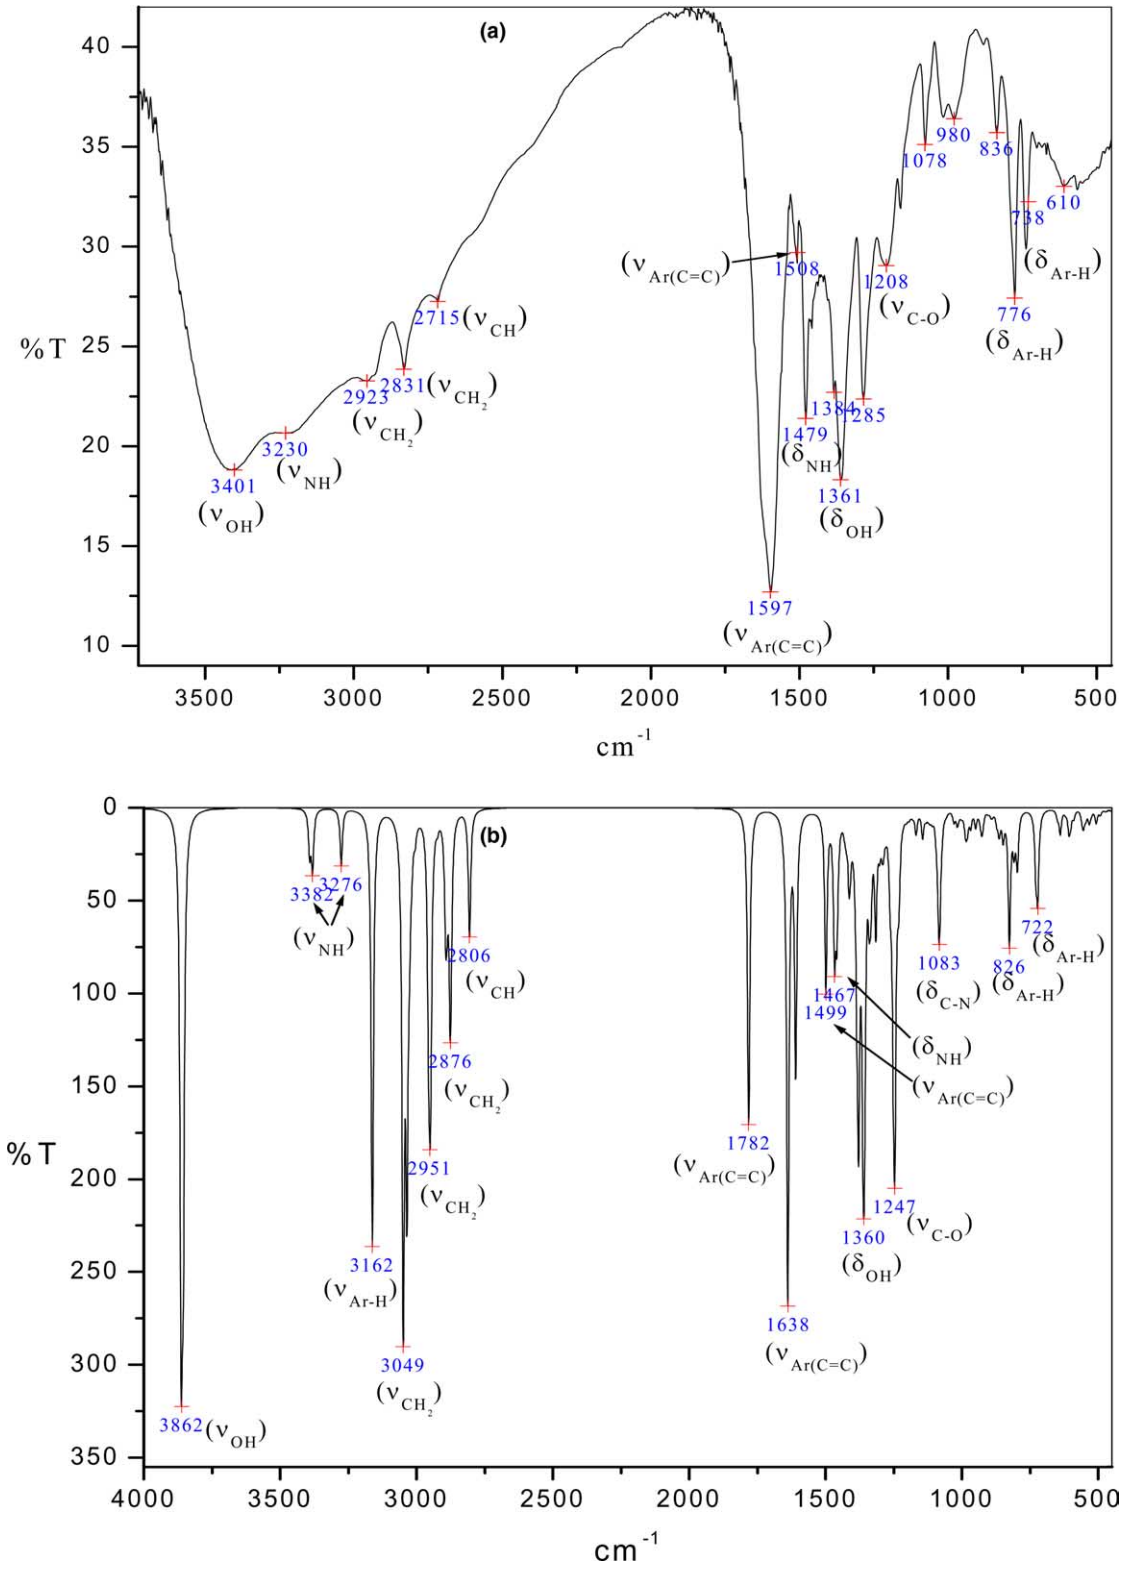

Fig. 3. Infrared spectrum of TMACHCAT: (a) experimental (KBr pellet) and (b) calculated (applying semi-empirical PM3 method).

respectively, whereas peak at 3.48 ppm was observed for the methine protons. The two peaks for the methylene groups one attached to cyclohexane ring and another to benzene ring were observed at 4.36 and 4.77 ppm, respectively. Three peaks for aromatic protons were observed at 6.62, 7.13 and 7.38 ppm. The calculated peaks for hydroxyl (H_{13}, H_{14}) and amine protons (H_1, H_5) were not observed experimentally.

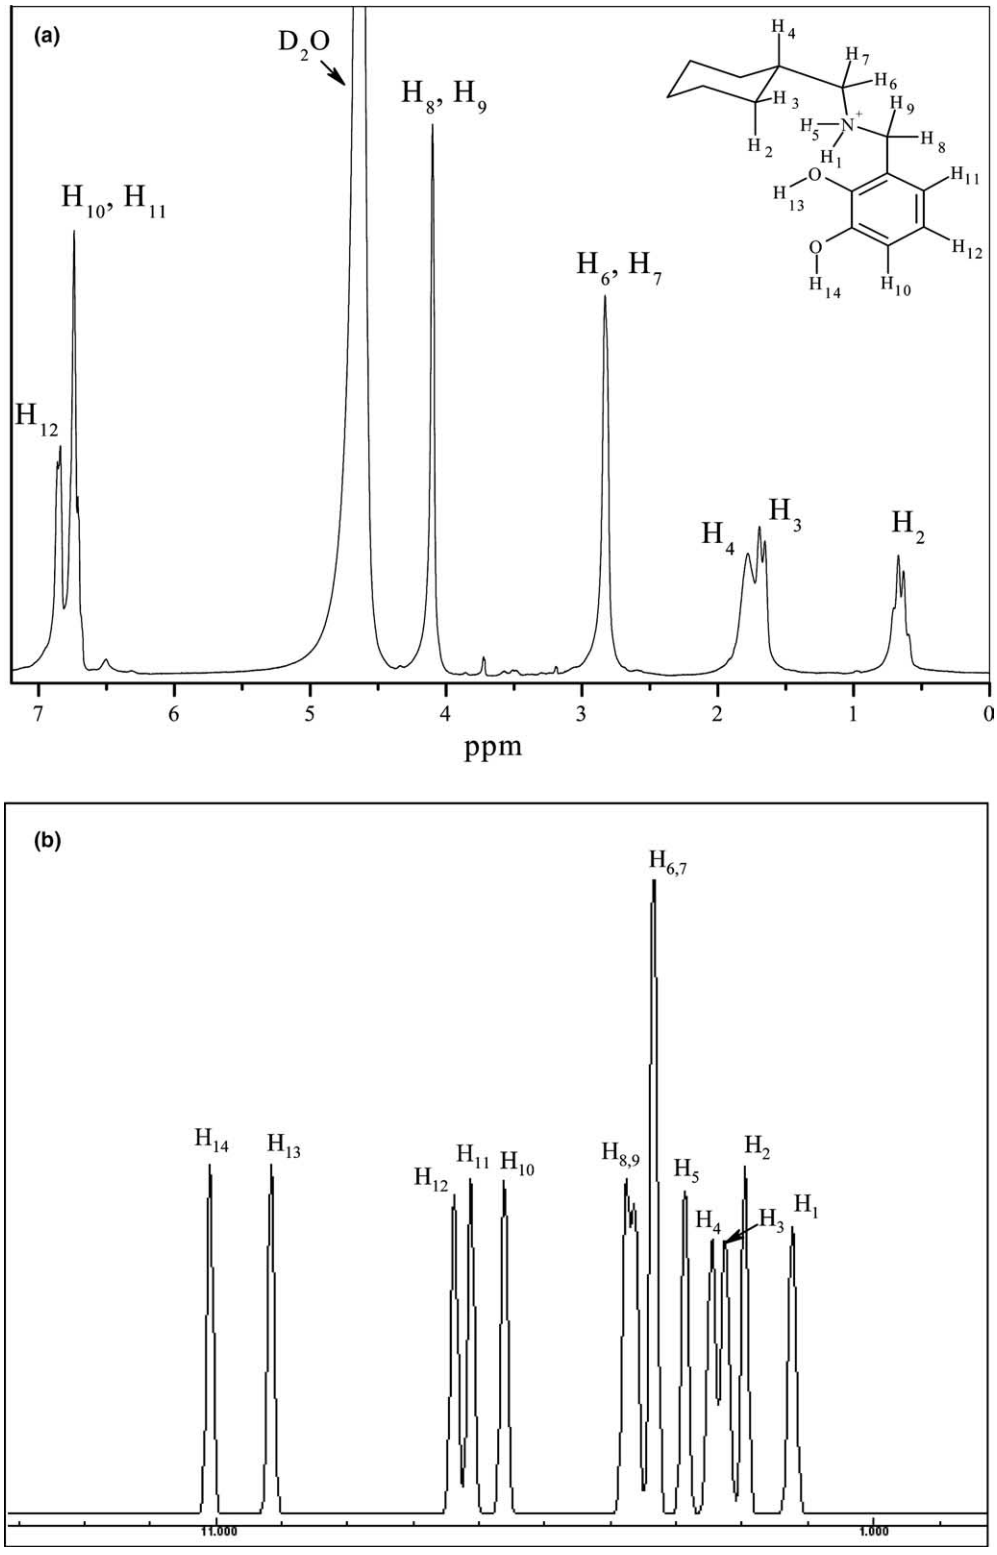

Fig. 4. ^{1}H NMR spectrum of TMACHCAT: (a) experimetral (D_2O, 300 MHz) and (b) calculated (applying semi-empirical TNDO/2 method).

Theoretical ^{1}H NMR chemical shifts gave qualitative trends although the values are not in quantitative agreement with the experiment measurements.

The trihydrochloride salt of the ligand in aqueous medium exhibits only one peaks at 281 nm attributed to $\pi \rightarrow \pi^*$ transitions associated with the chromophoric phenyl ring. Calculated electronic spectrum of TMACHCAT from PM3 (RHF) optimized structure by employing semi-empirical ZINDO method showed peaks with λ_{max} at 279 nm. The optimize structure along

with the HOMO at 279 nm is shown in Fig. 2(a) and the experimental and theoretical spectra are shown in Fig. 2(b).

3.2. Ligand protonation constants

The potentiometric titration of the ligand was carried out by adding excess measured amount of standard HCl to the ligand and titrating against standard KOH at $\mu = 0.1$ M KCl and 25 ± 1 °C in aqueous medium. The titration curve of the ligand is given in Fig. 5. Though upon addition of KOH deprotonation occurs, representation of the acid dissociation constants (K_a) in stability study usually expressed in terms of proton-ligand formation constant or protonation constant (Eq. (1)), and also used in the present communication. Analysis of the potentiometric titration curve using the program Hyperquad 2000 gave best fit for six protonation constants (Table 1) for the ligand as proposed by the Eq. (1) (charges are omitted for clarity):

$$LH_{n-1} + H \rightleftharpoons LH_n, \quad K_{1n} = \frac{[LH_n]}{[LH_{n-1}][H]} \tag{1}$$

The ligand TMACHCAT is a potentially hexa-protic acid. However, due to very low acidity of catechol ($pK_{a1} = 9.13$, $pK_{a2} = 13.00$) [24] subunits it is to be considered as a triprotic acid. In fact, in the present experimental conditions adopted here (pH < 11) only one of the two acidic functions of catechol can be deprotonated, while a very high basic condition is required to deprotonate the second one. It was possible to determine only the protonation constants of the secondary amino groups and three of the phenolic oxygens of the ligand.

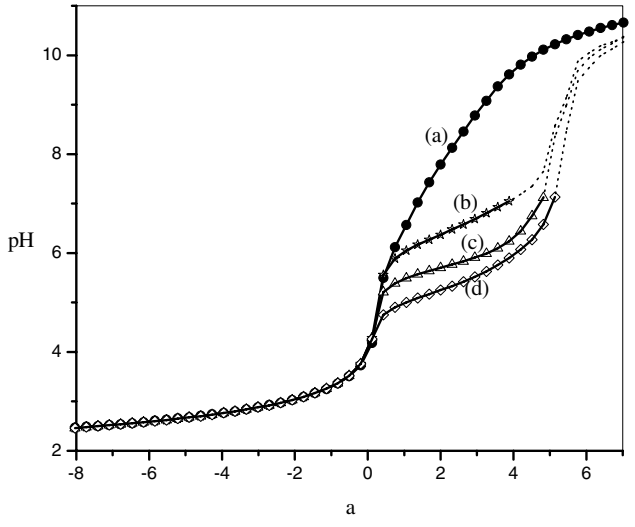

Fig. 5. Potentiometric titration curves of TMACHCAT in absence (a) and presence of metal ions (b) La(III), (c) Gd(III) and (d) Lu(III) in 1:1 ligand–metal molar ratio, where '*a*' is moles of base added per mole of ligand present (symbols and solid lines indicate the experimental values and simulated results, respectively).

The superscript i refer to the shorter arms.

Accordingly, the neutral TMACHCAT is addressed as LH_3 and the fully protonated form is considered as LH_6^{+3}. The simulated titration curve obtained using the results (Table 1) for the ligand titration is given as solid line whereas experimental titration data are marked as • in Fig. 5. There is a close agreement of the above two. The titration curve for ligand showed a sharp inflection at $a = 0$, where 'a' is moles of base added per mole of ligand present, which is due to the neutralization of excess hydrogen ions whereas other sharp inflection was observed for deprotonation from –OH or $-NH_2^+$ groups. The species distribution diagram of TMACHCAT as a function of pH (Fig. 6) indicates that in acidic solution TMACHCAT initially exists 100% in the fully protonated form as LH_6 below pH < 4.5. As the pH is increases, deprotonation starts with formation of LH_5 which exists between pH 5–8 with maximum concentration (75%) at pH ~ 7. The other species LH_4, LH_3, LH_2 and LH are formed and successively with increase in pH and show maximum concentration of 55%, 75%, 55% and 40% at pH ~ 8, ~9, ~10 and ~11, respectively.

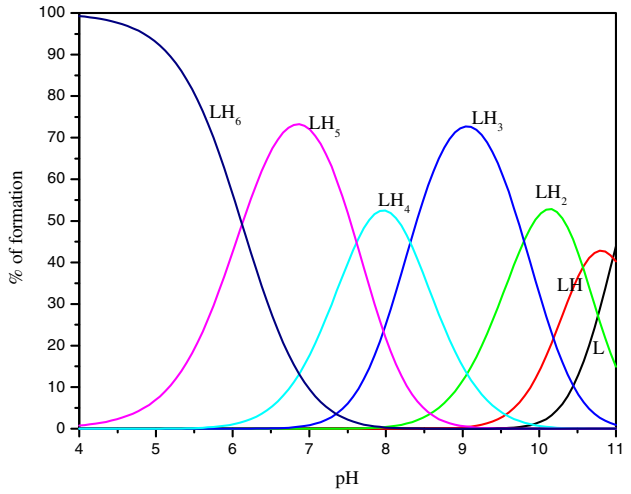

Fig. 6. pH-dependent species distribution curves for TMACHCAT.

The protonation constants of the ligand were also determined by spectrophotometric method. The electronic spectra (220–400 nm) of the ligand were recorded in the pH range 4.29–10.32 and given in Fig. 7(a). Inclusion of whole range of data resulted six protonation constants (Table 1). The predicted electronic spectra of the ligand at various experimental pH ranges are given in Fig. 7(b) and agreeable with the experimental one (Fig. 7(a)) while that of all the species whose protonation constants have been determined and the protonated ligands are given in Fig. 8. The state of equilibrium between deprotonated ligand and protonated ligand was examined from the shifting of peaks towards longer wavelength and formation of isosbestic points. No appreciable change in the electronic spectra was observed below the experimental pH < 4.29 and the spectra overlapped with each other. As the pH increases, the spectra showed a bathochromic shift in the absorption band from 281 nm (assigned for $\pi \rightarrow \pi^*$ transitions) to 292 nm and a concomitant increase in absorbance. The shifting was continued till pH 8.27 and between this, the spectra showed two isosbestic points at 270 and 283 nm. Calculation by exclusion of spectra above pH 8.27 gave only three protonation constants, which may be due to the basic $-O^-$ groups of catechol. Since the catechol group is the only significant

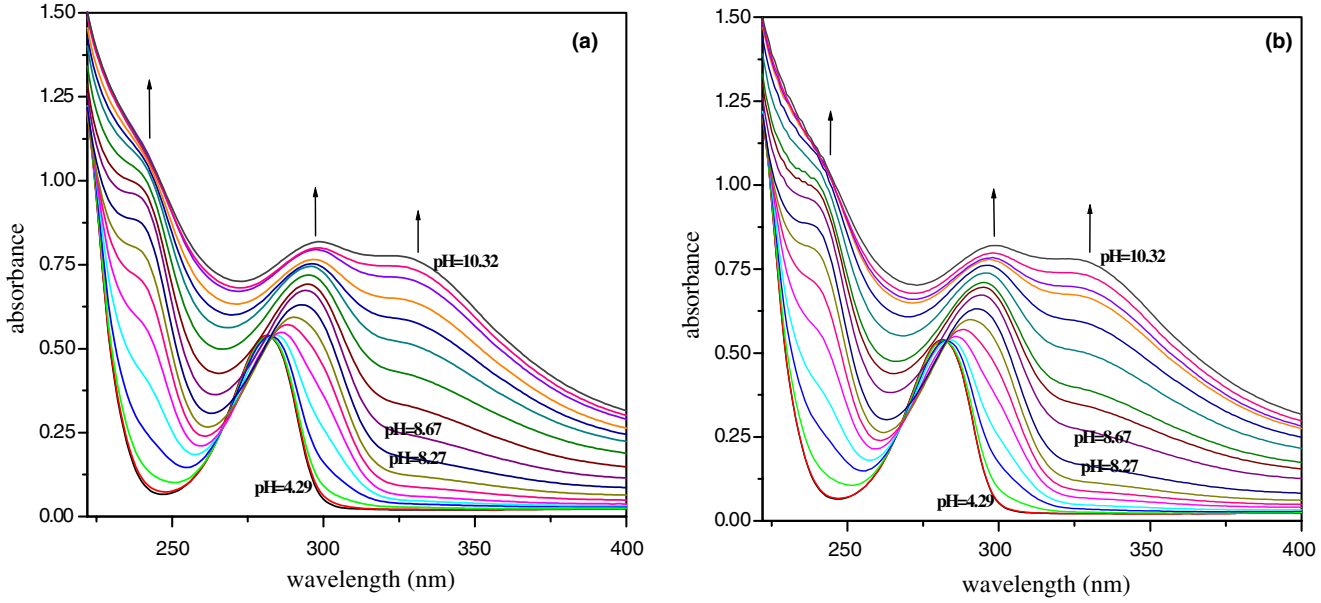

Fig. 7. (a) Experimental electronic spectra and (b) predicted electronic spectral data of TMACHCAT as a function of pH (4.29–10.32) during a spectrophotometric titration: [TMACHCAT] = 0.041 mM; [KCl] = 0.1 M and $T = 25 \pm 1$ °C.

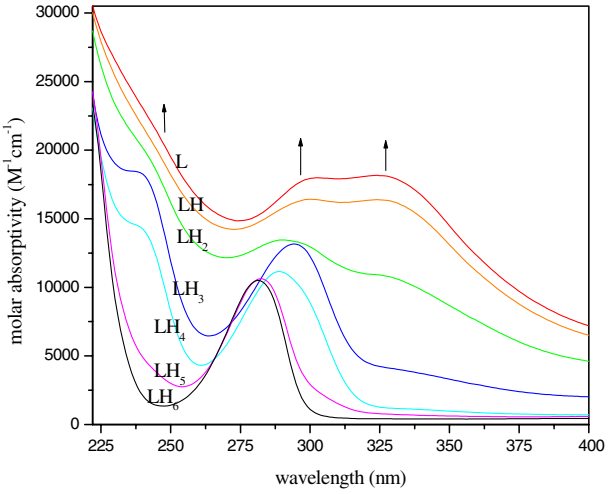

Fig. 8. Electronic spectra of the seven species as a function of molar absorptivity and wavelength predicted from pHAb using experimental data for TMACHCAT.

chromophore in TMACHCAT, any major change in the electronic spectra is attributable to deprotonation from any one of the hydroxy groups, which can able to provide additional opportunity for charge delocalization and thus providing smaller energy increments for transition to excited state. Further, as the deprotonation started from $-NH_2^+$ groups above pH 8.27, no more isosbestic points were observed for the spectra and shifted hyperchromically.

Table 1 summarizes the protonation constants of TMACHCAT along with the related compounds TRENCAT [27], TRNS [40], TAMS [40], TAPS [40] and TACS [40] and their parent tripodal amine TMACH [41], TREN [24], TACH [42], TAME [43] and TAP [44] for comparison. The first three values for TMACHCAT are similar with TRENCAT and TRNS (assigned for deprotonation from –NH– group), while differences are observed for pK_{a3} with TAPS, TACS and TAMS (assigned for deprotonation from OH group). It has been suggested by Orvig et al. that [40], if the parent amine has a $pK_a < 8$, the first deprotonation takes place from amine group followed by phenolic –OH, whereas when $pK_a > 8$ in the parent amine becomes elevated in the corresponding amine phenol. This hypothesis also indicates that in TMACHCAT, the deprotonation reactions started from catecholic –OH groups. Thus, the first three protonation constants viz., 11.26, 10.65 and 9.80 correspond to the secondary amino groups (–NH–) and the next three values viz., 8.48, 7.61 and 6.23 for the protonation of phenolate ($-O^-$) groups of the three catechol units; the later is clearly shown by variable pH UV spectroscopy where, between pH 4.24 and 8.27 there is a bathochromic shift in absorption maxima typical of phenols. Although the protonation constants for the amino groups of TMACHCAT, TRENCAT and TRNS are very similar, these values are higher than their parent amine TMACH and TREN and also the protonation constants for the phenolic groups of TMACHCAT (also for TRENCAT and TRNS) are lower than the 4-sulfophenol ($pK_{1a} = 8.60$) and catechol ($pK_{1a} = 9.13$). This significant difference in the values of protonation constants may be due to the formation of strong ion-hydrogen bonds between the protonated amine and the closest deprotonated phenolate ions. Further, the difference in basicity of the hydroxyl groups for TMACHCAT with respect to catechol ($\Delta \log K = 9.13 - 8.48 = 0.65$) is similar to TRENCAT ($\Delta \log K = 9.13 - 8.51 = 0.62$) but larger than TRNS as compared to with 4-sulfophenol ($\Delta \log K = 8.60 - 8.07 = 0.53$) can be attributed for the formation of secondary hydrogen bonding between the phenolate and the phenolic groups in each catechol units. These observations indicate that the farthest hydroxyl groups are unaffected by change of pH.

In order to verify the validity and assignment made for the experimental protonation constants, gas-phase free energy for the entire representative species was calculated through semi-empiric PM3 quantum mechanical approach. For an acid species AH, the pK_a defined as the negative logarithm of the dissociation constant of the reaction $AH = A^- + H^+$, is given by the thermodynamics relation $pK_a = \Delta G_{gas,AH}/2.303RT$. The change in free energy in gas phase is obtained according to the following equation:

$$\Delta G_{gas,AH} = (G_{gas,A^-} + G_{gas,H^+}) - G_{gas,AH}. \quad (2)$$

For which the proton free energy [45] at 298 K and 1 atm is:

$$G_{gas,H^+} = 2.5RT - T\Delta S^\circ = 1.48 - 7.76 = -6.28 \text{ kcal/mol}$$

The greater acidity belongs to the group in which its hydrogen release is easier and there must be a decrease in ΔG values in the deprotonation process. A clear decrease in ΔG was observed in case TMACHCAT (Fig. 9) as the deprotonation take place from catecholic oxygens followed by protonated amines from fully protonated free ligand, LH_6. The validity of this calculated ΔG_{gas} for the different species of TMACHCAT was compared with the calculated experimental pK_a, which resulted an acceptable correlation with $R^2 = 0.9987$.

3.3. Metal complex formation

Potentiometric titrations of TMACHCAT (L) with La(III), Gd(III) and Lu(III) ions were carried out in 1:1 and 1:2 metal–ligand molar ratios at $\mu = 0.1$ M KCl and 25 ± 1 °C in aqueous medium. The experimental titration curves for the 1:1 metal–ligand molar ratio are given in Fig. 5. The deviation in the metal–ligand titration curves from the free ligand titration curve implies the formation of metal complexes. Complexes

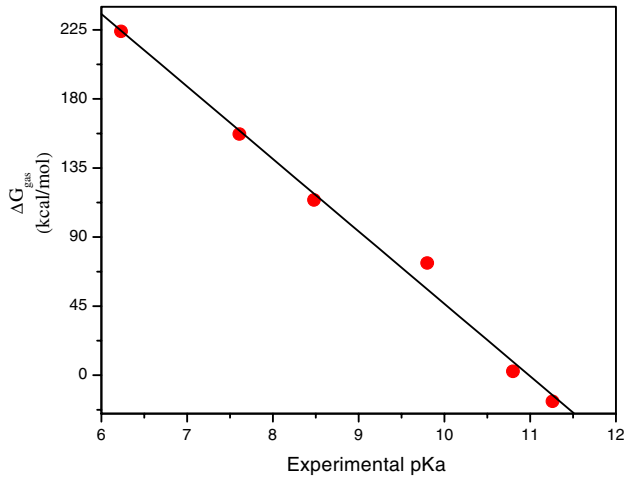

Fig. 9. Correlation between experimental pK_a and the calculated free energy $\Delta G_{gas,AH}$.

due to La(III) formed at higher pH (~5.5), while Lu(III) at the lowest (~4.0) and Gd(III) in between La(III) and Lu(III) (i.e., at ~5), which indicate that the stability of the complexes depends significantly on the charge density of the metal ions. Formation of turbidity and precipitate appeared only after $a > 5$ (a = moles of OH^-/moles of ligand), which implies that five protons have been displaced before hydrolysis of lanthanide ions, and complexation occurred prior to this. Data beyond this (after pH ~ 7) were excluded from calculation. Keeping in view these preliminary observations many sets of possible complexes were tested in the minimization programme and the best-fit model was obtained when formation of protonated species of the types MLH_3, MLH_2 and MLH were considered. From the data of 1:2 metal–ligand molar ratio an additional species ML_2H_6 was also observed. The overall formation constants ($\log\beta$) of the species were calculated using Hyperquad 2000 program and the derived stepwise formation constants ($\log K$) of complexes are summarized in Table 2. The equilibrium reactions for the overall formations of the complexes are given below by Eqs. (3)–(6) (charges are omitted for clarity):

$$M + L + H \rightleftharpoons MLH, \quad \log\beta_{111} = \frac{[MLH]}{[M][L][H]} \tag{3}$$

$$M + L + 2H \rightleftharpoons MLH_2, \quad \log\beta_{112} = \frac{[MLH_2]}{[M][L][H]^2} \tag{4}$$

$$M + L + 3H \rightleftharpoons MLH_3, \quad \log\beta_{113} = \frac{[MLH_3]}{[M][L][H]^3} \tag{5}$$

$$M + 2L + 6H \rightleftharpoons ML_2H_6, \quad \log\beta_{126} = \frac{[ML_2H_6]}{[M][L]^2[H]^6} \tag{6}$$

In order to predict the reaction path sometime it is advantageous to represent the equilibrium reactions in terms of successive formation of complexes. MLH_3 may be regarded to be formed by the reaction of M and LH_3, whereas MLH_2 and MLH may be formed due to dissociation of protons in steps from MLH_3. Also, the species ML_2H_6 is treated as the product of reaction between MLH_3 and LH_3. Accordingly, the derived successive formation constants may be represented as Eqs. (7)–(9).

$$M + LH_3 \rightleftharpoons MLH_3, \quad \log K^{LH_3}_{MLH_3} = \frac{[MLH_3]}{[M][LH_3]} \tag{7}$$

$$MLH_3 \rightleftharpoons MLH_2 + H, \quad \log K^{MLH_3}_{MLH_2} = \frac{[MLH_2][H]}{[MLH_3]} \tag{8}$$

$$MLH_2 \rightleftharpoons MLH + H, \quad \log K^{MLH_2}_{MLH} = \frac{[MLH][H]}{[MLH_2]} \tag{9}$$

$$MLH_3 + LH_3 \rightleftharpoons ML_2H_6, \quad \log K^{MLH_3}_{ML_2H_3} = \frac{[ML_2H_3]}{[MLH_3][LH_3]} \tag{10}$$

The interaction of lanthanide ions with TMACHCAT (L) was also studied by spectrophotometric method to explain the different possible coordination modes of the species in solution. Spectrometric titrations of TMACHCAT was carried out in 1:1 and 1:2 metal-to-ligand ratios with the ligand concentration $[L] = 4.02 \times 10^{-5}$M and

the metal ion concentrations $[M(III)] = 4.02 \times 10^{-5}$M (M:L::1:1) and 2.01×10^{-5}M (M:L::1:2) with increasing pH between 2.5 and 8.0. No spectral changes were observed at low pH (between pH ~ 2.5–4.0) and graphs in this region are excluded. The experimental electronic spectra of TMACHCAT-M(III) systems are given in Fig. 10. Major spectral changes were observed between pH ~ 4.5–8.0, which may be due to the formation of metal complexes. After pH ~ 8, the solution became turbid. The variations in electronic spectra for all metal ions at different pH are almost similar with respect to TMACHCAT indicate similar mode of complexation. The ligand peak at 281 nm (pH ~ 4) was shifted towards higher wavelength with formation of two isosbestic points. No additional band specific to the chelate(s) appeared at long wavelengths. The best-fit model was obtained when formation of the species MLH_3, MLH_2, MLH and ML_2H_6 were considered. The formation constants were calculated from the spectral data using computer program pHAb and the values are given in Table 2.

The pH dependent species distribution curves (Fig. 11) indicate that in acidic condition MLH_3 and MLH_2 predominate whereas in neutral condition MLH and ML_2H_6 predominate. Also, Fig. 11 shows that interaction of ligand with the metal ion takes place in the form of LH_3 to give MLH_3 at pH 4.5, where the free ligand started releasing protons from the more acidic hydroxyl group of catechol (Fig. 6). Comparison of the electronic spectra of LH_3 and MLH_3 also support the above fact. The species LH_3 shows maximum absorbance at 294 nm in the free ligand, whereas in 1:1 M/L solution the said peak appeared at 280 nm assignable

to the coordination of the three catecholic groups to the metal ion. Thus, MLH_3 may be presented as a capped configuration with the coordination of three more acidic catecholic oxygen at *ortho* (Fig. 12a). Raymond et al. have reported the formation constant for the protonated mononuclear catecholate complex $\log K_{Eu(Hcat)}$ to be 7.3 [21]. To the best of our knowledge $\log K_2$, $\log K_3$ or $\log \beta_3$ for catechol with lanthanides have not been reported so far. Considering only the statistical factor, the theoretical $\log \beta_3$ for the formation of $[Eu(Hcat)_3]$ should be 20.9. Since the ligand under study contains three catechol units, the expected formation constant is about 20.9. The stability of MLH_3 ($\log \beta_1 = 39$–42, Table 2) compared with that of $[Eu(Hcat)_3]$ reveals that there is definitely a chelate effect and preorganization in the ligand favouring coordination to lanthanide ions. Molecular modeling calculation of free ligand species LH_3 and $GdLH_3$ (Fig. 13) also indicates that the geometry is stabilized due to the preorganization of ligand architecture by intramolecular hydrogen bonding between protonated nitrogens and phenolic oxygens.

As the pH increases, successive deprotonation from MLH_3 leads to the formation of partially protonated MLH_2 and MLH. Release of these protons from MLH_3 can either take place from the NH_2^+ groups for which the protonation constant values have been evaluated or from catechol ones, for three of which the protonation constant values are unknown. These two probabilities lead to two distinct geometries either nitrogen–oxygen encapsulated or oxygen–oxygen encapsulated. In the first case, for nitrogen–oxygen encapsulated, if the metal ion enters into the nitrogen–oxygen cavity with release of one/two protons from NH_2^+ upon coordination may get repulsive force due to its larger size in the presence of two or one protonated NH_2^+ groups, which on coordination results a six membered chelate ring. However, in second case oxygen–oxygen encapsulated, the ligand coordinates through its more basic catecholic oxygens as anionic donor to form five membered chelate rings. Since the five membered chelate rings is more stable than six membered chelate rings [46] and the latter is more preferable. Also, the bathochromic spectral shifting with concomitant rise in absorbance upon deprotonation from MLH_3 assignable to the coordination of chromophoric catecholic oxygens. This type of coordination is expected for the large size lanthanide (III) metal ions because the binding between lanthanide metals and donor atoms is predominantly ionic in character, and the cations display a strong preference for negatively charged O donor ligands [47]. Moreover, reported results show that tripodal ligands derived from TREN possessing six oxygen functions yielded cationic or neutral complexes in which the nitrogen atoms (imine or amide functions) were not involved

in coordination [48], which was also confirmed by X-ray crystal structure study. This observation strongly suggests that M(III) in the capped MLH_3 is not efficiently protected by the wrapped podand and remain accessible for further complexation to give encapsulated partially protonated complex as shown in Fig. 12(b) and (c). Again, the negative logarithms of stepwise formation constants indicate the instability of the partially protonated complexes. Molecular modeling calculations were carried out to calculate the strain energy for the proposed metal complexes formed in solution. Based on the strain energy (Table 3), it can be suggested that in capped MLH_3 complex, the ligand retain its equatorial conformation but in the encapsulated complex the ligand prefers axial conformation. This change involves a ring-flip into energetically disfavour axial conformer, which is compensated due to coordination to form the encapsulated metal complex. Such ring-flip upon complexation was observed with many TACH derived tripodal ligands [49], but no evidence was reported for conformational interconversion in the uncomplexed ligand. This interconversion in TMACHCAT on forming encapsulated complexes may leads to the negative logarithms of stepwise formation constants.

Formation of ML_2H_6 species was also observed at higher pH for which a bicapped configuration may be proposed (Fig. 12(d)). Comparison of results with other phenol–amines and catechol–amine complexes of lanthanides (Table 2) reveals that, the stability of MLH_3 complexes of TMACHCAT are higher than TRNS lanthanides complexes [$\Delta \log K = 1.65$ for La(III) and 2.14 for Gd(III)]. These increases in stabilizing effect may be due to preorganization of the ligand and easy deprotonation of three highly basic catechol hydrogens of the ligand on complexation profit the coordination of lanthanides to TMACHCAT. Moreover, the stability of TMACHCAT complexes are slightly higher than TRENCAT lanthanide complexes, reflects that increase in cavity size on introducing cyclohexane ring as spacer group, favours more towards the encapsulation chelation of hard cations.

4. Conclusion

Experimental and theoretical studies of the newly synthesized ligand TMACHCAT indicate the presence of intramolecular H-bond, which provide a rigid tripodal framework for complexation. The ligand shows effective binding properties towards trivalent lanthanides due to the increase in cavity size by introducing cyclohexane as spacer unit. The stability increases with decrease in metal ions size. The pH dependent metal–ligand species shows formation of three different structures: (i) capped, (ii) bicapped and (iii) encapsulated, in which only catecholic oxygens take part in complexation whereas protonated amines formed intramolecular hydrogen bonding. It is important to mention here from the ligand

TMACHCAT shows a potential to form mononuclear encapsulated complex at nearly physiological condition, which is important for use as contrast agents in magnetic resonance imaging.

Abstract

Compound **1** has been prepared by the reaction of 4-nitrophthalonitrile and 2-nitro-2-methyl-1,3-propanediol by the common method of nucleophilic substitution of an activated nitro group in an aromatic ring. Interesting binuclear metallophthalocyanines (M = Zn and Co), compounds **2** and **3**, respectively, of a new type have been synthesized from compound **1**, 4,5-bis(hexylthio)phthalonitrile, and the corresponding metal salts [$Zn(OAc)_2$ and $CoCl_2$] by the method of statistically mixed condensation. Compound **2** was converted to the tetranuclear zinc (II) phthalocyanine **4** by the reaction with NaOH solution and activated zinc powder in a mixture of MeOH and THF as the solvent. Impedance spectroscopy (IS) and d.c conductivity ($\sigma_{d.c}$) measurements were performed on spin coated films of these compounds as a function of temperature (290–400 K) and frequency (40–10^5 Hz.) The sensing properties for volatile organic compounds (VOCs) were also investigated. Although the d.c conductivity shows typical Arrehenius behaviour for compound **2**, a discontinous point was observed in the slope of $\ln \sigma_{d.c}$ versus $1/T$ plot for compound **4**. Unlike the films of **2** and **4,** the d.c behaviour of compound **3** obeys the variable range hopping (VRH) model. At room temperature, a curved line was observed from the complex plane plots of impedance for all compounds. These curved lines transformed into a full semicircle with increasing temperature. The a.c conductivity of the films is represented by the form ω^s. The dependency of the frequency exponent s on temperature suggests a correlated barrier hopping. A sensor using compound **4** as the sensing layer had the highest sensitivity for all volatile organic compounds investigated and showed complete reversibility even at room temperature. The results indicated that the film of compound **4** has potential as a sensitive coating for the monitoring of VOC vapours.

1. Introduction

Metal phthalocyanines (MPcs) have been well studied as liquid crystals [1,2], photosensitizers [3], catalysts [4–9], molecular thermometers [10], magnets [11], electrochromic displays [12,13], photovoltaic cells [14], optical limiting devices [15] and gas sensors [16–18] over the last few years. Especially, cobalt phthalocyanine (CoPc) and its derivatives are shown to catalyze reactions like the reduction of oxygen, CO_2, formic acid, formaldehyde, trichloro acetic acid and cysteine-containing proteins. The catalytic behaviour of CoPc complexes is associated with the redox activity of the central metal which undergoes oxidation and reduction related with the Co(3+)/Co(2+) and Co(2+)/Co(I) electrochemical reactions [4–9]. The values of the oxidation or reduction potentials of the central metal in

doi:10.1016/j.poly.2005.07.046

CoPc thus strongly influence the catalytic behaviour of the complexes which is essential for the design of more efficient catalysts. Spectroelectrochemical studies of the phthalocyanines facilitate the understanding of the nature of the redox processes which may occur at either the central metal atom or the phthalocyanine ring, but this cannot usually be distinguished by using electrochemistry alone. Spectroelectrochemical studies of the phthalocyanines are also important with regard to their possible use as electrochromic materials which display several colours depend on the applied potential on the electrode surface [19]. In these respects, the synthesis [20–23], electrochemical [23–25], spectroelectrochemical [23,25–27] and electrocatalytic behaviour [4–9] of cobalt phthalocyanine derivatives have been extensively investigated under different experimental conditions. In particular, multinuclear cobalt phthalocyanines having various kinds of linkage have been the subject of interest in electrocatalysis for the reduction of oxygen at a fuel cell cathode, because the electrocatalyst can participitate in a concerted fashion with a multi-electron reduction which makes it an effective oxygen reduction catalyst to hydrogen peroxide [25].

It is well known that the adsorption of the oxidizing or reducing gases on the surface of MPc films affects their electronic properties. Although many recent reports have been published on the response of MPc films to electron donor and electron acceptor gases such as NH_3 [28], NO_x [29] and halogens [16], very little work has appeared on volatile organic compound (VOC) sensing properties of MPc films. The use of MPcs for the detection of VOC vapours is limited due to the low reactivities of organic gases compared with inorganic gases. In spite of the inadequacy of MPcs for VOC sensing, there has been increasing effort towards the design and synthesis of new molecules to detect and identify VOCs at low concentration that are important in many fields. The determination of the electrical properties of the MPc films is crucial in order to realize the sensing mechanism and their future applications.

We have previously synthesized a triazine carrying three phthalocyaninato zinc (II) macrocycles through amino groups [30] and a new type of sandwich dilutetium tetraphthalocyanine, which exhibits variable range hopping conductivity, as inorganic semiconductors and also observed electrochromic effects from cyclic voltammetric (CV) measurements [31]. In the present work, novel binuclear zinc (II) and cobalt (II) phthalocyanines with alkyl thio substituents have been synthesized from compound **1** and 4,5-bis-(hexylthio)phthalonitrile as two different dinitriles and the corresponding metal salts [$Zn(OAc)_2$ and $CoCl_2$] in a mixed condensation [32]. Binuclear zinc (II) phthalocyanine (**2**) has been converted to a new type of tetranuclear zinc (II) phthalocyanine (**4**). Both d.c and a.c behaviour of the spin coated films of these compounds were studied by using complex impedance spectroscopy. In addition, the response characteristics of the films to organic solvent molecules has been investigated as a function of temperature.

2. Experimental

Routine IR were recorded on a Shimadzu IR-470 Infrared spectrometer as KBr pellets, electronic spectra on a UNICAM UV 500 UV–Vis spectrometer. Elemental analysis was performed by the LECO CHNS 932 in the Instrumental Analysis Laboratory of TUBITAK Ankara Research Center. ^1H NMR spectra were recorded on a Bruker Avance DPX-400 spectrometer. Ten-finger interdigital gold electrodes with 100 μm gap were deposited photolithographically on a pre-cleaned corning glass substrate (substrates were first cleaned thoroughly with soap solution and distilled water). Prior to vacuum evaporation, the glass substrates were cleaned ultrasonically in 2-propanol for 5 min. Thin films of the compounds were obtained by spin-coating chloroform solutions (5×10^{-6} M) of the product over the electrode arrays to obtain devices suitable for electrical and gas sensing measurements. A close-cycle liquid helium cryostat was used to allow electrical characteristics to be measured over a wide temperature range. D.c conductivity measurements were performed between 290 and 400 K by using a Keithley 617 electrometer. A.c conductivity measurements were carried out with a Keithley 3330 LCZ meter in the frequency range 40 Hz to 100 kHz, in the temperature range from 290 to 400 K. During the measurement the temperature of the sample was controlled with a Leybold LTC 60 temperature controller. All the measurements were performed under 10^{-3} mbar in the dark, but the values did not change under illumination with indoor lighting. The conductivity data were recorded using an IEEE 488 data acqusition system incorporating a personal computer. For the gas sensing measurements, the sensors were placed in a teflon chamber and when the sensors were stable, they were exposed to five VOC gases: chloroform, carbon tetrachloride, acetone, methanol and ethanol. The test gases were mixed with dry nitrogen (N_2) using computer derived mass flow controllers (Heastings 200/202 series). The concentration of the target gas was adjusted to 200 ppm. A typical experiment consisted of repeated exposure to an organic solvent vapour and subsequent purging with dry N_2 to reset the baseline. The results obtained under these conditions were reproducible with an uncertainity of less than 3%.

All reagents and solvents were of reagent grade quality, obtained from commercial suppliers. The solvents were stored over molecular sieves (4 Å). 4-Nitrophthalonitrile [33] and 4,5-bis(hexylthio)phthalonitrile [34] were prepared by the literature methods.

3. Syntheses

*3.1. 2-Nitro-2-methyl-1,3-bis(3,4 dicyanophenoxymethyl) propane (**1**)*

A mixture of 2-nitro-2-methyl-1,3-propanediol (2.56 g, 0.019 mol), 4-nitrophthalonitrile (7.96 g, 0.046 mol) and K_2CO_3 (2 g) in 100 ml of DMSO was intensively stirred

for 22 h at 70 °C. After that, 2 g of K_2CO_3 was added and reaction was continued for 11 h at the same temperature. The reaction was monitored by thin layer chromotography (TLC). Then, the reaction mixture was poured into 500 ml of water, and acetic acid (140 ml) was added to the mixture. The residue was filtered off, flushed several times with water until the filtrate was neutral. After that it was washed with diethyl ether (40 ml) and dried in vacuo. After the product had been refluxed in EtOH (400 ml), it was filtered while hot. The yellow precipitate was washed successively with water, ethanol and diethyl ether prior to drying in vacuum at room temperature. The pure product was soluble in DMF, DMSO, ethyl acetate and THF but insoluble in hexane, chloroform and diethyl ether. Yield: 3.49 g, 47%. Melting point 121–123 °C. IR (KBr), $\nu(cm^{-1})$: 3065 (H–Ar), 2215 (C≡N), 1580 (Ar C=C), 1552 (NO_2), 1477, 1406, 1332 (NO_2), 1276, 1249 (Ar–O–C), 1161, 1090, 965, 918, 849, 521. ^{1}H NMR (d_6-DMSO): $\delta = 8.38$–7.28 (m, 6H, ArH), 5.37 (s, 4H, $ArOCH_2$), 1.79 (s, 3H, O_2NCCH_3).

3.2. [(RS)$_6$ZnPc]$_2$NO$_2$ (2)

A mixture of compound **1** (0.100 g, 0.258 mmol), 4,5-bis (hexylthio) phthalonitrile (0.558 g, 1.55 mmol), $Zn(OAc)_2 \cdot 2H_2O$ (0.119 g, 0.542 mmol) and dry quinoline (2 ml) was heated and stirred at 180–190 °C under argon for 24 h. After cooling to room temperature, the dark green mixture was diluted with ethanol (10 ml) and the crude product precipitated. This was filtered off. After having been washed with hot water and hot ethanol to remove the unreacted organic materials, the precipitate was dissolved in chloroform (90 ml), the solution was filtered and the filtrate evaporated to a smaller volume (ca. 20 ml) from which a dark green precipitate was obtained by addition of acetone (180 ml). It was filtered, washed successively with DMSO (3×20 ml), ethyl acetate (3×20 ml), ethanol (3×20 ml) and acetone (3×20 ml) prior to drying in vacuo. Finally, pure **2** was obtained by chromatography with silica gel using $CHCl_3$ as the first eluent and then CCl_4:THF = 10:1. The dark green product was soluble in $CHCl_3$, benzene and THF but only moderately soluble in diethyl ether. Yield: 0.252g, 36%. Melting point >300 °C IR (KBr, cm^{-1}): 3010 (CH aromatic), 2890–2830 (CH_2, CH_3), 2340, 1580 (Ar C=C), 1540 (NO_2), 1447, 1393, 1367 (NO_2), 1232 (Ar–O–C), 1177, 1075, 1054, 935, 443, 426. ^{1}H NMR (*d*-chloroform) δ: 7.94–6.96 (m, 18H, ArH), 5.34 (s, 4H, $ArOCH_2$), 2.11 (br s, 24H, SCH_2), 1.72 (s, 3H, O_2NCCH_3), 1.50–1.09 (m, 96H, CH_2), 0.82 (s, 36H, CH_3).

3.3. [(RS)$_6$CoPc]$_2$NO$_2$ (3)

A mixture of compound **1** (0.100 g, 0.258 mmol), 4,5-bis(hexylthio) phthalonitrile (0.558 g, 1.55 mmol), $CoCl_2 \cdot 6H_2O$ (0.128 g, 0.535 mmol) and ethylene glycol (4 ml) was heated and stirred at 170–180 °C under argon for 22 h. After cooling to room temperature, water (5ml) was added to the mixture. The precipitate was filtered and washed with hot water several times followed by hot ethanol and acetone, and then dried. The crude product was dissolved in $CHCl_3$ (150 ml) and filtered. After the filtrate had been evaporated to a smaller volume (ca. 20 ml), it was reprecipitated with ethyl acetate (170 ml) and the precipitate was washed with hexane (3×20 ml), CCl_4 (3×20 ml), hot DMSO (3×20 ml), ethyl acetate (3×20 ml), ethanol (3×20 ml), acetone (3×20 ml) nad diethyl ether (3×20 ml). It was then dried in a vacuum at room temperature. Compound **3** was isolated on a silica gel column first with $CHCl_3$ and then with CCl_4:THF = 10:1 as eluents. The dark green product was soluble in $CHCl_3$ and THF. Yield: 0.168g, 24%. Melting point >300 °C IR (KBr, cm^{-1}): 3010 (CH aromatic), 2895–2830 (CH_2, CH_3), 2340, 1584 (Ar C=C), 1540 (NO_2), 1401, 1370 (NO_2), 1232, (Ar–O–C), 1061, 948.

3.4. [(RS)$_6$ZnPc]$_4$N$_2$ (4)

A mixture of compound **2** (90 mg, 0.0336 mmol), NaOH solution (1 ml, 0.268 M), MeOH (4 ml) and THF (20 ml) was stirred at room temperature for 15 min. Then, activated zinc powder (8.71 mg, 0.134 mmol) was added to the reaction mixture and refluxed for 8 h. After completion of the reaction, the reaction mixture was filtered while hot and the residue on the filter was washed with 15 ml of MeOH. After that, concentrated HCl (12 ml, 37%) was added to the filtrate until it was neutral and the precipitate was filtered, washed successively with water, MeOH (2×20 ml), EtOH (2×20 ml), ethyl acetate (2×20 ml), benzene (2×20 ml),acetone (2×20 ml), chloroform (2×20 ml) and diethyl ether (2×20 ml) prior to drying in vacuo. The dark green product was soluble in hot DMF, hot DMSO and hot THF. Yield: 60 mg, 68%. Melting point >300 °C IR (KBr, cm^{-1}): 3010 (CH aromatic), 2915–2840 (CH_2, CH_3), 2340, 1580 (Ar C=C), 1401, 1232 (Ar–O–C), 1075, 1054, 935, 443, 426. ^{1}H NMR (*d*-DMSO) δ: 8.62–6.92 (m, 36 H, ArH), 4.17 (s, 8H, $ArOCH_2$), 3.31–2.63 (m, 48H, SCH_2), 1.73 (s, 192H, CH_2), 1.47 (s, 6H, –N=NCCH$_3$), 0.95 (s, 72H, CH_3).

4. Results and discussion

Our key starting material is compound **1** which can be obtained via a single step reaction of 2-nitro-2-methyl-1,3-propanediol with 4-nitrophthalonitrile in dry DMSO as the solvent in the presence of K_2CO_3 as the base in a yield of 47% (Scheme 1). A new type of binuclear metallo phthalocyanine (M = Zn, Co) was synthesized from compound **1** and 4,5-bis(hexylthio)phthalonitrile and the corresponding metal salts [$Zn(OAc)_2$, $CoCl_2$] by the method of statistically mixed condensation. The high boiling solvents of choice for these reactions were quinoline for binuclear zinc (II) phthalocyanine (**2**) and ethylene glycol for binuclear cobalt (II) phthalocyanine (**3**). After work-up, the product mixtures were purified by chromatography over silica. The first fraction proved to be the corresponding

octa(hexylthio)phthalocyanine, identified by TLC comparison with an authentic sample [34]. The second fraction, which still contained traces of the octa(hexylthio)phthalocyanine together with the slower moving compound, gave after additional chromatography the products **2** and **3**. Binuclear zinc (II) phthalocyanine (**2**) was converted to the novel tetranuclear zinc (II) phthalocyanine (**4**) by the reaction with NaOH solution and activated zinc powder in a mixture of MeOH and THF. All of the new compounds were characterized by elemental analysis (Table 1), IR, UV–Vis (Table 2) and ^{1}H NMR spectroscopic techniques.

3	$CHCl_3$	715 (4.42), 639 sh (4.27), 315 (4.61)
4	DMF	697 (4.63), 634 sh (4.03), 367 (4.30)

sh, shoulder.

The spectroscopic data of the new compounds were in accordance with the structures. The IR spectra taken with KBr pellets showed a $-NO_2$ peak at 1552 and 1332 cm^{-1} and an intense absorption attributable to Ar–O–C at 1249 cm^{-1}, an Ar C=C peak at 1580 cm^{-1} and an aromatic CH peak at 3065 cm^{-1} for compound **1**. After conversion of compound **1** to pc **2** and **3**, the sharp C≡N vibration at 2215 cm^{-1} disappeared. The IR spectra of the metal phthalocyanines, which are very similar to each other, showed Ar–O–C peaks at 1232 cm^{-1} for all of the phthalocyanines. In addition, the stretching peaks at 2890–2830, 2895–2830 and 2915–2840 cm^{-1} indicate the presence of $-CH_2$ and $-CH_3$ in the substituents for the phthalocyanines **2**–**4**, respectively.

The ^{1}H NMR spectra were also in good correlation with the structures of the synthesized compounds. In the ^{1}H NMR spectrum of compound **1**, which was taken in DMSO, the aromatic protons appeared at 8.38–7.28 ppm as a multiplet. The peaks at 5.37 and 1.79 ppm indicated the presence of a $ArOCH_2$ group and a O_2NCCH_3 group in the structure, respectively. In the ^{1}H NMR spectrum of zinc (II) phthalocyanine **2**, which was taken in *d*-chloroform, the aromatic protons appeared at 7.94–6.96 ppm, $ArOCH_2$ protons at 5.34 ppm, O_2NCCH_3 protons at 1.72 ppm, the $-CH_2-$ protons in the long aliphatic chain at 1.50–1.09 ppm and the $-CH_3$ at the end of the chain at 0.82 ppm. The peak at 2.11 ppm indicated the presence of a $-SCH_2-$ group neighboring an aromatic ring in the structure. The ^{1}H NMR spectrum of compound **4** was similar to that of compound **2**. The aromatic protons were found at 8.62–6.92 ppm, the $ArOCH_2$ protons at 4.17 ppm and the $N{=}NCCH_3$ protons at 1.47 ppm. The $-CH_2-$ protons in the long aliphatic chain were observed at 1.73 ppm, $-SCH_2$ protons neighboring an aromatic ring at 3.31–2.63 ppm and the $-CH_3$ protons at the end of the chain at 0.95 ppm. ^{1}H NMR measurements were precluded for the cobalt (II) phthalocyanine (**3**) owing to its paramagnetic nature [35–38].

The phthalocyanines show typical electronic spectra with two strong absorption regions, one of them in the UV region at about 300–400 nm (B band) and the other in the visible portion at 600–700 nm (Q band). While the monomeric species with D_{2h} symmetry, i.e metal-free derivatives, show two intense absorptions of comparable intensity around 600–700 nm, those having D_{4h} symmetry give only a single band in this region.

The typical UV–Vis spectra of phthalocyanine **2** exhibited characteristic Q and B bands, one in the visible region at 712 nm (Q-band) attributed to the the $\pi \rightarrow \pi^*$ transition from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO) of the pc^{2-} ring, and the other in the UV region at 322 nm (B-band) arising from the deeper π levels $\rightarrow$ LUMO transition. The electronic spectra are especially fruitful in establishing the structure of phthalocyanines **3** and **4**. The electronic spectra of the metal phthalocyanines show the characteristic Q-band absorptions as a single peak at 715 nm in the binuclear cobalt phthalocyanine **3** (Fig. 1) and at 697 nm in the tetranuclear zinc phthalocyanine **4** (Fig. 2). B bands of the phthalocyanines **3** and **4**, arising from the deeper π levels $\rightarrow$ LUMO transitions, are observed in the UV region at about 315 and 367 nm, respectively. The phthalocyanine **3** shows an additional band centered at ca. 70 nm to the blue of the normal Q-band as a result of aggregation through exciton coupling of the phthalocyanine units [25] (Table 2). In compound **4**, this band is attributed as a Q-band satellite. The intensity of

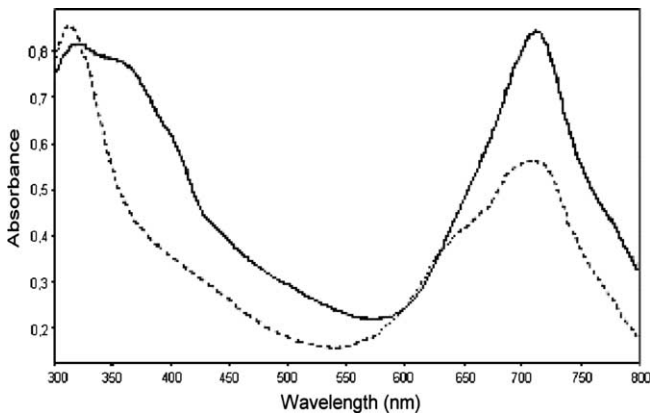

Fig. 1. UV–Vis spectra for the phthalocyanines **2**(—-) and **3** (·····).

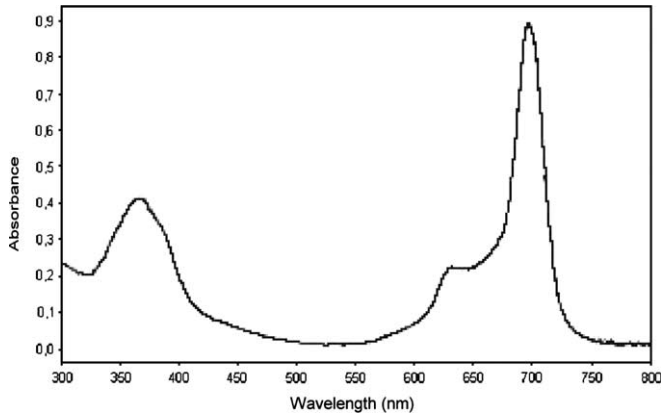

Fig. 2. UV–Vis spectra for the phthalocyanine **4.**

the Q-band relative to B is also low for binuclear cobalt phthalocyanine **3** (Fig. 1). This result is similar to those previously observed for binuclear cobalt phthalocyanines [24].

The temperature dependence of the dark d.c conductivity was obtained by the rapid cooling method which allows the avoidance of the influence of the sorption-desorption process. Fig. 3 shows the variation of d.c conductivity of compounds **2**–**4** as a function of reciprocal temperature in the temperature range 290–400 K. The well defined straight line obtained from the Arrehenius plot suggests the presence of only one conduction mechanism in the temperature range of 290–400 K for the film **2**. Thus, it is reasonable to represent the temperature dependence of conductivity for the film **2** by the well known expression,

$$\sigma_{d.c} = \sigma_0 \exp\left(-\frac{E_A}{kT}\right), \quad (1)$$

where E_A is the activation energy and k is the Boltzmann's constant. The value of the activation energy, derived from the slope of the $\log\sigma_{d.c}$ versus $1/T$ graph, is 0.91 eV for compound **2**. A deviation from linearity of the $\log\sigma_{d.c}$ versus $1/T$ plot at ~353 K was observed for compound **4**. As seen from Fig. 3, the graph splits into two different linear regions, and each region can be ascribed a different activation energy corresponding to a different dominant excitation. The activation energies obtained for region I and II were found to be 0.46 and 1.24 eV, respectively. Two different linear regions in the Arrehenius plot and hence two activation energy values, as in our case, is interpreted as a transition from extrinsic to intrinsic conduction by Nakada et al. [39]. Robinet and Clarisse [40] reported that adsorbed O_2 molecules introduce an acceptor level within the band gap and demonstrates itself as a break in the $\ln\sigma_{d.c}$ versus $1/T$ graph indicating the change from an extrinsic to an intrinsic region. A discussion of the O_2 kinetics is not the aim of this paper, but indicating that the anamoly in conductivity is not an intrinsic phenomenon. A completely different conduction mechanism was observed for compound **3**. It is clear from Fig. 3 that the temperature dependence of d.c conductivity cannot be explained by the band conduction model. This type of conduction is described by variable range hopping (VRH) of barriers in 3-dimensions, as proposed by Mott [41]. The VRH model has been extensively applied to various amorphous semiconductors over the last few decades, and recently has also been applied with a varying degree of success to conducting polymers [42]. Recently Altındal et al. [43] have shown the applicability of Mott's VRH model in spin coated phthalocyanine films. According to the VRH model, the temperature dependence of conductivity is given by

$$\sigma_{d.c} = \sigma_0 \exp\left[-\left(\frac{T_0}{T}\right)^{\gamma}\right], \quad (2)$$

where σ_0 is the high temperature limit of conductivity and T_0 is associated with the degree of localization of the electronic wave function. The exponent γ determines the dimensionality of the medium. We have plotted the d.c conductivity data as a function of $T^{-1/4}$ in Fig. 4. It is evident from the plot of $\ln\sigma_{d.c}$ versus $T^{-1/4}$ that the three-dimensional VRH model gives an excellent fit

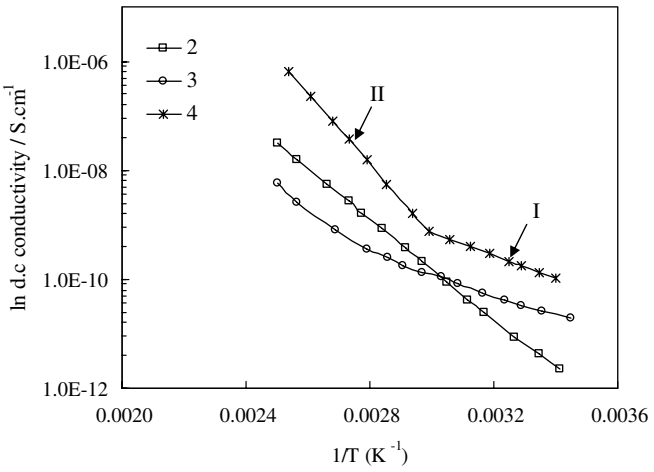

Fig. 3. Dependence of d.c conductivity on the inverse of temperature for spin coated films of compounds **2** –**4**.

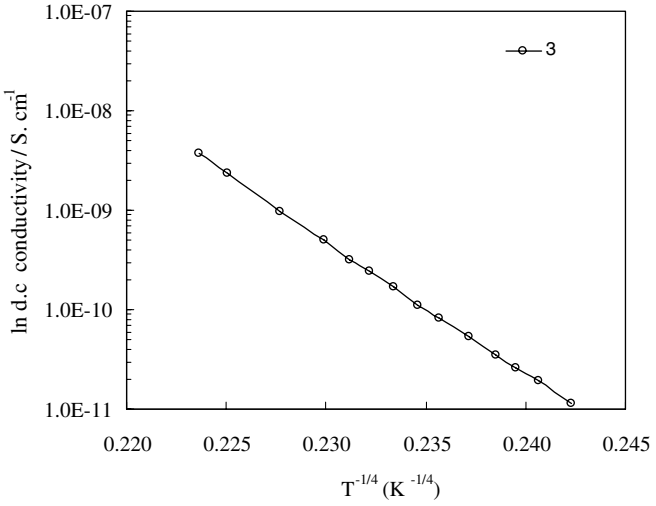

Fig. 4. D.c conductivity of film **3** as plotted against $T^{-1/4}$.

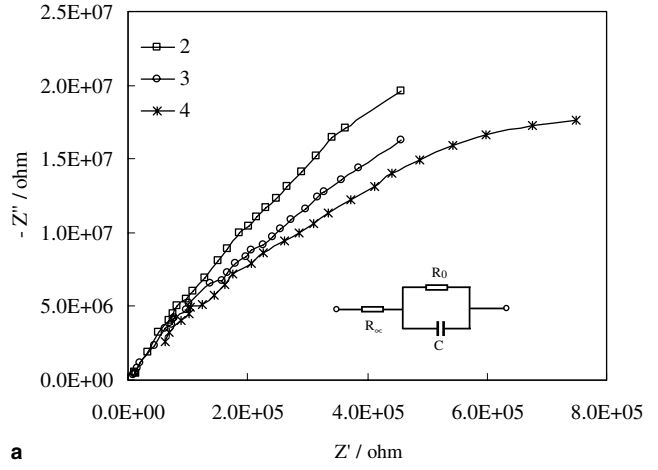
to the experimental results. Fig. 4 predicts that three-dimensional charge transport occurs in film **3**.

Cole–cole spectra of the complex impedance, $Z = Z' + jZ''$, of the pc films were recorded in the frequency range from 40 Hz to 100 kHz. The impedance spectra of compounds **2**–**4** measured at room temperature (Fig. 5(a)) and 400 K (Fig. 5(b)) are shown in Fig. 5. A quasi-vertical line was observed in the Nyquist plot for all the samples at room temperature. This results means that the impedance becomes capacitive even at a relatively high frequency. In this case, the measured impedance data can be modelled as a capacitor in parallel with a resistor in series with another resistor as shown in Fig. 5(a). The resistance R_0 in the equivalent circuit is defined as $R_0 = R_{d.c} - R_\infty$. R_∞ and $R_{d.c}$ represent the resistance at $\omega \to \infty$ and $\omega \to 0$, respectively. The impedance response of the compounds significantly changes with temperature. On the complex plane plot, only depressed semicircles with different radius were observed for compounds **2**–**4** at 400 K, indicating deviation from the Debye dispersion relation. In the case of a depressed semicircle in the impedance spectra, the relaxation time is considered as a distribution of values, rather than a single relaxation time.



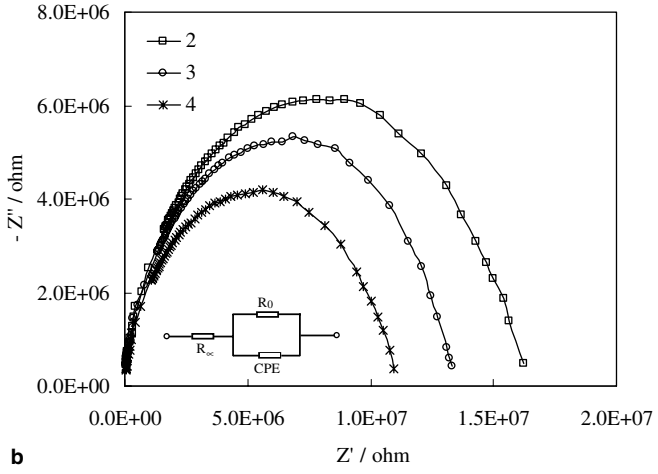


Fig. 5. Nyquist plot (Z'' vs. Z') of the samples: at room temperature (a) and 400 K (b).

Therefore, the equivalent circuit is modified to include a constant phase element (CPE) as shown in Fig. 5(b). The series resistance in the equivalent circuit represents the ohmic losses in the test fixture and electrode sheet resistance. The parallel resistance is of the coating material in parallel with that of the substrate. The presence of the constant phase element represents a slight distribution of relaxation times instead of a discrete relaxation time. This conclusion was supported by another type of Bode plot (log $|Z|$ versus log $|f|$). The Bode plot for compound **4** is shown in Fig. 6. The dependence of log $|Z|$ versus log $|f|$ shows a slope of -0.987, corresponding to capacitive behaviour at room temperature. At 400 K, the slope for log $|Z|$ versus log |f| is -0.505 which indicates the presence of a CPE . Similar results of the Bode plot were found for compounds **2** and **3**.

The total conductivity, $\sigma_{tot.}$, over a range of frequencies, may often be expressed according to the following expression:

$$\sigma_{tot.} = \sigma_0 + \sigma(\omega), \tag{3}$$

where σ_0 is the d.c conductivity. The frequency dependent part of the total conductivity, $\sigma(\omega)$, is given by the power law of the form [44],

$$\sigma(\omega) = A\omega^s \tag{4}$$

where A and s are temperature dependent parameters. As a representative result, the temperature dependence of the measured a.c conductivity as a function of frequency at the indicated temperature are shown in Fig. 7 for film **4.** Low frequency conductivity measurements could not be performed below 337 K due to its high resistivity. As seen from Fig. 7 for a temperature above 337 K, there is a nearly constant conductivity at low frequency and after a certain characteristic frequency it increases with the power law. Similar results were obtained for films **2** and **3**. Various models such as quantum mechanical tunelling (QMT) and correlated barrier hopping (CBH) has been proposed to explain this type of behaviour, but it is not easy to decide which of those mechanism is responsible for the observed

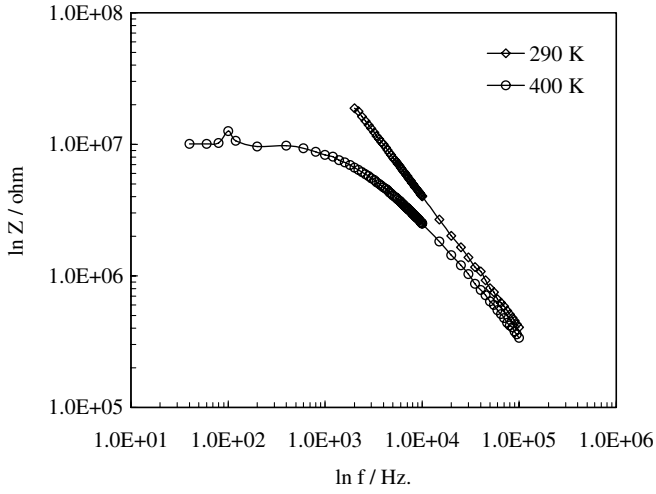

Fig. 6. Bode plot for compound **4** at room temperature and 400 K.

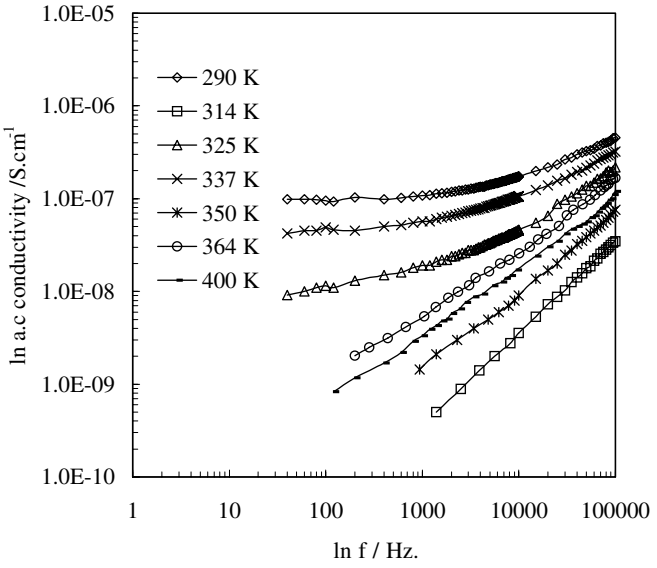

Fig. 7. Frequency dependent conductivity of film **4** at selected temperatures.

conduction mechanism. However, the behaviour of the exponent s with temperature can help in determining the possible conduction mechanism. Fig. 8 shows the thermal variation of the frequency exponent s for all compounds The values of s are calculated from the slope of $\ln\sigma(\omega, T)$ versus ln f graphs and were generally found to decrease with increasing temperature. The behaviour of s with temperature cannot be explained by the QMT model. This model, which is based on phonon asissted tunnelling of electrons predicts a temperature independent frequency exponent s with a constant value around 0.8. According to the CBH model, which was developed by Eliot [45], the a.c conductivity which can be expressed to a first-order approximation as

$$\sigma(\omega) = \frac{\pi^2 N^2 \varepsilon}{24}\left[\frac{8e^2}{eW_m}\right]^6 \frac{\omega^s}{\tau_0^\beta}, \tag{5}$$

where N is the density of localized states, ε the permittivity, τ_0 the effective relaxation time, e the electronic charge and s is predicted to be temperature dependent following an equation of the form,

$$s = 1 - \frac{6kT}{W_m} \tag{6}$$

where W_m is the optical band gap. Unlike the QMT model, the CBH model predicts a temperature dependent s parameter which decreases with increasing temperature.

It is clear from the temperature dependence of the frequency exponent s (Fig. 8) that our data are quantitatively consistent with the prediction of the CBH model.

It is known that when a test gas molecule is adsorbed on the surface of a phthalocyanine film it causes a variation in physical or chemical properties, such as conductivity. The effect of the same concentration (200 ppm) of five different VOC vapours on the conductivity of the film of **4** is shown in Fig. 9 at room temperature. As usual, a d.c voltage of 0.6 volt was applied to the sensor during the measurements. At a sensing temperature of 290 K, the current level in nitrogen environment was 1.05×10^{-10} A. After exposure to 200 ppm VOC vapours, the current increased sharply in the initial doping stage for a few minutes and then the rate of increase slowed down to reach a current of 5.6×10^{-10} and 2.42×10^{-10} A after 10 min for chloroform (maximum current change) and ethanol (minimum current change), respectively. Although a complete steady-state current, which quantifies the VOC concentration, cannot be approached during a period of 10 min even at an operating temperature of 400 K, the incease in current is adequate to indicate the presence of VOC vapours in the atmosphere. Fig. 9 also shows that the response characteristics of compound **4** to VOC vapours are different. It is noticed that there are two stages of current changes, an initial fast decrease followed by a slow drift, in the recovery processes. The kinetics of adsorption can be described, bearing in

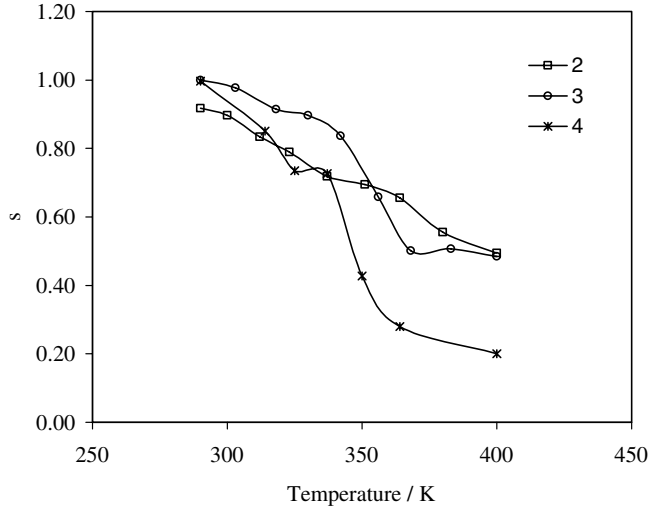

Fig. 8. The variation of the frequency exponent s with temperature for compounds **2**–**4**.

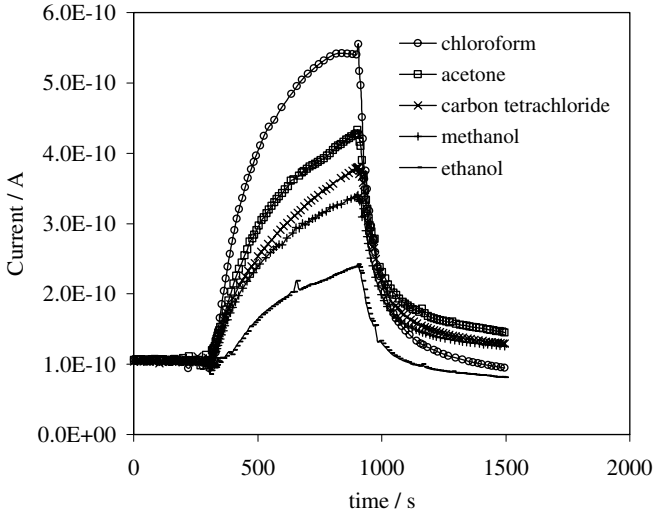

Fig. 9. Current vs. time of a spin coated film of **4** exposed to 200 ppm of five different VOC vapours.

mind that phthalocyanines are p-type semiconductors, in terms of a charge transfer interaction between the phthalocyanine and VOC vapours.

In our case the VOCs would play an electron acceptor role. When the VOC molecules interact with the π-elecron network of the phthalocyanines, it causes the transfer of an electron from the phthalocyanine ring to the VOC molecule. Thus, the induced positive holes on the film surface give rise to an increase in the p-type conductivity of the film. The failure to return to baseline after the VOC vapours are removed originates from the strong bonding of the VOC molecules on the surface. Similar response characteristics were obtained for other sensors based on phthalocyanine films [46]. In order to determine the optimal working temperature, the sensing measurements were carried out in the temperature range of 290–400 K. Fig. 10 shows the sensitivity of the film **4** to 200 ppm concentrations of VOC vapours as a function of sensing temperature, where the sensitivity (S) is defined as

$$S = \frac{1}{C}\left[\frac{\Delta I}{I_0}\right], \tag{7}$$

where ΔI is the change in current at a concentration of organic solvent vapor (C), I_0 is the reference value of the coated devices expoed to dry nitrogen (without the doping VOC vapours). Maximum sensitivity was obtained at room temperature and the sensitivity of the film decreases rapidly with increasing temperature (Fig. 10). This type of behaviour has previously been reported [47] and was explained on the basis of the negative heat of adsorption. In general, the sensitivity of the sensor has been related to the number of the active adsorption sites on the sensing layer.

The present result shows that the increase in temperature gives a significant effect in reducing the sensitivity. Electron microscopy studies of thin phthalocyanine films show that heat treatment induces crystallization of the amorphous region [48]. The decrease of sensitivity with increasing temperature is consistent with the thermally induced structural changes. Like the device coated with **4**, the sensors coated with **2** and **3** also exhibited a reduction of sensitivity with increasing temperature. Consequently, the sensitivity of the compound **4** film is the highest for all the VOC vapours investigated. The maximum sensitivity with all the sensors are obtained at room temperature for all organic solvents. In light of the above result, it seems that the surface processes occuring on the sensing layer during the exposure to VOC vapours still need to be given detailed research.

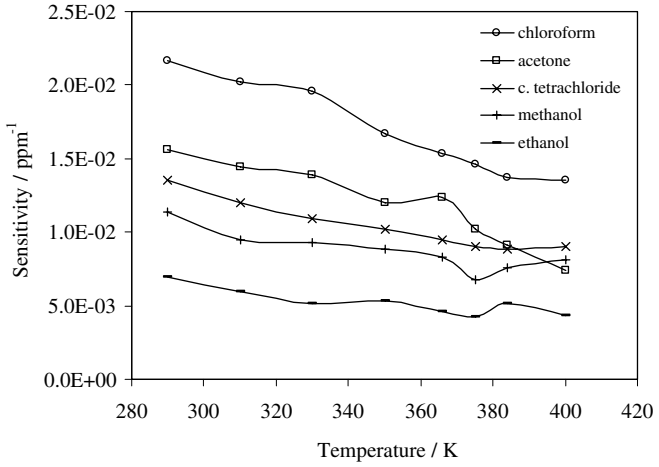

Fig. 10. The variation of the sensitivity with temperature for film **4** for the indicated VOC vapours.

5. Conclusion

2-Nitro-2methyl-1,3-bis(3,4-dicyanophenoxymethyl)propane was synthesized and used as a key compound for the preparation and characterization of novel multinuclear metallophthalocyanines (Zn, Co) with alkylthio substituents. The d.c and detailed a.c impedance spectroscopy techniques have been used to investigate the charge transport mechanism and the response characteristics of novel multinuclear metallophthalocyanines with alkylthio substituents to VOC vapors. While the d.c conductivity of film **2** shows an Arrhenius dependence in the temperature range of 290–400 K, a transition from extrinsic to intrinsic conductivity at ~353 K was observed for film **4.** The temperature dependence of the d.c conductivity of compound **3** was well represented by the variable range hopping model, $T^{-1/4}$ law, in the whole temperature range. The a.c. conductivity $\sigma(\omega)$ varied as ω^s , where the exponent s was found to be a temperature dependent variable and always less than unity. An analysis of the measured a.c conductivity data and the dependency of frequency exponent s on temperature indicated that the conduction mechanism can be explained by the correlated barrier hopping (CBH) model for all compounds. It was found from the gas sensing measurements that the increase in temperature reduces the sensitivity of the films to VOC vapors. The impedance spectra of the films can be represented by an electrical equivalent circuit.

Abstract

Reactions of $[(4\text{-}MeOC_6H_4COCH_2)Ph_3P]Br$ (**1c**) with $(4\text{-}XC_6H_4COCH_2)_2TeBr_2$ (X = H, **2a**; Me, **2b**; OMe, **2c**) lead to Te–C bond cleavage to afford $[(4\text{-}MeOC_6H_4COCH_2)Ph_3P]_2[TeBr_6]$ (**3c**). The analogous complexes $[(4\text{-}MeC_6H_4COCH_2)Ph_3P]_2[TeBr_6]$ (**3b**) and $[(C_6H_5COCH_2)Ph_3P]_2[TeBr_6]$ (**3a**) are obtained from the reaction of the corresponding phosphonium bromide with **2c**. The 1:1 adducts $[(4\text{-}XC_6H_4COCH_2)Ph_3P]^+[(4\text{-}XC_6H_4COCH_2)_2TeBr_3]^-$, formed as intermediates, could be isolated only in case of X = H or Me. The crystal structure of **3b**, which crystallizes with one molecule of dichloromethane, shows the presence of close C–H···Br/Cl contacts among the ions and solvated molecules. These weak interactions distort, though marginally, the otherwise ideal octahedral shape of the $[TeBr_6]^-$ anion adopted as a consequence of stereochemical inertness of the lone pair on the central tellurium atom. The supramolecular extended arrays of ionic molecular units formed by means of solvated head-to-tail linkers are identified.

Keywords: Te–C bond cleavage; Intramolecular coordination; Secondary interaction; Anionic complexes; Supramolecular association

1. Introduction

Hexahalotellurates(IV) and their oligomeric anionic species are interesting examples of stereochemical inertness of a lone pair on the central atom. Similar anionic species containing one or two Te–C bonds have been comparatively less studied [1,2] though the first of such five-coordinate anions, $[MeTeCl_4]^-$, was prepared as early as 1929 [3]. Anions with two Te–C bonds are comparatively rare and appear to be particularly stable when the two Te–C bonds are part of a cycle, e.g., $[-(CH_2)_4-TeX_4]^{2-}$ [2]. We have recently reported the preparation and structural characterization of bis(4-substitutedbenzoylmethyl)tellurium dihalides (**2**) [4]. The crystal structure of **2a**, its iodide anologue and **2c** showed the presence of rare intramolecular 1,4-Te···O(C) secondary interactions which tend to saturate the Te atom coordinatively and discourage ubiquitous intermolecular Te···X (halide) bonding in the solid state. It appeared, therefore, of interest to examine the acceptor property of **2** towards a few phosphonium bromides with varying electronic environments at the phosphorus center.

2. Results and discussion

Reactions of (4-substitutedbenzoylmethyl)triphenylphosphonium bromides, $[(4\text{-}XC_6H_4COCH_2)Ph_3P]Br$, (X = H, **1a**; Me, **1b**; OMe, **1c**) with bis(4-substitutedbenzoylmethyl)tellurium dibromides, $(4\text{-}XC_6H_4COCH_2)TeBr_2$ (X = H, **2a**; Me, **2b**; OMe, **2c**) have been carried out in dichloromethane or chloroform. The isolable product in the reaction of **1c** with **2a**, **2b** or **2c** is the phosphonium salt of hexabromotellurate(IV), $[(4\text{-}MeOC_6H_4COCH_2)Ph_3P]_2[TeBr_6]$ (**3c**). Similarly, reaction of **1a** or **1b** with **2c** affords the corresponding $[(4\text{-}XC_6H_4COCH_2)Ph_3P]_2[TeBr_6]$, [X = H, **3a**; Me, **3b**]. All these reactions must involve cleavage of both the Te–C bonds of **2** while the P–C bonds remain intact. The ^{1}H NMR spectra of **3** show a multiplet for aryl protons and a doublet for P–CH_2 protons with $^2J(^{31}P\text{–}^1H)$ ~12 Hz. The molar conductivity of **3** in nitrobenzene (40–42 Ω^{-1} cm^{-1} mol^{-1}) is consistent with the 2:1 electrolytic nature.

The reaction between **1a** and **2a** or **1b** and **2b** in 1:1 or 2:1 ratios initially affords the expected 1:1 adduct, $[(4\text{-}C_6H_4COCH_2)Ph_3P]^+[(4\text{-}XC_6H_4COCH_2)_2TeBr_3]^-$ (X = H, **4a**; Me, **4b**) along with the separation of traces of elemental tellurium. Both **4a** and **4b** give reasonably good elemental analyses and are 1:1 electrolytes as shown by their conductivity measurements. It is their ^{1}H NMR spectra which are intriguing. The ^{1}H NMR spectra of **4a** and **4b** show, in addition to a multiplet for aryl protons, a doublet for P–CH_2[$^1J(^{31}P\text{–}^1H)$ = 12.01–12.30 Hz] and a singlet for Te–CH_2 protons in a 1:1 ratio rather than the expected 1:2 ratio. The spectrum of **4b** (X = Me) also consists of an additional two singlets in a 1:1 ratio for the methyl protons. These observations suggest disproportionation of the 1:1 adducts (**4a** or **4b**) in $CDCl_3$ (Eq. (1)). While the formation of **A** is less likely as the reaction of **1a** with **2a** or **1b** with **2b** even in a 2:1 molar ratio affords only **4a** or **4b**, the complex **B** receives support from

$$[RPh_3P]_2[TeBr_6.TeR_2]_{\mathbf{B}} \xleftarrow[\text{or}-2RH]{-R-R} 2[RPh_3P][R_2TeBr_3] \xrightarrow[-R_2TeBr_2]{} \underset{\mathbf{A}}{[RPh_3P]_2[R_2TeBr_4]}$$
$$R = 4 - XC_6H_4COCH_2; (X = H, Me) \quad (1)$$

the recent isolation of $[TeBr_6\cdot(SeBr_2)_2]^-$ and $[TeBr_6\cdot(Se_2Br_2)_2]^-$ anions with unsymmetrical phosphonium cations [5]. However, repeated attempts to crystallize **4b**, in dichloromethane, eventually afford X-ray grade crystals of **3b**. It is thus interesting to note that the MeO substituent in the phenyl ring of the phenacyl ligand promotes the cleavage of Te–C bonds and leads to the instantaneous formation of **3** while the Me substituent initially gives the 1:1 adduct.

2.1. Crystal structure of *3b*

The crystal structure of $[(4\text{-}MeC_6H_4COCH_2)Ph_3P]_2[TeBr_6]\cdot CH_2Cl_2$ together with the atom numbering scheme is shown in Fig. 1, and the bond parameters are presented in Table 1. The lattice is composed of discrete $[TeBr_6]^-$ anions and $[(4\text{-}MeC_6H_4COCH_2)Ph_3P]^+$ cations together with dichloromethane molecules. The asymmetric unit consists of one cation and only halves of the anion and the solvated molecule. The geometry of the hexabromotellurate anion is nearly octahedral,

Symmetry transformations used to generate equivalent atoms: #1x, $-y-1/2$, $-z+2$.

typical of TeX_6^{2-} (X = Cl [6], Br [7], I [8]) anions, which are reported to be unaffected by the size of the counter cations [9]. This geometry is reminiscent of stereochemical inactivity of the lone pair on the central atom in 14-electron AX_6E species, which is believed to be a manifestation of interligand repulsion that predominates when the separation among the large monoatomic electronegative X ligands becomes less than the van der Waals' separation. It is thus assumed that the lone pair on Te atom resides in the stereochemically inert 6s orbital. In the compound **3b**, although the three independent Te–Br bond lengths vary over a wider range (2.6638(3)–2.7434(3) Å) in comparison to those in K_2TeBr_6 [7a], $[H_9O_4][TeBr_6]$ [7b] or $[Me_3PhN][TeBr_6]$ [7d], the mean value, 2.7036 Å, remains almost the same. However, the angular distortion (with the largest deviation of 6.202° and 3.655° in the *trans* and *cis* Br–Te–Br angles, respectively) is greatest of the observed values so far. Besides other crystal forces, the interionic C–H···Br contacts, closer than the van der Waals' separation (3.05 Å) and listed in Table 2, may also be held responsible for the observed distortion of the octahedral anion. Each of the bromine ligands with a partial negative charge interacts with the benzene ring or methylene C–H proton donors of neighboring cations (Fig. 2). Similar, though smaller, distortion of the $TeBr_6$ octahedron in the anions $[TeBr_6(Se_2Br_2)]^{2-}$ [5a] and $[TeBr_6(SeBr_2)]^{2-}$ [5b] due to non-covalent Se···Br interactions (involving only four of the six bromine ligands) has been observed earlier. The significant importance of the relatively weak C–H···X interactions (X = P, O, N, Cl, Br, I) to the organization of the solid state has been widely recognized [10].

The benzoylmethyl group in the phosphonium cation $[(4\text{-}MeC_6H_4COCH_2)Ph_3P]^+$ adopts a cisoidal conformation and the intramolecular distance between the phosphorus and the carbonyl oxygen atom [2.9161(18) Å], is shorter than the sum of their van der Waals radii (3.32 Å).This suggests a significant direct electron-donative interaction from the carbonyl oxygen atom to the positively charged P atom. A comparable intramolecular P···O separation 2.878(12) Å observed in the crystal structure of the benzyl(2-methoxyphenyl)phosphonium bromide was also supported by energy minimization calculations [11]. The short P···O distance in the present case is not a result of geometrical constrain as could be in the case of the 2-methoxyphenylphosphonium cation. However, there is no appreciable lengthening of the P–C31 bond compared to the other three P–C bonds, in spite of an almost linear O···P–C31 alignment {∠O···P–C31 = 160.990(76)°}. The P···O interaction may, therefore, be electrostatic in nature instead of a σ^*(P–C) ← n(O) covalent interaction. The observed cisoidal orientation of the benzoylmethyl group also facilitates the C17–H···Cl(CH_2Cl_2) close contact. The methylene fragment of the dichloromethane solvate simultaneously acts as a multiple proton donor to the Br2 atoms of a $TeBr_6^{2-}$ anion. Extended supramolecular chains of molecular units (consisting of a $TeBr_6^{2-}$ anion encompassed by a pair of phosphonium cations) linked by means of solvated CH_2Cl_2 molecules thus become apparent (Fig. 3). In addition, there are other C–H···Br van der Waals' contacts that govern the packing of such chains in the solid state.

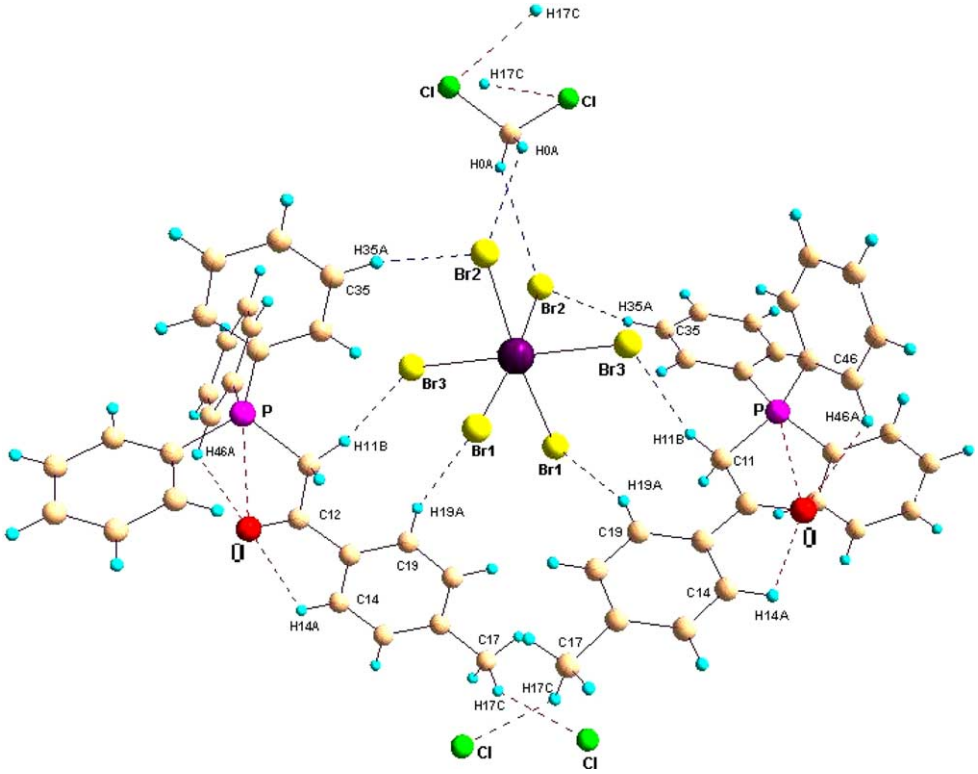

Fig. 2. A selected segment of the crystal lattice depicting interlinking of $TeBr_6^-$ anions through C–H···Br interactions.

3. Experimental

3.1. General

Commercial tellurium powder (Fluka) was dried at 120 °C and ground for 15 min just before use. 4-Substitutedbenzoylmethyl bromides were prepared by bromination of the parent acetophenones in glacial acetic acid. The phosphonium salts, $[(4\text{-}XC_6H_4COCH_2)Ph_3P]Br$, (X = H, **1a**; Me, **1b**; OMe, **1c**) were prepared and characterized following the literature method [12]. Bis(4-substitutedbenzoylmethyl)tellurium dibromides, $(4\text{-}XC_6H_4COCH_2)_2TeBr_2$ (X = H, **2a**; Me, **2b**; OMe, **2c**) were prepared as reported earlier [4]. Melting points were recorded in capillary tubes and are uncorrected. ^1H NMR spectra were recorded at 300.13 MHz in $CDCl_3$on Varian 300 spectrometers, using Me_4Si as internal standard. Microanalyses (carbon and hydrogen) were carried out using a Carlo Erba 1108 make analyzer. Conductance measurements were made using Toshniwal conductivity bridge and dip type cell (cell constant 0.80) in 10^{-3} M nitrobenzene solutions. Tellurium was estimated volumetrically and the halogen content gravimetrically as silver halide.

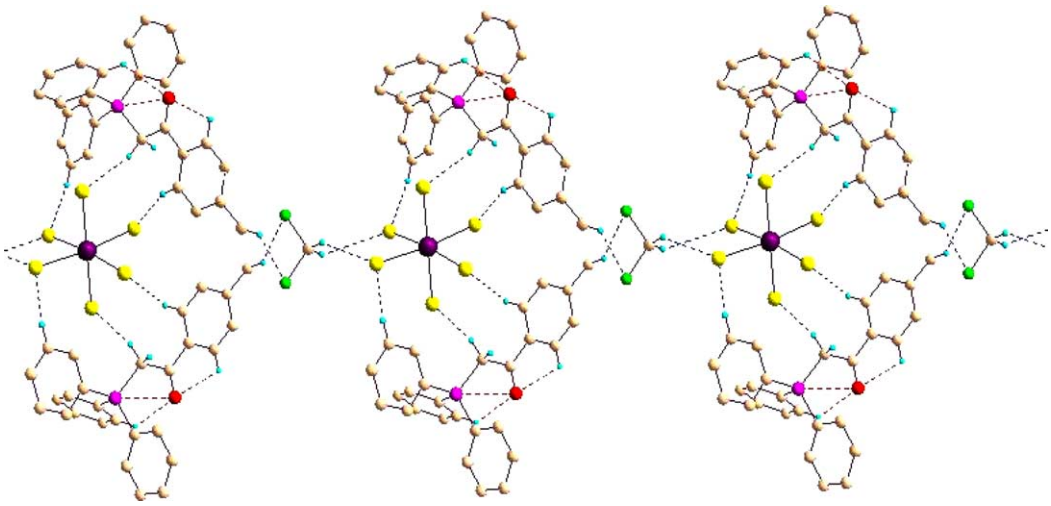

Fig. 3. Projection of a segment of the crystal lattice of **3b** showing an extended array.

*3.1.1. (I) Reaction of [(4-MeOC$_6$H$_4$COCH$_2$)Ph$_3$P]Br (**1c**) with (4-XC$_6$H$_4$COCH$_2$)$_2$TeBr$_2$ (X = H, **2a**; Me, **2b**; OMe, **2c**)*

To a solution of **1c** (0.5 g, 1 mmol) in dichloromethane (15 ml) was added **2c** (0.58 g, 1 mmol) in the same solvent (15 ml) and stirred for 5 h. A dark greyish residue (~0.06 g) was filtered off. After concentrating the filtrate to ~10 ml, pet-ether (~15 ml) was added. The yellow solid was filtered, washed with pet-ether and crystallized from dichloromethane to give orange needles of [(4-MeOC$_6$H$_4$COCH$_2$)Ph$_3$P]$_2$[TeBr$_6$] (**3c**). Yield: 0.3 g (40%; based on **2c**); m.p. 92 °C (shrank), 211 °C (dec.); *Anal.* Calc. for C$_{54}$H$_{48}$O$_4$Br$_6$P$_2$Te: C, 45.36; H, 3.38; Br, 33.53; Te, 8.92. Found: C, 45.21; H, 3.40; Br, 33.50; Te, 8.58%. ^{1}H NMR (CDCl$_3$), δ(ppm), 6.97–8.43 (m, arom.), 6.20 (d, CH$_2$–P) [^2J(^{31}P–^{1}H), 12.01 Hz], 3.96 (s, OCH$_3$); Cond. (nitrobenzene), 41.82 Ω^{-1} cm^{-1} mol^{-1}.

The same product was obtained in ~45% yield when **1c** was reacted with **2a** or **2b** under similar conditions.

*3.1.2. (II) Reaction of [(4-MeC$_6$H$_4$COCH$_2$)Ph$_3$P]Br (**1b**) with (4-XC$_6$H$_4$COCH$_2$)$_2$TeBr$_2$ (X = H, **2a**; Me, **2b**; OMe, **2c**)*

(a) A solution of **1b** (0.48 g, 1 mmol) (15 ml) and **2b** (0.55 g, 1 mmol) in dichloromethane or chloroform (40 ml) was stirred vigorously for 6 h at room temperature. A very small amount of elemental tellurium separated. It was filtered off and the filtrate concentrated to ~10 ml before adding pet-ether (~10 ml). A yellow solid precipitated which was filtered and washed with pet-ether (2 × 5 ml), until it showed a single spot on TLC. It was found to be the 1:1 adduct [(4-MeC$_6$H$_4$COCH$_2$)Ph$_3$P]$^+$[(4-MeC$_6$H$_4$COCH$_2$)$_2$TeBr$_3$]$^-$. Yield: 0.44 g (43%); m.p. 183 °C; *Anal.* Calc. for C$_{45}$H$_{42}$O$_3$Br$_3$PTe: C, 52.52; H, 4.11; Br, 23.29; Te, 12.40. Found: C, 51.90; H, 4.00; Br, 23.63; Te, 12.03%. ^{1}H NMR (CDCl$_3$), δ (ppm), 7.30–8.26 (m, arom.), 6.22 (d, CH$_2$–P) [^2J(^{31}P–^{1}H), 12.03 Hz], 5.44 (s, CH$_2$–Te), 2.46 (s, CH$_{3(cation)}$), 2.30 (s, CH$_{3(anion)}$); Cond. (nitrobenzene), 20.12 Ω^{-1} cm^{-1} mol^{-1}.

The same product was obtained when the reaction was carried out in 2:1 molar ratio.

Attempted crystallization for diffraction quality crystals by dissolving the adduct in dichloromethane and adding pet-ether initially gave a semi-solid which was triturated with pet-ether to give an orange solid. On repeated attempts it eventually afforded orange crystals of [(4-MeC$_6$H$_4$COCH$_2$)Ph$_3$P]$_2$[TeBr$_6$]. CH$_2$Cl$_2$, **3b**. m.p. 192 °C; *Anal.* Calc. for C$_{55}$H$_{50}$O$_2$Br$_6$Cl$_2$P$_2$Te: C, 44.55; H, 3.40; Br, 32.23; Te, 8.60. Found: C, 43.91; H, 3.40; Br, 31.80; Te, 8.86%. ^{1}H NMR (CDCl$_3$), δ (ppm), 7.32–8.03 (m, arom.), 5.88 –5.92 (d, CH$_2$–P) [^2J(^{31}P–^{1}H), 12.30 Hz], 2.60 (s, CH$_3$); Cond. (nitrobenzene), 42.00 Ω^{-1} cm^{-1} mol^{-1}.

3.2. Crystallography

The X-ray diffraction measurements were performed at 103(2) K on a Bruker PS4 diffractometer employing graphite monochromated Mo Kα radiation (λ = 0.71073 Å) to a θ_{max} value of 28.47° via ω scans (completeness 97.0% to θ_{max}). A total of 40 887 reflections were collected and the data were reduced and corrected for absorption using the programs SAINT and SADABS [13]. The structure was solved by direct methods and difference Fourier synthesis using SHELXS-97, implemented in WIN GX 2002 [14]. The non-hydrogen atoms were refined anisotropically while the hydrogen atoms, introduced at calculated positions, were refined isotropically. An acceptance criterion of $I > 2\sigma(I)$ was used and the final cycle of full-matrix least squares refinement based on 6806 independent reflections and 309 parameters converged with unweighted (R_1) and weighted (wR_2) agreement factors of 0.0245 and 0.0537, respectively. Lattice parameters and structure solution of the title compound are: $C_{55}H_{49}Br_6Cl_2O_2P_2Te$, M = 1481.84, orthorhombic, *Pbna*, a = 14.6483(10) Å, b = 17.0962(10) Å, c = 22.1458(10) Å, V = 5546.0(6) Å^3, Z = 4, D_x = 1.775 Mg/m^3, $F(000)$ = 2884, μ = 5.053 mm^{-1}. The max. and min. residual electron densities were 0.667 and −1.023 e Å^{-3}. Figures were created using the DIAMOND package.

4. Supplementary material

Crystallographic data for the structure analysis have been deposited with the Cambridge Crystallographic Data Center, CCDC No. 269986 for $[(4\text{-}MeC_6H_4COCH_2)Ph_3P]_2[TeBr_6]$. CH_2Cl_2 (**3b**). Abstract

New Pd(II), Pt(II) and Re(V) complexes of 3-aminosalicylic acid (H_2salNH_2) and 3-hydroxyantranilic acid (HantOH) have been prepared, *cis*-[Pt (HsalNH)$(PPh_3)_2$]· $0.25C_2H_5OH$ (**1**), *trans*-[PdCl$(salNH_2)(PPh_3)_2$] (**2**), *trans*-[$ReOI_2(HsalNH_2)(PPh_3)$]$\cdot(CH_3)_2CO$ (**3**), *cis*-[Pt(HantO)$(PPh_3)_2$] (**4**), *trans*-[PdCl(antOH)$(PPh_3)_2$]$\cdot 4H_2O$ (**5**), [PdCl(antOH)(bipy)]$\cdot C_2H_5OH$ (**6**), [$PdCl_2$(HantOH)$_2$] (**7**) and *trans*-[ReOI(HantO)$(PPh_3)_2$]$\cdot(CH_3)_2CO$ (**8**). The crystal structure of complex **1** was determined showing chelation of $HsalNH^{2-}$ through the adjacent nitrogen and oxygen atoms of the amino and phenolate groups. Infrared and ^1H NMR spectroscopic data for the complexes are presented.

Keywords: 3-Aminosalicylic acid; 3-Hydroxyanthranilic acid; Crystal structure; Palladium; Platinum; Rhenium

1. Introduction

We have been studying the coordination modes of aromatic ambidentade ligands, such as 3-hydroxypicolinic acid [1,2], 2-hydroxynicotinic acid [3] and 2,3-, 3,4- and 2,6-dihydroxybenzoic acids, with 2nd and 3rd row transition metals and the lanthanides [4–6]. In the present work a comparative study was done on Pd(II), Pt(II) and Re(V) complexes with 3-aminosalicylic (H_2salNH_2) and 3-hydroxyantranilic acids (HantOH), respectively. The two ligands are constitutional isomers: 3-aminosalicylic acid is 3-amino-2-hydroxybenzoic acid (Fig. 1(a)), and 3-hydroxyanthranilic acid is 2-amino-3-hydroxybenzoic acid (Fig. 1(b)).

3-Aminosalicylic acid can bind to metals by several coordination modes: monodentate O or N donor, bridging, or by two different chelates either the O,O-chelate, involving the carboxylate group and the oxygen in position-2, resulting in a six-membered chelate-ring, or the N,O-chelate, involving the amino group nitrogen and the oxygen in position-2, with the formation of a five-membered chelate-ring. A similar O,O-chelate is found in complexes of salicylic acid and derivatives, such as $[MoO_2L_2]^{2-}$ (H_2L = salicylic acid, 4- or 5-methylsalicylic acids), $[PdL_2]$ (H_2L = salicylic acid) [7], $[MoO_2L_2]^{2-}$, $[OsO_2(py)_2L]$, [ReOIL(PPh_3)] (H_2L = 2,6-dihydroxybenzoic acid; py = pyridine) [8].

When deprotonated, 3-hydroxyanthranilic acid can also bind to metals by several coordination modes: monodentate O or N donor, bridging, or by two possible N,O-chelating modes, involving the nitrogen atom and the oxygen atom of either the hydroxyl group (forming a five-membered chelate-ring) or the carboxyl group (forming a six-membered chelate-ring). The former is found in complexes with 2-aminophenolate and

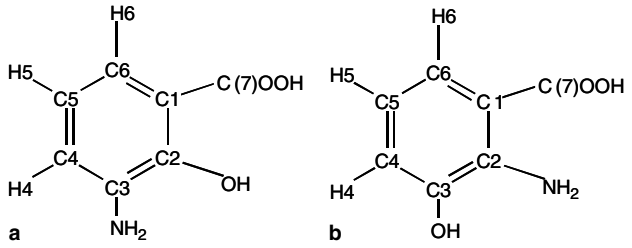

Fig. 1. 3-Aminosalicylic (a) and 3-hydroxyanthranilic (b) acids and numbering scheme adopted.

derivatives such as $[MoO_2(HL)_2]$ (H_2L = 2-amino-4-clorophenol, 2-amino-4-methylphenol) and $[OsL_3]$ (H_2L = 2-amino-4-methylphenol, 2-amino-4-^{t}butylphenol), $[MoO_2(HL)_2]$ [9] and $[PtL(PPh_3)_2]$ [10] (H_2L = 2-aminophenol), $[V(=NPh)(OC_6H_2(CH_2NMe_2)\text{-}2\text{-}Me_2\text{-}4,6)_2]$ [11], $[V(OC_6H_2(CH_2NMe_2)\text{-}2,6\text{-}Me\text{-}4)_3]$ and $[VCl(OC_6H_2(CH_2NMe_2)\text{-}2\text{-}Me\text{-}4)_2]$ [12]. The latter chelating mode is found in complexes of anthranilic acid like $[MoCl_3\{2\text{-}(HN)C_6H_4CO_2\}\{2\text{-}Me_3SiO_2CC_6H_4N\}]^-$, $[MoCl_3\{2\text{-}(HN)C_6H_4CO_2\}(NC_6H_3Pr^i_2\text{-}2,6)]^-$ [13] and $[Ba(2\text{-}NH_2C_6H_4CO_2)_2(OH_2)]_n$ [14].

The N,O-chelating mode in H_2salNH_2 is similar to the N,O-chelating mode with HantOH, forming five-membered chelate-rings. The formation of six-membered chelate-rings is in the case of H_2salNH_2 achieved through bonding to a carboxylate O atom and a hydroxyl O atom, and in the case of HantOH to a carboxylate O atom and an amino N atom. The coordination modes described were investigated in Pd(II), Pt(II) and Re(V) complexes using spectroscopic data and in one case X-ray diffraction data. The crystal structure of the Pt(II) compound **1** was determined and in this complex the 3-aminosalicylato ligand shows coordination through the nitrogen and oxygen atoms of the amino and phenolate groups (N,O-chelating mode). Spectroscopic characterisation of the remaining compounds suggests that other coordination modes may occur.

2. Results and discussion

2.1. Preparations

Suspensions of *cis*-$[PtCl_2(PPh_3)_2]$ or *trans*-$[PdCl_2(PPh_3)_2]$ and H_2salNH_2 or HantOH in an ethanol/methanol mixture in the presence of triethylamine gave complexes *cis*-$[Pt(HsalNH)(PPh_3)_2]\cdot 0.25C_2H_5OH$ (**1**), *trans*-$[PdCl(HsalNH_2)(PPh_3)_2]$ (**2**), *cis*-$[Pt(HantO)(PPh_3)_2]$ (**4**) and *trans*-$[PdCl(antOH)(PPh_3)_2]\cdot 4H_2O$ (**5**). When $K_2[PdCl_4]$ was used as starting material, the compound obtained was $[PdCl_2(HantOH)_2]$ (**7**). Reaction of the 2,2′-bipyridine (bipy) complex $[PdCl_2(bipy)]$ with HantOH gave compound **6**, $[PdCl(antOH)(bipy)]\cdot C_2H_5OH$. The complexes *trans*-$[ReOI_2(HsalNH_2)(PPh_3)]\cdot(CH_3)_2CO$ (**3**) and *trans*-$[ReOI(HantO)(PPh_3)_2]\cdot(CH_3)_2CO$ (**8**) were synthesised by refluxing *trans*-$[ReOI_2(OEt)(PPh_3)_2]$ with H_2salNH_2 or HantOH in acetone.

2.2. Crystal structure of *1*

The X-ray diffraction study of **1** shows that its crystal structure is built up from an asymmetric unit composed of one molecule of *cis*-$[Pt(HsalNH)(PPh_3)_2]$ and several solvent molecules of ethanol all with reduced occupancy. An ORTEP view showing the overall geometry of the complex and the atomic notation scheme is presented in Fig. 2. Bond lengths and angles are listed in Table 1 for complex **1**. The platinum(II) centre is surrounded by the nitrogen and oxygen atoms from the amino and phenol groups of the $HsalNH^{2-}$ ligand and the phosphorus atoms of the two PPh_3 ligands in a distorted square planar coordination environment. The angle N–Pt–O of 79.32(3)° is dictated by the O–N bite angle of the $HsalNH^{2-}$ ligand while the remaining angles in the metal coordination sphere are the result of

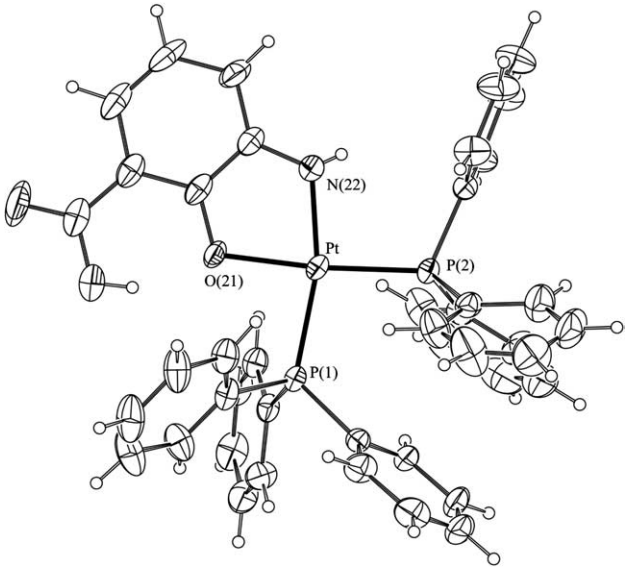

Fig. 2. An ORTEP view of *cis*-$[Pt(HsalNH)(PPh_3)_2]$ (**1**) showing the overall molecular geometry. Ellipsoids are drawn at 30% probability level.

Table 1

the minimisation of the steric interactions between the $HsalNH^{2-}$ ligand and the two bulky PPh_3 ligands. The bond lengths to the metal centre are within the values found for related complexes such as *cis*-[PtCl(picOH)$(PPh_3)_2$] [1] and *cis*-[PtCl(HnicO)$(PPh_3)_2$] [3].

2.3. Infrared spectra

Infrared data for H_2salNH_2, HantOH and complexes **1**–**8** are given in Table 2. Tentative assignments are based on those found in the literature for 3-aminosalicylic acid [15], salicylic acid [7], anthranilic acid and derivatives [16,17], 2-aminophenol [9], 3-hydroxypicolinic acid [1,2], and respective complexes. The most sensitive bands to metal coordination were selected, namely the C=O and C–O stretches of the carboxyl group, ν(C=O) and $\nu(C–O)_c$, the bending mode of the amino group, $\delta(NH_2)$, the C–O stretch of the phenolic group, $\nu(C–O)_{OH}$, and the C–NH_2 stretch, $\nu(C–NH_2)$.

The bending frequency of the NH_2 group, $\delta(NH_2)$, of 3-aminosalicylic acid is assigned at 1537 cm^{-1} and of 3-hydroxyanthranilic acid at 1548 cm^{-1}. In all complexes, this frequency shifts to higher wavenumbers. For complexes **5** and **6** it shifts only 3 cm^{-1}. For complexes **1**, **3**, **4**, **7** and **8** this shift is higher than 42 cm^{-1} showing that the amino group may be involved in the coordination to metals. It suggests that in complexes **5** and **6** the coordination may involve only the carboxylate or phenolate groups.

Two strong bands at 1651 and 1394 cm^{-1} in the spectrum of 3-aminosalicylic acid are assigned to the C=O and C–O stretches, ν(C=O) and $\nu(C–O)_c$, of the carboxyl group, respectively. In the spectrum of 3-hydroxyanthranilic acid these bands are seen at 1651 cm^{-1} and 1344 cm^{-1}, respectively. The ν(C=O) frequency decreases in complexes **5** and **6**, and the $\nu(C–O)_c$ frequency increases. The calculated $\Delta\nu(CO_2)$ values, defined by Deacon and Phillips as $\nu_{as}(CO_2) - \nu_s(CO_2)$, of 267 and 233 cm^{-1} for **5** and **6**, respectively, indicate a typical COO^- coordination fashion, possibly unidentate [18,19]. In **1**–**4**, **7** and **8**, the carboxyl group is possibly not involved in the coordination because of the increase of the ν(C=O) frequency. In complex **1**, the charge balance constrains a 2− charge in the deprotonated form of the 3-aminosalicylic acid. Assuming the 1721 cm^{-1} frequency as the C=O stretch, characteristic of the carboxyl group, the deprotonation possibly occurs in the phenolic and amino groups (according to crystal structure data). Similar deprotonation was described for $[MoCl_3\{2\text{-}(HN)C_6H_4CO_2\}\{2\text{-}Me_3SiO_2CC_6H_4N\}]^-$, $[MoCl_3\{2\text{-}(HN)C_6H_4CO_2\}(NC_6H_3Pr^i{}_2\text{-}2,6)]^-$ [13] and $[Pt\{2\text{-}(HN)C_6H_4O\}(PPh_3)_2]$ [10]. The stretching C–O frequency of the phenolic group, $\nu(C–O)_{OH}$, (1319 cm^{-1} in H_2salNH_2 spectra and 1299 cm^{-1} in HantOH) shifts to lower wavenumbers in the spectra of all complexes. It is particularly significant for complexes **1**–**4** and **8**, suggesting that in these complexes the oxygen atom of the phenolic group may be involved in coordination to the metals. The decrease in the C–NH_2 stretch frequency, $\nu(C–NH_2)$, in the spectra of the complexes **1**, **3**, **4**, **7** and **8** indicates that the amino group may be coordinated to the metals.

The results described suggest the following coordination modes of 3-aminosalicylic or 3-hydroxyanthranilic acids: in complexes **1**, **3**, **4** and **8** via chelation-NO through the nitrogen atom of the amino group and the oxygen atom of the phenolate group; in complexes **5** and **6** through one of the oxygen atoms of the carboxylate group; in complex **2** via monodentate-O of the phenolate group; and in complex **7** via monodentate-N.

The spectra of compounds **1**–**5** and **8** show three characteristic bands of the PPh_3 ligands, around 1480, 1435 and 1095 cm^{-1}, assigned to the symmetric and asymmetric stretching and bending of P–Ph bonds, respectively [17,19]. The strong bands at 974 and 979 cm^{-1} in the spectra of the rhenium complexes **3** and **8**, respectively, are assigned to Re=O stretch [1].

trans-[ReOI(HantO)(PPh_3)$_2$] · (CH_3)$_2$CO (**8**)[c]	6.98 dd (5, 26)	6.74 t (26)	7.33 dd (5, 27)

[A] *J* values in parentheses (Hz); dd, doublet-doublet; t, triplet; d, doublet.
[a] In CD_3OD.
[b] In $CDCl_3$.
[c] In dmso-d_6.
[d] D_2O.

2.4. ^{1}H NMR spectra

^{1}H NMR data and tentative assignments for 3-aminosalicylic and 3-hydroxyanthranilic acids and its complexes are shown in Table 3. Assignments are based on those find in the literature for salicylic acid [20] and derivates [16] and 2-aminophenol [9,21], anthranilic acid [13,18] and derivates [17] and salicylic acid complexes [7].

The ^{1}H NMR spectrum of 3-aminosalicylic acid in CD_3OD shows a triplet at 6.72 ppm assigned to the H5 proton and two doublet-doublets at 7.02 and 7.37 ppm assigned to the H4 and H6 protons, respectively. Similarly the ^{1}H NMR spectrum of 3-hydroxyanthranilic acid in CD_3OD shows a triplet at 6.45 ppm assigned to the H5 proton, a doublet-doublet at 6.80 ppm assigned to the H4 proton and another doublet-doublet at 7.35 ppm assigned to the H6 proton.

The proton signals of $HsalNH_2^-$ in complex **2** and of $antOH^-$ in complex **5** are overlapped with the PPh_3 signals. In the spectra of complex **6**, the major shifts downfield are observed for H4 and H6 protons. These are higher than the shifts observed in complexes **4** and **8** with suggested NO-chelation. Relative to the free ligand, the protons of $HsalNH^{2-}$ ligand in the Pt complex **1** shift upfield and in the Re complex **3** shift downfield; the same trend is observed for the protons of $HantO^-$ ligand in complexes **4** (Pt) and **8** (Re), having all the suggested NO-chelation .

3. Experimental

3.1. Preparation of complexes

All chemicals were of at least reagent grade and used as supplied by Aldrich. The starting complexes, *trans*-[$PdCl_2$(PPh_3)$_2$] [22], *cis*-[$PtCl_2$(PPh_3)$_2$] [23], [$PdCl_2$(bipy)] [24] and *trans*-[$ReOI_2$(OEt)(PPh_3)$_2$] [25] were prepared by the respective literature procedures.

3.1.1. *cis*-[Pt(HsalNH)(PPh_3)$_2$] · 0.25C_2H_5OH (**1**)

To a stirred suspension of *cis*-[$PtCl_2$(PPh_3)$_2$] (0.12 g, 0.15 mmol) in ethanol (5 cm^3) was added a methanolic suspension (5 cm^3) of 3-aminosalicylic acid (0.05 g, 0.3 mmol) and triethylamine (0.08 cm^3, 0.6 mmol). The resulting yellow suspension was stirred for one day. It was centrifuged and a yellow solid isolated. Orange crystals were formed by recrystallisation in ethanol, washed whith water and dried over silica gel. Yield: 0.05 g, 0.06 mmol, 40%.

Elemental analysis. Calc.: C, 58.3; H, 4.3; N, 1.6. Exp.: C, 59.9; H, 4.1; N, 1.6%. MS = 871; MW = 870.768 calculated for [Pt(HsalNH)(PPh_3)$_2$].

3.1.2. *trans*-[PdCl(HsalNH_2)(PPh_3)$_2$] (**2**)

To a stirred suspension of *trans*-[$PdCl_2$(PPh_3)$_2$] (0.15 g, 0.15 mmol) in ethanol (5 cm^3) was added a methanolic suspension (5 cm^3) of 3-aminosalicylic acid (0.05 g, 0.3 mmol) and triethylamine (0.08 cm^3, 0.6 mmol). The resulting suspension was refluxed for 1 h and filtered. To the orange filtrate was added 10 cm^3 of water and a orange solid was formed. It was centrifuged, washed with water and dried over silica gel. Yield: 0.05 g, 0.06 mmol, 40%.

Elemental analysis. Calc.: C, 63.1; H, 4.4; N, 1.7. Exp.: C 61.4, H 4.6, N 1.7%.

3.1.3. *trans*-[$ReOI_2$(HsalNH_2)(PPh_3)] · (CH_3)$_2$CO (**3**)

A suspension of *trans*-[ReOI(OEt)$_2$(PPh_3)$_2$] (0.31 g, 0.3 mmol) and 3-aminosalicylic acid (0.05 g, 0.3 mmol) in acetone (20 cm^3) was refluxed for 1 h. It was centrifuged and a green solid obtained. It was washed with acetone and dried over silica gel. Yield: 0.20 g, 0.21 mmol, 68%.

Elemental analysis. Calc.: C, 36.2; H, 2.9; N, 1.5. Exp.: C, 36.3; H, 3.1; N, 1.6%.

3.1.4. *cis*-[Pt(HantO)(PPh$_3$)$_2$] (**4**)

To a stirred suspension of *cis*-[PtCl$_2$(PPh$_3$)$_2$] (0.12 g, 0.15 mmol) in ethanol (5 cm^3) was added a methanolic suspension (5 cm^3) of 3-hydroxyanthranilic acid (0.05 g, 0.3 mmol) and triethylamine (0.08 cm^3, 0.6 mmol). The resulting yellow suspension was stirred for one day. It was centrifuged and a yellow solid isolated, washed with ethanol and dried over silica gel. Yield: 0.11 g, 0.13 mmol, 87%.

Elemental analysis. Calc.: C, 59.3; H, 4.1; N, 1.6. Exp.: C, 59.9; H, 4.1; N, 1.6%. MS = 871; MW = 870.768 calculated for [Pt(HantO)(PPh$_3$)$_2$].

3.1.5. *trans*-[PdCl(antOH)(PPh$_3$)$_2$] · 4H$_2$O (**5**)

To a stirred suspension of *trans*-[PdCl$_2$(PPh$_3$)$_2$] (0.35 g, 0.5 mmol) in ethanol (5 cm^3) was added a methanolic suspension (4 cm^3) of 3-hydroxyanthranilic acid (0.15 g, 1 mmol) and triethylamine (0.28 cm^3, 2 mmol). The resulting suspension was stirred for 1 h. It was centrifuged and a orange solution was obtained. Part of the solvent was evaporated and a red solid was obtained by addition of an equal amount of water. This solid was washed with water and dried over silica gel. Yield: 0.13 g, 0.27 mmol, 54%.

Elemental analysis. Calc.: C, 58.0; H, 5.0; N, 1.6. Exp.: C, 58.0; H, 5.3; N, 2.1%.

3.1.6. [PdCl(antOH)(bipy)] · C$_2$H$_5$OH (**6**)

To a stirred suspension of [PdCl$_2$(bipy)] (0.05 g, 0.15 mmol) in ethanol (5 cm^3) was added a methanolic suspension (5 cm^3) of 3-hydroxyanthanilic acid (0.05 g, 0.3 mmol) and triethylamine (0.08 cm^3, 0.6 mmol). The resulting yellow suspension was stirred for three days. It was centrifuged and a brownish solid isolated, washed with ethanol and dried over silica gel. Yield: 0.07 g, 0.14 mmol, 93%.

Elemental analysis. Calc.: C, 46.0; H, 4.1; N, 8.5. Exp.: C, 45.9; H, 4.1; N, 9.9%. MS = 413; MW = 414.731 calculated for [Pd(antOH)(bipy)]$^+$.

3.1.7. [PdCl$_2$(HantOH)$_2$] (**7**)

A methanolic suspension (4 cm^3) of 3-hydroxyanthranilic acid (0.15 g, 1 mmol) was added to an aqueous solution (5 cm^3) of K$_2$[PdCl$_4$] (0.16 g, 0.5 mmol). The resulting orange suspension was stirred for one day. It was centrifuged and a yellow solid isolated, washed with ethanol and dried over silica gel. Yield: 0.22 g, 0.45 mmol, 90%.

Elemental analysis. Calc.: C, 34.8; H, 2.9; N, 5.8. Exp.: C, 34.6; H, 3.4; N, 6.2%. MS = 485; MW = 483.596 calculated for [PdCl$_2$(antOH)$_2$]. MS = 411; MW = 412.690 calculated for [Pd(antOH)$_2$]$^{2+}$.

3.1.8. *trans*-[ReOI(HantO)(PPh$_3$)$_2$] · (CH$_3$)$_2$CO (**8**)

A suspension of *trans*-[ReOI$_2$(OEt)(PPh$_3$)$_2$] (0.31 g, 0.3 mmol) and 3-hydroxyantharanilic acid (0.05 g, 0.3 mmol) in acetone (10 cm^3) was refluxed for 30 min. After cooling to room temperature, 10 cm^3 of water were added and a brownish solid was formed, isolated, washed with water and dried over silica gel. Yield: 0.20 g, 0.19 mmol, 63%.

Elemental analysis. Calc.: C, 51.9; H, 4.0; N, 1.3. Exp.: C, 54.9; H, 4.1; N, 1.5%.

3.2. X-ray diffraction

$C_{44.50}H_{40}NO_{3.75}P_2Pt$ (**1**), $M_r = 905.80$, triclinic, space group $P\bar{1}$, $a = 9.749(12)$ Å; $b = 13.954(15)$ Å; $c = 16.333(17)$ Å; $\alpha = 74.23(1)°$; $\beta = 84.14(1)°$, $\gamma = 74.15(1)°$, $U = 2056.0$ Å^3, $Z = 2$, $\rho_{calc} = 1.463$ Mg m^{-3}, μ(Mo Kα) = 3.531 mm^{-1}.

X-ray data were collected at room temperature on a MAR research plate system using graphite monochromatised Mo Kα radiation ($\lambda = 0.71073$ Å) at Reading University. The crystal was positioned at 70 mm from the image plate. 95 frames were taken at 2° intervals with an adequate counting time. Data analysis was performed with the XDS program [26]. Intensities were corrected empirically for absorption effects, using a DIFABS version modified for image plate geometry [27].

The structure was solved by a combination of direct methods and difference Fourier syntheses. The hydrogen atoms on the parent carbon atoms and aliphatic nitrogen atoms were included in calculated positions and giving thermal parameters equivalent 1.2 times those of the atom to which were attached. The non-hydrogen atoms were refined with anisotropic thermal parameters

The final refinement of 464 parameters by full-matrix least-squares method against F^2 until convergence to be achieved leading to final indices $R_1 = 0.0412$ and $wR_2 = 0.1126$ for 5710 reflections with $I > 2\sigma(I)$ and $R_1 = 0.0521$ and $wR_2 = 0.1205$, for all intensity data comprising 6578 reflections. The residual electronic density was in the range −1.189 to 2.347 e Å^{-3}, with positive hole 0.96 Å within platinum coordination sphere while the negative one is only 1.44 Å way from the calculated position for an hydrogen atom. All calculations required to solve and to refine the structure were carried out using the SHELX-97 system programs [28]. Molecular diagrams were drawn with PLATON [29].

3.3. Instrumentation

Infrared spectra were measured as KBr pellets on a Mattson 7000 FT instrument. ^{1}H NMR spectra were recorded on a Brüker AMX300 spectrometer at 300 MHz and referenced to SiMe$_4$ or the solvent. Microanalyses

(C, H and N) were measured by the Department of Chemistry, University of Aveiro.

Density functional study of the properties of isomeric aminophenylhydroxamic acids and their copper (II) complexes

Rita Kakkar *, Rajni Grover, Pragya Gahlot

Department of Chemistry, University of Delhi, Delhi 110 007, India

Received 20 June 2005; accepted 26 July 2005
Available online 1 September 2005

Abstract

The three isomeric aminophenylhydroxamic acids and their copper (II) complexes have been investigated by the density functional theory using different potentials. The GGA-PBE approach is found to be best suited for such studies. A comparison is made of the electronic structures of the acids to understand why they form different types of complexes. 2-Aminophenylhydroxamic acid is found to be the most stable of the three isomers due to extensive hydrogen bonding, but the complex formation energy for square planar complexes is highest for the 4-aminophenyl isomer. The different properties of the three acids and their Cu(II) complexes are satisfactorily explained from these studies. The nature of bonding in these complexes is also investigated.

1. Introduction

The accurate calculation of properties of transition metal complexes by refined theories is very difficult for several reasons. The first is the vast number of electrons that needs to be considered, and the significant relativistic effects, which implies the use of relativistic pseudopotentials or relativistic calculations. The second is the existence of unpaired electrons in the d shells of most transition metals (except d^{10} systems), which makes an unambiguous assignment of the ground state difficult. Jahn–Teller distortions and other such effects imply that even the symmetry of the complex is often unknown; thus, open-shell calculations that take approximately twice the computational time required for restricted closed shell calculations, need to be performed on these systems. The SCF convergence is also slow for these systems because of the mixing of d orbitals and the s orbitals.

The significance of transition metals in chemistry, however, is immense [1], e.g. in organometallic and bioinorganic chemistry, organic catalysis, etc., and hence the need of having reliable and precise theoretical methods for their calculation. Significant progress in this direction has been made in recent years, and today we have several theoretical papers describing accurate calculations on these systems. The first and foremost conclusion that emerges from these studies is the remarkable accuracy that even surpasses and challenges experimental results. In particular, density functional (DFT) methods (especially gradient-corrected and hybrid functionals) achieve good results for relatively low computational cost. Gradient corrected functionals are much faster and can be efficiently used with plane wave basis sets in solid state calculations. However, for the dissociation of transition metal–oxygen bonds, these functionals produce large errors for the dissociation energy [2], but they do reproduce trends correctly. Hybrid

doi:10.1016/j.poly.2005.07.036

functionals, such as B3LYP, though more accurate for metal-oxide dissociation energies, cannot efficiently be used with plane waves, and are hence not useful for calculations on solid materials.

The model complexes used in the present study contain the hydroxamic acid moiety. Metal–hydroxamate complexes exhibit structural diversity [3–10]. Hydroxamate ions have two oxygen atoms and may bond to the metal ion in two different ways: monodentate and bidentate configurations. Besides, they may also coordinate through the nitrogen atom and one oxygen atom. However, the bulk of experimental data favor the bidentate mode using two oxygen atoms. Investigations on the complex formation with simple primary hydroxamic acid ligands in aqueous solution demonstrated clearly that, depending on the pH, two (*O*,*O*) binding modes of the ligands are accessible to metal ions like Cu(II) and V(IV) [3,4]. The more common hydroxamato (1-) type mode arises from the first deprotonation step and involves the coordination of the NHO^- moiety. The hydroximato (2-) form of the ligand is produced by further metal-induced deprotonation of the NHO^- at high pH.

The coordination of the nitrogen atom of the hydroxamic moiety was never found in metal complexes formed by simple hydroxamic acids even if this nitrogen atom can be converted into a very effective binding site in aminohydroxamates, as demonstrated by studies on aminohydroxamates, both in solution and in the solid state [5].

Hydroxamic acids have been found to bind in other coordination modes as well [10]. It was therefore also considered worthwhile to investigate the Cu(II) complexes of three isomeric aminophenylhydroxamic acids, whose crystal data have become available [9], and seek an explanation for their different structures.

2. Computational details

DFT methods are best suited for electronic structure calculations on inorganic complexes. We have performed these calculations using the DMol^3 program [11,12] available from Accelrys Inc. in the Materials Studio package Ver. 3.1. DMol^3 supports two local gradient-corrected exchange-correlation functionals (LDA) and eight nonlocal gradient-corrected exchange-correlation functionals (GGA). VWN [13] and PWC [14] are the two local functionals available in DMol^3. The LDA description tends to overbind atoms, so that the bond lengths are usually underestimated by a few percent. GGA corrects this error, but can underbind instead, leading to slightly long bond lengths. We, therefore, carried out calculations with the ten methods for a model compound whose structure has recently been elucidated by X-ray crystallography [9], and compared the optimized geometry with the experimental one to gauge the relative accuracy of the methods. The eight GGA functionals explored are PW91 [14], BP [14,15], PBE [16], BLYP [15,17], BOP [18], VWN-BP [13–15], RPBE [19] and HCTH [20].

Our calculations employed numerical basis sets of double-ζ quality plus polarization functions (DNP) to describe the valence orbitals. This is the numerical equivalent of the Gaussian 6-31G** basis set. The use of numerical basis sets minimizes the basis set superposition error (BSSE) [21]. The core electrons were treated using DFT semi-local pseudopotentials (DSPP) [22], which replace the effects of core electrons with a simple potential. These core potentials include some degree of relativistic effects and are thus very useful approximations for heavier elements, and the calculation is less computationally expensive since the core electrons are dropped. Complete geometry optimizations were carried out, and the energies corrected for the zero-point vibrational contribution.

The charge distributions were estimated using the molecular electrostatic potential fitting approach [23], since the Mulliken method has well-known shortcomings because of the uncertainty in uniquely defining a charge-partitioning scheme [24], particularly for unbalanced basis sets. For the sake of comparison, however, we also report the Mulliken populations. Since our model complexes contain a Cu(II) ion, which is an open-shell system (d^9), we have performed unrestricted calculations. Mayer bond orders [25] were calculated to describe the bonding in the complexes.

3. Results and discussion

3.1. Choice of an appropriate methodology

As our test ligands, we have chosen the three isomeric aminophenylhydroxamic acids. As mentioned in the introduction, although hydroxamate ions usually bind to metal ions through the two oxygen atoms (i.e. as (*O*,*O*)-bidentate chelating agents), other binding modes are also possible, and this range can be greatly increased if the hydroxamate ligand contains secondary binding groups, resulting in many diverse and intriguing structures [10]. This was found in the complexes formed between the isomeric aminophenylhydroxamic acids ($AphaH_2$) and $CuSO_4 \cdot 5H_2O$ [9]. Whilst 4-aminophenylhydroxamic acid (4-$AphaH_2$) gives the simple square planar complex Cu(4-$AphaH)_2 \cdot 2H_2O$, 2-aminophenylhydroxamic acid (2-$AphaH_2$) gives a fused 'dimeric' metallocrown of the formula $[Cu_5(2\text{-}Apha)_4(\mu\text{-}SO_4) \cdot (H_2O)_2]_2$, in which the metal ions display extensive magnetic coupling (with potential applications in the field of magnetoelectronics). The complex has a 'clam-like' structure, in which (2-$Apha^{2-}$) is doubly deprotonated 2-aminophenylhydroxamic acid. The

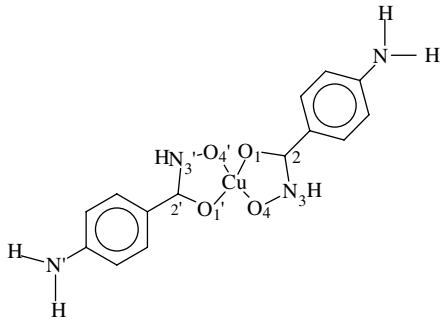

Fig. 1. Structure of the Cu(II) complex of 4-aminophenylhydroxamic acid.

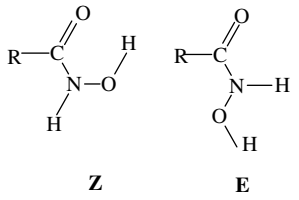
coordination is through deprotonated nitrogen and it contains bridging hydroximate (2-) functions, combined with the $\{O, \mu_2\text{-}O'\}$ chelating/bridging mode. 3-Aminophenylhydroxamic acid (3-AphaH$_2$) gives a trinuclear helical polymer of formula $[Cu_3(3\text{-AphaH})_4SO_4\cdot(H_2O)]_n\cdot 8H_2O$, which has a supramolecular structure with large open cavities, which can be useful in trapping guest molecules.

We optimized the geometries of the 4-aminophenylhydroxamic acid copper complex (see Fig. 1) with the different potentials available in DMol^3, and calculated the relative errors in comparison with experimental determinations (Table A1, Supplementary information). The following conclusions can be drawn: Both the LDA geometries, particularly VWN, are in good agreement with experiment, but the gradient-corrected DFT methods tend to exaggerate the Cu–O$_1$ bond length when compared with the experimental [9] value. This agrees with similar observations made earlier [26,27] for inorganic complexes. On the other hand, LDA-VWN overbinds the Cu–O$_4$ bond, yielding a bond length that is too short by 0.034 Å. Some of the GGA functionals, namely BOP, RPBE and HCTH, are particularly bad when it comes to predicting Cu–O bond lengths. The only GGA functional that gives good agreement with experiment is PBE, for which the error is only 1.6% in relation to experiment, in spite of the fact that the latter refer to the solid state, which is subject to deformation because of solid state effects. In particular, this is the only method that predicts equal Cu–O$_1$ and Cu–O$_4$ bond lengths (see Fig. 1) for the two rings, in agreement with experiment. All other methods predict asymmetry in the two rings. We have, therefore, performed further calculations with the GGA-PBE functional. Table A1 also reveals that, in most cases, the overall errors are smaller for bond angles than for bond distances.

3.2. Structures of the three isomeric aminophenylhydroxamic acids

Table 1 gives the zero-point corrected binding energies of the various structures investigated here. As for other similar systems, the keto tautomer of pyruvic acid is found to be more stable [28]. Moreover, this tautomer may exist in two conformations, namely *Z* and *E*.



Z **E**

It may be noted that the *Z* conformers of 2- and 4-aminophenylhydroxamic acid isomers have the same energy before zero-point corrections, but 4-aminophenylhydroxamic acid turns out to be lowest in energy after application of the correction (see Table 1). Contrary to expectations, the 2-aminophenyl isomer is lower in energy than the 3-aminophenyl isomer despite the two hydrogens in close proximity in the former. The structures of the *Z* forms of the isomeric aminophenylhydroxamic acids in the free-state are shown in Fig. 2 and Table 2 gives the optimized bond lengths, along with the calculated bond orders.

All three acids are stabilized by intramolecular hydrogen bonding. The existence of the hydrogen bond is indicated from the following:

(i) the distances (∼1.8 Å, see Table 2) between the protons of OH and the carbonyl oxygens are smaller than the sum of the van der Waals radii (ca. 2.7 Å) of the hydrogen and oxygen atoms,
(ii) the high positive charge densities (∼0.4) on the protons of the OH groups, as well as the negative charge densities (∼−0.5) on the carbonyl oxygens,
(iii) the OH···O bond angles of ∼124° are higher than the cut-off angle (90° of arc) [29], and
(iv) the Mayer bond orders (Table 2) of the carbonyl oxygen to hydroxyl hydrogen (0.13), and total valences, 2.03 and 1.02, respectively, on the carbonyl oxygen and hydroxyl hydrogen, which are slightly higher than the ideal values of 2 and 1.

For the simple hydroxamic acids investigated earlier [28], the *trans E* conformers were also found to be stable. For the aminophenylhydroxamic acids, in each case, the *Z* form is found to be more stable by several

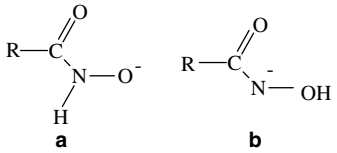
[b] N is the amino nitrogen, which is N_{13} for 2-, N_{14} for 3-, and N_{12} for 4-aminophenylhydroxamic acid.

kcal/mol (see Table 1) as a result of intramolecular hydrogen bonding. Besides, we found that the *E* forms are nonplanar and do not represent energy minima in the case of 2-aminophenylhydroxamic acid, which possesses a small imaginary frequency (155 cm^{-1}) and the 4-aminophenyl isomer, for which the imaginary frequency is 45 cm^{-1}.

The aminophenylhydroxamic acids could also be *N*-acids (*a*) or *O*-acids (*b*).



Our earlier calculations for simple hydroxamic acids [28] had shown that only the *cis* form of the *a* anion (shown above) is important, and this is the one formed by deprotonation from the hydroxyl hydrogen of the more stable *Z* conformer, while the *trans* isomer would be the result of deprotonation from the *E* conformer. Moreover, this has the correct conformation for chelation with metal ions. We, therefore, restricted our calculations to the *a* (*cis*) and *b* anions formed by ionization of an OH proton or NH proton, respectively, from the *Z* conformers of the acids. For the hydroxamic acids investigated earlier, the *b* anions were found to be more stable, making them *N*-acids. In this case, too, the acids are *N*-acids, as the *b* anion is more stable than *a* in all cases. The difference in energies between the two anions is highest for the anion of 2-aminophenylhydroxamic acid (see Table 1), as there is extensive hydrogen bonding in the *b* anion in this case (see Fig. 3). This partly explains why this isomer has a tendency to form complexes by deprotonation from both nitrogen and oxygen, while the other acids undergo deprotonation at oxygen only on complex formation.

Since the *a* anion is the one involved in chelation with metal ions, we have collected the bond lengths and bond orders of these anions in Table 3. It is found that anion formation increases the O_1C_2 bond length and decreases the C_2N_3 bond length.

3.3. Structures of the three isomeric aminophenylhydroxamic acid complexes

The binding energies for the 2-, 3- and 4- isomeric complexes are given in Table 1. Again, the 2-amino isomer complex appears to be more stable despite the two hydrogens in close proximity. However, the relative stabilities of the complexes may be determined more accurately from the complexation energies, $\Delta E = E_{\text{product}} - E_{\text{reactant}}$, i.e.

$$\Delta E = E_{\text{complex}} - E_{Cu^{2+}} - 2E_{\text{anion}},$$

where $E_{Cu^{2+}}$, the binding energy of the Cu^{2+} ion, is 669.6 kcal/mol, and E_{anion} is the energy of the *a* anion.

The complexation energies for the three complexes are −702.5, −704.2 and −705.5 kcal/mol. These calculations prove the slightly greater stability of the 4-aminophenyl isomer. In these calculations, the effects of hydrogen bonding get cancelled as it is present in both the reactant and the product. Moreover, for the 2-amino-

[b] N is the amino nitrogen, which is N_{13} for 2-, N_{14} for 3-, and N_{12} for 4-aminophenylhydroxamic acid.

phenylhydroxamate complex, there are three small imaginary frequencies, 32, 37 and 50 cm^{-1}.

Selected optimized bond lengths and bond orders for the three complexes are given in Table 4. It can be observed that complexation leads to a further increase in the O_1C_2 bond length (and consequent decrease in bond order) and further strengthening of the C_2N_3 bond, particularly for the Cu(II) complex of 4-aminophenylhydroxamic acid. In each complex, both five-membered Cu–hydroxamate rings are planar, causing delocalization of electrons in the $O_1C_2N_3$ moiety. The C_2C_6 bond is essentially single, permitting the phenyl ring to rotate about this bond. The phenyl rings are twisted with respect to the hydroxamate grouping by ~20° in each case. Similar results were obtained in single-crystal studies of three bis(*N*-methylbenzohydroxamato-*O*,*O*′) copper (II) complexes, except the observation [30] of significant angular strain on the sp^2 carbonyl carbon, which was not found to be the case in the present studies.

3.4. Charge population analysis

Table 5 presents the ESP fitted and Mulliken atomic charges and group charges of the three complexes. The group charge was calculated by the summation over the atomic charges of all of the atoms that comprise the group. As shown in Table 5, the group charge of the hydroxamate ligand in the free state is −1.0, while the ESP charges of the ligands in the three complexes, 2-, 3- and 4-aminophenylhydroxamic acid, are −0.308, −0.314 and −0.301, respectively. It is seen that the group charges of the ligand decrease in magnitude in the complexes coordinating with Cu(II), which indicates that electron transfer from the ligands to Cu(II) has occurred and the coordination bonds have formed. This is also evident from the calculated Cu–O_4 bond distance

[a] See Figs. 1 and 2 for numbering. Geometrical parameters of only one ligand are given. The complete set of optimized geometrical parameters can be found in the Supplementary information.

[b] N is the amino nitrogen, which is N_{13} for 2-, N_{14} for 3-, and N_{12} for 4-aminophenylhydroxamic acid.

(1.93 Å), which is slightly smaller than the sum of the ionic radii of Cu^{2+} and O^{2-}, which is 1.97 Å.

The atomic charge calculations can give a feature for the relocation of the electron density of the ligands. As shown in Table 5, the atomic charges of the coordinated atoms, O_4, remain unchanged (∼−0.438) for the 2-aminophenyl isomer. In contrast, the atomic charges of O_1 (from −0.483 to −0.409) decrease for the 2-aminophenyl isomer. This indicates that there is no general rule to predict the atomic charges for the coordinated atoms. There is a large variation in the charge densities on nitrogen and carbon, too. Instead of gaining electron density in the anion, the nitrogen becomes almost neutral in the anion and complex. The carbon remains almost constantly positively charged throughout. However, the charges on Cu^{2+} (Table 5) demonstrate that 1.384 e transfers from the ligands to Cu(II) in the complex, suggesting that an electron moves from the coordinated atoms to Cu(II) and the electron transfers synchronously from other parts of the ligands to the coordinated atoms. For the other two complexes, the situation is similar. For the 4-aminophenyl isomer, there is a slightly larger transfer of charge from the ligands to the Cu^{2+} ion, as the positive charge on Cu^{2+} is the least in this case.

A comparison with the Mulliken charges indicates that the Mulliken partial charge on Cu in the three complexes is smaller, ∼0.4 e, compared to ∼0.6 e for the ESP charges. This indicates that Mulliken charges ascribe higher covalency to the complex. This is a failing of Mulliken charges. Another drawback of the Mulliken charges is their tendency to be basis-size dependent. To confirm this, we calculated the partial charge on copper as a function of the size of the basis set for the 4-aminophenylhydroxamate copper (II) complex. The calculated Mulliken charges for the minimal (MIN), double zeta (DN), 6-31G* (DND) and 6-31G** (DNP) basis sets are 0.928, 0.380, 0.434 and 0.392, respectively, while the corresponding ESP charges are 0.893, 0.725, 0.607 and 0.602, respectively. It can be seen that the latter converge to 0.6 as the basis set is increased in size, while the former do not follow any particular order. Therefore, the ESP charges may be considered reliable.

The calculated Mayer bond orders for the *Z* forms of the acids, their corresponding anions and the Cu(II) complexes are given in Tables 2–4, where we have given all bond orders $\geqslant 0.1$, even when the two atoms are not connected. Both in the *Z* conformers of the three acids (Table 2) and their anions formed by deprotonation of the hydroxyl proton (Table 3), it may be noted that the carbonyl bond of the hydroxamate grouping is weak, with an average bond order of 1.67 in the former and 1.62 for the latter, compared to the expected value of 2. For the acids, this can be traced to hyperconjugative interactions with N_3 and hydrogen bonding with H_5. The interaction with the N_3 lone pair puts electron density into the carbonyl π* orbital, reducing its bond

[a] See Figs. 1 and 2 for numbering. The complete set of partial atomic charges and Mayer free valences is available as Supplementary information.

order. In the anion, removal of H_5 removes hydrogen bonding interaction, but increases hyperconjugative interaction with N_3, as reflected in the further decrease in the carbonyl bond order and decreased electron density at nitrogen in the anion. The Mayer total valence on the nitrogen also increases from an average value of 3.27 in the acids to 3.60 in the anions.

The calculated Cu–O Mayer bond orders for the 4-aminophenylhydroxamate complex show that the Cu–O_4 bonds are stronger than the Cu–O_1 bonds (Table 4). This is also evident from the shorter bond length of the former. The complexes have sizeable covalent character, the total valence of copper being 2.24. For the 2-aminophenylhydroxamate Cu(II) complex, however, all four Cu–O bonds have similar bond orders, 0.58, and the total valence on copper is 2.36. The case of the 3-aminophenylhydroxamate Cu(II) complex is similar (Table 4).

However, the electron distribution is not apparent from the partial atomic charges. In Fig. 4 is given the plot of the electrostatic potential for the *a* forms of the anions. It can be seen that the negative charge (yellow areas) is distributed throughout. In the case of the 4-aminophenylhydroxamic acid complex, there is greater accumulation of charge density away from the two coordinating oxygens. Thus the difference in the three complexes is a result of the different electronic distributions in the anions themselves.

We have also plotted the electrostatic potential maps for the three complexes in Fig. 5. These maps give an idea about the range of electron density around the complex. For 2- and 3-aminophenylhydroxamate complexes, the isoelectronic contour plotted is at 0.016 au (10 kcal/mol). However, this was not possible for the 4-aminophenylhydroxamate complex, as the potential extends only between -5.1×10^{-4} and 2.9×10^{-7} au, and hence the contour is for 1×10^{-10} au.

The three maps demonstrate the differences in the electronic behavior of the three complexes. The 2- and 3-aminophenylhydroxamate complexes have similar maps, but that of the 3-aminophenyl isomer is smaller and hence more compact, showing that the charge is concentrated in the latter. However, the map for the 4-aminophenylhydroxamate complex bears no resemblance to that of the other two. While in the former cases, the potential near the Cu(II) ion is positive (yellow), in this case it is negative at the center, but positive elsewhere. The smaller extent of the potential in the case of the 4-aminophenylhydroxamate complex may explain its reluctance to polymerize.

One can also note that in the 2- and 3-aminophenylhydroxamic acid complexes, the potential is

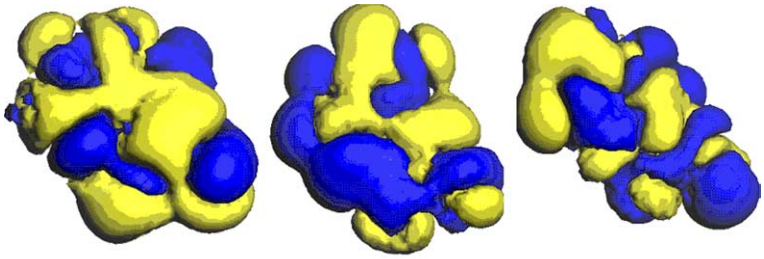

Fig. 4. Isopotential maps for the *a* anions of 2-, 3- and 4-aminophenylhydroxamic acid (isovalue $= 1\times10^{-17}$ au).

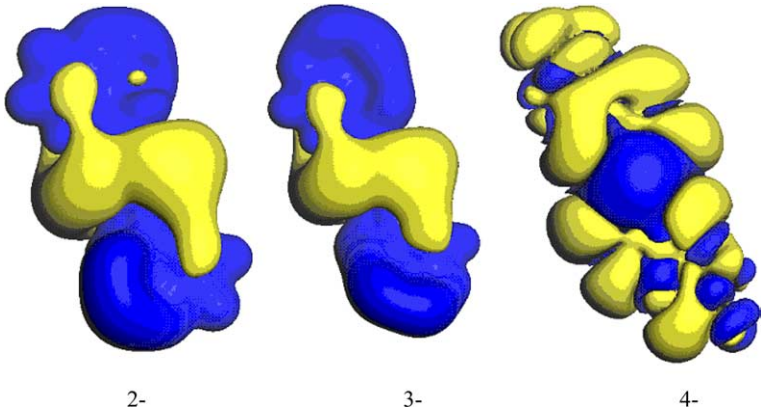

Fig. 5. Isopotential maps for the Cu(II) complex of 2- and 3-aminophenylhydroxamic acid (isovalue = 0.016 au), and 4-aminophenylhydroxamic acid (isovalue $= 1\times10^{-10}$ au).

positive throughout (blue areas) unlike the case of the hydroxamate ions.

4. Conclusions

Density functional calculations have been performed on a copper hydroxamate complex of experimentally determined structure to determine the applicability of this approach to study the properties of inorganic complexes. It has been found that:

- Most of the potentials yield very good geometries when compared with experiment.
- The GGA-PBE and LDA-VWN pseudopotentials, in particular, are best suited for these studies, but because of a tendency to overbind atoms in the latter, the former is preferred.
- The results demonstrate that 2-aminophenylhydroxamic acid is the most stable of the three isomers in spite of two hydrogens in close proximity, but the complex formation reaction is most exothermic for the 4-aminophenylhydroxamic acid complex, although the differences are small.
- All the acids are *N*-acids, but bind in the (*O*,*O*)-coordination mode. The 2-aminophenyl isomer, however, has a more acidic proton at the nitrogen and therefore undergoes further deprotonation.
- Hyperconjugative interactions with the nitrogen lone pair weaken the carbonyl bond.
- Electrostatic potential fitted charges give a better description of the charge distribution than the Mulliken charges.
- The complexes have considerable covalent character, the Cu–O bond orders being slightly higher than 0.5 in each case.
- There is greater delocalization of charge away from the coordinating oxygens, both in the anion and in the complex, for the 4-aminophenyl isomer.
- The differences in the coordination geometries of the three complexes can be satisfactorily explained using DFT calculations.

Abstract

Aminobis(phenol) ligands (H_2L^n) carrying either a dimethylamino, a pyridyl or a methoxy sidearm donor were used in the preparation of new tungsten and molybdenum complexes. Treatment of $[W(eg)_3]$ (eg = 1,2-ethanediolate dianion) with H_2L^n under hydrolytic conditions in a $CHCl_3$–MeOH mixture gave the *cis*-dioxotungsten(VI) complexes $[WO_2(L^n)]$ in good yields. The corresponding molybdenum complexes $[MoO_2(L^n)]$ were prepared from $[MoO_2(acac)_2]$ and respective ligands. The solid-state structures of two molybdenum and one tungsten compounds were determined by single crystal X-ray diffraction, which revealed that the dianionic aminobis(phenolate) backbones of the ligands have coordinated to the metal centre as [O,N,O] donors, whereas the last coordination sphere has been occupied by a N or O donor atom of the ligand sidearm. All synthesized new complexes can catalyse the oxotransfer reaction between benzoin and dmso at 120 °C.

1. Introduction

High-valent molybdenum and tungsten complexes which bear *cis*-MO_2 units have attracted considerable interest due to their applications in catalytic oxotransfer reactions [1,2]. In particular, these complexes are known to catalyse various industrially valuable processes, e.g. asymmetric olefin epoxidation and alcohol oxidation [3]. Molybdenum and tungsten are also necessary elements in diverse biological systems, since nature has made use of these metal centres in numerous redox enzymes [4]. Catalytic activities of artificial and biological catalysts are commonly associated with the coordinative unsaturation of the metal centre, which allows the substrate molecules to coordinate to the reactive metal species. There are few reports on tetrahedral 4-coordinate [5–7] and trigonal bipyramidal 5-coordinate [3d,7,8] dioxomolybdenum(VI) complexes, but generally *cis*-dioxo complexes of molybdenum(VI) and tungsten(VI) have saturated octahedral coordination. The coordination sphere around the metal centre is frequently completed by solvent molecules or through dimerization.

In respect to occurrence, metallurgy, and properties of the metals, molybdenum and tungsten are remarkably similar elements [9]. They have also rather similar chemical properties, as they are able to form structurally identical compounds. However, there are some differences between these metals in various categories of compounds, thus compounds of the same structural type may differ noticeably in their formation and reactivities. For example, numerous *cis*-dioxomolybdenum(VI) complexes with a variety of supporting ligands have been prepared and studied as catalyst model compounds [10], whereas chemistry of analogous tungsten complexes is still inadequately

studied [2,3,11]. One reason for the relatively low number of known *cis*-dioxotungsten(VI) complexes is apparently the poor availability of suitable starting materials, whereas appropriate precursor for corresponding molybdenum complexes are easily accessible. In some cases, tungstate ion [WO_4^{2-}] can be used in acidic, aqueous solution to prepare new *cis*-dioxotungsten(VI) complexes [11,12]. Other procedures employ moisture-sensitive, poorly soluble [WO_2Cl_2] or its more convenient derivatives, i.e., [WO_2Cl_2(dme)] and [WO_2(acac)$_2$] (dme = 1,2-dimethoxyethane) [2,11,13,14]. Monomeric trisdiolatotungsten(VI) complex [W(eg)$_3$] (eg = ethylene glycolate) [15] is a straightforwardly available, air-stable and moderately soluble compound, which can be easily converted to a variety of new tungsten(VI) alkoxide and phenoxide complexes [16]. Therefore, we have previously used it as a precursor for various oxotungsten(VI) complexes with aminobis(phenol)s [16c,16d,16e]. During these studies we have found that [W(eg)$_3$] can react with linear, tetradentate diaminobis(phenol)s (H_2ONNO^R) under hydrolytic conditions to produce air-stable *cis*-dioxocomplexes [$WO_2(ONNO^R)$] [16e]. In this article, we shall describe the synthesis and characterization of a series of new 6-coordinate *cis*-dioxomolybdenum(VI) complexes [$MoO_2(L^n)$] as well as structurally analogous tungsten complexes [$WO_2(L^n)$] with potentially tetradentate symmetric aminobis(phenolate) ligands (Chart 1).

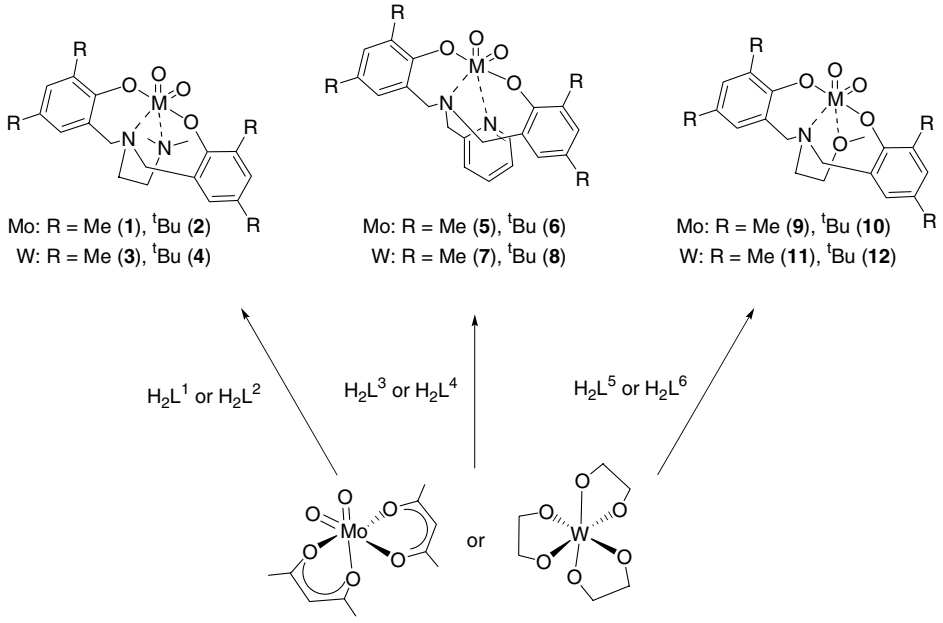
We have earlier observed that dioxomolybdenum(VI) complexes with tridentate aminobis(phenolate)s tend to dimerize in the absence of strongly coordinating solvent, which causes poor solubility and may also inhibit catalytic activity [17]. In the present study, the ligand design is used to prevent unwanted dimerization. Consequently, the aminobis(phenolate) backbones of the ligands coordinate to the *cis*-MO_2 moieties as dianionic tridentate [O,N,O] donors, while the sixth coordination sites are occupied by N or O sidearm donor atoms.

2. Results and discussion

2.1. Syntheses and spectroscopic characterization of complexes

Some dioxomolybdenum(VI) complexes with tripodal tetradentate aminobis(phenolate)s have been previously prepared from [MoO_2(acac)$_2$] and relevant ligand precursors in high yields using a simple ligand displacement reactions [18], whereas other examples employ the use of an acidic solution of [NH_4]$_6$[Mo_7O_{24}]·4H_2O [2a,2b,2c]. In our experiments, the syntheses involved the treatment of [MoO_2(acac)$_2$] with ligand precursors H_2L^n (see Chart 1) in chloroform solutions (Scheme 1). When starting materials dissolved and the ligand substitution reactions were initiated, the reaction mixtures turned yellow. These yellow solutions were treated with methanol to enhance crystallization and the reaction mixtures were then kept overnight at room temperature. Filtration followed by washing with methanol led to the isolation of pure complexes [$MoO_2(L^n)$] as yellow prismatic crystals or crystalline solids in high yields. All solid complexes are stable in air under ambient conditions. Complex **6** with bulky ligand tends to crystallize as a methanol triadduct, which decomposes slowly due to the partial loss of solvent molecules. All complexes [$MoO_2(L^n)$] were also prepared by the reaction of ligand precursors with [MoO_2Cl_2(dmf)$_2$], but the yields were generally lower and obtained materials had to be purified by recrystallization, as the initial depositions were disturbed by the co-precipitation of additional base or unreacted ligand as a hydrochloride adduct.

Although useful precursors for new dioxomolybdenum(VI) complexes are easily available, there are just a few appropriate starting materials for corresponding dioxotungsten(VI) chemistry. The rare examples of aminobis(phenolate) complexes of dioxotungsten(VI) have been prepared using [WO_2Cl_2(dme)] as a tungsten precursor [2a,2b,2c]. In this study, tungsten trisdiolate [W(eg)$_3$] was allowed to react with tripodal, tetradentate aminobis(phenol)s H_2L^n in a mixture of $CHCl_3$ and MeOH. The pale yellow reaction mixtures were then stirred at 70 °C for an hour and subsequently kept at room temperature for 12 h. Slow crystallization provided analytically pure complexes [$WO_2(L^n)$] in moderate to good yields (Scheme 1). Sterically most hindered ligand precursor H_2L^4 appears to react slower than other studied aminobis(phenols), therefore the formation of the complex **8** in a synthetically useful yield required 8 h reaction in EtOH at reflux temperature. Presumably the mechanism for the formation of these dioxocomplexes includes alkoxide ligand displacement



Scheme 1. Formation of complexes $[MO_2(L^n)]$.

reaction in association with hydrolytic cleavage of two diolato groups, so the role of the alcohol solvents is most likely to carry a necessary amount of water to the reaction.

All complexes $[MoO_2(L^n)]$ and $[WO_2(L^n)]$ are moderately soluble in chloroform, dmf and dmso. In general, *tert*-butyl-substituted complexes are more soluble in organic solvents than their methyl-substituted counterparts. Unsurprisingly, structurally analogous Mo and W complexes have considerably similar IR and NMR spectra. The most significant differences between particular molybdenum complex and its tungsten counterpart can been seen in their M=O stretching frequencies. The IR spectra of compounds $[MoO_2(L^n)]$ present two distinctive absorption maxima for MoO_2^{2+} moiety in the expected IR region [2]. The symmetric and asymmetric stretches are observed at 915–935 and 890–905 cm^{-1}, respectively. Similarly, $[WO_2(L^n)]$ show two characteristic *cis*-WO_2 vibrational bands at 935–950 and 900–910 cm^{-1} in their IR spectra [2]. The former bands occur generally at 10–25 cm^{-1} higher frequencies than those for their molybdenum congeners. ^1H and ^{13}C NMR spectra of these molybdenum and tungsten complexes in $CDCl_3$ are consistent with supposed distorted octahedral structures, and they present typical resonances for C_s-symmetric aminobis(phenolate) complexes [2a,19,20].

2.2. Solid-state structures

Complexes **1**, **3**, and **9** crystallized from reaction mixtures as single crystals suitable for X-ray crystallographic analyses (see Table 1). All three complexes form mononuclear molecules, in which the aminobis(phenolate) moiety is coordinated to the dioxometal(VI) unit as a tripodal tetradentate ligand (see Figs. 1–3, Table 2). In all cases, the coordination sphere around the central metal presents distorted octahedral geometry with the terminal oxo ligands *cis* to each other. Two anionic phenolate oxygens and two neutral donor atoms of the ligands are *trans* and *cis*, respectively, as expected for octahedral dioxo complexes. The O=M=O angles and M=O distances are typical for six-coordinated dioxomolybdenum(VI) and -tungsten(VI) complexes [2,6,11]. In complex **1**, the rather long Mo–$O_{aryloxide}$ distances are associated with small Mo–O–C_{aryl} angels. In principal, these two parameters may correlate with the electron donation from aryloxide oxygen lone pair to the metal centre [21]. However, it has been shown that the M–O–C distances and angles in early d-block transition metal aryloxides are exceedingly flexible parameters, which give little insight into M–OAr bonding [22], whereas bonding parameters in these solid-state structures may be mostly controlled by steric effects and packing forces.

2.3. Oxotransfer studies and electrochemistry

Dioxomolybdenum(VI) and tungsten(VI) complexes are known to catalyze oxotransfer reaction from dmso to organic substrates or phosphines [1,2,10a,10b]. Generally, molybdenum-based catalysts are more active in these reactions than their tungsten counterparts. In the present study, the utility of new dioxomolybdenum(VI) and -tungsten(VI) complexes to catalyze oxotransfer reactions was investigated in dmso solutions using benzoin as the substrate, while the conversion of benzoin to benzil was detected by ^1H NMR spectroscopy. As expected, all studied complexes catalyzed oxotransfer from

dmso to benzoin. In individual experiments, the detected yields of oxidized products were 40–60% after 24 h heating at 120 °C. These oxotransfer reactions turned out to be very slow at lower temperatures, and no reactions were noticed at room temperature. Although molybdenum-based oxotransfer catalysts are usually reported to be more active than their tungsten counterparts [2], we did not observe any noteworthy differences between these metals. On the grounds of structurally comparable molybdenum and tungsten-based catalyst systems, we can suppose, that the dioxometal(VI) complexes react with benzoin to yield oxometal(IV) complexes and benzil. The central metal ions are then rapidly oxidized back to the initial dioxocompounds with dmso to complete the catalytic cycle [2a,2b]. Although reduced molybdenum and tungsten species are expected to be strongly coloured, no colour changes were observed during these catalytic reactions, which indicates that the re-oxidation process of metal is very rapid and/or only small amount of complex units are actually reactive. We also attempted to gather possible reduced species by running stoichiometric reactions of benzoin and dioxometal(VI) complexes in various solvents (dmf, $CHCl_3$, MeCN). However, even though the reactions in dmf at high temperatures yielded slight coloration of solutions, we could not isolate any reduced metal complexes.

The electrochemical properties of the complexes $[MoO_2(L^n)]$ ($n = 1$–6) and $[WO_2(L^n)]$ ($n = 4$, 6) were studied by cyclic voltammetry (Table 3). All these complexes present an irreversible one-electron reduction process characteristic for the conversion of M^{VI} to M^{V}. For molybdenum complexes this reduction peak shows reversible character as the scan rate is increased, which indicates that the formed molybdenum(V) species decompose rapidly via some homogeneous reactions. The metal-based reduction potentials for the tungsten complexes are more negative by 0.4–0.5 V and reductions are more irreversible than those of the analogous molybdenum compounds, which is in accordance with earlier studies of dioxomolybdenum(VI) and tungsten(VI) compounds [2,3c]. The substituents on the phenolic ring of the ligand seem to have a minor effect on the reduction potential, which is also consistent with

the electron donating characters of methyl and *tert*-butyl groups.

3. Conclusion

Potentially tetradentate aminobis(phenol) ligands (H_2L^n), which carry either a dimethylamino, a pyridyl or a methoxy sidearm donor were used in the preparation of new tungsten and molybdenum complexes. Tris-diolatotungsten(VI) $[W(eg)_3]$ (eg = 1,2-ethanediolate dianion) reacts with H_2 L^n in a $CHCl_3$–MeOH mixture under hydrolytic conditions to yield the *cis*-dioxotungsten(VI) complexes $[WO_2(L^n)]$. The corresponding molybdenum complexes $[MoO_2(L^n)]$ were prepared by the reaction of $[MoO_2(acac)_2]$ with respective ligands. The spectral analyses and crystal structure investigations revealed that the dianionic aminobis(phenolate) backbones of the ligands have coordinated as [O,N,O] donors, whereas the last coordination sphere has been occupied by a N or O donor atom of the ligand sidearm. All synthesized new complexes can catalyse the oxo-transfer reaction between benzoin and dmso at 120 °C, while little difference is observed between activities of Mo and W complexes.

4. Experimental

Starting materials $[MoO_2(acac)_2]$ [23], $[W(eg)_3]$ [15] and H_2L^n [19,24,25] were prepared according literature procedures. Solvents were of HPLC grade and were used as purchased. All syntheses were performed under ambient laboratory atmosphere. ^1H and ^{13}C NMR spectra (400 MHz) were recorded in $CDCl_3$ solutions and were referenced internally to $SiMe_4$. IR spectra were recorded as Nujol mulls. Crystalline samples were dried in vacuum at 40 °C for 4 h prior to elemental analyses. Cyclic voltammograms of studied complexes were recorded at ambient temperature with a Princeton Applied Research model 283 potentiostat using a platinum working electrode, a 1 mm diameter platinum counter electrode and a Ag/AgCl reference electrode (3.4 M KCl). Samples were dissolved in MeCN containing 0.1 M of $(Bu_4N)ClO_4$ as the supporting electrolyte. Typically, a 1.0 mM solution of sample was purged with argon and then the voltammograms were recorded at scan rate of 50 mV s^{-1} over the potential range of 0.0 to −2.0 at ambient temperature.

4.1. Preparation of $[MoO_2(L_n)]$

General procedure. 1.0 mmol of $[MoO_2(acac)_2]$ and 1.0 mmol of a ligand precursor H_2L^n were dissolved in 10 ml of $CHCl_3$ by gentle heating during 15 min. Orange-yellow solution that formed was cooled to room temperature, then 15 ml of MeOH was added to enhance the precipitation of solid product $[MoO_2(L^n)]$. The reaction mixture was then allowed to stand for 12 h at room temperature to complete the crystallization. Bright yellow crystals or crystalline solids were then collected by filtration and washed with cold MeOH.

*$[MoO_2(L^2)]$ (**2**)*. Yellow crystalline solid, yield 69% (448 mg). IR: 1458vs, 1412m, 1364s, 1310m, 1244vs, 1202s, 1169s, 1126m, 1094m, 1028s, 974w, 916s, 894vs, 874s, 871s, 843m, 828s, 806m, 779m, 773m, 752s, 650 w, 602m, 594w, 556m, 496m. ^1H NMR: δ 7.30 (2H, aryl), 7.00 (2H, aryl), 4.14 (d, $J = 14$ Hz, 2H, CH_2), 4.01 (d, $J = 14$ Hz, 2H, CH_2), 3.50 (2H, CH_2) 2.88 (overlapping s + d, 8H, $N(CH_3)_2 + CH_2$), 1.40 (18H, $C(CH_3)_3$), 1.30 (18H, $C(CH_3)_3$). ^{13}C NMR: δ 161.15, 142.62, 136.28, 123.63, 123.39, 122.76, 61.26, 56.63, 53.76, 50.87, 50.59, 35.01, 34.28, 31.66, 30.43. *Anal*. Calc. for $C_{34}H_{54}MoN_2O_4$: C, 62.8; H, 8.4; N, 4.3. Found: C, 62.4; H, 8.1; N, 4.1%.

*$[MoO_2(L^3)]$ (**5**)*. Yellow microcrystals, yield 93% (467 mg). IR: 1611s, 1574w, 1454vs, 1379s, 1319m, 1304m, 1256s, 1221m, 1159m, 1098m, 1059m, 1024m, 961w, 916vs, br, 878s, 851vs, 829vs, 787m, 783m, 731m, 727m, 691w, 648m, 594m, 558m, 519w, 488w. *Anal*. Calc. for $C_{24}H_{26}MoN_2O_4$: C, 57.4; H, 5.2; N, 5.6. Found: C, 57.1; H, 5.4; N, 5.3%.

*$[MoO_2(L^4)] \cdot 3MeOH$ (**6**)*. Yellow crystals, yield 65% (499 mg). IR: 1611s, 1576w, 1456vs,br, 1410w, 1364s, 1304m, 1238s, 1202m, 1157s, 1128m, 1099m, 1057m, 1028m, 972w, 951w, 930s, 905vs, 872s, 833s, 808m, 788m, 746m, 732m, 652w, 602m, 592m, 557m, 498w.^1H NMR: δ 9.11 (d, $J = 5$ Hz, 1H, Py), 7.50 (t, $J = 8$ Hz, 1H, Py), 7.12 (t, $J = 8$ Hz, 1H, Py), 7.10 (2H, aryl), 6.96 (2H, aryl), 6.74 (d, $J = 8$ Hz, 1H, Py), 4.98 (d, $J = 14$ Hz, 2H, CH_2), 3.97 (2H, CH_2Py), 3.75 (d, $J = 14$ Hz, 2H, CH_2), 3.71 (q, J = 23 Hz, 9H, CH_3OH) 1.27 (18H, $C(CH_3)_3$), 1.23 (18H, $C(CH_3)_3$). ^{13}C NMR: δ 159.38, 155.31, 151.41, 142.23, 139.05, 137.64, 123.90, 123.75, 122.68, 121.56, 121.17, 69.17, 63.80, 59.24, 58.35, 50.66 (CH_3OH), 34.93, 34.20, 31.60, 29.89, 18.33. *Anal*. Calc. for $C_{36}H_{50}MoN_2O_4$: C, 64.5; H, 7.5; N, 4.2. Found: C, 64.1; H, 7.4; N, 4.3%.

*[$MoO_2(L^5)$] (**9**)*. Yellow crystals, yield 63% (296 mg): 1456vs,br, 1322w, 1316 m, 1268s, 1254s, 1219s, 1161s, 1101m, 1069m, 1032m, 976w, 953w, 920vs, 897vs, 864vs, 849s, 831m, 789m, 746w, 735m, 693w, 686w, 592m, 557m, 514w. ^{1}H NMR: δ 6.97 (2H, aryl), 6.76 (2H, aryl), 4.46 (d, $J = 14$ Hz, 2H, CH_2), 3.87 (3H, OCH_3), 3.77 (d, $J = 14$ Hz, 2H, CH_2), 3.41 (t, $J = 6$ Hz, 2H, CH_2), 2.83 (t, $J = 6$ Hz, 2H, CH_2), 2.26 (6H, CH_3), 2.25 (6H, CH_3). ^{13}C NMR: δ 158.02, 131.60, 129.73, 126.72, 126.42, 121.78, 69.09, 62.70, 62.34, 52.87, 20.54, 16.24. *Anal*. Calc. for $C_{21}H_{27}MoNO_5$: C, 53.7; H, 5.8; N, 3.0. Found: C, 53.8; H, 5.6; N, 2.8%.

*[$MoO_2(L^6)$] (**10**)*. Yellow microcrystals, yield 64% (296 mg): IR: 1456vs, 1412m, 1364m, 1316m, 1244s, 1202m, 1167m, 1123m, 1096m, 1067vs, 1013m, 972w, 934s, 909vs, 878s, 858s, 833m, 812w, 746w, 735w, 669w, 606w, 592w, 557m, 510w. ^{1}H NMR: δ 7.32 (2H, aryl), 6.96 (2H, aryl), 4.65 (d, $J = 14$ Hz, 2H, CH_2), 3.81 (3H, OCH_3), 3.77 (d, $J = 14$ Hz, 2H, CH_2), 3.34 (t, $J = 6$ Hz, 2H, CH_2), 2.88 (t, $J = 6$ Hz, 2H, CH_2), 1.43 (18H, $C(CH_3)_3$), 1.29 (18H, $C(CH_3)_3$). ^{13}C NMR: δ 158.00, 142.66, 137.53, 124.15, 123.65, 121.90, 69.17, 63.68, 63.04, 58.31, 56.18, 52.94, 35.02, 34.03, 31.62, 29.92, 18.32. *Anal*. Calc. for $C_{33}H_{51}MoNO_5$: C, 62.2; H, 8.1; N, 2.2. Found: C, 62.6; H, 8.1; N, 2.3%.

4.2. Preparation of *[$WO_2(L^n)$]*

General procedure. 1.0 mmol of [W(eg)$_3$] and 1.0 mmol of aminobis(phenol) H_2L^n were dissolved in a combination of $CHCl_3$ (10 ml) and MeOH (10 ml) by heating the reaction mixture to ca. 70 °C for an hour. The pale yellow solution that formed was cooled to room temperature and subsequently allowed to stand for 12 h to precipitate [$WO_2(L^n)$]. White or pale yellow (**7**) crystalline solids were then collected by filtration and washed with cold MeOH. Complex **8** was prepared by refluxing 1.0 mmol of [W(eg)$_3$] and 1.0 mmol of H_2L^4 in 20 ml of EtOH for 8 h, whereas pale yellow solid material crystallized upon cooling to the room temperature.

*[$WO_2(L^1)$] (**3**)*. White crystals, yield 67% (382 mg). IR: 1456vs, 1327w, 1312m, 1254vs, 1219s, 1161s, 1094m, 1040w, 1015m, 962w, 947w, 932vs, 906m, 891vs, 864vs, 849s, 801m, 788m, 735w, 694w, 591m, 556m. ^{1}H NMR: δ 7.00 (2H, aryl), 6.78 (2H, aryl), 4.57 (d, $J = 14$ Hz, 2H, CH_2), 3.60 (d, $J = 14$ Hz, 2H, CH_2), 2.69 (overlapping s + t, 8H, $N(CH_3)_2 + CH_2$), 2.57 (t, $J = 6$ Hz, 2H, CH_2), 2.29 (6H, CH_3), 2.22 (6H, CH_3). ^{13}C NMR: δ 158.27, 131.00, 129.22, 126.96, 126.11, 121.72, 63.00, 57.03, 51.99, 49.51, 20.91, 16.33. *Anal*. Calc. for $C_{22}H_{30}N_2O_4W$: C, 46.3; H, 5.3; N, 4.9. Found: C, 46.0; H, 5.3; N, 4.7%.

*[$WO_2(L^2)$] (**4**)*. White crystalline solid, yield 57% (421 mg). IR: 1454vs, 1364s, 1312m, 1238s, 1202m, 1169m, 1094m, 1028m, 974w, 945s, 904vs, 874s, 849m, 829s, 806m, 779m, 754m, 650 w, 602m, 594w, 556m. ^{1}H NMR: δ 7.36 (d, $J = 2.5$ Hz, 2H, aryl), 6.99 (d, $J = 2.5$ Hz, 2H, aryl), 4.21 (d, $J = 14$ Hz, 2H, CH_2), 4.11 (d, $J = 14$ Hz, 2H, CH_2), 3.50 (2H, CH_2) 2.99 (overlapping s + d, 8H, $N(CH_3)_2 + CH_2$), 1.50 (18H, $C(CH_3)_3$), 1.30 (18H, $C(CH_3)_3$). ^{13}C NMR: δ 159.00, 143.02, 137.51, 124.03, 123.22, 122.58, 61.74, 57.26, 54.31, 51.03, 50.88, 35.00, 34.25, 31.68, 30.55. *Anal*. Calc. for $C_{34}H_{54}N_2O_4W$: C, 55.3; H, 7.4; N, 3.8. Found: C, 55.6; H, 7.3; N, 4.0%.

*[$WO_2(L^3)$] (**7**)*. Pale yellow crystalline solid, yield 46% (271 mg). IR: 1611s, 1574w, 1454vs, 1393m, 1377s, 1321m, 1304m, 1246s, br, 1223m, 1159s, 1098s, 1059m, 1032m, 961w, 934vs, 901vs, 878s, 853vs, 829s, 770m, 763m, 727m, 721m, 689w, 648m, 590m, 556s, 519w, 488w. *Anal*. Calc. for $C_{24}H_{26}N_2O_4W$: C, 48.8; H, 4.4; N, 4.8. Found: C, 48.9; H, 4.6; N, 4.9%.

*[$WO_2(L^4)$] (**8**)*. Pale yellow crystalline solid, yield 41% (310 mg). IR: 1611s, 1574w, 1456vs,br, 1412w, 1388s, 1364s, 1304m, 1238s, 1202m, 1167s, 1128m, 1096m, 1057m, 1028m, 972w, 948vs, 906vs, 874s, 835s, 808m, 770m, 760m, 748m, 732m, 650w, 602m, 588m, 556m, 498m. ^{1}H NMR: δ 9.18 (d, $J = 5$ Hz, 1H, Py), 7.54 (t, $J = 8$ Hz, 1H, Py), 7.17 (2H, aryl), 7.15 (t, $J = 8$ Hz, 1H, Py), 6.95 (2H, aryl), 6.77 (d, $J = 11$ Hz, 1H, Py), 5.09 (d, $J = 13$ Hz, 2H, CH_2), 4.10 (2H, CH_2Py), 3.80 (d, $J = 14$ Hz, 2H, CH_2), 1307 (18H, $C(CH_3)_3$), 1.27 (18H, $C(CH_3)_3$). ^{13}C NMR: δ 157.27, 156.02, 152.06, 142.65, 139.45, 138.60, 124.15, 123.81, 122.82, 121.46, 120.93, 64.05, 59.49, 53.45, 50.89, 34.91, 34.20, 31.63, 30.30, 29.89, 18.30. *Anal*. Calc. for $C_{36}H_{50}N_2O_4W$: C, 57.0; H, 6.6; N, 3.7. Found: C, 56.7; H, 6.6; N, 3.8%.

*[$WO_2(L^5)$] (**11**)*. White crystalline solid, yield 86% (479 mg). IR: 1456vs, 1323m, 1302m, 1269m, 1254s, 1219s, 1163s, 1094m, 1063s, 1032s, 972w, 939s, 899vs, 864vs, 858s, 831m, 789m, 739w, 733m, 693w, 688m, 592m, 556m, 514w. ^{1}H NMR: δ 7.04 (2H, aryl), 6.80 (2H, aryl), 4.79 (d, $J = 14$ Hz, 2H, CH_2), 3.86 (3H, OCH_3), 3.77 (d, $J = 14$ Hz, 2H, CH_2), 3.27 (t, $J = 6$ Hz, 2H, CH_2), 2.95 (t, $J = 6$ Hz, 2H, CH_2), 2.31 (6H, CH_3), 2.29 (6H, CH_3). ^{13}C NMR: δ 155.56, 132.06, 130.08, 127.74, 126.68, 121.46, 70.72, 63.59, 52.87, 20.52, 16.16. *Anal*. Calc. for $C_{21}H_{27}NO_5W$: C, 45.3; H, 4.9; N, 2.5. Found: C, 45.6; H, 4.7; N, 2.6%.

*[$WO_2(L^6)$] (**12**)*. White crystalline solid, yield 63% (455 mg). IR: 1456vs, 1412m, 1366m, 1318m, 1244s, 1204m, 1169m, 1123m, 1092m, 1069vs, 1026m, 1010m, 970w, 957s, 941m, 909vs, 880s, 851s, 835m, 820w, 812w, 744w, 735w, 669w, 608w, 592w, 557m, 510w. ^{1}H NMR: δ 7.34 (2H, aryl), 6.86 (2H, aryl), 4.59 (d, $J = 14$ Hz, 2H, CH_2), 3.83 (3H, OCH_3), 3.76 (d, $J = 14$ Hz, 2H, CH_2), 3.29 (t, $J = 6$ Hz, 2H, CH_2), 2.90 (t, $J = 6$ Hz, 2H, CH_2), 1.30 (18H, $C(CH_3)_3$), 1.26 (18H, $C(CH_3)_3$). ^{13}C NMR: δ 157.26, 142.65, 138.59,

124.14, 123.63, 121.71, 69.17, 64.65, 64.04, 59.47, 53.45, 53.08, 35.03, 34.33, 31.63, 29.90, 18.28. *Anal*. Calc. for $C_{33}H_{51}NO_5W$: C, 54.6; H, 7.1; N, 1.9. Found: C, 54.9; H, 7.5; N, 2.2%.

4.3. Oxotransfer catalysis

In a typical test reaction, 0.10 mmol (21 mg) of benzoin was dissolved in 0.7 ml of deoxygenated dmso in a NMR tube and then treated with 0.01 mmol of catalyst. The reaction mixture was kept at 120 °C for 24 h and subsequently cooled to the room temperature. The conversion of benzoin to benzil was detected by ^{1}H NMR. Detected yield of benzil was 40–60% in all experiments.

4.4. X-ray crystallography

Crystals suitable for X-ray measurements were grown from reaction mixtures. Crystallographic data for **1**, **3** and **9** along with other experimental details are summarized in Table 1. The crystal data were collected at 173 K on a Nonius Kappa CCD area-detector diffractometer using graphite monochromatised Mo Kα radiation ($\lambda = 0.71073$ Å). The data collection was performed using φ and ω scans. The data were processed using DENZO-SMN v0.93.0 [26]. SHELXA [27] absorption correction was applied for the data of all compounds. The structures were solved by direct methods using the SHELXS-97 program and full-matrix least-squares refinements on F^2 were performed using the SHELXL-97 program [28]. For all compounds the heavy atoms were refined anisotropically. The CH hydrogen atoms were included at the fixed distances with fixed displacement parameters from their host atoms. Figures were drawn with ORTEP-3 for Windows [29].

Appendix A. Supplementary data

Crystallographic data (excluding structure factors) for the structures reported in this paper have been deposited with the Cambridge Crystallographic Data Centre as deposition numbers CCDC 276480–276482 for **1**, **3**, and **9**, respectively. Copies of the data can be obtained free of charge on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK [fax: +44 1223/336 033; e-mail: deposit@ccdc.cam.ac.uk]. Supplementary data associated with this article can be found, in the online version at doi:10.1016/j.poly.2005.07.037.

Abstract

Coordination of copper (I) and (II) salts to melamine (Mel) produces [CuX(Mel)] [X = Cl (**5a**), Br (**5b**), I (**5c**), NO_3 (**5d**)], [CuX_2-$(Mel)_2$] · S [X = Cl, S = H_2O (**6a**); X = Cl, S = 2 MeOH (**6b**); X = Br, S = 1/2H_2O (**6c**); X = OAc, S = none (**6d**)], and [$Cu(OAc)_2$(Mel)] (**7**). The chemical identity of the complexes has been confirmed by elemental analysis, X-ray powder diffraction, thermogravimetry, and infrared analysis.

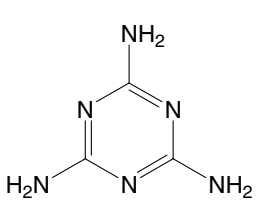
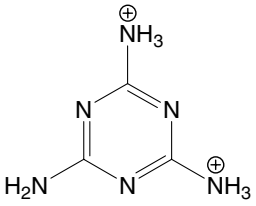
1. Introduction

Melamine (2,4,6-triamino-*s*-triazine, **1**) has long been known as a monomer for melamine formaldehyde resins, but it is also an important fire retardant additive for polymers [1]. As part of our ongoing studies of copper complexes as fire retardant/smoke suppression additives for chlorinated polymers [2], we decided to undertake an investigation of the coordination chemistry of copper salts with melamine (Mel). Despite its apparent promise as a ligand, investigations into the coordination chemistry of melamine in the literature are remarkably few (see below). This fact probably owes much to the insolubility of melamine in all common solvents, except hot water. Nevertheless, our studies have also shown that melamine is a surprisingly poor ligand, especially in aqueous medium. The likely reason for the foregoing observations is the extensive hydrogen bonding that causes melamine to form a robust network structure [3].



1



2

The metal compounds of melamine that have been reported to date are almost exclusively limited to group 11 metals and largely fall into one of three categories: melaminium dication (**2**) salts associated with coordination anions [4], inorganic salts cocrystallized with melamine (showing hydrogen bonding but not coordination between the two networks) [5], and a few serendipitously formed coordination complexes [6]. Two of the latter complexes have been structurally characterized. Reaction of diacetylmelamine with $Cu(NO_3)_2$ in methanol provided melamine complex **3**, and $AgClO_4$ reacted with melamine in water/methanol produced **4**. The dimer units that comprise the Cu(II) complex **3** contain internal hydrogen bonds between methanol or methoxide oxygen atoms and melamine

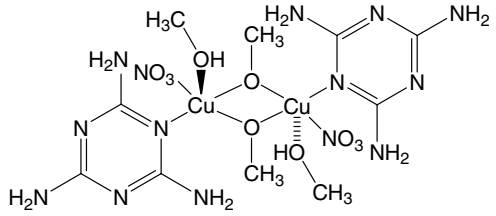
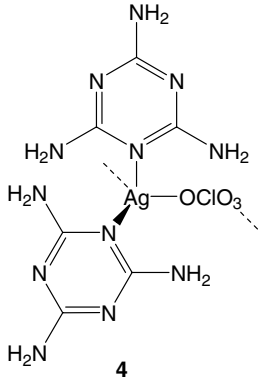
doi:10.1016/j.poly.2005.08.022

hydrogen atoms. In addition, the intermolecular hydrogen bonds knit the dimer units into sheets, similar to those found for melamine itself [3]. The structure of the Ag(I) cation **4** is simpler, consisting of $[Ag(Mel)_2]^+$ units linked into chains through weakly bridging perchlorate–silver interactions and additionally by hydrogen bonds between the perchlorate oxygen atoms and melamine hydrogen atoms. The coordination of melamine in both of these complexes occurs through one aromatic nitrogen atom, with no evidence of chelation to the amine nitrogen atoms.



3



4

There has been a report of Cu(II) salt reactions with melamine [7]. The reported complexes $[CuCl_2(Mel)_2]$ and $[CuX_2(Mel)]$ (X = Cl, Br, OAc) were formed by heating butanol or methanol solutions of Cu(II) salt with melamine. No crystal structures were reported in this study. Herein we report the synthesis and characterization of a series of Cu(I) and Cu(II) melamine complexes.

2. Experimental

2.1. General

All compounds were reagent grade and were used as received, except for CuCl and CuBr, which were freshly recrystallized from HCl and HBr, respectively. $[Cu(NCMe)_4]BF_4$ was prepared according to a literature method [8]. All copper-containing products were analyzed for copper content by atomic absorption as previously described [9]. Analyses for C, H, and N were carried out by Atlantic Microlabs, Norcross, GA. Thermogravimetric analyses (TGA) were run using a TA Instruments Q500 instrument in high resolution mode (heating rate dependent upon mass loss activity) under 60 mL/min N_2 flow. X-ray powder diffraction analyses were carried out on a Scintag XDS 2000 diffractometer (Cu Kα, 3–60°, 0.05° step, 1.0 s/step) and manipulated using the JADE software package [10]. Infrared (IR) spectra were collected from KBr pellets on a Digilab FTS 7000 FTIR spectrophotometer.

2.2. Preparation of *[CuBr(Mel)]* (*5b*)

Copper (I) bromide (217 mg, 1.51 mmol) was dissolved in 30 mL Ar-degassed MeCN. The solution was filtered through Celite. Melamine (126 mg, 1.00 mmol) was added. The suspension was sealed in a thick-walled glass tube and heated to 100 °C with stirring in an oil bath. After 20 h, the MeCN had lost the pale green color associated with the solution of CuBr. The suspended solid was collected by means of filtration, washed with fresh MeCN and diethyl ether, and then dried under vacuum (white solid, 235 mg, 0.872 mmol, 87.4%). *Anal.* Calc. for **5b**: Cu, 26.73; C, 16.67; H, 2.80; N, 38.35. Found: Cu, 26.67; C, 16.63; H, 2.79; N, 38.84%. Selected IR data (cm^{-1}): 3459, 3425, 3352, 3195, 3140, 1659, 1600, 1575, 1541, 1477, 1448, 1028, 798.

2.3. Preparation of *[CuCl(Mel)$_{1.1}$]* (*5a*)

Synthesized as for **5b** but CuCl was added. Mint solid, yield 87.5%. *Anal.* Calc. for **5a**: Cu, 26.73; C, 16.67; H, 2.80; N, 38.35. Found: Cu, 26.67; C, 16.63; H, 2.79; N, 38.84%. Selected IR data (cm^{-1}): 3454, 3426, 3348, 3199, 3137, 1664, 1601, 1577, 1540, 1467, 1447, 1031, 797.

2.4. Preparation of *[CuI(Mel)]* (*5c*)

Synthesized as for **5b** but CuI was added. White solid, yield 91.6%. *Anal.* Calc. for **5c**: Cu, 20.07; C, 11.38; H, 1.91; N, 26.55. Found: Cu, 20.03; C, 11.54; H, 1.84; N, 26.31%. Selected IR data (cm^{-1}): 3469, 3408, 3326, 3145, 1703, 1688, 1653, 1623, 1566, 1530, 1498, 1020, 816.

2.5. Preparation of *[CuNO$_3$(Mel)]* (*5d*)

Synthesized as for **5b** except "$CuNO_3$" was first prepared in MeCN solution through conproportionation of $Cu(NO_3)_2 \cdot 2.5H_2O$ with Cu wool until the solution was colorless. Excess copper wool was then removed, melamine was added, and the procedure for **5b** was followed. White solid, yield 93.5%. *Anal.* Calc. for **5d**: Cu, 25.25; C, 14.32; H, 2.40; N, 38.96. Found: Cu, 24.57; C, 14.53; H, 2.37; N, 38.68%. Selected IR data (cm^{-1}): 3459, 3426, 3337, 3195, 3143, 1672, 1660, 1618, 1571, 1541, 1466, 1450, 1026, 790.

2.6. Preparation of *[CuCl$_2$(Mel)$_2$] · 2MeOH* (*6b*)

Copper (II) chloride dihydrate (171 mg, 1.00 mmol) was dissolved in 30 mL Ar-degassed MeOH. Melamine (252 mg, 2.00 mmol) was added. The mixture was sealed

in a thick-walled glass tube and heated to 100 °C with stirring in an oil bath. After 14 h, the lime green MeOH had bleached to a very pale green color and the white solid had become yellow-green. The solid was collected by means of filtration, washed with fresh MeOH and diethyl ether and then dried under vacuum. (white solid, 347 mg, 0.770 mmol, 77.0%). *Anal*. Calc. for **6b**: Cu, 14.10; C, 21.32; H, 4.47; N, 37.29. Found: Cu, 14.64; C, 20.60; H, 4.37; N, 37.95%. Selected IR data (cm^{-1}): 3331, 3157, 1651, 1540, 1474, 1017, 801, 783.

2.7. Preparation of $[CuCl_2(Mel)_2] \cdot H_2O$ (6a)

Synthesized as for **6b** except the solvent used was BuOH. Yellow solid, yield 92.5%. *Anal*. Calc. for **6a**: Cu, 15.70; C, 17.81; H, 3.49; N, 41.53. Found: Cu, 15.77; C, 17.67; H, 3.44; N, 40.65%. Selected IR data (cm^{-1}): 3425, 3410, 3373, 3312, 3177, 1702, 1680, 1652, 1622, 1561, 1535, 1475, 1023, 804, 782.

2.8. Preparation of $[CuBr_2(Mel)_2] \cdot 1/2H_2O$ (6c)

Synthesized as for **6b** except $CuBr_2$ was added and the solvent used was MeCN. Pea green solid, yield 99.6%. *Anal*. Calc. for **6c**: Cu, 13.11; C, 14.87; H, 2.70; N, 34.68. Found: Cu, 13.19; C, 15.06; H, 2.94; N, 34.50%. Selected IR data (cm^{-1}): 3425, 3410, 3373, 3312, 3214, 3171, 1702, 1680, 1652, 1622, 1535, 1475, 1020, 804, 781.

2.9. Preparation of $[Cu(OAc)_2(Mel)_2] \cdot H_2O$ (6d)

Synthesized as for **6b** except $Cu(OAc)_2 \cdot H_2O$ was added and the solvent used was MeCN. Aqua solid, yield 85.5%. *Anal*. Calc. for **6d**: Cu, 14.00; C, 27.68; H, 4.18 ; N, 38.74. Found: Cu, 14.06; C, 27.61; H, 4.09; N, 38.63%. Selected IR data (cm^{-1}): 3470, 3410, 3337, 3249, 3191, 3133, 1653, 1627, 1553, 1468, 1437, 1028, 814.

2.10. Preparation of $[Cu(OAc)_2(Mel)]$ (7)

Synthesized as for **6b** except $Cu(OAc)_2 \cdot H_2O$ and melamine were reacted in equimolar proportions in MeCN. Aqua solid, yield 91.5%. *Anal*. Calc. for **7**: Cu, 20.65; C, 27.32; H, 3.93; N, 27.31. Found: Cu, 20.43; C, 27.00; H, 3.96; N, 28.18%. Selected IR data (cm^{-1}): 3470, 3420, 3353, 3244, 3137, 1651, 1626, 1553, 1467, 1437, 1031, 813.

3. Results and discussion

3.1. Synthesis

Initial attempts to form Cu(I)–melamine complexes in our lab focused on the use of aqueous ammoniacal solutions of copper (I) ion, which are produced via hydroxylamine reduction of $CuSO_4 \cdot 5H_2O$ [11]. Melamine (Mel) was dissolved in warm degassed water and was added via syringe to a nitrogen-purged colorless solution of "Cu_2SO_4" prepared as previously described [11]. Encouragingly, the solution remained colorless, showing no sign of copper oxidation. Slow cooling of the solution to 5 °C, resulted in the formation of colorless crystals. However, these crystals contained no copper and were shown by melting point analysis to be merely recrystallized melamine. Thus, under these experimental conditions (0.20 M Cu_2SO_4, 0.60 M melamine 3.0 M NH_3), ammonia coordination proved to be favored over that of melamine.

A non-aqueous approach was pursued next. The use of organic solvents necessitated working with melamine as a suspended solid in copper-containing solutions. Acetonitrile was the solvent of choice for most of the reactions, however, methanol and *n*-butanol were also effective for several of the copper (II) salt reactions. The reaction mixtures containing the dissolved copper salt and solid melamine were heated overnight in sealed, thick-wall reaction tubes. Typically, the solution color lessened during the reaction, indicating the transfer of copper to the suspended melamine. The products were filtered and subjected to chemical analysis.

The favored products of CuX (X = Cl, Br, I, NO_3) with melamine conformed to the formula [CuX(Mel)] (**5**). The only problematic results came from the CuCl reaction, which reproducibly formed **5a** as $[CuCl(Mel)_{1.1–1.3}]$. A replicate CuCl reaction was carried out in the presence of copper wool to help prevent possible formation of Cu(II). Although the product of this reaction was whiter in color, chemical analysis still revealed excess melamine. The use of large excesses (about 10-fold) of copper salt resulted in the materials roughly conforming to $[(CuX)_2(Mel)]$ for X = Cl, Br. However, elemental analyses for these products were not of high quality. Although X-ray powder diffraction and thermogravimetry results suggested that $[(CuX)_2(Mel)]$ might be an independent phase (see below), a mixture of **5** and CuX could not be ruled out. Nevertheless, no evidence was found for the formation of $[(CuX)_2(Mel)]$ products for X = I, NO_3; instead the isolated solids invariably analyzed as **5c** and **5d**. Attempts to dissolve away any adsorbed (rather than bonded) copper salt were carried out by heating the various Cu(I)–melamine complexes in fresh acetonitrile at 100 °C over several days. These experiments produced no changes in sample composition. Products of reactions involving the use of excess melamine yielded irreproducible chemical analyses. Subsequent X-ray analysis of these powders clearly revealed the presence of both **5** and free melamine. Hence, copper-poor phases with melamine do not appear to exist.

When $[Cu(NCMe)_4]BF_4$ was dissolved in MeCN and heated with melamine, the solid recovered proved to be unreacted melamine. What makes this result particularly surprising is the demonstrated reaction of the nitrate salt with melamine. Conproportionation of $Cu(NO_3)_2 \cdot 2.5H_2O$ with Cu in acetonitrile produces "$CuNO_3$", which almost certainly exists in solution as $[Cu(NCMe)_4]NO_3$. The formation of $[CuNO_3(Mel)]$ (**5d**) but not of $[CuBF_4(Mel)]$ under essentially identical conditions points to the possible

necessity of anion coordination since NO_3^- is a superior ligand to BF_4^-.

All of the Cu(I)–melamine products were white or nearly white in color. This absence of color suggests that copper coordination is occurring through the amine nitrogen atoms, rather than those of triazine. The known Cu(I) complexes of diazine and triazine ligands invariably show significant color due to metal to ligand charge transfer absorptions in the visible spectrum [9,12].

In contrast to the results obtained with Cu(I), the Cu(II) salts generally formed products analyzing as $[CuX_2(Mel)_2]$ (**6**). Water or alcohol solvent was retained in several cases, presumably as an additional ligand for copper. The only 1:1 Cu(II):Mel product realized was $[Cu(OAc)_2(Mel)]$ (**7**). The lack of isolated 1:1 complexes for $CuCl_2$ and $CuBr_2$ with melamine in the current study stands in contrast to the results reported previously [7].

3.2. X-ray powder diffraction

X-ray powder diffraction analysis was used to help characterize the new products. Sharp line diffractograms were obtained in all cases, indicating good sample crystallinity. Comparison of diffraction patterns was used to help confirm that the products were single-phase materials. Thus for example, the powder diffraction pattern of **5a** was compared to those of CuCl and melamine, see Fig. 1. The diffraction pattern of **5a** revealed no evidence of CuCl or melamine peaks. The diffractogram from the material provisionally identified as $[(CuCl)_2(Mel)]$ also appeared to be distinct from those of CuCl, melamine and **5a** (Fig. 1). Within the sensitivity constraints of X-ray powder diffraction, neither melamine nor copper salts were observed as contaminant phases in any of the copper–melamine products. Although the X-ray data were not of sufficient quality to allow for cell indexing, the occurrence of similar powder

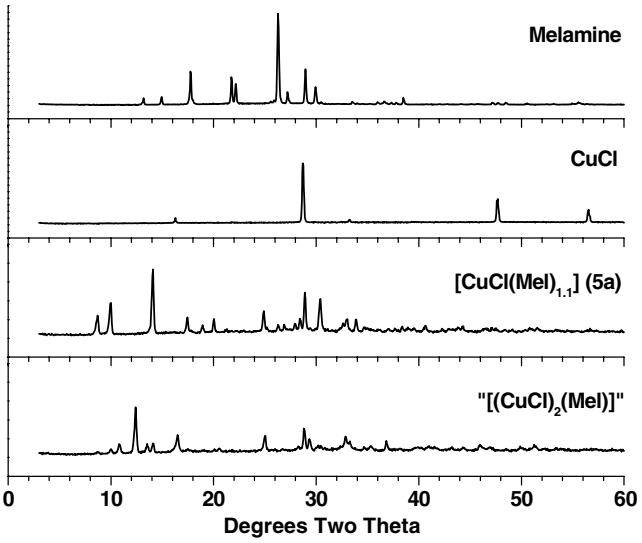


Fig. 1. X-ray powder diffraction traces for CuCl–melamine compounds.

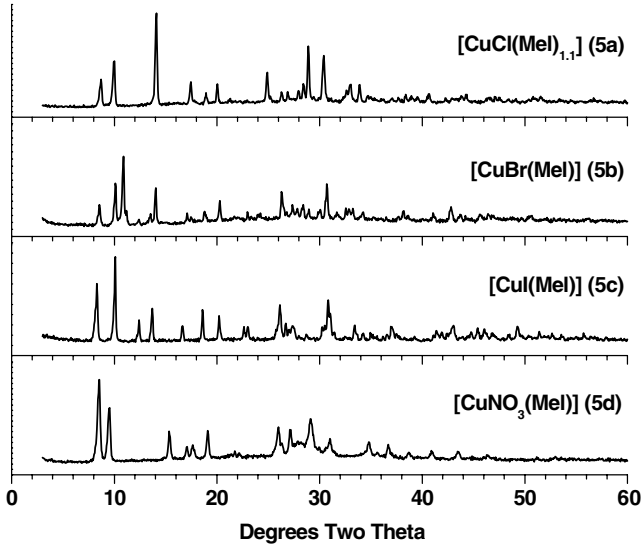

Fig. 2. X-ray powder diffraction traces for the Cu(I)–melamine compounds (**5**).

patterns for the **5** products shown in Fig. 2 suggests possible crystallographic isomorphism between these apparently low symmetry phases.

3.3. Thermogravimetric analysis

All of the melamine complexes were examined using TGA. The results and interpretations are collected in Table 1. Melamine itself sublimes between about 210 and 260 °C under the TGA conditions used. The TGA results for compounds **5** are shown in Fig. 3. Thermal analysis results for **5a** show four closely spaced mass losses occurring above 300 °C and separated from one another by shallow plateaus. The first three steps appear to represent the stepwise loss of melamine illustrated in the following equations:

$$2[CuX(Mel)]\ (\mathbf{5}) \rightarrow [(CuX)_2(Mel)] + Mel\uparrow \quad (1)$$

$$2[(CuX)_2(Mel)] \rightarrow [(CuX)_4(Mel)] + Mel\uparrow \quad (2)$$

$$[(CuX)_4(Mel)] \rightarrow 4CuX + Mel\uparrow \quad (3)$$

The mass percent represented in the first plateau corresponds well to $[(CuCl)_2(Mel)]$. Also suggestive is the fact that, after the initial mass loss from **5a**, the subsequent mass loss profiles for the **5a** residue and that of the material provisionally identified as $[(CuCl)_2(Mel)]$ were identical. The plateau at about 380–390 °C may represent $[(CuCl)_4(Mel)]$, a phase that has not been synthesized. Volatilization of the remainder of the melamine leaves CuCl. The decomposition temperature of the residual CuCl from the melamine complexes corresponds to that of free CuCl. However, while authentic CuCl largely sublimes, leaving only a few percent residual mass, the decomposition of CuCl from the melamine complexes leaves significant residual mass, nearing that of the initial copper content. Hence, in addition to CuCl sublimation, reductive elimination, reaction (4) is also occurring, as has previously been observed [12].

Table 1
Thermogravimetric analysis results

Complex	Temp. (°C)	Possible product	wt% (theory)	wt% (expt)
5a	205–340	$(CuCl)_2(Mel)$	68	66
	340–390	$(CuCl)_4(Mel)$	55	51
	390–425	CuCl	42	37
	425–510	Cu	27	24
5b	235–335	$(CuBr)_2(Mel)$	77	75
	335–380	CuBr	53	60
	380–620	Cu/sublimation		9
5c	215–330	CuI	60	58
	500–580	Cu	24	21
5d	220–410	$CuNO_3$	50	57
	410–435	Cu	25	29
6a	190–350	$CuCl_2$	33	33
	350–590	Cu	16	14
6b	45–240	$CuCl_2(Mel)_2$	86	91
	240–335	$CuCl_2$	30	35
	335–590	Cu	14	15
6c	200–350	$(CuBr_2)_2(Mel)$	59	58
	350–480	$CuBr_2$	46	47
	350–675	Cu	13	14
6d	195–215	$Cu(OAc)_2(Mel)$	71	76
	215–290	CuOAc	28	30
	300–630	Cu	15	16
7	185–210	$Cu(OAc)_2$	59	64
	210–270	CuOAc	40	45
	315–470	Cu	21	26

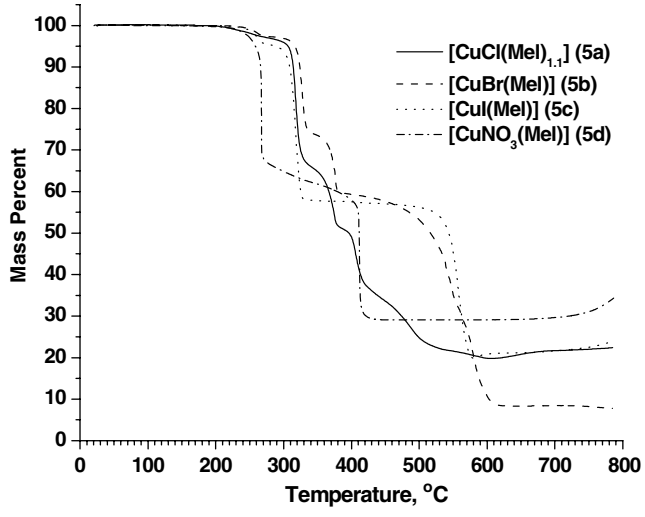

Fig. 3. TGA traces for the Cu(I)–melamine compounds (**5**).

$$2\ CuX \rightarrow Cu + X_2\uparrow \quad (4)$$

The behavior of the copper (I) bromide sample **5b** was similar to that of the **5a**, with the notable exception that there is no evidence of a $[(CuBr)_4(Mel)]$ phase. In addition, the residual CuBr undergoes sublimation to a greater extent, leaving little final residue at high temperature. Nevertheless, the onset of decomposition for the analogous CuCl- and CuBr-derived materials is similar. In contrast to the behavior of the chloride and bromide complexes, **5c** and **5d** fail to show evidence of any more copper-rich phases, see Fig. 3. Consistent with this observation is the fact that no copper-rich CuI or $CuNO_3$ materials could be synthesized. Reductive elimination (Eq. (4)) is favored for the iodide and nitrate, the residual mass corresponding closely to the original copper content of the samples.

The copper (II) complexes exhibited somewhat more complicated decomposition behavior (see Fig. 4). The $[CuCl_2(Mel)_2]$ complexes (**6a** and **6b**) underwent the loss of solvent and melamine to give $CuCl_2$, which then reduced to copper in a complicated series of steps. The TGA traces showed only slight inflections during the loss of melamine. In contrast to this behavior, the bromide **6c** trace presented several possible intermediates during the loss of melamine. The most significant plateau corresponded to a possible formula $[(CuBr_2)_2(Mel)]$. Following this possible intermediate, an inflection corresponding to $CuBr_2$ was noted, followed by a series of steps ending with copper metal. The two $Cu(OAc)_2$–melamine complexes appear to undergo a series of decomposition steps that are summed up in the following equation:

$$[Cu(OAc)_2(Mel)_2]\ (\mathbf{6d}) \rightarrow [Cu(OAc)_2(Mel)]\ (\mathbf{7}) \rightarrow Cu(OAc) \rightarrow Cu \quad (5)$$

3.4. Infrared analysis

The IR spectrum of melamine has long been known and has been reinterpreted fairly recently [13,14]. The IR spectrum of melamine consists of three principal absorption regions. The 2800–3500 cm^{-1} region encompasses the N–H stretching modes, the sharp higher frequency bands corresponding to non-hydrogen bonded N–H and the broad lower frequency bands representing hydrogen bonded N–H. The 1440–1650 cm^{-1} region contains ring distortion, N–H bending, and two complex

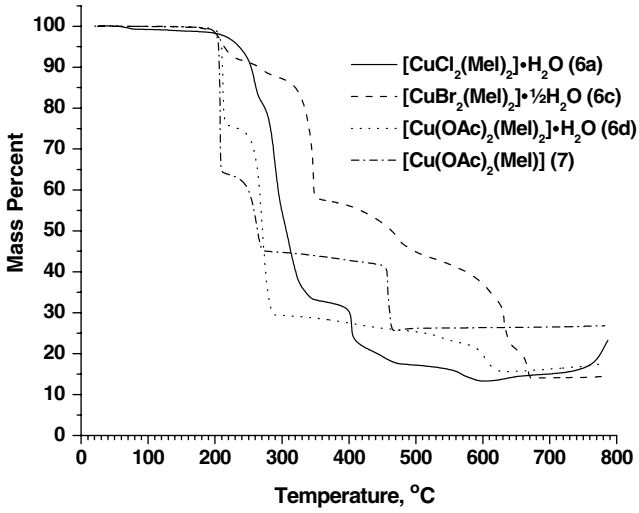

Fig. 4. TGA traces for the Cu(II)–melamine compounds (**6** and **7**).

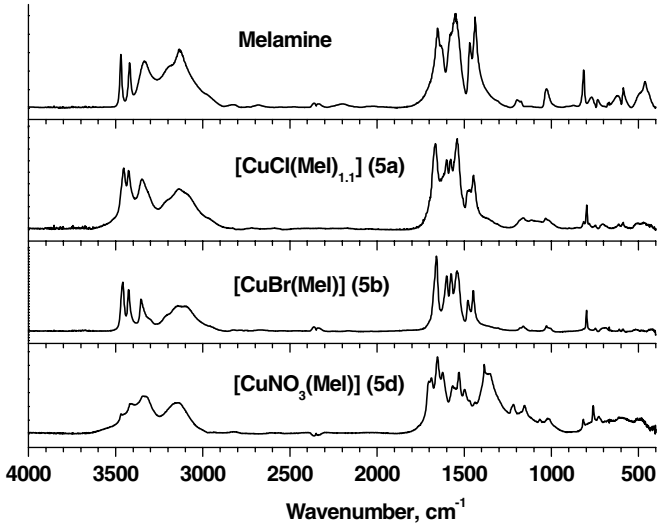

Fig. 5. IR spectra for Cu(I)–melamine compounds (**5**).

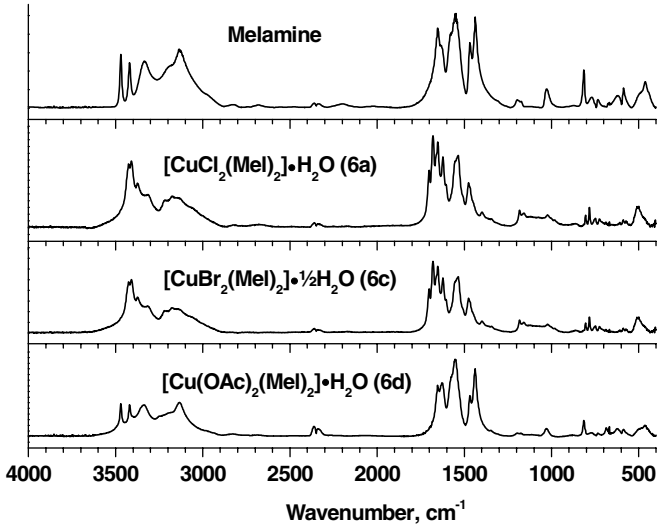

Fig. 6. IR spectra for Cu(II)–melamine compounds (**6** and **7**).

molecular modes. The 800–1050 cm^{-1} region contains two additional complex molecular modes. The spectrum of melamine is compared with those of the copper–melamine complexes in Figs. 5 and 6 and in Table 2. The band identities are adapted from the literature [14] and are interpreted under D_{3h} symmetry.

Several trends can be noted from examination of the data. All of the copper complexes retain both free and hydrogen bonded N–H stretching bands. Relative to melamine, the Cu(I)–melamine complexes' two free amine bands tend to move closer to one another in frequency, while the hydrogen bonded amine bands shift to higher frequencies. The Cu(II) complexes show a primarily downward shift in N–H stretching frequency. The fact that all of the copper–melamine products, with the exception of the acetate complexes (see below), show changes in the N–H stretching region is consistent with the lack of color in these complexes in suggesting amine, rather than triazine, coordination.

In the N–H stretching region, and throughout the IR spectrum, the $Cu(OAc)_2$–melamine complexes **6d** and **7** show almost no differences from melamine itself. This result possibly indicates little or no melamine coordination with copper, possibly due to the presence of the chelating acetate anion. Two hydrogen bonded hybrid networks between melamine and $Cu(PyHy)_2$ and $Cu(H_2NTA)Cl$ [PyHy = 5-(2-pyridylmethylene)hydantoin and H_2NTA = dihydrogen nitrilotriacetate] have been characterized previously [5], representing precedent for non-coordinating metal–melamine network formation.

The E′ ring distortion IR band is blue shifted for all of the Cu complexes except **5c**, **6b** and the aforementioned acetate complexes. This shift suggests an increase in ring rigidity, perhaps due to increased network interaction. Removal of E′ band degeneracy is evident in many of the Cu compound spectra. This removal of degeneracy is even more evident in the N–H bending bands. Once again, it is noteworthy that the acetate complexes show neither splitting nor shifting of these bending bands. Upon coordination there is a consistent red shift of the A_1' symmetrical bending mode (1626 cm^{-1} for melamine). The four low frequency bands (1468, 1436, 1027, and 814 cm^{-1} for melamine) show fairly consistent trends in their coordination shifts: the 1468 cm^{-1} band shows blue shifts, 1436 cm^{-1}

Table 2
IR data for melamine and copper–melamine complexes[a,b]

Compound	Free N–H	Hydrogen bonded N–H	E′ ring distortion	A_1' and E′ N–H bending		E′ and A_1' modes		E′ mode	A_2'' mode

[a] All data in cm^{-1}.
[b] See [13] for more detailed melamine band assignments.

shows blue shifts for Cu(I) products, and 1027 and 814 cm^{-1} bands show red shifts. No splitting of these bands is evident. Given the vibrational complexity of the underlying modes, the trends for these low frequency bands are difficult to interpret.

4. Conclusion

Melamine has been shown to act as a ligand for both Cu(I) and Cu(II) salts. The resulting insoluble networks reveal 1:1 metal salt:melamine stoichiometry for Cu(I), with the exception of CuCl, which forms $[CuCl(Mel)_{1.1–1.3}]$. In addition 2:1 complexes were realized for CuCl and CuBr. For Cu(II) salts 1:2 stoichiometry was favored. Only $Cu(OAc)_2$ produced a 1:1 compound. Thermogravimetric analysis results suggested step-wise removal of melamine for the CuCl and CuBr complexes. Infrared analysis reveals modest shifts and symmetry removal in the complexes, with the possible exception of the $Cu(OAc)_2$ products. It is possible that the latter materials are composed of separate $Cu(OAc)_2$ and melamine networks, probably associated through hydrogen bonds. Lack of Cu(I) charge transfer color and analysis of IR data suggest melamine coordination occurs through amine groups.

Acknowledgments

Grateful acknowledgement is made to Prof. Steven Aubuchon (Virginia Commonwealth University) for the use of thermogravimetric equipment. This research was supported in part by the National Science Foundation (Grant No. CHE-9983374), the Camille and Henry Dreyfus Foundation (Grant No. TH-99-010), the Thomas F. and Kate Miller Jeffress Memorial Trust (J-678), and also a Howard Hughes Medical Institute grant through the Undergraduate Biological Sciences Education Program to the College of William and Mary.

Abstract

A new series of nitrate M(II) (M = Co, Ni, Cu and Cd) complexes with a tetrapyridyl pendant-armed hexaazamacrocyclic ligand (L) has been synthesized. The complexes have been characterized by microanalysis, FAB-MS, conductivity measurements, IR, UV–Vis, ^{1}H NMR spectroscopy and magnetic measurements at room temperature. In all cases, complexes with 1:1 and 2:1 metal:ligand molar ratios were obtained depending on the stoichiometry. Crystal structures of $[Co_2L(NO_3)_4]\cdot 2H_2O$, $[Cu_2L(H_2O)_2](NO_3)_4$, $[Cd_2L(NO_3)_2](NO_3)_2\cdot 5H_2O\cdot CH_3CN$ and $[CdL](NO_3)_2\cdot 6H_2O$ have been determined. The X-ray studies show that in $[Co_2L(NO_3)_4]\cdot 2H_2O$ and $[Cu_2L(H_2O)_4](NO_3)_4$, the metal atoms are exocyclically coordinated to the pyridine pendant arms and the tertiary amine nitrogen atoms in a distorted square pyramid [N4O] and distorted octahedral geometry [N4O2], respectively. In both cases, the pyridine rings of the macrocyclic backbone (bridgehead) are not coordinated. In contrast, in $[Cd_2L(NO_3)_2](NO_3)_2\cdot 5H_2O\cdot CH_3CN$ the metal atoms are coordinated by both types of pyridine group (bridgehead and pendant arm) and the tertiary amine with an [N5O2] core in a distorted capped octahedral geometry. Finally, the structure of the 1:1 cadmium complex $[CdL](NO_3)_2\cdot 6H_2O$ was also resolved and this showed the metal centre in a distorted octahedral geometry [N6] with the metal coordinated by both types of pyridine group and the tertiary amine.

Keywords: Pyridyl macrocyclic ligand; *N*-alkylation; Metal complex; X-ray structure

1. Introduction

Over the last three decades, the chemistry of polyazamacrocycles has become a fruitful research area due to the ability of these systems to interact with different substrates such as metal ions or anionic species [1]. The presence of pyridine groups in the macrocyclic framework offers the possibility of obtaining complexes with high levels of metal and this has attracted considerable interest in recent years [2].

A great deal of effort has since been focused on pendant-armed ligands and their metal complexes due to the fact that the ligating groups attached to the macrocyclic backbone can offer additional donor groups and enhance complex stability [3]. The flexibility of the pyridyl pendant arms together with the steric requirements of the metal ion employed and the coordinative behaviour of the counterions, make it possible for intramolecular coordination to the parent metal ion to occur as well as intermolecular coordination to other metal ions.

L

Fig. 1. Tetrapyridyl pendant-armed hexaazamacrocyclic ligand, L.

Such an arrangement could give rise to higher nuclearity or polymeric structures [4].

We have previously reported the synthesis of metal complexes of different nuclearity starting from silver nitrate [5] and perchlorate metal salts [6] and the hexaazamacrocyclic pendant-armed ligand L (Fig. 1), which bears tetrapyridyl pendant groups. In order to investigate possible modifications of the coordination behaviour of the macrocyclic ligand and, consequently, changes in the crystal structure due to the well-known different coordinative properties between perchlorate and nitrate anions, we report here our results obtained in the synthesis of a series of nitrate metal complexes.

Metal complexes of L with Co(II), Ni(II), Cu(II) and Cd(II) nitrate salts were prepared and characterized by microanalysis, FAB-MS, conductivity measurements, IR, UV–Vis, ^{1}H NMR spectroscopy and magnetic studies. The X-ray crystal structures of $[Co_2L(NO_3)_4]\cdot 2H_2O$, $[Cu_2L(H_2O)_2](NO_3)_4$, $[Cd_2L(NO_3)_2](NO_3)_2\cdot 5H_2O\cdot CH_3CN$ and $[CdL](NO_3)_2\cdot 6H_2O$ were also determined.

2. Experimental

2.1. Chemicals and starting materials

2,6-Pyridinedimethanol, ethylenediamine, 2-picolyl chloride hydrochloride and hydrated nitrate salts were commercial products (from Alfa and Aldrich) and were used without further purification. Solvents were of reagent grade and were purified by standard methods.

2.2. Synthesis of the macrocycle L

The ligand L was prepared from the hexaazamacrocycle precursor [7] by alkylation with picolyl chloride using a previously reported method [8].

2.3. Synthesis of the metal complexes

2.3.1. General procedure

The appropriate metal salt (0.25 mmol in a 1:1 synthesis or 0.5 mmol in a 2:1 synthesis) was dissolved in acetonitrile (10 mL) and the solution added to a stirred solution of the ligand L (0.25 mmol) in acetonitrile (30 mL) under reflux. The reaction mixture was heated under reflux for 2 h and concentrated using a rotary evaporator to give a volume of ca. 5–6 mL. The resulting product was filtered off and dried. In all cases, the complexes were obtained in a 1:1 or 2:1 metal:ligand molar ratio.

2.3.2. $[CoL](NO_3)_2\cdot 5H_2O$

Anal. Calc. for $C_{42}H_{56}N_{12}O_{11}Co$ (MW: 963): C, 52.3; H, 5.8; N, 17.4. Found: C, 51.4; H, 5.5; N, 17.7%. Yield: 49%. IR (KBr, cm^{-1}): 1609, 1591, 1475, 1437 [ν(C=N)$_{py}$ and ν(C=C)], 1384, [$\nu(NO_3^-)$]. MS (FAB, m/z): 812 $[CoL(NO_3)]^+$, 750 $[CoL]^{2+}$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 260 (2:1). Colour: brown.

2.3.3. $[Co_2L(NO_3)_4]\cdot 2H_2O$

Anal. Calc. for $C_{42}H_{50}N_{14}O_{14}Co_2$ (MW: 1092): C, 46.1; H, 4.6; N, 18.0. Found: C, 46.5; H, 4.5; N, 18.3%. Yield: 47%. IR (KBr, cm^{-1}): 1606, 1590, 1475, 1436 [ν(C=N)$_{py}$ and ν(C=C)], 1443, 1383, 1314, 810 [$\nu(NO_3^-)$]. MS (FAB, m/z): 994 $[Co_2L(NO_3)_3]^+$, 812 $[CoL(NO_3)]^+$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 365 (3:1). Colour: pink.

2.3.4. $[NiL](NO_3)_2\cdot 4H_2O$

Anal. Calc. for $C_{42}H_{54}N_{12}O_{10}Ni$ (MW: 946): C, 53.3; H, 5.7; N, 17.9. Found: C, 53.3; H, 5.7; N, 17.9%. Yield: 58%. IR (KBr, cm^{-1}): 1609, 1591, 1475, 1437 [ν(C=N)$_{py}$ and ν(C=C)], 1384 [$\nu(NO_3^-)$]. MS (FAB, m/z): 812 [NiL(NO$_3$)]+, 750 $[NiL]^{2+}$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 290 (2:1). Colour: brown.

2.3.5. $[Ni_2L(NO_3)_4]\cdot 2H_2O$

Anal. Calc. for $C_{42}H_{50}N_{14}O_{14}Ni_2$ (MW: 1092): C, 46.2; H, 4.6; N, 17.9. Found: C, 46.1; H, 4.7; N, 18.0%. Yield: 53%. IR (KBr, cm^{-1}): 1607, 1589, 1472, 1432 [ν(C=N)$_{py}$ and ν(C=C)], 1445, 1384, 1312, 811 [$\nu(NO_3^-)$]. MS (FAB, m/z): 994 $[Ni_2L(NO_3)_3]^+$, 932 $[Ni_2L(NO_3)_2]^{2+}$, 811 $[NiL(NO_3)]^+$, 750 $[NiL]^{2+}$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 402 (3:1). Colour: blue.

2.3.6. $[CuL](NO_3)_2\cdot 2H_2O$

Anal. Calc. for $C_{42}H_{50}N_{12}O_8Cu$ (MW: 913): C, 55.2; H, 5.5; N, 18.4. Found: C, 53.7; H, 5.5; N, 18.1%. Yield: 48%. IR (KBr, cm^{-1}): 1612, 1591, 1476, 1436 [ν(C=N)$_{py}$ and ν(C=C)], 1384 [$\nu(NO_3^-)$]. MS (FAB, m/z): 815 $[CuL(NO_3)]^+$, 753 $[CuL]^{2+}$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 275 (2:1). Colour: green.

2.3.7. $[Cu_2L(H_2O)_2](NO_3)_4$

Anal. Calc. for $C_{42}H_{50}N_{14}O_{14}Cu_2$ (MW: 1102): C, 37.8; H, 4.0; N, 16.4. Found: C, 37.7; H, 3.9; N, 16.4%. Yield: 52%. IR (KBr, cm^{-1}): 1609, 1588, 1481, 1434 [ν(C=N)$_{py}$ and ν(C=C)], 1384 [$\nu(NO_3^-)$]. MS (FAB, *m/z*): 1002 $[Cu_2L(NO_3)_3]^+$, 942 $[Cu_2L(NO_3)_2]^{2+}$, 880 $[Cu_2L(NO_3)]^{3+}$, 753 $[CuL]^{2+}$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 460 (4:1). Colour: blue.

2.3.8. $[CdL](NO_3)_2 \cdot 6H_2O$

Anal. Calc. for $C_{42}H_{58}N_{12}O_{12}Cd$ (MW: 1036): C, 48.6; H, 5.6; N, 16.2. Found: C, 48.9; H, 5.4; N, 16.0%. Yield: 48%. IR (KBr, cm^{-1}): 1602, 1588, 1436 [ν(C=N)$_{py}$ and ν(C=C)], 1383 [$\nu(NO_3^-)$]. MS (FAB, *m/z*): 866 $[CdL(NO_3)]^+$, 803 $[CdL]^{2+}$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 258 (2:1). Colour: white.

2.3.9. $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$

Anal. Calc. for $C_{44}H_{59}N_{15}O_{17}Cd_2$ (MW: 1297): C, 40.7; H, 4.6, N, 16.2. Found: C, 40.6, H, 4.7, N, 15.9%. Yield: 71%. IR (KBr, cm^{-1}): 1602, 1588, 1436 [ν(C=C) and ν(C=N)$_{py}$], 1436, 1383, 1316, 817 [$\nu(NO_3^-)$]. MS (FAB, *m/z*): 1040 $[Cd_2L(NO_3)_2]^{2+}$, 866 $[CdL(NO_3)]^+$, 803 $[CdL]^{2+}$. $\Lambda_M/\Omega^{-1}\,cm^2\,mol^{-1}$ (in CH_3CN): 392 (3:1). Colour: white.

2.4. Physical measurements

Elemental analyses were performed in a Carlo-Erba EA microanalyser. Infrared spectra were recorded as KBr discs on a Bruker IFS-66V spectrophotometer. FAB mass spectra were recorded using a Kratos-MS-50T spectrometer connected to a DS90 data system using 3-nitrobenzyl alcohol as the matrix. Conductivity measurements were carried out in 10^{-3} mol dm^{-3} acetonitrile solutions at 20 °C using a WTW LF3 conductivimeter. ^1H NMR spectra were recorded on a Bruker 500 MHz spectrometer and CD_3CN was used as the solvent in all cases. Solid-state electronic spectra were recorded on a Hitachi 4-3200 spectrophotometer using $MgCO_3$ as reference. Magnetic studies were determined at room temperature on a vibration sample magnetometer (VSM) (Digital Measurement System 1660) with a magnetic field of 5000 G.

2.5. Crystal structure determination

The X-ray crystal measurements were made on a Bruker SMART CCD 1000 area diffractometer. All data were corrected for Lorentz and polarization effects. Empirical absorption corrections were also applied for all the crystal structures obtained [9]. Complex scattering factors were taken from the program package SHELXTL [10]. The structures were solved by direct methods, which revealed the position of all non-hydrogen atoms. All the structures were refined on F^2 by a full-matrix least-squares procedure using anisotropic displacement parameters for all non-hydrogen atoms. The hydrogen atoms were located in their calculated positions and refined using a riding model. Molecular graphics were generated using ORTEP-3 [11].

3. Results and discussion

Metal complexes of Co(II), Ni(II), Cu(II) and Cd(II) with 1:1 and 2:1 stoichiometries were prepared by reaction of a tetrapyridyl pendant-armed hexaazamacrocyclic ligand (L) with hydrated metal nitrate salts, in acetonitrile, in 1:1 and 2:1 metal:ligand molar ratios. The complexes were synthesized by a one-step procedure as described in Section 2 and the reactions gave good yields of analytically pure products.

The complexes appear to be air stable; they are soluble in acetonitrile, dimethylformamide and dimethylsulfoxide, some of them are soluble in water, methanol and ethanol, but are insoluble in dichloromethane and chloroform.

3.1. Crystal structures

The details of the X-ray crystal structure solutions and refinement are given in Table 1.

3.1.1. Crystal structure of $[Co_2L(NO_3)_4] \cdot 2H_2O$

Pink crystals of $[Co_2L(NO_3)_4] \cdot 2H_2O$ were obtained by slow recrystallization of the complex from acetonitrile. The molecular structure of the complex and selected bond lengths (Å) and angles (°) relating to the coordination environment of the metal are given in Fig. 2. The unit cell contains a dinuclear complex with the two cobalt atoms separated by 9.33 Å. Both metal centres present a similar six-coordinate N4O2 core in a distorted octahedral geometry. Each cobalt is bound to four nitrogen atoms – two contiguous tertiary amines from the macrocyclic backbone and their corresponding two pyridyl pendant groups – and two oxygen atoms from two monodentate nitrate anions. All the donor atoms are disposed in a *cis* arrangement. Neither of the bridgehead pyridyl groups are coordinated. Examination of the coordination spheres in more detail shows that there are few differences between the two metal ions. The equatorial plane of Co(1) can be considered to be formed by two pyridyl pendant nitrogen atoms [N(7), N(8)], one amine nitrogen, N(3), and an oxygen from a nitrate molecule, O(4n), [N(7) N(8) N(3) O(4n), rms 0.3619] and the axial axis consists of the other amine nitrogen N(2) and O(1n) [N(2)–Co(1)–O(1n), 164.2(4)°]. In contrast, the equatorial plane for Co(2) is better described by the other two amine nitrogen atoms [N(6), N(5)], one pyridyl pendant nitrogen atom, N(9), and an oxygen atom from a nitrate molecule, O(10n), [N(6)

N(5) N(9) O(10n), rms 0.2459]. The axial axis is now determined by the other pyridyl pendant nitrogen atom N(10) and O(7n) [N(10)–Co(2)–O(7n), 163.3(4)°]. The main distortions from a regular octahedral geometry can be attributed to the five-membered chelate rings formed on the macrocyclic ligand.

The average values of the bond lengths between the metal ions and the N atoms of the macrocycle are 2.275 and 2.156 Å for $Co–N_{am}$ and $Co–N_{py}$, respectively, with the longer distance corresponding to Co(1)–N(2), 2.356(9) Å. The average value of the Co–O bond length is 2.078 Å, which is similar to that found in other monodentate nitrate complexes of octahedral Co(II) [12].

The macrocyclic backbone is slightly folded with a dihedral angle between the pyridyl groups of 46.14°. Finally, the crystal structure is completed by two water solvent molecules that are not coordinated to the metal centre.

3.1.2. Crystal structure of $[Cu_2L(H_2O)_2](NO_3)_4$

The molecular structure of $[Cu_2L(H_2O)_2](NO_3)_4$ is shown in Fig. 3 together with selected bond lengths (Å) and angles (°). The complex structure is similar to that found for the corresponding perchlorate complex [6]. The dinuclear complex is disposed around a crystallographic inversion centre. The symmetry-related metal ions are separated by 8.76 Å. The crystal structure shows that the copper atoms are also exocyclically coordinated by two contiguous amine nitrogen atoms from the macrocyclic backbone and their corresponding two pyridyl pendant groups. The fifth coordination position is, in this case, completed by one water molecule. Therefore, the copper atoms are five-coordinate with an N_4O donor set. The τ factor is 0.27 and this show that the coordination geometry around the metal ion is best described as a fairly distorted square pyramid than a distorted trigonal bipyramid [13], with the basal plane formed by the amine nitrogen atoms N(2) and N(3)#1 and their corresponding pyridyl pendant groups N(4) and N(5) also in a *cis* disposition. The apical position of the pyramid is occupied by oxygen atom O(1w) of a water molecule. The largest deviation from the mean N(2) N(3)#1 N(4) N(5) basal plane (rms = 0.1876) is 0.2044 Å for N(2). The copper atom is displaced by 0.2792 Å toward the apical site. The angles at the metal atom in the three five-membered chelate rings deviate significantly from 90° [83.00(10)°, 85.59(10)° and 81.96(10)° for N(5)–Cu(1)–N(3)#1, N(2)–Cu(1)–N(3)#1 and N(2)–Cu(1)–N(4), respectively] due to the geometrical constrains of the macrocyclic ligand. All of the Cu–N distances are similar, with the pyridyl pendant-arm distances [Cu(1)–N(4) 2.017(2) Å, Cu(1)–N(5) 2.018(3) Å] shorter than the amine nitrogen atom distances [Cu(1)–N(2) 2.030(2) Å, Cu(1)–N(3)#1 2.072(2) Å]. The average Cu–N bond length is 2.034 Å. The longer coordination bond corresponds to the Cu(1)–O(1w) distance, 2.216(2) Å, and this is in the range found for axially coordinated water molecules in other similar pentacoordinated Cu(II) complexes [14].

The macrocyclic backbone is almost in a plane. The bridgehead pyridine groups are parallel to one another and the planes containing each of them are 0.59 Å away. The nitrate ions are not coordinated to the metal centres but interact with the water molecules through hydrogen

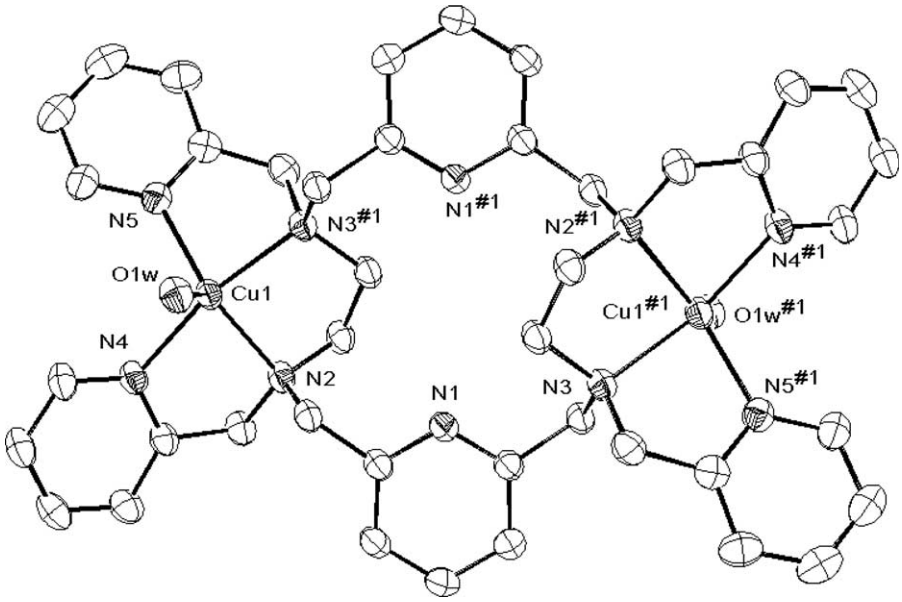

Fig. 3. Crystal structure of $[Cu_2L(H_2O)_2](NO_3)_4$ and selected bond lengths (Å) and angles (°). Cu(1)–N(3)#1 2.072(2), Cu(1)–N(5) 2.018(3); Cu(1)–N(4) 2.017(2), Cu(1)–N(2) 2.030(2), Cu(1)–O(1w), 2.216(2), N(4)–Cu(1)–N(5) 107.04(11), N(4)–Cu(1)–N(2) 81.96(10), N(5)–Cu(1)–N(2) 151.34(10), N(4)–Cu(1)–N(3)#1 167.34(10), N(5)–Cu(1)–N(3)#1 83.00(10), N(2)–Cu(1)–N(3)#1 85.59(10), N(4)–Cu(1)–O(1w) 87.02(10), N(5)–Cu(1)–O(1w) 96.14(10), N(2)–Cu(1)–O(1w) 111.70(11), N(3)#1–Cu(1)–O(1W) 99.77(9). bonds [2.716(0) Å, 169.14(0.02)° for O(2n)—O(1w) and O(1w)–H(1s)–O(2n), respectively, and 2.729(0) Å, 175.46(0.02)° for O(5n)–O(1w) and O(1w)–H(2s)–O(5n), respectively].

3.1.3. Crystal structure of $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$

The dinuclear complex $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$ was obtained by recrystallization (acetonitrile) of the complex obtained from the reaction between Cd(II) nitrate and the macrocyclic ligand in a 2:1 molar ratio. The crystal structure was studied by X-ray diffraction and the molecular structure of the complex is shown in Fig. 4 together with the atomic numbering scheme adopted and selected bond length distances (Å) and angles (°).

The complex presents a crystallographically imposed symmetry in the unit cell. The intramolecular Cd–Cd distance is 5.784 Å. The metal atoms are seven-coordinate with an N5O2 core. In this case, all the nitrogen atoms of the ligand are coordinated. Each cadmium ion is coordinated to one pyridyl bridgehead unit, two tertiary amine nitrogens contiguous to that pyridyl bridgehead, and to their corresponding pyridyl pendant arms. The coordination environment is completed by a bidentate nitrate anion. The geometry around the metal ions can be described as distorted capped octahedral, or distorted octahedral if both oxygen atoms of the nitrate anion are considered to occupy one coordination position.

In this case, the pyridyl bridgehead of the macrocyclic backbone provides the strongest bond to the metal atoms [Cd–N1, 2.304(2) Å]. This distance is slightly shorter than that corresponding to pyridyl pendant arms [Cd–N3, 2.319(3) Å and Cd–N4, 2.346(2) Å]. The longer Cd–N distance corresponds to the amine groups [Cd–N2, 2.536(3) Å and Cd–N5, 2.502(3) Å] and these distances are in the range expected for this type of bond [15]. Two of the nitrate ions act in anisobidentate mode [Cd–O4n, 2.397(2) Å and Cd–O5n, 2.579(3) Å] and the average value of 2.488 Å is in accordance with other similar seven-coordinate nitrate Cd(II) complexes [12,16].

The macrocyclic ligand is in a step conformation. The dihedral angle between the pyridyl bridgeheads is 0° due to crystallographic symmetry requirements and the angle between these rings and the plane described for the tertiary amine nitrogen atoms (rms 0) is 76.31°.

3.1.4. Crystal structure of $[CdL](NO_3)_2 \cdot 6H_2O$

Crystals of $[CdL](NO_3)_2 \cdot 6H_2O$ were obtained by the reaction between Cd(II) nitrate and the macrocyclic ligand in a 1:1 molar ratio. The molecular structure of the complex together with selected bond lengths (Å) and angles (°) relating to the coordination environment of the metal are given in Fig. 5. The structure is similar to that found for the metal complex obtained from the perchlorate cadmium salt and the same ligand [6]. The X-ray crystal structure confirms the presence of a mononuclear endomacrocyclic complex constituted by the cation $[CdL]^{2+}$, two well-separated nitrate anions and three water molecules of hydration. The crystal structure is centrosymmetric and the metal atom is six-coordinate with a distorted octahedral geometry [N6] arising from coordination of the two pyridyl bridgehead rings of the macrocyclic backbone, two opposite tertiary amine

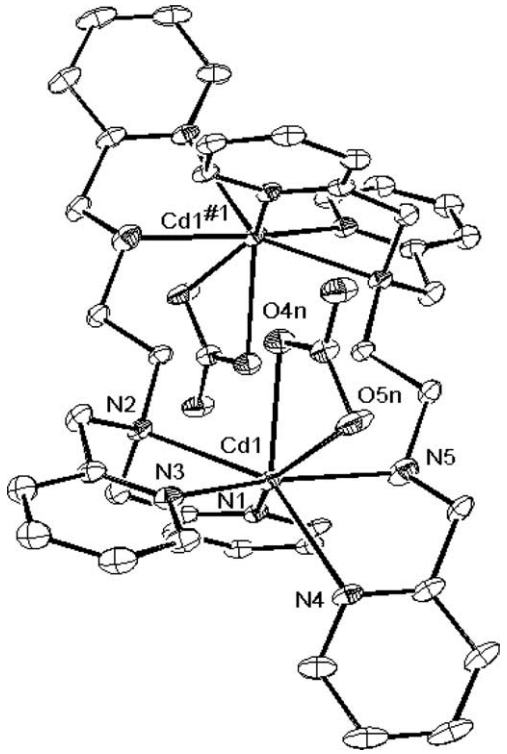

Fig. 4. Crystal structure of $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$ and selected bond lengths (Å) and angles (°). Cd–N(1) 2.304(2), Cd–N(3) 2.319(3), Cd–N(4) 2.346(2), Cd–O(4n) 2.397(2), Cd–N(5) 2.502(3), Cd–N(2) 2.536(3), Cd–O(5n) 2.579(3), N(1)–Cd–N(3) 124.12(9), N(1)–Cd–N(4) 95.82(9), N(3)–Cd–N(4) 95.93(9), N(1)–Cd–O(4n) 124.23(8), N(3)–Cd–O(4n) 85.85(8), N(4)–Cd–O(4n) 129.81(8), N(1)–Cd–N(5) 71.51(9), N(3)–Cd–N(5) 161.41(9), N(4)–Cd–N(5) 70.79(9), O(4N)–Cd–N(5) 92.79(8), N(1)–Cd–N(2) 68.93(8), N(3)–Cd–N(2) 71.22(8), N(4)–Cd–N(2) 145.94(9), O(4n)–Cd–N(2) 81.82(8), N(5)–Cd–N(2) 126.98(8), N(1)–Cd–O(5n) 153.68(9), N(3)–Cd–O(5n) 82.20(9), N(4)–Cd–O(5n) 79.06(8), O(4n)–Cd–O(5n) 51.39(7), N(5)–Cd–O(5n) 82.50(9), N(2)–Cd–O(5n) 127.71(8).

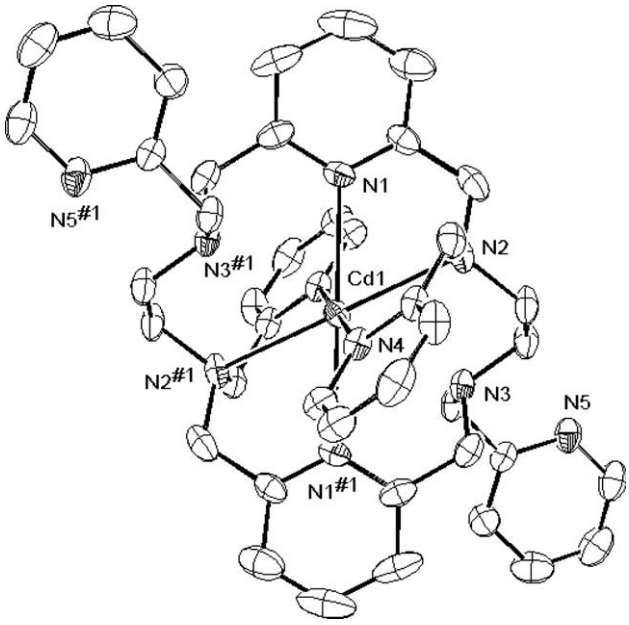

Fig. 5. Crystal structure of $[CdL](NO_3)_2 \cdot 6H_2O$ and selected bond lengths (Å) and angles (°). Cd(1)–N(4) 2.352(6), Cd(1)–N(4)#1 2.352(6), Cd(1)–N(1)#1 2.546(7), Cd(1)–N(1) 2.546(7), Cd(1)–N(2)#1 2.610(7), Cd(1)–N(2) 2.610(7), N(4)–Cd(1)–N(4)#1 180.000(1), N(4)–Cd(1)–N(1)#1 80.0(2), N(4)#1–Cd(1)–N(1)#1 100.0(2), N(4)–Cd(1)–N(1) 100.0(2), N(4)#1–Cd(1)–N(1) 80.0(2), N(1)#1–Cd(1)–N(1) 180.0, N(4)–Cd(1)–N(2)#1 110.9(3), N(4)#1–Cd(1)–N(2)#1 69.1(3), N(1)#1–Cd(1)–N(2)#1 64.2(3), N(1)–Cd(1)–N(2)#1 115.8(3), N(4)–Cd(1)–N(2) 69.1(3), N(4)#1–Cd(1)–N(2) 110.9(3), N(1)#1–Cd(1)–N(2) 115.8(3), N(1)–Cd(1)–N(2) 64.2(3), N(2)#1–Cd(1)–N(2) 180.000(1). Symmetry transformations used to generate equivalent atoms: #1 $-x+1/2$, $-y+1/2$, $-z+1$.

nitrogen atoms and their corresponding pyridyl pendant arms – all of which are in a *trans* disposition. The other two aliphatic amine nitrogen atoms and their corresponding pyridyl pendant arms are not coordinated. The main distortion from a regular octahedral geometry can also be attributed to the three five-membered chelate rings of the macrocyclic ligand.

The Cd–N bond distances are different and are slightly shorter than that observed for the perchlorate complex mentioned above. The pyridyl pendant-arm nitrogen atoms provide the strongest bond to the ion [Cd–N4, 2.352(6) Å]. This is shorter than pyridyl bridgehead [Cd–N1, 2.546(7)] and tertiary amine [Cd–N2, 2.610(7)] bond lengths. The macrocycle is not folded and the pyridyl bridgehead units are parallel with one another.

3.2. Spectroscopic and magnetic studies

The IR spectra of the complexes were recorded as KBr discs and all show similar features. The ν(C=N) and ν(C=C) of the pyridine rings are generally shifted to higher wave numbers than in the free ligand, suggesting coordination of the pyridyl groups to the metal ions [17]. In the all of the mononuclear as well as the dinuclear Cu(II) complexes, the band at 1383 cm^{-1} associated with the presence of ionic nitrate is observed. This shows that uncoordinated nitrate groups are present, as it has been found in the crystal structures of $[CdL](NO_3)_2 \cdot 6H_2O$ and $[Cu_2L(H_2O)_2](NO_3)_4$. On the other hand, in Co(II), Ni(II) and Cd(II) dinuclear complexes, the band at 1383 cm^{-1} (probably due to the interchange between nitrate and bromide groups of the KBr disc) is accompanied by several bands in the region associated with nitrate vibrations and these clearly identify the coordinated nitrate groups [18] – as found in the crystal structures of $[Co_2L(NO_3)_4] \cdot 2H_2O$ and $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$.

The reflectance spectra of $[CoL](NO_3)_2 \cdot 5H_2O$ and $[Co_2L(NO_3)_4] \cdot 2H_2O$ show two d–d transition bands at ca. 10000 and 20000 cm^{-1}, which are due to the $^4T_{2g} \leftarrow {}^4T_{1g}$ and $^4T_{1g}(P) \leftarrow {}^4T_{1g}(F)$ transitions, respectively, and are of the type expected for distorted octahedral high spin Co(II) complexes [19].

The reflectance spectra of the nickel complexes $[NiL](NO_3)_2 \cdot 4H_2O$ and $[Ni_2L(NO_3)_4] \cdot 2H_2O$ show three bands at ca. 10 300, 16 400 and 26 000 cm^{-1}. These bands are attributable to the $^3T_{2g} \leftarrow {}^3A_{2g}$, $^3T_{1g}(F) \leftarrow {}^3A_{2g}$ and $^3T_{1g}(P) \leftarrow {}^3A_{2g}$ transitions, respectively, and are indicative of octahedral Ni(II) compounds. One absorption band at ca. 14 780 cm^{-1} is also present in $[Ni_2L(NO_3)_4] \cdot 2H_2O$, probably due to the spin forbidden transition $^1E_g \leftarrow {}^3A_{2g}$ usually observed in Ni(II) complexes [20].

The electronic reflectance spectrum of the pentacoordinated complex $[Cu_2L(H_2O)_2](NO_3)_4$ shows one broadband, probably a multicomponent band, between 17 200 and 12 500 cm^{-1}. This band is consistent with a five-coordinate $[CuN_4O]$ square pyramidal geometry around the metal [21]. Nevertheless, the UV–Vis spectrum of the 1:1 complex $[CuL](NO_3)_2 \cdot 2H_2O$ exhibits a broadband at ca. 17 000 cm^{-1} and an octahedral geometry is proposed for this system by analogy with the corresponding mononuclear perchlorate complex [6].

The room temperature magnetic moments obtained for $[CoL](NO_3)_2 \cdot 5H_2O$ and $[Co_2L(NO_3)_4] \cdot 2H_2O$ are 4.7 BM (per Co atom), which is consistent with the presence of high-spin octahedral Co(II) ions [22]. The magnetic moments at room temperature for the Ni(II) and Cu(II) complexes were 2.9 and 1.8 BM (per metal atom), respectively, and these values are within the range usually observed for octahedral Ni(II) and d^9 systems, respectively [22].

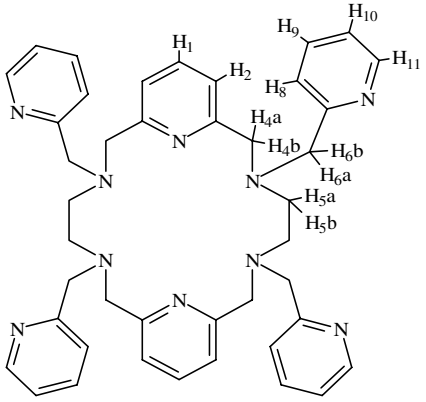
The molar conductance values for the complexes of L measured in acetonitrile at 25 °C lie in the range reported for 2:1 electrolytes for the complexes $[CoL](NO_3)_2 \cdot 5H_2O$, $[NiL](NO_3)_2 \cdot 4H_2O$, $[CuL](NO_3)_2 \cdot 2H_2O$ and $[CdL](NO_3)_2 \cdot 6H_2O$, 3:1 electrolytes for $[Co_2L(NO_3)_4] \cdot 2H_2O$, $[Ni_2L(NO_3)_4] \cdot 2H_2O$ and $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$, while the complex $[Cu_2L(H_2O)_2](NO_3)_4$ acts as 4:1 electrolytes in this solvent [23].

The FAB mass spectra for all the complexes indicate the presence of the macrocyclic ligand and the metal ion and, as is common with complexes of this type, a characteristic fragmentation pattern resulting from stepwise loss of counterions from the neutral parent ion is observed.

The ^1H NMR spectra of $[CdL](NO_3)_2 \cdot 6H_2O$ and $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$ were recorded in CD_3CN and D_2O, respectively.

The ^1H NMR spectrum for $[CdL^1](NO_3)_2 \cdot 6H_2O$ is complicated and contains a large number of signals, indicating that the complex adopts an asymmetric structure in solution where the ligand has lost its fourfold symmetry. Nevertheless, the ^1H NMR spectrum of $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$ is very clear (Table 2). The assignments of the proton signals were based upon standard 2D homonuclear (COSY) and $^1H/^{13}C$ heteronuclear spectra (HMQC). The pyridine hydrogens H_a and H_b appear as the expected triplet and doublet, respectively. The geminal protons H_{4a} and H_{4b}, H_{5a} and H_{5b} and H_{6a} and H_{6b} appear as separate doublets, showing that they are chemically and magnetically inequivalent. In general, all the proton signals are shifted downfield in comparison to those in the free ligand.

Table 2
^1H NMR spectrum for $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$ in D_2O



Assignment	δ (ppm)
H_1	7.65 (t, 2H)
H_2	7.15 (d, 4H)
H_{4a} and H_{4b}	4.16 (d, 4H) and 4.41 (d, 4H)
H_{5a} and H_{5b}	2.45 (m, 4H) and 2.99 (m, 4H)
H_{6a} and H_{6b}	3.86 (d, 4H) and 4.05 (d, 4H)
H_8, H_9, H_{10} and H_{11}	8.17 (d, 4H), 7.43 (t, 4H), 8.03 (t, 4H) and 7.58 (d, 4H)

4. Conclusion

The position and number of donor atoms together with the flexibility of the tetrapyridyl pendant-armed macrocyclic ligand, L, make this a versatile molecule that can bind the metal through different nitrogen donor atoms and can adopt different conformations depending on the steric requirements of the metal ion employed.

Reaction of this ligand with Co(II), Ni(II), Cu(II) and Cd(II) nitrate salts gives metal complexes with 1:1 or 2:1 stoichiometries depending on the metal:ligand molar ratio employed in the synthesis.

Different features were found for the dinuclear complexes $[Co_2L(NO_3)_4] \cdot 2H_2O$, $[Cu_2L(H_2O)_2](NO_3)_4$ and $[Cd_2L(NO_3)_2](NO_3)_2 \cdot 5H_2O \cdot CH_3CN$. For example, the Co(II) and Cu(II) complexes are exocyclically bonded to all the pyridyl pendant arms and tertiary amine nitrogen atoms but the pyridyl bridgehead of the macrocyclic ligand is not coordinated. In the case of Cd(II), all the pyridyl groups (pendant arms and bridgehead) and also the tertiary amine nitrogen atoms are coordinated.

In the mononuclear complex $[CdL](NO_3)_2 \cdot 6H_2O$ the metal ion is coordinated to six nitrogen donor atoms: the two pyridyl bridgehead groups and to half of the tertiary amine nitrogen atoms and their pyridyl pendant arms.

Crystal data for other mononuclear metal complexes were not obtained, but the microanalysis, spectroscopic and magnetic results suggest in all cases the formation of mononuclear complexes in which the metal atom is in an octahedral environment – similar to that found for the Cd(II) nitrate described above or to the equivalent perchlorate complexes. Finally, a dinuclear structure similar to $[Co_2L(NO_3)_4] \cdot 2H_2O$ is suggested for the 2:1 Ni(II) complex.

Abstract

Dinuclear cyclopalladated compounds (μ-Br)$_2$[κ^2-***N2′***,***C1***-1-Pd-2-{(2′-RCH=NC$_6$H$_4$)C$_6$H$_4$}]$_2$ [**1a** (R = 2,4,6-trimethoxyphenyl), **1b** (R = 2,6-dichlorophenyl) and **1c** (R = 2,6-difluorophenyl)] and (μ-Br)$_2$[κ^2-***N2′***,***C1***-1-Pd-2-{(2′-NH$_2$C$_6$H$_4$)C$_6$H$_4$}]$_2$ (**1d**) reacted with but-2-ynedioic acid dimethyl ester (molar ratio 1–2) to afford the dinuclear cyclopalladated compounds (μ-Br)$_2$[κ^2-***N2′***,***C1***-1-Pd-2-{(2′-RCH=NC$_6$H$_4$)C$_6$H$_4$}-*cis*-1,2-(CO$_2$Me)$_2$–C=C]$_2$ [**2a** (R = 2,4,6-trimethoxyphenyl), **2b** (R = 2,6-dichlorophenyl) and **2c** (R = 2,6-difluorophenyl)] and (μ-Br)$_2$[κ^2-***N2′***,***C1***-1-Pd-2-{(2′-NH$_2$C$_6$H$_4$)C$_6$H$_4$}-*cis*-1,2-(CO$_2$Me)$_2$–C=C]$_2$ (**2d**), which derived from the monoinsertion of the alkyne into the palladium–carbon σ bonds of the cyclopalladated dimers **1**. Compounds **2a** and **2b** reacted with PPh$_3$ (molar ratio 1–4) to give a mixture of the mononuclear compound *trans*-***N***,***P***-{[κ^2-***N2′***,***C1***-1-Pd-2-{(*Z*-2′-RCH=NC$_6$H$_4$)C$_6$H$_4$}-*cis*-1,2-(CO$_2$Me)$_2$–C=C]Br(PPh$_3$)} and *trans*-***P***,***P***-{[κ^1-***C1***-1-Pd-2-{(*E*-2′-RCH=NC$_6$H$_4$)C$_6$H$_4$}-*cis*-1,2-(CO$_2$Me)$_2$–C=C]Br(PPh$_3$)$_2$} in a molar ratio of 1–2 and ca. 1–12, respectively. Compound **2c** reacted with PPh$_3$ in a molar ratio 1–4 giving *trans*-***P***,***P***-{[κ^1-***C1***-1-Pd-2-{(*E*-2′-RCH=NC$_6$H$_4$)C$_6$H$_4$}-*cis*-1,2-(CO$_2$Me)$_2$–C=C]Br(PPh$_3$)$_2$} (R = 2,6-difluorophenyl)-(compound **4c**) and compound **2d** reacted with PPh$_3$ in a molar ratio of 1–2, affording the mononuclear cyclopalladated compound *trans*-***N***,***P***-{[*cis*-κ^2-***N2′***,***C1***-1-Pd-2-{(2′-NH$_2$C$_6$H$_4$)C$_6$H$_4$}-1,2-(CO$_2$Me)$_2$–C=C]Br(PPh$_3$)} (compound **3d**). Notably, the ^{31}P{^{1}H} NMR of compounds **4** produced an AB spin system, showing that compounds **4** were chiral. In addition, we report the X-ray molecular structure of the *E* isomer of the free Schiff base **a** [biphenyl-2-yl-(2,4,6-trimethoxy-benzylidene)-amine].

Keywords: Palladacycle; Schiff base; Insertion; Alkyne

1. Introduction

Cyclopalladated compounds containing a biphenyl cyclopalladated unit have been used as starting materials in organic and organometallic synthesis [1–8] and as precursors of catalytic species in C–C and C–N coupling reactions [9,10]. Furthermore, an intramolecular C–H bond activation of a biphenyl group in a palladium(II) centre has been proposed in catalytic cycles that transform a C–H bond into a C–C bond [11,12].

In earlier papers [13–15], we have described the synthesis of the dinuclear cyclopalladated compounds **1a**–**d** containing a biphenyl cyclopalladated unit (see Scheme 1 for their structural formula). The *exo*-cyclopalladated imine **1a** consisted, in relation to the *E* or *Z* configuration adopted by their azomethine functional groups, almost exclusively of the (*E*,*E*) isomer, while compounds **1b**

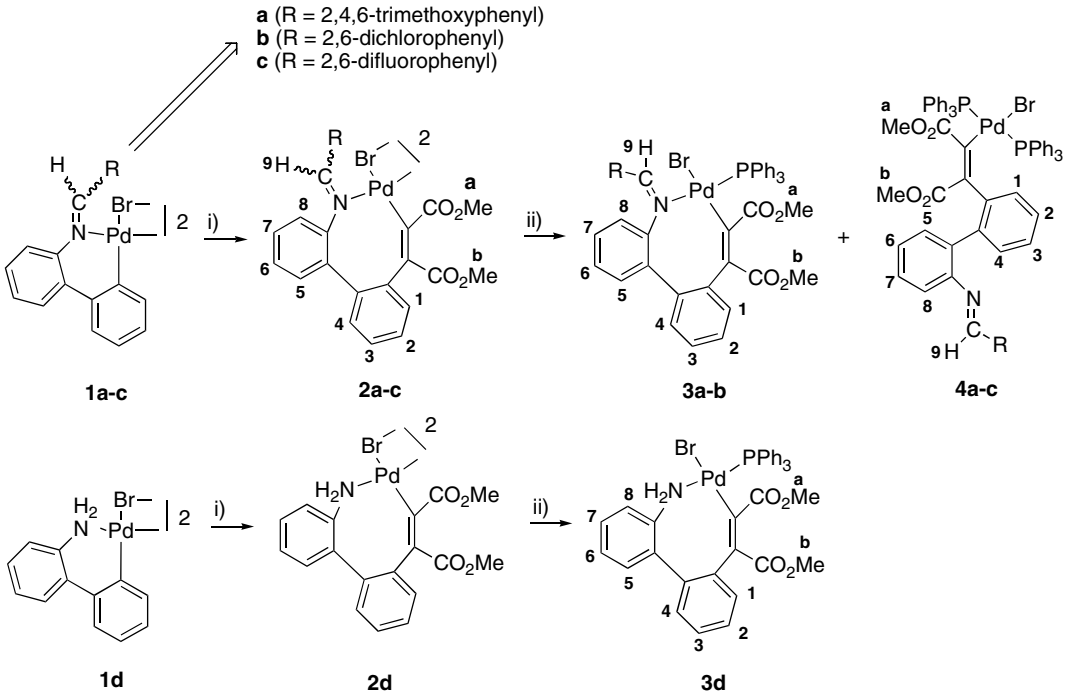

Scheme 1. (i) but-2-ynedioic acid dimethyl ester, chloroform (**a**: reflux, 24 h; **b**: 0 °C, 72 h; **c**: 0 °C, 48 h; **d**: 0 °C, 24 h), molar ratio **1**/but-2-ynedioic acid dimethyl ester = 1/2; (ii) PPh_3 (**a**: THF, 0 °C, 24 h, molar ratio **2a**/PPh_3 = 1/4; **b** (or **c**): THF, 0 °C, 6 h, molar ratio **2b** (or **2c**)/PPh_3 = 1/4; **d**: $CHCl_3$, −10 °C, 4 h, molar ratio **2d**/PPh_3 = 1/2).

and **1c** were a mixture of the (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) isomers. ^{1}H NMR spectra of compounds **1b** and **1c** suggested that the ratio of their azomethine functional groups in *E* and *Z* form was about one to one. Note that the metal atom is not accounted for the *E* or *Z* assignment of the configuration of the azomethine functional group in *exo*-cyclometallated imines and that the *endo*- and *exo*-descriptors are used to differentiate between the regioisomers of cyclometallated imines; the *exo*-descriptor indicates that the double bond of the azomethine functional group is not included in the metallacycle [13,16]. These conventions have been also applied throughout the present paper. Fig. 1 shows the structure of the (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) isomers of compound **1b**.

It is well known that the reaction between internal alkynes and cyclometallated compounds may produce mono-, di- or tri-inserted compounds, which depending on their electronic or steric properties may evolve to the formation of organic compounds. Internal alkynes with electron-withdrawing substituents favour the monoinsertion reaction, while internal alkynes with electron-donating substituents favour the diinsertion reaction. In some cases the chemoselectivity of the reaction cannot be controlled and the product of double insertion is formed, regardless the stoichiometry between the cyclometallated compound and the alkyne [17–23].

In this context, we were interested in expanding a six-membered palladacycle to an eight-membered palladacycle by monoinsertion of an alkyne into its palladium–carbon σ bond. Few examples of this transformation have been described in the literature for six-membered palladacyles, starting from cyclopalladated

compounds containing a biphenyl cyclopalladated unit or an *ortho*-palladated 2-benzylpyridine (Fig. 2) [1,3,5,7,23]. Thus, we chose to study the reactivity of compounds **1a**–**d** towards but-2-ynedioic acid dimethyl ester in a molar ratio of 1–2. The results of this study are described here. In addition, we report the X-ray crystal structure of the *E* isomer of the free Schiff base **a** [biphenyl-2-yl-(2,4,6-trimethoxy-benzylidene)-amine].

2. Results and discussion

Scheme 1 shows the new compounds described in this paper and the numbering of their protons.

In a first attempt to prepare the monoinserted compounds **2**, we treated compounds **1** with but-2-ynedioic acid dimethyl ester in a molar ratio 1–2 in refluxing chloroform for 24 h. These reaction conditions afforded only positive results for the reaction between compound **1a** and but-2-ynedioic acid dimethyl ester, allowing the isolation of the dinuclear cyclopalladated compound **2a** in high yield (70–90%). In spite of this result, this reaction using as starting materials compounds **1b**–**d** was complicated by the formation of palladium(0). Thus, in order to optimize the reaction between compounds **1b**–**d** and but-2-ynedioic acid dimethyl ester in chloroform in a molar ratio of 1–2, this reaction was studied at different temperatures and reaction times. The best results were obtained at 0 °C and reaction times of three days, two days and one day for the reactions with **1b**, **1c** and **1d**, respectively. In the latter reaction conditions the formation of palladium(0) was not observed, and from the red solutions that formed, after concentration of the solvent and elution of the crude of the reactions through a flash column chromatography, the monoinserted compounds **2c**–**d** were isolated in high yield (70–90%).

Compounds **2** were stable yellow (**2a**) or orange (**2c**–**d**) solids. Their IR spectra presented a strong band at 1710–1720 cm^{-1}, corresponding to the C=O stretching of the ester groups of the inserted alkynes. Furthermore, the IR spectra of the azomethine compounds **2a**–**c** presented a band of medium intensity in the interval 1621–1609 cm^{-1}, which was assigned to the C=N stretching of their azomethine functional groups, and the IR spectrum of the amino compound **2d** showed two bands of low intensity at 3286 and 3218 cm^{-1}, which were assigned to the N–H stretchings of its amino groups. The FAB^+ spectra of compounds **2** produced intense signals corresponding to $M + H^+ - MeOH$ and $M + H^+ - HBr$, which were consistent with a dinuclear bromo-bridged structure [24].

$CDCl_3$ solutions of compounds **2** were stable at room temperature. Thus, we registered their ^1H NMR spectra at 200 MHz. The ^1H NMR spectrum of compound **2a** presented a single set of signals. The proton of its azomethine functionality appeared as a singlet at 8.41 ppm, high field shifted relative to the free imine, which indicated that its azomethine functional groups presented an *E* configuration [13,25]. The aromatic protons of the 2,4,6-trimethoxyphenyl group appeared as a singlet at 6.14 ppm. This result indicated that, in compound **2a**, there was free rotation through the carbon–carbon σ bond between the azomethine carbon and the 2,4,6-trimethoxyphenyl group. The aliphatic protons of the 2,4,6-trimethoxyphenyl group appeared as a singlet at 3.84 ppm with an integral corresponding to nine protons. Note that the 4-methoxy group resonated at the same frequency of the 2,6-dimethoxy groups by accident. In addition, the methyls of the inserted alkyne gave place to two singlets at 3.69 and 3.49 ppm. The precedent data indicated that compound **2a** consisted of only a single geometrical isomer, which we assigned, according to the literature [25], to the *trans*-(*E*,*E*) geometrical isomer.

In contrast, compounds **2b** and **2c** gave place to complex ^{1}H NMR spectra, but three groups of well-separated signals were observed in the intervals 9.04–8.40, 8.07–6.55 and 4.00–3.20 ppm, which were assigned to azomethinic, aromatic and aliphatic protons, respectively. The azomethinic region presented eight singlets and their chemical shift suggested that compounds **2b** and **2c** were a mixture of the (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) geometrical isomers, some of them consisting of a mixture of *trans* and *cis* geometrical isomers or of a mixture of conformational isomers [13]. In addition, the ^{1}H NMR spectrum of compound **2d** produced broad signals for the aromatic and some of the aliphatic protons, suggesting the presence in solution of a dynamic equilibrium between different isomers of this compound [13,25].

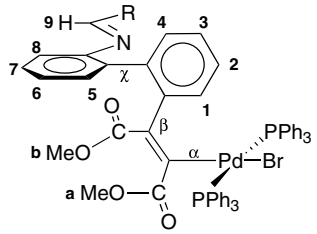
Compounds **2** were treated with PPh_3 in a molar ratio of 1/2 in acetone at room temperature. Usually, this treatment converts cyclopalladated dimers of general formula $(\mu\text{-}X)_2[Pd(C,N)]_2$ into mononuclear cyclopalladated compounds of formula *trans*-***N***,***P***-[Pd(C,N)X(PPh_3)] (X = OAc, Cl or Br) [13–15,25–27]. But this reaction in the latter conditions and using as starting material the imino compounds **2a**–**c** was complicated by the hydrolysis of the azomethine functionality, as indicated by the ^{1}H NMR spectra of the reaction crudes. In addition; in all cases, including the reaction which used as starting material the amino compound **2d**, the initial yellow solution slowly changed to a red solution. This change of color could be related to a reorganization of the eight-membered palladacycle of compound **3d** to a spirocyclic compound, such as that described in reference [23]. Attempts to obtain mononuclear derivatives of general formula *trans*-***N***,***N***-[Pd(C,N)Br(py-d_5)] by reacting solutions of compounds **2** in $CDCl_3$ with py-d_5 at room temperature were not successful.

In view of the precedent results, the imino compounds **2a**–**c** were treated with PPh_3 in a molar ratio of 1/4 in anhydrous tetrahydrofuran at 0 °C and the amino compound **2d** was treated with PPh_3 in a molar ratio of 1/2 in chloroform at −10 °C. In these conditions, stable yellow solutions were formed which after concentration of the solvent and addition of a minimum volume of diethyl ether to the residues yielded stable yellow solids. Analysis of freshly prepared solutions of these solids in C_6D_6 by ^{1}H and ^{31}P{^{1}H} NMR showed that they were a mixture of compounds **3a** and **4a** in a molar ratio of 1/2, a mixture of compounds **3b** and **4b** in a molar ratio of ca. 1/12, compound **4c** and compound **3d**.

Compounds **3d** and **4c** produced satisfactory elemental analyses, FAB$^+$, IR, ^{1}H and ^{31}P{^{1}H} NMR spectra, and the mixtures of compounds **3a** and **4a** and **3b** and **4b** gave rise to satisfactory IR, FAB$^+$, ^{1}H and ^{31}P{^{1}H} NMR spectra. The molar fraction between compound **3a** and **4a** and **3b** and **4b** in these latter mixtures was determined by the ratio between the integrals of the azomethine protons.

In the ^{1}H NMR spectra of the imino compounds **3a** and **3b**, the azomethine protons appeared downfield shifted relative to the free imines, indicating that the azomethine functionality in these compounds presented the *Z* configuration. Furthermore, consistent with their *Z* configuration and the *cis* arrangement between the phosphorus nuclei and the proton of the azomethine functionality, the coupling constant between these two nuclei was ca. 4 Hz. In contrast, the azomethinic proton of compounds **4a**–**c** gave a singlet, whose chemical shift was consistent with an *E* configuration for their azomethine functional group [25]. Furthermore, the protons of the amino group of compound **3d** appeared at 4.60 ppm as a broad signal. This latter result showed that the interconversion between the enantiomeric conformations of the palladacycle of compound **3d** was in the fast exchange region at room temperature [15]. The ^{31}P{^{1}H} NMR spectra of compounds **3** and **4** produced a singlet and a second order spectrum derived from an AB spin system, respectively. It should be noted that according to the different *trans* influence of the atom *trans* to the phosphorus in compounds **3** and **4**, a nitrogen atom for compounds **3** and a phosphorus atom for compounds **4**, the ^{31}P signal of compounds **3** was downfield shifted in relation to the ^{31}P signal of compounds **4** [28]. In addition, the ^{31}P signals of compounds **3** and **4** appeared between 30 and 15 ppm, which is the expected interval for compounds of general formula *trans*-***N***,***P***-[Pd(C,N)X(PPh_3)] and *trans*-***P***,***P***-[PdRX(PPh_3)$_2$] [13–15,25,29].

Notably, the fact that compounds **4** in the ^{31}P{^{1}H} NMR produced a second order spectrum, indicated that these compounds were chiral. In order to study the origin of the chirality in compounds **4**, 2D ^{1}H–^{1}H COSY and ROESY experiments at 500 MHz were undertaken for compound **4c**. These experiments allowed the assignment of all of its protons (see Section 3). The data from the 1D ^{1}H and the 2D ^{1}H–^{1}H ROESY experiments suggested that compound **4c** adopted in solution the conformation shown in Fig. 3. In the 1D experiment, two doublets corresponding to aromatic protons appeared at the unusual chemical shifts of 9.95 and 5.44 ppm.



R = 2,6-difluorophenyl

Fig. 3. Proposed conformation in solution for compound **4c**.

The signal at 9.95 was assigned to proton **1**. This assignment was consistent with the presence in the ROESY experiment of negative off-diagonal peaks between proton **1** and the protons of the PPh_3 ligands. These NMR data were consistent with proton **1** residing in a pseudo fifth coordination position above the square planar palladium(II) centre and therefore with a restricted rotation through the σ bonds labeled as α and β in Fig. 3 [30]. In addition a negative off-diagonal peak between **9** and **8** protons was consistent with and *E* configuration for the azomethine functionality and the ^1H–^1H COSY experiment allowed the assignment of the **5**–**8** protons. These assignments showed that the second aromatic proton with the unusual chemical shift of 5.44 ppm was proton **5**. The chemical shift of proton **5** should be a consequence of its proximity to the carbonyl group of the inserted alkyne, and this suggested that rotation through the σ bond labeled as χ in Fig. 3 was restricted and that the biphenyl group adopted an orthogonal conformation. Note that in this particular conformation the molecule is asymmetric and the phosphorus atoms are not equivalent. Therefore, they could produce a spectrum derived from an AB spin system. In support of this, we should note that 2,2′-disubstitued biphenyls with bulky substituents are usually chiral [31].

During the progress of this work we obtained monocrystals of the *E* isomer of the free imine **a** [biphenyl-2-yl-(2,4,6-trimethoxy-benzylidene)-amine]. Thus, its X-ray molecular structure is reported here. It should be noted that the benzaldimine **a** in solution consisted of only one isomer [13]; which was assumed to be, according to the literature [32], the *E* isomer. Fig. 4 shows the X-ray molecular structure of **a** and Table 1 gives selected bond distances angles for **a**.

Compound **a** crystallized in the $P\bar{1}$ triclinic space group with $Z = 2$. The structure consisted of discrete molecules separated by van der Waals distances and presented interactions between C–H bonds and aromatic π systems which produced dimers and chains in the crystal [33]. As expected, the imines adopted the *E* configuration around the azomethine functional group [dihedral angle C14–C13–N–C12 = 177.41(18)°], and differences in distances and angles with the molecules of the *E* isomer of phenyl–benzilidene–amine of formula Ph–CH=N–Ph, were a consequence of the electronic and steric requirements introduced by the substituents on going from the phenyl–benzilidene–amine to the Schiff base **a** [34]. The most noticeable feature of the σ coordination through the N and the deprotonated C1 atoms of the Schiff base **a** to the $PdBr(PPh_3)$ fragment turned out to be an increase of the C14–C13–N angle from 126.1(2)° to 130.5(6)°, due to the steric repulsion between the 2,4,6-trimethoxyphenyl group bonded to the C13 atom and the $PdBr(PPh_3)$ fragment [13]. Note that the driving force for the $E \rightarrow Z$ isomerization of *exo*-cyclic cyclopalladated Schiff bases has been related to the steric repulsion between the PdX fragment (X represents the co-ligands of the palladium atom) and the aryl group bonded to the carbon of the azomethine functionality [13,25].

3. Experimental

3.1. General remarks

Compounds **1a**–**d** were prepared as previously reported [13–15]. Elemental analyses of C, H and N were

performed with Eager 1108 or Carlo Erba 1106 microanalyzers. Infrared spectra were recorded on a Nicolet 520 FT-IR spectrophotometer using pressed discs of diluted samples of the compounds in KBr. ^{1}H NMR at 200 and 500 MHz were recorded on Varian Gemini 200 and VRX-500 instruments, respectively. ^{31}P{^{1}H} NMR at 101.2 MHz were recorded on a Varian Bruker 250 instrument. Chemical shifts are reported in δ values (ppm) relative to $SiMe_4$ for ^{1}H and relative to $P(OMe)_3$ ($\delta = 140.18$ ppm) for ^{31}P. FAB$^+$ mass spectra were obtained with a VG-Quatro Fisions instrument, using 3-(nitro-phenyl)-methanol as matrix. All chemicals were of commercial grade and used as received. Solvents were distilled before use as follows: chloroform over CaO; methanol over $CaCl_2$; and tetrahydrofuran and diethyl ether over sodium and benzophenone.

3.2. Preparation of compounds 2

Compound ***2a***. A suspension formed by 300 mg of **1a** (0.28 mmol) and 80 mg of but-2-ynedioic acid dimethyl ester (0.56 mmol) was treated at reflux of chloroform (20 mL) for 24 h. The red solution formed was concentrated under vacuum and the residue was eluted through a SiO_2 flash column chromatography with a solution of methanol in chloroform in a 2-to-100 volume ratio. The first coloured band was concentrated under vacuum. Addition of diethyl ether (5 cm^3) to the residue produced the precipitation of **2a** as a yellow powder, which was filtered and dried under vacuum. Compound **2b**: A suspension formed by 300 mg of **1b** (0.29 mmol) and 83 mg of but-2-ynedioic acid dimethyl ester (0.58 mmol) was treated in chloroform (20 mL) at 0 °C for 72 h. The red solution formed was concentrated under vacuum at 0 °C and the residue was eluted through a SiO_2 flash column chromatography with a solution of methanol in chloroform in a 2-to-100 volume ratio. The intense coloured bands were concentrated under vacuum. Addition of diethyl ether (5 cm^3) to the residue produced the precipitation of **2b** as an orange powder, which was filtered and dried under vacuum. Compound **2c**: A suspension formed by 300 mg of **1c** (0.31 mmol) and 89 mg of but-2-ynedioic acid dimethyl ester (0.63 mmol) was treated in chloroform (20 mL) at 0 °C for 48 h. The red solution formed was concentrated under vacuum at 0 °C and the residue was eluted through a SiO_2 flash column chromatography with a solution of methanol in chloroform in a 2-to-100 volume ratio. The intense coloured bands were concentrated under vacuum. Addition of diethyl ether (5 cm^3) to the residue produced the precipitation of **2c** as an orange powder, which was filtered and dried under vacuum. Compound **2d**: A suspension formed by 300 mg of **1d** (0.42 mmol) and 117 mg of but-2-ynedioic acid dimethyl ester (0.83 mmol) was treated in chloroform (20 mL) at 0 °C for 24 h. The red solution formed was concentrated under vacuum at 0 °C and the residue was eluted through a SiO_2 flash column chromatography with a solution of methanol in chloroform in a 4-to-100 volume ratio. The intense coloured bands were concentrated under vacuum. Addition of diethyl ether (5 cm^3) to the residue produced the precipitation of **2d** as an orange powder, which was filtered and dried under vacuum. The yield of isolation of compounds **2** ranged between 70% and 90%. Compound **2a** consisted almost exclusively of the (*E*,*E*) isomer and **2b** and **2c** consisted of a mixture of the (*E*,*E*), (*E*,*Z*) and (*Z*,*Z*) isomers. *Characterization data*: **2a**: *Anal*. Calc. for $C_{56}H_{52}Br_2N_2O_{14}Pd_2$: C, 49.8; H, 3.9; N, 2.1. Found C, 49.2; H, 3.9; N, 2.0%. FAB$^+$ (most intense peaks): 1269 ($M + H^+ - HBr$); 644 ($M/2 + H^+ - MeOH$); 594 ($M/2 + H^+ - HBr$). IR (cm^{-1}): 1712 (C=O st); 1621 (C=N st); 1206 (C–O st). ^{1}H NMR (200 MHz, $CDCl_3$): 8.41 s (1H, H^9); 7.70–7.05 (8H, H^1–H^8); 6.14 s (2H, aromatic protons of 2,4,6-trimethoxyphenyl); 3,84 s (9H, Me groups of 2,4,6-trimethoxyphenyl); 3.69 s (3H, Me, inserted alkyne); 3.49 s (3H, Me, inserted alkyne). Compound **2b**: *Anal*. Calc. for $C_{50}H_{36}Br_2Cl_4N_2O_8Pd_2$: C, 45.9; H, 2.8; N, 2.1. Found C, 45.4; H, 2.8; N, 2.0%. FAB$^+$ (most intense peaks): 1227 ($M + H^+ - HBr$); 622 ($M/2 + H^+ - MeOH$); 574 ($M/2 + H^+ - HBr$). IR (cm^{-1}): 1711 (C=O st); 1609 (C=N st); 1208 (C–O st). ^{1}H NMR (200 MHz, $CDCl_3$): 9.04–8.40, 8 singlets, H^9; 8.07–6.55 aromatic protons; 3.90–3.35, 10 singlets, Me, inserted alkyne. Compound **2c**: *Anal*. Calc. for $C_{50}H_{36}Br_2F_4N_2O_8Pd_2$: C, 48.4; H, 2.9; N, 2.3. Found C, 47.3; H, 3.0; N, 2.2%. FAB$^+$ (most intense peaks): 1211 ($M + H^+ - MeOH$); 1161 ($M + H^+ - HBr$); 540 ($M/2 + H^+ - HBr$). IR (cm^{-1}): 1711 (C=O st); 1609 (C=N st); 1208 (C–O st). ^{1}H NMR (200 MHz, $CDCl_3$): 9.00–8.40, 8 singlets, H^9; 7.95–6.55 aromatic protons; 4.00–3.20, singlets, Me inserted alkyne. Compound **2d**: *Anal*. Calc. for $C_{36}H_{32}Br_2N_2O_8Pd_2$: C, 43.5; H, 3.2; N, 2.9. Found C, 42.5; H, 3.4; N, 2.8%. FAB$^+$ (most intense peaks): 963 ($M + H^+ - MeOH$); 913 ($M + H^+ - HBr$). IR (cm^{-1}): 3286 and 3218 (N–H st), 1715 (C=O st); 1251 and 1216 (C–O st). ^{1}H NMR (200 MHz, $CDCl_3$): 7.80–6.80, broad signals, aromatic protons; 4.00–3.20, NH_2 and Me inserted alkyne.

3.3. Preparation of the mixture of compounds 3a and 4a

A suspension formed by 100 mg (0.074 mmol) of compound **2a**, 78 mg (0.296 mmol) of PPh_3 and anhydrous THF (30 mL) was stirred at 0 °C for 24 h. The yellow solution formed was concentrated at 0 °C under vacuum, the residue was treated with diethyl ether (5 mL) and the solid was filtered and dried under vacuum. A sample of ca. 100 mg was obtained which was a mixture of compounds **3a** (*Z* isomer) and **4a** (*E* isomer) in a ca. 1–2 molar ratio. *Characterization data*: ^{1}H NMR (500 MHz, C_6D_6) (selected data): 10.69 d $^4J_{HP} = 4.1$ Hz (H^9, **3a**); 10.05 d $^3J_{HH} = 7.5$ Hz (H^1,

4a); 9.06 s (H^9, **4a**), 5.97 s (aromatic protons of the 2,4,6-trimethoxy group of **4a**); 5.66 s (aromatic protons of the 2,4,6-trimethoxy group of **3a**); 5.54 d $^3J_{HH} = 8.1$ Hz (H^5, **4a**). $^{31}P\{^1H\}$ NMR (101.2 MHz, C_6D_6): 22.02 s (**3a**); 15.59 AB spin system (**4a**). FAB^+ (most intense peaks): 1199 ($M_{4a} + H^+$); 938 ($M_{3a} + H^+$ or $M_{4a} + H^+ - PPh_3$); 856 ($M_{3a} + H^+ - HBr$ or $M_{4a} + H^+ - HBr - PPh_3$). IR ($cm^{-1}$): 1721, 1700 (C=O st) (**3a** and **4a**).

3.4. Preparation of the mixture of compounds *3b* and *4b*

A suspension formed by 100 mg (0.076 mmol) of compound **2b**, 80 mg (0.306 mmol) of PPh_3 and anhydrous THF (30 mL) was stirred at 0 °C for 6 h. The yellow solution formed was concentrated at 0 °C under vacuum, the residue was treated with diethyl ether (5 mL) and the solid was filtered and dried under vacuum. A sample of ca. 100 mg was obtained which was a mixture of compounds **3b** (*Z* isomer) and **4b** (*E* isomer) in a ca. 1–12 molar ratio. *Characterization data*: ^1H NMR (500 MHz, C_6D_6) (selected data): 9.96 d $^3J_{HH} = 7.5$ Hz (H^1, **4b**); 9.92 d $^4J_{PH} = 4.1$ Hz (H^9, **3b**); 8.76 s (H^9, **4b**); 5.54 d $^3J_{HH} = 8.1$ Hz (H^6, **4b**); 3.30 s and 3.07 s (Me inserted alkyne **3b)**, 2.99 s and 2.78 s (Me inserted alkyne **4b)**. $^{31}P\{^1H\}$ NMR (101.2 MHz, C_6D_6): 28.43 s (**3b**); 21.44 AB spin system (**4b**). FAB^+ (most intense peaks): 916 ($M_{3b} + H^+$ or $M_{4b} + H^+ - PPh_3$); 836 ($M_{3b} + H^+ - HBr$ or $M_{4b} + H^+ - HBr - PPh_3$). IR ($cm^{-1}$): 1717, 1703 (C=O st) (**3b** and **4b**).

3.5. Preparation of compound *4c*

A suspension formed by 100 mg (0.081 mmol) of compound **2c** and 87 mg (0.322 mmol) of PPh_3 and anhydrous THF (30 mL) was stirred at 0 °C for 6 h. The yellow solution formed was concentrated at 0 °C under vacuum and the residue was treated with diethyl ether (5 mL). This treatment produced the precipitation of compound **4c** (*E* isomer), which was filtered and dried under vacuum. Yield: 65%. *Characterization data*: *Anal.* Calc. for $C_{61}H_{48}BrF_2NO_4P_2Pd$: C, 64.0; H, 4.2; N, 1.2. Found C, 62.6; H, 4.1; N, 1.2%. FAB^+ (most intense peaks): 884 ($M + H^+ - PPh_3$); 802 ($M + H^+ - HBr - PPh_3$). IR (cm^{-1}): 1718 and 1681 (C=O st); 1621 (C=N st); 1238 (C–O st), 1095 (*q* X-sensitive mode of the coordinated PPh_3). ^1H NMR (500 MHz, C_6D_6): 9.95 d $^3J_{HH} = 8.1$ Hz (1H, H^1); 8.76 s (1H, H^9); 7.85–7.73 m (12H, *ortho* protons of PPh_3), 7.56 d $^3J_{HH} = 8.1$ Hz (1H, H^4), 7.28 t $^3J_{HH} = 8.1$ Hz (1H, H^2); 7.21 t $^3J_{HH} = 8.1$ Hz (1H, H^3); 6.98 m (19 h, H^7 and *para* and *meta* protons of PPh_3); 6.92 d $^3J_{HH} = 8.1$ Hz (1H, H^8); 6.60 t $^3J_{HH} = 8.1$ Hz (1H, H^6); 6.38 m (1H, proton in position 4 of 2,6-difluorophenyl); 6.25 t $^3J_{HH} = {}^3J_{FH} = 8.1$ Hz (2H, protons in position 3 and 5 of 2,6-difluorophenyl), 5.44 d $^3J_{HH} = 8.1$ Hz (1H, H^5); 2.98 s (3H, Me^a inserted alkyne); 2.77 s (3H, Me^b inserted alkyne). $^{31}P\{^1H\}$ NMR (101.2 MHz, C_6D_6): 21.44 AB spin system.

3.6. Preparation of compound *3d*

A suspension formed by 100 mg (0.101 mmol) of compound **2d** and 53 mg (0.202 mmol) of PPh_3 and anhydrous THF (30 mL) was stirred at −10 °C for 4 h. The yellow solution formed was concentrated at −10 °C under vacuum and the residue was eluted through a SiO_2 column chromatography with a solution of methanol in chloroform in a 2-to-100 volume ratio. The second yellow band was collected and concentrated under vacuum. Addition of diethyl ether (5 cm^3) to the residue produced the precipitation of **2d** as pale yellow powder, which was filtered and dried in vacuum. Yield: 63%. *Characterization data*: *Anal.* Calc. for $C_{36}H_{31}BrNO_4PPd$: C, 57.0; H, 4.1; N, 1.8. Found C, 57.1; H, 4.3; N, 1.9%. FAB^+ (most intense peaks): 728 ($M + H^+ - MeOH$); 678 ($M + H^+ - HBr$); 416 ($M + H^+ - HBr - PPh_3$). IR (cm^{-1}): 3297 and 3184

Table 2
Crystal data and structure refinement for biphenyl-2-yl-(2,4,6-trimethoxy-benzylidene)-amine

Empirical formula	$C_{22}H_{21}NO_3$
Formula weight	347.40
T (K)	293(2)
λ (Å)	0.71069
Crystal system	triclinic
Space group	$P\bar{1}$
Unit cell dimensions	
a (Å)	9.247(3)
b (Å)	9.843(2)
c (Å)	10.856(3)
α (°)	95.13(2)
β (°)	102.54(2)
γ (°)	108.43(2)
V (Å^3)	901.6(4)
Z	2
D_{calc} (Mg/m^3)	1.280
Absorption coefficient (mm^{-1})	0.085
$F(000)$	368
Crystal size (mm)	$0.1 \times 0.1 \times 0.2$
θ Range for data collection (°)	2.21–29.95
Index ranges	$-12 \leqslant h \leqslant 12$, $-13 \leqslant k \leqslant 13$, $0 \leqslant l \leqslant 15$
Reflections collected/unique (R_{int})	2703/2703 (0.0121)
Completeness to $\theta = 29.95°$ (%)	51.6
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	2703/0/238
Goodness-of-fit on F^2	1.009
Final R indices [$I > 2\sigma(I)$]	$R_1 = 0.0363$, $wR_2 = 0.0494$
R indices (all data)	$R_1 = 0.0777$, $wR_2 = 0.0534$
Largest difference in peak and hole (e Å^{-3})	0.113 and −0.140

(N–H st), 1704 (C=O st); 1206 (C–O st), 1097 (*q* X-sensitive mode of the coordinated PPh_3). ^1H NMR (200 MHz, $CDCl_3$): 7.63–7.20 (15 h, H^{4-8} and protons of PPh_3), 7.14 t $^3J_{HH} = 7.7$ Hz (1H, H^3); 6.98 t $^3J_{HH} = 7.7$ Hz (1H, H^2); 6.22 d $^3J_{HH} = 7.7$ Hz (1H, H^1); 4.60 broad signal (2H, NH_2), 3.37 s (3H, Me inserted alkyne); 3.25 s (3H, Me inserted alkyne). $^{31}P\{^1H\}$ NMR (101.2 MHz, C_6D_6): 29.82 s.

3.7. Crystallographic studies

Crystals for the X-ray molecular structure determination of biphenyl-2-yl-(2,4,6-trimethoxy-benzylidene)-amine were obtained by slow evaporation of a solution of this imine in ethanol/chloroform. A prismatic crystal was selected and mounted on an Enraf-Nonius CAD4 four-circle diffractometer. The structure was solved by direct methods using the SHELXS computer program [35] and refined by the full-matrix least-squares method, with the SHELXL computer program [36]. A summary of crystallographic data and some details of the refinement are given in Table 2.

4. Supplementary material

Crystallographic data for the structural analyses of biphenyl-2-yl-(2,4,6-trimethoxy-benzylidene)-amine has been deposited at the Cambridge Crystallographic Data Centre, CCDC No. 274705. Copies of this information can be obtained from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1233 336 033; e-mail: deposit@ccdc.ac.uk or www: http://www.ccdc.cam.ac.uk).

Abstract

A new 2,2′-bipyridine-based phosphadithiamacrocycle: 3,3′-5-phenyl-2,8-dithia-5-phospha[9]-2,2′-bipyridinophane (L) has been synthesized by reacting 6,6′-bis(bromomethyl)-2,2′-bipyridine and dilithium 3-phenyl-3-phosphapenta-1,5-dithiolate. The phosphoryl derivative: 3,3′-5-oxo-5-phenyl-2,8-dithia-5-phospha[9]-2,2′-bipyridinophane (Lox) synthesized by direct oxidation of L at open atmosphere. Both compounds have been isolated as white solids containing different amounts of LiBr.

The reaction of acetonitrile solutions of these solids with Fe(II) perchlorate gave the complexes $[FeBr(L)](ClO_4)\cdot 2H_2O$ and $[FeBr(Lox)](ClO_4)\cdot 3H_2O$, which were crystallized as $[FeBr(L)]Br\cdot H_2O$ and $[FeBr(Lox)](ClO_4)\cdot 1\frac{1}{6}MeOH$ salts from nitromethane or methanol, respectively. Both compounds were characterized by X-ray diffraction analysis. In both cases, a distorted octahedral environment is achieved at the Fe(II), with five sites occupied by the macrocycles L and Lox and the sixth by a monodentate bromine ligand. The bond distances found in the complex cation $[FeBr(Lox)]^+$ are compatible with a high-spin configuration. However, the same parameters for $[FeBr(L)]^+$ and their magnetic character are only compatible with a low-spin configuration.

Keywords: Phosphathiamacrocycles; Polypyridine; Iron(II) complexes

1. Introduction

The chemistry of macrocyclic ligands containing phosphane groups as donor atoms has been less developed than those of their oxygen or nitrogen equivalents [1]. This fact has been mainly attributed to the air-sensitivity behavior of these compounds and the poor yields obtained in their preparations by high-dilution or template methods, although several high yield synthesis of homoleptic triphosphamacrocycles have recently been reported [2]. However, phosphathiamacrocycles seem to be more accessible as free ligands, and several examples can be found in the literature [3–6]. As a general trend, the interest in the chemistry of asymmetric phosphorus–sulfur donor ligands is mainly focused on the phenomenon of their hemilability and their potential use in catalytic processes [7,8]. Other possibilities are found when these P–S donor systems are integrated in macrocyclic systems, such as the documented ability of their phosphoryl [9,10], and thiophosphoryl [11] derivatives to interact selectively with ionic species that act as chemical sensors for anions.

On the other hand, the introduction of heteroaromatic subunits, such as bipyridine or 1,10-phenantroline into the macrocyclic structures generates different families of compounds which combine the special complexation features of these macrocycles [12] with the well-known photophysical, photochemical or electrochemical properties exhibited by the metal complexes of these heterocycles [13]. In this context, several 1,10-phenantroline containing polyaza and polythiamacrocycles have recently

doi:10.1016/j.poly.2005.08.006

been reported and their complexing [14], luminescent [15] and sensing [16] properties studied.

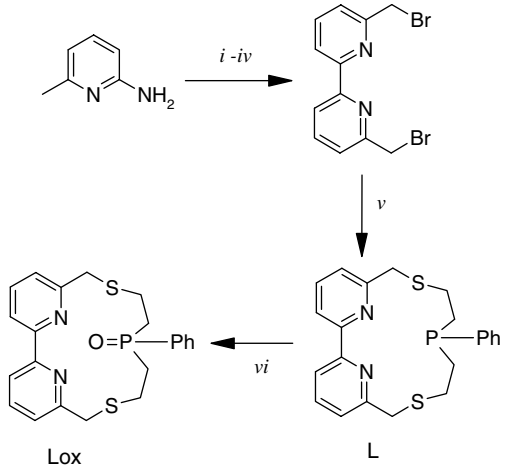
Examples may be found of similar studies on polyaza and polyamidamacrocycles containing 2,2′-bipyridene units [14a,17], but less information is available on mono or polybipyridine-containing macrocycles [18], including the softer donor atoms.

As a part of our work in this field, we report herein on the synthesis of the new bipyridine-based phosphadithiamacrocycle: 3,3′-5-phenyl-2,8-dithia-5-phospha[9]-2,2′-bipyridinophane (L) and their phosphoryl derivative: 3,3′-5-oxo-5-phenyl-2,8-dithia-5-phospha[9]-2,2′-bipyridinophane (Lox). The reactivity of these systems in the presence of Fe(II) salts is also investigated. At present, this is the first example of a phosphathmacrocycles containing polypyridine units.

2. Results and discussion

The synthetic pathway leading to the ligand L (Scheme 1) starts with the bromination of the 2-amino-6-picoline, followed by the reaction of the 2-bromo-6-picoline with Raney-Ni to afford the 6,6′-dimethyl-2,2′-bipyridine, which was finally halogenated with NBS to produce the 6,6′-bis(bromomethyl)-2,2′-bipyridine in an overall 10% yield [19,20]. Subsequent cyclisation of equimolar amounts of this dibromo derivative under high dilution conditions with the dilithium 3-phenyl-3-phosphapenta-1,5-dithiolate (obtained by previously reported methods [21]) produced low yields of the required macrocycle.

The $^{31}P\{^{1}H\}$ NMR spectrum of L shows a single signal at −21.29 ppm, which is in the range observed for similar dialkylarylphosphane-containing macrocyclic molecules [2d,5b,5d,22]. No additional downfield signals were observed, indicating that no phosphoryl or phosphonium derivatives are present in the final product obtained via this procedure.



Scheme 1. Reagents and conditions: (i) $NaNO_2$ 1 M, Br_2 and HBr 98%; (ii) Ni-Raney, toluene; (iii) H_2O, 40 °C, 2 h; (iv) NBS, CCl_4, 3 h; (v) $Ph–P(–CH_2–CH_2–S^-Li^+)_2$, thf; (vi) stirring at open atmosphere, 24 h.

The ^{1}H NMR spectrum displays a complex pattern due to the high inversion barrier of the phosphane group [23], which makes non-equivalent the geminal methylene protons. The S–CH_2-bipy protons appear as a pair of doublets centered at 4.0 ppm (AB system), and three groups of signals attributed to the —S–CH_2–CH_2–P– methylene protons coupled with the phosphorus atom are observed in the interval 2.4–3.1 ppm. The COSY spectrum shows coupling between three multiplets, which evidences that all four methylene protons and the phosphorus atom define an ABMNX system similar to those found in related macrocyclic molecules [24,6].

The $^{13}C\{^{1}H\}$ NMR spectrum shows a singlet for each different carbon atom in the molecule, split in some cases by the P–C coupling, thus indicating the conformational flexibility of the ligand L. The assignation of this spectrum was made on the basis of the literature data for the P–C coupling constants [25] and the observed chemical shifts of related phosphane macrocycles [5b,6]. Alkyl phosphanes are easily oxidized to their phosphoryl derivatives [26] and ligand L is no exception to this behavior. Exposing stirred chloroformic solutions of L to air yields almost quantitatively the phosphorylic macrocycle Lox. The patterns of the ^{1}H and $^{13}C\{^{1}H\}$ NMR spectra of Lox are very similar to that described for L, whereas the $^{31}P\{^{1}H\}$ NMR spectrum again shows a single signal at 37.21 ppm, which is in the expected position for a dialkyl aryl phosphine oxide [25,27].

The spectroscopic properties of the ligands L and Lox, including mass spectra, were consistent with the proposed structure; however, the elemental analyses of the two compounds were not coincident with those calculated from their empirical formulas. Taking into account that there was no spectroscopic evidence for the presence of additional organic compounds and no insoluble residues remained when L and Lox were dissolved in organic solvents, we proceeded with the study of their complexing abilities.

The reaction of the ligands L and Lox with equimolar amounts of hydrated $Fe(ClO_4)_2$ in a CH_2Cl_2–CH_3CN mixture affords red–purple microcrystalline materials corresponding to the respective iron (II) complexes. As in the case of the free ligands, elemental analysis of both complexes did not fit any empirical formula derived from simple metal to ligand to perchlorate counteranion relations. Hopefully, these complexes may easily crystallize, producing suitable materials for X-ray diffraction analysis, which could reveal (Figs. 1 and 2) the presence of the monocationic complex units $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$, which contain one ligand (L and Lox, respectively), and one bromine atom bound to a Fe(II) atom in an octahedral environment. The presence of bromine in both compounds could only be explained if some of the LiBr generated in the synthesis of L is not completely removed by the purifica-

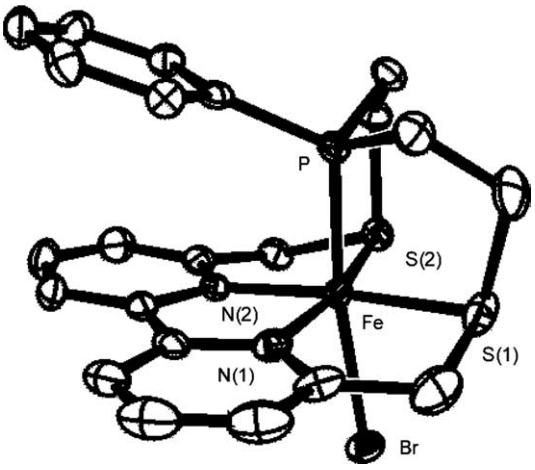


Fig. 1. Perspective view of the complex cation $[\mathbf{1}]^+$ showing 30% displacement ellipsoids. Hydrogen atoms are omitted for clarity.

tion procedures used in the isolation of L and Lox. This assumption was confirmed by the Li analysis of both ligands using atomic emission spectrometry. The LiBr present in the Lox ligand can be easily removed by treating its chloroformic solutions with water. However, all the attempts made to purify L by the same or other procedures gave rise to its partial oxidation, and the separation of these L and Lox mixtures was unsuccessful. Furthermore, all attempts to synthesize Fe(II) complexes with the purified Lox ligand were also unsuccessful.

The complex cations $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ were initially obtained as purple microcrystalline perchlorate salts showing a different degree of solubility in organic solvents. The $[\mathbf{1}]^+$ perchlorate salt was sufficiently soluble in acetonitrile to be fully studied by NMR spectroscopy, a fact which reflects diamagnetic character, whereas the low solubility of $[\mathbf{2}]^+$ perchlorate salt prevented further solution studies. The $^{31}P\{^1H\}$ NMR spectrum of $[\mathbf{1}](ClO_4)$ shows a single signal at 132.52 ppm which suggests the presence of only one species in solution. These low-field shifts are characteristic of co-ordinated phosphanes in fused five-membered chelate rings [28] and several Fe(II)–triphosphamacrocyclic complexes showing similar shifts in the ^{31}P NMR spectra have recently been reported [2a,2c]. Between 4.8 and 2.4 ppm, the ^1H NMR spectrum presents the same groups of multiplets, corresponding to the methylene protons found in the free ligand, but low-field shifted. However, the number of signals of the bipyridine rings increases with respect to the ligand L, which reflects the loss of the local symmetry by the effect of the co-ordination to the metal centre.

The $^{13}C\{^1H\}$ NMR spectrum also shows the same number of signals as the free ligand, but in this latter case the most important differences are found in the region corresponding to the methylene groups, where the pair of doublets corresponding to the $–S–CH_2–CH_2–P–$ carbon atoms (22.4 and 33.5 ppm) appears high and low field displaced with respect to the L ligand (27.7 and 28.7 ppm). These data suggest that in solution the complex cation $[\mathbf{1}]^+$ maintains its monomeric character, which is in agreement with the well-known kinetic stability of the low-spin octahedral Fe(II) complexes [29].

The crystal structures of the L and Lox Fe(II) complexes, which crystallize as $[\mathbf{1}]Br \cdot H_2O$ and $[\mathbf{2}](ClO_4) \cdot 1\frac{1}{6}MeOH$ salts, showed the presence of the aforementioned $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ complex cations without significant interactions with the counter-anions and the solvate molecules. The diagrams for these complex cations are shown in Figs. 1 and 2, respectively. Crystallographic data for the structures are listed in Table 1; selected bond distances and angles for $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$ are summarized in Tables 2 and 3, respectively.

As was mentioned above, the co-ordination geometry at the Fe(II) atoms in both complex cations is a distorted octahedron defined by the five donor atoms of the ligands and an additional bromine atom which is placed in a *trans* position with respect to the phosphorus-phophane atom for $[\mathbf{1}]^+$ or to the oxygen-phosphoryl atom for $[\mathbf{2}]^+$. The major distortion in both octahedral environments is observed in the value of the S–Fe–S bond angles (105.30(6)° and 120.99(9)° for $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$, respectively), and this can be attributed to the geometric constraint imposed by the simultaneous co-ordination of the two bipyridine nitrogen atoms and the two thioether sulfur atoms, thus defining three contiguous five-membered chelate rings. These four donor atoms and the metal ion are almost coplanar in

the complex cation $[\mathbf{1}]^+$ whereas in $[\mathbf{2}]^+$ the iron atom deviates 0.191(2) Å from the N_2S_2 plane.

The Fe–Br bond distances observed for both complexes are similar (2.5108(9) and 2.4887(15) Å for $[\mathbf{1}]^+$ and $[\mathbf{2}]^+$, respectively), and lie in the same range as those reported for related octahedral Fe(II) complexes containing non-bridging bromine ligands [30]. This situation is similar for the Fe–O(phosphoryl) bond distance in $[\mathbf{2}]^+$, which shows a value (2.107(5) Å) comparable to that observed in the few reported structures containing octahedral Fe(II) complexes with coordinated phosphoryl ligands [31]. However, the Fe–P(phosphine) bond distance for $[\mathbf{1}]^+$ (2.1780(13) Å) is somewhat less when compared with those observed in other low-spin Fe(II) complexes with aryl-dialkyl phosphines [32,33].

The Fe–N(bipyridine) distances for $[\mathbf{1}]^+$ (1.918(4) and 1.921(4) Å) are also slightly less than the average Fe–N bond length (ca. 2.00 Å) obtained through a Cambridge Crystallographic Data Base (CCDB) search [34] on octahedral Fe(II) complexes containing bipyridine as ligand and covering 47 structures. However, the same distances for $[\mathbf{2}]^+$ (2.134(7) and 2.113(7) Å) are ca. 0.20 Å longer than those found in $[\mathbf{1}]^+$ and similar to those reported for related octahedral high-spin Fe(II)–bipyridine complexes [35]. The same trends are also observed for the Fe–S(thioether) distances, which in the case of $[\mathbf{1}]^+$ (2.2604(15) and 2.2667(14) Å) are very close to the Fe–S bond lengths observed in low-spin Fe(II) complexes of homoleptic polythiamacrocycles [36] and azathiamacrocycles [37] whereas in the complex cation $[\mathbf{2}]^+$ these distances are noticeably longer (2.558(3) and 2.579(3) Å) and similar to those reported for high-spin Fe(II) complexes with different thioether containing ligands [32,38]. These structural data confirm the low-spin nature of the Fe(II) metal ion in the complex $[\mathbf{1}]^+$. However the bond distances and angles in the complex cation $[\mathbf{2}]^+$ are only compatible with a high-spin electronic configuration for the Fe(II) metal ion, a fact that can be attributed to the increase in the macrocyclic ligand hardness when the phosphane group in L is replaced by their phosphoryl derivative. Only the Br–Fe distance is slightly short in $[\mathbf{2}]^+$ than in $[\mathbf{1}]^+$, which may be due to the *trans*-effect of the P(phosphane) atom in $[\mathbf{1}]^+$ in comparison with the O(phosphoryl) atom in [**2**] [2].

3. Experimental

The syntheses were carried out using standard Schlenk techniques under dry dinitrogen atmosphere. The solvents were dried by conventional methods and distilled under dinitrogen before use. Dilithium 3-phenyl-3-phosphapenta-1,5-dithiolate and 6,6′-bis(bromomethyl)-2,2′-bipyridine [20,21] were prepared according to published procedures. Chemical analyses were performed in the Chemical Analysis Service of the Universitat Autònoma de Barcelona. Elemental analyses were carried out using a Carlo Erba EA-1108 instrument. Li determinations were made by atomic emission spectrometry (AES) using a Perkin–Elmer 2100 instrument; the samples were previously prepared treating them with HNO_3/H_2O (1:1) at 180 psi during 40 min in a microwaves digestor (CEM2000). The NMR spectra were run in the NMR Service of the Universitat Autònoma de Barcelona. ^1H and $^{13}C\{^1H\}$ NMR spectra were recorded using a Bruker 400 MHz AM instrument and the $^{31}P\{^1H\}$ NMR spectra were recorded using a Bruker 250 MHz AC instrument with chemical shifts given as ppm relative to 85% H_3PO_4. COSY and HNQC experiments were made in order to assign the ^1H and ^{13}C spectra by using general standard parameters. Mass spectra were recorded using a HP298S GC/MS system.

4. Syntheses

4.1. 3,3′-5-phenyl-2,8-dithia-5-phospha[9]-2,2′-bipyridinophane (L)

Under a dinitrogen atmosphere, a solution of dilithium 3-phenyl-3-phosphapenta-1,5-dithiolate in thf (100 cm^3, 0.09 M) and a solution of 6,6′-bis(bromomethyl)-2,2′-bipyridine (3.10 g, 9 mmol) in thf (100 cm^3) were added simultaneously to thf (500 cm^3) over a period of 5 h at room temperature. After the addition, the mixture was stirred for a further 48 h. The thf was removed under vacuum and the resulting oily yellow residue was extracted with diethyl ether (3×60 cm^3). The ethereal layer was separated, evaporated under vacuum, and the residue was dissolved in the minimum amount of CH_2Cl_2. After slow addition of petroleum ether (40–60°) to this solution a white precipitate appeared which was filtered off and vacuum dried. Yield (calculated for L · 2LiBr) 0.54 g, 10%. *Anal.* Calc. for $C_{22}H_{23}N_2PS_2Li_2Br_2$: C, 45.23; H, 3.97; N, 4.79; S, 10.98; Li, 2.38. Found: C, 44.4; H, 3.8; N, 4.1; S, 10.2%; Li (determined by AES), 21.7 mg Li/1 g sample, 2.2%. ^1H NMR (400 MHz, $CDCl_3$): δ 2.07 (m, 2, –S–CH_2–CH_2–P–), 2.45 (m, 2, –S–CH_2–CH_2–P–), 2.84 (m, 4, –S–CH_2–CH_2–), 3.90 (d, 2, –S–CH_2–Ph, $J = 13.9$ Hz), 4.02 (d, 2, –S–CH_2–Ph, $J = 13.9$ Hz), 7.42–7.77 (m, 11, Ar). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 27.71 (d, S–CH_2–CH_2–P–, $J = 10.5$ Hz), 28.72 (d, –S–CH_2–CH_2–P–, $J = 20.9$ Hz), 37.92 (–S–CH_2–Ph), 119.32, 124.62, 139.31 (Bipy), 128.08 (d, P–Ph, $J = 7.0$ Hz), 128.54 (d, P–Ph, $J = 15.7$ Hz), 131.45 (d, P–Ph, $J = 19.2$ Hz), 131.86 (d, P–Ph, $J = 19.4$ Hz), 152.45, 158.58 (Bipy). $^{31}P\{^1H\}$ NMR (101 MHz, $CDCl_3$): δ − 21.29. 4.2. 3,3′-5-oxo-5-phenyl-2,8-dithia-5-phospha[9]-2,2′-bipyridinophane (Lox)

A solution of L · 2LiBr (0.200 g, 0.34 mmol) in $CHCl_3$ (30 cm^3) was stirred at open atmosphere and room temperature for 24 h. The resulting solution was evaporated to dryness and the resulting solid collected. Yield (calculated for Lox · 2LiBr) 0.198 g, 97%. *Anal.* Calc. for $C_{22}H_{23}N_2OPS_2Li_2Br_2$: C, 44.02; H, 3.86; N, 4.67; S, 10.68; Li, 2.31. Found: C, 43.8; H, 3.4; N, 4.6; S, 10.3%; Li (determined by AES), 24.8 mg Li/1 g sample, 2.5%. ^1H NMR (400 MHz, $CDCl_3$): δ 2.35 (m, 2, –S–CH_2–CH_2–P–), 2.80 (m, 6, –S–CH_2–CH_2–P–), 3.81 (d, 2, –S–CH_2–Ph, $J = 13.9$ Hz), 3.92 (d, 2, –S–CH_2–Ph, $J = 13.9$ Hz), 7.38–7.89 (m, 11, Ar). $^{13}C\{^1H\}$ NMR (100 MHz, $CDCl_3$): δ 30.98 (d, –S–CH_2–CH_2–P–, $J = 14.8$ Hz), 31.95 (d, S–CH_2–CH_2–P–, $J = 18.5$ Hz), 36.27 (–S–CH_2–Ph), 120.60, 123.66 (Bipy), 128.81 (d, P–Ph, $J = 11.09$ Hz), 130.09 (d, P–Ph, $J = 9.2$ Hz), 130.50 (d, P–Ph, $J = 9.4$ Hz), 132.04 (s, P–Ph), 138.78, 138.93, 160.46 (Bipy). $^{31}P\{^1H\}$ NMR (101 MHz, $CDCl_3$): δ 37.21. Mass spectrum (EI); *m/z* 426 (M^+).

4.3. [FeBr(L)](ClO4) · 2H2O · [1](ClO4) · 2H2O

A solution of $Fe(ClO_4)_2 \cdot 6H_2O$ (44 mg, 0.122 mmol) in acetonitrile (5 cm^3) was slowly added to a solution of L · 2LiBr (50 mg, 0.086 mmol) in dichloromethane (2 cm^3). The solution changed immediately to red–purple and a solid of the same colour appeared which was filtered off, washed with dichloromethane and vacuum dried. Yield: 17 mg, 29%. *Anal.* Calc. for $C_{22}H_{27}BrClFeN_2O_6PS_2$: C, 38.76; H, 3.99; N, 4.11; S, 9.45. Found: C, 38.9; H, 3.6; N, 4.2; S, 9.3%. ^1H NMR (400 MHz, CD_3NO_2): δ 2.37 (m, 4, –S–CH_2–CH_2–P–), 3.13 (m, 4, –S–CH_2–CH_2–P–), 4.67 (d, 2, –S–CH_2–Ph, $J = 18.0$ Hz), 4.81 (d, 2, –S–CH_2–Ph, $J = 18.0$ Hz), 6.24–7.00 (m, 6, Bipy), 7.78 (m, 5, P–Ph). $^{13}C\{^1H\}$ NMR (100 MHz, CD_3NO_2): δ 22.51 (d, –S–CH_2–CH_2–P–, $J = 29.7$ Hz), 33.41 (d, S–CH_2–CH_2–P–, $J = 31.5$ Hz), 44.36 (–S–CH_2–Ph), 117.18, 117.56 (Bipy), 128.81 (d, P–Ph, $J = 11.09$ Hz), 124.42 (d, P–Ph, $J = 8.9$ Hz), 124.89 (d, P–Ph, $J = 9.1$ Hz), 126.53 (s, P–Ph), 130.41, 153.59, 159.14 (Bipy). $^{31}P\{^1H\}$ NMR (101 MHz, $CDCl_3$): δ 132.52.

4.4. [FeBr(Lox)](ClO$_4$) · 3H$_2$O · [2](ClO$_4$) · 3H$_2$O

The compound was prepared as for [**1**](ClO$_4$) · 2H$_2$O using Lox as ligand. Yield: 19 mg, 29%. *Anal.* Calc. for $C_{22}H_{29}BrClFeN_2O_8PS_2$: C, 36.92; H, 4.08; N, 3.91; S, 8.96. Found: C, 36.4; H, 3.9; N, 3.8; S, 8.2%.

5. Crystallography

The slow evaporation of a nitromethane solution of [**1**](ClO$_4$) · 2H$_2$O and a methanol solution of [**2**](ClO$_4$) · 3H$_2$O produced crystalline materials corresponding to [**1**]Br · H$_2$O and [**2**](ClO$_4$) · $1\frac{1}{6}$MeOH, respectively. Single-crystal data were performed at ambient temperature on a Rigaku AFC5S diffractometer using graphite monochromatized Mo Kα radiation. The unit cell parameters for both compounds were determined by least-squares refinement of 25 carefully centered reflections. All data obtained were corrected for empirical absorption (P scan). A total of 4563 and 5557 reflections giving 4296 and 5198 unique reflections ($R_{int} = 0.0179$ and 0.0562) were collected by T/2 scan mode ($2\theta_{max} = 50°$) for [**1**]Br · H$_2$O and [**2**](ClO$_4$) · $1\frac{1}{6}$MeOH, respectively.

Both structures were solved by direct methods and least-squares refinements were performed using the SHELX-97 program system [39]. For [**1**]Br · H$_2$O non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms were included in the calculations at the fixed distances from their host atoms and treated as riding atoms using the SHELX-97 default parameters.

The asymmetric unit of [**2**](ClO$_4$) · $1\frac{1}{6}$MeOH consists of the complex unit [**2**]$^+$, disordered perchlorate ion, one methanol molecule at common position and 1/6 of disordered methanol molecule at threefold axis. The perchlorate ion shows rotational disorder, the Cl–O(2) bond being common shared by both rotamers. The disordered oxygen atoms of the perchlorate ion and the methanol molecules were refined with isotropic displacement parameters; the rest of the non-hydrogen atoms were refined with anisotropic displacement parameters. Hydrogen atoms of the methanol molecules could not be reliably positioned but the remainder of the hydrogen atoms were included in the calculations at fixed distances from their host atoms and treated as riding atoms by using the SHELX-97 default parameters.

6. Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request. CCDC Nos.: 274557 and 274558 for [**1**]Br · H$_2$O and [**2**](ClO$_4$) · $1\frac{1}{6}$MeOH, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk)

Abstract

A series of binuclear complexes of a general formula $[(dppbO_2)Ln(NO_3)_3(\mu\text{-}dppbO_2)Ln(NO_3)_3(dppbO_2)]$ (Ln = Pr (**1**), Nd (**2**), Sm (**3**), Dy (**4**), Lu (**5**)) were prepared by reacting bis(diphenylphosphino)butane dioxide ($dppbO_2$) with lanthanide nitrates under solvothermal conditions. All compounds were characterized by analytical and spectroscopic techniques, such as infrared spectroscopy and mass spectrometry with electrospray ionization, and their molecular structures were determined by single crystal X-ray diffraction analysis in four cases. In contrast to the majority of lanthanide complexes with bis(diphenylphosphino)ethane dioxide which were previously reported as 2D polymeric networks, the present compounds are strictly molecular. This is evidently manifestation of the longer and flexible ligand backbone that allows a chelating binding mode.

Keywords: Bis(diphenylphosphino)butane dioxide; Lanthanides; Binuclear complexes; X-ray crystallography; Electrospray mass spectrometry

1. Introduction

Recently we have studied the reactivity of bis(diphenylphosphino)ethane dioxide $Ph_2P(O)–CH_2CH_2–P(O)Ph_2$ ($dppeO_2$) with lanthanide salts [1]. While bis(diphenylphosphino)methane dioxide ($dppmO_2$) had already been known to form a range of various chelates with lanthanide cations [2], we have prepared a series of coordination polymers with its one-carbon longer homologue. We have observed different coordination geometries and polymeric architectures, depending on the ancillary non-bridging ligands and the reaction conditions involved.

Our current investigation was targeted on the reactivity of diphosphine dioxide ligands with longer central chains. There have been several publications studying the steric properties of the bidentate diphosphine ligands in connection with the structural and catalytic features of resulting complexes [3–5]. The $Ph_2P–(CH_2)_n–PPh_2$ series in particular, provided the opportunity to study the steric effects by the simple variations in *n*, without significantly affecting the electronic properties of ligands [6]. The oxidized series, $Ph_2P(O)–(CH_2)_n–P(O)Ph_2$, seemed suitable for similar investigations on lanthanides, which are generally coordinated by phosphorus to a lesser extent.

We will show in the following, that in contrast to the observed polymeric nature of $dppeO_2$ complexes, the reversal to the molecular character was featured in lanthanide complexes of bis(diphenylphosphino)butane dioxide ($dppbO_2$). These were prepared by the solvothermal reactions of $dppbO_2$ with lanthanide nitrates and characterized structurally and spectroscopically. Electrospray ionization technique has been used successfully to ionize both non-volatile and thermally labile inorganic compounds for mass spectrometric detection [7] and it proved a valuable tool in the characterization of the prepared lanthanide complexes **1**–**6**.

2. Results and discussion

The solvothermal synthesis is a variation to the well-known hydrothermal process, in which water is substituted by a general solvent. The hydrothermal and solvothermal methods are widely used in material design and crystal engineering, with the view to obtain the products of desired structure, texture and crystallinity [8–11]. Using solvothermal synthesis, we have successfully prepared good quality crystals of coordination polymers of $dppeO_2$ with lanthanides [1]. We have therefore used the reaction in an autoclave for the preparation of coordination compounds of $dppbO_2$. One-day heating of the ligand with a respective lanthanide nitrate in methanol yielded block-shaped crystals of excellent quality. In all cases, the single crystal X-ray diffraction analysis revealed the binuclear complexes of a general formula [($dppbO_2$)-$Ln(NO_3)_3$-(μ-$dppbO_2$)-$Ln(NO_3)_3$($dppbO_2$)] (Ln = Pr (**1**), Nd (**2**), Sm (**3**), Dy (**4**)) (see Fig. 1). The reaction with $Lu(NO_3)_3 \cdot 2H_2O$ led to a microcrystalline solid, which decomposed to powder on exposure to air, most probably because of a loss of the solvent of crystallization. Even though the lutetium complex was not studied by the X-ray diffraction, its binuclear nature is apparent from the electrospray mass spectra (see Table 3).

The molecular structures of **1**–**4** are similar to the binuclear complex [($dppeO_2$)$Lu(NO_3)_3$-(μ-$dppeO_2$)-$Lu(NO_3)_3$($dppeO_2$)] (**6**), which was isolated as the only molecular compound from the solvothermal reaction of $dppeO_2$ with lanthanide nitrates [1]. The fact that all other $dppeO_2$ complexes with lighter lanthanides were polymeric, we ascribed to the effect of the lanthanide contraction. The formation of binuclear compounds with $dppbO_2$ is obvious throughout the whole rare earth metal series, thus the longer ligand backbone is clearly responsible for the transition from polymeric to molecular complexes.

All compounds combine chelating as well as bridging bonding modes for the bidentate $dppbO_2$. While the bridging ligands have their P=O groups in an *anti* conformation as they do in their uncoordinated form [12], in chelate rings they naturally adopt the *syn* conformation. Mean deviations from P1–O1–P2–O2 planes are 0.049, 0.049, 0.047, and 0.043 Å for **1**–**4**, respectively. Considering the coordination sphere of the lanthanide cation as being pseudooctahedral, the ligands are meridionally disposed. The selected bond lengths and angles are listed in Table 2. With decreasing ionic radius of Ln^{3+}, the oxygen atoms get progressively closer to the cation, with consistent difference of about 0.2 Å in Ln–O(N) and Ln–O(P) distances.

The IR spectra are very similar to those obtained for the $dppeO_2$ coordination polymers [1]. Again we observe the grouping of bands at 1467–1487, 1291–1323, 1029–1031, and 816–820 cm^{-1}, which we assign to the bidentate nitrate groups, in agreement with previous data [13,14]. The band at 1384–1385 cm^{-1} is also apparent and belongs to the ionic nitrate. According to Lees et al. [14], the NO_3^- anion is displaced from the complex by Br^- from the KBr pellet. The most prominent bands are at 1139–1159 cm^{-1} which correspond to the P=O stretching frequency. In the present compounds, they usually appear in pairs, suggesting the chelating and bridging nature of the P=O moieties.

We studied the binuclear complexes of the $dppbO_2$ ligand **1**–**5** and the complex **6** with the shorter $dppeO_2$

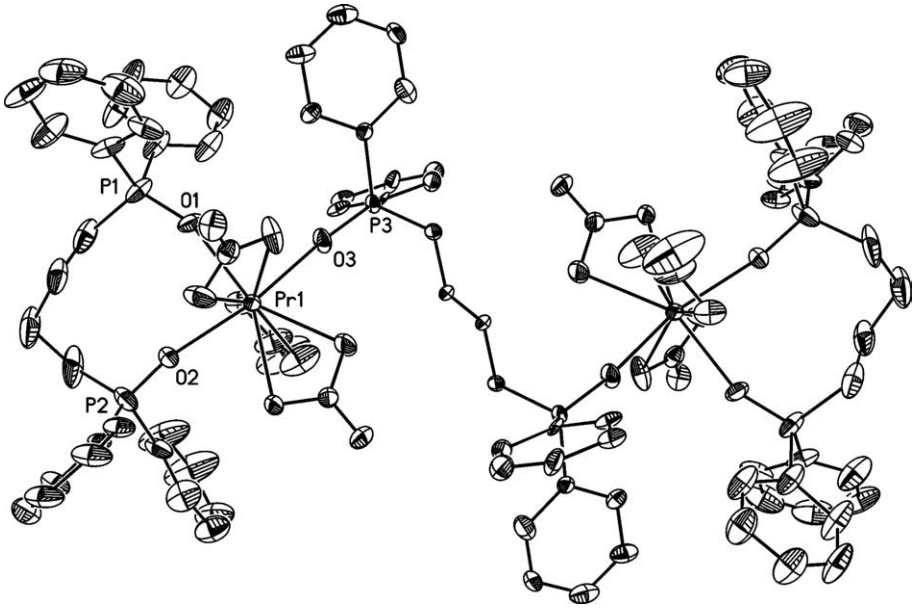

Fig. 1. The molecular structure of [($dppbO_2$)$Pr(NO_3)_3$-(μ-$dppbO_2$)-$Pr(NO_3)_3$($dppbO_2$)] (**1**). The thermal ellipsoids were drawn at the 50% probability level and hydrogen atoms were omitted for clarity. The compounds **2**–**4** are isostructural with **1**.

ligand by ESI–MS in acetonitrile/water (1:1) solutions to ascertain their stability and ionization and fragmentation pathways (see Fig. 2). Molecular ions of all compounds were not visible in the positive mode most probably because of an easy loss of a nitrate group and a ligand to form the positively charged fragments of the highest observed mass (see Table 3). The signal for $[M - NO_3]^+$ cation was registered as a weak peak in the spectrum of **6**. In the spectra of **1**–**5**, the signal for $[M - NO_3]^+$ is very weak or absent but the binuclear $[(dppbO_2)_2Ln_2(NO_3)_5]^+$ fragments, formed by further loss of a neutral $dppbO_2$ ligand, are quite prominent in all compounds and substantiate the existence of the intact binuclear species in solution. The presence of two lanthanide atoms in these ions was clearly demonstrated by the correspondence of measured and theoretical isotope pattern for the Nd, Sm, and Dy (see Fig. 3) complexes. A subsequent loss of a neutral $Ln(NO_3)_3$

moiety provides the most intense signals $[(dppbO_2)_2Ln(NO_3)_2]^+$ in all spectra (see Table 3). Two most abundant ions $[(dppbO_2)_2Ln_2(NO_3)_5]^+$ and $[(dppbO_2)_2Ln(NO_3)_2]^+$ were mass selected and fragmented in MS^2 experiments. The loss of neutral $Ln(NO_3)_3$ and the sequential detachment of $dppbO_2$ was corroborated in every complex. In the next MSMS step (MS^3) all fragments $[(dppbO_2)Ln(NO_3)_2]^+$ were found to lose 47 amu. This loss could correspond to HNO_2. The general fragmentation pathway is summarized in Fig. 2. Addition of 0.1% of HCOOH to enhance ionization or changing the solvent to methanol/water (1:1) had no effect on the signal intensities or the appearance of the spectra. Experiments acquired in the negative ion mode displayed fragmentation patterns similar to the positive mode but with much weaker signal intensities and the spectra were dominated by the $[Ln(NO_3)_4]^-$ ions.

To conclude, we have prepared and characterized five binuclear lanthanide complexes as a continuation of our thorough study on the interaction of lanthanide cations with the ligands of diphosphine dioxide type. In the series of $Ph_2P(O)–(CH_2)_n–P(O)Ph_2$ ($n = 1, 2, 4$) ligands, the shortest one was previously found to form chelates with lanthanides [2]; we have prepared 2D coordination polymers with the medium length ligand [1]; and finally, in the present work, we observed the restoration of the molecularity in the complexes with $dppbO_2$. It is obvious, that the lack of rigid backbone allows the aliphatic ligands to take upon chelate arrangements. Thus, for the preparation of polymeric complexes the appropriate combination of length and rigidity will be of crucial importance.

3. Experimental

The preparation of $Ph_2P(O)–(CH_2)_4–P(O)Ph_2$-($dppbO_2$) was based on the previously described method [15]. IR spectra (KBr pellets, 4000–400 cm^{-1}) were collected on an EQUINOX 55/S/NIR FTIR spectrometer. Microanalyses were performed using a ThermoFinnigen Co. CHN Analyzer Flash EA 1112. Melting points were measured on a Boetius melting-point apparatus.

A mixture of $dppbO_2$ (250 mg, 0.545 mmol) and the lanthanide nitrate (0.273 mmol) in methanol (30 ml) was sealed in a 250-ml stainless-steel reactor Berghof HR-200 with a Teflon liner, heated for 24 h to 140 °C with a RHS-295 heater controlled by a BAR-945 unit, and then slowly cooled to room temperature. After next 24 h the autoclave was opened and a crystalline solid was collected and washed with methanol.

4. Mass spectrometry

The ion trap mass spectrometer Esquire 2000 (Bruker, Germany) with electrospray ionization was used for ESI–MS analyses. Solid samples were dissolved in water and diluted in acetonitrile/water (1:1). The samples were injected directly into the electrospray ion source at a flow rate of 4 μl min^{-1}. The spectra were recorded both in positive and negative mode. The capillary voltage was 4500 V. Smart Parameter Settings mode was used to optimize other parameters for MS and MSMS operation. The temperature of sampling capillary was set to 200 °C (or 250 °C).

5. Crystallography

Diffraction data were collected on a KUMA KM-4 κ-axis diffractometer equipped with a CCD detector, with Mo Kα radiation ($\lambda = 0.71073$ Å). The temperature during data collection was 120(2) K. The intensity data were corrected for Lorentz and polarization effects; absorption correction was applied for all data. The structures were solved by direct methods and refined by full-matrix least-squares methods. The structures are isomorphous, the contraction in lattice parameters reflects the decreasing ionic radius in the lanthanide series. The asymmetric part is built of the $(dppbO_2)Ln(NO_3)_3(Ph_2P(O)CH_2CH_2)$ mononuclear unit, which yields the whole binuclear molecule upon inversion operation. There is a significant disorder in all structures, mainly in the bridging $dppbO_2$ ligand. Its Ph_2P moieties were refined over two sites with almost equal occupancies; the central chain was modelled over three paths in an approximately 0.5:0.25:0.25 ratio. To ensure the reasonable description of a thermal motion in disordered phenyl groups, the rigid-bond restraint was applied for the ring carbon atoms. Nevertheless, in sporadic cases some of the anisotropic displacement parameters became 'non-positive definite' (mainly the *ipso* carbons in phenyl groups), therefore the attempts to describe them anisotropically were abandoned. For all other non-hydrogen atoms the anisotropic thermal parameters were used. The amount of the solvent was initially refined, and later fixed to 0.75 molecules of methanol per asymmetric unit.

The software packages used were: XCALIBUR CCD system for the data collection/reduction [16], and SHELXTL for the structure solution, refinement, and drawing preparation [17]. Details of the data collection and structure refinement are listed in Table 1. Crystallographic data for structures reported in this paper are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk; www: http://www.ccdc.cam.ac.uk) on request, quoting the Deposition Nos. CCDC 275118–275121.

Abstract

An inexpensive bidentate ligand *N*,*N*′-methylene-bis(2-aminopyridyl) (**1**) has been synthesized. Reaction of **1** with [Pd(COD)Cl_2] affords a stable chelate complex, [{$NC_5H_4N(H)(\mu\text{-}CH_2)(H)NC_5H_4N\text{-}\kappa N,\kappa N$}$PdCl_2$] (**2**). The kinetics of the pseudo-unimolecular reaction of *N*,*N*′-methylene-bis(2-aminopyridyl) with Pd(1,5-cyclooctadiene)Cl_2 has been studied over the range $3.0 \leqslant 10^3$ [**1**] $\leqslant 7.0$ mol dm^{-3}, 30 °C $\leqslant t \leqslant$ 40 °C. The rate constants and equilibrium constants were calculated. Entropy and enthalpy of the reaction are found to be -42 ± 1 J K^{-1} mol^{-1} and 75 ± 1 kJ mol^{-1}, respectively, which clearly indicates that the substitution reaction follows associative mechanism. The complex **2** was tested for the Suzuki-cross-coupling reaction of a variety of aryl halides with aryl boronic acids in methanol at room temperature or at 60 °C, giving generally high yields for both activated and inactivated aryl bromides. The effect of solvents as well as the effect of base on the Suzuki-coupling reaction is also investigated.

Keywords: Reaction kinetics; Nitrogen donor ligands; Palladium complex; Catalysis; Suzuki-cross-coupling reactions

1. Introduction

In general, substitution reactions of square-planar complexes and particularly that of Pd(II) and Pt(II) have received much attention from various investigations over the past two decades [1]. Palladium or platinum complexes containing nitrogen donor ligands are widely employed in kinetics and mechanistic investigations. Most of the palladium(II) complexes exhibit 10^4–10^5 times higher reactivity than platinum(II) complexes, although their structural and equilibrium behavior is similar [2]. This interest of studying the Pd(II) and Pt(II) complexes mainly focuses on the ability to use steric and electronic effects to tune the solubility, acidity and reactivity of such complexes for their probable utility as antitumor drugs [3] and as homogeneous catalysts [4].

Palladium complexes containing phosphines [5], phosphates [6], and phosphine oxides [7] are widely used as catalyst in Suzuki-Miyaura cross-coupling reactions. However, these catalysts are sensitive to moisture and air, therefore require air free handling to minimize ligand oxidation or stable oxidative addition products. Recently, nitrogen donor ligands have emerged as efficient partners for the Suzuki reaction in order to circumvent the problems associated with tertiary phosphine derivatives [8]. The nitrogen donor ligands such as *N*-heterocyclic carbenes [9] imine and amine palladacycles [10], oxime palladacycles [11] and diazobutadiene derivatives [12] have shown excellent activity for Suzuki-reactions. Current technologies demand new catalysts that are inexpensive, accessible, moisture and air stable,

doi:10.1016/j.poly.2005.08.013

non-toxic, and most importantly effective under mild experimental conditions towards aryl halides. In view of this and as a continuation of our work in designing new ligand systems for exploring their organometallic chemistry and catalytic utility in organic synthesis [13], here in we report the synthesis of a cheap, air and moisture stable, phosphine free ligand *N*,*N*′-methylene-bis(2-aminopyridyl) (**1**) and the kinetic study of **1** with $Pd(COD)Cl_2$. The catalytic utility of $[\{NC_5H_4N(H)\text{-}(\mu\text{-}CH_2)(H)NC_5H_4N\text{-}\kappa N,\kappa N\}PdCl_2]$ (**2**) in Suzuki-cross-coupling reactions is also described.

2. Results and discussion

Reaction of two equivalent of 2-amino pyridine with 37% aqueous solution of formaldehyde at 0 °C gives the *N*,*N*′-methylene-bis(2-aminopyridyl) (**1**) in 72% yields (Scheme 1). The IR spectrum of **1** shows two major bands at 3394 and 3023 cm^{-1} for ν(N–H) and ν(C–H), respectively. The ^1H NMR spectrum shows a broad singlet at 6.35 ppm for N–H protons and a triplet at 5.03 ppm for methylene protons. Treatment of **1** with $[Pd(COD)Cl_2]$ in toluene gives the metal complex **2** in good yield, which is insoluble in most of the organic solvents so it cannot be characterized fully. The IR spectrum of complex **2** shows ν(N–H) at 3343 cm^{-1}. The elemental analysis is in good agreement with the proposed molecular compositions.

2.1. Spectra and kinetics

Spectral changes resulting from mixing metal precursor $[Pd(COD)Cl_2]$ and ligand **1** solution were recorded over the range 250–600 nm to establish a suitable wavelength at which kinetic measurements could be performed. Addition of $Pd(COD)Cl_2$ solution to a solution of *N*,*N*′-methylene-bis(2-aminopyridyl) resulted in an increase in absorbance in the visible range. The absorbance spectra of the mixture of $Pd(COD)Cl_2$ and *N*,*N*′-methylene-bis(2-aminopyridyl) and shifting of λ_{max} from ~330 to ~350 nm indicates the formation of complex **2** (Fig. 1).

Pd(II) complexes are usually considered as soft acids [14]. In $Pd(COD)Cl_2$ complex, palladium(II) is in square planner geometry. Rate is very sensitive to the nature of entering group. In the ligand *N*,*N*′-methylene-bis (2-aminopyridyl), the nucleophilicity of the pyridyl nitrogens is more as compared to the nitrogen of the secondary amine groups. Hence the ligand binds the metal through the pyridine nitrogen rather than the amine nitrogen (Scheme 1).

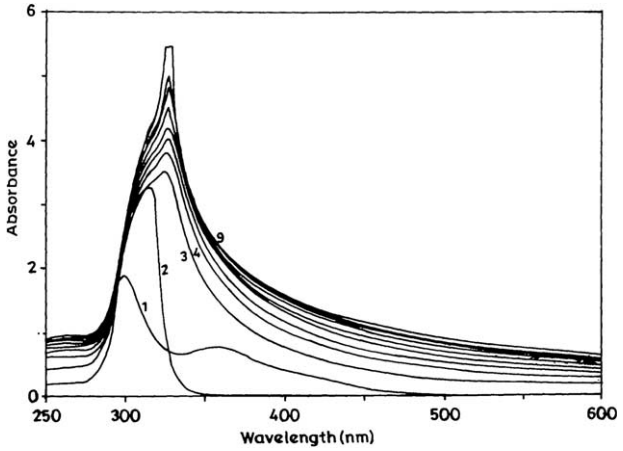

Fig. 1. Spectral difference among $[Pd(COD)Cl_2]$, *N*,*N*′-methylene-bis(2-aminopyridyl) and the product complex. 1. $[Pd(COD)Cl_2] = 3.0 \times 10^{-4}$ mol dm^{-3} at 30 °C; 2. *N*,*N*′-methylene-bis(2-aminopyridyl) = 9.0×10^{-3} at 30 °C; 3. product complex after 4 min at 30 °C; 4. after 5 min; 5. after 6 min; 6. after 7 min; 7. after 9 min; 8. after 11 min and 9. after 14 min.

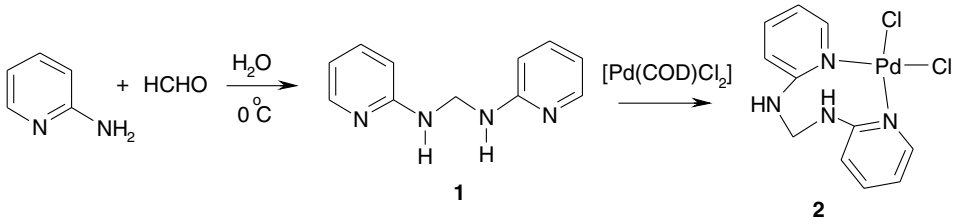
2.2. Effect of $[Pd(COD)Cl_2]$ on the reaction rate

In the first set of kinetic experiments, the $[Pd^{2+}]_T$ was varied at constant concentration of ligand 5.0×10^{-3} mol dm^{-3} at 40 °C temperature and toluene medium. The pseudo-first-order plots are linear, giving $10^3 k_{obs} = 4.5$ s^{-1} when $[Pd^{2+}]_T$ was changed from 3.0×10^{-4} to 1.0×10^{-3} mol dm^{-3}. The independence of k_{obs} at 40 °C under the condition $[\mathbf{1}] = 5.0 \times 10^{-3}$ and over the $[Pd^{2+}]_T$ range from 3.0×10^{-4} to 1.0×10^{-3} mol dm^{-3} is in agreement with first-order dependence on $[Pd^{2+}]_T$. To verify this we have also carried out the reaction of two equivalent of $[Pd(COD)Cl_2]$ with *N*,*N*′-methylene-bis(2-aminopyridyl)} and the product was characterized through FT IR and elemental analysis. The product showing a strong N–H peak at 3342 cm^{-1}, which



Scheme 1.

indicates only pyridine nitrogen atoms are coordinating to the palladium center. The rate law therefore is given by the following equation:

$$\text{Rate} = -\mathrm{d}[\mathrm{Pd}^{2+}]_T/\mathrm{d}t = k_{obs}[\mathrm{Pd}^{2+}]_T. \quad (1)$$

2.3. Effect of N,N′-methylene-bis(2-aminopyridyl) on reaction rate

The effect of ligand concentration on the reaction rate was studied at fixed metal concentration 3.0×10^{-4} mol dm^{-3} at various temperatures. The concentration of ligand was varied from 3.0×10^{-3} to 7.0×10^{-4} mol dm^{-3}. The rate constants are presented in Table 1, which are comparable with previous literature data [1a]. It is observed that as ligand concentration increases, the rate constant increases in a linear fashion (Fig. 2), which is characteristic of the ligand substitution reactions of square planar complexes. It proceeds according to the associative mechanism [15].

The probable mechanism for the substitution reaction may be delineated as in Scheme 2.

The rate law can be derived for the substitution reaction in the following manner:

$$\mathrm{d}[C]/\mathrm{d}t = k_{ip}[\mathrm{B}]_e = k_{ip}K_{ip}[\mathrm{A}]_e[\mathrm{LH}_2], \quad (2)$$

$$\begin{aligned}[\mathrm{A}]_T &= [\mathrm{A}]_e + [\mathrm{B}]_e \\ &= [\mathrm{A}]_e + K_{ip}[\mathrm{A}]_e[\mathrm{LH}_2] \\ &= [\mathrm{A}]_e\{1 + K_{ip}[\mathrm{LH}_2]\} \\ &= [\mathrm{A}]_e = [\mathrm{A}]_T/\{1 + K_{ip}[\mathrm{LH}_2]\},\end{aligned}$$

$$\mathrm{d}[C]/\mathrm{d}t = k_{ip}K_{ip}[\mathrm{A}]_T[\mathrm{LH}_2]/\{1 + K_{ip}[\mathrm{LH}_2]\},$$

$$\text{Rate} = k_{obs}[\mathrm{A}]_T, \quad (3)$$

Table 1
Effect of reaction rate on *N*,*N*′-methylene-bis(2-aminopyridyl)[a]

10^3[**1**] (mol dm^{-3})	T (°C)	$10^3 k_{obs}$ (s^{-1})	$10^2 k_{ip}$ (s^{-1})	K_{ip}
3.0	30	1.7	0.4	207.5
4.0	30	1.8		
5.0	30	2.0		
6.0	30	2.4

6.0	40	4.8		
7.0	40	5.0		

[a] Values of $10^3 k_{obs}$ (s^{-1}) at different ligand concentrations and different temperatures keeping the metal concentration constant $[\mathrm{Pd}^{+2}] = 3.0 \times 10^{-4}$ mol dm^{-3}.

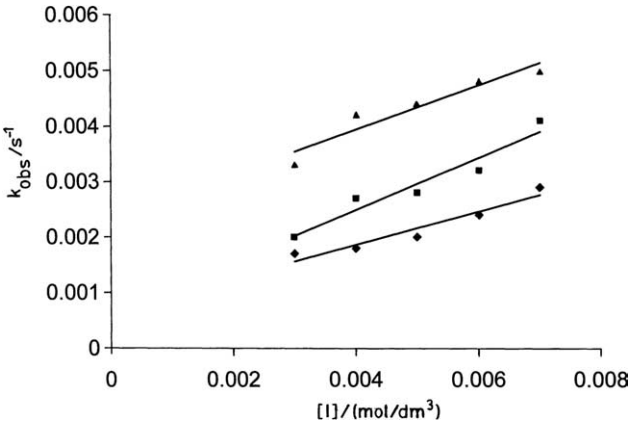

Fig. 2. Rate constants vs. ligand concentration at various temperatures. ▲, at 40 °C, ■, at 35 °C, ◆, at 30 °C.

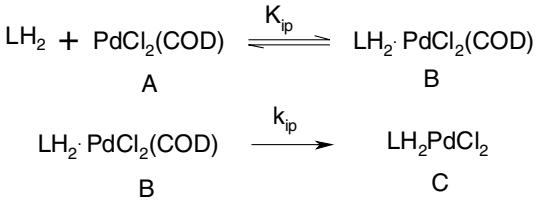

Where LH_2 = N, N'-methylene-bis(2-aminopyridyl)
K_{ip} = equilibrium constant
k_{ip} = ion-pair rate constant

Scheme 2.

$$k_{obs} = k_{ip}K_{ip}[\mathrm{LH}_2]/\{1 + K_{ip}[\mathrm{LH}_2]\},$$

$$1/k_{obs} = 1/k_{ip} + 1/k_{ip}K_{ip}[\mathrm{LH}_2]. \quad (4)$$

The plot of $1/k_{ip}$ versus $1/[\mathrm{LH}_2]$ should be linear with an intercept $1/k_{ip}K_{ip}$. This plot is linear at all temperatures studied. k_{ip} is determined from the reciprocal of the intercept and K_{ip} is calculated from intercept/slope ratio. The values of k_{ip}, K_{ip} are given in Table 1.

2.4. Effect of temperature on the rate

The reaction is studied at three different temperatures with different ligand concentrations. Activation parameters were calculated using Eyring equation and compared with literature data of the analogous systems. The low $\Delta H^{\#}$ value with negative $\Delta S^{\#}$ value, suggest an associative mechanism [1a,16]. The values of $\Delta H^{\#}$ and $\Delta S^{\#}$ are 75 kJ mol^{-1} and -42 J K^{-1} mol^{-1}, respectively, which are comparable with the analogous systems (Table 2). ΔH^0 and ΔS^0 values were calculated from the $\ln K$ versus $10^3/T$ plot. ΔH^0 is calculated from the slope and ΔS^0 is calculated from the intercept. ΔH^0 and ΔS^0 values were found to be 32.68 kJ mol^{-1} and 148.5 J K^{-1} mol^{-1}, respectively.

Table 2
Effect of temperature on the rate

Comparison of activation parameters with analogous systems.

2.5. Catalytic studies

The complex **2** effectively catalyses the Suzuki-cross-coupling reaction of a variety of aryl halides with phenyl boronic acid, affording the desired biaryls in high yields (Table 3). All the reactions were carried out at room temperature using 1 mol% of catalyst in methanol. It is notable that the deactivated, electron-rich aryl halides (entries 3 and 4) as well as activated, electron poor ones (entry 1) also resulted in high yields. In general, this coupling can be satisfactorily carried out at room temperature. When there is a need to improve the yield, it is carried out at elevated temperature (60 °C). We have also studied the coupling of some heterocycles and sterically bulky or highly substituted aryl bromides with phenyl boronic acid. The coupling of 2-bromo pyridine and 2-bromo thiophene with phenyl boronic acid give the moderate yield (54% and 66%, respectively), at room temperature. Surprisingly, when these reactions were carried out at 60 °C, both 2-bromo pyridine and 2-bromo thiophene give excellent conversions (entries 6 and 7). The highly substituted 2,4-dimethoxy-1-bromo benzene gives low coupling product at room temperature as well as at elevated temperature (entry 8). The high efficiency of the catalyst at room temperature and 60 °C makes it a valuable for thermally sensitive substrates. In the literature, few catalysts are known for Suzuki-cross-coupling reactions, which are effective at room temperature [5c,10a,17].

The activity of complex **2** is found to be superior to that in $Pd(OAc)_2$/Dabco, where reaction were carried out with 3 mol% and at 110 °C [18]. In comparison with other N-coordinated palladium catalysts, the catalytic activity of **2** is similar to those found in the $Pd_2(dba)_3$/pyrazole-tethered system whose reaction were carried out in dioxane at 55 °C [19], and a palladium ferrocenylamine complex at room temperature in methanol [4c].

To examine the solvent effect, the coupling between 4-bromoacetophenone and phenyl boronic acid catalyzed by the catalyst **2** with a number of solvents (Table 4). It is found that polar solvent such as MeOH is more productive. This may be due to higher complex solubility. Although, non-polar solvents like toluene also give good conversions, it takes more time for the reaction.

The influence of base on the coupling reaction of 4-bromoacetophenone and phenyl boronic acid is also carried out. The inorganic bases (Cs_2CO_3, KOH, Na_2CO_3, KF and K_2CO_3) and organic base (Et_3N) are

Table 3

[a] Reaction conditions: catalyst 1 mol%, 4-bromo acetophenone (0.5 mmol), phenyl boronic acid (0.75 mmol), base (1 mmol), MeOH (5 mL), 1 h.
[b] Conversion to the coupled product determined by GC, based on aryl bromide or dodecane; average of two runs.

taken into consideration for the coupling reaction. It is observed that all most all the bases are giving excellent conversions with in 1 h (Table 5).

3. Summary

In conclusion, we have synthesized an inexpensive ligand *N*,*N*′-methylene-bis(2-aminopyridyl) and its palladium complex **2**. We also studied the substitution reaction kinetics of **1** with [Pd(COD)Cl_2], which follows the associative mechanism. The complex **2** was found to be excellent catalyst for the Suzuki-coupling reaction for a variety of aryl halides with phenyl boronic acid under mild conditions. The Suzuki-coupling reactions of other highly substituted and bulky aryl halides as well as other reactions such as Heck reaction, amination, hydrogenation using this catalyst system are underway.

4. Experimental

The metal precusor $PdCl_2$ (1,5-cyclooctadiene) is prepared according to the published procedure. Others chemicals were obtained locally and used without further purifications. Solvents were dried and distilled prior to use by conventional methods. The kinetic studies were done using JASCO V-570 UV/VIS/NIR spectrophotometer. The ^{1}H NMR (δ in ppm) spectra were obtained on a VRX 400 spectrometer operating at frequency of 400 MHz. The spectra were recorded in $CDCl_3$ (or DMSO-d_6) solutions with $CDCl_3$ as an internal lock; TMS was used as external standards for ^{1}H NMR. Positive shifts lie downfield of the standard in all of the cases. Infrared spectra were recorded on a Nicolet Impact 400 FT IR instrument in KBr disk or nujol mull. Microanalyses were carried out on a Carlo Erba Model 1106 elemental analyzer. Melting points of all compounds were determined on Veego melting point apparatus and were uncorrected. GC analyses were performed on a Perkin–Elmer Clarus 500 GC fitted with packed column.

4.1. Synthesis of *N*,*N*′-methylene-bis(2-aminopyridyl) (**1**)

To the solution of 2-aminopyridine (2 g, 0.02 mol) in water (20 mL), 37% formaldehyde solution (0.86 mL, 0.01 mol) was added dropwise at 0 °C and the reaction mixture was stirred at room temperature for 8 h. The white precipitate formed was filtered, washed several times with water and then with diethyl ether and dried. It was dissolved in acetone, dried over Na_2SO_4 and concentrated, which on cooling to −25 °C, gives analytically pure product of **1**. Yield: 72% (1.53 g). m.p.: 122–124 °C. *Anal*. Calc. for $C_{11}H_{12}N_4$: C, 65.97; H, 6.06; N, 27.97. Found: C, 65.76; H, 5.98; N, 27.89%. FT IR (KBr disk) cm^{-1}: ν_{NH} 3394 s, 3258 s; ν_{CH}, 3023 s. ^{1}H NMR (400 MHz, $CDCl_3$): δ 8.11 (d, 2H, Py), 7.36 (t, 2H, Py), 6.59 (t, 2H, Py), 6.41 (d, 2H, Py), 6.35 (br, 2H, NH), 5.03 (t, 2H, CH_2).

4.2. Synthesis of $(NC_5H_4NH)CH_2PdCl_2$ (**2**)

To the solution of Pd(COD)Cl_2 (0.05 g, 0.175 mmol) in toluene (6 mL) was added a solution of ligand **1** (0.035 g, 0.175 mmol) also in toluene (8 mL) and stirred at room temperature for 3 h. The yellow precipitate formed was filtered and washed with Et_2O and dried. This product **2** was insoluble in almost all the organic solvent. Yield: 88% (0.058 g). m.p.:196 °C (dec). *Anal*. Calc. for $C_{11}H_{12}Cl_2N_4Pd$: C, 34.99; H, 3.20; N, 14.84. Found: C, 34.75; H, 3.09; N, 14.78%. FT IR (KBr disk) cm^{-1}: ν_{NH} 3343 s, ν_{CH} 3023 s.

4.3. Procedure for kinetic study

A small measured volume (0.1 mL) of 0.01 M metal solutions was taken in an UV–visible cell. The calculated amount of 0.01 M ligand solution was added to it. The total solution taken was 3 mL. So the required amount of toluene is added to the cell to maintain the fixed volume. The contents of the cell were thoroughly mixed by rapid shaking and variations of the absorbance were monitored at 480 nm as a function of time. All the reactions were carried out under pseudo-first-order conditions with ligand in at least 10-fold excess. The temperature dependence of k_{obs} was studied over the range 30-40 °C. The rate constants k_{obs} were obtained from the slopes of $\ln(A_\infty - A_t)$ versus 't' plots

$$\ln(A_\infty - A_t) = k_{obs}t + C, \quad (5)$$

where A_t and A_∞ are absorbance of the reaction at time 't' and at equilibrium, respectively.

4.4. General procedure for the coupling reaction

In a two-necked round bottom flask under dry nitrogen were placed metal complex **2** (1.9 mg, 0.005 mmol) and 5 mL of methanol. After stirring for 5 min, aryl bromide (0.5 mmol), phenyl boronic acid (0.091 g, 0.75 mmol) and K_2CO_3 (0.138 g, 1 mmol) were introduced into the reaction flask. The mixture was stirred at room temperature or 60 °C for the required time under atmosphere of nitrogen (the course of reaction was monitored by GC analysis). Then the solvent was removed under reduced pressure. The resultant residual mixture was diluted with H_2O (10 mL) and Et_2O (10 mL), followed by extraction twice (2×6 mL) with Et_2O. The combined organic fraction was dried ($MgSO_4$), stripped of the solvent under vacuum and the residue was redissolved in 5 mL of dichloromethane. An aliquot was taken with a syringe and subjected to GC analysis. Yields were calculated versus aryl bromide or dodecane as an internal standard.

Preface

In Honour of Professor Mike Hursthouse

Professor Michael B. Hursthouse

When we were recruiting a Lecturer in Inorganic Chemistry at QMC in 1966 I insisted that we should appoint someone who had experience in X-ray crystallography and fortunately we were able to appoint Mike to that post.

Although he had only a second-hand manual diffractometer at his disposal, Mike swiftly settled in and, with his characteristic drive and energy, established a productive X-ray structural group. He was a charismatic teacher who introduced his subject into the undergraduate curriculum. Soon he was attracting substantial research funds and in 1978 obtained a computer-controlled automated diffractometer which transformed the output of structures and enabled him to broaden his collaborations both within and outside the Department. A particularly fruitful collaboration was with Sir Geoffrey Wilkinson at Imperial College. Mike was appointed Reader in Structural Chemistry in 1979 and to a Personal Chair in 1987. Meanwhile he had established a National Crystallographic Service with funding from the Science Research Council, a resounding success, and was becoming recognised worldwide. He also played a leading role with the RSC Chemical Crystallography Group being Chairman from 1983 to 1986.

When I became Executive Editor of *Polyhedron* in 1981, I was fortunate in persuading Mike to deal with the X-ray structural content of all papers submitted to the journal thus establishing the high standards associated with that publication.

Sadly for QMC, Mike was appointed to the Established Chair of Structural Chemistry in the University of Wales, Cardiff, in 1991, then moving to his present Chair at Southampton in 1998.

Mike Hursthouse was an inspiring teacher of undergraduate and postgraduate students and a congenial colleague who enlivened Staff meetings with his forthright contributions.

It was a privilege and a great pleasure having him as a colleague and a friend for life.

Note from the Editors

As past PhD students of Mike Hursthouse we were pleased to be asked to serve as guest editors for this special issue of *Polyhedron*. It is testimony to the respect and affection that colleagues have for Mike that all the authors we approached were immediately enthusiastic about contributing to the issue. We thank them for their submissions, the referees for their hard work and constructive comments, and the editorial and production staff at Elsevier for bringing this issue to fruition to coincide with Mike's 65th birthday.

Dedicated to Prof. M.B. Hursthouse on the occasion of his 65th birthday, in recognition of the enormous contibution he has made to chemical crystallography.

Abstract

Reduction of the sulfur–sulfur bond of naphtho[1,8-*cd*]-1,2-dithiole with 2 equivalents of $Li(BEt)_3H$ to give the dilithium salt followed by the addition of an equivalent of bis(pentamethyl)metallocene dichloride $[(Cp)^*_2MCl_2, M = Ti, Zr, Hf, Cp^* = C_5Me_5]$ gives the sulfur bonded complexes $(Cp)^*_2TiS_2C_{10}H_6$ (**1**), $(Cp)^*_2ZrS_2C_{10}H_6$ (**2**) and $(Cp)^*_2HfS_2C_{10}H_6$ (**3**) containing six-membered MS_2C_3 rings. The products were obtained in moderate yield as crystals and have been fully characterised and had their X-ray crystal structures determined.

Keywords: Complex; Thiolates; X-ray structure; Titanium; Sulfur

1. Introduction

The chemistry of the group IV metallocenes has been extensively studied with the majority of the work on complexes of titanocene. Complexes containing a bidentate ligand bound to titanium are quite common, with many examples via a pair of chalcogen atoms. These chalcogens can be bridged by groups such as other chalcogen atoms to give a polychalcogen ring [1,2], phosphorus [3], alkyl groups [4] or nitrogen [5]. Titanocene can also give complexes bound to two monodentate ligands which are essentially similar complexes where the two chalcogen atoms are not connected to each other [6]. These have practical uses in that they can be used in ligand transfer to give platinum thiolato complexes [7]. More recently, we have synthesised a series of titanocene complexes containing a mixture of thiolato, sulfinato and sulfenato ligands [8] linked by an organic aromatic backbone. Dimeric titanocene complexes with two bridging thiolato ligands have been reported [9] and shown to exhibit crown ether like properties, with a silver or copper cation contained in the centre of the structure.

Complexes of zirconocene with a bidentate phosphorus ring [10] or sulfur ring [1], or with two monodentate nitrogen bound ligands have been described [11]. The majority of other chalcogen containing zirconocene complexes contain either two monodentate ligands [12–15] or exist as dimers with two bridging chalcogen atoms [16–18].

Hafnocene is known to exist in a similar complex to zirconocene with two phosphorus atoms bound to the hafnium atom and another phosphorus atom bridging the two to give a four-membered ring [10] and $Cp^*_2HfH_2$ has also been shown to react with RN_3 to give

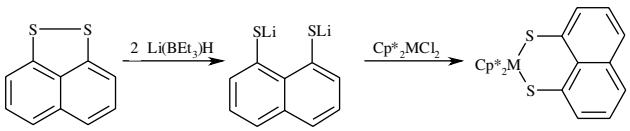
doi:10.1016/j.poly.2005.07.009

an interesting complex with a bidentate N_3 ligand which will lose N_2 at 80 °C [19]. Hafnocene complexes with two monodentate ligands bound through carbon [20] which will thermally decompose to give a complex containing one bidentate ligand are known. Similarly to titanocene and zirconocene complexes, hafnocene complexes with two monodentate sulfur bound ligands have also been described [21] while a dimeric structure with two bridging chalcogen atoms has been reported [18].

However, there are very few examples of a homologous series of complexes being produced to allow comparison of all three members of the group. Here, we report the synthesis and X-ray crystal structures of a series of three group IV metallocene complexes containing a bidentate aromatic ligand bound to the metal centre through two sulfur atoms.

2. Results and discussion

The salt elimination reactions of the dilithium salt of naphtho[1,8-*cd*]-1,2-dithiole with the group IV bis(pentamethyl)metallocene dichlorides $Cp^*_2MCl_2$ (M = Ti, Zr, Hf) proceed smoothly in tetrahydrofuran at room temperature to give $Cp^*_2TiS_2C_{10}H_6$ (**1**), $Cp^*_2ZrS_2C_{10}H_6$ (**2**) and $Cp^*_2HfS_2C_{10}H_6$ (**3**) in moderate yield (34–64%)



(1)

The purification and isolation of these compounds is straightforward; removal of insoluble salts by re-dissolving in toluene and filtering through celite followed by recrystallisation from toluene/hexane gives crystals which are of extremely high purity. The ^{1}H NMR data (CD_2Cl_2) for complexes **1**–**3** all show the expected peaks, with three separate multiplets in the aromatic region (7.05–7.52 ppm) representing the three pairs of different protons on the naphthalene backbone and a singlet at 1.81, 1.84 and 1.87 ppm, respectively, representing the 10 methyl groups on the cyclopentadienyl rings. No fluxionality was noticed in the ^{1}H NMR spectra of these complexes down to 183 K. The ^{13}C NMR (CD_2Cl_2) are also excellent, each displaying the three quaternary and three non quaternary peaks of the naphthalene backbone plus a peak representing the quaternary carbon atoms of the cyclopentadienyl rings and a single peak at 12.7, 11.6 and 10.5 ppm, respectively, representing the carbon of the ten methyl groups bound to the cyclopentadienyl rings.

Excellent elemental analyses were obtained for all complexes and electrospray mass spectral data were consistent with the proposed structures showing in each case $[M]^+$ and $[M + Na]^+$.

3. Molecular structures

The crystal structures of **1**–**3** (Fig. 1, Tables 1 and 2) are very similar, indeed they are isomorphous which allows for a comparison of bond lengths and angles which are not influenced by packing effects. All three complexes exist in an envelope conformation folded along the sulfur–sulfur axis. The S–M–S bond angles are in the range 82.40(2)–83.82(4)°; close to previously studied complexes containing a six-membered TiS_2C_3 ring [8]. The other angles in these six-membered rings are also in accord with the literature values. The angle which varies most markedly between the three complexes is the splay angle (the deviation from the two S–C bonds being parallel). The splay angles of complexes **1**–**3** are 21.0°, 22.8° and 22.9°, respectively. This can be explained by the size of the metal atom which is between the two sulfur atoms, resulting in longer M–S distances and causing the S–C bonds to stray from being parallel. Zirconium has a greater atomic radius than titanium, therefore it forces the sulfur atoms further apart and gives a larger splay angle. Hafnium has a very similar atomic radius to zirconium so has a similar effect on the splay angle. The bond lengths in **1**–**3** are also very similar and are close to the values in related complexes. The only bond lengths which differ slightly are the M–S and M–Cp bond lengths. The M–S(1) bond lengths of complexes **1**–**3** are 2.406(2), 2.5033(7) and 2.4832(13) Å, respectively, while the M–S(9) bond lengths are 2.428(2), 2.5107(7) and 2.4901(10) Å. These results are to be expected when the atomic radii of the three metal atoms are considered. The M–S bond lengths are very close to similar complexes [12–14,17,21–25]. This pattern where the Zr–S and Hf–S bond lengths are both very similar and noticeably longer than the Ti–S bond length has been seen before in a series of group IV metallocene complexes [26]. The M–Cp bond lengths show an identical pattern to that previously mentioned for the M–S bond lengths.

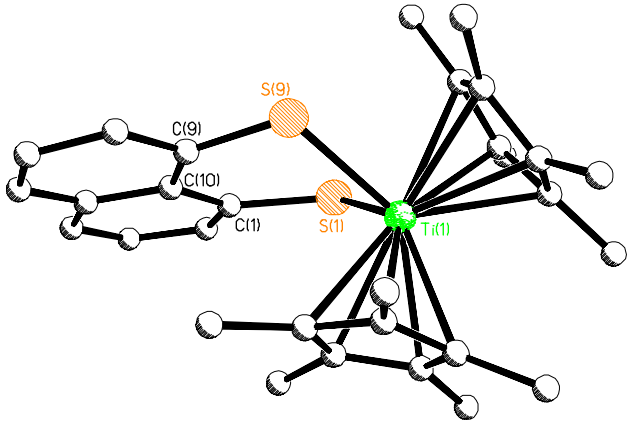


Fig. 1. Molecular structure of $Cp^*_2Ti(S_2C_{10}H_6)$ **1** in the crystal. The structures of **2** and **3** are isomorphous and have been numbered analogously.

4. Conclusion

We have prepared and fully characterised a series of new group IV complexes (M = Ti, Zr, Hf) by reduction of the sulfur–sulfur bond of naphtho[1,8-*cd*]-1,2-dithiole with two equivalents of super hydride ($LiBEt_3H$) followed by the addition of one equivalent of $Cp^*_2MCl_2$. We have also made a good comparison of the bond lengths and angles around the central metal atom.

5. Experimental

5.1. General

Manipulations were performed under an oxygen free nitrogen atmosphere using standard Schlenk techniques and glassware. Solvents were dried, purified and stored according to common procedures [27]. The compound, naphtho[1,8-*cd*]-1,2-dithiole, was prepared according to the literature procedures [28,29].

^{1}H (270 MHz) and ^{13}C (67.9 MHz) NMR spectra were recorded on a Jeol DELTA GSX270 spectrometer with δ(H) and δ(C) referenced to external Me_4Si. Elemental analyses were performed by the University of St. Andrews Microanalysis Service and ES$^+$ mass spectra were carried out by the University of St. Andrews Mass Spectrometry Service.

5.2. Bis(pentamethyl)titanocene 1,8-dithiolato-naphthalene (*1*)

Naphtho[1,8-*cd*]-1,2-dithiole (0.072 g, 0.38 mmol) was dissolved in tetrahydrofuran (10 cm^3) and a 1.0 M solution of $LiBEt_3H$ (0.75 cm^3, 0.75 mmol) was added via syringe. Upon addition, an immediate colour change

from red to pale yellow was observed along with the evolution of gas. Bis(pentamethyl) titanocene dichloride (0.147 g, 0.38 mmol) was added and this solution was allowed to stir for 24 h. The solvent was removed under reduced pressure and the residue extracted into hot toluene. This was filtered through celite, dried and recrystallised from toluene/hexane to give green crystals. Yield: 0.125 g, 64%. Microanalysis: *Anal.* Calc. for $C_5Me_{52}TiS_2C_{10}H_6$: C, 70.84; H, 7.13; S, 12.58. Found: C, 70.79; H, 7.55; S, 12.36%. ^{1}H NMR (CD_2Cl_2): $\delta =$ 7.41 (dd, 2H, aromatics), 7.33 (dd, 2H, aromatics), 7.05 (td, 2H, aromatics), 1.81 (s, 30H, $10 \times$ Me). ^{13}C NMR (CD_2Cl_2): $\delta = 147.8$, 137.0, 120.6 (all quaternary aromatic), 134.4, 124.6, 123.6 (all aromatic), 125.1 (aromatic Cp groups), 12.7 (methyl). ES$^+$ MS: *m*/*z*, 531 $[M + Na]^+$, 508 $[M]^+$.

5.3. Bis(pentamethyl)zirconocene 1,8-dithiolatonaphthalene (2)

This was prepared as per compound **1** using naphtho[1,8-*cd*]-1,2-dithiole (0.072 g, 0.38 mmol) and Bis(pentamethyl) zirconocene dichloride (0.164 g, 0.38 mmol) to give **2** as dark red crystals. Yield: 0.071 g, 34%. Microanalysis: *Anal.* Calcd. for $C_5Me_{52}ZrS_2C_{10}H_6$: C, 65.43; H, 6.59; S, 11.62. Found: C, 65.26; H, 6.58; S, 11.83%. ^{1}H NMR (CD_2Cl_2): $\delta = 7.52$ (dd, 2H, aromatics), 7.38 (dd, 2H, aromatics), 7.07 (td, 2H, aromatics), 1.84 (s, 30H, $10 \times$ Me). ^{13}C NMR (CD_2Cl_2): $\delta = 144.8$, 139.9, 121.8 (all quaternary aromatic), 136.4, 123.8, 122.1 (all aromatic), 125.8 (aromatic Cp groups), 11.6 (methyl). ES$^+$ MS: *m*/*z*, 573 $[M + Na]^+$, 550 $[M]^+$.

5.4. Bis(pentamethyl)hafnocene 1,8-dithiolatonaphthalene (3)

This was prepared as per compound **1** using naphtho[1,8-*cd*]-1,2-dithiole (0.072 g, 0.38 mmol) and Bis(pentamethyl) hafnocene dichloride (0.197 g, 0.38 mmol) to give **3** as dark red crystals. Yield. 0.087 g, 36%. Microanalysis: *Anal.* Calc. for $(C_5Me_5)_2HfS_2C_{10}H_6$: C, 56.23; H, 5.66; S, 9.52. Found: C, 56.70; H, 5.91; S, 9.99%. ^{1}H NMR (CD_2Cl_2): $\delta = 7.51$ (dd, 2H, aromatics), 7.34 (dd, 2H, aromatics), 7.08 (td, 2H, aromatics), 1.87 (s, 30H, $10 \times$ Me). ^{13}C NMR (CD_2Cl_2): $\delta = 137.4$, 126.2, 123.7 (all quaternary aromatic), 128.0, 121.7, 116.0 (all aromatic), 117.3 (aromatic Cp groups), 10.5 (methyl). ES$^+$ MS: *m*/*z*, 663 $[M + Na]^+$, 640 $[M]^+$.

5.5. Crystal structure analysis

Single crystals suitable for X-ray diffraction studies of compounds $Cp^*_2TiS_2C_{10}H_6$ (**1**), $Cp^*_2ZrS_2C_{10}H_6$ (**2**) and $Cp^*_2HfS_2C_{10}H_6$ (**3**) were obtained by recrystallisation from toluene/hexane.

Data for **1**, **2** and **3** were collected at 93 K using a Rigaku MM007/Mercury CCD diffractometer (Mo Kα radiation, confocal optic $\lambda = 0.71073$ Å). All refinements were performed using SHELXTL (Version 6.10, Bruker AXS, 2002). In **3**, the large residual peak in the final map is located close to the Hf atom.

Dedicated to Professor M.B. Hursthouse on the occasion of his 65 birthday.

Abstract

The structure of $W_2(OBu^t)_6$ was determined via a single crystal X-ray diffraction study. In the space group *C2/c*, there are 1.5 $W_2(OBu^t)_6$ molecules in the asymmetric unit, with one half molecule located on a crystallographic inversion center and one full molecule in a general position. The W≡W bond distances are 2.328(1) and 2.335(1) Å and the average W–O distances are 1.89(1) Å. The alkoxide alkyl groups are found oriented in the "one distal, two proximal" arrangement with respect to the W–W vector, giving on average, W–W–O angles of 99(1)° for the distal alkoxide and 110(1)° for the proximal. This arrangement is common to other $W_2(OR)_6$ compounds. Computational studies employing density functional theory on several conformers of the model compound $W_2(OMe)_6$ were undertaken. The results for the total bonding energies for each conformer indicate that this "one distal, two proximal" arrangement is only slightly more stable than the all-distal, D_{3d} and the alkoxide-eclipsed D_{3h} structures in the gas phase. This small difference in conformer energy suggests that the proximality preference is likely due to steric effects that are important in the solid state.

1. Introduction

$W_2(OBu^t)_6$ was among the first of the reported ethane-like $(M{\equiv}M)^{6+}$ triply-bonded dimers of formula $X_3M{\equiv}MX_3$, where M = Mo, W [1]. It is prepared by the alcoholysis of $W_2(NMe_2)_6$ with 6 or more equivalents of Bu^tOH in hydrocarbon solvents [2]. The preferred method of purification is crystallization by the cooling of concentrated solutions of $W_2(OBu^t)_6$ in aliphatic hydrocarbon solvents. Crystallization in this manner yields ruby-red, plate-like crystals [2].

$W_2(OBu^t)_6$ exhibits a varied and rich chemistry. It undergoes reversible association with Lewis bases such as pyridine [3]. It also undergoes metathesis with various alkynes and organic nitriles to give alkylidynes $(Bu^tO)_3W{\equiv}CR$ and the nitride $(Bu^tO)_3W{\equiv}N$ [4]. It reacts with NO to give oxidative cleavage of the WW triple bond [5]. and with ethyne [6] and allene [7] to give π-adducts. The ethyne adduct exists in equilibrium with the methylidyne complex and undergoes coupling with additional ethyne to give $W_2(\mu\text{-}C_4H_4)(OBu^t)_6$ [6a]. The addition of CO to $W_2(OBu^t)_6$ yields a carbonyl adduct $[W_2(\mu\text{-}CO)(OBu^t)_6]_2$ with a remarkably low CO stretching frequency, $\upsilon(CO) = 1575\ cm^{-1}$ [8]. The W–O bonds are labile toward insertion reactions with CO_2 [9] and arylcyanates, ArNCO [10]. In reactions with less sterically-demanding alcohols, tetranuclear clusters such as $W_4(OPr^i)_{12}$ [11] and $W_4(OR)_{12}(HOR)$ [12] are obtained where R = CH_2-c-Bu and CH_2-c-Pen.

Despite this extensive coordination chemistry, the molecular structure of $W_2(OBu^t)_6$ was not previously

doi:10.1016/j.poly.2005.07.010

determined. Several attempts (by various research groups) have been made to study the compound by single-crystal X-ray crystallography. In all cases, the ruby-red crystals either failed to yield good diffraction data or the data proved insufficient for a structure determination. Other $W_2(OR)_6$ compounds have been crystallographically characterized, e.g., for $R = Pr^i$, C_6H_{11}, and $SiMe_2Bu^t$ [13]. The latter compound contained a disordered W_2 unit within the cage of a pseudo octahedral $OSiMe_2Bu$ ligands. There was little doubt that $W_2(OBu^t)_6$ was structurally related to these compounds; however, interest has remained in its structure as it sometimes shows different reactivity from other members of this family. Furthermore, spectroscopic studies have been conducted on $W_2(OBu^t)_6$, in which knowing the experimental bonding parameters, especially the W–W–O and W–O–C angles, would prove useful.

One interesting characteristic of the $X_3W{\equiv}WX_3$ compounds, where $X = CH_2R$ or OR was pointed out by Gilbert et al. in a recent study [13a]. This characteristic is the varied arrangements of the R-alkyl substituents with respect to the WW vector. The $M_2(NMe_2)_6$ compounds, where M = Mo and W, exhibit well-defined proximal and distal methyl substituents due to a strong N(p) to unfilled WW δ and δ^* donation [14]. This donation relieves some of the electronic deficiency on the formally 12 e^- W atoms. However, within the $W_2(OR)_6$ compounds, the O(p) WW δ and δ^* donation may occur when the alkyl substituents align in either of the proximal/distal combinations. This preference has been further examined in this work by employing DFT computations on several conformers of the model compound $W_2(OMe)_6$.

2. Experimental

2.1. Synthesis and X-ray structure determination of $W_2(OBu^t)_6$

$W_2(OBu^t)_6$ was synthesized via the alcoholysis of $W_2(NMe_2)_6$ with a fourfold excess (24 equiv.) of Bu^tOH in thf. The reaction is slow in this solvent and the reaction solution must be stirred for several days for the reaction to proceed to completion at room temperature. Crystals of the product were grown by a slow evaporation of the thf/Bu^tOH solution. The identity of the product was confirmed by ^1H NMR spectroscopy (δ 1.62 in benzene-d_6 solution).

The data collection crystal was a red-orange plate. Examination of the diffraction pattern on a Nonius Kappa CCD diffractometer indicated a monoclinic crystal system. All work was done at 200 K using an Oxford Cryosystems Cryostream Cooler. The data collection strategy was set up to measure a quadrant of reciprocal space with a redundancy factor of 4.2, which means that 90% of the reflections were measured at least 4.2 times. A combination of φ and ω scans with a frame width of 1.0° was used.

The initial unit cell obtained at 200 K for the data collection crystal was a C-centered monoclinic cell with $a = 28.614$ Å, $b = 17.339$ Å, $c = 9.845$ Å and $\beta = 95.27°$. But data integration did not proceed well with this cell and it was discovered that the unit cell had changed during data collection. A new unit cell was obtained at the end of data collection by using only the latter half of the frames. This new unit cell is also C-centered monoclinic, but it has twice the volume of the original unit cell with the c axis almost doubled and the β angle slightly smaller by 3°: $a = 29.196(2)$ Å, $b = 17.349(2)$ Å, $c = 19.227(2)$ Å and $\beta = 92.222(3)°$. The crystal quality at the end of data collection was not as good as it was at the beginning of data collection. It appeared that the crystal had undergone a phase transition during data collection. [A DSC scan of $W_2(OBu^t)_6$ revealed that there is a phase transition for the crystalline solid near −10 °C.] With the data crystal still on the diffractometer, the temperature of the Cryostream was increased from 200 to 260 K and the unit cell was redetermined. The original small unit cell was found at this temperature.

In order to salvage this data set, only the latter half of the data set was used and it was integrated with the larger unit cell. This latter half of the data set consists of 253 frames out of a total of 531 frames, or 48% of the data. Because the data set was collected with a redundancy factor of 4, we were able to salvage enough of the data set to obtain a reasonable structure. Data integration was done with Denzo [15], and scaling and merging of the data were done with Scalepack [15]. Merging the data and averaging the symmetry equivalent reflections resulted in an R_{int} value of 0.085.

The structure was solved by the Patterson method in *C2/c* using SHELXS-97 [16a]. There are 1.5 molecules in the asymmetric unit: one molecule (labeled as A) contains a crystallographic inversion center and the second one (labeled as B) is located on a general position. During the final stages of refinement, the difference electron density map shows large peaks at about 4–5 e $Å^{-3}$ located near the W–W portions of both molecule A and molecule B. These peaks could be construed to be alternate positions of the W–W atoms, with the assumption that the dimer is disordered over several orientations.

Some of these large residual peaks associated with molecule B were labeled as W atoms, with pairs of peaks chosen which are approximately 2.3 Å apart. Among these, there are three W–W pairs, which may represent alternative orientations of the W–W vector. All of the occupancy factors for these W atoms were tied together with the SUMP command. One of the Bu^t groups of molecule A is disordered and is treated with a second orientation (C6AA, C7AA and C8AA). Both sets of carbon atoms for this group are kept isotropic. Full-matrix

least-squares refinements based on F^2 were performed in SHELXL-97 [16b], as incorporated in the WINGX package [17].

The hydrogen atoms were included in the model at calculated positions using a riding model with U(H) = 1.5* Ueq(attached C atom). The final refinement cycle was based on 7785 intensities, 459 variables and 22 restraints and resulted in agreement factors of $R_1(F) = 0.135$ and $wR_2(F^2) = 0.208$. For the subset of data with $I > 2^*\sigma(I)$, the $R_1(F)$ value is 0.072 for 4562 reflections. The final difference electron density map contains maximum and minimum peak heights of 5.00 and −1.94 e Å^{-3}. The largest peaks are still near the W atoms. Neutral atom scattering factors were used and include terms for anomalous dispersion [18]. The experimental details for the X-ray structure determination of $W_2(OBu^t)_6$ are summarized in Table 1. Two separate attempts to conduct X-ray studies at other temperatures, 260 and 120 K, resulted in data sets from which no solution could be obtained.

Table 1
Crystallographic, experimental details for $W_2(OBu^t)_6$

Empirical formula	$C_{24}H_{54}O_6W_2$
Formula weight	806.37
Temperature	200(2) K
Wavelength	0.71073 Å
Crystal system	monoclinic
Space group	*C2/c*
Unit cell dimensions	
a (Å)	29.196(2)
b (Å)	17.349(2)
c (Å)	19.227(2)
β (°)	92.222(3)
Volume (Å)	9732(2)
Z	12
D_{calc} (Mg m^{-3})	1.651
Absorption coefficient (mm^{-1})	7.116
F(000)	4728
Crystal size (mm^3)	0.08 × 0.19 × 0.23
θ Range for data collection (°)	2.12–25.03
Index ranges	$-34 \leqslant h \leqslant 34$, $-20 \leqslant k \leqslant 20$, $-22 \leqslant 1 \leqslant 22$
Reflections collected	25016
Independent reflections [R_{int}]	7785 [0.085]
Completeness to $\theta = 25.03°$	90.5%
Refinement method	full-matrix least-squares on F^2
Data/restraints/parameters	7785/22/459
Goodness of fit on F^2	1.069
Final *R* indices [$I > 2\sigma(I)$]	$R_1 = 0.0719$, $wR_2 = 0.1710$
R indices (all data)	$R_1 = 0.1348$, $wR_2 = 0.2078$
Largest difference in peak and hole	5.00 and −1.94 e Å^{-3}

2.2. DFT computational study of several isomers of $W_2(OMe)_6$

Density functional theory calculations were performed using the Amsterdam Density Functional (ADF) program, version 2002.03, developed by Baerends et al. [19] and vectorized by Ravenck [20]. The numerical integration scheme used was developed by te Velde et al. [21], and the geometry optimizations were carried out under full symmetry using the local exchange-correlation potential of Vosko et al. [22] and the non-local exchange and correlation corrections of Perdew and Wang (PW91) [23]. For tungsten, the electronic configuration was described using a double-ζ STO basis for 5s and a triple-ζ for 6s, 5p, 5d and 4f, augmented by a 6p and a 5f polarization function. The core was frozen and was defined to be 4d and below. For oxygen and carbon, a triple-ζ STO basis was used for the valence 2s and 2p orbitals, augmented by a 3d and a 4f polarization function, with the core 1s frozen. Hydrogen was also treated using a triple-ζ STO basis for its 1s, and was augmented with a 2p and a 3d polarization function. All atoms were also corrected for relativistic effects using the zeroth order regular approximation (ZORA) [24] method. All accuracy and convergence parameters were left at the default level, with the exception of the general integration accuracy, which was set to 7.0. Total bonding energies in ADF are calculated with respect to dissociation into spin-restricted fragment atomic in the gas phase.

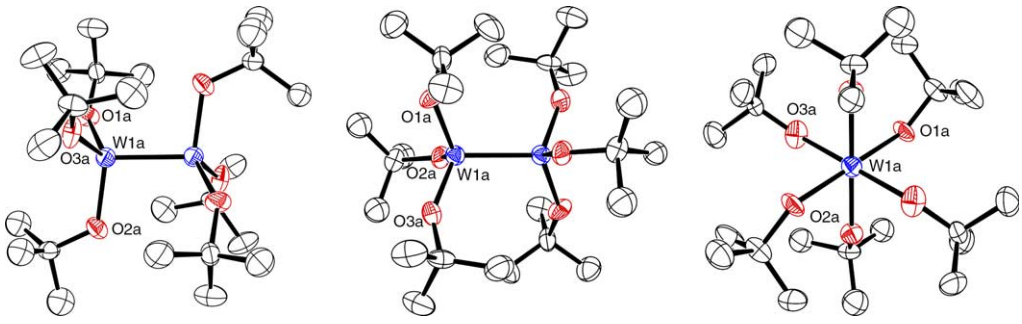

Fig. 1. Three orientations of $W_2(OBu^t)_6$; molecule **A**. Only one Bu^t orientation is shown for the disordered Bu^t group. Only one set of symmetry equivalent atoms is labeled. The symmetry transformation to generate equivalent atoms is: $-x+2,-y+1,-z+1$. Thermal ellipsoids are drawn at the 30% probability level.

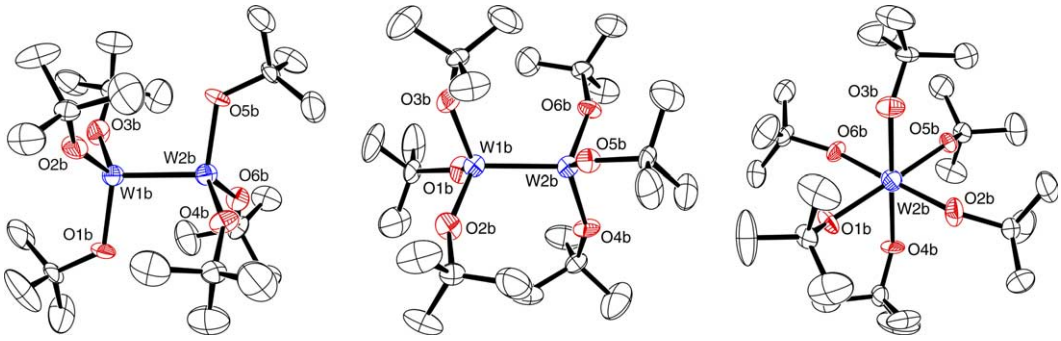

Fig. 2. Three orientations of $W_2(OBu^t)_6$; molecule **B**. Thermal ellipsoids are drawn at the 30% probability level.

3. Results and discussion

3.1. X-ray crystal structure of $W_2(OBu^t)_6$

The structure solution reveals 1.5 molecules in the asymmetric unit, which give two dinuclear species upon expansion of the unit cell. The molecule located on a crystallographic inversion center is labeled **A**, and the molecule located on a general position is labeled molecule **B**. Several views of the refined geometries for these molecules **A** and **B** are shown in Figs. 1 and 2.

For both independent molecules **A** and **B**, there were extra peaks located in the difference map corresponding to what may be construed as different orientations of W atoms within the six alkoxide ligand framework. The W atoms depicted for molecule **A** were the only W atoms refined for molecule **A**. Although there was one other "W" atom of less than 4% occupancy that gives a WW bond of ca. 2.5 Å, this tungsten atom was not included in the model for molecule **A**. The W–W orientation depicted for molecule **B** in Fig. 1 is the major W–W contributor found at 86% occupancy. There are three other W–W atom pairs of less occupancy located for molecule **B** and these can be construed as alternate representations of the W–W species within the ligand environment of six alkoxides (see Figs. 3 and 4). The problem of multiple W–W orientations was also reported to occur in the X-ray structure refinement for the related compounds: $W_2(OAdamantyl\text{-}C_5H_{11})_6$ [13a] and $W_2(OSiMe_2Bu^t)_6$ [13c].

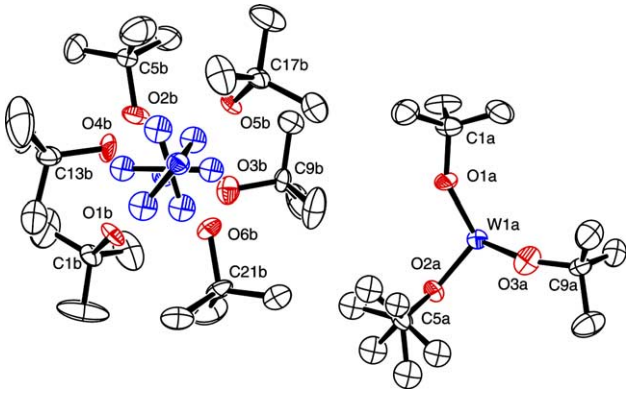

Fig. 3. The asymmetric unit of $W_2(OBu^t)_6$. All three major W–W orientations for molecule **B** are shown. The alternate Bu^t orientation for C(5) on molecule **A** is also shown. Only the quaternary carbon atoms for each Bu^t group are labeled.

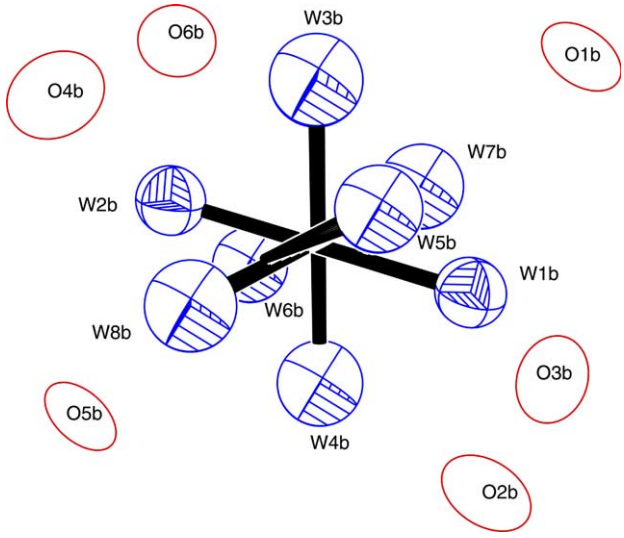

Fig. 4. Diagram indicating the refined W–W moieties for molecule **B** of $W_2(OBu^t)_6$. W(1b)–W(2b) is the unit that refined with the largest occupancy (>86%).

Table 2
Selected W–W and W–O bond distances and e.s.d.'s for $W_2(OBu^t)_6$; molecules **A** and **B**

Bond type	Molecule **A**		Molecule **B**	
	Bond descriptor	Distance (Å)	Bond descriptor	Distance (Å)
W–W	W(1A)–W(1A)*	2.328(1)	W(1B)–W(2B)	2.335(1)
W–O	W(1A)–O(1A)	1.88(1)	W(1B)–O(1B)	1.92(1)
	W(1A)–O(2A)	1.92(1)	W(1B)–O(2B)	1.84(1)
	W(1A)–O(3A)	1.89(1)	W(1B)–O(3B)	1.91(1)
			W(2B)–O(4B)	1.87(1)
			W(2B)–O(5B)	1.91(1)
			W(2B)–O(6B)	1.84(1)

Table 3
Refined W–W bond distances and occupancy factors for molecules **A** and **B**

Bond descriptor	Distance (Å)	Occupancy factor
W(1A)–W(1A)*	2.328(1)	1.000
W(1B)–W(2B)	2.335(1)	0.864(3)
W(3B)–W(4B)	2.27(2)	0.063(3)
W(5B)–W(6B)	2.30(2)	0.046(3)
W(7B)–W(8B)	2.24(3)	0.049(3)

Selected bond distances and angles for molecules **A** and **B** are shown in Tables 2–4. Table 3 contains the W–W bond lengths and occupancy factors for all of the refined W–W units in the structure of $W_2(OBu^t)_6$. The W–O bond distances for the lesser W–W contributors for molecule **B** are not reported here. They have been calculated for each W–W orientation and fall within the range of 1.74 to 2.53 Å. It is likely that the refined orientation of oxygen atoms does not represent the true environment of alkoxide oxygen atoms for the smaller W–W contributors and that the true oxygen peaks are lost within the background of this problematic structure.

4. Electronic structure calculations

$W_2(OR)_6$ compounds are only isolable when R is bulky. Bulky alkoxide ligands lead to a staggered W_2O_6 skeleton as a result of the minimization of alkyl–alkyl repulsions across the WW bond. However, for $W_2(O\text{-}c\text{-}C_6H_{11})_6$, a near eclipsed W_2O_6 skeleton is present. One other interesting feature is seen in the geometries of $W_2(OR)_6$ compounds and that is the orientation of alkyl groups with respect to the W–W bond. These can be either directed over the WW bond and termed "proximal" or directed away or "distal". An all proximal arrangement leads to steric congestion over the MM bond although this arrangement is seen for the secondary alkoxide $W_2(O\text{-}c\text{-}C_6H_{11})_6$. An all-distal arrangement maximizes steric repulsion along the axes of the WW bond and has not been observed in the known structures of $W_2(OR)_6$ compounds. A more common geometry is that wherein one distal and two proximal alkoxide arrangement is present at each tungsten center with an overall approximation to C_{2h} symmetry. Intuitively, this would seem to represent a best structure based on a compromise or minimization of steric repulsive interactions. This structure is seen here for

Table 4
Selected WWO, OWO, and WOC bond angles for molecules **A** and **B**

Angle type	Molecule **A**		Molecule **B**	
	Angle descriptor	Angle (°)	Angle descriptor	Angle (°)
W–W–O	W(1A)*–W(1A)–O(1A)	110.3(4)	W(2B)–W(1B)–O(1B)	99.4(4)
	W(1A)*–W(1A)–O(2A)	98.6(3)	W(2B)–W(1B)–O(2B)	109.7(4)
	W(1A)*–W(1A)–O(3A)	111.0(4)	W(2B)–W(1B)–O(3B)	109.8(4)
			W(1B)–W(2B)–O(4B)	107.7(4)
			W(1B)–W(2B)–O(5B)	99.6(4)
			W(1B)–W(2B)–O(6B)	109.8(4)
O–W–O	O(1A)–W(1A)–O(2A)	116.3(5)	O(1B)–W(1B)–O(2B)	113.9(6)
	O(1A)–W(1A)–O(3A)	106.8(5)	O(1B)–W(1B)–O(3B)	116.0(6)
	O(2A)–W(1A)–O(3A)	113.7(5)	O(2B)–W(1B)–O(3B)	107.7(6)
			O(4B)–W(2B)–O(5B)	117.3(6)
			O(4B)–W(2B)–O(6B)	110.1(6)
			O(5B)–W(2B)–O(6B)	111.6(6)
W–O–C	W(1A)–O(1A)–C(1A)	145.7(9)	W(1B)–O(1B)–C(1B)	123(1)
	W(1A)–O(2A)–C(5A)	122.8(9)	W(1B)–O(2B)–C(5B)	154(1)
	W(1A)–O(3A)–C(9A)	150(1)	W(1B)–O(3B)–C(9B)	146(1)

	View down x-axis	View down y-axis	View down z-axis	relative TBE (kcal mol^{-1})
dpp				0
ecl				+ 20.89
ddd				+ 21.17

$W_2(OBu^t)_6$ and was also found for W_2(OAdamantyl-$C_5H_{11})_6$ [13a] (see Table 5).

In order to interrogate the role of steric and electronic factors influencing the structures of the $W_2(OR)_6$ molecule, we carried out electronic structure calculations on the model compound $W_2(OMe)_6$ in various conformations. The specific conformers investigated were D_{3d} and D_{3h} isomers having all distal methyl groups and the C_{2h} molecule having two distal and one proximal alkoxide alkyl substituents. Each structure was allowed to optimize within the overall symmetry constraint: D_{3h}, D_{3d} or C_{2h}. The calculated metric parameters are listed in Table 6. The calculated energies of these three structures varied by less than 22 kcal mol^{-1} with the C_{2h} structure being the calculated minimum energy structure. This small difference in energy certainly supports the view that geometries seen in the solid-state are almost entirely a consequence of steric factors. Inversion at oxygen (through W–O–C = 180°) will readily allow the interconversion of a proximal/distal arrangement of alkyl groups about the WW axis (see Table 7).

Table 7
Calculated bonding parameters for the converged geometries of the three $W_2(OMe)_6$ isomers

Distance (Å) or angle (°)	ddd	dpp	ecl
W–W	2.319	2.326	2.330
W–O	1.935	1.899 (p) 1.930 (d)	1.927
O–C	1.444	1.436 (p) 1.426 (d)	1.432
W–W–O	100.9	101.0 (p) 104.8 (d)	100.8
O–W–O	116.5	110.2 (p. to d.) 117.0 (d. to d.)	116.6
W–O–C	124.2	116.7 (p) 132.7 (d)	119.0

5. Concluding remarks

The crystal and molecular structure of $W_2(OBu^t)_6$ has finally been solved and the problems observed in determining its structure reveal insight into why earlier attempts were unsuccessful. The arrangement of the Bu^t groups in a two-proximal plus one distal manner at each W center, together with the disorder of the WW axis and one Bu^t alkyl group is as seen for other $W_2(OR)_6$ compounds (R = adamantly and $SiMe_2Bu^t$) [13] and, together with the electronic structure calculations on the model compound $W_2(OMe)_6$, testify to the dominant role of steric factors in the packing of the R groups at the dimetal center.

6. Crystallographic data

Crystallographic data for the title compound is available from the Cambridge Crystallographic Center, CCDC #263305. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: + 44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

This study is dedicated to Prof. Mike Hursthouse, University of Southampton, on the occasion of his 65th birthday.

Abstract

The reaction of $RhCl_3 \cdot 3H_2O$ with $SbPh_3$ (Ph, C_6H_5) in ethanol produced *mer*-[$RhCl_3(SbPh_3)_3$] (**1**), as the main product, together with *trans*-[$RhCl_2(Ph)(SbPh_3)_3$] (**2**) (R. Cini, G. Giorgi, L. Pasquini, Inorg. Chim. Acta 196 (1992) 7; A. Cavaglioni, R. Cini, J. Chem. Soc., Dalton Trans. (1997) 1149). Ways to improve the yield for **1** and **2** were a subject of further works by this laboratory during the past decade and the reactivity of the organometallic compound **2** was investigated towards a variety of bases. Long sought single crystals of **1** suitable for X-ray diffraction have been obtained from hot acetone solution. The metal centre has a pseudo-octahedral coordination environment with the three chloride anions and the three $SbPh_3$ molecules in *mer* positions. The Rh–Cl bond *trans* to Sb is significantly weakened by the high *trans* influence by antimony itself. This gives the rationale for the formation of **2** from $RhCl_3$ and $SbPh_3$ via the preliminary formation of **1**, followed by dissociation of the activated chloride anion, and the subsequent formation of the Rh–C(Ph) linkage. The reaction of **1** with 2-thio-1,3-pyrimidine (Htpym) in ethanol produces crystalline [Rh($\underline{N}^1$,$\underline{S}^2$-tpym)$_2$($\underline{N}^1$(Sb),$\underline{S}^2$(Rh)-tpym)($SbPh_3$)] (**3**). Single crystals suitable for X-ray diffraction studies as obtained from ethanol/diethyl-ether contain a complex molecule and a quarter of an ethanol molecule in the asymmetric unit. Two out of three $tpym^-$ anions chelate the metal centre via the N^1 and S^2 atoms, whereas the third $tpym^-$ anion behaves as mono-dentate through the S^2 atom only. The sixth co-ordination position is occupied by the Sb atom. Interestingly, one of the N atoms of the monodentate $tpym^-$ anion behaves as electron donor to Sb and a Sb–N linkage forms ($d_{(Sb-N)}$, 2.846 Å). As a consequence, an unusual totally hetero-atomic five-membered co-ordination ring of the type RhSCNSb(Rh) forms. A molecular modelling analysis at the hybrid density functional level DFT-B3LYP was performed on selected co-ordination molecules.

1. Introduction

The synthesis of platinum group metal complexes with pyrimidine and purine derivatives as ligands has acquired new impetus in the past decade. This happened because several reasons, some of which are the following. First, on the basis of pure co-ordination chemistry pyrimidines

and purines are very versatile ligands and show a huge variety of ligating modes as a function of the metal and the environmental conditions. Much has to be learnt on this matter even though a large amount of experimental and theoretical work has already been done [1–11]. The information collected from the preparative, structural and reactivity studies have high significance for several fields which span from the bio-sciences to the material sciences. Second, pyrimidines and purines, often called nucleobase derivatives (to stress their importance in the life of the cell), have in some cases pharmaceutical activity, for instance as anti-tumoral or anti-viral agents. Third, for this type of drugs the complex formation with specific metals may improve the activity towards certain diseases and hopefully may increase the activity spectrum [12]. The combination of two or more different molecules into the same compound may bring to a multi-therapeutic agent which can be expanded by the synergic action of the metal residue (especially for platinum group metals) once the co-ordination compound dissociate inside the target tissue. Fourth, it has recently been suggested that photo-activation of DNA thiobases, may offer a novel approach for the treatment of non-malignant diseases like psoriasis or of superficial tumours that are accessible via photo-therapy [13]. Rhodium–thiopyrimidine and –thiopurine systems are not much investigated by the community of inorganic and co-ordination chemists, at least as it is revealed by the small number of structures deposited at the Cambridge Structural Database (CSD) (Release November 2004, ca. 10 structures) [14].

We reasoned that the synthesis of platinum group metal–thiopyrimidine complexes would be worth of efforts. On continuing our project on co-ordination chemistry of rhodium, we found that this metal has a renewed interest in oncology [15]. These ideas and the search for comparative analyses with ruthenium complexes from here [11f] suggested to prepare rhodium–thiopyrimidine complexes. We wish to report in this paper on the synthesis and the structural characterisation of $[Rh(\underline{N}^1,\underline{S}^2\text{-tpym})_2(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})(SbPh_3)]$ (**3**) (see Scheme 1 for the structural formulas of Htpym and $tpym^-$). The structure of the parent compound $[RhCl_3(SbPh_3)_3]$ (**1**), has also been studied and is here reported. The complex eluded many crystal growth attempts carried out for many years. The finding of the activation of a Rh–Cl bond helps in understanding the process of formation of $[RhCl_2(Ph)(SbPh_3)_3]$ from the reaction of $RhCl_3$ with $SbPh_3$ [11a,11b].

2. Experimental

2.1. Materials

$RhCl_3 \cdot 3H_2O$ (reagent grade, r.g., Acros), Htpym (r.g., Sigma), $SbPh_3$ (r.g., Fluka), Ethanol (EtOH, analytical grade, a.g., Baker), Acetone (a.g., Baker), Diethylether (Et_2O, a.g., Baker), DMSO-d_6 (99.5 at.% D, Fluka) were used as purchased.

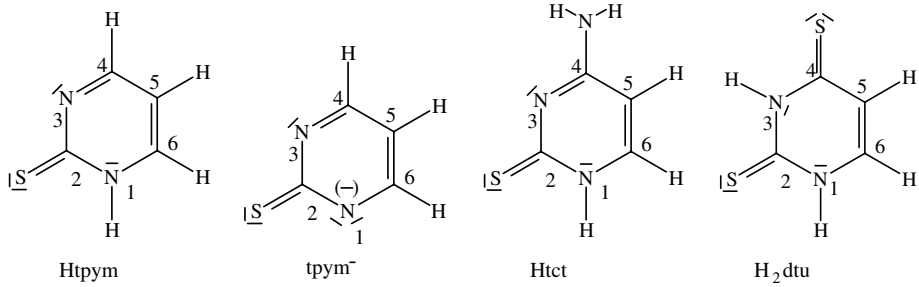
2.2. Syntheses

2.2.1. *mer-*$[RhCl_3(SbPh_3)_3] \cdot CH_3COCH_3$ (**1** $\cdot CH_3COCH_3$)

The compound was prepared according to the procedures previously reported from this laboratory [11a]. Single crystals suitable for X-ray diffraction studies were prepared by slowly evaporating a saturated solution of the crude compound in acetone, at 22 °C. The solution was stored in dust-free, dark, thermostated room, carefully devoid of vibrations. The crystals that formed within three weeks as thin orange plates were filtered, washed with acetone and then stored at 5 °C. *Anal.* Calc. for $C_{57}H_{51}Cl_3ORhSb_3$ (MW = 1326.6): C, 51.61; H, 3.88; Cl, 8.02. Found: C, 51.30; H, 3.70; Cl, 8.22%.

2.2.2. $[Rh(\underline{N}^1,\underline{S}^2\text{-tpym})_2(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})(SbPh_3)] \cdot 0.25C_2H_5OH$ (**3** $\cdot 0.25C_2H_5OH$)

A suspension consisting of **1** $\cdot CH_3COCH_3$ (260 mg, ca. 0.2 mmol), Htpym (70 mg, ca. 0.6 mmol) and EtOH (12 mL) was refluxed in air. After some 15 mins of reflux the solid material dissolved and the resulting orange clear solution was refluxed for two more hours. The solution was cooled down to 22 °C, then concentrated to 3 mL and added by 30 mL of Et_2O. Finally, the mixture was covered and stored at room temperature (22 °C). Orange-red crystals suitable for X-ray diffraction studies formed within 24 h, which were filtered off and then stored in the air atmosphere at 5 °C. Yield: 50%. *Anal.* Calc. For



Scheme 1. Structural formulas for 2-thio-1,3-pyrimidine (Htpym) and 2-thio-1,3-pyrimidinate ($tpym^-$), and the atom numbering. The formulas of thiocytosine (Htct) and dithiouracil (H_2dtu) are also represented.

IR. Selected absorption bands: Htpym, 1605 cm^{-1} (strong, s; ring motion), 1211 (medium, m; NCS vibrations), 1053 (m; CS vibration); **3**, 1562 cm^{-1} (s), no band detectable in the regions around 1200 and 1050 cm^{-1}.

^{1}H NMR. Selected signals: Htpym, 8.21 ppm (doublet, 2H, H^4 and H^6), 6.77 (triplet, 1H, H^5); **2**, 7.20–7.55 ppm (multiplet, ca. 17H, $SbPh_3$ protons and H^4 and H^6 protons of tpym(3)), 7.05, 6.71 and 6.52 (three triplets, 1H each, H^5 of tpyms), 8.55–8.05 (four multiplets, 1H each, tpym(1) and tpym(2)).

2.3. Spectroscopy

IR spectra were recorded by using the KBr pellet technique through a Perkin–Elmer FT1600 spectrometer.

^{1}H NMR spectra were recorded in DMSO-d_6 solutions (0.01 mol L^{-1}) through a Varian XL 200 Machine at 200 MHz and 25 °C.

2.4. X-ray crystallography

2.4.1. *mer*-$[RhCl_3(SbPh_3)_3]\cdot CH_3COCH_3$ (**1**$\cdot CH_3COCH_3$)

2.4.1.1. Data collection. An orange thin crystal fragment was selected under the polarising microscope and mounted on a glass capillary. Preliminary X-ray diffraction experiments, performed through the Weissenberg technique allowed the evaluation of the approximate cell constants, the crystal setting (monoclinic) and the space group ($P2_1/c$). The accurate cell parameters (Table 1) and data set were measured through a Siemens P4 automatic four circle diffractometer at 292 ± 2 K. Graphite mono-chromatised Mo Kα radiation ($\lambda = 0.71073$ Å) was used. The data were corrected for Lorentz-polarisation and absorption effects (ψ-scan technique). The collected reflections totalled 7286, 4519 of which were independent with $I > 2\sigma(I)$. No appreciable decay was observed on monitoring periodically three standard reflections. The intensities of diffraction were very weak at angles beyond $2\theta = 46°$, probably because of the shape and quality of the crystal (thin fragment) and the presence of some cracks, probably due to some efflorescence of co-crystallised acetone. For this reason the data collection was not performed beyond $2\theta = 46°$.

2.4.1.2. Structure solution and refinement. The structure was solved via the Patterson and Fourier techniques. The difference-Fourier map computed after a 12-cycle refinement at the isotropic level on the non-hydrogen atoms of the complex molecule showed four new peaks attributable to the atoms of a co-crystallised molecule of acetone, in agreement with the analytical data. The hydrogen atoms for the two molecules of the asymmetric unit were included in calculated positions through the HFIX and AFIX options of SHELX-97 [16] and were allowed to ride on the atoms to which they are linked (with the thermal parameter equal to 1.2 times the value for the corresponding heavy atom). All the non-hydrogen atoms were treated as anisotropic whereas all the hydrogen atoms were treated as isotropic during the last cycles of refinement. The final agreement factors converged to $R_1 = 0.0491$ and $wR_2 = 0.0938$ over the observed reflections. All the calculations

were carried out with the SHELX-97, PARST-97 [17] and ORTEP3 [18] computer programs implemented on Pentium machines.

2.4.2. [Rh($\underline{N}^1$,$\underline{S}^2$-tpym)$_2$($\underline{N}^1$(Sb),$\underline{S}^2$(Rh)-tpym)-($SbPh_3$)] · 0.25C_2H_5OH (**3** · 0.25C_2H_5OH)

2.4.2.1. Data collection. An orange-red crystal was selected under the polarising microscope, mounted on a glass capillary. The accurate cell parameters (Table 1) and data set were measured with device and method above reported for **1** · CH_3COCH_3. The collected reflections were 7111, 6006 of which were independent with $I > 2\sigma(I)$. No appreciable decay was observed on monitoring periodically three standard reflections.

2.4.2.2. Structure solution and refinement. The structure was solved via the procedure as reported above for **1** · CH_3COCH_3. The difference-Fourier map computed after a 12-cycle refinement at the isotropic level on the non-hydrogen atoms of the complex molecule showed three new peaks attributable to the atoms of a co-crystallised molecule of ethanol. The peak assigned to the oxygen atom was sitting on an inversion centre, so that the ethanol molecule is affected by a statistical disorder. The occupancy of the three non-hydrogen atoms of the co-crystallised ethanol molecule was refined via a trial and error method based on the thermal parameters and on the analytical data (C, H, N, S). An acceptable fitting of the experimental data and the thermal parameter was obtained by fixing the occupancy of the oxygen atom (namely O1E) at 0.125 and that of the carbon atoms at 0.25. The hydrogen atoms were included in calculated positions through the HFIX and AFIX options of SHELX-97 and were allowed to ride on the atoms to which they are linked (with the thermal parameter equal to 1.2 times the value for the corresponding heavy atom). The non-hydrogen atoms were treated as anisotropic whereas all the hydrogen atoms were treated as isotropic during the last cycles of refinement. The final agreement factors converged to $R_1 = 0.0373$ and $wR_2 = 0.1040$ over the observed reflections. All the calculations were carried out as above reported for **1** · CH_3COCH_3.

2.5. Molecular modelling: density functional methods

All the density functional calculations were carried out through the GAUSSIAN-98/RevA.7 package [19] implemented on an Origin 3800 SG machine at CINECA (Inter-University Computing Centre, Casalecchio di Reno, Bologna, Italy). Geometry optimisations, population analysis and vibration frequency calculations have been obtained by using the B3LYP method [20] and different basis sets [20] depending on the atom type and on the molecule (see Section 3). The models optimised were: $SbH_2CH{=}CH_2$; $M(SbH_2CH{=}CH_2)^+$ for M = Cu, Ag, Au; $M(SbH_2CH{=}CH_2)^{2+}$ for M = Zn, Cd, Hg; Htpym; $tpym^-$; M(tpym) for M = Cu, Ag, Au; $M(tpym)^+$ for M = Zn, Cd, Hg; Rh($\underline{N}^1$,$\underline{S}^2$-tpym)$^{2+}$ for quintet, triplet, singlet. Molecular drawings were obtained through the ORTEP3 package [18].

3. Results and discussion

3.1. X-ray crystallography

3.1.1. mer-[$RhCl_3(SbPh_3)_3$] · CH_3COCH_3 (**1** · CH_3COCH_3)

The complex molecule **1** is depicted in Fig. 1 whereas the selected bond lengths and bond angles are listed in Table 2. The rhodium(III) centre has a pseudo-octahedral co-ordination environment, the donors being the three chloride anions (*mer* position) and the three antimony atoms from triphenylstibine.

The three Rh–Cl bond distances differ significantly, the two vectors *trans* to each other being significantly shorter (2.350(3) and 2.362(3) Å) than the one *trans* to Sb (2.399(3) Å). This effect is related to the higher *trans* influence exerted by Sb when compared to Cl. The Rh–Sb bond distances are 2.558(1) Å (*trans* to Cl), and 2.577(1) and 2.626(1) Å. Interestingly, all the three chloride anions are involved in several C–H···Cl interactions. Cl(1) is the H-acceptor for the intramolecular interactions: C(126)–H···Cl(1) (CH···Cl, 2.946 Å; 146°); C(326)–H···Cl(1) (CH···Cl, 3.115 Å; 106°); C(236)–H···Cl(1) (CH···Cl, 2.768 Å; 147°); and the intermolecular interaction: C(124)–H($-x+2$, $y-0.5$, $-z+0.5$)···Cl(1) (CH···Cl, 2.927 Å; 138°). Cl(2) is the H-acceptor for the intramolecular interactions: C(116)–H···Cl(2) (CH···Cl, 2.939 Å; 111°); C(236)–H···Cl(2) (CH···Cl, 3.038 Å; 104°); and the intermolecular interactions: C(223)–H(x, $-y-0.5$, $z+0.5$)···Cl(2) (CH···Cl, 3.100 Å; 134°); C(4s)–H($-x+1$, $y-0.5$, $-z+0.5$)···Cl(2) (2.726 Å; 176°). Cl(3) is the H-acceptor for the intramolecular interactions:

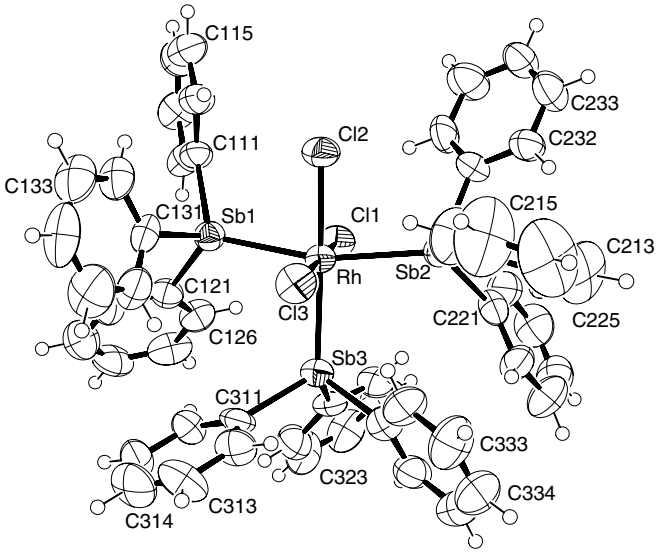

Fig. 1. Drawing of the complex molecule for *mer*-[$RhCl_3(SbPh_3)_3$] · CH_3COCH_3 (**1** · CH_3COCH_3). The ellipsoids enclose 50% probability. The labelling of selected atoms only is included for the sake of clarity.

Cl(1)–Rh–Sb(1)	85.96(8)
Cl(2)–Rh–Sb(1)	81.93(8)
Sb(3)–Rh–Sb(1)	98.46(4)
Cl(3)–Rh–Sb(2)	97.12(9)
Cl(1)–Rh–Sb(2)	86.58(8)
Cl(2)–Rh–Sb(2)	84.85(8)
Sb(3)–Rh–Sb(2)	95.76(4)
Sb(1)–Rh–Sb(2)	164.38(4)

C(332)–H···Cl(3) (2.676 Å; 145°); C(216)–H···Cl(3) (2.853 Å; 134°); and intermolecular interactions: C(214)–H($-x+1$, $y-0.5$, $-z+0.5$) (2.801 Å; 161°); C(3s)–H($-x$, $y+0.5$, $-z+0.5$)···Cl(3) (3.112 Å; 132°). The analysis of the bond distances reveals the activation of the Rh–Cl (*trans* to Sb) bond towards dissociation and formation of chloride anion and of a penta-co-ordinate intermediate state. It is reasonable to assume that the activation of a $SbPh_3$ ligand towards dissociation of a Sb–C linkage occurs at the level of the intermediate state. Some activation on $Sb(2)Ph_3$ towards the formation of $SbClPh_2$ [11a] and the Rh–Ph linkage [11a,11b] occurs. In favour of this hypothesis is the fact that the C(111)–Sb(2)–C(131) bond angle (105.1(4)°) is the largest of all the C–Sb–C angles for **1** and $[RhCl_2(Ph)(SbPh_3)_3]$ and that the Cl(2)···Sb(2) contact distance (3.265 Å) is short. However, it has to be noted that no lengthening of any Sb–C bond is observed in the structure of **1**. Although, the intra-molecular activation of a Sb–C bond for a Rh(III)–$SbPh_3$ molecule is evident from the structure of **3** (see below).

3.1.2. $[Rh(\underline{N}^1,\underline{S}^2\text{-tpym})_2(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})\text{-}(SbPh_3)]\cdot 0.25C_2H_5OH$ ($\mathbf{3}\cdot 0.25C_2H_5OH$)

The complex molecule **3** is shown in Fig. 2 and the selected geometrical parameters are reported in Table 3. The rhodium centre has the usual octahedral co-ordination arrangement and it is chelated by two $tpym^-$ anions. Two *cis* positions are occupied by the sulfur atom from the third $tpym^-$ anion and by the Sb atom from triphenylstibine. Interestingly, the antimony donor is five-co-ordinate, being linked to one of the nitrogen atoms from the mono-dentate $tpym^-$ anion, to the three phenyl groups and the metal centre. A completely hetero-atomic five-membered co-ordination ring of the type Rh–S–C–N-Sb(Rh) is unusually operating in the complex molecule. The sulfur atoms (S(1) and S(2)) from the chelating $tpym^-$ molecules are *trans* to each other and at longer distances (2.365(2), 2.378(1) Å) from Rh than the sulfur donor of the third ligand (S(3), 2.322(1) Å). The two Rh–N bond distances are equal within one time the standard deviations and average 2.082(4) Å in agreement with corresponding values found previously for Rh(III) complexes [11,21]. The Rh–Sb bond distance, 2.5344(8) Å is slightly short when compared to other octahedral Rh(III) complexes which contain only one $SbPh_3$ ligand [11b]. The Rh···N(13) contact distance 3.469 Å is rather long and excludes a significant linking interaction between the two atoms. Bond angles around the Rh(III) centre deviate significantly from the idealised values of 90° and 180°, mostly because the strains related to the presence of two four-membered chelate rings. For instance, the S(1)–Rh–N(11) and S(2)–Rh–N(12) bond angles are 69.2(1)° and 68.9(1)°, respectively; the S(1)–Rh–S(2) angle is 162.58(6)° whereas the S(3)–Rh–N(12) angle is 166.2(1)°. The linking interaction between the $tpym^-$ and the $SbPh_3$ ligand is evidenced by a short Sb–N(13) distance: 2.846(3) Å and by the geometrical parameters for the sphere around the antimony atom. In fact, the N(13) atom is roughly *trans* with respect to the C(111) atom, the N(13)–Sb–C(111) angle being 168.7(1)°. The *trans* influence exerted by the nitrogen atom is evidenced by the lengthening of the Sb–C(111) vector (bond distance, 2.164(5) Å) with respect to the Sb–C(121) and Sb–C(131) vectors (bond distances, 2.129(4) and 2.114(5) Å, respectively). Moreover, the enlarging of the C(121)–Sb–C(131) bond angle (110.1(2)°) upon the formation of the N-Sb linkage is evident from the inspection of the C(111)–Sb–C(121) (95.8(2)°) and C(111)–C(131) (95.9(2)°) bond angles. A sort of activation of the $SbPh_3$ ligand can therefore be hypothesised via the formation of the complex molecule **3**, which could evolve towards the release of a phenyl group. This type of mechanism, has been proposed for the formation of *trans*-$[RhCl_2(Ph)(SbPh_3)_3]$ and $ClSbPh_2$ from a mixture of $RhCl_3$ and $SbPh_3$ in ethanol via the complex molecule of *mer*-$[RhCl_3(SbPh_3)_3]$ [11a,11b].

3.2. Molecular modelling

3.2.1. $SbH_2CH{=}CH_2$ (structures **I** and **II**), $M(SbH_2CH{=}CH_2)^+$, and $M(SbH_2CH{=}CH_2)^{2+}$ for M = Cu, Ag, Au, and Zn, Cd, Hg (structures **III**–**VIII**, respectively)

The goal of the analysis was that to investigate the reliability of the computational method for metal-stibine co-ordination molecules and to study the influence of the

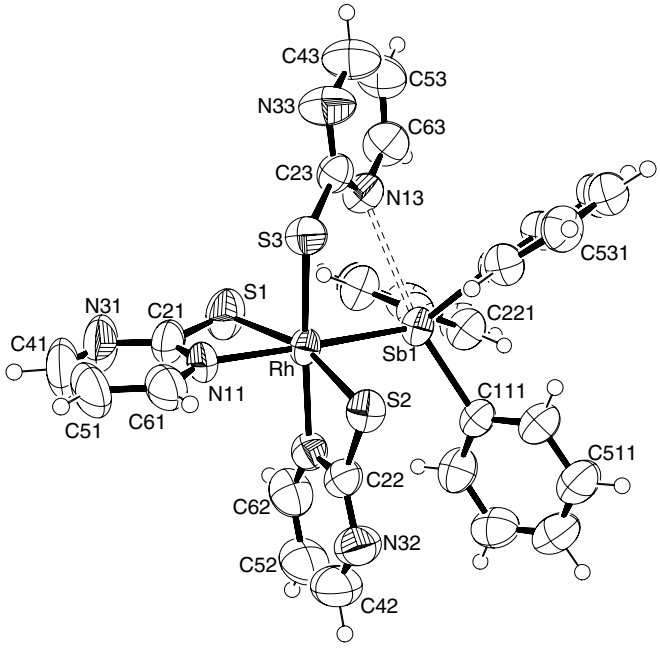

Fig. 2. Drawing of the complex molecule for $[Rh(\underline{N}^1,\underline{S}^2\text{-tpym})_2(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})(SbPh_3)]\cdot 0.25C_2H_5OH$ ($\mathbf{3}\cdot 0.25C_2H_5OH$). The ellipsoids enclose 50% probability. The labelling of selected atoms only is included for the sake of clarity.

metal ligation to antimony on the Sb–C and (Sb)C–C bond distances. The computation have been performed at the B3LYP/Lanl2dz level. The $SbH_2CH{=}CH_2$ molecule was used as a model for triphenylstibine with the aim to reduce the computational costs. Several attempts to optimise $Rh(SbH_2CH{=}CH_2)^{3+}$, singlet, triplet and quintet states did not succeed. The $CH{=}CH_2$ system was restrained to be planar; no other restraint was applied. Two computed minimum energy structures were obtained for $SbH_2CH{=}CH_2$, namely **I** and **II** (Fig. 3), for which the H–Sb–C–C torsion angle is 134.6° and −10.5°, respectively, and the difference between the electronic energy ΔE_{el} is small (0.596 kcal), **I** being the most stable. The computed Sb–C bond distance is 2.158 Å in nice agreement with the experimental value found for tris(2-thienyl)stibine [22] and for triphenylstibine [23]. Even the H–Sb–C and H–Sb–H bond angles (**I**, 94.0° and 90.5°) compare well with the C–Sb–C angles for $SbPh_3$ and for several of its metal-complexes (solid state) [11a,11b,24]. The computed C–C bond distance is 1.352 Å (**I**), slightly larger than the corresponding computed value for ethene, 1.348 Å.

The computed structures of closed shell complexes $M(SbH_2CH{=}CH_2)^+$ for M = Cu(I) (structure **III**), Ag(I) (**IV**), Au(I) (**V**) (Fig. 4), have the metal almost coplanar with the $CH{=}CH_2$ group (M–Sb–C–C torsion angle, 0.0°, 0.0° and 1.5°, respectively). The computed M–Sb bond distances are 2.515, 2.718 and 2.584 Å, respectively, in agreement with the X-ray data at the solid state for related structures [25,26]. The computed Sb–C bond distances for **III**, **IV** and **V** are 2.115, 2.117 and 2.107 Å, respectively, significantly shorter than for free $SbH_2CH{=}$

Table 3
Selected bond lengths (Å) and angles (°) $[Rh(\underline{N}^1,\underline{S}^2\text{-tpym})_2(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})(SbPh_3)]\cdot 0.25C_2H_5OH$ ($\mathbf{3}\cdot 0.25C_2H_5OH$)

CH_2. The same trend happens in the solid state for selected structures [23,25,26]. The computed M–Sb–C bond angles are 116.9°, 118.1° and 113.7° in perfect agreement with

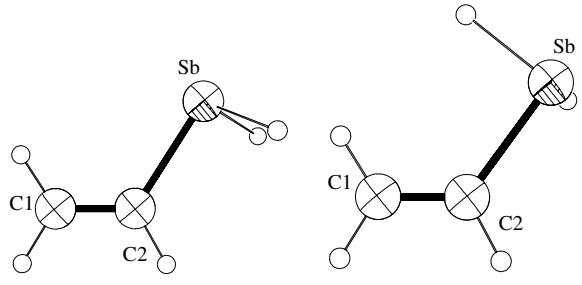

Fig. 3. Drawings of the optimised structures for $SbH_2CH{=}CH_2$.

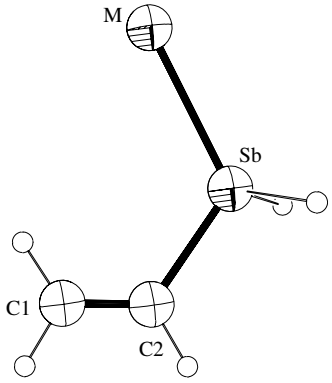

Fig. 4. Drawing of the general structures for $M(SbH_2CH{=}CH_2)^+$ (M = Cu, Ag, Au).

the experimental values found for Rh–$SbPh_3$ groupings from this work.

The computed M′–Sb bond distances are 2.835, 2.970 and 2.983 Å, for $M(SbH_2CH{=}CH_2)^{2+}$, M = Zn(II) (structure **VI**), Cd(II) (**VII**) and Hg(II) (**VIII**), larger than those for the copper triad. The only structure of stibine ligands with zinc triad bivalent cations, deposited in the CSD [14] is that of $I_2CdSb(CH_2CH_3)_2Sb(CH_2CH_3)_2CdI_2$ [27] whose Cd–Sb bond distance is 2.822 Å.

From this analysis, one can say that first the method and level of theory used in this analysis reproduces fairly well the main structural features of the SbR_3 ligands both free and in metal complexes. Second, no any activating effect on the Sb–C linkage upon metal co-ordination could be revealed.

3.2.2. Htpym (structure *IX*) and tpym$^-$ (structure *X*)

The structure **IX** (Fig. 5), as optimised at the B3LYP/(6-31G**) level, has the C^2-S^2 and N^1–C^2 bond lengths of 1.667 and 1.374 Å in agreement with the X-ray structure of thiocytosine [28]. The corresponding bond lengths for structure **X** (same computation level) are 1.719 and 1.382 Å, somewhat larger than those for **IX** (in agreement with deprotonation). In the case the B3LYP/(Lanl2dz(C,H,N);6-31G**(S)) [20] level was used the computed C^2-S^2 and N^1–C^2 bond distances are 1.666 and 1.393 Å for **IX** and 1.713 and 1.408 Å for **X**, respectively. Therefore, the two basis sets compute very close distances for corresponding bonds both for Htpym and tpym$^-$ molecules.

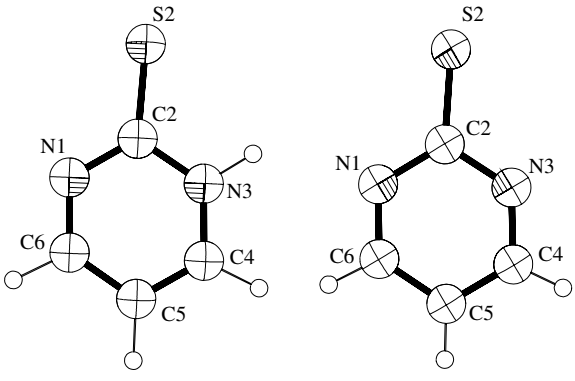

Fig. 5. Drawings of the optimised structures for Htpym and tpym$^-$.

3.2.3. M($\underline{N}^1$,$\underline{S}^2$-tpym) for M = Cu, Ag, Au (structures *XI*, *XII*, *XIII*), and M($\underline{N}^1$,$\underline{S}^2$-tpym)$^+$ for M = Zn, Cd, Hg (structures *XIV*, *XV*, *XVI*)

The structures **XI**–**XIII** (Fig. 6) have the tpym$^-$ anion as chelator via S and N and were optimised at the B3LYP/(Lanl2dz(C,H,N);6-31G**(S)) level. The computed M–S bond distances are 2.315, 2.503, 2.328 Å, whereas the M–N bond distances are 2.085, 2.473 and 3.054 Å. The CSD [14] reports only a complicate structure of a Cu(I)-complex (polycentric) with a tpym$^-$ derivative (*N*,*S*-chelate) as ligand [29]. The Cu–S and Cu–N bond distances are around 2.25 and 2.03 Å, respectively. The only Ag(I)-($\underline{N}^1$,$\underline{S}^2$-tpym) complex found through CSD (it also has a complicate polycentric structure) has Ag-S and Ag-N bond distances of 2.48-2.99 and 2.40 Å [30]. The search on CSD for Au(I)-($\underline{N}^1$,$\underline{S}^2$-tpym) species shows the absence of any effective chelation of the tpym$^-$ anion to a single gold centre. A dimeric structure for bis(μ_2-4,6-dimethylpyrimidine-2-thiolato)digold(I) has Au(1)–S, Au(2)–N, Au(1)–N and Au(2)–S bond distances of 2.26, 2.09, 3.50 and 3.51 Å, respectively [31]. The C–S bond distances are 1.742, 1.745 and 1.768 Å in agreement with the computed values for the free tpym$^-$ anion (see above).

The computed M–S and M–N bond distances are 2.302 and 2.039, 2.494 Å and 2.273, 2.546 and 2.461 Å for **XIV**, **XV**, **XVI**, respectively. A variety of Zn–S and Zn–N bond distances were found for the four structures that contain the Zn(II)-($\underline{N}^1$,$\underline{S}^2$-tpym) group from the CSD. The structure of bis(6-amino-2-thiouracilato)aquazinc(II) has Zn–S and Zn–N lengths of 2.35 and 2.23 Å [32]. The structure of (1,10-phenanthroline)-bis(pyrimidine-2-thionato-*N*,*S*)-cadmium(II) has Cd–S and Cd–N lengths of 2.55–2.59 and 2.42–2.52 Å [33]. The structure of (4-amino-5-methylthiopyrimidine)methylmercury(II) has Hg–S and Hg–N bond distances of 2.39 and 2.81 Å, respectively [34]. The

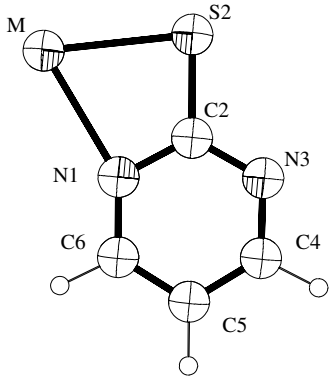

Fig. 6. Drawing of the general structures for M($\underline{N}^1$,$\underline{S}^2$-tpym) (M = Cu, Ag, Au) and M($\underline{N}^1$,$\underline{S}^2$-tpym)$^+$ (M = Zn, Cd, Hg) and Rh($\underline{N}^1$,$\underline{S}^2$-tpym)$^{2+}$.

computed C–S bond distances are 1.773, 1.771 and 1.772 Å, i.e., longer than those for the copper triad.

3.2.4. $Rh(\underline{N}^1,\underline{S}^2\text{-tpym})^{2+}$ (structure *XVII*)

The computed Rh–S bond distances at the B3LYP/(Lanl2dz(C,H,N,Rh);6-31G**(S)) level are 2.177, 2.320, 2.296 Å for the singlet, triplet and quintet states. The experimental data found for **3** (diamagnetic, singlet) are in the range 2.322(1)–2.378(1) Å. The singlet state reproduces well the co-ordination to N found at the solid state, the computed Rh–N distance being 2.016 Å (found for **3**, 2.082 Å, average for tpym(1) and tpym(2)).

3.2.5. $Rh(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})(SbH_3)^{2+}$

Several attempts to optimise reasonable structures for $Rh(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})(SbH_3)^{2+}$ (in different multeplicity states) to simulate the possible formation of a Rh–S–C–N-Sb(Rh) co-ordination ring, starting from Sb···N contact distance of 2.86 Å, did not converge. The calculations were interrupted when the Sb···N distance reached 4.5 Å.

4. Conclusion

In conclusion, this work produced an efficient method for the synthesis of the new crystalline complex $[Rh(\underline{N}^1,\underline{S}^2\text{-tpym})_2(\underline{N}^1(Sb),\underline{S}^2(Rh)\text{-tpym})(SbPh_3)]$ (**3**). The novelty of this compound consists in having two different types of co-ordinated thiopyrimidine moieties, and a Rh–S–C–N-Sb(Rh) co-ordination ring for which the antimony atom acts both as electron donor to Rh and acceptor from nitrogen. The work shows that the co-ordination of the third $tpym^-$ anion via S only causes an activation of a Sb–C(Ph) bond through the N···Sb intramolecular interaction. The density functional analysis shows that the DFT-B3LYP methods is able to reproduce fairly well the main co-ordination behaviour of $tpym^-$ but it does not model the RhSCNSb(Rh) ring. This suggests to perform further investigation by using more sophisticate molecular models and more accurate computational tools to theoretically investigate the unusual co-ordination mode.

The X-ray diffraction analysis for **1** has confirmed an activation of a Rh–Cl bond through the *trans* influence from an antimony atom assisted by (Ph)C–H···Cl(Rh) hydrogen bond type interactions. The short Cl(2)···Sb(2) contact distance and the lengthening of the Rh–Sb(2) bond suggests that Cl(2) could behave like the $tpym(3)^-$ ligand of **3** and it can activate a Sb–C bond toward dissociation. The X-ray diffraction data and the DFT analysis did not unveil any direct lengthening of Sb–C bonds via metal ligation to antimony that can give a rationale for the formation of *trans*-$[RhCl_2(Ph)(SbPh_3)_3]$ (**2**), from **1**. Instead, the solid state data from this work and from the literature, and theory show a shortening of Sb–C bonds upon metal ligation. From the experimental data at the solid state both for **3** and **1**, it appears that the intervention of a nucleophilic particle on the Sb atom of a $SbPh_3$ ligand is requested to activate the triphenylstibine molecule towards a Sb–C bond breakage and a Rh–Sb dissociation. The effect of an approaching chloride anion to antimony has not been investigated through theoretical and experimental tools, yet. It has to be noted that even the solvent molecules may play a role in the formation of **2**. Further experimental and theoretical efforts must therefore be performed to understand the reaction mechanism.

Dedicated to Professor Mike Hursthouse, in gratitude for his friendship over the last three decades. Happy Birthday Mike!

Abstract

Lithium bis(diphenylphosphino)amide, $(THF)_3LiN(PPh_2)_2$ reacts with $Ni(COD)_2$ or $PtMe_2(COD)$ to give the corresponding bimetallic complexes $(THF)_3LiN(PPh_2)_2Ni(COD)$ and $(THF)_3LiN(PPh_2)_2PtMe_2$. Reaction of $(THF)_3LiN(PPh_2)_2Ni(COD)$ with Me_3SnCl gave the Ni–Sn derivative, also accessible from $Me_3SnN(PPh_2)_2$. The silyl derivatives $Me_3SiN(PPh_2)_2M$ [M = Ni(COD), $PtMe_2$] were obtained similarly as red and colourless crystals, respectively. By contrast, the reaction with $PdCl_2(COD)$ afforded an insoluble yellow adduct which, on attempted recrystallisation afforded a small amount of a Pd(I) product, $[PdCl\{HN(PPh_2)_2\}]_2$. The crystal structures of the Ni and Pt complexes are based on MP_2N four-membered rings. The geometric parameters proved rather insensitive to changes in the N-main group element bond. In all cases the amido-nitrogen atom deviated slightly from trigonal-planar geometry, most probably as the consequence of packing forces.

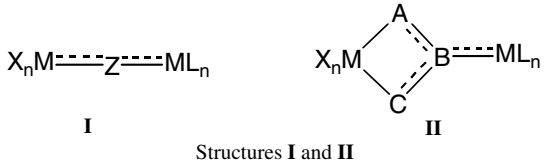
1. Introduction

The control of steric and electronic properties of catalytically active metal centres is a fundamental problem in catalyst design [1]. As part of a general study of new ligands directed towards olefin polymerisation catalysts, we became interested in the possibility of influencing the electronic characteristics of one, potentially active metal centre by connecting it to a second metal complex via a ligand capable of allowing electronic interactions, as shown schematically in structures **I** and **II**.



I **II**

Structures **I** and **II**

As a preliminary to such studies we became interested in complexes of bis(diphenylphosphino)amine, since on the one hand derivatives of this ligand have been shown to produce active catalysts [2], while on the other the amine can be deprotonated and metallated [3]. We report here the synthesis and structures of bis(diphenylphosphino) amide complexes of group 10 metals of type **II**, where $ML_n = Li(THF)_3$, $SiMe_3$ and $SnMe_3$. Neutral complexes of the type $(Ph_2PNPPh_2)MX(L)$

(M = Ni, Pd; X = Cl or Br; L = phosphine) as well as bis(diphenylphosphino)amine complexes [PtCl(L)-(dppa)]Cl are well known [4,5] [dppa = $HN(PPh_2)_2$].

2. Results and discussion

2.1. Syntheses

Lithium bis(diphenylphosphino)amide, $(THF)_3LiN(PPh_2)_2$ (**1**) is readily accessible from butyllithium and $HN(PPh_2)_2$ in THF [3] and was isolated as a crystalline solid. Treatment of **1** in THF with $Ni(COD)_2$ or $PtMe_2$-(COD) afforded the corresponding phosphine complexes of Ni(0) and Pt(II), dark-red **NiLi** and colourless **PtLi**, respectively (Scheme 1).

As a test for the coordination of metals other than lithium to the nitrogen in the $dppa^-$ anion, **1** was reacted with trimethyltin chloride to give $Me_3SnN(PPh_2)_2$ (**2**) which on treatment with $Ni(COD)_2$ gave the expected complex $Me_3SnN(PPh_2)_2Ni(COD)$ (**NiSn**). The same product was obtained by reacting **NiLi** with Me_3SnCl. The compound was isolated as red crystals in good yield (Scheme 2).

In a similar manner, the reaction of $Me_3SiN(PPh_2)_2$ with $Ni(COD)_2$ and $PtMe_2(COD)$ gave the complexes $Me_3SiN(PPh_2)_2Ni(COD)$ (**NiSi**) and $Me_3SiN(PPh_2)_2$-$PtMe_2 \cdot$ toluene (**PtSi**) as crystalline products in good yields.

^{31}P NMR spectroscopy was found to be a convenient way of following these reactions (Table 1). There is remarkably little difference in chemical shift on substituting lithium in **1** for the rather more covalently bonded $SnMe_3$ group. Similarly, complexation of **1** to a Ni(COD) residue results in only a relatively small low-field shift of ca. 13 ppm. By contrast, coordination of **1** to Pt(II) produces a shift of ca. 20 ppm to higher field, with platinum–phosphorus coupling constants of 740–770 Hz.

While these reactions of nickel and platinum compounds readily gave crystalline products, the analogous

[a] Ref. [3].

reaction of $Me_3SiN(PPh_2)_2$ with $PdCl_2(COD)$ generated a poorly soluble yellow powder which analysed for $Me_3SiN(PPh_2)_2PdCl_2$. During attempted recrystallisations from a large volume of THF/CH_2Cl_2 a few crystals were isolated which turned out to be a decomposition product and were identified by X-ray diffraction as a Pd(I)–dppa complex, $[PdCl\{HN(PPh_2)_2\}]_2 \cdot 3CH_2Cl_2$ (Scheme 3). This compound has previously been made as the acetone solvate by a more rational route, the comproportionation of $PdCl_2(NCPh)_2$ and $Pd_2(dba)_3 \cdot CHCl_3$ in the presence of dppa (dba = dibenzylideneacetone) [6].

The reactivity of these complexes in polymerisation reactions and as synthons for bimetallic species will be reported elsewhere.

2.2. Molecular structures

The crystal structures of **NiLi**, **NiSn**, **PtLi** and **PtSi** were determined. In all cases the structures of the complexes are based on MP_2N four-membered rings. Although the polarities of the N–Li, N-Si and N–Sn bonds are expected to differ widely in reflection of the differences in electronegativity, these changes turned out to have remarkably little effect on the geometric parameters of the resulting complexes.

The nickel–lithium compound $(THF)_3LiN(PPh_2)_2$-Ni(COD) (**NiLi**) has a core of a planar, four-membered NiP_2N ring, with the lithium atom bound to the nitrogen atom N(2) (Fig. 1). Selected bond distances and angles are collected in Table 2. The lithium ion is displaced 0.415(3) Å from the NiP_2N plane. The nitrogen atom is almost trigonal-planar, with an angle sum of 357.75°, and is moved 0.151(2) Å out of the LiP_2 plane. As

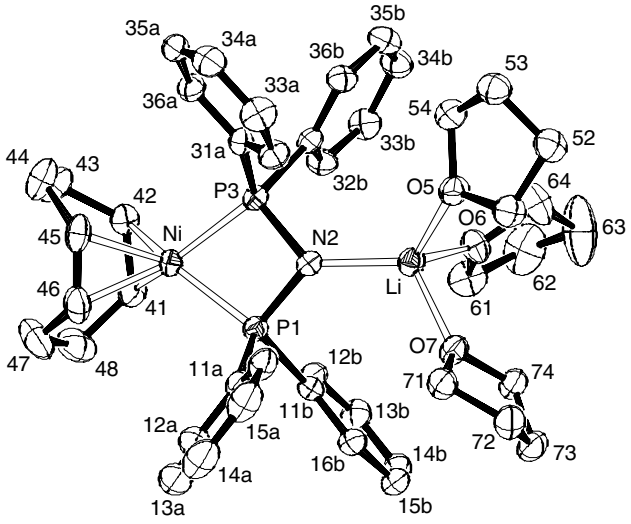

Fig. 1. Molecular structure of $(THF)_3LiN(PPh_2)_2Ni(COD)$ (**NiLi**), indicating the atom numbering scheme; the atoms labelled '*n*' denote the carbon atoms C(*n*). Thermal ellipsoids are shown at the 50% probability level.

expected for a bidentate chelate, the P–N–P angle in **NiLi** is 95.46(9)°, very much smaller than the PNP angle of 124.7(3)° in uncoordinated $(THF)_3LiN(PPh_2)_2$ [3]. The mean Ni–P–N angle is 97.59(14)°.

The nickel atom is four-coordinate (taking the two Ni–π interactions to the centres of the C=C bonds as occupying two coordination sites) in a roughly tetrahedral pattern. The chelating P–Ni–P angle is acute, at 69.36(2)°. The COD ligand is saddle-shaped, with a twist (so that there is no eclipsing of bonds). The lithium atom is four-coordinate. In spite of the angular changes around N the Li–N(2) distance in **NiLi** of 2.012(4) Å is very close to that in free $(THF)_3LiN(PPh_2)_2$ [2.030(1) Å]. The coordination geometry of Li is completed by three THF ligands, in a more obviously tetrahedral pattern. The THF ligands of O(6) and O(7) have envelope-like conformations, with C(63) and C(72) forming the out-of-plane flap atoms. The O(5) THF ring has a minimum torsion angle of 10.8(2)°, and the overall ring shape is more 'half-chair' than 'envelope'.

Overall the shape of $Me_3SnN(PPh_2)_2Ni(COD)$ (**NiSn**) is rather similar to **NiLi** (Fig. 2 and Table 3). There are two independent molecules in the asymmetric unit. They

look very similar but show some subtle conformational differences.

The nickel atom is four-coordinate, with a much distorted tetrahedral pattern. The mean P–Ni–P angle is 73.21(7)°. The four atoms of the NiP_2N core in molecule A (containing Ni(1)) are coplanar, but in molecule B (of Ni(2)) there is a mean deviation of 0.024(2) Å of these atoms from their mean-plane. As in **NiLi**, the nitrogen atoms are not quite trigonal-planar, with angle sums of 356.8° and 358.4° for molecules 1 and 2, respectively. The N–Sn bonds are tilted slightly out of the core planes, so that Sn(2) lies 0.653(2) Å and Sn(6) 0.394(2) Å from those planes. Correspondingly, the nitrogen atoms N(2) and N(6) are displaced 0.188(5) and 0.133(6) Å from their SnP_2 planes.

The tin atoms show little distortion from regular tetrahedra in their bonds to the nitrogen atoms and three methyl carbon atoms. The COD ligands have the same twisted saddle-shapes as in **NiLi**. However, when the molecules are viewed down the Ni–N vectors and the orientations of the $SnMe_3$ groups are aligned, we note that the COD ligands are twisted in opposite directions. In molecule A, the projection of Sn(2)–C(21) bisects the

C(45)–C(46) bond (similar to the arrangement in **NiLi**), whereas Sn(6)–C(61) lies parallel to the projection of the Ni–C(85) bond.

The structures of the platinum(II) complexes **PtLi** and **PtSi** are shown in Figs. 3 and 4, respectively. Bond lengths and angles are given in Tables 4 and 5. In both cases the platinum centres are square planar with two methyl groups in a *cis* arrangement, and a chelating PPh_2NPPh_2 ligand. In **PtLi** the Pt atom is displaced

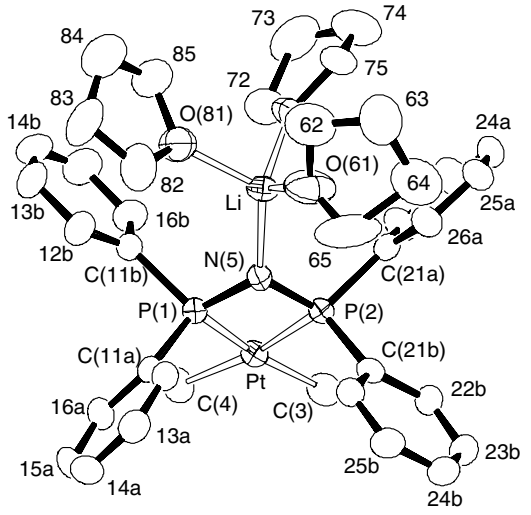

Fig. 3. View a molecule of $(THF)_3LiN(PPh_2)_2PtMe_2$ (**PtLi**). Atoms labelled as "*n*" represent the carbon atoms C(*n*). Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level.

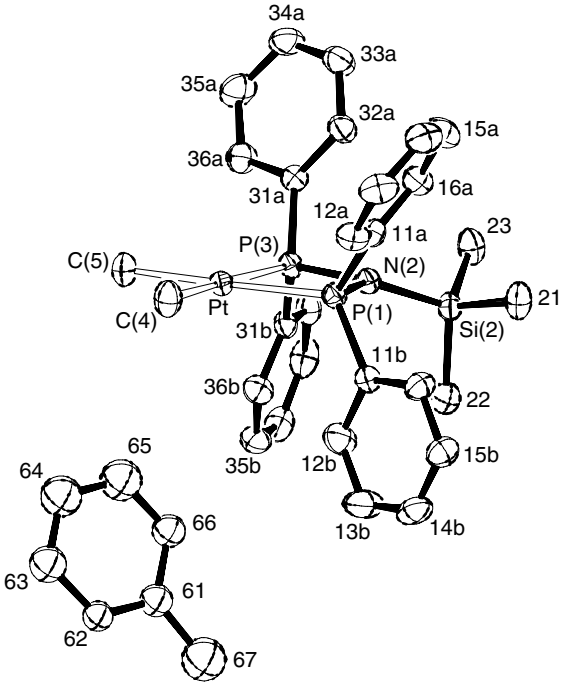

Fig. 4. Molecular structure of $Me_3SiN(PPh_2)_2PtMe_2 \cdot 0.5$ toluene (**PtSi**). Hydrogen atoms are omitted for clarity. Thermal ellipsoids are drawn at the 50% probability level.

0.016(3) Å to one side of the P_2C_2 mean-plane; N(5) and Li are on the opposite side, at −0.194(5) and −1.314(11) Å from the plane. The nitrogen atom of the PNP ligand is bonded to the Li atom, and the three angles about N(5) add up to 351.5°, the most highly pyramidalised N atom of all the structures considered here. The central core of the molecule is thus seen to curve gently from the methyl carbon atoms through the Pt, P and N atoms to the Li atom.

The three THF ligands give Li a distorted tetrahedral coordination pattern. The three N–Li–O angles are all rather larger than the regular tetrahedral value, and two of the three O–Li–O angles are much smaller than 109.5°. There is disorder (which has been clearly resolved) of a methylene group in one THF ligand; several other carbon atoms in these ligands have large thermal parameters but no further disorder has been identified.

The platinum atom in $Me_3SiN(PPh_2)_2PtMe_2 \cdot 0.5$ toluene (**PtSi**) lies close to the mean-plane through the C_2P_2 coordinating atoms. Atom N(2) lies only 0.044(4) Å from that plane and Si(2) dips away rather more, to lie 0.601(3) Å out-of-plane. The arrangement about N(2) is close to trigonal planar (angle sum 356.2°), and the N-atom is 0.193(3) Å from the P_2Si plane, a distortion presumably resulting from the close packing of the $SiMe_3$ methyl groups against the phenyl groups on the P atoms.

Pairs of toluene molecules lie disordered about centres of symmetry; one or other of the pair is present at any centre, and the atoms of this molecule are well resolved.

The main geometric parameters of these four complexes are compared in Table 6. In all cases the P–N bonds are elongated compared to uncomplexed $(THF)_3LiN(PPh_2)_2$ [3]. The P–N–P angles are reduced from 124.7° to ca. 95–98°, irrespective of the metal. Whereas in free $(THF)_3LiN(PPh_2)_2$ there are two P–N–Li angles due to the interaction of one of the PPh_2 groups with the Li atom, in the complexes all these angles substantially exceed 120°. In all cases the N atom deviates slightly from ideal trigonal-planar geometry, although there is no correlation between the size of this deviation and the nature of the N-bound main group element.

The molecular structure and selected geometric parameters of the Pd(I) product $[PdCl\{HN(PPh_2)_2\}]_2 \cdot 3CH_2Cl_2$ are given in Fig. 5 and Table 7, respectively.

The Pd complex molecule is dimeric, the two halves related by a twofold symmetry axis which passes through the two nitrogen atoms. The N–H bonds lie along the symmetry axis and are directed towards the solvent chlorine atoms, Cl(41′) and Cl(41″) which also lie on the symmetry axis at H···Cl distances of 2.88 and 2.82 Å. Viewed down the symmetry axis, the angle between the normals to the two PNP planes is 67.1°. There are three principal arrangements of the CH_2Cl_2 solvent molecules: that of Cl(41), C(42), Cl(43) lies to one side of the symmetry axis or to the other side; on the opposite side of the axis to that molecule, the molecule of Cl(51) and Cl(53) lies in one of several orientations; the third molecule, of Cl(61), etc., lies disordered about a centre of symmetry in one of several possible orientations.

Since the remaining structural features are essential identical to those reported by Uson for the acetone solvated compound the bonding parameters will not be discussed here further.

3. Conclusion

The reaction of $(THF)_3LiN(PPh_2)_2$ with $Ni(COD)_2$ or $PtMe_2(COD)$ readily affords Ni(0) and Pt(II) bimetallic complexes of type II containing the $LiN(PPh_2)_2$ ligand framework, in which lithium is covalently rather than ionically bonded. In an effort to test the suitability of these compounds as synthons for the preparation of other bimetallic derivatives, the substitution of Li by Me_3Sn or Me_3Si was investigated. A comparison of the solid-state structures of these complexes showed the geometric parameters of the NP_2 bridge to be remarkably insensitive to changes of either the transition or the main group metal.

4. Experimental

4.1. Methods and materials

Syntheses were performed under nitrogen using standard Schlenk techniques. Solvents were distilled over sodium–benzophenone (diethyl ether, THF), sodium (toluene), sodium–potassium alloy (light petroleum, bp. 40–60 °C), or CaH_2 (dichloromethane). NMR solvents (C_6D_6, THF-d_8, CD_2Cl_2) were dried over activated 4 Å molecular sieves and degassed by several freeze–thaw cycles. NMR spectra were recorded using a Bruker Avance DPX-300 spectrometer. Chemical shifts are reported in ppm and referenced to residual solvent resonances. Nitrogen and argon were purified by passing through columns of supported P_2O_5 with moisture indicator, and activated 4 Å molecular sieves. Elemental analyses were performed by the Microanalysis Services of the School of Chemical Sciences and Pharmacy. $HN(PPh_2)_2$ [1], $LiN(PPh_2)_2 \cdot 3THF$ [3] and $Ni(COD)_2$ [7] were prepared according to the literature procedures.

4.2. Preparation of $(THF)_3LiN(PPh_2)_2Ni(COD)$, *NiLi*

To a mixture of solid $(THF)_3LiN(PPh_2)_2$ (1.0 g, 1.65 mmol) and $Ni(COD)_2$ (0.45 g, 1.65 mmol) in a round bottom flask was added THF (30 mL) at −78 °C. The solution was allowed to warm to room temperature and stirred for 5 h. Reduction of the solvent volume to one third induced the formation of microcrystals which were dissolved by warming. Crystallisation at −26 °C gave dark-red crystals of the title compound (1.1 g, 86%). *Anal.* Calc. for $C_{44}H_{56}LiNNiO_3P_2$: C, 64.89; H, 6.66; N, 2.10. Found: C, 63.55; H, 6.62; N, 1.82%. ^1H NMR (300.13 MHz): δ 1.74 (br, THF), 1.89 (s, CH_2), 2.04 (s, CH_2), 3.58 (br, THF), 3.97 (s, CH), 7.09–7.57 (Ph). $^{13}C\{^1H\}$ NMR (75.46 MHz): δ 36.18 (s, CH_2), 83.04 (s, CH), 130.03–151.93 (Ph). ^{31}P NMR (121.49 MHz): δ 66.22.

4.3. Preparation of $(THF)_3LiN(PPh_2)_2PtMe_2$, *PtLi*

To a mixture of $(THF)_3LiN(PPh_2)_2$ (0.39 g, 0.65 mmol) and $PtMe_2(COD)$ (0.22 g, 0.65 mmol) was added THF (20 mL) at −78 °C. The solution was allowed to warm to RT and stirred for 3 h. The solvent was then reduced to 5 mL and the solution cooled to −26 °C to give colourless crystals of the product, yield 0.39 g (72%). *Anal.* Calc. for $C_{38}H_{50}LiNO_3P_2Pt$: C, 54.81; H, 6.05; N, 1.68. Found: C, 54.50; H, 6.20; N, 1.76%. ^1H

NMR (300.13 MHz): δ 0.31 (t, $J_{P-H} = 37$ Hz, $PtMe_2$), 1.74 (m, THF), 3.58 (m, THF), 7.20–7.73 (Ph). ^{31}P NMR (121.49 MHz): δ 29.77 (t, $J_{Pt-P} = 740$ Hz).

4.4. Preparation of $Me_3SnN(PPh_2)_2$ (2)

To a solution of $(THF)_3LiN(PPh_2)_2$ (2.9 g, 4.77 mmol) in THF (30 mL) was added Me_3SnCl (0.95 g, 4.77 mmol) in small portions using a bent finger. The reaction was complete within 1 h. The solvent was removed and the product extracted with light petroleum (50 mL) to give white microcrystals, yield 2.2 g (84%). ^1H NMR (300.13 MHz, C_6D_6): δ 0.26 (s, $SnMe_3$), 7.01–7.67 (Ph). $^{13}C\{^1H\}$ NMR (75.46 MHz): δ −1.31 (s, Me), 129.00–143.39 (Ph). ^{31}P NMR (121.49 MHz): δ 61.24.

4.5. Preparation of $Me_3SnN(PPh_2)_2Ni(COD)$, NiSn

Method 1: A mixture of **2** (1.0 g, 1.82 mmol) and Ni(COD)$_2$ (0.50 g, 1.82 mmol) in THF (30 mL) was stirred for 3 h at 25 °C. The solvent volume was reduced to 10 mL, and crystallisation was initiated by adding light petroleum (ca. 30 mL). On cooling to −26 °C the product was obtained as red crystals, yield 0.95 g (73%). *Anal.* Calc. for $C_{35}H_{41}NNiP_2Sn$: C, 58.79; H, 5.78; N, 1.96. Found: C, 58.57; H, 5.91; N, 1.86%. ^1H NMR (300.13 MHz): δ −0.27 (s, Me_3Sn), 2.38 (br, CH_2), 4.77 (br, CH), 7.12–7.93 (Ph). $^{13}C\{^1H\}$ NMR (75.46 MHz): δ −2.70 (s, Me_3Sn), 28.50 (s, CH_2), 85.07 (s, CH), 128.94–142.20 (Ph). ^{31}P NMR (121.49 MHz): δ 83.67.

Method 2: To a suspension of **NiLi** (0.32 g, 0.41 mmol) in toluene (20 mL) was added Me_3SnCl (0.08 g, 0.41 mmol) in small portions using a bent finger. The mixture was stirred overnight at room temperature and filtered. The solvent volume was reduced to ca. 5 mL and light petroleum was added (3 mL) to give a product identical to that from method 1 (0.15 g, 51%).

4.6. Preparation of $Me_3SiN(PPh_2)_2PtMe_2 \cdot 0.5$ toluene, PtSi

A mixture of $Me_3SiN(PPh_2)_2$ (0.34 g, 0.74 mmol) and $PtMe_2(COD)_2$ (0.25 g, 0.74 mmol) in THF (20 mL) was stirred for 3 h at room temperature. The solvent volume was reduced to 2 mL, and light petroleum (30 mL) and toluene (2 mL) were added to induce crystallisation. Red microcrystals formed on cooling to −26 °C, yield 0.35 g (61%). *Anal.* Calc. for $C_{29}H_{35}NP_2PtSi \cdot 0.5C_7H_8$: C, 55.80; H, 5.59; N, 1.90. Found: C, 54.98; H, 5.49; N, 1.81%. ^1H NMR (300.13 MHz): δ −0.39 (s, $SiMe_3$), 1.47 (t, $J_{P-H} = 36.7$ Hz $PtMe_2$), 7.03–8.05 (Ph). ^{31}P NMR (121.49 MHz): δ 35.00 (t, $J_{Pt-P} = 769.9$ Hz).

4.7. Preparation of $Me_3SiN(PPh_2)_2Ni(COD)$, NiSi

To a mixture of $Me_3SiN(PPh_2)_2$ (0.50 g, 1.09 mmol) and Ni(COD)$_2$ (0.30 g, 1.09 mmol) in a round bottomed flask was added THF (30 mL). The solution was stirred at room temperature for 5 h. The solution was concentrated to 5 mL and light petroleum was added (10 mL). Cooling to −26 °C gave red crystals, yield 0.45 g (66%). *Anal.* Calc. for $C_{35}H_{41}NNiP_2Si$: C, 67.32; H, 6.62; N, 2.42. Found: C, 66.94; H, 6.69; N, 2.12%. ^1H NMR (300.13 MHz, C_6D_6): δ −0.30 (s, $SiMe_3$), 2.32 (s, CH_2), 4.64 (s, CH), 7.14–8.01 (Ph). $^{13}C\{^1H\}$ NMR (75.46 MHz): δ 36.18 (s, CH_2), 83.04 (s, CH), 127.89–140.08 (Ph). ^{31}P NMR (121.49 MHz): δ 82.84.

4.8. Preparation of $Me_3SiN(PPh_2)_2PdCl_2$ and formation of $[PdCl(dppa)]_2 \cdot 3CH_2Cl_2$

A mixture of $Me_3SiN(PPh_2)_2$ (0.21 g, 0.46 mmol) and $PdCl_2(COD)_2$ (0.13 g, 0.46 mmol) in THF (15 mL) was stirred overnight at 20 °C. The product was poorly soluble in THF and was isolated by filtration as a yellow powder, yield 0.22 g (76%). *Anal.* Calc. for $C_{27}H_{29}Cl_2NP_2PdSi$: C, 51.08; H, 4.60; N, 2.21; Cl, 11.17. Found: C, 51.35; H, 4.47; N, 2.18; Cl, 11.22%. ^1H NMR (300.13 MHz, THF-d_8): δ 0.41 (s, $SiMe_3$), 7.30–8.14 (Ph). ^{31}P NMR (121.49 MHz, THF-d_8): δ −35.85.

Attempts to recrystallise the complex from a large amount of THF in the presence of dichloromethane over a period of two weeks led to the isolation of a few crystals of the Pd(I)–dppa complex $[PdCl(dppa)]_2 \cdot 3CH_2Cl_2$ which was identified by X-tray diffraction.

4.9. X-ray crystallography

Crystals were mounted on glass fibres and fixed in the cold nitrogen stream on a Rigaku R-Axis IIc image plate diffractometer equipped with a rotating anode X-ray source (Mo Kα radiation) and graphite monochromator. Data were collected at 140(1) K and processed using the DENZO/SCALEPACK [8] programs. The structures were determined by the direct methods routines in the SHELXS program [9] and refined by full-matrix least-squares methods, on F^2's, in SHELXL [9]. Non-hydrogen atoms were refined with anisotropic thermal parameters, and hydrogen atoms were included in idealised positions with their U_{iso} values set to ride on the U_{eq} values of the parent carbon and nitrogen atoms. Scattering factors for neutral atoms were taken from reference [10]. Computer programs used in this analysis have been noted above or in Table 4 of [11], and were run on a Silicon Graphics Indy at the University of East Anglia, or a DEC-AlphaStation 200 4/100 in the Biological Chemistry Department, John Innes Centre.

Crystal data are collected in Table 8.

[a] Reflection weighting scheme: $w = [\sigma^2(F_o^2) + (AP)^2 + BP]^{-1}$ where $P = (F_o^2 + 2F_c^2)/3$.

The crystal of $[PdCl\{HN(PPh_2)_2\}]_2 \cdot 3CH_2Cl_2$, the best of several examined, diffracted strongly but reflection profiles were large and poorly defined, with patterns from small crystals in addition to that from the major crystal. Using 4° oscillations, 48 exposures of 27 min. each were made. Total no. of reflections accepted, to $\theta_{max} = 20°$, was 7624 of which 2513 were unique ($R_{int} = 0.48$); 1761 were 'observed' with $[I > 2\sigma(I)]$. In addition to the Pd complex, there are regions of solvent, CH_2Cl_2, molecules which are disordered and not fully resolved.

5. Supplementary material

Dedicated to Professor Mike Hursthouse on the occasion of his 65th birthday.

Abstract

Radical initiated hydrobromination and methoxycarbonylation using a Pd(0) complex have been used to convert octavinylsilsesquioxane to species functionalised with alkyl bromide and linear methyl propanoate groups on all eight reactive sites, respectively. The two new molecules, 1,3,5,7,9,11,13,15-octakis[ethylbromide]octasiloxane and 1,3,5,7,9,11,13,15-octakis[methylpropanoate]octasiloxane, have been characterised using NMR (^{1}H, ^{13}C and ^{29}Si) and IR spectroscopy, elemental analysis and single crystal X-ray diffraction.

Keywords: Silsesquioxanes; Methoxycarbonylation; Hydrobromination; X-ray diffraction

1. Introduction

Polyhedral oligomeric silsesquioxanes (POSS) are a class of molecules commonly derived from the hydrolytic condensation of organotrihalosilanes. These molecules have the general formula $(RSiO_{3/2})_n$ (where R is an organic group and n is an even number >6) and provide excellent platforms for the synthesis of new inorganic-organic hybrid materials [1,2]. The most common members of the family have an almost cubic silica-like core surrounded by eight organic groups ($n = 8$), which makes them topologically ideal for the preparation of intimate nanocomposite materials [3] with the size of the inorganic region precisely defined by the size of the core. This has led to proposed uses of these molecules as hard blocks or reinforcing particles in high performance polymer materials [4].

The cubic topology of these molecules offers opportunities to prepare interesting micro- or mesoporous materials as it is geometrically difficult to link cubes through their corners and fill all available space [5–7]. The shape of the silsesquioxane core also lends itself well to the preparation of dendrimers, where the large number of external branching sites on the core leads to a high concentration of branch ends after relatively few generations [8,9]. Dendrimers of this type have been studied as potential catalysts, where phosphine functionalised molecules have been found to have positive effects on the selectivity of hydroformylation reactions [10].

Key to all these potential uses of silsesquioxanes is the ease with which their external organic functionality can be altered in controlled and high yielding ways to produce new molecules suitable for further reaction. A relatively wide range of derivatisation reactions is possible, although care must be taken to avoid acidic, basic or overly oxidising environments as the silsesquioxane core is vulnerable under such conditions. Even with these restrictions there are now many examples in the literature of functional silsesquioxanes. Many of these preparations are based on addition to multiple bonds. In this paper, we report two methods of functionalising the vinyl functionalised POSS species

(**1**). Firstly, regiospecific radical addition of hydrogen bromide across the double bond leads to a high yield of the terminally bromide functionalised material **2** (Fig. 1). Clearly, alkyl halide functionality of this type is a useful potential starting point for further derivatisation of the molecule.

A potentially very interesting target for functional silsesquioxanes is those functionalised with carboxylic acid or ester groups because they can be further functionalised to provide novel molecules. In a previous paper, we reported the use of platinum-catalysed hydrosilation using protected aldehyde reactants as a route to aldehyde- and carboxylic acid-functionalised silsesquioxanes [11]. However, the oxidation reactions in this route are difficult to control. Another approach involves the formation of carboxylic ester functionalised silsesquioxanes. Feher et al. [12] have reported previously the hydrosilation of methyl-3,3-dimethyl-4-pentenoate onto the octahydrido silsesquioxane core to form the methyl ester functionalised silsesquioxane. Here, we report an alternative route to the preparation of ester functionalised molecules using direct methoxycarbonylation of the octavinyl silsesquioxane **1**.

Methoxycarbonylation of terminal and internal alkenes under mild conditions in the presence of a palladium bis-(di-*tert*-butylphosphinomethyl)benzene complex, $L_2Pd(dba)_3$ (where L_2 = 1,2-bis(di-*tert*-butylphosphinomethyl)benzene and dba = *trans*,*trans*-dibenzylideneacetone) has been reported recently as a highly selective route to industrially important methyl esters [13]. In this paper, we describe how this methodology can also be applied to form the terminal methyl ester **3** with high selectivity (Fig. 1).

One of the reasons that silsesquioxanes of this type are of interest is their rather unusual architectures, and so structural studies are important in assessing and predicting the properties of the materials. For example, some phosphine-terminated silsesquioxane-based dendrimers are highly selective catalytic ligands in hydroformylation reactions, [10,14] and this can be traced back, at least to some extent, to the structure of the silsesquioxane core based on molecular modelling [15]. Unfortunately, however these types of silsesquioxanes are notoriously difficult to crystallise and single crystal X-ray diffraction is often problematical because of the disorder in the organic groups [9,16]. In this paper we do, however, report single crystal X-ray diffraction structures of both compounds **2** and **3**. Both structures illustrate some of the problems associated with structure determinations on such highly functional molecules. They are weakly scattering crystals with relatively poor data:parameter ratios in the refinement. However, while **2** has a relatively well-behaved structural characterisation **3** is more troublesome; problems that are probably caused by unresolved disorder leading to poor crystallinity.

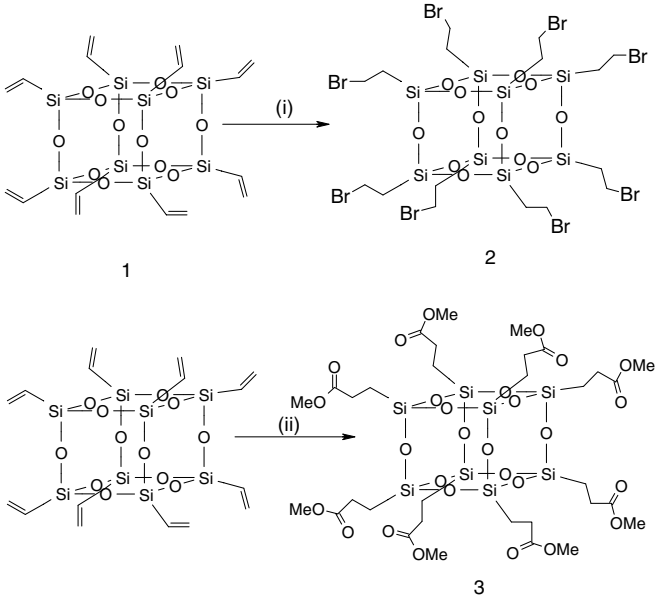

Fig. 1. The synthesis of compounds **2** and **3**. Reaction conditions (i) and (ii) are given in Section 2.

2. Experimental

All manipulations were carried out under an atmosphere of argon. Solvents were dried according to established procedures. NMR spectra were recorded on a Varian 300 or a Bruker 300 spectrometer. FTIR spectra were recorded on a Perkin–Elmer 1710 spectrometer. Chemical analysis was carried out by the University of St. Andrews Microanalysis service on a Carlo Erba model 1106 elemental analyser.

2.1. Synthesis

The starting materials for these preparations, octavinyl-octa-silsesquioxane (**1**), was prepared according to the literature methods [17].

2.1.1. 1,3,5,7,9,11,13,15-Octakis[ethylbromide]octasiloxane (**2**)

Hydrogen bromide gas was bubbled through octavinylsilsesquioxane (0.90 g, 1.42 mmol) and benzoyl peroxide (0.30 g, 1.24 mmol) in toluene (50 ml) at 50 °C for 2 h. After 1 h more benzoyl peroxide (0.30 g, 1.24 mmol) in toluene (10 ml) was added. The reaction mixture was stirred at RT overnight. Argon was then bubbled through the reaction mixture to quench any remaining radicals. The solvent was removed in vacuo and the residue dissolved in dichloromethane (150 ml) and washed with sodium carbonate solution (2×50 ml, 0.05 mol dm^{-3}) and water (50 ml). The resulting colourless liquid was dried over Na_2SO_4, filtered and the solvent removed. The residue was recrystallised using acetone and methanol to yield white crystals (0.87 g, 48%). ^1H NMR ($CDCl_3$, 300 MHz): δ_H 1.45 (16H, t, J_H 8.3, CH_2CH_2Br) and 3.45 (16H, t, J_H 8.3, CH_2CH_2Br). ^{16}C NMR ($CDCl_3$): δ_C 17.90 (16H, CH_2CH_2Br) and 27.10 (16H, CH_2CH_2Br). ^{29}Si NMR ($CDCl_3$): δ_{Si} −70.45 (8Si, s, O_3SiCH_2). IR (nujol mull): ν/cm^{-1} 790 (C–Br str), *Anal*. Calc. for CHN: C, 15.01; H, 2.52. Found: C, 14.35; H, 2.15%.

2.1.2. 1,3,5,7,9,11,13,15-Octakis[methylpropanoate] octasiloxane (**3**)

$Pd_2(dba)_3$ (45.7 mg, 7.283×10^{-5} mol) [dba = dibenzylidene-acetone], 1,2-bis(di-*tert*-butylphosphinomethyl)benzene (198 mg, 5.018×10^{-4} mol) and **1** (500 mg, 7.90×10^{-4} mol) were dissolved in toluene (30 ml) under argon. Methanol (5 ml) and methanesulfonic acid (65 μl, 1×10^{-3} mol) were added and the reaction mixture was transferred into a Hastelloy autoclave, which had been evacuated and fitted with a paddle stirrer. The autoclave was pressurised to 30 bar CO and heated to 80 °C for 41 h. The autoclave was then cooled, vented, the contents removed and the product purified on a fluorosil column (ethyl acetate/petroleum ether). The product was recrystallised from ethyl acetate/petroleum ether to yield small, white needle like crystals (0.38 g, 43%). ^{1}H NMR ($CDCl_3$, 300 MHz): δ_H 0.9 (16H, m, SiCH_2CH$_2$), 2.3 (16H, m, SiCH$_2$$CH_2$) and 3.6 (24H, s, OMe). ^{13}C NMR ($CDCl_3$, 75 MHz) δ_C 7.17 (8C, SiCH_2CH$_2$), 27.64 (8C, SiCH$_2$$CH_2$), 52.10 (8C, OMe) and 174.65 (8C, COO). ^{29}Si NMR ($CDCl_3$, 59.6 MHz): δ_{Si} −67 (8Si, CH_2SiO_3). IR (nujol mull): ν/cm^{-1} 1738 (–O–C=O str.), 1236 (CO str.) and 1095 (CO str.). *Anal.* Calc. for CHN: C, 34.52; H, 5.07. Found: C, 34.90; H, 4.71%.

2.2. X-ray crystallography

The single crystal X-ray diffraction studies on crystals of **2** and **3** were performed at 293 K using a Bruker SMART diffractometer with graphite-monochromated Mo Kα radiation ($\lambda = 0.71074$). The crystal structures were solved using the direct methods program SHELXS-97 and refined with a full-matrix least-squares technique using the program SHELXL-97.

3. Results and discussion

3.1. Synthesis and structure of **2**

Radical addition of HBr across olefinic double bonds is a well known synthetic reaction in organic chemistry, leading to Markovnikov addition. Here we have shown that such an approach leads to quantitative addition of the bromide on all eight corners of the vinyl functionalised POSS species. The reaction is regioselective; there is no evidence for addition of the bromine atom to anything other than the terminal carbon of the vinyl group. ^{1}H NMR spectroscopy indicated that complete conversion of **1** to the linear ethyl bromide product (δ_H 1.45 and 3.45) could be achieved after 2 h of bubbling HBr gas through the reaction mixture and then allowing the reaction to stir overnight. NMR (^{1}H and ^{13}C), IR and single crystal X-ray crystallography all reveal the expected structure. Despite the crystals used in this structure determination exhibiting relatively poor scattering of X-rays the refinement against the X-ray diffraction data is reasonable given the fact that the data:parameter ratio is only just acceptable at ~10. The details of the refinement are shown in Table 1 and the final refined crystal structure is shown in Figs. 2 and 3. All non-hydrogen atoms in

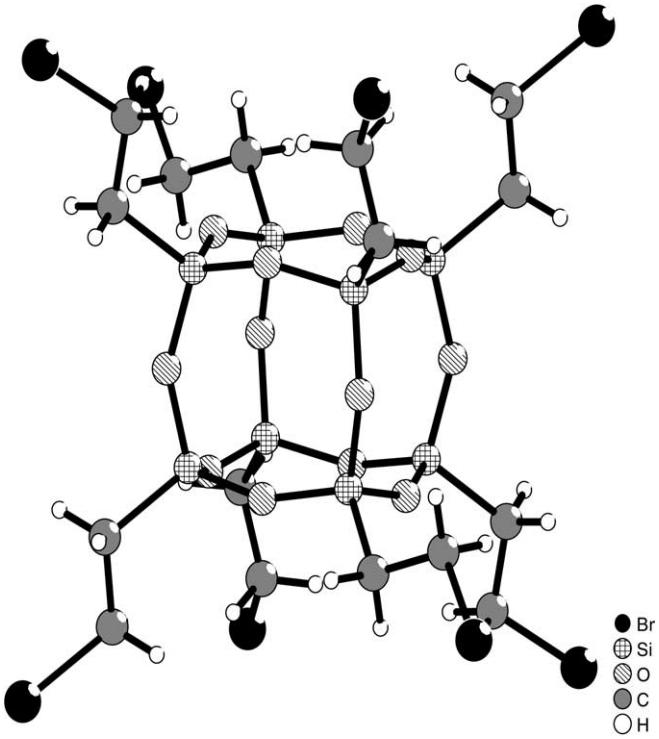

Fig. 2. The structure of compound **2**.

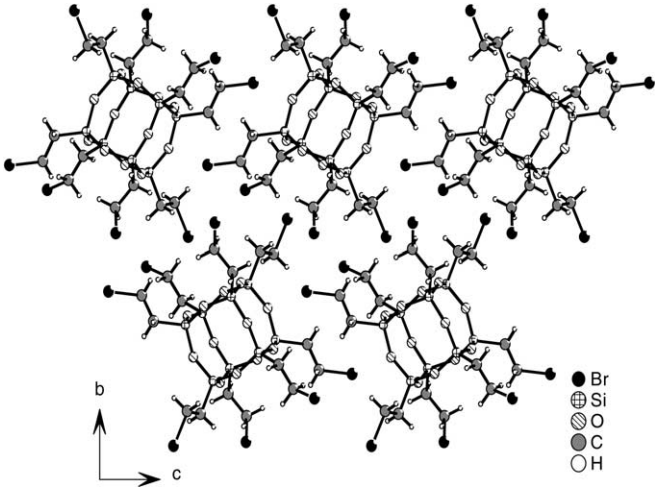

Fig. 3. Packing diagram for compound **2**.

the structure were refined using anisotropic displacement parameters and the hydrogen atoms were geometrically placed and restrained to refine as riding atoms together with the carbon atoms to which they are bonded.

The structure of **2** comprises half of the molecule in the asymmetric unit, 4 independent silicon atoms and four ethylbromide units. The geometry of the core is as would be expected from crystal structures of other silsesquioxane molecules. The Si–O interatomic distances range from 1.603 (10) to 1.629 (10) Å, the O–Si–O angles indicate almost regular tetrahedral coordination about silicon, ranging from 108.1 (7)° to 111.5 (7)° and the Si–O–Si angles from 145.9 (7)° to 152.8 (7)°. The ethyl bromide arms on the structure also show reasonably good geometry with Si–C, C–C and C–Br interatomic distances ranging from 1.827 (14) to 1.854 (14) Å, 1.45 (2) to 1.50 (2) Å and 1.893 (17) to 1.967 (15) Å, respectively. The atomic displacement parameters for the individual atoms in the core have relatively normal values; the equivalent isotropic displacement parameters for the silicon atoms 0.044 $Å^2$ and the oxygen atoms 0.050 $Å^2$. However, the atoms on the periphery of the molecule the displacement parameter values have larger values of around 0.090 $Å^2$ for the bromine atoms. The packing diagram for **2** is shown in Fig. 3 and shows that there are two orientations of the silsesquioxane cores. The arms of the molecules interlink in such a way as to produce the closest intermolecular contact between the bromine on the periphery of one molecule and one of the faces of the cubic core of another. The bromine points almost at the centre of one of these faces with Br–O interatomic distances ranging from 3.715 to 3.909 Å.

The crystal structure of a related molecule where the starting molecule was an allyl terminated POSS has been reported before [18] but we believe this is the first time that reaction of a vinyl-POSS species has been reported in this reaction. Clearly, the presence of alkyl-bromide functionality in the exterior of these silsesquioxane molecules opens up the possibility of many further reactions.

3.2. Synthesis and structure of *3*

Alkoxycarbonylation of alkenes is an important process in which vinyl groups are converted to alkyl esters. A wide range of products is accessible using this approach; from high molecular weight 'polyketones' [19] to methyl propanoate [20,21]. Here, we report the methoxycarbonylation of octavinylsilsesquioxane to form a silsesquioxane species functionalised with eight methyl propanoate groups, **3**, accomplished using the zero valent $L_2Pd(dba)_3$ complex [where L_2 = 1,2-bis(di-*tert*-butylphosphinomethyl)benzene and dba = *trans*,*trans*-dibenzylideneacetone] as the catalyst. The reaction was performed under 30 bar CO at 80 °C in a Hastelloy autoclave. The reaction could also be performed at room temperature on a smaller scale by bubbling CO through the solution, however the scale up of this procedure proved problematic.

Nuclear magnetic resonance (^1H and ^{13}C) spectroscopy indicated that all the vinyl resonances (δ_H 5.7–6.1) of **1** had disappeared after 41 h. The ^1H NMR showed the emergence of two multiplet resonances (δ_H 0.9 and 2.3), which were assigned to the CH_2 groups of the alkyl chains in the molecule and a singlet peak (δ_H 3.6) assigned to the methoxy group. In line with steric requirements of the system, there was no evidence of formation of the branched ester product. Therefore, as a far as could be deduced from NMR 100% conversion to the linear ester product had been achieved. Chemical analysis and ^{29}Si NMR further proved that addition to all corners of the silsesquioxane cube had been achieved. The IR spectrum showed the expected ester carbonyl stretch at 1738 cm^{-1}. Purification of

the product by chromatography followed by recrystallisation resulted in the formation of white needle-like crystals. Diffraction data were collected at room temperature on a laboratory diffractometer equipped with a CCD detector. It was clear that the low angle scattering was relatively strong but that the intensity of the diffraction decreased markedly at high 2θ angles. Structure solution was accomplished using direct methods techniques, and revealed the location of the central silsesquioxane core of the molecule (Fig. 2). Difference Fourier syntheses were used to complete the molecule. The final cycle of least-squares refinement included anisotropic displacement parameters for all the non-hydrogen atoms except those of the minor disordered ester group, which were refined isotropically. Hydrogen atoms on the methylene groups were placed geometrically and were refined as riding atoms on the carbon atoms to which they were attached. Hydrogen atoms on the ester methyl groups were not modelled. To ensure that the external ester groups retained chemically sensible geometry some restraints on bond distances and angles were required. Details of the refinement are listed in Table 1 and Figs. 4 and 5 show the final refined structure.

The structure of **3** comprises one quarter of the molecule in the asymmetric unit; two independent silicon atoms together with two of the organic arms of the molecule. The silsesquioxane core of the structure is crystallographically well-behaved with good inferred geometry and anisotropic displacement parameters of the expected magnitude. Comparison with the structure of compound **2** indicate very similar geometry for the silsesquioxane core, with Si–O interatomic distance ranges (1.601 (10)–1.650 (10) Å) and O–Si–O angle ranges (107.6 (6)–111.4 (7)°) show no statistically significant difference between compounds **2** and **3**. The Si–O–Si angle ranges (143.7 (8)–148.7 (8)°) are slightly smaller than those for compound **2** but fall well in the range seen in other molecules of this type. However, the least-squares refinement of the atoms on the organic arms of the molecule is less satisfactory. The further away from the silsesquioxane core the atom is the larger the anisotropic displacement parameters become, as would be expected, but the magnitudes of the displacement parameters are such that they must be due to some unresolved disorder and/or severe molecular motion of the terminal units. Disorder of the terminal carbon and oxygen atoms was resolvable on half of the ester groups (i.e., one of the two crystallographically independent units), with occupancy factors for the two disordered units of 0.66 (4) and 0.31 (4). However, there remains some significant disorder of the remaining ester group that we were not able to model satisfactorily. Collecting data at lower temperature (150 K) using the synchrotron source at Daresbury did not improve the quality of the diffraction experiment to any great degree. This type of problem is by no means unusual in the structural chemistry of silsesquioxane materials of this kind. In fact there are examples where the crystallinity of the materials is such that only the cubic silsesquioxane core can be located using these techniques, the organic groups being so disordered as to render them unlocatable using X-ray diffraction [17]. However, for **3** all the non-hydrogen atoms were found from the difference Fourier syntheses, but the subtle details of the structure cannot be elucidated unambiguously. The packing diagram for **3** is shown in Fig. 5. It shows a number of similarities to that of **2**. Again there are two different orientations of

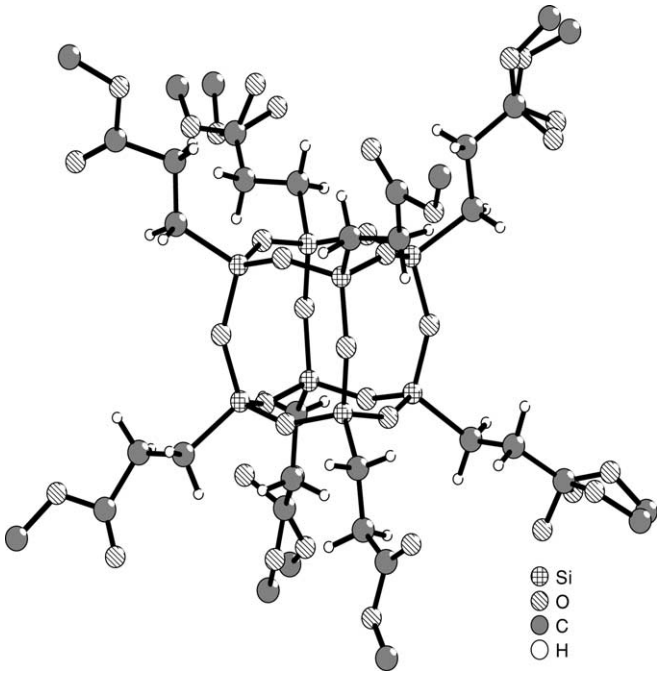

Fig. 4. The structure of compound **3**. The disorder the external ester groups can be seen on half the arms of the molecule.

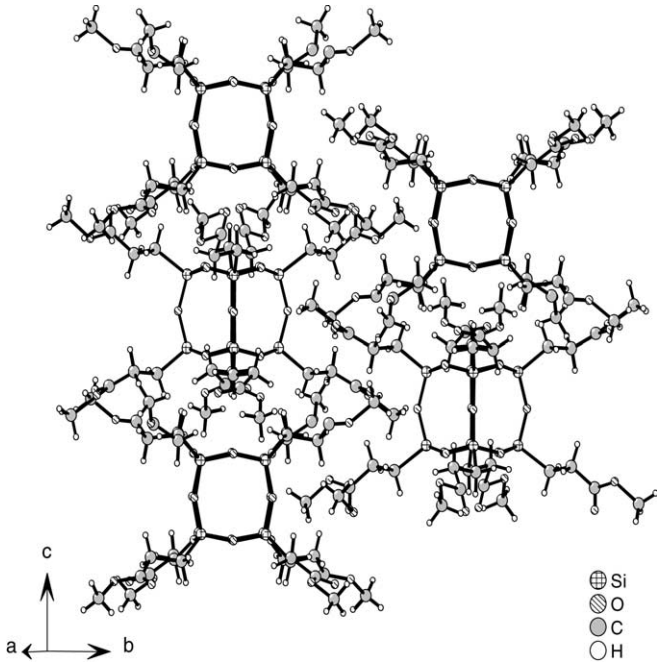

Fig. 5. Packing diagram for compound **3**. For clarity, only the major component of the disordered ester groups are shown.

the polyhedral silsesquioxane core and the organic arms of the molecules interlock so that the methyl carbon of one molecules points approximately towards the centre of the face of the silsesquioxane core on the next molecule. The distance from the methyl carbon to the oxygen atoms of the nearest face range from 3.817 to 4.019 Å.

We have the reported the synthesis and characterisation of two new octafunctionalised silsesquioxane molecules. The new molecules present potentially useful starting materials for the further preparation of further functionalised molecules. The direct methoxycarbonylation reaction to produce ester groups on the exterior of the molecules is a particularly interesting reaction. We are currently exploring further synthetic uses of this molecule using hydrolysis of the ester and also transesterification reactions.

4. Supplementary material

CCDC 279579, corresponding to **2**, and CCDC 263076, to **3** contain the supplementary crystallographic data for this paper. These data can be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html (or from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK; fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk).

Dimethylxanthene- and dibenzofuran-diamido complexes of titanium

Robin M. Porter, Andreas A. Danopoulos *

School of Chemistry, University of Southampton, Highfield Campus, Southampton, Hants SO17 1BJ, UK

Received 4 July 2005; accepted 21 September 2005
Available online 27 October 2005

Honouring the outstanding chemist and special friend Professor Michael B. Hursthouse on the occasion of his retirement.

Abstract

The new ligands 4,5-dialkyl-and-diaryl-amido-9,9-dimethylxanthene and 4,6-dialkyl-and-diaryl-amido dibenzofuran serve as rigid, pre-organised and tunable 'spectators' for group 4 metals. The structure of a titanium complex with 4,5-di-cyclohexylamido-9,9-dimethylxanthene is reported.

Keywords: Amido titanium; Crystal structure; Xanthene dibenzofuran; Catalytic amination

1. Introduction

The development of new rigid, pre-organised ligands is an active area of research. Of particular interest is their use in homogeneous catalysis, where a geometric perturbation introduced by such ligands could improve the activity or selectivity of the catalyst. Demonstrations of this concept in the catalytic aziridination, cyclopropanation, C–H/C–C activation and hydroformylation reactions appeared recently [1]. The use of rigid preorganised ligands with early transition metals is less common. In addition to certain *ansa*-cyclopentadienyls [2], recent work has focussed on amido ligands, which could offer wide scope for electronic and steric tuning and ligand design [3]. The generation of low coordination number, electronically/sterically unsaturated metal species, the suppression of β-hydrogen elimination and the modulation of the rate of insertion reactions are attractive goals, where ligand preorganisation may prove useful. Rigid xanthene and dibenzofuran bridged chelating diphosphines have successfully been used in Rh catalysed hydroformylation. In this case, the *n*-/*i*-aldehyde ratio is influenced by the bite angle of the chelating diphosphine [1d].

As part of our ongoing research aiming at the development of novel ligands for the early transition metals, we report here a facile method for the synthesis of chelating dialkyl- and diaryl-amido ligands with xanthene and dibenzofuran backbones and initial results on the synthesis of their titanium complexes. The tunable rigidity, bite-angle, N-attached bulk and donor characteristics make these ligands useful building blocks for the design of the metal coordination environment. They are complementary to the family of the tridentate diamido ligands developed by Schrock et al. [4]. Hagadorn et al. [5] has recently prepared bimetallic xanthene bis-amidinate complexes of Zr and Ti. A review on the catalytic activity of Ti complexes in C–C and C–N bond formation reactions has recently appeared [6].

2. Experimental

2.1. General methods

Elemental analyses were carried out by the University College, London, microanalytical laboratory. All manipulations were performed under nitrogen in a Braun

doi:10.1016/j.poly.2005.09.011

glove-box or using standard Schlenk techniques, unless stated otherwise. Solvents were dried using standard methods and distilled under nitrogen prior use.

The starting materials 4,5-dibromo-2,7-di-*tert*-butyl-9,9-dimethylxanthene [7], 4,5-dibromo-dibenzofuran [8], Ti$(NMe_2)_2Cl_2$ [9] and Ti(benzyl)$_4$ [10] were prepared by literature methods.

NMR data were recorded on Bruker AMX-300 and DPX-400 spectrometers, operating at 300 and 400 MHz (^{1}H), respectively. The spectra were referenced internally using the signal from the residual protio-solvent (^{1}H) or the signals of the solvent (^{13}C). Mass spectra (ES^+) were run from acetonitrile solutions on a VG Biotec platform.

2.2. 4,5-(N,N′-bis-cyclohexylamino)-2,7-di-tert-butyl-9,9-dimethyl-xanthene ($L_a{}^{cy}H_2$)

An ampoule was charged with 4,5-dibromo-2,7-di-*tert*-butyl-9,9-dimethyl-xanthene (2.80 g, 5.83 mmol), sodium *tert*-butoxide (1.70 g, 17.5 mmol), Pd(dba)$_2$ (0.10 g, 0.175 mmol), 1,3-bis-(2,6-diisopropylphenyl)imidazolinium chloride (0.15 g, 0.35 mmol) and 1,4-dioxane (40 cm^3). To the mixture was added cyclohexylamine (1.27 g, 12.83 mmol) and the ampoule was closed under reduced pressure and heated at 100 °C for 60 h. The reaction was allowed to cool and water (40 cm^3) was added. The mixture was extracted with diethyl ether (2×100 cm^3 then 50 cm^3). The combined organic extracts were filtered and dried with $MgSO_4$. Evaporation of the volatiles under reduced pressure yielded a pale yellow solid that was recrystallised from boiling petroleum (60/80) to give $L_a{}^{cy}H_2$ as a pale yellow solid. Yield: 2.29 g, 76%. Mass spectrometry (EI): *m*/*z*, 517 $(M+1)^+$ δ_H ($CDCl_3$): 1.20–2.15 (20H, m, cyclohexyl CH_2), 1.35 (18H, s, Bu^t), 1.62 (6H, s, CH_3), 3.40–3.50 (2H, m, cyclohexyl CH α to amino N), 4.03 (2H, d, NH), 6.62 (2H, s, aromatics), 6.77 (2H, s, aromatics). ^{13}C{^{1}H} ($CDCl_3$): 25.30, 26.75 (cyclohexyl CH_2s), 32.25 (methyls), 32.32 (Bu^t), 34.07 (cyclohexyl CH_2), 35.30, 35.58 (tertiary carbons), 52.04 (cyclohexyl CH α to amino N), 107.61, 110.58 (aromatic CHs), 130.12, 135.59, 137.36, 146.13 (quaternary aromatics).

2.3. 4,5-(N,N′-bis-mesitylamino)-2,7-di-tert-butyl-9,9-dimethyl-xanthene ($L_a{}^{mes}H_2$)

An ampoule was charged with 4,5-dibromo-2,7-di-*tert*-butyl-9,9-dimethyl-xanthene (3.00 g, 6.25 mmol), sodium *tert*-butoxide (1.80 g, 18.75 mmol), Pd(dba)$_2$ (0.18 g, 0.3 mmol), 1,3-bis-(2,6-diisopropylphenyl)imidazolinium chloride (0.26 g, 0.6 mmol) and 1,4-dioxane (60 cm^3). To this was added 2,4,6-trimethylaniline (1.86 g, 13.74 mmol), the ampoule was closed under reduced pressure and heated at 105 °C for 4 days. The reaction was allowed to cool and water (40 cm^3) was added. The mixture was extracted with diethyl ether (3×100 cm^3). The combined organic extracts were filtered and dried with $MgSO_4$. Volatiles were removed in vacuo and the residue was recrystallised from boiling ethanol to yield the product as a cream coloured solid. Yield: 2.53 g, 69%. Mass spectrometry (EI): *m*/*z*, 590 $(M+1)^+$. δ_H ($CDCl_3$): 1.39 (18H, s, Bu^t), 1.89 (6H, s, xanthene CH_3), 2.38 (12H, s, mesityl CH_3), 2.44 (6H, s, mesityl CH_3), 5.73 (2H, s, NH), 6.37 (2H, s, aromatics), 7.03 (2H, s, aromatics), 7.09 (4H, s, mesityl aromatics). ^{13}C{^{1}H} ($CDCl_3$): 18.98, 21.55 (mesityl CH_3), 32.15 (xanthene CH_3), 32.20 (But), 35.18, 35.67 (tertiary carbons), 108.34, 111.49 (aromatic CHs), 129.86 (mesityl aromatic CHs), 130.35, 134.60, 135.43, 135.77, 136.45, 137.55, 146.11 (quaternary aromatics).

2.4. 4,6-(N,N′-bis-mesitylamino)-dibenzofuran ($L_b{}^{mes}H_2$)

An ampoule was charged with 4,6-dibromo-dibenzofuran (1.00 g, 3.1 mmol), sodium *tert*-butoxide (0.88 g, 9.2 mmol), Pd(dba)$_2$ (0.18 g, 0.3 mmol), 1,3-bis-(2,6-diisopropylphenyl)imidazolinium chloride (0.26 g, 0.6 mmol) and 1,4-dioxane (20 cm^3). To this was added 2,4,6-trimethylaniline (0.99 g, 7.3 mmol) and the ampoule was closed under reduced pressure and heated at 105 °C for 18 h. The reaction was allowed to cool and water (100 cm^3) was added before extracting the reaction into diethyl ether (3×100 cm^3). The organic extracts were combined, filtered and dried with $MgSO_4$. Volatiles were removed in vacuo and the residue was recrystallised from boiling ethanol to yield the product as a white solid. Yield: 0.82 g, 61%. Mass spectrometry (EI): *m*/*z*, 435 $(M+1)^+$ δ_H ($CDCl_3$): 2.28 (12H, s, mesityl methyls), 2.36 (6H, s, mesityl methyls), 5.69 (2H, s, NH), 6.28 (2H, d, aromatics), 7.01 (4H, s, mesityl aromatics), 7.09 (2H, t, aromatics), 7.33 (2H, d, aromatics). ^{13}C{^{1}H} ($CDCl_3$): 18.94, 21.64 (mesityl methyls), 109.86, 110.46, 124.27 (aromatic CHs), 125.85 (quaternary aromatic), 129.98 (mesityl aromatic CHs), 133.23, 135.55, 136.43, 136.79, 145.01 (quaternary aromatics).

2.5. Bis-(N,N′-mesitylamido-dibenzofuran) dilithium salt ($L_b{}^{mes}Li_2$)

To a stirred, cooled (−78 °C) solution of ($L_b{}^{mes}H_2$) (0.22 g, 0.5 mmol) in petroleum (20 cm^3), was added slowly via cannula Bu^{n}Li (0.4 cm^3 of 2.45 M solution in hexanes, 1.0 mmol). The mixture was stirred at −78 °C for 1 h, allowed to reach room temperature and stirred for 15 h. This gave a colourless precipitate, which was isolated by filtration and dried in vacuo. Yield: 0.190 g, 85%. δ_H (C_6D_6): 1.65 (12H, s, mesityl methyls), 2.09 (6H, s, mesityl methyls), 6.32 (2H, d, aromatics), 6.63 (4H, s, mesityl aromatics), 6.90–7.05 (4H, m, aromatics). ^{13}C{^{1}H} (C_6D_6): 19.70, 21.33 (mesityl methyls), 107.27, 112.15 (aromatic CHs), 126.94 (quaternary aromatics), 127.84 (aromatic CHs), 131.27 (mesityl aromatic CHs), 131.94, 132.12, 142.25, 145.49, 146.40 (quaternary aromatics). The dilithium salts of ($L_a{}^{cy}H_2$), and ($L_a{}^{mes}H_2$) were prepared in an analogous way.

2.6. $(L_b^{mes})Ti(NMe_2)_2$

To a stirred, cooled (−78 °C) solution of ($L_b^{mes}H_2$) (0.24 g, 0.41 mmol) in diethyl ether (10 cm^3), was added slowly via cannula Bu^nLi (0.34 cm^3 of 2.45 M solution in hexanes, 0.81 mmol). The mixture was stirred at −78 °C for 1 h, allowed to reach room temperature and stirred for a further hour to give an orange solution with a colourless precipitate. The mixture was cooled to −25 °C and a cooled (−25 °C) solution of $Ti(NMe_2)_2Cl_2$ in diethyl ether (7 cm^3) was added slowly via cannula. The reaction was slowly allowed to reach room temperature and stirred for ca. 15 h to give a red solution and grey precipitate. The volatiles were removed in vacuo and the residue extracted into petroleum (20 cm^3) and filtered through Celite. Removal of the volatiles in vacuo gave (L_b^{mes})$Ti(NMe_2)_2$ as an orange/red oil. Yield: 0.157 g, 53%. δ_H (C_6D_6): 1.23 (18H, s, Bu^t), 1.74 (6H, s, xanthene methyls), 2.17 (6H, s, mesityl methyls), 2.22 (12H, s, mesityl methyls), 2.83 (12H, s, dimethylamides), 6.26 (2H, s, aromatics), 6.80–7.00 (6H, m, aromatics). $^{13}C\{^1H\}$ (C_6D_6): 19.92, 21.64 (mesityl methyls), 29.20 (xanthene methyls), 32.64 (Bu^t), 35.76, 37.38 (tertiary carbons), 45.99 (dimethylamides), 108.18, 109.01 (aromatic CHs), 129.79 (mesityl aromatic CHs), 132.04, 133.66, 134.23, 142.57, 147.73, 148.01, 149.39 (quaternary aromatics).

2.7. $(L_a^{cy})Ti(NMe_2)_2$

This was prepared as the complex described above from $L_a^{cy}H_2$ (0.18 g, 0.35 mmol) and $Ti(NMe_2)_2Cl_2$ (0.072 g, 0.35 mmol). It was isolated as orange solid from petroleum. X-ray quality crystals were obtained from concentrated diethyl ether solutions by cooling at 0 °C for one week. Yield: 0.14 g, 65%.

δ_H (C_6D_6) 1.10–2.10 (20H, m, cyclohexyl), 1.44 (18H, s, Bu^t), 1.64 (6H, s, methyls), 3.10 (12H, s, dimethylamides), 4.04 (2H, br m, cyclohexyl CH α to amido N), 6.77 (2H, s, aromatic), 7.12 (2H, s, aromatic).

2.8. $(L_a^{cy})Ti(Bz)_2$

In the absence of light an NMR tube equipped with Young's tap was charged with a C_6D_6 solution of ($L_a^{cy}H_2$) (0.020 g, 0.039 mmol) and $Ti(benzyl)_4$ (0.016 g, 0.039 mmol) and the base of the NMR tube was covered in foil. A ^1H NMR spectrum was run after the mixing and showed only the presence of the two starting materials. The sample was left at RT for ca. 15 h before the ^1H NMR spectrum was recorded again. The spectrum now contained a small set of peaks assignable to the (L_a^{cy})$Ti(benzyl)_2$ complex and free toluene as well as the more pronounced peaks due to the two starting materials. The NMR tube was then heated at 80 °C for 3 h and appeared to show complete conversion of the starting materials to the product. The volatiles were removed in vacuo and the dark red residue redissolved in C_6D_6 to obtain the spectra of the pure product.

δH (C_6D_6): 1.10–2.65 (20H, m, cyclohexyl CH2s), 1.35 (18H, s, Bu^t), 1.57 (6H, s, methyls), 2.92 (4H, s, benzyl CH_2s), 5.78 (2H, br m, cyclohexyl CH α to amido N), 6.70–6.85 (4H, m, aromatics), 6.95–7.05 (6H, m, aromatics), 7.10–7.20 (4H, m, aromatics). $^{13}C\{^1H\}$: 27.57, 28.24, 29.86 (cyclohexyl CH_2s), 32.57 (Bu^t), 33.05 (methyls), 35.02, 35.74 (cyclohexyl CH2s), 38.56, 38.86 (tertiary carbons), 60.57 (cyclohexyl CH α to amido N), 84.53 (benzyl CH_2s), 107.85, 111.75, 123.50 (aromatic CHs), 127.94 (quaternary aromatic), 128.02, 129.16 (aromatic CHs), 142.32, 143.74, 148.52, 149.01 (quaternary aromatics).

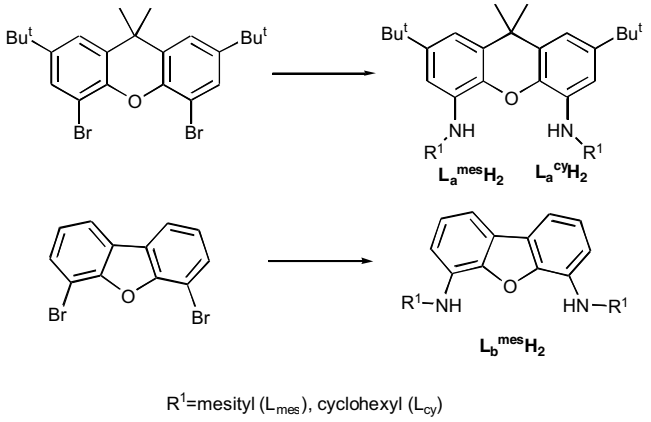
2.9. Structure determination of $(L_a^{cy})Ti(NMe_2)_2$

The data set was collected on a Bruker Nonius Kappa CCD area detector diffractometer with rotating anode FR591 and an Oxford Cryosystems low-temperature device operating in omega scanning mode with phi and omega scans to fill the Ewald sphere. The programs used for control and integration were COLLECT, SCALEPACK and DENZO [11,12]. An orange air sensitive crystal was mounted on a glass fibre with silicon grease, from Fomblin vacuum oil. Chemical formula $C_{39}H_{62}N_4OTi$. $C_4H_{10}O$; crystal system triclinic; space group $P\bar{1}$; cell dimensions $a = 10.2581(4)$ Å, $b = 12.2629(6)$ Å, $c = 18.6460(11)$ Å, $\alpha = 94.693(2)°$, $\beta = 95.234(3)°$, $\gamma = 107.671(2)°$; $Z = 2$, μ/mm^{-1} 0.230; $F(000)$ 708.0; number of data collected 23,300; number of unique data 7739; R_{int} 0.0981; final $R(|F|)$ for $I > 2\sigma(I)$ 0.0955; final $R(F^2)$ for all data 0.1547. All solutions and refinements were performed using the WINGX package [13] and all software packages within. All non-hydrogen atoms were refined using anisotropic thermal parameters and hydrogens were added using a riding model. The quality of the data was affected by the small size of the crystal and the rapid deterioration of the crystal quality during crystal selection possibly due to solvent loss. The structure contains a highly disordered molecule of diethylether and attempts to satisfactorily model this failed. As a result it was removed using the squeeze algorithm (P.v.d. Sluis, A.L. Spek, Acta Crystallogr., Sect. A 46 (1990) 194).

3. Results and discussion

The ligands $L_a^{mes}H_2$, $L_a^{cy}H_2$ and $L_b^{mes}H_2$ can be easily synthesised in multigram quantities from commercially available or easily accessible dibromo-xanthene or -dibenzofurans by Buchwald–Hartwig amination (Scheme 1).

The best conversions and selectivities are obtained with primary alkyl and aryl amines with a catalytic system comprising [1, 3-bis(2, 6-$Pr^i_2C_6H_3$)imidazolinium]chloride/$Pd_2(dba)_3$/Bu^tONa in dioxane [14]. Low catalyst loadings result in monoamination and dehalogenation giving rise to monoamines. The only alternative methods that have been used for the introduction of the amino (NH_2) group to xanthene ring were based on Curtius rearrangement with diphenylphosphorylazide and benzyl alcohol followed by



Scheme 1. Reagents and conditions: 2.2 equiv. R^1NH_2, 6 equiv. Bu^{t}ONa, 0.2 equiv. [1,3-bis(2,6-$Pr^i_2C_6H_3$)imidazolinium] chloride, 0.2 equiv. $Pd(dba)_2$, dioxane 100 °C, 12 h.

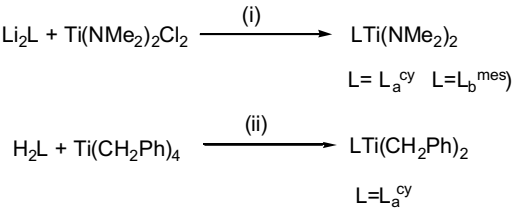
hydrogenolysis of the resulting carbamate [15]. Introduction of one dimethylamino (NMe_2) group has been accomplished by Ullman amination of the iodides under forcing conditions [16] and is of limited scope.

The new diamines were converted in almost quantitative yields to extremely air/moisture sensitive dilithium salts by reaction with Bu^{n}Li in petroleum.

The introduction of the L_a and L_b to group 4 transition metals has been successfully carried out by salt elimination from dilithium amides and metal halides or by alkane elimination from Ti tetralkyls and $L_a^{cy}H_2$ as shown in Scheme 2.

Even though the conversions are quantitative (by ^{1}H NMR spectroscopy) the yields of the isolated products are lower due to their high solubility in non-polar solvents. The new complexes were characterised by ^{1}H and $^{13}C\{^1H\}$ NMR spectroscopy. Elemental analysis data were not reproducible, possibly due to the formation of solvates (see below). The spectroscopic data support the presence of a C_s symmetric structure in solution with the plane of symmetry being perpendicular to the aromatic plane of the ligand and passing through the metal centre and the oxygen donor. The structure of $\mathbf{L_a^{cy}Ti(NMe_2)_2}$ in the solid state was determined by single crystal X-ray diffraction. A diagram of the molecule is shown in Fig. 1.

The coordination geometry around the metal can be best described as distorted square pyramidal ($\tau = 0.0186$), [17] with one dimethylamide nitrogen occupying the axial position. The diamidoxanthene ligand coordinates in the



Scheme 2. Reagents and conditions: (i) ether, −78 °C to room temperature; (ii) Me_3SiCl, toluene; (iii) toluene, 80 °C, 3 h.

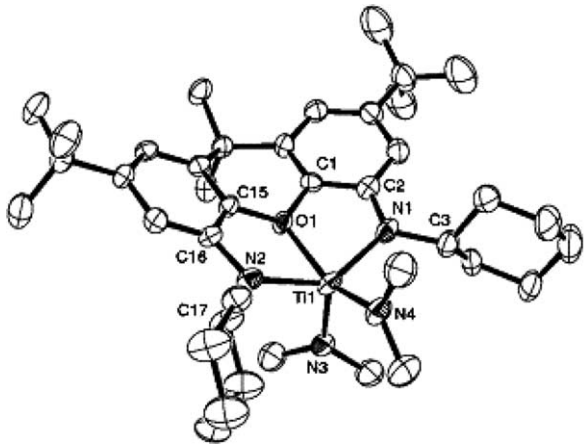


Fig. 1. ORTEP representation of the structure of $\mathbf{L_a^{cy}Ti(NMe_2)_2}$. One disordered ether molecule present in the unit cell as well as hydrogen atoms are omitted for clarity. Selected bond lengths (Å) and angles (°): N(1)–Ti(1) = 2.057(4); N(2)–Ti(1) = 2.040(4); N(3)–Ti(1) = 1.887(4); N(4)–Ti(1) = 1.893(4): O(1)–Ti(1) = 2.132(3) and N(3)–Ti(1)–N(4) = 105.15(18); N(3)–Ti(1)–N(2) = 103.92(17); N(4)–Ti(1)–N(2) = 101.64(17); N(3)–Ti(1)–N(1) = 105.55(17); N(4)–Ti(1)–N(1) = 97.36(17); N(2)–Ti(1)–N(1) = 139.08(15); N(3)–Ti(1)–O(1) = 99.97(16); N(4)–Ti(1)–O(1) = 154.80(16); N(2)–Ti(1)–O(1) = 73.73(13); N(1)–Ti(1)–O(1) = 73.72(13).

'*mer* fashion' as anticipated. The two Ti–dimethylamido bond lengths [Ti(1)–N(3) 1.888(4) Å; Ti(1)–N(2) 1.892(4) Å] are equal within the observed e.s.d.'s and shorter than the cyclohexylarylamido bonds [Ti(1)–N(1) 2.056(4) Å; Ti(1)–N(2) 2.039(4) Å]. The latter are in the range reported for less rigid 'pincer' or NON^{2-} diamido ligands [18]. All the amido groups are virtually planar. Of particular interest is the deviation of the ligand backbone from planarity due to structural constraint imposed by the linking groups (O and CMe_2). The angle defined by the two aromatic rings is ca. 15^0. In solution the structure is possibly non-rigid (idealised C_{2v}) with equivalent dimethylamido groups and methyl substituents on the 9-position.

In solution, complexes $\mathbf{L_b^{mes}Ti(NMe_2)_2}$ and $\mathbf{L_a^{cy}Ti(Bz)_2}$ exhibit spectra with features similar to $\mathbf{L_a^{cy}Ti(NMe_2)_2}$ and, therefore, are expected to adopt analogous structures. We have been unable to grow crystals of $\mathbf{L_b^{mes}Ti(NMe_2)_2}$ and $\mathbf{L_a^{cy}Ti(Bz)_2}$ suitable for X-ray diffraction. The electron deficient $\mathbf{L_a^{cy}Ti(Bz)_2}$ is stable at room temperature in solution. This behaviour contrasts with the more flexible and less bulky (NON)Ti(alkyl)$_2$ which show limited stability in solution and the solid state [18b].

In summary, we have developed a general method based on Pd catalysed aromatic amination for the preparation of preorganised xanthene and dibenzofuran diamines. The diamido ligands that originate from them provide a useful tunable environment for the stabilisation of early transition metals. Extension of the scope of the catalytic amination to the synthesis of preorganised carbazole and dibenzothiophenes as well as studies of the chemistry of the new early transition metal amides as a function of ligand structural parameters is currently in progress.

4. Supplementary material

The crystallographic data for this paper have been pre-deposited at the Cambridge Crystallographic Database (CCDC 276930). These data can be obtained free of charge via www.ccdc.cam.ac.uk/data_request/cif, or by emailing data_request@ccdc.cam.ac.uk, or by contacting The Cambridge Crystallographic Data Centre, 12, Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336033).

Abstract

Novel organometallic and metal–organic indium complexes, $[Et_2In(OS_2CNMe^nBu)]_2$ (**1**), $[In\{(SeP^iPr_2)_2N\}(S_2CNEt_2)_2]$ (**2**) and $[In\{(SeP^iPr_2)_2N\}(S_2P^iBu_2)_2]$ (**3**), have been synthesised and characterised. Compound (**1**) was formed by the insertion of oxygen atoms into the M–S bonds of thiocarbamate ligands, whereas the mixed-chalcogenide complexes (**2**) and (**3**) were prepared by the reaction of $Na(S_2CNEt_2)_2$ or $Na(S_2P^iBu_2)_2$ with $In[(SeP^iPr_2)_2N]_2Cl$. The structures of all three compounds were determined by X-ray single crystallographic methods. The dimeric structure of (**1**) consists of two five membered and one four membered rings formed by chelating and bridging of both dithioperoxycarbamato ligands. The structures of both (**2**) and (**3**) are based on monomers in each case the coordination around indium is distorted octahedral.

1. Introduction

A significant amount of work has been carried out on tetraorganodichalcogeno-diphosphinato $[R_2P(E)–N–P(E)R_2]$-(E = O, S, Se) ligands because of their versatility in forming inorganic chelate rings that are the analogs of β-diketonates [1]. Metal complexes of such ligands show a variety of structural and coordination modes. For example, indium complexes of the bidentate ligand tetraphenylimidodiphosphinate and its derivatives form six coordinate complexes, i.e., $[In\{(EPPh_2)_2N]_3$ (E = O, S, Se) [2,3]. While five coordinate indium(III) bis-chelate complexes with general formula $In[(EP^iPr_2)_2N]_2Cl$ (E = S, Se) have also been reported [4]. Metal complexes of such ligands have been shown to be effective single source molecular precursors for the synthesis of thin films by chemical vapour deposition (CVD) [5] and the preparation of quantum dots [6].

A number of mixed-alkyl indium dithiocarbamate complexes, $(R_2InS_2CNR'_2)$ (R = Me, Et, Np; R′ = Et, Me^nBu), have been synthesised and used as single-source precursors for indium sulfide thin films [7]. One closely related complex $[Et_2In(S_2CNMe^nBu)]$, a clear liquid, has been successfully utilised to prepare nanorods of tetragonal β-In_2S_3 [8].

The oxidation of 1,1 dithiolate ligands by elemental sulfur in nickel(II) complex, was first reported by Coucouvanias and Fackler [9]. Insertion of sulfur expanded the ring from four to five membered ring and gave rise to a new chelate perthiodithiolate ligand. This sulfur insertion was further established in the X-ray structure of $[Fe(p\text{-}MeC_6H_4SC_2)_2$ $(p\text{-}MeC_6H_4CS_3)]$ in which sulfur has been inserted into a Fe–S bond [10]. Similar ring expansion by the insertion of

oxygen instead of sulfur has been reported by Martin et al. [11] in a chromium complex prepared by the reaction of $Na(S_2CNR_2)$ (R = Et or Me) with $K_2Cr_2O_7$ in aqueous solution. The X-ray single crystal structure of this complex is based on a monomer in which chromium is pseudo-octahedral with two normal dithiocarbamato (dtc) ligands and one dithioperoxycarbamato (odtc) ligand resulting from the insertion of oxygen into a Cr–S bond $[Cr(S_2CNR_2)_2(OS_2CNR_2)]$ [12]. This chromium complex has been further studied electrochemically along with the dithiocarbamato complex.

In this work, we report a unique complex with a double ring expansion where oxygen is inserted in both dithiocarbamato ligands of $[Et_2In(S_2CNMe^nBu)]$ to form $[Et_2In(OS_2CNMe^nBu)]_2$ (**1**). Initially, the compound was prepared serendipitously when the toluene solution of $[In(S_2CNMe^nBu)_3]$ and triethylindium was exposed to air through a leak in the system. The reaction gave reproducible results when repeated with stirring in an open flask for 2 min. The same reaction in dry toluene under strict air sensitive conditions produced the complex $[Et_2In(S_2CNMe^nBu)]$ as a clear viscous liquid. Furthermore, we report the synthesis and structural characterisation of indium complexes containing both imidodiphosphinates and dithiocarbamate or dithiophosphinate ligands.

2. Experimental

The synthesis of $[NH(SeP^iPr_2)_2]$, [1d] $In[(SeP^iPr_2)_2N]_2Cl$ [4] and $[In(S_2CNMe^nBu)_3]$ [13] was carried out according to the reported methods. Carbon disulfide, sodium hydroxide, sodium diisobutyldithiophosphinate and diethylamine were bought from Aldrich Chemical Company Limited and used as received. All manipulations and reactions were carried out in an inert atmosphere using Schlenk techniques and a vacuum line. The solvents were distilled and degassed prior to use. ^1H, ^{13}C and ^{31}P NMR studies were carried out using a Bruker AC300 FTNMR instrument. Elemental analysis was performed by the University of Manchester micro-analytical laboratory.

2.1. Synthesis of $[Et_2In(OS_2CNMe^nBu)]_2$ (1)

Tris(methyl(*n*-butyl)dithiocarbamato)indium(III) and triethylindium were reacted in 1:2 stoichiometric ratio at room temperature under nitrogen for 10 min and then allowed to stir in open air for 2 min. Yield: 85%. ^1H NMR (C_6D_6, 300 MHz) δ/ppm: 0.90 (q, 4H, In–CH_2), 1.41 (t, 6H, In–CH_2–CH_3), 3.41 (s, 6H, N–CH_3), 3.85 (t, 4H, N–CH_2–CH_2–), 1.79 (q, 4H, N–CH_2–CH_2), 1.40 (m, N–CH_2–CH_2–CH_2), 1.0 (t, 6H, N–CH_2–CH_2–CH_2–CH_3); $^{13}C\{H\}$ NMR (C_6D_6, 125 MHz) δ/ppm: 203.19 (CS), 55.32 (N–CH_2), 40.67 (N–CH_3), 28.75 (N–CH_2–CH_2), 19.90 (In–CH_2–CH_3), 13.71 (N–CH_2–CH_2–CH_2–CH_3), 12.22 (N–CH_2-CH_2–CH_2–CH_3), 9.92 (In–CH_2). *Anal.* Calc. for $C_{20}H_{44}O_2N_2S_4In_2$: C, 34.2; H, 6.3; N, 4.0, S, 18.3. Found: C, 33.8; H, 6.2; N, 3.8; S, 18.4%.

2.2. Synthesis of $[In\{(SeP^iPr_2)_2N\}(S_2CNEt_2)_2]$ (2)

CS_2 (0.4 ml, 6.25 mmol) was added to a cold, stirring solution of $NH(C_2H_5)_2$(0.65 ml, 6.25 mmol) in NaOH (0.25 g, 6.25 mmol). After stirring for 30 min, while on ice bath, $In[(SeP^iPr_2)_2N]_2Cl$ [4] (5.8 g, 6.02 mmol) dissolved in 40 ml THF was added dropwise to the solution and stirred overnight. The colour of the solution changed from orange to light yellow. Removal of solvent in vacuo led to a viscous liquid, which was crystallised by adding hexane. The product was recrystallised from THF. Yield: 72%. ^1H NMR ($CDCl_3$, 300 MHz) δ/ppm: 1.10–1.30 (m, 24H, P–CH(CH_3)$_2$) 1.10–1.30 (m, 12H, N–CH_2–CH_3), 3.85 (qs, 8H, N–CH_2–CH_3), 2.10–2.75 (ms, 4H, P–CH(CH_3)$_2$) $^{31}P\{H\}$ NMR ($CDCl_3$, 400, 162 MHz) δ/ppm: 59.90, 60.93 (m, 2P, *P*–CH–) *Anal.* Calc. for $C_{20}H_{48}InN_3P_2S_4Se_2$: C, 32.3; H, 5.9; N, 5.1, S, 15.8. Found: C, 31.5; H, 5.9; N, 5.1; S, 15.7%.

2.3. Synthesis of $[In\{(SeP^iPr_2)_2N\}(S_2P^iBu_2)_2]$ (3)

$Na(S_2P^iBu_2)_2$ (0.39 g, 1.34 mmol) was added to a stirred solution of $In[(SeP^iPr_2)_2N]_2Cl$ (1.28 g, 6.01 mmol) in 20 ml THF and the colour immediately turned into intense yellow. The reaction was refluxed for 1 h after which a orange colour solution was obtained. After removal of the solvent

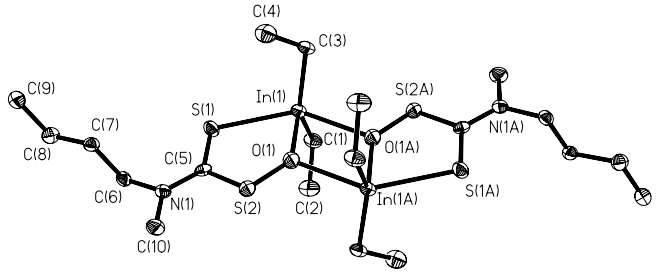

Fig. 1. Molecular structure of $[Et_2In(OS_2CNMe^nBu)]_2$. Hydrogen atoms have been omitted for clarity.

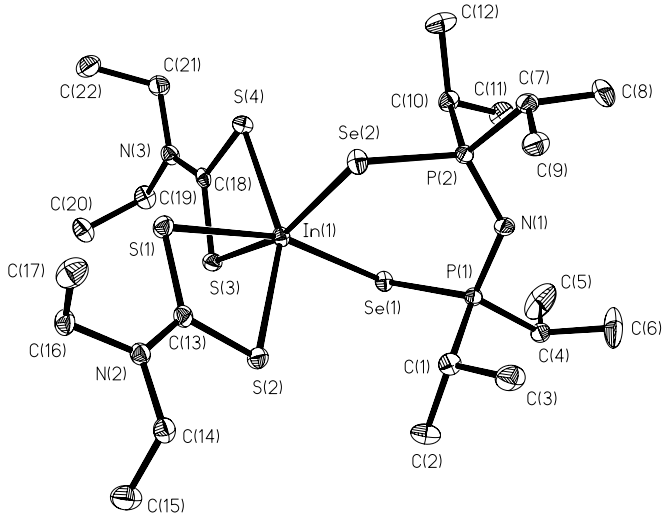

Fig. 2. Molecular structure of $[In\{(SeP^iPr_2)_2N\}(S_2CNEt_2)_2]$. Hydrogen atoms have been omitted for clarity.

in vacuo, an orange colour powder was obtained which was recrystallised from DCM. Yield: 78%. ^{1}H NMR ($CDCl_3$, 300 MHz) δ/ppm: 1.15–1.30 (m, 24H, P–CH_2–CH(CH_3)$_2$), 1.30–1.39 (m, 24H, P–CH(CH_3)$_2$), 2.18 (m, 4H, P–CH(CH_3)$_2$), 2.32–2.58 (m, 12H, P–CH_2–CH(CH_3)$_2$) ^{31}P{H} NMR ($CDCl_3$, 400, 162 MHz) δ/ppm: 59.95 (d/d, 2P, *P*–CH–), 66.07 (d/d, 2P, *P*–CH_2–). *Anal*. Calc. for $C_{28}H_{64}InNP_4S_4Se_2$: C, 35.2; H, 6.9; N, 1.5, P, 13.2. Found: C, 33.9; H, 6.4; N, 2.0; P, 12. 8%.

2.4. X-ray single crystallography

Measurements were made using graphite monochromated Mo Kα radiation on a Bruker APEX diffractometer.

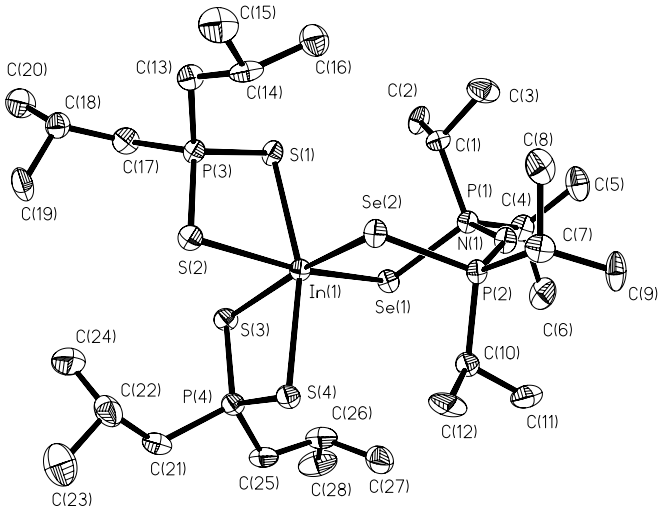

Fig. 3. Molecular structure of [In{(SeP^{i}Pr$_2$)$_2$N}(S$_2$P^{i}Bu$_2$)$_2$].

The structures were solved by direct methods and refined by full-matrix least-squares on F^2 [14]. All calculations were carried out using the SHELXTL package [15]. All non-hydrogen atoms were refined with anisotropic atomic displacement parameters. Hydrogen atoms were placed in calculated positions and assigned isotropic atoms. Figs. 2 and 3 have 50% thermal ellipsoids. Crystallographic details and selected interatomic distances and angles are summarised in Tables 1 and 2.

3. Results and discussion

Compound (**1**) was initially prepared serendipitously by exposure of [In(S$_2$CNMe^{n}Bu)$_3$] and triethylindium solution to air. The reaction gave reproducible results when repeated by stirring the reaction mixture in an open flask for 2 min. The same reaction in dry toluene under strictly air sensitive conditions produced a viscous liquid [Et$_2$In(S$_2$CNMe^{n}Bu)] which has successfully been used for the deposition of In_2S_3 nanorods by AACVD [8]. Compound (**1**) is soluble in most organic solvents and was crystallised from a toluene solution to give transparent cubic crystals. It gave satisfactory microelemental analysis. ^{1}H NMR spectrum gave an overlapping quartet and a triplet at 0.90–1.00 ppm for methylene protons of ethyl group attached with indium and for methyl protons of *n*-butyl group. A clear singlet for N–CH_3 at 3.41 ppm and a triplet at the lowest field (3.85 ppm) for the *N*-methylene protons of the *n*-butyl group are seen. A quintet is shown for β-methylene protons N–CH_2–CH_2 at 1.79 ppm and a triplet for methyl protons of ethyl group at indium and a multiplet appears for γ-proton of *n*-butyl group at 1.40 ppm. ^{13}C NMR gives an eight line spectrum as expected. CS

carbon gives a signal at the lowest field (203.19 ppm) and the In–CH_2 carbon at the highest field (9.92 ppm).

Our repeated attempts to prepare a *tris* indium complex $In[(SeP^iPr_2)_2N]_3$ even on addition of excess ligand were unsuccessful. This behaviour of the indium complex $In[(SeP^iPr_2)_2N]_2Cl$ has also been reported previously [4]. However, the reaction between $In[(SeP^iPr_2)_2N]_2Cl$ and NaS_2CNEt_2 at room temperature readily produced a mixed ligand (imidodiphosphinate and dithiocarbamate)indium (III) complex $[In\{(SeP^iPr_2)_2N\}(S_2CNEt_2)_2]$ (**2**). Using similar method, another mixed ligand complex (imidodiphosphinate and dithiophosphinate) $[In\{(SeP^iPr_2)_2N\}(S_2P^iBu_2)_2]$ (**3**) was prepared by the reaction of $In[(SeP^iPr_2)_2N]_2Cl$ and $NaS_2P^iBu_2$. Both compounds are soluble in common organic solvents and were crystallised from THF and DCM, respectively, and are air and moisture stable for months.

^1H NMR and ^{31}P NMR data for compounds (**2**) and (**3**) are given in Section 2. In ^1H NMR spectrum of compound (**2**), methyl protons of isopropyl group are shown as overlapping multiplets at δ 1.10–1.1.30 ppm. Similarly, the methyl protons of ethyl group also appear in the same range as overlapping multiplets. The methylene protons of ethyl group appear as overlapping quartets at δ 3.85 ppm and the methyne protons of isopropyl group give four sets of multiplets in the range δ 2.10–2.75 ppm. ^1H NMR spectrum of compound (**3**) gives multiplets for methyl protons of isobutyl groups at δ 1.15–1.30 ppm and the methyl protons of isopropyl groups appear at δ 1.30–1.39 ppm as multiplets as well. Methylene protons and methyne protons of both isobutyl and isopropyl groups give multiplets in the range δ 2.18–2.58 ppm. Only two phosphorus signals are observed at δ 59.95 and δ 66.07 ppm as expected.

3.1. X-ray structures

The structure of complex (**1**) is based on a dimer in which each indium is five co-ordinated with bonding to two ethyl groups, two oxygen and one sulfur atom (Fig. 1). Both dithioperoxycarbamato ligands (odtc) act as both chelating and bridging through oxygen atoms, hence forming two five membered rings (S(1), C(5), S(2), O(1), In (1)) and (S(2A), C(5A), S(1A), In(1A), O(1A)) and a four membered ring (In, O, O, In). The geometry around indium is highly distorted which is reflected in its bond angles; C(1)–In–C(3) being 141.8°, O(1)–In–O(1A) is 67.12° and C(1)–In–O(1) is 113.0°. The bond length In(1)–O(1A) 2.489(3) Å is considerably longer than In(1)–O(1) (2.186(3) Å) as the first one is bridging and the latter is chelating. A similar effect on the bond lengths of In–O was observed in $[Et_2In(\mu,\lambda O_2C)–C_6H_4–2\text{-}NH_2]_n$ where indium to bridging oxygen bond length was In(1)–O(1a) 2.554(4) Å and indium to non-bridging oxygen was In(1)–O(2a) 2.264(3) Å [16]. In–C bond lengths are normal, 2.144(4) Å. In–S bond distances are longer In(1)–S(1) (2.691(13) Å) than those observed in $[In(SOCN^iPr_2)_3]$ In–S(3) 2.481(2) Å [17] but are comparable to those reported for ($Me_2InS_2CNEt_2$) where In–S distances are 2.56(10) and 2.68(10) Å [18].

X-ray structures of compounds (**2**) and (**3**) are shown in Figs. (2) and (3). The reaction of sodium salts of dithiocarbamate or dithiophosphinate with parent compound $In[(SeP^iPr_2)_2N]_2Cl$ replaces axial chlorine and one of the iminobis(diisopropylphosphine selenide) in the trigonal bipyramidal geometry to give a distorted octahedron. In compound (**2**), two distinct sets of In–S bond lengths are seen with the distances of one set longer (In(1)–S(3) 2.648(6) Å) than the other (In(1)–S(2) 2.592(7) Å). Similar pattern has been noted before in other indium dithiocarbamates, e.g. $[Me_2InS_2CNEt_2]$ [18], $In(S_2CNEt)_3$ [19] and $In[S_2P(OEt)_2]_3$ [20]. The In–S bond lengths [2.649(2)–2.68(2) Å] in compound (**3**) are also noticeably different but lie with in the range observed for other indium dithiophosphinate species [21]. No significant difference between In and Se bond lengths is observed in both compounds. Nevertheless, these are comparatively shorter than the In–Se bond lengths found in $In[(SePPh_2)_3N]_3$ (2.75(3) Å) [3] and $In[(SeP^iPr_2)_2N]_2Cl$ (2.720(3) Å) [4].

These In–Se bond lengths are closer to those measured for the less crowded $[In\{Se(2,4,6\text{-}^tBu_3C_6H_2)\}_3]$ compound [22].

In compound (**2**), the S–In–S bite angles (av. 68.62 (10) Å) are smaller than the corresponding Se–In–Se bite angles (99.79 (19) Å) due to the constraint imposed by the dithiocarbamato groups. Similar S–In–S bite angles are observed in $[Et_2InS_2CNEt_2]$ (68.77(3) Å) [18]. The Se–In–Se angle in compound (**2**) readily compares with other octahedral compounds having symmetrical ligands [3]. Similar bonding mode is observed in compound (**3**). In both compounds, P–S bond lengths are enlarged and the N–P bond lengths are shortened as compared to those in their free acids, reflecting the increased delocalisation as a consequence of deprotonation.

4. Conclusion

Three novel indium complexes have been synthesised and completely characterised including their X-ray structures. The insertion of oxygen atoms into the M–S bonds of indium complex, $[Et_2In(S_2CNMe^nBu)]$, produced a unique compound with a dimeric structure. The structure consists of two five membered and one four membered rings formed by chelating and bridging of both dithioperoxycarbamato ligands. Both compounds (**2**) and (**3**) which contain more than one type of ligand are monomers, and in each case indium is six coordinate as compared to the parent indium compound which is five coordinate.

5. Supplementary material

Crystallographic data for the structural analysis have been deposited with the Cambridge Crystallographic Data Center. CCDC reference numbers for the compounds are 234614, 267172 and 267173. Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail: deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

This paper is dedicated to Prof. Mike Hursthouse on the occasion of his 65th birthday.

Abstract

This paper describes the syntheses and structures of two coordination networks based on reaction of diimine-tetracyanoruthenate(II) complexes with lanthanide(III) cations, in the presence of additional bidentate ligands to occupy some of the coordination sites on the lanthanide(III) centres. Reaction of the known complex $K_2[Ru(phen)(CN)_4]$ (phen = 1,10-phenanthroline) with $Gd(NO_3)_3 \cdot 6H_2O$ in the presence of additional phen afforded crystals of $[Ru(phen)(CN)_4]_3[Gd(phen)(H_2O)_3]_2 \cdot 6H_2O$, in which each $[Ru(phen)(CN)_4]^{2-}$ unit is connected to two Gd(III) centres via Ru–CN–Gd bridges using the equatorial pair of cyanide ligands *trans* to the phen ligand. Each Gd(III) centre is the recipient of three bridging cyanide interactions (all from different Ru units) and is additionally coordinated by one phen and three water ligands, making it 8-coordinate. The structure consists of two-dimensional sheets in which the Ru–CN–Gd bridges result in formation of $Ru_6Gd_6(\mu\text{-}CN)_{12}$ rings with a Gd(III) ion at each corner and a Ru(II) ion in the centre of each edge; this sheet is capped above and below by the phen ligands. The new dinuclear cyanometallate $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ (bpym = 2,2′-bipyrimidine) was prepared by reaction of bpym with >2 equivalents of hexacyanoruthenate, and contains eight cyanide ligands which can potentially bridge. Reaction with $Gd(hfac)_3(H_2O)_2$ in MeCN/water afforded $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)(H_2O)_4]_2 \cdot 10H_2O$, (hfac = 1,1,1,5,5,5,-hexafluoro-pentane-2,4-dionate) which has a three-dimensional network structure based on Ru–CN–Gd bridges. Six of the cyanide ligands of each $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ unit connect to Gd(III) ions, and each Gd(III) centre has in additional bidentate hfac ligand and four waters, making it nine-coordinate. The three-dimensional cyanide-bridged lattice contains square cross-section channels which are occupied by water molecules.

Keywords: Coordination network; Gadolinium; Ruthenium; Cyanide; Crystal structures

1. Introduction

As part of our ongoing study into the use of d-block chromophores to act as antennae for generating sensitized near-infrared luminescence from lanthanide(III) ions [1,2], we have recently prepared a series of coordination oligomers and polymers in which the cyanometallate luminophore $[Ru(bipy)(CN)_4]^{2-}$ [3] was crystallized with lanthanide(III) cations, affording networks based on Ru–CN–Ln bridges [2]. These short bridges were effective at facilitating energy-transfer from the ^{3}MLCT state of $[Ru(bipy)(CN)_4]^{2-}$ to the lanthanide centre, as long as the lanthanide had low energy f–f excited states which were available to act as energy-acceptors, i.e., using the series of near-IR emitting lanthanide(III) ions Yb(III), Er(III), Nd(III) and Pr(III). In these cases the Ru-based emission was largely quenched, and sensitized lanthanide

luminescence was observed, following excitation of the $[Ru(bipy)(CN)_4]^{2-}$ unit and energy-transfer to a low-lying f–f excited state of the lanthanide(III) centre.

Accordingly, we are interested in the further study of hybrid coordination networks based on combination of other cyanometallate luminophores with lanthanide(III) ions. Such cyanometallate/lanthanide networks have attracted interest from other workers [4–6], largely for their beautiful structures (e.g. Shore and co-workers) [4], although there has been interest in the photophysical properties of networks based on $[M(CN)_2]^-$ (M = Ag, Au) and lanthanide(III) cations from Patterson and co-workers [5] as the high energy of these cyanometallate excited states makes them effective sensitizers for visible-emitting lanthanides. The magnetic properties of mixed-metal cyanometallate networks has also attracted attention [6]. In this paper, we describe prototypes of two new series of cyanide-bridged d–f coordination networks, viz. the structures derived from (i) crystallisation of $[Ru(phen)(CN)_4]^{2-}$ with Gd(III) in the presence of extra phen to block some of the Gd(III) coordination sites, and (ii) crystallization of the new cyanometallate $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ with $Gd(hfac)_3 \cdot 2H_2O$.

2. Results and discussion

Our aims were twofold: firstly, to use cyanometallate chromophores other than the relatively well-known $[Ru(bipy)(CN)_4]^{2-}$ as components of the networks; secondly, to use additional ligands (such as phenanthroline or a β-diketonate) to block coordination sites on the lanthanide(III) centre which would otherwise be occupied by solvent molecules and possibly have an inhibiting effect on the luminescence [7]. We chose $[Ru(phen)(CN)_4]^{2-}$ as it has superior photophysical properties to $[Ru(bipy)(CN)_4]^{2-}$, with a higher luminescence quantum yield and longer lifetime [8], and so it is likely to be a more effective energy donor. In contrast, the dinuclear complex $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ was chosen for structural reasons, because it has eight externally directed cyanide groups to act as potentially bridging ligands, and may therefore result in more structurally elaborate coordination networks than species such as $[Ru(bipy)(CN)_4]^{2-}$ which can form, at most, four bridging interactions to lanthanide(III) ions [2]. $[Ru(phen)(CN)_4]^{2-}$ is available from the literature [8]; $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ was prepared by reaction of 2,2′-bipyrimidine with >2 equivalents of potassium hexacyanoruthenate under forcing conditions, followed by ion-exchange chromatography to separate it from mononuclear $[Ru(CN)_4(bpym)]^{2-}$.

Slow evaporation of an aqueous solution containing a 3:2 mixture of $K_2[Ru(phen)(CN)_4]$ and $Gd(NO_3)_3$ did not initially yield any crystalline products, However, in the presence of excess phenanthroline [1 equivalent per Gd(III) centre] a good crop of orange block-like crystals grew, whose structure is shown in Figs. 1 and 2. The compound so formed is $[Ru(phen)(CN)_4]_3[Gd(phen)(H_2O)_3]_2 \cdot 6H_2O$, and consists of two-dimensional sheets based on Ru–CN–Gd bridges. Fig. 1 shows the asymmetric unit, plus a few additional atoms to complete the coordination sphere around each of the metal centres. The structure contains two independent $[Ru(phen)(CN)_4]^{2-}$ units, of which one [containing Ru(1)] is in a general position, and the second [containing Ru(2)] lies on a twofold axis such that half of it is in the asymmetric unit. The Gd(III) centre, connected to both of these via cyanide bridges, is also in a general position; the asymmetric unit therefore contains 1.5 cyanoruthenate anions (charge 2- each) to balance the Gd^{3+} cation. The Gd(III) centre is 8-coordinate, from a chelating phenanthroline ligand, three water molecules, and the N-termini of three cyanide bridges from Ru(II) centres.

Fig. 2 illustrates the sheet-like structure of the extended network, viewed from two perspectives. The top view shows the Ru–CN–Gd sheet 'edge-on' and shows how it is capped above and below by the phenanthroline ligands. Successive sheets like this fit together by intermeshing of the 'downward' pointing phenanthroline units from one sheet with the 'upward' pointing phenanthrolines of the layer below. The lower view shows the latter structure face-on, with everything except the Ru, Gd, and cyanide

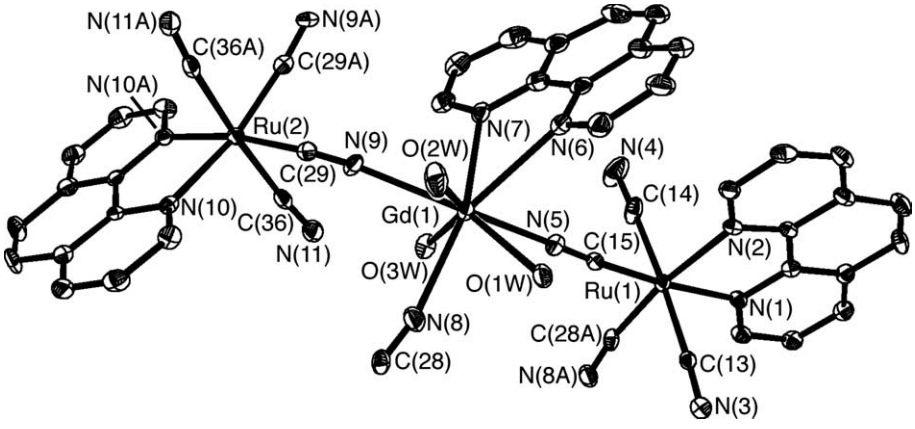

Fig. 1. ORTEP diagram (thermal ellipsoids at 40% level) of the asymmetric unit of $[Ru(phen)(CN)_4]_3[Gd(phen)(H_2O)_3]_2 \cdot 6H_2O$ (solvent molecules omitted).

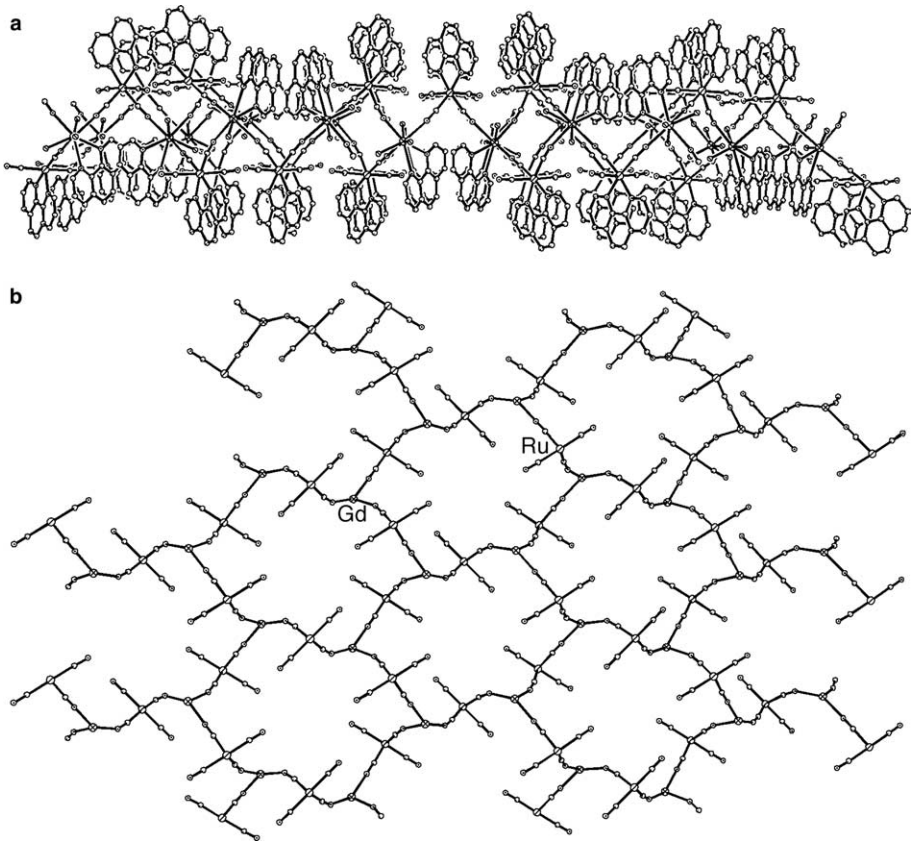

Fig. 2. (a) Edge-on view of a two-dimensional layer in $[Ru(phen)(CN)_4]_3[Gd(phen)(H_2O)_3]_2 \cdot 6H_2O$, with lattice solvent molecules omitted for clarity and (b) face-on view of the two-dimensional layer with only Ru, Gd and cyanide atoms showing.

atoms shown for clarity. It is clear that the sheet structure consists of 36-membered rings consisting of 6 Ru centres, 6 Gd centres and 12 bridging cyanide ligands. Each Ru(II) unit is connected to two adjacent Gd(III) centres via the 'equatorial' pair of cyanide ligands that are *trans* to the phenanthroline group; the 'axial' pair of cyanide ligands is not involved in bridging. In contrast each of the Gd(III) centres is connected to three Ru(II) centres via bridging cyanides, and this provides a mechanism for the rings to fuse together, with each Gd(III) centre being at the point where three $Ru_6Gd_6(CN)_{12}$ rings meet. The topology of this network is accordingly similar to that of a layer of fused hexagons in graphite, with the Ru atoms in the centre of each edge (connected to two vertices) and the Gd atoms at the vertices, connected to three different edges. The Ru···Gd separations are 5.45 Å [Ru(2)···Gd(1)], 5.55 Å [Ru(1A)···Gd(1A)] and 5.34 Å [Ru(2)···Gd(1)].

Reaction of $K_4[\{Ru(CN)_4\}_2(\mu\text{-bpym})]$ with $Gd(hfac)_3(H_2O)_2$ would, it was hoped, generate a network in which the two labile water ligands of $Gd(hfac)_3(H_2O)_2$ would be replaced by cyanide ligands, such that the lanthanide(III) centre would be solvent-free and coordinated only by three diketonate and two cyanide ligands. However, slow evaporation of a mixture of these components from aqueous MeCN solution afforded a good crop of crystals of $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)(H_2O)_4]_2 \cdot 10H_2O$ (Figs. 3 and 4) in which each Gd centre has lost two of its hfac ligands; thus, two $\{Gd(hfac)\}^{2+}$ units balance the charge of each $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ unit. Fig. 3 shows the asymmetric unit of the structure, with a few extra symmetry-equivalent atoms included to complete the coordination sphere about each metal ion. Gd(1) is 9-coordinate, from the remaining bidentate diketonate ligand, four water ligands, and three N atoms from bridging cyanides; one of the water ligands [O(3)] is disordered over two sites, so there is little point in analyzing the coordination geometry. The F atoms of the hfac ligands were likewise disordered over two sites corresponding to different orientations of the CF_3 substituents. The $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ unit is involved in six Ru–CN–Gd bridging interactions, with all four cyanide ligands on Ru(1) interacting with Gd(III) centres, wheras only two cyanides on Ru(2) – the equatorial 'cis'-related pair in the same plane as the bpym ligand – are bridging to Gd(III) centres.

The bridging cyanide interactions in this case result in a three-dimensional network, as shown in Figs. 4 and 5. The view down the *a* or *b* axis (Fig. 4, with the water and hfac ligands removed for clarity) shows how the interaction of each $[\{Ru(CN)_4\}_2(\mu\text{-bpym})]^{4-}$ unit with six Gd(III) centres generates the three-dimensional network. The view down the *c* axis (Fig. 5, with hfac and water ligands included) shows how the Ru–CN–Gd network contains

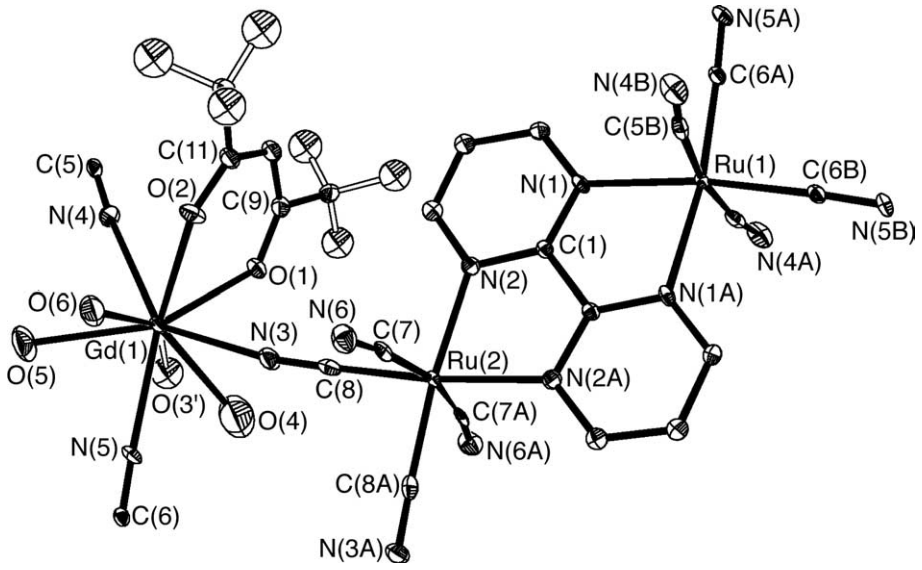

Fig. 3. ORTEP diagram (thermal ellipsoids at 40% level) of the asymmetric unit of $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)(H_2O)_4]_2 \cdot 10H_2O$ (solvent molecules omitted). The F atoms and O(3) are disordered over two sites; only the major component is shown, with the bonds to these atoms being hollow.

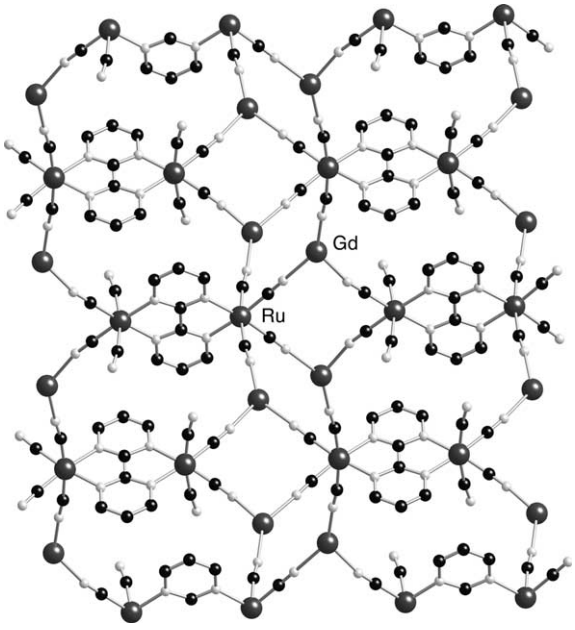

Fig. 4. A view of the three-dimensional lattice in $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)(H_2O)_4]_2 \cdot 10H_2O$, showing only the Ru, Gd, bipyrimidine and cyanide atoms.

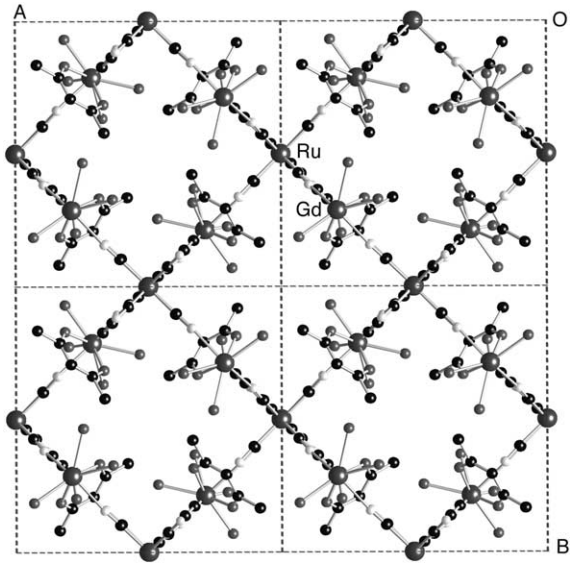

Fig. 5. Alternative view (down the *c* axis) of the three-dimensional lattice in $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)(H_2O)_4]_2 \cdot 10H_2O$, emphasizing the square cross-section array of channels which contain water molecules (omitted for clarity).

square channels; these are filled with water molecules which are involved in hydrogen-bonding interactions with each other and with the water ligands coordinated to Gd(III), as shown by numerous O···O separations of 2.7–3 Å. The Ru···Gd separations are 5.53 Å [Ru(2)···Gd(1)], 5.68 Å [Ru(1)···Gd(1)] and 5.61 Å [Ru(1A)··· Gd(1)].

In conclusion, the cyanoruthenate chromophores that we have been interested in for their photophysical properties also form attractive coordination networks with lanthanide ions, in which we expect that, with an appropriate choice of lanthanide(III) ion, photoinduced d → f energy will transfer will occur following the examples we described recently [2]. Photophysical studies are in progress and will be described separately.

3. Experimental

3.1. General details

The compounds $K_2[Ru(phen)(CN)_4]$ [8] and $Gd(hfac)_3 \cdot (H_2O)_2$ [9] were prepared according to the literature procedures. 2,2′-Bipyrimidine and potassium hexacyanoruthenate

were purchased from Aldrich and Alfa respectively, and used as received.

3.2. Preparation of $K_4[\{Ru(CN)_4\}_2(\mu\text{-bpym})]$

A solution of 2,2′-bipyrimidine (0.079 g, 0.5 mmol) and $[K_4Ru(CN)_6]\cdot 3H_2O$ (0.513 g, 1.1 mmol) in aqueous HCl at pH 1.3 was heated to reflux with stirring for 24 h and then cooled down to room temperature. The resulting dark red–brown solution was neutralised with KOH and the solution was evaporated to dryness. The solid residue was dissolved in the minimum quantity of water, and MeOH was added to precipitate unreacted $K_4[Ru(CN)_6]\cdot 3H_2O$ which was filtered off. The residue was again evaporated to dryness, dissolved in the minimum quantity of water; addition of acetone precipitated the crude product which was filtered off and washed with acetone. The product was purified by column chromatography on SEPHADEX QAE-25, eluting with aqueous KI. Use of 0.15 M KI resulted in elution of the mononuclear by-product $K_2[Ru(bpym)(CN)_4]$ (which is the major product); increasing the KI concentration to 0.25 M then resulted in elution of dark red $K_4[\{Ru(CN)_4\}_2(\mu\text{-bpym})]$, which was collected and reduced in volume to 5 cm^3. The complex was precipitated by the addition of acetone and further recrystallized from H_2O/acetone, and dried in vacuo to give the pure product as a red solid. Yield: 34%. *Anal.* Calc. for $K_4[\{Ru(CN)_4\}_2\text{-}(\mu\text{-bpym})]$: C, 26.5; H, 0.8; N, 23.2. Found: 27.5; H, 1.0; N, 23.9%. ^{1}H NMR (D_2O): δ 7.80 (1H, t; $J = 5.5$ Hz), 9.35 (2H, d; $J = 5.5$ Hz).

3.3. Preparation of $[Ru(phen)(CN)_4]_3[Gd(phen)(H_2O)_3]_2\cdot 6H_2O$

An aqueous solution containing $K_2[Ru(phen)(CN)_4]$, $Gd(NO_3)_3\cdot 6H_2O$ and 1,10-phenanthroline in a 3:2:2 ratio afforded crystals of the product as orange blocks following slow evaporation over several weeks. *Anal.* Calc. for $[Ru(phen)(CN)_4]_3[Gd(phen)(H_2O)_3]_2\cdot 6H_2O$: C, 42.2; H, 3.2; N, 15.0. Found: C, 42.5; H, 3.0; N, 14.6%.

3.4. Preparation of $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)(H_2O)_4]_2\cdot 10H_2O$

A solution of $K_4[\{Ru(CN)_4\}_2(\mu\text{-bpym})]$ (0.015 g, 20 μmol) in MeCN/water (1:1, 1.5 cm^3) was added to a solution of $Gd(hfac)_3(H_2O)_2$ (0.080 g, 200 μmol) in MeCN/water (1:1, 2.5 cm^3) with stirring. Slow evaporation of the resulting solution afford red plate-like crystals in 75% yield. *Anal.* Calc. for $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)(H_2O)_4]_2\cdot 10H_2O$: C, 19.3; H, 2.7; N, 10.4. Found: C, 19.5; H, 2.3; N, 10.7%.

3.5. X-ray crystallography

X-ray crystallographic data are summarised in Tables 1–3. For each compound a suitable crystal was coated with hydrocarbon oil and attached to the tip of a glass fibre and transferred to Bruker-SMART diffractometer under a stream of cold N_2. Data were collected using a Siemens SMART CCD area diffractometer (graphite monochromated Mo Kα radiation, $\lambda = 0.71073$ Å) with an Oxford Cryosystems low temperature system. The data were corrected for Lorentz and polarisation effects and for absorption by semi-empirical methods (SADABS) based on symmetry-equivalent and repeated reflections. The structures were solved by direct methods or heavy atom Patterson methods and refined by full-matrix least-squares methods on F^2. Hydrogen atoms were placed geometrically and refined with a riding model and with U_{iso} constrained to be 1.2 (1.5 for methyl groups) times U_{eq} of the carrier atom. All non-hydrogen atoms were refined anisotropically unless otherwise stated. The programs used in the determination and refinement of the structures were Siemens

SMART [10] and SAINT [11] for control and integration software, and the SHELXTL package [12] comprising SHELXS-97 [13] and SHELXL-97 [14] for structure solution and refinement.

In the structure of $[\{Ru(CN)_4\}_2(\mu\text{-bpym})][Gd(hfac)$-$(H_2O)_4]_2 \cdot 10H_2O$, atom O(3) [coordinated to Gd(1)] is disordered over two closely spaced sites with site occupancies of 0.69 and 0.31; these disordered atoms were refined with isotropic thermal parameters. The minor component O(3′) ends up quite close to O(4) [1.87 Å] but atom O(4) shows no sign of also being disordered, with unit site occupancy and unremarkable thermal parameters. The six F atoms of the CF_3 groups on the hfac ligand were also all disordered over two sites which refined with site occupancies of 0.57 and 0.43; these F atoms were also refined with isotropic thermal parameters.

4. Supplementary material

Supplementary data (cif files for the two structures) are available on request from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge, CB2 1EZ, UK, quoting deposition Nos. 274160 and 274161 (see www: http://www.ccdc.cam.ac.uk).

Dedicated to Professor Michael B. Hursthouse on the occasion of his 65th birthday.

Abstract

Reactions of appropriate bis(6,6-dmch) (dmch = dimethylcyclohexadienyl) complexes of titanium(II) or zirconium(IV) with dichloroethane or phosphines, respectively, have led to loss of one dienyl ligand, and the formation of mono(6,6-dmch) complexes of Ti(III) or Zr(IV). The polymeric $[Ti(6,6\text{-dmch})Cl_2]_n$ and $Zr(6,6\text{-dmch})Br_3(dmpe)$ (dmpe = 1,2-bis(dimethylphosphino)ethane) have thus been isolated, and fully characterized.

Keywords: Dimethylcyclohexadienyl complex; Pentadienyl titanium(III) structure; Pentadienyl zirconium(IV) structure

1. Introduction

A substantial body of chemistry has developed based on open and half-open metallocenes [1]. In these compounds, two dienyl ligands are present, both being the electronically open pentadienyl ligand or a substituted variant in the former class of compounds, while in the second class, one electronically open pentadienyl ligand is joined by an aromatic cyclopentadienyl ligand. Particularly for the early transition metal systems, whose pentadienyl chemistry has been found to be quite rich [2], it would be advantageous to have available mono(pentadienyl) metal halide complexes as starting materials for further exploration. Herein, we report reactions of $Ti(6,6\text{-dmch})_2$ and of $Zr(6,6\text{-dmch})_2Br_2$ that lead readily to such species.

2. Experimental

All reactions were conducted under a nitrogen atmosphere in Schlenk apparatus. Solvents were dried and deoxygenated by passing them through columns of activated alumina under a nitrogen atmosphere, while benzene-d_6 was dried and deoxygenated by vacuum transfer from sodium benzophenone ketyl. Spectroscopic studies were carried out as previously described [3]. ^{13}C NMR spectra were not precisely integrated, but numbers of carbon atoms are given in accord with their assignments. $Ti(6,6\text{-dmch})_2$ [4] and $Zr(6,6\text{-dmch})_2(PMe_3)_2$ [5] were prepared as previously described. Due to the high solubility of the former in hydrocarbons, its crude solutions were used directly for further reactions. Elemental analyses were obtained from Desert Analytics.

2.1. Dichloro(6,6-dimethylcyclohexadienyl)titanium(III), $[Ti(6,6\text{-dmch})Cl_2]_n$

To a brown-green solution of $Ti(6,6\text{-dmch})_2$ (nominally 0.58 g, 2.2 mmol) in 20 mL of hexane, 1,2-dichloroethane (0.18 mL, 2.2 mmol) was added. The color of the solution slowly changed to dark brown. The reaction mixture was left overnight unstirred. The next day, brown crystals suitable for X-ray analysis had grown on the bottom of the

reaction flask (0.12 g, 24%). The compound was insoluble in common organic solvents.

Anal. Calc. for $C_8H_{11}Cl_2Ti$: C, 42.52; H, 4.91. Found: C, 42.00; H, 5.11%.

2.2. Tribromo[1,2-bis(dimethylphosphino)ethane](6,6-dimethylcyclohexadienyl)zirconium(IV), Zr(6,6-dmch)(dmpe)(Br)$_3$

To a dark black-red solution of Zr(6,6-dmch)$_2$(PMe$_3$)$_2$ (0.61 g, 1.3 mmol) in 30 mL of hexanes was added 1,2-dibromoethane (0.23 mL, 2.4 mmol). A bright red-orange precipitate immediately formed. The reaction mixture was allowed to stir for 30 min. The solvent was removed in vacuo, leaving a red-orange residue which was dissolved in 20 mL of THF. Next, 1,2-bis(dimethylphosphino)ethane (dmpe, 0.45 mL, 2.4 mmol) was added and the solution color immediately changed to dark purple. After ~1 h of stirring at room temperature the color of the solution changed again to bright orange-red. After the reaction mixture was stirred for an additional 2 h, the solvent was removed, leaving an orange residue. The solid was extracted with ca. 40 mL of toluene and filtered through a Celite pad on a coarse frit. The product was crystallized by concentrating the solution to 5 mL and placement in a −60 °C freezer, yielding 0.42 g (54% yield) of red-orange solid.

2.3. Crystallographic studies

Single crystals of each compound were protected from the air by a coating of Paratone oil, and then fixed to a glass fiber and transferred to a Nonius Kappa CCD diffractometer. Structure solutions and refinements were carried out using the SIR-97 and SHELXL-97 program packages. The Ti(6,6-dmch)Cl$_2$ structure suffered a disorder involving a 75:25 ratio of overlapping images. The C4, C6, C7, and chlorine atom positions overlapped their analogues in the second image, and hence appeared as single atoms. As such, their bonding parameters must be considered less reliable than indicated. Most nonhydrogen atoms could be refined anisotropically. The exceptions were the resolved carbon atoms of the minor image, C1′, C2′, C3′, C5′, and C8′, which were refined isotropically. Hydrogen atoms were allowed to ride on their respective carbon atoms. An alternative solution in the centrosymmetric space group $P2_1/m$ was judged incorrect due to the 3:1 ratio of the images that would be averaged, and the fact that refinements of the structure in this space group were poorly behaved and led to *R* factors of ca. 20%. For Zr(6,6-dmch)Br$_3$(dmpe), all nonhydrogen atoms were refined anisotropically, while the hydrogen atoms were refined isotropically (see Table 1).

3. Results and discussion

Earlier studies have demonstrated that Zr(6,6-dmch)$_2$(PMe$_3$)$_2$ and Zr(C$_5$H$_5$)(6,6-dmch)(PMe$_3$)$_2$ react with 1,2-C$_2$H$_4$X$_2$ to yield the first general series of higher valent metal pentadienyl complexes, Zr(6,6-dmch)$_2$X$_2$ and Zr(C$_5$H$_5$)(6,6-dmch)X$_2$ (X = Cl, Br, I) [6,7]. Prior to these reports, few such higher valent species were known [8], nearly all of which incorporated strong π-donor ligands [9], whose function may have been to reduce the buildup of positive charge on the metal center, thereby allowing for better overlap between the metal valence orbitals and those of the wide pentadienyl ligands. Conceivably, the added electron density might also have allowed for some δ backbonding, which can be an especially strongly bonding interaction for metal pentadienyl compounds [1]. It has therefore become of interest to investigate the possibility of preparing a general series of high valent titanium

pentadienyl complexes. As in the case of zirconium, it appeared that the 6,6-dmch ligand (**1**) would be ideal for such attempts. Early work with this ligand by the Wolczanski group has shown that this ligand displays electronic properties which are intermediate between those of cyclopentadienyl and typically strongly δ acidic pentadienyl ligands [4,10]. Indeed, a reaction readily occurred between Ti(6,6-dmch)$_2$ and 1,2-$C_2H_4Cl_2$, leading to the loss of one 6,6-dmch ligand and the formation of a brown, crystalline product having the stoichiometry Ti(6,6-dmch)Cl_2, analogous to the known $[Ti(C_5H_5)Cl_2]_n$ [11]. A single crystal X-ray diffraction study (Table 2, Fig. 1) revealed that the titanium centers achieved a four-legged piano stool structure through the formation of a one-dimensional polymeric network involving chloride bridges. A similar structure is thus conceivable for the C_5H_5 analogue. Although the +3 oxidation state is not generally considered to be that high, it is not all that common for metal pentadienyl complexes, presumably for the same reasons that tetravalent and higher oxidation states are rare. Indeed, one observes a similar though somewhat less exaggerated pattern in the M–C bond distances as observed for the tetravalent zirconium analogues. In particular, the Ti–C(3) distance (2.333(4) Å) is shorter than the Ti–C(2,4) distances (2.337(6), 2.416(4) Å), and still shorter than the Ti–C(1,5) distances (2.457(5), 2.526(6) Å). As for the Zr(IV) complexes, it appears that the contracted Ti(III) orbitals do not overlap effectively with those of a wide pentadienyl ligand, leading to a strong interaction with the central dienyl carbon atom, and progressively longer interactions with the subsequent carbon atoms. Thus, one observes what may be regarded as the initiation of the expulsion of a pentadienyl ligand from a higher valent metal center. The C–C bond distances follow a short-long-long-short pattern, consistent with the above formulation, and with **2**. Given that the chlorine atom positions are really composites of two images, the Ti–Cl distances for the major one, ranging from 2.458(1) to 2.519(1) Å, are fairly regular. Those for the second image appear to be less regular, with two long interactions being compensated by two short ones. If real, this could reflect packing requirements for the attached Ti(6,6-dmch) residue.

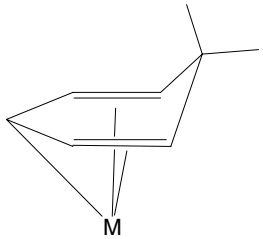
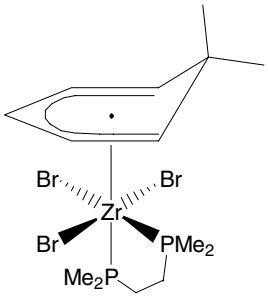
1



2

Access to a mono(6,6-dmch) complex of zirconium(IV) was obtained from the reaction of Zr(6,6-dmch)$_2Br_2$ with dmpe [1,2-bis(dimethylphosphinoethane)]. Interestingly, a dark purple intermediate was immediately formed, of unknown formulation, and this slowly was converted to the orange-red color of the subsequently isolated product. The rapid incorporation of the dmpe into a sterically crowded Zr(6,6-dmch)$_2Br_2$ complex seems unusual, but could be promoted by the slipped nature of the 6,6-dmch ligand in the high valent complex. Spectroscopic, analyti-

cal, and structural characterization revealed the product to be Zr(6,6-dmch)Br_3(dmpe), **3**.



3

As the product contains more bromine than the starting complex, the addition of dmpe to Zr(6,6-dmch)$_2Br_2$ led to some sort of disproportionation. Whether this simply involves a redistribution of 6,6-dmch ligands, or perhaps loss of 6,6-dmch ligand to yield a Zr(III) intermediate which then undergoes redox and bromide redistribution processes is unclear, but further investigation of the purple intermediate would be of interest. Notably, the reaction of Zr(6,6-dmch)$_2$(PMe_3)$_2$ with 1,2-$C_2H_4I_2$ has been found to lead to an analogous species, Zr(6,6-dmch)I_3(PMe_3)$_2$, as well as Zr(6,6-dmch)$_2I_2$ [6].

The structure of **3** (Fig. 2, Table 3) may be regarded as a *mer*,*cis*-pseudooctahedral coordination geometry. Such an arrangement has been established earlier for U($C_5H_4CH_3$)Cl_3(THF)$_2$ [12]. Subsequently, this geometry has been established for numerous transition metal complexes,

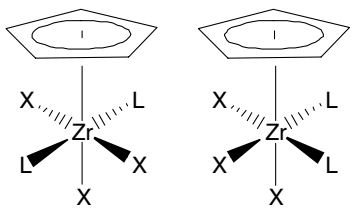
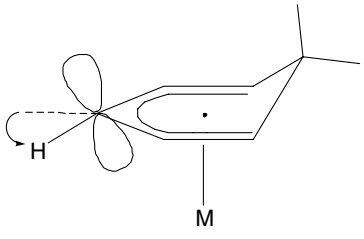
including a number of Zr(C_5H_5)Cl_3(L)$_2$ species (L$_2$ = dme [13], L = H_2O [14], and L = THF or dmf [15]), as well as for Ti(C_5H_5)Cl_3(dmpe) [16]. Interestingly, appropriate tethering of the Lewis bases (L) to the dienyl ligand has led to the alternative *mer*,*trans* [17,18] and *fac* [19] isomers (**4**, **5**). A pseudo-octahedral arrangement has also been found for Zr(*c*-C_8H_{11})(H)(dmpe)$_2$ (C_8H_{11} = octadienyl), and presumably also exists for Zr(*c*-C_6H_7)(H)(dmpe)$_2$ (C_6H_7 = hexadienyl) [20]. Given the large size of the 6,6-dmch ligand, it is not surprising that the four adjacent ligands tilt substantially down toward the P(2) donor site, with P2–Zr–Br angles ranging from 74.35(2)° to 77.71(2)°. The P2–Zr–P1 angle is still smaller, at 71.75(2)°, as a result of the chelating nature of the dmpe ligand. The Zr-dmch bonding follows the expected trend for a higher valent metal pentadienyl complex, having the shortest interaction involving the central dienyl carbon atom, with the subsequent carbon atoms being located progressively further from the metal center. The short–long–long–short pattern in dienyl C–C bond distances is consistent with this (cf., **2**). As in the case of [Ti(6,6-dmch)Cl_2]$_n$ and the other high valent metal pentadienyl complexes, the structural data reflect an inability of the contracted metal orbitals to interact effectively with the entire dienyl fragment, leading to the initiation of ligand slippage. The observed structure may be viewed as an intermediate between η^5 and η^1 coordination modes, which can play a major role in facilitating the loss of pentadienyl ligands from their high valent complexes, and thus helps explain the extreme preference



4 **5**

exhi-bited by pentadienyl ligands to bond to metals in lower oxidation states.

Some additional indications of the $\eta^5-\eta^1$ slippage can be seen in the dienyl fragment. As noted above for $[Ti(6,6\text{-dmch})Cl_2]_n$ and the other high valent complexes, one observes a short–long–long–short pattern of C–C bond distances, consistent with **2**. Furthermore, resonance form **2** implicates a partial contribution of sp^3 hybridization on the central carbon atom, and this is reflected by the C2–C3–C4 bond angle being smaller than those for C1–C2–C3 and C3–C4–C5 (116.4(3) vs. 121.1(3)° and 121.3(3)°). Finally, tilts of the hydrogen atom substituents out of the plane are telling. Typically in metal-pentadienyl compounds, the dienyl substituents tilt significantly down toward the metal center, in an attempt to improve metal–ligand overlap, as in **6**. That is indeed observed here for H1, H2, H4, and H5. The tilts for H2 and H4 (0.13, 0.21 Å) seem to be greater than those for H1 and H5 (0.11, 0.14 Å). This may indicate that the Zr–C(1,5) distances have become so long that little can be gained from the substituent tilting. In contrast, the central hydrogen atom experiences essentially no tilt, 0.02(3) Å, and in fact, in other high valent complexes the tilting actually occurs in a direction *away from* the metal center, in accord with the partial contribution of sp^3 hybridization on C3.



6

The availability of these mono(dmch) complexes of Ti(III) and Zr(IV), along with the previously reported $Zr(C_5H_5)(6,6\text{-dmch})X_2$ and $Zr(6,6\text{-dmch})_2X_2$ complexes, should now allow for the first extensive investigations of higher valent metal pentadienyl chemistry. Already it is clear that this chemistry differs dramatically from the lower valent species, and many worthwhile possibilities await exploration.

4. Supplementary material

Crystallographic data for the structural analysis has been deposited with the Cambridge Crystallographic Data Centre, CCDC, Nos. 273154-273155 for compounds $[Ti(6,6\text{-dmch})Cl_2]_n$ and $Zr(6,6\text{-dmch})Br_3(dmpe)$, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk.

Dedicated with admiration to Professor Michael B. Hursthouse on the occasion of his 65th birthday.

Abstract

Five heterobimetallic Cu–Ln complexes of general formula $[CuLn(HL)_2(NO_3)_3(MeCN)_2]\cdot 2Et_2O$ (Ln = Eu **1**, Tb **2**, Er **3**, Yb **4** and Nd **5**) were prepared with a new multidentate benzimidazole ligand based on 4-bromo-2-[2-(5-bromo-2-hydroxy-3-methoxy-phenyl)-benzoimidazol-1-ylmethyl]-6-methoxy-phenol ($\mathbf{H_2L^1}$) or its bis-methoxy substituted analog ($\mathbf{H_2L^3}$). In the solid state the structures of **1**–**4** exhibit supramolecular 3D-networks which are formed by the linking of C–H···O and C–H···π interactions. Compound **5** does not exhibit an extended supramolecular network.

1. Introduction

Mononuclear transition metal complexes are now well established as versatile building blocks in supramolecular chemistry [1]. In many cases successful strategies for engineering the assemblies of materials take advantage of non-bonded interactions such as hydrogen-bonding and π–π stacking between building blocks. More recently molecular assemblies incorporating dinuclear metal species as rigid or semi-rigid corner units have become the focus of active research [2]. Although heterobimetallic 3d–4f metal complexes are of interest for their catalytic, electronic, magnetic or optical properties there are relatively few reports of supramolecular assemblies which comprise these units as building blocks [3]. As part of our ongoing interest in 3d–4f complexes we have investigated the use of modified "salen" type Schiff base complexes such as $\mathbf{H_2L^2}$ [4]. This ligand may be conveniently prepared at room temperature. However, in refluxing ethanol it is converted into the benzimidazole ligand $\mathbf{H_2L^1}$ (Scheme 1). This type of transformation is well known and in the case of $\mathbf{H_2L^1}$ produces a substituted benzimidazole with two 5-bromo-3-methoxy-phenolic substituents. One is linked directly to the center carbon of the benzimidazole group and the other via a CH_2 group to a nitrogen atom [5]. Despite the asymmetric nature of $\mathbf{H_2L^1}$ we have found that two deprotonated units of it can stabilize 3d–4f heterobimetallic complexes via benzimidazole nitrogen, phenolic oxygen and methoxy oxygen atoms. Interestingly, in the solid state the structures of these compounds exhibit supramolecular 3D-networks formed by C–H···O hydrogen bonding and C–H···π interactions.

We have also isolated and characterized an analogous Cu–Nd complex which has a similar benzimidazole ligand but with two OMe substituents on the phenylene backbone.

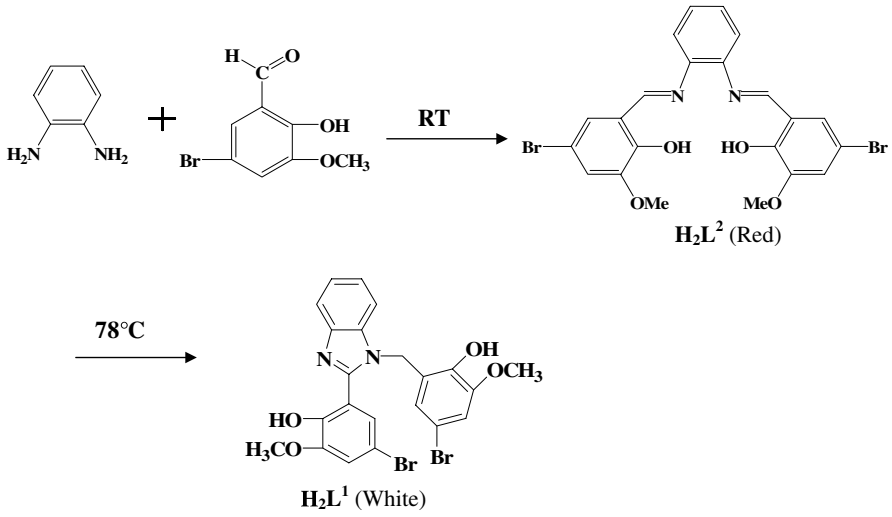

Scheme 1.

In this case, no supramolecular 3D-network was found in the solid state.

2. Results and discussion

2.1. Free Schiff base ligand H_2L^1

The reaction of *o*-phenylenediamine with 5-bromo-2-hydroxy-3-methoxybenzaldehyde in ethanol of room temperature gives the bright-red Schiff base $\mathbf{H_2L^2}$ in high yield (Scheme 1) [4]. However if this reaction is carried out under refluxing conditions (10 h) the colorless benzimidazole derivative $\mathbf{H_2L^1}$ is produced in good yield. In order to confirm the identity of this product the solid state structure of $\mathbf{H_2L^1}$ was determined via an X-ray crystallographic study (Table 1). Two views of the molecule are shown in Fig. 1. The two substituted aryl groups are both twisted with respect to the planar benzimidazole unit, no doubt in order to reduce steric interactions. The dihedral angles are 53.6° and 78.1°. Hydrogen bonding interactions (O–H···N) link adjacent molecules of the free ligand into one-dimensional strands ($N_{1A}\cdots O_{4B} = 2.691$ Å), as shown in Fig. 1. Key bond lengths and angles for $\mathbf{H_2L^1}$ are given in Table 2.

2.2. Metal complexes

Reactions of $\mathbf{H_2L^1}$ with $Cu(OAc)_2$ and $Ln(NO_3)_3 \cdot 6H_2O$ in MeCN/EtOH produce blue solutions from which the dinuclear complexes $[CuLn(HL^1)_2(NO_3)_3(MeCN)_2] \cdot 2Et_2O$ (Ln = Eu **1**, Tb **2**, Er **3** and Yb **4**) may be isolated in 30–60% yields as blue crystalline solids. X-ray crystallographic studies have shown that **1**–**4** are isomorphous with central dinuclear units comprising neutral $[CuLn(HL^1)_2(NO_3)_3(MeCN)_2]$ moieties. The minor differences in the metric parameters for these molecules reflect the effects of the lanthanide contraction. A view of **1** is shown in Fig. 2 and important bond lengths and angles are presented in Table 3. The molecular structure of **1** features Cu(II) and Eu(III) ions complexed by two deprotonated $\mathbf{HL^1}$ ligands.

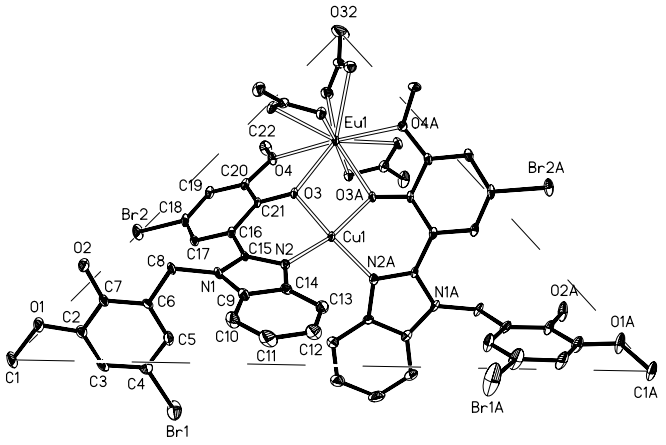

Fig. 2. View of the crystal structure of **1** (C(1)···C(1A): 20.005 Å, C(1)···O(32): 15.650 Å). Thermal ellipsoids are drawn at the 25% probability level. Two weakly coordinated MeCN molecules bond to Cu(1) and all hydrogen atoms are omitted for clarity.

In each case the molecule sits on a crystallographic 2-fold axis which runs through the lanthanide and Cu atoms. The unsubstituted nitrogen atoms of the benzimidazole group are bound to the Cu(II) center while the deprotonated phenolic groups bridge both metals. The Cu^{2+} ion has a pseudo-octahedral coordination environment which is completed by two weakly bond molecules of MeCN in axial positions (N(3)–Cu(1) = 2.564 Å). The Cu(1)–Eu(1) distance is 3.482 Å. The overall structure has a distinctly triangular structure of nanoscale proportions (20.0 × 15.7 × 15.7 Å) and has a C_2-axis which runs through O(32)–Cu(1)–Eu(1). The Eu^{3+} ion is 10 coordinate with an inner coordination environment provided by oxygen atoms; four from two $\mathbf{HL^1}$ ligands and six from the three bidentate nitrates. The pseudo-octahedral coordination geometry of Cu(1) (pseudo-square planar if the two weakly bound MeCN groups are ignored) causes the deprotonated $\mathbf{HL^1}$ ligand to adopt a more planar configuration. Thus, the dihedral angle between the benzimidazole group and the aryl ring which bears the deprotonated

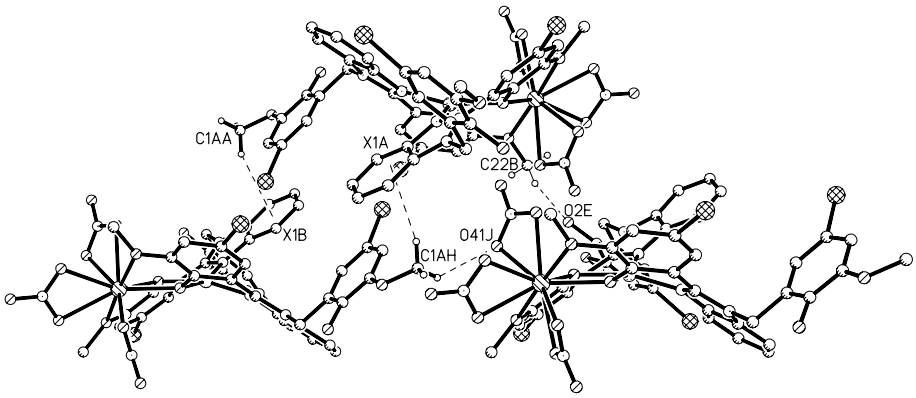

Fig. 3. View of the intermolecular interactions in **1**: C–H···π interactions (H(1AH)···X1A: 2.854 Å, C–H–π: 153.3°; H(1AA)···X1B: 2.860 Å, C–H–π: 147.3°) and hydrogen bonds (O(2E)···H–C(22B): 2.473 Å, O–H–C: 102.7°; O(41J)···H–C(1AH): 2.619 Å, O–H–C: 99.5°).

phenolic group is now considerably smaller than that in the free ligand (31.2° versus 53.6°).

The crystal packing behavior for **1**–**4** is of particular interest. Both intermolecular C–H···O hydrogen bonding and C–H···π_{aryl} interactions combine to give these compounds 3D supramolecular frameworks. Fig. 3 shows details of the C–H···π_{aryl} interactions between methoxy hydrogens and the phenylene rings of the benzimidazole groups as well as C–H···O interactions between methoxy hydrogens and either phenolic or nitrate oxygen atoms. The C–H···O(phenolic) interactions create a one-dimensional strand along the *b*-axis. The C–H···π_{aryl} interactions and C–H··· O(nitrate) interactions then create a 3D open network structure with extended channels running along the *b*-axis (Fig. 4). These channels measure approximately 8×9 Å and accommodate guest molecules of diethylether. There are short hydrogen bonded interactions between the entrapped diethylether molecules and the surrounding supramolecular framework (aryl-OH···O(ether) O···O = 2.722 Å). Fig. 5 provides a view of the supramolecular formwork of **1** showing the diethylether located in the channels of the open framework.

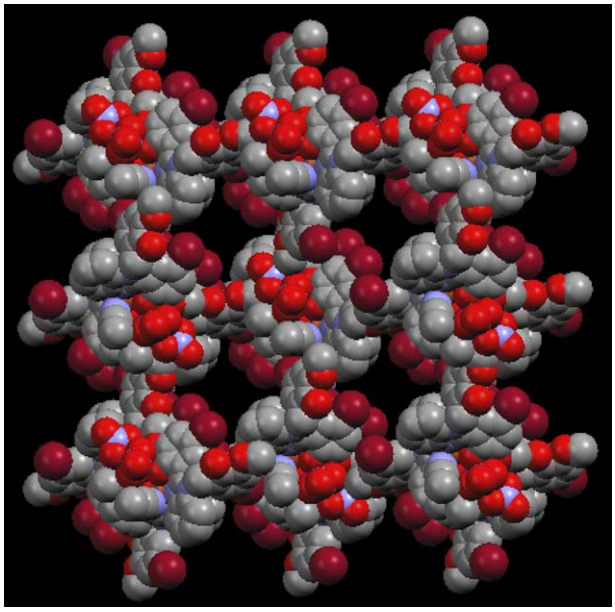

Fig. 4. View of **1** along the *b*-axis showing the 3D-network.

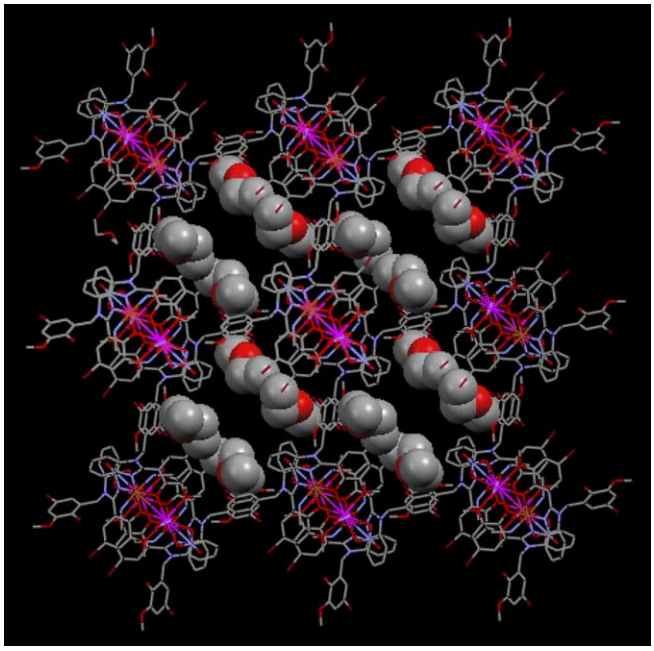

Fig. 5. View of **1** showing the entrapped diethylether molecules.

As part of our studies of Schiff base ligands capable of stabilizing 3d–4f combinations we have also investigated the use of $\mathbf{H_2L^4}$, the methoxy substituted analog of $\mathbf{H_2L^2}$. In refluxing ethanol in the presence of Cu(II) and Nd(III) $\mathbf{H_2L^4}$ is converted into the benzimidazole derivative ($\mathbf{H_2L^3}$) (Scheme 2) and, in deprotonated form, this serves as a ligand to stabilize a heterobimetallic Cu–Nd species. Thus the reaction of $\mathbf{H_2L^4}$ with a mixture of $Cu(ClO_4)_2 \cdot 6H_2O$ and $Nd(NO_3)_3 \cdot 6H_2O$ in MeCN/EtOH under reflux gave a red-brown solution from which crystals of $[CuNd(HL^3)_2(NO_3)_3(MeCN)_2] \cdot 2Et_2O$ (**5**) were isolated in 42% yield. The molecular structure of **5** is shown in Fig. 6, crystallographic details are in Table 1 and selected bond lengths and angles are in Table 4. We were interested in the effects that the two methoxy groups had on both the

molecular structure and the overall crystal packing. The core structure of **5** is similar to those of **1**–**4** and so a detailed discussion of it is unnecessary. However, the methoxy groups appear to disrupt the molecular packing of dinuclear units so that there are no significant intermolecular contacts which would result in an extended supramolecular framework.

3. Experimental

All operations were performed under a dry oxygen-free dinitrogen atmosphere using standard Schlenk techniques. Metal salts, methylenechloride, acetonitrile and absolute ethanol were purchased from Aldrich Chemicals. The solvents were distilled under nitrogen prior to use. Physical measurements: mass spec: ESI and FAB; Finnigan MAT TSQ 700; NMR: Varian 300 Unity Plus spectrometer (^{1}H, 300 MHz) at 298 K (chemical shifts referenced to the deuterated solvent). IR: Nicolet IR 200 FTIR spectrometer. UV–Vis Beckman DU 640 spectrophotometer. Melting points were obtained in sealed glass capillaries under dinitrogen and are uncorrected. Microanalytical data for the metal complexes were not reproduceable, probably due to eratic loss of solvent molecules.

3.1. Synthesis

3.1.1. Preparation of ligand H_2L^1

A solution of *o*-phenylenediamine (1.08 g, 0.01 mol) in ethanol (20 ml) was added to a solution of 5-bromo-2-hydroxy-3-methoxybenzaldehyde (4.62 g, 0.02 mol) in

ethanol (60 ml). The mixture was refluxed for 10 h and the colorless solid product filtered and washed with ethanol (20 ml). The material was recrystallized from hot ethanol. Yield 2.90 g, 60%. m.p. 195 °C. ESI-MS (CH_3CN) *m/z* (%): 534 (100) $[M + H^+]^+$. ^1H NMR (DMSO-d_6, δ, ppm): 3.806 (s, 3H), 3.828 (s, 3H), 5.378 (s, 2H), 6.635 (s, 1H), 6.857 (s, 1H), 7.013 (s, 1H), 7.212 (s, 1H), 7.428 (m, 2H), 7.480 (d, 1H), 8.052 (d, 1H). IR (CH_3CN, cm^{-1}): 3748, 1655, 1635, 1619, 1560, 1521, 1505, 1458, 1416, 1254, 745, 671. Single crystals for X-ray crystallographic analysis were obtained by vapor diffusion of diethyl ether into solutions of $\mathbf{H_2L^1}$ in EtOH.

3.1.2. Preparation of ligand H_2L^4

1,2-Dimethoxy-4,5-diaminobenzene was prepared using the published procedure [6]. A solution of 1,2-dimethoxy-4,5-diaminobenzene (0.74 ml, 5.0 mmol) in ethanol (5 ml) was added dropwise with stirring to a solution of 5-bromo-3-methoxysalicylaldehyde (2.31 g, 10 mmol) in ethanol (30 ml). The reaction mixture was stirred at room temperature (2 h), after which the solvent was removed under vacuum using a rotary evaporator. The product *N*,*N*′-bis(5-bromo-3-methoxysalicylidene)-4,5-dimethoxy phenylene-1,2-diamine was obtained as a reddish-brown solid. Yield: 91%. m.p. 179–186 °C; IR, (Nujol, cm^{-1}): 3410 b, 2934 s, 2851 b, 1627 s, 1572 b, 1473 b, 1396 s, 1343 s, 1250 b, 1101 s, 1048 b, 975 s; FAB-MS *m/z*: 596 $[M^+ - CO]$; ^1H NMR (DMSO-d_6, δ, ppm): –OCH_3, 3.74–3.92 (m, 12H); aromatic *H*, 6.9–8.9 (m, 6H); N=C*H* 8.57 (m, 2H).

3.1.3. Preparation of complexes 1–4

All complexes were prepared by the same procedure. A typical procedure is given for **1**.

3.1.4. $[CuEu(HL^1)_2(NO_3)_3(MeCN)_2]\cdot 2Et_2O$ (1)

A mixture of $\mathbf{H_2L^1}$ (0.106 g, 0.20 mmol) and $Cu(OAc)_2\cdot 2H_2O$ (0.022 g, 0.10 mmol) in 1:1 MeCN/EtOH (20 ml) was stirred and heated under reflux (20 min). A solution of $Eu(NO_3)_3\cdot 6H_2O$ (0.045 g, 0.10 mmol) in EtOH (10 ml) was added and the mixture was stirred and refluxed for (2 h). The mixture was allowed to cool to room temperature and filtered. Diethylether was allowed to diffuse slowly into the solution in a closed vessel at room temperature. Blue single crystals of **1** were formed after 1 month. Yield 0.093 g, 55%. ESI-MS (CH_3CN) *m/z* (%): 1129 (85) $[M + H^+ - 2Et_2O - 2MeCN - 3(NO_3^-) - Eu^{3+}]^+$, 1506 (10) $[M + H^+ - 2Et_2O - MeCN]^+$. m.p. > 330 °C (dec). IR (CH_3CN, cm^{-1}): 3514, 1653, 1635, 1613, 1589, 1558, 1489, 1473, 1349, 1233, 745, 669.

3.1.5. $[CuTb(HL^1)_2(NO_3)_3(MeCN)_2]\cdot 2Et_2O$ (2)

$Tb(NO_3)_3\cdot 5H_2O$ (0.044 g, 0.10 mmol) was used. Yield: 0.068 g, 40%, blue crystals. ESI-MS (CH_3CN) *m/z* (%): 1129 (80) $[M + H^+ - 2Et_2O - 2MeCN - 3(NO_3^-) - Tb^{3+}]^+$. m.p. > 315 °C (dec). IR (CH_3CN, cm^{-1}): 3642, 1656, 1632, 1611, 1591, 1540, 1492, 1470, 1353, 1230, 746, 668.

3.1.6. $[CuEr(HL^1)_2(NO_3)_3(MeCN)_2]\cdot 2Et_2O$ (3)

$Er(NO_3)_3\cdot 5H_2O$ (0.044 g, 0.10 mmol) was used. Yield: 0.089 g, 52%, blue crystals. ESI-MS (CH_3CN) *m/z* (%): 685 (30) $[M - 2Et_2O - 2MeCN - 2(NO_3^-)]^{2+}$, 1129 (85) $[M + H^+ - 2Et_2O - 2MeCN - 3(NO_3^-) - Er^{3+}]^+$, 1517 (15) $[M + H^+ - 2Et_2O - MeCN]^+$. m.p. > 320 °C (dec). IR (CH_3CN, cm^{-1}): 3533, 1652, 1630, 1615, 1590, 1555, 1483, 1475, 1348, 1232, 745, 670.

3.1.7. $[CuYb(HL^1)_2(NO_3)_3(MeCN)_2]\cdot 2Et_2O$ (4)

$Yb(NO_3)_3\cdot 5H_2O$ (0.045 g, 0.10 mmol) was used. Yield: 0.060 g, 35%, blue crystals. ESI-MS (CH_3CN) *m/z* (%): 1129 (90) $[M + H^+ - 2Et_2O - 2MeCN - 3(NO_3^-) - Yb^{3+}]^+$. m.p. > 310 °C (dec). IR (CH_3CN, cm^{-1}): 3520, 1650, 1636, 1613, 1586, 1553, 1487, 1472, 1357, 1230, 745, 669.

3.1.8. Preparation of complex 5

A solution of $Cu(ClO_4)_2\cdot 6H_2O$ (0.1 g, 0.32 mmol) in ethanol (5 ml) was added to a solution of *N*,*N*′-bis(5-bromo-3-methoxysalicylidene)-4,5-dimethoxyphenylene-1,2-diamine ($\mathbf{H_2L^4}$), 0.014 g, 0.024 mmol) in acetonitrile (3 ml) giving a reddish-brown solution. The mixture was heated under reflux (40 min) and the resulting solution was allowed to cool to room temperature after which a solution of $Nd(NO_3)_3\cdot 6H_2O$ (0.01 g, 0.027 mmol) in ethanol (3 ml) was added. The mixture was heated under reflux (40 min) and then filtered and the filtrate transferred into a test tube. Diethylether was allowed to diffuse slowly into the filtrate at room temperature in an enclosed vessel. After six weeks, crystals suitable for X-ray diffraction studies were obtained. They were collected and dried under vacuum. Yield: 42%. $[CuNd(HL^3)_2(NO_3)_3(MeCN)_2]\cdot 2Et_2O$ m.p. > 310 °C; IR (Nujol, cm^{-1}): 2923 s, 2853 b, 1626 s, 1558 b, 1467 s, 1295 s, 1231 s, 1106 b, 789 s; FAB-MS *m/z*: 612 $[M - 2Et_2O - 2MeCN]^+$; ^1H NMR (DMSO-d_6, δ, ppm): –OCH_3, 3.7–3.9 (m, 12H); –N=C*H*, 8.6 (m, 2H); aromatic *H*, 6.9–8.9 (m, 6H); UV–Vis (DMSO, 1.7 μM): very broad absorption at λ_{max} 325 nm.

3.2. X-ray crystallographic studies

Details of crystallographic parameters, data collection and refinements are listed in Table 1. Selected bond lengths (Å) and angles (°) for $\mathbf{H_2L^1}$, **1** and **5** are listed in Tables 2–4, respectively. Crystallographic data files for **2**–**4** are supplied as supplementary material. Intensities were collected on a Nonius Kappa CCD diffractometer with graphite monochromated Mo Kα radiation ($\lambda = 0.71073$ Å) at 153 K. Absorption corrections were applied using GAUSSIAN. The structures were solved by direct methods and refined anisotropically using full-matrix least-squares methods with the SHELX 97 program package [7]. The coordinates of the non-hydrogen atoms were refined anisotropically, while hydrogen atoms were included in the calculation isotropically but not refined. Neutral atom scattering factors were taken from Cromer and Waber [8].

4. Supplementary material

Crystallographic data for the complexes have been deposited with the Cambridge Crystallographic Data Centre, CCD 278165–278170 for $\mathbf{H_2L^1}$, **1**–**5**. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK (fax: +44 1223 336033; e-mail: deposit@ccdc.cam.ac.uk or web: http://www.ccdc.cam.ac.uk).

Abstract

It has been established that triazinyl bipyridines (*hemi*-BTPs) and bis-triazinyl pyridines (BTPs), ligands which are currently being investigated as possible ligands for the separation of actinides from lanthanides in nuclear waste, are able to form homoleptic complexes with first row transition metals such as cobalt(II), copper(II), iron(II), manganese(II), nickel(II) and zinc(II). The metal complexes exhibit six-co-ordinate octahedral structures and redox states largely analogous to those of the related terpyridine complexes. The reactivity of the different redox states of cobalt bis-*hemi*-BTP complex in aqueous environments has been studied with two-phase electrochemistry by immobilisation of the essentially water-insoluble metal complexes on graphite electrodes and the immersion of this modified electrode in an aqueous electrolyte.

It was found that redox potentials for the metal-centred reactions were pH-independent whereas the potentials for the ligand-centred reactions were strongly pH-dependent. The reductive degradation of these complexes has been investigated by computational methods. Solvent extraction experiments have been carried out for a range of metals and these show that cobalt(II) and nickel(II) as well as palladium(II), cadmium(II) and lead(II) were all extracted with the ligands **1e** and **2c** with higher distribution ratios that was observed for americium(III) under the same conditions. The implications of this result for the use of these ligands to separate actinides from nuclear waste are discussed.

1. Introduction

The aqueous solution (PUREX first cycle raffinate) remaining after the extraction of uranium and plutonium from dissolved used nuclear fuel by the PUREX process is a complex mixture of fission products and corrosion products [1] that also contains the transplutonium actinides, americium and curium. These actinides, together with the residual plutonium, are responsible for the majority of the radiotoxicity that will be present between 300 and 20 000 years in the future [2]. If these metals were removed from the PUREX raffinate then the majority of the radiotoxicity will decay during the likely lifetime of a stainless steel drum [3]. After removal from the PUREX raffinate, the actinides could be disposed of separately, or transmutated by nuclear means or employed in medical [4] or industrial applications. The lanthanides have similar properties to the trivalent

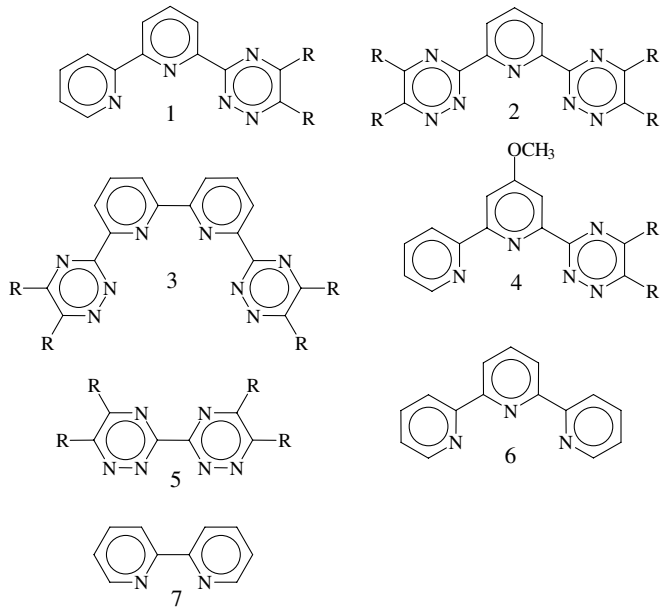

Fig. 1. Key to parent structures. *Hemi*-BTP (**1**), BTP (**2**), BTBP (**3**), methoxy-*hemi*-BTP (**4**), 3,3′-bi-1,2,4-triazinyl (**5**), terpyridine (**6**), 2,2′-bipyridine (**7**). Key to ancillary groups, hydrogen (**a**), methyl (**b**), ethyl (**c**), *n*-propyl (**d**) and *n*-pentyl (**e**).

actinides since they have high neutron cross-sections and they are abundant among the fission products of ^{235}U (the atom yield for the lanthanides is ca. 28%). Recently, we have investigated the lanthanide coordination chemistry of triazinyl pyridines such as the triazinyl bipyridines (*hemi*-BTPs, **1**) [5], the bis-triazinyl pyridines (BTPs, **2**) [6] and the bis-triazinyl bipyridines (BTBPs, **3**) [7]. However, when compared with the oligopyridines, little is known about the coordination chemistry of the 1,2,4-triazines with the first row transition metals [8–10]. It has been shown during an actinide extraction test using tetrapropyl-BTP (**2d**) that much of the iron, ruthenium and palladium present in the acid aqueous feed solution enters the organic phase [11] so that a transition metal could inhibit the extraction of the desired metals by sequestering the extractant. Also the transition metal could enter a product or waste stream where it could cause undesirable reactions such an exothermic reactions during the bituminisation of waste [12]. It is therefore appropriate to carry out a systematic investigation of the first row transition metal coordination chemistry of tridentate triazinyl-pyridines. In this paper, we report the synthesis and the spectroscopic, crystallographic and electrochemical characterisation of a series of transition metal complexes with a variety of 1,2,4-triazinyl pyridine ligands shown in Fig. 1.

2. Experimental

2.1. Synthesis

All organic reagents were purchased from Acros or Aldrich, while inorganic reagents were obtained from either BDH or Aldrich. 6-(5,6-diethyl-[1,2,4]triazin-3-yl)-[2,2′]bipyridinyl (diethyl-*hemi*-BTP, **1c**) and 6-(5,6-dimethyl-[1,2,4]triazin-3-yl)-[2,2′]bipyridinyl (dimethyl-*hemi*-BTP, **1b**) were prepared as previously described [5] while 6-(5,6-diethyl-[1,2,4]triazin-3-yl)-[2,2′]bipyridinyl (dipentyl-*hemi*-BTP, **1e**) was prepared by an analogous procedure. 4-Methoxy-2,2′-bipyridine-*N*-oxide was obtained by the nitration and subsequent methanolysis of 2,2′-bipyridine-*N*-oxide [13]. Oxalodihydrazonic acid diamide was formed by the reaction of dithiooxamide (rubeanic acid) and hydrazine in ethanol (*WARNING*: The reaction forms a large volume of toxic gas [hydrogen sulfide]) [14]. ^{1}H, ^{13}C-{^{1}H} and ^{13}C NMR spectra were recorded using either a Bruker AMX400 or an Avance DPX250 instrument. Chemical shifts are reported in ppm downfield from tetramethylsilane. Magnetic moments were determined in dichloromethane also using the Avance DPX250 by the Evans' NMR method. Carbon, hydrogen and nitrogen microanalysis was performed by Medac Limited.

2.1.1. 2,6-Bis-(5,6-diethyl-[1,2,4]triazin-3-yl)-pyridine (tetramethyl BTP, **2b**) [15]

Pyridine-2,6-dihydrazonic acid diamide (3.19 g) was combined with THF (100 mL), triethyl amine (3 mL) and butane-2,3-dione (6 mL) and heated under reflux (3 h). After cooling toluene was added to the reaction flask, and the mixture heated briefly under reflux. After allowing the mixture to cool, the orange solid was isolated by filtration. After washing with ethanol and diethyl ether the solid (2.66 g; 55%) was allowed to dry in air. δ_H 8.81 (2H, d, 7.9 Hz), 8.14 (1H, t, 7.9 Hz), 2.80 (3H, s) and 2.74 (3H, s) ppm.

2.1.2. 2,6-Bis-(5,6-diethyl-[1,2,4]triazin-3-yl)-pyridine (tetraethyl BTP, **2c**)

Pyridine-2,6-dihydrazonic acid diamide (5.47 g) was combined with THF (175 mL), triethyl amine (10 mL) and hexane-3,4-dione (10 mL). The resulting mixture was heated under reflux (2 h). After allowing the mixture to cool, the first crop (4.61 g; 47%) was obtained by filtration and washing with a small volume of ethanol. By concentration of the mother liquor a second crop (2.18 g; 22%) was obtained giving an overall yield of 69%. *Anal.* Calc. for $C_{19}H_{23}N_7 \cdot 0.5EtOH$: C, 62.0; H, 6.7; N, 25.3. Found: C, 62.0; H, 6.9; N, 26.7%. δ_H 8.77 (2H, d, 7.9 Hz), 8.12 (1H, t, 7.9Hz), 3.06 (8H, m) and 1.47 (12 H, m). δ_C 163.36 (quat), 161.41 (quat), 161.00 (quat), 154.00 (quat), 138.62, 125.70, 27.67 (CH_2), 26.15 (CH_2), 12.82 and 12.13. MS (CI) 350 $(MH)^+$ and 240 amu. Molecular ion found at 350.2104 amu, $^{12}C_{19}{}^{1}H_{24}{}^{14}N_7$ requires 350.2093 amu (error of 3.2 ppm).

2.1.3. 6-(5,6-Dimethyl-[1,2,4]triazin-3-yl)-4-methoxy-[2,2′]bipyridinyl (dimethyl methoxy hemi BTP, **4b**)

To a solution of 4-methoxy-2,2′-bipyridine-*N*-oxide (6.67 g) in dichloromethane (100 mL) was added trimethylsilyl cyanide (5 mL) and dimethyl carbomyl chloride (3.5 mL). After allowing the mixture to stand for 3 days,

the solvent was evaporated. The solid was redissolved in dichloromethane, and the resulting solution was filtered through a silica pad before being evaporated again to give the nitrile as a white solid (5.70 g; 82%). δ_H ($CDCl_3$) 8.59 (1H, m), 8.37 (1H, m), 8.11 (1H, d, 2.4 Hz), 7.77 (1H, ddd 7.8, 7.8 and 1.8 Hz), 7.29 (1H, m), 7.15 (1H, d, 2.4 Hz). δ_C 167.36, 159.84, 154.38, 149.52, 137.58, 134.46, 125.20, 122.12, 117.78, 116.62, 108.96 and 56.38. The nitrile (2.03 g) was suspended in a mixture of ethanol (25 mL) and hydrazine monohydrate (8 mL), and the resulting slurry was heated to 50 °C (4 h). After allowing the mixture to cool, the volatile solvents were removed in vacuum to furnish a damp solid. Water (30 mL) was added and the mixture stirred to form a slurry and the solid was collected by filtration. The solid was washed with water (2 × 10 mL). In all 4.92 g of the damp solid was obtained. δ_H (CD_3OD) 8.66 (1H, m), 8.53 (1H, m), 7.97 (1H, ddd, 7.8, 7.8 and 1.8 Hz), 7.92 (1H, d, 2.4 Hz), 7.56 (1H, d, 2.4 Hz), 7.47 (1H, m) and 3.99 (3H, s). Part of the damp solid (2.32 g) was stirred in THF (60 mL), butane-2,3-dione (7 mL) was added and the resulting mixture boiled under reflux (2 h). After cooling, all volatile solvents were removed in vacuum before the resulting solid was recrystallised from hot ethanol to form a bright yellow crystalline solid (944 mg; 71% from nitrile, 58% overall). *Anal.* Calc. for $C_{16}H_{15}N_5O$ C, 65.5; H, 5.2; N, 23.9. Found: C, 65.3; H, 5.2; N, 23.7%. δ_H ($CDCl_3$) 8.60 (2H, m), 8.08 (1H, d, 2.5 Hz), 8.06 (1H, d, 2.5 Hz), 7.77 (1H, ddd, 7.7, 7.7 and 1.9 Hz), 7.26 (1H, m), 3.98 (3H, s), 2.71 (3H, s) and 2.63 (3H, s). δ_C ($CDCl_3$) 168.10 (quat), 162.00 (quat), 159.76 (quat), 158.85 (quat), 157.35 (quat), 156.05 (quat), 154.54 (quat), 149.37, 137.32, 124.49, 122.39, 111.00, 108.33, 56.12, 22.52 and 20.06.

2.1.4. 6-(5,6-Diethyl-[1,2,4]triazin-3-yl)-4-methoxy-[2,2′]bipyridinyl (diethyl methoxy hemi BTP, **4c**)

A sample of the dihydrazonic acid diamide formed from the nitrile (0.52 g) was dissolved in THF (10 mL), hexane-3,4-dione (2 mL) was added and the resulting mixture heated under reflux (2 h). After cooling, the product (502 mg; 63%) was isolated by removal of the solvent in vacuum. δ_H ($CDCl_3$) 8.60 (2H, m), 8.07 (2H, m), 7.77 (1H, ddd, 7.7, 7.7 and 1.8 Hz), 7.25 (1H, m), 3.97 (3H, s), 3.02 (2H, q, 7.5 Hz), 2.90 (2H, q, 7.4 Hz) and 1.38 (6H, m). δ_C ($CDCl_3$) 168.05 (quat), 162.78 (quat), 161.68 (quat), 160.63 (quat), 158.72 (quat), 156.10 (quat), 154.74 (quat), 149.30, 137.33, 124.46, 122.34, 111.08, 107.93, 56.06, 27.49 (CH_2), 26.08 (CH_2), 12.65 and 11.58. MS (CI) 322 $(MH)^+$ and 212 amu. Molecular ion found at 322.1669 amu, $^{12}C_{18}{}^{1}H_{20}{}^{14}N_5{}^{16}O$ requires 322.1668 amu (error of 0.4 ppm).

2.1.5. 5,6,5′,6′-Tetraethyl-[3,3′]bi[[1,2,4]triazinyl] (**5c**)

Oxalodihydrazonic acid diamide (26.7 g) was dissolved in a mixture of ethanol (300 mL) and THF (300 mL). To this solution was added triethyl amine (75 mL) and hexane-3,4-dione (75 mL). The mixture was heated under reflux (3 h), before being allowed to cool. The mixture was treated with decolourising charcoal, and filtered. The filtrate was concentrated in vacuum. The residue was triturated with petrol (100 mL, 40–60 °C fraction) before the solid was collected by filtration. After washing with diethyl ether (4 × 50 mL), the solid was dried in air (44.54 g; 71%). *Anal.* Calc. for $C_{14}H_{20}N_6$ C, 61.7; H, 7.4; N, 30.8. Found: C, 60.9; H, 7.4; N, 29.9%. δ_H 3.12 (4H, q, 7.5 Hz), 2.99 (4H, q, 7.5 Hz), 1.44 (12 H, m). δ_C 163.32 (quat), 161.78 (quat), 160.58 (quat), 27.63 (CH_2), 26.26 (CH_2), 12.76 and 11.96. MS (CI) 273 $(MH)^+$ and 163 amu. Molecular ion found at 273.1823 amu, $^{12}C_{14}{}^{1}H_{21}{}^{14}N_6$ requires 273.1827 amu (error of 1.6 ppm).

2.1.6. Typical procedure for the synthesis of the complexes of manganese, iron, copper and zinc

In method A, a solution of **1b** (201 mg) in hot ethanol (10 mL) was treated with iron(II) chloride tetrahydrate (76 mg) dissolved in water (3 mL). After cooling this red solution was treated with the sodium perchlorate solution, before concentrating in vacuum. The resulting solid was collected on a paper filter before being washed twice with water, ethanol and diethyl ether to give a deep red solid (280 mg; 94%). Method B is similar to method A except that the reaction mixture was evaporated to remove all the organic solvent before the addition of water.

2.1.7. Typical procedure for the synthesis of a complex of cobalt

Method C: To a deoxygenated suspension of **4b** (141.6 mg) in a mixture of ethanol (10 mL) and THF (5 mL) was added cobalt(II) chloride hexahydrate (57.6 mg). After stirring (4.5 h) this mixture was concentrated by evaporation. After dissolution in water (10 mL), a sodium perchlorate solution was added. The resulting red solid was collected by filtration before being washed with water, ethanol and ether.

2.1.8. Typical procedure for the synthesis of a complex of nickel

Method D: To a deoxygenated suspension of **4b** (145.7 mg) in a mixture of ethanol (10 mL) and THF (5 mL) was added nickel(II) chloride hexahydrate (59.0 mg). After being heated under reflux (4 h), the mixture was allowed to cool to room temperature before being concentrated by evaporation. After dissolution in water (10 mL), a sodium perchlorate solution was added. The resulting tan solid was collected by filtration before being washed with water, ethanol and ether.

CAUTION: Treat all materials containing both organic matter and perchlorate anions as potential explosives [16].

2.2. Crystallography

Crystallographic data are given in Table 1. All data were measured with Mo Kα radiation using the MARresearch Image Plate System. The crystals were positioned at

70 mm from the Image Plate and 100 frames were measured at 2° intervals with a counting time of 5 min. Data analyses were carried out with the XDS program [17]. The structures were solved using direct methods with the SHELX-86 program [18]. Non-hydrogen atoms were refined with anisotropic thermal parameters. The hydrogen atoms bound to carbon were included in geometric positions and given thermal parameters equivalent to 1.2 times those of the atom to which they were attached. The majority of structures contained some disordered solvent. All crystals were of poor quality and gave misshapen spots and as a result the crystal structures were solved with high R values. Empirical absorption corrections were applied using DIFABS [19]. The structures were refined on F^2 using SHELXL [20]. Crystal data have been deposited at the Cambridge Crystallographic Data Centre (reference numbers CCDC 277000–277004 inclusive).

2.3. Electrochemistry

All electrochemical experiments were conducted using a computer-controlled Autolab potentiostat (PGSTAT 30, Eco-chemie, Netherlands). Solution state electrochemical experiments were performed in deoxygenated acetonitrile in the presence of tetraethyl ammonium perchlorate (0.25 M). The tetraethyl ammonium perchlorate was obtained by the addition of perchloric acid to aqueous tetraethyl ammonium bromide, and was recrystallised twice from water before being dried in vacuum to a constant mass. *CAUTION: Treat all organic perchlorates as potential explosives; tetraethylammonium perchlorate is a known explosive* [16]. The working electrode was a 3 mm glassy carbon disk purchased from Bioanalytical Systems, a silver wire was used as a quasi-reference electrode and the counter-electrode was a platinum wire. Solution state potentials were measured using the ferrocene/ferrocenium couple (ferrocene added as an internal standard). Cyclic voltammetry was performed using a staircase waveform with a step size typically of 0.1 mV, while differential square wave experiments were performed at 25 Hz using an amplitude of 10 mV and a step size of 1 mV. For reversible electrochemical events, the formal potentials were calculated as the midpoint of potentials of the anodic and cathodic current peaks. For both reversible and irreversible redox processes formal potentials were also measured by using the peak potential obtained with differential square wave voltammetry. Two-phase voltammetry was performed using a 4.9 mm diameter basal plane pyrolytic graphite working electrode with microparticles adhering to the surface, a saturated calomel reference electrode, and a platinum gauze counter-electrode all immersed in an aqueous electrolyte solution. All experiments were conducted in argon (BOC) atmosphere and at a temperature of 22 ± 2 °C.

2.4. Computational chemistry

Density functional calculations were performed by using the ADF program [21]. Slater-type orbital basis sets of triple zeta quality for the valence orbitals were employed with polarisation functions on the ligand atoms (2p for H, and 3d for C and N) and additional valence p-orbitals on metal atom. Scalar relativistic effects were included via the Zora protocol. The Generalised Gradient Approximation was used with Becke88 exchange and Perdew86 correlation gradient corrections.

2.5. Metal extraction

All solvent extraction experiments were performed as previously described [22]. Organic phases were either solutions of **2c** (different concentrations) in kerosene/*n*-octan-1-ol (7:3 vol.) or solutions of **1e** (different concentrations) with 0.5 M 2-bromohexanoic acid in *tert*-butylbenzene. Aqueous solutions were Cr(III), Mn(II), Fe(III), Co(II), Ni(II), Cu(II), Zn(II), Sr(II), Y(III), Zr(IV), Ru(II) (added as $RuNO(NO_3)_3$), Rh(III), Pd(II), Cd(II), Ba(II), La(III)–Lu(III) (without Pm and Tm), Pb(II) (1 mg/L each) + ^{241}Am(III) (900 Bq/mL) in nitric acid of different concentrations. Equal volumes (1 mL each) of organic and aqueous phases were contacted for 4.5 h by vigorous shaking using an orbital shaker (IKA KS 250), the diameter of the circular path was ca. 15 mm, and the rotation rate was 9.2 Hz. During mixing the temperature was 20 °C. Samples were centrifuged, and phases were separated. Aliquots of each phase were taken for analysis. ^{241}Am activity was determined in 0.2 mL of each sample by gamma counting. 0.2 mL of each aqueous sample was diluted with 4.8 mL HNO_3 2% (suprapur) and analysed by ICP-MS. 50 μL (kerosene/octanol samples) or 25 μL (*tert*-butylbenzene samples) of each organic sample was dissolved in 4.95 or 4.975 mL of a solution of (10 g/L Triton X-100 in HNO_3 2% (suprapur)) and analysed by ICP-MS. In each case, standards were prepared accordingly.

3. Results and discussion

3.1. Metal extraction

Extraction experiments were carried out with Mn(II), Ni(II), Sr(II), Zr(IV), Ru(II) nitrosyl, Rh(III), Cd(II), Ba(II), Pb(II) and Am(III). Am(III), Pb(II), Cd(II) and Zr(IV) were extracted by an ion exchange process (Eq. (1) and Fig. 2), which was favoured by a low nitric acid concentration. The lanthanides were only weakly extracted; when the concentrations of **1e** and nitric acid were 0.020 and 0.1 M, respectively, the lanthanide distribution ratios were 2×10^{-3} or lower

$$M_{(aq)}^{n+} + n\mathrm{RCOOH}_{(org)} + x\mathbf{1e}_{(org)} \leftrightarrow [M(\mathrm{RCOO})_n(\mathbf{1e})_x]_{(org)} + n\mathrm{H}_{(aq)}^{+} \quad (1)$$

Similar behaviour was observed for americium with a solution of diethyl-*hemi*-BTP + bromodecanoic in an aliphatic diluent (Hydrogenated propylene trimer, also known as TPH) [5]. the ruthenium nitrosyl distribution ratio was independent of the nitric acid concentration indicating that a solvation mechanism (such as that in Eq. (2)) was also in operation

$$M_{(aq)}^{n+} + n\mathrm{NO}_3^- + x\mathbf{1e}_{(org)} \leftrightarrow [M(\mathbf{1e})_x] \cdot n\mathrm{NO}_{3(org)} \quad (2)$$

No extraction of either strontium or barium observed, and rhodium and manganese were only very weakly extracted (D_M was always less than 10^{-3}, NB: $D_M = [M_{organic}]/[M_{aqueous}]$). Nickel was totally extracted from all samples of the aqueous phase and hence it was not possible to elucidate the mechanism of the nickel extraction. The solutions of **3e** in *tert*-butylbenzene/bromohexanoic acid mixtures were only able to weakly extract nickel and it was deduced that nickel(II) has a high affinity for *hemi*-BTP [22] (see Fig. 3).

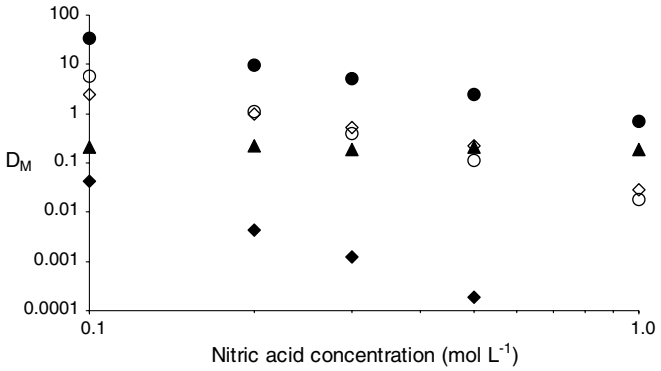

Fig. 2. Distribution ratios for metals with **1e** (0.02 M) in bromohexanoic acid (0.5 M) in *tert*-butylbenzene from nitric acid solutions. The *x*-axis has a logarithmic scale. *Key*: ◆, Am; ◇, Zr; ▲, Ru; ●, Cd; and ○, Pb.

In a similar way, solutions of **2c** in a 3:7 (v/v) mixture of octanol and keroscene were tested for their ability to extract metals. In common with the solution of **1e** the solution of **2c** did not extract strontium or barium, and the rhodium was only weakly extracted. cobalt(II), nickel(II), palladium(II), cadmium(II) and lead(II) were all extracted with higher distribution ratios than was observed for americium(III) under the same conditions. Zirconium(IV) and ruthenium nitrosyl were both extracted but the distribution ratios are lower than those observed for americium(III). Many of the metals are extracted by a solvation mechanism similar to that in Eq. (2), further work will be required in order to clearly identify the extraction mechanims. It is clear that metals such as nickel and palladium would, if present at high concentrations, be able to disrupt an americium extraction process by sequestering the extraction agent. Since it had been shown that nickel(II) has an exceptional ability to bind to **1e** and **2c**, a detailed investigation of the coordination chemistry of the triazinyl pyridines with the first row transition metals was initiated (see Fig. 3).

3.2. Synthesis and some properties of the metal complexes

An immediate colour change occurred on combining **1c**, **2c**, **4b**, **4c** or terpyridine (**6**) with manganese(II) chloride, iron(II) chloride, cobalt(II) chloride or copper(II) nitrate, and it can be assumed that aqueous zinc acetate reacts rapidly with the tridentate ligands although no colour change is discernable. While nickel(II) chloride started to react within seconds, owing to the lower water exchange rate of this metal, all reactions using nickel salts were heated under reflux for at least 3 h [23,24]. Iron(II) chloride was reacted with a bis-triazinyl (**5c**), bis-(5,6-dimethyltriazinyl)

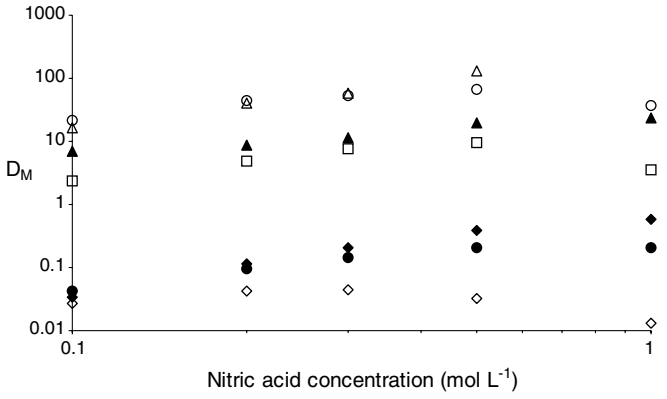

Fig. 3. Distribution ratios for selected metals with **2c** (0.01 M) in 3:7 (v/v) octanol/kerosene mixture from nitric acid solutions. The *x*-axis has a logarithmic scale. *Key*: ◆, Am; ◇, Zr; ▲, Pd; ●, Mn; △, Ni; □, Co; and ○, Pb.

pyridine (dimethyl-BTP, **2b**) and dimethyl-*hemi*-BTP (**1b**). All the complexes were collected as solids after anion metathesis with sodium perchlorate or ammonium perrhenate: Acceptable microanalytical data were obtained for all the solids (Table 2).

In common with iron(II) bis-terpyridine salts, the perchlorate salts of the iron(II) homoleptic complexes of **1c**, **2c**, **4b**, **4c** and **5c** were examined by NMR experiments and found to be diamagnetic indicating that the two triazinyl pyridine ligands provide the metal with an octahedral coordination environment that has a strong ligand field. The iron complexes of **1b** and **2b** were too insoluble for NMR experiments to be carried out but it can be assumed that they would also be diamagnetic. It is interesting that the metal complexes of **4b** were soluble in both dichloromethane and acetonitrile, suggesting that the methoxy group significantly enhances the solubility. Owing to the paramagnetism of the manganese, cobalt, nickel and copper complexes only the iron and zinc complexes were characterised by ^{1}H and ^{13}C NMR, the NMR spectra are in agreement with the proposed homoleptic distorted octahedral structure of the complexes. The Evans' NMR method was used to examine the nickel complexes in dichloromethane solution and it was found that each nickel atom in **1c** has 2.3 unpaired electrons and in **4b** had 2.2 unpaired electrons suggesting that, in these octahedral complexes, the axial perturbation of the ligand field is too weak to permit a singlet ground state.

All redox potentials are expressed relative to the ferrocene/ferrocenium couple (Fc/Fc^{+}). For reversible couples the redox potentials are the mean of the anodic and cathodic peaks observed during cyclic voltammetry experiments (200 mV s^{-1}). For irreversible reductions the redox potential expressed is the potential of the cathodic peak relative to the cathodic peak for the reduction of ferrocenium ions.
Key: *, irreversable reduction; £, partly reversible reduction; $, measured using differential square wave voltammetry; and –, not observed.

3.3. Crystallography

Crystals of the complexes formed between Mn, Fe, Co and Zn with diethyl-*hemi*-BTP (**1c**) were obtained by the liquid diffusion of diethyl ether and petrol (60–80 °C fraction) into dichloromethane solutions of the metal complexes and crystal structures were obtained (Fig. 4). The structure of the iron compound with **4c** was also determined (Fig. 5). A search was made of the crystallographic database [25,26] for related structures. The triazine nitrogens in $[Fe(\mathbf{4c})_2]\cdot 2ClO_4$ are at similar distances from the iron at 1.955(6) and 1.946(6) Å to the triazine nitrogens in $[Fe(\mathbf{5b})_3]^{2+}$ [10] which are at 1.940 and 1.932 Å. The M–N bond lengths listed in Table 3 for the five structures suggest that of all the metals, iron has the highest affinity and manganese the lowest affinity for the *hemi*-BTPs. The Fe(II) and Co(II) complexes have coordination environments which are closest to ideal octahedral and for these metals the triazine nitrogens form shorter bonds to the metal than the outer pyridine nitrogens which contrasts with the fact that the pyridine and triazine nitrogens in the dichlorocopper complex of 2-(5,6-diphenyl-[1,2,4]triazin-3-yl)-[1,10]phenanthroline are approximately equidistant from the metal atom at lengths of 2.100 and 2.116 Å [27]. In common with the iron and cobalt complexes of **1c** in the ruthenium(II) complexes of 2-(5,6-diphenyl-[1,2,4]triazin-3-yl)-[1,10]phenanthroline, 9-[1,10]phenanthrolin-2-yl-7,8,10-triaza-fluoranthene and 3-[1,10]phenanthrolin-2-yl-phenanthro[9,10-*e*][1,2,4]triazine, the triazine nitrogen to metal bond is shorter than the pyridine nitrogen to metal bond, e.g., 2.072 versus 2.106 Å in the case of the diphenyl-triazinyl ligand [28]. This difference, which was observed for the ruthenium, iron and cobalt complexes can be readily rationalised by the difference in the steric demands of the two different heterocylic rings. The two rings differ in steric demands because in the case of the 2-pyridyl group adjacent to the nitrogen atom is a carbon bearing a hydrogen, in the triazinyl group this CH unit has been replaced by a nitrogen atom which has a smaller steric effect. The structures of the zinc and manganese complexes are more distorted from ideal octahedral geometry. In the Mn(II) complex the bonds to triazine are shorter than those to pyridine, while in the Zn(II) complex in one ligand these bonds are equivalent while in the other ligand the bond to the triazine nitrogen is significantly longer than that to pyridine nitrogen. For these d^{10} and high-spin d^5 complexes the N(21)–M–N(51) angle is distorted by more than 15° away from the expected angle (180°) for a perfect octahedral complex compared to a value of ca. 5° in the iron (d^6) and cobalt (d^7) complexes. The steric crystal packing effects are more likely to be able to distort the coordination environment of a d^{10} or a high spin d^5 metal centre, where ligand field energy effects are absent, than d^6 and d^7 octahedral metal centres.

3.4. Electrochemical characterisation

Next, the electrochemical characteristics of the homoleptic metal complexes of Mn, Fe, Co, Ni, and Zn with 1,2,4-triazin-3-yl-pyridine ligands were explored. A change in redox state during the extraction process is likely to have a significant impact on the rate of formation or on the degradation of these metal complexes and, therefore, voltammetric measurements were undertaken in both organic and aqueous environments. In order to study the metal complexes in organic solution, acetonitrile was employed as the solvent. The very low solubility of the metal complexes in aqueous media, required for the successful two-phase extraction process, prevented the study of electrochemical properties in aqueous solution. However, two-phase (solid metal complex|aqueous electrolyte solution) electrochemical data were readily obtained by immobilisation of the solid metal complexes at basal plane pyrolytic graphite electrodes and immersion into aqueous media [35].

In acetonitrile solution, several metal and ligand-centred redox processes were observed (see Table 2) for all metal complexes. The metal-centred redox reactions were reversible, and were analogous to the reported metal-centred redox chemistry of the homoleptic bis-terpyridine complexes of Mn, Fe, Co and Ni [29,30]. The Cu(II)/Cu(I) redox chemistry of the copper complexes was very similar to that of the bis-4′-methylsulfanyl-[2,2′;6′,2″]terpyridine complex [31]. In contrast, many of the ligand-centred reductions appeared to be chemically irreversible at a scan rates of 0.1 V s^{-1}. In some cases the reduction of the ligand led to the formation of a coating on the glassy carbon working electrode (vide infra), which could be partly removed during the subsequent oxidation (for Co and Fe) or only by polishing with alumina (for Cu). In contrast to the formation of copper metal during reduction of the bis-4′-methylsulfanyl-[2,2′;6′,2″]terpyridine copper(I) complex [31], unreactive non-conductive coatings were formed during the reduction of copper(I) complexes.

When scanning over a wide potential window (from +1.2 to −2.4 V) three reduction processes (ligand-centred) and one oxidation process (metal-centred) for $[Fe(\mathbf{1c})_2]^{2+}$ were observed (see Fig. 6). The oxidation process is highly reversible and well defined. The reduction processes appear to be one electron in nature (by comparison with the oxidation) and diffusion-controlled. However, the smaller re-oxidation signals and spurious product signals at −0.7 V versus $Fc^{+/0}$ indicate a follow-up reaction and limited chemical inertness of the reduction products.[1] Sharp peaks are observed for the reduction at −2.3 V versus $Fc^{+/0}$ and the re-oxidation at −1.7 V versus $Fc^{+/0}$ which are consistent with the precipitation of a neutral intermediate $[Fe(\mathbf{1c})_2]^0$ onto the electrode, followed by either a solid state phase transformation or a stripping reaction during either the reduction or oxidation. An analogous process has been reported for the formation of the neutral complexes $[M(bipy)_3]^0$ (M = Fe, Ru and Os) [32].

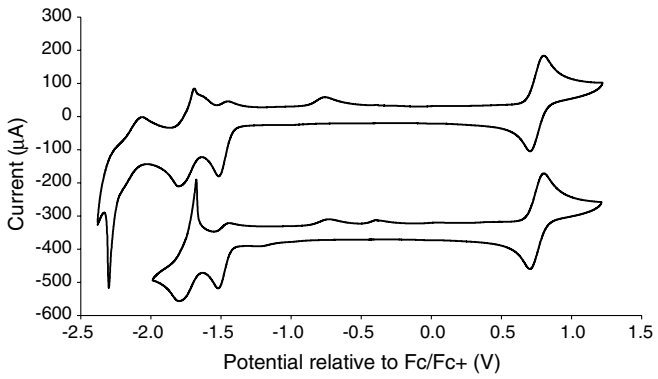

Fig. 6. Cyclic voltammograms of $[Fe(\mathbf{1c})_2]^{2+}$ scanned at 200 mV s^{-1} over two different potential ranges.

Since no adsorption of electroactive materials was observed during experiments using solutions of $[Fe(\mathbf{5c})_3]^{2+}$, it was considered possible that the formation of an anionic complex through a reversible reaction might prevent electrocrystallisation on the electrode. To test this hypothesis cobalt complexes of *hemi*-BTP and BTP ligands were prepared and examined with cyclic voltammetry, as it is known that for the bis-terpyridine cobalt complex the Co(I)/(II) couple has a potential intermediate between the Co(II)/(III) and ligand-centred redox couples. It was found for the cobalt complexes of BTP and *hemi*-BTP ligands that the ligand-centred reduction events were irreversible and resulted in the formation of an electroactive coating on the electrode, indicating that after reduction the triazinyl pyridine ligands were converted to other species. The electroactive coating was readily removed by polishing the electrode. Such degradations have not been observed

[1] The exact provenance of the small anodic peaks is unclear. When the potential range for the iron, cobalt and nickel complexes is restricted to the range in which only the reversible metal centred redox events occur, these anodic peaks are absent, upon the irreversible ligand centred reductions these anodic peaks appeared suggesting a redox active coating was formed upon the working electrode. For example, when $[Ni(\mathbf{1c})_2]^{2+}$ and $[Ni(\mathbf{4b})_2]^{2+}$ was reduced (respectively) to −2.5 and −1.5 V on subsequent scans, new oxidation peaks at 0.26 and −0.04 V were observed. By polishing the working electrode the material responsible for these new peaks were removed.

for the bis-vinylterpyridine complex of iron in either acetonitrile or dimethylformamide in the range from −0.4 to −2.1 V versus Fc/Fc^+ [29,33].

For the metal-centred redox events, the methoxy groups in ligand (**4b**) caused a cathodic shift in redox potential for the complexes by an average of 61 mV. This cathodic shift due to the resonance effect of the methoxy group can be contrasted with the anodic shift caused by the introduction of a pyridyl group at the 4′ positions of the terpyridines attached to an iron-centre [34]. On the other hand, the replacement of the two *hemi*-BTP ligands by BTP ligands resulted in a higher anodic shift of 98 mV. One rationalisation for this higher value is that the triazine ligands are stronger π-acids and weaker σ donors.

In order to obtain an understanding of the redox chemistry of the metal complexes of the 1,2,4-triazin-3-yl-pyridines in the presence of aqueous media, an investigation of the solid metal complexes adhered to graphite electrodes and immersed in aqueous electrolyte media was undertaken [35,36]. The resulting two-phase system (solid metal complex|aqueous electrolyte) allows well-defined voltammograms to be recorded and the aqueous redox chemistry related to the solution phase redox chemistry in acetonitrile. While microparticles of $[Co(\mathbf{2c})_2]\cdot 2ClO_4$, $[Co(\mathbf{1c})_2]\cdot 2ClO_4$ and $[Co(\mathbf{4b})_2]\cdot 2ClO_4$ on a graphite surface immersed in aqueous sodium perchlorate solution gave reversible and reproducible electrochemical responses, microparticles of the analogous Mn(II), Fe(II), Ni(II) and Cu(II) solids gave weaker and often less well-defined responses. This difference can be rationalised by the fact that the Co(II) complexes are the only metal complexes, which can be both reduced and oxidised reversibly (metal-centred) hence facilitating electrical conduction through the passage of electrons and holes through the crystal lattice (a requirement for the solid state electrochemical process to occur). All further microparticle voltammetry was performed using $[Co(\mathbf{1c})_2]\cdot 2ClO_4$.

It was found that microparticles of $[Co(\mathbf{1c})_2]\cdot 2ClO_4$ exhibit a chemically reversible Co(II)/Co(III) redox couple at 35 mV versus SCE (Fig. 7) when the solid is in contact with neutral sodium perchlorate solution. The anodic and cathodic current peaks are at 0 and 70 mV versus SCE, respectively. This process is consistent with the metal-centred Co(II)/Co(III) process observed in acetonitrile solution (see Table 2).

For the solid-state process, it is likely that perchlorate anions can be reversibly inserted into the solid in order to allow charge neutrality to be maintained during the redox process. In contrast to the solution state cyclic voltammetry, the anodic and cathodic current peaks were proportional not to the square root of the scan rate suggesting that an immobilised redox system reacts and that diffusion was not rate limiting. On increasing the scan-rate the anodic current peak occurred at a more cathodic (reducing) potential. This is the opposite of the relationship between the potential of the anodic peak and the scan-rate that was observed for a quasi-reversible couple with slow

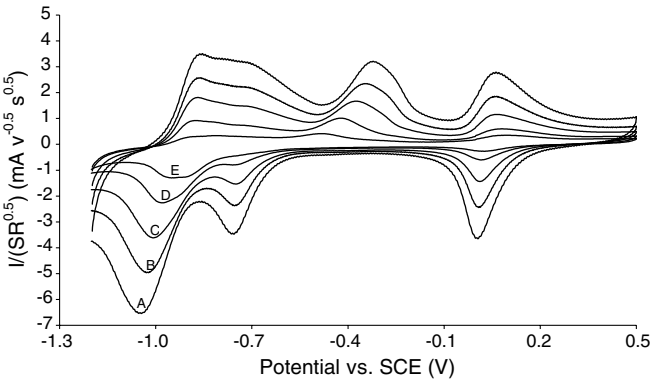

Fig. 7. Two-phase cyclic voltammetry of solid $[Co(\mathbf{1c})_2]\cdot 2ClO_4$ immobilised at a 4.9 mm diameter basal plane pyrolytic graphite electrode. Voltammograms were recorded at 100 (A), 50 (B), 25 (C), 10 (D) and 5 (E) mV s^{-1}. For clarity the current has been divided by the square root of the scan-rate (SR).

electron transfer. Over the range of scan-rates used the cathodic peak appears to be normal for a redox event with fast electron transfer.

A clear reduction peak can be observed also for the second metal-centred Co(I)/Co(II) reduction process at −742 mV versus SCE, while the peak due to the corresponding anodic process is at −706 mV versus SCE. This potential is in good agreement with that predicted based on the solution phase study (see Table 2). At even more negative potentials (−1045 mV versus SCE) the ligand-centred reductions can be observed and these seem to be chemically reversible based on the detection of the Co(II)/Co(III) system at more positive potentials. The ligand-centred reduction processes are multi-electron in nature and may involve protonation of the ligand. In contrast with the solution phase electrochemical observations this ligand-centred reduction appears to be chemically reversible probably owing to the stabilising nature of counterions and the solid matrix. It is possible that by constraining the shape of the ligand by coordination to a metal, and embedding the resulting complex in a crystal lattice that the reduced form of the ligand was stabilised.

It is interesting to explore the mechanism for the metal and ligand-based reductions in more detail. The magnitude of the currents suggests that the ligand-centred reduction was a multielectron process associated with corresponding anodic reactions at −848 mV versus SCE. For the metal-centred Co(II)/Co(I) reduction process a corresponding oxidation process was observed only at −250 mV versus SCE which was much more positive than expected. By varying the cathodic limit of the cyclic voltammetry scan (see Fig. 8) it was shown that the Co(II)/Co(I) metal centred redox system was fully reversible, resulting in a symmetric reduction–oxidation couple. However, scanning the potential into the ligand centred potential results in the formation of a new product detected at −300 mV versus SCE. The ligand reduction appears to stabilise the Co(I) centre that is possible by protonation of the triazine ligand. When this experiment was repeated using aqueous

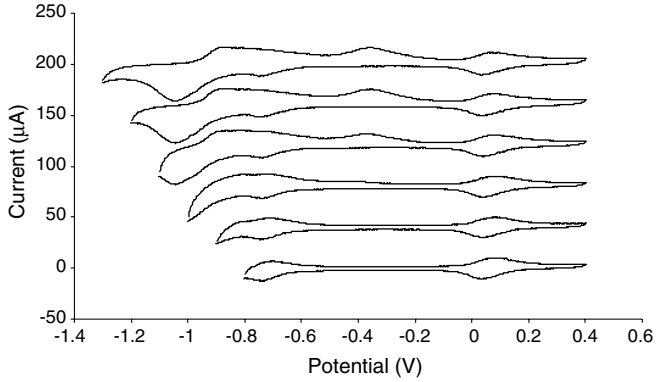

Fig. 8. Two-phase voltammetry of solid $[Co(\mathbf{1c})_2]\cdot 2ClO_4$ immobilised at a 4.9 mm diameter basal plane pyrolytic graphite electrode recorded at 100 mV s^{-1} with variation of the negative potential limit.

potassium perchlorate (0.1 M) in place of the sodium perchlorate solution the redox chemistry was unchanged indicating that the reversible intercalation of alkali metal ions does not facilitate the solid state redox chemistry.

In order to test the protonation hypothesis, the pH of the aqueous solution was varied. On replacement of the sodium perchlorate solution with perchloric acid (0.1 M), it was found that while the Co(II)/Co(III) couple remained as before (confirming the charge compensation mechanism via perchlorate exchange), the ligand-centred reduction was subject to a clear anodic shift and it was no longer possible to observe the Co(I)/Co(II) redox event independently. This anodic shift confirmed that the ligand-centred reduction involves protonation. In order to investigate this further a series of experiments employing aqueous electrolytes with different pH values were performed. In order to ensure that the majority of the anions present in the aqueous phase were perchlorates, a large amount of sodium perchlorate (0.2 M) and a small amount of sodium phosphate (0.02 M) were dissolved in water. This aqueous solution was then titrated with aqueous perchloric acid (0.1 M) in order to provide aqueous solutions with pH values between 11.0 and 1.8. When the pH was high, an additional reduction was observed with (cathodic and anodic peaks at −1.114 and −0.888 V, respectively), which could be due to a reversible Co(I) → Co(O) or a ligand-centred reduction. It is likely that this reduction can only be observed at low proton concentrations because protons interfere with this chemistry either by reacting with the Co(O) species or by obscuring this new peak with the peak arising from the formation of dihydrogen from protons. When the pH was below 4 it was found that the potential at which the ligand reduction occurred was subject to an anodic shift of −69 mV per pH unit, which suggests that 1.2 protons were required for the transfer of every electron. This compares well with the proton facilitated reduction of 1,2,4-triazines which has been reported in *N*,*N*-dimethylformamide [37]. The ligand-centred reduction observed between pH 1 and 6, was subject also to an anodic shift of −25 mV per pH unit suggesting that the loss of 0.43 protons could be required for the loss of each electron (see Fig. 9).

It is interesting to compare these results with those for $[Fe(\mathbf{1c})_2]^{2+}$ shown in Fig. 6. The formation of the product peak in acetonitrile was very similar to that observed in aqueous media and protonation due to traces of water present in acetonitrile cannot be ruled out.

3.5. Computational chemistry

Within an industrial plant separating the transplutonium metals from spent fuel the extractant will be exposed to high doses of radiation. It is vital that the radiolysis of the extraction agent should be addressed. It is known that when dissolved in hexanol, gamma irradiation (1 kGy) is able to degrade **2c** and that electrochemical reduction of the triazinyl ligands can result in degradation it was thought that the reduction of the iron complexes should be modelled. It has been demonstrated by trapping experiments that radiolytically generated solvated electrons are responsible for the dechlorination of polychlorobiphenyls (PCBs) [38] and for the degradation of **2a** [39]. Calculations was performed upon the homoleptic transition metal complexes $[ML_2]^{n+}$ with tridentate ligands and $[ML_3]^{n+}$ with bidentate ligands using density functional theory (DFT) via the ADF program [21]. Since the alkyl side groups attached to the triazinyl have little influence on the metal coordination chemistry, the complexes of the parent unsubstituted BTP (**2a**), *hemi*-BTP (**1a**) and the related ligands (**6**, **5a**, **7**, **8a**, and **4a**) were studied in the gas phase. Geometry optimisations were carried out for these species with alternative charges 2, 1, and 0 and possible spin states. Starting models were taken from the crystal structures, but C_2 or D_{2d} symmetry was imposed on all models. The geometry of all structures converged successfully and in all cases one specific spin state was easily identifiable as the lowest energy. For complexes with **1a**, for Mn(II) the lowest energy was obtained with 1 unpaired electron compared to 3 with relative energy at 1.06 eV and to 5 at 0.86 eV, for Fe(II) the lowest energy structure contained no

unpaired electrons rather than 2 and 4 at 1.14, 1.44 eV higher in energy and for Co(II), the complex with one unpaired electron was lower in energy by 2.03 eV than the complex with three unpaired electrons. All these results confirm that the low spin complex is the most stable, consistent with the magnetic measurements detailed above. For Ni(II), 2 unpaired electrons were preferred to 0 by 1.02 eV against consistent with the experimental results.

Thus, the triazinyl pyridine ligands provided the metals with a strong ligand field M–N bond lengths somewhat shorter by between 0.05 and 0.10 Å than those obtained in the crystal structures. The one anomaly, however, was found for calculations with Mn. Here, the three energies for 1,3 and 5 unpaired electrons were −13.57632, −13.52898, and −13.53661 a.u suggesting that the cation was likely to have only 1 unpaired electron. However, the bond lengths in the crystal structure are typical of Mn–N bond lengths in octahedral structures [25,26] in which the metal has 5 unpaired electrons rather than 1. Indeed, the DFT calculations also bear this out with Mn–N distances of 1.978 Å to the outer pyridine nitrogen), 1.882 Å to the inner pyridine nitrogen, 1.902 Å to the triazine nitrogen for 1 unpaired electron, compared to 1.997, 1.898, 1.923 Å, respectively, for three unpaired electrons and 2.216, 2.121, 2.095 Å, respectively, for five unpaired electrons. It seems most likely therefore that in the crystal the Mn has 5 unpaired electrons rather than the 1 predicted for the isolated cation due no doubt to the effect of the anion and the crystal packing. A recent experimental paper [40] describing Fe(II) terpy complexes has shown that different anions give rise to different spin states for the metal even in identical cations.

As shown in Table 3, the trends in distances between the three M–N bonds, calculated with the ADF program and found in the crystal structures are the same in that the bond to the inner pyridine N(21) is the shortest bond while for Mn, Fe, Co and Cu the distance to the outer pyridine N(11) is longer than the distance to the triazine N(31), while the reverse is the case for Zn. We were unable to obtain crystals of the Ni(II) complex, but the DFT calculations provide distances between the metal and N(11) and N(31) of 2.052 and 2.033 Å, respectively. There is very little difference in dimensions between those found in $[Fe(\mathbf{1a})_2]^{2+}$ and in $[Fe(\mathbf{4a})_2]^{2+}$ and it is clear that the presence of the methoxy group makes little difference to the bonding of the ligand to the iron atom. In $[Fe(\mathbf{1a})_2]^{2+}$ and $[Fe(\mathbf{4a})_2]^{2+}$, the bonds to the outer pyridine rings via N(11) and N(41) are ca. 0.051 and 0.059 Å, respectively, shorter than those to the outer triazine rings via N(31) and N(61). It is noteworthy that the outer pyridine nitrogen to iron distance in $[Fe(\mathbf{6})_2]^{2+}$ is at 1.915 Å slightly shorter than the analogous bond (1.927 Å) in $[Fe(\mathbf{1a})_2]^{2+}$ and the triazine nitrogen iron bond lengths in $[Fe(\mathbf{2a})_2]^{2+}$ (1.894 Å) are longer than the equivalent bond to the triazine ring in $[Fe(\mathbf{1a})_2]^{2+}$ (1.876 Å). It appears that the M–N(triazine) bond in $[Fe(\mathbf{1a})_2]^{2+}$ is strengthened at the expense of the M–N(pyridine) bond. Within the crystallographic literature a large number of metal complexes of 1,2,4-triazines exist in which N(31) is bonded to the metal [33,34], but none with N(33) bonded have been reported (see Figs. 4 and 5 for numbering scheme). To investigate this the complex of iron with **1a** (designated as **1a′**) binding through N(33) of the triazine ring rather than N(31) was calculated to be 0.76 eV less stable. This is due primarily to electronic effects in unsubstituted ligands, though the steric effects of any alkyl groups bonded to C(34) of the triazine ring will reinforce the preference of binding through N(31) rather than N(33). Hence, coordination via N(33) is so unlikely that it does not need to be considered further.

The LUMO/HOMO energy gap for the complexes show some variations. The latest value is found for $[Fe(\mathbf{1a})_2]^{2+}$ 1.986 eV while complexes with ligands **2a**, **1a**, and **1a′** are similar at 1.919, 1.852 and 1.877 eV, while **4a** is significantly lower at 1.614 eV. In the iron complexes of **6**, **1a**, **2a**, **4a**, the three highest occupied orbitals are all concentrated within d-orbitals of the iron, while the next two have no iron component. On the other hand, the LUMOs are primarily concentrated on the ligands rather than the metal and distributed out over many atoms. From the HOMO–LUMO gaps, assuming that the energy required to spin-pair an electron is the same for all three complexes, the ligand-field stabilisation energy of the complexes of the triazinyl pyridines are slightly smaller (BTP complex 1.9%, and *hemi*-BTP complex 4.2%) than that which is predicted for the terpyridine complex. The HOMO/LUMO energy gap of the tris-bipyridine complex $\{[Fe(\mathbf{7})_3]^{2+}\}$ is 0.036 eV larger than that of the tris-[3,3′-bi-(1,2,4-triazinyl)] complex $\{[Fe(\mathbf{5a})_3]^{2+}\}$, while the HOMO/LUMO energy gap for *fac*-$[Fe(\mathbf{8a})_3]^{2+}$ is 0.029 eV greater than that of the tris-bipyridine complex. The iron complexes with ligands **6, 2a, 1a** and **1a′** were also considered with charges of +1 and 0 and were geometry optimised with the ADF program at various spin states and the results together with those from the complexes with charge +2 are shown in Table 4. For complexes with **2a, 1a, 1a′** and **4a**, in all cases the outer pyridine nitrogens are less electron rich than the inner pyridine nitrogens. The charges on the metal atom are significantly less for the **2a** complex at 0.87e compared to ca. 1.0 for the other ligands which allied to the large HOMO–LUMO gap again demonstrates the uniqueness of the BTP ligand. The Mulliken atomic charges on the iron and pyridine nitrogen atoms varied little as the charge on the complex is reduced from 2 to 1 to 0. Indeed, the extra electron(s) is distributed primarily over the ligand. The most marked increase in electron density was observed for the triazine nitrogen N(33) which is not bonded to the metal but even in this case the increase is less than 0.1e. The lone pair associated with N(33) points outwards from the molecule and is an obvious point at which an electrophile could attack a metal complex for example following an electrochemical or radiochemical reduction process (vide infra).

Of the triazinyl-pyridine complexes of iron studied by cyclic voltammetry $[Fe(\mathbf{5c})_3]^{2+}$ was unique by virtue of

Table 4

[a] Energies for complexes containing **1a**′ are relative to that of $[Fe(\mathbf{1a})_2]^{2+}$.

the fact that after the ligand-centred reduction no degradation occurred, one explanation is that the additional electron density is spread over a larger number of triazine rings. According to the DFT calculations the N(4) triazine nitrogen has an unusually low electron density (−0.175 in the complex $[Fe(\mathbf{5a})_3]^{2+}$) hence making the attack of electrophiles much less likely.

Metal complexes of tetraethyl-BTP (**2c**) with iron, cobalt and nickel in a range of oxidation states were studied with the ADF program in the gas phase and also in solution via the COSMO method. From these results it was possible to calculate the potential at which a series of redox event would occur using the general method of Peover [41] as later adapted by Shalev and Evans [42]. For the three metals, the energies of the metal complexes of **2a** with different charges and all possible spin states were calculated in the gas phase. Subsequently, the spin states with the lowest energy were used in calculations with **2c** complexes with the same range of metals and charges were calculated both with and without solvation in acetonitrile ($\varepsilon_r = 38$). It was found that solvation had little influence upon the structure of the complex; the atoms whose positions changed most were on the periphery of the complex. In common with the iron complexes, the atomic charge on either the cobalt or nickel atom did not vary with the overall charge of the complex. It was noted that on going from Fe to Co to Ni that the metal atom became more positively charged.

Hence, the nickel complex is more reducible than the cobalt or iron complexes. As the complexes become more positively charged, the atoms within the ethyl groups become more positively charged, due to inductive effects but this is less noticeable for the atoms in the terminal methyl groups.

A graph of calculated redox potentials against experimental values suggested that, while the absolute difference between the redox potentials of the nickel BTP complexes were overestimated, the order and relative magnitude of these redox potentials were correctly predicted. The calculations confirmed that of the three metal complexes (Fe, Co, Ni), the nickel can be most readily reduced to the uncharged zero-valent metal complex. The DFT calculations predicted that the difference between the $E^{2/3}$ and $E^{1/2}$ would be less for cobalt than it would be for nickel, but this potential gap for cobalt was significantly overestimated (see Table 5).

$$E^{2/3} = \text{Energy } (+2 \text{ form}) - \text{Energy } (+3 \text{ form}).$$
$$E^{1/2} = \text{Energy } (+1 \text{ form}) - \text{Energy } (+2 \text{ form}).$$
$$E^{0/1} = \text{Energy } (+0 \text{ form}) - \text{Energy } (+1 \text{ form}).$$

Table 5
Absolute redox potentials of $[M(\mathbf{2c})_2]^{2+}$ predicted by DFT calculations (M = Fe, Co and Ni)

Redox potential (V)	Metal		
	Fe	Co	Ni
$E^{2/3}$	5.34	3.77	4.83
$E^{1/2}$	−3.19	−3.45	−3.07
$E^{0/1}$	−6.22	−6.38	−3.91

4. Conclusions

It has been established that the triazinyl pyridines were able to bind strongly to the transition metals, in a manner analogous to that of terpyridine. The 1,2,4-triazine rings are more electron withdrawing than pyridine rings. Upon solution state reduction of the triazinyl pyridine ligands degradation was often observed, an accumulation of negative charge at N(33) of the triazine ring has been predicted computationally and is a possible step in a reductive degradation. It is hoped that it will be possible to design metal extraction agents lacking N(33) like nitrogens which will have a better resistance to radiolytic degradation. A solid-state electrochemical study of a cobalt complex indicates that the ligand reduction is a reversible event that is promoted and modified by the presence of a Brönsted acid.

This paper is dedicated to Professor Mike Hursthouse.

Abstract

Five new complex salts $[Pt(SC(NH_2)_2)_4][dc]$ (dc = adipate (**1**), isophthalate (**2**), terephthalate (**3**), 4,4′-biphenyldicarboxylate (**4**), 1,4-naphthalenedicarboxylate (**5**)) have been characterized by single-crystal X-ray diffraction. Thiourea–carboxylate interactions have proven to be a reliable supramolecular synthon, yielding in all the examples charge-assisted hydrogen-bonded 3D networks via N–H···O interactions.

1. Introduction

Recently, developments in inorganic crystal engineering have made significant progress towards the goal of the rational synthesis of crystalline materials [1–5]. Employing metal-containing building blocks allows the use of co-ordinate bonds in addition to non-covalent bonds to design molecular networks. Metal-organic frameworks (MOFs) represent a fast growing class of materials which have a variety of applications [6,7]. On the other hand, hydrogen-bonded frameworks derived from metal complexes have also attracted a great deal of interest [8–11]. One frequently employed strategy in the production of networks is the use of pyridine ligands bearing carboxylic acid or amide groups, as the hydrogen-bonded dimers of these groups are well known supramolecular synthons in organic crystal engineering [12–14]. Although this approach has proven very successful, there are very few examples of 3D structures assembled through ligand–ligand hydrogen bonds (which may be classed as 'second sphere' coordination complexes) [8–10]. The use of metal cations and neutral ligands means that the resultant cationic network must be balanced by the presence of counterions. A possible solution to avoid this is the inclusion of the anions in the network design [15,16]. Similar approaches involving crystallization of organic cations with hydrogen bond donor groups and metallate anions has been used by Orpen, Hosseini and others [17–20], resulting in the characterization of one, two and 3D networks stabilized by charge-assisted hydrogen bonds.

Urea and thiourea derivatives have been widely used in organic crystal engineering, being the bidentate urea–carboxylate interactions a well known and exploited motif in carboxylate recognition chemistry, forming complexes which show appreciable stability in polar solvents [21]. Despite these examples, the supramolecular aggregation of metal complexes containing these ligands is largely unexplored [22–24]. This prompted us to test the suitability of

the tetrakis(thiourea)platinum(II) complex with dicarboxylates as molecular building blocks in the synthesis of hydrogen-bonded networks. The stability of the complex toward ligand substitution allow the use of carboxylate anions, which might otherwise displace some of the neutral ligands or co-ordinate to the metal centre, as demonstrated by Burrows et al. [25–27] in the case of Zn(II) thiourea complexes. The set of four coordinated thiourea groups in a semiflexible square planar arrangement is capable of propagating hydrogen bonding interactions in three dimensions through the interactions with the dicarboxylate dianions (see Chart 1).

2. Experimental

2.1. Materials

Tetrakis(thiourea)platinum(II)dichloride was prepared according to published procedures [28]. Dipotassium tetrachloroplatinate, adipic acid, terephthalic acid, isophthalic acid, 1,4-naphthalene dicarboxylic acid and 4,4′-biphenyl dicarboxylic acid were obtained commercially and used without further purification. Methanolic solutions of dicarboxylic acids were treated with two equivalents of potassium hydroxide and the resulting dipotassium dicarboxylate salts obtained as white microcrystalline powder by removing the solvents.

2.2. Synthesis of the complex salts *[Pt(SC(NH$_2$)$_2$)$_4$][dicarboxylate]*

2.2.1. *[Pt(SC(NH$_2$)$_2$)$_4$][adip] (**1**)*

Tetrakis(thiourea)platinum(II)dichloride (0.05 g, 0.088 mmol) was dissolved in 1.5 mL of DMSO. To this solution, an aqueous solution (1 mL) of adipic acid dipotassium salt (0.02 g, 0.089 mmol) was added and acetone allowed to diffuse slowly into the mixture. Colourless crystals suitable for X-ray diffraction appeared within five days. Yield 0.028 g (49%).

Elemental analysis calc. for **1** · 2DMSO: C, 21.02; H, 4.54; N, 14.01. Found: C, 20.51; H, 4.50; N, 13.67%.

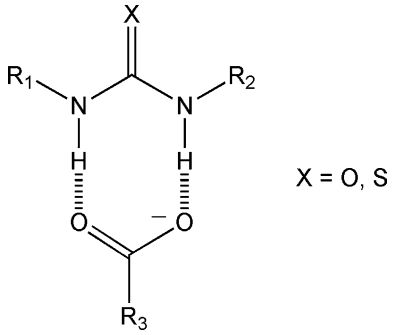

Chart 1. Schematic representation of the urea/thiourea–carboxylate interaction.

2.2.2. *[Pt(SC(NH$_2$)$_2$)$_4$][ipht] (**2**)*

A DMSO solution (1.5 mL) of tetrakis(thiourea)platinum(II)dichloride (0.05 g, 0.088 mmol) was mixed with an aqueous solution of isophthalic acid dipotassium salt (0.022 g, 0.088 mmol). Acetone vapour was allowed to diffuse slowly into the mixture, and yellow blocks appeared within five days. Yield 0.024 g (36%).

Elemental analysis calc. for **2**: C, 21.72; H, 3.04; N, 16.88. Found: C, 21.50; H, 3.08; N, 16.66%.

2.2.3. *[Pt(SC(NH$_2$)$_2$)$_4$][tpht] (**3**)*

Tetrakis(thiourea)platinum(II)dichloride (0.04 g, 0.07 mmol) was dissolved in 1.5 mL of DMSO. To this solution, an aqueous solution of terephthalic acid dipotassium salt (0.017 g, 0.07 mmol) was added and acetone allowed diffusing slowly into the mixture. Yellow crystals suitable for X-ray diffraction appeared within three days. Yield 0.024 g (36%).

Elemental analysis calc. for **3** · 2DMSO · 2H$_2$O: C, 22.45; H, 4.24; N, 13.09. Found: C, 22.08; H, 4.14 H; N, 13.08%.

2.2.4. *[Pt(SC(NH$_2$)$_2$)$_4$][bphdc] (**4**)*

A DMSO solution (1.5 mL) of tetrakis(thiourea)platinum(II)dichloride (0.05 g, 0.088 mmol) was mixed with an aqueous solution of 4,4′-biphenyldicarboxylic acid dipotassium salt (0.028 g, 0.088 mmol). Acetone vapour was allowed to diffuse slowly into the mixture, and colourless blocks appeared within five days. Yield 0.036 g (55%).

Elemental analysis calc. for **4** · 3OC(CH$_3$)$_2$: C, 35.48; H, 4.63; N, 12.26. Found: C, 35.68; H, 4.73; N, 12.36%.

2.2.5. *[Pt(SC(NH$_2$)$_2$)$_4$][naphdc] (**5**)*

Two solutions containing tetrakis(thiourea)platinum(II)dichloride (0.05 g, 0.088 mmol) and 1,4-naphthalene dicarboxylic acid dipotassium salt (0.027 g, 0.088 mmol) in DMSO and water, respectively, were mixed and acetone allowed to slow diffuse into it. Pale yellow crystals suitable for X-ray diffraction appeared within two days. Yield 0.031 g (47%).

Elemental analysis calc. for **5** · 2DMSO: C, 27.61; H, 3.94; N, 12.88. Found: C, 27.97; H, 4.05; N, 12.69%.

2.3. Crystal structure determination

Data for all structures were collected using Phi and omega scans on a Bruker Nonius Kappa CCD area detector diffractometer with a rotating Mo (0.71073 Å) anode following standard procedures. Data were corrected for absorption using SADABS [29]. Structure solution was performed using SHELXS 97 [30] and refinement carried out on F^2 using SHELXL 97 [31]. Hydrogen atoms were placed in idealized positions and refined using a riding model. The non-merohedrally twinned data for **1** were processed using evalCCD [32] and the data were not merged; the

twin relationship was a 180° rotation about 0 0 1. The carbon chains of the two half adipate molecules in **1** were modelled as disordered 50:50 over two conformations. The DMSO in **3** was disordered 60:40 over two positions. CCDC Nos. 281329–281333 contain the supplementary crystallographic data for this paper. These data can be obtained free of charge from The Cambridge Crystallographic Data Centre via www.ccdc.cam.ac.uk/data_request/cif. Crystal data and structure refinement details are summarized in Table 1. Selected hydrogen bond parameters are given in Table 2.

3. Results and discussion

Reaction of $[Pt(SC(NH_2)_2)_4]Cl_2$ in DMSO with potassium salts of the dicarboxylates shown in Chart 2 led to the corresponding complex salts in which the chloride anions have been substituted by the dicarboxylates. These salts were crystallized and characterized by single-crystal X-ray diffraction.

The crystal structure determination of complex **1** revealed that the salt crystallizes in the presence of two DMSO molecules. The coordinated thiourea groups

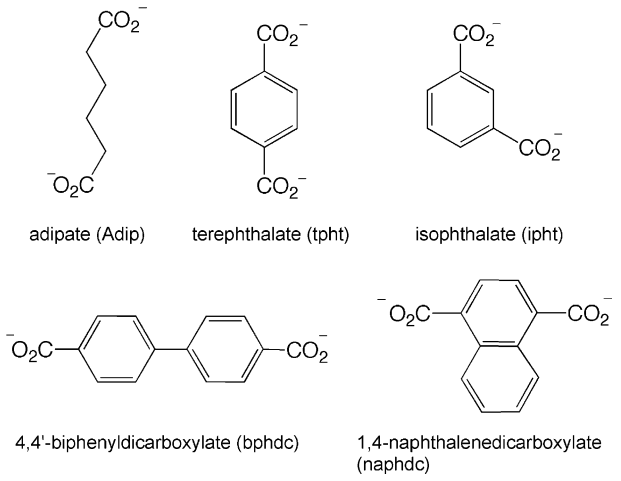

Chart 2. Dicarboxylates used as counter anions within this work.

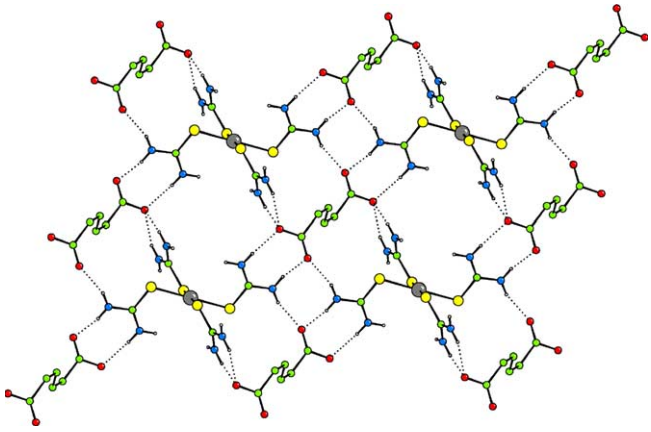

Fig. 1. Hydrogen bonding interactions within sheets in compound **1**.

adopted a 1,2-alternate[1] conformation with respect to the plane containing the platinum and sulfur atoms. Adipate dianions form strong double hydrogen bond interactions with thiourea groups forming infinite 1D chains. These chains are inter-linked via N–H···O interactions involving four thiourea groups (graph set $R_2^1(6)$ and *D*) to form two crystallographically independent sheets cross-linked via one DMSO and one adipate molecule (Fig. 1). The two crystallographically independent DMSO molecules are bound in slightly different ways. The first DMSO is bound by two hydrogen bonds from adjacent thiourea groups in the same platinum complex. The second DMSO is also bound by two hydrogen bonds but bridges two thiourea groups in different platinum complexes. When viewed down the *a*-axis these DMSO molecules sit in pseudo-channels (Fig. 2).

X-ray analysis of complex **2** reveals that the structure does not contain additional solvent molecules. The hydrogen bonding pattern is very similar to that found in the case of compound **1**, with three types of hydrogen bond interactions between the coordinated thiourea groups and the isophthalate dianions. Two thiourea groups in a *trans* disposition form DD:AA hydrogen bonding interactions with the isophthalate (graph set $R_2^2(8)$) with N···O distances 2.864 (3) and 2.805 (3) Å and bond angles 171.1°

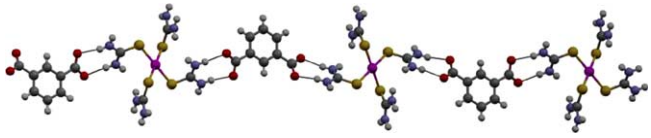

Fig. 3. View of the neutral chain defined by thiourea–carboxylate interactions in compound **2**.

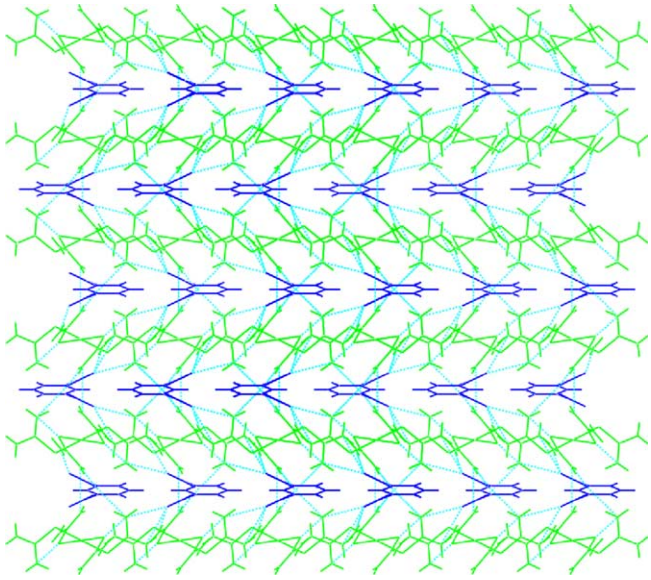

Fig. 4. Hydrogen-bonded 3D network of compound **2** viewed down crystallographic axis *a*.

[1] The nomenclature used to describe the conformation of the platinum complexes has been 'borrowed' from calix[4]arene chemistry. 1,3-Alternate means each thiourea group is oriented away from the PtS_4 plane in an alternating fashion whilst 1,2-alternate describes an arrangement where two adjacent thiourea molecules are oriented in one direction away from the PtS_4 plane whilst the other two thiourea molecules are oriented in the opposite direction.

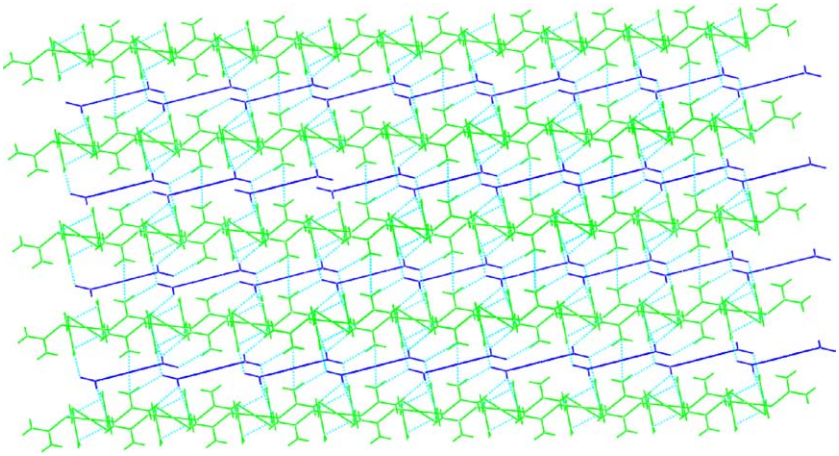

Fig. 5. Hydrogen-bonded 3D network of compound **2** viewed down crystallographic axis *b*.

and 170.4°, forming a neutral chain (Fig. 3), which is cross-linked to form a 3D network by two hydrogen bond interactions (graph set *D* and $R_2^1(6)$) between the other two urea groups and four additional isophthalate groups (Figs. 3–6).

In the case of compound **3** the complex salt crystallized together with two molecules of water and two molecules of DMSO. Again, the coordinated thiourea groups are found in a 1,2-alternate conformation but in this case only discrete hydrogen bond interactions (graph set *D*) are found between them and the terephthalate dianions (N2–H2B···O1 bond distance 2.989(5) Å, bond angle 166.5°). The hydrogen bonding environment of each complex cation included four molecules of water and four molecules of DMSO (Fig. 7). Water molecules were found bridging

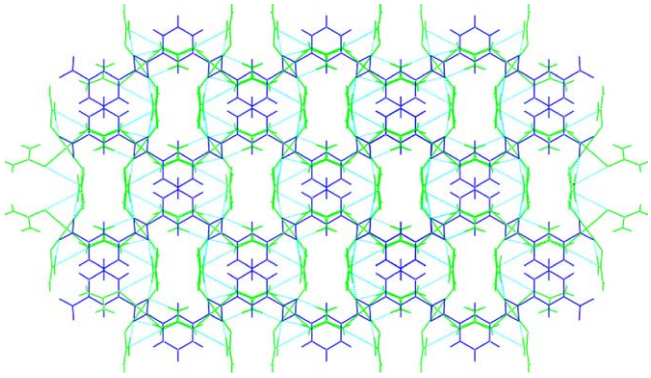

Fig. 6. Hydrogen-bonded 3D network of compound **2** viewed down crystallographic axis *c*.

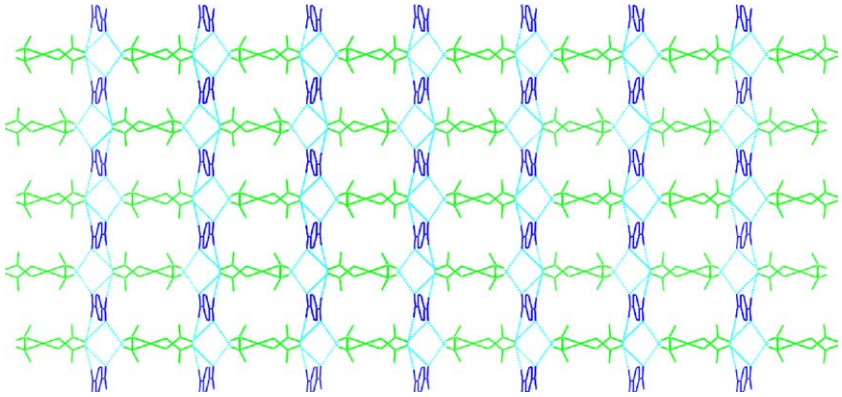

Fig. 8. View down crystallographic axis *a* of compound **3** network (solvents omitted for clarity).

the terephthalate and platinum complexes meanwhile the DMSO molecules are contained in channels running along the crystallographic *a*-axis, with two of these molecules displaying discrete contacts and the other two bridging two coordinated thiourea ligands (graph set $R_2^1(10)$) (Fig. 8).

The crystal structure of **4** revealed that the lattice contains three acetone molecules. In this case, the co-ordinated thiourea ligands adopt a 1,3-alternate conformation and this arrangement is stabilized by two intramolecular hydrogen bonds between adjacent thiourea groups S(6) with N2–H2B···S2 3.532(3) Å and N3–H3B···S1 3.405(3) Å. The hydrogen bond network might be explained in terms of a neutral chain composed by strong DD:AA interactions between two thiourea groups in *cis* arrangement and two dicarboxylate anions (Fig. 9) which is inter-linked by discrete contacts with thiourea groups belonging to other five platinum complexes (Figs. 10 and 11). The acetone molecules form N–H···O interactions with coordinated thiourea groups with one of them bridging two thiourea groups belonging to two different platinum complexes. The platinum complexes form centro-symmetric dimers via N–H···S hydrogen bonds with the N···S distance being 3.263(7) Å.

The complex salt **5** was found to contain two molecules of DMSO as solvent included in the crystal structure. There are two half platinum complexes in the asymmetric unit as the central atoms sit on special positions. The coordinate thiourea ligands again adopt a 1,2-alternate conformation around the platinum(II) centre. A neutral 1D chain along the crystallographic *b*-axis is formed by means of strong DD:AA interactions between two of the thiourea ligands in *trans* disposition and the dicarboxylate dianion, with N···O distances 2.883(3) and 2.948 (3) Å and bond angles from 167.3° and 169.2° (graph set $R_2^2(8)$) (Fig. 12). This motif is expanded into a 3D network through additional interactions with other coordinated ligands (Fig. 13). The crystal structure included two DMSO molecules which are found displaying N–H···O hydrogen bonds with two thiourea groups in a *cis* position within a platinum complex (graph set $R_2^1(10)$) (Fig. 14).

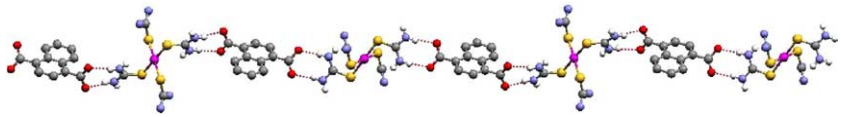

Fig. 12. Infinite 1D neutral chain defined by thiourea–carboxylate interactions in compound **5**.

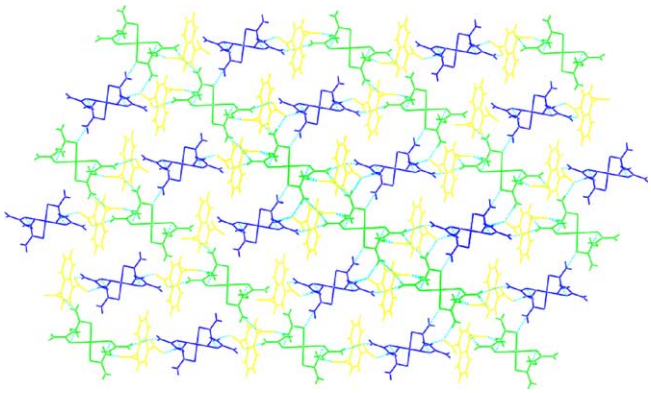

Fig. 13. Crystal structure of compound **5** viewed down crystallographic axis *a* (solvents omitted for clarity).

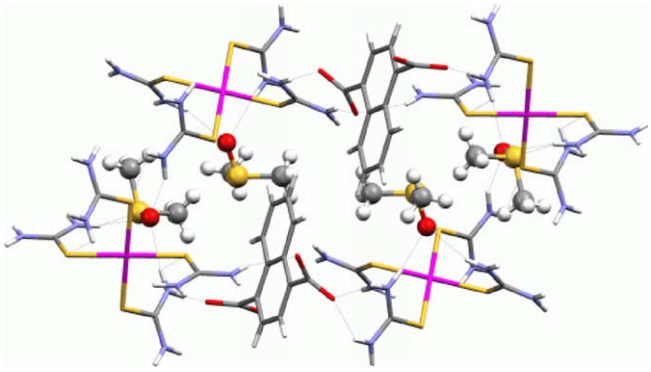

Fig. 14. Detail of the hydrogen bonding environment of the DMSO molecules included in the crystal structure of compound **5**.

Compounds **1**, **2**, **4** and **5** contain in their structures neutral 1D chains resulting from bidentate N–H···O interactions ($R_2^2(8)$) between coordinated thiourea ligands and carboxylate groups. These chains are formed by thiourea groups in *trans* disposition but in the case of compound **4**, in which the 1,3-alternate disposition of thiourea groups means that the chains are propagated through mutually *cis*-ligands. These chains are inter-linked by secondary thiourea–carboxylate interactions to yield in all the examples 3D networks.

Formally, only two carboxylate groups are needed to balance the positive charge carried by the platinum complex, which include four thiourea ligands. This result in an "excess" of hydrogen bond donors relative to hydrogen bond acceptors, making the nets prone to include guest molecules with hydrogen bond acceptor properties. In fact, all compounds except compound **2** were crystallized including solvent molecules in their structure, e.g., DMSO or acetone, acting as hydrogen bond acceptors fulfilling the donor properties of the thiourea groups. Compound **3** includes in its crystal structure not only DMSO but water. This event has a profound effect in the resultant structure and no bidentate thiourea–carboxylate interactions are present but only discrete N–H···O interactions. Water molecules participate in the hydrogen-bonded network bridging the terephthalate dianions and the coordinated thiourea molecules creating a series of channels where the DMSO molecules are included. Overall, this structure can be seen as a failure in the ligand-anion recognition process, induced by the inclusion of the water molecules.

4. Conclusions

Tetrakis(thiourea)platinum(II) is an adequate molecular tecton for the construction of hydrogen-bonded networks. Its inertness towards ligand substitution makes it ideal for studies employing anions with high coordinative potential, like the carboxylates employed in this work, whereas the spatial disposition of the thiourea groups allowed the translation of the interactions into the three dimensions of the crystal. Double thiourea–carboxylate hydrogen bond interactions appeared in four of the five structures presented, a supramolecular yield of 80%, despite the presence of competitive anions and solvent in the reaction media, making of this motif a reliable supramolecular synthon. We are continuing to study the use of the tetrakis(thiourea)platinum(II) unit in crystal engineered network formation. The results of these studies will be published shortly.

Abstract

A macrobicylic ligand **1** formed by the A,D-bridging of a calix[6]arene with a 2,9-disubstituted 1,10-phenanthroline unit reacts with Yb(III) under basic conditions in dimethylformamide (dmf) to give a neutral, mononuclear complex characterised by X-ray crystallography as [Yb(**1**-3H)(dmf)] · 3dmf. The structure shows that although the metal can be considered to lie within a cavity formed by the "concave reagent" ligand, this does not entirely prevent its coordination to a dmf molecule between arms of the macrobicycle. Stability constant measurements indicate that **1** forms complexes of similar strength across the lanthanide(III) series.

1. Introduction

In analogy with many enzyme active sites where a metal ion is held within a cavity of restricted dimensions [1], the complexation of metal ions by donor atoms attached to or within a hollow synthetic receptor raises prospects for many forms of catalysis [2,3]. The synthesis of ligands for such purposes is not straightforward, though one simplification is to use as reactants molecules which already have the capacity to adopt conformations of a cavity form. This property is well known for the calixarenes, including in particular calix[6]arenes [4], and we have previously described [3,5] the synthesis and structure of a calix[6]arene, bridged between the A,D rings by a 1,10-phenanthroline moiety (**1**, Fig. 1), which does indeed appear to behave as a "concave reagent" for binding metal ions [3]. An analogous derivative of calix[8]arene has also been recently described [6].

One of the unanticipated properties of **1** was its conformational lability, theoretical calculations indicating the probable presence of numerous forms of similar energy [5]. This implies that an interaction such as metal ion coordination might well enforce conformations quite different from those of the free ligand [5], an extreme case being that where ligands completing the coordination sphere of the metal, potentially those involved in catalysis, do not lie within the cavity of **1**. The formation of 2:1 M:L complexes of **1** with transition metals [7] provides evidence in support of this possibility. Thus, it was of interest to establish the structure of a metal complex of **1**, a lanthanide (Ln) ion complex, given the typically high coordination numbers and irregular geometry of simple Ln(III) ions [8], being seen as offering a stringent test of the capacity of **1** to restrict the full coordination environment of a bound metal. It is well known, in the case of cryptand complexes, for example [9], that simple unidentate ligands can bind to

2.1. Synthesis

*[Yb(**1**-3H)(dmf)] · 3dmf*. Addition of a solution of $[Yb(dmso)_8](ClO_4)_3$ [10] (45 mg) in dry dmf (1 mL) to a solution of **1** (50 mg) in dmf (1 mL) containing a fourfold molar amount of triethylamine led to a yellow solution from which small yellow crystals slowly (over days) deposited. After one week, the crystals, one of which proved suitable for a structure determination, were collected and washed with acetonitrile followed by diethyl ether. Yield: 28 mg (50%). FAB-MS: *m*/*z* 1349 (parent peak) = $[Yb(\mathbf{1}\text{-}2H)]^+$.

2.2. Stability constant determinations

A solution of **1** (10^{-3} mol L^{-1}) in dimethylsulfoxide (dmso) containing a fourfold molar amount of triethylamine was titrated with an equimolar solution prepared from either $[Ln(dmso)_4(NO_3)_3]$ [11] (Ln = La) or $[Ln(dmso)_8](ClO_4)_3$ (Ln = Eu, Tb, Yb) in dmso, spectral changes being monitored in the visible region (350–700 nm). Measurements were made at 298 K, with data being analysed using Specfit 32 [12].

2.3. Crystallography

2.3.1. Structure determination

A full sphere of CCD area-detector diffractometer data were measured (Bruker AXS instrument, ω-scans, $2\theta_{max} = 50°$; monochromatic Mo Kα radiation, $\lambda = 0.71073$ Å; *T* ca. 153 K) yielding 150 882 total reflections, these merging to 14 424 independent after 'empirical'/multiscan 'absorption correction' (proprietary software; $R_{int} = 0.095$. $\mu = 1.14$ mm^{-1}; specimen: $0.30 \times 0.06 \times 0.05$ mm; '*T*'$_{min/max} = 0.87$), 7434 with $F > 4\sigma(F)$ being used in the large block least squares refinement (anisotropic displacement parameters for the non-hydrogen atoms, $(x, y, z, U_{iso})_H$ included at estimated values). Conventional residuals on |*F*| at convergence were $R = 0.055$, $R_w = 0.057$ (reflection weights: $(\sigma^2(F) + 0.0006F^2)^{-1}$). Neutral atom complex scattering factors were employed within the Xtal 3.7 program system [13]. *t*-Butyl groups 14, 44, 54 were modelled as disordered (about their pendent bonds), as also were the coordinated and solvent dmf molecules. The disorder is apparently concerted, site occupancies refining to 0.613(9) and complement for major and minor components (exception: *t*-butyl 54 where the occupancies were set at 0.5); for the minor components, the isotropic displacement parameter form was used, solvent dmf 4 being modelled with a rigid body constraint. The geometries of dmf(30) and *t*-Bu(54) were constrained at idealised values. The phenolic O(51) was assigned as protonated on the basis of difference map evidence, coupled with geometrical considerations. Pertinent results are presented below, and in Table 1, and Fig. 1, the latter showing the non-hydrogen atoms with 50% probability amplitude displacement envelopes, hydrogen atoms having arbitrary radii of 0.1 Å.

2.3.2. Crystal data

$[Yb(\mathbf{1}\text{-}3H)(dmf)] \cdot 3dmf \equiv C_{92}H_{117}N_6O_{10}Yb$, $M = 1640.0$. Orthorhombic, space group *Pbca* (D_{2h}^{15}, No. 61), $a =$

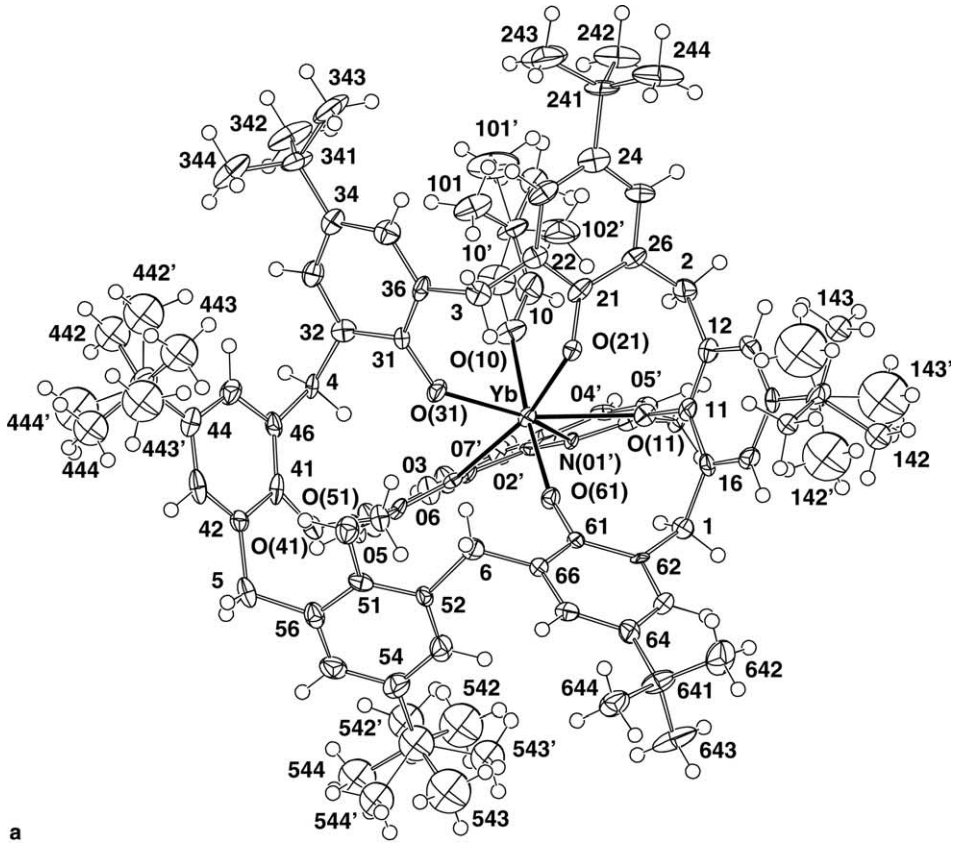
r (Å) is the Yb–ligand atom distance; other entries in the matrix are the angles subtended by the relevant atoms at the head of the row and column. Yb–O(n1)–C(n1) ($n = 1,2,3,6$) are 120.8(5), 147.1(6), 138.2(5), 165.5(6); Yb–O(10)–C(10,10′) 153(1), 133(2)°.

30.707(6) Å, $b = 17.440(4)$ Å, $c = 32.377(8)$ Å, $V = 17339$ Å^3. D_{calc} ($Z = 8$) = 1.25$_6$ g cm^{-3}.

3. Results and discussion

The molecular entity [Yb(**1**-3H)(dmf)] found within the lattice of [Yb(**1**-3H)(dmf)] · 3dmf in the present low-temperature, single-crystal X-ray diffraction study is shown, with atom numbering, in Fig. 2(a). It is an addition to the relatively short list of mononuclear Ln(III) complexes of phenoxide-form calixarenes known [14] and presumably the essential inclusion of the metal within the ligand cavity retards association through such means as phenoxide-*O* bridging (otherwise commonly observed [14]). The Yb centre shows O_5N_2 seven-coordination (Fig. 2(b); Table 1), again not unusual for a lanthanide/calixarene species, with the longest Yb–O interaction involving one of the ether-*O* donor centres formed as a result of alkylation of the calixarene by the phenanthroline unit. This interaction may explain the unsymmetrical binding of the metal to the



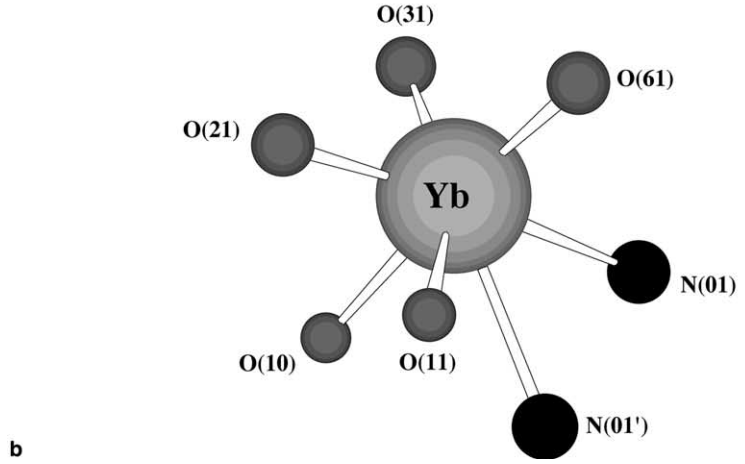


Fig. 2. (a) Projection of a molecule of [Yb(**1**-3H)(dmf)] through the macrocycle. (b) The coordination environment of Yb(III) in [Yb(**1**-3H)(dmf)].

phenanthroline-*N* donors, though this also is not unusual in very heavy metal complexes of 1,10-phenanthroline itself [15]. That the Yb–O bond distances, including those involving uncharged oxygen, are shorter than Yb–N is typical of Ln(III) ions [8]. The metal ion thus does not appear to be under particular geometric constraints in its interaction with **1**. O(41), which is directed away from the Yb centre, is assigned as carrying the residual ligand proton required for charge balance.

A significant feature of the metal ion environment in [Yb(**1**-3H)(dmf)] is that the *O*-bound dmf ligand approaches the metal between the ligand arms defined by the phenanthroline bridge and half the calixarene macrocycle, so that it cannot be considered to have been drawn into what it was hoped would be a cone-like cavity formed by the calix[6]arene entity. In fact, the coordination of three phenoxide-*O* atoms to Yb, although it may be regarded as assisting the formation of a cavity by orienting three *p*-*t*-butylphenyl rings in the same sense as the two attached to the phenanthroline unit, actually orients these "blocking" entities away from the sides of the phenanthroline plane so that they must do little to inhibit approach of a

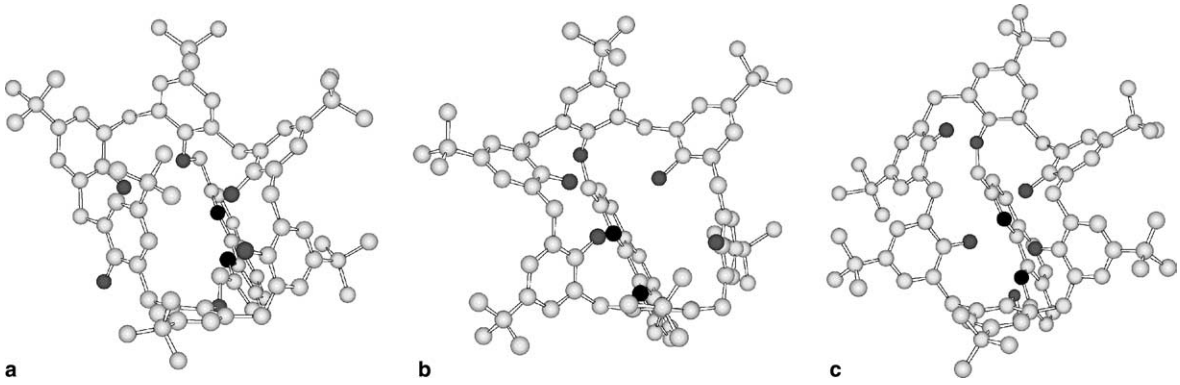

Fig. 3. Conformations of the molecule **1**, viewed with similar projections of the phenanthroline unit and with only one component of disordered sections of the molecule shown, as found in: (a) the water/acetonitrile/chloroform solvate of the ligand; (b) the water/pyridine solvate of the ligand; and (c) the formally trianionic form of the ligand found in its Yb(III) complex. (Atom colour coding: C, white; N, black; O, pale grey.)

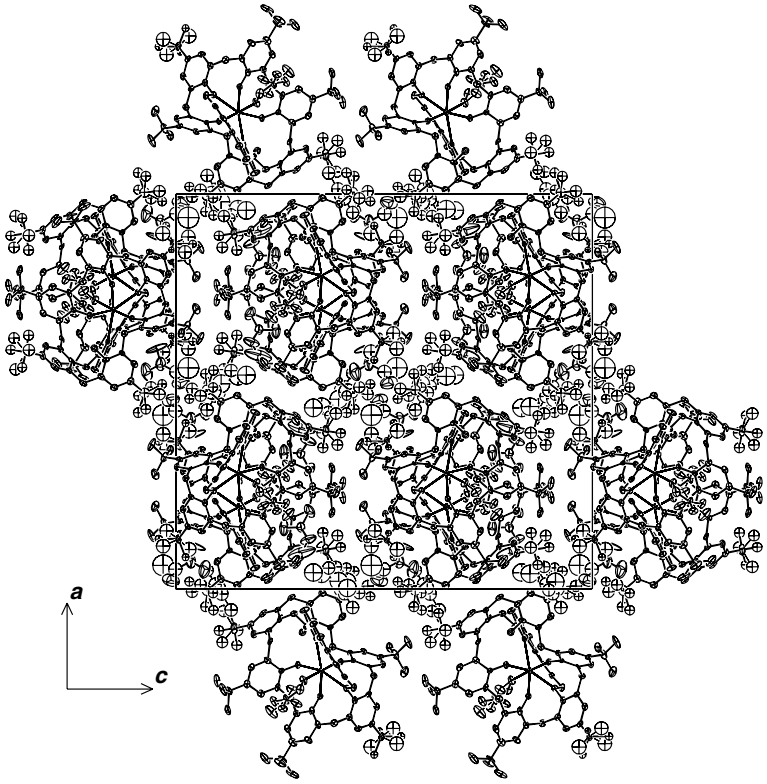

Fig. 4. The unit cell contents projected down *b*, i.e., down the columns of complex molecules parallel to that axis within which the Yb sites undulate. The complex columns are partitioned by columns of disordered solvent molecules.

small molecule such as dmf. Nonetheless, it may be noted that the (disordered) *N*-methyl groups of the bound dmf do come within ~3.5 Å of the centroids of two phenyl rings, indicating that inclusion effects of the ''side pockets'' might still be possible.

The conformation of **1** as its trianion bound to Yb(III) differs markedly from those of the neutral ligand as its water/acetonitrile/chloroform and water/pyridine solvates (Fig. 3), though the latter two conformations also differ markedly, apparently in response to different H-bonding interactions, as has been discussed previously [5]. In all three cases, nonetheless, the ligand can be regarded as forming a cavity offering a site for inclusion of other molecules. In the case of the Yb(III) complex, it is not the lattice dmf which occupies these cavities but adjacent, similarly oriented complex units, possibly largely due to edge-to-face phenanthroline–phenyl interactions, so that the complexes can be viewed as forming zig-zag chains down *b* through the lattice, with Yb···Yb 9.117(2) Å (Fig. 4). Such inclusion of a neighbouring molecule is seen in many metal complexes of calixarenes, sometimes resulting in hermaphrodite pair formation [16] rather than polymer formation as in the present case. Since the nature of the cavity is influenced, even if indirectly, by the metal ion, a prospect for catalysis by inclusion but without direct coordination still exists.

While the binding of the trianion of **1** to Yb(III) does not seem to restrict further binding of at least one small ligand, it does appear to eliminate interaction with a second molecule of **1**, since analysis of the spectral changes on addition of Ln(III), Ln = La, Eu, Tb, Yb, to **1** in dmso solution were consistent with the formation of just a 1:1 species in all instances. Given the apparent flexibility of **1** and the unexceptional nature of the coordination sphere of Yb in [Yb(**1**-3H)(dmf)]·3dmf, marked selectivity in the solution complexation of Ln(III) by **1** would be surprising, and indeed the values ($\log K_{stab}$) obtained of 4.0 ± 0.3 (La), 4.7 ± 0.3 (Eu), 4.5 ± 0.3 (Tb) and 4.2 ± 0.3 (Yb) indicate, assuming linear interpolations are justified, that **1** shows little discrimination across the lanthanide series. (Note that these values correspond to effective stability constants, since the K_a values for **1** in dmso are unknown.)

4. Conclusions

Ligand design for a specific objective is difficult [17] and it is somewhat ironic that the carefully planned synthesis of the ligand **1** appears not to have resulted in a desired objective, the placing of reactive substrates within a protected environment through coordination drawing them into a molecular cavity, when this has been achieved unintentionally in a much simpler calixarene system [18]. However, the fact that La(III), for example, frequently shows higher coordination numbers than Yb(III) [8], this being true in particular in complexes of a simple podand polyaryloxide [19], may justify further examination of lanthanide complexes of **1** to see whether lighter lanthanides may attract not only a ligand sited between the macrocyclic arms but also one drawn through the calixarene cavity. The similar affinity of **1** for all the lanthanides means, of course, that the full gamut of magnetic and spectroscopic properties of the lanthanides would be available for exploitation in such complexes.

5. Supplementary information

Full crystallographic data have been deposited with the CCDC under deposition number 284795. These data may be obtained free of charge via www.ccdc.cam.ac.uk/conts/retrieving.html or from the Cambridge Crystallographic Data Centre, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033 or e-mail: deposit@ccdc.cam.ac.uk).

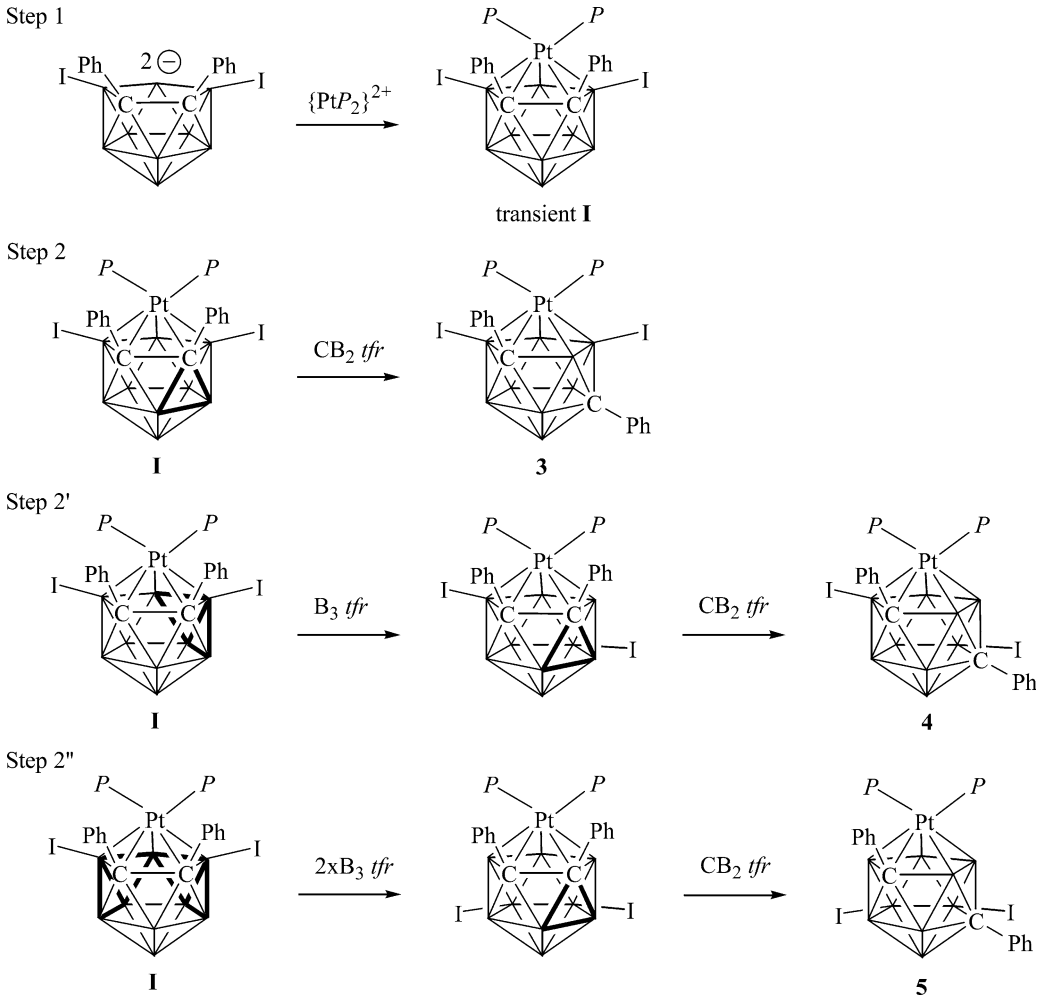

Scheme 1. Possible formation of platinacarboranes **3**–**5** by triangle face rotations (tfrs) starting from an implied transient species **I**. In each tfr the face highlighted in bold is assumed to rotate by 120°. In Steps 2′ and 2″ the B_3 and CB_2 tfrs could be sequential or synchronous. $P = PMe_2Ph$.

are also formed [7c,7d], whereas addition of bulky $\{PtL_2\}^{2+}$ always gives 2,1,8-PtC_2B_9 products [4,7b,7d], although in one case [7b] we were also able to isolate a 3,1,2-PtC_2B_9 species and show that it represented an intermediate by its isomerisation to 2,1,8-PtC_2B_9 on gentle warming.

In this paper, we extend these studies by describing the synthesis of new mono- and disubstituted nido-diphenylcarboranes and the results of subsequent metallation of the latter with a $\{PtL_2\}^{2+}$ fragment.

2. Experimental

2.1. Synthetic and spectroscopic studies

Experiments were performed under dry, oxygen-free N_2 using standard Schlenk techniques, with some subsequent manipulation in the open laboratory. Solvents were freshly distilled over CaH_2 (CH_2Cl_2) or Na wire (THF, Et_2O, 40–60 petroleum ether), or were stored over 4 Å molecular sieves [$CDCl_3$, $(CD_3)_2CO$]. Preparative thin layer chromatography (TLC) employed 20 × 20 cm Kieselgel 60 F_{254} glass plates. NMR spectra at 200.13 (^{1}H), 400.13 MHz (^{1}H), 128.38 (^{11}B) or 161.98 MHz (^{31}P) were recorded on Bruker AC 200 or DPX 400 spectrometers from $CDCl_3$ or $(CD_3)_2CO$ solutions at ambient temperature, chemical shifts being recorded relative to $SiMe_4$ (^{1}H), $BF_3 \cdot OEt_2$ (^{11}B) or H_3PO_4 (^{31}P). IR spectra were recorded from KBr disks on a Perkin–Elmer Spectrum RX FT-IR spectrophotometer. Elemental analyses were determined by the EPS School service. The starting materials 1,2-Ph_2-1,2-*closo*-$C_2B_{10}H_{10}$ [9] and *cis*-$PtCl_2(PMe_2Ph)_2$ [10] were prepared by literature methods or slight variants thereof. All other reagents and solvents were supplied commercially and were used as received.

2.1.1. Synthesis of [$HNMe_3$][7,8-Ph_2-9-I-nido-$C_2B_9H_9$] (*1*)

1,2-Ph_2-$C_2B_{10}H_{10}$ (1.000 g, 3.38 mmol) and KOH (0.430 g; 8.45 mmol) were heated to reflux in EtOH (50 ml) for 72 h. Excess KOH was removed by reaction with CO_2 and filtering off the K_2CO_3 formed. To the clear colourless solution of K[7,8-Ph_2-*nido*-7,8-$C_2B_9H_{10}$] was added I_2 (0.870 g, 3.41 mmol) in ethanol (30 ml). The reaction

mixture was heated to reflux for 2 h, during which time the solution decolourised. The volume of solution was reduced to ca. 10 ml in vacuo and distilled water (50 ml) added. Filtration and addition of aqueous $HNMe_3Cl$ (0.380 g, 4.00 mmol) gave a white precipitate which was filtered off and dried in vacuo. An alternative procedure involves extraction of the precipitate into CH_2Cl_2 (3×30 ml), drying over $MgSO_4$ and subsequent removal of the drying agents and solvents. An oily solid was recovered which was recrystallised from CH_2Cl_2/40–60 petroleum ether to give a white crystalline solid. Yield 1.000 g, (63% based on diphenylcarborane). *Anal.* Calc. for $C_{17}H_{29}B_9IN$: C, 43.3; H, 6.21; N, 2.97. Found: C, 43.3; H, 6.39; N, 2.56%. IR ν_{max} (cm^{-1}): 2537 (B–H str). ^1H NMR δ (ppm): 7.2–6.8 (m, 10H, C_6H_5), 3.1 (s, 9H, NCH_3). ^{11}B–{^1H} NMR δ (ppm): −5.70 (1B), −14.42 (4B), −20.13 (1B), −23.96 (1B), −29.73 (1B), −35.68 (1B).

2.1.2. Synthesis of [$HNMe_3$][7,8-Ph_2-9,11-I_2-7,8-*nido*-$C_2B_9H_8$] (**2**)

To a solution of K[7,8-Ph_2-*nido*-7,8-$C_2B_9H_{10}$] (1.69 mmol) in EtOH (50 ml) prepared as above, was added I_2 (1.080 g, 4.23 mmol) in ethanol (30 ml). The reaction mixture was heated to reflux for 18 h, during which time the solution decolourised. The volume of solution was reduced to ca. 10 ml in vacuo and distilled water (50 ml) added. Filtration and addition of aqueous $HNMe_3Cl$ (0.173 g, 1.80 mmol) gave a white precipitate which was filtered off and dried in vacuo. Again, an alternative work-up involves extraction of the precipitate into CH_2Cl_2 (3×30 ml), drying over $MgSO_4$ and subsequent removal of the drying agents and solvents. A white solid was recovered which was recrystallised by evaporation of a dichloromethane solution to give colourless crystals. Yield 0.230 g (23% based on diphenylcarborane). *Anal.* Calc. for $C_{17}H_{28}B_9I_2N$: C, 34.2; H, 4.73; N, 2.34. Found: C, 34.1; H, 4.76; N, 2.27%. IR ν_{max} (cm^{-1}): 2546 (B–H str). ^1H NMR δ (ppm): 7.2–6.8 (m, 10H, C_6H_5), 3.2 (s, 9H, NCH_3). ^{11}B–{^1H} NMR δ (ppm): −13.26 (3B), −16.55 (2B), −18.43 (2B, B9,11), −28.17 (1B), −35.30 (1B).

2.1.3. Syntheses of 1,8-Ph_2-2,2-(PMe_2Ph)$_2$-6,7-I_2-2,1,8-$PtC_2B_9H_7$ (**3**), 1,8-Ph_2-2,2-(PMe_2Ph)$_2$-6,12-I_2-2,1,8-$PtC_2B_9H_7$ (**4**) and 1,8-Ph_2-2,2-(PMe_2Ph)$_2$-10,12-I_2-2,1,8-$PtC_2B_9H_7$ (**5**)

Salt **2** (0.180 g; 0.30 mmol) was suspended in dry ether (30 ml) at 0 °C and ^{n}BuLi (0.24 ml of a 2.5 M solution in hexanes, 0.60 mmol) was added dropwise. The solution was stirred at room temperature for 18 h. All volatiles were removed and THF (30 ml) added. The THF solution of Li_2[7,8-Ph_2-9,11-I_2-7,8-*nido*-$C_2B_9H_7$] was added to a frozen suspension of *cis*-$PtCl_2(PMe_2Ph)_2$ (0.163 g, 0.30 mmol) in THF (25 ml) at −196 °C. The mixture was refrozen, then slowly warmed to room temperature and stirred for 18 h. All volatiles were removed in vacuo and CH_2Cl_2 (20 ml) added. The yellow suspension was filtered and evacuated to dryness to yield a yellow solid. The product was purified by TLC, eluting with 50/50 CH_2Cl_2/40–60 petroleum ether to give three yellow bands, respectively, compounds **3** ($R_f = 0.65$), **4** ($R_f = 0.56$) and **5** ($R_f = 0.45$).

3: yield 0.060 g (20%). *Anal.* Calc. for $C_{30}H_{39}B_9I_2P_2Pt$: C, 35.8; H, 3.91. Found: C, 34.9; H, 3.88%. 2.2. Crystallographic studies

Single crystals suitable for X-ray diffraction were grown by evaporation of a CH_2Cl_2 solution (salt **2**), from diffusion of a CH_2Cl_2 solution and 40–60 petroleum ether at −30 °C (compounds **3** and **5**) or from diffusion of a CH_2Cl_2 solution and diethylether at −30 °C (compound **4**). Salt **2** crystallises with $1\frac{1}{2}$ equivalents of CH_2Cl_2 and compound **4** with 1 equivalent of Et_2O. Data were collected at 100 K (cold N_2 gas) on a Bruker AXS *P*4 diffractometer producing graphite-monochromated Mo Kα radiation ($\lambda = 0.71069$ Å) using ω scans to $\theta_{max} = 25°$, and were corrected for absorption by psi scans. Structures were solved by direct and difference Fourier methods and refined [11] by full-matrix least-squares against F^2. Refinement was completed with all non-hydrogen atoms assigned anisotropic displacement parameters. For the anion of **2** H_{exo} atoms were refined subject to a restrained B–H distance of 1.10(2) Å, whilst the H_{endo} atom was freely refined. For **3**–**5** cage H atoms were allowed to ride on their bound boron with B–H constrained to 1.10 Å (1.12 Å for **3**). In all structures CH atoms were similarly constrained, with C–H = 0.95 (phenyl), 0.98 (CH_3) or 0.99 (CH_2) Å. H atoms except methyl H atoms were assigned displacement parameters set at 1.2 times that of the U_{eq} of their bound atom, with methyl H atoms assigned displacement parameters calculated as 1.5 times the bound carbon atom U_{eq}. H atoms were included in all molecules of solvation. For **3** the maximum and minimum residual e-density are significant but both are within 1 Å of Pt2 and thus chemically

meaningless. Table 1 contains details of the crystallographic studies.

3. Results and discussion

3.1. B-substituted carboranes

Electrophilic iodination of K[7,8-Ph_2-*nido*-7,8-$C_2B_9H_{10}$] with elemental I_2 proceeds smoothly in refluxing ethanol to generate, after metathesis with $HNMe_3Cl$, the new B-substituted nido diphenylcarboranes [$HNMe_3$][7,8-Ph_2-9-I-*nido*-7,8-$C_2B_9H_9$] (**1**) and [$HNMe_3$][7,8-Ph_2-9,11-I_2-7,8-*nido*-$C_2B_9H_8$] (**2**).

Use of one equivalent of I_2 affords a good yield of the monosubstituted 9-I species with <5% of the disubstituted 9,11-I_2 carborane also formed, as observed by ^{11}B spectroscopy. Addition of two equivalents of I_2 gives pure disubstituted compound, albeit in somewhat less good yield. Further substitution is not observed even with large excesses of I_2. The synthesis of salt **1** is analogous to that used by Hawthorne and Olsen to prepare the related species [NMe_4][9-I,-7,8-*nido*-$C_2B_9H_{11}$], although this early paper [12] does not report further substitution to the diiodo product. Both **1** and **2** are appreciably soluble in acetone and acetonitrile and sparingly soluble in halogenated solvents, but insoluble in 40/60 petroleum ether and toluene.

The compounds **1** and **2** were fully characterised by microanalysis, NMR and IR spectroscopies. In both cases the ^{1}H NMR spectra reveal signals due to cage phenyl and *N*-methyl hydrogen atoms in the correct relative integrals. ^{11}B NMR spectra are more informative. In the ^{11}B–{^{1}H} spectrum of **1** a 1:4:1:1:1:1 pattern, from high to low frequency, is observed, although the anticipated C_1 symmetry of the product requires the integral-4 signal to be a 1 + 1 + 1 + 1 coincidence. In the ^{11}B spectrum the uncoupled resonance due to the B atom bearing the iodine substituent is not obvious, and is presumed to lie within the envelope of these coincident signals. Compound **2** has a 3:2:2:1:1 pattern, its anticipated C_s symmetry requiring the highest frequency resonance to be a 2 + 1 coincidence. This time, however, the signal due to the two, symmetry equivalent, substituted B atoms is clear in the ^{11}B spectrum at δ −18.43.

Electrophilic attack on a nido carborane is expected to occur at the open face, but, to establish an unequivocal structure, a crystallographic determination of salt **2**, as its $1\frac{1}{2}CH_2Cl_2$ solvate, was undertaken.

Fig. 1 shows a perspective view of a single anion and Table 2 lists selected interatomic distances and interbond angles. The 9,11-disubstitution by iodine is confirmed. The endo H atom H10a is semi-bridging the B10–B11 edge, B10–H10a 1.17(5) Å, B11–H10a 1.56(5) Å, consistent with the optimised structure of [7,8-*nido*-$C_2B_9H_{12}$]$^-$ [13]. As anticipated [14], the (H-bridged) B10–B11 edge, 1.842(7) Å, is consequently somewhat longer that the unbridged but otherwise equivalent B9–B10 edge, 1.805(8) Å. The C7–C8 distance in **2** is 1.610(6) Å, almost identical to that in the unsubstituted analogue [7,8-Ph_2-7,8-*nido*-$C_2B_9H_{10}$]$^-$ (1.590(5) Å for the [$HNEt_3$]$^+$ salt and 1.602(3) Å in the [$C_6H_5CH_2NMe_3$]$^+$ salt) [15] and to that

in the substituted species $[C_6H_5CH_2NMe_3][5\text{-}I\text{-}7,8\text{-}Ph_2\text{-}7,8\text{-}nido\text{-}C_2B_9H_9]$ (1.609(10) Å) [7a]. In C-adjacent diphenylcarborane derivatives we conveniently describe the conformation of the Ph rings with respect to the cage by parameter θ_{Ph}, the modulus of the average C_{cage}–C_{cage}–C_{Ph}–C_{Ph} torsion angle [16]. The measured values in **2** are 10.0° for the ring on C7 and 8.0° for the ring on C8, these low values quantifying the clear conclusion from Fig. 1 that the Ph rings stand effectively perpendicular to the nido face of the carborane. The B–I bonds in **2** are 2.210(5) Å for B9–I9 and 2.195(5) Å for B11–I11, essentially the same as that in the anionic $[5\text{-}I\text{-}7,8\text{-}Ph_2\text{-}7,8\text{-}nido\text{-}C_2B_9H_9]^-$, 2.211 (7) Å [7a], but slightly longer than those in the neutral compounds $9,12\text{-}I_2\text{-}1,2\text{-}closo\text{-}C_2B_{10}H_{10}$, average 2.178(5) Å [17], $1,2\text{-}Ph_2\text{-}9,12\text{-}I_2\text{-}1,2\text{-}closo\text{-}C_2B_{10}H_8$, 2.175(5) Å [7a], $1,2\text{-}Ph_2\text{-}9\text{-}I\text{-}1,2\text{-}closo\text{-}C_2B_{10}H_9$, 2.178(4) Å [18], and $9,10\text{-}I_2\text{-}1,7\text{-}closo\text{-}C_2B_{10}H_{10}$, average 2.153(14) Å [19].

3.2. Platincarboranes

We have previously noted that, as is logical, metallation of asymmetrically-substituted carboranes leads to a greater number of isomerised products than does metallation of symmetrically-substituted species. Thus, we have chosen to platinate the 9,11-disubstituted carborane **2** to promote isomerisation and track its mechanism. Deprotonation of **2** was effected with ^{n}BuLi in diethyl ether to produce $Li_2[7,8\text{-}Ph_2\text{-}9,11\text{-}I_2\text{-}7,8\text{-}nido\text{-}C_2B_9H_7]$. Addition of a THF solution of this to a suspension of $cis\text{-}PtCl_2(PMe_2Ph)_2$ in the same solvent at −196 °C, followed by warming to room temperature and stirring for 18 h afforded a yellow solution. On work-up by TLC three products were isolated. The fastest moving band **3** transpired to be the major component, being approximately twice as abundant as each of the two slower bands **4** and **5**.

Compound **3** was initially characterised by microanalysis and IR and multinuclear NMR spectroscopy. As is typical of such compounds the ^{1}H NMR spectrum proved relatively uninformative in terms of detailed structural information, simply revealing signals consistent with the presence of phenyl and methyl H atoms with the correct relative integrals. ^{11}B–{^{1}H} NMR spectroscopy was also of limited use: although the chemical shift range observed, δ −4 to −24, indicates a closo species (more consistent with an isomerised $2,1,8\text{-}PtC_2B_9$ architecture that with a slipped $3,1,2\text{-}PtC_2B_9$ cage [7b,7d]), the relative broadness of the signals and the presence of significant signal overlap precludes definitive interpretation and, specifically, prevents identification of signals which remain uncoupled in the ^{11}B spectrum. The ^{31}P–{^{1}H} NMR spectrum reveals the presence of inequivalent phosphorus nuclei, each signal showing the expected ^{195}Pt satellites (average $^1J_{Pt-P} = 3256$ Hz). Careful analysis also reveals residual $^2J_{P-P}$ coupling, however the value is too small to quote accurately.

The structure of **3** was established by crystallographic study. Fig. 2 shows a perspective view of one molecule while Table 3 lists selected interatomic distances and interbond angles. The compound is thus revealed to be $1,8\text{-}Ph_2\text{-}2,2\text{-}(PMe_2Ph)_2\text{-}6,7\text{-}I_2\text{-}2,1,8\text{-}closo\text{-}PtC_2B_9H_7$, the cage having undergone a 1,2 → 1,7 C atom isomerisation (confirming the interpretation of the ^{11}B chemical shift range). The substituted (iodine-bearing) boron atoms are B6 and B7. The metal atom is bound to a CB_4 face which is folded into the usual envelope conformation (dihedral angle between B3C1B6 and B6B11B7B3 planes 14.0°) and, moreover,

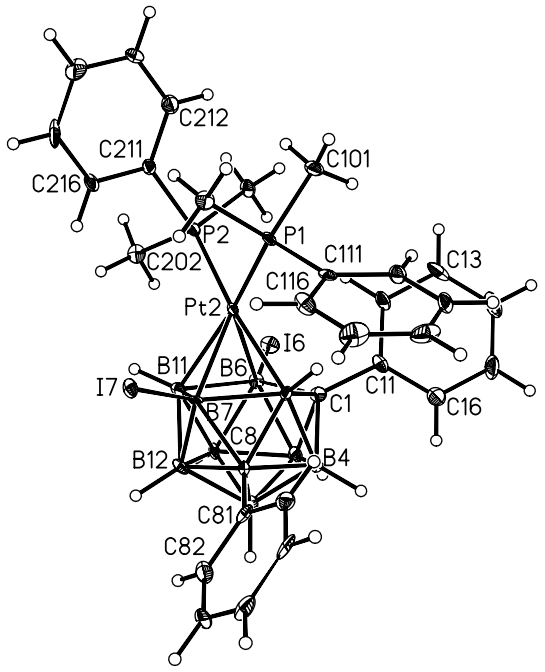

Fig. 2. Perspective view of 1,8-Ph_2-2,2-$(PMe_2Ph)_2$-6,7-I_2-2,1,8-*closo*-$PtC_2B_9H_7$ (**3**). Atoms are drawn as 50% probability ellipsoids except for H atoms.

the Pt atom is slipped away from C1 ($\Delta = 0.47$ Å) resulting in a long Pt2–C1 distance, 2.666(7) Å, emphasised by its non-inclusion in Fig. 2. The (electronic) reasons underlying these slipping and folding distortions are well documented [20] but we believe that in the present case the slipping is enhanced by a (steric) contribution arising from the orientation of the Ph ring on C1. The presence of an adjacent I atom, I6, requires the plane of this Ph ring to lie perpendicular to the metal-bonded CB_4 plane (a convenient measure of this is ζ, the modulus of the average Pt2–C1–C11–C torsion angles, $\zeta = 66.3°$) pushing back the $\{Pt(PMe_2Ph)_2\}$ fragment.

Compound **4** was similarly initially characterised by microanalysis and IR and multinuclear NMR spectroscopy, and ultimately by X-ray diffraction. The ^1H NMR spectrum was broadly similar to that of **3**, showing Ph and Me resonances with the correct relative integrals. The ^{11}B–$\{^1H\}$ NMR spectrum again revealed resonances between δ −4 and −24, indicative of a 2,1,8-*closo*-PtC_2B_9 cage. Once more the resonance(s) due to B–I could not clearly be discerned in the corresponding ^{11}B spectrum. In the ^{31}P–$\{^1H\}$ spectrum once more were two signals, each with Pt satellites (average $^1J_{Pt-Pt} = 3262$ Hz) and showing small residual J_{P-P} coupling.

The crystallographic study of **4** (Fig. 3 and Table 3) reveals a very similar molecular structure to that established for **3** except that the second substituted B atom is now B12 as opposed to B7. Thus, compound **4** is 1,8-Ph_2-2,2-$(PMe_2Ph)_2$-6,12-I_2-2,1,8-*closo*-$PtC_2B_9H_7$. The PtC_2B_9 cage of **4** resembles that of **3** in many respects: the Pt-bonded CB_4 face is envelope-folded by 15.6°, and

the Ph group on C1 subtends a high ζ angle, 84.8°, thus extending the slip distortion of the $\{Pt(PMe_2Ph)_2\}$ fragment to $\Delta = 0.48$ Å, Pt2–C1 = 2.666(7) Å.

The final product of the metallation, compound **5**, moves slowest on the TLC plate. ^1H NMR spectroscopy revealed the expected phenyl and methyl resonances and the ^{11}B–$\{^1H\}$ NMR spectrum showed only four peaks, δ −6 to −32, presumably reflecting significant coincidences. Once more, it was not possible to assign those resonance(s) due to the substituted B atoms. Asymmetrically disposed phosphorus atoms were again evident from the observation of two signals (with attendant Pt satellites) in the ^{31}P–$\{^1H\}$ NMR spectrum, the average $^1J_{Pt-P}$ being 3319 Hz.

The result of a crystallographic study of compound **5** is shown in Fig. 4, and Table 3 again lists key molecular parameters. This time *both* substituted B atoms (B10

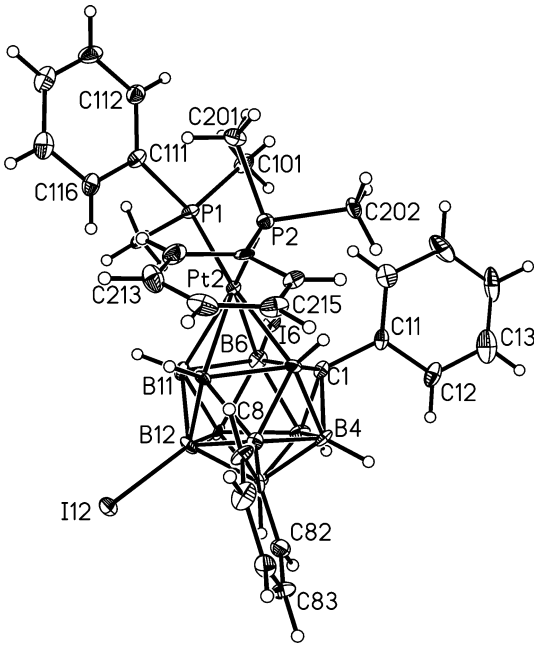

Fig. 3. Perspective view of 1,8-Ph_2-2,2-$(PMe_2Ph)_2$-6,12-I_2-2,1,8-*closo*-$PtC_2B_9H_7$ (**4**). Atoms are drawn as 50% probability ellipsoids except for H atoms.

and B12) are in the lower half of the molecule, which is thus identified as 1,8-Ph_2-2,2-$(PMe_2Ph)_2$-10,12-I_2-2,1,8-*closo*-$PtC_2B_9H_7$. Although the upper CB_4 face is still envelope-folded, this time by 15.6°, the non-adjacency of a substituted B atom to C1 means that the Ph ring on this

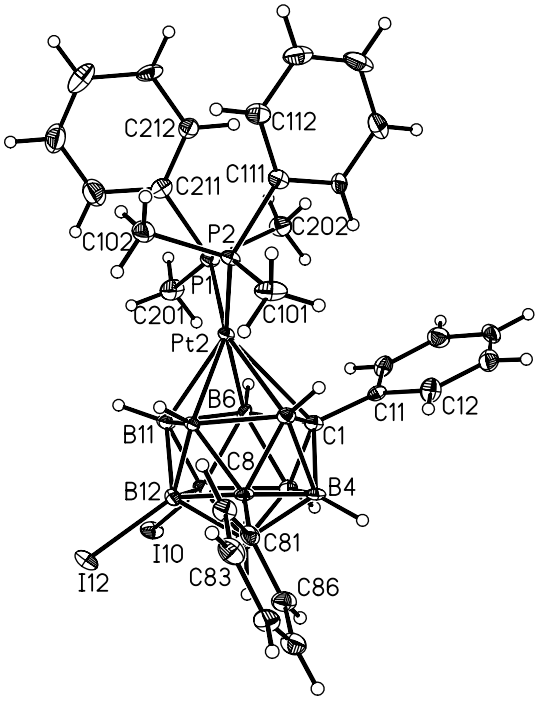

Fig. 4. Perspective view of 1,8-Ph_2-2,2-$(PMe_2Ph)_2$-10,12-I_2-2,1,8-*closo*-$PtC_2B_9H_7$ (**5**). Atoms are drawn as 50% probability ellipsoids except for H atoms.

last atom can adopt an orientation which simply minimises steric repulsion between it and the phosphine ligands. Thus, ζ is only 10.9°, as a result of which both the slip parameter Δ, 0.36 Å, and the Pt2–C1 distance, 2.609(5) Å, are reduced in **5** relative to equivalent values in **3** and **4**.

In compounds **3**–**5** collectively, the six B–I distances span the range 2.165(6)–2.231(8) Å. The two B6–I6 distances (compounds **3** and **4**) are the two longest, but it is not obvious why this should be. Certainly the four distances measured here to B7, B10 and B12, 2.169(6)–2.181(6) Å, correspond well with those, 2.169(9)–2.204(12) Å, previously found in 1,8-Ph_2-2,2-$(PMe_2Ph)_2$-X-I-2,1,8-*closo*-$PtC_2B_9H_8$, X = 7, 10, 12 [7d].

3.3. Possible mechanistic implications

In several recent contributions [7] we have interpreted the results of both 1,2 → 1,2 and 1,2 → 1,7 C atom isomerisations in B-substituted nickel- and platinacarboranes in terms of either one or two triangle face rotations (tfrs), starting from a crowded, transient, 3,1,2-MC_2B_9 species (in one case [7b] this intermediate was actually isolated).

In Scheme 1 we show how the formation of the platinacarboranes **3** could also be explained by a tfr. In Step 1 the overcrowded, transient species **I** is formed by simple complexation of the metal fragment and carborane ligand. To relieve this overcrowding, a CB_2 face in **I** undergoes a tfr (Step 2) affording the major product **3**. (note that since **I** has C_s symmetry either one of two equivalent CB_2 faces could rotate).

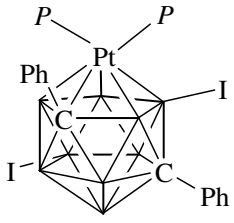
The formations of the minor products **4** and **5** cannot be so simply rationalised, but two factors appear relevant here. Firstly, we are fully confident that isomerisation only occurs following metallation since ^{n}BuLi deprotonation of **2** as described in Section 2.1.3 followed by reprotonation on addition of aqueous $HNMe_3Cl$ regenerates only **2** as shown by ^{11}B NMR spectroscopy. Secondly, it is likely that **3**–**5** are formed via parallel rather than sequential isomerisation steps given the mild conditions under which they are prepared and our subsequent inability to convert from one to another by heating (either nothing happens or we observe substantial decomposition).

We thus suggest Step 2′, as an alternative to Step 2, in which one of two possible B_3 triangle faces in **I** rotates to position one iodine substituent antipodal to a cage C atom, synchronous with, or followed immediately by, a CB_2 tfr analogous to that in Step 2, this overall process generating product **4**. Moreover, Step 2″, with both iodine substituents moving antipodal to cage C atoms, synchronous with or followed by CB_2 tfr, affords product **5**.

We acknowledge that above mechanism is highly speculative, and that it raises several issues. Firstly, we have previously [7d] considered rotation of a CB_2 face involving two B vertices from the lower pentagon (shown in Step 2) as less likely than one involving one upper and one lower B atom. Secondly, with regard to Step 2′, one could equally

reasonably anticipate the combination of one of the tfrs shown with the symmetry-equivalent of the other, affording a further product 1,8-Ph_2-2,2-$(PMe_2Ph)_2$-7,10-I_2-2,1,8-*closo*-$PtC_2B_9H_7$ (**II**) but this has not yet been identified.

Clearly a number of questions about the mechanism(s) of isomerisation that afford(s) compounds **3**–**5** remain, and studies designed to answer these are in hand. This is entirely consistent with the approach to chemical crystallography that Michael Hursthouse instilled in one of us as a postgraduate student – that molecular structure determination by crystallography should not be regarded simply as the end of one chemical investigation but, equally, based upon what that structure may mean in terms of chemical bonding or chemical reactivity, the beginning of another.



II

4. Supplementary material

Crystallographic data for the structure analyses have been deposited with the Cambridge Crystallographic Data Centre, CCDC Nos. 281522–281525 for **2**–**5**, respectively. Copies of this information may be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge CB2 1EZ, UK (fax: +44 1223 336 033; e-mail deposit@ccdc.cam.ac.uk or www: http://www.ccdc.cam.ac.uk).

2.2. Crystal structure determination of $Ti(NMe_2)_4$

The capillary containing the sample was mounted onto a Stoe Stadi-4 four-circle diffractometer equipped with an Oxford Cryosystems low-temperature device [8]. After initial cooling to just below the melting point (263 K), the temperature was slowly raised until a single crystallite remained. The sample was then cooled leading to formation of a single crystal. Data were then collected at 105 K in $\omega - 2\theta$ mode to $2\theta = 60°$ using on-line profile-fitting [9]. The structure was solved by direct methods [10] and refined by full-matrix least-squares against $|F|^2$ [11]. H-atoms were located in a difference synthesis, and they were treated as freely rotating rigid groups with $r(\text{C–H}) = 0.98$ Å and $U_{iso}(\text{H}) = 1.5U_{eq}(\text{C})$. All non-H atoms were refined with anisotropic displacement parameters. The final conventional R factor [calculated using $|F|$ and 2980 data with $|F| > 4\sigma(|F|)$] was 0.0446; further data collection and refinement data are collected in Table 1. Bond distances and angles are given in Table 2, and torsion angles are listed in Table 3.

2.3. Structure analysis and visualisation software

Crystal structures were visualised using the programs CAMERON, DIAMOND, MERCURY and XP [12–15]. Analyses were carried out using PLATON, as incorporated in the WIN-GX suite [16,17]. Searches of the Cambridge Database were performed with the program CONQUEST and version 5.26 of the database with updates up to November 2004 [18,19].

2.4. Ab initio calculations

Calculations were carried-out to rationalise the change from a highly symmetric molecule in the gas phase (S_4 symmetry) to a less symmetric molecule in the solid state (C_1 symmetry). Geometry and frequency optimisations were performed using density functional theory (DFT)

Table 3

calculations (PW91PW91/6-311G*) starting from the geometry of the S_4 conformer determined in the gas phase. Calculations were also undertaken at the MP2 level of theory employing a basis of better than double-ζ plus polarisation quality; this comprised the standard 6-311+G* basis for Ti, the 6-31+G* basis for N and the 6-31G* basis set for C and H. The molecular geometry observed in the crystal structure (C_1 symmetry) was also optimised at the same level of theory as the DFT calculations on the S_4 conformer. All calculations were performed using the GAUSSIAN-94 or 03 program suites [20,21].

3. Results and discussion

3.1. The structure of $Ti(NMe_2)_4$ in the solid state

The crystal structure of $Ti(NMe_2)_4$ consists of monomeric $Ti(NMe_2)_4$ molecules in which the metal has approximately tetrahedral coordination (Fig. 1). The Ti–N bond distance in $Ti(NMe_2)_4$ obtained in the gas phase by electron diffraction is 1.917(3) Å [5]. In the solid state the individual Ti–N distances show some variation (Table 2): the bonds to N2, 3 and 4 span 1.897(2) to 1.908(2) Å, while Ti1–N1 measures 1.924(2) Å. At the low temperature of this data collection (105 K) the librational correction to the Ti–N distances is only 0.002 Å [15], and three of the Ti–N distances are thus significantly shortened relative to the gas phase. These are also substantially shorter than

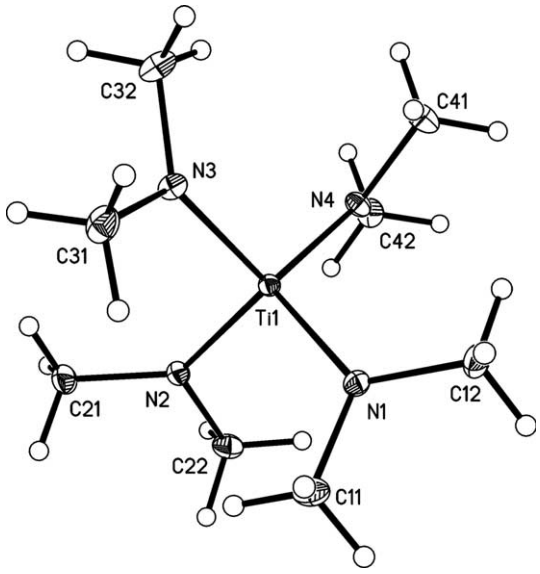

Fig. 1. The structure of $Ti(NMe_2)_4$ in the solid state. Ellipsoids enclose 30% probability surfaces, H-atoms are drawn as circles of arbitrary radius.

the Ti–N distances of 2.230(1) and 2.095(1) Å found in $Ti(ONMe_2)_4$ [22].

In the gas-phase $Ti(NMe_2)_4$ was modelled as having S_4 symmetry with two N–Ti–N angles of 114.2(17)° and four of 107.2(9)°. The distortion away from ideal tetrahedral angles has been rationalised in terms of the ligand-close-packing model by Gillespie and co-workers [23]. The structure in the solid state is reduced from S_4 symmetry to C_1 [16]. The N–Ti–N angles are less regular and span a narrower range [105.89(9)–111.89(8)°] in the solid than in the gas.

During refinement against the gas-phase electron-diffraction data the Ti–N–C angles were all constrained to be equal [124.3(3)°]. In the solid there is a significant variation in the Ti–N–C bond angles for the dimethylamido groups containing N2, N3, and N4, with one small Ti–N–C angle [116.88(15)–121.42(15)°] and one large [127.06(15)–131.29(15)°]. Since all four N–C–N angles are essentially identical [range: 111.07(18)–111.81(19)°], this corresponds to a distortion in three of the TiNC2 planes such that there is a tilting of one of the carbons towards the titanium. The larger Ti–N–C angles are all made within fragments of small N–Ti–N–C torsion angles, for example, N3–Ti1–N2–C21 is −1.7(2)°, whereas the smallest torsion angle involving C22 is 60.98(17)° (N4–Ti1–N2–C22). It seems likely that the asymmetry in the Ti–N–C angles is simply the result of ligand repulsion. Similar effects are observed in the structure of $(NMe_2)_3Zr(\mu\text{-}NMe_2)_2\text{-}Zr(NMe_2)_3$, in which the methyl groups associated with the terminal amino ligands bend away from the methyl groups associated with the bridging NMe_2 groups [6]. The Ti–N–C angles in the amino group based on N1 are more symmetrical, but here the smallest torsions involving C12 and C22 are −35.51(18)° and 28.13(19)°. In the gas phase the magnitudes of the smallest N–Ti–N–C angles

are 10.5 and 67.5 at each amido group [5], and so a similar asymmetry would be expected; the results of our ab initio calculations lend some support to this (see below).

Torsion angles are 'softer' parameters than primary bond distances and angles, and it would be anticipated that the largest differences between the solid and gas-phase structures would occur in the N–Ti–N–C angles. A superposition of the structures in the two phases is shown in Fig. 2; equivalent torsion angles are compared in Table 3. The largest differences are found at the amido group based on N3.

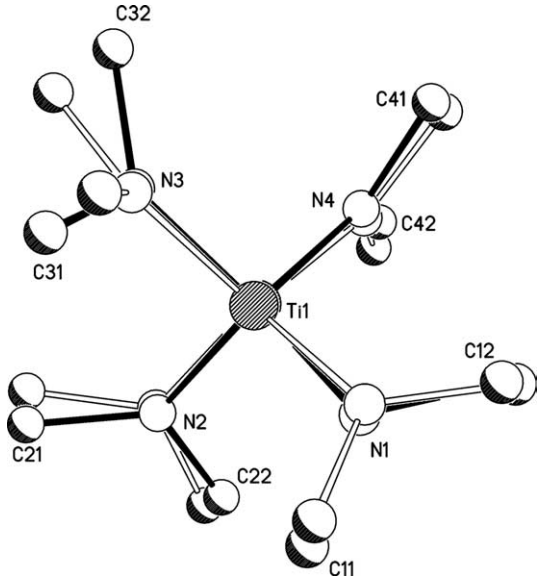

Fig. 2. Superposition of the gas phase and solid phase structures of $Ti(NMe_2)_4$. The gas-phase structure is drawn with open bonds. H-atoms have been omitted for clarity.

3.2. Intermolecular interactions

The differences between the intramolecular geometric parameters in the gas phase and crystal structures must be ascribable to crystal packing forces. There are, however, no intermolecular interactions falling within the sums of the van der Waals radii of the relevant atoms [24]. The shortest intermolecular distances comprise three contacts, each formed across inversion centres, in which Ti...Ti distances are 6.074, 6.227 and 6.650 Å (Fig. 3). These interactions form a net which is formed parallel to the (1 0 0) planes in the crystal. Successive planes are formed by lattice-repeats along [100], with Ti...Ti distances in the range 8.27–9.56 Å.

Crystal structures of essentially non-interacting, isometric molecules frequently show the same topologies as the familiar hard-sphere packings [cubic or hexagonal close-packed, or body-centred cubic (BCC)], pseudo-BCC being the most common [25]. Analysis of the Voronoi–Dirichlet polyhedron constructed on the basis of the distribution of the molecular centroids in $Ti(NMe_2)_4$ shows that each molecule is in contact with 14 others in the first coordination shell. Overall, the coordination sequence (i.e., the number of molecules in the first, second and third coordination spheres) is 14-52-114, comparing to 14-50-110 for BCC topology [26].

We have seen that optimised superposition of the gas phase and crystal molecular structures showed that while the conformations of the amido groups based on N1, N2

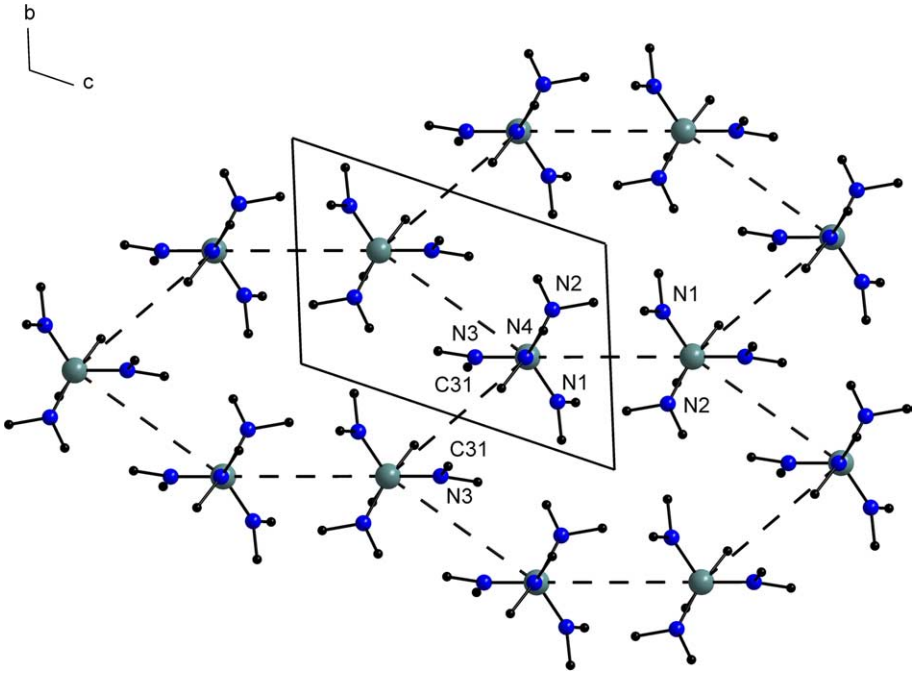

Fig. 3. Packing in the crystal structure of $Ti(NMe_2)_4$. Ti...Ti distances falling between 6 and 7 Å are shown as dashed lines. H-atoms are omitted for clarity.

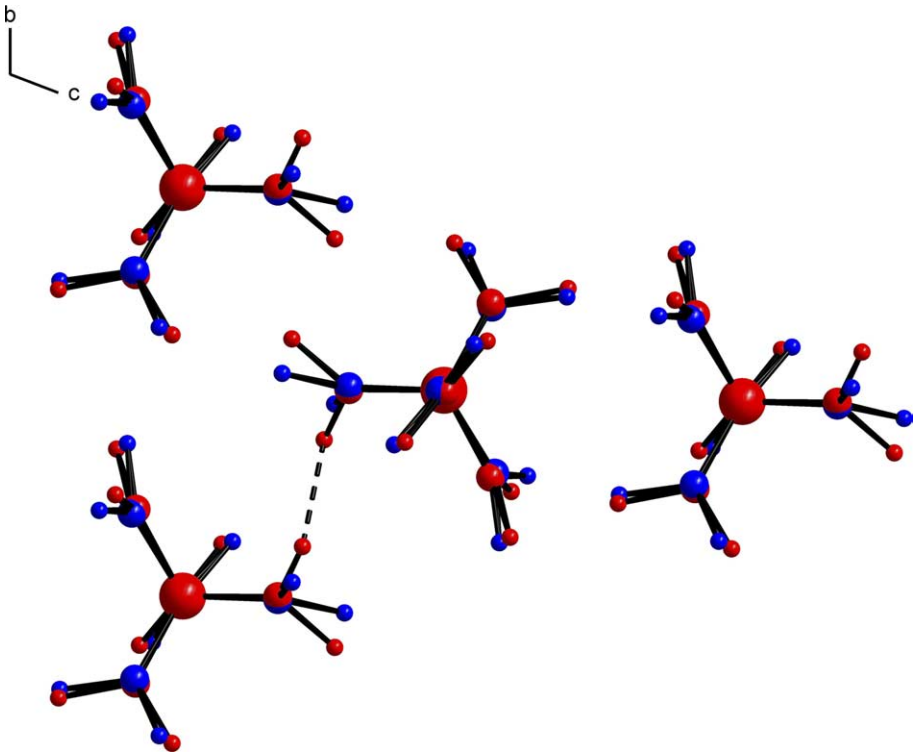

Fig. 4. Superposition of the observed crystal structure (blue) with a model structure in which the molecules have their S_4 gas-phase geometry (red). The short methyl–methyl contact referred to in the text is shown as a dashed line. (For interpretation of the references to colour in this figure legend, the reader is referred to the web version of this article.)

and N4 were similar in both phases, that of the group based on N3 was different. Fig. 3 shows that the amido groups based on N1, N2 and N4 approach one another in the crystal structure across the shortest of the Ti...Ti vectors in the (1 0 0) planes. The Ti–N bonds across this interaction are staggered with respect to each other in order to minimise repulsions between methyl groups. The shortest C···C distances formed between this pair of molecules is 3.700 Å. When the gas-phase S_4-symmetry model of $Ti(NMe_2)_4$ is positioned into the crystal structure (Fig. 4) it is clear that minimal torsional rearrangement about Ti1–N1,2 or 4 is necessary to accommodate this interaction, even though this is the closest intermolecular centroid–centroid distance in the structure.

By contrast, had the gas-phase structure been retained in the solid, the methyl group at C31 would have formed a contact across an inversion to a symmetry-equivalent methyl group measuring only 2.28 Å (Fig. 4). The twisting of the amido group based on N3 in the crystal away from its gas-phase orientation can therefore be ascribed to the avoidance of methyl–methyl close contacts; the equivalent C31···C31 contact in the crystal structure measures 3.790 Å.

3.3. Ab initio calculations

The geometry of the S_4 conformer, as observed by gas-phase electron diffraction, was optimised using MP2 and DFT methods, and the theoretical and experimental results are listed in Table 4. There is very little difference between the results of the two levels of theory. Values of bond lengths are in excellent agreement with those obtained by electron diffraction. Bond angles about the metal were calculated to be close to tetrahedral values, N–Ti–N = 109.6° or 109.4°, but were found to deviate further from tetrahedral in the GED study [N–Ti–N = 114.2(17)° or 107.2(9)°]. In the electron-diffraction refinement [5] all Ti–N–C angles were constrained to be equal, and the refined value of this parameter was 124.3(3)°. Our calculations of

C–N–C	112.0	112.6	111.4
Mean N–C–H	111.1	111.4	109.3(7)
C–N–Ti–N	45.8	43.3	51(1)

Bond distances are in Å, bond angles and torsions are in °.

Ti–N–C bond angles yield an average value of 124.0° (MP2) or 123.7° (DFT), in agreement with the experiment, though the $-NMe_2$ groups are predicted to deviate noticeably from C_2 symmetry leading to Ti–N–C bond angles of 118.6° and 128.7°. The C–N–Ti–N torsion angle is calculated to be 45.8° (MP2) or 43.3° (DFT), in fair agreement with the experimental value of 51(1)°.

Examination of the predicted vibrational frequencies of Ti(NMe2)4 revealed the presence of many frequencies below 200 cm^{-1}, indicating that large amplitude motion would be expected to be present in the gas phase at ambient temperature. In particular, the four torsional motions associated with the twisting of the –NMe2 groups are predicted to lie in the region of 40–60 cm^{-1} implying that only a relatively small amount of energy is required to twist these groups from the equilibrium structure found in the gas phase to that observed in the solid phase.

The geometry of the C_1 conformer of $Ti(NMe_2)_4$ was optimised by DFT methods, starting from the structure observed in the solid state. A comparison of the calculated parameters of the C_1 conformer with those of the crystal structure showed that they were in fair agreement (Tables 2 and 3). Though the range of Ti–N bond distances is larger in the crystal structure [1.897(2)–1.924(2) Å] than in the optimised calculated structure (1.920–1.930), the shortest and longest distances are formed to the same N-atoms is each case.

The vibrational frequencies for this conformer were all real, indicating that the structure corresponds to an energy minimum, with the S_4 conformer lying only 0.2 kJ mol^{-1} lower in energy. The small energy difference between the two conformations indicates that a transition from S_4 to C_1 symmetry would be extremely facile in the gas phase. Furthermore, it suggests that distortion of the gas-phase molecular symmetry on crystallisation would only carry a minor energy penalty in terms of the intramolecular energy. This penalty would be easily overcome by alleviation of the possible intermolecular repulsion depicted in Fig. 4.

resulted in the formation of white $[SnF_4L_2]$ complexes in high yield. The solids are moisture sensitive, tenaciously retain organic solvents – clearly evident in the ^1H NMR spectra, and are only modestly soluble in chlorocarbons. Solubility is not significantly better in acetone or nitromethane and stronger donor solvents were generally avoided for spectroscopic studies since they can lead to some displacement of the neutral ligands. The complexes could be recrystallised from a large volume of anhydrous CH_2Cl_2. The complexes with Ph_3PO, Ph_3AsO and Me_3PO were briefly reported in larger compilations of their metal complexes many years ago [4–6] but characterisation was limited to microanalysis and partial IR spectra. Our IR spectra (Table 1) are generally in good agreement with those reported; where differences occur they are probably attributable to various amounts of *cis* and *trans* isomers present in the samples resulting from differences in the isolation procedures and/or solvents used [18]. Three diphosphine dioxide complexes, $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]$, $[SnF_4\{o\text{-}C_6H_4(P(O)Me_2)_2\}]$ and $[SnF_4\{Ph_2P(O)\text{-}CH_2P(O)Ph_2\}]$ were made similarly.

The multinuclear NMR data (Tables 1 and 2) show the presence of both *cis* and *trans* isomers in CH_2Cl_2 solution for the R_3PO and R_3AsO complexes, the approximate isomer ratios being determined from the $^{19}F\{^1H\}$ NMR spectra. For $[SnF_4(Ph_3PO)_2]$ the two isomers have similar abundance but for the other three the *trans* isomer predominates. Although resonances were observed at ambient temperatures in the ^1H, ^{31}P and ^{19}F spectra, the ^{119}Sn spectra showed broad and poorly resolved features and the samples were cooled to 273 K to improve resolution. The $^{31}P\{^1H\}$ NMR spectra show singlet resonances for each isomer with very similar chemical shifts, and no resolved coupling to ^{19}F, but with weak $^{119/117}Sn$ satellites. The $^2J(^{119/117}Sn–^{31}P)$ which lie in the range 20–65 Hz, appeared as single lines rather than as separate features for the two tin isotopes – no doubt the differences were lost in the line width, since from the magnetogyric ratios $\gamma^{119}Sn/\gamma^{117}Sn$ (1.046) the values are expected to differ by <2 Hz. The $^{19}F\{^1H\}$ spectra show singlet resonances for the *trans* isomers and two triplets for the *cis* (Table 2), with $\delta(^{19}F)$ in the range −135 to −170, and with $^1J(^{119}Sn–^{19}F)$ 1700–1950 Hz, similar to the values in substituted fluorostannates(IV) [3]. In these cases, the $^1J(^{117}Sn–^{19}F)$ satellites were also clearly resolved and although not quoted in Table 2, the magnitudes were consistent with expectation based upon $\gamma^{119}Sn/\gamma^{117}Sn$. Obtaining good quality ^{119}Sn NMR spectra proved difficult due to the modest receptivity of the tin ($D_c = 25$), poor solubilities, the presence of both isomers and also the complexity of the coupling patterns. For example, for $[SnF_4(Me_3PO)_2]$ the symmetrical quintet of triplets of the *trans* isomer was clearly evident centred at δ −781.8 Underlying this resonance is another weaker and more complex pattern centred at δ −769.0 attributed to the *cis* isomer. Based upon the various coupling constants obtained from the $^{19}F\{^1H\}$ and $^{31}P\{^1H\}$ spectra the major lines of the expected 27 line multiplet (t,t,t) were identified. The solubility of $[SnF_4(Ph_3PO)_2]$ is lower, but again two multiplets can be discerned consistent with approximately equal amounts of the two geometric isomers, although in this case the spectral quality was poor. For the $[SnF_4(R_3AsO)_2]$ complexes, the quintet due to the *trans* isomer was clearly identified in each case, but the resonance (t,t) of the less abundant *cis* form appeared near coincident and hence the chemical shift assignment less clear, although the more intense lines of the multiplets were found.

The diphosphine dioxide complexes $[SnF_4(L–L)]$ ($L–L = Ph_2P(O)CH_2P(O)Ph_2$, $o\text{-}C_6H_4(P(O)Ph_2)_2$) are, as expected, *cis* isomers showing (Table 2) two triplets in the $^{19}F\{H\}$ NMR spectra and singlets in the $^{31}P\{^1H\}$ spectra. At temperatures a little above ambient the resonances in the $^{19}F\{H\}$ NMR spectra broaden, presumably due to some dynamic process, probably chelate ring opening. On cooling the solutions the complexes precipitate which prevented low temperature studies. The $[SnF_4\{o\text{-}C_6H_4(P(O)Me_2)_2\}]$ was insoluble in chlorinated solvents, but dissolved with some decomposition (diphosphine dioxide displacement) in anhydrous *N*,*N*-dimethylformamide The $^{19}F\{H\}$ and $^{31}P\{^1H\}$ NMR spectra of the complex are given in Table 2, but the poor solubility and partial decomposition prevented a ^{119}Sn spectrum from being obtained.

2.2. Structures of *trans*-$[SnF_4(Me_3PO)_2]$, $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]$ and $[o\text{-}C_6H_4(P(O)Ph_2)_2]$

Colourless crystals of $[SnF_4(Me_3PO)_2]$ were grown from a sample containing both isomers by vapour phase diffusion of hexane into a CH_2Cl_2 solution. These proved on structure solution to be the *trans* isomer (Table 3 and Fig. 1). The molecule is centrosymmetric with Sn–F = 1.937(2), 1.954(2) Å, not significantly different from the values in *cis*-$[SnF_4(2,2'\text{-bipy})]$ 1.924(3)–1.948(3) Å [1]. Comparison of *d*(P–O) in the complex (1.532(3) Å) with that in Me_3PO (1.489(6) Å) [19] shows the bond is significantly lengthened upon coordination.

The crystal structures of (*cis*) $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]$ (Table 4, Fig. 2) and of the parent ligand, $o\text{-}C_6H_4(P(O)Ph_2)_2$ (Table 5, Fig. 3) have also been determined and the key bond lengths may be compared similarly. The *d*(Sn–F) are very similar to those in $[SnF_4(Me_3PO)_2]$, and essentially independent of the nature of the *trans* ligand. The *d*(Sn–O) at 2.088(5) and 2.071(5) Å are rather longer than in the Me_3PO complex which probably reflects the effect of the seven-membered chelate ring. As found for

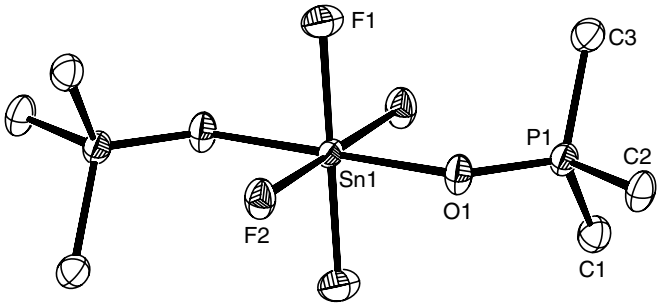

Fig. 1. Structure of *trans*-$[SnF_4(Me_3PO)_2]$ showing the atom numbering scheme. Atomic displacement ellipsoids are drawn at the 50% probability level and H atoms omitted for clarity. There is a centre of symmetry at the Sn1 atom.

the Me_3PO case, coordination of the diphosphine dioxide to the SnF_4 results in a significant lengthening of the P–O bond, from 1.484(2), 1.485(2) in the "free" ligand to 1.512(5), 1.525(5) Å in the complex. A few poor quality crystals were also obtained from a solution of $[SnF_4\{o\text{-}C_6H_4(PMe_2)_2\}]$ in CH_2Cl_2 after several weeks. X-ray examination of these established them as the compound $[SnClF_3\{o\text{-}C_6H_4(P(O)Me_2)_2\}]$ containing a chelating diphosphine dioxide. The origin of the chlorine atom is presumably from reaction with the solvent and the oxygen in the phosphine oxide from aerial oxidation.[1]

Most interesting is the comparison with data on other tin(IV) phosphine oxides. Tudela [18] noted that in *cis*- and *trans*-$[SnBr_4(Ph_3PO)_2]$ the Sn–O (2.080(8), 2.101(9) Å) and P–O (1.515(8), 1.516(9)(av) Å) distances were the same within the usual criteria showing that the geometric isomer present has no effect, as might be expected for hard donor–acceptor interactions on a p-block metal. However, when one compares the key distances along the series $[SnX_4(R_3PO)_2]$ (Table 6) one finds that Sn–O increases with X F < Cl < Br < I. The substantially shorter Sn–O distance in the tin(IV) fluoride is clearly consistent with stronger binding of the ligand indicative of stronger Lewis acidity of the SnF_4. Moreover, studies of phosphine oxide complexes of hard early transition metals such as Y(III) or Sc(III) have shown that the metal–oxygen distances are independent of the R group (Me or Ph), although they do vary with the metal coordination number [20,21]. From Table 6 it is also notable that the P–O distance in the fluoride complex is markedly longer than in the other examples, (albeit some of the comparator data are not of high precision) which also supports stronger donation from O → Sn. The trends are replicated in $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]$ where the data in Table 4 can be compared with the structural data on $[SnI_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]$ [13] (Table 6). In the iodo-complex the *d*(Sn–O) are much longer, consistent with the relative Lewis acidity of the tin centres.

2.3. $[SnX_4L_2]$ X = Cl, Br or I; L = Ph_3PO, Ph_3AsO or Me_3PO – some comparisons

These complexes have been studied on several occasions and structures have been reported for *cis*-$[SnX_4(Ph_3PO)_2]$ (X = Cl or Br) [18,23,25] and *trans*-$[SnBr_4(Ph_3PO)_2]$ [22,24]. The IR spectra have been discussed in detail [5,6,26] and our data are generally in agreement with the literature and hence not discussed further. Curiously, little NMR data have been reported previously and complete data are presented in Table 7. As can be seen, whilst both isomers are present in CH_2Cl_2 solutions of the chloro-complexes, only one isomer was present for the iodo-complexes, and only small amounts or essentially none of the second form

[1] Crystal data for $[SnClF_3\{o\text{-}C_6H_4(P(O)Me_2)_2\}] \cdot 1/2CH_2Cl_2$: $M_w = 483.77$; orthorhombic, space group *Pbcn* (no. 60), $Z = 8$, $T = 120$ K, $a = 15.290(5)°$, $b = 17.266(6)°$, $c = 13.380(3)$ Å, $V = 3532.3(19)$ Å^3; 3772 unique data gave $R_1 = 0.095$, $wR_2 = 0.173(I > 2\sigma(I))$ based on 186 independent parameters with $S = 0.95$.

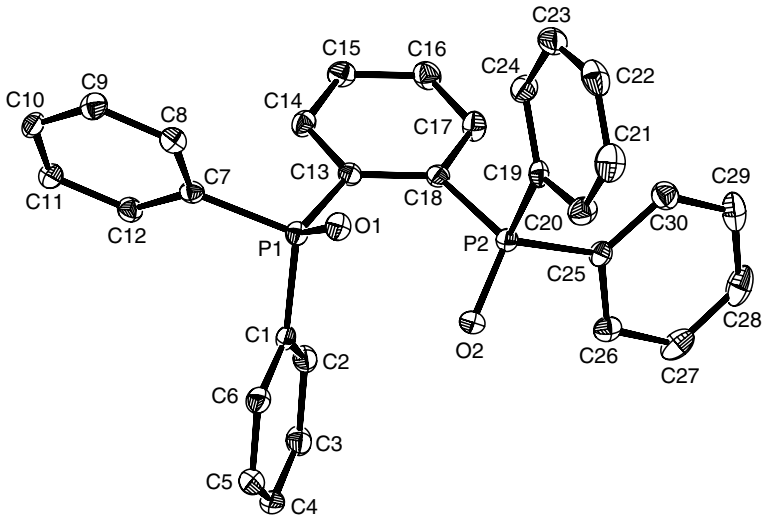

Fig. 3. Structure of $[o\text{-}C_6H_4(P(O)Ph_2)_2]\cdot CH_2Cl_2$ showing the atom numbering scheme. Atomic displacement ellipsoids are drawn at the 50% probability level and H atoms omitted for clarity.

in the bromo-complexes. The complexes are labile in solution and cooling the samples is necessary to observe sharp resonances and resolve couplings; the temperatures at which the presented data were obtained are given in Table 7. The trends in the spectroscopic data were also examined to see if support for the greater Lewis acidity of the SnF_4 was forthcoming. The IR data, specifically the *ν*(PO), are not useful due to the broadness of the bands and the presence of overlapping bands of the geometric isomers, but even if this were not the case, coupling with other vibrations would complicate any comparisons. The $^{31}P\{^1H\}$ NMR data are more useful (Tables 2 and 7). The chemical shift differences between the geometric isomers are small and therefore one can compare directly the changes in chemical shift simply as a function of the halide present. This shows a small but clear shift to high frequency along the series F > Cl > Br > I consistent with decreased acceptor power along this series and in agreement with the conclusions from the X-ray data above. The ^{119}Sn NMR data are not useful in this respect since the chemical shifts reflect a number of competing factors including electronegativity of the substituents, mutual ligand interactions and ligand polarisabilities [7,29]. The shift to low frequency $[SnCl_4(R_3EO)_2] > [SnF_4(R_3EO)_2] > [SnBr_4(R_3EO)_2]$ parallels that in the hexahalostannates(IV) [27–29]. Tin-119 resonances are rarely observed for iodotin species mainly due to exchange reactions in solution resulting from the weak Lewis acidity of SnI_4. The data show that SnF_4 is the strongest Lewis acid in the series SnX_4 (X = F, Cl, Br, I) towards hard bases.

3. Experimental

All compounds were made under a dinitrogen atmosphere using dry solvents and standard Schlenk and glove box techniques. SnF_2, $SnCl_4$, $SnBr_4$ and SnI_4 were obtained from Aldrich and used as received. $[SnF_4(MeCN)_2]$ and $[SnF_4(THF)_2]$ were made as described [17]. Ligands were obtained from Aldrich (Me_3PO, Ph_3PO, Ph_3AsO) and were dried by heating in vacuo before use. Other ligands were made by literature methods: $o\text{-}C_6H_4(P(O)Ph_2)_2$, $o\text{-}C_6H_4(P(O)Me_2)_2$, Me_3AsO, $Ph_2P(O)CH_2P(O)Ph_2$ [13,30,31]. IR spectra were recorded as Nujol mulls on a Perkin Elmer PE 983G spectrometer, ^1H NMR spectra in $CDCl_3$ solutions on a Bruker AV300, $^{31}P\{^1H\}$, $^{19}F\{^1H\}$ and ^{119}Sn NMR spectra on a Bruker DPX400 and referenced to 85% H_3PO_4, $CFCl_3$ and neat $SnMe_4$, respectively. Microanalytical measurements were performed by the microanalytical service, Strathclyde University.

3.1. $[SnF_4(Ph_3PO)_2]$

$[SnF_4(MeCN)_2]$ (0.277 g, 1.0 mmol) was suspended in CH_2Cl_2 (20 mL) and Ph_3PO (0.612 g, 2.2 mmol) added

and the mixture stirred at room temperature for 2 h. The white solid was filtered off, recrystallised from hot CH_2Cl_2 and dried in vacuo. Yield: 0.66 g, 88%. *Anal*. Calc. for $C_{36}H_{30}F_4O_2P_2Sn \cdot 3CH_2Cl_2$: C, 46.6; H, 3.6. Found: C, 47.1; H, 3.7%.

3.2. $[SnF_4(Ph_3AsO)_2]$

Prepared similarly from $[SnF_4(MeCN)_2]$ (0.156 g, 0.56 mmol) and Ph_3AsO (0.40 g, 1.24 mmol). Yield: 0.30 g, 64%. *Anal*. Calc. for $C_{36}H_{30}As_2F_4O_2Sn \cdot 2CH_2Cl_2$: C, 45.2; H, 3.4. Found: C, 45.3; H, 3.2%.

3.3. $[SnF_4(Me_3PO)_2]$

Prepared similarly from $[SnF_4(MeCN)_2]$ (0.28 g, 1.0 mmol) and Me_3PO (0.19 g, 2.05 mmol) and stirred for 8 h. Yield: 0.30 g, 79%. *Anal*. Calc. for $C_6H_{18}F_4O_2P_2Sn$: C, 19.0; H, 4.8. Found: C, 18.2; H, 4.7%.

3.4. $[SnF_4(Me_3AsO)_2]$

Prepared similarly from $[SnF_4(MeCN)_2]$ (0.32 g, 1.15 mmol) and Me_3AsO (0.34 g, 2.5 mmol). Yield: 0.495 g, 92%.

3.5. $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]$

$[SnF_4(MeCN)_2]$ (0.138 g, 0.50 mmol) and $o\text{-}C_6H_4(P(O)Ph_2)_2$ (0.239 g, 0.50 mmol) were stirred together for 0.5 h in CH_2Cl_2 (20 mL). The white precipitate was filtered off and dried in vacuo. Yield: 0.23 g, 68%. *Anal*. Calc. for $C_{30}H_{24}F_4O_2P_2Sn \cdot 0.5CH_2Cl_2$: C, 51.2; H, 3.5. Found: C, 51.2; H, 3.3%.

3.6. $[SnF_4\{Ph_2P(O)CH_2P(O)Ph_2\}]$

Powdered $Ph_2P(O)CH_2P(O)Ph_2$ (0.22 g, 0.53 mmol) and $[SnF_4(MeCN)_2]$ (0.133 g, 0.48 mmol) were dissolved in CH_2Cl_2 (10 mL) and stirred at room temperature overnight. The white precipitate was then filtered off and dried in vacuo. Yield: 0.27 g, 92%. *Anal.* Calc. for $C_{25}H_{22}F_4O_2P_2Sn \cdot 0.5CH_2Cl_2$: C, 46.9; H, 3.6. Found: C, 46.5; H, 3.7%.

3.7. $[SnF_4\{o\text{-}C_6H_4(P(O)Me_2)_2\}]$

$[SnF_4(THF)_2]$ (0.30 g, 0.88 mmol) was dissolved in CH_2Cl_2 (5 mL), $o\text{-}C_6H_4(P(O)Me_2)_2$ (0.20 g, 0.87 mmol) dissolved in CH_2Cl_2 (5 mL) was added and the mixture stirred at room temperature for 2 h. The white solid was filtered off and dried in vacuo. Yield: 0.257 g, 68%.

3.8. $[SnX_4L_2]$ (X = Cl, Br or I; L = Ph_3PO, Ph_3AsO or Me_3PO)

These were made by reaction of the anhydrous tin(IV) halide with the ligand in anhydrous CH_2Cl_2 using literature methods [6,26].

3.9. X-ray experimental

Crystals of $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}] \cdot CH_2Cl_2 \cdot H_2O$ were obtained from CH_2Cl_2 solution layered with hexane and $o\text{-}C_6H_4(P(O)Ph_2)_2$ from CH_2Cl_2 solution. Brief details of the data collection and refinement are presented in Table 8. Data collection used a Bruker–Nonius Kappa CCD diffractometer with the crystal held at 120 K in a cold nitrogen stream. Structure solution [32] and refinement [33]

Table 8

[b] $R_1 = \sum\|F_o| - |F_c\|/\sum|F_o|$, $wR_2 = [\sum w(F_o^2 - F_c^2)^2/\sum wF_o^4]^{1/2}$.

were routine. In $[SnF_4\{o\text{-}C_6H_4(P(O)Ph_2)_2\}]\cdot CH_2Cl_2\cdot H_2O$ the $CH_2Cl_2$was disordered with one of the chlorine atoms occupying three sites. The two remaining peaks in the difference map were interpreted as half occupancy water molecules with the O···O distance appropriate for an H-bond. No H atoms were included for these solvate molecules. Several attempts were made to grow X-ray quality crystals of $[SnF_4(Me_3AsO)_2]$ by vapour diffusion from EtOH and Et_2O. The data from the crystals obtained did not lead to a structure possibly due to twinning.

4. Supplementary data

Crystallographic data in cif format have been deposited with the Cambridge Crystallographic Data Centre (CCDC) and given numbers 278050–278052. Copies of the data can be obtained free of charge from The Director, CCDC, 12 Union Road, Cambridge, CB2 1EZ, UK, fax: +44 1223 366 033, e-mail: deposit@ccdc.ac.uk or on the web www: http://www.ccdc.cam.ac.uk.

Acknowledgements

We thank EPSRC for support (MFD), and M.J. Darmody for the preparation of some of the tin(IV) complexes in Section 3.8.

2. Experimental

2.1. Preparation of 1–6

The preparations were carried out using 0.2 molar aqueous solutions of D,L-tartaric acid and LiOH and a second hydroxide MOH, where M = Li (**1**), Na (**2**), K (**3**), Rb (**4**), Cs (**5**) and NH_4 (**6**). A liquid handling robot was used to prepare mixtures of these solutions in the wells of a well plate. Crystals suitable for X-ray crystallography were obtained after approximately one week.

2.2. X-ray crystallography

Intensity data for structures **1**–**6** were recorded at 120 K, using a Nonius Kappa CCD area-detector diffractometer mounted at the window of a rotating anode FR591 generator with a molybdenum anode ($\lambda = 0.71073$ Å). φ and ω scans were carried out to fill the Ewald sphere [10]. An empirical absorption correction was carried out using SORTAV [11,12]. The structures were solved by direct methods and refined on F^2 by full-matrix least-squares refinements [13]. All hydrogen atoms were identified in a difference map. The positions of hydroxyl hydrogen atoms were constrained to idealised geometries. Geometrical restraints were applied to refine the positions of the water hydrogen atoms. The NH_4 hydrogen atoms in structure **6** were treated in the same manner. Details for the structure determination of **1**–**6** are listed in Table 1. Parameters of hydrogen bonds in **1**–**6** are available as supplementary data.

3. Results and discussion

3.1. $Li_2(C_4H_4O_6) \cdot 3H_2O$ (1)

Racemic dilithium tartrate trihydrate was first reported by Scacchi in 1867 [14,15]. The optical microscopic characterisation was limited by his inability to obtain the compound subsequently. It therefore represents one of the earliest examples of a disappearing form [16]. The trihydrate crystals in our hands remain unaltered, and we have been unable to obtain any other dilithium tartrate. This different behaviour is probably due to the relative purity of the chemicals available to us. Examples of disappearing forms are often related to chemical purity issues [17].

The crystal structure of **1** proved to be unusually complex. The space group is $P2_1/c$, and the unit cell contains sixteen formula units, i.e. the asymmetric unit has 24 different entities (8 Li, 12 water molecules and 4 tartrate ions). The structure is composed of two topologically different two-dimensional coordination networks $[Li_6(C_4H_4O_6)_3(H_2O)_9]_n$ (A) and $[Li_2(C_4H_4O_6)(H_2O)_3]_{2n}$ (B) which propagate parallel to the *ab*-plane. A and B are structural isomers. Both nets are shown in Figs. 1 and 2.

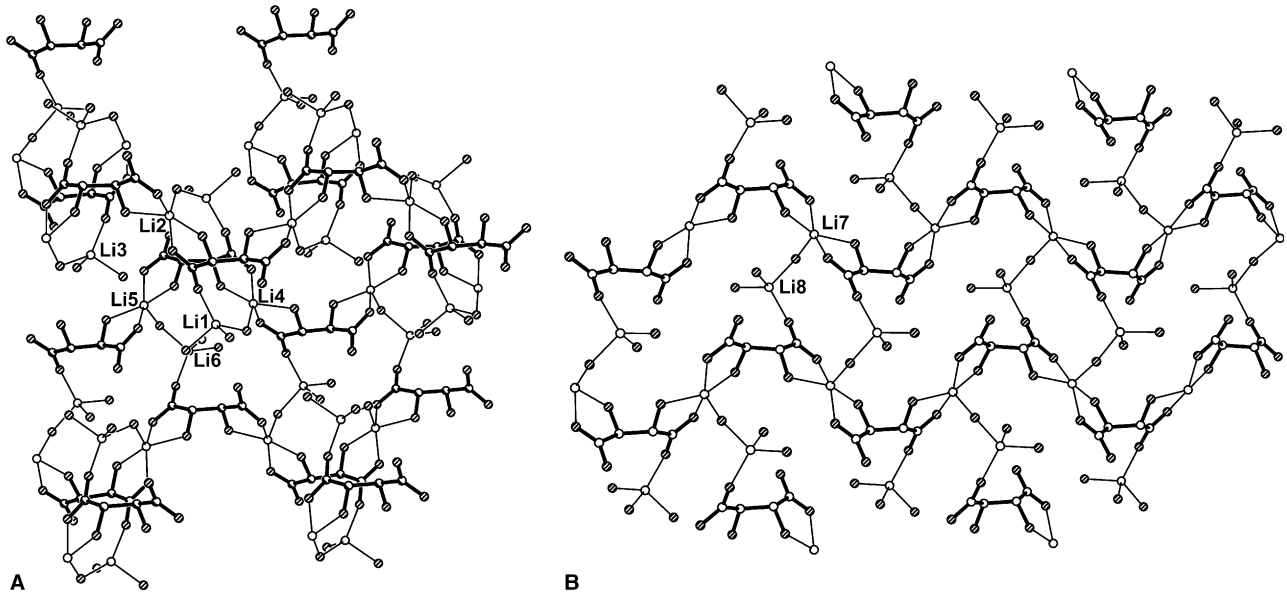

Fig. 1. Two-dimensional nets in structure **1**. Left: net $[Li_6(C_4H_4O_6)_3(H_2O)_9]_n$ (A). Right: net $[Li_2(C_4H_4O_6)(H_2O)_3]_{2n}$ (B).

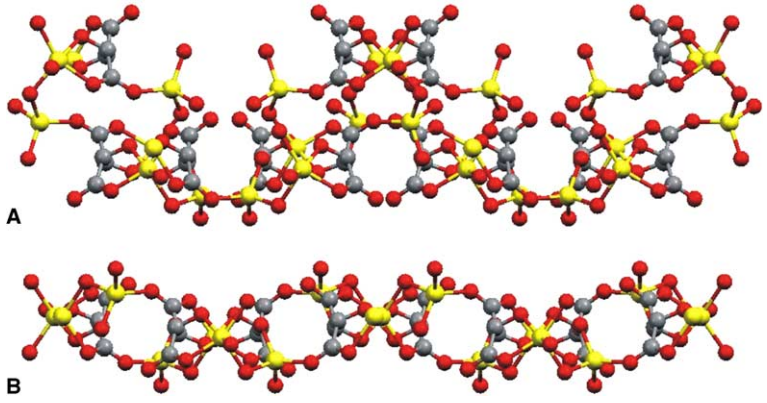

Fig. 2. Two-dimensional nets in structure **1**, viewed along *c*. Top: net $[Li_6(C_4H_4O_6)_3(H_2O)_9]_n$ (A). Bottom: net $[Li_2(C_4H_4O_6)(H_2O)_3]_{2n}$ (B).

In A, Li2, Li4 and Li5 are coordinated by oxygen in a distorted square-pyramidal fashion. The base of each pyramid is formed by two chelating tartrate ligands, while a water molecule occupies the apical position. Chelation is realised through adjacent carboxyl and hydroxyl oxygen atoms of each tartrate ion. By contrast, Li1, Li3 and Li6 are surrounded in tetrahedral fashion by three water molecules and one carboxyl oxygen. The apical water molecule in each LiO_5 unit bridges to a tetrahedral centre, Li4–O100–Li1, Li2–O102–Li3 and Li5–O105–Li6. Hence, each tetrahedral Li centre is connected to one tartrate molecule and one LiO_5 unit, while each square-pyramidal Li is linked to one Li [4] and two tartrate ions. Only one of the six oxygen sites in each tartrate ion (a carboxyl oxygen) is not involved in the coordination of Li.

Net B is centrosymmetric and contains two independent Li positions. Li7 and Li8 are surrounded by tartrate and water in a square-pyramidal and in a tetrahedral fashion, respectively, and their coordination polyhedra, linked by a Li7–O109(water)–Li8 bridge, share a common edge. The tartrate ion chelates to two Li7 centres in the same manner as described for net A. One of the remaining carboxyl oxygens additionally coordinates a Li8 centre. Hence, the Li centres, tartrate ions and water molecules are linked in a very similar fashion in nets A and B. However, the resulting two net topologies are different.

The Li–O distances in **1** lie between 1.912(4) and 2.227(4) Å, and the longest bonds are observed between the penta-coordinated Li5 and the apical water molecule. The structure of **1** is a BAABAA stack, i.e., the A:B ratio is 2:1. Adjacent A-nets are related by inversion, and there is no mutual parallel interpenetration [18] of either {A + A} or {A + B} nets. The resulting arrangement is depicted in Fig. 3. All hydrogen atoms of all water molecules and hydroxyl groups are engaged in hydrogen bonds. Fig. 4 illustrates that these interactions facilitate the intra-net stabilisation of A and B as well as the linkage of adjacent A- and B-nets into a three-dimensional hydrogen-bonded framework.

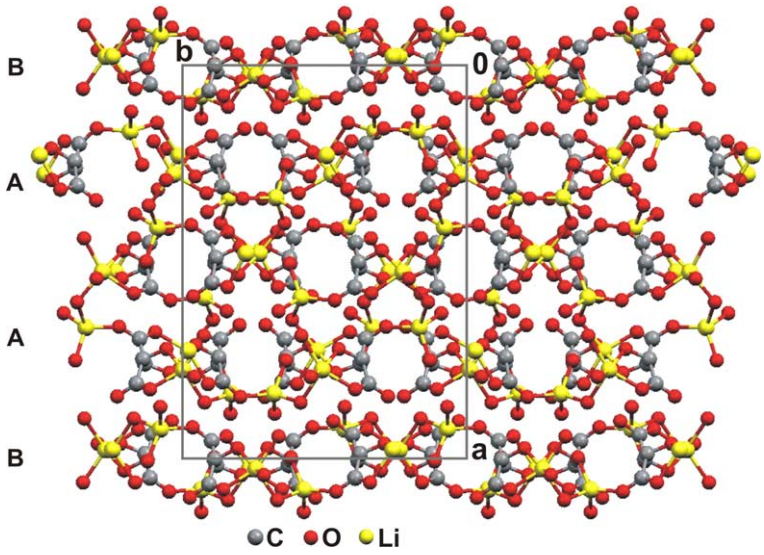

Fig. 3. BAAB sequence of two-dimensional nets in structure **1** viewed along *c*. There is no mutual interpenetration of adjacent nets.

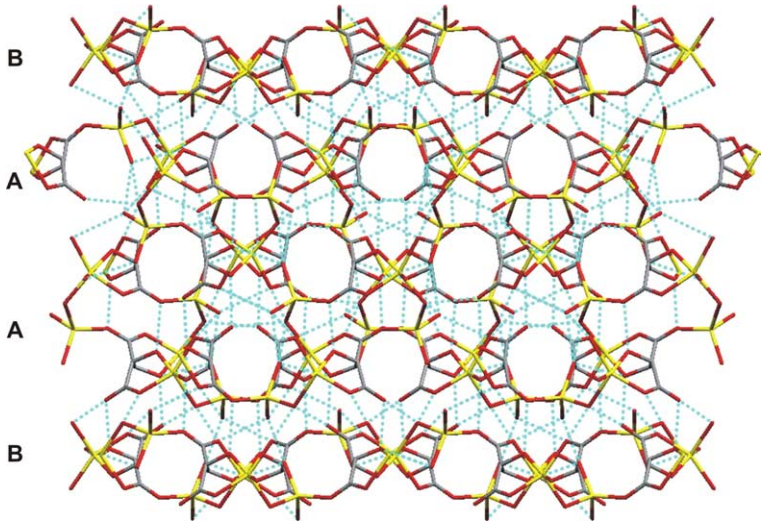

Fig. 4. Representation of **1** showing the same part of the structure, a BAAB sequence, as Fig. 3. A and B nets are connected by hydrogen bonds (indicated by dotted lines).

3.2. $LiNa(C_4H_4O_6)\cdot 2H_2O$ (**2**)

Racemic lithium sodium tartrate dihydrate crystallises in the space group *C*2/*c* with one formula unit per asymmetric unit. The structure contains two sodium atoms in special position, one on a twofold axis (Na1) and one at a centre of inversion (Na2) Na–O and Li–O bond distances for two are listed in Table 2. Li is coordinated in a distorted square-pyramidal fashion by the carboxyl and adjacent hydroxyl oxygens of two tartrate ions, and a water molecule (O8) occupies the apical position. The centrosymmetric unit $[Li(C_4H_4O_6)(H_2O)]_2$ shown in Fig. 5 is formed as a result and the Li–O lie distances between 1.940(5) and 2.192(5) Å. These units are linked via NaO_6 polyhedra.

Na1 is surrounded by four carboxyl oxygen atoms (O1, O6) of four different tartrate ions and two water molecules (*cis*, O7) in a distorted octahedral fashion, and Na1–O distances lie between 2.339(2) and 2.517(2) Å. Na2 is coordinated by two carboxyl oxygen atoms (*trans*, O6) of two different tartrate ions and four water molecules (O7 and O8) in an almost perfect octahedral fashion. Na2–O distances lie between 2.3926(19) and 2.4034(19) Å. Thus, two carboxyl oxygens (O5 and O2) do not participate in the coordination of any metal centre, while O6 coordinates Li1, Na1 as well as Na2. O1 coordinates Li1 and Na1. The Na1 octahedron shares a single edge with each of two Li and two Na2 polyhedra. Additionally, the LiO_5 polyhedron shares an edge with the octahedron around Na2. Thus, chains of edge-sharing LiO_5 and NaO_6 polyhedra are formed which run parallel to the *c*-axis. One example of such a chain is shown in Fig. 6. A diagram of the three-dimensional coordination network of **2** which is the

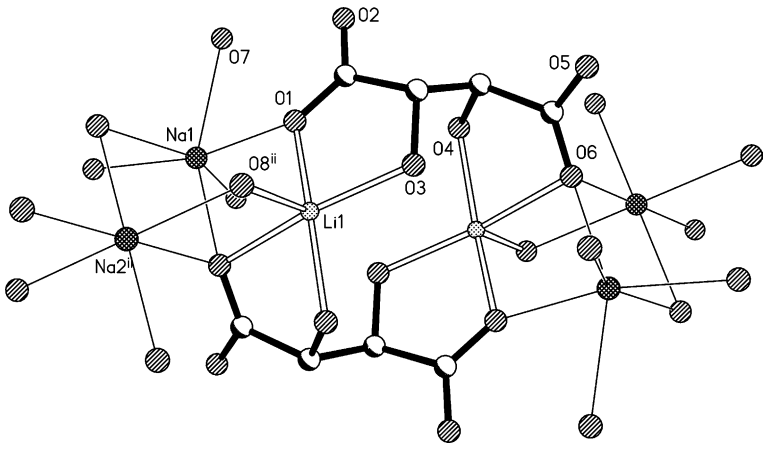

Fig. 5. Centrosymmetric $[Li(C_4H_4O_6)(H_2O)]_2$ unit in **2**, sharing oxygen atoms with four NaO_6 polyhedra.

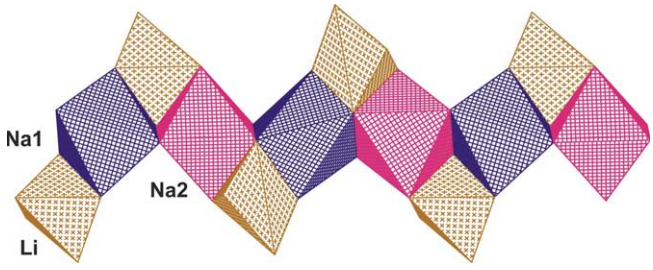

Fig. 6. Chain of edge-sharing NaO_6 and LiO_5 polyhedra in **2** running parallel to the *c*-axis.

result of the described structural features is shown in Fig. 7. This network is stabilised by hydrogen bonds in which the hydrogen atoms of all water molecules and hydroxyl groups are engaged.

*3.3. $LiM(C_4H_4O_6)\cdot H_2O$ with M = K (**3**), Rb (**4**), Cs (**5**), NH_4 (**6**)*

The racemic tartrate monohydrates **3**, **4**, **5** and **6** are isostructural. In this respect, they are similar to the series of chiral anhydrous K, Rb, Cs and NH_4 hydrogen tartrates [15–18] and their racemic counterparts [1]. Here, it was also observed that the racemic series produces mixed crystals.

3–**6** crystallise in the space group *C*2/*c*. The asymmetric unit contains one formula unit. M occupies two independent positions (M1 and M2) on a twofold axis. Each lithium centre is tetrahedrally surrounded by one water molecule and three carboxyl oxygens. Two of these oxygen atoms are related by inversion symmetry and bridge between adjacent lithium centres, so that planar Li_2O_2 rings are formed.

In the structures **3**–**5**, M1 is coordinated by 10 oxygen atoms which belong to four different tartrate ions. Two of these ligands are tridentate, and the others are bidentate. Tridentate linkage involves one carboxyl (O5) and both hydroxyl oxygen atoms (O3, O4). Bidentate linkage involves the other O of the same carboxyl group (O6) and the hydroxyl O not adjacent to it (O3). The shape of the M1 polyhedron changes considerably when the size of the alkali metal cation increases, and the relative order of the M1–O distances observed for the potassium (**3**)

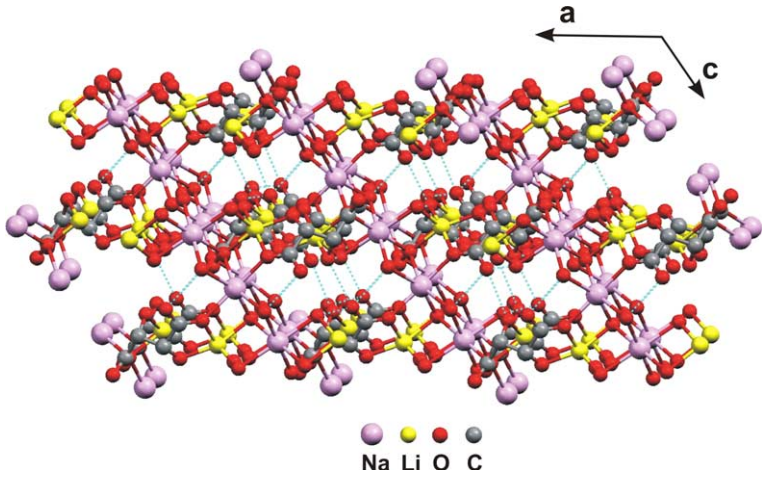

Fig. 7. Three-dimensional coordination network of **2** which is stabilised by hydrogen bonds (indicated by dotted lines).

Li1–O8^{ii}	w	2.06(2)
Li1–O6^{i}	c	2.192(5)

[a] Symmetry transformations: (i) $-x+1/2, -y-1/2, -z+1$; (ii) $x, -y, z+1/2$; (iii) $x-1/2, -y-1/2, z-1/2$.

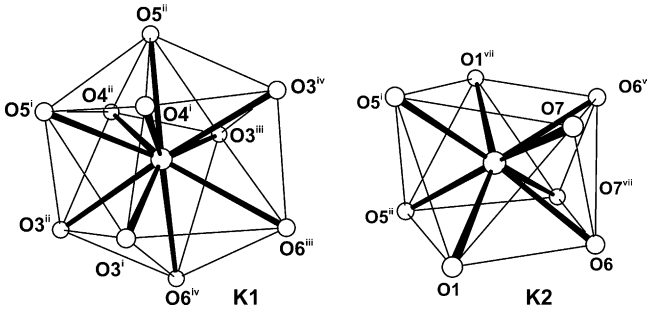

Fig. 8. Left: KO_{10} coordination polyhedron around K1 in **3**. Right: KO_8 coordination polyhedron around K2 in the same structure.

and caesium (**5**) analogues is therefore rather different (see Table 3). Fig. 8 shows the KO_{10} coordination polyhedron around K1 in structure **3**. This coordination may also be described as [8+2] since two crystallographically identical K1–O(carboxyl) bonds to bidentate ligands are considerably elongated (see K1–O6^{iii} in Table 3). In structure **5**, by contrast, the Cs1–O6^{iii} distance of 3.240 Å lies in the same range as the other four independent Cs1–O distances. Moreover, Cs1–O6^{iii} is even shorter than the corresponding K1–O6^{iii} value in **3** (3.319 Å), despite the larger radius of the metal ion.

The coordination polyhedron around M2 is a distorted square antiprism. The metal centre is surrounded by two water molecules (O7) and six carboxyl oxygens of six different tartrate molecules (O1, O5, O6). The water molecule bridges between Li and M2. All tartrate oxygens are employed in the coordination of metal centres. Of the four carboxyl oxygens, O1 is connected to M2, O2 bridges between two Li centres, O5 between M1 and M2 and O6 between M2 and two different M1 centres. One hydroxyl oxygen (O3) links two M1, while the other (O4) is only connected to M1. Thus, a three-dimensional network of edge-sharing MO_{10}, MO_8 and LiO_4 polyhedra is generated, as shown in Fig. 9.

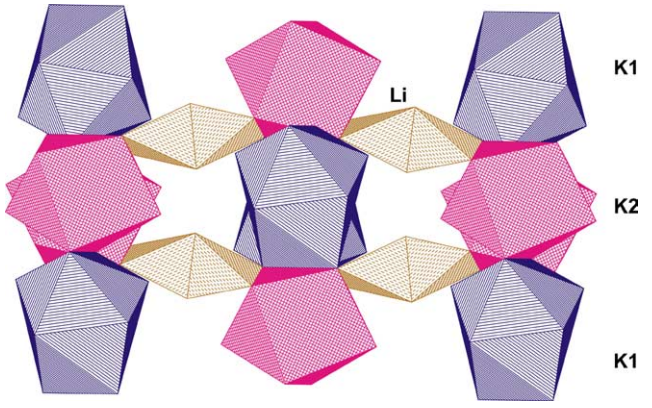

Fig. 9. The three-dimensional network in **3** generated by edge-sharing MO_{10} (K1), MO_8 (K2) and LiO_4 coordination polyhedra.

The structures of **3**–**6** may be described as stacks in which two-dimensional $[Li(C_4H_4O_6)\cdot H_2O]_n$ nets (Fig. 10) that propagate in the *ab*-plane (see Figs. 10 and 11) alternate with layers composed of M1 and M2. The three-dimensional coordination network is eventually produced

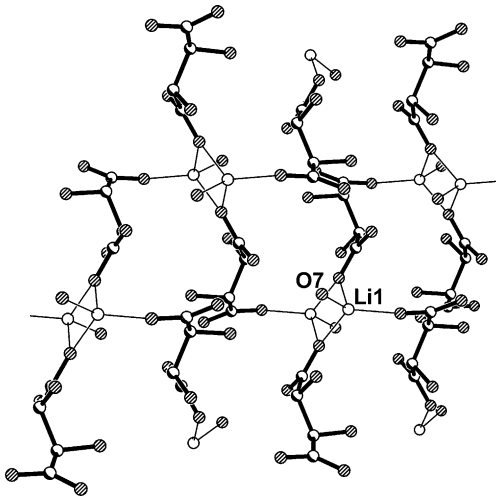

Fig. 10. Two-dimensional net $[Li(C_4H_4O_6)(H_2O)]_n$ in **3**.

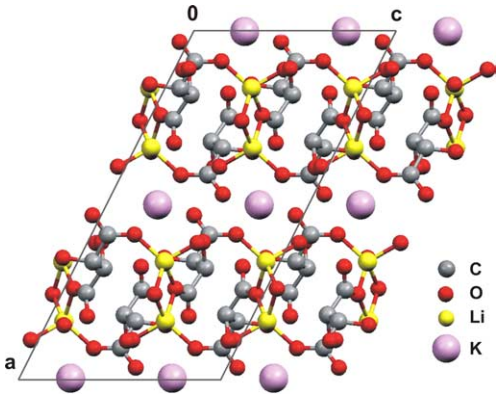

Fig. 11. Arrangement of alternating potassium (M1 + M2) and $[Li(C_4H_4O_6)(H_2O)]_n$ layers in **3** (structure viewed in the direction of the *b*-axis). K–O contacts omitted for clarity.

by coordination of M1 and M2 by the oxygens of the two neighbouring $[Li(C_4H_4O_6)(H_2O)]_n$ layers. The structures in this series contain four potential hydrogen bond donors (water molecules, hydroxyl groups) which are all engaged in H-bonding that connects adjacent $[Li(C_4H_4O_6)(H_2O)]_n$ nets. This is illustrated in Fig. 12.

In **6**, the M1 and M2 sites are occupied by NH_4. The NH_4 at the antiprismatic M2 site is hydrogen bonded to four carboxylate oxygen atoms. By contrast, NH_4 at the M1 site is linked via four bifurcated hydrogen bonds to six hydroxyl and two carboxyl oxygens.

A second product was obtained from the reaction of racemic tartaric acid with LiOH and CsOH which was subsequently shown to be the dihydrate, $LiCs(C_4H_4O_6) \cdot 2H_2O$ [19].

4. Concluding remarks

The limited set of structures considered here reinforces some of the observations noted in the previous study on racemic alkali hydrogen tartrates [2]. K, Rb, Cs and NH_4 form an isostructural set in each case. Although these two series are different with regard to the hydrogen bonding patterns they exhibit and the presence of Li and water molecules, the size difference between K and Cs is accommodated in each case by different degrees of distortion of the square antiprismatic or decahedral coordination polyhedra around the metal centre. However, the resulting Cs structures are not so well stabilised, so that an alternative Cs form was observed in each case, a polymorph in the hydrate tartrate series and the dihydrate in the present study, to be discussed elsewhere [19]. The position of the alkali metal can be adopted by NH_4 in each series under formation of hydrogen bonds NH···O. When the second cation M in LiM tartrates is a smaller Li or Na ion, then

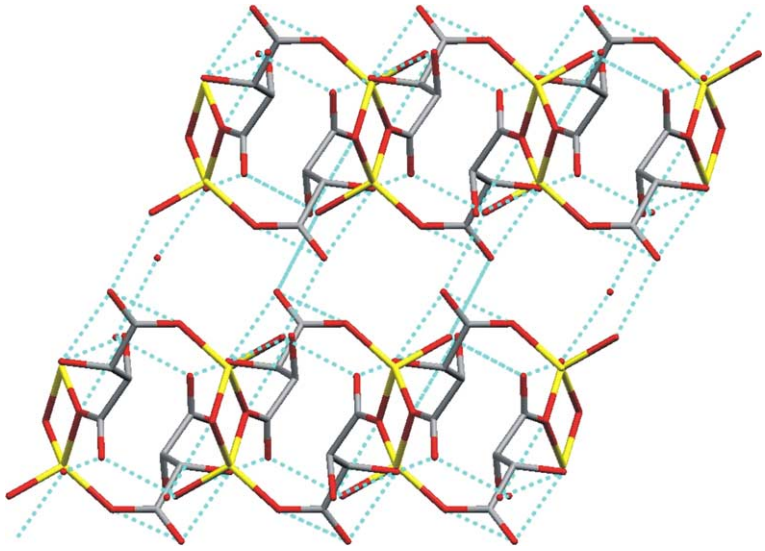

Fig. 12. Representation of **3** showing the same part of the structure as Fig. 11. Adjacent $[Li(C_4H_4O_6)(H_2O)]_n$ layers are connected by hydrogen bonds (indicated by dotted lines). K atoms omitted for clarity.

totally new structures with little similarity to their K, Rb and Cs counterparts are formed.

Appendix A. Supplementary data

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting the deposition numbers CCDC 283271–283276. Supplementary data associated with this article can be found, in the online version, at doi:10.1016/j.poly.2005.10.018.

manner. Therefore, a systematic, consolidated and comparative discussion on complexes of this series may prove useful. In continuation of our search for new nickel(II) complexes has led to this paper in which we report synthesis of nickel(II) complexes of the types, $Ni[S_2P(OR)_2]_2$, (R = *o*-, *m*-, *p*-C_6H_4Me, Ph, CH_2Ph) and their characterization by various spectroscopic techniques. We also report on the X-ray single crystal structures of $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$, and $Ni[S_2P(OCH_2Ph)_2]_2$.

2. Results and discussions

Reactions of nickel(II) chloride with ammonium salts of *O*,*O*′-ditolyl/diphenyl/dibenzyl dithiophosphates in 1:2 molar ratio in aqueous solution yield nickel(II) complexes of the types, $Ni[S_2P(OR)_2]_2$

$$NiCl_2 + 2NH_4S_2P(OR)_2 \longrightarrow Ni[S_2P(OR)_2]_2 + 2NH_4Cl$$

(R = *o*-, *m*-, *p*-OC_6H_4Me, Ph and CH_2Ph).

The precipitated purple solid was separated by filtration and repeatedly washed with benzene. All of these nickel(II) complexes are purple, powdery solids, soluble in all common organic solvents and were characterized by elemental analysis, IR, UV–Vis, ^1H and ^{31}P NMR spectroscopy.

2.1. Electronic absorption spectra

The electronic spectra of the nickel(II) complexes, recorded in C_6H_6, show three bands in the region 681–690, 517–530 and 390–395 nm in the visible region with a single band at 320–322 nm in the near ultraviolet region. The first three bands can be assigned to $^1A_{1g} \rightarrow {}^1A_{2g}$, $^1A_{1g} \rightarrow {}^1B_{2g}$, and $^1A_{1g} \rightarrow {}^1E_g$ transitions, respectively. Almost identical electronic transitions for open chain and cyclic dithiophosphate complexes were observed [25,26] indicating consistent square-planar geometry.

2.2. IR spectra

The relevant assignments of the IR bands (Table 1) have been made by comparisons with the spectra of the ammonium salts of *O*,*O*′-ditolyl/diphenyl/dibenzyl dithiophosphates [27,28] and analogous nickel(II) *O*,*O*′-dialkyl dithiophosphate complexes [25,29]. The two strong intensity bands present in the 1043–985 and 835–770 cm^{-1} regions are assigned to *ν*[(P)–O–C] and *ν*[P–O–(C)] stretching vibrations, respectively. Bands due to *ν*(P═S) or $\nu(P\text{–}S)_{asym}$ and *ν*(P–S) or $\nu(P\text{–}S)_{sym}$ observed at 690–670 and 595–540 cm^{-1} in the ditolyl dithiophosphoric acids and their ammonium salts, are shifted to lower frequency by ca. 10–30 cm^{-1} in the corresponding nickel(II) complexes, indicating bidentate attachment of the ligand to the metal atom. In addition, the bands characteristic of *ortho* substitution can be seen in the region 1944–1733w cm^{-1}, 755s cm^{-1}, those of meta substitution in 1952–1809w cm^{-1}, 897, 778s cm^{-1} and those of para substitution in 1884–1745w cm^{-1}, 816s cm^{-1}. Similarly, mono substitution in complexes **4** and **5** are observed in the region 1952–1809w cm^{-1} as well as two peaks at 695, 744s cm^{-1} [30].

2.3. ^1H NMR spectra

The spectra were recorded in $CDCl_3$ solutions at room temperature. The ^1H NMR data of nickel(II) complexes are remarkably similar to those of the salts of dithiophosphoric acids [31] probably due to the large separation between the nickel and protons. Negligible shift for methyl protons is observed in complexes **1**–**3** as compared to the corresponding salts, showing a singlet in the range 2.24–2.37 ppm. The phenyl protons appear in the region 6.85–7.41 ppm in complexes **1**–**5**, undergoing slight down field shifts of ca. 0.1–0.2 ppm compared to their position in the free ligand, presumably as a consequence of the coordination of the ligand.

2.4. ^{31}P NMR spectra

The ^{31}P NMR spectra of complexes **1**–**5**, show a relatively sharp, singlet in the region 79–94 ppm, indicating that the phosphorous nuclei are equivalent and only one type of phosphorous is present in each case in solution. The ^{31}P NMR chemical shifts for these complexes are shifted approximately 20–25 ppm upfield from those of the corresponding salts of dithiophosphoric acids.

2.5. Molecular structures of $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$ and $Ni[S_2P(OCH_2Ph)_2]_2$

$Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$ (**1**) crystallizes in the space group $P2_1/n$ and $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$ (**2**) and $Ni[S_2P(OCH_2Ph)_2]_2$ (**5**) crystallize in the space group $P\bar{1}$. The ORTEP diagram in Fig. 1 shows the single molecule in

4	$Ni[S_2P(OC_6H_5)_2]_2$	1005m	723m	667, 603s	562m
5	$Ni[S_2P(OCH_2C_6H_5)_2]_2$	985s	821m	654, 603s	565m

[a] Key: s = strong, m = medium, w = weak.

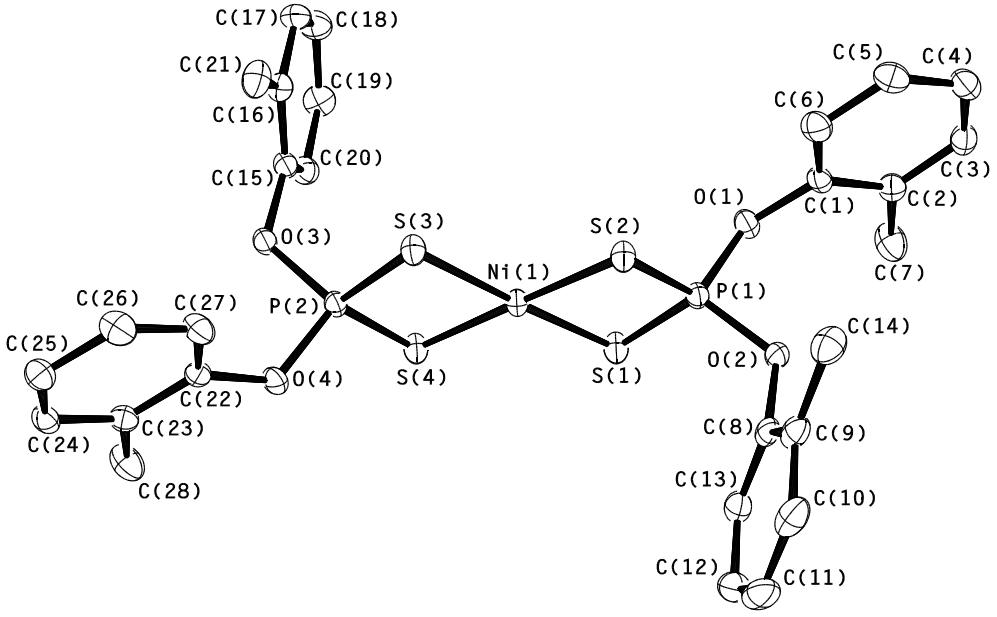

Fig. 1. ORTEP plot of $Ni\{S_2[P(OC_6H_4CH_3\text{-}o)_2]_2\}_2$. The non-hydrogen atoms are drawn with 50% probability ellipsoids. Hydrogen atoms omitted for clarity.

the asymmetric unit of **1**. In displaying the expanded two molecules of the asymmetric unit of **2** (Fig. 2) and the one and one-half molecules in the asymmetric unit of **5** (Fig. 3), the hydrogen atoms were omitted for clarity. Figs. 1–3 illustrate that the immediate environment about the Ni atom is essentially distorted square-planar and that the two dithiophosphate groups are bidentate in both complexes. The average Ni–S distance is 2.2332(6) for **1**, 2.236(6) for

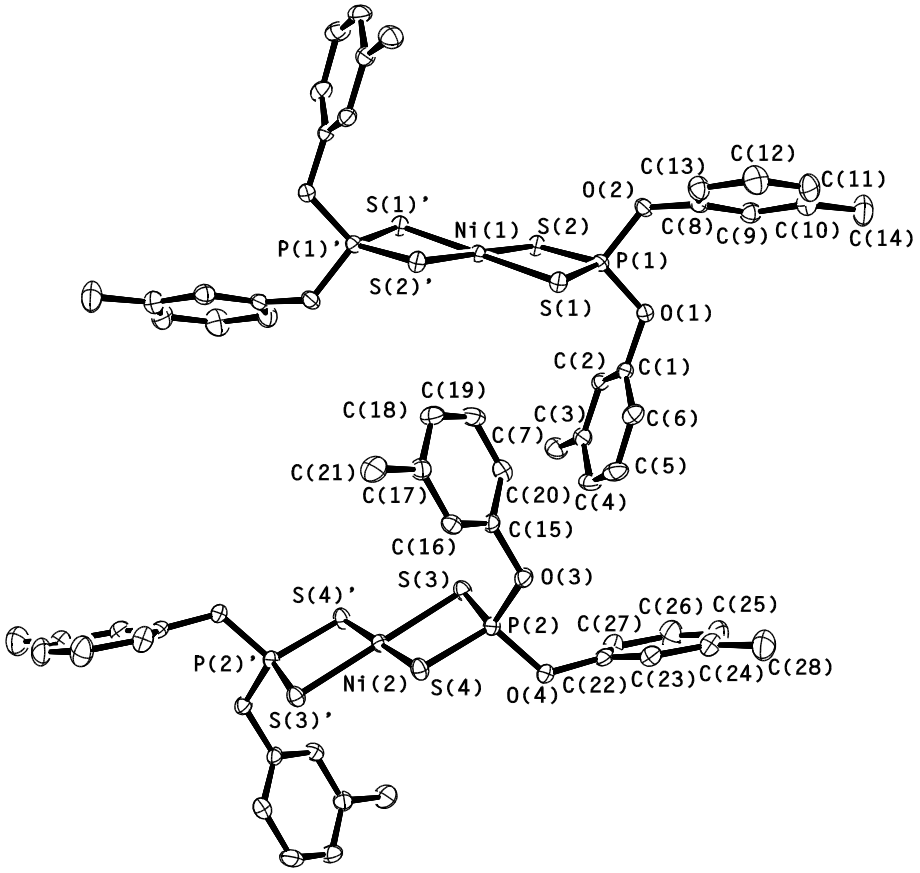

Fig. 2. ORTEP plot of the expanded two independent molecule of $Ni[S_2P(OC_6H_4CH_3\text{-}m)_2]_2$. The non-hydrogen atoms are drawn with 50% probability ellipsoids. Hydrogen atoms omitted for clarity.

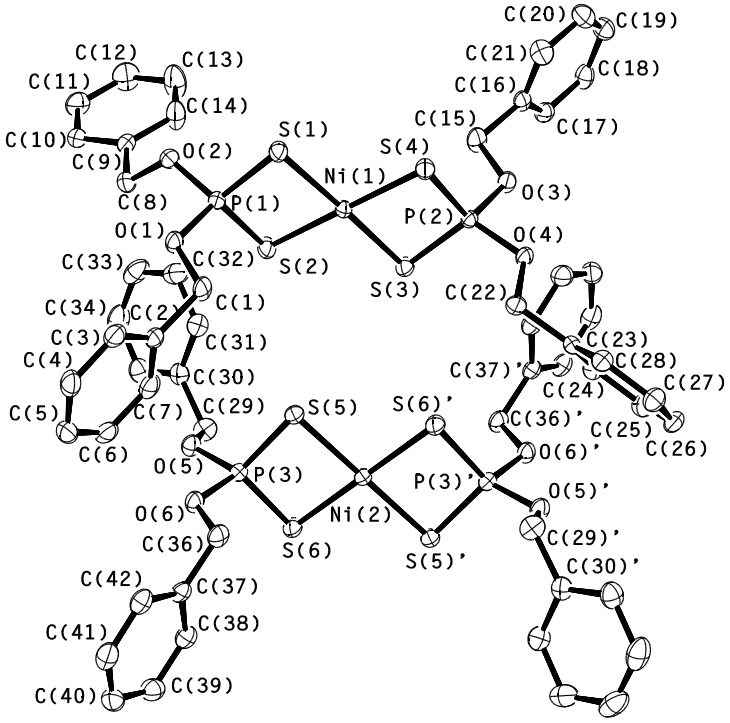

Fig. 3. ORTEP plot of the two independent molecules of $Ni[S_2P(OCH_2Ph)_2]_2$. The non-hydrogen atoms are drawn with 50% probability ellipsoids. The hydrogen atoms are omitted for clarity.

both molecules in **2** and 2.235(7) Å for those in **5**, are similar to the average value of 2.232(4) Å for $Ni[S_2P(OC_6H_4Me\text{-}p)_2]_2$ [23]. This bond length is marginally longer than found in dialkyl dithiophosphate analogue, $Ni[S_2P(OEt)_2]_2$ (2.21 Å) [32,33] and $Ni[S_2P(OPr^i)_2]_2$ (2.222(5) Å) [34]. The average S–P distances are 1.9841(7) in **1**, 1.982(7) in **2** and 1.996(5) Å in **5**, which are comparable to the values observed in $Ni[S_2P(OC_6H_4Me\text{-}p)_2]_2$ (1.976(2) Å), $Ni[S_2P(OEt)_2]_2$(1.97) and $Ni[S_2P(OPr^i)_2]_2$ (1.992(1) Å). The average P–O distances of 1.586(1) in **1**, 1.585(5) in **2** and 1.578(4) Å in **5**, lie between the values reported for the analogues, $Ni[S_2P(OEt)_2]_2$ (1.63) and $Ni[S_2P(OPr^i)_2]_2$ (1.565(1) Å) while that of **2** is identical to that of $Ni[S_2P(OC_6H_4Me\text{-}p)_2]_2$ (1.585(2) Å).

The S–Ni–S ligand bite angles are 88.39(2)° and 88.59(2)° in **1**, are 88.79(2)° and 89.18(2)° in the two molecules of **2**, and range from 87.95(3)° to 88.52(3)° in **5**; similar to the values in $Ni[S_2P(OC_6H_4Me\text{-}p)_2]_2$ (89.12(2)°) and the two analogues, $Ni[S_2P(OEt)_2]_2$ (88°) and $Ni[S_2P(OPr^i)_2]_2$ (88.10(4)°). The S–P–S bond angles vary from 103.32(3)° to 103.69(3)° in **1** and range from 104.18(4)° to 104.80(4)° in **2**, thus, having similar values as in the *para* substituted analogue, $Ni[S_2P(OC_6H_4Me\text{-}p)_2]_2$ (104.85(3)°). The values are marginally smaller in the OCH_2Ph derivative **5** (101.73(4)–102.81(4)°). The angles reported in $Ni[S_2P(OEt)_2]_2$ and $Ni[S_2P(OPr^i)_2]_2$ are 103° and 101.7(1)°, respectively. The O–P–O bond angles are 99.37(7)–99.24(7)° in **1**, range from 99.83(9)° to 100.20(9)° in **2** and are 99.39(7)° in $Ni[S_2P(OC_6H_4Me\text{-}p)_2]_2$. These values are bracketed by those in **5** ranging from 95.22(8)° to 101.04(9)°. Thus, there appear to be no significant changes or obvious trends in the distances and bond angles as the nature of R is changed in the $Ni[S_2P(OR)_2]_2$ complexes although in general the tolyl derivatives, $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}p)_2]_2$, probably show the most similarities.

3. Experimental

Nickel chloride, benzyl alcohol, *o*-, *m*-, *p*-cresols were purchased from E. Merck. Solvents (benzene, *n*-hexane, diethyl ether) were dried by standard methods before use. Stringent precautions were taken to exclude moisture during experimental manipulations. Literature methods were used for the preparation of *O*,*O*′-ditolyl [27] and *O*,*O*′-diphenyl [28] dithiophosphoric acids. *O*,*O*′-dibenzyl dithiophosphoric acid was prepared by the reaction of P_2S_5 and benzyl alcohol in 1:4 molar ratio. Ammonium salts of the dithiophosphoric acids were prepared by the reaction of parent acids with an equimolar amount of ammonia in benzene.

3.1. Preparations

3.1.1. $Ni[S_2P(OC_6H_4Me\text{-}o)_2]$ (1)

Typically, to an aqueous solution of $NiCl_2 \cdot 6H_2O$ (0.287 g, 1.2073 mmol), was added an aqueous suspension of $NH_4S_2P(OC_6H_4Me\text{-}o)_2$ (0.801 g, 2.449 mmol) in 1:2 molar ratio with constant stirring. A purple solid was immediately obtained. After stirring for 3 h, the precipitated $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$ was filtered off. The compound was purified with repeated washing with dried

benzene. Purple powdery solid. Yield: 0.768 g, 94%; m.p. 90 °C. Calc. for $C_{28}H_{28}O_4S_4P_2Ni$: Ni, 8.71; S, 18.90. Found: Ni, 8.75; S, 18.72%. ^1H NMR ($CDCl_3$): δ 2.25 (s, Me), 7.04–7.41 (m, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 84.10 ppm. UV/Vis electronic absorption spectral data [λ_{max}, nm(A)] in benzene 685, 520, 392, 322.

3.1.2. $Ni[S_2P(OC_6H_4CH_3\text{-}m)_2]_2$ (2)

Method as above gave a purple powdery solid. Yield: 0.807 g, 93%; m.p. 106 °C. Calc. for $C_{28}H_{28}O_4S_4P_2Ni$: Ni, 8.71; S, 18.90. Found: Ni, 8.60; S, 18.98%. ^1H NMR ($CDCl_3$): δ 2.38 (s, Me), 7.07–7.29 (dm, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 84.95 ppm. UV/Vis electronic absorption spectral data [λ_{max}, nm(A)] in benzene 690, 517, 394, 320.

3.1.3. $Ni[S_2P(OC_6H_4CH_3-p)_2]_2$ (3)

Method as above gave a pale purple powdery solid. Yield: 0.797 g, 89%; m.p. 171 °C. Calc. for $C_{28}H_{28}O_4S_4\text{-}P_2Ni$: Ni, 8.71; S, 18.90. Found: Ni, 8.47; S, 18.88%. ^1H NMR ($CDCl_3$): δ 2.31 (s, Me), 6.85–7.37 (m, OC_6H_4), ^{31}P NMR ($CDCl_3$): δ 79.10 ppm. UV/Vis electronic absorption spectral data [λ_{max}, nm(A)] in benzene 681, 530, 395, 322.

3.1.4. $Ni[S_2P(OPh)_2]_2$ (4)

Method as above gave a purple powdery solid. Yield: 0.759 g, 91%; m.p. 122 °C. Calc. for $C_{24}H_{24}O_4S_4P_2Ni$: Ni, 8.28; S, 18.53. Found: Ni, 8.12; S, 18.60%. ^1H NMR ($CDCl_3$): δ 7.23–7.32 (dm, OC_6H_5), ^{31}P NMR ($CDCl_3$): δ 84.59 ppm. UV/Vis electronic absorption spectral data [λ_{max}, nm(A)] in benzene 688, 525, 394, 321.

3.1.5. $Ni[S_2P(OCH_2Ph)_2]_2$ (5)

Method as above gave a purple powdery solid. Yield: 0.668 g, 86%; m.p. 125 °C. Calc. for $C_{28}H_{28}O_4S_4P_2Ni$: Ni, 8.71; S, 18.90. Found: Ni, 8.64; S, 18.78%. ^1H NMR ($CDCl_3$): δ 5.22 (s, OCH_2), 6.99–7.33 (bs, C_6H_5), ^{31}P NMR ($CDCl_3$): δ 93.66 ppm. UV/Vis electronic absorption spectral data [λ_{max}, nm(A)] in benzene 683, 527, 390, 320.

3.2. Physical measurements

Sulfur was estimated gravimetrically as barium sulfate (Messenger's method) and Nickel as dimethylglyoximate. IR spectra were recorded on a Perkin–Elmer 577 spectrophotometer in KBr pellets in the range 4000–200 cm^{-1}. Electronic spectra in the range 200–800 nm were recorded on UV visible spectrophotometer-2201 in C_6H_6. ^1H NMR spectra were recorded on a Bruker DRX300 (300MHzFT NMR) spectrometer in $CDCl_3$ using TMS as an internal standard.

[a] Symmetry equivalent positions ($x+1$, $-y+1$, $-z$) given by a prime and ($-x$, $-y$, $-z$) by a double prime.

diffractometer, with ϕ and ω scans chosen to give a complete asymmetric unit. Cell refinement [35] gave cell constants corresponding to a monoclinic for **1** and triclinic cells for **2** and **5** whose dimensions are given in Table 2 along with other experimental parameters. An absorption correction was applied [36].

The structure was solved by direct methods [37] and was refined using the WINGX version [38] of SHELXL97 [39]. All of the non-hydrogen atoms were treated anisotropically. Hydrogen atoms were included in idealized positions with isotropic thermal parameters set at 1.2 times that of the carbon atom to which they were attached. The final cycle

[a] Symmetry equivalent positions $(-x+1, -y, -z+1)$ given by a double prime and equivalent distances and angles not listed are Ni(2)–S(5)″ 2.236(1), Ni(2)–S(6)″ 2.2313(8) Å; S(6)″–Ni(2)–S(5)″ 87.95(3)°, S(6)–Ni(2)–S(6)″ 180.00°, S(6)–Ni(2)–S(5)″ 92.05(3)°.

of full-matrix least-squares refinement was based on 6621 (for **1**), 6973 (for **2**) and 10 182 (for **5**), observed reflections (5515 (for **1**), 5651 (for **2**) and 7969 (for **5**) for $F^2 > 4\sigma(F^2)$) and 356 (for **1**), 355 (for **2**) and 571 (for **5**) variable parameters and converged (largest parameter shift was 0.001 times its esd).

Selected distances and bond angles are given in Tables 3–5 for molecules **1**, **2** and **5**, respectively, and ORTEP diagram are displayed in Figs. 1–3.

4. Concluding comments

We have successfully prepared and characterized the following complexes, $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$, $Ni[S_2P(OC_6H_4CH_3\text{-}p)_2]_2$, $Ni[S_2P(OC_6H_5)_2]_2$ and $Ni[S_2P(OCH_2Ph)_2]_2$. The IR, UV–Vis and ^1H NMR spectra of all of these nickel complexes are consistent with the proposed structure. The molecular structures of $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$ and $Ni[S_2P(OCH_2Ph)_2]_2$ were all determined to have a distorted square-planar environment around nickel, as has been found for the structures reported for the analogues, complexes $Ni[S_2P(OEt)_2]_2$ and $Ni[S_2P(OPr^i)_2]_2$.

5. Supplementary material

Additional material available from the Cambridge Crystallographic Data Centre (CCDC Nos. 280426, 280427, and 280706 for $Ni[S_2P(OC_6H_4Me\text{-}o)_2]_2$, $Ni[S_2P(OC_6H_4Me\text{-}m)_2]_2$, and $Ni[S_2P(OCH_2Ph)_2]_2$, respectively, comprises the final atomic coordinates for all atoms, thermal parameters, and a complete listing of bond distances and angles). Copies of this information may be obtained free of charge on application to The Director, 12 Union Road, Cambridge CB2 2EZ, UK (fax: +44 1223 336033; email: deposit@ccdc.cam.ac.uk or http://www.ccdc. cam.ac.uk).

Acknowledgements

One of us (M.N.) is grateful to CSIR, New Delhi for financial support. M.E.L. thanks the UK Engineering and Physical Sciences Council for support of the X-ray facilities at Southampton University. J.E.D. wishes to thank the University of Windsor for financial support. We are thankful to RSIC, CDRI, Lucknow for the spectral analyses.

stereoisomerism [3], because the three phosphorus atoms of each cyclophosphazene ring have different substitution patterns and those that are part of the bridge, >P(N-spiro), are stereogenic, i.e., there are *R* and *S* forms. It was shown that spermine-bridged compounds such as **4** are diastereoisomeric and exist in 1:1 mixtures of meso (*RS*/*SR*) and racemic (*RR*/*SS*) forms [3]. Compound **4** was synthesised by the reaction at room temperature of 1,3-propanediol with **1** and, although a second compound was reported as the tri-spiro derivative, it was not characterized [3]; this compound is expected to be chiral and to exist as a racemic mixture.

Reaction of 1,3-propanediol with compound **1** could, in principle, give rise to a number of different derivatives; if only one functional group of the diol is used, this would give open chain forms, whilst utilisation of both functional groups of the diol can give rise to spiro, ansa and bridged derivatives. Reaction of $N_3P_3Cl_6$ with ethane-, 1,3-propane- and 1,4-butane-diols (in the presence of pyridine to neutralise the hydrochloride formed) predominantly gave spiro derivatives for all three diols, whereas ansa derivatives were rare products obtained only in small yields [9]. A bridged derivative was observed as a minor product with butanediol, indicating that chain length was a contributing factor in determining derivative-type [9]. It was also found that ansa-derivatives may be formed using sodium salts of diols as reagents in polar solvents such as THF [10]. The spiro- and ansa-derivatives of **1** should exhibit a range of stereogenic properties (achiral, meso, racemic, diastereoisomeric). The purpose of the present work is to investigate the reaction of the sodium derivative of 1,3-propanediol with compound **1** in THF under different reaction conditions, to characterize the structures and stereogenic properties of the products and to show how widespread the question of chirality should be considered in cyclophosphazene chemistry.

2. Experimental

2.1. Materials

Hexachlorocyclotriphosphazene (Otsuka Chemical Co., Ltd.) was purified prior to use by fractional crystallisation from hexane. The following chemicals were obtained from Merck; spermine (⩾97.0%), diethyl ether, dichloromethane, benzene, *n*-hexane, 1,3-propanediol (⩾99.0%), silica gel 60, sodium hydride (60% oil suspension), tetrahydrofuran, ethyl acetate, chloroform and *n*-heptane. The deuterated solvents for NMR spectroscopy were obtained from Apollo Scientific (toluene-d_8, $CDCl_3$) and the chiral solvating agent, (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol, was obtained from Aldrich Chemical Co.

2.2. Measurements

Elemental analyses were obtained using a Carlo Erba 1106 Instrument. Mass spectrometric measurements were recorded on a VG Zab Spec GC–MS spectrometer using the fast atom bombardment (FAB) method (35 kV) with MNBA as the matrix; ^{35}Cl values were used for calculated masses. Analytical Thin Layer Chromatography (TLC) was performed on Merck silica gel plates (Merck Kieselgel 60, 0.25 mm thickness) with F_{254} indicator. Column chromatography was performed on silica gel (Merck 60, 230–400 mesh; for 3 g, crude mixture, 100 g, silica gel was used in a column of 3 cm in diameter and 60 cm in length). ^1H and ^{31}P NMR spectra were recorded in $CDCl_3$ or toluene-d_8 solutions on a Bruker DRX 500 MHz spectrometer using TMS as an internal reference for ^1H and 85% H_3PO_4 as an external reference for ^{31}P. For all new compounds both proton-coupled and proton-decoupled ^{31}P NMR spectra were recorded. Experiments involving the chiral solvating agent (CSA) were performed by addition of small aliquots of a dilute solution of CSA in the solvent used for NMR spectroscopy and the ^{31}P NMR spectrum recorded at each addition.

2.3. Synthesis

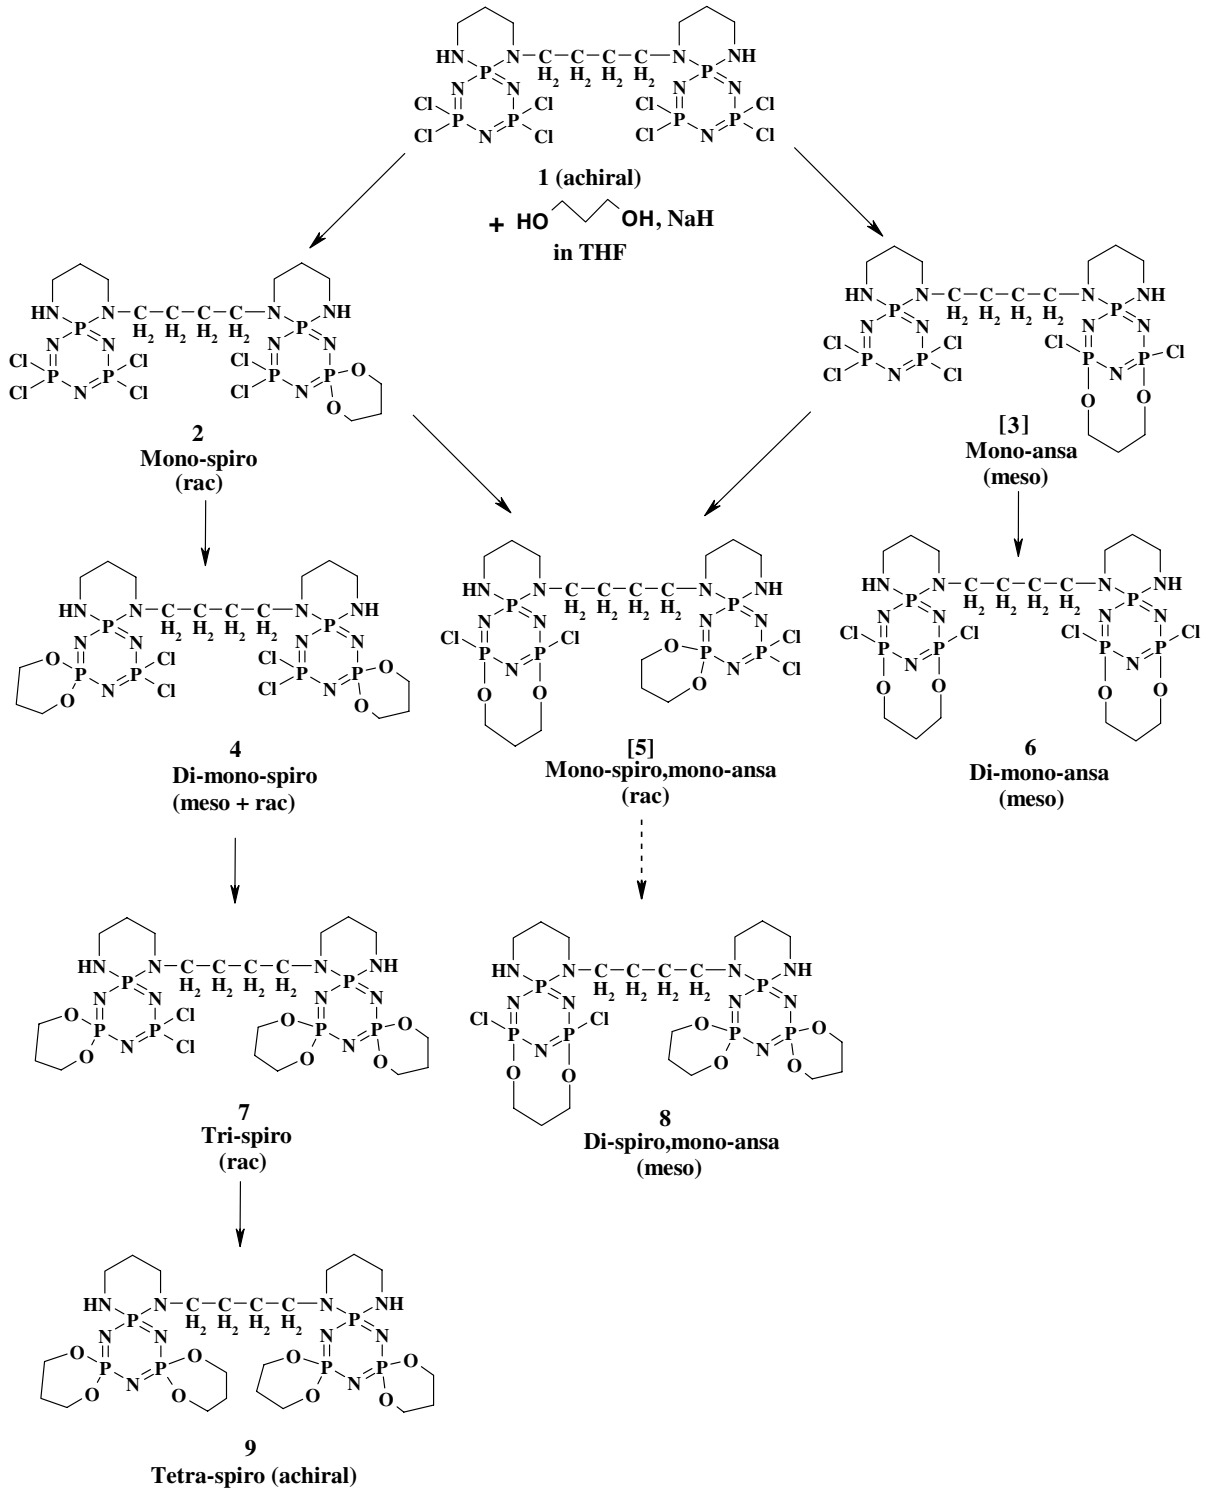
Reaction of the sodium derivative of 1,3-propanediol with compound **1** in THF at different molar ratios gave a number of spiro and ansa derivatives as summarized in Scheme 1.

2.3.1. 4:1 mole ratio

1,3-Propanediol (0.4 g, 5.3 mmol) and previously prepared [8] compound **1** (1 g, 1.33 mmol) were dissolved in 50 mL of dry THF in a 250 mL three-necked round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (60% oil suspension, 0.42 g, 10.6 mmol) in 50 mL of dry THF was added under an argon atmosphere. The reaction mixture was stirred for 21 h at room temperature and the reaction followed to completion by TLC on silica gel plates using $CHCl_3$:ethyl acetate (3:1) as the solvent system. The reaction mixture was filtered to remove the sodium chloride formed, the THF was removed under reduced pressure and the resulting white solid subjected to column chromatography using $CHCl_3$:ethyl acetate(3:1) as eluent. Two fractions were obtained and isolated as white powders and recrystallised from chloroform:hexane (1:1). The first fraction is the dispiro-monoansa compound, **8**, (yield: 0.29 g, 25%, m.p. 147–149 °C; isolated as a chloroform adduct). *Anal*. Calc. for $C_{20}H_{41}Cl_5N_{10}P_6O_6$ requires: C, 27.27; H, 4.69; N, 15.90, M^+, 761.34. Found: C, 27.02; H, 4.20; N, 15.12% $(M + H)^+$, 761. The second fraction is the tetraspiro-derivative, **9**, whose NMR spectral data [11] and X-ray structure [12] have been characterized previously (yield: 0.33 g. 32%, mp >250 °C). *Anal*. Calc. for $C_{22}H_{46}N_{10}O_8P_6$ requires: C, 34.56; H, 6.06; N, 18.32, M^+, 764.52. Found: C, 34.35; H, 6.2; N, 17.68% $(M + H)^+$, 764.

2.3.2. 3:1 mole ratio

1,3-Propanediol (0.9 g, 11.95 mmol) and previously prepared [8] compound **1** (3 g, 3.98 mmol) were dissolved in



Scheme 1. Stereogenicity confirmed by X-ray (or by NMR + CSA) except for compounds with numbers in brackets.

200 mL of dry THF in a 500 mL three-necked round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (60% oil suspension, 0.95 g, 23.9 mmol) in 50 mL of dry THF was added under an argon atmosphere. The reaction mixture was stirred for 24 h at room temperature and was followed by TLC on silica gel plates using THF:CH_2Cl_2 (5:2). The reaction mixture was filtered to remove the sodium chloride formed, the THF was removed under reduced pressure and the resulting white solid subjected to column chromatography using THF:CH_2Cl_2 (5:2) as eluent. Two fractions were obtained; the first fraction was isolated as a white powder (yield 0.22 g, 7.3%), (m.p. 84–90 °C) and characterized as the tri-spiro compound, **7**. *Anal*. Calc. for $C_{19}H_{40}Cl_2N_{10}O_6P_6$ requires: C,

30.00; H, 5.30; N, 18.40, M^+, 760. Found: C, 30.48; H, 5.14; N, 17.95%, $(M + H)^+$, 761. ^{1}H NMR, $CDCl_3$, 298 K: OCH_2 signals at 4.52m, 2H and 4.4m, 10H; 3.23m, 4H, NCH_2; 3.1m, 4H, NCH_2; 2.8m 4H, $NHCH_2$; 2.5, broad triplet, 2H, NH; O-spiro, N-spiro and bridge CCH_2 signals at 2.1m, 4H; 1.9m, 4H; 1.7, 8H. The second fraction was isolated as a white powder (yield: 0.5 g, 16.5%) (m.p. 147–149 °C), re-crystallized from CH_2Cl_2:THF:hexane (1:2:1) and characterized as the dispiro-monoansa compound, **8**. *Anal*. Calc. for $C_{19}H_{40}Cl_2N_{10}O_6P_6$ requires: C, 29.97; H, 5.30; N, 18.40, M^+, 760. Found: C, 29.30; H, 5.90; N, 17.68%. $(M + H)^+$, 760.8.

2.3.3. 2:1 mole ratio

1,3-Propanediol (1.06 g, 13.2 mmol) and previously prepared [8] compound **1** (5 g, 6.6 mmol) were dissolved in 140 mL of dry THF in a 500 mL three-necked round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (60% oil suspension, 1.056 g, 26.4 mmol) in 100 mL of dry THF was quickly added under an argon atmosphere. The reaction was stirred for 23 h at room temperature and was followed by TLC on silica gel plates using CH_2Cl_2:ethyl acetate (6:1). The reaction mixture was filtered to remove NaCl formed, the THF was removed under reduced pressure and the resulting white solid subjected to column chromatography using CH_2Cl_2:ethyl acetate (6:1). Two fractions were obtained. The first fraction has been characterized previously as the di-monospiro derivative **4** (isomer mixture, m.p. 210–216 °C) [3] and the meso form characterized by X-ray crystallography [11]. The second major fraction was isolated as a white powder, re-crystallized from dichloromethane:hexane (1:1) and characterized as the di-monoansa derivative **6** (yield: 0.4 g, 8%) (m.p. >250 °C decomposition). *Anal*. Calc. for $C_{16}H_{34}Cl_4N_{10}O_4P_6$ requires: C, 25.35; H, 4.52; N, 18.47, M^+, 756. Found: C, 25.91; H, 4.08; N, 17.88%. $(M + H)^+$, 757. ^{1}H NMR, $CDCl_3$, 298 K: 4.48m, 4H, OCH_2 signals; 4.21m, 4H, OCH_2 signals; 3.23m, 4H, NCH_2; 3.13m, 4H, NCH_2; 2.92m 4H, $NHCH_2$; ansa CCH_2 signals at 2.2m, 2H and 1.9m, 2H; spiro and bridge CCH_2 signals at 1.75m, 4H and 1.68m, 4H.

2.3.4. 0.75:1 mole ratio

1,3-Propanediol (0.25 g, 3.2 mmol) and previously prepared [8] compound **1** (3.3 g, 4.3 mmol) were dissolved in 150 mL of dry THF in a 500 mL three-necked round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (60% oil suspension, 0.26 g, 6.4 mmol) in 50 mL of dry THF was quickly added under an argon atmosphere. The reaction was stirred for 24 h at room temperature and was followed by TLC on silica gel plates using CH_2Cl_2–ethyl acetate (1:2) as eluent. The reaction mixture was filtered to remove the sodium chloride, the THF was removed under reduced pressure and the resulting white solid subjected to column chromatography using CH_2Cl_2:ethyl acetate (1:2). Two fractions were obtained, the first is the starting compound **1** [8], isolated as a white powder (recovery of starting material: 0.16 g, 5%) whose ^{1}H NMR has not been previously reported in detail. ^{1}H NMR, $CDCl_3$, 298 K: 3.24m, 4H, NCH_2; 3.14m, 4H, NCH_2; 2.84m 4H, $NHCH_2$; 2.67 broad quartet, 2H, NH; spiro and bridge CCH_2 signals at 1.82m, 4H and 1.56m, 4H. The second fraction was also isolated as a white powder (yield: 0.45 g, 14%), (m.p. 150–151 °C), recrystallised from CH_2Cl_2:hexane:ethyl acetate (2:1:1) and characterized as the mono-spiro compound **2**. *Anal*. Calc. for $C_{13}H_{28}Cl_6N_{10}O_2P_6$ requires: C, 20.68; H, 3.74; N, 18.55 M^+, 754. Found: C, 19.90; H, 3.50; N, 18.40% $(M + H)^+$, 754.9. ^{1}H NMR, $CDCl_3$, 298 K: 4.53m 2H, OCH_2 signals; 4.37m 2H, OCH_2 signals; 3.1–3.3m, 8H, NCH_2; 2.8–2.9m, 4H, $NHCH_2$; 2.64, broad quartet, 1H, NH; 2.52, broad triplet, 1H, NH; CCH_2 signals at 2.14m, 1H; 1.75–1.9m, 5H; 1.6m, 4H. ^{1}H NMR, toluene-d_8, 298 K: 4.53m 2H, OCH_2 signals; 4.37m 2H, OCH_2 signals; 3.25m 4H, NCH_2; 3.1–3.3m 8H, NCH_2; 3.15m 4H, NCH_2; 2.85m 4H, $NHCH_2$; 2.64, broad quartet, 1H, NH; 2.52, broad triplet, 1H, NH; CCH_2 signals at 2.14m, 1H; 1.75–1.9m, 5H; 1.6m, 4H.

2.4. X-ray crystallography

Intensity data were recorded at low temperature (120 K) on a Nonius KappaCCD diffractometer situated at the window of an FR591 rotating anode generator, driven by COLLECT [13] and DENZO [14] software. Details of data collection and refinement are given in Table 1. All structures were determined using the direct methods procedure in SHELXS-97 [15] and refined by full-matrix least-squares on F^2 using SHELXL-97 [16]. The structure of **8** exhibits a solvent of crystallisation ($CHCl_3$) and some disorder in the central chain (atom C8/C8′), which is modelled at 55:45%. Full details of data collection and structure determination have been deposited with the Cambridge Crystallographic Data Centre (CCDC).

3. Results and discussion

3.1. Formation of spiro- and ansa-substituted spermine-bridged cyclotriphosphazenes

Reaction of the sodium derivative of 1,3-propanediol with the spermine-bridged cyclophosphazene **1** in different mole ratios (4:1, 3:1, 2:1, 0.75:1) in THF gave a number of spiro- and ansa-substituted derivatives as shown in Scheme 1. In order to investigate all major reaction products, the crude reaction mixtures were routinely characterized by proton-decoupled ^{31}P NMR, as well as all major fractions isolated. Reaction of 1,3-propanediol with **1** in a 4:1 mole ratio for 21 h at room temperature gave the fully substituted dispiro-monoansa **8** and tetra-spiro **9** derivatives, whereas reaction at a 3:1 mole ratio under the same solution conditions gave the tri-spiro derivative **7** and the isomeric compound **8**. Reaction of 1,3-propanediol with **1** in a 2:1 mole ratio for 23h at room temperature gave the

[a] Isolated as a 1:1 adduct with chloroform.

di-monospiro **4** and di-monoansa **6** derivatives and reaction at a 0.75:1 mole ratio for 24 h at room temperature gave the mono-spiro **2** and mono-ansa **3** derivative. It is obvious from Scheme 1 that the mono-spiro derivative **2** is the precursor of the spiro-substituted compounds **4** (di), **7** (tri), and **9** (tetra), and the mono-ansa derivative **3** is a precursor of **6** (di-mono-ansa) and **8** (di-spiro/mono-ansa). The mono-spiro/mono-ansa derivative **5** could be formed from either the mono-spiro **2** or the mono-ansa compound **3** and the dispiro/mono-ansa derivative **8** should have compound **5** as precursor. Attempts were made to prepare the mono-spiro/mono-ansa compound **5**, but amounts in the reaction mixtures were too small to isolate and characterize independently. Each of the new compounds **2**, **6** and **8** was characterised by X-ray crystallography and by elemental analysis, MS and ^{31}P NMR using both proton-decoupled and proton-coupled spectra. Although crystals suitable for X-ray crystallography could not be obtained for **3** and **7**, these compounds were characterized by ^{31}P NMR spectroscopy. The ^{31}P NMR results for all of the compounds are summarised in Table 2.

3.2. X-ray crystal structures of the spiro- and ansa-derivatives (*2,6,8*) of the spermine-bridged compound, *1*

The molecular structures of compounds **2**, **6** and **8** are shown in Figs. 1–3, respectively. The crystal structures of the meso form of the di-mono-spiro compound **4** [11] and the tetra-spiro compound **9** [12] have been published previously.

3.2.1. Compound *2*

The molecular structure of the mono-spiro compound **2** in Fig. 1 depicts an asymmetrically-bridged molecule, in which one of the cyclophosphazene moieties is unsubstituted and the other exhibits a mono-spiro substituted phosphorus site. Both N_3P_3 rings of compound **2** are nearly planar, with the maximum deviations from the mean ring plane being 0.092 Å (atom P2) and 0.104 Å (atom N8) for rings 1 (spiro derivative) and 2 (un-substituted), respectively. Ring 2 exhibits slight ring compression with a shortened non-bonded separation between ring phosphorus atoms of 2.699 Å (P4···P5), whereas the expected distance surveyed from the Cambridge Structural Database [17] is about 2.78 Å. The spermine bridge introduces chirality to the molecule at the phosphorus sites linking it to the unsymmetrically-substituted cyclophosphazene ring and is found to be *S* for atom P3. The molecule is chiral and exists as a racemate. The relative conformation of the two cyclophosphazene rings around the tetra-methylene bridge is neither pure syn nor anti, but is approximately 2/3 of the way towards the latter, forming an angle of 59.5° between the two ring planes. Hydrogen-bonding occurs at the N_3P_3 moiety containing the spiro-propanedioxy group and gives rise to discreet dimers through an N–H···N interaction (N4–H4N···N2 D···A distance = 3.282 Å). Eight-membered hydrogen-bonded rings are formed, in which the two heavy atom distances are equal at 3.282 Å and result in a twist-boat conformation. At distances >3.4 Å a more complex hydrogen-bonded motif links the molecules into an infinite layer structure.

[a] 202.45 MHz ^{31}P NMR measurements in $CDCl_3$ solutions at 298 K. Chemical shifts referenced to external 85% H_3PO_4.
[b] Abbreviations: sp, spiro; an, ansa; r, racemate; m, meso.
[c] Data taken from [3].
[d] Data on toluene-d_8 at 298 K. It is noted that, in comparison of the ^{31}P NMR spectra of the mono-spiro substituted ring of both compounds **2** and **7** in toluene-d_8 and $CDCl_3$ solutions, changes occur not only in chemical shifts (as expected) but also in ^{2}J(PP) values.
[e] Data taken from [11].
[f] Unequivocal assignment of meso (m) and racemic (r) forms resulted from characterization of the meso form of the diastereoisomer by X-ray crystallography [11].

3.2.2. Compound *6*

The molecular structure of the di-monoansa compound **6** in Fig. 2 is that of a symmetrically-bridged spermine derivative, where the cyclophosphazene substituents both possess a propanedioxy ansa-bridged moiety, giving rise to a centrosymmetric structure with the centre of inversion about the central C–C bond of the spermine bridge. The cyclophosphazene ring is heavily distorted, as observed in similar ansa-bridged examples [18], with a maximum deviation from the mean ring plane of

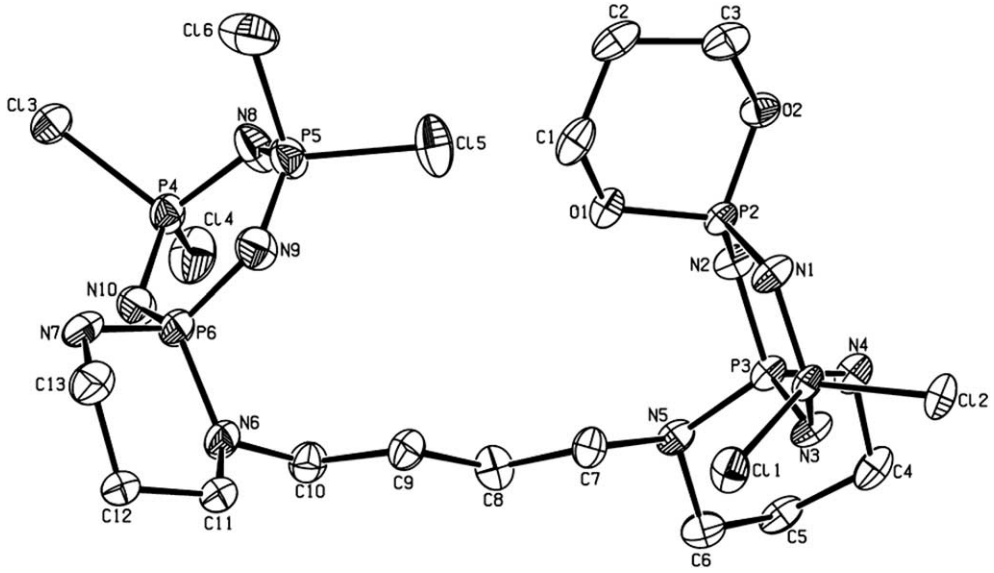

Fig. 1. Crystal structure of the mono-spiro compound **2**.

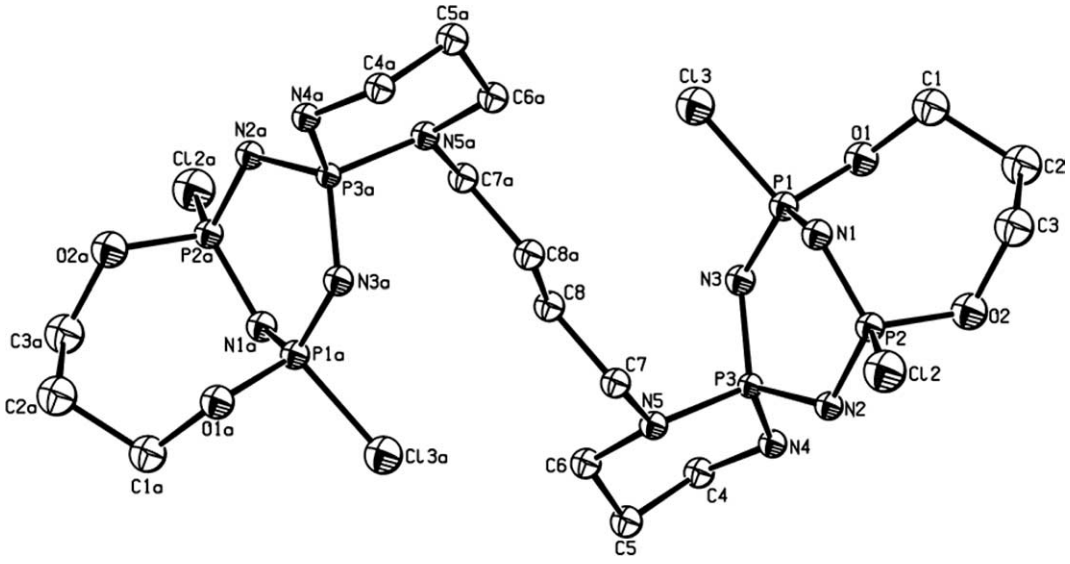

Fig. 2. Crystal structure of the di-mono-ansa compound **6**.

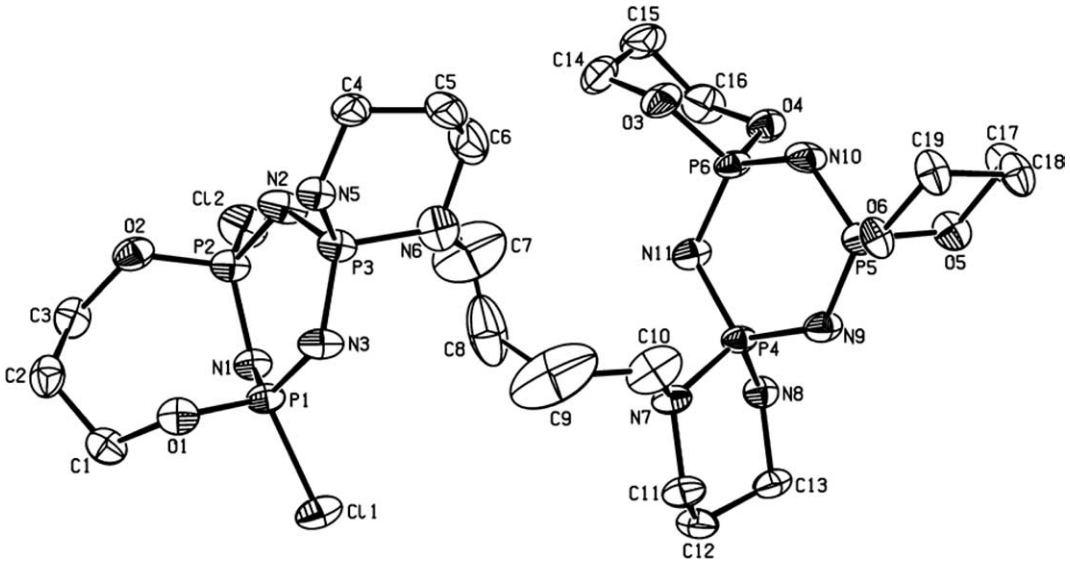

Fig. 3. Crystal structure of the di-spiro/mono-ansa compound **8**, with disorder (about atom C8) and the $CHCl_3$ solvent molecule removed for clarity.

0.328 Å for the nitrogen atom (N1) bridged by the ansa group. This give rise to compression of the cyclophosphazene ring, where the non bonded P···P separation between atoms P1 and P2 is 2.615 Å. The ansa bridge introduces chirality into the molecule such that P1 = *R* and P2 = *S*, with the symmetry generated partners having the opposite chirality due to the inversion centre resulting in **6** being a meso compound. As a result of the centrosymmetric nature of the structure, the two cyclophosphazene rings are disposed exactly syn to each other with respect to the spermine bridge. The supramolecular structure is that of a hydrogen bonded dimer, where an NH of the spermine group interacts with a cyclophosphazene ring nitrogen in a head to tail fashion (N4–H4N···N2 D···A distance = 3.154 Å). Longer range interactions arrange these dimers into an infinite sheet structure. This arrangement is similar to that of the hydrogen bonded structure of **2**, apart from the conformation of the eight-membered hydrogen-bonded ring, which forms a slightly twisted chair in the crystal structure of **6**.

3.2.3. Compound *8*

The molecular structure of the dispiro-monoansa compound **8** in Fig. 3 is that of a spermine moiety bridging two asymmetrically-substituted cyclophosphazene rings, one with an ansa propanedioxy substituent and the other with two spiro groups. As in the structure of **6** the cyclophosphazene ring of the ansa-bridged moiety is highly distorted, with the ansa-bridged cyclophosphazene ring nitrogen (N1) positioned out of the mean ring plane by 0.31 Å and with the compressed non bonded P···P

separation between atoms P1 and P2 being 2.627 Å. On the other hand, the di-spiro substituted cyclophosphazene ring is nearly planar with a maximum deviation from the mean ring plane of 0.117 Å for atom P6. Although the ansa bridge introduces chirality into the molecule such that P1 = *S* and P2 = *R*, overall the molecule is meso. The relative conformation of the two cyclophosphazene rings around the tetra-methylene bridge is in an approximate syn conformation with an angle of 26.7° between the two ring planes. As observed in structures **2** and **6** the hydrogen bonded structure of **8** is that of a dimer, formed between the NH hydrogen of the spermine group and a cyclophosphazene ring nitrogen, with the separation between donor and acceptor atoms being 3.039 and 3.140 Å. These unequal distances result in a saddle-shape hydrogen-bond ring conformation. The hydrogen-bonded motifs occur at both ends of these molecules, thus forming an infinite chain.

3.3. Characterization of the chiral configurational properties of compounds 2 and 7 by ^{31}P NMR on addition of a chiral solvating agent, (S)-(+)-2,2,2-trifluoro-1-(9-anthryl)-ethanol

It is found that one set of proton-decoupled ^{31}P NMR signals are observed for compounds **2**, **3**, **6**–**9** whereas two sets of closely-spaced signals are observed for the di-monospiro compound **4**. The latter two sets of signals correspond to the meso and racemic forms of compound **4** as shown previously for analogous spermine-bridged compounds [3]. On addition of chiral solvating agent [19], (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol, CSA, in $CDCl_3$ or toluene-d_8 solution some of the ^{31}P NMR signals for compounds **2** and **7** separate into two signals of equal intensity characteristic of racemic mixtures. X-ray crystallography has shown that compound **2** is chiral and exists as a racemate, whereas crystals of compound **7** suitable for X-ray analysis could not be obtained. As an example, the stereogenic properties of the tri-spiro compound **7** are demonstrated by NMR spectroscopy in Fig. 4. The proton-decoupled ^{31}P NMR spectrum of compound **7** in toluene-d_8 shown in Fig. 4(a) consists of five multiplets corresponding to an AMX spin system for the mono-spiro substituted cyclophosphazene ring [signals expanded in Fig. 4(b)] and an A_2X spin system for the di-spiro-substituted ring. Assignment of the ^{31}P NMR signals of the AMX part of compound **7** to >PCl_2, >P(N-spiro) and >P(O-spiro) groups was made by comparison of proton-coupled (not shown) and proton-decoupled spectra, whereas assignment of the A_2X spin system to >P(N-spiro) and >P(O-spiro) follows simply from the triplet and doublet signals, respectively. Addition of CSA to the solution of compound **7** causes changes in chemical shifts of all signals indicating complexation and, as shown in Fig. 4(c), it also causes splitting of all peaks for the AMX part of the spectrum, which is consistent with compound **7** being chiral and existing as a racemate.

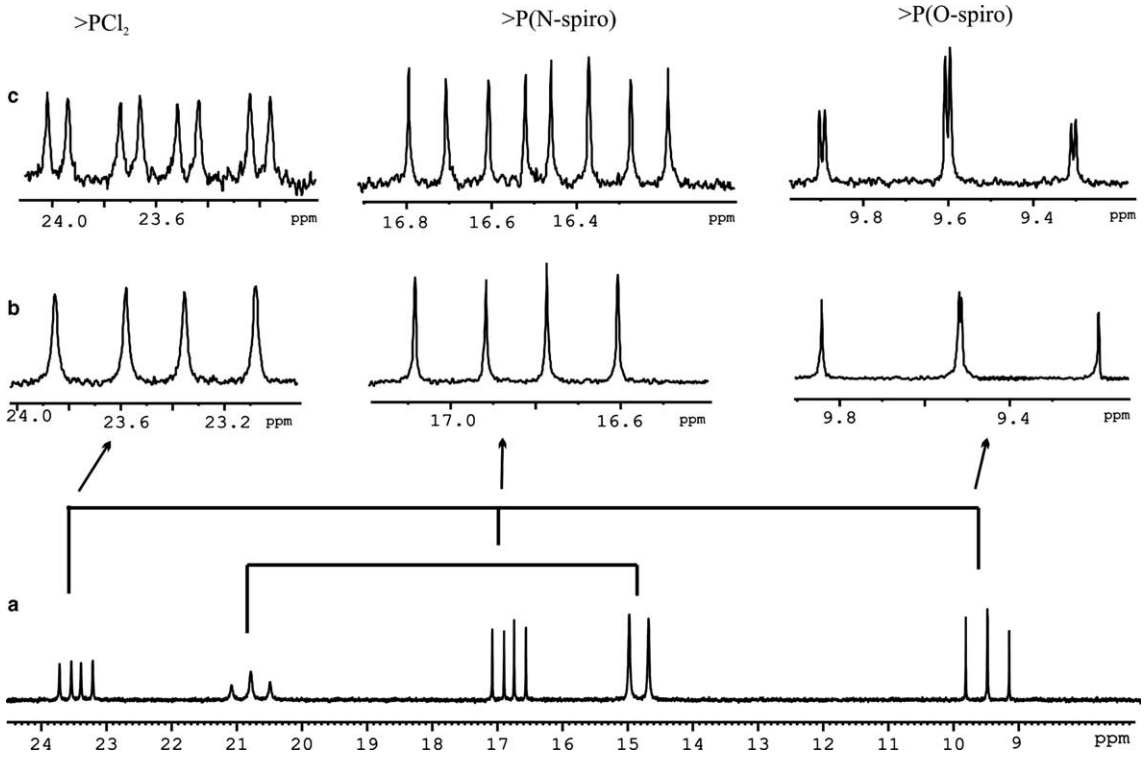

Fig. 4. 202.45 MHz proton-decoupled ^{31}P NMR spectra of the tri-spiro substituted compound **7** in toluene-d_8 solution at 298 K. (a) The AMX spin system corresponds to the mono-spiro substituted ring and the A_2X spin system corresponds to the di-spiro substituted ring. (b) Expanded signals of the AMX spin system of the mono-spiro substituted ring. (c) Addition of CSA causes each line of the AMX signals to split into two, corresponding to the two enantiomers.

The effect of addition of CSA on chemical shifts of all the spiro and ansa derivatives in either $CDCl_3$ or toluene-d_8, as appropriate, is summarised in Table 3 at a molar ratio of CSA:compound of 10:1. It is found that changes in chemical shifts occur for all compounds indicating complexation with CSA, whether the compounds are racemic, meso or achiral. Normally there is a differential effect on signals probably reflecting the mode of complexation of CSA with the compound and the proximity of the CSA to each of the groups in the complex. For example, it is found that the effect of CSA on the P(N-spiro) group of all compounds is negative (signals move to low frequency), whereas the effect on the PCl_2 and P(O-spiro) groups is smaller and can be either positive or negative. It is likely that the NH moiety of the P(N-spiro) group of all compounds is a major site of complexation of CSA, in line with previous work on many different compounds containing NH and OH groups [19]. It is also found that the effect of CSA on chemical shifts of compound **2** is greater for solutions in toluene-d_8 compared with $CDCl_3$ (Table 3), which prompted the choice of toluene-d_8 for NMR investigation of the stereogenic properties of compound **7** in solution.

It is found that care must be taken in interpreting the stereogenic properties of compounds by NMR spectroscopy on addition of CSA (or CSR) to the solution, because there are many cases of false positive results. It has already been shown [11] that the ^{31}P NMR signals of meso forms of spermine-bridged compounds such as compound **4** may exhibit doubling of peaks on addition of CSA. Another 'false positive effect' may be observed for ^{31}P NMR signals of meso compounds because the changes in chemical shifts on addition of CSA cause the spectra to change from A_2X-like to an A_2B spin system; this was observed for the 'doublet' signals of the >P(OR)Cl group of meso compound **6**, in which each resonance split into two signals of unequal and small separation (e.g., 1.8 and 2.4 Hz at an 18:1 mole ratio) that may be due to an A_2B (or even ABX) spin system rather than as a result of a stereogenic effect (Table 3). An analogous, but larger, effect has also been observed for compound **8** in this work (Table 3). On addition of CSA the 'doublet' signals of the >P(OR)Cl groups of meso compound **8** split into two signals of unequal and small separation (e.g., 3.1 and 3.8 Hz at a 17:1 mole ratio) that could be fitted as an ABX spin system, but not an A_2B spin system, which

Table 3
Effect of addition of CSA on ^{31}P NMR chemical shifts of spiro- and ansa-forms of 1,3-propanedioxy-substituted spermine-bridged cyclophosphazenes

[a] s, spiro; a, ansa; ach, achiral, m, meso; r, racemate.
[b] $\Delta\delta = (\delta_{CSA} - \delta_{orig.})$; $\Delta\delta$ positive for high frequency shifts on addition of CSA in $CDCl_3$ unless otherwise noted.
[c] Data from [11].
[d] Although compound **4** was known to exhibit meso and racemic forms in [3], the effect of CSA (or CSR) was not reported. The effect of CSA on the meso form was reported in [11].
[e] On addition of CSA the 'doublet' signals of the >P(OR)Cl group of meso compound **6** split into two signals of unequal and small separation (e.g., 1.8 and 2.4 Hz at an 18:1 mole ratio) due to the A_2B spin system rather than as a result of a stereogenic effect; cf. [11].
[f] Signals are broad and mask any effect of CSA.
[g] Signals are sharp but no effect is observed up to 84:1 mole ratio.
[h] Approximate value derived by extrapolation of effect from higher mole ratios (between 46:1 and 84:1).
[i] In toluene-d_8 solution.
[j] On addition of CSA the 'doublet' signals of the >P(OR)Cl group of meso compound **8** split into two signals of unequal and small separation (e.g., 3.1 and 3.8 Hz at a 17:1 mole ratio) that could be fitted as an ABX spin system rather than an A_2B spin system, which probably indicates another type of example of the 'anomalous meso effect' (cf. [11]).

probably indicates another example of the 'anomalous meso effect' (as in [11]).

4. Conclusions

The chiral configurational isomers of spiro- and ansa-substituted spermine-bridged cyclophosphazene compounds have been investigated by X-ray crystallography and ^{31}P NMR spectroscopy. The symmetry of spermine-bridged cyclophosphazene compound **1** indicates that it is achiral, though it contains two potential homotopic stereogenic centres [>P(N-spiro) moiety of the two N_3P_3 units], which could lead to chiral compounds if substitution of the cyclophosphazene rings leads to asymmetry in the molecule. Substitution with 1,3-propanediol gives a series of spiro- and ansa-substituted spermine-bridged cyclo-phosphazene compounds; unsymmetrically-substituted bridged compounds are found to be chiral and exist as racemic mixtures of *R* and *S* forms, viz. mono-spiro **2** and tri-spiro **7**, whereas symmetrically-substituted bridged compounds may be meso, such as the di-mono-ansa **6** and di-spiro-mono-ansa **8** derivatives, or achiral, such as the tetra-spiro derivative **9**. Using X-ray crystallography and ^{31}P NMR spectroscopy with addition of a chiral solvating agent, (*S*)-(+)-2,2,2-trifluoro-1-(9-anthryl)ethanol, it has been shown previously that the di-mono-spiro derivative **4** exists as a 1:1 mixture of meso and racemic forms [11]. In this work, X-ray crystallographic studies have provided definitive proof of the stereogenic properties of compounds **2**, **6** and **8**, which have been confirmed using ^{31}P NMR spectroscopy and addition of a chiral solvating agent. In addition, the stereogenic properties of chiral compounds **2** and **7** have been elucidated using ^{31}P NMR spectroscopy and addition of CSA. The work demonstrates that derivatives of bridged cyclophosphazene compounds exhibit a range of stereogenic properties and that the question of chirality is an important consideration in cyclophosphazene chemistry.

5. Supplementary material

Supplementary data are available from the CCDC, 12 Union Road, Cambridge CB2 1EZ, UK on request, quoting deposition numbers CCDC 27630–276732 for compounds **2**, **6** and **8**, respectively.

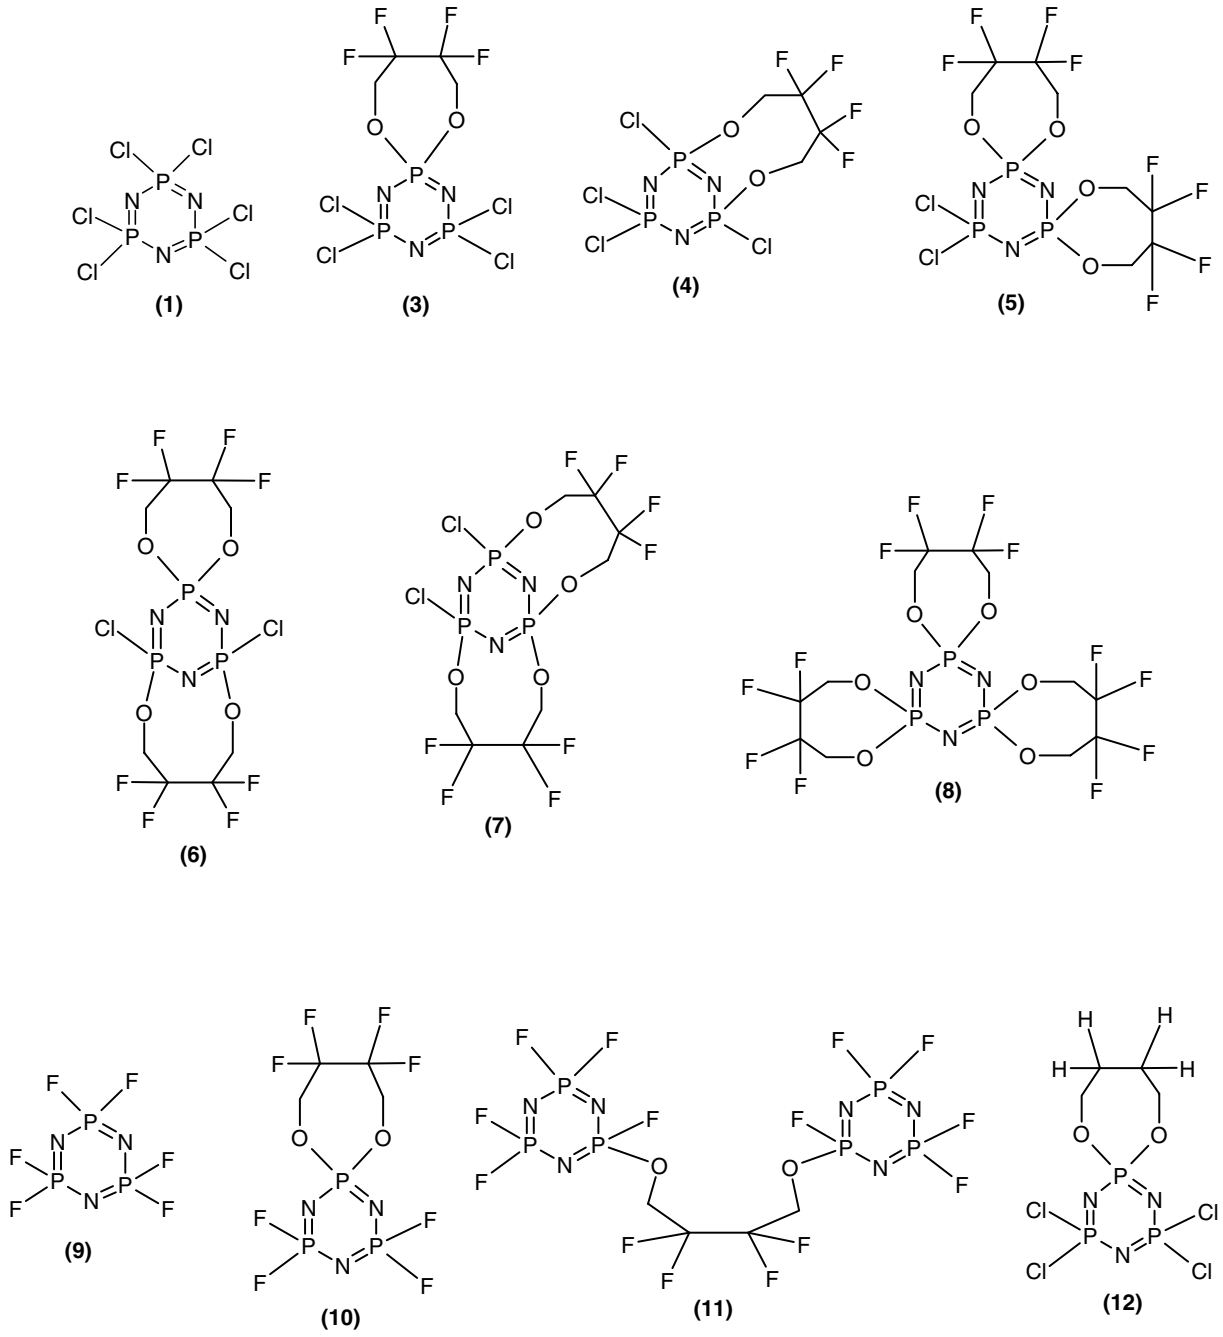

Fig. 1. Structures of compounds.

chain lengths $n > 5$ only bridged compounds were reported by Guerch et al. [4]. On the other hand, only ansa derivatives were obtained with structurally rigid di-functional reagents such as the di-lithium derivatives of ferrocene, ruthenocene and dibenzylchromium [5–8]. Herberhold and co-workers [9] reported that the reactions of the Li salt of the ferrocene (fc) diol with cyclophosphazenes (**1**) and $N_3P_3F_6$ (**9**), gave ansa derivatives, but only spiro-derivatives were obtained when the Li salts of the di-thiol or di-selenol ferrocene were used as reagents, in spite of the larger linking atoms. This mirrors the behaviour of monofunctional oxygen and sulphur nucleophiles, whose attack on the hexachloride (**1**), are predominantly non-geminal (cf. ansa with difunctional reagents) for the former [10,11] and predominantly geminal (cf. spiro with difunctional reagents) for the latter [12]. A recent report on the reactions of the hexafluoride (**9**) with sodium phenoxide again shows a non-geminal pattern [13].

Reaction of **1** with the dilithiated diol, $FcCH_2P(S)(CH_2OLi)_2$, at −80 °C yielded one spiro and two ansa (endo and exo) derivatives in the ratio ca. 1:4 [14], whereas the reaction of the silyl derivative of 2,2,3,3-tetrafluorobutane-1,4-diol (**2**), $(Me_3SiOCH_2CF_2)_2$, with **9** afforded two products; the mono-spiro derivative, $N_3P_3F_4(OCH_2CF_2CF_2CH_2O)$ (**10**), and a derivative of the singly-bridged compound, $(N_3P_3F_5)_2(OCH_2CF_2CF_2$-

CH_2O) (**11**) [15]. A second polymorph of **10** has been reported subsequently [16]. No other derivatives were observed and no reaction of the silyl reagent of **2** with the hexachloride (**1**) could be effected [15]. The purpose of the present study is to investigate the reaction of the sodium derivative of 2,2,3,3-tetrafluorobutane-1,4-diol (**2**) with hexachlorocyclotriphosphazene (**1**) and compare the results with those obtained previously for reaction with butane-1,4-diol [1] and the other related reactions [14,15].

2. Results and discussion

2.1. Reaction of hexachlorocyclotriphosphazene (1) with 2,2,3,3-tetrafluoro-1,4-butanediol (2) to form compounds (3)–(8)

We too observed no reactions between the hexachloride (**1**) and the silyl derivatives of alcohols in agreement with previous work [15], although it is known that silyl derivatives of the monophosphazene, $HN{=}PR_3$, do react with both the hexafluoride (**9**), and hexachloride (**1**), to give the analogous mono-substituted derivatives, $N_3P_3F_5(NPR_3)$ and $N_3P_3Cl_5(NPR_3)$ [17]. In the latter reaction the ease of formation of products decreased in the series [17]: $R_3 = (NMe_2)_3$, Me_3, Me_2Ph, $MePh_2$, Ph_3, $(OEt)_3$, which is in line with substituent basicity constants described and evaluated elsewhere [18]. It is clear that in addition to the driving force of formation of the Si–F (and to a lesser degree of the Si–Cl) bond, the nucleophilicity of the monophosphazene nitrogen atom plays a major role and, hence by implication, that of any other atom attached to the silyl reagent. It is also noted that silyl derivatives of alcohols should be less reactive than those of amines [17]. In order to overcome the lack of reactivity of silyl derivatives of alcohols with chlorophosphazenes, it was decided to use the sodium derivative of the fluorinated diol (**2**), as the nucleophile.

Six products were isolated from the reaction of **1** with **2** in THF at two stoichiometries (1:1.2 and 1:3). The products were the mono-spiro compound, $N_3P_3Cl_4(OCH_2CF_2CF_2CH_2O)$ (**3**), its ansa isomer (**4**), a di-spiro derivative $N_3P_3Cl_2(OCH_2CF_2CF_2CH_2O)_2$ (**5**), its spiro-ansa (**6**) and non-gem *cis* bis-ansa (**7**) isomers and a tri-spiro compound $N_3P_3(OCH_2CF_2CF_2CH_2O)_3$ (**8**). All reaction mixtures were analyzed by ^{31}P NMR spectroscopy and no other compounds were observed. The reaction of the hexachloride (**1**) with the sodium derivative of the fluorinated diol (**2**), in THF was also investigated at a stoichiometry of 1:0.4 and examination of the reaction mixture showed largely the same range of products, spiro (**3**) > ansa (**4**) > di-spiro (**5**). Reaction of **1** with **2** in THF was also effected in the presence of pyridine at room temperature; in this case, although there was evidence of the formation of spiro (**3**) and ansa (**4**) compounds as major products of the reaction, many more minor derivatives were formed, including decomposition products. All the ansa and spiro derivatives reported in this work were found to be unaffected by exposure to air and/or moisture, in contrast to previous reports [14,19] that spiro isomers are highly unstable to air and/or moisture, though their ansa isomers are stable. The reaction of the hexachloride (**1**) with the sodium derivative of the fluorinated diol (**2**) was also carried out at −78 °C, in order to compare our results most closely with those reported by Elias and co-workers [14]. The reagent **2** was added step-wise, one mole at a time and the reaction mixtures were investigated by ^{31}P NMR spectroscopy. With a stoichiometry of 1:1, examination of the reaction mixture showed largely the same range of products as the reaction at room temperature, viz. spiro (**3**) > ansa (**4**) ≈ di-spiro (**5**) > spiro-ansa (**6**) > tris-spiro (**8**). A similar range of products was formed at a stoichiometry of 1:2 though the relative proportions were changed; di-spiro (**5**) > spiro (**3**) > spiro-ansa (**6**) > ansa (**4**) > tris-spiro (**8**), whilst at a 1:3 ratio it was tris-spiro (**8**) ≫ di-spiro (**5**) > spiro-ansa (**6**). On addition of an excess of reagent only the tri-spiro compound **8** was observed. It was also found that reaction of the mono-ansa derivative **4** with an excess of reagent **2** converted it to the tri-spiro compound **8**, which was confirmed by TLC, mpt. and ^{31}P NMR.

2.2. Characterization of compounds 3–8 by ^{1}H, ^{31}P and ^{19}F NMR spectroscopy

Each of the compounds **3**–**8** was characterized by mass spectrometry and NMR spectroscopy, and the results are summarized in Table 1. The ^{31}P NMR spectra of cyclophosphazene derivatives containing the spiro moiety are observed as A_2X (or A_2B) spin systems with characteristic chemical shifts that reflects the number of spiro substituents in the compound, i.e., both the $\gtrdot PCl_2$ and $\gtrdot P(OR)_2$ chemical shifts move to high frequency (downfield) about 4.5–5.5 ppm per tetrafluorobutanedioxy moiety, as expected [20]. Similarly, the chemical shifts of the $\gtrdot P(OR)Cl$ group of the ansa derivatives move to high frequency (downfield) as the cyclophosphazene (**4**) is further substituted with spiro (**6**) or ansa (**7**) tetrafluorobutanedioxy moieties (Table 1). Whilst the chemical shifts of the PCl_2 [for isomers **3** and **4**] and $P(OR)_2$ groups [for isomers **5**, **6** and **7**] seem to be insensitive to the nature of the disposition of the P–Cl bonds (geminal or *cis*-non-geminal), the shifts of the P(OR)Cl group [for isomers **6** and **7**] show some differences. It is noteworthy that in these isomers the two P–Cl bonds of **7** represent the only example in this series, where these two bonds are in a *trans*-relationship.

The proton-decoupled ^{19}F NMR spectrum of the spiro form of the 2,2,3,3-tetrafluoro-1,4-butanedioxy moieties exists as a single line with essentially the same chemical shift (Table 1) for compounds **3**, **5**, **6** and **8**, whereas the ansa form gives rise to an AB spin system with $^{2}J(FF)$ ca. 283 Hz for compounds **4** and **6** and two AB spin systems with $^{2}J(FF)$ ca. 288 Hz for the non-gem *cis* bis-ansa compound **7**. The magnitudes of $^{2}J(FF)$ are in line with previous results on geminal coupling [21]. It should be

[d] sp = spiro and an = ansa.

noted that the line-widths of the ^{19}F NMR signals of the spiro moiety are narrower than those for the ansa moiety, which might reflect the fact that the spiro moiety is more flexible than the ansa moiety.

The ^{1}H NMR spectra of the spiro compounds **3**, **5** and **8**, are complex multiplets with similar chemical shifts (Table 1), whereas those for the mono-ansa moieties in compounds **4** and **6** are observed as two complex multiplets and for the non-gem *cis* bis-ansa compound **7** as four complex multiplets. Although analysis of these multiplets, in principle, could lead to ^{3}J(FH) and ^{3}J(PH) magnitudes and a conformational analysis of the spiro and ansa rings, in practice, this is not feasible because the appropriate Karplus-type relations for ^{3}J(FH) and ^{3}J(PH) magnitudes in such cyclophosphazene derivatives are not known. However, the conformations of the spiro and ansa rings have been determined by X-ray crystallography.

2.3. X-ray crystallographic characterization of compounds 3–8

The X-ray crystal structures are reported for compounds **3**–**8** (Figs. 2–7) and appropriate crystallographic data are summarized in Table 2.

The ($OCH_2CF_2CF_2CH_2O$) moiety forms spiro derivatives in compounds **3**, **5** and **8**, ansa derivatives in **4** and **7**, whereas compound **6** exhibits both spiro and ansa functionality. Each structure is composed of a cyclotriphosphazene core which, in all cases, exhibits no unusual deviations in geometry from either that of the parent $N_3P_3Cl_6$ structure (CSD code KAGKUY), [22] or from that observed in similar structures in the Cambridge Structural Database [23]. The cyclophosphazene rings are essentially planar, in which the deviation of individual atoms from the N_3P_3 plane in all the compounds reported here is less than 0.1 Å. However, the compounds are of structural interest

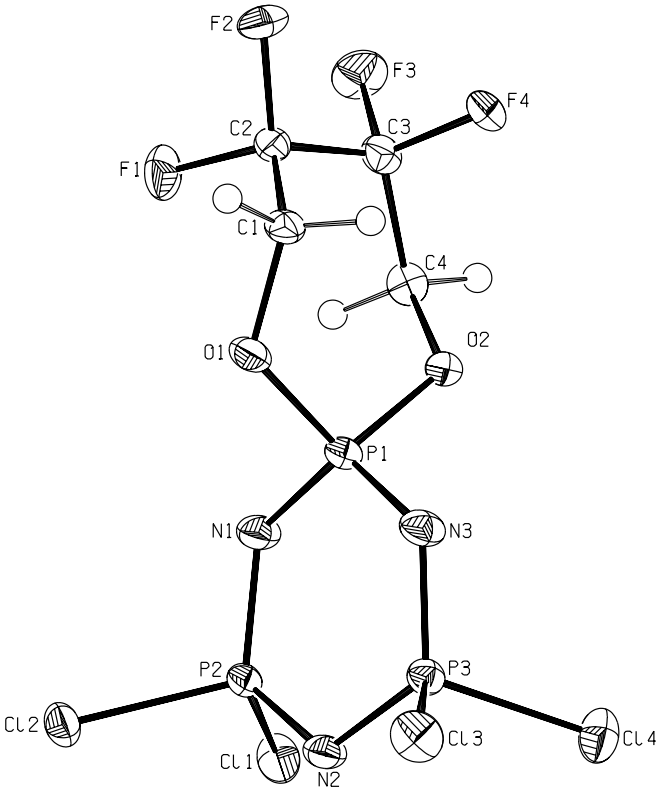

Fig. 2. The molecular structure of **3**, showing the atomic numbering scheme.

in that they are systematically substituted at the phosphorus centres by an increasing number of ($OCH_2CF_2CF_2$-CH_2O) moieties in either the spiro or ansa configurations.

The spiro rings in the spiro-substituted structures are all found to have similar twisted-chair conformations with a strictly alternating positive/negative torsion angle sequence around the ring and each ring component in a *gauche* conformation with respect to its neighbour. The twist of the

7-membered P($OCH_2CF_2CF_2CH_2O$) spiro moiety gives a sense of chirality to the individual molecules which have been denoted as positive (*p*) or negative (*n*) depending on the sign of the O–P–O–C dihedral angle [16]. For the compounds measured in this work, positive twist angles are observed for the mono-spiro derivative **3** and both spiro rings of one molecule of the di-spiro compound **5**, whereas negative twist angles are observed for the spiro-ansa derivative **6** and both spiro rings of the second molecule in the unit cell of **5**. Interestingly, the tri-spiro derivative **8** has two *p* and one *n* form of twisted-chair conformation. A useful measure of ring conformation is puckering analysis [24], where calculation of the mean plane and puckering parameters afford a unique quantitative descriptor, the total puckering amplitude (Q), for a ring conformation. When subjected to ring puckering analysis the spiro substituted structures all have a total puckering amplitude, Q, in the range 0.7979–0.8359.

The spiro-containing structures exhibit intermolecular interactions, in that there are a large number of C–H···F close contacts present. Whilst not considered as 'classical' hydrogen-bonds, there is considerable evidence that interactions do exist between these moieties [25]. The range of D···A separations (some 20 in total for these 4 structures) varies from 3.073(6)Å for C1–H1A···F4 in **8** to an upper limit of 3.484(8) Å. Other notable D···A separations are: 3.102(6) Å for C8–H8B···F4 in **5**; 3.134(4) Å for C1–H1A···F4 in **3**; and 3.177(5) Å for C4–H4···F2 in **6**. Also present in structures (**5**) and (**6**) are short F···F contacts, which are currently the subject of much discussion [26], e.g., F3···F10 = 2.730(7) Å in **5** and F1···F6 = 2.885(6) Å in **6**.

The ansa-substituted structures in compounds **4**, **6** and **7** adopt the same general 9-membered ring conformation, which can best be described as a deformed crown having an anti conformation about the CH_2–CF_2 bonds. The total puckering amplitude [24] of the ansa rings is in the range 1.1878–1.1882, showing a remarkable degree of consistency. There are only a few intermolecular interactions present in these systems ranging from D···A separations for C–H···F contacts of 3.177(6) Å in **6** to 3.301(7) Å in **7**. The cyclophosphazene ring for the ansa compounds

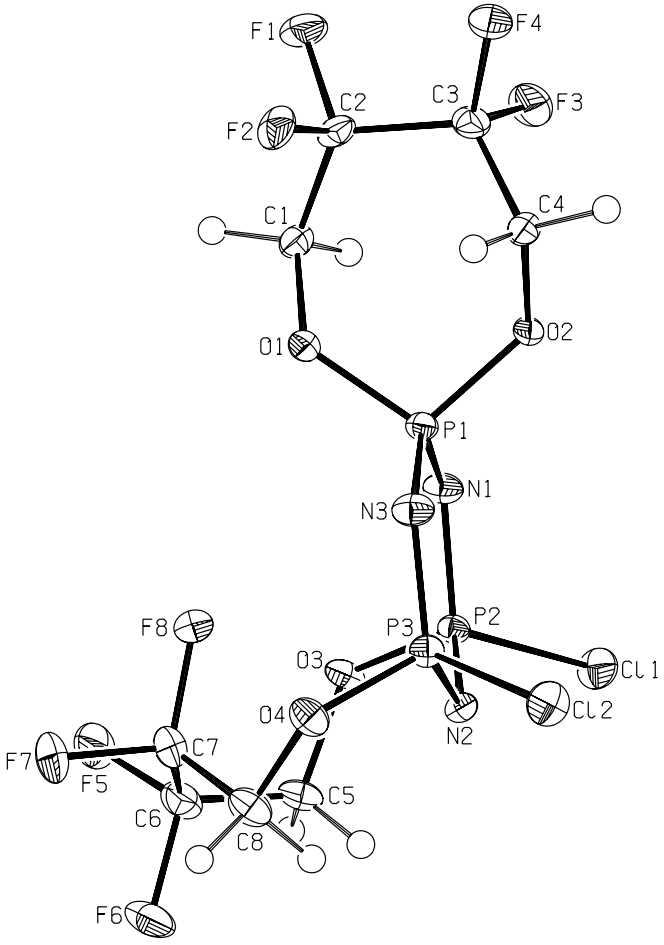

Fig. 5. The molecular structure of **6**, showing the atomic numbering scheme.

characterized in this work is essentially planar, which has also been observed for macrocyclic-phosphazene compounds having a 16-membered ansa ring [27,28]; this is in contrast to that discussed for 8-membered ansa rings (i.e., propanedioxy, propanolamino and ruthenocene) [29] and propanedioxy derivatives where the central CH_2 has been replaced by the ferrocenylCH_2P(S) moiety [14]. For the 8-membered ansa ring derivatives of cyclophosphazene, the deviation from the N_3P_3 plane of the nitrogen atom between the phosphorus atoms carrying the ansa moiety is usually greater than 0.2 Å [14,29,30]. The difference in behaviour of the ansa compounds is likely to reflect the higher degree of flexibility of the 16- and even the 9-membered rings compared to the 8-membered ansa ring system.

Whilst ansa structures of cyclophosphazenes have been known for about 20 years, ansa–ansa structures are relatively rare. There are two types of ansa–ansa structures; geminal, where the two ansa moieties share the same two phosphorus atoms, and non-geminal, where they share only one phosphorus atom. Published examples of the former all contain the tetraethyleneoxy macrocyclic group, $O(CH_2CH_2O)_4$, with the second group as either binaphthoxy [27a], ethylenediamino [27b], or another tetraethyleneoxy macrocyclic group [27c]. The ansa–ansa compound **8** reported here is only the second bis non-geminal structure in chlorocyclotriphosphazenes, the other having one tetraethyleneoxy macrocyclic ring and one binaphthoxy group [27a]. A similar structure has been proposed for a fluorocyclotriphosphazene derivative, but no crystallographic data were presented [31].

*2.4. Comparison of the electron-releasing capacity of a geminal pair of substituents for compounds derived from **1** by analysis of crystal structures*

The structure of the mono-spiro compound **3** formed from the tetrafluorobutanediol (**2**) is compared with that of its butane-1,4-diol analogue **12**, which does not have the fluorine atoms in the dioxy substituent, and also compared with a compound with an identical fluorinated spiro group, but having the 4 P–Cl bonds replaced by 4 P–F bonds, (**10**). The data are presented in Table 3 using the descriptions of bond lengths and angles shown in Fig. 8.

Comparison of the P–O bond length and POC bond angle of the butanedioxy derivative **12** with its tetrafluorobutanedioxy analogue **3** in Table 3 indicates that there is a considerably greater electron supply to the phosphazene ring of **12**, as demonstrated by a shorter P–O bond and a greater POC bond angle, resulting from the greater

lone-pair de-localization from the oxygen atom towards the N_3P_3 ring. Within the phosphazene ring there is also the usual pattern associated with a more electron-supplying substituent [28,32,33]: a smaller α and a larger β angle, a longer P–N bond (a) adjacent to the electron-supplying substituent, concomitant with a shorter P–N bond adjacent to it (b). This results in the Δ(P–N) value ($a-b$, as defined in Table 3) of 0.031 Å in the butanedioxy derivative **12** [32] compared to one of only 0.007 Å in its tetrafluoroalkoxy analogue **3**. Hence, there is only a very small electron-supply from the tetrafluorobutanedioxy group, which is barely distinguishable on this measure from that of a PCl_2 group.

Another approach to the electron-releasing capacity of a geminal pair of substituents is the effect this has on the average value of the P–Cl bonds in the two remaining PCl_2 groups (Table 3) compared with the value for compound **1** of 1.984 Å [22]. Although the changes are small in the sequence, (**3**) 1.990, (**12**) 1.994 [32], 1.998 Å for $N_3P_3Cl_4Ph_2$ [34] and 2.021 Å for $N_3P_3Cl_4(NPPh_3)_2$ [35], they are in keeping with the electron-supply properties

discussed above. For the tetra-substituted compounds the P–Cl bond lengths are, as expected, rather larger: 2.002 Å for the di-spiro derivative **5** and 2.017 Å for $N_3P_3Cl_2Ph_4$ [36]. This larger effect is not surprising, because in the latter compounds the effects of 4 donor groups are spread over only 2 P–Cl bonds, whereas for the di-substituted derivatives the effects of 2 donors are spread over 4 P–Cl bonds. Nevertheless, both the changes in Δ(P–N) values and the changes in average P–Cl bond lengths demonstrate that the spiro tetrafluorobutanedioxy group has a small, but definite, electron-releasing effect relative to a PCl_2 group.

Fluorine has a much greater electronegativity than chlorine, yet comparison of the data for compound **3** with compound **10** in Table 3 shows that most of the structural parameters of the compound containing 4 P–Cl bonds are very similar to the one containing 4 P–F bonds. Perhaps the greater inductive electron-withdrawing effect of fluorine is compensated for by a more pronounced tendency to a mesomeric back-donation from its lone pairs of electrons.

2.5. Explanation of the difference in formation of spiro, ansa and bridged derivatives

It is necessary to explain the different nature of the products obtained with tetrafluorobutanediol in this work (spiro and ansa compounds) and that obtained earlier for butanediol (predominantly spiro). We also note that Shreeve and co-workers [15] reported only spiro and bridged compounds, although the same reaction solvent, THF, was used in their work as well as in ours. In both investigations the reaction mixtures were examined by NMR spectroscopy, so it can be assumed that all major products were accounted for. Shreeve and co-workers [15] found that heating the singly-bridged derivative caused partial conversion to the mono-spiro compound and it is therefore not clear how much of their spiro-derivatives are primary or secondary reaction products. Spiro derivatives are clearly the thermodynamically more stable form, which is also confirmed by the work of Elias and co-workers [30] on the transformation of fluorophosphazenes from ansa to spiro compounds in the presence of CsF. These authors also suggested that the absence of ansa compounds in the reactions with silylated reagents [15] was due to the catalytic conversion of these moieties to spiro groupings. As the PF_2 and PCl_2 groups are more electrophilic than either the PF(OR) or PCl(OR) moieties, the former would be the preferred reaction sites under kinetic control. The crystallographic data presented above show a slight, but definite, electron-supply by the spiro-tetrafluorobutanedioxy group and by implication also for the related PF(OR) and PCl(OR) groupings. However, in this work, reaction of **1** with the sodium salt of the diol (**2**) produced the ansa as well as the spiro derivative. For example, using the same molar ratio (1:0.4) of the cyclophosphazene (**1**) to the sodium salt of the diol (**2**) as used by Shreeve et al. [15], we observed by NMR spectroscopy approximately 60% unchanged $N_3P_3Cl_6$ and about 20% each of the mono-spiro (**3**) and the mono-ansa (**4**) derivatives, together with a trace of the dispiro compound **5**.

We also compared the products of the starting material, $N_3P_3Cl_6$ (**1**) with the sodium and lithium salts of the tetrafluorobutanediol (**2**) in THF using a molar ratio of 1:0.5 to confine the products to mono-substitution as much as possible. The ratio of mono-spiro (**3**):mono-ansa (**4**) was approximately 2:1 for the sodium derivative, but approximately 5:1 for the lithium reagent. As the lithium ion is smaller and its nuclear charge less shielded than that of the sodium ion, Li^+ is likely to form a stronger ion pair and hence make lithium alkoxides less reactive than their sodium analogues. THF is also probably solvating the sodium ion more strongly than the lithium ion and this too would enhance the reactivity of its alkoxide ion. Conductometric studies on the titration of alkali metal acetates with perchloric acid in acetic acid [37] and complexation studies of both the alkali metal ions with phosphazene lariat ethers by Bartsch et al. [38] indicate that ion-pairing will be stronger for lithium than for sodium alkoxides. The

counterion of the alkoxide is likely to be freer in the sodium reagent, making it more reactive than the lithium analogue, and hence proportionally more ansa derivative is obtained with the sodium alkoxide. A similar explanation can be offered for the observation that CsF acted as catalyst in the ansa to spiro transformation in fluorocyclotriphosphazenes, but LiF was reported to be inactive [14]. Reaction of **1** with the dilithiated diol, $FcCH_2P(S)(CH_2OLi)_2$, at −80 °C yielded one spiro and two ansa (endo and exo) derivatives in the ratio ca. 1:4 [14]. Reactions of the ansa isomer with the disodium salt of propane-1.3-diol indicated partial conversion of the ansa group to the spiro isomer [14], again consistent with the greater reactivity of the sodium derivative in line with the explanation above. This reaction [14] differs from the present study on the reaction of **1** with the lithium derivative of **2**, which gave significantly more spiro than ansa derivatives. The difference is likely to be a consequence of the reactions of the dilithiated diol, $FcCH_2P(S)(CH_2OLi)_2$, giving rise to spiro and ansa structures each containing one less atom than the ones reported here. The greater nucleophilic reactivity of the diol, $FcCH_2P(S)(CH_2OLi)_2$, than that of the sodium or lithium derivatives of tetrafluorobutanediol (**2**), and the low temperature of −80 °C undoubtedly also play a part. Elias and co-workers [30] have shown that for fluorophosphazenes 8-membered ansa groupings rearrange in the presence of catalysts to the thermodynamically more stable 6-membered spiro moieties and that this accelerates with increasing temperature. Whilst Elias and co-workers report that ansa derivatives of chlorocyclotriphosphazenes do not rearrange to their spiro derivatives, we infer that a similar rearrangement does take place with the 9-membered ansa groupings to 7-membered spiro moieties. We deduce this, because the plethora of ansa derivatives **4**, **6** and **7**, observed, when the molar ratio of phosphazene (**1**) to diol (**2**) was 1:1.2, whilst with an excess of the sodium derivative of **2** only the tri-spiro derivative (**8**) was observed. Clearly the ansa moiety in all three ansa carrying species rearranged at some stage to a spiro group. To prove this we treated the most abundant of these, the mono-ansa derivative **4**, with an excess of the sodium derivative of the reagent to yield the the tri-spiro derivative **8**. We cannot thus state, precisely, at which state of chlorine replacement this transformation occurred.

This raises the further question to what extent the spiro moieties observed in the reaction with a reactant ratio of 1:1.2 are primary reaction products or a result of a subsequent rearrangement. The answer was given by the NMR analysis of the low temperature reaction mixtures, which showed that the range of products and their ratios was largely the same as those observed at room temperature.

Why ansa and not bridging compounds? In the reactions of $N_3P_3Cl_6$ (**1**), with mono-functional reagents, such as secondary amines, giving rise to non-geminally di-substituted derivatives, the yields of the *trans*-isomer are generally substantially larger than that of the *cis*-isomer and steric effects were invoked to rationalize these observations [39]. However, for the reaction of **9** with NaOR [13,40,41] the reverse behaviour was observed, producing a slight predominance of the *cis* over *trans*-isomer, which was rationalized in terms of the co-ordination of the sodium ion by the lone pairs of electrons of the oxygen atom in the P–OR group already present after mono-substitution. A similar sodium ion solvation was also postulated by Brandt and co-workers [27,42] to account for the exclusive formation of *cis*-ansa macrocyclic-cyclophosphazene derivatives. Formation of such a *cis*-ansa product might be dictated by steric effects for short-chain diols, but for longer chain derivatives such as tetraethylene glycol, which were always used as sodium salts [27,42], the sodium solvation step by the existing PCl(OR) moiety may well play an important role. On the other hand, with the silylated diol no such solvation is possible and, because PF_2 is marginally more reactive than PF(OR), reaction occurs to form bridging compounds, especially as the molar ratio employed showed an excess of $N_3P_3F_6$ (**9**).

It can be seen that the nature of the products (spiro, ansa, bridged) depends, amongst other factors, on the avidity for each other of the electrophilic phosphorus-containing reagent and nucleophilic activity of the diol. The present work has shown that with an unchanged electrophile the lowered reactivity of the nucleophile favours spiro over ansa. Other work with an unchanged nucleophile has also found that a reduction in the electrophilic character of the phosphazene has the same effect, e.g., on substitution of some chlorine atoms in $N_3P_3Cl_6$ by electron-releasing substituents such as the phenyl or tertiary-butylamino groups. However, this is not the whole story, because we have observed that in the reactions of the hexachloride (**1**) with the two diols, propane-1,3-diol and 2,2-dimethylpropane-1,3-diol (using pyridine as the hydrogen halide acceptor), the former forms only traces of the ansa compound, whilst the latter does so in significant quantities [43], which has been explained in terms of the Thorpe–Ingold Effect [44]. Thus, relatively subtle changes between different nucleophiles can tilt significantly the spiro/ansa balance, which is likely to be the reason why the sodium derivative of **2** gave such a range of products that differed markedly from those obtained by the reaction of compound **12** in the presence of pyridine [1]. In case the difference was due to the diol/pyridine reagent, we have also investigated the initial stages of the same reaction using the sodium derivative of butane1,4-diol and found substantially the same range of products as with diol/pyridine reagent and most noticeably the absence of ansa-derivatives. The case of the reaction of compound **9** with the silylated derivative of **2** provides another subtle change in the nature of the nucleophile, further complicated by this reaction being largely driven by the strengths of the Si–F being formed ([17] and references therein). Much remains to be explained, such as the observation that the mono-ansa compound **4** reacts with pyrrolidine with retention of configuration [45].

3. Experimental

3.1. Materials

Hexachlorocyclotriphosphazene (Otsuka Chemical Co., Ltd) was purified by fractional crystallisation from hexane. Sodium hydride, 60% dispersion in mineral oil (Merck), the latter removed by washing with dry heptane (Merck) followed by decantation. Hexane, heptane (Merck) and 2,2,3,3-tetrafluoro-1,4-butanediol (Aldrich) were used as received. THF was distilled over a sodium–potassium alloy under an atmosphere of dry argon. All reactions were performed under a dry argon atmosphere. For column chromatography silica gel (230–400 mesh Merck) was used.

3.2. Methods

Elemental analyses were obtained using a Carlo Erba 1106 Instrument. Mass spectra were recorded on a VG Zab Spec GC–MS spectrometer using the fast atom bombardment (FAB) method (35 kV) with MNBA as the matrix; ^{35}Cl values were used for calculated masses. Analytical thin layer chromatography (TLC) was performed on Merck Silica gel plates (Merck Kieselgel 60, 0.25 mm thickness) with F_{254} indicator. Column chromatography was performed on silica gel (Merck 60, 230–400 mesh; for 3 g crude mixture, 100 g silica gel was used in a column of 3 cm in diameter and 60 cm in length). ^{1}H, ^{19}F and ^{31}P NMR spectra were recorded in $CDCl_3$ solutions on a Bruker DRX 500 MHz spectrometer using TMS as an internal reference for ^{1}H, $CFCl_3$ as an internal reference for ^{19}F and 85% H_3PO_4 as an external reference for ^{31}P. In order to assign the signals of some compounds both proton-coupled and proton-decoupled ^{19}F and ^{31}P NMR spectra were recorded.

3.3. Reaction of hexachlorocyclotriphosphazene (*1*) with 2,2,3,3-tetrafluoro-1,4-butanediol (*2*) in a 1:1.2 ratio to form compounds *3*–*7*

Hexachlorocyclotriphosphazene (**1**), (3.48 g, 10 mmol) and 2,2,3,3-tetrafluoro-1,4-butanediol (1.94 g, 12 mmol), (**2**), were dissolved in 300 mL of dry THF under an argon atmosphere in a 500 mL three-necked round-bottomed flask The reaction mixture was cooled in an ice-bath and NaH (60% oil suspension, 0.96 g, 24 mmol) in 30 mL of dry THF was quickly added to a stirred solution under an argon atmosphere. The reaction mixture was stirred for 2 h at room temperature and the reaction followed on TLC silica gel plates using hexane–dichloromethane (1:1) as eluant. Five products were observed and none of compound **1** remained. The reaction mixture was filtered to remove the sodium chloride formed and the solvent removed under reduced pressure. The resulting colorless oil was subjected to column chromatography, using hexane-dichloromethane (2:1) as eluant. The first product is the mono-spiro derivative $[N_3P_3Cl_4(OCH_2CF_2CF_2CH_2O)]$ (**3**), (1.23 g, 28%, m.p. 95 °C). *Anal.* Calc. for $C_4H_4Cl_4F_4N_3O_2P_3$: C, 11.00; H, 0.92; N, 9.62. Found: C, 10.97; H, 0.93; N, 9.52%. The second product is the isomeric mono-ansa derivative $[N_3P_3Cl_4(OCH_2CF_2CF_2CH_2O)]$, (**4**), (0.6 g, 14%, m.p. 145 °C). *Anal.* Found: C, 11.05; H, 0.93; N, 9.40%. The third product is the bis-spiro derivative $[N_3P_3Cl_2(OCH_2CF_2CF_2CH_2O)_2]$ (**5**), (0.39 g, 7%, m.p. 204 °C). *Anal.* Calc. for $C_8H_8Cl_2F_8N_3O_4P_3$: C, 18.27; H, 1.53; N, 7.99. Found: C, 18.27; H, 1.52; N, 7.65%. The fourth product is the isomeric spiro-ansa derivative $[N_3P_3Cl_2(OCH_2CF_2CF_2CH_2O)_2]$ (**6**), (0.22 g, 4%, m.p. 120 °C). *Anal.* Found: C, 18.38; H, 1.47; N, 7.64% and the fifth product is the isomeric non-gem *cis* bis-ansa derivative $[N_3P_3Cl_2(OCH_2CF_2CF_2CH_2O)_2]$ (**7**), (0.1 g, 2%, m.p. > 270 °C). *Anal.* Found: C, 18.25; H, 1.52; N, 7.89%. All of the new compounds were crystallized from hexane–dichloromethane (1:2) and obtained as colorless crystals.

3.4. Reaction of *1* with *2* in a 1:3 ratio to form compound *8*

1 (1.74 g, 5 mmol) and **2** (2.425 g, 15 mmol) were dissolved in 100 mL of dry THF under argon atmosphere in a 250 mL three-necked round-bottomed flask. The reaction mixture was cooled in an ice-bath and NaH (60% oil suspension, 1.2 g, 30 mmol) in 30 mL of dry THF was quickly added to a stirred solution under an argon atmosphere. The reaction mixture was stirred for 24 h at room temperature and the reaction followed by TLC on silica gel plates using hexane–THF (1:1). Only one product was observed and no starting material **1** was detected. The reaction mixture was filtered to remove the sodium chloride formed, the solvent removed under reduced pressure and the resulting colorless oil subjected to column chromatography, using THF as eluant. The product is the tri-spiro derivative $[N_3P_3(OCH_2CF_2CF_2CH_2O)_3]$ (**8**), (1.72, 56%, m.p. 332), a colorless solid, which was re-crystallized from THF–hexane (1:1). *Anal.* Calc. for $C_{12}H_{12}F_{12}N_3O_6P_3$: C, 23.43; H, 1.97; N, 6.83. Found: C, 23.45; H, 1.98; N, 6.81%.

3.5. Reactions of hexachlorocyclotriphosphazene (*1*) with 2,2,3,3-tetrafluoro-1,4-butanediol (*2*) at −78 °C

Hexachlorocyclotriphosphazene, (**1**), (3.48 g, 10 mmol) and 2,2,3,3-tetrafluoro-1,4-butanediol (1.62 g, 10 mmol), (**2**), were dissolved in 90 mL of dry THF under an argon atmosphere in a 100 mL three-necked round-bottomed flask at ≈−78 °C (acetone–liquid nitrogen). NaH (60% oil suspension, 0.8 g, 20 mmol) in 3 mL of dry THF was quickly added to a stirred solution under an argon atmosphere. The reaction mixture was stirred for 3 h at low temperature (−78 °C) and the reaction followed on TLC silica gel plates using hexane–dichloromethane (3:1) as eluant. 1/3 of the reaction mixture was removed for NMR analysis; 3 products **3**, **4** and **5** were observed and no starting material **1** remained. Reagent **2** and NaH were then added to achieve a 1:2 stoichiometry under the same conditions

and the reaction mixture stirred for a further 3 h. Half of this reaction mixture was removed for NMR analysis and five products (**3**, **4**, **5**, as well as **6**, **7**) were observed. Reagent **2** and NaH were again added to the remaining reaction mixture to achieve a 1:3 stoichiometry. The reaction mixture was stirred for 3 h at −78 °C, followed by 20 h at room temperature and the reaction followed on TLC silica gel plates using hexane–dichloromethane (1:1) as eluant. It was observed that all the compounds were transformed into the tri-spiro compound **8** as confirmed by TLC, mpt. and ^{31}P NMR.

3.6. Reaction of *4* with *2* in a 1:3 ratio to form compound *8*

Mono-ansa (**4**), (0.65 g, 1.5 mmol) and 2,2,3,3-tetrafluoro-1,4-butanediol (0.73 g, 4.5 mmol) (**2**), were dissolved in 10 mL of dry THF under an argon atmosphere in a 100 mL three-necked round-bottomed flask at room temperature. NaH (60% oil suspension, 0.36 g, 9 mmol) in 2 mL of dry THF was quickly added to a stirred solution under an argon atmosphere. The reaction mixture was stirred for 20 h at room temperature and the reaction followed on TLC silica gel plates using hexane-dichloromethane (1:1) as eluent. It was observed that all of compound **4** was transformed into the tri-spiro compound **8**, as was confirmed by TLC, mpt. and ^{31}P NMR.

4. X-ray structure determinations

Data were collected by means of combined phi and omega scans on a Bruker-Nonius KappaCCD area detector situated at the window of a rotating anode (λ Mo Kα = 0.71073 Å). The structures were solved by direct methods, SHELXS-97 and refined using SHELXL-97 [46]. Hydrogen atoms were included in the refinement, but thermal parameters and geometry were constrained to ride on the atom to which they are bonded. The data were corrected for absorption effects using SORTAV [47,48]. Supplementary data in the form of CIF files have been deposited with the Cambridge Crystallographic Data Centre with deposition numbers CCDC 277314–277319 inclusive.

Acknowledgements

The authors thank the Otsuka Chemical Co. Ltd for gifts of $N_3P_3Cl_6$, Professor D. Feakins for helpful discussions on the solvation of alkali metal ions, the EPSRC for funding the National Crystallographic Service (Southampton, UK) and Gebze Institute of Technology (GIT) Research Fund for partial support (S.B. and A.K.).

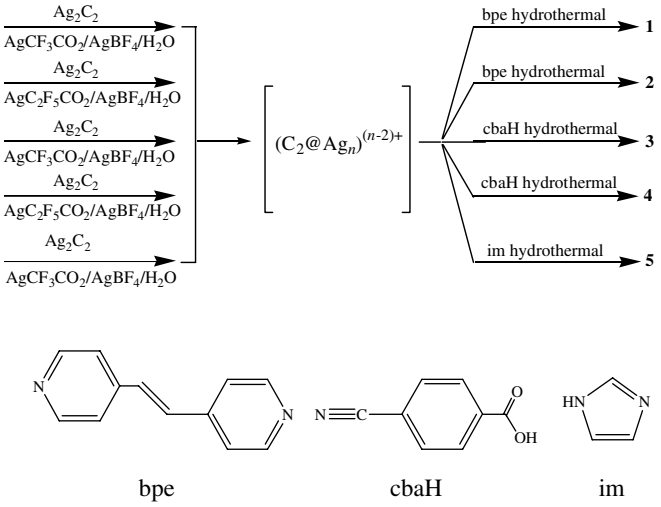

Scheme 1.

coordination sites [4]; besides this, they are capable of creating supramolecular architectures through π–π interaction and/or hydrogen bonding (involving the aromatic ring, carboxylate group of cbaH and the possible protonated forms of bpe and im) [5]. Execution of the synthetic procedure shown in Scheme 1 yielded the following five complexes, whose structures are described in the present report.

$(bpeH_2 \cdot 2H_2O)[Ag_8(C_2)(CF_3CO_2)_8(H_2O)_2] \cdot 2H_2O$ (**1**),
$[Ag_{14}(C_2)_2(C_2F_5CO_2)_{10}(H_2O)_4(bpe)] \cdot H_2O$ (**2**),
$[Ag_7(C_2)(CF_3CO_2)_2(cba)_3]$ (**3**),
$[Ag_7(C_2)(C_2F_5CO_2)_5(cbaH)(H_2O)_2]$ (**4**),
$(imH)_3[Ag_8(C_2)(CF_3CO_2)_9] \cdot H_2O$ (**5**).

2. Experimental

2.1. Synthesis

All chemicals were purchased from ACROS and Aldrich and used without further purification. Ag_2C_2 was prepared as described previously [6]. *CAUTION! Thoroughly dried Ag_2C_2 detonates easily upon mechanical shock, and only a small quantity of freshly prepared sample should be used in any chemical reaction. Excess amounts can be disposed of via slow decomposition in an alkaline solution* [7]. *To ensure safety, we used moist Ag_2C_2 in all preparations.*

2.1.1. $(bpeH_2 \cdot 2H_2O)[Ag_8(C_2)(CF_3CO_2)_8(H_2O)_2] \cdot 2H_2O$ (1)

Freshly prepared Ag_2C_2 was added to an aqueous solution (1 mL) of $AgCF_3CO_2$ (0.44 g, 2 mmol) and $AgBF_4$ (0.39 g, 2 mmol) in a plastic beaker with stirring until saturation was attained. The excess amount of Ag_2C_2 was filtered off and then *trans*-1,2-bis(4-pyridyl)ethylene (45 mg, 0.25 mmol) was added to the filtrate. The resulting suspension was placed in a 25 mL Teflon-lined stainless-steel reaction vessel and subjected to hydrothermal conditions at 115 °C for 36 h, and subsequently cooled to room temperature at 6 °C/h. Colorless block-like crystals of **1** were isolated in ~50% yield. *Anal*. Calc. for **1**: C, 17.30; H, 1.16; N, 1.34. Found: C, 17.22; H, 1.19; N 1.29%.

2.1.2. $[Ag_{14}(C_2)_2(C_2F_5CO_2)_{10}(H_2O)_4(bpe)] \cdot H_2O$ (2)

Complex **2** was synthesized in a similar manner to **1** except that $AgC_2F_5CO_2$ was used instead of $AgCF_3CO_2$. Colorless block-like crystals were obtained in ~40% yield. *Anal*. Calc. for **2**: C, 15.96; H, 0.58; N, 0.81. Found: C, 16.02; H, 0.61; N, 0.78%.

2.1.3. $[Ag_7(C_2)(CF_3CO_2)_2(cba)_3]$ (3)

The synthetic procedure for **1** was repeated using 4-cyanobenzoic acid instead of *trans*-1,2-bis(4-pyridyl)ethylene. Colorless block-like crystals of **3** were obtained in ~52% yield. *Anal*. Calc. for **3**: C, 24.96; H, 0.84; N, 2.91. Found: C, 25.02; H, 0.79; N, 2.96%.

2.1.4. $[Ag_7(C_2)(C_2F_5CO_2)_5(cbaH)(H_2O)_2]$ (4)

Complex **4** was synthesized in a similar manner to **3** except that $AgC_2F_5CO_2$ was used in place of $AgCF_3CO_2$. Colorless block-like crystals were obtained in ~65% yield. *Anal*. Calc. for **4**: C, 16.89; H, 0.51; N, 0.79. Found: C, 16.82; H, 0.48; N, 0.83%.

2.1.5. $(imH)_3[Ag_8(C_2)(CF_3CO_2)_9] \cdot H_2O$ (5)

The synthetic procedure for **1** was repeated using imidazole instead of *trans*-1,2-bis(4-pyridyl)ethylene. Colorless block-like crystals of **5** were obtained in ~48% yield. *Anal*. Calc. for **5**: C, 16.36; H, 0.80; N, 3.95. Found: C, 16.41; H, 0.79; N 3.91%.

2.2. X-ray crystallography

Selected single crystals were used for measurement on a Bruker SMART 1000 CCD diffractometer using Mo Kα radiation ($\lambda = 0.71073$ Å) at 293 K for **1**, **2**, **4** and **5**. Data collection and reduction were performed with the SMART and SAINT software [8]. An empirical absorption correction was applied using the SADABS program [9]. For complex **3**, the intensities were collected on a Rigaku AFC7R four-circle diffractometer in the variable ω-scan mode using Mo Kα radiation at 293 K. Intensity data were obtained in the range $2.3° < \theta < 25°$, and an empirical absorption correction based on ψ-scan was applied [10]. All five crystal structures were solved by direct methods and refined by full-matrix least squares on F^2 using the SHELXTL program package [11]. The crystal data and details of refinement for **1**–**5** are summarized in Table 1, and selected bond distances are listed in the legends for figures. In complex **5**, one of the three independent imH groups is orientationally disordered.

3. Results and discussion

As described before, Ag_2C_2 readily dissolves in a concentrated aqueous solution of silver(I) salts to form polyhedral

species of the type $[C_2@Ag_n]^{(n-2)+}$ ($n = 6$–10). The introduction of a bpe, cbaH, or im ligand to an aqueous system of this kind afforded a precipitate, which was then manipulated under hydrothermal conditions for the generation of new structural motifs. Comparison of the present work with our previous studies of the $Ag_2C_2/AgBF_4/R_fCO_2Ag$ system [12] shows that the employment of such ligands expands the scope of supramolecular assembly of new solid-state architectures.

3.1. $(bpeH_2\cdot 2H_2O)[Ag_8(C_2)\ (CF_3CO_2)_8(H_2O)_2]\cdot 2H_2O$ (*1*)

Single-crystal X-ray analysis revealed that complex **1** represents an unusual example of an inclusion complex constructed with silver(I) polyhedra each containing an encapsulated C_2^{2-} dianion. In the crystal structure of **1**, the building block is a centrosymmetric $C_2@Ag_8$ single cage in the shape of a slightly distorted cube, as shown in Fig. 1. Atoms in the face (Ag1aAg2Ag3Ag4) are coplanar within 0.0748 Å. The enclosed C_2^{2-} species retains its triple-bond character (C1–C1a = 1.24(1) Å) and binds its neighboring silver atoms via multiple σ/π Ag–C interactions in the range of 2.242(5)–2.509(5) Å.

The trifluoroacetate ligands function in μ_2- or μ_3-coordination modes, the latter further interlinking the $C_2@Ag_8$ cages into an infinite zigzag silver(I) chain along the *a* direction (Fig. 1).

Another prominent structural unit in **1** is a centrosymmetric aggregate composed of two Ag_2O_2 rhombuses connected by a pair of Ag–Ag edges. This Ag_4O_4 aggregate may be described as a distorted cube with two cleaved Ag–O edges. The relevant Ag–O (trifluoroacetate oxygen) bond distances range from 2.386(4) to 2.451(4) Å, whereas the Ag–Ag bond lengths are 2.848(1) Å. The Ag–O–Ag angles are 106.2° and 105.7° and the O–Ag–O angles are all 73.1°. The groups of atoms that form each of the six faces of the incomplete cube deviate slightly from

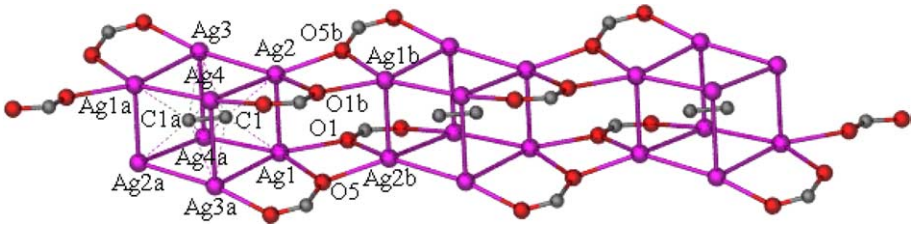

Fig. 1. A portion of polymeric chain in **1** generated from the linkage of centrosymmetric $C_2@Ag_8$ single cages via μ_3-*O*,*O*,*O*′-trifluoroacetate ligands. Selected bond distances [Å]: C1–C1a 1.24(1), C1–Ag1 2.242(5), C1–Ag2 2.244(5), C1–Ag3 2.509(5), C1–Ag4 2.420(5).

planarity, and their deviations from the respective best planes vary between 0.005 and 0.110 Å. Such a Ag_4O_4 aggregate is similar to that first found in $Ag_2C_2 \cdot 6CHF_2CO_2Ag$ [13].

The bpe molecule located at a $\bar{1}$ site is fully protonated to satisfy the charge balance. Of the three independent water molecules in **1**, O1w forms an acceptor hydrogen bond with a terminal of the $(bpeH_2)^{2+}$ dication (N1–O1w = 2.71(1) Å, H1a···O1w = 1.86, N1–H1a···O1w = 172.3°), O2w serving as an aqua ligand binds to Ag3 at 2.525(5) Å, and O3w lying on a 2-axis functions as a bridge between aqua and trifluoroacetate oxygen atoms belonging to adjacent silver(I) chains (O2w···O3w 2.661 Å and O3w···O2 2.854 Å). The resulting layer-type structure is both new and unprecedented. It is also noteworthy that hydrogen-bonded $(bpeH_2 \cdot 2H_2O)^{2+}$ moieties are accommodated between the anionic host layers, forming an inclusion complex (Fig. 2).

3.2. $[Ag_{14}(C_2)_2(C_2F_5CO_2)_{10}(H_2O)_4(bpe)] \cdot H_2O$ (2)

In the crystal structure of **2**, the building block is a centrosymmetric double cage composed of 14 silver(I) atoms, with each component single cage encapsulating an acetylenediide dianion stabilized by multiple σ- and π-interactions with silver(I) in the range of 2.124(9)–2.69(1) Å. Each single cage is in the form of a distorted triangulated dodecahedron. Atom sets, (Ag1Ag2Ag3Ag1a) and (Ag4Ag5Ag6Ag3b), are each coplanar within 0.095 and 0.144 Å, respectively, making a dihedral angle of 100.6°. The double cages are further fused together at edge Ag3Ag3b to form an infinite silver(I) column along the *a*-direction, as shown in Fig. 3.

Three kinds of pentafluoropropionate coordination modes exist in **2**, namely μ-*O*, μ_2-*O*,*O*′ and μ_3-*O*,*O*,*O*′. The μ_3-*O*,*O*,*O*′ ligand further links an additional silver atom of type Ag7 to the silver(I) column. The resulting two-dimensional network is consolidated by cross-linkage of the columns through $[Ag_2(C_2F_5CO_2)_2]$ bridging involving Ag7 (Fig. 4).

The rigid bpe ligand binds to Ag5 at 2.132(7) Å, serving as a connector that further interlinks the layers into a three-dimensional porous framework with channels running parallel to the *a*-direction, which are filled by the hydrophobic pentafluoropropyl groups (Fig. 5).

Of the three independent water molecules in **2**, one serves as an aqua ligand bound to Ag2 at O1w–Ag2 2.526(8) Å, the second functions as a bridge across Ag1 and Ag4 at O2w–Ag1 2.40(1) Å and O2w–Ag4 2.53(1) Å, and the third (with half site occupancy) is involved in donor hydrogen bonding with an oxygen atom of the pentafluoropropionate group at O3w···O10 2.402 Å.

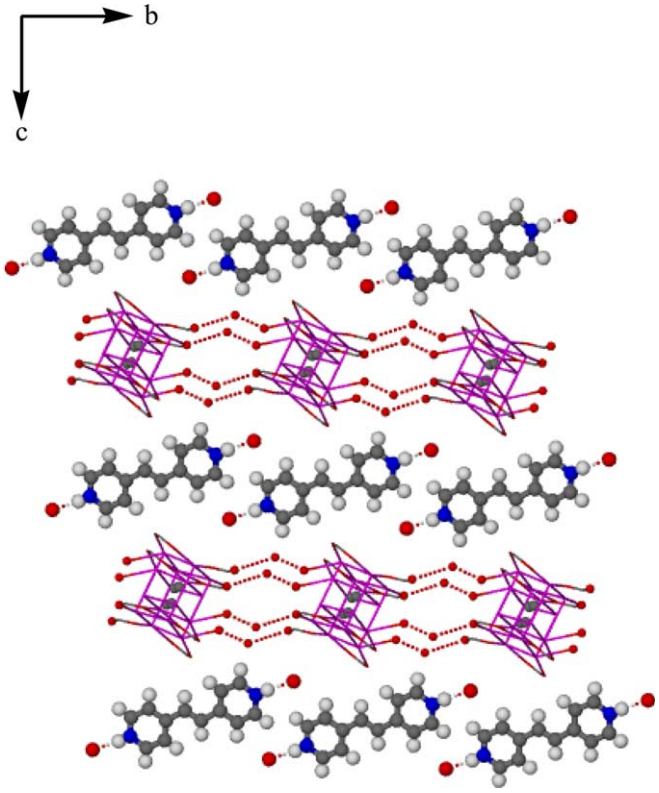

Fig. 2. Layer structure of **1** constructed from hydrogen bonds linking one-dimensional silver(I) chains viewed along the *a*-axis, with hydrogen-bonded $(bpeH_2 \cdot 2H_2O)^{2+}$ moieties accommodated between the host layers. Some $CF_3CO_2^-$ ligands, and also the CF_3 parts of the $CF_3CO_2^-$ ligands included in the figure, have been omitted for clarity.

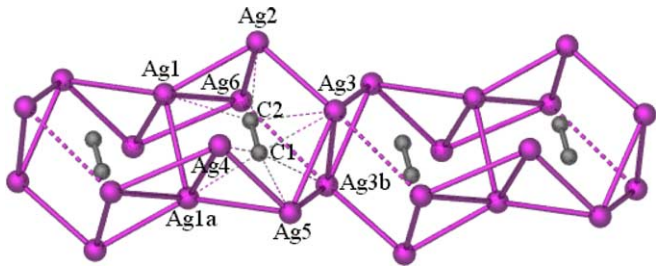

Fig. 3. A portion of silver(I) column generated from fusion of centrosymmetric double cages in **2**. Symmetry code: (a) $-x+1, -y+2, -z-1$; (b) $-x+2, -y+2, -z-1$. Selected bond distances [Å]: C1–C2 1.21(1), C2–Ag1 2.485(9), C2–Ag2 2.203(8), C1–Ag3 2.449(9), C2–Ag3 2.69(1), C1–Ag4 2.315(9), C1–Ag5 2.127(9), C2–Ag6 2.124(9).

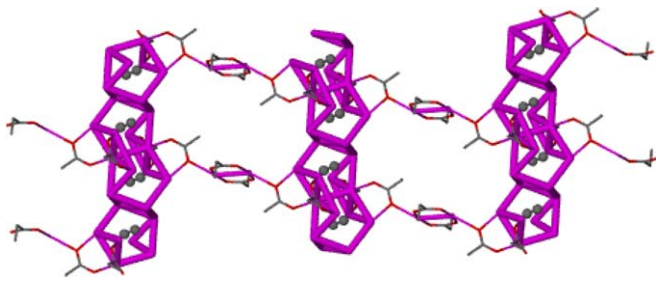

Fig. 4. Ball-and-stick representation of the two-dimensional architecture generated from the linkage of silver(I) columns by $[Ag_2(C_2F_5CO_2)_2]$ units in **2**. Some $C_2F_5CO_2^-$ ligands, and also the F atoms of the $C_2F_5CO_2^-$ ligands included in the figure, have been omitted for clarity.

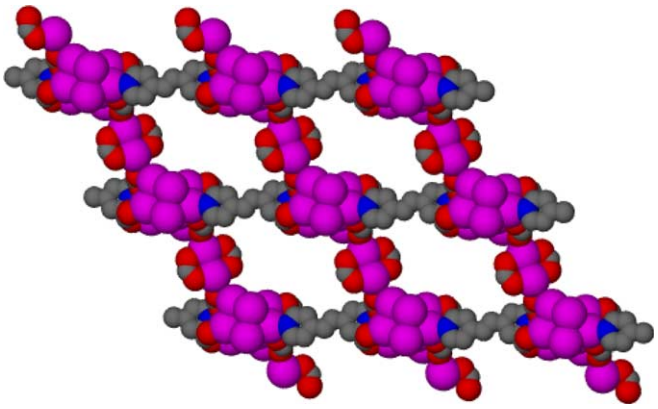

Fig. 5. Space-filling diagram showing a cross-section of the three-dimensional porous framework extending parallel to the *a*-axis in **2**. Some $C_2F_5CO_2^-$ ligands, the C_2F_5 groups of the $C_2F_5CO_2^-$ ligands included in the figure, and all hydrogen atoms have been omitted for clarity.

3.3. $[Ag_7(C_2)(CF_3CO_2)_2(cba)_3]$ (**3**)

Similar to that in **2**, the basic building block in **3** is also a centrosymmetric $(C_2)_2@Ag_{14}$ double cage. Each component single cage takes the shape of a distorted bicapped trigonal prism, in which atom sets (Ag1Ag2Ag3) and (Ag4Ag5Ag4a) constitute two triangular faces, making a dihedral angle of 8.5°. One of the silver atoms was found to exhibit positional disorder over two sites; it was represented by Ag3 with a site occupancy factor (sof) of 0.8 and Ag3′ with sof = 0.2 in structure refinement. Re-collection of a new set of intensity data using a second crystal selected from a freshly prepared sample confirmed the disordered model, but this did not result in an improvement of the *R* indices. The mean deviations of the rectangular faces capped by atoms Ag6 and Ag7 are 0.1674 and 0.2556 Å, respectively. A C_2^{2-} species is enclosed in each silver polyhedron and stabilized by mixed σ/π Ag–C interactions in the range of 2.154(8)–2.617(8) Å. Two such single cages share an edge Ag4Ag4a to form the double cage, and such double cages are connected by argentophilic interaction of the type Ag1–Ag1b (2.958(2) Å) to form an infinite chain along the *a*-direction (Fig. 6).

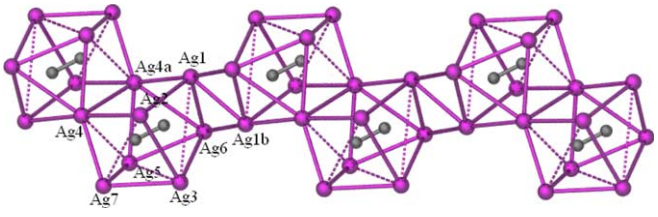

Fig. 6. Infinite silver(I) chain along the *a*-direction generated from fusion of $(C_2)_2@Ag_{14}$ double cages in **3**. Ag···Ag distances longer than 3.4 Å (twice the van der Waals radius of silver) are represented by thick broken lines. Symmetry code: (a) $-x+1, -y+2, -z+1$. Selected bond lengths [Å]: C1–C2 1.23(1), C2–Ag1 2.154(8), C1–Ag2 2.430(8), C2–Ag2 2.505(8), C2–Ag3 2.419(8), C1–Ag3 2.486(9), C1–Ag4 2.274(9), C1–Ag5 2.330(8), C2–Ag6 2.272(8), C1–Ag7 2.227(9).

There are three independent cba ligands labeled as types I, II and III around the $(C_2)@Ag_{14}$ double cage (Fig. 7(a)). The silver columns are linked via ligands I and II to form a (4,4) network (N1–Ag3 2.194(8) Å, N2–Ag2 $(-x, -y+2, -z+1)$ 2.367(8) Å, N2–Ag6 2.449(8) Å), and the nodes are further doubly bridged by III (N3–Ag7 2.285(9) Å) to form a three-dimensional coordination network (Fig. 7(b)). An alternative description is that the silver(I) columns are arranged in a hexagonal array, and each column is linked to an adjacent one by a pair of cba ligands. Every three neighboring silver columns encircle a triangular channel, and a cross-section of the three-dimensional network has the (3,6) (or 3^6) topology (Fig. 7(c)) [15]. This kind of topology is quite similar to that found in $(Ag_2C_2)(AgCF_3CO_2)_4(4\text{-pyCN})_2$ (4-pyCN = 4-cyanopyridine) [12a].

3.4. $[Ag_7(C_2)(C_2F_5CO_2)_5(cbaH)(H_2O)_2]$ (**4**)

Complex **4** was obtained in a similar manner to **3** except that $AgC_2F_5CO_2$ was used instead of $AgCF_3CO_2$ under hydrothermal conditions. The basic building unit is also a centrosymmetric $(C_2)_2@Ag_{14}$ double cage constructed from face-sharing of two $C_2@Ag_8$ single cages, each having the geometry of a distorted bicapped trigonal prism. Atom sets (Ag1Ag2Ag2a) and (Ag3Ag3aAg4) constitute two triangular faces making a dihedral angle of 167.9°. The mean deviations of the two rectangular faces capped by atom Ag6 and Ag7 are 0.0672 and 0.2777 Å, respectively. A C_2^{2-} species is enclosed in each silver polyhedron and stabilized by mixed σ/π Ag–C interactions in the range of 2.09(1)–2.59(1) Å. Two such single cages share face (Ag1Ag2Ag1aAg2a) to form the double cage, and such double cages are fused together via Ag3bAg3c edge-sharing to generate an infinite silver(I) column along the *a*-direction (Fig. 8).

Interlinkage of silver columns via neutral cbaH with bond type O12–Ag4 2.367(8) Å, N1–Ag7 2.14(1) Å generate a two-dimensional network oriented parallel to the *ab*-plane (Fig. 9). Both water molecules serve as aqua ligands bound to silver atoms (O1w–Ag7 2.34(1) Å, O2w–Ag3 2.48(1) Å).

3.5. $(imH)_3[Ag_8(C_2)(CF_3CO_2)_9]\cdot H_2O$ (**5**)

Single-crystal X-ray analysis revealed that the basic building block in **5** is a $C_2@Ag_8$ single cage in the shape of a triangulated dodecahedron located on a twofold axis. Silver cages of such type are connected by μ_3-*O*,*O*,*O*′-trifluoroacetate ligands to form a zigzag anionic silver(I) column along the *a*-direction (Fig. 10).

All three independent imidazole moieties are protonated to satisfy the overall charge balance in the crystal structure. Notably, the resulting $(imH)^+$ cations play a key role in the construction of the three-dimensional architecture. As shown in Fig. 11, the silver(I) columns are interconnected

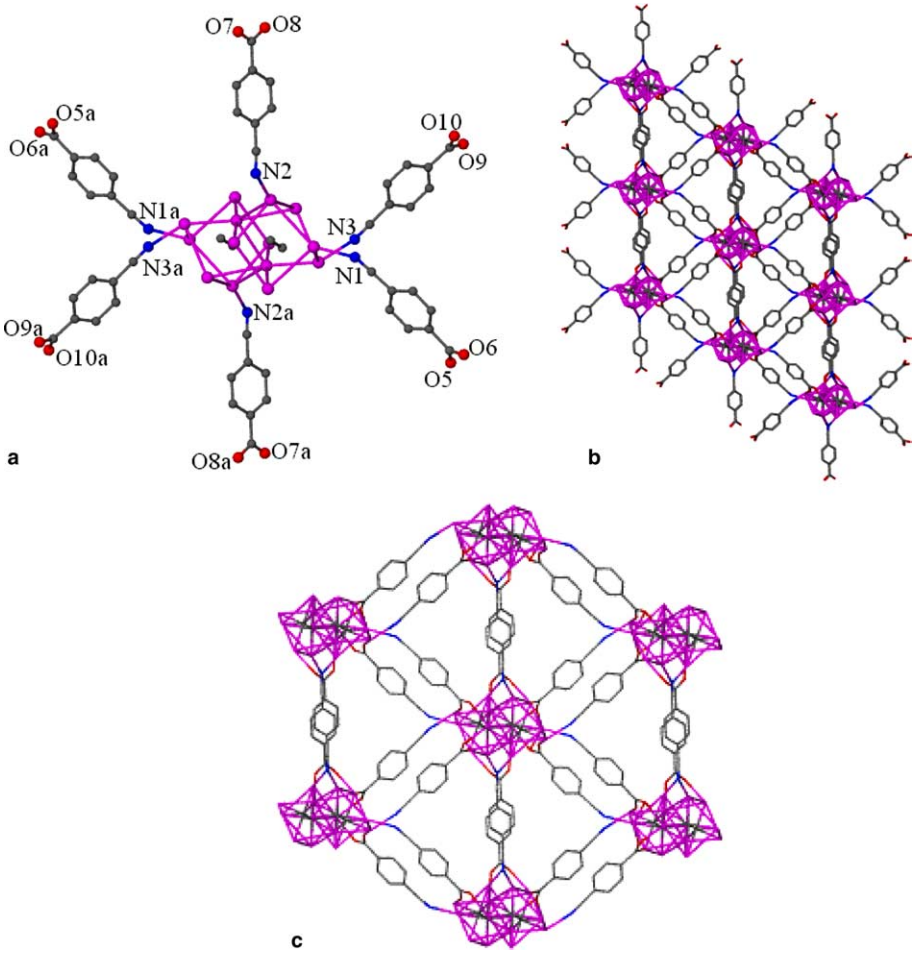

Fig. 7. (a) Various cba ligands surrounding a double silver cage in **3**. (b) Three-dimensional architecture of **3** constructed from interlinkage of silver(I) chains via cba ligands. All the $CF_3CO_2^-$ ligands and hydrogen atoms have been omitted for clarity. (c) Schematic showing the (3,6) network in **3**. All the $CF_3CO_2^-$ ligands and hydrogen atoms have been omitted for clarity.

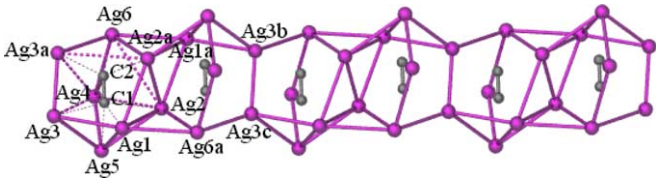

Fig. 8. A portion of the silver(I) column in **4** generated from edge sharing of centrosymmetric $(C_2)_2@Ag_{14}$ double cages. The Ag–C bonds are deleted in the other symmetry-generated cages for clarity.

by hydrogen bonding with the $(imH)^+$ cation serving as donors and *O*,*F* atoms of trifluoroacetate ligands as acceptors to form the three-dimensional architecture. The bond lengths and angles of hydrogen bonds are shown in Table 2.

The C–C bond lengths of the acetylenediide dianion in **1**–**5** are in the range 1.18(1)–1.24(1) Å, which indicate that the entrapped C_2^{2-} species retains its triple-bond character, in accordance with the previous finding in a variety of $C_2@Ag_n$ cages. In addition, the Ag···Ag distances of the silver cages in **1**–**5** lie in the ranges of 2.848(1)–3.145(1), 2.857(1)–3.288(2), 2.861(2)–3.348(3), 2.744(2)–3.258(2), 2.849(2)–3.2934(8) Å (within twice the van der Waals radius of the silver atom), respectively. This is indicative of the existence of significant argentophilic interaction [14].

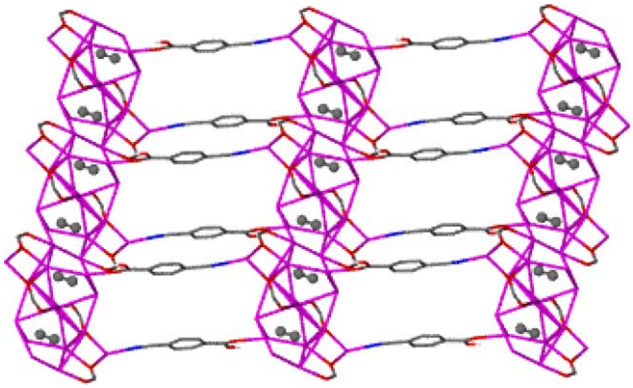

Fig. 9. Two-dimensional architecture of **4** constructed from cbaH-bridged silver(I) columns. The water molecules, some $C_2F_5CO_2^-$ ligands, and the C_2F_5 groups of the $C_2F_5CO_2^-$ ligands included in the figure have been omitted for clarity.

4. Conclusion

Through the hydrothermal reaction of potentially exobidentate ligands with $Ag_2C_2/AgR_fCO_2/AgBF_4$, we have synthesized five new $C_2@Ag_n$-containing supramolecular complexes showing unusual structure features. Complex **1** represents the first example of a hydrogen-bonded layer-type host structure containing $C_2@Ag_n$ that features the inclusion of organic guest species. This implies the possibility of introducing other cationic guest molecules between the anionic host layers, which may lead to new supramolecular materials. The slightly distorted Ag_4O_4 incomplete cube found in **1** and **5** are quite rare. Another surprising feature of **5** is the three-dimensional network constructed from $(imH)^+$-connected silver(I) columns via hydrogen bonds. The present report demonstrates that suitably chosen ancillary ligands can be used to design and construct Ag_2C_2-containing metal–organic assemblies, in which hydrogen bonding dictates the manifestation of the solid-state structures. Also, the preparation of these complexes under hydrothermal conditions demonstrates a potentially versatile approach to the construction of silver(I)-alkynyl complexes. Nevertheless, due to the presence of various subtle interactions in such supramolecular systems, the crystal engineering of Ag_2C_2-containing coordination networks is still at a primitive stage and defies predictability. Further experimentation in a systematic study of the synthesis of polynuclear silver(I) cage complexes bearing various bridging ligands is needed to shed some light on rational design and supramolecular assembly.

example of the insertion of a carbodiimide into a boron–nitrogen bond. We also report a single-crystal X-ray diffraction study of previously synthesized **4** [19].

2. Experimental

2.1. General procedures

All manipulations and reactions were performed under a dry, oxygen-free, catalyst-scrubbed argon atmosphere using a combination of standard Schlenk techniques or in an M-Braun or Vacuum Atmospheres drybox. All glassware was oven-dried and vacuum- and argon flow-degassed before use. All solvents were distilled over sodium benzophenone ketyl, except dichloromethane, which was distilled over CaH_2, and degassed prior to use. *N*,*N*,*N*′-Tris(trimethylsilyl)benzamidine [21], bis(trimethylsilyl)amido boron dichloride [22], and $[MeC\{N^iPr\}_2]BCl_2$ (**4**) [19] were prepared according to the literature procedures. The compounds 1,3-dicyclohexylcarbodiimide, 1,3-diisopropylcarbodiimide, boron halides, bis(trimethylsilyl)amidolithium, and alkyl-lithium solutions were obtained commercially and used without further purification.

2.2. Spectroscopic measurements

Low-resolution CI mass spectra were obtained on a Finnigan MAT TSQ-700 mass spectrometer and high-resolution CI mass spectra recorded on a VG Analytical ZAB-VE sector instrument. All MS analyses were performed on samples that had been sealed in glass capillaries under an argon atmosphere. ^1H, $^{13}C\{^1H\}$, and ^{11}B NMR spectra were recorded at 295 K in C_6D_6 solutions on a GE EQ-300 instrument (^1H, 300 MHz; ^{13}C, 75 MHz; ^{11}B, 96 MHz) immediately following removal of the samples from the drybox. ^1H and $^{13}C\{^1H\}$ chemical shift values are reported in parts per million (ppm) relative to $SiMe_4$ (δ 0.00), using residual solvent resonances as internal standards. ^{11}B NMR data are referenced to $BF_3{:}OEt_2$ (δ 0.00). Melting points (uncorrected) were obtained on a Fisher–Johns apparatus after flame-sealing the samples in glass capillaries under argon.

2.3. Single-crystal X-ray structure determinations

For compounds **1**, **2**, and **4**, a crystal of suitable quality was removed from a Schlenk flask under positive argon pressure, covered immediately with degassed hydrocarbon oil and mounted on a glass fiber. The X-ray diffraction data were collected at 153 K on a Nonius Kappa CCD diffractometer equipped with an Oxford Cryostream low-temperature device and a graphite-monochromated Mo Kα radiation source ($\lambda = 0.71073$ Å). Corrections were applied for Lorentz and polarization effects. All structures were solved by direct methods [23] and refined by full-matrix least-squares cycles on F^2. All non-hydrogen atoms were allowed anisotropic thermal motion, and hydrogen atoms were placed in fixed, calculated positions using a riding model (C–H 0.96 Å). Selected crystal data, and data collection and refinement parameters are listed in Table 1.

2.4. Synthesis of $[^tBuC\{N(Cy)\}_2]BCl(Ph)$ (**1**)

tert-Butyllithium (2 mL of a 2.5 M solution in diethyl ether, 5.0 mmol) was added to a cold (−78 °C) solution of 1,3-dicyclohexylcarbodiimide (1.03 g, 5.0 mmol) in 15 mL of diethyl ether. The stirred colorless reaction mixture was warmed to room temperature, then cooled to

−78 °C following which $PhBCl_2$ (0.794 g, 5.0 mmol) was added dropwise. After being stirred at room temperature for 2 h, the reaction mixture was filtered through Celite® and the solvent was stripped from the filtrate to afford a white powder. Recrystallization of this powder from hexane solution afforded a crop of colorless crystals of **1** (1.12 g, 58% yield, mp 124–126 °C).

^{1}H NMR (C_6D_6): δ 8.02 (d, 2H, Ph); 7.35 (m, 2H, Ph); 7.26 (m, 1H, Ph); 3.53 (m, 2H, Cy); 2.07 (m, 4H, Cy); 1.62–1.53 (br m, 10H, Cy); 1.28–1.15 (m, 6H, Cy); 1.08 (s, 9H, ^{t}Bu). ^{13}C NMR (C_6D_6): δ 178.25 (N*C*N); 135.84; 135.62; 133.68; 127.83 (Ph); 56.39 (Cy–C_1); 35.08 (Cy); 34.60 (Cy); 28.49 (*C*–Me_3); 26.45; 26.43 (Cy); 25.80 (C–*Me*$_3$). ^{11}B NMR (C_6D_6): δ 6.50 (s). MS (CI^+, CH_4): *m*/*z* 386 (M+H), 351 (M−Cl). HRMS (CI, CH_4) calcd. for $C_{23}H_{36}N_2BCl$, 386.2660; found: 386.2655.

2.5. Synthesis of [^{n}BuC{N(Cy)}$_2$]BCl(Ph) (2)

Colorless crystalline **2** (mp 99–101 °C) was prepared in 63% yield from ^{n}butyllithium (2 mL of a 2.5 M solution in diethyl ether, 5.0 mmol), 1,3-dicyclohexylcarbodiimide (1.03 g, 5.0 mmol) in 15 mL of diethyl ether and $PhBCl_2$ (0.794 g, 5.0 mmol) using the procedure described above for **1**.

^{1}H NMR (C_6D_6): δ 8.08 (d, 2H, Ph); 7.39 (m, 2H, Ph); 7.26 (m, 1H, Ph); 3.19 (m, 2H); 1.98 (s, 4H); 1.83 (m, 2H); 1.57–1.28 (br m, 10H); 1.16–0.96 (br m, 10H); 0.74 (t, 3H, C*H*$_3$). ^{13}C NMR (C_6D_6): δ 166.93 (N*C*N); 133.54; 128.07; 127.99; 125.53 (Ph); 54.73 (Cy–C_1); 46.71 (*C*H$_2$CH$_2$CH$_2$-CH$_3$); 34.50 (Cy); 29.10 (Cy); 26.55; 26.45 (Cy); 25.77 (CH$_2$*C*H$_2$CH$_2$CH$_3$); 24.95 (CH$_2$CH$_2$*C*H$_2$CH$_3$); 14.03 (CH$_2$CH$_2$CH$_2$*C*H$_3$). ^{11}B NMR (C_6D_6): δ 6.47 (s). MS (CI^+, CH_4): *m*/*z* 387 (M+H), 352 (M−Cl). HRMS (CI, CH_4) calcd. for $C_{23}H_{36}N_2BCl$, 386.2660; found: 386.2660.

2.6. Synthesis of [(Me$_3$Si)$_2$NC{NCy}$_2$]BCl$_2$ (3) via metathesis

Bis(trimethylsilyl)amidolithium (0.81 g, 4.8 mmol) was added to a cold (−78 °C) solution of dicyclohexylcarbodiimide (1.00 g, 4.8 mmol) in 15 mL of hexane. The stirred colorless reaction mixture was allowed to warm to room temperature, following which it was cooled to −78 °C and BCl_3 (4.8 mL of 1.0 M solution in hexane, 4.8 mmol) was added dropwise. After being stirred at room temperature for 2 h, the reaction mixture was filtered through Celite® and the solvent was stripped from the filtrate to afford a white powder. Recrystallization from toluene at −40 °C afforded a crop of pale yellow crystals of **3** (1.63 g, 77%, mp 97–99 °C). ^{1}H NMR (C_6D_6): 3.31 (m, 2H); 2.01 (m, 4H); 1.64 (m, 8H); 1.05 (m, 8H); 0.143 (s, 18H); ^{13}C NMR (C_6D_6): 166.57 (N*C*N); 53.78 (Cy–C_1); 33.82 (Cy); 26.41 (Cy); 25.89 (Cy); 2.15 (Si*Me*$_3$); ^{11}B NMR (C_6D_6): 4.16 (s). MS (CI^+, CH_4): *m*/*z* 449 (M+H), 412 (M−Cl). HRMS (CI, CH_4) calcd. for $C_{19}H_{40}N_3BCl_2Si_2$, 447.2231; found: 447.2227.

2.7. Synthesis of [(Me$_3$Si)$_2$NC{NCy}$_2$]BCl$_2$ (3) via carbodiimide insertion

Bis(trimethylsilylamido)boron dichloride (0.589 g, 2.43 mmol) in 5 mL of hexane was added to a solution of dicyclohexylcarbodiimide (0.50 g, 2.43 mmol) in

15 mL of diethyl ether at ambient temperature. A colorless reaction mixture resulted, which was stirred overnight at room temperature, following which the solvent was removed under reduced pressure to afford a white powder (0.94 g, 89% yield, mp 97–99 °C). All NMR data were identical to those obtained for **3** via the metathesis route. MS (CI^+, CH_4): *m/z* 449 (M+H), 412 (M−Cl). HRMS (CI, CH_4) calcd. for $C_{19}H_{40}N_3BCl_2Si_2$, 447.2231; found: 447.2233.

3. Results and discussion

3.1. Synthesis of boron amidinates

Alkyl-lithium insertion into carbodiimides represents a well precedented method for the synthesis of lithium amidinates (Scheme 1). In the present case, the requisite lithium reagents were prepared by treatment of 1,3-dicyclohexylcarbodiimide with ^{t}BuLi, ^{n}BuLi, or $(Me_3Si)_2NLi$ at low temperature (−78 °C). In turn, reaction of these lithium amidinates with $PhBCl_2$ or BCl_3 afforded the boron amidinates **1**, **2**, and **3** as stable crystalline solids in yields of 58%, 63% and 77%, respectively. Compound **3** can also be prepared by insertion of CyN=C=NCy into the B–N bond of $(Me_3Si)_2NBCl_2$ as summarized in Scheme 2. The yield obtained by this method is slightly higher than that obtained by the metathesis route.

In previous work, we have demonstrated that the carbodiimides will insert into the B–C bonds of both ferrocenyldibromoborane [19] and dichlorophenylborane [20]. Collectively, these represent the first examples of the synthesis of boron amidinates by means of carbodiimide insertion [24]. Intriguingly, we have found that BEt_3 and $B(NMe_2)_3$ fail to undergo carbodiimide insertion reactions. Recent theoretical studies indicate that the initial step in this insertion reaction is coordination of the carbodiimide nitrogen lone-pairs to the vacant p_z orbital of the borane [20,25,26]. Clearly, the Lewis acidity of the borane depends on the stereoelectronic characteristics of the substituents. In the case of tris(dimethylamido)borane the Lewis acidity is diminished by N → B π-bonding involving the nitrogen lone pairs and the vacant boron 2p orbital thus precluding formation of the initial donor–acceptor complex with the carbodiimide. In the case of the attempted reaction of CyN=C=NCy with BEt_3, initial formation is disfavored due to both electronic and steric effects of the C_2H_5 substituents.

3.2. Crystal structures

Single-crystal X-ray diffraction studies were carried out on both **1** and **2** to assess their structural and bonding characteristics. Compounds **1** and **2** crystallize as monomers and there are no unusually short intermolecular contacts. The molecular structure of **1** is illustrated in Fig. 1. Both molecules feature an essentially planar B–N–C–N ring and an approximately tetrahedral geometry around the boron atom. The B–N–C–N four-membered ring torsion angles are −3.35(10)° and −1.1(2)° for **1** and **2**, respectively. The B–N, B–Cl, and B–C_{Ph} bond distances are similar to those reported previously for [^{n}BuC{N(^{t}Bu)}$_2$]BCl(Ph) [27]. The C–N bond distances (averages 1.34035(19) Å for **1** and 1.3325(4) Å for **2**) are intermediate between those anticipated for single and double bonds and are indicative of delocalization at the NCN moiety. The B–N bonds in **1** and **2** are similar in length and fall in the range observed for B–N bonds in four-coordinate boron centers bound to three-coordinate nitrogen atoms [28].

The molecular structure of **4** was of interest to determine the effect, if any, of changing the steric bulk of the nitrogen and boron substituents (see Fig. 2). Overall, the metrical parameters for **4** are very similar to those for **1** and **2** (Table 2). However, the B–N–C–N ring is less distorted from planarity (0.69(18)°) than those of the cyclohexyl-substituted amidinates, presumably due to the smaller size of the diisopropyl substituent.

4. Conclusions

Three new boron amidinates have been prepared, thus adding to the short list of compounds of this type. Two of the three new compounds have been characterized by single-crystal X-ray diffraction along with a previously reported amidinate-substituted boron halide. One of the new compounds was prepared by the carbodiimide insertion reaction of CyN=C=NCy with $(Me_3Si)_2NBCl_2$. To our knowledge, this represents the first example of the insertion of a carbodiimide into a boron–nitrogen bond. Finally, since all four compounds feature boron–chlorine bonds, it is anticipated that they will prove to be useful synthons.

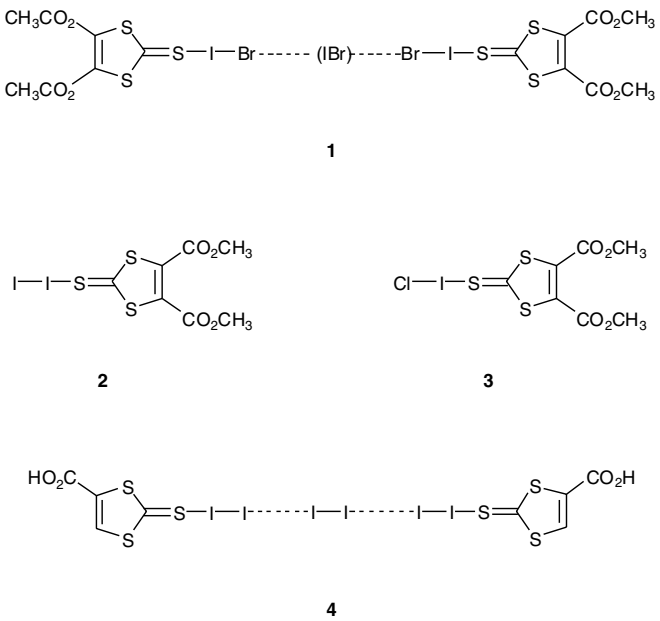

Chart 1.

derivative (**4**), which forms strong dimers through hydrogen bonding.

2. X-ray crystallography

2.1. Asymmetric units

Single crystal X-ray diffraction studies were performed on compounds **2**–**4**; the asymmetric units of each structure are illustrated in Fig. 1 and associated data given in Table 1. Throughout this paper, short intramolecular and intermolecular contacts are those in which the distance between two atoms is less than the sum of the van der Waals radii for the corresponding atoms.[1] The heterocycles bind through the thiocarbonyl functionality to the halogen species with S···I distances of 2.9122(13) Å (**2**), 2.5911(12) Å (**3**) and 2.7328(12) Å (**4**). Due to the bonding nature of the adducts (injection of electron density into the antibonding orbitals of the halogen species), we see an elongation in the bond length for diiodine (2.7899(7) Å for **2**; 2.8193(5) Å for **4**) and iodine monochloride (2.6030(11) Å), compared with the uncoordinated species in the solid state (2.715(6) Å for I_2 [13,14] and 2.446(6) Å for ICl [15]). The bond angles for S···I–I(Cl) are quasi-linear and are in the range 172–178° (Table 1). These values are typical for pnicogen–halogen and chalcogen–halogen adducts: Laurence et al. report that the mean X–Y···donor angle from 219 structures is 176.1(0.2)° [7]. In the case of **4**, the asymmetric unit consists of the expected diiodine adduct and an additional half molecule of diiodine [I(11)–I(11′) 2.7247(5) Å; symmetry code $2-x, -y, 1-z$], which is coordinated by I(1) at a bond length of I(1)···I(11) = 3.4414(6) Å.

For compounds **2**–**4**, a secondary interaction prevails between one of the sulfur atoms of the dithiole ring and the coordinated iodine atom of the dihalogen (3.55–3.62 Å, see Fig. 1 and Table 1). The bond angles between the corresponding sulfur atoms and the coordinated I_2 or ICl molecules are in the range 125–129° (Table 1). This interaction completes a four-membered ring between the coordinated iodine atoms and the two electron donating sulfurs of each structure. Each ring has a significant degree of planarity, with torsion angles of S(2)–C(1)–S(1)–I(1) = 2.4(3)° for **2**, S(2)–C(1)–S(1)–I(1) = 9.77(3)° for **3** and S(2)–C(1)–S(1)–I(2) = 2.2(3)° for **4**.

Intramolecular chalcogen–chalcogen close contacts are observed within each heterocyclic unit through oxygen atoms of the ester or acid functionalities and the sulfurs of the dithiole rings. For the esters, O(sp^3)···S interactions are in the range 2.73–3.00 Å with the shortest contacts seen for compound **2**. For compound **4**, the carbonyl oxygen is responsible for the chalcogen–chalcogen interaction with a contact distance of O(sp^2)···S = 2.88 Å. Interestingly, the latter provides a near planar four-membered ring with a torsion angle of 4.5(5)° (S(3)–C(3)–C(4)–O(2)), whereas compound **2**, which features the strongest O···S interactions but involves O(sp^3) atoms, affords less planar analogous rings with torsion angles of 12.9(5)° (S(3)–C(3)–C(6)–O(3)) and 18.1(4)° S(2)–C(2)–C(4)–O(1). The corresponding four-membered rings are further twisted in **3** (29.8(5)° for S(2)–C(2)–C(4)–O(2); 48.6(5)° for S(3)–C(3)–C(6)–O(4)).

2.2. Supramolecular structures

2.2.1. Compound 2

In the crystal structure of compound **2**, the most noticeable intermolecular interaction concerns a short contact between the thiocarbonyl sulfur and I(2) of an adjacent adduct (S(1)···I(2) = 3.5052(13) Å). This leads to polymeric

[1] The van der Waals radii (in Å) for relevant atoms are taken as: H, 1.20; O, 1.52; S, 1.80; Cl, 1.75; I, 1.98.

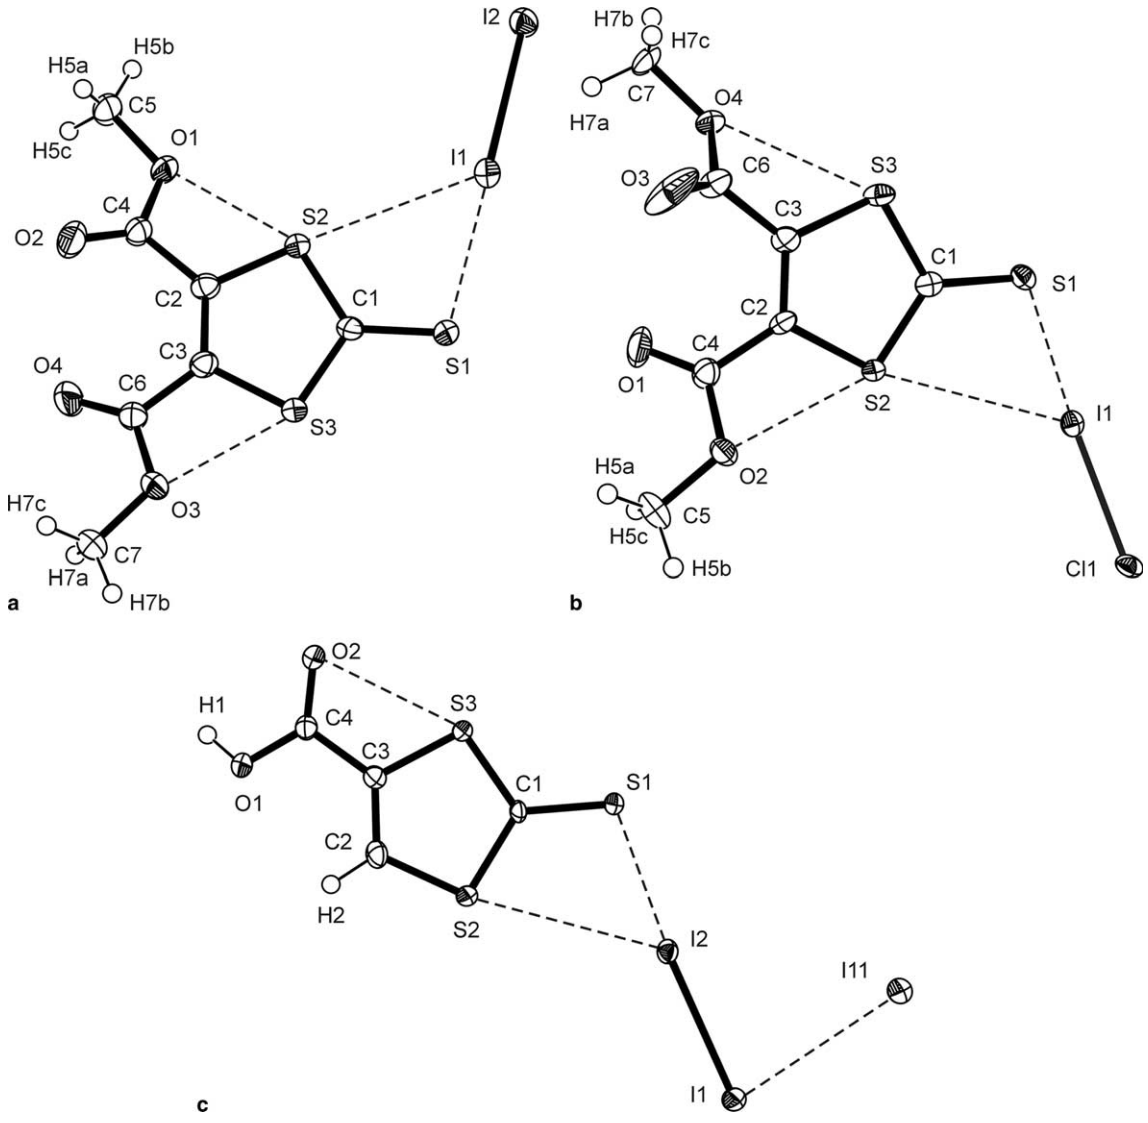

Fig. 1. Asymmetric units of compounds **2** (a), **3** (b) and **4** (c), showing intramolecular close contacts shorter than the van der Waals radii of the corresponding atoms [S, 1.80 Å; I, 1.98 Å; O, 1.52 Å].

chains of adducts in which the repeat units are linked by S(1)···I(1) and S(1)···I(2) contacts (Fig. 2(a)). The chains are held together in the perpendicular dimension by two hydrogen bonds (O(2)···H(7c) = 2.6101(11) Å; O(4)···H(5c) = 2.587(3) Å), which essentially form stacks of adducts (Fig. 2(b)). There are no further significant close contacts in the structure of **2**.

2.2.2. Compound *3*

In adduct **3**, the thione sulfur atom interacts with both atoms of the ICl molecule (S(1)···I(1) and S(1)···Cl(1), Table 1, Fig. 3(a)) in the same way that the corresponding sulfur atom binds to I_2 in **2**. Whereas the polymeric structure of **2** is essentially planar, neighbouring molecules in the chains of **3** (Fig. 3(a)) are tilted through approximately 60° with respect to one another. Within the chains, one strong (S(3)···O(2) = 3.116(3) Å) and one weak (S(2)···S(3) = 3.5956(15) Å) chalcogen–chalcogen interaction support the polymeric links of the sulfur–halogen contacts, as well as intermolecular hydrogen bonding between O(3)···H(7B) (2.450(5) Å, see Fig. 3(b)). The chains themselves form dimers through two interactions, viz. S(1)···S(1) and S(2)···I(1) (Table 1, Fig. 3(a)). Each chain of dimers is held together by three hydrogen bonds (O(1)···H(7C), O(3)···H(5A) and O(4)···H(5C), Table 1), and, together with the chalcogen and halogen based interactions, provide a network of intermolecular short contacts along the *a*-axis.

2.2.3. Compound *4*

Compound **4** incorporates an additional molecule of diiodine, positioned between two 'formal' adducts and coordinated by two I(1) atoms (Table 1, Fig. 4(a)). An intermolecular interaction between S(1) and I(1) atoms

(3.7186(16) Å) produces a twelve membered ring of formula $I_{10}S_2$ (Fig. 4(a)). The rings are fused together with a common edge consisting of I(1)···I(11)–I(11′)···I(1′) atoms to give a ribbon-type polymeric structure (Fig. 4(b)). An additional S–I contact between adducts (S(2)···S(3), 3.3465(16) Å), affords an eight-membered ring

involving two heterocycles and one molecule of diiodine, I(1)–I(2). Classical dimerisation of the carboxylic acid groups is observed within the same plane, with an O···H distance of 1.831(5) Å. The acid functionalities are linked to the heterocyclic units by a weaker H-bond of bond length 2.617(6) Å (O(2)···H(2)). These interactions provide

planar sheets of adducts (Fig. 4(b)), which are themselves linked by sulfur–sulfur close contacts (S(1)···S(1), 3.5206(16) Å, Fig. 4(c)).

3. Experimental

3.1. Synthesis

The neutral donor molecules, 1,3-dithiole-2-thione-4-carboxylic acid and dimethyl 1,3-dithiole-2-thione-4,5-dicarboxylate, were prepared according to the literature procedures [16–18]. Formation of the adducts was achieved by refluxing the organic compounds with a two-fold excess of diiodine or iodine monochloride in acetonitrile. In each case, slow evaporation of the solvent afforded crystalline material, which was isolated by filtration. The materials slowly lose the halogen species upon standing, which hinders the characterisation of the materials by elemental analysis. Melting point determination demonstrated that the adducts rapidly decompose above 50 °C. Raman spectroscopy of the dark red/brown crystals of **2**, **3** and **4** produced very poor quality spectra consisting of a large fluorescence signal across the range 100–900 cm^{-1} which rendered meaningful analysis impossible. The IR spectra of dimethyl 1,3-dithiole-2-thione-4,5-dicarboxylate and 1,3-dithiole-2-thione-4-carboxylic acid exhibit strong bands at 1055 cm^{-1} and 1089 cm^{-1}, respectively, attributable to ν(C=S) stretching of the thiocarbonyl bond [9,19,20]. The interaction between the C=S moiety and the dihalogen/interhalogen leads to a reduction in the bond order and a shift to lower frequency of the ν(C=S) bands in the complexes, which occur at 1035 cm^{-1} in **2**, 1012 cm^{-1} in **3**, and 1039 cm^{-1} in **4**.

3.2. X-ray structure determination

Suitable single crystals were selected and data collected on a Bruker Nonius KappaCCD Area Detector at the window of a Bruker Nonius FR591 rotating anode ($\lambda_{Mo\ K\alpha} = 0.71073$ Å) driven by COLLECT [21] and DENZO [22] software at 120 K. The structure was determined in SHELXS-97 [23] and refined using SHELXL-97 [24]. Geometry calculations were performed using PLATON [25].

Further details of data collection and structure refinement are given in Table 2.

4. Conclusions

We have presented the synthesis and characterisation by X-ray crystallography of three new donor–acceptor charge transfer complexes. The diiodine and iodine monochloride adducts of 1,3-dithiole-2-thione-4-carboxylic acid and dimethyl 1,3-dithiole-2-thione-4,5-dicarboxylate provide the expected basic structure of chalcogen Lewis base–halogen adducts. The participation of all three sulfur atoms of the dithiole-thione provides a high number of supramolecular interactions. However, the carboxylic acid and ester functionalities significantly raise the dimensionality of intermolecular contacts, resulting in 3-D cross-linked structures. These functionalities could therefore be useful to 'double charge-transfer' materials in providing long range order for interesting magnetic and/or conducting properties.

5. Supplementary data

Crystallographic data (excluding structure factors) for the structures in this paper has been deposited with the Cambridge Crystallographic Data Centre as Supplementary Publication Nos. CCDC 217932, 282612 and 282613. Copies of the data can be obtained, free of charge, on application to CCDC, 12 Union Road, Cambridge CB2 1EZ, UK, www.ccdc.cam.ac.uk/conts/retrieving.html (fax: +44(0) 1223 336033 or e-mail: deposit@ccdc.cam.ac.uk).

octahedral environment. While the discrete $[SnX_3]^-$ (X = Cl, Br) anion is observed in compounds such as $KCl \cdot KSnCl_3 \cdot H_2O$ [3] and $NH_4Br \cdot NH_4SnBr_3 \cdot H_2O$ [4], in the SnX_2 parent compounds the trigonal pyramids bridge to form infinite chains of $(SnX_2)_n$ [5]. Similar environments are seen in plumbous halides, but in these cases the distortions are often less pronounced than in the Sn(II) analogues.

In fact it is somewhat misleading to describe the non-bonding valence electrons as an *inert pair*. There are many examples where the interaction between the 5s or 6s orbitals on Sn and Pb, respectively, with empty orbitals on neighbouring anions leads to stabilisation of certain structures. Using a combination of crystallographic and simulation techniques, we have shown that layered structures of the type AB_2X_5 (A = NH_4, Rb, Cs, In; B = Sn, Pb and X = Cl, Br, I) are stabilised through the formation of cluster orbitals involving both Sn/Pb 5s/6s orbitals and empty orbitals on the halides [6]. In some cases, these interactions can lead to the complete removal of stereochemical distortion through electronic population of low-lying conduction bands, as in $CsSnBr_3$ [7].

Very little structural characterisation has been carried out on the alkaline earth metal tin(II) or lead(II) halides, the crystal structure of $Sr(SnCl_3)_2 \cdot 5H_2O$ being the only example [8]. The $Sr(MX_3)_2 \cdot 5H_2O$ (M = Sn, Pb; X = Br, Cl) system affords us the opportunity to examine the electron distribution around the $[MX_3]^-$ anion through the synergistic combination of crystallographic and electronic structure calculation techniques. While it is possible to synthesise the tin chloride, tin bromide and lead bromide analogues through conventional solution methods, the relative insolubility of $PbCl_2$ prevents synthesis of $Sr(PbCl_3)_2 \cdot 5H_2O$ in this way and we describe here how the structure of this compound can be predicted through total energy minimisation techniques.

2. Experimental

2.1. Preparation

Stoichiometric amounts of $SrCO_3$ and either $SnCl_2 \cdot 2H_2O$, $SnBr_2$ or $PbBr_2$ were weighed directly into a small beaker and the compounds dissolved in a minimum amount of dilute HX in a stream of N_2. In the cases of the tin containing compounds, a piece of tin metal was added to prevent oxidation of the product. The solution was heated to boiling and evaporated until approximately 50% of the original volume remained. Crystals appeared on cooling the solution in an ice bath and were collected by vacuum filtration. The crystals were dried in vacuo over silica gel. Attempts to synthesise the $Sr(PbCl_3)_2 \cdot 5H_2O$ analogue were unsuccessful and invariably resulted in precipitation of $PbCl_2$.

2.2. X-ray diffraction

Single-crystal X-ray diffraction data for $Sr(SnCl_3)_2 \cdot 5H_2O$, $Sr(SnBr_3)_2 \cdot 5H_2O$ and $Sr(PbBr_3)_2 \cdot 5H_2O$ were collected on an Enraf Nonius CAD-4 diffractometer at 293 K in $\omega/2\theta$ mode using graphite monochromated Mo Kα ($\lambda = 0.71073$ Å) radiation. The structures were solved by Patterson methods using SHELXS-86 and refined using SHELXL [9]. Oxygen atoms were located using difference Fourier methods. For the two tin containing compounds, the positions of the H atoms were refined in their geometric

positions. For $Sr(PbBr_3)_2 \cdot 5H_2O$, H atom positions were first optimised using density functional theory as described below and refined using geometrical constraints. Anisotropic thermal parameters were refined for all non-hydrogen atoms. All data were corrected for absorption by empirical methods (ψ-scan) [10] and subsequently corrections were applied to the isotropic models using DIFABS [11]. Molecular graphics were obtained using ORTEP-3 [12]. Material for publication was prepared using WinGX [13]. Crystal and refinement parameters are summarised in Table 1, with refined atomic coordinates in Table 2. CCDC reference numbers 415711–415713.

2.3. Electronic structure calculations

Calculations were performed using CPMD [14] with density functional theory (DFT) employed in its plane wave pseudo-potential implementation. A local density approximation (LDA) was used for the electronic exchange and correlation functional, along with Goedecker norm-conserving pseudopotentials [15,16] for each atom present in the unit cell and a plane-wave energy cut-off of 100 Ry. The electronic wave functions were transformed into their corresponding maximally localised Wannier functions using the method of Berghold et al. [17] and the centre of these Wannier functions was used to describe the positions of the electron pairs and the degree of ionicity of the chemical bonds. For $Sr(SnCl_3)_2 \cdot 5H_2O$ and $Sr(SnBr_3)_2 \cdot 5H_2O$ the electronic structure was computed at the experimental geometry as determined by X-ray diffraction. For $Sr(PbBr_3)_2 \cdot 5H_2O$, the positions of the H atoms were optimised while constraining the position of all other atoms to their experimental values. In the case of $Sr(PbCl_3)_2 \cdot 5H_2O$, the initial ionic positions were inferred by substituting Br for Cl in the optimised structure of $Sr(PbBr_3)_2 \cdot 5H_2O$ and using the $Sr(SnCl_3)_2 \cdot 5H_2O$/$Sr(SnBr_3)_2 \cdot 5H_2O$ unit cell parameter ratios to calculate the model cell parameters for the lead bromide analogue. These were calculated as $a = 9.071$ Å, $b = 11.813$ Å, $c = 13.659$ Å, $\beta = 101.41°$ in space group $I2/a$. An unconstrained (space group symmetry constraints only) optimisation of the atomic positions was then carried out followed by a Wannier analysis. The optimisations of the ionic positions were performed using a linearly scaling BFGS algorithm [18] and were terminated when the largest atomic gradient component was below 10^{-5} H bohr^{-1}. The optimised fractional coordinates of $Sr(PbCl_3)_2 \cdot 5H_2O$ are included in Table 2. All calculations were performed on a cluster of Apple X-Serve computers at Queen Mary, University of London.

3. Results and discussion

The refined structural parameters for $Sr(SnCl_3)_2 \cdot 5H_2O$, $Sr(SnBr_3)_2 \cdot 5H_2O$ and $Sr(PbBr_3)_2 \cdot 5H_2O$ are given in Table 2 with significant contact distances in Table 3. These compounds are seen to be essentially isostructural. Only minor differences in bond lengths are seen in the structure of $Sr(SnCl_3)_2 \cdot 5H_2O$ compared to the previous determination of this structure [8]. In $Sr(SnCl_3)_2 \cdot 5H_2O$ (Fig. 1) stereochemical activity of the non-bonding valence electrons on tin is evident in the asymmetric coordination environment adopted by this atom. The primary bonding contacts from tin are to three chlorine atoms together constituting the trichlorostannate anion, $[SnCl_3]^-$. Four longer secondary contacts (3.22–3.70 Å) to chlorine atoms on neighbouring $[SnCl_3]^-$ anions complete sevenfold coordinate geometry for tin. The bond lengths and angles of the trichlorostannate anion seen in the present work are comparable with those seen in other structures where the isolated anion is found, for example $KCl \cdot KSnCl_3 \cdot H_2O$ [3] (ave. Sn–Cl = 2.57 Å, ave. Cl–Sn–Cl = 88.7°) and $NH_4Cl \cdot NH_4SnCl_3 \cdot H_2O$ [19] (ave. Sn–Cl = 2.56 Å, ave. Cl–Sn–Cl = 88.4°). In $Sr(SnCl_3)_2 \cdot 5H_2O$, Sr^{2+} exhibits ninefold coordination, with two contacts to Cl(2) of 3.05 Å and seven to oxygen atoms of water molecules. The structure of $Sr(SnBr_3)_2 \cdot 5H_2O$, like the tin chloride analogue, shows

a strong stereochemically distorting influence of the non-bonding valence electron pair on tin. The tribromostannate anion $[SnBr_3]^-$ exhibits distorted trigonal pyramidal geometry, with Sn–Br bond lengths of 2.75–2.80 Å and is similar to the geometry seen in $NH_4Br \cdot NH_4SnBr_3 \cdot H_2O$ [4] (ave. Sn–Br = 2.73 Å, ave. Br–Sn–Br = 89.4°). Longer secondary contacts to a further four Br atoms at distances between 3.30 and 3.76 Å, complete seven coordination geometry for Sn. The structure of $Sr(PbBr_3)_2 \cdot 5H_2O$ is again basically isostructural with the tin bromide analogue, but appears to show less significant stereochemical distortion. Although it is possible to consider the discrete tribromoplumbate anion, $[PbBr_3]^-$ as being present in this structure, the difference between the primary bonding Pb–Br distances and secondary contacts to Br is significantly smaller than seen in the tin analogues. It is therefore more accurate to describe Pb as being located in a seven coordinate site, with three shorter (2.95–3.02 Å) and four longer contacts (3.16–3.41 Å) to Br. The evidence for stereochemical activity of the non-bonding valence electron pair on Pb in $Sr(PbBr_3)_2 \cdot 5H_2O$ is in contrast to the more regular octahedral coordination environments seen in compounds such as $KPbBr_3 \cdot H_2O$ [20] and $K_2PbBr_4 \cdot H_2O$ [21].

The predicted structure of $Sr(PbCl_3)_2 \cdot 5H_2O$ maintains the basic structure seen in the other analogues. In order to test the optimisation procedure, an unconstrained optimisation of the structure of $Sr(PbBr_3)_2 \cdot 5H_2O$ was carried out and the optimised structure was found to show a root mean square deviation of 0.201 Å from the observed crystal structure. This deviation can be attributed to the use of a local density approximation in the calculations. However, it has been shown that for lead containing inorganic systems, this functional leads to coordination geometries in generally good agreement with those experimentally observed [22]. The optimised structural parameters for $Sr(PbCl_3)_2 \cdot 5H_2O$ are given in Table 2d with significant contact distances included in Table 3. The structure of $Sr(PbCl_3)_2 \cdot 5H_2O$ differs somewhat from the lead bromide analogue in that the Pb atom has an extended coordination

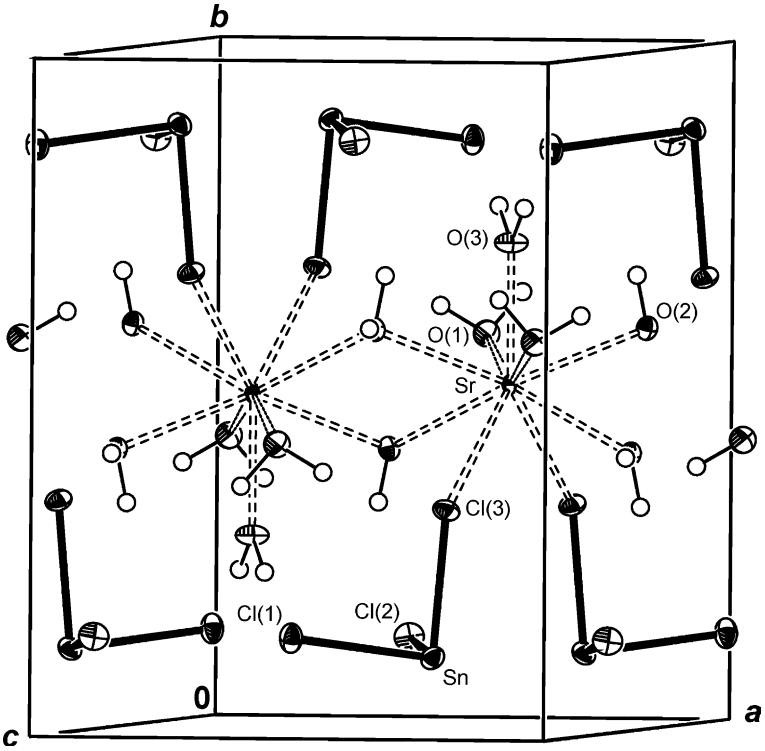

Fig. 1. Thermal ellipsoid (50% probability) plot showing part of unit cell contents of $Sr(SnCl_3)_2 \cdot 5H_2O$.

of six rather than seven and in that way is more comparable to the Sn containing analogues. Three short Pb–Cl contacts are seen with (ave. 2.76 Å). Three longer contacts ranging from 2.90 to 3.25 Å, complete distorted octahedral geometry. Interestingly, the Sr–O contacts show some significant variation, ranging from 2.43 to 2.82 Å, which may be indicative of some problems in modelling this essentially ionic interaction. However, the average Sr–O distance of 2.60 Å, is similar to the values seen in the structural analogues.

The structures of $Sr(MX_3)_2 \cdot 5H_2O$ (M = Sn, Pb; X = Br, Cl) clearly reflect the stereochemical distorting influence of the non-bonding valence electron pair on the Sn and Pb atoms. The tin chloride system has the most significant distortion, while the lead bromide system is the least distorted. The difference in electronegativity of the halide ions is evident in the difference in the degree of distortion between the tin chloride and the tin bromide structures. Similarly, the loss of distorting influence of the non-bonding valence electron pair with increase in atomic number is seen on comparing the tin bromide and lead bromide structures, the latter showing a much more spherical coordination environment.

In order to interpret the density functional results and, in particular, to focus on the position of the non-bonding valence electron pair on Sn and Pb atoms, we decided to localise the DFT orbitals obtained for each structure into a set of maximally localised Wannier functions and their corresponding centres. The Wannier functions are defined in terms of a unitary transformation of the Bloch orbitals, while requiring the total spread of the localised functions to be minimal [23–25]. The position of the Wannier centres locates the maximum density for the localised orbital concerned and can be used as a reliable indication of the centre of charge. This observation has been used to calculate successfully molecular dipole moments in ab initio molecular dynamics [26] and analyse the bonding in solid state and molecular systems [24].

The influence of both the halide X^- and the cation M^{2+} in the $[MX_3]^-$ systems, in the gas phase and in the solid state, can be compared by looking at the isosurface of the localised Wannier orbital corresponding to the non-bonding electron pair (Fig. 2). The corresponding distances between the centre of the localised Wannier orbital and the metal centre are given in Table 4. In the gas phase, we see that the non-bonding electron pair contracts toward the metal centre in both cases (Sn and Pb) when Cl^- is substituted for the larger and less electronegative Br^-, with contractions of 10% and 9%, respectively. This trend is also observed in the solid state for the two lead compounds, where a large contraction of nearly 41% is observed. However, in the case of the two Sn compounds, a small increase in this distance is observed in the solid state. The substitution of Sn for Pb results in a contraction in the distance between the metal centre to the centre of the localised Wannier orbital corresponding to the non-bonding electron pair by 24% for both halide systems in the gas phase.

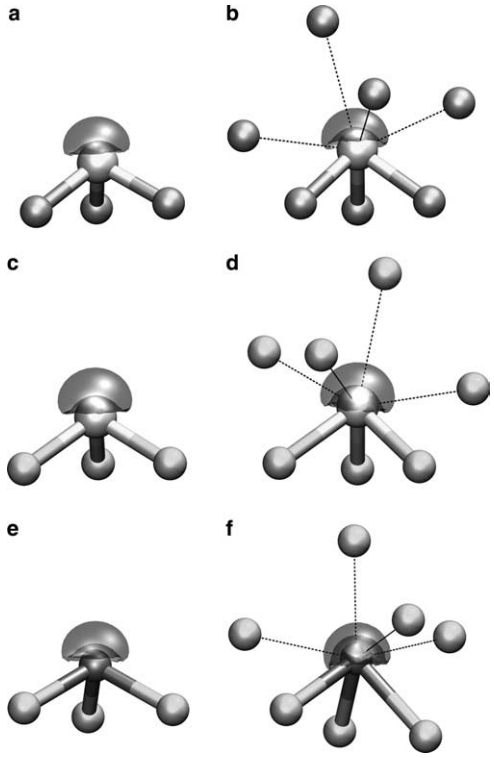

Fig. 2. Isosurfaces showing the extent of the localised Wannier function associated with the non-bonding valence electron pair of Sn and Pb in: (a) gas phase $[SnCl_3]^-$, (b) $Sr(SnCl_3)_2 \cdot 5H_2O$, (c) gas phase $[SnBr_3]^-$, (d) $Sr(SnBr_3)_2 \cdot 5H_2O$, (e) gas phase $[PbBr_3]^-$, and (f) $Sr(PbBr_3)_2 \cdot 5H_2O$.

Table 4
Distances (Å) between the metal centre and the computed maximum of the localised Wannier function (m) for the metal atom non-bonding valence electrons in gas phase $[MX_3]^-$ and $Sr(MX_3)_2 \cdot 5H_2O$

	M–m	
	$[MX_3]^-$ (gas phase)	$Sr(MX_3)_2 \cdot 5H_2O$
M = Sn, X = Cl	0.515	0.282
M = Sn, X = Br	0.467	0.287
M = Pb, X = Cl	0.390	0.138
M = Pb, X = Br	0.354	0.081

The trend is enhanced in the solid state with a contraction of this distance by 51% in the chloride and 73% in the bromide systems. Fig. 3 shows a contour plot of localised Wannier density in the Br(1)–M–Br(3) plane and clearly illustrates the contraction of the non-bonding electron pair orbital on metal substitution. These observations indicate that in a covalent environment such as the isolated $[MX_3]^-$ ion in the gas phase, the non-bonding valence electrons around lead are much closer to the metal centre than in tin and are consistent with the increased nuclear charge of lead compared to tin. In addition, the increased contraction of the non-bonding electron pair towards the Pb metal centre compared to Sn in the solid state is consistent with a decrease in stereochemical activity and directionality of the non-bonding valence electron pair orbital on Pb

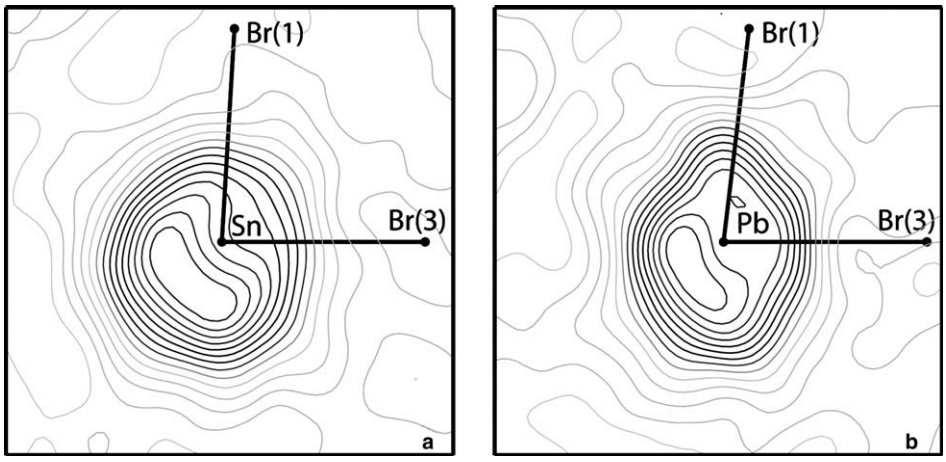

Fig. 3. Contour plots of localised Wannier density in the Br(1)–M–Br(3) plane associated with the non-bonding valence electron pair on (a) Sn in $Sr(SnBr_3)_2 \cdot 5H_2O$ and (b) Pb in $Sr(PbBr_3)_2 \cdot 5H_2O$.

compared to Sn, resulting in more regular coordination environments in the former.

Table 5 shows the distances between the maxima of the localised Wannier orbitals corresponding to all valence electrons and the M and X atom centres in $Sr(MX_3)_2 \cdot 5H_2O$. There is a clear difference observed in these distances between maxima corresponding to bonding and non-bonding electron pairs. In all cases, the maxima associated with non-bonding pairs are significantly closer to the X atom centres than those associated with bonding pairs, while the reverse is true for maxima around the metal atom centres. An indication of the degree of covalency in bonds around the Sn and Pb atoms is the percentage deviation of the charge centre maxima from the bond centre, $\%D_{cen}$ (Eq. 1). Table 6 summarises these values for the compounds under study.

$$\%D_{cen} = \frac{d_{M\text{–}m} - \frac{d_{M\text{–}X}}{2}}{d_{M\text{–}X}} \times 100\%, \quad (1)$$

Table 6
Percentage deviation of computed maxima (m) of the localised Wannier function from M–X bond centre in $Sr(MX_3)_2 \cdot 5H_2O$

m	M = Sn, X = Cl	M = Sn, X = Br	M = Pb, X = Br	M = Pb, X = Cl
m(1)	27	24	30	30
m(2)	26	24	29	29
m(3)	27	26	29	30
m(10)	33	36	32	32

where $d_{M\text{–}m}$ is the metal to maximum distance and $d_{M\text{–}X}$ is the metal to halide distance. In the case of the two tin containing compounds the more covalent interactions, Sn–X(1), Sn–X(2) and Sn–X(3) are characterised by average deviations from the bond centre of 27% and 25% for the chloride and bromide, respectively. The secondary contact to X(2a) (M–m(10)) shows a significant increase in this deviation reflecting the more electrostatic nature of this interaction. This is also reflected in the X(2)–m(10) distances in Table 5, which are similar to the other non-bonding interactions, X(1)–m(8) and X(1)–m(9) and significantly shorter than the X(2)–m(2) distances in the bonding orbital. In the case of the two lead compounds, the difference between the primary and secondary contacts is not as significant, and reflects the reduced stereochemical activity of the non-bonding electron pair.

4. Conclusions

The structures of $Sr(SnCl_3)_2 \cdot 5H_2O$, $Sr(SnBr_3)_2 \cdot 5H_2O$ and $Sr(PbBr_3)_2 \cdot 5H_2O$ are essentially isostructural. All show stereochemical activity of the non-bonding valence electron pair on Sn and Pb, with the degree of distortion less significant in the lead compound. Structure optimisation methods have allowed for prediction of optimised H atom positions in $Sr(PbBr_3)_2 \cdot 5H_2O$ and the complete structure in the case of $Sr(PbCl_3)_2 \cdot 5H_2O$.

Electronic structure calculations reveal a contraction towards the metal centre of the orbital associated with

the non-bonding valence electrons, on substitution of Sn by Pb, both in the gas phase and in the solid state. Similar contractions are observed on substitution of Cl^- by the less electronegative Br^- in the gas phase, however, this is not reflected in the solid state for the tin containing system. The relatively large deviations of the charge centre maxima from the bond centre in the M–X bonds are an indication of the degree of polarity of these bonds. While in the case of the Sn containing compounds there is a clear difference between primary and secondary M–X contacts, in the case of the Pb containing compounds this difference is less clear. This leads us to the conclusion that while the $[SnX_3]^-$ anion appears to be a discrete entity within the system $Sr(SnX_3)_2 \cdot 5H_2O$, there is less evidence for the existence of a corresponding discrete $[PbX_3]^-$ anion in lead analogues. A greater degree of polarity in the primary Pb–X interactions would be entirely consistent with the calculated contraction of the non-bonding valence electron pair orbital and the observed decrease in stereochemical distortion in the Pb coordination environment.

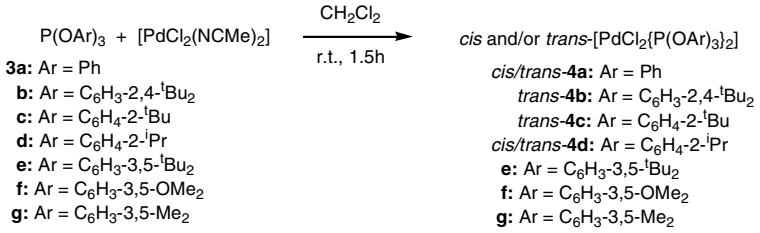

Scheme 1.

present. The IR spectrum of complex **4c** shows a single ν(Pd–Cl) at 382 cm^{-1} indicating that the chloride ligands are *trans* to one another. This value is close to that reported for the complex **4b** [9]. The *trans*-geometry was confirmed by X-ray analysis, the results of which are presented in Fig. 1.

Presumably the high steric profile of ligand **3c** in complex **4c** over-rides the electronic advantages associated with the *cis* arrangement, in which the π-acidic triarylphosphite ligands would be *trans* to the π-basic chlorides. Indeed when the 2-*tert*-butyl group is replaced with the smaller 2-isopropyl function to give complex **4d**, then a mixture of isomers is obtained. The ^{31}P NMR spectrum of complex **4d** shows two singlets at 84.4 (major) and 80.5 (minor) ppm (approximate ratio 9:1). Comparison with the ^{31}P NMR spectroscopic data for the complexes **4a**–**c** suggests that the major, higher field signal is due to the *trans* isomer. The IR spectrum indicates that in the solid state the major isomer is the *trans* complex with a single ν(Pd–Cl) at 375 cm^{-1}.

We were interested to see what the effect of steric bulk in the *meta*-positions of triarylphosphite ligands would have on the geometry of the resultant bis(phosphite) dichloropalladium complexes. To this end we synthesized the complexes **4e**–**g**. The ^{31}P NMR spectra indicate the presence of only one isomer in all cases with singlets observed at δ 76.6, 83.5 and 79.7 ppm for **4e, f, g**, respectively. In all cases the IR spectra are indicative of *cis* disposition of the chloride ligands.

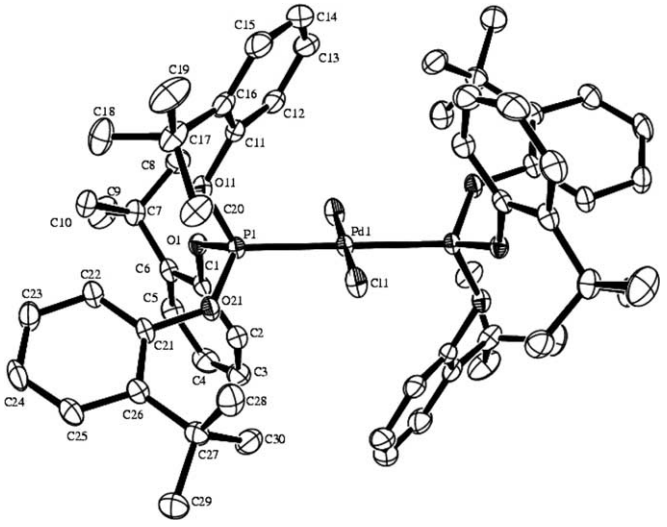

Fig. 1. The single crystal X-ray structure of *trans*-[$PdCl_2${$P(OC_6H_4$-2-^{t}Bu)$_3$}$_2$] (**4c**). Selected bond lengths (Å) and bond angles (°): Pd1–P1, 2.2895(6); Pd1–Cl1, 2.2826(5) and P1–Pd1–Cl1, 89.38(2).

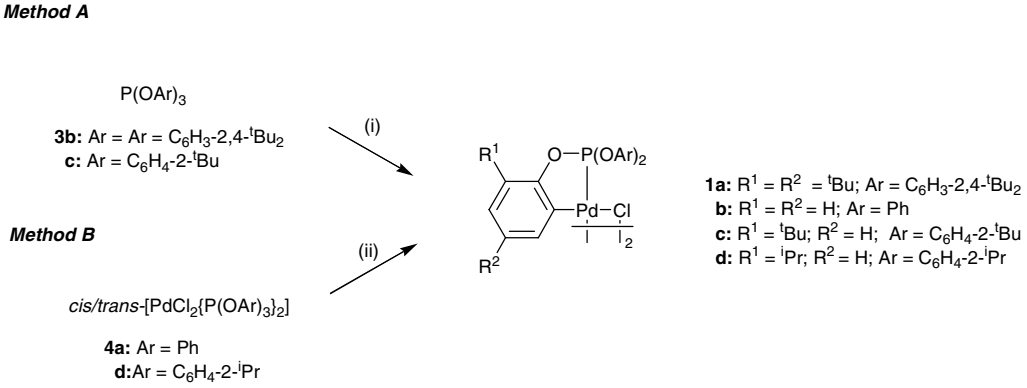
2.2. Orthometallated dimeric complexes

We have previously shown that the bulky phosphite **3b** readily reacts with palladium dichloride to produce the dimeric palladacycle **1a** (Scheme 2, method **A**) [9]. By contrast, we find this method cannot be used with the much smaller ligand, triphenylphosphite, **3a**. In this case the desired complex **1b** has been synthesised previously by Albinati et al. by the reaction of the pre-formed bis-phosphite complex **4a** with one equivalent of palladium dichloride in toluene at reflux temperature (Scheme 2 method **B**) [8].

Tris(2-*tert*-butylphenyl)phosphite (**3c**) is sufficiently bulky that it is not necessary to employ method **B** (Scheme 1) for the synthesis of the orthopalladated dimer **1c**, rather it can be prepared directly by the reaction of the ligand with palladium dichloride (method **A**). Interestingly, from a synthetic perspective, tris(2-isopropyl)phosphite (**3d**) represents the cross-over point between the two methods. ^{31}P NMR spectroscopic analysis of a crude sample of the product mixture from the reaction performed using method **A** (Scheme 2) indicates that whilst the desired dimeric product **1d** is obtained, several other phosphorus containing species are also present. However, clean **1d** can be readily prepared by employing the method **B**.

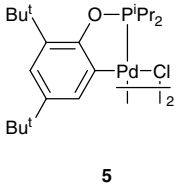
The previously reported ^{31}P NMR spectra of complexes **1a** and **b** show them to be a mixture of *cis* and *trans* isomers in solution [9,8]. Complex **1d** is also obtained as a mixture of *cis* and *trans* isomers as evidenced by ^{31}P NMR spectroscopy which shows two peaks at 122.1 and 120.3 ppm, in close agreement with the value obtained for **1a** and **1b**. By contrast, the presence of only one isomer of complex **1c** in $CDCl_3$ solution is indicated by a singlet at 121.0 ppm in the ^{31}P NMR spectrum and by the lack of signals for a second isomer in the ^{1}H NMR spectrum. The single crystal X-ray structure of complex **1c** was determined and the molecule and selected data are presented in Fig. 2.

As can be seen, the molecule adopts a *trans* configuration, in line with previously reported orthopalladated triarylphosphite dimers and the related phosphinite complex **5**. The structure is grossly similar to those of complexes **1a** and **6**, with little or no significant difference between the bonds lengths about palladium [1,9]. Comparing the structure with that of the non-orthometallated complex **4c**, it can be seen that there is a slight decrease in the Pd–P bond length on orthometallation (~0.15 Å) and a slight increase in the Pd–Cl bond lengths (0.14 and 0.12 Å for the chlorides *trans* to the carbon and phosphorus donors, respectively).

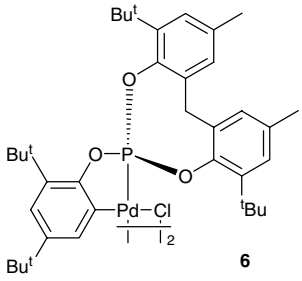


Scheme 2. Conditions: (i) 1 equiv. $PdCl_2$, 2-methoxyethanol, △, 2 h and (ii) 1 equiv. $PdCl_2$, toluene, △, 5 h.

Selected bond lengths (Å) and bond angles (°): Pd1–P1, 2.1425(6); Pd1–C2, 2.015(2); Pd1–Cl1, 2.4079(5); Pd1–Cl2, 2.4239(6) and P1–Pd1–C2, 80.85(6); P1–Pd1–Cl1, 172.22(2); P1–Pd1–Cl2, 95.86(2); C2–Pd–Cl1, 96.87(6); C2–Pd–Cl2, 175.32(6); Cl1–Pd–Cl2, 86.827(19).



5



6

To the best of our knowledge, the crystal structures of all orthopalladated *triaryl*phosphite dimers – as well as the related phosphinite complex **5** – indicate that, in the solid state, the *trans* isomer crystallizes preferentially [1,9,10], although a *cis*-aryldialkylphosphite-based palladacycle has been structurally characterized [11]. Therefore, it came as a surprise that a single crystal X-ray analysis of complex **1b** shows that it adopts a *cis* configuration. The results of the structural analysis are presented in Fig. 3.

The driving force for the formation of the *cis* isomer in this case is revealed by investigating the dominant intermolecular interactions in the crystal structure, as shown in Fig. 4. From this it can be seen that adjacent molecules are arranged as head-to-tail supramolecular dimers, such that the aromatic rings are stacked in a face to face arrangement. Moreover, these supramolecular dimers are further 'locked' in position by an interaction of the ring hydrogen *para* to the oxy moiety with the orthometallated ring in a neighbouring molecule. These electrostatic interactions involving π electrons are enabled by the lack of steric bulk around the aromatic rings. The slightly offset disposition of the aromatic rings with respect to each other and the centroid–centroid separations ($\pi\cdots\pi = 4.368$ and 4.443 Å and C–H$\cdots\pi = 2.597$ and 2.717 Å) are in accordance with literature values that describe the nature of this

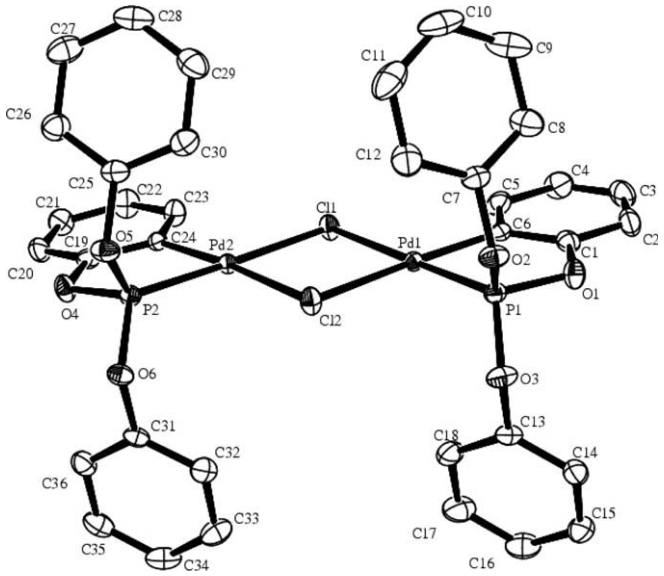


Fig. 3. The single crystal X-ray structure of *trans*-[{Pd(μ-Cl)(κ^2-*P*,*C*-P(OC$_6$H$_4$)(OPh)$_2$)}$_2$] (**1b**). Selected bond lengths (Å) and bond angles (°): Pd1–P1, 2.1499(5); Pd1–C6, 2.0105(19); Pd1–Cl1, 2.4098(5); Pd1–Cl2, 2.4099(5); Pd2–P2, 2.1516(5); Pd2–C24, 2.0096(18); Pd2–Cl1, 2.4189(5); Pd2–Cl2, 2.4179(5) and P1–Pd1–C6, 81.47(6); P1–Pd1–Cl1, 179.331(19); P1–Pd1–Cl2, 93.105(19); C6–Pd1–Cl1, 98.10(6); C6–Pd1–Cl2, 174.53(6); Cl1–Pd1–Cl2, 87.326(18); P2–Pd2–C24, 81.01(6); P2–Pd2–Cl1, 178.320(18); P2–Pd2–Cl2, 94.494(19); C24–Pd2–Cl1, 97.59(6); C24–Pd2–Cl2, 174.96(5); Cl1–Pd2–Cl2, 86.941(18).

interaction [12]. If the aromatic rings were stacked directly above each other and at a shorter separation (ca. 3.4 Å) the two π regions would repel each other, however, when they are offset and slightly further apart (in the region of ca. 4.2–4.6 Å) then the σ electrons may interact attractively with the π orbitals [13]. Due to the bidirectional configuration of the pendant aromatic groups in the molecule the crystal structure is composed of discrete tapes or ribbons. The ribbons associate with those in layers above and below through a further π···π interaction (4.034 Å).

It is easy to see that the introduction of steric bulk into both the orthometallated and non-orthometallated aryl residues would lead to a disruption in these intermolecular interactions. Presumably the preferred *trans* configuration obtained with bulky ligands results from an overall reduction of unfavourable steric interactions.

2.3. Phosphine adducts of phosphite-based palladacycles

We have previously shown that the reaction of tricyclohexylphosphine with the bulky dimeric complex **1a** in acetonitrile leads to the formation of the mononuclear adduct **2a** in which the phosphorus donors adopt a *cis* disposition (Scheme 3) [7]. By contrast, the *N*-heterocyclic carbene adducts of both the bulky complex **1a** and the smaller analogue **1b** – complexes **7** – adopt a geometry in which the carbene ligand is invariably *trans* to the phosphite ligand, regardless of the bulk of the triarylphosphite [14].
